ERROR BOUNDS FOR DYNAMIC RESPONSES IN FORCED VIBRATION PROBLEMS*

CHRISTIAN CABOS†

Abstract. When using mode superposition in large applications, generally only relatively few approximate eigenmodes are linearly combined. Block Lanczos iteration is an efficient method of determining such modes. In this paper new a posteriori bounds are developed that estimate the error when approximating the exact result of mode superposition with a linear combination of the output vectors of block Lanczos iteration. Mode superposition can be regarded as a way of computing $g(S)f$, a function g of a selfadjoint matrix S applied to a vector. One formula is developed that estimates the norm of the unknown error vector. A second inequality gives a bound for the error when computing linear functionals $\langle v, g(S)f\rangle$ of the response. The error bounds require that f and possibly v are contained in the Lanczos starting block and that all Ritz vectors are used to compute the result. No gaps in the spectrum of S need to be known. The bounds can be evaluated at a small cost compared to the eigenpair extraction in large systems. In a forced response calculation for a container ship with $\approx$ 38,000 degrees of freedom the error is overestimated by two to four orders of magnitude.

1. Introduction.

Certain systems of linear ordinary differential equations with constant coefficients can be decoupled by the method of mode superposition. The equations of motion for a linear system in structural dynamics are one example where the method has proven particularly useful when the system is large. The reason is that often only few eigenmodes need to be superposed to approximate the response to a dynamic load. The block Lanczos algorithm has been applied in this context [9] because it can efficiently determine few modes near some specified frequency. In this paper a posteriori bounds are developed that estimate the error when approximating the exact result of mode superposition with a linear combination of the output vectors of block Lanczos iteration. The term eigenmodes will be used as a synonym for eigenvectors.

Suppose that mode superposition is carried out with the input vector f representing an external load. Then since the exact calculation consists in amplifying each eigenvector component of f by some function g of the respective eigenvalue λ_i, the whole process can be regarded as computing $u = g(S)f$, a matrix function applied to a vector. S is the selfadjoint system matrix with eigenvalues λ_i, $i = 1, \ldots, n$. The exact vector u, called *response* in the following, will be approximated by the vector $\tilde{u}$ obtained by superposing few approximate eigenmodes.

Setting $g(x) = 1/x$, for example, $u = S^{-1}f$ is computed. In [15], among other functions, $S^{-1}f$ and $\exp(S)f$ are approximated in this way. In [4] the functions $\exp(-tS)f$, $\exp(-tS^{0.5})f$, and $\cos(tS^{0.5})f$ arising in partial differential equations are examined and a priori bounds are given for these functions. The number t is a parameter. An expansion for the error vector when approximating $\exp(S)f$ is derived in [12] and a posteriori norm estimates are found by truncating this expansion. All these articles refer to iterations with blocksize one.

The function $g(x) = \frac{1}{\alpha+\gamma x}$ with complex α and γ leads to the evaluation of the modally damped response to a harmonic load in structural dynamics. A common procedure in the field of forced vibrations consists in superposing only those modes that have been obtained with a given accuracy. In 1982, Wilson, Yuan, and Dickens [16] suggested not using only

these "exact" eigenvectors of the structural system. Rather, they superposed all so-called Ritz vectors generated by the Lanczos algorithm with starting vector f, where f represents the static displacement due to the spatial distribution of the dynamic load. Numerical experiments showed that the error in calculating shear and moments at specific points was significantly smaller when using Ritz vectors instead of the same number of exact eigenvectors. Application of this idea to the dynamic analysis of large structures (more than 10^5 degrees of freedom) showed a factor 2–3 improvement in throughput time [1]. In [9] the idea is extended to the block Lanczos method. The error bounds given below rely on the fact that all Ritz vectors are superposed.

Since the determination of eigenmodes is very expensive when the systems are large, error bounds can provide such useful information as when to stop the Lanczos iteration. As stated in [2], in the context of forced vibrations there is no justifiable error estimate showing how many Lanczos vectors are needed to approximate the response to a given accuracy. The stopping criterion used in [8] and [9] is based on participation factors $E_k^\top F$ of the dynamic load $Fe^{i\omega t}$. Here E_k is the kth Lanczos block obtained and ω is the circular frequency of the dynamic load. The Lanczos iteration is stopped after step r if the norm of $E_{r+1}^\top F$ falls below a specified limit. However, the relation between the participation factors and the error in the response is not clear [2]. In [7] the participation of the last Lanczos vector in the approximate solution of heat conduction problems is used for an error criterion.

This paper is organized as follows. After introducing notation, a formula for the norm of the error in the calculated response is given. This is a measure for the (mean square) overall accuracy of the result. However, in engineering applications a common task is the evaluation of the response at a specific degree of freedom or a linear combination thereof (e.g., element stresses). This can be described as calculating linear functionals of the response. A second bound is developed for estimating the error in evaluating such linear functionals of the response.

An important application is the computation of forced vibrations in structural dynamics. Evaluation of the error bounds can be simplified in case of Rayleigh's damping. As a numerical example the forced vibrations of a container ship are examined with respect to their accuracy. The finite element model used contains approximately 38,000 degrees of freedom.

2. Overview of block Lanczos method. To introduce some notation, the basic equations for the block Lanczos method will be given. For a more detailed description of this algorithm see, e.g., [5] and the references therein. The scalar product used below may be of generalized form $\langle a, b\rangle := a^*Mb$ where M is a Hermitian positive definite matrix and * denotes the complex conjugate transpose. $\langle ., .\rangle$ will also be used if a and b have more than one column. In this case $\langle a, b\rangle$ is a matrix. The norm induced will be called $\|a\|_M^2 := \langle a, a\rangle$ to distinguish it from the euclidean norm $\|b\|$. Orthonormality and selfadjointness always refer to this generalized scalar product if vectors or systems of dimension n are involved.

Assume that E_1 is the $n \times b$ orthonormal *starting block* for the Lanczos algorithm with selfadjoint $n \times n$ iteration matrix S. The integer b is called the *blocksize*. By a combination of iteration and orthogonalization the Lanczos method generates blocks of vectors $E_1, \ldots, E_r$. These are used as input vectors for the Ritz method. The Lanczos algorithm enforces the following recursion among successive blocks:

$$E_{r+1}B_{r+1} = SE_r - E_rA_r - E_{r-1}B_r^\top. \tag{1}$$

Here r denotes the total number of Lanczos steps so far and $E = (E_1, E_2, \ldots, E_r)$ is the matrix of the first $m = b \cdot r$ Lanczos vectors. Typical values of n, m, and b used in this paper are $n = 40{,}000$, $m = 200$, $b = 10$. The columns of E are mutually orthonormal and span the block Krylov space $\mathcal{E} = \text{span}(E)$. The $b \times b$ block coefficients A_i and B_i

can be assembled to form the symmetric block tridiagonal matrix

$$T = \langle E, SE \rangle. \tag{2}$$

The A_i are the diagonal blocks; $B_i^\top$ and B_i are on the sub- and superdiagonal, respectively. An eigendecomposition $TQ = Q\tilde{\Lambda}$ of T with $\tilde{\Lambda} = \operatorname{diag}(\tilde{\lambda}_i, i = 1, \ldots, m)$ produces *Ritz values* $\tilde{\lambda}_i$, which approximate the exact eigenvalues λ_j, $j = 1, \ldots, n$ of S. The *Ritz vectors* $\tilde{X} = EQ$ are approximations of the exact eigenvectors X. They also span $\mathcal{E}$.

It is of particular importance for the error bounds given below that in the absence of roundoff errors one has access to the exact size of the residual vector $(S - \tilde{\lambda}_k)\tilde{X}_k$ for each k. If Q_{rk} denotes the b last elements of column k of Q (i.e., its rth block row), then with

$$\beta_{rk} := B_{r+1} Q_{rk}, \tag{3}$$

we have

$$(S - \tilde{\lambda}_k)\tilde{X}_k = E_{r+1}\beta_{rk}. \tag{4}$$

This can be derived by multiplying the Lanczos recursion $SE = ET + (0, \ldots, 0, 0, E_{r+1}B_{r+1})$ by Q from the right. The b-dimensional vector β_{rk} can be computed during the Lanczos iteration at negligible cost once Q has been found.

3. The error in the response. In this section the overall error in approximating the response $g(S)f$ is examined. That is, an estimate is sought for the norm of the error vector

$$u - \tilde{u} = g(S)f - \tilde{X}g(\tilde{\Lambda})\langle \tilde{X}, f \rangle. \tag{5}$$

Approximate mode superposition is a three-step process:

- project f onto the Ritz vectors $\tilde{X}_k$,
- multiply by functions $g(\tilde{\lambda}_k)$ of the Ritz values $\tilde{\lambda}_k$, and
- linearly combine the Ritz vectors to obtain $\tilde{u}$.

One possibility would therefore be to develop bounds that estimate the errors in each of these steps. These quantities must be combined to produce the final result. As a basis, bounds on the Ritz values and Ritz vectors would have to be used. One major disadvantage of this technique is that to find bounds on the Ritz vectors, gaps in the spectrum of S must be known (see [6] or [11]). Another drawback is that since all Ritz vectors should be included in the calculation, large intermediate error quantities appear. The technique developed below combines all steps of mode superposition into a single estimate thereby avoiding the above disadvantages.

For a differentiable function g, define Δg by

$$\Delta g(x, y) := \begin{cases} \frac{g(x)-g(y)}{x-y} & \text{if } x \neq y, \\ g'(x) & \text{if } x = y. \end{cases} \tag{6}$$

THEOREM 3.1. *Suppose that r steps of the Lanczos iteration with selfadjoint system matrix S and blocksize b produce the Ritz values $\tilde{\Lambda} = \operatorname{diag}(\tilde{\lambda}_k)$ and Ritz vectors $\tilde{X} = (\tilde{X}_k)$, $k = 1, \ldots, m$. Let f be completely represented in the space of Ritz vectors, $f \in \mathcal{E}$, and g be a differentiable function on the real axis. Both f and g may be real or complex valued. Then the norm of the error when approximating $u = g(S)f$ by $\tilde{u} = \tilde{X}g(\tilde{\Lambda})\langle \tilde{X}, f \rangle$ is bounded by*

$$\|u - \tilde{u}\|_M^2 \leq b \max_{j=1}^{n} \left\| \sum_{k=1}^{m} \Delta g(\lambda_j, \tilde{\lambda}_k)\beta_{rk} f_k \right\|^2, \tag{7}$$

where $f_k := \langle \tilde{X}_k, f\rangle$. *The numbers* λ_j, $j = 1, \ldots, n$, *are the exact eigenvalues of* S, *and* β_{rk} *is given by* (3).

Proof. Expand f in terms of the Ritz vectors

$$u - \tilde{u} = \sum_{k=1}^{m} (g(S) - g(\tilde{\lambda}_k))\tilde{X}_k f_k. \tag{8}$$

The norm of this error vector will be calculated by summing up the squares of its X_j-components. The X_j-component of the kth summand above has the form

$$\langle X_j, (g(S) - g(\tilde{\lambda}_k))\tilde{X}_k f_k\rangle = (g(\lambda_j) - g(\tilde{\lambda}_k))\langle X_j, \tilde{X}_k f_k\rangle. \tag{9}$$

This can be seen using the definition $g(S) := \sum_{i=1}^{n} X_i g(\lambda_i)\langle X_i, .\rangle$. If $\lambda_j \neq \tilde{\lambda}_k$, then a factor $(S - \tilde{\lambda}_k)/(\lambda_j - \tilde{\lambda}_k)$ can be added with similar reasoning

$$(g(\lambda_j) - g(\tilde{\lambda}_k))\langle X_j, \tilde{X}_k f_k\rangle = \frac{g(\lambda_j) - g(\tilde{\lambda}_k)}{\lambda_j - \tilde{\lambda}_k}\langle X_j, (S - \tilde{\lambda}_k)\tilde{X}_k f_k\rangle. \tag{10}$$

In case $\lambda_j = \tilde{\lambda}_k$, the left-hand side of (10) is zero and so is $\langle X_j, (S - \tilde{\lambda}_k)\tilde{X}_k f_k\rangle = \langle(\lambda_j - \tilde{\lambda}_k)X_j, \tilde{X}_k f_k\rangle$. Therefore, for $\lambda_j = \tilde{\lambda}_k$ the difference quotient in (10) can be replaced by any finite number, particularly $g'(\tilde{\lambda}_k)$. Taking advantage of the definition of Δg, we combine (9) and (10) to obtain

$$\langle X_j, (g(S) - g(\tilde{\lambda}_k))\tilde{X}_k f_k\rangle = \Delta g(\lambda_j, \tilde{\lambda}_k)\langle X_j, (S - \tilde{\lambda}_k)\tilde{X}_k f_k\rangle, \tag{11}$$

which is valid for all λ_j and all values of $\tilde{\lambda}_k$.

From the Lanczos recursion (see (4)) we know that $(S - \tilde{\lambda}_k)\tilde{X}_k = E_{r+1}\beta_{rk}$. The X_j-component of the sum over k hence becomes

$$\sum_{k=1}^{m} \langle X_j, (g(S) - g(\tilde{\lambda}_k))\tilde{X}_k f_k\rangle = \langle X_j, E_{r+1}\rangle \sum_{k=1}^{m} \Delta g(\lambda_j, \tilde{\lambda}_k)\beta_{rk} f_k. \tag{12}$$

The norm of the error can be found by summing up the squares of the absolute values over j

$$\begin{aligned} \|u - \tilde{u}\|_M^2 &= \sum_{j=1}^{n} \left| \langle X_j, E_{r+1}\rangle \sum_{k=1}^{m} \Delta g(\lambda_j, \tilde{\lambda}_k)\beta_{rk} f_k \right|^2 \\ &\leq \sum_{j=1}^{n} \|\langle X_j, E_{r+1}\rangle\|^2 \left\| \sum_{k=1}^{m} \Delta g(\lambda_j, \tilde{\lambda}_k)\beta_{rk} f_k \right\|^2, \end{aligned} \tag{13}$$

where the Cauchy–Schwarz inequality has been applied. $\langle X_j, E_{r+1}\rangle$ is a b-dimensional row vector. Taking the maximum over j in (13) we get the desired result since $\sum_{j=1}^{n} \|\langle X_j, E_{r+1}\rangle\|^2 = b$. □

In case we have no additional information about the spectrum of S, we must evaluate

$$\|u - \tilde{u}\|_M \leq \sqrt{b} \sup_{\xi \in \mathbb{R}} \left\| \sum_{k=1}^{m} \Delta g(\xi, \tilde{\lambda}_k)\beta_{rk} f_k \right\|. \tag{14}$$

Each maximization step in (14) produces the cost of $O(bm)$ flops, the sum represents a b-dimensional column vector. The maximum can, of course, be restricted to known subsets of

$\mathbb{R}$ containing the whole spectrum of S. For example, all exact eigenvalues are nonnegative if one calculates forced vibrations.

In Fig. 1 a typical shape of the function $h(\xi) := \left\| \sum_{k=1}^{m} \Delta g(\xi, \tilde{\lambda}_k)\beta_{rk} f_k \right\|$, which is maximized in (14), is shown (dashed line). The drawn lines correspond to the example given in §7.2 with $\frac{\omega}{2\pi} = 6$ Hz and are plotted against eigenfrequency. Frequency ν can be transformed to ξ by $\xi = (2\pi\nu)^2$.

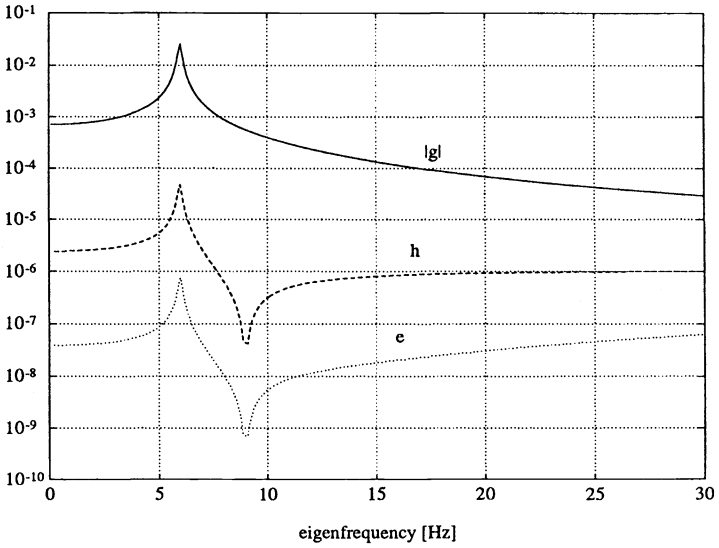

FIG. 1. *Typical shapes of* $|g|$, h, *and* e *plotted against eigenfrequency.*

To insure that $f \in \mathcal{E}$, the vector f should be included in the starting block of the Lanczos iteration. The fastest way of computing the response vector u is to combine the Lanczos vectors E without ever forming Ritz vectors. This also has the advantage that no additional cost of order n is introduced when all Ritz components are used. Ignoring some of the computed Ritz vectors, e.g., using only exact eigenvectors, therefore means no significant time savings but less accurate results as shown in the examples.

Now assume that a vector $f_\perp$ that is orthogonal to $\mathcal{E}$ is added to f. As long as we do not know about gaps in the spectrum, we must always assume that $f_\perp$ is parallel to an eigenvector X_p and that g attains its maximum at λ_p. So, in this case, the term $\|f_\perp\|_M \sup_{\xi\in\mathbb{R}} |g(\xi)|$ would have to be added to (14).

4. The error in evaluating functionals of the response. The response vector is evaluated at a single point or at a linear combination of points by applying a linear functional v to it. The error in the result is

$$\langle v, u\rangle - \langle v, \tilde{u}\rangle = \big\langle v, g(S)f - \tilde{X}g(\tilde{\Lambda})\langle \tilde{X}, f\rangle \big\rangle. \tag{15}$$

If f is contained in $\mathcal{E}$ but v possibly is not, this error can be estimated using the Cauchy–Schwarz inequality

$$|\langle v, u\rangle - \langle v, \tilde{u}\rangle| \le \|v\|_M \, \|g(S)f - \tilde{X}g(\tilde{\Lambda})\langle \tilde{X}, f\rangle\|_M. \tag{16}$$

Now the results of the last section can be applied to the second factor. $|\langle v, u\rangle - \langle v, \tilde{u}\rangle|$ can be regarded as a seminorm of the error vector $u - \tilde{u}$. As an abbreviation of the names Cauchy and Schwarz, inequality (16) will be called *CS seminorm error bound* in the sequel.

If, apart from f, v is also completely represented in $\mathcal{E}$, the actual error is generally smaller and better bounds can be given. To take advantage of this improvement, f and v should be included in the starting block of the Lanczos iteration. Similar to the last section, we define for a twice differentiable function g

$$\Delta^2 g(x,y,z) := \begin{cases} \frac{\Delta g(x,z)-\Delta g(y,z)}{(x-y)} & \text{if } x \neq y, \\ \frac{g'(y)-\Delta g(y,z)}{(y-z)} & \text{if } x = y \text{ and } x \neq z, \\ g''(x)/2 & \text{if } x = y = z. \end{cases} \tag{17}$$

THEOREM 4.1. *Apart from the assumptions in Theorem* 3.1 *let v also be completely represented in the space of Ritz vectors, $v \in \mathcal{E}$. The vector v may be real or complex valued and define $v_k := \langle \tilde{X}_k, v\rangle$. The function g shall be twice differentiable. Then the absolute value of the error in approximating $\langle v, u\rangle$ is bounded by*

$$\left|\langle v,u\rangle - \langle v,\tilde{u}\rangle\right| \leq b \cdot \max_{j=1}^{n} \left\| \sum_{l=1}^{m}\sum_{k=1}^{m} \bar{v}_l \beta_{rl} \Delta^2 g(\lambda_j, \tilde{\lambda}_l, \tilde{\lambda}_k) \beta_{rk}^{\top} f_k \right\|. \tag{18}$$

Proof. Both v and f are expanded in terms of Ritz vectors

$$\langle v, u-\tilde{u}\rangle = \sum_{l=1}^{m}\sum_{k=1}^{m} \left\langle \tilde{X}_l v_l, (g(S) - g(\tilde{\lambda}_k))\tilde{X}_k f_k \right\rangle. \tag{19}$$

Using the orthogonality among Lanczos blocks and relation (4), one can see that $(S-\tilde{\lambda}_k)\tilde{X}_k$ is orthogonal to $\mathcal{E}$ for all k. Consequently, each scalar product can be modified

$$\left\langle \tilde{X}_l v_l, (g(S) - g(\tilde{\lambda}_k))\tilde{X}_k f_k \right\rangle = \left\langle \tilde{X}_l v_l, (g(S) - g(\tilde{\lambda}_k) - b_{l,k}(S-\tilde{\lambda}_k))\tilde{X}_k f_k \right\rangle \tag{20}$$

with arbitrary numbers $b_{l,k}$. Choose $b_{l,k}$ as

$$b_{l,k} := \Delta g(\tilde{\lambda}_l, \tilde{\lambda}_k). \tag{21}$$

Without adding this term, the difference quotient in (23) would be unbounded near Ritz values. This in turn would make it impossible to find a sensible bound for the error.

The scalar product will be evaluated by summing up X_j-coordinates. Observe that if $\lambda_j \neq \tilde{\lambda}_l$ and $\lambda_j \neq \tilde{\lambda}_k$,

$$\langle \tilde{X}_l v_l, X_j\rangle \left\langle X_j, (g(S) - g(\tilde{\lambda}_k) - b_{l,k}(S-\tilde{\lambda}_k))\tilde{X}_k f_k \right\rangle \tag{22}$$

$$= \langle (S-\tilde{\lambda}_l)\tilde{X}_l v_l, X_j\rangle \frac{g(\lambda_j) - g(\tilde{\lambda}_k) - b_{l,k}(\lambda_j - \tilde{\lambda}_k)}{(\lambda_j - \tilde{\lambda}_l)\cdot(\lambda_j - \tilde{\lambda}_k)} \langle X_j, (S-\tilde{\lambda}_k)\tilde{X}_k f_k\rangle. \tag{23}$$

If $\lambda_j = \tilde{\lambda}_l$ or $\lambda_j = \tilde{\lambda}_k$, one of the scalar products in (23) is zero and so is (22). Therefore, the difference quotient can be replaced by an arbitrary number in these cases. Using the definition of $\Delta^2 g$, (22) now equals

$$\langle (S-\tilde{\lambda}_l)\tilde{X}_l v_l, X_j\rangle \Delta^2 g(\lambda_j, \tilde{\lambda}_l, \tilde{\lambda}_k) \langle X_j, (S-\tilde{\lambda}_k)\tilde{X}_k f_k\rangle \tag{24}$$

for all λ_j, $\tilde{\lambda}_l$, and $\tilde{\lambda}_k$.

At this point information from the Lanczos method (4) is introduced:

$$\langle X_j, (S-\tilde{\lambda}_k)\tilde{X}_k f_k\rangle = \langle X_j, E_{r+1}\rangle \beta_{rk} f_k = f_k \beta_{rk}^{\top} \langle E_{r+1}, X_j\rangle \tag{25}$$

and the same can be done with $\langle (S-\tilde{\lambda}_l)\tilde{X}_l v_l, X_j\rangle$. Summing up (23) over l, k, and j, we get

$$\begin{aligned}\langle v,u\rangle - \langle v,\tilde{u}\rangle &= \sum_{l=1}^{m}\sum_{k=1}^{m}\sum_{j=1}^{n}\langle X_j, E_{r+1}\rangle \bar{v}_l\beta_{rl}\Delta^2 g(\lambda_j,\tilde{\lambda}_l,\tilde{\lambda}_k)\beta_{rk}^{\top}f_k\langle E_{r+1},X_j\rangle \\ &= \sum_{j=1}^{n}\langle X_j,E_{r+1}\rangle\Bigg(\sum_{l=1}^{m}\sum_{k=1}^{m}\bar{v}_l\beta_{rl}\Delta^2 g(\lambda_j,\tilde{\lambda}_l,\tilde{\lambda}_k)\beta_{rk}^{\top}f_k\Bigg)\langle E_{r+1},X_j\rangle. \qquad (26)\end{aligned}$$

Note that up to now we have equality. Each summand of the outer sum can be estimated by taking norms

$$|\langle v,u\rangle - \langle v,\tilde{u}\rangle| \le \sum_{j=1}^{n}\|\langle E_{r+1},X_j\rangle\|^2\left\|\sum_{l=1}^{m}\sum_{k=1}^{m}\bar{v}_l\beta_{rl}\Delta^2 g(\lambda_j,\tilde{\lambda}_l,\tilde{\lambda}_k)\beta_{rk}^{\top}f_k\right\|. \qquad (27)$$

More exactly, the norm of the double sum could be replaced by the radius of the numerical range of this matrix. Because $\sum_{j=1}^{n}\|\langle X_j,E_{r+1}\rangle\|^2 = b$, we can take the maximum over the right factors to obtain the desired result. □

Inequality (18) will be called *full seminorm error bound* in the sequel. Again, if we have no additional information about the spectrum of S

$$|\langle v,u\rangle - \langle v,\tilde{u}\rangle| \le b\cdot\sup_{\xi\in\mathbb{R}}\left\|\sum_{l=1}^{m}\sum_{k=1}^{m}\bar{v}_l\beta_{rl}\Delta^2 g(\xi,\tilde{\lambda}_l,\tilde{\lambda}_k)\beta_{rk}^{\top}f_k\right\|. \qquad (28)$$

As in the last section one should, of course, take advantage of any such information, e.g., about gaps in the spectrum. Figure 1 shows the typical shape of the norm $e(\xi)$ of the double sum (dotted line) which is maximized in (28). Reference is again made to the numerical example given in §7.2. The double sum in (28) represents a $b\times b$ matrix. Instead of the euclidean matrix norm, the Frobenius norm is used in all calculations in this paper.

Care must be taken for calculating the differential quotients Δg and $\Delta^2 g$. Cancellation can occur. In case the numerator and the denominator approach zero, the quotient must be substituted by the appropriate derivative.

The factor $\Delta^2 g(\xi,\tilde{\lambda}_l,\tilde{\lambda}_k)$ can be regarded as an $m\times m$ matrix with indices l and k. Therefore, the function that must be maximized in (28) produces the cost of $O(bm^2)$ operations per evaluation. Since for $\xi\neq\tilde{\lambda}_l$ we have

$$\Delta^2 g(\xi,\tilde{\lambda}_l,\tilde{\lambda}_k) = \frac{1}{\xi-\tilde{\lambda}_l}(\Delta g(\xi,\tilde{\lambda}_k) - \Delta g(\tilde{\lambda}_l,\tilde{\lambda}_k)), \qquad (29)$$

the matrix multiplication can be economized. The matrix product

$$\sum_{k=1}^{m}\Delta g(\tilde{\lambda}_l,\tilde{\lambda}_k)\beta_{rk}^{\top}f_k \qquad (30)$$

must be found and stored once. Factorizing the rest of the computation into a k- and an l-part, only $O(bm)$ operations remain for any subsequent ξ in the maximization process.

5. Application to the calculation of forced vibrations. Calculating forced vibrations leads to evaluating functions of a matrix S applied to the load vector. Suppose that the dynamic behaviour of a structural system is described by the linear second-order differential equation

$$M\ddot{u}(t) + C\dot{u}(t) + Ku(t) = Fe^{i\omega t}, \qquad (31)$$

where M, C, and K are symmetric mass, damping, and stiffness matrix, respectively. The vector F represents the time-independent spatial distribution of the load and ω is its circular frequency. The solution $u(t) = ue^{i\omega t}$ is the time-dependent vector of nodal displacements and t represents time. A dot above a symbol denotes differentiation with respect to t. The damping matrix C shall be diagonalizable simultaneously with M and K. That is, modal damping will be applied. Formally C is a function of M and K, $C = Mc(M^{-1}K)$. Rayleigh's damping is obtained by setting $c(x) = a_1 + a_2 x$ with constants a_1 and a_2. C is never formed explicitly but is rather applied for each mode.

Equation (31) can be solved by obtaining a complete generalized eigendecomposition $KX_j = \mu_j MX_j$, $j = 1, \ldots, n$, of the matrix pencil (K, M). One may assume that the eigenvectors X_j form a complete orthonormal set. The scalar product used is $\langle a, b\rangle := a^* Mb$. In eigenvector coordinates, (31) decouples and the solution $u(t)$ can be given explicitly (see, e.g., [3])

$$u(t) = \sum_{j=1}^{n} X_j \frac{1}{\mu_j + i\omega c(\mu_j) - \omega^2} X_j^\top F e^{i\omega t}, \tag{32}$$

or when applying an arbitrary shift σ,

$$u(t) = \sum_{j=1}^{n} X_j \frac{\mu_j - \sigma}{\mu_j + i\omega c(\mu_j) - \omega^2} \langle X_j, (K - \sigma M)^{-1} F\rangle e^{i\omega t}. \tag{33}$$

When solving the generalized eigenproblem the Lanczos method is usually applied in "shift and invert mode" [13], [10], that is, $S := (K - \sigma M)^{-1} M$ is chosen as iteration matrix. Then S is selfadjoint with respect to $\langle ., .\rangle$ and convergence to eigenpairs is best for $\mu \approx \sigma$. The eigenvalues of the transformed system S are $\lambda_j = 1/(\mu_j - \sigma)$ and the eigenvectors X_j remain the same. Therefore, the solution of (31) can be written as

$$u(t) = g_{K,\omega}(S)(K - \sigma M)^{-1} F e^{i\omega t} \quad \text{with} \quad g_{K,\omega}(\lambda) := \frac{1}{1 + \lambda(\sigma - \omega^2 + i\omega c(1/\lambda + \sigma))}. \tag{34}$$

For $\sigma = 0$ this function $g_{K,\omega}$ is called "dynamic amplification factor." Alternatively,

$$u(t) = g_{M,\omega}(S) M^{-1} F e^{i\omega t} \quad \text{with} \quad g_{M,\omega}(\lambda) := \lambda g_{K,\omega}(\lambda), \tag{35}$$

which has the disadvantage that M^{-1} must be applied to generate the starting vector $M^{-1}F$. The input vector f will be defined either by $f = (K - \sigma M)^{-1} F$ or by $f = M^{-1} F$, whichever method as given above is applied. The index ω will frequently be dropped.

For viscous nonmodal damping the response u generally cannot be expressed in the form $g(S) f$ for some function g. Hence the theory of the previous sections does not apply.

The functions g given by (34) and (35) exhibit a sharp peak for $\lambda \approx \frac{1}{\omega^2 - \sigma}$ if σ is not near to ω^2. A semilogarithmic graph of $|g|$ for the example in §7.2 and $\frac{\omega}{2\pi} = 6$ Hz is given in Fig. 1 (solid line). Note that $|g|$ is plotted over eigenfrequency ν. Plotted against $\lambda = 1/((2\pi\nu)^2 - \sigma)$, the peak is narrower still. On one hand, this shape of g makes it possible to obtain good approximations of the response with relatively few eigenmodes corresponding to values around ω^2. On the other hand, finding good error bounds is difficult in this case if they rely on the approximation of g by a polynomial of degree r as in [4].

6. Rayleigh's damping. In the case of Rayleigh's damping, the expressions $\Delta g(\xi, \tilde{\lambda}_k)$ and $\Delta^2 g(\xi, \tilde{\lambda}_l, \tilde{\lambda}_k)$ can be written as a product and closed error formulas can be found. Set $c(\mu) := a_1 + a_2 \mu$ with constants a_1 and a_2, then g_M has the form $g_M(\lambda) = \frac{\lambda}{\alpha + \gamma\lambda}$. Here the

numbers α and γ are defined by $\alpha := 1 + i\omega a_2$ and $\gamma := \sigma - \omega^2 + i\omega(a_1 + a_2\sigma)$. Now the identities

$$\Delta g_M(x, y) = \frac{\alpha}{(\alpha + \gamma x)(\alpha + \gamma y)} \tag{36}$$

and

$$\Delta^2 g_M(x, y, z) = \frac{-\alpha\gamma}{(\alpha + \gamma x)(\alpha + \gamma y)(\alpha + \gamma z)} \tag{37}$$

can be derived easily. By pulling the ξ-dependent part out of inequalities (14) and (28) and by explicitly calculating the maximum of $|\frac{1}{\alpha+\gamma\xi}|$, one obtains the formulas

$$\|u - \tilde{u}\|_M \leq \sqrt{b}\, \frac{|\alpha\gamma|}{|\Im(\bar{\alpha}\gamma)|} \left\| \sum_{k=1}^{m} \frac{f_k}{\alpha + \gamma\tilde{\lambda}_k} \beta_{rk} \right\| \tag{38}$$

and

$$|\langle v, u\rangle - \langle v, \tilde{u}\rangle| \leq b\, \frac{|\alpha\gamma^2|}{|\Im(\bar{\alpha}\gamma)|} \left\| \left(\sum_{l=1}^{m} \beta_{rl} \frac{\bar{v}_l}{\alpha + \gamma\tilde{\lambda}_l} \right) \left(\sum_{k=1}^{m} \frac{f_k}{\alpha + \gamma\tilde{\lambda}_k} \beta_{rk}^{\top} \right) \right\|. \tag{39}$$

Both bounds are valid under the assumptions of Theorems 3.1 and 4.1 with $g = g_M$. For $g = g_K$, the right-hand sides must be multiplied by a factor $|\frac{\gamma}{\alpha}|$. The symbol $\Im$ denotes the imaginary part of a complex number. Both expressions can be evaluated with a small multiple of bm flops.

7. Numerical examples. The above methods have been applied to a forced response calculation for a container ship. The ship's finite element model contained 38,292 degrees of freedom (a hidden line plot is given in Fig. 2). The stiffness matrix K was a band matrix with a mean bandwidth of 400. The main point of investigation was the response to moments produced by gas forces in the engine. Three different spatial load distributions have been included in the calculation. The response was evaluated at 9 degrees of freedom. To include all these vectors, the blocksize was chosen to be 12. Twenty iterations have been performed and the shift σ was chosen corresponding to a frequency of 9 Hz. The implementation of the Lanczos algorithm contained "partial reorthogonalization" as described in [14].

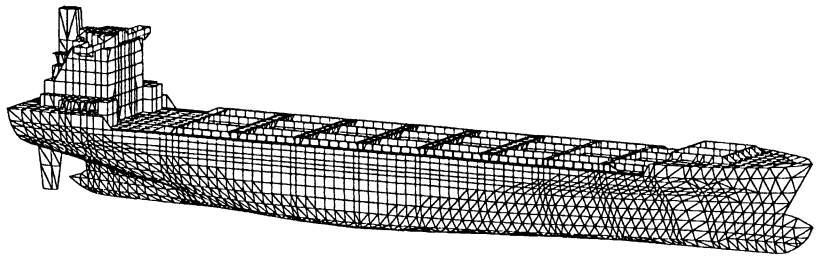

FIG. 2. *Finite element model of container ship.*

A lumped (diagonal) mass matrix was used. Therefore, M^{-1} could be applied and the method chosen was the one defined by g_M in (35). Numerical experience with different examples shows that the error bounds become slightly better when using the method given by g_K in (34). This improvement is achieved by one additional (expensive) application of S. The error bounds are, of course, equally applicable to the case of a nondiagonal mass matrix. Then evaluation of M^{-1} should be avoided and hence the g_K-method would have to be used.

All graphs in this section are plotted against frequency of excitation; that is, the parameter ω is varying in $g_{M,\omega}(\lambda)$.

7.1. Rayleigh's damping. The critical damping ratio was chosen to be linear in frequency, 0% at 0 Hz and 3% at 10 Hz. Figure 3 shows the relative norm errors after various numbers of iteration steps. More precisely, the lines show $\|u - \tilde{u}\|_M / \|\tilde{u}\|_M$, the error bound as given by (38) divided by the norm of the calculated response. As expected the results are most accurate around the shift σ.

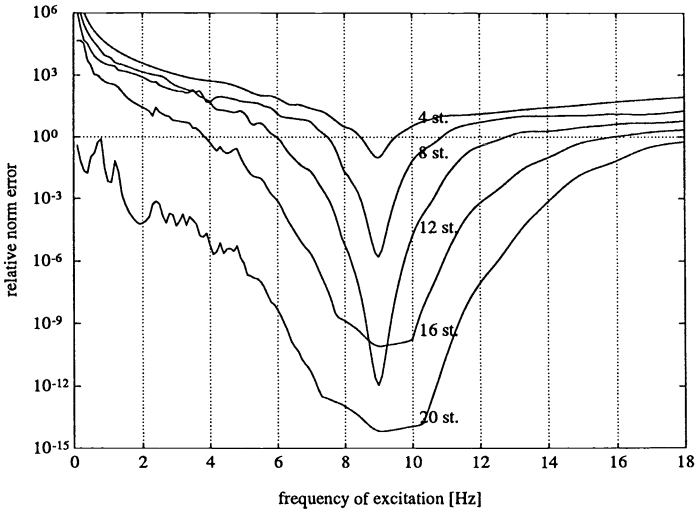

FIG. 3. *Relative norm error bounds after various numbers of iteration steps.*

For the comparisons in Figs. 4–6, the response was evaluated at a particular degree of freedom on the ship's bridge. The solid lines in Fig. 4 show the relative errors found using (39) after 8, 14, and 20 iteration steps. The CS seminorm error bounds are given by the dashed lines. Clearly, it is advisable to include the vectors v of measurement degrees of freedom (which define the evaluation functionals) in the starting block to be able to prove additional accuracy in the results.

In Fig. 5 the full seminorm error bounds (solid lines) are compared to the actual error (dashed lines). The term *actual error* will be used for the difference to the response after 20 steps (plus its error estimate) in the following. The error bound after 20 steps is given for reference. Between 6 and 16 Hz the error is overestimated by two to three orders of magnitude. Due to finite precision (about 16 decimals), the actual error does not fall below a certain limit (here 10^{-14}) although the error bounds predict better approximation.

Figure 6 shows the effect of ignoring bad Ritz vectors. In these examples, the term *bad* will be used for those Ritz pairs with negative values and with values above 30 Hz. Conventionally, such Ritz pairs would not be included in a forced response calculation with the given frequencies of excitation. According to the relative error bound $\|\beta_{rk}\|/|\lambda_k|$ (see [11, p. 69]) all mentioned Ritz values had been found with a relative precision less than 70%. The solid lines give the actual errors if all Ritz vectors are used for calculating the response. Omitting bad Ritz pairs leads to the errors shown by the dashed lines. One can say that including inexact eigenvectors leads to more accurate results at those points where a modest degree of accuracy has already been achieved.

7.2. Quadratic damping below 10 Hz. Here the critical damping ratio was chosen to be a quadratic function of frequency, 0.5% at 0 Hz, 0.9% at 4 Hz, and 3% at 10 Hz. Above 10 Hz the same damping function as in the previous section was used. Force vector f and

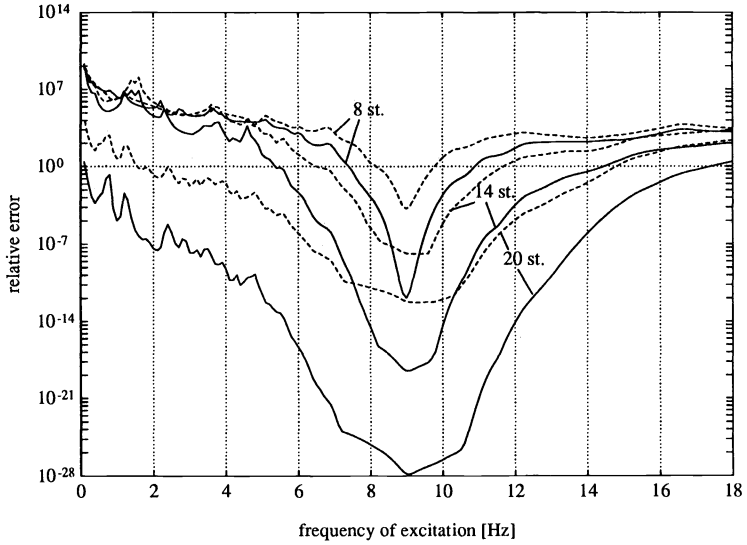

FIG. 4. *Comparison of error bounds for the evaluation of the response at a specific degree of freedom. Dashed line*: CS *seminorm error bounds. Solid line*: *Full seminorm error bounds.*

measurement vector v were the same as above. The maximum in the error bounds was taken over all of $\mathbb{R}^+$. After 20 steps all eigenvalues between 0 and 9 Hz had been found. Consequently, gaps in this interval could be excluded from the maximum in this case.

Figure 7 shows that the norm error is higher than for Rayleigh's damping. More steps are needed to obtain a given accuracy. In Fig. 8 the full seminorm error bound after 16 steps (solid line) is compared to the actual error (dashed line) as explained in the previous example. The response error after 20 steps is again given for reference. Between 6 and 13 Hz the error is overestimated by about four orders of magnitude. The dashed-dotted line gives the actual errors when ignoring bad Ritz vectors in the same way as in the previous example.

