THE CONVERGENCE OF AN EXACT DESINGULARIZATION FOR VORTEX METHODS*

T. Y. HOU†, J. LOWENGRUB‡, AND M. J. SHELLEY§

Abstract. Expanding upon an observation of Hou [*Math. Comp.*, submitted], exact desingularizations are presented of the Euler equations in two and three dimensions for which the singularity within the Biot-Savart integrand is reduced by one order. The reformulated equations are then solved numerically using either the point vortex method or the vortex blob method. The increased smoothness of the Biot-Savart integrand allows us to prove convergence of these methods in the maximum norm. Our numerical experiments show that discretization of the reformulated equations display increased stability relative to discretizations of the original equations. The improvement in stability is manifested as a more slowly growing error in time.

Key words. vortex method, exact desingularization

1. Introduction.

Expanding upon an observation of Hou [16], we present exact reformulations of the Euler equations in two and three dimensions for which the singularity within the Biot-Savart integrand is reduced by one order. The reformulated equations are then solved numerically using either the point vortex method or the vortex blob method. The increased smoothness of the Biot-Savart integrand allows us to prove convergence of these methods in the maximum norm. Our numerical experiments show that discretization of the reformulated equations display increased stability relative to discretizations of the original equations. The improvement in stability is manifested as a more slowly growing error in time.

In two dimensions, our reformulation of the Euler equations is based on the following simple observation: the velocity at the center of a radially symmetric distribution of vorticity is exactly zero. At each point in the fluid we modify the Biot-Savart integral. We subtract a specified vorticity distribution which is radially symmetric about the fluid point. This vorticity distribution is smooth, compactly supported, and its value at the center is equal to the fluid vorticity at that point. We then discretize the resulting equations using a point or blob vortex method. The discretized integrand will be one order less singular than the original point vortex discretization [25], provided that the vorticity is at least Lipschitz continuous. We refer to such a reformulation as an exact desingularization of the Biot-Savart integral. We also make similar observations and operations in three dimensions.

It is crucial to our results that the subtracted vorticity distribution be smooth and of compact support. In [16], Hou advocated subtracting and adding at each point in the fluid a constant vorticity distribution, with value equal to the fluid vorticity at that point. This constant vorticity was supported on a set that contains the fluid vorticity. A trapezoidal rule was then applied to a modified Biot-Savart integral, with the added

vorticity handled through other means [7]. Again, the order of the singularity in the integrand was reduced. However, because the subtracted vorticity in Hou's original method does not vanish smoothly at the boundary of the computational support, the trapezoidal rule for a bounded domain gives, at best, second-order accuracy. This is in contrast to the higher-order accuracy that would be obtained if the vorticity vanished smoothly [11]. Actually, it is more appropriate to divide the computational domain into boxes and use a composite midpoint rule. Careless use of a trapezoidal rule may result in only first-order accuracy. In the method presented here, this disadvantage is circumvented because the subtracted vorticity is smooth and of compact support. Thus, the standard trapezoidal rule will provide second-order approximation for the point vortex method and high-order approximation for the vortex blob method.

The fact that our method is stable in maximum norm allows us to prove the convergence of a particular local regridding scheme. The local regridding method is given in [18] and we do not present it here. We simply remark that the existence of its proof of convergence now gives a theoretical basis for other similar regridding algorithms.

Although it may be tempting to make the subtracted vortex local, we show that the error constants grow as the support of the vortex diminishes. This is not surprising, because the method becomes the original point vortex method as the support of the subtracted vortex vanishes. This is also reflected in our numerical experiments: the larger the support of the subtracted vortex, the more slowly growing the error is in time. Thus, the size of the subtracted vortex should not be coupled to the mesh size. By our choice of reformulation, the discretized sums remain of convolution type, and the existence of fast summation algorithms for such sums is known [5]. Our numerical calculations were performed using direct summation on a Stardent GS2000 computer where the code was both vectorized and run in parallel on four processors.

Our computational domain must now include some marker particles that lie outside the support of the vorticity. This is due to the fact that we must accurately represent the subtracted vortices centered on the boundary of the support of the vorticity.

In addition, as our subtracted vortices are smooth, we are able to obtain an asymptotic error expansion for the point vortex approximation. In principle, the existence of such an expansion allows us to extrapolate to get higher-order accurate methods, and the increased stability of the basic new scheme enables these higher-order accurate methods to be more stable as well.

2. The equations of motion and vortex methods.

The Euler equations of two-dimensional, incompressible fluid flow in the vorticity-stream formulation are given by

$$\omega_t + u \cdot \nabla\omega = 0 \tag{1}$$

and

$$u(x, t) = \int_{\mathbf{R}^2} K(x-y)\omega(y, t)\, dy, \tag{2}$$

where $u(x, t) = (u_1(x, t), u_2(x, t))$, $x = (x_1, x_2)$ is the fluid velocity, $\omega(x, t)$ is the scalar vorticity, and

$$K(x) = \frac{1}{2\pi|x|^2}(-x_2, x_1) \tag{3}$$

is the Biot-Savart kernel. Equation (1) demonstrates that the vorticity in two dimensions is conserved along particle paths, while (2) (the Biot-Savart integral) gives the relation between the velocity and the vorticity due to the incompressibility constraint, and the definition of the vorticity.

We introduce the vortex or particle method by rewriting (1) and (2) in Lagrangian coordinates. $X(\alpha, t)$ is defined so that $X(\alpha, t)$ gives the position at time t of a particle that started at position α. That is,

$$\frac{dX(\alpha, t)}{dt} = u(X(\alpha, t), t), \qquad X(\alpha, 0) = \alpha. \tag{4}$$

Now by (1) we have

$$\omega(X(\alpha, t), t) = \omega(\alpha, 0) = \omega_0(\alpha), \tag{5}$$

since vorticity is conserved along particle paths. This yields the Lagrangian formulation:

$$\begin{aligned} \frac{dX(\alpha, t)}{dt} &= \int_{\mathbf{R}^2} K(X(\alpha, t) - X(\alpha', t))\omega_0(\alpha')\, d\alpha', \\ X(\alpha, 0) &= \alpha. \end{aligned} \tag{6}$$

The vortex method is concerned with the solution of this infinite-dimensional set of ordinary differential equations. Note that $K(x)$ is singular at the origin with the integrable singularity $1/|x|$.

The simplest and oldest vortex method consists of approximating the integral in (6) by the trapezoidal rule, omitting the singular self-interaction term, and solving the differential equations

$$\frac{d\tilde{X}_i(t)}{dt} = \sum_{j \neq i} K(\tilde{X}_i - \tilde{X}_j)\omega_j h^2, \qquad \tilde{X}_i(0) = \alpha_i = (i_1 h, i_2 h), \tag{7}$$

where $\omega_j = \omega_0(\alpha_j)$. This is the point vortex method (PVM) [25]. It has the following difficulty: as two point vortices approach one another, the velocity each induces on the other becomes unbounded. That is, there can be strong grid-scale interactions that lead to a rapid loss of accuracy in numerical calculations.

Nonetheless, this method has been proved convergent by Goodman, Hou, and Lowengrub [13]. A necessary condition for the stability of this scheme is that the method be accurate enough over a given time interval. The accuracy, however, depends on the grid size, the gradients of the solution, and the properties of the kernel K. In typical calculations though, this required accuracy can be lost in time rather quickly due to the development of large velocity gradients (which result in large Lagrangian grid distortions) and the singular nature of the kernel K (see [3], [13], and [23], for example).

To alleviate these difficulties, Chorin [8] introduced the idea of using a mollified kernel, K_δ, or equivalently, vortex blobs with a fixed shape, instead of point vortices to approximate the flow

$$\frac{d\tilde{X}_i^\delta(t)}{dt} = \sum_j K_\delta(\tilde{X}_i^\delta - \tilde{X}_j^\delta)\omega_j h^2, \qquad \tilde{X}_i^\delta(0) = \alpha_i, \tag{8}$$

where $K_\delta = K * f_\delta$, $f_\delta(x) = (1/\delta^2)f(x/\delta)$ where f is an mth order cutoff function satisfying

(i) $\displaystyle\int_{\mathbf{R}^2} f(x)\, dx = 1,$

(ii) $\displaystyle\int_{\mathbf{R}^2} x^\beta f(x)\, dx = 0$ for all multi-indices β such that $i \leqq |\beta| \leqq m - 1$.

This gives a computationally more stable method than the point vortex method if the smoothing size δ is larger than the grid size h. Convergence of the vortex blob method (VBM) has been well established. See [1]-[4], [9], [12], [15], and [24] as well as the review articles [6], [19], and [20] for a bibliography.

The grid distortion exhibited in the PVM is still present for the VBM, although its effects are not as catastrophic due to the mollification of K by K_δ. Consequently, both the VBM and the PVM produce relatively large errors for large time calculations [3], [13], [23]. The purpose of this paper is to introduce a new desingularization to maintain the overall accuracy for longer times with the same initial grid sizes.

3. Our method. We now present our method. It is based on the desingularization idea of Hou [16] and our observation that the velocity at the center of a radially symmetric vortex is zero.

Let $g(x)$ be a smooth function of compact support satisfying

$$g(x)=g(|x|)=\begin{cases}1, & |x|\leqq R_1,\\ 0, & |x|\geqq R_2.\end{cases} \tag{9}$$

We see that

$$\begin{aligned}\frac{dX_i}{dt}&=\int_{\mathbf{R}^2} K(X_i-X(\alpha))\omega_0(\alpha)\,d\alpha\\ &=\int_{\mathbf{R}^2} K(X_i-X(\alpha))(\omega_0(\alpha)-\omega_i g(X_i-X(\alpha)))\,d\alpha,\end{aligned} \tag{10}$$

since

$$\omega_i\int_{\mathbf{R}^2} K(X_i-X(\alpha))g(X_i-X(\alpha))\,d\alpha=\omega_i\int_{\mathbf{R}^2} K(x)g(x)\,dx=0, \tag{11}$$

as $X(\alpha)$ is an area-preserving transformation and $K(x)g(x)$ is an odd function in x. Again, this is just the statement that the velocity at the center of a radially symmetric vorticity distribution is zero. We refer to (10) as an exact desingularization of the Biot-Savart integral. The point vortex and vortex blob quadratures of (10) will be referred to as the desingularized point vortex and desingularized vortex blob methods (DPVM and DVBM).

In [16], Hou used $g(x)\equiv 1$, where the integrals in (10) and (11) are taken over the support of the vorticity (or some set containing it), assumed to be finite, and denoted by Ω. He considered the reformulated equations

$$\frac{dX_i}{dt}=\int_\Omega K(X_i-X(\alpha))(\omega_0(\alpha)-\omega_i)\,d\alpha+\omega_i\int_\Omega K(X_i-X(\alpha))\,d\alpha.$$

The second integral is the velocity induced at X_i by a patch of constant vorticity of strength ω_i and filling Ω. This integral is no longer zero, but can be computed explicitly over triangulations of the underlying mesh, or as a boundary integral [7]. However, note that the subtracted vorticity distribution does not vanish smoothly at $\partial\Omega$. Therefore, discretizations of the first integral must be based upon quadrature rules that take careful account of the boundary; misrepresentation of the boundary can lead to $O(h)$ errors. This problem is completely circumvented by using a subtracted vorticity distribution that is smooth and decaying (compact support). In addition, our method is simpler, as there is no correction term to calculate (the second integral above).

Here, we consider the point vortex and blob discretizations of (10), or

$$\tag{12} \begin{aligned} \frac{d\tilde{X}_i^\delta(t)}{dt} &= \sum_{\substack{j\neq i\\ jh\in\Delta_h}} K_\delta(\tilde{X}_i^\delta-\tilde{X}_j^\delta)(\omega_j-\omega_i g(\tilde{X}_i^\delta-\tilde{X}_j^\delta))h^2 \equiv \tilde{u}_i^\delta,\\ \tilde{X}_i^\delta(0) &= \alpha_i. \end{aligned}$$

To ensure the consistency of our scheme, our discretization must cover a set $\tilde{\Omega}$, which contains Ω, with the property that

$$\tag{13} \min \operatorname{dist}(\partial\tilde{\Omega}, \partial\Omega) \geqq R_2.$$

This condition is necessary to ensure that the discretization of (11) is zero to $O(h^2)$ for those points $X(\alpha_i, t)$ such that $\operatorname{dist}(X(\alpha_i, t), \partial\Omega) \leqq R_2$. That is, we carry marker particles in the region $\tilde{\Omega}-\Omega$. These particles carry no vorticity but will effect the velocity calculation at points $X_i \in \Omega$ such that $\operatorname{dist}(X_i, \partial\Omega) \leqq R_2$.

We now present our convergence theorems.

THEOREM 1 (convergence of the DPVM). *Assume that* $\omega_0, g \in C_0^2(\mathbf{R}^2)$ *and that* g *satisfies* (9) *and* $\tilde{\Omega}$ *satisfies* (13). *Then, for* $0\leqq t\leqq T$, *there exists* $h_0(\omega_0, T, g)$ *such that*

$$\max_i |X_i-\tilde{X}_i| \leqq C(T)h^2 \quad \text{and} \quad \max_i |u_i-\tilde{u}_i| \leqq C(T)h^2,$$

for all $0<h\leqq h_0$, *where* $X_i = X(\alpha_i, t)$ *and* $u_i = u(X_i, t)$ *are the exact solutions of the Euler equations and* $\tilde{X}_i$ *and* $\tilde{u}_i$ *are the solutions of* (12) *with* $\delta = 0$.

THEOREM 2 (convergence of DBVM). *Assume that* $f(x)$ *is an mth order cutoff function,* $g, f, \omega_0 \in C_0^r(\mathbf{R}^2)$, g *satisfies* (9), *and* $\tilde{\Omega}$ *satisfies* (13). *We assume that* $\delta = h^q$ *with* q *such that* mq *and* $(1-q)r+2q$ *are both* $\geqq 1+2\alpha_0$ *for some* $\alpha_0>0$. *This is so that the method is more than first-order accurate. Then, there exists* $h_0(\omega_0, f, g, T)$ *for* $0\leqq t\leqq T$ *such that*

$$\max_i |X_i-\tilde{X}_i^\delta| \leqq C(T)\left(\delta^m + \left(\frac{h}{\delta}\right)^r \delta^2\right)$$

and

$$\max_i |u_i-\tilde{u}_i^\delta| \leqq C(T)\left(\delta^m + \left(\frac{h}{\delta}\right)^r \delta^2\right)$$

for all $h\leqq h_0$, *where* $\tilde{X}_i^\delta$ *and* $\tilde{u}_i^\delta$ *are the solutions of* (12).

Remark 1. (i) Thanks to a smooth g, we can obtain an asymptotic error expansion in the case $\delta = 0$, in even integer powers of h.

(ii) We will prove only Theorem 1. Theorem 2 is proved using the bounds of Theorem 1 and follows directly from the standard analyses of vortex methods (see [1]-[4], [9], [12], [15], and [24], for example).

Proof of Theorem 1. As usual, we divide the proof into two parts: consistency and stability. We begin with consistency.

CONSISTENCY LEMMA. *Suppose that* $g, \omega_0 \in C_0^\infty(\mathbf{R}^2)$, *and* $\tilde{\Omega}$ *satisfies* (13) *with* Δ_h *as its Lagrangian discretization. Then there exists* $h_0(T, g, \omega_0)$ *such that for all* $0<h\leqq h_0$

$$\tag{14} \begin{aligned} \rho_i &\equiv \int_{\mathbf{R}^2} K(X_i - X(\alpha))\omega_0(\alpha)\,d\alpha - \sum_{\substack{jh\in\Delta_h\\ j\neq i}} K(X_i-X_j)(\omega_j-\omega_i g(X_i-X_j))h^2\\ &= C_2(X_i, t, g)h^2 + C_4(X_i, t, g)h^4 + \cdots + O(h^N) \end{aligned}$$

for any N. The constants $C_{2n}(X_i, t, g)$ $(n \geqq 1)$ are smooth functions of X_i. Furthermore, if g, $\omega_0 \in C_0^2(\mathbf{R}^2)$ then the expansion stops at the fourth order and we only obtain $\|\rho\|_{l^\infty} \leqq C(T)h^2$.

Proof of consistency. We rewrite ρ_i as follows:

$$\begin{aligned}\rho_i &= \int_{\mathbf{R}^2} K(X_i - X(\alpha))\omega_0(\alpha)\,d\alpha - \sum_{\substack{jh\in\Delta_h\\ j\neq i}} K(X_i - X_j)(\omega_j - \omega_i g(X_i - X_j))h^2\\ &= \int_{\mathbf{R}^2} K(X_i - X(\alpha))(\omega_0(\alpha) - \omega_i g(X_i - X(\alpha)))\,d\alpha\\ &\quad - \sum_{\substack{jh\in\Delta_h\\ j\neq i}} K(X_i - X_j)(\omega_j - \omega_i g(X_i - X_j))h^2,\end{aligned}$$

since the velocity at the center of a radially symmetric vortex patch is zero.

Using assumption (13) and the fact that g is smooth with compact support, we can apply the consistency argument of Goodman, Hou, and Lowengrub [13]. We need only to replace their Lemma 2 by the following lemma.

LEMMA 2′. *For any N, we have*

$$\begin{aligned}&K(X(0) - X(\alpha))(\omega_0(\alpha) - \omega_0(0)g(X(0) - X(\alpha)))\\ &\quad = l_0(\alpha) + l_1(\alpha) + l_2(\alpha) + \cdots + O(|\alpha|^N),\end{aligned}$$

where l_n is homogeneous of degree n in α. Then, using l_n instead of m_n in the proof of Lemma 1 in [13], *we get the result*

$$\rho_i = C_2h^2 + C_4h^4 + \cdots + O(h^N)$$

for any N. Furthermore, the coefficients are rapidly decaying, as before [13], *and thus we obtain the desired result.*

The proof of Lemma 2′ is accomplished by expanding $X(\alpha)$, $K(X(0) - X(\alpha))$, and $g(X(0) - X(\alpha))$ in power series in α and then multiplying them appropriately. The presence of the term $\omega_0(0)g(X(0) - X(\alpha))$ eliminates the most singular term that appears in Lemma 2 of [13]. This completes the proof of the Consistency Lemma.

We now turn to the Stability Lemma.

STABILITY LEMMA. *If*

$$\|X(t) - \tilde{X}(t)\|_{l^\infty} \leqq h^{1+s}$$

for $t \leqq T^*$ and any $s > 0$, then there exists $E(T)$ such that

$$\begin{aligned}&\max_i \left| \sum_{\substack{jh\in\Delta_h\\ j\neq i}} K(X_i - X_j)(\omega_j - \omega_i g(X_i - X_j))h^2 - \sum_{\substack{jh\in\Delta_h\\ j\neq i}} K(\tilde{X}_i - \tilde{X}_j)(\omega_j - \omega_i g(\tilde{X}_i - \tilde{X}_j))h^2 \right|\\ &\quad \leqq E(T)\|X - \tilde{X}\|_{l^\infty}.\end{aligned} \tag{15}$$

Proof of stability. Define

$$F_{ij}(y) = K(y)(\omega_j - \omega_i g(y)) \tag{16}$$

and $e_i = X_i - \tilde{X}_i$. Furthermore, we define

$$\sigma_i = \sum_{\substack{jh\in\Delta_h\\ j\neq i}} F_{ij}(X_i - X_j)h^2 - \sum_{\substack{jh\in\Delta_h\\ j\neq i}} F_{ij}(\tilde{X}_i - \tilde{X}_j)h^2. \tag{17}$$

By the mean value theorem, we have

$$\sigma_i = \sum_{\substack{jh\in\Delta_h\\ j\neq i}} \nabla F_{ij}(X_i - X_j + X_{ijk}) \cdot (e_i - e_j)h^2, \tag{18}$$

where $X_{ijk} = \theta_k(e_i - e_j)$ for some $|\theta_k| \leqq 1$ and $k = 1, 2$ denotes the component of ∇F. The mean value theorem is applicable here because F_{ij} is nonsingular in the region considered:

$$\begin{aligned} |X_i - X_j + X_{ijk}| &\geqq |X_i - X_j| - |X_{ijk}| \\ &\geqq |X_i - X_j| - 2h^{1+s} \\ &\geqq C(T)|\alpha_i - \alpha_j| - 2h^{1+s} \\ &\geqq \frac{C(T)}{2}|\alpha_i - \alpha_j| \end{aligned} \tag{19}$$

for $t \leqq T^*$ and h small enough, where we have used $|X(\alpha_i) - X(\alpha_j)| \geqq C(T)|\alpha_i - \alpha_j|$ due to the smoothness of the inverse flowmap X^{-1}.

Now we examine ∇F_{ij}. Differentiating both sides of (16), we get

$$\nabla F_{ij}(y) = \nabla K(y)(\omega_j - \omega_i g(y)) - K(y)\omega_i \nabla g. \tag{20}$$

Since $g(y)$ is smooth, we have by the mean value theorem $g(y) = g(0) + \nabla g(\xi) y$ for some $|\xi| \leqq |y|$. Recall that $g(0) = 1$. Thus we obtain

$$\nabla F_{ij}(y) = \nabla K(y)(\omega_j - \omega_i) - (\omega_i \nabla g(\xi)) y \nabla K(y) - K(y)\omega_i \nabla g. \tag{21}$$

As a consequence, we obtain

$$|\nabla F_{ij}(X_i - X_j + X_{ijk})| \leqq \frac{D(T)}{|\alpha_i - \alpha_j|}, \tag{22}$$

where we have used (19) and the boundedness of ∇g. Then it follows from (18) and (22) that

$$|\sigma_i| \leqq D(T)\|e\|_{l^\infty} \sum_{\substack{jh \in \Delta_h \\ j \neq i}} \frac{h^2}{|\alpha_i - \alpha_j|} \leqq E(T)\|e\|_{l^\infty}, \tag{23}$$

which proves the Stability Lemma.

We are now ready to complete the proof of Theorem 1. Define

$$e_i(t) = X_i(t) - \tilde{X}_i(t)$$

and

$$T^* = \inf\{t \mid 0 \leqq t \leqq T, \|e(t)\|_{l^\infty} \leqq h^{1+s}\}$$

for some $0 < s < 1$. We have

$$\frac{de_i}{dt}(t) = \sigma_i(t) + \rho_i(t).$$

It follows from the Consistency and Stability Lemmas that for $t \leqq T^*$,

$$\frac{d}{dt}\|e\|_{l^\infty} \leqq E(T)\|e\|_{l^\infty} + C(T)h^2. \tag{24}$$

Gronwall's inequality then implies that

$$\|e\|_{l^\infty} \leqq H(T)h^2 \quad \text{for } t \leqq T^*. \tag{25}$$

But $H(T)$ is independent of T^*. Thus, for h small enough, we have $\|e\|_{l^\infty} \leqq h^{1+s}/2$. Hence we conclude that $T^* = T$, which completes the proof of Theorem 1.

Remark 2. (i) Our parameters R_1, R_2 allow for the fine tuning of the error. Clearly, as the difference $R_2 - R_1$ increases, our stability constants will decrease. Increasing R_1 and fixing the distance $R_2 - R_1$ will also result in a decrease of the stability constants.

(ii) Decreasing R_2 or $R_2 - R_1$ will increase the stability constant because ∇g becomes larger; see (21).

(iii) As a result of our asymptotic error expansion, we can extrapolate, using different grid sizes, to obtain higher-order accurate methods. In this way, we do not need to use explicit values of the vorticity gradients, we simply need to know that they are smooth.

4. Numerical results. In this section, we present some results of numerical experiments in which both the DPVM and the DVBM are implemented to simulate the two-dimensional Euler equations. These results are only intended to be illustrative of the advantages of the increased stability for vortex methods based on exact desingularization. It is clear that there are many ways in which the method could be further improved and fine tuned.

On a simple test problem, the convergence rates predicted by the convergence theorems are demonstrated. It is shown that increased stability accompanies wider support of the cutoff function $g(|x|)$, as indicated in Remark 2(i). Furthermore, these methods are compared with both the classical point vortex and vortex blob methods. The results indicate that the DPVM and the DVBM show increased stability relative to these methods, and consequently remain more accurate over longer times.

As our test case, we consider the motion of a smooth, radially symmetric distribution of vorticity. Such distributions are steady solutions to the Euler equations, in which fluid particles move with constant speed on circles about the origin. In particular, we use

$$\omega(x) = \begin{cases} (1-|x|^2)^7 & \text{if } |x| \leqq 1, \\ 0 & \text{if } |x| > 1. \end{cases}$$

The velocity field is then given by

$$u(x) = f(|x|)\,\frac{(-x_2, x_1)}{|x|}$$

with speed

$$f(r) = \begin{cases} (1-(1-r^2)^8)/(16r) & \text{if } r \leqq 1, \\ 1/(16r) & \text{if } r > 1. \end{cases}$$

The vorticity itself lies in $C^6(R^2)$. This particular test case has been used by many others; see [23], for example. It is a nontrivial test case for a Lagrangian method, as there is a good deal of grid distortion and stretching. As an illustration, consider the motion of a material curve that at $t=0$ is the line segment connecting $(0,0)$ and $(1,0)$. By $t=20$ this material curve has increased its length eightfold. This particular material curve is also a coordinate line in our calculations.

For our methods, many choices must be made. First, a cutoff function $g(r)$ must be chosen, which may itself involve further parameters (say R_1 and R_2 in (9)). Furthermore, a discretization of the exactly desingularized Biot-Savart integral (10) must be specified. We have discussed the point vortex and vortex blob approximations, though perhaps there are others worth entertaining. For definiteness, we consider here the cutoff function

$$g(r) = \begin{cases} 1 & \text{if } r \leqq R_1, \\ (1 - s(r)^8)^7 & \text{if } R_1 < r < R_2, \\ 0 & \text{if } r \geqq R_2, \end{cases}$$

where $s(r)^2 = (r^2 - R_1^2)/(R_1^2 - R_2^2)$. Note that g also lies in $C^6(R^2)$, and generally should be chosen to be at least in the same continuity class as the vorticity. Figure 1 shows g with $R_1 = \frac{1}{2}$ and $R_2 = 1$.

Using the DPVM, with the above choices of R_1 and R_2, Fig. 2 shows the maximum error in velocity, $\|e(t)\|_\infty$, for $h = 0.2$ (medium dash), 0.1 (short dash), and 0.05 (solid), on $0 \leqq t \leqq 20$. The time integration method is a fourth-order, Adams-Moulton predictor-corrector [11]. The timestep was chosen small enough to remove time discretization errors from Fig. 2. Initially, the computational points were placed on a square grid over the vorticity. Here the set covering the vorticity was taken large enough to satisfy condition (13). That the error is of second-order is evident in Fig. 3, which displays $\log_2(\|e(2h, t)\|_\infty / \|e(h, t)\|_\infty)$ for $h = 0.05$. This function should be approximately two for a second-order method.

Now we consider the effect of varying both R_1 and R_2 upon the DPVM. Let $R_1 = \alpha/2$ and $R_2 = \alpha$. Then as $\alpha \downarrow 0$, we recover the classical point vortex approximation. For $h = 0.1$, Fig. 4 shows the error as α is varied as $\alpha = 1$ (solid), $\frac{1}{2}$ (short dash), $\frac{1}{4}$ (medium dash), and 0 (long dash, the classical point vortex approximation). We note that the initial error in velocity (the discretization error) for all four cases is approximately $2.0 \cdot 10^{-3}$. As indicated by our convergence theorems, α is chosen for stability

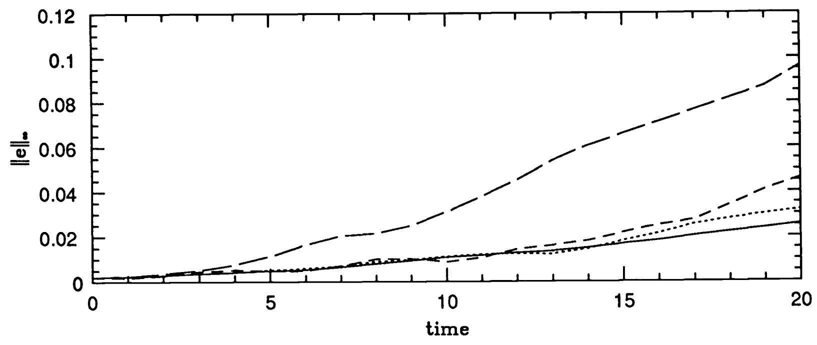

FIG. 4. *Comparison of the velocity error for the* DVPM *as the patch function g changes. We let $R_1 = \alpha/2$ and $R_2 = \alpha$. Then the curves are the error for $\alpha = 1$ (solid line), $\alpha = \frac{1}{2}$ (short dash), $\alpha = \frac{1}{4}$ (medium dash), $\alpha = 0$ (long dash), and $h = .1$.*

considerations, rather than for accuracy. Note from Fig. 4 that as α becomes larger and the support of the cutoff function grows, the growth of error decreases in time.

It is informative to decompose this error into that part associated with consistency and that with stability. As is usual, the error associated with consistency is given by

$$\int_{\mathbf{R}^2} K(X_i - X(\alpha))\omega_0(\alpha)\, d\alpha - \sum_{\substack{jh\in\Delta_h\\ j\neq i}} K(X_i - X_j)(\omega_j - \omega_i g(X_i - X_j))h^2,$$

and that for stability by

$$\sum_{\substack{jh\in\Delta_h\\ j\neq i}} K(X_i - X_j)(\omega_j - \omega_i g(X_i - X_j))h^2 - \sum_{\substack{jh\in\Delta_h\\ j\neq i}} K(\tilde{X}_i - \tilde{X}_j)(\omega_j - \omega_i g(\tilde{X}_i - \tilde{X}_j))h^2,$$

where $X_i(t)$ and $\tilde{X}_i$ are the exact and approximate solutions, respectively. Figure 5 shows these two errors (in maximum norm) for the classical PVM (dash) and for the desingularized PVM (solid). It is clear that the dominant error in both methods is that associated with stability, and that the stability control associated with the use of exact desingularization leads to much decreased error growth in time. An additional benefit from using exact desingularization here is a slower growth of the consistency error as the mesh becomes distorted and stretched.

We reach similar conclusions when comparing the DVBM with the classical VBM. Figure 6 shows the maximum error in velocity, with $h = 0.1$, for the DVBM (solid)

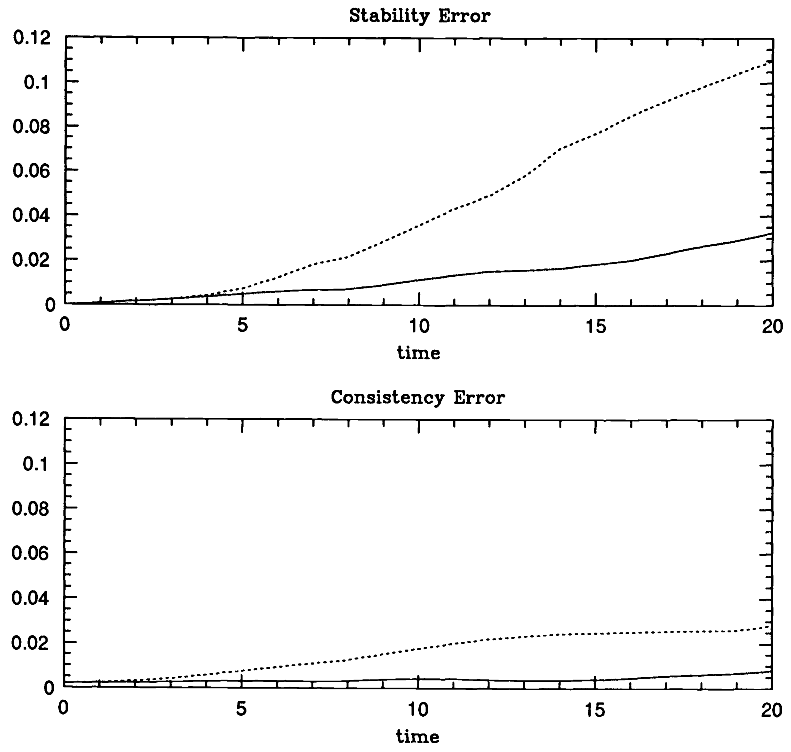

FIG. 5. (a) *Stability error for the* DVPM (*solid line*) *with g of Fig.* 1 *vs.* PVM (*dashed line*) *for* $h = .1$. (b) *Consistency error for the* DVPM *with g of Fig.* 1 (*solid line*) *vs.* PVM (*dashed line*) *for* $h = .1$.

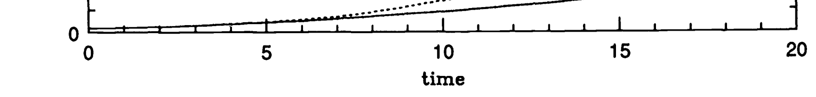

FIG. 6. *Comparison of the maximum error in velocity for the* DVBM *with g of Fig.* 1 (*solid line*) *vs.* VBM *with* $h = .1$, $\delta = h^{.95}$, *and a fourth-order cutoff function* (*Beale and Majda* [3]).

and the classical VBM (dashed). Here we have used a fourth-order kernel (Beale and Majda [3]), with small blob size $\delta = h^{0.95}$. Note that the vertical scale in Fig. 6 is one-half that in Figs. 4 and 5. For this choice of δ, Theorem 2 gives an order of accuracy of $O(h^{2.2})$, which is only slightly higher than that of the PVM. However, we expect to have a further improvement in the stability of the scheme. This expectation is justified by Fig. 6. Also note that while the VBM was initially more accurate than the DPVM (Fig. 4) by $t = 20$ this situation has reversed, and the DPVM has become more accurate. Figure 7 shows the associated stability and consistency errors. Again, the method based

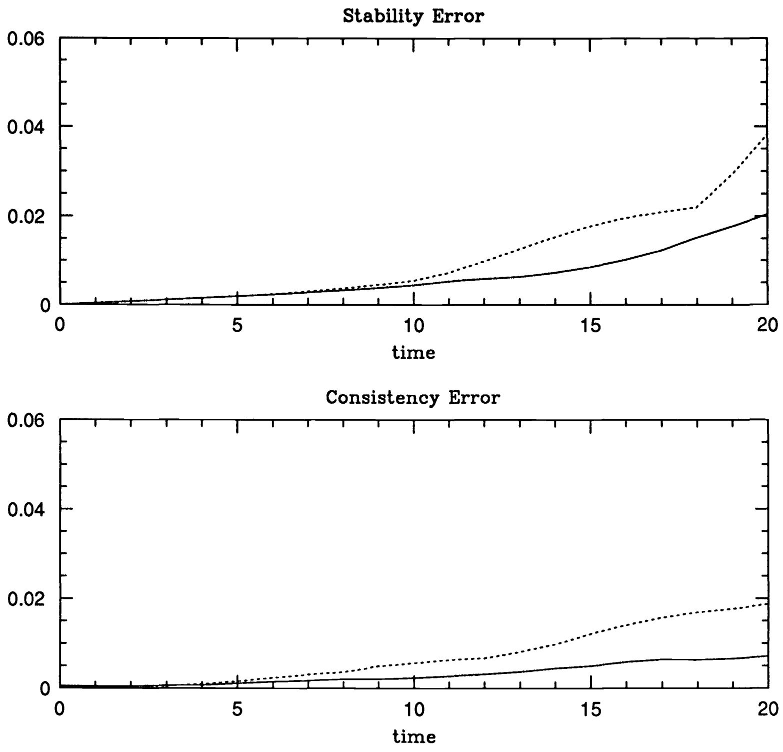

FIG. 7. (a) *Stability error for* DVBM *with g of Fig.* 1 (*solid line*) *vs.* VBM (*dashed line*) *with* $h = .1$. (b) *Consistency error for* DVBM *with g of Fig.* 1 (*solid line*) *vs.* VBM (*dashed line*).

upon exact desingularization shows both decreased stability and consistency error relative to the standard methods.

Finally, we present some preliminary calculations of the interaction of two like-signed vortices. Again, these calculations illustrate the computational advantages of exact desingularization, but they also demonstrate that our methods offer no panacea to a fundamental source of error in Lagrangian methods, which is grid distortion and stretching. We consider the initial vorticity distribution

$$\omega(x, y) = (\max(0, (.25 - (|x| - .5)^2 - y^2)))^7/.25^7.$$

Contours of this vorticity distribution are shown in Fig. 8. Evolution from this initial condition was calculated by Nordmark [22], who showed that the accuracy of vortex methods could be much improved through periodic rezoning of the particle positions. We do not present a comparison with his work here, but only seek a more interesting example with which to study our methods.

The initial particle positions are on a square grid covering the vorticity distribution. To visualize the motion of the vortices, we have placed marker particles on the four contours of the vorticity shown in Fig. 8. Initial point positions are shown on the left set of contours. The inner two contours each have 50 points, while the outer two have 200 points. The outermost contours coincide with the boundary of the support of the vorticity. The velocity of a marker particle with position $Y(t)$ is calculated by

$$\frac{dY(t)}{dt} = \sum_{jh \in \Delta_h} K_\delta(Y - \tilde{X}_j^\delta)(\omega_j - \omega(Y(0))g(Y - \tilde{X}_j^\delta))h^2.$$

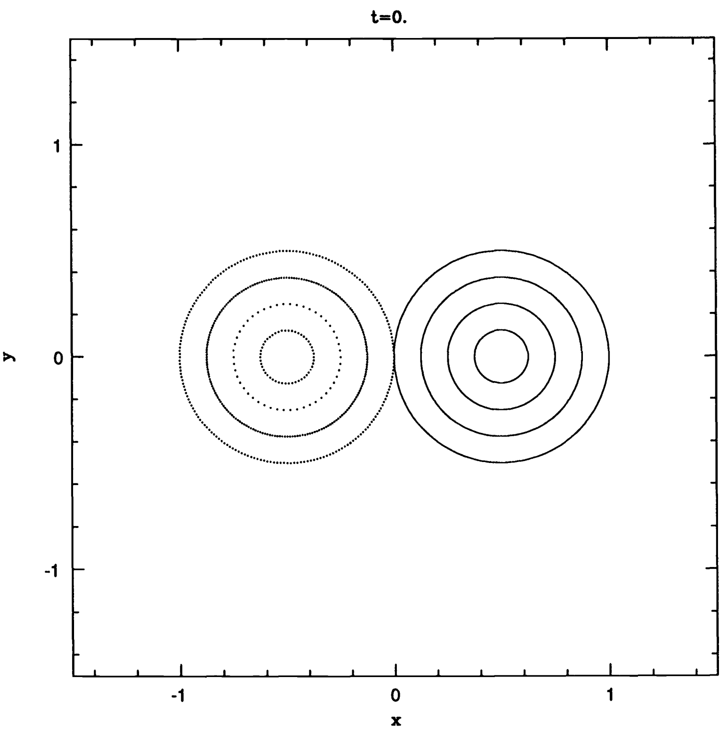

FIG. 8. *Initial position of marker particles for the two-patch problem.*

Figures 9(a) and 9(b) show the evolution of these marker particles at $t = 10.$ and $t = 20.$, using the DVBM with $h = .05$, $\delta = h^{.95}$, and $\alpha = 1$ for g, as given above. The lack of smoothness of the inner contours at $t = 20.$ is nonphysical, as Nordmark's careful calculations show. From these figures it is clear that vortex methods based upon exact desingularization would also benefit from a rezoning strategy. In Figs. 10(a) and 10(b) we show the same calculation, now using the classical VBM. The conclusions are self-evident.

We close this section with several remarks.

(i) The existence of fast summation techniques for a particle method is an important consideration. The first part of the sum (12),

$$h^2 \sum_{j \neq i} K_\delta(\tilde{X}_i^\delta - \tilde{X}_j^\delta)\omega_j,$$

can be evaluated by methods already developed for Biot–Savart sums (see Greengard and Rokhlin [14]). Because of the nature of our cutoff function, the second part of the sum,

$$h^2\omega_i \sum_{j \neq i} K_\delta(\tilde{X}_i^\delta - \tilde{X}_j^\delta)g(\tilde{X}_i^\delta - \tilde{X}_j^\delta),$$

remains of convolution type. That is, $\hat{K} = K_\delta g$ is convolved with 1. General fast summation techniques have also been developed for such sums (see Brandt [5]).

(ii) We do not present results for three-dimensional calculations using the exact desingularization for the three-dimensional Euler equations to be discussed in § 5. We are currently implementing this method.

(iii) Merriman [21] has pointed out that further subtractions, which account for yet higher-order information of the vorticity, may not only increase stability, but also improve accuracy.

(iv) Evolving the marker particles in the region $\tilde{\Omega}-\Omega$ is costly. While the use of fast summation techniques will considerably ameliorate this cost, much can be done in optimizing the cutoff function g to reflect the vorticity distribution.

We now turn to the three-dimensional extension of our desingularization.

5. Generalization to the three-dimensional grid-free vortex method. The three-dimensional incompressible Euler equations in vorticity-stream function formulation are

$$w_t+(u\cdot\nabla)w=(w\cdot\nabla)u, \tag{26}$$

where

$$u(x,t)=\int_{\mathbf{R}^3}K(x-x')w(x',t)\,dx' \tag{27}$$

and

$$K(x)=\frac{-1}{4\pi|x|^3}\begin{pmatrix}0 & x_3 & -x_2\\ -x_3 & 0 & x_1\\ x_2 & -x_1 & 0\end{pmatrix}.$$

The particle formation is, using incompressibility,

$$\frac{dX}{dt}(\alpha,t)=u(X(\alpha,t),t)=\int_{\mathbf{R}^3}K(X(\alpha,t)-X(\alpha',t))w(X(\alpha',t),t)\,d\alpha' \tag{28}$$

and

$$\begin{aligned}\frac{dw}{dt}(X(\alpha,t))&=(w\cdot\nabla)u\\ &=w(X(\alpha,t),t)\cdot\int_{\mathbf{R}^3}\nabla K(X(\alpha,t)-X(\alpha',t))\cdot w(X(\alpha',t),t)\,d\alpha'.\end{aligned} \tag{29}$$

The reformulation idea presented in § 3 applies to the three-dimensional method as well.

As in § 3, we define a radial scalar function g, satisfying $g(|x|)=0$ for $|x|\geqq R_2$, $g(|x|)=1$ for $|x|\leqq R_1$, and smoothly varying in between. Then, it is clear that

$$\int_{\mathbf{R}^3}K(X(\alpha,t)-X(\alpha',t))w(X(\alpha,t),t)g(X(\alpha,t)-X(\alpha',t))\,d\alpha'=0, \tag{30}$$

since K is odd. Therefore,

$$\begin{aligned}&\int_{\mathbf{R}^3}K(X(\alpha)-X(\alpha'))w(X(\alpha'))\,d\alpha'\\ &\quad=\int_{\mathbf{R}^2}K(X(\alpha)-X(\alpha'))(w(X(\alpha'))-w(X(\alpha))g(X(\alpha)-X(\alpha')))\,d\alpha',\end{aligned} \tag{31}$$

which reduces the singularity of K by one order.

The particle equations (28), (29) can be desingularized as follows. Consider the integral

$$\begin{aligned}&\int_{\mathbf{R}^3}\nabla K(X(\alpha)-X(\alpha'))w(X(\alpha))g(X(\alpha)-X(\alpha'))\,d\alpha'\\ &\quad=\int_{\mathbf{R}^3}\nabla K(x-x')w(x)g(x-x')\,dx'.\end{aligned} \tag{32}$$

Without loss of generality, we consider the case $x=0$. Then (32) reduces to

$$\int_{\mathbf{R}^3} \nabla K(-x')w(0)g(-x')\,dx'. \tag{33}$$

The integrand is a matrix whose elements have the following form:

$$\frac{\pm 3x_i'x_j'}{|x'|^5}\gamma_k g(-x')+\frac{\kappa_{ij}\gamma_k g(-x')}{|x'|^5}[3x_i'^2-(x_1'^2+x_2'^2+x_3'^2)], \tag{34}$$

where $\kappa_{ij}=\pm 1$ if $i\neq j$, $\kappa_{ii}=0$, and $w(0)=(\gamma_1,\gamma_2,\gamma_3)$. Thus, since g is a radial function, the integral of the first term in (34) vanishes due to oddness in each coordinate axis. The integral of the second term vanishes due to exact cancellation of integrals.

Therefore, the reformulation of (28), (29) can be stated as:

$$\frac{dX}{dt}(\alpha,t)=\int K(X(\alpha)-X(\alpha'))(w(X(\alpha'))-w(X(\alpha))g(X(\alpha)-X(\alpha')))\,d\alpha', \tag{35}$$

$$\frac{dw}{dt}(\alpha,t)=\int \nabla K(X(\alpha)-X(\alpha'))(w(X(\alpha'))-w(X(\alpha))g(X(\alpha)-X(\alpha')))\,d\alpha', \tag{36}$$

with $X(\alpha,0)=\alpha$ and $w(\alpha,0)=w_0(\alpha)$. The numerical method is then given by:

$$\frac{d\tilde{X}_i}{dt}=\sum_{\substack{jh\in\Delta_h\\ j\neq i}} K_\delta(\tilde{X}_i-\tilde{X}_j)(\tilde{w}_j-\tilde{w}_i g(\tilde{X}_i-\tilde{X}_j))h^3, \tag{37}$$

$$\frac{d\tilde{w}_i}{dt}=\sum_{\substack{jh\in\Delta_h\\ j\neq i}} \nabla K_\delta(\tilde{X}_i-\tilde{X}_j)(\tilde{w}_j-\tilde{w}_i g(\tilde{X}_i-\tilde{X}_j))h^3, \tag{38}$$

with $\tilde{X}_i(0)=\alpha_i$ and $\tilde{w}_i(0)=w_0(\alpha_i)$, and where $\delta\geqq 0$.

We remark that this method is less physical than the corresponding two-dimensional method. The reason for this is that our requirement of compact support for g is tantamount to assuming that vortex lines end. However, we hope that the reduction of the singularity of the summands in (37) and particularly (38) makes three-dimensional computations more feasible.

The convergence of the desingularized method (37), (38) can be obtained by either following Beale's proof for the VBM [2] or by following the proof of Cottet, Goodman, and Hou [10] for the PVM. In either case, the stability is easier, and in the case of the PVM, the factor $\log(1/h)$ [10] can be eliminated.

Acknowledgments. It is a pleasure to thank G. Baker, R. Caflisch, J. Keller, and especially B. Merriman for their interest and valuable discussions concerning this work. The authors also wish to thank C. Anderson (Reviewing Editor, SISC) and a reviewer for their useful comments.

SOME NUMERICAL ASPECTS OF COMPUTING INERTIAL MANIFOLDS*

ROBERT D. RUSSELL†, DAVID M. SLOAN‡, AND MANFRED R. TRUMMER†

Abstract. Various aspects of the problem of computing inertial manifolds for dissipative partial differential equations are investigated. In particular, methods are proposed which generalize previous ones and improve upon some of their limitations. The basic ideas and techniques are exemplified mainly for the Kuramoto-Sivashinsky equation. This equation is chosen because it is fairly simple but the dynamics are sufficiently complicated, and it is a classical case for which a considerable amount of computational experience has been well documented.

Key words. dissipative PDE, inertial manifold, inertial form, spectral method, Galerkin method, differential-algebraic equations, reaction diffusion equation, Kuramoto-Sivashinsky equation

1. Introduction. Recently there has been considerable interest, especially in the dynamical systems community, in the computation of inertial manifolds for dissipative partial differential equations (PDEs). This process is carried out by first splitting the solution space H into two subspaces PH and QH, where P is an orthogonal projection on H with finite-dimensional range and $Q = I - P$. The projection components in PH and QH are denoted, respectively, by p and q, and these components are governed by a system of ordinary differential equations (ODEs). The q-variables are expressed in terms of the p-variables by some relation $q = \phi(p)$, and the dynamics of this reduced system of ODEs for the p-variables are then used to mimic the dynamics of the underlying PDE.

We consider an evolution equation of the form

$$u_t + Au + F(u) = 0, \tag{1}$$

where A is a selfadjoint positive operator with compact resolvent (the dissipative part) defined on a Hilbert space H, and $F(u)$ is the nonlinear part defined on the domain of A. The dissipative nature of the PDE imparts it with a number of important properties (e.g., see [CFNT]), one of which is that the solution map $u_0 \to u(t) = S(t)u_0$ satisfies the following: There exists a compact, convex set $Y \subset H$ such that, for any bounded set $F \subset H$ there exists $t_0 = t_0(F)$ with $S(t)u_0 \in Y$ for all $t \geqq t_0$, $u_0 \in F$. We are interested in studying the long-term dynamics of the PDE. Although these dynamics can be extremely complicated, we can show under suitable general conditions that the PDE has an *inertial manifold* Ω, which is a manifold in Y with the following properties [LS]:

(i) Ω is invariant, i.e., $S(t)\Omega \subset \Omega$ for all $t \geqq 0$;
(ii) Ω attracts all solutions of (1) exponentially; and
(iii) Ω is a finite-dimensional C^1 manifold.[1]

[1] The C^1 smoothness is a regularity result following from the definition.

It follows that all of the long-term dynamics take place on this inertial manifold. In particular, the global attractor [CFNT] is a subset of this manifold. While the rate of attraction to the global attractor may be slow, all solutions are attracted to the inertial manifold exponentially fast.

For most PDEs of the form (1) which have been considered to date, the linear operator A is sufficiently simple (the negative Laplacian $-\Delta$ or bi-Laplacian Δ^2 operator) that a spectral method can be straightforwardly used to approximate $u(t)$. In particular, suppose that $w_1, w_2, \dots$ are the orthogonal eigenfunctions of A with corresponding eigenvalues $0 < \lambda_1 \leqq \lambda_2 \leqq \cdots$, so that

$$Aw_j = \lambda_j w_j, \qquad j = 1, 2, \dots . \tag{2}$$

Define P and $Q := I - P$ to be the usual spectral projections with P projecting onto the subspace spanned by the first n eigenfunctions, i.e.,

$$Pu = p := \sum_{j=1}^{n} \alpha_j(t) w_j := \sum_{j=1}^{n} \frac{(u, w_j)}{(w_j, w_j)} w_j, \tag{3}$$

where (,) is the scalar product on H. Under suitable conditions, such as that the eigenvalues grow sufficiently fast to satisfy a *gap condition* [LS], it is possible to determine an (upper bound on) n such that Ω is the graph of a function ϕ satisfying $QS(t)u_0 = \phi(PS(t)u_0)$ for all $t \geqq 0$ whenever $Qu_0 = \phi(Pu_0)$. In this case, Ω is an n-dimensional manifold in H. Since P and Q commute with A, it follows that not only is the PDE (1) equivalent to the ODE system

$$\dot{p} + APp + PF(p+q) = 0, \tag{4a}$$

$$\dot{q} + AQq + QF(p+q) = 0, \tag{4b}$$

but its long-term dynamics (solution stability, hyperbolicity, bifurcations) are completely determined by the finite-dimensional ODE system

$$\dot{p} + APp + PF(p + \phi(p)) = 0 \tag{5}$$

with *no* error. This last system is called an *inertial form* for (1).

In practice, Q is approximated by truncating its corresponding spectral projection, which under suitable conditions can be theoretically justified. To facilitate the presentation, we assume (unless stated otherwise) that this has been done for m sufficiently large and simply denote

$$Qu = q := \sum_{j=n+1}^{m} \alpha_j(t) w_j := \sum_{j=n+1}^{m} \frac{(u, w_j)}{(w_j, w_j)} w_j \tag{6}$$

for Q and q in (4b). As a consequence of this truncation process and the subsequent numerical solution, $\phi(p)$ is replaced by an approximation, say $\phi_a(p)$, and the corresponding graph Ω_a defines an approximate inertial manifold (AIM). Henceforth in this paper we shall assume that the truncation (6) has been effected: we shall drop the subscript a on ϕ and Ω and assume that Ω denotes an AIM.

Determination of the long-term solution behaviour for the dissipative PDE (1) now reduces to computing solutions to (5), and this requires that an approximate ϕ be computed. The trivial approximation $\phi(p) \equiv 0$ yields the traditional Galerkin approximation; in the context here, it is called the *flat Galerkin method* since Ω is approximated as being "flat." For a *nonlinear Galerkin method* [MT], a nontrivial approximation for ϕ is used, providing a nonlinear manifold instead of a subspace. Approximations to ϕ can be obtained in a variety of ways. Basically, the methods involve either (i) solving a PDE for $\phi(p)$, which is derived from (4a), (4b), or (ii) using (4b) to find an approximate $\phi(p)$, which is then used in (5). See [LS] for a list of references and for a review of different methods, along with some of their theoretical and practical properties.

Methods from class (ii) wherein $q = \phi(p)$ is approximated using (4b) appear to be more straightforward to use in practice than those from class (i), and we restrict our attention to class (ii). In the next few sections, we discuss previously used methods and propose several new variants.

2. Solving the ODE (4b). The most straightforward method of approximating $q = \phi(p)$ is to discretize (4b). Simple low-order methods are normally used. The groundbreaking papers [FJKST] and [FST], which introduce the problem of computing AIMs, use the backward Euler method with one iteration, taking $q = 0$ as the initial approximation. If τ is the stepsize, we simply have

$$q = \hat{\phi}(p) = -\tau(I + \tau AQ)^{-1} QF(p). \tag{7}$$

A nontrivial decision is how to choose n and τ. While a small value of τ gives better accuracy (smaller local truncation error), it only guarantees that the graph of $\hat{\phi}(p)$ is close to Ω if $q = 0$ is a sufficiently accurate initial approximation. If this is not the case, (4a) and (4b) must be integrated in enough steps that (p, q) is sufficiently close to the manifold. Making use of the exponential rate of attraction to Ω and assuming n is chosen such that λ_{n+1} is sufficiently large, the strategy (7) with $\tau \approx 1/\lambda_{n+1}$ can be given some theoretical justification. However, as an illustration of practical difficulties that can arise, we give the following example.

Example 1. Consider the reaction diffusion equation

$$u_t - \nu u_{xx} + u^3 - u = 0, \qquad u(0, t) = u(\pi, t) = 0 \tag{8}$$

with $\nu = (1/2.5)^2 = 0.16$. We have $Au := -\nu u_{xx}$, so if $m = 3$, then $u(x, t) = \sum_{j=1}^{3} \alpha_j(t) \sin(jx)$. In the case $n = 2$, the relationship (7) is found explicitly in [FJKST] as $\alpha_3 = (\alpha_1^3 - 3\alpha_1\alpha_2^2)(\tau/4(9\tau\nu + 1))$. Using the techniques developed in the next section, we can show that a *general* backward Euler inner iteration (to converge from $q = 0$ to the approximation for the first Euler step)

$$q^{(l+1)} = -\tau(I + \tau AQ)^{-1} QF(p + q^{(l)}) \tag{9}$$

is a fixed-point iteration (also called Picard iteration) on

$$\alpha_3 = \frac{-\tau}{4(9\nu\tau + 1)} \{-\alpha_1^3 + 3\alpha_1\alpha_2^2 + [6\alpha_1^2 + 6\alpha_2^2 + 3\alpha_3^2 - 4]\alpha_3\}. \tag{10}$$

The exact Euler-Galerkin solution is the fixed point of (10) (it is easy to see that a fixed point exists for all values of α_1 and α_2); however, ordinary iteration only converges for certain values of α_1 and α_2, depending on ν and τ. This is illustrated in Fig. 1, which shows a cross section of $\alpha_3 = \alpha_3(\alpha_1, \alpha_2)$ for $\alpha_1 = 0.9$. The derivative of the iteration function in (10) at a fixed point α_3 is

$$\frac{-\tau}{4(9\nu\tau + 1)} \{6\alpha_1^2 + 6\alpha_2^2 + 9\alpha_3^2 - 4\} \tag{11}$$

(this derivative must have a modulus less than 1 for convergence), and a simple *necessary* condition for convergence of the Picard iteration is

$$|6\alpha_1^2 + 6\alpha_2^2 - 4| < \frac{4(9\nu\tau + 1)}{\tau}.$$

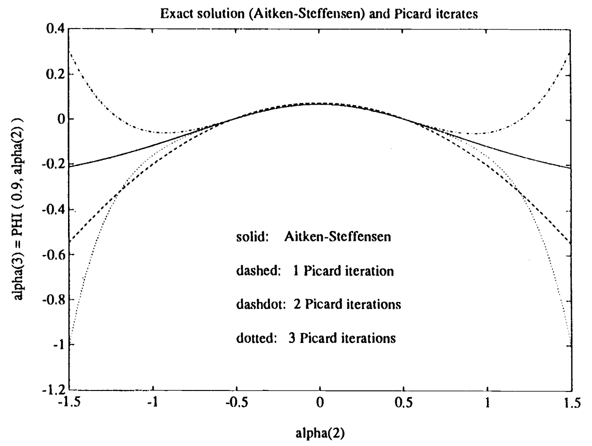

FIG. 1. *Nonconvergence of Picard iteration.*

Figure 2 brings these convergence results under one hat; it shows the region given by the essential convergence condition provided by (11) for $\nu = 0.16$ and $\tau = 1$, and the prediction is confirmed by numerical experiments. This region grows with ν, i.e., added dissipation, but shrinks with increasing τ. Note that in this simple case, the exact solution of (10) can be obtained via an Aitken–Steffensen iteration (see Fig. 1) or by employing a Newton method (see also below). The Euler–Galerkin AIM, as described in [JKT1] and [FST], would actually involve only one iteration of (9) with $m \geqq 6$ when $n = 2$. The lower bound for m is the maximum number of modes which can be stimulated in one iteration of (9) from an initial state $q = 0$. This lower bound depends in an obvious way on the nature of the nonlinearity in $F(u)$. In the case of a polynomial nonlinearity of degree r, for example, the minimum value of m is rn. If k iterations are performed on (9) starting from $q = 0$, the minimum value of m will be $r^k n$. It is shown in [FST] that for n sufficiently large convergence of (9) is guaranteed in an absorbing ball about the solution when there is no truncation of the series (6). On the other hand, our approach throughout is to fix n *and* m a priori and to solve the truncated problem accurately. We shall return to this point later.

Figure 1 in [FJKST] shows a plot of the approximate inertial manifold produced by one Picard iteration of the Euler–Galerkin scheme and the location of five steady-state solutions, with the same parameter values as used here ($\nu = 0.16$, $\tau = 1$). The

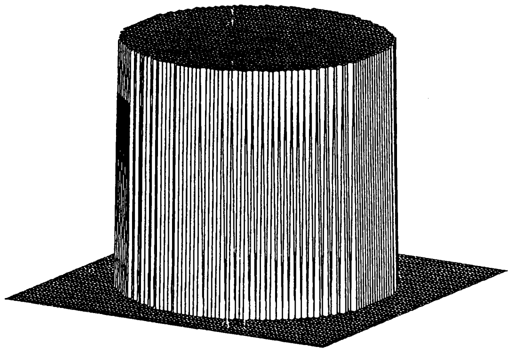

FIG. 2. *Convergence region.*

steady states with $\alpha_1 = 0$ have $\alpha_3 = 0$, and are therefore perfectly reproduced by any iteration scheme starting with initial guess zero. There is a steady state close to the point $\alpha_1 = 1.1143$, $\alpha_2 = 0$, $\alpha_3 = 0.1491$ (which we have computed using a three-mode flat Galerkin approximation). The first Picard iterate for (10) (with $\alpha_1 = 1.1143$, $\alpha_2 = 0$) starting from $\alpha_3 = 0$ produces the value 0.1418, whereas the exact Euler–Galerkin solution is $\alpha_3 = 0.1045$. Thus, while the first iterate overshoots the fairly poor "desired" Euler–Galerkin approximation by around 40 percent, it fortuitously *does* come close to the true steady-state solution. As τ grows without bound, the exact solution of (10) approaches the value $\alpha_3 = 0.1474$, which is indeed close to the desired steady-state value 0.1491, whereas the first Picard iterate overshoots the correct value again, this time giving the poor approximation 0.2402. These results show not only the potential difficulty of choosing a suitable value of τ, but also of using a fixed, small number of Picard iterations.

We shall see that as τ increases, backward Euler and the methods discussed next give virtually identical results, and that for the Kuramoto–Sivashinsky (KS) equation, this in fact happens for most realistic choices of τ.

3. The differential-algebraic equation approach with Picard iteration. An important approach for approximating $\phi(p)$, which is due to Titi [T], involves setting $\dot{q} = 0$ in (4b) and solving

$$G(q) := Aq + QF(p+q) = 0. \tag{12}$$

This defines the so-called *steady approximate inertial manifold* Ω_S with graph $q = \phi_S(p)$. Although not previously interpreted in the literature this way, finding the solution of the (approximate) inertial form (5) with $\phi_S(p)$ is equivalent to solving the semi-explicit differential-algebraic equations (DAEs) (5) and (12). By assumption, the relation $q = \phi_S(p)$ can be determined from (12), so the DAE is of index one and its numerical solution avoids many of the difficulties arising for higher-index problems [AP]. While such an approximation may appear somewhat crude, theoretical arguments can be made for why $\dot{q}$ may be ignored, and the method can give very useful results in practice [JKT1], [JKT2]. One reason for this is because the AIM obtained from solving the algebraic part of this DAE contains all exact steady-state solutions involving only the first m modes (or all those for the flat Galerkin method with m modes), so computations based on the steady AIM give a faithful representation of the steady states for the inertial manifold if one exists for these m modes. In this sense the AIM and the inertial manifold are "threaded together."

The method that has been suggested for solving (12) is the Picard iteration

$$q^{(l+1)} = -A^{-1}QF(p+q^{(l)}) \tag{13}$$

with only one or two iterations and $q^{(0)} = 0$ [JKT1]. Under suitable conditions, justification can be given for this two-iteration case, which gives the so-called *pseudosteady solution* and the corresponding *pseudosteady* AIM $\Omega_{\hat{S}}$, the graph of $q = \phi_{\hat{S}}(p)$. This is done in [JKT1] and [JKT2] for the KS equation. The pseudosteady approach does not involve truncation of the series (6), but since KS involves the quadratic nonlinearity uu_x, truncation of (6) at $m \geqq 4n$ has no effect on the outcome. As with $q^{(0)} = 0$ and k iterations of (13), all components α_j of $q^{(k)}$ (see (6)) with $j > 2^k n$ will be zero. Therefore, (6) may be truncated at $m \geqq 2^k n$. Since k may be large it is convenient to refer to this as the "m unlimited" case.

Recall that our approach is, instead, to fix m and then iterate (13). This approach has several features to recommend it. Since the discrete problem is fixed and independent of the method used to solve it, we need not use Picard iteration and can consider alternatives, such as Newton's method to solve (12). A nontrivial initial approximation for q has no adverse influence; this is particularly beneficial in continuation, where good approximations for q are available. With m fixed, our implementation is not strongly affected by the particular type of nonlinearity. With "m unlimited," on the other hand, m grows rapidly for many types of nonlinearities (e.g., $m=3^k n$ for the Cahn-Hilliard equation, where $F(u)$ involves a u^3 term) and becomes unbounded for others (like $\sin u$). Nevertheless, there is a need to understand the effect of fixing m a priori on the theory of AIMs based upon estimates of the truncation error [JKT1], [T].

Following [JKT1], we take the KS equation in the form

$$u_t + 4u_{xxxx} + \theta[u_{xx} + uu_x] = 0, \qquad 0 \leqq x \leqq 2\pi, \tag{14a}$$

where $\theta \geqq 0$ and with boundary conditions

$$u(x,t) = u(x+2\pi, t), \qquad u(x,t) = -u(2\pi - x, t), \tag{14b}$$

corresponding to the odd case.[2] Note that $A = 4\Delta^2 = 4D^{(4)}$ is the linear dissipation term and the nonlinearity consists of a Burgers nonlinearity uu_x and an antidissipative term Δ. Thus, the eigenvalues and eigenfunctions in (2) are $\lambda_j = 4j^4$ and $w_j = \sin jx$, $j = 1, 2, \ldots$. Note that the linear antidissipative term is not incorporated into the linear operator A.

Introducing the operator notation $B(u,v) = uv_x$, $u, v \in H$, where H is the space of odd 2π-periodic functions in the Sobolev space $H^1(0, 2\pi)$, the Picard iteration (13) takes the form

$$4D^{(4)} \sum_{j=n+1}^{m} \alpha_j^{(l+1)} w_j = -\theta D^{(2)} \sum_{j=n+1}^{m} \alpha_j^{(l)} w_j - \theta Q B(p+q^{(l)}, p+q^{(l)}), \tag{15}$$

where

$$p + q^{(l)} = \sum_{j=1}^{n} \alpha_j w_j + \sum_{j=n+1}^{m} \alpha_j^{(l)}(\alpha_1, \ldots, \alpha_n) w_j.$$

Writing, for convenience, $\alpha_j = \alpha_j^{(l)}$, $j = n+1, \ldots, m$, and taking the projection Q of the convolution sums, it follows that

$$\sum_{j=n+1}^{m} \alpha_j^{(l+1)} w_j = \sum_{j=n+1}^{m} \left\{ \frac{\theta}{4j^2} \alpha_j - \frac{\theta}{8j^4} \beta_j \right\} w_j, \tag{16}$$

where

$$\beta_j = \left\{ \sum_{i=1}^{m-j} (i\alpha_i)\alpha_{i+j} - \sum_{i=j+1}^{m} (i\alpha_i)\alpha_{i-j} + \sum_{i=1}^{j-1} (i\alpha_i)\alpha_{j-i} \right\}$$

are the Fourier coefficients of $2uu_x$. The first two sums combine to give $-j(\sum_{i=1}^{n} \alpha_i \alpha_{j+i} + \sum_{i=n+1}^{m-j} \alpha_i \alpha_{i+j})$. Now we split the third sum into three sums, from 1 to $j-n-1$, from $j-n$ to n, and from $n+1$ to $j-1$ if $j-n-1 \leqq n$ and from 1 to n, from $n+1$ to $j-n-1$, and from $j-n$ to $j-1$ if $j-n-1 > n$, and then combine the first and third of these.

[2] The inertial manifold (IM) has been known to exist for this odd case for some time [FST]; it was recently shown that the KS equation is generally dissipative [I], so existence of the IM follows from the general theory for such systems [FST]. The techniques presented here apply to the more general case, but we restrict attention to the odd case since our purpose is to contrast the numerical results to those obtained previously.

The split-up separates summations into parts that are homogeneous of degrees zero, one, or two in the q-coefficients. Collecting terms, we have

$$\beta_j = -j\left(\sum_{i=1}^{n} \alpha_i\alpha_{i+j} + \sum_{i=n+1}^{m-j} \alpha_i\alpha_{i+j} - \Sigma_3\right) + \Sigma_4, \tag{17}$$

where

$$\Sigma_3 = \sum_{i=1}^{j-n-1} \alpha_i\alpha_{j-i}, \quad \Sigma_4 = \sum_{i=j-n}^{n} i\alpha_i\alpha_{j-i} \quad \text{if } j-n-1 \leqq n$$

and

$$\Sigma_3 = \sum_{i=1}^{n} \alpha_i\alpha_{j-i}, \quad \Sigma_4 = \sum_{i=n+1}^{j-n-1} i\alpha_i\alpha_{j-i} \quad \text{if } j-n-1 > n.$$

The updated iterate values follow directly from (16).

Thus any number of Picard iterations for the KS equation (14) can be computed from (16). The algorithm determines an approximation to $q = \phi_S(p)$, i.e., for fixed n and m, given any value of p we can compute the q components $\alpha_j = \alpha_j(\alpha_1, \alpha_2, \ldots, \alpha_n)$ for $j = n+1, n+2, \ldots, m$, to any accuracy if (16) converges. In § 5 we perform computational experiments to investigate how many Picard iterations can be necessary in practice.

4. The DAE approach with a Newton method. Here we consider Newton and quasi-Newton methods to solve the nonlinear algebraic equations (12). Since

$$\frac{\partial G}{\partial q} = AQ + Q\frac{\partial F}{\partial q}(p+q),$$

Newton iteration gives an update q_{new} to an approximation q_{old} via the relationship

$$[A+J]q_{\text{new}} = -QF(p+q_{\text{old}}) + Jq_{\text{old}}, \tag{18}$$

where $J = Q(\partial F/\partial q)(p+q_{\text{old}})$. The matrix on the left-hand side of (18) is the trailing principal submatrix of dimension $m-n$ for the Jacobian of the full nonlinear system corresponding to (4) with $\dot{p}=0$, $\dot{q}=0$. We denote this full Jacobian by $\bar{A}+(\partial F/\partial\alpha)$ where $\alpha = (\alpha_1, \ldots, \alpha_m)^T$. A calculation along the same lines as used in deriving (17) yields $\bar{A} = 4S^4$, where $S = \operatorname{diag}(1, 2, \ldots, m)$ and

$$\frac{\partial F}{\partial \alpha} = \theta\left(\frac{1}{2}S(T-H) - S^2\right). \tag{19}$$

Here T is the skew-symmetric Toeplitz matrix with first row $(0, -\alpha_1, -\alpha_2, \ldots, -\alpha_{m-1})$, and H is the Hankel matrix with first row $(\alpha_2, \alpha_3, \ldots, \alpha_m, 0)$ and all zeros in the last row.

From (19) we see that the Jacobian has a very simple structure and is easy and cheap to calculate. If $m \leqq 2n+1$, the Jacobian $A+J$ is a *constant* matrix, i.e., (12) is a linear system of equations in q. This particular property of the Jacobian holds whenever the nonlinearity is a product of powers of only two derivatives of u (see [RST], which examines the form of the Jacobian for the spectral method for general nonlinear PDEs).

It is interesting to interpret the Picard iteration (13) in the context of iterative methods for solving systems of linear equations. When J is constant it amounts to a "partial" Jacobi iteration, where (15) is written with the diagonal term $4j^4$ multiplying

$\alpha_j^{(l+1)}$ instead of the full diagonal term $4j^4 - \theta j^2$. A useful study could be to compare this with Jacobi or Gauss-Seidel iteration, although that is not our purpose here.

We end this section with some remarks about how the Picard iteration for (12) compares with the iteration (9) for the backward Euler approximation to (4b) to arrive at an approximation to $q = \phi(p)$. The iteration matrix for (9) is simply

$$\operatorname{diag}\left(\frac{\tau}{4(n+1)^4*\tau+1}, \frac{\tau}{4(n+2)^4*\tau+1}, \dots, \frac{\tau}{4m^4*\tau+1}\right)*J,$$

where $A+J$ is the constant Jacobian in (18). For (13) the iteration matrix is

$$\operatorname{diag}\left(\frac{1}{4(n+1)^4}, \frac{1}{4(n+2)^4}, \dots, \frac{1}{4m^4}\right)*J.$$

It is interesting to note the mathematical similarity between these iterative methods; for the Euler-Galerkin approach the term λ_j in the Picard iteration is replaced by $(1/\tau)+\lambda_j$, which corresponds to a regularization. However, for practical choices of τ—sufficiently large that the theory predicts that we will move close to Ω—$4\tau(n+1)^4$ is generally much larger than 1, and the two iteration processes should produce virtually identical results for the KS equation. This has been our experience in practice, so the Euler-Galerkin results for the KS equation are not given here. Finally, we note that approximating $q = \phi(p)$ by solving the ODE (4b) is related to the basic strategy of applying the Hadamard graph transform [LS], and it is interesting that this approach with an Euler approximation, albeit a simple one, is nearly equivalent computationally to the qualitatively different strategy of solving the DAE for a steady-state approximation.

5. Numerical results. In this section we employ inertial manifold techniques in numerical computations with the KS equation (14). Our interest in the various iterative methods for approximating $q = \phi(p)$ lies more in investigating how well and efficiently they describe the qualitative behaviour of the KS equation as demonstrated in its bifurcation diagram than in presenting detailed computation of the AIMs themselves. Most of our computations use AUTO, a FORTRAN code developed by Doedel [D1] to compute bifurcation diagrams for ODEs (see also [KNS] and [JKT1]). Except where otherwise noted, default parameters are as given in [D2, p. 143]. In particular, solution tolerances are 10^{-4}, although results are frequently verified with smaller error tolerances. All runs are made on a SUN SPARCstation in double precision (roughly 16 decimal digits).

The bifurcation diagrams show plots of the bifurcation parameter θ versus the L^2-norm of the solution. Solid lines correspond to stable steady-state solutions, and broken lines correspond to unstable ones. White squares denote steady-state bifurcation points, and black squares denote Hopf bifurcation points. In the plots for periodic solutions, the time-averaged L^2-norm of the solution is plotted. White circles correspond to unstable periodic solutions, black circles correspond to stable periodic solutions. Period-doubling points are marked with two triangles.

Frequently, the bifurcation diagrams show overlapping branches corresponding to different solutions (with the same L^2-norm). These superimposed branches can have different bifurcation properties. As a result, bifurcation points can be missed if all branches are not searched carefully, and stability assignments for branches can be obscured by their overlap.

To distinguish between the concepts of steady-state solution branches, and "steady" approximate inertial manifolds, we will consistently refer to the former as "steady states," and to the latter as simply "steady." "Pseudosteady" refers to the "steady" AIM approximated by two Picard iterations with "m unlimited."

We will first look at steady-state computations. In interpreting the bifurcation diagrams for the various methods, we must realize that the nonlinear equations arising for the n modes p and $m-n$ modes q nonlinear Galerkin case are *the same* as those for the flat Galerkin method involving m modes, namely

$$APp + PF(p+q) = 0, \qquad AQq + QF(p+q) = 0.$$

In the nonlinear Galerkin method we solve the equations in a way that is rather akin to a nonlinear block Gauss-Seidel method. Starting with an initial guess for p, we determine q by satisfying the second equation and use this value in the first equation to update p.

When we compare the diagrams for an m-mode flat Galerkin method to the ones for an $n+(m-n)$-mode nonlinear Galerkin, then the latter will only show the L^2-norm of the first n Fourier coefficients, whereas the flat Galerkin method will show the L^2-norm of the first m Fourier coefficients. Thus, even if the methods gave identical results, the bifurcation diagrams could differ. But while the bifurcation branches for nonlinear Galerkin tend to lie below those for flat Galerkin, the difference is normally small, as almost all the energy is concentrated in the low modes. Note also that the nonlinear Galerkin method cannot detect bifurcations occurring only in its q-modes.

5.1. Steady-state solutions ($m = 2n$). We consider the problem of computing steady-state solutions for the KS equation. Thus, after approximately solving (12) for $q = \phi(p)$, we compute a bifurcation diagram of steady-state solutions of the ODE (4a) using AUTO. Previously, computations have been done by using either one or two Picard iterations on (12), with the initial guess $q = 0$. We also use the two Picard iteration method (which gave qualitatively the same results as the pseudosteady method in all our examples where those results were accurate) and compare it to approximations to the steady-state solution obtained with Picard iteration (and more than two iterations) or with Newton iteration.

First, we consider the cases $m = 2n = 8$ and 10. For comparison, the "exact" bifurcation diagram is first computed with the flat Galerkin method with 12 modes, and the result is given in Fig. 3. The two Picard iteration results for $m = 8$ and 10 are given in Figs. 4 and 5, respectively. The corresponding steady results, obtained with

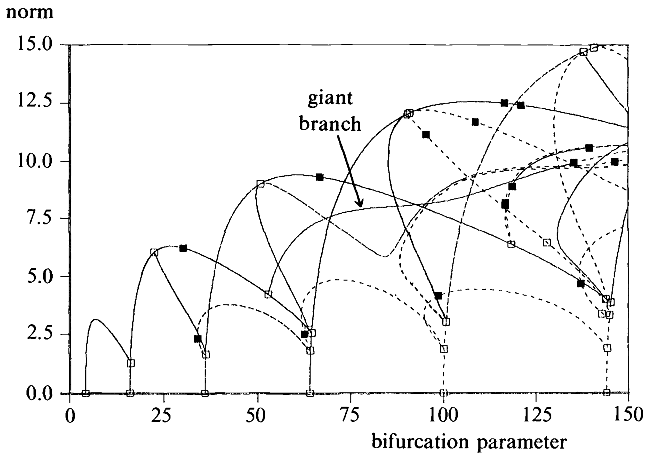

FIG. 3. *Flat Galerkin,* 12 *modes.*

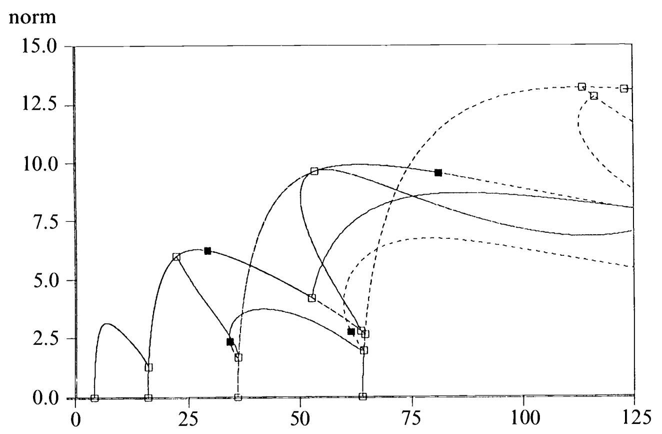

FIG. 4. 4+4 *Nonlinear Galerkin, two Picard iterations.*

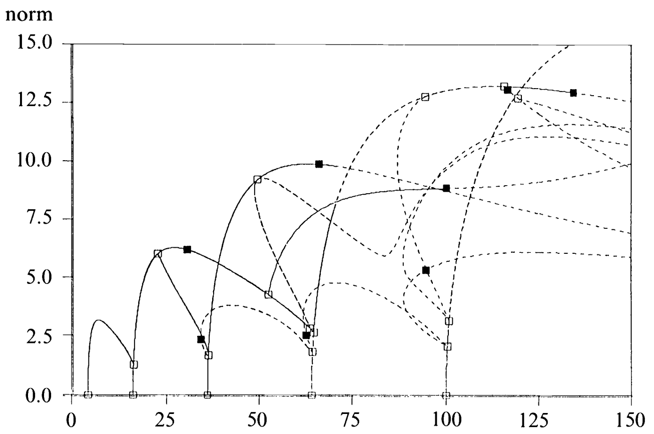

FIG. 5. 5+5 *Nonlinear Galerkin, two Picard iterations.*

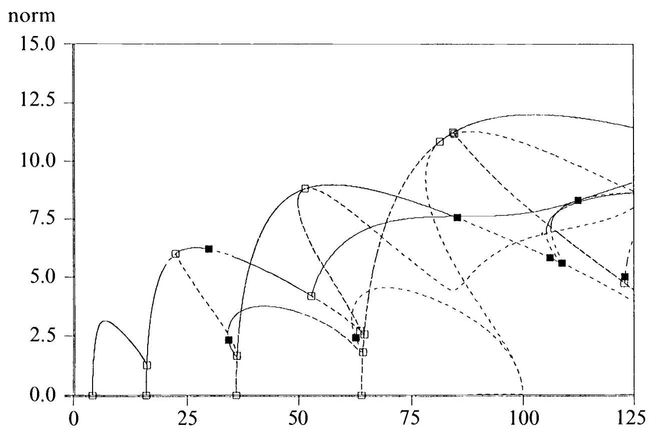

FIG. 6. 4+4 *Nonlinear Galerkin, steady.*

one Newton iteration, are in Figs. 6 and 7.[3] Here and elsewhere, no significant difference in the number of continuation steps used by AUTO was observed for the different flat and nonlinear Galerkin methods. Pseudosteady computations were also done (using truncation at $m=4n$), and the results were not qualitatively different from those in Figs. 4 and 5.

The diagrams in Figs. 3-7 show clearly how the steady solution gives qualitatively better information than the solution computed with only two Picard iterations. It is interesting that useful qualitative information about the steady-state solutions can even be obtained beyond values of θ where an inertial manifold with graph $q=\phi(p)$ exists. The p-variables can no longer be used as coordinates for the manifold, because the assumption that the DAE is index 1 is invalid and hence this relationship does not even hold for all steady-state solutions. Specifically, the term $4(n+1)^4-\theta(n+1)^2$ eventually becomes zero, and for $p=0$ (along the horizontal axis) the diagonal matrix expressing q in terms of p from (12) passes through a singularity (one of the diagonal elements becomes zero). Figures 3, 4, and 6 demonstrate this for $m=8$, where the singularity occurs for $\theta=100$. This raises the point that we may be able to approximate dynamics *locally* with a very low-dimensional manifold—lower than the dimension of any inertial manifold that exists in terms of the basic p-variables—although a safe reliability check of the computations could be difficult to find.

5.2. Steady-state solutions ($m \geqq 2n$). We complete our steady-state computations by considering more numerical results in the case where $m>2n$. We present some results which show that the rate of convergence for Picard iteration can be very slow, in which case the results are bad for large θ. Even for small θ the approximation using two Picard iterations might have only 1 to 2 digits accuracy. It is far from clear when such accuracy is sufficient to correctly capture the qualitative solution information.

Consider data set 1, consisting of $n=4$, $p:=\{4.2182, -3.9175, 0.8192, -0.1037\}$, and $\theta=10$. The solution to (12) is computed for $m=8$, 10, 12, and 16 with Picard and Newton iteration, using $q^{(0)}=0$ and terminating the iteration when

$$\|q^{(i+1)}-q^{(i)}\|_\infty \leqq TOL^* \|q^{(i+1)}\|_\infty, \tag{20}$$

where $\|q\|_\infty$ denotes the Fourier coefficient of q of largest magnitude. For $m=16$, to

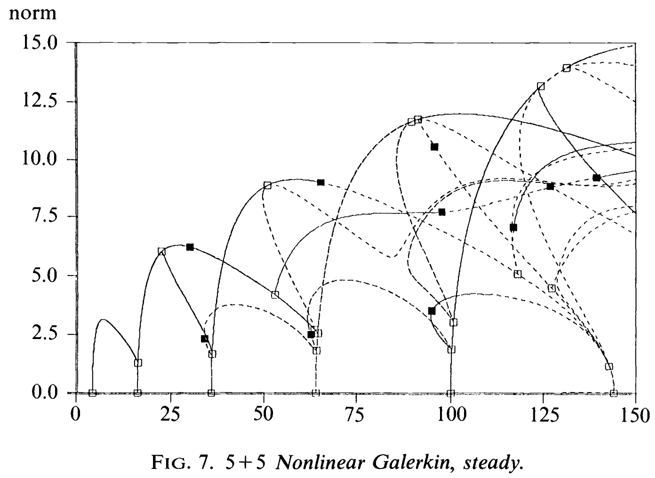

FIG. 7. 5+5 *Nonlinear Galerkin, steady.*

[3] AUTO continuation parameter values are adjusted to DSMIN = .001 and DSMAX = 1 when necessary for obtaining the finer resolution required in the diagrams.

four significant digits, q is {.4021(−1), −.5637(−2), .1019(−2), −.1641(−3), .2381(−4), −.3806(−5), .5521(−6), −.8140(−7), .1180(−7), −.1669(−8), .2365(−9), −.3298(−10)}. Corresponding q-values for the other values of m differ at most in the last digit shown. The relative residual values $\|q^{(i)}-q\|_\infty/\|q\|_\infty$ for the Picard iterates $q^{(i)}$ are .93(−1), .72(−2), .43(−3), .27(−4), .16(−5), .19(−6). In the constant Jacobian case $m=2n$, this compares well with the rate of convergence that analysis would predict, namely, linear convergence with convergence factor $\rho(A^{-1}*J)\approx .084$ ($A^{-1}J$ has eigenvalues $\lambda=.074\pm .04i$, $-.066$, and $-.045$). For the Newton iteration, the relative residual values are .26(−4), .17(−15), ... when $m=16$; for the other values of m, the relative residual is also at roundoff error level after two iterations, with basically the same values. As an estimate of the relative efficiency of Picard versus Newton iteration, we calculate $CPU_P :=$ CPU time for Picard iteration, $CPU_N :=$ CPU time for Newton iteration, and $E=CPU_P/CPU_N$, and values of E are given for various tolerances (TOL) in Fig. 8(a). Note that even though Newton's method converges much faster on an iterate by iterate basis, it is sufficiently expensive for large m that the Picard iteration is more efficient. However, Picard iteration is sufficiently slow that the two-iteration solution has only one digit of accuracy; for example, for $m=8$, $q^{(2)}=${.3992(−1), −.5473(−2), .9118(−3), −.1308(−3)}, and for $m=16$, $q^{(2)}$ has the same first four components and remaining components {.1469(−4), −.1769(−5), .1873(−6), −.1582(−7), .1028(−8), −.4750(−10), .1505(−11), −.2629(−13)}.

Data set 2 consists of $n=8$, $p:=${9.91, 8.87, −7.79, 6.65, 5.53, −4.47, 3.31, 2.29}, and $\theta=10$, and we solve for $m=16$, 18, and 32. The Picard iteration converges fairly rapidly, e.g., for $m=32$ the relative residuals (in the maximum norm) are .25(−1), .62(−3), .19(−4), .96(−6), .25(−7), .92(−9), ... As a result, even though only two Newton iterations are required for $m=18$ and 32 to almost reach roundoff error level, Picard iteration is generally more efficient (cf. Fig. 8(c)). Indeed, the two-Picard iteration solution is quite accurate in this case, e.g., for $m=16$ all except the last coefficient have two to three significant digits.

For large θ, Newton's method becomes more appealing. Taking data set 3 to be the same as data set 1 except that $\theta=100$, the q values decrease at a much slower rate. For $m=16$ they are {.9566, −.4830, .3683, −.1548, .6022(−1), −.2661(−1), .1111(−1), −.5850(−2), .2767(−2), −.1271(−2), .5530(−3), −.2294(−3)}, and q values obtained using lower values of m differ substantially from corresponding components in this vector. For example, with $m=8$, the q components are {.9615, −.4762, .3823, −.1711}. Picard iteration converges much more slowly than before—the eigenvalues of $A^{-1}*J$ are 10 times the values for $\theta=10$—and the two-Picard iteration solution is inaccurate: for $m=16$ it is $q^{(2)}=${.7100, −.1610, .6332(−1), −.1190(−1), .1469(−2), −.9249(−3), .1510(−3), −.1493(−4), .1028(−5), −.4750(−7), .1505(−8), −.2629(−10)}. Still, Newton's method converges to roundoff error levels after four iterations, and its general superiority to Picard iteration in this case, especially for small m, is seen from Fig. 8(b).

While we have run experiments to compare Picard and Newton iteration on a number of data sets, the above are representative of our findings. For $m=2n\leqq 20$, one Newton iteration is cheaper than six Picard iterations. Newton's method has proven very reliable and gives rapid convergence, but it is not always superior to the Picard iteration method. For small θ and large m the rate at which the coefficients of q decay can vary substantially depending upon the value of p, giving fairly slow linear convergence for Picard iteration. However, even then, Picard iteration can be quite competitive with Newton iteration; this is not totally surprising, since the dimensions of the Jacobian matrix (19) become large.

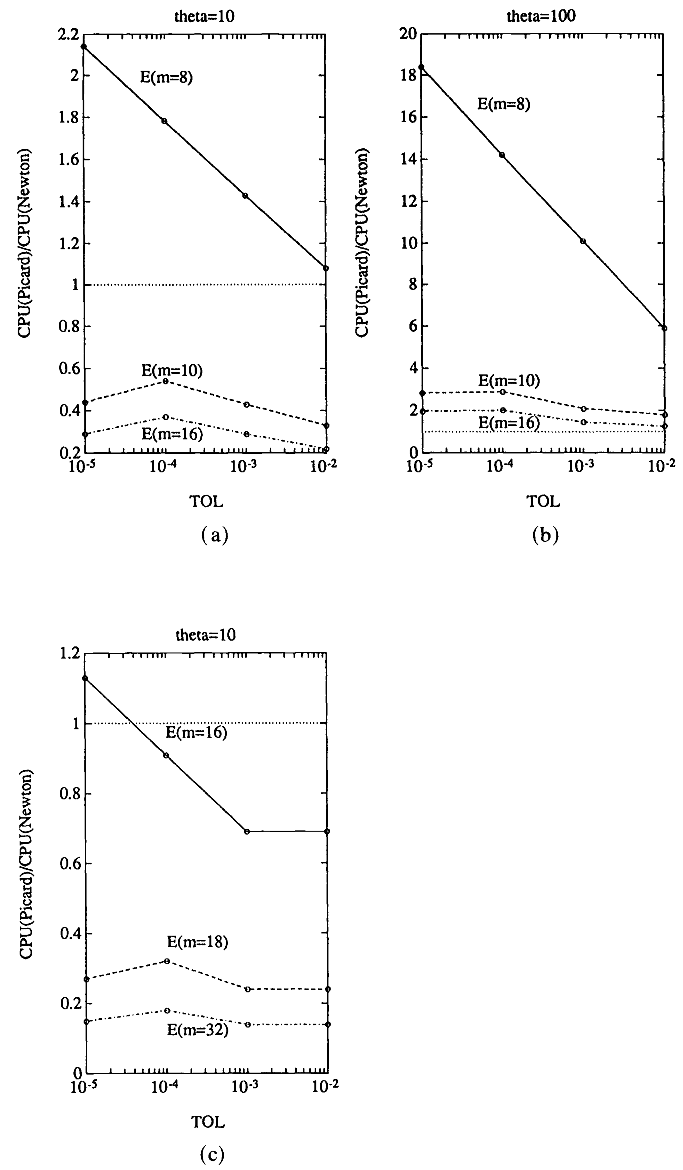

FIG. 8. *Relative efficiency.*

5.3. Steady-state solutions ($m > 2n$), Quasi-Newton methods. The Picard iteration method can be interpreted as a quasi-Newton method obtained by setting $j = 0$ in (18). We have tried other simple quasi-Newton methods when $m > 2n$, which involve choosing only part of J and then performing a frozen Jacobian (fixed-point) iteration. If we use only the components of J which involve p, then the Jacobian approximation consists of the sum of a diagonal and a Toeplitz matrix. This fixed-point iteration turns out to be generally unsatisfactory, since it is not as fast as Picard iteration when the latter works well, and can fail to converge in cases where Picard iteration does not work well. Another strategy is to choose $\hat{m} = 2n + 1$, to solve for the corresponding values $\alpha_{n+1}, \alpha_{n+2}, \ldots, \alpha_{\hat{m}}$, which involves only solving a linear system since the

Jacobian for this problem is constant, and then to approximate the Jacobian (for the $m-n$ coefficients of q) by only using the components of J which involve the first $\hat{m}=2n+1$ coefficients. This method, although again not providing any significant advantage over Picard iteration when the latter converges rapidly, is an efficient fixed-point iteration in other cases. For instance, when $m=16$, $n=4$, and $\theta=10$, the first iterate for q is .4021(−1), −.5637(−2), .1019(−2), . . . , and the relative residual reaches roundoff error level after one iteration for the complete q. For $\theta=100$, six iterations are needed.

5.4. Giant branch computations. We now compare some of the iterative methods for computing steady-state solutions along the so-called *giant branch* or *coherent structure branch*, which is labeled in Fig. 3. For discussion of the importance of the giant branch solutions, we refer to [JKT2]. What is of interest here is to approximate this giant branch with moderately small values of n and to have the computed solution preserve the dissipation in the PDE. In the bifurcation diagram, preservation of dissipation is related to the computed giant branch solution growing in magnitude but not switching back toward the vertical axis. For $\theta \leqq \theta_0(n)$ the flat Galerkin solutions preserve dissipation, as do the steady solutions for the nonlinear Galerkin method, but the pseudosteady solutions do not have this property [JKT2].

In order to compute nonlinear Galerkin solutions that do preserve dissipation, Jolly, Kevrekidis, and Titi [JKT2] use several approaches. One involves a "pseudo-Euler–Galerkin" approximation formed by dropping one term from the discretized equations. Another involves attempting to "prepare" the PDE by dropping terms. The latter proves less than ideal because the qualitative properties of the prepared PDE can differ significantly from those of the original PDE, but this seems difficult to predict from the analysis. In general, it appears difficult to analytically predict when and/or if the computed giant branch solutions accurately describe the actual ones for these modified methods.

Our approach here is to verify that the steady solution (with m fixed) preserves dissipation, and thereby to emphasize the importance of solving the discretized equation for this solution *accurately*. (This solution is equivalent to the m-mode flat Galerkin solution, which is known to preserve dissipation [JKT2].) Solving (12) exactly is easy since the Jacobian is constant when $m=2n$, and only one Newton iteration is required. The results are compared with those obtained with flat Galerkin directly.

The flat Galerkin solutions for $m=6$, 12, and 24 are shown in Figs. 9(a), 9(b), and 9(c), respectively. The flat Galerkin results for $m=40$ are virtually identical to those for $m=24$ except for a slight shift in the location of the second Hopf bifurcation point. The nonlinear Galerkin solutions for $m=2n=6$ are depicted in Figs. 10(a)–10(c) for the cases of 2 and 25 Picard iterations and for Newton's method.[4] These solutions show what typically happens for a fixed number of Picard iterations. The solutions start rising rapidly at some point, and there are spurious Hopf bifurcations near the region of breakdown. These indicate the appearance of complex eigenvalues, which probably arise from onset of ill-conditioning of the nonlinear systems (however, this point deserves further study). Working with a fixed number (even 25) of Picard iterations eventually becomes unreliable as θ increases, although in this particlular case the giant

[4] The results from two Picard iterations in Fig. 10(a) are unchanged when solution tolerances are reduced to 10^{-7}. Interestingly, the corresponding pseudosteady solution branch originates from the origin in the same way but then does *not* make the turn back to the right, continuing instead to grow without bound as it approaches the vertical axis [JKT2]. Thus, two iterations seem to be insufficient regardless of m.

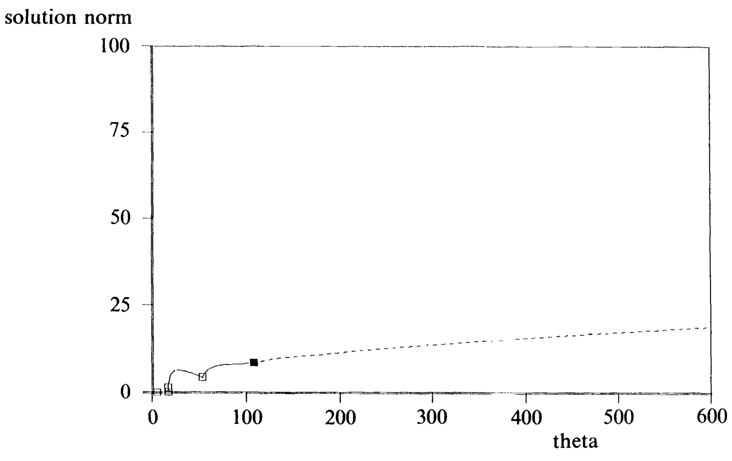

FIG. 11(c). 6+18 *Nonlinear Galerkin, steady (Newton),* TOL = 1E − 6.

branch computations do eventually diverge like the ones for the steady solution and the flat Galerkin solution with $m=6$.

The steady solutions for $m=2n=12$ are shown in Fig. 11(a). Again, the results demonstrate clearly that the steady solutions have the nice dissipation properties of the flat Galerkin solution and that the solution breakdown is characterized by the appearance of a large number of spurious Hopf bifurcations.

Finally, we choose n small and investigate how much qualitative information can be extracted from the steady solution as compared to the corresponding flat Galerkin solution with $2n$ modes. Figure 11(c) shows the results from computing the steady solution with Newton's method for $m=3n=18$. While the first Hopf bifurcation point is shifted somewhat and in the absence of higher modes the second one is not detected, the qualitative information about the giant branch is otherwise accurate. Even though an inertial manifold cannot exist globally past $4(n+1)^2=196$, the local qualitative information around the giant branch is accurate over the parameter range [0,600]. This is to be contrasted with previous cases when $n=6$.

If the initial approximation $q=0$ is used, then Newton's method does not converge for values around $\theta=450$. To obtain the results in Fig. 11(b) we use the solution q from the previous parameter value θ as an initial approximation q for a new value of θ. This is a natural choice for the continuation process, and allows for a speedier computation. Even if this is done and three Newton iterations are used in each continuation step, then trouble arises around $\theta=450$, where spurious Hopf bifurcations enter the picture.

5.5. Periodic solutions. We finish this section with computations of *nonsteady-state* solutions, viz., periodic solutions branching from Hopf bifurcation points. We limit consideration to two Hopf bifurcation points, located near (34.25, 2.3) and (30.3, 6.2) on the $(\theta, \|u\|)$ plane. Results are limited to a rough computational comparison of flat Galerkin with $m=10$ and nonlinear Galerkin with $m=2n=10$. Default parameter values are again used in AUTO unless otherwise specified. The nonlinear Galerkin solution branches emanating from the two Hopf bifurcation points are shown in Fig. 12.

Finer detail of the periodic solutions generated from the lower Hopf bifurcation point with the nonlinear Galerkin method is seen in Fig. 13. One period doubling is

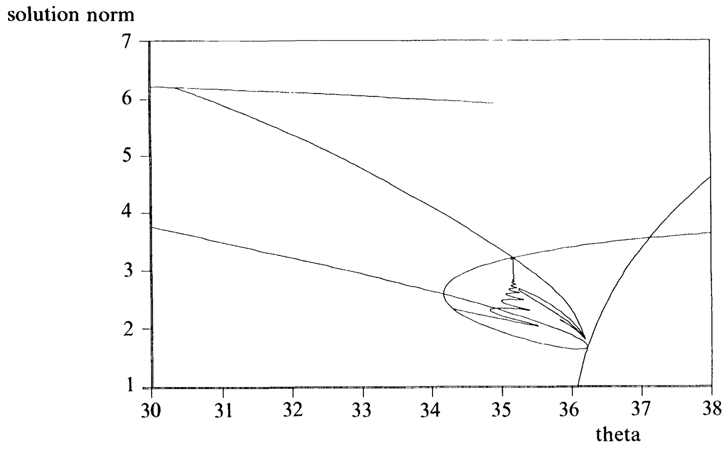

FIG. 12. 5+5 *Nonlinear Galerkin, six Picard iterations.*

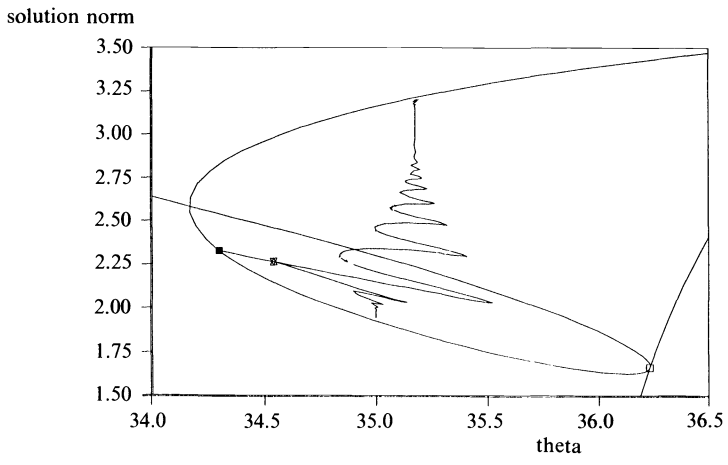

FIG. 13. 5+5 *Nonlinear Galerkin, six Picard iterations.*

found, and the corresponding periodic solution branch also computed.[5] Both branches consist entirely of unstable periodic solutions. These two periodic branches indicate Silnikov-type homoclinic trajectories approaching steady-state solution branches. In general, we have observed that the flat Galerkin computations require more computer time than those for nonlinear Galerkin (with the same m and $m=2n$), and this difference is particularly significant for the periodic solutions. We have also computed pseudosteady solutions with $m=4n=20$ in order to compare with the other nonlinear Galerkin results. As in the steady-state solution case, no improvement has been observed over the corresponding method with m fixed ($m=2n=10$, and two Picard iterations).

A blowup of part of the periodic solution branch generated from the top Hopf bifurcation point with the nonlinear Galerkin method is shown in Fig. 14. The flat Galerkin method runs into considerably more difficulty following this branch, although further study would be required before we could predict whether or not this is to be

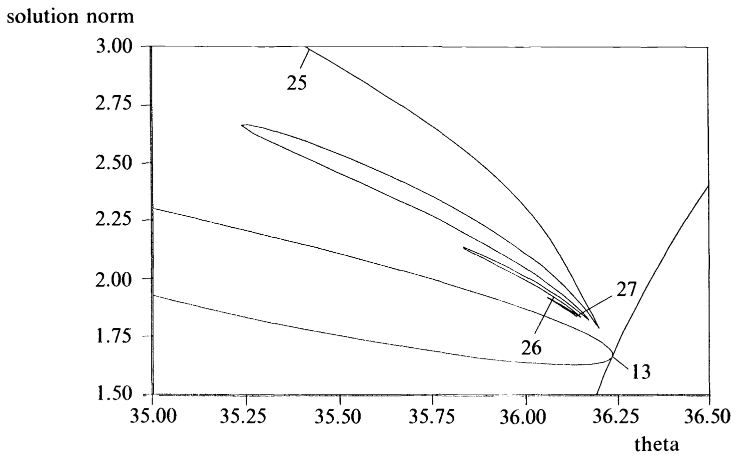

FIG. 14. 5+5 *Nonlinear Galerkin, Newton.*

[5] See [GS] for a description of a richer underlying structure of periodic solutions, much of which can be recovered using more careful continuation with AUTO.

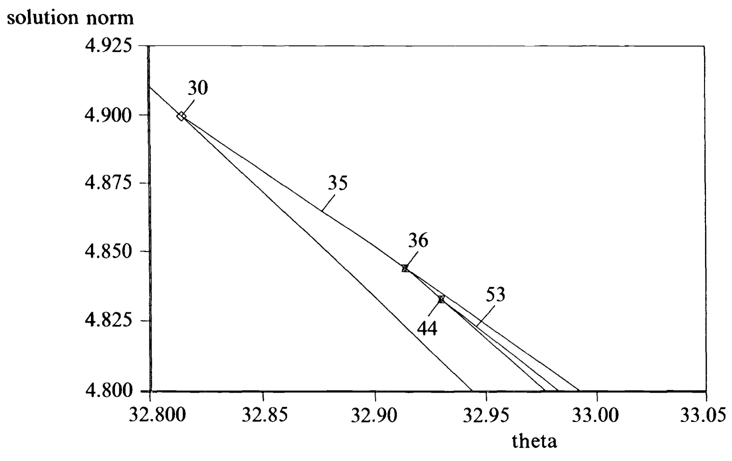

FIG. 15(a). 5+5 *Nonlinear Galerkin, Newton.*

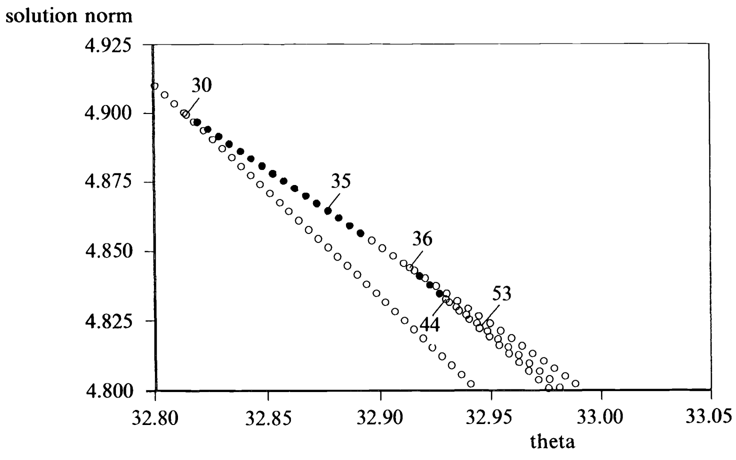

FIG. 15(b). 5+5 *Nonlinear Galerkin, Newton.*

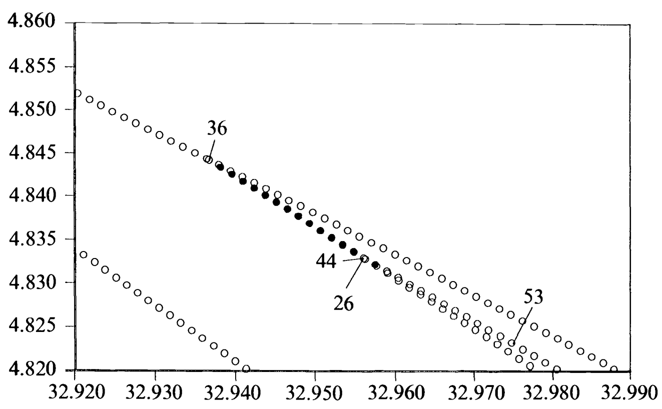

FIG. 15(c). 5+5 *Nonlinear Galerkin, Newton.*

expected. Finer detail of the nonlinear Galerkin results are shown in Figs. 15(a)–15(c). The periodic solutions emerging from the top Hopf bifurcation point as θ increases begin stable, but lose stability at a bifurcation point around (32.82, 4.9). The results displayed in Fig. 15 suggest that at this point, stable and unstable periodic solutions are generated. The stable periodic solution loses stability at a period-doubling point around (32.92, 4.85). The stable period-doubled branch becomes unstable at a second period-doubling point around (32.93, 4.84). At this latter point both emerging periodic branches appear to be unstable, and no further close-by period doublings are observed (with the default parameter values for AUTO). The corresponding flat Galerkin method finds another bifurcation point on the periodic solution branch nearby the top Hopf bifurcation point but misses the second period-doubling point. The location of this second period-doubling point was verified with a nonlinear Galerkin method using $p = q = 7$. It is only one of a wealth of period-doubling and bifurcation points in this region [SW]. It is of interest to note that bifurcations from the top Hopf bifurcation point have been calculated and discussed in [JKT1]. Their calculations reveal, inter alia, a sequence of period doublings, with stability inherited by the period-doubled branch at each bifurcation. They also make the point that details of the periodic solutions may be captured using a variety of three-mode AIMs.

Indeed, it is important to emphasize that results can quickly become sensitive and bifurcation points may be missed (see Doedel's ample description in [D1]), and more careful study requires changing parameter values in AUTO (e.g., setting smaller tolerances or increasing the number of subintervals for spline collocation). This in turn can greatly increase computation time, particularly for periodic solution branches. Nevertheless, the fine detail given by the nonlinear Galerkin approximation is impressive.

As an independent test of the reliability of these results, we have taken output from AUTO as initial data for a numerical integration of (14) with respect to time. The Fourier coefficients corresponding to particular points shown in the bifurcation diagram in Fig. 15 are obtained using a nonlinear Galerkin method based on a Newton iteration. These coefficients are used as initial conditions for the nonlinear dynamical system arising from the spectral discretization of (14), and this system is then integrated in time using a standard routine (ode23 of MATLAB). In particular, we investigate the time evolution of the periodic solutions corresponding to labels 36, 44, and 53 in Fig. 15. The corresponding θ values are 32.93678, 32.95609, and 32.97492. The stability of the solution corresponding to label 36 is evident from Fig. 16(a), which displays the results of integrating over six periods (results over 60 integration periods are not qualitatively different). Nevertheless, the solution's stability region is small, as perturbation of the initial data by 1 percent causes the integration to converge to a stable steady-state solution on the branch above this one (in the $(\theta, \|u\|)$-plane); see Figs. 16(a), 7, and 12 for the location of the branches in the bifucation diagram. The initial data for the solution corresponding to label 44 appears to be virtually identical to that for label 36, varying in only the fourth decimal place (and thus of the same order as the 10^{-4} tolerances used in AUTO to compute these solutions). Nevertheless, the period-doubled solution in t is evident in Fig. 16(b) (the label 36 and label 44 solutions are superimposed). AUTO estimates only one Floquet multiplier greater than unity in magnitude, and it only barely so. This is consistent with the numerical integration which shows that the solution is moderately unstable at worst. The solution corresponding to label 53, with a Floquet multiplier approximately 12 in magnitude, indeed displays instability in numerical integration (results not shown). Fig. 16(c) shows the initial solution profile for label 36 (the graph for the label 44 solution is indistinguishable

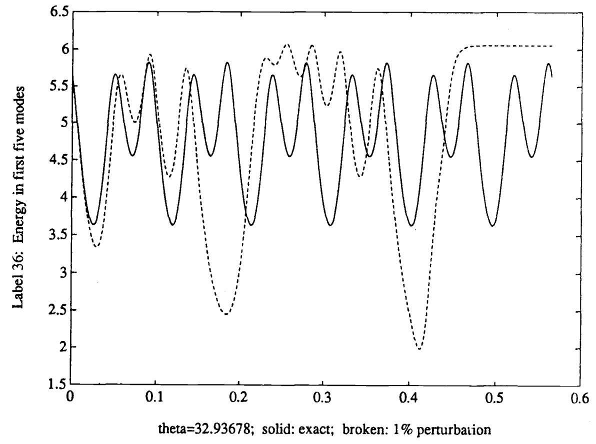

FIG. 16(a). *Time integration over six periods* (5+5 *Newton-Galerkin*).

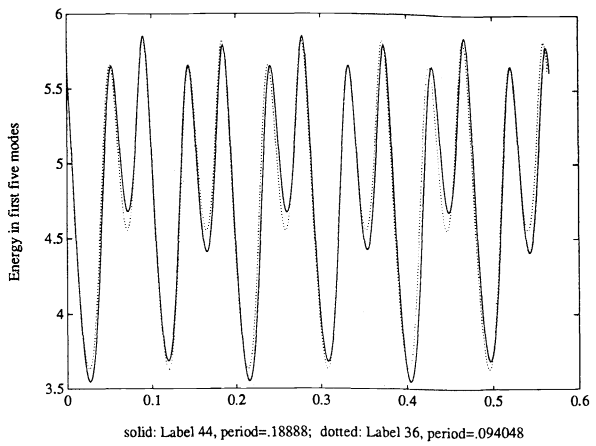

FIG. 16(b). *Period doubling* (5+5 *Newton-Galerkin*).

from the one for label 36), and Fig. 16(d) gives the time evolution of $u(x, t)$ over three periods.

6. Conclusions. During the last few years the study of inertial manifolds for dissipative PDEs has been a very active area of research. One of the principal approximations of these manifolds is the steady AIM. To date, numerical techniques for their computation have been limited to the use of at most two cycles of a Picard iteration. Here we have shown that solving the governing nonlinear equations by this rather limited technique could lead to erroneous results. Numerical experiments using AUTO [D1] have shown, inter alia, that steady-state bifurcation diagrams are computed more accurately if a general Picard iteration (more than two iterations) is used.

We have also demonstrated that Newton's method is a viable and valuable tool for the computation of a steady AIM. For the KS equation, for example, where the nonlinearity is quadratic, the Jacobian has been shown to be constant, with a particularly simple structure, if the number of high modes does not exceed the number of low modes by more than one. A two-level quasi-Newton method has also been introduced, and evidence indicates that this approach is of value in certain circumstances. This

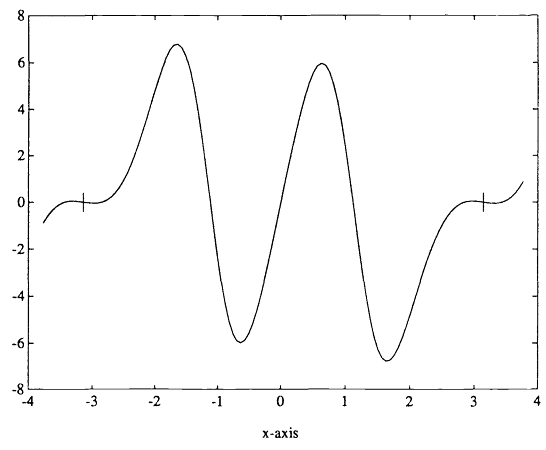

FIG. 16(c). *Snapshot* $u(x, 0)$ *for periodic solution at* $\theta = 32.95609$.

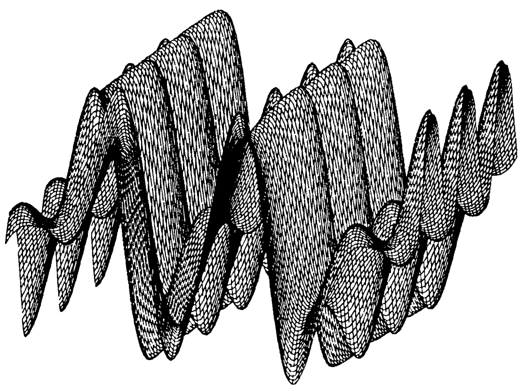

FIG. 16(d). *Time evolution* $u(x, t)$ *over three periods.*

two-level method is readily extended to give a multilevel scheme: the use of such a scheme will be examined in situations where the dissipative effects are less pronounced than they are in the KS equation.

The usefulness of the AIM for the KS equation has been established. When this AIM is computed accurately with a Newton or Picard iteration, the dissipative properties of low-dimensional AIMs are preserved without recourse to techniques such as modifying the PDE itself. Good qualitative approximations to the giant branch are found at relatively little cost. Furthermore, fine-scale qualitative approximations to nonsteady-state solutions are also accurately computed using a low number of modes.

An important departure from previous approaches for computing AIMs has been the replacement of the projection Q of infinite rank by one of finite rank. Fixing the number of q-modes permits the use of arbitrary initial approximations, an often essential and in any event efficient process when doing continuation to construct bifurcation diagrams. Also, the implementation is then not as strongly affected by the type of nonlinearity appearing in the PDE.

This approach of fixing the discretization parameters n and m has additional advantages. It allows us to check the accuracy of the two-Picard iteration method, which as the theory nicely predicts, is satisfactory for moderate values of θ but is insufficient as θ grows. Yet even though there is no AIM (global manifold capturing the dynamics of the inertial form) of dimension n for a range of values of θ, we have seen that we can still compute reasonable local approximations (or local manifolds). We need to develop a theory to better understand the nonlinear Galerkin approach with m fixed in this way and to guide the selection of both n and m.

Investigations of inertial manifolds have thus far dealt with cases where the exact eigenfunctions of the linear dissipative operator A of the PDE are known. In situations involving more than one space dimension and irregular domains, this is unlikely to be the case, and we will have to resort to space discretization. We have performed numerical experiments in one space dimension with finite differences and the pseudo-spectral method. The results are accurate to the "expected" order of such approximations, but predictably, this approach is computationally less efficient than the use of exact projection techniques. An area open for investigation is the study of the viability of inertial manifolds for problems in dissipative dynamics for which exact eigenfunctions are not available. One of the ultimate goals is the long-time solution of the Navier–Stokes equations in such a situation using a finite number (hopefully small) of nonlinear ODEs. Preliminary steps have been made by Jauberteau, Rosier, and Temam [JRT] in the search for this elixir.

Acknowledgements. We would like to thank Edriss Titi for sharing his enthusiasm for inertial manifolds with us, and for keeping us abreast of theoretical developments in the field. We are also indebted to Lixin Liu, who was a valuable source of AUTO expertise. Finally, we are grateful to Mike Jolly and Yannis Kevrekidis, whose helpful comments have led to improvements in the original version of this work.

FAST SOLUTION OF NONLINEAR POISSON-TYPE EQUATIONS*

BRETT M. AVERICK† AND JAMES M. ORTEGA‡

Abstract. For certain nonlinear Poisson-type equations, it is possible to make a change of variable so that the solution is obtained by solving a Poisson equation followed by solving one-dimensional nonlinear equations. For those problems for which a Fast Poisson Solver may be used, this method is considerably faster than methods that solve a discretization of the original equation by Newton-type methods. Moreover, there is excellent parallelism in the solution of the one-dimensional equations. Numerical results are given for some model problems on a CRAY-2 and comparisons are made with other methods.

Key words. Poisson equation, nonlinear equations, parallel

AMS(MOS) subject classifications. 65F10, 65N20

1. Introduction.

In [3], we considered methods for the numerical solution of nonlinear Poisson-type equations of the form

$$\nabla \cdot [K(u)\nabla u] = f, \tag{1.1}$$

where K is a positive differentiable function. If (1.1) is discretized by finite difference methods, we obtain a discrete system of the form

$$F(\mathbf{u}) = A(\mathbf{u})\mathbf{u} - \mathbf{b}(\mathbf{u}), \tag{1.2}$$

where the matrix $A(\mathbf{u})$ is symmetric positive definite for all $\mathbf{u}$. Newton's method applied to (1.2) is

$$F'(\mathbf{u}^k)\delta^{k+1} = -F(\mathbf{u}^i), \qquad k = 0, 1, \dots, \tag{1.3}$$

where the Jacobian matrix is of the form

$$F'(\mathbf{u}) = A(\mathbf{u}) + B(\mathbf{u}). \tag{1.4}$$

The Jacobian matrix has the usual sparsity of Poisson problems, and we would like to solve the Newton systems (1.3) by a conjugate gradient method. The matrix $B(\mathbf{u})$ in (1.4) is not symmetric, however, which would require using methods such as GMRES [8] for nonsymmetric systems.

An alternative approach considered in [3] is based on the fact that $\|B(\mathbf{u})\|$ is small compared with $\|A(\mathbf{u})\|$ in many cases. This motivated the use of the approximate Newton method

$$A(\mathbf{u}^k)\delta^{k+1} = -F(\mathbf{u}^k), \qquad k = 0, 1, \dots, \tag{1.5}$$

in which the systems of (1.5) are solved by the Incomplete Cholesky Conjugate Gradient (ICCG) method.

In the present paper, we consider an entirely different approach based on the formulation [4] of (1.1) as

$$\nabla^2\phi(u) = f. \tag{1.6}$$

* Received by the editors September 9, 1991; accepted for publication (in revised form) March 20, 1992.

† Army High Performance Computing Research Center, University of Minnesota, 1100 Washington Avenue South, Minneapolis, Minnesota 55415. The research of this author was supported in part by Army Research Office grant DAALO3-89-C-0038.

‡ Department of Computer Science, University of Virginia, Charlottesville, Virginia 22903. The research of this author was supported in part by National Aeronautics and Space Administration grant NAG-1-1112-FDP.

If ϕ is a function such that

$$\phi'(u) = K(u), \tag{1.7}$$

then

$$\nabla^2\phi(u) = \nabla \cdot (\phi'(u)\nabla u) = \nabla \cdot (K(u)\nabla u), \tag{1.8}$$

and (1.6) is equivalent to (1.1). Thus, we can obtain the solution of (1.1), in principle, by a two-stage process: I. Solve the Poisson equation

$$\nabla^2 w = f. \tag{1.9}$$

II. Solve the one-dimensional nonlinear equations

$$\phi(u_P) = w_P, \tag{1.10}$$

where w_P denotes the solution of (1.9) at a point P in the domain.

In the actual algorithm we consider, the domain is first discretized so that (1.9) becomes a discrete Poisson equation, and w_P is the solution of this discrete problem at grid point P. Under the assumption that $K(u)$ is positive, solutions of (1.10) will be unique. If we assume further that $K(u)$ is bounded away from zero, then a solution of (1.10) will exist for any w_P.

Even on conventional machines this approach may have considerable merit since it allows the use of fast Poisson solvers whenever the domain is suitable. Results given in the next section show that for a small two-dimensional problem run on a Sun 3/60, this new method is considerably faster than the best method considered in [3]. On parallel and vector computers, the advantage is even greater since the solution of the nonlinear equations (1.10) has excellent parallelism (or vectorization) across the grid points. In the next section, we will give numerical results for a fairly large (250,000+ unknowns) three-dimensional problem considered in [3]. Comparison to the results in [3] on a CRAY 2 shows considerable superiority of the new method. The method does have limitations, however. These are given in § 3, along with further discussion of parallelism and other properties.

2. Numerical results. We first consider results on a serial computer (a Sun 3/60) for a two-dimensional problem of the form (1.1) on the unit square and with $K(u) = .33 + .91u$; this problem was considered in [3]. We use the Dirichlet boundary conditions $u(x, y) = x^2 + y^2$ and choose the forcing function f of (1.1) so that $x^2 + y^2$ is the exact solution of (1.1). The boundary conditions for the Poisson equation (1.9) are given by

$$w_\Gamma = \phi(u_\Gamma), \tag{2.1}$$

where w_Γ and u_Γ are values of w and u on the boundary Γ, respectively.

We discretize the Poisson equation (1.9) by the usual five-point finite differences on an $N \times N$ mesh of interior grid points. The discrete Poisson problem is then solved by a fast Poisson solver (FPS). Since K is linear, ϕ is quadratic and the solutions of (1.10) are easily evaluated. However, for consistency with more general equations, we used a Newton iteration for these one-dimensional equations. Timing results using double-precision arithmetic are given in Table 1 for $N = 31$ and $N = 63$. The second

TABLE 1
Times (seconds) for two-dimensional problem on a Sun 3/60.

N	FPS	NL	Total	TANICCG	Speedup
31	4.2	1.7	5.9	79.8	13.6
63	23.5	7.2	30.7	669.3	21.8

column gives times for the FPS. NL is the time for solving the nonlinear equations (1.10). For comparison, Table 1 also lists times for the same problem using the TANICCG method from [3]. This method solves the approximate Newton systems (1.5) by ICCG(0), using truncation in the sense of [5] to determine the number of inner iterations; further details may be found in [3]. The last column of Table 1 gives the ratios of the TANICCG times to those of the new method.

We next consider a three-dimensional problem treated in [3] in which

$$K(u)=\frac{(100+27u)^{\frac{3}{2}}}{300+27u}, \tag{2.2}$$

so that

$$\phi(u)=209.6\tan^{-1}(.135u+.5)^{\frac{1}{2}}+(3u+11.1)^{\frac{1}{2}}(2u-37). \tag{2.3}$$

The domain is the unit cube, and the forcing function f of (1.1) was chosen so that $x^2+y^2+z^2$ is the exact solution of the differential equation. Thus, the boundary values are also given by $x^2+y^2+z^2$, and then the boundary values for the Poisson equation (1.9) are obtained from (2.1).

Table 2 gives timings for single-precision arithmetic on a single processor of a CRAY 2 for $N=31$ (29,791 equations) and $N=63$ (250,047 equations). As in Table 1, the second column is the time for the FPS, and NL is the time for solving the nonlinear equations (1.10). These one-dimensional nonlinear equations were solved by Newton's method, vectorized across all the grid points.

In [3], we used for (1.5) the initial approximation

$$u^0_{i,j,k}=x_i+y_j^2+z_k^2, \tag{2.4}$$

which is a linear interpolation of the boundary values in the x-direction. For the Newton iterations for (1.10), we used (2.4) and we also chose $u^0_{i,j,k}$ as the solution of the discrete Poisson problem at the i, j, k grid point. Of these two ways to choose $u^0_{i,j,k}$, (2.4) was the best and only these times are reported in Table 2. The next-to-last column gives times for the best version of the TANICCG method in [3], and the last column again shows the ratios of the TANICCG times to those of the new method. (The times for TANICCG given in [3] were obtained on a CRAY 2 at the NASA Langley Resarch Center and do not agree with those of Table 2, which were obtained on a CRAY 2 at the University of Minnesota Army High Performance Computing Research Center.) In [3] we used the convergence test

$$\|F(\mathbf{u}^k)\|_2\leqq\|F(\hat{\mathbf{u}})\|_2, \tag{2.5}$$

where F is the function (1.2), $\mathbf{u}^k$ is the iterate of (1.5), and $\hat{\mathbf{u}}$ is the exact solution of the differential equation evaluated at the grid points. This test, although impractical in practice, ensures that the convergence error is commensurate with the discretization error. A similar test was used for the Newton iterates $u_P^{(k)}$ for (1.10):

$$|\phi(u_P^{(k)})-w_P|\leqq|\phi(\hat{u}_P)-w_P|. \tag{2.6}$$

TABLE 2
Times (seconds) for three-dimensional problem on a CRAY 2.

N	FPS	NL	Total	TANICCG	Speedup
31	.06	.05	.11	1.1	10
63	.31	.35	.66	17.4	25

Here, w_P is the solution of the discrete Poisson problem, and $\hat{u}_p$ is the exact solution of the differential equation. The test (2.6) was implemented as a vector compare across all the grid points so that the vector lengths remain the same for all tests. This may cause some additional work for equations that have already converged, and other tests may be more efficient on some problems. (In our case, no more than three Newton iterations were required for each equation.) Although (2.5) and (2.6) are different tests, each suited to their particular methods, we also used (2.5) for the vector of one-dimensional Newton iterates of the new method and found that the same number of iterations were required as using (2.6). The actual errors in the final iterates produced by the two methods differ by about 15 percent.

The times in Table 2 for the TANICCG method are significantly worse than those of the new method, but some caveats are in order. The ICCG method in [3] was implemented by using the red/black ordering to obtain long vector lengths for the CRAY 2. It is known (see, e.g., [6] and, for a recent review, [7]) that this ordering may seriously degrade the rate of convergence of ICCG, and it is quite likely that better results would be obtained by using the diagonal ordering, as, for example, in [1]. Also, more sophisticated versions of ICCG or the use of other methods might give better results. However, on the basis of the times in Table 2, it is reasonable to conjecture that no iterative method for solving the Newton systems (1.3), or some approximation of them such as (1.5), will be competitive with the new method. Moreover, our fast Poisson solver was a triple Fourier analysis method that used the vectorized one-dimensional fast sine transformations of VFFTPACK obtained from *netlib*. It is known that other fast Poisson solvers that use, for example, cyclic reduction, are faster so that this would give further advantage to the new method.

3. Further discussion of the method. Although the results in the preceding section indicate significant potential for the new method, we must point out several limitations. First, it is necessary to integrate $K(u)$ to obtain $\phi(u)$. Even for the relatively simple function (2.2), the corresponding ϕ of (2.3) is rather complicated and was found only by using MACSYMA. For other K it may be impossible or impractical to obtain the integral explicitly. Recall that ϕ is needed in (2.1) to obtain the boundary values of the Poisson equation and to solve the nonlinear equations (1.10). In both cases, ϕ could be approximated by numerical integration, but this would introduce additional error as well as computing time. Moreover, it seems impossible to apply this approach if K is also an explicit function of the spatial variables, $K = K(u, x, y, z)$, or if K is a vector, as in the equation $(K_1(u)u_x)_x + (K_2(u)u_y)_y = f$.

One reason the times presented in the preceding section were so good is that a FPS could be used. If the domain is such that this is not possible, a multigrid iteration might be a good choice for solving the Poisson equation. If a conjugate gradient method is used, however, then the solution of the Poisson equation may be considerably more expensive. This is illustrated in Table 3, where the discrete Poisson equation of the three-dimensional problem of the preceding section is solved by ICCG. The time for this is given in the column labeled ICCG; NL is, as before, the time to solve the

TABLE 3
Solution of Poisson equation by ICCG *on a CRAY* 2.

N	ICCG	NL	Total	Previous total
31	.527	.046	.57	.11
63	9.87	.38	10.25	.70

nonlinear equations (1.10). The last column in Table 3 reproduces the times from Table 2 using the FPS. Note that even without the FPS, the new method is still almost twice as fast as the TANICCG method.

Clearly, the new method is potentially very good for parallel computation since the solutions of the one-dimensional equations are completely independent. However, the load balancing could be degraded by an unequal number of Newton iterations on different equations. For example, if the initial approximation at grid point P_1 is much better than that at grid point P_2, the Newton iteration at P_2 could take longer to converge. On the other hand, on distributed memory machines, no communication is needed in the Newton iterations except for the convergence test. Most important, if the domain is such that a fast Poisson solver can be used, then a good FPS routine must be available for the particular parallel machine.

Finally, another possible benefit of the new method is discretization error. The best results we have been able to obtain mathematically [2] for the discretization (1.2) of (1.1) is that the local discretization error is $O(h)$, although experimental results indicate it is probably $O(h^2)$. For the new method, however, the only discretization error occurs in the Poisson equation and is $O(h^2)$.

Acknowledgments. We are indebted to Professor Irena Lasiecka of the University of Virginia for reference [4], to Barry F. Smith of Argonne National Laboratory for his assistance in using the VFFTPACK package, and to an anonymous referee for suggestions that improved the presentation.

A DOMAIN DECOMPOSITION METHOD FOR INCOMPRESSIBLE VISCOUS FLOW*

JOHN C. STRIKWERDA† AND CARL D. SCARBNICK‡

Abstract. A method for using domain decomposition to solve the equations of incompressible viscous flow is presented. The method is described in detail, and test results are given for two test problems. A notable feature of the method is that the incompressibility constraint is never explicitly imposed. The domain decomposition uses finite difference and spectral methods on overlapping domains, with second-order accurate interpolation of the velocity relating the solutions on the different domains. The method is shown to be globally second-order accurate by the test results.

1. Introduction.

In applying finite difference methods to a specific problem, one of the most important considerations is the design of the finite difference grid. The choice of a finite difference grid is easily made for problems with simple geometry, such as rectangular or circular domains, however, for problems on domains which are more complex the designing of a grid can be a significant problem. The choice of grid also affects many aspects of the finite difference method. The efficiency of the numerical solution algorithm and the accuracy of the computed solution are strongly dependent on the finite difference grid. The type of grid can also restrict the choice of the numerical algorithm.

In this paper we present a method of using overlapping grid systems for solving incompressible fluid dynamics problems. By using several grids that overlap, one has more flexibility in the placement of grid points than by using one global grid system. The crucial aspect of using overlapping grids is the interpolation of values between grids. This paper discusses the grids and interpolation methods used on particular test problems, and presents insights into the use of overlapping grids for other problems. It is shown that overlapping grid systems can be used to obtain accurate solutions to the equations for incompressible viscous flow. The solutions are obtained efficiently using iterative methods.

Our method is a special case of the general method of domain decomposition, which has been applied to single second-order elliptic equations by many researchers (see the collection of papers in [5]), and to incompressible viscous flow in [1], [3], and [4] using the finite element method. Much of the work on domain decomposition revolves around methods of accelerating the iterative solution procedure and implementation of domain decomposition on parallel computers. The emphasis of this paper is on the features of the domain decomposition that are independent of the particular solution algorithm used on each domain. The iterative method used on the subdomains in this work is not to be regarded as very fast. In a subsequent publication we will describe an iterative method that, based on simple test cases, promises to significantly improve the convergence rate [12].

A notable feature of the method presented here is the handling of the conservation of mass. By properly reformulating the equations, the troublesome integrability constraint on the boundary data is removed. The divergence-free nature of the solution is obtained as a result of the consistency of the scheme to the differential equation.

In this paper we regard the overlapping grids as several overlapping domains, each with its own grid which is independent of other grids. Thus we refer to our method as the method of overlapping domains. This way of referring to the method calls attention to the central problem of relating the values of the solution on the several domains and deemphasizes the construction of the particular grids. As shown in §5, some of the primary difficulties are not specific to the choice of grid or the finite difference scheme.

We also restrict our attention to the steady Stokes equations because they are useful to illustrate the basic ideas of the method of overlapping domains as applied to incompressible flow. Overlapping domains can be used with the incompressible Navier–Stokes equations, both steady and time-dependent. The extra features introduced by the more general equations can be incorporated into the method without significant difficulties. The method is applicable to three-dimensional problems.

Also, related to the work presented here is the work of Thompson and Ferziger [17] and Vanka [18], in which the multigrid iteration scheme was applied to the incompressible Navier–Stokes equations. Each of these works used staggered grids which limit their methods to rectilinear domains. As we demonstrate by our computational results, our method maintains second-order accuracy even when the grids are not both rectilinear (see also [10]). A use of the multigrid iteration method to accelerate the rate of convergence of the iterative method will appear soon [12].

A typical example of the use of overlapping grids is in the computation of the flow past several bodies with nonsimple shapes. Boundary-fitted coordinate systems should be used near the bodies to insure good accuracy. However, away from the bodies it is simplest and most convenient to use a standard global cartesian grid or other such simple grid. One may indeed blend the boundary-fitted grids with the grid system used away from the bodies, but it is not done easily, nor can it be done by any simple general procedure. The approach advocated here is that of constructing the boundary-fitted and the global grids independently, but large enough to overlap. The values of the solution on the boundary of each grid are determined by interpolation of values from the other grids.

The chief advantages of the use of overlapping grids are the flexibility and generality of the method. It can be used with any geometric configuration and, in principle, the grid can be altered as needed. Local refinement grids and adaptive grid methods can also be used to improve the resolution of the solution. The flexibility of the method can be seen in comparison with global grid generation techniques and grid patching techniques. The need for higher resolution in one area of the domain usually forces both higher resolution in areas that do not need the resolution and lower resolution in other areas.

The use of overlapping grids can be used with the grid generation method to produce grids which enable solutions to be computed efficiently. The elliptic grid generation method of Thompson [16], and methods of Kreiss [7] and Chesshire [2], can be used to construct boundary-fitted grids around bodies. Farther from the bodies a cartesian grid or similar simple grid can be used. Boundary-fitted grids are essential for obtaining accurate solutions near bodies, while the use of simple cartesian grids is important for obtaining efficiency in computations.

2. The Stokes equations on overlapping domains. We first consider questions of uniqueness and existence of solutions to the steady Stokes system of equations on overlapping domains. These questions are not difficult to resolve, but they are interesting and important because of the insight they give to the numerical approximations.

We begin by considering two domains Ω_1 and Ω_2 which overlap, i.e., $\Omega_1 \cap \Omega_2$ is nonempty (see Fig. 1). We also assume that neither domain is included in the other. We consider the Stokes system of equations, given by

$$\nabla^2 \vec{u} - \vec{\nabla} p = 0, \tag{2.1}$$

$$\vec{\nabla} \cdot \vec{u} = 0, \tag{2.2}$$

on each separate domain. Boundary data for each domain is specified only on that part of the boundary which is not interior to the other domain. For purposes of discussion, we assume that the velocity $\vec{u}$ is specified by data $\vec{b}$ on the boundary of $\Omega_1 \cup \Omega_2$. For that part of $\partial\Omega_1$ (the boundary of Ω_1) that lies within Ω_2 we require that the velocity be equal to the velocity obtained from the solution of the Stokes system on Ω_2, and similarly for that portion of $\partial\Omega_2$ within Ω_1.

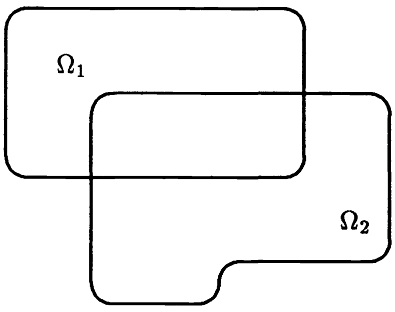

FIG. 1

We also assume that the integrability condition holds on the whole domain, i.e.,

$$\int_{\partial(\Omega_1 \cup \Omega_2)} \vec{b} \cdot \vec{n} = 0. \tag{2.3}$$

In our finite difference method some of the boundary data for a subdomain will be obtained by interpolation from other domains, and it would be difficult to explicitly impose the integrability constraint on the data for each subdomain. Thus we will consider a slightly more general case in which the divergence of the velocity field is required to be constant. That is, (2.2) is replaced with

$$\vec{\nabla} \cdot \vec{u}_i = d_i \quad \text{on} \quad \Omega_i. \tag{2.4}$$

The constant d_i is determined by the integrability condition for the domain, i.e.,

$$\int_{\partial\Omega_i} \vec{u}_i \cdot \vec{n} = d_i \; |\Omega_i|. \tag{2.5}$$

As will be seen, this formulation avoids the difficulties inherent in methods that require that the boundary data satisfy the integrability constraint on each subdomain; see [1].

The mathematical statement of the problem is then described as follows. In Ω_1,

$$\nabla^2\vec{u}_1 - \vec{\nabla}p_1 = 0, \qquad \vec{\nabla}\cdot\vec{u}_1 = d_1, \tag{2.6}$$

and in Ω_2,

$$\nabla^2\vec{u}_2 - \vec{\nabla}p_2 = 0, \qquad \nabla\cdot\vec{u}_2 = d_2 \tag{2.7}$$

with boundary conditions

$$\begin{aligned} \vec{u}_1 &= \vec{b} \quad \text{on} \quad \partial\Omega_1\backslash\Omega_2, \\ \vec{u}_1 &= \vec{u}_2 \quad \text{on} \quad \partial\Omega_1\cap\Omega_2, \\ \vec{u}_2 &= \vec{b} \quad \text{on} \quad \partial\Omega_2\backslash\Omega_1, \\ \vec{u}_2 &= \vec{u}_1 \quad \text{on} \quad \partial\Omega_2\cap\Omega_1, \end{aligned} \tag{2.8}$$

where $\vec{b}$ is the velocity data on the boundary of $\Omega_1 \cup \Omega_2$.

We make the assumption that the Stokes system of equations (2.6), (2.7) has a unique solution for each domain here when the velocity is specified on the boundary. By a unique solution we mean that the velocity function is determined uniquely and that the pressure function is determined to within an additive constant. The uniqueness of the solution to (2.6), (2.7) with the velocity specified on the boundary follows from the uniqueness of the Stokes system (2.1), (2.2). This assumption is certainly justified for all problems of physical significance. See Temam [15] for a discussion of existence and uniqueness of the stationary Stokes equations.

Notice that we do not assume a priori that $\vec{u}_1$ and $\vec{u}_2$ are the same on $\Omega_1\cap\Omega_2$. Also, notice that the pressure on one domain does not directly interact with the pressure on the other domain. In particular, we cannot specify the pressure as a boundary condition along with the velocity, as this would result in overdetermined boundary value problems on the subdomains.

It is useful to consider the following iterative procedure, essentially the Schwarz alternating procedure (see [8]), to solve the overlapping domain problem. We begin with any velocity field $\vec{u}_1^0$ defined on Ω_1. This need not be divergence-free. Using $\vec{u}_1^0$ as the boundary condition on $(\partial\Omega_2)\cap\Omega_1$, solve the system (2.7) for $\left(\vec{u}_2^0, p_2^0\right)$. Then using $\vec{u}_2^0$ as boundary data on $(\partial\Omega_1)\cap\Omega_2$, solve (2.6) for $\left(\vec{u}_1^1, p_1^1\right)$. Continue in this way, so that $(\vec{u}_1^\nu, p_1^\nu)$ is determined from $\vec{u}_2^{\nu-1}$ and $(\vec{u}_2^\nu, p_2^\nu)$ is determined from $\vec{u}_1^\nu$. The values of d_1^ν and d_2^ν are determined at each step by the integrability conditions. Supposing that the iterative method converges, we may indeed ask if the final values of constants d_1 and d_2 are the same, and if $(\vec{u}_1, p_1)$ and $(\vec{u}_2, p_2)$ together may be regarded as a solution on the total domain $\Omega_1\cup\Omega_2$. The convergence of this procedure can be shown using the methods of [8].

First, a solution to this problem exists. This is seen by considering the one problem defined on $\Omega_1 \cup \Omega_2$, the union of the two domains. The data vector function $\vec{b}$ is defined on the boundary of $\Omega_1\cup\Omega_2$, and thus by our assumption, a solution exists.

Next we show that the solution is unique. Assuming that solutions $(\vec{u}_1, p_1)$ and $(\vec{u}_2, p_2)$ exist on Ω_1 and Ω_2, respectively, the first question to be addressed is whether they agree on the intersection $\Omega_1 \cap \Omega_2$. Since $\vec{u}_1$ and $\vec{u}_2$ are equal on the boundary of $\Omega_1 \cap \Omega_2$, it follows by our uniqueness assumption that there is a unique solution and that d_1 and d_2 must be equal by the integrability condition on $\Omega_1 \cap \Omega_2$. Moreover, the pressure functions p_1 and p_2 differ at most by an additive constant. It then follows that the two solutions $(\vec{u}_1, p_1)$ and $(\vec{u}_2, p_2)$ can be regarded as a solution to the global boundary value problem on $\Omega_1 \cup \Omega_2$. Hence d_1 and d_2 are zero because of the integrability condition (2.3) on $\Omega_1 \cup \Omega_2$.

An observation that is important in the numerical approximation is that the two pressure fields, p_1 and p_2, differ by a constant whose value is not determined by the solution. Thus there are two undetermined parameters in the solution: the average value of p_1 on Ω_1 and the average value of p_2 on Ω_2. In general, there is an undetermined additive constant for the pressure on each subdomain in the decomposition.

It is important to note that it is by comparing the two different problems on the intersection of the domains that we see that they define a global solution on the union of the domains. This suggests that the *conditioning* of the problem is dependent on the size of the intersection. This conditioning is evident in the numerical investigations. A smaller overlap domain requires more iterations for convergence and gives less accuracy in the answers, although the same order of accuracy.

The increase in error with the smaller overlap is most likely due to the greater interaction between the interpolation done on the two boundaries. The error induced by interpolation to a boundary point on domain 1 affects the solution in the interior of domain 1. The use of interpolation from domain 1 back to the boundary of domain 2 carries that error to domain 2. Thus the errors introduced by interpolation are coupled together. However, because the system is elliptic, the effect of boundary errors on the solution at a point is smaller the farther the point is from the boundary; see [14]. Thus a larger overlap region could be expected to reduce the coupling between the interpolations at the two boundaries.

3. Interpolation between domains.

An important feature of the approach taken here is that the overall method is composed of relatively independent components. For example, the finite difference methods used on the different subdomains need not be the same. Also, the exact form of the iterative methods on the subdomains do not depend on each other.

The topic of this section, namely, the interpolation between domains, is also relatively independent of the other aspects of the overall problem. In particular, the interpolation is not dependent on the finite difference methods nor on the iterative method. As shown in this section, the choice of interpolation method is primarily based on convenience and the need for accuracy in the solution.

For each of the test cases for which the numerical experiments were made there were two grids. In the first set of cases the two grids are both cartesian grids, but rotated with respect to each other (see Fig. 2), while for the second set of test cases, one grid is a standard cartesian grid with uniform spacing and the other grid is a polar coordinate grid, also with uniform spacing in each coordinate direction (see Fig. 3). Rather than discuss the interpolation in general, we will confine ourselves to these two situations.

The basic interpolation problem is a local problem, that is, given a discrete function defined on a cartesian grid, how should a value be assigned to a point that is not on the grid? To mathematically formulate the problem in two space dimensions we consider a uniform cartesian grid with points (x_i, y_j) given by $x_i = ih$ and $y_j = jh$, where the grid spacing h is a positive number. Given a general point $(\bar{x}, \bar{y})$ there is a grid point (x_i^*, y_j^*) which is closest to $(\bar{x}, \bar{y})$. A second parameter of significance is the quadrant relative to (x_i^*, y_j^*) in which $(\bar{x}, \bar{y})$ lies. Without loss of generality we

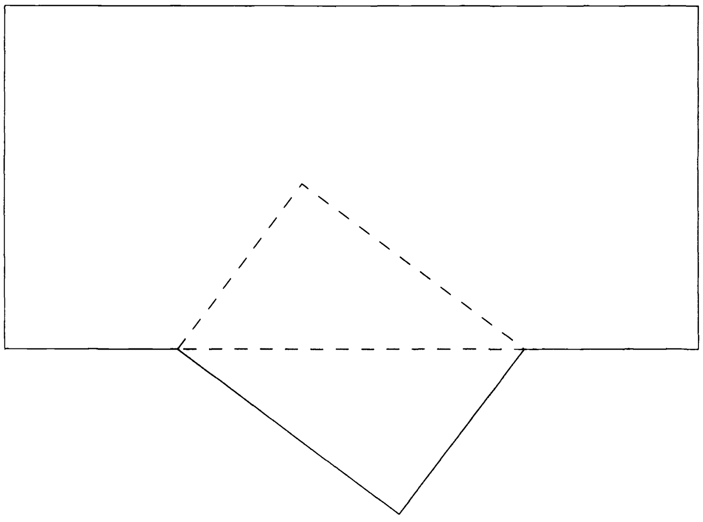

FIG. 2

can assume that (x_i^*, y_j^*) is $(0, 0)$. The general case can be reduced to this special case by a simple translation. We can also assume, to simplify the discussion, that $(\bar{x}, \bar{y})$ is in the first quadrant, that is, both $\bar{x}$ and $\bar{y}$ are positive.

The first interpolation method that we consider is bilinear interpolation. In this case the value of a function at $(\bar{x}, \bar{y})$ is given by

$$\begin{aligned} f &= f_{0,0} + \bar{x}\left(f_{1,0} - f_{0,0}\right)/h + \bar{y}\left(f_{0,1} - f_{0,0}\right)/h \\ &\quad + \bar{x}\bar{y}\left(f_{1,1} - f_{1,0} - f_{0,1} + f_{0,0}\right)/h^2, \end{aligned} \tag{3.1}$$

where $f_{0,0} = f(x^*, y^*)$, $f_{1,0} = f(x^* + h, y^*)$, $f_{0,1} = f(x^*, y^* + h)$, and $f_{1,1} = f(x^* + h, y^* + h)$. Bilinear interpolation is only accurate of order one. The order of accuracy is equal to the highest degree of polynomial for which the interpolation must be exact. Thus (3.1) is exact for any polynomial of first degree, but is not exact for all second-degree polynomials. The use of bilinear interpolation gave only first-order accuracy in the solution.

The second interpolation method that we consider is quadratic interpolation (see Fig. 3). The particular formula we used is

$$\begin{aligned} f &= f_{0,0} + \bar{x}\left(f_{1,0} - f_{-1,0}\right)/2h + \bar{x}^2\left(f_{1,0} - 2f_{0,0} + f_{-1,0}\right)/2h^2 \\ &\quad + \bar{y}\left(f_{0,1} - f_{0,-1}\right)/2h + \bar{y}^2\left(f_{0,1} - 2f_{0,0} + f_{0,-1}\right)/2h^2 \\ &\quad + \bar{x}\bar{y}\left(f_{1,1} - f_{1,0} - f_{0,1} + f_{0,0}\right)/h^2. \end{aligned} \tag{3.2}$$

In the test cases it was found that quadratic interpolation gave overall second-order accuracy, which is the same order as the finite difference schemes, so no methods of higher order were investigated.

Henshaw and Chesshire [6] reduced the amount of overlap as the grid spacing was reduced, and reported that a third-order interpolation was necessary to maintain the overall second-order accuracy of the solution. Since we consider the domain fixed, independent of the grid spacing, we are able to use interpolation of the same order as the scheme.

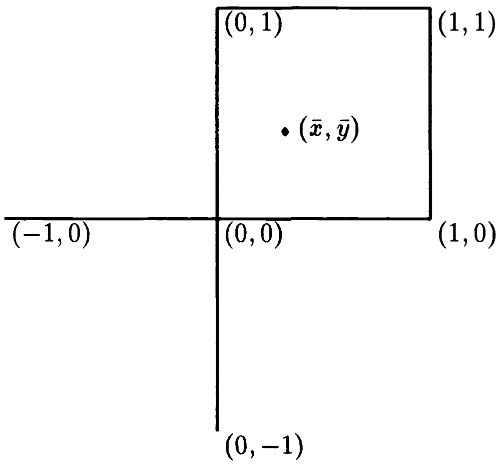

FIG. 3

For the interpolation from the polar grid to the cartesian grid in the second test problem, a method based on Fourier interpolation was used. This method was very natural to use because the numerical method on the polar grid used finite Fourier series to approximate the derivatives with respect to the angular variable. The finite Fourier series are discussed in §6.

The polar grid used in the numerical experiments consisted of grid points $(r_i,\ \theta_j)$ where $r_i = r_{\min} + i \cdot \Delta r$ for $0 \le i \le N$ and $\theta_j = j \cdot \Delta\theta$ for $0 \le j \le J$ with $\Delta\theta = \pi/J$ and $\Delta r = (r_{\max} - r_{\min})/N$. The even spacing of the grid is not crucial to the method; it was used for simplicity. Indeed, because the grid spacing in the two grids was independent of each other, good resolution with the polar grid could easily be obtained using a uniform grid without significantly increasing the overall computational effort.

The actual interpolation procedure was as follows. Given a point $(\bar{x},\bar{y})$ on the boundary of the cartesian grid for which data had to be supplied from the polar grid for a function f, its polar coordinates $(\bar{r},\bar{\theta})$ were first computed. The three values of r_i nearest to $\bar{r}$ were determined, and then using Fourier interpolation, values of $f(r_i,\bar{\theta})$ were obtained. Finally, one-dimensional quadratic interpolation in r was used to obtain $f(\bar{r},\bar{\theta})$.

Both the bilinear interpolation (3.1) and quadratic interpolation (3.2) were tested in place of this method to interpolate values from the polar grid to the cartesian grid. Both of these methods were far less accurate than was the use of the finite Fourier series. The inaccuracy of the quadratic interpolation for this case is due to the large grid spacing in the angular direction.

To interpolate the velocity from one grid to another, the different representation of the velocity on each grid must be accounted for. We found it best to interpolate the velocity components independently, and then transform them to the proper representation. For example, in interpolating from a cartesian representation to a polar representation, the cartesian velocity components are interpolated, and then transformed to the polar representation of the velocity.

The basic data for interpolation to a given point from a grid consists of the coordinates of the nearest grid point and the quadrant in which the given point lies relative to the nearest grid point. In many applications it would be best to determine this data prior to the main calculation. In the applications employed here the basic data was computed as needed. Because of the simplicity of the two grids used, i.e., cartesian and polar, the necessary computations were relatively easy and straightforward. For calculations being done on vector processors it would presumably be more efficient to store the interpolation data, rather than recompute it. This would also be true when using any grid for which it is difficult to determine the nearest grid point to a given point.

4. The iterative solution procedure. Before discussing the finite difference approximation we give a brief description of the iterative solution procedure. This is done before the discussion of the finite difference methods themselves to highlight those aspects which relate to the considerations discussed in the section on the overlapping domains for the Stokes system.

The (inner) iterative method used on the cartesian domain is based on point successive overrelaxation and is described in detail in [11]. The iterative method used on the polar domain is based on line successive overrelaxation and is well suited for methods using finite Fourier series methods. This method was also used in [13], where it is described in detail. Multigrid methods are also suitable; see [12]. One outer iteration consists of a single inner iteration on each subdomain with boundary data obtained from the other domain.

The basic inner iteration step to update the solution on a domain consists of two parts. The first part consists of updating the velocity using one step of a method, such as successive overrelaxation. This step uses only the first vector equation in (2.6) or (2.7). In the second part, the pressure is updated based on the local velocity divergence, which is the second equation in (2.6) or (2.7).

For the cartesian grid, assuming equal grid spacing of h and assuming the standard second-order accurate five-point Laplacian, these formulas are:

$$\begin{aligned} u_{ij} &\leftarrow u_{ij} + \omega\left(\frac{1}{4}(u_{i+1,j} + u_{i-1,j} + u_{i,j+1} + u_{i,j-1}) - u_{i,j} - \frac{h^2}{4}\delta_{x,r}p_{i,j}\right), \\ v_{ij} &\leftarrow v_{ij} + \omega\left(\frac{1}{4}(v_{i+1,j} + v_{i-1,j} + v_{i,j+1} + v_{i,j-1}) - v_{i,j} - \frac{h^2}{4}\delta_{y,r}p_{i,j}\right), \end{aligned} \tag{4.1}$$

where $\delta_{x,r}$ and $\delta_{y,r}$ represent regularized central difference approximations to the derivatives with respect to x and y, respectively. Formulas for $\delta_{x,r}$ and $\delta_{y,r}$ are given in §6. The algorithm uses immediate replacement, so that only one copy of the solution needs to be kept. The iteration parameter ω was chosen as for standard successive overrelaxation (see §7).

After the velocity has been updated, the pressure is updated by

$$p_{ij} \leftarrow p_{ij} - \gamma(\delta_{x,r}u_{ij} + \delta_{y,r}v_{ij}) \tag{4.2}$$

for all interior points. Here, as before, $\delta_{x,r}$ and $\delta_{y,r}$ represent regularized central difference approximations, but have a different shift than they did for the gradient terms in (4.1). The iteration parameter γ was chosen proportional to the grid spacing; see §7 for more on the choice of γ. After all the interior points were updated, the boundary values of the pressure are set by quadratic extrapolation using formulas such as

$$p_{0j} = 3(p_{1j} - p_{2j}) + p_{3j}$$

along the boundary given by $i = 0$. Similar formulas are used along the other boundaries. This extrapolation is of high enough order not to affect the overall second-order accuracy of the solution (see [14]). The stopping criteria for the iterative method are discussed in §7. The formula to update the pressure, given by (4.2) is part of the classical Uzawa algorithm and related methods (see [15, p. 139]).

When solving a problem on overlapping domains the procedure we have adopted is as follows. The solution on one domain, say Ω_1, is updated as in one step of the iterative method for a single domain. The values of the velocity on the boundary of Ω_2 are determined by interpolation from the latest values on Ω_1, and then the solution is updated on Ω_2 as in one step of the iterative method for a single domain. The boundary values of Ω_1 are then updated by interpolation of the velocity on Ω_2. This describes one step of the outer iterative method. The iteration proceeds until the solution on each domain has converged to within the specified tolerance.

Note that since only one sweep of the inner iteration is done on each domain, this method is *not* the Schwarz method. The Schwarz method requires that the solution be obtained on each subdomain before moving to the next domain.

Convergence is determined by examining the norm of the changes in velocity and the deviation of the changes of the pressure from a constant (see §7). Thus, the solution is determined as converged when on each subdomain the changes in velocity are small and the changes in the pressure are essentially constant.

Because the pressure and changes in pressure are determined only to within an additive constant, they are measured in the norm of L^2 *modulo constants*. By (4.2) the convergence requirement on pressure is equivalent to requiring that the discrete divergence of the velocity field is also constant, i.e., it is d_i on subdomain Ω_i. The relationship between the change in pressure and the value of d_i is that the change in the pressure on Ω_i is $-\gamma d_i$. Since the constants d_i are set by the boundary data and the interpolation between domains, this shows that one cannot use formula (4.2) and expect that the pressure changes can converge to zero. Note that the values of d_i are not needed explicitly because of the choice of norms. West's algorithm [19] is used to compute the norms of the pressure and the pressure changes. The mean values of the pressure and pressure changes are computed during the computation of the norms, but are not needed elsewhere in the calculation.

It is important to notice that at no time is it required that the velocity field be divergence-free or satisfy a similar numerical condition. Also, the pressure is not constrained so as to determine the unimportant additive constant. This avoids entirely problems such as those arising in the use of divergence-free finite elements (see [1]).

In particular, (4.2) does not enforce the condition that the discrete divergence must be zero at convergence, it only enforces the condition that the discrete divergence is constant on each subdomain. This is similar to the algorithm discussed in §2, and as in the proof of the uniqueness of the solution in §2, the divergence-free property is a result of the properties of the system and the boundary data.

Notice that the pressure fields on the two domains do not directly affect each other. In particular, their difference in the overlap is not restricted to being a constant. In fact, it is not clear how best to compare the pressure values, since they are defined on different grids.

These observations can be used to give a posteriori error checks. The deviation of the velocity fields from being divergence-free and the deviation from a constant of the difference of the two pressure fields on the overlap can be used to indicate the accuracy of the final solution.

We have made no attempt to prove that this iterative method will converge. It appears that such a proof is beyond our current methods of analysis. In practice, the method has performed very well. The solutions have been obtained in a reasonable number of steps.

For the second test problem, the size of the overlap region had a noticeable effect on the results. The method converged faster and gave more accurate results, when the overlap region was larger. One result of a smaller overlap region is that the errors resulting from interpolation from one domain to another have a greater interact with each other. Elliptic systems of finite difference schemes have the property that non-smooth boundary data give rise to smooth solutions in the interior of domains [14]. The effect of irregularities in boundary data obtained from interpolation from another domain will be smoothed out in the interior of the domains, but if the data used for interpolation is taken from near the boundary, some effect of the boundary irregularity can be propagated back to the other domain. The size of the overlap region affected only the magnitude of the errors, not the actual order of accuracy.

5. The reentrant corner difficulty. One difficulty which was discovered and finally surmounted is of sufficient interest to warrant special attention. This difficulty occurred with the second test problem and has to do with the corners of the cartesian grid resulting from the exclusion of portions of that grid from the computational domain. These corners, such as the points R_1 and R_2 in Fig. 4, are distinguished by being reentrant corners.

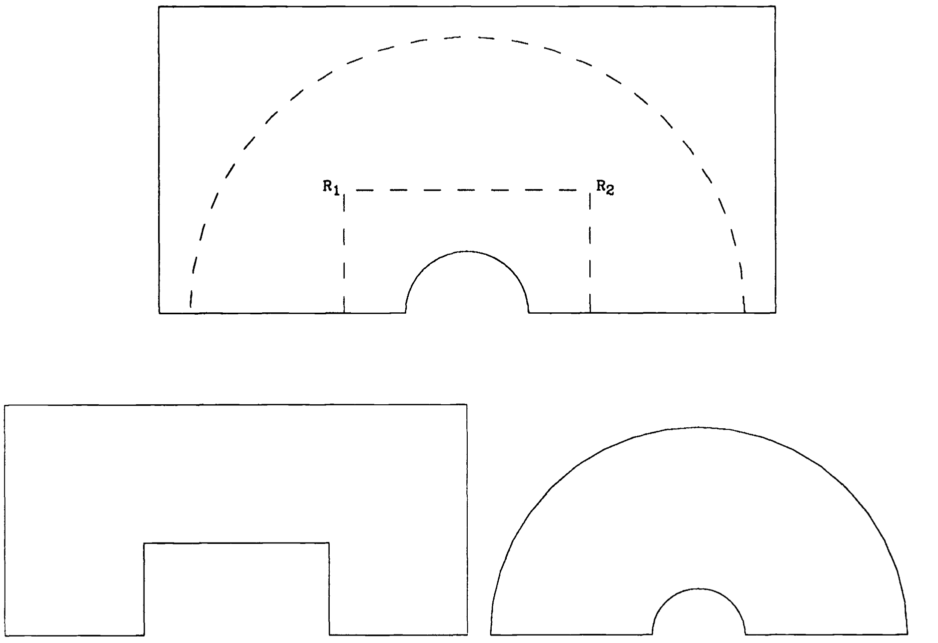

FIG. 4

For the Navier–Stokes or Stokes equations in a region with reentrant corners the solution will in general have a pressure singularity at such a corner. Usually this is studied only for flows over steps, in which the velocity is zero along the sides of the step (see [9]), however, the pressure singularity exists at reentrant corners for general data.

For the overlapping domains of the second problem the true solution has no singularity at the reentrant corners since the reentrant corners are interior to the other domain. However in the numerical approximation, the data given by the interpolation introduces errors which cause a pressure singularity to appear in the error. In the test problem the graphical display of the error showed that these pressure singularities were the dominant feature of the error. The singularity in the pressure error caused a vortical flow in the velocity error. The discovery of the pressure error singularity was made possible by graphically displaying the errors.

Two approaches were used to improve the solution by decreasing the strength of these pressure error singularities. The first of these we call "rounding off the corner." It is based on the observation that the grid points at the reentrant corners can be treated as interior points of the cartesian grid. Both the pressure and velocity at these corner points were updated as interior points. This is possible because all the nearest neighbors are also part of the grid. Interpolation is done then only at points which are missing at least one neighbor in the grid. This simple procedure gave a dramatic improvement in the accuracy of the solution.

The second method was to "chop off" the corner so that the one 270° angle is replaced by two 225° angles. This method introduced more programming difficulties and did not give a significant improvement over the method of rounding off the corner, and so will not be discussed further.

It is important to remember that the reentrant corner pressure error singularity is inherent in the use of overlapping domains. This can be seen by considering the overlapping domain problem for the differential equations as discussed in §2. If we assume that the specification of boundary values on the overlap portions of the boundary, i.e., $(\partial\Omega_1)\cap\Omega_2$ and $(\partial\Omega_2)\cap\Omega_1$, is not exact but contains some error, then in general there will be a pressure singularity at each reentrant corner. The strength of the singularity will be directly related to the amount of error in the boundary specification.

6. The finite difference method for the Stokes equations. The finite difference methods used in the numerical experiments with the overlapping domain method are variations of the regularized difference schemes introduced by the first author [10]. This class of schemes is the only one for which published results are given to demonstrate the second-order accuracy of the solution in nonsimple domains.

In cartesian coordinates the Stokes equations are

$$\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}-\frac{\partial p}{\partial x}=0, \tag{6.1}$$

$$\frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}-\frac{\partial p}{\partial y}=0, \tag{6.2}$$

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0, \tag{6.3}$$

and in polar coordinates they are

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial u}{\partial r}\right)+\frac{1}{r^2}\frac{\partial^2 u}{\partial \theta^2}-\frac{u}{r^2}+\frac{2}{r^2}\frac{\partial v}{\partial \theta}-\frac{\partial p}{\partial r}=0, \tag{6.4}$$

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v}{\partial r}\right)+\frac{1}{r^2}\frac{\partial^2 v}{\partial \theta^2}-\frac{v}{r^2}-\frac{2}{r^2}\frac{\partial u}{\partial \theta}-\frac{1}{r}\frac{\partial p}{\partial \theta}=0, \tag{6.5}$$

$$\frac{1}{r}\frac{\partial (ru)}{\partial r}+\frac{1}{r}\frac{\partial v}{\partial \theta}=0. \tag{6.6}$$

In (6.1), (6.2), and (6.3) the variables (u,v) denote the velocity components in the cartesian representation, while in (6.4), (6.5), and (6.6) they denote the components in the polar representation. No confusion should result from not distinguishing between the choice of representation since the two coordinate systems are treated separately.

The first test problem is on the domain consisting of the rectangle $-1 \le x \le 1$, $0 \le y \le 1$, with a right triangle with legs of length 0.8 and 0.6 attached to the rectangle along the hypotenuse at $-0.5 \le x \le 0.5$ (see Fig. 2). The two grids used to compute the solution were both cartesian grids. On each domain the equations have the form (6.1)–(6.3), but the velocity components on one grid must be rotated by the angle of the tilt between the grids to obtain the velocity components on the other grid.

The region for which the second set of numerical experiments were run is the rectangle $-1 \le x \le 1, 0 \le y \le 1$ with the exclusion of a circle of radius r_{min} centered at the origin. This region is displayed in Fig. 4. The grid system consisted of an evenly spaced cartesian grid with equal spacing in each direction and a polar grid with uniform spacing in each of the radial and angular directions.

The domain covered by the cartesian grid was the large rectangle with the exclusion of a smaller rectangle around the excluded circle as displayed in Fig. 4. The grid spacings on this, the cartesian domain, were given by

$$\Delta x = \Delta y = 1/M \tag{6.7}$$

for some positive integer M. The omitted grid points were those in the rectangle

$$-i_0\Delta x < x < i_0\Delta x, \qquad 0 \le y < i_0\Delta y. \tag{6.8}$$

The domain covered by the polar grid was the region displayed in the lower right portion of Fig. 4, given by

$$r_{\text{min}} \le r \le r_{\text{max}}, \qquad 0 \le \theta \le \pi. \tag{6.9}$$

Various values of r_{min} and r_{max} were used in the studies. Typical values were 0.2 for r_{min} and 0.9 for r_{max}. The grid spacings for this domain, the polar domain, were given by

$$\Delta r = (r_{\text{max}} - r_{\text{min}})/N \quad \text{and} \quad \Delta\theta = \pi/J \tag{6.10}$$

for some positive integers N and J.

In all the tests an analytical solution of the Stokes equations was used to assess the accuracy of the method. The first problem used Dirichlet boundary conditions, in which the velocity was specified along the boundary.

For the second problem the solutions which were used were symmetric about the x axis. The boundary conditions imposed were that the velocity was specified along the boundaries given by $x = -1, x = 1, y = 1$, and also $r = r_{\min}$. Along the boundary $y = 0$ symmetry conditions were used. These were

$$\frac{\partial u}{\partial y} = 0 \quad \text{and} \quad v = 0.$$

For the cartesian grid the finite difference method was based on second-order accurate central differences for all derivatives. However, the use of the standard central difference for the divergence equation and for the pressure gradient results in nonsmooth solutions. The loss of smoothness can be avoided by using regularized central differences, as introduced in [10] (see also [11]). These approximations are

$$\frac{\partial p}{\partial x} \simeq \delta_{x,r}p = \frac{p_{i+1,j} - p_{i-1,j}}{2\Delta x} - \frac{p_{i+2,j} - 3p_{i+1,j} + 3p_{i,j} - p_{i-1,j}}{6\Delta x}, \tag{6.11}$$

$$\frac{\partial p}{\partial y} \simeq \delta_{y,r}p = \frac{p_{i,j+1} - p_{i,j-1}}{2\Delta y} - \frac{p_{i,j+2} - 3p_{i,j+1} + 3p_{i,j} - p_{i,j-1}}{6\Delta y}, \tag{6.12}$$

$$\frac{\partial u}{\partial x} \simeq \delta_{x,r}u = \frac{u_{i+1,j} - u_{i-1,j}}{2\Delta x} - \frac{u_{i+1,j} - 3u_{i,j} + 3u_{i-1,j} - u_{i-2,j}}{6\Delta x}, \tag{6.13}$$

$$\frac{\partial v}{\partial y} \simeq \delta_{y,r}v = \frac{v_{i,j+1} - v_{i,j-1}}{2\Delta y} - \frac{v_{i,j+1} - 3v_{i,j} + 3v_{i,j-1} - v_{i,j-2}}{6\Delta y}. \tag{6.14}$$

Notice that the additional regularizing terms are third-order divided differences which are shifted forward for the pressure and shifted backward for the velocity derivatives. At grid points near the boundaries, where the approximations (6.11)–(6.14) cannot be applied, the third-order difference is shifted the other way.

For the polar grid of the second problem, a method was employed which uses both finite differences and Fourier methods. The solutions were assumed to be symmetric about the line $y = 0$, and thus the components of the velocity in polar representation and the pressure can be expressed as

$$u_{ij} = u(r_i, \theta_j) = \frac{1}{2}a_0(r_i) + \sum_{k=1}^{J-1} a_k(r_i) \cos k\theta_j + \frac{1}{2}(-1)^j a_J(r_i), \tag{6.15}$$

$$v_{ij} = v(r_i, \theta_j) = \sum_{k=1}^{J-1} b_k(r_i) \sin k\theta_j, \tag{6.16}$$

$$p_{ij} = p(r_i, \theta_j) = \frac{1}{2}c_0(r_i) + \sum_{k=1}^{J-1} c_k(r_i) \cos k\theta_j + \frac{1}{2}(-1)^j c_J(r_i). \tag{6.17}$$

In these formulas $r_i = r_{\min} + i \cdot \Delta r$ and $\theta_j = j\Delta\theta$. The formulas (6.15), (6.16), and (6.17) express the function in terms of their finite Fourier series for a fixed value of r_i. The determination of the coefficients a_k, b_k, and c_k are easily determined from the function values. Because of the assumed symmetry in the solution, u and p are even functions in θ and v is an odd function.

Approximations to the derivatives with respect to θ are obtained by regarding the variable θ as a continuously varying variable on the right-hand side of (6.15), (6.16), and (6.17). For example,

$$\frac{\partial v}{\partial \theta}(r_i, \theta_j) \simeq \sum_{k=1}^{J-1} b_k(r_i) k \cos k\theta_j. \tag{6.18}$$

The finite Fourier representation is used only to obtain the approximations to the derivatives with respect to θ. The derivatives are used to evaluate the left-hand side of equations (6.4), (6.5), and (6.6) as part of the iterative solution technique.

The importance of using regularized differences also applies to the Fourier approximation. In this case, the coefficients $a_J(r_i)$ and $c_J(r_i)$ must be constrained (see also [13]). These coefficients are related through (6.4), but some relation other than given by (6.4), (6.5), and (6.6) is needed to determine these values. To control the magnitude of the coefficients $c_J(r_i)$ in (6.17), the approximation of some derivative must be altered. Note that the derivative of p with respect to θ occurs only in (6.5), which relates the coefficients of p, i.e., the $c_k(r_i)$, with those of v, i.e., the $b_k(r_i)$, but there is no mode for k equal to J in the representation for v. It would be possible to allow for a coefficient $b_J(r_i)$ in the representation for v. This coefficient $b_J(r_i)$ would be proportional to $c_J(r_i)$ and could be constrained through (6.6). Note that since $\sin J\theta_j$ is identically zero, this coefficient would have no direct effect on v. Equivalently, $b_J(r_i)$ was not explicitly used; instead a term equal to

$$-\tfrac{1}{4}(-1)^j c_J(r_i)$$

was added to the approximation of the divergence equation (6.6). The form of the iterative method then forced the coefficient $c_J(r_i)$ to decrease. The rate of decrease is $1 - \gamma/2$, where γ is the iterative parameter in (4.2). Some such constraint on the coefficients $c_J(r_i)$ is necessary; without it, the dominant pressure errors are in the coefficient $c_J(r_i)$. Since this coefficient relates to the highest frequency supported by the grid there is no concern with consistency in treating this term.

7. The numerical experiments.

The first set of numerical experiments were run using the domain shown in Fig. 2. On each domain the grid is a cartesian grid. For the cases shown in Table 1, the grid spacing was $1/M$ in both directions for the larger grid and was $.8/M$ for Δx and $.6/M$ for Δy on the smaller tilted grid. On each domain the Stokes equations have the form (6.1)–(6.3), but the components of the velocity vectors are related by the rotation of the coordinate system. After interpolating the velocity vector components from one grid to the other, the components in the new coordinate system have to be computed using the appropriate rotation.

The solution for which most of the tests of the first problem were made is

$$u = \tfrac{1}{2}\left((x+0.5)^2 - (y+0.5)^2\right) / \left((x+0.5)^2 + (y+0.5)^2\right)$$
$$-\tfrac{1}{2}\log\left((x+0.5)^2 + (y+0.5)^2\right),$$
$$v = (x+0.5)(y+0.5) / \left((x+0.5)^2 + (y+0.5)^2\right),$$
$$p = 2(x+0.5) / \left((x+0.5)^2 + (y+0.5)^2\right) + p_0,$$

TABLE 1

	Main grid errors

24	5.06(−5)	2.74(−5)	2.00(−3)	−4.2(−7)
30	2.96(−5)	1.71(−5)	1.19(−3)	−1.6(−7)

TABLE 2

	Main grid errors			Tilted grid errors		
M_1/M_2	u	v	p	u	v	p
10/16	2.26	2.13	2.54	2.60	1.83	1.96
16/24	2.80	2.71	2.66	3.02	2.99	2.30
24/30	2.52	2.10	2.59	2.40	2.11	2.33

in the cartesian coordinates of the larger domain. The origin is taken as the midpoint of the lower boundary of the larger domain. In Table 1 the L^2 norms of the errors for several cases are shown. For these cases, the iteration parameters ω and γ were chosen as $\omega = 2/(1+4\Delta x)$ and $\gamma = 4\Delta x$, where Δx is the x grid spacing on the larger grid. Table 1 also shows the values of d_i, the average divergence, for each domain; see (2.4). The values of d_i are on the order of the error for the computed solution, and thus are acceptable.

The values of ω and γ that were used were found to give about the best convergence rates. Moreover, their dependence on the grid spacing resulted in the number of iterations being roughly proportional to M. The stopping criterion for the iterative methods was to stop when the norms of the changes in the velocities and the norm of the deviation between the divergence of the velocity field and d_i were all sufficiently small. The number of iterations for the cases shown in Table 1 were 179, 327, 527, and 677, respectively, when the L^2 norms of the updates were less than 10^{-5}.

Table 2 gives the convergence rates of the accuracy of successive runs. The convergence rate for runs with values of M equal to M_1 and M_2, with M_1 less than M_2, is

$$\log(\text{error}(M_1)/\text{error}(M_2)) \,/\, \log(M_2/M_1)\,.$$

These experimentally determined convergence rates are consistent with the overall method being second-order accurate.

The second set of numerical experiments were run using the domain shown in Fig. 4. The grid was generated by constructing a cartesian grid on the domain shown in the lower left portion of Fig. 4, and a polar grid on the domain shown in the lower

TABLE 3

	Cartesian errors			
M	u	v	p	d
10	5.31(−3)	4.73(−3)	2.28(−1)	−3.1(−4)
20	1.21(−3)	9.47(−4)	2.19(−2)	−2.5(−5)
30	5.47(−4)	4.31(−4)	7.81(−3)	−8.9(−6)
40	3.12(−4)	2.45(−4)	4.60(−3)	−2.4(−6)

	Polar errors			
M	u	v	p	d
10	2.50(−3)	1.12(−2)	2.17(−1)	2.8(−4)
20	8.19(−4)	2.79(−3)	4.83(−2)	3.3(−5)
30	3.99(−4)	1.22(−3)	2.11(−2)	1.3(−5)
40	2.25(−4)	6.99(−4)	1.22(−2)	7.0(−6)

right portion of Fig. 4. In the top domain shown in Fig. 4, the dotted lines show the overlap between the two domains. In almost all the cases tested Δx and Δy were equal and i_0 and j_0 were also equal.

Several exact solutions were used to test the numerical method. A very useful solution was, in the cartesian representation,

$$u = x, \qquad v = -y, \qquad p = 0, \tag{7.1}$$

or, in polar representation,

$$u = r\cos 2\theta, \qquad v = -r\sin 2\theta, \qquad p = 0. \tag{7.2}$$

This solution has the property that it exactly satisfies the difference approximations to the Stokes equations on both grids of the second problem. Thus the only errors introduced by the method were due to the interpolation. With the use of the finite Fourier expansion for the interpolation from the polar to the cartesian domain, this simple exact solution had essentially no error. The only errors measured were on the order of the arithmetic accuracy of the computer.

The solution for which most of the tests of the second problem were made is

$$\begin{aligned} u &= \tfrac{1}{2}\left(x^2 - y^2\right) / \left(x^2 + y^2\right) - \tfrac{1}{2}\log\left(x^2 + y^2\right), \\ v &= xy/\left(x^2 + y^2\right), \\ p &= 2x/\left(x^2 + y^2\right) + p_0, \end{aligned}$$

in cartesian representation. In Table 3 the L^2 norms of the errors are shown for a representative series of runs. For these runs M and N, as defined by (6.7) and (6.10), were equal. The values of $r_{\min}$ and $r_{\max}$ were 0.2 and 0.9, respectively. The value J was 14 for all runs. For these cases, the iteration parameters ω and γ were chosen as $\omega = 2/(1 + 9\Delta x)$ and $\gamma = 9\Delta x$, where Δx is the x grid spacing on the cartesian grid. As for the first case, these values for ω and γ gave good rates of convergence for the iterative method.

TABLE 4

	Cartesian errors			Polar errors		
M_1/M_2	u	v	p	u	v	p
10/20	2.13	2.32	3.38	1.61	2.01	2.17
20/30	1.96	1.94	2.54	1.77	2.04	2.05
20/40	1.96	1.94	2.25	1.86	1.97	1.99
30/40	1.95	1.96	1.84	1.99	1.94	1.90

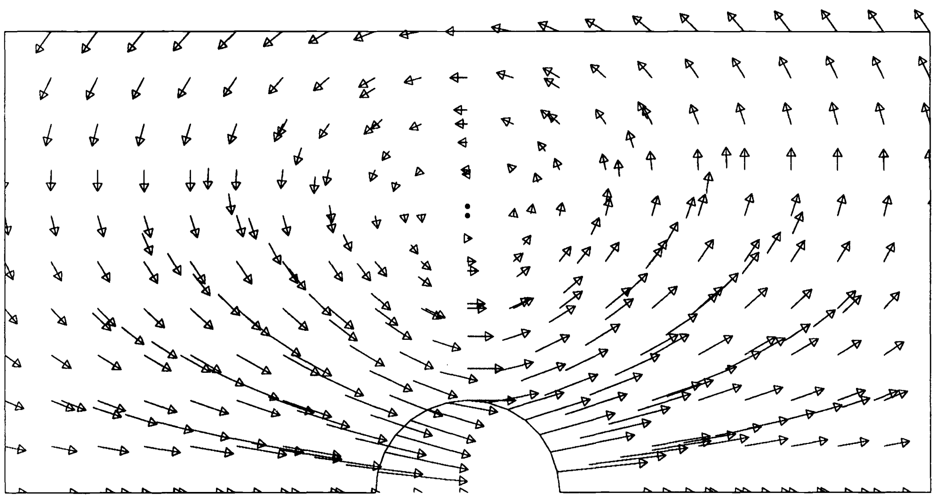

FIG. 5

Table 4 displays the convergence rates for the accuracy of successive runs. The convergence rates were computed as for Table 2. As with the first case, these experimentally determined convergence rates are consistent with the overall method being second-order accurate.

The pressure error norms are computed in a way similar to the computation of a statistical variance, that is, the pressure error norm measures the deviation of the pressure from its mean value. The algorithm that was used is due to West [19]. In this way, the effect of an additive constant is canceled. The norm of the difference between the divergence and d_i was also computed using this algorithm. As used here, d_i corresponds to the statistical average, and the norm of the difference is obtained as the standard deviation.

The velocity field for the run given in Table 3 with M equal to 20 is shown in Fig. 5, and in Fig. 6 the pressure contours are shown. As shown by Fig. 5, the solution provides a good test problem by being nontrivial. Figure 6 was obtained by overlaying the contour plots from each of the domains.

As mentioned in §2 the size of the overlap between the domains affected the error of the solution. For example, if the value of $r_{\max}$ was decreased from 0.9 to 0.6 the errors increased by about 50 percent. The efficiency was also affected by decreasing

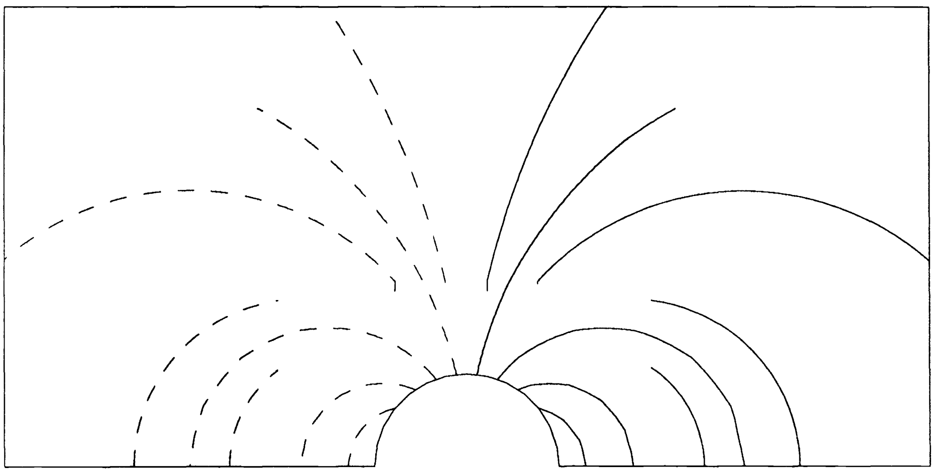

FIG. 6

$r_{\max}$. The number of iterations required to achieve a given convergence criterion was more than four times as great for $r_{\max}$ of 0.6 as for $r_{\max}$ of 0.9. This increase in error when the overlap is decreased is most likely due to the interaction of the errors induced by the interpolation on the boundaries.

8. Conclusions. The domain decomposition method presented here has been demonstrated to compute accurate solutions to the equations describing incompressible viscous flow. The method described here can be extended to computing flows of engineering significance involving the Navier–Stokes equations. It is anticipated that there will be few difficulties encountered in extending this method from the Stokes equations to the Navier–Stokes equations for low Reynolds number flows.

Research is being done to extend this work to cases with more than two subdomains. There are also plans to study the algorithm on parallel architectures to see what speedup can be achieved.

We appreciate the suggestions and corrections made by the referees.

SOME PRACTICAL ASPECTS OF EXPLORATORY PROJECTION PURSUIT*

JIAYANG SUN†

Abstract. This paper shows how to choose the number of terms in a projection pursuit index and how to select a projection pursuit algorithm. It also demonstrates that Friedman's index [*J. Amer. Statist. Assoc.*, 82 (1987), pp. 249–266] works better than Hall's [*Ann. Statist.* 17 (1989), pp. 589–605] in detecting separations or clusters.

Key words. projection pursuit, optimizations, P-values, consistency

AMS(MOS) subject classifications. 62H99, 62G99, 62E30, 65C05, 65K10

1. Introduction. Projection pursuit explores interesting "nonlinear structures"[1] (such as clusters and separations) of a high-dimensional data set by projecting the data onto some low-dimensional space. In this paper we denote the high p-dimensional independent and identically distributed (i.i.d.) data set from a population $\mathcal{F}$ by $Y_1, \dots, Y_N$ and pursue the case of projecting to one-dimensional space. (Extension to the case of two dimensions is possible.)

The two key elements in projection pursuit are the related index and algorithm. A *projection pursuit index* $I(\alpha)$ is an estimate of a measure of distance between the distribution of the projection of the data in the direction $\alpha = (\alpha_1, \dots, \alpha_p)$ and some "*uninteresting distribution*." Of course, we only need to consider vector α with $\alpha^T\alpha = 1$. A *projection pursuit algorithm* is an optimization algorithm that maximizes $I(\alpha)$. Since classical statistics can be used to handle the data from a normal distribution well (cf. [1]), a natural uninteresting distribution is a normal distribution. The two recent projection pursuit indices proposed by Friedman [4] and Hall [6] are to find the "least normal" structures.

Let $\Phi(x)$, $\phi(x)$ be the distribution and density function of an $\mathcal{N}(0,1)$ random variable (r.v.), respectively. Denote the density function of $X = \alpha^T Y$ by $p_\alpha(x)$. Assume for the moment that $E(Y_i) = 0$ and $\operatorname{cov}(Y_i) = I$, the identity matrix. The m-term *Hall's index* I_m^H is an estimate of the sum of the first m terms of Hermite polynomial expansion of $\mathcal{L}_2$ distance between p_α and ϕ:

$$(1)\qquad \begin{aligned} I_m^H(\alpha) = &\sum_{j=1}^{m} \frac{\sqrt{\pi}}{j! \cdot 2^{j-1}} \left\{ \frac{1}{N} \sum_{i=1}^{N} H_j(\alpha^T Y_i)\phi(\alpha^T Y_i) \right\}^2 \\ &+ 2\pi^{1/2} \left\{ \frac{1}{N} \sum_{i=1}^{N} \phi(\alpha^T Y_i) - \frac{1}{\sqrt{2}\pi^{1/4}} \right\}^2, \end{aligned}$$

where the Hermite polynomials H_j are defined as follows:

$$H_0(r) = 1, \qquad H_1(r) = 2r, \qquad H_j'(r) = 2jH_{j-1}(r),$$

*Received by the editors September 10, 1990; accepted for publication December 8, 1991.

†Department of Statistics, University of Michigan, 1444 Mason Hall, Ann Arbor, Michigan 48109-1027.

[1]The term "nonlinear structures" refers to those structures that cannot be detected easily by using solely sample mean and covariance matrix of the data, in contrast to classical multivariate statistics.

$$\int_{-\infty}^{\infty} H_j^2(r)\,\phi^2(r)dr = \frac{j!\,2^{j-1}}{\sqrt{\pi}} \quad \text{for } j = 2, 3, \ldots.$$

Under the transformation $X \longrightarrow R = 2\Phi(X) - 1$, the density $p_\alpha(x)$ is transformed to the density function $q_\alpha(r)$ of $R = 2\Phi(\alpha^\tau Y) - 1$, and a standard normal r.v. will be transformed to a uniform r.v. on $(-1, 1)$. The m-term *Friedman's index* I_m^F is an estimate of the sum of the first m terms of Legendre polynomial expansion of $\mathcal{L}_2$ distance between q_α and $\frac{1}{2}$:

$$I_m^F(\alpha) = \sum_{j=1}^{m} \frac{2j+1}{2} \left[\frac{1}{N}\sum_{i=1}^{N} L_j\left\{2\Phi(\alpha^\tau Y_i) - 1\right\}\right]^2, \tag{2}$$

where the recursive definition of Legendre polynomials L_j is given as follows:

$$L_0(r) = 1, \quad L_1(r) = r, \quad L_2(r) = \frac{1}{2}(3r^2 - 1),$$

$$L_j(r) = \frac{1}{j}\left\{(2j-1)rL_{j-1}(r) - (j-1)L_{j-2}(r)\right\} \quad \text{for } j = 3, \ldots.$$

In practice, $E(Y_i)$ and $\operatorname{cov}(Y_i)$ are unknown and arbitrary. People usually *sphere* the data before implementing the projection pursuit procedure based on the first set of summary statistics: sample mean $\overline{Y} = 1/N \sum Y_i$ and sample covariance matrix $\hat{\Sigma} = (1/N)\sum(Y_i - \overline{Y})(Y_i - \overline{Y})^\tau$. A typical version of the sphered data is

$$Z_i = \hat{D}^{-\frac{1}{2}}\hat{U}^\tau(Y_i - \overline{Y}), \qquad i = 1, \ldots, N, \tag{3}$$

where $\hat{U}\,\hat{D}\,\hat{U}^\tau = \hat{\Sigma}$ is an eigenvalue-eigenvector decomposition of $\hat{\Sigma}$. In other words, Y_i in (1) or (2) is often replaced by its sphered version, say Z_i, in practice.

In §2, the rules of thumb for choosing the appropriate number m of terms in the Friedman and Hall indices are given. It turns out that Friedman's index performs better than Hall's in detecting separations or clusters. In §3, projection pursuit algorithms are discussed for three typical situations: highly structured data, data from Gaussian noise, and none of the above.

2. How to choose the number of terms. The choice of the number m of terms included in a projection pursuit index depends on the data dimension p and sample size N. We give some general guidelines here.

Case 1. *Friedman's index.* Friedman [4] suggested that we choose

(a) $2 \le m \le 6$ in most cases.

In the following we show that m should be at least 3.

Let

$$\tilde{Y}_j(\alpha) = \sqrt{\frac{2j+1}{N}} \sum_{i=1}^{N} L_j(2\Phi(\alpha^\tau Z_i) - 1), \tag{4}$$

for $j = 1, \ldots, m$. Friedman's index can be rewritten as $I_m^F(\alpha) = (2N)^{-1}\sum(\tilde{Y}_j(\alpha))^2$. According to the large sample theory, in the unsphered data case $(Z_i = Y_i)$, these

$\tilde{Y}_j(\alpha)$, $j = 1, 2, \ldots, J$, are i.i.d. univariate standard normal random variables. Note that the sphered version $Z_1, \ldots, Z_N$ of data $Y_1, \ldots, Y_N$ satisfies

$$\sum_{i=1}^{N} Z_i = 0, \qquad \frac{1}{N}\sum_{i=1}^{N} Z_i Z_i^T = I_p, \tag{5}$$

and concentrates on a small neighborhood of 0 with a high probability, in which function $\Phi(x)$ can be approximated by a straight line $ax + \frac{1}{2}$. Thus $R_i = 2\Phi(\alpha^T Z_i) - 1 \approx 2a\alpha^T Z_i$. Hence the first term of Friedman's index $I_m^F(\alpha)$ is

$$\tilde{Y}_1(\alpha)^2 \approx \frac{3}{2}\left(\frac{1}{N}\sum_{i=1}^{N} 2a\alpha^T Z_i\right)^2 = 0.$$

The variance of the second term is also very small relative to the variances of other terms due to the second constraint in (5). We have done simulations to confirm this phenomenon. For example, in Table 1 the data are four-dimensional pseudo-normal random vectors from $\mathcal{N}(0, I_4)$, the sample size is N, and the simulation size M is 1000. We first compute $\tilde{Y}_j(\alpha)$ based on the sphered data for $j = 1, 2, 3, 4$ for each simulation and then calculate the sample mean and variance of $\tilde{Y}_j(\alpha)$. The sample mean and variance of the 1000 pseudounivariate standard normal random numbers (labeled st. normal) are also provided in Table 1.

TABLE 1
$\tilde{Y}_l(\alpha)$ in sphered case.

	$\alpha = (0, 3^{-1/2}, 3^{-1/2}, 3^{-1/2})$				$\alpha = (1,0,0,0)$	
	N=100		N=1000		N=1000	
	var	mean	var	mean	var	mean
$\tilde{Y}_1(\alpha)$	0.0414	0.0147	0.04	0.003	0.045	0.003
$\tilde{Y}_2(\alpha)$	0.22	-0.004	0.22	0.06	0.23	0.08
$\tilde{Y}_3(\alpha)$	0.92	-0.080	0.91	-0.03	0.98	-0.033
$\tilde{Y}_4(\alpha)$	0.853	0.0490	0.811	-0.04	0.89	-0.0856
st. normal	0.98503	0.061	0.98503	0.061	0.98503	0.061

In Table 1, the means of $\tilde{Y}_l(\alpha)$'s are reasonably close to zero; the variances of $\tilde{Y}_3(\alpha)$ and $\tilde{Y}_4(\alpha)$ are close to one, but the variance of $\tilde{Y}_1(\alpha)$ is only about 0.04, and the variance of $\tilde{Y}_2(\alpha)$ is about 0.22, which is closer to 0 rather than 1. Intuitively speaking, sphering reduces dimensionality of the projection pursuit index by 2. A theoretical justification can be found in the appendix. Therefore, we suggest modifying (a) as

(a′) $3 \le m \le 6$ in most cases.

Recall that Friedman's index, for example, estimates the sum of the first m terms of Legendre polynomial expansion of $\mathcal{L}_2$ distance between q_α and $\frac{1}{2}$ by substituting $E(L_j\{2\Phi(\alpha^T Y) - 1\})$ with the corresponding sample mean $1/N \sum L_j\{2\Phi(\alpha^T Y_i) - 1\}$ (cf. Friedman [4]). The $L_j\{2\Phi(\alpha^T Y) - 1\}$ all have similar variance; indeed, under normality, all have variance close to 1 for $j \ge 3$. However, if the $\mathcal{L}_2$ distance between distributions is finite, the means must converge to 0 as j increases. This implies that the L_j for large j will be poor at detecting nonnormality, especially when N is small. In practice, one may always assume a large finite support. Then the corresponding L_2 distance is finite. This assumption does not change the interesting structures of the data. Thus,

(b) if N is small, m should also be small.

The N data points in a higher-dimensional space suffer more from "the curse of the dimensionality" than the N data points do in a lower-dimensional space. In other words, this case can be treated as if the sample size is small. Consequently,

(c) the larger p is, the smaller m should be.

In summary, (a′), (b), and (c) form a rule of thumb for choosing the number of terms for Friedman's projection pursuit index. Less experienced users may find the examples in Friedman [4] useful.

Case 2. *Hall's index*. We discuss a motivating example first.

The bimodal model is an interesting model in applications. Suppose that the data $Y_1, \ldots, Y_N$ are i.i.d. from a four-dimensional population $\mathcal{G}_\mu$, which specifies that if $Y_i = (Y_1^i, Y_2^i, Y_3^i, Y_4^i)^\tau \overset{\text{dis}}{\sim} \mathcal{G}_\mu$, then

- the first component Y_1^i is a r.v. with the density function g_μ:

$$g_\mu(x) = \tfrac{1}{2}\phi(x) + \tfrac{1}{2}\phi(x-\mu), \qquad x \in (-\infty, \infty); \tag{6}$$

- the remaining components Y_2^i, Y_3^i, Y_4^i are i.i.d. from $\mathcal{N}(0,1)$;

and $Y_1^i, Y_2^i, Y_3^i, Y_4^i$ are independent. The truly interesting direction for this probability model is $\alpha^* = (1,0,0,0)$.

We shall compare the four-term Friedman index ($m = 4$) with the four-term Hall index under the above simple probability model in the case of sample size $N = 100$. In Hall's index, there are five terms if we count the zero term. The comparison will be given in terms of histograms explained below:

$$\begin{tikzcd} & & \arrow[r, squiggly] & \alpha_m^F \arrow[r, "\text{project}"] & \alpha_m^{F\tau} Z \arrow[r] & \text{histogram}_F \\ Y \arrow[r, "\text{sphere}"] & Z \arrow[ur] \arrow[dr] & & & & \\ & & \arrow[r, squiggly] & \alpha_m^H \arrow[r, "\text{project}"] & \alpha_m^{H\tau} Z \arrow[r] & \text{histogram}_H \end{tikzcd} \tag{7}$$

Here in (7) for each data Y from a bimodal model, we sphere Y to get the sphered version Z of Y, then obtain two different histograms in two different ways. Based on the data Z, one way is to run a projection pursuit algorithm with Friedman's index as the objective function to obtain a solution α_m^F, then take the histogram of the univariate data $\alpha_m^{F\tau} Z$ as an estimate of the density function of $\alpha_m^{F\tau} Z$. Another way is to run the same algorithm based on the same data Z with Hall's index as the objective function to reach a solution α_m^H, then graph the histogram of the data $\alpha_m^{H\tau} Z$ to estimate its density function. We interpret the projection pursuit index as performing well if the corresponding histograms are close to the density function of the original bimodal model, and/or its solution (α_m^F or α_m^H) is close to $\alpha^* = (1,0,0,0)$.

When μ in (6) is small, we may not be able to see a separation of two peaks from the raw data even if they are projected onto α^*. Therefore, we construct $Y_i = (Y_1^i, \ldots, Y_4^i)$'s independently as follows. Let W_1, W_2, W_3, W_4 be four i.i.d. $\mathcal{N}(0,1)$ pseudo r.v.'s which are independent of a uniform r.v. U on $(0,1)$. Define

$$Y_1^i = W_1 + \mu I_{\{U > \frac{1}{2}\}}, \quad Y_2^i = W_2, \quad Y_3^i = W_3, \quad Y_4^i = W_4.$$

For each set of $W_1, \ldots, W_4$, we consider an increasing sequence of μ's. Here $\mu = 0.4, 0.8, \ldots, 7.6, 8$.

Figure 1 presents the results of our first experiment where the histograms are of the sphered data projected on α_m^F and α_m^H in the sphered space for $\mu = 0.4, 0.8, \ldots, 8.0$. The only difference between these histograms and the histograms of the unsphered

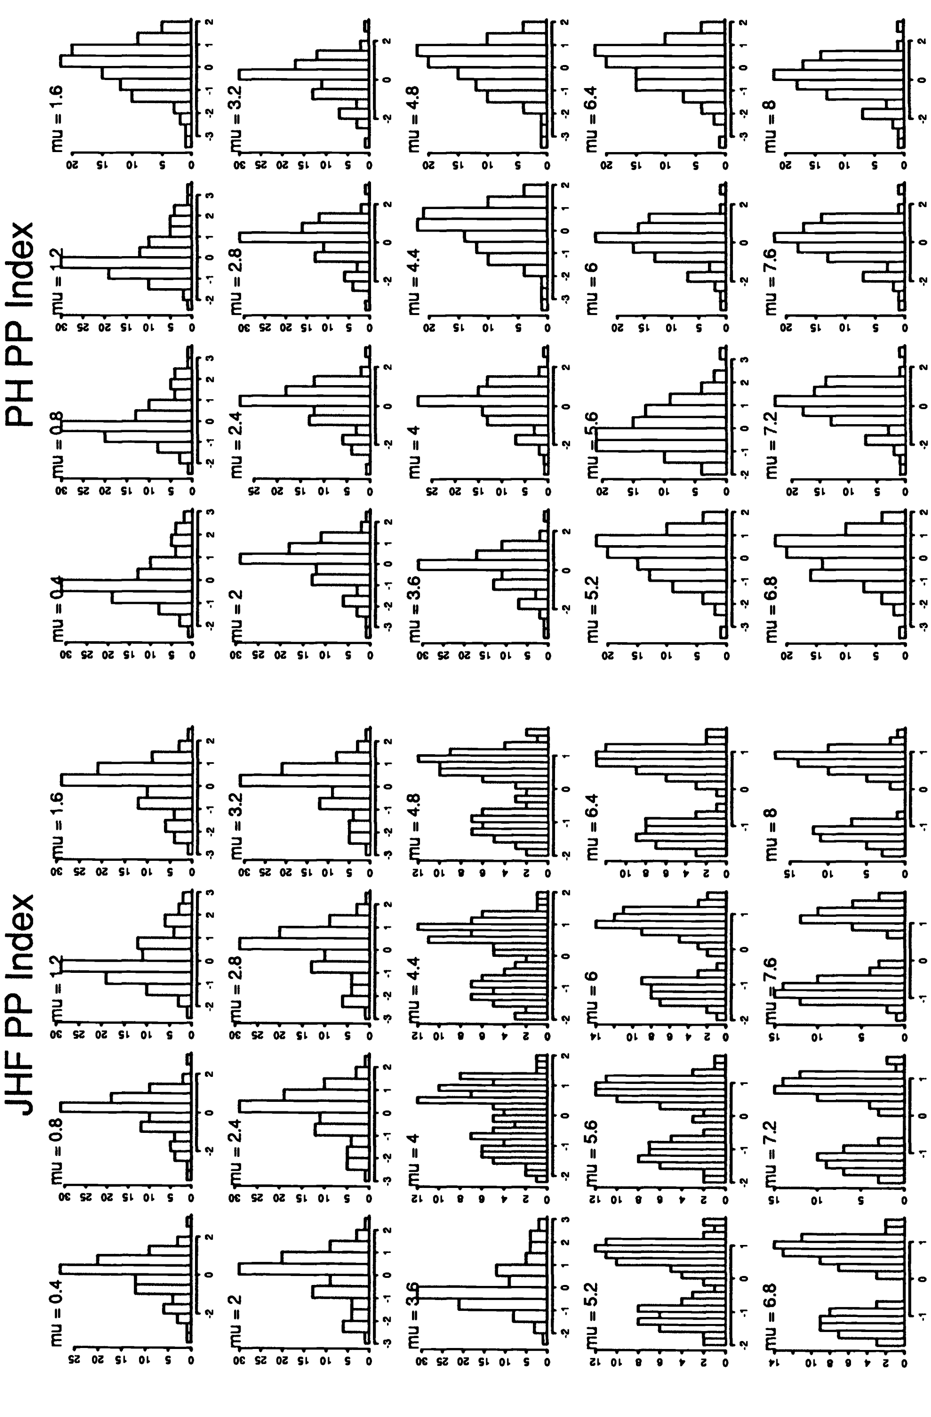

FIG. 1. *Histograms of the data projected on* α_m^F *and* α_m^H, I.

data projected to the projection pursuit solution in the original space is the scale. The separation is preserved in the sphered space. We see that with Friedman's index, the separation starts from $\mu = 4.4$, while with Hall's index no separation appears in any of these cases with μ chosen from $0.4, 0.8, \ldots, 8.0$. In fact, if we check the directions $\alpha_m^F(\mu)$ found by using Friedman's index, we notice that $\alpha_m^F(\mu)$'s *are* close to the line represented by the direction $\alpha^* = (1,0,0,0)$ for $\mu = 4.0, 4.4, \ldots, 8.0$, while for $\mu = 0.4, 0.8, \ldots, 8.0$, $\alpha_m^H(\mu)$ are *not*. Note that $(-1,0,0,0)$ and $(1,0,0,0)$ give the same straight line.

Figure 2 shows the second experiment, which is independent of the first one. We see separations starting from $\mu = 3.6$ up to 8.0 by applying Friedman's index, and separations at $\mu = 4.8$ and 6.0 up to 8.0 by using Hall's index.

Table 2 reveals that the lines represented by directions found by using Friedman's index are close to 1 when $\alpha^* = (1,0,0,0)$ for $\mu = 3.2$ up to 8.0. Those found by using Hall's index are close to $\alpha^* = (1,0,0,0)$ for $\mu = 4.8$ and 6.0 up to 8.0.

We have printed out 20 experiments, of which the first two are included in this paper. All of these 20 experiments show the same pattern as the first two. Friedman's four-term index is superior to Hall's four-term index for this bimodal model.

Explanations. By Cramér [2, p. 133 and pp. 221–224], the statistics formed from the third Hermite polynomial give the skewness of the data, and the statistics formed from the fourth Hermite polynomial give the kurtosis of the data. Recall the argument in Case 1 that if the data are sphered, with high probability, they are concentrated on a small neighborhood of zero. Therefore, in the four-term Hall's index, the zeroth, first, and second terms do not change much, as they have much smaller variances than those of the third and fourth terms. The third term is dominated by the skewness of

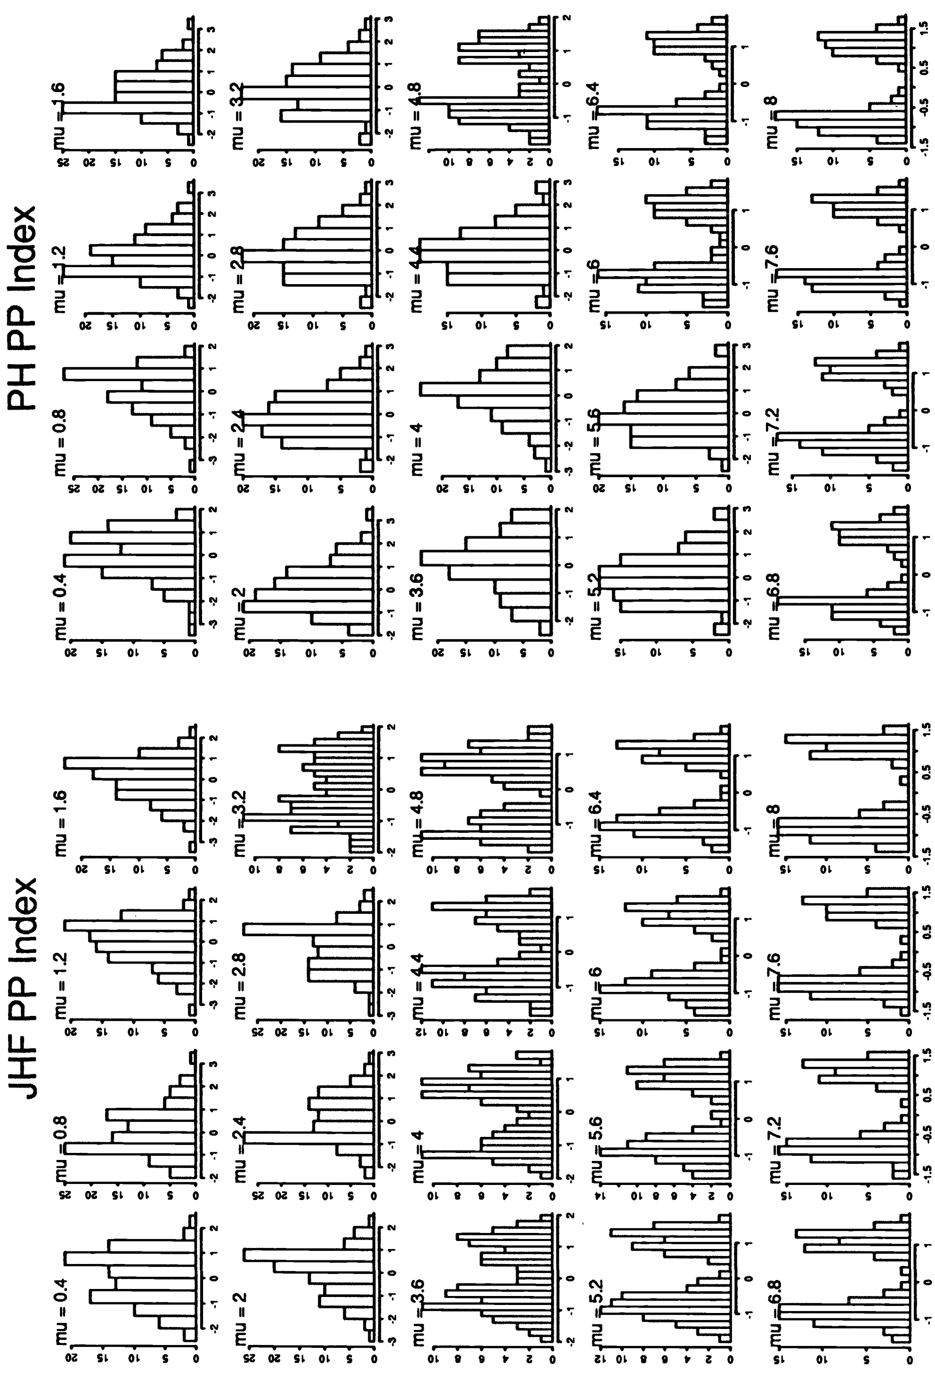

FIG. 2. *Histograms of the data projected on* α_m^F *and* α_m^H, II.

the data, and the fourth term by the kurtosis of the data. In our experiments, the four-term Hall's index places too much weight on the skewness of the data and picks up views with skewed density rather than bimodal density in many cases.

If more terms in Hall's index are used, one might get the same result as Friedman's index does for this model. In fact, we can make a connection between Hall's consistency result [6], and the number of terms that should be chosen in a projection pursuit index.

Denote by α^H the true maxima of the $\mathcal{L}_2$ distance between the densities p_α and ϕ and by α^F the true maxima of the $\mathcal{L}_2$ distance between the transformed densities $q_\alpha(\cdot)$ and $\frac{1}{2}$. Let α_m^H and α_m^F be the projection pursuit solutions of the indices $I_m^H(\alpha)$ and $I_m^F(\alpha)$. Under some regularity conditions for the density function of the data, the consistency result says that as $N, m \to \infty$,

$$\begin{aligned} \alpha_m^F - \alpha^F &= O_p(N^{-1/2}), \quad \text{if } m/N^{1/3} \to 0, \quad m/N^{1/4r} \to \infty, \\ \alpha_m^H - \alpha^H &= O_p(N^{-1/2}), \quad \text{if } m/N^{2/3} \to 0, \quad m/N^{1/2r} \to \infty, \end{aligned}$$

where $r \geq 1$. This result shows that the number of terms in Hall's index should be about the square of the appropriate number of terms in Friedman's index. In our experiments, sample size $N = 100$, $N^{\frac{1}{3}} = 4.64$, $N^{\frac{1}{4}} = 3.16$. According to the above consistency result, $m = 4$ in Friedman's index is reasonable, while $m = 16$ in Hall's index might give as good a result as the four-term Friedman index. In summary, a rule of thumb for choosing the number of terms in Hall's index is

(a) $3 \leq m \leq 36$ in most cases;
(b) the smaller N is, the smaller m should be;
(c) the bigger p is, the smaller m should be.

Computationally, the maximization of the higher-order polynomial objective function is much more expensive than the maximization of the lower-order polynomial objective function. If we include more terms in Hall's index to achieve the same accuracy of Friedman's index with fewer terms, some computational efficiency is lost.

Remark 1. It is easy to see that this loss of dimensionality due to sphering occurs for all polynomially based projection pursuit indices for any versions of sphering that satisfy (5). Hence the minimum number of terms for all such indices should be three.

3. How to select an algorithm. The primary goal of a projection pursuit algorithm is to find the direction which maximizes a projection pursuit index. Just like any other optimization algorithm, a projection pursuit algorithm is usually well suited to a particular type of problem, or a particular combination of projection pursuit index and data structure. By a naive (use of) algorithm, the computed value for the observed $\max I_J(\alpha)$ can be merely a local maximum of $I_J(\alpha)$, which is far away from the global maximum in some important cases. On the other hand, a projection pursuit procedure should find multiple views of a multivariate data set, i.e., it should enable one to keep running the algorithm based on some index until as many informative directions as possible are discovered (cf. Friedman [4]). Therefore, a good projection pursuit algorithm is one that can be used to find the first several largest local maxima in a reasonable time.

Friedman [4] gave a practical projection pursuit algorithm for his index. This algorithm has many computational advantages and uses an interesting idea called *structure removal*. Since the normal structure is the "least interesting" and is associated with directions that minimize the index, the idea of the structure removal is to transform the data along the "interesting" direction (found by the algorithm) into standard normal data while keeping the structure along the other orthogonal directions unchanged. The structure removal ensures that the interesting directions already found will not be found again later.

Friedman's projection pursuit algorithm can be described briefly as follows.

1. *Preliminary search*: search along p coordinates (or principle components in the sphered case); the one with largest projection pursuit index is called $\alpha^{(1)}$.
2. *Coarse search*: large stepping search along p orthogonal directions with origin at $\alpha^{(1)}$; the one with largest projection pursuit index is called $\alpha^{(2)}$.
3. *Local search*: starting from $\alpha^{(2)}$, search to a convergence point by using steepest ascent or quasi-Newton algorithm as the local optimizer. The direction with largest projection pursuit index after convergence of the algorithm is called $\alpha^{(3)}$.
4. *Structure removal*: transform the data along $\alpha^{(3)}$ into a standard normal data.
5. *Loop*: repeat above steps 2–4.

This algorithm is available from STATLIB.[2]

In the following, we shall discuss Friedman's algorithm and its modifications in three different situations: (a) the data set is highly structured; (b) the data set is pure noise; (c) neither (a) nor (b).

(a) *Data set is highly structured*. In this case, the objective function, i.e., the projection pursuit index based on the data, has a few big peaks surrounded by many small peaks. There is no doubt that Friedman's index performs well in this case.

Two questions arise naturally. First, How many structure removals should be performed? A small P-value associated with the current direction, or projection pursuit solution, signals the stop of structure removals. Then the problem becomes how to calculate the P-values, which is discussed in the next paragraph. Second, What happens if the data set is not highly structured? This is discussed in (c), later in this section.

(b) *Data set is pure noise*. This case occurs if (i) the data is just a result of Gaussian noise; (ii) the P-value of an observed projection pursuit solution is computed by using the Monte Carlo method. Specifically, the P-value is

$$P_o = P\left\{\max_{\alpha\in S^{p-1}} I_m(\alpha) \geq I^*_{\text{obs}}\right\} \tag{8}$$

under H_0' : Y_i 's are i.i.d. $\mathcal{N}(\mu, \Sigma)$ random samples with some p-dimensional vector μ, $p\times p$ nonsingular matrix Σ. Here $I_m(\alpha)$ is based on the sphered version Z_i's of Y_i's and $I^*_{\text{obs}} = I_m(\alpha^*) = \max_{\alpha\in S^{p-1}} I_m(\alpha)$ is the index evaluated at the observed projection pursuit solution. This P-value calculation gives a calibration for how large "large" is, or how much structure can be seen from a particular projection pursuit solution.

[2]This is a system for distributing statistical software and data. To obtain the program, contact `statlib@temper.stat.cmu.edu`, then request the algorithm: **send projpur from general**. Do not include a "subject."

When data is unstructured, the objective function $I_m(\alpha)$ has many bumps. Therefore, using Monte Carlo methods to estimate the P-value involves the repeated maximization for functions which have many local maxima with a similar size. Hence the corresponding optimization problem becomes very complicated and computationally intensive. Sun [8] has an easily applicable analytical formula for calculating P-values associated with Friedman's index. We recommend using this formula as a conservative measurement.

Day [3] showed apparent structures that can occur in projections of multivariate normal data. To ensure that apparent structures of the noise data are found, it is helpful to use the more thorough optimization procedure described in (c).

(c) *Neither of the above extreme cases*. In general, the data set may be neither pure noise nor highly structured. Hence, it is useful to improve computational speed, reliability, and accessibility of the projection pursuit algorithm so that the result is reliable for a much wider class of data structures.

Gill, Murray, Michael, and Wright [5] developed several refined versions of an optimization algorithm called NPSOL, which uses a sequential quadratic programming algorithm. It is considered one of the most efficient algorithms among the existing local optimizers. We have done many simulations to confirm its efficiency and reliability in the context of projection pursuit. NPSOL is now available as a subroutine called EO4UCF in NAG (mark 13). We suggest that the local optimizer in the third step of Friedman's algorithm be replaced by NPSOL (version 4.0 or the latest version).

If someone has the old IMSL (release 9.2), the subroutine called ZXMWD can be used as a substitute for steps 1–3 in Friedman's algorithm. With this substitution, the modified Friedman algorithm does slightly better than the original when no structure removal is used in the noise situation, because ZXMWD is a more exhaustive search procedure.

Friedman's idea of structure removal can be used as an enhancement to obtain the global maximum or directions close to it. The direction that maximizes the projection pursuit index among all the directions examined in the steps of the algorithm above can be regarded as the global maximum. Our experiment shows that p times structure removal is sufficient for a p-dimensional data set.

Since an optimization algorithm may not be rotation invariant, adding a *rotation* technique for the Monte Carlo simulation of P-value in projection pursuit is usually beneficial. The idea of the rotation is to run the same algorithm again for the rotated data set Y''s from the original data set Y's.

In summary, we suggest enhancing Friedman's algorithm in practice by the following steps.

3. *Local search*: replace the local optimizer by NPSOL.

5. *Loop* 1: repeat steps 2–4 p **times**.

6. *Loop* 2: **rotate** the original data and repeat steps 2–5. The resulting direction, which has the maximum index among all the above directions, is our first interesting direction.

7. *Next view*: if the associated P-value of the solution derived in step 6 is large, stop. Otherwise, remove the structure along the solution. Then repeat steps 1–6 to obtain the next interesting view.

Sun [7] has done many simulations. The theoretical P-value approximation to (8) (Sun [8]) is very good for the first view obtained from steps 1–6. In other words, we are confident that the algorithm suggested above works for a wide class of functions because it works even for the noise data case. The views collected from steps 6 and 7 are close to the most informative multiple views of a multivariate data set.

Remark 2. The idea of structure removal can be implemented in the maximization of an objective function that has known minima. Hence it has great potential, like simulated annealing in the field of optimization.

Remark 3. The projection pursuit procedure should be used only after some preliminary analysis and "structure removal" are done. For example, the sample mean and covariance matrix can serve as a good first set of summary statistics. Sphering the data removes the structure due to these first and second moments. If one or more of the variables are categorical, they show obvious structure and can be removed from the data set before implementing the projection pursuit procedure. See Friedman [4] for more discussion of these points.

Appendix. A theoretical justification. Notation here is the same as in previous sections. For example, $Y_1, \dots, Y_N$ are the data and $Z_1, \dots, Z_N$ are the sphered version of Y_i's defined in (3). In this appendix, we show that as $N \to \infty$ each $\tilde{Y}_j^s(\alpha)$ is distributed asymptotically according to a univariate normal population $\mathcal{N}(0, \sigma_j^2)$ for $j = 1, 2, \dots, J$, where σ_1^2, σ_2^2 are close to zero and $\sigma_3^2, \dots, \sigma_J^2$ are close to one. This gives a theoretical justification to the dimension reduction argument in Friedman's index. The idea is to apply Taylor expansions of $\tilde{Y}_j^s(\alpha)$ about $\alpha^\tau Z_i$'s at $\alpha^\tau \tilde{Z}_i$'s.

Without loss of generality, let $\Sigma = \sigma^2 I_p$ for a positive scalar σ^2 and a $p \times p$ identity matrix I_p. Denote $Y_i = (Y_{1i}, \dots, Y_{pi})^\tau$, $\bar{Y}_j = N^{-1}(Y_{j1} + \dots + Y_{jN})$, $\mu = (\mu_1, \dots, \mu_p)^\tau$, and $Z_i = (Z_{1i}, \dots, Z_{pi})^\tau$. Then

$$\tilde{Z}_i = (Y_i - \mu)/\sigma, \qquad \tilde{Z}_{1i} = (Y_{1i} - \mu_1)/\sigma. \tag{9}$$

Set $\hat{D}^{-1/2}\hat{U}^\tau = (\breve{\sigma}_{ij})_{p\times p}$. In Anderson [1], Theorem 3.4.4 and the paragraphs following it give

$$(\breve{\sigma}_{ij})_{p\times p} - I_p/\sigma = O_p\,(N^{-1/2}). \tag{10}$$

As usual, here and in the following, we mean "$O_p(\cdot)$ as $N \to \infty$" by $O_p(\cdot)$. Again, without loss of generality, let α be $(1, 0, \dots, 0)^\tau$ in $\tilde{Y}_j^s(\alpha)$'s. Then

$$\alpha^\tau Z_i = Z_{1i} = \sum_{j=1}^{p} \breve{\sigma}_{1j}(Y_{ji} - \bar{Y}_j) = (Y_{1i} - \bar{Y}_1)/\hat{\sigma}_{11} + R_i, \tag{11}$$

where $\hat{\sigma}_{11} = 1/\breve{\sigma}_{11}$, and $R_i = \sum_{j=2}^{p} \breve{\sigma}_{1j}(Y_{ji} - \bar{Y}_j)$. Equation (10) suggests that $\breve{\sigma}_{ij} = O_p(N^{-1/2}), \hat{\sigma}_{1j} = \sigma + O_p(N^{-1/2})$ for $i \neq 1$. Hence, as the distribution of $Y_{ji} - \bar{Y}_j$ is independent of i, it is easy to see that

$$R_i = O_p(N^{-1/2}) \quad \text{uniformly for } i = 1, \dots N, \tag{12}$$

and these Z_{1i}'s are close to $\tilde{Z}_{1i}$:

$$Z_{1i} - \tilde{Z}_{1i} = \frac{(Y_{1i} - \mu_1)(\sigma - \hat{\sigma}_{11})}{\sigma\hat{\sigma}_{11}} - \frac{(\bar{Y}_1 - \mu_1)}{\hat{\sigma}_{11}} + R_i = O_p(N^{-1/2}). \tag{13}$$

We now derive the asymptotic distribution of the first term $\tilde{Y}_1^s(\alpha)$. From (11)–(13), we have the Taylor expansion

$$\tag{14} \begin{aligned} \tilde{Y}_1^s(\alpha) = \tilde{Y}_j^u(\alpha) &+ \left(\frac{3}{N}\right)^{\frac{1}{2}} \sum_{i=1}^{N} \left\{ \frac{(Y_{1i}-\mu_1)(\sigma-\hat{\sigma}_{11})}{\sigma\hat{\sigma}_{11}} 2\phi\left(\frac{Y_{1i}-\mu_1}{\sigma}\right) \right\} \\ &- \left(\frac{3}{N}\right)^{\frac{1}{2}} \sum_{i=1}^{N} \left\{ \frac{(\bar{Y}_1-\mu_1)}{\hat{\sigma}_{11}} 2\phi\left(\frac{Y_{1i}-\mu_1}{\sigma}\right) \right\} + R + O_p\left(N^{-1/2}\right), \end{aligned}$$

where $R = (3/N)^{\frac{1}{2}} \sum [R_i 2\phi\{(Y_{1i}-\mu_1)/\sigma\}]$. From $E[(Y_{ji}-\mu_j)2\phi\{(Y_{1i}-\mu_1)/\sigma\}] = 0$ for all j and (12), we see

$$R = O_p\left(N^{-1/2}\right), \qquad N^{-1} \sum_{i=1}^{N} \left\{ (Y_{1i}-\mu_1) 2\phi\left(\frac{Y_{1i}-\mu_1}{\sigma}\right) \right\} = O_p\left(N^{-1/2}\right).$$

Hence, by $N^{\frac{1}{2}}(\sigma - \hat{\sigma}_{11}) = O_p(1)$, the second term in (14) is $O_p\left(N^{-1/2}\right)$. As

$$(2/N) \sum \phi\{(Y_{1i}-\mu_1)/\sigma\} = 1/\pi^{\frac{1}{2}} + O_p(N^{-1/2}),$$

the third term in (14) is

$$\left(\frac{3}{N}\right)^{\frac{1}{2}} \sum_{i=1}^{N} \left\{ \frac{(\bar{Y}_1-\mu_1)}{\sigma} 2\phi\left(\frac{Y_{1i}-\mu_1}{\sigma}\right) \right\} = R_{1s} + O_p\left(N^{-1/2}\right),$$

where $R_{1s} = (3/N)^{\frac{1}{2}} \sum (Y_{1i}-\mu_1)/(\sigma\pi^{\frac{1}{2}})$. Therefore,

$$\tilde{Y}_1^s(\alpha) = \tilde{Y}_1^u(\alpha) - R_{1s} + O_p\left(N^{-1/2}\right),$$

which can be easily distributed asymptotically as a $\mathcal{N}(0, \sigma_1^2)$ random variable with $\sigma_1^2 = 0.04507$.

Similarly, we can show that as $N \to \infty$ each $\tilde{Y}_j^s(\alpha)$ is distributed asymptotically as a $\mathcal{N}(0, \sigma_j^2)$ random variable for $j = 2, \ldots, J$, where σ_j^2 are as follows:

$j=2$	$j=3$	$j=4$	$j=5$	$j=6$	$j=7$	$j=8$
0.2421419	0.9665128	0.8642244	0.9933252	0.9536364	0.9977218	0.9788649

Acknowledgments. The author is grateful to David Siegmund, Iain Johnstone, Jerome Friedman, and Clive Loader for helpful discussions and suggestions. Thanks also go to the associate editor and the referees for nice comments, which made the current revision possible.

PARALLEL ALGORITHMS AND SUBCUBE EMBEDDING ON A HYPERCUBE*

ELEANOR CHU†‡ AND ALAN GEORGE†

Abstract. It is well known that the connection in a hypercube multiprocessor is rich enough to allow the embedding of a variety of topologies within it. For a given problem, the best choice of topology is naturally the one that incurs the least amount of communication and allows parallel execution of as many tasks as possible. In a previous paper we proposed efficient parallel algorithms for performing QR factorization on a hypercube multiprocessor, where the hypercube network is configured as a two-dimensional subcube-grid with an aspect ratio optimally chosen for each problem. In view of the very substantial *net* saving in execution time and storage usage obtained in performing QR factorization on an optimally configured subcube-grid, similar strategies are developed in this work to provide highly efficient implementations for three fundamental numerical algorithms: Gaussian elimination with partial pivoting, QR factorization with column pivoting, and multiple least squares updating. Timing results on Intel iPSC/2 and iPSC/860 hypercube multiprocessors are reported for all three algorithms.

1. Introduction.

This paper is a sequel to [3], where we propose medium-grain parallel algorithms for hypercubes with substantial startup cost and message-passing latency. This class of hypercube multiprocessors includes those commercially available from Intel and NCUBE. It is well known in practice and evident in the literature that fine-grain algorithms are designed for hypercubes with no startup cost and high communication bandwidth, and that their performance and analytical results do not carry over to medium-grain parallel algorithms.

In [3] we described medium-grain QR factorization algorithms that can dynamically adapt to topological reconfiguration and achieve substantial saving in time and storage. The topology we advocate is very closely related to the two-dimensional mesh and torus, but enjoys a number of distinct features important in designing efficient parallel algorithms. We obtain this topology by configuring the hypercube network as a two-dimensional *subcube-grid*. A subcube-grid is not a mesh-connected processor array. Although a $\gamma_1 \times \gamma_2$ subcube-grid has γ_1 processors in each column and γ_2 processors in each row, the neighboring processors in the grid may or may not be physically connected; instead, each row and each column of processors is required to form a hypercube of smaller dimension, which is a subcube.

We observed in [3] that different communication algorithms may be built on top of the basic subcube-doubling scheme by employing a variety of strategies in *updating* the message to be forwarded to the next neighbor. In particular, we show how *redundant updates* can maintain data proximity so that exactly the same synchronous communication steps may be followed by all processors throughout the computation for all possible choices of the dimensions γ_1 and γ_2. The communication scheme we proposed in [3] allows us to employ the optimal aspect ratio "γ_1/γ_2," which is

problem-dependent and is chosen at run time according to the particular dimensions of an input matrix. Since all $(p/2)$ disjoint pairs of processors exchange one message per communication step, the total number of messages is independent of the choice of the aspect ratio. The quantity that the optimal aspect ratio aims at reducing is the message length and hence the total communication volume.

The performance of the parallel QR factorization algorithm described in [3] varied widely, depending upon the choice of the aspect ratio. For some problems, the execution time for the worst aspect ratio was as much as six times greater than for the optimal aspect ratio.

In view of the very substantial *net* saving in execution time and storage usage obtained in our earlier work [3], a natural question to ask is whether the same topology can be adapted to parallelize other numerical algorithms efficiently. In this paper, we propose new subcube-grid algorithms for the efficient parallel implementation of the following numerical algorithms.

1. Gaussian elimination with partial pivoting. In §2, we show not only that its subcube-grid implementation enjoys the same saving as QR factorization, but also that partial pivoting can be incorporated without incurring extra message exchanges.

2. QR factorization with column pivoting. In §3, we show that column pivoting can be incorporated into our parallel algorithms in [3] without increasing the number of messages exchanged. We also show that the increase in computing cost is very small.

3. Multiple least squares updating. While the idea we use to develop the algorithms in [3] can be immediately applied to multiple least squares updating, it is equally important to have an efficient scheme to dynamically relocate the data of the computed Cholesky factor as the aspect ratio of the subcube grid changes. In §4, we show that with an appropriate mapping scheme, we can adapt the subcube doubling technique to obtain a *dynamic* data relocation algorithm for the Cholesky factor, and have thus obtained a feasible parallel algorithm for the continued process of multiple least squares updating.

Timing results for all three algorithms on Intel iPSC/2 and iPSC/860 hypercube multiprocessors are reported in §5, and they are compared with the performance of other known algorithms.

2. Gaussian elimination with partial pivoting. Due to its fundamental and practical role in solving linear systems of equations, Gaussian elimination is often the first numerical algorithm considered when experimenting on a new computer architecture. Since 1985, the year in which hypercube multiprocessors became commercially available, much work has been done on the efficient implementation of this algorithm and its variants on hypercubes [1], [2], [5], [7]–[11], [13]–[16], [22], [23]. The topologies employed include the embedded ring, spanning-tree, and two-dimensional mesh-connected processor array. The communication algorithms devised for these embedded topologies often employ pipelining techniques to reduce communication delay in message passing. The data-mapping strategies considered include column- and row-oriented block or wrap mapping as well as submatrix block mapping. In [22], the theoretical lower bound for communication complexity of the Gaussian elimination (with no pivoting) on a nearest-neighbor mesh network was established to be $O\left(n^2/\sqrt{p}\right) + O\left(n\sqrt{p}\right)$ for a lock-step (synchronous communication) Gaussian elimination algorithm, and $O\left(n^2/\sqrt{p}\right) + O\left(\sqrt{p}\right)$ for any pipelined Gaussian elimination algorithm, where p is the total number of processors. However, we should note that the lower bounds above are obtained assuming that there is *no* startup cost, and that a vector message is pipelined on an element-by-element basis in passing to consecutive processors. These assumptions are not sensible for an iPSC-type hypercube. Optimal concurrent algorithms for Gaussian elimination with and without pivoting are also proposed in [7]. However, since the algorithms proposed in [7] achieve optimality only on a large hypercube machine with little latency and high communication bandwidth, they are not suitable for currently available Intel or NCUBE machines.

While the row or column interchange step is recognized to be crucial in maintaining stable computation in practice, it often causes extra communication and unwelcome disturbance in an otherwise well-pipelined flow of messages. Thus the reduction of the latency caused by pivoting has been the subject of several studies. In [11], Geist and Romine compare the performance of several recently developed pivoting strategies that balance the work load while keeping the communication cost low. They implement all strategies in the C language and report their performance when factoring a matrix of dimension 1024 on an Intel iPSC/1 hypercube of 32 processors. The fastest algorithm is row-oriented, uses a synchronous spanning tree fan-in/fan-out communication algorithm, employs the dynamic pivoting strategy proposed in [11], and applies four pivot rows at a time using a loop unrolling technique. During each of the $(n-1)$ elimination steps, there are two $\log_2 p$ sweeps of the minimum spanning tree rooted at the manager node processor. The two sweeps fan-in/fan-out a short message consisting of the pivot element and the pivot row number. In addition, there is a third $\log_2 p$ sweep of a spanning tree rooted at the node processor that owns the pivot row to be broadcast. Additional communications between possibly nonadjacent nodes are necessary to explicitly permute the pivot row, although they show that the cost is quite modest when the wrap mapping of rows to the p processors need not be maintained. Another topology included in their experiment embeds a ring into the hypercube network, which allows the column-oriented algorithm to run efficiently when the communications can be pipelined. However, since pipelining interferes with loop unrolling, the asynchronous column-oriented algorithm loses to the synchronous row-oriented one on the iPSC/1 hypercube when loop unrolling is allowed.

In this work, we investigate the role of a subcube-grid topology for implementing Gaussian elimination with partial pivoting on hypercubes with substantial message-passing latency. *The algorithm we propose incurs exactly* $\log_2 p$ *synchronous message exchanges between neighboring processors during each elimination step, regardless of whether interchanges occur.* Since the total number of message exchanges is a constant independent of the aspect ratio of the subcube-grid, a square or close-to-square subcube-grid can be employed to reduce the message length and hence the communication volume. Furthermore, since the message length is reduced when the number of processors increases, the subcube-grid algorithms are expected to scale up well.

2.1. A new parallel implementation. We describe the algorithm for factoring a matrix of order n on a hypercube of dimension d. The hypercube is configured as a $\gamma_1 \times \gamma_2$ subcube-grid, where $\gamma_1 = 2^{d_1}$, $\gamma_2 = 2^{d_2}$, and $d_1 + d_2 = d$. The rows of the matrix are wrapped around the γ_1 subcube-rows. Within each subcube-row, the elements are wrapped around the γ_2 processors (that form the subcube) according to their column subscripts. Although our implementation is independent of the aspect values, the chosen d_1 and d_2 should be equal or differ by at most 1 to achieve the optimal performance. The following algorithm is executed by all $p = 2^d$ processors concurrently. The reader should keep in mind that the right-most d_1 bits of the processor *id* correspond to the row mapping, and the left-most d_2 bits correspond to the column mapping.

```
for $i \in [1, n-1]$
    if my share of the matrix contains column $i$ then
        update my message to be my share of column $i$
    else
        label my message content as dummy data
    end if
    $b \leftarrow d_2$ low-order bits of my $id$
    $\ell \leftarrow d_2$
    while $\ell > 0$ do
        send my message to processor with $id$ different
            from my $id$ in bit $b_{\ell-1}$
        receive a message
        if my message contains dummy data then
            update my message to contain the message received
        end if
        $\ell \leftarrow \ell - 1$
    end while
    Store the final content of my message as the pivot column
    Designate the row segment corresponding to the largest element
        in the pivot column as the local pivot row
    if my share of data contains elements from row $i$ and
        the local pivot row number $\neq i$ then
        permute the two segments
    end if
    Update my message to contain the pivot element,
        the local pivot row segment and its row number
    $b \leftarrow d_1$ high-order bits of my $id$
    $\ell \leftarrow d_1$
    while $\ell > 0$ do
        send my message to processor with $id$ different
            from my $id$ in bit $b_{\ell-1}$
        receive a message
        if the magnitude of the pivot element in the message received is
            larger than the magnitude of the pivot element in my message then
            update my message to be the message received
        else if the magnitude of the pivot element in the message received is
            smaller than the magnitude of the pivot element in my message then
            if the message received is marked as row $i$ then
                mark my message as row $i$
                if my message contains my share of data then
                    permute the received message into the local pivot row
                end if
            end if
        else {a tie occurs}
            if the row number in the received message is smaller
                than the row number in my message then
                update my message to be the message received.
            end if
        end if
        $\ell \leftarrow \ell - 1$
    end while
    Use the final content of my message as the pivot row
    if my share of the matrix contains row $i$ and
        the pivot row is different then
        permute my message content into my share of row $i$
    end if
    Use the pivot column and pivot row segments to update my share of data
end for
```

Assuming that $\gamma_1 = \gamma_2 = \sqrt{p}$, the message sizes in the ith reduction step are $\lceil (n-i)/\sqrt{p} \rceil$ for the pivot column and $\lceil n/\sqrt{p} \rceil$ for the pivot row. During each reduction step, the pivot column messages are exchanged between neighboring processors for $\frac{1}{2}\log_2 p$ times, as are the pivot row messages, resulting in a total of exactly $\log_2 p$ synchronous bidirectional exchanges per reduction step. Since the processor that needs to update a message content and the one that needs to perform a local permutation cannot be the same, the *redundant* permutations are *free* concurrent activities.

3. Parallel QR factorization with column pivoting. To incorporate column pivoting into the subcube-grid algorithm in [3], the communication scheme is the same as that proposed in §2 for Gaussian elimination with partial pivoting, apart from applying the redundant (free) permutations to select the pivot column segment instead of the pivot row segment. However, we must note that the criterion for choosing the local pivot column is now different and it uses the "column norm." To avoid communication in updating the column norms after each reduction step, we make use of the important property that the two-norms of vectors are *invariant* under orthogonal transformation. The modification to our original algorithm [3] is quite minor as described below.

First, we compute the initial n column norms and distribute them to the appropriate processors along with the data, i.e., the processor that is assigned data from the ith column will be sent the initial norm of the ith column. Therefore, all of the γ_1 processors in each subcube-column have the initial norms of the same $\lceil n/\gamma_2 \rceil$ columns. This amounts to distributing one extra row segment to each processor, and the cost is not significant if $(m/\gamma_1) \gg 1$, where m is the row dimension of the input matrix.

Second, we observe that since the norm is invariant under orthogonal transformation, the norm of the remaining $(n-i)$ elements in each column can be computed by simply subtracting the norm of the single ith row element from the current norm. This can be accomplished without communication because every processor receives the corresponding segment from the ith row after the last message exchange during the ith reduction step in the original algorithm [3]. Of course, in using this technique, one must avoid loss of accuracy through numerical cancellation. Although our test code does not do this, in a production version some mechanism would have to be incorporated to monitor for this problem, and recompute the column norms when trouble was detected. We do not believe this feature would materially change our timing results or our conclusions.

We can thus conclude that the communication complexity remains the same order as our results in [3], and that the extra computing cost incurred in updating the norms is evidently small.

4. Multiple least squares updating. The implementation of the *multiple* least squares updating algorithm on the hypercube was first studied by Kim, Agarwal, and

Plemmons in [18]. The proposed algorithms in [18] wrap mapped the Cholesky factor and the incoming rows to the p processors either following the processor *ids* or the processor order of an embedded linear array. Thus the communication cost in updating an $n \times n$ Cholesky factor by annihilating the input $m \times n$ matrix is $O\left(n^2 \log_2 p\right)$ in either case. We obtain the same result in [3] when employing the hypercube as a $p \times 1$ subcube-grid in reducing an $m \times n$ matrix to upper triangular form via orthogonal transformation. Although the communication cost is *independent* of the row dimension m of the input matrix and this configuration of the subgrid would be the optimal choice if $m \gg n$, it is not the desirable algorithm otherwise. Due to the usually stringent time constraint in engineering applications, it is rare for $m \gg n$ when the Cholesky factor must be updated by the newly available data. Thus it is very important that the parallel implementation be flexible and efficient for all cases. Since the algorithm we proposed in [3] was designed to work equally well for matrices of all possible dimensions, it is certainly a good candidate for multiple least squares updating on the hypercube. We show here that by using a different data-mapping strategy for the computed Cholesky factor, we obtain a parallel algorithm that not only always chooses the optimal aspect ratio for the embedded subcube-grid according to the row and column dimensions of the newly available data, but also allows *dynamic* relocation of the Cholesky factor if the aspect ratio changes. We also show that the new data-mapping strategy maintains the work load as balanced as before.

Let us express the multiple least squares updating problem by

$$\begin{pmatrix} R_{n\times n} \\ A_{m\times n} \end{pmatrix} \longrightarrow \begin{pmatrix} \tilde{R}_{n\times n} \\ 0 \end{pmatrix},$$

where $\tilde{R}$ results from modifying the upper triangular factor R by zeroing out all elements in the $m \times n$ matrix A via orthogonal transformations. We describe the new data-mapping strategy and the dynamic data relocation scheme in the following sections.

4.1. New data-mapping strategy. Instead of wrap mapping the rows and columns of $R_{n\times n}$ and $A_{m\times n}$ to the $\gamma_1 \times \gamma_2$ subcube-grid, we propose *block* mapping for the rows while maintaining wrap mapping for the columns. That is, each subcube-row of processors contains a block of $\lceil n/\gamma_1 \rceil$ consecutive rows from $R_{n\times n}$ and a block of $\lceil m/\gamma_1 \rceil$ rows from $A_{m\times n}$. With each subcube-row, the data from each block are wrap mapped to the γ_2 processors in the subcube according to their column subscripts, exactly as proposed in [3].

We want to emphasize here that the wrap mapping of rows was necessary to maintain balanced work load in reducing a full $m \times n$ matrix to its upper triangular form, but it is no longer necessary if the entire matrix A is zeroed out by updating an available triangular R. The reasons are two-fold:

1. In the latter case, all elements in the same column of $A_{m\times n}$ are modified the same number of times regardless of the row number.

2. The subcube-doubling communication algorithm as adapted in [3] has the unique feature that all processors always perform $\log_2 p$ synchronous exchanges of messages regardless of the location of the pivot row. Consequently, the fact that each processor owns consecutive pivot rows from R will not affect the work load distribution at all.

4.2. A dynamic parallel data relocation scheme. Since the row dimension of the data matrix A varies with the amount of data available at different times, the subcube-grid is to be dynamically configured to achieve the optimal aspect ratio and the new input matrix will be distributed to the processors accordingly.

When the aspect ratio differs from the one used in the previous update, it becomes necessary to *relocate* the previously distributed Cholesky factor R. The mapping strategy we proposed above allows us to relocate R to the new $\tilde{\gamma}_1 \times \tilde{\gamma}_2$ subcube-grid efficiently. The following observations are the keys to the design of the parallel algorithm.

1. $\tilde{\gamma}_1 = 2^{\tilde{d}_1}$ and $\tilde{\gamma}_2 = 2^{\tilde{d}_2}$, where $\tilde{d}_1 + \tilde{d}_2 = d$, and d is the dimension of the hypercube.

2. $\tilde{\gamma}_1 = \gamma_1 \times 2^i$ and $\tilde{\gamma}_2 = \gamma_2 \times 2^{-i}$, for $-d_1 \le i \le d_2$. By this observation, we simply need an algorithm for $i = 1$, because the same algorithm can be executed $i > 1$ times to get the resulting distribution. This observation contributes to the simplicity of the algorithm.

3. The sequential ordering of processors on the subcube-grid following the processor *id* row by row plays an important role in the parallel algorithm.

4.2.1. The parallel algorithm. Since the row dimension of the input matrix is initially known to the host, we require the host to compute the new aspect $\tilde{\gamma}_1$ and send it to all p node processors in the hypercube together with the data from the input matrix A. Therefore, there is *no* extra communication involved in broadcasting the value $\tilde{\gamma}_1$ to all processors in the subcube-grid, and $\tilde{\gamma}_2 = p/\tilde{\gamma}_1$ can then be computed by each processor. The parallel algorithm can be best explained by an example. We consider the case of changing a 4×4 subcube-grid to a 2×8 subcube-grid as shown below.

$$\begin{array}{llll} P_0 & P_1 & P_2 & P_3 \\ P_4 & P_5 & P_6 & P_7 \\ P_8 & P_9 & P_{10} & P_{11} \\ P_{12} & P_{13} & P_{14} & P_{15} \end{array} \longrightarrow \begin{array}{llllllll} P_0 & P_1 & P_2 & P_3 & P_4 & P_5 & P_6 & P_7 \\ P_8 & P_9 & P_{10} & P_{11} & P_{12} & P_{13} & P_{14} & P_{15} \end{array}$$

Since the columns of the factor R were wrap mapped to the processors in each subcube row, processors P_0, P_1, P_2, and P_3 can simultaneously send half of the data (corresponding to appropriate columns) to P_4, P_5, P_6, and P_7. Since a block of consecutive rows are stored in each processor, processors P_4, P_5, P_6, and P_7 will send one-half of their data (corresponding to appropriate columns) to processors P_0, P_1, P_2, and P_3 at the same time. The processors P_8, P_9, P_{10}, and P_{11} will understandably exchange the same amount of data with processors P_{12}, P_{13}, P_{14}, and P_{15} at the same time. Again, because of the subcube-grid connectivity, this amounts to "one" synchronous message exchange between a pair of directly connected processors. Each message consists of half of the data the processor previously has and thus data distribution remains balanced.

4.2.2. Communication complexity results. We can thus conclude that for $i = 1$, the communication cost is one near-neighbor exchange of one message of $(n^2/2p)$ floating-point numbers. Since $i \le d$, the communication volume for relocating R is $\left((n^2 \log_2 p)/2p\right)$ in the worst case.

5. Numerical experiments on an iPSC/2 and an iPSC/860.

In this section we report timing results on a 64-node Intel iPSC/2 hypercube and a 128-node iPSC/860 hypercube at Oak Ridge National Laboratory. The ratio of communication speed (measured by eight-byte one-hop transfer time λ) to computation speed (measured by eight-byte multiply time τ) is $\lambda/\tau \approx 59$ for the iPSC/2 and $\lambda/\tau \approx 1000$ for the iPSC/860 [6]. Our analysis in [3] suggests that the optimal aspect ratio of the subcube-grid is insensitive to such a hardware characteristic. Our conclusion is supported by the consistent performance of our various subcube-grid algorithms on iPSC/1 [3], iPSC/2, and iPSC/860. Our algorithms are implemented in double-precision Fortran 77. We have two implementations for the QR factorization algorithm. The basic version uses Givens rotation and an enhanced version uses a hybrid scheme [21] adapted for subcube-grid implementation in [3]. The QR factorization times represent the basic Givens version unless they are specifically indicated as being from the hybrid version. Our Fortran programs are compiled using the Green Hill Fortran compiler (v1.8.5). The compile time option is specified in each table.

5.1. Sequential times. In Table 1 we report the sequential execution times for both Gaussian elimination with partial pivoting, T_{GEPP}, and QR factorization with column pivoting, T_{QRCP}. Since our parallel code reduces to a sequential code with negligible overhead when running on a 1×1 subcube- grid, the sequential times are obtained from running the parallel code on a single node on the iPSC/2 or the iPSC/860 machine.

TABLE 1
Sequential times on an iPSC/2 *and an* iPSC/860.

Sequential times on an iPSC/2
(f77 compile time option: -OLM)

$m = n$	T_{GEPP} (sec)	T_{QRCP} (sec)
100	4.7	13.5
200	37.4	102.6
300	125.4	340.3
400	296.1	799.3
500	577.0	1552.9

Sequential times on an iPSC/860
(f77 compile time option: - OLM)

$m = n$	T_{GEPP} (sec)	T_{QRCP} (sec)
100	0.2	0.76
200	1.4	4.4
300	4.8	13.1
400	11.3	28.7
500	22.1	53.6

For larger matrices, the estimates for the sequential times were obtained from the data in Table 1 through a least squares fit of the polynomial representing the analytical expression for the execution time. Listed in Table 2 are the estimated times for matrices of dimensions 1000, 1024, 2000, and 2048. These values are useful in estimating the speedup and efficiency of the parallel algorithms.

5.2. Parallel times and performance comparison with other algorithms.

5.2.1. Gaussian elimination with partial pivoting. Efficient C programs for parallel Gaussian elimination with partial pivoting as proposed by Geist and Romine [11] were provided by the authors in the appendix of report [12]. Since the C programs in [12] were originally coded for an iPSC/1, the older first generation of hypercube, we have made necessary changes to call the iPSC/2 and iPSC/860 message-passing primitives. In addition, we have also converted the C code from the original single-precision mode to double-precision mode so that their performance can be compared with our algorithms, which are coded in double-precision Fortran.

TABLE 2
Least squares estimates on an iPSC/2 *and an* iPSC/860.

Least squares estimates on an iPSC/2		
$m = n$	T_{GEPP} (sec)	T_{QRCP} (sec)
1000	4,595	12,293
1024	4,933	13,196
2000	36,678	97,833
2048	39,381	105,034

Least squares estimates on an iPSC/860		
$m = n$	T_{GEPP} (sec)	T_{QRCP} (sec)
1000	176	388
1024	189	416
2000	1,406	2,944
2048	1,510	3,157

The test matrices we use for comparison are of dimensions 1024, 2048, and 4096 for $p = 32$, 64, and 128, because the code in [12] does not run if the matrix dimension n is not an integral multiple of p, the number of processors.

For the RSRP algorithm [11], [12], the effectiveness of the loop unrolling technique is measured by applying i pivot rows at a time (nmod=i, $i = 1, 2, 3, 4$). The pipelined CSRP algorithm was originally coded for applying two pivot columns at a time (nmod=2) [11], [12]. The timing results in Table 3 indicate that the technique of loop unrolling appears to be much less effective on an iPSC/860 than on an iPSC/2. Second, the results in Table 3 indicate that the pipelined CSRP algorithm performs significantly better than RSRP for both $p = 32$ and $p = 64$ processors on an iPSC/860, while CSRP performs better than RSRP on an iPSC/2 with 64 processors. Third, for a 1024 × 1024 matrix, there is little improvement to the iPSC/860 execution time by doubling the number of processors from 32 to 64 due to the dominating communication cost.

TABLE 3
Execution times of C code by Geist/Romine [12].

Gaussian elimination with partial pivoting						
Execution times of C code by Geist/Romine [12] (modified for iPSC/2 in double-precision) cc compile time option: –OLM						
n	p	RSRP				pipelined CSRP
		nmod = 1	nmod = 2	nmod = 3	nmod = 4	nmod = 2
1024	32	172.5 sec	139.4 sec	136.1 sec	133.8 sec	139.0 sec
	64	99.3 sec	84.2 sec	84.3 sec	84.9 sec	79.1 sec
Execution times of C code by Geist/Romine [12] (modified for iPSC/860 in double-precision) cc compile time option: –OLM						
n	p	RSRP				pipelined CSRP
		nmod=1	nmod=2	nmod=3	nmod=4	nmod=2
1024	32	17.7 sec	16.7 sec	17.8 sec	17.8 sec	10.3 sec
	64	16.5 sec	16.1 sec	16.7 sec	16.8 sec	7.7 sec

Table 4 compares the double-precision C implementation of the RSRP and the pipelined CSRP algorithms [11], [12] with our Fortran implementation of Gaussian elimination with partial pivoting. Our Fortran times were obtained when the optimal aspect ratio was used to configure the subcube-grid. Some RSRP times are missing from Table 4 because the factorization was not completed in a reasonable length of time. Our correspondence with the author indicates that the execution times were probably prolonged by calls to trap handlers such as underflow.

	128		164.2 sec	152.8 sec

5.2.2. QR factorization with column pivoting. In Table 5 we report the iPSC/2 and iPSC/860 times obtained from running our parallel QR factorization algorithm with and without pivoting on the optimal subcube-grid configuration.

The most current QR factorization with column pivoting times was reported by Coleman and Plassmann [4], [19], [20] and is quoted in Table 6. The algorithm proposed in [4] and [19] wrap maps the rows of an $m \times n$ matrix $(m \geq n)$ to a ring of processors embedded in a hypercube network. Comparing the performance of our subcube-grid (Givens) algorithm with that of the Householder algorithm implemented on a ring of p processors [19] in Table 6, we observe that the saving in communication time by employing an optimal subcube-grid enables the Givens algorithm to be competitive in the cases $m = n = 400$ $(p = 16, 32)$; $m = 400$, $n = 200$ $(p = 32)$; $m = 400$, $n = 100$ $(p = 32)$; and $m = 200$, $n = 100$ $(p = 16, 32)$. The actual differences in the execution times appear to be smaller when the compile time option –OLM is used. In the case of $m = n = 400$ and $p = 16$, the subcube-grid Givens algorithm is slightly faster than the Householder algorithm without the –OLM option (68.3 seconds versus 70.7 seconds), but the situation reverses when the –OLM option is used (58.2 seconds versus 53.6 seconds).

In general, we note that the differences between the f77 times and f77 –OLM times appear to be consistently more drastic in Plassmann's Householder algorithm: the reduction in times ranges from 28 percent to 31 percent in most cases. This is contrary to the 14 percent to 20 percent reduction in the subcube-grid Givens algorithm and the 10 percent to 15 percent reduction in the subcube-grid hybrid algorithm.

Since Plassmann's algorithm employs row-oriented Householder transformations, the timing results reported in [19] are also compared with a *hybrid* version of our

subcube-grid algorithm. The hybrid version combines Householder transformations and Givens rotations. It involves slightly more arithmetic operations than using Householder transformations alone, but it is particularly suitable for the subcube-grid implementation [3]. This idea of using both types of transformations in a somewhat different context was proposed by Pothen and Raghavan in [21]. The results in Table 6 indicate the significant saving from running the hybrid algorithm on the optimal subcube-grid. In addition, while Plassmann's times include the transformation of right-hand side [4], [19], [20], our times include extra arithmetic due to the scaling operations employed in our implementations to avoid overflow and underflow. Finally, none of the sequential or parallel implementations use LINPACK BLAS. The results in Table 6 again indicate the influence of compile time option –OLM. While compiling the code without the –OLM option, running the hybrid algorithm on the optimal subcube-grid gives the minimum execution times. With the –OLM option, we note that the QRFAC routine from MINPACK [17] gives the fastest sequential times after a reduction of 28–29 percent. Comparing the parallel Householder algorithm with the subcube-grid hybrid algorithm, the timing results are comparable for cases when $m \gg n$ and the optimal $\gamma_1 \times \gamma_2$ is given by $p \times 1$ or $(p/2) \times 2$. The saving in communication time by employing the optimal subcube-grid becomes evident in cases $m = n = 400$ ($p = 16, 32$), $m = 400$, $n = 200$ ($p = 32$), $m = 200$, $n = 100$ ($p = 16, 32$). More significant saving in execution times can thus be expected from the subcube-grid hybrid algorithm for cases $m < n$.

5.2.3. Multiple least squares updating. In Table 7 we report the times for updating an $n \times n$ Cholesky factor by an $m \times n$ matrix, and the worst possible relocation

cost. Our experiments show tremendous saving by relocating the Cholesky factor in all cases. As noted in Table 7, Givens rotations were employed in our algorithm to update the Cholesky factor. The updating time can therefore be further reduced by using the hybrid QR factorization scheme.

Acknowledgments. We thank Oak Ridge National Laboratory for the use of their iPSC/2 and iPSC/860 hypercube multiprocessors, and we would like to acknowledge programming assistance by the following students: Tom Abbott, Willis Constantineau, Phil Edmonds, and Darcy Quesnel.

STABILITY OF COMPUTATIONAL METHODS FOR CONSTRAINED DYNAMICS SYSTEMS*

URI M. ASCHER† AND LINDA R. PETZOLD‡

Abstract. Many methods have been proposed for numerically integrating the differential-algebraic systems arising from the Euler–Lagrange equations for constrained motion. These are based on various problem formulations and discretizations. We offer a critical evaluation of these methods from the standpoint of stability.

Considering a linear model, we first give conditions under which the differential-algebraic problem is well conditioned. This involves the concept of an essential underlying ODE. We review a variety of reformulations which have been proposed in the literature and show that most of them preserve the stability of the original problem. Then we consider stiff and nonstiff discretizations of such reformulated models. In some cases, the same implicit discretization may behave in a very different way when applied to different problem formulations, acting as a stiff integrator on some formulations and as a nonstiff integrator on others. We present the approach of projected invariants as a method for yielding problem reformulations which are desirable in this sense.

Key words. differential-algebraic equations, Euler–Lagrange equations, stability, multibody systems, numerical ODEs

AMS(MOS) subject classifications. 65L05, 70H35

1. Introduction.

Various techniques have been proposed in the literature for the numerical solution of the Euler–Lagrange equations, which govern the motion of mechanical systems with constraints [19]. Several of these techniques are used in commercial codes. The equations to be solved form a system of second-order ordinary differential equations (ODEs) for the (generalized) multibody coordinates. They also involve Lagrange multiplier functions and are subject to constraints, e.g., on configuration and/or motion. Mathematically, this may be considered as a system of differential-algebraic equations (DAEs) of index 3 in a special semi-explicit form [6]. It is well known that a direct discretization of such a DAE yields numerical difficulties; this is what gives rise to a multitude of other, more specific solution techniques.

Typically, such a solution technique consists of a step of problem reformulation, which involves reducing its index, followed by a discretization of the resulting formulation. In recent work [9], [10] it has been shown that for a certain model problem, some of these formulations can be equivalent. An important consideration in selecting an appropriate solution method (i.e., a combination of formulation and discretization) is the stability of the method and the subsequent stability restrictions that a chosen step size must satisfy. In this paper we investigate the stability of various solution techniques.

In order to be more specific, we write the Euler–Lagrange equations for a constrained multibody system

$$M(\mathbf{p})\mathbf{p}'' = \mathbf{f}(\mathbf{p},\mathbf{v}) - G^T(\mathbf{p})\lambda - \hat{G}^T(\mathbf{p})\hat{\lambda}, \tag{1.1a}$$

$$\text{(1.1b)} \qquad \mathbf{0} = \mathbf{g}(\mathbf{p}),$$
$$\text{(1.1c)} \qquad \mathbf{0} = \hat{G}(\mathbf{p})\mathbf{v} + \hat{\mathbf{g}}(\mathbf{p}).$$

Here the unknowns are: $\mathbf{p}$, the generalized coordinates; $\mathbf{v} \equiv (d\mathbf{p}/dt) \equiv \mathbf{p}'$, the generalized velocities; and λ and $\hat{\lambda}$, the Lagrange multiplier functions. In (1.1a) M is the mass matrix (we consider such formulations where $M(\mathbf{p})(t) \in \mathcal{R}^{n_p \times n_p}$ is symmetric positive definite), $\mathbf{f}$ stands for the applied forces, and $G(\mathbf{p})$ is the Jacobian matrix of the holonomic constraints

$$\text{(1.2)} \qquad G(\mathbf{p}) = \mathbf{g}_\mathbf{p}, \qquad G(\mathbf{p})(t) \in \mathcal{R}^{n_\lambda \times n_p}.$$

Similarly, $\hat{G} = \hat{\mathbf{g}}_\mathbf{p}, \hat{G}(\mathbf{p})(t) \in \mathcal{R}^{n_{\hat{\lambda}} \times n_p}$, and we assume that the matrix $\begin{pmatrix} G^T & \hat{G}^T \end{pmatrix}$ has a full column rank (i.e., the constraints are independent) for each t.