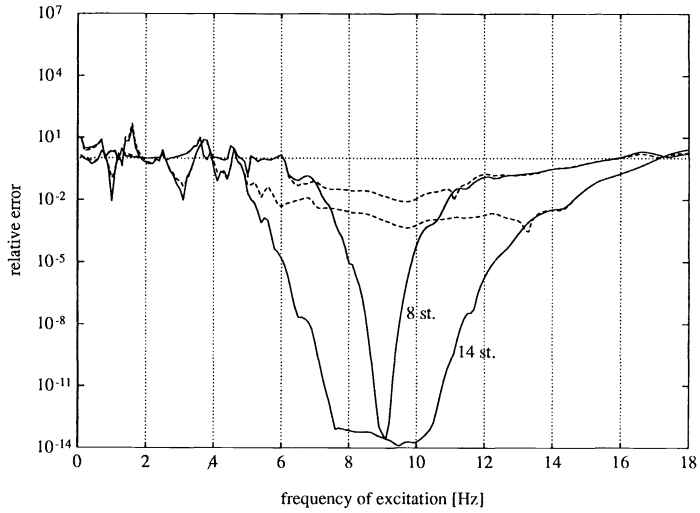

FIG. 6. *Comparison of actual errors with and without ignoring bad Ritz vectors. Solid line: Actual error. Dashed line: Actual error, bad vectors ignored.*

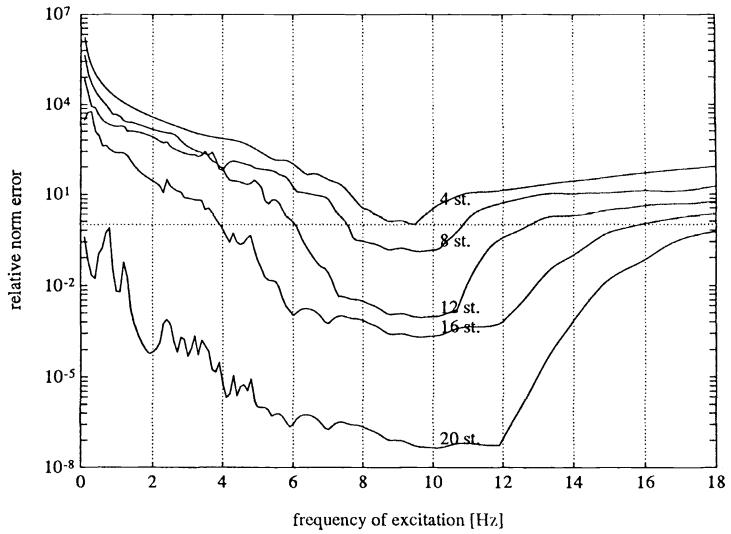

FIG. 7. *Relative norm error bounds after various numbers of iteration steps.*

7.3. Reduced number of relevant eigenmode components in the input vectors. This example shows that the error bounds can also provide useful information in a frequency range where several eigenpairs have not yet been found. S was chosen to be diagonal and M was set to the identity matrix. With other words, the canonical scalar product has been used. System dimension was $n = 1000$. The first 320 entries of the diagonal of S were set to the eigenvalues below 25 Hz of the container ship above. Six hundred and eighty eigenvalues higher than 25 Hz have been chosen at random with roughly the same spacing as the first 320 values. Diagonal test matrices in connection with the Lanczos algorithm have, for example, been used in [15]. Since the Lanczos algorithm only applies to a given system, it does not take advantage of the special form of S.

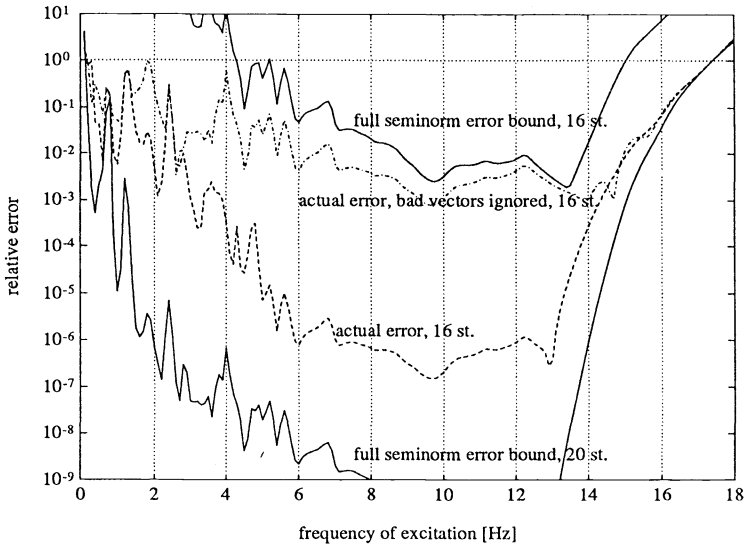

FIG. 8. *Comparison full seminorm error bound—actual errors with and without ignoring bad Ritz vectors.*

The vectors f and v were chosen at random such that about 350 of the entries of f and 220 of those of v had absolute values between 10^{-1} and 10^{-5}. The other entries had absolute values around 10^{-8}. Since f was complex and v was real, the blocksize was chosen to be $b = 3$. The starting block contained v and the real and imaginary parts of f. Lanczos iteration was stopped after ten steps and damping was chosen as in §7.1.

In Fig. 9 the exact eigenvalues are shown by a plus (+) sign. An x marks an eigen value found by the Lanczos iteration. Its vertical position represents the estimate $\|\beta_{rk}\|/|\lambda_k|$ for its relative accuracy (see above). Between 12 and 15 Hz only 14 out of 29 eigenvalues and -vectors have been approximated. Nevertheless, the error bounds show that the calculated response has a relative error less than 10% in this interval. This is true for the norm (dashed line) as well as for the functional of the response (solid line, full seminorm error bound).

The described effect can become useful if the structure under consideration contains a large number of eigenmodes that are not relevant near the points of excitation and evaluation, but correspond to eigenvalues near ω^2. In particular this refers to vibrating subsystems. The error bounds can predict good approximation of the response even if these modes have not been found. As a result, the Lanczos iteration can be stopped earlier as when using a conventional stopping criterion like "calculate all modes in the desired frequency range."

8. Conclusions. Using the formulas developed above, it is possible to obtain a posteriori error bounds for the process of mode superposition. The bound for the norm error gives the overall error of the approximate solution if the input vector is included in the starting block of the Lanczos algorithm. In case the response is evaluated at a single degree of freedom or at a linear combination thereof, the second bound gives more favourable results. Then the functional for this evaluation should also be included in the starting block.

The error estimates do not make use of bounds on the Ritz vectors. They directly measure the accuracy of the whole process of approximating the response. This is in contrast to the approach of dividing it into the three usual steps of mode superposition. No specific information (e.g., gaps) about the spectrum of the system matrix needs to be known.

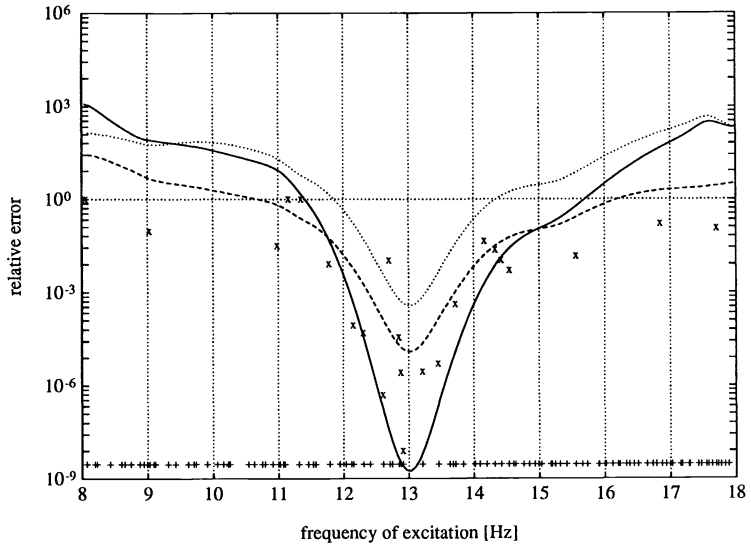

FIG. 9. *Response approximation when input vectors contain* $\approx$ *25% relevant eigenmode components. Solid: full seminorm error bound. Dashed: norm error bound. Dotted: CS seminorm error bound.* +: *exact eigenvalues.* x: *found eigenvalues.*

The error bounds can be included in an implementation of the Lanczos method. There they provide a stopping criterion for the iteration that reflects the quality of the overall result instead of measuring intermediate quantities. It might well be that the response is predicted with satisfactory precision although the Ritz vectors would not be regarded as sufficiently accurate. In the case of forced vibrations it is possible that they predict good approximation in a frequency range where some modes have not yet been found by the Lanczos iteration. These missing modes would be those with a very small component in the starting block. In other words, the iteration can be stopped at an early stage, thereby reducing computational cost when contrasted to a conventional stopping criterion such as "calculate all modes in the desired frequency range."

The effect of improving results by including all Ritz vectors in the calculation has already been stated in the literature. The numerical examples given show that the improvement mainly occurs at points where a moderately accurate result has already been achieved. In case Lanczos vectors are combined directly to find the response, ignoring some of the Ritz vectors means no significant time savings but less accurate calculations.

Numerical examples show that if the bounds predict good approximation, the error is overestimated by about two to four orders of magnitude in large-scale engineering applications. The cost for their calculation is $O(bm)$ floating-point operations in the case of norm errors where m is the number of Ritz values found and b is the blocksize. The cost for bounding seminorms of the error is dominated by a small multiple of bm^2 flops. If Rayleigh's damping is applied, all bounds can be evaluated with a small multiple of bm flops.

It is straightforward to apply the results to different matrix functions such as the matrix exponential.

Acknowledgments. The author would like to thank Dr. H. G. Matthies for many valuable discussions and Dr. R. Ansorge and Dr. H. Voß for their advice and support.

GLOBAL OPTIMIZATION DECOMPOSITION METHODS FOR BOUNDED PARAMETER MINIMAX RISK EVALUATION*

ERIC GOURDIN†, BRIGITTE JAUMARD‡, AND BRENDA MACGIBBON§

Abstract. There has been much recent statistical research in the area of inference under constraints. The problem considered here is that of bounded parameter estimation, in particular that of normal and Poisson means, using minimaxity as the criterion of evaluation. Because of the ease of calculation of linear minimax rules, the ratio of these risks to the nonlinear minimax risks for these problems is also studied. To find the minimax solution, the dual problem of finding the least favorable prior distribution is often considered. On bounded parameter spaces the least favorable prior is often discrete, so the finding of the minimax estimator and its risk is equivalent to a global optimization problem with constraints. Previously published numerical specifications of the priors have used iterative (often heuristic) procedures. Two global optimization procedures are proposed. The first is based on multivariate Lipschitz optimization and makes use of bounds on the first-order derivatives. The second is a decomposition procedure that utilizes the partial concavity of the Bayes risk function. Both procedures are compared, and the decomposition method appears to be much more efficient. It is shown that the Ibragimov–Hasminskii constant, the maximum of the ratio of linear to nonlinear minimax risks, is different for the Poisson and normal problems.

AMS subject classifications. 90C26, 62-04, 62F10

1. Introduction.

In the framework of statistical decision theory, many interesting problems can be resolved by finding minimax procedures. These problems include the areas of estimation, hypothesis testing, experimental design, and robust statistics, among others. Recently, the problem of estimating the mean of a standard Gaussian shift experiment, when it is known to be in an infinite-dimensional bounded convex subspace, has been studied by Pinsker [27] in the ellipsoid case, and by Donoho, Liu, and MacGibbon [7] for more general bodies.

More precisely, it is supposed that

$$x_i = \theta_i + \varepsilon_i, \qquad i = 0, 1, 2, \ldots,$$

where the ε_i are independent identically distributed $N(0, \sigma^2)$, σ^2 known and θ_i unknown, but known to lie in an orthosymmetric quadratically convex ℓ_p ($p \geq 2$) body Θ. An estimator $\hat{\theta}^*$ of θ is minimax with respect to quadratic loss if

$$\sup_{\theta \in \Theta} E\left(\sum (\hat{\theta}_i^* - \theta_i)^2\right) = \inf_{\hat{\theta}} \sup_{\theta \in \Theta} E\left(\sum (\hat{\theta}_i - \theta_i)^2\right).$$

The estimator $\hat{\theta}^*$ is linear minimax if it is linear and satisfies the above equation with the infimum over $\hat{\theta}$ referring only to linear procedures. The resulting risk is called the linear minimax risk. The fact that linear procedures are much easier to calculate raises interest in the study of the ratio of linear to nonlinear minimax risk. Donoho, Liu, and MacGibbon [7] showed that this ratio for the orthosymmetric quadratically convex ℓ_p body problem ($p \geq 2$)

could be bounded by the ratio for the hardest one-dimensional subproblem. Thus the problem is reduced to studying the ratio $\mu_N(m)$ of linear minimax risk to nonlinear minimax risk for the estimation of a bounded normal mean; that is, estimating the mean of a normal population $N(\theta, 1)$ given that $|\theta| \leq m$, on the basis of one observation $X = x$. It is well known that the minimax linear risk is m^2/m^2+1, and if $r_N(m)$ denotes the minimax risk among all estimators, then the ratio of interest $\mu_N(m)$ is defined by

$$\mu_N(m) = \frac{m^2}{(1+m^2)r_N(m)}.$$

Let $\mu_N^* = \sup_m \mu_N(m)$. This constant, the worst-case ratio, is referred to as the Ibragimov–Hasminskii constant [17], since they were the first to study the behaviour of $\mu_N(m)$ and to prove that μ_N^* is finite.

Casella and Strawderman [6] were the first to provide analytic and numerical results for the minimax risk $r_N(m)$ for the one-dimensional normal mean problem. To find the minimax solution, the dual problem of finding the least favorable prior distribution for the corresponding Bayes problem is often considered. The duality theory ensures that, if there exist solutions to both problems, then the Bayes procedure with respect to the least favorable prior distribution will be minimax (see Wald [33], Ferguson [11], Berger [3], Kempthorne [20], Brown [5]).

For many of these problems, particularly for constrained inference (see, e.g., Ghosh [13]), the least favorable prior distribution is a discrete measure with finite support. Thus, the finding of a minimax solution becomes a global optimization of a nonlinear, nonconvex function. Kempthorne [20] was the first to describe a convergent iterative procedure for the numerical specification of such priors. Donoho, Liu, and MacGibbon [7] used Brown's identity (see Bickel [4]) involving the Bayes risk and Fisher information to approximate an upper bound for the minimax risk $r_N(m)$ in the bounded normal mean problem, thus reducing the optimization to that of minimizing a convex functional subject to convex constraints. The numerical specification was achieved using the optimization system NPSOL of Gill, Murray, Saunders, and Wright [12]. Within four-digit accuracy, Donoho, Liu, and MacGibbon [7] showed that the Ibragimov–Hasminskii constant was bounded by 1.2497. A more recent numerical study by Feldman and Brown [10] suggests that the constant is approximately 1.2465.

Johnstone and MacGibbon [18] studied the problem of estimating a bounded Poisson parameter under normalized quadratic loss. Using an iterative procedure similar to Kempthorne's algorithm involving local optimization techniques (see Kempthorne [20]), they calculated the minimax risk and obtained an upper bound of 1.251 for the ratio of nonlinear to linear minimax risk for this Poisson problem.

An interesting question now becomes whether or not this ratio is the same for the normal and Poisson problems. Since the specification of the minimax solution is a global optimization problem, it seems essential to develop such techniques with sufficient accuracy to resolve this issue.

We first designed a new Lipschitz algorithm concerned with the following global optimization problem :

$$(P)\begin{cases} \text{maximize} & f(x), \\ \text{subject to :} & g_i(x) \leq 0, \qquad i = 1, 2, \ldots, m, \\ & x \in \mathbb{R}^n, \end{cases}$$

where the functions f and g_i $(i = 1, 2, \ldots, m)$ satisfy a Lipschitz condition, but are not necessarily either concave or linear.

Such problems are very difficult to solve in practice. Most often, they are solved heuristically, using nonlinear optimization algorithms that only yield a local optimum or an unproved global optimum. However, more efficient algorithms can be designed if specific properties are taken into account, e.g., polynomial expressions of the constraints (see, e.g., Duffin, Peterson, and Zener [8], Ecker [9]) or convexity/linearity of the constraints functions (see, e.g., Horst and Tuy [16], Rosen [31]). The multivariate Lipschitz algorithm we propose, although exact and theoretically convergent, did not allow us to reach highly precise results in a reasonable amount of computing time. Therefore, we considered a second algorithm.

The Bayes risk function involved in the minimax estimation problem presents an interesting property of partial concavity (see Kempthorne [20], Johnstone and MacGibbon [18]). To take advantage of this property, we improved our first algorithm, using decomposition techniques.

The second algorithm deals with the following partially concave global optimization problem:

$$(\tilde{P}) \begin{cases} \text{maximize} & f(x, y), \\ \text{subject to :} & g_i(x, y) \leq 0, \qquad i = 1, 2, \ldots, m, \\ & x \in \mathbb{R}^{n_x},\ y \in \mathbb{R}^{n_y}, \end{cases}$$

where the functions f and g_i $(i = 1, 2, \ldots, m)$ satisfy a Lipschitz condition with respect to x, and are continuous and concave with respect to y.

Both algorithms are applied to the evaluation of the minimax risk for a bounded Poisson mean with a suitably normalized quadratic loss function. The second algorithm appears to be much more efficient than the first one.

The paper is organized as follows. The next section is devoted to the two algorithms. First, we introduce the Lipschitz optimization theory (§2.1); then we explain our new multivariate Lipschitz optimization algorithm (§2.2). Finally, we present the decomposition algorithm (§2.3). Section 3 will be devoted to the minimax estimation of bounded Poisson and normal means and the calculation of the Ibragimov–Hasminskii constants for these problems. Computational experiences, including some on the minimax risk evaluation for the bounded normal and Poisson mean problems, are reported in §4. Conclusions are drawn in §5.

2. Global optimization methods.

2.1. Introduction to Lipschitz optimization. Piyavskii's algorithm [28], [29] (see also Shubert [32]) is one of the most classical algorithms of univariate Lipschitz optimization. It addresses the problem of maximizing a continuous univariate function f over an interval [a,b], assuming it satisfies a Lipschitz condition

$$\forall x, y \in [a, b], \quad | f(x) - f(y) | \leq L | x - y |,$$

where L is a constant.

The algorithm generates a sampling sequence of points $x^1, x^2, \ldots, x^k$, where the function f is evaluated, and builds a piecewise linear upper bounding function, also called a sawtooth cover due to its shape, and consists of the lower envelope of functions $F_i(x) = f(x^i) + L | x - x^i |$ for $i = 1, 2, \ldots, k$.

Although it is not a best possible algorithm, it can be modified so that it becomes nearly optimal; see Hansen, Jaumard, and Lu [15].

Piyavskii's algorithm can be generalized (see Piyavskii [29], Mladineo [26]) to handle the problem of maximizing a continuous multivariate function $f(x)$, $x \in \mathbb{R}^n$, over an n-cube $C = \{x \in \mathbb{R}^n \mid a \leq x \leq b\}$, assuming f satisfies a Lipschitz condition

$$\forall x, y \in C \quad | f(x) - f(y) | \leq L \| x - y \|,$$

where L is a constant and $\| \cdot \|$ defines the Euclidean norm. Other algorithms, using different partitioning techniques, have been proposed, see, e.g., Meewela and Mayne [23], [24].

The graph of the upper bounding function generalizing the univariate sawtooth cover to the multidimensional case, is made up of several intersecting cones that approximate the graph of f. In using Piyavskii's sampling rule for computations, one must find the peaks of the approximating surface, which are cone intersections, and, of those, the one that is the highest. This is rather difficult in practice, as it reduces to a system of $n + 1$ equations (n linear and one quadratic).

Indeed, it is easier to build a piecewise constant upper bounding function, where each cone is approximated by its cover. This new algorithm is described in the next section.

2.2. A multivariate Lipschitz optimization algorithm (MLip). The algorithm described in this section is designed for multivariate Lipschitz optimization problems:

$$\begin{cases} \text{maximize} & f(x), \\ \text{subject to:} & x \in C = [a_1, b_1] \times [a_2, b_2] \times \cdots \times [a_n, b_n], \end{cases}$$

where f satisfies a Lipschitz property with a constant L.

2.2.1. Description of the algorithm. The algorithm subdivides the initial n-cube into an increasing number of n-rectangular cells and approximates the objective function by a constant in each cell.

More precisely, suppose that at a given stage of the algorithm, the original n-cube C is already subdivided in k cells $C^1, C^2, \ldots, C^k$, such that

$$C = \bigcup_{i=1}^{k} C^i,$$

$$\forall i \quad C^i = \{x \in \mathbb{R}^n \mid a^i \leq x \leq b^i\}.$$

Also suppose that a constant upper bound F^i of function f has been computed in each cell C^i. We call each pair (F^i, C^i) a subproblem of the original problem, and we denote it by P^i. The algorithm finds the subproblem $P^r = (F^r, C^r)$ of highest upper bound

$$F^r = \max_{i=1,\ldots,k} F^i.$$

This value is also the current best overestimation of f^* (the maximum of f over C):

$$F_{\text{opt}}^{k+1} = F^r.$$

The corresponding cell C^r is sliced along its longest edge in p equal subcells $C^{r_1}, C^{r_2}, \ldots, C^{r_p}$. In practice, $p = 3$ performed better than $p = 2$, odd values were better than even ones, and large values tended to increase the memory requirements. It was decided that the choice of $p = 3$ is a good compromise. The midpoint x^{r_j} of each subcell C^{r_j} is found and $f(x^{r_j})$ is computed. The value of the $f(x^{r_j})$ for $j = 1, 2, \ldots, p$, is used to update f_{opt}, the current best underestimation of f^*:

$$f_{\text{opt}}^{k+1} \longleftarrow \max\Big(\max_{i=1,2,\ldots,k} f_{\text{opt}}^i, f(x^{r_1}), f(x^{r_2}), \ldots, f(x^{r_p}) \Big).$$

The size D^{r_j}, i.e., the length of the diagonal of each subcell, is also computed, and a new constant upper bound is found in each subcell, according to

$$F^{r_j} = f(x^{r_j}) + \frac{1}{2} L D^{r_j}.$$

Note that each F^{r_j}, $j = 1, 2, \ldots, p$, improves strictly on F^r. Subproblem $P^r = (F^r, C^r)$ is then replaced, in the list $\mathcal{L}$ of all subproblems, by the p subproblems

$$P^{r_j} = (F^{r_j}, C^{r_j}), \qquad j = 1, 2, \ldots, p.$$

Before considering a new cell, the algorithm discards from the list $\mathcal{L}$ all subproblems with an upper bound smaller than f_{opt}, as they cannot contain a vector x^* of optimal value $f(x^*) = f^*$. The process is carried out until $F_{\text{opt}} - f_{\text{opt}}$ becomes less than a chosen tolerance ε.

Although the upper bounding function built by this algorithm is less precise than the sawtooth cover considered in the multidimensional Lipschitz algorithm introduced in the previous section, experiments show that this does not affect the efficiency of the method in practice, both in terms of computing time and in terms of function evaluations. In most of the cases, it even leads to better results.

2.2.2. Algorithm MLip. The details of the algorithm are given below.

Notations:
L is a Lipschitz constant for f over C,
$\mathcal{L}$ is the list of active (that is, not yet discarded) subproblems.
At the current iteration, a subproblem $P^k = (F^k; C^k)$ is characterized by:
C^k, the cell $[a_1^k, b_1^k] \times [a_2^k, b_2^k] \times \cdots \times [a_n^k, b_n^k]$,
F^k, an upper bound of f in cell C^k,
$\ell_i^k = b_i^k - a_i^k$, the length of the ith edge of the cell C^k,
$D^k = \sqrt{(\ell_1^k)^2 + (\ell_2^k)^2 + \cdots + (\ell_n^k)^2}$, the size of cell C^k.

Initialization

$C^1 \longleftarrow [a_1, b_1] \times [a_2, b_2] \times \cdots \times [a_n, b_n]$;

$x^1 \longleftarrow \left(a_1 + \frac{1}{2}\ell_1, a_2 + \frac{1}{2}\ell_2, \ldots, a_n + \frac{1}{2}\ell_n\right)$;

$D^1 \longleftarrow \sqrt{\ell_1^2 + \ell_2^2 + \cdots + \ell_n^2}$;

$x_{\text{opt}} \longleftarrow x^1$;

$f_{\text{opt}} \longleftarrow f(x_{\text{opt}})$;

$F^1 \longleftarrow f(x^1) + \frac{1}{2} L D^1$;

$F_{\text{opt}} \longleftarrow F^1$;

$P^1 \longleftarrow (F^1; C^1)$;

$\mathcal{L} \longleftarrow \{P^1\}$;

$p \longleftarrow 3$;

Upper bounding cover

While $F_{\text{opt}} - f_{\text{opt}} > \varepsilon$ **do**

Let P^r be the subproblem of $\mathcal{L}$ with the largest upper bound F^r:

$P^r = (F^r; C^r)$;

$\ell_{i_\circ}^r \longleftarrow \max_{i=1,2,\ldots,n} \ell_i^r$;

$D^r \longleftarrow \left(\sum_{\substack{i=1 \\ i \neq i_\circ}}^{n} \left(\ell_i^r\right)^2 + \left(\frac{\ell_{i_\circ}^r}{p}\right)^2 \right)^{\frac{1}{2}}$;

Remove P^r from $\mathcal{L}$;

For j : 1 through p **do**

$A^{r_j} \longleftarrow \left(a_1^{r_j}, a_2^{r_j}, \ldots, a_{i_\circ-1}^{r_j}, a_{i_\circ}^{r_j} + \frac{j-1}{p}\ell_{i_\circ}^{r_j}, a_{i_\circ+1}^{r_j}, \ldots, a_n^{r_j}\right)$;

$L^{r_j} \longleftarrow \left(\ell_1^{r_j}, \ell_2^{r_j}, \ldots, \ell_{i_\circ-1}^{r_j}, \frac{\ell_{i_\circ}^{r_j}}{p}, \ell_{i_\circ+1}^{r_j}, \ldots, \ell_n^{r_j}\right)$;

$x^{r_j} \longleftarrow A^{r_j} + \frac{1}{2}L^{r_j}$;

$F^{r_j} \longleftarrow f(x^{r_j}) + \frac{1}{2}L D^{r_j}$;

If $f_{\text{opt}} < f(x^{r_j})$ **then**

$f_{\text{opt}} \longleftarrow f(x^{r_j})$;

$x_{\text{opt}} \longleftarrow x^{r_j}$

Endif;

Add the subproblem $P^{r_j} = (F^{r_j}\ ;\ C^{r_j})$ to $\mathcal{L}$

EndFor;

Discard from $\mathcal{L}$ all subproblems with an upper bound smaller than f_{opt}

EndWhile.

The last step, which consists in discarding subproblems from $\mathcal{L}$, is not necessary for the convergence of the algorithm. Its aim is only to improve the practical efficiency of the algorithm. Moreover, a *max-min heap* (see Atkinson et al. [1]) can also be used to improve the efficiency. It corresponds to the merging of a *max-heap* and a *min-heap* containing all the subproblems of $\mathcal{L}$ ranked, respectively, in decreasing order and in increasing order, by their upper bound.

2.2.3. The constrained case. Consider now the constrained optimization problem

$$\begin{cases} \text{maximize} & f(x), \\ \text{subject to :} & g_i(x) \leq 0 \quad i = 1, 2, \ldots, m, \\ & x \in C = [a_1, b_1] \times [a_2, b_2] \times \cdots \times [a_n, b_n], \end{cases}$$

where both the objective f and the constraint functions g_i, $(i = 1, 2, \ldots, m)$ satisfy a Lipschitz property with respective constants L and L_i, $(i = 1, 2, \ldots, m)$.

The algorithm of §2.2.2 can be used to handle constrained optimization with the following modifications and new tests.

Updating the incumbent value. The incumbent value f_{opt} should now be updated whenever a better value of the objective function has been found, but with the restriction that the corresponding point is feasible with respect to the constraints.

Checking redundant constraints. As the constraint functions are Lipschitz, piecewise constant upper bounding functions $\overline{G}_i^{r_j} = g_i(x^{r_j}) + \frac{1}{2}L_i D^{r_j}$ can be built in each cell C^{r_j}. Then the constraints g_i are such that $\overline{G}_i^{r_j} < 0$ are redundant and therefore can be omitted.

Infeasibility. Piecewise constant lower bounding functions $\underline{G}_i^{r_j} = g_i(x^{r_j}) - \frac{1}{2}L_i D^{r_j}$ can also be similarly built in each cell C^{r_j},. Then the subproblem can be discarded whenever it contains a constraint g_i such that $\underline{G}_i^{r_j} > 0$.

2.3. A decomposition-based algorithm (Dec). Consider again the problem

$$(\tilde{P}) \begin{cases} \text{maximize} & f(x, y), \\ \text{subject to :} & g_i(x, y) \leq 0, \qquad i = 1, 2, \ldots, m, \\ & x \in \mathbb{R}^n, \qquad y \in \mathbb{R}^{p-n}, \end{cases}$$

in which the functions are partially concave.

For any given value x^k, we define the restriction of problem $(\tilde{P})$ to variable y,

$$(\tilde{P}(x^k)) \begin{cases} \text{maximize} & f(x^k, y), \\ \text{subject to :} & g_i(x^k, y) \leq 0, \qquad i = 1, 2, \ldots, m, \\ & y \in \mathbb{R}^{p-n}, \end{cases}$$

and we denote by $\tilde{v}(x^k)$ its optimal value.

This last problem can be easily solved.

Apply the constrained Lipschitz optimization algorithm of §2.2.3 with objective function $\tilde{v}$. The evaluation of this new objective function at the successive points x^{r_j} is the result of a constrained concave maximization with respect to variable y. Efficient algorithms can then be applied; see, e.g., Avriel [2], Minoux [25], Wolfe [34]. The algorithm converges to the (global) maximum f^* as the sequence F^k_{opt} converges to f^*.

3. The statistical problem.

3.1. General theory of minimax estimation. Let us consider the classical statistical problem of making an inference about an unknown parameter λ, in particular, the estimation of λ, given an observation of $X \in \mathbf{X}$, where X is a random variable whose distribution depends on the parameter $\lambda \in \Lambda$, the parameter space. A solution consists of a nonrandomized estimator or decision procedure δ, which is a measurable function from the sample space $\mathbf{X} \to \Lambda$. Let $\mathcal{A}$ denote the space of all possible estimates. It will henceforth be assumed that $\mathcal{A}$ is convex. A risk function $R(\delta, \lambda)$ characterizes the performance of a decision procedure δ for each value of the parameter λ. The risk function is usually defined in terms of an underlying loss function $L(\delta, \lambda)$. A loss function maps $\mathcal{A} \times \Lambda \to \mathbb{R}^+ \cup \{0\}$ (where $\mathbb{R}^+$ is the positive real line) and defines the cost of estimating δ when λ is the true value of the parameter. To be able to confine our attention to nonrandomized estimators, it will be assumed that the loss function is convex in δ and that $\mathcal{A}$ and Λ are also convex (see, e.g., Lehmann [22]). The loss function will usually be assumed to equal $(\delta - \lambda)^2$; that is, the quadratic loss function or a normalized version of this function. The risk of an estimator δ when λ is true, $R(\delta, \lambda)$, is then the average loss incurred from using δ; that is,

$$R(\delta, \lambda) = E_\lambda L(\delta(X), \lambda). \tag{1}$$

An estimator δ^* is minimax for the above problem, if

$$\sup_{\lambda \in \Lambda} R(\delta^*, \lambda) \leq \sup_{\lambda \in \Lambda} R(\delta, \lambda) \quad \text{for all } \delta \epsilon D. \tag{2}$$

Minimax problems are often solved by considering the corresponding Bayes problems. A distribution or prior probability measure π is specified on the parameter space Λ, and a measure of the performance of a procedure δ is given by its Bayes risk

$$\tilde{r}_\Lambda(\delta, \pi) = \int_\Lambda R(\delta, \lambda) \pi(d\lambda). \tag{3}$$

δ_π is called the Bayes procedure with respect to the prior probability measure π if δ_π minimizes the Bayes risk. The minimum Bayes risk r of a distribution or prior probability measure π on Λ is defined as

$$r_\Lambda(\pi) = \tilde{r}_\Lambda(\delta_\pi, \pi). \tag{4}$$

Henceforth, $r_\Lambda(\pi)$ will be called the Bayes risk of π. A distribution or prior probability measure π^* is "least favorable" if its Bayes risk is greater than or equal to that of any other distribution; that is,

$$r_\Lambda(\pi^*) \geq r_\Lambda(\pi) \quad \text{for any distribution } \pi \text{ on } \Lambda. \tag{5}$$

Subject to the decision problem satisfying sufficient regularity conditions, a least favorable prior distribution exists and the corresponding Bayes procedure is minimax (see Wald [33], Kempthorne [20], or Brown [5]).

3.2. The bounded Poisson and normal mean problems. One of the problems considered here is that of estimating the mean of a Poisson distribution under the additional assumption that the true mean lies in a bounded interval of the form $[0, m]$ for $m > 0$. The Bayes risk $r_\Lambda(\pi)$ for a probability measure π on $\Lambda = [0, m]$ will be denoted by $r_m(\pi)$.

Let X be a random Poisson variable with mean λ; that is, the probability that $X = x$ denoted by $P(X = x) = e^{-\lambda}(\lambda^x/x!)$ for $x = 0, 1, 2, \ldots$ and $= 0$ otherwise. The normalized quadratic loss function used is defined by

$$L(\delta, \lambda) = \frac{(\delta - \lambda)^2}{\lambda}. \tag{6}$$

For $R(\delta, 0)$ to be finite, it follows that a minimax estimator must satisfy

$$\delta(0) = 0. \tag{7}$$

Henceforth, we shall only consider estimators satisfying (7). The risk of such an estimator can be written as

$$E_\lambda L(\delta(X), \lambda) = \lambda e^{-\lambda} + \sum_{x=1}^{\infty} (\delta(x) - \lambda)^2 \frac{\lambda^{x-1}}{x!} e^{-\lambda}. \tag{8}$$

Now, considering the dual Bayes problem, it follows from Ghosh's results [13] that a least favorable prior on $[0, m] = \Lambda$ will put mass on at most a finite number of points.

More precisely, as shown by Johnstone and MacGibbon [18], the "least favorable" prior $\pi^*(d\lambda)$ is of the form $\sum_{i=1}^{k} a_i \epsilon_{\{b_i m\}}$ $(k < \infty)$, where the Dirac measure

$$\begin{aligned} &\left\{ \begin{array}{ll} \epsilon_{\{b_i m\}}(x) = 1 & \text{if } x = b_i, \\ \epsilon_{\{b_i m\}}(x) = 0 & \text{otherwise,} \end{array} \right\} \quad \text{for } 0 \leq b_1 < \cdots < b_k = 1, \\ &\sum_{i=1}^{k} a_i = 1 \quad \text{with } a_i \geq 0 \quad \text{for all } k. \end{aligned} \tag{9}$$

The Bayes risk of π^* is defined as

$$r_P(m) = r_m(\pi^*) = \sum_{i=1}^{k} a_i R(\delta_{\pi^*}, b_i m). \tag{10}$$

Thus the statistical problem is reduced to the following global optimization problem.

Maximize $r_m(\pi^*)$ where π^* consists of a sequence of points $b_i m$ with weights a_i. Since the global unconstrained minimax risk on $[0, +\infty[$ is one (see Lehmann [22]), then $r_m(\pi^*) \leq 1$ for each m.

The general mathematical problem can be expressed as follows:

$$\text{Maximize } \theta(a, b) = \sum_{i=1}^{k} a_i g_i(a, b)$$

subject to:

$$\begin{aligned} &\sum_{i=1}^{k} a_i = 1, \\ &0 \leq a_i \leq 1, \qquad i = 1, 2, \ldots, k, \\ &0 \leq \theta \leq 1, \\ &0 \leq b_i \leq 1, \qquad i = 1, 2, \ldots, k, \end{aligned}$$

where

$$g_i(a, b) = b_i m e^{-b_i m} + \sum_{x=1}^{\infty} (b_i m - \delta_\pi(x))^2 \frac{(b_i m)^{x-1}}{x!} e^{-b_i m}$$

for $i = 1, 2, \ldots, k$;

$$\delta_\pi(x) = \frac{\sum_{i=1}^{k} a_i (b_i m)^x e^{-b_i m}}{\sum_{i=1}^{k} a_i (b_i m)^{x-1} e^{-b_i m}}, \qquad x \neq 0,$$

and $\delta_\pi(0) = 0$, $a = (a_1, a_2, \ldots, a_k)$, $b = (b_1, b_2, \ldots, b_k)$.

As shown in Johnstone and MacGibbon [18], the ratio of nonlinear to linear risk for this problem is

$$\mu_P(m) = \frac{m}{(1+m) r_P(m)}, \tag{11}$$

where $r_P(m)$ is the optimum value of $r_m(\pi^*)$ in the above optimization problem for fixed m and the Ibragimov–Hasminskii constant is

$$\mu_P^* = \sup_m \mu_P(m). \tag{12}$$

Since the optimization problem is nonconvex and nonlinear, global optimization techniques must be used to solve it exactly. However, due mainly to the difficulty of estimating the Lipschitz constants and the massive numerical calculations involved for this problem, global Lipschitz optimization algorithms seem to be practical only for a small number of variables. So as a first step, we will restrict ourselves to the solution of the problem when $k = 3$.

Johnstone and MacGibbon [18] gave upper bounds on $r_P(m)$; in particular, $r_P(m) \leq 1.249$ for all $m \geq 2.7$. The arguments they used to show that the two point prior is least favorable on $[0, m]$ for all $m \in (m_0, m_1]$ with $m_0 \simeq .57$ and $m_1 \simeq 1.27$ can be extended to show that on $[0, m]$ for all $m \in (m_1, m_2]$ with $m_2 \simeq 2.7$, the least favorable prior is supported on three points. On the interval $[0, m]$ with $m \in [0, 2.7]$, the minimax risk $r_P(m)$ will be calculated solving the following maximization problem.

For fixed m, find a_2, a_3, and b satisfying $0 \le a_2 \le 1$, $0 \le a_3 \le 1$, $0 \le a_2 + a_3 \le 1$, and $0 \le b \le 1$, such that $\pi^* = (1 - a_2 - a_3)\epsilon_{\{0\}} + a_2\epsilon_{\{bm\}} + a_3\epsilon_{\{m\}}$ is least favorable; that is, $r_m(\pi^*)$ is a global maximum over all prior probability measures π on $[0, m]$. (We can restrict our attention to measures of the form (9).) The problem can be expressed as follows.

Maximize $\theta(a_2, a_3, b) = (1 - a_2 - a_3)g_1(a_2, a_3, b) + a_2 g_2(a_2, a_3, b) + a_3 g_3(a_2, a_3, b)$, where

$$g_1(a_2, a_3 b) = \delta(1)^2 \quad \text{if } 1 - a_2 - a_3 > 0,$$
$$= 0 \quad \text{if not,}$$

$$g_2(a_2, a_3, b) = bm2^{-bm} + \sum_{x=1}^{\infty} \big(bm - \delta(x)\big)^2 \frac{(bm)^{x-1}}{x!} e^{-bm},$$

(13)
$$g_3(a_2, a_3, b) = me^{-m} + \sum_{x=1}^{\infty} \big(m - \delta(x)\big)^2 \frac{m^{x-1}}{x!} e^{-m},$$

$$\delta(x) = m \frac{a_2 b^x e^{-bm} + a_3 e^{-m}}{a_2 b^{x-1} e^{-bm} + a_3 e^{-m}} \quad \text{if } x \neq 0, 1,$$

$$\delta(1) = m \frac{a_2 be^{-bm} + a_3 e^{-m}}{a_2 e^{-bm} + a_3 e^{-m} + 1 - a_2 - a_3},$$

$$\delta(0) = 0,$$

subject to

$$0 \le a_2 \le 1,$$
$$0 \le a_3 \le 1,$$
$$0 \le b \le 1,$$
$$a_2 + a_3 \le 1.$$

This problem was solved using both the multivariate Lipschitz optimization algorithm (MLip) and the global optimization decomposition method (Dec) described in §2. This latter possibility arises from the fact that the objective function is concave with respect to the variables a_1, a_2, and a_3. This can be deduced from the strict concavity of r_m as a function of π (see Johnstone and MacGibbon [18]); that is

$$r_m(\alpha\pi + (1 - \alpha)\pi') > \alpha r_m(\pi) + (1 - \alpha) r_m(\pi') \quad \text{for all } \pi, \pi' \quad \text{and } 0 \le \alpha \le 1.$$

An analogous theory also holds for the normal bounded mean estimation problem on the interval $[-m, m]$ under quadratic loss, where the least favorable prior distribution π is now of the form

$$\sum_{i=1}^{k} a_i \varepsilon_{\{b_i m\}} + \sum_{i=1}^{k} a_i \varepsilon_{\{-b_i m\}} + \left(1 - 2\sum_{i=1}^{k} a_i\right) \varepsilon_{\{0\}},$$

where

(14)
$$0 \le b_i \le 1, \quad i = 1, 2, \ldots, k-1, \quad b_k = 1,$$
$$0 \le a_i \le 1, \quad i = 1, 2, \ldots, k,$$

and

$$0 \leq 1 - 2\sum_{i=1}^{k} a_i \leq 1.$$

The problem is to maximize the Bayes risk of π on $[-m, m]$ denoted by

$$\begin{aligned} r_m(\pi) &= \sum_{i=1}^{k} a_i R(\delta_\pi, b_i m) + \sum_{i=1}^{k} a_i R(\delta_\pi, -b_i m) + \left(1 - 2\sum_{i=1}^{k} a_i\right) R(\delta_\pi, 0) \\ &= 2\sum_{i=1}^{k} a_i R(\delta_\pi, b_i m) + \left(1 - 2\sum_{i=1}^{k} a_i\right) R(\delta_\pi, 0), \end{aligned}$$

where

$$R(\delta_\pi, \theta) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} \big(\delta_\pi(x) - \theta\big)^2 e^{-1/2(x-\theta)^2}\, dx$$

and

$$\delta_\pi(x) = \frac{\displaystyle\sum_{i=1}^{k} a_i (b_i m) e^{-\frac{1}{2}(x-b_i m)^2} + \sum_{i=1}^{k} a_i (-b_i m) e^{-\frac{1}{2}(x+b_i m)^2}}{\left(1 - 2\displaystyle\sum_{i=1}^{k} a_i\right) e^{-\frac{1}{2}x^2} + \displaystyle\sum_{i=1}^{k} a_i e^{-\frac{1}{2}(x-b_i m)^2} + \sum_{i=1}^{k} a_i e^{-\frac{1}{2}(x+b_i m)^2}}. \tag{15}$$

If we let $r_N(m) = \max_\pi r_m(\pi)$ denote the nonlinear minimax risk, then both $r_N(m)$ and the ratio of linear to nonlinear risk, $\mu_N(m)$, as defined in the Introduction will be calculated. For this problem we shall take advantage of the calculations of Donoho, Liu, and MacGibbon [7]; i.e., that for $m \geq 2$, $\mu_N(m) \leq 1.242$ with four-digit accuracy and the fact that for $m \leq 2$ a three-point prior suffices (see Casella and Strawderman [6]). Thus our problem is reduced to the maximization problem for $k = 1$ on this interval. For this univariate problem, the fact that $r_m(\pi)$ is a concave function of a_1 follows from the concavity of r_m as a function of π (see Bickel [4]); thus Fibonacci's method can be used to solve it.