In (1.1b) there are n_λ configuration (position) constraints and in (1.1c) there are $n_{\hat{\lambda}}$ motion or other constraints. For simplicity of presentation we shall often assume that either $n_{\hat{\lambda}} = 0$ (hence $\hat{\lambda}$ disappears from (1.1a) as well), i.e., that there are only holonomic constraints, or that $n_\lambda = 0$ (whence λ disappears from (1.1a)).

Clearly, two differentiations of the constraints (1.1b) allow elimination of λ from (1.1a). Thus the original DAE has index 3. On the other hand, if $n_\lambda = 0$ and $n_{\hat{\lambda}} > 0$, then only one differentiation of (1.1c) is needed to eliminate $\hat{\lambda}$ and obtain an ODE, so the index is 2. Both of these cases can be cast in the form (2.1) below with $m = 2$ and $m = 1$ (for the equivalent first-order form of (1.1a)), respectively.

In order to give a methodical stability discussion we proceed in stages and consider the linearized form of the DAE (1.1). The class of nonlinear problems considered here behaves like its linear variational form away from singularities (i.e., in a neighborhood of an isolated solution). Thus our arguments will be valid in these general circumstances. We assume that the given linear DAE problem is well conditioned, and in §2 specify precisely what this means using a constructed *essential underlying ODE* (EUODE). The theory includes the linearizations of (1.1) as special cases.

In §3 we then consider a variety of problem reformulations and show that they also are well conditioned under certain reasonable assumptions. We cover the Baumgarte stabilization technique, a variety of "stabilized" and direct index reductions, and transformations to state-space form. This allows us to consider in §4 discretizations of the various formulations.

We consider stiff and nonstiff discretizations of such reformulated models. In some cases, the same backward differentiation formula (BDF) discretization (see, e.g., [6]), or other stiff discretizations, may behave in a very different way when applied to different reformulations of the same problem, acting as a stiff integrator on some formulations and as a nonstiff integrator on others. The need to restrict the step size in BDF for numerical stability occasionally arises even in formulations that explicitly enforce the constraints. For (1.1), assuming that there are only position constraints which vary on the scale of the solution, such a situation may arise if the mass matrix M has both large and moderate eigenvalues, in which case $M^{-1}G^T$ may be much less pleasant than G. (A corresponding physical situation is a heterogeneous multibody system, i.e., a system that includes bodies with very different masses.[1]) We present the approach of *projected invariants* with a particular choice of the projection as a method for yielding problem reformulations that are desirable in this sense. Section 5 concludes with a summary and recommendations based on our results.

[1]We thank Dr. Dan Rosenthal of RASNA Corporation for illuminating us on this point.

Throughout this paper, we use the following notation: Let $|\cdot|$ be the Euclidean vector norm. For a matrix A we denote the induced matrix norm by $\|A\|$. For a function $\mathbf{u}(t)$, $0 \le t \le t_f$, we denote the corresponding max function norm by $\|\mathbf{u}\| := \max\{|\mathbf{u}(t)|, 0 \le t \le t_f\}$.

2. Problem conditioning.

The DAE of order m,

$$\mathbf{x}^{(m)} = \mathbf{f}(\mathbf{z}(\mathbf{x}), \mathbf{y}, t), \tag{2.1a}$$

$$\mathbf{0} = \mathbf{g}(\mathbf{x}, t), \tag{2.1b}$$

where $\mathbf{z}_j(t) \equiv \mathbf{x}^{(j-1)}(t) := (d^{j-1}\mathbf{x}(t)/dt^{j-1})\,(1 \le j \le m)$ and

$$\mathbf{z}(\mathbf{x})(t) = (\mathbf{x}^T(t), (\mathbf{x}')^T(t), \ldots, (\mathbf{x}^{(m-1)})^T(t))^T, \tag{2.2}$$

has index $m+1$ if $\mathbf{g_x f_y}$ is nonsingular for all t, $0 \le t \le t_f$. The Euler–Lagrange equations for dynamical systems with holonomic constraints are in this form with $m = 2$, $\mathbf{x}$ the generalized coordinates, and $\mathbf{y}$ the Lagrange multipliers. Here we consider the linear (or linearized) form

$$\mathbf{x}^{(m)} = \sum_{j=1}^{m} A_j \mathbf{z}_j + B\mathbf{y} + \mathbf{q}, \tag{2.3a}$$

$$\mathbf{0} = C\mathbf{x} + \mathbf{r}, \tag{2.3b}$$

where A_j, B, and C are smooth functions of t, $0 \le t \le t_f$, $A_j(t) \in \mathcal{R}^{n_x \times n_x}$, $j = 1, \ldots, m$, $B(t) \in \mathcal{R}^{n_x \times n_y}$, $C(t) \in \mathcal{R}^{n_y \times n_x}$, $n_y \le n_x$, and CB is nonsingular for each t (hence the DAE has index $m+1$). All matrices involved, together with their derivatives, are assumed to be uniformly bounded in norm by a constant of moderate size. The inhomogeneities are $\mathbf{q}(t) \in \mathcal{R}^{n_x}$ and $\mathbf{r}(t) \in \mathcal{R}^{n_y}$.

We derive a stability result for this system. As in [1], there exists a smooth, bounded matrix function $R(t) \in \mathcal{R}^{(n_x - n_y) \times n_x}$ whose linearly independent, normalized rows form a basis for the nullspace of B^T (R can be taken to be orthonormal). Thus, for each t, $0 \le t \le t_f$,

$$RB = 0. \tag{2.4}$$

We assume that there exists a constant K_1 of moderate size such that

$$\|(CB)^{-1}\| \le K_1 \tag{2.5}$$

uniformly in t, and determine (see [1, Lemma 2.1]) that there is a constant K_2 of moderate size such that

$$\left\| \begin{pmatrix} R \\ C \end{pmatrix}^{-1} \right\| \le K_2. \tag{2.6}$$

The constant K_2, in addition to K_1, depends also on $\|B\|$, $\|C\|$, and $\|R\|$. Let K_3 be a moderate bound on B, C, R, and their derivatives:

$$\|B^{(j)}\|, \|C^{(j)}\|, \|R^{(j)}\| \le K_3, \qquad j = 0, 1, \ldots, m. \tag{2.7}$$

Define new variables

$$\mathbf{u} = R\mathbf{x}, \qquad 0 \le t \le t_f. \tag{2.8}$$

Then, using (2.3b), the inverse transformation is given by

$$\mathbf{x} = \begin{pmatrix} R \\ C \end{pmatrix}^{-1} \begin{pmatrix} \mathbf{u} \\ -\mathbf{r} \end{pmatrix} \equiv S\mathbf{u} - F\mathbf{r}, \tag{2.9}$$

where $S(t) \in \mathcal{R}^{n_x \times (n_x - n_y)}$ satisfies

$$RS = I, \qquad CS = 0, \tag{2.10}$$

and

$$F := B(CB)^{-1}. \tag{2.11}$$

By our assumptions and (2.6), this mapping is well conditioned. Both S and F are smooth and bounded. The first m derivatives of S and F are bounded by a constant involving K_2 and K_3. Taking m derivatives of (2.8) yields

$$\mathbf{u}^{(m)} = (R\mathbf{x})^{(m)} = \sum_{j=1}^{m} \left[RA_j + \begin{pmatrix} m \\ j-1 \end{pmatrix} R^{(m-j+1)} \right] \mathbf{z}_j + R\mathbf{q}. \tag{2.12}$$

Further, using $m-1$ derivatives of (2.9) we obtain the *essential underlying ODE*

$$\mathbf{u}^{(m)} = \sum_{j=1}^{m} \left[RA_j + \begin{pmatrix} m \\ j-1 \end{pmatrix} R^{(m-j+1)} \right] [(S\mathbf{u})^{(j-1)} - (F\mathbf{r})^{(j-1)}] + R\mathbf{q}. \tag{2.13}$$

For a unique solution of (2.3) one needs to impose $m(n_x - n_y)$ independent boundary conditions

$$B_0\mathbf{z}(0) + B_1\mathbf{z}(t_f) = \beta. \tag{2.14}$$

These could be, for instance, initial conditions which, together with (2.3b) and its first $m-1$ derivatives all sampled at $t = 0$, form mn_x initial conditions which specify $\mathbf{z}(0)$. The boundary conditions can be written as $m(n_x - n_y)$ conditions on $\mathbf{u}$ and its first $m-1$ derivatives needed to specify a unique solution for the EUODE (2.13). If this ODE problem is stable, i.e., if Green's function $\mathcal{G}(t, s)$ and its first $m-1$ derivatives in t are bounded in norm by a constant of moderate size, say K_4 (cf. [3, Chap. 3]), then a similar conclusion holds for the DAE. We obtain the following theorem.

THEOREM 2.1. *Let the* DAE (2.3) *have smooth, bounded coefficients, and assume that* (2.5) *holds and that the underlying problem for* (2.13) *is stable. Then there is a constant K of moderate size such that*

$$\|\mathbf{z}\| \leq K \left(\|\mathbf{q}\| + \sum_{j=0}^{m-1} \|\mathbf{r}^{(j)}\| + |\beta| \right), \tag{2.15a}$$

$$\|\mathbf{y}\| \leq K \left(\|\mathbf{q}\| + \sum_{j=0}^{m} \|\mathbf{r}^{(j)}\| + |\beta| \right). \tag{2.15b}$$

Proof. Our assumptions guarantee the well-conditioning of the transformation from $\mathbf{x}$ to $\mathbf{u}$ and back. The boundary data for $\mathbf{u}$ is therefore bounded by $\sum_{j=0}^{m-1} \|\mathbf{r}^{(j)}\|+$

$|\beta|$ times a moderate constant. We may write $\mathbf{u}(t)$ in terms of Green's function $\mathcal{G}(t,s)$, differentiate $m-1$ times, and take norms, obtaining

$$\|\mathbf{u}^{(l)}\| \le \tilde{K}\left(\|\mathbf{q}\| + \sum_{j=0}^{m-1}\|\mathbf{r}^{(j)}\| + |\beta|\right), \qquad 0 \le l \le m-1$$

with $\tilde{K}$ a moderate constant depending on K_2, K_3, and K_4. Conclusion (2.15a) is then obtained using (2.9).

Now, given $\mathbf{x}$ we obtain $\mathbf{y}$ through multiplying (2.3a) by C, yielding

$$\mathbf{y} = (CB)^{-1}C\left(\mathbf{x}^{(m)} - \sum_{j=1}^{m} A_j\mathbf{z}_j - \mathbf{q}\right). \tag{2.16}$$

Differentiating (2.3b) m times we substitute for $C\mathbf{x}^{(m)}$ in (2.16), and using (2.15a), obtain the bound (2.15b). □

Remark. The EUODE (2.13) is not unique. For any nonsingular, smooth, well-conditioned transformation $T(t) \in \mathcal{R}^{(n_x-n_y)\times(n_x-n_y)}$, the transformed $R(t)$ given by

$$R \leftarrow TR \tag{2.17}$$

still satisfies (2.4), (2.6), and (2.7). Hence R is unique only up to such a transformation and, correspondingly, so is the EUODE. However, a transformation of the variables $\mathbf{u}$ in (2.8) corresponding to (2.17) does not alter the existence (or lack thereof) of a bound of moderate size on the Green's function, and hence the stability properties are properly reflected in Theorem 2.1. For later theoretical purposes, we may wish to choose T such that the EUODE (2.13) is amenable to a direct discretization. In particular, for $m = 1$ and a BDF discretization we can choose T so that the resulting matrix $(RA_1 + R')S$ is essentially diagonally dominant or block upper triangular (see [14], [15], and [3]). □

We remark that a bound similar to (2.15) may also be obtained using Theorem 2.1 of [1] applied to the index-2 DAE

$$\mathbf{z}_j' = \mathbf{z}_{j+1} + B\mu_j, \qquad j = 1, \ldots, m-1, \tag{2.18a}$$

$$\mathbf{z}_m' = \sum_{j=1}^{m} A_j\mathbf{z}_j + B\mathbf{y} + \mathbf{q}, \tag{2.18b}$$

$$\mathbf{0} = C\mathbf{z}_1 + \mathbf{r}, \tag{2.18c}$$

$$\mathbf{0} = C\mathbf{z}_2 + C'\mathbf{z}_1 + \mathbf{r}', \tag{2.18d}$$

$$\vdots$$

$$\mathbf{0} = \sum_{j=1}^{m}\binom{m-1}{j-1} C^{(m-j)}\mathbf{z}_j + \mathbf{r}^{(m-1)} \tag{2.18e}$$

subject to the original boundary conditions (2.14). Here we have applied a particular so-called *stabilized index reduction* technique [11], adding multiplier functions $\mu_j(t) \in \mathcal{R}^{n_y}$ to compensate for insisting that the constraint (2.3b) and its first $m-1$ derivatives be all satisfied at all t. This DAE problem has the same exact solution as the original higher-index problem (2.3), (2.14) because differentiation and substitution for each of the algebraic constraints in (2.18) yields $CB\mu_j = 0$, which implies $\mu_j = 0$, $j = 1, \dots, m-1$. The EUODE for (2.18) is obtained using R of (2.4) m times, i.e., for the variables

$$\mathbf{w}_j := R\mathbf{z}_j = R\mathbf{x}^{(j-1)}, \qquad j = 1, \dots, m, \tag{2.19}$$

we obtain

$$\mathbf{w}'_j = R\mathbf{z}_{j+1} + R'\mathbf{z}_j, \qquad j = 1, \dots, m-1, \tag{2.20a}$$

$$\mathbf{w}'_m = \sum_{j=1}^{m} RA_j\mathbf{z}_j + R'\mathbf{z}_m + R\mathbf{q}, \tag{2.20b}$$

where $\mathbf{z}_j$ are expressed in terms of $\mathbf{w}$ using the recursive relation

$$\mathbf{z}_j = S\mathbf{w}_j - F\left[\mathbf{r}^{(j-1)} + \sum_{l=1}^{j-1} \begin{pmatrix} j-1 \\ l-1 \end{pmatrix} C^{(j-l)}\mathbf{z}_l\right], \qquad j = 1, \dots, m. \tag{2.21}$$

It is easily shown that the "stabilized" index-2 form (2.18) with (2.14) is stable whenever the original high-index equation (2.3) is.

3. Other transformations. The EUODE (2.13) uses a minimal number of constraint differentiations. Therefore, we view the assumption that it is stable with the given boundary operator as essential. From this we now derive stability for a number of other problem reformulations that have appeared in the literature.

3.1. Baumgarte stabilization. The most straightforward transformation of the DAE (2.3) into an ODE involves replacing the constraint

$$\mathbf{g}(\mathbf{x}, t) \equiv C\mathbf{x} + \mathbf{r} = \mathbf{0}$$

with its mth time derivative plus initial conditions:

$$\mathbf{g}^{(m)} = \frac{d^m\mathbf{g}(\mathbf{x}(t), t)}{dt^m} = \mathbf{0}, \tag{3.1a}$$

$$\mathbf{g}(\mathbf{x}(0), 0) = \frac{d}{dt}\mathbf{g}(\mathbf{x}(0), 0) = \cdots = \frac{d^{m-1}}{dt^{m-1}}\mathbf{g}(\mathbf{x}(0), 0) = \mathbf{0}. \tag{3.1b}$$

However, this causes well-known drift difficulties. A generalization of Baumgarte's method [4] replaces (3.1a) with the equation

$$\sum_{j=0}^{m} \alpha_j \frac{d^j}{dt^j}\mathbf{g}(\mathbf{x}(t), t) = \mathbf{0}, \tag{3.2}$$

where α_j are chosen so that $\alpha_m = 1$ and the roots of the polynomial

$$\sigma(\tau) = \sum_{j=0}^{m} \alpha_j \tau^j \tag{3.3}$$

are all nonpositive. For instance, one may choose $\sigma(\tau) = (\tau + \gamma)^m$ for some $\gamma \geq 0$. We now investigate the stability of (2.3a), (3.2), (2.14), and (3.1b).

In (3.2) we have an expression for $C\mathbf{x}^{(m)}$ that we may substitute into (2.3a) multiplied by C and eliminate $\mathbf{y}$:

$$\begin{aligned} \mathbf{y} = -(CB)^{-1}\Bigg\{ & \textstyle\sum_{j=1}^{m} \left[CA_j + \binom{m}{j-1} C^{(m-j+1)} \right] \mathbf{z}_j \\ & + C\mathbf{q} + \mathbf{r}^{(m)} + \textstyle\sum_{l=0}^{m-1} \alpha_l \mathbf{g}^{(l)} \Bigg\}. \end{aligned} \tag{3.4}$$

Substituting back into (2.3a) we obtain an ODE for $\mathbf{x}$

$$\begin{aligned} \mathbf{x}^{(m)} &= \sum_{j=1}^{m} \left[HA_j - \binom{m}{j-1} FC^{(m-j+1)} \right] \mathbf{z}_j \\ &\qquad + H\mathbf{q} - F\mathbf{r}^{(m)} - F \sum_{l=0}^{m-1} \alpha_l \mathbf{g}^{(l)}, \end{aligned} \tag{3.5a}$$

$$\mathbf{g}^{(l)} = \sum_{j=1}^{l+1} \binom{l}{j-1} C^{(l-j+1)} \mathbf{z}_j + \mathbf{r}^{(l)}, \tag{3.5b}$$

with F given by (2.11) and H the projection

$$H = I - FC = SR. \tag{3.6}$$

We then ask the question regarding the stability of the ODE problem (3.5), (2.14), (3.1b). Obviously, the differentiation in (3.2) has enlarged the size of the ODE problem, so the question really is whether the new solution modes thus introduced (together with (3.1b)) cause an instability.

To resolve this question, define

$$\mathbf{u} = R\mathbf{x}, \qquad \mathbf{v} = C\mathbf{x}. \tag{3.7}$$

Then

$$\mathbf{x} = S\mathbf{u} + F\mathbf{v} \tag{3.8}$$

(cf. (2.9)). So, by (2.6),

$$\|\mathbf{x}\| \le K_2(\|\mathbf{u}\| + \|\mathbf{v}\|).$$

To see what $\mathbf{u}$ and $\mathbf{v}$ satisfy, multiply (3.5a) by R and by C. This gives

$$\mathbf{u}^{(m)} = \sum_{j=1}^{m} \left[RA_j + \binom{m}{j-1} R^{(m-j+1)} \right] [(S\mathbf{u})^{(j-1)} + (F\mathbf{v})^{(j-1)}] + R\mathbf{q}, \tag{3.9a}$$

$$\mathbf{v}^{(m)} = -\sum_{j=0}^{m-1} \alpha_j \mathbf{v}^{(j)} - \sum_{j=0}^{m} \alpha_j \mathbf{r}^{(j)}, \tag{3.9b}$$

$$\mathbf{v}^{(j)}(0) = -\mathbf{r}^{(j)}(0), \qquad j = 0, \dots, m-1. \tag{3.9c}$$

Now, letting $t_f \to \infty$, we have in (3.9b), (3.9c) a uniformly stable initial value problem for $\mathbf{v}$ as long as at most one root of $\sigma(\tau)$ is 0 and the rest have negative real parts. For instance, with

$$\sigma(\tau) = (\tau + \gamma)^m, \tag{3.10}$$

any choice of $\gamma > 0$ yields a uniformly, *asymptotically* stable problem for $\mathbf{v}$, while the choice $\gamma = 0$, which corresponds to using (3.1a) in place of (3.2), allows for a mild instability, viz. a polynomial error growth (of degree $m-1$), to occur. Moreover, if the EUODE is asymptotically stable and $\gamma > 0$, then the ODE (3.5) is also asymptotically stable. In other words, the solution modes introduced by the Baumgarte technique are strictly decreasing if $\gamma > 0$.

Once $\mathbf{v}$ is integrated it may be substituted into (3.9a) to obtain the EUODE for $\mathbf{u}$. The problem for (3.9) is therefore stable, and by (3.8), so is the problem that the Baumgarte technique yields.

This analysis agrees with practical observations. First, the direct index reduction (3.1) has only a mild instability for a stable original problem. This instability gets worse as m increases, i.e., it is worse for the DAE with position constraints (1.1a), (1.1b) than for the DAE with motion constraints (1.1a), (1.1c). Second, any $\gamma > 0$ in (3.10) yields a stable problem in (3.5). The difference in performance for different values of $\gamma > 0$, when there is any, is due to discretization effects applied to stable ODE problems. This is taken up in §4, but we may already expect here that if K in (2.15) is indeed of moderate size and the discretization mesh is very fine, then the results will not be sensitive to the choice of γ. In practice, the choice of γ in sensitive situations is far from clear.

3.2. Reduction to index 2. In (3.1) and (3.2) we have differentiated $\mathbf{g}(\mathbf{x}, t)$ m times, reducing the index to 1. A subsequent elimination of $\mathbf{y}$ gives an ODE. If instead we differentiate the constraints only $m-1$ times, we obtain a DAE of index 2 consisting of (2.3a) and

$$\sum_{j=0}^{m-1} \hat{\alpha}_j \frac{d^j}{dt^j} \mathbf{g}(\mathbf{x}(t), t) = \mathbf{0}, \tag{3.11}$$

with $\hat{\alpha}_{m-1} = 1$. This is subject to (2.14) and

$$\mathbf{g}(\mathbf{x}(0), 0) = \cdots = \frac{d^{m-2}}{dt^{m-2}} \mathbf{g}(\mathbf{x}(0), 0) = \mathbf{0}. \tag{3.12}$$

The stability analysis for this problem formulation proceeds precisely as before: using the transformation (3.7), (3.8) we obtain (3.9a) and

$$\sum_{j=0}^{m-1} \hat{\alpha}_j \mathbf{v}^{(j)} = -\sum_{j=0}^{m-1} \hat{\alpha}_j \mathbf{r}^{(j)}, \tag{3.13a}$$

$$\mathbf{v}^{(j)}(0) = -\mathbf{r}^{(j)}(0), \qquad j = 0, \ldots, m-2. \tag{3.13b}$$

The ODE (3.13a) is asymptotically stable if the roots of $\hat{\sigma}(\tau) = \sum_{j=0}^{m-1} \hat{\alpha}_j \tau^j$ all have negative real parts. Considering in particular

$$\hat{\sigma}(\tau) = (\tau + \gamma)^{m-1}, \tag{3.14}$$

there is asymptotic stability if $\gamma > 0$ and a polynomial growth of order $m-2$ if $\gamma = 0$. The latter corresponds to direct index reduction. In particular, for mechanical systems with $m = 2$ one direct differentiation of the constraints ($\gamma = \hat{\alpha}_0 = 0$) yields a stable, although not asymptotically stable, problem (3.13) for $\mathbf{v}$.

The stability of the index-2 problem (2.3a), (3.11), (2.14), (3.12) follows, as before, from that of (3.13) and the analysis of §2.

The justification for considering this type of index reduction is that certain implicit discretization schemes like BDF may already be successfully applied to the resulting formulation (cf. [6], [16], and [1]). This is considered in §4.

Another problem reformulation that reduces the index to 2 is, of course, the stabilized index reduction technique of (2.18). In §3.5 below we consider an entire family of additional stabilized index reductions.

3.3. State-space form. The problem formulations considered hitherto in this section all end up in an ODE of size mn_x, requiring supplementary boundary conditions. In contrast, the EUODE (2.13) only has size $m(n_x - n_y)$, and no supplementary conditions are required for the problem reformulation. Moreover, incorporation of the constraint (2.3b) and its first $m-1$ derivatives into the transformation has insured no drift in a subsequent discretization.

This can be done more generally: Let $\tilde{R}(t)$ be a smooth, bounded function, $\tilde{R}(t) \in \mathcal{R}^{(n_x-n_y)\times n_x}$, such that

$$\left\| \begin{pmatrix} \tilde{R} \\ C \end{pmatrix}^{-1} \right\| \leq \tilde{K}, \quad \|\tilde{R}^{(j)}\| \leq \tilde{K}, \quad j = 0,1,\ldots,m \tag{3.15}$$

for a constant $\tilde{K}$ of moderate size. (We do not require $\tilde{R}B = 0$.) Define

$$\tilde{\mathbf{u}} = \tilde{R}\mathbf{x}, \qquad \mathbf{x} = \begin{pmatrix} \tilde{R} \\ C \end{pmatrix}^{-1} \begin{pmatrix} \tilde{\mathbf{u}} \\ -\mathbf{r} \end{pmatrix} \equiv \tilde{S}\tilde{\mathbf{u}} - \tilde{F}\mathbf{r}. \tag{3.16}$$

Taking $\alpha_0 = \cdots = \alpha_{m-1} = 0$ in (3.5a) (i.e., $\gamma = 0$ in (3.10)), we multiply it by $\tilde{R}$ to obtain

$$\tilde{\mathbf{u}}^{(m)} = \sum_{j=1}^{m} \left[\tilde{R}HA_j + \begin{pmatrix} m \\ j-1 \end{pmatrix} (\tilde{R}^{(m-j+1)} - \tilde{R}FC^{(m-j+1)}) \right] \mathbf{z}_j$$

$$+\tilde{R}H\mathbf{q} - \tilde{R}F\mathbf{r}^{(m)} \tag{3.17a}$$

$$\mathbf{z}_j = (\tilde{S}\tilde{\mathbf{u}})^{(j-1)} - (\tilde{F}\mathbf{r})^{(j-1)}, \qquad 1 \leq j \leq m. \tag{3.17b}$$

This state-space ODE is subject to the boundary conditions (2.14), suitably transformed. The EUODE is obtained as a special case with $\tilde{R} = R$.

The stability of the problem formulation (3.17) follows immediately upon relating $\tilde{\mathbf{u}}$ and $\mathbf{u}$ through $\mathbf{x}$, i.e., using (3.16), (2.8), (2.9), and their derivatives. The obtained stability bound depends on $\tilde{K}$ (and of course on K of (2.15)).

A favorite practical choice for $\tilde{R}$ is as a piecewise constant function [20], [18]. Thus, choosing $\tilde{R}$ at a certain reference time t_c so that (3.15) is satisfied, one proceeds to integrate in t, holding this $\tilde{R}$ constant so long as (3.15) holds with a reasonable $\tilde{K}$. When (3.15) is deemed violated, a new constant matrix $\tilde{R}$ is chosen based on a new reference point, giving a different ODE (3.17). The segments are connected in such switching points through continuity of $\mathbf{z}$. The lack of nonzero derivatives of $\tilde{R}$ over the integrated segment gives (3.17) an attractive form. A robust detection scheme for the necessity to change $\tilde{R}$ may prove to be the more difficult aspect of such a procedure, as discussed in §4.

3.4. Overdetermined DAE. Consider deriving the EUODE from the first-order form

$$\mathbf{z}'_j = \mathbf{z}_{j+1}, \qquad j = 1, \ldots, m-1, \tag{3.18a}$$

$$\mathbf{z}'_m = \sum_{j=1}^{m} A_j \mathbf{z}_j + B\mathbf{y} + \mathbf{q}. \tag{3.18b}$$

We proceed to define $\mathbf{w}_j = R\mathbf{z}_j$ and obtain the back-transformation using

$$\mathbf{0} = \sum_{l=1}^{j} \begin{pmatrix} j-1 \\ l-1 \end{pmatrix} C^{(j-l)} \mathbf{z}_l + \mathbf{r}^{(j-1)}, \qquad j = 1, \ldots, m. \tag{3.19}$$

The transformation matrix for each j is $\binom{R}{C}$. If we now write down the equations to be satisfied, (3.18), (3.19), they form an overdetermined DAE (ODAE). This overdetermination is subsequently resolved when multiplying (3.18a) and (3.18b) by R, obtaining the EUODE (2.20) in terms of

$$\mathbf{w} = (\mathbf{w}_1, \ldots, \mathbf{w}_m)^T. \tag{3.20}$$

The fact that (3.18), (3.19) is indeed an ODAE is reflected by the fact that we could replace (3.18a) by the "stabilized form"

$$\mathbf{z}'_j = \mathbf{z}_{j+1} + B\mu_j, \tag{3.21}$$

and obtain precisely the same EUODE, as in (2.18). Note that the DAE (3.21), (3.18b), (3.19) is not overdetermined any more, and that we have not used the fact that $\mu_j = \mathbf{0}$.

The ODAE (3.18), (3.19) subject to (2.14) has a unique solution, but when we replace it by a discretized form using one of the conventional difference schemes, we cannot expect an exact solution to exist. Still, one can multiply the discretized (3.18) by R, and (3.21) can replace (3.18a) provided that R and B are sampled at the same point t. The discretized DAE (3.21), (3.18b), (3.19) is therefore equivalent to a particular projection for solving the problem of minimizing the residual of the discretized ODAE subject to satisfying the discretized (3.19) (cf. [9] and [10]).

Similar arguments apply when replacing R by a more general smooth, bounded $\tilde{R}$ satisfying (3.15). Before applying $\tilde{R}$ we must differentiate the constraints once more and substitute (3.1) into (3.18b) to eliminate $\mathbf{y}$, obtaining

$$\mathbf{z}'_m = \sum_{j=1}^{m} \left[HA_j - \begin{pmatrix} m \\ j-1 \end{pmatrix} FC^{(m-j+1)} \right] \mathbf{z}_j + H\mathbf{q} - F\mathbf{r}^{(m)}. \tag{3.22}$$

A particular projected solution for the discretized ODAE (3.18a), (3.19), (3.22) with (3.19) treated as constraints is then obtained from the same discretization applied to (3.17) written in first-order form, and this in turn is equivalent to the discretized form of the DAE (3.22), (3.19) and

$$\mathbf{z}'_j = \mathbf{z}_{j+1} + \tilde{B}\mu_j, \qquad j = 1, \ldots, m-1, \tag{3.23}$$

with $\tilde{B}(t) \in \mathcal{R}^{n_x \times n_y}$ having full rank and satisfying

$$\tilde{R}\tilde{B} = 0. \tag{3.24}$$

For other possibilities, see [9], and [10]. Here we note that the stability treatment of the ODAEs we have described is covered by our previous stability analysis.

3.5. Projected invariants. Consider the following general procedure: Differentiating the constraints (2.3b) m times and eliminating $\mathbf{y}$ from (3.18b), we obtain (3.22), which, together with (3.18a), forms an explicit ODE system for $\mathbf{z}$. However, this allows for unacceptable drifts in the constraints after discretization, so we reimpose the first k constraints of (3.19), for some integer $k \leq m$,

$$\mathbf{0} = \sum_{l=1}^{j} \begin{pmatrix} j-1 \\ l-1 \end{pmatrix} C^{(j-l)}\mathbf{z}_l + \mathbf{r}^{(j-1)}, \qquad j = 1, \ldots, k. \tag{3.25}$$

The constraints (3.25) form an invariant of the ODE (3.18a), (3.22) (cf. Gear [12]). To satisfy these constraints even after discretization, we project the ODE as follows.

For k given smooth, full-rank bounded matrix functions $R_j(t) \in \mathcal{R}^{(n_x-n_y)\times n_x}$ satisfying (3.15) (for $\tilde{R} = R_j$), require that

$$\text{(3.26a)} \quad R_j\mathbf{z}_j' = R_j\mathbf{z}_{j+1}, \qquad j = 1, \ldots, \min(k, m-1),$$

$$\text{(3.26b)} \quad R_m\mathbf{z}_m' = R_m \left\{ \sum_{j=1}^{m} \left[HA_j - \begin{pmatrix} m \\ j-1 \end{pmatrix} FC^{(m-j+1)} \right] \mathbf{z}_j + H\mathbf{q} - F\mathbf{r}^{(m)} \right\} \quad (\text{if } k = m).$$

This is equivalent to writing

$$\text{(3.27a)} \quad \mathbf{z}_j' = \mathbf{z}_{j+1} + B_j\mu_j, \qquad j = 1, \ldots, m-1,$$

$$\text{(3.27b)} \quad \mathbf{z}_m' = \sum_{j=1}^{m} \left[HA_j - \begin{pmatrix} m \\ j-1 \end{pmatrix} FC^{(m-j+1)} \right] \mathbf{z}_j + H\mathbf{q} - F\mathbf{r}^{(m)} + B_m\mu_m,$$

where $B_j = 0$ if $j > k$, but for $1 \leq j \leq k$, $B_j(t) \in \mathcal{R}^{n_x\times(n_x-n_y)}$ have full rank and satisfy for each t

$$B_j = N_jC^T, \qquad R_jB_j = 0, \tag{3.28}$$

with N_j smooth well-conditioned matrices. The additional unknowns $\mu_j(t) \in \mathcal{R}^{n_y}$ are multipliers.

Using a discretization on a mesh, the discretized equations (3.26) or (3.27) are required to hold together with (3.25) at all mesh points.

Clearly, the obtained system (3.27), (3.25) is a DAE of index 2 in Hessenberg form, which, together with (2.14), is well conditioned if the original problem is. Also, the projected invariant approach can be viewed as an ODAE approach, although we feel that it gives more insight. The advantage here compared with the stabilized index reduction (2.18) is that there the stabilizer B is dictated by the problem while here we may choose B_j (i.e., R_j, as long as (3.15) is satisfied). This proves useful in cases where C^T behaves very differently from B, because here we may in fact choose $B_j = C^T$ (see Examples 3 and 4 in §4).

Summarizing the results of this section, we have seen that the stability of the original problem is preserved by problem reformulations such as stabilized index reduction, introduction of (properly chosen) Baumgarte parameters, and reduction to state-space form. Direct index reduction leads to a mild instability (i.e., the possible error growth is polynomial, not exponential)[2], which becomes progressively worse for higher-index problems. Finally, overdetermined DAEs can be regarded as a special case of one of the above forms, depending on the projection that is used in the numerical solution procedure. In the next section, we will consider the stability of discretization methods applied to these various formulations.

4. Discretization.

4.1. Backward Euler for an index-2 DAE.

To better understand the stability behavior of numerical methods applied to the above formulations, consider the Hessenberg index-2 system

$$\mathbf{x}' = A\mathbf{x} + B\mathbf{y} + \mathbf{q}, \tag{4.1a}$$

$$\mathbf{0} = C\mathbf{x} + \mathbf{r}, \tag{4.1b}$$

which is a special case of (2.3) for $m = 1$ and may arise from stabilized or direct reduction of a higher-index system to index 2. For simplicity of presentation, we will consider discretizing (4.1) by the backward Euler method, which gives

$$\mathbf{x}_n = \mathbf{x}_{n-1} + hA_n\mathbf{x}_n + hB_n\mathbf{y}_n + h\mathbf{q}_n, \tag{4.2a}$$

$$\mathbf{0} = C_n\mathbf{x}_n + \mathbf{r}_n. \tag{4.2b}$$

Note that, if we first derive an explicit ODE in $\mathbf{x}$ by differentiating (4.1b), use this to eliminate $\mathbf{y}$, and then discretize using backward Euler, we get

$$\mathbf{x}_n = (I - hHA + hFC')^{-1}[\mathbf{x}_{n-1} + hH\mathbf{q} - hF\mathbf{r}']$$

(all quantities are sampled at t_n, unless otherwise noted). So the amplification matrix is

$$(I - hHA + hFC')^{-1}. \tag{4.3}$$

But for (4.2) we obtain, upon multiplying (4.2a) by C and substituting (4.2b) to eliminate $\mathbf{y}_n$,

$$\mathbf{x}_n = H(\mathbf{x}_{n-1} + hA\mathbf{x}_n + h\mathbf{q}) - F\mathbf{r}.$$

Then, using

$$H_n\mathbf{x}_{n-1} = \mathbf{x}_{n-1} - F(C_{n-1} + hC'_{n-1} + O(h^2))\mathbf{x}_{n-1}$$

yields

$$\mathbf{x}_n = (I - hHA)^{-1}[(I - hFC' + O(h^2))\mathbf{x}_{n-1} + hH\mathbf{q} - F(\mathbf{r}_n - \mathbf{r}_{n-1})],$$

so the amplification matrix is approximately

$$(I - hHA)^{-1}(I - hFC'). \tag{4.4}$$

[2]We note that this result cannot be achieved by merely looking at local eigenvalues. For an example, see [10]. We also note that in some engineering applications, any significant drift from the original constraint manifold may be considered unacceptable; thus even the mild instability may pose a problem.

Taking $A = 0$ for simplicity, we see that, while in (4.3) we have the backward Euler matrix for the ODE

$$\mathbf{x}' = -FC'\mathbf{x}, \tag{4.5}$$

in (4.4) we have the forward Euler matrix for the same ODE. If (4.5) is stiff then the backward Euler scheme for (4.1) behaves like a nonstiff method!

The same phenomenon can also be seen as follows. Let $\mathbf{u}_n = R_n\mathbf{x}_n$, where $R_n = R(t_n)$ (cf. (2.4), (2.8)). Then $\mathbf{x}_n = S_n\mathbf{u}_n - F_n\mathbf{r}_n$. Multiplying (4.2a) by R_n and changing variables to $\mathbf{u}$, we find that

$$\mathbf{u}_n = \mathbf{u}_{n-1} + h((R'S)_{n-1} + O(h))\mathbf{u}_{n-1} + hRAS\mathbf{u}_n - h(R' + O(h))F\mathbf{r} + hR\mathbf{q}. \tag{4.6}$$

We note that (4.6) is a consistent discretization of the EUODE, but it is not the same as backward Euler applied directly to the EUODE because in (4.6), the term involving $R'S$ is discretized *explicitly*. Thus for problems where $R'S$ is large but the solution is smooth, we would expect that the step size for (4.2) must be restricted to maintain numerical stability.[3] A similar problem of numerical instability arises when the higher-index problem is discretized directly by such a method.

The analysis using $\mathbf{u}$ has the advantage that the amplification matrix has a smaller size (because there are fewer unknowns). But it depends on the choice of R as per (2.17), whereas (4.3)–(4.5) are independent of the choice of R. When considering (4.6) and $R'S$ one must avoid premature conclusions about suitability of the backward Euler scheme, although a positive stability conclusion (upon finding that $R'S$ is not large for a given problem) is immediate.

It is natural to ask under what conditions and for which formulations FC' (or $R'S$ for the best scaling) can become large. The question is more immediately answered for $FC' = B(CB)^{-1}C'$. If we assume that the solution $\mathbf{x}$ varies at a rate similar to that of C, so that the step size taken for accuracy reasons satisfies $h||C'|| << 1$, then FC' can be large only if $||B||$ or $||(CB)^{-1}||$ are large (and forming the product $B(CB)^{-1}$ does not cancel this effect). Assume also that $||C||, ||(CC^T)^{-1}|| = O(1)$. In such a case the projected invariant approach (3.27) with $k = m = 1$ and $B_1 = C^T$ is rather useful: the obtained index-2 DAE, which is subsequently discretized, is

$$\mathbf{x}' = (HA - FC')\mathbf{x} + H\mathbf{q} - F\mathbf{r}' + C^T\mu, \tag{4.7a}$$

$$\mathbf{0} = C\mathbf{x} + \mathbf{r}, \tag{4.7b}$$

so C^T plays the role that B plays in (4.1) and a BDF discretization is expected to behave like a stiff solver because $C^T(CC^T)^{-1}C'$ is not large in norm. This is demonstrated below, in Example 2. The price paid to obtain (4.7) does include an additional differentiation of the constraints.

We note further that for systems such as (4.7), where $B = C^T$, $R'S$ is of moderate size, *even if* $||(CC^T)^{-1}||$ *is large*. We show this for the case where C has a smooth singular value decomposition (SVD)

$$C^T = U\begin{pmatrix}\Sigma\\0\end{pmatrix}V^T$$

[3]This property of inherently explicit treatment of $R'S$ when the index-2 problem is discretized directly is shared also by higher-order BDF and by most implicit Runge–Kutta schemes. We note also that because of the strong relationship between semi-explicit index-2 problems and fully implicit index-1 problems [11], this problem of numerical instability can also be expected to occur for certain fully implicit index-1 DAEs.

(which is guaranteed if C is analytic [7]). We may choose $R = (\,0 \quad I\,)U^T$. Then (for each t)

$$(\,F \quad S\,) = \begin{pmatrix} C \\ R \end{pmatrix}^{-1} = U \begin{pmatrix} (V\Sigma)^{-1} & 0 \\ 0 & I \end{pmatrix},$$

so

$$S = U \begin{pmatrix} 0 \\ I \end{pmatrix}.$$

It follows that

$$R'S = (\,0 \quad I\,)U'^TU \begin{pmatrix} 0 \\ I \end{pmatrix}.$$

Hence for most reasonable C, the performance of numerical methods based on discretization of the projected invariants formulations should not degrade due to stability when approaching a rank-deficiency in C (i.e., no smaller step sizes are enforced due to stability).

4.2. Discretization and stiffness. A number of numerical methods currently implemented in CAD codes consist of more or less standard stiff or nonstiff discretizations applied to one of the formulations in §3. By a "nonstiff discretization" we mean a difference scheme (e.g., explicit Runge–Kutta) that works efficiently for a nonstiff initial value ODE, but becomes inefficient for a stiff ODE because absolute stability restrictions force a step size selection h that is much smaller than what accuracy requirements alone would dictate. A "stiff discretization," e.g., a BDF scheme, does not usually suffer from such absolute stability restrictions and is inherently an implicit difference scheme.

We now consider such methods:

1. Baumgarte stabilization, followed by (i) a nonstiff discretization or by (ii) a stiff discretization.

2. Safe reduction to index 2 (as in §§3.5 or 3.2 or in (2.18)), followed by a stiff discretization.

3. Reduction to state space form, followed by (i) a nonstiff discretization or by (ii) a stiff discretization.

Given that we consider essentially the same discretization schemes applied to problem reformulations that we have just proved equivalent under mild conditions, one might expect all of these methods to perform equally well. As it turns out, however, it is surprisingly easy to give examples (as we shall do below) where each of the three methods significantly outperforms the other two. Indeed, it is often not very clear in the literature what is meant by the term "stiffness" when it is applied to a higher-index DAE. To understand this, we distinguish among four cases for the EUODE (2.13) (or (2.20)).

1. The EUODE is nonstiff; B and C vary slowly.

2. The EUODE is nonstiff; B or C do not vary slowly.

3. The "frozen coefficients part" of the EUODE, viz. $\hat{\mathbf{u}}^{(m)} = \sum_{j=1}^{m} RA_jS\hat{\mathbf{u}}^{(j-1)}$ (or the homogeneous (2.20) with constant (frozen) coefficients) is stiff; B and C vary slowly. In this case, the stiffness is caused by the "ODE part" of the system.

4. The "variable coefficients part" of the EUODE, i.e., what remains after subtracting out the frozen coefficient part, is stiff. In this case, the stiffness is caused by time- or solution-dependent coupling of the constraints with the differential equations.

Case 1. Many mechanical systems yield ODEs that are not stiff. If no part of the mechanical system moves rapidly in time and the system is not heterogeneous, we may expect a nonstiff ODE to result in all problem formulations of §3. In this case, a Baumgarte stabilization (3.5) with, say, $\gamma = 1$ in (3.10), can be efficiently solved using a nonstiff discretization. For such examples, see [4]. Note that γ should not be taken large in this case, because this may introduce artificial stiffness (cf. (3.9b)).

While the Baumgarte technique yields a nonstiff ODE (so, for instance, an explicit difference scheme may be applied to (3.5)), the other two reformulations require satisfaction of constraints and therefore have an implicit part, even if the reduced ODE is discretized using an explicit scheme [18] (similarly [16]). In simple situations (where the mth constraint differentiation is not a bother either), such a Baumgarte technique is therefore more efficient.

Case 2. Generally, a robust discretization would have to use a step size commensurate with the variation of B and C. With such a step size, a Baumgarte technique or an index-2 reduction method should perform well, as above, except that the additional constraint differentiation or a poorly scaled choice of the parameter in the Baumgarte technique might increase errors.

With C varying significantly, however (e.g., corresponding to a rapidly rotating shaft), the robustness of a state-space form reduction using a constant $\tilde{R}$ may be called into question.

Example 1. For

$$C(t) = (\sin(\nu t), \cos(\nu t)), \qquad 0 \le t,$$

with $\nu \ge 1$ a parameter, an appropriate choice for $\tilde{R}$ satisfying (3.15) at $t_c = 0$ is

$$\tilde{R} = (1, 0), \qquad 0 \le t \le 1.$$

But then,

$$\begin{pmatrix} \tilde{R} \\ C \end{pmatrix}$$

is singular at $t = (j + 1/2)\pi/\nu$ for all j integers. It is clear that one must restart $\tilde{R}$ (i.e., switch coordinates) at steps $O(1/\nu)$ apart. While the discretization step for any of the other methods must be $O(1/\nu)$ as well, a simple discretization step involves much less effort than a restart.

What is potentially worse, detecting restart points is not easy in practice. (This is somewhat similar to using a Riccati method for stiff boundary value ODEs; see [8].) To see what happens when a singularity point is missed, we continue the example as follows:

$$\mathbf{x}' = -\mathbf{x} + By + \mathbf{q},$$

$$0 = C\mathbf{x} + r,$$

with $B = C^T$, $x_1(0) = 1$, and $\mathbf{q}$ and r are chosen to be

$$\mathbf{q} = \begin{pmatrix} 2e^t + \frac{\sin(\nu t)e^t}{(2-t)} \\ 2e^t + \frac{\cos(\nu t)e^t}{(2-t)} \end{pmatrix},$$

$$r = -(\sin(\nu t) + \cos(\nu t))e^t$$

such that the solution is $\mathbf{x}^T = e^t(1,1)$, $y = -e^t/(2-t)$. With

$$R(t) = (\cos(\nu t), -\sin(\nu t)),$$

we have $S^T = R$, $F^T = C$, and the homogeneous part of the EUODE is

$$u' = -u,$$

with $u(0)$ given. This problem is stable, with $K = O(\nu)$ in (2.15), independently of ν.

The state-space form with $\tilde{R} = (1,0)$ gives, on the other hand, an ODE whose homogeneous part is

$$\tilde{u}' = -(1 + \nu \tan(\nu t))\tilde{u}.$$

So, if one ignores or misses a singularity point, then one may end up integrating an unstable ODE.

In Table 4.1 we list some results obtained using a backward Euler discretization with step size $h = .01$ for $\nu = 1000$. The problem is solved over the interval $t \in [0,1]$. We denote by γ the Baumgarte parameter (i.e., we have replaced the constraint $g(\mathbf{x},t) = 0$ with $g' + \gamma g = 0$ except for the case $\gamma = \infty$, which corresponds to a direct discretization of the given problem). The discretization of (4.7) is referred to as projected invariant. The reported errors are the max-norm of errors in both components of $\mathbf{x}$, and the reported drift is the magnitude of the residual of the original constraint, at the endpoint of the time interval.

TABLE 4.1
Behavior of methods for example 1.

State-space form ($\tilde{R} = (1,0)$)	NA	.42e+1	0

This example shows the index-2 reduction method in a particularly favorable light: since $|g'| >> |g|$, a rather large γ is needed for the Baumgarte technique to work well. Insisting on satisfying (4.1b) or (4.7b) in the context of an index-2 Hessenberg DAE is advantageous. □

Case 3. We apply the same BDF scheme to discretize the three formulations. It is well known that BDF schemes usually perform well for stiff initial value ODEs. It is less well known that the theory justifying this performance is at present incomplete, and applies mainly to scalar equations. Consider a stiff initial value ODE

$$\mathbf{x}' = A(t)\mathbf{x} \tag{4.8}$$

and its backward Euler discretization

$$h_n^{-1}(\mathbf{x}_n - \mathbf{x}_{n-1}) = A_n \mathbf{x}_n, \tag{4.9}$$

where $0 = t_0 < t_1 < \cdots < t_N = 1$, $h_n = t_n - t_{n-1}$, $A_n := A(t_n)$. Given a nonsingular transformation $T(t)$, let

$$\mathbf{w} = T^{-1}\mathbf{x}. \tag{4.10}$$

Then $\mathbf{w}$ satisfies the ODE

$$\mathbf{w}' = (T^{-1}AT - T^{-1}T')\mathbf{w} \equiv U\mathbf{w}. \tag{4.11}$$

If U is upper triangular with off-diagonal elements that are not too large, or if U is essentially diagonally dominant (see [14], [15], or [3, Chap. 10]),then a backward Euler scheme applied to (4.11), i.e., the discretization is applied *after* the transformation, performs well as a stiff discretization scheme. (To see this we may consider the diagonal part of U first, obtaining stability results for a scalar equation for each of the equations in (4.11), and follow this by a contraction argument for the full U.) But if we apply the transformation (4.10) after the discretization (4.9), we obtain $(\mathbf{w}_n := T_n^{-1}\mathbf{x}_n)$,

$$h_n^{-1}(\mathbf{w}_n - \mathbf{w}_{n-1}) = T_n^{-1}A_nT_n\mathbf{w}_n - (T_{n-1}^{-1}T'_{n-1} + O(h_n))\mathbf{w}_{n-1}. \tag{4.12}$$

Therefore, the variable transformation term $T^{-1}T'\mathbf{w}$ is discretized explicitly at $n-1$ instead of at n. Usually the term $T^{-1}AT$ dominates, accounting for the practical success of the backward Euler and higher-order BDF schemes.

Our Case 3 corresponds to the domination of $T^{-1}AT$ in (4.11), (4.12): It is easy to see that the frozen coefficient part of the EUODE (2.20) is preserved in various transformations even after discretization (i.e., it is not significant whether the reformulation precedes discretization or vice versa). Therefore, a BDF discretization of any of the three formulations in this case results in a stiffly stable numerical method and performs well. The method of reduction to index 2 without the extra differentiation is most straightforward under these circumstances.

Case 4. In contrast to Case 3 above, the variable coefficient part of the various transformations, i.e., those terms involving derivatives of R, S, C, etc. in (2.13), (2.20), (3.5), and (3.17), does not generally get reproduced under discretization, as we saw in §4.1. The phenomenon is similar to that in (4.12), but it may be practically worse because unlike in the ODE case, R and S (and $\tilde{R}$) do not depend on A_j of (2.3) at all, so it is easy to envision situations where the variable coefficients part of the EUODE dominates. In such circumstances a backward Euler discretization may behave like a nonstiff discretization, causing a possible slowdown in an automatic integrator. Application of a state-space form method may be advantageous, then, if the restart difficulty is not present.

Example 2. Consider for $0 \le t \le 1$

$$\begin{aligned} x_1' &= (2-t)\nu y + q_1(t), \\ x_2' &= (\nu - 1)y + q_2(t), \\ 0 &= (t+2)x_1 + (t^2-4)x_2 + r(t), \end{aligned}$$

with $x_1(0) = 1$. Here $\nu \ge 1$ is a parameter. The inhomogeneities $\mathbf{q}$ and r are chosen to be

$$\begin{aligned} \mathbf{q} &= \begin{pmatrix} (1+\nu)e^t \\ (1+\frac{\nu-1}{2-t})e^t \end{pmatrix}, \\ r &= -(t^2+t-2)e^t, \end{aligned}$$

such that the exact solution is $x_1 = x_2 = e^t$, $y = -(e^t/(2-t))$.

This is essentially the same example as Example 1 in [1], but with $A_1 = 0$, so there is no frozen coefficient part in the EUODE. With

$$R(t) = \nu^{-1}(1-\nu, (2-t)\nu),$$

we have

$$\begin{pmatrix} R \\ C \end{pmatrix}^{-1} = (4-t^2)^{-1} \begin{pmatrix} (4-t^2)\nu & (2-t)\nu \\ (t+2)\nu & \nu - 1 \end{pmatrix},$$

so (2.5), (2.6), and (2.7) are satisfied with $K_1 = O(1)$, $K_2 = O(\nu)$, $K_3 = O(1)$. The EUODE for the homogeneous problem is

$$u' = R'Su = -\frac{\nu}{2-t}u$$

subject to an initial condition. Hence this is a stable problem with $K_4 = O(1)$, $K = O(\nu)$ in (2.15). Note also that $||F|| = O(\nu)$ and $||C'|| = O(1)$.

We certainly expect any of the numerical methods mentioned in this section to work well when the discretization step size $h = \max_n h_n$ satisfies $h\nu << 1$. It is more interesting to find out what happens, say, when $h\nu = 10$, which for $\nu = 1000$ yields a rather small step relative to the variation of the solution.

First consider a state-space reduction using $\tilde{R} = (1, 0)$. Thus $\tilde{S}^T = (1, 1/(2-t))$ and the homogeneous part of the ODE (3.17) is

$$\tilde{u}' = -\tilde{R}FC'\tilde{S}\tilde{u} = -\frac{\nu}{2-t}\tilde{u}.$$

If the inhomogeneous version of this ODE is discretized by a BDF scheme, or any other L-stable scheme, then not only is stability maintained for $h\nu$ large, but also accuracy *improves* as ν increases with h fixed, because there is only a fast, stable solution mode present and no slow ones. The transformation back from $\tilde{u}$ to $\mathbf{x}$ preserves this accuracy. Thus, the state-space reduction performs superbly here.

In contrast, the same BDF discretization applied to the other formulations has a significant nonstiff behavior. In Table 4.2 we display results using Baumgarte's technique with backward Euler and applying backward Euler directly to the original index-2 DAE. Tests are performed with $\nu = 1000$, $h = .01$.

A comparison between Tables 4.1 and 4.2 confirms that the practical control of the Baumgarte parameter may indeed be a nontrivial affair. Note also the excellent performance of the discretization of (4.7). □

Example 3. This example is a linear model in the form of a "mechanical system." We consider the initial value problem for the system

$$\begin{aligned} &(4.13a) & \mathbf{p}' &= \mathbf{v}, \\ &(4.13b) & M\mathbf{v}' &= \mathbf{f}(\mathbf{p},\mathbf{v},t) - G^T\lambda, \\ &(4.13c) & \mathbf{0} &= \mathbf{g}(\mathbf{p},t), \end{aligned}$$

with $\mathbf{g} = C(t)\mathbf{p} + r(t)$, $G = C$, and where $M(t)$ is symmetric positive definite. For $0 \le t \le 1$ we choose

$$\mathbf{f} = \begin{pmatrix} 0 & 0 \\ 0 & \frac{1}{(2+t)\nu} \end{pmatrix} \mathbf{v} + \mathbf{q}(t), \qquad C = (1, t-2),$$

$$M(t) = \frac{1}{(2+t)\nu^2} \begin{pmatrix} \frac{\nu^2+(\nu-1)^2}{2-t} & -\nu(2\nu-1) \\ -\nu(2\nu-1) & 2(2-t)\nu^2 \end{pmatrix},$$

resulting in

$$B = M^{-1}C^T = \begin{pmatrix} (4-t^2)\nu \\ (\nu-1)(t+2) \end{pmatrix}.$$

The inhomogeneous terms $\mathbf{q}(t)$ and $r(t)$ and the initial conditions have been chosen so that the solutions for both components of $\mathbf{p}$ and $\mathbf{v}$ are e^t, and $\lambda = e^t/(2-t)$. This example is closely related to Example 2, and in particular, it has the same term $R'S$ with $R'' = 0$. We will consider its solution in two different formulations. In the first formulation, the twice-differentiated constraint is used to eliminate λ, and then the original constraint is reintroduced via a new Lagrange multiplier μ, to obtain

$$\begin{aligned} &(4.14a) & \mathbf{p}' &= \mathbf{v} + D\mu, \\ &(4.14b) & \mathbf{v}' &= HM^{-1}\mathbf{f} - Fz, \\ &(4.14c) & \mathbf{0} &= \mathbf{g}(\mathbf{p},t), \end{aligned}$$

where $z = 2C'\mathbf{v} + C''\mathbf{p} + r''$. This is the projected invariant formulation (3.27) with $m = 2, k = 1$. We will consider various choices for the projection matrix $D(t)$, satisfying that CD is nonsingular for each t. The second formulation is the following stabilized index-2 system,

$$\begin{aligned} &(4.15a) & \mathbf{p}' &= \mathbf{v} + D\mu, \\ &(4.15b) & M\mathbf{v}' &= \mathbf{f} - G^T\lambda, \\ &(4.15c) & \mathbf{0} &= \mathbf{g}, \\ &(4.15d) & \mathbf{0} &= \mathbf{g}' \equiv G\mathbf{v} + \mathbf{g}_t \end{aligned}$$

(in our linear case $\mathbf{g}' = C\mathbf{v} + C'\mathbf{p} + r'$). The latter formulation was proposed in [13] for $D = G^T$ $(= C^T)$.

In Table 4.3 we present the results for the projected invariant formulation (4.14) with projections D given by B, C^T, "unit" $= (0,1)^T$, and for the direct index-two ("d-2") formulation (i.e., where the constraints in (4.13) have been simply differentiated once), for values of $\nu = 1, 100$ and 1000. In Table 4.4 we present the results for the stabilized index-2 formulation (4.15) under the same conditions. All test results are with the backward Euler scheme on the interval $[0, 1]$, with a uniform step size $h = .01$. The recorded errors are measured at $t = 1$ in the indicated variable (maximum over the two components). For the first nine rows of Table 4.3 (and Tables 4.5 and 4.7 as well), "Drift" indicates the drift in the velocity constraint (derivative of the original constraint) at the endpoint of the interval. For direct index-2 formulation, where the drift in velocity constraint is 0 but the drift in position constraint is not, the latter is indicated. Since the drifts for the stabilized formulation (4.15) are essentially zero (except when everything blows up), they are not recorded in Table 4.4.

Additional experiments were carried out for the problem (4.13) with $\mathbf{f} = \mathbf{0}$ and the same exact solution. The results are summarized in Tables 4.5 and 4.6, which are analogous to Tables 4.3 and 4.4, respectively.

We note that, as predicted, methods using the B-projection or involving B in a Hessenberg index-2 formulation (even when stabilized using other projections) can

experience a serious error growth when $h\nu$ is large, due to the large size of the $R'S$-term. Only the projected invariant formulations using the "good" projections C^T and "unit" yield acceptable results for both choices of $\mathbf{f}$ when $h\nu = 10$. The backward Euler scheme performs like a nonstiff integrator in these circumstances for the other methods. The good behavior of the projected invariant formulation for the projections C^T and "unit" follows directly from the discussion earlier in this section.

Let us calculate the EUODE for this example. Writing (4.13) with $\mathbf{f} = E(t)\mathbf{v}$ in the form (2.3), we have $m \leftarrow 2$, $\mathbf{x} \leftarrow \mathbf{p}$, $\mathbf{y} \leftarrow -\lambda$, $A_1 \leftarrow 0$, $A_2 \leftarrow M^{-1}E$. With R and S as in Example 2 we obtain

$$(RA_1 + R'')S\mathbf{u} = 0,$$

$$(RA_2 + 2R')(S\mathbf{u})' = \nu[RM^{-1}E + 2(0,-1)][Su' + S'u].$$

For E corresponding to Tables 4.3 and 4.4, $RM^{-1}E = (0,1)$, so by (2.13) the homogeneous EUODE is

$$u'' = -\frac{\nu}{2-t}u' - \frac{\nu}{(2-t)^2}u.$$

For $E = 0$ corresponding to Tables 4.5 and 4.6, the homogeneous EUODE is

$$u'' = -\frac{2\nu}{2-t}u' - \frac{2\nu}{(2-t)^2}u.$$

So the EUODE in both cases is stable for $\nu > 0$ and stiff for $\nu >> 1$.

If we now choose

$$E = \begin{pmatrix} 0 & 0 \\ 0 & \frac{2}{(2+t)\nu} \end{pmatrix},$$

then $RA_2 = -2R'$, so the EUODE is nonstiff. In Tables 4.7 and 4.8 we record results analogous to Tables 4.3 and 4.4 for this case where the EUODE is nonstiff.

TABLE 4.7
Example 3 with a nonstiff EUODE, projected invariant formulation.

unit	100	.13e+4	.14	.13e+6
unit	1000	.28e−2	.26e−1	.27

We note with no surprise that the problem does not get easier when the large terms in the EUODE cancel one another. The results in Table 4.7 for the projections with C^T and "unit" are independent of ν: this is because (4.14b) is independent of ν in this special case. □

Example 4 [2]. This example is also in the "mechanical system form" (4.13). This time we choose $M = I$ but let the constraint matrix vary possibly rapidly, as in Example 1. We set

$$\mathbf{g} = C(t)\mathbf{p} + r(t), \quad G = C = (\sin(\nu t), \cos(\nu t)) = B^T, \quad \mathbf{f} = -\nu^2\mathbf{v} + \mathbf{q}(t)$$

and choose initial conditions and inhomogeneities such that the solution is the same as in Example 3. The stability of this problem is discussed in [2].

Here we test the performance of two projected invariant formulations, in addition to the previous reformulations (4.14) and (4.15) (with $D = G^T$). In both of these additional formulations we require satisfaction not only of the "position constraints" (4.15c), but also of their derivative (4.15d) ("velocity constraints"). The first of these additional formulations is as in §3.5 with $k = m = 2$ and $B_1 = B_2 = C^T$. This gives the system

$$\mathbf{p}' = \mathbf{v} + G^T\mu, \tag{4.16a}$$
$$\mathbf{v}' = HM^{-1}\mathbf{f} - Fz + G^T\tau, \tag{4.16b}$$
$$\mathbf{0} = \mathbf{g}(\mathbf{p}, t), \tag{4.16c}$$
$$\mathbf{0} = \mathbf{g}' \equiv G\mathbf{v} + \mathbf{g}_t. \tag{4.16d}$$

The method (4.16) should certainly perform well for Example 3, but here the matrix function $L \equiv (\partial\mathbf{g}'/\partial\mathbf{p})$ $(= C')$ may contain large elements when ν is large. The second variant balances this out by adding another stabilizing term to (4.16a), replacing it by

$$\mathbf{p}' = \mathbf{v} + G^T\mu + L^T\tau. \tag{4.17}$$

In Table 4.9 we compare numerical results for various values of ν and h using a backward Euler discretization of (i) the previous, simpler projected invariant formulation (4.14) with $D = G^T$ (denoted "Pa"); (ii) the projected invariant method (4.16) (denoted "Pb"); (iii) the projected invariant method (4.17), (4.16b), (4.16c), (4.16d) (denoted "Pc"); and (iv) the stabilized index reduction method (4.15) with $D = G^T$ [13] (denoted "S").

Note that the various variants perform qualitatively similarly when $h\nu$ is small. But when $h\nu = 10$, there are large errors in $\mathbf{v}$ for the formulations Pb and S (these two are almost identical for this problem). The projected invariant formulations Pa and Pc, which do balance the constraint matrix and the multiplier matrix in the index-2 formulation, perform significantly better for $h\nu$ large. The scheme Pc is more complicated than Pa, though, so computing and using L in (4.17) may not be desirable for reasons other than stiff stability. $\square$

A number of methods have been proposed in the literature (see [9] and references therein, [1], [12], [16], and [17]), where at each step in t, an integration step for the ODE (3.18a), (3.22) or another form of the DAE is followed by a projection using a weighted least squares norm to satisfy the constraints (3.25) at the end of the step. Thus, using, e.g., backward Euler for the unstabilized (4.14a) (i.e., with $D = 0$) and (4.14b), we have at the nth step

$$h^{-1}(\tilde{\mathbf{p}}_n - \mathbf{p}_{n-1}) = \mathbf{v}_n, \tag{4.18a}$$
$$h^{-1}(\mathbf{v}_n - \mathbf{v}_{n-1}) = H_nM_n^{-1}\mathbf{f}_n - F_n\mathbf{z}_n, \tag{4.18b}$$

and then we find $\mathbf{p}_n$, which satisfies

$$\mathbf{g}(\mathbf{p}_n, t_n) = \mathbf{0} \tag{4.19}$$

and minimizes

$$(\mathbf{p}_n - \tilde{\mathbf{p}}_n)^T W_n(\mathbf{p}_n - \tilde{\mathbf{p}}_n), \tag{4.20}$$

TABLE 4.9

where W_n is a symmetric positive definite matrix. This idea can clearly be written in the generality of §3.5 and gives another variant for resolving overdetermination.

The necessary conditions for the constrained minimization (4.19), (4.20) are

$$W_n(\mathbf{p}_n - \tilde{\mathbf{p}}_n) = C_n^T \mu_n, \tag{4.21}$$

where μ_n is a Lagrange multiplier. Therefore,

$$\mathbf{p}_n = \tilde{\mathbf{p}}_n + W_n^{-1} C_n^T \mu_n = \mathbf{p}_{n-1} + h\mathbf{v}_n + W_n^{-1} C_n^T \mu_n. \tag{4.22}$$

However, an unfortunate choice of W_n may again produce a nonstiff behavior out of a BDF scheme, because (4.22) is in essence a backward Euler discretization of (4.14a) with $D = W^{-1}C^T$. For Example 3, in particular, the choice $W = M$ is not advisable.

For some schemes, though, the choice of W is not sufficiently arbitrary. For instance, in [1] the integration step is an implicit Runge–Kutta (or collocation) step applied directly to an index-2 DAE (4.1). This necessitates in the following projection the choice of W so that $W^{-1}C^T = B$. Therefore, that method applied to Example 2 also behaves like a nonstiff integrator. A way to remedy this is to transform (4.1) into (4.7) before applying the projected Runge–Kutta method. For Example 2, this works very well.

In the context of mechanical systems, we note that the projected invariant scheme (4.14) satisfies precisely only the position constraints, not their derivative relation $\mathbf{g}' = \mathbf{0}$ (which gives velocity constraints). Should the latter be deemed important to satisfy precisely as well, it can be achieved with the formulation (4.14) as described above, i.e., by projecting $\mathbf{v}_n$ at the end of each step to satisfy (4.15d), minimizing the required change in $\mathbf{v}_n$ (in the least squares norm) and keeping $\mathbf{p}_n$ unchanged (cf. [2]).

5. Conclusions. We have considered various problem formulations and their discretizations for higher-order, higher-index DAEs such as those that arise in the numerical integration of Lagrange's equations of the first kind for multibody dynamics. A linearized form of the equations was considered, allowing a methodical examination of a number of methods that are in use in practice with respect to stability. While the numerical examples we use do not derive directly from particular mechanical systems, they are simple to follow thoroughly and at the same time they highlight effects that we believe occur in some actual mechanical systems. This yields a number of tentative conclusions, based on the methods considered.

1. All reasonable problem reformulations used in practice are stable under certain mild assumptions. The exception is a direct index reduction, which has an algebraic instability of degree $m-1$. Thus, for holonomic constraints, two direct constraint differentiations yield a linear instability. Applying only one direct differentiation is still stable, though not asymptotically stable. (Note, however, that asymptotic stability of $\mathbf{v}$ in (3.9b) does not yield a similar statement for $\mathbf{u}$ in (3.9a).)

2. Applying the same discretization to two stable problem formulations does not necessarily yield similar method characteristics.

3. For simple, slowly varying nonstiff problems, a number of good alternatives exist. One is a Baumgarte stabilization coupled with an explicit discretization. Another is the half-explicit methods; see, e.g., [17] and [5].

4. For problems with a stiff frozen coefficient part, a BDF (or other stiff) discretization applied to a stable index-2 reduction is recommended.

5. For heterogeneous problems, where the mass matrix has widely varying eigenvalues (or when C is much better behaved than B in (2.3)), and for problems with rapidly varying constraints, the projected invariants stabilization (4.14) (with the projection based on C^T) coupled with a BDF discretization or other suitable stiff method is recommended. If it is important that the velocity constraints be satisfied precisely, then we recommend either the projected invariants method Pa (4.14) followed by a projection onto the velocity constraints as described at the end of §4, or else the projected invariants method Pc (4.17), (4.16b), (4.16c), (4.16d).

REDUCING THE SYMMETRIC MATRIX EIGENVALUE PROBLEM TO MATRIX MULTIPLICATIONS*

SHING-TUNG YAU† AND YA YAN LU‡

Abstract. A numerical method for the symmetric matrix eigenvalue problem is developed by reducing it to a number of matrix–matrix multiplications. For matrices of size n, the number of such multiplications is on the order of $\log_2 n$. On high performance parallel computers, it is important to minimize memory reference, since the movement of data between memory and registers can be a dominant factor for the overall performance. The matrix–matrix multiplication is more efficient than matrix–vector or vector–vector operations, since it involves $O(n^3)$ floating point operations while creating only $O(n^2)$ data movements. The number of data movements of the traditional methods based on reduction to the tridiagonal form is $O(n^3)$, while that of our method is $O(n^2 \log_2 n)$. Asymptotically, there are fast numerical algorithms for matrix multiplications that require less than $O(n^3)$ floating point operations. One example is the $O(n^{2.376})$ method of Coppersmith and Winograd [*Proc. 19th Ann. ACM Symp. Theory Comput.*, 1987, pp. 1–6]. Therefore, in principle, our method for the symmetric matrix eigenvalue problem requires only $O(n^{2.376} \log_2 n)$ operations.

1. Introduction.

Recently, much effort has been devoted to developing efficient numerical algorithms for matrix eigenvalue problems on high performance parallel computers. New methods and modifications of the traditional methods [27], [18], [24] developed on sequential computers are being studied in the new environment. The Jacobi method [14] has attracted much attention [22], [4], since it is natural for parallelization. Meanwhile, the idea that one first reduce the matrix to a condensed form through orthogonal similarity transform is still the basis for many studies. The reduction process itself has been analyzed and the resulting block methods [3], [23], [7], [12] could have a better performance on parallel computers. When the matrix is symmetric, new methods have been developed for the condensed form: tridiagonal matrices. The method in [17], [13], and [15] is based on evaluating the characteristic polynomial of the tridiagonal matrix. It computes the eigenvalues through multisectioning and the eigenvectors through inverse iteration. Methods based on the idea of divide and conquer have been developed and implemented in [6] and [9]. Recursively, two smaller tridiagonal eigenvalue problems are first solved, then combined to obtain the eigensystem of the larger tridiagonal matrix.

One important issue that appeared in the high-performance computers is the cost of data movement. It becomes necessary to organize the algorithms such that we reuse the data as much as possible. Matrix–matrix multiplication performs $O(n^3)$ operations (without using any asymptotically faster algorithms) on $O(n^2)$ data, and it is more efficient than matrix–vector or vector–vector operations. Therefore, it is desirable to develop algorithms that are rich in matrix–matrix operations. This has led to the development of block algorithms for matrix computations [10]. These block algorithms are usually variants of the original well-established sequential algorithms. We believe that it is helpful to think about the problem from a new starting point and to

develop new algorithms that fully take advantage of the new computer architectures.

In this paper, we develop a method that reduces the symmetric matrix eigenvalue problem to a number of matrix multiplications. The total number of such multiplications is $O(\log_2 n)$. The traditional algorithm performs $O(n^3)$ floating point operations requiring $O(n^3)$ data movement. Without using any asymptotically fast matrix multiplication algorithms, our method performs $O(n^3 \log_2 n)$ operations with $O(n^2 \log_2 n)$ data movement. Meanwhile, much effort has been devoted to achieving a lower asymptotic bound [19], [25] for matrix multiplications. The method in [5] requires only $O(n^{2.376})$ operations to multiply two $n \times n$ matrices. Practical implementation of the Strassen method [25] that requires $O(n^{\log_2 7})$ operations on the CRAY-2 has been reported [2]. In any circumstance, from a theoretical point of view, the number of operations required in our algorithm has a lower asymptotic bound: $O(n^{2.376} \log_2 n)$.

2. Basic ideas. Consider a real symmetric matrix A with eigenvalues λ_1, λ_2, $\ldots$, λ_n and eigenvectors g_1, g_2, $\ldots$, g_n. Starting from an initial vector expanded in terms of the eigenvectors as

$$v_0 = \alpha_1 g_1 + \alpha_2 g_2 + \cdots + \alpha_n g_n,$$

we can construct a polynomial of A, say $P_N(A)$, and multiply it by the vector v_0. We obtain

$$P_N(A)v_0 = \alpha_1 P_N(\lambda_1) g_1 + \alpha_2 P_N(\lambda_2) g_2 + \cdots + \alpha_n P_N(\lambda_n) g_n.$$

The central idea in the polynomial acceleration methods, such as those for a linear system of equations, is to choose the polynomial so that it peaks up at one of the eigenvalues and is close to zero otherwise. The vector $P_N(A)v_0$ can thus be regarded as an approximation to the corresponding eigenvector.

There are several difficulties with this approach. It apparently only computes one eigenpair at a time. Meanwhile, the initial peak of the polynomial may not be so close to the desired eigenvalue that the computed vector is not accurate enough, and we need to shift the peak of $P_N(A)$ and repeat the process. All of these are too expensive to be of any practical interest.

The main purpose of this paper is to introduce the fast Fourier transform (FFT) into this process, such that the above difficulties can be overcome and all the eigenvalues of A can be computed simultaneously.

Consider a unitary matrix B whose eigenvalues $\mu_1, \mu_2, \ldots, \mu_n$ all lie on the unit circle. Let $P_N(z)$ be a polynomial that has a peak at $z = 1$ and is constructed to be close to zero on the unit circle away from the vicinity of $z = 1$. Let the eigenvectors of B be $g_1, g_2, \ldots, g_n$ (the same notations that are used for the eigenvectors of A) and the initial vector v_0 be expanded as $v_0 = \sum_{j=1}^{n} \alpha_j g_j$. We have that

$$u(\lambda) = P_N(e^{-i\lambda}B)v_0 = \sum_{j=1}^{n} \alpha_j P_N(e^{-i\lambda}\mu_j) g_j.$$

Apparently, if λ is chosen such that μ_{j_0} is close to $e^{i\lambda}$ and other eigenvalues of B are not "close" to $e^{i\lambda}$, then the coefficients of g_j will be small except when $j = j_0$. Thus $u(\lambda)$ can be regarded as an approximation to the eigenvector of μ_{j_0}. If the polynomial $P_N(z)$ is written as

$$P_N(z) = \sum_{j=0}^{N-1} \beta_j z^j,$$

then we have that

$$u(\lambda) = \sum_{j=0}^{N-1} \beta_j B^j v_0 e^{-ij\lambda}$$

$$= \sum_{j=0}^{N-1} \beta_j v_j e^{-ij\lambda},$$

where $v_j = B^j v_0$. Therefore, if the vectors v_j are computed first, FFT can be used to compute $u(\lambda)$ at many different values of λ simultaneously.

In order to apply the above approach to the symmetric matrix eigenvalue problem, we need to first link the matrix A with a unitary matrix, then find a suitable polynomial $P_N(z)$ and finally compute the vectors v_j. After the vectors $u(\lambda)$ are computed through FFT, we need to select the vectors that can be regarded as eigenvectors. When there are close or multiple eigenvalues, a local refined scheme with possible supplementary vectors is proposed such that all the eigenvalues can be computed to the full double precision. We discuss these issues in the next sections.

3. Unitary matrix. The natural choice for the unitary matrix B is e^{iA}. The fact that A is a symmetric matrix brings an important difference between e^{iA} and e^{A}. The eigenvalues of e^{A} may be extended to a large range such that the finite precision arithmetic computers may regard e^{A} as near rank deficient. The situation for e^{iA} is different, since all the eigenvalues have norm one.

However, we still want to avoid the situation where all the eigenvalues of e^{iA} lie in just part of the unit circle. We prefer a more or less uniform distribution on the unit circle for more efficiency of our algorithm. Therefore, we first estimate the largest and smallest eigenvalues of A, and find a lower bound and an upper bound for the spectrum. Then, the matrix is shifted and scaled (still denoted by A) such that its eigenvalues are within the interval $[0, 2\pi)$.

Estimating the extreme eigenvalues of A is not a difficult task, since we do not really need any high precision for the extreme eigenvalues—only the true lower and upper bounds are needed. A few steps of the Lanczos method are usually sufficient for this purpose. A small number of matrix–vector multiplications are needed in this step.

The computation of e^{iA} is an expensive step. On sequential computers, this could be a more difficult task than the symmetric matrix eigenvalue problem itself. However, the situation on high-performance parallel computers is different, since its computation can be carried out in a small number of efficient matrix–matrix multiplications. The following method requires only six such multiplications to compute $\cos(A)$ with double precision. The expansion for $\sin(A)$ is also given, although we only use it to compute $\sin(A)v_0$, where v_0 is the initial vector. (If $\sin(A)$ is desired, we can compute it in two more matrix multiplications.) The method is based on the Chebyshev expansions of $\cos(\pi x)$ and $\sin(\pi x)/x$ for x within $[-1, 1]$ and it essentially uses the method for evaluating polynomials of a matrix proposed by Paterson and Stockmeyer [20] and Van Loan [26].

For $\cos(\pi x)$, we have

$$\cos(\pi x) = \tilde{c}_0 + \tilde{c}_1 T_2(x) + \tilde{c}_2 T_4(x) + \cdots + \tilde{c}_{10} T_{20}(x) + \cdots.$$

No terms after T_{20} are needed for double precision. Using the formula $T_{j+k} = 2T_j T_k - T_{j-k}$ (for $j > k$), we can rewrite the above expansion in terms of $T_0, T_2, \ldots, T_{10}$. A

similar expansion is developed for $\sin(\pi x)$ based on the even function $\sin(\pi x)/x$. We have

$$\cos(\pi x) \approx c_0 + c_1T_2 + c_2T_4 + \cdots + c_5T_{10} + T_{10}(c_6T_2 + c_7T_4 + \cdots + c_{10}T_{10}),$$
$$\sin(\pi x)/x \approx s_0 + s_1T_2 + s_2T_4 + \cdots + s_5T_{10} + T_{10}(s_6T_2 + s_7T_4 + \cdots + s_{10}T_{10}).$$

For the symmetric matrix A whose eigenvalues are within $[0, 2\pi)$, we define $X = A/\pi - I$. Therefore, $e^{iA} = -e^{i\pi X}$. Using the formula $T_{j+k} = 2T_jT_k - T_{j-k}$, we can compute $T_2(X), T_4(X), T_6(X), T_8(X)$, and $T_{10}(X)$ in a total of five matrix multiplications, $\cos(\pi X)$ in one more multiplication. However, $\sin(\pi X)$ requires two more multiplications, since the expansion used is for the even function $\sin(\pi x)/x$. Fortunately, only the multiplication of $\sin(\pi X)$ with a given initial vector is really needed, which can be computed by the above expansion with only matrix–vector multiplications involved. Therefore, a total of six multiplications each involving two real symmetric matrices are needed. We list the coefficients in Table 1.

4. Chebyshev polynomial. We consider a polynomial of degree $N-1$, $P_N(z)$, such that its real part has a peak at $z = 1$ and is small on the unit circle except at the vicinity of $z = 1$. We can scale the value of $P_N(z)$ at $z = 1$. This leads to a constrained uniform approximation problem: find $\beta_0, \beta_1, \beta_2, \ldots, \beta_{N-1}$, such that the polynomial $P_N(z) = \sum_{k=0}^{N} \beta_k z^k$ satisfies the following two conditions:

1. $P_N(1) = 1$;
2. The maximum of $|Re(P_N(z))|$ over the part of the unit circle defined as

$$S_\delta^1 = \{z = e^{i\theta} | \delta\pi \le \theta \le (2-\delta)\pi\}$$

is minimized, where δ is a small number that we can choose.

It turns out that the coefficients $\beta_0, \beta_1, \ldots, \beta_{N-1}$ can be taken as real numbers because of the symmetry with respect to the real axis on the complex z plane.

Therefore,

$$\begin{aligned} Re(P_N(z)) &= \beta_0 + \beta_1 \cos(\theta) + \cdots + \beta_{N-1} \cos((N-1)\theta) \\ &= \beta_0 + \beta_1 T_1(\cos(\theta)) + \cdots + \beta_{N-1} T_{N-1}(\cos(\theta)) \\ &= Q_N(\cos(\theta)). \end{aligned}$$

The polynomial $Q_N(x)$ defined above satisfies the conditions: (i) $Q_N(1) = 1$; and (ii) $\max |Q_N(x)|$ over $-1 \le x \le \cos(\delta\pi)$ is minimized. Therefore, $Q_N(x)$ is the Chebyshev polynomial [21] translated to the interval $[-1, \cos(\delta\pi)]$ and scaled with a constant. That is,

$$Q_N(x) = \frac{T_{N-1}\left(\dfrac{2x + 1 - \cos(\delta\pi)}{1 + \cos(\delta\pi)}\right)}{T_{N-1}\left(\dfrac{3 - \cos(\delta\pi)}{1 + \cos(\delta\pi)}\right)}.$$

The coefficients $\beta_0, \beta_1, \ldots, \beta_{N-1}$ are simply the Chebyshev expansion coefficients of $Q_N(x)$,

$$Q_N(x) = \beta_0 T_0(x) + \beta_1 T_1(x) + \cdots + \beta_{N-1} T_{N-1}(x).$$

In order to compute these coefficients, we define $\beta_j^{(k)}$ by

$$T_k(ax + b) = \sum_{j=0}^{k} \beta_j^{(k)} T_k(x),$$

for $k = 0, 1, \ldots, N-1$, where

$$a = \frac{2}{1 + \cos(\delta\pi)}, \qquad b = \frac{1 - \cos(\delta\pi)}{1 + \cos(\delta\pi)}.$$

The first two sets of coefficients are

$$\beta_0^{(0)} = 1; \quad \beta_0^{(1)} = b, \quad \beta_1^1 = a.$$

Let $\beta_j^{(k)} = 0$; if $j > k$, we have the following recurrence relationships:

$$\beta_j^{(k+1)} = a\left(\beta_{j-1}^{(k)} + \beta_{j+1}^{(k)}\right) + 2b\beta_j^{(k)} - \beta_j^{(k-1)}$$

for $j > 1$, and

$$\beta_0^{(k+1)} = a\beta_1^{(k)} + 2b\beta_0^{(k)} - \beta_0^{(k-1)},$$

$$\beta_1^{(k+1)} = a\left(2\beta_0^{(k)} + \beta_2^{(k)}\right) + 2b\beta_0^{(k)} - \beta_0^{(k-1)}.$$

These recurrence relationships are used to compute the coefficients $\beta_j^{(k)}$ for increasing values of k. After $\beta_0^{(N-1)}, \beta_1^{(N-1)}, \ldots, \beta_{N-1}^{(N-1)}$ are computed, we simply multiply by $\kappa = 1/T_{N-1}((3 - \cos\delta\pi)/(1 + \cos\delta\pi))$ to obtain $\beta_0, \beta_1, \ldots, \beta_{N-1}$.

The total number of floating point operations involved in this step is $O(N^2)$. Meanwhile, it is efficient on vector and parallel computers because of its highly vectorizable nature.

5. v_j and $u(\lambda)$. We consider the computation of the vectors $v_j = e^{ijA}v_0$ for $j = 1, 2, \ldots, N-1$. The straightforward approach requires $N - 1$ matrix–vector multiplications. While v_0 is the initial vector, $v_1 = e^{iA}v_0$ can be computed easily. Since we have computed $\cos(A)$, we are ready to obtain the real part of v_1. The expansion developed for $\sin(A)$ can be used to compute $\sin(A)v_0$ in just a few matrix–vector multiplications. The remaining vectors can be obtained through the recursive formula

$$v_{j+1} = 2\cos(A)v_j - v_{j-1}$$

for $j \geq 1$. N is usually taken as $O(n)$, therefore, computing all v_j (for $j = 1, 2, \ldots, N-1$) requires a similar amount of operations as the orthogonal reduction of a symmetric matrix to a tridiagonal matrix used in the standard method. Because of the efficiency of matrix–matrix operations, we reformulate the algorithm as follows:

$$\begin{aligned}
&\text{(a)} \quad B_1 = \cos(A),\\
&\qquad\; v_2 = 2B_1v_1 - \overline{v}_0;\\
&\text{(b)} \quad B_2 = \cos(2A),\\
&\qquad\; (v_3, v_4) = 2B_2(v_1, v_2) - \overline{(v_1, v_0)};\\
&\text{(c)} \quad B_4 = \cos(4A),\\
&\qquad\; (v_5, v_6, v_7, v_8) = 2B_4(v_1, v_2, v_3, v_4) - \overline{(v_3, v_2, v_1, v_0)};\\
&\text{(d)} \quad \ldots\ldots\ldots\ldots
\end{aligned}$$

In $\log_2 N$ steps, all these vectors are computed.

Once these vectors are computed, they are used to compute the vectors $\{u(\lambda)\}$, which can be kept real. We have

$$\begin{aligned}
u(\lambda) &= Re \sum_{j=0}^{N-1} \beta_j v_j e^{-ij\lambda}\\
&= \sum_{j=0}^{N-1} \beta_j Re(v_j)\cos(j\lambda) + \beta_j Im(v_j)\sin(j\lambda).
\end{aligned}$$

The vectors $v_0, v_1, \ldots, v_{N-1}$ are complex (except that the initial v_0 can be taken as real). Therefore, we can have a FFT program that computes real vectors $u(\lambda)$ at $2N$ different values of λ and overwrites the memory space of $v_0, v_1, \ldots, v_{N-1}$. For $l = 0, 1, \ldots, 2N-1$, we denote $u(\lambda)|_{\lambda = l\pi/N}$ by u_l, that is,

$$u_l = Re \sum_{j=0}^{N-1} \beta_j e^{-ijl\pi/N} v_j.$$

When N is taken as a power of 2, the resulting FFT is quite efficient.

6. Selection and refinement. We have now computed the vectors

$$\begin{aligned}
u_l &= Re P_N(e^{-il\pi/N}e^{iA})v_0\\
&= \sum_{k=1}^{n} \alpha_k P_N(e^{i(\lambda_k - l\pi/N)})g_k
\end{aligned}$$

for $l = 0, 1, \ldots, 2N-1$, where $P_N(z) = \sum_{j=0}^{N-1} \beta_j z^j$ is the previously defined polynomial; λ_k, g_k are the eigenvalues and eigenvectors of matrix A, respectively; and the initial vector v_0 (normalized) is expanded as

$$v_0 = \sum_{k=1}^{n} \alpha_k g_k.$$

The purpose of this section is to devise a method of computing the eigenvalues and eigenvectors of A using as much information in $\{u_l\}$ as possible. When one eigenvalue, say λ_{k^*}, is well separated from the others, if l^* is an integer such that $l^*\pi/N$ is the closest to λ_{k^*}, then u_{l^*} will be very close to g_{k^*} subject to a scaling. An estimate of λ_{k^*} is obtained as

$$\tilde{\lambda}|_{l=l^*} = \frac{u_{l^*}^T A u_{l^*}}{u_{l^*}^T u_{l^*}}.$$

Of course, we do not know l^*, but we can compute $\tilde{\lambda}|_l$ for all l, then compare it with $l\pi/N$. When the difference between them is small (or reaches a local minimum), that particular value of l can be saved, and the corresponding u_l and $\tilde{\lambda}|_l$ give rise to an approximate eigenpair of A.

The problem with this approach is that it only works for isolated eigenvalues. If there are two eigenvalues that are close, the value of N may be too small to separate them. Meanwhile, for a multiple eigenvalue, we will only get one eigenvector, which is the component of v_0 on its eigenspace. The method presented below overcomes these difficulties by a subspace method that computes eigenvalues in each well-separated cluster and by adding supplementary vectors when necessary.

Given the vectors $u_0, u_1, \ldots, u_{2N-1}$, we first group them into clusters that are orthogonal with each other and select the most valuable vectors from each cluster.

Recall that related to the polynomial $P_N(z)$, there is a number $\kappa = 1/T_{N-1}((3 - \cos\delta\pi)/(1+\cos\delta\pi))$ such that $|ReP_N(e^{i\theta})| \leq \kappa$ if $|\theta| \leq \delta\pi$ (for $-\pi \leq \theta < \pi$). Apparently, δ is a measure of the narrowness of the peak at $z = 1$ of $P_n(z)$. When δ is chosen (usually $O(1/n)$), we choose N such that κ is smaller than the desired accuracy for eigenvectors. The eigenvalues can be computed as accurately as $O(\kappa^2)$ (but this is also limited by the machine epsilon). Therefore, if we are happy with nine significant digits for the eigenvectors and require full double precision for the eigenvalues, we may choose $\kappa \approx 10^{-9}$. The corresponding N is approximately $8/\delta$.

Let $\epsilon(> \kappa)$ be a small multiple of κ. We retain only the vectors whose two-norms are larger than ϵ. In other words, we find $\{k_j^b, k_j^e\}$ for $j = 1, 2, \ldots, n_c$, such that

$$\begin{aligned} |u_k|_2 &> \epsilon, && \text{if for some } j, \quad k_j^b \leq k \leq k_j^e, \\ |u_k|_2 &\leq \epsilon, && \text{otherwise.} \end{aligned}$$

Thus $\{k_j^b, k_j^e\}$ defines the jth cluster and n_c the total number of clusters. The vectors in different clusters are orthogonal to the accuracy of ϵ.

Inside each cluster, we only retain those vectors whose two-norms are local maxima and not too small (close to ϵ). They are further arranged in decreasing two-norms as

$$W_j = \left[w_1^j, w_2^j, \ldots, w_{p_j}^j\right]$$

for the jth cluster, where p_j is the number of vectors retained in this cluster. The number of all the retained vectors is

$$p = p_1 + p_2 + \cdots + p_{n_c}.$$

If $p = n$, all n eigenpairs can be found based on these chosen vectors. As we will show later, a small symmetric eigenvalue problem with a $p_j \times p_j$ matrix is solved for the jth cluster and the p_j eigenpairs of the matrix A in this cluster are obtained.

When $p < n$, we first need to supplement $n - p$ vectors in order to compute all n eigenpairs. Starting from $n - p$ random vectors, we orthonormalize them with the p retained vectors and obtain

$$W = [w_{p+1}, w_{p+2}, \dots, w_n]$$

satisfying the following conditions:

$$w_k^T w_l^j = 0, \quad \text{for } j = 1, 2, \dots, n_c, \quad l = 1, 2, \dots, p_j, \quad k = p+1, p+2, \dots, n,$$

$$w_k^T w_l = \delta_{kl}, \quad \text{for } k, l = p+1, \quad p+2, \dots, n.$$

Then $W^T A W$ is an $(n - p) \times (n - p)$ symmetric matrix. Its eigenvalue problem is solved, and we obtain the following:

$$W^T A W = Q \begin{pmatrix} \tilde{\mu}_{p+1} & & & \\ & \tilde{\mu}_{p+2} & & \\ & & \ddots & \\ & & & \tilde{\mu}_n \end{pmatrix} Q^T,$$

where Q is an $(n-p) \times (n-p)$ orthogonal matrix. For $\tilde{W} = WQ = [\tilde{w}_{p+1}, \tilde{w}_{p+2}, \dots, \tilde{w}_{p+1}]$, we have

$$\tilde{W}^T A \tilde{W} = \begin{pmatrix} \tilde{\mu}_{p+1} & & & \\ & \tilde{\mu}_{p+2} & & \\ & & \ddots & \\ & & & \tilde{\mu}_n \end{pmatrix}.$$

The $n - p$ vectors of $\tilde{W}$ are grouped into different clusters. For vector $\tilde{w}_k$, we define $\tilde{l}_k$ by

$$\tilde{l}_k = N \tilde{\mu}_k / \pi.$$

If for some j, $k_j^b \le \tilde{l}_k \le k_j^e$, then $\tilde{w}_k$ belongs to the jth cluster. If $\tilde{w}_k$ does not belong to any cluster, then $\{\tilde{\mu}_k, \tilde{w}_k\}$ is an eigenpair of A and no further computation is necessary. This latter case corresponds to the situation where the initial vector has no component in that eigenvector (or the component is so small that we must ignore it). Therefore, each of these $n - p$ vectors is either combined with one of the clusters or left alone as an individual eigenvector. We still denote the number of vectors in the jth cluster by p_j, with the understanding that p_j may have been increased. After an orthonormalization process, we have

$$W_j = [w_1^j, w_2^j, \dots, w_{p_j}^j]$$

such that $(w_k^j)^T w_l^j = \delta_{kl}$. Then the reduced eigenvalue problem for the $p_j \times p_j$ symmetric matrix $W_j^T A W_j$ is solved as a subproblem and we obtain the following:

$$W_j^T A W_j = Q_j \begin{pmatrix} \mu_1^j & & & \\ & \mu_2^j & & \\ & & \ddots & \\ & & & \mu_{p_j}^j \end{pmatrix} Q_j^T,$$

where Q_j is a $p_j \times p_j$ orthogonal matrix. Let

$$\tilde{W}_j = W_j Q_j = [\tilde{w}_1^j, \tilde{w}_2^j, \ldots, \tilde{w}_{p_j}^j].$$

The column vectors of $\tilde{W}_j$ are the eigenvectors of A in the cluster and the corresponding eigenvalues are $\mu_1^j, \mu_2^j, \ldots, \mu_{p_j}^j$.

The method presented in this section selects the most useful vectors from the $2N$ vectors $u_0, u_1, \ldots, u_{2N-1}$, groups them into a number of orthogonal clusters, adds more vectors, if necessary, and reduces to a small symmetric matrix eigenvalue problem in each cluster. We note that the reduced eigenvalue problems in different clusters can be solved simultaneously, therefore, this part of the algorithm is highly parallel. The complete algorithm will be presented in the next section.

7. The algorithm. Consider a real symmetric matrix A. The following steps find the eigenvalues and eigenvectors of A to the desired precision.

1. Scaling and translation. Use any available method, e.g., the Lanczos method, to find the largest and smallest eigenvalues of A approximately, then translate and scale the matrix A, such that the resulting matrix has eigenvalues in the interval $[0, 2\pi)$.

2. Computing the coefficients $\beta_0, \beta_1, \ldots, \beta_{N-1}$. Take $\delta \approx 1/n$, N (power of 2 preferred) is the smallest integer such that

$$\kappa = 1/T_{N-1}((3-\cos\delta\pi)/(1+\cos\delta\pi)) < \text{ desired accuracy for eigenvectors.}$$

The coefficients $\beta_0, \beta_1, \ldots, \beta_{N-1}$ are defined by

$$Q_N(x) = \frac{T_{N-1}((2x+1-\cos(\delta\pi))/(1+\cos(\delta\pi)))}{T_{N-1}((3-\cos(\delta\pi))/(1+\cos(\delta\pi)))} = \sum_{k=0}^{N-1} \beta_k T_k(x),$$

and computed through the recursive formula in §4.

3. Computing the matrix $\cos(A)$. Let $X = A/\pi - I$. The matrices $T_2(X)$, $T_4(X)$, $T_6(X)$, $T_8(X)$, and $T_{10}(X)$ are computed in five matrix multiplications based on $T_{k+l} = 2T_kT_l - T_{k-l}$. Then $\cos(A) = \cos(\pi X)$ is computed in one more matrix multiplication based on the following expansion:

$$\cos(\pi X) \approx c_0 + c_1T_2 + c_2T_4 + \cdots + c_5T_{10} + T_{10}(c_6T_2 + c_7T_4 + \cdots + c_{10}T_{10}),$$

where the coefficients are given in §3.

4. Computing the vectors $v_j = e^{ijA}v_0$. The real part of v_1 is easily obtained from $\cos(A)$. The imaginary part is based on the expansion

$$\begin{aligned} -\sin(A)v_0 &= \sin(\pi X)v_0 \\ &\approx X[s_0 + s_1T_2 + s_2T_4 + \cdots + s_5T_{10} \\ &\qquad + T_{10}(s_6T_2 + s_7T_4 + \cdots + s_{10}T_{10})]v_0. \end{aligned}$$

After v_1 is computed, the other vectors are computed following these steps:

$$\begin{aligned}
&\text{(a)}\quad B_1 = \cos(A),\\
&\qquad v_2 = 2B_1 v_1 - \overline{v}_0;\\
&\text{(b)}\quad B_2 = \cos(2A) = 2B_1^2 - I,\\
&\qquad (v_3, v_4) = 2B_2(v_1, v_2) - \overline{(v1, v0)};\\
&\text{(c)}\quad B_4 = \cos(4A) = 2B_2^2 - I,\\
&\qquad (v_5, v_6, v_7, v_8) = 2B_4(v_1, v_2, v_3, v_4) - \overline{(v_3, v_2, v_1, v_0)};\\
&\text{(d)}\quad \dots\dots\dots\dots
\end{aligned}$$

In practice, the matrices $B_1, B_2, B_4, \dots$ are overwritten and stored in one real symmetric matrix, and all the computed vectors are stored in a complex $n \times N$ matrix $V = [v_0, v_1, v_2, \dots, v_{N-1}]$.

5. Using the Fourier transform. For $\lambda = k\pi/N$, $k = 0, 1, 2, \dots, 2N-1$, the vectors

$$\begin{aligned}
u_k = u(\lambda)|_{\lambda = k\pi/N} &= Re \sum_{j=0}^{N-1} \beta_j v_j e^{-i\pi jk/N}\\
&= \sum_{j=0}^{N-1} \beta_j Re(v_j)\cos(jk\pi/N) + \beta_j Im(v_j)\sin(jk\pi/N)
\end{aligned}$$

are computed through FFT. The matrix V is now overwritten by the real $n \times 2N$ matrix

$$U = [u_0, u_1, \dots, u_{2N-1}].$$

6. Finding the eigensolution. A threshold ϵ is first chosen as a small multiple of κ, the column vectors of U are then grouped into a total of n_c clusters: $\{k_j^b, k_j^e\}$ for $j = 1, 2, \dots, n_c$, such that

$$\begin{aligned}
|u_k|_2 &> \epsilon, && \text{if for some } j, \quad k_j^b \le k \le k_j^e,\\
|u_k|_2 &\le \epsilon, && \text{otherwise.}
\end{aligned}$$

In the jth cluster, p_j vectors are found such that their two-norms reach local maxima. These p_j vectors are ordered with decreasing two-norms and orthonormalized. They are

$$W_j = \left[w_1^j, w_2^j, \dots, w_{p_j}^j\right].$$

$p = p_1 + p_2 + \cdots + p_{n_c}$ is the total number of vectors selected. If $p < n$, $n - p$ random vectors are first generated then orthonormalized with the column vectors of $W_1, W_2, \dots, W_{n_c}$ and we obtain

$$W = [w_{p+1}, w_{p+2}, \dots, w_n].$$

The symmetric matrix eigenvalue problem for the $(n-p) \times (n-p)$ matrix W^TAW is solved:

$$W^TAW = Q \begin{pmatrix} \tilde{\mu}_{p+1} & & & \\ & \tilde{\mu}_{p+2} & & \\ & & \ddots & \\ & & & \tilde{\mu}_n \end{pmatrix} Q^T,$$

where Q is an $(n-p) \times (n-p)$ orthogonal matrix. Let $\tilde{w}_{p+1}, \tilde{w}_{p+2}, \dots, \tilde{w}_{p+1}$ be the $n-p$ column vectors of WQ. For $l = p+1, p+2, \dots, n$, if there exists j such that $k_j^b \le N\tilde{\mu}_l/\pi \le k_j^e$, then the vector $\tilde{w}_l$ is added to the jth cluster. That is,

$$w^j_{p_j+1} = \tilde{w}_l, \qquad p_j := p_j + 1.$$

If $\tilde{w}_l$ cannot be put into any cluster, it is left alone as an eigenvector of A with corresponding eigenvalue $\tilde{\mu}_l$.
Finally, for each cluster W_j, a $p_j \times p_j$ symmetric matrix eigenvalue problem is solved:

$$W_j^TAW_j = Q_j \begin{pmatrix} \mu_1^j & & & \\ & \mu_2^j & & \\ & & \ddots & \\ & & & \mu^j_{p_j} \end{pmatrix} Q_j^T,$$

where Q_j is a $p_j \times p_j$ orthogonal matrix. The column vectors of W_jQ_j are the eigenvectors of A in the jth cluster and the corresponding eigenvalues are $\mu_1^j, \mu_2^j, \dots, \mu^j_{p_j}$.

The method presented above works even if the eigenvalues of A are poorly distributed. However, if many eigenvalues have almost the same value, the work for the supplementary vectors and the resulting clusters is expensive. In most cases, say, for a random matrix, p is close to n, so the operations spent on the supplementary vectors are negligible. Usually, the subproblems in each cluster only involve small matrices. That is, p_j is usually quite small compared with n. These subproblems for supplementary vectors and for the clusters can be solved by the standard EISPACK routines or the same algorithm recursively.

8. Error analysis. For this algorithm to be useful, the computed eigenvalues and eigenvectors must not be sensitive to the initial errors that are present in the matrix A and in computing e^{iA} by an expansion. Since we are using matrix exponentials and repeated squares, we might suspect that our algorithm can be unstable. However, this is not true.

First, we must emphasize that for a symmetric matrix A, e^{iA} is a well-behaved unitary matrix. The usual fear of exponential growth of error does not apply here. The difference between $e^{i(A+E)}$ and e^{iA} is small, when E is a symmetric matrix with small entries. This is related to the fact that the eigenvalues of A and E are real, and the nice properties of sine and cosine are valid here.

Second, while we are computing $v_j = e^{ijA}v_0$ for $j = 1, 2, \dots, N-1$, our results are not based on v_{N-1} and other vectors with large subscripts only. If, at the initial stage, our expansion for e^{iA} gives us an approximation that can be written as $e^{i(A+E)}$, the best we can do for the vector v_j is to obtain $e^{ij(A+E)}v_0$. Indeed, when j is large, the difference between $e^{ijA}v_0$ and $e^{ij(A+E)}v_0$ is significant. However, our computation is based on

$$u_k = Re \sum_{j=0}^{N-1} \beta_j e^{-ijk\pi/N} v_j$$

for $k = 0, 1, \ldots, 2N-1$. If $e^{ij(A+E)}v_0$ is plugged into the above equation for v_j, the computed vectors $\{u_k\}$ simply correspond to the matrix $A+E$, and are very useful when E can be kept small.

The expansion designed for e^{iA} in §3 gives rise to an accurate and reliable scheme for its numerical computation. The computed error for each entry of the matrix is limited by a small multiple of machine epsilon ϵ_0 for double precision (2^{-52} here), which is almost the best we can have. Of course, since we use approximate expansions for both $\cos(A)$ and $\sin(A)$, it is quite impossible to write these two computed matrices in terms of one small symmetric matrix E as $\cos(A+E)$ and $\sin(A+E)$. Rather, we must introduce two small matrices E_1 and E_2 for $\cos(A)$ and $\sin(A)$, respectively. However, the computed imaginary part of v_1, that is, $\sin(A+E_2)v_0$ can be written as $\sin(A+E_1)(v_0+v_e)$, where v_e is a vector with $O(\epsilon_0)$ elements. From the recursive formula, we conclude that for vectors v_j, we obtain

$$\begin{aligned}\hat{v}_j &= \cos(j(A+E_1))v_0 + i\sin(j(A+E_1))(v_0+v_e)\\ &= e^{ij(A+E_1)}v_0 + i\sin(j(A+E_1))v_e.\end{aligned}$$

The computed values for u_k are

$$\begin{aligned}\hat{u}_k &= Re \sum_{j=0}^{N-1} \beta_j e^{-ijk\pi/N} e^{ij(A+E_1)}v_0 + \sum_{j=0}^{N-1} \beta_j \sin(jk\pi/N)\sin(j(A+E_1))v_e\\ &= Re \sum_{j=0}^{N-1} \beta_j e^{-ijk\pi/N} e^{ij(A+E_1)}v_0 + \hat{u}_e.\end{aligned}$$

The first part corresponds to the exact u_k for a perturbed matrix $A+E_1$. The second part $\hat{u}_e$ gives rise to a small error because of the inconsistent approximations for $\sin(A)$ and $\cos(A)$. When v_e is expanded in terms of the eigenvectors of $A+E_1$, say

$$v_e = \hat{\alpha}_1\hat{g}_1 + \hat{\alpha}_n\hat{g}_n + \cdots + \hat{\alpha}_n\hat{g}_n,$$

we see that

$$\hat{u}_e = \sum_{k=1}^{n} \hat{\alpha}_k \sum_{j=0}^{N-1} \beta_j \sin(jk\pi/N)\sin(j\hat{\lambda}_k)\hat{g}_k.$$

The absolute value of the coefficient of $\hat{g}_k$

$$\left| \hat{\alpha}_k \sum_{j=0}^{N-1} \beta_j \sin(jk\pi/N)\sin(j\hat{\lambda}_k) \right| \le |\hat{\alpha}_k| \sum_{j=0}^{N-1} \beta_j = |\hat{\alpha}_k|.$$

Therefore, the two-norm of $\hat{u}_e$ cannot exceed that of v_e, whose entries are on the order of machine epsilon.

The selection of vectors from the set $\{u_k\}$ is based on their two-norms. Those vectors with small norms are ignored. Therefore, the errors $\hat{u}_e$ will not have much impact for our final result and the scheme based on them is stable and reliable.

9. Numerical test. We have tested our algorithm for many matrices. The computed eigenvalues and eigenvectors are compared with the result by EISPACK. The accuracy of the eigenvalues is full double precision, while we limit our accuracy for eigenvectors to nine digits. All the results we computed are found to be correct when compared with those by EISPACK.

The parameter δ is usually taken as $1/n$ and $N = 8/\delta \approx 8n$ is the number of vectors (complex) that we must compute in order to guarantee the nine-digit accuracy for eigenvectors. Unfortunately, δ cannot be taken much larger to reduce the memory space, because we might end up with a situation where the vectors $\{u_k\}$ cannot be separated into different clusters (thus the subproblem is the same size as the original problem).

For random matrices, the eigenvalues are usually well distributed. But some close eigenvalue clusters also exist. Meanwhile, supplementary vectors are usually necessary. However, in all our testing of random matrices, the number of supplementary vectors is significantly less than n and the resulting clusters usually only have a few eigenvalues. For $n = 128$, the size of all the subproblems (for supplementary vectors and for clusters) seldom exceeds 10. Therefore, at least for our choice of δ and N, the time spent on these subproblems is usually not a significant part of the total time. Of course, the sizes of these subproblems depend on the distribution of eigenvalues. If the eigenvalues are extremely clustered, our method can face a difficulty. For simplicity, the subproblems are solved by the EISPACK routines for real and symmetric matrices.

The most time-consuming part of the algorithm is the computation of v_j for $j = 1, 2, \ldots, N-1$. On sequential computers, v_j can be obtained directly by the recursive formula involving $\cos(A)$. Each complex vector v_j requires a multiplication of the real symmetric matrix $\cos(A)$ and the complex vector v_{j-1}. If $N = 8n$, the total number of operations (for both summation and multiplication of real numbers) is approximately $32n^3$. The QR method for the symmetric matrix requires approximately $9n^3$ flops [11] when eigenvectors are also desired. Therefore, this part is already three to four times slower. If we rearrange the computation of v_j as presented in §§5 or 7, we need $\log_2 N - 1$ multiplications of two real symmetric matrices. If a straightforward method is used for matrix multiplications, and $N = 8n$, we need $(\log_2 n+2)n^3$ more operations. Of course, the computation of v_j can now be used in multiplications of real symmetric $n \times n$ matrices with complex matrices of order $n \times 1, n \times 2, n \times 4, \ldots, n \times N/2$. On parallel computers, the efficiency of BLAS3 routines can justify the use of the extra multiplications. A more practical aspect of its advantage over parallel computers will be reported in a separate paper. For the moment, on sequential computers for $n = 128$, the extra work of nine multiplications of real symmetric matrices makes this part of the algorithm four to five times slower than the EISPACK routine.

The computation of $\cos(A)$ requires six multiplications of real symmetric matrices. The total number of operations is $6n^3$. We do not compute $\sin(A)$, since only $\sin(A)v_0$ is needed. The other part of the algorithm is relatively efficient. Although $2N$ could be quite a large number, the step for computing u_k is still efficient, because of the FFT algorithm. The selection and refinement process usually does not involve large subproblems, and it is quite efficient.

Following is a typical example. We consider the matrix

$$A = (\sin(3000(i + j - 2)^2)).$$

For $n = 128$, its eigenvalues are shown in Fig. 1, where each vertical line represents an eigenvalue. We can see that some of the eigenvalues are very close. In our compu-

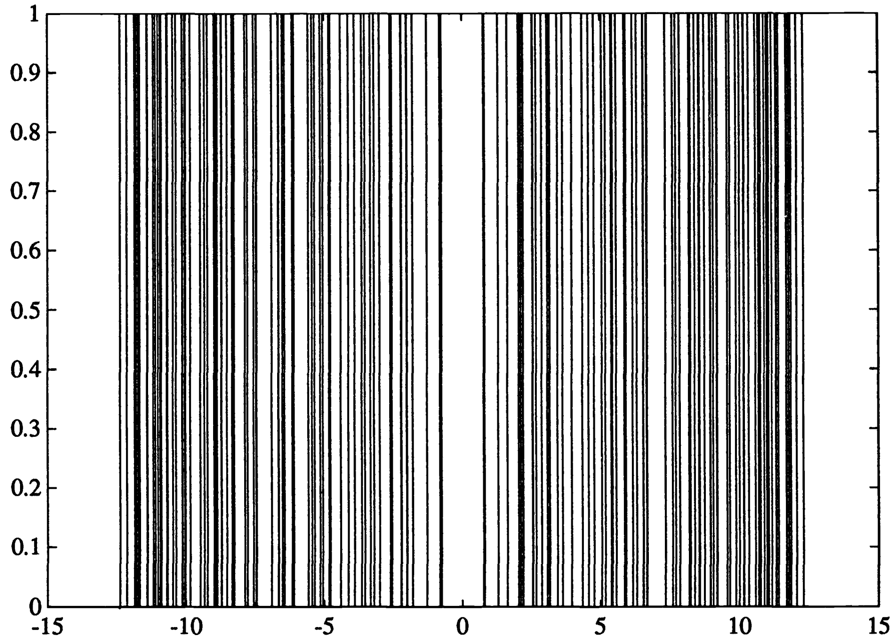

FIG. 1. *Eigenvalues of* $(\sin(3000(i+j-1)^2))$ *for* $n = 128$. (*Each eigenvalue is represented by a vertical line.*)

tation, the parameters are chosen as $\delta = 1/n$, $N = 8n$. With a random initial vector, 11 supplementary vectors are necessary. The result is a total of 59 clusters, classified according to their size (the number of eigenvalues in the cluster) and listed in Table 2. All the eigenvalues are accurate with at least 14 significant digits and the corresponding eigenvectors with nine digits when compared with the results by EISPACK routines. The accuracy of the eigenvectors is controlled in step 2 of the algorithm. Here, we have chosen N and δ such that $\kappa < 10^{-9}$. Therefore, nine accurate digits for the eigenvectors are expected. Let $Q = [q_1, q_2, \dots, q_n]$ be the numerically computed eigenvectors, and $\lambda_1, \lambda_2, \dots, \lambda_n$ be the computed eigenvalues. We have also calculated the following two matrices:

$$R_1 = Q^T Q - I, \qquad R_2 = Q^T A Q - \begin{pmatrix} \lambda_1 & & \\ & \ddots & \\ & & \lambda_n \end{pmatrix}.$$

The entries of these two matrices are all approximately 10^{-9}. Their Frobenius norms (square root of the summation of all the entries squared) are obtained:

$$\frac{1}{n}|R_1|_F = 8.171 \times 10^{-9}, \qquad \frac{1}{n}|R_2|_F = 5.678 \times 10^{-9}.$$

Similar results are obtained for various other testing matrices.

10. Conclusion. We have shown that for a symmetric $n \times n$ matrix A, its eigenvalues and eigenvectors can be found through a number of matrix multiplications. The number of such multiplications is $O(\log_2 n)$.

The principle of this method is based on the fact that matrix multiplication can be implemented more efficiently than matrix–vector or vector–vector operations. The advantage of BLAS3 operations is expected to be more important in future supercomputers with more processors. Our algorithm starts with six symmetric matrix multiplications to compute $\cos(A)$, then computes intermediate vectors in roughly $\log_2 n$ steps, each involving two matrix multiplications. Although the total number of operations used in our algorithm is much larger than the standard method based on the reduction to tridiagonal matrices, we expect it to be useful on parallel computers in the future.

In theory, the $O(n^3)$ operations required in the straightforward method for matrix multiplication can be reduced significantly. Strassen [25] first discovered a method that requires $O(n^{2.807})$ operations. Later, Pan [19] developed a method that only requires $O(n^{2.496})$ operations. Recently, an $O(n^{2.376})$ method was developed by Coppersmith and Winograd [5]. These methods with lower asymptotic powers are of significant theoretical interest. A number of important problems, such as solving a set of linear systems of equations and inversion of a matrix, can be reduced to matrix multiplications [1]. Our study here links the symmetric eigenvalue problem to the matrix multiplication. An asymptotic efficient algorithm for matrix multiplications can thus be used, which results in an $O(n^{2.376} \log_2 n)$ algorithm for the symmetric eigenvalue problem.

AN IMPLEMENTATION OF THE LOOK-AHEAD LANCZOS ALGORITHM FOR NON-HERMITIAN MATRICES*

ROLAND W. FREUND[†][‡], MARTIN H. GUTKNECHT[§], AND NOËL M. NACHTIGAL[†]

Abstract. The nonsymmetric Lanczos method can be used to compute eigenvalues of large sparse non-Hermitian matrices or to solve large sparse non-Hermitian linear systems. However, the original Lanczos algorithm is susceptible to possible breakdowns and potential instabilities. An implementation of a look-ahead version of the Lanczos algorithm is presented that, except for the very special situation of an incurable breakdown, overcomes these problems by skipping over those steps in which a breakdown or near-breakdown would occur in the standard process. The proposed algorithm can handle look-ahead steps of any length and requires the same number of matrix–vector products and inner products as the standard Lanczos process without look-ahead.

Key words. Lanczos method, orthogonal polynomials, look-ahead steps, eigenvalue problems, iterative methods, non-Hermitian matrices, sparse linear systems

AMS(MOS) subject classifications. 65F15, 65F10

1. Introduction.

In 1950, Lanczos [20] proposed a method for successive reduction of a given, in general non-Hermitian, $N \times N$ matrix A to tridiagonal form. More precisely, the Lanczos procedure generates a sequence $H^{(n)}$, $n = 1, 2, \ldots$, of $n \times n$ tridiagonal matrices which, in a certain sense, approximate A. Furthermore, in exact arithmetic and if no breakdown occurs, the Lanczos method terminates after at most L $(\leq N)$ steps with $H^{(L)}$ a tridiagonal matrix that represents the restriction of A or A^T to an A-invariant or A^T-invariant subspace of $\mathbb{C}^N$, respectively. In particular, all eigenvalues of $H^{(L)}$ are also eigenvalues of A, and, in addition, the method produces basis vectors for the A-invariant or A^T-invariant subspace found.

In the Lanczos process, the matrix A itself is never modified and appears only in the form of matrix–vector products $A \cdot v$ and $A^T \cdot w$. Because of this feature, the method is especially attractive for sparse matrix computations. Indeed, in practice, the Lanczos process is mostly applied to large sparse matrices A, either for computing eigenvalues of A or, in the form of the closely related biconjugate gradient (BCG) algorithm [21], for solving linear systems $Ax = b$. For large A, the finite termination property is of no practical importance and the Lanczos method is used as a purely iterative procedure. Typically, the spectrum of $H^{(n)}$ offers good approximations to some of the eigenvalues of A after already relatively few iterations, i.e., for $n \ll N$. Similarly, BCG, especially if used in conjunction with preconditioning, often converges in relatively few iterations to the solution of $Ax = b$.

Unfortunately, in the standard nonsymmetric Lanczos method a breakdown, more precisely, division by 0, may occur before an invariant subspace is found. In finite-precision arithmetic, such exact breakdowns are very unlikely; however, near-breakdowns may occur, which lead to numerical instabilities in subsequent iterations. The

possibility of breakdowns has brought the nonsymmetric Lanczos process into discredit and has certainly prevented many people from using the algorithm on non-Hermitian matrices. The symmetric Lanczos process for Hermitian matrices A is a special case of the general procedure in which the occurrence of breakdowns can be excluded.

On the other hand, it is possible to modify the Lanczos process so that it skips over those iterations in which an exact breakdown would occur in the standard method. The related modified recurrences for formally orthogonal polynomials were mentioned by Gragg [14, pp. 222–223] and by Draux [7]; also, in the context of the partial realization problem, by Kung [19, Chap. IV] and Gragg and Lindquist [15]. However, a complete treatment of the modified Lanczos method and its intimate connection with orthogonal polynomials and Padé approximation was presented only recently, by Gutknecht [16], [17]. Clearly, in finite-precision arithmetic, a viable modified Lanczos process also needs to skip over near-breakdowns. Taylor [27] and Parlett, Taylor, and Liu [25], with their look-ahead Lanczos algorithm, were the first to propose such a practical procedure. However, in [27] and [25], the details of an actual implementation are worked out only for look-ahead steps of length 2. We will use the term *look-ahead Lanczos method* in a broader sense to denote extensions of the standard Lanczos process which skip over breakdowns and near-breakdowns. Finally, note that, in addition to [16] and [17], there are several other recent papers dealing with various aspects of look-ahead Lanczos methods (see [1], [2], [4], [5], [9], [13], [18], and [23]).

The main purpose of this paper is to present a robust implementation of the look-ahead Lanczos method for general complex non-Hermitian matrices. Our intention is to develop an algorithm that can be used as a black box. In particular, the code can handle look-ahead steps of any length and is not restricted to steps of length 2. On many modern computer architectures, the computation of inner products of long vectors is a bottleneck. Therefore, one of our objectives is to minimize the number of inner products in our implementation of the look-ahead Lanczos method. The proposed algorithm requires the same number of inner products as the classical Lanczos process, as opposed to the look-ahead algorithm described in [27] and [25], which always requires additional inner products. In particular, our implementation differs from the one in [27] and [25] even for look-ahead steps of length 2.

The outline of the paper is as follows. In §2, we recall the standard nonsymmetric Lanczos method and its close relationship with orthogonal polynomials. Using this connection, we then describe the basic idea of the look-ahead versions of the Lanczos process. In §3, we present a sketch of our implementation of the algorithm with look-ahead and some of its basic properties. In §4, we discuss in more detail issues related to the look-ahead feature of the algorithm, while in §5 we are concerned with issues related to the implementation of the algorithm. Finally, in §6, we report a few numerical experiments with the algorithm, for both eigenvalue problems and linear systems, and in §7, we make some concluding remarks.

We remark that an extended version of the present paper is available as a technical report [11]. In particular, details omitted here can be found therein. Furthermore, the look-ahead Lanczos process can be used to compute approximate solutions to $Ax = b$, which are defined by a quasi-minimal residual (QMR) property. The resulting QMR algorithm is described in detail in [12] and [13].

For notation, we will adhere to the Householder conventions with only a few exceptions, which we will note. Throughout the paper, all vectors and matrices can be assumed to be complex. As usual, $M^T = [\mu_{ji}]$ and $M^H = [\overline{\mu}_{ji}]$ denote the transpose and the conjugate transpose, respectively, of the matrix $M = [\mu_{ij}]$. The largest and smallest singular values of M are denoted by $\sigma_{\max}(M)$ and $\sigma_{\min}(M)$, respectively. The vector norm $\|x\| = \sqrt{x^H x}$ is always the Euclidean norm and $\|M\| = \sigma_{\max}(M)$ denotes the corresponding matrix norm. The notation

$$K_n(c, B) := \operatorname{span}\{c, Bc, \ldots, B^{n-1}c\}$$

is used for the nth Krylov subspace of $\mathbb{C}^N$ generated by $c \in \mathbb{C}^N$ and the $N \times N$ matrix B.

$$\mathcal{P}_n := \{\Psi(\lambda) \equiv \gamma_0 + \gamma_1\lambda + \cdots + \gamma_n\lambda^n \mid \gamma_0, \gamma_1, \ldots, \gamma_n \in \mathbb{C}\}$$

denotes the set of all complex polynomials of degree at most n. Furthermore, A is always assumed to be a possibly complex and in general non-Hermitian $N \times N$ matrix.

Finally, we note that in our formulation of the nonsymmetric Lanczos algorithm and its look-ahead variant, we use A^T rather than A^H. This was a deliberate choice in order to avoid complex conjugation of the scalars in the recurrences; the algorithms can be formulated equally well in either terms (cf. (2.18)).

2. Background.

In this section, we briefly recall the classical nonsymmetric Lanczos method [20] and its close relationship with *formally orthogonal polynomials* (FOPs). Using this connection, we then describe the basic idea of the look-ahead Lanczos algorithm.

Given two nonzero starting vectors $v_1 \in \mathbb{C}^N$ and $w_1 \in \mathbb{C}^N$, the standard nonsymmetric Lanczos method generates two sequences of vectors $\{v_n\}_{n=1}^L$ and $\{w_n\}_{n=1}^L$ such that, for $n = 1, \ldots, L$,

$$\begin{aligned} \operatorname{span}\{v_1, v_2, \ldots, v_n\} &= K_n(v_1, A), \\ \operatorname{span}\{w_1, w_2, \ldots, w_n\} &= K_n(w_1, A^T), \end{aligned} \tag{2.1}$$

and

$$w_i^T v_j = \left\{ \begin{array}{ll} \delta_i \neq 0 & \text{if } i = j, \\ 0 & \text{otherwise,} \end{array} \right\} \quad \text{for all} \quad i, j = 1, \ldots, n. \tag{2.2}$$

The actual construction of the vectors v_n and w_n is based on the three-term recurrences

$$\begin{aligned} v_{n+1} &= Av_n - \alpha_n v_n - \beta_n v_{n-1}, \\ w_{n+1} &= A^T w_n - \alpha_n w_n - \beta_n w_{n-1}, \end{aligned} \tag{2.3}$$

where

$$\alpha_n = \frac{w_n^T A v_n}{\delta_n} \quad \text{and} \quad \beta_n = \frac{w_{n-1}^T A v_n}{\delta_{n-1}} = \frac{\delta_n}{\delta_{n-1}}$$

are chosen to enforce (2.2). For $n = 1$, we set $\beta_1 = 0$ and $v_0 = w_0 = 0$ in (2.3). Letting

$$V^{(n)} := [v_1\ v_2\ \cdots\ v_n] \quad \text{and} \quad W^{(n)} := [w_1\ w_2\ \cdots\ w_n] \tag{2.4}$$

denote the matrices whose columns are the first n of the vectors v_j and w_j, respectively, and letting

$$H^{(n)} := \begin{bmatrix} \alpha_1 & \beta_2 & 0 & \cdots & 0 \\ 1 & \alpha_2 & \ddots & \ddots & \vdots \\ 0 & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \beta_n \\ 0 & \cdots & 0 & 1 & \alpha_n \end{bmatrix}$$

denote the tridiagonal matrix containing the recurrence coefficients, we can rewrite (2.3) as

$$\begin{aligned} AV^{(n)} &= V^{(n)}H^{(n)} + [0 \ \cdots \ 0 \ \ v_{n+1}], \\ A^TW^{(n)} &= W^{(n)}H^{(n)} + [0 \ \cdots \ 0 \ \ w_{n+1}]. \end{aligned} \tag{2.5}$$

Moreover, the biorthogonality condition (2.2) reads as

$$(W^{(n)})^TV^{(n)} = D^{(n)} := \operatorname{diag}(\delta_1, \delta_2, \ldots, \delta_n). \tag{2.6}$$

Let L be the largest integer such that there exist vectors v_n and w_n, $n = 1, \ldots, L$, satisfying (2.1) and (2.2). Note that $L \leq N$ and that, in view of (2.3), L is the smallest integer such that

$$w_{L+1}^Tv_{L+1} = 0. \tag{2.7}$$

Moreover, let

$$L_r = L_r(v_1, A) := \dim K_N(v_1, A) \quad \text{and} \quad L_l = L_l(w_1, A^T) := \dim K_N(w_1, A^T)$$

denote the *grade* of v_1 with respect to A and the *grade* of w_1 with respect to A^T, respectively (cf. [29, p. 37]). There are two essentially different cases for fulfilling the termination condition (2.7). The first case, referred to as *regular termination*, occurs when $v_{L+1} = 0$ or $w_{L+1} = 0$. If $v_{L+1} = 0$, then $L = L_r$ and the *right* Lanczos vectors $v_1, \ldots, v_{L_r}$ span the A-invariant subspace $K_{L_r}(v_1, A)$. Similarly, if $w_{L+1} = 0$, then $L = L_l$ and the *left* Lanczos vectors $w_1, \ldots, w_{L_l}$ span the A^T-invariant subspace $K_{L_l}(w_1, A^T)$. Unfortunately, it can also happen that the termination condition (2.7) is satisfied with $v_{L+1} \neq 0$ and $w_{L+1} \neq 0$. This second case is referred to as *serious breakdown* [29, p. 389]. Note that, in this case,

$$L < L_\star := \min\{L_l, L_r\},$$

and the Lanczos vectors span neither an A-invariant nor an A^T-invariant subspace of $\mathbb{C}^N$.

It is the possibility of serious breakdowns, or, in finite-precision arithmetic, of *near-breakdowns*, i.e.,

$$w_{n+1}^Tv_{n+1} \approx 0, \quad \text{but} \quad w_{n+1} \not\approx 0 \quad \text{and} \quad v_{n+1} \not\approx 0,$$

that has brought the classical nonsymmetric Lanczos algorithm into discredit. However, by means of a look-ahead procedure, it is possible to leap (except in the very special case of an incurable breakdown [27]) over those iterations in which the standard algorithm would break down. Next, using the intimate connection between the Lanczos process and FOPs, we describe the basic idea of the look-ahead Lanczos algorithm.

First, note that

$$\begin{aligned} K_n(v_1, A) &= \{\Psi(A)v_1 \mid \Psi \in \mathcal{P}_{n-1}\}, \\ K_n(w_1, A^T) &= \{\Psi(A^T)w_1 \mid \Psi \in \mathcal{P}_{n-1}\}. \end{aligned} \tag{2.8}$$

In particular, in view of (2.3), for $n = 1, \ldots, L$,

$$v_n = \Psi_{n-1}(A)v_1 \quad \text{and} \quad w_n = \Psi_{n-1}(A^T)w_1, \tag{2.9}$$

where $\Psi_{n-1} \in \mathcal{P}_{n-1}$ is a uniquely defined monic polynomial. Then, introducing the formal inner product

$$(2.10)\qquad (\Phi, \Psi) := \left(\Phi(A^T)w_1\right)^T (\Psi(A)v_1) = w_1^T \Phi(A)\Psi(A)v_1,$$

and using (2.1), (2.8), and (2.9), we can rewrite the biorthogonality condition (2.2) in terms of polynomials:

$$(2.11)\qquad (\Psi_{n-1}, \Psi) = 0 \quad \text{for all} \quad \Psi \in \mathcal{P}_{n-2}$$

and

$$(2.12)\qquad (\Psi_{n-1}, \Psi_{n-1}) \neq 0.$$

Note that, except for the Hermitian case, i.e., $A = A^H$ and $w_1 = \overline{v}_1$, the formal inner product (2.10) is indefinite. Therefore, in the general case, there exist polynomials $\Psi \neq 0$ with "length" $(\Psi, \Psi) = 0$ or even $(\Psi, \Psi) < 0$.

A polynomial $\Psi_{n-1} \in \mathcal{P}_{n-1}$ of exact degree $n-1$ that fulfills (2.11) is called a FOP (with respect to the formal inner product (2.10)); we refer the reader to, e.g., [3], [7], and [16]. Note that the condition (2.11) is empty for $n = 1$, and hence any $\Psi_0 = \gamma_0 \neq 0$ is a FOP of degree 0. From (2.11),

$$\Psi_{n-1}(\lambda) \equiv \gamma_0 + \gamma_1\lambda + \cdots + \gamma_{n-1}\lambda^{n-1}, \quad \text{where} \quad \gamma_{n-1} \neq 0,$$

is a FOP of degree $n-1$ if and only if its coefficients $\gamma_0, \ldots, \gamma_{n-1}$, are a nontrivial solution of the linear system

$$(2.13)\qquad \begin{bmatrix} \mu_0 & \mu_1 & \mu_2 & \cdots & \mu_{n-2} \\ \mu_1 & \iddots & & \iddots & \vdots \\ \mu_2 & & \iddots & & \vdots \\ \vdots & \iddots & & & \mu_{2n-5} \\ \mu_{n-2} & \cdots & \cdots & \mu_{2n-5} & \mu_{2n-4} \end{bmatrix} \begin{bmatrix} \gamma_0 \\ \gamma_1 \\ \gamma_2 \\ \vdots \\ \gamma_{n-2} \end{bmatrix} = -\gamma_{n-1} \begin{bmatrix} \mu_{n-1} \\ \mu_n \\ \mu_{n+1} \\ \vdots \\ \mu_{2n-3} \end{bmatrix}.$$

Here

$$\mu_j := w_1^T A^j v_1 = (1, \lambda^j), \qquad j = 0, 1, \ldots,$$

are the moments associated with (2.10). A FOP Ψ_{n-1} is called *regular* if it is uniquely determined by (2.11) up to a scalar, and it is said to be *singular* otherwise. We remark that FOPs of degree 0 are always regular. In particular, a regular FOP is unique if it is required to be monic. Moreover, singular FOPs occur if and only if the corresponding linear system (2.13) has a singular coefficient matrix, but is consistent for some $\gamma_{n-1} \neq 0$. If (2.13) is inconsistent when $\gamma_{n-1} \neq 0$, then no FOP Ψ_{n-1} exists. This case is referred to as *deficient*. By relaxing (2.11) slightly, one can define so-called *deficient FOPs* (see [16] for details). Simple examples (see, e.g., [12, §13]) show that the singular and deficient cases do indeed occur. Thus, regular FOPs need not exist for every degree $n-1$. We would like to stress that this phenomenon is due to the indefiniteness of (2.10). For a positive definite inner product $(\cdot,\cdot)$, unique monic formally orthogonal polynomials always exist, up to the degree equal to the grade of v_1 with respect to A. Such a definite inner product is induced in the Hermitian case $A = A^H$ and $w_1 = \overline{v_1}$. In this case, the FOPs are true orthogonal polynomials with respect to a positive weight whose support is a set of points on the real axis (see, e.g., [26]). In addition, they have real coefficients and therefore

$$(\Psi, \Psi) = w_1^T \Psi(A)\Psi(A)v_1 = v_1^H \overline{\Psi}(A^H)\Psi(A)v_1 = \|\Psi(A)v_1\|^2 .$$

Finally, given a regular FOP Ψ_{n-1}, it is easily checked whether a regular FOP of degree n exists. Indeed, using (2.13), one readily obtains the following lemma.

LEMMA 2.1. *Let Ψ_{n-1} be a regular* FOP *(with respect to the formal inner product* (2.10)) *of degree $n-1$. Then, a regular* FOP *of degree n exists if and only if* (2.12) *is satisfied.*

Let us return to the standard nonsymmetric Lanczos process (2.3). Using (2.7), (2.9), (2.10), and Lemma 2.1, we conclude that a serious breakdown occurs if and only if no regular FOP exists for some $L < L_\star$. In this case, the termination index L is the smallest integer L for which there exists no regular FOP of degree L.

On the other hand, there is a maximal subset of indices

$$(2.14) \quad \{n_1, n_2, \ldots, n_J\} \subseteq \{1, 2, \ldots, L_\star\}, \qquad n_1 := 1 < n_2 < \cdots < n_J \le L_\star,$$

such that, for each $j = 1, 2, \ldots, J$, there exists a monic regular FOP $\Psi_{n_j - 1} \in \mathcal{P}_{n_j - 1}$. Note that $n_1 = 1$ since $\Psi_0(\lambda) \equiv 1$ is a monic regular FOP of degree 0. It is well known [7], [15] that three successive regular FOPs $\Psi_{n_{j-1}-1}$, $\Psi_{n_j - 1}$, and $\Psi_{n_{j+1}-1}$ are connected via a three-term recurrence. Consequently, setting, in analogy to (2.9),

$$v_{n_j} = \Psi_{n_j - 1}(A)v_1 \quad \text{and} \quad w_{n_j} = \Psi_{n_j - 1}(A^T)w_1,$$

we obtain two sequences of vectors $\{v_{n_j}\}_{j=1}^J$ and $\{w_{n_j}\}_{j=1}^J$ which can be computed by means of three-term recurrences. These vectors will be called *regular* vectors, since they correspond to regular FOPs. Note that the starting vectors v_1 and w_1 are always regular. The look-ahead Lanczos procedure is an extension of the classical nonsymmetric Lanczos algorithm; in exact arithmetic, it generates the vectors v_{n_j} and w_{n_j}, $j = 1, \ldots, J$. If $n_J = L_\star$ in (2.14), then these vectors can be complemented to a basis for an A-invariant or A^T-invariant subspace of $\mathbb{C}^N$. An incurable breakdown occurs if and only if $n_J < L_\star$ in (2.14). Finally, note that

$$w_{n_j}^T v = w^T v_{n_j} = 0 \quad \text{for all} \quad v \in K_{n_j - 1}(v_1, A), \; w \in K_{n_j - 1}(w_1, A^T), \quad j = 1, \ldots, J.$$

The look-ahead procedure we have sketched so far only skips over exact breakdowns. It yields what is called the *nongeneric* Lanczos algorithm in [16]. Of course, in finite-precision arithmetic, the look-ahead Lanczos algorithm also needs to leap over near-breakdowns. Roughly speaking, a robust implementation should attempt to generate only the "well-defined" regular vectors. In practice, then, one aims to generate two sequences of vectors $\{v_{n_{j_k}}\}_{k=1}^K$ and $\{w_{n_{j_k}}\}_{k=1}^K$ where

$$(2.15) \qquad \{n_{j_k}\}_{k=1}^K \subseteq \{n_j\}_{j=1}^J, \qquad j_1 := 1,$$

is a suitable subset of (2.14). We set $j_1 = 1$, since v_1 and w_1 are always regular. The problem of how to determine the set (2.15) of indices of the "well-defined" regular vectors will be addressed in detail in §4.

In order to obtain complete bases for the subspaces $K_n(v_1, A)$ and $K_n(w_1, A^T)$, we need to add vectors

$$(2.16) \quad \begin{aligned} &v_n \in K_n(v_1, A) \setminus K_{n-1}(v_1, A) \quad \text{and} \quad w_n \in K_n(w_1, A^T) \setminus K_{n-1}(w_1, A^T), \\ &\qquad\qquad n = n_{j_{k-1}} + 1, \ldots, n_{j_k} - 1, \qquad k = 2, 3, \ldots, K, \end{aligned}$$

to the two sequences $\{v_{n_{j_k}}\}_{k=1}^K$ and $\{w_{n_{j_k}}\}_{k=1}^K$, respectively. Clearly, (2.16) guarantees that (2.1) remains valid for the look-ahead Lanczos algorithm. The vectors in (2.16) are called *inner* vectors. Moreover, for each k, the vectors v_n, $n = n_{j_k}, n_{j_k}+1, \ldots, n_{j_{k+1}}-1$, and correspondingly for w_n, are referred to as the kth *block*. The inner vectors of a block built because of an exact breakdown correspond to singular or deficient FOPs, while the inner vectors of a block built because of a near-breakdown correspond to polynomials that in general are combinations of regular, singular, and deficient FOPs. We will refer to both the regular and the inner vectors v_n and w_n generated by the look-ahead variant as right and left Lanczos vectors, in analogy to the terminology of the standard nonsymmetric Lanczos algorithm.

So far, we have not specified how to actually construct the inner vectors. The point is that the inner vectors can be chosen such that the v_n's and w_n's from blocks corresponding to different indices k are still biorthogonal to each other. More precisely, with $V^{(n)}$ and $W^{(n)}$ defined as in (2.4), we have, in analogy to (2.6),

$$(2.17)\qquad (W^{(n)})^T V^{(n)} = D^{(n)}, \quad n = n_{j_l}-1, \quad l = 2,3,\ldots,K.$$

Here, $D^{(n)}$ is now a nonsingular block diagonal matrix with $l-1$ blocks of respective size $(n_{j_{k+1}}-n_{j_k})\times(n_{j_{k+1}}-n_{j_k})$, $k = 1,\ldots,l-1$. Similarly, (2.5) holds, for $n = n_{j_l}-1$, $l = 2,3,\ldots,K$, where $H^{(n)}$ is now a block tridiagonal matrix with diagonal blocks of size $(n_{j_{k+1}}-n_{j_k})\times(n_{j_{k+1}}-n_{j_k})$, $k = 1,\ldots,l-1$ (cf. (3.4)–(3.5)).

There are two fundamentally different approaches for constructing inner vectors with the property (2.17). In both cases, inner vectors are first generated using a simple three-term recurrence. However, in the first approach, each inner vector in a block is then biorthogonalized against the previous block as soon as it is constructed. This variant will be called the *sequential algorithm*. In the second approach, all the inner vectors in a block are first constructed using the three-term recurrence, and then the entire block is biorthogonalized against the previous block and possibly, depending on the size of the current block, against vectors from blocks further back. This variant will be called the *block algorithm*. The sequential algorithm is more suitable for a serial computer, while the block algorithm is more suitable for a parallel computer. In this paper, we describe only the sequential algorithm and its implementation. A sketch of the block algorithm can be found in [11]. Details of an actual implementation and numerical results will be presented elsewhere.

Finally, two more notes. First, the inner product (2.10) could have been defined as

$$(2.18)\qquad (\Phi,\Psi) := \left(\overline{\Phi}(A^H)\overline{w_1}\right)^H (\Psi(A)v_1) = \overline{w_1}^H \Phi(A)\Psi(A)v_1,$$

and the algorithm could be formulated equally well in either terms. Second, in the rest of the paper, we will use the notation $n_k := n_{j_k}$ for the indices of the "well-defined" regular vectors. However, notice that there is no guarantee that the indices n_k generated by the look-ahead Lanczos algorithm in finite-precision arithmetic actually satisfy (2.15).

3. The sequential algorithm. In this section, we start the discussion of the sequential Lanczos algorithm with look-ahead. We present a sketch of the algorithm and its basic properties, then discuss some aspects related to its practical implementation in the next two sections.

First, we introduce some notation. As in the last section, $n = 1,2,\ldots,$ denote the indices of the Lanczos vectors v_n and w_n. The index $k = 1,2,\ldots,$ is used as a counter for the blocks built by the look-ahead algorithm. Moreover, we always use $l = l(n)$ to denote the index of the block which contains the Lanczos vectors v_n and w_n. Recall that by n_k we denote the indices of the computed regular vectors, which are always the first vectors in each block k. Thus, n_l is the index of the last computed regular vector with index $\leq n$. We have $n_1 = 1$. Capital letters with subscript k denote the matrices containing quantities from block k. For example,

$$V_k := \begin{bmatrix} v_{n_k} & v_{n_k+1} & \cdots & v_{n_{k+1}-1} \end{bmatrix}$$

is the matrix whose columns are the Lanczos vectors from a completed block k. Capital letters with superscripts $^{(n)}$ denote matrices containing quantities from steps 1 through n, as in (2.4). With this notation, the matrix form of the sequential algorithm with look-ahead is similar to (2.5)–(2.6)

$$\begin{aligned} AV^{(n)} &= V^{(n)}H^{(n)} + \begin{bmatrix} 0 & \cdots & 0 & v_{n+1} \end{bmatrix}, \\ A^TW^{(n)} &= W^{(n)}H^{(n)} + \begin{bmatrix} 0 & \cdots & 0 & w_{n+1} \end{bmatrix}, \end{aligned} \tag{3.1}$$

and

$$(W^{(n)})^TV^{(n)} = D^{(n)}. \tag{3.2}$$

Here

$$D^{(n)} = \operatorname{diag}(\delta_1, \delta_2, \ldots, \delta_l), \quad \delta_k := W_k^TV_k, \quad k = 1, 2, \ldots, l = l(n), \tag{3.3}$$

is block diagonal, and the blocks $\delta_1, \delta_2, \ldots, \delta_{l-1}$ are nonsingular. If $n = n_{l+1} - 1$, then the lth block, δ_l, in (3.3) is also nonsingular and it is called *complete*. In particular, if δ_l is complete, then $D^{(n)}$ itself is nonsingular, and (3.3) reduces to (2.17). In this case, the next regular vectors $v_{n_{l+1}}$ and $w_{n_{l+1}}$ can be computed and start a new block.

In (3.1),

$$H^{(n)} = \begin{bmatrix} \alpha_1 & \beta_2 & 0 & \cdots & 0 \\ \gamma_2 & \alpha_2 & \ddots & \ddots & \vdots \\ 0 & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \beta_l \\ 0 & \cdots & 0 & \gamma_l & \alpha_l \end{bmatrix} \tag{3.4}$$

is an $n \times n$ block tridiagonal upper Hessenberg matrix with blocks of the form

$$\alpha_k = \begin{bmatrix} * & \cdots & \cdots & \cdots & * \\ 1 & \ddots & & & \vdots \\ 0 & \ddots & \ddots & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & 1 & * \end{bmatrix}, \qquad \gamma_k = \begin{bmatrix} 0 & \cdots & \cdots & 0 & 1 \\ \vdots & \ddots & & & 0 \\ \vdots & & \ddots & & \vdots \\ \vdots & & & \ddots & \vdots \\ 0 & \cdots & \cdots & \cdots & 0 \end{bmatrix}, \tag{3.5}$$

while the β_k's are in general full matrices. Note that here we violate the Householder conventions by using small Greek letters to denote quantities which may be matrices. The justification is that in general the algorithm takes regular steps, and hence these quantities are usually scalars. Let $h_k := n_{k+1} - n_k$, $k = 1, 2, \ldots$, be the size of the kth block. For $k < l = l(n)$ the matrices α_k, β_k, and γ_k are of size $h_k \times h_k$, $h_{k-1} \times h_k$, and $h_k \times h_{k-1}$, respectively. In general, however, the lth block need not be complete. Hence, the matrices α_l, β_l, and γ_l corresponding to the current (lth) block are of size $\tilde{h}_l \times \tilde{h}_l$, $h_{l-1} \times \tilde{h}_l$, and $\tilde{h}_l \times h_{l-1}$, respectively, where $\tilde{h}_l := n + 1 - n_l$.

We will assume that the inner vectors in a block are generated using a three-term recursion of the form

$$\begin{aligned} v_{n+1} &= Av_n - \zeta_n v_n - \eta_n v_{n-1}, \\ w_{n+1} &= A^T w_n - \zeta_n w_n - \eta_n w_{n-1}, \end{aligned} \tag{3.6}$$

where ζ_n and η_n are recursion coefficients and $\eta_{n_k} = 0$, $k = 1, 2, \ldots$. One may choose these coefficients so that they remain the same from one block to the next and change only with respect to their index inside the block, $n - n_k$, or one may choose these coefficients so that they change from one block to the next. For instance, one practical choice for the polynomials in (3.6) are suitably scaled and translated Chebyshev polynomials, so that the inner vectors are generated by the Chebyshev iteration [22]. In this case, the translation parameters could be adjusted using spectral information obtained from previous Lanczos steps. We do not necessarily advocate the use of fancy recursions in (3.6). From our experience, the algorithm we propose builds very small blocks, typically of size 2 or 3. Except for p-cyclic matrices (cf. Example 6.3 in §6) or contrived examples, the largest block we observed in test runs with "real-life" matrices was of size 4. It occurred for a matrix arising in oil-reservoir simulations where out of 1500 steps, the algorithm built 2×2 blocks 49 times, 3×3 blocks 7 times, and one 4×4 block (see [13, Ex. 2]). Hence, the recursion in (3.6) is not overly important, and in our experiments, we have used the recursion coefficients $\zeta_n = 1$ and, if $n \neq n_k$, $\eta_n = 1$. On the other hand, for the block version of the algorithm, where larger blocks are built, more attention needs to be paid to the recursion used. As indicated, details of the block algorithm will be presented elsewhere. Finally, one could consider orthogonalizing (in the Euclidean sense) the right, respectively, left, Lanczos vectors within each block. However, for the blocks we have seen built, such an orthogonalization process did not lead to better numerical properties of the algorithm. Therefore, in view of the additional inner products that need to be computed, orthogonalizing within each block is not justified.

In practice, for reasons of stability, one computes scaled versions of the right and left Lanczos vectors, rather than the "monic" vectors v_n and w_n corresponding to monic FOPs. A proven choice (see [25] and [27]) is to scale the Lanczos vectors to have unit length. We denote by $\hat{v}_n$ and $\hat{w}_n$ the scaled versions defined by

$$\hat{v}_n := v_n / \|v_n\| \quad \text{and} \quad \hat{w}_n := w_n / \|w_n\|,$$

and more generally, we will denote by hat ($\hat{}$) quantities containing or depending on the scaled vectors. For example, setting

$$\hat{H}^{(n)} := \operatorname{diag}(\|v_1\|, \|v_2\|, \ldots, \|v_n\|) H^{(n)} \operatorname{diag}(1/\|v_1\|, 1/\|v_2\|, \ldots, 1/\|v_n\|),$$

$$\hat{H}_e^{(n)} := \begin{bmatrix} \hat{H}^{(n)} \\ \rho_{n+1} e_n^T \end{bmatrix}, \quad \rho_{n+1} := \frac{\|v_{n+1}\|}{\|v_n\|}, \quad e_n := [0 \quad \cdots \quad 0 \quad 1]^T \in \mathbb{R}^n,$$

we can rewrite the first relation in (3.1) in terms of scaled vectors as follows:

$$A\hat{V}^{(n)} = \hat{V}^{(n+1)} \hat{H}_e^{(n)}. \tag{3.7}$$

With this note, we now present a sketch of the sequential Lanczos algorithm with look-ahead.

```
ALGORITHM 3.1 (SEQUENTIAL LANCZOS ALGORITHM WITH LOOK-AHEAD).
(0) Choose $\hat{v}_1,\ \hat{w}_1 \in \mathbb{C}^N$ with $\|\hat{v}_1\| = \|\hat{w}_1\| = 1$;
    Set $\hat{V}_1 = \hat{v}_1,\ \hat{W}_1 = \hat{w}_1,\ \hat{\delta}_1 = \hat{W}_1^T \hat{V}_1$;
    Set $n_1 = 1,\ l = 1,\ \hat{v}_0 = \hat{w}_0 = 0,\ \hat{V}_0 = \hat{W}_0 = \emptyset,\ \rho_1 = \xi_1 = 1$;
For $n = 1, 2, \ldots$ :
(1) Decide whether to construct $\hat{v}_{n+1}$ and $\hat{w}_{n+1}$ as regular or inner vectors
    and go to (2) or (3), respectively;
(2) (Regular step.) Compute
```

$$\begin{aligned} \tilde{v}_{n+1} &= A\hat{v}_n - \hat{V}_l\ \hat{\delta}_l^{-1}\hat{W}_l^T A\hat{v}_n - \hat{V}_{l-1}\hat{\delta}_{l-1}^{-1}\hat{W}_{l-1}^T A\hat{v}_n, \\ \tilde{w}_{n+1} &= A^T\hat{w}_n - \hat{W}_l\ \hat{\delta}_l^{-T}\hat{V}_l^T A^T\hat{w}_n - \hat{W}_{l-1}\hat{\delta}_{l-1}^{-T}\hat{V}_{l-1}^T A^T\hat{w}_n, \end{aligned} \tag{3.8}$$

```
    set $n_{l+1} = n + 1,\ l = l + 1,\ \hat{V}_l = \hat{W}_l = \emptyset$, and go to (4);
(3) (Inner step.) Compute
```

$$\begin{aligned} \tilde{v}_{n+1} &= A\hat{v}_n - \zeta_n\hat{v}_n - (\eta_n/\rho_n)\,\hat{v}_{n-1} - \hat{V}_{l-1}\hat{\delta}_{l-1}^{-1}\hat{W}_{l-1}^T A\hat{v}_n, \\ \tilde{w}_{n+1} &= A^T\hat{w}_n - \zeta_n\hat{w}_n - (\eta_n/\xi_n)\,\hat{w}_{n-1} - \hat{W}_{l-1}\hat{\delta}_{l-1}^{-T}\hat{V}_{l-1}^T A^T\hat{w}_n; \end{aligned} \tag{3.9}$$

```
(4) Compute $\rho_{n+1} = \|\tilde{v}_{n+1}\|$ and $\xi_{n+1} = \|\tilde{w}_{n+1}\|$;
    If $\rho_{n+1} = 0$ or $\xi_{n+1} = 0$, stop;
    Otherwise, set
```

$$\begin{aligned} &\hat{v}_{n+1} = \tilde{v}_{n+1}/\rho_{n+1}, \quad \hat{w}_{n+1} = \tilde{w}_{n+1}/\xi_{n+1}, \\ &\hat{V}_l = [\,\hat{V}_l \quad \hat{v}_{n+1}\,], \quad \hat{W}_l = [\,\hat{W}_l \quad \hat{w}_{n+1}\,], \quad \hat{\delta}_l = \hat{W}_l^T\hat{V}_l; \end{aligned} \tag{3.10}$$

```
(5) Add the nonzero elements of the nth column to $\hat{H}^{(n)}$
    and set $(\hat{H}_e^{(n)})_{n+1,n} = \rho_{n+1}$.
```

Note that, if $\hat{v}_{n+1}$ and $\hat{w}_{n+1}$ are inner vectors, the size of the current incomplete block l is increased by 1; if they are regular vectors, then the lth block is complete and a new block, the $(l+1)$st, is started, with $\hat{v}_{n+1}$ and $\hat{w}_{n+1}$ as its first vectors. Finally, we remark that, in view of (3.7), the nonzero elements of the nth column of $\hat{H}^{(n)}$ occur as coefficients in the first recursion of (3.8), respectively, (3.9).

4. Building blocks.

In this section, we discuss the criteria used in step (1) of Algorithm 3.1 to decide whether a pair of Lanczos vectors $\hat{v}_{n+1}$ and $\hat{w}_{n+1}$ is built as inner vectors or as regular vectors. We propose three criteria, namely, (4.3), (4.4), and (4.5) below. If all three checks (4.3)–(4.5) are satisfied, then $\hat{v}_{n+1}$ and $\hat{w}_{n+1}$ are constructed as regular vectors; otherwise, they are constructed as inner vectors. Let us motivate these three criteria.

First, recall (cf. (3.3)) that for $\hat{v}_{n+1}$ and $\hat{w}_{n+1}$ to be built as regular vectors it is necessary that $\hat{\delta}_l$ be nonsingular. Therefore, it is tempting to base the decision "regular versus inner step" solely on checking whether $\hat{\delta}_l$ is close to singular, and to perform a regular step if and only if

$$\sigma_{\min}(\hat{\delta}_{l(n)}) \geq \text{tol}, \tag{4.1}$$

for some suitably chosen tolerance tol. For example, Parlett [23] suggests tol $= \epsilon^{1/4}$ or tol $= \epsilon^{1/3}$, where ϵ denotes the roundoff unit. Then (4.1) would guarantee that complete blocks of computed Lanczos vectors satisfy

$$\sigma_{\min}(\hat{\delta}_k) \geq \text{tol}, \qquad k = 1, 2, \ldots.$$

This, together with (3.3), would imply by [23, Thm. 10.1] that

$$\sigma_{\min}(\hat{V}^{(n)}) \geq \frac{\text{tol}}{\sqrt{n}} \quad \text{and} \quad \sigma_{\min}(\hat{W}^{(n)}) \geq \frac{\text{tol}}{\sqrt{n}}, \quad n = n_k - 1, \quad k = 1, 2, \ldots. \tag{4.2}$$

Since the columns of $\hat{V}^{(n)}$ and $\hat{W}^{(n)}$ are unit vectors, $\sigma_{\min}(\hat{V}^{(n)})$ and $\sigma_{\min}(\hat{W}^{(n)})$ are a measure of the linear independence of these vectors; in particular, (4.2) would ensure that the Lanczos vectors remain linearly independent. However, in the outlined algorithm, the block orthogonality (3.2)–(3.3) is enforced only among two or three successive blocks, and in finite-precision arithmetic, biorthogonality of blocks whose indices are far apart is typically lost. The theorem assumes that (3.2)–(3.3) hold for all indices, and without this, the theorem fails in finite arithmetic. We illustrate this with a simple example.

Example 4.1. In Fig. 4.1, we plot $\sigma_{\min}(\hat{\delta}_{l(n)})$ (dots), $\min_{1\leq k<l(n)}(\sigma_{\min}(\hat{\delta}_k))$ (solid line), and $\sqrt{n}\,\sigma_{\min}(\hat{V}^{(n)})$ (dotted line), as functions of the iteration index $n = 1, 2, \ldots$, for a random 50×50 dense matrix. The theorem predicts that

$$\sqrt{n}\,\sigma_{\min}(\hat{V}^{(n)}) \geq \min_{1\leq k<l(n)}(\sigma_{\min}(\hat{\delta}_k)),$$

which is clearly not the case.

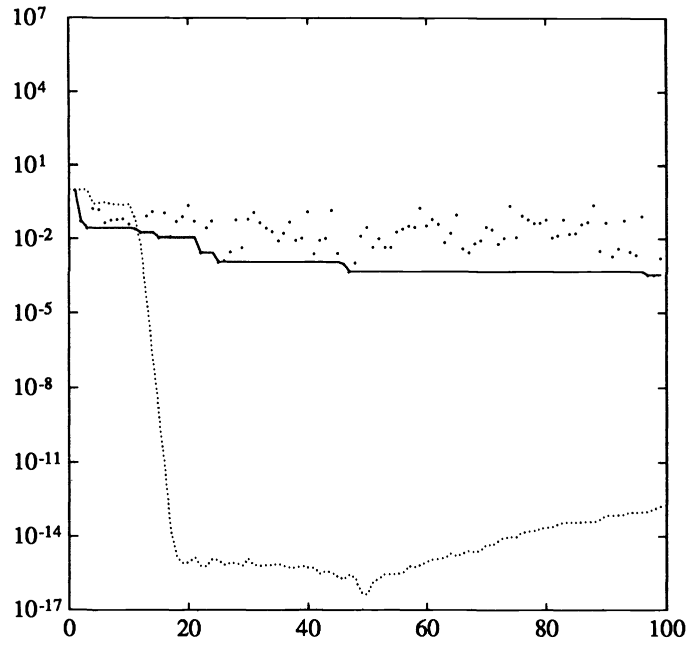

FIG. 4.1. $\sigma_{\min}(\hat{\delta}_{l(n)})$ *(dots),* $\min_{1\leq k<l(n)}(\sigma_{\min}(\hat{\delta}_k))$ *(solid line), and* $\sqrt{n}\,\sigma_{\min}$ $(\hat{V}^{(n)})$ *(dotted line), plotted versus the iteration index n.*

As this simple example shows, the check (4.1) alone does not ensure that the computed Lanczos vectors are sufficiently linearly independent. In particular, if the look-ahead strategy is based only on criterion (4.1), the algorithm may produce within a block Lanczos vectors that are almost linearly dependent. When this happens, the check (4.1) usually fails in all subsequent iterations and thus the algorithm never completes the current block, i.e., it has generated an *artificial* incurable breakdown.

In addition, numerical experience indicates another problem with (4.1): for values of tol that are "reasonably" larger than machine epsilon, the behavior of the algorithm is very sensitive with respect to the actual value of tol. We also illustrate this with an example.

Example 4.2. We applied the Lanczos algorithm to a nonsymmetric matrix A obtained from discretizing a three-dimensional partial differential equation (cf. Example 6.5 in §6). This example was run on a machine with $\epsilon \approx$ 1.3E-29. In the first case, we set tol $= \epsilon^{1/4} \approx$ 6.0E-08, while in the second case, we set tol $= \epsilon^{1/3} \approx$ 2.3E-10. In Fig. 4.2, we plot $\sigma_{\min}(\hat{\delta}_{l(n)})$ versus the iteration index n for the two runs, the dotted line for $\epsilon^{1/4}$ and the solid line for $\epsilon^{1/3}$. In the first case, the algorithm starts building a block that it never closes, and the singular values clearly become smaller and smaller. Yet if tol is only slightly smaller, as in the second case, the algorithm runs to completion, in this case solving the linear system to the desired accuracy, and thus indicating that the block built in the first case was not a true, but an artificial incurable breakdown.

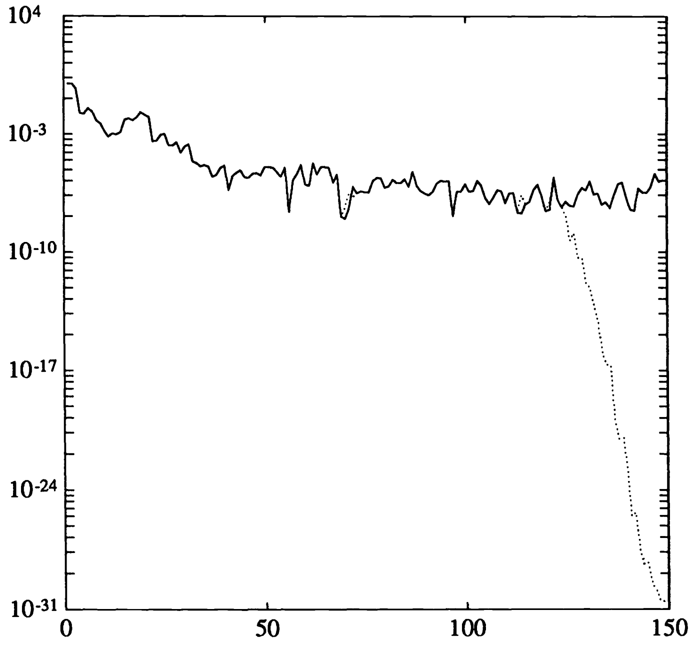

FIG. 4.2. $\epsilon^{1/4}$ *(dotted line) and* $\epsilon^{1/3}$ *(solid line), plotted versus the iteration index* n.

We note that the sensitivity of look-ahead procedures to the choice of tolerances, such as tol in (4.1), was also observed in [5]. However, no remedy for this phenomenon is given in [5]. Furthermore, we remark that the problem of generating almost linearly dependent vectors is not specific to the Lanczos biorthogonalization process. Indeed, similar effects can also occur in true orthogonalization methods (cf. [28]).

Examples 4.1 and 4.2 clearly show that the decision "regular versus inner step" cannot be based on (4.1) alone. Instead, we propose to relax the check (4.1), so that it merely ensures that $\hat{\delta}_{l(n)}$ is numerically nonsingular, and to add the checks (4.4)–(4.5) below, which guarantee that the computed Lanczos vectors remain sufficiently linearly independent. Hence, instead of (4.1), we check for

$$\sigma_{\min}(\hat{\delta}_{l(n)}) \geq \epsilon, \tag{4.3}$$

where ϵ denotes the roundoff unit.

Our numerical experiments have shown that typically the algorithm starts to generate Lanczos vectors which are almost linearly dependent, once a regular vector $\hat{v}_{n+1}$ was computed whose component $A\hat{v}_n \in K_{n+1}(v_1, A)$ is dominated by its component in the previous Krylov space $K_n(v_1, A)$ (and similarly for $\hat{w}_{n+1}$). In order to avoid the construction of such regular vectors, we check the l_1-norm of the coefficients for $\hat{V}_{l-1}$ and $\hat{V}_l$ in (3.8); $\hat{v}_{n+1}$ can be computed as a regular vector only if

$$\sum_{j=n_{l-1}}^{n_l-1} \left|(\hat{\delta}_{l-1}^{-1}\hat{W}_{l-1}^T A\hat{v}_n)_j\right| \leq n(A) \quad \text{and} \quad \sum_{j=n_l}^{n} \left|(\hat{\delta}_l^{-1}\hat{W}_l^T A\hat{v}_n)_j\right| \leq n(A). \tag{4.4}$$

Here $n(A)$ is a factor depending on the norm of A; we will indicate later how this factor is computed. Similarly, we check the l_1-norm of the coefficients for $\hat{W}_{l-1}$ and $\hat{W}_l$ in (3.8); $\hat{w}_{n+1}$ can be computed as a regular vector only if

$$\sum_{j=n_{l-1}}^{n_l-1} \left|(\hat{\delta}_{l-1}^{-T}\hat{V}_{l-1}^T A^T\hat{w}_n)_j\right| \leq n(A) \quad \text{and} \quad \sum_{j=n_l}^{n} \left|(\hat{\delta}_l^{-T}\hat{V}_l^T A^T\hat{w}_n)_j\right| \leq n(A). \tag{4.5}$$

The pair $\hat{v}_{n+1}$ and $\hat{w}_{n+1}$ is built as regular vectors only if the checks (4.3)–(4.5) hold true.

We need to indicate how $n(A)$ is chosen in (4.4)–(4.5). Numerical experience with matrices whose norm is known indicates that setting $n(A) = \|A\|$ is too strict and can result in artificial incurable breakdowns. A better setting seems to be $n(A) = 10 \cdot \|A\|$, but even this is dependent on the matrix. In any case, in practice one does not know $\|A\|$, and there is also the issue of a maximal block size, determined by limits on available storage. To solve the problems of estimating the norms and a suitable factor $n(A)$, as well as cope with limited storage and yet allow the algorithm to proceed as far as possible, we propose the following procedure. Suppose we are given an initial value for $n(A)$, based either on an estimate from the user (for example, $n(A)$ from a previous run with the matrix A), or by setting

$$n(A) = \max\left\{\|A\hat{v}_1\|, \|A^T\hat{w}_1\|\right\}.$$

Note that here A denotes the matrix actually used in generating the Lanczos vectors, thus including the case when we are solving a preconditioned linear system. We then update $n(A)$ dynamically, as follows. In each block, whenever an inner vector is built because one of the checks (4.4)–(4.5) is not satisfied, the algorithm keeps track of the size of the terms that have caused one or more of (4.4)–(4.5) to be false. If the block closes naturally, then this information is not needed. If, however, the algorithm is about to run out of storage, then $n(A)$ is replaced with the smallest value which has caused an inner vector to be built. The updated value of $n(A)$ is guaranteed to pass the checks (4.4)–(4.5) at least once, and hence the block is guaranteed to close. This also frees up the storage that was used by the previous block, thus ensuring that the algorithm can proceed.

5. Implementation details. We now turn to a few implementation details. In particular, we wish to show how one can implement the sequential algorithm with the same number of inner products per step as the classical Lanczos algorithm. For a regular step, one needs to compute $\hat{\delta}_l$, $\hat{W}_l^T A\hat{v}_n$, and $\hat{W}_{l-1}^T A\hat{v}_n$ in (3.8). For an inner step, one needs to compute $\hat{W}_{l-1}^T A\hat{v}_n$ in (3.9) and to update $\hat{\delta}_l$ in (3.10). We will show that for a block of size h_l, only $2h_l$ inner products are required: $2h_l - 1$ will be required to compute $\hat{\delta}_l$, and one inner product will be required to compute $\hat{W}_l^T A\hat{v}_n$. We will obtain $\hat{W}_{l-1}^T A\hat{v}_n$ without performing any inner products. To simplify the derivations, we will use the "monic" vectors v_n and w_n. All quantities involving the scaled vectors $\hat{v}_n$ and $\hat{w}_n$ can be obtained from the corresponding quantities involving v_n and w_n simply by scaling. Finally, we remark that, using a similar argument as in (5.1) below, one easily verifies that

$$W_l^T A v_n = V_l^T A^T w_n \quad \text{and} \quad W_{l-1}^T A v_n = V_{l-1}^T A^T w_n.$$

Therefore, the coefficients $\hat{\delta}_l^{-T}\hat{V}_l^T A^T \hat{w}_n$ and $\hat{\delta}_{l-1}^{-T}\hat{V}_{l-1}^T A^T \hat{w}_n$, which occur in the recursions for the left Lanczos vectors in (3.8) or (3.9), can be generated from $\hat{\delta}_l^{-1}\hat{W}_l^T A\hat{v}_n$ and $\hat{\delta}_{l-1}^{-1}\hat{W}_{l-1}^T A\hat{v}_n$, without computing any additional inner products.

First consider δ_l. Using (2.9) and the fact that polynomials in A commute, we deduce that

$$w_i^T v_j = w_1^T \Psi_i(A)\Psi_j(A)v_1 = w_1^T \Psi_j(A)\Psi_i(A)v_1 = w_j^T v_i. \tag{5.1}$$

This shows that the matrix δ_l is symmetric, and hence we only need to compute its upper triangle.

We will now show that once the diagonal and first superdiagonal of δ_l have been computed by inner products, the remaining upper triangle can be computed by recurrences. Let w_i and v_j be two vectors from the current block. Using (3.6) and the fact that the inner vectors from block l are orthogonal to the vectors from the previous block, we have

$$\begin{aligned} w_i^T v_j &= w_i^T (A v_{j-1} - \zeta_{j-1} v_{j-1} - \eta_{j-1} v_{j-2}) \\ &= (A^T w_i)^T v_{j-1} - \zeta_{j-1} w_i^T v_{j-1} - \eta_{j-1} w_i^T v_{j-2} \\ &= (w_{i+1} + \zeta_i w_i + \eta_i w_{i-1})^T v_{j-1} - \zeta_{j-1} w_i^T v_{j-1} - \eta_{j-1} w_i^T v_{j-2} \\ &= w_{i+1}^T v_{j-1} + \zeta_i w_i^T v_{j-1} + \eta_i w_{i-1}^T v_{j-1} - \zeta_{j-1} w_i^T v_{j-1} - \eta_{j-1} w_i^T v_{j-2}. \end{aligned}$$

Thus, $w_i^T v_j$ depends only on elements of δ_l from the previous two columns, and hence, with the exception of the diagonal and the first superdiagonal, can be computed without any additional inner products. Note that the recurrences and the orthogonality used in the above derivation are enforced numerically, and so computing $w_i^T v_j$ by the above recurrence should give the same results—up to roundoff—as computing the inner product directly.

We will now show how to compute $W_l^T A v_n$ with only one additional inner product, while $W_{l-1}^T A v_n$ can be obtained with no additional inner products. Consider $w_i^T A v_n$, for w_i a vector from either the current or the previous block. Then, we have

$$\begin{aligned} w_i^T A v_n &= (A^T w_i)^T v_n = (w_{i+1} + \zeta_i w_i + \eta_i w_{i-1})^T v_n \\ &= w_{i+1}^T v_n + \zeta_i w_i^T v_n + \eta_i w_{i-1}^T v_n. \end{aligned}$$

For $i < n_l - 1$, $W_{l-1}^T v_n = 0$, and hence $w_i^T A v_n = 0$. For $i = n_l - 1$, the above reduces to $w_{n_l-1}^T A v_n = w_{n_l}^T v_n$, which is computed as part of the first row of δ_l. For $n_l \le i < n_{l+1}$, all of the terms needed are available from δ_l. Finally, for the last vector in the current block, $i = n_{l+1} - 1$, we do not have $w_{n_{l+1}}^T v_n$, and hence have to compute it directly, thus requiring another inner product.

6. Numerical examples.

We have performed extensive numerical experiments with our implementation of the look-ahead Lanczos algorithm, both for eigenvalue problems and for the solution of linear systems. In this section, we present a few typical results of these experiments. Further numerical results are reported in [12] and [13].

Approximations to the eigenvalues of A can be obtained from the look-ahead Lanczos algorithm by computing some or all of the eigenvalues of the Lanczos matrix $\hat{H}^{(n)}$, the so-called *Ritz values*. In general, *spurious* approximate eigenvalues, caused by a loss of orthogonality among the Lanczos vectors, can occur among the Ritz values. This phenomenon is not due to the nonsymmetry of the matrix A; indeed, it also appears in the symmetric Lanczos process. We have used the heuristic due to Cullum and Willoughby [6] to identify and eliminate spurious Ritz values. Although this procedure was originally proposed for the scalar tridiagonal matrices generated by the standard Lanczos process, we also found it to work satisfactorily for the block tridiagonal matrices $\hat{H}^{(n)}$ produced by the look-ahead Lanczos algorithm. The eigenvalues of $\hat{H}^{(n)}$ were always computed using standard EISPACK routines.

For the solution of nonsingular linear systems

$$Ax = b, \tag{6.1}$$

we combine the look-ahead Lanczos algorithm with the QMR approach. More precisely, let $x_0 \in \mathbb{C}^N$ be any initial guess for (6.1) and choose the normalized starting residual vector

$$\hat{v}_1 := r_0/\rho_0, \qquad r_0 := b - Ax_0, \qquad \rho_0 := \|r_0\|,$$

as the first right Lanczos vector in Algorithm 3.1. The QMR method then generates approximate solutions to (6.1) defined by

$$x_n = x_0 + \hat{V}^{(n)} z_n, \qquad n = 1, 2, \ldots, \tag{6.2}$$

where z_n is the solution of the least-squares problem

$$\min_{z \in \mathbb{C}^n} \left\| \rho_0 e_1 - \hat{H}_e^{(n)} z \right\|, \qquad e_1 := [1 \quad 0 \quad \cdots \quad 0]^T \in \mathbb{R}^{(n+1)}. \tag{6.3}$$

We remark that, using (3.7), one easily verifies that the residual vector corresponding to the iterate (6.2) satisfies

$$r_n := b - Ax_n = \hat{V}^{(n+1)} \left(\rho_0 e_1 - \hat{H}_e^{(n)} z_n \right). \tag{6.4}$$

Thus the choice (6.3) of z_n just guarantees that the Euclidean norm of the coefficient vector in the representation (6.4) is minimal. For details and further properties of the QMR method, we refer to [13].

Example 6.1. This example is an eigenvalue problem, taken from [6]. Consider the differential operator

$$\begin{aligned} Lu := &-\frac{\partial}{\partial x}\left(e^{-xy}\frac{\partial u}{\partial x}\right) - \frac{\partial}{\partial y}\left(e^{xy}\frac{\partial u}{\partial y}\right) \\ &+ 20(x+y)\frac{\partial u}{\partial x} + 20\frac{\partial}{\partial x}\left((x+y)u\right) + \frac{1}{1+x+y}u \end{aligned} \tag{6.5}$$

on the unit square $(0,1) \times (0,1)$. We discretize (6.5) using centered differences on a 29×29 grid with mesh size $h = 1/30$. This leads to a nonsymmetric matrix of order $N = 900$. Unit vectors with random entries were used as starting vectors $\hat{v}_1$, $\hat{w}_1$ for Algorithm 3.1. The look-ahead Lanczos process was run for 320 steps, during which it built seven blocks of size 2. In Fig. 6.1, we plot the Ritz values (marked by "o") generated by the look-ahead Lanczos process after n = 40, 80, 160, 320 steps. We note that after 40 steps, the complex conjugate pair of Ritz values with maximal real part had converged to eigenvalues of A. After 80 steps, 12 Ritz values (all on the right edge of the spectrum) had converged, while after 160 steps the 30 Ritz values (24 on the right edge and 6 on the left edge of the spectrum) had converged to eigenvalues of A. In many cases, the standard and the look-ahead Lanczos procedures give similar results. In particular, for this example, the results obtained from both the standard and the look-ahead Lanczos algorithm match those reported in [6].

Example 6.2. This example is an eigenvalue problem, taken from [24], whose exact eigenvalues are known. Generally, problems of this type arise in modeling concentration waves in reaction and transport interaction of chemical solutions in a tubular reactor. The particular test problem used here corresponds to the so-called Brusselator wave model. This example was run for a matrix A of size $N = 100$. Again, unit vectors with random entries were used as starting vectors $\hat{v}_1$, $\hat{w}_1$. The look-ahead Lanczos algorithm needs $n = 112$ steps to obtain all the eigenvalues of A; it built two blocks of size 2. For this example, we have also run the standard Lanczos process without look-ahead, and computed the Ritz values after n = 100, 112, 120 steps. The denominators $\hat{w}_n^T\hat{w}_n$ were checked to exceed $\sqrt{\epsilon}$ in magnitude. In all three cases, some of the Ritz values obtained from the standard Lanczos process after deleting spurious eigenvalues do not correspond to any of the eigenvalues of A. In particular, the standard Lanczos process does not obtain the smallest eigenvalues of A even after 120 steps, and generates incorrect Ritz values, as shown in the plot. In Fig. 6.2, we plot the Ritz values generated by the look-ahead Lanczos process (marked by "o") and the Ritz values generated by the standard Lanczos process (marked by "+"), both after 120 steps.

Example 6.3. Here we consider a 6-cyclic matrix

$$A = \begin{bmatrix} I_1 & 0 & 0 & 0 & 0 & B_1 \\ B_2 & I_2 & 0 & 0 & 0 & 0 \\ 0 & B_3 & I_3 & 0 & 0 & 0 \\ 0 & 0 & B_4 & I_4 & 0 & 0 \\ 0 & 0 & 0 & B_5 & I_5 & 0 \\ 0 & 0 & 0 & 0 & B_6 & I_6 \end{bmatrix}, \tag{6.6}$$

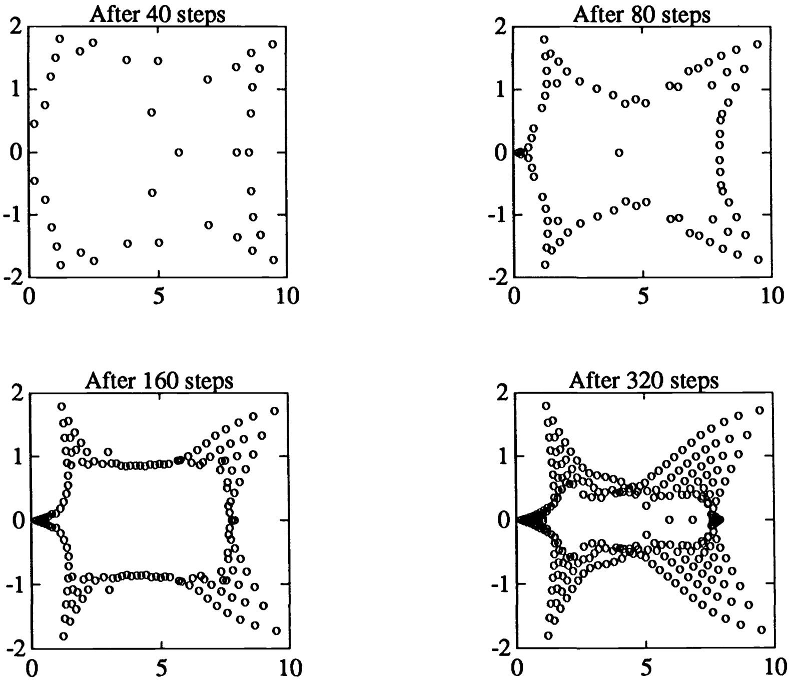

FIG. 6.1. *Ritz values for Example* 6.1, *obtained after* $n = 40, 80, 160, 320$ *steps of the look-ahead Lanczos algorithm.*

where the diagonal blocks I_1, I_2, I_3, I_4, I_5, and I_6 are identity matrices of size 827, 844, 827, 838, 831, and 838, respectively, so that A is a matrix of order $N = 5005$. This matrix arises in Markov chain modeling. For general p-cyclic matrices A of the form (6.6), Freund, Golub, and Hochbruck [10] have shown that work and storage of the look-ahead Lanczos process can be reduced to approximately $1/p$, as compared to arbitrary starting vectors, if v_1 and w_1 have only one nonzero block conforming to the block structure of A. Here, we have chosen

$$\hat{v}_1 = \begin{bmatrix} f_1 \\ 0 \end{bmatrix}, \quad \hat{w}_1 = \begin{bmatrix} g_1 \\ 0 \end{bmatrix},$$

where f_1, $g_1 \in \mathbb{R}^{827}$ have random entries. The look-ahead Lanczos algorithm generates blocks that alternately have sizes 1 and 5, starting with a block of size 1. In Fig. 6.3, we plot the Ritz values (marked by "o") generated by the look-ahead Lanczos process after $n = 40$, 80, 160, 320 steps. The standard Lanczos algorithm without look-ahead generates one Ritz value 1 in the first step, and then breaks down in the second step. Clearly, this example shows that the use of look-ahead is crucial if one wants to exploit the special structure of p-cyclic matrices.

Example 6.4. Here we solve a linear system (6.1) where A is the SHERMAN5 matrix taken from the Harwell–Boeing test collection of sparse matrices [8]. The matrix is of dimension $N = 3312$ and has 20793 nonzero elements. The right-hand side b in (6.1), as well as the first left Lanczos vector $\hat{w}_1$ were generated as different

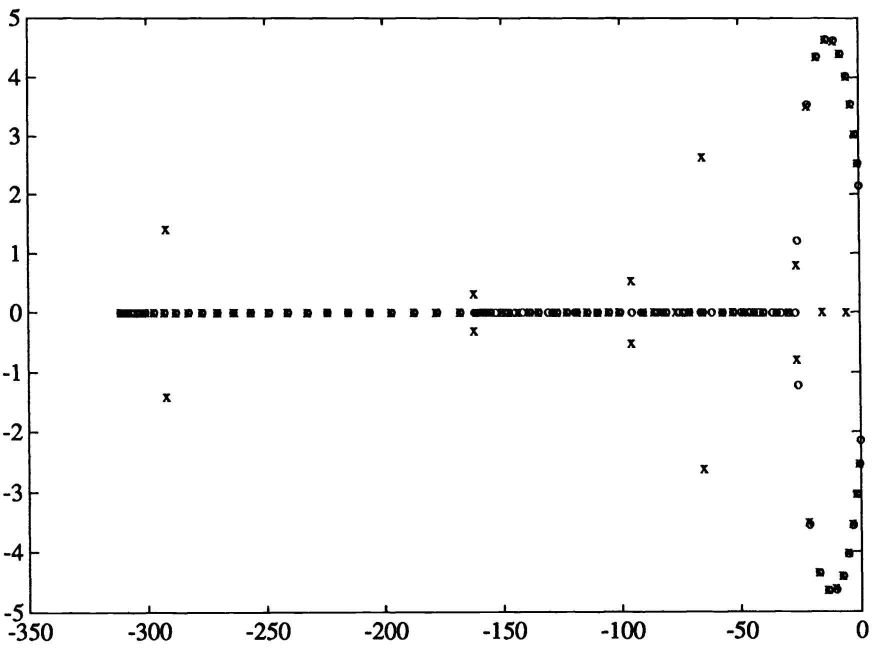

FIG. 6.2. *Ritz values (marked by "o," respectively "+") for Example* 6.2, *obtained from the look-ahead, respectively standard, Lanczos algorithm.*

unit vectors with random entries, and we set $x_0 = 0$ and $\hat{v}_1 = r_0 = b$. The QMR method takes $n = 1652$ steps to reduce the norm of the initial residual by a factor of 10^{-6}; see Fig. 6.4, where the residual norm $\|r_n\|$ is plotted versus n (solid line). The underlying look-ahead Lanczos algorithm built 34 blocks of size 2 and 7 blocks of size 3. We would like to stress that, for this example, look-ahead is crucial. Indeed, if look-ahead is turned off, then QMR based on the standard Lanczos algorithm does not converge. The corresponding stagnating residual norms (dashed line) are also depicted in Fig. 6.4.

Example 6.5. Here we consider the partial differential equation

$$Lu = f \quad \text{on} \quad (0,1) \times (0,1) \times (0,1), \tag{6.7}$$

where

$$\begin{aligned} Lu = &- \frac{\partial}{\partial x}\left(e^{xy}\frac{\partial u}{\partial x}\right) - \frac{\partial}{\partial y}\left(e^{xy}\frac{\partial u}{\partial y}\right) - \frac{\partial}{\partial z}\left(e^{xy}\frac{\partial u}{\partial z}\right) \\ &+ \beta(x+y+z)\frac{\partial u}{\partial x} + \left(\gamma + \frac{1}{1+x+y+z}\right)u, \end{aligned}$$

with Dirichlet boundary conditions $u = 0$. The right-hand side f is chosen such that

$$u = (1-x)(1-y)(1-z)\left(1-e^{-x}\right)\left(1-e^{-y}\right)\left(1-e^{-z}\right)$$

is the exact solution of (6.7). We set the parameters in (6.7) to $\beta = 30$ and $\gamma = -250$, and then we discretize (6.7) using centered differences on a uniform $15 \times 15 \times 15$

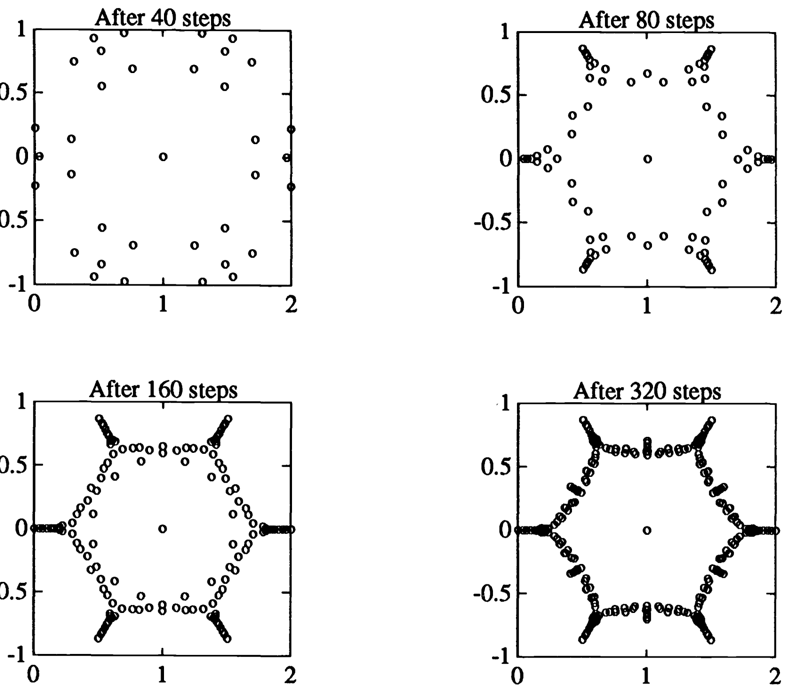

FIG. 6.3. *Ritz values for Example* 6.3, *obtained after* $n = 40, 80, 160, 320$ *steps of the look-ahead Lanczos algorithm.*

grid with mesh size $h = 1/16$. This leads to a linear system (6.1) with coefficient matrix A of order $N = 3375$ and 22275 nonzero elements. The QMR iteration was started with $x_0 = 0$. For the first pair of Lanczos vectors, we have chosen $\hat{w}_1 = \hat{v}_1 = b/\|b\|$ in Algorithm 3.1. The QMR approach takes $n = 149$ steps to reduce the norm of the initial residual by a factor of 10^{-6}; see Fig. 6.5, where the relative norm $\|r_n\| \,/\, \|r_0\|$ is plotted versus n (solid line). For this run, the underlying look-ahead Lanczos algorithm built three blocks of size 2. Next, we note that the matrix A is just the one used in Example 4.2. Recall that the look-ahead Lanczos algorithm based on the check (4.1) with tolerance tol$= \epsilon^{1/4} \approx$ 6.0E-08 encountered an artificial incurable breakdown. We also ran QMR based on this version of the look-ahead Lanczos algorithm, and the resulting convergence curve is shown as the dotted line in Fig. 6.5. Notice that, due to the artificial incurable breakdown, QMR does not converge in this case (cf. Fig. 4.2). Finally, we remark that QMR based on the standard Lanczos algorithm without look-ahead also converges for this example and gives a curve similar to the solid line in Fig. 6.5.

7. Conclusion.

We have proposed an implementation of the look-ahead Lanczos algorithm for non-Hermitian matrices. Our implementation can handle look-ahead steps of any length. Also, the proposed algorithm requires the same number of inner products as the standard Lanczos process without look-ahead. It was our intention to develop a robust algorithm which can be used in a black box.

WAVELET-LIKE BASES FOR THE FAST SOLUTION OF SECOND-KIND INTEGRAL EQUATIONS*

B. ALPERT†, G. BEYLKIN‡, R. COIFMAN§, AND V. ROKHLIN¶

Abstract. A class of vector-space bases is introduced for the sparse representation of discretizations of integral operators. An operator with a smooth, nonoscillatory kernel possessing a finite number of singularities in each row or column is represented in these bases as a sparse matrix, to high precision. A method is presented that employs these bases for the numerical solution of second-kind integral equations in time bounded by $O(n \log^2 n)$, where n is the number of points in the discretization. Numerical results are given which demonstrate the effectiveness of the approach, and several generalizations and applications of the method are discussed.

Key words. wavelets, integral equations, sparse matrices, fast numerical algorithms

AMS(MOS) subject classifications. 42C15, 45L10, 65R10, 65R20

Introduction. Integral equations are a well-known mathematical tool for formulating physical problems. As a numerical tool they have several strengths (good conditioning, dimensionality reduction, and the ability to treat arbitrary regions), but have one overriding drawback: the high cost of working with the associated dense matrices. For a problem requiring an n-point discretization, the inverse of a dense $n \times n$ matrix must be applied to a vector. Even to apply the matrix itself to a vector requires order $O(n^2)$ operations; application of its inverse by a direct (noniterative) method requires order $O(n^3)$ operations. If an iterative method is employed, the number of iterations depends on the condition number of the problem and each iteration requires application of the $n \times n$ matrix. For large-scale problems, the resulting costs are often prohibitive.

In recent years a number of algorithms ([5], [10], [11], [14]) have been developed for the fast application of linear operators naturally expressible as dense matrices, the best known of which are the particle simulation algorithms developed by Greengard and Rokhlin [10]. These schemes combine low-order polynomial interpolation of the function, which defines the matrix elements with a divide-and-conquer strategy. They achieve (the equivalent of) order $O(n)$ application of a dense $n \times n$ matrix to a vector.

Over a somewhat longer period, mathematical bases have been constructed with certain *multiscale* properties. Families of functions $h_{a,b}$,

$$h_{a,b}(x) = |a|^{-1/2}\, h\left(\frac{x-b}{a}\right), \quad a, b \in \mathbf{R}, \quad a \neq 0,$$

derived from a single function h by dilation and translation, which form a basis for $L^2(\mathbf{R})$, are known as *wavelets* (Grossman and Morlet [12]). These families have

been studied by many authors, resulting in constructions with a variety of properties. Meyer [13] constructed orthonormal wavelets for which $h \in C^{\infty}(\mathbf{R})$. Daubechies [7] constructed compactly supported wavelets with $h \in C^{k}(\mathbf{R})$ for arbitrary k, and [7] gives an overview and synthesis of the field.

A recent paper [6] establishes a connection between the fast numerical algorithms and the multiscale bases. It introduces the use of wavelets for the application of an integral operator to a function in $O(n \log n)$ operations, where n is the number of points in the discretization of the function. Alpert's thesis [4] gives an earlier report of the present work. Another paper [2] constructs a class of simple wavelet-like bases for $L^2[0,1]$ in which a variety of integral operators are sparse. In the present paper, rather than employ a wavelet basis for L^2, we construct a class of bases that transform the dense matrices resulting from the discretization of second-kind integral equations into sparse matrices. The $n \times n$ matrices resulting from an n-point discretization are transformed into matrices with order $O(n \log n)$ nonzero elements (to arbitrary finite precision). In these bases, the inverse matrices are also sparse, and are obtained in order $O(n \log^2 n)$ operations by a classical iterative method (due to Schulz [15]).

The method of this paper was developed with the aim of solving integral equations resulting from problems in potential theory, characterized by integral kernels that are smooth apart from diagonal singularities. In these problems, when high frequency modes have a significant presence in the given field (the right-hand side of the equation), a large number of points will be required in the discretization. The discretization must also be maintained for the integral operator, which dictates the need to solve a large-scale system of equations. If, instead, one has an integral operator with a globally smooth kernel, no large-scale system is required. In this case a direct method is entirely adequate, and preferable to the method given here.

In §1 we present the mathematical construction of the new bases. In §2 we briefly introduce Nyström's method for the solution of integral equations, and show how the wavelet-like bases result in sparse representation of integral operators and their inverses. We demonstrate that the Schulz method of matrix inversion is efficient in this context. In §3 we present the numerical algorithms for computation of the new bases, transformation of an integral operator into the bases, and computation of its inverse, and we analyze the time complexity of these algorithms. A variety of numerical examples are presented in §4 to demonstrate the effectiveness of the approach, and generalizations and applications are discussed in §5.

1. Wavelet-like bases.

1.1. Properties of the bases.

Given a set of n distinct points $S = \{x_1, x_2, \ldots, x_n\} \subset \mathbf{R}$ (the discretization) we construct an orthonormal basis for the n-dimensional space of functions defined on S. For simplicity, we assume that $n = k \cdot 2^l$, where k and l are positive integers, and that $x_1 < x_2 < \cdots < x_n$. The basis has two fundamental properties:

1. All but k basis vectors have k vanishing moments; and
2. The basis vectors are nonzero on different scales.

Figure 1 illustrates a matrix of basis vectors for $n = 128$ and $k = 4$. Each row represents one basis vector, with the dots depicting nonzero elements. The first k basis vectors are nonzero on $x_1, \ldots, x_{2k}$, the next k are nonzero on $x_{2k+1}, \ldots, x_{4k}$, and so forth. In all, one-half of the basis vectors are nonzero on $2k$ points from S, one-fourth are nonzero on $4k$ points, one-eighth are nonzero on $8k$ points, etc. Each of these $n/2 + n/4 + n/8 + \cdots + k = n - k$ basis vectors has k zero moments, i.e., if

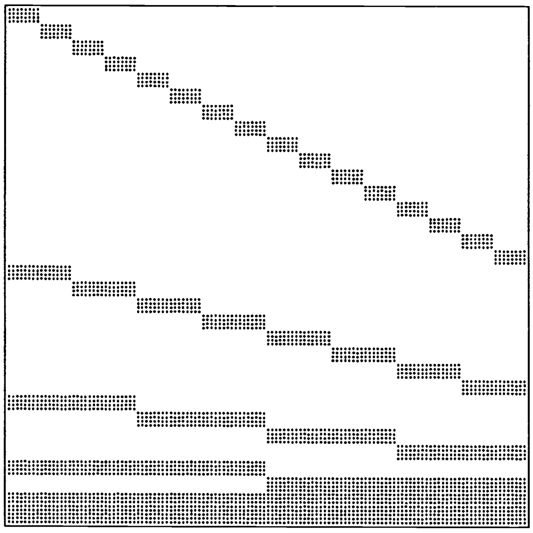

FIG. 1. *The matrix represents a wavelet-like basis for a discretization with* 128 *points, for* $k = 4$. *Each row denotes one basis vector, with the dots depicting nonzero elements. All but the final* k *rows have* k *vanishing moments.*

$b = \langle b_1, \ldots, b_n \rangle$ is one of these vectors, then

$$\sum_{i=1}^{n} b_i \cdot x_i{}^j = 0, \qquad j = 0, 1, \ldots, k-1.$$

The final k vectors result from orthogonalization of the moments $\langle x_1{}^j, x_2{}^j, \ldots, x_n{}^j \rangle$ for $j = 0, 1, \ldots, k-1$.

These properties of local support and vanishing moments lead to efficient representation of functions that are smooth except at a finite set of singularities. The projection of such a function on an element of this basis will be negligible unless the element is nonzero near one of the singularities. As a simple example, we consider the function $f(x) = \log(x)$ on the interval $[0, 1]$ with the uniform discretization $x_i = i/n$. A hand calculation shows that for any $c > 0$, f may be interpolated on the interval $[c, 2c]$ by a polynomial of degree 7 with error bounded by 4^{-9}, or roughly single precision accuracy. If we choose $k = 8$ in constructing the basis, f will be represented to this accuracy by the k basis vectors nonzero on $x_1, \ldots, x_{2k}$, the k basis vectors nonzero on $x_1, \ldots, x_{4k}$, and so forth, down to the k basis vectors nonzero on $x_1, \ldots, x_n$, in addition to the k orthogonalized moment vectors. The number of nonnegligible coefficients in the expansion of f in this basis grows logarithmically in n, the number of points of the discretization. Although this example is idealized, its behavior is representative of the general behavior of an analytic function near a singularity.

1.2. Construction of the bases. The conditions of "local" support and zero moments determine the basis vectors uniquely (up to sign) if we require somewhat more moments to vanish. Namely, out of the k vectors nonzero on $x_1, \ldots, x_{2k}$, we require that one have k vanishing moments, a second have $k+1$, a third have $k+2$, and so forth, and the kth have $2k-1$ vanishing moments. We place the same condition on the k basis vectors nonzero on $x_{2k+1}, \ldots, x_{4k}$, and so on, for each block of k basis vectors among the $n-k$ basis vectors with zero moments.

We construct the basis by construction of a finite sequence of bases (shown in Fig. 2), each obtained by a number of orthogonalizations. The first basis results from $n/(2k)$ Gram–Schmidt orthogonalizations of $2k$ vectors each. In particular, the vectors $\langle x_1{}^j, \ldots, x_{2k}{}^j \rangle$ for $j = 0, \ldots, 2k-1$ are orthogonalized, the vectors $\langle x_{2k+1}{}^j, \ldots, x_{4k}{}^j \rangle$ for $j = 0, \ldots, 2k-1$ are orthogonalized, and so forth, up to the vectors $\langle x_{n-2k+1}{}^j, \ldots, x_n{}^j \rangle$ for $j = 0, \ldots, 2k-1$, which are orthogonalized.

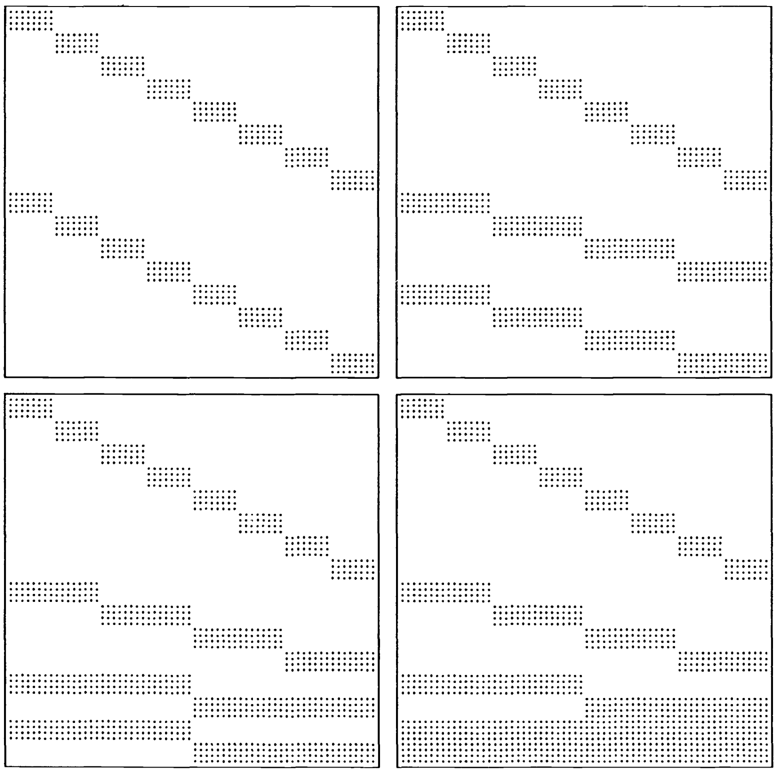

FIG. 2. *Each of the four matrices represents one basis, as in Fig. 1. The upper-left matrix is formed by orthogonalizing moment vectors on blocks of* $2k$ *points. The upper-right matrix is obtained from the upper-left matrix by premultiplying by an orthogonal matrix which is the identity on the upper half. Similarly, the lower matrices are obtained by further orthogonal transformations. The lower-right matrix represents the wavelet-like basis for* $n = 64, k = 4$.

Half of the n vectors of the first basis have at least k zero moments; in forming the second basis, these vectors are retained; the remaining $n/2$ basis vectors are transformed by an orthogonal transformation into basis vectors, each of which is nonzero on $4k$ of the points $x_1, \ldots, x_n$, and half of which have at least k vanishing moments. The orthogonal transformation results from $n/(4k)$ Gram–Schmidt orthogonalizations of $2k$ vectors each. Similarly, the third basis is obtained from the second basis by an orthogonal transformation that itself results from $n/(8k)$ Gram–Schmidt orthogonalizations of $2k$ vectors each. Before we can specify these orthogonalizations, we require some additional notation.

Suppose that V is a matrix whose columns $v_1, \ldots, v_{2k}$ are linearly independent. We define W=Orth(V) to be the matrix that results from the column-by-column Gram–Schmidt orthogonalization of V. Namely, denoting the columns of W by $w_1, \ldots, w_{2k}$, we have

$$\left.\begin{aligned} \text{linear span}\{w_1, \ldots, w_i\} &= \text{linear span}\{v_1, \ldots, v_i\}, \\ w_i^T w_j &= \delta_{ij}, \end{aligned}\right\} \quad i, j = 1, \ldots, 2k.$$

For a $2k \times 2k$ matrix V we let V^U and V^L denote two $k \times 2k$ matrices, V^U consisting of the upper k rows and V^L the lower k rows of V,

$$V = \begin{pmatrix} V^U \\ V^L \end{pmatrix}.$$

Now we proceed to the definition of the basis matrices. Given the set of points $S = \{x_1, \ldots, x_n\} \subset \mathbf{R}$ with $x_1 < \cdots < x_n$, where $n = k \cdot 2^l$, we define the $2k \times 2k$ moments matrices $M_{1,i}$ for $i = 1, \ldots, n/(2k)$ by the formula

$$M_{1,i} = \begin{pmatrix} 1 & x_{s_i+1} & \cdots & {x_{s_i+1}}^{2k-1} \\ 1 & x_{s_i+2} & \cdots & {x_{s_i+2}}^{2k-1} \\ \vdots & & & \vdots \\ 1 & x_{s_i+2k} & \cdots & {x_{s_i+2k}}^{2k-1} \end{pmatrix}, \tag{1}$$

where $s_i = (i-1)2k$. The first basis matrix U_1 is the $n \times n$ matrix given by the formula

$$U_1 = \begin{pmatrix} {U_{1,1}}^L & & & \\ & {U_{1,2}}^L & & \\ & & \ddots & \\ & & & {U_{1,n_1}}^L \\ {U_{1,1}}^U & & & \\ & {U_{1,2}}^U & & \\ & & \ddots & \\ & & & {U_{1,n_1}}^U \end{pmatrix},$$

where ${U_{1,i}}^T = \text{Orth}(M_{1,i})$ and $n_1 = n/(2k)$. The second basis matrix is U_2U_1, with U_2 defined by the formula

$$U_2 = \begin{pmatrix} I_{n/2} & \\ & U_2' \end{pmatrix},$$

where I_m is the $m \times m$ identity matrix and the $n/2 \times n/2$ matrix U_2' is given by the formula

$$U_2' = \begin{pmatrix} {U_{2,1}}^L & & & \\ & {U_{2,2}}^L & & \\ & & \ddots & \\ & & & {U_{2,n_2}}^L \\ {U_{2,1}}^U & & & \\ & {U_{2,2}}^U & & \\ & & \ddots & \\ & & & {U_{2,n_2}}^U \end{pmatrix},$$

where $n_2 = n/(4k)$, ${U_{2,i}}^T = \text{Orth}\,(M_{2,i})$, and the $2k \times 2k$ matrix $M_{2,i}$ is given by

$$M_{2,i} = \begin{pmatrix} {U_{1,2i-1}}^U M_{1,2i-1} \\ {U_{1,2i}}^U M_{1,2i} \end{pmatrix}$$

for $i = 1, \ldots, n/(4k)$. In general, the jth basis matrix, for $j = 2, \ldots, \log_2(n/k)$, is $U_j \cdots U_1$, with U_j defined by the formula

$$U_j = \begin{pmatrix} I_{n-n/2^{j-1}} & \\ & U_j' \end{pmatrix},$$

where U_j' is given by the formula

$$U_j' = \begin{pmatrix} {U_{j,1}}^L & & & \\ & {U_{j,2}}^L & & \\ & & \ddots & \\ & & & {U_{j,n_j}}^L \\ {U_{j,1}}^U & & & \\ & {U_{j,2}}^U & & \\ & & \ddots & \\ & & & {U_{j,n_j}}^U \end{pmatrix},$$

where $n_j = n/(2^j k)$; $U_{j,i}$ is given by

(2) $$ {U_{j,i}}^T = \text{Orth}(M_{j,i});$$

and $M_{j,i}$ is given by

(3) $$M_{j,i} = \begin{pmatrix} {U_{j-1,2i-1}}^U M_{j-1,2i-1} \\ {U_{j-1,2i}}^U M_{j-1,2i} \end{pmatrix}$$

for $i = 1, \ldots, n/(2^j k)$. The final basis matrix $U = U_l \cdots U_1$, where $l = \log_2(n/k)$, represents the wavelet-like basis of parameter k on $x_1, \ldots, x_n$. Note that the matrices

U and U_j are of dimension $n \times n$, U'_j is $n/2^{j-1} \times n/2^{j-1}$, $U_{j,i}$ and $M_{j,i}$ are $2k \times 2k$, and $U^L_{j,i}$ and $U^U_{j,i}$ are $k \times 2k$.

Remark 1.1. The definitions given for the basis matrices are mathematical definitions only; in a numerical procedure, considerable roundoff error would be introduced by the orthogonalizations defined above. In the actual implementation, the matrices $M_{j,i}$ are shifted and scaled, resulting in a numerically stable procedure that is equivalent to the above definitions (in exact arithmetic). Details of this procedure are provided in §3.

It is apparent that the application of the matrix U to an arbitrary vector of length n may be accomplished in order $O(n)$ operations by the application of $U_1, \ldots, U_l$ in turn. Similarly, $U^{-1} = U^T$ may be applied to a vector in order $O(n)$ operations. Certain dense matrices, in particular those arising from integral operators, are sparse in the basis of U and their similarity transformations can be computed in $O(n \log n)$ operations. These techniques are developed in the following sections.

Figure 3 illustrates the vectors of one basis from this class.

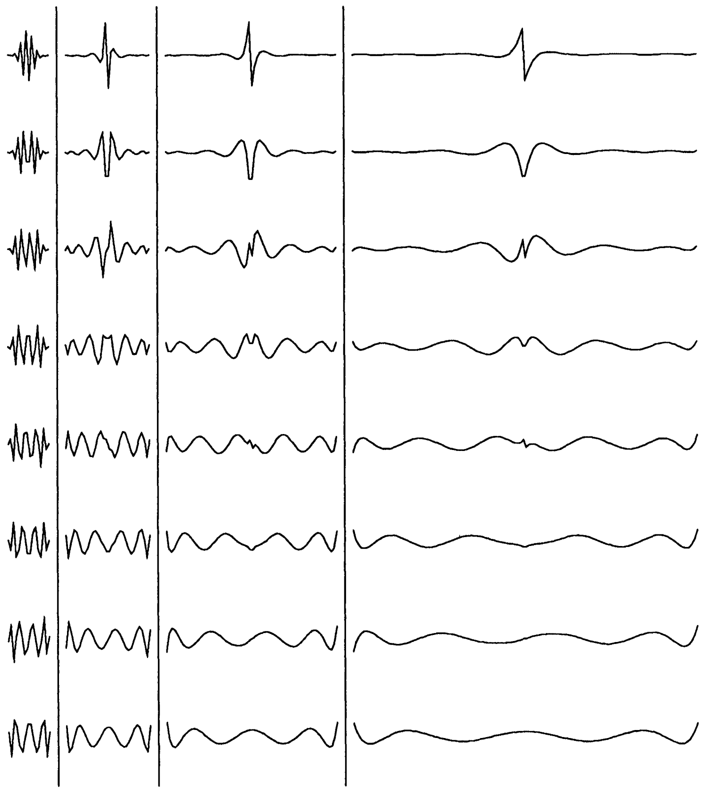

FIG. 3. *Basis vectors on four scales are shown for the basis where $n = 128$, points $x_1, \ldots, x_n$ are equispaced, and $k = 8$. The first column of vectors consists of rows 1–8 of U, the second column consists of rows 65–72, etc. Note that half of the vectors are odd and half are even functions, and that the odd ones are generally discontinuous at their center.*

2. Second-kind integral equations.

2.1. Nyström method. A linear Fredholm integral equation of the second kind is an expression of the form

$$f(x) - \int_a^b K(x,t)\, f(t)\, dt = g(x), \tag{4}$$

where the kernel K is in $L^2[a,b]^2$ and the unknown f and right-hand side g are in $L^2[a,b]$. We use the symbol $\mathcal{K}$ to denote the integral operator of (4), which is given by the formula

$$(\mathcal{K}f)(x) = \int_a^b K(x,t)\, f(t)\, dt,$$

for all $f \in L^2[a,b]$ and $x \in [a,b]$. Then (4), written in operator form, is

$$(I - \mathcal{K})f = g. \tag{5}$$

The Nyström, or *quadrature*, method for the numerical solution of integral equations approximates the integral operator $\mathcal{K}$ by the finite-dimensional operator R, characterized by points $x_1, x_2, \ldots, x_n \in [a,b]$ and weights $w_1, w_2, \ldots, w_n \in \mathbf{R}$, and given by the formula

$$(Rf)(x) = \sum_{j=1}^{n} w_j\, K(x, x_j)\, f(x_j), \tag{6}$$

for all $f \in L^2[a,b]$ and $x \in [a,b]$. Substitution of R for $\mathcal{K}$ in (5), combined with the requirement that the resulting equation holds for $x = x_1, x_2, \ldots, x_n$, yields the following system of n equations in the n unknowns $f_1, f_2, \ldots, f_n$:

$$f_i - \sum_{j=1}^{n} w_j\, K(x_i, x_j)\, f_j = g(x_i), \qquad i = 1, \ldots, n. \tag{7}$$

The approximation $\langle f_1, \ldots, f_n \rangle$ to the solution f of (4) may be extended to all $x \in [a,b]$ by the natural formula

$$f_R(x) = g(x) + \sum_{i=1}^{n} w_j\, K(x, x_j)\, f_j, \tag{8}$$

which satisfies $f_R(x_i) = f_i$ for $i = 1, \ldots, n$. How large is the error $e_R = f - f_R$ of the approximate solution? We follow the derivation by Delves and Mohamed in [8]. Rewriting (7) in operator form, we have

$$(I - R)f_R = g, \tag{9}$$

and combining (5) and (9) yields $(I - \mathcal{K})e_R = (\mathcal{K} - R)f_R$. Provided that $(I - \mathcal{K})^{-1}$ exists, we obtain the error bound

$$\|e_R\| \leq \|(I - \mathcal{K})^{-1}\| \cdot \|(\mathcal{K} - R)f_R\|. \tag{10}$$

The error depends, therefore, on the conditioning of the original integral equation, as is apparent from the term $\|(I - \mathcal{K})^{-1}\|$, and on the fidelity of the quadrature R to the integral operator $\mathcal{K}$. It is not necessary that $\|\mathcal{K} - R\|$ be small, rather merely that R approximate $\mathcal{K}$ well near the solution f. Quadrature rules that have this property, but that are defined only on the points $x_1, \ldots, x_n$, are developed in [3]. In these rules the quadrature weights w_j of (6) become w_{ij}, which depend on the point of definition x_i, for $i = 1, \ldots, n$. The quadrature rules converge rapidly for kernels with singularities of known location and type. These rules are used below in the numerical examples of §4.

2.2. Sparse representation of integral operators. We concern ourselves here with kernels $K = K(x,t)$, which are analytic except at $x = t$, where they possess an integrable singularity. We initially discretize the integral operator $\mathcal{K}$ using a simple equispaced quadrature. Given $n \geq 2$, we define points $x_1, \ldots, x_n$ to be equispaced on the interval $[a, b]$,

$$x_i = a + (i-1)(b-a)/(n-1), \tag{11}$$

and define the elements T_{ij} of the $n \times n$ matrix T by the formula

$$T_{ij} = \begin{cases} \frac{1}{n-1} K(x_i, x_j), & i \neq j, \\ 0, & i = j. \end{cases} \tag{12}$$

Note that the matrix $T = T(n)$ corresponds to a primitive, trapezoid-like quadrature discretization of the integral operator $\mathcal{K}$. The matrix T possesses the same smoothness properties as the kernel $K(x,t)$. Transformation of T by the bases developed in §1 produces a matrix that is sparse, to high precision. The number of elements is effectively bounded by order $O(n \log n)$.

When the matrix representing the quadrature corrections developed in [3] is added to T, producing high-order convergence to the integral operator, this complexity bound remains valid.

The matrix T, transformed by the orthogonal $n \times n$ matrix U, can be decomposed into the sum of a sparse matrix and a matrix with small norm. Given $\epsilon > 0$, there exists $c_\epsilon > 0$, independent of n, such that the transformed matrix can be written in the form

$$UTU^T = V + E,$$

where the number of elements in $V = V(n)$ is bounded by $c_\epsilon n \log n$ and $E = E(n)$ is small: $\|E\| < \epsilon \|T\|$. We do not prove this assertion here; the proof parallels the proofs of similar statements in [2], but is somewhat more tedious.

2.3. Solution via Schulz method. The sparse matrix representing the integral operator also has a sparse inverse, which can be computed rapidly.

Schulz's method [15] is an iterative, quadratically convergent algorithm for computing the inverse of a matrix. Its performance is characterized in the following lemma.

LEMMA 2.1. *Suppose that A is an invertible matrix, X_0 is the matrix given by $X_0 = A^H/\|A^H A\|$, and for $m = 0, 1, 2, \ldots$ the matrix X_{m+1} is defined by the recursion*

$$X_{m+1} = 2X_m - X_m A X_m.$$

Then X_{m+1} satisfies the formula

$$I - X_{m+1}A = (I - X_m A)^2. \tag{13}$$

Furthermore, $X_m \to A^{-1}$ *as* $m \to \infty$ *and for any* $\epsilon > 0$ *we have*

$$\|I - X_m A\| < \epsilon \quad \textit{provided} \quad m \geq 2\log_2 \kappa(A) + \log_2 \log(1/\epsilon), \tag{14}$$

where $\kappa(A) = \|A\| \cdot \|A^{-1}\|$ *is the condition number of* A *and the norm is given by* $\|A\| = (\text{largest eigenvalue of } A^H A)^{1/2}$.

Proof. Equation (13) is obtained directly from the definition of X_{m+1}. Bound (14) is equally straightforward. Noting that $A^H A$ is symmetric positive-definite and letting λ_0 denote the smallest, and λ_1 the largest, eigenvalue of $A^H A$ we have

$$\begin{aligned} \|I - X_0 A\| &= \left\| I - \frac{A^H A}{\|A^H A\|} \right\| \\ &= 1 - \lambda_0/\lambda_1 \\ &= 1 - \kappa(A)^{-2}. \end{aligned} \tag{15}$$

From (13) we obtain $I - X_m A = (I - X_0 A)^{2^m}$, which in combination with (15) and simple manipulation yields bound (14). □

The Schulz method is a notably simple scheme for matrix inversion and its convergence is extremely rapid. It is rarely used, however, because it involves matrix–matrix multiplications on each iteration; for most problem formulations, this process requires order $O(n^3)$ operations for an $n \times n$ matrix. We observe, however, that a sparse matrix, possessing a sparse inverse, whose iterates X_n are also sparse, may be rapidly inverted using the Schulz method. We have seen above that a discretized integral operator $I - T$, similarity-transformed to the representation $A = I - UTU^T$, has only order $O(n \log n)$ elements (to finite precision). In addition, $A^T A$ and $(A^T A)^m$ are similarly sparse. This property enables us to employ the Schulz algorithm to compute A^{-1} in order $O(n \log^2 n)$ operations.

2.4. Oscillatory coefficients. We now consider a somewhat more general class of integral equations, in which the integral operator is given by the formula

$$(D\mathcal{K}f)(x) = p(x) \int_a^b K(x,t)\, f(t)\, dt,$$

where the kernel K is assumed to be smooth, but the coefficient function p can be oscillatory. In particular, we only restrict p to be positive. In terms of generality, these problems lie between the problems with smooth kernels (and constant coefficient) and those with arbitrary oscillatory kernels.

Writing the corresponding integral equation in operator form, we obtain the equation

$$(I - D\mathcal{K})f = g. \tag{16}$$

Although D is a diagonal operator, and $\mathcal{K}$ is smooth, it is clear that the discretization of the operator $D\mathcal{K}$ will not be a sparse matrix in wavelet coordinates. In this framework, it would appear that the construction of this paper is inapplicable. If we instead consider the operator $D^{1/2}\mathcal{K}D^{1/2}$, in which oscillations in the rows match those in the columns, it becomes clear that the construction of §1 can be revised. Rather than constructing basis functions orthogonal to low-order polynomials x^j, we can construct them to be orthogonal to $p(x)^{1/2}\, x^j$. The sole revision in our definition of basis matrices $U_1, \ldots, U_l$ is to replace the definition (1) of the moments matrices $M_{1,i}$ for $i = 1, \ldots, n/(2k)$, by the new definition

$$M_{1,i} = \begin{pmatrix} p_{s_i+1} & 0 & \cdots & 0 \\ 0 & p_{s_i+2} & \cdots & 0 \\ \vdots & & & \vdots \\ 0 & \cdots & 0 & p_{s_i+2k} \end{pmatrix} \begin{pmatrix} 1 & x_{s_i+1} & \cdots & {x_{s_i+1}}^{2k-1} \\ 1 & x_{s_i+2} & \cdots & {x_{s_i+2}}^{2k-1} \\ \vdots & & & \vdots \\ 1 & x_{s_i+2k} & \cdots & {x_{s_i+2k}}^{2k-1} \end{pmatrix},$$

where $s_i = (i-1)2k$ and $p_j = p(x_j)^{1/2}$.

Now the integral equation (16) can be transformed to the equation

$$(I - D^{1/2}\mathcal{K}D^{1/2})(D^{-1/2}f) = (D^{-1/2}g),$$

which is discretized to a system that is sparse in the revised wavelet-like coordinates. The inverse matrix is also sparse.

3. Numerical algorithms.

In §1 we defined a class of bases for functions defined on $\{x_1, \ldots, x_n\}$, and in §2 we showed that, to finite precision, second-kind integral operators and their inverses are asymptotically sparse in these bases. In this section we present procedures for computation of the bases, discretized integral operators in these bases, and the inverses of these operators. In §4 we give some numerical examples based on our implementations of these procedures.

The computation of the new bases is discussed next, followed by a discussion of the transformation of the integral operators to the new bases. We defer discussion of the computation of the inverses, sketched above, to §3.3, which contains detailed descriptions of all of the algorithms. Finally, §3.4 gives the complexity analysis for the algorithms.

3.1. Computation of wavelet-like bases.

It was mentioned in §1 that the mathematical definition of $U_1, \ldots, U_l$, if used directly, would result in a numerical procedure that would create large roundoff errors. A correct procedure is obtained by shifting and scaling the matrices $M_{j,i}$ defined there.

For a pair of numbers $(\mu, \sigma) \in \mathbf{R} \times (\mathbf{R}\backslash\{0\})$ we define a $2k \times 2k$ matrix $S(\mu, \sigma)$ whose (i,j)th element is the binomial term

$$S(\mu,\sigma)_{i,j} = \binom{j-1}{i-1} \frac{(-\mu)^{j-i}}{\sigma^{j-1}} \tag{17}$$

for $i \le j$, and $S(\mu,\sigma)_{i,j} = 0$ otherwise. The matrix $S(\mu,\sigma)$ is upper-triangular and nonsingular, and its inverse is given by the formula

$$S(\mu,\sigma)^{-1} = S(-\mu/\sigma, 1/\sigma). \tag{18}$$

Furthermore, the product formula

$$S(\mu_1,\sigma_1)S(\mu_2,\sigma_2) = S(\mu_1 + \mu_2\sigma_1, \sigma_1\sigma_2) \tag{19}$$

is easily verified.

We define $M'_{j,i}$ for $j = 1, \ldots, l$ and $i = 1, \ldots, n/(2^j k)$ by the formula

$$M'_{j,i} = M_{j,i}S(\mu_{j,i}, \sigma_{j,i}), \tag{20}$$

where $\mu_{j,i} = (x_{1+(i-1)k2^j} + x_{ik2^j})/2, \sigma_{j,i} = (x_{ik2^j} - x_{1+(i-1)k2^j})/2$, and the matrix $M_{j,i}$ is defined by (1) and (3) in §1. The matrix $U_{j,i}$ is given by the formula

$$U_{j,i}{}^T = \mathrm{Orth}(M'_{j,i}), \tag{21}$$

which is equivalent to the definition given by (2). This equivalence immediately follows from the fact that $S(\mu, \sigma)$ is upper-triangular and nonsingular.

The matrices $M'_{1,i}$ for $i = 1, \ldots, n/(2k)$ are actually computed by the formula

$$M'_{1,i} = \begin{pmatrix} 1 & \frac{x_{s_i+1}-\mu_{1,i}}{\sigma_{1,i}} & \cdots & \left(\frac{x_{s_i+1}-\mu_{1,i}}{\sigma_{1,i}}\right)^{2k-1} \\ 1 & \frac{x_{s_i+2}-\mu_{1,i}}{\sigma_{1,i}} & \cdots & \left(\frac{x_{s_i+2}-\mu_{1,i}}{\sigma_{1,i}}\right)^{2k-1} \\ \vdots & & & \vdots \\ 1 & \frac{x_{s_i+2k}-\mu_{1,i}}{\sigma_{1,i}} & \cdots & \left(\frac{x_{s_i+2k}-\mu_{1,i}}{\sigma_{1,i}}\right)^{2k-1} \end{pmatrix}, \tag{22}$$

where $s_i = (i-1)2k$. Likewise, the matrices $M'_{j,i}$ for $j = 2, \ldots, l$ and $i = 1, \ldots, n/(2^j k)$ are computed by the formula

$$M'_{j,i} = \begin{pmatrix} U_{j-1,2i-1}{}^U M'_{j-1,2i-1} S^1_{j,i} \\ U_{j-1,2i}{}^U M'_{j-1,2i} S^2_{j,i} \end{pmatrix}, \tag{23}$$

where $S^1_{j,i}$ and $S^2_{j,i}$ are defined by the formulae

$$S^1_{j,i} = S(\mu_{j-1,2i-1}, \sigma_{j-1,2i-1})^{-1} S(\mu_{j,i}, \sigma_{j,i}), \tag{24}$$

$$S^2_{j,i} = S(\mu_{j-1,2i}, \sigma_{j-1,2i})^{-1} S(\mu_{j,i}, \sigma_{j,i}). \tag{25}$$

Application of the inverse and product rules given in (18) and (19) to (24) and (25) yields formulae by which $S^1_{j,i}$ and $S^2_{j,i}$ can be computed:

$$S^1_{j,i} = S((\mu_{j,i} - \mu_{j-1,2i-1})/\sigma_{j-1,2i-1},\ \sigma_{j,i}/\sigma_{j-1,2i-1}), \tag{26}$$

$$S^2_{j,i} = S((\mu_{j,i} - \mu_{j-1,2i})/\sigma_{j-1,2i},\ \sigma_{j,i}/\sigma_{j-1,2i}). \tag{27}$$

The matrices $M'_{j,i}$ given by (22) and (23) are easily seen to be mathematically equivalent to those defined by (20); nonetheless, computation of $M'_{j,i}$ using (22) and (23) avoids the large roundoff errors that would otherwise result.

3.2. Transformation to wavelet-like bases. We assume that for equispaced points $x_1, \ldots, x_n$ (defined in (11)) and some k, the orthogonal matrices $U_1, \ldots, U_l$ defined in §1 have been computed ($l = \log_2(n/k)$). We now present a procedure for computation of UTU^T, where $U = U_l \cdots U_1$ and T is the discretized integral operator defined in (12).

3.2.1. Simple example. We begin with a simplified example in which T is replaced by an $n \times n$ matrix V of rank k whose elements V_{ij} are defined by the equation

$$V_{ij} = \sum_{r=1}^{k} \sum_{s=1}^{k} \Lambda_{rs} x_i{}^{r-1} x_j{}^{s-1}, \qquad i, j = 1, \ldots, n.$$

Each row and each column of V contains elements that are the values of a polynomial of degree $k-1$. The matrix V can be written as $V = P^T \Lambda P$, where the elements of the $k \times n$ matrix P are defined by $P_{ij} = {x_j}^{i-1}$ and Λ is the $k \times k$ matrix with elements Λ_{ij}. Recalling that the last k rows of the basis matrix U consist of an orthogonalization of the moment vectors $\langle {x_1}^j, \ldots, {x_n}^j \rangle$ for $j = 0, \ldots, k-1$, we can rewrite V as $V = (P')^T \Lambda' P'$. Here the $k \times n$ matrix P' consists of the last k rows of U and Λ' is a new $k \times k$ matrix with elements Λ'_{ij}.

By the orthogonality of U, it is clear that the $n \times n$ matrix $UVU^T = U(P')^T \Lambda' P' U^T$ consists entirely of zero elements except the $k \times k$ submatrix in the lower-right corner, which is the matrix Λ'. Given a function to compute elements of the $n \times n$ matrix V, the matrix Λ' can be computed in time independent of n by using a $k \times k$ extract of values from V. We form the $k \times k$ matrix V' with elements V'_{ij} defined by the formula

$$V'_{ij} = V_{in/k,jn/k}, \qquad i,j = 1, \ldots, k. \tag{28}$$

Then $V' = (P'')^T \Lambda' P''$, where P'' is the $k \times k$ extract of P' with elements given by $P''_{ij} = P'_{i,jn/k}$. Thus we obtain

$$\Lambda' = ((P'')^T)^{-1} V' (P'')^{-1} \tag{29}$$

from P'' and V' readily in $O(k^3)$ operations, and we have obtained UVU^T.

3.2.2. General case. The integral operator matrix T is, of course, not of low rank, but it can be divided into submatrices, each approximately of rank k (see Fig. 4). The submatrices near the main diagonal are of size $k \times k$, those next removed are $2k \times 2k$, and so forth up to the largest submatrices, of size $n/4 \times n/4$. The total number of submatrices is proportional to n/k. Given an error tolerance $\epsilon > 0$, k may be chosen (independently of n) so that each submatrix of T, say T^i, may be written as a sum, $T^i = V^i + E^i$, where the elements of V^i are given by a polynomial of degree $k-1$ and $\|E^i\| < \epsilon \|T^i\|$.

The simplified example, in which the matrix to be transformed is of rank k, is now applicable. Each submatrix of T is treated as a matrix of rank k and is transformed to the new coordinates (for its own scale) in order $O(k^3)$ operations. To make this precise, we write $T = T_0 + \cdots + T_{l-2}$ where T_i consists of the submatrices of size $2^i k \times 2^i k$. For each i, the submatrices of T_i may be interpolated by rank k submatrices, as indicated by the extract of (28), to obtain matrices V_i. Thus $T_i = V_i + E_i$, where $\|E_i\|$ is small. In the simplified example above, we have shown that the transformed matrices

$$\begin{aligned} W_0 &= V_0, \\ W_1 &= U_1 V_1 {U_1}^T, \\ W_2 &= U_2 U_1 V_2 {U_1}^T {U_2}^T, \\ &\vdots \\ W_{l-2} &= U_{l-2} \cdots U_1 V_{l-2} {U_1}^T \cdots {U_{l-2}}^T \end{aligned} \tag{30}$$

can be computed by many applications of (29), all in order $O(nk^2)$ operations. This estimate follows from the fact that there are $O(n/k)$ submatrices, each of which is transformed in $O(k^3)$ operations. Now we define $n \times n$ matrices $R_0, \ldots, R_l$ recursively:

$$R_i = \begin{cases} W_0, & i = 0, \\ U_i R_{i-1} {U_i}^T + W_i, & i \geq 1 \end{cases} \tag{31}$$

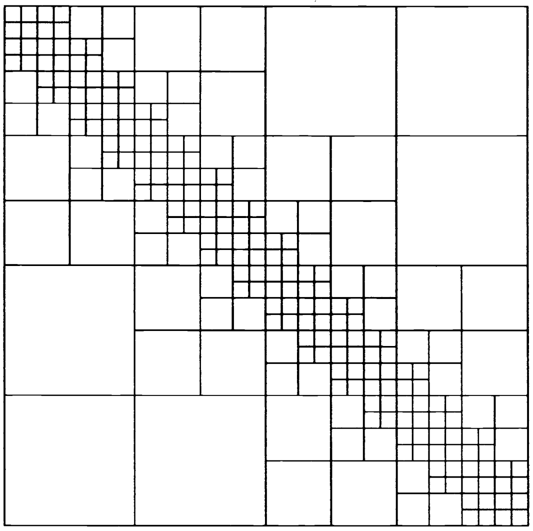

FIG. 4. *The matrix represents a discretized integral operator with a kernel that is singular along the diagonal. The matrix is divided into submatrices of rank k (to high precision) and transformed to a sparse matrix with order $O(n \log n)$ elements. Here $n/k = 32$.*

(here $W_{l-1} = W_l = 0$). Then R_l contains the final result, $R_l = U(T - E)U^T$, where $E = E_0 + \cdots + E_{l-2}$.

The matrix–matrix products in the definition of $R_0, \ldots, R_l$ can be computed directly, since the factors and the products contain no more than $O(n \log n)$ elements. A simple implementation with standard sparse matrix structures results in a total operation count of order $O(n \log^2 n)$, but an implementation using somewhat more elaborate data structures, in which repetitive handling of data is avoided, requires only order $O(n \log n)$ operations.

Computation using the result R_l is made more efficient by removing the elements of R_l which can be neglected, within the precision with which R_l approximates UTU^T. For a given precision ϵ, we discard a matrix E' by eliminating elements from R_l below a threshold τ. The threshold depends on the choice of norm; in our implementation, we use the row-sum norm

$$\|A\| = \max_i \sum_{j=1}^{n} |A_{ij}|,$$

for an $n \times n$ matrix A. The element threshold

$$\tau = \frac{\epsilon}{n}\|T\| \tag{32}$$

clearly results in a discarded matrix E' with $\|E'\| < \epsilon\|T\|$.

3.3. Detailed descriptions of algorithms.

PROCEDURE TO COMPUTE $U_1, \ldots, U_l$

Comment [Input to this procedure consists of the number of points n, the number of zero moments k, and the points $x_1, \ldots, x_n$. Output is the matrices $U_{j,i}$ for $j = 1, \ldots, l$ and $i = 1, \ldots, n/(2^j k)$, which make up the matrices $U_1, \ldots, U_l$ (note $l = \log_2(n/k)$).]

Step 1

Compute the shifted and scaled moments matrices $M'_{1,i}$ for $i = 1, \ldots, n/(2k)$ according to (22).

Step 2

Compute $U_{1,i}$ from $M'_{1,i}$ by (21) using Gram–Schmidt orthogonalization for $i = 1, \ldots, n/(2k)$.

Step 3

Comment [Compute $M'_{j,i}$ and $U_{j,i}$ for $j = 2, \ldots, l$ and $i = 1, \ldots, n/(2^j k)$.]

```
do $j = 2, \ldots, l$
   do $i = 1, \ldots, n/(2^j k)$
      Compute $U_{j-1,2i-1}{}^U M'_{j-1,2i-1}$ and $U_{j-1,2i}{}^U M'_{j-1,2i}$.
     Compute $S^1_{j,i}$ by (26) and $S^2_{j,i}$ by (27);
        multiply to obtain $M'_{j,i}$ by (23).
      Orthogonalize $M'_{j,i}$ to obtain $U_{j,i}$ by (21).
   enddo
enddo
```

PROCEDURE TO COMPUTE UTU^T
Comment [Input to this procedure consists of n, k, the matrices $U_{j,i}$ computed above, a function to compute elements of T, and the chosen precision ϵ. Output is a matrix R_l such that $\|R_l - UTU^T\| < \epsilon \|T\|$.]

Step 4

Compute the $k \times k$ extracts, indicated by (28), of the submatrices of T shown in Fig. 4.

Step 5

Extract the matrices P'' (29) from $U_1, U_2U_1, \ldots, U_{l-2} \cdots U_1$ and compute $W_0, \ldots, W_{l-2}$ according to (30).

Step 6

Compute $R_0, \ldots, R_l$ by (31), discarding elements below a threshold τ determined by the precision ϵ (32).

PROCEDURE TO COMPUTE $UT^{-1}U^T$
Comment [Input to this procedure consists of n, the matrix R_l which approximates UTU^T, and the precision ϵ. Output is a matrix X_m which approximates $UT^{-1}U^T$.]

Step 7

Compute the matrix $X_0 = R_l{}^T / \|R_l{}^T R_l\|$ by direct matrix multiplication, discarding elements below a threshold τ determined by the precision ϵ (32).

Step 8

Comment [Obtain the inverse by Schulz iteration.]

```
do $m = 0, 1, \ldots$ while $\|I - X_m R_l\| \geq \epsilon$
   Compute $X_{m+1} = 2X_m - X_m R_l X_m$, discarding elements below threshold.
enddo
```

3.4. Complexity analysis. In Table 1, we provide the operation count for each step of the computation of $UT^{-1}U^T$.

TABLE 1

Step	Complexity	Explanation
1	$O(nk)$	There are $n/(2k)$ $2k \times 2k$ matrices; each element of the matrices is computed in constant time.
2	$O(nk^2)$	For each of the $n/(2k)$ matrices, perform a Gram–Schmidt orthogonalization requiring order $O(k^3)$ operations.
3	$O(nk^2)$	For each of $n/(4k)+n/(8k)+\cdots+1 = n/(2k)-1$ matrices, compute four products of a $k \times 2k$ matrix with a $2k \times 2k$ matrix, construct two $2k \times 2k$ matrices, and orthogonalize one $2k \times 2k$ matrix.
4	$O(nk)$	There are $6(1+3+7+\cdots+(n/(2k)-1))+ 3(n/k)-2$, or order $O(n/k)$, submatrices of T and for each matrix we compute k^2 elements.
5	$O(nk^2)$	There are $n/(2k)+n/(4k)+\cdots+1 = n/k-1$ matrices P'', each the product of two $k \times k$ matrices. These are each inverted and multiplied with the $O(n/k)$ matrices of the previous step.
6	$O(n \log n)$	The diagonally banded matrix W_0, which contains $O(n)$ elements, grows to $O(n \log n)$ elements by the computation of UW_0U^T, as can be seen by simply examining pictures of W_0 and U. The nonzero elements of the transformed $W_1, \ldots, W_{l-2}$ are a subset of those of W_0.
7	$O(n \log^2 n)$	Multiplication of two matrices, each with order $O(n \log n)$ elements, to obtain a product with order $O(n \log n)$ elements.
8	$O(n \log^2 n)$	Two multiplications like that of Step 7 are made per iteration; the number of iterations is independent of n and given by bound (14).
Total	$O(n \log^2 n)$	

4. Numerical examples.

In this section we present operators from several integral equations, the discretization and transformation of the operators to our wavelet-like bases, and the inversion of the operators via Schulz method.

4.1. Uncorrected quadratures. We first examine simple quadratures with equal weights, except weight zero at the singularity, as represented by matrix $T = T(n)$ defined by (12). We transform the matrix $I - T$ to wavelet-like coordinates as described in §3.2, then compute $(I - T)^{-1}$.

These discretizations are not particularly useful for the solution of the integral equations, due to their slow convergence to the integral operators. They nonetheless make good illustrative examples, for they retain the smoothness of the operator kernels and produce correspondingly sparse matrices. In the next section, we examine the results of using high-order quadratures.

For various sizes n of discretization, we tabulate the average number of elements per row in the transformed matrix $U(I - T)U^T$ and the computation time to obtain the matrix. In addition, we display the average number of elements per row of its inverse, and the time to compute the inverse. Finally, we show the error introduced by these computations. The error is determined by the application of the forward and inverse transformations to a random vector: Choose a vector v of length n with uniformly distributed pseudorandom elements; compute $(I - T)v$ directly, by a standard procedure requiring order $O(n^2)$ operations; transform to wavelet-like coordinates, obtaining $U(I - T)v$; apply the computed value of $U(I - T)^{-1}U^T$ to the vector $U(I - T)v$; transform to original coordinates by application of U^T; compare the result v' to v. The measure of error is the relative L^2 error, defined by the formula

$$e_{L^2} = \left(\frac{\sum_{i=1}^{n} [v_i' - v_i]^2}{\sum_{i=1}^{n} v_i{}^2} \right)^{1/2}.$$

The programs to transform and invert, as well as those to determine the error, were implemented in FORTRAN. All computations were performed in double-precision arithmetic on a Sun Sparcstation 1.

The first set of examples is for the kernel $K(x,t) = \log|x - t|$, for a wavelet-like basis of order $k = 4$ and various choices of precision ϵ. The matrix sparsities, execution times, and errors appear in Table 2. Although the sparse matrices are not banded, we loosely refer to the average number of matrix elements per row as the matrix *bandwidth*. We make the following observations.

TABLE 2
The operator $I - \mathcal{K}$ defined by the formula $((I - \mathcal{K})f)(x) = f(x) - \int_0^1 \log|x - t|\, f(t)\, dt$ is discretized, transformed to the wavelet-like coordinates with $k = 4$, and inverted. For various precisions ϵ and various sizes of discretization, we tabulate the average number of elements/row N_1 of the matrix in wavelet-like coordinates and the time in seconds t_1 to compute it, corresponding statistics N_2 and t_2 for the inverse, and the error (see text).

		Transform.		Inversion		L^2
ϵ	n	N_1	t_1	N_2	t_2	Error
10^{-2}	64	7.2	2	8.3	2	0.503E−02
	128	5.9	3	6.5	4	0.257E−02
	256	3.8	7	4.4	4	0.250E−02
	512	2.8	13	3.1	6	0.236E−02

	128	32.1	6	34.3	111	0.140E−03
	256	34.5	15	37.5	302	0.161E−03
	512	33.1	31	35.8	618	0.177E−03
	1024	30.2	63	33.6	1280	0.189E−03
	2048	25.0	121	27.6	2040	0.192E−03

1. The bandwidths N_1, N_2 of the operator and its inverse *decrease* with increasing matrix size. In other words, in the range of matrix sizes tabulated, the number of matrix elements grows more slowly than the matrix dimension n.

2. The operator matrix in wavelet-like coordinates is computed in time that grows nearly linearly in n.

3. The inverse matrix is computed in time which grows sublinearly in n. This is due to the fact that the cost of multiplying the sparse matrices is roughly order $O(nN^2)$, for size n and bandwidth N. One result is that the cost sometimes drops as n increases.

4. The accuracy is within the precision specified. In fact, due to the conservative element thresholding (32), the actual error is considerably less than ϵ.

5. The cost increases with increasing precision ϵ, due to the increasing bandwidths generated. The bandwidths increase approximately as $\log(1/\epsilon)$.

6. For $k = 4$, our fast transformation algorithm does not maintain the specified precision of $\epsilon = 10^{-4}$. This anticipated result follows from the error estimate for polynomial interpolation of logarithm on intervals separated from the origin. An unanticipated attendant result is that the bandwidth increases as the quality of approximation deteriorates (compare to $k = 8$, below). As a result, we did not complete examples for $n = 4096$, 8192.

7. The inversion of the 8192×8192 matrix preserving three-digit accuracy is done in five minutes on the Sparcstation. This compares to 95 days (estimated) for inverting the dense matrix by Gauss–Jordan and to 24 minutes for one dense matrix–vector multiplication of that size.

The condition number of the problem, as approximated by the product of the row-sum norms of $U(I - T)U^T$ and its computed inverse, is 3 (independent of size). Five iterations were required by the Schulz method to achieve convergence.

In Fig. 5 we show stages in the transformation of the matrix $I - T$. In particular, for $\epsilon = 10^{-3}$ and $n = 64$, the matrices $R_0, \ldots, R_{l-1}$ defined in (31) are shown. In addition, for $n = 128$, the transformed matrix $U(I - T)U^T$ and its inverse are shown in Fig. 6.

In the next set of examples, for which results are displayed in Table 3, we used the wavelet-like basis of order $k = 8$. We observe the following.

1. The bandwidths of the operator matrix and its inverse are less for $k = 8$ than for $k = 4$. The inversion times are correspondingly smaller.

2. The time required to compute the operator matrix is almost four times as large as that for $k = 4$. This is due to the cost of transforming the near-diagonal band, which is twice as wide for $k = 8$ as for $k = 4$.

3. The obtained accuracy exceeds the specified precision consistently.

4. As for $k = 4$, the scaling with size n is linear for the transformation step and sublinear for the inversion step.

In the final set of examples in which uncorrected quadratures were used, we perform computations for $k = 4$ and $\epsilon = 10^{-3}$, with various operator kernels. Table 4 presents the results. The first three kernels contain singularities of the types $s(x) = \log(x)$ and $s(x) = x^\alpha$ for $\alpha = \pm\frac{1}{2}$, and are nonsymmetric and nonconvolutional. It is readily seen that the bandwidth is strongly dependent on the type of singularity, with the singularity $x^{-1/2}$ producing the greatest bandwidth. We mention also that this particular integral equation is poorly conditioned; the condition numbers of the discretizations for $n = 64, 128, 256, 512, 1024$ are $9, 17, 34, 98, 469$, respectively.

The fourth kernel provides an example with an oscillatory coefficient $p(x) = (1 + \frac{1}{2}\sin(100x))$. The bases developed in §2.4, which depend on p, are used to transform the discretized integral operator to sparse form. We see in Table 4 that the inverse is also very sparse.

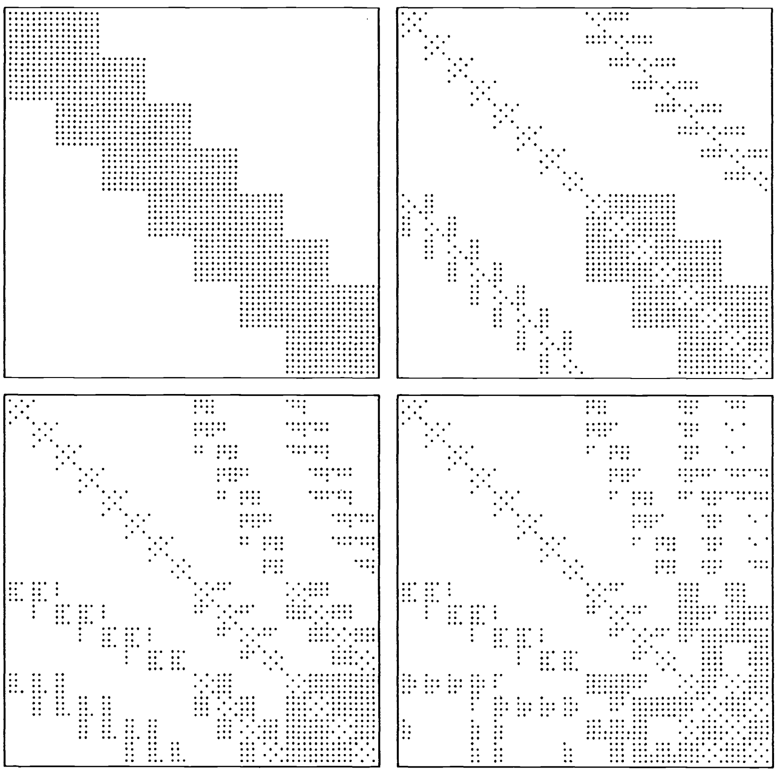

FIG. 5. *The matrices constructed in the transformation of* $I - T$*, matrices* $R_0, \ldots, R_3$ *defined in* (31)*, are shown for kernel* $K(x,t) = \log|x-t|$, $\epsilon = 10^{-3}$*, and* $n = 64$*. Matrix* R_4 *looks like* R_3 *and is not shown.*

4.2. Solution of integral equations. In the preceding subsection, we examined the characteristics of various integral operators and their inverses in wavelet-like coordinates. We used completely straightforward discretizations; the quadratures represented sums of the integrands at equispaced points (excluding singular points). Such simple quadratures converge too slowly to the integral operators to be of much use in solving integral equations, and we now turn to the high-order quadratures developed in [3].

We first present examples that correspond to the various kernels already tested and shown in Table 4. In Table 5 we tabulate the results, and bandwidth differences from Table 4 reflect the effect of the quadratures.

For the remaining examples we choose integral equations that can be solved analytically, so that the accuracy of the method can be checked. We consider a class of integral equations with logarithmic kernel,

$$f(x) - p(x) \int_0^1 \log|x-t|\, f(t)\, dt = g_m(x), \qquad x \in [0,1], \tag{33}$$

where the right-hand side g_m is chosen so that the solution f is given by the formula $f(x) = \sin(mx)$. The integration can be performed explicitly, yielding

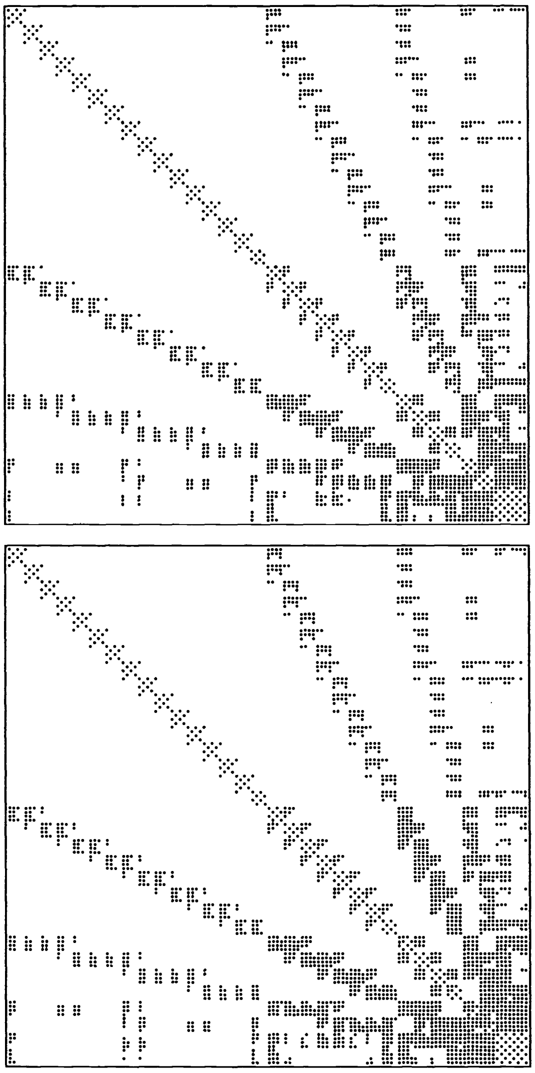

FIG. 6. *Transformed matrix $U(I-T)U^T$ (top) and its inverse (bottom) are shown for kernel $K(x,t)=\log|x-t|$, $\epsilon=10^{-3}$, and $n=128$.*

$$\int_0^1 \log|x-t|\, m\,\sin(mt)\,dt = \log(x)-\cos(m)\log(1-x) \\ -\cos(mx)[\mathrm{Ci}(mx)-\mathrm{Ci}(m(1-x))] \\ -\sin(mx)[\mathrm{Si}(mx)+\mathrm{Si}(m(1-x))],$$

where Ci and Si are the cosine integral and sine integral (see, e.g., [1, p. 231]). Equation (33) clearly requires quadratures with increasing resolution as m increases; for our examples we let $n=m$, which corresponds to 2π points per oscillation of the right-hand side g_m.

TABLE 3

The operator $I - \mathcal{K}$ defined by the formula $((I - \mathcal{K})f)(x) = f(x) - \int_0^1 \log|x-t|\, f(t)\,dt$ is discretized, transformed to the wavelet-like coordinates with $k = 8$, and inverted. (See Table 2 and text.)

		Transform.		Inversion		L^2

	4096	17.7	561	19.1	2610	0.798E−05

Initially we choose coefficient $p(x) = 1$. The results are given in Table 6. Here the error shown is the error of the computed solution relative to the true solution of the integral equation. Many of the observations of the preceding examples can be repeated here; additionally, we make the following comments.

1. The bandwidths are greater than for the uncorrected quadratures, but this effect generally decreases with increasing size.

2. The integral equations are solved to within the specified precision in every case but one. The exception, for $\epsilon = 10^{-4}$ and $n = 64$, is likely due to the small number of quadrature points and high specified precision.

3. An integral equation requiring an 8192-point discretization is solved to three-digit accuracy in less than 20 minutes on the Sparcstation.

For our second set of integral equations, we let the coefficient p be the oscillatory function given by the formula $p(x) = 1 + \frac{1}{2}\sin(100x)$. We carry out the transformation described in §2.4 to solve the integral equation (33). The results are shown in Table 7, and as with Table 6, the error refers to the error of the computed solution relative to the true solution of the integral equation. For the oscillatory coefficient we see performance similar to the constant-coefficient problem, but the cost is higher.

5. Generalizations and applications. In this paper, we have constructed a new class of vector-space wavelet-like bases in which a variety of integral operators

TABLE 4

The operator $I-\mathcal{K}$ defined by the formula $((I-\mathcal{K})f)(x) = f(x) - \int_0^1 K(x,t)\, f(t)\, dt$, for nonsymmetric, nonconvolutional kernels $K(x,t)$ shown below, is discretized, transformed to the wavelet-like coordinates with $k = 4$ and $\epsilon = 10^{-3}$, and inverted. (See Table 2 and text.)

are represented as sparse matrices. The inverses of these matrices are also sparse, a fact which enables the corresponding integral equations to be solved rapidly. We have asserted that the time complexity for an n-point discretization is bounded by order $O(n \log^2 n)$, but observed order $O(n)$ performance in practice. This cost should be contrasted with a cost of order $O(n^2)$ for direct application of a dense matrix, and order $O(n^3)$ for direct inversion.

A number of limitations exist in the procedures described above. These restrictions may be categorized as "software limitations" and "research questions." We discuss software limitations first.

5.1. Software limitations. Throughout the paper, we have assumed that the size of the problem n has the form $n = 2^l k$ for some l. This restriction is not fundamental; it merely simplifies the software.

A second software restriction is the assumption of only diagonal singularities. This case is an important one in practice, but in certain situations we may encounter

TABLE 5

The operator $I-\mathcal{K}$ defined by the formula $((I-\mathcal{K})f)(x) = f(x)-\int_0^1 K(x,t)\,f(t)\,dt$, for nonsymmetric, nonconvolutional kernels $K(x,t)$ shown below, is discretized with the corrected trapezoidal rules, transformed to the wavelet-like coordinates with $k = 4$ and $\epsilon = 10^{-3}$, and inverted. (Compare to Table 4.)

singularities or near-singularities off the main diagonal. The scheme described in §3.2 for transformation of a matrix to wavelet-like bases can be readily revised to an adaptive scheme, which works as follows: an $m \times m$ submatrix A is transformed to wavelet-like coordinates under the assumption that it can be approximated to high precision along both rows and columns by polynomials of degree less than k. This assumption is then checked by dividing A into four submatrices, each of dimension $m/2 \times m/2$, transforming each submatrix, and "gluing" the pieces together. If the results from the two computations match (to high precision), no further refinement of the original submatrix is needed. Otherwise, the procedure is repeated recursively on the $m/2 \times m/2$ submatrices. The cost of this adaptive procedure is roughly five times as great as the cost of a static procedure in which the structure of the singularities is known a priori.

5.2. Research questions. The list of research issues is, of course, much longer. One of the most pressing issues is the generalization to two and three dimensions. Although, conceptually, the generalization of the wavelet-like bases to several dimensions is quite straightforward (see, e.g., [2]), actual procedures to perform the required orthogonalizations have not been developed. Also, the issue of high-order quadratures for two and three dimensions has not been resolved.

Another question is whether similar "custom-constructed" bases can be used to create sparse representations of integral operators with oscillatory kernels. Initial

TABLE 6

The integral equations $f(x) - \int_0^1 \log|x-t|\, f(t)\, dt = g_m(x)$, for which an explicit solution is known, are solved by the methods of this chapter (compare to Table 2 and see text). For $\epsilon = 10^{-2}, 10^{-3}, 10^{-4}$ we set $k = 4, 4, 8$, respectively.

		Transform.		Inversion		L^2

efforts in this direction for a limited class of such operators, in particular for Fourier transforms with nonequispaced points and frequencies, appear promising [9].

5.3. Applications. In this paper the primary application of our new wavelet-like bases has been the solution of second-kind integral equations. The bases are very effective for the fast solution of a wide class of such problems. In addition, we expect many other classes of problems to be solved efficiently using these techniques. We list a few of these problem types.

1. Elliptic partial differential equations rewritten as integral equations by the Lippman–Schwinger method, in which the Green's functions are nonoscillatory.

2. Evolution of homogeneous parabolic partial differential equations (PDEs) with constant or periodic boundary conditions, by explicit time steps. This method consists of repeated squarings of the operator for a single time step, leading to an order $O(n \log t)$ algorithm for evolving an n-point discretization for t time steps.

3. Evolution of general parabolic PDEs by implicit time steps, in which the elliptic problem on each time step is solved in wavelet-like coordinates.

4. Evolution of hyperbolic PDEs by a method of operator squaring analogous to the scheme proposed for homogeneous parabolic PDEs above.

5. Problems of potential theory and pseudodifferential operators.

6. Signal compression, including signals of seismic, visual, and vocal origin. There is also reason to expect that analysis of such compressed data will be simpler than analysis of data resulting from less efficient compression schemes.

TABLE 7
The integral equations $f(x) - p(x)\int_0^1 \log|x-t|\,f(t)\,dt = g_m(x)$, for which an explicit solution is known, are solved by the methods of this chapter (compare to Table 2 and see text). For $\epsilon = 10^{-2}, 10^{-3}, 10^{-4}$ we set $k = 4, 4, 8$, respectively.

In this paper we strayed from the original mathematical definition of wavelets to construct classes of bases tailored for numerical computation. The basis vectors' principal properties of local support and vanishing moments lead to sparse representations of functions and operators that are smooth except at a small number of singularities. There is little doubt that other bases can be constructed along similar lines to possess various properties. One current challenge is the construction of bases suitable for the efficient representation of a variety of oscillatory operators.

AN h-r-ADAPTIVE APPROXIMATE RIEMANN SOLVER FOR THE EULER EQUATIONS IN TWO DIMENSIONS*

MICHAEL G. EDWARDS†‡, J. TINSLEY ODEN†, AND LESZEK DEMKOWICZ†

Abstract. A new adaptive strategy for solving the Euler equations of compressible flow is presented. The method of Roe [*J. Comput. Phys.*, 43 (1981), pp. 357–372] is extended into two dimensions for an arbitrary quadrilateral grid and is coupled with the h-adaptive quadrilateral refinement-unrefinement algorithm of Demkowicz and Oden [*TICOM* Report 88-02]. Refinement of a quadrilateral grid retains a certain grid structure which is fully exploited by the extension of the higher-order version of the method into two dimensions. A total variation diminishing (TVD) analysis is presented for a nonuniform grid, together with an assessment of the solution error induced by the nonuniformity in the grid. Grid movement is also considered and adaptive strategies are discussed and tested. The adaptive scheme proves to be highly robust. Improved accuracy and large savings in computer time are obtained.

Key words. adaptive, grid refinement, higher-order, TVD, Riemann solver, compressible Euler equations

1. Introduction.

In the early seventies, much of the research on numerical methods for hyperbolic conservation laws focused on producing schemes that were known to produce physically meaningful solutions whenever they converged to the exact solution. At the same time, schemes were sought that did not oscillate in the vicinity of shocks. The first family of schemes that fulfilled these requirements were the so-called monotone difference schemes in which the numerical fluxes are monotone functions of the cell-centered values of the discrete solutions.

Unfortunately, monotone schemes were found to suffer from two major deficiencies: they are no more than first-order accurate, and they are usually overdissipative, smearing shocks over several grid spacings. These defects promoted an extensive series of investigations for the "holy grail" in conservation law solvers: schemes that did not oscillate but did yield higher-order (e.g., second-order) accuracy.

An advance in this direction for the case of one-dimensional scalar conservation laws was made by Harten [3], who introduced the notion of a TVD (total variation diminishing) scheme. The idea is that if the total variation of the solution can be controlled so that it never increases over a timestep, then a nonoscillating solution with second-order accuracy can be obtained. This can be accomplished by limiting the values of the numerical flux ("flux-limiting methods"); several alternative flux-limiting strategies were discussed by Sweby [4]. Among these is the method of Roe [1], which, while usually very effective, may violate the entropy condition for the conservation law. An "entropy fix" was proposed by Harten and Hyman [5] for overcoming this defect in Roe's approach.

It should also be noted that most of the theoretical results were developed for one-dimensional scalar conservation laws. Goodman and LeVeque [6] argued that

any two-dimensional TVD scheme had to also be monotone, and hence, may be only first-order accurate. However, numerical experiments suggest that two-dimensional generalizations of one-dimensional TVD schemes (which are not strictly TVD schemes in two dimensions) can be second-order accurate in many cases. Moreover, they can also be robust and yield nonoscillating, high-resolution simulation of shocks (see, e.g., Yee [7]).

The simple but less reliable alternative to using a TVD scheme is to resort to some variant of a Lax–Wendroff scheme and combine it with an ad hoc artificial viscosity method, which can be tuned to eliminate spurious oscillations in some cases [8].

However, the resolution of discontinuities obtained by any discrete scheme will still be limited by the local cell size. Adaptive grid techniques have been developed by several authors, (e.g., [9], [10], [11], [12], and [13]) with a common aim of concentrating (either by inserting or moving) grid nodes into the areas of the flow field where they are most needed (where the flow gradients are large), thereby reducing the discretization error as the element size reduces. For a numerical scheme of given accuracy, grid adaption can lead to increased accuracy and a reduction in computer time and computer storage requirements.

Although adaptive techniques can improve on the results obtained with artificial viscosity methods, any spurious oscillations that occur can be highlighted by the adaptive grid and amplified [9]. This provides a strong motivation for combining TVD schemes with adaptivity. In particular, the combination of a second-order flux-limited scheme on an adaptive quadrilateral grid has a two-fold advantage over its triangular counterpart.