4. Numerical results. We now present the numerical results obtained when applying both algorithms (MLip) and (Dec) of §2 to minimax risk evaluation for a bounded Poisson mean. The algorithms were implemented in Fortran77 and run on a Sun Sparc 4/330-32 (16 mips). The results are first interpreted in terms of computational efficiency leading to a comparison of the two algorithms. Answers are then provided in terms of the evaluation of the minimax risk for a bounded Poisson mean.

4.1. Comparison between the two algorithms. The evaluation of the performance of both algorithms are based on the following parameters:

- iter for the number of function evaluations,
- cpu for the computation time in seconds,
- memo for the virtual memory size in Kbytes, and
- ε for the tolerance required on the value of the objective function.

The performances of both algorithms, in terms of computing time (cpu) and number of function evaluations (iter), for a tolerance of $\varepsilon = 10^{-2}$, are compared in Table 1.

As foreseen, the number of evaluations iter and the cpu processing time are closely related, which seems to indicate that iter is an accurate indicator of the algorithm performance. A single evaluation costs less in algorithm (MLip) ($\simeq$ 1/30 s) than in algorithm (Dec) ($\simeq$ 1/10 s), which

is easily explained by the relative complexity of algorithm (Dec), but the convergence (iter) is faster in the case of algorithm (Dec). It follows that algorithm (Dec) finds the solution faster. Indeed the speedup (i.e., the ratio of the cpu needed by algorithm (MLip) to the cpu needed by algorithm (Dec) to obtain results with the same tolerance ε) varies from 650 for $m = 1.0$ to 50 for $m = 3.0$ with an average value of 200.

The second improvement due to the decomposition method used in algorithm (Dec), is the small amount of memory it needs, whatever tolerance is asked, (memo $\simeq$ 200 Kbytes); whereas in algorithm (MLip), the amount of memory increases drastically with the tolerance (memo $\simeq$ 400 Kbytes for $\varepsilon = 10^{-1}$, memo $\simeq$ 7000 Kbytes for $\varepsilon = 10^{-2}$).

4.2. Results of the minimax risk evaluation. The algorithm was run for several values of the parameter m. The variables a_2, a_3, b are bounded by $[\varepsilon, 1]$ where $\varepsilon = 10^{-2}$. When one of those variables is near to ε, we assume it is zero. This occurs for a_2 from $m = 1$ to $m = 1.27$, where it was already known theoretically that the two-point prior is sufficient (see Johnstone and MacGibbon [18]). It is confirmed by the algorithm that yields very small values of a_2. Hence the variable b is not really significant until $m \simeq 1.3$ or more, where the three-point prior clearly appears as a_2 starts to increase away from zero. At this stage of the study, we cannot be sure of the largest value of m for which the three-point prior suffices. Other computational methods suggest that this value is near 4.5 (see, e.g., Johnstone and MacGibbon [18]).

The infinite sum for the risk in (8) was limited to ten terms. This gave a bound of 10^{-9} on the remaining terms for the range of parameters considered. (See Appendix 1.) The method of calculating the Lipschitz constants is also given there.

The numerical results yielding a precision of $\varepsilon = 10^{-4}$ for the bounded Poisson mean problem using the decomposition method are presented in Table 2.

The numerical results in Table 2, combined with $\mu_P(m) \leq 1.249$ for $m \geq 2.7$, indicate a largest value $\mu_P(2.05) = 1.250826$. From (13) we deduce

$$\frac{d\mu_P(m)}{dr_P(m)} = \frac{-m}{(1+m)r_P^2(m)} \leq 0.$$

This implies a precision on μ_P,

$$\Delta\mu_P \simeq \frac{m}{(1+m)r_P^2(m)}\Delta r_P,$$

where $\Delta r_P = \varepsilon = 10^{-4}$ is the precision for r_P. For $m = 2.05$, this yields a value of $\Delta\mu_P \simeq 0.510^{-4}$. Finally, as μ_P is a decreasing function of r_P, our evaluation of the Ibragimov–Hasminskii constant μ_P^* for the Poisson problem on $[0, m]$, is

$$\underbrace{\mu_P(2.05) - \Delta\mu_P}_{=1.250776} \leq \mu_P^* \leq \underbrace{\mu_P(2.05)}_{=1.250826}. \tag{16}$$

The optimization problem for the bounded normal mean on $[-m, m]$ is one of concave maximization and hence the Fibonacci method was used.

The error analysis was carried out as follows. (See Appendix 2 for details.)

Setting $k = 1$ in (16) and (17) and letting $\alpha = 1 - 2a_1$, our aim is to maximize

$$r(\alpha) = (1-\alpha)R(\delta_\alpha(x), m) + \alpha R(\delta_\alpha(x), 0),$$

where

$$\delta_\alpha(x) = \frac{(1-\alpha)m\tanh(mx)}{(1-\alpha)+\alpha e^{\frac{m^2}{2}}\cosh(mx)},$$

$$R(\delta_\alpha(x), m) = \frac{1-\alpha}{\sqrt{2\pi}}\int_{-\infty}^{\infty} f(x)dx = I_\alpha,$$

$$R(\delta_\alpha(x), 0) = \frac{1-\alpha}{\sqrt{2\pi}}\int_{-\infty}^{\infty} g(x)dx = J_\alpha,$$

with

$$f(x) = [\delta_\alpha(x) - m]^2 e^{-\frac{1}{2}(x-m)^2} \text{ and } g(x) = [\delta_\alpha(x)]^2 e^{-\frac{1}{2}x^2}.$$

The errors due to the approximation of I_α by $\tilde{I}_\alpha = (1-\alpha/\sqrt{2\pi})\int_{-M}^{M} f(x)dx$ and J_α by $\tilde{J}_\alpha = (1-\alpha/\sqrt{2\pi})\int_{-M}^{M} g(x)dx$ can be bounded by

$$9m^2(1-\alpha)e^{-\frac{(M-m)^2}{4}} + \alpha m^2 e^{-M^2/4}. \tag{17}$$

Integrating $\tilde{I}_\alpha$ and $\tilde{J}_\alpha$ by the trapezoid rule with n subdivisions, the errors can be expressed as

$$\frac{M^3}{3n^2}\sup_{|x|\le M}|f''(x)|\frac{(1-\alpha)}{\sqrt{2\pi}} + \frac{M^3}{3n^2}\sup_{|x|\le M}|g''(x)|\frac{\alpha}{\sqrt{2\pi}}. \tag{18}$$

With $M = 10$, the first error given by (17) $\simeq 2 \times 10^{-10}$. With $n = 100,000$, the second error given by (18) yielded a maximum value of 2×10^{-4} for the values of m of interest. The error arising from the use of the Fibonacci method is of order 10^{-10}.

Table 3, combined with the upper bound of $\mu_N(m) \le 1.242$ for $m \ge 2$ obtained by Donoho, Liu, and MacGibbon [7], shows a highest value $\mu_N(1.6) = 1.246609$. A reasoning similar to that for μ_P^* yields an Ibragimov–Hasminskii constant bounded by

$$\underbrace{\mu_N(1.6) - \Delta\mu_N}_{=1.246509} \le \mu_N^* \le \underbrace{\mu_N(1.6)}_{=1.246609}. \tag{19}$$

This agrees with the previous upper bound of Donoho, Liu, and MacGibbon [7] for μ_N^* of 1.2497 and the approximation of Feldman and Brown [10] of 1.2465.

Clearly, (16) and (19) lead us to conclude that the Ibragimov–Hasminskii constants for the normal and the Poisson problems are different.

5. Conclusion. The experimental results of the previous section show that minimax risk evaluation problems on bounded parameter spaces of small size can be solved optimally using multivariate global optimization techniques, and that this, combined with upper bounds for larger values of m, suffices for the calculation of Ibragimov–Hasminskii constants. However, one should seek heuristics to solve problems for larger values of m.

The success of the decomposition method in improving the efficiency of global optimization algorithms leads us to believe that this technique could be applied to many other optimization problems in statistics. In particular, it could be extremely useful in maximum likelihood estimation in multiparameter families where the problem could be decomposed into two parts: for some parameters, standard convex optimization methods would suffice, while for others, a global optimization method would be necessary.

In the particular problem of bounded parameter minimax risk evaluation, we have been able to conclude here that the Ibragimov–Hasminskii constants are different for the normal problem under quadratic loss and the Poisson problem under normalized quadratic loss. This exact minimax result should be contrasted with the asymptotic minimax result obtained by Johnstone and MacGibbon [19], where by means of the polydisc transform, an equivalence was obtained between the problems of Poisson estimation on bounded $2p$-dimensional domains under information normalized quadratic loss and $2p$-dimensional normal estimation under quadratic loss. More work is indicated both in the calculation of Ibragimov–Hasminskii constants for different bounded parameter estimation problems and in asymptotic minimax theory to truly understand the relationship between these problems.

Appendix 1. Specification of the Lipschitz constant for the Poisson estimation problem. After some calculations, the objective function θ used in problem (15) can be reformulated as follows:

$$\theta(a_2, a_3, b) = (a_2 b e^{-bm} + a_3 e^{-m}) m(1 - \delta(1)) + m^2(a_2 b^2 e^{-bm} + a_3 e^{-m}) + \sum_{x=2}^{\infty} \underbrace{\frac{a_2 a_3 (1-b)^2}{a_3 + a_2 b^{x-1} e^{(1-b)m}} \frac{b^{x-1} m^{x+1}}{x!} e^{-bm}}_{\Phi(a_2, a_3, b)}.$$

Considering a rectangular domain of $\mathbb{R}^3$ defined as $[\underline{a}_2, \overline{a}_2] \times [\underline{a}_3, \overline{a}_3] \times [\underline{b}, \overline{b}]$, a Lipschitz constant L for the function θ can easily be deduced from the variations of θ. Some analytical computations provide the following bounds on the partial derivatives of θ:

$$\left|\frac{\partial \theta}{\partial a_2}\right| \leq m^2 \overline{b}^2 e^{-\overline{b}m} + m^2 \frac{(\overline{a}_2 \tilde{b} e^{-\tilde{b}m} + \overline{a}_3 e^{-m})}{(\tilde{a_1} + \overline{a}_2 e^{-\underline{b}m} + \overline{a}_3 e^{-m})^2} M_1 + \sum_{x=2}^{\infty} \frac{\partial \Phi}{\partial a_2}(\underline{a}_2, \overline{a}_3, \tilde{b}),$$

$$\left|\frac{\partial \theta}{\partial a_3}\right| \leq m^2 e^{-m} + m^2 \frac{(\overline{a}_2 \tilde{b} e^{-\tilde{b}m} + \overline{a}_3 e^{-m})}{(\tilde{a_1} + \overline{a}_2 e^{-\underline{b}m} + \overline{a}_3 e^{-m})^2} M_2 + \sum_{x=2}^{\infty} \frac{\partial \Phi}{\partial a_2}(\overline{a}_2, \underline{a}_3, \tilde{b}),$$

$$\left|\frac{\partial \theta}{\partial b}\right| \leq m \overline{a}_2 e^{-\underline{b}m} sup\{(1 - bm + 2bm^2 - b^2 m^3)\} + m^2 \frac{(\overline{a}_2 \tilde{b} e^{-\tilde{b}m} + \overline{a}_3 e^{-m})}{(\tilde{a_1} + \overline{a}_2 e^{-\underline{b}m} + \overline{a}_3 e^{-m})^2} M_3 + \sum_{x=2}^{\infty} \frac{\overline{a}_2 \overline{a}_3 \overline{b}^{x-2} (1 - \underline{b}) m^{x+1} e^{-\underline{b}m}}{(\underline{a}_3 + \underline{a}_2 \tilde{b}^{x-1} e^{(1-\tilde{b})m}) x!} M_4,$$

where

$$\begin{aligned}
\tilde{b} &= \min\{\underline{b}, \overline{b}, 1/m\},\\
\tilde{a_1} &= \min\{0, 1 - \overline{a}_2 - \overline{a}_3\},\\
M_1 &= \max\{\overline{a}_3 e^{-m}(1 - e^{-\overline{b}m}) + 2\tilde{b} e^{-\tilde{b}m}, \overline{a}_2 b e^{-\tilde{b}m}(1 - e^{-\overline{b}m})\\
&\qquad + 2\overline{a}_3 \tilde{b} e^{-\tilde{b}m}(1 - e^{-m}) - \underline{a}_3 e^{-m}(1 - e^{-\underline{b}m})\},\\
M_2 &= \max\{\overline{a}_2 \tilde{b} e^{-\tilde{b}m}(1 - e^{-m}) + 2e^{-m} - 2\underline{a}_2 e^{-m}(1 - e^{-\underline{b}m}) - \underline{a}_3 e^{-m}(1 - e^{-m}),\\
&\qquad 2\overline{a}_2 e^{-m}(1 - e^{-\overline{b}m}) + \overline{a}_3 e^{-m}(1 - e^{-m}) - 2e^{-m}\}\\
M_3 &= \max\{2(1 - \underline{a}_2 - \underline{a}_3 + \underline{a}_2 e^{-\underline{b}m} + \underline{a}_3 e^{-m}) + m(\overline{a}_2 \tilde{b} e^{-\tilde{b}m} + \overline{a}_3 e^{-m})\\
&\qquad - m\underline{b}(\tilde{a_1} + \overline{a}_2 e^{-\underline{b}m} + \overline{a}_3 e^{-m}), m\overline{b}(1 - \underline{a}_2 - \underline{a}_3 + \underline{a}_2 e^{-\underline{b}m} + \underline{a}_3 e^{-m})\\
&\qquad - 2(\tilde{a_1} + \overline{a}_2 e^{-\underline{b}m} + \overline{a}_3 e^{-m}) - m\underline{a}_3 e^{-m}\},\\
M_4 &\max\{\overline{a}_3(x+1)(1 - \underline{b}) - \underline{a}_3(m(1 - \overline{b})\underline{b} + \underline{b} + 1) - 2\underline{a}_2 \underline{b}^{x+1} e^{(1-\overline{b})m},\\
&\qquad \overline{a}_3(m(1 - \underline{b})\overline{b} + \overline{b} + 1) + 2\overline{a}_2 \overline{b}^{x+1} e^{(1-\underline{b})m} - \underline{a}_3(x+1)(1 - \overline{b})\}
\end{aligned}$$

Appendix 2. Normal bounded mean estimation. Considering the case $k = 1$, using (14) (i.e., $b_1 = 1$) and letting $\alpha = 1 - 2a_1$, the Bayes risk can be rewritten in the following way:

$$r_m(\pi) = \overbrace{\frac{(1-\alpha)}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} f(x)\, dx}^{I_\alpha} + \overbrace{\frac{\alpha}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} g(x)\, dx}^{J_\alpha},$$

where

$$f(x) = \left[\delta_\alpha(x) - m\right]^2 e^{-\frac{1}{2}(x-m)^2}, \text{ and let } g(x) = \left[\delta_\alpha(x)\right]^2 e^{-\frac{1}{2}x^2}.$$

Since π now depends only on α, we will henceforth denote the Bayes risk by $r(\alpha)$.

Step 1. *First approximation.* Approximate I_α by

$$\tilde{I}_\alpha = \frac{(1-\alpha)}{\sqrt{2\pi}} \int_{-M}^{M} f(x)\,dx$$

and J_α by

$$\tilde{J}_\alpha = \frac{\alpha}{\sqrt{2\pi}} \int_{-M}^{M} g(x)\,dx.$$

Let $\tilde{M}_I = |I_\alpha - \tilde{I}_\alpha|$ and $\tilde{M}_J = |J_\alpha - \tilde{J}_\alpha|$ be the errors due to this approximation.

We obtain the following bounds on these errors:

$$\tilde{M}_I \le 9(1-\alpha)m^2 e^{-\frac{(M-m)^2}{4}},$$
$$\tilde{M}_J \le \alpha m^2 e^{-\frac{M^2}{4}}.$$

Step 2. *Second approximation.* Approximate now $\tilde{I}_\alpha$ and $\tilde{J}_\alpha$, respectively, by $\hat{I}_\alpha$ and $\hat{J}_\alpha$, where

$$\hat{I}_\alpha = \frac{(1-\alpha)}{\sqrt{2\pi}} \frac{M}{n} \left[f(M) + f(-M) + 2\sum_{i=1}^{n-1} f\left(-M + \frac{2M}{n} i\right)\right],$$
$$\hat{J}_\alpha = \frac{(1-\alpha)}{\sqrt{2\pi}} \frac{M}{n} \left[g(M) + g(-M) + 2\sum_{i=1}^{n-1} g\left(-M + \frac{2M}{n} i\right)\right].$$

Let

$$\hat{M}_I = |\tilde{I}_\alpha - \hat{I}_\alpha| = \frac{M^3}{3n^2} \sup_{-M\le x\le M} |f''(x)| \times \frac{(1-\alpha)}{\sqrt{2\pi}},$$
$$\hat{M}_J = |\tilde{J}_\alpha - \hat{J}_\alpha| = \frac{M^3}{3n^2} \sup_{-M\le x\le M} |g''(x)| \times \frac{\alpha}{\sqrt{2\pi}},$$

be the errors due to this approximation. We then have

$$\sup_{-M\le x\le M} |f''(x)| \le \frac{m}{(A+B)^2} \left[\left[\max\left\{2Am, 2Am\frac{A+B\cosh(mM)}{A\cosh(mM)+B}\right\} + (M+m)(A+B)\right]^2 + 2m^2 A\sinh(mM)|B-A| + Am \max\left\{2Am, 2Am\frac{A+B\cosh(mM)}{A\cosh(mM)+B}\right\} + A + B\right],$$

$$\sup_{-M\le x\le M} |g''(x)| \le \frac{Am}{(A+B)^2} \left[\left[\max\left\{2m, 2m\frac{A+B\cosh(mM)}{A\cosh(mM)+B}\right\} + M\sinh^2(mM)\right]^2 + 2m^2\sinh(mM)\frac{|B-A|}{(A+B)} + m\cosh(mM)\max\left\{2m, 2m\frac{A+B\cosh(mM)}{A\cosh(mM)+B}\right\} + \sinh^2(mM)\right],$$

where $A = 1 - \alpha$ and $B = \alpha e^{m^2/2}$.

Step 3. Maximizing $\hat{r}_\alpha = \hat{I}_\alpha + \hat{J}_\alpha$ by the Fibonacci method and letting $r_N(m)$ denote the errorless optimum, that is, the errorless minimax risk at m, we have an approximation of the optimum with an error ε, i.e.,

$$|\max_{0\le\alpha\le1}(\hat{r}_\alpha) - r_N(m)| < \varepsilon.$$

Let

$$r_{\max} = \max_{0\le\alpha\le1}(\hat{r}_\alpha).$$

Step 4. The cumulative error can be bounded as follows; we have

$$|I_\alpha - \hat{I}_\alpha| = |I_\alpha - \tilde{I}_\alpha + \tilde{I}_\alpha - \hat{I}_\alpha| \le |I_\alpha - \tilde{I}_\alpha| + |\tilde{I}_\alpha - \hat{I}_\alpha| \le \tilde{M}_I + \hat{M}_I,$$
$$|J_\alpha - \hat{J}_\alpha| \le \tilde{M}_J + \hat{M}_J.$$

Since $r(\alpha) = I_\alpha + J_\alpha$, then $|r(\alpha) - \hat{r}(\alpha)| \le \tilde{M}_I + \tilde{M}_J + \hat{M}_I + \hat{M}_J$, where $\tilde{M}_I$, $\tilde{M}_J$, $\hat{M}_I$, and $\hat{M}_J$ are functions of α and the relation holds true for all α, particularly for the $\alpha_{\max}$ obtained by the Fibonacci method (with an ε_α error, i.e., $|\alpha_{\max} - \alpha^*| \le \varepsilon_\alpha$). Hence $|r(\alpha_{\max}) - r_{\max}| \le \tilde{M}_I(\alpha_{\max}) + \tilde{M}_J(\alpha_{\max}) + \hat{M}_I(\alpha_{\max}) + \hat{M}_J(\alpha_{\max})$, which implies that $|r(\alpha_{\max}) - r_{\max}| \le \tilde{M}_I(\alpha_{\max}) + \tilde{M}_J(\alpha_{\max}) + \hat{M}_I(\alpha_{\max}) + \hat{M}_J(\alpha_{\max}) + \varepsilon$.

Note. Details of the computations outlined in the Appendices can be found in E. Gourdin, B. Jaumard, and B. MacGibbon, *Global optimization decomposition methods for bounded parameter minimax risk evaluation*, Cahiers du GERAD G90-48 (ISSN 0711-2440), Montréal, 1990 (revised version 1992).

Acknowledgments. The authors would like to express their thanks to the referees for their useful comments and suggestions.

SMALL-SAMPLE STATISTICAL CONDITION ESTIMATES FOR GENERAL MATRIX FUNCTIONS*

C. S. KENNEY† AND A. J. LAUB†

Abstract. A new condition estimation procedure for general matrix functions is presented that accurately gauges sensitivity by measuring the effect of random perturbations at the point of evaluation. In this procedure the number of extra function evaluations used to evaluate the condition estimate determines the order of the estimate. That is, the probability that the estimate is off by a given factor is inversely proportional to the factor raised to the order of the method. The "transpose-free" nature of this new method allows it to be applied to a broad range of problems in which the function maps between spaces of different dimensions. This is in sharp contrast to the more common power method condition estimation procedure that is limited, in the usual case where the Fréchet derivative is known only implicitly, to maps between spaces of equal dimension. A group of examples illustrates the flexibility of the new estimation procedure in handling a variety of problems and types of sensitivity estimates, such as mixed and componentwise condition estimates.

1. Introduction.

If a scalar real-valued function f has a large derivative at $x \in \mathbb{R}$, then the relationship

$$f(x+\delta) = f(x) + f'(x)\delta + O(\delta^2)$$

shows that small perturbations in x can lead to relatively large changes in f. The idea that the magnitude of the derivative provides a measure of the sensitivity or conditioning of f carries over to higher-dimensional maps [5], [23], [30], [31], [34], [35], [40], [45]. For example, if f maps $\mathbb{R}^n$ into $\mathbb{R}$, the gradient of f at $x \in \mathbb{R}^n$ is the row vector $\nabla f(x) = (\partial f(x)/\partial x_1, \ldots, \partial f(x)/\partial x_n)$, and the Taylor expansion of f has the form

$$f(x+\delta z) = f(x) + \delta \nabla f(x) z + O(\delta^2), \tag{1}$$

where $\|z\| = 1$ with $\|\cdot\|$ denoting the vector 2-norm defined by $\|z\|^2 = \Sigma |z_i|^2$. For notational convenience in the sequel, we use v^T to denote the gradient

$$v^T \equiv \nabla f(x). \tag{2}$$

It can be seen from (1) that the norm of the gradient ($\|\nabla f(x)\| = \|v\|$) is an appropriate measure of the local sensitivity of f. Nonlocal sensitivity in the sense of a Lipschitz-type condition measure is much harder to deal with. Demmel [8] has shown that for some problems, local condition information gives upper and lower bounds on nonlocal sensitivity. However, the depth of this subject is beyond the scope of this paper, and we are concerned only with the issue of estimating local sensitivity. For simplicity of exposition, we also assume throughout this paper that all functions considered are at least twice continuously differentiable.

Somewhat surprisingly, rigorous probability arguments show that only a few function evaluations are needed to obtain estimates of the norm of v that are accurate and reliable in a sense described below. These results are then applied to the problem of condition estimation for more general matrix functions such as the matrix exponential map $X \mapsto e^X$ and the map $(A, F, G) \mapsto X$, where X satisfies an algebraic Riccati equation

$$0 = G + A^T X + XA - XFX. \tag{3}$$

This is illustrated in §4 with many other examples. This section also compares the small-sample statistical method with the more traditional power method of condition estimation. Sections 2 and 3 develop the theoretical basis for the small-sample methods.

The central idea of this method is that the norm of the gradient can be estimated if we can afford another function evaluation beyond $f(x)$, say, at $x + \delta z$. If z has unit norm, then the Newton difference defined by

$$dz \equiv \frac{f(x + \delta z) - f(x)}{\delta} \tag{4}$$

satisfies

$$dz = v^T z + O(\delta). \tag{5}$$

If z is selected uniformly and randomly from the unit sphere S_{n-1} in n dimensions, then (see Theorem 2.1) the expected value of $|v^T z|$ is given by

$$E(|v^T z|) = \|v\| E_n, \tag{6}$$

where $E_1 = 1$, and for $n > 1$

$$E_n = \frac{1 \cdot 3 \cdot 5 \cdots (n-2)}{2 \cdot 4 \cdot 6 \cdots (n-1)} \quad \text{for } n \text{ odd}, \tag{7}$$

$$E_n = \frac{2}{\pi} \frac{2 \cdot 4 \cdot 6 \cdots (n-2)}{1 \cdot 3 \cdot 5 \cdots (n-1)} \quad \text{for } n \text{ even}. \tag{8}$$

We will use the standard symbol !! to indicate the "skip" factorial [1], [18], so that $7!! = 1 \cdot 3 \cdot 5 \cdot 7$ and $6!! = 2 \cdot 4 \cdot 6$ with $0!! = 1$. Thus $E_n = (n-2)!!/(n-1)!!$ when n is odd, etc. Since the expected value function E_n plays such a central role in statistical condition estimation, a short discussion of its evaluation for large values of n is given in the Appendix.

By (5)–(6), the condition estimator $|dz|/E_n$ has expected value equal to the true condition number $\|v\|$ plus a term of order δ. Typically, we can take δ sufficiently small (say, less than 10^{-12}), so that for the purposes of estimating $\|v\|$ the expected value of $|dz|/E_n$ is more than adequate. To avoid having to add terms of order δ to all of our results, we will now make the simplifying assumption that for any given vector $z \in S_{n-1}$ we are able to evaluate $v^T z$ with the understanding that in real life we are merely able to evaluate dz as in (4). This is reasonable when we remember that for most sensitivity estimates, we only need to know the true condition number to within a factor of 10 or so, and we can often tolerate errors in the estimate up to a factor of 100.

The important question then becomes, what is the probability that the estimator

$$\zeta \equiv |v^T z|/E_n$$

lies within a given factor w of $\|v\|$? In §2 we derive an exact formula (see Theorem 2.3) for this probability, and we show that for $w > 1$

$$\Pr\left(\frac{\|v\|}{w} \le \zeta \le w\|v\|\right) \ge 1 - \frac{2}{\pi w} + O\left(\frac{1}{w^2}\right). \tag{9}$$

Thus ζ is a linear or first-order condition estimate in the sense that the chance of a catastrophically low or high estimate is inversely proportional to the size of the error. For example,

$\Pr(\|v\|/100 \le \zeta \le 100\|v\|) \ge 0.9936$, so that the chance of being off by more than a factor of 100 is less than 1 in 100.

While this is good, there are some situations in which we need more reliability. One way to achieve this is to use more function evaluations to get different values $\zeta^{(1)}, \zeta^{(2)}, \ldots, \zeta^{(m)}$ corresponding to independently randomly generated vectors $z^{(1)}, z^{(2)}, \ldots, z^{(m)}$ in S_{n-1} and then to take the average

$$\zeta(m) \equiv \frac{\zeta^{(1)} + \cdots + \zeta^{(m)}}{m}. \tag{10}$$

(As a matter of notation, we use subscripts to denote particular entries in a vector and superscripts in parentheses to distinguish between different vectors.)

This is the standard Monte Carlo method [22], [44], [51] for finding the expected value, and we can show that for $w > 1$

$$\Pr\left(\frac{\|v\|}{w} \le \zeta(m) \le w\|v\|\right) \ge 1 - \frac{1}{m!}\left(\frac{2m}{\pi w}\right)^m + O\left(\frac{1}{w^{m+1}}\right) \tag{11}$$

with asymptotic equality as $w \to +\infty$ or $m \to +\infty$. Thus $\zeta(m)$ is an mth-order condition estimator. That is, the probability that the estimator is off by more than a factor of w is less than a constant times w^{-m}. For example, with $m = 3$, which corresponds to three extra function evaluations, we have $\Pr(\|v\|/100 \le \zeta(3) \le 100\|v\|) \ge 0.99999884$, so that the chance of being off by a factor of 100 or more is approximately one in a million. Hence very reliable condition estimates can be obtained with only a few extra function evaluations. Note that this is in contrast to most Monte Carlo applications that usually involve thousands of population samples to estimate the expected value. Thus the method given above could be described as a "small-sample Monte Carlo method." However, to avoid the usual large-sample connotations of this phrase, we use instead the alternative description "averaged small-sample statistical method."

Remark 1. From (4) and (5) we can get the true value of $\|v\|$ at a price of $m = n$ extra function evaluations by simply setting $z^{(i)} = e^{(i)}$ and actually forming the gradient vector. (Here $e^{(i)}$ denotes the unit vector with a one in the ith position.) In general, however, this is much too costly because n may be in the hundreds or thousands.

Although the method of averaging is entirely adequate, we can obtain sharper estimates that are more easily analyzed by exploiting the geometry of the situation. For example, suppose that we know $v^T z^{(1)}$ and $v^T z^{(2)}$. From this information we can find the projection of v onto the span of $z^{(1)}$ and $z^{(2)}$. If $z^{(1)}$ and $z^{(2)}$ are orthogonal vectors in S_{n-1}, then the norm of this projection is given by

$$\left(|v^T z^{(1)}|^2 + |v^T z^{(2)}|^2\right)^{1/2}.$$

If we further assume that $z^{(1)}$ and $z^{(2)}$ are chosen so that their span is uniformly and randomly selected from the space of all two-dimensional subspaces of $\mathbb{R}^n$, then the expected value of the norm of the projection is given by (see Theorem 3.1)

$$E\left(\sqrt{|v^T z^{(1)}|^2 + |v^T z^{(2)}|^2}\right) = \frac{E_n}{E_2}\|v\|, \tag{12}$$

where E_n and E_2 are defined by (7) and (8). (Selecting $z^{(1)}$ and $z^{(2)}$ so that the above assumptions are satisfied is not difficult; from the work in [43] and [47] we may select $z^{(1)}$ and $z^{(2)}$ randomly and uniformly from S_{n-1} and then find an orthonormal basis for their span by using, say, a Gram–Schmidt procedure or a QR decomposition [16]. A similar procedure can

be used to randomly generate higher-dimensional subspaces and is described in more detail in §4.)

We see from (12) that the condition estimator defined by

$$\nu \equiv \frac{E_2}{E_n}\sqrt{|v^T z^{(1)}|^2 + |v^T z^{(2)}|^2} \tag{13}$$

has expected value equal to $\|v\|$. It can be shown (see Theorem 3.3) that for $w > 1$,

$$\Pr\left(\frac{\|v\|}{w} \le \nu \le w\|v\|\right) = \left(1 - \left(\frac{E_n}{E_2 w}\right)^2\right)^{(n-2)/2} - \left(1 - \left(\frac{E_n w}{E_2}\right)^2\right)^{(n-2)/2} \tag{14}$$

$$\approx 1 - \frac{\pi}{4w^2}, \tag{15}$$

which is slightly better than the corresponding estimate (11) for $\zeta(2)$.

This estimation method, which we refer to as the "subspace statistical method," can easily be extended: let $z^{(1)}, \ldots, z^{(m)}$ be an orthonormal basis for a subspace of dimension m that has been randomly and uniformly selected from the space of all m-dimensional subspaces of $\mathbb{R}^n$. (As above, this can be done by choosing m random vectors and then orthogonalizing.) Then $\left(|v^T z^{(1)}|^2 + \cdots + |v^T z^{(m)}|^2\right)^{1/2}$ is the norm of the projection of v onto the span of $z^{(1)}, \ldots, z^{(m)}$ and the expected value of this norm is (see Theorem 3.1)

$$E\left(\sqrt{|v^T z^{(1)}|^2 + \cdots + |v^T z^{(m)}|^2}\right) = \frac{E_n}{E_m}\|v\|. \tag{16}$$

Thus the subspace condition estimator defined by

$$\nu = \nu(m) \equiv \frac{E_m}{E_n}\sqrt{|v^T z^{(1)}|^2 + \cdots + |v^T z^{(m)}|^2} \tag{17}$$

has expected value $\|v\|$. These condition estimators give better results than the averaged statistical estimators and are analytically very tractable. For example, the kth moment of $\nu(m)$ is given by the formula (see Theorem 3.1)

$$E(\nu^k(m)) = \frac{E_n E_{n+1} \cdots E_{n+k}}{E_m E_{m+1} \cdots E_{m+k}} \left(\frac{\|v\| E_m}{E_n}\right)^k. \tag{18}$$

Additionally, a simple recursion can be derived (see Theorem 3.3) that gives exact values for the probability that $\nu(m)$ lies within a factor of w of $\|v\|$. Let us denote this probability by $P_m(w)$:

$$P_m(w) \equiv \Pr\left(\frac{\|v\|}{w} \le \nu(m) \le w\|v\|\right). \tag{19}$$

Table 1 gives lower bounds (independent of n) for $P_m(w)$ for the first few values of m and for a range of values of w.

Section 2 develops the theory of the averaged estimator $\zeta(m)$. Then in §3 results are presented for the subspace estimator $\nu(m)$.

2. Averaged statistical condition estimates.

2.1. Notation. It is convenient to begin this section with a review of some definitions from probability theory [13]. Let ϕ be a random variable and let $d(s; \phi)$ denote the value at s of the probability density function associated with ϕ. That is, for all $t \in \mathbb{R}$,

TABLE 1
Lower bounds on the probability that $\nu(m)$ equals $\|v\|$ to within a factor of w.

w	Lower bound for $P_1(w)$	Lower bound for $P_2(w)$	Lower bound for $P_3(w)$	Lower bound for $P_4(w)$
3	0.7736	0.9156	0.9632	0.9831
5	0.8732	0.9691	0.9916	0.9976
10	0.9364	0.9922	0.9989	0.9998
10^2	0.9936	0.9999	$1-10^{-5}$	$1-10^{-7}$
10^3	0.9994	$1-10^{-6}$	$1-10^{-8}$	$1-10^{-11}$

$$\Pr(\phi \le t) = \int_{-\infty}^{t} d(s;\phi)ds. \tag{20}$$

Similarly, if $\phi_1, \ldots, \phi_m$ are random variables, let $d(s_1, \ldots, s_m; \phi_1, \ldots, \phi_m)$ denote the value at $(s_1, \ldots, s_m)$ of the joint probability density function associated with $\phi_1, \ldots, \phi_m$. That is, for all $(t_1, \ldots, t_m) \in \mathbb{R}^m$,

$$\Pr(\phi_1 \le t_1, \ldots, \phi_m \le t_m) = \int_{-\infty}^{t_1} \cdots \int_{-\infty}^{t_m} d(s_1, \ldots, s_m; \phi_1, \ldots, \phi_m)ds_m \cdots ds_1. \tag{21}$$

If g is a measurable function from $\mathbb{R}^m$ to $\mathbb{R}$, and A is a measurable set in $\mathbb{R}$, then the probability that the random variable $g(\phi_1, \ldots, \phi_m)$ takes on a value in A is given by

$$\Pr(g(\phi_1, \ldots, \phi_m) \in A) = \int_{g \in A} d(s_1, \ldots, s_m; \phi_1, \ldots, \phi_m)ds_m \cdots ds_1, \tag{22}$$

where the notation $g \in A$ denotes the set of points $(s_1, \ldots, s_m)$ such that $g(s_1, \ldots, s_m) \in A$. The expected value of $g(\phi_1, \ldots, \phi_m)$ is defined to be

$$E(g(\phi_1, \ldots, \phi_m)) = \int_{-\infty}^{+\infty} \cdots \int_{-\infty}^{+\infty} g(s_1, \ldots, s_m)d(s_1, \ldots, s_m; \phi_1, \ldots, \phi_m)ds_m \cdots ds_1. \tag{23}$$

If $\phi_1, \phi_2, \ldots, \phi_m$ are independent, then

$$d(s_1, \ldots, s_m; \phi_1, \ldots, \phi_m) = d(s_1; \phi_1) \cdots d(s_m; \phi_m). \tag{24}$$

Because of the multiple integrals involved in higher dimensions, it is occasionally useful to switch from Cartesian coordinates to polar coordinates [11]

$$\begin{aligned} x_1 &= r\cos\theta_1, \\ x_2 &= r\sin\theta_1\cos\theta_2, \\ &\vdots \\ x_{m-1} &= r\sin\theta_1\sin\theta_2 \cdots \sin\theta_{m-2}\cos\theta_{m-1}, \\ x_m &= r\sin\theta_1\sin\theta_2 \cdots \sin\theta_{m-2}\sin\theta_{m-1}. \end{aligned}$$

The Jacobian of the transformation from $x_1, x_2, \ldots, x_m$ to $r, \theta_1, \theta_2, \ldots, \theta_{m-1}$ is given by

$$J = \left| \frac{\partial x_1, \ldots, x_m}{\partial r, \theta_1, \ldots, \theta_{m-1}} \right| = r^{m-1}\sin^{m-2}\theta_1 \sin^{m-3}\theta_2 \cdots \sin\theta_{m-2}.$$

2.2. Inner product distributions on S_{n-1}. Since inner products of the form $v^T z$ are invariant under an orthogonal rotation of v and z, we may select a coordinate system in which the vector v is just a scalar multiple of the vector $e^{(1)} \equiv (1, 0, \ldots, 0)^T$. This means that $|v^T z| = \|v\|\,|z_1|$, where $z = (z_1, \ldots, z_n)^T$. Because of this, our concern is with the distribution of $|z_1|$ when z is uniformly and randomly distributed over the unit sphere S_{n-1} in $\mathbb{R}^n$. For simplicity we assume that $n \ge 3$ throughout the rest of this paper.

The density function for z_1 is given by [42]

$$d(s_1; z_1) = c\left(1 - s_1^2\right)^{(n-3)/2} \quad \text{for } -1 \le s_1 \le 1, \tag{25}$$
$$= 0 \quad \text{otherwise,}$$

where c is a normalization constant given by

$$c = \left(\int_{-1}^{1} \left(1 - s_1^2\right)^{(n-3)/2} ds_1\right)^{-1}. \tag{26}$$

The density function for $|z_1|$ is thus seen to be

$$d(s_1; |z_1|) = 2c\left(1 - s_1^2\right)^{(n-3)/2} \quad \text{for } 0 \le s_1 \le 1, \tag{27}$$
$$= 0 \quad \text{otherwise.}$$

The probability that $|z_1|$ is less than or equal to a given nonnegative value ϵ is

$$\Pr(|z_1| \le \epsilon) = 2c \int_0^{\epsilon} \left(1 - s_1^2\right)^{(n-3)/2} ds_1, \tag{28}$$

and the expected value of $|z_1|$, which we denote by E_n, is

$$E_n \equiv E(|z_1|) = 2c \int_0^1 |s_1| \left(1 - s_1^2\right)^{(n-3)/2} ds_1 = \frac{2c}{n-1}. \tag{29}$$

In the following we use the symbol !! to denote the "skip" factorial defined in §1.