First, a dynamically refined quadrilateral grid is far less likely to produce badly distorted elements than a dynamically refined triangular grid, and therefore, we can expect convergence on a quadrilateral grid.

Second, the flux-limiting concept can be naturally generalized to an adaptive quadrilateral grid.

In this paper, we develop an adaptive, two-dimensional TVD scheme for systems of hyperbolic conservation laws, particularly Euler's equations. This scheme functions on an arbitrary unstructured mesh of quadrilateral cells (unstructured in the sense that the cells may be dynamically refined or unrefined). We employ an extended version of Roe's scheme in two dimensions with flux limiting and an entropy fix.

Error indicators are computed at the end of a designated number of timesteps, and the mesh is automatically refined (an h-method) or unrefined using the technique of Demkowicz and Oden [2]. This adaptive technique is applicable to both time-dependent and steady-state problems.

In addition (currently only) for steady-state problems, grid node relocation (an r-method) is induced according to an equidistribution principle. The grid is postprocessed and automatically aligns grid lines along discontinuities.

The r-method is also combined with the h-method (currently) for steady-state problems. After the grid has been relocated and subsequently refined, results superior to those of h-adaptive schemes without node relocation are obtained.

In all of the numerical experiments performed, the adaptive h-scheme (for time-dependent and steady-state problems) and the h-r scheme (for steady-state problems) perform surprisingly well, giving excellent resolution of flow features on rather coarse grids. Large savings in computer time were also observed with the same code taking four times longer to run on equivalent uniform fine grids.

2. Roe scheme. We begin by reviewing the scheme proposed by Roe [14], [15] for the scalar conservation law

$$\begin{aligned} &u_t + f(u)_x = 0 \quad t > 0 \quad x \in \mathbb{R}, \\ &u(x,0) = u_o(x), \end{aligned} \tag{2.1}$$

where $u(x,t)$ has initial data $u(x,0) = u_o(x)$. We also write (2.1) in the form

$$u_t + a(u)u_x = 0, \qquad a(u) = \frac{df}{du}.$$

We next partition the domain $\mathbb{R}$ into finite difference cells $I_i = [x_{i-\frac{1}{2}}, x_{i+\frac{1}{2}}]$ $i \in Z$, with centroids x_i. A piecewise constant mesh function W takes on values $W_i = W(x_i)$. We use the following standard notation for differences:

$$\Delta W_{i+\frac{1}{2}} = \Delta_- W_{i+1} = \Delta_+ W_i = W_{i+1} - W_i;$$

for the grid ratio μ:

$$\mu = \Delta t / \Delta x; \tag{2.2a}$$

for the local CFL number ν:

$$\nu_{i+\frac{1}{2}} = \frac{\mu \Delta f_{i+\frac{1}{2}}}{\Delta u_{i+\frac{1}{2}}} = \mu a(u_i, u_{i+1}) = \mu a_{i+\frac{1}{2}}; \tag{2.2b}$$

and $a(u_i, u_{i+1})$ is the discrete wave speed at $i + \frac{1}{2}$.

The first-order Roe [14] scheme (in space and time) is the conservative upwind scheme

$$u_i^{n+1} = \begin{cases} u_i^n - \nu_{i-\frac{1}{2}} \Delta u_{i-\frac{1}{2}}^n, & \nu_{i-\frac{1}{2}} \geq 0, \\ u_i^n - \nu_{i+\frac{1}{2}} \Delta u_{i+\frac{1}{2}}^n, & \nu_{i+\frac{1}{2}} < 0, \end{cases} \tag{2.3}$$

which is stable and oscillation free for

$$|\nu| \leq 1. \tag{2.4}$$

We note that (2.3) can be written as

$$u_i^{n+1} = u_i^n - \mu (h_{i+\frac{1}{2}} - h_{i-\frac{1}{2}}), \tag{2.5a}$$

where

$$h_{i+\frac{1}{2}} = h(u_{i+1}, u_i) = \tfrac{1}{2}(f(u_i^n) + f(u_{i+1}^n) - |a_{i+\frac{1}{2}}| \Delta u_{i+\frac{1}{2}}^n) \tag{2.5b}$$

is a consistent numerical flux function with

$$h(u,u) = f(u).$$

It is well known that this scheme must be modified to ensure entropy satisfaction, which is achieved here by employing the Harten and Hyman entropy fix [5]. Roe [14] extended his scheme to second-order accuracy and assured monotonicity preservation (monotone data at time level n remains monotone at time level $n+1$) by the use of a flux limiter, a device previously used by van Leer [16]. The monotonicity-preserving schemes of Chakravarthy and Osher [17] and Harten [3] employ similar devices, and the relationships between the schemes is discussed by Sweby [4], who presents a unified approach to designing such schemes.

All of the above-mentioned schemes can be shown to be TVD, a notion first introduced by Harten [3]. The total variation, at time level $n+1$, TV(u^{n+1}), of the solution is defined by

$$\text{TV}\ (u^{n+1}) = \sum_i \left|u^{n+1}_{i+1} - u^{n+1}_i\right|. \tag{2.6}$$

Harten [5] defined a TVD scheme for which

$$\text{TV}\ (u^{n+1}) \leq \ \text{TV}\ (u^n). \tag{2.7}$$

One immediate consequence of (2.7) is that the total variation remains bounded, which is one of the criteria that must be satisfied in order to establish convergence of a difference scheme approximating (2.1) (see [18], [19], and [20]).

An important practical consequence of (2.7) is that the solutions obtained from a TVD scheme are free of spurious oscillations, which follows from Harten's [3] observation that a TVD scheme is monotonicity preserving.

Harten [3] has also shown that sufficient conditions for a scheme of the form

$$u^{n+1}_i = u^n_i - C_{i-\frac{1}{2}}\Delta u^n_{i-\frac{1}{2}} + D_{i+\frac{1}{2}}\Delta u^n_{i+\frac{1}{2}} \tag{2.8a}$$

to be TVD are

$$0 \leq C_{i-\frac{1}{2}}, \quad 0 \leq D_{i+\frac{1}{2}}, \quad 0 \leq C_{i+\frac{1}{2}} + D_{i+\frac{1}{2}} \leq 1. \tag{2.8b}$$

From (2.3) and (2.4) , it follows that the first-order upwind scheme satisfies (2.8b) (and is therefore TVD) if for all i,

$$|\nu_{i+\frac{1}{2}}| \leq 1. \tag{2.9}$$

3. A TVD scheme on a nonuniform grid. While much attention has been focused on the application of the Roe scheme via the use of uniform grids, very little attention has been given in the case of nonuniform grids [21]. Since the usual definitions of accuracy on a uniform grid do not necessarily apply to nonuniform grids, we shall refer to the usual first-order scheme as the low-order scheme, and the usual second-order schemes as the high-order scheme on nonuniform grids.

In this section we shall consider how to construct a high-order TVD scheme on a nonuniform grid in one dimension. Our primary concern is that the scheme remains conservative on a nonuniform grid. We shall consider the question of accuracy after deriving a TVD scheme in conservation form on a nonuniform grid.

Consider the Lax–Wendroff scheme on a uniform grid:

$$u^{n+1}_i = u^n_i - \tfrac{1}{2}(\nu_{i-\frac{1}{2}}\Delta u^n_{i-\frac{1}{2}} + \nu_{i+\frac{1}{2}}\Delta u^n_{i+\frac{1}{2}}) + \tfrac{1}{2}(|\nu_{i+\frac{1}{2}}|^2\Delta u^n_{i+\frac{1}{2}} - |\nu_{i-\frac{1}{2}}|^2\Delta u^n_{i-\frac{1}{2}}). \tag{3.1}$$

This scheme may be written in conservation form as

$$u^{n+1}_i = u^n_i - \frac{\Delta t}{\Delta x}(h_{i+\frac{1}{2}} - h_{i-\frac{1}{2}}), \tag{3.2}$$

where

$$h_{i+\frac{1}{2}} = \left(\frac{f_i + f_{i+1}}{2}\right) - \frac{\Delta t}{2\Delta x}|a_{i+\frac{1}{2}}|^2 \Delta u^n_{i+\frac{1}{2}}. \tag{3.3}$$

The scheme (3.2) is said to be conservative since conservation may be demonstrated immediately by summing (3.2) over all grid points i to obtain

$$\sum_i (u_i^{n+1} - u_i^n)\Delta x = -\Delta t \sum_i (h_{i+\frac{1}{2}} - h_{i-\frac{1}{2}}). \tag{3.4}$$

Omitting boundary terms, the contribution on the right of (3.4) is zero, hence

$$\sum_i (u_i^{n+1} - u_i^n)\Delta x = 0, \tag{3.5}$$

and (3.5) indicates that the area (or "mass") $\int u dx$ is conserved. So far we have assumed that Δx is constant, but if we consider the nonuniform grid shown in Fig. 1, then we can replace Δx with the local element length Δx_i in (3.2)–(3.4) and retain conservation. The nonuniform grid approximation is

$$u_i^{n+1} = u_i^n - \frac{\Delta t}{\Delta x_i}(h_{i+\frac{1}{2}} - h_{i-\frac{1}{2}}), \tag{3.6}$$

where

$$h_{i+\frac{1}{2}} = \left(\frac{f_i + f_{i+1}}{2}\right) - \frac{\Delta t}{2\Delta x_{i+\frac{1}{2}}}|a_{i+\frac{1}{2}}|^2 \Delta u_{i+\frac{1}{2}}, \tag{3.7a}$$

$$\Delta x_{i+\frac{1}{2}} = (x_{i+1} - x_i). \tag{3.7b}$$

Note the introduction of $\Delta x_{i+\frac{1}{2}}$ in $h_{i+\frac{1}{2}}$, which ensures that the flux summation will continue to cancel for a nonuniform grid.

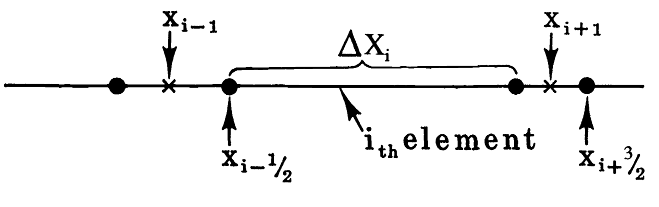

FIG. 1. *Nonuniform grid.*

The low-order scheme of §2 can be similarly generalized to a nonuniform grid with (3.7a) replaced by

$$h_{i+\frac{1}{2}} = \tfrac{1}{2}(f_i + f_{i+1}) - \tfrac{1}{2}|a_{i+\frac{1}{2}}|\Delta u_{i+\frac{1}{2}}, \tag{3.8}$$

while (3.6) remains unchanged. Expanding (3.6) and (3.8) and taking the case $a_{i+\frac{1}{2}} \geq 0$, the scheme can be written in the upwind form

$$u_i^{n+1} = u_i^n - \frac{\Delta t a_{i-\frac{1}{2}}}{\Delta x_i} \Delta u^n_{i-\frac{1}{2}}. \tag{3.9}$$

As in the case for uniform grids [4], the Lax–Wendroff scheme can be rearranged as the first-order upwind scheme together with an antidiffusive term, i.e.,

$$u_i^{n+1} = u_i^n - \frac{\Delta t a_{i-\frac{1}{2}}}{\Delta x_i} \Delta u_{i-\frac{1}{2}}^n - \frac{\Delta_-}{\Delta x_i} \left[\frac{\Delta t}{2} \left(1 - \nu_{i+\frac{1}{2}}\right) a_{i+\frac{1}{2}} \Delta u_{i+\frac{1}{2}}^n \right]. \tag{3.10}$$

Following the usual TVD analysis [4] an antidiffusive term can be added in the conservation form

$$\frac{\Delta_-}{\Delta x_i} \left(\frac{\Delta t}{2} \left(1 - \nu_{i+\frac{1}{2}}\right) a_{i+\frac{1}{2}} \left(1 - \phi_{i+\frac{1}{2}}\right) \Delta u_{i+\frac{1}{2}} \right), \tag{3.11}$$

where $\phi_{i+\frac{1}{2}}$ is the flux limiter. The resulting scheme is

$$u_i^{n+1} = u_i^n - \frac{\Delta t a_{i-\frac{1}{2}}}{\Delta x_i} \Delta u_{i-\frac{1}{2}}^n - \frac{\Delta_-}{\Delta x_i} \left(\frac{\Delta t}{2} \left(1 - \nu_{i+\frac{1}{2}}\right) a_{i+\frac{1}{2}} \phi_{i+\frac{1}{2}} \Delta u_{i+\frac{1}{2}}^n \right). \tag{3.12}$$

Rearranging (3.12) into the form

$$u_i^{n+1} = u_i^n - c_{i-\frac{1}{2}} \Delta u_{i-\frac{1}{2}}^n, \tag{3.13}$$

where

$$c_{i-\frac{1}{2}} = \frac{a_{i-\frac{1}{2}}}{\Delta x_i} \Delta t \left(1 - \left(\frac{\phi_{i+\frac{1}{2}}}{r_i^+} - \phi_{i-\frac{1}{2}} \right) \frac{(1 - \nu_{i-\frac{1}{2}})}{2} \right), \tag{3.14}$$

$$r_i^+ = \frac{a_{i-\frac{1}{2}}(1 - \nu_{i-\frac{1}{2}}) \Delta u_{i-\frac{1}{2}}}{a_{i+\frac{1}{2}}(1 - \nu_{i+\frac{1}{2}}) \Delta u_{i+\frac{1}{2}}}, \qquad \nu_{i+\frac{1}{2}} = \frac{a_{i+\frac{1}{2}} \Delta t}{\Delta x_{i+\frac{1}{2}}}, \tag{3.15}$$

and comparing with (2.8), it follows that the scheme will be TVD for

$$0 \le c_{i-\frac{1}{2}} \le 1. \tag{3.16}$$

Taking ϕ to be positive the left-hand inequality of (3.16) is satisfied for

$$\frac{\phi_{i+\frac{1}{2}}}{r_i^+} \le \frac{2}{(1 - \nu_{i-\frac{1}{2}})}. \tag{3.17}$$

The right-hand inequality is satisfied for

$$\phi_{i-\frac{1}{2}} \le \frac{2}{(1 - \nu_{i-\frac{1}{2}})} \left(\frac{1}{\nu_i} - 1 \right), \tag{3.18a}$$

where

$$\nu_i = \frac{a_{i-\frac{1}{2}} \Delta t}{\Delta x_i}. \tag{3.18b}$$

The bound on ϕ for a uniform grid

$$\phi \le \min(2 r_i^+, 2) \tag{3.19}$$

is certainly obtained if

$$\frac{1}{\max(\nu_i)} - 1 \geq 1, \tag{3.20}$$

and $0 \leq \nu_{i-\frac{1}{2}} \leq 1$, and (3.20) is satisfied if

$$a_{i-\frac{1}{2}}\Delta t \leq \frac{\Delta x_i}{2}, \tag{3.21}$$

which corresponds to a maximum Courant–Friedrichs–Lewy (CFL) condition of $\frac{1}{2}$, but with respect to the mean cell length. A similar analysis can be performed for a negative wave such that $\phi \leq \min(2r^-_{i+1}, 2)$, where r^-_{i+1} is defined below.

The general high-order TVD scheme for a nonuniform grid which is used here can be written as

$$u_i^{n+1} = u_i^n - \mu(\Delta_- h_{i+\frac{1}{2}} + \Delta_-((\beta^+_{i+\frac{1}{2}}\phi(r_i^+) - \beta^-_{i+\frac{1}{2}}\phi(r^-_{i+1}))\Delta u^n_{i+\frac{1}{2}})), \tag{3.22a}$$

where $h_{i+\frac{1}{2}}$ is the first-order flux (3.8) and

$$\begin{aligned}
\beta^+_{i+\frac{1}{2}} &= (1 - \nu^+_{i+\frac{1}{2}})a^+_{i+\frac{1}{2}}/2,\\
\beta^-_{i+\frac{1}{2}} &= (1 + \nu^-_{i+\frac{1}{2}})a^-_{i+\frac{1}{2}}/2,\\
\nu^\pm_{i+\frac{1}{2}} &= \tfrac{1}{2}\,(\nu_{i+\frac{1}{2}} \pm |\nu_{i+\frac{1}{2}}|),\\
\mu &= \Delta t/\Delta x_i.
\end{aligned} \tag{3.22b}$$

$\nu_{i+\frac{1}{2}}$ is defined in (3.15) together with r_i^+. When the wave has a negative sign,

$$r^-_{i+1} = \frac{(1 + \nu_{i+\frac{3}{2}})a_{i+\frac{3}{2}}\Delta u_{i+\frac{3}{2}}}{(1 + \nu_{i+\frac{1}{2}})a_{i+\frac{1}{2}}\Delta u_{i+\frac{1}{2}}}$$

and $\phi(r)$ can be any of the usual flux limiters ranging from minmod to superbee [4].

4. Accuracy on a nonuniform grid. In Appendix A we show that while the low- and high-order schemes of (3.6)–(3.8) have a local truncation error of $O(1)$ on a nonuniform grid, the error in the solution converges with $O(\Delta x)$ and they are therefore supraconvergent schemes [22].

While this result holds for an arbitrary fixed nonuniform grid, we stress that the grids used in this paper are obtained via an equidistribution principle. The grid continually adapts with the solution such that the finest grid zones overlay the regions of the flow field with steep flow gradients. Away from the interfaces between grids with differing levels of refinement the grid is uniform and, therefore, the local truncation error of the scheme is restored to the uniform grid value, typically $O(\Delta x^2)$.

Therefore, although formally, only first-order convergence can be demonstrated, the adaptivity can be expected to provide a better convergence rate than that for a fixed arbitrary nonuniform grid.

5. Roe scheme for systems of conservation laws. The extension of the scalar algorithms described above to systems of equations is performed by applying a scalar algorithm to each characteristic equation obtained by decomposition. The main difficulty with this approach is ensuring that conservation is obtained upon recomposition to the conservative variables.

In Roe's scheme [1] for solving the system of conservation laws

$$\frac{\partial \boldsymbol{u}}{\partial t} + \frac{\partial \boldsymbol{f}(\boldsymbol{u})}{\partial x} = 0 \tag{5.1}$$

with initial data

$$\boldsymbol{u}(x,0) = \boldsymbol{u}_0(x),$$

a linearized equation is used to approximate the solution to the Riemann problem. A constant mean-value Jacobian $\tilde{\boldsymbol{A}}(\boldsymbol{u}_L, \boldsymbol{u}_R)$ is constructed such that the following three properties are satisfied:

(i) $\tilde{\boldsymbol{A}}(u_L, u_R)$ is consistent, as $\boldsymbol{u}_L \to \boldsymbol{u}_R$ $\tilde{\boldsymbol{A}}(\boldsymbol{u}_L, \boldsymbol{u}_R) \to \boldsymbol{A}(\boldsymbol{u})$, where $\boldsymbol{A}(\boldsymbol{u}) = \boldsymbol{f}_{\boldsymbol{u}}$;
(ii) For any $\boldsymbol{u}_L$, $\boldsymbol{u}_R$, $\tilde{\boldsymbol{A}}(\boldsymbol{u}_L, \boldsymbol{u}_R)\ (\boldsymbol{u}_R - \boldsymbol{u}_L) = \boldsymbol{f}(\boldsymbol{u}_R) - \boldsymbol{f}(\boldsymbol{u}_L)$;
(iii) The eigenvectors of $\tilde{\boldsymbol{A}}$ are linearly independent.

Condition (ii) ensures that the resulting scheme is conservative; (ii) and (iii) ensure that in the case of a single shock wave, the solution to the Riemann problem will be exact [1]. In order to apply the scalar scheme, the system is decomposed by expanding $\Delta \boldsymbol{u}$ as

$$\Delta \boldsymbol{u} = \sum_j \boldsymbol{e}_j \alpha_j, \tag{5.2}$$

and the flux difference $\Delta \boldsymbol{f}$ as

$$\Delta \boldsymbol{f} = \tilde{\boldsymbol{A}} \Delta \boldsymbol{u} = \sum_j \lambda_j \boldsymbol{e}_j \alpha_j, \tag{5.3}$$

where $\Delta \boldsymbol{u}$ and α_j are the changes in the conservative and characteristic variables, respectively, and λ_j and $\boldsymbol{e}_j$ are the eigenvalues and eigenvectors of $\tilde{\boldsymbol{A}}$, respectively.

Condition (ii) enables the first-order scheme to be written as

$$\boldsymbol{u}_i^{n+1} = \boldsymbol{u}_i^n - \mu(\boldsymbol{h}_{i+\frac{1}{2}} - \boldsymbol{h}_{i-\frac{1}{2}}), \tag{5.4a}$$

where now

$$\boldsymbol{h}_{i+\frac{1}{2}} = \left(\frac{\boldsymbol{f}_i + \boldsymbol{f}_{i+1}}{2}\right) - \frac{1}{2}\sum_j \boldsymbol{e}_j |\lambda_j| \alpha_j. \tag{5.4b}$$

This scheme is immediately applicable to nonuniform grids provided that the grid ratio μ defined in (3.22) is used in (5.4). The high-order version of this scheme can be derived as in the scalar case (3.22), by the addition of an antidiffusive flux to the first-order flux $\boldsymbol{h}_{i+\frac{1}{2}}$, resulting in

$$\boldsymbol{u}_i^{n+1} = \boldsymbol{u}_i^n - \mu\Delta_- \left(\boldsymbol{h}_{i+\frac{1}{2}} + \sum_j \boldsymbol{e}_j \left(\beta^{j^+}\phi\left(r_i^{j^+}\right) - \beta^{j^-}\phi\left(r_{i+1}^{j^-}\right)\right)\alpha_{i+\frac{1}{2}}^j\right), \tag{5.5}$$

where a superfix j represents the jth characteristic component; each component has its own wave speed λ^j and gradient α^j, and these replace the scalar wave speed a and the gradient Δu, respectively, in (3.15) and (3.22).

6. Two-dimensional scheme.

6. Two-dimensional scheme. Consider a system of conservation laws in two dimensions written in integral conservation form

$$\int_\omega (\boldsymbol{u}_t + \boldsymbol{f}_x + \boldsymbol{g}_y) d\tau = 0 \tag{6.1}$$

with initial data

$$\boldsymbol{u}(x,y,0) = \boldsymbol{u}_0(x,y).$$

In order to solve (6.1), the scheme of §5 is extended into two dimensions for an arbitrary, quadrilateral grid. Assuming that the conservation variables $\boldsymbol{u}$ have a piecewise constant variation over each element, an application of the Gauss flux theorem to (6.1) over a given element results in

$$\begin{aligned} \tau_e u_t &= -\sum_k \oint (f dy_k - g dx_k) \\ &= -\sum_k \oint \boldsymbol{F}_k d\ell_k, \end{aligned} \tag{6.2}$$

where

$$\boldsymbol{F} = \boldsymbol{f} c_k + \boldsymbol{g} s_k,$$

$$c_k = dy_k/\ell_k, \qquad s_k = -dx_k/\ell_k,$$

$$\ell_k^2 = dx_k^2 + dy_k^2,$$

(c_k, s_k) are the direction cosines of the kth outward normal, and τ_e is the element (e) area. By further assuming a one-dimensional variation in the variables $\boldsymbol{u}$ across each element face k, the resolved flux $\boldsymbol{F}_k$ can be regarded as being locally one-dimensional. Thus the scheme of §5 can be applied with the Roe flux (corresponding to F) substituted in the above summation (6.2) for each face of the element. The local Jacobian matrix is given by

$$\boldsymbol{A}(\boldsymbol{u}) = \frac{\partial \boldsymbol{F}}{\partial \boldsymbol{u}} = \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{u}} c + \frac{\partial \boldsymbol{g}}{\partial \boldsymbol{u}} s, \tag{6.3a}$$

and the corresponding eigenvectors and eigenvalues of this matrix (which appear in the Roe flux) must satisfy

$$\Delta \boldsymbol{u} = \sum_j \boldsymbol{e}_j \alpha_j, \qquad \Delta \boldsymbol{F} = \sum_j \lambda_j \boldsymbol{e}_j \alpha_j. \tag{6.3b}$$

Finally this scheme can be written in the classical finite-volume form as

$$\tau_e(\boldsymbol{u}_e^{n+1} - \boldsymbol{u}_e^n) = -\Delta t \left(\sum_i (\bar{\boldsymbol{f}}_i \Delta y_i - \bar{\boldsymbol{g}}_i \Delta x_i) - \sum_i \frac{\ell_i}{2} \left(\sum_j \boldsymbol{e}_j |\lambda_j| \alpha_j \right)_i \right), \tag{6.4a}$$

where

$$\bar{\boldsymbol{f}}_i = \tfrac{1}{2}\,(\boldsymbol{f}_e + \boldsymbol{f}_{e_i}), \qquad \bar{\boldsymbol{g}}_i = \tfrac{1}{2}\,(\boldsymbol{g}_e + \boldsymbol{g}_{e_i}), \tag{6.4b}$$

and the summation index i varies over the sides of the element e, $(\Delta x_i, \Delta y_i)$ being the vector element of the length tangential to side i and e_i being the ith neighboring element number.

The high-order version of this scheme can also be written in the form (6.4a). The antidiffusive flux of (5.5) is generalized into two dimensions by associating an antidiffusive flux contribution with each face of the element. The local eigenvalues and eigenvectors of (6.3) are used in the construction of the antidiffusive flux at each face. The flux limiters corresponding to the even- and odd-numbered faces of the element (Fig. 2) are evaluated with respect to the underlying x and y directions of the grid, respectively. Each antidiffusive term is then multiplied by its corresponding element face length and the sign of the local outward normal vector before being assembled on the right-hand side of (6.4).

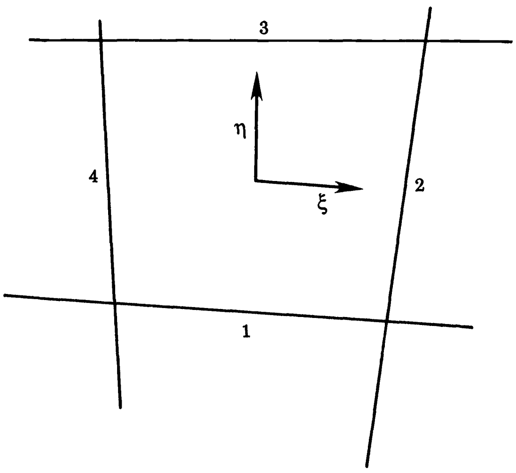

FIG. 2. *Local coordinate system.*

For a regular grid, the resulting scheme is second-order accurate with respect to the $x - y$ coordinate directions. Formal second-order accuracy, including cross-derivative terms, can be achieved via the time-splitting technique of Strang [23].

The Roe matrix A, together with the eigenvectors, eigenvalues, and characteristic increments α_j, are presented in Appendix B for the Euler equations of compressible flow in two dimensions.

7. Adaptive refinement and unrefinement. In this section we shall briefly describe some of the principle features pertaining to h-refinements which are contained within the general data structure developed by Demkowicz and Oden [2] for quadrilateral grids. A description of the logic and account of the structure is given by Demkowicz in [24].

Following the nomenclature of Demkowicz and Oden [2], when a refinement of a quadrilateral element takes place the element is divided into four subelements, which are called "sons." The group of four sons is called a "family" and the original element is called the "father" element (Fig. 3).

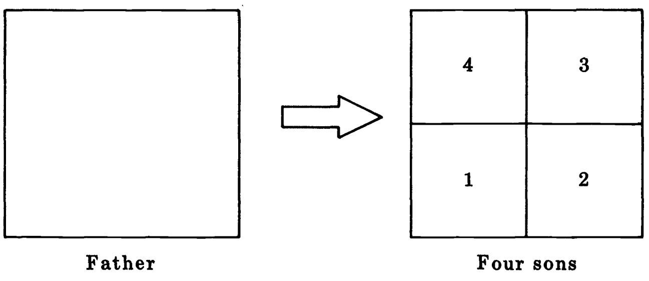

FIG. 3. *Initial refinement.*

A typical refinement, shown in Fig. 4, gives rise to nodes such as p which are called hanging nodes or irregular nodes. Whereas each regular node is located at the corner in common with all of its neighboring elements, the irregular node is not located at a corner for all of its neighboring elements. In this data structure only one irregular node per element side is permitted.

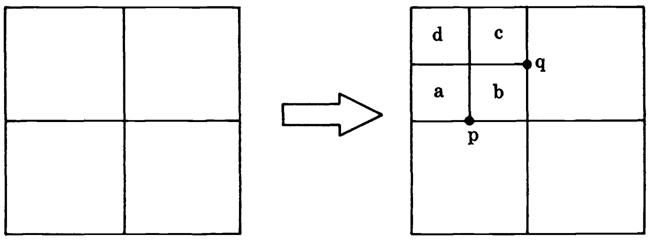

FIG. 4. *Refinement with irregular nodes p, q.*

Due to this constraint (one irregular node per side) any element can have a maximum of eight sides and eight neighbors. Following Devloo [25] the sides of the element are labeled one to eight in the sequence shown in Fig. 5.

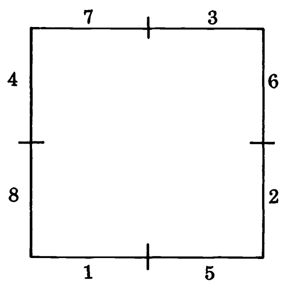

FIG. 5. *Element side numbering.*

This numbering sequence gives rise to some attractive logical relations which are exploited within the data structure [24], [25] and within the extension of the above two-dimensional scheme to an unstructured grid.

Returning to Fig. 4, if one of the sons (b) of the family is refined, the constraint (one irregular node per element side) causes the neighboring element to be refined so that some spreading of the refinement process can occur. This is illustrated in Fig. 6.

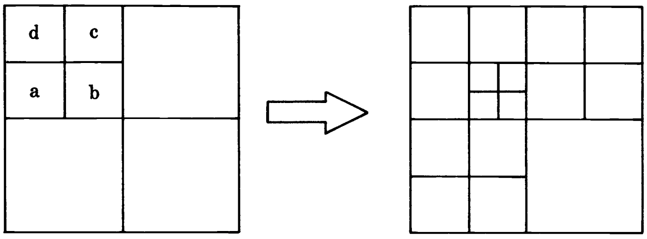

FIG. 6. *Spreading of refinement.*

Adaptive strategy. As in [9], a crude computational grid is generated by dividing the flow domain into a suitably small number of quadrilaterals. The initial crude grid is then globally refined to create a reasonable coarse grid (e.g., Fig. 12), which is used for the first part of the computation. After a specified number of timesteps (or iterations) the adaptive strategy (described below) is invoked.

The adaptive criteria for deciding when to refine an element and unrefine a family is based on monitoring the density gradient as in [9] and [10]. The density is chosen as the key variable because it is discontinuous at shocks and contact discontinuities.

The actual adaptive strategy is listed below. The condition on the gradient of the sons of the family in (iii)(a) makes the procedure much more robust.

(i) Define the refinement and unrefinement tolerances (user specified constants) $\in_r$, $\in_u$, respectively.

(ii) Find the maximum L_∞ density gradient throughout the field,

$$\|\nabla\rho\|_\infty = \max_{1\le NEL \le NRELEM} |\nabla\rho|_{NEL}.$$

(iii) Looping over the families (N_F = I,NRFAM), find the density gradient modulus $|\nabla\rho|_{e_i}$ of each son $e_i (i = 1, 4)$ of the family (number N_F). Define the mean family density gradient by

$$|\nabla\rho|_{N_F} = \tfrac{1}{4}\sum_{i=1}^{4} |\nabla\rho|_{e_i}.$$

If for each son (e_i) of the family (N_F),

$$\text{(a)}\quad |\nabla\rho|_{e_i} < \in_r \|\nabla\rho\|_\infty \text{ and}$$

$$\text{(b)}\quad |\nabla\rho|_{N_F} < \in_u \|\nabla\rho\|_\infty,$$

then unrefine the family and define the new element vector of conservation variables by

(7.1) $$u_{N_F} = \sum_{i=1}^{4} A_{e_i} u_{e_i} \Big/ \sum_{i=1}^{4} A_{e_i},$$

where u_{e_i} are the conservative variables of the ith son of the family N_F and A_{e_i} is the area of the ith son (element).

(iv) Looping over the elements (NEL = 1,NRELEM), find the density gradient modulus $|\nabla\rho|_{NEL}$ of each element NEL. If

$$|\nabla\rho|_{NEL} > \epsilon_r \, \|\nabla\rho\|_\infty,$$

refine the element NEL to produce four sons $e_i (i = 1, 4)$. The conservation variables for each of the four sons is defined by the value of the father, i.e.,

(7.2) $$u_{e_i} = u_{N_{EL}}.$$

The use of (7.1) and (7.2) ensure that conservation is maintained after a sequence of unrefinements and refinements.

The use of (7.2) is the most diffuse option. A bilinear interpolation would be more accurate, but then conservation would be more difficult to enforce.

8. Extension of the Roe scheme to an unstructured grid. The low-order scheme described in §6 is relatively easy to extend to an unstructured grid of the type discussed above. For an element-wise implementation of the scheme, instead of looping over sides one to four, as in the case of a structured grid, it is convenient to loop over sides one to eight, and test for the existence of a neighbor for any side N, say, between five and eight ($5 \le N \le 8$). If there is no neighbor, go to the end of the loop, otherwise the lengths Δx, Δy, ℓ defined in §6 are halved before performing the flux calculations of §6 for sides N and $N - 4$.

For side $N - 4$ the flux calculation will involve quantities at i and i_2 while for side N the flux calculation will involve quantities at i and i_6 (see Fig. 7).

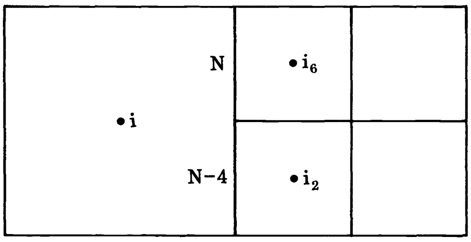

FIG. 7. *Flux calculation on unstructured grids.*

The extension of the higher-order scheme is far more complicated. The support of the scheme in the case of a structured grid is sketched in Fig. 8. Unlike the low-order scheme, which involves five elements, the higher-order scheme involves nine elements, the additional four elements being "neighbors of the neighbors" of the element in question.

The higher-order upwinding can be conveniently obtained on a structured grid where global curvilinear ξ and η "directions" may be identified and the flux limiting performed along these "directions."

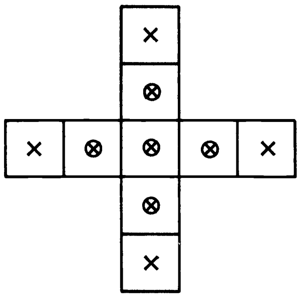

FIG. 8. *Support of two-dimensional first-order scheme* o *and second-order scheme* x.

Turning now to the case of an "unstructured grid" of the type discussed above, it is easy to see that while the grid is unstructured in the sense that certain grid lines terminate in the field, the grid still retains a certain structure in the sense that global ξ and η "directions" can still be identified throughout the grid. This property is completely exploited by constructing directional flux limiters corresponding to the even-numbered sides (ξ direction) and odd-numbered sides (η direction) of the element, respectively. (This extension of the flux-limited scheme would not be applicable to an unstructured triangular grid such as that generated in [10].)

For illustration we shall consider the construction of the flux limiters in the ξ direction (corresponding to a positive wave) which contribute to the solution at the central element (i). Various grid configurations that may occur in the "ξ direction" which affect the positive wave limiters are sketched in Fig. 9.

We introduce a notation (consistent with Fig. 6) that relates the standard flux limiters (§3) in the ξ direction to the even-numbered sides of the element, and that denotes the flux limiters corresponding to sides 2, 4, 6, and 8 by, ϕ_2, ϕ_4, ϕ_6, and ϕ_8, respectively. For a regular (structured) grid (Fig. 9(a)), the solution at element i will involve the usual flux limiters $\phi_2 = \phi(r_i^+)$ and $\phi_4 = \phi(r_{i-1}^+)$, where r_i^+ is defined in §4 as

$$r_i^+ = \frac{\nu_{i-\frac{1}{2}}(1-\nu_{i-\frac{1}{2}})(u_i - u_{i-1})}{\nu_{i+\frac{1}{2}}(1-\nu_{i+\frac{1}{2}})(u_{i+1} - u_i)}. \tag{8.1}$$

We shall adopt the more general notation

$$r(u_{i-1}, u_i, u_{i+1}) = r_i^+. \tag{8.2}$$

In the second configuration (Fig. 9(b)), ϕ_2, ϕ_4, and ϕ_6 now make contributions to the solution at element i, where now

$$\begin{aligned} \phi_2 &= \phi(r(u_{i-1}, u_i, u_{i_2})), \\ \phi_4 &= \phi(r(u_{i-2}, u_{i-1}, u_i)), \\ \phi_6 &= \phi(r(u_{i-1}, u_i, u_{i_6})), \end{aligned} \tag{8.3}$$

where i_2 and i_6 are the right-hand element numbers (Fig. 9(b)).

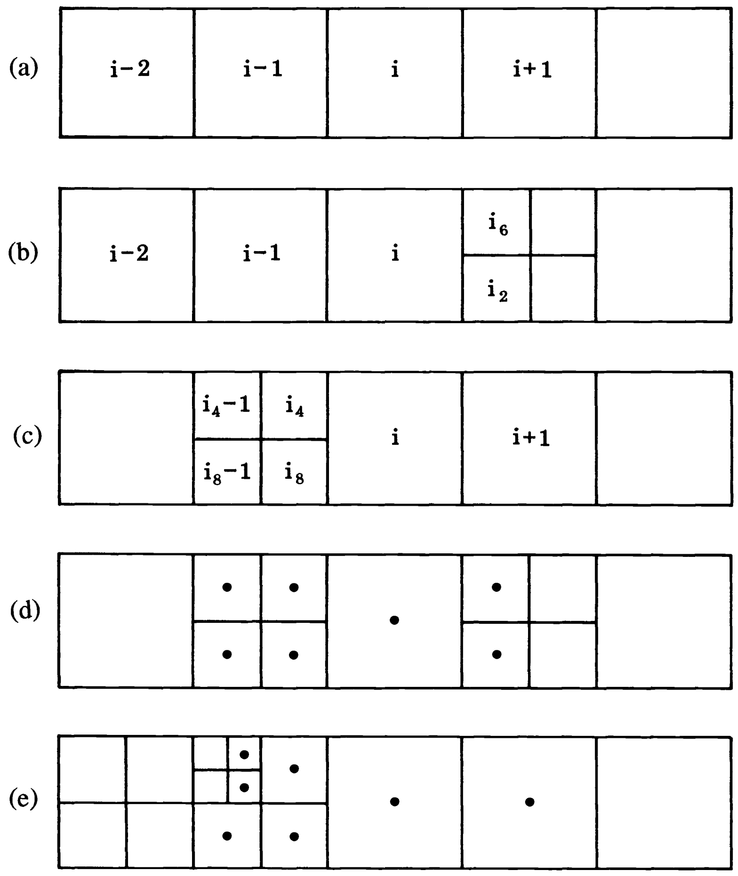

FIG. 9. *Adaptive support of scheme (ξ direction; $\nu > 0$).*

In the third configuration (Fig. 9(c)), ϕ_2, ϕ_4, and ϕ_8 make contributions to element i. In this case ϕ_2 is a function of both $r(u_{i_4}, u_i, u_{i+1})$ and $r(u_{i_8}, u_i, u_{i+1})$. As a general rule, whenever the flux limiter is a function of two ratios (as in this case), we shall define the limiter to be a minimum of the two possibilities. Therefore,

$$\begin{aligned} &\phi_2 = \min\left(\phi(r(u_{i_4}, u_i, u_{i+1})),\ \phi(r(u_{i_8}, u_i, u_{i+1}))\right), \\ (8.4) \qquad &\phi_4 = \phi(r(u_{i_{4-1}}, u_{i_4}, u_i)), \\ &\phi_8 = \phi(r(u_{i_{8-1}}, u_{i_8}, u_i)). \end{aligned}$$

In the fourth configuration (Fig. 9(d)), all of ϕ_2, ϕ_4, ϕ_6, and ϕ_8 make a contribution to element i. As in the third case, ϕ_2 is chosen as

$$\phi_2 = \min\left(\phi(r(u_{i_4}, u_i, u_{i_2})),\ \phi(r(u_{i_8}, u_i, u_{i_2}))\right).$$

Similarly, since ϕ_6 is now a function of two ratios, then

$$\phi_6 = \min\left(\phi(r(u_{i_4}, u_i, u_{i_6})),\ \phi(r(u_{i_8}, u_i, u_{i_6}))\right),$$

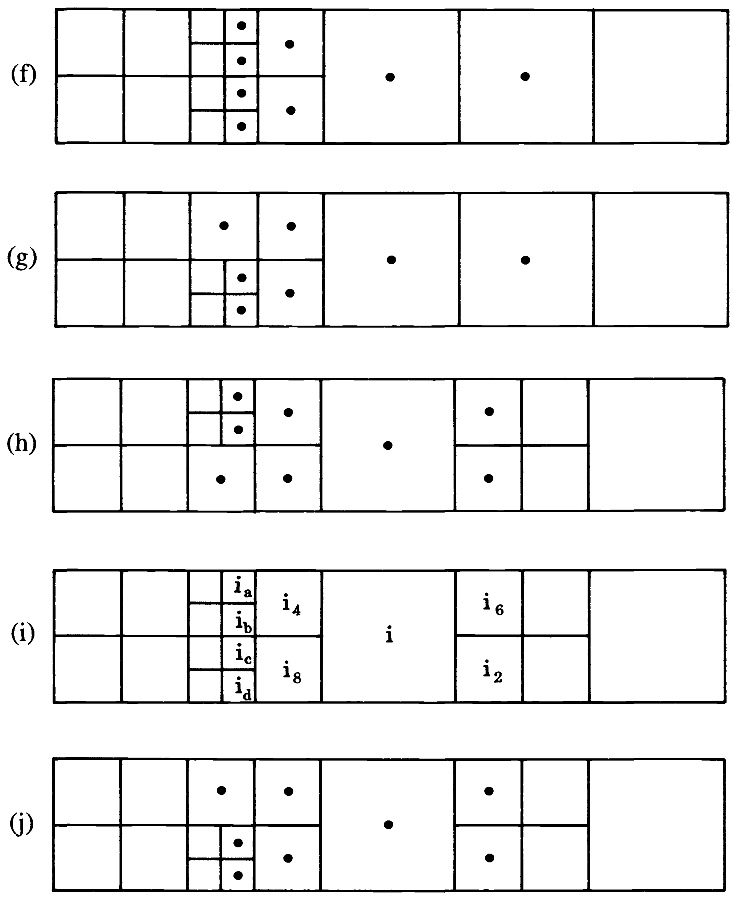

FIG. 9 (*continued*).

while the limiters ϕ_4 and ϕ_8 are evaluated as in the third case.

In the configurations in Figs. 9(e)–(g) the evaluation of ϕ_2 is identical to the third case described above, while for the configurations in Figs. 9(h)–(j) the evaluations of ϕ_2 and ϕ_6 are identical to the fourth case described above.

In configurations (e)–(j), ϕ_4 and/or ϕ_8 are functions of two ratios and we continue to apply the above rule, for example, in Fig. 9(i),

$$\phi_4 = \min(\phi(r(u_{i_a}, u_{i_4}, u_i)),\ \phi(r(u_{i_b}, u_{i_4}, u_i))),$$
$$\phi_8 = \min(\phi(r(u_{i_c}, u_{i_8}, u_i)),\ \phi(r(u_{i_d}, u_{i_8}, u_i))).$$

A similar analysis is performed for a negative wave with each configuration (e)–(j) inverted with extra refinements now appearing in the right-hand element of the support. Finally, the same analysis is performed for both positive and negative waves in the η direction, where the limiters on the upper side of the element are ϕ_3 and ϕ_7, while the limiters on the lower side of the element are ϕ_1 and ϕ_5.

9. Grid movement. The grid movement considered in this work is strictly for steady-state calculations and is induced via an equidistribution scheme constructed using

$$r_i^{(n+1)} = \sum_e \frac{r_e^n |\nabla\rho|_e}{\sum_e |\nabla\rho|_e}, \tag{9.1}$$

where $\underline{r}_e$ are the position vectors of the centers of gravity of the elements surrounding node i (with position vector $\underline{r}_i$), and the summation is performed over these elements. Similar approaches have been used in [9] and [26].

As noted in [26], the scheme (9.1) can be identified as an equidistribution technique in the limit as the iterative cycle converges. Consider the x component of (9.1) written as

$$x_i^{n+1} - x_i^n = \frac{\sum x_e^n w_e}{\sum w_e} - x_i^n, \tag{9.2}$$

where $w_e = |\nabla\rho|_e$. In one dimension the centers of the elements which surround node i are

$$x_{e_1} = \tfrac{1}{2}(x_i + x_{i-1}), \qquad x_{e_2} = \tfrac{1}{2}(x_{i+1} + x_i), \tag{9.3}$$

and

$$w_{e_1} = w_{i-\frac{1}{2}}, \qquad w_{e_2} = w_{i+\frac{1}{2}}. \tag{9.4}$$

Equations (9.2), (9.3), and (9.4) give

$$x_i^{n+1} - x_i^n = \frac{(x_{i+1}^n - x_i^n)w_{i+\frac{1}{2}} - (x_i^n - x_{i-1}^n)w_{i-\frac{1}{2}}}{(w_{i+\frac{1}{2}} + w_{i-\frac{1}{2}})}, \tag{9.5}$$

and as $x_i^{n+1} - x_i^n \to 0$, we obtain

$$\Delta x_{i+\frac{1}{2}} w_{i+\frac{1}{2}} = \Delta x_{i-\frac{1}{2}} w_{i-\frac{1}{2}} = \text{ constant.} \tag{9.6}$$

After some experimentation it was found that a reasonably robust equidistribution scheme can be defined as

$$r^{n+1} = \frac{\sum_e r_e^n((|\nabla\rho|_e/\|\nabla\rho\|_\infty)A_e\alpha) + \beta}{\sum_e((|\nabla\rho|_e/\|\nabla\rho\|_\infty)A_e\alpha) + \beta}, \tag{9.7}$$

where α is a user-defined constant which determines the strength of the grid movement, and $\beta(= 10^{-4})$ is a regularization constant which prevents any singularity from occurring (in (9.7)). A_e is the Jacobian of the eth element.

10. Results. The adaptive schemes described above are used to solve the Euler equations of compressible flow, written in conservation form

$$\boldsymbol{u}_t + \boldsymbol{f}_x + \boldsymbol{g}_y = \boldsymbol{0}, \tag{10.1}$$

where

$$\begin{aligned} \boldsymbol{u} &= (\rho,\ \rho u,\ \rho v,\ E)^T, \\ \boldsymbol{f} &= \Big(\rho u,\ \rho u^2 + p,\ \rho uv,\ u(E+p)\Big)^T, \\ \boldsymbol{g} &= \Big(\rho v,\ \rho uv,\ \rho v^2 + p, v(E+p)\Big)^T. \end{aligned} \tag{10.2}$$

Here ρ, p, and E are the density, pressure, and energy per unit volume for an ideal gas, (u, v) are the cartesian components of velocity, and

$$E = \rho\left[\tfrac{1}{2}(q^2) + p/\rho(\gamma - 1)\right],$$

γ being the ratio of specific heat capacities and $q^2 = u^2 + v^2$.

Three kinds of physical boundary conditions are imposed, namely, (i) supersonic inflow, (ii) supersonic outflow, and (iii) solid wall.

Since the scheme is cell-centered, a band of dummy nodes is required at all boundaries to complete the definition of the discretization of the scheme.

In condition (i) all conservation variables are specified at the dummy nodes with their free-stream values

$$u_{\text{dummy}} = u_{\text{free-stream}}.$$

In condition (ii) the dummy values are found by assuming that the normal gradients of the flow variables are zero at the outflow boundary, so that $\partial \underline{u}/\partial n = 0$, which results in

$$u_{\text{dummy}} = u_{\text{interior}}.$$

In condition (iii) at a solid wall, the normal velocity is set equal to zero while reflection conditions are used for the density ρ, energy E, and tangential velocity v^t with

$$\frac{\partial \rho}{\partial n} = \frac{\partial E}{\partial n} = \frac{\partial v^t}{\partial n} = 0,$$

where the tangential velocity v^t is defined by $v^t = \underline{q} \cdot \hat{\underline{t}}$ and q is the velocity vector. A second layer of dummy values are introduced (via reflection) at a solid wall to complete the support of the second-order scheme.

We present the results obtained for three test cases. In all cases the computed density contours will be shown for 30 uniform intervals both for uniform and adaptive grid computations, respectively.

For the first two cases involving steady-state flow, three kinds of adaptive strategy are tested: (i) grid movement using equidistribution; (ii) grid refinement/unrefinement; and (iii) grid refinement and movement.

10.1. Supersonic flow over a wedge. The wedge has an inclination of 20° to the horizontal. Initially the flow is assumed to be uniform throughout the field with a free-stream Mach number $M_\infty = 3.0$. An exact solution for this problem can be obtained [27], which consists of a uniform shock wave extending from the compression corner into the flow field at an angle of 37.5°.

The result obtained using a uniform 32 × 16 grid Fig. 10(a) is shown in Fig. 10(b). The exact solution lies within the band of density contours.

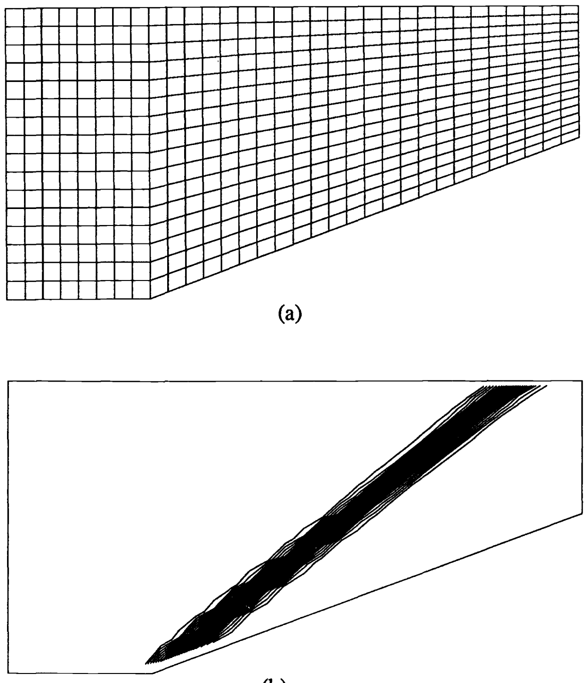

FIG. 10. *Wedge—regular grid.*

Using the uniform grid solution as an initial data for the equidistribution scheme (9.7), the solution and grid shown in Fig. 11 are obtained by applying (9.7) for three iterations, each iteration being performed after 300 steps, with $\alpha = 4.3$. A considerable improvement in shock resolution is obtained which may be due not only to the local reduction in the size of the element in the shock region, but also to the improvement in the local orientation of the grid relative to the shock.

Next we consider the h-refinement strategy of §7. An initial solution is obtained on a 16×8 grid (Fig. 12). The solution (and grid) obtained after two applications of the h-refinement strategy of §7 is shown in Fig. 13, and after a third application, in Fig. 14. Each application was made after 200 steps. The refinement and unrefinement tolerances are $\varepsilon_r = 0.16$ and $\varepsilon_u = 0.16$, respectively. The final solution is well aligned with the exact solution, and very good resolution of the shock has been obtained.

Finally, the combination refinement and movement $(h - r)$ is tested using the solution of Fig. 13 as an initial data; the result shown in Fig. 15 is obtained after three movements, one every 300 steps, with $\alpha = 5$.

10.2. Blunt body. The second steady-state problem that we consider is a blunt body placed in a supersonic flow field with free-stream Mach number $M_\infty = 6.57$ and $\gamma = 1.38$ at 0° angle of attack. The larger (extended body) version of this problem has been studied by Oden, Strouboulis, and Devloo [9] and Bey et al. [28].

An initial skeleton grid of 5×5 elements is generated and globally refined twice to produce a 20×20 uniform grid, which is smoothed by using (9.7) with the density gradient removed.

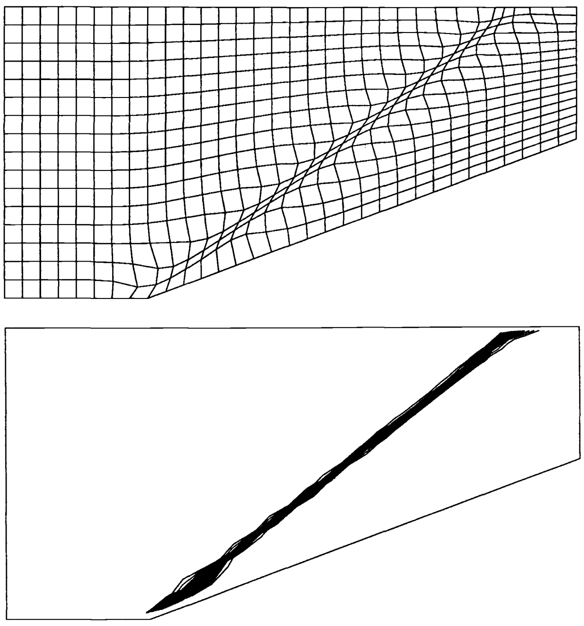

FIG. 11. *Wedge—regular grid with node relocation.*

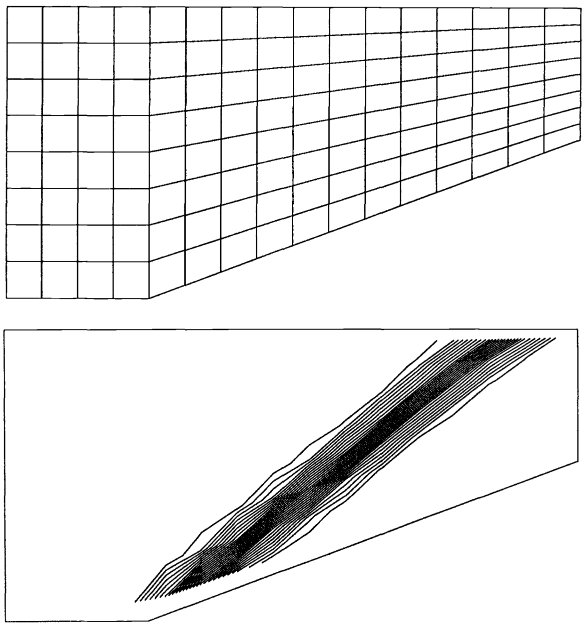

FIG. 12. *Wedge—initial coarse grid.*

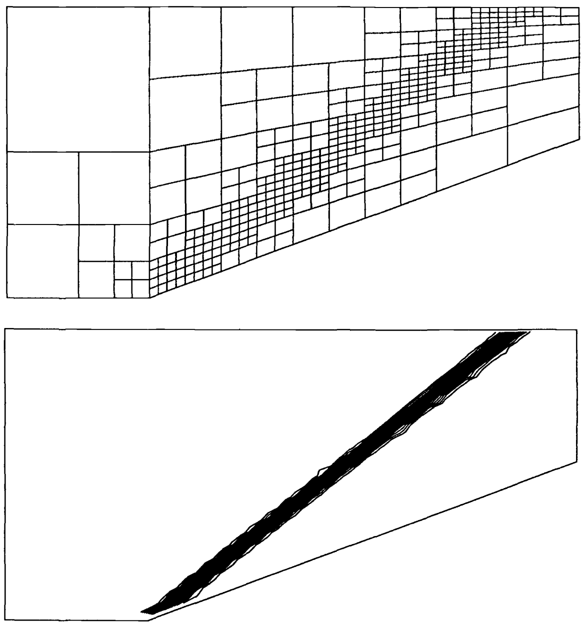

FIG. 13. *Wedge—with five grid levels of h-refinement.*

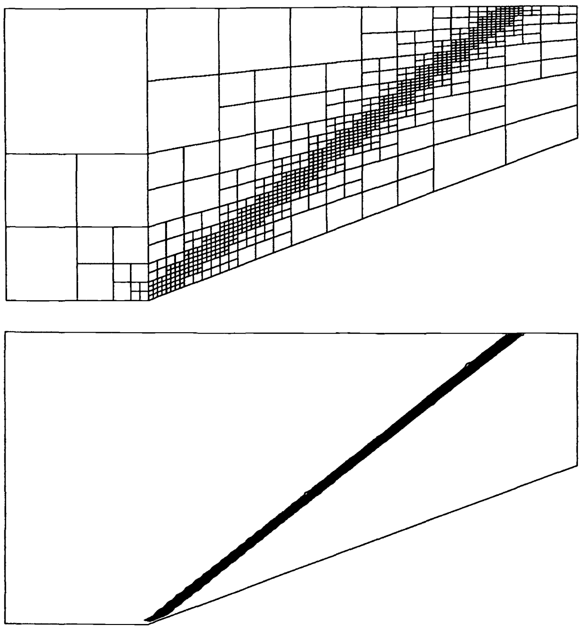

FIG. 14. *Wedge—with six grid levels of refinement.*

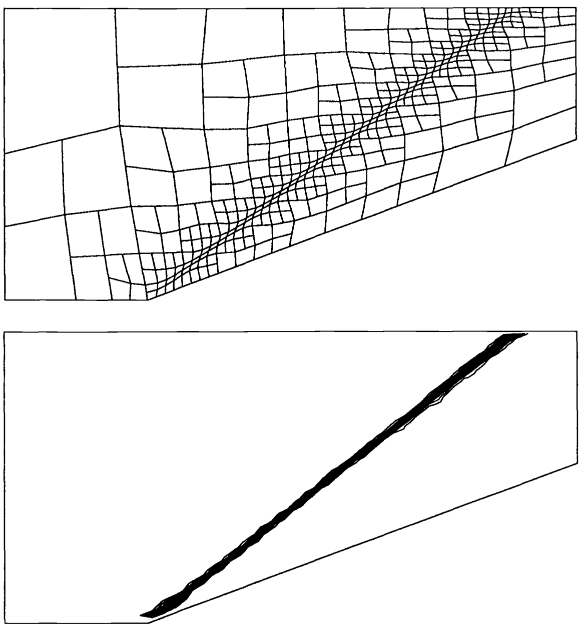

FIG. 15. *Wedge—h-r method.*

The solution obtained on the uniform 20×20 smoothed grid is shown in Fig. 16. The exact shock location of this problem is found following Billig [29] and lies at the center of the computed shock location.

As in the previous case, the uniform grid solution (Fig. 16) is used as an initial data for the equidistribution scheme (9.7). After using (9.7) for two iterations, one every 200 steps, the result in Fig. 17 is obtained. The effect of grid distortion upon the solution error is not analyzed here. However, in both of the steady-flow problems, (9.7) proves to be an extremely effective simple tool for enhancing the initial uniform grid solutions.

Next, the h-refinement strategy of §7 is applied. The refinement algorithm is applied (with $\varepsilon_r = 0.007$, $\varepsilon_u = 0.44$) using the solution in Fig. 16 as an initial data, then applied again after 100 steps and 500 steps. The solution obtained at convergence is shown in Fig. 18 together with the final grid. The shock resolution is much improved and is aligned with the exact solution.

Finally, the combination of h-refinement and movement is tested with six iterations of grid movement, one every 200 steps, with $\alpha = 5.0$. The resulting solution and grid are shown in Fig. 19. The residual $\|\rho^{n+1} - \rho^n\|_\infty$ is reduced to 0 (10^{-5}) by 2000 timesteps. All of the above results were computed with the non-time-split scheme using the van Leer flux limiter [16], [4] with

$$\phi(r) = (r + |r|)/(1 + |r|). \tag{10.3}$$

The superbee limiter [4] was also tried but gave some convergence problems for these cases.

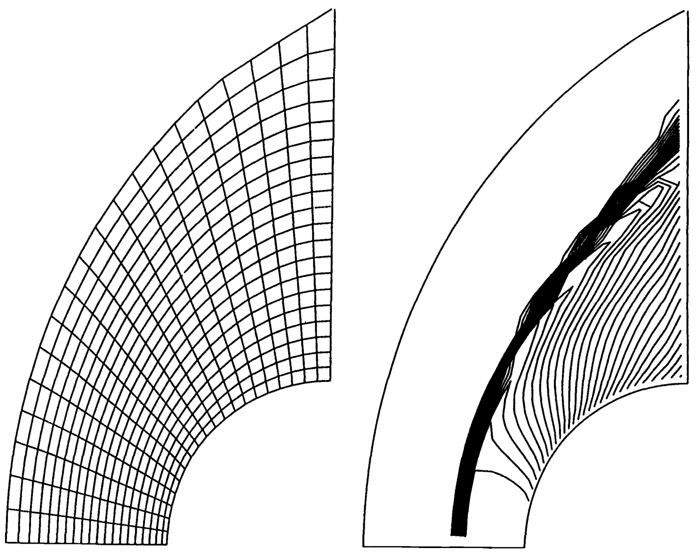

FIG. 16. *Blunt body, regular grid.*

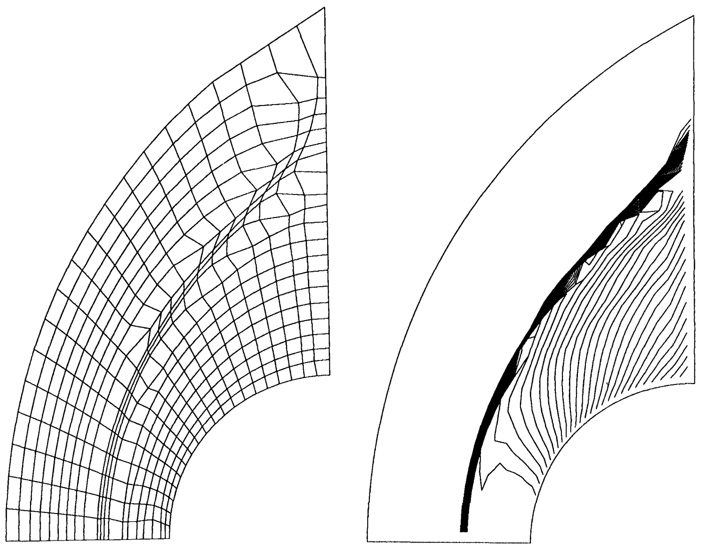

FIG. 17. *Blunt body, regular grid after node relocation.*

10.3. A Mach-3 wind tunnel with a step. This problem, used by Woodward and Colella [8] for comparing a variety of methods, is used here for a test of the transient behavior of the method and solution. The problem begins with a uniform Mach-3 flow throughout the field impinging on a step [8]. The sequence of results

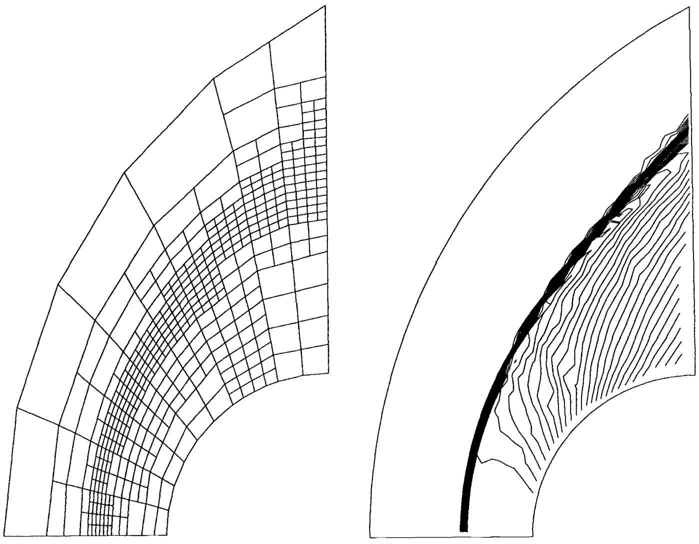

FIG. 18. *Blunt body, h-refinement.*

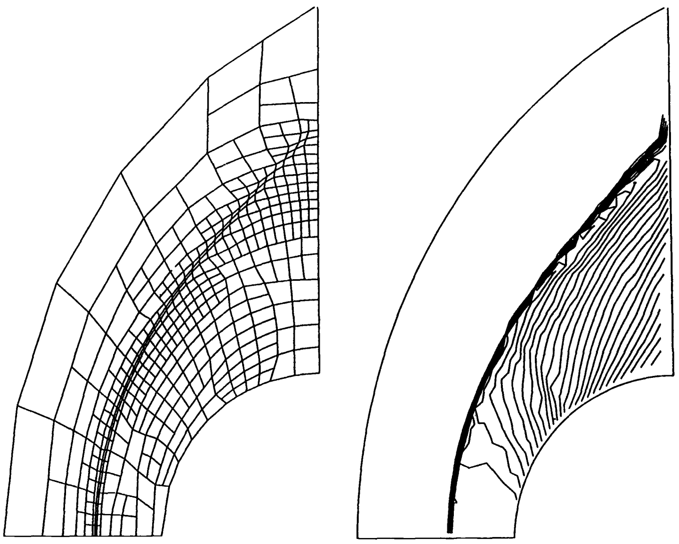

FIG. 19. *Blunt body, h-r method.*

obtained using the time-split scheme, together with the resulting adaptive grids, is shown in Figs. 20–24 for output times $t = 0.5, 1, 2, 3, 4$. These results were obtained by starting on a uniform $(\Delta x = \Delta y = 1/20)$ grid and applying the refinement algorithm in the sequence given in §7 after every 25 timesteps.

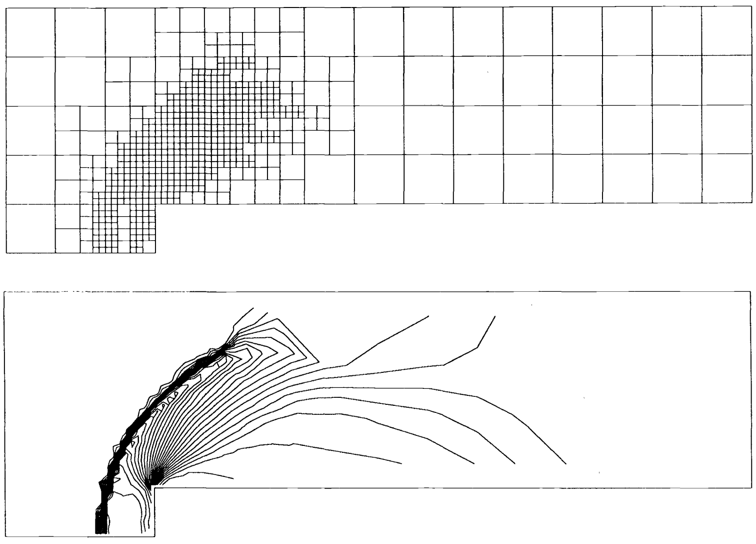

FIG. 20. $t = 0.5$, *fully second-order time-split scheme.*

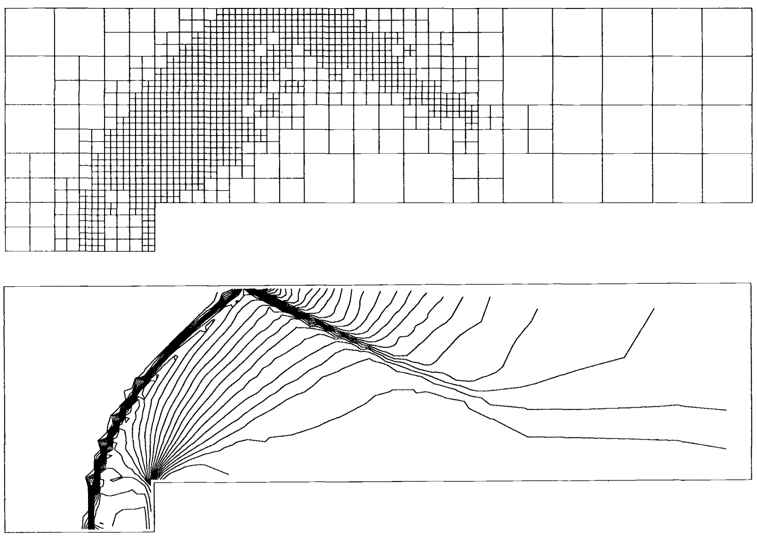

FIG. 21. $t = 1.0$, *fully second-order time-split scheme.*

The condition (iii)(a) of §7 was particularly important in ensuring consistently good results. The tolerances used are $\varepsilon_r = 0.061$ and $\varepsilon_u = 0.44$. The superbee flux limiter was used in all three formulations.

Excellent agreement is obtained between the adaptive- and fixed-grid solutions, e.g., at time $t = 2$ compare Fig. 22 with Fig. 25(a). In the final stage of the computation from $t = 3$ to $t = 4$ the fixed-grid method is unable to sustain the shock reflection

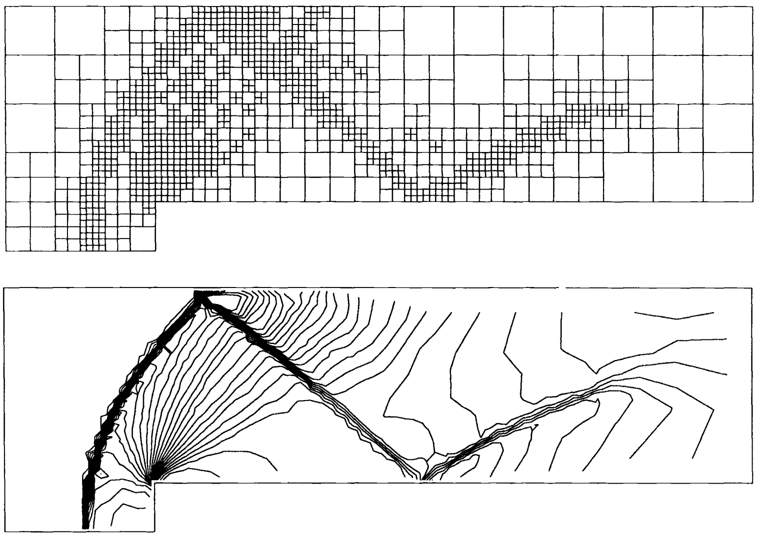

FIG. 22. $t = 2.0$, *fully second-order time-split scheme.*

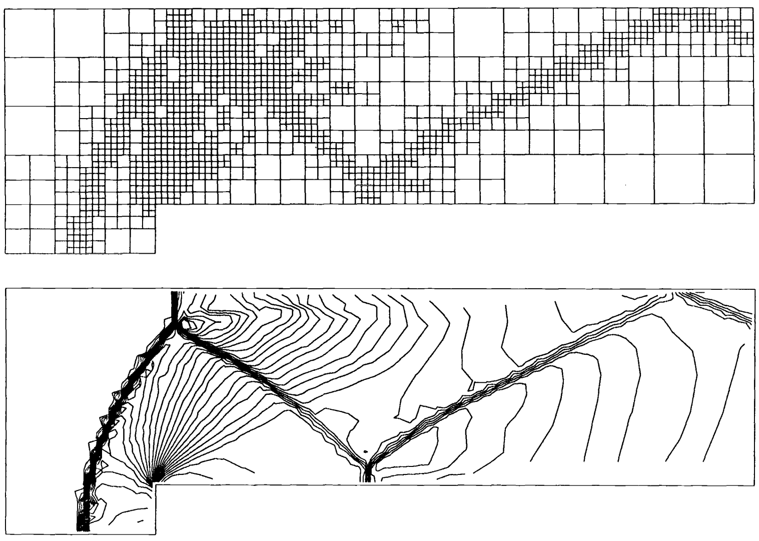

FIG. 23. $t = 3.0$, *fully second-order time-split scheme.*

on the upper wall of the tunnel (Fig. 25(b)), in striking contrast to the adaptive grid result of Fig. 24.

At transition cells (e.g., Fig. 7) the approximation (6.4a) induces truncation errors of $\pm O(1)$ in the two neighboring cells i_2 and i_6, respectively. However, since discontinuities never cross transition zones (due to adaptivity) this potential source of error is avoided. Also this error cancels in the global sum with respect to conservation.

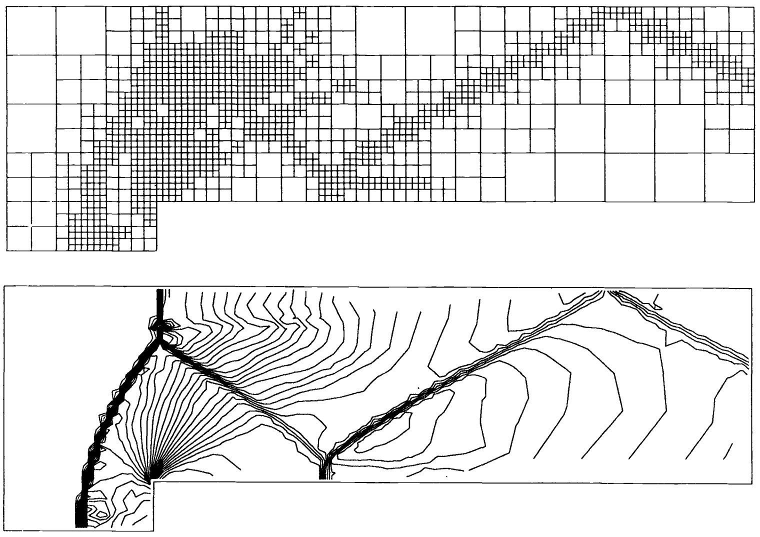

FIG. 24. $t = 4.0$, *fully second-order time-split scheme.*

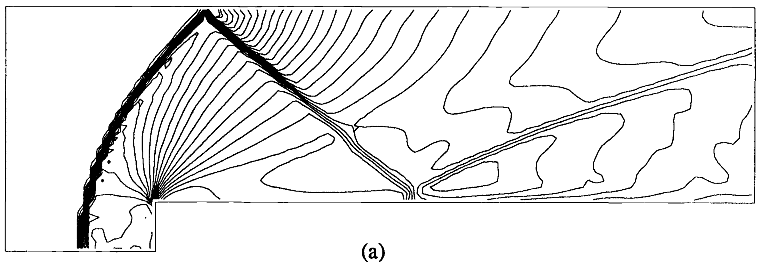
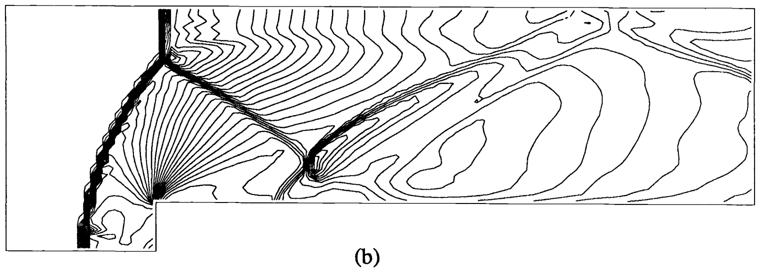


(a)



(b)

FIG. 25. *Uniform grid computation (time split).* (a) *Time* $t = 2.0$; (b) *Time* $t = 4.0$.

The current version of the computer code has not been optimized in any way and has been written mainly from the point of view of convenience. However, large savings in computer time are obtained in all cases. A typical comparison between an h-adaptive computation and a uniform fine grid (with the same level of refinement, using the same computer code) shows the adaptive method to be about four times faster. This factor tends to increase with grid level, thus, the gains obtained depend considerably upon the adaptive strategies employed, particularly for the steady-state cases.

Timestepping. A uniform timestep (fixed Δt throughout the grid) has been used in all of the work presented here. A point for further investigation would be to combine this method with the adaptive timestepping procedure of Berger [30], where a variable-size timestep is used according to the local level of grid refinement.

There is a striking contrast between the adaptive method of Berger and Oliger [11] and that employed here. Their method for refining the grid involves overlaying sequences of finer grids on the coarse-grid areas which contain steep flow gradients. This method inevitably involves using more elements than are required. Conversely, in the adaptive method used here, only the actual elements which detect large flow gradients are flagged for refinement, although in practice some transition elements are created (see §7). While the former approach is logically more simple than the latter, it would appear that it has a greater need for adaptive timestepping.

In Table 1, we give the grid level and number of elements for the adaptive grids shown in Figs. 14, 18, and 24. An inspection of Table 1, together with the corresponding grids and results, demonstrates that near optimal use has been made of the grid refinements and unrefinements, with the majority of elements packed into the regions of high flow gradients in each case.

TABLE 1
Grid levels and element counts.

	Grid level	Number of elements	Total
Wedge	4×2	1	
Case 1	8×4	10	
	16×8	35	
	32×16	71	
	64×32	161	
	128×64	588	866
Blunt body	5×5	4	
Case 2	10×10	37	
	20×20	119	
	40×40	276	436
Step	15×5	14	
Case 3	30×10	66	
	60×20	265	
	120×40	836	1181

From the table it is possible to deduce the effective advantage of adaptive timestepping. Assuming that the timestep is halved for each fine-grid level created, then for every eight minimum timesteps, Case 3 of Table 1 reveals a potential saving of 16 percent of the run time of the adaptive code. This assumes no extra overhead in performing the adaptive timestepping procedure. For the nine-point schemes used here the support can be across four interfaces simultaneously in one direction (§8), which complicates the logic of adaptive timestepping in two dimensions.

For steady-state problems, nonconservative local timestepping could be used.

However, Table 1 suggests that only a comparatively small reduction in computer time would be obtained in the steady-state cases 1 and 2.

11. Conclusions. A two-dimensional version of the higher-order approximate Riemann solver of Roe [14] is presented in finite-volume form for application to unstructured quadrilateral grids.

A one-dimensional analysis of the solution error indicates that convergence is formally $O(\Delta x)$ for an arbitrary nonuniform grid.

However, the quality of the results and the very fine resolution obtained by the high-order scheme on an adaptive grid is comparable with that obtained by the same scheme on a fixed uniform grid, with a cell size corresponding to that of the finest adaptive grid level.

Great savings in computer time are obtained; the adaptive code is a factor of 4 times faster than the same code run on the corresponding fixed uniform grid.

Appendix A. Question of accuracy on a nonuniform grid. In this appendix we will show that for a sufficiently smooth solution, when the cell-centered low-order upwind scheme is applied to the linear advection equation on a nonuniform grid, the error in the solution is of $O(h)$ while the local truncation error is $O(1)$. When the error in the solution is better behaved than the local truncation error the scheme is supraconvergent [22].

The low-order upwind scheme for linear advection (3.6), (3.8) can be written as

$$u_i^{n+1} = u_i^n - \frac{a\Delta t}{2\Delta x_i}(u_{i+1}^n - u_{i-1}^n) + \frac{|a|\Delta t}{2\Delta x_i}(u_{i+1}^n - 2u_i^n + u_{i-1}^n). \tag{A.1}$$

Substituting the exact solution $u(x,t)$ into (A.1) and performing Taylor series expansions about $u(x_i,t^n)$, the leading truncation error is found to be

$$\tau = au_{x_i}\frac{(\Delta x_{i+\frac{1}{2}} + \Delta x_{i-\frac{1}{2}} - 2\Delta x_i)}{2\Delta x_i} - |a|u_{x_i}\frac{(\Delta x_{i+\frac{1}{2}} - \Delta x_{i-\frac{1}{2}})}{2\Delta x_i} + O(\Delta t, \Delta x), \tag{A.2}$$

where

$$\Delta x_{i+\frac{1}{2}} = \tfrac{1}{2}\,(\Delta x_i + \Delta x_{i+1})$$

and Δx_i is the ith element length.

The local truncation (A.2) is $O(1)$, which suggests that the numerical solution will not converge to the physically correct solution. However, by performing an analysis similar to Kreiss et al. [22] we can show that the error in the solution is of $O(\Delta x)$.

First, we obtain the discrete error equation by subtracting the grid difference equation (A.1) from the truncation error which results in

$$\frac{e_i^{n+1} - e_i^n}{\Delta t} + \frac{a(e_{i+1}^n - e_{i-1}^n)}{2\Delta x_i} - \frac{|a|}{2\Delta x_i}(e_{i+1}^n - 2e_i^n + e_{i-1}^n) = \tau_i. \tag{A.3}$$

Multiplying (A.3) by Δx_i and summing over $i = 1$ to j gives

$$\begin{aligned}\sum_{i=1}^{j}\frac{e_i^{n+1} - e_i^n}{\Delta t}\Delta x_i + \frac{a}{2}(e_j^n + e_{j+1}^n) - \frac{|a|}{2}(e_{j+1}^n - e_j^n)\\ - \frac{a}{2}(e_1^n + e_0^n) + \frac{|a|}{2}(e_1^n - e_0^n) = \sum_{i=1}^{j}\tau_i\Delta x_i;\end{aligned} \tag{A.4}$$

using (A.2) gives

$$\sum_{i=1}^{j} \tau_i \Delta x_i = \tfrac{1}{2} \sum_{i=1}^{j} (a\Delta_-(\Delta x_{i+1} - \Delta x_i) - |a|(\Delta x_{i+\frac{1}{2}} - \Delta x_{i-\frac{1}{2}}))u_{x_i}.$$

Performing a summation by parts results in

$$\text{(A.5)} \qquad \sum_{i=1}^{j} \tau_i \Delta x_i = -\tfrac{1}{2} \sum_{i=1}^{j} ((\Delta x_{i+1} - \Delta x_i)a - \Delta x_{i+\frac{1}{2}}|a|)(u_{x_{i+1}} - u_{x_i}).$$

For u sufficiently smooth,

$$u_{x_{i+1}} - u_{x_i} = u_{xxi+\frac{1}{2}} \Delta x_{i+\frac{1}{2}} + 0\Delta x^2,$$

hence (A.5) is of $O(\Delta x)$.

Using the initial data at time $t = 0$ $(n = 0)$, $u_i^0 = u(x_i, 0)$ or

$$\text{(A.6)} \qquad e_i^0 = 0.$$

From (A.4), (A.5), and (A.6) it follows that

$$\text{(A.7)} \qquad \sum_{i=1}^{j} e_i^1 \frac{\Delta x_i}{\Delta t} = O(\Delta x).$$

Since (A.7) is true for any j, then

$$\text{(A.8)} \qquad e_i^1 \frac{\Delta x_i}{\Delta t} = O(\Delta x) \quad \forall\, i$$

and the CFL condition (3.21) ensures that

$$e_i^1 = O(\Delta x).$$

By induction it follows from (A.4) that

$$\text{(A.9)} \qquad e_i^{n+1} = O(\Delta x) \quad \forall\, i, n,$$

hence the solution converges with $O(\Delta x)$.

Observations. The same analysis can be applied to the higher-order scheme to show first-order convergence. For example, the Lax–Wendroff scheme used here (3.6), (3.7) has a leading truncation error of

$$\text{(A.10)} \qquad \frac{(\Delta x_{i+\frac{1}{2}} + \Delta x_{i-\frac{1}{2}} - 2\Delta x_i)}{2\Delta x_i} a u_{x_i} + O(\Delta x, \Delta t),$$

which is due to approximating the physical flux component of (3.7) by

$$\text{(A.11)} \qquad \frac{f_i + f_{i+1}}{2}.$$

Second-order convergence can be recovered in two ways: (i) Replace (A.11) by the second-order approximation

$$\text{(A.12)} \qquad \frac{\Delta x_{i+1} f_i + \Delta x_i f_{i+1}}{(\Delta x_{i+1} + \Delta x_i)},$$

which would reduce the truncation error to $O(\Delta x)$. However, the introduction of (A.12) into (3.7) results in a scheme which cannot be shown to be TVD, and the exact shock resolution property of the Roe scheme is lost on an arbitrary nonuniform grid.

(ii) Remove the $O(1)$ truncation error in (A.10) by defining Δx_i to be the mean cell length

$$\Delta x_i = \tfrac{1}{2}\left(\Delta x_{i+\frac{1}{2}} + \Delta x_{i-\frac{1}{2}}\right).$$

This definition effectively removes the distinction between cell-centered and node-based (cell vertex) schemes. However, it is not practical to carry over into two dimensions for the grids used here. (Note that the scheme (3.6), (3.7) would, therefore, achieve second-order convergence if it had been applied using cell vertices as opposed to cell centers in one dimension.)

Appendix B. The Roe decomposition for the Euler equations in two dimensions. In order to satisfy (6.3b), we follow a similar procedure to that presented by Roe and Pike [31] for the one-dimensional case and by Baines [32] in two dimensions. For the Euler equations (§10) the matrix $\boldsymbol{A}(\boldsymbol{u})$ defined in (6.3a) takes the form

$$\begin{bmatrix} 0 & c & s & 0 \\ \frac{1}{2}(\gamma-1)q^2c - uU & U + (2-\gamma)uc & (2-\gamma)vc - V & (\gamma-1)c \\ \frac{1}{2}(\gamma-1)q^2s - vU & V + (2-\gamma)us & U + (2-\gamma)vs & (\gamma-1)s \\ U\left((\gamma-1)q^2 - \frac{\gamma E}{\rho}\right) & \frac{\gamma E}{\rho}c + (1-\gamma)\left(\frac{q^2}{2}c + Uu\right) & \frac{\gamma E s}{\rho} + (1-\gamma)\left(\frac{q^2 s}{2} + Uv\right) & \gamma U \end{bmatrix}, \tag{B.1}$$

and has eigenvectors given by

$$\begin{aligned} e_{1,2} &= [1,\ u \pm ac,\ v \pm as,\ H \pm Ua]^T, \\ e_3 &= [0,\ as,\ -ac,\ -aV]^T, \\ e_4 &= [1,\ u,\ v,\ q^2/2]^T, \end{aligned} \tag{B.2}$$

where H is the enthalpy $(H = q^2/2 + \gamma p/\rho(\gamma-1))$, a is the sound speed $(a = \sqrt{\gamma p/\rho})$,

$$\begin{aligned} U &= \ \ uc + vs, \\ V &= -us + vc, \end{aligned} \tag{B.3}$$

with corresponding eigenvalues

$$\begin{aligned} \lambda_{1,2} &= U \pm a, \\ \lambda_3 &= U, \\ \lambda_4 &= U. \end{aligned} \tag{B.4}$$

Following [31] and [32], α_j (increments of the characteristic variables with respect to the primitive variables (ρ, u, v, p)) are found to be

$$\begin{aligned}\alpha_1 &= [\Delta p + a\rho(c\Delta u + s\Delta v)]/2a^2,\\ \alpha_2 &= [\Delta p - a\rho(c\Delta u + s\Delta v)]/2a^2,\\ \alpha_3 &= \rho(s\Delta u - c\Delta v)/a,\\ \alpha_4 &= \Delta\rho - \Delta p/a^2.\end{aligned} \tag{B.5}$$

Equation (6.3b) is satisfied provided that u, v, h, ρ, and a appearing in (B.1)–(B.5) are defined by

$$\begin{aligned}u &= \frac{u_R\sqrt{\rho_R} + u_L\sqrt{\rho_L}}{\sqrt{\rho_R} + \sqrt{\rho_L}},\\ v &= \frac{v_R\sqrt{\rho_R} + v_L\sqrt{\rho_L}}{\sqrt{\rho_R} + \sqrt{\rho_L}},\\ H &= \frac{H_R\sqrt{\rho_R} + H_L\sqrt{\rho_L}}{\sqrt{\rho_R} + \sqrt{\rho_L}},\\ \rho &= \sqrt{\rho_R}\sqrt{\rho_L},\\ a &= \sqrt{(H - q^2/2)(\gamma - 1)},\end{aligned} \tag{B.6}$$

respectively, and the difference operator is defined such that

$$\Delta\rho = \rho_R - \rho_L. \tag{B.7}$$

Acknowledgments. Thanks are given to Professor Earl Thornton for bringing [29] to our attention, Olivier Hardy of the TICOM Computing Laboratory who assisted with some computing difficulties, and to Jan Shrode for her dedication (and patience) in the typing of this report. Thanks are also due to the referees for their helpful comments and criticisms and the references [22], [30].

INTERACTION SPLINES WITH REGULAR DATA: AUTOMATICALLY SMOOTHING DIGITAL IMAGES*

CHONG GU†

Abstract. The idea of interaction spline was first proposed by Barry [*Ann. Statist.*, 14 (1986), pp. 934–953] in the context of nonparametric Bayesian multivariate regression. Wahba [*Computer Science and Statistics*, American Statistical Association, 1986, pp. 75–80] shows that Barry's model is a special case of a wider class of smooth functions which can be constructed from the tensor product of reproducing kernel Hilbert spaces. Algorithms for computing interaction splines with arbitrarily scattered data have been developed by Gu, Bates, Chen, and Wahba [*SIAM J. Matrix Anal. Appl.*, 10 (1989), pp. 457–480] and Gu and Wahba [*SIAM J. Sci. Statist. Comput.*, 12 (1991), pp. 383–398]. These algorithms require $O(n^3)$ flops for sample size n. The purpose of this work is to develop fast algorithms for computing interaction splines with data sampled from a regular product mesh. The algorithm is of order $O(n)$ for practical problem size. Smoothing parameters can be tuned using the generalized cross-validation. A possible application of the technique is image smoothing. In image smoothing, a periodic interaction spline is observed to be a low-pass filter of a certain form. Simulated examples are presented and practical aspects of the algorithms are discussed.

1. Introduction.

Suppose one observes $y_j = f(\mathbf{x}_j) + \epsilon_j$, $j = 1, \ldots, n$, where $\mathbf{x}_j \in [0,1]^d$, $\mathbf{E}\epsilon_j = 0$, $\text{var}(\epsilon_j) \propto w_j^{-1}$, and the ϵ_j's are uncorrelated. The solution f_λ to the penalized least square problem

$$\min \frac{1}{n}\sum_{j=1}^{n} w_j(y_j - f(\mathbf{x}_j))^2 + \lambda\|P_1 f\|^2, \qquad \text{s.t. } f \in \mathcal{H}, \tag{1.1}$$

defines a smoothing spline, where $\mathcal{H}$ is a reproducing kernel Hilbert space (RKHS) of functions on domain $\mathcal{X}$ with norm $\|\cdot\|$, and P_1 is the orthogonal projector onto a subspace $\mathcal{H}_1$ of co-dimension $M < n$. The solution has an expression $f_\lambda = \sum_{\nu=1}^{M} d_\nu \phi_\nu + \sum_{j=1}^{n} c_j \xi_j$, where $\{\phi_\nu\}_{\nu=1}^{M}$ is a basis for $\mathcal{H}_0$, the orthogonal complement of $\mathcal{H}_1$, and $\xi_j = P_1\tilde{\xi}_j$, where $\tilde{\xi}_j$ is the representer of the evaluation functional $[\mathbf{x}_j](\cdot)$. The reproducing kernel (RK) of $\mathcal{H}$ is a bivariate function $R(\cdot,\cdot)$ (symmetric in its two slots) such that $R(\mathbf{x},\cdot)$ is the representer of $[\mathbf{x}](\cdot)$. For $\mathcal{H} = \mathcal{H}_0 \oplus \mathcal{H}_1$, $\mathcal{H}_0$ and $\mathcal{H}_1$ are also RKHSs and the sum of their RKs R_0 and R_1 is equal to the RK R of $\mathcal{H}$. Substituting the solution expression into (1.1), the problem reduces to solving

$$\min \frac{1}{n}(\mathbf{y} - Q\mathbf{c} - S\mathbf{d})^T W(\mathbf{y} - Q\mathbf{c} - S\mathbf{d}) + \lambda\mathbf{c}^T Q\mathbf{c}, \tag{1.2}$$

where $(Q)_{j,k} = R_1(\mathbf{x}_j, \mathbf{x}_k)$, $(S)_{j,\nu} = \phi_\nu(\mathbf{x}_j)$, and $W = \text{diag}(w_1, \ldots, w_n)$; see [17, §1.3]. See also [1] for the definition and properties of RKHS. Note that the RK is uniquely determined by the norm and vice versa. The notion of smoothness for $f \in \mathcal{H}$ is defined as the deviation of f from $\mathcal{H}_0$, namely $\|P_1 f\|^2$. It is possible to specify different RKs for the same set of functions to reflect different meanings by the word "smoothness."

Interaction splines are defined on the tensor product RKHS (cf. [1]). Consider RKHS $\mathcal{H}^1 = \mathcal{H}_0^1 \oplus \mathcal{H}_1^1$ with the RK $R^1 = R_0^1 + R_1^1$ on $[0,1]$ and $\mathcal{H}^2 = \mathcal{H}_0^2 \oplus \mathcal{H}_1^2$ with the RK $R^2 = R_0^2 + R_1^2$ on $[0,1]$, where $\mathcal{H}_0^1$ and $\mathcal{H}_0^2$ are of finite dimension. The tensor product RKHS on $[0,1]^2$ has a tensor sum decomposition $\mathcal{H} = \mathcal{H}^1 \otimes \mathcal{H}^2 = (\mathcal{H}_0^1 \otimes \mathcal{H}_0^2) \oplus (\mathcal{H}_1^1 \otimes \mathcal{H}_0^2) \oplus (\mathcal{H}_0^1 \otimes \mathcal{H}_1^2) \oplus (\mathcal{H}_1^1 \otimes \mathcal{H}_1^2) = \mathcal{H}_{0,0} \oplus \mathcal{H}_{1,0} \oplus \mathcal{H}_{0,1} \oplus \mathcal{H}_{1,1}$. The norm in tensor product RKHS is usually defined indirectly via its RK, which is often taken as the product of the RKs of the component spaces; see [1]. For example, a RK in $\mathcal{H}_{1,0}$ can be taken as $R_{1,0}((x_1,x_2),(x_1',x_2')) = R_1^1(x_1,x_1')R_0^2(x_2,x_2')$. Let $\|\cdot\|$ be the norm in the tensor product RKHS $\mathcal{H}$ corresponding to the RK R^1R^2. It can be shown that $\|f\|_\theta^2 = \theta_0^{-1}\|P_{0,0}f\|^2 + \theta_1^{-1}\|P_{1,0}f\|^2 + \theta_2^{-1}\|P_{0,1}f\|^2 + \theta_{1,2}^{-1}\|P_{1,1}f\|^2$ defines a class of norms with the corresponding RK $\theta_0 R_0^1R_0^2 + \theta_1 R_1^1R_0^2 + \theta_2 R_0^1R_1^2 + \theta_{1,2}R_1^1R_1^2$, where the θ's are all positive and the $P_{i,j}$'s are projectors onto $\mathcal{H}_{i,j}$'s (cf. [11]). Letting $\mathcal{H}_0 = \mathcal{H}_{0,0}$ and $\mathcal{H}_1 = \mathcal{H}_{1,0} \oplus \mathcal{H}_{0,1} \oplus \mathcal{H}_{1,1}$ in (1.1), with the norm indexed by θ, one obtains interaction splines with multiple smoothing parameters λ/θ_1, λ/θ_2, and $\lambda/\theta_{1,2}$, where the θ's determine the contributions (weights) of the norms of the individual spaces $\mathcal{H}_{1,0}$, $\mathcal{H}_{0,1}$, and $\mathcal{H}_{1,1}$ to the combined norm of the space $\mathcal{H}_1$; see, e.g., [10], [11], [9], and [3]. Let $\{\phi_\nu^1\}_{\nu=1}^{M_1}$ be a basis in $\mathcal{H}_0^1$ and $\{\phi_\nu^2\}_{\nu=1}^{M_2}$ a basis in $\mathcal{H}_0^2$. It can be seen that the $M = M_1M_2$ product functions $\phi_{\nu_1}^1\phi_{\nu_2}^2$ form a basis for $\mathcal{H}_{0,0}$. The quantities in (1.2) are thus

$$(1.3)\qquad (Q)_{j,k} = \theta_1(R_1^1R_0^2)(\mathbf{x}_j,\mathbf{x}_k) + \theta_2(R_0^1R_1^2)(\mathbf{x}_j,\mathbf{x}_k) + \theta_{1,2}(R_1^1R_1^2)(\mathbf{x}_j,\mathbf{x}_k),$$

$$(1.4)\qquad (S)_{j,\nu} = \phi_\nu(\mathbf{x}_j) = (\phi_{\nu(1)}^1\phi_{\nu(2)}^2)(\mathbf{x}_j).$$

The generalization of the above procedure to $(d > 2)$-dimensional space is straightforward; see, e.g., [11]. Details are omitted here.

A class of RKHS of univariate functions on $[0,1]$ is the space $W_2^m = \{f : f^{(\nu)}$ abs.cont., $\nu = 0,\dots,m-1, \int (f^{(m)})^2 < 0\}$ with the norm

$$\|f\|^2 = \sum_{\nu=0}^{m-1}\left(\int_0^1 f^{(\nu)}\right)^2 + \int_0^1 (f^{(m)})^2$$

and the corresponding RK

$$R(s,t) = \sum_{\nu=0}^{m} k_\nu(s)k_\nu(t) + (-1)^{m-1}k_{2m}(|s-t|),$$

where $k_\nu = B_\nu/\nu!$ and B_ν is the νth Bernoulli polynomial. Write $W_2^m = \pi_m \oplus \mathcal{S}_m$, where π_m is the space of polynomials of order less than m with the norm $\sum_{\nu=0}^{m-1}(\int_0^1 f^{(\nu)})^2$, and $\mathcal{S}_m$ contains functions satisfying $\int f^{(\nu)} = 0$, $\nu = 0,\dots,m-1$, with the norm $\int_0^1(f^{(m)})^2$. The RK of π_m is

$$(1.5)\qquad \sum_{\nu=0}^{m-1} k_\nu(s)k_\nu(t),$$

and the RK of $\mathcal{S}_m$ is

$$(1.6)\qquad k_m(s)k_m(t) + (-1)^{m-1}k_{2m}(|s-t|);$$

see [4]. The subset of periodic functions of W_2^m comprises a RKHS of the form $\{1\} \oplus \mathcal{S}_m^{per}$, where $\mathcal{S}_m^{per}$ is the periodic subset of $\mathcal{S}_m$. The RK of $\{1\}$ is 1 and the RK of $\mathcal{S}_m^{per}$ is $(-1)^{m-1}k_{2m}(|s-t|)$; see [17, §2.1]. In fact, $\{k_\nu\}_{\nu=0}^{m-1}$ is an orthonormal basis for π_m with norm $\sum_{\nu=0}^{m-1}(\int f^{(\nu)})^2$, and k_ν's individually span m mutually orthogonal one-dimensional subspaces of π_m with norms $(\int f^{(\nu)})^2$. We shall use $\phi_\nu = k_{\nu-1}$, $\nu = 1, \dots, m$, as a basis for π_m. In this article, the term interaction spline refers to the case where the component spaces are either W_2^m's or their periodic restrictions.

The idea of interaction spline was first proposed by Barry [2] in the context of nonparametric Bayesian regression. Barry's model is equivalent to using $W_2^1 = \{1\} \oplus \mathcal{S}_1$ for all of the component spaces. The formulation sketched above follows Wahba's development [16]. The computation of interaction splines for arbitrarily scattered $\mathbf{x}_j$'s is studied by Gu, Bates, Chen, and Wahba [10] and Gu and Wahba [11], where it is argued that $O(n^3)$ operations are inevitable. Some asymptotic properties of interaction splines were investigated by Chen [3]. The purpose of this article is to develop fast algorithms for computing interaction splines, assuming that the $\mathbf{x}_j$'s fall on a tensor product mesh of equally spaced grids. We will restrict our development to $d = 2$. Extension to $d > 2$ is straightforward but tedious. A possible application of the technique is the automatic smoothing of digital images.

In §2, basic algorithms are developed for situations of different complexities. Section 3 discusses the implication of the periodic splines as automatic low-pass filters. In §4, numerical efficiency of the building blocks is studied and examples are presented. Section 5 concludes the article with discussion.

2. Algorithms.

We assume $d = 2$. The operator "$\otimes$" will hereafter stand for the Kronecker product of matrices. The superscript "H" will stand for the conjugate transpose of matrices and vectors.

2.1. Preliminaries.

It can be shown that the linear system

$$(WQ + n\lambda I)\mathbf{c} + WS\mathbf{d} = W\mathbf{y}, \quad S^T\mathbf{c} = 0 \tag{2.1}$$

gives a solution to problem (1.2); see, e.g., [9]. We will use the generalized cross-validation (GCV) method of Craven and Wahba [4] to automatically choose the smoothing parameters, which are the $n\lambda$ and the θ's hidden in the matrix Q. The GCV method has been proved to be asymptotically optimal for minimizing prediction mean square errors; see [17] for more references.

For $W = I$, letting $\hat{\mathbf{y}} = A(\lambda, \theta)\mathbf{y}$ denote the vector of predictions $f_\lambda(\mathbf{x}_j)$, the GCV score to be minimized is defined by $V(\lambda, \theta) = n(\mathbf{y} - \hat{\mathbf{y}})^T(\mathbf{y} - \hat{\mathbf{y}})/[\text{tr}(I - A(\lambda, \theta))]^2$. It can be shown that $(n\lambda)\mathbf{c} = \mathbf{y} - \hat{\mathbf{y}}$ and hence $V = n\mathbf{c}^T\mathbf{c}/[\text{tr}B]^2$ where $\mathbf{c} = B\mathbf{y}$. Let $P_S^\perp = I - P_S = I - S(S^TS)^{-1}S^T$ be the projection matrix to the orthogonal complement of the column space of S. Since $S^T\mathbf{c} = 0$, it is easy to see that $\mathbf{c} = P_S^\perp\mathbf{c}$. Applying $P_S^\perp$ from the left to the first equation of (2.1) (with $W = I$), it follows that

$$(P_S^\perp Q P_S^\perp + n\lambda I)\mathbf{c} = P_S^\perp\mathbf{y}. \tag{2.2}$$

We will solve $\mathbf{c}$ from (2.2) and calculate V via

$$V = n\mathbf{c}^T\mathbf{c}/[\text{tr}(P_S^\perp Q P_S^\perp + n\lambda I)^{-1}P_S^\perp]^2. \tag{2.3}$$

$\mathbf{d}$ can be solved from the first equation of (2.1). The computation for a general W will be discussed in §2.4.

Suppose one has $n = n_1n_2$ data on the regular mesh $\{(x_{1,j_1}, x_{2,j_2}) : j_1 = 1, \dots, n_1;$ $j_2 = 1, \dots, n_2\}$, where $x_{1,j} = (j - .5)/n_1$, $x_{2,j} = (j - .5)/n_2$. Define S_1 and S_2 with entries $(S_1)_{j,\nu} = \phi_\nu(x_{1,j})$ and $(S_2)_{j,\nu} = \phi_\nu(x_{2,j})$, where, $\phi_\nu = k_{\nu-1}$ form a basis for $\mathcal{H}_0^1$ and $\mathcal{H}_0^2$. From (1.5), it is easy to see that $R_0^1(x_{1,j}, x_{1,k}) = (S_1S_1^T)_{j,k}$ and $R_0^2(x_{2,j}, x_{2,k}) = (S_2S_2^T)_{j,k}$. Also define Q_1 and Q_2 such that $(Q_1)_{j,k} = R_1^1(x_{1,j}, x_{1,k})$ and $(Q_2)_{j,k} = R_1^2(x_{2,j}, x_{2,k})$. Order the data such that j_2 varies most frequently and order the basis functions of $\mathcal{H}_{0,0}$, $\phi_\nu = \phi^1_{\nu(1)}\phi^2_{\nu(2)}$, such that $\nu(2)$ varies most frequently. It follows from (1.3) and (1.4) that

$$\begin{aligned} Q &= \theta_{1,2}(Q_1 \otimes Q_2) + \theta_1(Q_1 \otimes S_2S_2^T) + \theta_2(S_1S_1^T \otimes Q_2), \\ S &= S_1 \otimes S_2. \end{aligned} \tag{2.4}$$

The developments below are based on (2.4).

2.2. Periodic spline with equal weights. Defining P_n as an $n \times n$ matrix with the (i,j)th entry $(P_n)_{i,j} = (-1)^{m-1}k_{2m}(|i-j|/n)$, where $k_{2m} = B_{2m}/(2m)!$ is the scaled Bernoulli polynomial, the key to the developments is the spectral decomposition

$$\Gamma_n^H P_n \Gamma_n = \Lambda_n,$$

where Γ_n is the Fourier matrix with entries $(\Gamma_n)_{j,k} = n^{-1/2}\exp(2\pi \mathrm{i}(j-1)(k-1)/n)$, where $\mathrm{i} = \sqrt{-1}$, and $\Lambda_n = \operatorname{diag}(\lambda_{1,n}, \ldots, \lambda_{n,n})$, where

$$\begin{aligned} \lambda_{1,n} &= 2n(2\pi)^{-2m}\textstyle\sum_{j=1}^{\infty}(jn)^{-2m}, \\ \lambda_{\nu,n} &= n(2\pi)^{-2m}\textstyle\sum_{j=-\infty}^{\infty}(\nu - 1 + jn)^{-2m}, \qquad \nu = 2, \ldots, n; \end{aligned} \tag{2.5}$$

see [4]. If both $\mathcal{H}^1$ and $\mathcal{H}^2$ are periodic, then $S_1 = 1$, $S_2 = 1$, $\Gamma_{n_1}^H Q_1 \Gamma_{n_1} = \Lambda_{n_1} = \Lambda_1$, and $\Gamma_{n_2}^H Q_2 \Gamma_{n_2} = \Lambda_{n_2} = \Lambda_2$, where S_1 has length n_1; S_2 has length n_2; Γ_{n_1}, Q_1, and Λ_1 are of dimension $n_1 \times n_1$; and Γ_{n_2}, Q_2, and Λ_2 have dimension $n_2 \times n_2$. Writing $\Gamma = \Gamma_{n_1} \otimes \Gamma_{n_2}$, $\tilde{\mathbf{y}} = \Gamma^H \mathbf{y}$, $\tilde{S} = \Gamma^H S = (\Gamma_{n_1}^H S_1) \otimes (\Gamma_{n_2}^H S_2)$, $\tilde{Q} = \Gamma^H Q \Gamma$, and $\tilde{\mathbf{c}} = \Gamma^H \mathbf{c}$, (2.2) becomes

$$(P_{\tilde{S}}^\perp \tilde{Q} P_{\tilde{S}}^\perp + n\lambda I)\tilde{\mathbf{c}} = P_{\tilde{S}}^\perp \tilde{\mathbf{y}}, \tag{2.6}$$

where $P_{\tilde{S}}^\perp = I - P_{\tilde{S}} = I - P_{\tilde{S}_1} \otimes P_{\tilde{S}_2}$. It follows that $\tilde{S}_1 = \sqrt{n_1}\mathbf{e}_1$ and $\tilde{S}_2 = \sqrt{n_2}\mathbf{e}_1$, where $\mathbf{e}_1 = (1, 0, \ldots, 0)^T$ have lengths n_1 and n_2, respectively. It can be seen that $P_{\tilde{S}}^\perp = \operatorname{diag}(0, I)$, $\tilde{Q} = \theta_{1,2}(\Lambda_1 \otimes \Lambda_2) + \theta_1(\Lambda_1 \otimes J_2) + \theta_2(J_1 \otimes \Lambda_2)$, where

$$J_1 = \operatorname{diag}(n_1, O)_{n_1 \times n_1} \quad \text{and} \quad J_2 = \operatorname{diag}(n_2, O)_{n_2 \times n_2}. \tag{2.7}$$

Hence (2.6) is a diagonal system with real diagonals. Since

$$\mathbf{c}^T\mathbf{c} = \tilde{\mathbf{c}}^H\tilde{\mathbf{c}} = \tilde{\mathbf{y}}^H P_{\tilde{S}}^\perp (P_{\tilde{S}}^\perp \tilde{Q} P_{\tilde{S}}^\perp + n\lambda I)^{-2} P_{\tilde{S}}^\perp \tilde{\mathbf{y}}$$

and

$$\operatorname{tr}B = \operatorname{tr}(\Gamma^H B \Gamma) = \operatorname{tr}[(P_{\tilde{S}}^\perp \tilde{Q} P_{\tilde{S}}^\perp + n\lambda I)^{-1} P_{\tilde{S}}^\perp],$$

the score V has an expression explicit in λ's and θ's and so do its derivatives. Hence V can be minimized with respect to the smoothing parameters via an appropriate Newton-type method. There is one redundant dimension in the smoothing parameters and one can simply fix $n\lambda$. See, e.g., [11], for a related algorithm. The calculation of $\tilde{\mathbf{y}} = \Gamma^H \mathbf{y}$, which is the forward two-dimensional discrete Fourier transform (DFT) of $\mathbf{y}$ on a two-dimensional array, can be conducted via the fast Fourier transform (FFT). A backward DFT of $\mathbf{c} = \Gamma\tilde{\mathbf{c}}$ via FFT gives the solution to the original problem (2.2). We can check that the one-dimensional coefficient d in this setup is equal to the overall average of the y's, which is independent of the smoothing parameters.

2.3. General spline with equal weights. For a general problem, $\tilde{Q}$ and $P_{\tilde{S}}$ are not diagonal. However, the matrix–vector multiplication of $\tilde{Q}\mathbf{x}$ (and of $P_{\tilde{S}}\mathbf{x}$) is of order $O(n)$ (note that $Q\mathbf{x}$ is not), and hence for fixed $n\lambda$'s and θ's one can solve (2.6) via the preconditioned conjugate gradient iteration; see, e.g., [8, Chap. 10]. To be specific, note that $\tilde{Q}_i = \Lambda_i + \tilde{\mathbf{t}}_i\tilde{\mathbf{t}}_i^H$ where $\tilde{\mathbf{t}}_i = \Gamma^H\mathbf{t}_i$ and $\mathbf{t}_i = (k_m(x_{i,1}), \ldots, k_m(x_{i,n_i}))^T$, $i = 1, 2$ (cf. (1.6)). It can be shown that

$$P_{\tilde{S}}^{\perp}\tilde{Q}P_{\tilde{S}}^{\perp} = P_{\tilde{S}}^{\perp}(\theta_{1,2}(\Lambda_1 + \tilde{\mathbf{t}}_1\tilde{\mathbf{t}}_1^H + (\theta_2/\theta_{1,2})\tilde{S}_1\tilde{S}_1^H) \otimes (\Lambda_2 + \tilde{\mathbf{t}}_2\tilde{\mathbf{t}}_2^H + (\theta_1/\theta_{1,2})\tilde{S}_2\tilde{S}_2^H))P_{\tilde{S}}^{\perp}.$$

A convenient preconditioner for the conjugate gradient iteration is

$$C = \theta_{1,2}(\Lambda_1 \otimes \Lambda_2) + \theta_1(\Lambda_1 \otimes J_2) + \theta_2(J_1 \otimes \Lambda_2) + n\lambda I, \tag{2.8}$$

where J_1 and J_2 are given in (2.7). It is easily seen that $P_{\tilde{S}}^{\perp}\tilde{Q}P_{\tilde{S}}^{\perp} + n\lambda I - C$ is of lower rank. We assume that S_1 and S_2 both have a column of constant.

To evaluate the GCV score V, one needs to calculate $\text{tr}((P_{\tilde{S}}^{\perp}\tilde{Q}P_{\tilde{S}}^{\perp} + n\lambda I)^{-1}P_{\tilde{S}}^{\perp})$. Girard [6] noticed that if one replaces $\mathbf{y}$ by a vector $\boldsymbol{\epsilon}$ of independent and identically distributed (i.i.d.) random noise with mean 0 and variance 1 and solves for $\mathbf{c}_\epsilon$, then $\mathbf{E}\mathbf{c}_\epsilon^T\boldsymbol{\epsilon} = \text{tr}((P_{\tilde{S}}^{\perp}\tilde{Q}P_{\tilde{S}}^{\perp} + n\lambda I)^{-1}P_{\tilde{S}}^{\perp})$. Therefore, he suggests using $\mathbf{c}_\epsilon^T\boldsymbol{\epsilon}$ or a slightly better version $n\mathbf{c}_\epsilon^T\boldsymbol{\epsilon}/\boldsymbol{\epsilon}^T\boldsymbol{\epsilon}$ to estimate the trace. Simulation results about this method can be found in [6] and further theoretical justifications can be found in [6] and [7].

We now describe another approximation for the trace term in the denominator of the GCV score which is appropriate for the current setup. Let $\mu_1 = \cdots = \mu_M = 0 < \cdots \leq \mu_n$ be the ordered eigenvalues of $P_{\tilde{S}}^{\perp}\tilde{Q}P_{\tilde{S}}^{\perp}$, where M is the number of columns in S. Write $P_{\tilde{S}}^{\perp}\tilde{Q}P_{\tilde{S}}^{\perp} = U\Delta U^H = (U_1, U_2)\Delta(U_1, U_2)^H$, where $\Delta = \text{diag}(\mu_j)$, U_1 consists of the eigenvectors of $\mu_1 = \cdots = \mu_M = 0$, and U_2 consists of the eigenvectors of the remaining $n - M$ positive eigenvalues. Since $P_{\tilde{S}}^{\perp}U_1 = O$ and $P_{\tilde{S}}^{\perp}$ is a projector, $P_{\tilde{S}}^{\perp} = U_2U_2^H$. It then follows that $\text{tr}((P_{\tilde{S}}^{\perp}\tilde{Q}P_{\tilde{S}}^{\perp} + n\lambda I)^{-1}P_{\tilde{S}}^{\perp}) = \text{tr}((\Delta + n\lambda I)^{-1}U^HU_2U_2^HU) = \sum_{j=M+1}^{n}(n\lambda + \mu_j)^{-1}$. Writing $\nu_1 \leq \cdots \leq \nu_n$ for the eigenvalues of $\tilde{Q}/\theta_{1,2} = (\Lambda_1 + \tilde{\mathbf{t}}_1\tilde{\mathbf{t}}_1^H + (\theta_2/\theta_{1,2})\tilde{S}_1\tilde{S}_1^H) \otimes (\Lambda_2 + \tilde{\mathbf{t}}_2\tilde{\mathbf{t}}_2^H + (\theta_1/\theta_{1,2})\tilde{S}_2\tilde{S}_2^H)$, it can be shown that $\theta_{1,2}\nu_j \leq \mu_{j+M} \leq \theta_{1,2}\nu_{j+M}$, $j = 1, \ldots, n - M$; see, e.g., [14, pp. 316-317, ex. 4]. Hence, the ν_j's can be used to calculate bounds for the denominator of the GCV score. Computationally, the ν_j's are just products of the eigenvalues of $Q_1 + \mathbf{t}_1\mathbf{t}_1^T + (\theta_2/\theta_{1,2})S_1S_1^T$ and $Q_2 + \mathbf{t}_2\mathbf{t}_2^T + (\theta_1/\theta_{1,2})S_2S_2^T$, which are available in $O(n_1^3) + O(n_2^3)$ flops. For the problems covered in this article, this method is preferable to Girard's method in both speed and precision; see §4.

2.4. Unequal weights. For a problem with unequal weights, (2.1) leads to

$$(P_{WS}^{\perp}W^{1/2}QW^{1/2}P_{WS}^{\perp} + n\lambda I)(W^{-1/2}\mathbf{c}) = P_{WS}^{\perp}(W^{1/2}\mathbf{y}), \tag{2.9}$$

where $P_{WS}^{\perp} = I - P_{WS} = I - W^{1/2}S(S^TWS)^{-1}S^TW^{1/2}$. Assuming $W^{1/2}\hat{\mathbf{y}} = A(W^{1/2}\mathbf{y})$ and $W^{-1/2}\mathbf{c} = B(W^{1/2}\mathbf{y})$, the GCV score is defined by

$$V = n(\mathbf{y} - \hat{\mathbf{y}})^TW(\mathbf{y} - \hat{\mathbf{y}})/[\text{tr}(I - A)]^2 = n\mathbf{c}^TW^{-1}\mathbf{c}/[\text{tr}B]^2, \tag{2.10}$$

where the last equation follows the fact that $(n\lambda)(W^{-1/2}\mathbf{c}) = W^{1/2}(\mathbf{y} - \hat{\mathbf{y}})$. The conjugate gradient iteration can be used to solve (2.9) for $W^{-1/2}\mathbf{c}$. It can be shown that

$$\begin{aligned}P^{\perp}_{WS}W^{1/2}QW^{1/2}P^{\perp}_{WS} = P^{\perp}_{WS}W^{1/2}\Gamma \\ &(\theta_{1,2}(\Lambda_1 + \tilde{\mathbf{t}}_1\tilde{\mathbf{t}}_1^H + (\theta_2/\theta_{1,2})\tilde{S}_1\tilde{S}_1^H) \\ &\quad\otimes(\Lambda_2 + \tilde{\mathbf{t}}_2\tilde{\mathbf{t}}_2^H + (\theta_1/\theta_{1,2})\tilde{S}_2\tilde{S}_2^H)) \\ &\Gamma^H W^{1/2}P^{\perp}_{WS}.\end{aligned}$$

We are not able to identify a convenient effective preconditioner for this iteration. A standard conjugate gradient iteration for solving (2.9) needs a pair of FFTs in each step.

The denominator of the GCV score involves

$$\mathrm{tr}((P^{\perp}_{WS}W^{1/2}QW^{1/2}P^{\perp}_{WS} + n\lambda I)^{-1}P^{\perp}_{WS}).$$

As indicated in §2.3, Girard's method may be used to approximate the trace. To apply the trace bounds based on the eigenvalues, one needs $W = W_1 \otimes W_2$, which in general is not true. Nevertheless, one might use an approximation of W with the form $W_1 \otimes W_2$ to obtain approximate bounds. An obvious choice for W_1 and W_2 is $W_1 = \mathrm{diag}(\tilde{w}_{1,\cdot}, \ldots, \tilde{w}_{n_1,\cdot})$ and $W_2 = \mathrm{diag}(\tilde{w}_{\cdot,1}, \ldots, \tilde{w}_{\cdot,n_2})$, where $\tilde{w}_{i,\cdot}$'s and $\tilde{w}_{\cdot,j}$'s are the row-wise and column-wise geometric means of the weight matrix W.

2.5. Penalized likelihood. For categorical and/or asymmetric random schemes it is usually assumed that y_j follow a distribution with log likelihood $l_j(\eta_j) = (y_j\eta_j - b(\eta_j))/a(\psi)$, where $\eta_j = f(\mathbf{x}_j)$ is the parameter to be modeled on $\mathbf{x}_j$ and ψ is a nuisance parameter common to all observations. The penalized likelihood method estimates f via

$$\min\ -\frac{2}{n}\sum_{j=1}^{n} l_j(f(\mathbf{x}_j)) + \lambda\|P_1 f\|^2, \qquad f \in \mathcal{H}.$$

It can be shown that the Newton method iterates on

$$\min\ \frac{1}{n}\sum_{j=1}^{n} w_j(\tilde{\eta}_j - f(\mathbf{x}_j))^2 + \lambda\|P_1 f\|^2, \qquad f \in \mathcal{H},$$

where $\tilde{\eta}_j = \eta_{0j} - u_j/w_j$, $\eta_{0,j}$ is the previous iterate of η_j, $u_j = -dl_j/d\eta_j|_{\eta_{0j}}$, and $w_j = -d^2l_j/d\eta_j^2|_{\eta_{0j}}$; see [9]. See also [12] and [13]. The algorithm of §2.4 can be used to implement the steps of this Newton iteration.

3. Interaction splines as low-pass filters. The algorithm of §2.2 for periodic interaction splines can be viewed as automatic low-pass filters for high-dimensional image. To see this, remember that $\hat{\mathbf{y}} = \mathbf{y} - (n\lambda)\mathbf{c}$, so the two-dimensional DFT of $\hat{\mathbf{y}}$ is

$$\tilde{\hat{\mathbf{y}}} = (I - (n\lambda)(P^{\perp}_{\tilde{S}}\tilde{Q}P^{\perp}_{\tilde{S}} + n\lambda I)^{-1}P^{\perp}_{\tilde{S}})\tilde{\mathbf{y}}.$$

Hence, the smoothed image is obtained by damping the spectrum of the observed image. The damping factor for the (i,j)th cell, $i, j > 1$, is

$$\delta_{i,j} = \theta_{1,2}\lambda_{i,n_1}\lambda_{j,n_2}/(\theta_{1,2}\lambda_{i,n_1}\lambda_{j,n_2} + n\lambda)$$

(cf. (2.5) and (2.6)); the factor for the $(i,1)$st cell, $i > 1$, is $\delta_{i,1} = (\theta_{1,2}\lambda_{i,n_1}\lambda_{1,n_2} + n_2\theta_1\lambda_{i,n_1})/((\theta_{1,2}\lambda_{i,n_1}\lambda_{1,n_2} + n_2\theta_1\lambda_{i,n_1}) + n\lambda)$; the factor for the $(1,j)$th cell, $j > 1$, is

$\delta_{1,j} = (\theta_{1,2}\lambda_{1,n_1}\lambda_{j,n_2} + n_1\theta_2\lambda_{j,n_2})/((\theta_{1,2}\lambda_{1,n_1}\lambda_{j,n_2} + n_1\theta_2\lambda_{j,n_2}) + n\lambda)$; and the factor for the $(1,1)$st cell is 1. The magnitude of $\lambda_{\nu,n}$ declines at a rate $O(\nu^{-2m})$ over $\nu = 2,\ldots,n/2$ (cf. [4]), hence the method is a low-pass filter. The threshold frequencies of the filter are determined by the magnitude of the $n\lambda/\theta$'s relative to that of the $\lambda_{\nu,n}$'s. Larger m leads to a greater declining rate in $\lambda_{\nu,n}$, and in turn to a sharper threshold boundary. The GCV method in this setting can be viewed as an effective method for automatically tuning the threshold frequencies.

As an illustration, we generated a 64×64 image on $(0,1)^2$ by adding Gaussian noise with mean 0 and variance .04 to the function

$$[\cos(3\pi((x_1 - .5)^2 + (x_2 - .5)^2)) + \cos(2\pi(x_1 - .5))\sin(2\pi(x_2 - .5))]/3.2, \tag{3.1}$$

and applied the algorithm to the image with $m = 2$. See §4 for more details about this example. The frequency responses and the equivalent smoothing kernel of the GCV tuned filter are plotted in Fig. 3.1.

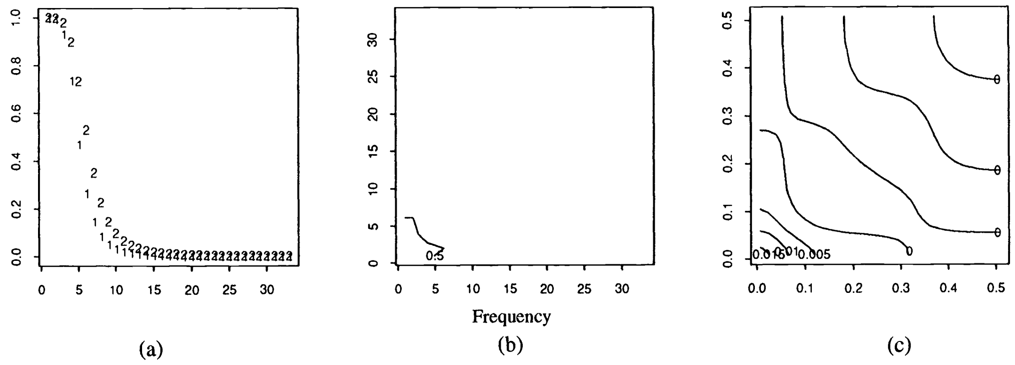

FIG. 3.1. *An automatic low-pass filter.* (a) *Frequency response on the edges: "1" indicates $\delta_{i,1}$ and "2" indicates $\delta_{1,j}$* ; (b) *Half-power contour of $\delta_{i,j}$* ; (c) *Contour of a quarter of the equivalent smoothing kernel on the space domain.*

4. Examples and practicalities. The algorithms described in §2 are certain combinations of primitive building blocks, namely the FFT, the Newton iteration, the preconditioned conjugate gradient iteration, and the trace bounds computation. Numerical performances of these building blocks are investigated in this section. The timing was done on a Sun–SparcStation/330.

4.1. Periodic spline with equal weights. To illustrate the periodic algorithm, we generated $n_1 \times n_2$ images, $n_1 = n_2 = 32, 64, 128$, on $(0,1)^2$ by adding Gaussian noise with mean 0 and variance .04 to the function in (3.1). We applied the algorithm with $m = 2$ to the image. Some timing results are summarized in Table 4.1. Also included in Table 4.1 are the mean square errors of the estimates, defined by

$$\text{mse} = \frac{1}{n}\sum_{j=1}^{n}(\hat{f}(\mathbf{x}_j) - f(\mathbf{x}_j))^2,$$

where $\hat{f}$ is the estimate and f is the true function.

TABLE 4.1
Timing and mean square errors for periodic algorithm.

n_1, n_2	FFT (sec./pair)	Newton (sec./iter.)	mse
32	0.24	0.60/7	.00138

128	4.94	8.46/6	.00018

The contour plots of the true function and the reconstruction from the 32×32 noisy image corresponding to the first line of Table 4.1 are presented in Fig. 4.1.

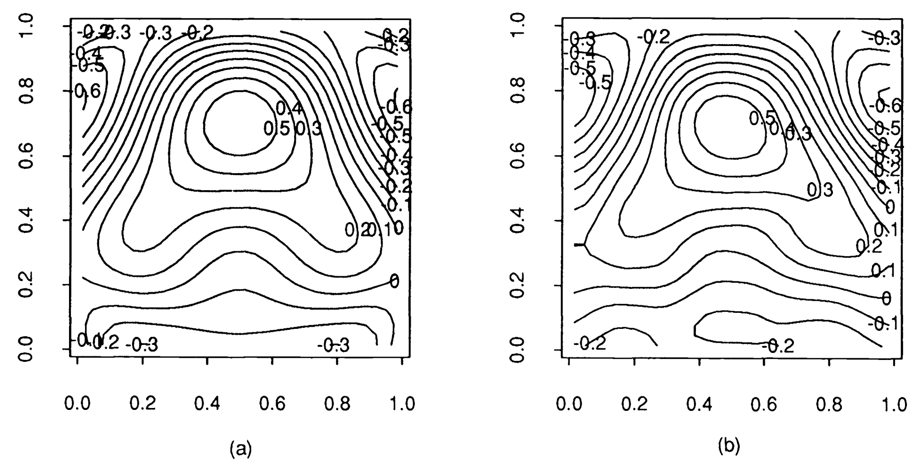

FIG. 4.1. *Reconstruction of a periodic image.* (a) *The contour of the true function.* (b) *The contour of a* 32×32 *reconstruction*

The calculation was done in double precision. The FFT was conducted using double precision modifications of routines from Swartztrauber's FFTPACK [15]. We used $n\lambda/\theta_1 = \text{tr}\Lambda_1/n_1$, $n\lambda/\theta_2 = \text{tr}\Lambda_2/n_2$, and $n\lambda/\theta_{1,2} = \text{tr}(\Lambda_1 \otimes \Lambda_2)/n_1n_2$ as starting values for the Newton iteration and the iteration converged in a few steps, where convergence meant that the achieved score V was estimated to be less than $1.001V_{\text{min}}$, where V_{min} is the true minimum. Note that the bottom of V could be very flat and one would be happy anywhere at the bottom. See [11] for a discussion. It can be seen that the timing for FFT went up at a rate of roughly $O(n \log n)$, and the timing for the Newton iteration (per step) went up at a rate of roughly $O(n)$. It can be seen that a pair of FFTs is roughly equivalent to three Newton steps. The Newton iteration usually dominates the execution, since it needs more than three steps. The practical order of the algorithm is slightly higher than $O(n)$.

4.2. General spline with equal weights. To test the general algorithm with preconditioned conjugate gradient iteration, we generated $n_1 \times n_2$ images by adding Gaussian noise from $N(0, .04)$ to Franke's [5] test function

$$.75\exp[-((9x_1-2)^2+(9x_2-2)^2)/4]+.75\exp[-(9x_1+1)^2/49-(9x_2+1)^2/10]$$
$$+.5\exp[-(9x_1-7)^2-(9x_2-3)^2/4]-.2\exp[-(9x_1-4)^2-(9x_2-7)^2/4].$$

We first applied the periodic algorithm to estimate the θ's and a starting $n\lambda$. To help the periodic algorithm choose reasonable smoothing parameters, we detrended the images at the outset by $P_S^{\perp}\mathbf{y}$. Since the GCV method chooses λ's and θ's that approximately minimize the mean square error of the smoothed image and since a periodic smoothing of a nonperiodic image generally introduces large errors on the boundary, the periodic GCV algorithm tends to choose smoothing parameters smaller than appropriate. It is known that the GCV score (and the mean square error) is less sensitive to the ratios of the smoothing parameters than to their magnitudes, so we decided to fix the θ's as returned from the periodic algorithm but to do a crude search on $n\lambda$ on the upper side of the $n\lambda$ returned from the periodic algorithm (say, $n\lambda_0$). We have run the preconditioned conjugate gradient iteration for $n\lambda = n\lambda_0, 3.18(n\lambda_0), 10(n\lambda_0), 31.8(n\lambda_0), 100(n\lambda_0)$. Table 4.2 summarizes some timing results, the GCV bounds, and the mean square errors.

TABLE 4.2

The contours of the true function and the 32×32 reconstruction corresponding to the second line of Table 4.2 are plotted in Fig. 4.2.

It can be seen that the GCV bounds provided very accurate approximation to the true score, and the GCV score followed the mean square error closely. The execution time for computing the trace bounds was negligible compared to the time for the conjugate gradient iterations, so speed-wise the bounds dominate Girard's method. To compare the precision of the two methods, we computed ten samples of Girard's approximate GCV score using $n\mathbf{c}_\epsilon^T\epsilon/\epsilon^T\epsilon$ as the trace for the case listed in the first line of Table 4.2. The mean of the 10 samples was .042707; the standard deviation was .000625. As a comparison, the 100 percent confidence interval for V using the trace bounds is $(.042659, .043015)$ with a width .000356. Only one sample of Girard's approximation out of the ten fell into this interval. Nevertheless, this comparative study by no means impairs the merits of Girard's method, which applies to more general problems and performs satisfactorily as a λ-selector on many problems when a single set of ϵ is used at all the λ values.

We finally remark on some practicalities about the algorithm. Comparing the two convenient choices, the preconditioner C of (2.8) performed much better than

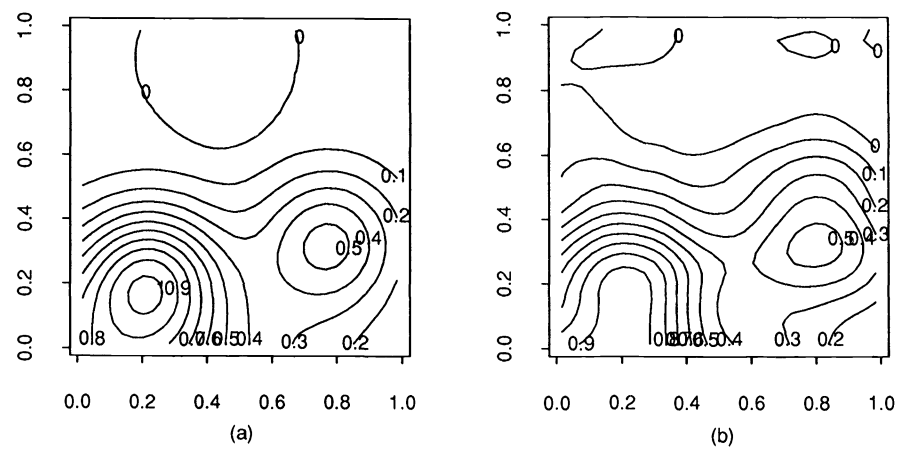

FIG. 4.2. *Reconstruction of Franke's function.* (a) *The contour of the true function.* (b) *The contour of a* 32 × 32 *reconstruction.*

the diagonal of $P_{\tilde{S}}^{\perp}\tilde{Q}P_{\tilde{S}}^{\perp} + n\lambda I$ in our test runs; we have not been able to locate other convenient preconditioners. We did have difficulty with the convergence of the conjugate gradient iteration when applying the algorithm to certain undetrended images, while detrending seemed to be effective in curing the problem. The problem was that the criterion we set (.001) seemed to be too stringent for the linear system with smoothing parameters chosen by the periodic algorithm for those undetrended images. The starting value for the conjugate gradient iteration in general does not seem to affect the speed of convergence, unless it is very close to the solution. However, double precision is essential to fast (and even eventual) convergence of the iteration.

4.3. Unequal weights. For unequal weights, we ran the algorithm on a 32 × 32 image generated by adding noise to Franke's test function. The noises were Gaussian from $N(0, .04)$ scaled by weights $w_{i,j}^{-1/2}$. For generating the weights, we generated two sets of uniform deviates from $U(0,1)$, mapped them onto $(-u/2, u/2)$, $u = 0, \ldots, 5$, and took these as $\log w_{i,j}$, where the unbalancedness increases as u increases and $u = 0$ corresponds to equal weights. This procedure generated 11 sets of weights in two groups (including the equal weights). Before applying the algorithms, we first scaled the weights to make their geometric mean equal to 1. We ran the equal weights periodic algorithm on $P_{WS}^{\perp}W^{1/2}\mathbf{y}$ to choose θ's and fix an $n\lambda_0$, then we applied the conjugate gradient iteration (without preconditioning) to solve (2.9) with $n\lambda = n\lambda_0, 3.18n\lambda_0, 10n\lambda_0, 31.8n\lambda_0$, and $100n\lambda_0$. The GCV scores based on the trace bounds using an approximate weight matrix $W_1 \otimes W_2$ were computed, where W_1 and W_2 are row-wise and column-wise geometric means of W. Girard's estimates of the GCV score were also computed using two sets of ϵ for all the cases. Some timing results for the $u = 5$ weights in the first group, together with the corresponding approximate GCV bounds, Girard's GCV estimates, the mean square errors, and the weighted mean square errors, are summarized in Table 4.3, where the weighted mean square error is defined by

TABLE 4.3

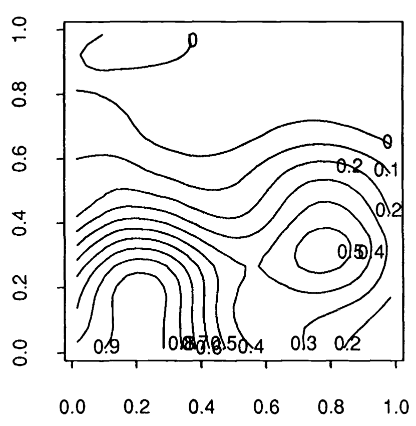

FIG. 4.3. *The contour of a* 32×32 *reconstruction of Franke's test function using unequal weights.*

$$\text{wmse} = \frac{1}{n}\sum_{j=1}^{n} w_j(\hat{f}(\mathbf{x}_j) - f(\mathbf{x}_j))^2.$$

Asymptotically, the minimizer of (2.10) is supposed to minimize the weighted mean square error; see [12] and [9].

The conjugate gradient iteration here mainly operates on real numbers and it takes less execution time per step than that of the preconditioned conjugate gradient iteration of the equal weights algorithm, which operates on complex numbers. However, the convergence is usually slower than that of the equal weights algorithm and the execution time is longer when being applied to an equal weights problem. Table 4.4 summarizes the centers of the approximate GCV bounds (V_c), the two sets of Girard's GCV estimate ($V_{g,1}$ and $V_{g,2}$), and the weighted mean square errors calculated with all the 11 sets of weights and the five relative levels of λ. It can be seen that the three GCV estimates roughly parallel each other. For the weights with large u in the first group, the GCV choices of λ tend to undersmooth the data, while the knowledge that a better λ should be on the upper side of the choice of the periodic algorithm prevents poorer choices. For the weights in the second group the GCV choices performed reasonably well at all unbalancedness levels. The contour of the reconstruction corresponding to the third line of Table 4.3 is plotted in Fig. 4.3.

5. Conclusion. In this article we have studied the computation of interaction splines when the data are sampled from a regular product mesh with noise. Algorithms

for situations of different complexities are proposed and their numerical performances are timed. An important aspect of the algorithms is the automatic smoothing parameter selection using the generalized cross-validation method, for which two methods were discussed and their merits in different situations explored. The ingredients of the algorithms have orders of $O(n)$ and $O(n \log n)$, where the $O(n \log n)$ of FFT is dominated by the $O(n)$ portion of the calculation. However, the overall execution time mainly depends on the convergence speed of the conjugate gradient iteration, which varies from problem to problem. Our simulations have demonstrated the effectiveness of the technique on nice continuous functions with Gaussian noise. Further study is needed to explore the effectiveness of the technique on other noise structures such as binary images and Poisson images.

A COLLECTION OF PROBLEMS FOR WHICH GAUSSIAN ELIMINATION WITH PARTIAL PIVOTING IS UNSTABLE*

STEPHEN J. WRIGHT†

Abstract. A significant collection of two-point boundary value problems is shown to give rise to linear systems of algebraic equations on which Gaussian elimination with row partial pivoting is unstable when standard solution techniques are used.

Key words. two-point boundary value problems, Gaussian elimination, partial pivoting

AMS(MOS) subject classifications. 65F05, 65L10, 65L20

1. Introduction.

It is well known that when Gaussian elimination with row partial pivoting is applied to a $k \times k$ real matrix, a growth factor of up to 2^{k-1} may be observed in the upper-triangular factor. A matrix which achieves this upper bound, due to Wilkinson [9, p. 212], has passed into the folklore of numerical linear algebra. However, matrices that exhibit growth factors which are exponential in their dimension have apparently not previously been observed in connection with any "practical applications." In the next section, we discuss two-point boundary value problems for which standard solution techniques give rise to matrices with this undesirable property. An extreme case is derived in §3. Some random trials, reported in §4, suggest that the collection of such problems may represent a significant fraction of the set of two-point boundary value problems with coupled end conditions.

2. Examples arising from two-point boundary value problems.

Consider the general two-point boundary value problem

$$y' = M(t)y + q(t), \qquad B_a y(a) + B_b y(b) = \beta, \qquad y(t) \in \mathbf{R}^n, \tag{1}$$

and the particular problem defined by

$$n = 2, \qquad M(t) \equiv \begin{bmatrix} -\frac{1}{6} & 1 \\ 1 & -\frac{1}{6} \end{bmatrix}, \qquad a = 0,\ b = 60, \qquad B_a = B_b = I. \tag{2}$$

(The values of $q(t)$ and β are not relevant to our present discussion.) The problem defined by the data (2) is well conditioned; that is, its solution y is insensitive to perturbations in the data $M(t)$, $q(t)$, B_a, B_b, and β which define it. To show this, we can construct the analytic solution as follows: First, define $Y(t) \in \mathbf{R}^{n\times n}$ as a fundamental solution of the homogeneous ordinary differential equation $y' = M(t)y$. Defining

$$Q = B_a Y(a) + B_b Y(b)$$

and

$$G(x,t) = \begin{cases} Y(x)Q^{-1}B_a Y(a) Y^{-1}(t) & t \le x, \\ -Y(x)Q^{-1}B_b Y(b) Y^{-1}(t) & t > x, \end{cases}$$

*Received by the editors October 2, 1991; accepted for publication (in revised form) February 6, 1992. Department of Energy, under contract W-31-109-Eng-38, and by a Raybould Fellowship from the University of Queensland, Australia.

†Argonne National Laboratory, 9700 South Cass Avenue, Argonne, Illinois 60439.

we can write

$$y(x) = Y(x)Q^{-1}\beta + \int_a^b G(x,t)q(t)\,dt \tag{3}$$

(see, for example, [1]). Well-conditioning is usually quantified in terms of norms of the two operators in (3). For the constant-coefficient problem (2) (with $M \equiv M(t)$) we have, choosing $Y(0) = I$, that

$$\begin{aligned} Y(t) &= e^{Mt}, \qquad Q = I + e^{60M}, \\ \kappa_1 &\overset{\triangle}{=} \sup_{a\le x\le b} \|Y(x)Q^{-1}\|_\infty \approx 1, \\ \kappa_2 &\overset{\triangle}{=} (b-a)\ \sup_{a\le t,x\le b} \|G(x,t)\|_\infty \approx (b-a), \end{aligned} \tag{4}$$

and so our claim of well-conditioning is verified.

A standard algorithm for problems of the form (1) is multiple shooting [6]. In its simplest form, this algorithm proceeds by partitioning $[a,b]$ into N subintervals, that is, defining a mesh $a = t_1 < t_2 < \cdots < t_{N+1} = b$ by

$$t_i = a + ih, \qquad i = 1,\ldots,N+1, \qquad h = (b-a)/N.$$

On each subinterval $[t_i, t_{i+1}]$, the following initial value problems are solved:

$$Y_i' = M(t)Y_i, \qquad Y_i(t_i) = I, \tag{5}$$

$$y_{pi}' = M(t)y_{pi} + q(t), \qquad y_{pi}(t_i) = 0. \tag{6}$$

Defining s_i as the value of the true solution y at t_i, we note that

$$y(t) = Y_i(t)s_i + y_{pi}(t), \qquad t \in [t_i, t_{i+1}], \qquad i = 1,\ldots,N.$$

Since, clearly, $y(t)$ must be continuous across the mesh points, we have

$$Y_i(t_{i+1})s_i + y_{pi}(t_{i+1}) = s_{i+1}, \qquad i = 1,\ldots,N. \tag{7}$$

Moreover, from the boundary conditions,

$$B_a s_1 + B_b s_{N+1} = \beta. \tag{8}$$

The equations (7) and (8) yield a system of linear equations whose solution is $s_1,\ldots,$ s_{N+1}. The coefficient matrix has the general form

$$A = \begin{bmatrix} B_a & & & & B_b \\ -Y_1(t_2) & I & & & 0 \\ & -Y_2(t_3) & I & & \vdots \\ & & \ddots & \ddots & 0 \\ & & & -Y_N(t_{N+1}) & I \end{bmatrix}. \tag{9}$$

For the data (2) we have in particular that $Y_i(t_{i+1}) = e^{Mh}$, and so (9) becomes

$$\bar{A} = \begin{bmatrix} I & & & & I \\ -e^{Mh} & I & & & 0 \\ & -e^{Mh} & I & & \vdots \\ & & \ddots & \ddots & 0 \\ & & & -e^{Mh} & I \end{bmatrix}. \tag{10}$$

The conditioning of the "shooting matrix" A can be related to the conditioning of the original problem (1) by a theorem of Osborne and Mattheij, which appears as Theorem 4.11 in Lentini, Osborne, and Russell [3].

THEOREM 2.1. *Suppose that* $\|[B_a|B_b]\|_\infty \leq 1$ *and that* N *is chosen large enough that*

$$\|Y_i(t_{i+1})\|_\infty \leq K', \qquad i = 1, \ldots, N.$$

Then

$$\operatorname{cond}_\infty(A) = \|A\|_\infty \|A^{-1}\|_\infty \leq (K'+1)(\kappa_1 + \kappa_2 N/(b-a)),$$

where κ_1 *and* κ_2 *are as defined in* (4).

For (10), this bound translates to

$$\operatorname{cond}_\infty(\bar{A}) \leq (\|e^{Mh}\|_\infty + 1)(1+N)$$

for h sufficiently small. (For (2) with $N = 200$, the bound is about 459.) Suppose that h is chosen small enough that all elements of e^{Mh} are less than 1 in magnitude. This is certainly possible for (2), since

$$(11) \qquad e^{Mh} = I + Mh + O(h^2) \approx \begin{bmatrix} 1-h/6 & h \\ h & 1-h/6 \end{bmatrix}.$$

If Gaussian elimination with row partial pivoting is applied to the matrix $\bar{A}$, *no pivoting occurs*, and the following factorization is obtained:

$$(12) \quad \bar{A} = \begin{bmatrix} I & & & & \\ -e^{Mh} & I & & & \\ & -e^{Mh} & I & & \\ & & \ddots & \ddots & \\ & & & -e^{Mh} & \hat{L} \end{bmatrix} \begin{bmatrix} I & & & & I \\ & I & & & e^{Mh} \\ & & I & & e^{2Mh} \\ & & & \ddots & \vdots \\ & & & I & e^{M(60-h)} \\ & & & & \hat{U} \end{bmatrix},$$

where $\hat{L}\hat{U} = (I + e^{60M})$ with $\hat{L}$ and $\hat{U}$ lower and upper triangular, respectively. Clearly, exponential element growth has taken place in the last column of U. When $N = 200$ ($h = 0.3$), the largest element in the U factor is approximately 2.59×10^{21}.

Poor performance of Gaussian elimination is not limited to matrices derived from the multiple-shooting algorithm (5)–(8). Similar behavior also occurs when "backwards shooting" (from the right-hand endpoint of each subinterval) is used and when a midpoint-rule finite difference discretization is applied to (1), (2).

As expected, a complete pivoting strategy produces a stable factorization. For the matrix $\bar{A}$, the largest element in the computed U factor is just 1.284, and both L and U factors are sparse (density 1.41 percent for L, 1.18 percent for U), though the fill-in pattern is somewhat irregular.

The behavior exhibited in (12) will occur whenever the coefficient matrix M has negative diagonal elements, since then, provided h is sufficiently small, e^{Mh} will have all its elements less than one in magnitude and no pivoting will occur. Terms of order $e^{M(b-a)}$ will therefore appear in the U factor, and these will be large if any of the eigenvalues of M have positive real parts.

Mattheij [5] has observed that stability of the partial pivoting strategy is closely related to the following feature of the pivoting pattern: if the matrix A is regarded as a collection of $N+1$ "row blocks," each containing n rows, then *the number of rows that are pivoted between row block i and row block $i+1$ $(i=1,\ldots,N-1)$ should equal the number of eigenvalues of M whose real parts are positive.* An assumption that the pivoting pattern has this property is crucial to the analysis of Wright [11]. Although this property appears to hold for most of the standard two-point boundary test problems in the literature, the matrices M just discussed lead to shooting matrices for which it is not satisfied.

The trouble is not confined to matrices M with negative diagonal entries for which no pivoting occurs during the factorization of the shooting matrix. The coefficient matrix

$$M=\begin{bmatrix} -10 & -19 \\ 19 & 30 \end{bmatrix}$$

has two positive eigenvalues, at approximately 3.755 and 16.245. Suppose we take the remaining data as in (2), construct the shooting matrix as in (5)–(8), and apply row partial pivoting. Blowup is again observed for sufficiently small h; when the shooting matrix is factorized, only one row is pivoted between each successive pair of block rows.

Neither is the blowup behavior restricted to constant-coefficient problems (i.e., those for which $M=M(t)$ is constant on $[a,b]$). Examples similar to those in this note, but with nonconstant coefficients or nonlinear dynamics, can easily be constructed by modifying the examples above. Such examples are actually more "relevant" since, in practice, they are often solved by multiple-shooting and finite difference algorithms and therefore run the risk of exhibiting the instability just described, whereas constant-coefficient problems are usually solved by other means.

In order to produce the unstable behavior, it is necessary for the problem to have coupled end conditions. If instead the boundary conditions have the separated form

$$\bar{B}_0 x(a)=\beta_a, \qquad \bar{B}_1 x(b)=\beta_b, \qquad \bar{B}_0\in \mathbf{R}^{n_a\times n}, \bar{B}_1\in \mathbf{R}^{n_b\times n}, \qquad n_a+n_b=n,$$

the matrix (9) is a permutation of a banded matrix that has a bandwidth of $2n$. Since element growth in row partial pivoting is at worst exponential in the bandwidth, the type of growth depicted above cannot occur.

Alternative stable and efficient means for producing factorizations of the matrices (9) are available. Wright [10] has described a structured QR factorization scheme for these matrices and proved its stability. (A later modification of this scheme, based on Givens rotations rather than Householder transformations, is stable while being not much less efficient than the LU algorithm discussed above.) If speed is an important consideration, the LU factorization can be attempted in the first instance and backup strategies (such as QR factorization of A or LU factorization of A^T) can be called on only if instability is detected. LU factorization of A^T will work for the problems discussed above, though it can fail on other problems, for example, the problem

$$n=2, \qquad M(t)\equiv\begin{bmatrix} \frac{1}{6} & -1 \\ -1 & \frac{1}{6} \end{bmatrix}, \qquad a=0,\ b=60, \qquad B_a=I, \qquad B_b=2I.$$

Whether there exist problems for which LU factorization of both A and A^T is unstable is an open question.

Liu and Russell [4] have apparently observed the effects of lack of stability of LU factorization on a practical problem. They use a continuation code for parametrized ordinary differential equations (ODEs) to solve the Kuramoto–Sivashinsky equation and try various factorization techniques to perform the core operation of solving the linear equations that arise repeatedly during the computation. (The coefficient matrices of these linear systems are actually bordered versions of the shooting matrices above.) They find that the continuation algorithm is less robust when an LU algorithm with partial pivoting is used to perform the factorization than when a QR algorithm is used.

3. Fraction of maximum possible growth. When $n = 1$, it is not possible to construct an example that leads to exponential blowup. A worst case appears to be the scalar problem

$$y' = q(t), \qquad y(a) + y(b) = \beta, \qquad y(t) \in \mathsf{R},$$

which, when algorithm (5)–(8) is applied, produces a matrix for which element growth of order N occurs in the U factor.

For $n = 2$, we can investigate how closely the upper bound on element growth for matrices of size $(N+1)n$, namely, $2^{(N+1)n-1}$, is approached when the matrix has the form (9). Consider a constant-coefficient problem defined by the data

$$\text{(13)} \quad n = 2, \qquad M = \lambda \begin{bmatrix} -\alpha & 1 \\ 1 & -\alpha \end{bmatrix}, \qquad a = 0, \;\; b = L, \qquad B_a = B_b = I,$$

where $\alpha \in (0,1)$. The matrix M has eigenvalues $\lambda(-\alpha \pm 1)$. By choosing N and setting $h = L/N$, we obtain a coefficient matrix similar to $\bar{A}$ in (10). To ensure that no pivoting occurs during the factorization, we must choose N large enough that no elements of e^{Mh} exceed 1. Explicit calculation of the matrix exponential shows that this requirement is equivalent to

$$e^{-\alpha\lambda h}[e^{\lambda h} + e^{-\lambda h}] \leq 2,$$

or, if we define $X = e^{\lambda h}$,

$$p(X) = X^2 - 2X^{1+\alpha} + 1 \leq 0.$$

Since, for $\alpha \in (0,1)$, $p(0) = 1$, $p(1) = 0$, $p'(1) < 0$, and $\lim_{X \to +\infty} p(X) = +\infty$, the equation

$$p(X) = 0$$

has a solution $X(\alpha)$ that is strictly greater than 1. Since $h = L/N > 0$, this is the solution of interest to us.

If we assume that no pivoting occurs during the Gaussian elimination, it follows from (12) that the largest element in the U factor is approximately equal to the largest element in e^{ML}. A little calculation shows that this is approximately

$$E = \tfrac{1}{2} e^{\lambda L(1-\alpha)}.$$

Given the upper bound on the growth for matrices of dimension $2(L/h+1)$, namely,

$$E_{\max} = 2^{2(L/h+1)-1},$$

we have

$$\rho(\alpha) \stackrel{\triangle}{=} \frac{\log_2 E}{\log_2 E_{\max}} = \frac{\dfrac{\lambda L(1-\alpha)}{\ln 2} - 1}{2(\frac{L}{h}+1) - 1}$$

$$\approx \frac{1}{\ln 2} \frac{\lambda h(1-\alpha)}{2}$$

$$= \frac{1}{2\ln 2}(1-\alpha)\ln X(\alpha).$$

Simple analysis of $p(X)$ shows that $X(\alpha) \to +\infty$ and $(1-\alpha)\ln X(\alpha) \to \ln 2$ as $\alpha \to 1^-$. Therefore,

$$\lim_{\alpha \to 1^-} \rho(\alpha) = \frac{1}{2}.$$

In fact, we can show that $\rho(\alpha)$ is monotonic increasing on the interval $(0,1)$, with $\lim_{\alpha\to 0^+} \rho(\alpha) = 0$.

We conclude that for multiple-shooting coefficient matrices arising from (13), the observed growth factor during Gaussian elimination may be as large as approximately 2^{N+1}.

4. Discussion. In [7], Trefethen writes with reference to real $k \times k$ matrices: "Perhaps large growth rates like 2^{k-1} correspond to unstable 'modes' that are themselves somehow unstable, in the sense that computations tend to drift away from them towards stabler configurations." The "drifting away" is precisely what *fails* to happen for the matrices described above. Rather, the unstable modes are propagated and reinforced because of the presence of a recurrence in which the relationship between any two successive terms is the same. The highly specialized structure of the matrices (9) and (10) accounts for the difference between our experience with randomly generated examples (reported below) and the experience of Trefethen and Schreiber [8], who worked with randomly generated *dense* matrices and observed an average growth rate of $k^{2/3}$ for real $k \times k$ matrices when partial pivoting was used.

Higham and Higham [2] present a number of dense matrices that arise naturally in applications for which the growth factors are between $n/2$ and n when both partial and complete pivoting are used. They point out that large growth factors do not necessarily imply large backward errors in the computed solution. However, for the problems described above, we would expect both the forward and backward errors in the computed solution to be large. Consider again the example (1), (2). Because $(1+e^{60M})$ is singular in double precision arithmetic, the computed U factor has a zero element in its bottom right-hand corner. Suppose we choose $q(t)$ and β in (1) such that the true solution has $y(t) = s_i = (1,1)^T$ for all t and i, and suppose that we avoid the singularity in U by setting $\hat{s}_{N+1} = s_{N+1}$, where the hat denotes a computed quantity. If we back-substitute for the remaining $\hat{s}_i$, we obtain a relative error of 2.88×10^5 in the computed solution of (7), (8). The backward error, which is defined as

$$\frac{\|c - A\hat{x}\|_2}{\|A\|_F \|\hat{x}\|_2},$$

TABLE 1
Number of "blowups" during each of five trials, each trial consisting of 100 *randomly generated problems.*

Trial	γ	$\mu \in (10^{10}, \infty)$ / $\mu \in (10^3, 10^{10}]$ $n = 2$	$n = 4$	$n = 6$
A	1	0/0	0/0	0/0
B	10	2/2	2/4	4/2
C	100	3/3	4/5	6/1
D	.1	0/0	0/0	0/0
E	2 ($B_a = B_b = I$)	2/2	5/5	10/6

where $\hat{x}$ is the computed solution of the system $Ax = c$, is found to be 0.0286. All computations here were performed in double precision.

An interesting open question is: Among all constant-coefficient problems of the form (1), is the set of triplets (M, B_a, B_b) that give rise to matrices on which Gaussian elimination fails truly a "nontrivial" subset of

$$\{(M, B_a, B_b) \mid M, B_a, B_b \in \mathbf{R}^{n \times n}, \quad \|[B_a|B_b]\|_\infty \leq 1\}?$$

Computational experiments with randomly generated constant-coefficient problems shed a little light on this question. We generated $n \times n$ matrices M $(n = 2, 4, 6)$ by choosing each matrix element from a uniform distribution on $[-10, 10]$. In the first four sets of trials, the elements of B_a and B_b were chosen likewise and then scaled so that $\|[B_a|B_b]\|_\infty = \gamma$. We chose $\gamma = 1$, 10, 100, and 0.1 in trials A, B, C, and D, respectively. In trial E, we set $B_a = B_b = I$. In each trial, 100 randomly generated problems were solved by using (5)–(8) with 1024 subintervals, with $a = 0$ and $b = 10$. For each trial we define the following quantity μ that measures the "blowup" in the U factor

$$\mu \triangleq \max(U) \ / \ \|[B_a|B_b]\|_\infty,$$

where max (U) is the magnitude of the largest element in the upper-triangular factor. Each entry in Table 1 has two components. The first is the number of problems (out of 100) for which μ exceeded 10^{10} and the second is the number of problems for which $\mu \in (10^3, 10^{10}]$. When $\mu > 10^{10}$, the resulting loss of precision is usually large enough to destroy the accuracy of the computed solution.

Three features of Table 1 are worth noting. First, the likelihood of blowup seems to increase as n increases. This is not a surprise—as n grows we would expect a mismatch between the number of positive eigenvalues and the number of rows that are pivoted between successive blocks (see §2) to become more likely. Second, the choice $B_a = I$ (which can be obtained by a simple transformation whenever the B_a in (1) is nonsingular) seems to be particularly inappropriate, though it is the "natural" choice in many circumstances. The reason for this should be clear from the discussion near the end of §2. Third, a wise strategy appears to be to scale B_a, B_b, and β by a moderately small constant. From Theorem 2.1 and the definitions of Q and κ_1, we see that this may cause some slight deterioration in the conditioning of the matrix (9), but trials A and D indicate that exponential blowup is much less likely to occur. A "too small" choice of γ may lead to Assumption 1 in [11] being violated during factorization of the first few row blocks, but after this initial phase, the pivoting pattern exhibits the "stable" pivoting feature described in §2.

Acknowledgments. The comments of Bob Russell, Nick Higham, and anonymous referees are gratefully acknowledged.

TIMELY COMMUNICATIONS

Under the "timely communications" policy for the SIAM Journal on Scientific Computing, papers that have significant timely content and do not exceed five pages automatically will be considered for a separate section of the journal with an accelerated reviewing process. It will be possible for the note to appear approximately six months after the date of acceptance.

AN OPTIMAL TWO-LEVEL OVERLAPPING DOMAIN DECOMPOSITION METHOD FOR ELLIPTIC PROBLEMS IN TWO AND THREE DIMENSIONS*

XIAO-CHUAN CAI†

Abstract. The solution of linear systems of algebraic equations that arise from elliptic finite element problems is considered. A two-level overlapping domain decomposition method that can be viewed as a combination of the additive and multiplicative Schwarz methods is studied. This method combines the advantages of the two methods. It converges faster than the additive Schwarz algorithm and is more parallelizable than the multiplicative Schwarz algorithm, and works for general, not necessarily self-adjoint, linear, second-order, elliptic equations. The GMRES method is used to solve the resulting preconditioned linear system of equations and it is shown that the algorithm is optimal in the sense that the rate of convergence is independent of the mesh size and the number of subregions in both R^2 and R^3. A numerical comparison with the additive and multiplicative Schwarz preconditioned GMRES is reported.

Key words. overlapping domain decomposition, elliptic equations, finite elements, iterative method

AMS(MOS) subject classifications. 65F10, 65N30

1. Introduction. The domain decomposition technique is a class of preconditioned iterative methods for solving partial differential equations and has been proved to be very effective for parallel computing. In this paper, we study a new class of methods based on the Dryja–Widlund decomposition [7], in which the usual finite element space is optimally decomposed into the sum of a finite number of uniformly overlapped, two-level subspaces. Based on this decomposition, two methods, the additive Schwarz (ASM) [3], [5], [7] and the multiplicative Schwarz methods (MSM) [2], [6], have been studied. A recent paper [4] shows that MSM, despite its having less parallelism, is substantially faster than ASM in terms of their algebraic convergence rates. In this paper, we develop a new method that can be viewed as a combination of ASM and MSM, and it converges faster than the additive Schwarz method and is more parallelizable than the multiplicative Schwarz method. If the number of processors is about the same as the number of subdomains that have the same color, which will be described in detail later, then the parallelism of the new method is as good as that of ASM. We show that the new method, accelerated by certain Krylov space-based iterative methods, such as GMRES, has an optimal convergence rate independent of the mesh sizes and the number of subproblems for general elliptic problems, not necessarily symmetric, in both two- and three-dimensional spaces. The main difference between the new method and MSM is the treatment of the coarse grid

operator. There are other recently developed iterative methods that make special use of the coarse grid operator; see, e.g., [1], [11], and [12].

The paper is organized as follows. In §2, we briefly introduce the elliptic finite element problem and the Dryja–Widlund decomposition. Then, we discuss the idea of transformed systems with certain well-known examples in §3. The new method is introduced in §4, in which the convergence rate of the new method is also analyzed. In §5, we provide a numerical comparison of the new method with the additive and multiplicative Schwarz methods. We conclude the paper with a few remarks in §6.

2. Model problem and Dryja–Widlund decomposition.

Let Ω be a bounded polygonal region in R^d ($d = 2$ or 3) with boundary $\partial\Omega$. We consider the weak form of the homogeneous Dirichlet boundary value problem: Find $u \in H_0^1(\Omega)$ such that

$$b(u,v) = (f,v) \quad \forall v \in H_0^1(\Omega), \tag{1}$$

where the bilinear form $b(u,v) = a(u,v) + s(u,v)$ and

$$a(u,v) = \sum_{i,j=1}^{d} \int_\Omega a_{ij} \frac{\partial u}{\partial x_i} \frac{\partial v}{\partial x_j} dx \quad \text{and} \quad s(u,v) = \sum_{i=1}^{d} \int_\Omega b_i \frac{\partial u}{\partial x_i} v dx + \int_\Omega cuvdx.$$

We assume that all coefficients are sufficiently smooth, the matrix $\{a_{ij}(x)\}$ is symmetric and uniformly positive definite, and $f \in H^{-1}(\Omega)$. We also assume that the equation has a unique solution and that $b(\cdot,\cdot)$ satisfies, for some positive constants c and C,

- $c\,\|u\|_a^2 \le b(u,u)$ for all $u \in H_0^1(\Omega)$,
- $\mid b(u,v) \mid \le C\,\|u\|_a \|v\|_a$ for all $u,v \in H_0^1(\Omega)$.

Here $\|\cdot\|_a = a(\cdot,\cdot)^{1/2}$ is the energy norm of $H_0^1(\Omega)$. We solve (1) by the Galerkin conformal finite element method. For simplicity, we use piecewise linear triangular elements in R^2 and the corresponding tetrahedral elements in R^3. Following Dryja and Widlund [7], we describe a two-level triangulation of Ω and the corresponding finite element spaces. We define $\{\Omega_i, i = 1, \ldots, N\}$ to be a shape-regular finite element triangulation of Ω, where the diameter of Ω_i is of order $O(H)$. We call Ω_i a substructure and $\{\Omega_i\}$ the coarse grid or H-level triangulation of Ω. In our second step, we further divide each Ω_i into smaller simplices of diameter $O(h)$, and the union of these forms a shape-regular finite element triangulation of Ω. We call it the fine mesh or h-level triangulation of Ω. We denote by V^H and V^h the continuous, piecewise linear finite element function spaces over the H-level and h-level triangulations of Ω, respectively. The Galerkin approximation of (1) is formulated as follows: Find $u_h^* \in V^h$, such that

$$b(u_h^*, v_h) = (f, v_h) \quad \forall v_h \in V^h. \tag{2}$$

We next describe the Dryja–Widlund decomposition of V^h. To decompose Ω into overlapping subregions, we extend each Ω_i to a larger subregion Ω_i', i.e., $\Omega_i \subset \Omega_i' \subset \Omega$. The overlap is of size $O(H)$, or more precisely $\operatorname{dist}(\partial\Omega_i' \cap \Omega, \partial\Omega_i \cap \Omega) \ge \alpha H$ for all i, for a constant $\alpha > 0$. We assume that $\partial\Omega_i'$ aligns with the h-level elements and denote $\Omega_0' = \Omega$. For each $\Omega_i', i > 0$, we define $V_i^h = \{v_h \in V^h \mid v_h(x) = 0,\ x\bar{\in}\Omega_i'\} \subset V^h$. We also use the subspace $V_0^h = V^H$. It is easy to see that V^h can be represented as the sum of the $N + 1$ subspaces,

$$V^h = V_0^h + V_1^h + \cdots + V_N^h.$$

We now regroup the subregions in terms of the following coloring strategy. Associated with the decomposition $\{\Omega_i'\}$, we define an undirected graph in which nodes represent the extended subregions and the edge intersections of the extended subregions. This graph can be colored, using colors $0, \ldots, J$, such that no connected nodes have the same color. We note that Ω_0' needs its own color. It is obvious that the coloring is not unique.

3. Transformed linear system. Let $b_i(\cdot,\cdot)$ be a bilinear form, defined on the subspace V_i^h, which we will refer to as the subspace preconditioner for $b(\cdot,\cdot)$. In this paper, we only consider two cases:

(i) $b_i(\cdot,\cdot) = b(\cdot,\cdot)$ for $i = 0, 1, \ldots, N$;

(ii) $b_0(\cdot,\cdot) = b(\cdot,\cdot)$ and $b_i(\cdot,\cdot) = a(\cdot,\cdot)$ for $i = 1, \ldots, N$.

We introduce the operator $T_i : V^h \longrightarrow V_i^h$ by

$$b_i(T_i u_h, v_h) = b(u_h, v_h) \quad \forall u_h \in V^h \quad \text{and} \quad \forall v_h \in V_i^h.$$

We note that among all these operators, T_0 is the only global operator and all the others are local. We recall that $u_h^* \in V^h$ denote the exact solution of the Galerkin equation (2). It is easy to see that the vector $T_i u_h^* \in V_i^h$ can be computed, without knowing u_h^*, by using the definition of T_i and the equation (2). As an immediate consequence, if we define

$$T = \text{poly}(T_0, T_1, \ldots, T_N)$$

as a polynomial of these T_i's such that $\text{poly}(0, \ldots, 0) = 0$, then $Tu_h^* \in V^h$ can also be computed without knowing u_h^* itself. By denoting $g = Tu_h^*$, we refer to

$$Tu_h^* = g \tag{3}$$

as the *transformed system* of (2). It is not difficult to prove the following theorem.

THEOREM 3.1. *If T is invertible, then the equation* (3) *has the same solution as the Galerkin equation* (2).

We now group these maps T_i in terms of the color that the subregion was assigned. For $j = 0, 1, \ldots, J$, we denote Q_j as the sum of all T_i's that correspond to the subregions with the jth color. In fact, $Q_0 = T_0$. We remark that N (the number of subregions) may be large, while J (the number of colors) can still be small. We next look at two special examples. The first one, which is the simplest case and the degree of $\text{poly}(\cdots)$ is one, is the additive Schwarz method, in which the operator has the form

$$T_{\text{ASM}} = Q_0 + Q_1 + \cdots + Q_J.$$

The second example is the so-called multiplicative Schwarz operator

$$T_{\text{MSM}} = I - E_{J+1},$$

where I is the identity map and $E_{J+1} = (I - Q_0)(I - Q_1) \cdots (I - Q_J)$. The degree of this polynomial depends on the number of colors, and the exact form of the polynomial depends on how the subregions are colored.

It is important to note that even if the original equation (2) is not well conditioned, the transformed systems can be uniformly well conditioned and more importantly the transformed system can be so arranged that a highly parallelizable algorithm can be developed for solving it. To build such a well-conditioned and easily parallelizable transformed system is the main purpose of this paper.

4. A new transformed system and its spectral bounds. The parallelism of MSM results mainly from the fact that, for $j \neq 0$, Q_j is a sum of some local independent subproblems that can be handled in parallel. However, the global operator $Q_0 v_h = T_0 v_h$ is very special and it cannot be handled in parallel with other local subproblems. It is not the case for ASM, in which all subproblems, including T_0, can be solved in parallel.

Motivated by the above observation, we now define an operator in which the global operator T_0 is made to be additive to the rest of the local operators:

$$T_{\text{new}} = \omega T_0 + I - E_J, \tag{4}$$

where $E_J = (I - Q_1) \cdots (I - Q_J)$ and $0 < \omega \in R$ is a balancing parameter. If we define $f_{\text{new}} = T_{\text{new}} u_h^*$, then our new algorithm can be described in the following way.

ALGORITHM. Find the solution of equation (2) by solving the transformed system

$$T_{\text{new}} u_h^* = f_{\text{new}} \tag{5}$$

with an iterative method.

We show in the next theorem that the operator T_{new} is, under certain assumptions, uniformly well conditioned. In other words, its spectral bounds are independent of the mesh parameter as well as the number of subproblems. The symmetric part of T_{new} is uniformly positive definite, which guarantees the convergence of a class of Krylov space-based iterative methods, such as the GMRES method [8], [9].

THEOREM 4.1. *There exist constants $H_0 > 0$ and $\omega > 0$, independent of h and H, such that if $H \leq H_0$, then*

$$\|T_{\text{new}}\|_a \leq C$$

and

$$a(T_{\text{new}} u_h, u_h) \geq \frac{c}{(J+1)^2} \|u_h\|_a^2 \quad \forall u_h \in V^h,$$

where $C = C(H_0)$ and $c = c(H_0)$ are positive constants independent of H and h.

In order to prove the main theorem, we need to quote some known results for the well-conditionedness of T_{MSM}.

THEOREM 4.2 (Cai and Widlund [6]). *There exist constants $H_0 > 0$, $\gamma_i > 0$, $i = 1, 2$, such that if $H \leq H_0$, then*

$$\|E_J\|_a \leq \sqrt{1 - \frac{\gamma_1 H^2}{J^2}} \quad \text{and} \quad \|E_{J+1}\|_a \leq \sqrt{1 - \frac{\gamma_2}{(J+1)^2}},$$

where $\gamma_i = \gamma_i(H_0)$ are independent of H and h.

LEMMA 4.3 (Cai and Widlund [5]). *There exists a constant $H_0 > 0$, such that if $H \leq H_0$, then for any $u_h \in V^h$,*

$$\|T_0 u_h\|_a \leq C \|u_h\|_a, \qquad \|T_0 u_h - u_h\|_{L^2} \leq CH \|u_h\|_a,$$

and

$$a(T_0 u_h, u_h) \geq \|T_0 u_h\|_a^2 - cH \|u_h\|_a^2,$$

where $c = c(H_0)$ and $C = C(H_0)$ are positive constants independent of H and h.

Proof of Theorem 4.1. It is easy to see that the following identity holds:

$$T_{\text{new}} = \omega T_0 - T_0 E_J + I - E_{J+1}. \tag{6}$$

The upper bound part of this theorem can be trivially proved by using Theorem 4.2 and Lemma 4.3.

For the lower bound part, we only prove the case where $b_i(\cdot,\cdot) = b(\cdot,\cdot)$ for $i = 0,\dots,N$. The proof for the other case can be obtained in a similar way. Directly from the identity (6), we have

$$a(T_{\text{new}}u_h, u_h) = \omega a(T_0 u_u, u_h) + a(u_h, u_h) - a(E_{J+1}u_h, u_h) - a(T_0 E_J u_h, u_h). \tag{7}$$

We now estimate the right-hand side of the above equality term by term. Following Theorem 4.2, we obtain

$$a(E_{J+1}u_h, u_h) \le (1-\tilde{c})\|u_h\|_a^2, \tag{8}$$

where the constant $\tilde{c} = 1 - \sqrt{1-\gamma_2/(J+1)^2} > 0$. It is easy to verify that

$$\begin{aligned} a(T_0 E_J u_h, u_h) &= b(T_0 u_h, T_0 E_J u_h) - s(u_h, T_0 E_J u_h) \\ &= a(T_0 u_h, T_0 E_J u_h) + s(T_0 u_h - u_h, T_0 E_J u_h). \end{aligned} \tag{9}$$

By using Lemma 4.3, Theorem 4.2, and the fact that $|s(u,v)| \le C\|u\|_{L^2}\|v\|_a$ for all $u, v \in H_0^1(\Omega)$, we have

$$|s(T_0 u_h - u_h, T_0 E_J u_h)| \le CH\|u_h\|_a^2$$

and hence

$$\begin{aligned} a(T_0 E_J u_h, u_h) &\le \|T_0 u_h\|_a \|T_0 E_J u_h\|_a + CH\|u_h\|_a^2 \\ &\le C_1\|u_h\|_a\|T_0 u_h\|_a + CH\|u_h\|_a^2 \\ &\le \frac{C_1\lambda}{2}\|u_h\|_a^2 + \frac{C_1}{2\lambda}\|T_0 u_h\|_a^2 + CH\|u_h\|_a^2, \end{aligned} \tag{10}$$

where λ is an arbitrary positive constant. By taking $\lambda = \tilde{c}/C_1$, we have

$$a(T_0 E_J u_h, u_h) \le \frac{\tilde{c}}{2}\|u_h\|_a^2 + \frac{C_1^2}{2\tilde{c}}\|T_0 u_h\|_a^2 + CH\|u_h\|_a^2. \tag{11}$$

Taking all the above estimates (7), (8), (11), and the last inequality of Lemma 4.3 into account, we have

$$\begin{aligned} a(T_{\text{new}}u_h, u_h) \ge{}& \tilde{c}\|u_h\|_a^2 + \omega\|T_0 u_h\|_a^2 - CH\omega\|u_h\|_a^2 \\ & -\frac{\tilde{c}}{2}\|u_h\|_a^2 - \frac{C_1^2}{2\tilde{c}}\|T_0 u_h\|_a^2 - CH\|u_h\|_a^2. \end{aligned} \tag{12}$$

Therefore, if we choose $\omega = C_1^2/(2\tilde{c})$, then

$$a(T_{\text{new}}u_h, u_h) \ge \frac{\tilde{c}}{2}\|u_h\|_a^2 - CH\|u_h\|_a^2. \tag{13}$$

Thus, if H is small enough, we have

$$a(T_{\mathrm{new}}u_h, u_h) \geq \frac{\tilde{c}}{4}\|u_h\|_a^2 \geq \frac{\gamma_2}{8(J+1)^2}\|u_h\|_a^2, \tag{14}$$

which completes the proof of the main theorem. □

A remark is in order here about the choice of ω. ω does not depend on the size of the linear system, nor the number of subproblems. Our numerical experiments (cf. the next section) show that the algorithm is not very sensitive to ω. In fact, $\omega = 1$ has always given us better convergence than ASM.

5. Numerical experiments and comparison with ASM and MSM.

In this section, we first briefly discuss the parallel complexity of the new algorithm as compared with ASM and MSM, and then present some numerical results.

Let us make some basic assumptions before providing a parallel complexity analysis with p parallel processors. In this paper, we only focus on these computer architecture independent factors. We assume that the communication, synchronization, and load balancing costs can be ignored, and also that each subproblem is solved by using only one processor.

Furthermore, we assume that all interior problems, defined on any extended substructures, are of relatively the same size and need t_i unit time (or number of arithmetic operations) to solve. Of course, t_i depends not only on how many unknowns each subregion has, but also on the method used to solve the interior problem. This is also true for t_c in the coarse mesh problem. Table 1 shows the parallel complexity of performing the preconditioner-vector multiplication by using multiplicative, additive, and the new Schwarz-type methods.

TABLE 1
The parallel complexity of the algorithms with p processors.

Method	# of iterations	p= # of subproblems	p = (max # of subdomains with the same color + 1)
MSM	$O(1)$	$Jt_i + t_c$	$Jt_i + t_c$
ASM	$O(1)$	$\max\{t_i, t_c\}$	$\max\{Jt_i, t_c\}$
NEW	$O(1)$	$\max\{Jt_i, t_c\}$	$\max\{Jt_i, t_c\}$

TABLE 2
Iteration counts for solving the Poisson equation ($\delta = 0$) with different h, H, and overlap sizes. Here $\omega = 1.0$.

$h^{-1} =$	32	64	128	32	64	128	64	128
Overlapping size	$H = 1/4$			$H = 1/8$			$H = 1/16$	
ovlp=h	8	8	10	8	7	7	6	6
ovlp=$2h$	8	8	8	7	7	7	6	6
ovlp=$4h$	6	7	8		7	7		6

We next present some numerical results for solving this equation where

$$-\triangle u + \delta u_x + \delta u_y = f \ \text{ in } \Omega \tag{15}$$

with $u = 0$ on $\partial\Omega$ and $\Omega = [0,1] \times [0,1]$. In all cases, the exact solution $u = e^{xy}\sin(\pi x)\sin(\pi y)$, and f can thus be set accordingly.

The unit square is subdivided into two-level uniform meshes, with h and H representing the fine and coarse mesh sizes. The elliptic operator is then discretized by the usual five-point central or upwinding difference methods over both meshes. The full GMRES method, without restarting, with zero initial guess is used for all of the transformed linear systems in the usual Euclidean norm, and the stopping criterion is the reduction of the initial preconditioned residual by five orders of magnitude in the L^2 norm.

We first test a special case $\delta = 0$. Although this is a symmetric problem, we still use GMRES as the outer iterative method. The iteration counts are given in Table 2.

Our second test problem is a nonsymmetric, constant coefficient problem. We specify the constant $\delta > 0$ in Table 3. The elliptic operator is discretized by two schemes, namely, the central difference method, for relatively small δ, and the upwind difference method, for relatively large δ.

The optimal choice of ω is not unique and $\omega = 1.0$ seems among the optimal choices for the example that we tested. An example can be found in Table 4.

We finally compare the new algorithm with ASM and MSM by listing the convergence history in Table 5. It is clear that the convergence rate of the new algorithm is faster than that of ASM but slower than MSM. Some results for the same test problems obtained using other domain decomposition methods can be found in [4].

TABLE 3

Iteration counts for solving the nonsymmetric model equation with various values of δ and two discretizations. The parameter $h = 1/128$. Here $\omega = 1.0$.

6. Concluding remarks.

In this paper, we introduced a new member in the class of Schwarz-type overlapping domain decomposition methods. This class of methods has been shown to be fast, even in the case involving boundary layers; see, e.g., the recent paper of Tang [10]. The new method shares the robustness of other Schwarz methods with added parallelism.

Acknowledgments. The author is indebted to Professors M. Dryja, O. Widlund, and B. Smith for many helpful discussions and suggestions. The author would also like to thank Professors W. Gropp and D. Keyes for providing their experimental domain decomposition codes, which inspired the new algorithm.

A NOTE ON COMPUTING EIGENVALUES OF BANDED HERMITIAN TOEPLITZ MATRICES*

WILLIAM F. TRENCH[†]

Abstract. It is pointed out that the author's $O(n^2)$ algorithm for computing individual eigenvalues of an arbitrary $n \times n$ Hermitian Toeplitz matrix T_n reduces to an $O(rn)$ algorithm if T_n is banded, with bandwidth r.

Key words. Toeplitz, Hermitian, banded, eigenvalue, eigenvector

AMS(MOS) subject classifications. 65F15, 15A18, 15A57

In a recent paper Arbenz [2] (see also [1]) presented a method for computing the eigenvalues of a Toeplitz matrix

$$T_n = (t_{i-j})_{i,j=1}^n, \tag{1}$$

where

$$t_\nu = t_{-\nu} \quad \text{and} \quad t_\nu = 0 \quad \text{if } |\nu| > r;$$

thus T_n is symmetric. If $n > r$ (which we assume henceforth), then T_n is also banded. Following Arbenz, we will say that T_n *has bandwidth* r.

Since [2] is so recent and easily accessible, there is no need to go into the details of Arbenz's algorithm here; rather, we focus on the important point that it yields the eigenvalues of T_n with a computational cost of $O(r(n + r^2))$ flops per eigenvalue. Another approach to this problem is discussed in [3] and [6].

It seems worthwhile to point out that the quite different algorithm given by the author in [9] for finding individual eigenvalues of a full Hermitian Toeplitz matrix with $O(n^2)$ flops per eigenvalue requires only $O(rn)$ flops per eigenvalue in the banded case. Here we will give the briefest description of the algorithm that suffices to make this point. For complete details, see [9]. For related results, see [10].

Theorems 1 and 2 of [9] imply the following theorem, which is the basis for the algorithm.

THEOREM 1. *Let T_n be a Hermitian Toeplitz matrix, let T_m $(1 \le m \le n)$ be its $m \times m$ principal submatrix, and define*

$$q_m(\lambda) = \frac{p_m(\lambda)}{p_{m-1}(\lambda)}, \qquad 1 \le m \le n,$$

where

$$p_0(\lambda) = 1 \quad \textit{and} \quad p_m(\lambda) = \det[T_m - \lambda I_m], \qquad 1 \le m \le n.$$

If λ is not an eigenvalue of any of the principal submatrices $T_1, \ldots, T_{n-1}$, then $q_1(\lambda), \ldots, q_n(\lambda)$ can be computed recursively as follows. Let

$$q_1(\lambda) = t_0 - \lambda, \qquad x_{11}(\lambda) = t_1/(t_0 - \lambda).$$

*Received by the editors July 22, 1991; accepted for publication (in revised form) May 27, 1992. This work was partially supported by National Science Foundation grants DMS 8907939 and DMS 9108254.

[†]Department of Mathematics, Trinity University, 715 Stadium Drive, San Antonio, Texas 78212.

Then, for $2 \le m \le n-1$,

$$q_m(\lambda) = [1 - |x_{m-1,m-1}(\lambda)|^2] q_{m-1}(\lambda),$$

$$x_{mm}(\lambda) = (q_m(\lambda))^{-1} \left[t_m - \sum_{j=1}^{m-1} t_j x_{m-j,m-1}(\lambda) \right], \tag{2}$$

and

$$x_{jm}(\lambda) = x_{j,m-1}(\lambda) - x_{mm}(\lambda)\bar{x}_{m-j,m-1}(\lambda), \qquad 1 \le j \le m-1. \tag{3}$$

Finally,

$$q_n(\lambda) = [1 - |x_{n-1,n-1}(\lambda)|^2] q_{n-1}(\lambda).$$

Moreover, if λ *is an eigenvalue of* T_n, *then*

$$Y_n(\lambda) = \begin{bmatrix} -1 \\ X_{n-1}(\lambda) \end{bmatrix}$$

is an associated eigenvector, where

$$X_{n-1}(\lambda) = \begin{bmatrix} x_{1,n-1}(\lambda) \\ x_{2,n-1}(\lambda) \\ \vdots \\ x_{n-1,n-1}(\lambda) \end{bmatrix}.$$

Let the eigenvalues of T_n be

$$\lambda_1 \le \lambda_2 \le \cdots \le \lambda_n,$$

and suppose that we wish to compute λ_k for a given k in $\{1, 2, \ldots, n\}$. We assume that λ_k is not an eigenvalue of any of the submatrices $T_1, \ldots, T_{n-1}$. From Sturm's theorem, the number of negative values in $\{q_1(\lambda), q_2(\lambda), \ldots, q_m(\lambda)\}$ equals the number of eigenvalues of $T_m - \lambda I_m$ less than λ. Therefore, if we can guess values a and b such that $\lambda_k \in (a, b)$, then Theorem 1 and bisection can be used to find a subinterval (α, β) of (a, b) which contains λ_k but no other eigenvalue of T_n nor any eigenvalue of T_{n-1}. Since q_n is continuous on (α, β), we can then use a more elaborate iterative rootfinder to compute λ_k as a zero of q_n. In [9] and [10] we chose the Pegasus modification [5, 7] of the rule of false position, which has order of convergence approximately 1.642. If $\{\mu_j\}$ is the sequence of iterates produced by the Pegasus computation, starting with $\mu_0 = \alpha$ and $\mu_1 = \beta$, then we terminate this phase of the computation at the first integer r such that

$$|\mu_r - \mu_{r-1}| < .5(1 + \mu_r)10^{-K}, \tag{4}$$

where K is a positive integer dictated by machine precision and accuracy requirements.

For a full Hermitian Toeplitz matrix T_n the computations in Theorem 1 require approximately n^2 flops for each λ. Therefore, the computation of each eigenvalue requires $0(n^2)$ flops, where the "constant" buried in the "0" depends on the number of iterations required for the given eigenvalue. Although this number depends upon the eigenvalue itself and on the starting values (a and b), computational experience (see [9]) shows that for a given choice of K in (4), its average value over all eigenvalues of a matrix of order n is essentially independent of n. Thus we can say that the cost of the procedure is roughly $M(K)n^2$ flops per eigenvalue. (For the computations reported in [9], $M(10) \approx 11$.) However, the point of the present note is that if T_n is banded, then the computations in Theorem 1 require only $O(rn)$ flops, so the algorithm in [9] yields eigenvalues of T_n at a cost of $O(rn)$ flops per eigenvalue. The reason for this is the following theorem, which is easily obtained from Theorem 1. We omit the proof.

THEOREM 2. *In addition to the assumptions of Theorem* 1, *let T_n have bandwidth $r < n$. Then $q_1(\lambda), \dots, q_n(\lambda)$ can be computed recursively as in Theorem* 1, *except that if $m > r$, then* (2) *and* (3) *can be replaced by*

$$x_{mm}(\lambda) = -\left(q_m(\lambda)\right)^{-1} \sum_{j=1}^{r} t_j x_{m-j,m-1}(\lambda), \tag{5}$$

and

$$x_{jm}(\lambda) = x_{j,m-1}(\lambda) - x_{mm}(\lambda)\bar{x}_{m-j,m-1}(\lambda), \quad 1 \le j \le r, \quad m-r \le j \le m-1 \tag{6}$$

if $m \ge r+1$.

It is significant that the summation in (5) involves only r products rather than $m-1$ as in (2), and we compute only $2r$ (fewer if $r < m < 2r$) components of $X_{n-1}(\lambda)$ in (6), as compared to m in (3). Therefore, Theorem 2 implies that for large n the algorithm of [9] requires approximately $(3r+1)n$ flops to compute $q_0(\lambda), q_1(\lambda), \dots, q_n(\lambda)$ for a given λ if T_n has bandwidth r. Since numerical experiments indicate no significant differences between convergence properties of the algorithm for banded and full matrices, this means that the average cost of computing a single eigenvalue of a banded Hermitian Toeplitz matrix is $M(K)(3r+1)n$ flops, where $M(10) \approx 11$ if $K = 10$ in (4).

Having obtained λ_k by computations based on Theorems 1 and 2, we have as a byproduct the first $r+1$ components,

$$y_{1n}(\lambda_k) = -1, y_{2n}(\lambda_k) = x_{1,n-1}(\lambda_k), \dots, y_{r+1,n}(\lambda_k) = x_{r,n-1}(\lambda_k),$$

and the last r components,

$$y_{n-r+1,n}(\lambda_k) = x_{n-r,n-1}(\lambda_k), \dots, y_{nn} = x_{n-1,n-1}(\lambda_k),$$

of the associated eigenvector $Y_n(\lambda_k)$. However, the last r components are not independent, since if λ_k is a simple eigenvalue of T_n, then either

$$y_{n-i+1,n}(\lambda_k) = y_{in}(\lambda_k) \quad \text{or} \quad y_{n-i+1,n}(\lambda_k) = -y_{in}(\lambda_k), \quad 1 \le i \le n$$

(see [4]). In any case, even if λ_k has multiplicity greater than one, the first r components of $Y_n(\lambda_k)$ determine the rest. To see this, we recall from [8] that the components of $Y_n(\lambda_k)$ satisfy the difference equation

$$\sum_{j=-r}^{r} t_j y_{i+j,n}(\lambda_k) = \lambda_k y_{in}(\lambda_k), \qquad 1 \le i \le n, \tag{7}$$

subject to the boundary conditions

$$y_{in}(\lambda_k) = 0, \qquad -r+1 \leq i \leq 0, \tag{8}$$

and

$$y_{in}(\lambda_k) = 0, \qquad n+1 \leq i \leq n+r.$$

Therefore, if

$$y_{1n}(\lambda_k), \ldots, y_{rn}(\lambda_k) \tag{9}$$

are known, then the remaining components of $Y_n(\lambda_k)$ can in principle be obtained by treating (8) as initial conditions and computing recursively from (7):

$$y_{i+r,n}(\lambda_k) = -\frac{1}{t_r} \sum_{j=-r}^{r-1} (t_j - \delta_{0j}\lambda_k) y_{i+j,n}(\lambda_k), \qquad i \geq 1. \tag{10}$$

Since the zeros of the characteristic polynomial

$$P(z) = \sum_{j=-r}^{r} t_j z^j - \lambda_k$$

of (7) occur in reciprocal pairs, the recursion (10) is unstable and therefore computationally useless; nevertheless, it proves our assertion that the components (9) completely determine $Y_n(\lambda_k)$.

From this it seems reasonable to make the (admittedly vague) conjecture that any meaningful question depending upon the eigenvector $Y_n(\lambda_k)$ can in principle be resolved from a knowledge of the components in (9), without actually computing the remaining ones. However, if the remaining components are required, then it is useful to recall from [9] that $X_{n-1}(\lambda_k)$ is the solution of the banded Toeplitz system

$$(T_{n-1} - \lambda_k I_{n-1})X = \begin{bmatrix} t_1 \\ t_2 \\ \vdots \\ t_r \\ 0 \\ \vdots \\ 0 \end{bmatrix}.$$

This is a tractable problem, since there are several well-known fast algorithms for solving banded Toeplitz systems.

EXPLOITING STRUCTURAL SYMMETRY IN A SPARSE PARTIAL PIVOTING CODE*

STANLEY C. EISENSTAT† AND JOSEPH W. H. LIU‡

Abstract. This short communication shows how to take advantage of structural symmetry to improve the performance of a class of partial pivoting codes for the LU factorization of large sparse unsymmetric matrices. Experimental results demonstrate the effectiveness of this technique in reducing the overall factorization time.

Key words. sparse LU factorization, partial pivoting, structural symmetry

AMS(MOS) subject classifications. 65F05, 65F50

1. Introduction.

Many implementations of sparse LU factorization with partial pivoting compute the factors one row or column at a time. Each step involves both symbolic operations (to determine the nonzero structure) and numeric operations. With the development of fast floating-point hardware and vector processors, the symbolic operations have come to represent a nontrivial fraction of the overall factorization time. Thus any sizable reduction in this symbolic overhead would have a significant impact.

The technique of *symmetric reduction* [4] exploits structural symmetry to decrease the amount of structural information required for the symbolic factorization of a sparse unsymmetric matrix (i.e., for obtaining the nonzero structures of the factor matrices). This has the practical advantage of decreasing the run-time.

In this short communication, we show how to use symmetric reduction to improve the performance of a class of partial pivoting codes for the LU factorization of large sparse unsymmetric matrices, in particular, Sherman's NSPFAC (a more recent version of NSPIV [8]) and a code of Gilbert and Peierls [7]. For some problems the speedup is more than a factor of two.

Notation. For an $n \times n$ matrix M and two sets I and J of subscripts, we let M_{IJ} denote the submatrix of M determined by the rows in I and the columns in J. As a special case, we let M_{I*} denote the submatrix of M determined by the rows in I.

We let $G(M)$ denote the associated directed graph. Here edges are directed from row to column; i.e., (r, c) is an edge in $G(M)$ if and only if m_{rc} is nonzero. We use the notation $r \xrightarrow{M} c$ to indicate the existence of an edge from r to c in $G(M)$, and $r \overset{M}{\Longrightarrow} c$ to indicate the existence of a path from r to c. We also adopt the convention that $i \overset{M}{\Longrightarrow} i$ for any i.

2. Unsymmetric symbolic factorization.

Let A be a sparse unsymmetric $n \times n$ matrix that can be decomposed (without pivoting) into $L \cdot U$, where L is lower triangular with unit diagonal and U is upper triangular. Let F denote the *filled matrix* $L + U$.

Assume that we have determined the nonzero structures of the first $k-1$ rows of L and U; i.e., letting $K = \{1, \ldots, k-1\}$ and $\overline{K} = \{k, \ldots, n\}$, we know the structure of

$$F_{K*} = L_{K*} + U_{K*} = \begin{pmatrix} L_{KK} & 0 \end{pmatrix} + \begin{pmatrix} U_{KK} & U_{K\overline{K}} \end{pmatrix}.$$

The following result relates the structures of the rows L_{k*} and U_{k*} to the existence of certain paths in $G(U_{K*})$.

THEOREM 2.1 (see [7]). *$k \xrightarrow{F} i$ if and only if $k \xrightarrow{A} m \overset{U_{K*}}{\Longrightarrow} i$ for some m.*

Thus, to determine the nonzero structure of $F_{k*} = L_{k*} + U_{k*}$, we can search $G(U_{K*})$ for nodes reachable from some node m for which $a_{km} \neq 0$.

3. Two sparse partial pivoting codes. We focus on two implementations of sparse LU factorization with partial pivoting: Sherman's NSPFAC (a descendant of NSPIV [8]) and Gilbert and Peierls's code [7] (referred to here as GP).

NSPFAC factors A by rows using column partial pivoting. While computing F_{k*}, it represents the structure of the current, partially formed row by an ordered, linked list of subscripts corresponding to nonzero columns. The linked list is initialized to the nonzero columns in A_{k*}. For each nonzero ℓ_{kj} (in increasing column order), the structural and numeric updates from U_{j*} to F_{k*} are applied in a single loop, one element at a time. The numeric update involves two levels of indirection.

Gilbert and Peierls [7] observed that it is not necessary to apply the row updates in increasing order—*any* order consistent with a *topological order* of $G(U_{KK})$ would suffice. They also noted that a depth-first search of $G(U_{K*})$ starting from the nonzero columns of A_{k*} gives the nonzero structure of F_{k*}, and that a topological ordering can be obtained as a byproduct, without additional work. Using this result, they show that GP runs in time proportional to the number of floating-point operations, a property not shared by other sparse partial pivoting codes.

In computing F_{k*},[1] GP first does a depth-first search to compute the structure of L_{k*} (but not U_{k*}) as above. Then, for each nonzero ℓ_{kj} (in topological order), it applies the structural updates from U_{j*} to U_{k*} and the numeric updates from U_{j*} to F_{k*} in a single loop, one element at a time.

To estimate the time NSPFAC and GP spend in nonnumeric computations, we wrote a sparse LU factorization code (called NF) that uses a predetermined pivot sequence and precomputed factor structures.[2] By using the same pivot sequence and factor structures as computed by NSPFAC or GP, we can measure how much time would be spent if the nonnumeric operations involving symbolic factorization and pivot selection were removed.

Table 2 gives the run-times[3] for ten problems from the Harwell–Boeing collection [3]. For each test matrix A, the rows of the matrix were preordered by a minimum degree ordering of AA^t, as suggested by George and Ng [5]. The results for the Sun SparcStation/1 show that the nonnumeric overhead can exceed 50 percent. For the

[1]Although GP computes the LU factorization by columns using row partial pivoting, to be consistent we describe the Gilbert–Peierls approach by rows. In the numerical experiments, GP factored A^t rather than A.

[2]NSPFAC scales rows by multiplying by the reciprocal of the pivot; GP scales columns by dividing by the pivot. To make the comparisons fair, we used two versions of NF.

[3]All programs were written in Fortran; use double-precision arithmetic; and were compiled with optimization enabled (`f77 -O` (SC1.0 Fortran V1.4) on the SparcStation/1, `xlf -O` (XL FORTRAN Compiler/6000 Version 2.2) on the RS/6000).

4. Symmetric reduction. Theorem 2.1 characterizes the nonzero structure of F_{k*} in terms of the structure of A_{k*} and paths in the graph $G(U_{K*})$. But by removing from $G(U_{K*})$ edges that are not needed to preserve the set of paths, a process called *transitive reduction* [1], we can decrease the amount of searching required to determine the structure.

If we remove all such redundant edges, then we get the *elimination dag* (*directed acyclic graph*) [6], the minimal subgraph that preserves paths. However, if we remove fewer redundant edges, we will still preserve the set of paths. The search time will be larger than for the elimination dag, but the total time (including the time for the reduction) may be less.

Symmetric reduction [4] is based on structural symmetry in the filled matrix F. The symmetric reduction of $G(U_{K*})$ is obtained by deleting all edges (i, m) for which $\ell_{ji} * u_{ij} \neq 0$ for some $j < \min\{k, m\}$. In effect, all nonzeros to the right of the first symmetric nonzero are deleted; if no such symmetric nonzero exists, then all nonzero entries are kept. We denote the resulting symmetrically reduced matrix by $\widetilde{U}_{K*}$.

Figure 1 shows the structures of two partial factor matrices $F_{K_4,*}$ and $F_{K_5,*}$, where $K_4 = \{1,2,3,4\}$ and $K_5 = \{1,2,3,4,5\}$. We use "•" to indicate a nonzero entry in the original matrix, and "∘" an entry that fills in. Since $\ell_{41} * u_{14}$ is the only symmetric nonzero pair in $F_{K_4,*}$, only the nonzeros to the right of u_{14} are pruned from $U_{K_4,*}$ to get $\widetilde{U}_{K_4*}$. On the other hand, there are two more symmetric nonzero pairs in $F_{K_5,*}$, $\ell_{52} * u_{25}$ and $\ell_{54} * u_{45}$, so that nonzeros are pruned in rows 2 and 4 to get $\widetilde{U}_{K_5,*}$.

$$F_{K_4,*} = \begin{pmatrix} 1 & & & \bullet & \bullet & & \bullet \\ & 2 & & & \bullet & \bullet & \\ \bullet & & 3 & \circ & \circ & & \circ \\ \bullet & & & 4 & \circ & \bullet & \circ \end{pmatrix} \qquad \widetilde{U}_{K_4,*} = \begin{pmatrix} 1 & & & \bullet & & & \\ & 2 & & & \bullet & \bullet & \\ & & 3 & \circ & \circ & & \circ \\ & & & 4 & \circ & \bullet & \circ \end{pmatrix}$$

$$F_{K_5,*} = \begin{pmatrix} 1 & & & \bullet & \bullet & & \bullet \\ & 2 & & & \bullet & \bullet & \\ \bullet & & 3 & \circ & \circ & & \circ \\ \bullet & & & 4 & \circ & \bullet & \circ \\ \bullet & \bullet & & \circ & 5 & \circ & \circ \end{pmatrix} \qquad \widetilde{U}_{K_5,*} = \begin{pmatrix} 1 & & & \bullet & & & \\ & 2 & & & \bullet & & \\ & & 3 & \circ & \circ & & \circ \\ & & & 4 & \circ & & \\ & & & & 5 & \circ & \circ \end{pmatrix}$$

Symmetric reduction preserves the set of paths in $G(U)$ (see [4]). The argument can be adapted to show that it also preserves the set of paths in $G(U_{K*})$. The following result is an immediate corollary of this observation and Theorem 2.1.

COROLLARY 4.1. *$k \xrightarrow{F} i$ if and only if $k \xrightarrow{A} m \overset{\widetilde{U}_{K*}}{\Longrightarrow} i$ for some m.*

5. Numerical experiments. We incorporated symmetric reduction into NSPFAC and GP. In the process, we made a number of small modifications to the codes.

In NSPFAC, we split the innermost loop so that, when applying the update from U_{j*} to F_{k*}, we complete the structural update *before* performing the numeric update. Furthermore, we removed one of the two levels of indirection from the numeric update.

In GP, we removed the structural update to U_{k*} from the innermost loop and disabled the test for accidental cancellation, for otherwise symmetric reduction might not preserve paths. Furthermore, we combined the symbolic computation of L_{k*} and U_{k*} into a single depth-first search that computes the structure of F_{k*} using Corollary 4.1.

Table 3 presents the ratios of the run-times of the original and two modified versions of NSPFAC and GP to the corresponding NF using the same pivot sequence. The versions labeled "Red" include only those changes needed to incorporate symmetric reduction; the versions labeled "Mod" also include the changes that remove one level of indirection (NSPFAC) or combine the depth-first searches (GP). As in Table 2, the rows of each test matrix A were preordered by a minimum degree ordering on AA^t.

The results show a dramatic decrease in the overall factorization time. The reduction is more pronounced on the RS/6000 due to the relatively faster floating-point hardware. An even more dramatic reduction would be expected on a vector processor.

There are other ways to improve these sparse partial pivoting codes. One is to use path-symmetric or partial path-symmetric reduction, as described in [4]. Another is to switch from nodal to supernodal elimination [2], which we expect will give a substantial improvement. A code with these features is currently under development by the authors.

Acknowledgment. The authors thank John Gilbert for making available a prerelease of sparse Matlab, which was used to generate the row orderings for the test problems, and for suggesting the notation used for edges and paths.

ANALYSIS OF THE IMPLICIT EULER LOCAL UNIFORM GRID REFINEMENT METHOD*

R. A. TROMPERT† AND J. G. VERWER†

Abstract. Attention is focused on parabolic problems having solutions with sharp moving transitions in space and time. An adaptive grid method is analysed that refines the space grid locally around sharp spatial transitions, so as to avoid discretization on a very fine grid over the entire physical domain. This method is based on static-regridding and local uniform grid refinement. Static-regridding means that for evolving time the space grid is adapted at discrete times. Local uniform grid refinement means that the actual adaptation of the space grid takes place using nested locally and uniformly refined grids. The present paper concentrates on stability and error analysis while using the implicit Euler method for time integration. Maximum norm stability and convergence results are proved for a certain class of linear and nonlinear partial differential equations. The central issue is a refinement condition with a strategy that distributes spatial interpolation and discretization errors in such a way that the spatial accuracy obtained is comparable to the spatial accuracy on the finest grid if this grid would be used without any adaptation. The analysis is confirmed with a numerical illustration.

1. Introduction.

Attention is focused on parabolic problems having solutions with sharp moving transitions in space and time, such as steep fronts and disappearing layers. For such problems, a space grid held fixed throughout the entire time evolution can be computationally very inefficient. We consider an adaptive grid method that refines locally around sharp spatial transitions so as to avoid discretization on a very fine grid over the entire physical domain.

Our method is based on the techniques called static-regridding and local uniform grid refinement (LUGR), as previously proposed by Berger and Oliger [3], Gropp [6]-[8], Arney and Flaherty [2], Flaherty, Moore, and Ozturan [11], Trompert and Verwer [13], and others. Static-regridding means that for evolving time the space grid is adapted at discrete times. This should be contrasted with dynamic-regridding, where the space grid moves continuously in the space-time domain. With the term LUGR we mean that the actual adaptation of the space grid takes place using local, uniform, refined grids. LUGR should be contrasted with pointwise refinement, which leads to truly nonuniform grids. In this connection, our LUGR method bears resemblance to the fast adaptive composite grid (FAC) method [10] for elliptic equations, where the basic computational objective is to solve on an irregular grid by way of regular grids only.

The idea of the method can be briefly described as follows. Given a coarse base grid and a temporal step size, nested, local, uniform subgrids are generated. These subgrids possess nonphysical boundaries and on each of these subgrids an integration is carried out. They are generated up to a level of refinement good enough to resolve the anticipated fine scale structures. Having completed the refinement for the current base space-time grid, the process is continued to the next one while the fine grid results computed at forward time levels are kept in storage so that they can be used for step continuation.

An attractive feature of the static-regridding approach is the possibility of dividing the solution process into the following computational procedures: spatial discretization, temporal integration, error estimation, regridding, and interpolation. Depending on the application, these individual procedures may range from simple or straightforward to very sophisticated. This flexibility is attractive since it makes it possible to treat different types of partial differential equation (PDE) problems with almost one and the same code, assuming that the grid and the associated data structure remain unchanged. Note that the choice of data structure is important for keeping the unavoidable overhead at an acceptable level, because at each time step grids may be created or removed, while communication between grids of adjacent levels of refinement frequently takes place.

The method we analyse in this paper has many similarities with the method constructed in Trompert and Verwer [13]. In fact, the grid and data structure, the spatial differencing, and the memory use are the same. However, in the present paper we concentrate on analysis rather than on construction, while using implicit Euler instead of the explicit Runge-Kutta-Chebyschev method for time integration. The main aim of this paper is to present a detailed error analysis and to prove stability and convergence for a certain class of PDEs. The central issue in this analysis is a refinement condition and a strategy that distributes spatial discretization and interpolation errors in such a way that the spatial accuracy obtained is comparable to the spatial accuracy on the finest grid if this grid would be used without any adaptation.

Section 2 is devoted to the problem class on which we will concentrate. In § 3 we introduce the tools and the formulation for the multilevel LUGR method. In § 4 we discuss the maximum norm stability of this method. We prove an unconditional stability result which is closely related to a maximum norm stability result of implicit Euler when applied on a single space grid. Section 5 is devoted to the error analysis. In this section we investigate the total local error with its component parts. Furthermore, here we introduce the refinement strategy underlying the so-called refinement condition. This condition enables us to control the contribution of the interpolation errors in favour of discretization errors. Due to this condition, we are able to prove a convergence result as if we are working on a single fixed grid. We further elaborate on this condition in § 6, where we show how to implement it for practical use. A numerical illustration of the error analysis is given in § 7. The numerical results found here are in complete agreement with the analysis. Finally, § 8 briefly discusses our future research plans.

2. The problem class.

Following the method of lines approach [12], we consider a real abstract Cauchy problem

$$u_t = L(t, u), \quad 0 < t \leqq T, \quad u(\underset{\sim}{x}, 0) = u^0(\underset{\sim}{x}), \tag{2.1}$$

where L represents a second-order partial differential operator that differentiates the (possibly vector-valued) solution $u(\underset{\sim}{x}, t)$ to its space variable $\underset{\sim}{x}$ in a space domain Ω in $\mathbb{R}$, $\mathbb{R}^2$, or $\mathbb{R}^3$. Boundary conditions are supposed to be included in the definition of L.

With (2.1) we associate a real Cauchy problem for an explicit ordinary differential equation (ODE) system in $\mathbb{R}^d$,

$$\frac{d}{dt} U(t) = F(t, U(t)), \quad 0 < t \leqq T, \quad U(0) = U^0, \tag{2.2}$$

which is defined by a finite-difference space discretization. Thus, U and F are vectors in $\mathbb{R}^d$ representing grid functions on a space grid ω covering the interior of the space domain. Each component of U and F is vector valued if u is vector valued. The dimension d is determined by the spatial dimension, the grid spacing, and the number of PDEs in (2.1). F is determined by the type of grid, by the actual finite-difference formulas and, of course, by the precise form of L and its boundary conditions. Note that boundary values have been eliminated and worked into the ODE system. In the following, our method description and analysis are centered around this system.

Next we introduce some notations and assumptions needed for further specifying (2.1) and (2.2). The symbol $\|\cdot\|$ denotes the maximum norm on the vector space $\mathbb{R}^d$ or the induced matrix norm. Throughout our analysis we will deal only with the maximum norm. The symbol $\mu[A]$ denotes the logarithmic matrix norm of the real $d\times d$ matrix $A=(a_{ij})$ associated with $\|\cdot\|$, i.e.,

$$\mu[A]=\max_i\left(a_{ii}+\sum_{j\neq i}|a_{ij}|\right); \tag{2.3}$$

$\mu[A]$ is a useful tool in the stability analysis of nonlinear, stiff ODEs and semidiscrete PDEs [4]. In this analysis, the structure of the Jacobian matrix $F'(t,\eta)=\partial F(t,\eta)/\partial\eta$ plays a decisive role.

We are now ready to list the assumptions we make in further specifying (2.1), (2.2). These assumptions are concerned with, respectively, the class of PDEs (2.1), the smoothness of u, the choice of spatial grid and actual finite-differencing, and the stability of the semidiscrete system (2.2).

(A1) The LUGR method is applicable in any number of space dimensions. Following [13], we concentrate on the two-dimensional case, while Ω is supposed to be the unit square. With minor changes Ω is allowed to be composed of a union of rectangles with sides parallel to the coordinate axes. In fact, as we will see later, refined grids normally are of this shape. In what follows, we will generally use the notation $u(x,y,t)$, rather than $u(\underset{\sim}{x},t)$.

(A2) The solution u of (2.1) uniquely exists and is as smooth as the numerical analysis requires. Specifically, for our purpose it suffices that u is a C^2-function in t and a C^4-function in (x,y).

(A3) We will invariably use uniform space grids. Thus our base grid can be written as

$$\omega=\{(x_i,y_j): x_i=ih_x, 1\leqq i\leqq M-1 \text{ and } y_j=jh_y, 1\leqq j\leqq N-1\}, \tag{2.4}$$

where $h_x=1/M$, $h_y=1/N$, and M, N are positive integers. The spatial differencing on ω is supposed to be based on three-point formulas of second-order consistency. As a rule, we use central differencing. For boundary conditions involving first-order derivatives, the one-sided, three-point formula is used.

(A4) A constant ν exists such that $\mu[F'(t,\eta)]\leqq\nu$ for all $t\in(0,T]$, $\eta\in\mathbb{R}^d$, and all grid spacings. Like (A1) and (A2), this assumption involves a restriction on the class of PDE problems. Of course, they are made only for the sake of (model) analysis. The LUGR method remains applicable in situations where these assumptions do not hold or cannot be verified. On the other hand, for interesting classes of operators, such as the scalar, nonlinear parabolic operator

$$L(t,u)=f_1(t,x,y,u,(p_1(t,x,y)u_x)_x)+f_2(t,x,y,u,(p_2(t,x,y)u_y)_y), \tag{2.5}$$

with standard restrictions on f_i and p_i, one can prove the existence of a constant ν [4].

The inequality $\mu[F'(t,\eta)]\leqq\nu$ is to be interpreted as a stability condition, both concerning the ODE system (2.2) and its implicit Euler discretization

$$U^n=U^{n-1}+\tau F(t_n,U^n),\qquad n=1,2,\dots, \tag{2.6}$$

where $\tau = t_n - t_{n-1}$ is the step size and U^n is the approximation for $U(t_n)$. This inequality enables us to formulate the following, powerful stability result for implicit Euler. Consider the perturbed form

$$\tilde{U}^n = \tilde{U}^{n-1} + \tau F(t_n, \tilde{U}^n) + r^n, \qquad n = 1, 2, \ldots, \tag{2.7}$$

where r^n is an arbitrary local perturbation and $\tilde{U}^{n-1}$, $\tilde{U}^n$ are perturbations to U^{n-1}, U^n. Then

$$\|\tilde{U}^n - U^n\| \leqq \frac{1}{1-\tau\nu} \|\tilde{U}^{n-1} - U^{n-1} + r^n\|, \qquad n = 1, 2, \ldots, \tag{2.8}$$

for all $\tau > 0$ satisfying $\tau\nu < 1$ [4]. Since ν is independent of the grid spacing, this stability inequality is valid uniformly in h_x and h_y. For $\nu = 0$ we have contractivity for all $\tau > 0$, while for $\nu < 0$ we even have damping for all $\tau > 0$. A result closely related to (2.8) will be derived in § 4.

3. The implicit Euler local uniform grid refinement method.

3.1. Outline. Although its elaboration readily becomes complicated, the idea behind LUGR is simple. Starting from ω, finer and finer uniform subgrids are created locally in a nested manner in regions of high spatial activity. These subgrids are created by bisecting sides of next coarser grid cells. A new initial-boundary value problem is solved at each subgrid, and the integration takes place in a consecutive order, from coarse to fine. Each of these integrations spans the same time interval. Required initial values are defined by interpolation from the next coarser subgrid or taken from a subgrid from the previous time step when available. Internal boundaries are treated as Dirichlet boundaries and values are also interpolated from the next coarser subgrid. The generation of subgrids is determined by the local refinement strategy and is continued until the spatial phenomena are described well enough by the finest grid.

During each time step the following operations are performed:

1. Integrate on coarse base grid.
2. Determine new finer uniform subgrid at forward time.
3. Interpolate internal boundary values at forward time.
4. Provide new initial values at backward time.
5. Integrate on subgrid using the same steplength.
6. If the desired level of refinement is reached, go to 7, else go to 2.
7. Inject fine grid values in coinciding coarser grid points.

Thus, for each time step, the computation starts at the coarse base grid using the most accurate solution available, since fine grid solution values are always injected in coinciding coarse grid points. Moreover, all subgrids are kept in storage for step continuation.

We consider the use of uniform grids attractive because uniform grids allow an efficient use of vector-based algorithms, and finite differences on uniform grids are faster and more accurate to compute than those on nonuniform grids. In this respect, the current approach is to be contrasted with pointwise refinement leading to truly nonuniform grids. Pointwise refinement techniques also require a more involved data structure [5]. On the other hand, with the LUGR method, there are nodes that exist on more than one grid at the same time, meaning that in these nodes integration takes place more than once during one time step. Hence, the total number of nodal integrations needed will be larger than on a comparable single nonuniform grid.

In [2], [3], [7] and [11] LUGR methods are examined based on noncellular refinement and truly rectangular subgrids, which may rotate and overlap to align with an evolving fine scale structure. We avoid these difficulties. Our local subgrids do not overlap, they may be disjunct, they need not be rectangles, and the actual refinement is cellular.

3.2. The mathematical formulation. LUGR methods solve PDEs on the whole domain at the coarsest grid only and on a part of the domain at finer subgrids. Our method can be interpreted as a sequence of operations on vectors in $\mathbb{R}^d$ with varying dimension d. The dimensions are time and level dependent because the number of nodes changes per level of refinement and per time step. This constitutes a problem for the formulation of the method. To bypass this difficulty, the fine grids will be expanded so that they cover the whole domain. The dimensions are then fixed per level of refinement, which facilitates the derivation of a concise mathematical formulation. We emphasise that this grid expansion is auxiliary. In actual application, only part of the expanded higher-level grids is processed.

Suppose that for a given time interval $[0, T]$ and a given base grid, l levels are needed to describe the spatial activity of a solution sufficiently accurately when integrating over the entire time interval $[0, T]$. Introduce for $k = 1, \dots, l$ the expanded uniform grids

$$\omega_k = \{(x_i, y_j): x_i = ih_{x,k}, 1 \leqq i \leqq 2^{k-1}M - 1 \text{ and } y_j = jh_{y,k}, 1 \leqq j \leqq 2^{k-1}N - 1\}, \tag{3.1}$$

where N and M are the same integers as in (2.4), and $h_{x,k} = h_x/2^{k-1}$, $h_{y,k} = h_y/2^{k-1}$. Note that for $k = 1$ the base grid $\omega_1 = \omega$ given by (2.4) is recovered.

Let the generic notation for a grid function η defined at ω_k be η_k, and let S_k denote the space of these grid functions. We then denote the semidiscrete system considered in S_k by

$$\frac{d}{dt} U_k(t) = F_k(t, U_k(t)), \quad 0 < t \leqq T, \quad U_k(0) = U_k^0. \tag{3.2}$$

Note that due to the grid expansion, only a part of the components of the ODE system (3.2) is integrated for $k > 1$ in reality.

We are now ready to formulate the implicit Euler LUGR method. The following formula defines the time step from step point t_{n-1} to t_n for l levels of refinement:

$$U_1^n = R_{l1} U_l^{n-1} + \tau F_1(t_n, U_1^n), \tag{3.3a}$$

$$U_k^n = D_k^n[R_{lk} U_l^{n-1} + \tau F_k(t_n, U_k^n)] + (I_k - D_k^n)[P_{k-1k} U_{k-1}^n + b_k^n], \tag{3.3b}$$

for $k = 2, \dots, l$, where

$U_k^n \in S_k^n$ is the approximation to u at ω_k at $t = t_n$,
$I_k : S_k \to S_k$ is the unit matrix,
$D_k^n : S_k \to S_k$ is a diagonal matrix with entries $(D_k^n)_{ii}$ either unity or zero,
$R_{lk} : S_l \to S_k$ is the natural restriction operator from ω_l to ω_k, $R_{ll} = I_l$,
$P_{k-1k} : S_{k-1} \to S_k$ is an interpolation operator from ω_{k-1} to ω_k,
$b_k^n \in S_k$ contains time-dependent terms emanating from the boundary $\partial\Omega$.

Specifically, the nonzero entries of D_k^n $(2 \leqq k \leqq l)$ are meant to determine that part of ω_k where the actual integration takes place. This integration has the fine grid solution $D_k^n R_{lk} U_l^{n-1}$ as initial function and is defined by

$$D_k^n U_k^n = D_k^n[R_{lk} U_l^{n-1} + \tau F_k(t_n, U_k^n)], \qquad k = 2, \dots, l. \tag{3.4}$$

The definition of D_k^n is provided by the refinement strategy. For the time being, there is no need to further specify D_k^n. Note that the nesting property of the integration domains is hidden in the precise definition of the matrices D_k^n. The interpolation step is defined by

$$(3.5)\qquad (I_k - D_k^n)U_k^n = (I_k - D_k^n)[P_{k-1k}U_{k-1}^n + b_k^n], \qquad k = 2, \dots, l,$$

where the grid function b_k^n contains various time-dependent terms occurring in physical boundary conditions. We need to include b_k^n because physical boundary conditions have been worked into the semidiscrete system. For the analysis to follow, b_k^n plays no role whatsoever.

The formulation (3.3a, b) automatically comprises the interpolation of boundary values at grid interfaces. This follows directly from the observation that for nodes at grid interfaces, the associated diagonal entry of D_k^n is zero (there is no integration at grid interfaces). Further, we note that (3.3) implies an order, (3.3a) is carried out for the coarse base grid and (3.3b) for $k = 2, \dots, l$ successively. Having done this, the updating will take place, meaning that U_k^n is replaced by $R_{lk}U_l^n$ from $k = l-1$ to 1. After this we move on to the next time step. Recall that, due to the grid expansion, in (3.3a, b) the interpolation is carried out for all nodal points outside the integration domain of ω_k. This enables the stability and convergence analysis to be carried out in the spaces S_k. However, in actual application, interpolation only takes place at the local subgrids. In § 6.2 it is shown that this does not interfere with the analysis.

4. Stability analysis.

4.1. Preliminaries.

Consider, along the same lines as (2.7) for $n = 1, 2, \dots$, the perturbed scheme

$$(4.1\text{a})\qquad \tilde{U}_1^n = R_{l1}\tilde{U}_l^{n-l} + \tau F_1(t_n, \tilde{U}_1^n) + r_1^n,$$

$$(4.1\text{b})\qquad \tilde{U}_k^n = D_k^n[R_{lk}\tilde{U}_l^{n-1} + \tau F_k(t_n, \tilde{U}_k^n)] + (I_k - D_k^n)[P_{k-1k}\tilde{U}_{k-1}^n + b_k^n] + r_k^n,$$

for $k = 2, \dots, l$ with local perturbations r_k^n, and introduce the errors $e_k^n = \tilde{U}_k^n - U_k^n$, for $k = 1, \dots, l$. To shorten the formulas, we introduce the auxiliary quantities e_0^n, D_1^n, and P_{01}, where $e_0^n = 0 \in S_1$, D_1^n is the unit matrix I_1, and P_{01} is the zero matrix. Then, by subtracting (3.3a, b) from (4.1a, b), we get

$$(4.2)\quad Z_k^n e_k^n = D_k^n R_{lk} e_l^{n-1} + (I_k - D_k^n)P_{k-1k}e_{k-1}^n + r_k^n, \quad n = 1, 2, \dots, \quad k = 1, \dots, l,$$

where $Z_k^n = I_k - \tau D_k^n M_k^n$ and M_k^n is the integrated Jacobian matrix

$$(4.3)\qquad M_k^n = \int_0^1 F'(t_n, \theta\tilde{U}_k^n + (1-\theta)U_k^n)\, d\theta,$$

which results from applying the mean value theorem for vector functions.

Assuming Z_k^n to be nonsingular, we can rewrite (4.2) as

$$(4.4)\qquad e_k^n = X_k^n e_{k-1}^n + \Gamma_k^n e_l^{n-1} + \phi_k^n, \quad n = 1, 2, \dots, \quad k = 1, \dots, l,$$

with

$$(4.5)\qquad \begin{aligned} X_k^n &= (Z_k^n)^{-1}(I_k - D_k^n)P_{k-1k}, \\ \Gamma_k^n &= (Z_k^n)^{-1}D_k^n R_{lk}, \\ \phi_k^n &= (Z_k^n)^{-1} r_k^n. \end{aligned}$$

Note that $X_1^n = 0$ and that the operators X_k^n, Γ_k^n are associated, respectively, to the interpolation and restriction. We can rewrite (4.4) in the standard form

$$(4.6)\qquad e_k^n = G_k^n e_l^{n-1} + \psi_k^n, \quad n = 1, 2, \dots, \quad k = 1, \dots, l,$$

where the amplification operators G_k^n and the local perturbation terms ψ_k^n are defined by

$$(4.7)\qquad \begin{aligned} &G_1^n = \Gamma_1^n, \\ &G_k^n = X_k^n G_{k-1}^n + \Gamma_k^n, \qquad k = 2, \dots, l, \end{aligned}$$

$$(4.8)\qquad \begin{aligned} &\psi_1^n = \phi_1^n, \\ &\psi_k^n = X_k^n \psi_{k-1}^n + \phi_k^n, \qquad k = 2, \dots, l. \end{aligned}$$

The error recurrence (4.6) describes the error propagation for all refinement levels. The main interest lies in the operator G_l^n and the local perturbation ψ_l^n, since coarse grid values are always updated by fine grid values. In (4.6) this is reflected by the presence of e_l^{n-1}.

The stability of the implicit Euler method in the above is contained in the following lemma.

LEMMA 4.1. *Let ν be the logarithmic norm value defined in assumption* (A4) *of* § 2. *Then,*

$$(4.9)\qquad \begin{aligned} &\|(Z_1^n)^{-1}\| \leqq \frac{1}{1-\tau\nu} \quad \forall \tau\nu < 1, \quad k = 1, \\ &\|(Z_k^n)^{-1}\| \leqq \begin{cases} 1/(1-\tau\nu) & \forall \tau\nu < 1 \quad \text{if } \nu > 0, \\ 1 & \forall \tau > 0 \quad \text{if } \nu \leqq 0, \end{cases} \quad k = 2, \dots, l. \end{aligned}$$

Proof. The result for $k = 1$ is standard since D_1^n is the unit matrix (see [4, p. 46]). The premultiplication of M_k^n for $k > 1$ with D_k^n has the effect that either entire rows of M_k^n are put to zero, or are left unchanged. From (2.3) we can then immediately deduce that for $\nu > 0$ the bound $(1-\tau\nu)^{-1}$ still holds, whereas for $\nu \leqq 0$ the zero rows introduce the bound 1. □

Observe that the replacement of the bound $(1-\tau\nu)^{-1}$ by the bound 1 for $\nu < 0$ implies that in this case we no longer exploit the damping property of implicit Euler. For the analysis to follow, this is no restriction since here we are merely interested in proving stability and convergence results. Specifically, the stability result we will prove is not dependent on the damping in implicit Euler. To shorten derivations, we first make another assumption.

(A5) The logarithmic norm bound ν from (A4) is nonpositive. Hence we now restrict ourselves to dissipative problems. This is not essential; results obtained for $\nu \leqq 0$ can be extended to the case $\nu > 0$ by inserting $(1-\tau\nu)^{-1}$ for the bound 1 any time the stability inequality $\|(Z_k^n)^{-1}\| \leqq 1$ is used.

4.2. Stability and linear interpolation. In this section we will prove a general stability result for the multilevel adaptive grid method (3.3) that is similar to the stability result (2.8) for the implicit Euler method applied without adaption.

THEOREM 4.2. *Let $\nu \leqq 0$ according to* (A5), *and suppose that linear interpolation is used. Then, for all $\tau > 0$ and all $n \geqq 1$,*

$$(4.10)\qquad \|G_k^n\| \leqq 1, \qquad k = 1, \dots, l,$$

$$(4.11)\qquad \|\psi_k^n\| \leqq \sum_{j=1}^{k} \|r_j^n\|, \qquad k = 1, \dots, l,$$

$$(4.12)\qquad \|e_l^n\| \leqq \|e_l^{n-1}\| + \sum_{k=1}^{l} \|r_k^n\|.$$

Proof. Inequality (4.12) is a trivial consequence of (4.10) and (4.11). Let us first prove (4.10). This is done by induction with respect to k. Suppose $\|G_{k-1}^n\| \leqq 1$. From (4.7) it follows that

$$\|G_k^n\| = \|X_k^n G_{k-1}^n + \Gamma_k^n\| = \|(Z_{k-1}^n)^{-1} Q_k^n\| \leqq \|Q_k^n\|, \tag{4.13}$$

where $Q_k^n = (I_k - D_k^n) P_{k-1k} G_{k-1}^n + D_k^n R_{lk}$.

Consider the ith row of this operator. Suppose $(D_k^n)_{ii} = 1$. Then

$$\sum_j |(Q_k^n)_{ij}| = \sum_j |(R_{lk})_{ij}| = 1, \tag{4.14}$$

by definition of the restriction operator R_{lk}. Next suppose $(D_k^n)_{ii} = 0$. Then

$$\sum_j |(Q_k^n)_{ij}| = \sum_j |(P_{k-1k} G_{k-1}^n)_{ij}| \leqq \|P_{k-1k} G_{k-1}^n\| \leqq \|P_{k-1k}\| \, \|G_{k-1}^n\| \leqq 1, \tag{4.15}$$

by virtue of the induction hypothesis and the norm

$$\|P_{k-1k}\| = 1 \tag{4.16}$$

of the linear interpolation operator P_{k-1k}. Combining (4.14) and (4.15) gives $\|Q_{k+1}^n\|$, and inequality (4.10) now follows from (4.13). The induction proof is finished if we can prove that $\|G_1^n\| \leqq 1$. This follows immediately from the observation that $G_1^n = \Gamma_1^n = (Z_1^n)^{-1} R_{l1}$.

There remains to prove (4.11). We have $\|\phi_k^n\| \leqq \|r_k^n\|$. It then follows from (4.8) that

$$\|\psi_k^n\| \leqq \|X_k^n\| \, \|\psi_{k-1}^n\| + \|r_k^n\|, \tag{4.17}$$

so that we are finished if we can prove that $\|X_k^n\| \leqq 1$. This is trivial due to (4.16) and $\|I_k - D_k^n\| = 1$. □

The inequality (4.12) is the counterpart of the inequality (2.8). We may conclude from Theorem 4.2 that when implicit Euler is stable and we interpolate linearly, our multilevel adaptive grid method (3.3) retains stability of implicit Euler through the bound $\|G_l^n\| \leqq 1$.

4.3. Stability and higher-order interpolation. A drawback of linear interpolation is its limited accuracy. In a genuine application, it might well be preferable to use higher-order interpolants (in [13] we successfully used fourth-order Lagrangian interpolation). Unfortunately, in this case we must have $\|P_{k-1k}\| > 1$, so that we are not able to prove the results of Theorem 4.2 when following the above method of proof. If $\|P_{k-1k}\| > 1$, then it is possible to prove (a constrained form of) stability by introducing an additional condition that underlies the intention of interpolating exclusively in low error regions. Unfortunately, this condition turns out to be of no direct practical use and is omitted here. On the other hand, numerical evidence suggests very strongly that those higher-order interpolants do not cause genuine stability problems in real application. We believe we owe this to the fact that the method interpolates in low error regions, so that, loosely speaking, this condition is satisfied implicitly.

5. Error analysis. We will present a detailed examination of the local error. From this we deduce the refinement condition which henceforth underlies the refinement strategy. This condition enables us to control the contribution of spatial interpolation errors in favour of spatial discretization errors. Due to this condition, we can prove a convergence result as if we are working on a single fixed grid. Specifically, it will be shown that the usual convergence behaviour applies and that the accuracy obtained is comparable to the accuracy obtained on the finest grid if this grid would be used without any adaptation.

5.1. The local level error. Let $u_k(t) \in S_k$ denote the pointwise restriction of the true solution $u(x, y, t)$ to ω_k. Consider (4.1). By replacing all $\tilde{U}$-values by associated u_k-values, the local perturbation r_k^n becomes the local level error at grid level k. For convenience, we will denote this error also by r_k^n:

$$r_k^n = u_k^n - D_k^n[R_{lk}u_l^{n-1} + \tau F_k(t_n, u_k^n)] - (I_k - D_k^n)[P_{k-1k}u_{k-1}^n + b_k^n], \tag{5.1}$$
$$n = 1, 2, \ldots, \qquad k = 1, \ldots, l,$$

where $u_k^n = u_k(t_n)$ and P_{01}, u_0^n, b_1^n are auxiliary and put to zero; r_k^n contains the following local error components, the local spatial error induced by the finite-difference approximation, the local temporal error of the implicit Euler method, and the interpolation error. We first discuss these different components. They are defined in the standard way by

$$\alpha_k(t) = \frac{d}{dt} u_k(t) - F_k(t, u_k(t)) \quad \text{(spatial discretization error)}, \tag{5.2}$$

$$\beta_k(t) = u_k(t) - u_k(t-\tau) - \tau \frac{d}{dt} u_k(t) \quad \text{(temporal error)}, \tag{5.3}$$

$$\gamma_k(t) = u_k(t) - P_{k-1k}u_{k-1}(t) - b_k(t) \quad \text{(interpolation error)}. \tag{5.4}$$

The grid function $b_k(t)$ in (5.4) has the same meaning as b_k^n in (3.5). In the following, we assume without loss of generality that $h_{x,k} = h_{y,k} = h_k$. In view of assumptions (A2) and (A3) in § 2, we have

$$\alpha_k(t) = \mathcal{O}(h_k^2), \qquad h_k \to 0, \tag{5.5}$$

with order constants determined by higher-order spatial derivatives of u and by PDE operator quantities. Likewise, (A2) implies $\beta_k(t) = \tau^2 C_k$ where $C_k = -\frac{1}{2}d^2u_k/dt^2$ evaluated at a time $t + (\kappa - 1)\tau$, $0 \leqq \kappa \leqq 1$. If u is a C^3-function in t, then

$$\beta_k(t) = -\frac{1}{2}\tau^2 \frac{d^2}{dt^2} u_k(t) + \mathcal{O}(\tau^3), \qquad \tau \to 0. \tag{5.6}$$

Let q denote the accuracy order of the (Lagrangian) interpolation. Then

$$\gamma_k(t) = \mathcal{O}(h_k^q), \qquad k = 2, \ldots, l, \tag{5.7}$$

and here the order constants again depend exclusively on higher spatial derivatives of u, assuming sufficient differentiability. If linear interpolation is used, then assumption (A2) implies $q = 2$ and second-order spatial derivatives determine the constants.

Now, using the relation $u_k^{n-1} = R_{lk}u_l^{n-1}$ for $k = 1, \ldots, l$, we can derive

$$r_k^n = D_k^n(\tau\alpha_k^n + \beta_k^n) + (I_k - D_k^n)\gamma_k^n, \quad n = 1, 2, \ldots, \quad k = 1, \ldots, l. \tag{5.8}$$

Note, by definition of D_k^n, that $D_k^n(\tau\alpha_k^n + \beta_k^n)$ is the restriction of the usual local discretization error $\tau\alpha_k^n + \beta_k^n$ to the integration domain of the grid ω_k, while $(I_k - D_k^n)\gamma_k^n$ represents the restriction of the interpolation error γ_k^n to the complement of this domain.

5.2. A crude global error bound. Denote the global discretization error by $e_k^n = u_k^n - U_k^n$ and suppose $e_k^0 = 0$. For any choice of D_k^n the consistency results (5.5)-(5.8) imply

$$r_k^n = \mathcal{O}(\tau h_k^2) + \mathcal{O}(\tau^2) + \mathcal{O}(h_k^q). \tag{5.9}$$

If we now suppose linear interpolation and assumption (A5), then application of (4.12) yields

$$\|e_l^n\| \leqq \|e_l^{n-1}\| + \|S^n\| \leqq \|S^1\| + \cdots + \|S^n\|, \qquad n = 1, 2, \ldots, \tag{5.10}$$

where $\|S^n\| = \mathcal{O}(\tau h_1^2) + \mathcal{O}(\tau^2) + \mathcal{O}(h_1^2)$. Here the coarsest mesh width occurs due to simply adding all normed local level errors in (4.15), including $\|r_1^n\|$. Following standard practice, we thus obtain at any fixed time point $t_n = n\tau$ the global error bound

$$\|e_l^n\| \leqq C_1\tau + C_2 h^2 + C_3 \frac{h^2}{\tau}, \tag{5.11}$$

where $h = h_1$ and C_1, C_2, and C_3 are positive constants independent of step size and mesh sizes.

The first two terms are due to the temporal integration and spatial discretization. They will vanish if mesh sizes and step size tend to zero independently of each other, thus reflecting the unconditional convergence of the method when applied without adaptation. On the other hand, if no relation is imposed between τ and h, then the third term can grow unboundedly as τ, $h \to 0$. This term is due to the interpolation. Hence, even though we have stability and consistency, this result shows that unconditional convergence cannot be hoped for. Fortunately, this conclusion is not as bad as it looks. By not specifying the matrices D_k^n and, subsequently, by adding norms of the local level errors, we have simply supposed arbitrary integration domains at all levels of refinement. This must lead to a crude error bound like (5.11). In application, the computations should be organized in such a way that the interpolation only takes place in low error regions so that the interpolation error is virtually absent. This poses the task of setting up a precise error analysis and the design of a local refinement strategy aimed at a suitable selection of the matrices D_k^n.

5.3. Local and global errors. According to (4.6), the global error e_k^n satisfies the recurrence relation

$$e_k^n = G_k^n e_l^{n-1} + \psi_k^n, \quad n = 1, 2, \ldots, \quad k = 1, \ldots, l, \tag{5.12}$$

where ψ_k^n is the local error defined by recursion (cf. (4.8), (4.5))

$$\begin{aligned} &\psi_1^n = (Z_1^n)^{-1} r_1^n, \\ &\psi_k^n = X_k^n \psi_{k-1}^n + (Z_k^n)^{-1} r_k^n, \qquad k = 2, \ldots, l. \end{aligned} \tag{5.13}$$

The operators G_k^n, X_k^n, and Z_k^n are supposed to be redefined (replace all $\tilde{U}$-values by associated u_k-values). Note that ψ_k^n is essentially different from the local level error r_k^n. While r_k^n is associated with the single kth level, ψ_k^n is associated with all levels up to this kth level according to (5.13). This recursion governs the propagation of each local level error when introducing higher and higher levels. Elaborating, it gives, for $k = 1, \ldots, l$,

$$\psi_k^n = \sum_{j=1}^{k} \left(\prod_{i=k}^{j+1} X_i^n \right) (Z_j^n)^{-1} r_j^n. \tag{5.14}$$

Next we split ψ_k^n into its temporal and spatial part denoted by, respectively, $\psi_{k,t}^n$ and $\psi_{k,s}^n$:

$$\psi_k^n = \psi_{k,t}^n + \psi_{k,s}^n, \qquad k = 1, \ldots, l, \tag{5.15}$$

and it follows from (5.8) that $\psi_{k,t}^n$ and $\psi_{k,s}^n$ are given, respectively, by

$$\psi_{k,t}^n = \sum_{j=1}^{k} \left(\prod_{i=k}^{j+1} X_i^n \right) (Z_j^n)^{-1} D_j^n \beta_j^n, \tag{5.16}$$

$$\psi_{k,s}^n = \sum_{j=1}^{k} \left(\prod_{i=k}^{j+1} X_i^n \right) (Z_j^n)^{-1} [\tau D_j^n \alpha_j^n + (I_j - D_j^n) \gamma_j^n]. \tag{5.17}$$

Let us first examine $\psi_{k,t}^n$. Since β_k^n does not depend on mesh sizes, we have $\beta_k^n = R_{lk}\beta_l^n$. Substitution into (5.16) then yields

$$\psi_{k,t}^n = \sum_{j=1}^{k} \left(\prod_{i=k}^{j+1} X_i^n \right) (Z_j^n)^{-1} D_j^n R_{lj} \beta_l^n, \tag{5.18}$$

and we see that this operator is just the amplification operator G_k^n featured in (5.12); see the recursion (4.7). In conclusion, $\psi_{k,t}^n$ satisfies

$$\psi_{k,t}^n = G_k^n \beta_l^n, \qquad k=1,\dots,l. \tag{5.19}$$

We next examine $\psi_{k,s}^n$. Using the definition of X_k^n given in (4.5), we rewrite (5.17) as

$$\begin{aligned} \psi_{k,s}^n &= (Z_k^n)^{-1}(I_k - D_k^n)P_{k-1k} \sum_{j=1}^{k-1} \left(\prod_{i=k-1}^{j+1} X_i^n \right) (Z_j^n)^{-1}[\tau D_j^n \alpha_j^n + (I_j - D_j^n)\gamma_j^n] \\ &\quad + (Z_k^n)^{-1}[\tau D_k^n \alpha_k^n + (I_k - D_k^n)\gamma_k^n] \\ &= (Z_k^n)^{-1}[\tau D_k^n \alpha_k^n + (I_k - D_k^n)\rho_k^n], \qquad k=1,\dots,l, \end{aligned} \tag{5.20}$$

where

$$\rho_k^n = \gamma_k^n + P_{k-1k}\psi_{k-1,s}^n, \qquad k=2,\dots,l, \tag{5.21}$$

and $\rho_1^n = 0$. In (5.20) the spatial local discretization error $D_k^n \alpha_k^n$ committed on the integration domain of grid ω_k is separated from the spatial local error part $(I_k - D_k^n)\rho_k^n$ defined outside this domain. Hence, ρ_k^n collects all spatial error contributions defined on the grids ω_j $(1 \leqq j \leqq k-1)$, including discretization error α_j^n and interpolation error γ_j^n, together with γ_k^n on ω_k. This separation enables us to formulate a refinement condition which ensures that when a new grid level is introduced, the spatial local accuracy outside its integration domain will be smaller than or equal to the spatial accuracy on the integration domain itself. This distribution of local space errors is desirable, as we never return to grid points lying outside a current integration domain.

The refinement condition constrains the matrices D_k^n, and is taken to be

$$\|(Z_k^n)^{-1}\tau D_k^n \alpha_k^n\| \geqq \frac{1}{c} \|(Z_k^n)^{-1}(I_k - D_k^n)\rho_k^n\|, \quad n=1,2,\dots, \quad k=2,\dots,l, \tag{5.22}$$

where $c>0$ is a constant specified in § 6. If (5.22) is true, then all errors $\psi_{k,s}^n$ satisfy

$$\|\psi_{k,s}^n\| \leqq (1+c)\|(Z_k^n)^{-1}\tau D_k^n \alpha_k^n\|, \tag{5.23}$$

and combining (5.12) with (5.15), (5.19) enables us to present the global error inequality

$$\begin{aligned} \|e_k^n\| \leqq \|G_k^n\|\,\|e_l^{n-1}\| + \|G_k^n \beta_l^n\| + (1+c)\|(Z_k^n)^{-1}\tau D_k^n \alpha_k^n\|, \\ n=1,2,\dots, \qquad k=1,\dots,l. \end{aligned} \tag{5.24}$$

The importance of the refinement condition (5.22) is reflected by the fact that in (5.24) the interpolation error contribution has been removed. This is in agreement with our goal of developing a local refinement strategy that generates refined subgrids such that the accuracy obtained on the final finest grid is comparable to the accuracy obtained if this finest grid would be used without adaptation. We will elaborate on condition (5.22) in § 6. Note that it suffices to consider (5.22) only for $k=l$, since it suffices to consider (5.23) and (5.24) for $k=l$.

5.4. Convergence and linear interpolation. Assuming linear interpolation and assumption (A5), as in § 5.2, (5.24) can be rewritten as

$$\|e_k^n\| \leqq \|e_l^{n-1}\| + \|\beta_k^n\| + (1+c)\tau\|\alpha_k^n\|, \quad n=1,2,\dots, \quad k=1,\dots,l. \tag{5.25}$$

Hence, following the same derivation as carried out for (5.11), for the highest level l the global error bound

$$\|e_l^n\| \leqq C_1\tau + C_2(1+c)h_l^2 \tag{5.26}$$

results where C_1 and C_2 are positive constants independent of step size and mesh sizes. This bound is unconditional in the sense that it assumes no relation between step size and mesh sizes and, according to our goal, the smallest mesh width h_l occurs. We have recovered an error bound similar to the standard error bound for implicit Euler when applied on a single grid.

5.5. Convergence and higher-order interpolation. As pointed out in § 4.3, for the case of higher-order Lagrangian interpolants, a powerful stability result like that of Theorem 4.2 is not available. However, assuming that higher-order interpolation in low error regions does not severely damage stability, as is strongly supported by our practical experience, it is natural to impose the refinement condition (5.22) also in the case of higher-order interpolation. Note that in the derivation of (5.22) no a priori choice was made for the interpolants.

6. The refinement condition.

6.1. Determining the integration domains. Condition (5.22) first needs to be elaborated into a workable form before it can be implemented for determining the integration domains. To begin with, we rewrite the error ρ_k^n as

$$\begin{aligned}\rho_k^n = \gamma_k^n + P_{k-1k}\sum_{j=1}^{k-1}\left(\prod_{i=k-1}^{j+1} X_i^n\right)(Z_j^n)^{-1}\tau D_j^n \alpha_j^n \\ + P_{k-1k}\sum_{j=2}^{k-1}\left(\prod_{i=k-1}^{j+1} X_i^n\right)(Z_j^n)^{-1}(I_j - D_j^n)\gamma_j^n, \qquad 2 \leqq k \leqq l.\end{aligned} \tag{6.1}$$

Next, we rewrite the first sum as

$$\begin{aligned}P_{k-1k}\sum_{j=1}^{k-1}\left(\prod_{i=k-1}^{j+1} X_i^n\right)(Z_j^n)^{-1}\tau D_j^n \alpha_j^n = P_{k-1k}(Z_{k-1}^n)^{-1}\tau D_{k-1}^n \alpha_{k-1}^n \\ + P_{k-1k}\sum_{j=2}^{k-1}\left(\prod_{i=k-1}^{j+1} X_i^n\right)(Z_j^n)^{-1}(I_j - D_j^n) \\ \cdot P_{j-1j}(Z_{j-1}^n)^{-1}\tau D_{j-1}^n \alpha_{j-1}^n,\end{aligned} \tag{6.2}$$

and substitute this expression into (6.1). It then follows that ρ_k^n can be written as

$$\rho_k^n = \lambda_k^n + P_{k-1k}\sum_{j=2}^{k-1}\left(\prod_{i=k-1}^{j+1} X_i^n\right)(Z_j^n)^{-1}(I_j - D_j^n)\lambda_j^n, \qquad k = 2, \dots, l, \tag{6.3}$$

where

$$\lambda_j^n = \gamma_j^n + P_{j-1j}(Z_{j-1}^n)^{-1}\tau D_{j-1}^n \alpha_{j-1}^n, \qquad j = 2, \dots, l. \tag{6.4}$$

The error function λ_j^n contains the interpolation error at level j and the prolongation of the spatial discretization error of level $j-1$ to level j. The derivation now rests upon monitoring the error $(Z_k^n)^{-1}(I_k - D_k^n)\rho_k^n$ occurring in (5.22) through monitoring all errors $(I_j - D_j^n)\lambda_j^n, j \leqq k$, occurring in (6.3). The idea is to select the matrices D_j^n such that the error functions $(I_j - D_j^n)\lambda_j^n$ become sufficiently small. This makes sense because if C_3 and C_4 are stability constants such that

$$\|(Z_j^n)^{-1}\| \leqq C_3, \qquad \left\|\prod_{i=k-1}^{j+1} X_i^n\right\| \leqq C_4, \tag{6.5}$$

then

$$\|(Z_k^n)^{-1}(I_k - D_k^n)\rho_k^n\| \leqq C_3(1+\|P_{k-1k}\|(k-2)C_3C_4) \max_{2\leqq j\leqq k} \|(I_j - D_j^n)\lambda_j^n\|. \tag{6.6}$$

Hence, if for $k=2,\dots,l$, the matrices D_k^n are selected such that

$$C_3(1+\|P_{k-1k}\|(k-2)C_3C_4) \max_{2\leqq j\leqq k} \|(I_j - D_j^n)\lambda_j^n\| \leqq c\|(Z_k^n)^{-1}\tau D_k^n\alpha_k^n\|, \tag{6.7}$$

then the refinement condition (5.22) is satisfied.

In general, the stability constants C_3 and C_4 are unknown. However, if the dissipativity assumption (A5) is satisfied, then the constant $C_3 \leqq 1$. Furthermore, if we use linear interpolation, then (4.16) applies and C_4 also can be set equal to one, so that (6.7) simplifies to

$$\max_{2\leqq j\leqq k} \|(I_j - D_j^n)\lambda_j^n\| \leqq \frac{c}{k-1} \|(Z_k^n)^{-1}\tau D_k^n\alpha_k^n\|, \qquad k=2,\dots,l. \tag{6.8}$$

If assumption (A5) does not hold or if higher-order interpolation is used, then C_3 and C_4 may be larger than one, but not by a considerable amount. C_3 shall generally be of moderate size in view of the excellent stability behaviour of implicit Euler. Our practical experience with fourth-order Lagrangian interpolation is that higher-order interpolation is unlikely to yield instability problems, thus indicating that $\|X_k^n\|$, and hence C_4, are also of moderate size. That is why we proceed with (6.8) and also use it in situations where (A5) may be violated and/or higher-order interpolation is used.

In application, it suffices to impose (5.22) for $k=l$ only, so that (6.8) can be replaced by

$$\max_{2\leqq k\leqq l} \|(I_k - D_k^n)\lambda_k^n\| \leqq \frac{c}{l-1} \|(Z_l^n)^{-1}\tau D_l^n\alpha_l^n\|. \tag{6.9}$$

In order to satisfy this condition, estimates of λ_k^n have to be computed. Therefore, to create an extra safety margin, we replace (6.9) by the slightly more conservative condition

$$\|(I_k - D_k^n)\zeta_k^n\| \leqq \frac{c}{l-1} \|(Z_l^n)^{-1}\tau D_l^n\alpha_l^n\|, \qquad k=2,\dots,l, \tag{6.10}$$

where, componentwise, ζ_k^n is defined as

$$(\zeta_k^n)_i = |(\gamma_k^n)_i| + |(P_{k-1k}(Z_{k-1}^n)^{-1}\tau D_{k-1}^n\alpha_{k-1}^n)_i|. \tag{6.11}$$

Condition (6.10) will determine the integration domain of ω_k. Let Ω_k^n be this integration domain and recall that when a node belongs to Ω_k^n, the corresponding diagonal entry of D_k^n is equal to one and zero otherwise. Suppose that the maximal level number l and $c(l-1)^{-1}\|(Z_l^n)^{-1}\tau D_l^n\alpha_l^n\|$ are known and that a solution at Ω_{k-1}^n, $k\leqq l$, has just been computed. Prior to the integration step on level k, our task is then to determine Ω_k^n. That is, we must define D_k^n such that (6.10) is satisfied and in such a way that the area of Ω_k^n is as small as possible. The actual selection of Ω_k^n is carried out by a flagging procedure that scans level-k grid points. A point is flagged if, using appropriate estimates,

$$(\zeta_k^n)_i > \frac{c}{l-1} \|(Z_l^n)^{-1}\tau D_l^n\alpha_l^n\|. \tag{6.12}$$

Hence, for such a point the corresponding diagonal entry $(D_k^n)_{ii}=1$, and for nonflagged points we define $(D_k^n)_{ii}=0$. Thus the refinement condition (6.10) is satisfied.

In conclusion, the solution at a node of grid ω_k is interpolated only if a corresponding component of ζ_k^n is smaller than the maximum of the spatial discretization error at the finest grid multiplied with $\tau c(l-1)^{-1}$. Otherwise, integration is carried out at this node. No doubt this imposes a severe restriction on the size of the interpolation errors. On the other hand, this restriction is natural because when going to a higher level within the current time step, we never return to a grid point where the solution has been interpolated, which means that the interpolation error will be carried along to the next time step. The fact that we do not return is a direct consequence of the nesting property of the integration domains, which we will discuss next.

6.2. Restricted interpolation and the nesting property. We now introduce the nesting property of the integration domains. Recall that this property, being hidden in the definition of the matrices D_k^n, has played no role in the foregoing analysis. We stipulate that in application the nesting is enforced by the flagging procedure; in other words, this procedure scans only level-k points lying within the previous integration domain Ω_{k-1}^n. A direct consequence is that, unlike (3.5), the interpolation is carried out only for level-k points within Ω_{k-1}^n. Here we will justify the deviation due to this restricted interpolation. We will argue that the restricted interpolation is in fact allowed by the inequality (6.10), where interpolation over the whole of ω_k is still assumed.

Consider the error $(Z_{k-1}^n)^{-1}\tau D_{k-1}^n\alpha_{k-1}^n$, contained in ζ_k^n. This spatial error is defined at level $k-1$ and, by definition of D_{k-1}^n, has zero components outside Ω_{k-1}^n. Hence, all its prolongated components are taken into account in the flagging procedure for determining Ω_k^n. For the interpolation error γ_k^n, which lives on the whole of ω_k (grid expansion), the situation is different. However, restricted interpolation is allowed if for all level-k points outside Ω_{k-1}^n, the interpolation error satisfies

$$|(\gamma_k^n)_i| \leq \frac{c}{l-1}\,\|(Z_l^n)^{-1}\tau D_l^n \alpha_l^n\|, \tag{6.13}$$

because then points outside Ω_{k-1}^n will not be flagged if the interpolation step (3.5) would be carried out on the whole of ω_k. In other words, if (6.13) holds outside Ω_{k-1}^n, then the integration domains found with the restricted interpolation over Ω_{k-1}^n are equal to the domains found if the interpolation would be carried out on the whole of ω_k, which is in accordance with the method description (3.3a, b).

The following argument shows that inequality (6.13) is very plausible with the restricted interpolation procedure. First we recall that Ω_1^n coincides with the entire physical domain. Hence for $k=2$ there is no restricted interpolation, so that for all level-2 points outside Ω_2^n, inequality (6.13) is trivially satisfied. Next consider the case $k=3$. Now the interpolation is restricted to level-3 points within Ω_2^n. Since for all level-2 points outside Ω_2^n inequality (6.13) is satisfied, we are justified in supposing that this is also true for all level-3 points outside Ω_2^n, in view of the consistency of the interpolation (level-3 interpolation errors are smaller than level-2 errors). Further, by construction of Ω_3^n, (6.10) is satisfied for all level-3 points within Ω_2^n and outside Ω_3^n, and so is (6.16). In conclusion, we may suppose that (6.13) is satisfied for all level-3 points outside Ω_3^n when using the restricted interpolation for $k=3$. For $k=4$ and so on this argument can be repeated.

6.3. Implementation aspects. On top of the flagging procedure implementing (6.12), a safety measure has been built. Any node for which (6.12) is true is flagged together with its eight neighbours. Next, to create an extra buffer, all sides of cells with at least one flagged corner node are bisected. This means that a buffer zone of two mesh widths is used around any intolerable node. Near boundaries, physical and internal ones, the buffering differs slightly. Although in theory this buffering could be omitted, in practice it is wise to create a buffer zone around intolerable nodes because the estimation of higher spatial derivatives contained in α_k^n and γ_k^n is prone to inaccuracies. After the flagging procedure, a cluster algorithm groups all flagged nodes together to form the newly defined integration domain.

The parameter c in (6.12) must be specified. In view of result (5.25), c should be taken small so that the spatial accuracy obtained is indeed nearly equal to the spatial accuracy obtained without adaptation. In fact, the smaller c is, the more points will be flagged and hence the safer the local refinement will be ($c=0$ implies global refinement). On the other hand, when c is too large, it can occur that space errors are large and refinement is necessary but no nodes are flagged because (6.12) is satisfied at every node. Hence, c is available as a tuning parameter. In the experiments in § 7 we have simply put $c=1$.

Estimates of spatial interpolation and discretization errors are required. For $2 \leqq k \leqq l$ we must estimate the interpolation error γ_k^n and the prolongated spatial discretization error $P_{k-1k}(Z_{k-1}^n)^{-1}D_{k-1}^n\alpha_{k-1}^n$. Further, an estimate of the spatial discretization error $(Z_l^n)^{-1}D_l^n\alpha_l^n$ committed at the final lth level must be available at all lower levels. Because we use local uniform grids, the estimation of these errors can be realized cheaply and easily. Consider the error α_k^n (cf. (5.2)) and let p be the order of consistency (in this paper $p=2$). The estimation we apply is based on the use of a second spatial discretization operator $\tilde{F}$ of a higher-order $\tilde{p}$. After some elementary calculations we obtain the approximation

$$\alpha_k^n \approx \tilde{F}_k(t_n, u_k(t_n)) - F_k(t_n, u_k(t_n)) \tag{6.14}$$

as an asymptotically correct estimator for α_k^n. The benefit of using uniform grids now lies in the fact that $\tilde{F}$ is easily constructed. At internal nodes our $\tilde{F}$ provides fourth-order accuracy (standard symmetrical differences), while at nodes adjacent to physical or internal boundaries third-order accuracy is realized (standard one-sided differences). The benefit of using uniform grids is also reflected in the estimation for the error γ_k^n (cf. (5.4)). So far we have implemented Lagrangian interpolation of second (linear) and fourth order. For the second-order interpolation we need to estimate spatial derivatives u_{xx}, etc., while in the fourth-order case spatial derivatives like u_{xxxx} appear. For both cases the estimation is straightforward.

We emphasise that, in spite of its simplicity, linear interpolation may become disadvantageous due to the low order of accuracy. Inspection of the various terms in (6.12) suggests a comparison between the following order relations:

$$\tau(P_{k-1k}(Z_{k-1}^n)^{-1}D_{k-1}^n\alpha_{k-1}^n)_i = \mathcal{O}(\tau h_{k-1}^2), \tag{6.15a}$$

$$\|\tau(Z_l^n)^{-1}D_l^n\alpha_l^n\| = \mathcal{O}(\tau h_l^2), \tag{6.15b}$$

$$(\gamma_k^n)_i = \mathcal{O}(h_k^2), \quad \text{second-order Lagrangian (linear)}, \tag{6.15c}$$

$$(\gamma_k^n)_i = \mathcal{O}(h_k^4), \quad \text{fourth-order Lagrangian}. \tag{6.15d}$$

In the discretization terms the step size τ is contained. Consequently, it is the interpolation error that may govern the refinement if τ is very small, and particularly so when the interpolation is linear. The comparison is clearly in favour of the fourth-order interpolation.