THEOREM 2.1. *The expected value function E_n is given by*

$$E_n = \frac{(n-2)!!}{(n-1)!!} \quad \textit{for } n \textit{ odd}, \tag{30}$$

$$E_n = \frac{2}{\pi} \frac{(n-2)!!}{(n-1)!!} \quad \textit{for } n \textit{ even}. \tag{31}$$

(*See also the Appendix.*)

Proof. Use the change of variables $s_1 = \cos\theta$ and the recursion formula [18, p. 369]

$$\int_0^{\pi/2} \sin^j \theta d\theta = \frac{j-1}{j} \int_0^{\pi/2} \sin^{j-2} \theta d\theta$$

in (29). □

To discuss the probability that $|z_1|$ is less than or equal to a given value ϵ, it is convenient to introduce the function $g_n = g_n(\epsilon)$ defined as follows: $g_n(\epsilon) = 0$ if $\epsilon \le 0$ and $g_n(\epsilon) = 1$ if $\epsilon \ge 1$. If n is odd and $0 < \epsilon < 1$, then

$$g_n(\epsilon) = \epsilon\left(1 + \frac{1}{2}(1-\epsilon^2) + \frac{1 \cdot 3}{2 \cdot 4}(1-\epsilon^2)^2 + \cdots + \frac{(n-4)!!}{(n-3)!!}(1-\epsilon^2)^{(n-3)/2}\right). \tag{32}$$

If n is even and $0 < \epsilon < 1$, then

$$g_n(\epsilon) = \frac{2}{\pi}\epsilon\left(\frac{\arcsin\epsilon}{\epsilon} + \left(1-\epsilon^2\right)^{1/2} + \frac{2}{3}\left(1-\epsilon^2\right)^{3/2} + \cdots + \frac{(n-4)!!}{(n-3)!!}\left(1-\epsilon^2\right)^{(n-3)/2}\right). \tag{33}$$

LEMMA 2.2. *For* $n \geq 3$,

$$\Pr(|z_1| \leq \epsilon) = g_n(\epsilon). \tag{34}$$

Proof. Let $\epsilon = \sin\delta$ and define $\Pr(|z_1| \leq \epsilon) \equiv Q_n(\delta)$. Direct evaluation shows that $Q_2(\delta) = \frac{2}{\pi}\arcsin\epsilon$ and $Q_3(\delta) = \epsilon$. Standard results from [18] show that

$$Q_{n+2}(\delta) = Q_n(\delta) + \frac{\sin(\delta)\cos^{n-1}(\delta)}{(n-1)\displaystyle\int_0^{\pi/2} \sin^{n-2}(\theta)d\theta}.$$

When combined with $\cos\delta = (1-\epsilon^2)^{1/2}$, the desired result is obtained by induction on n. □

Our principal concern is with the properties of

$$\zeta = \frac{|v^T z|}{E_n} \tag{35}$$

as a condition estimator, since the right-hand side of (35) can be evaluated numerically (see the Appendix).

THEOREM 2.3. *The expected value of* ζ *is* $\|v\|$, *and for* $w > 1$

$$\Pr\left(\frac{\|v\|}{w} \leq \zeta \leq w\|v\|\right) = g_n(wE_n) - g_n\left(\frac{E_n}{w}\right). \tag{36}$$

Proof. Using Lemma 2.2 and $|z_1| = |v^T z|/\|v\|$, we find that

$$\begin{aligned}\Pr\left(\frac{|v^T z|}{E_n} \leq w\|v\|\right) &= \Pr\left(\frac{|v^T z|}{\|v\|} \leq wE_n\right)\\ &= \Pr(|z_1| \leq wE_n)\\ &= g_n(wE_n)\,.\end{aligned}$$

Replacing w with $\frac{1}{w}$ gives $\Pr(|v^T z|/E_n \leq \|v\|/w) = g_n(E_n/w)$. Taken together these expressions give (36). The fact that $E(\zeta) = \|v\|$ follows from a similar argument or by noting that

$$E(\zeta) = E\left(\frac{|v^T z|}{E_n}\right) = \frac{E(|v^T z|)}{E_n} = \frac{E(\|v\|\,|z_1|)}{E(|z_1|)} = \|v\|. \qquad \square$$

Although (36) is exact, it is a little hard to work with. The next few results deal with the averaged variables $\zeta(m)$ and show that (36) can be replaced, for $m = 1$, by the simple bound

$$\Pr\left(\frac{\|v\|}{w} \leq \zeta \leq w\|v\|\right) \geq 1 - \frac{2}{\pi w} - \frac{4}{w}e^{-w^2/4} \quad \text{for } n \geq 4. \tag{37}$$

As in the discussion in the Introduction, if we can afford to make m extra function evaluations, then one way of increasing the reliability and accuracy of our condition estimates is to use the averaged estimator

$$\zeta(m) = \frac{|v^T z^{(1)}| + \cdots + |v^T z^{(m)}|}{mE_n}, \tag{38}$$

where $z^{(1)}, \ldots, z^{(m)}$ are independently, randomly, and uniformly chosen vectors from the unit sphere in n dimensions.

2.3. Underestimation. The following theorem bounds the probability that $\zeta(m)$ underestimates $\|v\|$ by a factor $w > 1$.

THEOREM 2.4. *Let $\zeta(m)$ be given by* (38). *Then*

$$\Pr\left(\zeta(m) \le \frac{\|v\|}{w}\right) < \left(\frac{2m}{\pi w}\right)^m \frac{1}{m!}. \tag{39}$$

Proof. Let $z_1^{(i)}$ denote the first component of $z^{(i)}$ for $1 \le i \le m$. The independence assumption together with (27) implies that the joint density function for $|z_1^{(1)}|, \ldots, |z_1^{(m)}|$ satisfies

$$d\left(s_1, \ldots, s_m; |z_1^{(1)}|, \ldots, |z_1^{(m)}|\right) = d\left(s_1; |z_1^{(1)}|\right) \cdots d\left(s_m; |z_1^{(m)}|\right) \tag{40}$$

$$= (2c)^m \left(1 - s_1^2\right)^{(n-3)/2} \cdots \left(1 - s_m^2\right)^{(n-3)/2} \tag{41}$$

$$\le (2c)^m \tag{42}$$

for $0 \le s_i \le 1$ and $1 \le i \le m$; otherwise the density is zero.

To establish (39), write

$$\begin{aligned}
\Pr\left(\zeta(m) \le \frac{\|v\|}{w}\right) &= \Pr\left(\frac{|v^T z^{(1)}| + \cdots + |v^T z^{(m)}|}{m E_n} \le \frac{\|v\|}{w}\right) \\
&= \Pr\left(\frac{|v^T z^{(1)}|}{\|v\|} + \cdots + \frac{|v^T z^{(m)}|}{\|v\|} \le \frac{m E_n}{w}\right) \\
&= \Pr\left(|z_1^{(1)}| + \cdots + |z_1^{(m)}| \le \frac{m E_n}{w}\right) \\
&= \int_T d(s_1, \ldots, s_m; |z_1^{(1)}|, \ldots, |z_1^{(m)}|)\, ds_m \cdots ds_1,
\end{aligned}$$

where T denotes the triangular wedge $\Sigma s_i \le m E_n / w$, $s_i \ge 0$. Standard calculus techniques suffice to show that this wedge has volume equal to $(m E_n / w)^m / m!$. Combining this with the bound on the density function shows that

$$\begin{aligned}
\Pr\left(\zeta(m) \le \frac{\|v\|}{w}\right) &\le \int_T (2c)^m \, ds_m \cdots ds_1 \\
&= \left(\frac{2cm E_n}{w}\right)^m \frac{1}{m!}.
\end{aligned}$$

However, $2cE_n = (n-1)E_n^2 < \frac{2}{\pi}$ by (29) and Lemma 6.1 in the Appendix. This completes the proof of (39). □

Remark 2. Slightly more analysis shows that the bound (39) is asymptotically an equality as $w \to +\infty$.

2.4. Overestimation. The probability that $\zeta(m)$ overestimates $\|v\|$ turns out to be rather insignificant. First, we need the following technical lemma.

LEMMA 2.5. *For $m \ge 1$ and $r_0 > \sqrt{2(m-1)}$*

$$\int_{r_0}^{+\infty} r^{m-1} e^{-r^2/2} dr \le 2 r_0^{m-2} e^{-r_0^2/2}. \tag{43}$$

Proof. Use the standard methods of [7]. □

THEOREM 2.6. *Let $z^{(1)}, \ldots, z^{(m)}$ be independently, randomly, and uniformly chosen from S_{n-1} and define $\zeta(m)$ by* (38). *Then for $n \geq 5$, $w \geq 4$, and $2 \leq m \leq n-3$, the probability that $\zeta(m)$ overestimates $\|v\|$ by a factor of w is bounded by*

$$\Pr(\zeta(m) \geq w\|v\|) < \frac{6}{(m-2)!!}\left(\frac{w\sqrt{m}}{2}\right)^{m-2} e^{-mw^2/8}. \tag{44}$$

Proof. As in the proof of Theorem 2.4,

$$\begin{aligned}\Pr(\zeta(m) \geq w\|v\|) &= \Pr\left(|z_1^{(1)}| + \cdots + |z_1^{(m)}| \geq mwE_n\right)\\ &= \int_O d(s_1, \ldots, s_m; |z_1^{(1)}|, \ldots, |z_1^{(m)}|)\, ds_m \cdots ds_1,\end{aligned}$$

where O denotes the outer triangular wedge $\Sigma s_i \geq mwE_n$, $s_i \geq 0$. However, the region O is contained in the outer annular wedge W defined by $\Sigma s_i^2 \geq mw^2E_n^2$ because

$$(mwE_n)^2 \leq \left(\sum_{i=1}^m s_i\right)^2 \leq m\sum_{i=1}^m s_i^2$$

by the Cauchy–Schwarz inequality.

We also need an upper bound on the density function; this can be obtained by using a clever trick from [42]. Since $1 - x \leq e^{-x}$ for all x, we have $(1 - s_i^2)^{(n-3)/2} \leq e^{-(n-3)s_i^2/2}$ and

$$d\left(s_1, \ldots, s_m; |z_1^{(1)}|, \ldots, |z_1^{(m)}|\right) \leq (2c)^m e^{-(n-3)/2\,(s_1^2+\cdots+s_m^2)}. \tag{45}$$

Altogether this gives

$$\begin{aligned}\Pr(\zeta(m) \geq w\|v\|) &\leq \int_W d(s_1, \ldots, s_m; |z_1^{(1)}|, \ldots, |z_1^{(m)}|)\, ds_m \cdots ds_1\\ &\leq \int_W (2c)^m e^{-(n-3)\,(s_1^2+\cdots+s_m^2)/2}\, ds_m \cdots ds_1\\ &= \mu_m (2c)^m \int_{\sqrt{m}wE_n}^{+\infty} \rho^{m-1} e^{-(n-3)\rho^2/2} d\rho,\end{aligned} \tag{46}$$

where the last equality was obtained by switching to polar coordinates in m dimensions with $\rho^2 = s_1^2 + \cdots + s_m^2$. The term μ_m is given by

$$\mu_m \equiv \int_0^{\pi/2} \cdots \int_0^{\pi/2} \sin^{m-2}(\theta_1) \cdots \sin(\theta_{m-2}) d\theta_{m-1} \cdots d\theta_1,$$

and satisfies $\mu_m \leq (\frac{\pi}{2})^{m/2}/(m-2)!!$. Now for $w \geq 4$ and $n \geq 5$, we make the change of variables $r = \sqrt{n-3}\,\rho$ above, and then we apply Lemma 2.5 with $r_0 \equiv \sqrt{m}w/2 < \sqrt{m}wE_n\sqrt{n-3}$ to get

$$\Pr(\zeta(m) \geq w\|v\|) < \frac{2}{(m-2)!!}\left(\frac{2c^2\pi}{n-3}\right)^{m/2}\left(\frac{w\sqrt{m}}{2}\right)^{m-2} e^{-mw^2/8}.$$

Finally, by (29) and Lemma 6.1 in the Appendix,

$$
\begin{aligned}
2\left(\frac{2c^2\pi}{n-3}\right)^{m/2} &< 2\left(\frac{n-1}{n-3}\right)^{m/2} \\
&= 2\left(1+\frac{2}{n-3}\right)^{m/2} \\
&< 2e^{m/(n-3)} \\
&< 6,
\end{aligned}
\tag{47}
$$

since $m \leq n-3$ by assumption. □

Remark 3. The restrictions $w \geq 4$, $n \geq 5$, and $m \geq 2$ in Theorem 2.6 were selected to reduce the complexity of the proof. Similar results can be obtained for weaker hypotheses.

3. Subspace statistical condition estimates. Let O_n denote the set of orthogonal matrices of order n. If U is randomly and uniformly selected from O_n [43], then $Ue^{(1)}$ is randomly and uniformly distributed over the unit sphere S_{n-1} in n dimensions, where $e^{(1)} = (1, 0, \ldots, 0)^T$. In fact, for any fixed unit vector w, the product Uw is randomly and uniformly distributed over S_{n-1}. Similarly, by using the methods of [28], the vectors $Ue^{(1)}, \ldots, Ue^{(m)}$ form an orthonormal basis for a subspace of dimension m which is randomly and uniformly distributed over the set of all subspaces of dimension m in $\mathbb{R}^n$.

Let $z^{(i)} = Ue^{(i)}$. Then $v^T z^{(i)} = v^T U e^{(i)} = (U^T v)^T e^{(i)} = \|v\|\, w^T e^{(i)}$, where $w = U^T v/\|v\|$. The importance of this is that the joint density function of the random variables $w_i \equiv w^T e^{(i)}$ is known [42]. Specifically, for $n \geq 3$ and $1 \leq m < n$,

$$
d(s_1, \ldots, s_m; w_1, \ldots, w_m) = c_1 \left(1 - r^2\right)^{(n-m-2)/2} \quad \text{for } 0 \leq r \leq 1,
\tag{48}
$$

where $r^2 = s_1^2 + \cdots + s_m^2$ and c_1 is a normalization constant. For r not in the interval [0, 1], the density is zero. Since

$$
\sqrt{(v^T z^{(i)})^2 + \cdots + (v^T z^{(m)})^2} = \|v\| \sqrt{(w^T e^{(1)})^2 + \cdots + (w^T e^{(m)})^2},
\tag{49}
$$

we need to consider the random variable ϕ defined by

$$
\phi = \phi(m) \equiv \sqrt{(w^T e^{(1)})^2 + \cdots + (w^T e^{(m)})^2}\,.
\tag{50}
$$

THEOREM 3.1. *The expected value of ϕ is given by*

$$
E(\phi(m)) = \frac{E_n}{E_m},
\tag{51}
$$

where E_n is defined by (7)–(8). *More generally, the kth moment of ϕ is given by*

$$
E(\phi^k(m)) = \frac{E_n\, E_{n+1} \cdots E_{n+k-1}}{E_m\, E_{m+1} \cdots E_{m+k-1}}.
\tag{52}
$$

Proof. After changing to polar coordinates in m dimensions and using (48), we find that

$$
E(\phi^k(m)) = \frac{I(k, n, m)}{I(0, n, m)},
\tag{53}
$$

where

$$I(i,n,m) \equiv \int_0^1 \left(1-r^2\right)^{(n-m-2)/2} r^{m+i-1}\, dr. \tag{54}$$

Equations (51) and (52) can then be proved by using (53) and induction, but the details are omitted for the sake of brevity. □

Remark 4. From (52), the variance of $\phi(m)$ is given by

$$\begin{aligned}\mathrm{Var}(\phi(m)) &= E\left(\phi^2(m)\right) - E^2(\phi(m)) \\ &= \frac{E_n\, E_{n+1}}{E_m\, E_{m+1}} - \frac{E_n^2}{E_m^2} \\ &= \frac{m}{n} - \frac{E_n^2}{E_m^2},\end{aligned}$$

because $E_k\, E_{k+1} = \frac{2}{\pi k}$. Since the variance is nonnegative, this gives $m E_m^2 \geq n E_n^2$. Thus, for $m \leq n$, we have $m E_m^2 \geq n E_n^2 \geq m E_n^2$, which gives $E_m \geq E_n$, i.e., E_n is decreasing with n. This is used in the proof of Lemma 6.1 in the Appendix. In fact, from the equality, $E_{n+2} = \left(\frac{n}{n+1}\right) E_n$, it is easily seen by induction that $E_n < 1/\sqrt{n}$.

Theorem 3.1 shows that the subspace estimator ν defined by

$$\nu = \nu(m) \equiv \frac{E_m}{E_n} \sqrt{|v^T z^{(1)}|^2 + \cdots + |v^T z^{(m)}|^2} \tag{55}$$

has expected value $\|v\|$. The significance of this is that ν can be calculated in m function evaluations as in the discussion in the Introduction (see also §4 for more details). Theorem 3.1 also shows that the kth moment of $\nu(m)$ is given by

$$E(\nu^k(m)) = \frac{E_n E_{n+1} \cdots E_{n+k-1}}{E_m E_{m+1} \cdots E_{m+k-1}} \left(\frac{\|v\| E_m}{E_n}\right)^k. \tag{56}$$

Using $E_k E_{k+1} = \frac{2}{\pi k}$ and Theorem 3.1, the variance and skewness of $\nu(m)$ can be found:

$$\begin{aligned}\mathrm{Var}(\nu(m)) &\equiv E((\nu(m) - E(\nu(m)))^2) \\ &= \left(\frac{m E_m^2}{n E_n^2} - 1\right) \|v\|^2, \\ \mathrm{Skew}(\nu(m)) &\equiv E((\nu(m) - E(\nu(m)))^3) \\ &= \left(\left(\frac{m+1}{n+1} - \frac{3m}{n}\right) \frac{E_m^2}{E_n^2} + 2\right) \|v\|^3.\end{aligned}$$

Note that skewness is defined in many statistics texts as the centered third moment divided by the variance, but, for convenience here, we shall refer to the centered third moment by this appellation.

We can now also determine the variance and skewness of the averaged statistical estimator $\zeta(m)$ because $\zeta(1) = \nu(1)$ and

$$\operatorname{Var}(\zeta(m)) = \frac{1}{m}\operatorname{Var}(\zeta(1))$$

$$= \frac{1}{m}\left(\frac{1}{nE_n^2} - 1\right)\|v\|^2,$$

$$\operatorname{Skew}(\zeta(m)) = \frac{1}{m^2}\operatorname{Skew}(\zeta(1))$$

$$= \frac{1}{m^2}\left(\left(\frac{2}{n+1} - \frac{3}{n}\right)\frac{1}{E_n^2} + 2\right)\|v\|^3.$$

For example, the first example in §4 deals with the sensitivity of the roots of the polynomial $p(t) = (t-1)\cdots(t-(n-1))$ with respect to variation in the n coefficients of p. A comparison of the variance and skewness of the averaged and subspace statistical estimators for this problem with $n = 9$ is given in Table 2, which shows that both the variance and the skewness of the subspace estimator are smaller in absolute value than for the averaged estimator.

TABLE 2
Variance and skewness comparison of the two estimators for $n = 9$.

m	$\operatorname{Var}(\zeta(m))$	$\operatorname{Var}(\nu(m))$	$\operatorname{Skew}(\zeta(m))$	$\operatorname{Skew}(\nu(m))$
1	$0.4861\,\|v\|^2$	$0.4861\,\|v\|^2$	$0.2167\,\|v\|^3$	$0.2167\,\|v\|^3$
2	$0.2430\,\|v\|^2$	$0.2046\,\|v\|^2$	$0.0542\,\|v\|^3$	$0.0125\,\|v\|^3$
3	$0.1620\,\|v\|^2$	$0.1146\,\|v\|^2$	$0.0241\,\|v\|^3$	$-0.006\,\|v\|^3$

To develop an expression for the probability that $\nu(m)$ lies within a factor w of $\|v\|$, we need some preliminary results. Define

$$g_{n,m}(\epsilon) \equiv \Pr(\phi(m) \le \epsilon)\,. \tag{57}$$

As in the proof of Theorem 3.1, $\phi(1) = |z_1|$ so that $g_{n,1} = g_n$, where g_n is defined by (32) and (33).

Using polar coordinates and (48) shows that for $0 \le \epsilon \le 1$,

$$g_{n,m}(\epsilon) = \frac{T_{n,m}(\epsilon)}{T_{n,m}(1)}, \tag{58}$$

where

$$T_{n,m}(\epsilon) \equiv \int_0^\epsilon \left(1 - r^2\right)^{(n-m-2)/2} r^{m-1}\,dr. \tag{59}$$

LEMMA 3.2. *For $0 \le \epsilon \le 1$ and $m = 2$, we have*

$$g_{n,2}(\epsilon) = 1 - \left(1 - \epsilon^2\right)^{(n-2)/2}\,. \tag{60}$$

For $m > 2$, the value of $g_{n,m}(\epsilon)$ can be found by using the values of $g_{n,1}(\epsilon)$ and $g_{n,2}(\epsilon)$ with the recursion

$$g_{n,m}(\epsilon) = g_{n,m-2}(\epsilon) - \frac{(n-2)!!\,\epsilon^{m-2}}{(m-2)!!\,(n-m)!!}\left(1-\epsilon^2\right)^{(n-m)/2} \quad \textit{for } m \textit{ even}, \tag{61}$$

$$= g_{n,m-2}(\epsilon) - \frac{(n-1)!!\,E_n\,\epsilon^{m-2}}{(m-2)!!\,(n-m)!!}\left(1-\epsilon^2\right)^{(n-m)/2} \quad \textit{for } m \textit{ odd}. \tag{62}$$

Proof. Use integration by parts with $v = -\left(1-r^2\right)^{(n-m)/2}/(n-m)$ and $u = r^{m-2}$ in the definition of $T_{n,m}$. For $m = 2$ this gives (60). For $m > 2$, we get

$$T_{n,m}(\epsilon) = \frac{m-2}{n-m} T_{n,m-2}(\epsilon) - \frac{\epsilon^{m-2}}{n-m}\left(1-\epsilon^2\right)^{(n-m)/2}, \tag{63}$$

which, when coupled with the definition of E_n, yields (61) and (62). □

THEOREM 3.3. *For $w > 1$ and $\nu(m)$ defined by* (55),

$$\Pr\left(\frac{\|v\|}{w} \le \nu(m) \le w\|v\|\right) = g_{n,m}\left(\frac{wE_n}{E_m}\right) - g_{n,m}\left(\frac{E_n}{E_m\, w}\right). \tag{64}$$

Proof. From the above, $\nu(m) = \|v\|\phi(m)E_m/E_n$, so

$$\begin{aligned}\Pr(\nu(m) \le w\|v\|) &= \Pr\left(\|v\|\phi(m)\frac{E_m}{E_n} \le w\|v\|\right)\\ &= \Pr\left(\phi(m) \le \frac{wE_n}{E_m}\right)\\ &= g_{n,m}\left(\frac{wE_n}{E_m}\right),\end{aligned}$$

by (57) with $\epsilon = wE_n/E_m$. Replacing w by $\frac{1}{w}$ gives $\Pr(\nu(m) \le \|v\|/w) = g_{n,m}(E_n/(E_m w))$. Taken together these expressions give (64). □

As an example, for $m = 2$ with $w > 1$ and $wE_n/E_2 \le 1$,

$$\Pr\left(\frac{\|v\|}{w} \le \nu(2) \le w\|v\|\right) = \left(1-\left(\frac{E_n}{E_2 w}\right)^2\right)^{(n-2)/2} - \left(1-\left(\frac{wE_n}{E_2}\right)^2\right)^{(n-2)/2}. \tag{65}$$

Using the above and some lengthy but standard expansions, we find

$$\Pr\left(\frac{\|v\|}{w} \le \nu(1) \le w\|v\|\right) \approx 1 - \frac{2}{\pi w}, \tag{66}$$

$$\Pr\left(\frac{\|v\|}{w} \le \nu(2) \le w\|v\|\right) \approx 1 - \frac{\pi}{4w^2}, \tag{67}$$

$$\Pr\left(\frac{\|v\|}{w} \le \nu(3) \le w\|v\|\right) \approx 1 - \frac{32}{3\pi^2 w^3}, \tag{68}$$

$$\Pr\left(\frac{\|v\|}{w} \le \nu(4) \le w\|v\|\right) \approx 1 - \frac{81\pi^2}{512w^4}. \tag{69}$$

These estimates are generally very accurate for $w \ge 10$. To handle the case of smaller values of w, we use the fact that the probability that $\nu(m)$ is within a factor of $\|v\|$ decreases toward a nonzero constant as n increases to infinity [20]. These lower bounds can be calculated by applying the Richardson extrapolation [3], [29] to the exact probability expressions given by Theorem 3.3 above for large values of n. For example, in calculating the lower bounds given in Table 1, we used $n = 10000$ and $n = 20000$.

Before turning to some numerical examples, we list here for reference the key estimators defined above:

ζ averaged statistical estimate,

$\zeta(m)$ averaged statistical estimate with m samples,

ν subspace statistical estimate,

$\nu(m)$ subspace statistical estimate with m samples.

4. Numerical examples.

4.1. Generating random vectors. Let $\tilde{z}_1, \ldots, \tilde{z}_n$ be normally distributed independent random variables with mean zero and variance one. Then the vector $z = \tilde{z}/\|\tilde{z}\|$ is uniformly and randomly distributed over S_{n-1} [47] where $\tilde{z} = (\tilde{z}_1, \ldots, \tilde{z}_n)^T$. Because of this, the sum of the squares of the first m components of z, which is equal to the subspace statistical variable ϕ^2 as in §3, will have a Beta distribution with $a = \frac{1}{2}$ and $b = \frac{n}{2}$ (see §26.5 in [1]). That is, for $0 \le x \le 1$,

$$\Pr(\phi^2 \le x) = \frac{B(a, b, x)}{B(a, b, 1)}, \tag{70}$$

where

$$B(a, b, x) = \int_0^x t^{a-1} (1-t)^{b-1}\, dt. \tag{71}$$

This means that the theory of §3 could have been developed by using

$$\begin{aligned} \Pr(\phi^2 \le x) &= \Pr(\phi \le \sqrt{x}) \\ &= \frac{B(a, b, \sqrt{x})}{B(a, b, 1)}. \end{aligned}$$

As in the discussion at the beginning of §3, to get a basis for a subspace of dimension m that is selected uniformly and randomly from the set of all subspaces of dimension m in $\mathbb{R}^n$, it is sufficient to generate m independent vectors $z^{(1)}, \ldots, z^{(m)}$ uniformly and randomly on S_{n-1} as above and then find an orthonormal basis for these vectors by using, say, a Gram–Schmidt procedure or a QR decomposition [16].

Remark 5. It is worth mentioning that independent normally distributed random variables can be generated by the following procedure: let r_1 and r_2 be independent random variables with uniform distribution in (0,1) and define $s = \sqrt{2\ln(1/r_1)}$ and $\theta = 2\pi r_2$. Then $\tilde{z}_1 = s\cos(\theta)$ and $\tilde{z}_2 = s\sin(\theta)$ are independent normally distributed random variables with mean zero and variance one.

4.2. Scalar examples. *Example* 1. Suppose that p is a polynomial of degree $n-1$: $p(t) = p_0 + p_1 t + \cdots + p_{n-1}t^{n-1}$, with roots $t_1, \ldots, t_{n-1}$. If p is perturbed to the form $p_\epsilon \equiv p + \epsilon q$ where $q(t) = q_0 + q_1 t + \cdots + q_{n-1}t^{n-1}$, then the roots become functions of ϵ. From the theory of algebraic functions [17], a root of multiplicity k at $\epsilon = 0$ gives rise to k roots that are analytic functions of $\epsilon^{1/k}$ in a neighborhood of $\epsilon = 0$. Thus, an isolated root, say t_1, will be differentiable at $\epsilon = 0$, and we may differentiate the relation

$$0 = p(t_1(\epsilon)) + \epsilon q(t_1(\epsilon))$$

to get

$$\frac{dt_1(0)}{d\epsilon} = -\frac{q(t_1(0))}{p'(t_1(0))} = \nabla t_1 z,$$

where $z \equiv (q_0, q_1, \ldots, q_{n-1})^T$ and

$$\nabla t_1 = \left(\frac{\partial t_1}{\partial q_i}\right) = \left(-\frac{1}{p'(t_1(0))}, -\frac{t_1(0)}{p'(t_1(0))}, \ldots, -\frac{t_1^{n-1}(0)}{p'(t_1(0))}\right).$$

See [48] for more details. We may apply the statistical method to this problem by considering the n polynomial coefficients as the input variables $x = (p_0, \ldots, p_{n-1})$ and the scalar function $f = f(x)$ to be the value of the root t_1. The sensitivity of the root is then the norm of the gradient of f at x: $v \equiv \nabla t_1^T$. The above equation shows that the exact value of $\|v\|$ is given by

$$\|v\| = \frac{1}{|p'(t_1(0))|}\sqrt{1 + t_1^2(0) + \cdots + t_1^{2(n-1)}(0)}.$$

For example, consider the polynomial

$$\begin{aligned} p(t) &= (t-1)(t-2)\cdots(t-8) \\ &= 40320 - 109584t + 118124t^2 - 67284t^3 + 22449t^4 - 4536t^5 + 546t^6 - 36t^7 + t^8, \end{aligned}$$

and suppose that we are interested in the sensitivity of the root $t = 6$. This root is moderately sensitive with $\|v\| \approx 7097.7$. Sample estimates of $\|v\|$ are given in Table 3 for three different runs (all results are rounded to integer values). Of course, three runs is too small a number to be statistically meaningful, but Table 3 does give some feel for how the estimates perform. From Table 2, we see that the variance of $\nu(m)$ is smaller than the variance of $\zeta(m)$ for $m = 2$ and $m = 3$; this is illustrated by the greater spread in the values of the averaged statistical estimator in Table 3.

TABLE 3
Comparison of the two estimators for Example 1.

m	Run number	$\zeta(m)$	$\nu(m)$	Exact value of $\|v\|$
1	1	20883	20883	7098
1	2	3372	3372	7098
1	3	2130	2130	7098
2	1	6673	10047	7098
2	2	7374	9743	7098
2	3	2588	10726	7098
3	1	3147	9642	7098
3	2	11632	10183	7098
3	3	1609	6398	7098

Example 2. This example has an unexpected twist to it since it focuses on a problem in which we want to know when the condition number is near zero. More specifically, a pair of matrices (A, B) has an uncontrollable eigenvalue at λ if λ is an eigenvalue of $A + BF$ for any compatibly dimensioned matrix F [50]. In general, however, it is not easy to test numerically for uncontrollability [12], [39]. Because of this, it is more common to use the distance to uncontrollability [33], which we denote by $\rho_c(A, B)$:

$$\rho_c(A, B) \equiv \min\{\, \|(\Delta A, \Delta B)\| \;:\; (A + \Delta A, B + \Delta B) \text{ is uncontrollable}\}. \tag{72}$$

It seems reasonable to expect that if (A, B) has an eigenvalue λ that is nearly uncontrollable, then the sensitivity of the map f defined by $x \mapsto \lambda(A+BF)$, where $x = \text{vec}(F)$, should be nearly zero. Here we use the symbol $\text{vec}(F)$ to denote the vector formed by stacking the columns of F [19]. In fact, if we assume that λ is an isolated eigenvalue of A, then by using standard perturbation arguments [49] it can be shown that the norm of the gradient of f gives an upper bound on $\rho_c(A, B)$. As an example, let A be a 10×10 matrix with main diagonal entries $a_{i,i} = i$ and ones on the first superdiagonal $a_{i,i+1} = 1$ and zeros elsewhere. If we let $B = \text{diag}\left(1, 10^{-1}, \ldots, 10^{-9}\right)$, then the feedback matrix F is 10×10 and the number of input parameters is $n = 100$. The matrix B for this problem offers decreasing control authority for the higher states; in fact, the norm of the gradient of the eigenvalue $\lambda = 10$ is 1.5×10^{-9}. That is, $\lambda = 10$ is nearly uncontrollable. Table 4 shows that this insensitivity is easily detected.

TABLE 4
Comparison of the two estimators for Example 2.

m	Run number	$\zeta(m)$	$\nu(m)$	Exact value of $\|v\|$
1	1	1.6×10^{-9}	1.6×10^{-9}	1.5×10^{-9}
1	2	4.4×10^{-10}	4.4×10^{-10}	1.5×10^{-9}
1	3	2.7×10^{-9}	2.7×10^{-9}	1.5×10^{-9}
2	1	2.6×10^{-9}	2.3×10^{-9}	1.5×10^{-9}
2	2	1.2×10^{-9}	2.8×10^{-9}	1.5×10^{-9}
2	3	7.8×10^{-9}	1.1×10^{-9}	1.5×10^{-9}
3	1	5.2×10^{-10}	1.3×10^{-9}	1.5×10^{-9}
3	2	6.7×10^{-10}	1.6×10^{-9}	1.5×10^{-9}
3	3	1.3×10^{-9}	3.1×10^{-9}	1.5×10^{-9}

4.3. Matrix examples. The preceding sensitivity theory of scalar functions can be extended to differentiable vector-valued functions. By using the vec operator [19], which maps matrices into vectors by stacking the columns, the set of vector-valued functions can be viewed as including the class of functions that map matrices into matrices. For example, the exponential map $X \mapsto e^X$ is equivalent to $x \mapsto f(x)$, where $x = \text{vec}(X)$ and $f(x) = \text{vec}(e^X)$.

If f is a twice continuously differentiable function that takes $\mathbb{R}^n$ into $\mathbb{R}^q$, then the Taylor expansion about $x \in \mathbb{R}^n$ has the form

$$f(x + \delta z) = f(x) + \delta L z + O(\delta^2), \tag{73}$$

where L is a matrix of size $q \times n$. The classical approach [40] to measuring the sensitivity of f at x is to use the norm of L to bound the perturbations in f:

$$\|f(x + \delta z) - f(x)\| \leq \delta \|L\| + O(\delta^2), \tag{74}$$

where we assume that z has unit norm.

For the matrix 2-norm, the norm of L can be estimated by using the power method to approximate the largest eigenvalue of $L^T L$. This method was used in [6] for linear systems and subsequently extended to a variety of other problems [4], [5], [15], [31], [34], [35]. Related estimation methods for other matrix norms can be found in [21], [26], and [27]. The idea behind these methods is that the matrix L is usually not known explicitly (or is too expensive to evaluate directly), but it is possible to evaluate $w = Lz$ for a given vector z either by solving an associated linear system or by using difference approximations. The same applies to L^T, although, in some cases such as problems associated with differential equations [31], the computation of the transpose vectors $L^T w$ is harder than the computation of Lz (see Example 4).

The transpose step of the power method also runs into difficulty when the function f maps between spaces of different dimensions, i.e., when L is not a square matrix. For example, if f maps $\mathbb{R}^n$ into $\mathbb{R}$, then L is $1 \times n$ and Lz can be evaluated by using a finite difference. However, the transpose step involves forming $L^T w$, as described below, and since L^T is $n \times 1$, this cannot be evaluated without knowing all the entries of L^T! Thus the power method is impractical for this problem because finding the entries of L (and hence L^T) via finite differences would require n extra function evaluations. In fact, it was this difficulty that originally inspired the research in this paper.

In general, if the Fréchet derivative of f is known only implicitly (i.e., if we can evaluate Lz but we do not know L explicitly) then the power method is limited to estimating the condition number of maps between spaces of the same dimension, although it is sometimes possible to get around this by working with restricted maps. For example, in considering the effect of perturbations in the coefficient matrices (A, F, G) for a solution X of an algebraic Riccati equation

$$0 = G + A^T X + XA - XFX,$$

Byers [5], and subsequently Kenney and Hewer [31], found it convenient to consider separately the three equal-dimensional maps $A \mapsto X$, $F \mapsto X$, and $G \mapsto X$, rather than to work with the complete map $(A, F, G) \mapsto X$. Power method estimates from the three equal-dimensional maps can then be combined to get upper and lower bounds on the condition of the complete map (see [31]).

The power method estimation of $\|L\|$ starts with an initial vector $z^{(1)}$ and then forms $z^{(2)} = L^T L z^{(1)}$ via two steps: $w^{(1)} = Lz^{(1)}$ and $z^{(2)} = L^T w^{(1)}$. The norm of L is then estimated by $\sqrt{\|z^{(2)}\|/\|z^{(1)}\|}$, and better estimates can be obtained by repeating the power iteration with $z^{(1)}$ replaced by $z^{(2)}$. The quality of the estimation is affected by the choice of the initial vector, and most schemes rely on either a "look-ahead" procedure for selecting $z^{(1)}$ (for example, [4], [6]) or use randomly generated initial vectors [31]. In general, the power method gives very good estimates of $\|L\|$ (usually within a factor of 10 or so) with only a few power iterations. Probabilistic results concerning the power method can be found in [10] and [36]. However, for brevity we omit a detailed discussion of these results, which are based on bounds derived from the Beta distribution.

One of the strengths of the power method is that for many problems the formation of $w = Lz$ is much cheaper than the initial evaluation of f. For example, in solving linear systems, the initial factorization needed to find $f(x)$ can be used in forming $w = Lz$ with considerable savings (see Example 3). Similarly, for any problem in which $f(x)$ is the solution to a problem that can be computed via a Newton method, the evaluation of $f(x + \delta z)$ is cheap in comparison to the effort needed to evaluate $f(x)$, because we can use $f(x)$ as a starting value in solving for $f(x + \delta z)$. For example, this is the case in solving for the roots of polynomials or more generalized problems such as solving an algebraic Riccati equation [32]. Since the matrix statistical methods described in this paper are also based on vectors of the form $w = Lz$, they inherit the efficiency of the power method estimators. Moreover, because the statistical methods do not require the domain and codomain (i.e., the space into which a function maps) spaces to be of equal dimension, they are more broadly applicable than the power method.

The 2-norm approach to conditioning is convenient because all of the sensitivity information about f at x is compressed into the scalar value $\|L\|$. However, we do pay a penalty for this compression since a large value of $\|L\|$ can disguise the fact that some of the entries of f may be insensitive to perturbations while others are not. For this reason, it makes sense to consider separately the sensitivity of each entry of f, especially since this entails no greater computational effort.

Close inspection of (73) reveals that the ith entry of f, which we denote by f_i, satisfies

$$f_i(x + \delta z) = f_i(x) + \delta v_i^T z + O(\delta^2), \tag{75}$$

where v_i^T is the ith row of L. In fact, the ith row of L is simply the gradient of the scalar function f_i. Because of this, we may apply the preceding results for scalar functions to the problem of estimating the norm of v_i^T for $1 \leq i \leq q$.

For example, to find the averaged statistical condition estimate for f at x, we need to evaluate f at $x + \delta z$, where z is selected uniformly and randomly from S_{n-1}. Next, form the Newton difference vector

$$w \equiv \frac{f(x + \delta z) - f(x)}{\delta} \tag{76}$$

for δ small and positive. Then the absolute value of the ith entry of w divided by E_n is the averaged statistical condition estimate for the gradient of f_i:

$$\zeta_i = \frac{|w_i|}{E_n}. \tag{77}$$

Repeating this procedure m times and then averaging the results gives the mth-order averaged statistical condition estimates.

Similarly, to form the subspace statistical estimates for $m \geq 1$, let $z^{(1)}, \ldots, z^{(m)}$ be orthonormal vectors chosen so that their span is uniformly and randomly selected from the space of all m-dimensional subspaces of $\mathbb{R}^n$, as described at the beginning of this section. Then evaluate $f(x + \delta z^{(i)})$ and form the Newton difference vectors

$$w^{(i)} \equiv \frac{f(x + \delta z^{(i)}) - f(x)}{\delta} \tag{78}$$

for $1 \leq i \leq m$. The subspace condition estimator for f_i is then given by

$$\nu_i(m) \equiv \frac{E_m}{E_n} \sqrt{\left(w_i^{(1)}\right)^2 + \cdots + \left(w_i^{(m)}\right)^2}. \tag{79}$$

Remark 6. If it is easier to form Lz directly rather than the Newton differences, then (76) should be replaced by $w = Lz$ and (78) should be replaced by $w^{(i)} = Lz^{(i)}$. This is illustrated in the following example.

Example 3. Consider the problem of solving a linear system of the form $Af = x$, where A and x are known and we want to find the vector $f = f(x)$. Since $f(x) = A^{-1}x$ and $f(x + \delta z) = f(x) + \delta A^{-1}z$, we see that $L = A^{-1}$ in (73). This means that the Newton difference approximation vectors $w^{(i)}$ in (76) and (78) can be found by solving

$$Aw^{(i)} = z^{(i)}. \tag{80}$$

The importance of this is that if the initial solution to $Af = x$ is carried out by using, say, an LU factorization, then the vector $w^{(i)}$ can be found in $O(n^2)$ flops. Since the LU factorization of A requires $O(n^3)$ flops, the condition estimation vectors $w^{(i)}$ can be computed very efficiently relative to the initial function evaluation. Similar remarks apply to the standard power method condition estimates that require the solution of $Aw^{(1)} = z^{(1)}$ followed by $A^T z^{(2)} = w^{(1)}$.

To illustrate this, let A be an Ostrowski matrix of order n [38]. That is, A is an upper triangular matrix with -1 on the main diagonal and all of the upper entries equal to 1. Even though all of the eigenvalues of A are equal to -1, this matrix is nearly singular if n is large,

with smallest singular value on the order of 2^{-n+1}. If we take $n = 30$, then the sensitivity of the first entry of the solution vector f is $\|\nabla f_1\| \approx 3.1 \times 10^8$. The sensitivity of the remaining entries decreases by a factor of about two per entry down to $\|\nabla f_{30}\| \approx 1.0$. Both the averaged and subspace statistical condition estimators perform well on this problem. For example, out of 100 runs for the subspace estimation method with $m = 2$, the greatest overestimation was 2.76 times the corresponding true condition number, and the worst underestimation was 0.057 for all 30 entries of the solution vector. For $m = 3$ the maximum overestimation out of 100 runs was a factor of 1.74 and the worst underestimation was a factor of 0.297.

Example 4. Although it simplifies the presentation of the underlying theory, it is not necessary to use the vec operator formulation to calculate the condition estimates. For example, consider the problem of estimating the sensitivity of the matrix exponential map $X \mapsto e^X$ where X is of order n_1. The number of input variables is then $n = n_1^2$.

The basic idea is to perturb the entries of X, find the exponential of the perturbed X, and then subtract the unperturbed exponential and divide by δE_n. The result is a matrix each of whose entries mirrors the sensitivity of the corresponding entry of e^X. For $m > 1$, this is repeated m times and the entries are combined to get the sensitivity estimate, either by averaging the absolute values of the entries in the case of the averaged statistical method, or by taking E_m times the square root of the sum of the squares of the entries in the case of the subspace statistical method.