To estimate the right-hand side term $\|(Z_l^n)^{-1}D_l^n\alpha_l^n\|$ of (6.12) for $2 \leqq k \leqq l-1$, we exploit the asymptotics. Since the mesh width of level k is half that of level $k+1$, we thus invoke

$$\|(Z_l^n)^{-1}D_l^n\alpha_l^n\| \approx 2^{-p(l-k)}\|(Z_k^n)^{-1}D_k^n\alpha_k^n\|, \qquad l \geqq k+1, \tag{6.16}$$

for $k = 1, 2, \ldots$. In theory it suffices to do this only for $k = 1$, but since for larger values of k this estimation will become more and more accurate, it is done for every k.

Finally, we will make a few remarks about the approximations (6.14) and (6.16). Our method, like every other adaptive grid method, is designed to solve PDEs with steep solutions. Yet (6.14) and (6.16) underlie asymptotics, which means that they are only accurate if the solution is sufficiently smooth on the grid in use. This constitutes a problem for LUGR methods, because these methods estimate errors on coarse grids. Nevertheless, if in practice the estimated error is not that accurate, it might still give a good indication of where the spatial error is large and where it is not and, specifically, the estimated error might still be in the same order of magnitude as the exact error, in which case the implemented refinement strategy based upon (6.14) will still work. In our experience so far, this is indeed the case. We believe this is due to the fact that estimation (6.16) is carried out for finer and finer subgrids with an increasing accuracy which partly remedies the problem. However, if solutions become very steep, it might be necessary to improve the implementation of the refinement condition (5.22).

7. Numerical example. This section is devoted to an illustration of the foregoing error analysis. Our goal here is to numerically illustrate that by imposing the refinement condition, the usual order behaviour is recovered. At the same time, the spatial accuracy obtained is comparable to the spatial accuracy on the finest grid if this grid would be used without adaptation.

7.1. The issue of implicitness. We use the implicit Euler method for time integration. In connection with implicitness, two points are worth mentioning. The first is that at any time step refinement takes place at different levels, resulting in a different Jacobian per level whose order usually varies. This impedes the profitable use of old Jacobians (like in sophisticated stiff ODE solvers), unless it is decided not to adapt grids at every time step, but instead per prescribed number of steps. We consider this as part of an overall strategy that can easily be placed on top of the existing one. We adapt grids at every time step since our main aim with the experiments is to illustrate the convergence analysis together with the refinement strategy. However, when dealing with real applications, it is most likely to be more advantageous to omit adaptation at every time step, just for efficiency reasons. The second point is that the Jacobians do not possess a regular band structure, since the integration domains Ω_k^n normally have an irregular shape. Unlike the first, this point is intrinsic to the local refinement method. In the experiments reported here, the Harwell sparse matrix solver MA28 has been used. This solver is well suited to coping with the structure we meet, but is rather time consuming for the present application. It is likely that standard iterative methods can be applied at lower costs.

7.2. The example problem. The problem is hypothetical and due to [1]. The equation is the linear parabolic equation

$$u_t = u_{xx} + u_{yy} + f(x, y, t), \quad 0 < x, y < 1, \quad t > 0, \tag{7.1}$$

and the initial function, the Dirichlet boundary conditions, and the source f are selected so that the exact solution is

$$u(x, y, t) = \exp[-80((x - r(t))^2 + (y - s(t))^2)], \tag{7.2}$$

where $r(t)=\frac{1}{4}[2+\sin(\pi t)]$ and $s(t)=\frac{1}{4}[2+\cos(\pi t)]$. This solution is a cone that is initially centered at $(\frac{1}{2},\frac{3}{4})$ and that symmetrically rotates around $(\frac{1}{2},\frac{1}{2})$ in a clockwise direction with a constant speed. We have used this problem to subdue our refinement method to a convergence test. Observe that the semidiscrete version of this problem satisfies the dissipativity assumption (A5).

7.3. Convergence experiments. We have carried out two identical convergence experiments. In the first, linear interpolation was used and in the second, fourth-order Lagrangian was used. In both the solution is computed four times over the interval $0\leqq t\leqq 2$, using a uniform 10×10 base grid and a constant time step size τ. In the first computation $l=1$, in the second $l=2$, and so on. Since per computation the smallest mesh width is halved, τ is simultaneously decreased by 2^2 in view of the first order of implicit Euler. Hence, in line with our analysis, per computation the maximal global error should also decrease by 2^2.

Table 7.1 shows the maxima of global errors restricted to the finest integration domain in use. This table also contains the maxima of the errors for the corresponding grid used without adaptation. The table clearly reveals the expected order behaviour. The errors of the $l=4$ runs are about a factor four smaller than the corresponding errors of the $l=3$ runs. Note that there is hardly a difference between the corresponding errors, showing that, as anticipated by our strategy, the choice of interpolant has no notable influence on the error. We emphasise that, in spite of the relatively large values for τ, the spatial error dominates the global errors shown in this table. For example, using $\tau=0.125$ instead of $\tau=0.5$ in the $l=2$ run, the same global errors are found (they deviate in the third or fourth decimal digit). In other words, conclusions on the spatial error behaviour induced by the local refinement algorithm can be drawn from this table. These results convincingly show, for the current example problem, that the use of the refinement condition ensures that the spatial accuracy obtained is very much comparable to the spatial accuracy on the finest grid if this grid is used without any adaptation. Finally we note that the choice $c=1$ apparently has no influence on the error. We owe this to the fact that the refinement condition has been derived from error bounds and is thus conservative.

The use of the two different interpolants is expressed in the slightly different integration domains shown in Figs. 7.1 and 7.2. As expected, at the higher levels linear

TABLE 7.1
Maxima of global errors restricted to the finest domain. Comparison with errors on a standard uniform grid.

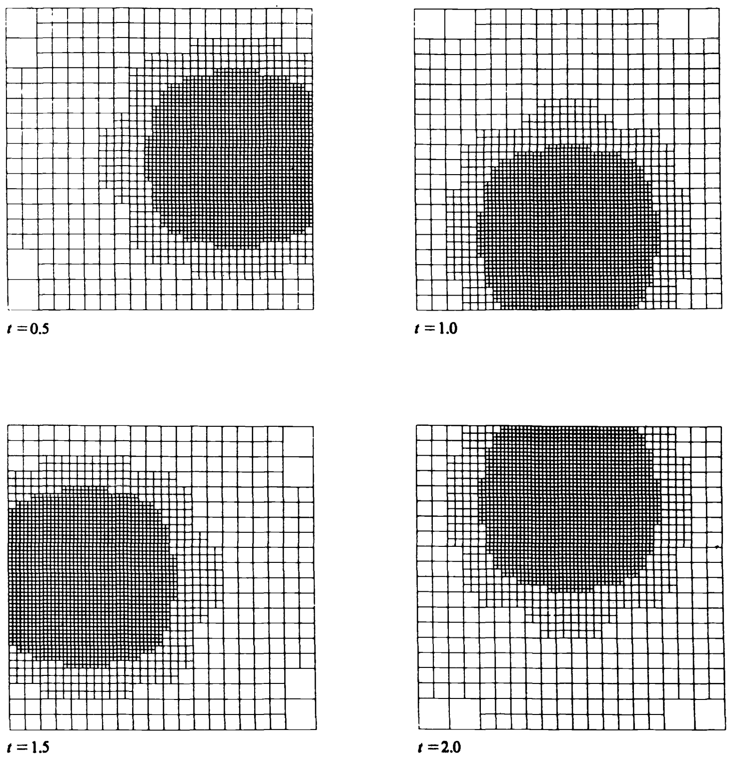

FIG. 7.1. *Linear interpolation. Integration domains for the $l = 4$ run at four different times. The size of the integration domains decreases only slowly with the number of levels. This is due to the fact that the cone is not very steep. At the end time,* $t = 2.0$, *the number of nodes amounts to* 121, 425, 813, *and* 1917, *respectively.*

interpolation gives rise to somewhat larger domains, showing that linear interpolation is more expensive. As a rule, fourth-order interpolation is to be preferred, as it leads to smaller domains. Note that for both interpolants the moving domains accurately reflect the symmetric rotation of the cone, which once again nicely illustrates the reliability of the implemented refinement condition with the various estimators.

8. Final remarks and future plans. In our future research we plan to pay more attention to time-stepping efficiency. Using the refinement strategy of this paper as a starting point, we plan to examine the application of methods possessing a higher order in time. Natural candidates belong to the class of Runge–Kutta methods. It should be stressed, though, that fully implicit methods can only be of serious advantage if the numerical algebra issue can be satisfactorily solved. In this connection splitting methods of the ADI and LOD type (see [9]) may therefore provide an attractive alternative to fully implicit ones, although they are usually less accurate in time. Another point of serious practical concern is to apply methods not only using an a priori chosen number of levels, but to also have the possibility to vary the number of levels. This might be useful for the computation of solutions that, for example, steepen in time, like the combustion problem in [13]. For such problems, the application of a variable number of levels should be combined with the use of variable temporal step sizes. Preferably, the complete adaptation should then be monitored by estimators of temporal and spatial errors in such a way that there is a balance between the two which aims at minimizing the waste of computing time.

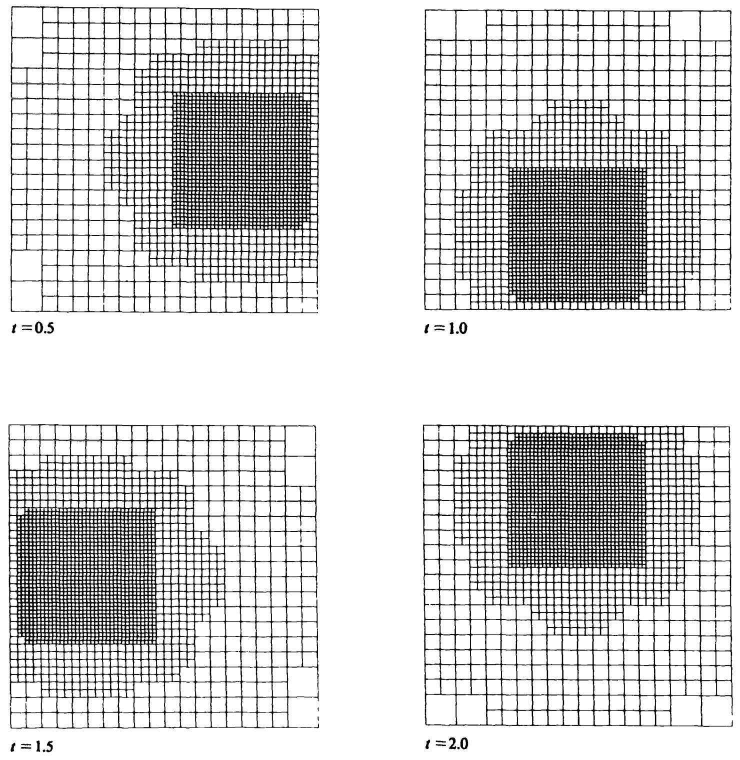

FIG. 7.2. *Fourth-order interpolation. Integration domains for the* $l = 4$ *run at four different times. At the end time,* $t = 2.0$, *the number of nodes amounts to* 121, 425, 813, *and* 1361, *respectively.*

Acknowledgment. We would like to thank Willem Hundsdorfer for his careful reading of the manuscript.

VECTOR-SUPERCOMPUTER EXPERIMENTS WITH THE PRIMAL AFFINE LINEAR PROGRAMMING SCALING ALGORITHM*

K. O. KORTANEK†

Abstract. The vector-supercomputer CRAY series has provided significant speed and significant digits accuracy for solving difficult, large-scale, and ill-conditioned linear programming problems with the linear programming (LP) primal scaling algorithm of Dikin [*Soviet Math. Dokl.*, 8 (1967), pp. 674-675]. Ranging from fully dense Chebyshev approximation-type matrices to highly sparse, relatively small, band-widths matrices generated from continuum mechanics problems, numerical results are presented that indicate good stability and objective function value accuracy. In a significant number of these experiments, a substantial speed-up in CPU time for obtaining good objective function accuracy has been obtained over a very stable implementation of the simplex method, termed LINOP. The companion QR-based scaling implementation, SHP, was applied to these dense problems, where high accuracy levels are required.

A conjugate gradient-based implementation, termed HYBY, was applied to a discretized plane strain plasticity problem for ill-conditioned problems having up to 7700 equations in as many as 9000 variables. The FORTRAN code includes an effective stability enhancement over the original affine scaling algorithm. The sparse LP matrix generator for these problems is available from the author (kort@icaen.uiowa.edu) or from Professor E. Christiansen in Odense, Denmark (edc@imada.ou.dk).

1. Introduction. LP approximations to semi-infinite programs. Generally speaking, difficult to solve linear programs arise when linear semi-infinite programs are approximated using finite discretizations. Regardless of the kind of discretization used, one usually obtains a finite linear inequality subsystem of the original infinite one, which is potentially ill conditioned.

Building on the work of Gustafson [18] and Gustafson and Kortanek [19], an LP approximation was taken as Phase I in the semi-infinite programming codes of Fahlander [12]. In her codes, Phase I provides a starting solution for the necessary optimality conditions appearing in the form of a nonlinear system of equations. In yet another, more recent, direction a discretization method of Hettich [21] relies exclusively on discretizations, but in a new way that permits a substantial reduction in the number of inequalities in the finite linear subsystem.

Until now these linear programs have generally been solved by simplex method implementations which strive to achieve stability and high accuracy. For example, a rather recent stable simplex method code has been developed based on Georg and Hettich [15], and it has been tested on some difficult two-sided approximation problems and on some vibrating membrane problems.

Recently, another computational approach for linear programming has arisen, based on the interior point LP methods of Dikin [11] and Karmarkar [27]. In this

paper the Dikin algorithm, termed the LP affine scaling algorithm, is tested on some discretized semi-infinite programming problems. Two classes of problems are studied that for different reasons can be considered large scale.

The first class consists of problems that owe their size to either single-precision or double-precision, fully dense, constraint matrices. These problems are principally two-sided approximation problems (also termed Chebyshev or L_∞-norm approximation problems). Within this class we investigate the following problems: (a) Chebyshev approximation of two variable transcendental functions by polynomials in two variables (see Hettich [21] and Hettich and Zencke [26]); (b) complex variable Chebyshev approximation arising in antenna beam-forming problems (see Streit and Nuttall [36] and Streit [34], [35]); and (c) Chebyshev approximation problems that arise in computing eigenvalues of a vibrating membrane (see Hettich [22] and Hettich, Haaren, Ries, and Still [24]).

The second class of problems stems from computing limit collapse loads in a plastic plane strain problem, as studied in engineering continuum mechanics, and the reader is referred to Christiansen and Kortanek [9], [10] for model details and numerical results. Basically, a linear program is obtained from two different kinds of discretizations: (i) possibly different finite element approximations for the strain and stress forces of the problem, and (ii) an outer linear approximation of the unbounded convex yield set of the stresses.

All computational experiments reported here were performed on CRAY supercomputers: first on a CRAY 1 at AT&T's Murray Hill, NJ, facility, in the spring of 1986, and then on a CRAY X-MP/48 at the University of Illinois's Urbana-Champaign Supercomputer Center during 1987 and 1988.

These results are given in §§ 4 and 5. But first, in the next section, a proof of the affine scaling algorithm's asymptotic linear convergence rate is given under the rather mild assumptions of Kortanek and Shi [28]. This section also contains Hettich's suggestion for a stability improvement, which has been found to be essential for the plasticity application.

Section 3 describes the characteristics of the FORTRAN codes used in the numerical experiments.

2. The primal LP affine scaling algorithm and a convergence analysis. Consider a standard form of an LP problem:

(I) Let c be an n-vector, b an m-vector, and A a full-rank $m \times n$ matrix, none of whose columns is zero.

$$\text{Find } v_I = \min\{c^T x \mid x \in R^n,\ Ax = b,\ x \geqq 0\}. \tag{1}$$

It is natural to assume that the matrix A has the opposite sign property because it may be readily imposed without loss of generality using classical LP regularization procedures. The opposite sign property is equivalent to the constraint set of (1) being spanned by its extreme points (a characterization that also holds in infinite dimensions).

2.1. The primal affine scaling algorithm (Dikin [11]).

Step 0. Let $x^{(0)}$ be an (I)-feasible point, satisfying $x_i^{(0)} > 0$, for $i = 1, \ldots, n$. Let α be a scalar $0 < \alpha < 1$ and set the iteration count k to 0.

Step 1. Let $\bar{c}_k = D_k c$, $\bar{A}_k = AD_k$, where $D_k = \operatorname{diag}(x^{(k)})$. Set $y^{(k)} = (\bar{A}_k \bar{A}_k^T)^{-1} \bar{A}_k \bar{c}_k$ and $c_P^{(k)} = \bar{c}_k - \bar{A}_k^T y^{(k)}$.

Step 2. Test: if $c_P^{(k)} \neq 0$, then continue to Step 3, else stop with optimal $x^{(k)}$ for (I) and $y^{(k)}$ optimal for dual LP of (I).

Step 3. Let $(1/\gamma_k) = \max_i c_{Pi}^{(k)}$. Set $\hat{c}_P^{(k)} = \gamma_k c_P^{(k)}$.

Step 4. Set $x^{(k+1)} = x^{(k)} - \alpha D_k \hat{c}_P^{(k)}$, $k := k+1$, and return to Step 1.

In Step 1, $c_P^{(k)}$ is the orthogonal projection of $\bar{c}_k$ onto the null space of $\bar{A}_k$, where $y^{(k)}$ is also the unique solution of the least squares minimization (where only the two-norm is used in this paper)

$$\min_{y \in R^m} \|\bar{c}_k - \bar{A}_k^T y\|^2. \tag{2}$$

For an explanation and geometric motivation of this algorithm, the reader may consult Strang [33, pp. 683-686], where the algorithm is referred to as the "rescaling algorithm." In addition, one may consult Bazaraa, Jarvis, and Sherali [3, pp. 412-418] for a discussion of the "affine scaling variant of Karmarkar's algorithm."

Various elementary properties of the algorithm have appeared in an expanding literature. For definiteness, we state the following lemma from Kortanek and Shi [28].

LEMMA 1. *Assume that the algorithm does not terminate. Then*

(a) $\gamma_k \|c_P^{(k)}\| \geqq 1$ *for each* k;

(b) $\bar{c}_k^T c_P^{(k)} = \|c_P^{(k)}\|^2$ *for each* k;

(c) $\lim_k \gamma_k \|c_P^{(k)}\|^2 = 0$; *and*

(d) $\lim_k c_P^{(k)} = 0$.

Sufficient conditions for convergence usually require some form of primal or dual nondegeneracy assumption. Among the weakest of such conditions are those independently derived in Sherali, Sharpness, and Kim [32, p. 407] and Kortanek and Shi [28, Thm. 2, p. 52]. Theorem 1 in the latter reference can be used to establish an asymptotic linear convergence rate of the algorithm under a weakened nondegeneracy assumption.

THEOREM 1 (see [28]). *Define a set of coordinate positions by* $S_0 = \{i \mid \underline{\lim}_k x_i^{(k)} > 0\}$. *Assume that the column subset* $\{A^j \mid j \in S_0\}$ *has rank* m. *Then any limit point of* $\{x^{(k)}\}_k$ *solves* (I), *and any* $\{y^{(k)}\}_k$ *convergences to an optimal solution of the dual program of* (I).

The related convergence rate result is now the following.

THEOREM 2. *Assume that not every feasible point of* (I) *is optimal. Then under the assumptions of Theorem* 1 *and a nonterminating sequence* $\{x^{(k)}\}_{k=1}^{\infty}$, *the following inequality holds for sufficiently large* k:

$$\frac{c^T x^{(k+1)} - c^T \bar{x}}{c^T x^{(k)} - c^T \bar{x}} \leqq 1 - \frac{\alpha \gamma_k \|c_P^{(k)}\|}{2\sqrt{n}}.$$

Proof. Let $\bar{x}$ be a limit point of $\{x^{(k)}\}$. By Theorem 1, $\bar{x}$ is a solution to (I), $\lim_k y^{(k)}$ exists (say $\bar{y}$), and $\bar{y}$ solves the dual problem, i.e., $\bar{y}^T A^j \geqq c_j, j = 1, \ldots, n$, and $c^T \bar{x} = \bar{y}^T b$. From the definition of the projection $c_P^{(k)}$, we have

$$c_j - y^{(k)T} A^j = c_{P_j}^{(k)} / x_j^{(k)} \quad \text{for } j = 1, 2, \ldots, n.$$

Hence, by Lemma 1(d) and the definition of S_0 in Theorem 1, it follows that

$$\bar{y}^T A^i = c_i \quad \text{for each } i \in S_0.$$

Now S_0 is contained in the set $T_0 := \{j \mid c_j - \bar{y}^T A^j = 0\}$, which cannot equal $\{1, 2, \ldots, n\}$ because otherwise every (I)-feasible point is optimal. Hence we can rewrite $Ax^{(k)} = b$ as $\sum_{j \in T_0} A^j x_j^{(k)} + \sum_{j \notin T_0} A^j x_j^{(k)} = b$, yielding

$$\sum_{j \in T_0} \bar{y}^T A^j x_j^{(k)} + \sum_{j \notin T_0} \bar{y}^T A^j x_j^{(k)} = \bar{y}^T b.$$

With appropriate substitutions this becomes

$$\sum_{j \in T_0} c_j x_j^{(k)} + \sum_{j \notin T_0} \bar{y}^T A^j x_j^{(k)} = c^T \bar{x}. \tag{3}$$

It also follows that for sufficiently large k,

$$(4)\qquad c_j - y^{(k)T}A^j > \tfrac{1}{2}(c_j - \bar{y}^T A^j) \quad \text{for all } j \notin T_0.$$

This motivates adding $\sum_{j\notin T_0} c_j x_j^{(k)}$ to both sides of (3) and rearranging in order to obtain

$$(5)\qquad \sum_{j=1}^{n} c_j x_j^{(k)} - c^T\bar{x} = \sum_{j\notin T_0} (c_j - \bar{y}^T A^j) x_j^{(k)}.$$

Combining (4) with (3) gives

$$(6)\qquad c^T x^{(k)} - c^T\bar{x} < 2 \sum_{j\notin T_0} (c_j - y^{(k)T}A^j) x_j^{(k)}.$$

Applying the classical inequality

$$\sum_{i=1}^{n} a_i b_i \leqq \sqrt{n}\left(\sum_{i=1}^{n} a_i^2 b_i^2\right)^{1/2}, \qquad a_i b_i > 0,$$

yields

$$\sum_{j\notin T_0} (c_j - y^{(k)T}A^j) x_j^{(k)} \leqq \sqrt{n}\, \|c_P^{(k)}\|,$$

which combines with (5) to yield

$$c^T x^{(k)} - c^T\bar{x} < (2\sqrt{n})\|c_P^{(k)}\|.$$

Step 4 of the algorithm and the fact that $\bar{c}_k^T c_P^{(k)} = \|c_P^{(k)}\|^2$ (Lemma 1(b)) yields

$$c^T x^{(k+1)} = c^T x^{(k)} - \alpha\gamma_k \|c_P^{(k)}\|^2.$$

Because of nontermination, $c^T x^{(k)} - c^T\bar{x} > 0$ for each k, and hence we conclude that for sufficiently large k,

$$(7)\qquad \frac{c^T x^{(k+1)} - c^T\bar{x}}{c^T x^{(k)} - c^T\bar{x}} \leqq 1 - \frac{\alpha\gamma_k \|c_P^{(k)}\|}{2\sqrt{n}}. \qquad \square$$

Remark 1. The proof has similarities and has benefitted from the proof in Barnes [1]. A related convergence result was obtained by Ferris and Philpott [13, p. 275] in a more general context.

Remark 2. Since $\gamma_k\|c_P^{(k)}\| \geqq 1$ for each k, (7) establishes that the asymptotic convergence rate is linear. Empirically easy to observe, one might obtain insight on the speed of convergence by observing $\gamma_k\|c_P^{(k)}\|$, but we have not done this in a systematic way.

2.2. Obtaining an initial point (Phase I calibration procedure). Let μ be a positive number, and let M be the $n \times n$ diagonal matrix with μ along the diagonal. Let $\mathbf{e}$ denote the n-vector of all ones and set $\mathbf{s}^0$, $s_{n+1}^0 = (\mathbf{e}, 1)$. For $k = 0, 1, 2, \ldots$, apply just one iteration of the primal affine scaling algorithm to

$$\min_{\mathbf{s}, s_{n+1}} \quad s_{n+1}$$

$$\text{subject to } AM\mathbf{s} + \frac{(b - AM\mathbf{s}^k)}{s_{n+1}^k} s_{n+1} = b$$

$$\text{and} \quad \mathbf{s}, s_{n+1} \geqq 0,$$

beginning with the exactly feasible initial solution $\mathbf{s}^k$, s_{n+1}^k, and delivering the next iterate $\mathbf{s}^{k+1}$, s_{n+1}^{k+1}. Terminate when s_{n+1}^k is below a specified positive tolerance. Many people have had extensive computational experience with this procedure, beginning with Cavalier and Soyster [5].

In our experiments, we did no additional stability checks on the accuracy of the projection in Step 1 of the algorithm for Phase I.

Typically, setting $\mathbf{x}^{(0)}=\mathbf{s}^{(k)}$ for relatively small numbers of iterations k gave a sufficiently accurate interior point starting solution for application of the algorithm to the original LP problem. Typically, once a starting solution $\mathbf{x}^{(0)}$ is available, application of the algorithm is then termed "Phase II." In our experience, Phase II definitely requires checking whether the projection $c_P^{(k)}$ lies in the null space of $\bar{A}_k$ for each k, as described in § 3.

2.3. A stability enhancement. Although the projection $c_P^{(k)}$ of Step 1 converges to zero, each vector, $\bar{c}_k$ and $\bar{A}_k^T y^{(k)}$, employed in the difference expression of Step 1 may be relatively large.

During his visit to Carnegie-Mellon University in spring 1986, Hettich suggested another least squares problem to replace (2) in an attempt to "shorten" each of the vectors used in the difference expression, namely:

$$(8)\qquad \min_{y_\delta\in R^m} \|\bar{c}_k^{(\delta)}-\bar{A}_k^T y_\delta\|^2,$$

where $\bar{c}_k^{(\delta)}=\bar{c}_k-\bar{A}_k^T y^{(k-1)}$. Thus, at the current iteration k, the vector $\bar{c}_k$ of Step 1 is replaced by $\bar{c}_k^{(\delta)}$, which depends on the previous solution $y^{(k-1)}$. The solution to (8), denoted $y_\delta^{(k)}$, becomes

$$(9)\qquad y_\delta^{(k)}=(\bar{A}_k\bar{A}_k^T)^{-1}\bar{A}_k(\bar{c}_k-\bar{A}_k^T y^{(k-1)})=y^{(k)}-y^{(k-1)}.$$

Under the conditions of Theorem 1, it follows that $\bar{c}_k^{(\delta)}$ and $y_\delta^{(k)}$ both converge to 0 as k increases. Finally, observe that the projection in (8) is $c_P^{(k)}$ itself, i.e.,

$$\begin{aligned}\bar{c}_k^{(\delta)}-\bar{A}_k^T y_\delta^{(k)}&=\bar{c}_k-\bar{A}_k^T y^{(k-1)}-\bar{A}_k^T y^{(k)}+\bar{A}_k^T y^{(k-1)}\\&=\bar{c}_k-\bar{A}_k^T y^{(k)}=c_P^{(k)}.\end{aligned}$$

While we cannot generally say that the original vectors $\bar{c}_k$ and $\bar{A}_k^T y^{(k)}$ are large enough to cause stability problems in computing $c_P^{(k)}$, (8) permits the expression of $c_P^{(k)}$ as a difference of two vectors, each converging to zero.

For implementation purposes, the following modification of (8) is employed:

$$(10)\qquad \min_{y_\beta\in R^m} \|\bar{c}_k^{(\beta)}-\bar{A}_k^T y_\beta\|^2,$$

where $y_\beta^{(k)}$ denotes the optimal solution at stage k, beginning with $y_\beta^{(0)}=y^{(0)}=(\bar{A}_0\bar{A}_0^T)^{-1}\bar{A}_0\bar{c}_0$ as the initialization, and where $\bar{c}_k^{(\beta)}=\bar{c}_k-\bar{A}_k^T y_\beta^{(k-1)}$.

The solution $y_\beta^{(k)}$ to (10) is then

$$y_\beta^{(k)}=(\bar{A}_k\bar{A}_k^T)^{-1}\bar{A}_k(\bar{c}_k-\bar{A}_k^T y_\beta^{(k-1)})=y^{(k)}-y_\beta^{(k-1)},$$

and thus, unlike the solution to (8), $y_\beta^{(k)}$ here becomes a telescoping series. Again, (10) yields a projection onto the null space of $\bar{A}_k$, and analogous to (8), it is also $c_P^{(k)}$:

$$\begin{aligned}\bar{c}_k^{(\beta)}-\bar{A}_k^T y_\beta^{(k)}&=\bar{c}_k-\bar{A}_k^T y_\beta^{(k-1)}-\bar{A}_k^T(y^{(k)}-y_\beta^{(k-1)})\\&=\bar{c}_k-\bar{A}_k^T y^{(k)}=c_P^{(k)}.\end{aligned}$$

The enhancement was employed only in the sparse matrix implementation of the primal affine algorithm, which is described in the next section.

3. Features of the FORTRAN codes: SHP, LINOP, HYBY. LINOP is a simplex method implementation based on Georg and Hettich [15], while SHP and HYBY are implementations of the primal affine scaling algorithm of § 2.1. All codes are written in FORTRAN 77.

3.1. SHP. SHP was written by Miao Gen Shi of Tsinghua University for highly dense problems requiring a very high level of accuracy. The solution to the least squares problem is accomplished by a Householder transformation-based QR decomposition of the matrix $\bar{A}_k^T$ implemented with LINPACK subroutines

$$\bar{A}_k^T = Q^{(k)}R^{(k)}, \quad \text{where } Q^{(k)} \text{ is an } n \times m \text{ matrix, } Q^{(k)T}Q^{(k)} = I,$$

and

$$R^{(k)} \text{ is right upper triangular } m \times m.$$

As is well known, one can dispense with the $R^{(k)}$ factor in computing the projection, i.e.,

$$c_P^{(k)} = (I - Q^{(k)}Q^{(k)T})\bar{c}_k.$$

In SHP the relative accuracy is denoted by EP. From Lemma 1(b) we know ideally that $\bar{c}^T c_P = \|c_P\|^2$ (ignoring k sub- and superscripts). Because of round-off error, the relative error RS is not zero, where

$$\text{RS} = |\bar{c}^T c_P - \|c_P\|^2| / \|c_P\|^2.$$

RS provides a measure of stability loss and is used as one of the termination criteria. Iterations continue as long as RS is below a stability parameter choice, usually 1.00 or 0.10, i.e., the position of $c_P^{(k)}$ is acceptable, unless the norm of the projection is sufficiently small, in which case the algorithm is also terminated.

As an additional termination check on the accuracy of the projection, we typically provide $\|Ax^{(k)} - b\|$ in the ∞- or two-norm.

We shall use the common FORTRAN edit descriptors e or d to record various constants in single or double precision. Thus, for example, $\text{e}-6 = 1.\text{e}-6 = 1.\text{d}-6 = 10^{-6}$.

For CRAY double-precision runs the choice of EP ranges from d − 17 to d − 21 (machine accuracy d − 28). For single-precision runs EP ranges from e − 12 to e − 13 (machine accuracy e − 14). The uniform choice of α in Step 0 of the algorithm is 0.999 for both phases, which could be termed an attempt at taking "long steps" in the descent directions. Smaller α leads to more iterations, with about the same accuracy.

3.2. LINOP. Full details of this FORTRAN code appear in "the package LINOP" by Hettich and collaborators. Georg and Hettich [15] have shown that the most stable simplex method implementation occurs when the orthogonal Q-matrix is retained and itself updated through successive iterations. See also Hettich and Zencke [25].

In LINOP the relative accuracy is denoted by EPS, where, for example, EPS = 1.e − 14 means that single-precision numbers are accurate up to 14 decimal places. EPS determines when a number should be set to 0, or when a QR factorization is inaccurate. EPS is also used to detect a nearly singular basis matrix. The code outputs error indications when any of these states are encountered.

Both LINOP and SHP were compiled on CRAY compilers available at Murray Hill, NJ, and at Urbana-Champaign, IL, which provide for a certain amount of automatic vectorization. But no other specific vectorization coding techniques were used in these basically serially written FORTRAN codes. Important possibilities for speed-up obtained by removing inhibitors to vectorization are reported in Zenios and Mulvey [42].

Because both of these codes retain the orthogonal factors in the matrix decompositions, comparisons between their performances should show them to be equal. While LINOP has a self-correcting Q-updating procedure and SHP does not, one might still expect similar performance in CPU time because of the many more simplex iterations needed, in contrast to the greatly reduced number of iterations of the scaling algorithm.

This has been confirmed in numerical experiments for classes of Chebyshev approximations problems.

3.3. HYBY. In early 1986, Kortanek wrote a FORTRAN code for a sparse implementation of the algorithm using the classical conjugate gradient algorithm for solving (10); see [20, Algorithm 4]. Two clear advantages of this approach are: (1) $\bar{A}_k$ can be stored in its sparse form, never having to compute $\bar{A}_k\bar{A}_k^T$, and hence saving on storage; and (2) one can use the current $y_\beta^{(k)}$, the solution to (10), for an initial, advanced start in the next iteration's least squares problem (10).

Analogous to various sparse matrix packages (for example, Paige and Saunders [30]), we use three arrays for the storage of $\bar{A}_k^T$. Array JMA lists the nonzero elements of $\bar{A}_k^T$, row by row. Array IM indicates the column number of each entry in JMA. Finally, array MM gives the number of nonzero entries in each row of $\bar{A}_k^T$.

The matrix $\bar{A}_k$ is preconditioned using a diagonal matrix with entries formed from the two-norm of the rows of $\bar{A}_k$. Other more effective preconditioners related to a Cholesky factorization of $\bar{A}_k\bar{A}_k^T$ are discussed, for example, in Georg and Liu [16].

HYBY employs the same stability check and stopping rules that SHP does. Typically, for single-precision CRAY runs, a cut-off for the norm of the residuals for the inner loop conjugate gradient iterations is taken to be about 1.e − 13. Relaxing this criterion gives projections that do not lie sufficiently within the null space of $\bar{A}_k$. HYBY is clearly less accurate than SHP, and so we always include a post-optimality check of the minimum of the "reduced costs," i.e.,

$$\min\{c_j - A_j^T y^{(k)} \mid j = 1, \dots, n\}, \tag{11}$$

ideally nonnegative, where A_j is the jth column of A. At this point we simply omit post-duality checking in SHP because of its rather high accuracy.

Our experience on CRAY machines is that running in double precision can result in increases in CPU time by a factor of at least 10. Therefore, it is essential to run HYBY in single precision when applied to large-scale LP problems.

We describe next the results of some numerical experiments.

4. Numerical experiments on vector-supercomputers.

4.1. Two-sided approximation by polynomials in two dimensions: SHP and LINOP with double precision. Historically, the task of solving finite LP approximations to infinite problems set in a continuum led to the development of LP codes, such as LINOP [15], having a high degree of accuracy when double precision is used.

A typical two-sided approximation problem can be viewed as a semi-infinite program and further discretized.

(A) Given (continuous) functions $f(x), u_1(x), \dots, u_n(x)$ defined on a set S in R^2 compute

$$v_P = \inf_{y_1,\dots,y_n,y_{n+1}} y_{n+1}$$

$$\text{s.t.} \quad \left|\sum_{i=1}^n y_i u_i(x) - f(x)\right| - y_{n+1} \leqq 0 \quad \text{for all } x \in S.$$

Removing the absolute value signs leads to the equivalent problem

$$v_P = \inf y_{n+1}$$

$$\text{s.t.} \quad \sum_{i=1}^n y_i u_i(x) + y_{n+1} \geqq f(x),$$

$$-\sum_{i=1}^n y_i u_i(x) + y_{n+1} \geqq -f(x) \quad \text{for all } x \in S.$$

The approximation problem to be solved will be obtained by discretizing the set S, i.e., selecting a finite subset T of S, and then constructing the dual to the above minimization program:

$$\text{(B)} \qquad \sup_{\lambda^+(x),\lambda^-(x)} \sum_x f(x)\lambda^+(x) - \sum_x f(x)\lambda^-(x)$$

$$\text{s.t.} \quad \sum_x \begin{pmatrix} u_1(x) \\ \vdots \\ u_n(x) \\ 1 \end{pmatrix} \lambda^+(x) - \sum_x \begin{pmatrix} u_1(x) \\ \vdots \\ u_n(x) \\ 1 \end{pmatrix} \lambda^-(x) = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix},$$

and all $\lambda^+(x)$, $\lambda^-(x) \geqq 0$, and where "$\sum_x$" denotes "$\sum_{x\in T}$."

Typically one can use a linear independence argument, which depends on properties of the u_i-functions and the mesh of the grid S to show that the constraint matrix in (B) has full row rank. It clearly has the opposite sign property because of the last equation. Observe that the constraint matrix is $(n+1)$ by $2 * (\# T)$, and that an interior point feasible solution is immediate; namely, assign $1/(2 * (\# T))$ to each variable in (B) where "#" means "the number of members of." Thus, applying SHP to (B) does not require a Phase I procedure. In the following problems, the full rank assumption holds for sufficiently fine uniform grids. For the first two experiments, note that if the polynomial has degree d, then the number of equations in (B) is $0.5(\mathrm{d}+2)(\mathrm{d}+1)+1$, as Tables 1 and 3 illustrate. In each case, the two-dimensional grids are simply uniform ones based on Cartesian products of respective one-dimensional grids.

In these experiments we test the codes SHP and LINOP on the dual problem (B) and provide results on the number of iterations, CPU time, and objective function values. In general, no further comparisons were made regarding primal or dual optimal solutions to (B) delivered by each code, but objective function value comparisons are given in Tables 2 and 4.

4.1.1. Experiment 1. Approximate x^y by

$$\sum_{i=0}^{d}\sum_{j=0}^{i} a_{ij}x^jy^{i-j}$$

on the square $[1,2]\times[1,2]$.

For the six problems counted in the order of increasing matrix size, the scaling precisions EP paired with the norms $\|Ax^{(k)}-b\|_\infty$ are, respectively, (d−19, 0.44e−15), (d−19, 0.44e−15), (d−19, 0.77e−15), (d−21, 0.41e−15), (d−21, 0.11e−14), (d−23, 0.23e−13). For LINOP the relative accuracy was chosen between d−19 and d−21.

For the 37×288 problem the two-norm of the difference of the dual vectors delivered by LINOP and SHP was about 0.90d−5. Dual vector components ranged from −0.96e−6 to 1.40 with most less than 1 in absolute value.

4.1.2. Experiment 2. Approximate $\log(x+y)\sin x$ by

$$\sum_{i=0}^{d}\sum_{j=0}^{i} a_{ij}x^jy^{i-j}$$

on the rectangle $[\varepsilon,1]\times[1,2.5]$, where $\varepsilon=1.\text{d}-5$. One could have also chosen $\varepsilon=0$ if desired.

TABLE 4
Comparisons of objective function values for the runs on Table 3.

Problem size (m,n)	LINOP: Simplex algorithm	Scaling algorithm
22,288	.15657066e−3	.1565698e−3
29,288	.3833631e−4	.3833208e−4
37,288	.9714904e−5	.9711184e−5
37,338	.9892332e−5	.9888688e−5
37,392	.9852445e−5	.9850761e−5
37,450	.9780506e−5	.9780050e−5

The experience on accuracy was similar to Experiment 1, except slightly more stable. For the scaling runs, EP was d − 19 for all but the largest run, where it was d − 21. The maximum norm $\|Ax^{(k)} - b\|_\infty$ ranged from .11e − 14 to .44e − 15.

4.2. Two-sided approximations for computing membrane eigenvalues: SHP and LINOP. We present next some numerical experiments on some two-sided approximation problems which arise in Hettich's parametric programming approach for computing eigenvalues of the problem $\Delta u = \lambda u$ in a region R with $u = 0$ on its boundary (see Hettich [22], Hettich, Haaren, Ries, and Still [24], and Hettich and Zencke [26]). In these experiments, for instance, R is an ellipse, and the LP problems are fully dense and rather ill conditioned. The LP preprocessors were written by Hettich and his colleagues. The computer runs were made in the spring of 1986 on AT&T's CRAY 1 at the Murray Hill, NJ, facility. Solution times were not recorded, merely iteration counts, and we tested SHP's Phase I procedure; see Table 5.

4.2.1. Experiment 3. In each problem the objective function values (OFVs) agreed up to seven figures. For the first two problems, the correct optimal bases were indicated by the scaling method with solution-component accuracy of three figures. For the third problem, a support set of 36 variables was indicated that had 32 variables in common with the 35-point support set returned by the simplex method. There is therefore strong reason to believe that the scaling method has indicated a nonextreme point optimal solution, having seven-digit OFV accuracy.

4.3. Complex function approximation for antenna array processing. Recent work in complex function approximation and its applications have appeared in Glashoff and Roleff [17]; Streit and Nuttall [36], [37]; Streit [34], [35]; and Watson [41] (see also Barrodale and Phillips [2]). We now present a prototype problem.

TABLE 5
CRAY 1 *double-precision solutions to selected membrane eigenvalue problems* (1986). *Number of iterations and some precision statistics.*

Problem size		LINOP:			Scaling algorithm			
Number of equations	Number of variables	Phase I	Phase II	EPS	Phase I	Phase II	$\|Ax - b\|_\infty$	EP
20	100	43	24	d − 19	2	17	0.35e − 19	d − 21
30	400	93	313	d − 19	2	20	0.39e − 15	d − 21
35	500	147	758	d − 19	2	37	0.22e − 14	d − 22

Let A_j denote the jth column of an $n \times m$ complex matrix A and let f be a complex m-vector, having components f_j. The unconstrained L_∞ complex approximation problem is then

$$(12)\quad \text{(CI)} \qquad \min_{z \in C^n} \max_{1 \leqq j \leqq m} |z^T A_j - f_j|,$$

where the vector of unknown z is taken to be a row vector, and "$|\cdot|$" is the complex absolute value.

A linearization of the nonlinear problem (CI) is based on the fact that

$$(13) \qquad |x + iy| = \max_{0 \leqq \theta < 2\pi} (x \cos \theta + y \sin \theta).$$

In order to obtain the tightest approximation based upon (13), a set of angles is selected according to

$$\theta_l = \pi(l-1)/p, \qquad l = 1, 2, \dots, 2p, \tag{14}$$

where $p \geqq 2$. We say that the *number of phase-shifted values* in an approximation based on (13) is $2p$. The integer p is thereby only *half* of them. Using this approximation problem, (CI) becomes

$$(\mathrm{CI}_p) \qquad \min_{z \in C^n} \max_{\substack{1 \leqq j \leqq m \\ 1 \leqq l \leqq 2p}} (z^T A_j - f_j)_{\theta_l},$$

where

$$\begin{aligned}(z^T A_j - f_j)_{\theta_l} &= (z^T A_j - f_j)^R \cos\theta_l + (z^T A_j - f_j)^I \sin\theta_l \\ &= z^R(A_j^R \cos\theta_l + A_j^I \sin\theta_l) + z^I(A_j^R \sin\theta_l - A_j^I \cos\theta_l) \\ &\quad - (f_j^R \sin\theta_l + f_j^I \sin\theta_l), \quad \text{a real quantity,}\end{aligned}$$

and where "R" and "I" denote real and imaginary parts of a complex quantity. Because of the choice of the θ_l's in (14), we see that

$$(z^T A_j - f_j)_{\theta_{p+l}} = (z^T A_j - f_j)_{(\pi + \theta_l)} = -(z^T A_j - f_j)_{\theta_l}.$$

Therefore, we may rewrite (CI_p) as an ordinary, two-sided, real approximation similar to the problems in § 4.1:

$$(\mathrm{CI}_p) = \min_{(z^R, z^I) \in R^{2n}} \max_{\substack{1 \leqq j \leqq m \\ 1 \leqq l \leqq p}} |(z^T A_j - f_j)_{\theta_l}|, \tag{15}$$

where the absolute value taken in (15) is just the real absolute value function.

As before, the primal LP problem associated with (15) will have $2n+1$ variables and $m(2p)$ linear inequalities. The dual LP problem, therefore, has $2n+1$ equations in $2pm$ variables. The current form of SHP will require taking (-1) times its objective function since SHP is a minimizer. Typically, for example, M could be 101 or 501. Typical numbers of full phase angle shifts yielding interesting problems could begin with 4, but recently Streit [34] has considered a class of problems with 1024 angle shifts.

A slight modification of the Streit and Nuttall [36] matrix generator, termed ZMAINS, generates the data for the following problem; see Streit [35].

In this application, a basis function is again of the form $\exp(ikx)$ over the interval $[u_0, 2-u_0]$, where k is a positive integer and where $u_0 = 0.0538117$. The function to be approximated is $f(x) = \exp(i49x)$. However, not all of the integers k from 1 to 48 are included in the list of basis functions. Some integer indices are to be omitted, specifically those in $\{7, 17, 21, 29\}$.

The experiments were conducted for approximating $f(x)$ by using various subsets of the full set of basis functions determined as follows.

Specify an integer N, $7 \leqq N \leqq 48$. Define $\{k_i\}_{i=1}^t$ to be $\{1, 2, \dots, N\} \backslash \{7, 17, 21, 29\}$, ordered according to $1 < k_1 < k_2 < \cdots < k_t$. Setting $\mathrm{NDEL} = \#\{1, 2, \dots, N\} \cap \{7, 17, 21, 29\}$ yields $t = N - \mathrm{NDEL}$. For example, if $N = 48$ and $M = 501$, then A is a complex matrix having 44 rows and 501 columns. If, in addition, there are $2p$ phase angle shifts, then the LP dual problem associated with (CI_p) of (15) has $2mp$ variables in $(2(N - \mathrm{NDEL}) + 1)$ equations.

The experiments reported below were done in single precision, which on the CRAY X-MP/48 gives approximately 14 digits. The decision on accuracy was based on the large, fully dense matrices generated for this problem. The numerical results are presented in Tables 6 and 7, where the initial start of § 4.1 was used for SHP.

It is our experience that EPS = 1.e − 12 is not sufficiently accurate for LINOP, and the small EPs of Table 6 are needed.

There is a loss of right-hand side accuracy with SHP compared to the approximation problems of §§ 4.1 and 4.2. $\|Ax^{(k)} - b\|_\infty$ ranges over (integer) * (10^{-6}) for the first five problems and (integer) * (10^{-5}) for the last three (and largest problems).

5. Computing the collapse state in material plastic limit analysis. During the last five years Christiansen and Kortanek have been applying sparse implementations of Dikin's [11] algorithm to a difficult class of LP problems arising in plastic collapse analysis. An earlier version of this manuscript contained preliminary results; see Beasley [4], which used the HYBY implementation of § 3. These results were improved using finer discretizations in Christiansen and Kortanek [9]. In 1989, they replaced the classical Hestenes and Stiefel conjugate gradient implementation with the highly accurate Paige and Saunders [30] least squares algorithm, and many variations of a two-dimensional plane strain problem were tested. In all of these experiments over all this time, Christiansen and Kortanek found that the stability enhancement of § 2 was essential.

The LP problems are constructed from a FORTRAN matrix generator that is easy to use. We give a description below so that others may also test their LP codes and compare their results with what we have obtained with the LP primal affine scaling algorithm.

The LP model has been put into the standard form (1) with the help of some slack variables based upon a discretization of the following plastic collapse problem. Consider a cube of a plastic material. In the y-x plane, make thin symmetric cuts $\frac{2}{3}$ of the distance to the center. Subject the cube to a uniform tensile force in the x-direction at the two surfaces given by $x=1$ and $x=-1$ (see Fig. 1) and increase this tensile force until the material collapses due to excessive interior stresses. The details are explained in Christiansen and Kortanek [9].

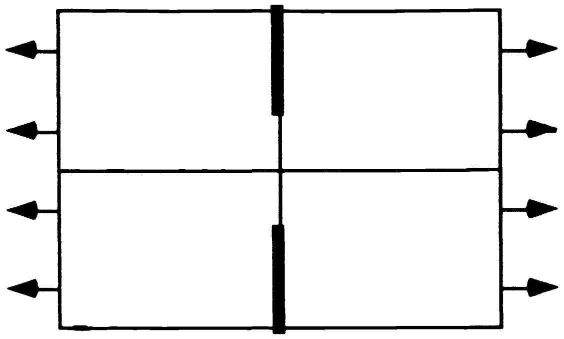

FIG. 1

The program takes as input the text file INDATA containing only one integer N, which must be a multiple of 3. $1/N$ is the element size in the finite element discretization. Varying N through values 3, 6, 9, ... will generate LP problems of increasing size. The outputs from the program are the data for LP (1) in sparse matrix form given in the three files discussed in § 3.3.

This test problem has a structure that is typical for problems in mechanics, but different from other LP test problems. The equality $\mathbf{Ax}=\mathbf{b}$ contains information on both the discrete equilibrium equation of the solid and on the inequalities (including slack variables) expressing the bounds on the stresses in the material.

It must be emphasized that not only the optimal value, but also primal and dual optimal vectors are important parts of the solution. There is evidence to the fact that at least the primal solution (representing the collapse stresses in the material) is not unique. In our experience Simplex codes cannot solve this problem as well as the LP primal affine scaling algorithm.

For large N the recent results obtained in Christiansen and Kortanek [10] were obtained using a modified version of the matrix generator. As it turned out, many of the linear constraints had positive slacks in the optimal solution obtained with the scaling algorithm. These constraints were eliminated and only checked a posteriori for the solution. This modification has not been possible when using Simplex codes. Insisting on extreme points apparently will introduce more active constraints "than necessary," when the optimal solution is nonunique. This modified set-up program is available upon request. Also available is a post-processor, which will extract fields for stresses and plastic flow from the primal and dual solutions and produce plots on a postscript printer.

6. Conclusions. All of the linear programs tested in this paper were constructed from discretizations of linear optimizations set in a continuum. Only the LP primal affine algorithm was tested on these problems during the five-year period beginning in 1985. An enormous amount of algorithmic development has occurred during this period, and a state-of-the-art survey on computer implementations was presented by Professor David Shanno at the SIAM National Meeting in Chicago in July, 1990.

In the numerical experiments reported in this paper, good convergence of objective function values was obtained within 20 Phase II iterations of the scaling algorithm. Whenever a Phase I routine was done, usually not more than three or four iterations were required. There were 30 computer runs reported in these experiments, on problems which can be considered large scale. Twenty-three of these were on fully dense Chebyshev approximation problems that are ill conditioned and require a large amount of storage. While the stable LP code LINOP provides the most accurate solutions, the scaling code SHP provides good approximations to the objective function values with significant speed-up in CPU time. For the membrane problem, there were additional checks on the accuracy of the optimal solutions themselves, and the results were favorable. In one membrane problem run, SHP indicated the presence of alternate optima.

No case was found where one code (LINOP or SHP) failed and the other did not. Typically, when a failure did occur, then ill-conditioning was experienced in SHP, while in LINOP an error message indicated that the QR factorization was inaccurate or that a nearly singular basis matrix had been detected. For the complex approximation problems, there was significant objective function value sensitivity to the choice of the relative precision parameters, EPS for LINOP and EP for SHP.

It is rather surprising that the large-scale results on these Chebyshev problems are "images" of earlier results obtained by solving much smaller Chebyshev approximation problems using PC equipment as well as an IBM 3083 mainframe at Carnegie-Mellon University. The number of Phase II iterations for these smaller problems were reported at the M.I.T. Mathematical Programming Symposium in August, 1985. They are quite consistent with the findings of the 23 experiments reported here.

Due in part to the immediate, interior point starting solution to the two-sided Chebyshev approximation problem, it can safely be asserted that the scaling algorithm returns a very good approximation to the objective function value at a significant speed-up over the simplex method.

Equally exciting are the results from applying HYBY to the highly sparse LP problem generated by the plane strain plastic limit analysis problem. The LP formulation is known to be highly degenerate with alternate optima. Over 15 years ago, Christiansen found that this was a difficult problem to solve because the extreme point solution delivered by a simplex method implementation depended upon the computer and simplex code used. It was therefore difficult to make inferences about the collapse fields of the true material whose extremal principal is formulated over a continuum.

Rather than presenting model details, we have referred the reader to Christiansen and Kortanek [9], [10] and made reference to the LP matrix generator, which the reader may obtain from either author. We have found the "stability enhancement" to be essential for these plasticity approximations, but perhaps readers and users may go directly to their own implementations of interior point methods to test their results against ours. We expect CPU speed-ups of at least a factor of 10 from using recently developed interior point methods. More essential for the understanding of material collapse, in our opinion, are the collapse fields themselves, which will require both primal and dual optimal linear programming solutions for particular discretizations.

Acknowledgments. This work greatly benefitted from discussions with R. Hettich during his sabbatical visit to Carnegie-Mellon University in the spring of 1986, and also from the earlier visits of Miao Gen Shi, E. Christiansen, and M. Vlach in 1985.

NUMERICAL COMPUTATION OF THE SCATTERING FREQUENCIES FOR A CYLINDRICALLY SYMMETRIC POTENTIAL*

MUSHENG WEI† AND GEORGE MAJDA‡

Abstract. In this paper, a novel numerical algorithm is described for computing the scattering frequencies (also called resonances, resonance poles, or poles of the scattering matrix) of a bounded, cylindrically symmetric potential with compact support in $\mathbb{R}^3$. The potential can be time independent, or it can depend periodically on time. The algorithm is based on a characterization of the scattering frequencies as the exponents in the long-time asymptotic expansion of the solution of the initial value problem for the time-dependent scalar wave equation perturbed by the potential. It uses a discretization of the initial value problem for the time-dependent wave equation perturbed by the potential combined with a procedure for extracting the exponents from the computed solution. A number of numerical computations are also presented to document the performance and reliability of the algorithm.

1. Introduction.

Scattering frequencies (SFs), also called resonances, resonance poles, or poles of the scattering matrix, form a discrete set of complex constants which occur in many scattering problems. Important examples include acoustic wave scattering by a bounded potential or in the exterior of a bounded obstacle, and electromagnetic wave scattering in the exterior of a dielectric or conducting body. In each of these problems, the SFs characterize the local rates of decay of a reflected wave, and thereby contain information about the scatterer (potential, obstacle, dielectric, conducting body). This fact is used by engineers and physicists to try to recover properties of a (usually unknown) scatterer from the SFs. See [1], [2], [5], [9], [13], and [14] for details.

Unfortunately, in each of the stated scattering problems, the precise relationship between a scatterer and its scattering frequencies is not completely understood. Furthermore, SFs can be explicitly determined in very few problems. In this paper, we develop a novel numerical algorithm for computing SFs. Our ultimate goal is to use the results of the calculations to help unravel the true relationship between a scatterer and its scattering frequencies (see [18] and [28]).

In this paper, we first consider scattering by a real-valued, compactly supported, time-independent potential $q(x)$ defined for $x \in \mathbb{R}^3$. We assume throughout this paper that $q(x) \in L^\infty(\mathbb{R}^3)$ and vanishes for $r = |x|_2 > R$ with $R < \infty$. ($L^\infty(\mathbb{R}^3)$ denotes the set of essentially bounded functions; $|\cdot|_2$ denotes the Euclidean norm.) Then we consider the case when a potential depends periodically on time.

The scattering frequencies of $q(x)$ can be characterized in several equivalent ways. See [28, § 4] for a short summary and [13] for a detailed explanation. We will state the two characterizations that are appropriate for our discussion.

The usual definition of a scattering frequency is a complex number σ for which there is a function $p(x)$ (not identically zero), called a *scattering eigenfunction*, such that

$$-\Delta p(x)+q(x)p(x)=\sigma^2 p(x), \tag{1.1}$$

$$p(x)\to \exp(-i\sigma r)/r \quad \text{as } r=|x|_2\to\infty. \tag{1.2}$$

Condition (1.2) is the classical outgoing radiation condition. This definition characterizes σ as a kind of eigenvalue. However, σ is not a true eigenvalue because $p(x)$ is not square integrable when $\operatorname{Im}\{\sigma\}>0$.

To formulate the second characterization of the SFs, we consider the initial value problem

$$u_{tt}-\Delta u+q(x)u=0 \quad \text{for } x\in\mathbb{R}^3, \quad t>0, \tag{1.3}$$

$$u(x,0)=f(x), \qquad u_t(x,0)=g(x), \tag{1.4}$$

where $f(x)$ and $g(x)$ have compact support. It can be shown (see [13] and [15]) that if

$$E(u(x,0))=\int_{\mathbb{R}^3}\left((g(x))^2+\sum_{i=1}^{3}(f_{x_i})^2\right)dx<\infty,$$

then for each fixed $x\in\mathbb{R}^3$, the solution of (1.3), (1.4) has a near-field expansion given by

$$u(x,t)\sim\sum_{j=1}^{\infty}c_j p_j(x)\,e^{i\sigma_j t} \quad \text{as } t\to\infty, \tag{1.5}$$

which is valid in the local energy norm. The constants c_j depend on the initial data, the functions $p_j(x)$ depend only on the potential and spatial location x (except in the case of multiple σ_j when powers of t may also occur), and the complex constants σ_j, the scattering frequencies, depend on the potential, but they are independent of the initial data and spatial location x. In fact, the functions $p_j(x)$ that appear in (1.5) are the solutions of (1.1), (1.2) with $\sigma=\sigma_j$.

A number of mathematical results have been proved about the SFs of a bounded compactly supported potential $q(x)$. In this introduction we state only those results that are relevant to our discussion.

For general (real) potentials $q(x)$, it is known that there are, at most, a countable number of complex SFs σ_j that are symmetric with respect to the imaginary axis and satisfy $\operatorname{Im}\{\sigma_j\}\to+\infty$ as $j\to\infty$ (see [13], [16], and [20]). Consequently, we can order the SFs by the relation $\operatorname{Im}\{\sigma_j\}\leqq\operatorname{Im}\{\sigma_{j+1}\}$. (The SFs σ_j, $j=1,\dots,N$ are called the first N leading SFs.)

More precise information is available for radially symmetric potentials $q(r)$ with $r=|x|_2$. Let (r,θ,φ) denote the usual spherical coordinates of a point in $\mathbb{R}^3$. Look for solutions of (1.3) with the form

$$u(x,t)=u(r,\theta,\phi,t)=e^{i\sigma t}h(r)Y_e^m(\theta,\varphi),$$

where $Y_e^m(\theta,\varphi)$ is a spherical harmonic of order l, $l=0,1,2,\dots$, and $|m|\leqq l$. Then $h(r)$ satisfies

$$-\frac{d^2h(r)}{dr^2}-\frac{2}{r}\frac{dh(r)}{dr}+\left(q(r)+\frac{l(l+1)}{r^2}\right)h(r)=\sigma^2h(r), \tag{1.6}$$

$$h(r)\to\exp(-i\sigma r)/r \quad \text{as } r\to\infty.$$

Newton (see [19] or [20, Chap. 12]) shows that the resonances (SFs) of $q(r)$ are precisely the values $\sigma_{l,j}$, $l=0,1,2,\dots,j=1,2,\dots$, such that (1.6) has a nontrivial solution $h(r)=h_{l,j}(r)$ when $\sigma=\sigma_{l,j}$. The SFs $\sigma_{0,j}$, $j=1,2,\dots$ are called the *radial scattering frequencies* of $q(r)$, while the remaining SFs of $q(r)$ are called *nonradial scattering frequencies.*

Despite the extensive work by mathematicians and physicists on the SFs of a potential, the properties of SFs are not completely understood. Since scattering frequencies can be explicitly determined only for very special potentials, it is important to develop reliable numerical algorithms to compute them.

There are several ways to numerically compute the SFs of a given potential. One method consists of discretizing the elliptic equation (1.1) with an appropriate boundary condition at the edge of a truncated domain. This procedure is discussed and applied in [6], [7], [22], and [23]. These authors are primarily concerned with long-range potentials which depend on the relative distances between several interacting particles. The methods in these papers have not been applied to potentials that have a nonradial spatial dependence, and they cannot be used when the potential depends periodically on time. A second method consists of rewriting (1.1), (1.2) as an appropriate integral equation and approximating the integral equation. Unfortunately, like the first procedure, this method cannot be used for potentials which depend periodically on time. A third method is based on the characterization of the SFs as the exponents in the long-time asymptotic expansion (1.5) of the solution of the initial value problem for (1.3). In a previous paper with Strauss [28], we used this characterization of the SFs to compute a finite number of leading radial SFs of some time-independent and periodically oscillating radially symmetric potentials. In this paper, we show how to modify the numerical algorithm in [28] in order to compute some nonradial SFs of a radially symmetric potential, and some SFs of potentials with cylindrical symmetry. The modified algorithm can be used to compute SFs for time-independent potentials and potentials that depend periodically on time.

Our numerical algorithm for computing the SFs of a potential consists of several steps. First, we choose a spatial location x and estimate a *finite time* $t_\infty(x)$, such that the asymptotic expansion (1.5) approximates the solution of (1.3), (1.4) for $t \geqq t_\infty(x)$. A formula for $t_\infty(x)$ based on the range of influence of the initial data is discussed in § 2.

In the second step, we solve the initial value problem (1.3), (1.4) using any convenient (but nontrivial) initial data with compact support. The numerical procedure can be any appropriate method such as a finite difference, Galerkin, or pseudospectral method. The main constraint on the numerical method is that it must produce an extremely accurate solution so that the SFs can be computed from the numerical solution. In § 3 we present a pseudospectral method for solving problem (1.3), (1.4) when the potential is cylindrically symmetric. In § 4 we discuss appropriate choices for the initial data (1.4), and in § 5 we explain the need for an extremely accurate numerical solution of problem (1.3), (1.4).

In the third step of our algorithm, we calculate the exponents in (1.5) from the numerical solution of (1.3), (1.4) evaluated at location x and at equally spaced times. To explain this procedure, set $t=t_k=t_\infty(x)+k\Delta T$, $u_k=u(x,t_\infty(x)+k\Delta T)$ for $k=1,2,\dots$, and $z_j=\exp(i\sigma_j\Delta T)$, $j=1,2,\dots$. Then the asymptotic expansion (1.5) approximates the exact solution and takes the form

$$u_k \approx \sum_{j=1}^{\infty} a_j(z_j)^k \quad \text{for } k=0,1,2,\dots,$$

where the a_j's are constants defined by $a_j = c_j p_j(x) \exp(i\sigma_j t_\infty(x))$. Therefore, in step 3 we calculate the z_j's from the u_k's. Of course, only a finite number of z_j's can be calculated. We have already discussed this delicate problem in [17], [26], and [27]. Our method implements a modified and improved version of a classical method due to Prony [21], which reduces the problem of computing the z_j's from the u_k's to solving overdetermined systems of linear equations (by least squares) and then finding roots of polynomials. In § 5 we discuss our version of Prony's method and the need for a highly accurate numerical solution of (1.3), (1.4).

In the last step of our algorithm, we check the accuracy of the results by repeating steps 1-3 using different sampling locations x with the same initial data. Since the mathematical theory of SFs shows that they are independent of the sampling location, the computed SFs should repeat when steps 1-3 are applied at different sampling locations.

In § 6 we present some numerical results that demonstrate the accuracy and reliability of our algorithm for computing nonradial SFs of time-independent radial potentials and potentials with cylindrical symmetry. We also consider potentials that depend periodically on time.

In § 7 we summarize the conclusions of our work and list other important scattering problems where our algorithm can be used.

Notation. The cylindrical coordinates (ρ, θ, z) of a point $(x, y, z) \in \mathbb{R}^3$ are defined by

$$x = \rho \cos\theta, \quad y = \rho \sin\theta, \quad z = z.$$

The spherical coordinates (r, θ, φ) of a point $(x, y, z) \in \mathbb{R}^3$ are defined by

$$x = r \sin\varphi \cos\theta, \quad y = r \sin\varphi \sin\theta, \quad z = r \cos\varphi.$$

2. Choice of $t_\infty(x)$.

It might seem difficult (if not impossible) to use the characterization of the SFs as the exponents in (1.5) to compute them. This characterization requires a long-time computation with a potentially large accumulation of roundoff and truncation errors which would destroy the accuracy of the computations. In [28] we presented an estimate for $t_\infty(x)$, the approximate time when (1.5) is valid at location x, when the potential $q(x)$ in (1.3) is radially symmetric. The argument in [28], based on Huyghen's principle for the wave equation in three dimensions, also applies when the potential is not radially symmetric.

If $q(x) \equiv 0$ for all $x \in \mathbb{R}^3$, the solution of (1.3), (1.4) propagates along the characteristics of the wave equation emanating from the initial data. Furthermore, if the supports of $f(x)$ and $g(x)$ are contained in a ball centered at the origin with finite radius R, then Huyghen's principle implies that for any $x \in \mathbb{R}^3$, the solution of (1.3), (1.4) satisfies $u(x, t) \equiv 0$ for $t \geqq |x|_2 + R$. Therefore, location x feels all of the influence of the initial data in the finite time interval $[0, |x|_2 + R]$.

If $q(x) \not\equiv 0$, then the solution of (1.3), (1.4) still propagates along the characteristics of the wave equation emanating from the initial data. Therefore, location x feels the direct influence of the initial data in the finite time interval $0 \leqq t \leqq |x|_2 + R$, and the residual influence of the initial data when $t > |x|_2 + R$. Consequently, we choose $t_\infty(x) = |x|_2 + R$. This choice is reasonable from the point of view of theory, and actual calculations on problems with exact solutions support this choice.

3. Numerical approximations of the perturbed wave equation.

In this section we describe a pseudospectral method to approximate the initial value problem (1.3), (1.4) when the potential q and the initial data are cylindrically symmetric. Before discussing the numerical method we make some important remarks.

Remark 1. We are able to determine a finite time $t_\infty(x)$ where (1.5) is approximately valid, so we only need to solve the initial value problem (1.3), (1.4) for a finite time interval $[0, T]$ with $T < \infty$ to compute the SFs from the numerical solution.

Remark 2. Let $B(0, R) = \{x \in \mathbb{R}^3 \colon |x|_2 \leqq R\}$. If the potential $q(x)$ and the initial data $f(x)$ and $g(x)$ have their supports contained in $B(0, R)$ with $R < \infty$, then Huyghen's principle implies that the solution of (1.3), (1.4) satisfies $u(x, t) \equiv 0$ for $|x| \geqq R + t$. Therefore, if we set $D = \{(x, t)\colon |x| \leqq R + T \text{ and } 0 \leqq t \leqq T\}$, then the initial value problem (1.3), (1.4) can be equivalently rewritten as the initial boundary value problem

$$u_{tt} - \Delta u + q(x)u = 0, \quad \text{for } (x, t) \in D, \tag{3.1}$$

$$u(x, 0) = f(x), \qquad u_t(x, 0) = g(x), \tag{3.2}$$

$$u(x, t) \equiv 0 \quad \text{for } |x| = R + T, \quad 0 \leqq t \leqq T. \tag{3.3}$$

This reformulation is used to reduce the amount of storage required to implement the numerical methods, and to suggest appropriate basis functions for the pseudospectral method.

Remark 3. Our numerical algorithm can be used to compute SFs of potentials $q(x)$ with $x \in \mathbb{R}^3$. However, due to computer storage limitations, we consider only the case when the potential and the initial data have cylindrical symmetry, that is, $q = q(\rho, z), f = f(\rho, z)$, and $g = g(\rho, z)$. Under this assumption the solution u of (3.1)-(3.3) is independent of θ, i.e., $u = u(\rho, z, t)$, and satisfies

$$u_{tt} - \left(u_{\rho\rho} + \frac{1}{\rho} u_\rho + u_{zz}\right) + q(\rho, z)u = 0 \tag{3.4}$$

$$\text{for } 0 < t \leqq T, \quad 0 \leqq \rho \leqq R + T = a, \quad |z| \leqq a,$$

$$u(\rho, z, 0) = f(\rho, z), \qquad u_t(\rho, z, 0) = g(\rho, z), \tag{3.5}$$

$$u_\rho(0, z, t) = 0 \quad \text{(regularity condition)}, \tag{3.6}$$

$$u(\rho, z, t) \equiv 0 \quad \text{for } \rho = a, \quad z = \pm a, \quad \text{and} \quad 0 \leqq t \leqq T. \tag{3.7}$$

We first tried to discretize problem (3.4)-(3.7) by finite difference methods in three different ways. A straightforward approximation of (3.4) using central difference quotients does not work due to the coordinate singularity at $r = 0$. We tried to modify this scheme by using a special averaging formula at the origin in the manner described by Strikwerda [30, pp. 386-387]. This method also did not produce an accurate solution. Finally, we approximated problem (3.4)-(3.7) using an idea due to Lapidus [29]. The idea is to solve the three-dimensional wave equation in Cartesian coordinates (to avoid the $1/r$ singularity) on an appropriate subset of grid points using the standard central difference approximation, and then to use the imposed symmetry and an interpolation procedure to generate an approximation to $u(\rho, \theta, t)$ at the other necessary grid points. This method produced reasonable results (see [26]) but the results were not as accurate as the ones obtained using the pseudospectral collocation method, which we will describe. Furthermore, this finite-difference procedure required a significantly longer CPU time to solve (3.4)-(3.7) than the pseudospectral method.

To discretize problem (3.4)-(3.7) by the pseudospectral method [10] or [25], we approximate $u(\rho, z, t)$ by

$$u_{N,M}(\rho, z, t) = \sum_{i=1}^{N} \sum_{j=1}^{M} b_{ij}(t) J_0(\lambda_i \rho / a) \sin(\pi j (z + a)/2a), \tag{3.8}$$

where $J_0(x)$ is the Bessel function of order zero, $a = R + T$, and λ_i, $i = 1, \dots, N+1$ are the first $(N+1)$ zeros of $J_0(x)$, which are arranged in increasing order so that $\lambda_{i+1} > \lambda_i$, $i = 1, \dots, N$. We use the Bessel functions $J_0(\lambda_i \rho/a)$ in the ρ-direction in order to eliminate the coordinate singularity at $\rho = 0$ in (3.4), and to make the numerical approximation $u_{N,M}(\rho, z, t)$ vanish at the boundary $\rho = a$. We use the functions $\sin(\pi j(z+a)/2a)$ in the z-direction because the exact solution of (3.4) satisfies $u(\rho, \pm a, t) = 0$ for $t < T$. Furthermore,

$$\frac{d^p u(\rho, \pm a, t)}{\partial z^p} = 0 \quad \text{for } p = 0, 1, 2, \dots \quad \text{and} \quad \frac{d^p}{dx^p} \sin(x)\bigg|_{x = \pm \pi j} = 0 \quad \text{for } p \text{ even},$$

so the choice of basis functions preserve some additional properties of the exact solution.

We use the collocation points given by

$$\text{(3.9)} \quad \rho_k = a\lambda_k/\lambda_{N+1}, \quad k = 1, \dots, N \quad \text{and} \quad z_l = a(2l/(M+1) - 1), \quad l = 1, \dots, M.$$

The collocation points z_l, $l = 1, \dots, M$ are equally spaced in the z-direction and, since $\lambda_k \approx (k - \frac{1}{4})\pi$, $k = 1, \dots,$ the collocation points ρ_k, $k = 1, \dots, N$ are nearly equally spaced in the ρ-direction. These facts permit us to use an explicit scheme with a reasonable time step when we discretize (3.4) in time (see (3.20)).

Equations for the unknowns $b_{ij}(t)$ are determined by substituting (3.8) into (3.4), evaluating the resulting expression at each collocation point (ρ_k, z_l), and using the definition of $J_0(x)$. This process yields the system of ordinary differential equations

(3.10)

$$\sum_{i=1}^{N} \sum_{j=1}^{M} \left(\frac{d^2}{dt^2} b_{ij}(t) + b_{ij}(t)(\lambda_i/a)^2 + b_{ij}(t)(j\pi/2a)^2 + b_{ij}(t) q(\rho_k, z_l) \right)$$
$$\times J_0(\lambda_i \lambda_k/\lambda_{N+1}) \sin(jl\pi/(M+1)) = 0 \quad \text{for } k = 1, \dots, N \quad \text{and} \quad l = 1, \dots, M.$$

System (3.10) can be rewritten in a concise way by introducing appropriate matrices. Set

$$U_{NM}(t) = (u_{NM}(\rho_k, z_l, t))_{N\times M},$$
$$J_N = (J_0(\lambda_i \lambda_k/\lambda_{N+1}))_{N\times N},$$
$$S_M = \sqrt{2/(M+1)}\,(\sin(jl\pi/(M+1)))_{M\times M},$$
$$B(t) = (b_{ij}(t))_{N\times M}, \qquad \Lambda_N = \operatorname{diag}((\lambda_1/a)^2, \dots, (\lambda_N/a)^2),$$
$$\Sigma_M = \operatorname{diag}((\pi/2a)^2, \dots, (M\pi/2a)^2),$$
$$V_{NM}(t) = (q(\rho_k, z_l) \cdot u_{NM}(\rho_k, z_l, t))_{N\times M},$$

then J_N is symmetric, S_M is orthogonal, i.e., $S_M^{-1} = S_M^T = S_M$, and $U_{NM}(t) = J_N B(t) S_M$. Furthermore, if J_N is invertible (see Remark 4), then

$$B(t) = J_N^{-1} U_{NM}(t) S_M^{-1} = J_N^{-1} U_{NM}(t) S_M,$$

and (3.14) can be rewritten as

$$\text{(3.11)} \quad \begin{aligned} \frac{d^2}{dt^2} U_{NM}(t) &= -(J_N \Lambda_N J_N^{-1} U_{NM}(t) + U_{NM}(t) S_M \Sigma_M S_M + V_{NM}(t)) \\ &= F(U_{NM}(t)). \end{aligned}$$

The initial conditions for (3.11), obtained from (3.5), are given by

$$\text{(3.12)} \qquad U_{NM}(0) = (f(\rho_k, z_l))_{N\times M} \quad \text{and} \quad \frac{dU_{NM}(0)}{dt} = (g(\rho_k, z_l))_{N\times M}.$$

Remark 4. We have been unable to prove that J_N is invertible for all values of N. However, we have numerically computed the eigenvalues and the condition numbers for J_N for $N \leqq 200$. In all cases, we have found that J_N is invertible, and that the condition number $K = \|J_N\|_2 \|J_N^{-1}\|_2 < AN^\alpha + B$, where $\alpha < 0.6$, A and $B < 10$, and $\|\cdot\|_2$ denotes the matrix norm subordinate to the usual Euclidean norm.

We approximate the second-order initial value problem (3.11), (3.12) by the stable variant of Stoermer's rule introduced by Henrici [12] combined with two steps of active Richardson extrapolation. An excellent discussion of this method is presented in [8]. Specifically, let $h > 0$ denote a time step, let $\tilde{v}^n$ denote the numerical approximation of $v_{NM}(nh)$, and set $\Delta_k = \tilde{v}^{k+1} - \tilde{v}^k$. The stable variant of Stoermer's rule is defined by

$$\Delta_0 = h\left(\dot{v}_{NM}(0) + \frac{h}{2} F(v_{NM}(0))\right), \qquad \tilde{v}^1 = v_{NM}(0) + \Delta_0, \tag{3.13}$$

$$\Delta_k = \Delta_{k-1} + h^2 F(\tilde{v}^k), \quad \tilde{v}^{k+1} = \tilde{v}^k + \Delta_k, \quad k = 1, \dots, l-1, \tag{3.14}$$

$$w^l = \frac{\Delta_{l-1}}{h} + \frac{h}{2} F(\tilde{v}^l). \tag{3.15}$$

(w^l is an approximation of $\dot{v}_{NM}(lh)$.) Gragg [11] showed that if the solution of (3.11) is sufficiently smooth in time, then

$$\tilde{v}^n = v_{NM}(nh) + h^2 c_2 + h^4 c_4 + 0(h^6), \qquad n = 1, \dots, l,$$

where c_2 and c_4 are constants. So Stoermer's rule is second-order accurate in time and two steps of active Richardson extrapolation can be applied at each step to obtain a sixth-order accurate approximation of $v_{NM}(nh)$, $n = 1, \dots, P$, in time.

To complete our discussion of the pseudospectral method, we first derive a sufficient condition for the stability of the pseudospectral method and then discuss the rate of convergence of the method.

We only need to determine conditions under which method (3.13)-(3.15) is stable because the stable variant of Stoermer's rule combined with two steps of Richardson extrapolation is also stable under the stability condition derived for method (3.13)-(3.15).

Equation (3.14) can be rewritten as

$$\tilde{v}^{k+1} - 2\tilde{v}^k + \tilde{v}^{k-1} - h^2 F(\tilde{v}^k) = 0, \qquad k = 1, \dots, l-1. \tag{3.16}$$

The potential $q \in L^\infty(\mathbb{R}^3)$, so we can set $V_{NM}(t) \equiv 0$ in (3.11) to determine a sufficient condition for stability. If $V_{NM}(t) \equiv 0$, then (3.16) becomes

$$J_N(\tilde{B}^{k+1} - 2\tilde{B}^k + \tilde{B}^{k-1} + h^2(\Lambda_N \tilde{B}^k + \tilde{B}^k \Sigma_M))S_M = 0, \tag{3.17}$$

where B^k is the $N \times M$ matrix satisfying $\tilde{v}^k = J_N \tilde{B}^k S_M$.

S_M is invertible and J_N is invertible by assumption, so (3.17) implies that

$$\tilde{B}^{k+1} - 2\tilde{B}^k + \tilde{B}^{k-1} + h^2(\Lambda_N \tilde{B}^k + \tilde{B}^k \Sigma_M) = 0. \tag{3.18}$$

Equation (3.18) constitutes a set of NM decoupled equations for the entries $\tilde{B}_{ij}$ given by

$$(\tilde{B}_{ij})^{k+1} - 2(\tilde{B}_{ij})^k + (\tilde{B}_{ij})^{k-1} + h^2\left(\left(\frac{\lambda i}{a}\right)^2 + \left(\frac{j\pi}{2a}\right)^2\right)(\tilde{B}_{ij})^k = 0,$$

$$i = 1, \dots, N, \qquad j = 1, \dots, M.$$

A straightforward calculation shows that $|\tilde{B}ij|\leqq 1$ for all i and j if and only if

$$h^2\left[\left(\frac{\lambda_N}{a}\right)^2+\left(\frac{M\pi}{2a}\right)^2\right]\leqq 4.$$

This inequality leads to the *stability condition*

$$h\leqq\frac{2a}{\sqrt{(\lambda_N)^2+((M\pi)/2)^2}}. \tag{3.19}$$

We note that the right side of (3.19) is easily estimated. Use the well-known asymptotic result $\lambda_N\approx(N-\frac{1}{4})\pi$ as $N\to\infty$ to get the *estimated stability condition*

$$h\leqq\frac{2a}{\pi\sqrt{(N-\frac{1}{4})^2+(M/2)^2}}. \tag{3.20}$$

We now present a result pertaining to the rate of convergence of the proposed pseudospectral method. In the theorem presented below, we prove that the approximate functions $u_{N,M}(\rho, z, t)$ defined by (3.8) converge to a C^∞ solution of problem (3.4)-(3.7) with infinite-order accuracy provided that the coefficients $b_{ij}(t)$ are the exact Fourier-Bessel coefficients. We believe that the solution of the semi-discrete pseudospectral collocation procedure defined by (3.11) and (3.12) also converges to a C^∞ solution of problem (3.4)-(3.7) with infinite-order accuracy; unfortunately, we have been unable to prove this. However, for the calculations that we perform in § 6, this result is not very important. In most of these calculations we consider potentials that are piecewise smooth. In such cases, the solution of problem (3.4)-(3.7) is not C^∞.

THEOREM. *Let $f(\rho, z)\in C^\infty([0,1],[0,2\pi])$ be a function that satisfies*

(i) $f(-\rho, z)=f(\rho, z)$,

(ii) $\partial f/\partial\rho(0, z)=0$,

(iii) $\partial^j f(1, z)/\partial\rho^j=0$ *for* $j=0, 1, 2, \dots,$ *and*

(iv) $(\partial^j f/\partial z^j)(\rho, 0)=0=(\partial^j f/\partial z^j)(\rho, 2\pi)$ *for* $j=0, 1, 2, \dots$.

Then the approximation

$$a_{N,M}(\rho, z)=\sum_{i=1}^{N}\sum_{j=1}^{M} c_{ij}J_0(\lambda_i\rho)\sin(\pi jz)$$

with

$$c_{ij}=\frac{4}{\pi J_0'(\lambda_i)^2}\int_0^\pi\int_0^1 f(\rho,\theta)J_0(\lambda_i\rho)\sin(j\theta)\rho\,d\rho\,d\theta$$

converges to $f(\rho, z)$ in the L_2 norm (with weight ρ) with infinite order of accuracy.

Proof. Mimic the argument in Gottlieb and Orszag [10, pp. 29-33] with respect to ρ and then z. The stated conditions permit unlimited integration by parts for c_{ij} in each variable, so the conclusion is justified.

4. Choice of initial data. To implement our algorithm for computing the SFs of a potential $q(x)$ we need to specify initial data (3.5). According to the mathematical theory in [13], the asymptotic expansion (1.5) is valid for any initial data with compact support and finite energy. So, in principle, any reasonable compactly supported initial data can be used in our algorithm to approximate SFs. In our computations we made special choices for the initial data motivated by some simple theoretical considerations.

We first consider the case when the potential $q(x)$ is radially symmetric, i.e., $q(x)=q(r)=q(|x|_2)$. The basic theoretical results about SFs presented in the introduction show that the SFs of a radial potential depend on the order l of the spherical harmonic $Y_l^m(\theta,\varphi)$, but not on the index m. Furthermore, for each value of l, each SF $\sigma_{l,j}$ corresponds to a scattering eigenfunction with the form $h_{l,j}(r,\theta,\varphi)=h_{l,j}(r)Y_l^0(\theta,\varphi)=h_{l,j}(r)S_l(\varphi)$. These results suggest that we should use initial data with the form

$$u(x,0)=h_1(r)S_l(\varphi),\quad u_t(x,0)=h_2(r)S_l(\varphi),\quad l=0,\dots, \tag{4.1}$$

where $h_1(r)$ and $h_2(r)$ are smooth, compactly supported functions, in order to compute the SFs $\sigma_{l,j}$, $j=0,1,\dots$, for each value of l. In the computations reported in § 6, we used cylindrically symmetric initial data with the form (4.1) with the specific values

$$\begin{aligned} u(\rho,z,0)&=\begin{cases}10^5r^2(0.3-r)S_0(\varphi)=10^5r^2(0.3-r) & \text{for } r=\sqrt{\rho^2+z^2}\leqq 0.3,\\ 0 & \text{for } r\geqq 0.3,\end{cases}\\ u_t(\rho,z,0)&=\begin{cases}r(0.3-r)S_0(\varphi)=r(0.3-r) & \text{for } r\leqq 0.3,\\ 0 & \text{for } r\geqq 0.3,\end{cases}\end{aligned} \tag{4.2}$$

to approximate a finite number of leading radial SFs $\sigma_{0,j}$, $j=1,2,\dots$,

$$\begin{aligned} u(\rho,z,0)&=\begin{cases}10^5r^2(0.3-r)S_1(\varphi)=10^5r(0.3-r)z & \text{for } r=\sqrt{\rho^2+z^2}\leqq 0.3,\\ 0 & \text{for } r\geqq 0.3,\end{cases}\\ u_t(\rho,z,0)&=\begin{cases}r^2(0.3-r)S_1(\varphi)=r(0.3-r)z & \text{for } r\leqq 0.3,\\ 0 & \text{for } r\geqq 0.3,\end{cases}\end{aligned} \tag{4.3}$$

to approximate a finite number of leading SFs $\sigma_{1,j}$, $j=1,2,\dots$, and

$$\begin{aligned} u(\rho,z,0)&=\begin{cases}10^5r^2(0.3-r)S_2(\varphi)=10^5(0.3-r)(3z^2-r^2) & \text{for } r=\sqrt{\rho^2+z^2}\leqq 0.3,\\ 0 & \text{for } r\geqq 0.3,\end{cases}\\ u_t(\rho,z,0)&=\begin{cases}r^2(0.3-r)S_2(\varphi)=(0.3-r)(3z^2-r^2) & \text{for } r\leqq 0.3,\\ 0 & \text{for } r\geqq 0.3,\end{cases}\end{aligned} \tag{4.4}$$

to approximate a finite number of leading SFs $\sigma_{2,j}$, $j=1,2,\dots$.

In the second case where the potential is not radially symmetric, there is no decomposition of the SFs according to the spherical harmonics $S_l(\phi)$. However, we have found that if we use initial data with the form (4.1), then we obtain interesting results about the SFs (see § 6). This choice for the initial data is just one out of numerous choices that can be made to compute SFs of nonradial potentials with our algorithm.

5. The computation of the scattering frequencies from the numerical solution. We have thoroughly discussed the important and delicate problem of computing scattering frequencies from a time series in [17], [26], [27], and [28]. Consequently, we only show how to formulate our problem so that we can use the numerical procedure discussed in these papers.

First, assume that the exact solution $u(x,t)$ of problem (1.3), (1.4) is known. By the discussion in § 2, for each fixed $x\in\mathbb{R}^3$,

$$u(x,t)=\sum_{j=1}^{N}c_jp_j(x)\,e^{i\sigma_jt}+\varepsilon_N(x,t)\quad\text{for } t\geqq t_\infty(x), \tag{5.1}$$

where $\varepsilon_N(x,t)=0(e^{\operatorname{Im}\sigma_Nt})\to 0$ as $N\to\infty$.

Fix the spatial location x and set $t=t_n=t_\infty(x)+n\Delta T$, $u^n=u(x,t_n)$, $d_j=c_jp_j(x)\exp(i\sigma_jt_\infty(x))$, $z_j=e^{i\sigma_j\Delta T}$, and $\varepsilon_N^n=\varepsilon_N(x,t_n)$. Then (5.1) becomes

$$u^n=\sum_{j=1}^N d_j(z_j)^n+\varepsilon_N^n, \qquad n=0,1,\dots, \tag{5.2}$$

where $\varepsilon_N^n\to 0$ as $n\to\infty$ with N fixed or as $N\to\infty$ with n fixed. (The positive constant ΔT is called the Prony sample rate.)

Now let v^n be the numerical solution at location x for time t_n. If v^n is computed by a stable and consistent numerical method, then

$$u^n=v^n-E^n, \qquad n=0,\dots,$$

for some error E^n and (5.2) becomes

$$v^n=\sum_{j=1}^N d_j(z_j)^n+\varepsilon_N^n+E^n, \qquad n=0,\dots. \tag{5.3}$$

Equation (5.3) shows that the numerical solution of problem (1.3), (1.4) contains a finite number of poles z_j, plus an error term $(\varepsilon_N^n+E^n)$. If the error is sufficiently small, then v^n contains only a finite number of poles, which we can compute by applying the version of Prony's method presented in [17] until a subset of poles repeats in successive trials.

6. Reliability of the computational method. In this section we present some computational results about the SFs of bounded, cylindrically symmetric potentials with compact support in $\mathbb{R}^3$. We consider a piecewise constant radially symmetric potential for which we can explicitly determine the SFs. We use this example to document the performance and reliability of our algorithm.

The primary check of the reliability of our numerical algorithm is to look for repetitions of the scattering frequencies as various parameters are changed. In particular, assuming that the numerical solution is sufficiently accurate, we change (i) the presumed number p of poles and (ii) the sample locations. By a sample location, we mean the fixed spatial point x, the time series sample rate ΔT, and the starting time $t_\infty(x)$. A calculation is considered accurate insofar as its repeats under a variety of choices (i) and (ii). In general, we have found that SFs start to repeat in successive trials only when the smallest singular value of the Prony data matrices (defined in [17]) has the same order as the numerical error in solving the wave equation. Furthermore, fewer than p SFs repeat when we assume that the solution contains p poles. See [17] for details.

In the first example, we consider the radially symmetric potential defined by

$$q(r)=6 \quad \text{for } 0\leqq r\leqq 0.3, \qquad q(r)=0 \quad \text{for } r>0.3. \tag{6.1}$$

The results in [19], quoted in the introduction to this paper, show that the SFs of $q(r)$ form a doubly indexed sequence $\sigma_{l,j}$, $l=0,1,\dots,j=1,2,\dots$. It is easily established [26] that each SF $\sigma_{l,j}$ is a root of the nonlinear equation

$$\frac{I_{l+1/2}(0.3\beta)}{I'_{l+1/2}(0.3\beta)}=\frac{\beta}{\lambda}\times\frac{K_{l+1/2}(0.3\lambda)}{K'_{l+1/2}(0.3\lambda)}, \tag{6.2}$$

where $'$ denotes the derivative, $\lambda=i\sigma_{l,j}$, $\beta=\sqrt{\lambda^2+6}$, and $I_{l+1/2}$, $K_{l+1/2}$ are the modified Bessel functions defined by

$$K_{l+1/2}(z)=z^{l+1/2}\left(\frac{1}{z}\frac{d}{dz}\right)^l\left(\frac{e^{-z}}{z}\right)$$

and

$$I_{l+1/2}(z) = z^{l+1/2}\left(\frac{1}{z}\frac{d}{dz}\right)^l\left(\frac{\sinh z}{z}\right).$$

In Table 6.1 we list the actual leading SFs ordered by $\operatorname{Im}\{\sigma_{l,j}\} \leqq \operatorname{Im}\{\sigma_{l,j+1}\}$ for each value of l. (These results were obtained by using Muller's method [3] with error tolerances 10^{-10}.)

We approximate the SFs of (6.1) by using the pseudospectral method combined with Prony's method. We use initial data (4.2)-(4.4) to compute approximations of $\sigma_{l,j}$, $l = 0, 1, 2$, respectively. The parameters for the pseudospectral method are $h = 0.01$, $N = 39$, $M = 79$, $a = 1.426$ for $l = 0$; $a = 1.433$ for $l = 1$; and $a = 1.434$ for $l = 2$. The Prony sample rate is $\Delta T = 0.02$ and the sampling location is $(\rho, z) = (\rho_1, z_{44})$, where ρ_1 and z_{44} are collocation points defined by (3.9). For each value of l, the SFs repeated in successive trials in the Prony algorithm when we assumed that the numerical solution at the sampling location contained 28, 29, and 30 SFs. The SFs repeated in successive trials with at least four significant digits, so we have reported all results with four digits. (All computations in this paper were done in single precision on the Cray 2 at the University of Minnesota and the Cray X/MP at the NSF Supercomputer Center in Pittsburgh.) The numerical approximations of the SFs of potential (6.1) are listed in Table 6.2.

Table 6.2 shows that for $l = 0$, our algorithm with the pseudospectral method computes six pairs of leading SFs with two to three significant digits of accuracy; for $l = 1$, the algorithm computes the leading SF with four significant digits of accuracy and the next four pairs of leading SFs with two to three significant digits of accuracy; and for $l = 2$, the algorithm computes the leading pair of SFs with one significant digit of accuracy and the next five pairs of leading SFs with one to two significant digits of accuracy.

$\pm 62.52 + 13.39i$		$\pm 60.31 + 13.09i$

Remark 5. In all calculations in this paper that used the pseudospectral method combined with the Prony algorithm, the parameters for the pseudospectral method, the Prony sample rate, and the sampling location are always the same ones used for potential (6.1). In all cases, the SFs repeated in successive trials in the Prony algorithm with at least four significant digits when we assumed that the numerical solution at the sampling location contained 28, 29, and 30 SFs.

For each potential we carried out a numerical convergence study by increasing the number of basis elements, reducing the time step, and changing the sampling location. When the number of basis functions was increased beyond $N = 39$ and $M = 79$, and the time step reduced below $h = 0.01$, the accuracy of the computed SFs at a given sampling location did not improve. When the sampling location was changed for a computed solution using $N \geqq 39$, $M \geqq 79$, and $h \leqq 0.01$, the SFs changed (in absolute value) by an amount $\leqq 10^{-3}$.

Now we discuss the numerical computation of the SFs for the potentials which depend periodically on time. We present an extension of the theory of SFs in this case (the main reference is [5]) and show that our algorithm for computing SFs applies in this case.

Let $q(x, t)$ be a bounded function that vanishes for $|x|_2 > R$, and is periodic in time with period P, so that $q(x, t+P) = q(x, t)$ for all x, t. Consider the equation

$$u_{tt} - \Delta u + q(x, t)u = 0, \quad x \in \mathbb{R}^3, \quad t > 0, \tag{6.3}$$

with initial conditions (1.4). If the initial data has compact support, then under reasonable conditions, it can be shown that for each fixed x

$$u(x, t) \to \sum_{j=1}^{\infty} c_j p_j(x, t)\, e^{i\sigma_j t} \quad \text{as } t \to \infty. \tag{6.4}$$

(The asymptotic expansion is valid in the local energy norm.) The constants c_j depend on the initial data; the functions $p_j(x, t)$ depend on the potential $q(x, t)$ and the spatial location x and are periodic with period P, so that $p_j(x, t+P) = p_j(x, t)$ (except in the case of multiple σ_j when powers of t may also occur); and the complex constants σ_j, the scattering frequencies, depend on the potential, but are independent of the initial data or spatial location. Since any integer multiple of ν, where $\nu = 2\pi/P$ is the frequency of the potential, can be freely added to a scattering frequency σ to get another one, we normalize the SFs by requiring that $0 \leqq \operatorname{Re}(\sigma) < \nu$.

The following facts about SFs have been proved: (i) There are at most a countable number of SFs σ_j and $\operatorname{Im}\{\sigma_j\} \to +\infty$ as $j \to \infty$ [4]. (ii) Each SF depends continuously on q in the uniform (L^∞) norm [4].

Our numerical algorithm for computing SFs of oscillatory potentials is identical to the one used for stationary potentials, except that some discussion about the Prony sample rate ΔT is needed. We have two practical possibilities:

(1) ΔT is an integer multiple of the period P. In this case $p(x, t_\infty(x) + k\Delta T) = p(x, t_\infty(x))$, and our algorithm for computing SFs is identical to the one used for stationary potentials.

(2) $\Delta T = P/m$ where m is an integer. In this case, Prony's method samples m data points per period, and we are able to see SFs of the form $\sigma = \alpha + i\beta$, $-\alpha + i\beta$, $-\nu + \alpha + i\beta$, $\nu - \alpha + i\beta$, where $\nu = 2\pi/P$. See [28, § 5] for a thorough discussion about this choice of sample rate.

It is well known [14] that the SFs of time-independent compactly supported potentials that are positive satisfy $\operatorname{Im}\{\sigma_j\} > 0$ for all $j = 1, 2, \ldots$, that is, all terms in (6.4) decay in time as t increases. However, it was conjectured in [24] (without proof or any numerical computations) that there exists a positive, oscillatory potential which has a growing mode, that is, Im $\{\sigma_j\} < 0$ for at least one SF σ_j in (6.4). We now present some computational results to corroborate this claim.

Consider the cylindrically symmetric potential

$$(6.5) \qquad q(\rho, z, t) = \begin{cases} 500, & 0.4R(1+0.9\sin(\omega\pi t)) \leqq \rho \quad \text{and} \quad r = \sqrt{\rho^2+z^2} \leqq R = 0.3, \\ 0, & \text{otherwise.} \end{cases}$$

We used the pseudospectral method described in § 3 with Prony sample rate $\Delta T = 0.02$ to compute the leading radial SF $\sigma_{0,1}$ of potential (6.5), excited by initial data (4.2), for a finite number of frequencies satisfying $0 \leqq \omega \leqq 100$. The results are listed in Table 6.3. The computations clearly show that potential (6.5) has a growing mode for several different frequencies. In fact, the numerical results in Table 6.3 suggest much more. They also suggest that the frequencies can be grouped into disjoint intervals with the property that the imaginary part of the leading radial SF changes sign as the frequency crosses the boundary of an interval.

TABLE 6.3
Leading radial SFs *for potential* (6.5) *with different frequencies.*

Frequency	Leading radial SF $\sigma_{0,1}$	Frequency	Leading radial SF $\sigma_{0,1}$
5.0	$16.2+0.59i$	14.5	$21.1-0.40i$
8.5	$16.3+0.75i$	15.0	$20.3+1.60i$
9.0	$14.1-0.7i$	15.5	$19.3+1.07i$
9.5	$14.9-3.0i$	16.0	$18.9+0.5i$
11.5	$18.0-3.58i$	16.5	$18.9+0.27i$
11.7	$18.5-3.47i$	17.5	$18.6+0.27i$
12.5	$19.6-3.1i$	20.0	$17.6+0.51i$
13.0	$20.5-2.61i$	25.0	$17.8+0.53i$
14.0	$20.5-1.13i$	50, 100	$17.8+0.53i$

More computational results are presented in [18]. These results are used to conjecture relationships between a potential and its SFs.

7. Conclusions and applications to other problems. In this paper we have presented a novel time-dependent computational algorithm for computing the scattering frequencies of a bounded compactly supported potential. Important points regarding the choice of $t_\infty(x)$, the initial data, the numerical method for solving the perturbed wave equation (1.3), and various sources of error have been discussed. A number of computations have been performed which demonstrate that our computational algorithm is capable of computing a number of leading pairs of SFs for a cylindrically symmetric potential with one to four (usually two) significant digits of accuracy. In particular, the computations reported here indicate that for radial potentials, our algorithm, combined with the pseudospectral method, computes for each spherical harmonic index l, five to six pairs of leading SFs with one to four significant digits of accuracy. For nonradial cylindrically symmetric potentials and initial data corresponding to each spherical harmonic, our algorithm, combined with the pseudospectral method, computes four to five pairs of leading SFs. These SFs repeat correctly to four significant digits when we alter the sampling location x and repeat the same calculation. Therefore on the basis of the radial potential results, we believe that these approximate SFs are accurate to one to four (probably two) significant digits of accuracy.

We have used our computational algorithm for computing SFs to present several interesting conjectures about the relationship between a potential and its SFs [18].

Our computational algorithm can be used to compute SFs in a number of other important scattering problems. It is known that under reasonable mathematical conditions, an asymptotic expansion with the form (1.5) or (6.4) holds in the following situations:

(i) Acoustic scattering in the exterior of a stationary or periodically vibrating obstacle [5], [13].

(ii) Electromagnetic scattering in the exterior of a stationary or periodically vibrating perfect conductor or dielectric [5], [13].

We have already performed some computations on these other problems, which will be reported in the future.

Acknowledgment. The authors thank David Gottlieb, Peter Lax, Walter Strauss, Greg Forest, and Mac Hyman for their interest in this problem and useful suggestions.

This work was carried out while Musheng Wei was visiting the Institute for Mathematics and Its Applications at the University of Minnesota, Ohio State University, and Michigan State University. He would like to thank the people at these institutions for their support and hospitality.

ANALYSIS OF ITERATIVE METHODS FOR THE STEADY AND UNSTEADY STOKES PROBLEM: APPLICATION TO SPECTRAL ELEMENT DISCRETIZATIONS*

YVON MADAY†§, DAN MEIRON‡, ANTHONY T. PATERA§, AND EINAR M. RØNQUIST§¶

Abstract. A new and detailed analysis of the basic Uzawa algorithm for decoupling of the pressure and the velocity in the steady and unsteady Stokes operator is presented. The paper focuses on the following new aspects: explicit construction of the Uzawa pressure-operator spectrum for a semiperiodic model problem; general relationship of the convergence rate of the Uzawa procedure to classical inf-sup discretization analysis; and application of the method to high-order variational discretization.

Key words. Stokes problem, Uzawa decoupling, iterative methods, inf-sup, spectral elements

AMS(MOS) subject classifications. 65I10, 65M70, 65N12, 65N25

1. Introduction. The Stokes equations describe the motion of incompressible viscous fluid flow at very low Reynolds numbers. However, the need to have efficient Stokes solvers is not only limited to inertia free flows, but is also of great importance when solving numerically the full time-dependent Navier-Stokes equations. For moderate Reynolds numbers the nonlinear convective term is often treated explicitly, while the linear (Stokes) part is treated implicitly. In order for this semi-implicit approach to be attractive, efficient unsteady Stokes solvers are required.

Numerous approaches have been proposed for solving the algebraic system of equations resulting from discretization of the steady and unsteady Stokes equations. One approach is to solve the momentum and continuity equations directly in coupled form (e.g., Yamaguchi, Chang, and Brown [45] and Bathe and Dong [4]). This direct approach is general and robust; however, it can be inefficient and memory intensive for large, three-dimensional problems, in particular, for high-order methods. A second approach is to replace the discrete continuity equations with a Poisson equation for the pressure (e.g., Chorin [15], Temam [41], Glowinski and Pironneau [23], Kleiser and Schumann [27], Kim and Moin [26], and Orszag, Israeli, and Deville [35]). This approach decouples the momentum and continuity except on the domain boundary; however, it may require a rediscretization of the continuous problem, and boundary conditions must be supplied for the pressure.

A third approach, which we study more closely in this paper, is to apply a global nested iterative decoupling procedure for the pressure and the velocity. This scheme is an extension of the classical Uzawa algorithm (see Arrow, Hurwicz, and Uzawa [1], Chorin [15], Temam [41], Glowinski [22], and Girault and Raviart [21] for more basic concepts; see Cahouet and Chabard [13], Maday, Patera, and Rønquist [30], Fischer, Rønquist, Dewey, and Patera [19], Bristeau, Glowinski, and Periaux [12], Maday and Patera [31], and Cahouet and Chabard [14] for more recent advances). The Uzawa

approach has several attractive features: It is more efficient in terms of computational complexity and memory requirement than a direct approach; it requires no pressure boundary conditions and no rediscretization of the original problem, and hence the convergence proofs for the original problem directly apply. In essence, by using a block Gaussian elimination procedure, this algorithm decouples the original saddle problem into two positive-semidefinite symmetric forms, one for the pressure and one for the velocity. Thus standard iterative procedures such as preconditioned conjugate gradient iteration and multigrid techniques can readily be applied.

In this paper we give a new and detailed analysis of the basic Uzawa algorithm. The paper focuses on the following new aspects: the explicit construction of the Uzawa pressure-operator spectrum for a particular case; the general relationship of the convergence rate of the Uzawa procedure to classical inf-sup discretization analysis [11], [3], and application of the method to high-order variational discretization. The outline of this paper is as follows. We start in § 2 by reviewing the basic discretization of the steady and unsteady Stokes equations based on the equivalent variational forms. In § 3.1 we review the Uzawa method for the steady Stokes problem, and in § 3.2 we consider the full Fourier case. In § 3.3 we proceed by presenting a new continuous analysis for a semiperiodic model problem. The analytical results regarding the good conditioning of the steady Stokes pressure operator are then verified numerically for optimal high-order spectral element discretizations. In § 3.4 we discuss how these results extend to multidimensional spectral element discretizations, and present examples of steady Stokes problems solved by a nested preconditioned conjugate gradient/multigrid iteration scheme. Last, in § 4 we analyze the Uzawa algorithm in the context of solving the unsteady Stokes equations.

2. The Stokes problems.

2.1. Steady Stokes. In this section we consider the steady Stokes problem in d space dimensions: Find a velocity $\mathbf{u}$ and a pressure p in a domain $\Omega \in \mathcal{R}^d$ such that

$$-\mu\Delta\mathbf{u}+\nabla p=\mathbf{f} \quad \text{in } \Omega, \tag{1}$$

$$-\nabla\cdot\mathbf{u}=0 \quad \text{in } \Omega, \tag{2}$$

subject to homogeneous Dirichlet velocity boundary conditions on the domain boundary $\partial\Omega$,

$$\mathbf{u}=\mathbf{0} \quad \text{on } \partial\Omega. \tag{3}$$

Here $\mathbf{f}$ is the prescribed force and μ is the viscosity. As mentioned in the Introduction, the solution to the Stokes problem (1), (2) is of interest, not only in its own right, but also in that it constitutes the major building block in many Navier–Stokes solvers. In this case, $\mathbf{f}$ can be viewed as an augmented force which includes the explicitly treated nonlinear convective contributions.

The equivalent variational formulation of (1), (2) is: Find $(\mathbf{u}, p)$ in $X\times M$ such that

$$\mu(\nabla\mathbf{u}, \nabla\mathbf{w})-(p, \nabla\cdot\mathbf{w})=(\mathbf{f}, \mathbf{w}) \quad \forall\mathbf{w}\in X, \tag{4}$$

$$-(\nabla\cdot\mathbf{u}, q)=0 \quad \forall q\in M, \tag{5}$$

where the proper spaces for $\mathbf{u}$ and p such that (4), (5) is well posed are [11], [21]

$$X=\mathcal{H}_0^1(\Omega), \tag{6}$$

$$M=\mathcal{L}_0^2(\Omega)=\mathcal{L}^2(\Omega)\cap\left\{\phi\in\mathcal{L}^2(\Omega);\ \int_\Omega \phi\, d\Omega=0\right\}. \tag{7}$$

Here $\mathcal{L}_0^2(\Omega)$ is the space of all functions that are square integrable over Ω with zero average, while $\mathcal{H}_0^1(\Omega)$ is the space of all functions that are square integrable, whose derivatives are also square integrable over Ω, and which satisfy the homogeneous boundary conditions (3).

Here we shall consider numerical approximations to the Stokes problem based on the variational form (4), (5): Find $(\mathbf{u}_h, p_h) \in (X_h, M_h)$ such that

$$\mu((\nabla \mathbf{u}_h, \nabla \mathbf{w}))_h - (p_h, \nabla \cdot \mathbf{w})_h = ((\mathbf{f}, \mathbf{w}))_h \quad \forall \mathbf{w} \in X_h, \tag{8}$$

$$-(\nabla \cdot \mathbf{u}_h, q)_h = 0 \quad \forall q \in M_h, \tag{9}$$

where for each value of the parameter h, $X_h \subset X$ and $M_h \subset M$ are compatible subspaces of X and M (see [11], [3], [21], and [9]) that approach X and M as the discretization parameter h goes to zero. In (8), (9) $(\cdot,\cdot)_h$ and $((\cdot,\cdot))_h$ denote evaluation of the continuous inner product $(\cdot,\cdot)$ by Gauss numerical quadrature (note, however, that the $(\cdot,\cdot)_h$ and $((\cdot,\cdot))_h$ may be different).

Choosing appropriate (compatible) discrete spaces X_h and M_h with associated bases, we arrive at a set of algebraic equations given in matrix form as

$$\mu \underline{A}\underline{u}_i - \underline{D}_i^T \underline{p} = \underline{B}\underline{f}_i, \qquad i = 1, \dots, d, \tag{10}$$

$$-\underline{D}_i \underline{u}_i = 0, \tag{11}$$

where $\underline{A}$ is the discrete Laplace operator, $\underline{B}$ is the mass matrix, $\underline{\mathbf{D}}^T = (\underline{D}_1^T, \dots, \underline{D}_d^T)$ is the discrete gradient operator, and the underscore refers to basis coefficients. In (10), (11), we assume that the homogeneous boundary conditions are imposed by eliminating appropriate rows and columns. Note that in the limit as the discretization parameter $h \Rightarrow 0$, $(X_h, M_h) \Rightarrow (X, M)$, and (10), (11) applies even for the continuous case.

2.2. Unsteady Stokes. The unsteady Stokes equations are given by

$$-\mu \Delta \mathbf{u} + \nabla p + \rho \frac{\partial \mathbf{u}}{\partial t} = \mathbf{f} \quad \text{in } \Omega, \tag{12}$$

$$-\nabla \cdot \mathbf{u} = 0 \quad \text{in } \Omega, \tag{13}$$

with boundary and initial conditions

$$\mathbf{u} = \mathbf{0} \qquad \text{on } \partial\Omega, \tag{14}$$

$$\mathbf{u}(\mathbf{x}, t = 0) = \mathbf{g}(\mathbf{x}) \quad \text{in } \Omega. \tag{15}$$

Here all variables are defined as in the steady case with t representing time, and ρ the density of the fluid. Although there are physical problems in which the unsteady Stokes equations are relevant, the unsteady problem is primarily of interest with regard to its role in unsteady Navier-Stokes calculations.

We proceed directly to the time discretization of (12), (13) by an implicit Euler backward method (readily extended to Crank-Nicolson)

$$-\mu \Delta \mathbf{u}^{n+1} + \nabla p^{n+1} + \rho \frac{\mathbf{u}^{n+1} - \mathbf{u}^n}{\Delta t} = \mathbf{f}^{n+1}, \tag{16}$$

$$-\nabla \cdot \mathbf{u}^{n+1} = 0, \tag{17}$$

in which $(\mathbf{u}^n, p^n)$ represents an approximation of $(\mathbf{u}(\mathbf{x}, n\Delta t), p(\mathbf{x}, n\Delta t))$, and Δt is the time step.

The spatial discretization of (16), (17) follows the same procedure as for the steady case. At each time step we search for a discrete solution $(\mathbf{u}_h^{n+1}, p_h^{n+1})$ in the finite-dimensional (compatible) subspaces $X_h \subset X$ and $M_h \subset M$, and we arrive at a set of algebraic equations to be solved for the nodal values $\underline{\mathbf{u}}^{n+1} = (\underline{u}_1^{n+1}, \dots, \underline{u}_d^{n+1})$ and $\underline{p}^{n+1}$,

$$\mu \underline{A}\underline{u}_i^{n+1} - \underline{D}_i^T \underline{p}^{n+1} + \rho \underline{B}\left(\frac{\underline{u}_i^{n+1} - \underline{u}_i^n}{\Delta t}\right) = \underline{B}\underline{f}_i^{n+1}, \qquad i = 1, \dots, d, \tag{18}$$

$$-\underline{D}_i \underline{u}_i^{n+1} = 0. \tag{19}$$

We note that for any discretization (18), (19) for which $\underline{A}$ is positive-definite symmetric, (18), (19) is unconditionally stable $(\mathbf{f} = \mathbf{0})$,

$$\|\mathbf{u}_h^{n+1}\|_{0,h} < \|\mathbf{u}_h^n\|_{0,h}, \tag{20}$$

as can be readily demonstrated by multiplying (18) and (19) by $\underline{u}_i^{n+1}$ and $\underline{p}^{n+1}$, respectively. In (20) $\|\cdot\|_{0,h}$ denotes the discrete $\mathscr{L}^2$-norm, $\|v\|_{0,h} = ((v, v))_h^{1/2}$.

3. Steady Stokes solvers.

3.1. The Uzawa algorithm.

The classical Uzawa scheme originates from economic theory as a saddle-point approach to solving constrained optimization problems (see Arrow, Hurwicz, and Uzawa [1]). Following Brezzi [11] and Girault and Raviart [21], the Stokes problem (4), (5) can be formulated as the following equivalent saddle-point problem: Find a pair $(\mathbf{u}, p) \in X \times M$ such that

$$\mathscr{T}(\mathbf{u}, q) \leqq \mathscr{T}(\mathbf{u}, p) \leqq \mathscr{T}(\mathbf{v}, p) \quad \forall \mathbf{v} \in X, \quad \forall q \in M, \tag{21}$$

where the quadratic Lagrangian functional $\mathscr{T}: X \times M \to \mathscr{R}$ is defined by

$$\mathscr{T}(\mathbf{v}, q) = \frac{\mu}{2}(\nabla \mathbf{v}, \nabla \mathbf{v}) - (\mathbf{f}, \mathbf{v}) - (q, \nabla \cdot \mathbf{v}). \tag{22}$$

The constraint in the Stokes problem is the incompressibility condition, while pressure plays the role of the Lagrange multiplier. In the case of finding a numerical approximation to the Stokes problem (1)-(3), the equivalence between the discrete formulation (8), (9) and a finite-dimensional saddle-point problem is now readily seen: Find $(\mathbf{u}_h, p_h) \in X_h \times M_h$ such that

$$\mathscr{T}_h(\mathbf{u}_h, q) \leqq \mathscr{T}_h(\mathbf{u}_h, p_h) \leqq \mathscr{T}_h(\mathbf{v}, p_h) \quad \forall \mathbf{v} \in X_h, \quad \forall q \in M_h, \tag{23}$$

where the quadratic Lagrangian functional $\mathscr{T}_h: X_h \times M_h \to \mathscr{R}$ is defined by

$$\mathscr{T}_h(\mathbf{v}, q) = \frac{\mu}{2}((\nabla \mathbf{v}, \nabla \mathbf{v}))_h - ((\mathbf{f}, \mathbf{v}))_h - (q, \nabla \cdot \mathbf{v})_h. \tag{24}$$

In terms of finding the nodal values $\underline{\mathbf{u}}$ and $\underline{p}$ in (10), (11), the classical Uzawa approach to solving the min-max problem (23) is characterized by the following gradient method [41]:

$$\mu \underline{A}\underline{u}_i^{m+1} = \underline{D}_i^T \underline{p}^m + \underline{B}\underline{f}_i, \qquad i = 1, \dots, d; \tag{25}$$

$$\tilde{\underline{B}}\underline{p}^{m+1} = \tilde{\underline{B}}\underline{p}^m - \alpha \underline{D}_i \underline{\mathbf{u}}_i^{m+1}. \tag{26}$$

Here m is the iteration counter, $\alpha \in \mathscr{R}$ is a positive iteration parameter, and $\tilde{\underline{B}}$ is the mass matrix associated with the bilinear form $(\phi, \psi)_h$ for all $\phi, \psi \in M_h$. In (25) we minimize $\mathscr{T}_h(\mathbf{v}, p_h^m)$ for all $\mathbf{v} \in X_h$, while in (26) we try to maximize $\mathscr{T}_h(\mathbf{u}_h^m, q)$ for all $q \in M_h$. For sufficiently small α, the two-level iteration scheme (25), (26) converges to the solution of (10), (11).

As is the case for many gradient algorithms, the Uzawa procedure in the form (25), (26) converges very slowly, especially for large multidimensional problems. The convergence rate can be improved by considering augmented Lagrangian methods (Fortin and Glowinski [20]), or multigrid schemes (Verfurth [44] and Maître, Musy, and Nigon [34]). However, replacing (25), (26) by conjugate gradient iteration can also accelerate the convergence significantly to give very good results. For details in the finite-element context, we refer to Glowinski [22] and Girault and Raviart [21]. In the following we shall demonstrate, both in terms of continuous analysis and numerical examples, that the latter approach is very attractive in terms of conditioning, computational complexity, and parallelism.

We begin with a decoupling of the original saddle problem (10), (11) into two positive (semi)definite symmetric forms, one for the velocity and one for the pressure. First, for each of the velocity components $\underline{u}_i$ from the momentum equations (10), we formally solve

$$\underline{u}_i = \underline{A}^{-1}\underline{D}_i^T\underline{p} + \underline{A}^{-1}\underline{B}\underline{f}_i, \qquad i = 1, \dots, d. \tag{27}$$

We then insert (27) into the continuity equation (11) to arrive at

$$0 = -\underline{D}_i\underline{u}_i = -\underline{D}_i\underline{A}^{-1}\underline{D}_i^T\underline{p} - \underline{D}_i\underline{A}^{-1}\underline{B}\underline{f}_i. \tag{28}$$

Thus the discrete saddle problem (10), (11) can be replaced with the discretely equivalent statement

$$\underline{A}\underline{u}_i - \underline{D}_i^T\underline{p} = \underline{B}\underline{f}_i, \tag{29}$$

$$\underline{S}\underline{p} = -\underline{D}_i\underline{A}^{-1}\underline{B}\underline{f}_i, \tag{30}$$

where the discrete pressure operator

$$\underline{S} = \underline{D}_i\underline{A}^{-1}\underline{D}_i^T \tag{31}$$

is a positive-semidefinite symmetric matrix. Hence, the saddle problem (10), (11) can be solved by first maximizing $\mathcal{T}_h(\mathbf{u}_h, q)$ for all $q \in M_h$ (see (30)), and then minimizing $\mathcal{T}_h(\mathbf{v}, p_h)$ for all $\mathbf{v} \in X_h$ (see (29)).

We now make several comments regarding the system (29), (30). First, we note that the equation set (29), (30) does not correspond to a rediscretization of the continuous problem, that is, (29), (30) is equivalent to (10), (11). This implies that the theoretical error estimates derived for (8), (9) directly apply (in the case of spectral element discretizations, we refer to Maday and Patera [31] and Maday, Patera, and Rønquist [30]). Second, since the system matrices $\underline{S}$ and $\underline{A}$ are symmetric positive (semi)definite, standard elliptic solvers such as conjugate gradient iteration or multigrid techniques can readily be applied. The system (29), (30) is solved by first solving (30) for the pressure $\underline{p}$ and then solving (29) for the velocity $\underline{u}_i$, $i = 1, \dots, d$ with $\underline{p}$ known. Third, the pressure-operator $\underline{S}$ is completely full due to the embedded inverse $\underline{A}^{-1}$, and thus clearly necessitates an iterative approach.

Heuristically we expect the *continuous* pressure-operator s to be close to the identity operator I and therefore to be well conditioned. To see this, we formally apply the Uzawa decoupling procedure to the continuous equations (1), (2) and neglect boundary conditions

$$s \sim \nabla \cdot (\Delta)^{-1}\nabla \sim I. \tag{32}$$

In the discrete case we do *not* expect $\underline{S}$ to be close to the identity matrix $\underline{I}$, but rather the variational equivalent of the identity operator, the mass matrix $\tilde{\underline{B}}$. Hence, we expect that

$$\tilde{\underline{B}}^{-1}\underline{S} \sim \underline{I}, \tag{33}$$

suggesting that we can invert $\underline{S}$ efficiently by conjugate gradient iteration, using the mass matrix $\tilde{\underline{B}}$ as a preconditioner. Note here the importance of the proper choice of bases and numerical quadratures in order to define a matrix $\tilde{\underline{B}}$ that is easy to invert, that is, in order for $\tilde{\underline{B}}$ to be diagonal.

The preconditioned conjugate gradient iteration (outer iteration) for the system (30) takes the form [24], [21],

$$\begin{gathered}\underline{p}_0; \quad \underline{r}_0 = \underline{D}_i \underline{A}^{-1} \underline{B} \underline{f}_i + \underline{S}\underline{p}_0; \quad \underline{\psi}_0 = \tilde{\underline{B}}^{-1} \underline{r}_0; \quad \underline{\phi}_0 = \underline{\psi}_0; \\ a_m = -\frac{\underline{\psi}_m^T \underline{r}_m}{\underline{\phi}_m^T \underline{S} \underline{\phi}_m}, \quad \underline{p}_{m+1} = \underline{p}_m + a_m \underline{\phi}_m, \quad \underline{r}_{m+1} = \underline{r}_m + a_m \underline{S}\underline{\phi}_m, \\ \underline{\psi}_{m+1} = \tilde{\underline{B}}^{-1} \underline{r}_{m+1}, \quad b_m = \frac{\underline{\psi}_{m+1}^T \underline{r}_{m+1}}{\underline{\psi}_m^T \underline{r}_m}, \quad \underline{\phi}_{m+1} = \underline{r}_{m+1} + b_m \underline{\phi}_m,\end{gathered} \tag{34}$$

where m refers to the iteration number, $\underline{r}_m$ is the residual, $\underline{\phi}_m$ is the search direction, $\tilde{\underline{B}}$ is the preconditioner, $\underline{\psi}_m$ is a vector associated with the preconditioning, and a_m and b_m are scalars.

The inner iteration is associated with the evaluation of the matrix-vector product $\underline{S}\underline{\phi}$ in the outer conjugate gradient iteration. From the definition of $\underline{S}$ in (31) this evaluation can be performed as follows:

$$\underline{y}_i = \underline{D}_i^T \underline{\phi} \qquad i = 1, \ldots, d, \tag{35}$$

$$\underline{A}\underline{z}_i = \underline{y}_i \qquad i = 1, \ldots, d, \tag{36}$$

$$\underline{S}\underline{q} = \underline{D}_i \underline{z}_i. \tag{37}$$

We see that for general discretizations, each matrix-vector product evaluation requires d standard elliptic Laplacian solves in $\mathcal{R}^d$. In order for this approach to be efficient for large multidimensional problems, the discrete Laplace operator $\underline{A}$ must be inverted by a fast solver, such as a good preconditioned conjugate gradient solver. In summary, the pressure is computed from (30) by effecting the *nested* inner/outer iteration procedure (34)-(37).

If the condition number of the matrix $\tilde{\underline{B}}^{-1}\underline{S}$ is order unity, we see that the above algorithm requires only order-d elliptic solves, and hence represents an ideal decoupling of the Stokes problem. We also note that the residual $\underline{r}$ in the outer conjugate gradient iteration (34) is precisely the discrete divergence $-\underline{D}_i \underline{u}_i$. This is a useful result, as it allows for direct control of the discrete divergence when specifying the tolerance for the outer iteration. (The proper choice of tolerances in any nested iterative procedure is an important issue, and will be addressed separately in a future paper.)

We now make some general remarks regarding the relation between the inf-sup condition due to Babuska [3] and Brezzi [11], and the accuracy and efficiency by which the pressure can be computed. The necessary and sufficient condition for well-posedness of the saddle problem (8), (9) can be written as: there exists a real $\beta_h > 0$ such that for all $q \in M_h$, there exists $\mathbf{v} \in X_h$,

$$\beta_h \|q\|_{0,h} \leqq \frac{(q, \nabla \cdot \mathbf{v})_h}{|\mathbf{v}|_{1,h}}, \tag{38}$$

where $\|\cdot\|_{0,h}$ is the discrete $\mathcal{L}^2$-norm associated with the pressure mesh (M_h),

$$\|q\|_{0,h}^2 = (q, q)_h = \underline{q}^T \tilde{\underline{B}} \underline{q}, \tag{39}$$

and $|\cdot|_{1,h}$ is the discrete seminorm associated with the velocity mesh (X_h),

$$|\mathbf{v}|_{1,h}^2 = ((\nabla v_i, \nabla v_i))_h = \underline{v}_i^T \underline{A} \underline{v}_i. \tag{40}$$

In (34) we suggest solving (30) by conjugate gradient iteration, using $\tilde{\underline{B}}$ as a preconditioner. To estimate the efficiency of this approach it is of interest to determine the condition number κ^S of the matrix $\tilde{\underline{B}}^{-1}\underline{S}$. For general discretizations it can be shown that the inf-sup parameter β_h is closely related to the minimum eigenvalue of the pressure-operator $\underline{S}$ (see Appendix A)

$$\beta_h^2 = \lambda_{\min}^S, \tag{41}$$

where $\lambda_{\min}^S$ is the minimum eigenvalue of $\underline{S}$ with respect to the mass matrix $\tilde{\underline{B}}$,

$$\lambda_{\min}^S = \min_{\underline{\phi}} \frac{\underline{\phi}^T \underline{S}\underline{\phi}}{\underline{\phi}^T \tilde{\underline{B}}\underline{\phi}}. \tag{42}$$

It can also be shown (see Appendix A) that the maximum eigenvalue of $\underline{S}$ with respect to $\tilde{\underline{B}}$, $\lambda_{\max}^S$, is of order unity, implying that the condition number κ^S is given as

$$\kappa^S = \frac{\lambda_{\max}^S}{\lambda_{\min}^S} = \frac{C}{\beta_h^2}, \tag{43}$$

where C is a constant of order unity. Thus the number of outer conjugate gradient iterations scales like $1/\beta_h$ [24]. If β_h is of order unity, the outer iteration (34) converges in order-one iterations.

The inf-sup parameter β_h also affects the accuracy by which the pressure can be computed; in fact, it can be shown that the error in the pressure p_h is inversely proportional to β_h, [11], [21], [10],

$$\|p - p_h\|_0 \leqq \frac{C}{\beta_h}\left(\inf_{q_h \in M_h} \|p - q_h\|_0 + \cdots\right), \tag{44}$$

where the dots indicate error terms originating from the velocity and forcing terms. However, the velocity remains unaffected by the inf-sup parameter

$$\|\mathbf{u} - \mathbf{u}_h\|_1 \leqq C\left(\inf_{\mathbf{v}_h \in X_{h,0}} \|\mathbf{u} - \mathbf{v}_h\|_1 + \cdots\right), \tag{45}$$

where

$$X_{h,0} = \{\mathbf{v}_h \in X_h \,|\, (\nabla \cdot \mathbf{v}_h, q_h)_h = 0 \;\forall q_h \in M_h\}, \tag{46}$$

thereby proving that the error in velocity is of the same size as the best fit by discrete divergence-free functions. Even though, in some cases, the presence of weakly spurious modes gives rise to poor approximation by $X_{h,0}$, in many interesting cases we have

$$\inf_{\mathbf{v}_h \in X_h} \|\mathbf{u} - \mathbf{v}_h\|_1 \sim \inf_{\mathbf{v}_h \in X_{h,0}} \|\mathbf{u} - \mathbf{v}_h\|_1 \tag{47}$$

[9], [10], [5], [39], [25].

For reasons of accuracy and efficiency we can now see that it is of great importance that β_h be independent of the mesh parameter h. In most finite-element applications the inf-sup parameter is resolution-independent as long as the discrete spaces are compatible. However, in spectral methods this is not the case, and *weakly* spurious modes [42] are observed. These modes are responsible for an inf-sup parameter β_h that depends on the mesh parameter $h \sim 1/N$, where N is the polynomial degree chosen for the approximation. For example, in the pure spectral case when X_h and M_h consist of all polynomials of degree $\leqq N$, and all (strong) spurious modes for the pressure are eliminated [9], there still exist weakly spurious modes responsible for an inf-sup parameter $\beta_h \sim \mathcal{O}(h) \sim \mathcal{O}(N^{-1})$ [7], [43]. This has led to the construction of alternative methods based on staggered meshes in order to avoid strong spurious modes and to minimize the effects of weakly spurious modes. We refer to Bernardi and Maday [6], and §§ 3.3 and 3.4 for a description of such methods.

The Uzawa algorithm is well known as an efficient way of solving the algebraic system of equations (10), (11) resulting from (low-order) finite-element discretization of the steady Stokes problem (1)-(3). The adaptation of the method to the spectral case is rather new, as described in Maday, Patera, and Rønquist [30], Streett, Hussaini, and Maday [40], Azarez, Labrosse, and Vandeven [2], and Lequéré [29]. In the following we investigate in detail the conditioning of the steady Stokes pressure operator; in particular we shall look at the full Fourier case, a semiperiodic model problem (both continuous and spectral element case), and the multidimensional spectral element case.

3.2. Full Fourier case. We start by first considering the simple case of Fourier discretization in $\mathscr{R}^d$, in which we choose the approximation spaces X_h and M_h to be

$$X_h = M_h^3, \tag{48}$$

$$M_h = \text{span}\,\{e^{i\mathbf{k}\cdot\mathbf{x}}, |k_j| < \mathscr{K}, \forall j = 1, \dots, d\} \tag{49}$$

where $\mathbf{k} = (k_1, k_2, k_3)$ is the wave vector, $\mathbf{x} = (x_1, x_2, x_3) \in \Omega$, and $\mathscr{K}$ is the maximum wave number in each spatial direction. Reality is imposed by conjugate symmetry. For this Fourier discretization it is clear that

$$\underline{B} \Rightarrow 1, \tag{50}$$

$$\underline{D} \Rightarrow ik_j, \tag{51}$$

$$\underline{A} \Rightarrow -k^2 = -\sum_{j=1}^{d} k_j k_j, \tag{52}$$

from which it follows that $\underline{S} = \underline{I}$ independent of $\mathscr{K}$. For the Fourier case the Uzawa algorithm is perfectly conditioned, as might be expected; see Maday and Quarteroni [33] for a numerical analysis of this spatial discretization.

3.3. Semiperiodic case.

3.3.1. Continuous case. Next, we turn to the analysis of the semiperiodic problem. This problem includes boundaries, and is thus much more instructive than the full Fourier case, yet it is sufficiently simple to allow for a complete analysis. The semiperiodic model problem corresponds to the domain $\Omega =]-1, 1[\times]0, 2\pi[$, with (x, y) denoting a point in Ω. The semiperiodic boundary conditions we consider are

$$\forall y \in]0, 2\pi[, \qquad \mathbf{u}(-1, y) = \mathbf{u}(1, y) = \mathbf{0}, \tag{53}$$

$$\forall x \in]-1, 1[, \qquad \mathbf{u}(x, 0) = \mathbf{u}(x, 2\pi), \tag{54}$$

and the associated spaces are

$$X = \{v \in \mathscr{H}^1(\Omega) | v \text{ satisfies (53)-(54)}\}, \tag{55}$$

$$M = \mathscr{L}_0^2(\Omega), \tag{56}$$

where $\mathscr{L}_0^2$ is defined in (7).

We now write the velocity, the pressure, and the data as a Fourier series in the periodic y-direction,

$$\mathbf{u}(x, y) = \sum_{k=-\infty}^{\infty} \hat{\mathbf{u}}^k(x)\, e^{iky}, \tag{57}$$

$$p(x, y) = \sum_{k=-\infty}^{\infty} \hat{p}^k(x)\, e^{iky}, \tag{58}$$

$$\mathbf{f}(x, y) = \sum_{k=-\infty}^{\infty} \hat{\mathbf{f}}^k(x)\, e^{iky}, \tag{59}$$

and use the orthogonality of the Fourier modes to reduce the steady Stokes problem to a series of decoupled (continuous) problems: Find $\hat{\mathbf{u}}^k = (\hat{u}^k, \hat{v}^k)$ and $\hat{p}^k$ in $\hat{X} \times \hat{M}$ such that

$$\hat{u}^k_{xx} - k^2 \hat{u}^k = \hat{p}^k_x + \hat{f}^k, \tag{60}$$

$$\hat{v}^k_{xx} - k^2 \hat{v}^k = ik\hat{p}^k + \hat{g}^k, \tag{61}$$

$$\hat{u}^k_x + ik\hat{v}^k = 0, \tag{62}$$

where

$$\hat{X} = \mathscr{H}^1_0(\Lambda), \tag{63}$$

$$\hat{M} = \mathscr{L}^2_0(\Lambda), \tag{64}$$

$\Lambda =]-1, 1[$, subscript x denotes differentiation with respect to x, $\hat{\mathbf{f}}^k = (\hat{f}^k, \hat{g}^k)$, and we consider wave numbers $k \neq 0$.

From (60)-(62) we now readily derive the following expression for the continuous pressure operator s^k acting on any $\hat{p}^k$ associated with wave number k in the periodic y-direction

$$s^k(\hat{p}^k) = \int_{-1}^{1} \left[\frac{\partial}{\partial x} G(x, x') \frac{\partial}{\partial x'} - k^2 G(x, x') \right] \hat{p}^k(x')\, dx', \tag{65}$$

where $G(x, x')$ is the Green's function for the second-order problem:

$$G_{xx} - k^2 G = \delta(x - x'), \tag{66}$$

$$G(-1, x') = G(1, x') = 0. \tag{67}$$

The solution to (66), (67) can be expressed in closed form as

$$G(x, x') = \frac{-1}{k \sinh 2k} \sinh k(1 + x^<) \sinh k(1 - x^>), \tag{68}$$

where

$$x^< = \begin{cases} x & \text{for } x < x', \\ x' & \text{for } x > x', \end{cases} \tag{69}$$

$$x^> = \begin{cases} x' & \text{for } x < x', \\ x & \text{for } x > x'. \end{cases} \tag{70}$$

To find the condition number of s^k, we analyze the spectrum of the following Fredholm integral equation

$$\int_{-1}^{1} \mathscr{G}(x, x') \chi(x')\, dx' = \lambda^S \chi(x), \tag{71}$$

where the kernel $\mathcal{G}$ follows from (65) as

$$\mathcal{G}(x,x')=\frac{\partial}{\partial x}G(x,x')\frac{\partial}{\partial x'}-k^2G(x,x'). \tag{72}$$

Substituting the expression (68) for the Green's function into (72), the solution to (71) can be found by inspection (see Appendix B). The *entire* spectrum of s^k is given as

$$\lambda_1^s(k)=\frac{1}{2}-\frac{k}{\sinh 2k}, \tag{73}$$

$$\lambda_2^s(k)=\frac{1}{2}+\frac{k}{\sinh 2k}, \tag{74}$$

$$\lambda_l^s(k)=1, \qquad l>2, \tag{75}$$

with only one nonunity eigenvalue for each boundary. The fact that there are only two nonunity λ_l^s's is related to the fact that for the Stokes problem, the pressure and velocity are only coupled at boundaries. (This can also be seen by taking the divergence of the momentum equation, which yields $\Delta p=\nabla\cdot\mathbf{f}$ in Ω, but indeterminacy at the boundaries. The proper boundary conditions are, in fact, $\nabla\cdot\mathbf{u}=0$.)

For a given wave number k, the condition number of s^k is given by

$$\kappa^s(k)=\left(\frac{1}{2}-\frac{k}{\sinh 2k}\right)^{-1}. \tag{76}$$

Since the spectrum (73)-(75) is clustered with only three distinct eigenvalues, the outer conjugate gradient iteration in the pressure solver will converge in three iterations independent of the condition number $\kappa^s(k)$. However, this result is only useful for semiperiodic discretizations; for truly multidimensional problems we must consider the condition number for all admissible k. In particular, if we allow wave numbers in the range $1\leqq k<k_{\max}$, we find that

$$\kappa^s=\left(\frac{1}{2}-\frac{1}{\sinh 2}\right)^{-1}\cong 4.46, \tag{77}$$

which *does not depend on* $k_{\max}$, and hence will not depend on the number of discrete degrees of freedom in the system.

3.3.2. Spectral element discretization. The above continuous analysis suggests that even in the presence of walls, the spectrum of the discrete pressure operator $\underline{S}$ with respect to the mass matrix $\underline{\tilde{B}}$ is clustered near unity, with a condition number that should be largely independent of the discretization parameter h. Here we are primarily interested in spectral element discretizations, corresponding to spaces X_h and M_h consisting of piecewise high-order polynomials [36], [31], [37].

In order to construct the discrete pressure operator $\underline{S}$, the decoupled (continuous) equations (60)-(62) for each Fourier mode k are discretized using spectral elements in the nonperiodic x-direction. The discretization procedure starts by breaking up the domain $\Lambda=]-1,1[$ into K equal elements

$$\bar{\Lambda}=\bigcup_{k=1}^{K}\bar{\Lambda}_k. \tag{78}$$

We then choose the subspaces to be

$$\hat{X}_h=\hat{X}\cap\mathcal{P}_{N,K}(\Lambda), \tag{79}$$

$$\hat{M}_h = \hat{M} \cap \mathscr{P}_{N-2,K}(\Lambda), \tag{80}$$

where

$$\mathscr{P}_{n,K}(\Lambda) = \{\Phi \in \mathscr{L}^2(\Lambda);\ \Phi|_{\Lambda_k} \in \mathscr{P}_n(\Lambda_k)\}, \tag{81}$$

and $\mathscr{P}_n(\Lambda_k)$ denotes the space of all polynomials of degree less than or equal to n with respect to x. The discretization parameter h is thus characterized by two numbers, the number of elements K, and the polynomial degree within each element N. In the following, we shall use the notation $h=(K, N)$. We refer to Maday, Patera, and Rønquist [30] and Bernardi, Maday, and Métivet [10] for a justification of the choice of discrete spaces.

The velocity and pressure are now expressed in terms of high-order Lagrangian interpolant bases through the Gauss-Lobatto and Gauss points, respectively [31]. This choice of bases results in minimal interelemental couplings, while still preserving the required C^0-continuity of the velocity across elemental boundaries. The inner products in (8), (9) are evaluated using Gauss numerical quadrature [16], Gauss-Legendre for $(\cdot,\cdot)_h$, and Gauss-Lobatto-Legendre for $((\cdot,\cdot))_h$. Choosing appropriate test functions, we arrive at a set of algebraic equations of the form (10), (11), which are then decoupled into the form (29), (30). Note that for Legendre spectral element discretizations, the quadrature points are the same as the collocation points, resulting in *diagonal* mass matrices $\underline{B}$ and $\tilde{\underline{B}}$ associated with the staggered mesh. This fact makes the preconditioning in (34) trivial.

We now proceed with the investigation of the conditioning of the discrete pressure operator resulting from spectral element discretization of the semiperiodic model problem. In Maday, Patera, and Rønquist [30], it is shown that the inf-sup parameter $\beta_h(k)$ associated with a particular wave number k is *independent* of the discretization $h=(K, N)$; see also [42] for another proof of this point. As long as the condition number κ^S is of order unity, this result is optimal with regard to both the accuracy of the discrete pressure and the efficiency by which the pressure can be computed. We now present numerical results demonstrating the good conditioning of the preconditioned pressure matrix $\tilde{\underline{B}}^{-1}\underline{S}$ for the semiperiodic problem; in what follows, $\lambda_l^S(k)$, $\kappa^S(k)$ will refer to the spectrum and conditioning of $\tilde{\underline{B}}^{-1}\underline{S}$ for a particular wave number k. The calculation of the eigenvalues is based on EISPACK routines.

We begin by plotting in Fig. 1 the $\lambda_l^S(k)$ for the spectral element discretization $h=(K, N)=(4,7)$ and wave number $k=1$. The agreement with the continuous operator spectrum is seen to be virtually exact. In Fig. 2 we again plot $\lambda_l^S(k)$ with $h=(K, N)=(4,7)$, but now for a wave number $k=12$. The low modes of the system are again in good agreement with the continuous spectrum. However, at this large value of k, the discrete system can no longer resolve exactly the higher modes, resulting in a cluster of eigenvalues at $\lambda_*^S \sim 1.2$. If we investigate the spectrum for $k=12$, but now using a discretization $h=(K, N)=(4,14)$, we see in Fig. 3 that the cluster of numerical eigenvalues has almost disappeared due to the higher spatial resolution in x.

In Fig. 4 we plot κ^S and κ^s as a function of k for the spectral element and continuous operators, respectively. For small and moderate k the two curves coincide; however, as $k \Rightarrow \infty$ the resolution becomes too low and the two curves diverge. For finer resolutions (e.g., larger N) the spectral element and the theoretical results agree over a larger range of wave numbers, as expected from Figs. 2 and 3. For large wave numbers k, the condition number $\kappa^S(k)$ for the spectral element discretization is larger than the value predicted by the continuous analysis, however, the value is still of order unity, as required for fast convergence of the outer iteration.

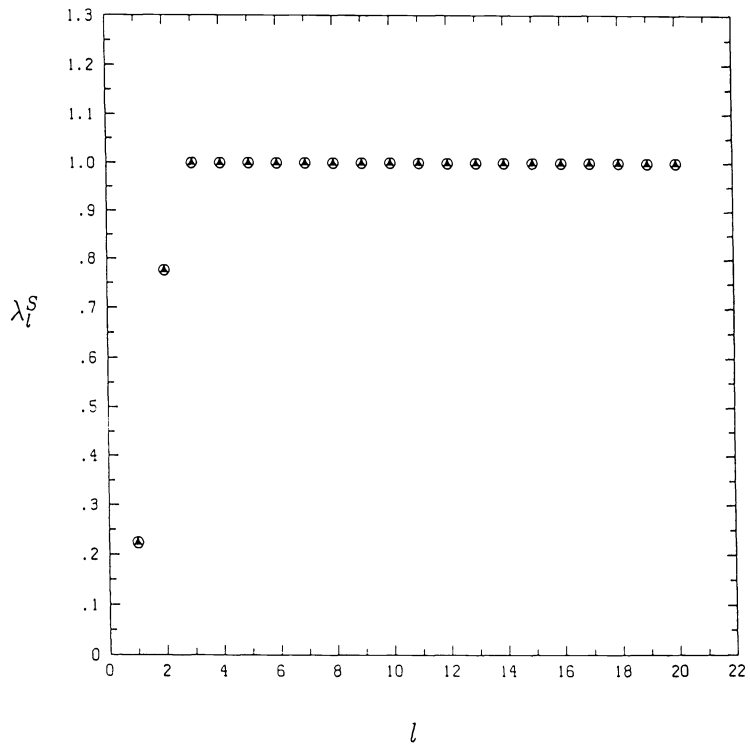

FIG. 1. *A plot of the spectrum $\lambda_l^S(k)$ of the preconditioned steady Stokes pressure matrix $\tilde{\underset{\sim}{B}}^{-1}\underset{\sim}{S}$, where $\underset{\sim}{S}$ is the pressure matrix given in* (31) *and $\tilde{\underset{\sim}{B}}$ is the mass matrix defined on the Gauss pressure mesh. The spectrum* (▲) *corresponds to a spectral element discretization* ($K=4$, $N=7$) *for a wave number $k=1$; the agreement with the continuous operator spectrum λ_l^s of* (73)–(75) (○) *is very good.*

3.4. Multidimensional spectral element case. Before we present any numerical results, we make some general remarks regarding iterative solvers. First, one major reason for using iterative solvers is to avoid the severe memory requirements associated with direct methods, especially for large multidimensional problems. The computational complexity associated with an iterative solver is essentially determined by two factors: the convergence rate of the method, and the operation count for a typical matrix-vector product evaluation. In this section we focus mostly on the conditioning of the Uzawa operator $\underset{\sim}{S}$, which is directly related to the convergence rate of the outer pressure iteration (34). However, we should point out that in the context of high-order methods, fast matrix-vector product evaluations are typically effected by a combination of tensor-product forms and vectorization.

The spectral element discretization procedure for the general multidimensional case is essentially a tensor-product extension of the (one-dimensional) procedure described in § 3.3. In summary, the key points are the use of variational projection operators, piecewise high-order polynomial subspaces, and tensor-product bases and quadratures, resulting in minimal interelemental couplings and efficient matrix-vector product evaluations.

We consider now the Uzawa decoupling procedure (29), (30) as applied to multidimensional spectral element approximations. As discussed earlier, the pressure $\underset{\sim}{p}$ is first computed from (30) by effecting a nested inner/outer iteration procedure, while (29) is solved for the velocity $\underset{\sim}{u}_i$, $i=1,\ldots,d$, with known pressure $\underset{\sim}{p}$. The number

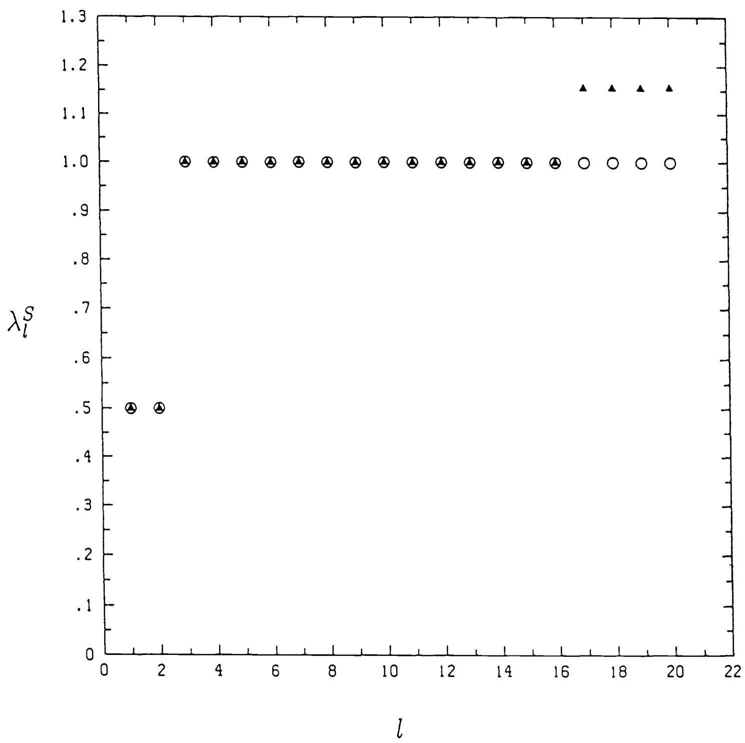

FIG. 2. *A plot of the spectrum* $\lambda_l^S(k)$ *of the preconditioned pressure matrix* $\tilde{\underline{B}}^{-1}\underline{S}$. *The spectrum* (▲) *corresponds to a spectral element discretization* ($K=4$, $N=7$) *for a wave number* $k=12$; *for this large value of* k *the discrete system can no longer resolve the higher continuous modes* (○).

of outer conjugate gradient iterations in (34) critically depends on the condition number κ^S, which we now investigate for multidimensional problems with Dirichlet velocity boundary conditions.

In order to find the condition number κ^S, we must compute the minimum and maximum eigenvalues of the matrix $\underline{S}$ with respect to the mass matrix $\tilde{\underline{B}}$. Since we never form any global system matrix explicitly, standard routines for calculating eigenvalues cannot be used. Instead, we compute the maximum eigenvalue $\lambda_{\max}^S$ using the ordinary power method [24], which involves the evaluation of matrix-vector products of the form $\underline{S}\underline{\phi}$. To compute the minimum eigenvalue $\lambda_{\min}^S$ we use the inverse power method [24], which requires inverting the matrix $\underline{S}$ for each iteration. Note that in order to do this inversion, we use the inner/outer iteration procedure described in (34)-(37).

We start by considering the solution to the steady Stokes equations (1), (2) on a square domain $\Omega =]-1, 1[^2$ with homogeneous Dirichlet velocity boundary conditions (3). Using a spectral element discretization with one single element, i.e., $K=1$, we compute the minimum eigenvalue $\lambda_{\min}^S$ of the discrete steady Stokes pressure-operator $\underline{S}$ for different values of the polynomial degree N. As we can see from Fig. 5, $\lambda_{\min}^S$ decreases as N increases, implying that the β_h in (41) is no longer independent of the discretization $h=(K, N)$. This is, in fact, numerical evidence of the presence of weak spurious modes [42]. Theoretically [8], the results indicate that $\beta_h \sim \mathcal{O}(N^{-1/2})$ as $N \to \infty$, and hence the number of outer conjugate gradient iterations would, at worst, scale like $N^{1/2}$. Note that the numerical results of Fig. 5 show that the theoretical

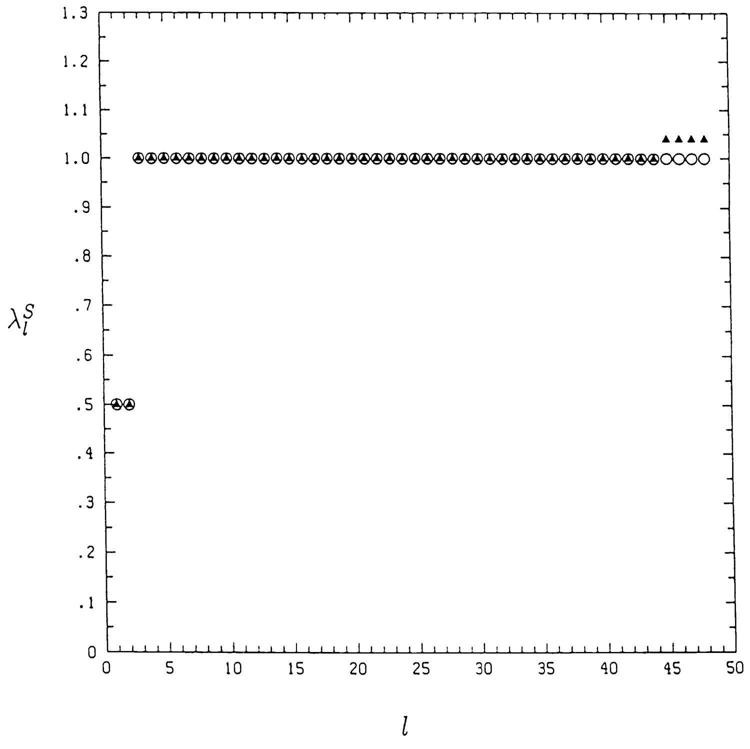

FIG. 3. *A plot of the spectrum* $\lambda_l^S(k)$ *of the preconditioned pressure matrix* $\tilde{\underline{B}}^{-1}\underline{S}$. *The spectrum* (▲) *corresponds to a spectral element discretization* ($K = 4$, $N = 14$) *for a wave number* $k = 12$; *due to the higher spatial resolution the agreement of the discrete spectrum with the continuous operator spectrum* (○) *is improved.*

result is pessimistic for the low values of N of interest in the spectral element context. Next, to see the effect of breaking up the domain Ω into several subdomains, we compare in Fig. 6 the minimum eigenvalue $\lambda_{\min}^S$ when using one single spectral element $K = 1$, and when using $K = 4$ and $K = 16$ equal spectral elements. The results clearly show that β_h is very insensitive to K, especially for larger N.

In Appendix A it is shown that the maximum eigenvalue $\lambda_{\max}^S$ is bounded from above, and that this bound is of order unity. To demonstrate numerically that this is indeed the case, in Fig. 7 we plot $\lambda_{\max}^S$ for different values of the polynomial degree N. The results show that the maximum eigenvalue is insensitive to the number of elements K and to asymptotes to a value below two, as N increases. In practice, the polynomial degree N is typically taken to be of order ten, suggesting that the outer pressure iteration will converge in order-one iterations. Our experience from solving a large variety of two-dimensional and three-dimensional problems is that about ten outer iterations suffice in most cases. We refer to Maday, Patera, and Rønquist [32] for theoretical proofs of the previous numerical evidence.

We now consider a two-dimensional steady Stokes test problem where preconditioned conjugate gradient iteration in the outer pressure iteration is combined with spectral element multigrid for the inner Laplacian solves. The test problem is creeping flow in a "wedge," but with the tip of the wedge removed. The spectral element discretization ($K = 40$, $N = 8$) is shown in Fig. 8(a), and the solution in the form of streamlines is shown in Fig. 8(b). In this test problem, we have removed the tip of the

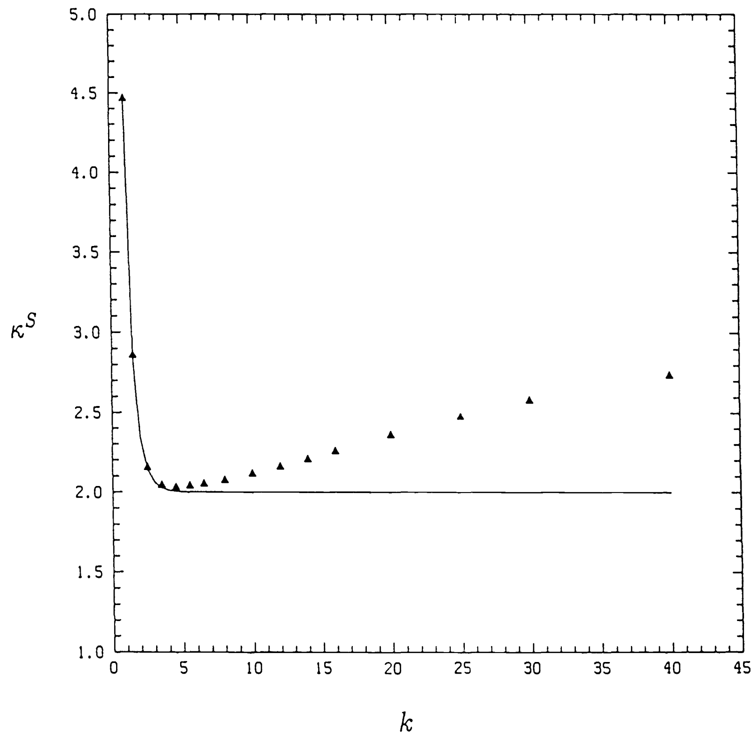

FIG. 4. *A comparison between the condition number $\kappa^S(k)$ of the spectral element operator $\tilde{\underline{B}}^{-1}\underline{S}$ (▲) and the condition number $\kappa^s(k)$ of the continuous operator s in (65) (solid line), as a function of Fourier wave number k. The spectral element discretization ($K = 4$, $N = 10$) is used. For small and moderate k the two curves coincide. However, as $k \Rightarrow \infty$ the two results diverge due to the finite resolution of the spectral element mesh.*

wedge in order to be able to break up the computational domain into spectral elements with aspect ratio approximately equal to unity (see Fig. 8(a)). As discussed in Rønquist [37], the convergence rate of the spectral element multigrid algorithm deteriorates as the aspect ratio of the elements becomes much different from unity. For this particular steady Stokes test problem the total speedup was about 2.5 using multigrid with $J = 4$ meshes instead of preconditioned conjugate gradient iteration for the inner Laplacian solves (timings on a CRAY-XMP). Note that due to the more inefficient vectorization of the matrix-vector products on the coarser meshes ($j = 1$, 2, and 3) compared to the finest mesh ($j = 4$), the computational cost on the coarser meshes ($j \neq J$) cannot be neglected.

Next, we consider the Uzawa decoupling procedure as applied to a three-dimensional steady Stokes problem (1), (2) in a domain Ω defined by $x_1 \in]0, 2\Gamma[$, $x_2 \in]-1, 1[$, $x_3 =]-1, 1[$, where Γ can be interpreted as the aspect ratio of the system. The prescribed force $\mathbf{f}$ is such that the exact solution is given by $\mathbf{u} = (u_1, u_2, u_3) = ((1 - x_2^2)(1 - x_3^2), 0, 0)$ and $p = \sin \pi x_1/\Gamma \cdot \cos \pi x_2 \cdot \cos \pi x_3$. For large three-dimensional problems it is a nontrivial task to compute the eigenvalues of the pressure operator $\underline{S}$, and we therefore instead produce convergence histories from which appropriate condition numbers can be inferred. In particular, we shall plot the residual $\|\underline{r}\|_{0,h}$ (essentially the root mean square of the divergence) as a function of the number of iterations m in the outer conjugate gradient iteration (34).

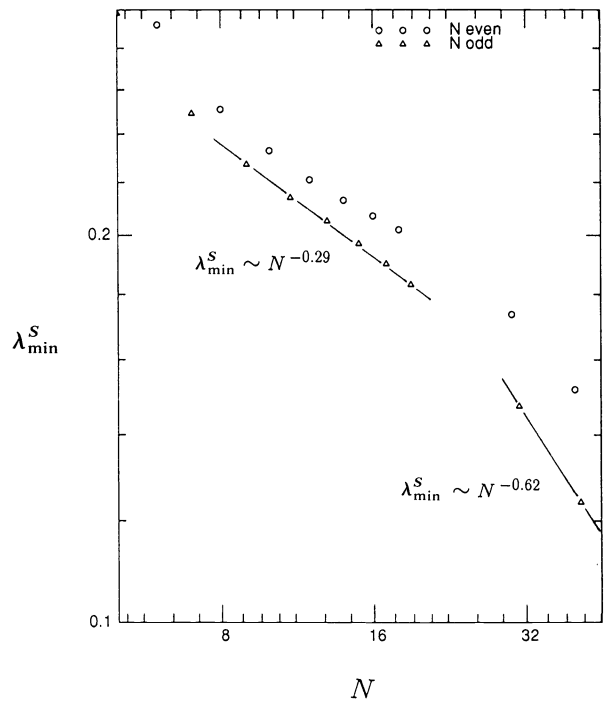

FIG. 5. *A log-log plot of the minimum eigenvalue $\lambda^S_{\min}$ of the discrete Stokes operator $\tilde{B}^{-1}\underline{S}$ as a function of the polynomial degree N (△, N odd; ○, N even). The steady Stokes equations are solved on a square domain $\Omega =]-1, 1[^2$ with homogeneous Dirichlet velocity boundary conditions using $K = 1$ spectral elements. For low values of N, $\lambda^S_{\min} \sim N^{-0.29}$, implying that $\beta_h \sim N^{-0.15}$. For larger values of N, $\lambda^S_{\min} \sim N^{-0.62}$, implying that $\beta_h \sim N^{-0.31}$. Theoretically (Bernardi and Maday [8]), β_h should at worst scale like $N^{-1/2}$, suggesting that the theoretical result is somewhat pessimistic for low values of N.*

In Fig. 9 we plot $\|\underline{r}\|_{0,h}$ as a function of m for an aspect ratio $\Gamma = 1$ and for spectral element discretizations corresponding to $K = 8$, $N = 7$ and 10. The initial convergence rate is almost independent of N, however, the asymptotic convergence rate does appear to be a weak function of N, in good agreement with the above discussion. In Fig. 10 we repeat the numerical experiment of Fig. 9, but now keeping the discretization parameter $h = (K, N) = (8, 10)$ fixed while varying the aspect ratio Γ. The convergence rate is somewhat lower for $\Gamma = 3$ as compared to $\Gamma = 1$, however, the effect is small. These results demonstrate that the good conditioning of the quasi-two-dimensional (semiperiodic) model problem does, indeed, extend to multidimensional problems.

To show the potential of the Uzawa algorithm we present results from a large three-dimensional problem with a complicated geometry. The problem we consider is solving the steady Stokes equations (1), (2) in a spiral-grooved bearing with 16 grooves. Although periodicity conditions could have been exploited, the full three-dimensional problem was discretized using 312,000 degrees of freedom. The set of algebraic equations (29), (30) was then solved on a 64-processor Intel Hypercube in about 16 minutes (160 MFLOPS). The convergence history for the outer pressure iteration (34) is plotted in Fig. 11. We see that the discrete divergence is reduced by three orders of magnitude in about 30 outer iterations. Thus we have demonstrated that the Uzawa algorithm works well for large realistic problems, and can successfully be implemented on a parallel computer. For a more detailed discussion of the parallel aspects of the algorithm, we refer to Fischer and Patera [18].

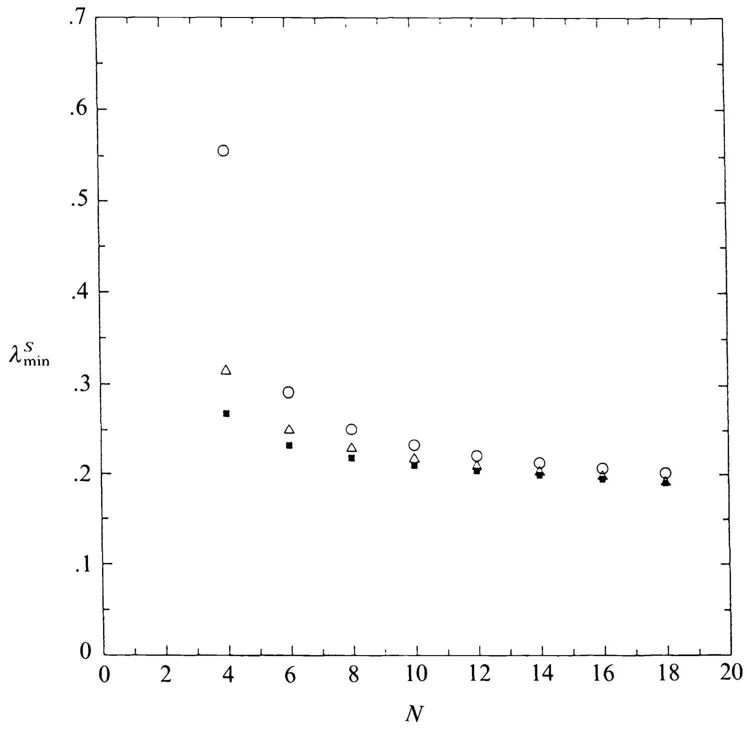

FIG. 6. *A plot of the minimum eigenvalue $\lambda^S_{\min}$ of the discrete Stokes operator $\tilde{\underline{B}}^{-1}\underline{S}$, as a function of the polynomial degree N. The steady Stokes equations are solved on a square domain $\Omega =]-1, 1[^2$ with homogeneous Dirichlet velocity boundary conditions using $K = 1$ (○), $K = 4$ (△), and $K = 16$ (■) spectral elements.*

4. Unsteady Stokes solvers. In § 2.2 we derived a set of algebraic equations (18), (19) resulting from a spectral element discretization of the *implicitly* treated unsteady Stokes problem (12)-(15). In order to compute the nodal values $\underline{u}^{n+1}$ and $\underline{p}^{n+1}$, a classical Uzawa scheme can again be constructed, but now with the discrete Laplace operator $\underline{A}$ in (25) replaced by the discrete Helmholtz operator

$$\underline{H} = \mu\underline{A} + \frac{\rho}{\Delta t}\underline{B}. \tag{82}$$

As in the steady case, the simple gradient method can be accelerated by using conjugate gradient iteration. However, in the unsteady case we must generally consider preconditioners other than the mass matrix $\tilde{\underline{B}}$ [28], [19], [38], [37], [14].

For reasons of efficiency and rigor (no rediscretization), our approach to solving the system (18), (19) will again be based on a global iterative technique. Proceeding in the same fashion as for the steady Stokes case, we arrive at the following decoupled system equivalent to the saddle problem (18), (19)

$$\underline{H}\underline{u}_i^{n+1} = \underline{D}_i^T\underline{p}^{n+1} + \underline{g}_i^n, \qquad i = 1, \dots, d, \tag{83}$$

$$\underline{S}_t\underline{p}^{n+1} = -\underline{D}_i\underline{H}^{-1}\underline{g}_i^n, \tag{84}$$

where

$$\underline{S}_t = \underline{D}_i\underline{H}^{-1}\underline{D}_i^T \tag{85}$$

is the unsteady Stokes pressure-operator analogous to the steady operator $\underset{=}{S}$ defined in (31), and

$$g_i^n = \underset{=}{B}\left(\underline{f}_i^n + \frac{\rho}{\Delta t}\underline{u}_i^n\right), \qquad i = 1, \ldots, d \tag{86}$$

represent the inhomogeneities associated with an implicit Euler backward time integration procedure. The advantages of the formulation (83), (84) are similar to those for

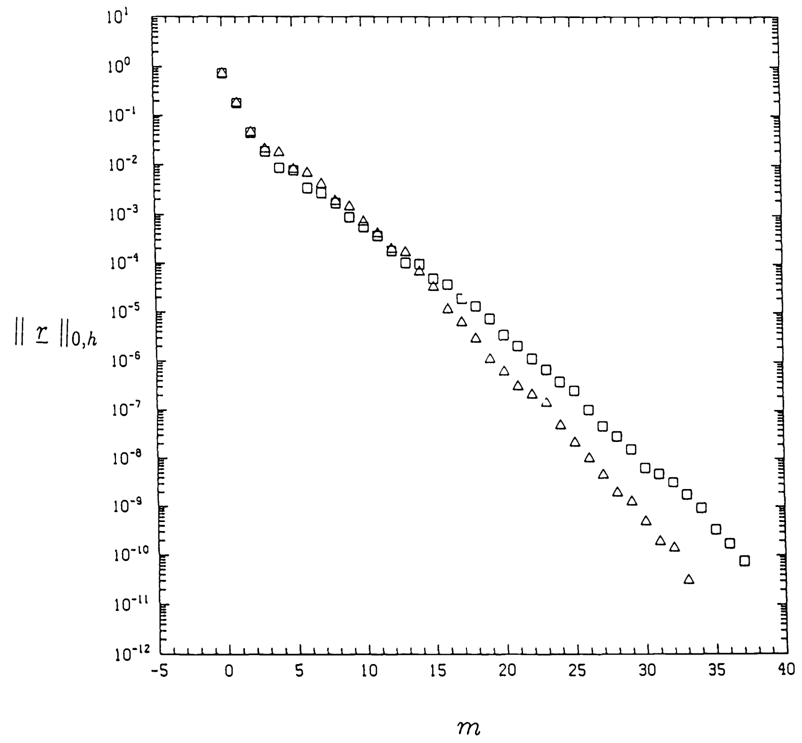

FIG. 9. *A plot of the residual* $\|\underline{r}\|_{0,h}$ *(the root-mean-square of the divergence) from* (34) *as a function of the number of outer conjugate gradient iterations m when solving the three-dimensional steady Stokes problem with solution* $\mathbf{u}=[(1-x_2^2)(1-x_3^2),0,0]$, $p=\sin \pi x_1/\Gamma\cdot\cos \pi x_2\cdot\cos \pi x_3$ *on the domain* $\Omega=]0,2\Gamma[\times]-1,1[\times]-1,1[$ *with* $\Gamma=1$. *The domain is broken up into* $K=8$ *equal spectral elements, with convergence histories shown for* $N=7$ ($\triangle$) *and* $N=10$ ($\square$). *The convergence rate decreases slightly with increasing N.*

the steady problem; it represents a complete, general, velocity-pressure decoupling that is discretely equivalent to the original discretization (18), (19). First, we solve (84) for the pressure, and then (83) is solved for each velocity component $\underline{u}_i^{n+1}$ with $\underline{p}^{n+1}$ known.

As for the steady Stokes problem the matrix S_t is completely full, and therefore solving (84) requires an iterative approach. Unfortunately, whereas the steady pressure-operator $\underline{S}$ is naturally well conditioned ($\underline{\tilde{B}}^{-1}\underline{S}$ is close to the identity), the same is not true for $\underline{S}_t$. For large time steps we can express $\underline{S}_t$ as

$$(87)\qquad \Delta t \Rightarrow \infty, \qquad \underline{S}_t \Rightarrow \frac{1}{\mu}\,\underline{S},$$

and it is thus well conditioned. However, for small time steps, $\underline{S}_t$ goes to the pseudo-Laplacian $\underline{E}$,

$$(88)\qquad \Delta t \Rightarrow 0, \qquad \underline{S}_t \Rightarrow \frac{\Delta t}{\rho}\,\underline{E},$$

where

$$(89)\qquad \underline{E}=\underline{D}_i\underline{B}^{-1}\underline{D}_i^T$$

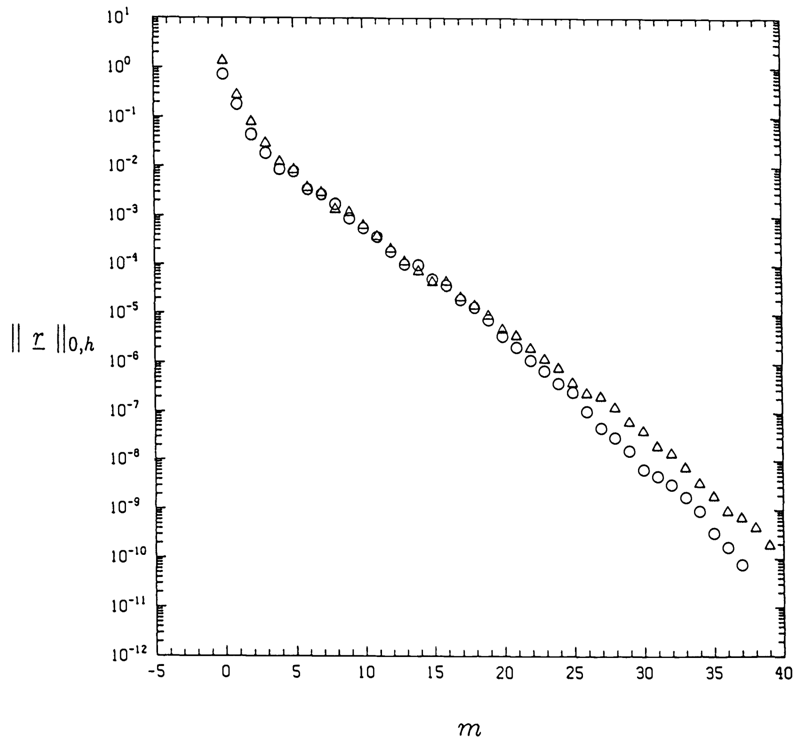

FIG. 10. *A plot of the residual* $\|\underline{r}\|_{0,h}$ *(the root-mean-square of the divergence) from* (34) *as a function of the number of outer conjugate gradient iterations* m *when solving the three-dimensional steady Stokes problem with solution* $\mathbf{u}=[(1-x_2^2)(1-x_3^2),0,0]$, $p=\sin \pi x_1/\Gamma\cdot\sin \pi x_2\cdot\cos \pi x_3$ *on the domain* $\Omega=]-1,\ 1[\times]-1,\ 1[\times]0,\ 2\Gamma[$ *with* $\Gamma=1$ (O) *and* $\Gamma=3$ (△). *Both domains are broken up into* $K=8$ *equal spectral elements, each of order* $N=10$. *The convergence rate decreases slightly as the aspect ratio* Γ *increases.*

is poorly conditioned. The matrix $\underline{E}$ is, in fact, the discrete consistent Poisson-operator resulting from spectral element discretization of the *explicitly* treated unsteady Stokes problem (12)-(15). The algorithm described for the steady case therefore needs to be modified.

Earlier spectral element solvers used a two-level Richardson inner/outer iteration scheme to solve the discrete unsteady Stokes and Navier-Stokes equations [38], [31]. Computational tests indicate that the approach of Cahouet and Chabard [13] is simpler and more efficient, and we shall therefore precondition the unsteady pressure-operator $\underline{S}_t$ directly. The preconditioner proposed is [14]

$$\underline{P}^{-1}=\mu\underline{\tilde{B}}^{-1}+\frac{\rho}{\Delta t}\underline{E}^{-1}, \tag{90}$$

which can be motivated by analyzing the two limits of very small and very large time steps. In both of these cases we expect $\underline{P}^{-1}\underline{S}_t$ to be close to the identity operator. As discussed in Cahouet and Chabard [14], the particular choice (90) as a preconditioner for $\underline{S}_t$ can perhaps be better motivated by considering the Fourier discretization (48), (49) in $\mathcal{R}^d$.

4.1. Multidimensional spectral element case. Our approach to inverting the unsteady pressure-operator is the same as for the steady case, namely, a *nested* global

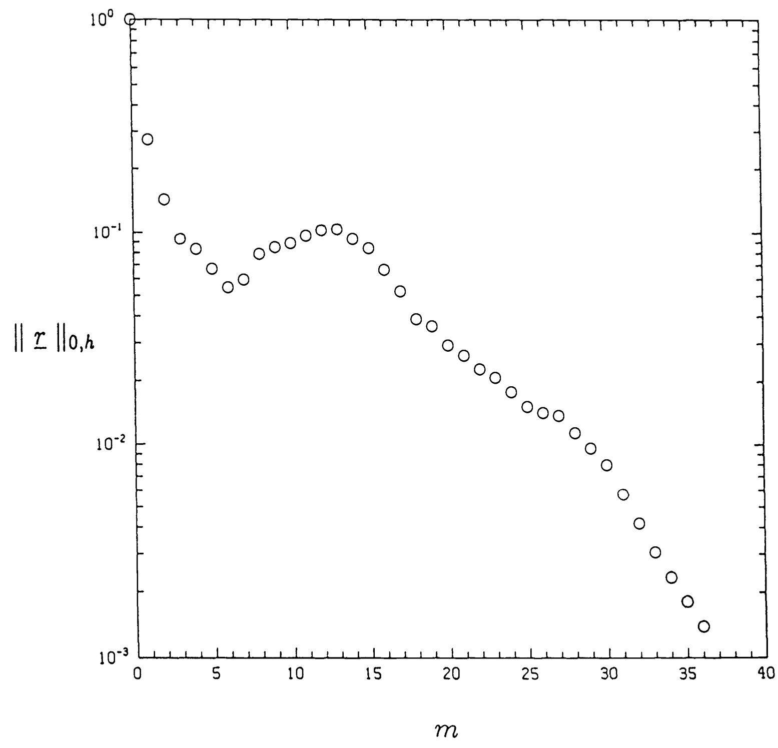

FIG. 11. *A plot of the residual* $\|\underline{r}\|_{0,h}$ (*the root-mean-square of the divergence*) *from* (34) *as a function of the number of outer conjugate gradient iterations m when solving the three-dimensional steady Stokes equations in a spiral-grooved bearing with* 16 *grooves. inner/outer iterative procedure based on preconditioned conjugate gradient iteration for the outer iteration, and spectral element multigrid for the inversion of the discrete Helmholtz operator $\underline{H}$. We note that the *structure* in the solution procedure is similar to the steady case, however, the computational *complexity* associated with the preconditioning in the outer iteration is very different. For the steady case the inversion of the *diagonal* mass matrix $\tilde{\underline{B}}$ is trivial, whereas the unsteady case requires the inversion of the pseudo-Laplacian $\underline{E}$. If we count the inversion of the $\underline{E}$-matrix as one standard elliptic solve, each iteration in the outer conjugate gradient iteration takes $d+1$ standard elliptic solves, as compared to d for the steady case. If the condition number of the matrix $\underline{P}^{-1}\underline{S}_t$ is order unity, we see that computing the pressure again requires only order-d elliptic solves. Once the pressure is known, another d elliptic solves is required to compute the velocity.

We now make some remarks regarding the $\underline{E}$-matrix, which is essentially a second-order operator with Neumann-like (pressure) boundary conditions. Our experience from numerical simulations has been that inverting $\underline{E}$ requires more iterations than inverting the standard Laplace operator $\underline{A}$ or Helmholtz operator $\underline{H}$ with Dirichlet (velocity) boundary conditions. The slower convergence rate is probably due to the mixed $\mathscr{L}^2 - \mathscr{H}^1$ spaces in the construction of the $\underline{E}$-matrix. The staggered mesh also makes it more difficult to construct a proper multigrid algorithm. To this end, standard conjugate gradient iteration has been used to invert $\underline{E}$, although a multigrid approach is in preparation.

To demonstrate the effect of the preconditioner $\underset{\sim}{P}$ in (90), we monitor the residual $\|\underset{\sim}{r}\|_{0,h}$ in the outer pressure iteration during the first time step when solving a (simulated) buoyancy-driven flow in a two-dimensional square cavity. We plot in Fig. 12 the convergence history for three different time steps. The larger time step $\Delta t = 1$ is of the order of the time it takes to reach steady state, and $\underset{\sim}{S}_t$ is therefore close to $\underset{\sim}{S}$ $(\mu = 1)$. As expected from the steady Stokes case, we see that about ten outer iterations suffice for convergence. The smaller time step $\Delta t = 10^{-4}$, however, is much smaller than a typical time scale in the system, and $\underset{\sim}{S}_t$ is close to the pseudo-Laplacian $\underset{\sim}{E}$. In fact, the time step is small enough for an explicit time-stepping procedure to be stable, and we see that convergence is reached in order-one iterations. In the limit as the time step $\Delta t \Rightarrow 0$ the unsteady pressure-operator becomes perfectly preconditioned, and the steady Stokes convergence rate represents an upper bound for how fast the outer pressure iteration converges.

For comparison, we repeat in Fig. 13 the experiment of Fig. 12, but now using the preconditioner from the steady Stokes case, that is, $\underset{\sim}{P} = \underset{\sim}{\tilde{B}}$. As expected, as long as $\underset{\sim}{S}_t$ is close to $\underset{\sim}{S}$, the convergence rate is almost identical to the previous case. However, as the time step becomes smaller and $\underset{\sim}{S}_t$ becomes closer to $\underset{\sim}{E}$, the steady Stokes preconditioner does a poor job. In conclusion, the preconditioner (90) is an excellent preconditioner for all time steps.

We close this section by remarking that the Uzawa algorithm can readily be extended to solve the full Navier–Stokes equations by treating the nonlinear convective

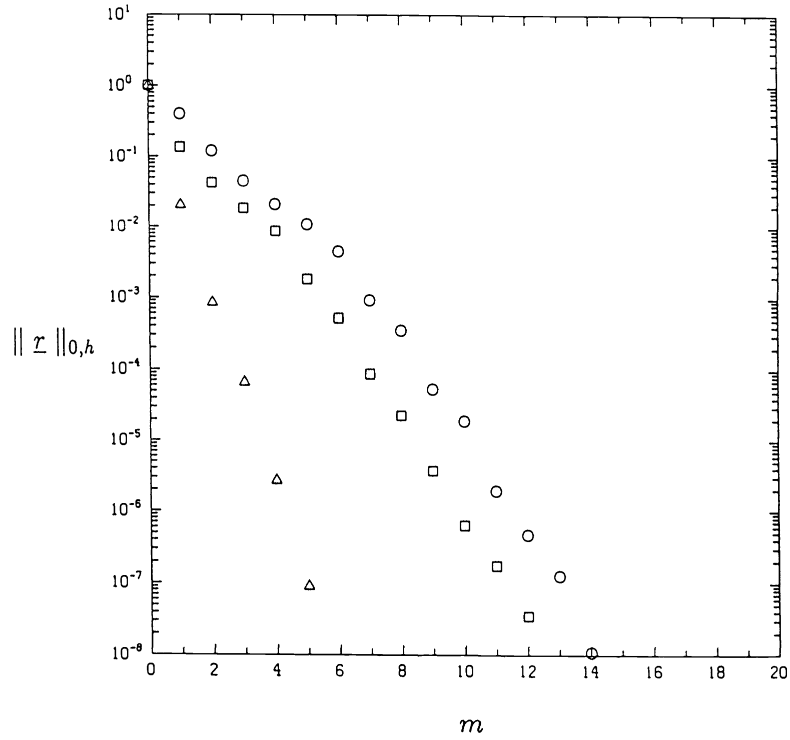

FIG. 12. *A plot of the residual* $\|\underset{\sim}{r}\|_{0,h}$ (*the root-mean-square of the divergence*) *as a function of the number of outer conjugate gradient iterations m when solving for the first time step of a* (*simulated*) *buoyancy-driven flow in a square cavity. term explicitly. This approach has been used with success in the context of spectral element discretizations [17].

Appendix A. This appendix deals with relations between the condition number of the algebraic system that arises from the Uzawa algorithm and the various parameters of the discretization, in particular, the inf-sup condition, but also other constants related to the exactness of the integration formulae. To this purpose, let us recall that we have set

$$a_h(u_h, v_h) = ((\nabla u_h, \nabla v_h))_h, \tag{A.1}$$

and introduce the following constants

$$c_1 = \sup_{\phi_h \in M_h} \frac{(\phi_h, \phi_h)_h}{(\phi_h, \phi_h)}, \tag{A.2}$$

$$c_1' = \inf_{\phi_h \in M_h} \frac{(\phi_h, \phi_h)_h}{(\phi_h, \phi_h)}, \tag{A.3}$$

$$\alpha = \inf_{\mathbf{v}_h \in X_h} \frac{a_h(\mathbf{v}_h, \mathbf{v}_h)}{\|\mathbf{v}_h\|_1^2}. \tag{A.4}$$

Let us first bound the maximum eigenvalue $\lambda_{\max}^{S}$ of the matrix $\underset{\sim}{S}$ with respect to the mass matrix $\tilde{\underset{\sim}{B}}$.

To this purpose, let us first consider the discrete Laplace operator defined by $\mathbf{u}_h = \Delta_h^{-1}\mathbf{g}$ if

$$a_h(\mathbf{u}_{h,i}, \mathbf{v}_i) = ((\mathbf{g}_i, \mathbf{v}_i))_h, \quad \forall \mathbf{v} \in X_h. \tag{A.5}$$

Let us now consider the operator div^T, transposed by the divergence operator with respect to the $(.,)_h$-scalar product, i.e.,

$$((\operatorname{div}^T p, \mathbf{v}))_h = (p, \operatorname{div} \mathbf{v})_h, \quad \forall p \in M_h, \quad \forall \mathbf{v} \in X_h.$$

LEMMA A.1. *For any p in $\mathscr{L}^2(\Omega)$, we have*

$$\|\Delta_h^{-1}(\operatorname{div})^T p\|_1 \leqq \frac{c_1}{\alpha}\|p\|_0.$$

Proof. This result is simply derived by taking $\mathbf{v} = \Delta_h^{-1}(\operatorname{div})^T p$ in (A.5) with $g = \operatorname{div}^T p$, and applying the Cauchy-Schwarz inequality.

It is important to note that with these definitions, the operator $\operatorname{div}(\Delta_h^{-1})\operatorname{div}^T$ is symmetric and that $\underset{\sim}{S}$ represents its matrix in the basis of the Lagrange interpolants. Due to the symmetry, the extreme eigenvalues are related to the upper and lower norms of the images of elements of M_h as follows:

$$(\lambda_{\max}^S) = \sup_{p \in M_h} ([\operatorname{div}(\Delta_h^{-1})\operatorname{div}^T]p, p)_h, \qquad (p,p)_h = 1 \tag{A.6}$$

and

$$(\lambda_{\min}^S) = \inf_{p \in M_h} ([\operatorname{div}(\Delta_h^{-1})\operatorname{div}^T]p, p)_h, \qquad (p,p)_h = 1. \tag{A.7}$$

Note that these eigenvalues are also those of the matrix $\underset{\sim}{S}$ with respect to the mass matrix $\underset{\sim}{\tilde{B}}$. From (A.2), (A.3), and Lemma A.1, it is an easy matter to check that

$$\lambda_{\max}^S \leqq \frac{c_1^2}{\alpha c_1'}.$$

Let us now consider $\lambda_{\min}^S$. We want to get the relationship between this eigenvalue and the inf-sup condition constant β_h given by

$$\beta_h = \inf_{p \in M_h} \sup_{\mathbf{v} \in X_h} \frac{(p, \operatorname{div} \mathbf{v})_h}{((\nabla \mathbf{v}_i, \nabla \mathbf{v}_i))_h^{1/2}}, \qquad (p,p)_h = 1.$$

Let p be given in M_h with $(p,p)_h = 1$. As noted by Vandeven [42, V, Théorème II.1], the elements $\mathbf{u}^*$ that realize the supremum related to the inf-sup condition, i.e.,

$$\sup_{\mathbf{v} \in X_h} \frac{(p, \operatorname{div} \mathbf{v})_h}{((\nabla \mathbf{v}_i, \nabla \mathbf{v}_i))_h^{1/2}} = \frac{(p, \operatorname{div} \mathbf{u}^*)_h}{((\nabla \mathbf{u}_i^*, \nabla \mathbf{u}_i^*))_h^{1/2}}, \tag{A.8}$$

are colinear to the element $\tilde{\mathbf{u}}^*$ of X_h, solution of the problem

$$\tilde{\mathbf{u}}^* = \Delta_h^{-1}\operatorname{div}^T p. \tag{A.9}$$

Since the proof of the fact is very short and simple, let us repeat it here. From (A.9) we have

$$\frac{(p, \operatorname{div} \mathbf{v})_h}{((\nabla \mathbf{v}_i, \nabla \mathbf{v}_i))_h^{1/2}} = \frac{((\nabla \tilde{\mathbf{u}}_i^*, \nabla \mathbf{v}_i))_h}{((\nabla \mathbf{v}_i, \nabla \mathbf{v}_i))_h^{1/2}}.$$

The Cauchy-Schwarz inequality then gives the inequality

$$\frac{(p, \operatorname{div} \mathbf{v})_h}{((\nabla \mathbf{v}_i, \nabla \mathbf{v}_i))_h^{1/2}} \leq ((\nabla \tilde{\mathbf{u}}_i^*, \nabla \tilde{\mathbf{u}}_i^*))_h^{1/2},$$

with the equality if and only if $\tilde{\mathbf{u}}_i^*$ and $\mathbf{v}$ are colinear. This leads from (A.9) to

$$\text{(A.10)} \quad \sup_{\mathbf{v} \in X_h} \frac{(p, \operatorname{div} \mathbf{v})_h}{((\nabla \mathbf{v}_i, \nabla \mathbf{v}_i))_h^{1/2}} = (\operatorname{div}^T p, (\Delta_h^{-1}) \operatorname{div}^T p)_h^{1/2} = ([\operatorname{div}(\Delta_h^{-1}) \operatorname{div}^T] p, p)_h^{1/2},$$

so that the inf-sup condition satisfies

$$\text{(A.11)} \qquad \beta_h = \inf_{p \in M_h} ([\operatorname{div}(\Delta_h^{-1}) \operatorname{div}^T] p, p)_h^{1/2}, \qquad (p, p)_h = 1.$$

Now recalling (A.7), we have

$$\lambda_{\min}^S = \beta_h^2.$$

Finally, the condition number κ^S is then bounded by $c_1^2 \beta_h^2 / \alpha c_1'$.

Appendix B. We consider here the solution to the eigenvalue problem (71):

$$\text{(B.1)} \qquad \int_{-1}^{1} \left\{ \frac{\partial}{\partial x} G(x, x') \frac{d\chi(x')}{dx'} - k^2 G(x, x') \chi(x') \right\} dx' = \lambda \chi(x),$$

where the Green's function $G(x, x')$ is given in closed form in (68).

To reduce the integral equation (B.1) to the form of a standard eigenvalue problem, we integrate the term involving the derivative of χ by parts,

$$\text{(B.2)} \qquad \int_{-1}^{1} \frac{\partial G}{\partial x} \frac{d\chi}{dx'} dx' = \frac{\partial G}{\partial x} \chi \Big|_{-1}^{x^-} + \frac{\partial G}{\partial x} \chi \Big|_{x^+}^{1} - \int_{-1}^{1} \frac{\partial^2 G}{\partial x \partial x'} \chi \, dx'.$$

Here the integral is broken up into two parts due to the jump discontinuity in the derivatives of G,

$$\text{(B.3)} \qquad \frac{\partial G}{\partial x'}(x, x^+) - \frac{\partial G}{\partial x'}(x, x^-) = 1.$$

Using (B.2) and (B.3), we can write (B.2) as

$$\text{(B.4)} \qquad \chi(x) - \int_{-1}^{1} \left\{ \frac{\partial^2 G}{\partial x \partial x'} + k^2 G \right\} \chi(x') \, dx' = \lambda \chi(x),$$

which is a homogeneous Fredholm integral equation of the second kind.

Using the explicit form of G from (68) and evaluating the derivatives, we obtain

$$\text{(B.5)} \qquad \begin{aligned} -\int_{-1}^{1} \frac{k^2}{k \sinh 2k} \{ &\cosh k(1 + x^<) \cosh k(1 - x^>) \\ &+ \sinh k(1 + x^<) \sinh k(1 - x^<) \} \chi(x') \, dx' \\ = (\lambda - 1) \chi(x)&. \end{aligned}$$

Using the definitions of $x^<$ and $x^>$ in (69), (70), (B.5) reduces to the following symmetric eigenvalue problem:

$$\text{(B.6)} \qquad \frac{-k}{\sinh 2k} \int_{-1}^{1} \cosh k(x + x') \chi(x') \, dx' = (\lambda - 1) \chi(x).$$

Expanding the kernel in (B.6) we arrive at

$$-\frac{k}{\sinh 2k}\left\{\cosh kx \int_{-1}^{1} \cosh kx'\chi(x')\,dx' + \sinh kx \int_{-1}^{1} \sinh kx'\chi(x')\,dx'\right\} = (\lambda-1)\chi(x). \tag{B.7}$$

By inspection, it is clear that there are two solutions to (B.7) given by

$$\chi^e = \cosh kx, \qquad \lambda^e = \frac{1}{2} - \frac{k}{\sinh 2k}, \tag{B.8}$$

$$\chi^o = \sinh kx, \qquad \lambda^o = \frac{1}{2} + \frac{k}{\sinh 2k}, \tag{B.9}$$

where superscripts e and o denote even and odd, respectively. In addition, there exists an infinite set of eigenfunctions χ corresponding to $\lambda = 1$, satisfying

$$\int_{-1}^{1} \cosh kx'\chi(x')\,dx' = \int_{-1}^{1} \sinh kx'\chi(x')\,dx' = 0. \tag{B.10}$$

For example, we can choose χ odd such that

$$\int_{-1}^{1} \cosh kx'\chi(x')\,dx' = 0, \tag{B.11}$$

or χ even such that

$$\int_{-1}^{1} \sinh kx'\chi(x')\,dx' = 0. \tag{B.12}$$

There are many ways to do this, which explains why the spectrum is clustered around unity.

Acknowledgments. We would like to thank Paul Fischer at Brown University, and Intel Scientific Computers for providing us with the parallel spectral element results.

EXPLICIT RUNGE–KUTTA PAIRS WITH ONE MORE DERIVATIVE EVALUATION THAN THE MINIMUM*

P. W. SHARP† AND E. SMART‡

Abstract. Existing classes of (4,5), (5,6), and (6,7) pairs use the minimum number of derivative evaluations per step. This ensures that the cost of each step is minimized. However, the cost per unit step is not necessarily minimized because it may be possible to take larger steps if an extra evaluation is used. The change in efficiency when one extra evaluation per step is used is investigated for classes of (4,5), (5,6), and (6,7) pairs with the minimum number of evaluations. The aim is to show that using an extra evaluation does not necessarily increase the cost per unit step, and that in some cases the cost may decrease.

The paper begins with the derivation of the new classes. Then the new and existing classes are compared using standard functions of the free parameters. Following this, numerical comparisons of representative pairs from the new and existing classes are presented. The new (4,5) and (5,6) pairs are found to be more efficient and just as reliable as the existing (4,5) and (5,6) pairs. For the (6,7) pairs, there is little difference in efficiency and reliability.

Key words. ordinary differential equations, explicit Runge–Kutta pairs, extra stage

AMS(MOS) subject classification. 65L05

1. Introduction.

Many classes of explicit Runge–Kutta pairs have been derived for the nonstiff initial value problem

$$y' = f(x,y), \quad x \in [x_0, x_f], \quad y(x_0) = y_0, \tag{1.1}$$

where $f : \mathbf{R} \times \mathbf{R}^n \mapsto \mathbf{R}^n$.

Existing pairs up to order (6,7) use the minimum number of derivative evaluations per step. This choice ensures that the cost of each step is minimized. However, the cost per unit step is not necessarily minimized, because it may be possible to take larger steps if an extra evaluation is used on each step. This situation arises with the (7,8) pairs of Verner [8]. While 12-stage pairs exist, Verner found 13-stage pairs more efficient.

Verner's result raises interesting questions about (4,5), (5,6), and (6,7) pairs. How is the efficiency of the pairs affected when an extra evaluation is used? Can the pairs be made more efficient, as for the (7,8) pairs?

For classes of efficient (4,5), (5,6), and (6,7) pairs, we investigate the effect of adding one derivative evaluation. The pairs generate order p and order $p-1$ approximations y_{i+1}, $\widehat{y}_{i+1}$, to $y(x_{i+1})$, $i = 0, \ldots$, according to

$$y_{i+1} = y_i + h\sum_{j=1}^{s} b_j f_j, \qquad \widehat{y}_{i+1} = y_i + h\sum_{j=1}^{s} \hat{b}_j f_j,$$

where

$$f_j = f\left(x_i + c_j h, y_i + h\sum_{k=1}^{j-1} a_{jk} f_k\right), \qquad j = 1, \ldots, s.$$

*Received by the editors August 14, 1989; accepted for publication (in revised form) February 3, 1992. This work was supported in part by the Natural Sciences and Engineering Research Council of Canada, and the Information Technology Research Centre of Ontario, Canada.

We assume that the solution is advanced using the higher-order (the order p) approximation because most pairs are implemented in this mode. We also assume, as is done for most pairs, that

$$c_i = \sum_{j=1}^{i-1} a_{ij}, \qquad i = 2, \ldots, s. \tag{1.2}$$

The performance of a pair of nonstiff problems depends primarily on the truncation coefficients of the two formulae in the pair. This observation suggests we could analyze the truncation coefficients to measure the changes in performance when a stage is added. The analysis is readily performed for very low-order pairs. But the analysis is difficult for (4,5), (5,6), and (6,7) pairs because the truncation coefficients depend on the free parameters of the class in a complicated way. Fortunately, even though very low-order pairs are used infrequently, analysis of their truncation coefficients gives insight into the possible changes for higher-order pairs. Hence, to motivate our work, we perform a simple analysis for three- and four-stage (2,3) pairs.

The order conditions for an s-stage third-order formula are

$$\sum_{i=1}^{s} b_i = 1, \quad \sum_{i=2}^{s} b_i c_i = \frac{1}{2}, \quad \sum_{i=2}^{s} b_i c_i^2 = \frac{1}{3}, \quad \sum_{i=3}^{s} b_i \sum_{j=2}^{i-1} a_{ij} c_j = \frac{1}{6}. \tag{1.3}$$

A third-order formula is found by solving (1.2) and (1.3). The order conditions for the embedded second-order formula are the first two equations of (1.3) with b_i replaced by $\hat{b}_i$. These two equations are satisfied by taking $\hat{b}_i$, $i = 3, \ldots, s$, as free parameters and solving for $\hat{b}_1$ and $\hat{b}_2$. To simplify the analysis, we take $c_s = 1$.

For $s = 3$, we take c_2 as a free parameter. The principal truncation coefficients of the third-order formula are $t_1 = (1 - 2c_2)/72$, $t_2 = 1/24$, $t_3 = -3t_1$, and $t_4 = -t_2$. The minimum possible value for the maximum of the magnitude of the truncation coefficients is 1/24. The minimum is attained for $0 \le c_2 \le 1$.

For $s = 4$, we take c_2, c_3, a_{42}, a_{43}, and b_4 as free parameters. As might be expected, since four-stage fourth-order formulae exist, the principal truncation coefficients for $s = 4$ can be made arbitrarily small. This does not mean the four-stage pairs can be *arbitrarily* more efficient than the three-stage pairs, because the fifth- and higher-order terms in the error expansion must be considered. However, the four-stage pairs can be *significantly* more efficient. To illustrate this, we solve the orbit problem D5 in DETEST (Enright and Pryce [2]), using a three-stage and a four-stage pair. The coefficients of the pairs are given in the Appendix. The pairs are implemented as described in §4. We use local error tolerances of 10^{-i}, $i = 2, 3, 4, 5$. The results are summarized in Fig. 1. The four-stage pair uses fewer functions than the three-stage pair to achieve the same end-point global error.

In §2 we give the derivation of the pairs. Then in §3 we investigate the new classes using standard functions of the free parameters. We also present a representative pair from each class. In §4 we summarize numerical comparisons of the representative pairs from the new and existing classes. Finally, in §5 we briefly summarize our work and possible extensions to it.

2. Derivation.

2.1. (4,5) pairs. Most classes of (4,5) pairs use six stages. One exception is the seven-stage class of Dormand and Prince [1]. However, the seventh stage in this

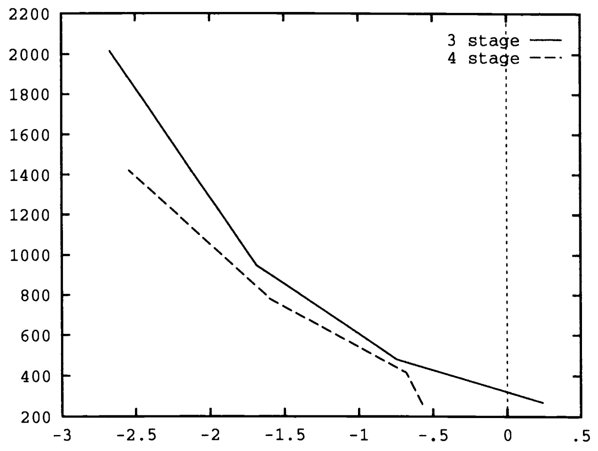

FIG. 1. *Number of derivative evaluations against the logarithm of the end-point global error for the three- and four-stage* (2,3) *pairs.*

class is reused as the first stage on the next step. Hence, the number of derivative evaluations performed on all accepted steps, except the first, is the same as for six-stage pairs. Pairs that reuse the last stage are often called FSAL (first same as last) pairs.

The numerical testing of Dormand and Prince [1] suggests that representative pairs from their FSAL class are more efficient than representative pairs from other (4,5) classes. Hence our (4,5) pairs are derived from the FSAL class. Our pairs are seven-stage non-FSAL.

We make the simplifying assumptions

$$C(i,k) \equiv \frac{c_i^{k+1}}{k+1} = \sum_{j=2}^{i-1} a_{ij} c_j^k, \quad i = 3,\dots,7, \quad k = 1,2, \tag{2.1}$$

and

$$R(j) \equiv \sum_{i=j+1}^{7} b_i a_{ij} = b_j(1-c_j), \qquad j = 1,\dots,7. \tag{2.2}$$

The simplifying assumptions imply $c_7 = 1$, $b_2 = 0$, and $\hat{b}_2 = 0$.

The independent order conditions are then

$$\sum_{i=1}^{7} b_i c_i^k = \frac{1}{k+1}, \qquad k = 0,\dots,4, \tag{2.3}$$

$$\sum_{i=1}^{7} \hat{b}_i c_i^k = \frac{1}{k+1}, \qquad k = 0,\dots,3, \tag{2.4}$$

$$\sum_{i=3}^{7} b_i c_i a_{i2} = 0, \tag{2.5}$$

$$\sum_{i=3}^{7} \hat{b}_i a_{i2} = 0. \tag{2.6}$$

These equations and the simplifying assumptions are solved as follows:

- Take b_7 as a free parameter and solve (2.3) for b_i, $i = 1, 3, \ldots, 6$.
- Solve $C(3,1)$, $C(3,2)$ for a_{32} and c_2, and $C(4,1)$, $C(4,2)$ for a_{42} and a_{43}.
- Take a_{52} as a free parameter and solve $C(5,1)$, $C(5,2)$ for a_{53} and a_{54}.
- Using $c_7 = 1$ and $R(2)$, (2.5) can be rewritten as

$$\sum_{i=3}^{6} b_i(1 - c_i)a_{i2} = 0.$$

Solve this for a_{62} and then (2.5) for a_{72}.

- Take a_{65} as a free parameter and solve $C(6,1)$ and $C(6,2)$ for a_{63} and a_{64}.
- Solve $R(6)$ for a_{76} and $R(5)$ for a_{75}.
- Solve $C(7,1)$ and $C(7,2)$ for a_{73} and a_{74}.
- Solve (1.2) for $a_{i1}, i = 2, \ldots, 7$.
- Take $\hat{b}_7$ as a free parameter and solve (2.4) and (2.6) for $\hat{b}_i$, $i = 1, 3, 4, 5, 6$.

The remaining simplifying assumptions are automatically satisfied. The derivation gives a class of seven-stage (4,5) pairs with c_3, c_4, c_5, c_6, a_{52}, a_{65}, $\hat{b}_7$, and b_7 as free parameters.

2.2. (5,6) pairs. Most classes of (5,6) pairs use eight stages. However, recently, several investigators (see Verner [9], for example) derived similar classes of nine-stage (5,6) FSAL pairs. The numerical testing of these investigators suggests that representative pairs from the new classes are more efficient than representative pairs from eight-stage classes. Hence we derive our (5,6) pairs from the FSAL class. Our pairs are ten-stage FSAL.

We make the simplifying assumptions $C(i,1)$, $i = 3, \ldots, 9$, $C(i,2), i = 4, \ldots, 9$, $R(j)$, $j = 1, \ldots, 9$, $a_{i2} = 0$, $i = 4, \ldots, 9$, $\hat{b}_3 = 0$, $b_3 = 0$, and $b_9 = 0$.

The simplifying assumptions imply $c_9 = 1$, $b_2 = 0$, and $\hat{b}_2 = 0$.

The independent order conditions are then

$$\sum_{i=1}^{9} b_i c_i^k = \frac{1}{k+1}, \qquad k = 0, \ldots, 5, \tag{2.7}$$

$$\sum_{i=1}^{10} \hat{b}_i c_i^k = \frac{1}{k+1}, \qquad k = 0, \ldots, 4, \tag{2.8}$$

$$\sum_{i=4}^{9} b_i c_i a_{i3} = 0, \tag{2.9}$$

(2.10) $$\sum_{i=4}^{10} \hat{b}_i a_{i3} = 0,$$

(2.11) $$\sum_{i=4}^{9} b_i c_i \sum_{j=2}^{i-1} a_{ij} c_j^3 = \frac{1}{24},$$

(2.12) $$\sum_{i=4}^{10} \hat{b}_i \sum_{j=2}^{i-1} a_{ij} c_j^3 = \frac{1}{20}.$$

These equations and the simplifying assumptions are solved as follows:

• Take b_4 as a free parameter and solve (2.7) for b_1, b_i, $i = 5, \ldots, 9$.

• Solve $C(3,1)$ for a_{32}, $C(4,1)$, $C(4,2)$ for a_{43} and c_3, and $C(5,1)$, $C(5,2)$ for a_{53} and a_{54}.

• Take a_{65} as a free parameter and solve $C(6,1)$, $C(6,2)$ for a_{63} and a_{64}.

• Take a_{75} and a_{76} as free parameters and solve $C(7,1)$, $C(7,2)$ for a_{73} and a_{74}.

• Using $c_9 = 1$ and $R(2)$, (2.9) can be rewritten as

$$\sum_{i=4}^{8} b_i(1 - c_i)a_{i3} = 0.$$

Solve this for a_{83}.

• Rewrite (2.11) as

$$\sum_{i=4}^{8} b_i(c_i - 1)q_{i3} = -\frac{1}{120},$$

where $q_{i3} = \sum_{j=2}^{i-1} a_{ij}c_j^3$. Solve this for q_{83}.

• Take a_{87} as a free parameter and solve $C(8,1)$, $C(8,2)$, $q_{83} = \sum_{j=2}^{7} a_{8j}c_j^3$ for a_{84}, a_{85}, and a_{86}.

• Solve $R(j)$, $j = 3, \ldots, 8$ for a_{9j}, $j = 3, \ldots, 8$.

• Set $c_{10} = 1$, $a_{10j} = b_j$, $j = 1, \ldots, 9$.

• Solve (1.2) for $a_{i1}, i = 2, \ldots, 9$.

• Take $\hat{b}_8$ as a free parameter, and solve (2.8), (2.10), and (2.12) for $\hat{b}_1$, $\hat{b}_i, i = 4, 5, 6, 7$, $\hat{b}_9$, and $\hat{b}_{10}$.

2.3. (6,7) pairs. Few numerical comparisons of (6,7) pairs have been made. Hence it is difficult to decide, using the efficiency of representative pairs, which class of pairs to base our pairs on. Instead, we use the most general class of pairs, which is that derived by Verner [8].

Verner derives his pairs by satisfying a set of conditions which ensure that a pair has the required order. The central idea of the derivation is to specify a vector of stage orders for the seventh-order formula. Once this is done, the seventh-order formula is found by solving recurrences and systems of linear equations. The sixth-order formula is then found by adding a stage and solving a recurrence and a system of linear equations. The details of the derivation are given in Verner [8]. Here, we discuss the selection of the vector of stage orders.

The seventh-order formula in Verner's (6,7) pairs uses the first nine stages. The vector of stage orders for the formula is

$$\xi = [7, 1, 2, 3, 3, 3, 3, 3, 3].$$

The seventh-order formula of our pairs uses the first ten stages, which means that one component must be added to ξ. There are two restrictions on the component: it must be less than three, and it must be added between the first and fourth component of ξ. Even with these restrictions the value and position of the component is not unique. We experimented with two choices and decided upon

$$\xi = [7, 1, 1, 2, 3, 3, 3, 3, 3, 3].$$

3. Selection. In this section, we summarize the selection of representative pairs from the new classes. The selection uses standard functions of the free parameters. Only a brief description of the functions is given here. See Prince and Dormand [5] or Shampine [6] for a more detailed description.

(i) The truncation coefficients in the higher-order formula should be small or close to their minimum value to make the pair efficient. We define the size of the truncation coefficients as

$$T_{p+1} = \left[\sum_{j=1}^{N_{p+1}} t_{p+1,j}^2 \right]^{1/2},$$

where N_{p+1} is the number of order conditions of order $p+1$, and $t_{p+1,j}$ is the jth truncation coefficient of order $p+1$. Small truncation coefficients will also lead to small errors in the local error estimate.

(ii) The ratio

$$R^{\text{opt}} \equiv \frac{\left[\sum_1^{N_{p+1}} (t_{p+1,j} - \hat{t}_{p+1,j})^2 \right]^{1/2}}{\hat{T}_p}$$

should be small. This helps to ensure that the local error estimate behaves like Ch^p. This in turn helps to ensure that the number of rejected steps is small.

(iii) The coefficients of the pair should not be large in magnitude to ensure that the roundoff error is insignificant (except possibly near limiting precision). We denote the maximum of the magnitude of the coefficients by $R^{\max}$. It is difficult to decide upon a suitable value for $R^{\max}$, because a small bound can prevent the selection of an efficient and reliable pair. After some numerical experiments, we chose $R^{\max} = 20$.

(iv) The region of absolute stability for the order p formula should be large. We measure the size, denoted by R^{stab}, along the negative real axis.

3.1. (4,5) pairs. As we might expect from the existence of seven-stage sixth-order formulae, the principal truncation coefficients of the fifth-order formula can be zero. This means we cannot search for an efficient pair by minimizing T_6. We minimize T_6 subject to $T_7 \leq kT_6$, $k > 0$. There is no obvious value for k. We found $k = 4$ led to useful pairs. For values of the free parameters that satisfy the above requirement, the ratio R^{opt} is usually between 1 and 1.5, and $R^{\max}$ is less than ten.

A representative seven-stage pair has $c_3 = 8/35$, $c_4 = 9/20$, $c_5 = 2/3$, $c_6 = 7/9$, $a_{52} = -7/20$, $a_{65} = 9/25$, $b_7 = 3/40$, and $\hat{b}_7 = 9/125$, for which $T_6 = 7.1 \times 10^{-5}$, $T_7 = 1.8 \times 10^{-4}$, $R^{\text{opt}} = 1.1$, $R^{\text{stab}} = -3.9$, and $R^{\max} = 0.86$.

3.2. (5,6) pairs. In a similar way to the (4,5) pairs, T_8 can be made arbitrarily small. A representative pair has $c_2 = 1/18$, $c_4 = 1/6$, $c_5 = 89/200$, $c_6 = 19/39$, $c_7 = 74/95$, $c_8 = 8/9$, $a_{65} = 8/61$, $a_{75} = -43/21$, $a_{76} = 83/33$, $a_{87} = 13/23$, $b_4 = 16/61$, and $\hat{b}_8 = 0$, for which $T_7 = 3.2 \times 10^{-6}$, $T_8 = 2.4 \times 10^{-5}$, $R^{\text{opt}} = 1.0$, $R^{\text{stab}} = -4.5$, and $R^{\max} = 13.3$.

3.3. (6,7) pairs. Adding one stage does not lead to a large reduction in the size of the truncation coefficients for the seventh-order formula. We find that T_8 can be made approximately three times smaller. A representative 11-stage pair is given by $c_2 = 1/50$, $c_3 = 27/125$, $c_4 = 41/100$, $c_5 = 57/100$, $c_6 = 43/100$, $c_8 = 18/25$, $c_9 = 5/6$, $a_{42} = 0$, and $a_{61} = -31/200$, for which $T_8 = 1.3 \times 10^{-5}$, $T_9 = 3.6 \times 10^{-5}$, $R^{\text{opt}} = 1.9$, $R^{\text{stab}} = -3.8$, and $R^{\max} = 9.4$.

4. Numerical comparisons. In this section, we summarize numerical comparisons of existing (4,5), (5,6), and (6,7) pairs with the pairs from the previous section. To help ensure fair comparisons, we have sought to use existing pairs that are efficient. This requirement presents little difficulty for (4,5) and (5,6) pairs. We use the (4,5) FSAL pair of Dormand and Prince [1] and the (5,6) FSAL pair of Verner [9]. The difficulty comes with the (6,7) pairs, because existing (6,7) pairs are either inefficient or unreliable. The (6,7) pair given in Verner [8] is for illustrative purposes only and is inefficient. The (6,7) pair of Fehlberg [3] has an unreliable local error estimate. To overcome these difficulties, we selected, using the criteria of §3, a pair from the ten-stage (6,7) class of Verner [8]. The values for the free parameters are $c_2 = 1/5$, $c_4 = 17/40$, $c_5 = 2/25$, $c_7 = 7/9$, and $c_8 = 5/6$. The remaining coefficients are found using Theorems 3 and 4 of Verner [8].

We use the test problems A1,...,A5, B1,...,B5, D1,...,D5, E1,...,E5 from DETEST (Enright and Pryce [2]). The problems are integrated in their scaled form and we refer to them as problems 1–20. We omit the C set of problems because the set contains mildly stiff problems.

The pairs are implemented in a similar way to the pair in DVERK (Hull, Enright, and Jackson [4]). After an accepted step, x and y are updated and a new stepsize is selected according to the formula

$$\min\left\{\alpha h_{\text{old}}, \beta(\text{TOL}/\text{est})^{1/p} h_{\text{old}}, h_{\max}\right\},$$

where $\alpha > 1$, β is a safety factor, TOL is the local error tolerance, est is the weighted norm of the local error estimate, $h_{\max}$ is the maximum stepsize allowed, and h_{old} is the previous stepsize. If the step is rejected, a new stepsize is calculated in one of two ways, depending on the number of consecutive rejected steps (denoted by n_r). If $n_r \leq m_{\text{opt}}$ where $m_{\text{opt}} \geq 0$, the new stepsize is calculated as

$$\max\left\{\alpha^{-1} h_{\text{old}}, \beta(\text{TOL}/\text{est})^{1/p} h_{\text{old}}, h_{\min}\right\},$$

where $h_{\min}$ is the minimum stepsize. For $n_r > m_{\text{opt}}$, the new stepsize is the maximum of $h_{\min}$ and $\alpha^{-1} h_{\text{old}}$. We use a maximum norm with absolute weights, $\alpha = 2$, $\beta = 0.9$, $h_{\max} = 5$, $h_{\min} = 10^{-8}$, and $m_{\text{opt}} = 1$. For each pair and test problem we use tolerances of 10^{-i}, $i = 2, \ldots, 10$.

We begin with comparisons of the efficiency. The comparisons are based on the normalized efficiency statistics printed by DETEST. The package calculates the statistics, for a given problem and pair, by first assuming a relationship of the form

$$\text{global error} = \text{CTOL}^{E},$$

where the global error is either the end point or maximum global error. The exponent E and the constant of proportionality C depend on the method and the problem. After the global error is found for several tolerances, values for E and C are found in a least squares sense. The values are then used to estimate the number of derivative evaluations required to achieve an expected accuracy (global error). The number of derivative evaluations is estimated for a range of expected accuracies to give the normalized efficiency statistics.

Once the statistics have been obtained, we take the pairs two at a time and form the intersection of the values of the expected accuracy for each problem. For these values, we take the estimated number of derivative evaluations and divide the larger value by the smaller value to give an efficiency ratio. We then form the efficiency gain by subtracting 1 from the ratio. If the second pair of the two pairs uses fewer evaluations, we multiply the gain by -1. Finally, we multiply the gains by 100, round the result to the nearest integer, and enter the numbers on a graph of the expected accuracy against the problem number. Efficiency gains of magnitude greater than 98 are entered as 99 (with the appropriate sign). See Sharp [7] for a more detailed discussion of efficiency gains.

Figures 2, 3, and 4 contain the efficiency gains for the new (4,5), (5,6), and (6,7) pairs against the existing pairs of the same order. Figures 5 and 6 contain the efficiency gains for the new (4,5) and (5,6) pairs against the new (6,7) pair. Table 1 contains the average of the efficiency gains for each problem in Figs. 2–6. The end point global error is used in the normalized statistics.

The new (4,5) pair is often significantly more efficient than the Dormand and Price (4,5) FSAL pair. The average gain in efficiency over all 20 problems and 9 tolerances is approximately 35 percent. The new (5,6) pair is often more efficient than Verner's (5,6) FSAL pair. But, the gain in efficiency is not as significant as for the (4,5) pair. The two (6,7) pairs are of comparable efficiency. The new (6,7) pair is significantly more efficient than the new (4,5) pair, but of comparable efficiency to the new (5,6) pair.

FIG. 2. *Efficiency gains for the Dormand and Prince* (4,5) *pair against the new* (4,5) *pair.*

One measure of the reliability of a pair is the accuracy of the local error estimate. Table 2 contains, for each problem and pair, the maximum of the norm of the local error on accepted steps divided by the tolerance (TOL). For example, the first entry for the Dormand and Price (4,5) pair is 0.6. This means, for problem one, that the norm of the local error on accepted steps for all nine tolerances was never greater than 0.6TOL.

If the local error estimate is accurate, the maximum norm should be no larger than TOL. (Because of the conservative nature of the stepsize selection, the maximum norm may be smaller than TOL.)

The new (4,5) and (5,6) pairs have a significantly more accurate local error estimate than the existing (4,5) and (5,6) pairs. However, there is little difference between the reliability of the two (6,7) pairs.

5. Discussion.

We derived classes of (4,5), (5,6), and (6,7) explicit Runge–Kutta pairs that use one more derivative evaluation per step than existing classes. We also tested representative pairs from the new and existing classes. We found the new (4,5) and (5,6) pairs were more efficient and just as reliable as the existing (4,5) and (5,6) pairs. The new and existing (6,7) pairs were of comparable efficiency and reliability.

Besides increasing the number of classes of suitable pairs for implementation in general-purpose software, our results have several possible implications. Because of the similarities between Runge–Kutta pairs and Nyström pairs for the general second-order initial-value problem, our conclusions may hold for Nyström pairs. For instance, an eight-stage (5,6) Nyström pair is easily obtained by applying a simple transformation to the coefficients of an eight-stage (5,6) Runge–Kutta pair. Hence it may be possible to improve the efficiency of the (5,6) Nyström pairs by adding a stage.

If interpolants for the new classes require no more extra stages than those for existing classes, then the relative cost of forming the interpolant will be less. In this case, the cost of generating dense output and using defect control will be less. We are currently investigating interpolants for the new classes.

Appendix.

The appendix contains the coefficients of the three- and four-stage (2,3) pairs used to produce the numerical results of §1.

SUPERPARALLEL FFTS*

HANS MUNTHE-KAAS†

Abstract. Fast Fourier transform (FFT) algorithms for single instruction multiple data (SIMD) machines are developed which simultaneously solve any combination of FFTs of different sizes and even different spatial dimensionalities. The only restrictions are that all the periods must be powers of two and that the initial data must satisfy some alignment requirements with the address space in the computer. The degree of parallelism is equal to the sum of the sizes of all the subproblems and the (parallel) solution time is proportional to $\log_2(m)$, where m is the number of points in the largest subsystem. It is shown that the task of unscrambling the data can be both executed and scheduled efficiently in parallel. Finally, implementations on the MasPar computer are described. The codes can be quickly and easily employed in solving complicated problems, and the interface for the routines may therefore be interesting for sequential FFT codes as well.

Key words. FFT, parallel computing, SIMD computers, superparallel algorithms

AMS(MOS) subject classifications. 65T20, 65Y05, 65Y10

1. Introduction.

Fast Fourier transforms (FFTs) constitute one of the most important classes of algorithms in scientific computations. Several papers deal with the problems of implementing FFTs on vector and multiprocessor systems; see [1], [26], and [27]. Various aspects of mapping FFT algorithms to Boolean cubes are discussed, for example, in [11] and [23].

In this paper we are concerned with the effective implementation of FFTs on massively parallel computer systems. Primarily, we have in mind fine-grained parallel machines of the single instruction multiple data (SIMD) stream type, often also called *data parallel computers.* SIMD machines are now commercially available with a number of processors ranging from a few thousand to almost a hundred thousand. Increasingly, we are faced with the luxury of having "too many processors."

Suppose that we wish to solve a mathematical problem of some characteristic size n (n is, e.g., the number of points in a grid, the number of pixels in an image, or some other size indicator). Parallel algorithms for solving the problem can typically be grouped into three main categories.

1. $p \ll n$. The number of processors is much smaller than the size of the problem. This is a typical situation for implementations on coarse-grained parallel systems with a moderate number of processors.
2. $p \sim n$. The number of processors matches the size of the problem. This is not as common in practice; it mainly occurs for benchmark model problems or for special-purpose machines built for a specific task.
3. $p \gg n$. The number of processors is much larger than the size of the problem. This problem class is becoming increasingly important as the number of processors grows, and is our concern in this paper.

As the maximum number of processors that can possibly be employed in solving a given problem is limited by (some function of) n, it is not likely that problem class 3 has efficient algorithms in the case where only a single instance of the problem is to be solved. On the other hand, it is often the case that we want to simultaneously

solve multiple occurrences of the same (or closely related) problems. Parkinson [22] uses the term *superparallel algorithms* to denote algorithms that in a SIMD fashion can solve multiple instances of similar problems (of possibly different sizes), with a degree of parallelism that is on the order of the sum of the sizes of all the subproblems. Superparallel algorithms are immensely important for the efficient utilization of massively parallel SIMD machines, as they in a sense make the SIMD machine behave as a MIMD (multiple instruction multiple data) stream machine, solving different problems simultaneously. Compared to a parallel scheduling of different jobs on a MIMD computer, superparallel algorithms have several advantages, since they require no load balancing or synchronizations.

Before we describe the superparallel FFT algorithms in detail, we will briefly address the main differences between sequential and data parallel programming, since this is a key issue for understanding the fundamental ideas. In a sequential programming style, the geometry information of a problem is typically controlled through the instruction stream (i.e., through the program code). For instance, in grid problems the size of the problem usually appears in the range of some looping variables. Data parallel programming [8], on the other hand, seeks to define geometries through the data streams. For example, grid problems are defined by mapping the grid onto the processors, and boundary effects are taken into account by modifying the data set near the boundary points. Since SIMD machines have many data streams, but only one instruction stream, defining the geometries through the data stream is the only way of obtaining superparallel algorithms.

Superparallel algorithms were previously known for problems such as the solution of linear tridiagonal equation systems and linear recurrences [22]. Superparallel FFT algorithms have, on the other hand, not been known. The reason for this is probably that it is less obvious how to define the geometries of FFTs through the data stream. Parkinson [22] writes: "[For the FFT algorithm], there does not appear to be a variable which would allow us to easily extend the algorithm to have the Super Parallel property."

In the following sections we will demonstrate that such a variable exists, and construct superparallel FFT algorithms. It came as a pleasant surprise that in many ways the corresponding codes are both simpler to program and simpler to use than their sequential counterparts.

2. The superparallel FFT.

2.1. Background and fundamental ideas.

Given an n-periodic vector

$$x(p+n) = x(p); \qquad p = 0, 1, \ldots, n-1,$$

the domain of this vector may be identified with the n-cyclic group $\mathcal{G} = \mathcal{Z}_n$, i.e., the integers $0, 1, \ldots, n-1$ under addition modulo n.

The Fourier transform on $\mathcal{Z}_n$ is defined as

$$\hat{x} = \sum_{q \in \mathcal{G}} x(q) \cdot e^{2\pi i p q/n},$$

or equivalently, in matrix form,

$$\hat{x} = F_n \cdot x,$$

where F_n is the Fourier matrix of order n

$$(F_n)_{p,q} = e^{2\pi i p q/n}. \tag{1}$$

The domain of $\hat{x}$ is the dual group $\hat{\mathcal{G}}$, which is isomorphic to $\mathcal{G}$. Or, in simpler language, $\hat{x}$ is also an n-periodic vector, and there is a natural 1–1 correspondence between the elements of $\hat{x}$ and the elements of x.

Now given a general finite Abel group $\mathcal{G}$, it can always be written as a direct product of cyclic groups $\mathcal{Z}_{n_i}$

$$\mathcal{G} = \mathcal{Z}_{n_{k-1}} \otimes \mathcal{Z}_{n_{k-2}} \otimes \cdots \otimes \mathcal{Z}_{n_1} \otimes \mathcal{Z}_{n_0}.$$

$\mathcal{G}$ can be identified with the set of all integer k-tuples

$$(l_{k-1}, l_{k-2}, \ldots, l_0); \qquad 0 \le l_i < n_i - 1,$$

under addition modulo $(n_{k-1}, n_{k-2}, \ldots, n_0)$. One can simply think of $\mathcal{G}$ as being a k-dimensional grid, periodic of period n_i in the direction i. The Fourier transform on $\mathcal{G}$ is given by

$$\hat{x}(p) = \sum_{q \in \mathcal{G}} x(q) \cdot e^{2\pi i \langle p,q \rangle / n},$$

where $\langle p, q \rangle$ is the bilinear pairing

$$\langle p, q \rangle = \frac{p_{k-1} q_{k-1}}{n_{k-1}} + \frac{p_{k-2} q_{k-1}}{n_{k-2}} + \cdots + \frac{p_1 q_1}{n_1} + \frac{p_0 q_0}{n_0}.$$

The transform can equivalently be written in matrix form

$$\hat{x} = (F_{n_{k-1}} \otimes F_{n_{k-2}} \otimes \cdots \otimes F_{n_0}) \cdot x,$$

where F_n is given by (1) and $\otimes$ denotes the matrix tensor product (see, e.g., [7] for its definition and properties). The domain of $\hat{x}$ is the dual group $\hat{\mathcal{G}}$, which again is isomorphic to the original group $\mathcal{G}$.

In the rest of the paper we make the assumption that all periods n_i are powers of two. It is our aim to develop superparallel FFTs that can simultaneously handle any collection of FFTs of (possibly) different sizes and different number of dimensions k, the only restriction being that all the periods are powers of two. Our approach is based on Cooley–Tukey FFTs [6].

The idea behind the radix-2 Cooley–Tukey FFT is an attempt to factor the group $\mathcal{Z}_n$ in a direct product of binary groups $\mathcal{Z}_2$. But since $\mathcal{Z}_n$ and $\mathcal{Z}_2 \otimes \mathcal{Z}_{n/2}$ are in general nonisomorphic groups, we cannot factor the matrix F_n as $F_2 \otimes F_{n/2}$. The closest we can get to a factorization of this kind is the following formula (described in §2.2):

$$P \cdot F_n = (I_2 \otimes F_{n/2}) \cdot T \cdot (F_2 \otimes I_{n/2}), \tag{2}$$

where P is a permutation matrix, called the *scrambling matrix.* I_k are identity matrices of order k, and T is a diagonal matrix containing the so-called *twiddle factors.*

Since $(I_2 \otimes F_{n/2}) \cdot (F_2 \otimes I_{n/2}) = (F_2 \otimes F_{n/2})$ is the FFT on the group $Z_2 \otimes Z_{n/2}$, we observe that apart from the twiddle factors T, and the scrambling matrix P, the FFTs on $\mathcal{Z}_n$ and $\mathcal{Z}_2 \otimes \mathcal{Z}_{n/2}$ are identical. We can continue to factor out binary groups and arrive at an equivalency between the FFT on

$$\mathcal{Z}_{n_{k-1}} \otimes \mathcal{Z}_{n_{k-2}} \otimes \cdots \otimes \mathcal{Z}_{n_1} \otimes \mathcal{Z}_{n_0}$$

and on the d-dimensional binary group

$$\mathcal{Z}_2 \otimes \mathcal{Z}_2 \otimes \cdots \otimes \mathcal{Z}_2,$$

where $d = \log_2(n_{k-1}\cdot n_{k-2}\cdots n_0)$, the only differences between the two transforms being the values of the twiddle factors and the scrambling of the results.

Thus, since all the geometric information about the transforms is contained in the twiddle factors (and in the scrambling of the results), it is possible to code the geometric information of FFT*s in the data stream instead of in the instruction stream. This is the basis for the development of superparallel* FFT*s.*

2.2. The basic algorithm. To give a precise meaning to the splitting formula (2), we must define a matching between the elements of different groups. This is done through the *bit representation* of the elements of a group, defined by stacking together the binary representation of each component of the group element.

For example, suppose we want to identify the elements of a group $\mathcal{G}_1 = \mathcal{Z}_8\otimes\mathcal{Z}_4\otimes\mathcal{Z}_4$ with the elements of the group $\mathcal{G}_2 = \mathcal{Z}_2\otimes\mathcal{Z}_4\otimes\mathcal{Z}_4\otimes\mathcal{Z}_4$. An element, say $g = (5,1,2) \in \mathcal{G}_1$, has the bit representation $(1,0,1,\ 0,1,\ 1,0)$. (Note that the second component is represented by the *two bits* $0,1$ since two bits are required to represent all numbers in $\mathcal{Z}_4$.) This element is identified with the element $(1,1,1,2) \in \mathcal{G}_2$, which has the same bit representation.

Thus the bit representation identifies a group element in $\mathcal{G}$ with an element of the binary group

$$\mathcal{G}_b = \mathcal{Z}_2\otimes\cdots\otimes\mathcal{Z}_2,$$

with the same cardinality as $\mathcal{G}$.

The binary representation will be the most used component-wise representation of a group element, *so from now on, unless otherwise stated,* $(g_{k-1}, g_{k-2}, \ldots, g_0)$ *refers to the bit representation of a group element* g.

The *perfect shuffle permutation* of the elements in a cyclic group $\mathcal{Z}_n$ is given by the transformation

$$\sigma(g) = \sigma((g_{k-1}, g_{k-2}, \ldots, g_0)) = (g_{k-2}, g_{k-3}, \ldots, g_0, g_{k-1}),$$

i.e., a cyclic rotation towards the left of its bit representation. The perfect shuffle permutation of a vector defined on a group $\mathcal{Z}_n$ is defined as the matrix S_n acting by

$$S_n\cdot x(q) = x(\sigma(q)). \tag{3}$$

Note 1. Permutation matrices defined in this way multiply together in a way opposite to what one may first think: if π_1 and π_2 are two permutations of the domain, and if the corresponding permutation matrices P_1 and P_2 are defined as in (3), we obtain

$$P_2\cdot P_1\cdot x(q) = P_1 x(\pi_2(q)) = x(\pi_1\circ\pi_2(q)),$$

where $\circ$ denotes function composition.

The Cooley–Tukey splitting of the FFT matrix is then given by the following lemma.

LEMMA 2.1. *Let S_n be the perfect shuffle. Then the Fourier matrix F_n can be factored as*

$$S_n\cdot F_n = (I_2\otimes F_{n/2})\cdot T_n\cdot(F_2\otimes I_{n/2}),$$

where T_n, the twiddle matrix, is diagonal. T_n acts on vectors in $\mathcal{G} = \mathcal{Z}_2 \otimes \mathcal{Z}_{n/2}$ according to

$$T_n \cdot x((g_1, g_0)) = \begin{cases} x((g_1, g_0)) & \text{if } g_1 = 0, \\ e^{2\pi i g_0/n} \cdot x((g_1, g_0)) & \text{if } g_1 = 1, \end{cases}$$

for all $g \in \mathcal{G}$, where (g_1, g_0) denotes the components of $g \in \mathcal{Z}_2 \otimes \mathcal{Z}_{n/2}$.

Proof. This is checked by a straightforward computation. For a survey of similar results, see, e.g., [24]. □

The Cooley–Tukey FFT algorithm applies this formula recursively. Starting with a matrix F_n, we first multiply from the left by S_n, then by $I_2 \otimes S_{n/2}$, $I_4 \otimes S_{n/4}$, and so on down to $I_{n/4} \otimes S_4$. This gives the complete binary factorization of F_n:

$$\begin{aligned} (4) \qquad & (I_{n/4} \otimes S_4) \times (I_{n/8} \otimes S_8) \cdots (I_2 \otimes S_{n/2}) \cdot S_n \times F_n \\ & = (I_{n/2} \otimes F_2) \times \left(I_{n/4} \otimes [T_4 \times (F_2 \otimes I_2)]\right) \cdots \left(I_2 \otimes \left[T_{n/2} \times (F_2 \otimes I_{n/4})\right]\right) \\ & \quad \times T_n \times (F_2 \otimes I_{n/2}). \end{aligned}$$

A multiplication of a vector by $I_{2^k} \otimes F_2 \otimes I_{2^l}$ is called a *butterfly* operation, and multiplication by $I_{2^k} \otimes T \otimes I_{2^l}$ a *twiddle* operation. The right-hand side in (4) is thus a series of butterfly and twiddle operations.

Let σ_l denote the perfect shuffle of the right-most l bits, i.e.,

$$\sigma_l(g) = (g_{k-1}, g_{k-2}, \ldots, g_l, g_{l-2}, g_{l-3}, \ldots, g_0, g_{l-1}).$$

Since $(I_{n/2^l} \otimes S_{2^l}) \cdot x(g) = x(\sigma_l(g))$, we find that

$$\begin{aligned} (I_{n/4} \otimes S_4) \cdot (I_{n/8} \otimes S_8) \cdots (I_2 \otimes S_{n/2}) \cdot S_n \cdot \, x(g) &= x(\sigma_{k-1} \circ \sigma_{k-2} \circ \cdots \circ \sigma_2(g)) \\ &= x((g_0, g_1, \ldots, g_{k-1})). \end{aligned}$$

Thus, as is well known, the results appear in *bit-reversed* order.

In the following we will describe how (4) is turned into a superparallel algorithm. This is best explained through pseudocodes.

The instruction stream of the superparallel FFT routine tells all the processors that they should compute the matrix–vector product as in the right-hand side of (4). It is, however, left to each processor to decide whether it should participate in each butterfly and twiddle operation, or if it should rest idle instead. Each processor must also decide which values it should use for the twiddle factors. By these decisions, (4) can be tuned to produce any matrix product of the form

$$(5) \qquad I_{n_l} \otimes F_{n_{l-1}} \otimes I_{n_{l-2}} \otimes F_{n_{l-3}} \otimes \cdots \otimes F_{n_1} \otimes I_{n_0},$$

where n_i are powers of two. We will see later that it is very useful to be able to include identity matrices in the product as well.

When the superparallel FFT routine is initially called, each processor must, of course, know which product it wants to compute, and this information must be *consistent.* For example, if a processor wants to participate in a butterfly operation, then its corresponding neighbor must want the same.

The type of matrix product each processor wants to compute is stored *locally* in an *active_list* containing *active groups*, i.e., a list of beginning bits and end bits for each term F_{n_i} in (5).

Example 1. Suppose the address space of the computer is 12 bits. If a processor wants to participate in the product

$$I_{2^3} \otimes F_{2^4} \otimes I_{2^2} \otimes F_{2^3},$$

then it creates the following list, containing two active groups

$$\text{active\_list} = \left\{ \begin{matrix} (8,5) \\ (2,0) \end{matrix} \right\},$$

indicating that F_{2^4} affects bits 8 to 5 and F_{2^3} affects bits 2 to 0. (It is most natural to start from the left since the reduction starts with the left-most bit first.)

See §3 for some practical examples.

Given the active list of each processor, the pseudocode in Algorithm 1 describes the main part of the algorithm. First, we present some preliminaries.

1. We assume that there are 2^k processors in the network and altogether 2^k data points. Initially, each processor stores the data point $x(g)$, where $g = (g_{k-1}, \dots, g_0)$ is the binary address of the processor. In §2.3 we discuss the case where there are more data points.

2. The symbol $\oplus$ denotes *exclusive or* (xor), i.e.,

$$\begin{aligned} 0 \oplus 0 &= 0, \\ 0 \oplus 1 &= 1, \\ 1 \oplus 0 &= 1, \\ 1 \oplus 1 &= 0. \end{aligned}$$

3. The *if*'s in the pseudocode denote parallel if's. That is, the processors that do not fulfill the condition in the test are masked as inactive and wait idle until the others are finished.

4. The final answers appear in bit-reversed order within each active group, e.g., in Example 1, processor $(g_{11}, g_{10}, \dots, g_0)$ will end up with the answer

$$\hat{x}((g_{11}, g_{10}, g_9, g_5, g_6, g_7, g_8, g_4, g_3, g_0, g_1, g_2)). \tag{6}$$

ALGORITHM 1.

```
# Basic version of superparallel FFT code
for $i = k-1, 0, -1$ # loop over all bits from left to right
    if ($i \in$ active_group) then
        # next line contains the interprocessor communication
        $tmp := x((g_{k-1}, \dots, g_{i+1}, g_i \oplus 1, g_{i-1}, \dots, g_0))$
        if ($g_i = 0$) then
            $x := x + tmp$
        else
            $x := tmp - x$
            $tw :=$ twiddle_factor($i$,active_group,$g$)
            $x := tw * x$
        endif
    endif
endfor
```

The algorithm takes $\mathcal{O}(p)$ parallel steps, where p is the number of bits that are active for some of the processors. For example, if the algorithm computes a collection of equally sized transforms, p is given as the $\log_2$ of the number of points in each transform.

From Lemma 2.1 we find that the twiddle factors are computed in the following ways.

ALGORITHM 2.

```
# Computation of twiddle factors
function twiddle_factor($i$, active_group,$g$)
    $ra$ := position_of_rightmost_bit_in_active_group
    # The right-hand side below is the binary representation of a
    real number
    $\theta = 0.g_{i-1}g_{i-2}\cdots g_{ra}$
    $tw := e^{2\pi\theta\sqrt{-1}}$
    return($tw$)
endfunction
```

It is amazing that such a simple code can simultaneously handle any collection of different-sized FFTs, even of different dimensionalities! The pseudocode is even simpler than the standard one-dimensional radix-2 FFT for a sequential computer. The simplicity of the code results from the inherent natural parallelism contained in the FFT.

2.3. Doubling the speed with bitswaps. The basic code has two flaws that should be corrected. First of all, it assumes that the total number of data points exactly matches the number of processors. The code must also be able to handle the case where more data points are available. For certain machines (e.g., the Connection Machine) the user is free to configure the number of *virtual processors*, i.e., the machine can, in a transparent way, pretend that it has more processors than it physically has. This is done in microcode. For other machines (e.g., the MasPar), the mapping of multiple points to a single processor is taken care of by either a high-level language compiler or, explicitly, by the programmer. We shall see that in the latter case it is possible to correct the second major drawback of the basic code, which is its efficiency.

Suppose the basic code is used to compute one large one-dimensional FFT, i.e., all the processors have a single active set covering all the address bits. First, all the processors swap one number with another processor; afterwards half of the processors compute a sum (while the rest are idle); and finally the second half of the processors compute a difference and perform the twiddle multiplication (while the first half is idle). Thus in a large part of the code, half of the machine is doing nothing.

Now assume that we have at least twice as many data points as processors. The way to handle this is to introduce some extra bits which refer to different locations in the memory of each processor. For example, if there are four times as many data points as processors, each processor stores four numbers and we get two extra address bits, which we call *memory bits.* Hereafter, we assume that the *left-most* bit is always a memory bit. The location of the other memory bits is of no importance, and, to simplify the exposition, we forget the rest of the memory bits and assume that we have *exactly* twice as many data points as we have processors. We define a *bitswap permutation* as a swapping of the left-most bit with another bit

$$B^i \cdot x((g_{k-1}, \ldots, g_i, \ldots,)) = x((g_i, \ldots, g_{k-1}, \ldots,)).$$

Note that B^i is its own inverse. The bitswap can be performed by the following pseudocode.

Algorithm 3.

```
# Computation of $x := B^i \cdot x$
function bitswap($i, x$)
   if $(g_{k-1} \neq g_i)$ then
      $x((g_{k-1}, \ldots, g_i, \ldots)) := x((g_{k-1} \oplus 1, \ldots, g_i \oplus 1, \ldots))$
   endif
endfunction
```

Note that the condition is true for exactly one of the two numbers in each processor, thus every processor is active and swaps exactly one number with another processor. The bitswap transfers all the "action" from bit i to the left-most bit by:

$$I_{n/2^i} \otimes [T_{2^i} \cdot (F_2 \otimes I_{2^{i-1}})] = B^i \cdot \tilde{T}_{2^i} \cdot (F_2 \otimes I_{n/2}) \cdot B^i, \tag{7}$$

where

$$\tilde{T}_{2^i} = B^i \cdot (I_{n/2^i} \otimes T_{2^i}) \cdot B^i$$

is a diagonal matrix of order n. Equation (7) can be substituted into (4). After some consideration, one realizes that the left-most bitswap in each substituted term commutes with everything to the left of it, and can be pulled out to the left and multiplied over to the other side of the equation. This gives the following "bitswap version" of (4):

$$\begin{aligned} &B^0 \cdot B^1 \cdots B^{k-1} \cdot (I_{n/4} \otimes S_4) \cdot (I_{n/8} \otimes S_8) \cdots (I_2 \otimes S_{n/2}) \cdot S_n \cdot F_n \\ &= \tilde{T}_2 \cdot (F_2 \otimes I_{n/2}) \cdot B^0 \cdot \tilde{T}_4 \cdot (F_2 \otimes I_{n/2}) \cdot B^1 \cdots \tilde{T}_{n/2} \cdot (F_2 \otimes I_{n/2}) \\ &\quad \times B^{k-2} \cdot \tilde{T}_n \cdot (F_2 \otimes I_{n/2}) \cdot B^{k-1}, \end{aligned} \tag{8}$$

where $\tilde{T}_2$ and B^{k-1} are identity matrices included to make the formula more symmetric.

In the basic variant of the algorithm, the data points were shuffled locally, i.e., they were only permuted to other processors with the same active_list as the processor where they started. In the bitswap version of the algorithm, data points are shuffled more globally, to processors that initially contained a different active_list. This means that in order to compute twiddle factors correctly, the active_list must also be bitswapped. Furthermore, if *any* processor wants to do a bitswap, we must force *all* processors to participate, even if they are not inside an active group. This is to ensure that the bitswaps define permutations of the data set. We use the word "all" to emphasize that no processor is allowed to be idle, and the word "any" to test if a parallel logical expression is true for at least one processor. This leads to the bitswap variant of the superparallel FFT.

Algorithm 4.

```
# Bitswap version of superparallel FFT code
for $i = k-1, 0, -1$ # loop over all bits from left to right
   if any ($i \in$ active_group) then
      all
         bitswap($i, x$)
         bitswap($i$,active_list)
      end all
   endif
   if ($i \in$ active_group) then
      $tmp := x((0, g_{k-2}, \ldots))$
```

```
            $x((0, g_{k-2}, \ldots)) := tmp + x((1, g_{k-2}, \ldots))$
            $x((1, g_{k-2}, \ldots)) := tmp - x((1, g_{k-2}, \ldots))$
            $tw :=$ twiddle_factor ($i$, active_group,g)
            $x((1, g_{k-2}, \ldots)) := tw * x((1, g_{k-2}, \ldots))$
        endif
    endfor
```

Note that the function twiddle_factor is the same as in the basic version of the algorithm.

In the computational part, this code computes two points in the same time that it takes the basic version to compute one point. If we neglect the bitswap of the active_list, each processor swaps one number for each i. Since each processor is computing twice as many numbers as in the basic version, we have also reduced the communication time by a factor of two. In practice, the code is divided into two parts, a symbolic preprocessing stage where the twiddle factors are computed, and a numerical phase where the actual transforms are done. In many situations the same geometries are used for many different transforms. Then the symbolic computation can be done once, and the cost of bitswapping the active_list and computing tw can be neglected. Thus, *on a* SIMD *machine, the bitswap version of the superparallel* FFT *is twice as fast as the basic version.*

The main drawback of the bitswap version is the more complicated scrambling of the results. As we shall see in §4, the bitswap version leaves the data in a much more disordered state than the basic version. For many applications, it is not necessary to unscramble the data. It suffices to know the identities of the results in each processor, and this is straightforward to compute. In other applications it is, however, desirable to unscramble the results. As we shall see in §4, efficient algorithms exist for unscrambling the results of both the basic and the bitswap version.

3. Defining problems and checking consistency.

Formally, the only restriction of the possible active_lists is that if a processor wants to participate in a multiplication by F_2, then its partner should want to do the same. However, this requirement alone allows some rather pathological cases, such as a two-dimensional field of numbers where every column wants to first do an FFT in the y-direction, but only the first column wants to afterwards do a transform in the x-direction as well. We cannot see any practical use for such a possibility. For debugging, it is useful to have the possibility of checking the active_lists for inconsistencies of this kind. In such situations, the unscrambling algorithms in the next section will give unpredictable results. We therefore want stricter rules for the possible active_lists. The following rule is general enough to allow all possible interesting transforms.

DEFINITION 1 (consistent active_lists). Given a point with active_list **al**, the set of bits not in any of the active groups is called *inactive*. The collection of all the active_lists is *consistent* if all points with the same values in the inactive bits also share the same active_list **al**.

It is a straightforward matter to check for consistency in this sense: simply mimic the FFT code, but instead of performing the butterfly and twiddle multiplications, check whether or not the active_lists of the neighbors are equal.

DEFINITION 2. A group of points sharing the same active_list and the same values for the inactive bits is called an FFT *chunk*. The values of the inactive bits define the *site* of the chunk.

The number of points in a chunk is given as 2^k, where k is the total number of *active* bits (bits inside the active groups).

We will now see some examples showing that the active_lists can easily be set up to solve rather complicated problems.

Example 2. Given a two-dimensional field of 512×256 points, suppose we want to divide the field into 8×8 square tiles, each of size 64×32, and perform two-dimensional FFTs on each tile. This is simply done by giving each point the active list

$$\text{active\_list} = \left\{ \begin{array}{c} (13,8) \\ (4,0) \end{array} \right\}$$

and calling the FFT routine.

This example also easily extends to the case where the domain is divided into rectangles of different sizes (as long as the sizes are powers of 2). For example, if we want to merge two tiles neighboring each other in the x-direction into one tile, we simply modify the active lists of these points to

$$\text{active\_list} = \left\{ \begin{array}{c} (13,8) \\ (5,0) \end{array} \right\}.$$

Example 3. Suppose we have a $64 \times 64 \times 64$ three-dimensional grid and we want to do an FFT on each two-dimensional $y-z$ plane. This is a practical problem arising from using spectral methods to simulate flow between plates. This problem is defined by giving each point the active list

$$\text{active\_list} = \left\{ \begin{array}{c} (17,12) \\ (11,6) \end{array} \right\}.$$

Compared to the more standard approach (for sequential computers) of solving these problems by looping over the independent FFTs, calling one-dimensional FFTs, transposing the data, looping and calling one-dimensional FFTs again, and finally transposing the matrix again, it is amazing how easily the superparallel FFT can be called to solve relatively complicated problems.

Now suppose we have a collection of different-sized problems, and that we are free to choose their initial positions as we like. We will show that it is always possible to solve these problems in an address space of size the smallest power of 2 larger than or equal to the sum of the sizes of all the subproblems. If there are no geometric relations between the different chunks, it is natural to store each chunk in a contiguous part of the address space. We are, however, not always allowed to pack the different chunks tightly together. Since the lowest address in a chunk is obtained by setting all the active bits to 0, the following *alignment requirement* must be satisfied.

LEMMA 3.1 (memory alignment). *An* FFT *chunk, with a total of k active bits, stored contiguously in the address space, must start in a memory location dividing* 2^k, *i.e., the right-most k bits are zero.*

If the alignment requirement is fulfilled, then the address succeeding the chunk must also divide 2^k. We conclude with the following theorem.

THEOREM 3.2. *If different-sized chunks are ordered in decreasing order according to their size, they can be stacked together contiguously with no interleave in the address space.*

COROLLARY 3.3. *Less than* 50 *percent of the address space is wasted due to the memory alignment requirement.*

Proof. The memory space needed is the smallest power of 2 containing all subproblems. □

Example 4. Suppose we have three one-dimensional FFTs of lengths 2, 4, and 8. Then we need four bits to define the problems:

```
chunk 1:
   site :   $q_3 = 0$
   active_list :  {(2,0)}
chunk 2:
   site :   $q_3 = 1$;  $q_2 = 0$
   active_list :  {(1,0)}
chunk 3:
   site :   $q_3 = 1$;  $q_2 = 1$;  $q_1 = 0$
   active_list :  {(0,0)}
```

The two points $(1,1,1,0)$ and $(1,1,1,1)$ are left unused.

4. Unscrambling the results. For many applications it is not necessary to unscramble the results. A call to an FFT is often followed with a call to an inverse FFT, and in between, the Fourier coefficients are often just multiplied by some diagonal matrix. If one has a pair of transforms, the FFT from ordered to scrambled, and the inverse working backwards from scrambled to unscrambled, then all one usually needs to know is the identities of each Fourier coefficient. After performing the (symbolic) FFT, this can easily be computed in parallel by computing backwards, using the information contained in the active_lists of the results and the information about which bits have been bitswapped.

Example 5. In a point $(g_{11}, g_{10}, \dots, g_0)$ the active_list is as in example (1) after the FFT (with bitswaps). Without bitswaps the point would contain the result as in (6). Suppose all bits have been swapped in the FFT; then the point contains the number

$$\begin{aligned} &B^{k-1} \cdots B^1 \cdot B^0 \cdot \hat{x}((g_{11}, g_{10}, g_9, g_5, g_6, g_7, g_8, g_4, g_3, g_0, g_1, g_2)) \\ &\quad = \hat{x}((g_2, g_{11}, g_{10}, g_9, g_5, g_6, g_7, g_8, g_4, g_3, g_0, g_1)). \end{aligned}$$

Note that a sequence of bitswaps produces an inverse perfect shuffle.

There are also, however, many applications where it is necessary to obtain the the results in unscrambled order (see, e.g., [3] and [16]). In this section we will derive efficient unscrambling algorithms. To study permutation algorithms it is necessary to assume a model for the computer interconnection network. A particularly useful network is the Beneš network [2], [13], [19]. This is one of the simplest networks capable of performing any permutation of 2^k objects. A permutation algorithm for a Beneš network can easily be transformed into efficient permutation algorithms for a variety of different networks (see the comments below, and for more details, [17]).

A (masked) *bit-exchange* permutation of bit i is given by

$$x((q_{k-1}, q_{k-2}, \dots, q_i, \dots, q_0)) \to x((q_{k-1}, q_{k-2}, \dots, q_i \oplus \chi, \dots, q_0)),$$

where $\chi(q) \in \{0,1\}$ is a Boolean function. We require this to be a permutation. This is equivalent to the condition

$$\chi((q_{k-1}, q_{k-2}, \dots, q_i, \dots, q_0)) = \chi((q_{k-1}, q_{k-2}, \dots, q_i \oplus 1, \dots, q_0)),$$

i.e., χ is a function independent of the value of bit q_i. The Beneš network on 2^k data points performs a series of $2k-1$ bit exchanges, where the bits are exchanged in the fixed order

$$q_{k-1}, q_{k-2}, \ldots, q_1, q_0, q_1, \ldots, q_{k-2}, q_{k-1}.$$

By choosing the functions χ_i (i.e., setting the switches in the network) in the right manner, it is known that the Beneš network can perform any permutation of its 2^k inputs. The major problem is the computation of the functions χ_i. This is called the *B-setting* problem. Given a B-setting for a permutation, it is straightforward to solve permutation problems for a variety of different interconnection topologies (see [17] for details).

• *The "many points per processor problem."* Given a network with $p = 2^d$ processors, $d < k$, where there are 2^m, $m = k - d$, data points per processor, suppose we know how to perform a general permutation of data spread by one point per processor. For example, on the MasPar the cheapest way to perform one-point-per-processor permutations is to call a "router" routine (black box permutation algorithm). The problem is: *How few router calls are necessary to perform a given permutation of the complete data set?* If the address bits are ordered so that the left-most m bits are memory bits, we see that the sequence of exchanges

$$q_{k-1}, \ldots, q_{k-m}$$

only involves a local reordering of the data. The sequence

$$q_{k-m-1}, \ldots, q_1, q_0, q_1, \ldots, q_{k-m-1}$$

can be collapsed into one permutation and performed by 2^m calls to the router (one for each memory location). Finally the sequence

$$q_{k-m}, \ldots, q_{k-1}$$

is again only a local reordering. Thus a B-setting provides us with an algorithm that can perform a general permutation by only 2^m router calls. For many permutations it is impossible to do this with fewer calls.

• *Shuffle-exchange networks* [25] can directly perform the same permutations as a Beneš network, by running it forward k steps and backward $k-1$ steps. Alternatively, the B-settings can be transformed into algorithms for performing the permutation in $3k-1$ forward steps [19], or by a somewhat more complex algorithm, in $3k-3$ forward steps [9].

• *Butterfly and omega networks* are equivalent to k forward loops in a shuffle-exchange network. Thus the comments above apply to computers based on these networks.

• *Hypercubes* are extensions of Beneš networks, where *any* of the k bits can be exchanged in each step. Thus a hypercube network can emulate a Beneš network simply by exchanging the bits in a fixed order. This will, however, only use one out of the possible k wires extending from each processor in each step. The main problem is how to efficiently use the full bandwidth of the network. In the case of 2^m points per processor, the technique above splits the permutation task into 2^m independent tasks. The full bandwidth of the network can be utilized by running k of these tasks in parallel over different wires. This can be done by cyclically shifting the order of the bits in each independent permutation, i.e., k different permutations are done simultaneously by exchanging the bits in the following order:

Task 0:	q_{k-1}	q_{k-2}	$\cdots$	q_1	q_0	q_1	$\cdots$	q_{k-1}
Task 1:	q_{k-2}	q_{k-3}	$\cdots$	q_0	q_{k-1}	q_0	$\cdots$	q_{k-2}
Task 2:	q_{k-3}	q_{k-4}	$\cdots$	q_{k-1}	q_{k-2}	q_{k-1}	$\cdots$	q_{k-3}
$\vdots$								
Task $k-1$:	q_0	q_{k-1}	$\cdots$	q_2	q_1	q_2	$\cdots$	q_0

If there is only one point per processor, this technique may be used, provided that each point is associated with so much data that it can be split into k different parts. Each part can then be permuted on a different set of wires.

• *Two-dimensional mesh-connected computers.* There are several ways to emulate a Beneš network on a two-dimensional mesh. These schemes involve $\mathcal{O}(N^{1/2})$ time for performing permutations. See [12] for special tricks related to the MasPar hardware.

• *Multistage crossbar networks,* where each crossbar performs a general permutation of 2^s wires, can be programmed by collapsing s consecutive bit exchanges into general permutations of 2^s points. For example, the hardware underlying the MasPar "router" construct is a three-stage crossbar. A B-setting of a permutation can, in principle, be used to increase the speed of this kind of hardware. However, we have not tried this approach for the MasPar, since there is no high-level language access to programming the router hardware.

Let $N = 2^k$. The best known algorithms for solving the general B-setting problem takes $\mathcal{O}(N\log(N))$ time on a sequential computer, $\mathcal{O}(N^{1/2})$ time on a mesh-connected parallel computer with $N^{1/2} \times N^{1/2}$ processors, $\mathcal{O}(k\log^3(N))$ time on a hypercube-connected computer with $\mathcal{O}(N^{1+1/k})$ processors where $1 \leq k \leq \log(N)$, and $\mathcal{O}(\log^2(N))$ time on an N-processor shared-memory computer [19]. Thus, unless the FFTs are to be performed many times with the same geometries, the general B-setting algorithms will be too expensive compared to the time of running the numerical parts of the FFTs. The high cost of the general B-setting algorithms has led to a search for classes of permutations that can be B-set *efficiently* on a parallel computer (i.e., where solving the B-setting problem takes no more time than actually performing the permutation). See [17], [13], [19], and [10] for fast B-setting algorithms. Unscrambling the results of the basic superparallel FFT (Algorithm 1) belongs to the classes of permutations that can be solved by the algorithms in these papers. For the more difficult problem of unscrambling the results of the bitswap version (Algorithm 4) these algorithms will generally fail, and a new algorithm is needed.

Before attacking this general unscrambling problem, we study two simpler problems:

1. Finding B-settings for unscrambling the results of the basic version of the superparallel FFT.

2. Finding B-settings for a product of bitswap permutations.

We define the shorthand notation

$$q_i := q_i \oplus \chi$$

to denote the permutation

$$x((\ldots, q_i, \ldots)) \to x((\ldots, q_i \oplus \chi, \ldots))\ .$$

A commonly used basic permutation is the xor of two different bits

$$q_i := q_i \oplus q_j.$$

As long as $i \neq j$, this defines a permutation. (When $i = j$ it is *not* a permutation, since $q_i \oplus q_i = 0$—two different numbers are collapsed into a single memory address.)

Let $\bar{q}_i$ denote the original values of the bits. A bit reversal, e.g.,

$$x((q_3, q_2, q_1, q_0)) \to x((q_0, q_1, q_2, q_3)),$$

can be performed by the following B-setting:

ALGORITHM 5. UNSCRAMBLING BIT-REVERSED DATA (example with four bits).

$$\begin{aligned}
q_3 &:= q_3 \oplus q_0 = \bar{q}_3 \oplus \bar{q}_0 \\
q_2 &:= q_2 \oplus q_1 = \bar{q}_2 \oplus \bar{q}_1 \\
q_1 &:= q_1 \oplus q_2 = \bar{q}_1 \oplus \bar{q}_2 \oplus \bar{q}_1 = \bar{q}_2 \\
q_0 &:= q_0 \oplus q_3 = \bar{q}_0 \oplus \bar{q}_3 \oplus \bar{q}_0 = \bar{q}_3 \\
q_1 &:= q_1 = \bar{q}_2 \\
q_2 &:= q_2 \oplus q_1 = \bar{q}_2 \oplus \bar{q}_1 \oplus \bar{q}_2 = \bar{q}_1 \\
q_3 &:= q_3 \oplus q_0 = \bar{q}_3 \oplus \bar{q}_0 \oplus \bar{q}_3 = \bar{q}_0
\end{aligned}$$

Note that when there is an odd number of bits, there will be a bit in the middle that is left unchanged. This algorithm extends readily to the more general case where several active groups are to be bit reversed. Even the situation where there are several different FFT chunks with different active groups to be bit reversed can be handled by this method, since each chunk is to be unscrambled within its own site, and since the above method only modifies the active bits of each chunk, i.e., there is no interference between different chunks. Thus this process solves the unscrambling problem for the basic algorithm.

Now to the problem of finding a B-setting for a product of bitswaps: For simplicity, we assume that all the bits are to be bit-swapped. (If some of the bits should not be bit-swapped, we simply ignore them and proceed as below.)

As noted in Example 5, a product of bitswaps amounts to doing an inverse perfect shuffle. Let

$$\bigoplus_{i=0}^{k-1} q_i = q_0 \oplus q_1 \oplus \cdots \oplus q_{k-1};$$

then

$$q_j := \bigoplus_{i=0}^{k-1} q_i \tag{9}$$

is a permutation. By performing this permutation cyclically, one obtains the perfect shuffle.

ALGORITHM 6. PERFECT SHUFFLE PERMUTATION.

$$q_{k-1} := \bigoplus_{i=0}^{k-1} q_i = \bigoplus_{i=0}^{k-1} \bar{q}_i$$
$$q_{k-2} := \bigoplus_{i=0}^{k-1} q_i = \bigoplus_{i=0}^{k-2} \bar{q}_i \oplus \bigoplus_{i=0}^{k-1} \bar{q}_i = \bar{q}_{k-1}$$
$$q_{k-3} := \bigoplus_{i=0}^{k-1} q_i = \bigoplus_{i=0}^{k-3} \bar{q}_i \oplus \bigoplus_{i=0}^{k-1} \bar{q}_i \oplus \bar{q}_{k-1} = \bar{q}_{k-2}$$
$$\vdots$$
$$q_j := \bigoplus_{i=0}^{k-1} q_i = \dots = \bar{q}_{j+1}$$
$$\vdots$$
$$q_1 := \bigoplus_{i=0}^{k-1} q_i = \bar{q}_2$$
$$q_0 := \bigoplus_{i=0}^{k-1} q_i = \bar{q}_1$$

on return only q_{k-1} needs correction :

$$q_{k-1} := \bigoplus_{i=0}^{k-1} q_i = \bar{q}_0$$

Now we are prepared to study the general problem of unscrambling the results of the bitswap version of the superparallel FFT. The permutation to be performed is a product of a local bit reversal of each active group (performed differently for each chunk), and a global inverse perfect shuffle of all the chunks. In a given chunk, there are some bits that can be exchanged without changing the site of the chunk. There are other bits that are more critical, since modifying them will change the site of the chunk. We call these bits *site defining.* A modification of the site-defining bits must be coordinated with all the other chunks where the bits are site defining. Note that the site-defining bits may change during the course of the algorithm. At some stage even a linear combination of all the bits in a chunk may be site defining.

Consider an example where the address space consists of five bits. Given a chunk with $q_4 = 1$, $q_0 = 0$, and active group $(3,1)$, Table 1 shows the site-defining bits during an inverse perfect shuffle.

TABLE 1

Step	Permutation	Site (after permutation)	
0	none	$q_4 = 1;$	$q_0 = 0$
1	$q_4 := \bigoplus_{i=0}^{4} q_i$	$\bigoplus_{i=0}^{4} q_i = 1;$	$q_0 = 0$
2	$q_3 := \bigoplus_{i=0}^{4} q_i = \bar{q}_4$	$q_3 = 1;$	$q_0 = 0$
3	$q_2 := \bigoplus_{i=0}^{4} q_i = \bar{q}_3$	$q_3 = 1;$	$q_0 = 0$
4	$q_1 := \bigoplus_{i=0}^{4} q_i = \bar{q}_2$	$q_3 = 1;$	$q_0 = 0$
5	$q_0 := \bigoplus_{i=0}^{4} q_i = \bar{q}_1$	$q_3 = 1;$	$\bigoplus_{i=0}^{4} q_i = 0$
6	$q_4 := \bigoplus_{i=0}^{4} q_i = \bar{q}_0$	$q_3 = 1;$	$q_4 = 0$

Steps 1, 2, 5, and 6 are critical, and since they change the site, they must be coordinated with the other chunks. Let the motion defined in (9) be denoted the *collective motion.* The idea of the unscrambling algorithm is to force all the chunks to follow the collective motion when they are in a critical section. Outside critical sections we impose a local motion within a chunk in such a manner that the active groups finally become bit reversed.

There is a critical section two bits long when entering an active group (the last bit outside, and the first bit inside, the active group), and one two bits long when exiting (the two bits succeeding the active group). Thus the movement in the two bits following the active group is forced according to the collective motion. The main problem is to arrange the local movement in the active group such that the two succeeding bits come out correctly when they participate in the collective motion.

The following algorithm solves this problem; thus it solves the problem of unscrambling the bitswap version of the superparallel FFT. For proof of correctness of this algorithm, see [15].

ALGORITHM 7. UNSCRAMBLING OF BITSWAP FFT RESULTS (local motion passing an active group (r, s)). The chunk wants to perform the motion:

$$(\ldots, q_{r+1}, q_r, q_{r-1}, \ldots, \ldots, q_s, q_{s-1}, \ldots, \ldots)$$
$$\downarrow$$
$$(\ldots, \ldots, q_{r+1}, q_s, q_{s+1}, \ldots, q_{r-1}, q_r, q_{s-1}, \ldots)$$

1. The bits q_{r+1}, q_r, q_{s-1} and q_{s-2} are critical sections. They follow the collective motion:

$$q_j := \bigoplus_{i=0}^{k-1} q_i.$$

2. The bits $q_{r-1}, q_{r-2}, \ldots, q_s$ are to be bit reversed. This is done as in Algorithm 5, with the following modifications:
   - On the way "down," the bits q_{r-1} and q_s are exchanged according to:

$$\begin{aligned} q_{r-1} &:= \textstyle\bigoplus_{i=0}^{k-1} q_i \oplus q_s, \\ q_s &:= \textstyle\bigoplus_{i=0}^{k-1} q_i \oplus q_{r-1}. \end{aligned}$$

   - On return, the bits q_s and q_{r-1} are corrected to their final values according to:

$$\begin{aligned} q_s &:= \textstyle\bigoplus_{i=s-1}^{p} q_i \quad \text{where } p = \lfloor (r+s)/2 \rfloor - 1, \\ q_{r-1} &:= q_{r-1} \oplus q_{s-1}. \end{aligned}$$

The computation of B-settings for the unscrambling of bitswap FFT results takes $\mathcal{O}(p)$ parallel steps, where p is the number of bits that are active for some of the processors.

We illustrate the algorithm with an example.

Example 6. $r = 9; s = 2$. The symmetry point is $p = 5$. The motion of this chunk passing the active group is done as:

$$\begin{aligned} q_9 &:= \textstyle\bigoplus_{i=0}^{k-1} q_i = \bar{q}_{10} \\ q_8 &:= \textstyle\bigoplus_{i=0}^{k-1} q_i \oplus q_2 = \bar{q}_2 \oplus \bar{q}_9 \\ q_7 &:= q_7 \oplus q_3 = \bar{q}_3 \oplus \bar{q}_7 \\ q_6 &:= q_6 \oplus q_4 = \bar{q}_4 \oplus \bar{q}_6 \\ q_5 &:= q_5 = \bar{q}_5 \\ q_4 &:= q_4 \oplus q_6 = \bar{q}_6 \\ q_3 &:= q_3 \oplus q_7 = \bar{q}_7 \end{aligned}$$

$$q_2 := \bigoplus_{i=0}^{k-1} q_i \oplus q_8 = \bar{q}_8 \oplus \bar{q}_6 \oplus \bar{q}_7 \oplus \bar{q}_9$$
$$q_1 := \bigoplus_{i=0}^{k-1} q_i = \bar{q}_9$$
$$q_0 := \bigoplus_{i=0}^{k-1} q_i = \bar{q}_1$$

on return the bits are corrected as

$$q_2 := q_1 \oplus q_2 \oplus q_3 \oplus q_4 = \bar{q}_8$$
$$q_6 := q_6 \oplus q_4 = \bar{q}_4$$
$$q_7 := q_7 \oplus q_3 = \bar{q}_3$$
$$q_8 := q_8 \oplus q_1 = \bar{q}_2$$

In this example $r - s$ is an odd integer, and the bit q_5 is left invariant. When $r - s$ is even the algorithm is similar, but without an invariant bit in the middle.

5. Implementations on MasPar. MasPar is a SIMD machine with up to 16,384 processors arranged in a two-dimensional array, with toroidal wraparound on the edges. The machine used in this study is a $64 \times 128 = 8192$-processor machine at the University of Bergen, Norway. There are essentially three different ways of permuting a data set spread by one element per processor:

1. The xnet. This is a mechanism for sending the data set a given distance d in one of the eight directions: north, northwest, west, and so on. There are no restrictions on the distance d. This mechanism is very fast for short distances, but the time grows proportionally with d; thus long xnets are costly.

2. Piped xnet. This is a fast version of xnet, where the time is (almost) independent on d. It can, however, only be used for sparse data sets, where all the processors between the senders and the receivers are idle. It is very useful for computations of inner products and log sums, but not for our FFTs.

3. The router. This is a general (black box) construct for performing arbitrary permutations of the data set (spread by one element per processor). The underlying hardware is a three-stage crossbar switch. The time for a router call depends on the permutation, but is comparable to an xnet of the longest distance (64). For general permutations it is definitely the cheapest mechanism.

A more detailed general description of the MasPar MP-1 computer can be found in [4], [5], and [20].

The MasPar implementation of the superparallel FFTs is based on the bitswap version of the algorithm. For more details on its use and performance, see [18]. The code is divided into three parts: a symbolic preprocessing phase, the actual transform phase, and the scrambling/unscrambling phase. The symbolic phase computes the twiddle factors and schedules the unscrambling of the results. If the user only wants the results in scrambled order, it computes the necessary pointers for referencing the Fourier coefficients. The symbolic phase needs to be called only once for each configuration of geometries, and the same data is used both for the forward and the inverse FFTs.

In Table 2, we show the elapsed time for various combinations of transforms having combined lengths of 16,384 and 262,144, using 32-bit arithmetic. For simplicity, all transforms have the same length, but we emphasize that any combination of transforms can be processed. These timings *exclude* the time for the symbolic preprocessing. The present version of the symbolic part of the code is not optimized, and uses between 5 and 10 times as much time as the actual transforms. There is, however, substantial room for improvement of this part of the code.

TABLE 2
Time in milliseconds and computational speed for FFT *algorithm* (8192-*processor* MP-1).

Length	#Transforms	Time (ms) without unscrambling	Mflops without unscrambling	Time (ms) with unscrambling	Mflops with unscrambling
Tot. no. of points: 16384					
8	2048	1.1	229	2.2	108
64	256	2.5	198	3.5	139
512	32	4.0	185	5.4	137
8192	2	5.4	199	7.2	147
16384	1	6.1	187	8.1	141
Tot. no. of points: 262144					
8	32768	14.5	270	33.8	117
8192	32	84	203	105	162
262144	1	124	191	175	135

The speed of transforms without unscrambling is, to a moderate degree, dependent on the geometries; when a lot of small transforms are processed, the communication distances are shorter and the speed somewhat higher than for long transforms. The cost of the unscrambling is dominated by the cost of calling the router. This is done once for every set of 8192 points, and takes between 0.5 and 1 millisecond per call (with some special tricks employed to increase the speed). Thus the cost of unscrambling grows linearly in N. This explains the phenomenon that, whereas short transforms are faster than long without unscrambling, long transforms are faster than short with unscrambling.

NUMERICAL EXPERIENCE WITH A CLASS OF ALGORITHMS FOR NONLINEAR OPTIMIZATION USING INEXACT FUNCTION AND GRADIENT INFORMATION*

RICHARD G. CARTER†

Abstract. For optimization problems associated with engineering design, parameter estimation, image reconstruction, and other optimization/simulation applications, low accuracy function and gradient values are frequently much less expensive to obtain than high accuracy values. The computational performance of trust region methods for nonlinear optimization is investigated for cases when high accuracy evaluations are unavailable or prohibitively expensive, and earlier theoretical predictions that such methods are convergent even with relative gradient errors of 0.5 or more is confirmed. The proper choice of the amount of accuracy to use in function and gradient evaluations can result in orders-of-magnitude savings in computational cost.

Key words. unconstrained optimization, trust region methods, inexact function evaluations, inexact gradients, variable-accuracy simulations

AMS(MOS) subject classifications. 65K05, 65K10, 49D37, 65C20

1. Introduction.

Consider the nonlinear optimization problem

$$\underset{x \in \Re^n}{\text{minimize}} \quad f(x), \tag{1}$$

where the function f has gradient ∇f, with ∇f assumed to be Lipschitz continuous. We are concerned with numerically solving this problem when function and gradient values are not known exactly.

Problems of this nature frequently occur in engineering design, parameter estimation, and many other situations. Consider, for example, the design of a heat sink for transferring excess heat away from an electronic component. Given the geometry of the sink (expressed, perhaps, as the spacing, thickness, and length of each cooling fin) and the heat flux from the component, we can mathematically model the temperature distribution in the sink and the surrounding medium by a system of partial differential equations (PDEs). If we wish to find the design geometry that minimizes the time-averaged temperature of the component, we must numerically solve this system of PDEs at each iteration of the optimization algorithm to determine an approximate value for the objective function f. Furthermore, a value for the gradient of f must be computed at each iteration through directly solving a different system of PDEs (sensitivity or adjoint equations [18]), through successively perturbing each component of x and recomputing f to obtain a finite difference approximation, or through applying an automatic differentiation package to the computations used to approximate f. Clearly, exact function and gradient values are not attainable for such a problem, and the computational expense of any approximation at a given iteration increases very rapidly as the required accuracy is increased. Let h be the discretization mesh size selected and m_d the number of spatial dimensions in the PDE, so that the number of

elements in the discretization is given by $k = O((1/h)^{m_d})$. If the order of the solution method is given by error $= O(h^{m_o})$, and the computational expense for the linear algebra associated with the problem is CPU $= O(k^{m_l})$, we have

$$\text{CPU/iteration} = O\left(\text{error}^{-l}\right) \tag{2}$$

for $l = m_d m_l / m_0$. Although this estimate is admittedly crude, it seems to hold for many applications and indicates that computational expense per iteration can rise *extremely* rapidly as more accurate solutions are required. In our example, if a two-dimensional model of the sink is being used with a direct linear algebra solver and an $O(h^2)$ solution method, we would have $m_d = 2, m_l = 3, m_0 = 2$; hence l would be 3 and a thousand-fold increase in computational time would be needed to increase the accuracy of any given approximation by one digit. Methods using iterative linear algebra solvers and problems involving systems of ordinary differential equations (ODEs) rather than PDEs tend to be more benign with much smaller values of l ($\frac{1}{4}$ to $\frac{1}{10}$ for most ODE applications), but computational expense still increases geometrically with accuracy. Similar results often hold for stochastic, particle-based simulation methods.

Since low accuracy function and gradient evaluations can be orders of magnitude less expensive than high accuracy evaluations, it behooves us to consider optimization algorithms that do not require the maximum possible accuracy at each iteration. Trust region methods are a natural candidate for investigation because of their reputation for robustness and efficiency. A number of authors have established global convergence results for trust region methods using inexact gradients [13], [4], [19], and inexact function evaluations have also been treated [3]. In this paper, we investigate the numerical behavior of the algorithms presented in [4] and [3] in order to answer the following questions.

1. How much error can we allow in our evaluations before the algorithm fails? Does this level agree with theoretical predictions?
2. The performance of the algorithm will certainly decrease when less accurate evaluations are used. How fast does performance degrade and how problem-dependent is the rate of degradation?
3. How does this lessened performance balance with the greatly decreased computational cost associated with less accurate evaluations?
4. How well do the techniques suggested in [3] for estimating and controlling gradient error work in practice?

The remainder of this paper is organized as follows.

In §2, we present the trust region algorithm and review the conditions on permissible levels of error established in [3]. These conditions depend on some of the parameters of the trust region method but are remarkably relaxed: typically, relative errors in the gradient of 0.5 or more are permissible. In §3, we examine the performance of the algorithm on the set of standard test problems from Moré, Garbow, and Hillstrom [14] when synthetically generated errors are added to the gradients at each iteration. Our results confirm the theoretical predictions for the algorithm, and we note that the number of iterations required by the algorithm tends to increase exponentially with the relative error induced in the gradient. When balanced against (2), however, we find that allowing low accuracy evaluations is still attractive. In §4, we examine the performance of the algorithm on a multidimensional numerical integration problem in order to confirm our results without resorting to synthetically induced errors or invoking (2). Both direct and Monte Carlo variable-accuracy integration techniques are demonstrated in this example. In §5 we solve a parameter identification problem found in the literature and verify a technique for estimating and controlling error when the gradient is approximated by finite differences. Section 6 summarizes our results.

2. Trust region algorithms and permissible error in function and gradient evaluations.

The class of trust region methods we consider for solving (1) each generate a sequence of iterates$\{x_k\}$ by approximately solving a sequence of constrained quadratic model problems. Each local quadratic model is of the form

$$\Psi_k(x_k + s) = f_k + g_k^T s + \tfrac{1}{2}s^T B_k s \tag{3}$$

where f_k is an approximation to $f(x_k)$, g_k is an approximation to the gradient $\nabla f(x_k)$, and the symmetric matrix $B_k \in \Re^{n\times n}$ is an approximation to the Hessian matrix $\nabla^2 f(x_k)$. At each iteration, we take $x_{k+1} = x_k + s_k$, where s_k is an approximate solution to the *trust region subproblem*

$$\underset{s\in\Re^n}{\text{minimize}}\, \Psi_k(x_k + s) \quad \text{subject to } \|D_k s\| \le \Delta_k. \tag{4}$$

The positive scalar Δ_k is known as the *trust radius*, and the nonsingular matrix $D_k \in \Re^N$ is the *scaling* or *preconditioning* matrix (often taken to be a fixed diagonal matrix). At each iteration, Δ_k is adjusted so that the ball $\|D_k s_k\| \le \Delta_k$ represents the region over which we expect (3) to adequately model the function f.

A number of techniques are available for computing an approximate solution to (4). An excellent survey of the main classes of these methods can be found in [13]. In most of our computations, we chose to use an *optimal locally constrained* (OLC) technique [7]. Similarly, a number of techniques can be used to generate the Hessian approximation $\{B_k\}$, but we selected the popular BFGS secant update

$$B_{k+1} = B_k + \frac{(g_{k+1} - g_k)(g_{k+1} - g_k)^T}{(g_{k+1} - g_k)^T s_k} - \frac{B_k s_k s_k^T B_k^T}{s_k^T B_k s_k}, \tag{5}$$

provided that

$$(g_{k+1} - g_k)^T s_k \ge 10^{-6}(g_{k+1} - g_k)^T(g_{k+1} - g_k), \tag{6}$$

and $B_{k+1} = B_k$ otherwise. Since g_k is only an approximation to $\nabla f(x_k)$, [4] and [3] suggest that upper bounds of the form

$$\|B_k\| \le c_1 \tag{7}$$

or

$$g_k^T B_k g_k \le c_1 g_k^T g_k \tag{8}$$

be directly enforced for some appropriately large c_1. This could be easily done by using the replacement operation

$$B_k := \min\left\{1, \frac{c_1}{\|B_k\|}\right\} B_k \tag{9}$$

at each iteration. Although bounds such as (7) and (8) are needed to establish convergence results, in practice we found (9) unnecessary.

A simple version demonstrating the salient features of the trust region approach is as follows.

ALGORITHM 1. An implementation of the trust region method.
Let the constants $0 < \eta_1 < \eta_2 < \eta_3 < 1$ be prespecified. Select an initial guess $x_0 \in \Re^N$ and an initial trust radius Δ_0. Compute f_0 and g_0, and compute or initialize B_0.

```
For $k = 0, 1, \ldots$ until "convergence" do:
    (a) Determine an approximate solution $s_k$ to problem (4).
    (b) Calculate the predicted function reduction
```

$$\text{pred}_k(s_k) = -g_k^T s_k - \tfrac{1}{2} s_k^T B_k s_k \tag{10}$$

```
        and the computed function reduction
```

$$\text{cred}_k(s_k) = f_k - f_{k+1}. \tag{11}$$

```
        If necessary, recompute $f_{k+1}$ and/or $f_k$ to greater accuracy.
    (c) Compute the ratio
```

$$\rho_k = \frac{\text{cred}_k(s_k)}{\text{pred}_k(s_k)}. \tag{12}$$

```
    (d) If $\rho_k < \eta_1$, then the step is unacceptable. Set $\Delta_k := \frac{1}{10}\Delta_k$ and return to (a).
    (e) If $\eta_1 \le \rho_k < \eta_2$, then set $\Delta_{k+1} = \frac{1}{2}\Delta_k$,
        Else if $\eta_3 < \rho_k \le (2 - \eta_3)$, then set $\Delta_{k+1} = 2\Delta_k$,
        Else set $\Delta_{k+1} = \Delta_k$.
    (f) Set $x_{k+1} = x_k + s_k$, compute $g_{k+1}$, and compute or update $B_{k+1}$.
End loop
End algorithm
```

Typical values for the step acceptance/trust radius update parameters are $\eta_1 = 0.001$, $\eta_2 = 0.1$, and $\eta_3 = 0.75$. Note that no step is accepted unless $\rho_k \ge \eta_1$, and that the trust radius is never reduced unless $\rho_k \le \eta_2$. Further note that g_k is only computed once per major iteration.

Two conditions are required of the approximate function values. Define

$$\text{ared}_k(s_k) = f(x_k) - f(x_k + s_k). \tag{13}$$

We then require

$$|\text{ared}_k(s_k) - \text{cred}_k(s_k)| \le \zeta_{f,1}\, \text{pred}_k(s_k) \tag{14}$$

and

$$|\text{ared}_k(s_k) - \text{cred}_k(s_k)| \le \zeta_{f,2}\, |\text{cred}_k(s_k)| \tag{15}$$

for some constants $\zeta_{f,1}$ and $\zeta_{f,2}$. A stronger variation of these conditions that is typically more practical is

$$|f_{k+1} - f(x_{k+1})| + |f_k - f(x_k)| \le \zeta_{f,1}\, \text{pred}_k(s_k) \tag{16}$$

and

$$|f_{k+1} - f(x_{k+1})| + |f_k - f(x_k)| \le \zeta_{f,2}\, |\text{cred}_k(s_k)|. \tag{17}$$

Assuming error estimates are available for $|f_k - f(x_k)|$, [3] suggests that (16) and (17) be enforced by using the following procedure in place of step (b) of Algorithm 1.

PROCEDURE 2.
Let $\alpha \in (0,1)$ be prespecified. Given x_k, s_k, Ψ_k, and an estimate for $|f_k - f(x_k)|$, do the following.

(a) Calculate $\text{pred}_k(s_k)$ and $\text{emax} = \zeta_{f,1}\text{pred}_k(s_k)$.
(b) If necessary, recompute f_k to greater accuracy so that $|f_k - f(x_k)| \leq \alpha\,\text{emax}$.
(c) Compute f_{k+1} so that $|f_{k+1} - f(x_{k+1})| \leq (1-\alpha)\text{emax}$.
(d) Compute $\text{cred}_k(s_k)$. If (17) is satisfied, then exit procedure, else reduce emax and return to (b).

End procedure

The permissible level of error in the gradient evaluations can be characterized in two different ways. The preferable condition is

$$\frac{\|D_k^{-1}e_k\|}{\|D_k^{-1}g_k\|} \leq \zeta_g \tag{18}$$

for some constant ζ_g, with

$$e_k = g_k - \nabla f(x_k). \tag{19}$$

Under appropriate assumptions on f and $\{D_k\}$, (18) leads to the strong global convergence result $\lim_{k\to\infty}\|g_k\| = \lim_{k\to\infty}\|\nabla f(x_k)\| = 0$ [4, Thms. 3.3 and 4.1], [3, Thm. 3.4]. The weaker convergence result $\liminf_{k\to\infty}\|g_k\| = 0$ can be obtained [3, Thm. 3.3] using the condition

$$\frac{(D_k^{-1}e_k)^T\,(D_k^{-1}g_k)}{(D_k^{-1}g_k)^T\,(D_k^{-1}g_k)} \leq \zeta_g. \tag{20}$$

If each scaling matrix D_k is taken to be the identity, (18) and (20) become simply

$$\frac{\|e_k\|}{\|g_k\|} \leq \zeta_g \tag{21}$$

and

$$\frac{e_k^T g_k}{g_k^T g_k} \leq \zeta_g. \tag{22}$$

Finally, we must specify the allowed values for the error bounds $\zeta_{f,1}, \zeta_{f,2}$, and ζ_g. These values are given by the inequalities

$$\zeta_g + \zeta_{f,1} < 1 - \eta_2 \tag{23}$$

and

$$0 \leq \zeta_{f,2} < 1, \tag{24}$$

with $\zeta_g \geq 0$ and $\zeta_{f,1} \geq 0$. These limits are *remarkably* generous. If η_2 (the parameter controlling trust radius reduction) is 0.1, we could select $\zeta_{f,1} = 0.05, \zeta_{f,2} = 0.99$, and $\zeta_g = 0.8$—less than one significant bit of accuracy in the components of the gradient approximation.

3. Algorithm performance on Moré–Garbow–Hillstrom test problems with synthetically induced errors. The Moré–Garbow–Hillstrom test set [14] contains eighteen "typical" optimization problems. These problems are all algebraically defined, and thus function and gradient values are both inexpensive to compute and available to high accuracy. In order to test the effects of gradient error, we synthetically induced a random error into each gradient computed. More specifically, we computed a vector w_k with each component selected from a uniform distribution on [-1,1] and then set $g_k = \nabla f(x_k) + e_k$ with

$$e_k = 100 * w_k * \|\nabla f(x_k)\|/2^m, \tag{25}$$

where m is the smallest positive integer for which (21) is satisfied. For our first set of tests no errors were induced in the computation of function values.

For our optimization code, we used an implementation of the Dennis–Schnabel routines [5] using an "optimal locally constrained" step computation procedure (see [5, pp. 134–139] for details). The model Hessians B_k were computed using the standard BFGS procedure (5) with the normal test to ensure positive definiteness (6). We emphasize that no special techniques were used to account for gradient error when computing B_k, nor were safeguards such as (7), (8), or (9) enforced. The value for η_2 in the optimization code was 0.1, so that the theory in [4] and [3] suggests an upper limit of 0.9 for ζ_g. The constants η_1 and η_3 were selected to be 0.001 and 0.8, respectively. The Dennis–Schnabel "relative gradient" stopping criterion was used:

$$\max_{1\le i\le n} \frac{|(\nabla f(x_k))_i \max\{(x_k)_i, 1\}|}{\max\{|f_k|, 1\}} \le \epsilon_m^{1/3} \tag{26}$$

(where ϵ_m is machine epsilon and $(y)_i$ denotes the ith component of a vector y). The "true" gradient is used in (26) rather than the approximate gradient g_k to eliminate the possibility that e_k might also affect the convergence tests in our trials. A fairly stringent x convergence test was also used:

$$\|\tilde{s}_k\|_\infty \le \epsilon_m^{2/3}, \tag{27}$$

where $(\tilde{s}_k)_i \equiv |(s_k)_i|/\max\{(x_k)_i, 1\}$.

A run was also flagged as a failure if more than eight subiterations were attempted at any iteration without finding an acceptable new iterate.

For each problem in the test set, we considered 20 different values of ζ_g ranging from 0.0 to 0.95. For each value of ζ_g, we ran the algorithm with a number of different initializations for the random number generator used to compute e_k values, and tabulated the minimum, median, and maximum number of iterations required to converge to a local minimizer.[1] In all, over 5000 test cases were run on a network of SUN 3/50 workstations in FORTRAN 77 double precision.

For the majority of our problems, the failure test was rarely triggered until error levels reached 80 percent, and did not become prevalent until error levels reached 90 percent.[2] This corresponds well with the value predicted by theory.

Figures 1–5 show plots of our results for selected problems. Let $K(\zeta_g)$ denote the number of iterations required for convergence (using stopping criterion (26) and (27)) as a function of relative gradient error. The vertical axis in each plot represents

[1] Depending on the computational expense associated with a problem and the observed variability of results, between 5 and 100 test cases were run for each value of ζ_g.

[2] An exception was the Beale function, which began to trigger the failure test at 50 percent error.

the natural log of $K(\zeta_g)$, while the three traces in each plot represent the observed minimum, median, and maximum values.

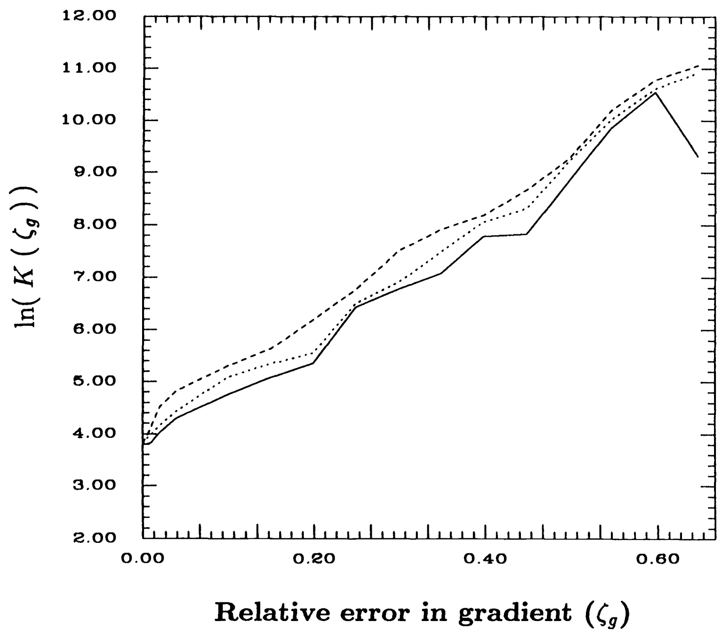

FIG. 1. *Number of iterations versus ζ_g for the Watson test function.*

Figures 1–3 are typical of most of our test cases, in which performance degrades exponentially:

$$K(\zeta_g) \approx K(0)\exp(b\zeta_g), \tag{28}$$

with observed decay coefficients b ranging from roughly 2 to 6 for the various problems. Figures 4 and 5 represent anomalous cases where $\ln(K(\zeta_g))$ has significant variation from linearity at small and large values of ζ_g.

Although the exponential performance degradation given by (28) is a telling argument against using low accuracy gradients if high accuracy evaluations are obtainable without greatly increased computational expense, low accuracy evaluations are still attractive in cases where the computational expense increases rapidly with increasing accuracy. Suppose, for instance, that

$$\text{CPU/iteration} \approx c_2\zeta_g^{-l} \tag{29}$$

for some constants c_2 and l. The total computational expense for solving a given problem will then be proportional to $\zeta_g^{-l}K(\zeta_g)$. Figures 6–10 show the predicted total computational cost of the median curves for $K(\zeta_g)$ in Figs. 1–5 for the values $l = \frac{1}{2}, 1$, and 2 (with each curve normalized so that the minimum value is 1.0).

Note that each curve of total computational cost increases very rapidly as $\zeta_g \to 0$ or $\zeta_g \to 1$, and has a relatively large, flat minima. This behavior holds for both the "typical" cases (Figs. 6–8) and the anomalous cases (Figs. 9 and 10). Interestingly,

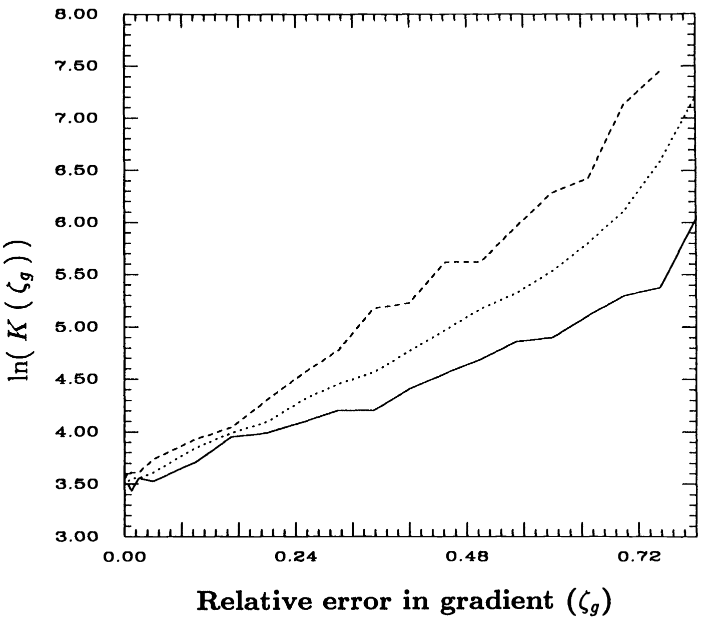

FIG. 2. *Number of iterations versus ζ_g for the Brown and Dennis test function.*

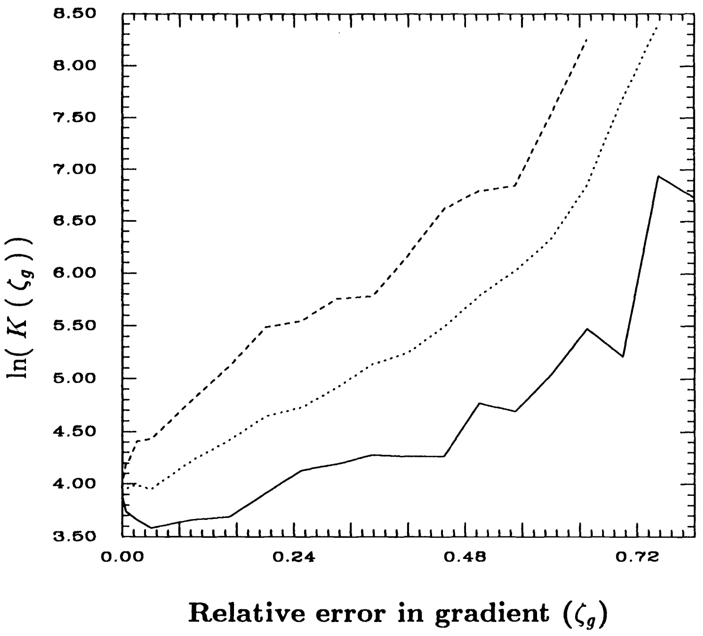

FIG. 3. *Number of iterations versus ζ_g for the extended Powell singular test function.*

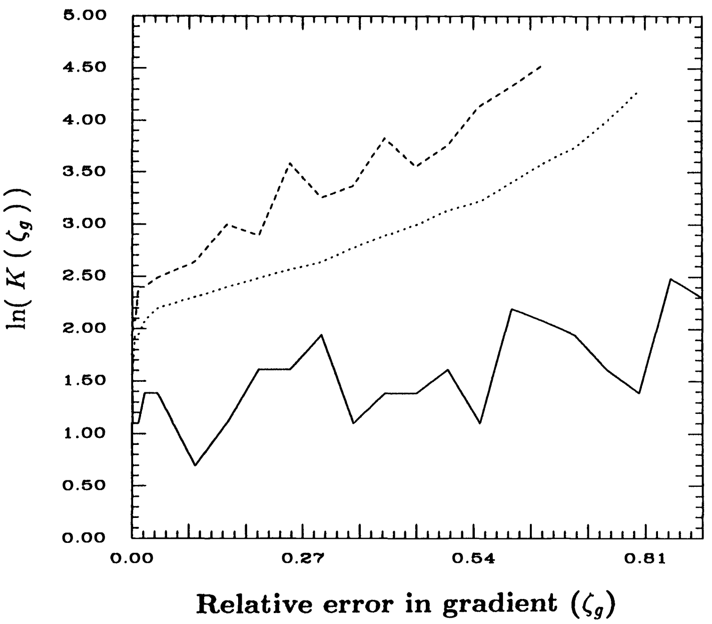

FIG. 4. *Number of iterations versus ζ_g for the Gaussian test function.*

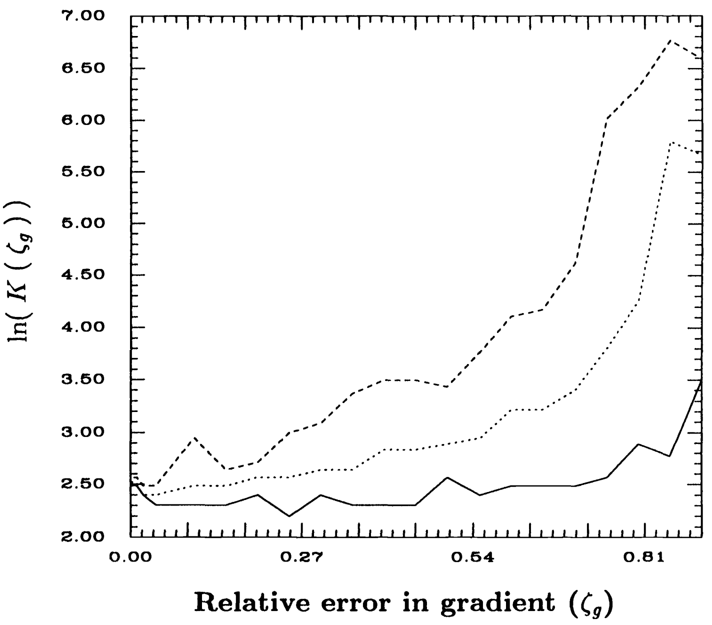

FIG. 5. *Number of iterations versus ζ_g for the trigonometric test function.*

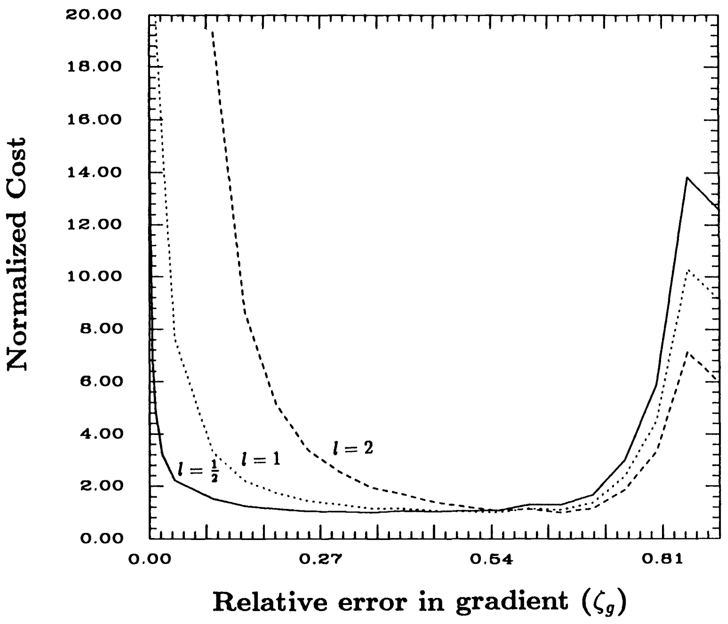

FIG. 10. *Computational cost profiles for the trigonometric test function.*

combining the idealizations (28) and (29) into

$$\text{CPU} \approx K(0)c_2\zeta_g^{-l}\exp(b\zeta_g) \tag{30}$$

yields the theoretical "best" value

$$\zeta_g^* = \frac{l}{b}. \tag{31}$$

Using the observed "typical" value $b = 4$ yields the rule-of-thumb choice

$$\zeta_g^* = \frac{l}{4}, \tag{32}$$

which worked quite well for all of our test problems.

For values of $\zeta_g \leq 0.75$, the x convergence test (27) was rarely triggered. As ζ_g approached $1 - \eta_2$, an increasing ratio of the trials terminated on (27) rather than the relative gradient test (26). These "solutions" are somewhat suspect, so iteration count data in the preceding figures at the highest error levels (0.75 up) should be considered an underestimate.

A number of variations on these numerical tests were also tried. Rather than (29), we also considered the idealization

$$\text{CPU/iteration} \approx c_2\zeta_g^{-l} + c_3, \tag{33}$$

where c_3 represents a fixed "overhead" cost per iteration. For moderate values of c_3, the character of the overall computational cost behavior remained unchanged. Errors in function values were also considered with ζ_g fixed at 0.1. The algorithm proved to be quite insensitive to these errors for $\zeta_{f,1} < 0.5$. Indeed, the algorithm works in practice even if $\zeta_{f,1} > 1$ provided the *average* value of $|\text{ared}_k(s_k) - \text{cred}_k(s_k)| \ / \ \text{pred}_k(s_k)$ is sufficiently less than $1 - \eta_2 - \zeta_g$. As pointed out in [3], this is a very reasonable result since function values are only used to update the trust radii, and a mistake at any given iteration will not cause the algorithm to fail.

4. Algorithm performance on problems involving numerical integration in several dimensions. The test problems of the previous section are well known and widely used by optimization researchers and software developers, and because they are algebraically defined, we were able to run an enormous number of test cases to examine the ranges of possible behavior in the presence of errors. It should be remembered, however, that our interpretation of these results rests both on the character of the synthetic noise added to each gradient evaluation and on idealization (29). In order to verify our results, we also tested our algorithm on several other problems.

Let $(y)_i$ denote the ith component of a vector y, and define

$$h_1(t) = \exp\left(-\sum_{i=1}^{n} \frac{(t)_i}{i}\right) \quad \text{and} \quad h_2(t,x) = \cos\left(\sum_{i=1}^{n} \frac{(t)_i}{(x)_i}\right). \tag{34}$$

Our problem is to find x to match the surfaces h_1 and h_2 over the box $\Omega = \{t : 0 \leq (t)_i \leq 1, i = 1, \ldots, n\}$ in the least squares sense. That is, we wish to minimize

$$f(x) = \int_{t\in\Omega} (h_2(t,x) - h_1(t))^2 dt. \tag{35}$$

The components of the gradient of f are simply

$$\frac{\partial f}{\partial (x)_k} = \int_{t\in\Omega} 2\ (h_2(t,x) - h_1(t)) \sin\left(\sum_{i=1}^{n} \frac{(t)_i}{(x)_i}\right) \frac{(t)_k}{(x)_k^2}\, dt. \tag{36}$$

For the purpose of demonstration, we will assume that n is small and calculate f and ∇f separately by numerical integrations using (a) a recursive Simpson's rule with uniform mesh,[3] and (b) a simple stochastic scheme. The starting point $x = [1\ 1 \ldots 1]^T$ is used in all of our runs, which were executed on an IBM RS-6000 in double precision FORTRAN 77.

In practice, values for f (and similarly the components of ∇f) can be computed to any desired accuracy by successively decreasing the stepsize h in Simpson's rule. For instance, halving the stepsize for sufficiently small h will result in decreasing the error by a factor of roughly 16. Thus we can approximate $|f_k^h - f(x_k)|$ by $|f_k^h - f_k^{h/2}|$ and $|f_k^{h/2} - f(x_k)|$ by $|f_k^h - f_k^{n/2}|/2^4$, where f_k^h is our computation for $f(x_k)$ using stepsize h. More specifically, for a given commanded accuracy ϵ, and two trial stepsizes h_k and h_{k-1}, we compute our next trial h by

$$h_{k+1} = \left\{\frac{0.9\epsilon}{|f_k^{h_k} - f_k^{h_{k-1}}|}\right\}^{1/4} \tag{37}$$

[3] In practice one would of course consider more sophisticated schemes such as Gaussian quadrature or adaptive stepsize methods (or simply solve the problem analytically), but for demonstration we selected the simplest possibility.

(and safeguarding h_{k+1} such that $\frac{1}{2}h_k \le h_{k+1} \le \frac{7}{8}h_k$). This simple rule works very well in practice for target error levels less than 0.1. Typically, the rule results in successively halving h until the estimated error is within an order of magnitude of the target error ϵ, and then selecting an "almost optimal" h in $[\frac{1}{2}h_k, \frac{7}{8}h_k]$. For $n > 2$, the total computational cost is little greater than the expense of evaluating f with the final h. We considered $n = 2$, $n = 3$, and $n = 4$. As n increases, the curve describing computational expense as a function of accuracy becomes increasingly hostile: CPU per f evaluation is $O(\epsilon^{-n/4})$.

For comparison, we first attempted to solve this problem naively requiring fixed absolute accuracy in f (and fixed relative accuracy in the components of g) of six digits, with $n = 4$. Using the same code as in the previous section and terminating when the predicted reduction became less than the specified accuracy in f, we reduced f from 0.71484 to 0.0263596 using 11,004 seconds of CPU time (just over three hours). Using seven digits gave the same function reduction in 16,619 seconds. In contrast, if we solved the same problem using a fixed accuracy of $\zeta_g = 0.1$ in the components of g and computing f values via Procedure 2 (with $\alpha = 0.5$, $\zeta_{f,1} = 0.4$, and $\zeta_{f,2} = 0.99$), we were able to solve the problem to the same accuracy in only 59 seconds—more than 200 times faster.

Clearly, a dramatic difference in computational expense can be expected in cases where computational expenses rise rapidly with increasing accuracy requirements. Much less dramatic effects are to be expected when the rise of computational costs is not so steep. Table 1 shows our results for a variety of values of n.

If n is not small, stochastic integration techniques are, of course, preferable to recursive integration rules, since accuracy increases proportionally to the square root of the number of sample points independent of n: CPU per f evaluation is $O(\epsilon^{-2})$. We considered the simplest possible stochastic integration scheme: for a given x, compute a sequence of h_1 and h_2 values at a sequence of points $\{t_j\}$ uniformly distributed over Ω, take the mean of $\{(h_2(t_i, x) - h_1(t_i))^2\}$, $i = 1, \ldots, j$ to be the jth approximation to the integral, and estimate the error in our approximation by three standard deviations of the mean of $\{(h_2(t_i, x) - h_1(t_i))^2\}$. The components of g are computed by a similar integration. Our results are presented in Table 2.

The final row of Table 2 represents the maximum accuracy attempted for this approach; this run was terminated prematurely due to excessive time requirements (greater than 200 hours on the RS-6000). Note that the final function reduction attained for $\zeta_g = .002$ is actually *less* than that attained using $\zeta_g = .2$, yet $\zeta_g = .002$ uses almost 3812 times as much CPU time—truly a compelling argument for using the minimal sufficient accuracy on problems where costs rise this fast with increased commanded accuracy.

5. Algorithm performance on a parameter identification problem. Our final example is a parameter identification problem from [11] and [12]. Consider the accidental release of the radioactive gas tritium into an enclosure surrounding a nuclear reactor. The tritium will react with water vapor in the containment to produce other tritium-based species via

$$T_2 + H_2O \rightleftharpoons HT + HTO, \tag{38}$$

and some of the HTO may be adsorped into the surface of the containment. This adsorped tritium species represents a significant cleanup problem.

Given the reaction rate constant in (38) and the adsorption and release rates of HTO on the surfaces of the containment, the physical problem can be modeled by a system of four coupled, initial-value ODEs:

$$Y'(t;x) = h(t, Y(t;x)), \qquad Y(0;x) = Y_0, \tag{39}$$

with the components $Y : \Re \times \Re^3 \to \Re^4$ being species concentrations. Unfortunately, the rate constants are not directly measurable. Maroni, Land, and Minkoff performed an experiment in which a known amount of tritium was introduced into a small enclosure and the total tritium concentration $(Y)_1 + (Y)_2 + (Y)_3$ was measured at m discrete time points. The rate constants $(x)_1, (x)_2,$ and $(x)_3$ can then be estimated by minimizing $f : \Re^4 \to \Re$ with

$$f(x) = \frac{1}{2}\sum_{i=1}^{m}\left[\sum_{j=1}^{3}(Y)_j(t_i, x) - O_i + (x)_4\right]^2 / (O_i)^2, \tag{40}$$

where O_i is the observed experimental concentration

$$O_i = Y_1(t_i) + Y_2(t_i) + Y_3(t_i), \tag{41}$$

and $(x)_4$ is an additional variable representing an unknown experimental bias in the instrument for measuring (41).

Equation (40) is a classical inverse problem. Note that each function evaluation for a given iterate x_k involves the numerical solution of four coupled ODEs. Gradient values can be computed via finite differences, or by the numerical solution of a larger system of coupled ODEs derived using the sensitivity [12] or adjoint equations (see, for instance, [18]). Although the latter techniques are usually preferable in practice, we used the more difficult approach of estimating g_k by finite differences so that we could investigate techniques suggested in [3] for estimating and controlling gradient error.

Our numerical experiments with (40) were designed as follows. In order to approximate f at a given point x_k, (39) was solved using ODEPACK [8], which uses an adaptive solution technique. An important feature of ODEPACK is that it allows a desired level of accuracy (either absolute or relative) to be prespecified for each component of Y. In order to achieve an accuracy of, say, ε_k in $f(x_k)$, we specified a desired accuracy of $\alpha_{k-1}\varepsilon_k$ in each component of Y, where α_{k-1} was the amount of accuracy lost due to cancellation in evaluating (40) at the last iteration. This simple procedure worked remarkably well: the actual error in f_k was typically in the range $[1/10\varepsilon_k, 2\varepsilon_k]$ in our preliminary tests of this technique.

Each gradient was initially approximated by a central difference formula using $2n$ extra function evaluations, where each function evaluation was computed with a specified desired relative accuracy of $\bar{\varepsilon}_k$. Denote this approximation $\bar{g}_k$. We then computed a more accurate estimate of the directional derivative of f in the direction $\bar{g}_k$ (or $(D_k^T D_k)^{-1}\bar{g}_k$ if the scaling matrix is not the identity) as suggested in [3], using the formula

$$\bar{d}_k = \frac{1}{2\delta_k}(f(x_k + \delta_k \bar{g}_k) - f(x_k - \delta_k \bar{g}_k)). \tag{42}$$

Each function evaluation in (42) was computed with a specified desired relative accuracy of $\bar{\varepsilon}_k/10$. The perturbation length δ_k was taken to be

$$\delta_k = \left(\frac{\bar{\varepsilon}_k}{10}\right)^{1/3} |f_k|/g_k^T g_k\ , \tag{43}$$

a value expected to perturb two-thirds of the accurate digits of f. Using (19) and (42), we can then estimate the error term in (22) via

$$\frac{e_k^T \bar{g}_k}{\bar{g}_k^T \bar{g}_k} = 1 - \frac{\nabla f(x_k)^T \bar{g}_k}{\bar{g}_k^T \bar{g}_k} \approx 1 - \frac{\bar{d}_k}{\|\bar{g}_k\|^2}. \tag{44}$$

If this error was larger than the desired gradient error level ζ_g, then $\bar{\varepsilon}_k$ was decreased before the next iteration; if it was significantly larger, then $\bar{\varepsilon}_k$ was immediately decreased and $\bar{g}_k$ was recomputed. (In practice, this seldom occurred except at the first gradient computation.) Figure 11 shows the agreement between actual and requested gradient error. Even with the simple procedures used to adjust $\bar{\varepsilon}_k$, the error estimate given by (42) and (44) allows us to control, with reasonable certainty, the level of accuracy in $\bar{g}_k$.

The approximation $\bar{g}_k$ can be further improved at no additional cost by setting

$$g_k = \frac{\bar{d}_k}{\|\bar{g}_k\|^2}\bar{g}_k \tag{45}$$

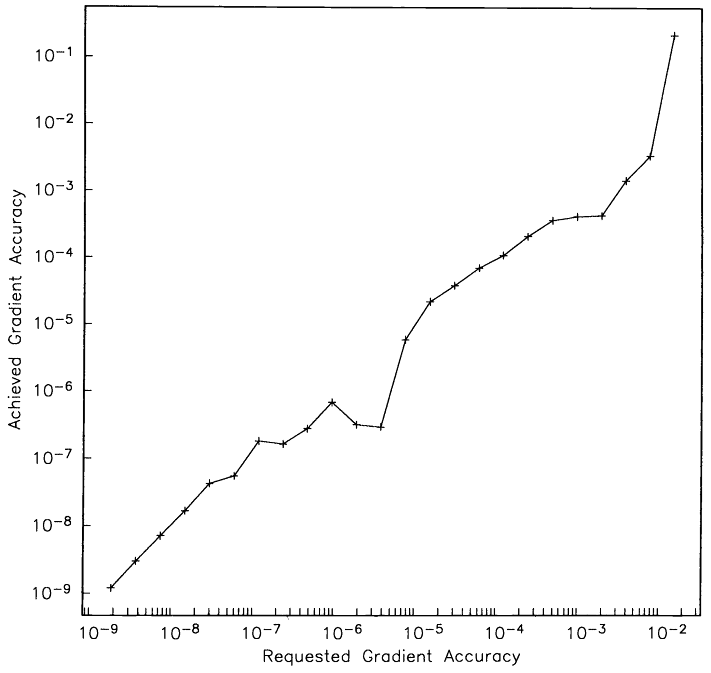

FIG. 11. *Actual versus commanded error in the gradient for the tritium parameter estimation problem.*

so that

$$\frac{e_k^T g_k}{g_k^T g_k} = 1 - \frac{\nabla f(x_k)^T \bar{g}_k}{\bar{d}_k}. \tag{46}$$

Figure 12 shows the CPU time required to achieve a given level of accuracy using (45) in addition to the previously discussed procedure for adjusting $\bar{\varepsilon}_k$. We see that computational expense increases geometrically as accuracy increases.[4]

Given these methods of evaluating f_k and g_k to some specified accuracy, we recorded the computational time required to solve (40) for a number of different values of ζ_g, and for the following three cases.

1. Each f_k value was computed to high relative accuracy (10^{-8}), and each g_k value was computed as previously described *including* the correction (45).

2. Each f_k was computed to high relative accuracy (10^{-8}), and each g_k was computed as described previously but *without* doing correction (45).

3. Each f_k was computed using Procedure 2 with $\zeta_{f,1} = 0.1$ and $\zeta_{f,2} = 0.99$, and each g_k value was computed as previously described *including* correction (45).

[4] The idealized cost profile (29) yields a very close fit to this plot if l is taken to be $\frac{1}{10}$. However, tests with different values of x_k showed that with better empirical form this problem is

$$\text{CPU/gradient evaluation} \approx c_2 \|g_k\|^{-1} \zeta_g^{-1/10}.$$

Nonetheless, the rule-of-thumb choice (32) with $l = \frac{1}{10}$ proved to be close to the optimal selection in our numerical tests.

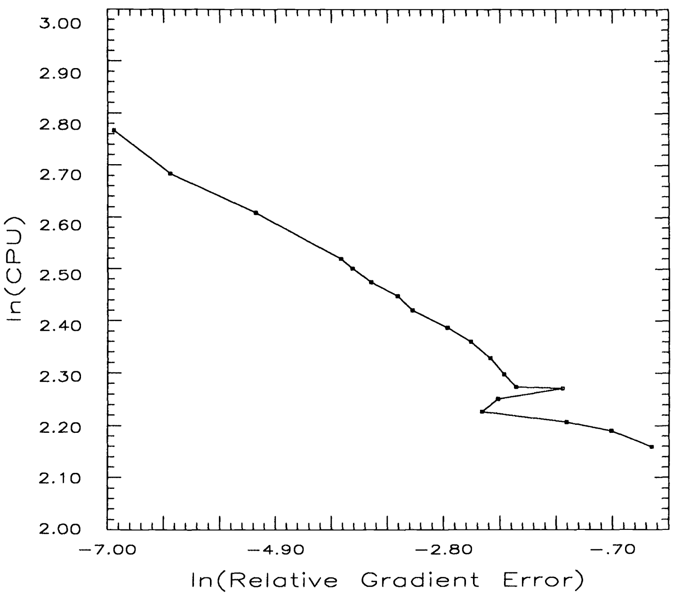

FIG. 12. *Solution time required for one gradient evaluation in tritium parameter identification problem.*

A somewhat different implementation of the trust region method was used rather than the Dennis–Schnabel code used in the last section. First, we included nonnegativity constraints on the first three components of x to be consistent with the physics of the problem. This was done by replacing the ellipsoidal trust region in (4) with the rectangular trust region $\|D_k s\|_\infty \le \Delta_k$, and by using a quadratic programming code at each iteration to exactly solve the trust region subproblem subject to the nonnegativity constraints on x. Second, we used the Hessian safeguarding techniques proposed in [2] in addition to the standard BFGS update (5).[5] Third, we used a simplified stopping criterion for comparison purposes. Each test case was terminated when $f_k - f^* \le \frac{1}{100}(f_0 - f^*)$, where f^* was the optimal value of f.

We remark that the convergence theory developed in [4] and [3] does *not* apply to algorithms that use nonellipsoidal trust regions or impose constraints on the variables; it is therefore interesting to investigate whether this modified implementation still performs well in practice in the presence of gradient errors.

Figure 13 shows the results of our tests.

Case 1 was tested for 15 different values of ζ_g. Note that the total computational time required is less than 8000 seconds for $\zeta_g = 0.015$, but rises to almost 16,000 and 24,000 seconds for $\zeta_g = 1.5 \times 10^{-5}$ and $\zeta_g = 0.25$, respectively. Fewer data were collected for cases 2 and 3, but note that the correction (45) appears to make

[5] This safeguarding procedure monitors the quantity $g_k^T B_k g_k / g_k^T g_k$ and compares it to the maximum observed problem curvature. If the quantity appears too large, B_k is "corrected" by performing a supplemental BFGS update involving one extra gradient evaluation at the point $x_k + s_\epsilon$, with $s_\epsilon = -\epsilon g_k$ for some small ϵ.

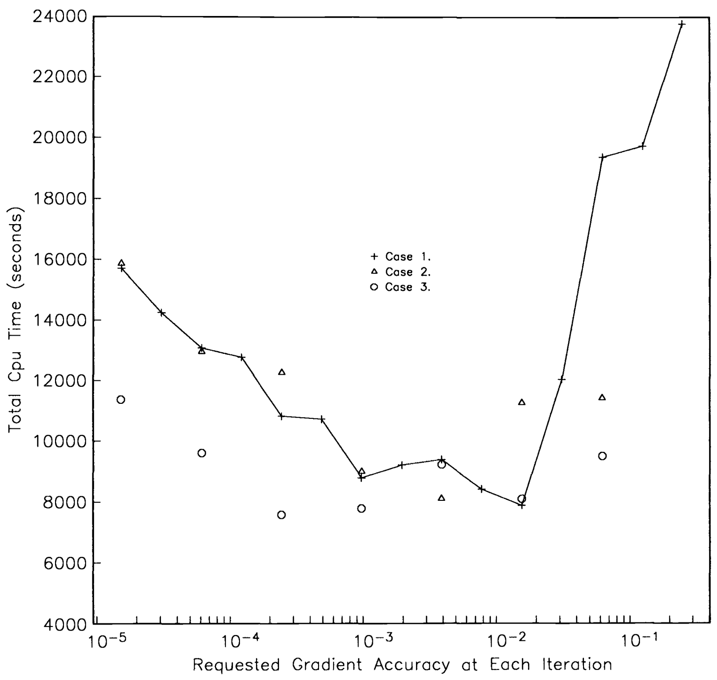

FIG. 13. *Solution time for numerical optimization of the tritium parameter identification problem.*

little difference to the algorithm when $e_k^T g_k / g_k^T g_k$ is small. On the other hand, using Procedure 2 rather than computing each f_k to a fixed accuracy of 10^{-8} resulted in a moderately faster algorithm.

In addition to the above three cases, a number of other numerical tests were made. Rather than keeping ζ_g fixed throughout the algorithm, we tried setting

$$\zeta_g^{k+1} = \begin{cases} 1/10 & \text{if } k = 0 \\ \max\{\zeta_g^k/2, 10^{-5}\} & \text{otherwise,} \end{cases} \tag{47}$$

or conversely,

$$\zeta_g^{k+1} = \begin{cases} 10^{-5} & \text{if } k = 0 \\ \min\{2\zeta_g^k\ , \ 1/10\} & \text{otherwise.} \end{cases} \tag{48}$$

The idea behind (47) is to try to obtain the fast local convergence properties of the BFGS method when accurate gradients are available, while the idea behind (48) is to avoid highly accurate gradient approximations near the solution where they are likely to be most expensive. Interestingly, both of these approaches performed similarly, requiring 8887 and 10,647 seconds, respectively.

Although the correction (45) appears to be of little use when $e_k^T g_k / g_k^T g_k$ is already small, it does appear to be useful in preventing the algorithm from failing due to occasionally encountering highly inaccurate gradient evaluations. In tests where an extremely large synthetic error ($\zeta_g \approx 1$) was added to the gradient approximation every p iterations, the algorithm was much more robust when (45) was used (although the algorithm still had problems involving convergence to a point with $g_k = 0$ and $\nabla f(x_k) \neq 0$, as predicted in [3]). In a similar vein, the gradient accuracy test given by (42) and (44) should be useful in verifying the accuracy of analytically derived gradients.

6. Summary. We have examined the numerical behavior of trust region algorithms for nonlinear optimization when function and gradient values are not computed exactly. This class of algorithms has proven remarkably robust, and can be successfully implemented even with very large errors in the function and gradient evaluations.

In a large number of tests using standard test problems with synthetically induced gradient errors, we observed that the algorithm performance, as measured by the number of iterations required for convergence, tends to degrade exponentially as the relative gradient error increases. This is a telling argument for using accurate evaluations provided they can be obtained at reasonable expense. For many optimization/simulation problems, however, the computational expense of these evaluations rises sharply with increasing accuracy, and low accuracy evaluations are again attractive. A good choice for the amount of relative gradient error allowed in the algorithm can result in orders-of-magnitude savings in computational cost. If (29) holds, then the choice $\zeta_g = l/4$ was nearly optimal for all of our test problems.

Using a parameter estimation problem based on the numerical solution of a system of ODEs, we tested a technique for estimating and controlling the amount of error in a gradient approximation. This technique was very successful when used in conjunction with the "user-specified accuracy" feature in the numerical differential equation solver ODEPACK. Actual computational costs for various values of relative gradient error were examined to confirm the behavior observed in the test problems with synthetically induced errors.

A MULTIRESOLUTION METHOD FOR DISTRIBUTED PARAMETER ESTIMATION*

JUN LIU[†]

Abstract. A multiresolution method for distributed parameter estimation (or inverse problems) is studied numerically. The identification of the coefficient of an elliptic equation in one dimension is considered as our model problem. First, multiscale bases are used to analyze the degree of ill-posedness of the inverse problem. Second, based on some numerical results, it is shown that the method of scale-by-scale multiresolution yields robust and fast convergence. Finally, it is shown how the method gives a natural regularization approach which is complementary to Tikhonov's regularization.

Key words. identification, distributed parameter, multiresolution, Haar basis, BFGS optimization

1. Introduction.

Inverse problems are usually considered difficult problems. One essential question is how to obtain a stable solution rapidly. The idea of multiscale representation has suggested various parallel and iterative algorithms. For example, multigrid methods have been widely used for solving partial differential equations (direct problems) [4], [5] in order to accelerate the convergence. However, this idea has seldom been used until now for inverse problems (lack of theory). Recently, some approximation frameworks have been developed for inverse problems [2] and wavelet theory (multiscale bases) has appeared [14], [13]. This allows the idea of multiresolution to be used for inverse problems with little modification from the classical optimization methods.

We take as our model a simple elliptic problem that is well known as being nonlinear and ill posed. A number of studies of this problem have already been done (for example, [12]). In this paper, we first analyze the inverse problem using the Haar basis (a multiscale basis). We remark that the objective function is more "ill posed" (or nonlinear) with respect to the coefficients corresponding to the finer scales, but it is less sensitive with respect to these coefficients. Then we investigate numerically the behavior of a BFGS optimization routine in the IMSL library [11] when the unknown parameter is represented in the usual local basis, and in the Haar basis. This leads us to propose a multiresolution, or scale-by-scale, optimization method to solve the parameter estimation problem. This method turns out to be very robust (convergence is obtained for any initialization of the optimization algorithm) and efficient (a good solution is obtained with a very small number of iterations). The multiresolution method allows us to perform, for the problem under consideration, a global optimization with a local optimizer. Moreover, a method of rescaling of the variables and the objective function for each optimization run can be easily performed to accelerate the convergence. Finally we give regularization methods that are complementary to Tikhonov's regularization. This paper emphasizes some numerical results and does not give a global convergence proof.

2. A simple model inverse problem.

We consider the following elliptic equation:

$$-\frac{d}{dx}\left(a(x)\frac{du(x)}{dx}\right) = f(x), \qquad x \in (0,1) \tag{1}$$

with the Dirichlet boundary condition

$$u(0) = u(1) = 0, \tag{2}$$

where $f(x) \in L^2(0,1)$ is known.

The direct problem is:

(DP) let Q_{ad} be the convex set $\{a(x)\,|\,0 \le m \le a(x) \le M\ , x \in (0,1)\} \subset L^2(0,1)$; given $a(x) \in Q_{ad}$, we solve for $u(x)$ in (1), (2), where *ad* denotes admissible.

This problem is very simple, as (1), (2) have a unique solution $u(x)$ denoted by $\Phi(a)$. The application Φ is continuous from Q_{ad} equipped with the L^2-norm into $H_0^1(0,1) \subset L^2(0,1)$.

The inverse problem is:

(IP) given a distributed observation $z(x) \in L^2(0,1)$ of $u(x)$, we minimize the objective function (output least squares error)

$$J(a) = \|\Phi(a) - z\|^2 = \int_0^1 (u(x) - z(x))^2 dx \tag{3}$$

over $a \in Q_{ad}$.

The problem is a typical ill-posed nonlinear problem. There are two types of "ill-posedness." First, $a(x)$ cannot be determined by (1) on the set $\{x|u_x(x) = 0\}$ so that there is no uniqueness for the solution if $measure(\{x|u_x(x) = 0\}) > 0$. Second, from homogenization theory [3], we remark that there is a sequence $a_n(x)$ which is not convergent in L^2, but still the sequence $u_n(x) = \Phi(a_n(x))$ is convergent in $H_0^1(0,1)$, so that the solution is not stable.

Remark. We can easily obtain an analytical solution of (1), (2):

$$u(x) = \frac{\int_0^1 b(y)F(y)dy \int_0^x b(y)dy}{\int_0^1 b(y)dy} - \int_0^x b(y)F(y)dy \tag{4}$$

with

$$b(x) = a(x)^{-1}, \qquad F(y) = \int_0^y f(s)ds. \tag{5}$$

This analytical solution will be used in §3.2.

For the numerical solution of (IP), we shall consider the following discretized problem (IP_h^H):

$$\text{Minimize} \quad J_h(a_H) = \sum (u_h - z_h)^2 \tag{6}$$

with

$$A_h(a_H)u_h = f_h, \tag{7}$$

where u_h and a_H are the discretizations of $u(x)$ and $a(x)$, respectively ($h = 1/n$ and $H = 1/N$); u_h is a piecewise linear function which consists of the $n-1$ values of u_h

at the nodes $x_i = ih$, $i = 1, \dots, n-1$; and a_H is a piecewise constant function which consists of the N values of a_H on intervals $](i-1)H, iH[$, $i = 1, 2, \dots, N$.

Remark. For well-posedness of the discrete problem (IP_h^H), the condition $h \le H$ is necessary. When $H = h$, we have $N = 1/H$ numbers to be estimated, but only $N-1$ observation numbers.

3. Using multiscale bases to analyze the inverse problem.

3.1. Multiscale bases. Multiscale bases have been known for a very long time. The first one that appeared in the literature was the Haar basis, presented at the beginning of this century. They were, however, relatively little used for numerical computations, until the general interest in wavelets developed in the early 1980s. Presented first as a challenge to Fourier analysis, wavelets quickly turned out to be a systematic way of constructing multiscale bases of function spaces. The use of these multiscale bases is now being widely investigated for the resolution of partial differential equations (direct problem). We show in this paper that they can be a very valuable (and simple) tool for the resolution of the inverse problem stated in §2. Because the parameter $a(x)$ that we are looking for is required only to be in $L^2(0,1)$, we shall use the simplest multiscale basis, namely the Haar basis. Of course, in inverse problems where the unknown parameter is more regular, we must resort to more sophisticated wavelet bases.

Let Z be the set of integers, using the characteristic function

$$\phi(x) = \begin{cases} 1, & x \in (0,1), \\ 0, & \text{otherwise.} \end{cases}$$

The mth scale approximation of a general function $a(x)$ is represented by

$$a^m(x) = \sum_{i \in Z} a_i^m \phi(2^m x - i), \tag{8}$$

where a_i^m is the mean value of $a(x)$ over the interval $[i/2^m, (i+1)/2^m]$.

The corresponding multiscale basis is the Haar basis, made of the functions $\psi_i^j(x) = \psi(2^j x - i)$ for all $i, j \in Z$, which are constructed from the following mother wavelet function:

$$\psi(x) = \begin{cases} -1, & x \in (0, \frac{1}{2}), \\ +1, & x \in (\frac{1}{2}, 1), \\ 0, & \text{otherwise.} \end{cases}$$

The ψ_i^j, $i, j \in Z$ form a complete orthogonal basis of $L^2(R)$, which is multiscale in the sense that the mth scale approximation $a^m(x)$ is simply obtained by setting to zero all coefficients of ψ_i^j with $j \ge m$ in the expansion of the function

$$a(x) = \sum_{i \in Z, j \in Z} c_i^j \psi_i^j(x) \tag{9}$$

on the basis.

Remark. For the space $L^2(0,1)$ and a fixed mth scale approximation, we have two equivalent orthogonal bases: the characteristic basis made of $\{\phi(2^m x - i + 1) \mid i = 1, \dots, 2^m\}$ and the Haar basis made of $\{\psi(2^j x - i + 1) \mid j = 0, \dots, m-1, i = 1, \dots, 2^j\}$ and of the constant function $\psi^0(x) = \phi(x) = 1$ over [0,1].

3.2. Curvature analysis. A geometrical theory for general nonlinear least-squares problems [7] shows that the velocity and the curvature along curves of the solution space which are images by Φ of segments in Q_{ad} are important to measure the "degree of ill-posedness" of the inverse problem in the output least-squares formulation. In the limiting case, the curvature is equal to zero for a linear problem.

In this section, we suppose that $f(x) = 1$. Algebraic computation systems (Macsyma, Maple, etc.) allow us to calculate the velocity and the curvature along the curve $\Phi(a + t\delta a)$ at $t = 0$ in the directions of the basis functions

$$\delta a(x) = \begin{cases} 0, & x \in (0, t-h), \\ -1, & x \in (t-h, t), \\ 1, & x \in (t, t+h), \\ 0, & x \in (t+h, 1), \end{cases}$$

for the exact mapping Φ, i.e., without any approximation to the solution $u(x)$ of (1) and (2).

For the velocity V and the curvature K in the direction $\delta a(x)$ at $a(x) = 1$, we obtain the following formulae:

$$V^2 = \frac{h^3(180hs^2 + 5h + 30h^3 + 40s^2 - 24h^2)}{60}, \tag{10}$$

$$\begin{aligned} K^2 = -480(&1230h^7 - 600h^8 - 940h^6 + 317h^5 - 40h^4 + 1800h^7s^2 - 400s^4 \\ &-3000h^6s^2 + 7200h^4s^4 + 2640h^4s^2 + 480h^2s^4 + 240h^2s^2 \\ &-1480h^3s^2 - 8400h^3s^4 - 330h^5s^2 + 7200hs^6 + 1600hs^4 - 4800s^6) \\ \times(&180hs^2 + 5h + 30h^3 + 40s^2 - 24h^2)^{-3}h^{-4}, \end{aligned} \tag{11}$$

where $s = t - \frac{1}{2}$.

From these formulae, we have

$$V^2 \sim \frac{2h^3s^2}{3}, \quad K \sim 6h^{-2}, \quad \text{as} \quad h \to 0. \tag{12}$$

We conclude that the objective function is more nonlinear with respect to the coefficients of the finer scales, but is less sensitive with respect to these coefficients. For illustration, we plot the curves $\log(V)$ and $\log(1 + K^2)$ at five different scales in Fig. 1 (bottom).

Remark. In the same way, for the characteristic basis we have

$$V^2 = \frac{h^2(h^3 + 30h^2s^2 - 20hs^2 + 10s^2 + 120s^4)}{120}, \tag{13}$$

$$K^2 = -\frac{4800h^3s^2(10hs^2 + 2h - 12s^2 - 1 - h^2)}{(h^3 + 30h^2s^2 - 20hs^2 + 10s^2 + 120s^4)^3}, \tag{14}$$

$$V^2 \sim \frac{h^2s^2(1 + 12s^2)}{12}, \quad K^2 \sim \frac{4.8h^3}{s^4(1 + 12s^2)^2} \quad \text{as} \quad h \to 0 \tag{15}$$

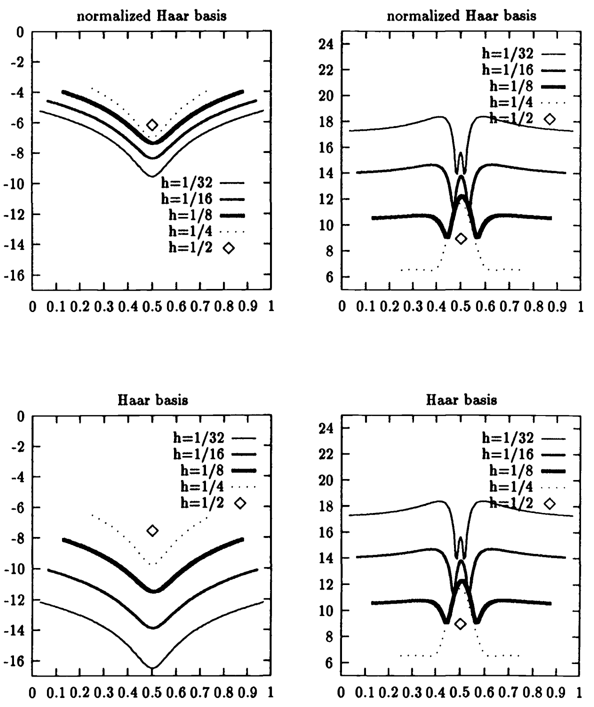

FIG. 1. *Left:* $\log(V^2)$ *and right:* $\log(1+K^2)$ *at different scales.*

in the direction of the basis function

$$\delta a(x) = \begin{cases} 0, & x \in (0, t-h/2), \\ 1, & x \in (t-h/2, t+h/2), \\ 0, & x \in (t+h/2, 1), \end{cases}$$

where $s = t - \frac{1}{2}$.

Remark. If we take $b(x) = a(x)^{-1}$ as the parameter to be estimated, we do not get the same result. The curvature K in the direction $\delta b(x)$ at $b(x) = 1$ is the following:

$$K^2 = \frac{9600h^2(5-24h+60s^2+30h^2-90hs^2)}{(5h+40s^2-24h^2+180hs^2+30h^3)^3}, \tag{16}$$

$$K^2 \sim \frac{3h^2(1+12s^2)}{4s^6} \quad \text{as} \quad h \to 0, \tag{17}$$

where $s = t - \frac{1}{2}$ and

$$\delta b(x) = \begin{cases} 0, & x \in (0, t-h), \\ -1, & x \in (t-h, t), \\ 1, & x \in (t, t+h), \\ 0, & x \in (t+h, 1). \end{cases}$$

It is not surprising that the values of K in (12), (15), and (17) are very different. Equation (12) shows that singularity directions for $K \to \infty$ correspond to $h \to 0$ and from (15) and (17), singularity directions for $K \to \infty$ correspond to $h \to 0$ and $s \sim h$. These two kinds of singularity directions correspond exactly to the two kinds of ill-posedness mentioned in §2, which can also be recovered by the singularity directions for $V \to 0$ from (12). So the inverse problem is not only insensitive but also very nonlinear for the singularity directions.

4. Multiscale parametrization, multiresolution, and regularization. In this section we investigate various strategies for the practical computation of a_H by minimization of the objective function J_h. In all runs we have used the subroutine BCONF of the IMSL library based on the BFGS algorithm [11]. The only initializations required in this subroutine are the initial guess of the unknown parameter. The other parameters are given by default values (the initialization of the Hessian is an identity matrix).

Our investigations concerned first the behavior of the BFGS algorithm for various initializations and various parametrizations of a_H associated to different bases of R^{32}: the characteristic (or local) basis (§4.1) and multiscale bases (§4.2). In many cases, parametrization in the usual Haar basis will prove to yield much better convergence of the BFGS algorithm than the usual local basis.

Our analysis of this phenomenon will lead us to experiment with a multiresolution (scale-by-scale) optimization approach in §4.3, which turns out to be very robust and yields the fastest convergence. Finally, we show in §4.4 how multiscale parametrization and multiresolution can be efficiently combined with a regularization approach in order to stabilize the estimation of a_H with noisy data.

Here we summarize the data common to all runs: the elliptic equation (1), (2) (with right-hand side $f(x) = 1$) was discretized using a finite difference scheme with a mesh size $h = 1/32$, and the parameter a_H was also discretized with $H = 1/32$ (hence we are faced with the estimation of 32 unknown parameters).

The data z_h (exact in §4.1, 4.2, and 4.3 and noisy in §4.4) were generated using the above finite difference scheme and the following "true parameter"

$$a_H^{\text{true}}(x) = \begin{cases} 1, & x \in (0, 1/5), \\ 10, & x \in (1/5, 2/3), \\ 50, & x \in (2/3, 1). \end{cases}$$

Note that a_H^{true} is quite strongly heterogeneous! Because of the Dirichlet boundary condition, z_h consisted of only 31 numbers representing the solution $u(x)$ at $x = h/2, 3h/2, \ldots, 63h/2$. Hence the problem of the estimation of a_H from z_h was clearly undetermined!

Two initializations were used, corresponding to $a_H^{\text{init}} \equiv 1$ and $a_H^{\text{init}} \equiv 10$. The first initial guess is "poor" (underestimated), and the second one is "good" (in the range of the values of a_H^{true}). The corresponding initial values of J_h are 215 and 0.84, respectively. Optimization runs using the local basis were made with the bound constraint of $0.1 \le a_H \le 100$ (except one run in §4.2), and optimization runs using the multiscale basis or using the multiresolution method were performed without any constraint.

4.1. The BFGS algorithm and the local basis. The traditional method is to perform one optimization run to simultaneously estimate 32 numbers representing the value of a_H on each interval. If we use the subroutine BCONF in this way, we obtain the result shown at the bottom left of Fig. 2 after 1000 iterations with

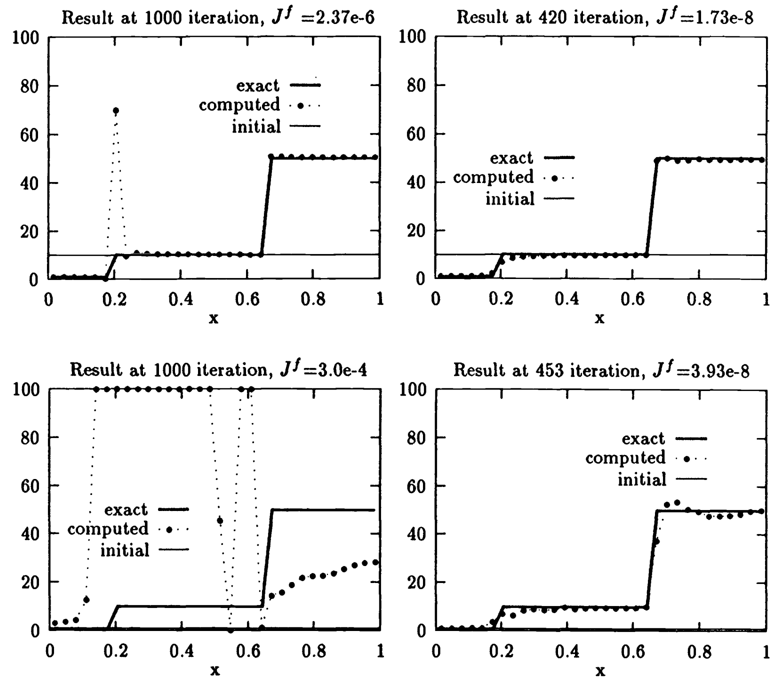

FIG. 2. *The comparison of the final results of minimization for different initializations (bottom $a_{\text{init}} = 1$, top $a_{\text{init}} = 10$) and for different parametrizations of the unknown parameter (left: local basis, right: Haar basis). The bound constraint* $[0.1, 100]$ *was used with the local basis and no constraint was used with Haar basis.*

initialization $a_H^{\text{init}} = 1$. The algorithm is not convergent and the final relative objective function (i.e., the ratio of the final value of J_h to the initial value of J_h: $J^f = J_h(a_H^{\text{comp}})/J_h(a_H^{\text{init}})$) is equal to 3.0×10^{-4}. If we choose the better initialization $a_H^{\text{init}} = 10$, we obtain the result shown at the top left of Fig. 2. We have recovered the "true" parameter a_H^{true}, but the rate of convergence is slow. To understand in more detail the behavior of the algorithm on the problem, we plot the evolution of the relative errors for parameters at different scales in L^2 during the procedure of optimization in Figs. 3 and 4. The result coincides with the analysis in §3. The coefficients of finer scales do not converge toward the "true" coefficients at all when the "bad" initialization $a_H^{\text{init}} = 1$ is used.

4.2. The BFGS algorithm and multiscale bases. We tested the influence of the representation of a_H on the Haar basis (orthogonal) as in (9), on the normalized Haar basis (orthonormal), and on the local basis (orthonormal) when a minimization without constraints was performed for the three bases. Note that quasi-Newton algorithms are expected to produce the same sequence of iterates when an orthonormal change of basis is performed on the unknown parameter and when the Hessian is initialized with an identity matrix in both cases. Hence one expects that using the local basis or the normalized Haar basis will not influence the behavior of the BFGS algorithm. This is what we observe in Fig. 5. However, the decrease of the objective function is slightly better with the normalized Haar basis for the two initializations $a_H^{\text{init}} = 1$ and $a_H^{\text{init}} = 10$.

Then we used the usual Haar basis for the representation of the unknown parameter a_H. As we already noted in [8], the convergence of the BFGS algorithm was

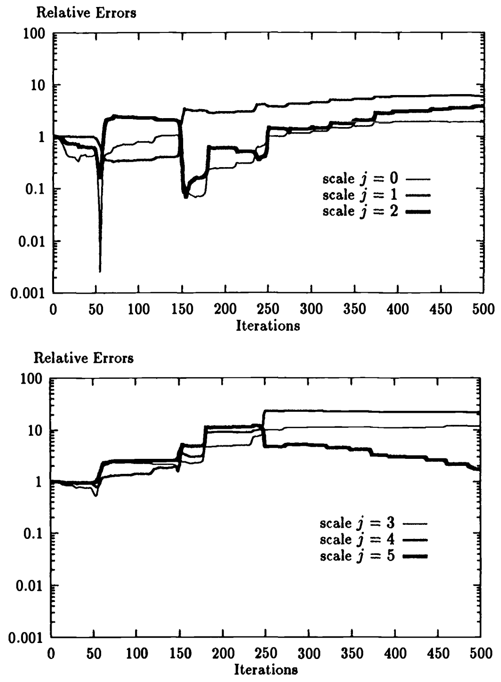

FIG. 3. *The evolution of relative errors on different scales for parameter $a(x)$ in L^2 during the optimization with the local basis, $a_{\text{init}} = 1$ and bound constraint $= [0.1, 100]$.*

much better with this basis for the two initializations $a_H^{\text{init}} = 1$ and $a_H^{\text{init}} = 10$ (Fig. 5). We now try to give an explanation for this phenomenon. We note first that in the Haar basis, the L^2-norm of the basis function is decreasing when the scale index is increasing. Hence replacing the local or normalized Haar basis by the Haar basis amounts to performing a rescaling of the unknown parameter depending on the scale level: the sensitivity to an unknown is decreased proportionally to its scale index (this is apparent by comparing the top and bottom of the left part of Fig. 1). Surprisingly at first glance, this rescaling goes in the opposite direction of what would be required to try to "spherize" the objective function J_h around its minimum: the discrepancy in sensitivity in all basis directions is much larger with the Haar basis (bottom left of Fig. 1) than with the normalized Haar basis (top left of Fig. 1)! Here "spherizing" means the scaling of the diag($\nabla^2 J_h(a)$). Numerical experimentation with an "overnormalized" Haar basis (for which all scales had approximately the same sensitivity) did not produce any enhancement of the convergence.

The explanation may come from the nonlinear effects. As we already mentioned in §3.2, the nonlinearity is increasing with scale index, hence "spherizing" the objective function, which boosts up the sensitivity of fine (high-index) scales, and also boosts up the nonlinear effects associated with these fine scales, so that the "convergence domain" around the exact solution becomes extremely small, and the quasi-Newton method is not able to find its way to the global minimum once the initial guess is not too good. Conversely, "despherizing" the objective function, i.e., diminishing the sensitivity of fine (high-index) scales (which is performed by using the Haar basis), also lowers the influence of the strong nonlinearities associated with fine-scale coefficients: at the beginning, the objective function seems to depend almost entirely on the low scales having low nonlinear coefficients. It is only after these low-scale coefficients have been approximately set that the influence of the finer-scale coefficients becomes apparent. This is confirmed in Figs. 6 and 7, where the evolution of the relative errors on a_H is plotted for each scale against the iteration index. On Fig. 6 for example, we see that coefficients associated to scales 1 and 2 begin to adjust only after iteration 20, when the scale zero (mean value) coefficient has been approximated to 10 percent. Similarly, until iteration 150, the BFGS algorithm, does not touch the coefficient of the finer scales (third, fourth, and fifth), and hence performs an optimization in the four-dimensional space associated with scales 0, 1, and 2! Furthermore, we see that the coefficients of the finest (fifth) scale really begin to adjust only after iteration 340, where the error on all coarser scales becomes less than 10 percent!

This behavior strongly suggests trying to optimize the objective function successively on spaces of increasing dimension associated with finer and finer scales. This is the subject of the next section.

4.3. Multiresolution algorithms. As we have seen above, the nonlinear effects are increasing when finer scales are added, and the size of the corresponding "domain of convergence" of the quasi-Newton method is decreasing. It is hence natural to solve first the optimization problem on a small number of (coarser) scales, which is likely to yield the global minimum as the nonlinear effects are small, and to use this point as initial guess for an optimization run including finer scales. The hope is that the initial guess from the coarser optimization will be inside the "convergence domain" of the new, more nonlinear problem. This is the basis of the multiresolution algorithm.

Another argument comes from estimates of approximation error. In the solution of the partial differential equation (direct problem), we have the following error estimate [1], [9]:

$$\|u_h - u\| \leq K h^{\alpha}. \tag{18}$$

This error estimate is usually considered as essential for the full multigrid methods (nested algorithms) [5]. For inverse problems, an approximation theory has also been developed recently for elliptic problems in some special cases [2], [10] under the condition $h \sim H$, which gives (for nonnoisy data) a similar estimate:

$$\|a_H - a\| \leq K_2 H^{\beta}. \tag{19}$$

This also suggests using a nested algorithm for our inverse problem.

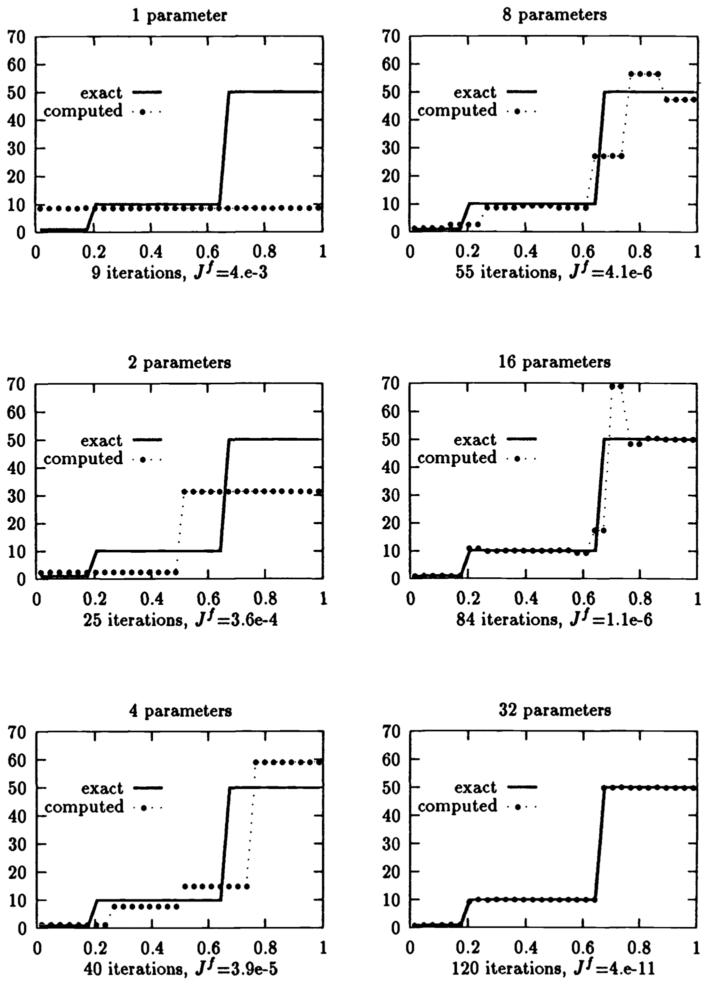

FIG. 9. *The parameter obtained at the end of each step (scale level) of the multiresolution method without noise.*

The multiresolution algorithm is as follows. We solve first the optimization problem with scale zero (one unknown), and the result is used as initial value for an optimization run with scale one (two unknowns), etc. For each optimization run, we use a rescaling method to get better convergence. The rescaling method is to reformulate the optimization problem Min$J(a)$ with initial value a^0 (suppose $a_i^0 \neq 0$, for all i) as Min$\hat{J}(b) = J(b{*}a^0)/J(a^0)$ with the initial value $b^0 = [1, 1, \ldots, 1]^T$, where $b{*}a^0 = [b_1 a_1^0, b_2 a_2^0, \ldots]^T$. The Hessian matrix is initialized as an identity matrix.

This algorithm can be implemented using either the local basis or the Haar basis. The advantage of the local basis is that it allows an easy implementation of the bound constraint, but our numerical experiments show that with the multiresolution algorithm, the solution does not tend to hit the constraints. The multiscale basis allows us to easily perform multigrid patterns such as V, W cycles [5]. But the inverse problem does not have the same behavior as the direct problem and until now we have not found any need to use such patterns.

We illustrate in Figs. 8, 9, and 10 the behavior of the local basis implementation of the multiresolution algorithm. Figure 8 shows that multiresolution achieves an

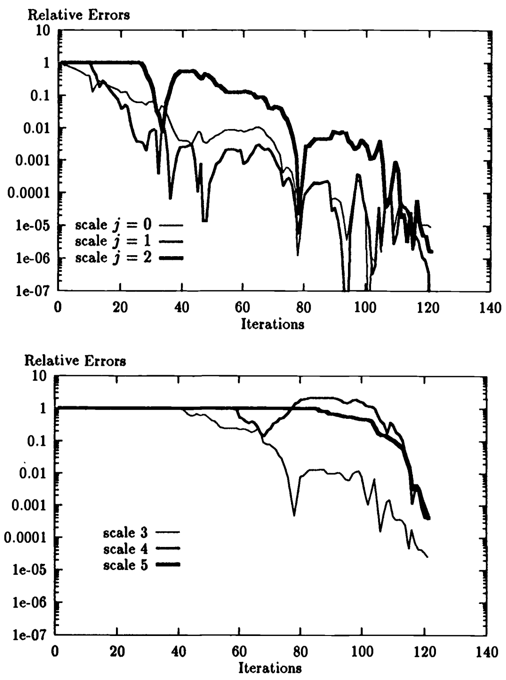

FIG. 10. *The evolution of relative errors on different scales for parameter $a(x)$ in L^2 during the optimization with $a_{\text{init}} = 1$ and bound constraint $[0.1 : 100]$ using multiresolution.*

excellent fit (the final objective function $= 10^{-10}$) in only 120 iterations, and clearly beats (mono)resolution with either the local or the Haar basis (compare, also, with Fig. 5). The rescaling for each optimization has the effect of reducing the number of iterations from 380 to 120 (by a factor of 3!) on the example considered. Figure 9 shows the parameter obtained at the end of each of the six optimization runs (scales 0, 1, 2, 3, 4, and 5), and Fig. 10 shows the evolution of the relative error in the parameter associated with each scale.

4.4. Multiscale bases, multiresolution, and regularization. When the data are noisy, the error estimate becomes [1], [9]

$$\|a_H - a\| \le K_1 \mathrm{dist}(z, \phi(Q_{ad}))H^{-s} + K_2 H^{\beta}. \tag{20}$$

So a_H may be far from a when H is sufficiently small. To stabilize the solution of an inverse problem, the classical method is to use Tikhonov's regularization [15], for example, replacing the objective function $J(a)$ by

$$J_1(a) = J(a) + \alpha \left\| \frac{da(x)}{dx} \right\|^2. \tag{21}$$

This function, of course, can be efficiently minimized using the multiresolution algorithm of §4.3. The numerical results corresponding to $\alpha = 10^{-6} J_h(a_H^{\text{init}})$ and 5 percent noisy data are shown in Fig. 11. We see that a stabilization is achieved at the price of a less accurate fit to the true parameter values.

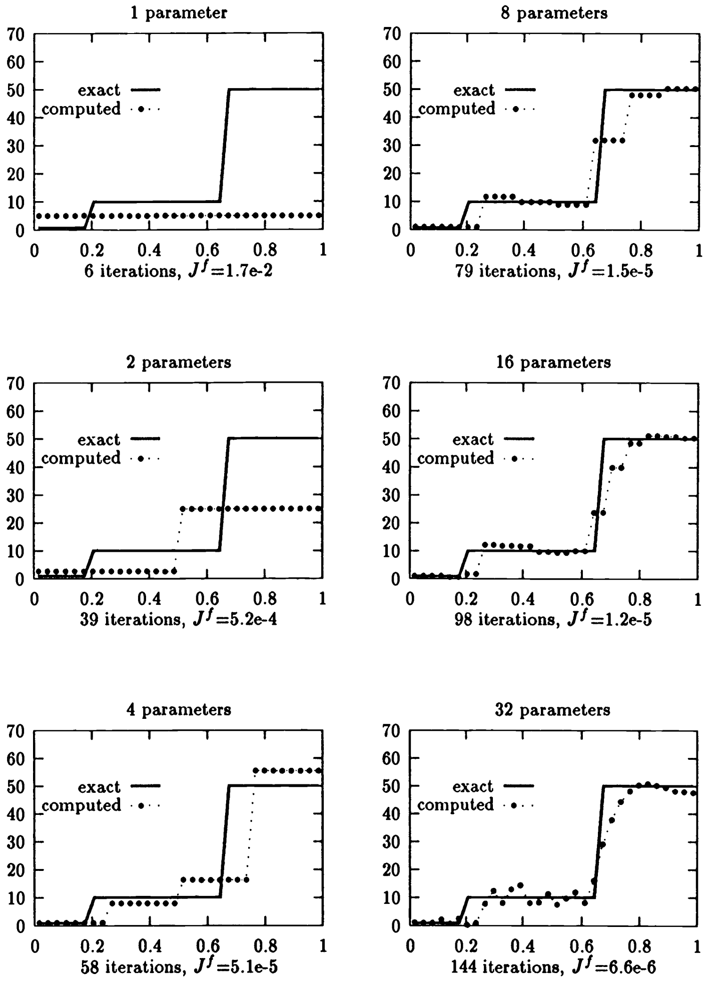

FIG. 11. *The parameter obtained at the end of each step (scale level) of the multiresolution method applied to Tikhonov's regularized problem and data with* 5 *percent noise.*

The use of the multiscale basis and/or the multiresolution algorithm leads naturally to two other types of regularization.

If we use a multiscale basis, we can express the smoothness of a function by the decay of the coefficient in the expansion. So we can replace $J(a)$ by (cf. [8])

$$J_2(a) = J(a) + \sum_j \alpha_j \sum_i (c_i^j)^2. \tag{22}$$

Hence the regularization is obtained by limiting the amplitude of the small-scale oscillations of a_H (compare with the usual regularization (21), where all scales are affected!). We refer to [8] for numerical results for this approach.

With the procedure of multiresolution, a very simple type of regularization (corresponding to the limit case of (22) with $\alpha_j = 0, j = 0, \dots, m$, and $\alpha_j = \infty$, $j > m$) can be performed simply by stopping at a reasonable scale m during the multiresolution procedure. Different regularizations can be obtained using different multiscale bases. For example, it is interesting to use some regular multiscale basis as in Meyer [14].

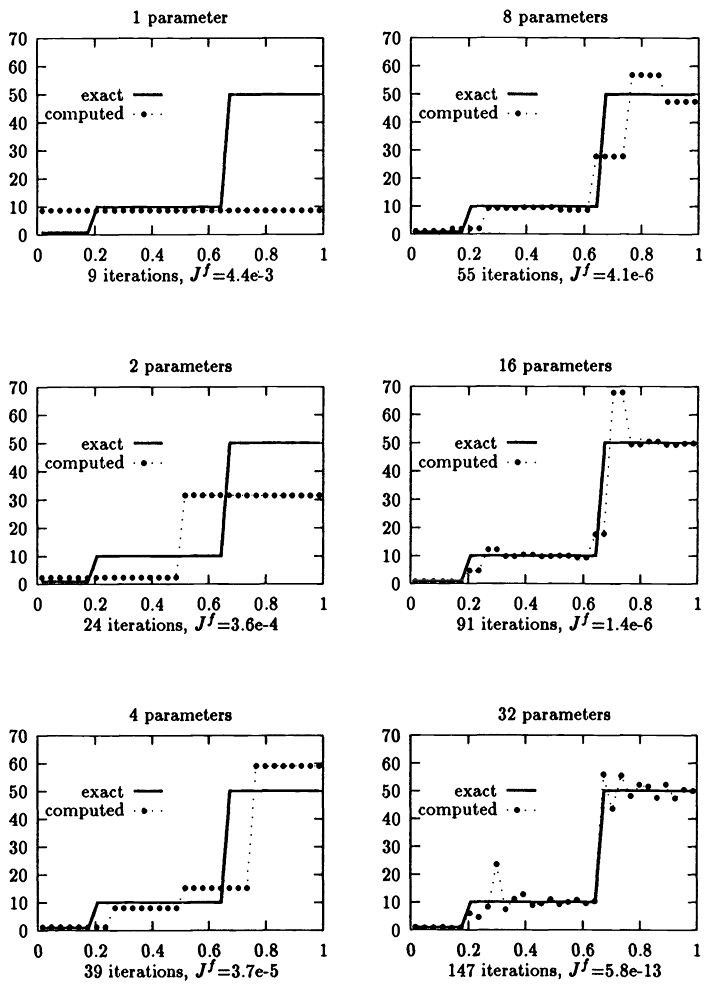

FIG. 12. *The parameter obtained at the end of each step (scale level) of the multiresolution method applied to the unregularized problem and data with* 1 *percent noise.*

Figures 12 and 13 show the parameters obtained at different scales for 1 percent noise and for 5 percent noise, respectively. As the noise increases, the oscillation increases also, hence we should stop the optimization procedure at an adequate scale to regularize the solution. For example, we can stop at the fourth scale (16 numbers) for 1 percent noise and at the third scale (eight numbers) for 5 percent. We remark that the solutions up to the third scale are the same with 5 percent noise or without noise (Figs. 9, 12, and 13).

5. Conclusion. We have numerically studied the use of a multiresolution approach for the inverse problem in a one-dimensional elliptic equation. It has been shown that the methodology of multiresolution is well suited to solving this ill-posed nonlinear problem. The advantages of this method are:

- The final solution is independent of the choice of the initial parameters;
- Some local minima can be avoided;

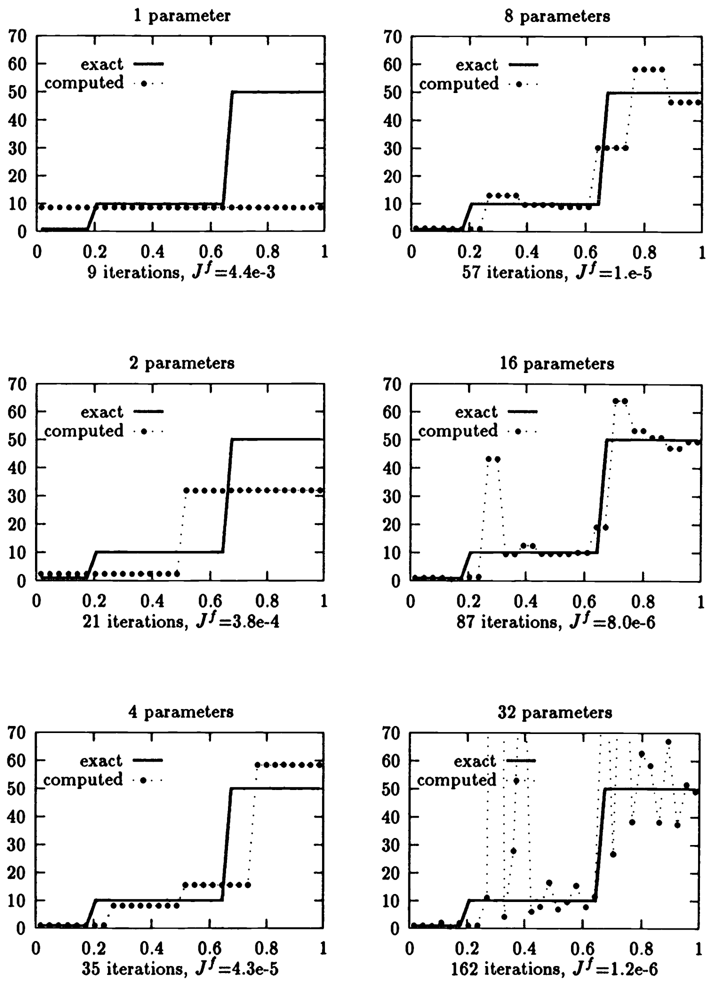

FIG. 13. *The parameter obtained at the end of each step (scale level) of the multiresolution method applied to the unregularized problem and data with* 5 *percent noise.*

- Very fast convergence is achieved for the numerical examples considered; and
- It leads naturally to the use of new types of regularizations which are likely to perturb the coarse-scale components of the optimal solution less.

The methodology proposed in this paper is very general. It has also been used for the identification of the conductivity coefficient in a parabolic equation [8], and for the identification of the relative permeabilities and capillary pressure [6]. However, many theoretical problems are still open. We believe that this method will also prove to be powerful for more complicated inverse problems.

Acknowledgments. I am greatly indebted to Professor Guy Chavent for many helpful conversations, and I would also like to thank the referee for many useful comments.

A PARALLEL IMPLEMENTATION OF AN ITERATIVE SUBSTRUCTURING ALGORITHM FOR PROBLEMS IN THREE DIMENSIONS*

BARRY F. SMITH[†]

Abstract. Numerical results from a parallel implementation of a class of iterative substructuring algorithms are reported. The algorithms are for solving self-adjoint elliptic partial differential equations in three dimensions. Results are given for several variants of the algorithm. In the first variant, exact interior solvers are used; in the second, one multigrid V-cycle is used to solve the interior problems approximately. The results are compared with theoretical behavior of the algorithm reported in previous work. A numerical experiment involving the equations of linear elasticity is also included.

1. Introduction.

Much of the work on domain decomposition algorithms has focused on the abstract analysis of the algorithms, with less discussion of implementation issues and few nontrivial numerical results. This paper focuses on the parallel implementation of several iterative substructuring algorithms for elliptic partial differential equations in three dimensions. Full analysis of some of the algorithms, using standard domain decomposition techniques, can be found in Smith [21] and Dryja, Smith, and Widlund [12]. The underlying algorithm was first introduced in Smith [22].

Iterative substructuring algorithms are domain decomposition algorithms in which nonoverlapping subdomains are used. A preconditioned conjugate gradient method is used to solve the linear system obtained by a finite element discretization of the partial differential equation. The preconditioner is obtained by separately solving linear systems associated with the interiors of the subdomains, the faces between subdomains, and a coarse grid system that provides global coupling between the subdomains.

There is a fundamental difference in the nature of finite element solutions of elliptic problems in two and three dimensions. The formulation of the coarse grid system that works well in two dimensions results in poor convergence in three dimensions; see Smith [21]. Hence, new analysis and numerical experiments must be carried out for problems in three dimensions. Earlier theoretical work on the subject that has strongly influenced our work can be found in Bramble, Pasciak, and Schatz [5], Dryja [11], Dryja and Widlund [13], Mandel [20], and Smith [21]. For a modern treatment of iterative substructuring algorithms in three dimensions, see Dryja, Smith, and Widlund [12]. Other large-scale experimental work in domain decomposition is described in Bjørstad and Hvidsten [1], Bjørstad, Moe, and Skogen [2], Keyes and Gropp [16], [17], De Roeck [9], De Roeck and Le Tallec [10], Le Tallec, De Roeck, and Vidrascu [18], and Mandel [19].

Any good iterative substructuring algorithm with exact interior solvers can be reformulated to use approximate interior solvers. This approach has been analyzed with some success in Börgers [4] and Haase, Langer, and Meyer [15]. In this paper we

[†]Argonne National Laboratory, 9700 South Cass Avenue, Argonne, Illinois 60439-4844 (bsmith@mcs.anl.gov).

report on experiments in which both approximate and exact interior solvers are used. We use multigrid for the approximate interior solver in our experiments.

This paper is organized as follows. In §2 we introduce the algorithm using matrix notation. In §3 we discuss the implementation of the algorithm on distributed-memory machines. In §4, we present numerical results for some piecewise constant coefficient problems. In §5, we present an example from linear elasticity. In §6, we discuss future work, which will focus on the application of the algorithms to more difficult multicomponent elliptic partial differential equations.

2. Matrix form of preconditioner. Consider a scalar, second-order, self-adjoint, H^1-coercive, bilinear form $a_\Omega(u,v)$ on $\Omega \subset R^3$, and impose a homogeneous Dirichlet boundary condition on $\Gamma_0 \subset \partial\Omega$ and a Neumann boundary condition on $\partial\Omega \setminus \Gamma_0$. We assume that the underlying elliptic operator has no zero-order terms. Let $H^1_{\Gamma_0}(\Omega)$ be the subspace of functions in $H^1(\Omega)$ that vanish on Γ_0. The variational problem is to find $u \in H^1_{\Gamma_0}(\Omega)$ such that

$$a_\Omega(u,v) = (f,v) \quad \forall v \in H^1_{\Gamma_0}(\Omega).$$

We triangulate the domain Ω using the usual rules for finite element triangulations. Let $V^h(\Omega) \subset H^1_{\Gamma_0}(\Omega)$ be the space of continuous, piecewise linear functions on the triangulation that vanish on Γ_0. In addition, for the construction of the preconditioner, we assume that the set of elements is partitioned into disjoint substructures Ω_i. Let H be the characteristic diameter of the substructures; that is, assume that there exist constants c and C independent of h and H such that for all substructures, $cH \leq \operatorname{diam}(\Omega_i) \leq CH$. In the experiments reported here, the substructures are always logically brick-shaped, but this is not necessary for the algorithm.

The discrete problem is to find $u^h \in V^h(\Omega)$ such that

$$a_\Omega(u^h,v^h) = (f,v^h) \quad \forall v^h \in V^h(\Omega). \tag{1}$$

If u^h is expanded in the standard nodal basis $u^h = \sum_k u_k\phi_k$, the variational problem (1) can be written as the linear system

$$K\underline{u} = \underline{f}.$$

In previous work [21], we constructed preconditioners for this system that involve separately solving linear systems associated with the interiors of the subdomains, the faces shared by pairs of subdomains, and a system associated with the remaining degrees of freedom. The application of our preconditioner results in a convergence rate that is independent of the number of subdomains and is independent of jumps in the coefficients of the partial differential equation between subdomains.

We partition the unknown coefficients into those associated with the interiors of the subdomains, $\underline{u}_I$, those associated with the faces shared by exactly two subdomains, $\underline{u}_F$, and those shared by more than two subdomains (the wirebasket), $\underline{u}_W$. We use $\underline{u}_B$ to denote the vector of coefficients $(\underline{u}_F, \underline{u}_W)$. In addition, we let $\underline{u}^{(i)}$ represent the coefficients associated with the closure of subdomain Ω_i. The stiffness matrix K can be written in block form as

$$\begin{pmatrix} K_{II} & K_{IF} & K_{IW} \\ K_{IF}^T & K_{FF} & K_{FW} \\ K_{IW}^T & K_{FW}^T & K_{WW} \end{pmatrix}.$$

The Schur complement after we eliminate the interior unknowns is given by

$$\begin{pmatrix} S_{FF} & S_{FW} \\ S_{FW}^T & S_{WW} \end{pmatrix} = \begin{pmatrix} K_{FF} & K_{FW} \\ K_{FW}^T & K_{WW} \end{pmatrix} - \begin{pmatrix} K_{IF}^T \\ K_{IW}^T \end{pmatrix} K_{II}^{-1} \begin{pmatrix} K_{IF} & K_{IW} \end{pmatrix}.$$

We express the inverse of the stiffness matrix in partially factored form as

$$\begin{pmatrix} I & -K_{II}^{-1}K_{IF} & -K_{II}^{-1}K_{IW} \\ 0 & I & 0 \\ 0 & 0 & I \end{pmatrix} \begin{pmatrix} I & 0 & 0 \\ 0 & I & -S_{FF}^{-1}S_{FW} \\ 0 & 0 & I \end{pmatrix} \begin{pmatrix} K_{II}^{-1} & 0 & 0 \\ 0 & S_{FF}^{-1} & 0 \\ 0 & 0 & \tilde{S}_{WW}^{-1} \end{pmatrix}$$

$$\begin{pmatrix} I & 0 & 0 \\ 0 & I & 0 \\ 0 & -S_{FW}^T S_{FF}^{-1} & I \end{pmatrix} \begin{pmatrix} I & 0 & 0 \\ -K_{IF}^T K_{II}^{-1} & I & 0 \\ -K_{IW}^T K_{II}^{-1} & 0 & I \end{pmatrix}.$$

The matrix S_{FF} represents that part of the Schur complement, after the interior nodes have been eliminated, that is associated with the coupling between the nodes on the faces of the subdomains. $\tilde{S}_{WW}$ is the Schur complement associated with the wirebasket once the unknowns of the interior and the faces have been eliminated. We do not explicitly form these matrices; instead, the preconditioner is constructed by replacing various blocks with more computationally attractive matrices. We note that K_{II}^{-1}, S_{FF}^{-1}, $S_{FF}^{-1}S_{FW}$, and $\tilde{S}_{WW}^{-1}$ may be replaced.

The K_{II} is a block diagonal matrix with a block for each subdomain interior. For K_{II}^{-1} we use either a sparse factorization (in particular, the Yale Sparse Matrix Package, which uses the minimum-degree algorithm to reorder to reduce fill-in) or at least one multigrid V-cycle to approximate the action of the inverse. In the latter case, the approximate inverse can be written as $\tilde{K}_{II}^{-1} = (I - M_\nu)K_{II}^{-1}$. M_ν is the symmetric error iteration matrix for ν multigrid V-cycles, and $\rho(M_\nu) < 1$. We note that there is considerable freedom in choosing the multigrid solver and the number of V-cycles. When exact interior solvers are used, we can eliminate the unknowns $\underline{u}_I$ initially and iterate on only $\underline{u}_B$, using one solver involving K_{II} per iteration. Once $\underline{u}_B$ is known, we can backsolve for $\underline{u}_I$. If an approximate solver is used for the interior, then two interior solvers are needed per iteration, and all of the variables are present in the iterative process.

We replace the Schur complement S_{FF} with a block diagonal matrix with one block for each face. Let $\tilde{S}_{FF}$ be the generic substitution. Several candidates exist for the matrix blocks. They are all derived by extending earlier results for problems in two dimensions. Unfortunately, no one substitution exists that is appropriate for all situations. Each has its own advantages and disadvantages in terms of computational expense and convergence properties. See §5 for an example where the need for a face preconditioner is avoided.

1. We can explicitly use the blocks from the Schur complement. The advantage of this approach is that the block is automatically well adapted for each differential equation. Unfortunately, it is very expensive to calculate the blocks, except for small subdomains. This method is probably practical only for extremely ill conditioned problems where no good substitutes exist.

2. We can use a suitable scaling of the J operator. The J operator is the square root of the two-dimensional discrete Laplacian on a regular, rectangular mesh. See Bramble, Pasciak, and Schatz [5] for a discussion of why this leads to good results. It has been shown that J is spectrally equivalent to the explicit block of the Schur complement. It is computationally cheap to apply the action of J^{-1} to a vector. It does not, however, adapt to the particular partial differential equation and for anisotropic problems can have very poor convergence properties.

3. For constant-coefficient elliptic partial differential equations on rectangular subdomains with a uniform finite difference mesh, we can exactly diagonalize the Schur complement associated with a face, using fast sine transforms. For two dimensions, Chan and Hou [6] have proposed the use of this fast spectral decomposition to approximate the actual Schur complement. This approach could be extended to three dimensions. Again, as with the J operator, this requires that we use a regular, rectangular mesh on brick-shaped subdomains.

4. We could use a multilevel preconditioner. This is an extension to three dimensions of the hierarchical Schur complement preconditioner considered in Smith and Widlund [23]; see also Haase, Langer, and Meyer [15]. This is not a spectrally equivalent preconditioner, but is nearly so. Like the J operator, it does not adapt to the particular partial differential equation.

5. Another approach is to use the tangential component of the original operator restricted to that face. It can be obtained easily and adapts reasonably well to the partial differential equation. This approach is taken in Chan and Keyes [7] and Keyes and Gropp [17]. It does not perform well, however, when the components of the operator that are normal to the face dominate.

6. The method of probing (see Chan and Keyes [7] and Chan and Mathew [8]) could be used to calculate diagonal or band diagonal approximations to the Schur complement on each face. This approach also does not result in a spectrally equivalent preconditioner; at best, the condition number grows like $(H/h)^{1/2}$.

We observe that the operator $S_{FF}^{-1}S_{FW}$ maps values from the boundaries of the faces to the faces. It is known that the most important property of the mapping is that it maps a constant value on the boundary of the face onto the face as the same constant. We use a simple mapping that preserves this property. We map the average of the unknowns on the boundary of the face onto the face; see Smith [21] for the underlying theory. Let T^T denote this mapping. More sophisticated interpolation schemes are also possible and may be needed for more difficult problems.

For $\tilde{S}_{WW}^{-1}$, inspired by Mandel [20], we use the matrix defined by the following minimization problem:

$$(2)\qquad \min_{\underline{u}} \sum \min_{\bar{w}^{(i)}} \delta_i(H/h)(\underline{u}_W^{(i)} - \bar{w}^{(i)}z^{(i)})^T I(\underline{u}_W^{(i)} - \bar{w}^{(i)}z^{(i)}) - \underline{u}_W^T f_W.$$

The $z^{(i)}$ is a vector of all ones of the same dimension as $\underline{u}_W^{(i)}$, and δ_i is a function of H/h given below. We let G_{WW} denote the matrix defined by the minimization given above. For nontrivial problems, a diagonal (or block diagonal) matrix that is adapted to the particular partial differential equation may be substituted in place of the identity matrix in the above formula. A simpler choice for this part of the preconditioner would be the block diagonal part of the original stiffness matrix associated with the wirebasket. This choice, however, results in a preconditioned system whose condition number grows faster than C/H^2, while the former choice results in a condition number bounded by $C(1 + \log(H/h))^2$; see Smith [21].

We write the generic form of the inverse of the preconditioner as

$$\begin{pmatrix} I & -\tilde{K}_{II}^{-1}K_{IF} & -\tilde{K}_{II}^{-1}K_{IW} \\ 0 & I & 0 \\ 0 & 0 & I \end{pmatrix} \begin{pmatrix} I & 0 & 0 \\ 0 & I & -T^T \\ 0 & 0 & I \end{pmatrix} \begin{pmatrix} \tilde{K}_{II}^{-1} & 0 & 0 \\ 0 & \tilde{S}_{FF}^{-1} & 0 \\ 0 & 0 & \tilde{S}_{WW}^{-1} \end{pmatrix}$$
$$\begin{pmatrix} I & 0 & 0 \\ 0 & I & 0 \\ 0 & -T & I \end{pmatrix} \begin{pmatrix} I & 0 & 0 \\ -K_{IF}^T\tilde{K}_{II}^{-1} & I & 0 \\ -K_{IW}^T\tilde{K}_{II}^{-1} & 0 & I \end{pmatrix}.$$

We consider five specific preconditioners in the first set of numerical studies. The first involves diagonal preconditioning of the original stiffness matrix. We denote the preconditioner by D. The second and third preconditioners both use exact interior solvers. The first version involves solving the wirebasket problem with the technique introduced above and in Smith [21]. We can express this preconditioner as

$$B_G^{-1} = \begin{pmatrix} T^T \\ I \end{pmatrix} G_{WW}^{-1} \begin{pmatrix} T & I \end{pmatrix} + \begin{pmatrix} I \\ 0 \end{pmatrix} \tilde{S}_{FF}^{-1} \begin{pmatrix} I & 0 \end{pmatrix}.$$

In the second version, we solve the wirebasket problem using a diagonal matrix

$$B_D^{-1} = \begin{pmatrix} 0 \\ I \end{pmatrix} D_{WW}^{-1} \begin{pmatrix} 0 & I \end{pmatrix} + \begin{pmatrix} I \\ 0 \end{pmatrix} \tilde{S}_{FF}^{-1} \begin{pmatrix} I & 0 \end{pmatrix}.$$

The last two preconditioners use approximate solvers on the interior subproblems.

$$B_{GA}^{-1} = \begin{pmatrix} I & -\tilde{K}_{II}^{-1}K_{IB} \\ 0 & I \end{pmatrix} \begin{pmatrix} \tilde{K}_{II}^{-1} & 0 \\ 0 & B_G^{-1} \end{pmatrix} \begin{pmatrix} I & 0 \\ -K_{IB}^T\tilde{K}_{II}^{-1} & I \end{pmatrix},$$

$$B_{DA}^{-1} = \begin{pmatrix} I & -\tilde{K}_{II}^{-1}K_{IB} \\ 0 & I \end{pmatrix} \begin{pmatrix} \tilde{K}_{II}^{-1} & 0 \\ 0 & B_D^{-1} \end{pmatrix} \begin{pmatrix} I & 0 \\ -K_{IB}^T\tilde{K}_{II}^{-1} & I \end{pmatrix}.$$

For the piecewise constant coefficient problems considered in this paper, we use a multiple of the J operator as our face preconditioner. For our model problems, this approach works almost as well as the computationally more expensive explicit Schur complement.

3. Implementation issues. We have implemented the algorithm on a distributed-memory machine in which each processor has its own local memory and can communicate, either directly or indirectly, with all other processors by using explicit message passing. The specific architecture is the Intel iPSC/860. These machines have from 8 to 128 Intel i860 processors, each of which is capable of sustained rates of more than 4 megaflops with compiled Fortran or C. The peak performance for hand-coded assembler is somewhat higher. Each processor has between 8 and 16 megabytes of local memory. The Intel iPSC/860 machine has a hypercube connection between the nodes. For messages greater than 100 bytes in length, the startup time for nearest neighbor nodes is roughly 150 microseconds, while the peak transfer rate is 2.5 megabytes per second. These results were obtained experimentally by Bokhari [3].

Communication time on these machines is slow compared to the floating-point speed. Hence, data locality and the minimization of communication are vital.

The particular implementation of our algorithm is closely related to the work of Keyes and Gropp [16] for problems in two dimensions. Keyes and Gropp subdivide the domain into rectangular tiles. Each tile is then discretized by using a regular mesh. This is a very natural approach combining flexibility of the domain with regular subdomains and the possibility of local uniform mesh refinement.

The three-dimensional domain is partitioned into brick-shaped subdomains, each of which is assigned a uniform finite element or finite difference mesh. To simplify the coding, we require that adjacent subdomains share an entire face, entire edge, or vertex; see Fig. 1. This requirement is necessary for our implementation, but not for the underlying mathematical algorithms.

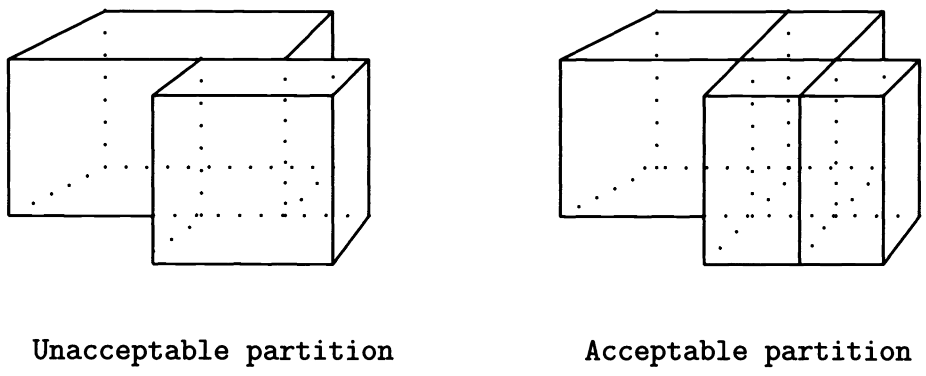

FIG. 1. *Unacceptable and acceptable partitions of a domain.*

Each processor is assigned one or more subdomains. The information pertaining to the interior of the subdomain is uniquely owned by that processor and is not directly available to any other processor. Each face, edge, or vertex is jointly owned by several subdomains and hence potentially by several processors. Because of this joint ownership, whenever a change is made to the part of the solution associated with a face, edge, or vertex of one subdomain, this information must be conveyed to the other joint owners by using explicit message passing. We refer to this process as *merging of partial data.* For each face, edge, and vertex, we designate one of the joint owners as the main owner and the others as auxiliary owners.

Essentially three types of communication between processors are required when the preconditioned conjugate gradient method is used to solve the linear system. The first is multiplication by the stiffness matrix. After the calculation of the local contribution to the matrix multiplication, the parts of the product vector that are shared by two or more processors must be merged. This merging of partial results can be performed in several ways. At this time a naive approach is used. The partial sums on each face, edge, and vertex are accumulated by the main owner and then sent out to the joint owners. For large problems, when using the full preconditioner, we find that less than five percent of the time is spent doing communication related to the matrix multiplication. With diagonal preconditioning, the matrix multiply dominates the entire solution time. Hence, optimizing the communication in the matrix multiply becomes important.

The application of the preconditioner is the most expensive operation in terms of communication. The principal reason is that the preconditioner is designed to provide for global communication of information in each step of the iteration process. When less communication is provided, more iterations are needed, although at a lower cost per iteration. With simple diagonal preconditioning, for instance, no cross-processor communication is needed. This fact suggests that for many well-conditioned problems diagonal scaling is the optimal approach for parallel computing systems of the type considered in this paper.

We list below the steps currently used in the application of the preconditioner B_G^{-1}. The steps in braces are the additional steps needed when approximate interior solvers are used.

1. {Approximate solvers on interior problems.}
2. {Merge results.}
3. Interpolate face averages onto the edges.
4. Merge results.
5. Calculate an average on the wirebasket for each subdomain, and send this to the coarse solver.
6. Solve the face problems and coarse problem simultaneously.
7. Interpolate the coarse solution to the wirebasket.
8. Merge results.
9. {Approximate solvers on interior problems.}

The conjugate gradient method requires several inner products per iteration. When possible, we use a direct call to a low-level implementation of a cross-processor inner product.

4. Experimental results for piecewise constant coefficient problems. In this section we report on experiments with scalar elliptic problems with piecewise constant coefficients. The reason for examining such problems is threefold: we can compare the well-developed theory with the numerical results, we can obtain a lower bound on how well the algorithm will perform for more difficult problems, and we can resolve questions about the optimal scaling of different parts of the preconditioner.

The total solution time depends on the number of iterations needed and the average amount of time needed per iteration. Information useful for comparing different algorithms is provided by the number of iterations needed to obtain a fixed accuracy of the solution. The square root of the condition number of the preconditioned system gives a bound on the number of iterations needed.

4.1. On the local bounds. In this algorithm, as with most iterative substructuring algorithms (see Dryja, Smith, and Widlund [12]), it is possible to bound the condition number of the preconditioned matrix by bounds obtained locally, that is,

$$\kappa(B_G^{-1}S) \le \frac{\max C_i}{\min c_i},$$

where the c_i and C_i satisfy

$$c_i \underline{u}^{(i)^T} B_G^{(i)} \underline{u}^{(i)} \le \underline{u}^{(i)^T} S^{(i)} \underline{u}^{(i)} \le C_i \underline{u}^{(i)^T} B_G^{(i)} \underline{u}^{(i)} \quad \forall \underline{u}^{(i)}.$$

We wish to determine how close the local bounds are to the actual condition numbers as a function of the number of subdomains. We have performed two sets of experiments, one using the exact blocks of the Schur complement, and the other using the

J operator as the face preconditioner. In both this and the following section, the domains are unit cubes. In all of the experiments we use the Lanczos algorithm to calculate the extreme eigenvalues from which we calculate the condition numbers. We make two observations from Table 1:

- The condition numbers when using either the explicit Schur complement or the J operator are virtually identical for the Laplace operator.
- The bounds obtained from the local analysis quite closely predict the condition numbers even for a relatively small number of subdomains.

The positions in the table denoted by a dash are cases for which experiments were not carried out because of time or memory constraints.

TABLE 1
Condition numbers and local bounds.

	Explicit Schur complement					J operator				
	Local	Number of subdomains				Local	Number of subdomains			
H/h	bound	27	64	125	216	bound	27	64	125	216
4	9.66	8.33	8.77	8.82	9.22	10.25	8.72	9.41	9.35	9.92
5	11.18	9.57	10.28	10.20	10.68	12.10	9.86	10.78	10.61	11.30
6	12.40	10.87	11.52	11.43	–	13.64	11.05	12.07	11.85	12.89
7	14.04	11.83	12.63	–	–	15.07	11.96	13.56	13.30	14.51
8	15.86	12.83	14.05	–	–	16.31	12.87	15.00	14.70	16.06
9	17.59	13.62	–	–	–	17.54	13.63	16.37	–	–
10	19.23	–	–	–	–	19.26	14.38	17.67	17.61	18.91
16	–	–	–	–	–	–	21.12	24.20	24.16	25.98
20	–	–	–	–	–	–	24.15	27.88	27.78	29.83

4.2. On the scaling of the coarse problem. We can express the preconditioned problem when using exact interior solvers as

$$B_G^{-1} = \begin{pmatrix} T^T \\ I \end{pmatrix} G_{WW}^{-1} \begin{pmatrix} T & I \end{pmatrix} + \begin{pmatrix} I \\ 0 \end{pmatrix} \tilde{S}_{FF}^{-1} \begin{pmatrix} I & 0 \end{pmatrix}.$$

The mathematical analysis of the algorithm (see Smith [21] and Dryja, Smith, and Widlund [12]) tells us that asymptotically, for large H/h, we should scale G_{WW} by a factor $\delta_i(H/h) = C(1+\log(H/h))$. The analysis gives no information, however, about the selection of the constant C nor whether the scaling is important for relatively small values of H/h. We shall refer to the case with $\delta_i(H/h) = 1$ as the natural scaling. In our experiments, we determine for each mesh size the optimal scaling $\delta_i(H/h)$ using a simple bisection method and compare the condition number with that obtained using the natural scaling. The results are presented in Table 2.

A related question is whether, in the construction of G_{WW} (see (2)), we should scale the diagonal elements for the nodes associated with the vertices of the subdomains differently from those nodes associated with the edges. The most natural choice is to scale the former elements by $\frac{1}{2}$, since those nodes are contained in exactly twice as many subdomains. We refer to the resulting choice as a weighted G_{WW}. We make the following conclusions from Table 2:

- For the range of computationally practical meshes on the subdomains (i.e., $H/h \leq 32$), the natural scaling is only trivially worse than the optimal scaling.
- Using the weighted G_{WW} results in only a trivial improvement in the condition number.

TABLE 2
Natural versus optimal scaling of coarse problem: condition numbers.

$G^{(i)}$	Scaling	H/h							
		4	8	12	16	20	24	28	32
Natural	Natural	9.4	15.0	20.1	24.2	27.9	31.1	33.9	36.5
	Optimal	8.8	14.0	19.3	23.8	27.6	30.9	33.9	36.5
Weighted	Natural	–	14.2	19.3	23.6	27.2	–	–	–
	Optimal	–	13.6	18.8	23.3	27.1	–	–	–

4.3. The growth of the condition numbers. Mathematical analysis predicts the growth in the condition number as a function of the mesh refinement H/h, and the number of subdomains, but it does not give good estimates of the actual numerical values. Our results are given in Tables 3 and 4. For the preconditioner labeled B_{G^A} we have used one multigrid V-cycle to solve the subdomain problems approximately. The difference in the condition number between using one multigrid V-cycle, two multigrid V-cycles, and an exact interior solver is very small. Similar results have previously been noted by Börgers [4] and Haase, Langer, and Meyer [15] for problems in two dimensions but they have not yet been fully explained theoretically.

4.4. A comparison with a Bramble, Pasciak, and Schatz algorithm. Since our basic algorithm is similar to one of the important algorithms introduced by Bramble, Pasciak, and Schatz [5], we have reproduced the experiments reported in their paper using the preconditioner B_G^{-1}. The first set of experiments is for a unit cube divided into eight subcubes. The stiffness matrix is derived from the usual finite difference discretization for the Laplace operator. The second problem is for a unit cube divided into 27 subcubes with a different constant coefficient on each subcube; see [5] for the values used. We see from Tables 5 and 6 that for this class of problem, the two preconditioners produce similar condition numbers. We note that these are relatively small problems and that diagonal scaling also works well.

4.5. Timings. We next present timing results on a 32-node Intel iPSC/860 hypercube for a set of intentionally simple examples. We consider three problems. The first two problems are on the unit cube; the third is on a more complicated region depicted in Fig. 2. The unit cube is uniformly divided into subcubes Ω_{ijk}. In the third problem we use 244 subdomains which are not cubes; their aspect ratios are 4:5:20.

PROBLEM 1. Find u^h such that

$$\sum_{ijk} \int_{\Omega_{ijk}} \epsilon_{ijk}(\nabla u^h, \nabla v^h) = \int_\Omega f v^h \quad \forall v^h \in V^h.$$

The boundary conditions are given by $u^h = 0$ on $\partial\Omega$. The coefficients ϵ_{ijk} are constant on each subdomain and have large jumps between neighboring subdomains. Specifically, $\epsilon_{ijk} = \sin^2(16z)(e^{18x\sin(4y)} + e^{15(1-x)}) + 1$, where (x, y, z) is the center of Ω_{ijk}. The right-hand side is given by $f(x, y, z) = ze^x \sin(y)$.

PROBLEM 2. Find u^h such that

$$\int_\Omega (\nabla u^h, \nabla v^h) = \int_\Omega f v^h \quad \forall v^h \in V^h.$$

The solution u^h is constrained to be zero on one face of the cube and is free on the rest of the boundary. The right-hand side is the same as in Problem 1.

PROBLEM 3. This problem is the same as in Problem 2 except that the domain is as depicted in Fig. 2. The solution u^h is fixed on the bottom of the object and free on the rest of the object's boundary.

All the results are for one multigrid V-cycle sweep as an approximate solver for the interior problems, that is, two sweeps per subdomain per iteration. This choice was made because additional multigrid sweeps did not result in a decrease in the

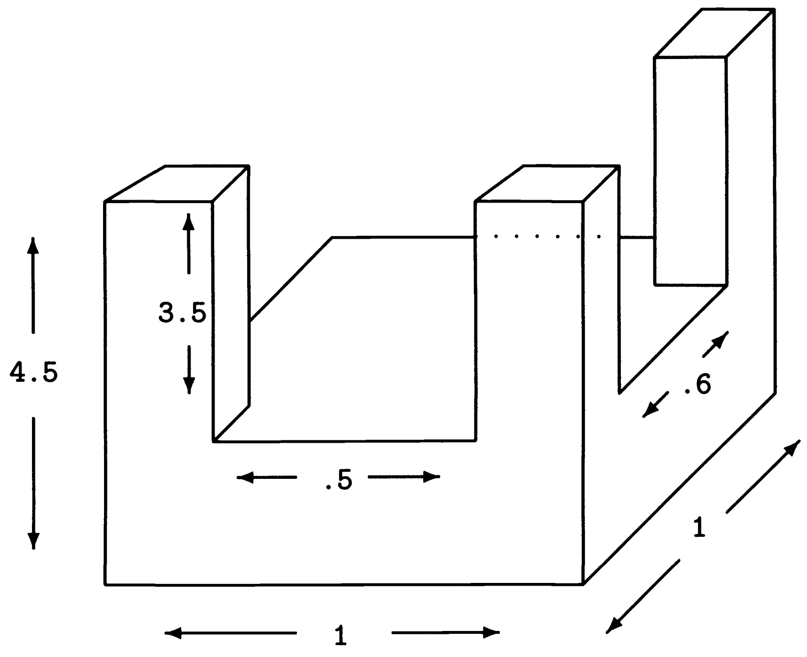

FIG. 2. *Domain for Problem* 3.

number of outer iterations. The times needed when exact interior solvers are used (i.e., with $B_G^{-1}S$) are much higher than those for the approximate solver. In addition, we cannot run the large problems when using exact interior solvers, as the sparse factors take a large percentage of the available space. For instance, for Problem 2 with 64 subdomains, the largest problem we could solve using the sparse interior solver was with a mesh of $H/h = 16$, while with multigrid we could solve problems with meshes up to $H/h = 32$. This fact suggests that for well-behaved problems like the Poisson problem, exact interior solvers, such as banded or sparse linear system solvers, are too expensive to be competitive. For more difficult problems, we do not yet know which approach is superior. We used the ordering routines in the Yale Sparse Matrix Package to order the unknowns for the sparse interior solvers. The nested dissection ordering might be a better choice.

The results for Problems 1 and 2 are given in Tables 7 and 8, respectively. We note that for Problem 2 both diagonal scaling and iterative substructuring without a coarse problem perform poorer than for Problem 1, while iterative substructuring performs essentially the same. This is due to the Neumann boundary conditions in Problem 2. The bounds on the convergence of iterative substructuring algorithms are independent of the ratio of Neumann boundary conditions to Dirichlet; see the comment in Smith [21]. On the other hand, the condition number of the original stiffness matrix deteriorates as one increases the percentage of the boundary with Neumann conditions.

For Problem 3 (see Table 9), the iteration counts are slightly higher than for Problem 2. It is well known that increasing aspect ratios cause a decay in the convergence rate of domain decomposition algorithms. In Problem 3 the algorithm with a diagonal scaling as the wirebasket problem performs poorly; see the column labeled

$B_{DA}^{-1}K$ in Table 9. This poor performance results because the condition number of the preconditioned problem grows like $1/H^2$, so the preconditioner becomes less effective when a large number of subdomains is used.

4.6. Speed of computational kernels. Most large numerical codes have a few routines that perform the bulk of the numerical calculations and use most of the CPU time. We refer to these routines as the computational kernels. The best known computational kernels are the BLAS and FFT. The computational kernels involve no communication with other processes and should ideally vectorize and pipeline well. It is also important that they use the data and instruction caches well. Since the computational kernels dominate the time of the entire calculation, their optimization is important. On certain processors, the Intel i860, for example, the replacement of Fortran or C computational kernels with assembler language kernels can result in large decreases in the time of the calculation at the expense of a great deal of careful hand-coding of assembler code. We note that improvement in the speeds of computational kernels is a *local* optimization and does not involve communication or parallelization.

The present code is all written with standard Fortran and C computational kernels. We have observed the following floating-point speeds (see Fig. 3):

- Dot product: 4.9 million floating-point operations per second (MFLOPS).
- Matrix multiply: 7.8 MFLOPS.
- DAXPY: 4.8 MFLOPS.
- Multigrid solver: 3.4 MFLOPS.
- Diagonal preconditioner: 2.7 MFLOPS.

- Sparse factorization: 3.8 MFLOPS.
- Sparse triangular solvers: 4.9 MFLOPS.

These results were obtained from the largest set of problems listed in Table 8. They do not fit completely in cache.

In the problem with 2,130,048 unknowns listed in Table 8, the per-processor flop rate for the entire calculation (from distributing the geometric information to the nodes, to solving the system) was 4.0 MFLOPS for the diagonal preconditioner and 3.1

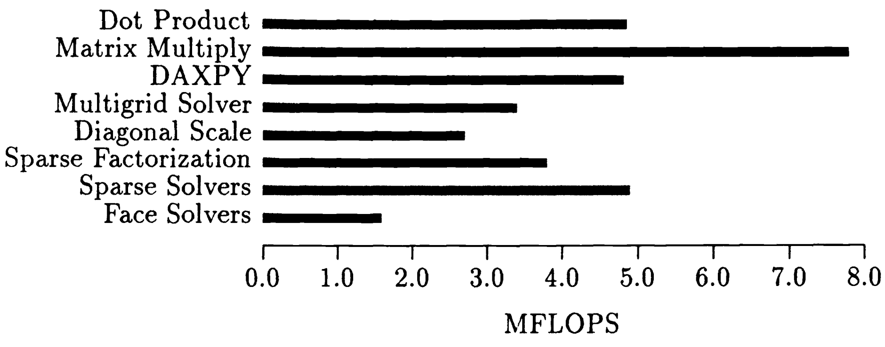

FIG. 3. *Flop rate in the computational kernels.*

MFLOPS for the more sophisticated preconditioner. Yet the diagonal preconditioner took more than twice as much time. The lower overall flop rate for the sophisticated preconditioner can be explained by the much lower flop rate of the multigrid solver.

The per-processor flop rate was obtained by taking the total number of floating-point operations performed on the processor and dividing by the total time the processor was in operation, including the time it was communicating with the other processors. While this number is a useful indicator of how well the processor is being utilized, it should not be overemphasized. The goal is to *minimize total computation time.* The best algorithm is the one that does exactly that, even if its per-processor flop rate is lower than that for other algorithms.

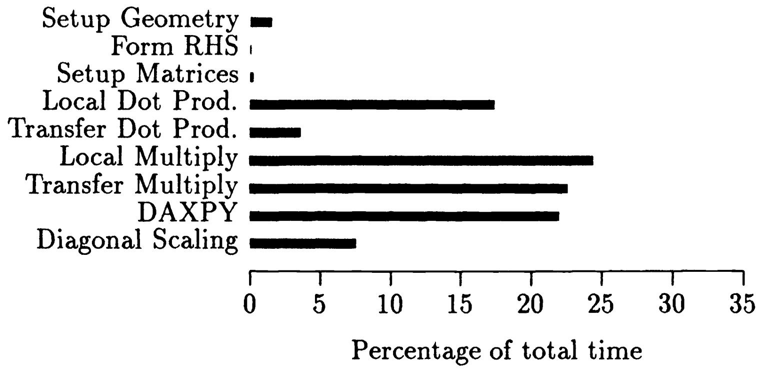

FIG. 4. *Percentage of time in different states, diagonal preconditioner.*

In Figs. 4 and 5, we graph the percentage of total wall-clock time spent in each portion of the code for the diagonally preconditioned and fully preconditioned problems. This gives a clear indication of what part of the code can most fruitfully be optimized. We also graph, in Fig. 6, the percentage of wall-clock time spent in various parts of the code for Problem 2 when the sparse interior solver is used. This is for 64 subdomains with a mesh of $H/h = 16$, the largest problem we could fit onto 32 processor nodes while using the sparse direct solver to solve the interior problems. The overall flop rate obtained here was 3.8 MFLOPS.

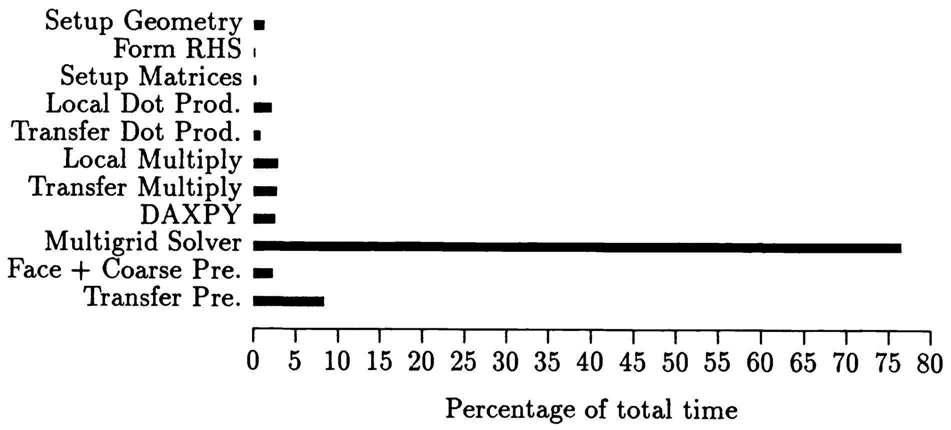

FIG. 5. *Percentage of time in different states, full preconditioner.*

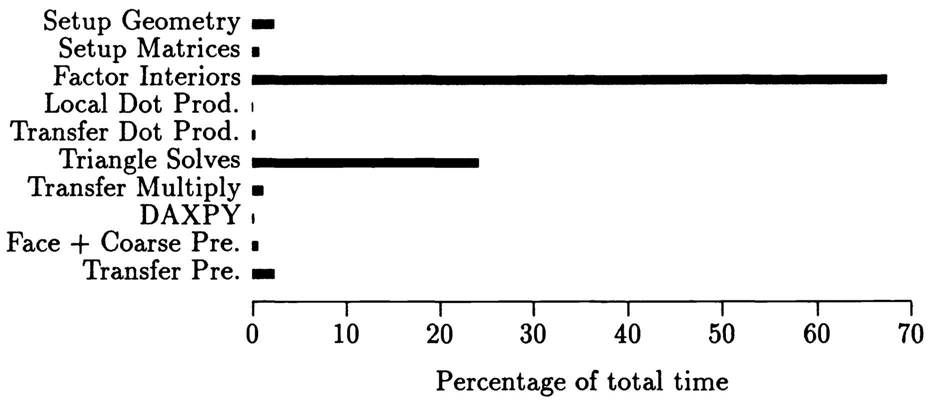

FIG. 6. *Percentage of time in different states, sparse solver.*

For the largest problem for which the sparse solver was used, 4.7 percent of the total computation time was spent on interprocessor communication. When multigrid was used to solve the interior problems approximately, the communication time increased to 11.7 percent of the total time. With diagonal preconditioning, 26.2 percent of the time was devoted to interprocessor communication.

5. Domain decomposition for elasticity. In this section we present numerical results for a minimal overlapping domain decomposition preconditioner applied to the equations of linear elasticity. The equations of linear elasticity are a self-adjoint coupled elliptic system that can be written as

$$\frac{E}{1+\nu}\left(\Delta \mathbf{u} + \frac{1-\nu}{1-2\nu}\nabla\nabla\cdot\mathbf{u}\right) = \mathbf{f}.$$

E is the Young's modulus, and ν is the Poisson ratio; both constants depend on the physical properties of the material being modeled. For our experiments we used

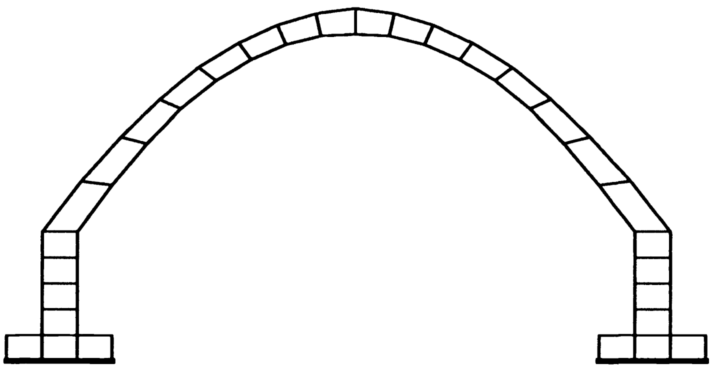

FIG. 7. *Arch domain.*

$E = 1$ and $\nu = 0.3$. The stopping criteria was a relative decrease in the l^2 norm of the residual of 10^{-5}.

We consider the domain as indicated in Fig. 7 and discretize the problem using 20-node, incomplete quadratic serendipity elements (cf. Zienkiewicz and Taylor [24]). We divide the domain into six subdomains. Since for the equations of linear elasticity we do not have a simple face preconditioner like the J operator, we use an overlap between domains of one mesh width; see Dryja and Widlund [14].

The stiffness matrix for the problem is extremely ill conditioned; for instance, even for a discretization with fewer than 1000 unknowns, the conjugate gradient method with diagonal scaling fails to converge even after 5000 iterations. The calculations given in Table 10 were carried out on a Sun Sparcstation 2. For this experiment we used exact interior solvers with a nested dissection ordering.

6. Conclusions and future directions. We believe that our results indicate that variants of the iterative substructuring approach are viable techniques for the solution of elliptic partial differential equations in three dimensions on modern distributed-memory machines. For model problems, the iterative substructuring algorithm performs better than diagonal scaling, but not by an enormous factor, indeed, not by enough to justify the extra burden imposed by coding the algorithms. However, we believe that for nontrivial problems, the difference between the two approaches in terms of computational time will increase. An example of this is given in §5, where diagonal scaling does not even converge, but the preconditioned problem requires fewer than 20 iterations.

We also note that for solving extremely large model problems, it is important to use approximate solvers for the interior problems. The fill from a band or sparse solver begins to dominate the memory usage, making it impossible to solve extremely large problems. For difficult problems, we may not be able to find an iterative solver for the interior problems that performs well enough to replace the direct solver, and this fact might limit the size of the problems that we can solve.

The iterative substructuring algorithm considered here works well on simple, piecewise, constant coefficient problems. To be useful in practice, it must be adaptable to a wide range of multicomponent elliptic partial differential equations. We therefore plan to focus on adapting each piece of the algorithm to a wide range of differential equations. The parts of the algorithm that must be generalized are the face preconditioners, the wirebasket coarse problem, and the interpolation onto the faces from the wirebasket. In addition, we shall consider other approaches to building interior iterative solvers, such as incomplete factorizations. Finally, we shall consider nonsymmetric problems.

Acknowledgments. I thank William Gropp for his excellent advice on the development of this implementation of the algorithm. In addition, I thank Olof Widlund for his comments on an early draft of this paper.

MODIFIED CHOLESKY FACTORIZATIONS FOR SPARSE PRECONDITIONERS*

TAMAR SCHLICK†

Abstract. In large-scale unconstrained optimization problems, preconditioned conjugate gradient techniques are often used to solve the Newton equations approximately. In certain applications, "natural" sparse preconditioners can be derived from the structure of the problem and can accelerate convergence significantly. Since these preconditioners are not necessarily positive definite, modified Cholesky (MC) factorizations can be applied to construct related positive definite preconditioners. This paper describes such an adaptation of two MC techniques–GMW (Gill–Murray–Wright) and SE (Schnabel–Eskow)–in a truncated Newton minimization method. This paper then analyzes their effects on three interesting test problems of moderate size. The preliminary results suggest that the two MC algorithms perform quite differently in practice. Trends can be noted for sparse problems that differ from the dense case. Differences in the size of the modifications and in their variances throughout the minimization are observed and related to problem structure and minimization progress. These differences suggest that, for the minimization method examined, SE may be advantageous for highly nonlinear functions, while GMW may be more effective for functions that are well approximated by locally convex quadratic models.

AMS(MOS) subject classifications. 49, 65, 92

1. Introduction.

In large-scale unconstrained optimization problems, preconditioned conjugate gradient (PCG) techniques are often used to solve the Newton equations approximately. This approximate solution of the Newton equations produces a search vector at every step. In this general framework, each iteration involves minimization of a quadratic model of the objective function $F(\mathbf{x})$, $\mathbf{x} \in \mathbf{R}^n$, around the current iterate $\mathbf{x}_k$. This approximation along a direction $\mathbf{p}$ is given by

$$F(\mathbf{x}_k + \mathbf{p}) \approx F(\mathbf{x}_k) + \mathbf{g}_k^T\mathbf{p} + \tfrac{1}{2}\mathbf{p}^T H_k \mathbf{p}, \tag{1}$$

where $\mathbf{g}_k$ and H_k are the gradient vector and Hessian matrix, respectively, of F at $\mathbf{x}_k$. Minimization leads to the Newton system of equations:

$$H_k\mathbf{p} = -\mathbf{g}_k. \tag{2}$$

The next iterate is defined by $\mathbf{x}_{k+1} = \mathbf{x}_k + \lambda_k \mathbf{p}_k$, where $\mathbf{p}_k$ solves (2) approximately, and $\lambda_k > 0$ is determined in a line search algorithm to guarantee sufficient function decrease [3], [10].

Truncated Newton methods form a subclass of Newton methods that control the size of the residual of (2) systematically [2], [4], [15]–[18], [21], [22], [24], [26]. For large-scale problems, PCG methods are natural for solving (2). Indeed, with a good combination of preconditioner and truncation strategy, truncated Newton methods can exhibit rapid convergence in relation to "nontruncated" analogues and other unconstrained minimization algorithms [15], [21], [22], [24], [26].

"Natural" preconditioners arise in many optimization applications from the separability of the objective function. For example, in computational chemistry problems, a sparse preconditioner is suggested by the existence of short-range and long-range chemical interactions: The "local" energy components, in contrast to the "nonlocal" terms, are rapid to evaluate, tend to cluster near the diagonal, and are typically large in magnitude [23], [24]. In mathematical biology problems involving interaction of elastic structures and fluid dynamics (e.g., models of blood clotting), the local connectivity structure describing the forces also leads to natural sparse preconditioners [22]. In computational geometry applications involving crystal solidification (as in formation of ice in water), the energy describing the evolution of the liquid/solid phase boundary contains a surface term for the interface and a volume integral; the boundary term leads to a natural preconditioner since it is both sparse and stiff in comparison to the volume term [1].

When the preconditioner M is not sufficiently positive definite, modified Cholesky (MC) factorizations can be adapted for the minimization method to construct a related positive definite sparse preconditioner $\overline{M}$. While the idea of *indefinite* preconditioners may be unconventional for certain applications, we have found this strategy to work well in practice in applications as mentioned above. In the typical case, the "natural" preconditioner may be indefinite only in some early Newton iterations; it becomes positive definite at later iterations [22].

The choice of MC strategy may play a critical role in governing performance in this context. The Gill–Murray–Wright (GMW) [10] and Schnabel–Eskow (SE) [8], [25] MC schemes offer two approaches. Both methods augment the original matrix by a nonnegative diagonal matrix. They differ both in the numerical choices for the modifications and in the process by which diagonal modifications are applied. Here we report computational results from truncated Newton minimization involving the two MC techniques for modifying sparse preconditioners.

In §2 we briefly review the GMW and SE MC algorithms. In §3 we describe the use of the MC factorizations in our truncated Newton minimization algorithm. Numerical results are presented and analyzed in §4. We use three problems of moderate size, two from computational chemistry and one a familiar optimization test problem. We discuss the results alongside eigenvalue analysis for the corresponding preconditioners and Hessians. Our observations regarding the performance of the algorithms using the GMW and SE schemes are summarized in §5. Results suggest various trends of MC effects for sparse problems that differ from the dense case. Different overall variances in the size of the modifications are observed and related to problem structure and minimization progress.

2. MC factorizations.

MC techniques are used to solve linear systems $M\mathbf{z} = \mathbf{r}$ for coefficient matrices M that are symmetric but not necessarily positive definite. They are not intended to solve systems in the usual sense, since the modified system $\overline{M}\bar{\mathbf{z}} = \mathbf{r}$, with $\overline{M} \neq M$, may produce a solution $\bar{\mathbf{z}}$ that bears no resemblance to $\mathbf{z}$. They are appropriate, however, when justification exists for modifying a linear system, as in Newton-type methods for nonlinear optimization.

MC algorithms begin with a symmetric $n \times n$ matrix M and produce a factorization

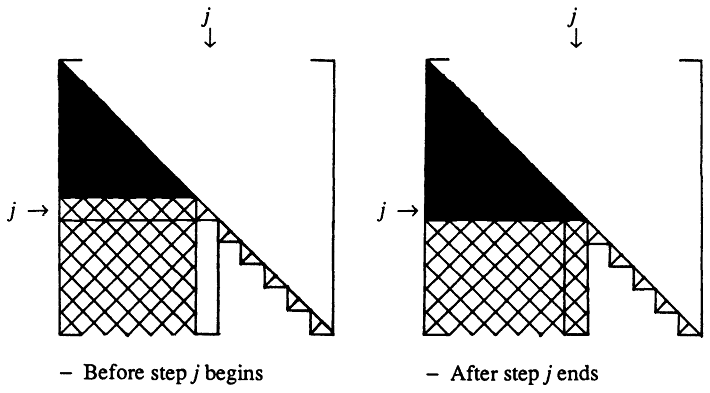
$$LDL^T = \overline{M} = M + E, \tag{3}$$

where L is unit lower-triangular, D is a positive diagonal matrix, $\overline{M}$ is positive definite, and E is a nonnegative diagonal matrix, at similar cost to a standard Cholesky factorization. The MC algorithm of GMW [10] has been used extensively in nonlinear optimization, exhibiting very good performance. The more recent MC scheme of SE [25] presents an alternative. Since it is impossible to define the "best" choice of $\overline{M}$ for an indefinite system, the two MC algorithms attempt to balance several practical and theoretical issues. Both attempt to combine the objectives of keeping $\|E\|$ small and producing a well-conditioned $\overline{M}$. That is, by balancing the amounts added to the diagonal at earlier and later iterations of the factorization, the modification strategy attempts to balance: (1) on one extreme, selecting large modifications that guarantee positive-definiteness but perturb the original matrix excessively; with (2) on the other extreme, choosing small, just sufficient additions that may lead to very large modifications later. In comparison to GMW, the SE procedure has: similar cost (involving an additional multiple of n^2 operations to the standard Cholesky factorization); a lower a priori upper bound on $\|E\|_\infty$; and, in many instances, a smaller value for $\|E\|_\infty$ [25].

The two procedures (without interchanges) are summarized below; see [10], [8], and [25] for details. The inclusion of interchanges does not alter the upper bounds on $\|E\|_\infty$, although it tends to produce better results in practice. Consider a single step of a row-wise MC factorization without interchanges. At the beginning of step j, $j = 1, \ldots, n$, final values are in place for the first $j-1$ elements of D and the first $j-1$ rows of L (see Fig. 1). The space originally occupied by M is overwritten while performing the factorization, and all subscripted quantities actually refer to locations in the M array. Here we treat portions of this array as two conceptual matrices: a diagonal matrix $\tilde{D}$ and an auxiliary matrix C. $\tilde{D}$ is initialized to the diagonal of M; element j of $\tilde{D}$ may be viewed as a trial value for d_j. The matrix C is stored in the first $j-1$ columns of rows j through n. The following calculations are performed during step j.

1. Compute row j of L:

$$\ell_{js} = c_{js}/d_s, \qquad s = 1, \ldots, j-1. \tag{4}$$



■ contains final L and D factors

⊠ contains the auxiliary quantities of LD

◺ contains updated diagonal elements

FIG. 1. *Step j of the MC factorization.*

2. Compute $\mathbf{c}_j = (c_{j+1,j}, c_{j+2,j}, \ldots, c_{n,j})^T$ (column j of C):

(5) $$c_{sj} = m_{sj} - \sum_{k=1}^{j-1} \ell_{jk} c_{sk}, \qquad s = j+1, \ldots, n.$$

Calculate the nonnegative quantity θ_j from $\mathbf{c}_j$:

(6) $$\theta_j = f(\mathbf{c}_j),$$

where the function f varies with the MC algorithm (see below).

3. Use θ_j, as specified by the MC algorithm, to compute $e_j \geq 0$. Set the final value of d_j to

(7) $$d_j = \tilde{d}_j + e_j.$$

We refer to e_j as the *modification*; when $e_j > 0$, we say that d_j has been *modified*.

4. Update $\tilde{D}$:

(8) $$\tilde{d}_s = \tilde{d}_s - c_{sj}^2 / d_j, \qquad s = j+1, \ldots, n.$$

The details of steps 2–4 above will now be discussed in turn for the two factorizations.

2.1. The GMW factorization. In GMW, the values for e_j are chosen so as to minimize an a priori upper bound on $\|E\|_\infty$ subject to the condition that positive definite matrices will not be perturbed (i.e., M positive definite $\Rightarrow E = 0$). Two numbers are required to perform the algorithm: ϵ_m (machine precision) and τ, the smallest acceptable value for any element of D, often $\sqrt{\epsilon_m}$ or $\sqrt[3]{\epsilon_m}$. Three other quantities are computed before the factorization begins:

(9) $$\gamma = \max_j \{ |m_{jj}| \},$$

(10) $$\xi = \max_{j>s} \{ |m_{js}| \},$$

and the bound

(11) $$\beta = \max \left\{ \gamma, \frac{\xi}{\max\{1, \sqrt{n-1}\}}, \epsilon_m \right\}.$$

In step 2, the GMW definition of θ is

(12) $$\theta_j = \|\mathbf{c}_j\|_\infty = \max\{|c_{sj}|\}, \quad s = j+1, \ldots, n.$$

In step 3, d_j is given by

(13) $$d_j = \max\{|\tilde{d}_j|, \tau, \theta^2/\beta\},$$

which defines e_j implicitly.

Note here the following properties: (1) The matrix M must be assembled a priori so that γ and ξ can be computed. (2) It follows from (13) that $\tilde{d}_j$ may be modified even when it is positive and greater than the lower bound τ; this situation arises when M is not "sufficiently" positive definite. When $\tilde{d}_j$ is negative but exceeds both τ and θ^2/β in magnitude, the final d_j is taken as $|\tilde{d}_j|$, which corresponds to a modification $e_j = 2|\tilde{d}_j|$. This result often occurs when M has at least one nonnegligible negative eigenvalue. (3) The restriction that $d_j \geq \theta^2/\beta$ implies that

(14) $$d_s \|\ell_{sj}^2\|_\infty \leq \beta;$$

hence the name "bound" for β.

2.2. The SE factorization. In SE, an attempt is made to compute the standard Cholesky factorization ("Phase 1") but include a special *phase test* that indicates when the smallest element of $\tilde{D}$ has become "too small." Once the phase test becomes true at any step, the SE modification rule is applied at all subsequent steps.

Two quantities must be specified: τ_1 and τ_2, typically of order $\sqrt[3]{\epsilon_m}$. The quantity γ (the largest magnitude of any diagonal of M) is defined by (9) as in GMW. At step j, let $d_{\min}$ denote $\min\{\tilde{d}_j, \ldots, \tilde{d}_n\}$. If

$$d_{\min} < \tau_1 \gamma, \tag{15}$$

the SE procedure enters Phase 2 and thereafter modifies diagonal elements according to the following rules. The value of θ_j (step 2) is the one-norm of $\mathbf{c}_j$:

$$\theta_j = \sum_{s=j+1}^{n} |c_{sj}| = \|\mathbf{c}_j\|, \tag{16}$$

so that θ_j is the current Gerschgorin radius for row j [11]. The modification for e_j, $1 \le j \le n-2$, is specified as

$$e_j = \max\{0, -\tilde{d}_j + \max\{\theta, \tau_2\gamma\}, e_{j-1}\}. \tag{17}$$

For steps $n-1$ and n, the SE procedure uses the explicit eigenvalues of the remaining 2×2 submatrix. At the end of step $n-2$, let $\lambda_{\ell o}$ and λ_{hi} denote these eigenvalues, with $\lambda_{\ell o} \le \lambda_{hi}$. Then e_{n-1} and e_n are both defined as

$$e_{n-1} = e_n = \max\left\{0, e_{n-2}, -\lambda_{\ell_0} + \tau_2 * \max\left\{\frac{1}{1-\tau_2}(\lambda_{hi} - \lambda_{\ell o}), \gamma\right\}\right\}. \tag{18}$$

The SE strategy produces a value for $\|E\|_\infty$ that is bounded above by the magnitude of the most negative lower Gerschgorin bound of the unfactorized matrix when Phase 2 begins. It also leads to a smaller a priori upper bound for $\|E\|_\infty$ than the GMW approach [25]. For GMW, the upper bound is roughly n^2 times the maximum element in M, whereas for SE it is roughly $2n$ times the maximum element in M.

3. MC factorizations in truncated Newton optimization.

MC factorizations are useful in nonlinear optimization for modifying the Hessian or some approximation to it involved in solving the Newton equation (2) for the search direction $\mathbf{p}$. Recall that truncated Newton methods solve the Newton equations only approximately, usually by some version of the conjugate gradient method. The rationale for the approximation is that global convergence can be achieved if the search direction is bounded away from orthogonality to the negative gradient; thus, it is never "necessary" to solve (2) accurately for global convergence. The size of the residual $\mathbf{r}_k = H_k\mathbf{p} + \mathbf{g}_k$ is controlled systematically at every step, and asymptotic quadratic convergence can be achieved if $\mathbf{r}_k$ is systematically made sufficiently small near the solution [2].

Truncated Newton methods are generally competitive with other large-scale optimization methods only when preconditioning is applied to the Newton equations [21], [26]. Fortunately, many applications in computational chemistry, geometry, and meteorology produce sparse preconditioners naturally from the "physics" of the problem. Often, such a "natural" preconditioner M can be derived from the separability of the objective function. It provides an approximation to H but may not be positive definite. An MC factorization can therefore be applied to produce a modified preconditioner, $\overline{M}$, that is positive definite.

We have adapted a truncated Newton algorithm targeted to sparse but not necessarily structured preconditioners [21], [22]. The linear system involving the preconditioner, $M\mathbf{z} = \mathbf{r}$, is solved by a *sparse* MC procedure based on the Yale Sparse Matrix Package [5]–[7]. Instead of a vector $\mathbf{z} = M^{-1}\mathbf{r}$ used in standard PCG algorithms, we obtain the MC solution $(\overline{M})^{-1}\mathbf{r}$. Our algorithm "TN," as used in the tests reported here, is described below. (Other variations have been considered; see [21] and [22] for details.) In this version, we assume that the sparsity structure of the preconditioner remains constant. This is a common situation in computational chemistry applications, since structure depends on the molecular connectivity, specified a priori.

3.1. Algorithm TN1: Outer loop of the truncated Newton method.

1. *Initialization*
   - Set $k = 0$ and evaluate $F(\mathbf{x}_k)$ and $\mathbf{g}_k$.
   - If $\|\mathbf{g}_k\| \le 10^{-8}\max\{1, \|\mathbf{x}_k\|\}$, where $\|\cdot\|$ is the standard Euclidean norm, exit algorithm. Otherwise, continue to step 2.
2. *Preparation for sparse* MC *factorization*
   - Determine the *pattern* of the preconditioner M. Since the upper triangle of M is stored in a compressed row format, the pattern is specified by two integer arrays that serve as row and column pointers [21].
   - Compute the permutation matrix P that minimizes *fill-in* (that is, produces a sparse Cholesky factor L for PMP^T, assuming that M is positive definite) by the minimum-degree reordering algorithm [5]–[7].
   - Compute the *symbolic factorization* of M. This involves determining the sparsity structure of the Cholesky factor L and preparing the corresponding data structure.
   - Evaluate the preconditioner and, optionally, the Hessian[1] (M_k and H_k, respectively).
3. (**Algorithm TN2**) *Inner loop*

   Compute a search vector $\mathbf{p}_k$ by solving $H_k\mathbf{p} = -\mathbf{g}_k$ approximately using a PCG method; see below.
4. *Line search*
   - Compute a step length λ by safeguarded cubic and quadratic interpolation [3], [14], so that $\mathbf{x}_{k+1} = \mathbf{x}_k + \lambda\mathbf{p}_k$ will satisfy

$$F(\mathbf{x}_{k+1}) \le F(\mathbf{x}_k) + \alpha\lambda\mathbf{g}_k^T\mathbf{p}_k, \tag{19}$$

$$|\mathbf{g}_{k+1}^T\mathbf{p}_k| \le \beta|\mathbf{g}_k^T\mathbf{p}_k|, \tag{20}$$

where $\alpha = 10^{-4}$ and $\beta = 0.9$.

[1] The Hessian is used only for the Hessian/vector products, $H\mathbf{d}$, in each PCG iteration of the inner loop (see Algorithm TN2). In some situations (e.g., H is sparse and structured), $H\mathbf{d}$ can be computed without explicit assembly of H. In many large-scale applications, H is dense and prohibitively expensive to calculate, but $H\mathbf{d}$ can be computed with *one* additional gradient evaluation by the finite-difference approximation $H\mathbf{d} \cong [\mathbf{g}(\mathbf{x}_k + \Delta x\,\mathbf{d}) - \mathbf{g}(\mathbf{x}_k)]/\Delta x$ where Δx is a suitably chosen interval, such as $\Delta x = 2\sqrt{\epsilon_m}(1 + \|\mathbf{x}_k\|)/\|\mathbf{d}\|$ [9], [21]. The user specifies the method of choice for the calculation of $H\mathbf{d}$.

- Set $\mathbf{x}_{k+1} = \mathbf{x}_k + \lambda \mathbf{p}_k$ and $k \leftarrow k+1$. (The new function value and gradient are known after the line search.)

5. *Convergence tests*
   If $\|\mathbf{g}_k\| \leq 10^{-8} \max\{1, \|\mathbf{x}_k\|\}$, exit algorithm. Otherwise, continue to step 6.
6. *Preparation for next Newton step*
   - Compute the preconditioner and, optionally, the Hessian (see previous footnote 1) at the new point (M_k and H_k, respectively).
   - Perform a "symmetric reordering" of M_k according to the permutation P. This only involves internal rearrangement of M.
   - Go to step 3.

3.2. Algorithm TN2: Inner loop k of the truncated Newton method. The sequence $\{\tilde{\mathbf{p}}_i\}$ below represents the PCG vectors used to construct $\mathbf{p}_k$ in step 3 of Algorithm TN1. We omit the Newton subscripts k from $\mathbf{p}$, $\mathbf{g}$, H, and M for clarity.

1. *Initialization*
   - Set $i = 0$, $\tilde{\mathbf{p}}_i = 0$, and $\mathbf{r}_i = -\mathbf{g}$.
   - Set the parameter η_k controlling the accuracy of the computed search vector:

$$\eta_k = \min\{\delta/k, \|\mathbf{g}\|\}, \tag{21}$$

   where $\delta \leq 1$.
2. *Preparation for sparse* MC *factorization*
   - Perform the *numerical factorization* of (the permuted) M by the chosen MC scheme. The resulting factors L and D of $P\overline{M}P^T = PMP^T + E = LDL^T$ are stored in the same sparse row format used for M. We refer to $\overline{M}$ as the "effective preconditioner."
   - Solve for $\mathbf{z}_i$ in

$$\overline{M}\mathbf{z}_i = \mathbf{r}_i \tag{22}$$

   by using the Cholesky factors in the system $(P\overline{M}P^T)P\mathbf{z}_i = P\mathbf{r}_i$:

$$L\mathbf{x} = P\mathbf{r}_i, \quad L^T\mathbf{y} = D^{-1}\mathbf{x}, \quad \mathbf{z}_i = P^T\mathbf{y}. \tag{23}$$

   - Set $\mathbf{d}_i = \mathbf{z}_i$.
3. *Negative curvature test*
   - Compute the matrix–vector product $\mathbf{q}_i = H\mathbf{d}_i$.
   - *If*

$$\mathbf{d}_i^T\mathbf{q}_i \leq \zeta(\mathbf{d}_i^T\mathbf{d}_i) \tag{24}$$

   (where ζ is a small number such as $\epsilon_m/100$)
   exit inner loop with search direction

$$\mathbf{p} = \begin{cases} \mathbf{z}_i & \text{if } i = 0, \\ \tilde{\mathbf{p}}_i & \text{else;} \end{cases} \tag{25}$$

   else continue to step 4.
4. *Truncation test*
   - Update the quantities

$$\begin{aligned} \alpha_i &= \mathbf{r}_i^T\mathbf{z}_i/\mathbf{d}_i^T\mathbf{q}_i, \\ \tilde{\mathbf{p}}_{i+1} &= \tilde{\mathbf{p}}_i + \alpha_i\mathbf{d}_i, \\ \mathbf{r}_{i+1} &= \mathbf{r}_i - \alpha_i\mathbf{q}_i. \end{aligned}$$

- *If*

$$\|\mathbf{r}_{i+1}\| \leq \eta_k \|\mathbf{g}\|, \tag{26}$$

exit inner loop with search direction

$$\mathbf{p} = \tilde{\mathbf{p}}_{i+1}; \tag{27}$$

else continue to step 5.

5. *Continuation of* PCG
   - Compute $\mathbf{z}_{i+1}$ as in step 2 (23) by reusing the MC factors of (the permuted) $\overline{M}$ so that

$$\overline{M}\mathbf{z}_{i+1} = \mathbf{r}_{i+1}. \tag{28}$$

   - Update the quantities

$$\begin{aligned} \beta_i &= \mathbf{r}_{i+1}^T \mathbf{z}_{i+1} / \mathbf{r}_i^T \mathbf{z}_i, \\ \mathbf{d}_{i+1} &= \mathbf{z}_{i+1} + \beta_i \mathbf{d}_i, \\ i &\leftarrow i + 1. \end{aligned}$$

   - Go to step 3.

3.3. Remarks on TN. In the negative curvature test of (24), we use the value $\zeta = 10^{-10}$. For the truncation test of (26), we use $\delta = 1$ in (21). (For diagnostic purposes, we also use $\delta = 10^{-8}$ in some runs to mimic a "nontruncated" version.) Thus the inner PCG loop can terminate if a direction $\mathbf{d}$ of negative curvature is detected, or if the truncation test is satisfied (see steps 3 and 4 above). In the first case, the resulting search direction (for the outer loop) is $-(\overline{M}_k)^{-1}\mathbf{g}_k$ if this occurs at the first PCG iteration, or the current PCG iterate, $\tilde{\mathbf{p}}_i$, otherwise. In the second case, the relative residual of the Newton equations $\tilde{r}_k = \|\mathbf{r}_k\|/\|\mathbf{g}_k\| \leq \eta_k < 1$ and $\lim_{k\to\infty} \sup(\tilde{r}_k/\|\mathbf{g}_k\|) < \infty$, which can be used to produce asymptotic quadratic convergence for the method [2]. Weaker, superlinear convergence can be obtained if the *forcing sequence* η_k is chosen so that $\lim_{k\to\infty} \eta_k = 0$ and $\tilde{r}_k \leq \eta_k < 1$ [2], [4]. Although we have found the residual test of (21) and (26) to work very well in practice, several alternatives have been suggested to produce an affine invariant truncation [4] or to avoid an excessive number of inner iterations [17], possible, for example, when $\|\mathbf{g}\|$ is small or H is ill conditioned.

Since the sparsity structure of the preconditioner remains constant throughout minimization, the permutation P is determined at the beginning of the algorithm. A no-pivoting MC algorithm is used to retain this structure. The symbolic factorization of M is also performed only once. In each inner loop, one numerical factorization is performed, whereas in each inner PCG iteration numerical solutions are required to solve $M\mathbf{z} = \mathbf{r}$ repeatedly for different right-hand side vectors ((22) for $i = 0$ and (28) for $i \geq 0$).

3.4. MC variations. In addition to the no-pivoting implementation of the MC factorization, our experience has suggested a variation of the SE formula in (17) and (18) for choosing the modification e_j. This involves omitting: (1) the condition $e_j \geq e_{j-1}$ in (17), and (2) the explicit eigenvalue strategy for e_{n-1} and e_n in (18). While $\|E\|_\infty$ may indeed be smaller if the original formulas are used, the special treatment of the last two variables may destroy inherent symmetry of the problem; furthermore, only small improvement on $\|E\|_\infty$ can generally be expected for large-scale systems. The *deletion* of the requirement that e_j be at least as large as e_{j-1} may be beneficial in our preconditioning context since fewer overall modifications to M may be involved. Moreover, for very large sparse systems, the rationale behind the original strategy (that a *larger* d_j may lead to a less negative trial value $\tilde{d}_{j+1}$ and hence a *smaller* modification e_{j+1}) may be irrelevant if $\ell_{j+1,j}$ or $c_{j+1,j}$ is zero (see (8)). In all our SE MC implementations, we omit the special strategy for determining e_n and e_{n-1}. We refer to versions "SE(a)" and "SE(b)" as the SE strategies where the formulas of (17) and

$$e_j = \max\{0, -\tilde{d}_j + \max\{\theta, \tau_2\gamma\}\}, \quad j = 1, \ldots, n, \tag{29}$$

are used, respectively.

4. Numerical experiments.

The following numerical examples are intended to suggest various trends that may occur in practice in our truncated Newton utilization of the various MC factorizations. Clearly, the special adaptation of MC for TN restricts any conclusions to the present context. The notion of "optimality" for one MC strategy versus another is very difficult because the *overall* effect on minimization is cumulative; only a thorough investigation on a wide variety of problems can attempt to address this question. However, our current experience may already prove useful, and we share it in the hope that further investigations will be motivated.

Three types of objective functions are examined, with variations of size, starting points, parameters, and preconditioners. The problems are chosen of moderate size to permit a thorough investigation of the MC segment, including eigenvalue analysis for H and M at every Newton iteration. Two functions are chosen from computational chemistry: one describing a typical case of a molecule with few and well-separated, low-energy conformational regions; and one of a cluster of molecules, for which many energetically favorable configurations exist. The third is a well-known, unconstrained minimization test function, sometimes called "trigonometric" [12], [13]; its Hessian is indefinite at the standard starting point, with many negative and clustered eigenvalues, and typically remains indefinite for many iterations. In general, many "standard" test problems are inappropriate for our comparison since natural, much less indefinite, nondiagonal preconditioners are nontrivial to formulate. For the trigonometric function, the Hessian is dense, so there is some justification for formulating various band preconditioners, which are also indefinite (see § 4.4).

4.1. Measures of overall performance.

Overall performance with the truncated Newton method can be measured by the total number of outer (Newton) iterations, inner (PCG) iterations (i.e., the sum over all Newton steps), and function and gradient evaluations. These quantities determine the computing time. Since function and gradient values are evaluated as a pair in the line search, we refer to this measurement as a "function evaluation."

The number of Newton iterations provides information on overall progress. Many Newton iterations, for example, typically indicate that indefiniteness of H has been detected, in which case the inner loop is terminated without the satisfaction of the truncation criterion. The number of PCG iterations has been suggested as a good overall measure of truncated Newton performance [2]. The number of function evaluations—at least one per Newton step and more if required by the line search to satisfy (19) and (20)—can be a good indicator of time for large-scale functions if function and gradient calculations dominate over the cost involved in Hessian and preconditioner calculations.[2]

An important consequence of the truncated Newton approach is that different algorithmic variations (e.g., truncation parameters, MC strategies) generate a different sequence of search vectors. This effect can lead to different overall performance. The effect of different MC procedures on overall minimization in our method will therefore be indirect and cumulative. While the relation between the MC strategy and the required number of PCG iterations to solve *a* given Newton system to completion is easier to measure, it is of more practical importance to understand the MC effect on overall minimization progress. This overall consideration is also relevant since in many large-scale problems, the number of PCG iterations is often limited to a number $\ll n$ due to the high cost of the inner iteration [16]. This implies that different MC strategies may lead to very different search directions from the same iterate. The total number of PCG iterations is both a measure of overall progress and a cumulative indicator of the step-by-step MC effect.

All computations were performed in double precision on a DEC Vax-3600 computer at the Courant Institute of Mathematical Sciences, New York University. Machine precision is of order 10^{-17}. We refer to the three MC strategies as: GMW (§2.1), SE(a), and SE(b) (§2.2 with variations indicated above). The MC tolerance parameters are: $\tau_1 = \tau_2 = 10^{-5}$ for SE, and $\tau = 10^{-8} * \max\{1, \gamma, \xi\}$ for GMW. This value of τ for GMW is chosen since our typical largest diagonal of M, γ in the computational chemistry problems has a value of $O(10^3)$ and satisfies $\gamma > \xi$.

4.2. A nucleic acid component. In "molecular mechanics," a potential energy function of atomic positions is minimized to predict three-dimensional structures of biomolecules for a given composition (e.g., base sequence for DNA) [19], [23]. Thus the independent variables are the Cartesian coordinates of all atoms in the system, denoted collectively by the vector $\mathbf{x}$. Potential energy surfaces are typically complex, involving many local minima, maxima, and transition points. Since the energy naturally decomposes into local and nonlocal interactions, the local components (among atoms in bonded sequences of atom pairs, triplets, and quadruplets) provide a natural sparse preconditioner which grows linearly in size with n [22]. We have found this choice of preconditioner ("M_{PE}") to work very well in practice in relation to other preconditioners and to no-preconditioning versions [22], [24].

Deoxycytidine (dC), is a component of DNA that can be modeled with $n = 87$, [19], [23]. Well-tested energy parameters are available, and specific local minima for dC are known experimentally. The energy function $F(\mathbf{x})$ is typically written in terms of the *internal* variables (interatomic distances r_{ij}, bond lengths b_i, bond angles θ_i, and dihedral angles τ_i), which are in turn computed from $\mathbf{x}$ through geometric relations [19]. It has the form:

$$(30)\quad \begin{aligned} F = &\sum_{i,j\in S_{NB}} \left[-\frac{A_{ij}}{r_{ij}^6} + \frac{B_{ij}}{r_{ij}^{12}} + \frac{Q_iQ_j}{r_{ij}} \right] + \sum_{i\in S_B} S_i(b_i - \bar{b}_i)^2 \\ &+ \sum_{i\in S_{BA}} K_i(\cos\theta_i - \cos\bar{\theta}_i) + \sum_{i\in S_{DA}}{}' \sum_m V_{m_i}(1 + \cos m\tau_i). \end{aligned}$$

[2] The costs for the Hessian/vector products $H\mathbf{d}$ (see step 3 of Algorithm TN2) and solutions of $M\mathbf{z} = \mathbf{r}$ (see (22) and (28)) depend on the problem structure. The finite-difference approximation to $H\mathbf{d}$ (see footnote 1) will generally provide a time advantage, without sacrifice in performance, if the "analytic" $H\mathbf{d}$ calculation is considerably more costly than one gradient evaluation. The $M\mathbf{z} = \mathbf{r}$ solution depends on the sparsity pattern of M and can be as low as $O(n)$ [21].

The first component represents the van der Waals (attraction/repulsion) and Coulombic interactions for atom pairs (i,j), $i<j$, in the nonbonded set S_{NB}. The second and third energy terms penalize deviations from reference bond lengths $(\bar{b}_i)$ or bond angles $(\bar{\theta}_i)$ for the bonds and angles in the sets S_B and S_{BA}, respectively. The last term accounts for rotations of two groups of atoms about the bond connecting them and associates with each such dihedral angle in S_{DA} a periodicity m (typically $m = 2,3,6$) and barrier height V_m. The symbols A, B, Q, S, and K are energy parameters associated with a particular pair interaction, bond, or angle type (e.g., O$-$O where O = oxygen). M_{PE} is assembled from the second derivatives of the bond length, bond angle, and dihedral angle terms.

Many minimization starting conformations were investigated for dC, and the three different choices (**X1**, **X2**, **X3**), examined in Tables 1–4, are representative of different energies and eigenvalue distributions (see Tables 3 and 4). All Hessians and preconditioners are indefinite at the starting points. Tables 1 and 2 show minimization results from the three points: in Table 1 with the truncation parameter $\delta = 1$ (see (21)), and in Table 2 with $\delta = 10^{-8}$. The total number of Newton iterations, PCG iterations, and function evaluations required for convergence is given. The minimum, maximum, and median values for $\|E\|_\infty$, computed over all Newton iterations, and the number of Newton iterations for which $\|E\|_\infty > 0$ ("modified iterations") provide the MC information. Each run from the **X1**, **X2**, and **X3** groups produced the minima **X6**, **X5**, and **X7**, respectively. Tables 3 and 4 provide eigenvalue information for H and M at these six points.

From Table 1 ($\delta = 1$), we note that overall convergence to a local minimum is very rapid: $< n/4$ outer iterations, $< n$ inner iterations, and $\sim n/2$ function evaluations. M_{PE} is modified in only one or two Newton iterations (typically the first and second), and in those cases $e_j > 0$ only for the last three or four factorization steps ($j \geq 83$). The values of $\|E\|_\infty$ are larger for GMW than SE, by about a factor of two, but in both strategies $\|E\|_\infty$ is greater than $\lambda_{\min}$ by one or two orders of magnitude. When a modification occurs in only one Newton iteration, $\|E\|_\infty$ corresponds to $\lambda_{\min}$ of M at the starting point (Table 3). When two such modifications are made, the recorded value for $\|E\|_\infty$ corresponds to a $\lambda_{\min}$ of M (at another Newton iteration) that is slightly smaller in magnitude than $\lambda_{\min}$ at the starting point. (In the second iteration of SE(a) for **X1**, $\lambda_{\min} = -0.22$ versus $\|E\|_\infty = 2.4$; in the second iteration of SE(a) for **X3**, $\lambda_{\min} = -0.01$ versus $\|E\|_\infty = 6.1$.) Overall, the smaller SE modifications do not produce a systematic reduction of PCG iterations for the modified iterations.

Only about one to three PCG iterations per Newton iteration are performed for all Newton iterations. The differences between the two SE versions are small.

When the truncation parameter is made more strict ($\delta = 10^{-8}$), Table 2 shows a large increase in the number of required PCG iterations (a factor of three or more). This demonstrates the effectiveness of the truncated Newton approach in allowing larger residuals in many cases. The number of function and gradient evaluations is usually decreased as well.

Overall, both the GMW and SE strategies perform quite similarly in this example despite the fact that $\|E\|_\infty$ is systematically greater for GMW than for SE. This suggests that the size of E alone is not a simple factor correlated with better performance in TN; larger modifications to M may subsequently produce equally effective search directions. Indeed, in earlier tests, we encountered a case where $\|E\|_\infty$ of GMW was larger by nearly two orders of magnitude than that of SE; yet minimization performance of the GMW version was more rapid overall. Although the differences here are not large, the GMW version appears slightly more efficient in the usual TN context of $\delta = 1$. Between the two SE versions, performance differences are small. Analysis shows that allowing e_{j-1} to exceed e_j can slightly increase the average modification per Newton step but may cause fewer elements to be modified. Systematic effects of this difference cannot be noted here since few nonzero diagonal modifications are involved, all of which occur in the last few Cholesky factorization steps.

The rapid minimization progress and its insensitivity to the MC strategy may be attributed to the fact that this optimization problem is straightforward, with distinct convex conformational regions. In almost all runs, H becomes positive definite after the first Newton iteration and remains positive definite. M_{PE} is an excellent preconditioner (nonpreconditioned runs required a factor of ten or more PCG iterations [22]) and is positive definite except during one or two Newton iterations. As later results suggest, this overall performance may be related to the existence of only one *isolated* negative eigenvalue for M_{PE} near the starting point; all three MC strategies modify only few diagonals and are equally successful in our TN context.

4.3. Water clusters. Our second model of water clusters [20] has an energy function similar to (30) except that the van der Waals term is summed over O–O atom pairs only, the coulombic interactions are summed over all intermolecular pairs (O–O, O–H, and H–H), and there is no dihedral angle term (H = hydrogen). The physical picture is entirely different from that of dC, since the interaction among the different water molecules is long range and the many local minima (close in energy) correspond to different hydrogen-bonding networks. The complexity of these networks increases as the cluster size grows. This property produces a Hessian for the water model that is often indefinite. Furthermore, the same definition of local M_{PE} does not contain the major energy contributions. The electrostatic potential that leads to formation of hydrogen bonds is dominant here. However, it is not practical to formulate a preconditioner from these long-range interactions, especially in the context of large-scale truncated Newton minimization. In practice, these features are reflected in TN minimization by frequent termination of the inner loop when a direction of negative curvature is detected and by nonzero MC modifications at every Newton iteration. In combination with the difficulty of choosing good starting points (i.e., predicting the hydrogen bonding patterns a priori), this minimization problem is far more difficult than dC and requires a large number of iterations and function calls.

In all water runs, the truncation parameter δ is set to unity and the limiting number of inner iterations (*per* outer iteration) is set to n to make the MC comparisons as fair as possible. Results for a water dimer ($n = 18$) are summarized in Table 5. Run (A) uses M_{PE}. Run (B), chosen for diagnostic purposes, adds to M_{PE} nonlocal O–O interactions. This adds an off-diagonal 3×3 block to the block-diagonal M_{PE} composed of two 9×9 blocks. There is only one minimum for the dimer corresponding to a linear hydrogen-bonded pair [20].

Run (A) shows convergence in about 40 Newton iterations for all MC versions. GMW requires a smaller number of inner iterations and function evaluations ($\sim$ 80 percent) in relation to the SE runs. The size of $\|E\|_\infty$ for GMW is on the order of the prescribed parameter τ of (13), since very small trial diagonals—$O(10^{-13} - 10^{-20})$—appear toward the end of the factorization ($j > 15$). The SE versions switch to Phase 2 early, producing more diagonal modifications but also avoiding formation of very small tentative diagonals. Table 6(a) provides an illustration of this behavior.

In contrast, run (B) shows that *overall* performance of all three MC strategies is very similar. The mean GMW $\|E\|_\infty$ is now *greater* by about one order of magnitude

TABLE 5

	SE(b)	45	297	134	1.5E+01	9.2E+02	4.7E+02	45

than SE. Thus, the noted tendency of GMW to begin diagonal modifications at later factorization steps produces here an overall larger $\|E\|_\infty$. Table 6(b) illustrates this behavior in comparison to run (A).

A minimization series of water clusters in increasing sizes was then performed. These experiments correspond to case (A) of the water dimer, using M_{PE}. Starting configurations are constructed pseudorandomly in the computational domain [20], and are thus high in energy and far from optimal structures. The various geometric possibilities that different cluster sizes can adopt [20], in combination with the random aspect of choosing the starting points, produce differences in minimization performance that are not always correlated to the cluster size.

Table 7 shows performance for water clusters of dimensions $n = 27$ to $n = 576$, and Table 8 provides eigenvalue information for the corresponding starting and final points (including the water dimer). In the reported runs for each dimension, the resulting minima are very close in energy although they may not be identical. In such cases, corresponding eigenvalue information at the final points is very similar for each group, and the reported values in Table 8 are representative.

In comparison with results for the water dimer, similar behavior in the size of $\|E\|_\infty$ can be observed for larger water models, but a new dimension-dependent trend emerges among the MC versions. While the GMW version appears more efficient for smaller dimensions in the number of iterations and function evaluations, the SE strategy, in particular SE(b), shows better performance with increasing size. Differences in the number of PCG iterations, in particular, become large (by factors of two to more than four) in many cases.

Analysis reveals the following explanation. The Hessian is indefinite at the starting point and remains so for many iterations; thus, the inner loop often ends with detection of negative curvature. M_{PE} is also indefinite, with approximately $n/9$ negative eigenvalues (all very close to zero) throughout the run, forcing nonzero modifications at every Newton iteration. Now, GMW produces $\|E\|_\infty$ sizes on the order of the tolerance τ ($O(10^{-5})$), while the Gerschgorin estimates of SE lead to much larger modifications ($O(10^3)$), similar to the situation illustrated in Table 6(a). The resulting GMW search directions often produce very slow progress for many iterations, and the number of H's negative eigenvalues decreases slowly; it is likely that these directions are close to perpendicular to the gradient. When H becomes positive definite, the truncation criterion is stricter (see (21)) and many PCG iterations are then involved. The SE strategy enters positive definite regions of H more quickly and typically displays more rapid progress thereafter. Version SE(b) performs better than SE(a) because diagonal modifications are made less often and a smaller number of PCG iterations generally results.

* Entries leading to zero modifications were not recorded.

Performance with a stricter truncation criterion was very similar since only the last several iterations (that do not end in detection of negative curvature) are affected, but for these the allowed residual is already very small. Performance with larger values of τ (the minimum allowable value of each positive diagonal modification), such as by two to five orders of magnitude, produced somewhat better overall progress for the GMW runs, but progress is still not competitive with SE. Performance with *smaller* τ led to some underflow/overflow for the larger dimensions. This suggests that here ill-conditioned preconditioners $\overline{M}$ are disadvantageous. For the structure in these examples, larger tolerances for GMW are an effective way to increase $||E||_\infty$, whereas in SE, $||E||_\infty$ is larger—even with small τ—due to the use of the Gerschgorin estimates.

Why does the GMW version display faster convergence for smaller dimensions? The number of negative eigenvalues and percentage of iterations when H is indefinite seem to play key roles in steering the minimization progress. Table 8 shows that H has about $n/3$ negative eigenvalues at the starting point, with a $\lambda_{\min}$ of magnitude $O(10^0-10^1)$ and a $\lambda_{\max}$ of $O(10^3)$. The number of M's negative eigenvalues is about $n/9$, but they are all very small in magnitude and clustered. Thus, when only a few tentative diagonals are small (say, one to three), GMW is more efficient in terms of iterations and function evaluations because its small modifications apparently do not affect the "quality" of the computed search direction for TN dramatically; as the number of small tentative diagonals increases and more resulting diagonals have magnitude τ, 10^{-5}, we observe slower progress. The SE strategy detects indefiniteness early in the factorization (Phase 1 is typically false after about ten steps) and modifies the diagonals more substantially. This appears advantageous as the size and complexity of the problem increase due to the better conditioning of the preconditioner. In other

words, when H is mainly positive definite, GMW does better because M is closer to H, whereas when H is often indefinite SE does better because M is better conditioned.

4.4. The trigonometric function. A well-known test function for optimization, known as "trigonometric," offers a problem structure with many negative eigenvalues of larger magnitudes. This function of variable dimension n is given as [12]

$$F(\mathbf{x}) = \sum_{j=1,\ldots,n} \left(n - \sum_{i=1}^{n} \cos x_i + j(1 - \cos x_j) - \sin x_j \right)^2 . \tag{31}$$

At $\mathbf{x}_0 = (1/n, \ldots, 1/n)^T$, H is indefinite. We study four sets of minimization runs from $\mathbf{x}_0$, for $n = 50$, 100, 250, and 1000. For each set, we use the diagonal, tridiagonal, and pentadiagonal elements of the Hessian to construct preconditioners (denoted as D, T, and P). The truncation parameter δ is set to unity, and the limiting number

of PCG iterations (per Newton step) is set to ten.[3] Typically, the residual is very small after a small number of PCG iterations, so this PCG limit has only a small effect. Since the residual is reduced rapidly in the inner loop, a smaller δ value also has little effect on performance. Since very similar linear systems are solved at every step, we expect our MC comparisons to reflect systematic differences at each Newton step. For all runs, we use a stricter overall minimization termination criterion of $\|\mathbf{g}\|/\sqrt{n} \leq 10^{-12} * \max\{1, \|\mathbf{x}\|\}$; since $\|\mathbf{g}(\mathbf{x}_0)\|$ is already small, we wanted to ensure continuation of the minimization until quadratic convergence of $\|\mathbf{g}\|$ is observed.

Table 9 shows results for the four sets of runs. Table 10 lists $\lambda_{\min}$ and $\lambda_{\max}$ for H and for P at both $\mathbf{x}_0$ and $\mathbf{x}_*$ (the solution). The corresponding eigenvalues for D and T are very similar. (This is probably a consequence of the small magnitudes of off-diagonals with respect to diagonal elements: typical values of γ and ξ are $\gamma \sim 2.0$ and ξ of $O(10^{-2} - 10^{-1})$.) We note that both H and M have 60 percent of their eigenvalues negative at $\mathbf{x}_0$. A complete spectral analysis shows that all eigenvalues have magnitudes $O(10^{-1} - 10^{-2})$, most of them of $O(10^{-1})$. For example, for $n = 100$, the 61 negative eigenvalues of P range between -0.59 and -0.02. All eigenvalues at $\mathbf{x}_0$ for H and M are concentrated in the interval $[-1.0, 1.5]$. At $\mathbf{x}_*$, H and M are positive definite, with $\lambda_{\min}$ of $O(10^{-2})$ and $\lambda_{\max}$ approximately 3.0 for H and 2.0 for M.

The runs with preconditioner D show that performance with the GMW strategy is more rapid for each dimension. The number of "modified" iterations in GMW is smaller for $n > 50$ and equal to SE for $n = 50$. The size of $\|E\|_\infty$ is typically greater for GMW by a factor of two. This relation is expected since $\theta = 0$ and $|\tilde{d}_j| > \tau$ (see (13) and (17)). Thus, GMW generally modifies tentative negative diagonals m_{jj} to

[3] This limit is imposed to mimic a practical situation where H is dense and the inner iterations are costly when $H\mathbf{d}$ is computed analytically.

$|m_{jj}|$, and SE produces elements d_j of magnitude τ. The small diagonals appear to produce search directions that lead to slower minimization progress (more below).

As off-diagonal elements are added to M, more iterations, function evaluations, and nonzero modifications can be observed for GMW in comparison to SE. The ratio of the largest elements in E in GMW versus SE is in the range 2–3 for T and 3–13 for P. Version SE(a) produces the most rapid performance as the size of the problem increases. Figure 2 illustrates the difference in minimization progress by comparing $\lambda_{\min}$ with $\|E\|_\infty$ for the runs with T and $n = 250$. During the first five Newton iterations, the number of negative eigenvalues of M in the GMW version is reduced slowly from 152: $\{152, 135, 102, 44, 55, 31\}$. In comparison, the SE(a) and SE(b) sequences of negative eigenvalues per Newton iteration are $\{152, 5, 2, 0, 0, 0\}$ and $\{152, 5, 4, 0, 0, 0\}$, respectively. At later iterations, the number of negative eigenvalues in GMW ranges from zero to 65, while the range for the SE versions is between zero and eight.

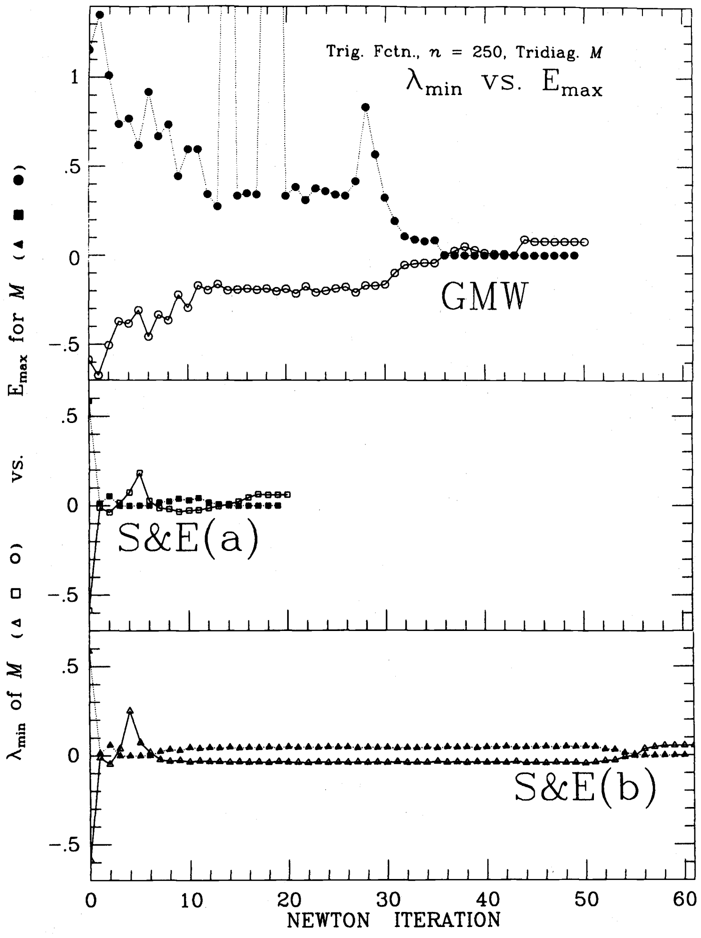

FIG. 2. *$\lambda_{\min}$ versus $\|E\|_\infty$ for the trigonometric function.*

For the first Newton iteration, the modification schedule is quite similar for all MC versions: GMW modifies diagonals $99 \le j \le 250$, and the SE runs enter Phase 2 at $j = 97$. Two PCG iterations are performed for GMW, and one PCG iteration is performed for SE(a) and SE(b), until a direction of negative curvature is detected. Notable differences emerge thereafter. At the second Newton iteration, GMW modifies negative tentative diagonals $96 \leq j \leq 250$ of magnitude range $O(10^{-1} - 10^{-3})$. Both SE versions enter Phase 2 at $j = 153$ and modify a few small negative tentative diagonals as well as small positive diagonal candidates of $O(10^{-2} - 10^{-4})$; subsequent diagonals do not become negative. This pattern for all MC versions repeats for several Newton iterations, involving fewer and fewer diagonal modifications at each iteration.

The tendency of small diagonal entries to form during the MC factorization is reversed for the GMW and SE versions in the case of diagonal and nondiagonal preconditioners. GMW handles this by specifying larger modifications in the diagonal case, while SE applies a different two-phase modification schedule in the nondiagonal cases. As observed in the water minimization, a systematic trend of small, positive diagonals of $O(\tau)$ slows minimization progress in TN. The clustered eigenvalue structure of the trigonometric function appears to work more favorably with the SE MC scheme. Interestingly, it has been observed that SE produces the most significant improvement in $\|E\|_\infty$ over GMW for problems where the eigenvalues are clustered between -1 and 1 [25].

5. Summary.

The GMW and SE MC factorizations were examined in the context of modifying indefinite preconditioners in a truncated Newton algorithm. No pivoting versions were examined since a variable reordering is determined at the beginning of the optimization procedure to minimize fill-in for the sparse preconditioner. The two factorizations differ both in their formulas for diagonal modifications and in the manner by which these formulas are activated. While GMW subjects all tentative diagonals to the same modification formula, SE employs a two-phase strategy. Phase 1 denotes the state when all diagonal modifications, e_j, are zero (positive definite matrices always remain in Phase 1), and Phase 2 is entered when a phase test indicates that a diagonal element will become negative or very "small." Only at Phase 2 is the Gerschgorin-based formula of SE applied. In the last two steps, explicit eigenvalue information is used. Whereas the phase test in SE requires that the diagonal elements of the matrix be updated at every step, this is not a requirement in GMW. While GMW requires the full matrix a priori, SE only needs the diagonal at the start. A variation of the SE factorization was suggested here to produce the same modification formula for all diagonal elements. In addition, an SE variation in which the modification e_j was not required to be as large as e_{j-1} was examined.

Our three test problems, with variations of size, preconditioners, starting points, and truncation parameters, involve three different eigenvalue distributions that are typically encountered in practice: an isolated negative eigenvalue, several near-zero positive and negative eigenvalues, and a large percentage of negative eigenvalues. In the first case, represented by a molecular model with distinct and well-separated energy minima, nonzero diagonal modifications to M were required in only one or two Newton iterations. The GMW and SE factorizations behaved very similarly, though GMW was slightly more efficient despite the typically larger $\|E\|_\infty$ (factor of two). In the second case, a molecular ensemble possessing numerous and clustered minima with a characteristically indefinite potential surface, nonzero modifications were made in all Newton iterations. GMW appeared more efficient for smaller dimensions but SE(b) (the version where e_j was not required to exceed e_{j-1}) became much more efficient as size increased; $\|E\|_\infty$ was typically around the set tolerance τ, $O(10^{-5})$ for GMW, and $O(10^2 - 10^3)$ for SE. In the third case of the trigonometric function, nonzero modifications were involved in some Newton iterations. GMW demonstrated more rapid performance for diagonal preconditioners of various dimensions, but SE(a) (the version where $e_j \geq e_{j-1}$) produced better performance as off-diagonals were added to the preconditioner. $\|E\|_\infty$ was typically larger for GMW by a factor of two to ten.

Our results suggest that differences in performance between the GMW and SE MC factorizations depend on such problem characteristics. The following conclusions may be drawn from the test problems examined *and* our special preconditioner-modifier context.

(1) The size of $\|E\|_\infty$ may not be a crucial factor governing minimization performance. Although in some cases $\|E\|_\infty$ from SE is smaller than that of GMW, minimization progress is not directly correlated with this number, especially for problems with few isolated negative eigenvalues. This behavior is both a consequence of the indirect effect of $\|E\|_\infty$ on the computed search direction and the inherent approximation in the truncated Newton approach.

(2) The trends in the size of $\|E\|_\infty$ for the GMW and the SE schemes may be distinct for the dense and sparse matrix cases. Whereas dense test problems reveal that the SE MC often produces smaller values of $\|E\|_\infty$ than GMW [25], sparse matrices may exhibit an opposite trend. The Gerschgorin-based estimates of SE may lead to much larger modifications than GMW in sparse systems, especially in problems with many near-zero eigenvalues. However, the possibility that these observations stem from the eigenvalue patterns of the matrices—whether the matrices are sparse or dense—cannot be excluded.

(3) Producing very small $\|E\|_\infty$ (i.e., so that $M + E$ is nearly singular) is usually disadvantageous in our context, unless M has only a few negative eigenvalues. Such near-singular "effective preconditioners" often require many inner (PCG) iterations at each Newton step and produce very slow progress overall. This slow progress is most pronounced for large dimensions. This observation suggests that larger tolerances for the minimum-allowed $\|E\|_\infty$ would be more effective in these cases.

(4) The largest difference between the two factorizations appears to be related to their different modification *schedules*. In many cases, the GMW diagonal modifications begin at later stages of the factorization than SE; tentative diagonal values may then grow more negative and require larger modifications later on. With modifications at earlier stages of the factorization, the SE scheme may prevent future diagonals from growing very large and negative. Overall, these differences in schedule and modification formulas tend to produce, in general, a smaller *variance* of $\|E\|_\infty$ for the SE algorithm for the problems examined: $\|E\|_\infty$ for SE is rarely very large or very small. In particular, the observation that $\overline{M}$ is rarely barely positive definite with SE appears advantageous in our optimization context, especially for highly nonlinear problems. Since it has been suggested that limited-memory quasi-Newton methods perform better than truncated Newton methods for highly nonlinear functions [16], the SE MC may improve the competitiveness of truncated Newton methods for highly nonlinear functions that arise in practice.

OPTIMAL PARALLEL SOLUTION OF SPARSE TRIANGULAR SYSTEMS*

FERNANDO L. ALVARADO[†] AND ROBERT SCHREIBER[‡]

Abstract. This paper considers the parallel solution of a sparse system $Lx = b$ with triangular matrix L, which is often a performance bottleneck in parallel computation. When many systems with the same matrix are to be solved, the parallel efficiency can be improved by representing the inverse of L as a product of a few sparse factors. The factorization with the smallest number of factors is constructed, subject to the requirement that no new nonzero elements are created. Applications are to iterative solvers with triangular preconditioners, to structural analysis, or to power systems applications. Experimental results on the Connection Machine show the method to be highly valuable.

Key words. sparsity, sparse matrices, numerical linear algebra, triangular matrices, iterative methods, parallel computation

1. Introduction.

Consider the solution of a sparse, nonsingular, lower-triangular linear system $Lx = b$ in a parallel environment. (All our results extend in a trivial way to upper-triangular systems, a fact we shall not mention again.) We consider the case where the problem must be solved for multiple right-hand side vectors b, and these vectors are not available all at once. By preprocessing, we shall reduce the number of parallel steps required.

Important applications where multiple right-hand sides arise include finite element applications, preconditioned iterative solvers for linear systems, solution of initial value problems by implicit methods, and variants of Newton's method for the solution of nonlinear equations.

There are two possible approaches to the parallel solution of triangular systems of equations. The usual approach is to exploit whatever parallelism is available in the usual substitution algorithm [4], [10]. The second, which requires preprocessing, works with some representation of L^{-1}. In sequential sparse matrix computation, substitution is universally favored because it retains the sparsity of the problem [7], while L^{-1} is usually much denser than L [8].

Here we consider a factorization

$$L^{-1} = \prod_{k=1}^{m} Q_k$$

with sparse factors. Such a factorization is possible in which the factors have no more nonzeros than L [2], [3], [8]. The chief advantage of a factorization of L^{-1} is that all the necessary multiplications for the computation of $Q_k x$ can be performed concurrently. The necessary additions can be done in time logarithmic in the largest

number of nonzeros in a row of Q_k. Thus it is possible to take advantage of more parallelism in the solution of these equations. The remainder of this introduction reviews the use of partitioned inverses of L.

Any triangular matrix L can be expressed as a product

$$L = L_1 L_2 \cdots L_n,$$

where

$$\begin{aligned} (L_k)_{ik} &= L_{ik} \quad \text{for} \quad k \le i \le n, \\ (L_k)_{jj} &\equiv 1 \quad \text{for} \quad j \ne k, \\ (L_k)_{ij} &\equiv 0 \quad \text{otherwise}. \end{aligned}$$

The matrices L_k are known as elementary lower-triangular matrices. They can be grouped into several factors,

$$L = \prod_{k=1}^{m} P_k, \tag{1}$$

where

$$P_k = L_{e_{k-1}+1} L_{e_{k-1}+2} \cdots L_{e_k} \tag{2}$$

and

$$0 = e_0 < e_1 < \cdots < e_m = n. \tag{3}$$

Here $\{e_k\}_{k=0}^{m}$ is a monotonically increasing integer sequence. The factor P_k is lower triangular and is zero below its diagonal in all columns except columns $e_{k-1} + 1$ through e_k, where it is identical to L. Consider, for example,

$$L = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 \\ 3 & 2 & 3 & 0 \\ 4 & 0 & 1 & 1 \end{bmatrix}.$$

By choosing $e_0 = 0, e_1 = 2$, and $e_2 = 4$, L is partitioned as

$$L = (L_1 L_2)(L_3 L_4) = P_1 P_2 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 \\ 3 & 2 & 1 & 0 \\ 4 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 3 & 0 \\ 0 & 0 & 1 & 1 \end{bmatrix}.$$

It follows from (1) that

$$x = L^{-1} b = \prod_{k=m}^{1} P_k^{-1} b. \tag{4}$$

Thus, we may compute x as follows:

```
$x = b$;
for $k = 1$ to $m$ do
    $x = P_k^{-1} x$;
od;
```

1.1. Problems addressed. We say that the matrix X is *invertible in place* if $X_{ij} = 0 \Rightarrow (X^{-1})_{ij} = 0$. Elementary lower-triangular matrices are invertible in place. Thus every lower-triangular matrix has at least one partition (1) with factors that invert in place.

DEFINITION 1. A partition (1) in which the factors P_k are invertible in place is called a no-fill partition. A no-fill partition of L with the smallest possible number of factors is a *best no-fill partition.*

Let $G(L)$ be a digraph with vertices $V = \{1, 2, \ldots, n\}$ and directed edges $E = E(L) \equiv \{(j,i) \mid L_{ij} \neq 0\}$. Think of the edge (j,i) as an arrow going from vertex j to vertex i. If L is lower triangular, then for all edges (j,i) we have $i > j$. $G(L)$ is therefore an acyclic digraph.

Consider the matrix L with graph $G(L)$ illustrated in Fig. 1. L has a best no-fill partition

$$L = (L_1)(L_2)(L_3L_4)(L_5)(L_6L_7).$$

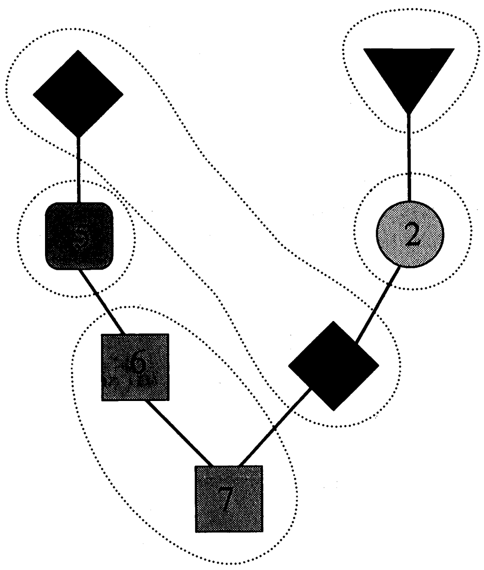

FIG. 1. *Best no-fill partition for a graph without reordering. Five factors are required.*

This partition has five factors. It is possible to symmetrically permute the rows and columns of L such that L remains lower triangular and $G(L)$ is as illustrated in Fig. 2. A best no-fill partition of this reordered L is

$$L = (L_1L_2)(L_3L_4)(L_5L_6L_7),$$

which has only three factors.

DEFINITION 2. A *best reordered partition* of L is a symmetric permutation of the rows and columns of L such that the permuted matrix is triangular and has a best no-fill partition with the fewest possible factors.

The aims of this work, and an outline of the paper, are as follows. First, we develop a theory of efficient algorithms for computing best no-fill and best reordered

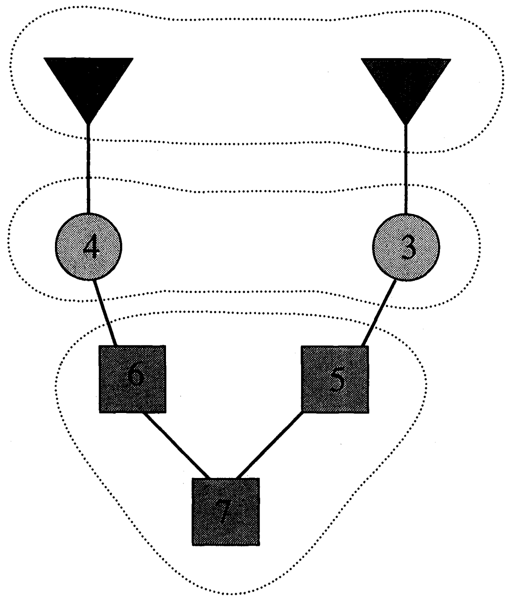

FIG. 2. *Best no-fill partition for a reordered graph. Only three factors are required.*

partitions. We give a proof of correctness for the procedure of Alvarado, Yu, and Betancourt for best no-fill partitioning in §2. In §3 we give an efficient procedure (and proof) for best reordered partitioning. Second, we determine how useful these ideas are in practice by means of some experiments (§4). Our conclusions are in §5.

We allow arbitrary lower-triangular matrices. Pothen and Alvarado [13] give a simplified version of our methods for the case of Cholesky factors (they exploit the fact that the graph of a Cholesky factor is chordal) that has $O(n)$ complexity.

Efficient methods for Cholesky factorization exploit cliques of vertices having the same adjacency, all of which are eliminated as a group; these vertex subsets are called supernodes [5]. It is possible to take advantage of the dense submatrices of L corresponding to supernodes in both substitution and partitioned inverse methods. Our results are stronger; all members of a supernode are included in the same factor in a best no-fill partition, but the converse is not true.

1.2. Terminology. A *topological ordering* of an acyclic digraph is a numbering of vertices in which $(j,i) \in E$ implies $j < i$. Every acyclic digraph has topological orderings. The digraph of every triangular matrix is acyclic; moreover, its conventional ordering is topological. If $G(L)$ is reordered so that vertex i is numbered $\alpha(i)$ and the new ordering is topological, then the symmetric permutation of rows and columns that moves row i to row $\alpha(i)$ leaves L triangular.

For $(j,i) \in E$ we say that j is a *predecessor* of i and i is a *successor* of j.

The *indegree* of a vertex i is the number of vertices j such that $(j,i) \in E$. The indegree of vertex i is the number of nonzeros in the ith row of L, which is the number of predecessors of i.

Let $G = G(L)$. For $j \in V$, madj(j) is the set of higher numbered neighbors of j, i.e., the set $\{i > j \mid L_{ij} \neq 0\}$. The set madj$(j)$ is the set of rows that are nonzero in the jth column of L, which is the set of successors of j.

The *transitive closure* of a digraph $G = (V, E)$ is the graph $G' = (V, E')$ where $E' = \{(j, i) \mid \text{there is a } j \to i \text{ path in } G\}$. The digraph $G = (V, E)$ is *transitively closed* if it is equal to its own transitive closure.

LEMMA 1 (Gilbert [9]). *If L is a nonsingular lower-triangular matrix, then $G(L^{-1})$ is the transitive closure of $G(L)$.*

DEFINITION 3. Let $G = G(L) = (V, E)$ be an acyclic digraph. Given a subset $S \subseteq V$, define the *column subgraph* $G_S = (V, E_S)$ (where $E_S \equiv \{(j, i) \in E | j \in S\}$); this is the graph of the lower-triangular matrix obtained by zeroing all columns of L not in S.

The proof of the following result follows immediately from Lemma 1.

THEOREM 2. *Let a partition* (3) *and corresponding factorization* (1) *be given. The factors P_k are invertible in place if and only if each column subgraph $G(P_k) = G_{\{e_{k-1}+1,\ldots,e_k\}}$ is transitively closed.*

We write $\eta(X)$ for the number of nonzeros in the matrix X.

2. Best no-fill partitioning.

The following algorithm was proposed by Alvarado, Yu, and Betancourt (who call it PA2) [3].

ALGORITHM P1.
Input: $L = L_1 L_2 \cdots L_n$.
Output: A best no-fill partition of L.

```
$i \leftarrow 1$;   $k \leftarrow 1$;
while ($i \leq n$) do
    (Find the largest integer $r \geq i$ such that $L_i \cdots L_r$ is invertible in place.)
    $r \leftarrow i$;
    while every successor of $r$ is a successor of all the predecessors of $r$ do
        $r \leftarrow r + 1$;
    od
    $P_k \leftarrow L_i \cdots L_r$;
    $k \leftarrow k + 1$;   $i \leftarrow r + 1$;
od
```

Alvarado, Yu, and Betancourt did not mention the issue of optimality. Here we show that Algorithm P1 determines a best no-fill partition.

LEMMA 3. *If $L_1 \cdots L_r$ is invertible in place, then $L_2 \cdots L_r$ is, too.*

Proof. The graph obtained by removing a source vertex and its incident edges from a transitively closed graph is transitively closed. The lemma thus follows from Lemma 1.

THEOREM 4. *Algorithm* P1 *produces a best no-fill partition of L.*

Proof. We use induction on the number of columns of L that are nonzero below the diagonal. The base of the induction is provided by the trivial case $L = I$. We assume that the result is true if the first column of L is zero below the diagonal, and then show it to be true for any lower-triangular matrix L.

Suppose that Algorithm P1 produces a partition $L = P_1 \cdots P_m$. Let $Q \equiv P_2 \cdots P_m$. Clearly, there does not exist a no-fill partition with e_1 any larger than that produced by Algorithm P1. Let $L = \hat{P}_1 \cdots \hat{P}_{m'}$ be a different no-fill partition. Suppose that $P_1 = \hat{P}_1$. By the inductive hypothesis, Algorithm P1, when applied to Q, produces a best no-fill partition, so at least $m - 1$ factors are required in any no-fill partition of Q. Thus $m' \geq m$.

On the other hand, perhaps $\hat{P}_1 = L_1 \cdots L_{e_1'}$ with $e_1' < e_1$, i.e., $\hat{P}_1$ has *fewer* nonzero columns than does P_1. The matrix $\hat{Q} \equiv \hat{P}_2 \cdots \hat{P}_{m'}$ has a no-fill partition with $(m' - 1)$ factors. By the previous lemma, we may remove the leftmost elementary lower-triangular factor of $\hat{Q}$ and still have an $m' - 1$ factor no-fill partition. Continuing in this way we find such a partition of Q. But by the inductive hypothesis, any no-fill partition of Q has at least $m - 1$ factors. Thus we again see that $m' \geq m$. □

Best no-fill partitions are not unique. For example,

$$L = \begin{bmatrix} x & & & \\ 0 & x & & \\ x & x & x & \\ 0 & x & x & x \end{bmatrix}$$

has best no-fill partitions

$$L = L_1(L_2L_3L_4)$$

and

$$L = (L_1L_2)(L_3L_4).$$

Let $G = (V, E)$ be an acyclic digraph. Define level$(i), i \in V$ to be the length of the longest path from a source vertex to vertex i. The computation of levels is straightforward, requiring $O(\eta(L))$ time. Any parallel implementation of a substitution method for solving $Lx = b$ requires at least as many parallel steps as there are levels in $G(L)$.

3. Best reordered partitioning.

This section describes two new algorithms for best reordered partitioning. Each algorithm finds a topological ordering of an acyclic digraph G such that the reordered graph has a best no-fill partition with the smallest possible number of factors. The first algorithm (RP1; see Fig. 3) is a straightforward but inefficient "greedy" algorithm. We present it in order to motivate a better algorithm, RP2.

Consider the following graph model of best reordered partitioning. Let $G = G(L) = (V, E)$. We seek a partition $V = \bigcup_{k=1}^{m} S_k$. We number the vertices within a subset S_k consecutively. We reorder rows and columns of L according to this vertex numbering, and then partition L as in (3). The factors P_k and the subsets S_k will correspond; that is, the columns of P_k that are nonzero below the diagonal will be those corresponding to the vertices in S_k. We call the subsets S_k in this partition *factors* in analogy with their corresponding factors P_k of L.

In order to have factors P_k that invert in place, we require that the column subgraphs G_{S_k} be transitively closed (Theorem 2). Second, in order for the new vertex ordering to be topological, we require that the partition of V be consistent with the partial order E: if $r > s$, then there is no edge in E from a member of S_r to a member of S_s. We produce the required topological ordering of $G(L)$ starting with a topological ordering of S_1, then of S_2, and so on.

```
ALGORITHM RP1 (Reorder, Permute 1).
Input: An acyclic digraph $G(L)$.
Output: A permutation $\alpha : V \longrightarrow \{1, \ldots, n\}$ and a partition of $L$.
Compute level$(v)$ for all $v \in V$;
```

```
max-level $\leftarrow \max_{v\in V}(\text{level}(v))$;
$i \leftarrow 0$;   $k \leftarrow 1$;   $e_0 \leftarrow 0$;
**while** $i < n$ **do**
    $S_k \leftarrow \emptyset$;   $e_k \leftarrow i$;
    $\ell \leftarrow \min\{j \mid$ there is an unnumbered vertex at level $j\}$;
    **repeat**
        **for** every vertex $v$ at level $\ell$ **do**
            **if** (([Condition 1] $v$ is unnumbered) **&&**
                ([Condition 2] Every predecessor of $v$ has been numbered) **&&**
                ([Condition 3] Every successor of $v$ is a successor of all
                      $u \in S_k$ such that $u$ is a predecessor of $v$)) **then**
                $i \leftarrow i+1$;   $\alpha(v) \leftarrow i$;
                $S_k \leftarrow S_k \cup \{v\}$;   $e_k \leftarrow e_k + 1$;
            **fi**
        **od**
        $\ell \leftarrow \ell + 1$;
    **until** $\ell >$ max-level or no vertices at level $\ell - 1$ were included in $S_k$;
    $P_k \leftarrow L_{e_{k-1}} \cdots L_{e_k}$;   $k \leftarrow k+1$;
**od**
```

Figure 3 illustrates the reason for Condition 3. Different node shapes are used to denote different factors. It is possible to combine nodes 1, 2, and 5 into the same factor according to Condition 3: all the successors of 5 are successors of the predecessors of 5. It is *not* possible, however, to combine node 6 into the same factors as nodes 3 and 4 because this rule is violated. Figure 4 illustrates a case where it would be possible to merge node 5 into S_1, along with nodes 2 and 3, without violating the requirement of transitive closure: Condition 3 is satisfied by 5. But, since one of the predecessors of 5 is not yet numbered when node 5 is considered, it cannot be included, since the resulting ordering would then fail to be topological. Condition 2 does not hold. Thus node 5 must be in a different factor.

THEOREM 5. *Algorithm* RP1 *finds a best-reordered partition.*

Proof. The proof is by induction, as is the proof of Theorem 4. Consider any permutation Γ and partition $L_\Gamma = \Gamma L \Gamma^T = \prod_{k=1}^{m} P_k$ with P_k defined by (2) and (3), and with P_k invertible in place. We claim that the partition point e_1 is no larger than that produced by RP1. For it follows from the construction of P_1 that any vertex of $G(L)$ not included in S_1 by RP1 either has an unnumbered predecessor, or else its inclusion renders G_{S_1} not transitively closed. Hence the subset S_1 selected by RP1 is maximal. Now, by the inductive hypothesis, RP1 partitions $G \setminus S_1$, using $m-1$ invertible-in-place factors. Moreover, by the argument used to prove Lemma 3, a graph obtained by adding source vertices to $G \setminus S_1$ requires at least $m-1$ factors in any optimal partition. Thus if we take a subset $\hat{S}_1$ of S_1 as the first factor, we can achieve nothing better. $\square$

We would like to ensure that running time is bounded by a small constant multiple of $\eta(L)$. But the running time of Algorithm RP1 is large in some cases. Consider a dense lower-triangular matrix of order n. RP1 takes $O(n^3)$ time in this case, since the cost of checking whether all successors of vertex j are also successors of its predecessors is $O(j(n-j))$.

We now introduce two new data structures in order to improve the efficiency of RP1. We can improve the performance of RP1 (to $O(n^2)$ for a dense matrix) by

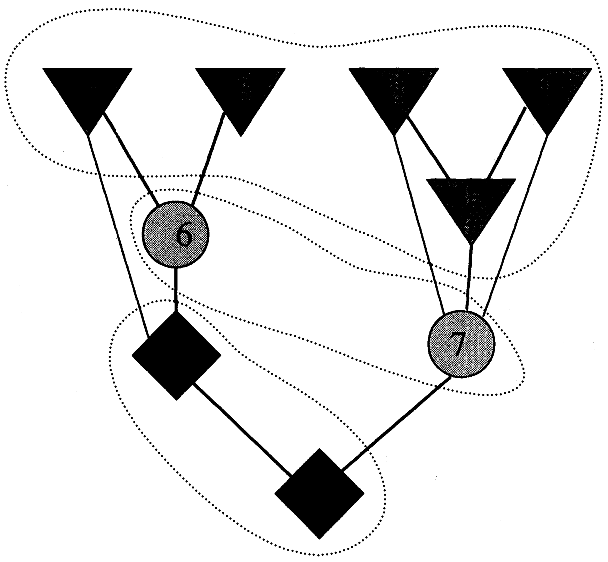

FIG. 3. *Illustration of Condition* 3. *Successors of predecessors of a node must be successors of the node itself. Node* 5 *can be included in the same factor as nodes* 1 *and* 2, *but node* 6 *cannot be included with* 3 *and* 4. *Factors are denoted by shapes and shading.*

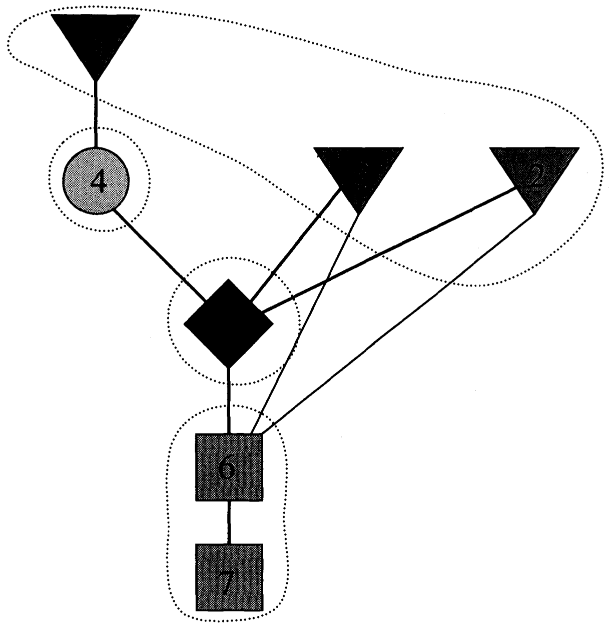

FIG. 4. *Illustration of Condition* 2. *A node must be excluded from a factor because some of its predecessors are not numbered. One predecessor of node* 5 *(node* 4*) has not been numbered by the time node* 5 *becomes eligible to join the factor containing nodes* 2 *and* 3.

ensuring that a vertex is not examined for possible inclusion in S_k until all of its predecessors have been numbered. To do so, for every vertex we count the number of its unnumbered predecessors. Initially, this is its indegree. When the count reaches zero we can consider the vertex for inclusion in a factor. This is a standard technique for finding topological orderings [11].

We can avoid much of the work associated with the checking at Condition 3 of RP1. Let u and v be numbered vertices, both of which have been included in the current factor S_k. Assume that v is a successor of u. Then we must have that $\text{madj}(v) \subseteq \text{madj}(u)$, otherwise v would have failed the test at Condition 3. Thus we need not consider vertex u when applying the requirements of Condition 3 to a vertex that is also a successor of v. We make use of this in the faster implementation (RP2; see Fig. 3) by keeping track of the set of predecessors of each vertex that may need to be examined in checking Condition 3. In the situations above, when v is included in S_k we remove u from the predecessor sets of v's successors, thus avoiding the unnecessary checking.

ALGORITHM RP2 (Reorder, Permute 2).
Input: An acyclic digraph $G(L)$.
Output: A permutation *and* a partition of L.

```
forall $v \in V$ do
    $\text{pred}(v) \leftarrow \{u \mid L_{vu} \neq 0\}$;
    $\text{count}(v) \leftarrow \text{indegree}(v)$;
    Compute $\text{level}(v)$;
od
$\text{max-level} \leftarrow \max_{v \in V}(\text{level}(v))$;
$i \leftarrow 0$;    $k \leftarrow 1$;    $e_0 \leftarrow 0$;
$E \leftarrow \{v \in V \mid \text{count}(v) = 0\}$;
while $i < n$ do
    $S_k \leftarrow \emptyset$;    $e_k \leftarrow i$;
    $\ell \leftarrow \min\{j \mid$ there is an unnumbered vertex at level $j\}$;
    repeat
        for every vertex $v \in E$ at level $\ell$ do
            if ([Condition 3′] Every successor of $v$ is a successor of all
                        $u \in \text{pred}(v)$) then
                $i \leftarrow i + 1$;    $\alpha(v) \leftarrow i$;
                $S_k \leftarrow S_k \cup \{v\}$;    $e_k \leftarrow e_k + 1$;
                for every successor $w$ of $v$ do
                    $\text{pred}(w) \leftarrow \text{pred}(w) \setminus \text{pred}(v)$;
                    $\text{count}(w) \leftarrow \text{count}(w) - 1$;
                    if $\text{count}(w) = 0$ then $E \leftarrow E \cup \{w\}$;  fi
                od
            fi
        od
        $\ell \leftarrow \ell + 1$;
    until $\ell >$ max-level or no vertices at level $\ell - 1$ were included in $S_k$;
    $P_k \leftarrow L_{e_{k-1}} \cdots L_{e_k}$;    $k \leftarrow k + 1$;
od
```

The computation of $\text{pred}(v)$ is straightforward, requiring $O(\eta(L))$ time. Clearly, the innermost loop of Algorithm RP2 is executed $\eta(L)$ times. For we have that the sum of count(v) over all vertices v is just $\eta(L)$, and this sum decreases by one for every execution of this innermost loop. The other statements in the scope of the **then** clause are executed no more than n times. It is still possible that testing Condition $3'$ will be costly. Indeed, we can construct examples for which the running time is greater than $\eta(L)$, but in practice this is unlikely to happen.[1]

4. Examples. This section gives several examples of the performance of the proposed algorithms. Several examples compare P1 and RP1 with respect to the number of factors in the partitions they find. We also examine the effect of the initial ordering of rows and columns of a matrix A on the number of factors in a best reordered partition of its Cholesky or incomplete Cholesky factor L. An experiment shows that on the Connection Machine, the solution process (4) can be faster than substitution by orders of magnitude. (The experiments and illustrations were done with the aid of Alvarado's Sparse Matrix Manipulation System [1].)

First, we compare Algorithms P1 and RP1. Table 1 uses five power system matrices ranging in size from 118 to 1993. Table 2 gives results for matrices arising from five-point finite difference discretizations.

TABLE 1

In each case, the original coefficient matrix is first ordered, then the structure of its Cholesky factor L is found. We need to distinguish this first fill-reducing ordering of A from the reordering of L found by RP1. We call the ordering of A the primary ordering. Three primary ordering procedures are used: the minimum degree algorithm [14], the multiple minimum degree (MMD) algorithm [12], and the minimum level, minimum degree (MLMD) algorithm [6].

[1] Consider a graph with $3k$ vertices arranged in three levels of k each. All vertices at level ℓ are adjacent to all at level $\ell + 1$, for $\ell = 1, 2$. Running time is $O(\eta(L)^{3/2})$ again.

For each matrix and primary ordering algorithm, two partitioning methods are compared: Algorithm P1, which simply partitions L optimally without reordering it, and Algorithm RP1 which reorders the matrix and generates an optimal partition. In most cases, Algorithm RP1 gives a smaller number of factors than PA1, while in a few cases both algorithms give the same number of factors.

We observe that RP1 reduces the number of factors at no expense in added fills. Its effect is most dramatic if the underlying primary ordering is the minimum degree algorithm. On the other hand, the best results are obtained when the MLMD algorithm is used for the primary ordering, even though the relative improvement attainable by Algorithm RP1 over Algorithm P1 is small. The results for the MMD algorithm fall somewhere between minimum degree and MLMD. The reduction in the number of factors achieved by RP1 in comparison with P1 is quite dramatic when MMD is the primary ordering. (MLMD tends to produce more fill than MMD, so the question of which is preferable is not simple.)

Figures 5 and 6 provide a different illustration of the effect of primary ordering on matrix structure and partitioning. The matrix L is the Cholesky factor for a 10×10 finite difference grid.

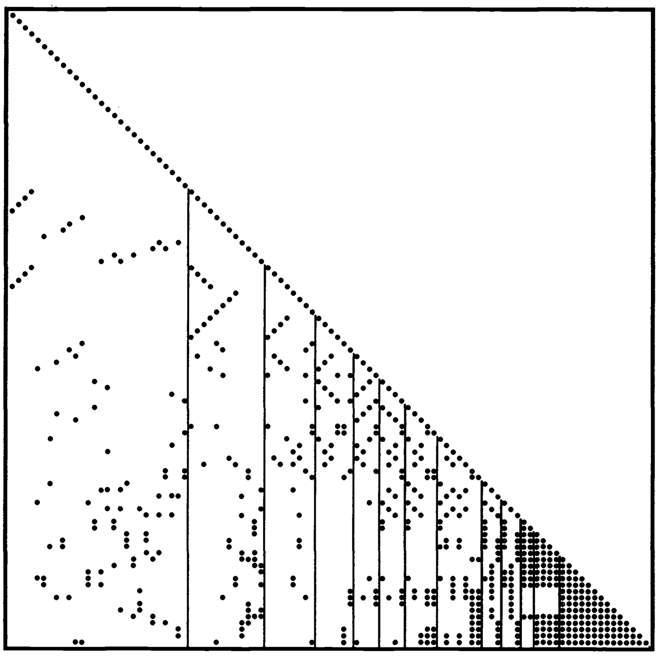

FIG. 5. *Five-point finite difference matrix for* 10 *by* 10 *grid. Matrix ordered by the minimum degree algorithm, then reordered and partitioned by* RP1. *Thirteen factors result.*

The second experiment we report compares the solution procedure (4) with a data-parallel forward substitution method on the Connection Machine model CM-2, a highly parallel single instruction multiple data (SIMD) computer.

An efficient, parallel substitution algorithm is implemented in CM Fortran, a dialect of Fortran 90.

The data structure consists of several arrays of length equal to $\eta(L)$. We associate, at least conceptually, a set of $\eta(L)$ virtual processors, one with each position in these

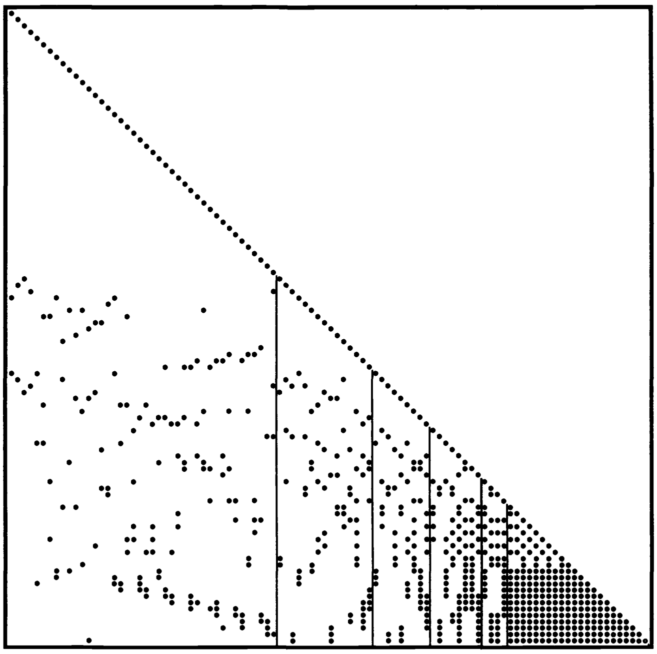

FIG. 6. *Five-point finite difference matrix for* 10 *by* 10 *grid. Matrix ordered by* MLMD, *then reordered and partitioned by* RP1. *Six factors result.*

arrays. We choose to store the factors $\hat{L}$ and D where $L = \hat{L}D$ and $\hat{L}$ is unit triangular, and solve $Lx = b$ via $\hat{L}x = D^{-1}b$, since this removes a multiplication from the inner loop. The matrix $\hat{L}$ is stored as a one-dimensional array containing its nonzeros in column-major order. In addition, the level of vertex j in $G(L)$ is stored along with $\hat{L}_{ij}$. The elements of b are stored at the processors containing the diagonal of $\hat{L}$. The solution x overwrites b. Finally, a boolean vector indicates the location of the diagonal elements in the arrays. This vector thus segments the arrays into columns of differing lengths; in other words, the matrix is stored as a ragged array of columns of nonzeros. The Connection Machine software provides some operations for such data structures. It allows broadcast of values from diagonal elements to all elements of the corresponding column (called a segmented copy scan) and summation of the values in a column (with a segmented add scan). Also, the Connection Machine router allows processors to send data to any other processor or read from any other processor; this is expressed using a vector-valued subscript in CM Fortran. Calls to utility library routines were used for the scan operations, which are not part of CM Fortran.

The algorithm loops sequentially over levels of $G(L)$, starting with the sources (level zero). At the beginning of step ℓ, those elements x_j for which level$(j) = \ell$ are known. Recall that x_j is stored in the processor holding $\hat{L}_{jj}$. These known values of x are sent to the processors holding the corresponding column of $\hat{L}$ by a segmented copy scan. These processors then multiply their $\hat{L}$ value by the element of x they receive. The router is then used to permute all these products into row-major order, so that the elements of each set $R_i \equiv \{\hat{L}_{ij}x_j \mid L_{ij} \neq 0 \text{ and level } (j) = \ell\}$ are stored in consecutive locations. The vector-valued subscript used to accomplish this permutation is computed in a preprocessing step. The rows R_i are now a ragged array. A segmented add scan forms the sums of these partial results within rows. Finally, the router is used to send the sum of the elements of R_i to the processor holding $\hat{L}_{ii}$ and b_i where it can be subtracted from b_i. (In fact, our code avoids this last subtraction entirely, doing it as part of the add scan above.)

Thus, an iteration of the loop involves one parallel multiplication, one copy scan and one add scan, and two uses of the router for permutation of data. The time required to set up and load the data structure, including the computation of the permutation used, the loading of b, and the extraction of x, was not timed.

The sequential algorithm for solving a triangular system looks nearly identical to the code for matrix–vector products with a triangular matrix. Thus it may come as no surprise that our partitioned solution method in CM Fortran is nearly identical to our substitution method. The inner loop involves the same operations. But the number of executions of the loop is equal to the number of factors in the partition of L rather than the number of levels in its graph.

We report the CM performance of these two methods for an $n \times n$, dense, unit lower-triangular matrix L. Our results are obtained with CM Fortran in the "slicewise" execution model, which treats each Weitek chip of the CM-2 as a processor. For this experiment we used 256 Weitek processors on the Connection Machine at NASA Ames. Results are given in Table 3. Clearly, the partitioned method is superior, by a factor roughly equal to the ratio of the number of levels in $G(L)$ (n) to the number of factors (one) in the partition of L.

TABLE 3
CM-2 *times for full matrix substitution and partitioned solution.*

n	Nonzeros	Levels in $G(L)$	Substitution time	Factors	Partitioned soln. time
256	32,896	256	7.34 secs	1	0.04 secs
512	131,328	512	50.22 secs	1	0.21 secs

Next, we performed an experiment using several large, sparse, unit lower-triangular matrices. We begin with a sparse matrix A of order 4037, obtained from a triangular mesh in the region around a three-element airfoil. Three matrices L_1, L_2, and L_3 are obtained by approximate factorization.

L_1 is obtained by an incomplete LU factorization of A; we carry out the Gaussian elimination process, but we allow nonzeros in L (and U) only where there is a nonzero in A^2. The ordering of A is obtained from a lexicographic sort of the (x, y) coordinates of the grid which leads to the matrix; this ordering produces a large number of levels in $G(L)$.

L_2 is the incomplete LU factor obtained when a variant of MLMD is used as the primary ordering of A.

L_3 is the exact lower-triangular factor of A, with the same primary ordering as for L_2.

In Table 4 we give the size of these factors, the number of levels, which is proportional to the time required for our parallel substitution algorithm, and the number of partitions, which is in practice proportional to the time required by the partitioned solution algorithm (4).

These results confirm that the time required to solve a triangular system by partitioning of the inverse is quite well predicted by the number of factors in the partition. It has also shown that the number of levels in $G(L)$ is also a good predictor

TABLE 4
CM-2 *times for sparse triangular substitution and partitioned solution.*

Matrix	Ordering	Factorization	Nonzeros	Levels in $G(L)$	Substitution time	Factors	Partitioned soln. time
L_1	RCM	ILU	23,526	823	19.22 secs	816	11.66 secs
L_2	MLMD	ILU	26,793	78	1.38 secs	66	1.20 secs
L_3	MLMD	exact	118,504	311	16.78 secs	16	0.87 secs

of the time required for solution by substitution methods. We see that when L has a fairly rich structure there is a great advantage to the use of the partitioned method, but when L is very sparse there is little gained. The use of an MLMD primary ordering improves both substitution and partitioned methods. However, with the introduction of the additional fill in the exact factor L_3 (compared with L_2), the number of levels in $G(L)$ increases sharply (as does the time for substitution) while the number of factors in the best reordered partition drops dramatically. The difference in the solution time, even for this problem of modest size, is about a factor of twenty. Thus we conclude that the method can be quite useful in highly parallel machines when the matrix L has a rich enough structure, as happens when it is an exact triangular factor.

5. Conclusions. An algorithm for no-fill partitioning of lower-triangular matrices with the fewest possible factors has been presented and proven to be optimal.

We have done a number of experiments with the Cholesky factors of sparse matrices, A. The structure of these factors is influenced by the ordering of rows and columns of A. (This ordering is chosen to reduce fills during the factorization process.) This primary ordering also influences the benefits attainable by the proposed algorithm. If L is constructed with the minimum degree algorithm, the best no-fill partition of L (without a change of ordering) tends to have many more factors than the best reordered partition developed here. This number can be further reduced if an MLMD primary ordering is used.

An experiment on the Connection Machine has shown that solution time is roughly proportional, for fixed nonzero count, to either the number of factors or the number of levels in $G(L)$. Finally, we have seen that for Cholesky factors, a best reordered partition can have far fewer factors than there are levels, so that the method is highly valuable. We conjecture that for sufficiently filled incomplete factors there will be some benefit as well, although for very sparse incomplete factors the improvement is quite modest.

A FLEXIBLE INNER-OUTER PRECONDITIONED GMRES ALGORITHM*

YOUCEF SAAD†

Abstract. A variant of the GMRES algorithm is presented that allows changes in the preconditioning at every step. There are many possible applications of the new algorithm, some of which are briefly discussed. In particular, a result of the flexibility of the new variant is that any iterative method can be used as a preconditioner. For example, the standard GMRES algorithm itself can be used as a preconditioner, as can CGNR (or CGNE), the conjugate gradient method applied to the normal equations. However, the more appealing utilization of the method is in conjunction with relaxation techniques, possibly multilevel techniques. The possibility of changing preconditioners may be exploited to develop efficient iterative methods and to enhance robustness. A few numerical experiments are reported to illustrate this fact.

Key words. Krylov subspace methods, GMRES, non-Hermitian systems, preconditioned conjugate gradient, variable preconditioners

AMS(MOS) subject classification. 65F10

1. Introduction.

Krylov subspace techniques have increasingly been viewed as general-purpose iterative methods, especially since the popularization of preconditioning techniques [2] in the mid-seventies. Although iterative methods lack the robustness of direct methods, they are effective for the large class of problems arising from partial differential equations of the elliptic type. An important gap in the literature concerns the development of truly general-purpose iterative solvers that could replace direct methods with a minimum risk of failure. A comparison between existing software based on direct methods and software based on iterative methods reveals that the direct solvers have evolved quite differently and have acquired a level of sophistication that far exceeds that of iterative methods.

In order to be able to enhance robustness of iterative solvers, we should be able to determine, e.g., by means of heuristics, whether or not a given preconditioner is suitable for the problem at hand. If not, one can attempt another possible iterative method/preconditioner and switch periodically if necessary. It is desirable to be able to switch within the outer iteration instead of restarting. For the GMRES algorithm [5], this can be accomplished with the help of a rather simple modification of the standard algorithm, referred to as the flexible GMRES (FGMRES), which is presented in this paper. An important property of FGMRES is that it satisfies the residual norm minimization property over the preconditioned Krylov subspace just as in the standard GMRES algorithm [5].

For motivation, we mention that there are cases in which relaxation-type preconditioners are more attractive than the usual ILU preconditioners. These include the case in which a red-black ordering is used. In this situation, the single-step SSOR preconditioner and the ILU preconditioning may perform very poorly. However, our experience is that if a higher level-of-fill ILU or a multiple-step SSOR (or SOR) preconditioner is used, then the preconditioned method can perform rather well [4]. In this situation, SOR and SSOR have a distinct advantage over the ILU-type preconditioners, in that they preserve their high degree of parallelism, which is of order N.

* Received by the editors November 6, 1991; accepted for publication (in revised form) April 3, 1992.

† Computer Science Department and Minnesota Supercomputer Institute, University of Minnesota, 200 Union Street S.E., Minneapolis, Minnesota 55455.

In contrast, a serious loss of parallelism is incurred for the incomplete factorization preconditioners with high level-of-fill. A few other advantages are discussed in [4]. Thus we wish to be able to apply an arbitrary number of SOR or SSOR steps in the preconditioning phase, for example, in order to solve the preconditioning system $My = v$ to a given tolerance. We may also wish to change the relaxation parameter ω, possibly at each GMRES step, in order to attempt to achieve optimality.

The FGMRES algorithm presented in this paper allows us to incorporate these changes in the preconditioner into the GMRES framework at little additional cost. To be precise, there is no additional cost incurred in the arithmetic but the memory requirement doubles. On the other hand, FGMRES may enable one to utilize the memory more efficiently since the vectors that are normally not being used in a given FGMRES step can be fully exploited to compute a preconditioned vector, e.g., via another GMRES run that uses these vectors. A few tests based on this approach will be presented in §3. We will present some applications of the technique to show how the method can be used to improve the robustness of the standard GMRES algorithm. We should point out that another illustration of the benefits of FGMRES in the finite element framework is described by Tezduyar, Behr, Abadi, and Ray [6].

2. Krylov subspaces with variable preconditioning. The basic principle of preconditionings is to use a Krylov subspace method for solving a modified system such as

$$AM^{-1}(Mx) = b.$$

Clearly, the matrix AM^{-1} need not be formed explicitly: we only need to solve $Mz = v$ whenever such an operation is required. Thus a fundamental requirement is that it should be easy to compute $M^{-1}v$ for an arbitrary vector v. In some cases, solving a linear system with the matrix M consists of forming an approximate solution by performing one or a few steps of a relaxation-type method, or a Chebyshev iteration. It is natural to consider preconditioners that do not use only a single step of an iterative method, but as many as are needed to solve a linear system within a given tolerance. In fact, this would be the equivalent of a higher level-of-fill in the usual ILU preconditioners, except that the preconditioner is no longer constant but is allowed to vary from one step to another in the outer iteration. A similar situation in which the preconditioner is "not constant" is when another Krylov subspace method, e.g., one that is based on the normal equations approach, is used as a preconditioner. These applications and others lead us to raise the question of whether or not it is possible to accommodate such *variations in the preconditioners* and still obtain an algorithm that satisfies an optimality property similar to the one satisfied by the original iterative method. This question has been avoided in the past because in the Hermitian case there does not seem to exist a version of the usual preconditioned conjugate gradient algorithm that satisfies a short vector recurrence and that allows the preconditioner to vary at each step. In the non-Hermitian case and for methods that do not rely on short vector recurrences, such as GMRES, variations in the preconditioner can be handled without difficulty, as we now show.

2.1. The algorithm. We start by describing the standard GMRES algorithm with right preconditioning and then show the flexible modification which allows such variations.

ALGORITHM 2.1. GMRES with right preconditioning.

```
1. Start: Choose $x_0$ and a dimension $m$ of the Krylov subspaces. Define an
   $(m+1) \times m$ matrix $\bar{H}_m$ and initialize all its entries $h_{i,j}$ to zero.
2. Arnoldi process:
   (a) Compute $r_0 = b - Ax_0$, $\beta = \|r_0\|_2$, and $v_1 = r_0/\beta$.
   (b) For $j = 1, \dots, m$ do
       • Compute $z_j := M^{-1}v_j$;
       • Compute $w := Az_j$;
       • For $i = 1, \dots, j$, do  $\left\{ \begin{array}{l} h_{i,j} := (w, v_i), \\ w := w - h_{i,j}v_i; \end{array} \right.$
       • Compute $h_{j+1,j} = \|w\|_2$ and $v_{j+1} = w/h_{j+1,j}$.
   (c) Define $V_m := [v_1, \dots, v_m]$.
3. Form the approximate solution: Compute $x_m = x_0 + M^{-1}V_m y_m$ where
   $y_m = \text{argmin}_y \|\beta e_1 - \bar{H}_m y\|_2$ and $e_1 = [1, 0, \dots, 0]^T$.
4. Restart: If satisfied stop, else set $x_0 \leftarrow x_m$ and goto 2.
```

The Arnoldi loop simply constructs an orthogonal basis of the preconditioned Krylov subspace

$$\text{Span}\{r_0, AM^{-1}r_0, \dots, (AM^{-1})^{m-1}r_0\}$$

by a modified Gram–Schmidt process, in which the new vector to be orthogonalized is obtained from the previous vector process. The last step in the above algorithm forms the solution as a linear combination of the preconditioned vectors $z_i = M^{-1}v_i, i = 1, \dots, m$. Because these vectors are all obtained by applying the same preconditioning matrix M^{-1} to the v's, we need not save them. We only need to apply M^{-1} to the linear combination of the $v's$, i.e., to $V_m y_m$. The question we can now ask is: what if we allowed the preconditioner to change at every step, i.e., z_j would be defined by

$$z_j = M_j^{-1} v_j,$$

but we saved these vectors to use them in updating x_m in step 3? In other words, we would like to consider the following "flexible" modification to the previous algorithm.

ALGORITHM 2.2. FGMRES: GMRES with variable preconditioning.

```
1. Start: Choose $x_0$ and a dimension $m$ of the Krylov subspaces. Define an
   $(m+1) \times m$ matrix $\bar{H}_m$ and initialize all its entries $h_{i,j}$ to zero.
2. Arnoldi process:
   (a) Compute $r_0 = b - Ax_0$, $\beta = \|r_0\|_2$, and $v_1 = r_0/\beta$.
   (b) For $j = 1, \dots, m$, do
       • Compute $z_j := M_j^{-1}v_j$;
       • Compute $w := Az_j$;
       • For $i = 1, \dots, j$, do  $\left\{ \begin{array}{l} h_{i,j} := (w, v_i), \\ w := w - h_{i,j}v_i; \end{array} \right.$
       • Compute $h_{j+1,j} = \|w\|_2$ and $v_{j+1} = w/h_{j+1,j}$.
   (c) Define $Z_m := [z_1, \dots, z_m]$.
3. Form the approximate solution: Compute $x_m = x_0 + Z_m y_m$ where $y_m =$
   $\text{argmin}_y \|\beta e_1 - \bar{H}_m y\|_2$ and $e_1 = [1, 0, \dots, 0]^T$.
4. Restart: If satisfied stop, else set $x_0 \leftarrow x_m$ and goto 2.
```

As can be observed, the only difference from the standard version is that we now save the preconditioned vectors z_i and update the solution using these vectors. It is clear that when $M_j = M$ for $j = 1, \ldots, m$, then the new method is mathematically equivalent to Algorithm 2.2. Note that we can define z_j in step 2(b) without reference to any preconditioner, i.e., we can simply pick a given new vector z_j. We would like to mention that the technique presented above can be viewed as an extension of a strategy presented in [1] in the context of using Krylov subspace methods for solving nonlinear equations. More recently, van der Vorst and Vuik developed a family of algorithms that have the same feature as FGMRES in that they also allow variations in the preconditioner [7].

2.2. Some basic properties. One notable difference between FGMRES and the usual GMRES algorithm is that the action of AM_j^{-1} on a vector v of the Krylov subspace is no longer in the span of V_{m+1}. Instead, it is easy to show that the following equality takes place:

$$AZ_m = V_{m+1}\bar{H}_m \ . \tag{1}$$

This replaces the simpler relation

$$(AM^{-1})V_m = V_{m+1}\ \bar{H}_m,$$

which holds for the standard preconditioned GMRES [5]. Following [5] we will denote by H_m the $m \times m$ matrix obtained from $\bar{H}_m$ by deleting its last row and by $\hat{v}_{j+1}$ the vector w obtained at the end of step 2(b) of the algorithm, i.e., the vector obtained before normalizing w to get v_{j+1}. Then an alternative to (1) that is valid even when $h_{m+1,m} = 0$ is the following:

$$AZ_m = V_m H_m + \hat{v}_{m+1} e_m^T \ . \tag{2}$$

We will now prove an optimality property similar to the one that defines GMRES. Consider the residual vector for an arbitrary vector $z = x_0 + Z_m y$ in the affine space $x_0 + \text{span}\{Z_m\}$. We have

$$\begin{aligned} b - Az &= b - A(x_0 + Z_m y) \\ &= r_0 - AZ_m y \qquad (3) \\ &= \beta v_1 - V_{m+1}\bar{H}_m y \\ &= V_{m+1}[\beta e_1 - \bar{H}_m y]. \qquad (4) \end{aligned}$$

If we denote by $J_m(y)$ the function

$$J_m(y) = \|b - A[x_0 + Z_m y]\|_2,$$

we observe that by (4) and the fact that V_{m+1} is unitary,

$$J_m(y) = \|\beta e_1 - \bar{H}_m y\|_2. \tag{5}$$

Since step 3 of Algorithm 2.2 minimizes this norm over all vectors y in R^m to yield y_m, it is clear that the approximate solution $x_m = x_0 + Z_m y_m$ has the smallest residual norm in $x_0 + \text{Span}\{Z_m\}$. Thus we have proved the following result.

PROPOSITION 2.1. *The approximate solution x_m obtained at step m minimizes the residual norm $\|b - Ax_m\|_2$ over $x_0 + \text{Span}\{Z_m\}$.*

We will now examine a case of breakdown in FGMRES, which occurs when $h_{j+1,j} = 0$ in the last part of step 3 in Algorithm 2.2. In this situation, the vector v_{j+1} cannot be computed and the algorithm breaks down. For the standard GMRES algorithm this is not a problem because when this breakdown occurs, then the approximate solution x_j is exact. In fact, breakdown is equivalent to convergence. In FGMRES this is no longer true. More specifically, we have the following result.

PROPOSITION 2.2. *Assume that $\beta = \|r_0\|_2 \neq 0$ and that $j-1$ steps of* FGMRES *have been successfully performed, i.e., that $h_{i+1,i} \neq 0$ for $i < j$. In addition, assume that the matrix H_j is nonsingular. Then x_j is exact if and only if $h_{j+1,j} = 0$.*

Proof. If $h_{j+1,j} = 0$, then we have the relation $AZ_j = H_j V_j$, and as a result,

$$J_j(y) = \|\beta v_1 - AZ_j y_j\|_2 = \|\beta v_1 - V_j H_j y_j\|_2 = \|\beta e_1 - H_j y_j\|_2.$$

If we assume that H_j is nonsingular, then the above function is minimized for $y_j = H_j^{-1}(\beta e_1)$ and the corresponding minimum norm reached is zero, i.e., x_j is exact.

Conversely, if x_j is exact, then from (2) and (3) we have

$$0 = b - Ax_j = V_j[\beta_1 e_1 - H_j y_j] + \hat{v}_{j+1} e_j^T y_j. \tag{6}$$

If the last component of y_j is zero, then (6) would mean that $H_j y_j = \beta e_1$ and, since $h_{i+1,i} \neq 0$ for $1 \leq i \leq j-1$, a simple back-substitution starting from the last equation will show that all components of y_j are zero. This would imply that $\beta = 0$ and contradict the assumption. Hence $e_j^T y_j \neq 0$. Therefore, since $\hat{v}_{j+1}$ is orthogonal to $v_1, \ldots, v_j$ the only way in which (6) can hold is that $\beta_1 e_1 - H_j y_j = 0$ and $\hat{v}_{j+1} = 0$, which implies $h_{j+1,j} = 0$. □

Note that the only difference between this result and the one in [5] concerning the standard GMRES algorithm is that we must make the additional assumption that H_j is nonsingular since this is no longer implied by the nonsingularity of A.

A consequence of the result is that if at a given step j, we have $Az_j = v_j$, i.e., if the preconditioning is "exact" at step j, then the approximation x_j will be exact if in addition H_j is nonsingular. This is because $w = Az_j$ is linearly dependent on previous v_i's (it is equal to v_j), and as a result we will obtain $\hat{v}_{j+1} = 0$ after the orthogonalization process.

A difficulty with the theory of the new algorithm is that we cannot prove general convergence results such as those in [5]. This is because the subspace of approximants is no longer a standard Krylov subspace and we have no isomorphism with the space of polynomials. However, the optimality property of Proposition 2.1 can be exploited in some specific situations. For example, if within each outer iteration we select *at least one* of the vectors z_j to be a steepest descent direction vector, e.g., for the function $F(x) = \|b - Ax\|_2^2$, then FGMRES is guaranteed to converge, independently of m.