More specifically, let $z^{(1)}, \ldots, z^{(m)}$ be orthonormal vectors of length $n = n_1^2$ such that their span is uniformly and randomly selected from the space of all m-dimensional subspaces of $\mathbb{R}^n$, as described at the beginning of this section. Now form the $n_1 \times n_1$ matrices $Z^{(i)} = \operatorname{unvec}(z^{(i)})$ by "unstacking" the vectors $z^{(i)}$. That is, $z^{(i)} = \operatorname{vec}(Z^{(i)})$. The matrix version $W^{(i)} = \operatorname{unvec}(w^{(i)})$ of the difference vectors $w^{(i)}$ in (78) is given by

$$W^{(i)} = (e^{X+\delta Z^{(i)}} - e^X)/\delta. \tag{81}$$

We then define the subspace condition estimators for each entry of e^X by

$$v_{ij}(m) \equiv \frac{E_m}{E_n} \sqrt{\left(W_{ij}^{(1)}\right)^2 + \cdots + \left(W_{ij}^{(m)}\right)^2}, \tag{82}$$

which is the matrix analog of (79). The averaged statistical estimators can be found by using the matrix analog of (77).

As a specific example, let

$$A = \begin{bmatrix} -131 & 19 & 18 \\ -390 & 56 & 54 \\ -387 & 57 & 52 \end{bmatrix},$$

which is Test Case 3 from [46]. This example showed that the exponential condition estimator in [46] can give conservative estimates that may be off by many orders of magnitude. For this problem, the estimator in [46] indicated that the computed exponential was accurate to at least four digits, whereas the actual number of accurate digits was 12. The conditioning of this problem was subsequently treated by a finite difference power method described in [34] that gave an accurate condition estimate at the cost of two extra exponential evaluations.

To see how well the statistical condition estimators work on this problem, let us first compute the exact answer for comparison. Let $|\nabla e^X|$ denote the matrix whose (i, j) entry is equal to the sensitivity of the (i, j) entry of e^X as measured by the norm of the gradient of the map $X \mapsto \left(e^X\right)_{ij}$. This matrix can be computed using finite differences

$$|\nabla e^X| = \begin{bmatrix} 39.9 & 8.4 & 5.2 \\ 146 & 30.8 & 18.9 \\ 136 & 28.7 & 17.5 \end{bmatrix}.$$

The matrix exponential is thus seen to be rather well conditioned for this example with the most sensitivity in the (2,1) position and the least sensitivity in the (1,3) position.

Using one extra function evaluation ($m = 1$) with the averaged statistical method gives the following estimate of $|\nabla e^X|$:

$$|\nabla e^X|_{\text{est}} = \begin{bmatrix} 25.0 & 4.7 & 3.7 \\ 96.7 & 18.4 & 14.2 \\ 79.8 & 14.9 & 12.0 \end{bmatrix}.$$

While this result is generally representative of the first-order estimates for this problem, it is probably better from a reliability standpoint to use more functions evaluations. For example, in 1000 runs using the subspace method with $m = 2$, we found that the ratio of estimated to true condition numbers ranged from a low of 0.011 to a high of 2.2. For $m = 3$, this range was 0.10 to 1.8.

The computational effort needed for the exponential condition estimates can actually be reduced by about half by using some results from [34]. In that work, it was shown that for a given initial matrix Z, the corresponding value of the matrix W in (81) is given by the integral representation of the exponential Fréchet derivative

$$W = \int_0^1 e^{(1-s)X} Z e^{sX} ds \; + \; O(\delta). \tag{83}$$

This integral can then be accurately approximated via the trapezoidal method by setting

$$\Omega_0 = \left(e^{X/2^p} Z + Z e^{X/2^p}\right)/2^{p+1} \tag{84}$$

and for $j = p, p-1, \ldots, 1$,

$$\Omega_{p+1-j} = \left(e^{X/2^j} \Omega_{p-j} + \Omega_{p-j} e^{X/2^j}\right). \tag{85}$$

Here p is the number of squarings used in the "scaling and squaring" method of evaluating e^X [46], and we assume that $\|e^{X/2^p} - I\| < \frac{1}{4}$ to ensure that Ω_p is equal to W to within a relative accuracy of 95% (see [34] for more details). In the scaling and squaring method, $e^{X/2^p}$ is approximated by using, say, a Padé approximation and the result is then squared p times to get e^X. This means that the matrices $e^{X/2^j}$ for $j = p, p-1, \ldots, 0$ are available sequentially, and the matrices Ω_{p+1-j} in (85) can be evaluated in step with the squaring. If we write

$$\Omega_{p+1-j} = \left(\left(e^{X/2^j} + \delta \Omega_{p-j}\right)^2 - e^{X/2^{(j-1)}} \right)/\delta \; + O(\delta), \tag{86}$$

then we can evaluate $\Omega_0, \ldots, \Omega_p$ in $p+1$ matrix multiplies. (The correspondence between (85) and (86) was discovered by noting that (85) is simply the Fréchet derivative of the matrix squaring map.) If we wish, we may evaluate as many matrices $W^{(i)}$ as we like in parallel with the squaring steps. Thus to get a subspace condition estimate of order m requires about $m(p+1)$ matrix multiplies. On the other hand, the effort to evaluate e^X is about $8 + p$ matrix multiplies. As noted in [34], a typical value of p is 6, in which case the subspace condition

estimate of order m requires about the same effort as $\frac{m}{2}$ function evaluations. Hence, the above procedure, which might be called a trapezoid-subspace method, is twice as efficient as the finite difference method described in [34]. The trapezoid-subspace method is also about twice as fast as the trapezoid-power method of [34] because of the sequential nature of the power method. The reason for this is that the power method iterates on the series in (85), and after the first pass through (85), which corresponds to the step $w = Lz$ described above in the vec formulation, the matrices $e^{X/2^j}$ must be regenerated on each pass through (85). Thus the trapezoid-power method uses $p+1$ matrix multiplies on the first pass through (85) and then $2p+1$ matrix multiplies on each subsequent pass. Here we assume that due to the variable nature of the number of squarings, a general purpose evaluator of e^X will not be set up to store all the matrices $e^{X/2^p}, e^{X/2^{p-1}}, \ldots, e^X$. If these matrices are stored, then the cost of the power method is the same as the subspace method.

We end this example by noting that Mathias [37] has shown that the trapezoidal approximation to the exponential Fréchet derivative can be extended to higher-order approximations, such as Simpson's rule, and that, except for the definition of Ω_0, the result is the same as (85). This means that these higher-order methods can also be combined with the subspace statistical method with the same efficiency as the trapezoid-subspace method.

Remark 7. So far we have been concerned with absolute rather than relative sensitivity, since the corresponding relative condition numbers can be obtained by dividing by $\|f(x)\|$ for overall relative sensitivity or by $|f_i(x)|$ for the relative sensitivity of the individual entries of f. However, there is some justification for considering other approaches. For example, suppose that we are interested in measuring the sensitivity of a function that takes two variables (x_1, x_2) into two values (f_1, f_2): $f(x_1, x_2) = (f_1(x_1, x_2), f_2(x_1, x_2))$, at the point $x_1^0 = 2$ and $x_2^0 = 100$. If we select a random perturbation on the unit circle of the form $(\cos\theta, \sin\theta)$, then the perturbed values $(x_1^0 + \cos\theta, x_2^0 + \sin\theta)$ can show up to 50% variation in the first component and only 1% variation in the second component. To correct this imbalance we can rescale the independent variables by defining new variables $y_1 = x_1/x_1^0$ and $y_2 = x_2/x_2^0$. We then work with the rescaled function $g(y) = f(x)$, i.e., $g_i(y_1, y_2) \equiv f_i(y_1 x_1^0, y_2 x_2^0)$ for $i = 1, 2$. Then $g(1, 1) = f(x_1^0, x_2^0)$ and random perturbations of y about $(1, 1)$ affect each component with the same level of variation. Using the chain rule we see that the Fréchet derivative of g at $(1, 1)$, which we denote by L_g, is equal to the Fréchet derivative L_f of f at (x_1^0, x_2^0) multiplied by the diagonal scaling matrix $D = \operatorname{diag}(x_1^0, x_2^0)$:

$$L_g = L_f D. \tag{87}$$

These ideas extend to higher dimensions and lead to what is usually called the mixed condition number [2], [9], [14], [25], [41]:

$$m(f, x^0) = \frac{\|L_f D\|}{\|f(x^0)\|}. \tag{88}$$

Similarly, if we wish to get relative sensitivity estimates for the individual entries of f, we can rescale g to form h where $h_i(y) = g_i(y)/f_i(x^0)$. This double scaling gives $h(1, 1, \ldots, 1) = (1, 1, \ldots, 1)$ and the Fréchet derivative of h at $(1, 1, \ldots, 1)$ is

$$L_h = F^{-1} L_f D, \tag{89}$$

where $F = \operatorname{diag}(f_1(x^0), f_2(x^0), \ldots)$. Taking the norm of L_h gives what is called the componentwise condition number of f at x^0:

$$c(f, x^0) = \|F^{-1} L_f D\|. \tag{90}$$

For a nice discussion of these concepts for linear systems see [24].

At least from the point of view of statistical condition estimates, we may work directly with the functions g or h using finite differences to approximate the absolute values of the entries of the Fréchet derivative matrices L_g or L_h, respectively. The only difference between this and the earlier statistical condition estimation is that we first scale the variables x to get g and scale both x and f to get h.

Example 5. Let $V(x)$ be the Vandermonde matrix associated with the vector x: $V_{ij} = x_j^{i-1}$. If we want to measure the mixed sensitivity at x^0, then we work with the scaled matrix function $G(y)$ where $G_{ij} = (y_j x_j^0)^{i-1}$ and measure the sensitivity of G about $y^0 = (1, 1, \ldots, 1)$. That is, we perturb y^0, evaluate G at the perturbed point, and then take the divided differences with the unperturbed matrix $G(y^0)$, as described above. This gives us a matrix whose entries are estimates of the corresponding 2-norms of the rows of L_g in (87). The results for the case $x^0 = (1, 2, 3, 4, 5, 6)$ are given in Table 5 which shows the lowest ratios of the estimated versus the exact mixed condition numbers taken over all of the entries of the matrix. (All of the high ratios were less than 3.0.) The low ratios for $\nu(1)$ reflect the fact that these ratios are taken over all 36 entries of G; in effect we are doing 36 scalar condition estimates. If this were a Bernoulli experiment with the number of trials t equal to 36 times the number of runs, say $t = 36r$, with a success being that the estimate is within a factor w of the true condition number, then by (66) the expected number of failures $E_f(t)$ for $\nu(1)$ in t trials would be approximately

$$E_f(t) = t\,\frac{2}{\pi w}. \tag{91}$$

For example, if we take $w = 3125 = 1/(3.2 \times 10^{-4})$ as in the second column of Table 5 with $r = 100$ runs, then the left-hand side of (91) gives the the expected number of failures as 0.73.

TABLE 5
Lowest ratios of estimated to exact mixed condition numbers.

Number of runs	Lowest ratios for $\nu(1)$	Lowest ratios for $\nu(2)$	Lowest ratios for $\nu(3)$
10	5.7×10^{-3}	0.0617	0.1699
100	3.2×10^{-4}	0.0209	0.0686
1000	6.8×10^{-5}	0.0097	0.0377

This heuristic argument points to an important conclusion: if we want the condition estimates of each entry of a matrix function to have a high probability of being near its respective true value, then we should use higher-order methods. The important question is then, how high an order do we need? While the Bernoulli trials reasoning used above has some drawbacks, a good argument can be given that it represents a worst-case scenario. If so, then the expected number of failures in r runs of a system with l function values is approximately bounded by $E_f(t, \nu(i))$, where $t = r \times l$ and

$$E_f(t, \nu(1)) \approx t\,\frac{2}{\pi w}, \tag{92}$$

$$E_f(t, \nu(2)) \approx t\,\frac{\pi}{4w^2}, \tag{93}$$

$$E_f(t, \nu(3)) \approx t\,\frac{32}{3\pi^2 w^3}, \tag{94}$$

$$E_f(t, \nu(4)) \approx t\,\frac{81\pi^2}{512w^4}. \tag{95}$$

More research is needed on this question, but for problems with a very large number of function values, we are usually interested in the sensitivity of some specific entries, in which case the above is not a problem, or in an overall estimate of conditioning, in which case an estimate of the norm of the Fréchet derivative is appropriate. In the latter case, the usual power method can be used, or the Frobenius norm of the Fréchet derivative can be estimated from the Frobenius norm of the individual sensitivity estimates [20]. This is illustrated in Table 6 for the mixed condition number estimates in the Vandermonde example. Here the norm estimates are remarkably accurate even for a large number of runs.

TABLE 6
Lowest ratios of estimated to exact Fréchet derivative Frobenius norm.

Number of runs	Lowest ratios for $\nu(1)$ Frob. norm est.	Lowest ratios for $\nu(2)$ Frob. norm est.	Lowest ratios for $\nu(3)$ Frob. norm est.
10	0.5560	0.6874	0.7448
100	0.3569	0.5235	0.6103
1000	0.2471	0.3838	0.4485

5. Conclusion. An analysis has been given of a new condition estimation method for differentiable matrix functions that is based on measuring the effect of random perturbations on the argument of the function. By using m such function evaluations, a condition estimate of order m is obtained, i.e., the probability that the estimate is off by a factor w is less than a constant times $1/w^m$. For example, using three function evaluations gives an estimate that has a chance of less than 1 in 7402 of being off by more than a factor of 20. Moreover, the "transpose-free" nature of this new method allows it to be applied to a broad range of problems in which the dimension of the domain and codomain spaces may be different. This is in sharp contrast to the more common power method condition estimation procedure, which is only applicable to maps between spaces of equal dimension. Illustrative examples have been given for a variety of problems including the classical problem of estimating the condition number of the matrix exponential map, as well as for problems involving mixed and componentwise condition estimation.

6. Appendix. This appendix gives a short discussion of the expected value function E_n and its evaluation for large n. For small n the value of E_n can be computed easily via (7) or (8). However, for larger values of n it is not convenient to use these formulas, and we would like to have simple approximations to E_n. There are at least two ways to obtain such approximations.

The first uses the relation

$$E_n\, E_{n+1} = \frac{2}{\pi n}, \tag{96}$$

which follows directly from (7) and (8). As noted previously (see the remark following Theorem 3.1), E_n decreases with n, i.e.,

$$E_n > E_{n+1}. \tag{97}$$

Together (96) and (97) imply the following.

LEMMA 6.1. *For E_n defined by* (7) *and* (8),

$$\sqrt{\frac{2}{\pi n}} < E_n < \sqrt{\frac{2}{\pi(n-1)}} \tag{98}$$

and

$$E_n = \sqrt{\frac{2}{\pi(n-\frac{1}{2})}} + O\left(n^{-3/2}\right). \tag{99}$$

Proof. By (96) and (97),

$$\frac{2}{\pi n} = E_n\, E_{n+1} < E_n^2.$$

Taking square roots of both sides gives

$$\sqrt{\frac{2}{\pi n}} < E_n.$$

Similarly, by replacing n with $n-1$ in (96), we find

$$\frac{2}{\pi(n-1)} = E_{n-1}\, E_n > E_n^2,$$

which completes the proof of (98). Standard arguments then give (99) from (98). □

The approximation

$$E_n \approx \sqrt{\frac{2}{\pi(n-\frac{1}{2})}} \tag{100}$$

is usually adequate for the purposes of condition estimation. Higher-order asymptotic approximations can be derived by using a multiplicative correction to the right-hand side of (100) of the form

$$\eta(n) = \left(\Sigma a_i n^{-i}\right)^{-1/2}.$$

The coefficients can then be chosen to satisfy the relationship (96) up to a given order of $\frac{1}{n}$ and to possibly improve the fit for small values of n as well. For example, a fourth-order approximation of this type is given by

$$E_n \approx \sqrt{\frac{2}{\pi(n-\frac{1}{2})}}\sqrt{\frac{184n^4}{1+23n+23n^2+184n^4}}, \tag{101}$$

which has a relative error of less than 10^{-5} for $n \geq 2$.

A second method of approximation involves writing E_n in terms of the gamma function [1], where $\Gamma(n) = (n-1)!$ for positive integers n

$$E_n = \frac{1}{2^{n-1}}\,\frac{\Gamma(n)}{\Gamma^2\left(\frac{n+1}{2}\right)}. \tag{102}$$

The right-hand side is then approximated by using

$$\Gamma(n) \approx e^{-n}n^n\sqrt{\frac{2\pi}{n}}\left(1+\frac{1}{12n}+\frac{1}{288n^2}-\frac{139}{51840n^3}-\frac{571}{2488320n^4}\right). \tag{103}$$

(This approximation, which is almost universally referred to as "Stirling's approximation," is apparently (see p. 2 in [7]) due to Laplace instead!) Using (103) in (102) gives an approximation to E_n with about the same accuracy as (101).

THE DAVIDSON METHOD*

M. CROUZEIX†, B. PHILIPPE‡, AND M. SADKANE§

Abstract. This paper deals with the Davidson method that computes a few of the extreme eigenvalues of a symmetric matrix and corresponding eigenvectors. A general convergence result for methods based on projection techniques is given and can be applied to the Lanczos method as well. The efficiency of the preconditioner involved in the method is discussed. Finally, by means of numerical experiments, the Lanczos and Davidson methods are compared and a procedure for a dynamic restarting process is described.

Key words. Davidson method, Lanczos method, Krylov space, preconditioner, eigenvalue, sparse matrices, eigenvectors

AMS subject classification. 65F15

1. Introduction.

To compute a few of the extreme eigenvalues and the corresponding eigenvectors of a large, sparse, and symmetric matrix, two classes of iterative methods are usually considered. Their common characteristic is to build a sequence of subspaces that contains, in the limit, the desired eigenvectors. The subspaces of the first class are of constant dimension; this class includes simultaneous iteration [1] and the trace minimization method [11]. In the second class of methods, the sequence is increasing, at least piecewise, since there often exists a restarting process that limits the dimension of the subspaces to a feasible size; the class includes the well-known Lanczos method which is based on Krylov subspaces [6]. This paper deals with another method of the same class, namely, the Davidson method.

Davidson published his algorithm in the quantum chemistry field [2] as an efficient way to compute the lowest energy levels and the corresponding wave functions of the Schrödinger operator. The original algorithm that computes the largest (or the smallest) eigenvalue of the matrix A can be expressed by the following algorithm where D stands for the diagonal of the matrix A.

Choose an initial unit vector v_1; $V_1 := [v_1]$;
for $k = 1, \ldots$ **do**
  Compute the interaction matrix $H_k := V_k^t A V_k$;
  Compute the largest (or the smallest) eigenpair (μ_k, y_k) of H_k;
  Compute the corresponding Ritz vector $x_k := V_k y_k$;
  Compute the residual $r_k := (\mu_k I - A)x_k$;
  if convergence **then** exit;
  Compute the new direction to be incorporated $t_{k+1} := (\mu_k I - D)^{-1} r_k$;
  Orthogonalize the system $[V_k; t_{k+1}]$ into V_{k+1};
end for

This algorithm looks like an algorithm of the Lanczos type with a diagonal preconditioning. When the dimension of the basis V_k becomes too large, the process restarts with the last Ritz vector as initial vector. In this paper we consider a more general method in the sense that

- several eigenpairs are sought at the same time;
- several vectors are incorporated in the basis at every step, leading to a block implementation;
- a general preconditioner is considered.

The block adaptation is important with supercomputers since it allows parallelism and efficient use of local memory.

Before analyzing the Davidson method, we formulate, in §2, a general convergence result for methods based on projection techniques; it can be applied to the Lanczos process as well. Consequences for the Davidson method are described in §3. Section 4 is devoted to a discussion on selecting the preconditioner and on the class of matrices on which the algorithm is the method of choice. In §5, numerical experiments illustrate the study and an improvement for the restarting process is proposed.

Notations and general assumptions. $A = (a_{ij})_{1\le i,\ j\le n}$ is a symmetric matrix supposedly large and sparse; $\lambda_1 \ge \cdots \ge \lambda_n$ are its eigenvalues and $u_1, \ldots, u_n$ a corresponding set of eigenvectors such that $u_i^t u_j = \delta_{ij}$ (Kronecker's symbol) for $1 \le i,\ j \le n$. The goal consists in computing the l ($l \ll n$) largest (or smallest) eigenpairs of A.

Throughout this paper, the symbol $\| \ . \ \|$ denotes the Euclidean norm and MGS stands for the modified Gram–Schmidt procedure. The orthogonal complement of the subspace spanned by the vectors $x_1, \ldots, x_k$ is denoted by $\{x_1, \ldots, x_k\}^\perp$.

$\rho(x) = x^t Ax/\|x\|^2$ is the Rayleigh quotient of the vector $x \ne 0$ and $R(x_1, \ldots, x_k) = \max_{x \in \mathrm{Span}(x_1,\ldots,x_k)} \rho(x)$ is the maximum of the Rayleigh quotient over the space spanned by the vectors $x_1, \ldots, x_k$.

$\{\mathcal{V}_k\}$ is a sequence of subspaces of $\mathbf{R}^n$ of dimension $n_k \ge l$ and V_k is a matrix whose column set is an orthonormal basis of $\mathcal{V}_k$. The matrix $H_k = V_k^t A V_k$ is called the Rayleigh or interaction matrix; it is of order n_k and its l largest eigenvalues are $\lambda_{k,1} \ge \cdots \ge \lambda_{k,l}$ with the corresponding eigenvectors $y_{k,1}, \ldots, y_{k,l}$, which constitute an orthonormal set of vectors in $\mathbf{R}^{n_k}$. The corresponding Ritz vectors $x_{k,1}, \ldots, x_{k,l}$ are defined by $x_{k,i} = V_k y_{k,i}$ for $i = 1, \ldots, l$. The reals $\lambda_{k,1}, \ldots, \lambda_{k,l}$ are called the Ritz values of A over $\mathcal{V}_k$.

2. Proof of convergence.

THEOREM 2.1. *Under the assumption*

$$x_{k,i} \in \mathcal{V}_{k+1} \quad \text{for } i = 1, \ldots l \quad \text{and} \quad k \in \mathbf{N},$$

the sequences $\{\lambda_{k,i}\}_{k\in\mathbf{N}}$ *are nondecreasing and convergent.*

Moreover, if, in addition, (i) *for any* $i = 1, \ldots, l$ *the set of matrices* $\{C_{k,i}\}_{k\in\mathbf{N}}$ *satisfies the following assumption: there exist* $K_1,\ K_2 > 0$ *such that for any* $k \in \mathbf{N}$ *and for any vector* $v \in \mathcal{V}_k^\perp$: $K_1 \| v \|^2 \le v^t C_{k,i} v \le K_2 \| v \|^2$;

(ii) *for any* $i = 1, \ldots, l$ *and* $k \in \mathbf{N}$, *the vector* $(I - V_k V_k^t) C_{k,i} (A - \lambda_{k,i} I) x_{k,i}$ *belongs to* $\mathcal{V}_{k+1}$, *then the limit* $\mu_i = \lim_{k\to\infty} \lambda_{k,i}$ *is an eigenvalue of* A *and the accumulation points of* $\{x_{k,i}\}_{k\in\mathbf{N}}$ *are corresponding eigenvectors.*

Proof. The first statement is a straight application of the well-known Courant–Fischer theorem [6] that characterizes the eigenvalues of a symmetric operator.

Let us prove the second statement. Let $r_{k,i} = (\lambda_{k,i} I - A) x_{k,i}$ and $w_{k,i} = (I - V_k V_k^t) C_{k,i} r_{k,i}$. Since the Ritz vectors are unit vectors and since $r_{k,i} = -(I - V_k V_k^t) A x_{k,i}$, the residuals $r_{k,i}$ belong to $\mathcal{V}_k^\perp$ and are uniformly bounded by $\|A\|$; hence the vectors $w_{k,i}$ are uniformly bounded as well. Moreover, since

$$w_{k,i}^t A x_{k,i} = -r_{k,i}^t C_{k,i} r_{k,i}, \tag{1}$$

and since the matrix $C_{k,i}$ is assumed to be positive definite on $\mathcal{V}_k^\perp$, we may ensure that $w_{k,i} = 0$ if and only if $r_{k,i} = 0$.

When $w_{k,i} \neq 0$, let us denote $v_{k,i} = w_{k,i} / \| w_{k,i} \|$ and $\Pi_k = [x_{k,1}, \ldots, x_{k,i}, v_{k,i}]$. Π_k is an $n \times (i+1)$ matrix whose columns are orthonormal. Consequently, the matrix $\Pi_k \Pi_k^t$ corresponds to the orthogonal projection onto a subspace of $\mathcal{V}_{k+1}$.

The matrix $\mathcal{H}_{k,i} = \Pi_k^t A \Pi_k$ has the following pattern:

$$\begin{pmatrix} \mu_{k,1} & & & \alpha_{k,1} \\ & \ddots & & \vdots \\ & & \mu_{k,i} & \alpha_{k,i} \\ \alpha_{k,1} & \ldots & \alpha_{k,i} & \beta_k \end{pmatrix},$$

where $\alpha_{k,j} = x_{k,j}^t A v_{k,i}$ for $j = 1, \ldots, i$ and $\beta_k = v_{k,i}^t A v_{k,i}$.

Let $\lambda_{k,1} \geq \lambda_{k,2} \geq \cdots \geq \lambda_{k,i} \geq \lambda_{k,i+1}$ be the eigenvalues of $\mathcal{H}_{k,i}$. Cauchy's interlace theorem and the optimality of the Rayleigh–Ritz procedure [6] ensure that

$$\mu_{k,j} \leq \lambda_{k,j} \leq \mu_{k+1,j}, \qquad j = 1, \ldots, i\ .$$

The Frobenius norm of the matrix $\mathcal{H}_{k,i}$ is

$$\sum_{j=1}^{i} \lambda_{k,j}^2 + \lambda_{k,i+1}^2 = 2 \sum_{j=1}^{i} \alpha_{k,j}^2 + \beta_k^2 + \sum_{j=1}^{i} \mu_{k,j}^2;$$

therefore

$$2 \sum_{j=1}^{i} \alpha_{k,j}^2 = \sum_{j=1}^{i} (\lambda_{k,j} - \mu_{k,j})(\lambda_{k,j} + \mu_{k,j}) + (\lambda_{k,i+1} - \beta_k)(\lambda_{k,i+1} + \beta_k).$$

Evaluating the trace of the matrix $\mathcal{H}_{k,i}$ by $\sum_{j=1}^{i} \mu_{k,j} + \beta_k = \sum_{j=1}^{i+1} \lambda_{k,j}$, we obtain

$$\begin{aligned} 2 \sum_{j=1}^{i} \alpha_{k,j}^2 &= \sum_{j=1}^{i} (\lambda_{k,j} - \mu_{k,j})(\lambda_{k,j} + \mu_{k,j} - \lambda_{k,i+1} - \beta_k) \\ &\leq 4 \| A \| \sum_{j=1}^{i} (\lambda_{k,j} - \mu_{k,j}), \end{aligned}$$

which implies

$$\alpha_{k,p}^2 \leq 2 \| A \| \sum_{j=1}^{i} (\mu_{k+1,j} - \mu_{k,j}) \quad \text{for} \quad p = 1, \ldots, i.$$

This last bound proves that $\lim_{k \to \infty} \alpha_{k,p} = 0$ for $p = 1, \ldots, i$. Therefore, since from (1), we have the relation

$$r_{k,i}^t C_{k,i} r_{k,i} = - \| w_{k,i} \| \alpha_{k,i}$$

so that $\lim_{k \to \infty} r_{k,i}^t C_{k,i} r_{k,i} = 0$. From the assumption of uniform positive definiteness of $C_{k,i}$ over ${\mathcal{V}_k}^{\perp}$, and since $r_{k,i} \in {\mathcal{V}_k}^{\perp}$, we may conclude that $\lim_{k \to \infty} r_{k,i} = 0$.

Let x_i be an accumulation point of the sequence $\{x_{k,i}\}$; then $\| x_i \| = 1$. From the definition of $r_{k,i}$, we obtain by continuity that $\mu_i x_i - A x_i = 0$. □

A straightforward application of the theorem may be obtained for a well-known version of the Lanczos method, namely, the block version with restarting process as defined in [8]. From

an initial block S of l vectors that constitute an orthonormal set, the matrix V_k is recursively built in such a way that its columns form an orthonormal basis of the Krylov space which is spanned by the columns of $S, AS, \ldots, A^{k-1}S$; this is done while $kl \leq m$, where m is a fixed maximum dimension. The Rayleigh matrix H_k, which is built from V_k, is a block tridiagonal matrix. When kl is larger than m, the process restarts with a new block S that corresponds to the Ritz vectors found with the last matrix V_k. Then, we claim the following corollary.

COROLLARY 2.2. *The block version of the Lanczos algorithm, used with restarting, converges.*

Proof. The Lanczos method corresponds to the situation where $C_{k,i}$ is the identity matrix and where $\mathcal{V}_k$ is the Krylov subspace generated from the block V_1. Therefore Theorem 2.1 may be applied. □

3. The generalized Davidson method.

3.1. Algorithm. The following algorithm computes the l largest (or smallest) eigenpairs of the matrix A; m is a given integer that limits the dimension of the basis.

Choose an initial orthonormal matrix $V_1 := [v_1, \ldots, v_l] \in \mathbf{R}^{n \times l}$;

for $k = 1, \ldots$ **do**

1. Compute the matrix $W_k := AV_k$;
2. Compute the Rayleigh matrix $H_k := V_k^t W_k$;
3. Compute the l largest (or smallest) eigenpairs $(\lambda_{k,i}, y_{k,i})_{1 \leq i \leq l}$ of H_k;
4. Compute the Ritz vectors $x_{k,i} := V_k y_{k,i}$ for $i = 1, \ldots, l$;
5. Compute the residuals $r_{k,i} := \lambda_{k,i} x_{k,i} - W_k y_{k,i}$ for $i = 1, \ldots, l$;
   if convergence **then** exit;
6. Compute the new directions $t_{k,i} := C_{k,i} r_{k,i}$ for $i = 1, \ldots, l$;
7. **if** $\dim(V_k) \leq m - l$
   then $V_{k+1} := \mathrm{MGS}(V_k, t_{k,1}, \ldots, t_{k,l})$;
   else $V_{k+1} := \mathrm{MGS}(x_{k,1}, \ldots, x_{k,l}, t_{k,1}, \ldots, t_{k,l})$;
   end if

end for

Steps (1)–(5) correspond to the classical Rayleigh–Ritz procedure [6]. We point out that only the last columns of W_k and H_k have to be computed at iteration k. At each iteration, the vectors $t_{k,i}$ are incorporated into the previous subspace. Unlike the Lanczos method, the Rayleigh matrix is dense.

The block size can be greater than l, and this may give faster convergence [3]. Since orthogonalization is performed at every iteration, too large a dimension for the basis implies prohibitive complexity. This is the reason for setting a maximum size for the basis. In §6, a dynamic choice for the restart point is described based on an index of efficiency for the iteration.

The selection of efficient preconditioners $C_{k,i}$ is studied in §4. As remarked in Corollary 2.2, the method becomes equivalent to the Lanczos method when the matrices $C_{k,i}$ are proportional to the identity matrix I. However, since in the Davidson method it is necessary to compute the Ritz vectors explicitly at every iteration, this version of the Lanczos algorithm has a much more expensive complexity than the regular version.

In the classical Davidson method, the preconditioners are built from the diagonal D of the matrix A: $C_{k,i} = (\lambda_{k,i} I - D)^{-1}$, which exists when $\lambda_{k,i}$ is not a diagonal entry of A. This choice is efficient when D is a good approximation of the matrix A in the sense that the matrix of eigenvectors of A is close to the identity matrix. More general preconditioners $C_{k,i} = (\lambda_{k,i} I - M)^{-1}$ have already been studied [5]; as for any preconditioning process,

the tradeoff consists in finding a matrix M that speeds up the convergence and keeps the complexity of the preconditioning step at a reasonable level. Finally, we mention that a block version of the Davidson method has already been introduced in [4].

Remark. It can be proved [10] that the accumulation points H of the sequence $\{H_k\}$ are of the form

$$H = \begin{pmatrix} \theta_1 & & & \mathbf{0} \\ & \ddots & & \\ & & \theta_l & \\ \mathbf{0} & & & E \end{pmatrix},$$

where $\theta_1 \geq \cdots \geq \theta_l$ are the l largest eigenvalues of H. Therefore, under the assumption that none of the θ_i, $i = 1, \ldots, l$ is an eigenvalue of the matrix E, the components of the corresponding eigenvectors of H are zero along the second block. As pointed out by Davidson [2], this fact can be used in practice to measure the convergence.

3.2. Convergence. In this section we assume that a diagonal preconditioner is used, i.e., $C_{k,i} = (\lambda_{k,i} - D)^{-1}$ for $i = 1, \ldots, l$, where D is the diagonal of A. We assume also that we require the largest eigenpair of A. The situation is analyzed in two different ways depending on the number of eigenpairs needed. The end of the section is devoted to an example of nonconvergence when the hypotheses of Theorem 2.1 are not satisfied.

3.2.1. Classical algorithm ($l = 1$). Theorem 2.1 ensures the convergence of the Davidson method when $(\lambda_{k,1} - D)^{-1}$ is positive definite. Since the sequence $\{\lambda_{k,1}\}$ is nondecreasing, it is sufficient to start with a vector v_1 such that $(\mu_{1,1} - D)^{-1}$ is positive definite. This can be ensured in the following way:

- Let i_o be the index of the largest diagonal entry of D. If the problem is not reducible into two smaller problems, there exists an index j_o such that $a_{i_o,j_o} \neq 0$.
- Let V_1 be the system $[e_{i_o}, e_{j_o}]$ built from the corresponding canonical vectors.

Since the matrix $H_1 = V_1^t A V_1$ is the matrix

$$\begin{pmatrix} a_{i_o,i_o} & a_{i_o,j_o} \\ a_{i_o,j_o} & a_{j_o,j_o} \end{pmatrix},$$

we have $\mu_{1,1} > a_{i_o,i_o} = \max_{1 \leq i \leq n} a_{i,i}$. In conclusion, the following bounds are obtained:

$$\|C_{k,1}\| \leq \frac{1}{\mu_{1,1} - a_{i_o,i_o}},$$
$$v^t C_{k,1} v \geq \alpha \|v\|^2 \text{ with } \alpha = \frac{1}{\max_{1 \leq i \leq n} (\mu_{1,1} - a_{i,i})}.$$

Hence Theorem 2.1 can be applied.

3.2.2. Block version ($l \neq 1$). The technique defined in the previous case can be used here to ensure that $(\lambda_{k,1} - D)^{-1}$ is positive definite; therefore the convergence is certain for the first eigenpair, but not for the others. However, it is possible to define another preconditioner $C_{k,i} = \operatorname{diag}(\mu_{k,i,1}, \ldots, \mu_{k,i,n})$ by $\mu_{k,i,j} = \min(|\lambda_{k,i} - a_{j,j}|^{-1}, M)$, where M is some large constant. With this preconditioning procedure, convergence is guaranteed for any initial system V_1.

Remark. The above choice of M is made only for the sake of the completion of the proof. In practice, the algorithm works regardless of this assumption.

3.2.3. Example of possible nonconvergence. The following example shows the importance of the assumption of positive definiteness for the preconditioning matrices. Let us assume that we look for the two largest eigenpairs ($l = 2$) of the matrix

$$A = \begin{pmatrix} 4 & 0 & 0 & 0 & 0 \\ 0 & -4 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 1 & 0 & 0 \end{pmatrix},$$

and that the process is initialized by $V_1 = [v_1, v_2]$, where

$$v_1 = \left(\sqrt{\tfrac{7}{8}}, \ \sqrt{\tfrac{1}{8}}, \ 0, \ 0, \ 0 \right)^t,$$

$$v_2 = \left(0, \ 0, \ \sqrt{\tfrac{3(5-\sqrt{5})}{20}}, \ \tfrac{\sqrt{3\sqrt{5}-5}}{2}, \ \sqrt{\tfrac{3(5-2\sqrt{5})}{10}} \right)^t.$$

We use diagonal preconditioner, i.e., $C_{k,i} = (\lambda_{k,1} - D)^{-1}$ and restart if $m \geq 4$. A straightforward computation shows that $(\lambda_{k,1}, x_{k,1}) = (3, v_1)$ and $(\mu_{k,2}, x_{k,2}) = (\frac{1}{2}, v_2)$ for all k, although neither 3 nor $\frac{1}{2}$ are eigenvalues of A. Of course, it is clear that the assumption of positive definiteness of the preconditioning matrices is violated.

Remarks. 1. Convergence of the Davidson method is automatic if restarting is not used, because eventually the subspace V_k fills up. The significance of Theorem 2.1 is that it proves convergence even when restarting is used.

2. Even when the sequence $\{r_{k,i}\}$ of the residuals converges to zero, it is not clear that the limit $\mu_i = \lim_{k\to\infty} \lambda_{k,i}$ is the ith eigenvalue of A, since we may create situations where the subspaces $\mathcal{V}_k$ remain orthogonal to a required eigenvector. However, it can be proved [10] that this situation would be unstable and is unlikely to happen in finite arithmetic; it may only increase the number of iterations significantly.

4. Quality of the preconditioner. In this section, we restrict the study to the case $l = 1$. We assume also that $C_{k,i} = C(\lambda_{k,i})$, where $C(\mu)$ satisfies a Lipschitz condition in a neighbourhood of the first eigenvalue of A. This is the situation when $C(\mu) = (\mu I - M)^{-1}$ with M symmetric with eigenvalues smaller than the largest eigenvalue of A.

Since $l = 1$ we replace the index $(k, 1)$ by k in the algorithm. To simplify the notations, we denote by λ, λ', and $\lambda_{\min}$ the first, second, and last eigenvalue of A, respectively. Let x be the eigenvector corresponding to λ ($\lambda \geq \mu_k > \lambda'$ is assumed). Let θ_k be the angle $\angle(x, x_k)$. We may write $x_k = \alpha_k x + \beta_k y_k$, where $\alpha_k = \cos(\theta_k)$, $\beta_k = \sin(\theta_k)$, and where y_k is a unit vector orthogonal to x. The first lemma relates the convergence of the sequences $\{\mu_k\}$, $\{\theta_k\}$, and $\{\|r_k\|\}$.

LEMMA 4.1. *The following relations are true*:

$$\sqrt{\frac{\lambda - \mu_k}{\lambda - \lambda_{\min}}} \leq |\sin(\theta_k)| \leq \sqrt{\frac{\lambda - \mu_k}{\lambda - \lambda'}}, \tag{2}$$

$$\frac{2\,\|r_k\|}{\sqrt{5}(\lambda - \lambda_{\min})} \leq |\sin(\theta_k)| \leq \frac{\|r_k\|}{\mu_k - \lambda'}. \tag{3}$$

Proof. The proof is based on the sin Θ theorem [6]. □

Lemma 4.2 provides an estimate for the effect of the preconditioning process within one iteration. We may define a unit vector z_k such that the system (x, y_k, z_k) is orthonormal and such that $t_k = \gamma_k x + \delta_k y_k + \sigma_k z_k$ for some scalars γ_k, δ_k, and σ_k.

LEMMA 4.2. *The preconditioning process implies that*

$$t_k = \beta_k C(\lambda)(\lambda I - A) y_k + u_k \quad \textit{where} \quad \|u_k\| = O(\beta_k^2) \tag{4}$$

and

$$0 \le \lambda - \mu_{k+1} \le K_1 (\lambda - \mu_k), \tag{5}$$

$$|\sin \theta_{k+1}| \le K_2 |\sin \theta_k|, \tag{6}$$

where

$$K_1 = \frac{(\frac{\sigma_k}{\delta_k})^2}{(\alpha_k - \frac{\beta_k \gamma_k}{\delta_k})^2 + (\frac{\beta_k \sigma_k}{\delta_k})^2} \frac{\lambda - \lambda_{\min}}{\lambda - \lambda'}, \tag{7}$$

$$K_2 = \frac{\left|\frac{\sigma_k}{\delta_k}\right|}{\sqrt{(\alpha_k - \frac{\beta_k \gamma_k}{\delta_k})^2 + (\frac{\beta_k \sigma_k}{\delta_k})^2}} \frac{\lambda - \lambda_{\min}}{\lambda - \lambda'}. \tag{8}$$

Proof. Since $t_k = C(\mu_k)(\mu_k I - A)x_k$, we may write

$$t_k = \alpha_k(\mu_k - \lambda)C(\mu_k)x + \beta_k C(\mu_k)(\mu_k I - A)y_k,$$

and therefore (2) and the Lipschitz condition on $C(\lambda)$ imply (4).

By definition, $\mu_{k+1} \equiv \rho(x_{k+1}) = R(v_1, \ldots, v_k, t_k)$. Let us consider the vector $s_k = x_k - (\beta_k/\delta_k)t_k$, which belongs to the subspace spanned by V_{k+1}. From the optimality of the Rayleigh–Ritz procedure, we have the bounds

$$\rho(x_{k+1}) \ge R(x_k, t_k) \ge \rho(s_k). \tag{9}$$

Since

$$s_k = \left(\alpha_k - \frac{\beta_k \gamma_k}{\delta_k}\right) x - \frac{\beta_k \sigma_k}{\delta_k} z_k, \tag{10}$$

we obtain from (9)

$$\rho(x_{k+1}) \ge \frac{(\alpha_k - \frac{\beta_k \gamma_k}{\delta_k})^2 \lambda + (\frac{\beta_k \sigma_k}{\delta_k})^2 z_k^t A z_k}{(\alpha_k - \frac{\beta_k \gamma_k}{\delta_k})^2 + (\frac{\beta_k \sigma_k}{\delta_k})^2}$$

$$\ge \lambda - \frac{(\frac{\beta_k \sigma_k}{\delta_k})^2}{(\alpha_k - \frac{\beta_k \gamma_k}{\delta_k})^2 + (\frac{\beta_k \sigma_k}{\delta_k})^2} (\lambda - \lambda_{\min}),$$

which implies

$$\lambda - \mu_{k+1} \le \beta_k^2 K_1 (\lambda - \lambda').$$

Since $\rho(x_k) = \alpha_k^2 \lambda + \beta_k^2 y_k^t A y_k$, we also have

$$\rho(x_k) \le \lambda - \beta_k^2 (\lambda - \lambda').$$

The relation (5) with (7) is obtained from the last two bounds.