2.3. Practical considerations and applications. The additional cost incurred by the flexible variant over the standard algorithm is only in the extra memory required to save the set of vectors $\{z_j\}_{j=1,\ldots,m}$. On the other hand, the added advantage of *flexibility* may certainly be worth this extra cost. There are a few applications in which this flexibility can be quite helpful, especially in the context of developing robust iterative methods or for developing preconditioners for massively parallel computers. Here is a sample of possible applications.

1. Use of *any* iterative techniques as preconditioners: block-SOR, SSOR, ADI, multigrid, etc., but also GMRES, CGNR, CGS, etc.

2. Use of chaotic relaxation-type preconditioners (e.g., in a parallel computing environment).

3. Mixing preconditioners to solve a given problem.

For an example of (3), see the recent work by Tezduyar, Behr, Adadi, and Ray [6], in which two types of preconditioners are alternately applied at each FGMRES step to mix the effects of "local" and "global" interactions. Tezduyar et al. reported good performance with this procedure, much better than using either of the two preconditioners by itself.

Note that any iterative method can now be used as a preconditioner. For example, we will show how to make some nonnegligible improvements to the performance of the basic GMRES algorithm by using GMRES as preconditioner to itself (using for memory space the unused vectors at the ith step of FGMRES(m)).

Preconditioners of particular interest within this framework are relaxation-type techniques. As an example, the SSOR preconditioning matrix defined by

$$M_{\text{SSOR}}(A) = (D - \omega E)D^{-1}(D - \omega F),$$

in which $-E$ is the strict lower part of A, $-F$ is the strict upper part of A, and D is the diagonal of A, has some important advantages, some of which have been briefly discussed in the introduction. In the context of preconditioning, it is customary to just take $\omega = 1$, as the gains from selecting an optimal ω are typically small. However, it is clear that one can use different values of ω at each step of FGMRES and this can open up the possibility of using heuristics to determine the best ω dynamically, by simply monitoring convergence. Alternatively, a mixture of ω's can be initially selected and then used cyclically, instead of arbitrarily taking only $\omega = 1$ as is usually done. We would also like to make an important point concerning SOR as a preconditioner. The usual one-step SOR is not popular as a preconditioner, mainly because it tends to distribute the eigenvalues of the preconditioned matrix around a circle (e.g., for the model problem). This is not very desirable for a CG-type solver. However, we found that when using multiple steps, SOR is often more economical than SSOR as a preconditioner.

We will not discuss these applications here but refer the reader to [4]. Rather, we would like to demonstrate the flexibility of FGMRES by simply combining it with other iterative methods to improve its robustness. We are particularly interested in combinations with CGNR, and with the standard GMRES itself. The reason why we chose CGNR is that we know that the method is globally convergent and as a result, adding one direction vector to the standard Krylov subspace will guarantee global convergence because of the optimality of FGMRES. We should add, however, that guaranteeing global convergence is not the ultimate goal, since the convergence can still be too slow to be of any practical value.

3. Numerical experiments.

For test purposes we consider the problems arising from the centered difference discretization of problems of the form

$$-\Delta u + \gamma(xu_x + yu_y) + \beta u = f \tag{7}$$

on square regions with zero Dirichlet boundary conditions. In our first test we select the parameters $\gamma = 10$ and $\beta = -100$ to make the problem indefinite. The grid consists of a square of 32 internal mesh points in each direction leading to a matrix of size $N = 1024$. The right-hand side is selected once the matrix is constructed so that the solution is known to be $x = (1, 1, \dots, 1)^T$. In all methods the initial vector is chosen so that its ith component for $i = 1, \dots, n$ is defined by $x_0(i) = i$. We have compared the following methods.

1. A standard ILU(0) preconditioned GMRES(m) iteration with $m = 20$ direction vectors.

2. The CGNR iteration (conjugate gradient, normal equations) using an ILQ preconditioner with level-of-fill equal to 5; see [3] for details on these preconditioners. The idea of ILQ is to perform an incomplete Gram–Schmidt factorization on the rows of A. The normal equations are preconditioned using this factorization and the conjugate gradient method (CGNR version) is used to solve these equations.

3. The FGMRES iteration using (the unpreconditioned) GMRES itself as a preconditioner. As was briefly mentioned in the introduction, this is run as follows. We observe that at step i of the FGMRES iteration, the space for the vectors $v_{i+2}, \ldots, v_{m+1}$ and $z_k, k = i+1, \ldots, m$ is unused. However, they can be exploited to generate a preconditioned version of v_i by running a standard GMRES iteration using $2m - i - 1$ direction vectors. In fact, the vectors v_j and z_j occupy the same array $wk(1:n, 1:2m)$ and the z_k's are stored backwards starting in column $2m$ to avoid collisions. Note that for fairness in the comparisons, we use here $m = 10$ so that the total number of vectors needed is $2m = 20$, the same as is required for the ILU(0)-GMRES in 1.

4. The FGMRES iteration using ILU(0)-GMRES as a preconditioner. This is similar to the previous method except that the method used to precondition is ILU(0)-GMRES instead of the unpreconditioned GMRES.

5. The FGMRES iteration using k steps of the unpreconditioned CGNR iteration as a preconditioner. In our first test we took $k = 5$ and in the second, $k = 2$. Other values of k have also been tested and performed similarly.

Figure 1 is a plot of the residual norm achieved by these five methods against the number of operations (in millions) required to reach that level for the first test problem. We chose to plot the residuals versus the number of operations because the number of iterations is no longer significant for making comparisons since the cost of each iteration can be quite different for each of the methods compared. Observe that the FGMRES iteration using the unpreconditioned GMRES (method 3) converges, although slowly, whereas the standard GMRES(20) (not shown) as well as the ILU(0) preconditioned GMRES(20) both stagnate. More interesting is the convergence of FGMRES with ILU(0)-GMRES as a preconditioner. ILU(0)-GMRES(20) alone fails to converge (stopped after 700 steps). Used as a preconditioner, the technique converges in 15 outer iterations and yields the second best performance in this test. In this test CGNRILQ(5) performed quite well.

In our second test we took the same partial differential equation as before, but with the parameters $\gamma = 1000$ and $\beta = 10.0$, to make the problem highly nonsymmetric. The grid is the same as before and so the size of the matrix is still 1024. The right-hand side and the starting vector are generated similarly to the previous example. We have run the same methods as before, except that the number of CGNR steps used in FGMRES-CGNR is two instead of five. The results are shown in Fig. 2. Note that this time, CGNR-ILQ does not perform as well. In fact, some of the conclusions of the previous test are reversed. Thus, FGMRES-ILU(0)-GMRES is now outperformed by the simpler ILU(0)-GMRES(20). The FGMRES with unpreconditioned GMRES outperforms the FGMRES with ILU(0)-preconditioned GMRES by a slight margin. In addition, FGMRES with CGNR preconditioner using just two steps of CGNR is now the overall best.

4. Conclusion.

An interesting observation from the above experiments is that for indefinite and/or highly nonsymmetric matrices the performance of a given precon-

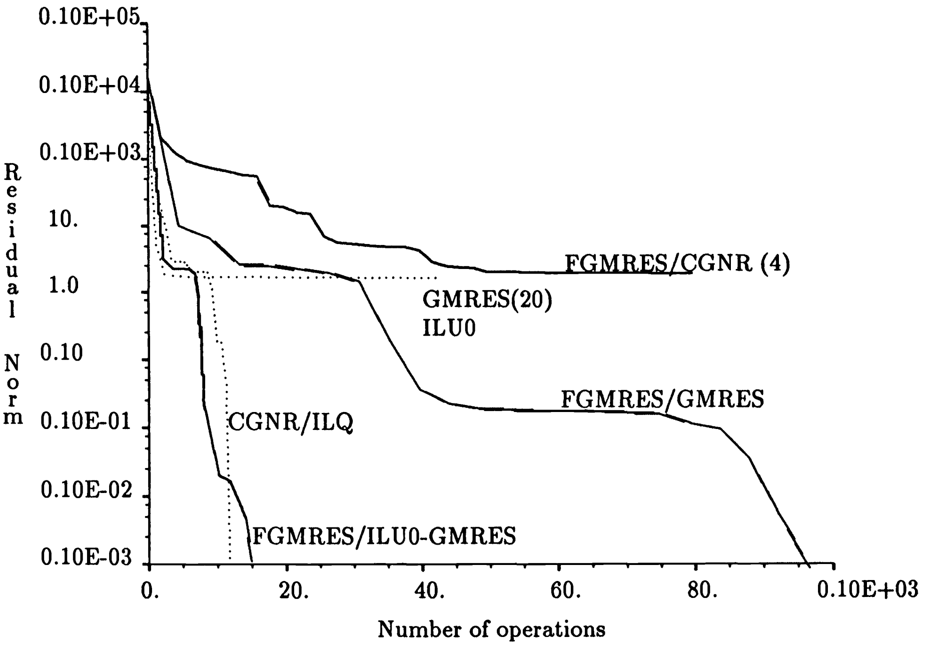

FIG. 1. *Performance of different iterative methods for first test problem.*

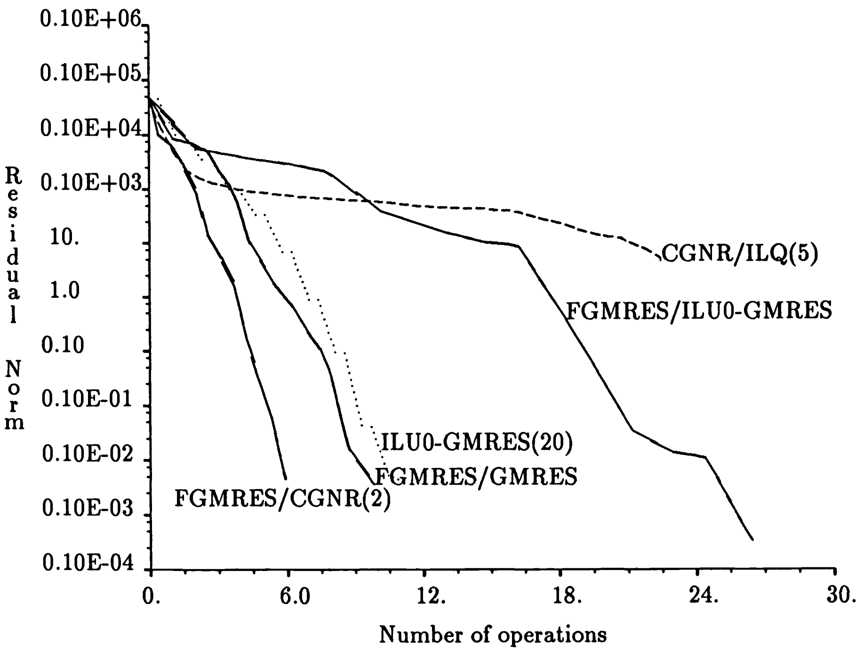

FIG. 2. *Performance of different iterative methods for second test problem.*

ditioner can be unpredictable. In these situations, it is essential to be able to switch preconditioners in order to improve robustness. FGMRES is an algorithm that allows arbitrary changes in the preconditioner and can be used to this end. There are many other uses of the flexible variant of GMRES. In addition, the difference in the coding of the two methods is so small that they can both be implemented, with no loss of efficiency, in a single subroutine that incorporates an option parameter.

Abstract. The biconjugate gradient method (BCG) for solving general non-Hermitian linear systems $Ax = b$ and its transpose-free variant, the conjugate gradients squared algorithm (CGS), both typically exhibit a rather irregular convergence behavior with wild oscillations in the residual norm. Recently, Freund and Nachtigal proposed a BCG-like approach, the quasi-minimal residual method (QMR), that remedies this problem for BCG and produces smooth convergence curves. However, like BCG, QMR requires matrix-vector multiplications with both the coefficient matrix A and its transpose A^T. In this note, it is demonstrated that the quasi-minimal residual approach can also be used to obtain a smoothly convergent CGS-like algorithm that does not involve matrix-vector multiplications with A^T. It is shown that the resulting transpose-free QMR method (TFQMR) can be implemented very easily by changing only a few lines in the standard CGS algorithm. Finally, numerical experiments are reported.

Key words. non-Hermitian linear systems, biconjugate gradients, transpose-free, conjugate gradients squared, quasi-minimal residual property

1. Introduction.

The classical conjugate gradient method (CG) [11] is one of the most powerful iterative schemes for solving large sparse linear systems

$$Ax = b \tag{1.1}$$

with Hermitian positive definite coefficient matrices A. The biconjugate gradient algorithm (BCG) [13], [3] is the "natural" extension of CG to linear systems (1.1) with general non-Hermitian nonsingular coefficient matrices. However, unlike CG, the BCG iterates are not characterized by a minimization property, which means that the algorithm can exhibit—and typically does—a rather irregular convergence behavior with wild oscillations in the residual norm. Furthermore, in the BCG algorithm, even breakdowns—more precisely, division by 0—may occur.

Recently, Freund and Nachtigal [7] proposed a BCG-like approach, the quasi-minimal residual method (QMR), that remedies the problems of BCG. The QMR iterates are defined by a quasi minimization of the residual norm, which leads to smooth convergence curves. Furthermore, QMR can be implemented based on a look-ahead version [14], [6] of the nonsymmetric Lanczos algorithm [12], which avoids possible breakdowns of the process, except for the very special situation of an incurable breakdown.

Except for special cases [8], such as complex symmetric matrices [4], BCG and QMR require matrix-vector multiplications with both the coefficient matrix A of (1.1) and its transpose A^T. This is a disadvantage for certain applications, such as linear systems arising in ordinary differential equation solvers [9], where A^T is not readily available. Sonneveld [15] derived a variant of BCG, the conjugate gradients squared algorithm (CGS), that does not involve A^T. However, like BCG, CGS also

exhibits rather erratic convergence behavior. Van der Vorst [16] proposed the Bi-CGSTAB algorithm, which uses local steepest descent steps to obtain a more smoothly convergent CGS-like process. While Bi-CGSTAB seems to work well in many cases, it still exhibits irregular convergence behavior for some difficult problems. Also, Bi-CGSTAB can converge considerably slower than CGS.

In this note, we demonstrate that the quasi-minimal residual approach can also be used to obtain a smoothly convergent CGS-like algorithm that does not require matrix-vector multiplications with A^T. We show that the resulting transpose-free QMR method (TFQMR) can be implemented very easily, by changing only a few lines in the standard CGS algorithm. We stress that the proposed TFQMR method and the original QMR algorithm [7] are not mathematically equivalent. In particular, the sets of iterates generated by the two schemes are different.

The rest of this paper is organized as follows. In §2, we briefly review the CGS algorithm. In §3, we present the transpose-free quasi-minimal residual approach. To derive an actual implementation, we first present an auxiliary result in §4 and then present the resulting TFQMR algorithm in §5. Numerical examples are reported in §6, and in §7, we make some concluding remarks.

Throughout the paper, all vectors and matrices are allowed to have real or complex entries. As usual, M^T and M^H denote the transpose and conjugate transpose of M, respectively. The vector norm $\|x\| = \sqrt{x^H x}$ is always the Euclidean norm, and $\|M\| = \max_{\|x\|=1} \|Mx\|$ is the corresponding matrix norm. The notation

$$K_n(c, M) := \operatorname{span}\{c, Mc, \ldots, M^{n-1}c\}$$

is used for the nth Krylov subspace of $\mathbb{C}^N$ generated by $c \in \mathbb{C}^N$ and the $N \times N$ matrix M. For $q \in \mathbb{R}$, $\lfloor q \rfloor$ is the largest integer $\leq q$. The set of all complex polynomials of degree at most n is denoted by

$$\mathcal{P}_n := \{\varphi(\lambda) \equiv \gamma_0 + \gamma_1\lambda + \cdots + \gamma_n\lambda^n \mid \gamma_0, \gamma_1, \ldots, \gamma_n \in \mathbb{C}\}.$$

The coefficient matrix A of (1.1) is always assumed to be a nonsingular, in general non-Hermitian, $N \times N$ matrix, and $b \in \mathbb{C}^N$. Generally, $x_n \in \mathbb{C}^N$, $n = 0, 1, \ldots$, denote iterates for (1.1) with corresponding residual vectors $r_n := b - Ax_n$. If necessary, quantities of different algorithms will be distinguished by superscripts, e.g., x_n^{BCG} and x_n^{CGS}.

2. The CGS algorithm.

Let $x_0 \in \mathbb{C}^N$ be any initial guess for (1.1) with residual vector $r_0 = b - Ax_0$, and let $\tilde{r}_0 \in \mathbb{C}^N$ be any vector such that $\tilde{r}_0^H r_0 \neq 0$, e.g., $\tilde{r}_0 = r_0$. The nth iterate, x_n^{BCG}, generated by the BCG process is defined by the Galerkin-type condition

$$w^H(b - Ax_n^{\mathrm{BCG}}) = 0 \quad \text{for all } w \in K_n(\tilde{r}_0, A^H), \quad x_n^{\mathrm{BCG}} \in x_0 + K_n(r_0, A). \tag{2.1}$$

Clearly, the corresponding residual vector r_n^{BCG} is of the form

$$r_n^{\mathrm{BCG}} = \varphi_n(A) r_0, \quad \text{where} \quad \varphi_n \in \mathcal{P}_n \quad \text{and} \quad \varphi_n(0) = 1. \tag{2.2}$$

Sonneveld [15] observed that the iterates $x_n \in x_0 + K_{2n}(r_0, A)$ whose residual vectors are just the "squares" of (2.2), i.e.,

$$r_n = (\varphi_n(A))^2 r_0, \tag{2.3}$$

can be computed by means of a BCG-like process that does not involve A^H. The resulting process is as follows.

ALGORITHM 2.1 (CGS ALGORITHM [15]).

```
(1) Start:
    (a) Choose $x_0 \in \mathbb{C}^N$;
    (b) Set $p_0 = u_0 = r_0 = b - Ax_0$, $v_0 = Ap_0$;
    (c) Choose $\tilde{r}_0$ such that $\rho_0 = \tilde{r}_0^H r_0 \neq 0$.
(2) For $n = 1, 2, \ldots$, do:
    (a) Set $\sigma_{n-1} = \tilde{r}_0^H v_{n-1}$, $\alpha_{n-1} = \rho_{n-1}/\sigma_{n-1}$;
            $q_n = u_{n-1} - \alpha_{n-1} v_{n-1}$;
    (b) Set $x_n = x_{n-1} + \alpha_{n-1}(u_{n-1} + q_n)$;
            $r_n = r_{n-1} - \alpha_{n-1} A(u_{n-1} + q_n)$;
        If $x_n$ has converged: stop;
    (c) Set $\rho_n = \tilde{r}_0^H r_n$, $\beta_n = \rho_n/\rho_{n-1}$;
            $u_n = r_n + \beta_n q_n$;
            $p_n = v_n + \beta_n(q_n + \beta_n p_{n-1})$;
            $v_n = Ap_n$.
```

In exact arithmetic, Algorithm 2.1 terminates after a finite number, say n_*, of iterations. Usually, $x_{n_*} = A^{-1}b$ is the solution of (1.1). However, for general A, the possibility cannot be excluded that Algorithm 2.1 terminates prematurely with $\sigma_{n_*} = 0$ or $\rho_{n_*} = 0$, before the solution of (1.1) has been found. If this happens, a continuation of the process would lead to division by 0 in step (2a) or (2c) of the next iteration, and therefore premature termination is also referred to as a "breakdown" of the algorithm. Fortunately, breakdowns are very rare in practice and, furthermore, they can be overcome by using look-ahead strategies (cf. §7). Here, for simplicity, we will consider only the standard CGS Algorithm 2.1, without look-ahead. We note that a modified CGS algorithm that avoids exact breakdowns was recently given by Brezinski and Sadok [1].

In the sequel, we always assume that $n \in \{1, 2, \ldots, n_*\}$. Note that

$$\alpha_{n-1} \neq 0 \quad \text{for all } n. \tag{2.4}$$

Moreover, we will make use of the relations

$$u_{n-1} = \varphi_{n-1}(A)\psi_{n-1}(A)r_0 \quad \text{and} \quad q_n = \varphi_n(A)\psi_{n-1}(A)r_0, \tag{2.5}$$

which are derived in [15]. Here the φ_n's are given by (2.2), and the polynomials ψ_n can be updated by means of

$$\psi_n(\lambda) \equiv \varphi_n(\lambda) + \beta_n \psi_{n-1}(\lambda), \tag{2.6}$$

where $\psi_0(\lambda) \equiv 1$. Finally, we note that

$$\varphi_n(\lambda) \equiv \varphi_{n-1}(\lambda) - \alpha_{n-1}\lambda\psi_{n-1}(\lambda). \tag{2.7}$$

3. The quasi-minimal residual approach. By (2.2) and (2.3), the CGS iterates are defined implicitly via the Galerkin condition (2.1), but they do not satisfy a residual norm minimization property. In this section, we demonstrate that, using the same sequence of vectors u_{n-1} and q_n as generated by Algorithm 2.1, one can also define iterates with a quasi-minimization property.

We set

$$(3.1)\qquad y_m = \begin{cases} u_{n-1} & \text{if } m = 2n-1 \text{ is odd,} \\ q_n & \text{if } m = 2n \text{ is even,} \end{cases}$$

and

$$(3.2)\qquad w_m = \begin{cases} (\varphi_n(A))^2 r_0 & \text{if } m = 2n+1 \text{ is odd,} \\ \varphi_n(A)\varphi_{n-1}(A) r_0 & \text{if } m = 2n \text{ is even.} \end{cases}$$

Note that, by (2.3),

$$(3.3)\qquad w_{2n+1} = r_n^{\text{CGS}}, \qquad n = 1, 2, \ldots, n_*.$$

In the sequel, it is always assumed that $m \in \{1, 2, \ldots, 2n_*\}$. Using (2.5) and (2.7), one readily verifies that the vectors (3.1) and (3.2) are related by

$$(3.4)\qquad Ay_m = \frac{1}{\alpha_{\lfloor (m-1)/2 \rfloor}} (w_m - w_{m+1}).$$

Note that, by (2.4), the denominator in (3.4) is guaranteed to be different from 0. Setting

$$\begin{aligned} Y_m &= [y_1 \quad y_2 \quad \cdots \quad y_m], \\ W_{m+1} &= [w_1 \quad w_2 \quad \cdots \quad w_m \quad w_{m+1}], \end{aligned}$$

we can rewrite the relations (3.4) in matrix form

$$(3.5)\qquad AY_m = W_{m+1} B_m^{(e)},$$

where

$$(3.6)\qquad B_m^{(e)} = \begin{bmatrix} 1 & 0 & \cdots & 0 \\ -1 & 1 & \ddots & \vdots \\ 0 & \ddots & \ddots & 0 \\ \vdots & \ddots & -1 & 1 \\ 0 & \cdots & 0 & -1 \end{bmatrix} \cdot \left(\operatorname{diag}(\alpha_0, \alpha_0, \alpha_1, \ldots, \alpha_{\lfloor (m-1)/2 \rfloor})\right)^{-1}$$

is an $(m+1) \times m$ lower bidiagonal matrix. Finally, note that in view of (2.6), (2.7), and (2.4), the polynomials φ_n and ψ_n are both of full degree n, and with (2.5) and (3.1), it follows that

$$(3.7)\qquad K_m(r_0, A) = \operatorname{span}\{y_1, y_2, \ldots, y_m\} = \{Y_m z \mid z \in \mathbb{C}^m\}.$$

After these preliminaries, we now begin our derivation of the quasi-minimal residual approach. By (3.7), any possible iterate $x_m \in x_0 + K_m(r_0, A)$ can be written in the form

$$(3.8)\qquad x_m = x_0 + Y_m z \quad \text{for some } z \in \mathbb{C}^m.$$

By (3.5) and since $w_1 = r_0$ (see (3.3)), the corresponding residual vector satisfies

$$r_m = r_0 - AY_m z = W_{m+1}\left(e_1^{(m+1)} - B_m^{(e)} z\right), \tag{3.9}$$

where $e_1^{(m+1)} = [1 \quad 0 \quad \cdots \quad 0]^T \in \mathbb{R}^{(m+1)}$. Ideally, we would like to choose the free parameter vector z in (3.8) such that the norm $\|r_m\|$ of (3.9) is minimized. However, since, in general, the matrix W_{m+1} is dense and its columns are not orthogonal to each other, this would require the solution of a dense $N \times (m+1)$ least-squares problem. Instead, we minimize only the length of the coefficient vector in the representation (3.9) of r_m. More precisely, let

$$\Omega_{m+1} = \operatorname{diag}(\omega_1, \omega_2, \ldots, \omega_{m+1}), \quad \omega_k > 0, \quad k = 1, 2, \ldots, m+1, \tag{3.10}$$

be any scaling matrix, and rewrite (3.9) as

$$r_m = W_{m+1}\Omega_{m+1}^{-1}\left(f_{m+1} - H_m^{(e)} z\right), \tag{3.11}$$

where

$$f_{m+1} = \omega_1 e_1^{(m+1)} \quad \text{and} \quad H_m^{(e)} = \Omega_{m+1} B_m^{(e)}. \tag{3.12}$$

We then define the mth iterate x_m of TFQMR by

$$x_m = x_0 + Y_m z_m, \tag{3.13}$$

where $z_m \in \mathbb{C}^m$ is the solution of the least-squares problem

$$\tau_m := \left\|f_{m+1} - H_m^{(e)} z_m\right\| = \min_{z \in \mathbb{C}^m} \left\|f_{m+1} - H_m^{(e)} z\right\|. \tag{3.14}$$

Note that by (3.6), (3.10), and (3.12), the matrix $H_m^{(e)}$ has full column rank m, and thus z_m is uniquely defined by (3.14). Furthermore, as we will show in the next two sections, the solution of (3.14) and hence x_m can be computed by means of simple recurrences.

Clearly, the iterates x_m still depend on the choice of the weights ω_k in (3.10). The standard strategy is to set

$$\omega_k = \|w_k\|, \qquad k = 1, 2, \ldots, m+1, \tag{3.15}$$

which means that all columns of $W_{m+1}\Omega_{m+1}^{-1}$ in the representation (3.11) are treated equally and scaled to be unit vectors. However, we will also consider a slightly less expensive choice of the weights in §5.

For the derivation of an actual implementation of the TFQMR method, the auxiliary iterates

$$\tilde{x}_m = x_0 + Y_m \tilde{z}_m, \quad \text{where} \quad \tilde{z}_m = H_m^{-1} f_m, \tag{3.16}$$

will be used. Here H_m denotes the $m \times m$ matrix obtained by deleting the last row of $H_m^{(e)}$. Using (3.6), (3.10), and (3.12), one readily verifies that H_m is indeed nonsingular and that

$$\tilde{z}_m = [\alpha_0 \quad \alpha_0 \quad \alpha_1 \quad \cdots \quad \alpha_{\lfloor (m-1)/2 \rfloor}]^T, \tag{3.17}$$

$$\omega_{m+1} = \left\| f_{m+1} - H_m^{(e)} \tilde{z}_m \right\|. \tag{3.18}$$

Finally, by comparing (3.16) and (3.17) with the update formula for the iterates x_n^{CGS} in step (2b) of Algorithm 2.1, we conclude that

$$\tilde{x}_{2n} = x_n^{\mathrm{CGS}}. \tag{3.19}$$

4. A lemma.

In this section, we show that the solutions of least-squares problems of the type (3.14) can be updated easily from step to step by using the auxiliary quantity $\tilde{z}_m$ defined in (3.16). This is true for more general upper Hessenberg matrices $H_m^{(e)}$, not only for the particular matrices given by (3.12) and (3.6). Therefore, we prove the following more general result, which might also be useful in other situations.

LEMMA 4.1. *Let $\omega_1 > 0$, $m \geq 1$, and*

$$H_m^{(e)} = \begin{bmatrix} H_m \\ h_{m+1,m} e_m^T \end{bmatrix} = \begin{bmatrix} H_{m-1}^{(e)} & * \\ 0 & h_{m+1,m} \end{bmatrix}, \tag{4.1}$$

where $e_m^T = [0 \ \cdots \ 0 \ 1]$, be an $(m+1) \times m$ upper Hessenberg matrix of full column rank m. For $k = m-1,\ m$, let $z_k \in \mathbb{C}^k$ denote the solution of the least-squares problem

$$\tau_k := \min_{z \in \mathbb{C}^k} \left\| f_{k+1} - H_k^{(e)} z \right\|, \quad \textit{where } f_{k+1} = \omega_1 e_1^{(k+1)} \in \mathbb{R}^{k+1}. \tag{4.2}$$

Moreover, assume that the $m \times m$ matrix H_m in (4.1) is nonsingular, and set $\tilde{z}_m := H_m^{-1} f_m$. Then

$$z_m = (1 - c_m^2) \begin{bmatrix} z_{m-1} \\ 0 \end{bmatrix} + c_m^2 \tilde{z}_m, \tag{4.3}$$

$$\tau_m = \tau_{m-1} \vartheta_m c_m, \tag{4.4}$$

where

$$\vartheta_m = \frac{1}{\tau_{m-1}} \left\| f_{m+1} - H_m^{(e)} \tilde{z}_m \right\|, \qquad c_m = \frac{1}{\sqrt{1 + \vartheta_m^2}}. \tag{4.5}$$

Proof. Let $k = m-1$ or $k = m$. The standard approach (see, e.g., [10, Chap. 6]) for solving the least-squares problem (4.2) is based on a QR factorization of $H_k^{(e)}$,

$$Q_{k+1} H_k^{(e)} = \begin{bmatrix} R_k \\ 0 \end{bmatrix}, \tag{4.6}$$

where Q_{k+1} is unitary and R_k is a nonsingular upper triangular matrix. The solution of (4.2) is then given by

$$z_k = R_k^{-1} g_k, \quad \text{where } \begin{bmatrix} g_k \\ \tilde{\gamma}_{k+1} \end{bmatrix} = Q_{k+1} f_{k+1}, \quad \tilde{\gamma}_{k+1} \in \mathbb{C}, \tag{4.7}$$

and

$$\tau_k = |\tilde{\gamma}_{k+1}|. \tag{4.8}$$

Furthermore, since $H_k^{(e)}$ is an upper Hessenberg matrix, we can choose the matrix Q_{k+1} as a product of k Givens rotations. In particular, the factorization (4.6) for $k = m$ can then be easily updated from the one for $k = m - 1$, by setting

$$Q_{m+1} = \begin{bmatrix} I_{m-1} & 0 & 0 \\ 0 & c_m & -\overline{s_m} \\ 0 & s_m & c_m \end{bmatrix} \cdot \begin{bmatrix} Q_m & 0 \\ 0 & 1 \end{bmatrix}, \tag{4.9}$$

where $c_m \geq 0$ and $s_m \in \mathbb{C}$ are suitably chosen with $c_m^2 + |s_m|^2 = 1$. Also, note that

$$R_m = \begin{bmatrix} R_{m-1} & * \\ 0 & * \end{bmatrix}. \tag{4.10}$$

Using (4.9) and (4.1), we deduce from (4.6) (with $k = m$) that

$$Q_m H_m = \operatorname{diag}(1, \ldots, 1, c_m) R_m, \tag{4.11}$$

which, in particular, implies $c_m > 0$. Moreover, with (4.9), one easily verifies that

$$g_m = \begin{bmatrix} g_{m-1} \\ \gamma_m \end{bmatrix}, \quad \gamma_m = c_m \tilde{\gamma}_m, \quad \text{and} \quad \tilde{\gamma}_{m+1} = s_m \tilde{\gamma}_m. \tag{4.12}$$

From (4.11), (4.12), and (4.7), it follows that

$$\tilde{z}_m = (Q_m H_m)^{-1} \begin{bmatrix} g_{m-1} \\ \tilde{\gamma}_m \end{bmatrix} = R_m^{-1} \begin{bmatrix} g_{m-1} \\ \gamma_m / c_m^2 \end{bmatrix} = R_m^{-1} \begin{bmatrix} R_{m-1} z_{m-1} \\ \gamma_m / c_m^2 \end{bmatrix}. \tag{4.13}$$

Using (4.7), (4.12), and (4.13), we obtain

$$z_m = (1 - c_m^2) R_m^{-1} \begin{bmatrix} R_{m-1} z_{m-1} \\ 0 \end{bmatrix} + c_m^2 \tilde{z}_m,$$

which, in view of (4.10), is just (4.3).

Since Q_{m+1} is unitary, the following holds:

$$\left\| f_{m+1} - H_m^{(e)} \tilde{z}_m \right\| = \left\| Q_{m+1} f_{m+1} - Q_{m+1} H_m^{(e)} \tilde{z}_m \right\|,$$

and with (4.6), (4.7), (4.13), and (4.12), we arrive at

$$\begin{aligned} \left\| f_{m+1} - H_m^{(e)} \tilde{z}_m \right\| &= \left\| \begin{bmatrix} g_{m-1} \\ \gamma_m \\ \tilde{\gamma}_{m+1} \end{bmatrix} - \begin{bmatrix} g_{m-1} \\ \gamma_m / c_m^2 \\ 0 \end{bmatrix} \right\| \\ &= \left\| \begin{bmatrix} \gamma_m |s_m|^2 / c_m^2 \\ \tilde{\gamma}_{m+1} \end{bmatrix} \right\| = |\tilde{\gamma}_m| \frac{|s_m|}{c_m}. \end{aligned} \tag{4.14}$$

Finally, setting $\vartheta_m = |s_m|/c_m$ and using (4.8), the relations (4.5) and (4.4) follow from (4.14) and the identity on the right-hand side of (4.12). □

5. The TFQMR algorithm. We now apply Lemma 4.1 to the particular least-squares problem (3.14). From (4.3), it follows that the TFQMR iterates (3.13) and the auxiliary iterates (3.16) are connected by

$$x_m = (1 - c_m^2)x_{m-1} + c_m^2 \tilde{x}_m. \tag{5.1}$$

Moreover, by (4.5), (4.4), and (3.18), we have

$$\vartheta_m = \frac{\omega_{m+1}}{\tau_{m-1}}, \quad c_m = \frac{1}{\sqrt{1+\vartheta_m^2}}, \quad \text{and} \quad \tau_m = \tau_{m-1}\vartheta_m c_m. \tag{5.2}$$

Setting

$$d_m = \frac{1}{\alpha_{\lfloor (m-1)/2 \rfloor}} \left(\tilde{x}_m - x_{m-1}\right), \tag{5.3}$$

we can rewrite (5.1) in the form

$$x_m = x_{m-1} + \eta_m d_m, \quad \text{where} \quad \eta_m = c_m^2 \alpha_{\lfloor (m-1)/2 \rfloor}. \tag{5.4}$$

Next note that by (3.16) and (3.17), we have

$$\tilde{x}_m = \tilde{x}_{m-1} + \alpha_{\lfloor (m-1)/2 \rfloor} y_m,$$

and together with (5.3) and (5.4) (both with m replaced by $m-1$), it follows that

$$d_m = y_m + \frac{\vartheta_{m-1}^2 \eta_{m-1}}{\alpha_{\lfloor (m-1)/2 \rfloor}} d_{m-1}, \quad \text{where} \quad \vartheta_{m-1}^2 := \frac{1 - c_{m-1}^2}{c_{m-1}^2}. \tag{5.5}$$

Next we note that with (3.1) and (3.3), the recursions for q_n and u_n in step (2a) and (2c) of Algorithm 2.1 can be rewritten as follows:

$$y_{2n} = y_{2n-1} - \alpha_{n-1} v_{n-1} \quad \text{and} \quad y_{2n+1} = w_{2n+1} + \beta_n y_{2n}. \tag{5.6}$$

Also, by multiplying the update formula for p_n in step (2c) of Algorithm 2.1 by A, we obtain the recursion

$$v_n =: Ay_{2n+1} + \beta_n (Ay_{2n} + \beta_n v_{n-1}) \tag{5.7}$$

for $v_n = Ap_n$. By (3.4), the w_m's can be generated via

$$w_{m+1} = w_m - \alpha_{\lfloor (m-1)/2 \rfloor} Ay_m. \tag{5.8}$$

Finally, by combining the recurrences (5.2), (5.4)–(5.8), we obtain an actual implementation for computing the iterates of the TFQMR method. First, we state the resulting algorithm for the standard weighting strategy (3.15).

ALGORITHM 5.1 (TFQMR ALGORITHM WITH WEIGHTS (3.15)).

```
(1) Start:
    (a) Choose $x_0 \in \mathbb{C}^N$;
    (b) Set $w_1 = y_1 = r_0 = b - Ax_0$, $v_0 = Ay_1$, $d_0 = 0$;
            $\tau_0 = \|r_0\|$, $\vartheta_0 = 0$, $\eta_0 = 0$;
    (c) Choose $\tilde{r}_0$ such that $\rho_0 = \tilde{r}_0^H r_0 \neq 0$.
(2) For $n = 1, 2, \dots$, do:
```

```
(a) Set $\sigma_{n-1} = \tilde{r}_0^H v_{n-1}$, $\alpha_{n-1} = \rho_{n-1}/\sigma_{n-1}$;
    $y_{2n} = y_{2n-1} - \alpha_{n-1} v_{n-1}$;
(b) For $m = 2n-1, 2n$ do:
    • Set $w_{m+1} = w_m - \alpha_{n-1} A y_m$;
    •     $\vartheta_m = \|w_{m+1}\|/\tau_{m-1}$, $c_m = 1/\sqrt{1+\vartheta_m^2}$;
    •     $\tau_m = \tau_{m-1}\vartheta_m c_m$, $\eta_m = c_m^2 \alpha_{n-1}$;
    •     $d_m = y_m + (\vartheta_{m-1}^2 \eta_{m-1}/\alpha_{n-1}) d_{m-1}$;
    •     $x_m = x_{m-1} + \eta_m d_m$;
    • If $x_m$ has converged: stop;
(c) Set $\rho_n = \tilde{r}_0^H w_{2n+1}$, $\beta_n = \rho_n/\rho_{n-1}$;
    $y_{2n+1} = w_{2n+1} + \beta_n y_{2n}$;
    $v_n = A y_{2n+1} + \beta_n (A y_{2n} + \beta_n v_{n-1})$.
```

The convergence check in step (2b) is usually based on the norm $\|r_m\|$ of the residual vector r_m corresponding to x_m. These vectors are not generated explicitly in Algorithm 5.1. However, we have the following upper bound available at no extra cost:

$$\|r_m\| \le \left\|W_{m+1}\Omega_{m+1}^{-1}\right\| \cdot \|f_{m+1} - H_m^{(e)} z_m\| \le \sqrt{m+1}\,\tau_m. \tag{5.9}$$

The inequalities in (5.9) follow from (3.11) (with $z = z_m$), (3.14), and

$$\left\|W_{m+1}\Omega_{m+1}^{-1}\right\| \le \sqrt{m+1}.$$

The latter estimate holds since, by (3.15), the columns of the $N \times (m+1)$ matrix $W_{m+1}\Omega_{m+1}$ all have unit length. Therefore, the convergence criterion in Algorithm 5.1 can be checked for the upper bound on the right-hand side of (5.9), and the actual norm $\|r_m\|$ only needs to be computed in the final stages of the iteration process.

Notice that the vectors w_{2n} in Algorithm 5.1 are not used directly; only their norms $\|w_{2n}\|$ are needed. We can eliminate the w_{2n}'s, and thus save one inner product per iteration, by approximating the weights ω_{2n} in (3.15) as follows. First, recall that by (3.3) and (2.3),

$$\|w_{2n+1}\| = \|r_n^{\mathrm{CGS}}\| = \left\|(\varphi_n(A))^2 r_0\right\|. \tag{5.10}$$

Since by (3.2), $w_{2n} = \varphi_n(A)\varphi_{n-1}(A) r_0$, the relation (5.10) suggests the approximation

$$\|w_{2n}\| \approx \sqrt{\|r_{n-1}^{\mathrm{CGS}}\| \cdot \|r_n^{\mathrm{CGS}}\|}.$$

This leads to the weighting strategy

$$\omega_m = \begin{cases} \|r_n^{\mathrm{CGS}}\| & \text{if } m = 2n+1 \text{ is odd,} \\ \sqrt{\|r_{n-1}^{\mathrm{CGS}}\| \cdot \|r_n^{\mathrm{CGS}}\|} & \text{if } m = 2n \text{ is even.} \end{cases} \tag{5.11}$$

In the case of (5.11) and, more generally, for any choice of weights $\omega_k > 0$ in (3.10) that does not require $\|w_{2n}\|$, we can eliminate w_{2n} in Algorithm 5.1. The resulting procedure is, except for the update of the different iterates in step (2b), identical with the CGS Algorithm 2.1, and it can be stated as follows.

Algorithm 5.2 (TFQMR Algorithm with General Weights $\omega_k > 0$).

```
(1) Start:
    (a) Choose $x_0 \in \mathbb{C}^N$;
    (b) Set $p_0 = u_0 = r_0^{\mathrm{CGS}} = r_0 = b - Ax_0$, $v_0 = Ap_0$, $d_0 = 0$;
            $\tau_0 = \omega_1$, $\vartheta_0 = 0$, $\eta_0 = 0$;
    (c) Choose $\tilde{r}_0$ such that $\rho_0 = \tilde{r}_0^H r_0 \neq 0$.
(2) For $n = 1, 2, \ldots,$ do:
    (a) Set $\sigma_{n-1} = \tilde{r}_0^H v_{n-1}$, $\alpha_{n-1} = \rho_{n-1}/\sigma_{n-1}$;
            $q_n = u_{n-1} - \alpha_{n-1} v_{n-1}$;
            $r_n^{\mathrm{CGS}} = r_{n-1}^{\mathrm{CGS}} - \alpha_{n-1} A(u_{n-1} + q_n)$;
    (b) For $m = 2n-1, 2n$ do:
        • Set $\vartheta_m = \omega_{m+1}/\tau_{m-1}$, $c_m = 1/\sqrt{1+\vartheta_m^2}$;
        •     $\tau_m = \tau_{m-1}\vartheta_m c_m$, $\eta_m = c_m^2 \alpha_{n-1}$;
        •     $d_m = y_m + (\vartheta_{m-1}^2 \eta_{m-1}/\alpha_{n-1}) d_{m-1}$,
        •         where $y_m = \begin{cases} u_{n-1} & \text{if } m = 2n-1, \\ q_n & \text{if } m = 2n; \end{cases}$
        •     $x_m = x_{m-1} + \eta_m d_m$;
        • If $x_m$ has converged: stop;
    (c) Set $\rho_n = \tilde{r}_0^H r_n^{\mathrm{CGS}}$, $\beta_n = \rho_n/\rho_{n-1}$;
            $u_n = r_n^{\mathrm{CGS}} + \beta_n q_n$;
            $p_n = u_n + \beta_n(q_n + \beta_n p_{n-1})$;
            $v_n = Ap_n$.
```

Finally, we note that x_n^{CGS} can be generated easily during the course of the TFQMR Algorithms 5.1 or 5.2, whenever a CGS iterate is desired. Indeed, in view of (3.19), (5.1), and (5.3), the CGS and TFQMR iterates are connected by

$$x_n^{\mathrm{CGS}} = x_{2n-1} + \alpha_{n-1} d_{2n}.$$

6. Numerical examples. We have performed numerical experiments with the CGS method, the Bi-CGSTAB algorithm, and the TFQMR algorithm with both weighting strategies (3.15) and (5.11). In this section, we present the results for two linear systems that are quite difficult to solve by iterative methods.

In both examples we used $x_0 = 0$ as starting vector, and $\tilde{r}_0$ was chosen as a vector with random entries from a normal distribution with mean 0.0 and variance 1.0. As stopping criterion, we used

$$\frac{\|r_n\|}{\|r_0\|} \leq 10^{-6} \tag{6.1}$$

for CGS and Bi-CGSTAB, and

$$\frac{\|r_m\|}{\|r_0\|} \leq 10^{-6} \tag{6.2}$$

for TFQMR. Note that CGS and Bi-CGSTAB both produce only one iterate x_n per iteration, while QMR generates two iterates x_m, with indices $m = 2n-1$ and $m = 2n$, in the nth step of the iteration. However, work and storage per iteration are roughly the same for all three methods. For both examples, we show the relative residual norm (6.1), respectively (6.2), plotted versus the iteration number n. The solid line is the convergence curve for the TFQMR Algorithm 5.1 (with weighting strategy (3.15)), the dotted line shows the behavior of CGS, and the dashed line is the Bi-CGSTAB convergence curve.

Example 6.1. We consider the partial differential equation

$$-\frac{\partial^2 u}{\partial x^2} - \frac{\partial^2 u}{\partial y^2} + \gamma\left(x\frac{\partial u}{\partial x} + y\frac{\partial u}{\partial y}\right) + \beta u = f \quad \text{on} \quad (0,1)\times(0,1), \tag{6.3}$$

with Dirichlet boundary conditions. We discretize (6.3) using centered differences on a uniform 63×63 grid with mesh size $h = 1/64$. The resulting linear system has a sparse coefficient matrix A of order $N = 3969$. The parameters in (6.3) were chosen to be $\beta = -200$ and $\gamma = 100$. Note that this choice guarantees that the cell Reynolds number is smaller than one, and hence centered differences yield a stable discretization of (6.3). The right-hand side was chosen such that the vector of all ones is the exact solution of the linear system. The convergence behavior is shown in Fig. 6.1. For this example, we have also plotted (dashed-dotted line) the convergence curve for the TFQMR Algorithm 5.2 with the slightly less expensive weighting strategy (5.11). Note that the TFQMR curves for both strategies (3.15) and (5.11) are very close. This behavior is typical, and it was also observed in other numerical tests.

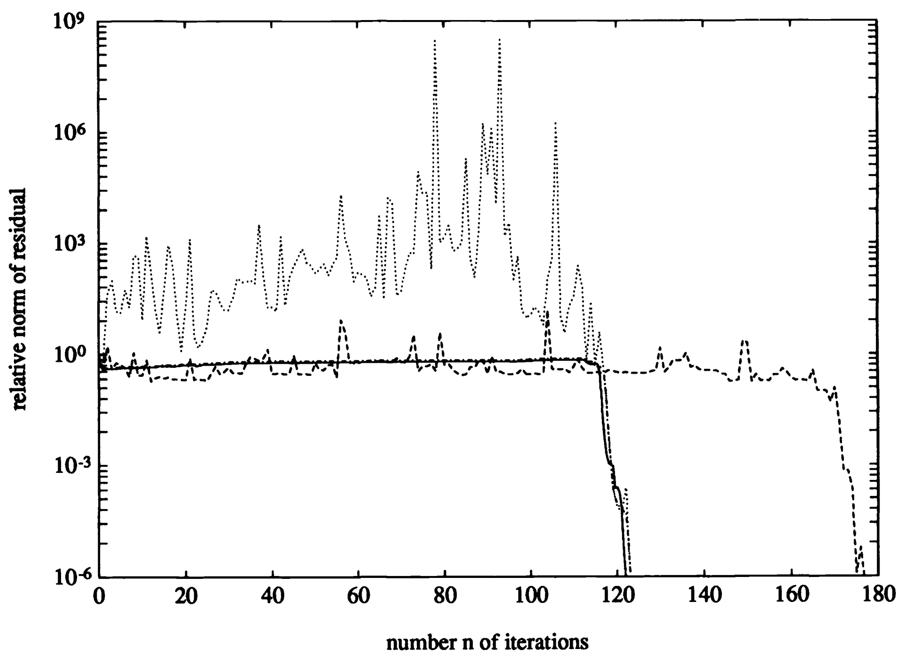

FIG. 6.1.

Example 6.2. This example was taken from the Harwell–Boeing set of sparse test matrices [2]. It is the fifth matrix from the SHERMAN collection, called SHERMAN5. It comes from a fully implicit black oil simulator on a $16 \times 23 \times 3$ grid, with three unknowns per grid point. The order of the matrix is 3312, and it has 20793 nonzero elements. The right-hand side b was also chosen as a vector with random entries. The convergence curves are shown in Fig. 6.2.

Both examples clearly demonstrate that the TFQMR method is certainly a remedy for the erratic convergence behavior of CGS. They also show that, in general, the residual norms for Bi-CGSTAB can still oscillate considerably, and that for difficult problems, convergence can be significantly slower than for CGS and TFQMR.

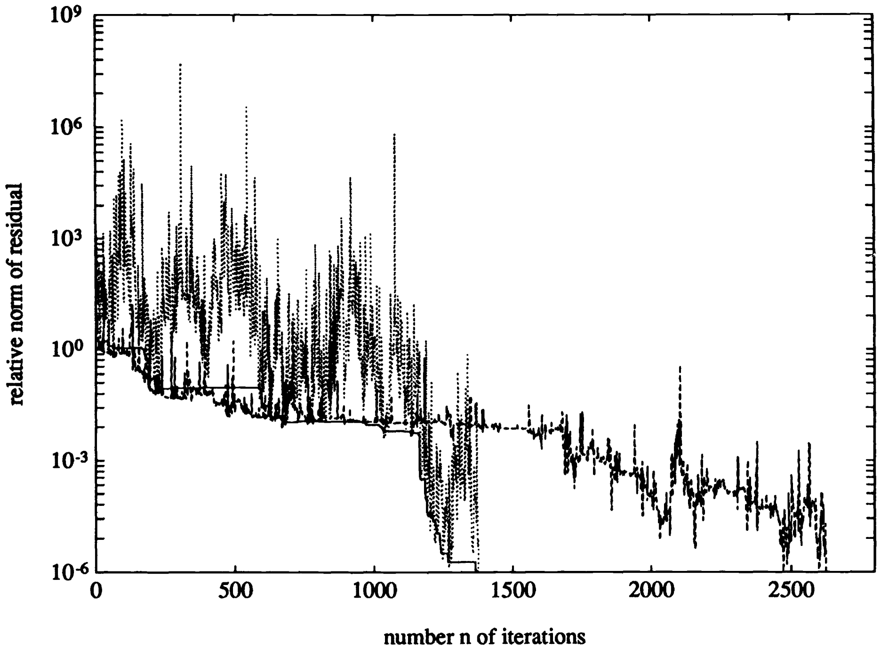

FIG. 6.2.

7. Conclusion. In this note, we proposed the TFQMR algorithm for solving general nonsingular non-Hermitian linear systems. The TFQMR method is closely related to the CGS algorithm, and it can be implemented by changing only a few lines in standard CGS. However, unlike CGS, the iterates of the TFQMR algorithm are characterized by a quasi minimization of the residual norm. This leads to smooth convergence curves for the TFQMR method, while CGS typically exhibits a rather irregular convergence behavior with wild oscillations in the residual norm.

Like standard CGS, the TFQMR algorithm described here can break down prematurely. Although these breakdowns are very rare in practice, for a robust implementation of the method that can be used as a black-box solver, it is crucial to incorporate look-ahead steps that allow to leap over those iterations in which exact breakdowns or near-breakdowns would occur in the standard process. The details of such a TFQMR algorithm with look-ahead will be presented elsewhere.

Finally, we remark that, based on the quasi-minimal residual property, one can derive upper bounds for the residual norms of the TFQMR iterates. Such a convergence result for the TFQMR method is given in [5, Thm. 6].

PRESERVING SYMMETRIES IN THE PROPER ORTHOGONAL DECOMPOSITION*

NADINE AUBRY[†], WEN-YU LIAN[†], AND EDRISS S. TITI[‡]

Abstract. The proper orthogonal decomposition (POD) (also called Karhunen–Loève expansion) has been recently used in turbulence to derive optimally fast converging bases of spatial functions, leading to efficient finite truncations. Whether a finite number of these modes can be used in numerical simulations to derive an "accurate" finite set of ordinary differential equations, over a certain range of bifurcation parameter values, still remains an open question. It is shown here that a necessary condition for achieving this goal is that the truncated system inherit the symmetry properties of the original infinite-dimensional system. In most cases, this leads to a systematic involvement of the symmetry group in deriving a new expansion basis called the symmetric POD basis. The Kuramoto–Sivashinsky equation with periodic boundary conditions is used as a paradigm to illustrate this point of view. However, the conclusion is general and can be applied to other equations, such as the Navier–Stokes equations, the complex Ginzburg–Landau equation, and others.

0. Introduction.

All computations involve a process of discretization in which infinite-dimensional (continuum) models, taking the form of partial differential equations (PDEs), are projected onto discrete or finite-dimensional forms. The way this finite projection is carried out is crucial for the accuracy and efficiency of the numerical simulation. Even if the process that is modeled is of low dimension, a finite projection may not be successful if it does not retain the essential dynamical features of the PDE such as the symplectic structure for Hamiltonian systems (see [18], [14], and [68]) or the preservation of dissipation in dissipative systems [29], [21], [38], [39]. In this paper, we are interested in reproducing the bifurcation diagram of dissipative equations based on the truncated proper orthogonal decomposition (POD) as defined below. In particular, we are concerned with deriving truncated dynamical systems that obey the symmetries of the original infinite-dimensional equation.

It is known that the long time behavior of certain PDEs such as the dissipative ones, is finite dimensional and sometimes relatively low dimensional. Moreover, it is sometimes possible to reduce the dynamics to a finite-dimensional system of ordinary differential equations (ODEs) in a rigorous manner. In the latter case, the reduced ODE is called an inertial form and the reduction takes place on a smooth finite-dimensional invariant manifold, which is called inertial manifold. More precisely, an inertial manifold is an invariant manifold that attracts all the trajectories exponentially fast and therefore it contains the global attractor [25]–[27]. The advantage is that stability and bifurcation calculations of the PDE can be performed for the inertial form [20], [38], [39]. In practice, an inertial manifold can be thought of as an

interaction law relating small and large scales, resembling an eddy viscosity model in turbulence [24]. The existence of an inertial manifold has been established for certain dissipative evolution PDEs such as the complex Ginzburg–Landau (CGL) equation, the Kuramoto–Sivashinsky equation (KSE), certain reaction-diffusion equations, the nonlocal Burgers equation, the Cahn–Hilliard equation, and others (see, e.g., [15] and references therein). Most recently, Kwak [44] has shown the existence of an inertial form for the two-dimensional Navier–Stokes equations with periodic boundary conditions. The difficulty, however, is that even when an inertial manifold is known to exist, it is often not unique and its exact form is unknown. Thus an approximation is necessary. Various approximation schemes have been developed to approximate inertial manifolds, or to directly approximate the global attractor (see, for example [20], [23], [27], [38], [39], [49], [66], and [67], and references therein).

Another approach to the issue of the finite projection of PDEs is the selection of "proper" modes, that is, modes that are relevant to the dynamics. These may be provided by the POD, also called Karhunen–Loève expansion, or empirical eigenfunctions method [45]–[48], [58], and [6]. The proper orthogonal decomposition of probability theory [45] has been developed, discussed, and extensively used to represent a random process. It has been proposed by Lumley [46]–[48] for identification of coherent structures in turbulence. It consists of decomposing a square integrable stochastic signal $u_\omega(x)$, where x belongs to the physical space X and ω is a random variable on the probability space Ω. For simplicity, we restrict ourselves to scalar functions, although the extension to vector-valued functions is straightforward. The proper orthogonal decomposition theorem [45] allows a decomposition of the random signal $u_\omega(x)$ into orthogonal deterministic functions $\varphi^n(x)$ and random coefficients a^n_ω :

$$u_\omega(x) = \sum_{n=1}^{\infty} a^n_\omega \varphi^n(x), \tag{1}$$

where the φ^n's are eigenfunctions, called in the literature POD modes or empirical eigenfunctions, of the following (Fredholm) integral equation:

$$\int_X R(x,x')\varphi(x')dx' = \lambda\varphi(x), \tag{2}$$

in which $R(x,x')$ denotes the two-(space)-point correlation function

$$R(x,x') = \langle u_\omega(x)u_\omega(x')\rangle_\omega, \tag{3}$$

that is, the ensemble average (over the random variable ω) of the product $u_\omega(x)u_\omega(x')$. It is well known (Hilbert–Schmidt and Mercer theorems; see, e.g., [56]) that if the correlation function is square integrable, then the set of eigenfunctions of the kernel $R(x,x')$ forms a complete set of $L^2(X)$. An important property of the POD is its optimally fast convergence in the sense that it maximizes the quantity $\langle (u_\omega,\varphi)^2\rangle_\omega$, where (.,.) denotes the canonical $L^2(X)$ scalar product, and $\|\varphi\|_{L^2} = 1$. On the other hand, the "energy" of the stochastic signal (defined as $\langle (u_\omega,u_\omega)\rangle_\omega$) is given by the sum of the eigenvalues λ (defined in (2)) counted with their multiplicities. Each eigenvalue, taken individually, represents the "energy" contribution of the corresponding eigenfunction. The method has been applied to various flows (see, for example, [9], [55], [50], [32], [33], [51], [57]–[61], [34], [16], [17], and references therein).

In the fluid mechanics literature, statistical stationarity and ergodicity are assumed (see, e.g., [6] and [58]). Indeed, under the assumption of the ergodicity of the flow on the global attractor, we can substitute the ensemble average by the time average, namely,

$$R(x,x') = \lim_{T\to\infty} \frac{1}{T} \int_0^T u(x,t)u(x',t)dt. \tag{4}$$

We stress the fact that, regardless of the ergodicity of the flow, we can still find a two-(space)-point correlation function using time averages, and find an orthonormal basis of $L^2(\mathrm{X})$ consisting of eigenfunctions of the correlation operator, defined in (4), provided the latter converges and satisfies the appropriate conditions (i.e., the conditions of Hilbert–Schmidt and Mercer theorems; see [56]). However, by implementing the long time average, as in (4), the "energy" contribution of the short-term events, such as the intermittent bursts in the presence of homoclinic orbits, might be very small. Therefore, we would not expect to be able to reproduce these events by taking only the largest "energy" POD modes in the Galerkin procedure. On the other hand, it is well known that, in certain cases, such short time events are responsible for an essential part of the chaotic dynamics. As a result, we might be obliged to take a larger Galerkin approximation, which will involve POD modes with almost zero "energy," in order to be able to reproduce the right dynamics. Indeed, a similar phenomenon can be observed in our computations in §4.2. The Galerkin approximation based on six POD modes, which contain 99.9995 percent of the "energy," could not reproduce the right dynamics. Only after taking seven modes are we able to get the right dynamics. This time-average procedure has been used by Aubry, Guyonnet, and Lima [4] to derive a space/time symmetric version of the expansion, the bi-orthogonal decomposition. This is a very useful tool to analyze space/time symmetries and bifurcations in complex spatio-temporal systems [2], [5], [7].

While the inertial manifold approach is global in the sense that such a manifold is invariant and contains the global attractor, the POD approach is local in phase space unless the global attractor is ergodic. Namely, the important POD modes, i.e., those with most of the "energy," span a linear manifold which closely approximates the ω-limit set of the particular trajectory that was used in the averaging process. The POD, indeed, leads to an optimally fast convergent expansion, in a certain sense, only for the particular signals $u(x,t)$ used in the determination of the two-(space)-point correlation function. Other signals, even those that are solutions of the same PDE for the same bifurcation parameter value, in particular those of other ergodic components of the global attractor, are likely to be poorly represented by the Galerkin approximation, based on a truncated set of these basis functions. In other words, spatial eigenfunctions derived from a particular solution necessarily provided a basis for $L^2(X)$, but a finite part of this basis may have absolutely no meaning for some components of the global attractor. Moreover, we emphasize that the characteristic spatial eigenfunctions, that is, those that have nonnegligible "energy," may completely change through bifurcations as the bifurcation parameter changes (see [2], [5], and [7]).

A finite-dimensional dynamical system has been derived by Aubry et al. [6] and Aubry and Sanghi [8], who projected the Navier–Stokes equation onto a finite number of basis spatial modes extracted from (2) and (4), where (4) had been previously experimentally determined. Low-dimensional dynamical systems thus derived could approximately reproduce the structure and dynamics of a turbulent flow in the vicinity of a wall. However, no parametric study with respect to Reynolds number was carried out and the global phase space study was not performed. One of the most important remaining issues is whether the POD method can be used to extract finite-dimensional approximations to a PDE in order to study global bifurcations. The aim is then to reconstruct the bifurcation diagram over a certain range of parameter values from a specific finite set of POD modes which would then be global on such a range. An attempt in this direction has been carried out by Sirovich and Rodriguez [57], [59] for the CGL equation. With three POD modes extracted from a chaotic solution, they could reproduce the period doubling route to chaos as first discovered by Keefe [40]. It is possible that a more careful bifurcation diagram analysis (including fixed points, precise bifurcation branch locations, etc.) may reveal problems of the type that will be pointed out in §4. (For a detailed global bifurcation analysis of the CGL equation, see, for instance, [12].) Along these lines, Deane et al. [16] have recently applied the POD method to the wake flow behind a cylinder at relatively small Reynolds number and observed similar difficulties. Finding a finite set of appropriate modes for the global bifurcation diagram is thus nontrivial. Although in this paper we do not answer this difficult question, we find a necessary condition that the finite set of global modes should satisfy. We are specifically interested in deriving Galerkin approximations that are inspired by the Karhunen–Loève procedure and that preserve the symmetric features of the problem and its global attractor (see Propositions 3 and 5 in §3).

The paper is organized as follows. In §1, we recall a few previous results concerning the KSE, which we need for our method implementation. In §2, we expand the solution of the equation by two complete sets of modes, the Fourier modes and the POD modes, and justify this operation in both cases. Then, in §3 we discuss the symmetries of the truncated finite sets of ODEs obtained by Galerkin projection of the PDE onto these modes. In the case of POD modes, we find a sufficient condition for the truncated system of ODEs which obeys the symmetries of the original PDE. This leads to a modification of the basic POD technique, by involving the average over the global symmetry group in the ensemble average. Finally, we show the necessity of this alternative procedure by studying the bifurcation diagram of stationary solutions of the KSE in §4. Moreover, in §4.2 we demonstrate that the modes with negligible "energy" are sometimes essential in reproducing the right dynamics, and hence must be included in the Galerkin projection. In conclusion, we raise the following questions: If it is not the "energy," then what should be the right criterion for determining the number of modes to be included in the Galerkin projection? What trajectories would be considered reliable to produce good PODs? And what should be the right ensemble average?

1. The Kuramoto–Sivashinsky equation.

As an example, we consider the KSE subject to periodic boundary conditions. This equation is a model for a variety of physical problems such as flame propagation and reaction-diffusion dynamics in combustion [62], [63]; thin film flows [10], [64], [35]; and, two-phase flows [30], [53]. It has been extensively studied analytically and numerically (see, for example, [38], [39], [31], [54], and references therein). Despite numerous bifurcations [41] and the complexity of some chaotic spatio-temporal solutions [36], [12], [13], [7], the KSE is known to have an inertial manifold [26], [27], [15] that is apparently low dimensional, as reflected by the numerical simulations. Foias et al. [20] and, Jolly, Kevrekidis, and Titi [38], [39] used the approximate inertial manifold technique to compute the bifurcation diagram in a relatively large range of the bifurcation parameter α (as defined below in (7)). Different approximate inertial manifolds and nonlinear Galerkin schemes were used and it was shown that, for a certain range of α, only three modes were enough to recover bifurcation branches. Along the same lines, Armbruster, Guckenheimer, and Holmes [1] used the center manifold technique to derive a four-dimensional ODE system to study local bifurcations around a critical parameter value.

We consider the normalized KSE

$$
\begin{aligned}
&\frac{\partial u}{\partial t}+\frac{\partial^4 u}{\partial x^4}+\frac{\partial^2 u}{\partial x^2}+u\frac{\partial u}{\partial x}=0, \qquad \text{where} \quad (x,t)\in R\times R^+,\\
&u(x,0)=u_0(x), \qquad \text{where} \quad x\in R,
\end{aligned} \tag{5}
$$

with periodic boundary conditions

$$
u(x,t)=u(x+L,t), \quad \text{with} \quad L>0, \tag{6}
$$

and

$$
\int_0^L u(x,t)dx=0.
$$

After rescaling time and space, (5) and (6) become

$$
\frac{\partial u}{\partial t}+4\frac{\partial^4 u}{\partial x^4}+\alpha\Big(\frac{\partial^2 u}{\partial x^2}+u\frac{\partial u}{\partial x}\Big)=0, \quad \text{where} \quad (x,t)\in R\times R^+, \tag{7}
$$

and where $\alpha = L^2/\pi^2$ is the bifurcation parameter. In this case, the boundary condition becomes

$$
u(x,t)=u(x+2\pi,t). \tag{8}
$$

In the following, we refer to (7) subject to the boundary condition (8) as the KSE. It is well known that the subspace of odd functions is an invariant subspace for this equation and the restricted system to this subspace is a dissipative system (see [52] and [65]). Recently, however, it was shown by Il'Yashenko [37] that the KSE is a dissipative system without the restriction to the odd case. Following the same proofs as in the odd case, and using the results of Il'Yashenko [37], we can show that the KSE has a compact global attractor and an inertial manifold. Moreover, since the space of solutions is invariant under translations $x \to x+\beta$ for every β (in the odd case β equals π only), namely, if $u(x,t)$ is a solution, then $u(x+\beta,t)$ is also a solution, the global attractor enjoys the same property. This translation symmetry is as crucial for the analysis performed in this paper as it was for the case in [1]. Generally, if the space of solutions of a dissipative system is invariant under a symmetry group G, then the global attractor will have the same property. Since certain dynamic behavior is structurally stable in the presence of symmetry, in general, we must ensure that the truncated system enjoys the symmetry properties of the nontruncated system.

2. Fourier modes and POD modes. In general, we can expand the solution of the KSE into a Fourier series

$$
u(x,t)=\sum_{j=1}^{\infty} a_j(t)\cos jx + b_j(t)\sin jx, \tag{9}
$$

where in the odd subspace, the a_j's are equal to zero. On the other hand, we can expand the solutions in terms of the eigenfunctions of the operator $\Re$ defined below, which will be referred to as POD modes. We denote by $\mathfrak{R} : L^2((0, 2\pi)) \to L^2((0, 2\pi))$ the operator

$$(\mathfrak{R}\varphi)(x) = \int_0^{2\pi} R(x, x')\varphi(x')dx',$$

where R is the two-(space)-point correlation function

$$R(x, x') = \lim_{T\to\infty} \frac{1}{T} \int_0^T u(x, t)u(x', t)dt, \tag{10}$$

and where $u(x, t)$ is a solution of the KSE. In general, there is no reason for the limit in (10) to converge. However, in real implementations we choose $u(x, t)$ for which the numerical limit in (10) exists. Hereafter, we will assume that the limit in (10) exists and that the correlation tensor is well defined.

PROPOSITION 1. *The eigenfunctions of* $\mathfrak{R}$, $\{\varphi_j\}$, *form a complete set of* $L^2((0, 2\pi))$.

Proof. It is clear that the operator $\mathfrak{R}$ is symmetric and nonnegative definite. Therefore, in order to apply the Hilbert–Schmidt and Mercer theorems (see, e.g., [56]), we must check that $R(x, x')$ is square integrable. The details of the proof are straightforward and based on both the regularity of the solutions of the KSE and the fact that it is a dissipative equation.

As a conclusion, every solution of the KSE can be expanded in terms of the φ_j's:

$$u(x, t) = \sum_{j=1}^{\infty} c_j(t)\varphi_j(x). \tag{11}$$

Remark 2. In view of the works of Il'Yashenko [37] and Foias and Témam [28], we can show that the solution of the KSE belongs to a Gevrey class of regularity. Therefore, we can implement the proof of Foias, Manley, and Sirovich [22] to show that the eigenvalues of the operator $\mathfrak{R}$ are bounded by an exponentially decaying function.

3. Symmetries.

It is expected that the Galerkin approximation based on the POD modes will converge optimally fast. However, the truncated system might not preserve the dynamical features of the original equations, such as dissipation (see [27], [21], [38], and [39]) or those originating from the symmetries. Since the space of solutions of the KSE is invariant under spatial translations, we are interested in deriving truncated dynamical systems that respect this property.

3.1. Symmetric POD modes.

We now seek conditions under which the POD eigenspaces enjoy the global symmetric properties of the solutions of the equation.

Suppose we have a PDE for which the space of solutions is invariant under a symmetry group G; namely, for every solution $u(x, t)$ of the PDE, $g \circ u(x, t)$ is also a solution (for every $g \in G$). The largest group with the above property will be called the global symmetry group. A symmetry group could be spatial, temporal, or spatio-temporal. In this paper, we will consider only spatial symmetry groups (for spatio-temporal symmetries, see, for instance, [5]). We call φ a symmetric POD mode if $g \circ \varphi$, for every $g \in G$, is an eigenfunction of the operator $\mathfrak{R}$ corresponding to the same eigenvalue. Each eigenspace of symmetric PODs is then invariant under the symmetry group G, and we call it a symmetric eigenspace. In Remark 4 (iv) we give some examples of particular solutions $u(x,t)$ for which the eigenspaces of the correlation functions, induced by $u(x,t)$, are symmetric eigenspaces. It is worth mentioning that if the flow is ergodic on the global attractor, then for almost every solution $u(x,t)$ in the global attractor, the POD eigenspaces of the correlation function, induced by $u(x,t)$, are symmetric eigenspaces (in this regard, see [11]). Since ergodicity is a rarity and is generally difficult to check, we propose a systematic method to produce symmetric POD modes by involving the average over the symmetry group in addition to the time average of the correlation function given by (10). In Proposition 3, we consider symmetry groups that are acting on the functions by changing variables on the physical space, such as reflections, translations, etc. (for spatio-temporal symmetries, see, for instance, [5]). We should mention that Sirovich [58] proposed using this idea to enlarge the data and generate more accurate POD modes, and has implemented it for this purpose in several applications (see, for example, [58], [61], and [17]).

However, our aim is fundamentally different. First, we mention that in many situations, the POD modes and the symmetric POD modes do not coincide. If we perform a data analysis only to carry out a local bifurcation study of the signal itself that provided the POD modes, the procedure of generating symmetric POD modes by averaging over the symmetry group is obviously not adequate because the POD modes prevent us from studying symmetry-related bifurcations. (See [5] for a full discussion and examples, and [42] and [43] for another approach using the PODs to study local bifurcation.) However, we emphasize that symmetric POD modes should necessarily be considered for the derivation of finite-dimensional dynamical systems that approximate the global dynamics of the equation (see Proposition 5). In general, this is an essential step, because, from the dynamical systems point of view, it is well known that certain dynamical features are structurally stable only in the presence of particular symmetries. Also, our computations in §4 demonstrate the importance of this step.

In this paper we consider only finite spatial symmetry groups. To be more specific, suppose that there is a symmetry group G consisting of N elements, such that for every $g \in G$, there is a one-to-one, invertible, and smooth function $\psi_g : D \to D$, where D is the domain in the physical space where the equation is defined, satisfying

$$\psi_{g\circ k}(x) = \psi_g(\psi_k(x)), \quad \psi_{g^{-1}}(x) = \psi_g^{-1}(x) \quad \text{and} \quad |\det(D\psi_g)| = 1. \tag{12}$$

Moreover, assume that if $u(x,t)$ is a solution to the PDE under consideration, then $g \circ u(x,t) = \alpha_g u(\psi_g(x),t)$, where α_g is a real number, is also a solution (i.e., the space of solutions is invariant under this kind of symmetry). Since G is a finite group we can easily show that α_g must be equal to either $+1$ or -1. We define the symmetric two-point correlation matrix as

$$R_s(x,x') = \lim_{T\to\infty} \frac{1}{NT} \int_0^T \sum_{g\in G} u(\psi_g(x),t)u(\psi_g(x'),t)dt, \tag{13}$$

and denote by $\mathfrak{R}_s$ the corresponding operator. Here again we assume that the limit in (13) exists.

PROPOSITION 3. *Under the above assumptions, if φ is an eigenfunction of $\mathfrak{R}_s$ with eigenvalues λ, then $\varphi(\psi_g(x))$ is also an eigenfunction corresponding to the same λ for every $g \in G$.*

Proof. Let φ be an eigenfunction of the operator $\mathfrak{R}_s$ so that it satisfies

$$\int_D R_s(x,x')\varphi(x')dx' = \lambda\varphi(x).$$

Using the definition of R_s in (13), and letting h be an arbitrary element of G, we can write

$$\begin{aligned}\int_D R_s(x,x')\varphi(\psi_h(x'))dx' &= \lim_{T\to\infty}\frac{1}{NT}\int_0^T\int_D\sum_{g\in G}u(\psi_g(x),t)u(\psi_g(x'),t)\varphi(\psi_h(x'))dx' \\ &= \lim_{T\to\infty}\frac{1}{NT}\int_0^T\int_D\sum_{g\in G}u(\psi_g(x),t)u(\psi_{g\circ h^{-1}}(y),t)\varphi(y)dy,\end{aligned}$$

where $y=\psi_h(x')$. Denoting $k=g\circ h^{-1}$, we obtain

$$\begin{aligned}\int_D R_s(x,x')\varphi(\psi_h(x'))dx' &= \lim_{T\to\infty}\frac{1}{NT}\int_0^T\int_D\sum_{k\in G}u(\psi_{k\circ h}(x),t)u(\psi_k(y),t)\varphi(y) \\ &= \lim_{T\to\infty}\frac{1}{NT}\int_0^T\int_D\sum_{k\in G}u(\psi_k(\psi_h(x)),t)u(\psi_k(y),t)\varphi(y)dy \\ &= \lambda\varphi(\psi_h(x)).\end{aligned}$$

Remark 4. (i) We remark that all the formal steps in the previous proof can be rigorously justified by using the regularity properties of the solution $u(x,t)$. Also note that for the same reason, $R(x,x')$ (and therefore $R_s(x,x')$) satisfies the conditions of Hilbert–Schmidt and Mercer theorems. Therefore, the number of linearly independent eigenfunctions in each eigenspace is finite. As a result, it is possible to choose an orthonormal basis $\{\varphi_j^s(x)\}_{j=1}^{\infty}$ of eigenfunctions of the operator $\mathfrak{R}_s$ such that $\mathfrak{R}_s\varphi_j^s = \lambda_j\varphi_j^s$, where $\lambda_1\geq\lambda_2\geq\cdots$, and any solution of the PDE can then be expanded as a series

$$u(x,t)=\sum_{j=1}^{\infty}c_j(t)\varphi_j^s(x).$$

(ii) In the case of the KSE with general periodic boundary conditions, the space of solutions is invariant under translations $T_\beta : x\to x+\beta$ for every β in $[0,2\pi]$. Therefore, it suffices to replace in Proposition 3 the summation $\sum_{g\in G}$ by the integral $\int_{[0,2\pi]}d\beta$ and to define $\psi_g(x)=\psi_\beta(x)=x+\beta$, where $\beta\in[0,2\pi]$. In this case, if $\varphi(x)$ is an eigenfunction of $\mathfrak{R}_s$ with eigenvalue λ, then $\varphi(x+\beta)$, for every $\beta\in[0,2\pi]$, is also an eigenfunction corresponding to the same λ. Moreover, here it can be easily shown that $R_s(x,x')$ is only a function of $x-x'$ and therefore the Fourier modes are eigenfunctions of $\mathfrak{R}_s$. However, they might not be ordered according to their wave numbers, because the mode with wave number 1, for instance, may not necessarily be the POD with maximum energy. As a result, the set of symmetric PODs in this case must coincide with the set of Fourier modes.

(iii) We observe that the subspace of odd solutions of the KSE is invariant under the Z_2 symmetry group generated by the translation $T_\pi : x\to x+\pi$. Note, also, that particular solutions may have additional symmetries, as we will see in §5.

(iv) If $R(x,x') = R_s(x,x')$, then the symmetric POD modes coincide with the regular ones, and in this case Proposition 3 is valid for the regular POD modes. This occurs, for instance, when the solution $u(x,t)$ used in the correlation function is itself invariant under the symmetry group (see [11]). Also, in the case of the translation symmetry group, the symmetric POD modes coincide with the regular ones in the cases of statistical homogeneity, or when the solution used in the correlation function is either a fixed point $u(x,t) = c$ or a traveling wave (in all three cases, R is only a function of $x - x'$). The case of traveling waves has been treated in detail in [5].

Next we show that the Galerkin projection of the KSE onto any finite number of symmetric eigenspaces gives an ODE system whose space of solutions is invariant under the translation symmetry group of the KSE. To illustrate our idea we consider the KSE restricted to the space of odd functions. However, we will discuss the general case as well as other equations in Remark 6.

Let $\{\varphi_j^s(x)\}_{j=1}^{\infty}$ be an orthonormal basis of symmetric eigenfunctions of $\mathfrak{R}_s$ for the KSE restricted to the space of odd functions. Let N satisfy $\lambda_{N+1} < \lambda_N$, where $\lambda_1 \geq \lambda_2 \geq \cdots$ are the eigenvalues of the operator $\mathfrak{R}_s$. Let

$$u_N(x,t) = \sum_{j=1}^{N} a_j(t)\varphi_j^s(x)$$

denote a solution to the Galerkin approximation of the KSE based on the φ_j^s's. It is clear from (7) that the $a_j(t)$'s satisfy the ODE system

$$\dot{a}_k + 4\sum_{j=1}^{N} A_{kj}a_j - \alpha\sum_{j=1}^{N} B_{kj}a_j + \alpha\sum_{j,m=1}^{N} C_{kjm}a_j a_m = 0 \quad \text{for } k = 1,2,\ldots,N, \tag{14}$$

where

$$\begin{aligned} A_{kj} &= \int_0^{2\pi} \varphi_j^{s''}(x)\varphi_k^{s''}(x)dx, \\ B_{kj} &= \int_0^{2\pi} \varphi_j^{s'}(x)\varphi_k^{s'}(x)dx, \\ C_{kjm} &= \int_0^{2\pi} \varphi_j^{s'}(x)\varphi_m^s(x)\varphi_k^s(x)dx, \end{aligned} \tag{15}$$

for $k,j,m = 1,2,\ldots,N$.

PROPOSITION 5. *Let* $\mathbf{a}(t) = (a_1(t),\ldots,a_N(t))^T$ *be a solution of* (14). *Denote by* $u_N(x,t) = \sum_{j=1}^N a_j(t)\varphi_j^s(x)$ *the corresponding solution to the Galerkin projection system. Then* $u_N(x+\pi,t) = \sum_{j=1}^N b_j(t)\varphi_j^s(x)$, *and* $\mathbf{b}(t) = (b_1(t),\ldots,b_N(t))^T$ *is a solution of* (14) (*i.e.,* $u_N(x+\pi,t)$ *is also a solution to the Galerkin projection*).

Proof. Because of Proposition 3 and Remark 4(i) there exists a matrix $\mathbf{\Gamma}$ such that for every $j = 1,\ldots,N$, we have

$$\varphi_j^s(x+\pi) = \sum_{k=1}^{N} \Gamma_{jk}\varphi_k^s(x). \tag{16}$$

Therefore,

$$\Gamma_{jk} = \int_0^{2\pi} \varphi_j^s(x+\pi)\varphi_k^s(x)dx = \int_0^{2\pi} \varphi_j^s(x)\varphi_k^s(x+\pi)dx = \Gamma_{kj}.$$

Moreover, we can easily check that $\mathbf{\Gamma}^2 = \mathbf{I}$. Hence,

$$\mathbf{\Gamma} = \mathbf{\Gamma}^T = \mathbf{\Gamma}^{-1}. \tag{17}$$

From (16) we can easily see that

$$u_N(x+\pi, t) = \sum_{j,k=1}^{N} a_j(t)\Gamma_{jk}\varphi_k^s(x) = \sum_{k=1}^{N} b_k(t)\varphi_k^s(x),$$

where $\mathbf{b}(t) = \mathbf{\Gamma}^T\mathbf{a}(t)$.

It remains to show that $\mathbf{b}(t)$ solves (14). From (15) it is easy to observe that

$$\mathbf{A} = \mathbf{A}^T, \quad \mathbf{B} = \mathbf{B}^T, \quad \mathbf{A} = \mathbf{\Gamma}\mathbf{A}\mathbf{\Gamma}^T, \quad \text{and} \quad \mathbf{B} = \mathbf{\Gamma}\mathbf{B}\mathbf{\Gamma}^T. \tag{18}$$

Next we show that

$$\sum_{j,k,m=1}^{N} \Gamma_{kl}C_{kjm}a_j a_m = \sum_{p,q=1}^{N} C_{lqp}b_q b_p \tag{19}$$

(the proof of (18) is similar and will be omitted). From (15) and because the functions $\varphi_m^s(x)$ are periodic of period 2π, we have

$$C_{kjm} = \int_0^{2\pi} \varphi_j^{s\prime}(x+\pi)\varphi_m^s(x+\pi)\varphi_k^s(x+\pi)dx;$$

by (16),

$$\begin{aligned} C_{kjm} &= \int_0^{2\pi} \sum_{i,p,q=1}^{N} \Gamma_{jq}\varphi_q^{s\prime}(x)\Gamma_{mp}\varphi_p^s(x)\Gamma_{ki}\varphi_i^s(x)dx \\ &= \sum_{i,p,q=1}^{N} \Gamma_{jq}\Gamma_{mp}\Gamma_{ki}C_{iqp}. \end{aligned}$$

From (14) and the above, we obtain

$$\begin{aligned} \sum_{j,m=1}^{N} C_{kjm}a_j a_m &= \sum_{i,p,q,j,m=1}^{N} \Gamma_{jq}\Gamma_{mp}\Gamma_{ki}C_{iqp}a_j a_m \\ &= \sum_{i,p,q=1}^{N} \Gamma_{ki}C_{iqp}(\mathbf{\Gamma}^T\mathbf{a})_q(\mathbf{\Gamma}^T\mathbf{a})_p. \end{aligned}$$

Hence, because of (17) and the above, we have

$$\begin{aligned} \sum_{j,m,k=1}^{N} \Gamma_{kl}C_{kjm}a_j a_m &= \sum_{j,m,k=1}^{N} \Gamma_{lk}C_{kjm}a_j a_m \\ &= \sum_{p,q=1}^{N} C_{lqp}(\mathbf{\Gamma}^T\mathbf{a})_q(\mathbf{\Gamma}^T\mathbf{a})_p, \end{aligned}$$

which proves (19).

To conclude our proof, we apply $\mathbf{\Gamma}^T$ to (14) and use (17), (18), and (19).

Remark 6. (i) The above proof can be easily extended to other equations with polynomial-type nonlinearities, and other kinds of symmetry, such as reflection. To be more specific, we can prove results similar to those of Proposition 5 for the CGL equation with periodic boundary conditions, and to the results of problems considered in [58], [17], and [16].

(ii) It is clear from the above proof (in particular, see (16)) that if the KSE is projected onto the Fourier modes, the space of solutions of the truncated system in this case is invariant with respect to the translation symmetry.

3.2. Dissipation and POD modes. Showing the dissipation property for the KSE is a little tricky, unlike other dissipative equations, such as the Navier–Stokes equations or the CGL equation (see [52] and [37]). Without knowing the spatial structure of the first N POD modes it will not be easy to show that the truncated system (14) is dissipative. In fact, if N is not large enough, depending on α, the system (14) might not be dissipative at all. Moreover, in the latter case, some of the solutions might even blow up in finite time. This issue of dissipativity of the discretized KSE has been discussed in detail for various numerical schemes in [38], [39], [21], and [27]. However, let us remark that in the cases of the Navier–Stokes equations or the CGL equation, for instance, the dissipation property always holds independently of the orthonormal basis with respect to which we truncate.

4. Computations of the Kuramoto–Sivashinsky equation. In this section we derive sets of ODEs via a Galerkin projection of the KSE onto both Fourier and POD modes. In order to demonstrate our point of view, it will be more instructive if we restrict our computations to the invariant subspace of odd functions. Otherwise, in view of Remark 4(ii), the symmetric PODs for the KSE will coincide with the Fourier modes. It is worth mentioning that certain interesting solutions, such as traveling waves, will not be allowed in the odd case. Nevertheless, the dynamics of the restricted KSE is still rich, as indicated in the computations of Jolly, Kevrekidis, and Titi [38], [39]. In this work, we are specifically interested in the bifurcation diagram for parameter values $0 \leq \alpha \leq 40$. In the following, the bifurcation diagrams are obtained by using the bifurcation package AUTO [19].

4.1. Projection onto Fourier modes. We first integrate a set of 14 ODEs derived from Fourier modes, as the bifurcation diagram thus obtained is qualitatively correct in the parameter range $0 \leq \alpha \leq 40$ for both steady and unsteady solutions. Indeed, by increasing the number of Fourier modes, we could not notice any major difference. As first noted by Brown [12] and Jolly, Kevrekidis, and Titi [38], we could even decrease the number of Fourier modes to 6, but 14 were kept for the computations described below. The steady-state bifurcation diagram is plotted in Fig. 1 from a set of 6 ODEs based on Fourier modes, and it will be our reference. (This diagram is identical to that obtained by Jolly, Kevrekidis, and Titi [38].)

We now recall in detail the symmetries of various branches since, as explained earlier, they play an essential role for the implementation of the POD modes (see, e.g., [41], [38], and references therein). First, for small values of $\alpha, \alpha < 4$, the trivial solution is asymptotically stable. A stability analysis of this trivial fixed point shows that a pitchfork bifurcation occurs at $\alpha = 4$ and that subsequent bifurcations take place on the trivial branch, from which primary steady branches emerge. It is fundamental to note that since the linear part of the KSE is diagonal, linearized modal equations decouple and single modes bifurcate: $\sin x$ at $\alpha = 4$, $\sin 2x$ at $\alpha = 16$,

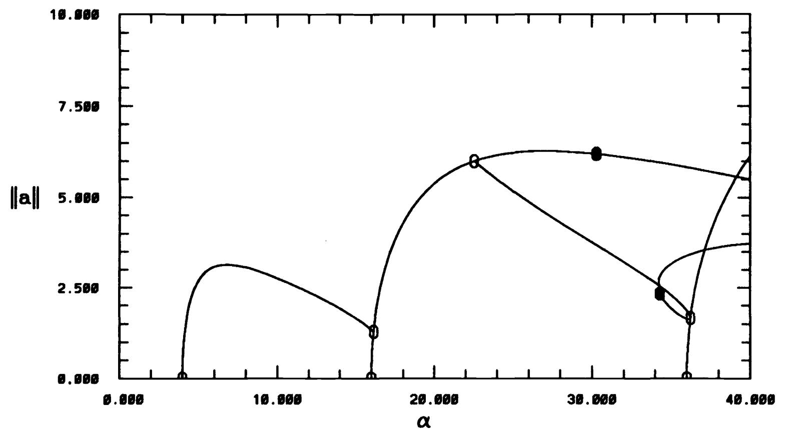

FIG. 1. *Steady-state bifurcation diagram of a dynamical system derived by projecting the* KSE *restricted to the odd subspace onto a set of six Fourier modes. The open circles represent steady-state bifurcation points, and the black circles represent Hopf bifurcations.*

$\sin 3x$ at $\alpha = 32$, $\sin 4x$ at $\alpha = 64$, etc. For this reason, branches thus born are called unimodal, bimodal, trimodal, or quadrimodal branches since young solutions (close to their birth) have one, two, three, or four humps, respectively. Then, by nonlinear quadratic interactions, multiple frequencies are activated so that solutions on an n-modal branch are linear combinations of $\sin jx$, $j = 1, 2, 3, \ldots$, and have a period of $2\pi/n$. Then secondary branches of various periods emerge from primary branches on which solutions may have various periods. In the parameter range $0 \le \alpha \le 40$, a secondary branch connects the bimodal and the trimodal branches before turning back to eventually go to the quadrimodal branch. The part connecting the bimodal and the trimodal branches is called the bitrimodal branch and has periodicity of 2π.

Now we remark that the global symmetry group of the KSE reduced to the odd subspace is the discrete Z_2 symmetry group, i.e., if $u(x,t)$ is a solution then $u(x+\pi,t)$ is also a solution. This implies that steady-state branches occur in pairs, both branches of the same pair being superposed in the bifurcation diagram. This is due to the fact that symmetric solutions are only distinct by a phase shift and therefore they have the same L^2 norm. Both symmetric odd-modal branches have the same stability, while both symmetric even-modal branches have different stabilities [41], [38].

4.2. Computation of POD modes. Let us recall that a Hopf bifurcation occurs on one of the bimodal branches at the parameter value $\alpha = 30.278$ (see [38]). The limit cycle thus born is stable and is invariant under the spatial and temporal symmetries $\widetilde{T} : t \to \tau/2$ and $T_\pi : x \to x + \pi$, so that $u(x,t) = u(x+\pi, t+\tau/2)$, where τ is the limit cycle (temporal) period. These symmetries have consequences on the POD modes and their coefficients that we do not exploit here [5], [7]. We remark that the symmetry of the bimodal branch $x \to x + \pi/2$ is lost, due to the fact that the Hopf bifurcation occurs on one of the two bimodal stationary branches only. The cycle has, however, the global symmetry of the KSE. At $\alpha = 32.85$, there is a symmetry-breaking bifurcation. The symmetric cycle becomes unstable while two stable asymmetric limit cycles appear in the phase space, symmetric one to the other through the symmetry $x \longrightarrow x + \pi$. Each asymmetric limit cycle then undergoes a period-doubling bifurcation sequence, leading to an apparently chaotic solution. (See [38] for a description of the whole bifurcation series from the bimodal branch. Also see [13] and [7] for a spatio-temporal analysis of stable solutions in this bifurcation series.) POD modes have been computed from such an apparently chaotic solution at the parameter value $\alpha = 33.005$. More precisely, Fourier coefficients of the POD modes are computed from the Fourier coefficients of the solution since we have

$$\sum_{m=1}^{N} R_{nm}\varphi_{mj} = \lambda_j \varphi_{nj}, \qquad n, j = 1, 2, \ldots, N,$$

where

$$\varphi_j(x) = \sum_{n=1}^{N} \varphi_{nj} \frac{\sin nx}{\sqrt{\pi}},$$

and

$$R_{ij} = \lim_{T \to \infty} \frac{1}{T} \int_0^T c_i(t) c_j(t) dt, \qquad 1 \le i \le N, 1 \le j \le N,$$

where c_k stands for the k Fourier coefficient of the solution $u_N(x,t)$, i.e., $u_N(x,t) = \sum_{n=1}^{N} c_n(\sin nx/\sqrt{\pi})$. Recall that in our computations $N = 14$.

In the computation of the apparently chaotic solution, the timestep used and time integration are 0.005 and 20, respectively (after 20 steps the time average was stabilizing), while the initial conditions were taken to be $c_1 = -0.9518, c_2 = 5.9054, c_3 = 5.9296, c_4 = -0.6256, c_5 = -0.9899, c_6 = -0.2159$, and $c_i = 0$ for all $i > 6$.

We denote by p_k the eigenvalue normalized by the energy

$$p_k = \frac{\lambda_k}{\sum_{i=1}^{N} \lambda_i},$$

and by S_k the partial energy

$$S_k = \sum_{i=l}^{k} \lambda_i.$$

The value of λ_k, p_k, and S_k are reported in Table 1. Fourier coefficients of POD modes are listed in Table 2. These tables show that the first two modes contain 96 percent of the energy and the first three modes, 99 percent of the energy. Although the first, second, and third POD modes get their main contribution from the second, third, and first Fourier modes, respectively, the other Fourier coefficients of the POD modes are not all zero: for example, φ_1 has nonnegligible first four Fourier coefficients.

First, we mention that the integration of the dynamical system retaining seven or more POD modes using the same initial conditions as those used in the dynamical system based on Fourier modes leads to a good reproduction of the apparently chaotic trajectory. However, we could not obtain a stable orbit of this type by reducing the number of POD modes to six or less: the trajectory was attracted by a stable fixed point. Although the quasi totality of the energy, namely 99.9995 percent, is included

in the first six modes, these modes do not seem to be sufficient to reproduce the dynamical system. In this regard, it is worth mentioning that we have found that the stability of the cycles appearing through the period-doubling sequence, as well as that of the apparently chaotic regime it leads to, is very sensitive to the precision of the numerical scheme. Thus it is not surprising that it is sensitive to the presence of high modes. We now return to the reconstruction of the bifurcation diagram of stationary solutions. Obviously, if the number of modes retained in the Galerkin projection is equal to the number of Fourier modes, the bifurcation diagram is exactly the same as that found with Fourier modes. Discrepancy starts appearing as the number of POD modes is decreased. In a first step, we are interested in reconstructing the steady-state bifurcation diagram for parameter values below $\alpha = 33.005$, at which the apparently chaotic solution has been computed for POD mode extraction. Bifurcation diagrams obtained with four, five, six, and seven POD modes are presented in Figs. 2, 3, 4, and 5, respectively. As we compare these diagrams with our reference (Fig. 1), discrepancies can be immediately observed, such as the parameter values of the steady-state bifurcations from the trivial branch when only four POD modes are retained. In particular, this shows that although four POD modes account for 99.96 percent of the total energy of the apparently chaotic solution at $\alpha = 33.005$, they are not sufficient for a correct reproduction of the full dynamical system. More importantly, a striking feature of Figs. 2 and 3 is that all branches appear in pairs, but each pair is not superposed as it should be by symmetry considerations. This decoupling has secondary consequences: The steady-state bifurcation at the intersection between the unimodal and bimodal branches and that at the intersection between the bimodal and secondary branch have disappeared. Branch decoupling still exists, but is less visible in Figs. 4 and 5, while the inexistence of the steady-state bifurcation point connecting the unimodal and the bimodal branches persists.

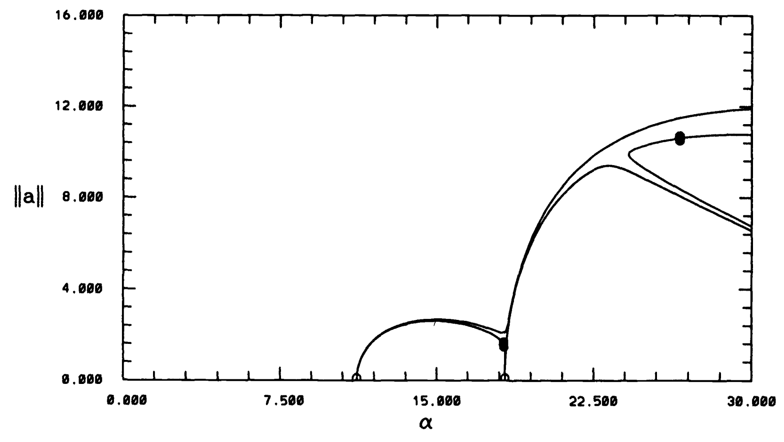

FIG. 2. *Steady-state bifurcation diagram of a dynamical system derived by projecting the* KSE *restricted to the odd invariant subspace onto the set of the first four* POD *modes extracted from an apparently chaotic solution at* $\alpha = 33.005$.

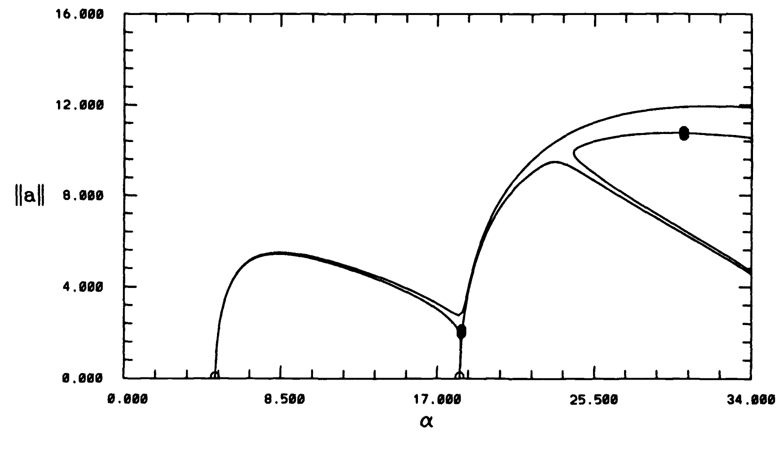

FIG. 3. *Same as Fig.* 2 *with the first five* POD *modes.*

The solutions of the truncated dynamical systems that we have derived are thus not invariant through the Z_2 symmetry $x \to x + \pi$ under which the space of solutions of the KSE is invariant. Therefore, in view of the work of Berkooz [11], this suggests that the apparently chaotic flow around $\alpha = 33.005$ is not ergodic. Hence, in order to impose this symmetry in the absence of ergodicity, we now compute the symmetric POD modes, as we previously proposed in §3. This is equivalent to taking into account the chaotic solution already considered and its symmetric companion. Symmetric POD modes and their respective eigenvalues are shown in Tables 3 and 4, respectively.

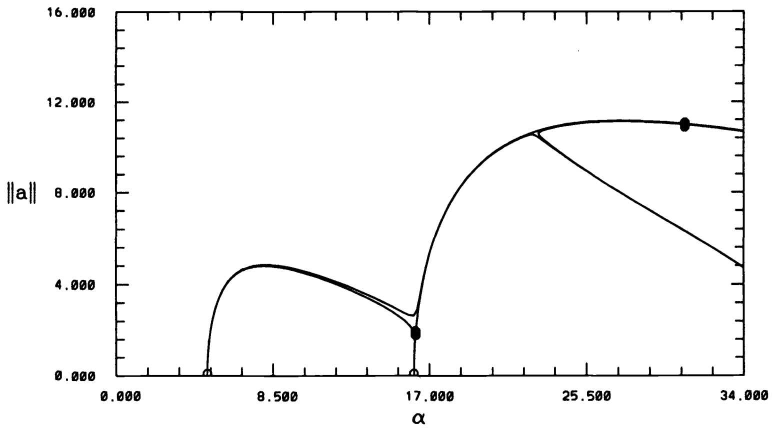

FIG. 4. *Same as Fig.* 2 *with the first six* POD *modes.*

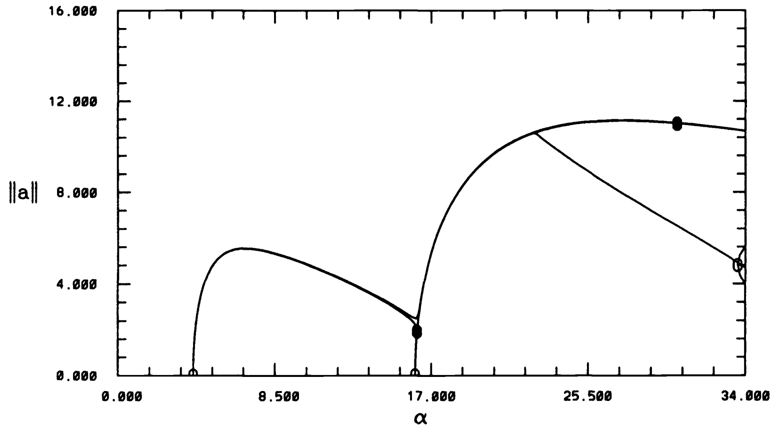

FIG. 5. *Same as Fig.* 2 *with the first seven* POD *modes.*

We note that the convergence given by the partial energies S_k is almost as fast as in the first case (Table 1) without symmetry involvement. An essential difference occurs among the eigenfunctions φ_k, which are now linear combinations of $\sin jx$,

where all the j's are either odd or even. Note that each one is invariant under the translation symmetry $x \to x+\pi$. Note that they were almost, but not quite, invariant in the previous case. (This small discrepancy was enough to make the POD modes nonsymmetric, which was reflected in the unimodal branch decoupling). Symmetric POD modes are therefore invariant under the global symmetry and, in this case, either $\varphi_k(x) = \varphi_k(\psi_g(x))$ or $-\varphi_k(x) = \varphi_k(\psi_g(x))$ (with $\psi_g(x) = x$ or $\psi_g(x) = x+\pi$) so that the eigenvalues are not degenerate. It immediately follows that any truncated system based on these modes is necessarily invariant under the symmetry group generated by T_π (see Proposition 5). This is immediately checked by reconstructing the steady-state bifurcation diagram: The pair of unimodal branches are now superposed as they should be and a steady-state bifurcation occurs when the pair meets with the bimodal branches. The same is true for the pair of bitrimodal branches that are now superposed and meet one bimodal branch through a steady-state bifurcation. This can be seen on bifurcation diagrams in Figs. 6, 7, 8, and 9, where four, five, six, and seven symmetric POD modes have been retained. However, the decoupling of the two bimodal branches still persists, due to the fact that the symmetry involved here is specific to the branch $(T_{\pi/2})$. Note that this symmetry cannot be imposed on physical grounds in our dynamical systems, as the global symmetry could. However, it tends to disappear as the dimension of the dynamical system increases; with six POD modes, it is no longer noticeable. The bifurcation diagram using six POD modes is qualitatively correct. However, we should recall that a truncated dynamical system based on six Fourier modes also gives good results. Therefore, we have not been able to decrease the number of necessary modes in the truncated dynamical system by taking POD modes, as we might have expected, not to mention that by using approximate inertial manifolds, three Fourier modes were enough to give the right qualitative diagram [20], [38], [39].

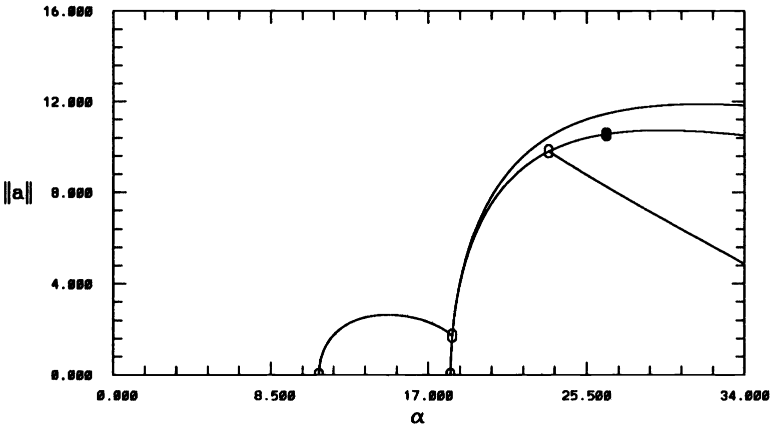

FIG. 6. *Same as Fig.* 2 *with the first four symmetric* POD *modes.*

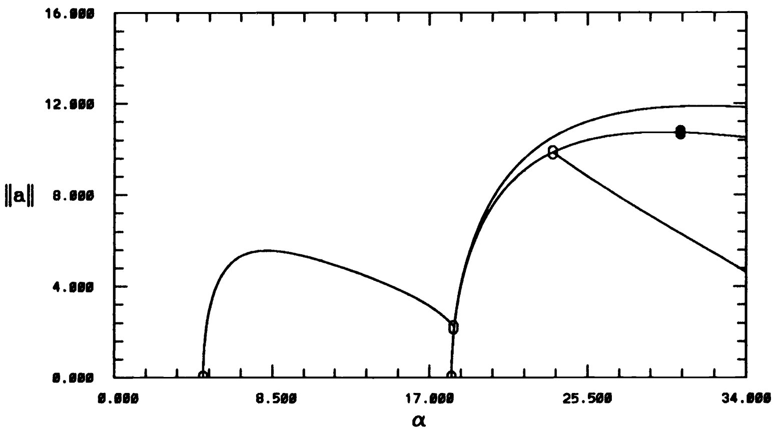

FIG. 7. *Same as Fig.* 2 *with the first five symmetric* POD *modes.*

5. Conclusion and discussion. We have proposed a technique to derive finite sets of ODEs based on POD modes that preserves the symmetry of the infinite-dimensional system. It consists of systematically involving the symmetry group in

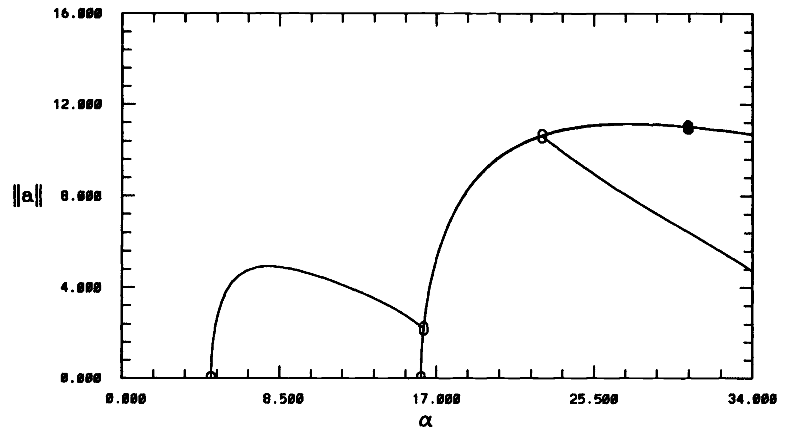

FIG. 8. *Same as Fig.* 2 *with the first six symmetric* POD *modes.*

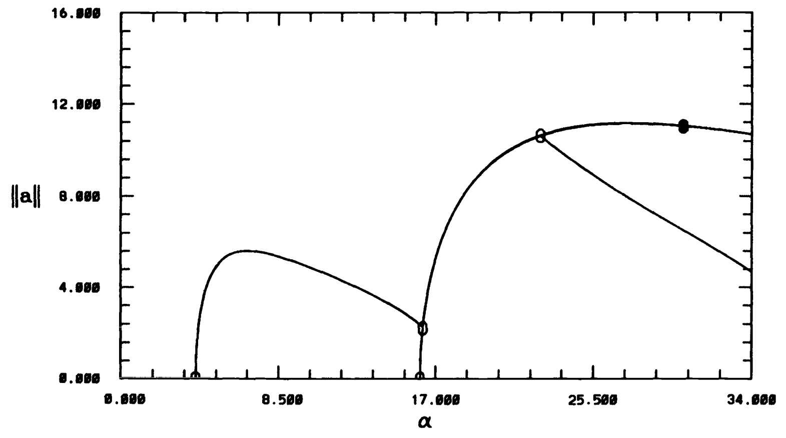

FIG. 9. *Same as Fig.* 2 *with the first seven symmetric* POD *modes.*

the derivation of basis modes. We have applied the technique to the KSE subject to periodic boundary conditions and restricted to the odd invariant subspace. However, we were not able to decrease the number of necessary POD modes below six, which is also the minimum number of Fourier modes necessary for the reconstruction of a qualitatively correct steady-state bifurcation diagram. POD modes that we have found numerically are not identical to Fourier modes. Even the first modes accounted for higher Fourier components, which are perhaps responsible for introducing extra dissipation in our dynamical system compared to a dynamical system based on Fourier modes. This could be the reason why the unbounded branches found by Jolly, Kevrekidis, and Titi [38], [39] do not occur as often in low-dimensional dynamical systems based on POD modes. The counterpart of this is perhaps a misrepresentation of low Fourier components in low-order POD modes. This did not have a major effect for values of parameters below 33, but it may have noticeable consequences on the trimodal branch on which the first steady-state bifurcation disappears when six (symmetric or nonsymmetric) POD modes are retained (see Fig. 10). Although our work focuses on the symmetry issue, we point out that this may not be the only problem in the procedure. Again, we recall that POD modes may completely change as the bifurcation parameter varies.

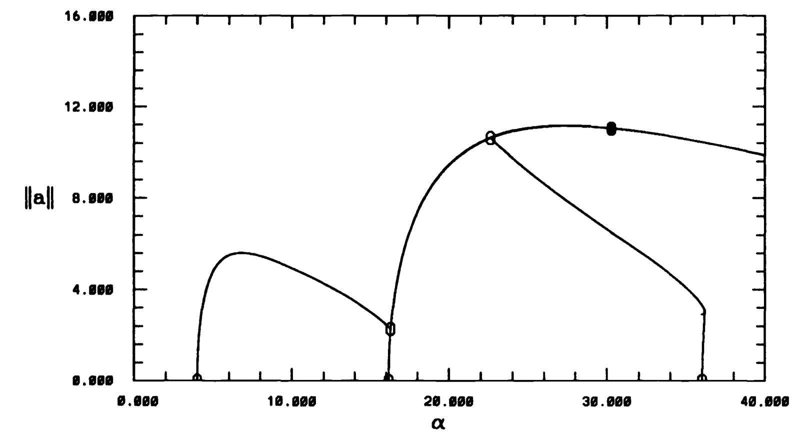

FIG. 10. *Same as Fig. 9 for a broader range of parameter values* $(0 < \alpha < 40)$.

To conclude, we point out that it is not trivial, at least for the PDE chosen as an example in this paper, to derive global modes that would be superior to Fourier modes and valid for a finite projection of the ODE over a relatively broad range of parameter values. This is not surprising since characteristic POD modes can dramatically change through bifurcations. From this point of view, local studies in phase space might be more promising [5], [7], [42], [43].

Acknowledgment. The authors would like to thank Professor I.G. Kevrekidis for the interesting discussions.

TIMELY COMMUNICATION

Under the "timely communications" policy for the SIAM Journal on Scientific Computing, papers that have significant timely content and do not exceed five pages automatically will be considered for a separate section of the journal with an accelerated reviewing process. It will be possible for the note to appear approximately six months after the date of acceptance.

WAVELETS AND MULTIGRID*

WILLIAM L. BRIGGS† AND VAN EMDEN HENSON‡

Abstract. This note explores the suggestive similarities between wavelet (multiresolution) and multigrid approaches to general operator equations. After presenting the essentials of wavelet and multigrid methods, it can be shown that classical multigrid methods use near-orthogonal basis functions to provide the same orthogonal decomposition of the fine grid space Ω^h that multiresolution methods generate for the maximum resolution space V_0.

Key words. wavelets, multigrid

AMS(MOS) subject classification. 65M55

1. Introducton.

The last few years have seen a remarkable amount of activity and interest in the field of wavelet theory and multiresolution analysis. With this heightened level of interest, researchers in diverse fields have begun to consider wavelet-based methods. The work presented in this paper was done in an exploratory spirit, by investigating the very suggestive similarities between multiresolution analysis and multigrid methods. The results are preliminary and only point to several avenues of future work.

Like many mathematical topics that suddenly gain currency, wavelet theory has origins that are not particularly recent. Both the history and the theoretical foundations of wavelets can be found in several recent and outstanding papers [3], [5], [6], [8], [9], [12]. By all accounts, the definitive treatise is the book by Meyer [11]. In this paper we have neither the space nor the audacity to duplicate the excellent presentations that already exist in these sources. Instead, we will review the essential features of multiresolution analysis that seem to pertain to multigrid algorithms.

2. Multiresolution analysis.

A *multiresolution analysis* is a framework that consists of a sequence of nested closed subspaces (typically of $L^2(\mathbf{R})$),

$$\cdots \subset V_2 \subset V_1 \subset V_0 \subset V_{-1} \subset V_{-2} \subset \cdots,$$

whose union is dense in $L^2(\mathbf{R})$. The important features of these subsets are that:

(a) V_0 is spanned by an orthonormal set consisting of integer translations of a single *scaling function* ϕ. For each integer j, V_j is spanned by an orthonormal set consisting of translations of scaled versions of ϕ:

$$V_j = \text{span } \{\phi(2^{-j}x - k)\}_k.$$

(b) For each integer j, $V_j = V_{j+1} \oplus W_{j+1}$, where each W_j is spanned by an orthonormal set consisting of translations of scaled versions of a single *wavelet function* ψ:

*Received by the editors June 10, 1991; accepted for publication September 6, 1992.

†Mathematics Department and Computational Mathematics Group, University of Colorado at Denver, Denver, Colorado 80217–3364.

‡Mathematics Department, Naval Postgraduate School, Monterey, California 93493.

$$W_j = \text{ span } \{\psi(2^{-j}x - k)\}_k.$$

(c) The doubly indexed set $\{\psi(2^{-j}x - k)\}_{j,k}$ spans $L^2(\mathbf{R})$.

Once a scaling function ϕ is found, the associated wavelet function ψ with all of the required orthogonality properties can be found directly. However, ϕ is clearly a rather extraordinary function and the discovery of such functions has been a major research quest. Computationally, there are several ways to produce a scaling function, among them to compute its Fourier transform first. An important property of scaling functions and the associated wavelet functions is that they are highly localized in both the spatial and the frequency domains. Summarizing a wealth of fascinating work, there appear to be three general classes of scaling functions:

(a) C^∞ scaling functions due to Meyer [10] that have noncompact support and polynomial decay,

(b) C^k scaling functions due to Battle [1] and Lemarie [7] that have noncompact support and exponential decay and are generated by orthogonalization of classical splines, and

(c) the Daubechies scaling functions D_{2k} [3] that have compact support, but smoothness that increases slowly with k.

In practice, when dealing with discrete problems such as image processing or signal analysis, the problem is posed on (or projected onto) a finite-dimensional space V_0 which represents the highest level of resolution that is desired. In a multigrid setting V_0 corresponds to Ω^h, the space of fine grid vectors. Given a function $u \in V_0$, the subspaces $V_1, \ldots, V_M$, for some M (corresponding to the coarse grid spaces $\Omega^{2h}, \Omega^{4h}, \ldots$ in multigrid) give representations of u on increasingly coarse levels. At each level, the difference between the projection of u in the spaces V_{j+1} and V_j is given by the projection of u in the space W_{j+1}. The V_j projection retains the smooth features of u, while the W_j projection captures the detail (or oscillatory) components of u.

Within the multiresolution framework it is possible to do a very efficient decomposition of a function over all of the subspaces of interest. Given a function $u \in V_0$, the orthogonality of ϕ and ψ may be used to find coefficients c_{0k} such that

$$u(x) = \sum_k c_{0k}\phi(x-k). \tag{1}$$

This may be regarded as a fine grid representation of u. Furthermore, coefficients c_{1k} and d_{1k} may be found for a coarse grid representation of u on V_1 and W_1 of the form

$$u(x) = \sum_k c_{1k}\phi\left(\frac{x}{2} - k\right) + d_{1k}\psi\left(\frac{x}{2} - k\right). \tag{2}$$

This process may be continued by decomposing each V_j representation of u on the next coarser pair of grids V_{j+1} and W_{j+1} until the coarsest grid is reached. The efficient Pyramid Algorithm for performing this decomposition (and the inverse synthesis) has been proposed by Mallat [8], [9]. The full decomposition of an $N = 2^M$-point sample of u over M levels requires $O(N)$ operations.

3. The multigrid connection.

With this brief survey, we turn to possible connections between multiresolution analysis and classical multigrid algorithms. We will consider a general operator equation of the form $Lu = f$ where L is a self-adjoint operator representing, for example, an elliptic boundary value problem. The notation can be simplified by letting

$$\phi_{jk} = \phi(2^{-j}x - k) \quad \text{and} \quad \psi_{jk} = \psi(2^{-j}x - k).$$

In addition, $\langle u, v\rangle$ will denote the appropriate inner product for the problem.

On the fine grid V_0 and the first coarse grid (V_1, W_1), the solution u may be represented as in (1) and (2). The data f also have a representation on V_0 and (V_1, W_1) with respective coefficients f_{0k}, f_{1k}, and g_{1k}. The fine grid problem after using orthogonality in a standard Galerkin way has the form

$$\sum_k c_{0k}\langle \phi_{0j}, L\phi_{0k}\rangle = f_{0j} \quad \forall j. \tag{3}$$

The known wavelets appear to have no special orthogonality properties with respect to standard elliptic operators so (3) represents a system of linear equations with generally narrow bandwidth, but with no obvious advantages over known discretizations.

In a similar way, the problem may also be represented on the coarse grid. Substituting the (V_1, W_1) representations for u and f and using orthogonality leads to

$$\sum_k c_{1k}\langle \phi_{1j}, L\phi_{1k}\rangle + d_{1k}\langle \phi_{1j}, L\psi_{1k}\rangle = f_{1j} \quad \forall j \tag{4}$$

and

$$\sum_k c_{1k}\langle \psi_{1j}, L\phi_{1k}\rangle + d_{1k}\langle \psi_{1j}, L\psi_{1k}\rangle = g_{1j} \quad \forall j. \tag{5}$$

The problem given in (4) may be regarded as the coarse grid problem for the smooth components of the solution, while (5) gives the coarse grid problem for the oscillatory components.

In classical multigrid algorithms, a solution is sought on a fine grid Ω^h (with grid spacing h) by using standard relaxation methods to approximate errors on the coarse grids $\Omega^{2h}, \Omega^{4h}, \ldots$. The details of the various multigrid cycles are not important for this discussion [2], except to say that vectors are transferred from coarse grids to finer grids with an interpolation operator denoted I_{2h}^{h}, while vectors are transferred from fine grids to coarser grids with a restriction operator denoted I_h^{2h}. The most common choice for interpolation is linear interpolation, while full weighting (averaging of neighbors) is one of the most commonly used restriction operators.

The use of linear interpolation in multigrid schemes corresponds to a representation of the solution in terms of piecewise linear hat functions ϕ_{0k}. The hat functions lack the required orthogonality to be genuine scaling functions. Nevertheless, an associated "wavelet" function ψ may be found for the hat functions (Fig. 1) that allows for an orthogonal decomposition of the fine grid space (V_0 or Ω^h). It is known that the functions ϕ_{1k} span the range of the interpolation operator I_{2h}^{h}, while the functions ψ_{1k} span the nullspace of the full weighting operator I_h^{2h}. Therefore, in multiresolution terms, we would write

$$V_0 = \text{ span } \{\phi_{1k}\} \oplus \text{ span } \{\psi_{1k}\} = V_1 \oplus W_1,$$

while in multigrid terms we would write

$$\Omega^h = \text{ span } \{\phi_{1k}\} \oplus \text{ span } \{\psi_{1k}\} = \text{ Range } \{I_{2h}^{h}\} \oplus \text{ Nullspace } \{I_h^{2h}\}.$$

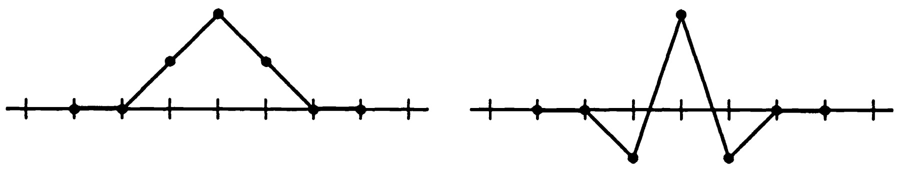

FIG. 1. *The hat functions (left) span V_1 (or the range of interpolation), while the teeth functions (right) span W_1 (or the nullspace of full weighting). These spaces provide an orthogonal decomposition of the fine grid space V_0 (or Ω^h).*

Thus multigrid with piecewise linear interpolation produces the same orthogonal decomposition of the fine grid Ω^h that multiresolution produces of the space V_0.

Classical multigrid methods apply limited relaxation to the fine grid problem (3). They deal only with the coarse grid equation for the smooth components (4). Furthermore, the second term of (4) representing oscillatory components is dropped and the matrix given by $\langle \phi_{1j}, L\phi_{1k} \rangle$ is precisely the multigrid coarse grid operator $L^{2h} = I_h^{2h} L^h I_{2h}^h$. The entire coarse grid equation for the oscillatory components (5) is also dropped in multigrid. The rationale for neglecting the oscillatory components in (4) and (5) is that relaxation is an extremely effective way to isolate or eliminate them.

In summary, multigrid formulations use simple, near-orthogonal basis functions that still allow for an orthogonal decomposition of the fine grid space (and similar decompositions of subsequent coarse grid spaces). Furthermore, multigrid does not attempt to solve for the oscillatory (W_j) components of the solution directly, but rather lets relaxation handle them indirectly. This choice of departing from orthogonality and incorporating relaxation (as well as the residual equation) accounts for the extreme efficiency of multigrid algorithms.

In closing, it should be said that preliminary work on wavelet-based multigrid algorithms for differential equations is in progress [4]. It appears that accuracy comparable to multigrid algorithms can be obtained using the D_{2k} compact wavelets on boundary value problems. However, considerable work on wavelet-based multilevel methods remains to be done.

COMPUTING REPRODUCING KERNELS WITH ARBITRARY BOUNDARY CONSTRAINTS*

C. J. DALZELL† AND J. O. RAMSAY‡

Abstract. Smoothing with L-splines involves the use of the penalty term $\|x\|_2^2 = \int (Lx)^2(t)\,dt$ where L is an arbitrary linear differential operator of order m. It also involves the choice of m constraint functionals to define two orthogonal function subspaces. The basis for a smoothing function is provided by the reproducing kernel for the associated Hilbert space. Computing the kernel for the subspace complementary to $H_1 = \ker L$ can be difficult. Techniques for computing these kernels for arbitrary linear differential operators and constraint functions are developed and illustrated.

Key words. spline smoothing, L-splines, reproducing kernel Hilbert space, Green's function, boundary constraints, nonparametric regression

AMS(MOS) subject classifications. 62J02, 65U05

1. Introduction.

In the spline smoothing problem the objective is to find a function $x(t)$ that will represent the set of observations $(\mathbf{y}, \mathbf{t}) = \{(y_j, t_j), j = 1, \ldots, p\}$. It is assumed that x is an element of the set H^m of functions with $m-1$ absolutely continuous derivatives and a square-integrable mth derivative, $m \geqq 1$. It will also be assumed that x is defined on the real interval $[0, T]$. The definition of the problem usually involves a linear differential operator

$$Lx = \sum_{j=0}^{m} \alpha_j D^j x, \tag{1}$$

where $D^{m-j}\alpha_j$ is an absolutely continuous function of t, $\alpha_m \neq 0$, $D^j x$ denotes the jth derivative of x, and $D^0 x = x$. Let the evaluation operator ρ_t be defined by $\rho_t(x) = (x(t_1), \ldots, x(t_p))'$. Then x is defined to be the minimizer of the smoothing criterion

$$Q(x \mid \mathbf{y}, \lambda) = \|\mathbf{y} - \rho_t(x)\|_N^2 + \lambda \|x\|_2^2, \tag{2}$$

where $\|\mathbf{y}\|_N^2 = \mathbf{y}' N \mathbf{y}$ for some symmetric positive definite matrix N and $\lambda > 0$. The norm in the second term is

$$\|x\|_2^2 = \int_0^T (Lx)^2(t)\,dt. \tag{3}$$

The use of L to define (3) implies that H^m is partitioned into subspace $H_1 = \ker L = \{u \mid Lu = 0\}$ of dimension m and a complementary subspace H_2. The variational problem (2) is solved by defining a reproducing kernel Hilbert space on H^m. This, in turn, involves a choice of inner products and reproducing kernels for the two subspaces H_1 and H_2 with respect to which they are orthogonal. If the bivariate reproducing kernels for H_1 and H_2 are denoted by k_1 and k_2, respectively, then the reproducing kernel for $H^m = H_0 = H_1 \oplus H_2$ is $k_0 = k_1 + k_2$, and these kernels satisfy the equations

$$\langle k_h(s, \cdot), x \rangle_h = x(s) \quad \forall x \in H_h, \quad h = 0, 1, 2.$$

* Received by the editors October 1, 1990; accepted for publication (in revised form) February 17, 1992. This work was partially supported by the Natural Sciences and Engineering Research Council of Canada through grants A320 and 3-31552.

† Canadian Red Cross, 1800 Alta Vista Drive, Ottawa, Ontario, Canada K1G 4J5.

‡ Department of Psychology, 1205 Dr. Penfield Avenue, Montreal, Quebec, Canada H3A 1B1. The work of this author was partially supported by the Educational Testing Service.

Thus the reproducing kernel $k_h(s,\cdot)$ is the representer in Hilbert space H_h of the evaluation functional $\rho_s = x(s)$, the existence of which is assured by the continuity of ρ_s in H^m and the Riesz representation theorem.

The inner products must define orthogonal Hilbert spaces H_1 and H_2, and this can be done by choosing a second linear operator $B: H^m \to R^m$ to be a set of m functionals such that $H_1 = \ker L$ and $H_2 = \ker B$. The orthogonality of H_1 and H_2 implies that $\ker L \cap \ker B = 0$. The inner product for H_1 can then be defined as

$$\langle x, y\rangle_1 = (Bx)'(By). \tag{4}$$

The smoothing function $x \in H_0$ does not depend on the choices of the two inner products and their associated reproducing kernels for the subspaces H_1 and H_2, and if one's sole interest is in x itself, these choices can be governed by mathematical convenience. In particular, Kimeldorf and Wahba [2], [3] and Wahba [7] describe reproducing kernels for the special class of differential operators

$$L = D\frac{1}{a_1}D\frac{1}{a_2}\cdots D\frac{1}{a_m}, \tag{5}$$

where the inner products for H_1 are based on initial value constraints associated with the differential equation $Lx = e$. In practice, almost all applications of spline smoothing have involved the operator $L = D^m$ associated with polynomial smoothing splines and the initial value constraints

$$B_0 = \{(D^j x)(0), j = 0, \dots, m-1\}.$$

There are important reasons for considering the problem of choosing inner products for H_1 and H_2 that are more general. Not all operators L that an application would suggest fall into the class (5). Moreover, the representations of the data in the subspaces H_1 and H_2 can have substantive significance, and interesting constraint operators B defining these subspaces may not correspond to standard initial or boundary value constraints discussed in most references on differential equations. Besse and Ramsay [1] and Ramsay and Dalzell [4] argued that in statistical applications of spline smoothing it is useful to look at the image of x in H_1 and H_2 separately, and also that these images will naturally depend on the nature of the inner products chosen. They further pointed out that inner products based on initial value constraints often do not have much substantive meaning.

The following example illustrates alternative choices of L and B. Suppose that one has data with a tendency to linear trend, and that it is desired to smooth the data in such a way that the linear component u in the smoothing function $x = u + e$ is identified independently of the nonlinear component e. Let $H = H^2[0, T]$ and $L(x) = D^2x$, for which $\ker L = \text{span}\{1, t\}$. If, for some reason, we require that this linear component u fit the data exactly for the first observation y_1, which we can take to be at $t = 0$, then we would use the initial value boundary functional defined by $B(u) = (u(0), (Du)(0))'$. H_1 then contains functions of the form $u(t) = c_1 + c_2 t$, with inner product $\langle u, v\rangle_1 = u(0)v(0) + (Du)(0)(Dv)(0)$, while H_2 contains functions without initial linear trend in the sense that $e(0) = (De)(0) = 0$ for all $e \in H_2$ and $\langle e, f\rangle_2 = \int D^2eD^2f\,dt$.

This approach might be unsuitable if the initial observation y_1 contains substantial observational error, or if there is no particular reason to pass the smoothing function exactly through this or any other observation. In data analysis, it would often appear more natural to use all observations to define the linear trend, and to use them symmetrically in the sense that the indices for t play identical roles in the smoothing process. In this context, a more natural choice for the boundary functionals would be $B(u)=(\int u(t)\,dt, \int tu(t)\,dt)'$. By setting $B(u)=0$ we are still defining H_1 as span $\{1, t\}$, but now with the inner product

$$\langle u, v\rangle_1 = \left[\int u(t)\,dt\right]\left[\int v(t)\,dt\right] + \left[\int tu(t)\,dt\right]\left[\int tv(t)\,dt\right]. \tag{6}$$

This inner product is uniform in that it depends on the behavior of u and v at all values of t rather than just on $t=0$. H_2 will have the same inner product as in the previous example, but will now consist of functions with linear trend eliminated by averaging across all t values.

Ramsay and Dalzell [4] considered an example in which the smoothing was by the shifted harmonic splines defined by

$$Lx = \omega^2 D + D^3,$$

so that $H_1 = \ker L$ is spanned by $\{1, \sin(\omega t), \cos(\omega t)\}$. In their application, H_2 was defined to be the set of $x \in H^m$ such that

$$\int_0^T x(t)\,dt = 0,$$

$$\int_0^T \sin(\omega t)x(t)\,dt = 0,$$

$$\int_0^T \cos(\omega t)x(t)\,dt = 0.$$

These constraints were natural with the periodic character of their data, consisting of observations of mean monthly temperature and precipitation, since there was no particular reason to single out any one month as the origin for the series.

The reproducing kernel k_1 is easily computed. Let $u_1, \dots, u_m$ be functions spanning H_1 and let $\mathbf{u} = (u_1, \dots, u_m)'$. Defining the matrix U_1 to be the order m symmetric matrix with values $\langle u_i, u_j\rangle_1$, $i, j, = 1, \dots, m$, we have

$$k_1(s, t) = \mathbf{u}(s)' U_1^{-1} \mathbf{u}(t). \tag{7}$$

Thus, for inner product (6), we have that

$$k_1(s, t) = 4(13 - 24(s+t) + 45st).$$

Computing the kernel k_2 is generally much more difficult, and this is the problem principally addressed by this paper. In the following section, the Green's function for the initial value operator B_0 is given, and it is shown how this can be transformed to give the Green's function for any linear operator satisfying the orthogonality condition $\ker L \cap \ker B = 0$. Because the actual reproducing kernel can be very complex if written out completely in univariate algebraic notation, the following section also develops an expression for the Green's function and the reproducing kernel in matrix notation that is more suitable for computation.

2. Computing the reproducing kernel k_2. We proceed here by first computing the Green's function $g_0(t; w)$ associated with the initial value condition

$$B_0 x = (x(0), (Dx)(0), \dots, (D^{m-1}x)(0))' = 0,$$

and then show how to modify this Green's function to obtain the Green's function for the desired B.

In the particular case where e is a real-valued function and L a linear differential operator of order m, the Green's function $g(t;\, w)$ associated with L and the boundary constraints $B(e)=0$ satisfies

$$e(t)=\int g(t;\, w)(Le)(w)\, dw, \quad \forall e \mid B(e)=0, \tag{8}$$

and has the additional properties

$$Bg(\cdot\,; w) \quad \forall w=0,$$
$$(L^*g)(t;\, w)=0 \quad \forall t\neq w,$$

L^* being the adjoint operator associated with L,

$$L^*x=\sum_{j=0}^{m}(-1)^jD^j(\alpha_jx), \tag{9}$$

and applied to g as a function of w (see Roach [5] and Schumaker [6, p. 426]). The Green's function

- provides a convenient means of computing the reproducing kernel,
- is useful when computing L_x,
- links the theory of reproducing kernel Hilbert spaces with the theory of ordinary differential equations.

The Green's function can be derived simply from k_2 since it follows from (8) that $Lk_2(s,\cdot)=g(s;\,\cdot)$, where L is applied to k_2 as a function of w for fixed s. Conversely, the reproducing kernel k_2 can also be computed from g as

$$\begin{aligned} k_2(s,t)&=\langle k_2(s,\cdot), k_2(t,\cdot)\rangle_2\\ &=\int Lk_2(s,w), Lk_2(t,w)\, dw \qquad (10)\\ &=\int g(s;\, w), g(t;\, w)\, dw. \end{aligned}$$

2.1. Green's function for the initial value condition. We follow here the exposition of Schumaker [6, pp. 422–429], in which it is assumed without loss of generality that L is in the form

$$L=D^m+\sum_{j=0}^{m-1}\alpha_jD^jx.$$

Let

$$\mathbf{u}=(u_1,\ldots,u_m)'=\operatorname{span}\{\ker L\}.$$

The Wronskian matrix $\mathbf{W}: T\to R^{mm}$ is the order m matrix-valued function with elements $D^{j-1}u_i$, $i,j=1,\ldots,m$. It is assumed that $\mathbf{W}(w)$ is nonsingular for all w. The adjoint functions $\mathbf{u}^*=(u_1^*,\ldots,u_m^*)'$ are defined by $\mathbf{u}^*=(\mathbf{W}^{-1})_m$, where $(\mathbf{W}^{-1})'_m$ is the mth row of $\mathbf{W}^{-1}$. The Green's function for the initial value condition is (Schumaker [6, Thm. 10.11])

$$g_0(t;\, w)=\mathbf{u}(t)'\mathbf{u}^*(w)=\sum_i^m u_i(t)u_i^*(w), \qquad w\leqq t, \tag{11}$$

and 0 otherwise.

Example 1: *Linear trend.* When $L = D^2$ with $\mathbf{u}(t) = (1, t)'$, $t \in [0, 1]$, we have that

$$W(w) = \begin{bmatrix} 1 & 0 \\ w & 1 \end{bmatrix}$$

and

$$\mathbf{W}(w)^{-1} = \begin{bmatrix} 1 & 0 \\ -w & 1 \end{bmatrix} \tag{12}$$

with $|\mathbf{W}| = 1$. Thus $g_0(t;\, w) = t - w$, $w \leqq t$, and 0 otherwise.

Example 2: *Harmonic variation with mean zero.* When

$$L = \theta^2 I + D^2 \quad \text{with } \mathbf{u}(t) = (\sin(\theta t), \cos(\theta t))',$$

we have that

$$\mathbf{W}(w) = \begin{bmatrix} \sin(\theta w) & \theta \cos(\theta w) \\ \cos(\theta w) & -\theta \sin(\theta w) \end{bmatrix}$$

and

$$\mathbf{W}(t)^{-1} = \begin{bmatrix} \sin(\theta w) & \cos(\theta w) \\ \theta^{-1} \cos(\theta w) & -\theta^{-1} \sin(\theta w) \end{bmatrix} \tag{13}$$

with $|\mathbf{W}| = -\theta^{-1}$. Thus

$$g_0(t;\, w) = \theta^{-1} \sin[\theta(t - w)], \qquad w \leqq t, \tag{14}$$

and 0 otherwise.

Example 3: *Harmonic variation with arbitrary mean.* When

$$L = \theta^2 D + D^3 \quad \text{with } \mathbf{u}(t) = (1, \sin(\theta t), \cos(\theta t))',$$

we have that

$$W(w) = \begin{bmatrix} 1 & 0 & 0 \\ \sin(\theta w) & \theta \cos(\theta w) & -\theta^2 \sin(\theta w) \\ \cos(\theta w) & -\theta \sin(\theta w) & -\theta^2 \cos(\theta w) \end{bmatrix}$$

and

$$\mathbf{W}(t)^{-1} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \theta^{-1} \cos(\theta w) & -\theta^{-1} \sin(\theta w) \\ \theta^{-2} & -\theta^{-2} \sin(\theta w) & -\theta^{-2} \cos(\theta w) \end{bmatrix} \tag{15}$$

with $|\mathbf{W}| = -\theta^{-3}$. Thus

$$g_0(t;\, w) = \theta^{-2}\{1 - \cos[\theta(t - w)]\}, \qquad w \leqq t, \tag{16}$$

and 0 otherwise.

2.2. Modifying g_0 to obtain g for arbitrary $Bx = 0$. Now let B be an arbitrary set of functions for which $\ker L \cap \ker B = 0$ and define the vector-valued function $\mathbf{b}_0$ by

$$\mathbf{b}_0(w) = Bg_0(\cdot;\, w).$$

Let order m matrix B^* have elements $b_i u_j$, where b_i is the ith functional in B; that is, $B^* = B\mathbf{u}'$.

THEOREM 1. *If B^* is nonsingular and the functionals b_i commute with integration in H^m, then the Green's function for the condition $Bf = 0$ is*

$$g(t;\, w) = g_0(t;\, w) - \mathbf{u}(t)' B^{*^{-1}} \mathbf{b}_0(w). \tag{17}$$

Proof. For any $f_0 \in \ker B_0$ let $f(t) = f_0(t) - \mathbf{u}(t)' B^{*^{-1}}(Bf_0)$. Then $Bf = 0$, and it is easy to show that the mapping $\ker B_0 \to \ker B$ defined in this way is a bijection. By $Lu = 0$,

$$\begin{aligned}\int g_0(t;\, w)(Lf)(w)\, dw &= f_0(t) - [B^{*^{-1}}(Bf_0)]' \int g_0(t;\, w)(Lu)(w)\, dw \\ &= f_0(t).\end{aligned}$$

Consequently,

$$\begin{aligned}\int g(t;\, w)(Lf)(w)\, dw = \int & g_0(t;\, w)(Lf_0)(w)\, dw \\ &- \mathbf{u}(t)' B^{*^{-1}} \int Bg(\cdot\,;\, w)(Lf)(w)\, dw \\ &= f_0(t) - \mathbf{u}(t)' B^{*^{-1}} B \int g(\cdot\,;\, w)(Lf)(w)\, dw \\ &= f_0(t) - u(t)' B^{*^{-1}} B f_0 \\ &= f(t). \qquad \square\end{aligned}$$

The condition of commutability of B and integration will hold for bounded functionals and for evaluations of derivatives up to order $m-1$, which includes all the cases discussed in this paper.

Example 1: *Linear trend with integral constraints.* In this case

$$B^* = (1/6)\begin{bmatrix} 6 & 3 \\ 3 & 2 \end{bmatrix}$$

and

$$\mathbf{b}_0(w) = (1/6)\begin{bmatrix} 3 - 6w + 3w^2 \\ 2 - 3w + w^3 \end{bmatrix},$$

so that

$$g(t;\, w) = \begin{cases} w^3(1-2t) + w^2(3t-2), & w \leqq t, \\ w^3(1-2t) + w^2(3t-2) + w - t, & w > t. \end{cases} \tag{18}$$

This yields

$$\begin{aligned} k_2(s, t) = [&4 - 22(s+t) + 156st - 210st^2 + 70t^3 - 70(t^4 + s^4) \\ &+ 105st(s^3 + t^3) + 21(s^5 + t^5) - 42st(s^4 + t^4)]/420, \qquad s \leqq t. \end{aligned} \tag{19}$$

The symmetry of k_2 provides the value of $k_2(s, t)$, $s > t$.

3. Matrix computation of g and k_2. The integrations involved in transforming g_0 to g as well as the final computation of the reproducing kernel k can be tedious, and are greatly facilitated by symbolic computation software. In particular, computation of k requires that the integration be performed separately for the subintervals $[0, t]$, $[t, s]$, and $[s, T]$, since g will have an expression for $[0, s]$ which differs from that for $[s, T]$. However, the calculations can be simplified as follows.

By (11) and (17), $g(\cdot\,; w) \in \ker L$ for $t \neq w$. Moreover, $g_0(t; \cdot) \in \ker L^*L$ for $t \neq w$, where L^* is the adjoint operator for L. Consequently,

$$g_0(t; w) = \mathbf{v}(w)'C_0\mathbf{u}(t), \qquad w < t,$$

and 0 otherwise, where $\mathbf{v} = (v_1, \cdots, v_{2m})'$ spans $\ker L^*L$. Moreover, $\mathbf{u}(t)'B^{*-1}\mathbf{b}_0(w)$ can be expressed in the form $\mathbf{v}(w)'C_1\mathbf{u}(t)$. Thus

$$g(t; w) = \begin{bmatrix} \mathbf{v}(w)'(C_0 - C_1)\mathbf{u}(t), & w \leqq t \\ -\mathbf{v}(w)'C_1\mathbf{u}(t), & w > t \end{bmatrix}, \tag{20}$$

and finally,

$$k_2(s, t) = \mathbf{u}(s)'[C_0'\mathbf{F}(s)C_0 - C_0'\mathbf{F}(s)C_1 - C_1'\mathbf{F}(t)C_0 + C_1'\mathbf{F}(T)C_1]\mathbf{u}(t), \quad s \leqq t, \tag{21}$$

and $k(s, t) = k(t, s)$, $s > t$, where

$$\mathbf{F}(s) = \int_0^s \mathbf{v}(w)\mathbf{v}(w)'\,dw.$$

These results imply that once the constant matrices C_0 and C_1 and the matrix function $\mathbf{F}$ are computed, the values of k_2 can be computed by simple matrix computations.

Example 2: *Harmonic variation, mean zero with integral constraints.* In this case,

$$v = (\sin(\theta w), \cos(\theta w), w \sin(\theta w), w \sin(\theta w))',$$

so that

$$C_0' = \theta^{-1}\begin{bmatrix} 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \end{bmatrix}. \tag{22}$$

Matrix $\theta[\theta^2T^2 - \sin^2(\theta T)]C_1$ works out to be

$$\begin{bmatrix} \theta T + \cos(\theta T)\sin(\theta T) & -\theta^2T^2 \\ \theta^2T^2 - \sin^2(\theta T) & 0 \\ -\theta\sin^2(\theta T) & \theta^2T - \theta\cos(\theta T)\sin(\theta T) \\ -\theta^2T - \theta\cos(\theta T)\sin(\theta T) & \theta\sin^2(\theta T) \end{bmatrix}. \tag{23}$$

Example 3: *Harmonic variation with arbitrary mean and integral constraints.* In this case,

$$\mathbf{v} = (1, w, \sin(\theta w), \cos(\theta w), w\sin(\theta w), w\sin(\theta w))',$$

so that

$$C_0' = \theta^{-2}\begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & 0 \end{bmatrix}. \tag{24}$$

Matrix C_1 can be expressed as C^*B^{*-1} where the matrix $(2\theta)B^*$ is

$$\begin{bmatrix} 2\theta T & 2(1-\cos(\theta T)) & 2\sin(\theta T) \\ 2(1-\cos(\theta T)) & \theta T - \sin(\theta T)\cos(\theta T) & \sin^2(\theta T) \\ 2\sin(\theta T), & \sin^2(\theta T) & \theta T + \sin(\theta T)\cos(\theta T) \end{bmatrix}, \tag{25}$$

and the matrix $(2\theta)^3 C^{*\prime}$ is

$$\begin{bmatrix} 2\theta T & -2\cos(\theta T) & 2\sin(\theta T) \\ -2\theta & 0 & 0 \\ 2\cos(\theta T) & \sin(\theta T)\cos(\theta T)-\theta T & \cos^2(\theta T)-2 \\ -2\sin(\theta T) & 1+\cos^2(\theta T) & -\sin(\theta T)\cos(\theta T)-\theta T \\ 0 & \theta & 0 \\ 0 & 0 & \theta \end{bmatrix}. \tag{26}$$

SPARSE MATRIX COMPUTATIONS ON PARALLEL PROCESSOR ARRAYS*

ANDREW T. OGIELSKI† AND WILLIAM AIELLO†

Abstract. This paper investigates the balancing of distributed compressed storage of large sparse matrices on a massively parallel computer. For fast computation of matrix-vector and matrix-matrix products on a rectangular processor array with efficient communications along its rows and columns it is required that the nonzero elements of each matrix row or column be distributed among the processors located within the same array row or column, respectively. Randomized packing algorithms are constructed with such properties, and it is proved that with high probability the algorithms produce well-balanced storage for sufficiently large matrices with bounded number of nonzeros in each row and column, but no other restrictions on structure. Then basic matrix-vector multiplication routines are described with fully parallel interprocessor communications and intraprocessor gather and scatter operations. Their efficiency is demonstrated on the 16,384-processor MasPar computer.

Key words. distributed data structures, linear algebra, load balancing, parallel algorithms, randomized algorithms, sparse matrices

1. Introduction.

Efficient computation in the data-parallel mode is achieved with distributed data structures that balance the processors' computation load and promote maximum parallelism of data communications. For parallel dense matrix linear algebra routines [2]-[4], [6], [7], [9], [12], a balanced distribution of computations to processors can be achieved together with very regular interprocessor communication patterns. In contrast, in the design of algorithms for unstructured sparse matrices, the data compression scheme may conflict with efficient communication. For instance, if a large matrix is evenly partitioned into blocks in correspondence with the processor array, the communications are similar to the dense case, but the computation time will be determined by the block with the largest number of nonzeros, which may be unacceptably large. Alternatively, if the nonzeros are densely packed into the processor array without regard for the row and column structure, the benefit of even processor load may be negated by overwhelming communication costs.

Universal distributed data structures that guarantee both fast computation and efficient compression for all sparse matrices have not been found. Therefore, we associate classes of sparse matrices with appropriate data structures and computational kernels. For unstructured sparse matrices, it is desirable to have few classes defined by simple and easily verified properties. Here we will only request that no row or column of a sparse matrix be too dense, with no other restrictions on matrix structure. We assume that the matrix remains unchanged during computation, and that it is accessed sufficiently often to justify preprocessing for well-balanced storage; this is the case in the family of Lanczos algorithms for the symmetric eigenvalue problem, conjugate gradient methods, and in many other numerical algorithms [7].

Suppose we have an $m \times n$ two-dimensional processor array with efficient communications along its rows and columns. Many parallel computers can be configured in this way. The processing element in the ith row and the jth column will be called

$PE(i,j)$. Let A be a sparse $M \times N$ matrix, $M \gg m$ and $N \gg n$. We will say that an assignment of matrix elements to the processor array preserves the *integrity* of the matrix if for every row (column) all its nonzero elements are placed into processors lying in a single row (column) of the array. In such an assignment each processor stores a submatrix, and the data communications required by linear operations can be carried out in parallel. The problem of finding an assignment that preserves the integrity of the matrix and minimizes the largest processor load is NP-complete. This can easily be shown by a reduction from bin packing [5]. Nonetheless, we show that if we do not require a deterministic, optimal solution, then a fast random assignment that preserves the matrix integrity and comes very close to optimal can be achieved with high probability.

We analyze two schemes for random assignments that preserve the integrity. In the simplest random assignment scheme each matrix row index is randomly and independently assigned a row of the processor array, and each matrix column index is randomly and independently assigned a column of the array. The dimensions of submatrices stored in different processors generally will be different.

This loss of uniformity is corrected in the second, more restricted scheme. Suppose that before the loading a random permutation of matrix rows and a random permutation of matrix columns are performed, and then the permuted matrix is partitioned into blocks of size $\lceil M/m \rceil \times \lceil N/n \rceil$ (the right-most and lowest blocks may be smaller). This results in an $m \times n$ matrix of blocks which are assigned in the natural way to the $m \times n$ processor array.

The second scheme is very convenient for algorithm design, but a priori it is not obvious that it can achieve as good a load balancing as the first method. Suppose that the matrix A has T nonzero elements and at most $R(C)$ nonzeros in each row (column). Let $|P_{i,j}|$ denote the number of nonzeros assigned to processor $PE(i,j)$; it is easily seen that for any assignment scheme we must have $\max_{i,j} |P_{i,j}| \geqq \lceil T/mn \rceil$. We prove that for sufficiently large T and sufficiently small R and C, either assignment scheme produces a well-balanced load with high probability. This is stated by showing that in both schemes $\Pr\{\max_{i,j} |P_{i,j}| \geqq (1+\varepsilon)^2 \lceil T/mn \rceil\}$ is bounded from above by $\exp\{-O(\varepsilon h(\varepsilon))\}$, where $h(x) = (1+x^{-1}) \ln(1+x) - 1$. The function $h(x)$ is strictly monotonically increasing, and $h(x) \approx x/2$ for $x \to 0$, $h(x) \approx \ln(x)$ for $x \to \infty$.

As far as we know, this is the first result on parallel sparse matrix computations with provably good storage efficiency for unstructured sparse matrices. The exact statement of the theorem and its proof are given in § 2. The proof for the first scheme makes repeated use of Bennett's inequality for large deviations from the expected value of a sum of independent random variables [1]. The second scheme uses an extension of this inequality to a special case of dependent random variables due to Hoeffding [8]. Incidently, very large randomly sparse matrices (where each element independently is nonzero with a fixed probability) with high probability give balanced load in the second scheme even without the row and column permutations (apply Bennett's inequality directly to block submatrices).

Once submatrices are assigned to processor elements, the nonzeros are stored in a compressed format. Although the structure (i.e., location of nonzeros) of submatrices stored in different processing elements (PEs) may vary, this does not impede the parallelism of data movement and execution of matrix primitives if scatter and gather techniques are used: data can be transmitted in parallel in regular patterns to buffers in PEs and then scattered to proper memory locations, or vice versa. For this we assume that the parallel computer supports indirect addressing; that is, the PEs can store pointers to their own memories. With indirect addressing the scatter and gather operations can be executed in parallel even on data-parallel machines, since each PE can access a different memory location in a single instruction.

In § 3 we assume a balanced distribution of nonzeros and show one possible implementation of the basic matrix-vector kernels for computation of Ax or $y^T A$ and their extensions to blocks of vectors assuming only the data-parallel computer model. We also present examples of both the efficiency of packing and the performance of kernels on a particular data-parallel computer, the 16,384-processor MasPar MP-1216.

The NP-completeness of the optimum integrity-preserving matrix assignment problem does not preclude the possibility that a deterministic, polynomial time algorithm may be able to produce an assignment that provably comes within a constant factor of the optimum. Finding such an algorithm is an interesting question for future research. We also expect that randomized storage of data in distributed data structures preserving the favorable communication patterns will be useful in other applications.

2. Balanced loading.

To distinguish the matrix row and column indices from the processor array indices we always use capital letters $I, J, \ldots$ for the matrix, and lower case letters $i, j, \ldots$ for the processors. For brevity, in this section we use $P_{i,j}$ to denote the processor $PE(i, j)$. Also, we will denote the set of integers from a to b inclusive by $[a, b]$.

We consider assignments of nonzero elements of an $M \times N$ sparse matrix A to processors in an $m \times n$ array (where $M \gg m$ and $N \gg n$) which preserve the integrity of matrix rows and columns. Any such assignment, by definition, can be described by two mappings: The row mapping $\rho : [0, M-1] \rightarrow [0, m-1]$, and the column mapping $\sigma : [0, N-1] \rightarrow [0, n-1]$. A matrix element $A_{I,J}$ is assigned to $P_{\rho(I),\sigma(J)}$; therefore, the processor P_{ij} stores the submatrix of A given by the rows in $\rho^{-1}(i)$ and the columns in $\sigma^{-1}(j)$. Let $|P_{i,j}|$ denote the number of nonzeros in this submatrix.

We analyze two fast probabilistic algorithms for the construction of row and column mappings that attempt to keep all the $|P_{i,j}|$ as close to the optimum value $\lceil T/mn \rceil$ as possible. To describe the first, let $\mathcal{F}_{M,m}$ be the uniform distribution on all functions from $[0, M-1]$ to $[0, m-1]$. We draw ρ according to $\mathcal{F}_{M,m}$ and σ according to $\mathcal{F}_{N,n}$. An explicit method to construct such random mappings is to assign a uniform random value from $[0, m-1]$ to $\rho(I)$ independently for each $I \in [0, M-1]$, and to assign a uniform random value form $[0, n-1]$ to $\sigma(J)$ independently for all $J \in [0, N-1]$.

The second type of random mapping is as follows. Let $\mathcal{G}_{M,m}$ be the uniform distribution on all functions ρ from $[0, M-1]$ to $[0, m-1]$ such that $|\rho^{-1}(i)| = \lceil M/m \rceil$ for $i \in [0, (M \bmod m) - 1]$ and $|\rho^{-1}(i)| = \lfloor M/m \rfloor$ for $i \in [M \bmod m, m-1]$. The row mapping is drawn according to $\mathcal{G}_{M,m}$ and the column mapping is drawn according to $\mathcal{G}_{N,n}$. This leads to the assignment scheme mentioned in the Introduction, since one way to generate a mapping according to $\mathcal{G}_{M,m}$ is to take a random permutation π of $[0, M-1]$ and break the permuted sequence into $M \bmod m$ consecutive subsequences of length $\lceil M/m \rceil$ and $m - (M \bmod m)$ subsequences of length $\lfloor M/m \rfloor$. Alternatively, we may use $\rho(I) = \pi(I) \bmod m$. This restriction on the size of each submatrix actually forces a slight inefficiency, as we will see. For ease of notation in handling this, let m' and n' be $M/\lceil M/m \rceil$ and $N/\lceil N/n \rceil$, respectively, when we are dealing with the distributions $\mathcal{G}_{M,m}$ and $\mathcal{G}_{N,n}$, and let them be simply m and n when dealing with the distributions $\mathcal{F}_{M,m}$ and $\mathcal{F}_{N,n}$.

We can now state our main theorem. As defined before, T is the total number of nonzeros of A, R is the largest number of nonzeros in a row, and C is the largest number of nonzeros in a column.

THEOREM. *If the row and column assignments are chosen either according to $\mathcal{F}_{M,m}$ and $\mathcal{F}_{N,n}$, respectively, or according to $\mathcal{G}_{M,m}$ and $\mathcal{G}_{N,n}$, respectively, then for any $\varepsilon > 0$ the*

$$\Pr\left\{\max_{ij}\{|P_{i,j}|\} \geqq (1+\varepsilon)^2 \frac{T}{m'n'}\right\}$$

is at most the minimum of

$$mn \exp\left\{-\frac{T}{m'R}\,\varepsilon h(\varepsilon)\right\} + Mn \exp\left\{-\frac{R}{n'}\,\varepsilon h(\varepsilon)\right\} + n \exp\left\{-\frac{T}{n'C}\,\varepsilon h(\varepsilon)\right\}$$

and

$$mn \exp\left\{-\frac{T}{n'C}\,\varepsilon h(\varepsilon)\right\} + Nm \exp\left\{-\frac{C}{m'}\,\varepsilon h(\varepsilon)\right\} + m \exp\left\{-\frac{T}{m'R}\,\varepsilon h(\varepsilon)\right\},$$

where $h(x) = (1+x^{-1})\ln(1+x) - 1$.

Proof. We first consider the case when the pair of index mappings (ρ, σ) is drawn according to $\mathcal{F}_{M,m} \times \mathcal{F}_{N,n}$. The proof involves three applications of a large deviation theorem due to Bennett [1]. When (ρ, σ) is drawn according to $\mathcal{G}_{M,m} \times \mathcal{G}_{N,n}$, the proof follows immediately once we argue that a certain extension of Bennett's inequality due to Hoeffding [8] applies.

For the statement of Bennett's inequality let $\xi_0, \xi_1, \ldots, \xi_{M-1}$ be independent random variables, bounded from above, and with finite first and second moments. Let $S = \sum_{I=0}^{M-1} \xi_I$, and let $\mathrm{Var}(S)$ be its variance.

Bennett's inequality. For all $d \geqq 0$ such that $\xi_I - \mathrm{E}(\xi_I) \leqq d$ for all I, and for all $\gamma \geqq 0$,

$$\Pr\{S \geqq \mathrm{E}(S) + \gamma\} \leqq \exp\left\{-\frac{\gamma}{d}\, h\left(\frac{d\gamma}{\mathrm{Var}(S)}\right)\right\}.$$

We need an application of Bennett's inequality to the following. Let $\bar{W} = \{W_0, \ldots, W_{M-1}\}$ be a set of M objects, each having a well-defined nonnegative "weight" $|W_I|$. Define the weight of a subset $\bar{X} \subseteq \bar{W}$ as the sum of the weights of the elements of $\bar{X}$. Suppose that we put each $W_I \in \bar{W}$ independently and uniformly into one of m bins, $\{B_0, B_1, \ldots, B_{m-1}\}$. Formally, each bin B_i, $i \in [0, m-1]$, is the set of objects W_I such that $\rho(I) = i$ where ρ is drawn according to $\mathcal{F}_{M,m}$. The weight of each bin $|B_i|$ is the sum of the weights of the elements in the bin. This can be written as $|B_i^{\bar{W}}| = \sum_{I=0}^{M-1}(\rho(I)=i)|W_I|$, where $(\rho(I)=i)$ is the indicator variable which is one when $\rho(I)=i$ and zero otherwise. Since ρ is drawn according to $\mathcal{F}_{M,m}$, for any fixed bin $i \in [0, m-1]$, the 0-1 random variables $(\rho(0)=i)$, $(\rho(1)=i), \ldots, (\rho(M-1)=i)$ are independent Bernoulli variables with probability of success $1/m$. Hence, the weight of each bin $|B_i^{\bar{W}}|$ has the same distribution as the weighted sum of independently and identically distributed Bernoulli variables (although $|B_0^{\bar{W}}|, \ldots, |B_{m-1}^{\bar{W}}|$ are themselves dependent random variables).

If we know a $w > 0$ such that $0 \leqq |W_I| \leqq w$ for all $I \in [0, M-1]$ then the expected value $\mathrm{E}(|B_i^{\bar{W}}|) = (1/m)\sum_{I=0}^{M-1}|W_I| = |\bar{W}|/m$, and variance,

$$\mathrm{Var}(|B_i^{\bar{W}}|) = \sum_{I=0}^{M-1} \mathrm{Var}((\rho(I)=i)|W_I|) = (1/m)(1-1/m)\sum_{I=0}^{M-1}|W_I|^2,$$

are bounded. Furthermore, $(\rho(I)=i)|W_I| - E((\rho(I)=i)|W_I|) \leqq (1-1/m)|W_I| \leqq (1-1/m)w$ for all $I \in [0, M-1]$. Hence, we may apply Bennett's inequality with

$d=(1-1/m)w$ and the union bound to get a bound on the weight of the largest bin,

$$\Pr\left\{\max_{i\in[0,m-1]}\{|B_i^{\bar{W}}|\}\geqq\frac{|\bar{W}|}{m}+\gamma\right\}\leqq m\exp\left\{-\frac{\gamma}{(1-1/m)w}h\left(\frac{wm\gamma}{\sum_I|W_I|^2}\right)\right\}$$
$$\leqq m\exp\left\{-\frac{\gamma}{w}h\left(\frac{wm\gamma}{\sum_I|W_I|^2}\right)\right\}.$$

Unfortunately, in the course of the remainder of the proof, we may not know enough about $\bar{W}$ to compute $\sum_{I=0}^{M-1}|W_I|$ or $\sum_{I=0}^{M-1}|W_I|^2$ exactly. Nonetheless, we will know an upper bound $W>0$ on the sum of the weights, $\sum_{I=0}^{M-1}|W_I|\leqq W$. This implies an upper bound of wW on $\sum_{I=0}^{M-1}|W_I|^2$. To see this, note that $\sum_{I=0}^{M-1}|W_I|^2\leqq w\sum_{I=0}^{M-1}|W_I|$ since $0\leqq|W_I|\leqq w$. This, in turn, is at most wW by the bound on the sum of the weights. Now we can get a simple upper bound on the probability that one of the m bins has large weight

$$(*)\quad \Pr\left\{\max_{i\in[0,m-1]}\{|B_i^{\bar{W}}|\}\geqq(1+\varepsilon)\frac{W}{m}\right\}\leqq\Pr\left\{\max_{i\in[0,m-1]}\{|B_i^{\bar{W}}|\}\geqq\frac{|\bar{W}|}{m}+\varepsilon\frac{W}{m}\right\}$$
$$\leqq m\exp\left\{-\frac{W}{mw}\varepsilon h(\varepsilon)\right\}.$$

The last inequality follows due to the fact that h is monotone.

We return now to the problem of assigning submatrices of A to processors in the array. Let the weight of an element $A_{I,J}$, denoted $|A_{I,J}|$, be 1 if $A_{I,J}$ is a nonzero, and zero otherwise. Let $A_{I,*}$ be the Ith row of A and let $|A_{I,*}|$ be the number of ones in the Ith row. Let R be an upper bound on the weights of the rows of A. Similarly, let $A_{*,J}$ be the Jth column of A and $|A_{*,J}|$ the number of ones in the Jth column. Let C be an upper bound on the weights of the columns of A.

For the purposes of this analysis we make the column assignment, σ, first and then the row assignment, ρ. Let $V_{I,j}$, $I\in[0,M-1]$, and $j\in[0,n-1]$ be the submatrices formed by the column assignment. That is, $V_{I,j}=\{A_{I,J}\,|\,J\in\sigma^{-1}(j)\}$. This defines the matrix V. Let $V_{*,j}$ be the jth column of V. It is the submatrix of A consisting of all the columns, $A_{*,J}$, such that $\sigma(J)=j$. That is, the column assignment σ assigns the objects $\bar{W}=\{A_{*,J}\,|\,J\in[0,N-1]\}$ uniformly and randomly to the bins $\{V_{*,j}\,|\,j\in[0,n-1]\}$. We can apply $(*)$ to bound the weight of the largest bin by recalling that $A_{*,J}$ has weight at most C, since it is simply a column of A, and $|\bar{W}|=\sum_J|A_{*,J}|$ is simply the total number of nonzeros of A, which is at most T. Hence,

$$\Pr_{\mathcal{F}_{N,n}}\left\{\max_{j\in[0,n-1]}\{|V_{*,j}|\}\geqq\frac{T}{n}(1+\varepsilon_3)\right\}\leqq n\exp\left\{-\frac{T}{nC}\varepsilon_3h(\varepsilon_3)\right\}.$$

A similar analysis can also be applied on a row by row basis. For a fixed row $I\in[0,M-1]$, σ assigns the Ith row of A, $\bar{W}=\{A_{I,J}\,|\,J\in[0,N-1]\}$, uniformly and independently to the Ith row of V, $\{V_{I,j}\,|\,j\in[0,n-1]\}$. For each $I\in[0,M-1]$ we can use $(*)$ to bound the weight of the largest bin, $\max_j\{|V_{I,j}|\}$, by recalling that each $|A_{I,J}|$ is at most one and $|\bar{W}|$ is simply $|A_{I,*}|$, which is at most R. Hence,

$$\Pr_{\mathcal{F}_{N,n}}\left\{\max_{j\in[0,n-1]}\{|V_{I,j}|\}\geqq\frac{R}{n}(1+\varepsilon_2)\right\}\leqq n\exp\left\{-\frac{R}{n}\varepsilon_2h(\varepsilon_2)\right\}.$$

Applying this to each row I and using the union bound we get

$$\Pr_{\mathcal{F}_{N,n}}\left\{\max_{\substack{I\in[0,M-1]\\ j\in[0,n-1]}}\{|V_{I,j}|\}\geqq\frac{R}{n}(1+\varepsilon_2)\right\}\leqq Mn\exp\left\{-\frac{R}{n}\varepsilon_2h(\varepsilon_2)\right\}.$$

We complete the assignment of submatrices of A to processors by making the row assignments. Rows of V are assigned to rows of P. That is, $P_{i,*}$ is the submatrix composed of rows of V, $V_{I,*}$, such that $\rho(I)=i$ where ρ is drawn from $\mathscr{F}_{M,m}$. In other words, for a fixed column $j\in[0,n-1]$, the objects $\{V_{I,j}\mid I\in[0,M-1]\}$ are assigned uniformly and independently to the bins $\{P_{ij}\mid i\in[0,m-1]\}$. We can apply (*) so long as we have upper bounds on the weights $|V_{ij}|$ and the sum of the weights $\sum_{I=0}^{M-1}|V_{I,j}|$.

Assume for now that after the column assignment (but before the row assignment) we have $|V_{I,j}|\leqq v$ for all $I\in[0,M-1]$ and $j\in[0,n-1]$, and that $\sum_{I=0}^{M-1}|V_{I,j}|=|V_{*,j}|\leqq V$ for all $j\in[0,n-1]$. Call the former event $\mathscr{E}_v$, the latter event $\mathscr{E}_V$, and their conjunction $\mathscr{E}_{v,V}$. For each column $j\in[0,n-1]$, we can apply (*) to the random row assignment

$$\Pr_{\mathscr{F}_{M,m}}\left\{\max_{i\in[0,m-1]}\{|P_{i,j}|\}\geqq\frac{V}{m}(1+\varepsilon_1)\;\middle|\;\mathscr{E}_{v,V}\right\}\leqq m\exp\left\{-\frac{V}{vm}\varepsilon_1 h(\varepsilon_1)\right\}.$$

Applying this to every column, we obtain

$$\Pr_{\mathscr{F}_{M,m}}\left\{\max_{\substack{i\in[0,m-1]\\ j\in[0,n-1]}}\{|P_{i,j}|\}\geqq\frac{V}{m}(1+\varepsilon_1)\;\middle|\;\mathscr{E}_{v,V}\right\}\leqq mn\exp\left\{-\frac{V}{vm}\varepsilon_1 h(\varepsilon_1)\right\}.$$

To achieve a similarly small probability for $\max_{i,j}\{|P_{i,j}|\}$ being large without the conditioning event $\mathscr{E}_{v,V}$, we need only show that the probability that $\mathscr{E}_{v,V}$ is not true is very small. That is,

$$\begin{aligned}\Pr\{\mathscr{F}\}&=\Pr\{\mathscr{F}\mid\mathscr{E}_{v,V}\}\Pr\{\mathscr{E}_{v,V}\}+\Pr\{\mathscr{F}\mid\bar{\mathscr{E}}_{v,V}\}\Pr\{\bar{\mathscr{E}}_{v,V}\}\\&\leqq\Pr\{\mathscr{F}\mid\mathscr{E}_{v,V}\}+\Pr\{\bar{\mathscr{E}}_{v,V}\},\end{aligned}$$

where $\mathscr{F}$ is the event that $\max_{i,j}\{|P_{i,j}|\}\geqq(V/m)(1+\varepsilon_1)$. If we choose $V=(1+\varepsilon_3)T/n$ and $v=(1+\varepsilon_2)R/n$ then we already have an upper bound for $\Pr\{\bar{\mathscr{E}}_v\cup\bar{\mathscr{E}}_V\}$.

Putting everything together we obtain

$$\begin{aligned}\Pr\left\{\max_{i,j}\{|P_{i,j}|\}\geqq\frac{T}{mn}(1+\varepsilon_3)(1+\varepsilon_1)\right\}&\leqq mn\exp\left\{-\frac{T}{mR}\frac{1+\varepsilon_3}{1+\varepsilon_2}\varepsilon_1 h(\varepsilon_1)\right\}\\&\quad+Mn\exp\left\{-\frac{R}{n}\varepsilon_2 h(\varepsilon_2)\right\}\\&\quad+n\exp\left\{-\frac{T}{nC}\varepsilon_3 h(\varepsilon_3)\right\}.\end{aligned}$$

The choice $\varepsilon_1=\varepsilon_2=\varepsilon_3$ gives a more tractable (but not necessarily optimal) bound. Of course, we can do the whole analysis by conditioning on the results of the row assignment first. This gives the same bound as the one above with the roles of M and N, m and n, and R and C interchanged. The actual bound is the minimum of these two.

The proof for the case where the row and column assignments are made according to $\mathscr{G}_{M,m}$ and $\mathscr{G}_{N,m}$, respectively, is nearly identical, except that we need an extension of Bennett's inequality, due to Hoeffding [8], to the following case. As before, let $\bar{W}$ be a set of M objects $\bar{W}=(W_0,\ldots,W_{M-1})$ with weights $|W_I|$. Let $\hat{B}^{\bar{W}}$ be the set of objects obtained by randomly selecting r objects from $\bar{W}$ without replacement, and let $\ddot{B}^{\bar{W}}$ be the set of objects obtained by randomly selecting r objects from $\bar{W}$ with replacement. Note that

$$E(|\hat{B}^{\bar{W}}|)=E(|\ddot{B}^{\bar{W}}|)=(r/M)\sum_{K=0}^{M-1}|W_K|=r|\bar{W}|/M.$$

Also observe that

$$\mathrm{Var}\,(|\ddot{B}^W|) = (r/M) \sum_{K=0}^{M-1} (|W_K| - |\bar{W}|/M)^2,$$

but that

$$\mathrm{Var}\,(|\hat{B}^W|) = ((M-r)/(M-1))\,\mathrm{Var}\,(|\ddot{B}^W|).$$

Bennett-Hoeffding inequality. For any $d \geqq 0$ such that $|W_I| - |\bar{W}|/M \leqq d$ for all $I \in [0, M-1]$ and any $\gamma \geqq 0$

$$\Pr\{|\hat{B}^W| \geqq E(|\hat{B}^W|) + \gamma\} \leqq \exp\left\{-\frac{\gamma}{d} h\left(\frac{d\gamma}{\mathrm{Var}\,(|\ddot{B}^W|)}\right)\right\}.$$

We apply this bound to the situation where we place exactly $\lceil M/m \rceil$ objects into bins $\hat{B}_i^W$, $i \in [0, (M \bmod m) - 1]$, and exactly $\lfloor M/m \rfloor$ objects into bins $\hat{B}_i^W$, $i \in [M \bmod m, m-1]$. Formally, $\hat{B}_i^W = \{W_I \mid I \in \rho^{-1}(i)\}$ where ρ has distribution $\mathscr{G}_{M,m}$. By symmetry we know that each $\hat{B}_i^W$, $i \in [0, (M \bmod m) - 1]$, has the same distribution as $\hat{B}^W$ above with $r = \lceil M/m \rceil$ and each $\hat{B}^W$, $i \in [M \bmod m, m-1]$, has the same distribution as $\hat{B}^W$ above with $r = \lfloor M/m \rfloor$. Using algebra similar to that used for deriving (*) from Bennett's inequality, it is straightforward to derive the following bound from the Bennett-Hoeffding inequality.

For any $W \geqq |\bar{W}|$, any $w > 0$ such that for all $I \in [0, M-1]$, $W_I \leqq w$, and $\varepsilon \geqq 0$,

$$\Pr_{\mathscr{G}_{M,m}}\left\{\max_{i \in [0, m-1]} \{|\hat{B}_i^W|\} \geqq W \frac{\lceil M/m \rceil}{M}(1+\varepsilon)\right\} \leqq m \exp\left\{-\frac{W}{w}\frac{\lceil M/m \rceil}{M} \varepsilon h(\varepsilon)\right\}.$$

This is the same bound as (*) when we substitute the m' and n' as previously defined. Hence, the remainder of the proof follows exactly as before. □

3. Data-parallel sparse matrix–vector multiplication. So far, we have analyzed randomized algorithms for the balanced assignment of nonzeros of a sparse matrix to a rectangular processor array. Such assignments preserve the alignment of matrix rows and columns for the design of efficient parallel sparse matrix routines. In this section we consider the design of the basic sparse matrix-vector multiplication kernels for parallel processor arrays under the restrictive conditions of the data-parallel single instruction multiple data (SIMD) machine model. Program-parallel multiple instruction multiple data (MIMD) machines are more powerful, and naturally include the SIMD model.

The minimum characteristics of a data-parallel computer model required here are:

1. There are p PEs interconnected by a communication network. Every PE has its own, identically organized local memory. It is assumed that the network is configured as a (virtual) two-dimensional rectangular grid, with efficient communication among the PEs along any row or column of the grid.

2. Each PE can be in the active or inactive state independently, depending on the local data, and this may change from instruction to instruction.

3. There is a separate processor (controller) executing the program and broadcasting instructions which are synchronously evaluated in all active PEs. It is assumed that the *indirect addressing* feature is available: The PEs can store local pointers to their local memories, thus each PE can access a different memory location in a single instruction. We will concentrate on the second (i.e., random permutation) assignment scheme. While both schemes produce balanced load under the same assumptions, and,

with balanced load, lead to similar matrix algorithms, only the second scheme guarantees the upper limit on the dimension of the submatrices allocated to each processor. This simplifies memory management and algorithm design for SIMD computers.

Therefore, suppose that for a large sparse matrix A, the random row and column permutations result in an acceptably balanced distribution of the nonzeros of A to the PEs. If the row permutation is represented by an $M \times M$ matrix P, and the column permutation is represented by an $N \times N$ matrix Q, then the assignment of nonzeros to PEs considered in § 2 can be written as $(PAQ^T)_{I,J} \rightarrow PE(I \bmod m, J \bmod n)$. In most matrix problems one may do the computations with PAQ^T instead of A and undo the permutations at the end. This is straightforward; therefore, from now on, we will ignore the permutations for the sake of simplicity, and we will set $P = \mathbf{I}_M$ and $Q = \mathbf{I}_N$.

Each PE stores the nonzeros of a sparse submatrix of A in a compressed data structure. The choice of compression scheme may be dictated by the PE architecture, available local memory, or other considerations [13], [14]. Here we use a simple symmetric scheme which allows for fast computation of both right and left multiplications, $y = Ax$ and $x^T = y^T A$. The processors' memory is therefore organized as follows: The nonzeros allocated to $PE(i,j)$ are stored in three aligned arrays, $a[k]$, $r[k]$, $c[k]$, $k = 0, 1, \ldots, |P_{ij}| - 1$, where a is the matrix element and r and c are its row and column indices, respectively.

It is not efficient to store dense vectors as matrices with one row or column. For communication efficiency and good load balance, it is preferable to distribute the components of a vector $x = (x_0, x_1, \ldots, x_{L-1})$ to processors according to a multilayer lexicographic scheme. In each PE define a local array $u[\,]$ of length $\lceil L/mn \rceil$. For row-wise lexicographic storage renumber the processors with a single index, so that $PE(i,j)$ gets the index $k = i \cdot n + j$, and place the component x_J in array element $u[\lfloor J/mn \rfloor]$ in the PE with index $k = J \bmod mn$, for $J = 0, 1, \ldots, L-1$. For column-wise lexicographic placement renumber the processors so that $PE(i,j)$ gets the index $k = j \cdot m + i$, and proceed as before.

We shall discuss only the routine for computation of $y = Ax$ in detail. Obvious modifications are required for the computation of $y^T A$, and for the extension to blocks of dense vectors. The vector x is distributed among processors in a row-wise lexicographic order and stored in the local arrays $u[\,]$, while vector y is distributed in the column-wise lexicographic order, and stored in the local arrays $v[\,]$. The multiplication routine requires an auxiliary local accumulator array acc[ ] of length $|P_{ij}|$, and an auxiliary local buffer array buf[ ] in each $PE(i,j)$, and proceeds in several phases.

For transparency, the pseudocode below is written for the case when the PE array dimensions divide the matrix dimensions, i.e., $M = rm$ and $N = sn$, and each PE has sufficient memory for the buffer array of length $\max(r, s)$. We note that indirect addressing is critical for data-parallel execution of the scatter and gather steps.

Matrix–vector multiplication $y = Ax$

```
1. Distribute vector components
      for $k = 0, \ldots, s-1$
          in parallel in each array column $j = 0, \ldots, n-1$
              $temp = k \bmod m$,
              $PE(temp, j)$ sends $u[\lfloor k/m \rfloor]$ to all PEs in column $J$,
              every PE copies received value in buf$[k]$.
2. Scatter: every $PE(i,j)$ in parallel
      for $k = 0, \ldots, |P_{ij}| - 1$
          acc$[k] \leftarrow$ buf$[(c[k] - j)/n]$.
```

```
3. Multiply: every $PE(i,j)$ in parallel
       for $k=0,\ldots,|P_{ij}|-1$
           $\mathrm{acc}[k] \leftarrow \mathrm{acc}[k] * a[k]$.
4. Gather: every $PE(i,j)$ in parallel
       for $k=0,\ldots,r-1$
           $\mathrm{buf}[k]=0$,
       for $k=0,\ldots,|P_{ij}|-1$
           $temp=(r[k]-i)/m$,
           $\mathrm{buf}[temp] \leftarrow \mathrm{buf}[temp]+\mathrm{acc}[k]$.
5. Row sums
       for $k=0,\ldots,r-1$
           in parallel in each array row $i=0,\ldots,m-1$
               compute the sum of $\mathrm{buf}[k]$ along row $i$,
               copy the sum to $v[\lfloor k/n \rfloor]$ in $PE(i, k \bmod n)$.
```

When the routine completes execution, the local array element $v[l]$ in $PE(i,j)$ stores the vector component $y_{lmn+jm+i}$, as determined by column-wise lexicographic order.

The number of parallel operations is as follows: $\lceil N/m \rceil$ vector copy steps; $\max_{i,j} |P_{ij}|$ each of the scatter, multiply, and gather steps; $\lceil M/m \rceil$ row sum evaluations. In practice, it may be more efficient to employ systolic techniques for the first and last stages, rather than use broadcast along array columns and segmented scan-adds, respectively. The distribute/scatter and gather/sum steps may be iterated if there is not enough memory for a long buffer array. Multiple iterations can be efficiently managed with pointers when the arrays a, r, and c are sorted in the order of increasing row index, $r[0] \leqq r[1] \leqq \cdots \leqq r[|P_{ij}|-1]$, and in the order of increasing column index via an auxiliary local pointer array $p[i]$ such that $c[p[0]] \leqq c[p[1]] \leqq \cdots \leqq c[p[|P_{ij}|-1]]$.

3.1. A practical implementation. In order to demonstrate the practicality of data structures and algorithms proposed in this report, we have implemented the matrix multiplication routines and load balancing on a commercially available computer, the MasPar MP-1216. This is a data-parallel machine with 16,384 RISC processors. Each processor has 64 kbytes of local memory, and operates on four-bit-wide data fields, with floating point instructions implemented in microcode. There are two separate communication networks: a two-dimensional toroidal mesh, and a global router. Only the mesh network is used in matrix calculations, and on the MP-1216 the PEs are connected as a 128×128 array. The programs have been written in MPL [11], which is a data-parallel extension of the ANSI standard C language [10]. Several parallel algorithms for dense matrix multiplication have been implemented and analyzed on this computer in [2].

We have found that the performance of the load balancing algorithm is much better in practice than guaranteed by our theorem. The reason for this is that in the proof some dependencies have been bounded by overcounting, and some bounds have been relaxed to obtain a compact final formula. An extended empirical study of our assignment scheme for a variety of structures and sizes is beyond the scope of this report, nonetheless, as an illustration we do present data for some large matrices, both unstructured and highly structured. Let $P_0=\lceil T/mn \rceil$ be the perfectly balanced load per PE. For the matrices described below we have estimated the distribution function $\Pr\{\max_{i,j} |P_{ij}|/P_0<\lambda\}$, which succinctly illustrates the performance of the randomized allocation algorithm. The probability distribution is the $\mathcal{G}_{M,m} \times \mathcal{G}_{N,n}$ of § 2, corresponding to independent randomly drawn row and column permutations. Empirical distribution functions were obtained from a few hundred independent assignments for each matrix.

For the first example we take a 25,629 × 56,530 matrix representing the frequencies of words occurring in more than two articles from the Academic American Encyclopedia. This is a sparse, unstructured matrix with $T = 2{,}843{,}956$ nonzeros, $C = 13{,}904$, and $R = 2{,}168$. However, despite the presence of some quite dense rows and columns the random permutation assignment works reasonably well. An estimate of $\Pr\{\max_{ij} |P_{ij}|/P_0 < \lambda\}$ for the 128 × 128 MasPar array is shown in Fig. 1. We see that a maximum load of at most $2P_0$ can be achieved in one attempt with probability about 0.22. This probability increases sharply when the requirement on the maximum load is relaxed. Qualitatively similar results have been obtained for other large sparse matrices representing word frequencies in different document databases.

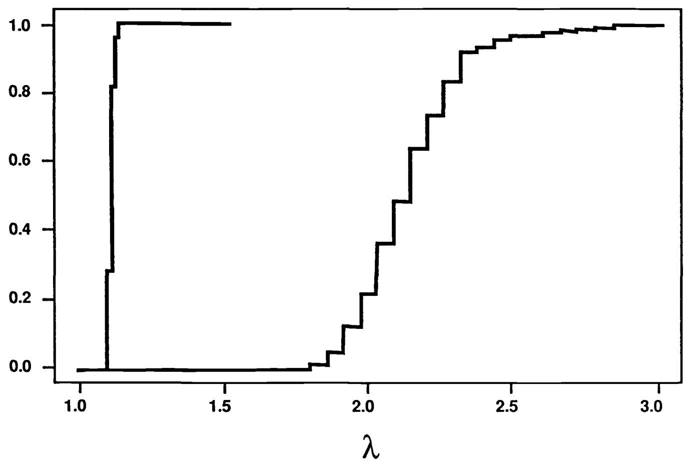

FIG. 1. *Estimated probability distributions Pr* $\{\max_{ij} |P_{ij}|/P_0 < \lambda\}$ *for the band matrix (left) and the word frequency matrix (right) described in the text.*

For a completely different example we consider a square 200,000 × 200,000 banded matrix with a half-bandwidth of 100. Although for such special matrices we would rather design a different distributed data structure, it is instructive to see the power of randomization: A direct tiling mapping of this matrix onto the 128 × 128 PE array would produce $\max_{i,j} |P_{ij}| = 151{,}350$ compared to $P_0 = 1221$. However, the random permutation assignment does very well (see Fig. 1): with probability of success over 0.99, we obtain an assignment that deviates from the perfectly balanced load by less than 15 percent.

In order to assess the performance of our implementation of the sparse matrix-vector multiplication routine, and to estimate the fraction of time spent on interprocessor communication and nonnumerical operations, we compare the performance of the routine to the machine's peak floating point computing speed. All performance figures are for the double precision (64 bits) floating point format for matrix and vector components. According to custom, we also characterize the routine's performance in terms of the number of floating point operations per second (flops), including all nonnumerical operations in the time measurement.

For a standard of the machine peak rate we consider two array operations $c[i] \leftarrow a[i]+b[i]$ and $c[i] \leftarrow a[i]*b[i]$ executing in parallel in the PEs without interprocessor communication. The timing of these instructions for long arrays on a 16,384-processor MasPar gives the average peak rate of 250 Mflops (register operations are about twice as fast, but not proper for comparisons with routines involving array references). For the sparse matrix-vector multiplication routine, the flop rate is determined by the number of nonzeros T, and in accordance with [7], is defined as $2T/\tau$, where τ is the routine execution time. The highest performance has been achieved with the perfectly balanced PE load (i.e., $\max_{ij} |P_{ij}| = T/16{,}384$) for large dense matrices cast in the sparse data structure, giving 116 Mflops, that is, about 45 percent of the peak machine rate determined above. For sparse matrices the ratio $\max_{ij} |P_{ij}|/P_0$ quantifies the performance loss resulting from load imbalance.

Our fastest implementation of the sparse matrix-vector multiplication on the MasPar utilizes only the nearest-neighbor communications in the vector distribution and row sum collection stages. We have analyzed its performance, obtaining a formula for the execution time τ,

$$\tau = \tau_1 \cdot m \cdot \lceil N/mn \rceil + \tau_2 \cdot \max_{i,j} |P_{ij}| + \tau_3 \cdot n \cdot \lceil M/mn \rceil.$$

The first term accounts for the vector distribution; the second for the scatter, multiply, and gather steps; and the last for the row sum collection. The expected operation times τ_i, measured on a 128×128 machine, are $\tau_1 = 17$ μs, $\tau_2 = 290$ μs, and $\tau_3 = 84$ μs (microseconds). The formula for τ predicts quite accurately the actual execution time for arbitrary matrices and imperfectly balanced loads, with a small uncertainty due to the dependence of the course of the scatter and gather operations on the data. For instance, for the first word frequency matrix described above, we obtained 48 Mflops, and for the banded matrix we obtained 70 Mflops. On this machine for a fixed T, the flop rate decreases with increasing matrix dimensions M and N; thus, for extremely sparse matrices with very large dimensions another algorithm could offer better performance.

Acknowledgments. We thank Tom Leighton and Michael Berry for useful discussions and Sue Dumais for examples of word-frequency matrices.

SOME ASPECTS OF CIRCULANT PRECONDITIONERS*

THOMAS HUCKLE†

Abstract. This paper studies circulant approximations of Hermitian Toeplitz matrices that are solutions of certain minimization problems relative to the Frobenius norm, the lub_1, or the lub_∞ norms. The examinations supplement the family of the so-called optimal and superoptimal preconditioners that have been proposed for the preconditioned conjugate gradient method for solving Toeplitz systems $T_n x = b$. For the new Frobenius norm approximations it is shown that they can be computed in $O(n \log(n))$ arithmetic operations, and that the eigenvalues of the preconditioned linear equations are asymptotically clustered around 1 if T_n is a leading principal submatrix of an infinite Toeplitz matrix connected with a positive function of the Wiener class.

Key words. Toeplitz matrix, circulant matrix, preconditioned conjugate gradient method

AMS(MOS) subject classifications. 65F10, 65F15

0. Introduction. In this paper we derive some new properties of circulant preconditioners for the solution of linear Toeplitz equations. A matrix T_n is a Hermitian Toeplitz matrix if

$$T_n = \begin{pmatrix} t_0 & t_1 & \cdots & \cdots & t_{n-1} \\ \bar{t}_1 & t_0 & t_1 & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & & \bar{t}_1 & t_0 & t_1 \\ \bar{t}_{n-1} & \cdots & \cdots & \bar{t}_1 & t_0 \end{pmatrix} = T_n(t_0, t_1, \ldots, t_{n-1}), \tag{1}$$

and a matrix C is a Hermitian circulant matrix if $C = T_n(c_0, c_1, c_2, \ldots, \bar{c}_2, \bar{c}_1)$. Strang in [14] proposed using the preconditioned conjugate gradient (PCG) method for solving symmetric positive definite Toeplitz systems. By the fast Fourier transform, linear equations with circulant matrices can be solved in $O(n \log(n))$ operations, and every circulant matrix has a diagonalization of the form $C = F_n^H \Lambda F_n$ with the Fourier matrix (see [7])

$$F_n^H := \frac{1}{\sqrt{n}} (\exp(2\pi ijk/n))_{j,k=0}^{n-1} = \frac{1}{\sqrt{n}} (w^{jk})_{j,k=0}^{n-1}, \tag{2}$$

where $w = \exp(2\pi i/n)$.

An infinite Toeplitz matrix $T = (t_{i-j})_{i,j=1}^{\infty}$ is connected with a function

$$f(\theta) := \sum_{j=-\infty}^{\infty} t_j e^{-ij\theta}, \qquad \theta \in [0, 2\pi],$$

which is said to be in the Wiener class if f is an l_1 function, thus $\sum_{j=-\infty}^{\infty} |t_j| \leqq M < \infty$. If the Toeplitz matrices T_n are leading principal submatrices of an infinite Toeplitz matrix T with underlying function f positive and in the Wiener class, the eigenvalues of the preconditioned systems $C^{-1}T_n$ are asymptotically clustered around 1 for many different circulant approximations C on T_n (see [1]-[4], [6], [10]-[13], [15], and [16]). Hence, the number of iterations in the PCG method is bounded independent of n in this case.

1. Frobenius norm approximations. In [6], T. Chan introduced the optimal circulant Frobenius norm approximation C_F for a given Hermitian matrix A. Every element c_k of C_F is the mean value of the corresponding elements on a kth diagonal of A. For the following, using the notation of relation (1), let us denote

$$\text{(3)} \qquad \operatorname{Circ}(A) := T_n(c_0, c_1, c_2, \dots, \bar{c}_2, \bar{c}_1) \quad \text{with } c_k := \frac{1}{n} \sum_{j=1}^{n} a_{j,j+k \bmod n}.$$

Then $C_F = \operatorname{Circ}(A)$. The convergence of the PCG method depends on the spectrum of $C^{-1/2}AC^{-1/2}$ or $C^{-1}A$. Hence, it seems to be more appropriate to look for a positive definite circulant matrix that minimizes $\|I - C^{-1}A\|$ for a certain norm. This leads to the superoptimal Frobenius norm approximation of Tyrtyshnikov [3], [15], [16] $C_T = \operatorname{Circ}(A^2) * \operatorname{Circ}(A)^{-1}$, which minimizes $I - C^{-1}A$ in the Frobenius norm. Here, $*$ denotes the standard matrix or scalar multiplication.

But this is not the true optimal approximation, because the Hermitian matrix which is used in the PCG method is $C^{-1/2}AC^{-1/2}$, and thus one should better minimize $\|I - C^{-1/2}AC^{-1/2}\|$ in some norm. For the Frobenius norm we can again solve this problem.

THEOREM 1. *Let A be a Hermitian positive definite $n \times n$ matrix. Let $B = F_nAF_n^H$, $D = B \circ \bar{B}$ be the Hadamard product of B and $\bar{B}$, $b = \operatorname{diag}(B)$, and $x = D^{-1}b$. Then D is positive definite. If all components of the vector x are positive, define*

$$\Lambda = \operatorname{diag}\left(\frac{1}{x_1}, \dots, \frac{1}{x_n}\right), \qquad C_B := F_n^H \Lambda F_n,$$

and it holds that

$$\|I - C_B^{-1/2}AC_B^{-1/2}\|_F = \min_{C \text{ circulant}} \|I - C^{-1/2}AC^{-1/2}\|_F.$$

Proof. With $C = F_n^H \Lambda F_n$,

$$\|I - C^{-1/2}AC^{-1/2}\|_F^2 = \|I - \Lambda^{-1/2}B\Lambda^{-1/2}\|_F^2 = 1 - 2\frac{b_{11}}{\lambda_1} + \sum_{j=1}^{n} \frac{|b_{1j}|^2}{\lambda_1 \lambda_j} + \cdots$$
$$= f(\lambda_1, \dots, \lambda_n).$$

The condition $\nabla f = 0$ is equivalent to the equations

$$\text{(4)} \qquad b_{kk} = \sum_{j=1}^{n} \frac{|b_{k,j}|^2}{\lambda_j}, \qquad k = 1, \dots, n.$$

Therefore, we get the minimal Frobenius norm approximation by solving this system of linear equations in $x = (1/\lambda_1, \dots, 1/\lambda_n)$ if all components of x are positive. Note that with A, the matrix D is also positive definite [9, Thm 5.3.1], and that b_{ii} are the eigenvalues of C_F with $\lambda_{\min}(A) \leqq b_{ii} \leqq \lambda_{\max}(A)$ [11], [12]. □

To show that this new preconditioner is competitive with C_F for Toeplitz matrices connected with positive functions of the Wiener class, we prove in the following that under this assumption

(a) the matrices B and D can be computed in $O(n \log(n))$,

(b) equation (4) can be solved in $O(n \log(n))$,

(c) the solution of (4) is positive for n large enough,

(d) C_F and C_B are asymptotically equivalent, and thus the eigenvalues of $C_B^{-1}T_n$ are clustered around 1 for large n [1], [2], [3].

First, let us consider (c) and (d).

THEOREM 2. *If $A = T_n$ is a Hermitian Toeplitz matrix with an underlying positive function f of the Wiener class, then*

$$\|C_B - C_F\|_2 \to 0 \quad \text{for } n \to \infty,$$

and thus C_B and C_F are asymptotically equivalent relative to the spectral norm. Hence, for n large enough, C_B and C_B^{-1} are well defined and of bounded spectral norm.

Proof. First, note that the diagonal elements of B are the eigenvalues of C_F and are contained in the interval $[m, M]$ with $0 < m = \min f \leqq M = \max f \leq \infty$ [1], [11], [12]. For the elements of B,

$$\begin{aligned} b_{i,j} &= \frac{1}{n} \sum_{k,m=1}^{n} a_{k,m} \bar{w}^{(i-1)(k-1)} w^{(j-1)(m-1)} \\ &= \frac{1}{n} \sum_{r=1-n}^{n-1} \bar{t}_r \bar{w}^{j-i+(i-1)r} \sum_{m=\max\{1,1-r\}}^{\min\{n,n-r\}} w^{(j-i)m}. \end{aligned} \tag{5}$$

Hence, we get

$$|b_{i,i}|^2 = \frac{1}{n^2} \sum_{r,k=1-n}^{n-1} t_k \bar{t}_r (n-|r|)(n-|k|) w^{(i-1)(k-r)}$$

and

$$\begin{aligned} \sum_{j=1}^{n} |b_{i,j}|^2 &= \frac{1}{n^2} \sum_{r,k=1-n}^{n-1} t_k \bar{t}_r w^{(i-1)(k-r)} \sum_{m_1=\max\{1,1-r\}}^{\min\{n,n-r\}} \sum_{m_2=\max\{1,1-k\}}^{\min\{n,n-k\}} w^{i(m_2-m_1)} \sum_{j=1}^{n} w^{(m_1-m_2)j} \\ &= \frac{1}{n^2} \sum_{r,k=1-n}^{n-1} t_k \bar{t}_r w^{(i-1)(k-r)} \sum_{m=\max\{1,1-r,1-k\}}^{\min\{n,n-r,n-k\}} n. \end{aligned}$$

Therefore, with the notation $B = (b_1, b_2, \ldots, b_n)$,

$$\begin{aligned} \|b_i\|_2^2 - b_{i,i}^2 &= \sum_{j \neq i, j=1}^{n} |b_{i,j}|^2 \\ &= \sum_{r,k=1-n}^{n-1} t_k \bar{t}_r w^{(i-1)(k-r)} \\ &\quad \cdot \left(\frac{[\min\{n, n-r, n-k\} - \max\{0, -r, -k\}]_+}{n} - \frac{(n-|r|)(n-|k|)}{n^2} \right) \\ &= \frac{1}{n^2} \sum_{r,k=1-n}^{n-1} t_k \bar{t}_r w^{(i-1)(k-r)} c_{r,k} \end{aligned}$$

with

$$c_{r,k} = \begin{cases} \min\{(n-|r|)|k|, (n-|k|)|r|\} & \text{for } rk \geqq 0, \\ -|rk| & \text{for } rk < 0 \text{ and } |k|+|r| \leqq n, \\ -(n-|r|)(n-|k|) & \text{for } rk < 0 \text{ and } |k|+|r| \geqq n, \end{cases}$$

and $[x]_+ := \max\{0, x\}$. Thus $|c_{r,k}| \leqq Mn$ for $|r| \leqq M$ or $|k| \leqq M$, M independent of n, and

$$\phi(n) := \max\{\|b_i\|_2^2 - b_{i,i}^2\} \to 0 \quad \text{for } n \to \infty. \tag{6}$$

For a proof of (6), see also the Corollary to Theorem 4 in [3]. With the notations of Theorem 1, $\|D-\operatorname{diag}(b_{11}^2,\ldots,b_{nn}^2)\|_\infty$ tends to 0 for increasing n, and therefore $\|D\|_\infty$, $\|D^{-1}\|_\infty$, and $\|x\|_\infty=\|D^{-1}b\|_\infty$ are bounded independent of n. Hence,

$$\begin{aligned}\max_i\left\{\left|b_{ii}-\frac{b_{ii}^2}{\lambda_i}\right|\right\} &= \|b-\operatorname{diag}(b_{11}^2,\ldots,b_{nn}^2)*x\|_\infty\\ &= \|(D-\operatorname{diag}(b_{11}^2,\ldots,b_{nn}^2))*x\|_\infty\\ &\leqq \|D-\operatorname{diag}(b_{11}^2,\ldots,b_{nn}^2)\|_\infty\|x\|_\infty\end{aligned}$$

tends to 0 for increasing n, and

$$0<m_1\leqq\lambda_i\leqq M_1<\infty,\qquad i=1,\ldots,n,$$

for large n. □

THEOREM 3. *For a Hermitian Toeplitz matrix T_n, the matrices $B=F_nT_nF_n^H$ and $D=B\circ\bar B$ can be computed in $O(n\log(n))$. Furthermore, for a vector a, the evaluation of $B*a$ and $D*a$ take $O(n\log(n))$ operations.*

Proof. Using (5), for $i\neq j$,

$$\begin{aligned}nb_{i,j}&=\sum_{r=1}^{n-1}\bar t_r\bar w^{j-i+(i-1)r}\sum_{m=1}^{n-r}w^{(j-i)m}+\sum_{r=1-n}^{-1}\bar t_r\bar w^{j-i+(i-1)r}\sum_{m=1-r}^{n}w^{(j-i)m}\\ &=\frac{1}{1-w^{j-i}}*(g_i-g_j+\bar g_j-\bar g_i),\end{aligned}$$

with $g_i:=\sum_{r=1}^{n-1}\bar t_r(\bar w^{(i-1)})^r$, $i=1,\ldots,n$, and $g=(g_1,\ldots,g_n)^T$ can be computed by the fast Fourier transform applied to $(0,\bar t_1,\ldots,\bar t_{n-1})$ in $O(n\log(n))$. Define the circulant Hermitian matrix

$$T_w:=\frac{1}{n}*T_n\left(0,\frac{1}{1-w},\ldots,\frac{1}{1-w^{n-1}}\right),$$

the purely imaginary matrix $G:=(g-\bar g)*(1,\ldots,1)$, and the rank-2 matrix $E:=G+G^H$. Then,

$$B=(E\circ T_w)+\operatorname{diag}(b_{11},\ldots,b_{nn})$$

and

$$D=(E\circ\bar E)\circ(T_w\circ\bar T_w)+\operatorname{diag}(b_{11}^2,\ldots,b_{nn}^2)$$

with $\operatorname{rank}(E\circ\bar E)\leqq 4$ (see [9, Thm 5.1.7]). Furthermore, with $e:=(1,\ldots,1)^T$, $h:=g-\bar g$, and $D(a):=\operatorname{diag}(a_1,\ldots,a_n)$ for a given vector a, we get

$$B*a=((h*e^T+e*h^H)\circ T_w)*a+\operatorname{diag}(b_{11},\ldots,b_{nn})*a,$$

and with [9, Lemma 5.1.3],

$$(T_w\circ(h*e^T))*a=\operatorname{diag}(T_w*D(a)*(e*h^T))=\operatorname{diag}((T_w*a)*h^T),$$

and

$$(T_w\circ(e*h^H))*a=\operatorname{diag}(T_w*D(a)*(\bar h*e^T))=T_w*(a\circ\bar h)$$

can be computed in $O(n\log(n))$. Obviously, the same holds for $D*a$. □

Remark. (1) In view of Theorem 4, it seems to be more efficient to apply the PCG method not to the original linear equations $T_nx=b$, but to the corresponding system $B(F_nx)=F_nb$. Each iteration of the PCG method with preconditioner C and matrix

T_n takes six Fourier transforms, but with diag $(b_{11}, \ldots, b_{nn})$ and B, it takes only four Fourier transforms for evaluating $T_w * a$ and $T_w * (a \circ \bar{h})$ with circulant T_w. Note that in this formulation the preconditioner is the diagonal of the underlying matrix of the linear system.

(2) A similar representation of a Toeplitz matrix by means of the Hadamard product of a rank-2 matrix with a unitary circulant matrix C_0 is given in [15]. The first row of C_0 is

$$\frac{2}{n(1-\sigma w^k)}, \quad k=0, \ldots, n-1, \quad \text{with } \sigma = \exp(\pi i/n),$$

and C_0 has the eigenvalues $\mu_k = \sigma^k$, $k=0, \ldots, n-1$. The eigenvalues of T_w are $\lambda_k = -\frac{1}{2} + (2k+1)/2n$, $k=0, \ldots, n-1$. Hence, μ_k and λ_k are connected by $\mu_k = \exp((\lambda_k - \lambda_0)\pi i)$, $k=0, \ldots, n-1$.

For general Hermitian positive definite matrix A, the matrices B and D are general Hermitian positive definite matrices. Thus it takes $O(n^2 \log(n))$ operations to compute B by $2n$ fast Fourier transforms and, in addition, $O(n^2)$ operations for D. But there are interesting cases for which the matrix D is of special form. Consider $A = C + E$, with C circulant and E of low rank. Then $B = \Lambda + F_n E F_n^H = \Lambda + \tilde{E}$ with rank $(\tilde{E}) =$ rank (E), and

$$D = \Lambda \circ \Lambda + \Lambda \circ \tilde{E} + \tilde{E} \circ \Lambda + \tilde{E} \circ \tilde{E} = \text{diagonal} + \tilde{E} \circ \tilde{E} = \text{diagonal} + \hat{E}$$

and rank $(\hat{E}) \leqq$ rank $(\tilde{E})^2$ (see [9, Thm. 5.1.7]). Then D can be computed in $O(n \log(n))$ operations, and $Dx = b$ can be solved in $O(n)$. For example, let

$$A = T_n(2, -1, 0, \ldots, 0) = T_n(2, -1, 0, \ldots, 0, -1) + e_1 e_n^T + e_n e_1^T$$

(see [5]). In this case, $D = \text{diagonal} + \hat{E}$ with rank $(\hat{E}) \leqq 4$ can be computed in $O(n)$ in view of the special structure of A. Unfortunately, numerical computations show that for this matrix A the vector x in Theorem 1 has exactly one negative component for many n. This is caused by the fact that the underlying l_1 function f is only nonnegative.

If x has negative components, we can define positive definite preconditioners by setting

$$\lambda_i := |1/x_i|, \quad C_{Bs} := F_n^H \operatorname{diag}(\lambda_i) F_n \quad \text{if } x_i \neq 0,$$

or better,

$$\lambda_i := \begin{cases} 1/x_i & \text{if } x_i > 0, \\ b_{ii} & \text{else,} \end{cases} \quad C_{Bb} := F_n^H \operatorname{diag}(\lambda_i) F_n.$$

In the last section we will give numerical results for C_{Bs} and C_{Bb}.

THEOREM 4. *For a Hermitian Toeplitz matrix with an underlying positive function of the Wiener class,* (4) *can be solved in* $O(n \log(n))$ *operations.*

Proof. Following (6), the spectrum of the matrix $R := \operatorname{diag}(b_{11}^{-2}, \ldots, b_{nn}^{-2}) * D$ is contained in the interval $[1 - \phi(n), 1 + \phi(n)]$ with $\phi(n) \to 0$ for $n \to \infty$. Let us use the PCG method for solving $Dx = b$ with preconditioner diag $(b_{11}^2, \ldots, b_{nn}^2)$. Note that for a vector a, $D * a$ can be computed in $O(n \log(n))$ operations in view of Theorem 3. The condition number κ of R is bounded by

$$\kappa \leqq \frac{1 + \phi(n)}{1 - \phi(n)},$$

and thus for

$$e_k := \sqrt{(A^{-1}b - x_k)^H A(A^{-1}b - x_k)},$$

the error after the kth step (see [8]),

$$\frac{e_k}{e_0} \leqq \left(\frac{1-\sqrt{(1+\phi(n))/(1-\phi(n))}}{1+\sqrt{(1+\phi(n))/(1-\phi(n))}}\right)^{2k} = \left(\frac{1-\sqrt{1-\phi(n)^2}}{\phi(n)}\right)^{2k} = \left(\frac{\phi(n)}{2} + O(\phi(n)^3)\right)^{2k}.$$

Hence, $e_k/e_0 \leqq \varepsilon$ is fulfilled if asymptotically

$$\left(\frac{\phi(n)}{2}\right)^{2k} \leqq \varepsilon,$$

or $\phi(n) \leqq 2 * \varepsilon^{1/(2k)}$. Therefore, the number of iterations of the PCG method for computing the vector x is bounded by $O(1/|\log(\phi(n))|)$, and the total number of operations for solving (4) is $O(n \log(n))$. □

We can consider a similar minimization problem that leads to another well-defined circulant approximation to a given matrix A. Let us look for the solution of

$$(7) \qquad \min_{C \text{ circulant}} \|C^{1/2} - A * C^{-1/2}\|_F.$$

Because of

$$\|C^{1/2} - A * C^{-1/2}\|_F = \|\Lambda^{1/2} - B * \Lambda^{-1/2}\|_F$$
$$= \lambda_1 - 2b_{11} + \frac{\|b_1\|_2^2}{\lambda_1} + \cdots,$$

the solution of (7) is given by the circulant matrix C_{F2} with eigenvalues $\lambda_i = \|b_i\|_2$, and we get with (3),

$$C_{F2} = \text{Circ}\,(A^2)^{1/2},$$

which is always defined, positive semidefinite, and asymptotically equal to C_F if $A = T_n$ is related to a positive function of the Wiener class. In view of the connection between C_T, C_F, and C_{F2}, C_{F2} can be computed in $O(n \log(n))$ [3], [15], [16], and the clustering property that holds for Toeplitz matrices with underlying positive l_1 function is true for $C_{F2}^{-1}T_n$ as well [1], [2], [3].

Note that the various Frobenius norm approximations fulfill

$$\text{Circ}\,(A) = \text{Circ}\,(C_F) = \text{Circ}\,(C_T * A^2) = \text{Circ}\,(A * C_B^{-1} * A),$$
$$\text{Circ}\,(C_{F2}^2) = \text{Circ}\,(A^2).$$

The equation for C_B follows from $\text{diag}\,(B * \text{diag}\,(1/\lambda_1, \ldots, 1/\lambda_n) * \bar{B}) = \text{diag}\,(B)$ [9, Lemma 5.1.3] and Theorem 2 in [3].

2. Approximations in other norms. Looking for a circulant matrix that minimizes $\|C - A\|_2$ is equivalent to minimizing

$$\|\Lambda - B\|_2$$

with a diagonal matrix Λ and $B = F_n A F_n^H$. In this section we will determine some circulant approximations that correspond to an (in some sense) optimal diagonal matrix Λ. First, let us remark that the Frobenius norm approximation C_F not only solves $\min \|\Lambda - B\|_F = \|C - A\|_F$, but also $\min \|\Lambda - B\|_1$ and $\min \|\Lambda - B\|_\infty$. A similar property is possessed by the circulant approximation of Strang [14], which for Toeplitz matrices solves $\min \|C - T_n\|_1 = \min \|C - T_n\|_\infty$.

We can also determine superoptimal diagonal approximations in the $\|\cdot\|_1$ norm.

THEOREM 5. *Let A be a Hermitian positive definite matrix. If $\|b_i\|_1 \leqq 2 * b_{ii}$, $i = 1, \dots, n$, then the matrix $\Lambda_F := F_n C_F F_n^H$ is a solution of*

$$\min_{\Lambda \text{ diagonal}} \|I - \Lambda^{-1} B\|_1.$$

Proof. It holds that

$$\|I - \Lambda^{-1}B\|_1 = \max_{i=1}^{n} \left\{ \left|1 - \frac{b_{ii}}{\lambda_i}\right| + \frac{\|b_i\|_1 - b_{ii}}{\lambda_i} \right\}.$$

For $b_{ii} \geqq \lambda_i$ the ith term takes its minimal value if $\lambda_i = b_{ii}$. For $b_{ii} < \lambda_i$ and $\|b_i\|_1 \leqq 2b_{ii}$, the minimum again is $\lambda_i = b_{ii}$. Finally, if $\|b_i\|_1/2 < b_{ii} < \lambda_i$, the optimal value of the ith term is 1 for $\lambda_i = \infty$. Thus, if $\|b_i\|_1 \leqq 2b_{ii}$ for $i = 1, \dots, n$, a solution is given by the diagonal matrix built up by the eigenvalues of C_F. □

THEOREM 6. *Let A be a Hermitian positive definite matrix and $B = F_n A F_n^H$. A solution of*

$$\min_{\Lambda \text{ diagonal}} \|\Lambda^{1/2} - B\Lambda^{-1/2}\|_1$$

is given by

$$\lambda_i = \begin{cases} b_{ii} & \text{for } 3b_{ii} \geqq \|b_i\|_1 \\ \|b_i\|_1 - 2b_{ii} & \text{for } 3b_{ii} < \|b_i\|_1. \end{cases}$$

Proof. It holds that

$$\|\Lambda^{1/2} - B\Lambda^{-1/2}\|_1 = \max_{i=1}^{n} \left\{ \left|\sqrt{\lambda_i} - \frac{b_{ii}}{\sqrt{\lambda_i}}\right| + \frac{\|b_i\|_1 - b_{ii}}{\sqrt{\lambda_i}} \right\}.$$

For $\lambda_i \leqq b_{ii}$ or $\lambda_i > b_{ii} \geqq \|b_{ii}\|_1/3$, the ith term takes its minimum value for $\lambda_i = b_{ii}$. If $b_{ii} < \lambda_i$ and $\|b_i\|_1 > 3b_{ii}$, the ith term is minimal for $\lambda_i = \|b_i\|_1 - 2b_{ii}$. □

Let us denote by C_1 the circulant approximation that corresponds to the diagonal matrix of Theorem 6.

The last two theorems show that the Frobenius norm approximation C_F is often an optimal circulant approximation to a given matrix A relative to the norm $\|A\|_{F1} := \|F_n A F_n^H\|_1$. But in some cases we get circulant approximations that depend on $\|b_i\|_1$. Therefore, we have to consider $\|B\|_1$ to show that C_1 is well defined.

THEOREM 7. *Let T_n be a symmetric Toeplitz matrix connected with a positive function of the Wiener class, and $B = F_n T_n F_n^H$. If*

$$\sum_{r=1}^{n} |rt_r| \tag{8}$$

is bounded, then $\|B\|_1$ is bounded.

Proof. With (5) we get, for $k \neq j$,

$$\begin{aligned} b_{k,j} &= \frac{1}{n} \sum_{r=1}^{n-1} t_r w^{(1-k)r} \sum_{m=0}^{n-r-1} w^{(j-k)m} + \frac{1}{n} \sum_{r=1-n}^{-1} t_r w^{(1-k)r} \sum_{m=1-r}^{n} w^{(j-k)(m-1)} \\ &= \frac{1}{n(1-w^{j-k})} \sum_{r=1}^{n} \{t_r (w^{(1-k)r} - w^{(1-j)r} + w^{(j-1)r} - w^{(k-1)r})\} \\ &= \frac{w^{(k-j)/2}}{n \sin((k-j)\pi/n)} \sum_{r=1}^{n-1} t_r \left(2i \sin\left(\frac{2\pi(1-k)r}{n}\right) + 2i \sin\left(\frac{2\pi(j-1)r}{n}\right)\right) \\ &= \frac{4iw^{(k-j)/2}}{n \sin((k-j)\pi/n)} \sum_{r=1}^{n-1} t_r \sin\left(\frac{\pi r(j-k)}{n}\right) \cos\left(\frac{\pi r(k+j-2)}{n}\right). \end{aligned}$$

Then, for $j=1,\ldots,n, j\neq k$,

$$|b_{k,j}|\leqq\left(\frac{4}{n|\sin((j-k)\pi/n)|}\right)\sum_{r=1}^{n-1}|t_r\sin((j-k)r\pi/n)|.$$

Hence,

$$\sum_{j=1,j\neq k}^{n}|b_{k,j}|\leqq\frac{4}{n}\sum_{j=1,j\neq k}^{n}\sum_{r=1}^{n-1}|t_r|*\left|\frac{\sin(\pi r(j-k)/n)}{\sin(\pi(j-k)/n)}\right|$$
$$=4*\sum_{r=1}^{n-1}|t_r|\left\{\frac{1}{n}\sum_{j=1}^{n-1}\left|\frac{\sin(\pi rj/n)}{\sin(\pi j/n)}\right|\right.$$
$$=4*\sum_{r=1}^{n-1}|t_r|*f(r).$$

By induction it is easy to prove that $f(r)\leqq r$ for $r=1,\ldots,n$, and thus $\|B\|_1$ is bounded if (8) is fulfilled. □

It can be shown that $f(r)$ asymptotically satisfies the stronger inequality $f(r)\leqq c*\log(r)$ with c independent of n. The proof uses a partitioning of $f(r)$ for $\pi jr/n\in[k\pi-\pi/4, k\pi+\pi/4]$ and $\pi jr/n\in[k\pi+\pi/4, k\pi+3\pi/4]$, $k=0,1,\ldots,r$. Thus condition (8) in Theorem 7 can be replaced by the weaker condition that $t_r\log(r)$ is an l_1 sequence.

For the preconditioner C_1 we can not give any clustering analysis. Besides, the computation of $\|b_i\|_1$, $i=1,\ldots,n$, takes $O(n^2)$ operations, and thus is unattractive in practice. But, in many cases, $C_1=C_F$. Thus the main result of this section is that C_F is often an optimal approximation to a given matrix, not only in the Frobenius norm, but in other norms, as well.

3. Numerical examples. To test the different preconditioners, we display the spectra of the preconditioned matrices with $n=16$ for

(a) $t_0=2.007$, $t_1=-1$, $t_i=0$ for $i=2,\ldots,15$,

(b) $t_0=2.006$, $t_1=-1$, $t_i=0$ for $i=2,\ldots,15$,

(c) $t_0=0.6$, $t_i=\cos(i)/(i+1)$ for $i=1,\ldots,15$.

For these examples, $C_1\neq C_F$. C_B is not defined only for (b), and in that case, we examine C_{Bs} and C_{Bb}. See Figs. 1-3.

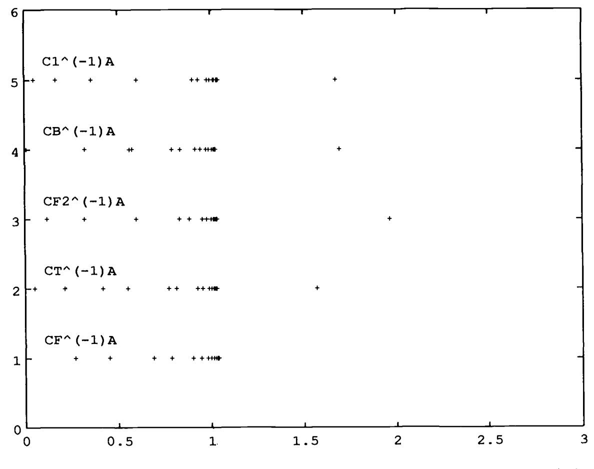

FIG. 1. *Spectra of the preconditioned systems for example (a).*

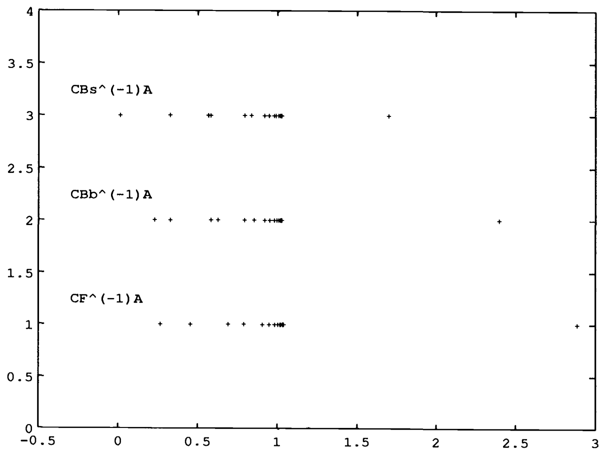

FIG. 2. *Spectra of the preconditioned systems for example* (*b*).

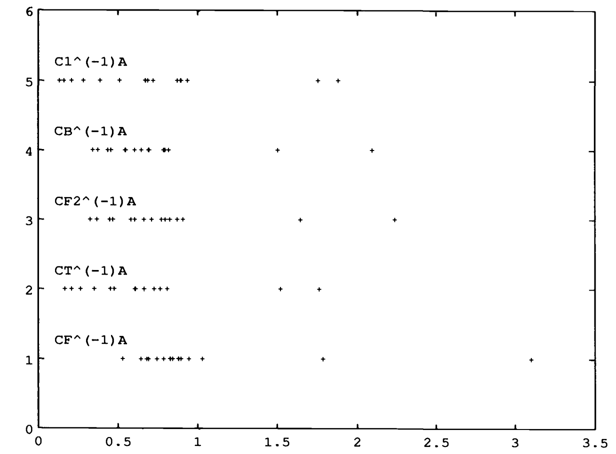

FIG. 3. *Spectra of the preconditioned systems for example* (*c*).

For example (b), Fig. 2 shows that C_{Bb} seems to be the better choice if C_B is not defined.

Next, we test the use of the PCG method for solving (4), $Dx = b$, with start vector $(1/b_{11}, \ldots, 1/b_{nn})^T$ for the examples (see Tables 1 and 2)

(d) $t(i) = 1/(i+1)^2, i = 0, \ldots, n-1$,

(e) $t_0 = 2, t_i = (1+\sqrt{-1})/(i+1)^{1.1}, i = 1, \ldots, n-1$.

TABLE 1
Error after the kth step for the PCG *method on* (4).

Example (d)	r_0	r_1	r_2
$n=8$	0.047	2.6×10^{-5}	1.2×10^{-7}
$n=16$	0.041	2.6×10^{-5}	5.7×10^{-8}
$n=32$	0.031	1.8×10^{-5}	5.6×10^{-9}
$n=64$	0.023	8.7×10^{-6}	9.0×10^{-10}
$n=128$	0.016	3.6×10^{-6}	2.2×10^{-10}

TABLE 2
Error after the kth step for the PCG *method on* (4).

Example (e)	r_0	r_1	r_2	r_3	r_4
$n=8$	0.096	0.0015	2.1×10^{-5}	2.4×10^{-7}	1.0×10^{-9}
$n=16$	0.13	0.0016	1.8×10^{-5}	2.6×10^{-7}	2.5×10^{-9}
$n=32$	0.13	0.0010	1.3×10^{-5}	1.8×10^{-7}	5.8×10^{-10}
$n=64$	0.12	4.5×10^{-4}	7.6×10^{-6}	7.1×10^{-8}	1.2×10^{-10}
$n=128$	0.095	1.8×10^{-4}	4.1×10^{-6}	2.0×10^{-8}	3.7×10^{-11}

Table 3 displays the number of iterations for the PCG method for solving $T_nx=b$ with example (e). The right-hand side is given by $b=(1,\dots,1)^T/\sqrt{n}$ and the initial guess is the zero vector. The algorithm stops if the Euclidean norm of the residuum is less than 10^{-6}.

Here, C_B is always defined, and C_1 differs from C_F for $n=64$ and $n=128$ on 2, respectively 8, positions.

TABLE 3
Number of iterations for different preconditioners in example (e).

n	C_F	C_{F2}	C_B	C_1
8	6	6	6	6
16	6	6	6	6
32	6	6	6	6
64	6	6	6	6
128	6	6	6	7

In most numerical experiments, the condition numbers of $C_B^{-1}T_n$ and $C_{F2}^{-1}T_n$ are smaller than that of $C_F^{-1}T_n$, but the clustering property of the spectrum of the preconditioned linear equation seems to be better for C_F.

A PARALLEL ALGORITHM FOR THE NONSYMMETRIC EIGENVALUE PROBLEM*

JACK J. DONGARRA† AND MAJED SIDANI‡

Abstract. This paper describes a parallel algorithm for computing the eigenvalues and eigenvectors of a nonsymmetric matrix. The algorithm is based on a divide-and-conquer procedure and uses an iterative refinement technique.

Key words. eigenvalue problem, divide and conquer, parallel computing

AMS(MOS) subject classification. 65F15

1. Introduction. The algebraic eigenvalue problem is one of the fundamental problems in computational mathematics. It arises in many applications and therefore represents an important area of algorithmic research. The problem has received considerable attention, which has resulted in reliable methods [17]-[19]. However, it is reasonable to expect that calculations might be accelerated through the use of parallel algorithms. A fully parallel algorithm for the symmetric eigenvalue problem was recently proposed in [7]. This algorithm is based on a divide-and-conquer procedure outlined in [4]. The latter was based on work in [11] and [2]. The fundamental principle behind this algorithm is that the partitioning by rank-one tearing interlaces the eigenvalues of the modified problem with the eigenvalues of the original problem (the matrix is first reduced to tridiagonal form). This approach in turn enables rapid and accurate determination, in parallel, of the eigenvalues and the associated eigenvectors.

In this paper we propose a parallel algorithm for the solution of the nonsymmetric eigenvalue problem. The approach uses some of the features of the divide-and-conquer algorithm for the symmetric case mentioned earlier. In particular, the original problem is divided into two smaller and independent subproblems by a rank-one modification of the matrix. (We assume that the matrix has already been reduced to Hessenberg form, and that the rank-one modification removes a subdiagonal element.) Once the eigensystems of the smaller subproblems are known, it is possible to compute those of the original matrix. In the nonsymmetric case, the eigenvalues of the modified matrix do not interlace with those of the original matrix. Indeed, the eigenvalues can scatter anywhere in the complex plane.

In our algorithm for the nonsymmetric case, the eigensystem of the subproblem is used only to construct initial guesses for an iterative process which yields the desired eigensystem of the original problem. Under suitable conditions, iterative refinement or continuation can be used to find the eigenpairs of the original problem. We report here on our application of an iterative refinement approach based on Newton's method; we shall not pursue the continuation method in this paper. Work on the continuation approach has been reported by [14] and [15]. For other divide-and-conquer approaches, see [1] and [12].

In § 2 we describe an algorithm that uses an iterative refinement procedure based on Newton's method. Section 3 covers the deflation step required to overcome multiple convergence to a particular eigenvalue. In § 5 the convergence behavior of the new algorithm is discussed. In § 4 we discuss the case when the matrix or its rank-one modification has a defective system of eigenvectors. Section 7 estimates the amount of work the parallel algorithm requires and compares this to the standard techniques. Section 6 describes the parallel algorithm and the different parallel implementations of the new algorithm, and gives numerical results. Section 9 describes how our ideas extend to the generalized eigenvalue problem.

2. The algorithm. Given a matrix H, an eigenpair (x_0, λ_0) of H can be thought of as a solution to the polynomial system

$$(S)\begin{cases} Hx-\lambda x=0, \\ L(x)=1, \end{cases}$$

where $L(x)$ is a scalar equation. Here, we set $L(x)=e_s^T x$, where e_s is the sth unit vector (in practice, we choose s so as to normalize a known approximation to an eigenvector of H). Let

$$F_s(x,\lambda)=\begin{pmatrix} Hx-\lambda x \\ e_s^T x-1 \end{pmatrix}.$$

Then, finding an eigenpair of H reduces to finding a zero of F_s. In what follows, unless otherwise mentioned, H is assumed to be a real, unreduced (no zeros on the subdiagonal), upper-Hessenberg matrix of order n. This does not restrict the type of problems we want to solve, since if H has a zero on the subdiagonal then finding its eigenvalues reduces to finding those of the blocks on the diagonal. We note also by our assumption that H is unreduced, an eigenvalue of H can only have geometric multiplicity one: this is quite easy to see since the first $n-1$ columns of $H-\lambda I$ are linearly independent. We assume for now that H has a simple spectrum. We can write H as

$$H=\left(\begin{array}{c|c} H_{11} & H_{12} \\ \hline \alpha e_1^{(k)} e_k^{(k)T} & H_{22} \end{array}\right),$$

where H_{11} and H_{22} are upper-Hessenberg of dimensions $k\times k$ and $n-k\times n-k$, respectively; $\alpha=h_{k+1,k}$, and $e_i^{(k)}$ is the ith unit vector of length k.

Let $H_0=H-\alpha e_{k+1}^{(n)} e_k^{(n)T}$. Then

$$H_0=\left(\begin{array}{c|c} H_{11} & H_{12} \\ \hline 0 & H_{22} \end{array}\right) \quad \text{and} \quad \sigma(H_0)=\sigma(H_{11})\cup\sigma(H_{22})$$

(where $\sigma(M)$ is the spectrum of M). The algorithm can then be described as follows. We first find the k eigenpairs of H_{11} and the $n-k$ eigenpairs of H_{22} by some method. These eigenpairs are then used to construct initial approximations to the eigenpairs of H. If λ is an eigenvalue of H_{11} and x is the corresponding eigenvector, then λ is viewed as an approximate eigenvalue of H with the corresponding approximate eigenvector taken to be $\binom{x}{0}$, where $n-k$ zeros are appended to x. Note that $\binom{x}{0}$ is an exact eigenvector of H_0 corresponding to λ. On the other hand, if λ is an eigenvalue of H_{22} and x is the corresponding eigenvector, then $\binom{0}{x}$, where k zeros are prefixed to x, is taken as an approximate eigenvector of H corresponding to the approximate eigenvalue λ. If λ is not an eigenvalue of H_{11} then the last $n-k$ components of an exact eigenvector of H_0 corresponding to λ,

$$\begin{pmatrix} (H_{11}-\lambda)^{-1}H_{12}x \\ x \end{pmatrix},$$

are the components of x. However, if λ is an eigenvalue of H_{11}, and if its geometric multiplicity is one as an eigenvalue of H_0, then no eigenvector of H_0 will have the components of x as its trailing components. We have chosen to take $\binom{0}{x}$ as initial eigenvector instead of

$$\begin{pmatrix} (H_{11}-\lambda)^{-1}H_{12}x \\ x \end{pmatrix}$$

in order to avoid the additional computation involved in solving a linear system. The choice proved adequate in practice, in that there was no significant difference in the convergence behavior of the algorithm.

Newton's method comes into this problem in a rather "natural" way. Indeed, suppose that (x, λ) is an approximate eigenpair of H, $Hx \approx \lambda x$. Let us find a way to compute a correction (y, μ) to this approximate eigenpair. Clearly, (y, μ) should satisfy

$$H(x+y) = (\lambda+\mu)(x+y).$$

Rearranging the latter equation yields

$$(H-\lambda)y - \mu x = \lambda x - Hx + \mu y. \tag{1}$$

Now we ignore the second-order term μy, and we impose a normalization condition on x, say $x_s = 1$, where x_s is the sth component of x. If we also assume that the desired eigenvector should satisfy the same condition, then (y, μ) is the solution of

$$\begin{pmatrix} H-\lambda I & -x \\ e_s^T & 0 \end{pmatrix} \begin{pmatrix} y \\ \mu \end{pmatrix} = \begin{pmatrix} r \\ 0 \end{pmatrix}, \tag{2}$$

with $r = \lambda x - Hx$. But, this is the same equation that we obtain when a Newton iteration is applied to the function F_s to find a correction to (x, λ). We note here a result from [5], where the author studied an iterative refinement technique to compute the correction (y, μ) to (x, λ) from (1) (i.e., without ignoring the second-order term) and proved that in *exact* arithmetic, that method and Newton's method produce the same final iteration.

So far we have not attempted to answer the question of which subdiagonal entry will introduce the zero. We will use first-order perturbation theory in order to shed some light on this issue. Let $E = -\alpha e_{k+1}e_k^T$, where as above, $\alpha = h_{k+1,k}$ (note that $H + E = H_0$, introduced above). Then given a simple eigenpair (x, λ) of H, classical results from function theory [13, V.2, pp. 119–134] allow us to state that in a small neighborhood of zero, there exist differentiable $(x(\varepsilon), \lambda(\varepsilon))$ that satisfy

$$(H+\varepsilon E)x(\varepsilon) = \lambda(\varepsilon)x(\varepsilon),$$

for all ε in that neighborhood. Clearly, $x(0) = x$ and $\lambda(0) = \lambda$. Let y^H be the left eigenvetor of H corresponding to λ. Then differentiating both sides with respect to ε we have

$$HD_\varepsilon x(\varepsilon) + Ex(\varepsilon) + \varepsilon ED_\varepsilon x(\varepsilon) = D_\varepsilon\lambda(\varepsilon)x(\varepsilon) + \lambda(\varepsilon)D_\varepsilon x(\varepsilon),$$

where D_ε denotes the differentiation operator. Multiplying by y^H and setting $\varepsilon = 0$ we get

$$y^H Ex = D_\varepsilon \lambda(0) y^H x,$$

and therefore

$$|D_\varepsilon \lambda(0)| = \frac{|y^H Ex|}{|y^H x|} = \frac{|\alpha||y_{k+1}||x_k|}{|y^H x|}. \tag{3}$$

The quantities that vary with k in this expression are in the numerator. However, $|\alpha|$, $|y_{k+1}|$, and $|x_k|$ are not really independent of one another; indeed, if $\alpha = 0$, then at least one of y_{k+1} or x_k is zero. Hence for α small, we can expect one of y_{k+1} and x_k to be correspondingly small, since the components of the eigenvectors vary continuously. Therefore, we have found it sufficient in practice to look for the smallest subdiagonal entry in a prespecified range, and accept it as the subdiagonal entry (in that range) with respect to which the eigenvalues of the matrix are least sensitive, and set it equal to zero.

An outline of the algorithm follows.

ALGORITHM 2.1. Given an unreduced upper-Hessenberg matrix H, the following algorithm computes the eigensystems of two submatrices of H and uses them as initial guesses for starting Newton iterations for determining the eigensystem of H.

Determine subdiagonal element α where

$$H = \left(\begin{array}{c|c} H_{11} & H_{12} \\ \hline 0^\alpha & H_{22} \end{array}\right)$$

should be split; Determine initial guesses from eigensystems of the two diagonal blocks H_{11} and H_{22}; For each initial guess (λ_i, x_i) iterate until convergence:

$$\begin{pmatrix} H - \lambda_i I & -x_i \\ \hline e_s^T & 0 \end{pmatrix} \begin{pmatrix} y \\ \mu \end{pmatrix} = \begin{pmatrix} r_i \\ 0 \end{pmatrix}; \quad \lambda_i \leftarrow \lambda_i + \mu; \quad x_i \leftarrow x_i + y;$$

end;
Check for duplicates and deflate if necessary;

More will be said about the last step, deflation, in § 3. In practice, the original matrix will be dense and we will need to reduce it to upper-Hessenberg form as a first step. This can be done in a stable fashion through a sequence of orthogonal similarity transformations, although elementary transformations can also be used with confidence, as in ELMHES [17].

A brief study of some sufficient conditions guaranteeing the convergence of our method will be touched upon in § 5. Now, assuming that the algorithm converges, it could happen that the same eigenpair of H is obtained more than once, i.e., starting from two (or more) distinct initial approximations, Newton's method converges to the same eigenpair of H. We have investigated methods to obtain further eigenpairs of H should this happen (see § 3).

We end this section with some implementational details. Our algorithm will accept (x, λ) as an eigenpair of H when $\|H_x - \lambda_x\| / \|x\| \, \|H\| < \text{tol}$, where tol is some specified tolerance of order ε, the machine unit roundoff. Under these conditions [9], (x, λ) is an exact eigenpair of a matrix obtained from H by a slight perturbation. Indeed,

$$\left(H+\frac{1}{x^H x} r x^H\right) x=\lambda x,$$

where $r=\lambda x-Hx$.

Starting from two complex conjugate initial approximations, Newton's method will converge to two complex conjugate zeros of F_s, or the same real zero. To prove this, it suffices to look at one iteration and show that when the current approximations are complex conjugate, Newton's method yields two complex conjugate corrections, or the same real correction. The system we must solve starting from (x, λ) is (2). For $(\bar{x}, \bar{\lambda})$ this becomes

$$\begin{pmatrix} H-\bar{\lambda} I & -\bar{x} \\ e_s^T & 0 \end{pmatrix}\begin{pmatrix} y' \\ \mu' \end{pmatrix}=\begin{pmatrix} \bar{r} \\ 0 \end{pmatrix}.$$

But this is the same linear system obtained when the conjugate of both sides in (2) is taken, since $\bar{H}=H$. Therefore, $y'=\bar{y}$ and $\mu'=\bar{\mu}$. This will allow significant savings in the computations.

Last, when starting from a real initial guess, only *real* corrections are computed. Therefore, the imaginary part of the eigenvalue should be perturbed if convergence ot a complex eigenpair is to be made possible. In practice, we have done this when real arithmetic does not lead to convergence after a prespecified number of corrections. A 2×2 real matrix whose eigenvalues are complex is a simple example of when perturbing the imaginary part of the eigenvalue is necessary.

3. Deflation.

When Newton's method is applied to solve the eigensystem of a matrix H, two distinct initial guesses may possibly converge to the same eigenpair of H. In fact, a naive implementation of the algorithm in § 2 may result in many eigenvalues being found multiple times and, consequently, some eigenvalues not being found at all. To avoid this unwanted situation, we included a deflation step in our algorithm that is designed to obtain further zeros.

Assume that when Algorithm 2.1 is applied to the $n\times n$ matrix H (we will assume for simplicity that it has no multiple eigenvalues) the eigenpair (x, λ) of H is obtained more than once, i.e., the algorithm converges to (x, λ) from several distinct initial guesses $(x_0^{(i)}, \lambda_0^{(i)})$, $i=1, \ldots, r$, $r>1$. There exist two classes of methods for finding the additional eigenpairs of H. The methods of one class produce an $(n-1)\times(n-1)$ matrix H' such that $\sigma(H')=\sigma(H)-\{\lambda\}$, and then Algorithm 2.1 is applied to H' starting from $r-1$ of these initial guesses. In this case, if the algorithm converges, then it will do so to eigenpairs different from (x, λ) since λ is no longer in the spectrum. Methods of this type will be discussed in §§ 3.1 and 3.3. The other class of methods will reapply Algorithm 2.1 to the original matrix H starting from $r-1$ of the initial guesses mentioned above, but will force convergence away from (x, λ) by ensuring, at all steps, that the current eigenvector forms a nonzero angle with x. A method of this type will be discussed in § 3.2.

A common drawback of all of these methods is that they tend to serialize the computation. However, it has been our experience that the need to deflate arises infrequently: less than 5 percent of the time in our tests.

3.1. Deflation using elementary transformations.

We now describe one possible deflating similarity transformation. We assume that H is an unreduced upper-Hessenberg matrix, λ is an eigenvalue of H, and x is the corresponding eigenvector.

Since we are assuming H to be upper-Hessenberg with no zeros on the subdiagonal, then $x_n \neq 0$, and the elementary transformation $M = [e_1, \dots, e_{n-1}, x]$ i.e.,

$$M = \begin{pmatrix} 1 & & & x_1 \\ & \ddots & & \vdots \\ & & 1 & x_{n-1} \\ 0 & & & x_n \end{pmatrix}, \tag{4}$$

is nonsingular. The inverse of this matrix is

$$M^{-1} = \begin{pmatrix} 1 & & & -x_1/x_n \\ & \ddots & & \vdots \\ & & 1 & -x_{n-1}/x_n \\ 0 & & & 1/x_n \end{pmatrix}. \tag{5}$$

It is easy to see that $M^{-1}x = e_n$, Now we let

$$\tilde{H} = M^{-1}HM. \tag{6}$$

It is easy to verify that $\tilde{H}$ is unreduced and upper-Hessenberg, and that the last column of $\tilde{H}$ is λe_n. Furthermore, the leading principal submatrix of order $n-1$ of $\tilde{H}$, which we will call H', is upper-Hessenberg, has the property that

$$\sigma(H') = \sigma(H) - \{\lambda\},$$

and differs from the leading $(n-1)\times(n-1)$ principal submatrix of H in the last column only. In fact, if we let h_{n-1} be the last column of the leading principal submatrix of H of order $n-1$, then it is straightforward to verify that the last column of H' is $h_{n-1} - h_{n,n-1}x'$, where

$$x' = \begin{pmatrix} x_1/x_n \\ \vdots \\ x_{n-1}/x_n \end{pmatrix}.$$

The strategy we have just described is given in [19] and applies regardless of whether the eigenpair (x, λ) is real or not. However, when (x, λ) is real we get a real matrix H'. In the case when (x, λ) is not real, the last column of H' alone is not real since, as we remarked earlier, the other columns are those of a leading principal submatrix of H. Hence the leading principal submatrix of H' of order $n-2$ is real. Also, in this case the complex conjugate of (x, λ), $(\bar{x}, \bar{\lambda})$ is an eigenpair of H, and therefore $\bar{\lambda}$ is an eigenvalue of $\tilde{H}$; a corresponding eigenvector is

$$M^{-1}\bar{x} = \begin{pmatrix} \bar{x}_1 - x_1(\bar{x}_n/x_n) \\ \vdots \\ \bar{x}_{n-1} - x_{n-1}(\bar{x}_n/x_n) \\ \bar{x}_n/x_n \end{pmatrix}.$$

Since $\sigma(H') = \sigma(H) - \{\lambda\}$, $\bar{\lambda}$ is an eigenvalue of H', and a corresponding eigenvector is the vector $\tilde{x}$ of length $n-1$, whose components are the first $n-1$ components of a scalar multiple of $M^{-1}\bar{x}$:

$$\tilde{x} = \begin{pmatrix} (\bar{x}_1 x_n - x_1\bar{x}_n)/i \\ \vdots \\ (\bar{x}_{n-1}x_n - x_{n-1}\bar{x}_n)/i \end{pmatrix},$$

where $i^2=-1$. This is due to the special structure of $\tilde{H}$. Now recall that H' has no zeros on the subdiagonal, and so we know that the last component of $\tilde{x}$ is nonzero. Note that $\tilde{x}$ is real. We can carry out a deflation that produces a matrix H'' of order $n-2$ with the property that

$$\sigma(H'')=\sigma(H')-\{\bar{\lambda}\};$$

in the same way, we obtained H' from H using the elementary transformation of order $n-1$:

$$M'=\begin{pmatrix} 1 & & \tilde{x}_1 \\ & \ddots & \vdots \\ & & \tilde{x}_{n-2} \\ 0 & & \tilde{x}_{n-1} \end{pmatrix}.$$

From a previous remark about this deflation strategy, we know that H'' differs from the leading principal submatrix of H' of order $n-2$ (which is real) in the last column only. The last column of H'' is $h'_{n-2}-h_{n-1,n-2}x''$, where h'_{n-2} is the last column of the leading principal submatrix of H', and x'' is the vector whose components are the first $n-2$ components of $\tilde{x}$. Since all of the quantities involved are real, H'' is real.

We remark here, as can be readily realized, that H' (or H'') is quite cheap to obtain in practice once an eigenpair of H is available. It requires $O(n)$ operations consisting of a vector normalization, a scalar-vector multiplication, and a vector-vector addition. However, the conditioning of the matrix M might raise concern. Indeed,

$$\operatorname{cond}_\infty(M)=\|M\|_\infty\|M^{-1}\|_\infty\approx\max(|x_i|)\max\left(\frac{|x_i|}{|x_n|}\right),$$

which can be large if $x_n \ll x_i$. Having noted this, it is clear that the ill-conditioning of M can be easily detected, and therefore one of the more stable (and costlier) methods that we introduce next and in the following sections can be used.

It is possible to prevent the ill-conditioning of M from bearing on the algorithm by avoiding a similarity transformation. More precisely, the eigenvalue problem we want to solve can be thought of as a generalized eigenvalue problem, $Hx=\lambda Bx$, with $B=I$. We want to find $\sigma(H)=\sigma(H,I)$. Now we know that given any nonsingular M and N,

$$\sigma(H,I)=\sigma(NHM,NM).$$

Given a particular eigenpair (x,λ), we would like to choose M and N in a way that solves the problem we set for ourselves at the beginning of this section, namely, we want to reduce the problem to one where λ is no longer in the spectrum. A closer look at the similarity transformation (6) reveals that its deflating property is due to the fact that $M^{-1}x=e_n$. But then M^{-1} is not the only matrix that can be used to accomplish this. In fact, the matrix N can be chosen to reduce x to a multiple of e_n: $N=DM^{-1}$, where D is the diagonal matrix with the entries

$$d_i=1,\quad \text{if } |x_i|/|x_n|\leqq 1,$$
$$d_i=-x_n/x_i\quad \text{if } |x_i|/|x_n|>1,$$

i.e., D is chosen so that all the entries in N are less than or equal to one. Then we have

$$(7)\qquad NHM=\left(\begin{array}{c|c} H' & 0 \\ \hline 0\quad\alpha & \gamma \end{array}\right),\qquad NM=\left(\begin{array}{c|c} D' & 0 \\ \hline 0 & \delta \end{array}\right),$$

with $\lambda = \lambda/\delta$. Also, $\sigma(H', D') = \sigma(H, I) - \{\lambda\}$, and therefore, by this transformation, λ has been "removed" from the spectrum. Working on the solution of a generalized eigenvalue problem from this point on will not generally cause any dramatic increase in the cost of the algorithm, mainly because D' is diagonal. A Newton step with this problem involves the following computation:

$$(8)\qquad \begin{pmatrix} H' - \lambda_i D' & -D'x_i \\ e_s^T & 0 \end{pmatrix} \begin{pmatrix} y \\ \mu \end{pmatrix} = \begin{pmatrix} r_i \\ 0 \end{pmatrix}, \quad \lambda_i \leftarrow \lambda_i + \mu; \quad x_i \leftarrow x_i + y,$$

where $r_i = \lambda_i D' x_i - H x_i$. Clearly, the previous computation involves an $O(n)$ increase in the cost of one step: this comes from the multiplications by D'. The details on how (8) is derived are given in § 9. If λ is complex, then after deflating λ and its conjugate $\bar{\lambda}$, the resulting matrices H' and D' are generally complex. This is the major drawback of this method.

Finally, we mention another approach that can be of interest when the similarity transformation (6) involves a very ill conditioned M. This approach consists of interchanging two components of x and the corresponding columns and rows in H so that the last component of x is large enough. More precisely, let x_s be the largest component of x (in absolute value), and let P_{ns} be the matrix obtained from the identity matrix by permuting the nth and sth columns. Then $(P_{ns}x, \lambda)$ is an eigenpair of the matrix $P_{ns}HP_{ns}$, since

$$(P_{ns}HP_{ns})(P_{ns}x) = \lambda P_{ns}x.$$

Now scale the vector $P_{ns}x$ so that the last component is 1 and call that vector $\tilde{x}$. Then, as above, the elementary transformation

$$M = \begin{pmatrix} 1 & & \tilde{x}_1 \\ & \ddots & \vdots \\ & & \tilde{x}_{n-1} \\ 0 & & 1 \end{pmatrix}$$

can be used to deflate the matrix $P_{ns}HP_{ns}$. The fact that here $P_{ns}HP_{ns}$ is not upper-Hessenberg is of no consequence. In fact, we can make the following general statement: Given any matrix A of order n, and any eigenpair (x, λ) of A, then a matrix Q satisfying

$$Q^{-1}x = e_1 \quad \text{or} \quad Q^{-1}x = e_n$$

can be used to deflate A, in the sense that

$$Q^{-1}AQ = [\lambda e_1, B_1] \quad \text{or} \quad Q^{-1}AQ = [B_2, \lambda e_n],$$

respectively, where B_1 and B_2 are $n \times (n-1)$ matrices.

Having thus deflated the matrix $P_{ns}HP_{ns}$, the leading principal submatrix of order $n-1$ of

$$(9)\qquad M^{-1}P_{ns}HP_{ns}M$$

(call it H') has all the eigenvalues of H except λ (if λ is simple). However, H' is not generally upper-Hessenberg, and therefore will be reduced back to Hessenberg form before applying Newton's iterations; this is meant to save on the cost of factorizing the Jacobian when solving the linear systems arising at each step of Newton's iteration. Note that it is only the trailing diagonal submatrix of order $(n-s+1)\times(n-s+1)$ of

H' that needs to be reduced and that if $s = n - 1$ or $s = n$, then H' is upper-Hessenberg. Moreover, s need not be chosen so that x_s is the largest component of x (in absolute value). Indeed, since the size of the matrix to be reduced to upper-Hessenberg form increases when s approaches 1, it is more advantageous to choose the largest s for which the ratios x_i/x_s are moderate. We wish, therefore, to define a threshold t for the size of these ratios on the basis of which s will be determined.

Let $\tilde{H}$ be the computed form of the matrix in (9). In [19, Chap. 9], Wilkinson established that if $\|x\|_\infty \leqq 1$, then the eigenvalues of $\tilde{H}$ are the exact eigenvalues of a matrix $\tilde{H}'$ satisfying

$$\|H - \tilde{H}'\|_\infty \leqq \|r\|_\infty + (n-1)\varepsilon,$$

where r is the residual $\lambda x - Hx$ and ε is the machine epsilon. With no assumptions on the infinity norm of x, this inequality becomes

$$\|H - \tilde{H}'\|_\infty \leqq \|r\|_\infty + (n-1)\|x\|_\infty \varepsilon. \tag{10}$$

Since, in our algorithm, our computed eigenpairs have residuals on the order of $n\|H\|_\infty \varepsilon$, we propose that $t = \|H\|_\infty$.

In addition to destroying the structure of the matrix, this last method of deflation suffers from the fact that in the case when the eigenvalue to be deflated is nonreal, the resulting matrix H' is complex, and therefore will considerably increase the cost of finding subsequent eigenpairs if a Newton process is restarted from a real initial guess.

3.2. Deflation with help from the left eigenvector. The method we introduce now is different in spirit from the ones in the previous section, in that no attempt is made to modify the matrix.

Assume that (x, λ) is an exact eigenpair of H and that λ is simple $Hx = \lambda x$. No assumption is made about the remaining eigenvalues of H.

Let (x, X) be such that

$$(x, X)^{-1} H (x, X) = \begin{pmatrix} \lambda & 0 \\ 0 & J \end{pmatrix}$$

where the right-hand side is the Jordan canonical form of H. Now set

$$(x, X)^{-1} = \begin{pmatrix} y^H \\ Y \end{pmatrix}.$$

Then it is clear that y^H is a left eigenvector of H corresponding to λ and furthermore that

$$y^H X = 0.$$

This property can be used to modify Newton's method to avoid convergence to the eigenpair (x, λ) a second time. Indeed, given λ, we can compute the left eigenvector y corresponding to it, and use it to confine the current eigenvector to the range $R(X)$ of X. Therefore, we can expect to converge to an eigenvector linearly independent of x and hence corresponding to a different eigenpair (since (x, λ) was assumed to be simple). When (x, λ) has already been computed once, our algorithm for avoiding it then consists of the following major steps.

Compute the left eigenvector y^H corresponding to λ, with $\|y\|_2=1$; Given the current eigenpair (z, μ) compute the Newton correction from Algorithm 2.1; Let z' be the approximate eigenvector obtained after adding the Newton correction to z; choose the next eigenvector z'' as:

$$z''=(I-yy^H)z'.$$

In the last step we are just projecting z' onto $R(X)$. We note that when this algorithm is applied, it could happen (as with all the deflation methods we are describing) that we obtain another eigenpair of H, (x', λ'), that was already computed. Then the process must be restarted and z'' will be obtained from z' by a projection onto $R(X')$, where $X=(x', X')$, in order to avoid both (x, λ) and (x', λ'); this will require the computation of the left eigenvector corresponding to λ' as well.

It is obvious why the known eigenpair must be simple for the algorithm just outlined to work. If λ is multiple, then left eigenvectors are no longer necessarily orthogonal to X. In fact, the algorithm will be adversely affected if the eigenvalue λ is ill conditioned, i.e., if y^Hx is very small. Indeed, in this case, if the current eigenvector $z=\alpha x+Xv$, where v is a vector of length $n-1$, then

$$(I-yy^H)z=z-(y^Hz)y=\alpha x+Xv-(\alpha y^Hx)y\approx z,$$

showing that z is hardly modified by the projection and therefore suggesting that the algorithm will not necessarily prevent a second convergence to (x, λ).

The algorithm generalizes to the case when λ is multiple in the following way. Let V be a right invariant subspace corresponding to λ. Let (V, V_c) be such that

$$(V, V_c)^{-1}H(V, V_c)=\begin{pmatrix} J_\lambda & 0 \\ 0 & J \end{pmatrix},$$

where the right-hand side is again the Jordan canonical form of H. J_λ is the Jordan block corresponding to λ; since H is assumed to be unreduced, there can be only one such block. If we set

$$(V, V_c)^{-1}=\begin{pmatrix} U^H \\ W \end{pmatrix},$$

then clearly U^H is a left invariant subspace corresponding to λ, and furthermore,

$$U^HV_c=0.$$

This last property will allow U^H to be used in much the same way as the left eigenvector was used earlier. However, the practical usefulness of this method is restricted to the case when the eigenvalue λ is simple. Indeed, the problem of determining the invariant subspace associated with a multiple eigenvalue λ is an extremely difficult one and can be prohibitively expensive.

This method in its simplest form (using the left eigenvector) adds $O(n^2)$ work to the cost of finding one eigenpair distinct from (x, λ). This is the cost of computing the left eigenvector corresponding to λ; the cost of a single projection is $O(n)$.

3.3. Deflation with orthogonal transformations. We present now a very stable method for obtaining an upper-Hessenberg matrix H' with the property that it has all the eigenvalues of H except for λ [19]. We assume for now that the eigenpair (x, λ) is *exact.*

The strategy consists of $n-1$ major steps, where at each step a new zero is introduced in the last column of $H-\lambda I$ starting from the bottom. The configuration at the beginning of the rth step looks like

$$\tilde{H} = \begin{pmatrix} * & \cdots & * & * \\ * & & & \vdots \\ & \ddots & \vdots & * \\ & & * & 0 \end{pmatrix}$$

with zeros in the last $r-1$ components of the last column. The rth step then consists in a post-multiplication by G_r, where G_r is the (possibly complex) rotation in the plane $(n-r, n)$ designed to annihilate the $(n-r, n)$ element

$$G_r = \begin{pmatrix} 1 & & & & & & & \\ & \ddots & & & & & & \\ & & 1 & & & & & \\ & & & c_r & & & & -s_r \\ & & & & 1 & & & \\ & & & & & \ddots & & \\ & & & & & & 1 & \\ & & & s_r & & & & c_r \end{pmatrix},$$

where $\|c_r\|^2 + \|s_r\|^2 = 1$. This post-multiplication will affect columns $n-r$ and n only, and therefore will not disturb zeros previously introduced in the last column. At the $(n-1)$ step, G_{n-1}, which is constructed to zero the $(2, n)$ element, will also zero the $(1, n)$ element. Indeed, assume that after the $(2, n)$ element has been zeroed we have some value α in the $(1, n)$ position; then we have

$$(H - \lambda I)G_1 \cdots G_{n-1} = \begin{pmatrix} * & \cdots & * & \alpha \\ * & & & \\ & \ddots & \vdots & \\ & & * & 0 \end{pmatrix}.$$

Now if we develop the determinant of this matrix by the last column we get

$$\det[(H - \lambda I)G_1 \cdots G_{n-1}] = \alpha b_1 \cdots b_{n-1},$$

where b_r is the rth subdiagonal element of $(H - \lambda I)G_1 \cdots G_{n-1}$:

$$\det[(H - \lambda I)G_1 \cdots G_{n-1}] = \det(H - \lambda I) = 0,$$

since $(\det(G_r) = 1)$ for $r = 1, \ldots, n-1$. But $b_r \neq 0$ for all r, since we have assumed that H had no zeros on the subdiagonal and since post-multiplication by a G_r can only increase the modulus of a subdiagonal element in $H - \lambda I$. Thus we must have $\alpha = 0$, and therefore, at the end of the $n-1$ steps just described, the last column is zero. Let us set $\mathcal{G} = G_1 \cdots G_{n-1}$ to simplify the notation. Then

$$\mathcal{G}^{-1} = \mathcal{G}^H = G_{n-1}^H \cdots G_1^H,$$

and it is straightforward to verify that the zeros of the last column of $(H - \lambda I)\mathcal{G}$ will be preserved when it is premultiplied by $\mathcal{G}^{-1}$, because the successive premultiplications by G_r^T, $r = 1, \ldots, n-1$, will preserve those zeros. Therefore, the last column of

$$\tilde{H} = \mathcal{G}^H(H - \lambda I)\mathcal{G} + \lambda I$$

is equal to λe_n. The eigenvector of $\tilde{H}$ corresponding to λ is e_n. Note, however, that $\tilde{H}$ is not upper-Hessenberg in this case. Indeed, nonzero elements will be introduced in the last row of $\tilde{H}$; in fact,

$$\tilde{H}=\begin{pmatrix} * & \cdots & & * & \\ * & & & & 0 \\ & \ddots & & \vdots & \\ & & * & * & \\ * & \cdots & & * & \lambda \end{pmatrix}.$$

This is not disturbing since if H' is the leading principal submatrix of $\tilde{H}$ of order $n-1$, then H' is upper-Hessenberg and $\sigma(H')=\sigma(H)-\{\lambda\}$.

If λ is a multiple eigenvalue of H of (algebraic) multiplicity m, then λ is an eigenvalue of H' of multiplicity $m-1$.

So far we have assumed that the eigenpair (x, λ) is exact. In practice, (x, λ) will only be approximate, in the sense that $Hx-\lambda x=r$ is of the order of the machine ε. In this case, roundoff errors will generally prevent G_{n-1} from annihilating the $(1, n)$ entry. In fact, the accuracy of the computed eigenvalue λ will come into play. If λ corresponds to an ill-conditioned eigenvalue of H, then it is possible that λ will be a rather poor approximation of the exact eigenvalue. As a consequence, the $(1, n)$ entry might not be negligible at all, and examples do exist where this is indeed the case [19]. A way around this difficulty is to construct the plane rotations $G_1, \ldots, G_{n-1}$ in a way to reduce the vector x to e_n and then apply the corresponding similarity transformation to H. Inequality (10) from § 3.1 holds when this is done (with obvious modification in the definition of H'). However, this will generally result in introducing nonzero entries below the subdiagonal of H and therefore H needs to be reduced to upper-Hessenberg form again. We refer the reader to [3] for an example of such an algorithm; the generalization of that algorithm to the case where the eigenvalue to be deflated is complex is straightforward.

In addition to the difficulty just mentioned, the deflation with plane rotations suffers from the fact that the deflated matrix will be complex if the eigenvalue to be deflated is complex. Indeed, it is unfortunately not true that when an eigenvalue and its complex conjugate are deflated by this method, the resulting matrix is real.

Example 3.1. When the two complex eigenvalues of the 4×4 upper-Hessenberg matrix

$$\begin{pmatrix} 0.2190 & -0.0756 & 0.6787 & -0.6391 \\ -0.9615 & 0.9032 & -0.4571 & 0.8804 \\ 0 & -0.3822 & 0.4526 & -0.0641 \\ 0 & 0 & -0.1069 & -0.0252 \end{pmatrix}$$

are deflated using plane rotations as just described, we obtain

$$\begin{pmatrix} 1.1593-0.0000i & 0.0000+1.0129i & 0.0000+0.0000i & 0.0000+0.0000i \\ 0.0000-0.3053i & 0.1740-0.0000i & 0.0000+0.0000i & 0.0000+0.0000i \\ -0.1534-0.3540i & 0.5717+0.0112i & 0.1082-0.4681i & 0.0000+0.0000i \\ -0.4640+0.1988i & 0.2187-0.3465i & 0.3964+0.0611i & 0.1082+0.4681i \end{pmatrix}.$$

After the deflation, we will be working with the upper 2×2 block of H' which is clearly complex.

3.4. Remarks on identifying duplicate eigenvalues. We have already remarked that the computed eigenpairs from our algorithm are the exact eigenpairs of a nearby matrix. Under those conditions [9],

$$|\lambda-\lambda_e| \leqq \|E\|/|s(\lambda_e)|,$$

where E is the error in the matrix, and $|s(\lambda_e)|$ is the condition number of the exact eigenvalue λ_e of the original matrix H. When λ_e is ill conditioned, we can expect unpredictably large errors (compared to the tolerated size of the residual) in the computed approximations to λ_e and therefore in the duplicates, if any. Identifying these duplicates becomes a rather daunting task: in particular, they will not be detected if their difference is compared to tol introduced earlier. Conversely, it can happen that under certain conditions the tolerated size of the residual will be much larger than the distance between certain exact eigenvalues and therefore between certain computed eigenvalues. In this case, it could happen that distinct computed eigenvalues will be declared as duplicates if their difference is compared to tol.