From (2) and (5), we obtain

$$\begin{aligned}\sin^2\theta_{k+1} &\leq \frac{\lambda-\mu_{k+1}}{\lambda-\lambda'}\\ &\leq K_1\frac{\lambda-\mu_k}{\lambda-\lambda'}\\ &\leq K_1\frac{\lambda-\lambda_{\min}}{\lambda-\lambda'}\sin^2\theta_k,\end{aligned}$$

which proves the relation (6) with (8). □

The best situation, which cannot be obtained in practice, would be to find a $C(\lambda)$ that admits x as an eigenvector and therefore $\{x\}^\perp$ as an invariant subspace. If we assume

$$\| (C(\lambda)(\lambda I - A) - I) |_{\{x\}^\perp} \| = \epsilon < 1,$$

then

$$\|t_k - \beta_k y_k\| = O(\beta_k(\beta_k + \epsilon)),$$

which implies

$$\begin{aligned}\gamma_k &= O(\beta_k(\beta_k+\epsilon)),\\ \sigma_k &= O(\beta_k(\beta_k+\epsilon)),\\ \delta_k &= \beta_k + O(\beta_k(\beta_k+\epsilon)),\end{aligned}$$

and therefore

$$\begin{aligned}\frac{\gamma_k}{\delta_k} &= O(\beta_k+\epsilon),\\ \frac{\sigma_k}{\delta_k} &= O(\beta_k+\epsilon).\end{aligned}$$

From (7) and (8), we obtain the estimate

$$K_1 = \left(\frac{\sigma_k}{\delta_k}\right)^2\left(\frac{\lambda-\lambda_{\min}}{\lambda-\lambda'}\right)(1+O(\beta_k(\beta_k+\epsilon)))\,,$$

$$K_2 = \left|\frac{\sigma_k}{\delta_k}\right|\left(\frac{\lambda-\lambda_{\min}}{\lambda-\lambda'}\right)(1+O(\beta_k(\beta_k+\epsilon)))\,.$$

Note that if $\epsilon = 0$, convergence is obtained after one step, since in this case $\sigma_k = 0$ and thus x belongs to the subspace spanned by (x_k, t_k).

The usual way to define the preconditioning matrix is to consider a matrix M that approximates A and hence the matrix $C(\lambda) = (\lambda I - M)^{-1}$. Let us consider two extreme situations: $M = I$ or $M = A$. In the former case, the method becomes equivalent to the Lanczos method as has been pointed out, while in the latter case, the method fails since $t_k = x_k$ and $w_k = (I - V_k V_k^T)t_k = 0$. Therefore M has to be an approximation of A, but with its largest eigenvalue smaller than λ to ensure the positive definiteness of the matrix $(\mu_k I - M)^{-1}$ as discussed in Theorem 2.1. With such a matrix we have

$$t_k = (\mu_k I - M)^{-1}(\mu_k I - A)x_k \tag{11}$$

$$= \alpha_k(\mu_k - \lambda)(\mu_k I - M)^{-1}x + \beta_k(\mu_k I - M)^{-1}(\mu_k I - A)y_k \tag{12}$$

and

$$x_k - t_k = \alpha_k \left(I - (\mu_k - \lambda)(\mu_k I - M)^{-1}\right) x + \beta_k \left(I - (\mu_k I - M)^{-1}(\mu_k I - A)\right) y_k. \tag{13}$$

Expressions (12) and (13) show that when the Ritz pair (μ_k, x_k) starts to approximate the solution (λ, x), then, provided $(\mu_k I - M)^{-1}$ is bounded and $\left(I - (\mu_k I - M)^{-1}(\mu_k I - A)\right)|_{\{x\}^\perp}$ is small in comparison with $\left(I - (\mu_k - \lambda)(\mu_k I - M)^{-1}\right) x$, the components of t_k in the direction of x are small, whereas the other components of t_k remain about the same as those of x_k. Therefore the vector $x_k - t_k$ has small components except those in the direction of x, and hence constitutes an improvement over x_k. We expect to have an efficient preconditioner when the angle $\angle(x, z_k)$ is smaller than the angle $\angle(x, x_k)$, where $z_k = x_k - t_k$. Table 2 illustrates this point in the context of Example 5.1.

To have an easy-to-invert matrix, the appropriate choice for M may be the main diagonal of A or its tridiagonal part, when A is strongly diagonally dominant in the sense that its eigenvectors are close to the vectors of the canonical basis.

5. Experimental results and implementation.

5.1. Efficiency of the preconditioner. The usual experience is to consider that the better the preconditioner approximates the matrix, the faster is the convergence. The diagonal preconditioner is the easiest to use, but often a larger part of the matrix, as, for example, the tridiagonal part brings a better efficiency. The following example illustrates an extreme case of the benefit that may be obtained from a good preconditioner.

Example 5.1. A is the matrix of order $n = 1000$ such that

$$a_{i,j} = \begin{cases} i & \text{if} \quad i = j, \\ 0.5 & \text{if} \quad j = i+1 \text{ or } j = i-1, \\ 0.5 & \text{if} \quad (i, j) \in \{(1, n), (n, 1)\}, \\ 0 & \text{otherwise.} \end{cases}$$

Table 1 displays the sequence of the residuals corresponding to the largest eigenvalue for the Lanczos and Davidson methods with diagonal and tridiagonal preconditioning, where multA is the number of matrix-vector multiplications. The algorithm is started as discussed in §3.2.1, which means here that $V_1 = [e_n, e_1]$ is used as starting vectors for the Davidson method, and $v_1 = V_1 y_1$ where y_1 is the eigenvector corresponding to the largest eigenvalue of the matrix $V_1^T A V_1$ is the starting vector for the Lanczos method.

Table 2 shows, as claimed in §4, that the efficient preconditioner approximates much better $z_k = x_k - t_k$ to x than does x_k. The vectors x_k, t_k, and x have been defined in (12) and (13) in §4.

Unfortunately, this rule of thumb may fail when the evaluation of the quality of a preconditioner is limited to only the consideration of the norm of its difference with the original matrix. It is well known that when two matrices are close, their spectrum are also close, but not necessarily their eigenvectors. Example 5.2 illustrates such a situation.

Example 5.2. A is the matrix of order $n = 1000$ such that

$$a_{i,j} = \begin{cases} 4 & \text{if} \quad i = j, \\ -1 & \text{if} \quad j = i+1 \text{ or } j = i-1, \\ -1 & \text{if} \quad j = i+2 \text{ or } j = i-2, \\ 0 & \text{otherwise.} \end{cases}$$

The diagonal preconditioner is not considered since, as already stated, a constant diagonal is equivalent to no preconditioning, and therefore the Lanczos and Davidson methods become equivalent. Figure 1 plots the behaviour of the residuals corresponding to the largest eigenvalue for the Lanczos and Davidson methods with tridiagonal preconditioning. Both methods have poor convergence. For the Lanczos method, this may be explained by the smallness of the gap ratio of λ_1 [6]: $\lambda_1 - \lambda_2/\lambda_2 - \lambda_n \approx 2.33\ 10^{-8}$, whereas for the Davidson method, the poor performance of the preconditioner may be explained by the near orthogonality of the eigenvectors corresponding to the largest eigenvalue of A and the largest eigenvalue of its tridiagonal part (angle $\approx \frac{\pi}{2}$).

Example 5.3. We consider the matrix $LAP30$ from the Harwell–Boeing test collection. This matrix is of order 900, symmetric with 4322 nonzero elements in its lower part. It is originated from a nine-point discretisation of the Laplacian on the unit square with Dirichlet boundary conditions. The eigenvalues as computed by EISPACK are $\lambda_1 = \lambda_2 = 11.9590598 \geq \lambda_3 = \lambda_4 = 11.9286959 \geq \lambda_5 = \lambda_6 = 11.8784356 \geq \cdots \geq \lambda_{900} = 0.0614628$.

The diagonal of this matrix is constant. So the Davidson method with diagonal preconditioning is equivalent to no preconditioning. We computed its four largest eigenpairs using the Davidson method with tridiagonal preconditioning. In this version of Davidson's algorithm, we decided to restart whenever the maximum size of the basis reaches 40. And once an eigenvector is converged, we put it at the beginning of the basis so that all vectors are orthogonalized against it and continue with a reduced block size. Since eigenvalues/eigenvectors seldom converge at the same time, this strategy can prevent harm and additional work in the most slowly converging eigenvectors. The stopping criterion was satisfied when the residual norm of the sought eigenpair is less than 10^{-7}.

We also computed the four largest eigenpairs of LAP30 by the Lanczos method. The version of the Lanczos method used here is the Lanczos algorithm with selective orthogonalization

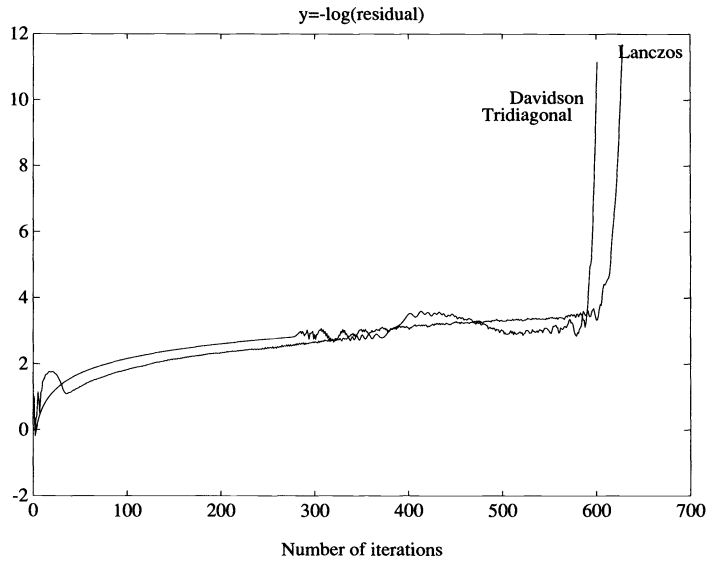

FIG. 1. *Example of a nonefficient preconditioner* (*Example* 5.2).

LASO2, developed by Parlett and Scott [8]. The blocksize, NBLOCK, for Lanczos was taken equal to four, and the number of decimal digits of accuracy desired in the eigenvalues, NFIG, was chosen equal to seven. The computations were carried out on one processor of a Cray 2 and the results are reported in Table 3. The error in eigenvalues and eigenvectors as given by Lanczos (LASO2) are also reported. Unfortunately, we do not have similar estimations for Davidson. But the residual norms and the execution times reveal that the Davidson method with tridiagonal preconditioning performs better on this example.

TABLE 3
Eigenpairs of the matrix LAP30 *by the Lanczos* (LASO2) *and Davidson methods.* (*Example* 5.3).

Method	Matrix–vector products	Time(sec)	Max residual norms	Max error in eigenvalues	Max error in eigenvectors
Lanczos	884	12.534	2.57 E−04	1.13 E−06	4.74 E−03
Davidson	607	11.487	9.36 E−08		

Example 5.4. In Table 4, we compare the Davidson method using diagonal preconditioning with the Lanczos method. (The version used is, again, the Lanczos algorithm with selective orthogonalization LASO2.) The matrix dealt with is of order 1000 and is generated randomly by setting its density of nonzero elements at 0.01. The nonzero off-diagonal entries are in the range $[-1, +1]$; the full diagonal entries are in the range [0, diagscal], where diagscal is a diagonal scaling factor to be varied. The four smallest eigenpairs are sought. The version of Davidson's algorithm uses the same technique concerning converged eigenvectors as described in Example 5.3. The stopping criterion was satisfied when the residual norm of the sought eigenpair is less than 10^{-7}. For the Lanczos algorithm, we chose the block size NBLOCK = 4, and the number of decimal digits of accuracy desired in the eigenvalues NFIG = 7. Experiments were run on a Cray 2. As expected the Davidson method becomes more efficient when the relative importance of the main diagonal increases. The efficiency of the Lanczos method is spectrum-dependent and is not sensitive to the dominance of the matrix.

TABLE 4
Davidson and Lanczos run time comparison (Example 5.4).

Diagonal factor	Time(sec)	
	Davidson	Lanczos
1	5.481	4.131
20	1.091	5.1531
40	0.844	11.574
60	0.657	9.959
80	0.537	16.062
100	0.400	11.171

5.2. Effect of the maximum size for the basis on the convergence. The easiest implementation for the restarting process consists in defining a fixed maximum size for the basis. The selection of an efficient value for m is difficult: too small a value increases the number of steps needed for convergence, whereas too large a value increases complexity and causes numerical problems.

Example 5.5 and Fig. 2 illustrate that the larger m is, the lower is the number of steps necessary to reach convergence.

Example 5.5. A is the matrix of order $n = 5000$ such that

$$a_{i,j} = \begin{cases} \text{if } i = j & \text{random in } [-10, +10], \\ \text{if } i \neq j & \begin{cases} \text{with probability } \alpha : & \text{random in } [-1, +1], \\ \text{ith probability } (1-\alpha) : & 0, \end{cases} \end{cases}$$

where $\alpha = 2 \times 10^{-3}$. There is an average of 11 nonzero entries per row. The eight largest eigenvalues ($l = 8$), that are sought, lie in the range [10.89, 11.57]. Convergence is obtained when the maximum of the L_1 norm of the residuals is smaller than $5. * 10^{-10}$. Experiments were run on an Alliant FX/80.

However, the value of m needs to be limited for three reasons.

1. The memory requirement is roughly proportional to nm, and this introduces a limit on m for large matrices.

2. The orthogonality of V_k is poorly maintained when the number of vectors in V_k is high (a loss of orthogonality plagues the convergence).

3. The complexity of the computation that is involved in one iteration increases with the number of vectors in V_k; therefore it may become too high compared to the benefit obtained from the decrease of the residual norms.

Actually, to be efficient, it is necessary to decide dynamically when to restart the process. The first reason implies a maximum for the size of the basis, but it can be more useful to restart before that limit. The second reason concerns a loss of orthogonality that is detected by an increasing sequence of the norms of the residuals; this may signal a necessary restarting. Let us now consider the detail of the computation involved in one iteration to define some index of efficiency that should indicate when it is worthwhile to restart.

The kth step since the last restart involves l multiplications by A and l applications of the preconditioning process that are of constant complexity. It involves also for the

computation of H_k:	kl^2n	flops;
diagonalization of H_k:	$O(k^3l^3)$	flops;
computation of the Ritz vectors:	kl^2n	flops;
computation of the residuals:	kl^2n	flops;
orthogonalization process:	$2kl^2n$	flops.

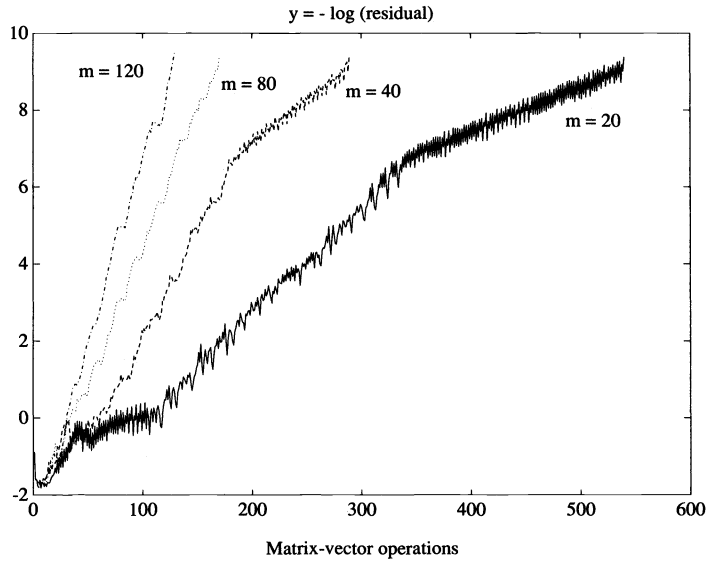

FIG. 2. *Influence of m on the convergence (Example* 5.5).

The diagonalization may be estimated as involving approximately $2k^3l^3$ flops. Let us denote by $C(k)$ the complexity involved at each iteration and by $\tau_k = \|R_k\|/\|R_{k-1}\|$ the local rate of convergence, where R_k stands for the matrix $[r_{k,1}, \ldots, r_{k,l}]$. The index of efficiency may be defined as

$$\mathcal{E}_k = \frac{1}{C_k \tau_k}.$$

By incorporating within the code a procedure that checks the variation of $\mathcal{E}_k$, the process can be restarted as soon as the index decreases significantly.

Example 5.6. The matrix under consideration is the same as in Example 5.5, where its eight largest eigenvalues and their corresponding eigenvectors are sought. Figure 3 plots the variation of the maximum of the residuals with respect to the number of iterations using dynamic restarting. We note in Fig. 3 that the convergence is reached within 140 iterations and 13 irregular restarts, while in Fig. 2 the same convergence with restarting at exactly every 20th step is reached within 500 iterations. This may be explained by the fact that dynamic restarting allows the algorithm to restart in due time, taking into account the quality of the basis for approximating the eigenvectors and the complexity involved during the iterations. The ratio $\tau_k = \|R_k\|/\|R_{k-1}\|$ also measures the changes in rate of convergence. In Table 5, the run with this dynamic restarting procedure is compared to the runs with a static restarting procedure for six values of the maximum block size (20, 40, 60, 80, 100, 120).

The efficiency of the dynamic restarting process is clearly seen in this example, since it corresponds to obtaining the optimum size of the basis automatically.

6. Conclusion. The Davidson method can be regarded as a preconditioned version of the Lanczos method. It appears to be the preferred method for some special classes of matrices, especially those where the matrix of eigenvectors is close to the identity. Although when used with a poor preconditioner it converges slowly, the Davidson method may overcome the Lanczos method tremendously.

PRECONDITIONING CAPACITANCE MATRIX PROBLEMS IN DOMAIN IMBEDDING*

WLODEK PROSKUROWSKI† AND PANAYOT S. VASSILEVSKI‡

Abstract. Various preconditioners for the capacitance matrix problems in domain imbedding (DI) are studied. Such preconditioners can be viewed as inverses of the preconditioners for the Schur complement domain decomposition (DD) methods. Preconditioning techniques based on the hierarchical basis (HB), the square root of $-d^2/ds^2$, and on the vector probing for solving the capacitance matrix problems using preconditioned conjugate gradient iterations are analyzed and tested numerically.

Key words. capacitance matrix, domain imbedding, domain decomposition, hierarchical basis, vector-probing, second order elliptic equation, finite elements

AMS subject classifications. primary 65N30, secondary 65F10

1. Introduction.

We consider second order elliptic problems in polygonal planar domains Ω with Dirichlet boundary conditions. Polygonal domain Ω is imbedded in a rectangle R on which a fast separable elliptic solver can be used. Hence we assume that the coefficients of the elliptic operator allow separation of variables. We study various preconditioners for the capacitance matrix in domain imbedding (DI). The purpose of the DI technique is that problems on irregular regions can be solved by minor modification of the software available for standard problems (i.e., on rectangular domains) thus avoiding more complicated data structure needed for the irregular domains.

This technique was proposed by Buzbee, Dorr, George, and Golub [10] as a direct procedure and studied later as an iterative process by Proskurowski and Widlund [26], [27], O'Leary and Widlund [23], Astrakhantsev [1], [2], Dryja [14], Börgers and Widlund [7], Nepomnyaschikh [22], and others. In Börgers and Widlund [7] a detailed study of the derivation and comparison of various capacitance matrix techniques and their practical performance was presented.

Similar approaches, namely to avoid complicated data structure and to take advantage of already available software for problems on standard domains, have been used in deriving efficient preconditioning techniques for elliptic problems on grids with local refinement, cf. McCormick and Thomas [20], McCormick [21], Bramble, Ewing, Pasciak, and Schatz [8], Ewing, Lazarov, and Vassilevski [17].

The essence of the capacitance matrix technique is that the solution to the original problem can be obtained as a low order modification to the problem on the imbedding rectangle. Domain decomposition (DD) and DI are usually complementary. DI is most efficient when a domain is a small perturbation of a larger separable region, while DD is more appropriate when a domain is a union of several separable regions. In DD, one is willing to repetitively solve subdomain problems. Not so in DI because the subdomains may be irregular. Instead, one is willing to repetitively solve a larger regular problem.

One can observe a duality between the capacitance matrix technique in DI and the Schur complement methods in DD. More precisely, the preconditioners in the first method can be viewed as the inverses of the preconditioners in the second one. Thus the DI technique can be seen from a new perspective that comes from DD: using the well-developed theory of the

preconditioners in DD we have immediate candidate preconditioners for the capacitance matrix problem that are straightforward to analyze. In the present paper we consider preconditioning techniques originally proposed for the DD Schur complement problems based on the square root of the one-dimensional Laplacian, on the hierarchical basis (HB), on the vector probing technique proposed by Keyes and Gropp [18] and Axelsson and Polman [3], as well as on the smoothing-correction technique proposed by Wittum [35], and apply them in the DI context.

The outline of the paper is as follows. In §2 we state the problem and derive the capacitance matrix equation following an earlier presentation by Dryja [14]. In §3 the preconditioners for the capacitance matrix are presented. Section 4 contains the numerical results for the model problem, as well as problems with anisotropic and discontinuous diffusion coefficients. Finally, in §5 some conclusions are drawn.

2. Problem formulation. Consider the following second order elliptic boundary value problem.

Given $f \in L^2(\Omega)$, find $u \in H_0^1(\Omega)$ such that

$$\mathcal{A}(u, \phi) = (f, \phi) \quad \text{for all } \phi \in H_0^1(\Omega),$$

where the open domain Ω is a planar polygon and

$$\mathcal{A}(u, \phi) = \int_\Omega \left\{ k_1(x) \frac{\partial u}{\partial x} \frac{\partial \phi}{\partial x} + k_2(y) \frac{\partial u}{\partial y} \frac{\partial \phi}{\partial y} + [\lambda_1(x) + \lambda_2(y)]\, u\phi \right\} dx\, dy. \tag{1}$$

The coefficients k_1, k_2 are assumed to be positive in Ω; and λ_1 and λ_2 are assumed to be nonnegative in Ω. Let R be a rectangle such that $R \supset \Omega$. In our model case shown in Fig. 1, Ω differs from the domain in which it is imbedded, $R = (0, 1)^2$, only along a connected segment. Generalization to more complicated domains Ω is straightforward, but its implementation may be more costly. The case of more general separable operators, nonsymmetric and indefinite, is treated in the forthcoming paper [25].

We assume that R can be triangulated on a right-angled triangular mesh $\mathcal{T}$ such that $\partial\Omega$ consists of edges of triangles from $\mathcal{T}$. This imposes some restriction on the polygonal form of Ω. A treatment of how to construct triangulations for the DI in a more general case was presented in Börgers and Widlund [7], see also Nepomnyaschikh [22]. Another possibility is to use patch local refinement in the neighborhood of the interface boundary across which Ω is imbedded in the rectangle R. Then one can use the efficient iterative elliptic solvers developed for problems on patched locally refined grids from McCormick and Thomas [20], McCormick [21], Bramble, Ewing, Pasciak, and Schatz [8], see also Ewing, Lazarov, and Vassilevski [17]. Note that these exploit fast elliptic solvers on the patches that are rectangles. However, at this point we shall not treat this subject more specifically.

So we assume that the boundary of Ω is aligned with the triangulation $\mathcal{T}$. Let W be the finite element space spanned by piecewise linear functions on $\mathcal{T}$, vanishing on ∂R and continuous in R. The subspace V of W consists of functions that have support in $\bar{\Omega}$.

Consider finally the bilinear form

$$\mathcal{B}(u, \phi) = \int_R \left\{ k_1(x) \frac{\partial u}{\partial x} \frac{\partial \phi}{\partial x} + k_2(y) \frac{\partial u}{\partial y} \frac{\partial \phi}{\partial y} + [\lambda_1(x) + \lambda_2(y)]\, u\phi \right\} dx\, dy.$$

We denote by A and B the stiffness matrices computed by the bilinear forms $\mathcal{A}(\cdot, \cdot)$ and $\mathcal{B}(\cdot, \cdot)$ using the finite element spaces V and W.

We note that problems with the matrix B can be solved very efficiently based on discrete variants of separation of variables (cf. Buzbee, Golub, and Nielson [9]), or on the odd-even

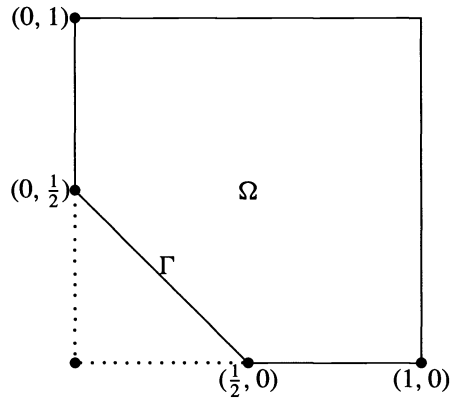

FIG. 1. *Polygon* Ω *imbedded in rectangle* $R = (0, 1)^2$.

cyclic reduction (cf. Swarztrauber [29]), or the generalized marching algorithm (cf. Bank and Rose [5] and Bank [6]). The cost is typically $O(N \log N)$ or $O(h^{-2} \log \frac{1}{h})$, where $N = O(h^{-2})$ is the number of nodes in $\mathcal{T}$ and h is the meshsize. A more refined implementation based on the fact that the right-hand sides of the problems to be solved on the rectangular imbedding domain are nonzero only on the interface boundary and based on the fact that the solution is also only needed on the interface will lead to a cost of $O(N) = O(h^{-2})$ operations, cf. Banegas [4], Kuznetsov [19], and Proskurowski [24].

The capacitance matrix method (CMM) relies on efficient solvers for problems with the matrix B. Next we derive the CMM in algebraic (i.e., matrix–vector) form following an earlier presentation of Dryja [14].

The original problem in Ω after discretization takes the form

$$A\mathbf{x}_1 = \mathbf{b}_1. \tag{2}$$

After imbedding Ω in R we consider the problem

$$B \begin{bmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \\ \mathbf{y}_0 \end{bmatrix} = \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ \mathbf{b}_0 \end{bmatrix} \begin{matrix} \} \\ \} \\ \} \end{matrix} \begin{matrix} \Omega \equiv \Omega_1, \\ R \setminus \bar{\Omega} \equiv \Omega_2, \\ \Gamma, \end{matrix}$$

where $\Gamma = \partial\Omega \setminus \partial R$ is the interface boundary across which Ω is imbedded in R. Note that B admits the following 3×3 DD block form

$$B = \begin{bmatrix} B_{11} & 0 & B_{10} \\ 0 & B_{22} & B_{20} \\ B_{01} & B_{02} & B_{00} \end{bmatrix} \begin{matrix} \} \\ \} \\ \} \end{matrix} \begin{matrix} \Omega_1, \\ \Omega_2, \\ \Gamma. \end{matrix}$$

Finally, note that $B_{11} = A$. Consider now the following extended matrix

$$A^E = \begin{bmatrix} A & 0 & B_{10} \\ 0 & B_{22} & B_{20} \\ 0 & 0 & I \end{bmatrix} \begin{matrix} \} \\ \} \\ \} \end{matrix} \begin{matrix} \Omega_1, \\ \Omega_2, \\ \Gamma. \end{matrix}$$

The problem $A\mathbf{x}_1 = \mathbf{b}_1$ can be rewritten as

$$A^E \begin{bmatrix} \mathbf{x}_1 \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ 0 \end{bmatrix}. \tag{3}$$

We seek $\mathbf{w}_0$ defined on Γ, such that

$$\mathbf{x}^E = B^{-1} \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ \mathbf{b}_0 \end{bmatrix} + B^{-1} \begin{bmatrix} 0 \\ 0 \\ \mathbf{w}_0 \end{bmatrix}$$

is the solution of (3). Then

$$\begin{aligned} 0 &= \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ 0 \end{bmatrix} - A^E \mathbf{x}^E \\ &= \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ 0 \end{bmatrix} - A^E \left\{ B^{-1} \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ \mathbf{b}_0 \end{bmatrix} + B^{-1} \begin{bmatrix} 0 \\ 0 \\ \mathbf{w}_0 \end{bmatrix} \right\}. \end{aligned} \tag{4}$$

Note now that

$$B = \begin{bmatrix} I & 0 & 0 \\ 0 & I & 0 \\ B_{01}B_{11}^{-1} & B_{02}B_{22}^{-1} & S \end{bmatrix} \begin{bmatrix} B_{11} & 0 & B_{10} \\ 0 & B_{22} & B_{20} \\ 0 & 0 & I \end{bmatrix} \begin{matrix} \} \ \Omega_1, \\ \} \ \Omega_2, \\ \} \ \Gamma, \end{matrix}$$

where

$$S = B_{00} - \sum_{i=1}^{2} B_{0i} B_{ii}^{-1} B_{i0}$$

is the so-called DD Schur complement of B. This shows that

$$B = \begin{bmatrix} I & 0 & 0 \\ 0 & I & 0 \\ B_{01}B_{11}^{-1} & B_{02}B_{22}^{-1} & S \end{bmatrix} A^E.$$

Hence

$$A^E B^{-1} = \begin{bmatrix} I & 0 & 0 \\ 0 & I & 0 \\ \star & \star & S^{-1} \end{bmatrix}, \tag{5}$$

where "$\star$," here and further, denotes submatrix or subvector that is of no immediate interest. From (4) and (5) we get

$$0 = \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ 0 \end{bmatrix} - \begin{bmatrix} I & 0 & 0 \\ 0 & I & 0 \\ \star & \star & S^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ \mathbf{b}_0 + \mathbf{w}_0 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \star \end{bmatrix}.$$

Thus, by construction, we have that the first two equations of (4) are satisfied. Hence we need to choose $\mathbf{w}_0$ such that the last equation of (4) is zero; i.e.,

$$\left(B^{-1} \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ \mathbf{b}_0 \end{bmatrix} \right) \Bigg|_\Gamma + \left(B^{-1} \begin{bmatrix} 0 \\ 0 \\ \mathbf{w}_0 \end{bmatrix} \right) \Bigg|_\Gamma = 0.$$

Since

$$B^{-1} \begin{bmatrix} 0 \\ 0 \\ \mathbf{w}_0 \end{bmatrix} = \begin{bmatrix} \star \\ \star \\ S^{-1}\mathbf{w}_0 \end{bmatrix}, \tag{6}$$

we obtain the following equation for $\mathbf{w}_0$,

$$S^{-1}\mathbf{w}_0 = - \left(B^{-1} \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ \mathbf{b}_0 \end{bmatrix} \right) \Bigg|_\Gamma .$$

Let

$$C = S^{-1} = \left(B_{00} - \sum_{i=1}^{2} B_{0i} B_{ii}^{-1} B_{i0} \right)^{-1}. \tag{7}$$

C is called the capacitance matrix. Note that C is symmetric and positive definite and that the actions of C are readily available since for any given vector $\mathbf{v}_0$ on Γ,

$$C\mathbf{v}_0 = \left(B^{-1} \begin{bmatrix} 0 \\ 0 \\ \mathbf{v}_0 \end{bmatrix} \right) \Bigg|_\Gamma .$$

Note however that the actions of S on vectors are not generally readily available. This is because the computation of $S\mathbf{v}_0$ for a given vector $\mathbf{v}_0$ on Γ involves the action of $B_{11}^{-1} = A^{-1}$ when computing the product $B_{01}B_{11}^{-1}B_{10}\mathbf{v}_0$ (see (7)) and A is the stiffness matrix in the irregular, by assumption, original domain Ω.

We now present the algorithm for solving problem (2) based on the capacitance matrix method. For any given vector $\mathbf{z}$ we use the decomposition

$$\mathbf{z} = \begin{bmatrix} \mathbf{z}_1 \\ \mathbf{z}_2 \\ \mathbf{z}_0 \end{bmatrix} \begin{matrix} \} \ \Omega_1, \\ \} \ \Omega_2, \\ \} \ \Gamma. \end{matrix}$$

ALGORITHM CMM

(i) Solve the problem

$$B\mathbf{y} = \begin{bmatrix} \mathbf{b}_1 \\ 0 \\ \mathbf{b}_0 \end{bmatrix} \begin{matrix} \} \ \Omega_1, \\ \} \ \Omega_2, \\ \} \ \Gamma. \end{matrix}$$

(ii) Iterate for $\mathbf{w}_0$

$$C\mathbf{w}_0 = -\mathbf{y}_0.$$

(iii) Solve the problem

$$B\mathbf{v} = \begin{bmatrix} 0 \\ 0 \\ \mathbf{w}_0 \end{bmatrix}.$$

(iv) The final solution of (2) is

$$\mathbf{x}_1 = \mathbf{y}_1 + \mathbf{v}_1.$$

3. Preconditioners for C. From now on we focus on step (ii) of Algorithm CMM solved by the preconditioned conjugate gradient (PCG) iterations and more precisely on finding a good preconditioner for the capacitance matrix C.

Recalling the relation (7) we see that any available preconditioner M_{DD} for S from the well-developed DD theory such that its action is readily computable (not necessarily the action of its inverse) will give a good preconditioner $M = M_{DD}^{-1}$ for $C = S^{-1}$.

We consider the following preconditioners.

1. *Dryja's preconditioner.* Let M be the matrix corresponding to the discretization of $-d^2/ds^2$, the second derivative along Γ. Then $M^{1/2}$ is readily available (based on the discrete FFT). In terms of preconditioning, $M^{-1/2}$ is a preconditioner that is spectrally equivalent to C. This is the case since $M^{1/2}$ is spectrally equivalent to $S = C^{-1}$. For details cf. Dryja [15], [16].

2. *Hierarchical Basis* (HB). Using the fact that (cf. Smith and Widlund [28] or Vassilevski [33])

$$\text{Cond}\left[J^T S J\right] = O(1 + \log^2 h),$$

where J is the transformation matrix from the HB to the nodal basis (on Γ only), we obtain that

$$\text{Cond}(J^{-1}S^{-1}J^{-T}) = \text{Cond}(J^{-1}CJ^{-T}) = O(1 + \log^2 h),$$

i.e., $J^{-1}CJ^{-T}$ is a much better conditioned matrix than C. Note that the actions of J^{-1} and J^{-T} are readily computable, cf., e.g., Yserentant [34].

3. *Vector probing* (A). If the coefficients of the bilinear form $\mathcal{A}(\cdot, \cdot)$ have strong variation, then, in practice, a choice of preconditioners based on algebraic vector-probing techniques might be preferable. For example, we can consider a symmetric tridiagonal matrix T defined on Γ by requiring for two vectors $\mathbf{v}_0^{(1)}$, $\mathbf{v}_0^{(2)}$ that

$$T\mathbf{v}_0^{(i)} = C\mathbf{v}_0^{(i)}, \quad i = 1, 2. \tag{8}$$

The choice of T to be tridiagonal is motivated by the fact that away from its main diagonal C has certain decay rate since S is approximately tridiagonal; for details cf. Keyes and Gropp [18], Axelsson and Polman [3], Chan and Mathew [11], and Chan, Mathew, and Shao [12]. For decay rates of inverses of band matrices, cf. Demko, Moss, and Smith [13] and Vassilevski [31]. The existence of such tridiagonal matrix T satisfying (8) is shown in Wittum [35] for a general choice of the probing vectors and in Axelsson and Polman [3] and Keyes and Gropp [18] for certain particular probing vectors. We consider a preconditioner T that corresponds to the following vectors proposed in Keyes and Gropp [18],

$$\mathbf{v}^{(1)} = \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \\ \vdots \end{bmatrix}, \qquad \mathbf{v}^{(2)} = \begin{bmatrix} 0 \\ 1 \\ 0 \\ 1 \\ \vdots \end{bmatrix}.$$

4. *Vector probing* (B). We also choose the following preconditioner M based on the smoothing-correction technique proposed by Wittum [35] and defined by

$$M^{-1} = T_1 + T_2, \tag{9}$$

where the symmetric tridiagonal matrices T_s, $s = 1, 2$, are defined by their actions on two prescribed vectors. Namely, T_s is defined by the equations

$$\mathbf{v}_0^{(r)} = T_s C \mathbf{v}_0^{(r)}, \quad r = 1, 2,$$

for the following probing vectors:

$$\mathbf{v}_0^{(1)} = \left\{ \sin\left(\frac{\nu_s i\pi}{n_b + 1} \right) \right\}_{i=1}^{n_b},$$

$$\mathbf{v}_0^{(2)} = \left\{ \sin\left(\frac{(\nu_s + 1) i\pi}{n_b + 1} \right) \right\}_{i=1}^{n_b}.$$

Here n_b is the number of the interface nodes on Γ; ν_s for $s = 1, 2$ are properly chosen frequencies corresponding to the so-called smooth and rough components, cf. Wittum [35]. In Wittum [35] it has also been shown that there is a unique symmetric tridiagonal matrix T that has the same actions on two given vectors as the actions of another symmetric matrix on those vectors (the vectors should satisfy some linear independence property, however). We remark that preconditioner (9) is an additive version of the smoothing-correction scheme, which is a stationary iterative method as proposed in Wittum [35]. We modify it to be used as a preconditioner in the CG method.

4. Numerical experiments. We report some numerical experiments performed on a Sparc 2 station in double precision FORTRAN. A double precision version of the subroutines BLKTRI and SINT from the current version of [30] obtained via Netlib were used for solving separable problems in a rectangle and as a real FFT, respectively.

In all the experiments as the polygonal region Ω, we chose the unit square $R = (0, 1)^2$ with the corner $\{(x, y) : y < \frac{1}{2} - x\}$ cut off, and $\lambda_1 = 0$ and $\lambda_2 = 0$ in (1).

The exact solution was $u(x, y) = \sin x \sin y$ with the corresponding values for the boundary condition and the source function f. We remark that the exact solution u is not actually

in $H_0^1(\Omega)$, but this is not a problem since after the discretization the boundary conditions are eliminated in the right-hand side $\mathbf{b}_1$ of the linear algebraic problem (2). The stopping criterion for the PCG iterations to solve the capacitance matrix equation (step (ii) in Algorithm CMM) here, and elsewhere in the experiments, was when the energy norm of the preconditioned residuals decreased by 10^{-6} from its initial value (with the zero initial guess for the solution $\mathbf{w}_0$). We denote the number of interior meshpoints in each coordinate direction by n and the number of meshpoints on the separator Γ, equal to the dimension of the capacitance matrix, by n_b. By *iter* we denote the number of PCG iterations. Note that the dominant cost of the whole algorithm is the cost of the separable solver BLKTRI called (*iter* + 2) times while the cost of the preconditioners is negligible.

Recall that the preconditioners, described in detail in §3, are:

(1) square root of the finite difference analog of $-(d^2/ds^2)$ along Γ,

(2) hierarchical basis,

(3) vector probing (*A*), ([18]),

(4) vector probing (*B*), ([35] in the form (9)).

The first example corresponded to the model bilinear form (1) with the coefficients chosen as

(Problem 1) $$k_1(x) = e^x, \qquad k_2(y) = e^y.$$

127	0.462D−06	0.253D−06	63	4	16.650
255	0.116D−06	0.628D−07	127	5	95.580

As the results in Table 1 indicate, the rate of convergence of the PCG iterations was essentially independent on the parameter of discretization $h = \frac{1}{n+1}$. The solution was clearly second order accurate, $O(h^2)$, here as well as in the remaining experiments; thus we do not report further on this item.

For comparison in Table 2 we include the results obtained without any preconditioner for the same problem and for the case with $k_1(x) = k_2(y) = 1$, i.e., for Δ (the Laplacian).

TABLE 2
Number of iterations for Problem 1 *and the Laplace operator* Δ *without preconditioning.*

n_b	Problem 1	Δ	$\Delta, u = random$
15	11	7	10
31	15	8	12
63	20	10	17
127	26	11	21

It appears that the convergence rate depends only weakly on n_b, particularly for the Laplacian and smooth solutions. It is known, e.g., Dryja [14], that in general $\text{Cond}(S) = O(\frac{1}{h})$, hence $\text{Cond}(C) = \text{Cond}(S^{-1}) = O(\frac{1}{h})$. This is very clearly seen for the example shown in the second and fourth columns of Table 2 (the number of iterations increased by about a factor of $\sqrt{2}$ as the number of meshpoints was doubled).

Next we tested anisotropic diffusion functions,

(Problem 2) $$k_1(x) = ce^x, \qquad k_2(y) = e^y,$$

where $c = 1, 10, 100$, and 1000 (because of symmetry results with $c := \frac{1}{c}$ were identical, here as well as in Tables 4, 5, and 6).

TABLE 3
Problem 2 and Preconditioner 1; number of iterations in case of anisotropy.

n_b	$c = 1$	$c = 10$	$c = 100$	$c = 1000$
15	3	6	10	14
31	4	7	11	18
63	4	7	12	20
127	5	7	12	22

Although the rate of convergence of the PCG iterations (see Table 3) slows down significantly with increased anisotropy, its behavior still suggests asymptotic independence for sufficiently high discretization parameter. (Note that $iter \leq n_b$.)

Next we proceed with the preconditioner based on a change to the hierarchical basis. The results (number of iterations) when we varied the anisotropy constant c are shown in Table 4.

TABLE 4
Problem 2 and Preconditioner 2; number of iterations in case of anisotropy.

n_b	$c = 1$	$c = 10$	$c = 100$	$c = 1000$
15	9	12	15	16
31	12	16	21	27
63	15	20	26	39
127	18	23	32	47

The results for problems with anisotropy with Preconditioner 3 based on the vector-probing technique defined by (8) are shown in Table 5. Similarly, the performance of Preconditioner 4 based on Wittum's smoothing-correction scheme defined by (9) is shown in Table 6. The specific frequencies ν_1, ν_2 which are used are also shown. These last two preconditioners showed very robust performance for problems with anisotropy. The preconditioner based on the two frequencies is not well understood although its performance is very satisfactory for properly chosen frequencies (so far, these were chosen experimentally). For more details cf. Wittum [35].

TABLE 5
Problem 2 and Preconditioner 3; number of iterations in case of anisotropy.

n_b	$c = 1$	$c = 10$	$c = 100$	$c = 1000$
15	14	13	11	11
31	18	17	14	13
63	20	20	18	16
127	25	24	22	21

TABLE 6
Problem 2 and Preconditioner 4; number of iterations in case of anisotropy.

n_b	$\nu_1,\ \nu_2$	$c = 1$	$c = 10$	$c = 100$	$c = 1000$
15	2, 4	9	7	6	4
31	3, 7	8	8	7	5
63	5, 15	8	9	9	5
127	10, 30	9	11	10	7

The final set of experiments (see Tables 7–10) was carried out for the discontinuous diffusion function in one direction:

(Problem 3)
$$k_1(x) = \begin{cases} ce^x & \text{for } x \geq 0.25, \\ e^x & \text{for } x < 0.25, \end{cases} \qquad k_2(y) = e^y.$$

Note that the line of discontinuity cuts the separator Γ. To ensure the continuity of the flux at the line of discontinuity of the diffusion function we chose the exact solution to be $u(x, y) = \sin(2\pi x)\sin(2\pi y)$. Note also that in the subdomain $\{(x, y)|x > 0.25\}$, Problem 3 is anisotropic like Problem 2.

TABLE 7
Problem 3 and Preconditioner 1; number of iterations in case of discontinuous coefficients.

n_b	$c = 1$	$c = 10$	$c = 100$	$c = 1000$	$c = 0.1$	$c = 0.01$	$c = 0.001$
15	4	10	12	15	10	12	12
31	4	10	14	20	11	18	20
63	4	10	15	21	12	20	33
127	5	10	15	23	12	21	36

Even in the case of discontinuous coefficients the rate of convergence of the PCG iterations is still essentially independent of the parameter of discretization, except for $c = 0.001$. At the same time, the convergence rate gradually deteriorates with the increased discontinuity.

TABLE 8
Problem 3 and Preconditioner 2; number of iterations in case of discontinuous coefficients.

n_b	$c = 1$	$c = 10$	$c = 100$	$c = 1000$	$c = 0.1$	$c = 0.01$	$c = 0.001$
15	9	13	15	15	13	13	14
31	12	17	25	27	17	23	25
63	15	20	31	42	21	30	42
127	18	23	36	56	24	36	57

For c=1, i.e., for continuous coefficients, one can observe the linear increase of the number of iterations with $\log(n_b + 1)$, the number of refinement levels as predicted by the theory. We saw that the HB preconditioner deteriorated with the anisotropy. This is also the case for the problem with discontinuous diffusion coefficients. Thus a proper stabilization of the HB-based preconditioner is worth providing. One possibility would be to use a hybrid multilevel iteration as proposed in [32].

The "$\star$" in Table 10 stands for nonpositive definiteness of Preconditioner 4. This is one of the difficulties with Wittum's smoothing-correction scheme when used as a preconditioner; namely, that the positive definiteness of the matrices constructed by probing is not a priori guaranteed.

TABLE 9
Problem 3 and Preconditioner 3; number of iterations in case of discontinuous coefficients.

n_b	$c = 1$	$c = 10$	$c = 100$	$c = 1000$	$c = 0.1$	$c = 0.01$	$c = 0.001$
15	14	13	15	15	14	14	15

5. Conclusions. Preconditioner 1 is the best for operators with smooth coefficients ($c = 1$ in all tables), but its performance deteriorates gradually with increased anisotropy.

For Preconditioner 2 a similar but even faster deterioration (aggravated by its dependence on the size of the problem, n_b) is observed. This preconditioner needs stabilization of the growth of the condition number. One possible approach that needs further investigation is to use more complicated hybrid multilevel iterations as proposed in Vassilevski [32]. This would require additional solutions with a sequence of matrices $\{B^{(k)}\}$ obtained by discretizations of the separable elliptic problem in the rectangle R on a sequence of uniformly refined meshes.

In contrast, Preconditioners 3 and 4 based on vector probing exhibit a slightly improved performance with increased anisotropy. At the same time Preconditioner 3 shows deterioration in condition number with increasing n_b (for fixed coefficients in the operator) and thus cannot be recommended in this context. On the other hand, Preconditioner 4 shows great promise in such situations. Its properties must be better understood to allow for automatic optimization of the smoothing-correcting frequencies, and thus making its performance fully robust.

Acknowledgment. The authors thank the referees for the suggestions and remarks that led to an improved presentation of the paper.

A FAMILY OF QUASI-MINIMAL RESIDUAL METHODS FOR NONSYMMETRIC LINEAR SYSTEMS*

CHARLES H. TONG†

Abstract. The quasi-minimal residual (QMR) algorithm by Freund, Gutknecht, and Nachtigal [*Research Institute for Advanced Computer Science Tech. Report* 91.09, NASA Ames Research Center, Moffett Field, CA; *Numer. Math.*, 60 (1991), pp. 315–339], in addition to its ability to avoid breakdowns, also improves the irregular convergence behavior encountered by the biconjugate gradient (BiCG) method through the incorporation of quasi minimization. This paper studies this quasi-minimal residual approach applied, for simplicity, to the nonlook-ahead version of the QMR method. In particular, a family of quasi-minimal residual methods is defined where on both ends lie the original QMR method and a minimal residual method while lying in between are the variants derived here. These variants are shown to consume a little more computational work per iterations than the original QMR method, but generally give an even better convergence behavior as well as lower iteration counts. The same idea was also applied to a recently proposed transpose-free quasi-minimal residual method. In particular, a few quasi-minimal residual variants of the Van der Vorst BiCGSTAB method are derived. Numerical results are presented comparing the quasi-minimal residual and transpose-free quasi-minimal residual variants derived in this paper.

Key words. Lanczos method, quasi-minimal residual approach, nonsymmetric linear systems, transpose-free methods

AMS subject classifications. 65F10, 65N20

1. Introduction.

Conjugate gradient-like methods for nonsymmetric problems generally fall into three classes: orthogonalization methods, e.g., GMRES [14]; biorthogonalization methods, e.g., biconjugate gradient [6], [11]; and methods based on normal equation approach, e.g., conjugate gradient normal residual (CGNR) [10]. Due to its short recurrences, and thus lower storage requirements, the class of biorthogonalization methods has been studied extensively in recent years. The earliest algorithm in this class is the biconjugate gradient (BiCG) algorithm, which was first proposed by Lanczos [11], and then rediscovered by Fletcher [6]. Despite its advantage, BiCG also suffers from a few well-known drawbacks. These drawbacks are the need for adjoint matrix vector multiplication ($A^T y$), the possibility of breakdowns or near breakdowns, and its irregular convergence behavior. Subsequently, transpose-free methods such as conjugate gradient squared (CGS) [16], BiCGSTAB [18], etc., were developed to alleviate the need for adjoint matrix vector multiplies. To address the breakdown or near-breakdown problem, Freund, Gutknecht, and Nachtigal [8], [9] proposed the quasi-minimal residual (QMR) algorithm, which is based on a look-ahead Lanczos procedure to overcome curable breakdowns. The quasi-minimization step, in addition to curing one of the breakdown problems, also gives a smoother convergence curve. Such a quasi-minimization step can be applied to the transpose methods such as CGS and BiCGSTAB, giving rise to the recently developed algorithms such as Freund's transpose-free QMR algorithm [7], the transpose-free QMR method of Chan, De Pillis, and Van der Vorst [3], and QMRCGSTABx algorithms of Chan et al. [4].

While Faber and Manteuffel [5] proved that generally there exists no conjugate gradient-type scheme that incorporates both short recurrences and a minimization property, the quasi-minimal residual approach represents a step toward a compromise between these two conflicting but desirable features. This paper shows that a family of quasi-minimal residual methods (for simplicity, the nonlook-ahead version is used here) can be defined that is based on the use of different weight matrices (to be defined later) in the quasi-minimization step. We show that

*Received by the editors April 28, 1992; accepted for publication (in revised form) February 15, 1993.

†Center for Computational Engineering, Sandia National Laboratory, Livermore, California 94551-0969 (chtong@california.sandia.gov).

when this weight matrix is very sparse (i.e., diagonal), we have a simplified (nonlook-ahead) version of the Freund, Gutknecht, and Nachtigal quasi-minimal residual method. On the other hand, if we allow the weight matrix to be very dense (i.e., upper triangular), we have a minimal residual method. However, this minimal residual method suffers again from long recurrences. The variants in this paper are derived by allowing the weight matrices to be other than the two extremes mentioned above. In particular, we consider weight matrices that are block diagonal having upper triangular blocks. We show that these QMR (and BiCGSTAB-based transpose-free QMR) variants generally give smoother convergence curves and lower iteration counts with increasing block sizes at the expense of little extra computation per iteration.

The outline of this report is as follows. In §2, the basic ideas of the QMR approach are described and a few QMR variants are then derived. In §3, implementation details of the QMR variants as well as their computational complexity are given. In §4, numerical results are presented and discussed. In §5, we consider the transpose-free QMR algorithms and then derive a few quasi-minimal residual variants of the Van der Vorst BiCGSTAB method [18]. In §6, implementation details of the transpose-free QMR variants are given. In §7, numerical results are presented and discussed. Finally, in §8, some concluding remarks are made.

2. A family of quasi-minimal residual algorithms.

2.1. The quasi-minimal residual approach. We give a nonsingular and nonsymmetric $N \times N$ matrix A and two initial nonzero vectors $v_1 \in \Re^N$ and $w_1 \in \Re^N$ such that $w_1^T v_1 \neq 0$. The classical nonsymmetric Lanczos procedure, in exact arithmetic and in the absence of breakdowns, generates two sequences of vectors

$$V_n = \{v_1\ v_2\ \cdots\ v_n\} \quad \text{and} \quad W_n = \{w_1\ w_2\ \cdots\ w_n\}, \tag{2.1}$$

which satisfy the following two properties. (i) The two sequences span two Krylov subspaces. That is,

$$\text{span}\{v_1, v_2, \ldots, v_n\} = \text{span}\{v_1, Av_1, \ldots, A^{n-1}v_1\} = K_n(v_1, A), \tag{2.2}$$

$$\text{span}\{w_1, w_2, \ldots, w_n\} = \text{span}\{w_1, A^T w_1, \ldots, (A^T)^{n-1}w_1\} = K_n(w_1, A^T). \tag{2.3}$$

(ii) The two sequences satisfy a biorthogonality condition

$$w_i^T v_j = \delta_{ij}, \tag{2.4}$$

where δ_{ij} is the Kronecker symbol (that is, $\delta_{ij} = 1$, when $i = j$, and 0 otherwise).

The nonsymmetric Lanczos procedure can be written in matrix form as

$$AV_n = V_{n+1}H_n^e, \tag{2.5}$$

where H_n^e is a $(n+1) \times n$ tridiagonal matrix defined by parameters generated in the Lanczos process.

This nonsymmetric procedure can be used to find the solution of a linear system $Ax = b$. In particular, let $x_0 \in \Re^N$ be any initial guess. The initial residual vector is then $r_0 = b - Ax_0$. If we let $v_1 = r_0 / \| r_0 \|$ and w_1 be arbitrary with unit 2-norm (for example, $w_1 = v_1$), then the iterate x_n (solution at iteration n) is

$$x_n = x_0 + V_n z,\ z \in \Re^N. \tag{2.6}$$

Moreover, after some manipulations, the residual vector can be written as

$$r_n = V_{n+1}\Omega_{n+1}^{-1}(d_n - \Omega_{n+1}H_n^e z), \tag{2.7}$$

where Ω_{n+1} is an $(n+1) \times (n+1)$ diagonal weight matrix (following the Freund and Nachtigal notation [9]), $e_1^{(n+1)} = [1\ 0\ \cdots\ 0]^T \in \Re^{n+1}$, $\rho_0 = \| r_0 \|$, and $d_n = \omega_1 \rho_0 e_1^{(n+1)}$.

Instead of minimizing the 2-norm of the residual $\| r_n \|$, which takes prohibitively large number of arithmetic operations, the QMR approach minimizes only the Euclidean norm of the expression $(d_n - \Omega_{n+1} H_n^e z)$. The solution of this least squares problem can be computed by a standard QR decomposition of $\Omega_{n+1} H_n^e$ giving

$$\Omega_{n+1} H_n^e = Q_n^T \begin{bmatrix} R_n \\ 0 \end{bmatrix}, \tag{2.8}$$

where Q_n is an orthogonal $(n+1) \times (n+1)$ matrix, and R_n is a nonsingular upper triangular $n \times n$ matrix. This gives

$$\min_{z \in \Re^n} \| d_n - \Omega_{n+1} H_n^e z \|_2 = \min_{z \in \Re^n} \left\| \left(Q_n d_n - \begin{bmatrix} R_n \\ 0 \end{bmatrix} z \right) \right\|_2 . \tag{2.9}$$

If we let t_n be an $n \times 1$ vector consisting of the first n elements of the $(n+1) \times 1$ vector $Q_n d_n$, then z_n and the solution x_n are given by

$$z_n = R_n^{-1} t_n \quad \text{and} \quad x_n = x_0 + V_n z_n, \tag{2.10}$$

respectively.

2.2. Generalization of the QMR approach. In the simplified (nonlook-ahead) QMR algorithm, the weight matrix Ω_{n+1} was chosen to be a diagonal matrix. In general, Ω_{n+1} does not have to be diagonal. In fact, by allowing Ω_{n+1}^{-1} to be upper triangular, it is possible to construct an Ω_{n+1} such that $V_{n+1}\Omega_{n+1}^{-1}$ is orthonormal. This gives a minimal residual algorithm since

$$\begin{aligned} \min_{z \in \Re^n} \| r_n \|_2 &= \min_{z \in \Re^n} \| V_{n+1} \Omega_{n+1}^{-1} (\rho_0 \Omega_{n+1} e_1^{(n+1)} - \Omega_{n+1} H_n^e z) \|_2 \\ &= \min_{z \in \Re^n} \| \rho_0 \Omega_{n+1} e_1^{(n+1)} - \Omega_{n+1} H_n^e z \|_2 . \end{aligned} \tag{2.11}$$

However, since now the matrix $\Omega_{n+1} H_n^e$ is dense upper Hessenberg instead of tridiagonal, the computation of z becomes very expensive and takes up a prohibitively large amount of storage. This algorithm is in fact similar to GMRES except that it is susceptible to breakdowns.

Another alternative is to find a sparse Ω_{n+1} (other than diagonal) so that $V_{n+1}\Omega_{n+1}^{-1}$ becomes closer to orthonormal at the expense of requiring to store and use a few more of the previous direction vectors. A simple variant is to make Ω_{n+1}^{-1} block diagonal where each block is a 2×2 upper triangular submatrix. This can be accomplished by orthonormalizing consecutive pairs of v_i's, i.e., orthonormalize v_2 against v_1, v_4 against v_3, and so on. We call this new weight matrix $(B_{n+1}^{(2)})^{-1}$ and then we solve a different least squares problem

$$\| d_n - (B_{n+1}^{(2)})^{-1} H_n^e z_n \|_2 = \min_{z \in \Re^n} \| d_n - (B_{n+1}^{(2)})^{-1} H_n^e z \|_2, \tag{2.12}$$

where d_n is the same as before ($(B_{n+1}^{(2)})^{-1} d_n = d_n$ since all except the first element of d_n is nonzero and $B_{n+1}^{(2)}(1,1) = 1$). As B_{n+1} is block diagonal with a block size of 2, $(B_{n+1}^{(2)})^{-1} H_n^e$ will have one more superdiagonal than H_n^e. Thus only one additional direction vector needs to be kept for computing the solution update compared to the QMR method. Also, as will be shown in later sections, this algorithm takes only one more inner product and one more daxpy

($y = ax + b$, where x, y, b are vectors and a is a scalar) operation per iteration compared to the QMR method. We call this QMR variant BQMR(2) in subsequent sections.

We can further generalize this approach by allowing the weight matrix to be a block diagonal matrix of block size 3, 4, and so on. In this paper, we implement up to a block size of 3 (which we call BQMR(3) and the weight matrix for this case is $(B_{n+1}^{(3)})^{-1}$). It becomes obvious that when the block size is $n+1$, $V_{n+1}B_{n+1}^{(n+1)}$ has orthonormal columns, and we have a minimal residual algorithm similar to GMRES. When the block size is 1, we have the simplified (based on the classical Lanczos procedure) QMR algorithm (to be consistent in the use of notations, the simplified QMR algorithm will also be called BQMR(1) in subsequent sections).

2.3. A residual bound for the BQMR(k) algorithms. Freund and Nachtigal [9] have given a residual bound for the QMR algorithm based on the the following theorem [9].

THEOREM 2.1. *Suppose that the $m \times m$ matrix H_m generated by m steps of the* QMR *algorithm is diagonalizable (m denotes the termination index of the look-ahead Lanczos, for details refer to* [9]*), and set*

$$H = \Omega_{m-1} H_m \Omega_{m-1}^{-1}. \tag{2.13}$$

Then, for $n = 1, 2, \ldots, m-1$, the residual vectors of the QMR *algorithm satisfy*

$$\| r_n \| \leq \| r_0 \| \kappa(H)\sqrt{n+1}\, \vartheta_n \max_{j=1,\ldots,n+1} (\omega_1/\omega_j), \tag{2.14}$$

where

$$\kappa(H) = \min_{X: X^{-1}HX \text{diagonal}} \| X \| \cdot \| X^{-1} \|, \tag{2.15}$$

and

$$\vartheta_n = \min_{P \in \Pi_n : P(0)=1} \max_{\lambda \in \lambda(A)} |P(\lambda)|. \tag{2.16}$$

This convergence theorem is contingent on the use of a look-ahead Lanczos procedure. The formulation of BQMR(k) in the last section, however, is based on the classical Lanczos procedure. Thus this theorem does not hold for BQMR(k), in general, because of the possibility of breakdowns. Nevertheless, suppose that for a given test problem, BQMR(k) does not encounter breakdowns of the type $w_n^T v_n = 0$, $v_n \neq 0$, $w_n \neq 0$. Then we can derive a similar convergence bound for the BQMR(k) algorithms. Since this bound is rather restricted or not rigorous, we will state it as a remark instead of a theorem.

Remark. Suppose an $N \times N$ linear system is given and in exact arithmetic, the BQMR(k) for some $k \leq N$ terminates at iteration $m \leq N$ with $\| v_{m+1} \| = 0$ or $\| w_{m+1} \| = 0$ (note that this index m is different from that defined in [9]), and no breakdown of the type $v_n^T w_n = 0$, $v_n \neq 0$, $w_n \neq 0$ occurs at iterations 1 through m. Furthermore, suppose the $m \times m$ matrix H_m generated by m steps of the BQMR(k) algorithm is diagonalizable, and set

$$H = (B_{m-1}^{(k)})^{-1} H_m B_{m-1}^{(k)}. \tag{2.17}$$

Then, for $n = 1, 2, \ldots, m-1$, the residual vectors of the BQMR(k) algorithm satisfy

$$\| r_n \| \leq \| r_0 \| \kappa(H)\sqrt{\left\lceil \frac{n+1}{k} \right\rceil}\, \vartheta_n, \tag{2.18}$$

where

$$\vartheta_n = \min_{P\in\Pi_n: P(0)=1} \max_{\lambda\in\lambda(A)} |P(\lambda)|. \tag{2.19}$$

Proof. The proof of this remark is similar to that of the Freund and Nachtigal theorem stated above. In this theorem, the factor $\sqrt{n+1}$ arises from bounding $\| V_{n+1} \|$. A tighter bound (by a factor of $\approx \sqrt{k}$) can be prescribed by realizing that $V_{n+1}B_{n+1}^{(k)}$ is k-orthonormal (columns 1 through k are orthonormal, columns k+1 through 2k are orthonormal, etc.). Moreover, since H_n^e is tridiagonal and $B_{n+1}^{(k)}$ is block diagonal with upper triangular blocks and nonzero diagonal elements, $(B_{n+1}^{(k)})^{-1}H_n^eB_{n+1}^{(k)}$ is upper Hessenberg with nonzero subdiagonal. Using this fact, together with the proof in [9], we obtain the same ϑ_n as in [9], and thus we arrive at the above remark. □

The above remark is given to shed some light on the convergence behavior of these QMR variants. This remark basically implies that the larger the block size (k) used, the tighter are the residual bounds if no breakdown occurs. In the limit when $k = n+1$ (or BQMR(∞)) and in absence of breakdowns, the residual bound is the same as the GMRES residual bound.

3. Implementation and complexity of the BQMR(k) algorithms.

3.1. Implementation details.

3.1.1. The BQMR(2) algorithm. Considering the BQMR(2) algorithm, solving the least squares problem

$$\| d_n - (B_{n+1}^{(2)})^{-1}H_n^e z_n \|_2 = \min_{z\in\Re^n} \| d_n - (B_{n+1}^{(2)})^{-1}H_n^e z \|_2 \tag{3.1}$$

basically involves three steps.

Step 1. Update $B_{n+1}^{(2)}$.

Step 2. Update the relatively sparse matrix $\tilde{H}_n^e = (B_{n+1}^{(2)})^{-1}H_n^e$.

Step 3. Perform QR decomposition on $\tilde{H}_n^e$ to get R_n, and apply the same Q_n to d_n to get $t_n = [\tau_1 \cdots \tau_n]^T$.

The solution can then be updated by

$$x_n = x_{n-1} + V_n R_n^{-1}[0 \cdots 0\ \tau_n]^T. \tag{3.2}$$

Since the update processes for the first and second step are different for odd and even iterations, we shall describe them separately.

At the odd iterations, $B_{n+1}^{(2)}$ and H_n^e are of the form

$$B_{n+1}^{(2)} = \begin{bmatrix} & & 0 \\ & B_n^{(2)} & \vdots \\ & & \delta_{n+1} \\ 0 & \cdots & \epsilon_{n+1} \end{bmatrix}, \qquad H_n^e = \begin{bmatrix} & & 0 \\ & H_{n-1}^e & \vdots \\ & & \beta_n \\ & & \alpha_n \\ 0 & \cdots\ 0 & \gamma_{n+1} \end{bmatrix}. \tag{3.3}$$

The new entries in $B_{n+1}^{(2)}$, namely, δ_{n+1} and ϵ_{n+1} can be computed by orthonormalizing v_{n+1} against v_n.

Let the nth column of H_n^e be denoted by $h_n = [0 \ \ldots\ \beta_n\ \alpha_n\ \gamma_{n+1}]^T$ (which has a vector of length $n+1$). Then, at the nth iteration, $\tilde{H}_n^e$ can be updated by performing a U-solve (solving a linear system where the matrix is upper triangular), that is, to find a vector u_n such that

$$B_{n+1}^{(2)}u_n = h_n, \tag{3.4}$$

where u_n will have the form $[0 \cdots 0\ \mu_4\ \mu_3\ \mu_2\ \mu_1]^T$.

At the even iterations, the derivation can be carried out similarly. Here no orthonormalization needs to be performed. Also $B_{n+1}^{(2)}$ is in a different form:

$$B_{n+1}^{(2)} = \begin{bmatrix} & & 0 \\ & B_n^{(2)} & \vdots \\ & & 0 \\ 0 & \cdots & 1 \end{bmatrix}. \tag{3.5}$$

Again, a U-solve is performed on $B_{n+1}^{(2)} u_n = h_n$, where now the fourth-to-the-last entry (μ_4 in the odd case) in u_n is 0.

Step 3 first applies the previous Givens rotations to u_n's so that

$$Q_{n-1} u_n = [0 \cdots 0\ v_4\ v_3\ v_2\ t_1\ \mu_1]^T. \tag{3.6}$$

Next a new Givens rotation is used to zero out the entry corresponding to μ_1 giving

$$Q_n u_n = [0 \cdots 0\ v_4\ v_3\ v_2\ v_1\ 0]^T, \tag{3.7}$$

which is the last column of R_n. The computation of $t_n = Q_n d_n$ can be performed the same way as in BQMR(1).

Finally, the expression $V_n R_n^{-1}[0 \cdots 0\ \tau_n]^T$ needs to be evaluated. This can be achieved by defining a sequence of vectors y_i where

$$Y_n = [y_1\ y_2\ \cdots\ y_n] = V_n R_n^{-1}, \tag{3.8}$$

and the solution can be updated by

$$x_n = x_{n-1} + \tau_n * y_n. \tag{3.9}$$

It is straightforward to show that

$$y_n = (v_n - v_2 y_{n-1} - v_3 y_{n-2} - v_4 y_{n-3})/v_1. \tag{3.10}$$

In [9], it was shown that the BQMR(1) residual can be updated by

$$r_n^{\mathrm{BQMR(1)}} = s_{n+1}^2 r_{n-1}^{\mathrm{BQMR(1)}} - c_{n+1} \tilde{\tau}_{n+1} v_{n+1}. \tag{3.11}$$

The BQMR(2) residual can be updated slightly differently by

$$r_n^{\mathrm{BQMR(2)}} = s_{n+1}^2 r_{n-1}^{\mathrm{BQMR(2)}} - c_{n+1} \tilde{\tau}_{n+1} \hat{v}_{n+1}, \tag{3.12}$$

where $\hat{v}_{n+1}$ is the $(n+1)$th column of $V_{n+1} B_{n+1}^{(2)}$.

The pseudocode for the BQMR(2) algorithm is presented in the following.

ALGORITHM BQMR(2)

(1) Initialization

(a) $r_0 = b - Ax_0$; $v_1 = r_0 / \| r_0 \|$; w_1 arbitrary

(b) $y_{-2} = y_{-1} = y_0 = v_{-1} = v_0 = w_{-1} = w_0 = 0$; $r_0^{\mathrm{BQMR(2)}} = r_0$

(c) $\tilde{\tau}_1 = \| r_0 \|$; $s_{-2} = s_{-1} = s_0 = 0$; $c_{-2} = c_{-1} = c_0 = -1$

(d) $\epsilon_0 = 1$; $\delta_0 = \beta_1 = \gamma_1 = 0$

(2) **For** $n = 1, 2, \ldots$ do

(a) $\alpha_n = w_n^T A v_n$
(b) $\tilde{v}_{n+1} = A v_n - \alpha_n v_n - \beta_n v_{n-1}$
(c) $\tilde{w}_{n+1} = A^T w_n - \alpha_n w_n - \gamma_n w_{n-1}$
(d) $\gamma_{n+1} = \| \tilde{v}_{n+1} \|$; $\beta_{n+1} = \tilde{w}_{n+1}^T \tilde{v}_{n+1} / \gamma_{n+1}$
(e) $v_{n+1} = \tilde{v}_{n+1} / \gamma_{n+1}$; $w_{n+1} = \tilde{w}_{n+1} / \beta_{n+1}$;

(3) U-solve to get the modified H matrix
(a) if n is odd
$\bar{v}_{n+1} = v_{n+1} - (v_{n+1}^T v_n) v_n$; $\hat{v}_{n+1} = \bar{v}_{n+1} / \| \bar{v}_{n+1} \|$
$\epsilon_{n+1} = 1 / \| \bar{v}_{n+1} \|$; $\delta_{n+1} = -(v_{n+1}^T v_n) * \epsilon_{n+1}$
$\mu_1 = \gamma_{n+1} / \epsilon_{n+1}$; $\mu_2 = \alpha_n - \delta_{n+1} * \mu_1$; $\mu_3 = \beta_n / \epsilon_{n-1}$; $\mu_4 = -\delta_{n-1} * \mu_3$
(b) else if n is even
$\mu_1 = \gamma_{n+1}$; $\mu_2 = \alpha_n / \epsilon_n$; $\mu_3 = \beta_n - \delta_n * \mu_2$; $\mu_4 = 0$
$\hat{v}_{n+1} = v_{n+1}$

(4) Perform quasi minimization
(a) $\nu_4 = s_{n-2} * \mu_4$; $t_3 = -c_{n-2} * \mu_4$
(b) $\nu_3 = -c_{n-1} * t_3 + s_{n-1} * \mu_3$; $t_2 = -s_{n-1} * t_3 - c_{n-1} * \mu_3$
(c) $\nu_2 = -c_n * t_2 + s_n * \mu_2$; $t_1 = -s_n * t_2 - c_n * \mu_2$
(d) if $(|\mu_1| > |t_1|)$ $t_a = -t_1 / \mu_1$; $s_{n+1} = 1/\sqrt{1 + t_a^2}$; $c_{n+1} = c_{n+1} * t_a$
(e) else $t_a = -\mu_1 / t_1$; $c_{n+1} = 1/\sqrt{1 + t_a^2}$; $s_{n+1} = c_{n+1} * t_a$
(f) $\nu_1 = -c_{n+1} * t_1 + s_{n+1} * \mu_1$; $\tau = -c_{n+1} \tilde{\tau}$; $\tilde{\tau} = -s_{n+1} \tilde{\tau}$
(g) $y_n = (v_n - \nu_2 y_{n-1} - \nu_3 y_{n-2} - \nu_4 y_{n-3}) / \nu_1$

(5) Update solution and residual
(a) $x_n = x_{n-1} + \tau y_n$
(b) $r_n^{\mathrm{BQMR(2)}} = s_{n+1}^2 r_{n-1}^{\mathrm{BQMR(2)}} - c_{n+1} \tilde{\tau} \hat{v}_{n+1}$

(6) **End for**

3.1.2. The BQMR(3) algorithm. The BQMR(3) algorithm can be derived in a similar way. The pseudocode for the BQMR(3) algorithm is presented here.

ALGORITHM BQMR(3)
(1) Initialization
(a) $r_0 = b - A x_0$; $v_1 = r_0 / \| r_0 \|$; w_1 arbitrary
(b) $y_{-3} = y_{-2} = y_{-1} = y_0 = v_{-1} = v_0 = w_{-1} = w_0 = 0$; $r_0^{\mathrm{BQMR(3)}} = r_0$
(c) $\tilde{\tau}_1 = \| r_0 \|$; $s_{-3} = s_{-2} = s_{-1} = s_0 = 0$
(d) $c_{-3} = c_{-2} = c_{-1} = c_0 = -1$; $\epsilon_0 = \epsilon_{-1} = 1$; $\delta_0 = \delta_{-1} = \eta = 0$

(2) **For** $n = 1, 2, \ldots$ do
same as step (2a)–(2e) in Algorithm BQMR(2)

(3) U-solve to get the modified H matrix
(a) if mod(n,3) = 1
$\bar{v}_{n+1} = v_{n+1} - (v_{n+1}^T v_n) v_n$; $\hat{v}_{n+1} = \bar{v}_{n+1} / \| \bar{v}_{n+1} \|$
$\epsilon_{n+1} = 1 / \| \bar{v}_{n+1} \|$; $\delta_{n+1} = -(v_{n+1}^T v_n) * \epsilon_{n+1}$
$\mu_1 = \gamma_{n+1} / \epsilon_{n+1}$; $\mu_2 = \alpha_n - \delta_{n+1} * \mu_1$; $\mu_3 = \beta_n / \epsilon_{n-1}$
$\mu_4 = -\delta_{n-1} * \mu_3 / \epsilon_{n-2}$; $\mu 5 = -\delta_{n-2} * \mu_4 - \eta * \mu_3$
(b) else if mod(n,3) = 2
$\bar{v}_{n+1} = v_{n+1} - (v_{n+1}^T v_{n-1}) v_{n-1} - (v_{n+1}^T \hat{v}_n) \hat{v}_n$; $\hat{v}_{n+1} = \bar{v}_{n+1} / \| \bar{v}_{n+1} \|$
$\epsilon_{n+1} = 1 / \| \bar{v}_{n+1} \|$; $\delta_{n+1} = -(v_{n+1}^T \hat{v}_n) * \epsilon_{n+1} * \epsilon_n$
$\eta = -\epsilon_{n+1} * v_{n+1}^T v_{n-1} - \epsilon_{n+1} * (v_{n+1}^T \hat{v}_n) * \delta_n$
$\mu_1 = \gamma_{n+1} / \epsilon_{n+1}$; $\mu_2 = (\alpha_n - \delta_{n+1} * \mu_1) / \epsilon_n$
$\mu_3 = \beta_n - \delta_n * \mu_2 - \eta * \mu_1$; $\mu_4 = \mu_5 = 0$

(c) else if mod(n,3) = 0

$\mu_1 = \gamma_{n+1}$; $\mu_2 = \alpha_n/\epsilon_n$; $\mu_3 = (\beta_n - \delta_n * \mu_2)/\epsilon_{n-1}$

$\mu_4 = -\delta_{n-1} * \mu_3 - \eta * \mu_2$; $\mu_5 = 0$; $\hat{v}_{n+1} = v_{n+1}$

(4) Perform quasi minimization

(a) $\nu_5 = s_{n-3} * \mu_5$; $t_4 = -c_{n-3} * \mu_5$

(b) $\nu_4 = -c_{n-2} * t_4 + s_{n-2} * \mu_4$; $t_3 = -s_{n-2} * t_4 - c_{n-2} * \mu_4$

(c) $\nu_3 = -c_{n-1} * t_3 + s_{n-1} * \mu_3$; $t_2 = -s_{n-1} * t_3 - c_{n-1} * \mu_3$

(c) $\nu_2 = -c_n * t_2 + s_n * \mu_2$; $t_1 = -s_n * t_2 - c_n * \mu_2$

(d) if $(|\mu_1| > |t_1|)$ $t_a = -t_1/\mu_1$; $s_{n+1} = 1/\sqrt{1+t_a^2}$; $c_{n+1} = c_{n+1} * t_a$

(e) else $t_a = -\mu_1/t_1$; $c_{n+1} = 1/\sqrt{1+t_a^2}$; $s_{n+1} = c_{n+1} * t_a$

(f) $\nu_1 = -c_{n+1} * t_1 + s_{n+1} * \mu_1$; $\tau = -c_{n+1}\tilde{\tau}$; $\tilde{\tau} = -s_{n+1}\tilde{\tau}$

(g) $y_n = (v_n - \nu_2 y_{n-1} - \nu_3 y_{n-2} - \nu_4 y_{n-3} - \nu_5 y_{n-4})/\nu_1$

(5) Update solution and residual

(a) $x_n = x_{n-1} + \tau y_n$

(b) $r_n^{\mathrm{BQMR(3)}} = s_{n+1}^2 r_{n-1}^{\mathrm{BQMR(3)}} - c_{n+1}\tilde{\tau}\hat{v}_{n+1}$

(6) **End for**

3.2. Complexity and storage analysis. Table 3.1 shows the operation counts required for the BQMR(1), BQMR(2), and BQMR(3) algorithms. Since the operation counts for the BQMR(2) algorithm are different between odd and even iterations, only their average is listed. The same is true for BQMR(3). BQMR(2) and BQMR(3) are only slightly more expensive than BQMR(1). When large block size k is used, the operation count for BQMR(k) per iteration grows with the square of the block size.

TABLE 3.1
Complexity and storage statistics per iteration.

Method	(1)	(2)	(3)	(4)	Total op. count	Storage
BQMR(1)	2	4	7	6	28N+2 (MVP + P)	12N+A
BQMR(2)	2	5	8	6	32N+2 (MVP + P)	13N+A
BQMR(3)	2	6	9	6	36N+2 (MVP + P)	14N+A

(1) Number of matrix vector multiplications

(2) Number of inner product calculations

(3) Number of daxpy operations

(4) Number of other (e.g., vector add) operations

P = preconditioning

MVP = matrix vector products.

4. Numerical experiments with BQMR(k) algorithms. The numerical examples used in this experiment range from a two-dimensional convection diffusion equation to the problems in the Harwell–Boeing collections [2]. cde31 and cde63 are the convection-diffusion equations

$$-\Delta u + \gamma\left(x\frac{\partial u}{\partial x} + y\frac{\partial u}{\partial y}\right) + \beta u = f, \tag{4.1}$$

where $\gamma = 50$ and 100, $\beta = -25$ and -100 for $n = 31$ (i.e., 31×31 grid) and $n = 63$, respectively. The rest of the problems were obtained from the Harwell–Boeing collection.

Table 4.1 shows the iteration counts for the different algorithms without preconditioning and with right ILUT(0) preconditioning. (This ILUT(0) was originally proposed by Saad [13]. The version used in this experiment, however, was borrowed from the implementation by Freund and Nachtigal.) The result for GMRES (nonrestarted version) is also included for comparison purposes since, when breakdown does not occur, GMRES is mathematically equivalent to BQMR(∞). The stopping criterion used here is $\| r_k \| / \| r_0 \| < 10^{-8}$. Moreover, $x_0 = 0$ and $\tilde{r}_0 = r_0$.

TABLE 4.1
Iteration counts for different problems.

(U) No preconditioning

(P) ILUT(0) preconditioning used

(a) > 2000 iterations

From Table 4.1, it can also be observed that the number of iterations needed for the BQMR(k) algorithms in most cases is not much more than the GMRES algorithm. The number of iterations for BQMR(k) decreases typically when k increases from one to three. However, Table 4.1 does not reflect the total cost for each method on a given problem, since the different methods have unequal cost per iteration.

If the total operation count is the sole criterion for determining efficiency, then BQMR(1) is more efficient than BQMR(2) and BQMR(3) in most problems considered here. However, for some problems such as orsreg1, BQMR(2) with preconditioning is more efficient. An analysis is given as follows.

- orsreg1 has $N = 2205$ and number of nonzeros $NNZ = 14133$.
- A matrix vector multiply takes $NNZ/N \times 2 \approx 12.8N$ operations.
- There are three matrix vector multiply and two ILUT(0) preconditioning per iteration $\Rightarrow$ cost = $12.8N \times 5 = 64N$ operations.
- Total operation count per iteration for BQMR(1) = $64N + 28N = 92N$.
- Total operation count per iteration for BQMR(2) = $64N + 32N = 96N$.
- Total operation count for BQMR(1) = $92N * 29 = 2668N$ operations.

- Total operation count for BQMR(2) = $96N * 27 = 2592N$ operations.

Even though BQMR(1) seems to be more efficient in most problems, there are other factors that can affect performance. For example, it is well known that matrix vector multiplication and preconditioning are much more expensive than vector operations, especially on some parallel computers and on supercomputers without efficient gather/scatter hardware support. Thus, on these advanced computers, BQMR(2) and BQMR(3) are potentially more efficient, in addition to giving smoother convergence curves than BQMR(1).

The convergence history of a convection diffusion equation cde63 is also plotted as shown in Fig. 1. The plots basically show that BQMR(1) does help to smooth out the irregular convergence behavior of BCG; and BQMR(2) and BQMR(3) most of the time give an even smoother convergence behavior.

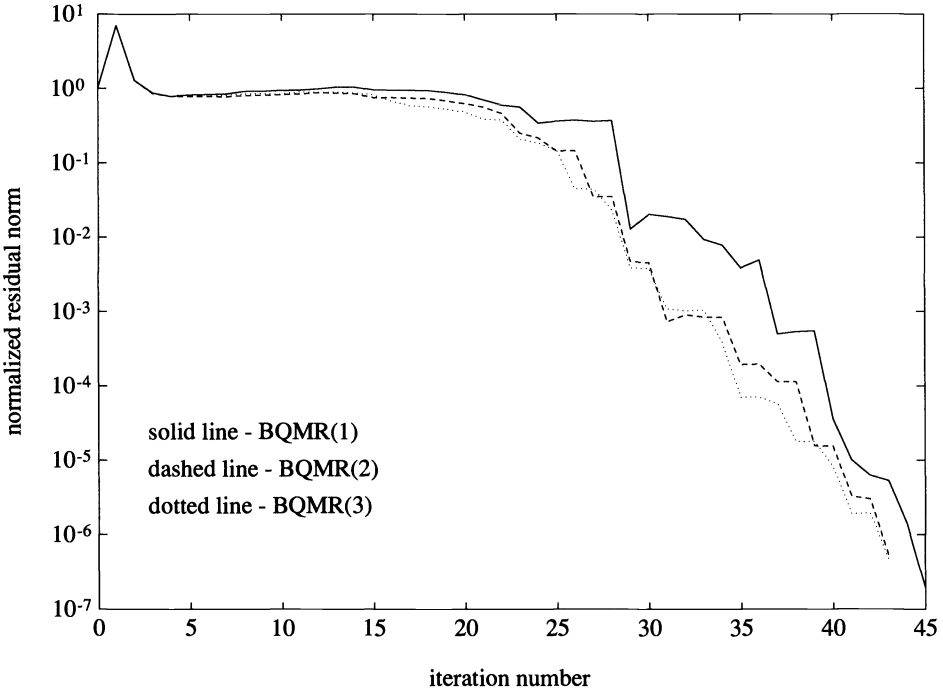

FIG. 1. *Convergence history for the* cde63 *problem* (ILUT(0) *preconditioned*).