Example 3.2. We illustrate this last case with the following matrix:

$$H=\begin{pmatrix} 2\times 10^{-7} & 0 & 0 \\ 2 & 10^{-7} & 0 \\ 0 & 2 & 10^{10} \end{pmatrix}.$$

The tolerated size of the residuals for this matrix as chosen in our algorithm is $\text{tol} \approx \|H\|\varepsilon > 10^{-6}$. Therefore, if we decide to declare as duplicates those eigenvalues whose difference is less than tol, then the first two distinct eigenvalues of H will be declared as duplicates.

The problems we have just raised do not have easy solutions [10], and indeed, more research is needed here.

3.5. Conclusion regarding deflation techniques. As we pointed out earlier, the need to deflate arises less than 5 percent of the time in our tests. Our method of choice has been the method of deflation using elementary transformations introduced in § 3.1. This method is indeed the least expensive among all those we have discussed. Also, the resulting deflated matrix is in upper-Hessenberg form and is real when a pair of complex conjugate eigenvalues has been deflated.

4. Defective case. Our being a nonstationary iteration (the iterating map is not fixed), it is not easy to analyze the behavior of the successive approximations. We try, however, to address this problem in this section with a particular emphasis on the case when either the matrix H or the modified matrix H_0 is defective, i.e., when either one of these matrices does not have a complete set of eigenvectors. As we remarked earlier, an eigenvalue of H (with no zeros on the subdiagonal) can only have geometric multiplicity one, and there H is defective whenever it has a multiple eigenvalue. An eigenvalue of H_0, on the other hand, can have geometric multiplicity one or two. In what follows, n is the order of H.

The connection between Newton's method and inverse iteration is well known [16]. We derive this relationship in a way that motivates the subsequent analysis: We let J be the Jacobian of the map F_s at (x, λ) defined in § 2,

$$J=\begin{pmatrix} H-\lambda I & -x \\ e_s^T & 0 \end{pmatrix},$$

and we assume that $x_s=1$. The order of the Jacobian is $n+1$. Then

$$J=J_0+e_{n+1}v^T$$

with

$$J_0 = \begin{pmatrix} H-\lambda I & -x \\ 0 & 1 \end{pmatrix}$$

and

$$v = e_s - e_{n+1} = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 1 \\ 0 \\ \vdots \\ -1 \end{pmatrix}.$$

Assume that J_0 is not singular; this is true if and only if λ is not an eigenvalue. Assume also that J is not singular. The correction to (x, λ) is computed in the following manner:

$$\begin{pmatrix} y \\ \mu \end{pmatrix} = J^{-1} \begin{pmatrix} r \\ 0 \end{pmatrix},$$

where $r = \lambda x - Hx$. Using the Sherman-Morrison formula [9], we can write J^{-1} as

$$J^{-1} = (J_0 + e_{n+1} v^T)^{-1} = J_0^{-1} - \frac{1}{1+v^T J_0^{-1} e_{n+1}} J_0^{-1} e_{n+1} v^T J_0^{-1}.$$

Therefore, letting $b(\begin{smallmatrix} r \\ 0 \end{smallmatrix})$, we have,

$$\begin{pmatrix} y \\ \mu \end{pmatrix} = J^{-1} b = J_0^{-1} b - \frac{v^T J_0^{-1} b}{1+v^T J_0^{-1} e_{n+1}} J_0^{-1} e_{n+1}. \tag{11}$$

It can be easily checked that

$$J_0^{-1} b = \begin{pmatrix} -x \\ 0 \end{pmatrix}$$

and that

$$J_0^{-1} e_{n+1} = \begin{pmatrix} \tilde{x} \\ 1 \end{pmatrix},$$

where $(H - \lambda I)\tilde{x} = x$. Now, if we let (x_1, λ_1) be the next eigenpair, we have from (11) and the subsequent equalities:

$$\begin{pmatrix} x_1 \\ \lambda_1 \end{pmatrix} = \begin{pmatrix} x \\ \lambda \end{pmatrix} + \begin{pmatrix} y \\ \mu \end{pmatrix} = \begin{pmatrix} x \\ \lambda \end{pmatrix} + \begin{pmatrix} -x \\ 0 \end{pmatrix} - \frac{v^T J_0^{-1} b}{1+v^T J_0^{-1} e_{n+1}} \begin{pmatrix} \tilde{x} \\ 1 \end{pmatrix}.$$

Furthermore,

$$\frac{v^T J_0^{-1} b}{1+v^T J_0^{-1} e_{n+1}} = \frac{-1}{\tilde{x}_s},$$

and so finally we see that our scheme reduces to the following: Given (x, λ), compute the next iterate (x_1, λ_1) via

$$(H - \lambda I)\tilde{x} = x, \quad x_1 = \frac{1}{\tilde{x}_s} \tilde{x}, \quad \lambda_1 = \lambda + \frac{1}{\tilde{x}_s}. \tag{12}$$

4.1. Case when H is defective. When the algorithm is expressed as in (12), we can readily see some of the difficulties that arise when the matrix H is defective or almost defective, which is generally more likely due to roundoff errors. These problems are similar to the kind of problems that we face with the application of inverse iteration. More precisely, assume that H is almost defective with $x_1, \dots, x_n$ as a complete set of eigenvectors. Let $\lambda_1, \dots, \lambda_l$ be a cluster of eigenvalues of H and suppose that the initial approximate eigenvalue λ corresponds to one of these. The eigenvectors $x_1, \dots, x_l$ corresponding to these eigenvalues are then almost linearly dependent. In general, the eigenvector corresponding to λ can be expected to converge to the space generated by $x_1, \dots, x_l$. As the eigenvalue λ approaches the cluster, however, continued corrections to the eigenvector cannot be expected to refine it. We refer the reader to the particularly lucid account in [16] for a justification of these claims. Solving as in inverse iteration (see INVIT [17]) is a possible way around this problem. Computing the residual with extended precision arithmetic is also an obvious approach, and has been successful in practice.

When approaching a singular solution, Newton's method loses its quadratic convergence rate. We will prove later (Theorem 5.1) that the Jacobian is singular at multiple eigenpairs. Therefore, we can expect slower convergence when multiple eigenpairs or almost multiple eigenpairs are the target: this is indicated in Fig. 1 by the large number of iterates separating the initial guesses from the converged values for an almost-defective matrix.

Recall the rate of change of λ that we derived in § 2:

$$|\lambda'(0)| = \frac{|\alpha| \, |y_{k+1}| \, |x_k|}{|y^H x|}.$$

We wish to caution against hastily drawing conclusions about the sensitivity of the eigenvalues of a defective matrix to our dividing process from this expression. Indeed, as an extreme case which will help to illustrate our point, the eigenvalues of a defective

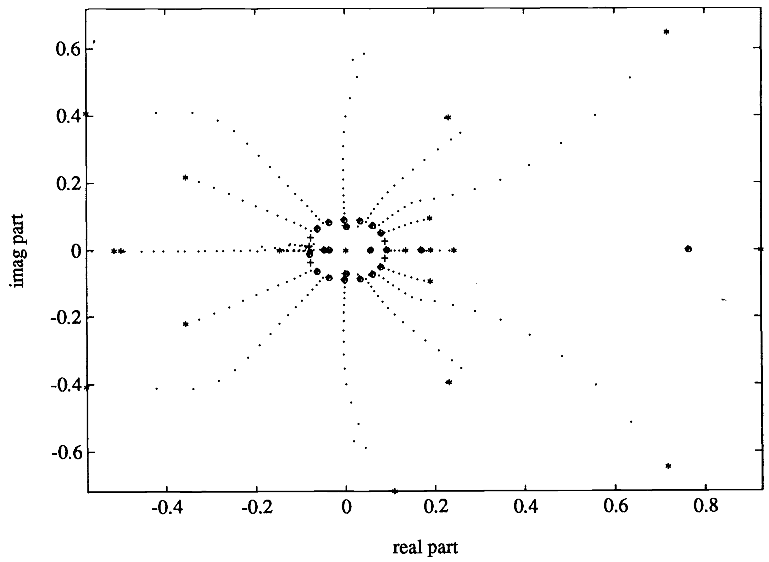

FIG. 1. *The behavior of the algorithm for an almost defective* 25×25 *matrix. The crosses are the eigenvalues of the original matrix; the stars are the initial guesses; the circles are the eigenvalues computed by our algorithm; the dots are the iterates arising in Newton's iterations.*

matrix can remain virtually unchanged after a zero has been introduced in the subdiagonal. An example is the 2×2 matrix

$$\begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}.$$

After the dividing process we have

$$\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

The starting eigenpairs are then $(\binom{1}{0}, 1)$ and $(\binom{0}{1}, 1)$. The second of these is, of course, the exact eigenpair. Now, even though the first starting eigenvector is orthogonal to the desired one, the equations arising during the first of Newton's iterations can be solved in such a way that the desired eigenvector is produced from the first step: zero pivots must be replaced by small numbers on the order of the machine unit roundoff (as is done in inverse iteration; see INVIT [17]).

Finally, we mention that the deflation process can contribute to the improvement of the condition of the eigenvalues. Indeed, if λ and λ' are pathologically close (and fairly distant from the rest of the eigenvalues), then by deflating λ, λ' will have a better condition number as an eigenvalue of the resulting matrix. Indeed, λ' is no longer part of a cluster.

4.2. Case when H_0 is defective. It can happen in this case (e.g., if H is nondefective) that the initial dividing process would leave us with a number of initial approximations that is smaller than n. In this case, random eigenvectors are used to complete the set of initial eigenvectors. Furthermore, whatever eigenpairs we have can be extremely poor approximations to the desired ones. An extreme situation is illustrated by the matrix

$$H = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}.$$

No matter where the zero is introduced on the subdiagonal, the resulting matrix has zero as its only eigenvalue, and we only have two initial approximations to the four distinct eigenpairs of H, namely,

$$\left(\begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}, 0\right), \quad \left(\begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}, 0\right),$$

if the zero is introduced in the $(3, 2)$ position.

Furthermore, the Jacobian is exactly singular at each of these initial approximations. Indeed, the Jacobian at

$$\left(\begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}, 0\right)$$

is

$$\begin{pmatrix} 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & -1 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \end{pmatrix},$$

which is clearly of rank four, since the first and the last columns are linearly dependent. Similarly, it can be seen that the Jacobian at

$$\left(\begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}, 0 \right)$$

is also singular. A remedy to this situation is to perturb the initial guess zero by a small amount, thereby making the Jacobian nonsingular. Indeed, this has been successful in practice. The problem in this case, as in most other similar cases, results from the particular structure of the matrix. In order to obtain further eigenvalues, we need to deflate the matrix each time a new eigenpair is computed which makes the algorithm almost serial.

4.3. Known failures. Some matrices of the structure mentioned at the end of § 4.2 (companion-like matrices), provided us with the only cases where the algorithm failed in practice to converge to the desired eigenpairs, i.e., failed to produce eigenpairs with small residuals after a fixed number of iterations. When these matrices were subjected to random orthogonal similarity transformations, however, and then reduced back to upper-Hessenberg form, the dividing process provided us with much better initial approximations and, indeed, the algorithm converged for all initial approximations. We are certainly not advocating this as a general viable scheme: we want to emphasize the fact that it is the structure of the matrix that caused the poor approximations and the failures, and not some inherent difficulty with the spectrum of these matrices.

5. Convergence. In § 2, we mentioned that computing an eigenpair of H reduces to computing a zero of

$$F_s(x, \lambda) = \begin{pmatrix} Hx - \lambda x \\ e_s^T x - 1 \end{pmatrix}.$$

The Jacobian of F_s at (x, λ) is

$$D_{(x,\lambda)}F_s(x, \lambda) = \begin{pmatrix} D_x(Hx - \lambda x) & D_\lambda(Hx - \lambda x) \\ D_x(e_s^T - 1) & D_\lambda(e_s^T - 1) \end{pmatrix} = \begin{pmatrix} H - \lambda I & -x \\ e_s^T & 0 \end{pmatrix},$$

where $D_x(F)$ denotes the derivative with respect to x of the function F. In this section, we give sufficient conditions for the convergence of our procedure. The result is a version of the Kantorovich theorem as it applies to our case.

THEOREM 5.1 (Wilkinson). *Assume that* (x, λ) *is an exact zero of* F_s. *Then*

$$\begin{pmatrix} H - \lambda I & -x \\ e_s^T & 0 \end{pmatrix}$$

is singular if and only if λ *is multiple.*

Proof. Let us assume first that λ is a multiple eigenvalue of H and that x is the corresponding (exact) eigenvector. Then there exists a nonzero vector y such that

$$y^H(H-\lambda I)=0 \quad \text{and} \quad y^H x=0;$$

y is simply a left eigenvector of H corresponding to λ. Thus $(y^H 0)$ is a nonzero vector and

$$(y^H 0)\begin{pmatrix} H-\lambda I & -x \\ e_s^T & 0 \end{pmatrix}=0.$$

This proves that the Jacobian is singular.

Now, conversely, if

$$\begin{pmatrix} H-\lambda I & -x \\ e_s^T & 0 \end{pmatrix}$$

is singular then there exists a nonzero vector $\binom{v}{\mu}$ such that

$$\begin{pmatrix} H-\lambda I & -x \\ e_s^T & 0 \end{pmatrix}\begin{pmatrix} v \\ \mu \end{pmatrix}=0.$$

But then $v_s=0$ and $(H-\lambda I)v=\mu x$. If $\mu=0$, then v is nonzero since $\binom{v}{\mu}\neq 0$, and so v is an eigenvector that is linearly independent of x, since $x_s=1$ and $v_s=0$. Hence λ is a multiple eigenvalue in this case. If $\mu\neq 0$, then v is also nonzero; if it were zero then we would have

$$\mu x=(H-\lambda I)v=(H-\lambda I)0=0,$$

and hence $x=0$, contradicting our assumption on x. But $(H-\lambda I)^2 v=\mu(H-\lambda I)x=0$, and thus v is a nonzero vector that has grade 2. Therefore, λ is multiple in this case as well. $\square$

Remark. Since we are assuming that H is upper-Hessenberg and unreduced, an eigenvalue can only be nonderogatory, i.e., the associated eigenspace has dimension one.

The previous result applies to the Jacobian at a zero of F_s. We wish to know more about the Jacobian at those approximations arising during Newton's iteration before convergence to an eigenpair.

THEOREM 5.2. *Assume that* (x, λ) *is not a zero of* F_s. *Then*

$$\begin{pmatrix} H-\lambda I & -x \\ e_s^T & 0 \end{pmatrix}$$

is singular if and only if at least one of the following is true:

(1) λ *is an eigenvalue of* H *and has an eigenvector whose sth component is zero.*

(2) x *belongs to the space generated by* $(c_1, \dots, c_{s-1}, c_{s+1}, \dots, c_n)$, *where* c_i *is the ith column of* $H-\lambda I$ (λ *may or may not be an eigenvalue*).

Proof. Assume first that (1) is true and let y be an eigenvector, $y_s=0$. Then $\binom{y}{0}$ is clearly in the null space of the Jacobian. If (2) holds and $x=(H-\lambda I)y$ with $y_s=0$, then $\binom{y}{1}$ is in the null space of the Jacobian.

Conversely, if the Jacobian is singular then there exists a vector $\binom{y}{\mu}$ such that,

$$\begin{pmatrix} H-\lambda I & -x \\ e_s^T & 0 \end{pmatrix}\begin{pmatrix} y \\ \mu \end{pmatrix}=0.$$

This implies that

$$(H-\lambda I)y=\mu x, \qquad e_s^T y=0,$$

and clearly $y_s=0$. We now consider two cases according to whether μ is zero or not. If μ is zero, then λ is an eigenvalue with corresponding eigenvector y; therefore, we are in case (1). If μ is not zero, then μx and hence x is in the range of $H-\lambda I$; therefore we are in case (2) since $y_s=0$. Note that λ may or may not be an eigenvalue in this last case. □

Remarks. The theorem tells us that more often than not, a singular Jacobian is an indication that the current eigenvalue has already converged, and this has been our experience indeed. The singularity of the Jacobian is also an indication of an ill-conditioned eigensystem. In fact, if we accept that the current eigenvector was moving in the "right" direction, then if it satisfies condition (2) of Theorem 5.2, we can say that the eigenvalue is acting like a multiple one since the eigenvector is also in the range of $(H-\lambda I)$. In practice, we have not encountered a situation where condition (1) applied. If we accept again that the eigenvector was moving in the right direction, then condition (1) implies that the eigenvalue is acting like an eigenvalue of geometric multiplicity more than one (since $x_s=1$), which is impossible since the matrix is unreduced.

The second derivative of F_s is a constant bilinear operator with norm equal to 2. In fact,

$$F_s''(x,\lambda)=\left(\begin{array}{cc|cc} 0 & -I & -I & 0 \\ 0 & 0 & 0 & 0 \end{array}\right).$$

Suppose now that our procedure is started with initial guess (x_0, λ_0). We now give sufficient conditions for the convergence of our procedure with the given initial guess. Let us first introduce

$$K=\|F_s'^{-1}(x_0,\lambda_0)\|$$

and

$$c_1=\|(x_1,\lambda_1)-(x_0,\lambda_0)\|,$$

where (x_1,λ_1) is the first iterate, i.e.,

$$(x_1,\lambda_1)^T=(x_0,\lambda_0)^T-F_s'^{-1}(x_0,\lambda_0)F_s(x_0,\lambda_0).$$

We call $(x_0,\lambda_0),\dots,(x_k,\lambda_k)$ the sequence of iterates produced by the algorithm. Now the classical Kantorovich theorem [6] gives the following result.

THEOREM 5.3. *If* $\beta_0=Kc_1<\frac{1}{4}$, *then the sequence* (x_k,λ_k) *converges quadratically starting from* (x_0,λ_0).

The process can be regarded as starting from any of the iterates (x_i,λ_i), and in fact it will often converge even when the conditions of the theorem are not satisfied at (x_0,λ_0). These conditions will then be met for some (x_k,λ_k) at which stage convergence becomes quadratic.

6. Parallel algorithms: Details and performance.

It is fairly straightforward to see from § 2 how to obtain a parallel algorithm. We discuss here certain details. The given, generally dense, matrix is first reduced to upper-Hessenberg form using a parallel blocked algorithm. Next comes the partitioning phase or "divide." This phase amounts to constructing a binary tree with each node representing a partition into two subproblems. It has been our practice to partition the matrix into a number of subproblems (at the lowest level) equal to the number of processors available on the target machine. Each of these problems may be spawned independently without fear of data conflicts; the computation at this level (the lowest) consists of calls to the EISPACK routine HQR2. The tree is then traversed in reverse order with Newton's method applied at each node, using the results from the children as initial approximations. Note here that the computation at a node does not have to wait for both children to complete in order to start: as a matter of fact, it can start as soon as one child has computed one eigenpair of a subproblem. In order to stress this point, we mention here that this is quite different from the situation in the symmetric case [7], where information from both children is needed before computations can start at the node. However, in practice, we have allowed computations to start at a node only after at least one child has completed; the need to check for duplicate eigenvalues and deflate if necessary has imposed further synchronization.

The algorithm has been implemented on computers with a shared memory and computers with distributed memory architectures.

6.1. Shared memory implementation. So far we have used SCHEDULE [8] to implement the algorithm on shared memory computers. SCHEDULE is a package of FORTRAN and C subroutines designed to aid in programming explicitly parallel algorithms for numerical calculations. An important part of this package is the provision of a mechanism for dynamically spawning processes even when such a capability is not present within the parallel language extensions provided for a given machine.

6.2. Distributed memory implementation. The current implementation on distributed memory machines requires that the matrix be stored on each processor. This obviously puts rather severe constraints on the size of problems that can be solved. With this implementation however, communication is needed only during the deflation phase. This implementation is best described through the contribution of a particular processor. Suppose that we have four processors at our disposal, $p_0, \ldots, p_3$, and that accordingly the matrix H has been divided into four subproblems, $H_0, \ldots, H_3$, that their common size is $n/4$, and that they occur in this order on the diagonal of the matrix. We describe now the contribution of p_2 by steps:

1. Call HQR2 to solve for the eigensystem of the matrix H_2.

2. Refine the output from step 1 to get $\frac{1}{2}$ the number of (i.e., $n/4$) eigenpairs of the matrix $H_{1/2}$

$$H_{1/2} = \left(\begin{array}{c|c} H_2 & B \\ \hline 0 \quad \alpha & H_3 \end{array}\right),$$

where $H_{1/2}$ is a submatrix of H.

3. Refine the output from step 2 to get $\frac{1}{4}$ the number of eigenpairs (i.e., $n/4$) of the matrix H.

As can be readily realized, no communication between processors is needed except for checking for eigenpairs to which convergence occurred from more than one initial approximation. For example, the eigenpairs of $H_{1/2}$ are generated on p_2 and p_3, and therefore we need to check for duplicate eigenpairs (on each processor separately, which requires no communication, and across both, which requires communication).

We are currently developing another implementation where blocks of columns of the matrix are stored on different processors. This storage scheme has been dictated to us by the need to call HQR2 at the lowest level. Indeed, to call the serial HQR2 requires that contiguous columns of the matrix reside on the same processor. Therefore, storage schemes more advantageous for linear system solving, such as wrap mapping of columns or rows, could not be used. The communication between processors for this second implementation is more intensive. Communication is needed when solving the linear systems arising in Newton's iterations as well as for the deflation phase. Also because of the storage scheme, we can expect the processors to become successively idle during the factorization of the Jacobian and the back solve for the correction. However, we have implemented an efficient scheme where the Jacobian is repartitioned by rows before the back solve takes place: the "reshuffling" of the submatrices takes place between processors that became idle after doing their part of the Gaussian elimination.

7. Work estimates. We assume in this section that we are given a real dense matrix A. Then, the first task in our algorithm is to reduce A to an upper-Hessenberg matrix H. This requires $10n^3/3$ operations (plus lower-order terms) if elementary transformations are used, since these matrices are to be accumulated.

The dividing process is now applied to H. Assume that $n=2^m r$ for some $m \geqq 1$, where r is not necessarily relatively prime to 2. In order to simplify the subsequent analysis we will assume that the dividing process produces submatrices of equal size, namely half the order of the original matrix. If we repeat the dividing process m times, we end up with 2^m matrices of size r, each of which is upper-Hessenberg. A submatrix of size $n/2^i$ obtained in the dividing process will be referred to as a matrix at the level i. The matrix H itself is at the level 0, and the r matrices referred to above are at the level m. Thus we have $m+1$ levels in total. Let $p'=2^m$ be the number of submatrices at the lowest level, and p the number of processors; we will assume that $p=2^q$, $q \leqq m$. The cost of finding the eigenpairs of a (Hessenberg) matrix at the lowest level (by the QR algorithm) is roughly 18 $(n/p')^3$. This figure is very approximate and assumes, among other things, that two QR steps are needed before a real or two complex conjugate eigenvalues are identified, and that the matrix has an equal number of real and complex eigenvalues [9]. Let $s_l=n/2^l$ be the size of one matrix at the level l. Let k_l be the average number of iterations needed to get one eigenpair of a matrix at the level l. k_l depends on the matrix and on its size, of course. We will make the following simplifying assumption, however: $k_l=k$, $l=0,\ldots,m$, i.e., we assume that the average number of steps required for convergence is the same at all levels. Our experience with the algorithm suggests that this is a realistic assumption as long as the size of the submatrices remains moderate. If the number of levels is increased to the point where we are left with small submatrices (less than 20×20, say), then k_l becomes significantly larger as l increases (for very small matrices it can be more than 10 on the average).

The cost of computing one correction at the level l is roughly $6s_l^2$. Indeed, one Newton iteration involves the solution of a linear system that is upper-Hessenberg, but for possible nonzeros in the last row, the order of this linear system is s_l+1. Therefore, two multipliers at most must be computed per column and, when updating the matrix, each of these will be used in $2(s_l+1-i)$ multiplications and additions, where i is the index of the column. The factorization of the Jacobian requires $2s_l^2$ operations in addition to $O(s_l)$ operations (including divisions and comparisons). The forward solve is $O(s_l)$ work and is negligible. The backsolve requires s_l^2 operations and computing the residual requires another s_l^2 operations. Therefore, for a real current approximation, one correction comes at the cost of $4s_l^2$. For a complex current eigenpair, this becomes $16s_l^2$ since the dominant operations are a roughly equal number of multiplications and additions. Since, as we indicated in § 2, only one of a conjugate pair of complex eigenpairs must be corrected, we can assume that $8s_l^2$ operations are required for correcting a complex eigenpair. Assuming again that the matrix has an equal number of real and complex eigenvalues, our estimate for the amount of work required for computing one correction at the level l becomes $6s_l^2$ operations.

We shall use n/p initial guesses to start n/p Newton processes on each processor. We now have the following work estimate on one processor, assuming that all processors share equally the cost of all the stages of the algorithm

$$W_p=\frac{10n^3}{3p}+18\left(\frac{p'}{p}\right)\left(\frac{n}{p'}\right)^3+\sum_{l=0}^{m-1}6\left(\frac{n}{p}\right)ks_l^2+2\frac{n^3}{p},$$

where $10n^3/3p$ is the processor's contribution to the reduction of the original matrix to upper-Hessenberg form; $18\ (p'/p)(n/p')^3$ is the cost of applying the QR algorithm to p'/p matrices of size n/p'; $\sum_{l=0}^{m-1} 6(n/p)ks_l^2$ is the cost of solving k linear systems with matrices of size s_l, repeating this for n/p initial guesses and for $l = 0, \ldots, m-1$; $2n^3/p$ is the processor's contribution to the computation of the eigenvectors of the original dense matrix A once those of H have been computed. The expression for the work can be rewritten as

$$W_p = \frac{n^3}{p}\left(\frac{16}{3} + \frac{18}{p'^2} + \frac{24k}{3}\left(1 - \left(\frac{1}{4}\right)^m\right)\right).$$

But $p' = 2^m$ and therefore $p'^2 = 4^m$, and hence

$$W_p = \frac{n^3}{p}\left(\frac{16}{3} + 8k + (18 - 8k)\frac{1}{4^m}\right), \tag{13}$$

where for ease of reference we redefine the various parameters: n is the order of the matrix, p is the number of processors, k is the average number of Newton iterations needed before an eigenpair is accepted, and m is the number of zeros introduced on the subdiagonal.

The cost of getting the eigenvalues and eigenvectors by the QR algorithm is $15n^3$ [9]. A reasonable value for k is 3; however, there are cases when k is 2 or less. There are also cases where k is larger than 3, mostly with matrices of small order or defective matrices.

It is easy to verify that for $k = 2$ and for $m = 1$ (one split) the model for the cost of the algorithm predicts that a sequential implementation of our algorithm is faster than EISPACK's Real General (RG). Our model predicts that a sequential implementation of our algorithm is slower than RG for problems where k equals or exceeds 2 (see Fig. 2). Here are some sample values of W_p, assuming that $k = 3$ and $p = p' = 2^m$, which means that the original problem is subdivided into a number of problems equal to the number of available processors.

$$p = 128 \rightarrow W_p = 0.2291n^3; \qquad p = 1024 \rightarrow W_p = 0.0286n^3.$$

Here we have assumed that the problem is large enough to allow the efficient use of that many processors. Note that the ratio of the work estimate from our model to the

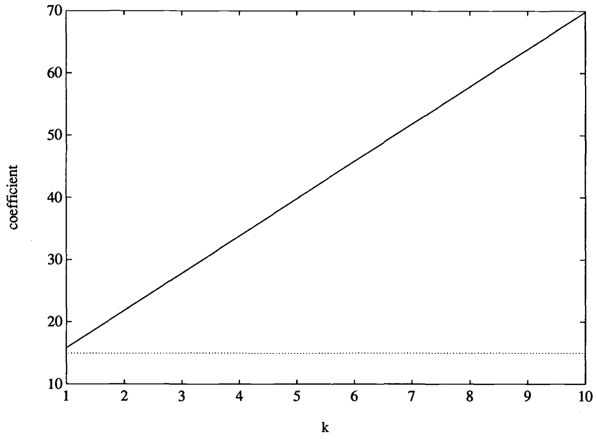

FIG. 2. *Variation of the coefficient of n^3 in work estimate model in terms of the number of steps k, with $m = 1$ and $p = 1$ (see expression for work).*

work estimate of QR is independent of n. This is due to the simplifying assumption on k made at the beginning of this section. That assumption has in effect "hidden" the dependency on n of the coefficient of n^3 in our model. Figures 2, 3, 4, and 5 show plots of the work estimate for various values of the parameters involved.

We note, finally, that the cost of our algorithm will increase when the matrix or the subproblems obtained in the divide process are ill conditioned (see § 4 and [12]). Furthermore, repeated deflations will also contribute to an increase in the cost.

8. Numerical results and performance. In this section we present the results of the implementation of the algorithm on a number of machines. The serial version of the code is available through NETLIB where it is called "nonsymdc."

The same algorithm has been run on the IBM RS/6000-550, the Alliant FX/8, the Intel iPSC/2, and the Intel iPSC/860. We compared our results to those of HQR2 from the EISPACK collection. We have used randomly generated upper-Hessenberg matrices in these tests, with entries uniformly distributed between -1 and 1; deflation

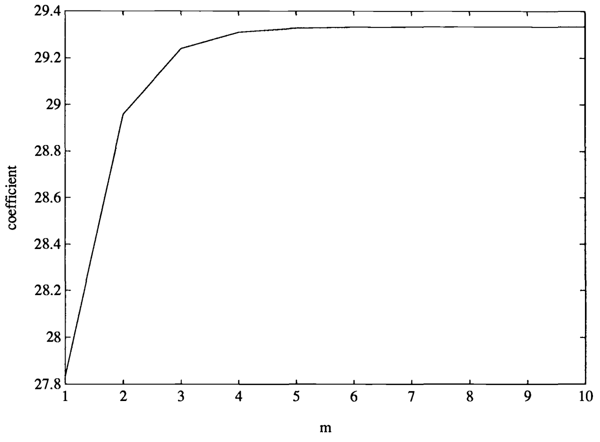

FIG. 3. *Variation of the coefficient of n^3 in work estimate model in terms of the number of splits m, with $k = 3$ and $p = 1$ (see expression for work).*

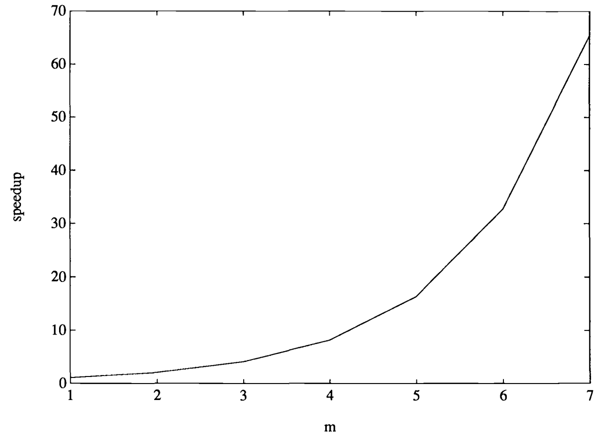

FIG. 4. *Predicted speedup over QR in terms of number of splits m, with $p = 2^m$ and $k = 3$ (see expression for work).*

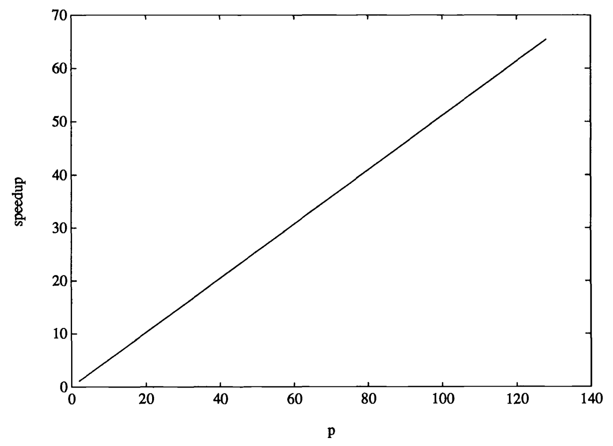

FIG. 5. *Predicted speedup over* QR *in terms of the number of processors* p, *with* $m=\log_2 p$ *and* $k=3$ (*see expression for work*).

was not performed. The storage requirement for our algorithm in a serial implementation is $4n^2+O(n)$, which is twice the storage requirement for a serial implementation of HQR [17].

Table 1 provides the results from the IBM RS/6000-550 implementation. The IBM RS/6000-550 is a single-processor computer with a RISC-based architecture. In the last column we have given the number of distinct eigenvalues that was computed by our algorithm (the test matrices had no multiple eigenvalues); some eigenvalues were found multiple times. Each matrix was divided into two subproblems, i.e., only one zero was introduced on the subdiagonal.

In an implementation on a shared memory machine, the storage allocated to the Jacobian (in serial mode) is multiplied by the number of processors used; this is meant to prevent concurrent write to the same memory locations. Table 2 provides some results from the Alliant FX/8 implementation. The Alliant FX/8 is a parallel machine with eight vector processors.

TABLE 1

The results on the Alliant were generally disappointing. The storage scheme for the Jacobian that we used on that machine seems to have inhibited the compiler's vector optimizations. HQR2, running on a single processor, *was* vector optimized.

Table 3 provides some results from the Intel iPSC/2 implementation. The largest size used was dictated by the memory capacity of a single node.

Table 4 provides some results from the Intel iPSC/860 implementation. We observe here that the speedups realized by our algorithm over the QR algorithm do not remain linear for a large number of processors. This is due to the fact that our algorithm is much less efficient on small matrices, and we had to work with small matrices when the number of processors became large. For example, with a matrix of order 600 and using 64 processors, matrices of average size 20 had to be solved on each node at level 5.

9. The generalized eigenvalue problem. We show here how the ideas behind our algorithm can be used to solve the generalized eigenvalue problem.

9.1. Basic algorithm. Given an upper-Hessenberg matrix H and an upper-triangular matrix U,

$$H = \left(\begin{array}{c|c} H_{11} & H_{12} \\ \hline 0^{\alpha} & H_{22} \end{array}\right), \qquad U = \left(\begin{array}{c|c} U_{11} & U_{12} \\ \hline 0 & U_{22} \end{array}\right),$$

we want to solve the generalized eigenvalue problem

$$Hx = \lambda Ux. \tag{14}$$

Without loss of generality, we can assume H to be unreduced and U to be nonsingular since otherwise the problem reduces to a smaller problem. Then our algorithm generalizes easily. Indeed, set

$$H_0 = H - \alpha e_{k+1} e_k^T,$$

and consider solutions of (or approximations of)

$$H_0 x = \lambda Ux, \tag{15}$$

as initial approximations to the sought eigenpairs. More precisely, solving (15) reduces to solving

$$H_{11} x = \lambda U_{11} x \quad \text{and} \quad H_{22} x = \lambda U_{22} x.$$

Let us denote these solutions by $(\tilde{x}_1, \lambda_1), \dots, (\tilde{x}_n, \lambda_n)$ (we have n solutions because of our assumption that U is nonsingular). These can be used to construct initial approximations $(x_1, \lambda_1), \dots, (x_n, \lambda_n)$ to the eigenpairs of the original generalized eigenproblem in much the same way we did in the case $U = I$. More precisely, we take

$$(x_i, \lambda_i) = \left(\begin{pmatrix} \tilde{x}_i \\ 0 \end{pmatrix}, \lambda_i \right)$$

if $\lambda_i \in \sigma(H_{11}, U_{11})$, and

$$(x_i, \lambda_i) = \left(\begin{pmatrix} 0 \\ \tilde{x}_i \end{pmatrix}, \lambda_i \right)$$

if $\lambda_i \in \sigma(H_{22}, U_{22})$ (appropriate number of zeros in each case).

Finally, solving the generalized eigenvalue problem (14) above is the same as solving the problem

$$Hx - \lambda Ux = 0, \quad L(x) = 1,$$

where $L(x)$ is a scalar equation, which we take to be a normalizing condition: $e_s^T x = 1$. Then for each initial eigenpair (x_i, λ_i), successive corrections can be computed via

$$\begin{pmatrix} H - \lambda_i U & -Ux_i \\ e_s^T & 0 \end{pmatrix} \begin{pmatrix} y \\ \mu \end{pmatrix} = \begin{pmatrix} r_i \\ 0 \end{pmatrix}, \quad \lambda_i \leftarrow \lambda_i + \mu; \quad x_i \leftarrow x_i + y,$$

where

$$r_i = \lambda_i U x_i - H x_i.$$

A possible stopping criterion for this scheme is the condition

$$\frac{\|Hx_i - \lambda_i U x_i\|}{\|x_i\|} \leqq f(n) \|H\| \, \|U\| \varepsilon,$$

where $f(n)$ is a modest function of n. It is easy to see that starting from two complex conjugate initial guesses the algorithm will compute complex conjugate corrections, therefore allowing savings similar to those in the case $U = I$.

9.2. Deflation in the generalized case. The method of deflation presented in § 3.1 generalizes to this case in the following manner. Let $Hx = \lambda Ux$ (of course, in practice, we only have an approximate eigenpair). Then it is true that if $w = Ux$ then $w_n \neq 0$. Indeed, if $w_n = 0$, then it can be shown that w is zero using the fact that H is unreduced. U being nonsingular implies that x is zero, which is not true.

Let

$$\begin{pmatrix} -v \\ 1 \end{pmatrix} = w/w_n$$

and

$$u = \begin{pmatrix} v \\ 1 \end{pmatrix}.$$

We know that $\sigma(H, U)$ is the same as $\sigma(NHM, NUM)$ for any nonsingular M and N. For our purposes, we take

$$M = [e_1, \dots, e_{n-1}, x]$$

and

$$N = [e_1, \dots, e_{n-1}, u].$$

Then it is easy to verify that we have

$$NHM = \left(\begin{array}{c|c} H' & 0 \\ \hline 0 \quad \alpha & \gamma \end{array}\right), \qquad NUM = \left(\begin{array}{c|c} U' & 0 \\ \hline 0 & \delta \end{array}\right), \tag{16}$$

where H' is upper-Hessenberg, U' is upper-triangular, and

$$\gamma/\delta = \lambda. \tag{17}$$

In fact, in this particular case we have $\gamma = \lambda$ and $\delta = 1$. Clearly,

$$\sigma(H', U') = \sigma(H, U) - \{\lambda\}.$$

Therefore, having "removed" λ from the spectrum we can get further eigenpairs. We note that, just as in the case $U = I$, H' and U' are very cheap to obtain once N has been determined. Indeed, H' differs from the $n-1 \times n-1$ principal submatrix of H in the last column only, whereas U' is the $n-1 \times n-1$ principal submatrix of U. The computation of N requires a matrix-vector multiply.

It is also easy to verify that deflating two consecutive complex conjugate eigenpairs results in real H' and U'.

The condition number of N might raise concern. We have

$$\text{cond}_\infty(N) \approx \max(|w_i|)^2.$$

It is therefore easy to detect an ill-conditioned N. We propose to handle this situation in the generalized case in the following manner. Let D be a diagonal matrix with its diagonal elements d_i defined by

$$d_i = 1, \qquad \text{if } \frac{|w_i|}{|w_n|} \leq 1,$$

$$d_i = -\frac{w_n}{w_i} \quad \text{if } \frac{|w_i|}{|w_n|} > 1.$$

Then, clearly,

$$\sigma(DNHM, DNUM) = \sigma(H, U),$$

since D is nonsingular. The multiplication by D cancels all the large entries in the last column of N. It is easy to see that (16) and (17) are satisfied when the premultiplication is done with DN instead of N. The disadvantage of having to premultiply by D is that after the deflation of two complex conjugate eigenpairs, the resulting H' and U' might still be complex.

ON ROW RELAXATION METHODS FOR LARGE CONSTRAINED LEAST SQUARES PROBLEMS*

ACHIYA DAX†

Abstract. This paper addresses the question of how to construct a row relaxation method for solving large unstructured linear least squares problems, with or without linear constraints. The proposed approach combines the Herman-Lent-Hurwitz scheme for solving regularized least squares problems with the Lent-Censor-Hildreth method for solving linear constraints. However, numerical experiments show that the Herman-Lent-Hurwitz scheme has difficulty reaching a least squares solution. This difficulty is resolved by applying the Riley-Golub iterative improvement process.

Key words. row relaxation methods, large unstructured least squares problems, linear constraints, iterative improvement of regularized solutions

AMS(MOS) subject classification. 65K99

1. Introduction. This paper presents a row relaxation method for solving constrained least squares problems of the form

$$\begin{aligned} &\text{minimize} && \tfrac{1}{2}\|A\mathbf{x}-\mathbf{b}\|^2 \\ (1.1)\qquad &\text{subject to} && \mathbf{a}_i^T\mathbf{x} \geqq b_i \quad \text{for } i=m+1,\dots,s \\ &\text{and} && \mathbf{a}_i^T\mathbf{x} = b_i \quad \text{for } i=s+1,\dots,t, \end{aligned}$$

where $\|\ \|$ denotes the Euclidean norm. Here and henceforth, A is a real $m \times n$ matrix, $\mathbf{b}=(b_1,\dots,b_m)^T \in \mathbb{R}^m$, and $\mathbf{x}=(x_1,\dots,x_n)^T \in \mathbb{R}^n$ denotes the vector of unknowns. $\mathbf{a}_i$, $i=m+1,\dots,t$, are given vectors in $\mathbb{R}^m$, and b_i, $i=m+1,\dots,t$, are given real numbers. The rows of A are denoted by $\mathbf{a}_i^T$, $i=1,\dots,m$, and the $t \times n$ matrix whose rows are $\mathbf{a}_i^T$, $i=1,\dots,t$, is denoted by $\tilde{A}$.

The term *row relaxation method* refers to an iterative scheme whose basic iteration is composed of a sweep along the rows of $\tilde{A}$. This type of method is suitable for problems in which $\tilde{A}$ is large, sparse, and unstructured. In particular, it was proved to be a useful tool for handling large linear systems that arise in the field of image reconstruction from projections. In this field, it is possible to avoid storing $\tilde{A}$. Instead, the nonzero entries of the ith row are newly generated from the experimental data at each iteration. For this reason these methods are also called *row generation methods* or *row action methods* (see Censor [2]). Perhaps the most famous method of this kind is the method of Kaczmarz [11], which was rediscovered under the name ART (algebraic reconstruction technique) in the field of image reconstruction from projections (e.g., Gordon, Bender, and Herman [7] and Herman, Lent, and Rowland [8]). This scheme is aimed at solving a consistent linear system of the form

$$(1.2)\qquad A\mathbf{x}=\mathbf{b},$$

and its basic iteration is composed of m steps where the ith step, $i=1,\dots,m$, considers the ith equation. Let $\mathbf{x}$ denote the current estimate of the solution at the beginning of the ith step. Then the change in $\mathbf{x}$ during the ith step is

$$w\mathbf{a}_i(b_i-\mathbf{a}_i^T\mathbf{x})/\mathbf{a}_i^T\mathbf{a}_i,$$

* Received by the editors August 20, 1990; accepted for publication (in revised form) May 19, 1992.

† Hydrological Service, P.O. Box 6381, Jerusalem 91060, Israel.

where $0<w<2$ is a preassigned relaxation parameter. Note that when $w=1$, the current point is projected onto the hyperplane $\{\mathbf{u} \mid \mathbf{a}_i^T\mathbf{u}=b_i\}$. Another interpretation of this scheme lies in the following observations. The dual of the minimum norm problem

$$\text{(1.3)} \qquad \begin{aligned} &\text{minimize} && \tfrac{1}{2}\|\mathbf{x}\|^2 \\ &\text{subject to} && A\mathbf{x}=\mathbf{b}, \end{aligned}$$

has the form

$$\text{(1.4)} \qquad \text{maximize} \quad \mathbf{b}^T\mathbf{y}-\tfrac{1}{2}\|A^T\mathbf{y}\|^2,$$

and if $\mathbf{y}^*$ solves the dual, then $A^T\mathbf{y}^*$ solves the primal. It is also easy to verify that $\mathbf{y}^*$ solves the dual if and only if it solves the system

$$\text{(1.5)} \qquad AA^T\mathbf{y}=\mathbf{b}.$$

Maximizing the dual objective function by changing one variable at a time results in the Gauss-Seidel method for solving (1.5). Moreover, let the sequence $\{\mathbf{y}_k\}$ be generated by applying the successive overrelaxation (SOR) method to solve this system, and let the sequence $\{\mathbf{x}_k\}$ be obtained by applying Kaczmarz's method, using $\mathbf{x}_0=A^T\mathbf{y}_0$ as the starting point. Then the equality

$$\text{(1.6)} \qquad \mathbf{x}_k=A^T\mathbf{y}_k$$

holds for all k (e.g., Björck and Elfving [1]). The relationship between Kaczmarz's method and the SOR method ensures that the sequence $\{\mathbf{x}_k\}$ always converges. If (1.2) is solvable then the limit point solves this system. Furthermore, if the starting point belongs to Range (A^T), then the limit point solves (1.3). However, when the system to be solved is inconsistent, the limit point is quite arbitrary and the method of Kaczmarz fails to provide a solution to the corresponding least squares problem

$$\text{(1.7)} \qquad \text{minimize} \quad \tfrac{1}{2}\|A\mathbf{x}-\mathbf{b}\|^2.$$

See Tanabe [14] and Dax [3] for a detailed explanation of this phenomenon. Example 1 in § 5 illustrates the inefficiency of Kaczmarz's method as a means for solving least squares problems. This raises the question of how to construct a modified Kaczmarz's method that is able to approach a least squares solution of an inconsistent system of linear equations.

One way to resolve this difficulty is to consider the regularized least squares problem

$$\text{(1.8)} \qquad \text{minimize} \quad \tfrac{1}{2}\varepsilon\|\mathbf{x}\|^2+\tfrac{1}{2}\|A\mathbf{x}-\mathbf{b}\|^2,$$

where ε is a positive constant. Let $\mathbf{x}_\varepsilon \in \mathbb{R}^n$ and $\mathbf{y}_\varepsilon \in \mathbb{R}^m$ denote the minimum norm solution of the extended linear system

$$\text{(1.9)} \qquad [A, \sqrt{\varepsilon}\, I]\begin{pmatrix}\mathbf{x}\\ \mathbf{y}\end{pmatrix}=\mathbf{b}.$$

Then $\mathbf{x}_\varepsilon$ provides the unique solution of (1.8). Moreover, since the extended system is solvable, it is possible to approach $\mathbf{x}_\varepsilon$ and $\mathbf{y}_\varepsilon$ by applying Kaczmarz's method on (1.9), which results in the method of Herman, Lent, and Hurwitz [9].

Tikhonov and others introduced the method of regularization as a means for improving the stability of ill-posed problems (e.g., Tikhonov [15] or Tikhonov and Arsenin [16]). In particular, it is a useful tool for handling unstable data-fitting problems. These are problems that result in an inconsistent system of linear equations $A\mathbf{x}=\mathbf{b}$, such that small changes in the data (i.e., the elements of A or $\mathbf{b}$) cause large changes in the minimum norm solution of (1.7). Recall that a point $\mathbf{x} \in \mathbb{R}^n$ solves (1.7) if and only if it solves the normal equations

$$A^T A\mathbf{x} = A^T \mathbf{b}. \tag{1.10}$$

Consequently, the minimum norm solution of (1.7) is defined as the unique vector $\mathbf{x}^*$, which solves the problem

$$\begin{aligned} &\text{minimize} && \tfrac{1}{2}\|\mathbf{x}\|^2 \\ &\text{subject to} && A^T A\mathbf{x} = A^T\mathbf{b}. \end{aligned} \tag{1.11}$$

Assume that we have an a priori estimate $\mathbf{z}_0$ of the solution of (1.7). Then it is possible to stabilize the solution by adding the term $\frac{1}{2}\varepsilon\|\mathbf{x}-\mathbf{z}_0\|^2$ to our objective function. Also, there is no loss of generality in shifting the origin to be $\mathbf{z}_0$. This results in a problem of the form (1.8), which is usually referred to as *standard regularization* or *Tikhonov's regularization.*

The behavior of the regularized solution $\mathbf{x}_\varepsilon$ as a function of ε is easily inspected by applying the singular value decomposition (SVD) of A. Let $U \in \mathbb{R}^{m\times m}$ and $V \in \mathbb{R}^{n\times n}$ be orthogonal matrices such that

$$A = USV^T,$$

where $S \in \mathbb{R}^{m\times n}$ is a diagonal matrix. Define $p = \min\{m, n\}$ and let r denote the rank of A. Then, S is assumed to have the form

$$S = \operatorname{diag}\{\sigma_1, \dots, \sigma_p\},$$

where

$$\sigma_1 \geqq \sigma_2 \geqq \cdots \geqq \sigma_r > 0,$$

and

$$\sigma_i = 0 \quad \text{for } i = r+1, \dots, p.$$

The columns of U and V are denoted by $\mathbf{u}_1, \dots, \mathbf{u}_m$ and $\mathbf{v}_1, \dots, \mathbf{v}_n$, respectively. Now it is easy to verify that

$$\mathbf{x}^* = \sum_{i=1}^{r} (\mathbf{u}_i^T\mathbf{b}/\sigma_i)\mathbf{v}_i \tag{1.12}$$

and

$$\mathbf{x}_\varepsilon = \sum_{i=1}^{r} \alpha_i(\mathbf{u}_i^T\mathbf{b}/\sigma_i)\mathbf{v}_i, \tag{1.13}$$

where

$$\alpha_i = \sigma_i^2/(\sigma_i^2 + \varepsilon).$$

This presentation shows that instability is related to the presence of small nonzero singular values, while regularization dampens the effect of singular values, which are smaller than $\sqrt{\varepsilon}$. Further consequences of (1.13) are the limits

$$\lim_{\varepsilon\to 0^+} \mathbf{x}_\varepsilon = \mathbf{x}^*, \tag{1.14}$$

$$\lim_{\varepsilon\to \infty} \mathbf{x}_\varepsilon = \mathbf{0}, \tag{1.15}$$

and the observation that, as ε moves from zero to infinity, $\mathbf{x}_\varepsilon$ changes continuously from $\mathbf{x}^*$ to $\mathbf{0}$.

The limit (1.14) suggests that by choosing a small value of ε, the method of Herman et al. [9] is capable of providing a good estimate of $\mathbf{x}^*$. However, as our experiments illustrate, in practice, this idea does not always work. The reason for this discrepancy lies in the equivalence between Kaczmarz's method and the SOR method for solving (1.5). This relationship indicates that the method of Herman et al. [9] is equivalent to the SOR method for solving the system

$$(AA^T + \varepsilon I)\mathbf{y} = \mathbf{b}. \tag{1.16}$$

Hence, for small values of ε, the two methods actually coincide in the first iterations. The smaller the ε, the larger the number of iterations in which the two methods follow a similar path, and this may prevent the Herman-Lent-Hurwitz scheme from approaching $\mathbf{x}^*$ within a reasonable number of iterations.

The remedy proposed in this paper is based on the following idea. We have seen that one justification for solving the regularized problem is the existence of an initial estimate $\mathbf{z}_0$. However, when the regularized problem is solved we obtain a new estimate, $\mathbf{z}_1$. Hence, by shifting the origin to $\mathbf{z}_1$, we obtain an improved regularized problem and an improved solution $\mathbf{z}_2$. Similarly, $\mathbf{z}_2$ can be used to generate $\mathbf{z}_3$ and so forth. The basic iteration of this process is as follows: Given $\mathbf{z}_k$, we define

$$\mathbf{b}_k = \mathbf{b} - A\mathbf{z}_k \tag{1.17}$$

and solve the regularized least squares problem

$$\text{minimize} \quad \tfrac{1}{2}\varepsilon \|\mathbf{x}\|^2 + \tfrac{1}{2}\|A\mathbf{x} - \mathbf{b}_k\|^2. \tag{1.18}$$

Then the next point is defined as

$$\mathbf{z}_{k+1} = \mathbf{z}_k + \mathbf{x}_k, \tag{1.19}$$

where $\mathbf{x}_k$ denotes the unique solution of (1.18).

The above iterative improvement process is due to Riley [13] and Golub [6], who considered it in the context of factorization methods for dense linear systems. An equivalent way to write this process is

$$\mathbf{z}_{k+1} = H\mathbf{z}_k + \mathbf{h}, \tag{1.20}$$

where

$$\mathbf{h} = (A^TA + \varepsilon I)^{-1}A^T\mathbf{b}$$

and

$$H = \varepsilon(A^TA + \varepsilon I)^{-1}.$$

The last equality enables us to express H in the form

$$H = VDV^T,$$

where D is a diagonal matrix,

$$D = \text{diag}\{d_1, \ldots, d_n\},$$

such that

$$d_i = \varepsilon/(\sigma_i^2 + \varepsilon) \quad \text{for } i = 1, \ldots, r,$$

and

$$d_i = 1 \quad \text{for } i = r+1, \ldots, n.$$

Golub [6] has used these relations to show that if $\mathbf{z}_0 = \mathbf{0}$, then

$$\mathbf{z}_k = \sum_{i=1}^{r} (1 - d_i^k)(\mathbf{u}_i^T\mathbf{b}/\sigma_i)\mathbf{v}_i, \tag{1.21}$$

and the sequence $\{\mathbf{z}_k\}$ converges to $\mathbf{x}^*$, the minimum norm solution of (1.7). Yet the fact that (1.20) describes a linear stationary iterative process enables us to extend this result in the following way. Since H is convergent and symmetric, and the system

$$(I-H)\mathbf{x}=\mathbf{h} \tag{1.22}$$

is solvable, the sequence $\{\mathbf{z}_k\}$ always converges, and the limit point solves this system. Moreover, if $\mathbf{z}_0 \in \text{Range }(I-H)$, then the limit point is the minimum norm solution of this system (see Dax [3, Corollary 6]). Now the definitions of $\mathbf{h}$ and H imply that $\mathbf{x}$ solves (1.22) if and only if it solves (1.10), and that Range $(I-H) =$ Range (A^T). In other words, the sequence $\{\mathbf{z}_k\}$ converges to a point that solves (1.7), and if $\mathbf{z}_0 \in$ Range (A^T), it converges to $\mathbf{x}^*$, the minimum norm solution of (1.7).

Let $\hat{\mathbf{z}}$ denote the limit point of the sequence $\{\mathbf{z}_k\}$. The optimality conditions of (1.18) imply the equality

$$\varepsilon \mathbf{x}_k = -A^T(A\mathbf{z}_{k+1}-\mathbf{b}). \tag{1.23}$$

This relation shows that $\mathbf{z}_{k+1}-\hat{\mathbf{z}} \in$ Range (A^T) and yields the inequality

$$\varepsilon \|\mathbf{x}_k\| = \|A^T(A\mathbf{z}_{k+1}-\mathbf{b})\| = \|A^TA(\mathbf{z}_{k+1}-\hat{z})\| \geqq \sigma_r^2 \|\mathbf{z}_{k+1}-\hat{\mathbf{z}}\|. \tag{1.24}$$

Hence, if the iterative improvement process stops at a point $\mathbf{z}_{k+1}$ that satisfies

$$\|\mathbf{x}_k\| \leqq \delta \|\mathbf{z}_{k+1}\|, \tag{1.25}$$

where δ is a small positive constant, we obtain the inequality

$$\|\mathbf{z}_{k+1}-\hat{\mathbf{z}}\| / \|\mathbf{z}_{k+1}\| \leqq \varepsilon\delta/\sigma_t^2, \tag{1.26}$$

which can be used to estimate the relative error in the computation of $\hat{\mathbf{z}}$. In particular, when $\mathbf{z}_0 = \mathbf{0}$, we conclude from (1.21) that

$$\|\mathbf{z}_k\| < \|\mathbf{z}_{k+1}\| < \|\mathbf{x}^*\|, \tag{1.27}$$

and (1.26) leads to

$$\|\mathbf{z}_{k+1}-\mathbf{x}^*\| / \|\mathbf{x}^*\| \leqq \varepsilon\delta/\sigma_r^2. \tag{1.28}$$

Let us return to the question of how to construct a row relaxation method that is able to find a least squares solution of an inconsistent linear system. If ε is not too small, then the SOR method for solving (1.6) enjoys a fast rate of convergence, and the Herman-Lent-Hurwitz scheme is likely to provide a good estimate of $\mathbf{x}_k$, the solution of (1.18), within a few iterations. This opens the way for practical implementation of the iterative improvement process as a row relaxation method. However, as equality (1.21) shows, a large value of ε slows down the convergence of the iterative improvement process. The success of the combined method depends, therefore, on a proper choice of ε that ensures a reasonable rate of convergence for both methods (see Table 1).

In the following sections we show that similar ideas can be used to construct a row relaxation method for solving constrained least squares problems. The properties of regularized problems of this kind are briefly discussed in § 2, while § 3 considers the corresponding iterative improvement process. Analysis of the constrained case requires a different approach, since now the SVD of A is not quite so helpful. The basic tool for handling large systems of linear inequalities is the method of Lent and Censor [12], which can be viewed as a row relaxation version of the method of Hildreth [10]. This scheme is discussed in § 4, in which we propose a modification that enables it to solve regularized constrained least squares problems. Combining the modified

Lent–Censor–Hildreth scheme with the iterative improvement process results in a row relaxation method that is able to solve large problems of the form (1.1). Finally, in § 5, we provide numerical experiments that demonstrate the feasibility of our ideas.

2. Regularization of constrained least squares problems. The regularized form of (1.1) is defined as

$$\begin{aligned} &\text{minimize} && \tfrac{1}{2}\varepsilon\|\mathbf{x}\|^2+\tfrac{1}{2}\|A\mathbf{x}-\mathbf{b}\|^2 \\ &\text{subject to} && \mathbf{a}_i^T\mathbf{x}\geqq b_i \quad \text{for } i=m+1,\dots,s, \\ &\text{and} && \mathbf{a}_i^T\mathbf{x}=b_i \quad \text{for } i=s+1,\dots,t, \end{aligned} \tag{2.1}$$

where, as before, ε is a given positive constant. In this section we show that the basic properties of (2.1) are similar to those of (1.1). It is assumed here that the feasible region is not empty, and this ensures that both (1.1) and (2.1) have solutions. The minimum norm solution of (1.1) is the unique vector $\mathbf{x}^*$ that solves the problem

$$\begin{aligned} &\text{minimize} && \tfrac{1}{2}\|\mathbf{x}\|^2 \\ &\text{subject to} && \|A\mathbf{x}-\mathbf{b}\|^2\leqq\|A\mathbf{z}-\mathbf{b}\|^2, \\ & && \mathbf{a}_i^T\mathbf{x}\geqq b_i \quad \text{for } i=m+1,\dots,s, \\ &\text{and} && \mathbf{a}_i^T\mathbf{x}=b_i \quad \text{for } i=s+1,\dots,t, \end{aligned} \tag{2.2}$$

where $\mathbf{z}$ denotes a solution of (1.1). We shall start by answering the question: what happens when ε tends to zero?

THEOREM 1. *Let $\{\varepsilon_k\}$ be a sequence of positive numbers such that*

$$\lim_{k\to\infty}\varepsilon_k=0, \tag{2.3}$$

and let $\mathbf{x}_k$ denote the solution of (2.1) *that corresponds to $\varepsilon=\varepsilon_k$. Then*

$$\lim_{k\to\infty}\mathbf{x}_k=\mathbf{x}^*. \tag{2.4}$$

Proof. The definitions of $\mathbf{x}^*$ and $\mathbf{x}_k$ imply

$$\|A\mathbf{x}^*-\mathbf{b}\|^2\leqq\|A\mathbf{x}_k-\mathbf{b}\|^2$$

and

$$\tfrac{1}{2}\varepsilon_k\|\mathbf{x}_k\|^2+\tfrac{1}{2}\|A\mathbf{x}_k-\mathbf{b}\|^2\leqq\tfrac{1}{2}\varepsilon_k\|\mathbf{x}^*\|^2+\tfrac{1}{2}\|A\mathbf{x}^*-\mathbf{b}\|^2.$$

Hence, by combining these inequalities we obtain

$$\tfrac{1}{2}\varepsilon_k\|\mathbf{x}_k\|^2+\tfrac{1}{2}\|A\mathbf{x}_k-b\|^2\leqq\tfrac{1}{2}\varepsilon_k\|\mathbf{x}^*\|^2+\tfrac{1}{2}\|A\mathbf{x}_k-\mathbf{b}\|^2$$

and

$$\|\mathbf{x}_k\|\leqq\|\mathbf{x}^*\|. \tag{2.5}$$

That is, the sequence $\{\mathbf{x}_k\}$ is bounded and has at least one cluster point, say $\hat{\mathbf{x}}$. Therefore, since (2.2) has a unique solution, it is sufficient to show that $\hat{\mathbf{x}}=\mathbf{x}^*$.

Let $\{\mathbf{x}_j\}$ be a subsequence of $\{\mathbf{x}_k\}$ such that

$$\lim_{j\to\infty}\mathbf{x}_j=\hat{\mathbf{x}}. \tag{2.6}$$

Then, since each $\mathbf{x}_j$ is a feasible point, $\hat{\mathbf{x}}$ is feasible. Similarly, the inequality (2.5) implies

$$\|\hat{\mathbf{x}}\| \leqq \|\mathbf{x}^*\|. \tag{2.7}$$

Hence, the proof is concluded by showing that $\hat{\mathbf{x}}$ solves (1.1).

Let $\hat{\mathbf{x}}$ be a feasible point, and let $Y(\hat{\mathbf{x}})$ denote the set of all the points

$$\mathbf{y} = (y_{m+1}, \dots, y_s, y_{s+1}, \dots, y_t)^T \in \mathbb{R}^{t-m},$$

such that

$$y_i \geqq 0 \quad \text{and} \quad y_i(\mathbf{a}_i^T\hat{\mathbf{x}} - b_i) = 0 \quad \text{for } i = m+1, \dots, s.$$

Then $\hat{\mathbf{x}}$ solves (1.1) if and only if there exists $\hat{\mathbf{y}} \in Y(\hat{\mathbf{x}})$ such that

$$A^T(A\hat{x} - \mathbf{b}) = \hat{A}^T\hat{\mathbf{y}}, \tag{2.8}$$

where $\hat{A}$ is the $(t-m) \times n$ matrix whose rows are $\mathbf{a}_i^T$, $i = m+1, \dots, t$. (These are the well-known Kuhn-Tucker optimality conditions.) Similarly, the optimality conditions of (2.1) indicate that for each $\mathbf{x}_j$ there exists a point $\mathbf{y}_j \in Y(\mathbf{x}_j)$ such that

$$\varepsilon_j\mathbf{x}_j + A^T(A\mathbf{x}_j - \mathbf{b}) = \hat{A}^T\mathbf{y}_j. \tag{2.9}$$

It is also easy to verify that the limit (2.6) implies the existence of an index $\hat{j}$ such that

$$\mathbf{y}_j \in Y(\hat{\mathbf{x}}) \quad \text{for } j \geqq \hat{j}. \tag{2.10}$$

A further use of (2.6) gives

$$\lim_{j\to\infty} \varepsilon_j\mathbf{x}_j = \mathbf{0} \tag{2.11}$$

and

$$\lim_{j\to\infty} \hat{A}^T\mathbf{y}_j = A^T(A\hat{\mathbf{x}} - \mathbf{b}). \tag{2.12}$$

Therefore, by the well-known projection theorem, there exists a point $\hat{\mathbf{y}} \in Y(\hat{\mathbf{x}})$ that solves the least squares problem

$$\begin{aligned} &\text{minimize} && \tfrac{1}{2}\|\hat{A}^T\mathbf{y} - A^T(A\hat{\mathbf{x}} - \mathbf{b})\|^2 \\ &\text{subject to} && \mathbf{y} \in Y(\hat{\mathbf{x}}), \end{aligned} \tag{2.13}$$

while (2.10) and (2.12) imply that $\hat{\mathbf{y}}$ solves (2.8). □

The arguments we have used in the above discussion are easily modified to establish the following assertions.

THEOREM 2. *Let $\{\varepsilon_k\}$ be a sequence of numbers such that*

$$\lim_{k\to\infty} \varepsilon_k = \infty, \tag{2.14}$$

and let $\mathbf{x}_k$ denote the solution of (2.1) *that corresponds to $\varepsilon = \varepsilon_k$. Then*

$$\lim_{k\to\infty} \mathbf{x}_k = \tilde{\mathbf{x}}, \tag{2.15}$$

where $\tilde{\mathbf{x}}$ denotes the unique solution of the least distance problem

$$\begin{aligned} &\textit{minimize} && \tfrac{1}{2}\|\mathbf{x}\|^2 \\ &\textit{subject to} && \mathbf{a}_i^T\mathbf{x} \geqq b_i \quad \textit{for } i = m+1, \dots, s, \\ &\textit{and} && \mathbf{a}_i^T\mathbf{x} = b_i \quad \textit{for } i = s+1, \dots, t. \end{aligned} \tag{2.16}$$

THEOREM 3. *Let $\{\varepsilon_k\}$ be a sequence of positive numbers such that*

$$\lim_{k\to\infty} \varepsilon_k = \varepsilon,$$

and let $\mathbf{x}_k$ denote the solution of (2.1) *that corresponds to $\varepsilon = \varepsilon_k$. Then*

$$\lim_{k\to\infty} \mathbf{x}_k = \mathbf{x}_\varepsilon,$$

where $\mathbf{x}_\varepsilon$ denotes the solution of (2.1).

Summarizing our results, we conclude that as ε moves from infinity to zero, $\mathbf{x}_\varepsilon$ changes continuously from $\tilde{x}$ to $\mathbf{x}^*$.

3. Iterative improvement under constraints. This section considers the iterative improvement process as a tool for solving constrained least squares problems of the form (1.1). The basic iteration of the modified process is carried out as follows. Given $\mathbf{z}_k$, we define

$$b_i^{(k)} = b_i - \mathbf{a}_i^T\mathbf{z}_k, \qquad i = 1, \dots, t,$$

and calculate $\mathbf{x}_k$, the unique solution of the problem

$$\begin{aligned} &\text{minimize} && \tfrac{1}{2}\varepsilon\|\mathbf{x}\|^2 + \tfrac{1}{2}\|A\mathbf{x} - \mathbf{b}_k\|^2 \\ &\text{subject to} && \mathbf{a}_i^T\mathbf{x} \geqq b_i^{(k)} \quad \text{for } i = m+1, \dots, s, \\ &\text{and} && \mathbf{a}_i^T\mathbf{x} = b_i^{(k)} \quad \text{for } i = s+1, \dots, t, \end{aligned} \tag{3.1}$$

where

$$\mathbf{b}_k = \mathbf{b} - A\mathbf{z}_k = (b_1^{(k)}, \dots, b_m^{(k)})^T \in \mathbb{R}^m. \tag{3.2}$$

Then the next point is defined as

$$\mathbf{z}_{k+1} = \mathbf{z}_k + \mathbf{x}_k. \tag{3.3}$$

The above definitions imply the inequality

$$\|A\mathbf{z}_k - \mathbf{b}\|^2 \geqq \tfrac{1}{2}\varepsilon\|\mathbf{x}_k\|^2 + \tfrac{1}{2}\|A\mathbf{z}_{k+1} - \mathbf{b}\|^2,$$

which shows that the sequence $\{\|A\mathbf{z}_k - \mathbf{b}\|^2\}$ is monotonic decreasing, and

$$\lim_{k\to\infty} \mathbf{x}_k = 0. \tag{3.4}$$

Another justification for applying this process lies in the following observation.

THEOREM 4. *Assume that the sequence $\{\mathbf{z}_k\}$ has a cluster point $\hat{\mathbf{x}}$. Then $\hat{\mathbf{x}}$ solves* (1.1).

Proof. Let $\{\mathbf{z}_j\}$ be a subsequence of $\{\mathbf{z}_k\}$ such that

$$\lim_{j\to\infty} \mathbf{z}_j = \hat{\mathbf{x}}. \tag{3.5}$$

Then, since each $\mathbf{z}_j$ is a feasible point, $\hat{\mathbf{x}}$ is feasible. On the other hand, the optimality conditions of (3.1) imply that for each k there exists a vector $\mathbf{y}_k \in Y(\mathbf{z}_{k+1})$ such that

$$\varepsilon\mathbf{x}_k + A^T(A\mathbf{z}_{k+1} - \mathbf{b}) = \hat{A}^T\mathbf{y}_k. \tag{3.6}$$

Hence, by combining (3.4), (3.5), and (3.6), we obtain the limit

$$\lim_{j\to\infty} \hat{A}^T\mathbf{y}_j = A^T(A\hat{\mathbf{x}} - \mathbf{b}), \tag{3.7}$$

where $\{\mathbf{y}_j\}$ denotes the subsequence of $\{\mathbf{y}_k\}$ that corresponds to $\{\mathbf{z}_j\}$. Another consequence of (3.5) is the existence of an index $\hat{j}$ such that $\mathbf{y}_j \in Y(\hat{\mathbf{x}})$ for all $j \geqq \hat{j}$. Therefore, the least squares problem (2.13) has a solution $\hat{\mathbf{y}} \in Y(\hat{\mathbf{x}})$ that satisfies (2.8), which proves that $\hat{\mathbf{x}}$ solves (1.1). $\square$

COROLLARY. *If* (1.1) *has a unique solution, then the sequence* $\{\mathbf{z}_k\}$ *converges to this point.*

4. A row relaxation method for regularized constrained least squares problems.

The original method of Hildreth [10] is designed to solve certain types of convex quadratic programming problems. Later, Lent and Censor [12] have suggested a row relaxation version of Hildreth's method that is aimed at solving least distance problems of the form

$$\text{(4.1)}\qquad \begin{aligned} &\text{minimize} \quad \tfrac{1}{2}\|\mathbf{x}\|^2 \\ &\text{subject to} \quad \mathbf{a}_i^T\mathbf{x} \geqq b_i \quad \text{for } i = 1, \ldots, m. \end{aligned}$$

The basic iteration of the Lent-Censor scheme is similar to that of Kaczmarz's method, but here, in addition to the primal variables, the algorithm stores and updates dual variables. Let $\mathbf{x}$ and $\mathbf{y} = (y_1, \ldots, y_m)^T \in \mathbb{R}^m$ denote the current estimates of the variables at the beginning of the ith step of the kth iteration, $i = 1, \ldots, m$, $k = 1, 2, \ldots$. Then the *ith* step is carried out as follows:

(a) Calculate $\delta = -\min\{y_i, w(\mathbf{a}_i^T\mathbf{x} - b_i)/\mathbf{a}_i^T\mathbf{a}_i\}$.

(b) Set $\mathbf{x} := \mathbf{x} + \delta\mathbf{a}_i$ and $y_i := y_i + \delta$.

The symbol := denotes arithmetic assignment. That is, $y_i := y_i + \delta$ means "set the new value of y_i to be $y_i + \delta$." The starting points must satisfy

$$\text{(4.2)}\qquad \mathbf{x} = A^T\mathbf{y}$$

and

$$\text{(4.3)}\qquad \mathbf{y} \geqq \mathbf{0},$$

and these relations are kept throughout the iterative process. The motivation behind the previous scheme lies in the observation that the dual of (4.1) has the form

$$\text{(4.4)}\qquad \begin{aligned} &\text{minimize} \quad \tfrac{1}{2}\|A^T\mathbf{y}\|^2 - \mathbf{b}^T\mathbf{y} \\ &\text{subject to} \quad \mathbf{y} \geqq \mathbf{0}, \end{aligned}$$

and if $\hat{\mathbf{y}}$ solves the dual, then the vector $\hat{\mathbf{x}} = A^T\hat{\mathbf{y}}$ provides the unique solution of (4.1). Note that when $w = 1$, the value of δ provides the solution of the one-parameter problem

$$\text{(4.5)}\qquad \begin{aligned} &\text{minimize} \quad f(\theta) = \tfrac{1}{2}\|A^T(\mathbf{y} + \theta\mathbf{e}_i)\|^2 - \mathbf{b}^T(\mathbf{y} + \theta\mathbf{e}_i) \\ &\text{subject to} \quad y_i + \theta \geqq 0, \end{aligned}$$

where $\mathbf{e}_i$ denotes the ith column of the $m \times m$ unit matrix. It is also easy to verify that $-w(\mathbf{a}_i^T\mathbf{x} - b_i)/\mathbf{a}_i^T\mathbf{a}_i$ is the change of y_i during the ith step of the SOR method for solving the system

$$\text{(4.6)}\qquad AA^T\mathbf{y} = \mathbf{b}.$$

Therefore, the updating rule of the dual variables can be viewed as a modified SOR method in which the variables are restricted to stay nonnegative. The discussion in Lent and Censor [12] provides an interesting geometric interpretation of this method. Moreover, let $\mathbf{x}_k$ denote the current estimate of the primal variables at the end of the kth iteration and assume that the feasible region is not empty. Then it is shown there that the sequence $\{\mathbf{x}_k\}$ converges, and the limit point solves (4.1).

The adaptation of the Lent-Censor scheme to handle equality constraints is done in the following way. Consider, for example, a linear equality of the form $\mathbf{a}_i^T\mathbf{x} = b_i$. Then by writing this equality as two inequalities, $\mathbf{a}_i^T\mathbf{x} \geqq b_i$ and $-\mathbf{a}_i^T\mathbf{x} \geqq -b_i$, we obtain that the corresponding dual variable y_i is not restricted to stay nonnegative. Hence, in this case, there is no need to store and update y_i, and the ith step of the Lent-Censor scheme coincides with that of Kaczmarz's method:

(a) Calculate $\delta = -w(\mathbf{a}_i^T\mathbf{x} - b_i)/\mathbf{a}_i^T\mathbf{a}_i$.

(b) Set $\mathbf{x} := \mathbf{x} + \delta\mathbf{a}_i$.

In other words, the Lent-Censor scheme is essentially an extended version of Kaczmarz's method, which enables us to handle inequality constraints. The observation that the Hildreth method can be extended to include linear equalities, in the manner described above, is also made in Elfving [5], where it is shown that this extension does not ruin the convergence properties.

The implementation of the Lent-Censor scheme to solve regularized problems of the form (2.1) is based on the following observation, which is a straightforward extension of Lemma 2 of Herman et al. [9]. Let the vectors $\tilde{\mathbf{x}} \in \mathbb{R}^n$ and $\tilde{\mathbf{y}} \in \mathbb{R}^m$ provide the minimum norm solution of the system

$$(4.7a) \qquad (A, \sqrt{\varepsilon}\, I)\begin{pmatrix}\mathbf{x}\\ \mathbf{y}\end{pmatrix} = \mathbf{b},$$

$$(4.7b) \qquad \mathbf{a}_i^T\mathbf{x} \geqq b_i \quad \text{for } i = m+1, \dots, s,$$

$$(4.7c) \qquad \mathbf{a}_i^T\mathbf{x} = b_i \quad \text{for } i = s+1, \dots, t.$$

Then $\tilde{\mathbf{x}}$ solves (2.1).

The minimum norm solution of (4.7) can be obtained by applying the Lent-Censor scheme to solve this system. The basic iteration of the resulting algorithm is as follows. For $i = 1, \dots, m$ the ith step coincides with Kaczmarz's method for solving (4.7a):

(a) Calculate $\delta = -w(\mathbf{a}_i^T\mathbf{x} + \sqrt{\varepsilon}\, y_i - b_i)/(\mathbf{a}_i^T\mathbf{a}_i + \varepsilon)$.

(b) Set $\mathbf{x} := \mathbf{x} + \delta\mathbf{a}_i$ and $y_i := y_i + \delta\sqrt{\varepsilon}$.

For $i = m+1, \dots, s$ the ith step coincides with the Lent-Censor scheme for solving (4.7b):

(a) Calculate $\delta = -\min\{y_i, w(\mathbf{a}_i^T\mathbf{x} - b_i)/\mathbf{a}_i^T\mathbf{a}_i\}$.

(b) Set $\mathbf{x} := \mathbf{x} + \delta\mathbf{a}_i$ and $y_i := y_i + \delta$.

For $i = s+1, \dots, t$ the ith step coincides with Kaczmarz's method for solving (4.7c):

(a) Calculate $\delta = -w(\mathbf{a}_i^T\mathbf{x} - b_i)/\mathbf{a}_i^T\mathbf{a}_i$.

(b) Set $\mathbf{x} := \mathbf{x} + \delta\mathbf{a}_i$.

The algorithm may start with any pair of points $\mathbf{x} \in \mathbb{R}^n$ and $\mathbf{y} \in \mathbb{R}^t$ that satisfy

$$(4.8) \qquad \mathbf{x} = \left(\sum_{i=1}^{m} \mathbf{a}_i y_i\right)\Big/\sqrt{\varepsilon} + \sum_{i=m+1}^{t} \mathbf{a}_i y_i$$

and

$$(4.9) \qquad y_i \geqq 0 \quad \text{for } i = m+1, \dots, s,$$

and these relations hold throughout the iterative process. Note that the algorithm does not store and updates the values of $y_{s+1}, \dots, y_t$. Let $\mathbf{x}_k$ denote the current estimate of the solution at the end of the kth iterations. Then the convergence properties of the Lent-Censor scheme indicate that the sequence $\{\mathbf{x}_k\}$ converges, and the limit point is the unique solution of (2.1).

The above scheme enables us to implement the iterative improvement process that has been described in the previous section. In practice there is no need to calculate the exact solution of (3.1), and $\mathbf{z}_{k+1}$ is obtained from $\mathbf{z}_k$ by applying a few iterations of the row relaxation scheme. The justification for this shortcut lies in the observation that Theorem 4 remains valid when the requirement that $\mathbf{x}_k$ solve (3.1) is replaced by the following three conditions.

(a) $GA\mathbf{z}_k-\mathbf{b}\|^2 \geqq \frac{1}{2}\varepsilon\|\mathbf{x}_k\|^2+\frac{1}{2}\|A\mathbf{z}_{k+1}-\mathbf{b}\|^2$.

(b) $\lim_{k\to\infty} \mathbf{d}_k=0$, where $\mathbf{d}_k$ denotes the distance between $\mathbf{z}_k$ and the feasible region.

(c) For each k, there exists a vector $\mathbf{y}_k \in Y(\mathbf{x}_{k+1})$ such that

$$\lim_{k\to\infty} \|\varepsilon\mathbf{x}_k+A^T(A\mathbf{z}_{k+1}-\mathbf{b})-\hat{A}^T\mathbf{y}_k\|=0.$$

5. Numerical results. In this section we present the results of some preliminary experiments with the regularization method, the method of Kaczmarz, and the iterative improvement technique. The regularization method refers to the scheme described in the previous section for solving (4.7). However, when solving an unconstrained problem it reduces to the method of Herman et al. [9]. The iterative improvement technique has been obtained from the corresponding regularization method by shifting the origin toward the current solution every ten iterations, leaving the vectors $\mathbf{x}$ and $\mathbf{y}$ in their current positions. The implementation of these methods has been carried out with various values of ε. The starting point in our experiments is always the origin point, i.e., $\mathbf{x}_0=\mathbf{0}$ and $\mathbf{y}_0=\mathbf{0}$. No attempt has been made to find an optimal relaxation parameter, and all the runs have been executed with $w=1$.

The test problems are generated by using a matrix A that has 1000 rows and 3000 columns. Each row of A has only three nonzero elements that have random locations. That is, the column indices of the nonzero elements are random integers between 1 and 3000. The values of the nonzero elements are random numbers from the interval $[-1,1]$. (The random number generators are of uniform distribution.) Let

$$\sigma_i=\mathbf{a}_i^T\mathbf{e}$$

denote the sum of elements in the ith row of A, where $\mathbf{e}=(1,1,\dots,1)^T\in\mathbb{R}^{3000}$. All the test problems have $n=3000$ unknowns, but the number of equations and constraints changes from problem to problem (see the following examples). The definition of the right-hand-side vector ensures that the point $\mathbf{x}^*=\mathbf{e}$ solves the problem. The results of our experiments are given in Tables 1-5, while Table 6 provides the corresponding starting values.

Constraints violation		.270E1	.270E1	.270E1	

Example 1: *An inconsistent system of linear equations.* This example considers a system of 1000 equations. The first 500 equations have the form

$$\mathbf{a}_i^T\mathbf{x} = 0.5\sigma_i, \qquad i = 1, \dots, 500,$$

while the other equations are

$$\mathbf{a}_i^T\mathbf{x} = 1.5\sigma_i, \qquad i = 1, \dots, 500.$$

Example 2: *A constrained least squares problem with inequality constraints.* This problem has the form

$$\begin{aligned} &\text{minimize} \quad \sum_{i=1}^{500} (\mathbf{a}_i^T\mathbf{x} - \alpha_i)^2 \\ &\text{subject to} \quad \mathbf{a}_i^T\mathbf{x} \geqq \beta_i \quad \text{for } i = 1, \dots, 500, \end{aligned}$$

where

$$\alpha_i = \min\{0, \sigma_i\},$$

and β_i satisfies the rule: $\beta_i = \sigma_i$ when $\sigma_i \geqq 0$, and $\beta_i = 2\sigma_i$ when $\sigma_i < 0$. The results of this problem are given in Table 2. Here, the objective function value parameter refers to the ratio

$$\left(\sum_{i=1}^{500} (\mathbf{a}_i^T\mathbf{x}_k - \alpha_i)^2 - \sum_{i=1}^{500} (\mathbf{a}_i^T\mathbf{x}^* - \alpha_i)^2\right) \Bigg/ \sum_{i=1}^{500} (\mathbf{a}_i^T\mathbf{x}^* - \alpha_i)^2,$$

while the constraints violation is defined as

$$\max_{1 \leqq i \leqq 500} \{\max\{0, \beta_i - \mathbf{a}_i^T\mathbf{x}_k\}\}.$$

Example 3: *A constrained least squares problem with equality constraints.* In this example, the problem to be solved has the form

$$\begin{aligned} &\text{minimize} \quad \sum_{i=1}^{500} (\mathbf{a}_i^T\mathbf{x} - \alpha_i)^2 \\ &\text{subject to} \quad \mathbf{a}_i^T\mathbf{x} = \sigma_i \quad \text{for } i = 1, \dots 4, 500, \end{aligned}$$

where $\alpha_i = 0$ for $i = 1, \dots, 500$. The objective function value is defined as in the previous example, while the constraints violation parameter is simplified to be

$$\max_{1 \leqq i \leqq 500} |\mathbf{a}_i^T\mathbf{x}_k - \beta_i|.$$

Note that any point that satisfies the constraints is also a solution of the constrained least squares problem. This explains why the regularization method manages to solve this problem when ε is large (see Table 3).

Example 4: *A constrained least squares problem with mixed constraints.* Here we solve the problem

$$\begin{aligned} &\text{minimize} \quad \sum_{i=1}^{500} (\mathbf{a}_i^T\mathbf{x} - \alpha_i)^2 \\ &\text{subject to} \quad \mathbf{a}_i^T\mathbf{x} \geqq \sigma_i \quad \text{for } i \in P \\ &\text{and} \quad \mathbf{a}_i^T\mathbf{x} = \sigma_i \quad \text{for } i \in N, \end{aligned}$$

where

$$\alpha_i = 0, \quad i = 1, \ldots, 500,$$
$$P = \{i \mid 1 \leqq i \leqq 500 \text{ and } \sigma_i \geqq 0\},$$

and

$$N = \{i \mid 1 \leqq i \leqq 500 \text{ and } \sigma_i < 0\}.$$

Here again the objective function value parameter is defined as in Example 2, while the constraints violation parameter is modified to be

$$\max\left\{\max_{i \in P} \{0, \sigma_i - \mathbf{a}_i^T \mathbf{x}_k\}, \max_{i \in N} |\mathbf{a}_i^T \mathbf{x}_k - \sigma_i|\right\}.$$

Example 5: *A consistent system of linear equations.* Although the proposed iterative improvement technique is aimed mainly at solving inconsistent and constrained problems, it is also interesting to watch its behavior when solving a consistent system. Therefore, the last example considers the solution of the system

$$\mathbf{a}_i^T \mathbf{x} = \sigma_i, \qquad i = 1, \ldots, 1000.$$

6. Conclusion. The results of our experiments clearly illustrate that the regularization method has difficulty reaching a least squares solution. Yet, when ε is properly chosen, the iterative improvement process shifts the computed solution toward a least squares solution and overcomes this difficulty.

PRECONDITIONING THE LANCZOS ALGORITHM FOR SPARSE SYMMETRIC EIGENVALUE PROBLEMS*

RONALD B. MORGAN† AND DAVID S. SCOTT‡

Abstract. A method for computing a few eigenpairs of sparse symmetric matrices is presented and analyzed that combines the power of preconditioning techniques with the efficiency of the Lanczos algorithm. The method is related to Davidson's method and its generalizations, but can be less expensive for matrices that are fairly sparse. A double iteration is used. An effective termination criterion is given for the inner iteration. Quadratic convergence with respect to the outer loop is shown.

Key words. eigenvalues, sparse matrices, Lanczos, preconditioning, Davidson's method

1. Introduction. We consider the problem of computing a few eigenvalues and eigenvectors of a large, sparse, symmetric matrix. It is assumed that factoring the matrix is impractical due to its size and sparsity structure. A method is presented that incorporates both the technique of preconditioning and the Lanczos algorithm. A double iteration scheme is used. The outside loop updates a certain preconditioned matrix; the inside loop applies the Lanczos algorithm. An effective termination criterion is given for the inner loop. This method can be very efficient if the matrix is fairly sparse and an approximate inverse is easily available.

This section briefly discusses background material on eigenvalue techniques and on preconditioning. Section 2 presents the method. Section 3 gives convergence results including asymptotic quadratic convergence with respect to the outer loop. Section 4 gives examples and looks at some implementation details. Comparisons are made with other methods.

Krylov subspace methods are popular for both eigenvalue problems and linear equations problems. Krylov subspaces are used by the Lanczos algorithm [11], [19] for eigenvalues and by the conjugate gradient method [2], [9], [10] for linear equations (see [7, p. 523] and [18] for the relation between the methods). Both methods have convergence problems if the distribution of eigenvalues is unfavorable. The Lanczos algorithm has difficulty if the desired eigenvalues are not well separated from the rest of the spectrum. The conjugate gradient method needs the spectrum to be somewhat separated from zero. Convergence of the conjugate gradient method is often improved by preconditioning (multiplying the matrix equation by an approximate inverse) [1], [3], [8], [13].

It would also be desirable to improve the convergence of the Lanczos algorithm with preconditioning, but this is not straightforward. Preconditioning can be applied indirectly to eigenvalue problems by using the preconditioned conjugate gradient method to solve equations for inverse iteration, the Rayleigh quotient iteration [12], [22], or shift-and-invert Lanczos [6], [20].

Davidson's method [4] and the generated Davidson (GD) method [15], [17] give a more direct approach to preconditioning eigenvalue problems. Suppose eigenvalues are sought for the matrix A. Then these methods generate a subspace with the operator $(M-\rho I)^{-1}(A-\rho I)$, where ρ is the latest approximate eigenvalue obtained by the

Rayleigh-Ritz procedure [19]. In Davidson's method, the operator M is D, the main diagonal of A. For the GD method, M can be any approximation to A. $M-\rho I$ is in effect a preconditioner for $A-\rho I$. Let (λ, z) be the desired eigenpair. Asymptotically, the subspace produced by these methods resembles a Krylov subspace generated by $(M-\lambda I)^{-1}(A-\lambda I)$. The operator $(M-\lambda I)^{-1}(A-\lambda I)$ has one eigenvalue at 0 with z as the associated eigenvector. The rest of the spectrum tends to be compressed around 1 by the preconditioning. This makes 0 well separated, and convergence is rapid toward z (see [17] for more detail).

The GD method is more expensive per iteration than the Lanczos algorithm. There is the cost of the preconditioning and also the cost of the Rayleigh-Ritz procedure. Full orthogonalization must be done. Davidson's method is often applied to problems for which the main expense is the matrix-vector products, and thus any reduction in the number of iterations is worthwhile. For other problems, particularly those where A is quite sparse, the orthogonalization costs are significant. Restarting reduces the expense but slows down the convergence.

A method is desired that could be preconditioned and could take advantage of the Lanczos recurrence. One possibility involves using the Lanczos algorithm to build the subspace for GD [16, pp. 71-83]. The Rayleigh-Ritz expense can be reduced by a factor of five. However, a double iteration is used and the cost still grows as the size of the subspace increases. In the next section, another method is presented that uses preconditioning and the Lanczos algorithm. The difference is that in this method the Rayleigh-Ritz procedure is not done with respect to A. A double iteration is again used, but the costs of order n are fixed as the subspace grows.

2. The Preconditioned Lanczos (PL) Algorithm.

Preconditioning the Lanczos algorithm was suggested by Scott [21] as a special case of a method for generalized eigenvalue problems, but it was not investigated, and the algorithm has not been given before for the standard eigenvalue problem. Our purpose here is threefold. We establish important convergence results. Scott's results [21] do not take into account preconditioning or early termination of the inner iteration. Second, we implement the method and show that it is useful. Third, we derive the method showing its connection with the Davidson and GD methods. This is important because it gives insight into why the method is effective and because Davidson's method is well known among quantum chemists.

The GD method uses the operator $N(\rho)\equiv(M-\rho I)^{-1}(A-\rho I)$ to generate a subspace, but it uses the operator A in the Rayleigh-Ritz procedure for extracting approximate eigenvectors from the subspace. However, since $N(\rho)$ has an eigenvector approximating one of A, the Rayleigh-Ritz procedure with a fixed $N(\rho)$ is also useful for computing an eigenvector of A. It is necessary to restart the Rayleigh-Ritz occasionally with a new ρ, because the eigenvector of $N(\rho)$ is only an approximation. We use this idea, but transform $N(\rho)$ to a symmetric operator so that the Lanczos algorithm can be applied. A positive definite preconditioner is required, so we replace $M-\rho I$ with M_k. The algorithm is called the PL Algorithm.

THE PL ALGORITHM. Given a vector x_0, compute $\rho_0 = x_0^T A x_0 / x_0^T x_0$, and FOR $k=0,1,2,\dots$, DO 1 to 5

1. Choose M_k to be a positive definite matrix approximating $A-\rho_k I$, and let $L_k L_k^T$ be its Cholesky factorization.
2. Define $W_k \equiv L_k^{-1}(A-\rho_k I)L_k^{-T}$.

3. Run the Lanczos iteration with W_k and starting vector $L_k^T x_k$, until the smallest Ritz value is bounded away from zero by the residual norm [19, p. 260]. Letting θ_k be the smallest Ritz value and y_k be the corresponding Ritz vector of unit length, this stopping test is $-\theta_k > \| W_k y_k - \theta_k y_k \|$.
4. Let $x_{k+1} = L_k^{-T} y_k$.
5. Set $\rho_{k+1} = x_{k+1}^T A x_{k+1} / x_{k+1}^T x_{k+1} = \rho_k + \theta_k / x_{k+1}^T x_{k+1}$.

The operator $W_k \equiv L_k^{-1}(A - \rho_k I) L_k^{-T}$ is related to $M_k^{-1}(A - \rho_k I)$ by a similarity transformation. And $M_k^{-1}(A - \rho_k I)$ has an eigenvector approximating an eigenvector of A. By applying the Lanczos iteration to W_k, computing a Ritz vector, and then transforming it back, we get x_{k+1}, an approximate eigenvector of A. The Rayleigh quotient ρ_{k+1} of x_{k+1} is an approximate eigenvalue. The residual norm [19, p. 69] of (ρ_{k+1}, x_{k+1}) with respect to A can be monitored to determine a stopping point for the PL iteration.

The main cost of the method is in the Lanczos loop. A matrix-vector product with A is required and systems of linear equations in L_k and L_k^T are solved. So it is important for the Lanczos iteration to converge quickly. The spectrum of W_k, or equivalently of $M_k^{-1}(A - \rho_k I)$, is the determining factor. Here the preconditioning improves the eigenvalue distribution just as it does for the GD method. The early termination test in step 3 of the PL Algorithm also reduces the number of Lanczos iterations. In the following section it is shown that the early termination test does not significantly impair the convergence of the outer iteration.

3. Convergence of PL. For convergence, the preconditioner does not need to be an accurate approximation. If there is boundedness, then the sequence $\{\rho_k\}$ in the PL Algorithm converges to an eigenvalue of A at an asymptotically quadratic rate. First, convergence of ρ_k to an eigenvalue is shown.

THEOREM 1. *Assume that both M_k and M_k^{-1} are uniformly bounded in norm. Then ρ_k converges to an eigenvalue of A.*

Proof. First we will establish the equality asserted in step 5 of the PL Algorithm.

$$
\begin{aligned}
\rho_{k+1} &= x_{k+1}^T A x_{k+1} / x_{k+1}^T x_{k+1} \\
&= \rho_k + (L_k^{-T} y_k)^T (A - \rho_k I) L_k^{-T} y_k / x_{k+1}^T x_{k+1} \\
&= \rho_k + y_k^T W_k y_k / x_{k+1}^T x_{k+1} \\
&= \rho_k + \theta_k / x_{k+1}^T x_{k+1}.
\end{aligned} \tag{1}
$$

Next we will show that θ_k is nonpositive, so that from (1), $\{\rho_k\}$ is a nonincreasing sequence. The $(1, 1)$ element of the tridiagonal matrix T that is generated by the Lanczos iteration is the Rayleigh quotient of the starting vector $L_k^T x_k$ with respect to W_k. It can be seen that this Rayleigh quotient is zero, since $\rho_k = x_k^T A x_k / x_k^T x_k$. Using Cauchy's interlace theorem, θ_k is less than or equal to zero, since θ_k is the smallest eigenvalue of T.

The sequence of ρ_k's is bounded below by the smallest eigenvalue of A. Therefore, ρ_k converges. Let the limit be τ, and let $\varepsilon_k = \rho_k - \tau$.

Because by assumption M_k^{-1} is bounded in norm, so also is L_k^{-1}. The vector y_k is of unit length, so $x_{k+1}^T x_{k+1} = (L_k^{-T} y_k)^T L_k^{-T} y_k$ is bounded. From (1),

$$
|\theta_k| = (\rho_k - \rho_{k+1}) x_{k+1}^T x_{k+1} \leqq \varepsilon_k x_{k+1}^T x_{k+1}. \tag{2}
$$

Therefore, θ_k converges to zero. But θ_k is within the residual norm bound of some eigenvalue of W_k, say ω_k. Because of the stopping test for the Lanczos iteration in step 3 of the PL algorithm, ω_k is within $|\theta_k|$ of θ_k and so within $2|\theta_k|$ of zero. Therefore, ω_k converges to zero.

Since W_k has an eigenvalue converging to zero, $\|W_k^{-1}\|$ goes to infinity. Since

$$\|W_k^{-1}\| = \|L_k^T(A-\rho_k I)^{-1}L_k\| \leqq \|L_k^T\|\,\|(A-\rho_k I)^{-1}\|\,\|L_k\|,$$

and $\|L_k^T\|$ and $\|L_k\|$ are bounded, ρ_k must be converging to an eigenvalue of A, and the proof is complete. □

The theorem does not say which eigenvalue ρ_k converges to, but it is extremely likely to be the smallest one. For this not to be the case would require that each starting vector of the Lanczos iteration have a very small component in the direction of the eigenvector associated with the smallest eigenvalue of W_k.

Let ρ_k converge to λ. The next theorem shows that this convergence is asymptotically quadratic. The "big O" notation will be used: $\beta = \gamma + O(\varepsilon)$ implies $|\beta - \gamma| \leqq c\varepsilon$ for $c > 0$.

THEOREM 2. *Assume that both M_k and M_k^{-1} are uniformly bounded in norm. Then ρ_k converges at an asymptotically quadratic rate.*

Proof. Using the definitions of W_k and y_k,

$$\begin{aligned}(A-\rho_k I)x_{k+1} &= L_k W_k L_k^T x_{k+1} = L_k W_k y_k \\ &= L_k[(W_k y_k - \theta_k y_k) + \theta_k y_k].\end{aligned}$$

Because of the stopping test in step 3 of the PL Algorithm and the fact that y_k is a unit vector,

$$\begin{aligned}\|(A-\rho_k I)x_{k+1}\| &\leqq \|L_k\|[\|W_k y_k - \theta_k y_k\| + |\theta_k|\,\|y_k\|] \\ &\leqq 2\|L_k\|\,|\theta_k|.\end{aligned} \tag{3}$$

Let the residual vector of x_{k+1} with respect to A be r_{k+1}:

$$\|r_{k+1}\| = \|(A-\rho_{k+1}I)x_{k+1}\| / \|x_{k+1}\|.$$

Using first the minimal residual property [19, p. 12], then (3),

$$\begin{aligned}\|r_{k+1}\| &\leqq \|(A-\rho_k I)x_{k+1}\| / \|x_{k+1}\| \\ &\leqq 2\|L_k\|\,|\theta_k| / \|x_{k+1}\|.\end{aligned}$$

With (2) and the fact that $\|L_k\|$ is bounded and $\|x_{k+1}\|$ is bounded away from zero, we have

$$\|r_{k+1}\| = O(\varepsilon_k). \tag{4}$$

Let γ_k be the gap between ρ_k and the nearest eigenvalue of A other than λ. This gap approaches a nonzero constant because ρ_k converges to λ. By the Kato-Temple inequality [19, p. 222],

$$|\rho_{k+1} - \lambda| \leqq \|r_{k+1}\|^2 / \gamma_{k+1}.$$

With (4), this becomes

$$\rho_{k+1} = \lambda + O(\varepsilon_k^2),$$

and we have quadratic convergence. □

4. Implementation and examples. Here examples are given and comparisons are made with other methods. First, some implementation details are discussed.

On the choice of preconditioner, one possibility is to pick M to be a portion of A. Then factor $M-\rho_k I$ in LDL^T form, and let M_k equal $L|D|L^T$. Small pivot elements during the factorization should be changed. Another approach is to let M_k be $M-\sigma I$, where σ is an estimate of the smallest eigenvalue of A and is below the spectrum of M. A powerful preconditioning approach is to use incomplete factorization [8], [13] of $A-\sigma I$. Here it is important that $A-\sigma I$ be positive definite. Even then, adjustment of small or negative pivot elements may be necessary for a stable factorization. The symmetric successive overrelaxation (SSOR) [9] preconditioner is another possibility.

If more than one eigenvalue is desired, a form of deflation can be used. The eigenvalues that are already computed can be shifted out of the way. For example, once (λ_1, z_1) has been computed, $A-\rho_k I$ can be replaced by $A-\rho_k I+\gamma z_1 z_1^T$, where γ is large enough to shift λ_1 away from the other desired eigenvalues. The shifting should be kept as small as possible to comfortably achieve this, because a large shift and the effect of M_k^{-1} could possibly produce a large eigenvalue for W_k. This would slow the convergence of the Lanczos loop. The starting vector for finding the second eigenvalue can be determined while the first eigenvalue is being computed. At some point, the second Ritz vector of W_k can be computed and multiplied by L_k^{-T}. In the examples that follow, the starting vectors for interior eigenpairs are calculated once the residual norm for the previous eigenpair reached two-thirds in orders of magnitude of the desired accuracy.

An additional stopping test is applied in the Lanczos loop to terminate early if it is likely that the desired accuracy has been attained. This is done by comparing the improvement in the residual norm with respect to W_k of the Ritz vector in the Lanczos loop with the improvement needed in the residual norm with respect to A of the approximate eigenvector. (The Lanczos loop is terminated when the log base 10 of the ratio of the residual norms of Ritz vectors at the beginning and current point of Lanczos is less than the log of the ratio of the residual norm of x_k to the specified residual tolerance, divided by a safety factor of 0.9 times the ratio of logs of improvements in residual norms for the previous k.) In our testing, this check for early termination helps the method avoid extra computation.

Example 1. The first test matrix is $A=\mathrm{Diag}(1,2,3,\dots,1000)$. For the preconditioner, let $M=\mathrm{Diag}(10.1, 10.2, 10.3,\dots,110)$ and $M_k=M-\rho_k I$. The starting vector is $(1, 1/2, 1/3,\dots,1/1000)^T$. The smallest eigenvalue and eigenvector are computed. The requested residual tolerance is 1×10^{-8}. Table 1 gives the results of the PL method. It lists the number of iterations in the Lanczos loop (this is the size of the Krylov subspace generated and also the number of matrix-vector products with A), the new approximate eigenvalue ρ_{k+1}, and the residual norm. It shows the expected quadratic convergence. The total number of iterations is 88. The standard Lanczos algorithm requires 194 iterations for the same task. So the preconditioning cuts the number of

TABLE 1
PL *for Example* 1.

k	Iterations	ρ_{k+1}	Residual norm
		4.55	24.2
0	3	1.67	4.5
1	8	1.064	1.0
2	13	1.00035	0.101
3	25	1.0000000058	0.56E−3
4	39	1.0000000000	0.76E−8

iterations in half. With better preconditioning, this can be improved. For example, with $M = \text{Diag}(1.1, 1.2, 1.3, \ldots, 101)$, the PL Algorithm converges in only 30 total iterations.

Next we compare three methods that use preconditioning: the PL Algorithm, the GD method, and the Rayleigh quotient iteration (RQI) [12], [22] with preconditioned SYMMLQ [18] in the inner loop. The GD method has a limit of 40 on the size of the subspace because of the orthogonalization costs. The RQI uses termination criterion in SYMMLQ of $\text{RTOL} = \text{Min}\{0.01 * \|r\|, \|r\|^3\}$, where $\|r\|$ is the residual norm at the previous step of RQI. The choice of termination criterion can affect the convergence a great deal, especially when the starting vector for RQI is not accurate. Three matrices with increasing difficulty are used. Let $A = \text{Diag}(1, 1+\delta, 1+2\delta, \ldots, 1+99\delta, 2+99\delta, 3+99\delta, \ldots, 901+99\delta)$, for $\delta = 1$, 0.1, and 0.01. M is as originally defined. Table 2 gives the total number of matrix-vector products used for each of these methods. For the toughest problem ($\delta = 0.01$), the PL Algorithm is much better than the GD method. Not only are fewer iterations required, but each iteration is considerably less expensive. The PL Algorithm has the advantage of being able to cheaply generate large subspaces, and for difficult problems, large subspaces are needed. The PL Algorithm also has an advantage when storage is limited and the vectors spanning the subspace must be stored on disk, because the GD method accesses these vectors at every iteration.

TABLE 2
Preconditioning methods.

	Number of matrix-vector products		
	Matrix	Matrix	Matrix
Method	$\delta = 1$	$\delta = 0.1$	$\delta = 0.01$
PL	88	247	555
GD	69	309	1584
RQI	99	333	582

The PL Algorithm and RQI are fairly comparable in this example. This is not surprising, since the two methods do resemble each other. The main difference is that the PL Algorithm has an eigenvalue problem in the inner loop instead of a linear equations problem. RQI does not require storage of the vectors spanning the subspace and has easier deflation. But the PL Algorithm has the advantage of being more reliable in converging to the smallest eigenvalue. To illustrate this with the first matrix ($\delta = 1.0$) and starting vector $(5, 5, 5, 5, 5, 1/6, 1/7, 1/8, \ldots, 1/1000)^T$, RQI converges to the fifth eigenvalue. The PL Algorithm still converges to the first eigenvalue. Of course, it is well known that to insure convergence to a particular eigenvalue, RQI needs a good starting vector or an implementation that combines it with inverse iteration.

The shift-and-invert Lanczos method with the preconditioned conjugate gradient method can also be used, but we have not found it to be competitive. For one implementation with early termination of the inner conjugate gradient iteration, 893 iterations were required with the matrix $\delta = 0.1$. However, there is probably a better implementation.

Example 2. This and the next example use matrices from the Harwell-Boeing sparse matrix collection [5]. The matrices selected are quite sparse and have small eigenvalues that are not well separated. The first matrix is SHERMAN1, from oil reservoir simulation. The dimension is 1000, and it has seven nonzero bands with half-bandwidth of 100. The six smallest eigenvalues are 0.000323, 0.00102, 0.00111, 0.00151, 0.00192, and 0.00205, and the largest is 5.04.

The elements of the starting vector are selected randomly on the interval $(0, 1)$. The computations are performed on an IBM 3090-170J computer using double precision arithmetic. The Lanczos algorithm is restarted every 250 steps and the GD method every 40. The small eigenvalue problems generated by these methods are solved with EISPACK routines, though an iterative method such as subspace iteration [19] might be better. The small problem is solved at the end of each 250 iterations of Lanczos, at every step for GD (as is required), and for PL at each of the first seven iterations and then at multiples of five. A few steps of inverse iteration are needed at the start of RQI. We let $\rho = 0$ for the first three outer iterations, then switch to regular RQI. The preconditioner for all methods is from incomplete factorization [13] of A, with no fill-in allowed.

First, the smallest eigenpair of the matrix is computed with residual norm tolerance of 1×10^{-8}. Table 3 lists the total number of matrix-vector products (MVPs) with A, along with the time in CPU seconds. The preconditioning methods need far fewer iterations than the Lanczos algorithm. The PL Algorithm is the fastest method, even though the GD method requires fewer iterations.

TABLE 3
Harwell-Boeing matrices.

	SHERMAN1		SHERMAN1		NOS6	
	One eigenpair		Five eigenpairs		One eigenpair	
Method	MVPs	Time	MVPs	Time	MVPs	Time
Lanczos	750	7.6	—		—	
PL	61	1.2	487	9.3	987	16.7
GD	39	2.2	149	9.7	6920	346
RQI	221	4.2	—		—	

Next the five smallest eigenpairs are computed. PL uses $\gamma = 0.01$ to shift computed eigenvalues. The results are not very sensitive to the choice of γ. (For example, with $\gamma = 0.002$, 445 matrix-vector products are needed, while PL with $\gamma = 0.1$ uses 533.) The PL and GD methods require about the same amount of time. The simple Lanczos algorithm with restarting has difficulty calculating these eigenvalues. A deflation scheme is possible, but it might be better to use a block Lanczos method [6] or out-of-core storage to avoid restarting. RQI is implemented with $\rho = 0$ for the first three outer iterations for each eigenvalue and with a small Raleigh-Ritz procedure [19] applied to the last five approximate eigenvectors to get each new starting vector. RQI finds the first, third, fifth, second, and ninth eigenvalues and uses 2001 total matrix-vector products. A different implementation might help, but this appears to be a difficult problem for RQI.

Example 3. Here we use a structural engineering matrix of dimension 675 called NOS6 in Simon's LANPRO collection [5]. The starting vector has entries distributed randomly on the interval $(-1, 1)$, and the residual tolerance is 1×10^{-4}. The two smallest eigenvalues are 1.0000153 and 1.0000254, which are extremely close considering that the matrix has elements of size 4×10^{6}. The maximum size subspace for the Lanczos algorithm and for the Lanczos iteration of PL is 350, while GD again uses dimension 40. The results for computing one eigenvalue are given in Table 3. The PL Algorithm is more than 20 times faster than GD. The Lanczos algorithm shows little sign of ever finding the smallest eigenvalue. RQI is implemented with initial steps of inverse iteration using $\rho = 0$ until the Rayleigh quotient is less than 1.00002, but it also cannot find this eigenvalue (it never switches from inverse iteration to RQI). In another test with $\rho = 1$ initially, RQI converges in 1961 total iterations and 30.2 seconds. So even with an extremely accurate initial estimate of the eigenvalue, RQI is slower than the PL Algorithm.

5. Conclusion.

Like the Davidson and GD methods, the PL Algorithm uses preconditioning to accelerate the convergence. However, the expense per iteration is reduced by applying the Lanczos iteration. A double iteration scheme is used. The inner iteration is terminated early for efficiency, but convergence is still asymptotically quadratic with respect to the outer loop.

The PL Algorithm can significantly reduce the expense of computing eigenvalues and eigenvectors of some matrices. It is most useful for sparse matrices, for difficult problems, and for computing only a very small number of extreme eigenpairs.

We conclude with some possibilities for further research. If an eigenvalue estimate σ is known, $A - \rho_k I$ can be replaced with $A - \sigma I$ in step 2 of the PL Algorithm, for the first few outer loops. Also, the method might be more robust if the x_k vectors are saved and combined using the Rayleigh-Ritz procedure with A. This would not be too expensive if only the last few x_k vectors are used. Finally, an interior implementation [14] of the Lanczos loop might allow computation of more than one eigenvalue without using deflation. This also might allow computation of several eigenvalues at a time if estimates are known of the desired eigenvalues.

Acknowledgments. The authors would like to thank the referees for many suggestions that considerably improved the paper.

THE HERMITE SPECTRAL METHOD FOR GAUSSIAN-TYPE FUNCTIONS*

TAO TANG†

Abstract. Although Hermite functions were widely used for many practical problems, numerical experiments with the standard (normalized) Hermite functions $\psi_n(v)$ worked poorly in the sense that too many Hermite functions are required to solve differential equations. In order to obtain accurate numerical solutions, it is necessary to choose a scaling factor α and use $\psi_n(\alpha v)$ as the basis functions. In this paper the scaling factors are given for functions that are of Gaussian type, which have finite supports $[-M, M]$. The scaling factor used is $\max_{0\leq j\leq N}\{\gamma_j\}/M$, where $\{\gamma_j\}_{j=0}^N$ are the roots of $\psi_{N+1}(v)$ and $N+1$ is the number of the truncated terms used. The numerical results show that after using this scaling factor, only reasonable numbers of the Hermite functions are required to solve differential equations.

Key words. spectral method, Hermite functions

AMS(MOS) subject classifications. 65M70, 33C25, 35K05

1. Introduction.

The normalized Hermite functions are

$$\psi_n(v)=\frac{1}{\sqrt{2^n n!}}H_n(v)\exp\left(-\frac{v^2}{2}\right), \tag{1.1}$$

where the $H_n(v)$ are the usual (unnormalized) Hermite polynomials. For physical problems posed on $v\in(-\infty,\infty)$ (i.e., infinite domain), a variety of spectral techniques have been developed in recent years. These include the use of Fourier series combined with domain truncation, sine function, Hermite functions, and algebraically mapped Chebyshev polynomials. Previous results for these techniques are summarized, for example, in Boyd [5, Chap. 14]. Many researchers have noticed that the close connection of Hermite functions to physics makes them a natural choice of basis functions for many fields of science and engineering. Numerical applications include many problems in continuum mechanics (see, e.g., [3]), particle physics (see, e.g., [9], [15], and [17]), tropical meteorology, and oceanography (see, e.g., [2], [8], and [14]). Also, one reason for using Hermite spectral methods is that the Hermite system has some very attractive properties from the numerical point of view. For example, in a recent paper, Weideman [19] showed that the spectral radii for the first and second Hermite differentiation matrices are $O(\sqrt{N})$ and $O(N)$, respectively, where $N+1$ is the number of truncated terms used. This places rather weak stability restrictions on the Hermite method. For example, if we consider the standard heat equation, then a maximum step size in the time direction of order $O(N^{-1})$ is required, whereas for Fourier and Chebyshev methods it is of order $O(N^{-2})$ and $O(N^{-4})$, respectively. In the actual calculations this means that we need not even consider implicit time integration methods with the Hermite method. A theoretical study of the Hermite method for the heat equation is given in a recent paper, [11], which is concerned with the stability and convergence properties of the method.

Although the Hermite spectral methods have some attractive properties, the direct spectral approach may not produce good approximations. In the practical calculations,

it is necessary to choose a scaling factor α since we can always use $\psi_n(\alpha v)$ as the basis set for any finite α. This freedom does not exist for a finite interval, but after a change of scale in v, an infinite domain is still an infinite domain. It was pointed out by Boyd [4]-[6] that α should increase with the truncated terms used, but the theory of choosing an optimum scaling factor is still incomplete. In this paper, we study how to choose a proper scaling factor for a class of functions that decay at infinity at least like $\exp(-pv^2)$ for some positive constants p (i.e., Gaussian type). Solutions of many practical problems behave like Gaussian-type functions at infinity, for example, the diffusion equations for heat flow and the Fokker-Planck equations for particle physics (see, e.g., [10] and [17]). The idea underlying our approach is the following: In using spectral collocation methods we choose a scaling factor α which depends on the ratio of the maximum root of $H_{N+1}(v)$ and the length of the finite support of the function. The usual method for dealing with the infinite interval is simply to truncate $(-\infty, \infty)$ to a finite interval $[-M, M]$. The scaling factor α is chosen so that all of the collocation points are within $[-M, M]$. The numerical results show that after using the scaling factor, reasonable numbers of Hermite functions are required to resolve a Gaussian-type function.

2. Hermite collocation methods. For a Gaussian-type function f, we have the expansion

$$f(v) = \sum_{n=0}^{\infty} a_n \psi_n(\alpha v), \qquad |v| < \infty, \tag{2.1}$$

which is equivalent to

$$f(v/\alpha) = \sum_{n=0}^{\infty} a_n \psi_n(v), \qquad |v| < \infty, \tag{2.2}$$

where α is a positive constant. The spectral method of order N is to approximate the function f using the first $N+1$ terms in the expansion series, i.e., the coefficients $\{a_n\}_{n=N+1}^{\infty}$ are set equal to 0. Therefore, we have the spectral approximations

$$f_N(v/\alpha) = \sum_{n=0}^{N} a_n \psi_n(v). \tag{2.3}$$

When solving differential equations, we need to relate the coefficients of the derived function to those of the original function, as given by

$$f^{(k)}(v/\alpha) = \sum_{n=0}^{N} a_n \psi_n^{(k)}(v) = \sum_{n=0}^{N} a_n^{(k)} \psi_n(v). \tag{2.4}$$

Using the recurrence formulas of Hermite functions we can obtain that

$$a_n^{(1)} = \frac{\alpha}{\sqrt{2}} \left(-\sqrt{n}\, a_{n-1} + \sqrt{n+1}\, a_{n+1}\right), \tag{2.5}$$

$$a_n^{(2)} = \frac{\alpha^2}{2} \left(\sqrt{(n-1)n}\, a_{n-2} - (2n+1) a_n + \sqrt{(n+1)(n+2)}\, a_{n+2}\right), \tag{2.6}$$

with $a_n = 0$ whenever $n < 0$ or $n > N$.

In pseudospectral methods, the optimum pseudospectral points are the roots of $H_{N+1}(v)$, which are denoted by $\{\gamma_j\}_{j=0}^{N}$ with the order $\gamma_0 > \gamma_1 > \cdots > \gamma_N$. Assuming that (2.3) is satisfied at the collocation points, we have

$$f_N\left(\frac{\gamma_j}{\alpha}\right) = \sum_{n=0}^{N} a_n \psi_n(\gamma_j), \qquad 0 \leq j \leq N. \tag{2.7}$$

Noting that

$$\sum_{n=0}^{N} \psi_n(\gamma_i)\psi_n(\gamma_j) = C_i\delta_{ij}, \qquad 0 \leqq i, j \leqq N, \tag{2.8}$$

$$C_i = \sum_{n=0}^{N} [\psi_n(\gamma_i)]^2, \qquad 0 \leqq i \leqq N, \tag{2.9}$$

we obtain from (2.7) that

$$a_n = \sum_{j=0}^{N} \frac{1}{C_j} f_N\left(\frac{\gamma_j}{\alpha}\right)\psi_n(\gamma_j), \qquad 0 \leqq n \leqq N. \tag{2.10}$$

The above relations between $\{a_n\}$ and $\{f_N(\gamma_j/\alpha)\}$ give a simple evaluation of the derivatives of $f_N(v)$ at the points $\{\gamma_j/\alpha\}_{j=0}^N$. Once $\{f_N(\gamma_j/\alpha)\}_{j=0}^N$ are known, the coefficients $\{a_n\}_{n=0}^N$ can be obtained by (2.10). Then, the first and second derivatives of f_N at points $\{\gamma_j/\alpha\}_{j=0}^N$ can be computed by (2.4)-(2.6). A higher order of derivatives can be obtained in a similar way. If $\{a_n\}_{n=0}^N$ are given, the function $f_N(v)$ is computed by

$$f_N(v) = \sum_{n=0}^{N} a_n\psi_n(\alpha v). \tag{2.11}$$

3. The scaling factor. Suppose that the function f has a finite support $[-M, M]$, i.e., $f(v) \sim 0$ for $|v| > M$. In order to compute $\{a_n\}_{n=0}^N$ by (2.10), we need to use information from the interval $[-M, M]$ only, since outside this region the function is almost zero and will not contribute much to a_n. This simple motivation suggests that

$$\left|\frac{\gamma_j}{\alpha}\right| \leqq M, \quad \text{for all } 0 \leqq j \leqq N. \tag{3.1}$$

The above condition is satisfied by choosing

$$\alpha = \alpha_N = \max_{0 \leqq j \leqq N} \{\gamma_j\}/M = \gamma_0/M. \tag{3.2}$$

Since $\gamma_0 \sim \sqrt{2N}$ (see, e.g., [1]), we obtain that

$$\alpha_N \sim \sqrt{2N}/M. \tag{3.3}$$

The Hermite spectral methods were rejected before because of their poor resolution properties. Gottlieb and Orszag [12] investigated the rate of convergence of Hermite series by considering the expansion of the sine functions. They found that to resolve p wavelengths of the sine function requires $O(p^2)$ polynomials. In the case when the function decays rapidly, we need to consider the sine functions which oscillate rapidly in a finite interval (i.e., $|v| \leqq \text{Const.}$). Consider

$$\sin(pv) = \sum_{n=0}^{\infty} c_{2n+1}H_{2n+1}(v), \tag{3.4}$$

where

$$c_{2n+1} = (-1)^n \frac{p^{2n+1}\exp(-p^2/4)}{2^{2n+1}(2n+1)!}, \tag{3.5}$$

for $n = 0, 1, \ldots$. Using the asymptotic expansion of $H_n(v)$ [1],

$$H_n(v) \sim \exp(v^2/2)\frac{n!}{(\frac{1}{2}n)!}\cos\left(\sqrt{2n+1}\, v - \frac{1}{2}n\pi\right), \tag{3.6}$$

and Sterling's formula

$$n! \sim \sqrt{2\pi}\, n^{n+1/2} \exp(-n), \tag{3.7}$$

we obtain the asymptotic behavior of the nth term of the right-hand side of (3.4) as

$$\text{term}_n \sim \frac{1}{\sqrt{2\pi}} \left(\frac{p^2}{4n}\right)^{n+1/2} \exp(n - p^2/4 + v^2/2). \tag{3.8}$$

It can be seen from the above equation that if $n \approx p^2/4$ then the nth term behaves like $\exp(v^2/2)/\sqrt{2\pi}$, which is in general not small. That is, to resolve p wavelengths of the sine functions requires more than $0.25p^2$ Hermite functions. This result is similar to that observed by Gottlieb and Orszag [12]. However, if we use the scaling factor α_N of the form (3.2), i.e., if we expand

$$\sin(pv) = \sum_{n=0}^{\infty} d_{2n+1} H_{2n+1}(\alpha_N v) \tag{3.9}$$

with $\alpha_N = \gamma_0$, then the nth expansion term is of the asymptotic form

$$\text{term}_n \sim \frac{1}{\sqrt{2\pi}} \left(\frac{p^2}{4n\alpha_N^2}\right)^{n+\frac{1}{2}} \exp\left(n - \frac{p^2}{4\alpha_N^2} + \frac{v^2}{2}\right). \tag{3.10}$$

Noting that $\alpha_N^2 \sim 2N$, we obtain

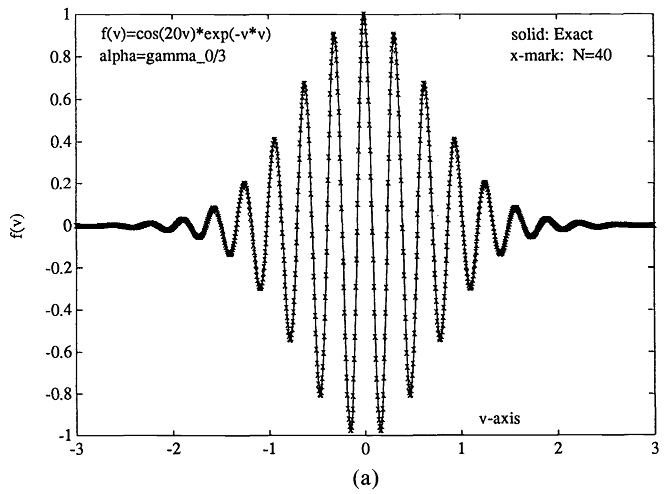
$$\text{term}_n \sim \frac{p}{4\sqrt{\pi n N}} \left[\frac{p^2}{8nN} \exp\left(1 - \frac{p^2}{8nN}\right)\right]^n \exp\left(\frac{v^2}{2}\right). \tag{3.11}$$

The right-hand side of the above equation decays exponentially when $n \geqq N \approx p$. This result shows that using the scaling factor can reduce the number of required polynomials to the best possible case. The above analysis is only given for the expansion in Hermite polynomials, but similar behavior can be seen for the expansion in the normalized Hermite functions (in this case, if the function has a finite support $[-M, M]$, then $N \approx Mp$). To see this, we expand

$$\cos(pv)\exp(-v^2) = \sum_{n=0}^{\infty} a_n \psi_n(\alpha v). \tag{3.12}$$

The coefficients $\{a_n\}_{n=0}^N$ are obtained by using (2.10) and the numerical curve is given by (2.11). It can be seen from Fig. 1 that, after scaling (i.e., $\alpha = \alpha_N = \gamma_0/3$), 20 and 30 expansion terms give good approximations to the function $\cos(pv)\exp(-v^2)$ with $p = 20$ and $p = 30$ (noting that the function $\cos(pv)\exp(-v^2)$ is an even function and the number of the expansion term is $N/2$ since the odd terms are zero). However, approximations without scaling (i.e., $\alpha = 1$) require more than 100 terms in the case $p = 20$; see Fig. 2. Furthermore, in Figs. 3 and 4, we have plotted the absolute values of the even coefficients in (3.12) (noting that the odd coefficients are zero) as a function of n in the case $p = 20$. In these two figures a log scale was used. Since $\psi_n(\alpha v) = O(n^{-1/4})$, the nth term of (3.12) is small only when its coefficient is small. Figure 3 suggests that in order to have the nth term less than 10^{-3}, for all $n \geqq N$, we need about 25 expansion terms (i.e., $N = 50$) when the scaling factor is used. However, Fig. 4 shows that about 140 expansion terms are required for the conventional expansion (i.e., $\alpha = 1$).

Many practical problems are required to approximate the distribution function of the form $\exp(-pv^2)$ with moderate and large values of p, for example, the heat equations with Gaussian-type initial distribution with small viscosity coefficients, and



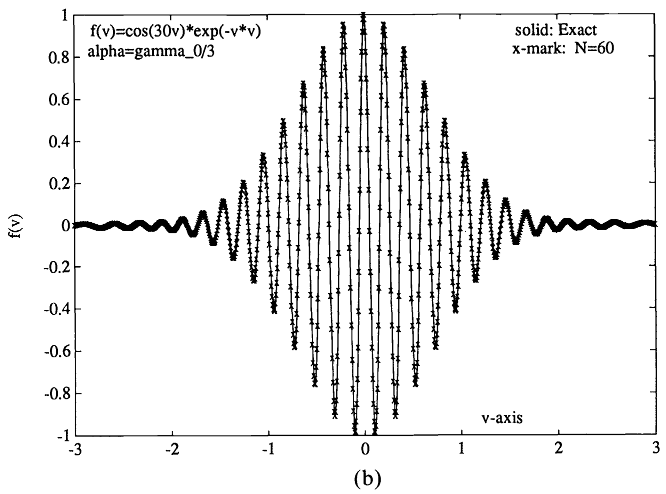


FIG. 1. (a) *Hermite spectral approximation for* $f(v) = \cos(20v)\exp(-v^2)$ *with* $N = 40$ *and* $\alpha = \gamma_0/3$; (b) *Hermite spectral approximation for* $f(v) = \cos(30v)\exp(-v^2)$ *with* $N = 40$ *and* $\alpha = \gamma_0/3$.

the Fokker-Planck equations with small thermal velocity (cf. [17]) or with small particle response time (cf. [10]). Since

$$\exp(-pv^2) = \sum_{n=0}^{\infty} c_{2n}\psi_{2n}(v), \tag{3.13}$$

where

$$c_{2n} = \frac{(-1)^n}{\sqrt{2^{2n}(2n)!(p+\frac{1}{2})}}\left(\frac{p-\frac{1}{2}}{p+\frac{1}{2}}\right)^n \frac{(2n)!}{n!}, \tag{3.14}$$

we obtain the asymptotic behavior of the nth term of the right-hand side of (3.13) as

$$\text{term}_n \sim \frac{1}{\sqrt{n\pi p}}\left(\frac{p-\frac{1}{2}}{p+\frac{1}{2}}\right)^n. \tag{3.15}$$

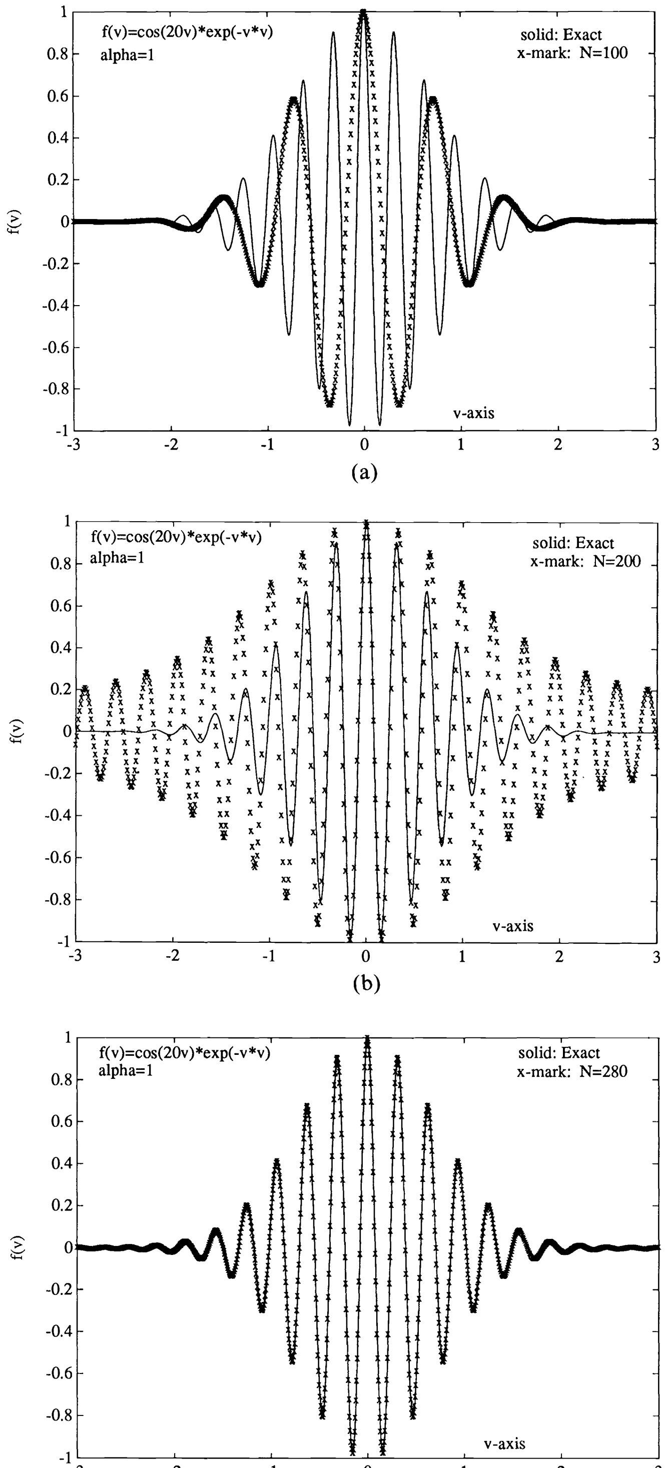

FIG. 2. *Hermite spectral approximation for* $f(v) = \cos(20v)\exp(-v^2)$ *without using a scaling factor.* (a) $N = 100$; (b) $N = 200$; *and* (c) $N = 280$.

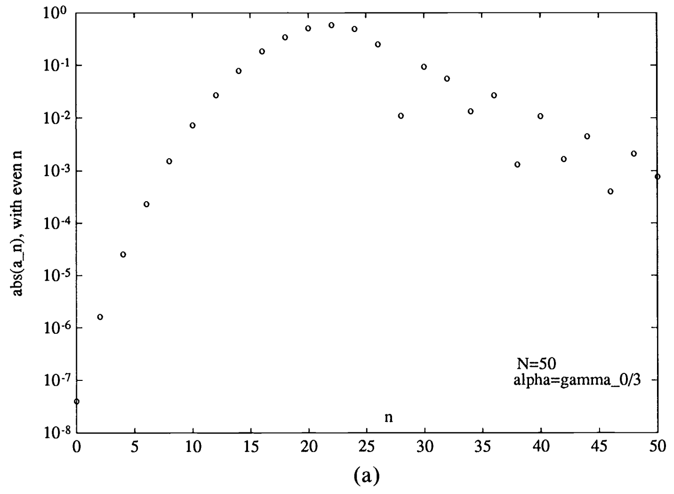

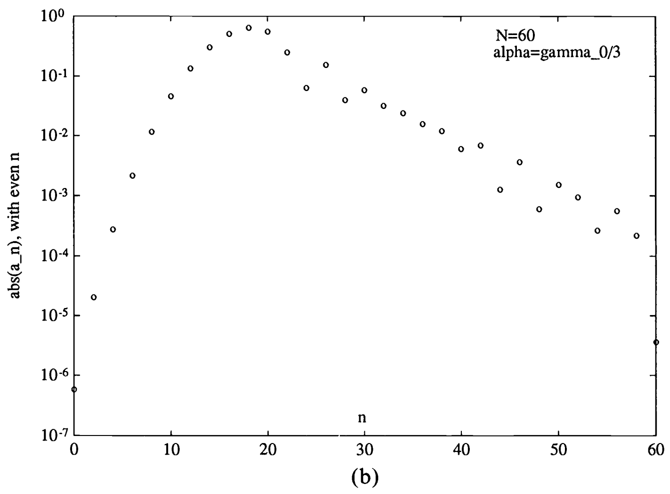

FIG. 3. *The even coefficients of the Hermite expansions for* $f(v)=\cos(20v)\exp(-v^2)$. (a) $N=50$ *and* $\alpha=\gamma_0/3$; (b) $N=60$ *and* $\alpha=\gamma_0/3$.

The above result is bad: for large p about $O(p)$ terms are required. This can be seen from the following. Since

$$\left(1-\frac{1}{x}\right)^x \leqq \lim_{a\to\infty}\left(1-\frac{1}{a}\right)^a = \frac{1}{e}, \qquad \text{for all } x \geqq 1, \tag{3.16}$$

then only when $n \geqq N \approx Cp$ with a positive constant C (which is quite large),

$$\text{term}_n \sim \frac{1}{\sqrt{n\pi p}}\, e^{-C}. \tag{3.17}$$

However, when applying the scaling technique to the same function, we obtain

$$\exp(-pv^2) = \sum_{n=0}^{\infty} d_{2n}\psi_{2n}(\alpha_N v) \tag{3.18}$$

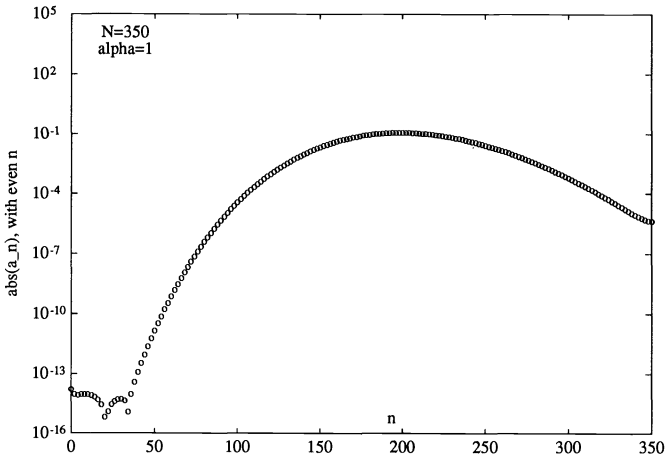

FIG. 4. *The even coefficients of the standard Hermite expansions* (i.e., $\alpha=1$) *for* $f(v)=\cos(20v)\exp(-v^2)$, $N=350$.

with $\alpha_N=\gamma_0/M$, as given in (3.2). The asymptotic form of the nth term is

$$\text{term}_n \sim \frac{\alpha_N}{\sqrt{n\pi p}}\left(\frac{p/\alpha_N^2-\frac{1}{2}}{p/\alpha_N^2+\frac{1}{2}}\right)^n, \tag{3.19}$$

which yields that

$$\text{term}_n \sim \sqrt{\frac{2N}{n\pi p M^2}}\left(\frac{M^2p/N-\frac{1}{2}}{M^2p/N+\frac{1}{2}}\right)^n. \tag{3.20}$$

If p is large, then M can be chosen as one. If $n \geqq N$, the right-hand side of (3.20) decays rapidly to zero when $N \geqq C(p/N+\frac{1}{2})$ with a positive constant C:

$$\begin{aligned}\text{term}_n &\sim \sqrt{\frac{2N}{n\pi p}}\left(1-\frac{1}{p/N+\frac{1}{2}}\right)^n\\ &\leqq \sqrt{\frac{1}{p}}\left(1-\frac{1}{p/N+\frac{1}{2}}\right)^{C(p/N+1/2)}\\ &\leqq \sqrt{\frac{1}{p}}e^{-C}.\end{aligned} \tag{3.21}$$

The requirement $N \geqq C(p/N+\frac{1}{2})$ is satisfied when $N=O(\sqrt{p})$. In Figs. 5 and 6 we consider a test function $f(v)=\exp(-2v^2)+\exp(-20v^2)$. It can be seen from Fig. 5 that after scaling ten expansion terms (again, since the function f is an even function, the number of expansion terms is $N/2$) give a good approximation. However, Fig. 6 shows that approximations without scaling need more than 50 expansion terms.

4. Numerical applications. Consider the eigenvalue problem [3, p. 126]

$$-u''(v)+v^4u(v)=\lambda u(v). \tag{4.1}$$

By the WKB method, the solution of the above equation has the asymptotic behavior

$$u(v)\sim \exp(-|v|^3/3). \tag{4.2}$$

It is obvious from (4.2) that $u\sim 0$ if $|v| \geqq M \approx 5$. In order to obtain accurate solutions of (4.1) efficiently, we need to choose the scaling factor $\alpha=\gamma_0/M$, where $\gamma_0=\max_{0\leqq j\leqq N}\{\gamma_j\}$, with γ_j the roots of $H_{N+1}(\gamma)$. Since the solutions of (4.1) are even

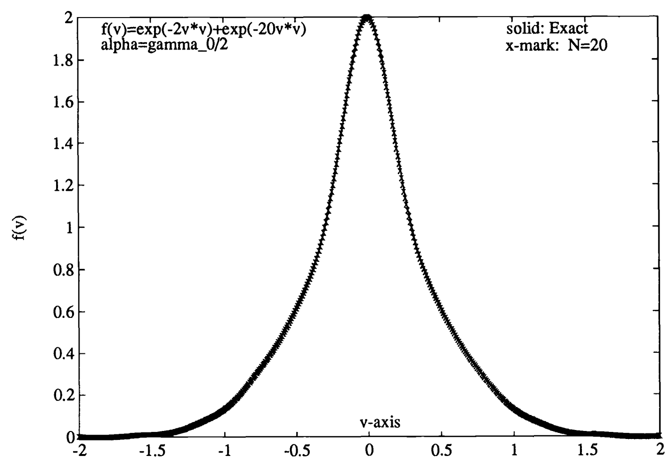

FIG. 5. *Hermite spectral approximation for* $f(v) = \exp(-2v^2) + \exp(-20v^2)$, *with* $\alpha = \gamma_0/2$ *and* $N = 20$.

functions, only $N/2$ expansion terms are required in the actual calculations. For $N = 60$, we predict that the scaling factor $\alpha \approx 10.16/5.0 \approx 2.0$. Birkhoff and Fix [3] used Galerkin's method with 30 Hermite functions (i.e., $N = 60$) to solve (4.1). They found that the standard Hermite functions (i.e., without scaling) gave the first 18 eigenvalues to only three decimal places, whereas using a scaling factor $\alpha = 2.154$ gave the same eigenvalues to 10 decimal places. That is, an increase of 10^{-7} in accuracy is obtained. They obtained the optimum scaling factor through trial and error (the procedure requires a considerable amount of computer time), but the present work provides an accurate scaling factor in a very simple way.

Finally, we apply the scaling technique to the one-dimensional heat equations. The numerical methods for heat equations have been studied extensively in the past (see, e.g., [16] and [18]). Consider the equation

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial v}\left(\nu \frac{\partial u}{\partial v}\right), \tag{4.3}$$

where ν is the viscosity coefficient. If an initial temperature distribution is known, then the problem is to determine the temperature distribution at later times. If the viscosity coefficient is a constant and the initial distribution is given as

$$u(v, 0) = \frac{1}{\sqrt{\nu\pi}} \exp\left(-\frac{v^2}{\nu}\right), \tag{4.4}$$

then the exact solution of (4.3) and (4.4) is

$$u(v, t) = \frac{1}{\sqrt{\pi\nu(4t+1)}} \exp\left(-\frac{v^2}{\nu(4t+1)}\right). \tag{4.5}$$

Problem (4.3), (4.4) has been chosen since it has an analytic solution and this allows us to compare our numerical results with the exact solution (4.5). We use the pseudospectral method introduced in § 2 to compute the numerical solutions. The numerical procedure can be applied to more complicated initial distributions and to variable viscosity coefficients. It can be seen from the previous section that the Hermite spectral methods work well for moderate values of ν, but about $O(1/\nu)$ expansion terms are needed when ν is small. However, if we apply the scaling technique, then fewer terms are required. To illustrate this, we shall consider the case when $\nu = 0.01$.

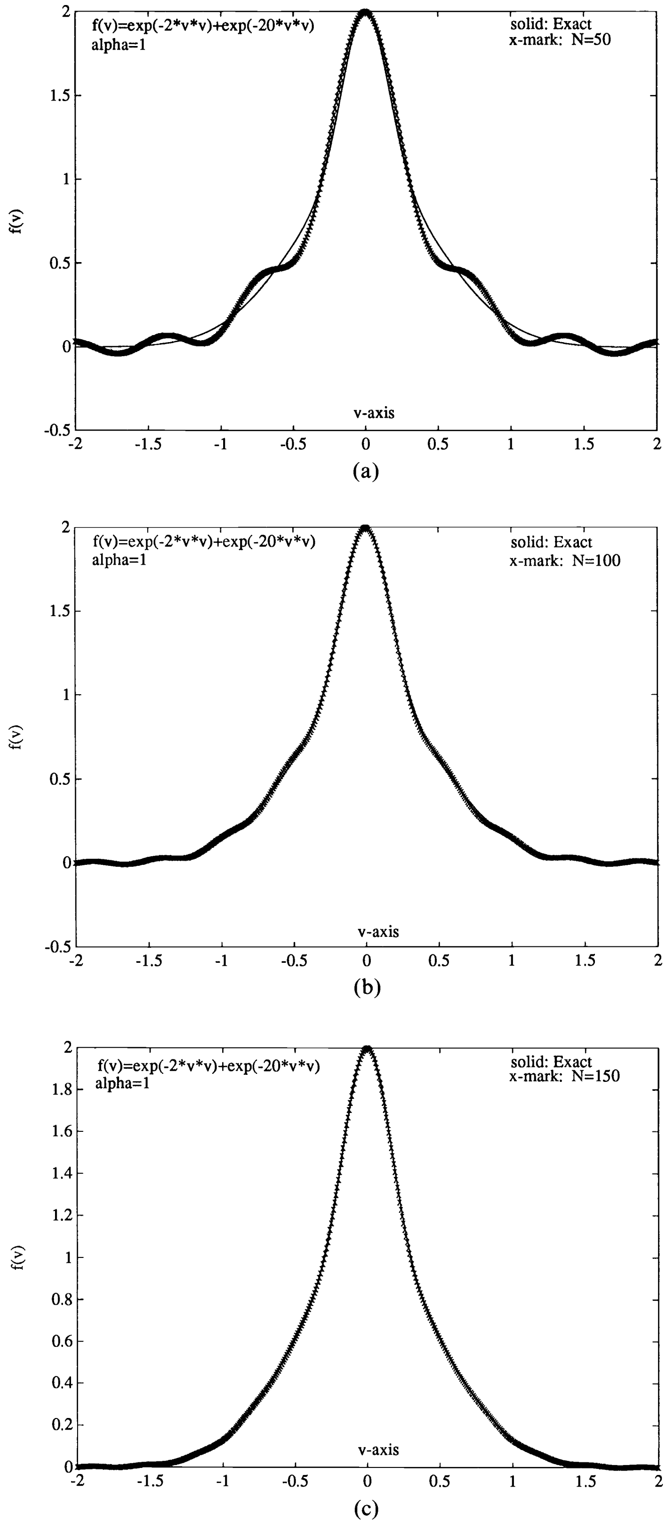

FIG. 6. *Hermite spectral approximation for* $f(v) = \exp(-2v^2) + \exp(-20v^2)$ *without using a scaling factor.* (a) $N = 50$; (b) $N = 100$; *and* (c) $N = 150$.

Let $U(t)=[u(\gamma_0/\alpha_N, t), \ldots, u(\gamma_N/\alpha_N, t)]^T$. Then (4.3) may be semidiscretized as

$$\frac{dU}{dt}=\nu D^{(2)}U, \tag{4.6}$$

where $D^{(2)}$ is the second-order differentiation matrix, which can be computed by (2.4), (2.6), and (2.10). When an explicit method is used to integrate (4.6) in time, the maximum allowable time step needs to satisfy

$$\Delta t=O\left(\frac{1}{\nu sr(D^{(2)})}\right), \tag{4.7}$$

where $sr(D^{(2)})$ denotes the spectral radius of the matrix $D^{(2)}$. Since $sr(D^{(2)})=O(\alpha_N^2 N)$ (see [19]) and $N=O(\sqrt{1/\nu})$ (see § 3), $\alpha_N=O(\sqrt{N})$, we obtain $\Delta t=O(1)$. This suggests that the time-step size can be independent of N when ν is small, which is unlike the finite difference methods [16] and the particle methods [18]. Figure 7 gives a comparison

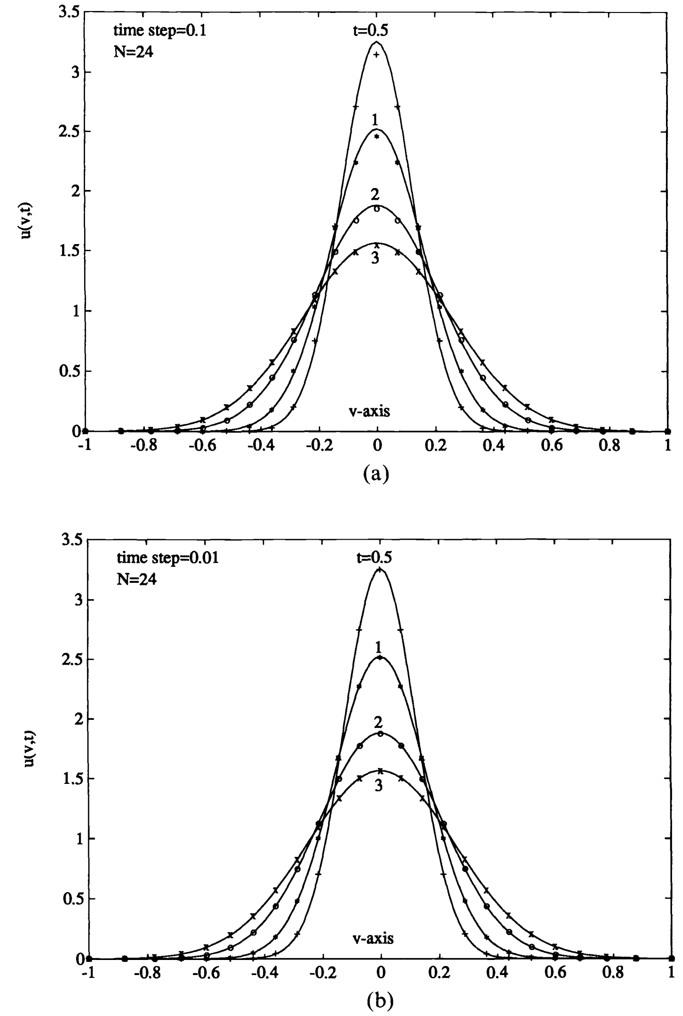

FIG. 7. *Comparison between the exact (lines) and numerical (marks) solution for the diffusion equation at different times.* (a) $\Delta t=0.1$ *and* $N=24$; (b) $\Delta t=0.01$ *and* $N=24$.

between the exact solution and the numerical results. The solution domain is $|v| \leqq 1$ and N is 24 (which corresponds to 12 expansion terms, since the solution is an even function). Figure 7(a) shows that even for a quite large step size, $\Delta t = 0.1$, stable numerical results can be obtained. The results differ only slightly from those obtained by using a smaller time-step size (see Fig. 7(b)). The numerical results are obtained by using the forward Euler method with constant time-step size Δt.

5. Discussions. The method presented in this paper can be used in solving differential equations with solutions that decay exponentially as $v \to \infty$. The idea of using a scaling factor can also be extended to other spectral methods for unbounded intervals, for example, Laguerre spectral methods (see, e.g., [13]) and rational spectral methods (see, e.g., [7] and [19]). It is known that Hermite spectral methods cannot handle functions that decay algebraically with v, but Laguerre and rational spectral methods are appropriate in approximating slowly decaying functions (see, e.g., [5]). It is expected that the use of Laguerre or rational spectral methods with a similar scaling technique can approximate solutions of some practical problems (e.g., problems in [7], [8], and [13]).

Acknowledgments. This research was initiated during my visit to University of Strathclyde, Scotland, in the summer of 1991. The hospitality of Professor Sean McKee is gratefully acknowledged. I wish to thank Mr. Qiang Lan for providing me with Fig. 7. I also wish to thank Professors J. P. Boyd and J. A. C. Weideman for their interest and comments on this work.

ACCELERATED MULTIGRID CONVERGENCE AND HIGH-REYNOLDS RECIRCULATING FLOWS*

A. BRANDT† AND I. YAVNEH‡

Abstract. Techniques are developed for accelerating multigrid convergence in general, and for advection-diffusion and incompressible flow problems with small viscosity in particular. It is shown by analysis that the slowing down of convergence is due mainly to poor coarse-grid correction to certain error components, and means for dealing with this problem are suggested, analyzed, and tested by numerical experiments, showing very significant improvement in convergence rates at little cost.

Key words. multigrid, incompressible flow, acceleration

AMS(MOS) subject classifications. 65N20, 76D05

1. Introduction.

Classical multigrid methods were originally developed for elliptic partial differential equations and systems. For such problems these methods have proved to be extremely efficient, enabling solution to the level of discretization errors in just a few minimal work units, so that the total work invested in the solution grows linearly with the number of variables, and usually at most several dozen operations per variable are required. When applied to nonelliptic and singular perturbation problems such as high-Reynolds flows, however, performance seems to deteriorate significantly, due in part to the fact that the solutions become more complex (e.g., boundary layers and characteristic directions along which high-frequency data may propagate to large distances). But poor multigrid behavior is exhibited even in simple problems with smooth solutions when the partial differential operator is nonelliptic (or has a nonelliptic component).

To learn how to treat the various troubles that appear in flow problems, it is necessary to distinguish them. One of the main distinctions that must be made is between *entering flows*, in which the flow enters through some boundary and follows a well-defined general orientation, and *recirculating* flows. In the former, relaxation can be made to resolve smooth components, and thus act (in part) as a *solver* and not just as a *smoother* in the multigrid solution process. Highly efficient multigrid solutions to problems of this type are demonstrated in [7]. The purpose of the present study is to show how to improve performance greatly in recirculating flows and other problems, in which relaxation significantly resolves only nonsmooth error components.

The main tool used in analysis and prediction of the performance of multigrid algorithms is local mode analysis (see, e.g., [2]). For elliptic partial differential systems it was shown in [4] that, under reasonable assumptions, the predicted performance can indeed be obtained for general domains by adding some processing, for negligible cost, at and near the boundaries. Hence, boundary effects may be neglected in the basic

analysis of multigrid solvers for elliptic problems. This is not the case in problems that are nonelliptic or have nonelliptic components, such as incompressible flows at high-Reynolds numbers. In such problems, high-frequency boundary data may propagate far into the domain, and it may be necessary to include boundary effects in the analysis (see [7]). However, when dealing with shear-driven recirculating flows we are once again in a position that is similar to the elliptic case with respect to boundary effects, since cross-stream behavior is determined by the (elliptic) viscosity terms no matter how small they may be (see [6]). For such flows the infinite-space local mode analysis is again useful.

Slow convergence of multigrid cycles can generally be traced to (at least) one of two major causes: poor smoothing or poor coarse-grid approximation to the fine-grid problem. Smoothing, which is reducing the amplitude of high-frequency errors that cannot be treated on the next coarser grid, is dealt with extensively in most publications on multigrid solvers for incompressible flows (see, e.g., [2] and [5]). Here we address the problem of poor coarse-grid corrections, which may require specialized methods that depend on the cause of the problem. When the poor approximation is caused by a local factor, say, some singularity in the boundary, the proper course is usually to employ local methods such as extra relaxation in the vicinity of the singularity (see [1] and [4]). But sometimes, in particular in high-Reynolds flows, the coarse grid fails to approximate the fine-grid problem well enough for certain components *throughout the domain.* Frequently, the best course of action then is to simply disregard this seemingly poor behavior, since those components, which are poorly approximated by the coarse grid, do not in turn approximate the differential solution well (see [2] and [3]). If, however, one is interested in obtaining good *algebraic* convergence and not just rapid convergence to a good approximation of the *differential* solution, special techniques must be employed to accelerate convergence.

Consider as our model problem the constant-coefficient advection-diffusion equation:

$$L_{ad}u = -\epsilon\triangle u + au_x = 0\,, \tag{1}$$

where $\triangle$ is the Laplacian operator and ϵ is a positive constant. Suppose that this equation is discretized by some finite difference scheme L^h_{ad} of order q on a uniform grid of mesh-size h whose orientation is general (and therefore choosing x to be the characteristic direction results in no loss of generality). The resulting discrete set of equations is solved by starting with some initial approximation to the discrete solution on the fine grid h (grid with mesh-size h) and iterating with the usual multigrid cycles. Soon one finds that (for vanishing ϵ) the residual norms are reduced at best by an amplification factor of $1 - 0.5^q$ by each cycle, even if the number of relaxation sweeps per level and the cycle index γ (defined below) are chosen to be quite large. The reason for this slow-down has been shown to be poor approximation of *smooth characteristic components* by the coarse grids. This property has already been explained in [3]. We return to it here, and in another context in [7], and present methods for treating the problem.

As usual, when researching the advection-diffusion equation, our object is to learn how to treat the Navier–Stokes equations. Since these exhibit similar behavior, we conclude that the problem of poor coarse-grid correction studied here is the main cause for the poor convergence rates of flow problems as well. Hence, although the analyses below are all done for the advection-diffusion equation, numerical experiments also include the incompressible flow equations, and indeed the behavior is seen to be influenced similarly by the methods proposed.

In §§2 and 3 the two-level and multilevel cycles are analyzed, and it is shown why the usual multigrid cycles exhibit poor convergence rates. In §4 it is shown by analysis and numerical examples that significant acceleration of convergence can be obtained at virtually no cost by overweighting some of the residuals that are transferred to the next coarser grid. In §5 a method of employing defect corrections within the multigrid cycle is introduced, and it is shown by analysis and numerical experiments that this method can be combined in various ways with residual overweighting to greatly improve the multigrid cycle's performance. The ultimate modified W cycle that is developed enables an asymptotic reduction of the error by a factor of nine per cycle in its two-level version for the first-order discretized advection-diffusion and incompressible Navier–Stokes equations, rather than the factor of two that is yielded by the usual two-level cycle. This performance is almost matched in the multilevel cycle as well, and here the improvement is still more dramatic, since the usual cycle's performance is shown to deteriorate rapidly as the number of levels grows. Conclusions and remarks are given in §6.

The accelerated multigrid analyses and methods developed in this article can be straightforwardly generalized to other cases in which multigrid convergence deteriorates due to poor coarse-grid corrections for some smooth components.

2. Two-level infinite-space local mode analysis. In order to have a clear and quantitative understanding of the slowing down of multigrid convergence due to poor coarse-grid correction, we will analyze here a multigrid cycle leaving out some irrelevant aspects: we will treat only smooth components, and hence neglect the effect of intergrid transfers, and employ the first differential approximation (FDA; see [11], [3], and [2, §7.5]) to the difference equations. We will also assume for simplicity that the diffusion coefficient ϵ tends to zero, which is indeed the case for which the multigrid performance is usually the worst. The FDA approximation to a qth-order discretization of L_{ad} then has the form

$$L_{ad}^h = -\epsilon_h a T_{q+1}(\partial_x, \partial_y) + a\partial_x \,, \tag{2}$$

where the first term on the right-hand side represents the first truncated term in the discretization of L_{ad}. T_{q+1} is a polynomial of degree $q+1$ of the form

$$T_{q+1}(\partial_x, \partial_y) = \sum_{j=0}^{q+1} a_j \, \partial_x^j \, \partial_y^{q+1-j}, \tag{3}$$

and $\epsilon_h = O(h^q)$. ϵ_h and the coefficients a_j are determined by the particular discretization and angle between the characteristic direction and the grid. For example, in the case of the usual first-order upstream discretization, the FDA is

$$\begin{aligned} L_{ad}^h = -\tfrac{1}{2}ha[\,&(\cos^3\phi + \sin^3\phi)\partial_{xx} + \sin 2\phi(\sin\phi - \cos\phi)\partial_{xy} \\ &+ \tfrac{1}{2}\sin 2\phi(\sin\phi + \cos\phi)\partial_{yy}\,] + a\partial_x \,, \end{aligned}$$

where ϕ is the angle that the characteristic direction x forms with the grid. (This is obtained by writing the artificial viscosity of upstream discretization in the coordinates of the grid, and transforming to the characteristic coordinates x and y.)

Consider an error component on the fine grid h given by

$$v^h = e^{i(\omega_1 x + \omega_2 y)} \,. \tag{4}$$

Generalization to higher dimensions is straightforward, and the following analyses apply directly. The residual due to this error is

$$r^h = -L^h_{ad}v^h = -\hat{L}^h_{ad}(\omega_1, \omega_2) \cdot e^{i(\omega_1 x + \omega_2 y)}\,, \tag{5}$$

where $\hat{L}^h_{ad}$ is called the *symbol* of L^h_{ad} (see also [2]). The correction problem solved on the coarse grid H is

$$L^H_{ad}v^H = r^h\,, \tag{6}$$

yielding

$$v^H = -\frac{\hat{L}^h_{ad}}{\hat{L}^H_{ad}}v^h\,. \tag{7}$$

Denoting

$$C(\omega_1, \omega_2) = \frac{\hat{L}^h_{ad}(\omega_1, \omega_2)}{\hat{L}^H_{ad}(\omega_1, \omega_2)}\,,$$

we obtain that the two-level amplification factor ν of the fine-grid error, defined as the ratio of the new fine-grid error (after the correction v^H has been added) to the original error v^h, is given by

$$\nu(\omega_1, \omega_2) = \frac{v^h + v^H}{v^h} = 1 - C(\omega_1, \omega_2)\,. \tag{8}$$

From (2), (3), and (8), for a qth-order discretization of the advection-diffusion operator, we obtain

$$\nu(\omega_1, \omega_2) = 1 - \frac{\epsilon_h T_{q+1}(i\omega_1, i\omega_2) + i\omega_1}{\epsilon_H T_{q+1}(i\omega_1, i\omega_2) + i\omega_1}\,. \tag{9}$$

For most smooth components (and small mesh-sizes) this amplification factor is close to zero, and multigrid convergence can hence be expected to be essentially as good as allowed by the smoothing rate and the number of relaxation sweeps per level. But consider smooth *characteristic error components*, which are smooth (and therefore nearly unaffected by any local-type relaxation), but much smoother in the characteristic direction x than in the cross-characteristic direction y. For such components, $\omega_1/\omega_2 \ll 1$, and their amplification factor is therefore much larger. In the limit of components which only vary in the cross-characteristic direction, we obtain that the two-level *convergence factor* ν_{tl}, which is defined as the maximal (in absolute value) ν over all the frequencies defined on the grid, is given by

$$\nu_{tl} = \nu(0, \omega_2) = 1 - \frac{\epsilon_h}{\epsilon_H} \approx 1 - 0.5^q\,. \tag{10}$$

Asymptotically the poorly corrected characteristic components become dominant, and the error norm is reduced at best by a factor of $1 - 0.5^q$, even with two-level cycles.

3. Multilevel local mode analysis. The multigrid *cycle index* γ is defined as the number of times a correction from the next coarser grid is taken by each intermediate level in calculating its solution, before that solution is used to correct the error on the next finer grid. Thus $\gamma = 1$ is the index of the so-called V cycle, and $\gamma = 2$ is the index of the W cycle. Actual multigrid cycles need to employ a fairly small cycle index γ if the total work is to grow only linearly with the number of variables: in d dimensions, γ must be smaller than 2^d. Let us therefore determine by analysis the expected multilevel amplification factor of an error component whose two-level amplification factor $1 - C$ is assumed to be independent of the mesh-size. This simplifying assumption is only valid for the extreme cases where, in (9), ω_1 vanishes, in which case C equals $\epsilon_h/\epsilon_{2h} \approx 0.5^q$, or where T_{q+1} vanishes, in which case C equals one. This is appropriate here since these extreme cases determine the worst-case amplification factor. Moreover, this analysis of the multigrid cycle is not restricted to the advection-diffusion equation.

Consider a multigrid cycle that is implemented on $n+1$ levels numbered $0, \dots, n$, with n denoting the finest grid. For each error component there corresponds a "solution level" i on which it is sufficiently nonsmooth so as to be eliminated efficiently by relaxation (or perhaps direct solution in the case $i = 0$). To simplify, we assume that every error component is eliminated completely on its solution level, but that on all finer grids it is unaffected by relaxation. Let us denote by $\nu_\gamma^{n-i}(C)$ the level-n amplification factor of an error component, whose two-level amplification factor is $1 - C$ and whose solution level is i, in a multigrid cycle with cycle index γ. Let $k = n - i$. Under the assumptions above, we have for $k = 0$

$$\nu_\gamma^0 = 0\,, \tag{11}$$

and for $k = 1$

$$\nu_\gamma^1 = 1 - C, \tag{12}$$

regardless of γ (the latter is simply the two-level cycle by definition). For $1 < k \le n$ the residual problem is transferred to the next coarser grid (level $k-1$), and γ multigrid cycles (in which the corresponding amplification factor for that component is ν_γ^{k-1}) are performed. As a result, the error in the solution to the coarse-grid problem is reduced by a factor of $(\nu_\gamma^{k-1})^\gamma$. This approximate correction is now transferred back to the fine grid, but multiplied by C (since even the exact solution to the coarse-grid problem only yields C times the required correction). This yields the following recurrence equation:

$$\nu_\gamma^k = 1 - C \cdot \left[1 - (\nu_\gamma^{k-1})^\gamma\right] = \nu_\gamma^1 + C(\nu_\gamma^{k-1})^\gamma\,, \qquad 1 \le k \le n\,. \tag{13}$$

3.1. Properties of the multilevel cycle. In the following discussion we consider only real values of C, since C is real in both extreme cases of the advection-diffusion equation: when the coarse-grid correction is worst, and when it is best. This assumption will greatly simplify the discussion. Also, it is of course unnecessary to consider nonpositive real values for C, since these would imply that the coarse grid does not approximate the corresponding components at all, in which case special measures need to be taken.

Remark 1. The fixed points of (13) are solutions of

$$\nu = 1 - C(1 - \nu^\gamma)\,. \tag{14}$$

$\nu = 1$ is a fixed point for every γ. When $C < 1$ it is the only one in the case of a V cycle ($\gamma = 1$). *W* cycles ($\gamma = 2$) have a second fixed point at $\nu = (1 - C)/C$.

PROPOSITION 1. *For every $k \geq 1$,*

$$\nu_1^k = 1 - C^k . \tag{15}$$

Proof. By induction: $\nu_1^1 = 1 - C$, and by (13) and the induction hypothesis,

$$\nu_1^k = 1 - C + C(1 - C^{k-1}) = 1 - C^k . \qquad \square$$

Conclusion. The convergence rate of the multigrid V cycle deteriorates rapidly as the number of levels grows, unless C is close to 1. In particular, the V cycle is clearly unsuitable for the advection-diffusion equation, even with first-order discretization.

PROPOSITION 2. *For all $0 < C < 1$ and all positive k and γ,*

$$0 \leq \nu_\gamma^{k-1} < \nu_\gamma^k < 1. \tag{16}$$

Proof. By induction: $0 < \nu_\gamma^1 = 1 - C < 1$, and by (13) and the induction hypothesis,

$$\nu_\gamma^{k+1} = 1 - C \cdot [1 - (\nu_\gamma^k)^\gamma] < 1 \tag{17}$$

and

$$\nu_\gamma^{k+1} - \nu_\gamma^k = C \cdot \left[(\nu_\gamma^k)^\gamma - (\nu_\gamma^{k-1})^\gamma\right] > 0 . \tag{18} \qquad \square$$

PROPOSITION 3. *For all $0 < C < 1$, ν_2^k tends to the smaller of the two fixed points (1 and $(1 - C)/C$) as k tends to infinity.*

Proof. For $k \geq 0$, by (16) we have

$$\begin{aligned} \frac{\left|\frac{1-C}{C} - \nu_2^{k+1}\right|}{\left|\frac{1-C}{C} - \nu_2^k\right|} &= \frac{\left|\frac{1-C}{C} - 1 + C \cdot [1 - (\nu_2^k)^2]\right|}{\left|\frac{1-C}{C} - \nu_2^k\right|} \\ &= \frac{\frac{1}{C}\left|(1-C)^2 - (C\nu_2^k)^2\right|}{\frac{1}{C}\left|1 - C - C\nu_2^k\right|} = \left|1 - C(1 - \nu_2^k)\right| < 1 . \end{aligned} \tag{19}$$

The proof follows from this and Proposition 2. $\square$

Conclusion. Proposition 3 implies that ν_2^k tends to one when $0 < C \leq 0.5$. Thus, the convergence factor of the W cycle for the advection-diffusion equation with first-order discretization tends to one as the number of levels tends to infinity.

We reiterate that this analysis assumes that relaxation is of a local type, and therefore has a negligible effect on all components that are smooth on the scale of the grid on which they are relaxed. A different situation may arise in cases such as *entering flow* problems, which are studied in [7]. When relaxation is performed in downstream ordering in such problems, it no longer has a purely local effect. Indeed, for the advection equation with upstream differencing, if relaxation is carried out in downstream ordering, it performs as a *solver* and not just as a *smoother*. Convergence of the advection-diffusion equation is discussed in [8], and much better rates than the ones predicted by our analysis are obtained. But the model problems are precisely of the entering flow type, and at least some of the relaxation sweeps are carried out in downstream ordering. This point, however, which explains a number of phenomena in the numerical results that are obtained there as well as in other publications, and which is the key to further achievements with much more complicated schemes, seems to have been overlooked. Also, in some flow problems, the actual Reynolds number in the regions of recirculation are very much smaller than the nominal values (because the velocities in these regions are small), and somewhat better performance may then be found (e.g., in [10]).

4. Method of overweighted residuals. A very simple and almost cost-free approach to accelerating convergence is the method of overweighted residuals (OWR). The idea, which is reminiscent of the method of successive overrelaxation (SOR), is to improve the coarse-grid correction to the error in the fine-grid approximation by multiplying the residuals that are transferred to the coarse grid by some constant η between one and two. Clearly, η should not be too large, since those components that usually receive the proper correction are now overcorrected. It is best to determine an optimal overweighting factor η, which will depend on the number of levels employed.

4.1. Two-level single-parameter optimization. Let ξ denote the minimal C over all the frequencies defined on the fine grid (for the advection-diffusion case, $\xi = 0.5^q$). Then the poorest (largest) corresponding error-amplification factor in the usual two-level cycle (with $\eta = 1$) is $1 - \xi$, whereas the best amplification factor is zero. When the residuals are multiplied by the factor η, however, the two extreme error-amplification factors are now given by $1 - \eta\xi$ and $1 - \eta$ (by (6–8)). Due to the monotonicity of these terms, the optimal two-level overweighting factor η_{tl} is obtained when

$$|1 - \eta_{tl}\xi| = |1 - \eta_{tl}|, \tag{20}$$

and therefore

$$\eta_{tl} = \frac{2}{1+\xi}. \tag{21}$$

The two-level convergence factor ν_{tl} decreases accordingly from $1 - \xi$ to

$$\nu_{tl} = 1 - \eta_{tl}\xi = \frac{1-\xi}{1+\xi}. \tag{22}$$

The two-level convergence factor of the advection-diffusion equation (with vanishing diffusion coefficient) employing first-order discretization, for example, improves from 0.5 to 0.33 with $\eta_{tl} = 4/3$.

4.2. Multilevel single-parameter optimization. Propositions 2 and 3 imply that the components that converge most slowly, for a fixed C in (0,1), are those whose solution level is the lowest ($k = n$). When the number of levels is large, the amplification factor of such errors by a W cycle tends to $(1 - C)/C$ when C is between one half and one. For the *overcorrected* components in a cycle with an even cycle index γ, however, we have the following.

PROPOSITION 4. *For all* $1 < C < 2$, *even* γ, *and* $k \geq 1$,

$$|\nu_\gamma^k| \leq |\nu_\gamma^1| = C - 1. \tag{23}$$

Proof. By induction: For $k \geq 1$

$$C - 1 - |\nu_\gamma^{k+1}| = C - 1 - |1 - C + C(\nu_\gamma^k)^\gamma|, \tag{24}$$

but

$$C - 1 + 1 - C + C(\nu_\gamma^k)^\gamma > 0\,, \tag{25}$$

and alternatively

$$C - 1 - (1 - C + C(\nu_\gamma^k)^\gamma) \geq 2(C-1) - C(C-1)^\gamma > 0\,, \tag{26}$$

where in (26) the first inequality is trivial for $k = 1$ and is due to the induction hypothesis for $k > 1$, and the second is due to the range of C. □

Conclusion. The components that converge most slowly when $1 < C < 2$ are those that are corrected on the *second-finest* level ($k = 1$), and the convergence factor for such overcorrected components is at least as good as the two-level rate when γ is even. This is true in particular for the W cycle ($\gamma = 2$). Hence, the optimal multilevel overweighting factor η_{ml} for the W cycle is obtained when

$$\left|\frac{1 - \eta_{ml}\xi}{\eta_{ml}\xi}\right| = |1 - \eta_{ml}|\,, \tag{27}$$

yielding

$$\eta_{ml} = \xi^{-1/2}\,. \tag{28}$$

This value is valid only when $\eta_{ml} < 2$. For $\xi \leq 0.25$ the multilevel convergence factor must tend to one as the number of levels grows. The W-cycle multilevel convergence factor ν_{ml} of the advection-diffusion equation with vanishing diffusion coefficient and first-order discretization thus improves from 1 to $\sqrt{2} - 1 \approx 0.41$, with the optimal overweighting factor $\eta_{ml} = \sqrt{2}$.

With a finite number of levels, the optimal overweighting factor is reduced somewhat, yielding slightly better convergence rates. It is thus possible to calculate the optimal overweighting factors for each level. These start with 4/3 for the second-coarsest grid and increase until they tend to $\sqrt{2}$ as the grid becomes finer. However, there is not much practical gain in doing such careful optimization, since on very coarse grids the assumptions made in the analysis are rather poor anyway, and also the optimal η quickly tends to $\sqrt{2}$. *One can thus uniformly use the overweighting parameter $\eta = \sqrt{2}$.*

4.3. Two-level multiparameter optimization. In the optimizations described above we have considered only a single cycle, and therefore only a single overweighting parameter η. But since we are dealing with asymptotic convergence rates, it is implied that several cycles are performed. Also, since (at least) W cycles need to be employed, more than one cycle per level is performed. This suggests using several different overweighting factors in order to further reduce the error-amplification factor. This is a special case of *polynomial acceleration*, and the optimal choice of overweighting factors, which is calculated with the aid of *Chebyshev polynomials*, yields *optimal Chebyshev acceleration* (see, e.g., [9]).

Consider a smooth error component for which the ratio between the fine-grid and coarse-grid symbols is C, $\xi \leq C \leq 1$. Suppose that m two-level cycles are performed, where the residuals in the jth cycle, $j = 1, \ldots, m$, are overweighted by a factor of η_j. The factor by which the error is amplified in this process is given by

$$[\nu^m(C)]^m = \prod_{j=1}^{m}(1 - \eta_j C)\,, \tag{29}$$

where $\nu^m(C)$ is the average amplification factor per cycle. Assuming, as above, that the extreme eigenvalues of the two-level operator are 0 and $1-\xi$, the optimal polynomial $\nu_{tl}^m(C)$, i.e., the one for which the maximal absolute value over all C's in the interval is minimized, is given by

$$\nu_{tl}^m(C) = \left[\frac{\mathcal{T}_m\left(\frac{1+\xi-2C}{1-\xi}\right)}{\mathcal{T}_m\left(\frac{1+\xi}{1-\xi}\right)}\right]^{1/m}, \tag{30}$$

where $\mathcal{T}_m$ is the Chebyshev polynomial of degree m, given by

$$\mathcal{T}_m(x) = \begin{cases} \cos(m\cos^{-1}x), & -1 \le x \le 1, \\ \cosh(m\cosh^{-1}x), & 1 < x \end{cases} \tag{31}$$

(see [9] for the general development). By (29) the optimal η_j's are the inverses of the zeros of ν_{tl}^m, which can easily be calculated from (31). For $m=1$ the optimal overweighting factor is indeed as in (21), and for $m=2$ the two optimal factors are given by

$$\eta_j = \frac{2}{1+\xi \pm \frac{1-\xi}{\sqrt{2}}}, \qquad j = 1,2. \tag{32}$$

The average amplification factor per cycle of the error is given by

$$\nu_{tl}^m(1) = \left[\mathcal{T}_m\left(\frac{1+\xi}{1-\xi}\right)\right]^{-1/m}. \tag{33}$$

For the advection-diffusion equation with first-order discretization ($\xi = 0.5$), the single-cycle optimization ($m=1$) thus yields a two-level convergence factor of 0.33 per cycle as shown above. Two-cycle optimization ($m=2$) yields an average two-level convergence factor of 0.24 with the optimal overweighting factors of 1.079 and 1.745, and the asymptotic (infinite number of cycles) average two-level convergence factor with optimal overweighting factors is 0.17. With second-order discretization ($\xi = 0.25$) the single-cycle optimization yields a two-level convergence factor of 0.60 per cycle with $\eta = 1.60$. Two-cycle optimization yields an average two-level convergence factor of 0.47 with the optimal overweighting factors of 1.123 and 2.779, and the asymptotic average two-level convergence factor with optimal overweighting is 0.33. However, large overweighting factors are unlikely to be useful in practice, if only because the corresponding amplification of nonsmooth error components means that much better smoothing is then required.

An automatic acceleration method, which would not require a priori analysis, is conceivably useful. However, since the ultimate goal is to employ at most one or two cycles per level in the solution process, methods whose usefulness relies on the execution of many cycles are unlikely to be truly efficient.

4.4. γ-cycle optimization. In a multigrid cycle with cycle index γ there are γ overweighting factors to be chosen for the γ visits to the next coarser grid at each level. Consider again a smooth error component for which the ratio between the fine-grid and coarse-grid symbols is C, $\xi \le C \le 1$. Then, if the overweighting factors η_j are chosen independently of the level, the error amplification factor *of γ cycles* on level $i+k$ is given by the recurrence equation

$$(\nu_\gamma^k)^\gamma = \prod_{j=1}^{\gamma} \left[1 - \eta_j C\left(1 - (\nu_\gamma^{k-1})^\gamma\right)\right] , \tag{34}$$

with

$$\nu_\gamma^0 = 0 . \tag{35}$$

Again a recurrence equation is obtained, for which 1 is a fixed point. The optimization of the η_j's generally needs to be done numerically. The optimal overweighting factors for the W cycle with $\xi = 0.5$ (e.g., for first-order approximations to the advection equation) are 1.085 and 1.843, yielding a convergence factor per single W cycle of 0.27, whereas the single-parameter optimization yields 0.41.

4.5. Numerical experiments. Numerical experiments were carried out with the advection-diffusion equation, discretized by second-order central differences with an added first-order isotropic artificial viscosity term discretized by the five-point star (the importance of the isotropy of the viscosity coefficients is elaborated upon in [6]). The problem solved was

$$-\epsilon \Delta u + \sin(\pi y) \cos(\pi x)\, u_x - \cos(\pi y) \sin(\pi x)\, u_y = 0 ,$$

over the unit square. The results reported here were obtained with Dirichlet boundary conditions and exact solution zero, in order to allow a very large number of cycles without encountering roundoff errors. The algorithms were tested with smooth nonzero solutions as well, and nearly identical performance was observed until (double-precision) roundoff errors were encountered. Since the physical viscosity coefficient ϵ was taken to be zero, the coefficients of the equation are very small at and near the stagnation point $(\frac{1}{2}, \frac{1}{2})$. When residuals are transferred with some averaging, such as the usual full-weighting that was used in these calculations, the right-hand side on the coarse grid in these regions may be much larger than the coefficients, resulting in reduced performance or even instability. This is best overcome by using averaged coefficients in the calculation of the artificial viscosity. Here we determined the artificial viscosity by adding the absolute value of the coefficient at the point of discretization with weight $\frac{1}{2}$ to those of the four nearest neighbors with weights $\frac{1}{8}$, and multiplying this weighted average by $\frac{h}{2}$ as usual. This averaging introduces only an $O(h^3)$ change in the usual artificial viscosity.

The asymptotic convergence factors of the dynamic residuals with various overweighting factors η are presented in Table 1 along with the predictions of the analyses presented above. The fine mesh-size for the two-level results is 1/64. The multilevel results were obtained with four levels, the finest mesh-size being 1/128, and the analytical prediction refers to a four-level (not infinite-level) cycle, and is calculated from (13). The optimal η is then 1.40—slightly smaller than the infinite-level optimum of $\sqrt{2}$.

The multilevel results were calculated with a W(2,1) cycle (a W cycle with two pre- and one postrelaxation per level), and it was verified that increasing the number of relaxation sweeps per level results in only a negligible improvement in the performance, so that indeed three sweeps per level reduce the high-frequency error components sufficiently, and the convergence rate is determined by the coarse-grid correction.

TABLE 1
Asymptotic residual convergence factors of numerical calculations for the advection-diffusion (AD) *equation and incompressible Navier–Stokes* (INS) *equations are compared with analytical predictions for various single overweighting factors η. Two pre- and one postrelaxation sweeps were employed.*

η	Two-level			Multilevel		
	Analytical prediction	Numerical AD	Numerical INS	Analytical prediction	Numerical AD	Numerical INS
1.00	0.50	0.50	0.49	0.69	0.68	0.66
1.10	0.45	0.45	0.45	0.62	0.61	0.61
1.20	0.40	0.39	0.40	0.55	0.54	0.54
1.30	0.35	0.34	0.33	0.47	0.46	0.45
1.33	0.33	0.33	0.33	0.44	0.44	0.46
1.40	0.40	0.38	0.40	0.40	0.40	0.51
1.50	0.50	0.45	0.51	0.50	0.50	0.63

The experiments were repeated with the incompressible Navier–Stokes (INS) equations in two dimensions, over the unit square with a square of side 0.25 removed from its center. Both the inner and outer squares' sides were aligned with the grid. Dirichlet boundary conditions for the velocities were specified at the inner and outer boundaries. The velocities normal to the boundaries were all made to vanish. The tangential velocities at the inner boundaries were set to zero as well, but the tangential velocities at the outer boundaries were prescribed to be

$$U_{\tan} = \sin \pi s\,,$$

with s varying from 0 to 1 along each side of the outer square, and $U_{\tan}$ driving the flow in the clockwise direction. These conditions and this domain yield a smooth flow with closed streamlines and almost no boundary layers. We chose such a flow because boundary layers constitute a separate problem that needs to be treated by its own specialized methods. Slow convergence due to poor resolution on coarse grids is unrelated to the problem of poor convergence of certain *smooth* components, which is examined here.

The cycle parameters chosen were the same as for the advection-diffusion (AD) equation tests. The discretization used in [5] and [2] was employed with first-order isotropic artificial viscosity, and the Reynolds number solved with was 10^{-6}, so that the physical viscosity was everywhere negligible relative to the artificial viscosity. This is implied by the analysis (and verified by experiments) to be the most difficult case with respect to rate of convergence. Adding physical viscosity, while fixing the overweighting factors, *always* resulted in improved convergence rates.

Now the number of cycles performed was limited by the double-precision roundoff errors. Distributive Gauss–Seidel relaxation with red-black ordering (see [2]) was used throughout. These results are also listed in Table 1 and compared with the analytical prediction for the AD equation.

The numerical results match the analytical prediction very closely. The only exceptions are INS multilevel results with large η's. These, and also the corresponding results in Table 2, indicate greater sensitivity to large overweighting factors in the solution of the system.

Note that *only the momentum equation residuals need to be overweighted.* This is due to the fact that the continuity equation contributes an elliptic component (the Laplacian operator) to the system, for which overweighting is unnecessary. This point has been verified by two-level analysis of the linearized incompressible flow equations.

Experiments were also carried out with the advection-diffusion problem using two different η's. The average two-level convergence factor was 0.34 with the theoretically optimal two-level overweighting factors, and the average multilevel convergence factor was 0.43 when two prerelaxation sweeps and one postrelaxation sweep were employed. The large overweighting factors apparently cause problems. One of these is that overweighting undesirably amplifies high-frequency residuals as well as low-frequency ones, so more smoothing is necessary. Also, since the coarse-grid correction is improved, still more smoothing is required in order to reduce high-frequency errors sufficiently for the smaller convergence factor. Indeed, better performance was obtained when the number of relaxation sweeps per level was increased. With two prerelaxation and two postrelaxation sweeps, the convergence factor attained with the two-level cycle was 0.26 (rather than the theoretical 0.24), and the multilevel factor was 0.37 (rather than the theoretical 0.27). It seems that the assumptions of the analysis are no longer valid, since now intermediate eigenvalues also figure in the convergence rates, and these are neither real nor grid independent.

It is possible to find somewhat smaller overweighting factors that may provide improved results. This requires either a more sophisticated analysis that takes into account high-frequency phenomena, or numerical experimentation in the form of an automatic acceleration process. But in view of the results presented below, this does not seem to be the most profitable course.

5. The defect-correction W (DCW) cycle. The method of defect-correction iterations is a well-known tool for obtaining solutions with high-order accurate operators that are unstable, and that therefore cannot be used directly. This method can be embedded into the multigrid cycle as a means of accelerating convergence.

The basic defect-correction method is as follows. Suppose we wish to obtain an approximate solution to some equation

$$Lu = f \tag{36}$$

with suitable boundary conditions. We would like to use some finite difference operator L_2^h for approximating the differential operator L on a grid with mesh-size h, but cannot use it directly, say, due to problems of instability. Instead, we use another (usually lower-order) operator L_1^h, which is stable, and we hope to approach the L_2^h approximation via the following iterative process:

$$L_1^h u_i^h = f^h + (L_1^h - L_2^h) u_{i-1}^h\,, \tag{37}$$

where $i \geq 1$ is the iteration number and $u_0^h = 0$. Here again the h superscripts denote functions and operators defined on grid h. If this process converges, it must clearly converge to the solution with the operator L_2^h. In elliptic cases the convergence is usually fast for smooth solution components, in terms of which L_1^h is indeed a good approximation to L_2^h, while the slow convergence of nonsmooth components may actually be an advantage, since for them L_1^h may be better than L_2^h.

A form of this defect-correction process can be used for accelerating the convergence rate when it is slowed down by the poor coarse-grid correction to certain components. We present this technique here as employed in a W cycle, but the generalization to greater cycle indices γ is straightforward.

The two-level *correction scheme* DCW cycle for the solution of the discrete problem

$$L^h u^h = f^h \tag{38}$$

is defined as follows:

1. Start with some initial approximation to u^h on the fine grid h. Smooth the error corresponding to this approximation by some number of relaxation sweeps, obtaining $\tilde{u}^h$.

2. Transfer residuals to the coarse grid H, and solve the first coarse-grid problem

$$L^H v_1^H = r^H \equiv I_h^H \left(f^h - L^h \tilde{u}^h\right) , \tag{39}$$

where the H superscripts denote operators and functions defined on the coarse grid and I_h^H is some transfer operator from grid h to grid H.

3. Calculate and add to the right-hand side a defect-correction term, and solve the second coarse-grid problem:

$$L^H v_2^H = r^H + (L^H - L_h^H) v_1^H , \tag{40}$$

where L_h^H is some approximation to L^h on grid H, which is significantly better than L^H, as explained below.

4. Interpolate and add the correction v_2^H to $\tilde{u}^h$, and smooth this new approximation with some number of relaxation sweeps.

The operator L_h^H used in (40) is some higher-order grid H approximation to the fine-grid operator L^h, which is not used directly, e.g., because it cannot be smoothed efficiently. For example, if L^h and L^H are first-order upstream discretizations of the advection operator on grid h and H, respectively, then they can be viewed as second-order central difference approximations with added artificial viscosity that is proportional to the mesh-size. L_h^H can then be chosen to be a central-difference discretization plus artificial viscosity with coefficients that correspond to grid h, all discretized on grid H. This is then a second-order approximation to L^h. More generally, if L^h is an approximation of order q on grid h to the differential operator L, and, similarly, L^H is a qth-order approximation to L (and L^h) on grid H, then L_h^H can be any operator on grid H which is (at least) a $q+$ 1st-order approximation to L^h.

The step described in (40) is an attempt to improve the correction yielded by the coarse-grid operator. An alternative view comes to light when $L^H v_1^H$ is subtracted from both sides of (40), yielding

$$L^H (v_2^H - v_1^H) = r^H - L_h^H v_1^H . \tag{41}$$

Viewed thus, the DCW acts as two cycles, except that the visit to the fine grid between the cycles has been skipped, and the process of adding v_1^H to the initial fine-grid approximation and recalculating the residuals is approximated on the coarse grid instead. This viewpoint will later be useful in the analysis.

The multilevel DCW correction cycle is similarly defined, except that the coarse-grid problems are not solved exactly, but rather by a similar DCW cycle (each) on the coarser grid. This is done recursively, and only on the coarsest grid are the problems solved exactly. Note that the cycle index is two (W cycle), which is the reason for the name DCW.

5.1. DCW with FAS. The DCW cycle can of course be implemented with the full approximation scheme (FAS), but it is important to note that the defect correction process must be applied only to the *correction* given by the first "leg" of the W cycle, and not to the full solution. As in the usual FAS algorithm, (39) is now replaced by

$$L^H u_1^H = L^H \hat{I}_h^H \tilde{u}^h + r^H, \tag{42}$$

where $\hat{I}_h^H$ is some transfer operator from grid h to grid H, which need not be the same as I_h^H. Equation (40) is replaced by

$$L^H u_2^H = L^H \hat{I}_h^H \tilde{u}^h + r^H + (L^H - L_h^H)(u_1^H - \hat{I}_h^H \tilde{u}^h). \tag{43}$$

Finally, $u_2^H - \hat{I}_h^H \tilde{u}^h$ is interpolated and added to $\tilde{u}^h$ as in the usual FAS multigrid cycle. It is easy to verify that for a linear problem this process is equivalent to the correction-scheme two-level DCW cycle.

5.2. Two-level local mode analysis. We analyze the DCW cycle by the same infinite-space analysis employed in the previous sections, again assuming that the factor that determines the rate of convergence is the coarse-grid correction of smooth error components, whereas high-frequency error components are reduced sufficiently by relaxation. Also, intergrid transfers are again neglected, and the FDA is employed.

Suppose the current error in our approximation to the solution of (38) is

$$v^h = e^{i(\omega_1 x + \omega_2 y)}. \tag{44}$$

The corresponding first coarse-grid problem for the correction is then

$$L^H v_1^H = -L^h v^h. \tag{45}$$

Let $C = C(\omega_1, \omega_2) = \hat{L}^h(\omega_1, \omega_2)/\hat{L}^H(\omega_1, \omega_2)$, as in the previous sections. Now

$$v_1^H = -C v^h,$$

and the second coarse-grid problem, following (41), is

$$L^H (v_2^H - v_1^H) = -L^h v^h (1 - C), \tag{46}$$

where no distinction has been made between the actual fine-grid operator L^h and its coarse-grid approximation L_h^H, since the two are equivalent under the FDA. The solution to (46) is

$$v_2^H - v_1^H = -C(1 - C) v^h,$$

and the error-amplification factor ν after the correction has been added to the fine-grid solution is

$$\nu = \frac{v_{new}^h}{v^h} = \frac{v^h + v_2^H}{v^h} = (1 - C)^2. \tag{47}$$

This result is quite expected from the point of view of skipping the fine grid. That is, under the present simplifying assumptions the error-amplification factor per cycle is the same as that per two regular cycles as calculated in §2. In particular, the predicted two-level convergence factor per cycle for the first-order discretized advection-diffusion equation is 0.25.

5.3. Multilevel local mode analysis. Following the notation of §3 and the fine-grid skipping viewpoint, we find that, for the multilevel DCW cycle, the one-dimensional map describing the error-amplification factor ν^k (see derivation of (13) with $\gamma = 2$ for the regular W cycle) is given by

$$\nu^k = \left[1 - C(1 - \nu^{k-1})\right]^2 \tag{48}$$

for $k > 0$, with $\nu^0 = 0$. γ is omitted in the notation, since we are only considering a W cycle. Observe now that (48) could also have been obtained from (13) with $\gamma = 2$ by squaring both sides and substituting ν^k and ν^{k-1} for $(\nu_2^k)^2$ and $(\nu_2^{k-1})^2$. So the multilevel DCW cycle is seen to be equivalent to two regular W cycles under the assumptions of this analysis.

Conclusion. The convergence factor of the multilevel DCW cycle for the advection-diffusion equation with first-order discretization ($\xi = 0.5$) tends to one as the number of levels tends to infinity.

5.4. Combining the DCW cycle with OWR. We have seen that the DCW cycle itself does not solve the problem of poor convergence rates when the number of levels is very large, although the rate is squared for a given number of levels. A natural approach is to try to incorporate residual overweighting into the DCW cycle.

5.4.1. η-optimization. The proper way of applying residual overweighting in the DCW cycle is again best seen from the fine-grid skipping point of view. So considered, it is clear that not only do the residuals need to be multiplied by the overweighting factor η, but so does the term $-L_h^H v_1^H$ in (41), which approximates the term that would have been added to the fine-grid residual had the fine grid been visited. By (47), the resulting two-level error-amplification factor with single-parameter overweighting is given by

$$\nu_{tl} = (1 - \eta\xi)^2, \tag{49}$$

where ξ is again the minimal $\hat{L}^h/\hat{L}^H$.

The optimal η is of course the same as that for the regular cycle given in (21) and, by (22), ν_{tl} with the optimal two-level overweighting factor is given by

$$\nu_{tl} = \left(\frac{1-\xi}{1+\xi}\right)^2. \tag{50}$$

This yields a very satisfactory two-level convergence factor per cycle of 0.11 for the first-order discretized advection-diffusion equation.

The optimal multilevel overweighting factor η_{ml} is also the same as for the regular W cycle ($\xi^{-1/2}$), and the multilevel convergence factor, following (27)–(28), is

$$\nu_{ml} = (1 - \xi^{-1/2})^2. \tag{51}$$

For the first-order discretized advection-diffusion equation, $\xi = 0.5$ and $\nu_{ml} = 0.17$.

Multiparameter optimization is also performed as in the case of a regular cycle.

5.5. Defect-correcting for finer levels. In the DCW cycle as presented above, the defect corrections were all used to improve the approximation to the problem on the next-finer grid. But since it is only the *finest*-grid problem whose solution is sought, and not those of the intermediate grids, faster convergence may be obtained by employing operators of a much finer grid in the defect-correction stage. Clearly this will not affect two-level performance, since then the finest grid is used in the defect correction anyway, but multilevel performance may be improved.

Many schemes are possible, and we consider here the ultimate one of using the operator of the finest grid in all the defect corrections. Under the assumptions of the present analysis, in which the effect of relaxation is disregarded, this scheme is equivalent to employing *double discretization* (see [2]) within a W cycle. (In the double discretization method, *all* the residuals are calculated with the fine-grid operator, but since the initial solution on intermediate levels is zero and the effect of relaxation is disregarded, it does not matter which operator is used on the first leg of the W cycle.) Since now the scheme used on each grid depends on the finest mesh-size, or rather on the ratio of the current mesh-size to the finest one, the multilevel local mode analysis produces a family of recurrence equations rather than just one. Let $k = n - i$ again denote the difference between the finest level n and the solution level i, and let $\nu^{j,k}$ denote the error-amplification factor at level $i + j$ when the finest level is $n = i + k$. Suppose that the error in the approximation to the equation on level $i + j$ is v^j. Then the first leg of the DCW cycle produces a correction v_1^{j-1} of $-C(1 - \nu^{j-1,k})v^j$, as in the regular W cycle, but the second leg now produces an additional correction $v_2^{j-1} - v_1^{j-1}$ of $C(1 - \nu^{j-1,k})[-1 + C^{k-j+1}(1 - \nu^{j-1,k})]v^j$, rather than $C(1 - \nu^{j-1,k})[-1 + C(1 - \nu^{j-1,k})]v^j$ of the usual DCW cycle, since the ratio of the symbol of the operator on level $i + j - 1$ to that of the finest-level operator is C^{k-j+1}. Hence, $\nu^{j,k}$ is given by

$$\nu^{j,k} = 1 - 2C(1 - \nu^{j-1,k}) + C^{k-j+2}(1 - \nu^{j-1,k})^2 \,, \tag{52}$$

for $j \geq 1$ with $\nu^{0,k} = 0$.

From (52) it is clear that for large values of k some of the $\nu^{j,k}$'s may be quite large in absolute value. But these only express the error-amplification factors for intermediate grids, which are unimportant, because the purpose of the algorithm is to reduce the error on the *finest grid* as efficiently as possible. The only interesting value is therefore $\nu^{k,k}$, which is given by

$$\nu^{k,k} = (1 - C^k)^{2^k} \,. \tag{53}$$

This result can be proved from (52) by fixing k and performing an induction on j to show that the appropriate binomial expansion is obtained when $j = k$. The proof is omitted due to its length and its irrelevance to the main theme. However, the result is again clear from the fine-grid skipping point of view, although now *all* the levels that are finer than the solution level are skipped. The correction on the solution level is only C^k times the required correction, but 2^k visits are made to this level, in agreement with (53).

PROPOSITION 5. *The maximal $\nu^{k,k}$ over all $\xi \leq C \leq 1$ and $k \geq 1$ tends to e^{-1} for $\xi = 0.5$ and to 1 for $0 \leq \xi < 0.5$.*

Proof. For a fixed k and $0 \leq C \leq 1$, $\nu^{k,k}$ in (53) decreases monotonically as C increases. Therefore, the maximum is obtained when $C = \xi$. Also, for all $k \geq 1$ and $0 < \xi \leq 0.5$,

$$\begin{aligned}\frac{\nu^{k+1,k+1}}{\nu^{k,k}} &= \frac{(1-\xi^{k+1})^{2^{k+1}}}{(1-\xi^k)^{2^k}} \\ &= \left(\frac{(1-\xi\cdot\xi^k)^2}{1-\xi^k}\right)^{2^k} \\ &= \left(\frac{1-2\xi\cdot\xi^k+\xi^{2k+2}}{1-\xi^k}\right)^{2^k} = \left(1+\frac{(1-2\xi)\cdot\xi^k+\xi^{2k+2}}{1-\xi^k}\right)^{2^k} > 1.\end{aligned} \tag{54}$$

Hence, the maximal $\nu^{k,k}$ is obtained when $k \to \infty$, and is given by

$$\nu_{ml} = \lim_{k\to\infty}(1-\xi^k)^{2^k} = \lim_{k\to\infty} e^{-(2\xi)^k} = \begin{cases} 1, & 0<\xi<0.5, \\ e^{-1}, & \xi = 0.5. \end{cases} \tag{55}$$ □

Conclusion. The present DCW cycle yields an error-amplification factor of e^{-1} with a multilevel cycle for the first-order discretized advection-diffusion equation.

5.5.1. Combining defect corrections for the finest level with OWR. From (53) it may seem that the method of overweighted residuals cannot be profitably combined with defect corrections for the finest level since, if $C > 1$, $\nu^{k,k}$ diverges as $k \to \infty$. Suppose, however, that the residuals are all transferred with an overweighting factor of η, and the defect-correction term is also multiplied by this factor (rather than by η^{k-j+1}, as is implied by the fine-grid skipping viewpoint). This yields the following recurrence equation for the error-amplification factors $\nu^{j,k}$ (compare with (52)):

$$\nu^{j,k} = 1 - 2\eta C(1-\nu^{j-1,k}) + \eta^2 C^{k-j+2}(1-\nu^{j-1,k})^2 . \tag{56}$$

PROPOSITION 6. *For all* $0.5 \le C \le 1$ *and all* $k \ge 1$, (56) *with the optimal two-level overweighting factor* $\eta = 4/3$ *satisfies*

$$\nu^{k,k}(C) \le \nu^{1,1}(1) = \tfrac{1}{9} . \tag{57}$$

Rather than attempting the difficult task of proving Proposition 6 directly, let us note again that in the present algorithm the solution level can be viewed as solving directly for the correction for the finest grid, rather than for its next-finer grid. But it only yields C^k of the required correction per visit (multiplied by some coefficient that depends on the overweighting factor η). Therefore, $\nu^{k,k}$, which is a polynomial in C with coefficients that depend on η, can also be written as a polynomial in C^k. Let us define accordingly

$$\mu^{k,k}(C^k) \overset{\text{def}}{=} \nu^{k,k}(C) . \tag{58}$$

$\mu^{k,k}$ also describes the amplification factor of the fine-grid error, but in units of the solution-level correction, rather than the finest-level correction. Therefore, it satisfies a recurrence relationship similar to (56), but with C replaced by 1. In particular, $\mu^{j,k} = \mu^{j,j}$ for all $1 \le j \le k$, yielding the recurrence relationship

$$\mu^{k,k}(C^k) = \left[1-\eta(1-\mu^{k-1,k-1}(C^k))\right]^2 \tag{59}$$

for $k > 1$, with

$$\mu^{1,1}(C^k) = \left(1-\eta C^k\right)^2 . \tag{60}$$

From this relationship it is fairly straightforward to prove Proposition 6, since the conditions that $\mu^{k,k}$ must satisfy can be traced back to sufficient conditions on $\mu^{1,1}$, which can be shown by induction to be satisfied. We omit the proof since it is irrelevant to the main issues and somewhat lengthy.

Conclusion. Under the present assumptions the optimal two-level convergence factor of 0.11 is attainable with a multilevel cycle.

5.6. Numerical experiments. Numerical experiments were carried out with the same problems as for the method of OWR (§4.5). The fine mesh-size in the two-level experiments was again 1/64, and four levels were employed in the multilevel cycles, the finest mesh-size again being 1/128. The same discretizations were employed.

The operator L_h^H was chosen to be a central-difference approximation (to the advection operator), plus artificial viscosity with coefficients that approximate (to second order) the viscosity coefficients corresponding to grid h.

The results with the regular DCW cycle, as described in §5.4 with various overweighting factors η, appear in Table 2. Two prerelaxation and two postrelaxation sweeps were performed, and the experiments were repeated with three pre- and three postrelaxations (results in parentheses).

TABLE 2
Asymptotic residual convergence factors of numerical calculations for the AD *equation and* INS *equations, solved with a* DCW *cycle, are compared with analytical predictions for various single overweighting factors η. Two (three) pre- and two (three) postrelaxation sweeps were employed.*

The numerical performance of the advection-diffusion solver again matches the prediction well. Performance obtained with large overweighting factors is somewhat better than predicted, especially when more relaxation sweeps are carried out. The reason for this is that, when η is larger than 4/3, the slowest components to converge have the second-finest level as their solution level. For these components, relaxation on the finest grid still has a nonnegligible effect, since their frequencies are fairly high. On the other hand, when η is smaller than 4/3, the slowest-converging components have solution levels that are very coarse, so that even if relaxation on their next-finer grid is very effective, the overall improvement in the convergence rate is very small. Results with the incompressible flow equations were not quite as good as predicted, although a very significant improvement was observed. These results improve further if a small amount of extra artificial viscosity is added, yielding a more effective smoother. When the viscosity coefficients are increased by 40 percent, for example, the asymptotic residual convergence factors with $\eta = 4/3$ and six relaxation sweeps per level improve to 0.14 (two-level) and 0.24 (multilevel). Of course, there is then a corresponding loss in accuracy, and the cost of performing more sweeps instead must be weighed against the cost of using slightly greater viscosity with a correspondingly finer grid to regain accuracy. Once again, as in the results listed in Table 1, greater overweighting factors than 4/3 yielded poorer results.

The multilevel experiments were repeated with the improvement of correcting the defect for the finest level, as introduced in §5.5. The results are compared with those predicted by numerical analysis of (56) in Table 3. Again, two (three) pre- and two (three) postrelaxations per level were performed. The numerical results match the predictions well for the advection-diffusion equation, although a total of four relaxation sweeps per level (with the present smoother) did not suffice to reduce the high-frequency errors enough. As more and more levels are used, the assumption of the analysis, that the only significant difference between the coarse-grid operators and the fine-grid ones is in the artificial viscosity, becomes poorer and poorer, since the correction level may be much coarser than the finest level. Hence, somewhat better results can be obtained by defect-correcting just a few levels up, and not all the way to the fine-grid operator. An optimal strategy may be worked out experimentally. The INS performance once again lags behind somewhat, but a highly significant improvement is shown, which is again increased by adding some artificial viscosity. When this viscosity is increased by 40 percent, the asymptotic residual convergence factor with $\eta = 4/3$ and six relaxation sweeps per level improves to 0.18. Once again, there is of course a loss of accuracy, which would require a correspondingly finer grid to offset. A slight further increase can be obtained by defect-correcting just a few levels up, rather than for the finest level.

TABLE 3

Asymptotic residual convergence factors of numerical calculations for the AD *equation and* INS *equations, solved with a* DCW *cycle with defect corrections, calculated by the finest-grid operator, are compared with analytical predictions for various single overweighting factors η, which are calculated numerically from* (56). *Two* (*three*) *pre- and two* (*three*) *postrelaxations were employed.*

6. Conclusions and remarks. Methods of acceleration of multigrid convergence have been developed, analyzed, and tested, the numerical results mostly matching the predictions of the analyses well. With the optimal method of combining residual overweighting and defect corrections within the W cycle, a multilevel convergence factor of about 0.2 has been obtained for the incompressible flow equations, and 0.1 for the advection-diffusion equations with first-order discretization. We note that large overweighting factors may show poorer behavior than expected for the Navier–Stokes solver, unless supplemented by extra relaxation sweeps. Some work may be saved by varying the number of sweeps per level.

Although the analyses and experiments were carried out for the case of vanishing diffusion coefficients, the methods apply to finite-viscosity calculations equally well. The optimal parameters are then reduced, and the results improve accordingly, but using the optimal parameters calculated herein will still yield convergence factors that are at least as good as in the vanishing-viscosity case. This has been verified experimentally, the convergence factors actually improving, even with the present optimal overweighting factors, apparently due to improved smoothing. Finally, these methods can also be used with anisotropic viscosity as in upstream differencing.

The methods as presented here are of quite limited value when used *directly* with second-order accurate discretization. Very large overweighting factors need then be applied, which also amplify high-frequency error components. An approach that appears promising is to employ overweighting in conjunction with upstream discretization and downstream ordering of relaxation. Early results with the advection-diffusion equation (with closed streamlines) have been successful, but only very simple examples have so far been attempted, and this approach requires extensive research.

Acknowledgment. We wish to thank Dr. Kees Venner, presently of the Weizmann Institute, for suggesting the particular averaging scheme used in the numerical experiments, and for verifying most of the numerical results reported with independent calculations.

SOLUTION OF ELLIPTIC SYSTEMS OF PARTIAL DIFFERENTIAL EQUATIONS BY CELL DISCRETIZATION*

JOHN GREENSTADT†

Abstract. The cell discretization algorithm is applied in a straightforward manner to a few very simple elliptic systems of partial differential equations. The discrete approximant of the solution depends, as usual, on sets of coefficients of intracell basis functions, one set for each cell. The usual transformation to new variables, one subset associated with interfaces and the other with cells, is easily generalized to the multivariable case. This renders the calculation almost entirely cellwise independent, and therefore readily parallelizable without special reorganization. The residual dependency in the calculation is in the solution of the system of equations for the interface variables. Because of the small sizes of all the equation systems for the uncoupled discrete variables, Gauss elimination was used throughout to solve them. Results for a simple gradient-divergence system, the Cauchy–Riemann equations, the Stokes problem, and the clamped-plate problem are shown in graphic form.

1. Introduction.

In [4], the treatment of a nonselfadjoint elliptic partial differential equation (PDE) by the cell discretization (CD) method was described. We shall show here how that treatment may be generalized to handle systems of PDEs and show a few simple computed examples of the application of the resulting algorithm.

The standard equation of this type for a single function ψ of x in a domain Ω (in R^n) with boundary Γ is

$$-\nabla\cdot(\overleftrightarrow{a}\cdot\nabla\psi)+\vec{b}\cdot\nabla\psi+c\psi=d, \tag{1.1}$$

where all coefficients may depend on the coordinates and the double arrow over a indicates that it is a diadic (here assumed to be positive-definite symmetric). The boundary condition assumed to hold on Γ is

$$P(s)\,\psi(s)+Q(s)\,\frac{\partial\psi}{\partial n}(s)=R(s), \tag{1.2}$$

where the argument s indicates that the point which it labels is on Γ; points in Ω are denoted by x, y, etc. The left-hand side of (1.2) may be regarded as the result of a so-called *trace* operator $\mathcal{U}$ on the function $\psi(x)$ to produce a function of s defined on Γ.

We shall generalize this equation by first assuming that there are N unknowns $\{\psi_1, \psi_2, \ldots, \psi_N\}$, and that they satisfy the equations

$$\sum_{\beta=1}^{N}\left[-\nabla\cdot(\overleftrightarrow{a}_{\alpha\beta}\cdot\nabla\psi_\beta)+\vec{b}_{\alpha\beta}\cdot\nabla\psi_\beta+c_{\alpha\beta}\,\psi_\beta\right]=d_\alpha \tag{1.3}$$

for $\alpha=1, 2, \ldots, N$. This form includes most of the linear systems which are important in applications.

Part of the CD algorithm is the partitioning of the domain Ω, in which the equations are satisfied, into a set of disjoint (open) subdomains $\{\Omega_1, \Omega_2, \ldots, \Omega_K\}$

which, with their boundaries, together cover Ω. The boundary of Ω is denoted by Γ and the interface between contiguous cells, e.g., Ω_k and Ω_m, is denoted by Γ_{km}. It was pointed out in [3] that all of the interface conditions in all problems (when they are linearized) may be written in the form

$$\begin{aligned}P_{km}(s)\,\psi_k(s) + Q_{km}(s)\,\frac{\partial\psi_k}{\partial n}(s) - R_{km}(s)\\ = P_{mk}(s)\,\psi_m(s) + Q_{mk}(s)\,\frac{\partial\psi_m}{\partial n}(s) - R_{mk}(s),\end{aligned} \tag{1.4}$$

in which the various trace operators are defined with reference to their own cells only. This means that we may treat Ω_k as if it were in isolation, and the interface conditions on its bounding faces as if they were boundary conditions on ψ_k. We follow the plan, therefore, of generalizing (1.2) on the boundary of a single cell, and assume that

$$\sum_{\beta=1}^{N}\left[P_{c\beta}(s)\,\psi_\beta(s) + Q_{c\beta}(s)\,\frac{\partial\psi_\beta}{\partial n}(s)\right] = R_c(s) \tag{1.5}$$

with $c = 1, 2, \ldots, C$, the number of boundary conditions. Note that C need not be equal to N.

2. The variational process. Because of the first-order derivative terms in (1.3), it is convenient, as in [4], to introduce paired variables, primal and dual, instead of just one self-dual variable. We denote these by $\{\psi_{\mathbf{p}\alpha}(x)\}$ and $\{\psi_{\mathbf{d}\alpha}(x)\}$, respectively. A functional whose variation with respect to the $\psi_{\mathbf{d}\alpha}$ leads to (1.3) as the Euler equation is

$$\begin{aligned}\Phi_0 \equiv \sum_{\alpha\beta}\int_\Omega \Big\{\nabla\psi_{\mathbf{d}\alpha}\cdot\overleftrightarrow{a}_{\alpha\beta}\cdot\nabla\psi_{\mathbf{p}\beta} + \psi_{\mathbf{d}\alpha}\,\vec{\xi}_{\alpha\beta}\cdot\nabla\psi_{\mathbf{p}\beta} + (\vec{\eta}_{\alpha\beta}\cdot\nabla\psi_{\mathbf{d}\alpha})\,\psi_{\mathbf{p}\beta}\\ + (c_{\alpha\beta} + \nabla\cdot\vec{\eta}_{\alpha\beta})\,\psi_{\mathbf{d}\alpha}\,\psi_{\mathbf{p}\beta}\Big\}\,d\Omega\\ - \sum_{\alpha}\int_\Omega\Big\{\psi_{\mathbf{p}\alpha}\,d_{\mathbf{d}\alpha} + \psi_{\mathbf{d}\alpha}\,d_{\mathbf{p}\alpha}\Big\}\,d\Omega\end{aligned} \tag{2.1}$$

with $\vec{\xi} - \vec{\eta} = \vec{b}$ and with $d_{\mathbf{d}\alpha}$ undetermined. (For conciseness, we often suppress the primal-dual subscripts, where the context suffices to reduce ambiguity.)

As we shall see, it is feasible to carry through the entire treatment of the many-variable case in a much-simplified manner by grouping the set $\{\psi_{\mathbf{p}\alpha}\}$ into a single vector $\psi_{\mathbf{p}}$. The same is done with $\{\psi_{\mathbf{d}\alpha}\}$, and all other sets of variables depending on the indices α, β, γ, etc. We thus define

$$\begin{aligned}&\{\psi_{\mathbf{p}\alpha}\}\to\psi_{\mathbf{p}},\quad \{\psi_{\mathbf{d}\alpha}\}\to\psi_{\mathbf{d}},\quad \{\overleftrightarrow{a}_{\alpha\beta}\}\to\overleftrightarrow{a},\quad \{\vec{b}_{\alpha\beta}\}\to\vec{b},\\ &\{c_{\alpha\beta}\}\to c,\quad \{d_{\mathbf{p}\alpha}\}\to d_{\mathbf{p}},\quad \{d_{\mathbf{d}\alpha}\}\to d_{\mathbf{d}},\end{aligned} \tag{2.2}$$

which are all matrices or vectors in the *matrix* sense. However, $\overleftrightarrow{a}$ and $\vec{b}$ are also a diadic (matrix) and a vector, respectively, in the *geometrical* sense. These must be kept conceptually distinct; hence, when we write, e.g., $\vec{b}^T$, the transpose refers to the matrix aspect only. With this understanding, (2.1) may be condensed to

$$\begin{aligned}\Phi_0 \equiv \int_\Omega \Big\{ &\nabla\psi_{\mathbf{d}}^T \cdot \overleftrightarrow{a} \cdot \nabla\psi_{\mathbf{p}} + \psi_{\mathbf{d}}^T\, \vec{\xi}\cdot\nabla\psi_{\mathbf{p}} + (\nabla\psi_{\mathbf{d}}^T\cdot\vec{\eta})\,\psi_{\mathbf{p}} \\ &+\psi_{\mathbf{d}}^T\,(c+\nabla\cdot\vec{\eta})\,\psi_{\mathbf{p}}\Big\}\,d\Omega \\ -\int_\Omega &\Big\{\psi_{\mathbf{p}}^T\,d_{\mathbf{d}} + \psi_{\mathbf{d}}^T\,d_{\mathbf{p}}\Big\}\,d\Omega,\end{aligned} \tag{2.3}$$

which we integrate by parts (Green's formula) to obtain a more convenient form to be used later:

$$\begin{aligned}\Phi_0 = &\int_\Omega \psi_{\mathbf{d}}^T\Big\{-\nabla\cdot(\overleftrightarrow{a}\cdot\nabla\psi_{\mathbf{p}}) + (\vec{\xi}-\vec{\eta})\cdot\nabla\psi_{\mathbf{p}} + c\,\psi_{\mathbf{p}} - d_{\mathbf{p}}\Big\}\,d\Omega \\ &+\int_\Gamma \psi_{\mathbf{d}}^T\,\{\hat{n}\cdot\overleftrightarrow{a}\cdot\nabla\psi_{\mathbf{p}} + \hat{n}\cdot\vec{\eta}\,\psi_{\mathbf{p}}\}\,d\Gamma - \int_\Omega \psi_{\mathbf{p}}^T d_{\mathbf{d}}\,d\Omega.\end{aligned} \tag{2.4}$$

To condense the notation for (1.5), we first define the trace operator $\mathcal{U}_c\psi$ to mean

$$\begin{aligned}\mathcal{U}_c\psi &\equiv \mathcal{U}_c[\psi_1,\psi_2,\ldots,\psi_N] \equiv \sum_{\alpha=1}^{N}\,[\mathcal{U}_{c\alpha}\psi_\alpha]\,(s) \\ &\equiv \sum_{\alpha=1}^{N}\left[P_{c\alpha}(s)\,\psi_\alpha(s) + Q_{c\alpha}(s)\,\frac{\partial\psi_\alpha}{\partial n}(s)\right],\end{aligned} \tag{2.5}$$

and the whole collection can be written

$$\mathcal{U}\psi = R, \tag{2.6}$$

with

$$\mathcal{U}\psi = \begin{bmatrix}\mathcal{U}_1\psi \\ \mathcal{U}_2\psi \\ \vdots \\ \mathcal{U}_C\psi\end{bmatrix} \tag{2.7a}$$

and

$$R = \begin{bmatrix}R_1 \\ R_2 \\ \vdots \\ R_C\end{bmatrix}. \tag{2.7b}$$

Note that $\mathcal{U}\psi$ may also be written

$$\mathcal{U}\psi \equiv P(s)\psi(s) + Q(s)\frac{\partial\psi}{\partial n}(s), \tag{2.8}$$

where P and Q are $(C \times N)$ matrix functions of s.

If we define the vector Lagrange multiplier

$$\lambda_{\mathbf{p}}(s) \equiv \begin{bmatrix}\lambda_{\mathbf{p}1}(s) \\ \lambda_{\mathbf{p}2}(s) \\ \vdots \\ \lambda_{\mathbf{p}C}(s)\end{bmatrix} \tag{2.9}$$

with a similar definition for $\lambda_{\mathrm{d}}(s)$, the augmented functional Φ which incorporates the boundary conditions becomes

$$\Phi \equiv \Phi_0 + \int_\Gamma \lambda_{\mathrm{d}}^T \{\mathcal{U}_{\mathrm{p}}\psi_{\mathrm{p}} - R_{\mathrm{p}}\}\, d\Gamma + \int_\Gamma \lambda_{\mathrm{p}}^T \{\mathcal{U}_{\mathrm{d}}\psi_{\mathrm{d}} - R_{\mathrm{d}}\}\, d\Gamma. \tag{2.10}$$

To derive the constrained primal Euler equation, we vary ψ_{d}, denoting its variation by $\delta\psi_{\mathrm{d}}$. The result is (cf., for example, [1])

$$\begin{aligned}\delta\Phi = &\int_\Omega \delta\psi_{\mathrm{d}}^T\Big\{-\nabla\cdot\overset{\leftrightarrow}{a}\cdot\nabla\psi_{\mathrm{p}} + (\vec{\xi}-\vec{\eta})\cdot\nabla\psi_{\mathrm{p}} + c\psi_{\mathrm{p}} - d_{\mathrm{p}}\Big\}\, d\Omega\\ &+ \int_\Gamma \delta\psi_{\mathrm{d}}^T\{\hat{n}\cdot\overset{\leftrightarrow}{a}\cdot\nabla\psi_{\mathrm{p}} + \hat{n}\cdot\vec{\eta}\psi_{\mathrm{p}}\}\, d\Gamma\\ &+ \int_\Gamma \left\{\delta\psi_{\mathrm{d}}^T P_{\mathrm{d}}^T + \left(\delta\frac{\partial\psi_{\mathrm{d}}}{\partial n}\right)^T Q_{\mathrm{d}}^T\right\}\lambda_{\mathrm{p}}\, d\Gamma,\end{aligned} \tag{2.11}$$

which must vanish for a stationary Φ. Note that we have taken the matrix transpose of the last integrand for convenience later on.

The term $\hat{n}\cdot\overset{\leftrightarrow}{a}\cdot\nabla\psi$ is often called the *coderivative* of ψ and, for the Laplace operator, is the standard normal derivative. We shall denote it by $\partial\psi/\partial n_a$. The expression $\hat{n}\cdot\vec{\eta}$, we shall denote by η_n. Note that $\partial\psi/\partial n_a$ is a *linear combination* of the gradients of several (possibly all) of the functions $\{\psi_\alpha\}$. The relationship is

$$\frac{\partial\psi_\alpha}{\partial n_a} \equiv \sum_\beta \hat{n}\cdot\overset{\leftrightarrow}{a}_{\alpha\beta}\cdot\nabla\psi_\beta. \tag{2.12}$$

3. Analysis of boundary conditions. We start by introducing new variables to replace ψ and its normal derivative. We have made a necessary distinction between the coderivative and the ordinary normal derivative (or, in any case, whatever kind of normal derivative is defined for use in the imposed boundary conditions). Let us use the more compact notation of having ψ_a mean the coderivative based on the diadic $\overset{\leftrightarrow}{a}$, and of having ψ_n mean the imposed normal derivative. We wish to replace $\psi(s)$ and $\psi_n(s)$ by new variables $\sigma(s)$ and $\tau(s)$ by means of a linear transformation.

This transformation is based on the matrices $P(s)$ and $Q(s)$ which we first arrange as a single composite matrix $[P, Q]$ with C rows and $2N$ columns. We assume that this matrix has full row rank, ensuring that the boundary conditions are linearly independent. It is then possible, by column combinations (i.e., elementary transformations from the right) to reduce $[P, Q]$ to a simple form. If the product of all the transformations is denoted by Y—a $(2N \times 2N)$ nonsingular matrix—then we have

$$[P, Q] \times Y = [I, 0], \tag{3.1}$$

where I is a unit matrix of order $(C \times C)$. The matrix Y can be partitioned as follows:

$$Y = \begin{bmatrix} J & K \\ L & M \end{bmatrix}, \tag{3.2}$$

and Y can in turn be inverted to yield back $[P, Q]$ as well as the submatrices R and S. The complete matrices then satisfy

$$\begin{bmatrix} P & Q \\ R & S \end{bmatrix} \times \begin{bmatrix} J & K \\ L & M \end{bmatrix} = \begin{bmatrix} PJ + QL, & PK + QM \\ RJ + SL, & RK + SM \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}. \tag{3.3}$$

It is important to note that all these relations hold, by construction, for all s on Γ. Also, if $2N - C \equiv D$, then the orders of the various matrices are as follows: P, Q are $(C \times 2N)$; R, S are $(D \times 2N)$; J, K are $(2N \times C)$; and L, M are $(2N \times D)$.

The new variables are introduced by

$$\begin{bmatrix} \sigma \\ \tau \end{bmatrix} = \begin{bmatrix} P & Q \\ R & S \end{bmatrix} \begin{bmatrix} \psi \\ \psi_n \end{bmatrix} \tag{3.4}$$

so that σ is a vector function of length C and τ is a vector function of length D, while ψ and ψ_n are both of length N. The inverse of (3.4) is

$$\begin{bmatrix} \psi \\ \psi_n \end{bmatrix} = \begin{bmatrix} J & K \\ L & M \end{bmatrix} \begin{bmatrix} \sigma \\ \tau \end{bmatrix}. \tag{3.5}$$

To proceed further with the analysis of the boundary conditions, we assume that the Euler equation holds in the interior, so that the integral over Ω in (2.11) may be ignored. Since we shall be varying the dual quantities, we can also ignore the other volume integral. The remaining terms relate to the surface only, so we shall denote what remains of the functional by Φ_S, which is

$$\begin{aligned} \Phi_S = &\int_\Gamma \psi_{\mathrm{d}}^T \{\psi_{\mathrm{p}a} + \eta b_n \psi_{\mathrm{p}}\}\, d\Gamma + \int_\Gamma \lambda_{\mathrm{d}}^T \{P_{\mathrm{p}}\psi_{\mathrm{p}} + Q_{\mathrm{p}}\psi_{\mathrm{p}n} - R_{\mathrm{p}}\}\, d\Gamma \\ &+ \int_\Gamma \lambda_{\mathrm{p}}^T \{P_{\mathrm{d}}\psi_{\mathrm{d}} + Q_{\mathrm{d}}\psi_{\mathrm{d}n} - R_{\mathrm{d}}\}\, d\Gamma. \end{aligned} \tag{3.6}$$

Here we treat the simplest case when $\psi_{\mathrm{p}n} = \psi_{\mathrm{p}a}$, and substitute for ψ and ψ_a in terms of σ and τ. The result is

$$\begin{aligned} \Phi_S = &\int_\Gamma \left(\sigma_{\mathrm{d}}^T J_{\mathrm{d}}^T + \tau_{\mathrm{d}}^T K_{\mathrm{d}}^T\right) \left[L_{\mathrm{p}}\sigma_{\mathrm{p}} + M_{\mathrm{p}}\tau_{\mathrm{p}} + \eta b_n (J_{\mathrm{p}}\sigma_{\mathrm{p}} + K_{\mathrm{p}}\tau_{\mathrm{p}})\right] d\Gamma \\ &+ \int_\Gamma \lambda_{\mathrm{d}}^T \{\sigma_{\mathrm{p}} - R_{\mathrm{p}}\}\, d\Gamma + \int_\Gamma \lambda_{\mathrm{p}}^T \{\sigma_{\mathrm{d}} - R_{\mathrm{d}}\}\, d\Gamma. \end{aligned} \tag{3.7}$$

The result of varying σ_{d} is just a formula for λ_{p}, but varying τ_{d} yields a consistency condition, which is

$$\begin{aligned} &K_{\mathrm{d}}^T \left[L_{\mathrm{p}}\sigma_{\mathrm{p}} + M_{\mathrm{p}}\tau_{\mathrm{p}} + \eta b_n (J_{\mathrm{p}}\sigma_{\mathrm{p}} + K_{\mathrm{p}}\tau_{\mathrm{p}})\right] \\ &\quad = K_{\mathrm{d}}^T (L_{\mathrm{p}} + \eta b_n J_{\mathrm{p}})\sigma_{\mathrm{p}} + K_{\mathrm{d}}^T (M_{\mathrm{p}} + \eta b_n K_{\mathrm{p}})\tau_{\mathrm{p}} \\ &\quad \equiv A_{\mathrm{p}}\sigma_{\mathrm{p}} + B_{\mathrm{p}}\tau_{\mathrm{p}} = 0. \end{aligned} \tag{3.8}$$

Since this is an identity in σ and τ, the two terms must vanish individually. This means, first, that

$$B_{\mathrm{p}} = 0. \tag{3.9}$$

σ_{p} may be evaluated by varying λ_{d} in (3.7). The result is

$$\sigma_{\mathrm{p}} = R_{\mathrm{p}}. \tag{3.10}$$

Hence, it is only necessary to have

$$A_{\mathrm{p}} R_{\mathrm{p}} = 0. \tag{3.11}$$

Conditions (3.9) and (3.11) constitute a concise test as to whether the "nullification" of a conflicting induced boundary condition by means of a boundary correction is necessary.

Appropriate modifications must be made in case $\psi_n \neq \psi_a$.

4. Construction of the nullifier. We shall follow the treatment in [5], but we shall keep track of the matrix relationships among the quantities arising in the many-variable case. We first adjoin to Φ_S another surface term Φ_N

$$\Phi^* \equiv \Phi_S - \Phi_N, \tag{4.1}$$

where

$$\Phi_N \equiv \int_\Gamma N(\sigma_{\mathbf{p}}, \tau_{\mathbf{p}}, \sigma_{\mathbf{d}}, \tau_{\mathbf{d}})\, d\Gamma. \tag{4.2}$$

The arguments of N (the "nullifier") are all vector variables.

When $\tau_{\mathbf{d}}$ is varied, the effect on Φ^* is

$$\delta\Phi^* = \int_\Gamma \delta\tau_{\mathbf{d}}(A\sigma_{\mathbf{p}} + B\tau_{\mathbf{p}})\, d\Gamma - \int_\Gamma \delta\tau_{\mathbf{d}} \frac{\partial N}{\partial \tau_{\mathbf{d}}}\, d\Gamma. \tag{4.3}$$

Hence, for a stationary Φ^*, we must have

$$\frac{\partial N}{\partial \tau_{\mathbf{d}}} = A\sigma_{\mathbf{p}} + B\tau_{\mathbf{p}}. \tag{4.4}$$

Similarly, it not hard to see that $\partial N/\partial \rho_{\mathbf{d}} = 0$. Hence, it is clear that

$$N = {\tau_{\mathbf{d}}}^T(A\sigma_{\mathbf{p}} + B\tau_{\mathbf{p}}) + \chi(\sigma_{\mathbf{p}}, \tau_{\mathbf{p}}, \sigma_{\mathbf{d}}), \tag{4.5}$$

where χ is an arbitrary function of its arguments. A particular choice of χ will serve to symmetrize N in some cases. This choice yields

$$N = {\tau_{\mathbf{d}}}^T A\sigma_{\mathbf{p}} + {\sigma_{\mathbf{d}}}^T A^T \tau_{\mathbf{p}} + {\tau_{\mathbf{d}}}^T B\tau_{\mathbf{p}}. \tag{4.6}$$

For a selfadjoint problem with $\vec{g} = \vec{a}$, we have $\sigma_{\mathbf{d}} = \sigma_{\mathbf{p}}$ and $\tau_{\mathbf{d}} = \tau_{\mathbf{p}}$, so interchanging the primal and dual variables has no effect. N is therefore symmetric.

Finally, we wish to restore the original variables ψ and ψ_g. This can be done most compactly by using the trace operator $\mathcal{U}$ and two new ones: $\mathcal{X}$ and $\mathcal{Y}$. These are defined as follows:

$$\sigma = P\psi + Q\psi_g \equiv \mathcal{U}\psi, \qquad \tau = R\psi + S\psi_g \equiv \mathcal{X}\psi, \tag{4.7}$$

so that N becomes

$$N = (\mathcal{X}_{\mathbf{d}}\psi_{\mathbf{d}})^T A(\mathcal{U}_{\mathbf{p}}\psi_{\mathbf{p}}) + (\mathcal{U}_{\mathbf{d}}\psi_{\mathbf{d}})^T A^T(\mathcal{X}_{\mathbf{p}}\psi_{\mathbf{p}}) + (\mathcal{X}_{\mathbf{d}}\psi_{\mathbf{d}})^T B(\mathcal{X}_{\mathbf{p}}\psi_{\mathbf{p}}). \tag{4.8}$$

The nullifier is rather more complicated when $\psi_n \neq \psi_a$.

5. Discretization. In the CD method, the boundary (and interface) conditions are imposed by the *moment collocation* process. For a single variable ψ and a single boundary condition, a set of *weight functions* $\{w_\kappa(s); \kappa = 1, \ldots, L\}$ is chosen. They are linearly independent and are capable of approximating any function in an appropriate class if L is large enough. (A system like this is called a Schauder basis.) For a single variable, we impose the collocation by forcing L moments of the boundary condition to vanish:

$$\int_\Gamma w_\kappa(s)\{\mathcal{U}\psi - R\}(s)\, d\Gamma = 0, \qquad \kappa = 1, \ldots, L. \tag{5.1a}$$

With primal and dual labels, (5.1a) should read

$$\begin{aligned}\int_\Gamma w_{\mathbf{d}\kappa}(s)\,\{\mathcal{U}_{\mathbf{p}}\psi_{\mathbf{p}} - R_{\mathbf{p}}\}\,(s)\,d\Gamma &= 0, \qquad \kappa = 1,\dots,L,\\ \int_\Gamma w_{\mathbf{p}\kappa}(s)\,\{\mathcal{U}_{\mathbf{d}}\psi_{\mathbf{d}} - R_{\mathbf{d}}\}\,(s)\,d\Gamma &= 0, \qquad \kappa = 1,\dots,L.\end{aligned} \tag{5.1b}$$

When there are C boundary conditions, and $C > 1$, we need correspondingly more sets of weight functions, one set for each boundary condition; e.g., $\{w_{c\kappa}(s); \kappa = 1,\dots,L(c); c = 1,\dots,C\}$ with the corresponding discrete boundary conditions

$$\int_\Gamma w_{c\kappa}\,\{\mathcal{U}\psi - R\}\;d\Gamma = 0; \quad \kappa = 1,\dots,L(c); \quad c = 1,\dots,C. \tag{5.2}$$

Combining this with (2.5), we obtain

$$\int_\Gamma w_{c\kappa}(s)\left\{\sum_{\alpha=1}^{N}\,[\mathcal{U}_{c\alpha}\psi_\alpha]\,(s) - R_c(s)\right\}\,d\Gamma = 0. \tag{5.3}$$

Following the usual procedure, we would now substitute a linear combination of basis functions for ψ. However, since we have N distinct ψ's, we may define N separate basis sets $\{\phi_{\alpha\mu}(x); \mu = 1,\dots,M(\alpha); \alpha = 1,\dots,N\}$ and set

$$\psi_\alpha(x) = \sum_{\mu=1}^{M(\alpha)} \phi_{\alpha\mu}(x)\theta_{\alpha\mu}. \tag{5.4}$$

Substituting this into (5.3) yields

$$\int_\Gamma w_{c\kappa}(s)\left\{\sum_{\alpha=1}^{N} \mathcal{U}_{c\alpha} \sum_{\mu=1}^{M(\alpha)} \phi_{\alpha\mu}(x)\theta_{\alpha\mu} - R_c(s)\right\}\,d\Gamma = 0. \tag{5.5}$$

To simplify the equations somewhat, we shall not always indicate the dependence of L on c and of M on α. We shall also not exhibit the arguments x and s, but leave their determination to the context. We then have

$$\begin{aligned}&\int_\Gamma w_{c\kappa}\left\{\sum_\alpha \mathcal{U}_{c\alpha}\sum_\mu \phi_{\alpha\mu}\theta_{\alpha\mu} - R_c\right\}\,d\Gamma\\ &= \int_\Gamma w_{c\kappa}\left\{\sum_\alpha\sum_\mu \mathcal{U}_{c\alpha}\phi_{\alpha\mu}\theta_{\alpha\mu} - R_c\right\}\,d\Gamma = 0\\ &= \sum_\alpha\sum_\mu \int_\Gamma [w_{c\kappa}\mathcal{U}_{c\alpha}\phi_{\alpha\mu}]\,d\Gamma\;\theta_{\alpha\mu} - \int_\Gamma w_{c\kappa}R_c\,d\Gamma = 0.\end{aligned} \tag{5.6}$$

If we define the arrays

$$\begin{aligned}U_{c\kappa,\alpha\mu} &\equiv \int_\Gamma w_{c\kappa}(s)\,[\mathcal{U}_{c\alpha}\phi_{\alpha\mu}]\,(s)d\Gamma(s),\\ R_{c\kappa} &\equiv \int_\Gamma w_{c\kappa}(s)R_c(s)\,d\Gamma(s),\end{aligned} \tag{5.7}$$

then (5.6) takes the simple form

$$\sum_{\alpha\mu} U_{c\kappa,\alpha\mu}\theta_{\alpha\mu} - R_{c\kappa} = 0. \tag{5.8}$$

The next simplification in notation is to combine c and κ into one "global" index, κ^*. To do this, we enumerate c, κ in the sequence

$$\begin{aligned}\{c,\kappa\} = \{&(1,1),(1,2),\dots,(1,L(1)),(2,1),(2,2),\dots,\\ &(2,L(2)),\dots,(C,1),(C,2),\dots,(C,L(C))\},\end{aligned} \tag{5.9}$$

while

$$\{\kappa^*\} = \{1,2,3,\dots,L^*\}.$$

This equation is an attempt to show that the composite index κ^* runs directly from 1 to L^*, the global collocation count, while the pair (c,κ) runs in the sequence shown. In like manner, we collect (α,μ) into one index μ^*, which runs from 1 to M^*, the global basis index count. In this way, we can condense (5.8) to

$$\sum_{\mu^*=1}^{M^*} U_{\kappa^*\mu^*}\theta_{\mu^*} - R_{\kappa^*} = 0, \tag{5.10}$$

which, in turn, can be written in terms of global matrices and vectors:

$$U\theta - R = 0, \tag{5.11}$$

where U is an $(L^* \times M^*)$ matrix, and θ and R are vectors of, respectively, M^* and L^* elements.

Next, we return to Φ_0, and substitute the expression (5.4) for ψ into (2.1). We get

$$\Phi_0 \equiv \sum_{\alpha\mu\beta\nu} S_{\alpha\mu;\beta\nu}\theta_{\mathbf{d}\alpha\mu}\theta_{\mathbf{p}\beta\nu} - \sum_{\alpha\mu}\theta_{\mathbf{p}\alpha\mu}T_{\mathbf{d}\alpha\mu} - \sum_{\alpha\mu}\theta_{\mathbf{d}\alpha\mu}T_{\mathbf{p}\alpha\mu}, \tag{5.12}$$

where

$$\begin{aligned} S_{\alpha\mu;\beta\nu} \equiv \int_\Omega \Big\{ &\nabla\phi_{\mathbf{d}\alpha\mu}\cdot\overleftrightarrow{a}_{\alpha\beta}\cdot\nabla\phi_{\mathbf{p}\beta\nu} + \phi_{\mathbf{d}\alpha\mu}\,\vec{\xi}_{\alpha\beta}\cdot\nabla\phi_{\mathbf{p}\beta\nu} + (\vec{\eta}_{\alpha\beta}\cdot\nabla\phi_{\mathbf{d}\alpha\mu})\,\phi_{\mathbf{p}\beta\nu} \\ &+ (c_{\alpha\beta} + \nabla\cdot\vec{\eta}_{\alpha\beta})\,\phi_{\mathbf{d}\alpha\mu}\,\phi_{\mathbf{p}\beta\nu}\Big\}\,d\Omega, \\ T_{\mathbf{d}\alpha\mu} &\equiv \int_\Omega \phi_{\mathbf{p}\alpha\mu}\,d_{\mathbf{d}\alpha}\,d\Omega, \\ T_{\mathbf{p}\alpha\mu} &\equiv \int_\Omega \phi_{\mathbf{d}\alpha\mu}\,d_{\mathbf{p}\alpha}\,d\Omega. \end{aligned} \tag{5.13}$$

By combining α and μ into μ^* and β and ν into ν^*, (5.12) becomes

$$\Phi_0 \equiv \sum_{\mu^*\nu^*} S_{\mu^*\nu^*}\theta_{\mathbf{d}\mu^*}\theta_{\mathbf{p}\nu^*} - \sum_{\mu^*}\theta_{\mathbf{p}\mu^*}T_{\mathbf{d}\mu^*} - \sum_{\mu^*}\theta_{\mathbf{d}\mu^*}T_{\mathbf{p}\mu^*}. \tag{5.14}$$

With this system of labeling, S and T play the same roles for several variables as do their counterparts in the single-variable case [4]. Therefore, we can go through all the standard procedures, always understanding that the modified labeling is in force. In particular, we can write

$$\Phi_0 \equiv \theta_{\mathbf{d}}^T S\theta_{\mathbf{p}} - \theta_{\mathbf{p}}^T T_{\mathbf{d}} - \theta_{\mathbf{d}}^T T_{\mathbf{p}}. \tag{5.15}$$

The completed functional, incorporating the boundary conditions is

$$\Phi \equiv \theta_{\mathbf{d}}^T S\theta_{\mathbf{p}} - \theta_{\mathbf{p}}^T T_{\mathbf{d}} - \theta_{\mathbf{d}}^T T_{\mathbf{p}} + \lambda_{\mathbf{d}}^T \left[U_{\mathbf{p}}\theta_{\mathbf{p}} - R_{\mathbf{p}}\right] + \lambda_{\mathbf{p}}^T \left[U_{\mathbf{d}}\theta_{\mathbf{d}} - R_{\mathbf{d}}\right], \tag{5.16}$$

and the discrete equations are

$$\begin{aligned} \frac{\partial \Phi}{\partial \theta_{\mathbf{d}}} &= S\theta_{\mathbf{p}} - T_{\mathbf{p}} + U_{\mathbf{d}}^T \lambda_{\mathbf{p}} = 0, \\ \frac{\partial \Phi}{\partial \theta_{\mathbf{p}}} &= S\theta_{\mathbf{d}} - T_{\mathbf{d}} + U_{\mathbf{p}}^T \lambda_{\mathbf{d}} = 0. \end{aligned} \tag{5.17}$$

We note again that the orders of the various quantities are $S{:}(M^* \times M^*)$; $\theta{:}(M^* \times 1)$; $T{:}(L^* \times 1)$; $U{:}(L^* \times M^*)$; $\lambda{:}(L^* \times 1)$.

We next construct the auxiliary matrices $V_{\mathbf{p}}$, $V_{\mathbf{d}}$, $Z_{\mathbf{p}}$, and $Z_{\mathbf{d}}$ of the following orders: $V_{\mathbf{p}}$ and $V_{\mathbf{d}}$ are $(M^* \times L^*)$ and $Z_{\mathbf{p}}$ and $Z_{\mathbf{d}}$ are $(M^* \times J^*)$, where $J^* \equiv M^* - L^*$. They have the properties

$$\begin{aligned} U_{\mathbf{p}}V_{\mathbf{p}} &= U_{\mathbf{d}}V_{\mathbf{d}} = I, \\ U_{\mathbf{p}}Z_{\mathbf{p}} &= U_{\mathbf{d}}Z_{\mathbf{d}} = 0, \\ Z_{\mathbf{d}}^T S V_{\mathbf{p}} &= V_{\mathbf{d}}^T S Z_{\mathbf{p}} = 0. \end{aligned} \tag{5.18}$$

The dominant terms in the number of standard floating-point operations needed to compute $V_{\mathbf{p}}$ and $Z_{\mathbf{p}}$ *for each cell* are $3M^{*3} + L^{*2}M^* - 2L^*M^{*2}$. We emphasize again that these calculations for a given cell are independent of those for any other cell. We use these matrices to transform from $\theta_{\mathbf{p}}$ and $\theta_{\mathbf{d}}$ to new variables $\sigma_{\mathbf{p}}$, $\sigma_{\mathbf{d}}$, $\rho_{\mathbf{p}}$, and $\rho_{\mathbf{d}}$ as follows:

$$\theta_{\mathbf{p}} = V_{\mathbf{p}}\sigma_{\mathbf{p}} + Z_{\mathbf{p}}\rho_{\mathbf{p}}, \qquad \theta_{\mathbf{d}} = V_{\mathbf{d}}\sigma_{\mathbf{d}} + Z_{\mathbf{d}}\rho_{\mathbf{d}}. \tag{5.19}$$

The σ's are $(L^* \times 1)$ and the ρ's are $(J^* \times 1)$. This transformation serves two important purposes: (1) It simplifies the boundary condition so drastically that it can almost be eliminated; (2) It decouples the σ's and ρ's so that they can be solved for completely independently. The latter is very important, in that it makes almost all of the calculations independent from cell to cell (as we shall see later) and hence makes the calculations almost completely parallelizable without any extra manipulation.

To show the first effect, we substitute for θ in (5.11) (both primal and dual variables satisfy the same relation):

$$\begin{aligned} U\theta - R &= U(V\sigma + Z\rho) - R = UV\sigma + UZ\rho - R \\ &= I \cdot \sigma + 0 \cdot \rho - R = \sigma - R = 0, \end{aligned} \tag{5.20}$$

which yields a trivially simple solution for σ.

Next, we substitute from (5.19) into (5.16) with the result

$$
\begin{aligned}
\Phi &\equiv [V_{\mathbf{d}}\sigma_{\mathbf{d}} + Z_{\mathbf{d}}\rho_{\mathbf{d}}]^T S\,[V_{\mathbf{p}}\sigma_{\mathbf{p}} + Z_{\mathbf{p}}\rho_{\mathbf{p}}] \\
&\quad - [V_{\mathbf{p}}\sigma_{\mathbf{p}} + Z_{\mathbf{p}}\rho_{\mathbf{p}}]^T T_{\mathbf{d}} - [V_{\mathbf{d}}\sigma_{\mathbf{d}} + Z_{\mathbf{d}}\rho_{\mathbf{d}}]^T T_{\mathbf{p}} \\
&\quad + \lambda_{\mathbf{d}}^T[\sigma_{\mathbf{p}} - R_{\mathbf{p}}] + \lambda_{\mathbf{p}}^T[\sigma_{\mathbf{d}} - R_{\mathbf{d}}] \\
&= \sigma_{\mathbf{d}}^T V_{\mathbf{d}}^T S V_{\mathbf{p}}\sigma_{\mathbf{p}} + \sigma_{\mathbf{d}}^T V_{\mathbf{d}}^T S Z_{\mathbf{p}}\rho_{\mathbf{p}} + \rho_{\mathbf{d}}^T Z_{\mathbf{d}}^T S V_{\mathbf{p}}\sigma_{\mathbf{p}} + \rho_{\mathbf{d}}^T Z_{\mathbf{d}}^T S Z_{\mathbf{p}}\rho_{\mathbf{p}} \\
&\quad - [V_{\mathbf{p}}\sigma_{\mathbf{p}} + Z_{\mathbf{p}}\rho_{\mathbf{p}}]^T T_{\mathbf{d}} - [V_{\mathbf{d}}\sigma_{\mathbf{d}} + Z_{\mathbf{d}}\rho_{\mathbf{d}}]^T T_{\mathbf{p}} \\
&\quad + \lambda_{\mathbf{d}}^T[\sigma_{\mathbf{p}} - R_{\mathbf{p}}] + \lambda_{\mathbf{p}}^T[\sigma_{\mathbf{d}} - R_{\mathbf{d}}],
\end{aligned} \tag{5.21}
$$

and we then have, for the primal discrete equations,

$$
\begin{aligned}
\frac{\partial\Phi}{\partial\sigma_{\mathbf{d}}} &= V_{\mathbf{d}}^T S V_{\mathbf{p}}\sigma_{\mathbf{p}} + V_{\mathbf{d}}^T S Z_{\mathbf{p}}\rho_{\mathbf{p}} - V_{\mathbf{d}}^T T_{\mathbf{p}} + \lambda_{\mathbf{p}} = 0, \\
\frac{\partial\Phi}{\partial\rho_{\mathbf{d}}} &= Z_{\mathbf{d}}^T S V_{\mathbf{p}}\sigma_{\mathbf{p}} + Z_{\mathbf{d}}^T S Z_{\mathbf{p}}\rho_{\mathbf{p}} - Z_{\mathbf{d}}^T T_{\mathbf{p}} = 0,
\end{aligned} \tag{5.22}
$$

with a like set for the duals. We can now see that were it not for the third set of relations in (5.18), the σ and ρ would be coupled, but by the use of (5.18), we decouple them and have

$$
\begin{aligned}
&V_{\mathbf{d}}^T S V_{\mathbf{p}}\sigma_{\mathbf{p}} - V_{\mathbf{d}}^T T_{\mathbf{p}} + \lambda_{\mathbf{p}} = 0, \\
&Z_{\mathbf{d}}^T S Z_{\mathbf{p}}\rho_{\mathbf{p}} - Z_{\mathbf{d}}^T T_{\mathbf{p}} = 0,
\end{aligned} \tag{5.23}
$$

with a similar set for the duals. As we shall see later, this decoupling can be carried through when there are multiple cells. The equations for ρ are always cell-by-cell.

It is important to note that, while the distinctness of the several ψ's is maintained for the θ's, the transformation vitiates this distinctness, so that it is no longer possible to associate any component of σ or ρ with any particular ψ. In this sense, the equations in discrete form are solved "all together" and not one-by-one.

6. The multicell case.

6. The multicell case. Once the various quantities in the multivariable case have been relabeled and coalesced into cellwise global assemblies, the treatment of the multicell case follows (formally) almost exactly the treatment of the single-variable multicell case. We therefore reproduce the treatment in [4], indicating when the present case differs from that one.

We partition Ω into K subdomains or cells, $\{\Omega_1, \Omega_2, \ldots, \Omega_K\}$. Between any two *contiguous* cells, say, Ω_k and Ω_m, we have an interface Γ_{km}. In cell discretization, *if two cells are not contiguous, they are not neighbors.* Each cell, say, Ω_k, will now have a boundary made up of more than one segment; we can label these segments by using the notation $\{m[k]\}$ to represent the set of labels for those cells which are contiguous neighbors of Ω_k, say B_k in number.

The vector function $\psi_{\mathbf{p}}(x)$ now becomes an *ensemble* of representations

$$\{\psi_{\mathbf{p}k}(x, \theta_{\mathbf{p}k})\},$$

one for each cell:

$$
\begin{aligned}
\psi_{\mathbf{p}k}(x) &\equiv \{\psi_{\mathbf{p}k\alpha}(x); \alpha = 1, N\} \\
&= \left\{ \sum_{\mu=1}^{M(\alpha)} \phi_{\mathbf{p}k\alpha\mu}(x)\,\theta_{\mathbf{p}k\alpha\mu}; \alpha = 1, N \right\}
\end{aligned} \tag{6.1}
$$

with a similar formula for the dual. The functional Φ_0 is now given as the sum of integrals over the cells

$$\Phi_0 \equiv \sum_{k=1}^{K} \Bigg\{ \int_{\Omega_k} \Big[\nabla\psi_{\mathbf{d}k}^T \cdot \overleftrightarrow{a}_k \cdot \nabla\psi_{\mathbf{p}k} + \psi_{\mathbf{d}k}^T\, \vec{\xi}_k \cdot \nabla\psi_{\mathbf{p}k} + (\nabla\psi_{\mathbf{d}k}^T \cdot \vec{\eta}_k)\,\psi_{\mathbf{p}k} + \psi_{\mathbf{d}k}^T\,(c_k + \nabla \cdot \vec{\eta}_k)\,\psi_{\mathbf{p}k}\Big]\, d\Omega_k - \int_{\Omega_k} \Big[\psi_{\mathbf{p}k}^T\, d_{\mathbf{d}k} + \psi_{\mathbf{d}k}^T\, d_{\mathbf{p}k}\Big]\, d\Omega_k \Bigg\}, \tag{6.2}$$

which combined with (6.1) becomes

$$\Phi_0 = \sum_k \left\{\theta_{\mathbf{d}k}^T\, S_k\, \theta_{\mathbf{p}k} - \theta_{\mathbf{p}k}^T\, T_{\mathbf{d}k} - \theta_{\mathbf{d}k}^T T_{\mathbf{p}k}\right\}, \tag{6.3}$$

with $S_k, T_{\mathbf{p}k}$, and $T_{\mathbf{d}k}$ given by (5.13), except that the formulas are evaluated for each cell.

For each interface Γ_{km}, we may have a separate set of (primal and dual) weight functions $\{w_{km;c\kappa}(s)\}$ and, of course, a separate set of (primal and dual) trace operators. By way of example, the arrays calculated by (5.7) become

$$\begin{aligned} U_{\mathbf{p}km;c\kappa,\alpha\mu} &\equiv \int_\Gamma w_{\mathbf{d}km;c\kappa}(s)\, [\mathcal{U}_{\mathbf{p}km;c\alpha}\phi_{\mathbf{p}k;\alpha\mu}]\,(s)d\Gamma(s), \\ R_{\mathbf{p}km;c\kappa} &\equiv \int_\Gamma w_{\mathbf{d}km;c\kappa}(s) R_{\mathbf{p}km;c}(s)\, d\Gamma(s), \end{aligned} \tag{6.4}$$

with a like set for the duals. Without going into more detail, it is sufficient that the multicell *interface* conditions corresponding to (1.4) are

$$U_{km}\theta_k - R_{km} = U_{mk}\theta_m - R_{mk}, \tag{6.5}$$

with U, θ, and R all appropriate cellwise global arrays. The special case when an "interface" is really a boundary segment is included by assuming that all quantities associated with the exterior of Ω vanish identically (as discussed in [2]).

The complete discretized functional is then

$$\begin{aligned} \Phi_0 = &\sum_k \left\{\theta_{\mathbf{d}k}^T\, S_k\, \theta_{\mathbf{p}k} - \theta_{\mathbf{p}k}^T\, T_{\mathbf{d}k} - \theta_{\mathbf{d}k}^T T_{\mathbf{p}k}\right\} \\ &- \sum_{km} \lambda_{\mathbf{d}km}^T \left\{[U_{\mathbf{p}km}\theta_{\mathbf{p}k} - R_{\mathbf{p}km}] - [U_{\mathbf{p}mk}\theta_{\mathbf{p}k} - R_{\mathbf{p}mk}]\right\} \\ &- \sum_{mk} \lambda_{\mathbf{p}mk}^T \left\{[U_{\mathbf{d}km}\theta_{\mathbf{d}k} - R_{\mathbf{d}km}] - [U_{\mathbf{d}mk}\theta_{\mathbf{d}k} - R_{\mathbf{d}mk}]\right\}. \end{aligned} \tag{6.6}$$

In order to pass from θ to σ and ρ, we must find the appropriate V's and Z's. We note first that cell Ω_k, for example, has not one boundary segment, but B_k. What we have previously referred to as a "global" array is, in fact, defined for each boundary segment $\Gamma_{km[k]}$ of Ω_k. Specifically, the B_k global matrices $\{U_{km[k]}\}$ may be collected into a "superglobal" U_k (with only one subscript) whose rows are the assembled rows of all of the individual coefficient matrices, each associated with a single face of Ω_k. Thus,

$$U_k = \begin{bmatrix} U_{km_1} \\ U_{km_2} \\ \vdots \\ U_{km_{B_k}} \end{bmatrix}. \tag{6.7}$$

We have assumed L^*_{km} moments on Γ_{km}, and M^*_k coefficients $\{\theta_{k\mu^*}\}$, so that U_{km} is an $(L^*_{km} \times M^*_k)$ matrix. U_k, therefore, is in turn an $(L^{**}_k \times M^*_k)$ matrix, where

$$L^{**}_k \equiv \sum_{m[k]} L^*_{km[k]}. \tag{6.8}$$

We assume, as usual, that U_k is nondegenerate, i.e., it has full row rank (requiring that $L^{**}_k \leq M^*_k$), so that we can construct a superglobal V_k and a Z_k using the procedure given in §5. The result is an $(M^*_k \times L^{**}_k)$ matrix V_k and an $(M^*_k \times J^{**}_k)$ matrix Z_k, where $J^{**}_k = M^*_k - L^{**}_k$. We again have

$$\begin{aligned} U_k V_k &= I, \\ U_k Z_k &= 0, \end{aligned} \tag{6.9}$$

with the understanding that the foregoing relations hold for primal and dual quantities. In addition, of course, we adjust the V's for each cell so that

$$V^T_{\mathbf{d}k} S_k Z_{\mathbf{p}k} = 0, \qquad Z^T_{\mathbf{d}k} S_k V_{\mathbf{p}k} = 0. \tag{6.10}$$

Remembering that these are superglobal matrices, we now *repartition* each V_k into a set $\{V_{km[k]}\}$ of submatrices, each with the same number of columns as the corresponding $U_{km[k]}$ has rows. Thus, matching (6.7), we have

$$V_k = [V_{km_1}, V_{km_2}, \ldots, V_{km_{B_k}}]. \tag{6.11}$$

Z_k remains a matrix associated with Ω_k as a whole, and not with any particular face or faces. These new matrices satisfy the following relationships based on (6.9):

$$U_{kp} V_{kq} = \delta_{pq} I, \qquad U_{kp} Z_k = 0, \tag{6.12}$$

for both primal and dual, and

$$V^T_{\mathbf{d}km} S_k Z_{\mathbf{p}k} = 0, \qquad Z^T_{\mathbf{d}k} S_k V_{\mathbf{p}km} = 0. \tag{6.13}$$

We are now ready to change variables. With the exception that the matrices are superglobal, as opposed to merely global, the treatment is identical to that in [4]. The transformation corresponding to (5.19) is

$$\theta_k = \sum_{p[k]} V_{kp}(\sigma_{kp} + R_{kp}) + Z_k \rho_k, \tag{6.14}$$

where the summation is, as the notation expresses, over the labels of the contiguous neighbors of Ω_k. When we apply the discrete trace operator U_{km} to θ_k, we obtain

$$\begin{aligned} U_{km}\theta_k &= \sum_{p[k]} U_{km} V_{kp}(\sigma_{kp} + R_{kp}) + U_{km} Z_k \rho_k \\ &= \sum_{p[k]} \delta_{mp}(\sigma_{kp} + R_{kp}) + 0 \cdot \rho_k \\ &= \sigma_{km} + R_{km} \end{aligned} \tag{6.15}$$

with a matching reduction for $U_{mk}\theta_m$. Equation (6.5) then reduces to

$$(\sigma_{km} + R_{km}) - R_{km} = (\sigma_{mk} + R_{mk}) - R_{mk} \tag{6.16}$$

or

$$\sigma_{km} = \sigma_{mk} \tag{6.17}$$

for primal and dual quantities.

Next, we substitute (6.14) into (6.5) (with a change of index names) to obtain the rather lengthy result:

$$\begin{aligned}\Phi = &\sum_{q=1}^{K} [\Phi_{\sigma\sigma,q} + \Phi_{\rho\rho,q} + \Phi_{\sigma\rho,q} + \text{constant}] \\ &-\sum_{\substack{q=1\\r=1}}^{K} \lambda_{\mathbf{d}qr}(\sigma_{\mathbf{p}qr} - \sigma_{\mathbf{p}rq}) - \sum_{\substack{q=1\\r=1}}^{K} \lambda_{\mathbf{p}qr}(\sigma_{\mathbf{d}qr} - \sigma_{\mathbf{d}rq})\end{aligned} \tag{6.18}$$

with

$$\begin{aligned}\Phi_{\sigma\sigma,q} = &\sum_{\substack{r[q]\\s[q]}} \left[\sigma^T_{\mathbf{d}qr} V^T_{\mathbf{d}qr} S_q V_{\mathbf{p}qs} \sigma_{\mathbf{p}qs} + \sigma^T_{\mathbf{d}qr} V^T_{\mathbf{d}qr} S_q V_{\mathbf{p}qs} R_{\mathbf{p}qs} \right. \\ &\left. \qquad + R^T_{\mathbf{d}qr} V^T_{\mathbf{d}qr} S_q V_{\mathbf{p}qs} \sigma_{\mathbf{p}qs} \right] \\ &- \sum_{r[q]} \left[\sigma^T_{\mathbf{d}qr} V^T_{\mathbf{d}qr} T_{\mathbf{p}q} + T^T_{\mathbf{d}q} V_{\mathbf{p}qr} \sigma_{\mathbf{p}qr} \right],\end{aligned} \tag{6.19}$$

$$\begin{aligned}\Phi_{\rho\rho,q} = &\rho^T_{\mathbf{d}q} Z^T_{\mathbf{d}q} S_q Z_{\mathbf{p}q} \rho_{\mathbf{p}q} + \sum_{r[q]} \left[R^T_{\mathbf{d}qr} V^T_{\mathbf{d}qr} S_q Z_{\mathbf{p}q} \rho_{\mathbf{p}q} + \rho^T_{\mathbf{d}q} Z^T_{\mathbf{d}q} S_q V_{\mathbf{p}qr} R_{\mathbf{p}qr} \right] \\ &- \rho^T_{\mathbf{d}q} Z^T_{\mathbf{d}q} T_{\mathbf{p}q} - T^T_{\mathbf{d}q} Z_{\mathbf{p}q} \rho_{\mathbf{p}q},\end{aligned} \tag{6.20}$$

and

$$\Phi_{\sigma\rho,q} = \sum_{r[q]} \left[\sigma^T_{\mathbf{d}qr} V^T_{\mathbf{d}qr} S_q Z_{\mathbf{p}q} \rho_{\mathbf{p}q} + \rho^T_{\mathbf{d}q} Z^T_{\mathbf{d}q} S_q V_{\mathbf{p}qr} \sigma_{\mathbf{p}qr} \right], \tag{6.21}$$

and the understanding that the double summations are only over values of q and r that label contiguous neighbors.

We can ignore the constant part because we are going to differentiate Φ with respect to the variables σ and ρ. It is very advantageous to decouple σ and ρ, so that the discrete equation for one will not involve the other. We shall see that this will confer the very attractive feature of being able to do almost everything cell-by-cell, as mentioned already in §5. The term interfering with this is $\Phi_{\sigma\rho,q}$, so we must make this vanish. All that is necessary is to choose the V's so as to satisfy

$$V^T_{\mathbf{d}qr} S_q Z_{\mathbf{p}q} = 0, \qquad Z^T_{\mathbf{d}q} S_q V_{\mathbf{p}qr} = 0. \tag{6.22}$$

Bearing in mind that r *labels only the contiguous neighbors* of Ω_q, i.e., the *faces of* Ω_q, it is clear that the conditions (6.22) refer to *each individual cell* Ω_q in turn. Hence, we can treat each cell exactly as in §5, i.e., group the $\{U_{qr}\}$ into one matrix, find the appropriate V and Z, and repartition the V, etc. Note also that the matrices chosen in this way cause the bracket in (6.20) to vanish.

To condense the formulas, we define

$$H_{qrs} \equiv V^T_{\mathbf{d}qr} S_q V_{\mathbf{p}qs}, \qquad A_q \equiv Z^T_{\mathbf{d}q} S_q Z_{\mathbf{p}q}, \tag{6.23}$$

(6.24)
$$G_{\mathbf{p}qr} \equiv V_{\mathbf{d}qr}^T T_{\mathbf{p}q} - \sum_{s[q]} H_{qrs} R_{\mathbf{p}qs},$$
$$G_{\mathbf{d}qr} \equiv V_{\mathbf{p}qr}^T T_{\mathbf{d}q} - \sum_{s[q]} H_{qrs}^T R_{\mathbf{d}qs},$$

and

(6.25)
$$J_{\mathbf{p}q} \equiv Z_{\mathbf{d}q}^T T_{\mathbf{p}q}, \qquad J_{\mathbf{d}q} \equiv Z_{\mathbf{p}q}^T T_{\mathbf{d}q}.$$

Then we have, for Φ,

(6.26)
$$\begin{aligned}\Phi = \sum_{q=1}^{K} \Bigg\{ \sum_{\substack{r[q]\\ s[q]}} \sigma_{\mathbf{d}qr}^T H_{qrs} \sigma_{\mathbf{p}qs} - \sum_{r[q]} \left[\sigma_{\mathbf{d}qr}^T G_{\mathbf{p}qr} + G_{\mathbf{d}qr}^T \sigma_{\mathbf{p}qr}\right] \\ + \rho_{\mathbf{d}q}^T A_q \rho_{\mathbf{p}q} - \rho_{\mathbf{d}q}^T J_{\mathbf{p}q} - J_{\mathbf{d}q}^T \rho_{\mathbf{p}q} \Bigg\} \\ + \sum_{\substack{q=1\\ r=1}}^{K} \lambda_{\mathbf{d}qr}(\sigma_{\mathbf{p}qr} - \sigma_{\mathbf{p}rq}) + \sum_{\substack{q=1\\ r=1}}^{K} \lambda_{\mathbf{p}qr}(\sigma_{\mathbf{d}qr} - \sigma_{\mathbf{d}rq}).\end{aligned}$$

To obtain the discrete equations for σ and ρ, we first differentiate with respect to $\rho_{\mathbf{d}k}$. (With the changed indices, it is much easier to follow the procedure correctly.) We obtain, for the primal,

(6.27)
$$A_k \rho_{\mathbf{p}k} = J_{\mathbf{p}k}.$$

Obviously, each ρ_k can be found for Ω_k independently of any other cell. This part of the solution can therefore readily be parallelized.

We next differentiate Φ with respect to $\sigma_{\mathbf{d}km}$. The result is

(6.28)
$$\sum_{s[k]} H_{kms} \sigma_{\mathbf{p}ks} - G_{\mathbf{p}km} + (\lambda_{\mathbf{p}km} - \lambda_{\mathbf{p}mk}) = 0.$$

The antisymmetry of the interface conditions is reflected in the antisymmetry of the combined λ terms. We make use of this important fact to eliminate the λ's. We interchange k and m in (6.28) and add the result back to (6.28). The λ terms cancel and we are left with

(6.29)
$$\sum_{s[k]} H_{kms} \sigma_{\mathbf{p}ks} + \sum_{s[m]} H_{mks} \sigma_{\mathbf{p}ms} - G_{\mathbf{p}km} - G_{\mathbf{p}mk} = 0.$$

The block diagonal part may be extracted from (6.29) by withdrawing the term with $s[k] = m$ from the first sum and the term with $s[m] = k$ from the second. Since $\sigma_{\mathbf{p}mk} = \sigma_{\mathbf{p}km}$, we get

(6.30)
$$\Lambda_{km} \sigma_{\mathbf{p}km} + {\sum_{s[k]}}' H_{kms} \sigma_{\mathbf{p}ks} + {\sum_{s[m]}}' H_{mks} \sigma_{\mathbf{p}ms} - G_{\mathbf{p}km} - G_{\mathbf{p}mk} = 0$$

with

(6.31)
$$\Lambda_{km} \equiv H_{kmm} + H_{mkk},$$

and the primes on the summations mean that the km and mk terms are left out. Equations (6.27) and (6.30) are the discrete equations to be solved. This was done by Gaussian elimination, since all of these equation systems are small for the problems to be discussed.

7. Numerical tests. All the problems are set within the square $(-1 \leq x \leq 1; -1 \leq y \leq 1)$. Unless otherwise indicated, it is divided into four equal square cells. All the problems were run with three or four moments per boundary or interface condition, because experience has shown that this generally gives good results for two-dimensional problems. The number of degrees of freedom within each cell was chosen so as to remove interface condition degeneracies. The basis functions and the weights were Legendre polynomials.

PROBLEM 1. A gradient-divergence problem. One of the simplest systems equivalent to Laplace's equation is

$$\vec{v} + \nabla p = 0, \qquad \nabla \cdot \vec{v} = 0 \tag{7.1}$$

in two dimensions. By taking the divergence of the first equation and subtracting the second, it is clear that p satisfies Laplace's equation. We can compare the results of solving a suitable boundary value problem in two different ways: as a single, second-order PDE, or as the system (7.1). It is not always clear what the interface conditions should be for the latter problem, even when those for the former are very well established. In this case, the single-variable problem serves as a good guide to the system problem.

To begin, we assume p to be equal to the real part of the analytic function $z^3+1.5z$, i.e., $p = x^3 - 3xy^2 + 1.5x$, and set the Dirichlet boundary conditions accordingly. The interface conditions are that p be continuous (in the weak sense of having the first four moments of the discrepancy vanish) across the interfaces. Similarly, the first four moments of the solution on the boundary must match those of the boundary data.

There are 36 degrees of freedom in each cell (seventh degree), of which $4 \times 4 = 16$ go to satisfy the boundary and interface conditions. The remaining 20 are free to make the representation of the unknown solution satisfy the PDE within each cell as closely as possible. The discrete equations (6.27) for the latter variables are therefore 20 in number for each cell and are independent of each other, as shown in §6. The degrees of freedom on each interface are four in number, so that there are $4 \times 4 = 16$ equations (6.30), also independent of the intracell equations. Thus, as indicated at the beginning of this section, the equations systems are all small and are easily solved directly. The solution comes out exactly.

The simplest functional whose primal Euler equation is (7.1) is

$$\Phi_0 \equiv \int_\Omega \{\vec{v}_{\mathrm{d}} \cdot (\vec{v}_{\mathrm{p}} + \nabla p_{\mathrm{p}}) + p_{\mathrm{d}}(\nabla \cdot \vec{v}_{\mathrm{p}})\}\, d\Omega, \tag{7.2}$$

and the simplest interface condition is to require the continuity of p, as for the single-variable case. Also, the value of p is specified on the boundary as before. With these specifications in the computer program, the solution found is shown in Fig. 1. The result is very poor, and can obviously be related to the lack of smoothness across the interfaces.

The difficulty is that, while in the single-variable case the variational process gives rise to *induced* (natural) interface conditions (as discussed in [3]), the system (7.1) is first-order, so that it is possible to have no induced interface conditions, as happens for (7.2). The reason for this is suggested by (2.4), in which an induced surface condition is shown, *but only if* $\vec{\eta} \neq 0$, which is not the case for (7.2), since no derivative of a dual variable appears. To remedy this, an alternative form for the functional may be chosen, e.g.,

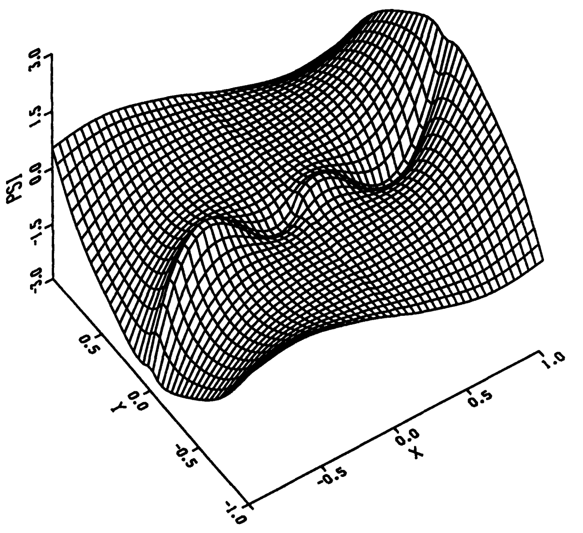

FIG. 1. *Gradient-divergence problem. Solution with simplest functional.*

$$\Phi_0 \equiv \int_\Omega \{\vec{v}_\mathrm{d} \cdot (\vec{v}_\mathrm{p} + \nabla p_\mathrm{p}) - \nabla p_\mathrm{d} \cdot \vec{v}_\mathrm{p}\}\, d\Omega, \tag{7.3}$$

which causes a surface term containing $\delta p_\mathrm{d} v_{\mathrm{p}n}$ to be induced on each side of each interface. The difference between these terms for cells Ω_k and Ω_m, for example, can be shown to vanish (in a particular sense; see [4, §6]). Roughly, it means that on Γ_{km}, $\delta p_{\mathrm{d}k}(v_{\mathrm{p}k})_n = \delta p_{\mathrm{d}m}(v_{\mathrm{p}m})_n$. If, therefore, $\delta p_{\mathrm{d}k} = \delta p_{\mathrm{d}m}$, then $(v_{\mathrm{p}k})_n = (v_{\mathrm{p}m})_n$. Thus the normal component of v_p is made weakly continuous across Γ_{km} and this, in turn, is equivalent to making $\partial p_\mathrm{p}/\partial n$ weakly continuous across Γ_{km}, as for the single-variable case.

The result of the computation bears out this reasoning. p again comes out exactly, and looks as shown in Fig. 2. The sizes of the equation systems are as follows: the number of degrees of freedom per cell is $3 \times 28 = 84$, of which $4 \times 4 = 16$ are used up on perimeter constraints, leaving 68, which is the size of the equation system in each cell. Since there are four constraints per interface, there is a total of $4 \times 4 = 16$ equations (6.30).

A set of boundary data (a zig-zag function) for which an exact solution is unknown leads to a solution of (7.1) shown in Fig. 3. The reference solution of the Laplace equation differs by about 1 percent.

PROBLEM 2. The Cauchy–Riemann equations. This system of first-order equations in the variables (u, v), which may represent the real and imaginary parts of a complex function, characterizes the analyticity of that function. It is one of the simplest (but also one of the most difficult) elliptic systems in two variables and is, in fact, the principal part of a canonical form for all linear elliptic first-order systems in two variables. The equations are

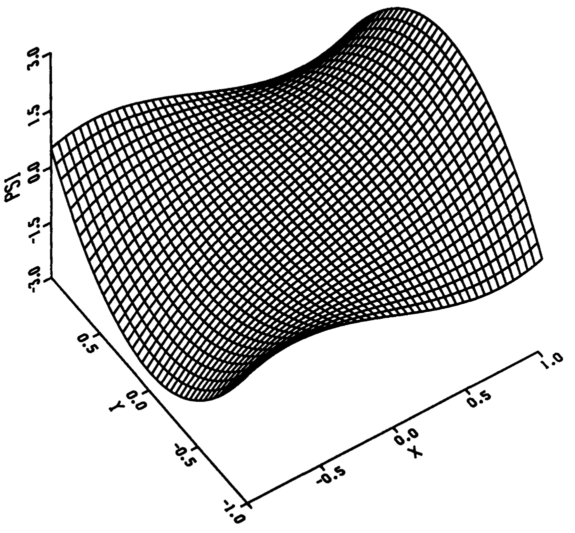

FIG. 2. *Gradient-divergence problem. Solution with altered functional.*

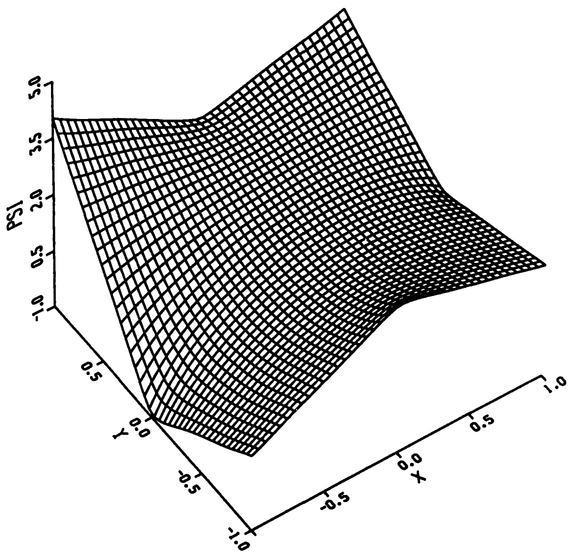

FIG. 3. *Gradient-divergence problem. Solution with zig-zag boundary conditions.*

$$\frac{\partial u}{\partial x} - \frac{\partial v}{\partial y} = 0, \qquad \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} = 0. \tag{7.4}$$

As is done in fluid dynamical studies, it is also useful to consider the couple $(u, -v)$ as a vector $\vec{w}$ which, because of the second equation of (7.4), is the gradient of a potential function $\psi(x, y)$. Thus

$$u = \frac{\partial \psi}{\partial x}, \qquad -v = \frac{\partial \psi}{\partial y}. \tag{7.5}$$

The first equation, in turn, results in ψ satisfying Laplace's equation. For this equation, appropriate boundary conditions are that ψ or $\partial\psi/\partial n$ (or a linear combination of the two) are to be equal to some boundary data. Since we wish to treat (7.4) strictly as a system in terms of u and v, we must choose a Neumann condition involving $\partial\psi/\partial n$ for the boundary condition. We note that since $\vec{w} = \nabla\psi$, we have

$$\frac{\partial \psi}{\partial n} = \vec{n}\cdot\nabla\psi = \vec{n}\cdot\vec{w} = w_n, \tag{7.6}$$

so that u is to be specified on the vertical sides of Ω, and $-v$ on the horizontal sides. As regards the interfaces, the same considerations apply; we must require that the normal component of $\vec{w}$ be (weakly) continuous across each interface.

The first, very simple problem tried has the solution $u = x, v = y$, i.e., the real and imaginary parts of the complex variable z. The boundary conditions are

$$\begin{aligned} u(-1,y) &= -1, \qquad & u(1,y) &= 1, \\ v(x,-1) &= -1, \qquad & v(x,1) &= 1. \end{aligned} \tag{7.7}$$

The solution is exactly the correct one: $(u,v) = (x,y)$.

The next problem is to find the solution $(u,v) = (x^2 - y^2, 2xy)$, which represents the real and imaginary parts of z^2. The boundary conditions are

$$\begin{aligned} u(-1,y) &= 1 - y^2, \qquad & u(1,y) &= 1 - y^2, \\ v(x,-1) &= -2x, \qquad & v(x,1) &= 2x. \end{aligned} \tag{7.8}$$

The solutions for u and v are unfortunately incorrect; they are shown in Figs. 4(a) and 4(b).

Various alternative ways of posing the problem were tried in an effort to make it give the right answer. Both u and v were forced to be weakly continuous across the interfaces, small additional terms were added to the equations, the terms in the functional were changed so as to induce interface conditions, and various alternative forms of the boundary conditions were applied. The only alteration that yielded the correct answer was the addition of a small multiple of the Laplacian of each variable to the corresponding equation. The actual system solved was

$$-\epsilon\nabla^2 u + \frac{\partial u}{\partial x} - \frac{\partial v}{\partial y} = 0, \qquad -\epsilon\nabla^2 v + \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} = 0, \tag{7.9}$$

with $\epsilon = 10^{-}5$, and this yielded the correct solution to 10 figures. It is not clear why this should be so, but it has been noticed that the presence of at least one singular diagonal block Λ_{km} is enough to give rise to an incorrect solution. Adding the second-order terms prevents this from happening. The correct solution is shown in Figs. 5(a) and 5(b).

The orders of the intracell and interface linear systems were 30 and 12, respectively. (Of course, there were four intracell sets.)

PROBLEM 3. The Stokes problem. The linearized Navier–Stokes equations for the flow of an incompressible fluid are (see, e.g., [6])

$$-\nabla^2\vec{v} + \nabla p = \vec{f}, \qquad \nabla\cdot\vec{v} = 0, \tag{7.10}$$

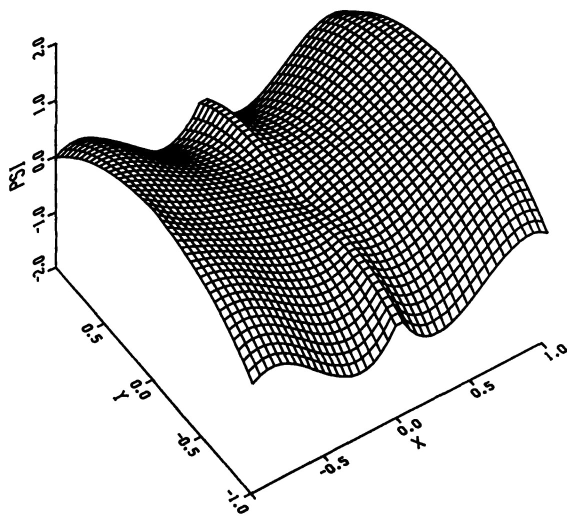

FIG. 4(a). *Cauchy–Riemann equations. Solution for u with no additional terms in functional.*

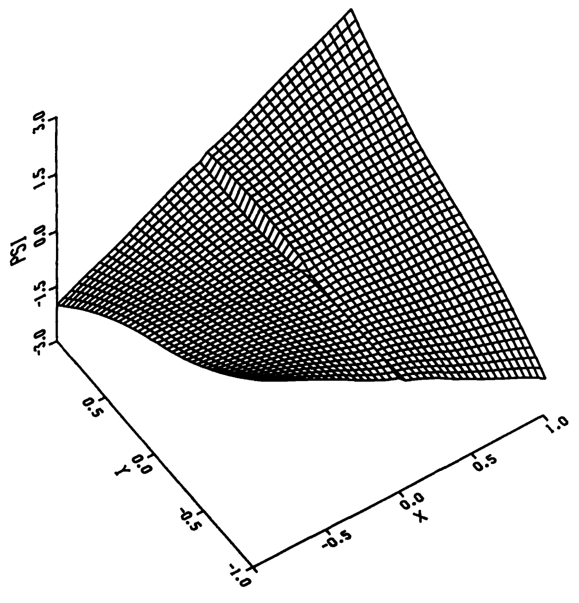

FIG. 4(b). *Cauchy–Riemann equations. Solution for v with no additional terms in functional.*

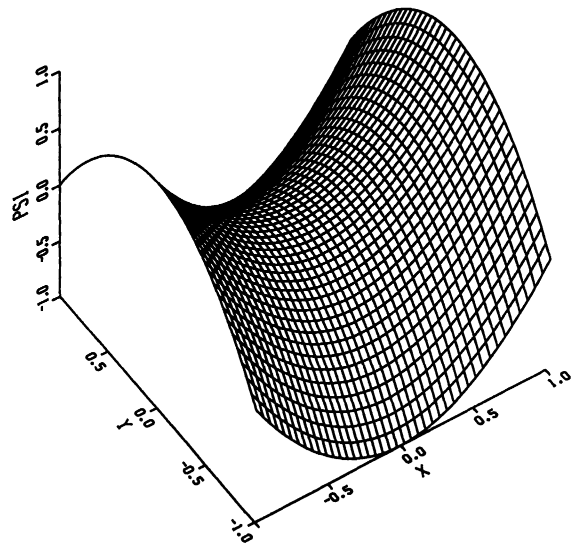

FIG. 5(a). *Cauchy–Riemann equations. Solution for u with additional terms.*

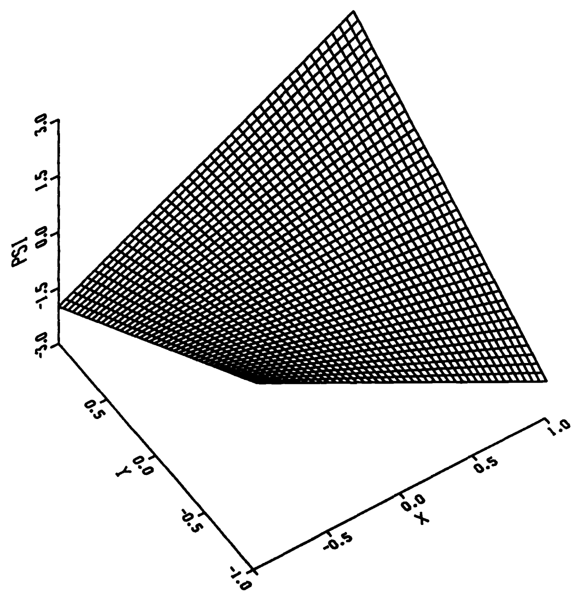

FIG. 5(b). *Cauchy–Riemann equations. Solution for v with additional terms.*

with the velocity $\vec{v}$ specified on the boundary. The pressure p is determined to within an additive constant.

The simplest functional was tried initially, viz.,

$$\Phi_0 = \int_\Omega \{\nabla\vec{v}_\mathbf{d} : \nabla\vec{v}_\mathbf{p} + \vec{v}_\mathbf{d} \cdot \nabla p_\mathbf{p} + p_\mathbf{d}\nabla \cdot \vec{v}_\mathbf{p}\}\, d\Omega. \tag{7.11}$$

The double-dot symbol between the two (diadic) gradients of the primal and dual velocities means that the two gradient operators are first dotted together, followed by the two velocity vectors (this is the same as the double contraction of the four-index tensor formed from the derivatives of $\vec{v}_\mathbf{d}$ and $\vec{v}_\mathbf{p}$).

The first case attempted calls for $\vec{v}_\mathbf{p} = (1, 1)$ on the boundary. There is no condition on $p_\mathbf{p}$. (Corresponding boundary conditions are applied to the dual variables.) As usual, the question arises as to what the proper interface conditions should be. The most obvious choice is again to apply the same kind of conditions at the interface as are applied at the boundary of a single domain. Therefore, the two components of $\vec{v}_\mathbf{p}$ are made weakly continuous across the interfaces. (The same condition is applied to $\vec{v}_\mathbf{d}$.) This choice yields the exact solution for the velocity components, viz., $\vec{v}_\mathbf{p} = (1, 1)$ throughout Ω.

On the other hand, the pressure, which should have the value $p(x, y) = x + y +$ constant, has nothing to force it to be continuous across the interfaces, so it comes out as shown in Fig. 6. By adding the appropriate constant to each of three cells, so as to relate them properly to the first, the global solution can be made continuous. This is not, however, a satisfactory solution. We might force weak continuity of p across the interfaces, but this results in three boundary conditions for each internal cell face, and this is too many. A resolution of this dilemma is to *induce* the constraint on p by changing the second term of the functional (7.11) into its adjoint, as was done with (7.3). The result is

$$\Phi_0 = \int_\Omega \{\nabla\vec{v}_\mathbf{d} : \nabla\vec{v}_\mathbf{p} - (\nabla \cdot \vec{v}_\mathbf{d})p_\mathbf{p} + p_\mathbf{d}\nabla \cdot \vec{v}_\mathbf{p}\}\, d\Omega, \tag{7.12}$$

so that the induced surface term resulting from the variation of the dual quantities is

$$\Phi_S = \int_\Gamma -\delta v_{\mathbf{d}n} p_\mathbf{p} d\Gamma. \tag{7.13}$$

The usual variational interface argument shows that if $\delta v_{\mathbf{d}n}$ is continuous across the interface, then so is $p_\mathbf{p}$. Hence, since continuity of $v_{\mathbf{d}n}$ is imposed (the dual variables have the same interface and boundary conditions as the primal), $p_\mathbf{p}$ should be weakly continuous. However, as Fig. 7 shows, this is not enough to give the correct solution. It was also necessary to add a small multiple of p to the second equation of (7.10). This combination of the altered functional and the small added term yields the correct continuous solution $p_\mathbf{p}$, as shown in Fig. 8, besides giving the correct result for the velocity, all to six figures, when the multiple of p was 10^{-7}.

Using this same setup of functionals and constraints, a somewhat more complicated example was tried. The boundary data were represented by cubic and quadratic polynomials, and care was taken to maintain the incompressibility at the corners, where the v-derivatives involved can actually be calculated from the given functions. Four moments were used in the collocation, in order to match the cubic boundary

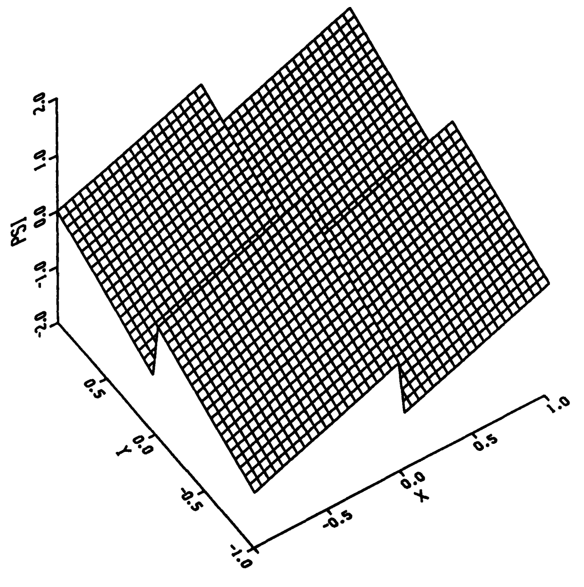

FIG. 6. *Stokes problem, flat velocity. Pressure solution with simplest functional.*

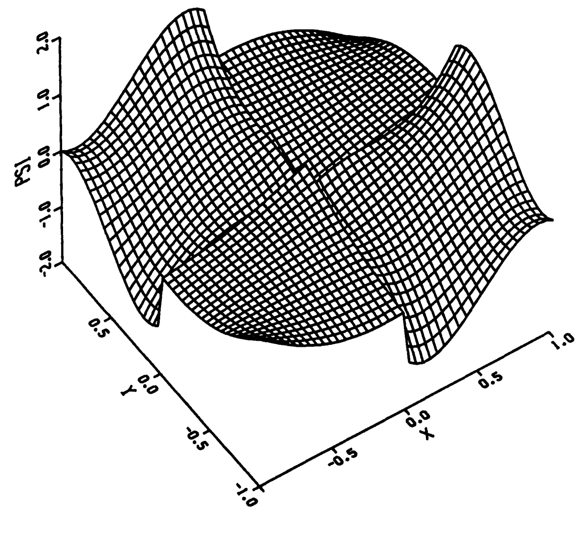

FIG. 7. *Stokes problem, flat velocity. Pressure solution with corrected functional.*

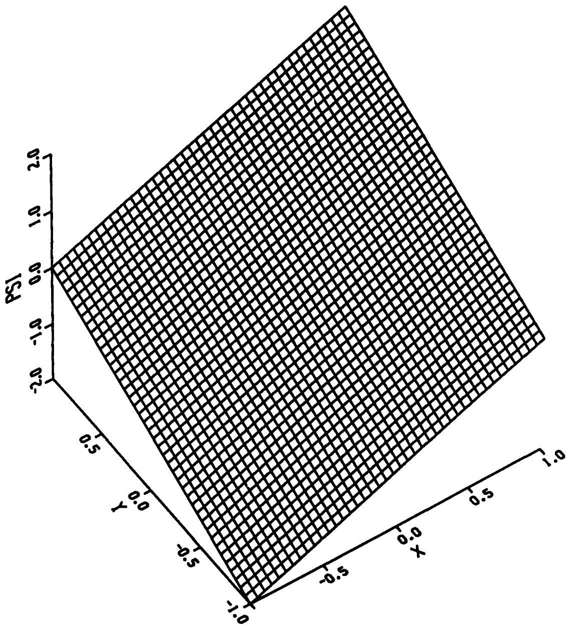

FIG. 8. *Stokes problem, flat velocity. Pressure solution with corrected functional and additional terms.*

data functions. The results for the velocity components are quite smooth, as can be seen in Figs. 9(a) and 9(b). The pressure is very sensitive to even slight irregularities in the velocity components, because it is related to their derivatives, but the result for the pressure is still satisfactory, as can be seen in Fig. 9(c).

The orders of the intracell and interface linear systems were 39 and 24, respectively, except for the wavy case, which required more moment collocations. In that case, the orders were 84 and 32.

PROBLEM 4. A clamped plate. Our last example consists of the solution of the equation

$$\nabla^4 u = d \tag{7.14}$$

with $d = 1$, and subject to the boundary conditions

$$u(s) = \frac{\partial u}{\partial n}(s) = 0, \tag{7.15}$$

with the second condition representing the clamping. In order to make the equations for the problem conform to (1.3), we introduce the auxiliary variable v and replace (7.14) by

$$-\nabla^2 u + v = 0, \qquad -\nabla^2 v = -d, \tag{7.16}$$

for which the simplest functional (in primal-dual form) is

$$\Phi_0 = \int_\Gamma \{\nabla u_\mathrm{d} \cdot \nabla u_\mathrm{p} + \nabla v_\mathrm{d} \cdot \nabla v_\mathrm{p} + u_\mathrm{d} v_\mathrm{p} + v_\mathrm{d} d\}\, d\Omega. \tag{7.17}$$

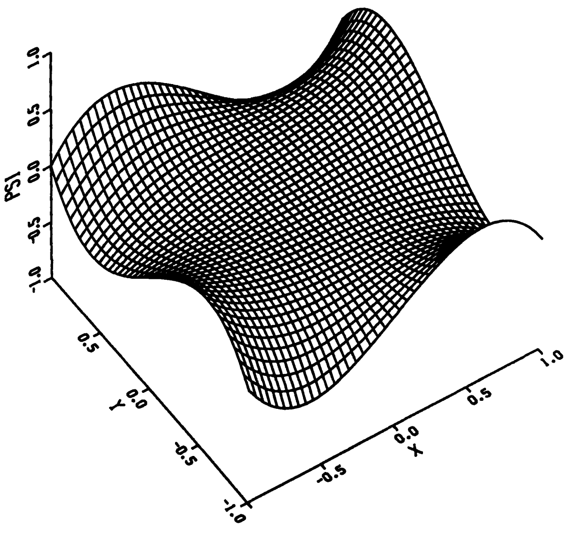

FIG. 9(a). *Stokes problem, wavy velocity. u-solution with corrected functional and additional terms.*

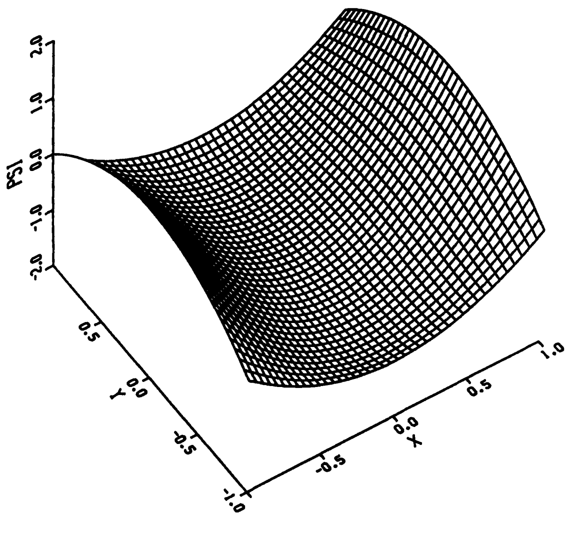

FIG. 9(b). *Stokes problem, wavy velocity. v-solution with corrected functional and additional terms.*

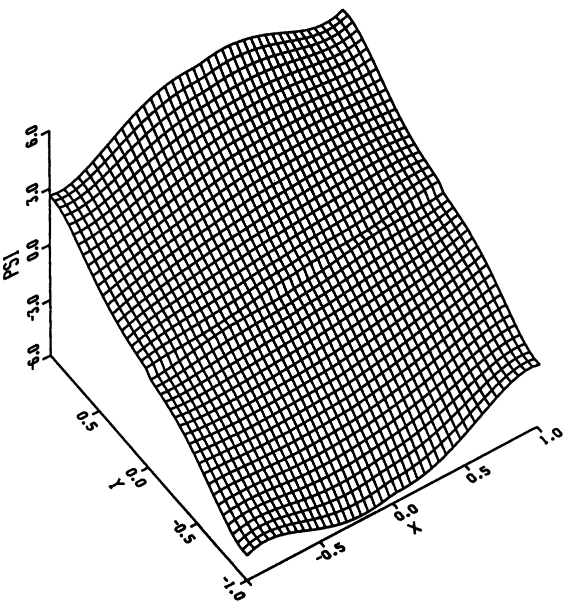

FIG. 9(c). *Stokes problem, wavy velocity. Pressure solution with corrected functional and additional terms.*

With these choices, the solution is not correct. Figure 10 shows the result for u_p with four cells and three moments on each interface, and with a sixth degree polynomial in each cell. On the other hand, when the equations (7.16) are *reordered*, we obtain the accurate result for u_p shown in Fig. 11. (In the last two figures, the ordinates have been rescaled to improve the appearance of the plots.)

The argument for exchanging the equation order is basically that the functional (7.17) is not unique, depending as it does on the association of the first equation in (7.16) with u_d and the second with v_d. Reversing the order of the equations amounts to interchanging u_d and v_d in the functional.

A rough idea of the error can be inferred by noting that the maximum value of u over the plotting grid is .020237 for the 4-cell case and .020245 for a 16-cell case (with otherwise all parameters the same), yielding a difference of .000008.

The orders of the intracell and interface linear systems for the four-cell case were 48 and 24, respectively.

8. Conclusions.

The cell discretization algorithm has proved successful in solving several quite different model problems involving systems of equations in more unknowns than one. The treatment of the discrete equations involves grouping the degrees of freedom (the θ's) for all of the unknowns into one global array for each cell, and transforming this vector to the usual two sets of auxiliary unknowns (the σ's and the ρ's) without associating them with particular unknowns. By this means, the usual auxiliary matrices (V's and Z's) can be constructed in a straightforward manner so that the σ's and ρ's are completely decoupled, and can be solved for separately. It

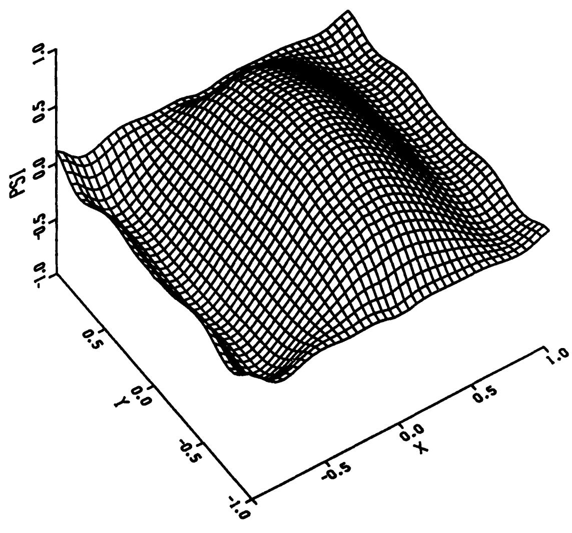

FIG. 10. *Clamped-plate, u-solution. Wrong equation ordering.*

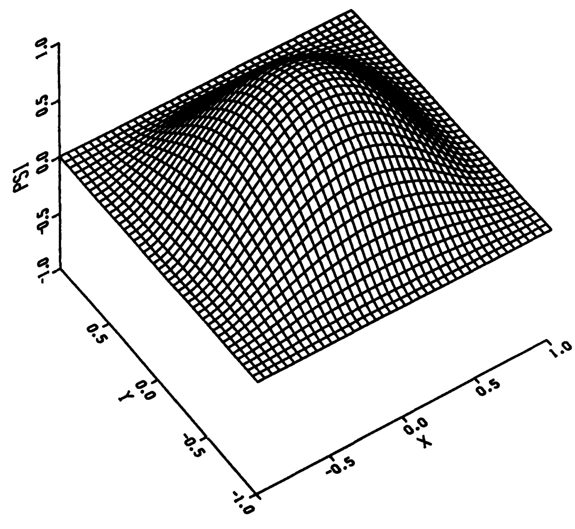

FIG. 11. *Clamped-plate, u-solution. Correct equation ordering.*

follows that the calculation can be parallelized almost completely with no artificial reshuffling of the variables.

Gauss elimination was used to solve the linear systems of equations for the intracell and interface variables with satisfactory results because the equation systems for these problems are all of modest size. A few unexpected complications arose, mostly due to the singular nature of the original problems. It was found necessary to add small additional terms to the original equations in order to render the discrete equations less degenerate. The question of what is the correct functional corresponding to a given (nonselfadjoint) set of PDEs therefore remains open. Moreover, a careful selection of the interface conditions was found to be necessary, coupled with the appropriate choice of terms in the functional used. However, there was nothing unnatural or bizarre in these choices.

Although the problems solved were very simple ones, they still contained some challenging complexities. It is encouraging that the CD method was capable of solving them without any basic modification. The major shortcoming of the computer program used for these computations is the absence of the capability of using "special" representations (e.g., nonpolynomial, general algebraic, and transcendental functions) for the solution approximations, which are nonlinear in the degrees of freedom. (This shortcoming has since been remedied.)

Acknowledgment. I am deeply indebted to Professor M.J.D. Powell for his kindness and forbearance in giving me the continuing opportunity to pursue this research in his Numerical Analysis Group in the Department of Applied Mathematics and Theoretical Physics at Cambridge University (as well as for his clarifying a matrix problem for me). Thanks are also due to Professor N. Sugimoto for several very helpful discussions, as well as to Drs. H. Yee and H. Lomax for providing me with the facilities at the NASA–Ames Research Center needed to revise this paper.

A PARALLEL GRAPH COLORING HEURISTIC*

MARK T. JONES† AND PAUL E. PLASSMANN†

Abstract. The problem of computing good graph colorings arises in many diverse applications, such as in the estimation of sparse Jacobians and in the development of efficient, parallel iterative methods for solving sparse linear systems. This paper presents an asynchronous graph coloring heuristic well suited to distributed memory parallel computers. Experimental results obtained on an Intel iPSC/860 are presented, which demonstrate that, for graphs arising from finite element applications, the heuristic exhibits scalable performance and generates colorings usually within three or four colors of the best-known linear time sequential heuristics. For bounded degree graphs, it is shown that the expected running time of the heuristic under the P-RAM computation model is bounded by $EO(\log(n)/\log\log(n))$. This bound is an improvement over the previously known best upper bound for the expected running time of a random heuristic for the graph coloring problem.

1. Introduction.

The determination of the chromatic number of a general graph is a well-known NP-hard problem [4]. However, a number of practical problems require the determination of nearly optimal graph colorings. For example, it has been shown [3] that the problem of directly estimating a sparse Jacobian by finite differences with a minimum number of function evaluations is equivalent to a graph coloring problem. Also, it has been shown [10] that the minimum number of parallel steps in the solution of the triangular systems involving incomplete Cholesky factors can be obtained by a matrix reordering derived from the solution of a graph coloring problem. Thus, the development of an effective parallel heuristic is of great practical, as well as theoretical, interest.

This paper presents an asynchronous graph coloring heuristic well suited to distributed memory parallel computers. Our heuristic consists of two phases: an initial, parallel phase that uses a random heuristic, followed by a local phase that utilizes one of several good sequential coloring heuristics. The initial phase maintains the good expected running time bounds obtained for a Monte Carlo algorithm for determining a maximal independent set [8]. In fact, for bounded degree graphs, we show that an upper bound for the expected running time of our heuristic under the P-RAM computation model is $EO(\log(n)/\log\log(n))$. This bound is an improvement over the previously known best upper bound of $EO(\log(n))$ for a random heuristic.

To illustrate the performance of this heuristic, we present experimental results obtained on an Intel iPSC/860. The results demonstrate that, for graphs arising from finite element applications, the heuristic exhibits scalable performance. In addition, for these problems the heuristic is shown to generate colorings usually using no more than three or four more colors than the best linear time sequential heuristics.

This paper is organized as follows. In §2 we introduce a new Monte Carlo heuristic that eliminates the need for global synchronization of the processors and allows for the more efficient use of data structures. We prove, in §3, that under the P-RAM computational model the expected running time of the asynchronous heuristic

affords an improvement over the upper bound for a Monte Carlo algorithm based on finding maximal independent sets. A distributed memory implementation of the asynchronous heuristic is detailed in §4. In §5 we present and discuss experimental results obtained on the iPSC/860. Finally, in §6 we discuss possible avenues for improving the heuristic.

2. An asynchronous parallel graph coloring heuristic.

In this section we introduce a graph coloring heuristic suitable for asynchronous parallel machines. First, we review the graph coloring problem. Consider the symmetric graph $G = (V, E)$ with vertex set V, with $|V| = n$, and edge set E. We say that the function $\sigma : V \rightarrow \{1, \ldots, s\}$ is an s-coloring of G, if $\sigma(v) \neq \sigma(w)$ for all edges $(v, w) \in E$. The minimum possible value for s is known as the *chromatic number* of G, which we denote as $\chi(G)$.

The question as to whether a general graph G is s-colorable is NP-complete [4]. It is known that unless $P = NP$, there does not exist a polynomial approximation scheme for solving the graph coloring problem [4]. In fact, the best polynomial time heuristic known [6] can theoretically guarantee a coloring of only size $c\,(n/\log n)\,\chi(G)$, where c is some constant.

Given these pessimistic theoretical results, it is quite surprising that, for certain classes of graphs, there exist a number of sequential graph coloring heuristics that are very effective in practice. For graphs arising from a number of applications, it has been demonstrated that these heuristics are often able to find colorings that are within one or two of an optimal coloring [3], [7].

    $\sigma(v_i)$ = smallest available consistent color;
    $V' \leftarrow V' \setminus \{v_i\}$;
**enddo**
```

FIG. 1. *A sequential greedy coloring heuristic.*

It is known that an optimal coloring can be obtained with a greedy heuristic if the vertices are visited in the correct order [1]. The basic structure of the greedy heuristic is shown in Fig. 1. The only aspect of the sequential heuristic that must be specified is the rule for choosing the vertex v_i. Many strategies for obtaining this vertex ordering have been proposed. One of the most effective heuristics is the saturation degree ordering (SDO) suggested by Brélaz [2]. The SDO vertex ordering is defined as follows. Suppose that vertices $v_1, \ldots, v_{i-1}$ have been chosen and colored. Vertex v_i is chosen to be a vertex adjacent to the maximum number of different colors in the vertex set $\{v_1, \ldots, v_{i-1}\}$. Note that this heuristic can be implemented to run in time proportional to $\sum_{v \in V} \deg^2(v)$, where $\deg(v)$ is the degree of vertex v.

A modification of the SDO heuristic is the *incidence degree ordering* (IDO) introduced by Coleman and Moré in their work [3] on using coloring heuristics to obtain consistent partitions for sparse Jacobian estimation. The IDO vertex ordering has the advantage that its running time is a linear function of the number of edges. To describe the IDO heuristic, we again suppose that vertices $v_1, \ldots, v_{i-1}$ have been chosen. Vertex v_i is chosen to be a vertex whose degree is a maximum in the subgraph of G induced by the vertex set $\{v_1, \ldots, v_{i-1}\} \cup \{v_i\}$. This heuristic can be implemented to run in time proportional to $\sum_{v \in V} \deg(v)$, or $O(|E|)$ time.

Unfortunately, these heuristics are essentially breadth-first searches of the graph and, as such, do not represent scalable, parallel heuristics. To do better, one notes that if the vertices v and w are not adjacent in G (i.e., are independent in G), then these vertices can be colored in parallel. Thus, a heuristic for determining an independent set in parallel could be adapted to a parallel coloring heuristic. This observation motivates the parallel coloring heuristic shown in Fig. 2.

$V' \leftarrow V$;
**While** $V' \neq \emptyset$ **do**
        Choose an independent set $I$ from $V'$;
        Color $I$ in parallel;
        $V' \leftarrow V' \setminus I$;
**enddo**
```

FIG. 2. *Outline of a parallel coloring heuristic.*

The problem of determining an independent set in parallel has been the focus of much theoretical research. An approach that has been successfully analyzed is to determine an independent set, I, based on the following Monte Carlo rule. Here we denote the set of vertices adjacent to vertex v by $\mathrm{adj}(v)$.

1. For each vertex $v \in V'$ determine a distinct, random number $\rho(v)$.
2. $v \in I \Leftrightarrow \rho(v) > \rho(w)$, for all $w \in \mathrm{adj}(v)$.

In the Monte Carlo algorithm described by Luby [8], this initial independent set is augmented to obtain a maximal independent set. The approach is the following. After the initial independent set is found, the set of vertices adjacent to a vertex in I, the neighbor set $N(I)$, is determined. The union of these two sets is deleted from V', the subgraph induced by this smaller set is constructed, and the Monte Carlo step is used to choose an augmenting independent set. This process is repeated until the candidate vertex set is empty and a maximal independent set (MIS) is obtained. The complete Monte Carlo algorithm suggested by Luby for generating an MIS is shown in Fig. 3. In this figure, we denote by $G(V')$ the subgraph of G induced by the vertex set V'. Luby shows that an upper bound for the expected time to compute an MIS by this algorithm on a CRCW P-RAM is $EO(\log(n))$. The algorithm can be adapted to a graph coloring heuristic by using it to determine a sequence of distinct maximal independent sets and by coloring each MIS a different color. Thus, this approach will solve the $(\Delta + 1)$ vertex coloring problem, where Δ is the maximum degree of G, in expected time $EO((\Delta + 1)\log(n))$.

```
$I \leftarrow \emptyset$;
$V' \leftarrow V$;
$G' \leftarrow G$;
**While** $G' \neq \emptyset$ **do**
        Choose an independent set $I'$ in $G'$;
        $I \leftarrow I \cup I'$;
        $X \leftarrow I' \cup N(I')$;
        $V' \leftarrow V' \setminus X$;
        $G' \leftarrow G(V')$;
**enddo**
```

FIG. 3. *Luby's Monte Carlo algorithm for determining a maximal independent set.*

A major deficiency of this approach on currently available parallel computers is that each new choice of random numbers in the MIS algorithm requires a global synchronization of the processors. A second problem is that each new choice of random numbers incurs a great deal of computational overhead, because the data structures associated with the random numbers must be recomputed. In Fig. 4, we present an asynchronous heuristic that avoids both of these drawbacks. The heuristic is written assuming that each vertex v is assigned to a different processor and the processors communicate by passing messages.

```
Choose $\rho(v)$;
$n\text{-}wait = 0$;
$send\text{-}queue = \emptyset$;
For each $w \in \mathrm{adj}(v)$ do
    Send $\rho(v)$ to processor responsible for $w$;
    Receive $\rho(w)$;
    if $(\rho(w) > \rho(v))$ then $n\text{-}wait = n\text{-}wait + 1$;
    else $send\text{-}queue \leftarrow send\text{-}queue \cup \{w\}$;
enddo
$n\text{-}recv = 0$;
While $(n\text{-}recv < n\text{-}wait)$ do
    Receive $\sigma(w)$;
    $n\text{-}recv = n\text{-}recv + 1$;
enddo
$\sigma(v)$ = smallest available color consistent with the
    previously colored neighbors of $v$;
For each $w \in send\text{-}queue$ do
    Send $\sigma(v)$ to processor responsible for $w$;
enddo
```

FIG. 4. *An asynchronous parallel coloring heuristic.*

With the asynchronous heuristic the first drawback (global synchronization) is eliminated by choosing the independent random numbers only at the start of the heuristic. With this modification, the interprocessor communication can proceed asynchronously once these numbers are determined. The second drawback (computational overhead) is alleviated because with this heuristic, once a processor knows the values of the random numbers of the vertices to which it is adjacent, the number of messages it needs to wait for can be computed and stored. Likewise, each processor computes only once the processors to which it needs to send a message once its vertex is colored. Finally, note that this heuristic has more of the "flavor" of the sequential heuristic, since we choose the smallest color consistent with the adjacent vertices previously colored.

One should be concerned that the expected running time of this heuristic is comparable to the expected running time of the heuristic based on the MIS Monte Carlo algorithm. In the next section, we show that under the P-RAM computational model, one is able to obtain an improvement over the upper bound for the expected running time of the MIS algorithm.

3. Expected running time of the asynchronous heuristic.

In this section we derive an upper bound for the expected running time of the heuristic presented in Fig. 4 under the P-RAM computational model. Most of the practical problems we are concerned with are generated from local, physical models. Thus, the maximum degree of the associated graphs is independent of the size of the system. It is reasonable, therefore, to consider the model problem of a graph G with n vertices and bounded degree Δ. Since we assume that Δ is bounded, the previous work by Luby [8] shows that a random heuristic for the $(\Delta+1)$ vertex coloring problem can be accomplished on the P-RAM model in $EO(\log(n))$ time. As discussed above, this heuristic is based on a synchronous random algorithm for determining a sequence of maximal independent sets.

To analyze the running time of our heuristic, we make the following observations. First, for the sake of comparison, we note that this heuristic can also be considered synchronous. Second, we assume that each vertex $v \in V$ chooses a unique independent random number $\rho(v)$. Define a *monotonic path* of length t to be a path of t vertices $\{v_1, v_2, \ldots, v_t\}$ in G, such that $\rho(v_1) > \rho(v_2) > \cdots > \rho(v_t)$. We have the following lemma.

LEMMA 3.1. *The running time of the P-RAM version of the asynchronous heuristic is proportional to the maximum length monotonic path in G.*

Proof. We assume that the asynchronous heuristic can be made synchronous by including a global synchronization point in the receive and send loops (i.e., all processors that have messages to send, send them; all available messages are received; and then the processors synchronize). Since each vertex has degree at most Δ, the number of messages to be received and sent by each processor is bounded by this constant. Under the P-RAM computational model we can assume that messages are sent between processors in constant time. Thus, the running time of the heuristic is proportional to the number of these synchronized steps.

It is clear that the number of steps is at least as long as the longest monotonic path in G. If the number of steps were longer, there would exist some step where the random number of a processor was greater than all its neighbors, yet for some reason it did not send its messages. Hence, we have that the running time of the heuristic is proportional to the maximum length monotonic path. □

To analyze the expected running time of the heuristic, we need to construct an upper bound to the probability of the existence of a monotonic path. We construct this bound in two parts, first by finding a bound on the number of paths of length t, and then by determining the probability that a path is monotonic. The following lemma gives a bound on the number of paths of length t in the graph G.

LEMMA 3.2. *The number, $\eta(t)$, of different paths in G of length t is bounded by*

$$\eta(t) \leq n\Delta(\Delta-1)^{t-2} \quad . \tag{3.1}$$

Proof. This bound can be obtained by induction. For $t=2$, the number of paths is at most $n\Delta$. Now suppose the lemma holds for paths of length $t-1$. Consider some vertex v and all paths of length $t-1$ starting from this vertex. Each of these paths ends at some vertex w. Because an extension of this path cannot return along the edge it used to get to w, there are at most $\Delta - 1$ ways to extend this path. Multiplying the bound for the number of paths of length $t-1$ by $\Delta-1$ yields the desired result. □

Let X be the random variable equal to the maximum length monotonic path in G. Since the random numbers assigned to the vertices are independent, the probability that a path of length t is monotonic is $(1/t!)$. Let $P\{X=t\}$ be the probability that the maximum length monotonic path is t. This probability is bounded by the probability that there exists a monotonic path of length t. Including the bound given in Lemma 3.2, we find

$$P\{X=t\} \leq \frac{\eta(t)}{t!} \leq \frac{n\Delta(\Delta-1)^{t-2}}{t!}. \tag{3.2}$$

THEOREM 3.3. *The expected value of the maximum length monotonic path, EX, is bounded by*

$$EX \le T + (\Delta - 1)^K \tag{3.3}$$

for any K, where T is the minimum integer satisfying

$$T! \ge n\Delta(\Delta - 1)^{T-K-1} \exp(\Delta - 1). \tag{3.4}$$

Proof. The expected value of X is given by

$$EX = \sum_{t=2}^{n} tP\{X = t\}. \tag{3.5}$$

For any integer $T \ge 2$ we have that

$$EX \le T + \sum_{t=T+1}^{n} tP\{X = t\}. \tag{3.6}$$

Thus, we can include the bound on the probability given in (3.2) to obtain

$$\begin{aligned} EX &\le T + \sum_{t=T+1}^{\infty} t\frac{n\Delta(\Delta-1)^{t-2}}{t!} \\ &\le T + \frac{n\Delta}{(\Delta-1)}\sum_{t=T}^{\infty}\frac{(\Delta-1)^t}{t!} \\ &\le T + \frac{n\Delta}{(\Delta-1)}\frac{(\Delta-1)^T}{T!}\exp(\Delta-1)\ . \end{aligned} \tag{3.7}$$

If we choose T to be the minimum integer such that

$$T! \ge n\Delta(\Delta - 1)^{T-K-1} \exp(\Delta - 1)\ , \tag{3.8}$$

we have that the expected maximum length monotonic path is bounded by

$$EX \le T + (\Delta - 1)^K. \tag{3.9}$$ □

As a corollary, we are able to achieve a bound in terms of n for the expected running time of this algorithm. To prove this corollary, we require the following short lemma.

LEMMA 3.4. *The inequality*

$$\frac{r!}{s^r} \ge \sqrt{2\pi s}\left(\frac{\Gamma(r/s)}{e^{1/12}\sqrt{2\pi}}\right)^s \tag{3.10}$$

holds for $r \ge s \ge 1$.

Proof. First, we recall the Gamma function identity

$$r! = r\,\Gamma(r) \tag{3.11}$$

and the formula

$$\Gamma(x) = \sqrt{2\pi}\, x^{x-\frac{1}{2}}\, e^{-x}\, e^{\frac{\theta(x)}{12}}, \tag{3.12}$$

which holds for $x \geq 1$ and for $0 < \theta(x) < 1$. For $r \geq 1$, we compute the lower bound

$$\Gamma(r) \geq \sqrt{\frac{2\pi}{r}} \left(\frac{r}{e}\right)^r \tag{3.13}$$

by setting $\theta = 0$ in (3.12). Thus, we have the bound

$$\frac{r!}{s^r} \geq \sqrt{2\pi r} \left(\frac{r}{se}\right)^r . \tag{3.14}$$

We set $\theta = 1$ in (3.12) to obtain an upper bound for the Gamma function and assume that $r \geq s \geq 1$. We let $r' = r/s$ and find

$$\begin{aligned} \sqrt{2\pi r} \left(\frac{r}{se}\right)^r &= \sqrt{2\pi r} \left(\left(\frac{r'}{e}\right)^{r'} \right)^s \\ &= \sqrt{2\pi r} \left(e^{\frac{1}{12}} \sqrt{\frac{2\pi}{r'}} \left(\frac{r'}{e}\right)^{r'} e^{-\frac{1}{12}} \sqrt{\frac{r'}{2\pi}} \right)^s \\ &\geq \sqrt{2\pi r} \left(\Gamma(r') e^{-\frac{1}{12}} \sqrt{\frac{r'}{2\pi}} \right)^s \\ &\geq \sqrt{2\pi s} \left(\Gamma(r') \frac{e^{-\frac{1}{12}}}{\sqrt{2\pi}} \right)^s . \end{aligned} \tag{3.15}$$

Combining (3.14) and (3.15), we obtain the desired bound

$$\frac{r!}{s^r} \geq \sqrt{2\pi s} \left(\frac{\Gamma(r/s)}{e^{\frac{1}{12}} \sqrt{2\pi}} \right)^s . \tag{3.16}$$

□

The Gamma function is not monotonic for $x \geq 1$. However, it is monotonic for slightly larger x, for example, $x \geq \frac{3}{2}$. To avoid this lack of uniqueness, we define the function $\Gamma^+(y) = \max\{ x \mid \Gamma(x) = y \}$, which is well defined for $y \geq 1$. We now prove the following corollary to Theorem 3.3.

COROLLARY 3.5. *For $\Delta \geq 2$, the expected number of steps*, EX, *for the random heuristic is bounded by*

$$EX \leq (\Delta - 1)\Gamma^+ \left(\sqrt{2\pi}\, e^{\frac{13}{12}} \left(\frac{n\Delta}{\sqrt{2\pi}\,(\Delta-1)^{\frac{3}{2}}} \right)^{\frac{1}{\Delta-1}} \right) + 2. \tag{3.17}$$

Proof. Choosing $K = 0$ in Theorem 3.3 and subtracting one from T in equation (3.4), we have the following inequality:

$$\frac{(T-1)!}{(\Delta-1)^{T-1}} \leq \frac{n\Delta}{(\Delta-1)} \exp(\Delta - 1) . \tag{3.18}$$

We assume that $(T-1) \geq (\Delta - 1) \geq 1$, and by Lemma 3.4 we have

$$\sqrt{2\pi(\Delta-1)} \left(\frac{e^{-\frac{1}{12}}}{\sqrt{2\pi}} \Gamma\left(\frac{T-1}{\Delta-1}\right) \right)^{\Delta-1} \leq \frac{(T-1)!}{(\Delta-1)^{T-1}} . \tag{3.19}$$

Combining the bounds in (3.18) and (3.19), we obtain

$$\Gamma\left(\frac{T-1}{\Delta-1}\right) \le \sqrt{2\pi}e^{\frac{13}{12}}\left(\frac{n\Delta}{\sqrt{2\pi}\,(\Delta-1)^{\frac{3}{2}}}\right)^{\frac{1}{\Delta-1}}. \tag{3.20}$$

Using the asymptotic inverse to the Gamma function defined above, we obtain the bound

$$T-1 \le (\Delta-1)\,\Gamma^{+}\left(\sqrt{2\pi}e^{\frac{13}{12}}\left(\frac{n\Delta}{\sqrt{2\pi}\,(\Delta-1)^{\frac{3}{2}}}\right)^{\frac{1}{\Delta-1}}\right). \tag{3.21}$$

Because we have chosen $K = 0$, by Theorem 3.3 we have that $EX \le T + 1$. Thus, consistent with our original assumption that $T \ge \Delta$, we have the desired bound for EX,

$$EX \le (\Delta-1)\,\Gamma^{+}\left(\sqrt{2\pi}e^{13/12}\left(\frac{n\Delta}{\sqrt{2\pi}\,(\Delta-1)^{\frac{3}{2}}}\right)^{\frac{1}{\Delta-1}}\right)+2. \qquad \square \tag{3.22}$$

By using the lower bound for the Gamma function obtained by choosing $\theta(x) = 0$ in (3.12) we note that, for fixed Δ, this bound is asymptotically $EO(\log(n)/\log\log(n))$. This bound is an improvement over the $EO(\log(n))$ upper bound obtained by Luby [8].

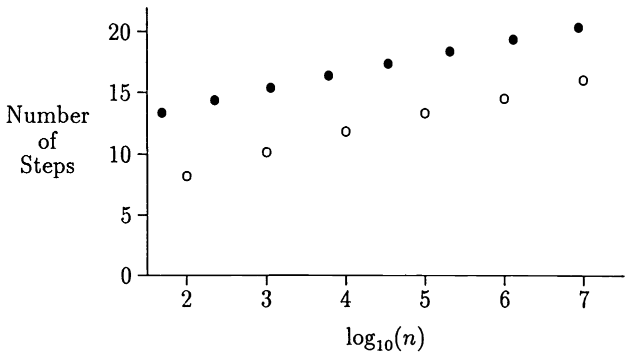

FIG. 5. *Bound obtained by choosing $K = -1$ for the expected value (●) versus experimental average (○) for regular, $\Delta = 4$, graphs.*

The bound given in Theorem 3.3 yields a surprisingly close fit to what we have observed in practice. In Fig. 5, we compare the bound for EX with our experimental results for regular graphs of degree 4. In the plot the open circles are the observed average number of steps for the asynchronous heuristic as a function of the base 10 logarithm of n. The closed circles are obtained from the bound given in Theorem 3.3, where we have chosen $K = -1$. The points are obtained by choosing a value for T and then solving (3.4) for the largest n that satisfies the inequality.

As a final note, we emphasize that, although the heuristics described above have a random component, their behavior in practice is essentially deterministic. In the above analysis, note that the probability that there exists a monotonic path of length greater than t asymptotically decays faster than exponentially. Thus, the bounds on the expected running time hold with very high probability. In addition, Luby [8] gives a prescription for converting his Monte Carlo MIS algorithm into a deterministic algorithm with the same running time. Hence, these heuristics are fundamentally different from those based on simulated annealing. Although the simulated annealing algorithms can be shown to ultimately obtain optimal solutions, running time bounds comparable to those above do not exist.

4. A medium grain heuristic for distributed memory computers.

Our primary interest is the development of a heuristic suitable for distributed memory computers. In this section, we describe how the asynchronous Monte Carlo heuristic presented in the preceding section can be combined with the heuristics that have been successful on sequential machines. Using this approach, in the next section we experimentally demonstrate that for certain classes of problems the performance is scalable.

Consider a distributed memory computer with p processors. We assume that the vertices of the graph $G = (V, E)$ are partitioned across these processors by the sets $\{V_1, \dots, V_p\}$. Let the function $\pi : V \rightarrow \{1, \dots, p\}$ return the number of the partition, or processor, to which each vertex is assigned. We define the *edge separator* E^S to be the set of edges $E^S \subseteq E$ where the edge $(v, w) \in E^S \Leftrightarrow \pi(v) \neq \pi(w)$. In addition, we define the set of *global vertices* to be the vertex set V^S, where a vertex is in this set if and only if the vertex is an endpoint for some edge in E^S. Let the set of *local vertices* V^L be the set $V \setminus V^S$. Finally, denote by V_i^S and V_i^L the vertex sets $V^S \cap V_i$ and $V^L \cap V_i$.

The following theorem shows that it is possible to decompose the asynchronous heuristic into two parts, the first part to color the global vertices, and the second part to color the local vertices. We show that the vertex labeling obtained by piecing together these colorings is a coloring for G. In this theorem we denote the subgraph of G induced by the vertex set V_i by $G(V_i)$.

THEOREM 4.1. *Let σ_S be a coloring for $G(V^S)$. This coloring, restricted to V_i^S, can be independently extended to a coloring σ_i for the subgraph $G(V_i)$. If we define the function σ by $\sigma(v) = \sigma_i(v)$, where $v \in V_i$, then σ is a coloring for G.*

Proof. Consider the vertices V_i on processor i. We assume that vertices V_i^S are consistently colored when the random heuristic colors $G(V^S)$. Thus, only the vertices V_i^L remain to be colored on this processor. By definition, the vertices V_i^L can be connected only to vertices in V_i. Because V_i^S has been colored, the vertices V_i^L may be colored independently from any other vertices in V. By the same observation, we note that if the coloring chosen for each V_i^L is consistent for $G(V_i)$, then these colorings combine to form a consistent coloring for the entire graph. $\square$

From Theorem 4.1, we observe that the parallel graph coloring problem can be accomplished in two phases:

1. Color $G(V^S)$ using the asynchronous Monte Carlo heuristic.
2. On processor i, color $G(V_i^L)$ given $\sigma_S(V_i^S)$ using a sequential heuristic.

A subtle point is that we need the Monte Carlo algorithm to generate independent sets in the graph $G_S = (V^S, E^S)$, not the graph $G(V^S)$. Note that G_S is a sparser graph than $G(V^S)$, since G_S does not contain edges (v, w) where $v, w \in V^S$ but $\pi(v) = \pi(w)$. Such edges are included in $G(V^S)$. We use the notation $\Delta_S = \Delta(G_S)$ and $n_S = |V^S|$.

```
Determine $V_i^S$, $V_i^L$;     {Partition vertices}
$color\text{-}queue = \emptyset$;
For each $v \in V_i^S$ do     {Set up queues for separator vertices}
    $n\text{-}wait(v) = 0$;
    $send\text{-}queue(v) = \emptyset$;
    For each edge $(v,w) \in E^S$ do
        Compute $\rho(w)$;
        if $(\rho(w) > \rho(v))$ then $n\text{-}wait(v) = n\text{-}wait(v) + 1$;
        else $send\text{-}queue(v) \leftarrow send\text{-}queue(v) \cup \{w\}$;
    enddo
    if $(n\text{-}wait(v) = 0)$ then
        $color\text{-}queue \leftarrow color\text{-}queue \cup \{v\}$;
enddo
Seq-color ($\sigma$, $color\text{-}queue$);     {Color any vertices in $V_i^S$ not}
$n\text{-}colored = |\, color\text{-}queue \,|$;     {waiting for messages}
Pack-and-send ($\sigma$, $color\text{-}queue$, $send\text{-}queue$);
$color\text{-}queue = \emptyset$;
While $(n\text{-}colored < |V_i^S|)$ do
    Receive $msg$;
    For each $w \in msg.vertex\text{-}list$ do
        $\sigma(w) = msg.vertex\text{-}color$;
        For each $v \in msg.vertex\text{-}adj$ do
            $n\text{-}wait(v) = n\text{-}wait(v) - 1$;
            if $(n\text{-}wait(v) = 0)$ then
                $color\text{-}queue \leftarrow color\text{-}queue \cup \{v\}$;
        enddo
    enddo
    Seq-color ($\sigma$, $color\text{-}queue$);     {Color subsets of $V_i^S$ once required}
    $n\text{-}colored = n\text{-}colored + |\, color\text{-}queue \,|$;     {messages are received}
    Pack-and-send ($\sigma$,$color\text{-}queue$, $send\text{-}queue$);
    $color\text{-}queue = \emptyset$;
enddo
Seq-color ($\sigma$, $V_i^L$ );     {Color local vertices last}
```

FIG. 6. *A distributed memory parallel coloring heuristic for the ith processor.*

Thus, we have $\Delta_S \leq \Delta(G(V^S))$, and the bounds detailed in Theorem 3.3 depend on the values of Δ_S and n_S.

In Fig. 6 we outline the complete distributed heuristic to be executed by the ith processor. The heuristic calls two procedures: *Seq-color* and *Pack-and-send.* Given a partial coloring of vertices stored in the array σ and a list *queue* of local vertices to be colored, *Seq-color*(σ, *queue*) colors these vertices with a sequential heuristic (such as the IDO heuristic discussed earlier). The procedure *Pack-and-send* sends the vertices in *queue* and their colors σ to nonlocal, adjacent vertices on other processors with lower random numbers. For vertex v this set is stored in the array *send-queue*(v), which is initialized at the beginning of the heuristic.

The ability to pack vertex information into messages allows for the optimization of interprocessor communication. For example, messages sent between processors can be packed to overcome the high message startup cost on machines like the Intel iPSC/860. The data structure *msg* that a processor receives contains a packed list of vertices, their colors, and the vertices assigned to the receiving processor to which they are adjacent. As before, the number of nonlocal vertices that must be colored before vertex v is computed at the beginning of the heuristic and stored in *n-wait*(v).

One last optimization to note is that if the pseudo-random number generator used to determine $\rho(v)$ depends only on the vertex number, then these values do not need to be sent between processors. Instead, each processor can determine these values locally, and the overhead involved with this interprocessor communication can be avoided. This optimization is included in the initialization section of Fig. 6.

5. Experimental results. We have implemented the heuristic described in Fig. 6 in the C programming language on a 64-node Intel iPSC/860. In this section we present results obtained with this implementation. One of our main objectives is to demonstrate the scalability of this heuristic consistent with the definition given in [5]. Thus, we would like to show that, for a fixed number of vertices per processor, the running time of the heuristic is only a slowly increasing function of the number of processors used.[1]

To achieve this objective, we have chosen test problems whose sizes can be easily scaled and that are also representative of problems encountered in applications. The problems we consider are generated from finite element models of structures and from finite difference schemes for two- and three-dimensional regular domains.

We consider two sets of structures problems; both are modeled by using three-dimensional, hexagonal linear elements, where the nonzero structure of the resulting assembled sparse system is used as a test matrix. The problems in Problem Set I are obtained from a model of a long rectangular beam of varying lengths, seven-by-seven finite elements thick, with the degrees of freedom constrained at both ends. The problems in the Problem Set II are generated from a model of a multistoried building of varying heights with constraints applied by elimination of the bottom layer of vertices.

For these two problem sets the vertex to processor assignment was made by assigning to each processor contiguously numbered blocks of columns based on an initial numbering. These blocks consist of n/p columns, where n is the order of the matrix and p is the number of processors. The initial numbering of the columns is chosen such that nearby nodes in the finite element models are generally close in number. Thus, this matrix partition scheme roughly corresponds to a physical partition.

In Tables 1 and 2 we show the sizes of the problems contained in these two sets. The number of vertices in the graphs is listed in the column labeled n, the number of edges is listed under m, and the maximum degree of the graph is shown under Δ. The number of colors used by a *sequential* implementation of the IDO heuristic and the SDO heuristic is given in the columns labeled χ_{IDO} and χ_{SDO}.

We also consider two sets of problems arising from standard finite differencing schemes for regular domains. In Table 3 we show the sizes of the test problems generated for the nine-point stencil on a square, two-dimensional domain. For these problems the domain is partioned into subsquares of equal size, resulting in equal numbers of vertices being assigned to each processor. To keep the aspect ratio of the subsquares the same as the problem is scaled, we change the size of the problems by a factor of four as the problem is scaled. In Table 4 we show the sizes of the test problems generated for the 27-point stencil on a cubic, three-dimensional domain.

[1]In our case, the running time will increase with problem size according to the *slowly* growing function given in Theorem 3.3.

TABLE 1
Problem Set I.

Problem	n	m	Δ	χ_{IDO}	χ_{SDO}
CUBE1	1,701	46,623	72	21	18
CUBE2	3,888	113,304	72	20	18
CUBE4	8,262	246,666	72	20	19
CUBE8	17,010	513,390	72	21	19
CUBE16	34,506	1,046,838	72	21	19
CUBE32	69,498	2,113,734	72	21	19
CUBE64	139,482	4,247,526	72	21	19

TABLE 2
Problem Set II.

Problem	n	m	Δ	χ_{IDO}	χ_{SDO}
SKY1	6,270	145,554	75	19	19
SKY2	12,540	298,751	76	21	20
SKY4	25,080	605,145	76	21	21
SKY8	50,160	1,217,933	76	21	21
SKY16	100,320	2,443,509	76	21	21
SKY32	200,640	4,894,661	76	22	22

Again, equal numbers of vertices are assigned to each processor because the domain is partioned into subcubes of equal size. For these problems the problem size increases by a factor of eight as the problem is scaled.

TABLE 3
Problem Set III.

Problem	n	m	Δ	χ_{IDO}	χ_{SDO}
9PT1	2,500	19,404	8	5	4
9PT4	10,000	78,804	8	5	4
9PT16	40,000	317,604	8	5	4
9PT64	160,000	1,275,204	8	5	4

Scaling results obtained for Problem Sets I–IV are shown in Tables 5–8. For the results presented in these four tables, the partitioning ensures that the average number of vertices per processor, $\langle n \rangle$, is essentially constant. The number of processors used is listed in the column labeled p. The number of vertices and maximum degree of G_S are given under n_S and Δ_S, respectively. The maximum time in seconds used by a processor in coloring G_S is given under T_S. T_L is the maximum time in seconds used by a processor to solve its local coloring problem. The average number of messages sent by the processors is listed under $\langle N_{\text{msg}} \rangle$. Also shown are $\tilde{\chi}_S$, the number of colors used in coloring G_S, and $\tilde{\chi}$, the number of colors used to color the entire graph. For these results the IDO heuristic is used to solve the local coloring problems.

Note that although we used the incidence degree heuristic to solve the local coloring problem for G_L, for the results presented in Tables 5–8, one could also employ the more expensive saturation degree heuristic. Recall that the SDO heuristic requires the colors used to color adjacent vertices to compute the saturation degree of each vertex. This information has already been communicated to each processor prior to the coloring of G_L; therefore, the SDO heuristic can be used to color G_L without necessitating any additional interprocessor communication. In Tables 9–12, we present the results for the parallel heuristic modified in this manner.

The results shown in Tables 5–12 demonstrate the scalable performance of the heuristic: for a fixed number of nonzeros per processor, the time required by the global and local phases is essentially constant [5]. Note that as the size of G_S increases, the average number of messages sent per processor gradually increases. By maintaining a reasonable average message size, the high communication overhead on the iPSC/860 can be partially amortized. Also, note that by using the SDO heuristic to solve the local coloring problem, a slight improvement in the total number of colors can be obtained. However, the SDO heuristic is significantly more expensive than the IDO heuristic in solving the local coloring problem.

In Tables 13 and 14, we fix the number of processors at 32 and examine the effect on the performance of the heuristic by varying the number of nonzeros per processor. For these results we use the IDO heuristic to solve the local coloring problem.

Overall, the number of colors required is relatively constant, even though the percentage of the vertices in G_S varies dramatically. To some extent this effect can be explained by noting that even though the relative size of G_S is increasing, the local structure of the separators is essentially the same, since the separators arise from physical partitions of a regular domain. In Table 14, when the relative size of G_S does became small enough to allow Δ_S to decrease, the number of colors used to color G_S, $\tilde{\chi}_S$, decreased. Finally, we note the good performance of the heuristic, both in terms of the number of colors used and execution time, as the size of the local problems becomes quite small.

6. Concluding remarks.

We have presented a new parallel graph coloring heuristic well suited to distributed memory computers. Experimental results demonstrate that this heuristic is scalable and that it produces colorings usually requiring no more than three or four more colors than the best-known linear time sequential

heuristics. We have also shown that under the P-RAM computational model, this heuristic has an expected run time bounded by $EO(\log(n)/\log\log(n))$.

This parallel heuristic takes full advantage of locality in the generation of the graph. For example, if the graph is generated by the assembly of a structures model or obtained from the spatial decomposition of a physical model, the asynchronous random phase of the heuristic can efficiently color the global separator. After the separator is colored, the remaining problem decomposes into independent local coloring problems. The only constraint on these local colorings is that they be consistent with the coloring determined for the separator. Thus, any sequential heuristic can be used to solve each of these local coloring problems simultaneously.

For many problems a physical partition can be used to generate a good vertex to processor assignment. When the determination of a partition is not straightforward, a partitioning heuristic would have to be used. For example, recent advances in the automatic partitioning of three-dimensional domains [11] or in spectral dissection methods [9] could be employed. We note that a partitioning that maintains locality is advantageous, although not essential, to the performance of the parallel heuristic. The heuristic requires only that the number of vertices assigned per processor allow for good load balancing.

An interesting observation is that even if the coloring obtained for the separator uses more colors than a good sequential heuristic, the separator subgraph is usually sparser than the entire graph. Thus, when coloring the denser local subgraphs, some of the difference between the parallel and sequential heuristics in the number of colors used for the separator subgraph can be offset by the use of a good sequential heuristic to color the remaining local subgraphs.

Finally, motivated by the following observation, we note a possible avenue for improving the heuristic. When one observes the distribution of colors produced by the heuristic, one often sees very few vertices using the highest colors. For example, when coloring the graph 27PT8 on eight processors, the results in Table 12 show that 15 colors were required by the parallel algorithm, but only 12 by the sequential algorithm. However, the number of vertices using the colors 15, 14, and 13 were

2, 12, and 70, respectively. An interesting topic for further research might be the introduction of a postprocessing step that would attempt to recolor these few vertices with lower color values, and thus decrease the total number of colors used.

Acknowledgment. We thank Tim Kiemel for help in the probabilistic analysis of the expected maximum length monotone path, and John Gilbert for bringing the paper by Michael Luby to our attention. We also thank the referees for detailed and helpful comments.

A CHOLESKY UP- AND DOWNDATING ALGORITHM FOR SYSTOLIC AND SIMD ARCHITECTURES*

CHRISTIAN H. BISCHOF[†], C.-T. PAN[‡], AND PING TAK PETER TANG[†]

Abstract. This paper presents an algorithm for maintaining Cholesky factors of symmetric positive definite matrices under arbitrary rank-one changes. The algorithm synthesizes Carlson's updating algorithm, and the downdating algorithm recently suggested by Pan to arrive at an algorithm which is both simple and allows for the pipelining of up- and downdates (in any order). On an array of $O(n^2)$ processors, the algorithm allows an $n \times n$ matrix to be updated at a cost per update that is independent of n. Implementation results on the 1024-processor AMT DAP-510 emphasize the simplicity and practicality of the proposed scheme.

Key words. Cholesky factorization, updating, downdating, systolic algorithm, SIMD algorithm

AMS(MOS) subject classifications. 15A23, 65F05, 68Q10

1. Introduction.

Given a symmetric positive definite matrix A, an important factorization of A is the Cholesky factorization

$$A = R^T R$$

where R is upper triangular. In many applications, it is desirable to recalculate the Cholesky factorization after A has been changed by a rank-one modification

$$\tilde{A} = A \pm zz^T = R^T R \pm zz^T.$$

Calculating the new factorization for $A + zz^T$ is known as *the updating problem*; recomputing $A - zz^T$ is called *the downdating problem* (see [5] for an overview).

Our work was mainly motivated by the recursive least squares filtering problem [1]. In that setting, one has to rapidly calculate a sequence of Cholesky factors $R^{(k)}$ of rank-one modified matrices

$$(R^{(k)})^T R^{(k)} = R^T R + \sigma_1 z_1 z_1^T + \cdots \sigma_k z_k z_k^T, \qquad \sigma_j \in \{-1, 1\}, k = 1, 2, \ldots.$$

Typically, k is much larger than n, the dimension of R, and often the $R^{(k)}$'s must be calculated in real time. Hence we would like to design a systolic algorithm where we maintain the Cholesky factor $R^{(k)}$ using $O(n^2)$ processors, while update vectors z_j are streaming through the processor array. To minimize the time per update, we would further like to overlap the processing of different updates so that processing of a new update vector can start at every time step. By pipelining the processing of updates in this fashion, the computation of $R^{(k)}$ is completed in $O(n + k)$ time steps, so that on the average a rank-one modification requires constant time.

The standard updating algorithm in LINPACK and the less well known one by Carlson [4] can easily be pipelined when a sequence of updates occurs. These algorithms are based on Givens rotations and operate on the upper triangular R in one pass from top to bottom.

*Received by the editors August 6, 1990; accepted for publication (in revised form) March 6, 1992. Unfortunately, this is not the case in the LINPACK downdating algorithm originally due to Saunders [10]. That algorithm completes the downdating task in two passes: a triangular solve that processes R from top to bottom, and then a set of Givens rotations that process R from bottom to top.

Recently, Pan proposed a variant of the LINPACK algorithm [8] that is at least as stable as the one in LINPACK but more economical and operates R only once—from top to bottom. In this paper, we show that by suitably combining Pan's downdating algorithm with Carlson's updating algorithm, we arrive at an algorithm that

- employs only orthogonal transformations, thereby avoiding the potential stability problems associated with hyperbolic transformations [1],
- allows the pipelining of any sequence of rank-one modifications, and
- is simple and well suited for systolic arrays and SIMD machines.

The simplicity of the algorithm, together with its low complexity, is its main virtue: the computation is extremely regular, data flow is straightforward, and no "special cases" arise. As a result, an efficient implementation of the algorithm on systolic arrays and SIMD machines is an easy task which does not require tricky coding.

We also mention that in most applications, and in particular in recursive least squares, the update of the Cholesky factor is usually followed by an equation solve. Pan and Plemmons [9] suggested a scheme to update the inverse of the Cholesky factor directly. A MIMD implementation of this scheme is described in [6]. This so-called "co-variance approach" is attractive since it replaces the triangular solve by a matrix-vector multiply. We chose here to consider the update of the Cholesky factor (the so-called "square root approach"), since it avoids potential stability problems with ill-conditioned factors, and because of the availability of efficient algorithms to handle the triangular solves on SIMD machines [11], [12].

In the next section, we present the up- and downdating algorithm that computes arbitrary sequences of rank-one modifications in a pipelined fashion. In §3 we consider the implementation of our algorithm on a massively parallel SIMD machine. Because our algorithm is simple, we are able to derive a very short and efficient program implementing our algorithm. Experiments on the 1024-processor Active Memory Technology DAP-510 parallel computer confirm the practicality and efficiency of our approach. Lastly, we summarize our results.

2. A pipelined algorithm for arbitrary up- and downdates.

Let

$$R = \begin{pmatrix} r_1^T \\ r_2^T \\ \vdots \\ r_n^T \end{pmatrix}$$

be the Cholesky factor of an $n \times n$ symmetric positive definite matrix, where r_j^T is the jth row of R. Furthermore, let

$$z^T = (\zeta_1, \zeta_2, \dots, \zeta_n)$$

be the vector determining the rank-one update or downdate.

Carlson's algorithm [4] for calculating T, $T^T T = R^T R + zz^T$, and Pan's algorithm [8] for calculating T, $T^T T = R^T R - zz^T$, are summarized in Figs. 1 and 2.

If one juxtaposes the algorithms in this fashion, it becomes apparent that there is a lot of commonality between them:

- the calculations for the α_j's and $z^{(j)}$'s are identical,

```
$\beta_0 := 1;\ z^{(0)} := z$
For $j = 1, 2, \ldots, n$ do
  $\alpha_j$   :=  $\zeta_j^{(j-1)}/r_{jj}$
  $\beta_j$   :=  $\sqrt{\beta_{j-1}^2 + \alpha_j^2}$
  $z^{(j)}$  :=  $z^{(j-1)} - \alpha_j r_j$
  $t_j$   :=  $(\beta_{j-1} r_j + \alpha_j z^{(j-1)}/\beta_{j-1})/\beta_j$
end do
```

FIG. 1. *Carlson's updating algorithm.*

```
$\beta_0 := 1;\ z^{(0)} := z$
For $j = 1, 2, \ldots, n$ do
  $\alpha_j$   :=  $\zeta_j^{(j-1)}/r_{jj}$
  $\beta_j$   :=  $\sqrt{\beta_{j-1}^2 - \alpha_j^2}$
  $z^{(j)}$  :=  $z^{(j-1)} - \alpha_j r_j$
  $t_j$   :=  $(\beta_j r_j - \alpha_j z^{(j)}/\beta_j) \Big/ \beta_{j-1}$
end do
```

FIG. 2. *Pan's downdating algorithm.*

- the calculations for the β_j's differ by only a sign, and
- the calculations for t_j share the factor $\sigma\alpha_j/(\beta_{j-1}\beta_j)$, where $\sigma = 1$ for update and $\sigma = -1$ for downdate.

As a result, one can easily merge the two algorithms to arrive at the algorithm shown in Fig. 3. Again the triangular factor R is overwritten with the updated factor T. When $\sigma = 1$, it is identical to Carlson's algorithm; when $\sigma = -1$, it is identical to Pan's algorithm.

```
$\beta_0 := 1;\ z^{(0)} := z$
For $j = 1, 2, \ldots, n$ do
  $\alpha_j := \zeta_j^{(j-1)}/r_{jj}$
  $\beta_j := \sqrt{\beta_{j-1}^2 + \sigma\alpha_j^2}$
  $z^{(j)} := z^{(j-1)} - \alpha_j r_j$
  if($\sigma == -1$) then { **downdate** }
    $t_j := (\beta_j/\beta_{j-1}) r_j + \sigma(\alpha_j/(\beta_j\beta_{j-1})) z^{(j)}$
  elseif ($\sigma == +1$) then {**update** }
    $t_j := (\beta_{j-1}/\beta_j) r_j + \sigma(\alpha_j/(\beta_{j-1}\beta_j)) z^{(j-1)}$
  end if
end do
```

FIG. 3. *Algorithm for up- and downdating.*

Recall that our objective is to calculate the Cholesky factorization of

$$(R^{(k)})^T R^{(k)} = R^T R + \sigma_1 z_1 z_1^T + \cdots \sigma_k z_k z_k^T, \qquad \sigma_j \in \{-1, 1\}, k = 1, 2, \ldots$$

for $k \gg n$ in $n + k$ steps. To that end we have to overlap the processing of different updates so that processing of different updates can start at every time step. Specifically, we wish to achieve the situation depicted in Fig. 4. Let us assume that initially

$$\begin{pmatrix} r & r & r & r & r \\ 0 & r & r & r & r \\ 0 & 0 & r & r & r \\ 0 & 0 & 0 & r & r \\ 0 & 0 & 0 & 0 & r \end{pmatrix} \Longrightarrow \begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 0 & r & r & r & r \\ 0 & 0 & r & r & r \\ 0 & 0 & 0 & r & r \\ 0 & 0 & 0 & 0 & r \end{pmatrix} \Longrightarrow \begin{pmatrix} 2 & 2 & 2 & 2 & 2 \\ 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & r & r & r \\ 0 & 0 & 0 & r & r \\ 0 & 0 & 0 & 0 & r \end{pmatrix}$$

$$\Longrightarrow \begin{pmatrix} 3 & 3 & 3 & 3 & 3 \\ 0 & 2 & 2 & 2 & 2 \\ 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & r & r \\ 0 & 0 & 0 & 0 & r \end{pmatrix} \Longrightarrow \begin{pmatrix} 4 & 4 & 4 & 4 & 4 \\ 0 & 3 & 3 & 3 & 3 \\ 0 & 0 & 2 & 2 & 2 \\ 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & r \end{pmatrix} \Longrightarrow \begin{pmatrix} 5 & 5 & 5 & 5 & 5 \\ 0 & 4 & 4 & 4 & 4 \\ 0 & 0 & 3 & 3 & 3 \\ 0 & 0 & 0 & 2 & 2 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

FIG. 4. *Pipelining up- and downdates.*

$R = R^{(0)}$ is stored in the processor array, as is indicated by the "r" entries. In the first time step, we update the first row of R to that of $R^{(1)}$ as shown in the second matrix of Fig. 4. Here (as in the following snapshots) a row of $R^{(j)}$ is denoted by j's. computed. In the next time step, we then compute the first row of $R^{(2)}$ and the second row of $R^{(1)}$ and so on. Thus, after k steps, the processor array would contain (from top to bottom)

$$(1) \qquad \begin{pmatrix} (r_1^{(k)})^T \\ (r_2^{(k-1)})^T \\ \vdots \\ (r_{n-1}^{(k-n)})^T \\ (r_n^{(k-n+1)})^T \end{pmatrix},$$

where

$$R^{(j)} = \begin{pmatrix} (r_1^{(j)})^T \\ \vdots \\ (r_n^{(j)})^T \end{pmatrix}$$

is the Cholesky factor after j up- and downdates have been performed.

Since our algorithm processes R in one pass from top to bottom, it is amenable to a pipelining implementation along the lines of Fig. 4. If we have $O(n^2)$ processors, we can dedicate j processors to computing the jth row of the updated R for $j = 1, \ldots, n$. As a result, the update of an r_j stored in a processor row takes constant time, and a new update vector z can be processed at every time step. We mention that this algorithm does compare favorably with other approaches to up- and downdating, in particular those based on hyperbolic rotations (see, for example, [2], [3] , [6], [8]; these articles contain further pointers on the rather substantial literature on this subject).

3. Experimental results. To demonstrate the practicality of our algorithm, we implemented it on an Active Memory Technology 1024-processor DAP-510 computer at Argonne's Advanced Computing Research Facility.

The DAP consists of a 32×32 array of one-bit processors and operates in SIMD mode driven by a 10-MHz clock (for an architecture overview, see [7]). The 32-bit arithmetic (applied to 1024 numbers at the same time) requires on the average 850 cycles for an add, 920 cycles for a square root, 1400 cycles for a multiply, and 1950 cycles for a divide. Communication primitives are very efficient. For example, a "spread" operation that turns a vector

$$x = \begin{pmatrix} \xi_1 \\ \vdots \\ \xi_n \end{pmatrix}$$

into a matrix

$$X = \begin{pmatrix} \xi_1 & \cdots & \xi_1 \\ \vdots & & \vdots \\ \xi_n & \cdots & \xi_n \end{pmatrix}$$

requires only 170 cycles. The DAP is not a powerful machine in terms of Mflops, but since arithmetic is performed in a bit-sliced fashion, an implementation can easily be custom tailored to specific bit lengths. That capability, together with its small power and space requirements, makes it an interesting machine for real-time embedded signal-processing applications.

The DAP can be conveniently programmed in DAP-Fortran, which contains extensions to Fortran that allow one to express operations on whole matrices and vectors with ease. Apart from the "spread" operation, we also use the "diag" primitive to extract the diagonal of a matrix in a vector, and the "shift_down" primitive, which returns

$$\begin{pmatrix} 0 \\ \xi_1 \\ \vdots \\ \xi_{n-1} \end{pmatrix}$$

for a vector x and works in an analogous fashion for matrices. Because of the SIMD nature of the machine, operations on matrices and vectors are to be understood elementwise, in other words, $C = A * B$ implies $c_{ij} = a_{ij} * b_{ij}$. Operations can be restricted to certain elements in a matrix or vector by using a so-called mask, which is an array of logical values that is **true** where an operation is to be applied. For two masks, mask1 and mask2, say, that partition a given array, we use the $\cup$ notation if a matrix is composed out of disjoint pieces, e.g.,

$$C = A(mask1) \cup B(mask2),$$

to stress the fact that no arithmetic is performed. In the description of the algorithm we use the "not" function to generate such complementary partitions.

It is easy to translate the algorithm in Fig. 3 into an efficient program for an SIMD machine such as the DAP. The program is shown in Fig. 5; to be consistent with the previous notation, we refer to matrices by upper-case roman letters, vectors by lower-case roman letters, and scalars by Greek letters. Built-in functions are denoted by bold type. The array R contains the updated Cholesky factor in the staggered form as in (1); Z contains the updated vectors $z^{(j)}$; s contains the σ's and b the β's; and *mask_down* is a mask indicating which rows are being updated and which are being downdated.

```
$Z = 0$; $s = 0$; $b = 1$; $mask\_down =$ **false**;
**for** $j = 1, 2, \ldots$ **do**
$Z(1, 1:n) = z_j$; $s(1) = \sigma_j$; $b(1) = 1$;
    $mask\_down(1) = \begin{cases} \textbf{true}, if \sigma_j = -1; \\ \textbf{false}, otherwise. \end{cases}$
    $b\_previous = b$; $Z\_previous = Z$;
    $a = \textbf{diag}(Z)/\textbf{diag}(R)$;
    $b = \textbf{sqrt}(b\_previous * *2 + s * (a * *2))$;
    $Z = Z\_previous - \textbf{spread}(a) * R$;
    $a\_bar = s * a/(b * b\_previous)$;
    $b\_bar = (b(mask\_down) \cup b\_previous(\textbf{not}(mask\_down)))$
            $/(b\_previous(mask\_down) \cup b(\textbf{not}(mask\_down)))$;
    $Z\_bar = Z\_previous(\textbf{spread}(\textbf{not}(mask\_down))) \cup Z(\textbf{spread}(mask\_down))$;
    $R = \textbf{spread}(b\_bar) * R + \textbf{spread}(a\_bar) * Z\_bar$;
    **shift\_down**($a$,$b$,$s$,$mask\_down$); **shift\_down**($Z$);
**end do**
```

FIG. 5. SIMD *program for computing rank-one Cholesky updates in a pipelined fashion.*

The simplicity of the algorithm is crucial to allow for such a short program. Particularly beneficial is the fact that we have only one if-statement whose branches perform the same operations (on different data). Remember that on an SIMD machine the branches of an if-statement

If (c) then a else b endif

are executed sequentially. First, all processors evaluate c, then the processors for which c evaluated to "true" evaluate a, and then the processors for which c evaluated to "false" evaluate b. If a and b contain arithmetic (which is expensive), the program is slowed down considerably. In our setting, statements a and b contain only data moves (which are much faster than arithmetic), since the update of R requires the same arithmetic operations (two multiplies and an add). Thus, if we ignore the time for data moves, one time step in our algorithm requires one square root, three adds, three divides, and eight multiplications. It is also easy to see that in one pass through the loop we compute (in parallel) $\frac{3}{2}n^2 + 5n$ multiplies, $n^2 + n$ adds, $3n$ divisions, and n square roots, and hence our SIMD algorithm does not compute any redundant floating-point operations compared to the sequential version.

The execution time of some experiments with matrices of size 32, 64, and 128 (computed with 32-bit floating-point arithmetic) is shown in Fig. 6. Here we generated random vectors z_j and alternated between up- and downdates. The straight lines confirm that the time per update is indeed constant: It is 2.9 milliseconds for 32×32 matrices, 5.9 milliseconds for 64×64 matrices, and 16.9 milliseconds for 128×128 matrices. Since we are limited to a fixed-size processor array (instead of having $O(n^2)$ as we assumed so far), the execution time does increase with problem size. Once n is greater than 32, matrices are folded onto the smaller 32×32 processor array, so one would expect the execution time to increase with $(n/32)^2$. In reality we do not see such growth, since we are using the hardware more efficiently when working with larger matrices: For 32×32 matrices we are only using half the available processors, for a 128×128 matrix we have 16 32×32 tiles, only four of which are triangular; all others are full.

4. Conclusions. Building on the work of Carlson [4] and Pan [8], we developed a stable algorithm for maintaining Cholesky factors of symmetric positive definite

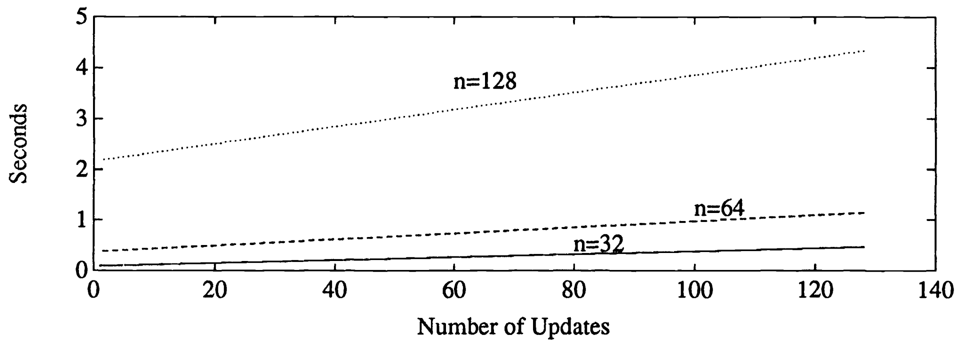

FIG. 6. *Execution time as a function of the number of updates performed.*

matrices under arbitrary rank-one modifications (as long as they maintain positive definiteness). Each rank-one modification requires only $\frac{3}{2}n^2$ multiplications and n^2 additions; and, for the most part, the computation of up- or downdates involves the same operation. As a result, one can easily pipeline different rank-one updates to arrive at an algorithm that on a systolic array or massively parallel SIMD machine requires constant time per update.

The new algorithm is well suited for signal processing applications. Its computational complexity compares favorably to that of other approaches, it avoids the potential stability problems associated with hyperbolic rotations, and as our implementation on the 1024-processor AMT DAP has shown, an efficient implementation on an SIMD machine or systolic array can be easily obtained.

INDEX REDUCTION IN DIFFERENTIAL-ALGEBRAIC EQUATIONS USING DUMMY DERIVATIVES*

SVEN ERIK MATTSSON† AND GUSTAF SÖDERLIND‡

Abstract. A new index reduction algorithm for DAEs is developed. In the usual manner, parts of the DAE are differentiated analytically and appended to the original system. For each additional equation, a derivative is selected to be replaced by a new algebraic variable called a *dummy derivative.* The resulting augmented system is at most index 1, but no longer overdetermined. The dummy derivatives are not subject to discretization; their purpose is to annihilate part of the dynamics in the DAE, leaving only what corresponds to the dynamics of a state-space form. No constraint stabilization is necessary in the subsequent numerical treatment. Numerical tests indicate that the method yields results with an accuracy comparable to that obtained for the corresponding state-space ODE.

Key words. differential-algebraic, index reduction, dummy derivative, constraint stabilization, solution invariant, automatic differentiation

AMS(MOS) subject classification. 65L05

1. Introduction.

We shall develop a new index reduction technique for differential-algebraic equations (DAEs)

$$F(t,x,\dot{x}) = 0. \tag{1.1}$$

We assume that the problem is *solvable* [4], with a unique, smooth solution when supplied with an appropriate number of consistent initial conditions. The *index* of the problem equals the minimum number of times that all or part of (1.1) must be differentiated with respect to t in order to determine $\dot{x}$ as a continuous function of x and t [4] and is assumed to be constant along the solution. In addition, F is assumed to be sufficiently differentiable to allow the proposed index reduction technique. For alternative definitions of the index, cf. [11] or [14].

It is well known that it is numerically difficult to solve a high-index DAE. Index reduction methods provided in the literature (see, e.g., [4, p. 33]) can be used as a remedy. However, it is often less satisfactory to solve the underlying ordinary differential equation, or UODE, that has been derived from the DAE through index reduction. The reason is that the set of solutions to the UODE is larger than the corresponding set of solutions to the original DAE; the algebraic relations of the DAE are only implicit in the UODE as solution invariants. Unless linear, these invariants are generally not preserved under discretization. As a result, the numerical solution drifts off the algebraic constraints, often leading to instabilities [10]. Consequently, so-called constraint stabilization techniques have been devised [1], [3], [12].

To avoid such difficulties, one may try to obtain a low-index formulation, with a solution set identical to that of the original problem. This can be achieved by augmenting the system as the index reduction proceeds: all original equations and their successive derivatives are retained in the process. The result is an overdetermined but consistent index-1 DAE. Like invariants, however, consistency is generally lost

when the system is discretized. Therefore, special projection techniques are required for the numerical solution (see, e.g., [8] or [9]). Related approaches using least-squares projections have been used in [2], [5], and [6].

The index reduction technique proposed in this paper, which was outlined in [16], overcomes the latter complication by introducing a new dependent variable for each new equation generated in the reduction process. This generates an augmented, determined index-1 DAE from the original problem. The method is related to classical reduction to state-space form; the remaining dynamics of the problem is represented by a selection of its original variables, forming a (local) UODE. The other variables are solved for in terms of the UODE states. The technique is applicable to large classes of problems and can be practically implemented, using symbolic or automatic differentiation [13], [18].

We shall outline our method in a simple example. Consider the DAE problem

$$\dot{x} = y, \tag{1.2a}$$

$$\dot{y} = z, \tag{1.2b}$$

$$x = f(t). \tag{1.2c}$$

This is an index-3 *derivative chain* with solution $x = f(t)$, $y = \dot{f}(t)$, and $z = \ddot{f}(t)$. It may be thought of as prototypical for prescribed-trajectory problems in mechanics, where one wants to calculate the (usually generalized) forces required for the system to accomplish the desired action. In such an application x, y, and z would represent position, velocity, and force per unit mass, respectively, and $f(t)$ is the prescribed trajectory for the system.

A sufficient condition for the index to be at most 1 is that we are able to solve for the highest-order derivatives in the system, i.e., $\dot{x}$, $\dot{y}$, and z. This is obviously impossible in (1.2). Differentiating (1.2a) once and (1.2c) twice yields, after reordering equations and variables,

$$\ddot{x} = \ddot{f}(t), \tag{1.2c$''$}$$

$$\dot{y} = \ddot{x}, \tag{1.2a$'$}$$

$$z = \dot{y}, \tag{1.2b}$$

which is index 1. Here (1.2a′) denotes the derivative with respect to t of (1.2a).

Now, consider the overdetermined but consistent system obtained by augmenting the original system by the successive derivatives of (1.2a) and (1.2c):

$$x = f(t), \tag{1.3c}$$

$$\dot{x} = \dot{f}(t), \tag{1.3c$'$}$$

$$\ddot{x} = \ddot{f}(t), \tag{1.3c$''$}$$

$$y = \dot{x}, \tag{1.3a}$$

$$\dot{y} = \ddot{x}, \tag{1.3a$'$}$$

$$z = \dot{y}. \tag{1.3b}$$

For each *differentiated equation* appended to the original system, we need one "new" dependent variable to make the augmented system determined rather than overdetermined. This is achieved by replacing one derivative from each *differentiated* equation by a new algebraic variable. Thus we eliminate $\ddot{x}$ by substituting a *dummy derivative* x'' for $\ddot{x}$ wherever it occurs in the system (1.3). Although $x'' \equiv \ddot{x}$, *the dummy* *derivative is a purely algebraic variable and is not subject to discretization.* Similarly, we replace $\dot{x}$ by x' and $\dot{y}$ by y'. We have chosen this notation for the dummy derivatives to directly indicate what they represent and how they were introduced into the augmented system.

We have thus obtained the augmented but determined system

$$x = f(t), \tag{1.4a}$$

$$x' = \dot{f}(t), \tag{1.4b}$$

$$x'' = \ddot{f}(t), \tag{1.4c}$$

$$y = x', \tag{1.4d}$$

$$y' = x'', \tag{1.4e}$$

$$z = y'. \tag{1.4f}$$

This purely algebraic (hence index-1) system is mathematically equivalent to (1.2). No initial conditions can be imposed, and no discretization is required for its numerical solution. The system is nonsingular since it is possible to solve algebraically for the six unknowns x, x', x'', y, y', and z. Although this example is rather special, it demonstrates an important aspect of the new reduction technique: that the system can be solved numerically without discretizing all derivatives.

In the following sections we shall describe how to proceed in the general case. We first show how to obtain the appropriate differentiated system and then how to select dummy derivatives to make the augmented system determined. We shall also deal with pivoting of the selected set of dummy derivatives, before presenting numerical results.

2. Differentiation and permutation of equations.

For notational convenience, we shall rewrite (1.1) as an operator equation

$$\mathcal{F}x = 0. \tag{2.1}$$

The dependent variables may appear algebraically or differentiated up to q times. We assume that for some $p \geq q$ the $\mathbb{R}^n$-valued function $x \in \mathcal{C}^p$. Similarly, $\mathcal{F}x \in \mathcal{C}^{p-q}$ is an $\mathbb{R}^n$-valued function.

Let $D = d/dt$ denote the differentiation operator, and let $\nu \in \mathbb{N}^n$ denote a multi-index $\nu = (\nu_1, \nu_2, \ldots, \nu_n)^T$. Then we define $D^\nu = \operatorname{diag}(D^{\nu_1}, \ldots, D^{\nu_n})$. We let $\mu(\mathcal{F}) \in \mathbb{N}^n$ denote a multi-index such that $D^{\mu(\mathcal{F})}x$ are the highest-order derivatives appearing in the DAE, i.e., $x_j^{(\mu_j)}$ is the highest-order derivative of x_j that appears in $\mathcal{F}x = 0$.

2.1. Structural properties and permutations.

Following [4, p. 21], we call a property of a matrix a *generic* or *structural property* if it holds almost everywhere in a neighborhood of the particular values of the *nonzero entries* of the matrix. A matrix A is structurally nonsingular if and only if there exists a permutation P_1 such that P_1A has a nonzero diagonal, often referred to as a *maximum transversal* or an *output set*. A structurally singular matrix is also singular, but the converse is not true. Similar definitions for a nonlinear system $g(v) = 0$ are obtained by requiring that the system's structural Jacobian can be permuted to obtain a nonzero diagonal. Likewise, we call the DAE problem (1.1) structurally nonsingular if there is an output set when we consider x to be unknown and do not distinguish algebraic and differentiated appearances of x.

We shall make use of block lower triangular (BLT) partitioning in order to decompose a problem into subproblems. By means of a simultaneous row and column permutation of P_1A, the matrix is transformed into $Q^T P_1 A Q = PAQ$, a BLT matrix with the same nonzero diagonal elements as P_1A. Output assignment and BLT partitioning are standard techniques in sparse matrix analysis; cf. [7].

2.2. Differentiations. For a structurally nonsingular DAE $\mathcal{F}x = 0$, it is always possible to find a differentiated problem $\mathcal{G}x = D^\nu \mathcal{F}x = 0$ with ν finite, such that the differentiated problem is structurally nonsingular with respect to its highest-order derivatives $D^{\mu(\mathcal{G})}x$. Pantelides's algorithm (cf. [17]) intended for finding consistent initial values for a DAE, establishes the minimum number of times each equation has to be differentiated, i.e., it finds the minimal $\nu(\mathcal{F})$. His algorithm also constructs the output set of interest automatically, and in the structural analysis step we need only construct the desired BLT partition.

By definition, the problem $\mathcal{F}x = 0$ is index 0 if it uniquely determines the highest-order derivatives $D^{\mu(\mathcal{F})}x$, with all $\mu_j(\mathcal{F}) > 0$, as continuous functions of t and lower derivatives. If the same condition holds with some $\mu_j(\mathcal{F}) = 0$, it is Index 1. The fact that it is not possible to solve uniquely for the highest-order derivatives does not imply that the index is greater than 1: consider the simple index-1 problem:

$$\dot{x} + \dot{y} = 1, \qquad x - y = 0.$$

Thus Pantelides's algorithm may call for an unnecessary differentiation step (here it would suggest differentiating the second equation once, resulting in an index-0 system) but it is simple to remove such superfluous differentiations. Whether this should be done or not depends on if one prefers to be able to solve for the highest-order derivatives or to reduce the index to 1 while introducing as few new variables as possible.

In our algorithm below, we must be able to solve for the highest-order derivatives. We defer comments on the singular case to §4.

2.3. Differentiation, permutation, index reduction algorithm. The index reduction procedure for $\mathcal{F}x = 0$ consists of the following steps:

1. If the problem is structurally singular, then return an error message.
2. *Differentiation.* Use Pantelides's algorithm to obtain
   (a) a vector $\nu(\mathcal{F}) \in \mathbb{N}^n$,
   (b) a differentiated problem $\mathcal{G}x = \mathcal{F}^\nu x = 0$ with $\mathcal{F}^\nu = D^{\nu(\mathcal{F})}\mathcal{F}$,
   (c) an output set for $\mathcal{F}^\nu x = 0$ with respect to its highest-order derivatives $D^{\mu(\mathcal{G})}x$ as unknowns.
3. *Permutation.* Since $P\mathcal{F}^\nu Q = PD^{\nu(\mathcal{F})}P^T P\mathcal{F}Q = D^{P\nu(\mathcal{F})}P\mathcal{F}Q$, BLT partitioning with respect to unknowns $D^{\mu(\mathcal{G})}x$ yields the permuted
   (a) undifferentiated problem $\mathcal{H}y = 0$ with $\mathcal{H} = P\mathcal{F}Q$ and $y = Q^T x$,
   (b) differentiated problem $\mathcal{H}^{P\nu}y = 0$ with $\mathcal{H}^{P\nu} = P\mathcal{F}^\nu Q$, i.e., $\nu(\mathcal{H}) = P\nu(\mathcal{F})$, and the latter problem is BLT with respect to its highest-order derivatives $D^{Q^T\mu(\mathcal{G})}y$.
4. *Index reduction.* Select derivatives to be replaced by dummy derivatives, blockwise as indicated by the BLT partition. If unable to select one dummy for each differentiated equation (singular case), manipulate original equations using information from differentiated equations and restart at step 1.

In the rest of this paper we will focus on the central index reduction step, i.e., how to select dummy derivatives. Note (cf. Step 4 below) that this relies on finding a *nonsingular* submatrix, implying that this step is numerical/mathematical as opposed to the two structural steps of differentiation and permutation. To simplify the notation we will without loss of generality view the BLT partitioned problem as our original problem, i.e., $\mathcal{F} = \mathcal{H}$.

3. Selection of dummy derivatives.

Consider the differentiated problem $\mathcal{G}x = \mathcal{F}^\nu x = 0$ in BLT form. For notational simplicity, let $g_i = 0$ represent the ith block of $\mathcal{G}x = 0$, let z_i denote the vector of highest-order derivatives of the unknowns associated with that block, and note that $\dim z_i = \dim g_i$. Let $f_i = 0$ be the corresponding block of the original problem $\mathcal{F}x = 0$. We make the following assumptions:

A1. $\mathcal{G}x = \mathcal{F}^\nu x = 0$ is in BLT form.

A2. The equations in each block have been sorted in descending order with respect to number of differentiations, i.e., $\nu_1(g_i) \geq \nu_2(g_i) \geq \cdots$.

A3. The Jacobian $\partial g_i/\partial z_i$ evaluated at the current point on the solution has full rank (the singular case will be discussed later).

To obtain an equivalent index-1 problem, the reduction algorithm constructs a sequence of $\nu_1(g_i) + 1$ problems indexed by a superscript $[j]$.

3.1. Index reduction algorithm.

Step 1: Set $z_i^{[1]} \leftarrow z_i$; $g_i^{[1]}(z_i^{[1]}) \leftarrow g_i(z_i)$; $G_i^{[1]} = \partial g_i^{[1]}/\partial z_i^{[1]} \leftarrow \partial g_i/\partial z_i$; $j \leftarrow 1$.

Step 2: If $g_i^{[j]} = 0$ has no differentiated equations, go to Step 6.

Step 3: If $g_i^{[j]} = 0$ has m differentiated equations, let $h_i^{[j]} = 0$ denote its m first equations. The Jacobian $H_i^{[j]} = \partial h_i^{[j]}/\partial z_i^{[j]}$ then equals the first m rows of $G_i^{[j]}$, due to the sorting with respect to number of differentiations.

Step 4: Next, select m columns $l_1, \ldots, l_m$ of $H_i^{[j]}$ to make a square, nonsingular matrix $M_i^{[j]}$. Selected columns indicate derivatives to be replaced: from the m equations $h_i^{[j]} = 0$ we select the m components of $\hat{z}_i^{[j]} = (\, z_{i,l_1}^{[j]} \ \cdots \ z_{i,l_m}^{[j]} \,)^T$ to be replaced (in Step 6) by dummy derivatives.

Step 5: Now decide how to use the *predecessor* of $h_i^{[j]} = 0$, denoted by $D^{-1}h_i^{[j]} = 0$, thus omitting the last differentiation. New candidates $z_i^{[j+1]}$ for possible replacement are $D^{-1}\hat{z}_i^{[j]}$, i.e., derivatives of one order less than those selected in Step 4. The components of $\hat{z}_i^{[j]}$ are all highest-order derivatives in $h_i^{[j]} = 0$ and are differentiated at least once. Hence, they represent derivatives of the original unknowns x, implying that $D^{-1}\hat{z}_i^{[j]}$ is well defined. The Jacobian $\partial g_i^{[j+1]}/\partial z_i^{[j+1]} = M_i^{[j]}$, as will be shown later. Thus, set

$$g_i^{[j+1]} \leftarrow D^{-1}h_i^{[j]}; \quad z_i^{[j+1]} \leftarrow D^{-1}\hat{z}_i^{[j]}; \quad G_i^{[j+1]} \leftarrow M_i^{[j]}; \quad j \leftarrow j+1,$$

and repeat from Step 2.

Step 6: Let $k_i = j$. We now obtain an index-1 formulation of $f_i = 0$ by collecting all original and all differentiated equations:

$$\begin{pmatrix} g_i^{[k_i]} \\ \vdots \\ g_i^{[1]} \end{pmatrix} = 0.$$

In all equations, introduce a unique *dummy derivative* for each derivative selected in Step 4 (i.e., the variables given by $\hat{z}_i^{[k_i]}, \ldots, \hat{z}_i^{[1]}$), to replace that derivative wherever it occurs. The system now consists of the original equations $f_i = 0$ and the sequence of differentiated equations leading to $g_i = 0$. The unknowns are the original ones and the newly introduced all-algebraic dummy derivatives. □

Before proving that the algorithm converts $f_i = 0$ to an equivalent index-1 formulation, let us first consider its application to a simple linear problem.

EXAMPLE 1. Let our problem $\mathcal{F}x = 0$ be defined as

$$x_1 + x_2 + u_1(t) = 0, \tag{3.1a}$$
$$x_1 + x_2 + x_3 + u_2(t) = 0, \tag{3.1b}$$
$$x_1 + \dot{x}_3 + x_4 + u_3(t) = 0, \tag{3.1c}$$
$$2\ddot{x}_1 + \ddot{x}_2 + \ddot{x}_3 + \dot{x}_4 + u_4(t) = 0, \tag{3.1d}$$

where the $u_m(t)$ are known forcing functions. The differentiated problem $\mathcal{G}x = 0$ is

$$\ddot{x}_1 + \ddot{x}_2 + \ddot{u}_1(t) = 0, \tag{3.1a$''$}$$
$$\ddot{x}_1 + \ddot{x}_2 + \ddot{x}_3 + \ddot{u}_2(t) = 0, \tag{3.1b$''$}$$
$$\dot{x}_1 + \ddot{x}_3 + \dot{x}_4 + \dot{u}_3(t) = 0, \tag{3.1c$'$}$$
$$2\ddot{x}_1 + \ddot{x}_2 + \ddot{x}_3 + \dot{x}_4 + u_4(t) = 0, \tag{3.1d}$$

which was obtained by differentiating (3.1a) and (3.1b) twice and (3.1c) once. The vector of highest-order derivatives in $\mathcal{G}x = 0$ is $z_1 = (\ddot{x}_1 \quad \ddot{x}_2 \quad \ddot{x}_3 \quad \dot{x}_4)^T$.

Block triangularization results in a single block, $g_1(x) = \mathcal{G}x$, and the differentiated problem is index 0, since the Jacobian with respect to the highest-order derivatives

$$\frac{\partial g_1}{\partial z_1} = G_1^{[1]} = \begin{array}{c} \\ (a'') \\ (b'') \\ (c') \\ (d) \end{array} \begin{array}{c} \begin{array}{cccc} \ddot{x}_1 & \ddot{x}_2 & \ddot{x}_3 & \dot{x}_4 \end{array} \\ \begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \\ 2 & 1 & 1 & 1 \end{pmatrix} \end{array}$$

is nonsingular. This matrix is set up in Step 1. Throughout the steps of the index reduction, we indicate at the Jacobians which equations and variables are presently being considered. The reduction process essentially takes $G_1^{[1]}$ and successively deletes rows and columns. The proper choice of dummy derivatives is deduced during this process.

We have three differentiated equations, and Step 3 gives

$$H_1^{[1]} = \begin{array}{c} \\ (a'') \\ (b'') \\ (c') \end{array} \begin{array}{c} \begin{array}{cccc} \ddot{x}_1 & \ddot{x}_2 & \ddot{x}_3 & \dot{x}_4 \end{array} \\ \begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \end{pmatrix} \end{array}.$$

At Step 4 we have two possibilities to select a nonsingular submatrix of $H_1^{[1]}$; columns 1, 3, and 4 or columns 2, 3, and 4. Let us take the first alternative:

$$M_1^{[1]} = \begin{array}{c} \\ (a'') \\ (b'') \\ (c') \end{array} \begin{array}{c} \begin{array}{ccc} \ddot{x}_1 & \ddot{x}_3 & \dot{x}_4 \end{array} \\ \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix} \end{array}.$$

Thus we use (3.1a″), (3.1b″), and (3.1c′) to replace the derivatives $\ddot{x}_1$, $\ddot{x}_3$, and $\dot{x}_4$. Then, at Step 5 we prepare for the next cycle and consider the predecessor of the present subproblem, omitting one differentiation:

$$G_1^{[2]} = \begin{array}{c} \\ (\text{a}') \\ (\text{b}') \\ (\text{c}) \end{array} \begin{array}{c} \begin{array}{ccc} \dot{x}_1 & \dot{x}_3 & x_4 \end{array} \\ \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix} \end{array}.$$

Now $j = 2$, and we repeat from Step 2. Since we still have differentiated equations, Step 3 yields

$$H_1^{[2]} = \begin{array}{c} \\ (\text{a}') \\ (\text{b}') \end{array} \begin{array}{c} \begin{array}{ccc} \dot{x}_1 & \dot{x}_3 & x_4 \end{array} \\ \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \end{pmatrix} \end{array}.$$

At Step 4 we have to select the two first columns, and we obtain

$$M_1^{[2]} = \begin{array}{c} \\ (\text{a}') \\ (\text{b}') \end{array} \begin{array}{c} \begin{array}{cc} \dot{x}_1 & \dot{x}_3 \end{array} \\ \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} \end{array}.$$

Thus we use (3.1a′) and (3.1b′) to replace $\dot{x}_1$ and $\dot{x}_3$. Step 5 therefore results in

$$G_1^{[3]} = \begin{array}{c} \\ (\text{a}) \\ (\text{b}) \end{array} \begin{array}{c} \begin{array}{cc} x_1 & x_3 \end{array} \\ \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} \end{array}.$$

Since there are no differentiated equations, we go to Step 6 and collect the pieces. To get a simple and clear notation, we let x_1'' denote the dummy derivative that is substituted for $\ddot{x}_1$, and similarly for other derivatives.

(3.2a) $$x_1 + x_2 + u_1(t) = 0,$$
(3.2b) $$x_1 + x_2 + x_3 + u_2(t) = 0,$$

(3.2a′) $$x_1' + \dot{x}_2 + \dot{u}_1(t) = 0,$$
(3.2b′) $$x_1' + \dot{x}_2 + x_3' + \dot{u}_2(t) = 0,$$
(3.2c) $$x_1 + x_3' + x_4 + u_3(t) = 0,$$

(3.2a″) $$x_1'' + \ddot{x}_2 + \ddot{u}_1(t) = 0,$$
(3.2b″) $$x_1'' + \ddot{x}_2 + x_3'' + \ddot{u}_2(t) = 0,$$
(3.2c′) $$x_1' + x_3'' + x_4' + \dot{u}_3(t) = 0,$$
(3.2d) $$2x_1'' + \ddot{x}_2 + x_3'' + x_4' + u_4(t) = 0.$$

The nine unknown variables are x_1, x_3, x_1', x_3', x_4, x_1'', x_3'', x_4', and x_2, which are all algebraic except for x_2, which appears differentiated twice.

The problem is now index 1, with the equations ordered as in Step 6. It is BLT with respect to its highest-order derivatives. The first block consists of the equations from the last loop of the selection procedure, which gave (3.2a) and (3.2b), from which we can solve for x_1 and x_3. The second block consists of the equations from the second-to-last loop, which gave (3.2a′), (3.2b′), and (3.2c), from which we can solve x_1', x_3', and x_4. The third and last block consists of the equations from the first loop, which gave (3.2a″), (3.2b″), (3.2c′), and (3.2d), from which we can solve x_1'', $\ddot{x}_2$, x_3'', and x_4'. □

3.2. Proof of index reduction. We shall outline proofs of the crucial parts of Steps 4, 5, and 6.

Step 4: First we will prove by induction that one can select a nonsingular matrix $M_i^{[j]}$ at Step 4. By assumption A3, $G_i^{[1]}$ has full rank. If $G_i^{[j]}$ has full rank and there are differentiated equations, then $H_i^{[j]}$ has full rank. Hence it is possible to select a square nonsingular submatrix $M_i^{[j]}$. Defining $G_i^{[j+1]} = M_i^{[j]}$ then implies that $G_i^{[j+1]}$ has full rank. By induction it follows that it is possible to select a full rank matrix $M_i^{[j]}$ each time we arrive at Step 4.

Step 5: Next, we show the formula $G_i^{[j+1]} = M_i^{[j]}$ at Step 5. It implies that $G_i^{[j]} = \partial g_i^{[j]}/\partial z_i^{[j]}$. Consider the element p, q of $G_i^{[j+1]}$. We have

$$G_{i,pq}^{[j+1]} = \partial g_{i,p}^{[j+1]}/\partial z_{i,q}^{[j+1]} = \partial D^{-1} g_{i,p}^{[j]}/\partial D^{-1} z_{i,l_q}^{[j]},$$

and for the same element of $M_i^{[j]}$, we have

$$M_{i,pq}^{[j]} = \partial h_{i,p}^{[j]}/\partial \hat{z}_{i,q}^{[j]} = \partial g_{i,p}^{[j]}/\partial z_{i,l_q}^{[j]}.$$

The formula $G_i^{[j+1]} = M_i^{[j]}$ now follows directly from the fact that for any differentiable function $e(t, v)$, $\partial e(t, v)/\partial v = \partial \dot{e}(t, v, \dot{v})/\partial \dot{v}$.

Step 6: We shall now show that the problem generated by the algorithm is at most index 1. We first consider the reduction of a block. The equations are $g_i^\star(z_i^\star) = 0$ with

$$g_i^\star = \begin{pmatrix} g_i^{[k_i]} \\ \vdots \\ g_i^{[1]} \end{pmatrix}, \qquad z_i^\star = \begin{pmatrix} z_i^{[k_i]} \\ \vdots \\ z_i^{[1]} \end{pmatrix}.$$

Considered as an algebraic problem, $g_i^\star(z_i^\star) = 0$ is BLT, where we can take the jth block to consist of the equations $g_i^{[j]} = 0$ with the unknowns $z_i^{[j]}$. Since the Jacobian $\partial g_i^{[j]}/\partial z_i^{[j]} = G_i^{[j]}$ is nonsingular, we can solve for all the unknowns $z^\star$. The variables of $z_i^{[j]}$ are of two categories. First, $z_i^{[j]}$ contains the variables $\hat{z}_i^{[j]}$ selected for replacement in Step 5 of the jth loop. The remaining variables clearly represent highest-order derivatives of the old variables x in the problem generated by the algorithm. Thus $z^\star$ contains all the highest-order derivatives of the problem generated by the algorithm, and since we can solve for them, the problem is at most index 1.

Finally, consider the complete problem. Sort the block subsystems $g_i^{[j]} = 0$ with respect to descending order of the index j, and with respect to descending order of the index i. The unknowns $z_i^{[j]} = 0$ are sorted similarly. The resulting problem is then BLT with nonsingular blocks. Consequently, the complete problem is at most index 1. □

The original problem and the problem resulting from the algorithm are mathematically equivalent in the sense that they have identical solution sets in the original (undifferentiated) dependent variables x. Original algebraic equations are still explicitly present. The advantage of the index reduction technique proposed here is that it excludes some derivatives from discretization; by treating the dummy derivatives as algebraic variables, the problem of inconsistency due to discretization is eliminated.

3.3. Removing superfluous differentiations. As was mentioned in §2, Pantelides's algorithm differentiates some problems to index 0 and others to index 1. If the differentiated problem is index 0, the number of dummy derivatives introduced can be decreased by reintroducing some of them as ordinary derivatives. This also reduces the total number of equations accordingly. The procedure is to modify Step 6 in the following way:

1. Do not include the equations of $g_i^{[1]} = 0$, which are differentiated.

2. Do not replace the corresponding selected components $\hat{z}_i^{[1]}$ with dummy derivatives, but replace them with the first-order derivative of the representatives for their predecessors, $D^{-1}\hat{z}_i^{[1]}$, some of which may be dummy derivatives.

EXAMPLE 2. Let us again consider the problem discussed in Example 1. The differentiated problem (3.1) is index 0, since it contains no algebraic variables. This implies that we can obtain a smaller index-1 formulation by disregarding the most differentiated equations, i.e., (3.2a″), (3.2b″), and (3.2c′). The corresponding highest-order derivatives $\ddot{x}_1$, $\ddot{x}_3$, and $\dot{x}_4$ are not replaced by dummy derivatives, but with dx_1'/dt, dx_3'/dt and $\dot{x}_4$, respectively. The problem then becomes

$$x_1 + x_2 + u_1(t) = 0, \tag{3.3a}$$
$$x_1 + x_2 + x_3 + u_2(t) = 0, \tag{3.3b}$$

$$x_1' + \dot{x}_2 + \dot{u}_1(t) = 0, \tag{3.3a'}$$
$$x_1' + \dot{x}_2 + x_3' + \dot{u}_2(t) = 0, \tag{3.3b'}$$
$$x_1 + x_3' + x_4 + u_3(t) = 0, \tag{3.3c}$$

$$2\dot{x}_1' + \ddot{x}_2 + \dot{x}_3' + \dot{x}_4 + u_4(t) = 0. \tag{3.3d}$$

The six unknowns are x_1, x_3, x_1', x_3', x_4, and x_2, which are all dynamic except for the two algebraic variables x_1 and x_3. The problem is index 1, since by differentiating all but the last equation once, we obtain an index-0 problem. □

This technique may also be applied to some problems that Pantelides's algorithm differentiates to index 1, viz., if the differentiated problem contains index-0 subproblems. Such subproblems may then be treated as in Example 2.

4. Pivoting of dummy derivatives. The algorithm described above assumes that the Jacobian with respect to the highest-order derivatives of the differentiated problem $\mathcal{F}^\nu x = 0$ is nonsingular. If the Jacobian is singular, a more detailed analysis is required. It should be noted that the index reduction algorithm given above transforms the original system *locally* to index 1. Clearly, it could happen that the Jacobian becomes singular along the solution trajectory. The singularity may be due to a (locally) inappropriate selection of dummy derivatives. Therefore, this selection must, in general, be dynamic; i.e., we must be prepared to "pivot" the selection of dummy derivatives.

EXAMPLE 3. The inevitable pendulum. Consider a planar pendulum of mass m and length L. In Cartesian coordinates, the equations of motion are

$$x^2 + y^2 - L^2 = 0, \tag{4.1a}$$

(4.1b) $$m\ddot{x} + (\lambda/L)x = 0,$$
(4.1c) $$m\ddot{y} + (\lambda/L)y + mg = 0,$$

where g is the gravitational constant and λ is the force in the string; the index is 3.

Applying Pantelides's algorithm, the length constraint is differentiated twice:

(4.1a) $$x^2 + y^2 - L^2 = 0,$$
(4.1a′) $$2x\dot{x} + 2y\dot{y} = 0,$$
(4.1a″) $$2x\ddot{x} + 2\dot{x}^2 + 2y\ddot{y} + 2\dot{y}^2 = 0.$$

Thus, the differentiated problem is

(4.1a″) $$2x\ddot{x} + 2\dot{x}^2 + 2y\ddot{y} + 2\dot{y}^2 = 0,$$
(4.1b) $$m\ddot{x} + (\lambda/L)x = 0,$$
(4.1c) $$m\ddot{y} + (\lambda/L)y + mg = 0.$$

The Jacobian J of the differentiated problem with respect to the highest-order derivatives $(\ddot{x} \quad \ddot{y} \quad \lambda)^T$ is

$$J = \begin{pmatrix} 2x & 2y & 0 \\ m & 0 & x/L \\ 0 & m & y/L \end{pmatrix}.$$

Since $\det(J) = -2m(x^2+y^2)/L = -2mL$, the differentiated problem is index 1 if and only if $m \neq 0$ and $L \neq 0$. In this case, the index reduction algorithm gives

$$\begin{array}{ccccc} & & \ddot{x} & \ddot{y} & \lambda \\ H_1^{[1]} = & (\mathrm{a}'') & (2x & 2y & 0). \end{array}$$

Neither x nor y is necessarily nonzero for all times. Due to the length constraint, however, they are not simultaneously zero. By choosing $M_1^{[1]} = (2x)$ when $|x| > |y|$ and $M_1^{[1]} = (2y)$ otherwise, we obtain a well-conditioned $M_1^{[1]}$.

Consider first the case $|x| > |y|$. Selecting $F_1^{[1]} = (2x)$ implies that the differentiated length constraint will be used to replace $\ddot{x}$ and $\dot{x}$, and we obtain

(4.2a) $$x^2 + y^2 - L^2 = 0,$$
(4.2a′) $$2xx' + 2y\dot{y} = 0,$$
(4.2a″) $$2xx'' + 2x'^2 + 2y\ddot{y} + 2\dot{y}^2 = 0,$$
(4.2b) $$mx'' + (\lambda/L)x = 0,$$
(4.2c) $$m\ddot{y} + (\lambda/L)y + mg = 0.$$

When $|x| \leq |y|$, we select $F_1^{[1]} = (2y)$. We then obtain the index-1 problem

(4.3a) $$x^2 + y^2 - L^2 = 0,$$
(4.3a′) $$2x\dot{x} + 2yy' = 0,$$
(4.3a″) $$2x\ddot{x} + 2\dot{x}^2 + 2yy'' + 2y'^2 = 0,$$
(4.3b) $$m\ddot{x} + (\lambda/L)x = 0,$$
(4.3c) $$my'' + (\lambda/L)y + mg = 0.$$

Changing the decision as to whether (4.1a″) and (4.1a′) should be used to replace $\ddot{x}$ and $\dot{x}$ or $\ddot{y}$ and $\dot{y}$, can be interpreted as a pivoting operation, and we refer to it at as *dummy pivoting.* From this example, it can be seen that dummy pivoting corresponds to a (locally necessary) change of mathematical models; cf. [15]. Switching from one model to the other is a simple operation, since in the augmented index-1 problem we solve also for the dummy derivatives. The initial values necessary to continue the numerical integration with the new model are readily available, and the need for restarting the integration can usually be avoided. □

A very simple first approach to handle dummy pivoting is to make a selection at the start and use the resulting equations as long as the numerical DAE solver is able to function properly and pivot only when necessary. In general, however, it is preferable to pivot so that the matrices $M_i^{[j]}$ remain well conditioned. It is therefore desirable to have a rather close integration of the index reduction method and the numerical DAE solver. This suggests that index reduction computations should be incorporated into the solver, rather than being considered as a separate preprocessing tool.

EXAMPLE 4. Lagrangian equations of motion. The Lagrangian equations of the first kind for a constrained mechanical system are written as a second-order equation:

$$M(p)\ddot{p} = F(p,\dot{p}) - G^T(p)\lambda, \tag{4.4a}$$
$$0 = g(p), \tag{4.4b}$$

where p is an n-vector representing the system's position, M is the nonsingular mass matrix, F represents applied forces, and λ is the m-vector of Lagrange multipliers associated with the m constraints (4.4b), assumed to have a full-rank constraint matrix $G(p) = \partial g/\partial p$. Thus the system has $n - m$ degrees of freedom, and the system of equations (4.4) is index 3. Two differentiations of the constraint equation results in

$$M(p)\ddot{p} = F(p,\dot{p}) - G^T(p)\lambda, \tag{4.4a}$$
$$0 = g(p), \tag{4.4b}$$
$$0 = G\dot{p}, \tag{4.4b$'$}$$
$$0 = \dot{G}\dot{p} + G\ddot{p}. \tag{4.4b$''$}$$

Here $\dot{G} = G'\dot{p}$, where G' is the Fréchet derivative of G with respect to p. We can solve for the highest-order derivatives $\ddot{p}$ and λ, since the regularity assumptions imply that $GM^{-1}G^T$ is regular. Selecting dummy derivatives implies choosing m dummies among the n variables $\dot{p}$, and m among $\ddot{p}$, using (4.4b′) and (4.4b″). Then we have a total of $n+3m$ equations, $n+m$ original variables p and λ, and $2m$ dummy derivatives (selected elements of $\dot{p}$ and $\ddot{p}$). The application of dummy derivatives to the Euler–Lagrange equations is similar to the method of *generalized coordinate partitioning.*

It is also instructive to apply the index reduction algorithm to the corresponding first-order system

$$\dot{p} = v, \tag{4.5a}$$
$$M(p)\dot{v} = F(p,v) - G^T(p)\lambda, \tag{4.5b}$$
$$0 = g(p), \tag{4.5c}$$

where the n-vector v represents velocity. Applying Pantelides's algorithm now requires also that (4.5a) is differentiated once, and as before, the resulting differentiated problem is second order. Apart from the same dummies as those selected in (4.4), one will have to select n dummy derivatives $v' = \dot{v}$. However, this variable merely accounts for a trivial action of substitution and can immediately be eliminated. If a first-order system is required, it can easily be obtained after a few more similar operations; it is identical to the first-order system that can be obtained from (4.4). $\square$

Let us finally comment on the singular case. Then, if the index of the differentiated problem is greater than one, it is, at least in principle, possible to derive an equation in which none of the unknown highest-order derivatives appears. However, since we need the whole sequence of differentiated equations, we shall manipulate the original, undifferentiated system so that the corresponding differentiated problem has the desired structure with a nonsingular Jacobian.

EXAMPLE 5. A singular system. Consider the following problem [4, p. 23]:

$$\dot{x} + t\dot{y} = f_1, \tag{4.6a}$$

$$x + ty = f_2. \tag{4.6b}$$

The problem is solvable, and the unique solution is $x = f_2 - t(\dot{f}_2 - f_1)$, $y = \dot{f}_2 - f_1$. Pantelides's algorithm differentiates the second equation once and yields

$$\dot{x} + t\dot{y} = f_1, \tag{4.6a}$$

$$\dot{x} + t\dot{y} + y = \dot{f}_2. \tag{4.6b$'$}$$

It is not index 1, since it is singular in $\dot{x}$ and $\dot{y}$.

The approach is now to consider the most differentiated equations and use them and their predecessors to eliminate variables in the other original equations. Equation (4.6b$'$) depends on $\dot{x}$ and $\dot{y}$. Try to solve (4.6b) for x or y. Solving for x, we obtain $x = f_2 - ty$ and $\dot{x} = \dot{f}_2 - y - t\dot{y}$. Substitution into (4.6a) yields $y = \dot{f}_2 - f_1$, in which neither $\dot{x}$ nor $\dot{y}$ appears. Let this equation replace (4.6a) and consider

$$y = \dot{f}_2 - f_1, \tag{4.7a}$$

$$x + ty = f_2 \tag{4.7b}$$

as the new original problem. The modified problem is then simpler than the original problem. In this particular case, it is algebraic, hence index 1, and can be solved immediately. $\square$

The example above demonstrates a more difficult type of index reduction. In contrast to the operations performed by the index reduction algorithm of §3, problems having a rank-deficient Jacobian with respect to the highest-order derivatives will also require that equations be solved symbolically or seminumerically. As the example indicates, this typically entails using an elimination process of Gaussian type. The index reduction algorithm of §3 will reveal whether such a process is necessary. However, we consider developing a full treatment of singular systems beyond the scope of this paper.

5. Numerical results.

We shall now present numerical results for the pendulum problem of Example 3 using the well-known solver DASSL. The numerical solution for various formulations is discussed in [4, pp. 150–157]. There, the evolution of the pendulum equations is computed for a short time interval covering less than a full period. Here we are concerned with the stability and numerical drift of constraints and invariants, thus requiring simulations long enough to reveal secular effects; in all cases, the problem was run for well over a hundred periods. In all the numerical results we use $g = 1$, $m = 1$, and $L = 1$.

In the discussion below, we follow the convention in [4] that the positive direction of the gravitational force is opposite to the direction of the y-axis in the Cartesian coordinate system. Note, however, that for their numerical results to be correct [4, pp. 155–157], we must assume that they have accidentally switched the direction of the y-axis, cf. the obvious misprint in the state-space equation (6.2.5) in [4, p. 151].

The state-space form of the planar pendulum equations is

$$\ddot{\varphi} + \frac{g}{L}\sin\varphi = 0, \tag{5.1}$$

where $x = L\sin\varphi$ and $y = -L\cos\varphi$. This model will be used as a reference model for comparing the numerical results.

Besides studying how well the length constraint is preserved in the numerical solutions, it is also of great interest to study the invariant total energy E, which is the sum of the kinetic energy and the potential energy. The rest state ($\varphi = 0$, $\dot{\varphi} = 0$) is taken as the reference level with $E = 0$. This gives

$$E = \frac{m}{2}L^2\dot{\varphi}^2 + mgL(1 - \cos\varphi).$$

A numerical solution should preserve the energy and keep E constant within numerical accuracy. The expression for the energy can also be used to calculate the amplitude φ_M of the oscillations.

We shall study two cases:

1. Small oscillations with $\varphi(0) = 0.1$ and $\dot{\varphi}(0) = 0.0$, which gives the amplitude $\varphi_M = 0.1$, period time $T \approx 6.29$, and energy $E = 1 - \cos 0.1$.

2. Large oscillations with $\varphi(0) = \pi/2$ and $\dot{\varphi}(0) = -1.0$ as used in [4], which gives an amplitude $\varphi_M = 2\pi/3$, period time $T \approx 8.63$, and energy $E = 1.5$.

The first case is almost linear, whereas the second, with its large amplitude, is strongly nonlinear and will require four dummy pivotings per full period. Whenever DAEs are solved below, the initial conditions are taken to be consistent.

The two problems will be solved for the following formulations:

a. State-space reference model (5.1).

b. Differentiated index-1 model (4.1a″), (4.1b), (4.1c).

c. Stabilized constraint index-2 model [4, pp. 154–155].

d. Dummy derivative index-1 model (4.3), case 1, and (4.2)–(4.3) for case 2.

In all cases the problems were run for 1000 units of time corresponding to approximately 159 periods in case 1, and 116 periods in case 2. Tolerance levels were kept sharp; the parameters ATOL and RTOL in DASSL were taken to be 10^{-9} for all components of the solution except for the model *c*, which cannot be solved with such requirements unless a looser tolerance is used for the two Lagrange multipliers λ and μ. These tolerances were set to 10^{-2}, which effectively corresponds to excluding these algebraic variables from the error tests; cf. [4, p. 156]. Numerical Jacobians were used.

The results for case 1 are displayed in Table 1. Apart from run statistics, we show the deviation ΔE in total energy at the end of the integration interval, and similarly the deviation ΔL in the length constraint. E-drift and L-drift refer to the drifts in E and L, respectively. Note that the length constraint is explicitly present in models *c* and *d*, but it is only an implicit invariant in model *b*. Thus, model *b* shows a drift, and the deviation in the table refers to the error at the end of the integration interval. For models *c* and *d*, there is no drift and the error corresponds to typical deviations throughout the integration. The energy, on the other hand, is an implicit invariant in all four models, resulting in a quite regular drift. For model b, the drift is quadratic in t, whereas the other models exhibit a linear drift. It is to be noted that the drift is less pronounced for models c and d than for the state-space model a.

Results for case 2 are shown in Table 2. Here model d yields the most accurate results, with an energy drift approximately four times smaller than for a, and 25 times smaller than for model c. From the efficiency point of view, the state-space model a is clearly preferable. However, given the rather significant difference in accuracy between models c and d, the modest performance disadvantage of model d seems to be of minor importance.

The results reported here are typical for the pendulum problem. A few other problems from applications in mechanics and electrical engineering have also been tried with good results using the dummy derivative technique.

TABLE 1
Numerical results for small oscillations (case 1) with models a–d.

6. Implementation aspects and conclusions. When the proposed index reduction technique is to be implemented, there are two main possibilities. One could either perform all operations completely using symbolic computations in a preprocessing step, or one could employ automatic differentiation [13], [18] to obtain a close integration of the index reduction process and the subsequent numerical treatment. The latter approach seems particularly attractive, since in the augmented system, function evaluations corresponding to differentiated equations must be performed using analytical derivatives that must be continually reevaluated. In addition, the subsequent numerical solution could take advantage of analytical Jacobians. The choice of differentiation technique is probably the most important decision in an implementation of the reduction method. The most important difference between symbolic and automatic differentiation is that the latter can be applied directly to the subprograms defining the DAE. Thus, neither a symbolic representation of the equations nor a code generation step is needed, making automatic differentation much more favorable in our context.

A second important issue is the choice of the matrices $M_i^{[j]}$ by selecting m linearly independent columns from $H_i^{[j]}$. We should aim for well-conditioned matrices, and hence the columns should be selected carefully. An obvious approach is to use a Gram–Schmidt procedure to successively find a set of "maximally" linearly independent columns. However, this approach will depend on the choice of the initial column selected, and it will generally not be possible to find the optimal set.

As far as the practical issues of dummy pivoting are concerned, it is required that one monitors the condition of the matrices $M_i^{[j]}$. Dummy pivoting corresponds to replacing one or more columns of $M_i^{[j]}$ by new columns from $H_i^{[j]}$. It is as yet unclear how this can be carried out inexpensively in large systems. Most likely, it is more demanding to continually monitor the condition than to actually perform the pivoting operation. It should be noted that well-conditioned matrices $M_i^{[j]}$ are needed to ensure that the selected dummy derivatives cancel the exact amount of dynamics in the augmented DAE system, leaving only what corresponds to the dynamics of a state-space form. If the selection is rank deficient, there is a risk that the numerical integration method will get stuck in a singular point. Such effects can readily be seen, e.g., in the pendulum problem; if one inappropriately uses (4.2) for small amplitudes (i.e., when $|x| \ll |y|$), it may very well happen that the integration method cannot get past $x = 0$.

In many cases of practical interest, one will not need a complete automatic reduction procedure, but only the handling of dummy derivatives. Thus, the structure (4.4) is common to all systems described by the Lagrangian equations of the first kind. Therefore, it is sufficient in such applications to select dummy derivatives properly.

The merits of the index reduction technique proposed in this paper lie in the fact that the dummy derivatives are identified and excluded from discretization. As a result, one avoids "over-discretization" of the DAE, and the differentiations inherent in a high-index DAE are carried out analytically rather than numerically. Since the algebraic equations are still present in their original form, there will be no numerical drift away from the solution manifold of the DAE, thus eliminating the need for constraint stabilization. As for invariants that are implicit in both the DAE and the state-space ODE (e.g., energy), the drift is very similar in both formulations. To sum up, the numerical experiments show that, by using the dummy derivative formulation, an accuracy comparable to that of solving a state-space formulation of the problem is obtained. Thus the technique may be considered a viable alternative not only to constraint stabilization, but even to state-space formulations whenever the latter are difficult to obtain.

Acknowledgments. The authors would like to acknowledge helpful discussions on this work with Prof. Steve Campbell and Dr. Bo Bernhardsson.

ILL-CONDITIONING IN NEURAL NETWORK TRAINING PROBLEMS*

S. SAARINEN[†], R. BRAMLEY[†], AND G. CYBENKO[†‡]

Abstract. The *training* problem for feedforward neural networks is nonlinear parameter estimation that can be solved by a variety of optimization techniques. Much of the literature on neural networks has focused on variants of gradient descent. The training of neural networks using such techniques is known to be a slow process with more sophisticated techniques not always performing significantly better. This paper shows that feedforward neural networks can have ill-conditioned Hessians and that this ill-conditioning can be quite common. The analysis and experimental results in this paper lead to the conclusion that many network training problems are ill conditioned and may not be solved more efficiently by higher-order optimization methods. While the analyses used in this paper are for completely connected layered networks, they extend to networks with sparse connectivity as well. The results suggest that neural networks can have considerable redundancy in parameterizing the function space in a neighborhood of a local minimum, independently of whether or not the solution has a small residual.

1. Introduction.

Some neural network techniques are, in a strictly mathematical sense, an approach to function approximation. As with most approximation methods, they require the estimation of certain (possibly nonunique) parameters which are defined by the problem to be solved [14]. In neural network terminology, finding those parameters is called the *training problem*, and algorithms for finding them are called *training algorithms*. This nomenclature comes from analogy with biological systems, since a set of inputs to the function to be approximated are presented to the network, and the parameters are adjusted to make the output of the network close in some sense to the known value of the function.

Feedforward neural networks use a specific parameterized functional form to approximate a desired input/output relation. Typically, a system is sampled resulting in a finite set of pairs $(t, \tau) \in \mathbb{R}^p \times \mathbb{R}$ where the first coordinate is a position in p-dimensional space and the second coordinate refers to the assigned value for the point. The feedforward neural network function, also from $\mathbb{R}^p \mapsto \mathbb{R}$, has a set of parameters, called weights, which must be determined so that the input and output values as given by the sample data are matched as closely as possible by the approximating neural network. The neural network function for the ith input pattern $(i = 1, 2, \ldots, m)$ can be written succinctly in the form

$$F = F(t_i, \mathbf{x}), \tag{1}$$

where t_i is a p-dimensional input vector, and where $\mathbf{x} \in \mathbb{R}^n$ is the weight vector of parameters to be determined. The form of the function $F(t_i, \mathbf{x})$ for a feedforward network is presented and derived in §3. Let the desired value (or output) for the ith input be denoted by τ_i. A common formulation of the training problem is to find

values of $\mathbf{x}$ such that the norm of $f(\mathbf{x}) = (f_1(\mathbf{x}), f_2(\mathbf{x}), \ldots, f_m(\mathbf{x}))^T$ is minimized, where f_i denotes the residual between the value of the approximating function and the desired value

$$f_i(\mathbf{x}) = F(t_i, \mathbf{x}) - \tau_i.$$

Often the l_2-norm is used in the minimization of such a function, and we obtain a least squares problem

$$\|f(\mathbf{x}^*)\|^2 = \min_{\mathbf{x}\in\mathbb{R}^n} \sum_i f_i(\mathbf{x})^2. \tag{2}$$

A numerical minimization algorithm is applied to this equation in order to find a suitable $\mathbf{x}^*$. This minimization is called training.

The current interest in using feedforward neural networks for pattern recognition problems has revealed that the training algorithms are computationally time consuming for a large class of algorithms [17]. Examples of these algorithms are backpropagation (which can be classified as a steepest descent algorithm), conjugate gradient algorithms, and other nonlinear optimization algorithms for parameter estimation. However, little research has been directed into the question of understanding why the training algorithms are slow to converge on neural networks even though the underlying techniques often perform very well for other problems. This paper addresses the question of why these algorithms converge slowly by showing that rank-deficiencies may appear in the Jacobian for a neural network, making the problem numerically ill conditioned.

Except for pattern search methods, the convergence properties of optimization algorithms for differentiable functions depend on properties of the first and/or second derivatives of the objective function [9]. For example, steepest descent explicitly requires the first derivative to define its search direction, and implicitly relies on the second derivative whose properties govern the rate of convergence. When optimization algorithms converge slowly (or not at all) for neural network problems, this suggests that the underlying derivative matrices are numerically ill conditioned. The obvious questions to ask in this case are:

- Will using a higher-order method help avoid this problem? For example, will a quasi-Newton or Newton method reduce the number of iterations?
- Is the mathematical formulation of the training problem the "correct" one? For example, by changing the parameterization or scaling of the problem, can the training algorithm be made more rapidly convergent?
- Is the difficulty of solving the training problem an intrinsic feature of the neural network itself, and not an artifact of the problem formulation and chosen training algorithm?

The proliferation of neural network techniques makes it impossible to answer these questions for all types of networks and all types of problems the networks are to solve. This paper concentrates on one type of network, a multilayer feedforward network, and one type of problem, approximating indicator functions of sets in the plane. These choices were made because multilayer feedforward networks are commonly used by researchers and the classification problem is one for which neural nets are potentially suitable; see [3], [15], and [8]. Furthermore, the training problems examined here are primarily *overdetermined*, that is, the number of training data points is greater than or equal to the number of network parameters. This seems to match the intended usage of neural networks, since for problems such as speech recognition or classification problems the amount of training data available exceeds the number of parameters that can be accommodated in a practical neural network. The results, however, also seem to apply to underdetermined problems.

It is important to observe that the rank-deficiency shown and explained in the subsequent analysis is independent of the size of the residual. Therefore, the fact that a network configuration cannot exactly "solve" a classification problem does not mean that the network parameterization is parsimonious or not redundant. In fact, rank-deficiency is an indication that redundancy does occur locally. As a simple example, consider using m polynomials of degree n or less, $n < m$, to perform a least squares fit on $m+1$ or more data points in general position: the residual will generically be nonzero, but the function class is inherently overparameterized. This redundancy is usually considered an advantage of neural networks, allowing some degree of fault tolerance.

In this paper we will first review nonlinear least squares problems; second, we will describe further the neural network problem and show general properties of the Jacobian for a feedforward neural network; and finally, we will investigate the Jacobian and Hessian for some examples. The analytic results about the Jacobian show that it can be rank-deficient in certain situations that can be enumerated. We then show that this rank-deficiency actually occurs in a number of experiments. For methods that use Hessian information explicitly, the rank-deficiency or ill-conditioning of the Jacobian still plays a role because the Jacobian part of the Hessian is dominant. We emphasize that this paper deals only with the least squares formulation of a training algorithm, and that all the results obtained are for this class of problems.

2. Review of nonlinear least squares. The material in this section establishes notation and describes the difficulties imposed by a rank-deficient or ill-conditioned Jacobian. We define the rank and the condition number of a matrix $A \in \mathbb{R}^{l\times q}$ $(l \geq q)$ by the singular value decomposition $A = U\Sigma V^T$, where $U^TU = I_l$, $V^TV = I_q$, and $\Sigma \in \mathbb{R}^{l\times q}$ is a diagonal matrix $\text{diag}(\sigma_1, \sigma_2, \ldots, \sigma_q)$ with $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_q \geq 0$. A has rank $r < q$ if $\sigma_{r+1} = \cdots = \sigma_q = 0$ and $\sigma_r \neq 0$. The *degree of rank-deficiency* of A is $q - r$. The *condition number* of A is $\kappa = \kappa(A) = \sigma_1/\sigma_r$, and A is *ill conditioned* if $\kappa(A)$ is "large." Except in special cases, in practice it is rare to find singular values exactly equal to zero, and numerically determining r is difficult (see, for example, Figs. 6–8). Because of this the numerical examples of this paper will take $q = r$, but the analytic descriptions will also discuss the $q < r$ case. Note that if $\sigma_{r+1}, \ldots, \sigma_q > 0$ are all very small relative to σ_1, A is close to being rank-deficient of degree at least $q - r$.

Letting $\phi(\mathbf{x}) = \frac{1}{2} \parallel f(\mathbf{x}) \parallel^2$ in (2), the gradient of ϕ is

$$\nabla\phi(\mathbf{x}) = J(\mathbf{x})^T f(\mathbf{x}), \tag{3}$$

and the Hessian matrix of ϕ is

$$H(\mathbf{x}) = J(\mathbf{x})^T J(\mathbf{x}) + \sum_{i=1}^{m} f_i(\mathbf{x}) H_i(\mathbf{x}), \tag{4}$$

where $[J_{ij}] = \partial f_i/\partial x_j$ is the Jacobian matrix of $f(\mathbf{x})$ and $H_i(\mathbf{x})$ is the Hessian matrix of the component function $f_i(\mathbf{x})$. For convenience, the explicit dependence on $\mathbf{x}$ will sometimes be omitted by writing $H = J^TJ + \sum_{i=1}^m f_iH_i$, etc. Algorithms for minimizing $\phi(\mathbf{x})$ usually take advantage of the special structure of $\nabla\phi(\mathbf{x})$ and $H(\mathbf{x})$; the reader is referred to [5] for a survey of such algorithms.

A given point $\mathbf{x}^*$ is a *critical point* of ϕ if $\nabla\phi(\mathbf{x}^*) = 0$, and $\mathbf{x}^*$ is a local minimum only if all the eigenvalues of $H(\mathbf{x}^*)$ are nonnegative. One of the weaknesses of commonly used neural network training algorithms is the failure to check the obtained "solution" for optimality, except in the trivial consistent case where $f(\mathbf{x}^*) = 0$. Optimization methods for solving the nonlinear least squares problem generate a search direction $\mathbf{p}$ and a stepsize α from the current iterate $\mathbf{x}$. The search direction and stepsize are usually chosen so that $\phi(\mathbf{x}+\alpha\mathbf{p}) < \phi(\mathbf{x})$. Table 1 shows the search directions used by some common optimization methods, assuming that J is full rank.

TABLE 1
Search directions used by various optimization methods.

Algorithm	Search direction
Steepest descent	$-J^T f$
Conjugate gradient	$-J^T f + \beta\tilde{p}$, with $\tilde{p}$ = previous search direction β = a scalar
Newton	$-(J^T J + \sum_{i=1}^m f_i H_i)^{-1} J^T f$
Gauss–Newton	$-(J^T J)^{-1} J^T f$
Levenberg–Marquardt	$-(J^T J + \rho_k I)^{-1} J^T f$
Quasi-Newton	$-(J^T J + B_k)^{-1} J^T f$, B_k satisfying a quasi-Newton condition

2.1. Local convergence. The local convergence properties of the methods in Table 1 depend on the size of the residual $f(\mathbf{x}^*)$ and the rank and condition number of $H(\mathbf{x}^*)$, the Hessian at the solution. Steepest descent has a q-linear rate of convergence (see [11] for a definition of q-linear) with an asymptotic error constant proportional to $(\kappa - 1)/(\kappa + 1)$, where κ is the condition number of $H(\mathbf{x}^*)$ [9]. Conjugate gradient methods generally have a linear rate of convergence, but their behavior depends on the definition of the conjugacy scalar β as well as the frequency of *restart*, i.e., reinitialization of the algorithm [13]. Quasi-Newton methods have a superlinear rate of convergence if, roughly speaking, $H(\mathbf{x}^*)$ is nonsingular and the matrices B_k are chosen so that $J^T J + B_k$ approximates $H(\mathbf{x}^*)$ along the search directions; see [4] for a more detailed description of both quasi-Newton methods and their convergence properties. Newton's method has a quadratic rate of convergence, provided that the Hessian is nonsingular at $\mathbf{x}^*$. The other methods have local convergence properties that can be seen by considering them as approximations to Newton's method. For example, if the residual is zero at $\mathbf{x}^*$, then $H(\mathbf{x}^*) = J^T(\mathbf{x}^*)J(\mathbf{x}^*)$ and the Gauss–Newton method shares the quadratic convergence rate of Newton's method if $J(\mathbf{x}^*)$ is full rank. Under the same conditions the Levenberg–Marquardt method has quadratic convergence when the ρ_k in Table 1 is zero; in practice, ρ_k is chosen to provide better global convergence. When the residual is large, however, Gauss–Newton and Levenberg–Marquardt methods have a linear convergence rate.

2.2. Global convergence. Minimization algorithms can spend the majority of their time in finding a neighborhood of the solution in which local convergence theorems apply, so the local convergence rate is irrelevant if the algorithm fails to enter that neighborhood or if it is extremely small. Note the critical dependence of all of the methods in Table 1 on the Jacobian J; each simply multiplies the *fundamental* search direction $-J^T f$ by some matrix estimating second-order information (for steepest descent the matrix is I) except for the conjugate direction, which has a linear combination of the current and previous vectors $-J^T f$ as its search direction. The search directions for the Newton or Gauss–Newton methods are ill defined when the Hessian is singular or the Jacobian is not full rank, respectively, but the Levenberg–Marquardt parameter ρ_k and the quasi-Newton matrix B_k are normally chosen to assure that their respective search directions are well defined. Unfortunately, if J or the Hessian are rank-deficient or ill conditioned at many of the iterate points, the methods can actually perform worse than steepest descent, which in turn can fail to converge in finite precision arithmetic.

2.3. Regularization. When J is rank-deficient or ill conditioned, these algorithms can be generalized by two common regularization approaches. The first replaces J with $J_r = U\Sigma_r V^T$, where $\Sigma_r = \mathrm{diag}(\sigma_1, \sigma_2, \ldots, \sigma_r, 0, \ldots, 0)$, $J = U\Sigma V^T$ is the singular value decomposition of J, and r is an estimate of the rank of J as discussed above. However, the computational determination of r is a difficult problem, and can have a dramatic effect on the resulting search direction (see the example in [6, p. 136]). Furthermore, the resulting search direction has nonzero components only in a subspace of dimension r. When $r \ll n$ and the subspace changes slowly from iteration to iteration, the method can fail to make sufficient progress to a minimum. Methods for circumventing this difficulty generally add a component in the orthogonal complement of the subspace of dimension r to the search direction, as in [6]. A second regularization approach adds a small multiple $\gamma \parallel \mathbf{x} \parallel$ of the norm of the weight vector to the objective function, possibly allowing γ to change on each iteration. This restricts the size of the weights, but unfortunately the weights frequently need to be large for accurate learning, i.e., a good least squares solution. So if γ is prevented from decreasing to zero the quality of solution can suffer, while if γ is decreased to zero eventually the same ill-conditioning problems are encountered. Nevertheless, the Levenberg–Marquardt algorithm used in §3.4 implicitly uses this second form of regularization (see [10]), and can provide adequate solutions in many cases.

For most overdetermined nonlinear least squares problems, these considerations are minor. Generally the Jacobian is full rank (but ill-conditioning can occur) and it is only at exceptional points that J is rank-deficient, but even then the rank-deficiency is small. For neural network problems, however, we show that a large number of columns of the Jacobian can easily be nearly linearly dependent and so the matrix is close in 2-norm to a matrix with a large degree of rank-deficiency.

3. Neural network training problems. A neural network consists of three types of computational elements or nodes arranged in layers: input layer nodes, hidden layer nodes, and output layer nodes with weighted connections between them. Each node has *several* inputs and only *one* output. A feedforward neural network has connections between neighboring layers with information flowing only in one direction. There are no connections within a layer. We further use networks which are fully connected between layers, that is, every node in a given layer has a directed connection with all the nodes in the previous layer and in the successive layer. Such a neural network with two hidden layers is depicted in Fig. 1. The flow of information is upwards in the figure. The input layer nodes and the output layer nodes are depicted by triangles, and the hidden layer nodes by circles. All arrows leaving a given node denote the unique output for the node. A hidden layer node forms its output o by first forming the weighted sum of its inputs u_i,

$$s = \sum_{i=1}^{j} x_i u_i + x_0,$$

where the $x_i, i = 0, \ldots, j$ are called weights and x_0 is called an offset. The hidden node then applies a univariate excitation function $\sigma(s)$ to the weighted sum s and this value, $o = \sigma(s)$, becomes the output of the node. The input layer and output layer nodes do not apply an excitation function to their inputs. Therefore, the ***inputs*** in Fig. 1 are the same as the network inputs (shown as v_1 and v_2). A more elaborate description of neural networks in general can be found in [15]. We will next derive the functional form of the network function.

FIG. 1. *A 2-3-2 feedforward neural network with the weights indicated by $x_i, i = 1, \ldots, 19$. The offsets are written inside the nodes (indicated by circles). The quantities P_j and Q_i are discussed in the text.*

Let the number of inputs to the network be h, the number of first layer nodes be p, and the number of second layer nodes be s. The network can then be concisely labeled as $h - p - s$ and Fig. 1 represents a 2-3-2 network. Let the total number of training data points be m and the total number of parameters (i.e., weights associated with the arcs and offsets in the nodes) be $n = p(h + s + 1) + 2s$.

For the ith training data input pattern we write

$$t_i = (v_1^{(i)}, v_2^{(i)}, \ldots, v_h^{(i)}),$$

and let weights associated with the input layer arcs be $x_{(j-1)(h+1)+1+k}$, $1 \le j \le p$ and $1 \le k \le h$, and the offsets associated with the first layer nodes be $x_{(j-1)(h+1)+1}$, where $1 \le j \le p$.

Then we can write for the output of the jth first layer node for the training data point i

$$\sigma(P_j^{(i)}) = \sigma\left(\sum_k x_{(j-1)(h+1)+1+k}\, v_k^{(i)} + x_{(j-1)(h+1)+1}\right), \tag{5}$$

where σ is a sigmoidal or excitation function. Similarly, for the second layer nodes let the weights on the arcs be $x_{t+(l-1)(f+1)+1+j}$, where $t = p(h+1)$, $1 \le l \le s$ and $1 \le j \le p$, and the offsets be $x_{t+(l-1)(p+1)+1}$, where $1 \le l \le s$. The output of the lth second layer node for training data point i is

$$\sigma(Q_l^{(i)}) = \sigma\left(\sum_j x_{t+(l-1)(p+1)+1+j}\, \sigma(P_j^{(i)}) + x_{t+(l-1)(p+1)+1}\right). \tag{6}$$

Furthermore, if the weights on the last layer are x_{u+l}, where $1 \le l \le s$ and $u = t + s(p+1)$, then the output of the network for training data point i is

$$F(t_i, \mathbf{x}) = \sum_l x_{u+l}\, \sigma(Q_l^{(i)}). \tag{7}$$

In this paper we assume that the node on the last layer will not apply an excitation function to its inputs (this will not make the problem less general but rather avoid using one extra parameter). The aim is to find the weights on the arcs and the offsets by minimizing (2) and using some input-output pairs of the patterns that the network should approximate.

The form of the excitation function can vary. Examples include

$$\sigma_1(x) = \frac{1}{1+e^{-x}} \quad \text{and} \quad \sigma_2(x) = \frac{2}{\pi}\tan^{-1} x. \tag{8}$$

The functions $\sigma_1(x)$ and $\sigma_2(x)$ are called sigmoidal functions, and their ranges are $(0,1)$ and $(-1,1)$, respectively. Note that both their derivatives approach 0 when $|x| \gg 1$. The general form of these functions can be obtained by making the transformation $x \mapsto \alpha x + \beta$, but the ranges of the functions and their general form stay the same. It has been shown that under very general conditions on the activation functions, such classes of neural networks as in (7) are universal approximators [3]. The main reason for choosing the two functions in (8) is that they can approximate the hard delimiter step function and are continuously differentiable. In this paper we will use $\sigma_1(x)$, but the method in this paper can be used to derive similar results for other excitation functions as well (including radial basis functions [2], [12]).

3.1. Explicit form of the Jacobian for a two-layer network. The Jacobian for the multilayer feedforward network problem can be written explicitly using the notation from the previous section. The Jacobian is a matrix of size $m \times n$, where each row of the Jacobian corresponds to a single training data point. We present the Jacobian layer by layer and specifically show the components for the arc weights separately from the offsets. Thus we will present a row of the Jacobian, J, but will show the row in blocks (the first subscript refers to the training data point i, and the

TABLE 2
Summary of the Jacobian.

Jacobian element	Formula	Corresponding unknowns
$J_{i,(j-1)(h+1)+1}$	$\sigma'(P_j^{(i)})\sum_l x_{u+l}x_{t+(l-1)(p+1)+1+j}\ \sigma'(Q_l^{(i)})$	First layer offsets
$J_{i,(j-1)(h+1)+1+k}$	$v_k^{(i)}\sigma'(P_j^{(i)})\sum_l x_{u+l}x_{t+(l-1)(p+1)+1+j}\ \sigma'(Q_l^{(i)})$	First layer weights
$J_{i,t+(l-1)(p+1)+1}$	$x_{u+l}\sigma'(Q_l^{(i)})$	Second layer offset
$J_{i,t+(l-1)(p+1)+1+j}$	$x_{u+l}\sigma(P_j^{(i)})\sigma'(Q_l^{(i)})$	Second layer weights
$J_{i,u+l}$	$\sigma(Q_l^{(i)})$	Last layer weights

second to the actual parameter or column of the Jacobian). The form of the resulting Jacobian is summarized in Table 2 and the third column in the table explains the origin of the term.

We can now write the ith row of the Jacobian (using its inherent block structure) for the 2-3-2 network in Fig. 1:

$$\begin{aligned}
J_{i,1\ldots3} &= [x_{18}x_{11}\sigma'(Q_1^{(i)}) + x_{19}x_{15}\sigma'(Q_2^{(i)})]\sigma'(P_1^{(i)})(1, v_1^{(i)}, v_2^{(i)})^T,\\
J_{i,4\ldots6} &= [x_{18}x_{12}\sigma'(Q_1^{(i)}) + x_{19}x_{16}\sigma'(Q_2^{(i)})]\sigma'(P_2^{(i)})(1, v_1^{(i)}, v_2^{(i)})^T,\\
J_{i,7\ldots9} &= [x_{18}x_{13}\sigma'(Q_1^{(i)}) + x_{19}x_{17}\sigma'(Q_2^{(i)})]\sigma'(P_3^{(i)})(1, v_1^{(i)}, v_2^{(i)})^T,\\
J_{i,10\ldots13} &= x_{18}\sigma'(Q_1^{(i)})(1, \sigma(P_1^{(i)}), \sigma(P_2^{(i)}), \sigma(P_3^{(i)}))^T,\\
J_{i,14\ldots17} &= x_{19}\sigma'(Q_2^{(i)})(1, \sigma(P_1^{(i)}), \sigma(P_2^{(i)}), \sigma(P_3^{(i)}))^T,\\
J_{i,18\ldots19} &= (\sigma(Q_1^{(i)}), \sigma(Q_2^{(i)}))^T.
\end{aligned}$$

Here $J_{i,j}$ denotes the element in the ith row and jth column of the Jacobian. From the dependency on i in each column of J, one row cannot be an exact linear combination of sets of rows. If there are some linear or near-linear dependencies between rows or columns in the Jacobian they must arise in some other manner.

3.2. Properties of the sigmoidal. An explanation of the rank-deficiency of the Jacobian relies on the properties of sigmoidal functions and their derivatives. We consider the sigmoidal function $\sigma(x) = \sigma_1(x)$ in (8), with derivative

$$\sigma'(x) = \frac{e^{-x}}{(1+e^{-x})^2}.$$

The columns of the Jacobian for the neural network function has terms of the form $\sigma(x)$, $\sigma'(x)$, $\sigma'(x)\sigma(y)$, and $\sigma'(x)\sigma'(y)$ with constant coefficients. To explain the near linear dependence between columns of J, we are therefore interested in the quantities

$$\begin{aligned}
\mathrm{A}(x,y) &= \sigma(x+y) - \sigma(x), & \mathrm{B}(x,y) &= \sigma'(x+y) - \sigma'(x),\\
\mathrm{C}(x,y) &= \sigma'(x+y)\sigma'(x), & \mathrm{D}(x,y) &= \sigma(x+y)\sigma'(x),
\end{aligned}$$

where $x \in [-\rho, \rho]$ and $y \in [-\delta, \delta]$.

Figure 2 contains the graph for $\mathrm{A}(x,y)$ for various values of $x \in [-10, 10]$ and as a function of $y \in [-20, 20]$. Note that the differences in the graphs for large values of

$|x|$ are small. Figure 3 shows the graph for $\mathrm{B}(x,y)$ for $x \in [-10,10]$ and $y \in [-20,20]$. Note that $\mathrm{B}(x,y)$ varies slowly with x. It is easy to see that $\sup_{x,y} \mathrm{A}(x,y) = 1$ and $\sup_{x,y} \mathrm{B}(x,y) = 0.25$ from the properties of σ and σ'. Similarly, $|\mathrm{C}(x,y)| \leq \frac{1}{16}$ and $|\mathrm{D}(x,y)| \leq \frac{1}{4}$, for any x and y. We show the form of these functions in Figs. 4 and 5. The upper limits of these functions are not as important as the fact that often the values of these functions are close to 0 for a large range of x and y.

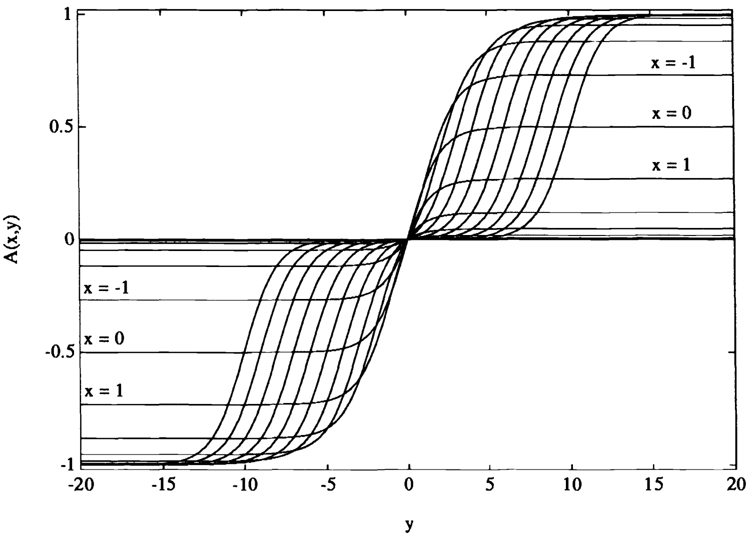

FIG. 2. *Function* $\mathrm{A}(x,y)$ *for various* x. *In the figure we have plotted curves for* $x = -10, -9, \ldots, 0, \ldots, 9, 10$, *and three are indicated.*

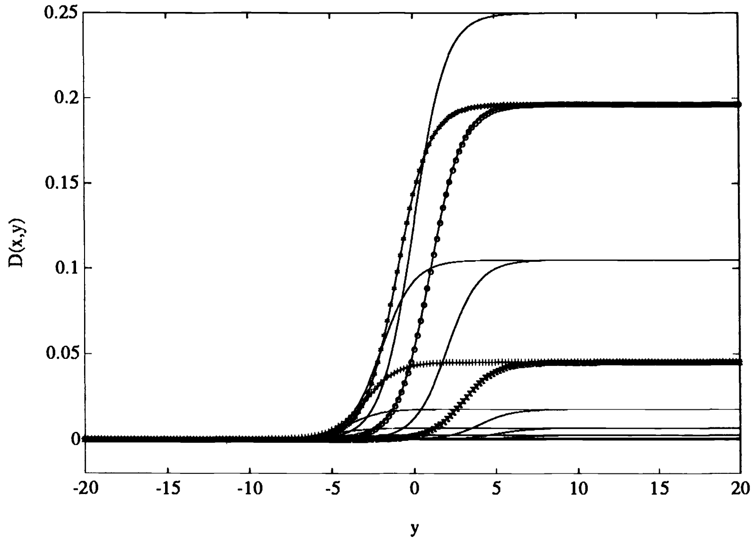

FIG. 5. *Function* $D(x, y)$ *for* $x = -10, -9, \ldots, 9, 10$. *The following curves are indicated:* $x = -1$ (*o*), $x = 1$ (***), $x = -3$ (x), *and* $x = 3$ (+).

3.3. Rank-deficiency of the Jacobian of a two hidden layer network. This section analyzes five situations where the Jacobian for a two hidden layer feed-forward network is ill conditioned or rank-deficient. These results easily extend to a network with more hidden layers and follow from three simple propositions.

PROPOSITION 3.1. *Let* B *be a submatrix of* A *consisting of columns of* A. *Then* $\kappa(B) \leq \kappa(A)$.

Proof. This follows immediately from a repeated application of [7, Corollary 8.3.3]. □

PROPOSITION 3.2. *Let $A = [x, y] \in \mathbb{R}^{n\times 2}$, and suppose that the angle θ between x and y satisfies $\cos(\theta) = 1 - \epsilon$ for some $\epsilon \in (0,1)$. Then*

$$\kappa^2(A) \geq \frac{1}{4\epsilon(2-\epsilon)} \cdot \left(\frac{\| y \|^2}{\| x \|^2} + \frac{\| x \|^2}{\| y \|^2} + 2 \right).$$

Proof. As noted before, the singular values of A are the square roots of the eigenvalues of $G = AA^T$. The eigenvalues of G are nonzero and satisfy

$$\lambda = \frac{1}{2}[x^Tx + y^Ty \pm \sqrt{(x^Tx - y^Ty)^2 + 4(x^Ty)^2}].$$

Using this and completing the square in $\kappa(G) = \lambda_{\max}/\lambda_{\min}$ gives

$$\kappa(G) = \frac{[x^Tx + y^Ty + \sqrt{(x^Tx - y^Ty)^2 + 4(x^Ty)^2}]^2}{4(x^Tx \cdot y^Ty - (x^Ty)^2)}.$$

Since $\cos(\theta) = \frac{x^Ty}{\|x\|\cdot\|y\|} = 1 - \epsilon$, $(x^Ty)^2 = (1-\epsilon)^2 x^Tx \cdot y^Ty$ and so

$$\kappa(G) \geq \frac{(x^Tx + y^Ty)^2}{4[1 - (1-\epsilon)^2]x^Tx \cdot y^Ty} = \frac{1}{4\epsilon(2-\epsilon)} \cdot \left(\frac{\| y \|^2}{\| x \|^2} + \frac{\| x \|^2}{\| y \|^2} + 2 \right). \qquad \square$$

Proposition 3.2 provides a lower bound on the condition number of a matrix when two columns are nearly collinear. In fact, if some number of columns of a matrix, say p, are almost collinear, then one should expect at least $p - 1$ singular values of the matrix to be relatively small. Thus the matrix would almost have a rank-deficiency of $p - 1$ in such a case. These claims can be made precise along the lines of Proposition 3.2, but now we assume that the columns are normalized.

PROPOSITION 3.3. *Let $A = [a_1, \ldots, a_p]$ be an $m \times p$ matrix with normalized columns, so that $a_i^T a_j = 1 - \epsilon_{ij}$ for all $1 \leq i, j \leq n$, with $\epsilon_{ii} = 0$ for $i = 1, 2, \ldots, p$. Suppose that $\epsilon_{ij} \leq \epsilon < 1$. Then A has one singular value at least as large as $\sqrt{p(1-\epsilon)}$ while the remaining singular values are no larger than $\sqrt{p\epsilon}$.*

Proof. By assumption, $A^TA = B - E$ where B is the matrix of all ones and $E = [\epsilon_{ij}]$. The eigenvalues of B are p (with multiplicity 1) and 0 (with multiplicity $p-1$), while the eigenvalues of E are no larger than $p\epsilon$ by the Gersgorin disk theorem. An application of the Wielandt–Hoffman theorem [7] shows that A^TA has one eigenvalue λ_p satisfying $|\lambda_p - p| \leq p\epsilon$, and the other eigenvalues λ_i satisfy $|\lambda_i| \leq p\epsilon$. Since the nonzero singular values of A are the square roots of the nonzero eigenvalues of A^TA, $\sigma_1 \geq \sqrt{p(1-\epsilon)}$ and $\sigma_i \leq \sqrt{p\epsilon}$ for $i = 2, 3, \ldots, p$. $\square$

The preceding results quantify the following argument. For a Jacobian J to be ill conditioned, it suffices to have two columns that are nearly dependent. If the cosine of the angle between those two columns is $1 - \epsilon$, then the condition number of J is at least $\mathcal{O}(\epsilon^{-1/2})$. If p of the columns of J are nearly multiples of each other (that is, the cosine of the angle between any pair of the p vectors satisfies $|\cos\theta| \geq 1 - \epsilon$) and the columns are normalized, then at least $p - 1$ singular values of J are $\mathcal{O}((p\epsilon)^{1/2})$, and one is $\mathcal{O}(p^{1/2})$. This implies that J is within $p\epsilon$ in the 2-norm to a matrix with degree of rank-deficiency at least $p-1$, which causes difficulties for linear least squares solvers.

To simplify the notation, define

$$\underline{\sigma}(Q_r) = (\sigma(Q_r^{(1)}), \sigma(Q_r^{(2)}), \ldots, \sigma(Q_r^{(m)}))^T$$

and define the vectors $\underline{\sigma}'(Q_r)$, $\underline{\sigma}(P_r)$, and $\underline{\sigma}'(P_r)$ similarly. We now describe five cases where conditions internal to the network lead to ill-conditioned and close to rank-deficient matrices.

Case 1. If for some j, $\underline{\sigma}(P_j)$ is a multiple of $e = (1, 1, \ldots, 1)^T$, then any pair of columns in the Jacobian corresponding to an arc and an offset, which have $\sigma(P_j^{(i)})$ as input, on the second layer will produce two identical columns of J. If this holds for K first layer nodes, then $K+1$ columns of J are identical. Since there are s second layer nodes, this gives a rank-deficiency of sK. Note that this condition is approximately satisfied if the angle between e and $\underline{\sigma}(P_j)$ is small.

Case 2. If $\underline{\sigma}'(Q_k)$ and $\underline{\sigma}'(Q_j)$ are multiples of each other then the block of columns in J corresponding to the parameters of the nodes k and j of the second layer are identical, producing a rank-deficiency of $(p+1)+(h+1)$. Note that this condition is approximately satisfied if the angle between $\underline{\sigma}'(Q_k)$ and $\underline{\sigma}'(Q_j)$ is small. The term $p+1$ appears from the second layer nodes (and parameters associated with them), and the term $h+1$ appears from the Jacobian calculated with respect to first layer parameters. This is shown in (9) for $k=1$ and $j=2$:

$$(9)\qquad \begin{aligned} J_{i,10\ldots13} &= x_{18}\ \sigma'(Q_1^{(i)})(1, \sigma(P_1^{(i)}), \sigma(P_2^{(i)}), \sigma(P_3^{(i)}))^T, \\ J_{i,14\ldots17} &= x_{19}\ \sigma'(Q_2^{(i)})(1, \sigma(P_1^{(i)}), \sigma(P_2^{(i)}), \sigma(P_3^{(i)}))^T. \end{aligned}$$

A rank-deficiency of $p+1=4$ occurs because the block array $[e, \underline{\sigma}(P_1), \underline{\sigma}(P_2), \underline{\sigma}(P_3)]^T$ is always identical in $J_{i,10\ldots13}$ and $J_{i,14\ldots17}$. In general, if $\text{rank}[\underline{\sigma}'(Q_1), \underline{\sigma}'(Q_2), \ldots, \underline{\sigma}'(Q_s)] = L$, then the rank-deficiency is $(s-L)(p+1+h+1)$.

Case 3. If $\underline{\sigma}'(P_k)$ and $\underline{\sigma}'(P_j)$ are multiples of each other then the block of columns corresponding to the first layer node k of J (i.e., the arcs and offset parameters) is a multiple of the block of columns corresponding to the first layer node j. Note that this condition approximately holds if $\underline{\sigma}'(P_k)$ and $\underline{\sigma}'(P_j)$ have a small angle between them. As in Case 2 above, the deficiency is $h+1$ because the block array $[e, \underline{v}_1, \underline{v}_2]^T$ is repeated in $J_{i,1\ldots3}$ and $J_{i,4\ldots6}$. More generally, if $\text{rank}[\underline{\sigma}'(P_1), \underline{\sigma}'(P_2), \ldots, \underline{\sigma}'(P_f)] = L$ then the rank-deficiency from this condition is $(p-L)(h+1)$.

Case 4. If $\underline{\sigma}(Q_k)$ and $\underline{\sigma}(Q_j)$ are multiples of each other then the columns corresponding to last layer parameters k and j are linearly dependent. This is shown in (10) for $k=1$ and $j=2$:

$$(10)\qquad J_{i,18\ldots19} = (\sigma(Q_1^{(i)}),\ \sigma(Q_2^{(i)}))^T.$$

More generally, if $\text{rank}[\underline{\sigma}(Q_1), \underline{\sigma}(Q_2), \ldots, \underline{\sigma}(Q_s)] = L$ then the rank-deficiency is $s-L$.

There is also a possible type of dependency in the columns of the Jacobian similar to Case 4 above, but which in fact rarely occurs.

Case 5. If $\underline{\sigma}(P_k)$ and $\underline{\sigma}(P_j)$ are multiples of each other, but $\underline{\sigma}(P_k)$ is not a multiple of e (so that Case 1 is excluded), then the columns corresponding to the arcs k and j are multiples of each other. More generally, if $\text{rank}[\underline{\sigma}(P_1), \underline{\sigma}(P_2), \ldots, \underline{\sigma}(P_f)] = L$ then the rank-deficiency from this condition is $(p-L)s$.

Finally, note that rank-deficiency can arise in less restrictive ways than indicated by the hypotheses above. For example, in Case 3 it is only necessary that $\sigma'(P_k)$ and $\sigma'(P_j)$ nearly be multiples of each other for those components i with $\sigma'(Q_1^{(i)})$ and $\sigma'(Q_2^{(i)})$ to be nonzero. Because the derivative of the sigmoidal is close to zero for arguments outside a small interval $[-\rho, \rho]$, this means that the hypotheses of the cases are effectively satisfied more often.

3.4. Computational results. We first examine the Jacobian for a network with random initial weights on all layers and give an example. After that we present the singular values of the Jacobian and Hessian (4) for some training problems at later iterations of a Levenberg–Marquardt algorithm.

The singular value decomposition is used to measure ill-conditioning. Although the rank of J is equal to the number of its nonzero singular values, numerically it is rare to compute a singular value exactly equal to zero. To avoid the need for ad hoc numerical determinations of rank, we present all of the singular values for a given problem. Singular values and eigenvalues were computed using Matlab 3.5 running on a Sun Sparcstation-1. Jacobian and Hessian matrices were computed with 48-bit mantissa arithmetic, using a form of automatic differentiation (see [16] for implementation details).

The 2-3-2 network in Fig. 1 has 19 parameters or weights and so the Jacobian has 19 singular values. Our two-dimensional input space is sampled on a uniform mesh in $[0,1]^2$ with 400 training data points in each case presented, and a maximum of 2000 function evaluations is allowed in the Levenberg–Marquardt algorithm unless indicated otherwise. The implementation of the Levenberg–Marquardt algorithm used here was written by Moré and is available in MINPACK. Note that the initial Jacobian is *independent* of the particular problem one is solving, but *dependent* on the network and the sample distribution of the input points, t_i.

Figures 6 and 7 show the singular values of J for different sets of initial weights chosen randomly from the intervals $(-1, 1)$ and $(-100, 100)$, respectively. Other commonly used intervals differ only by scale from these two. The random seeds were kept fixed and only the weight interval was changed. The condition numbers of the Jacobian are of order 10^7 and 10^{55}, respectively. Hence the condition number of $J^T J$, used in the Newton-like methods of Table 2, is close to or smaller than the inverse of the machine epsilon for a 48-bit mantissa computer. As an example of a larger network, Fig. 8 shows the singular values of the initial Jacobian for four cases for a 5-7-2 network with weights chosen randomly in the region $(-1, 1)$ and t_i sampled randomly in the cube $[0,1]^5$.

From the graphs we can conclude that the Jacobian becomes more ill conditioned as the norm of the weight vector increases. Considering that the initial conditions of the Jacobian in Figs. 6 and 7 are not unusual (since often the initial weights are chosen randomly from these two intervals), the numerical method starts with an ill-conditioned J. In Fig. 7 the weight vectors have a larger norm on average than in the other figure of the random weights and are representative of the situation during the solution process.

Next we will investigate an extreme example for the primary sources of rank-deficiency in the Jacobian using the notation and classification given in the previous sections. We use a 2-3-2 network because

- the network is simple to visualize (Fig. 1);
- the network does not contain too many superfluous nodes, i.e., ones unnecessary for the solution of the problem and that would create additional rank-deficiency of the Jacobian;
- the network is unlikely to find a good solution since it contains too few nodes. This allows exploration of behavior far from the optimum. However, this does not mean that the Jacobian would necessarily be of full rank for an "ideal" network or a large network.

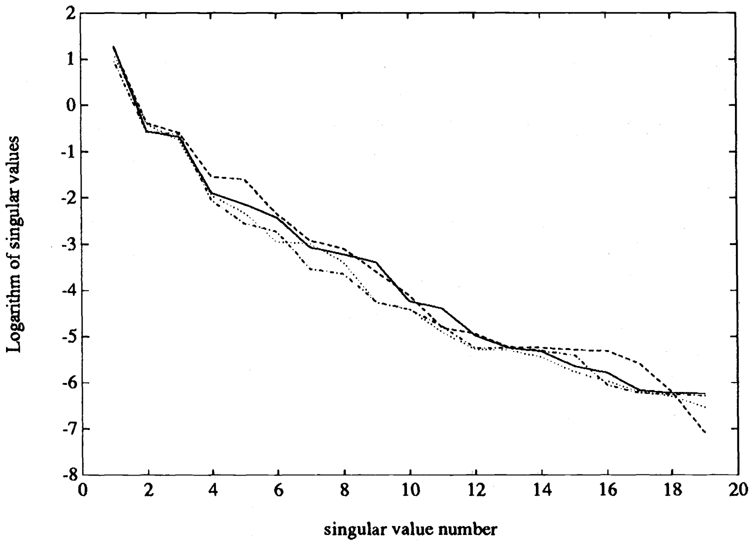

FIG. 6. *Computed singular values of four initial Jacobians for a 2-3-2 network with weights chosen randomly from* $(-1, 1)$.

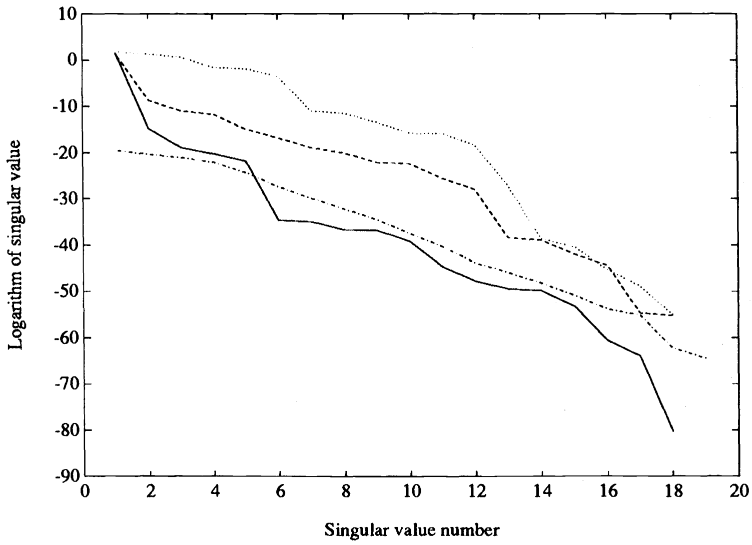

FIG. 7. *Computed singular values of four initial Jacobians for a 2-3-2 network with weights chosen randomly from* $(-100, 100)$.

As an example of the different classes of rank-deficiency, we use the initial condition in the (dash-dotted) curve in Fig. 7, where the Levenberg–Marquardt algorithm is allowed to proceed one iteration with a 2-3-2 network. The test figure is a spiral sampled on an equidistant grid as shown in Fig. 9. The value of the function inside the spiral swirls is one, and outside the swirls it is zero.

The results are summarized in Table 3. The cosines of the canonical angles between range spaces are used to measure how closely two blocks J_1 and J_2 of columns of J come to spanning the same space (as is needed for Cases 2 and 3). The method for

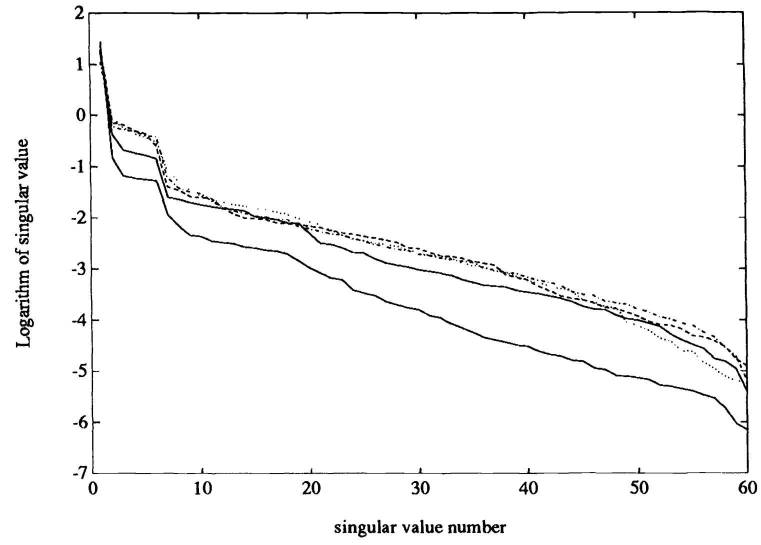

FIG. 8. *Computed singular values of five initial Jacobians for a* 5-7-2 *network.*

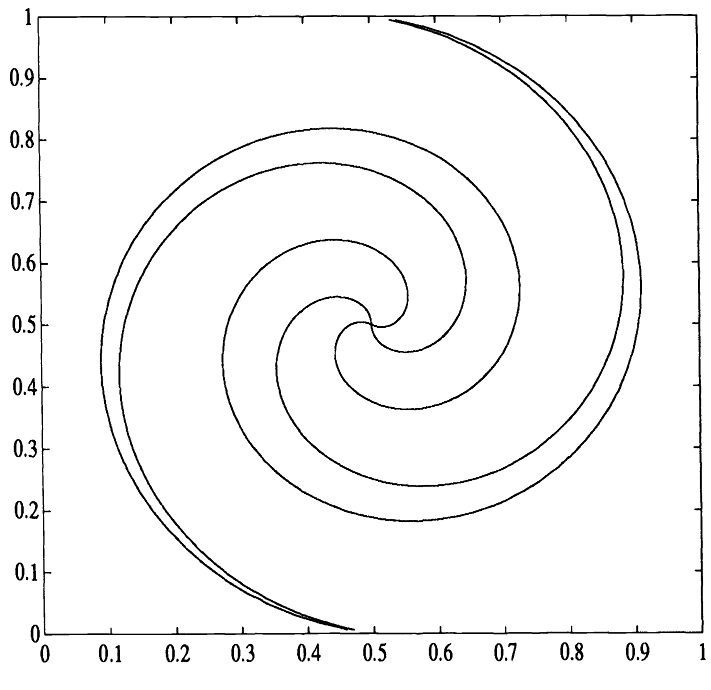

FIG. 9. *The spiral-problem. The function has value* 1 *inside the spiral and* 0 *outside.*

computing such cosines is from [1]. When some cosines are close to 1, then range(J_1) and range(J_2) are close to sharing a subspace spanned by the corresponding canonical vectors. The first column of Table 3 lists the first four dependency cases of §3.3. The second column gives the cosines of the angles between the vectors that determine rank-deficiency (for example, in Case 2 for a 2-3-2 network the determining vectors are $\underline{\sigma}'(Q_1)$ and $\underline{\sigma}'(Q_2)$), the third column specifies the columns of J with a potential resultant dependency, and the last column gives the cosine(s) of the angle(s) between the affected columns. The claims made in §3.3 are that when the angle between the determining vectors are small, then so are the angles between the affected columns as occurs for this extreme case. The singular values of columns 10–17 and columns 1–9 of the Jacobian are shown together with the singular values of the full Jacobian in Fig. 10.

TABLE 3
Example of rank deficiency.

Dependency case	Determining vectors and cosine of their angle	Affected block columns of J	Canonical cosines for affected cols.
I	e & $\underline{\sigma}(P_1)$ 0.99325	10 & 11, 14 & 15	0.99324, 0.99326

	$\underline{\sigma}'(P_1)$ & $\underline{\sigma}'(P_3)$ 0.99639	[1,2,3] & [7,8,9]	1.00000, 0.99852, 0.99503
	$\underline{\sigma}'(P_2)$ & $\underline{\sigma}'(P_3)$ 0.99861	[4,5,6] & [7,8,9]	1.00000, 0.99986, 0.99982
IV	$\underline{\sigma}(Q_1)$ & $\underline{\sigma}(Q_2)$ 0.99990	18 & 19	0.99990

Since the conditioning of network Jacobians can be represented succinctly by the singular values and the specific reason for rank-deficiency can be analyzed using the procedure above, we now show only the singular values of a few larger problems.

Figures 11 and 12 show the eigenvalues of $J^T J$ and the full Hessian for the spiral problem with a 2-14-7 network at some iterations. The initial weights are chosen randomly in the interval $[-1, 1]$. At a solution (Fig. 12) the 40-20-40 rule for a randomly chosen test set of size 1000 gives an error rate of 13.5 percent. This criterion assigns 0 to output values in [0,0.40], and 1 to values in [0.60,1]. Values in [0.40, 0.60] are labeled incorrect. Figure 13 for a 2-16-6 network shows eigenvalues at the solution (the initial weights are chosen from $[-1, 1]$). The Levenberg–Marquardt algorithm appears to be able to obtain an acceptable error norm for this problem for a large range of networks and initial conditions.

3.5. Determining cosines and rank-deficiency. We have monitored the determining and canonical cosines for some of the cases described above in a number of test problem configurations. While rank-deficiency of the Jacobian can result from interactions among columns outside of the groups analyzed separately in Cases 1–5 above, the plots show that the column groups identified above frequently exhibit in-

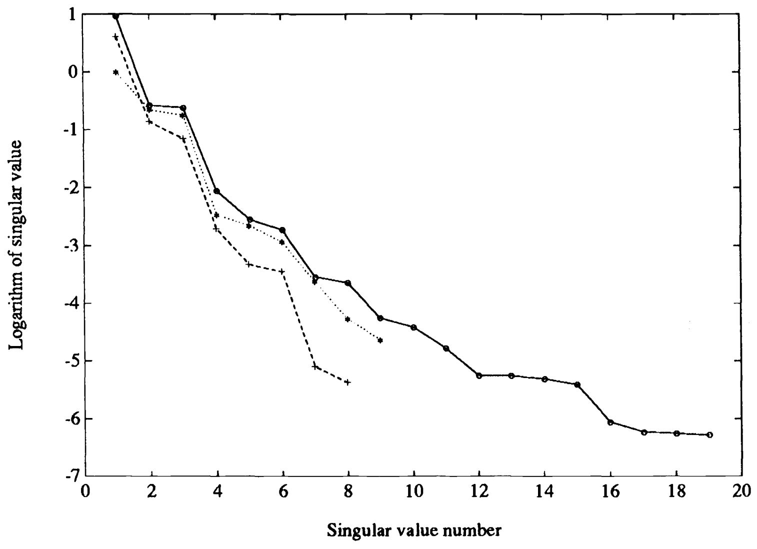

FIG. 10. *Computed singular values of columns* 10–17 (*labeled* + *with dashed line*), 1–9 (*labeled* * *with dotted line*), *and all columns* (*labeled o with solid line*) *of the Jacobian for the example discussed in the text and Table* 3 (*a* 2-3-2 *network used for the spiral problem*).

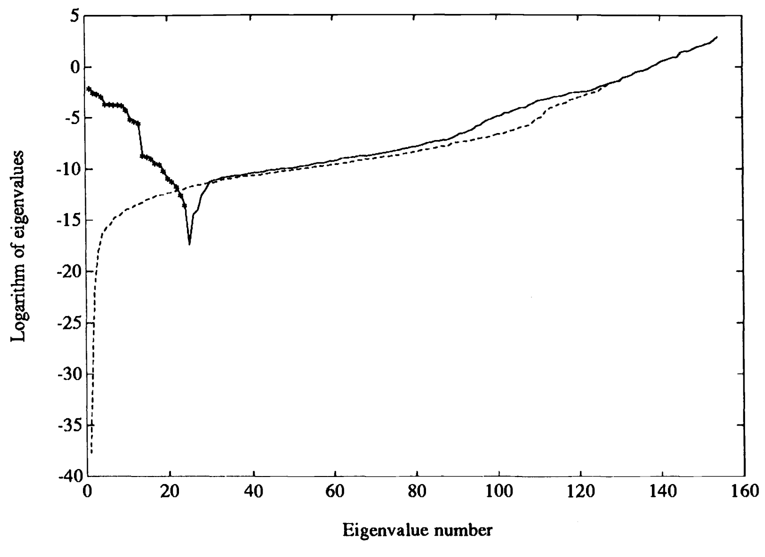

FIG. 11. *The computed eigenvalues of* $J^T J$ (*dashed line*) *and Hessian* (*solid line with* * *indicating negative eigenvalues*) *for the spiral problem with a* 2-14-7 *network at iteration* = 1000 (*the error norm was* $5.2 * 10^{-4}$).

ternal deficiency as predicted. Moreover, large determining cosines do act as sufficient conditions for rank-deficiency.

To demonstrate these facts, we have plotted the canonical and determining cosines for Case 2 in a run of the Levenberg–Marquardt solver. Those cosines as a function of the iteration number for a 2-3-2 network are shown in Fig. 14.

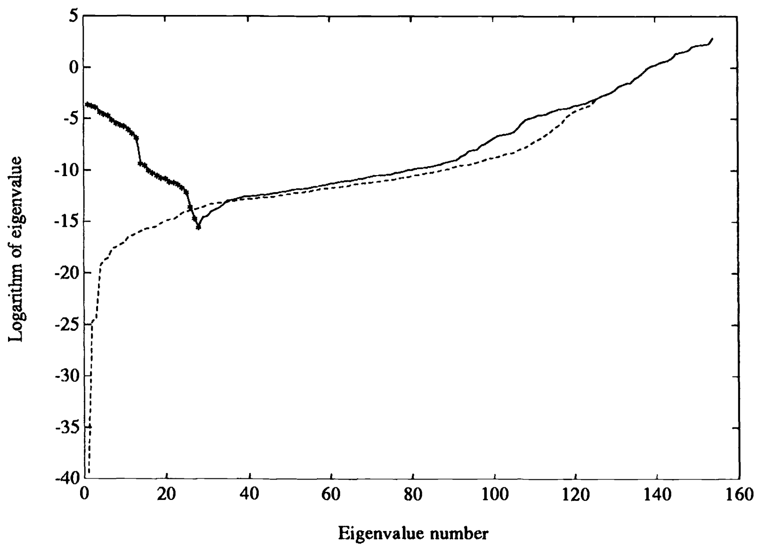

FIG. 12. *The computed eigenvalues of J^TJ (dashed line) and Hessian (solid line with * indicating negative eigenvalues) for the spiral problem (same as in the previous figure) at the solution (iteration 1832 with error norm = $4.1 * 10^{-5}$).*

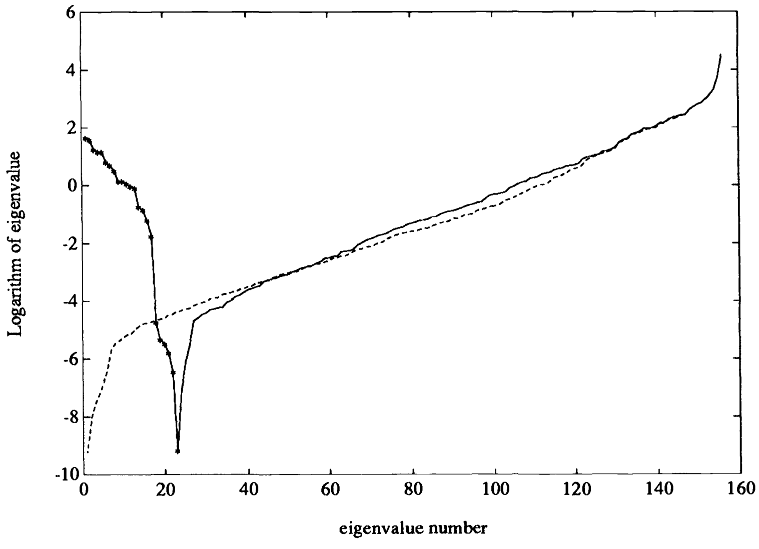

FIG. 13. *Computed eigenvalues of J^TJ (dashed line) and of the Hessian (solid line, negative eigenvalues are indicated with *) at the last iteration (error norm = 3.4 for 900 training data points and a maximum of 400 function evaluations) for the spiral problem with a 2-16-6 network. The 40-20-40 rule gives an error rate of 7.1 percent.*

Additionally, in Figs. 15 and 16 we show the canonical and determining cosines for two 2-8-4 networks, with different initial conditions, at the computed solution for each combination of columns (i.e., six pairs on the second layer). These results suggest that canonical cosines do explain rank-deficiency of the Jacobian in feedforward networks. In Fig. 16, Case 2 does not appear and the rank-deficiency comes from other causes.

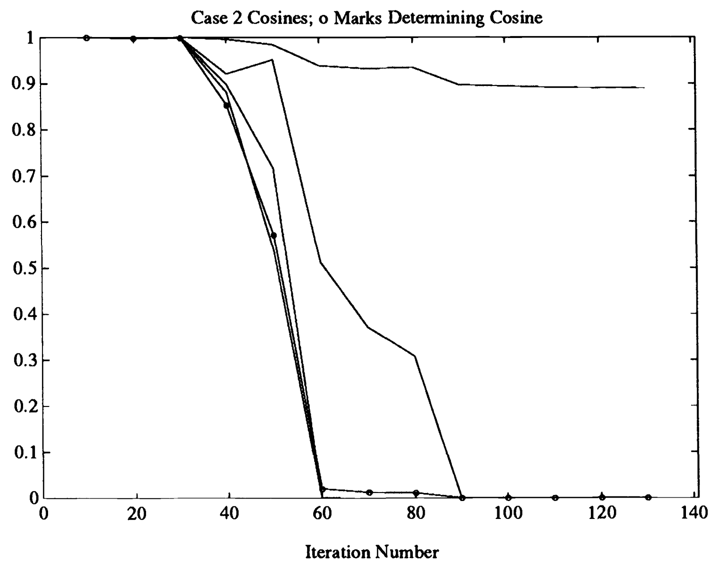

FIG. 14. *The computed cosines for Case* 2 *for a* 2-3-2 *network as a function of iteration number. The determining cosines are marked "o."*

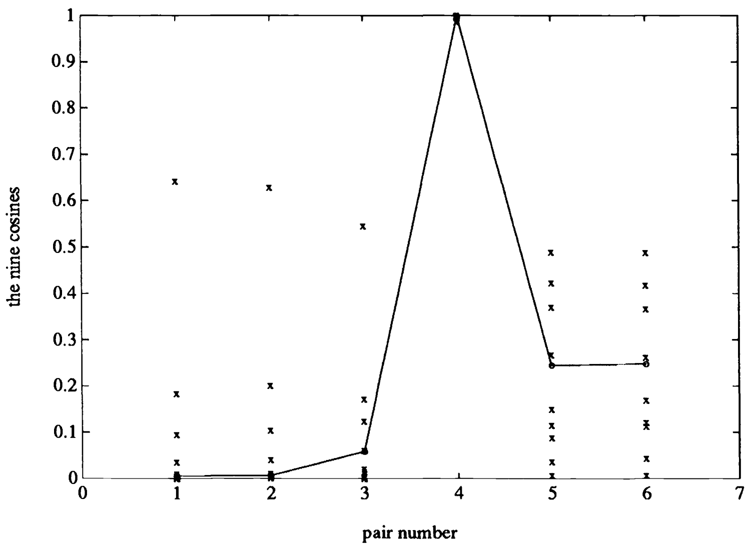

FIG. 15. *The resulting nine cosines from Case* 2 *for a* 2-8-4 *network shown versus the six pairs on the second layer. The determining cosines are indicated by "o" and connected with solid lines.*

In Figs. 17 and 18 we show the corresponding eigenvalues of the Hessian and $J^T J$ at the solution for these runs.

3.6. The Jacobian for a 2-3 network, with one hidden layer. This section presents the structure of the Jacobian for a one hidden layer network of size 2-3, that is, with two inputs and three nodes on the hidden layer. These networks have been successfully used in many neural network applications [17] and they can be used also

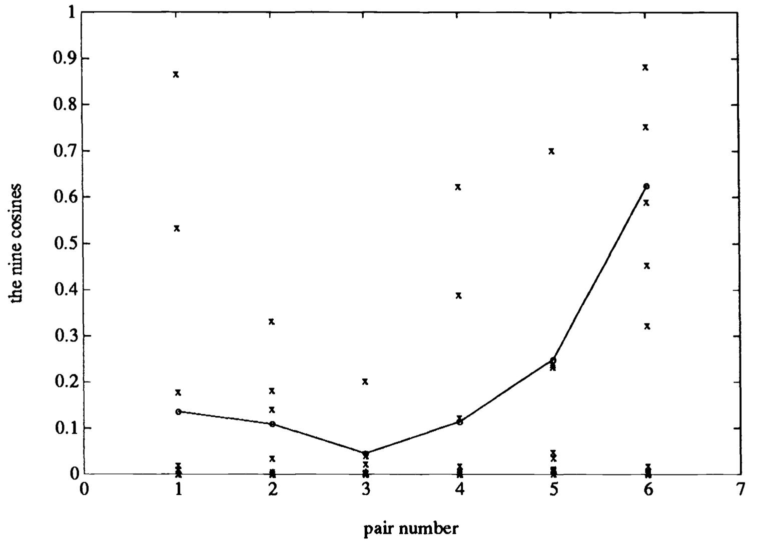

FIG. 16. *The resulting nine cosines from Case* 2 *for a* 2-8-4 *network shown versus the six pairs on the second layer. The determining cosine are indicated by "o" and connected with solid lines.*

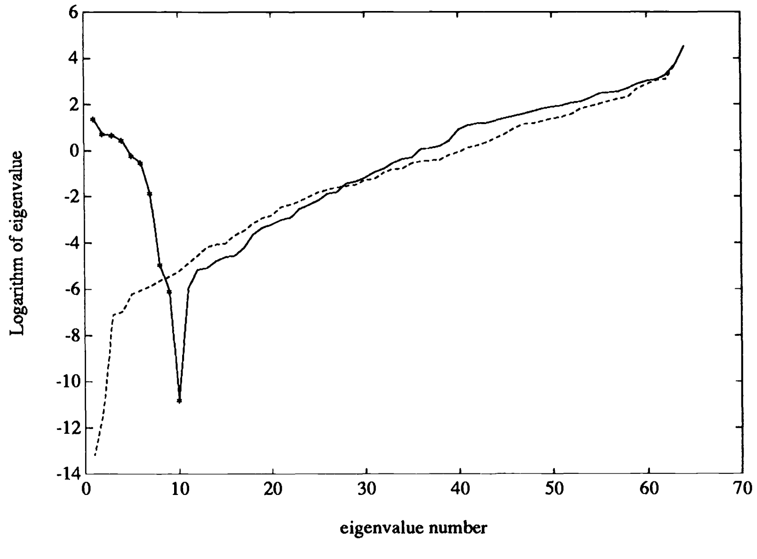

FIG. 17. *The computed eigenvalues for the Hessian (solid line with * indicating negative eigenvalues) and J^TJ (dashed line) at the solution for a* 2-8-4 *network (see also Fig.* 15). *The* 40-20-40 *rule gives the error rate* 5.5 *percent with a maximum of* 400 *iterations.*

as universal function approximators [3]. The form of the one hidden layer Jacobian is shown below with a numbering similar to that in Fig. 1.

$$\begin{aligned} J_{i,1\ldots3} &= x_{10}\sigma'(P_1^{(i)})(1, v_1^{(i)}, v_2^{(i)})^T, \\ J_{i,4\ldots6} &= x_{11}\sigma'(P_2^{(i)})(1, v_1^{(i)}, v_2^{(i)})^T, \\ J_{i,7\ldots9} &= x_{12}\sigma'(P_3^{(i)})(1, v_1^{(i)}, v_2^{(i)})^T, \\ J_{i,10\ldots12} &= (\sigma(P_1^{(i)}), \sigma(P_2^{(i)}), \sigma(P_3^{(i)}))^T. \end{aligned}$$

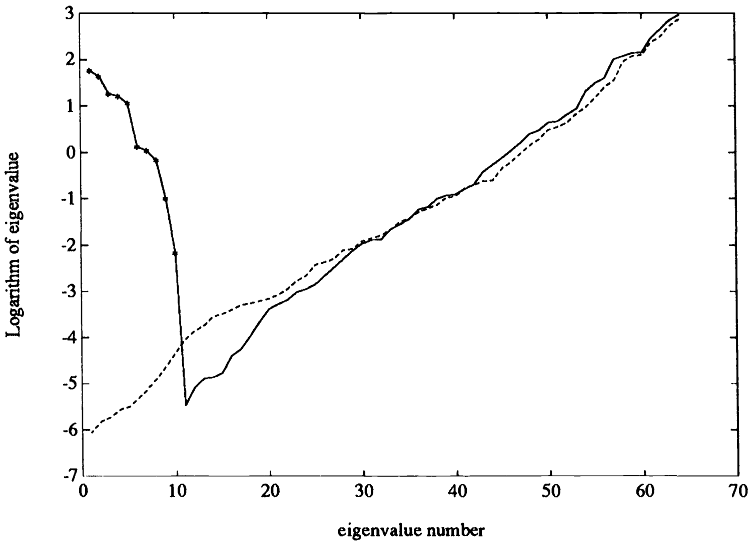

FIG. 18. *The computed eigenvalues for the Hessian (solid line with * indicating negative eigenvalues) and J^TJ (dashed line) at the solution for a* 2-8-4 *network (see also Fig.* 16). *The* 40-20-40 *rule gives the error rate* 15 *percent with a maximum of* 400 *iterations.*

The Jacobian for such a system is also likely to be rank-deficient because situations as in Case 2 appear in the equations. Columns 1–9 of the Jacobian above have the same three terms in common, i.e., the vector $(1, v_1^{(i)}, v_2^{(i)})$, which are multiplied by a term of the form $\sigma'(x)$.

4. Summary and conclusions. In a feedforward neural network the Jacobian is usually ill conditioned. Since many numerical schemes use it as a basis for their search direction, any rank-deficiency in the Jacobian causes the algorithm to obtain only partial information of the possible search directions, and in turn causes long training times. The rank-deficiency for a two hidden layer network often arises from the outputs of the second layer nodes because a sigmoidal applied to these outputs has a limited discrimination capability, especially if the weights for this level become large. Consequently, for a network with more hidden layers the rank-deficiency can only increase, but the rank-deficiency for a one hidden layer network could in principle be less severe.

Our experiments and analyses of partially connected networks and of single hidden layer networks do not indicate a significantly better conditioned Jacobian. Use of partially connected networks may inhibit rank-deficiency somewhat, but cannot guarantee complete avoidance of the intrinsic problems. A situation where some connections are omitted between two consecutive hidden layers appears in the Jacobian as the omission of some terms in the sum in (6). The apparent redundancy of a Jacobian can only be eliminated by a posteriori deletion of nodes and weights in a problem-specific way, so there would be no effect on the training process itself. Again, one could still have rank-deficient Jacobians arising in problems with either zero or nonzero residuals using reduced connectivity networks.

The Jacobian conditioning can possibly be improved by using a different form of the sigmoidal (i.e., a function with a better discrimination capability). A better initial condition might cause the Levenberg–Marquardt algorithm to find a solution with a weight vector that has a smaller norm, but practice shows that the weight vector at the solution has a large norm. The large norm of the weight vector (cf., (5)–(7)) is one reason that the algorithm causes the $\sigma'(x)$-function to approach its limit zero and therefore causes rank-deficiency in the Jacobian, as explained in §3.3.

In short, formulating feedforward neural network problems as least squares problems can cause undue strain on any numerical scheme which uses Jacobians, and a reformulation of the problem is called for.

Acknowledgments. The authors thank the anonymous referees and especially the Associate Editor, Margaret Wright, for their corrections and helpful suggestions, which have greatly improved this paper.

ITERATIVE LINE CUBIC SPLINE COLLOCATION METHODS FOR ELLIPTIC PARTIAL DIFFERENTIAL EQUATIONS IN SEVERAL DIMENSIONS*

A. HADJIDIMOS†, E. N. HOUSTIS†, J. R. RICE†, AND E. A. VAVALIS†

Abstract. This paper presents a new class of second- and fourth-order line cubic spline collocation methods (the LCSC methods) for multidimensional linear elliptic partial differential equations with no cross derivative terms. The LCSC methods approximate the differential operator along lines in each dimension independently and then combine the results into one large linear system. Expressed in terms of discretization stencils for the operator, these methods have nonzero entries only in the coordinate directions. The advantage of this approach is that the discretization is much simpler to derive and analyze. Further, iterative methods are easily applied to the resulting linear systems, especially on parallel computers. The disadvantage is that the resulting linear system is k times larger in k dimensions.

Using the simplicity of the methods, iterative schemes are analyzed and formulated in order to solve the resulting LCSC linear systems in the case of Helmholtz problems. Block Jacobi, extrapolated Jacobi (EJ), and successive overrelaxation (SOR) iteration methods are analyzed with the rates of convergence and the optimum relaxation parameters determined. The simple structure of the linear system makes these methods particularly suitable for parallel computation. It is shown that the overall efficiency of the method is attractive in spite of involving such a large linear system.

Experimental results presented here confirm the convergence results for both the discretization and iterative methods, and indicate that the convergence results hold for problems more general than Helmholtz problems.

1. Introduction.

In this paper we formulate iterative collocation methods based on cubic spline piecewise polynomials for approximating the solution u of the second-order elliptic linear partial differential equation (PDE)

$$Lu \equiv \sum_{i=1}^{k} \alpha_i \frac{\partial^2 u}{\partial x_i^2} + \sum_{i=1}^{k} \beta_i \frac{\partial u}{\partial x_i} + \gamma u = f \quad \text{in } \Omega, \tag{1a}$$

subject to Dirichlet or Neumann boundary conditions

$$Bu = g \quad \text{on } \partial\Omega \equiv \text{ boundary of } \Omega, \tag{2a}$$

where Bu is u (or $\partial u/\partial x_i$), $\Omega \equiv \prod_{i=1}^{k} \otimes[a_i, b_i]$ is a rectangular domain in R^k (the space of k real variables), and $\alpha_i(< 0)$, β_i, $\gamma(\geq 0)$, f, and g are functions of k variables. We carry out the derivation and analysis only for the Helmholtz problem, with Dirichlet boundary conditions and constant coefficients, that is

$$Lu \equiv \sum_{i=1}^{k} \alpha_i D_{x_i}^2 u + \gamma u = f \quad \text{in } \Omega, \tag{1b}$$

$$u = g \qquad \text{on } \partial\Omega. \tag{2b}$$

This paper was first presented at the First Copper Mountain Conference on Iterative Methods, Copper Mountain, Colorado, April 1–5, 1990.

The discretization is easily extended to the more general equation (1), but the analysis is not. Experimental results are given that indicate the behavior proved for this Helmholtz problem is present for more general problems.

First we formulate the cubic spline collocation discretization scheme that determines the cubic spline approximations to u along the mesh lines of a uniform partition of Ω. Throughout this paper we refer to this scheme as the *line cubic spline collocation* (LCSC) method. Following the techniques introduced in [7] and [8], we present second- and fourth-order LCSC methods for approximating the PDE problem (1b), (2b). The extension of the LCSC discretization to the more general problem (1a), (2a) is not difficult. The main objective of this paper is to define and analyze iterative linear equation solvers for computing the discrete LCSC approximation of u. For this reason, we adopt the tensor product formulation [6], [10] of the collocation equations and analyze the convergence of block Jacobi, EJ, and SOR schemes. It is worth noticing that the linear system of equations arising from the LCSC method (*the* LCSC *equations*) is nonsymmetric and lacks many of the properties found in Ritz–Galerkin-type finite element methods. Nevertheless, we derive analytic expressions for the spectral radius of the corresponding Jacobi iteration matrix, and from this we determine the convergence ranges and compute the optimal parameters for the EJ and SOR methods.

This paper is organized as follows. Section 2 includes the formulation of the second- and fourth-order LCSC schemes. Section 3 presents the formulation of first-order stationary iterative methods for the LCSC equations and the theoretical study of their convergence. The computational efficiency of these methods is analyzed also. Finally, in §4 we present the results of various numerical experiments designed for the verification of the theoretical behavior of the iterative LCSC solvers. For two Helmholtz problems in two and three dimensions, the experiments show very good agreement with the theoretical predictions about the convergence of the discretization error and the iterative method used. Although the theoretical results presented here hold for the model problem (1b), (2b), our experimental results indicate that the behavior of the iterative LCSC solvers on the general problem (1a), (2a) is similar. One of these has $\gamma = -10e^{x+y}$ in two dimensions, the other has $\alpha_1 = -1$, $\alpha_2 = -(x+z)$, $\alpha_3 = -(4-x-z)$, and $\gamma = -e^{x+y+z}$ in three dimensions.

2. The LCSC method.

2.1. Preliminary results. In this section we introduce a notation for the discrete geometric data used to define the space $S_{3,\Delta}$ of cubic splines in k dimensions and a line collocation approximation of u in $S_{3,\Delta}$. Furthermore, we adopt a representation of the coefficients of this approximation and define an interpolant S of u in $S_{3,\Delta}$ whose asymptotic behavior as a replacement of u is used to define optimal LCSC methods. The approach is to do everything uniformly in all variables so that a tensor product structure is introduced into the discretization. As is common with spline-based methods, we introduce one extra point beyond each end of the intervals $[a_i,\, b_i]$ defining the ith side of the domain Ω. This enlarged interval is then discretized uniformly with step size h_i by $\Delta_i \equiv \left\{\tau_\ell^i = a_i + \ell h_i; \ell = -1, \dots, N_i+1 \text{ with } h_i = (b_i - a_i)/N_i\right\}$. A complete discretization of Ω is obtained by taking the tensor product of these discretized lines, so the mesh $\Delta \equiv \prod_{i=1}^{k} \otimes\Delta_i$ provides an extended uniform partition of Ω. The interior mesh points are denoted by $(\tau_{n_1}^1, \tau_{n_2}^2, \dots, \tau_{n_k}^k)$, for all $\mathbf{n} \in \prod_{i=1}^{k} \otimes I_i$, where $I_i \equiv \{n_i \,:\, 1 \le n_i \le N_i - 1\}$. The set of mesh lines parallel to the x_i-axis are denoted by $\mathcal{L}^i(\mathbf{n}_i)$, where

$$\mathbf{n}_i \equiv (n_1, \ldots, n_{i-1}, n_{i+1}, \ldots, n_k)$$

indexes these $\Pi_{\ell=1}^{k}(N_\ell + 1)/(N_i + 1)$ lines. The mesh points of each set of lines $\mathcal{L}^i(\mathbf{n}_i)$ are represented by the vectors

$$\mathbf{T}_\ell^i \equiv (\tau_{n_1}^1, \ldots, \tau_{n_{i-1}}^{i-1}, \tau_\ell^i, \tau_{n_{i+1}}^{i+1}, \ldots, \tau_{n_k}^k), \quad \ell = 0, \ldots, N_i,$$

and these are used as collocation points.

The collocation approximation is made on each set $\mathcal{L}^i(\mathbf{n}_i)$ of lines using the B spline basis $\{B_\ell^i(x_i)\}_{-1}^{N_i+1}$ defined on Δ_i. We let $\mathbf{x} = (x_1, x_2, \ldots, x_k)$ denote a variable ranging over Ω and we partition it into $\mathbf{x}^i = (x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_k)$, and x_i. The collocation approximation u_Δ^i on each line in $\mathcal{L}^i$ is represented as follows:

$$u_\Delta^i(\mathbf{x}) = \sum_{\ell=-1}^{N_i+1} U_\ell^i(\mathbf{x}^i) B_\ell^i(x_i). \tag{3}$$

Observe that (3) is the sum of one-dimensional splines in the x_i variable whose coefficients $U_\ell^i(\mathbf{x}^i)$ are functions of the other $k-1$ variables. Note that $U_\ell^i(\mathbf{x}^i)$ is an array of size $N = \Pi_i \, (N_i + 3)$, the index ℓ varies along the ith dimension, and $\mathbf{x}^i$ varies over the other $k-1$ dimensions. Further, this approximation is "redundant" in that there are k choices for representing $u_\Delta^i(\mathbf{x})$, one for each coordinate direction. This notation is illustrated in §2.3 with an example for $k = 3$. Throughout, we use the notation $U_\ell^i(\mathbf{n}_i)$ or, more simply, $U^i(\mathbf{n})$ or U^i for the coefficient values

$$U_\ell^i(\tau_{n_1}^1, \ldots, \tau_{n_{i-1}}^{i-1}, \tau_{n_{i+1}}^{i+1}, \ldots, \tau_{n_k}^k).$$

The LCSC methods considered in this paper are based on some interpolatory relations satisfied by the interpolant S of u in $S_{3,\Delta}$ defined on each line $\mathcal{L}^i(\mathbf{n}_i)$ by the interpolating equations

$$S|_{\mathbf{T}_\ell^i} = u|_{\mathbf{T}_\ell^i} \quad \text{for } \ell = 0, \ldots, N_i \tag{4}$$

and

$$D_{x_i}^2 S|_{\mathbf{T}_v^i} = D_{x_i}^2 u|_{\mathbf{T}_v^i} \quad \text{for } v = 0 \text{ and } N_i. \tag{5}$$

In (4) and (5) a particular i is used, and all of these are combined in the final collocation methods.

The approximation properties of these interpolants are summarized in the following theorem [7], [8]. The analysis of the truncation error for the fourth-order method involves an operator L', which is a perturbation of L. Specifically, we introduce $\wedge_i$, the second-order central difference operator in the ith dimension by setting $H_i = (0, \ldots, 0, h_i, 0, \ldots, 0)$ with h_i in the ith location, and then

$$\wedge_i f(\mathbf{x}) \equiv f(\mathbf{x} + H_i) - 2f(\mathbf{x}) + f(\mathbf{x} - H_i).$$

The perturbation P_L of L is then the sum over the k dimensions of the second differences of the second derivatives,

$$P_L f(\mathbf{x}) \equiv \sum_{i=1}^{k} \frac{\wedge_i}{h_i^2} D_{x_i}^2 f(\mathbf{x})$$

and

$$L' = L + P_L.$$

See [8] for a fuller explanation and motivation of this pertürbation.

THEOREM 2.1. *Suppose that* $u \in C^6[\bar{\Omega}]$, *the coefficients of* L *are in* $C[\bar{\Omega}]$ *and* $f, g \in C^4[\bar{\Omega}]$. *Then at the mesh points* $\mathbf{T}^i_\ell$ *of each line* $\mathcal{L}^i$, *we have*

$$LS = f + O(h_i^2), \qquad \ell = 0, \ldots, N_i, \tag{6}$$

and at the interior mesh points, we have

$$L'S = f + O(h^4), \qquad \ell = 1, 2, \ldots, N_i - 1. \tag{7}$$

Thus the spline S interpolant of $u(x)$ using (4) and (5) satisfies the PDEs $Lu = f$ and $L'u = f$ to second- and fourth-order, respectively. This result leads, following the analysis of [8], to the fact that the approximation $u^i_\Delta(\mathbf{x})$ defined by (3) and using the collocation points $\mathbf{T}^i_\ell$, $\ell = 0, \ldots, N_i$ has discretization error of second (for L) or fourth (for L') order.

2.2. The second-order LCSC method. In this section we present a second-order line collocation method based on cubic splines. The collocation approximation $u^i_\Delta \in S_{3,\Delta}$ is forced to satisfy (1a) at the mesh points $\{\mathbf{T}^1_l\}_{l=0}^{N_i}$ of each line $\mathcal{L}^1(\mathbf{n}_1)$ and the boundary conditions (2a) at the end nodal points $(\mathbf{T}^1_0, \mathbf{T}^1_{N_1})$. We derive the discrete equations that determine u^i_Δ for the Helmholtz equation (1b) and Dirichlet boundary conditions (2b).

$$\left.\left(\sum_{i=1}^{k} \alpha_i \, D^2_{x_i} \, u^i_\Delta + \gamma u^1_\Delta\right)\right|_{\mathbf{T}^i_\ell} = f \,|_{\mathbf{T}^i_\ell} \quad \text{for } \ell = 0, 1, \ldots, N_i. \tag{8}$$

The derivation of the corresponding collocation system for (1a), (2a), is straightforward, and our implementation is applicable to this general problem.

From the assumed representation (3) of u^i_Δ, we conclude easily that

$$D^2_{x_i} u^i_\Delta |_{T^i_\ell} = [U^i_{\ell-1}(\mathbf{n}_i) - 2U^i_\ell(\mathbf{n}_i) + U^i_{\ell+1}(\mathbf{n}_i)]/h_i^2 \tag{9}$$

and

$$u^i_\Delta |_{T^i_\ell} = [U^i_{\ell-1}(\mathbf{n}_i) + 4U^i_\ell(\mathbf{n}_i) + U^i_{\ell+1}(\mathbf{n}_i)]/6 \tag{10}$$

at the mesh (collocation) points $\mathbf{T}^i_\ell$ for $\ell = 1, 2, \ldots, N_i - 1$. First, we observe that the collocation equations obtained from the boundary conditions and differential equation at the end points of each line can be explicitly determined as follows:

$$\begin{aligned} U^i_0 &= \frac{h_i^2 f(\mathbf{T}^i_0)}{6\alpha_i}, & U^i_{-1} &= -U^i_1 + \frac{2h_i^2 f(\mathbf{T}^i_0)}{3\alpha_i}, \\ U^i_{N_i} &= \frac{h_i^2 f(\mathbf{T}^i_{N_i})}{6\alpha_i}, & U^i_{N_i+1} &= -U^i_{N_i-1} + \frac{2h_i^2 f(\mathbf{T}^i_{N_i})}{3\alpha_i}. \end{aligned} \tag{11}$$

The rest of the unknowns are determined by solving the so-called *interior collocation* equations, that is, on those lines of $\mathcal{L}^i$ not in $\partial\Omega$.

Equations (8) $(2 \le \ell \le N_i - 2)$ *away* from the boundary can be written as

$$\sum_{i=1}^{k} \frac{\alpha_i}{h_i^2}\left[U_{\ell-1}^i(\mathbf{n}_i) - 2U_\ell^i(\mathbf{n}_i) + U_{\ell+1}^i(\mathbf{n}_i)\right] + \frac{\gamma}{6}[U_{\ell-1}^1(\mathbf{n}_1) + 4U_\ell^1(\mathbf{n}_1) + U_{\ell+1}^1(\mathbf{n}_1)] = f|_{T_\ell^i}. \tag{12}$$

For lines next to the boundary, the equations have similar form with appropriately modified right sides. For example, with $i = 1$, the leftmost equations (corresponding to $x_i = a_i + h_i$ or $\ell = 1$) from the lines $\mathcal{L}^1$ have the form

$$\sum_{i=1}^{k} \frac{\alpha_i}{h_i^2}(-2U_1^i(\mathbf{n}_i) + U_2^i(\mathbf{n}_i)) + \frac{\gamma}{6}[U_0^1(\mathbf{n}_1) + 4U_1^1(\mathbf{n}_1) + U_2^1(\mathbf{n}_1)] = f(T_\ell^1). \tag{13}$$

The full matrix form of these equations is given in §3. This complex notation is illustrated next for the three-dimensional case ($k = 3$).

This discretization has redundant coefficients. There are $\Pi_i(N_i+1)$ coefficients U_ℓ^i for each i, but two are known from (11) at the boundaries so there are $K = \Pi_i(N_i - 1)$ unknowns in each collocation approximation $u_\Delta^i(\mathbf{x})$. This redundancy is handled by requiring that all these approximations agree on the mesh points, that is

$$u_\Delta^1 = u_\Delta^2 = \cdots = u_\Delta^k \quad \text{on the mesh } \Delta. \tag{14}$$

For each line, the collocation equations (12)–(14) can be written in the form

$$\sum_{i=1}^{k} \frac{a_i}{h_i^2}\mathcal{T}_{-2}\{U_\ell^i(\mathbf{n}_i)\} + \frac{\gamma}{6}\mathcal{T}_4\{U_\ell^1(\mathbf{n}_1)\} = \tilde{f}(\mathbf{T}_\ell^i),$$
$$\frac{1}{6}\mathcal{T}_4\{U_\ell^1(\mathbf{n}_1)\} - \frac{1}{6}\mathcal{T}_4\{U_\ell^i(\mathbf{n}_i)\} = \tilde{g}(\mathbf{T}_\ell^i),$$

where $\mathcal{T}_m \equiv$ tridiag $(1, m, 1)$, and $\tilde{f}$, $\tilde{g}$ are the right sides of (12)–(14) after the elimination of the predetermined boundary unknowns (11).

2.3. A three-dimensional example. We illustrate the above derivation for the case $k = 3$, where Ω is the unit cube and the operator L is $D_{x_1}^2 u + 3D_{x_2}^2 u + 5D_{x_3}^2 u - 7u = 9$. The mesh Δ has $N_1 = 4$, $N_2 = 2$, and $N_3 = 3$. This mesh is shown in Fig. 1, where the legend describes some details of the example.

The key point is to see that the various lines and associated arrays $\mathbf{T}$ and $\mathbf{U}$ are indexed by the points in the coordinate planes, plus an index along one coordinate direction. Thus $U_\ell^i(\mathbf{n}_i)$ is described as "the coefficients of the spline approximation along the $\mathcal{L}^i$ lines for $\ell = 0, 1, \ldots, N_i$." The same description applies to $\mathbf{T}_\ell^i$ with "coefficients" replaced by "collocation points."

The discretization (8) (at an interior point of the mesh) is of the form

$$D_{x_1}^2 U_\Delta^1 + 3D_{x_2}^2 U_\Delta^2 + 5D_{x_3}^2 U_\Delta^3 - 7U_\Delta^1 = f.$$

Our example grid is too coarse to have an interior point, but we see that the form of the discretization is a sum of three terms, each term along one coordinate direction as a *different representation* of the collocation approximation is used for each coordinate.

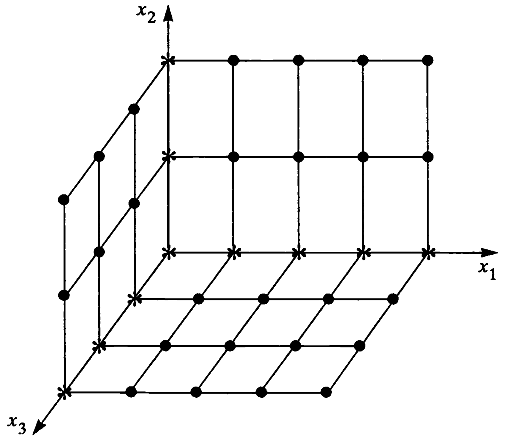

FIG. 1. *The mesh for* $k = 3$, $N_1 = 4$, $N_2 = 2$, *and* $N_3 = 3$. *The sets of lines* $\mathcal{L}^2$ *are indexed by the* 12 *points* $\mathbf{T}_0^1$ *on the plane at the left. These* 12 *points also index* $U_\ell^1(n_1) = U_\ell^1(\cdot, j_2, j_3)$ *for* $\ell = 0, \ldots, 4$, $j_2 = 0, \ldots, 2$, *and* $j_3 = 0, \ldots, 3$. *The collocation points* $\mathbf{T}_\ell^1$ *for* $\ell = 0, \ldots, 4$ *are five equally spaced points on a line starting at a* $\mathbf{T}_0^1$ *point, say* $(0, \tau_1^2 = 1/2, \tau_2^3 = 2/3)$, *and continuing to a* $\mathbf{T}_{N_1}^1$ *point, say* $(1, \tau_1^2, \tau_2^3)$.

Consider a mesh point $\mathbf{T}_j^2 = (\tau_{n_1}^1, \tau_j^2, \tau_{n_3}^3)$ on the line $\mathcal{L}^2$ (the jth point on the line indexed by $(n_1, \cdot, n_3)$). Then $D_{x_2}^2 u_\Delta^2(t)$ has three nonzero terms, namely, for those basis functions $B_j^2(x_2)$ associated with the mesh points on the (n_1, n_3) line of $\mathcal{L}^2$ having indices $j-1$, j, $j+1$. Similar considerations apply in the other two coordinates so the "stencil" for the approximation is as illustrated in Fig. 2. At the point $\mathbf{T}_j^2$, we see the seven-point star "stencil" created, i.e., the collocation equation at $\mathbf{T}_j^2$ has nonzero coefficients for the spline basis function associated with these seven points. At points next to the boundary, similar stencils are obtained with truncation as the boundary coefficients are known.

2.4. The fourth-order LCSC method. In this section, we consider the fourth-order LCSC method which uses high-order approximations of the derivatives $D_{x_i}^j u$, $j = 1, 2$. These approximations are defined as appropriate linear combinations of S and their derivatives at the mesh points [7]. Specifically, we approximate the second derivatives in the PDE operator (1b), (2b) by the difference scheme

$$\begin{aligned} D_{x_i}^2 u_\Delta^i \Big|_{\mathbf{T}_\ell^i} = {} & (U_{\ell-2}^i(\mathbf{n}_i) + 8U_{\ell-1}^i(\mathbf{n}_i) - 18U_\ell^i(\mathbf{n}_i) \\ & +8U_{\ell+1}^i(\mathbf{n}_i) + U_{\ell+1}^i(\mathbf{n}_i))/(12h_i^2). \end{aligned} \tag{15}$$

The collocation equations corresponding to the mesh points on a line $\mathcal{L}^i$ *away* $(2 \leq \ell \leq N_i - 2)$ from the boundary are written at the point T_ℓ^i as

$$\begin{aligned} \sum_{i=1}^{k} \frac{\alpha_i}{12h_i^2} & \left[U_{\ell-2}^i(\mathbf{n}_i) + 8U_{\ell-1}^i(\mathbf{n}_i) - 18U_\ell^i(\mathbf{n}_i) + 8U_{\ell+1}^i(\mathbf{n}_i) + U_{\ell+2}^i(\mathbf{n}_i)\right] \\ & + \frac{\gamma}{6}[U_{\ell-1}^1(\mathbf{n}_1) + 4U_\ell^1(\mathbf{n}_1) + U_{\ell+1}^1(\mathbf{n}_1)] = f|_{\mathbf{T}_\ell^i}. \end{aligned} \tag{16}$$

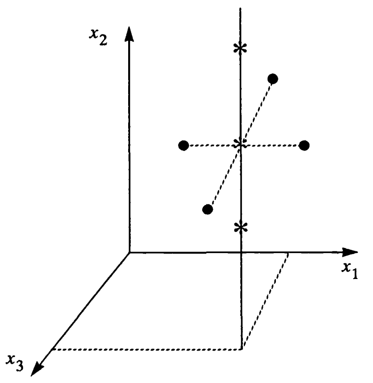

FIG. 2. *The "stencil" at an interior created by the* LCSC *approximation of* (8). *A line in $\mathcal{L}^2$ is shown with index (n_1, n_3). The three* x *mesh points on this line correspond to basis elements $B_j^2(x_2)$ which are nonzero at $\mathbf{T}_j^2$. The solid dots in the x_1 and x_2 directions from $\mathbf{T}_j^2$ are similar mesh points on other lines through $\mathbf{T}_j^2$.*

For lines *close* to the boundary, we have similar forms with appropriately modified right sides. More specifically, in the case of line $\mathcal{L}^1(2,1,\ldots,1)$, the corresponding equations have the form

$$\sum_{i=1}^{k} \frac{\alpha_i}{12h_i^2}[8U_{\ell-1}^i(\mathbf{n}_i) - 18U_\ell^i(\mathbf{n}_i) + 8U_{\ell+1}^i(\mathbf{n}_i) + U_{\ell+2}^i(\mathbf{n}_i)] + \frac{\gamma}{6}[U_{\ell-1}^1(\mathbf{n}_1) + 4U_\ell^1(\mathbf{n}_1) + U_{\ell+1}^1(\mathbf{n}_1)] = f|_{\mathbf{T}_\ell^i}. \tag{17}$$

This discretization has redundant coefficients just as the second-order LCSC method does. The same conditions (14) are used to reduce the number of coefficients to the number of equations. The nature of this discretization is changed from the previous one in that the stencils have five, rather than three, points along each coordinate direction.

3. Iterative solution of the interior LCSC equations.

In this section we consider the iterative solution of the interior collocation equations corresponding to the second- and fourth-order LCSC methods. For the matrix formulation of these equations, we introduce the notation $\mathcal{T}_m \equiv$ tridiag $(1, m, 1)$ and I for the identity matrix. Furthermore, we assume that the ordering for both the collocation equations and the unknowns in the vector $\mathbf{U}^i = \left\{U^i(\mathbf{n}), \mathbf{n} \in \prod_{i=1}^k \otimes I_i\right\}$ is the natural one. Following the above conventions and notations, the LCSC equations can be written in the form

$$\sum_{i=1}^{k} A_i \mathbf{U}^i(\mathbf{n}) = \mathbf{F}^1, \tag{18}$$

where the coefficient matrices are defined by

$$A_i \equiv \left(\prod_{j=1}^{k-i} \otimes I\right) \otimes \mathcal{E}_i \otimes \left(\prod_{j=k-i+2}^{k} \otimes I\right), \qquad i = 1, \ldots, k, \tag{19}$$

with

$$\mathcal{E}_1 = \frac{\alpha_1}{h_1^2}\mathcal{E} + \frac{\gamma}{6}\mathcal{T}_4 \quad \text{and} \quad \mathcal{E}_i = \frac{\alpha_i}{h_i^2}\mathcal{E}, \qquad i = 2,\ldots,k. \tag{20}$$

The matrix $\mathcal{E}$ depends on the discretization scheme applied. Specifically, $\mathcal{E} = \mathcal{T}_{-2}$ for the second-order discretization scheme and $\mathcal{E} = \frac{1}{12}\mathcal{T}_{10}\mathcal{T}_{-2}$ for the fourth-order one. In both cases, the system (18) is underdetermined with $\mathcal{K} = \prod_{j=1}^{k}(N_j - 1)$ equations and $k\mathcal{K}$ unknowns. For its completion, we consider the $k-1$ interpolation equations (14). If we order them according to the ordering of unknowns $\mathbf{U}^1(\mathbf{n})$, we obtain the equations

$$-B_i\mathbf{U}^1(\mathbf{n}) + D_i\mathbf{U}^i(\mathbf{n}) = \mathbf{F}^i, \qquad i = 2,\ldots,k, \tag{21}$$

where

$$B_i = \left(\prod_{j=1}^{k-1} \otimes I\right) \otimes \mathcal{T}_4, \qquad D_i = \left(\prod_{j=1}^{k-i} \otimes I\right) \otimes \mathcal{T}_4 \otimes \left(\prod_{j=k-i+2}^{k} \otimes I\right), \tag{22}$$
$$i = 2,\ldots,k.$$

Most of the components of $\mathbf{F}^i$ are zero, except those that include the effect of the elimination of the boundary conditions. Collecting together the interior equations (18) and the auxiliary interpolation equations (21), we obtain the order $k\mathcal{K}$ system of linear equations

$$\begin{pmatrix} A_1 & A_2 & A_3 & \ldots & A_k \\ -B_2 & D_2 & & & \\ -B_3 & & D_3 & & \\ \vdots & & & \ddots & \\ -B_k & & & & D_k \end{pmatrix} \begin{pmatrix} \mathbf{U}^1 \\ \mathbf{U}^2 \\ \mathbf{U}^3 \\ \vdots \\ \mathbf{U}^k \end{pmatrix} = \begin{pmatrix} \mathbf{F}^1 \\ \mathbf{F}^2 \\ \mathbf{F}^3 \\ \vdots \\ \mathbf{F}^k \end{pmatrix} \tag{23}$$

for the unknown $\mathbf{U}^i$.

3.1. Iterative solution of the LCSC equations. Various iterative solution methods for the LCSC equations (23) for two-dimensional problems have been considered in [7] and [8]. In this paper we formulate and analyze the block Jacobi, EJ, and SOR iteration scheme for the k-dimensional problems (1b), (2b). For the convergence analysis of these iterative schemes, we denote by $\rho(K)$ the spectral radius of a matrix K, ω either the extrapolation or the relaxation SOR parameter, and J, J_ω, and $\mathcal{L}_\omega$ the Jacobi, EJ, and the SOR iteration matrices, respectively.

Next we state two very useful lemmas for the analysis that follows. The first lemma is stated in [13, pp. 107–109], but the proof given here is more general.

LEMMA 3.1. *Let the $n\times n$ matrices $A_{i,j}, i,j = 1,\ldots,k$, possess a common linearly independent set of n eigenvectors $\mathbf{y}^{(\ell)}, \ell = 1,\ldots,n$, with corresponding eigenvalues $\lambda_{i,j}^{(\ell)}$. Then the eigenvalues of the matrix*

$$A = \begin{pmatrix} A_{1,1} & A_{1,2} & \ldots & A_{1,k} \\ A_{2,1} & A_{2,2} & \ldots & A_{2,k} \\ \vdots & \vdots & \vdots & \vdots \\ A_{1,k} & A_{k,2} & \ldots & A_{k,k} \end{pmatrix} \tag{24}$$

are the eigenvalues of the matrices

$$\Lambda_\ell = \begin{pmatrix} \lambda_{1,1}^{(\ell)} & \lambda_{1,2}^{(\ell)} & \cdots & \lambda_{1,k}^{(\ell)} \\ \lambda_{2,1}^{(\ell)} & \lambda_{2,2}^{(\ell)} & \cdots & \lambda_{2,k}^{(\ell)} \\ \vdots & \vdots & \vdots & \vdots \\ \lambda_{1,k}^{(\ell)} & \lambda_{k,2}^{(\ell)} & \cdots & \lambda_{k,k}^{(\ell)} \end{pmatrix}, \qquad \ell = 1, \dots, n. \tag{25}$$

$\sigma(A) = \cup\sigma(\Lambda_\ell)$, *where* $\sigma(K)$ *denotes the spectrum of a matrix* K.

Proof. First we consider the $n \times n$ matrix $Y = [\mathbf{y}^{(1)}\mathbf{y}^{(2)} \dots \mathbf{y}^{(n)}]$ whose columns are the linearly independent eigenvectors $\mathbf{y}^{(\ell)}, \ell = 1, \dots, n$, and the diagonal matrices $\Lambda_{i,j}, i, j = 1, \dots, n$, with diagonal elements the eigenvalues $\lambda_{i,j}^{(\ell)}$ of the matrices $A_{i,j}, i, j = 1, \dots, k$. From the invertibility of Y, we conclude that

$$A_{i,j} = Y\Lambda_{i,j}Y^{-1}, \qquad i, j = 1, \dots, k. \tag{26}$$

Furthermore, A can be written in the form

$$A = (I \otimes Y)\Lambda(I \otimes Y)^{-1}, \tag{27}$$

with

$$\Lambda = \begin{pmatrix} \Lambda_{1,1} & \Lambda_{1,2} & \cdots & \Lambda_{1,k} \\ \Lambda_{2,1} & \Lambda_{2,2} & \cdots & \Lambda_{2,k} \\ \vdots & \vdots & \vdots & \vdots \\ \Lambda_{k,1} & \Lambda_{k,2} & \cdots & \Lambda_{k,k} \end{pmatrix}. \tag{28}$$

This implies that A and Λ are similar matrices. Thus it is sufficient to show the similarity of Λ and of diag $(\Lambda_1, \dots, \Lambda_n)$ with $\Lambda_\ell, \ell = 1, \dots, n$, being given in (25). For this purpose, we construct the graph $G(\Lambda)$ of Λ (see Fig. 3), where only the diagonal elements of the submatrices $\Lambda_{i,j}$ are considered, including the zero ones. In view of $G(\Lambda)$, we construct the permutation matrix P such that $p_{i,j} = 1$ for (i, j) in the set

$$\begin{gathered}\{(1,1), (2, n+1), \dots, (n-1, (k-2)n+1), (n, (k-1)n+1), \\ (n+1, 2), (n+2, n+2), \dots, (2n-1, (k-2)n+2), (2n, (k-1)n+2), \\ \dots \\ ((k-1)n+1, n), ((k-1)n+2, 2n), \dots, (kn-1, (k-1)n), (kn, kn)\}.\end{gathered}$$

From the construction of P, we have $P\Lambda P^T = \text{diag}\,(\Lambda_1, \dots, \Lambda_n)$. This completes the proof of the lemma. $\square$

The second lemma to be used later for the eigenvalue analysis of the collocation coefficient matrix problem is stated as follows.

LEMMA 3.2. *Let the* $n \times n$ *matrices* $A_i, i = 1, \dots, k$, *possess a common linearly independent set of eigenvectors* $\mathbf{y}^{(j)}, j = 1, \dots, n$, *with corresponding eigenvalues* $\lambda_i^{(j)}$ $(i = 1, \dots, k, j = 1, \dots, n)$. *Then the matrix* $A \equiv A_1 \otimes A_2 \otimes \cdots \otimes A_k$ *possesses the* n^k *linearly independent eigenvectors* $\mathbf{y}^{(\underline{j})} \equiv \mathbf{y}^{(j_1)} \otimes \mathbf{y}^{(j_2)} \otimes \cdots \otimes \mathbf{y}^{(j_k)}$, *where* $\underline{j} \equiv (j_1, \dots, j_k)$ *and* $j_i = 1, \dots, n$, $i = 1, \dots, k$, *and eigenvalues* $\lambda^{(\underline{j})} = \lambda_1^{(j_1)}\lambda_2^{(j_2)} \dots \lambda_k^{(j_k)}$.

Proof. First, using tensor product properties, we can easily verify that $A\mathbf{y}^{(\underline{j})} = \lambda^{(\underline{j})}\mathbf{y}^{(\underline{j})}$. In order to prove the linear independence of the $\mathbf{y}^{(\underline{j})}$'s, we construct the

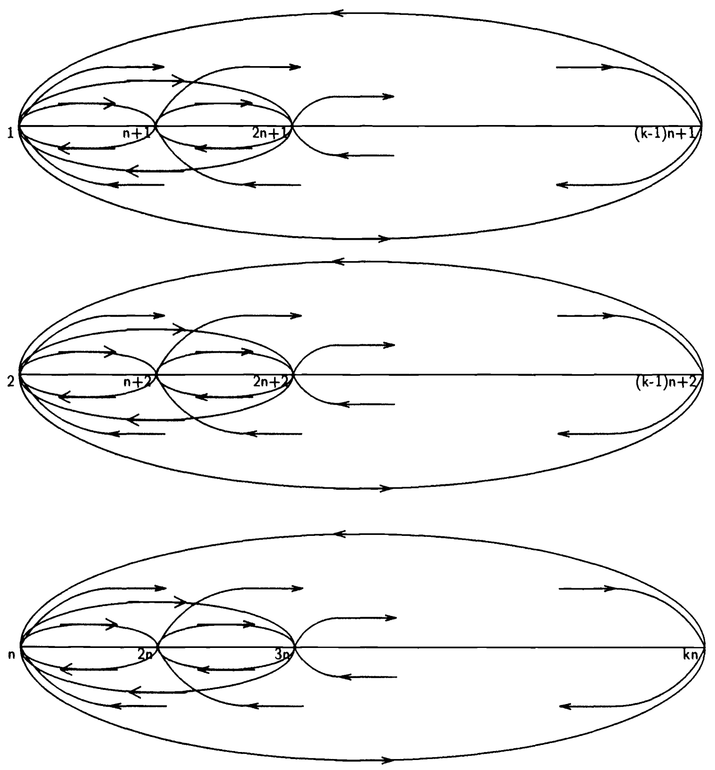

FIG. 3. *Graph $G(\Lambda)$ of the matrix Λ.*

$(n^k) \times (n^k)$ matrix Z whose columns are the n^k eigenvectors of A in the following order

$$\begin{aligned} Z = [&\mathbf{y}^{(1)} \otimes \mathbf{y}^{(1)} \otimes \ldots \otimes \mathbf{y}^{(1)}, \mathbf{y}^{(1)} \otimes \mathbf{y}^{(1)} \otimes \ldots \otimes \mathbf{y}^{(2)}, \ldots, \mathbf{y}^{(1)} \otimes \mathbf{y}^{(1)} \otimes \ldots \otimes \mathbf{y}^{(n)}, \\ &\mathbf{y}^{(1)} \otimes \mathbf{y}^{(1)} \otimes \ldots \otimes \mathbf{y}^{(2)} \otimes \mathbf{y}^{(1)}, \mathbf{y}^{(1)} \otimes \mathbf{y}^{(1)} \otimes \ldots \otimes \mathbf{y}^{(2)} \otimes \mathbf{y}^{(2)}, \ldots, \\ &\mathbf{y}^{(1)} \otimes \mathbf{y}^{(1)} \otimes \ldots \otimes \mathbf{y}^{(2)} \otimes \mathbf{y}^{(n)}, \ldots, \mathbf{y}^{(n)} \otimes \mathbf{y}^{(n)} \otimes \ldots \otimes \mathbf{y}^{(n)}]. \end{aligned}$$

Applying the tensor product notation, we obtain

$$Z = Y \otimes Y \otimes \cdots \otimes Y, \tag{29}$$

where $Y = [\mathbf{y}^{(1)}\mathbf{y}^{(2)} \ldots \mathbf{y}^{(n)}]$. From the assumed linear independence of $\mathbf{y}^{(j)}$, $j = 1, \ldots, n$, we conclude that Y^{-1} and $Z^{-1} = Y^{-1} \otimes Y^{-1} \otimes \cdots \otimes Y^{-1}$ exist. This implies the linear independence of the n^k eigenvectors and concludes the proof of the lemma. □

For the formulation of the block iterative solutions to the LCSC system (23), we consider the splitting $K - L - M$ of the coefficient matrix with $K \equiv \text{diag}(A_1, D_2, D_3, \ldots, D_k)$, $L \equiv \{L_{i,j}\}$, and $M \equiv \{M_{i,j}\}$, where the entries of the matrices L and

M are defined such that

$$
(30)\qquad \begin{aligned} L_{i,j} &\equiv \begin{cases} B_i & \text{if } j=1 \quad \text{and} \quad i=2,\dots,k, \\ 0 & \text{otherwise,} \end{cases} \\ M_{i,j} &\equiv \begin{cases} -A_i & \text{if } i=1 \quad \text{and} \quad j=2,\dots,k, \\ 0 & \text{otherwise.} \end{cases} \end{aligned}
$$

According to the above splitting, the block Jacobi, EJ, and SOR iteration equations of (23) are defined as follows:

$$
(31)\qquad K\mathbf{U}^{(s+1)} = (L+M)\mathbf{U}^{(s)} + \mathbf{F}, \qquad s=0,1,2,\dots,
$$

$$
(32)\qquad K\mathbf{U}^{(s+1)} = (1-\omega)K\mathbf{U}^{(s)} + \omega(L+M)\mathbf{U}^{(s)} + \omega\mathbf{F}, \qquad s=0,1,2,\dots,
$$

and

$$
(33)\qquad \begin{aligned} K\mathbf{U}^{(s+1)} = (1-\omega)K\mathbf{U}^{(s)} + \omega L\mathbf{U}^{(s+1)} + \omega M\mathbf{U}^{(s)} + \omega\mathbf{F}, \\ s=0,1,2,\dots. \end{aligned}
$$

THEOREM 3.1. *The eigenvalues μ of the block Jacobi iteration matrix $K^{-1}(L+M)$ defined in* (31) *are $\mu=0$ of multiplicity $(k-2)\prod_{i=1}^{k}(N_i-1)$ and pure imaginary given for the second-order collocation scheme by*

$$
(34)\qquad \mu := \mu^{(\underline{\ell})} = \pm i\sqrt{\frac{\sum_{j=2}^{k}\frac{\alpha_j}{h_j^2}\lambda_j^{(\ell_j)}(6+\lambda_j^{(\ell_j)})^{-1}}{\left(\frac{\alpha_1}{h_1^2}\lambda_1^{(\ell_1)}+\beta\right)(6+\lambda_1^{(\ell_1)})^{-1}}},
$$

while for the fourth-order scheme by

$$
(35)\qquad \mu := \mu^{(\underline{\ell})} = \pm i\sqrt{\frac{\sum_{j=2}^{k}\frac{\alpha_j}{h_j^2}\lambda_j^{(\ell_j)}(12+\lambda_j^{(\ell_j)})(6+\lambda_j^{(\ell_j)})^{-1}}{\left(\frac{\alpha_1}{h_1^2}\lambda_1^{(\ell_1)}(12+\lambda_1^{(\ell_1)})+12\beta\right)(6+\lambda_1^{(\ell_1)})^{-1}}},
$$

where $i=\sqrt{-1}$, $\underline{\ell}=(\ell_1,\dots,\ell_k), \lambda_j^{(\ell_j)} = -4\sin^2(\ell_j\pi/2N_j), \ell_j=1,\dots,N_j-1, j=1,\dots,k$, and $\beta=\frac{\gamma}{6}(6+\lambda_1^{(\ell_1)})$.

Proof. We start by pointing out that $\mathcal{T}_{10}=12I+\mathcal{T}_{-2}$ and $\mathcal{T}_4=6I+\mathcal{T}_{-2}$. Hence the matrices $\mathcal{T}_{10},\mathcal{T}_4$, and $\mathcal{T}_{-2}$ have a common linearly independent set of eigenvectors. Furthermore, in view of (19), (20), and (22), the matrices A_i, B_i, and D_i also have a common linearly independent set of $\mathcal{K}=\prod_{i=1}^{k}(N_i-1)$ eigenvectors. The block Jacobi iteration matrix $J\equiv K^{-1}(L+M)=\{J_{i,j}\}$, associated with the matrix coefficient in (23), can be described as

$$
(36)\qquad \begin{aligned} &J_{1,1}=0, \qquad \left\{\{J_{i,j}=0\}_{j=2}^{k}\right\}_{i=2}^{k}, \\ &\{J_{1,j}=-A_1^{-1}A_j\}_{j=2}^{k}, \qquad \{J_{i,1}=D_i^{-1}B_i\}_{i=2}^{k}. \end{aligned}
$$

Consequently, the $J_{i,j}$'s possess the same $\mathcal{K}$ linearly independent eigenvectors. So, if we denote by $\lambda_{J_{i,j}}^{(\underline{\ell})}$ the eigenvalue of the matrix $J_{i,j}$ associated with the $\underline{\ell}$ common eigenvector, and use Lemma 3.1, we conclude that

$$\det \begin{pmatrix} -\mu & \lambda_{H_2}^{(\underline{\ell})} & \lambda_{H_3}^{(\underline{\ell})} & \cdots & \lambda_{H_k}^{(\underline{\ell})} \\ \lambda_{G_2}^{(\underline{\ell})} & -\mu & & & \\ \lambda_{G_3}^{(\underline{\ell})} & & -\mu & & \\ \vdots & & & \ddots & \\ \lambda_{G_k}^{(\underline{\ell})} & & & & -\mu \end{pmatrix} = 0, \tag{37}$$

where $\lambda_{G_i}^{(\underline{\ell})}$ and $\lambda_{H_i}^{(\underline{\ell})}$ are eigenvalues of the matrices $G_i := D_i^{-1}B_i$ and $H_i := -A_1^{-1}A_i$, respectively, corresponding to the $\underline{\ell}$ common eigenvector. Using Lemma 3.2, (37) gives