5. Transpose-free quasi-minimal residual algorithms.

5.1. A transpose-free QMR algorithm based on BiCGSTAB. In many engineering applications the matrix vector product $A^T y$ is not easily computable. This, together with other efficiency issues, has motivated the transpose-free Lanczos-based algorithms. The first of these is CGS [16] that often gives extremely irregular convergence curves. Since Freund and Nachtigal [9] have shown that quasi minimization does help to give a smoother convergence behavior for BCG, quasi minimization has also been applied to transpose-free methods giving rise to the several transpose-free QMR methods such as Freund's transpose-free QMR method [7], the transpose-free implementation of the simplified QMR method of Chan, De Pillis, and Van der Vorst [3], and the transpose-free QMR method based on the BiCGSTAB algorithm of

Chan et al. [4] (QMRCGSTABx). Since this paper proposes variants of the QMRCGSTAB1 method, only this method will be described in detail.

QMRCGSTAB1 was developed in the same spirit as Freund developed his transpose-free QMR method from CGS. QMRCGSTAB1 was derived based on the matrix representation of Van der Vorst's BiCGSTAB algorithm [18]. In particular, the vectors generated by the BiCGSTAB process can be put into the following matrix form

$$AY_m = W_{m+1}L_m^e, \tag{5.1}$$

where $Y_m = [p_1\ s_1\ p_2\ s_2 \cdots]$, $W_m = [r_0\ s_1\ r_1\ s_2 \cdots]$, and p_i's, r_i's, and s_i's are defined in the BiCGSTAB algorithm [18]. Moreover, L_m^e is the product of an $(m+1) \times m$ bidiagonal matrix (which has unity diagonal and -1's on the subdiagonal) with an $m \times m$ diagonal matrix $(= \text{diag}[\alpha_1^{-1}\omega_1^{-1}\alpha_2^{-1}\omega_1^{-1} \cdots])$. The solution can be written in the form

$$x_m = x_0 + Y_m z \quad \text{for some } z \in \Re^m, \tag{5.2}$$

and the corresponding residual is

$$\begin{aligned} r_m &= r_0 - AY_m z \\ &= W_{m+1}(e_1^{(m+1)} - L_m^e z). \\ &= W_{m+1}\Omega_{m+1}^{-1}[\Omega_{m+1}(e_1^{(m+1)} - L_m^e z)]. \end{aligned} \tag{5.3}$$

The idea of QMRCGSTAB1 is to minimize the expression $\Omega_{m+1}(e_1^{(m+1)} - L_m^e z)$. Having the knowledge of the L_m^e matrix, quasi minimization can be carried out the same way it was done in deriving Freund's transpose-free QMR algorithm [7].

5.2. A family of transpose-free quasi-minimal residual algorithms. The generalization of the quasi-minimization step described in §2 can also be applied to the transpose-free Lanczos-based algorithms. In particular, we choose to start with the QMRCGSTAB1 algorithm [4]. (We can also start with the CGS algorithm giving rise to variants of Freund's transpose-free QMR algorithm.) In QMRCGSTAB1, Ω_{m+1} is a diagonal matrix. In general, Ω_{m+1} does not have to be a diagonal matrix. Again, if we let $\Omega_{m+1}^{-1} = B_{m+1}^{(k)}$ to be upper triangular such that $W_{m+1}B_{m+1}^{(k)}$ is orthonormal, we have a minimal residual algorithm. However, this is too expensive to compute. The strategy we propose in this paper is to determine a relatively sparse $B_{m+1}^{(k)}$ such that $W_{m+1}B_{m+1}^{(k)}$ is close to orthonormal. For example, we can orthonormalize s_1 against r_0. (These vectors are defined in [18], s_2 against r_1, and so on, so that $W_{m+1}B_{m+1}^{(k)}$ is pairwise orthonormal (having $\lceil (m+1)/2 \rceil$ subblocks where each subblock is orthonormal).) To accomplish this, $B_{m+1}^{(k)}$ is constructed to be block diagonal with block size 2 (each block is 2×2 upper triangular). We call this QMRCGSTAB(2). (To be consistent in naming the methods, QMRCGSTAB1 will subsequently be called QMRCGSTAB(1). We can further generalize this approach by generating orthonormal groups in W_{m+1} of size k. Again this can be accomplished by using a sparse $B_{m+1}^{(k)}$ weight matrix to be block diagonal with block size k. In this paper we also implement the case when $k = 4$ and we call this QMRCGSTAB(4).

6. Implementation and complexity of the transpose-free QMR algorithms.

6.1. Implementation details. Considering the QMRCGSTAB(k) algorithms, solving the least squares problem basically involves three steps.

Step 1. Update B_{m+1}^k.

Step 2. Update the relatively sparse matrix $\tilde{L}_m^e = (B_{m+1}^{(k)})^{-1}L_m^e$.

Step 3. Perform QR decomposition on $\tilde{L}_m^e$ to get R_m, and apply the same Q_m to $\rho_0 e_1^{(m+1)}$ to get $t_m = [\tau_1 \cdots \tau_m]^T$.
The solution can then be updated by

$$x_m = x_{m-1} + Y_m R_m^{-1}[0 \cdots 0\ \tau_m]^T. \tag{6.1}$$

The details of the QMRCGSTAB(k) algorithms for $k = 2, 4$ are described in the following sections.

6.1.1. Implementation of QMRCGSTAB(2) algorithms. The pseudocode for the QMRCGSTAB(2) algorithm is as follows.

ALGORITHM QMRCGSTAB(2)
(1) Initialization
(a) $r_0 = b - Ax_0$; $\tilde{r}_1$ arbitrary, $\tilde{r}_0 r_0 \neq 0$
(b) $p_0 = v_0 = d_0 = 0$; $\rho_0 = \alpha_0 = \omega_0 = 1$; $\tilde{\tau} = \tau = \| r_0 \|$
(c) $s_{-1} = s_0 = 0$; $c_{-1} = c_0 = -1$; $\epsilon_{11} = 1/\| r_0 \|$; $w_0 = \epsilon_{11} r_0$
(2) **For** $n = 1, 2, \ldots$ do
(a) $\rho_n = \tilde{r}_0^T r_{n-1}$; $\beta_n = (\rho_n \alpha_{n-1})/(\rho_{n-1}\omega_{n-1})$
(b) $p_n = r_{n-1} + \beta_n(p_{n-1} - \omega_{n-1} v_{n-1})$
(c) $v_n = Ap_n$; $\alpha_n = \rho_n/(\tilde{r}_0^T v_n)$; $y_n = r_n - \alpha_n v_n$
(3) U-solve to get the modified B matrix
$m = 2n - 1$; $\tilde{w}_m = y_n - (y_n^T w_{m-1}) w_{m-1}$; $\epsilon_{22} = 1/\| \tilde{w}_m \|$; $w_m = \epsilon_{22}\tilde{w}_m$
$\epsilon_{12} = -(y_n^T w_{m-1})\epsilon_{22}\epsilon_{11}$; $\mu_1 = -1/(\alpha_n \epsilon_{22})$; $\mu_2 = 1/[(\alpha_n - \epsilon_{12}\mu_1)\epsilon_{11}]$
$\nu_2 = s_{m-1}\mu_2$; $\delta_1 = -c_{m-1}\mu_2$
$\tilde{d}_m = p_n - \nu_2 d_{m-1}$
(4) Continue quasi minimization
if $(|\mu_1| > |\delta_1|)$ $\xi = -\delta_1/\mu_1$; $s_m = 1/\sqrt{1+\xi^2}$; $c_m = s_m \xi$
else $\xi = -\mu_1/\delta_1$; $c_m = 1/\sqrt{1+\xi^2}$; $s_m = c_m \xi$
$\nu_1 = -c_m\delta_1 + s_m\mu_1$; $\tau = -c_m\tilde{\tau}$; $\tilde{\tau} = -s_m\tilde{\tau}$; $d_m = \tilde{d}_m/\nu_1$
$x_m = x_{m-1} + \tau d_m$
(5) Continue with BiCGSTAB
$t_n = Ay_n$
$\omega_n = (y_n^T t_n)/(t_n^T t_n)$
$r_n = y_n - \omega_n t_n$
(6) second U-solve to get the modified B matrix
$m = 2n$; $\epsilon_{33} = 1/\| r_n \|$; $w_m = \epsilon_{33} r_n$
$\mu_1 = -1/(\omega_n \epsilon_{33})$; $\mu_2 = 1/(\omega_n \epsilon_{22})$
$\mu_3 = -(\epsilon_{12}\mu_2)/\epsilon_{11}$; $\nu_3 = s_{m-2}\mu_3$; $\delta_2 = -c_{m-2}\mu_3$; $\nu_2 = -c_{m-1}\delta_2 + s_{m-1}\mu_2$
$\epsilon_{11} = \epsilon_{33}$; $\delta_1 = -s_{m-1}\delta_2 - c_{m-1}\mu_2$, $\tilde{d}_m = y_n - \nu_3 d_{m-2} - \nu_2 d_{m-1}$
(7) Continue quasi minimization
if $(|\mu_1| > |\delta_1|)$ $\xi = -\delta_1/\mu_1$; $s_m = 1/\sqrt{1+\xi^2}$; $c_m = s_m \xi$
else $\xi = -\mu_1/\delta_1$; $c_m = 1/\sqrt{1+\xi^2}$; $s_m = c_m \xi$
$\nu_1 = -c_m\delta_1 + s_m\mu_1$; $\tau = -c_m\tilde{\tau}$; $\tilde{\tau} = -s_m\tilde{\tau}$; $d_m = \tilde{d}_m/\nu_1$
$x_m = x_{m-1} + \tau d_m$
(8) If x_m is accurate enough, stop
(9) **End for**

6.1.2. Implementation of QMRCGSTAB(4) algorithm. The pseudocode for the QMRCGSTAB(4) algorithm is as follows.

ALGORITHM QMRCGSTAB(4)

(1) Initialization

(a) $r_0 = b - Ax_0$; $\tilde{r}_1$ arbitrary, $\tilde{r}_0 r_0 \neq 0$

(b) $p_0 = v_0 = d_0 = 0$; $\rho_0 = \alpha_0 = \omega_0 = 1$; $\tilde{\tau} = \tau = \| r_0 \|$

(c) $s_{-3} = s_{-2} = s_{-1} = s_0 = 0$; $c_{-3} = c_{-2} = c_{-1} = c_0 = -1$

(d) $\epsilon_{11} = 1/\| r_0 \|$; $w_0 = \epsilon_{11} r_0$

(2) **For** $n = 1, 2, \ldots$ do

same as step (2a)–(2c) in Algorithm QMRCGSTAB(2)

(3) U-solve to get the modified B matrix

(a) if mod(n,2) = 1 ($m = 2n - 1$)

$\tilde{w}_m = y_n - (y_n^T w_{m-1}) w_{m-1}$; $\epsilon_{22} = 1/\| \tilde{w}_m \|$; $w_m = \epsilon_{22} \tilde{w}_m$

$\epsilon_{12} = -(y_n^T w_{m-1}) \epsilon_{22} \epsilon_{11}$; $\mu_1 = -1/(\alpha_n \epsilon_{22})$; $\mu_2 = 1/[(\alpha_n - \epsilon_{12}\mu_1)\epsilon_{11}]$

$\nu_2 = s_{m-1}\mu_2$; $\delta_1 = -c_{m-1}\mu_2$

$\tilde{d}_m = p_n - \nu_2 d_{m-1}$

(b) else if mod(n,2) = 0

$\tilde{w}_m = y_n - (y_n^T w_{m-1}) w_{m-1} - (y_n^T w_{m-2}) w_{m-2} - (y_n^T w_{m-3}) w_{m-3}$

$\epsilon_{44} = 1/\| \tilde{w}_m \|$; $w_m = \epsilon_{44} \tilde{w}_m$

$\epsilon_{14} = -\epsilon_{44}[(y_n^T w_{m-1})\epsilon_{11} + (y_n^T w_{m-2})\epsilon_{12} + (y_n^T w_{m-3})\epsilon_{13}]$

$\epsilon_{24} = -\epsilon_{44}[(y_n^T w_{m-2})\epsilon_{22} + (y_n^T w_{m-3})\epsilon_{33}]$

$\epsilon_{34} = -\epsilon_{44}(y_n^T w_{m-3})\epsilon_{33}$; $\mu_1 = -1/(\alpha_n \epsilon_{44})$; $\mu_2 = (1/\alpha_n - \epsilon_{34}\mu_1)/\epsilon_{33}$

$\mu_3 = -(\epsilon_{24}\mu_1 + \epsilon_{23}\mu_2)/\epsilon_{22}$; $\mu_4 = -(\epsilon_{14}\mu_1 + \epsilon_{13}\mu_2 + \epsilon_{12}\mu_3)/\epsilon_{11}$

$\nu_4 = -c_{m-3}\mu_4$; $\delta_3 = -c_{m-3}\mu_4$; $\nu_3 = -c_{m-2}\delta_3 + s_{m-2}\mu_3$

$\delta_2 = -s_{m-2}\delta_3 - c_{m-2}\mu_3$

$\nu_2 = -c_{m-1}\delta_2 + s_{m-1}\mu_2$; $\delta_1 = -s_{m-1}\delta_2 - c_{m-1}\mu_2$

$\tilde{d}_m = p_n - \nu_4 d_{m-3} - \nu_3 d_{m-2} - \nu_2 d_{m-1}$

(4) Continue quasi minimization–same as step (4) in QMRCGSTAB(2)

(5) Continue with BiCGSTAB–same as step (5) in QMRCGSTAB(2)

(6) second U-solve to get the modified B matrix

(a) if mod(n,2) = 1 ($m = 2n - 1$)

$\tilde{w}_m = r_n - (r_n^T w_{m-1}) w_{m-1} - (r_n^T w_{m-2}) w_{m-2}$

$\epsilon_{33} = 1/\| \tilde{w}_m \|$; $w_m = \epsilon_{33} \tilde{w}_m$

$\epsilon_{13} = -\epsilon_{33}[(r_n^T w_{m-1})\epsilon_{11} + (r_n^T w_{m-2})\epsilon_{12}]$; $\epsilon_{23} = -(r_n^T w_{m-2})\epsilon_{22}\epsilon_{33}$

$\mu_1 = -1/(\omega_n \epsilon_{33})$; $\mu_2 = (1/\omega_n - \epsilon_{23}\mu_1)/\epsilon_{22}$

$\mu_3 = -(\epsilon_{13}\mu_1 + \epsilon_{12}\mu_2)/\epsilon_{11}$; $\nu_3 = s_{m-2}\mu_3$; $\delta_2 = -c_{m-2}\mu_3$

$\nu_2 = -c_{m-1}\delta_2 + s_{m-1}\mu_2$; $\delta_1 = -s_{m-1}\delta_2 - c_{m-1}\mu_2$

$\tilde{d}_m = y_n - \nu_3 d_{m-2} - \nu_2 d_{m-1}$

(b) else if mod(n,2) = 0 ($m = 2n$)

$\epsilon_{55} = 1/\| r_n \|$; $w_m = \epsilon_{55} r_n$; $\mu_1 = -1/(\omega_n \epsilon_{55})$; $\mu_2 = 1/(\omega_n \epsilon_{44})$

$\mu_3 = -(\epsilon_{34}\mu_2)/\epsilon_{33}$; $\mu_4 = -(\epsilon_{24}\mu_2 + \epsilon_{23}\mu_3)/\epsilon_{22}$

$\mu_5 = -(\epsilon_{14}\mu_2 + \epsilon_{13}\mu_3 + \epsilon_{12}\mu_4)/\epsilon_{11}$; $\epsilon_{11} = \epsilon_{55}$

$\nu_5 = -c_{m-4}\mu_5$; $\delta_4 = -c_{m-4}\mu_5$

$\nu_4 = -c_{m-3}\delta_4 + s_{m-3}\mu_4$; $\delta_3 = -s_{m-3}\delta_4 - c_{m-3}\mu_4$

$\nu_3 = -c_{m-2}\delta_3 + s_{m-2}\mu_3$; $\delta_2 = -s_{m-2}\delta_3 - c_{m-2}\mu_3$

$\nu_2 = -c_{m-1}\delta_2 + s_{m-1}\mu_2$; $\delta_1 = -s_{m-1}\delta_2 - c_{m-1}\mu_2$

$\tilde{d}_m = y_n - \nu_5 d_{m-4} - \nu_4 d_{m-3} - \nu_3 d_{m-2} - \nu_2 d_{m-1}$

(7) Continue quasi minimization

if $(|\mu_1| > |\delta_1|)$ $\xi = -\delta_1/\mu_1$; $s_m = 1/\sqrt{1 + \xi^2}$; $c_m = s_m \xi$

else $\xi = -\mu_1/\delta_1$; $c_m = 1/\sqrt{1 + \xi^2}$; $s_m = c_m \xi$

$\nu_1 = -c_m\delta_1 + s_m\mu_1$; $\tau = -c_m\tilde{\tau}$; $\tilde{\tau} = -s_m\tilde{\tau}$; $d_m = \tilde{d}_m/\nu_1$

$x_m = x_{m-1} + \tau d_m$

(8) If x_m is accurate enough, stop

(9) **End for**

6.2. Complexity and storage analysis. Table 6.1 shows the operation counts for the QMRCGSTAB(1), QMRCGSTAB(2), and QMRCGSTAB(4) algorithms. Since the operation counts for the QMRCGSTAB(2) algorithm are different between odd and even iterations, only their average is listed. The same is true for QMRCGSTAB(4).

TABLE 6.1
Complexity and storage statistics per iteration.

Method	(1)	(2)	(3)	(4)	Total op. count	Storage
QMRCGSTAB(1)	2	6	8	0	28N+2 (MVP + P)	8N+A
QMRCGSTAB(2)	2	7	10	4	38N+2 (MVP + P)	9N+A
QMRCGSTAB(4)	2	9	14	4	50N+2 (MVP + P)	11N+A

(1) Number of matrix vector multiplications

(2) Number of inner product calculations

(3) Number of daxpy operations

(4) Number of other (e.g., vector add) operations

A = storage for the A matrix

P = preconditioning

MVP = matrix vector products.

7. Numerical experiments for the transpose-free QMR algorithms. The set of numerical examples used here is the same as in §4. Table 7.1 shows the iteration counts for the different algorithms. The initial solution x_0 is a random vector, $\tilde{r}_0 = r_0$, and the stopping criterion is $\| r_k \| / \| b \| < 10^{-8}$.

It can be observed from Table 7.1 that the number of iterations needed for the QMRCGSTAB (k) algorithms in most cases is about half of those of GMRES when preconditioning is used. Again, the number of iterations for QMRCGSTAB(k) is in most cases slightly lower when larger k is used. Again, due to unequal costs per iteration between the methods, iteration counts alone do not reflect the actual efficiency, which is affected by many other factors such as total operation counts and the target computer architecture on computers where matrix vector multiplication is much more expensive than vector operations (as on some supercomputers where efficient gather/scatter hardware is not available). Hence again, in addition to giving smoother convergence curves, the QMRCGSTAB(k) algorithms are potentially more efficient.

In addition to the iteration counts, the convergence history for a convection diffusion equation cde63 is also plotted in Fig. 2.

8. Concluding remarks. In this paper, we explored the use of different weight matrices in the quasi-minimal residual algorithms, and we derived several QMR variants such as BQMR(2) and BQMR(3) algorithms and transpose-free QMR variants such as QMRCGSTAB(2) and QMRCGSTAB(4) algorithms. These variants were shown to represent a few of the many possibilities lying in the spectrum of quasi-minimal residual (and transpose-free

QMR) algorithms where on the two ends are nonlook-ahead QMR and a GMRES-like minimal residual algorithm, respectively. We showed that these variants are only slightly more expensive than BQMR(1) and QMRCGSTAB(1) per iteration but they generally give smoother convergence curves. Moreover, in general these variants also give a slightly faster convergence rate. Thus these variants can potentially be more efficient for the following situations:

- when the reduction in iteration count is such that the total operation count is lower (e.g., orsreg1 for BQMR(2));
- when the percentage of nonzeros in the problem matrix is relatively high so that matrix vector multiply is relatively more expensive than the overhead for doing quasi minimization;
- when more powerful preconditioners are used (e.g., ILUT(k) for large k) so that the overhead for doing quasi minimization is relatively inexpensive;
- on certain computer platform (e.g., on some parallel computers or supercomputers with no gather/scatter hardware) where matrix vector multiply is much more expensive than daxpy and dot products.

Acknowledgments. The author would like to thank Roland Freund and Noel Nachtigal for their permission to use their ILUT subroutine and some of their support subroutines. Their comments on this work are also well taken. Most matrix and vector operations are performed through the use of the subroutines available in SPARSKIT. The author would also like to thank

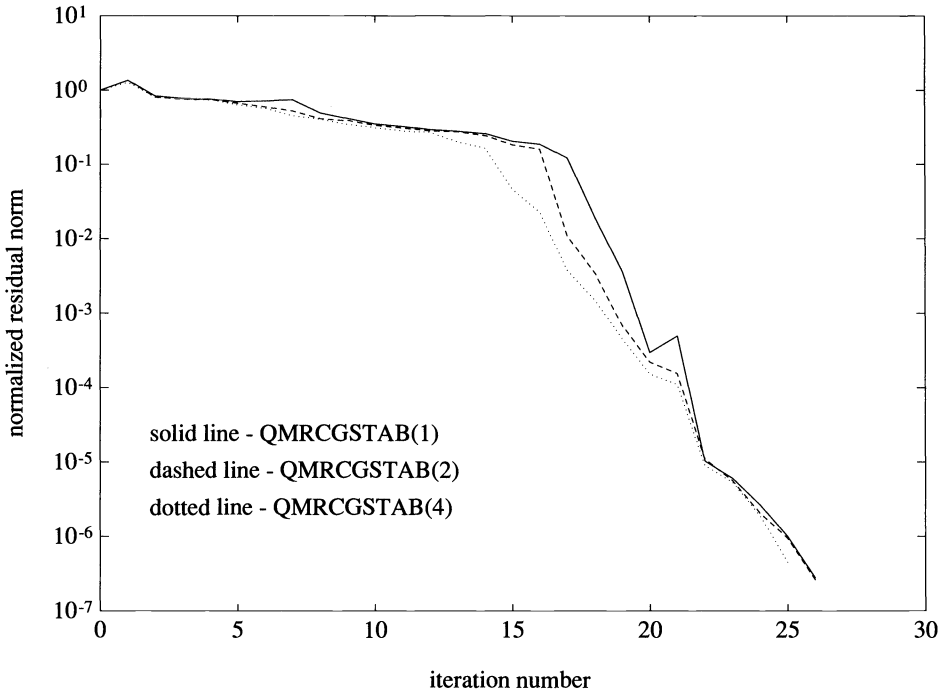

FIG. 2. *Convergence history for the* cde63 *problem* (ILUT(0) *preconditioned*).

Tony Chan for inspiring this work and Raymond Tuminaro for many helpful discussions. Finally, the constructive comments from Martin Gutknecht are greatly appreciated.

PHASE FIELD COMPUTATIONS OF SINGLE-NEEDLE CRYSTALS, CRYSTAL GROWTH, AND MOTION BY MEAN CURVATURE*

G. CAGINALP† AND E. SOCOLOVSKY‡

Abstract. The phase field model for free boundaries consists of a system of parabolic differential equations in which the variables represent a phase (or "order") parameter and temperature, respectively. The parameters in the equations are related directly to the physical observables including the interfacial width ϵ, which we can regard as a free parameter in computation. The phase field equations can be used to compute a wide range of sharp interface problems including the classical Stefan model, its modification to incorporate surface-tension and/or surface kinetic terms, the Cahn–Allen motion by mean curvature, the Hele–Shaw model, etc. Also included is anisotropy in the equilibrium and dynamical forms generally considered by materials scientists. By adjusting the parameters, the computations can be varied continuously from single-needle dendritic to faceted crystals.

The computational method consists of smoothing a sharp interface problem within the scaling of distinguished limits of the phase field equations that preserve the physically important parameters. The two-dimensional calculations indicate that this efficient method for treating these stiff problems results in very accurate interface determination without interface tracking. These methods are tested against exact and analytical results available in planar waves, faceted growth, and motion by mean curvature up to extinction time.

The results obtained for the single-needle crystal show a constant velocity growth, as expected from laboratory experiments.

1. Introduction.

The problem of numerical computation of a moving boundary has been under active study from a number of perspectives (see [Gl] for a survey). The phase field approach to free boundaries has two appealing features: (i) a broad spectrum of distinct problems that can be studied by means of a single set of equations, and (ii) the interface in these problems does not need to be tracked explicitly, as the computations use a system of parabolic equations in which the interface has been diffused.

The phase field equations specifically identify all macroscopic parameters, e.g., latent heat, diffusivity, etc., and a parameter ϵ that is a measure of interface thickness.

We begin by defining a set of sharp interface problems in a spatial region $\Omega \subset \mathbb{R}^n$ with the interface defined as $\Gamma(t)$ with $t \in \mathbb{R}^+$. A basic problem is to find a temperature function $T(x, t)$ and a curve (or surface) $\Gamma(t) \subset \Omega$ that satisfy the equations

$$\rho c_{\text{spm}} T_t = K \Delta T \quad \text{in } \Omega \setminus \Gamma(t), \tag{1.1}$$

$$\rho \ell v = K \nabla T \cdot n]_+^- \quad \text{on } \Gamma(t), \tag{1.2}$$

$$T - T_E = -\frac{\sigma}{[s]_E}\kappa - \alpha \frac{\sigma v}{[s]_E} \quad \text{on } \Gamma(t). \tag{1.3}$$

$T_E :=$ equilibrium melting temperature,
$\ell :=$ latent heat per unit mass,
$K :=$ thermal conductivity,
$\sigma :=$ surface tension between two phases,
$\rho :=$ density,

*Received by the editors July 27, 1992; accepted for publication (in revised form) February 23, 1993.

$c_{\text{spm}} :=$ specific heat per unit mass,

$[s]_E :=$ entropy difference between phases per unit volume,

$v :=$ normal velocity (positive if motion is directed toward liquid),

$\kappa :=$ sum of principal curvatures at the particular point on the interface,

$\nabla T \cdot n]_+^- :=$ jump in the normal component of the temperature (from solid to liquid),

$\alpha :=$ kinetic undercooling coefficient.

By defining a dimensionless temperature, $u := (T - T_E)c_{\text{spm}}/\ell$, a diffusion parameter $D := K/\rho c_{\text{spm}}$, and a "capillary length" $d_0 := \sigma c_{\text{spm}}/([s]_E \ell)$, one can rewrite (1.1)–(1.3) as

$$u_t = D\Delta u \quad \text{in } \Omega \setminus \Gamma(t), \tag{1.1'}$$

$$v = D\nabla u \cdot n]_+^- \quad \text{on } \Gamma(t), \tag{1.2'}$$

$$u = -d_0\kappa - \alpha d_0 v \quad \text{on } \Gamma(t). \tag{1.3'}$$

Note that the parameter D simply adjusts the time versus length scales in the problem. Thus one could set $D := 1$ by simply adjusting α (which has units of time/(space)^2, as does $\frac{1}{D}$). Within this scaling, the latent heat ℓ has been incorporated into the dimensionless temperature so that the coefficient of v in (1.2′) is unity. For the limiting situations such as Hele–Shaw in which latent heat approaches zero, one must adopt a scaling such as (1.1)–(1.3), which avoids division by ℓ.

The oldest mathematical model for an interface between two phases, e.g., liquid and solid, is known as the classical Stefan model and incorporates heat diffusion (1.1) and the latent heat due to fusion (1.2). Furthermore, it stipulates that the interfacial temperature remains at the melting temperature, i.e., $u = 0$ replaces (1.2). This last condition amounts to setting $\sigma = 0$ in (1.3) or $d_0 = 0$ in (1.3′). Although the capillarity length d_0 is often very small compared to the other length scales in the problem, such as κ^{-1}, it is nevertheless very significant as a stabilizing force [Ch].

The classical Stefan model's neglect of surface tension and surface kinetics can be partially remedied by the imposition of (1.3) with finite σ and α. The numerical study of the surface tension and kinetics model (1.1)–(1.3) then becomes even more challenging as a consequence of the curvature term in (1.3).

Another sharp interface problem that arises in the context of a fluid between two plates is the Hele–Shaw model, which can be expressed as equations (1.1)–(1.3) with the left-hand side of (1.1) set at zero. For the Hele–Shaw problem, u describes pressure, and the constants ℓ, κ, etc. represent different physical quantities (see [Oc], [Cr] and references contained therein).

Finally, one may consider the Cahn–Allen model of motion by mean curvature problem [AC], in which the interface moves with normal velocity

$$v = \frac{-1}{\alpha}\kappa \tag{1.4}$$

at each point on the interface $\Gamma(t)$.

Anisotropy may be considered in all of the problems above. In typical materials, the anisotropy is present in the surface tension σ and in the kinetic coefficient α so that (1.3′) becomes

$$u = -d_0(\theta)\kappa - \alpha(\theta)d_0(\theta)v, \tag{1.5}$$

where α is now a function of the orientation angle θ, and

$$d_0(\theta) := \frac{\sigma(\theta) + \sigma''(\theta)}{[s]_E \ell} c_{\text{spm}}. \tag{1.5'}$$

The term $\beta(\theta) := \alpha(\theta) d_0(\theta)$ is often called the mobility (see [Ta] for general discussion). The orientation angle θ may be defined as the angle between the normal to the interface and a fixed direction, or the angle between a fixed direction and the line from a central point to a point of the interface.

The precise nature of anisotropy and its interaction with undercooling (liquid below the equilibrium freezing temperature) is important in determining the shape of the interface, and one can obtain both a single-needle crystal and cubic crystal growth from a cubic symmetry material (see §5 for details).

Another approach to free boundary problems involves the use of a phase or "order" parameter φ that specifies the phases ($\varphi \backsimeq 1$ is liquid, $\varphi \backsimeq -1$ is solid) while the level set $\varphi = 0$ is now the interface. This approach has its origins in Landau theory [LL], Cahn–Hilliard type equations [CaHi], [La], and the application of mean field theory to critical phenomena [HH].

Phase field theories are generally rooted in the idea that each molecule or "spin" is under the influence of all others that effectively constitute an average "field" of interactions. This, of course, is a vast simplification over evaluating the sum over all possible states to calculate the partition function and, thereby, the free energy. Preliminary reports on a system of equations closely related to those discussed here (but with a different scaling that does not precisely attain any of the sharp interface models defined above) include [Ca] and [F].

The variable φ represents the mean field or "averaged" description of the phase at each point (t, x) in time-space. This mean field approach has been used with some, but not complete, success in the subtle area of equilibrium critical phenomena. The application to ordinary phase transitions is actually quite different in that the correlation length (i.e., mean distance at which molecules are "aware" of one another's presence) is very small, whereas it is very large in the critical region. In fact, the large correlation length provided the original justification for this approach. (See references in [Ca2] for further discussion.) Another difference between the critical region and ordinary phase transitions is that critical phenomena can rely on universality, which states that the critical exponents should be independent of the details of the system. For solidification, it is generally desirable to specify all material parameters and to obtain quantitatively reliable results.

Using the scaling introduced in [Ca1], we write the phase field equations in the form

$$c_{\text{spm}} T_t + \frac{\ell}{2} \varphi_t = \frac{K}{\rho} \Delta T, \tag{1.6}$$

$$\alpha \epsilon^2 \varphi_t = \epsilon^2 \Delta \varphi + \frac{1}{2}(\varphi - \varphi^3) + \frac{\epsilon}{3} \frac{[s]_E}{\sigma} (T - T_E), \tag{1.7}$$

where ϵ is a parameter that is a measure of the interface width and all other constants are as defined earlier. In 1985 it was shown [Ca1], using asymptotics, that the major free boundary problems could be attained as distinguished limits of the phase field equations in the form (1.6), (1.7). In particular, if ϵ approaches zero while all other parameters including σ are held fixed, then the asymptotic solutions of (1.6), (1.7) are governed to leading order by the surface tension and kinetics model (1.1)–(1.3).

The classical Stefan model can be similarly recovered in the distinguished limit as *both* ϵ and σ vanish with $\epsilon/\sigma \to 0$. The formal asymptotics have been made mathematically rigorous

in some cases of special symmetry such as traveling waves [CN] and general $1d$ and radially symmetric [CC]. Other important free boundary models such as the Hele–Shaw equations and motion by mean curvature are also obtained from the phase field equations [Ca2].

Using the variables defined before (1.1′)–(1.3′), the equations (1.6), (1.7) can be written in the form

$$u_t + \frac{1}{2}\varphi_t = D\Delta u, \tag{1.6′}$$

$$\alpha\epsilon^2\varphi_t = \epsilon^2\Delta\varphi + \frac{1}{2}(\varphi - \varphi^3) + \frac{\epsilon}{3d_0}u. \tag{1.7′}$$

With d_0 and/or α possibly depending on θ, the solutions of (1.6′), (1.7′) approach those of (1.1′), (1.2′), (1.5). In a philosophical sense, this approach to solidification computation problems is similar to artificial viscosity methods [PT] in gas dynamics in that the success of the method depends on whether the interface development is independent of ϵ for some range $(0, \epsilon_0)$.

The boundary conditions imposed on (1.6′), (1.7′) are the same as the sharp interface problem for u, with compatible conditions for φ. In particular, if one imposes Dirichlet conditions $u = u_{\partial_\pm}$, then the corresponding values of φ are the roots of

$$\frac{1}{2}(\varphi_\pm - \varphi_\pm^3) + \frac{\epsilon}{3d_0}u_{\partial_\pm} = 0, \tag{1.8}$$

where the plus and minus denote the liquid and solid portions of the boundary, respectively.

In this paper we discuss the numerical study of the phase field equations with the aim of demonstrating that a single system of equations can be used to compute a broad spectrum of phenomena that are generally associated with the sharp interface problems defined above. The advantages of the phase field model include the following: (i) The variety of phenomena ranging from motion by mean curvature to stable anisotropic crystal growth to single-needle dendrites are all obtained by simply varying parameters. (ii) The system of equations has smooth solutions and does not involve explicit conditions on the interface. Hence the interface is simply the level set $\varphi = 0$ and interface tracking is not required. (iii) All of the physical parameters are clearly identified so that the system can be used to obtain quantitatively reliable numbers. (iv) Computations involving self-interactions of the interface do not pose difficulties for the phase field model.

To illustrate how intersections create problems, we consider the following example. Two solid spheres with a small space between them are surrounded by the liquid that is undercooled so that the spheres grow slowly. At some point the spheres touch and begin to solidify. If one models this situation using (1.1)–(1.3), then there is the appearance of a mathematical singularity due to (1.3) when the spheres touch. This is a mathematical artifact; however, because (1.3) is not a physically complete description of the interfaces in this complex situation, as condition (1.3) has not been defined when the classical normal is not defined. On the other hand, the phase field equations are guaranteed to have a smooth solution (φ, T) if the initial and boundary conditions are sufficiently smooth. Thus the phase field model naturally describes the evolution of intersecting interfaces, such as this example, as it is based on a free energy description of the phases rather than a macroscopic derivation for a particular (smooth) geometry. The situation may be summarized by stating that the sharp interface problems such as (1.1)–(1.3) or (1.4) are a macroscopic approximation for simple geometries, so that a discrepancy between these models and the phase field is generally resolved by noting that the sharp interface model is not a correct approximation for the physical problem when the conditions for their derivation are no longer valid.

Figure 1.1 displays the computational evolution (using the phase field equations) of two such spheres surrounded by a slightly undercooled melt. The spheres increase in size until they touch, at which point the two interfaces fuse into a single one, which then has two points of (negative) high curvature. The curvature of these points diminishes rapidly due to the interface conditions that are implicit in the phase field equations. Figure 1.2 is a computation of the same problem with crystalline anisotropy included in the form discussed at the end of §5. In this case, the initial spheres evolve toward the dynamic Wulff shape discussed in §5 for a single seed. This evolution conforms to the theoretical predictions for an interface condition with anisotropic mobility, i.e., (1.5′) with α depending on orientation. The two seeds meet at a corner and then evolve into a single Wulff shape, i.e., a new square. In both computations, there is an absence of any unphysical singularities or blow-ups. In both Figs. 1.1 and 1.2 all parameters and conditions are identical with those described in §5 for Fig. 5.1, with anisotropy excluded from the equations for Fig. 1.1.

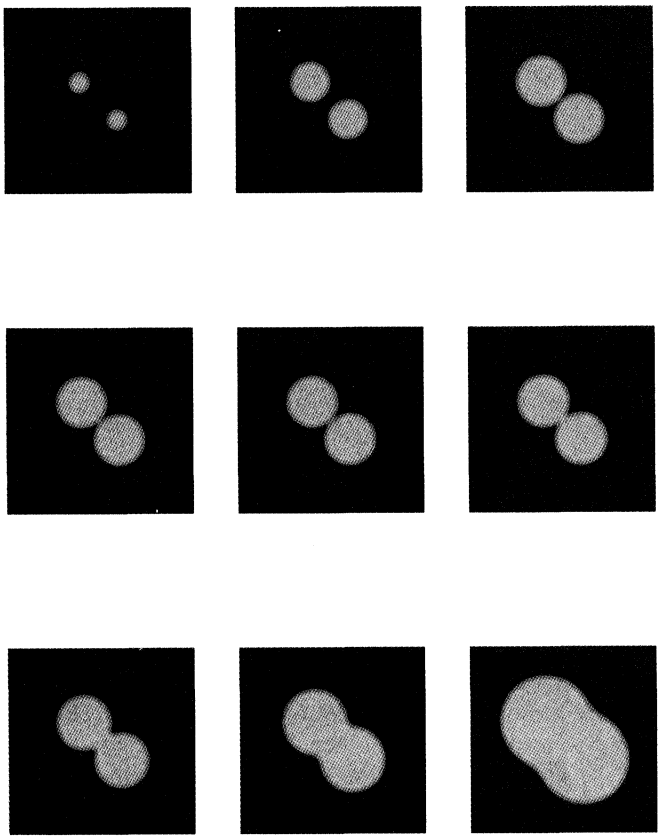

FIG. 1.1. *Self-intersection of interfaces without anisotropy. Two seeds of solid are surrounded by a slightly undercooled melt. The intersection of the interfaces poses no difficulty for the computation of the phase field equations.*

The numerical study of (1.6), (1.7) must confront the issue that the true physical size of ϵ (which is of the order of the width of the interface) is about 10^{-8} cm, while the overall domain of interest may vary between 10^{-1} cm for dendritic growth and 10^{2} cm for casting of metals. Since the grid spacing cannot be significantly larger than ϵ without large errors [CS1], [CS2], a simple application of the phase field equations with physical parameters would imply a grid of at least $10^{7} \times 10^{7}$ for dendritic growth and $10^{10} \times 10^{10}$ for casting, for example. This

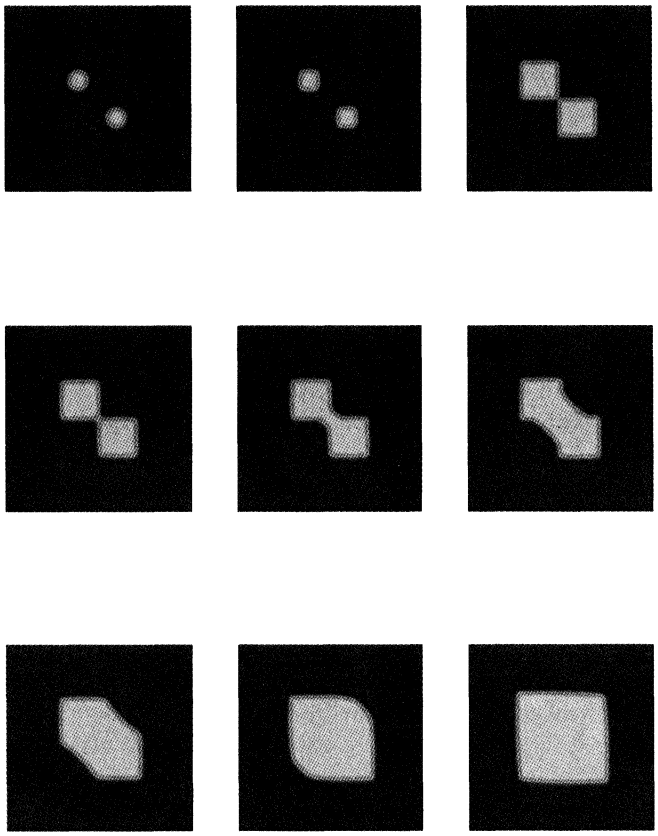

FIG. 1.2. *Self-intersections of interfaces with anisotropy. Two seeds of solid are surrounded by a slightly undercooled melt. The spheres evolve into squares (the Wulff shape) which then merge.*

grid size is prohibitive for practical computations. With this motivation, [CS1] and [CS2] studied the ansatz that ϵ can be made orders of magnitude larger (i.e., the interface can be spread) within the limitations of (a) and (b) below, without significant error, provided that this stretching is done within the proper scaling limits [Ca1], [Ca2] so that the crucial quantities such as the surface tension are not altered even by a small amount. The two key restrictions are that: (a) ϵ must be smaller than the radius of curvature; (b) ϵ cannot be large enough to destroy the double-well nature of the potential $\frac{1}{2}(\varphi - \varphi^3) \pm \frac{\epsilon}{3}\frac{1}{d_0}u$. The restriction (b) is easily remedied with a modification such as that introduced in [CC], where u is multiplied by a factor $(1-\varphi^2)^2$ or a similar function. This has the effect of trivializing the role of temperature outside of the interfacial region where it is usually very small. On the other hand, restriction (a) is fundamental and is intrinsic to the physical problem. In particular, independent of the specific method, one does not expect to resolve an interface with a radius of curvature R by means of a mesh spacing $\triangle x$ that is greater than R. Within this natural limitation, [CS1] and [CS2] showed that quantitatively reliable calculations could be performed using (1.6), (1.7).

In particular, [CS1] and [CS2] studied the one-dimensional and radially symmetric equations corresponding to (1.6), (1.7), compared the computations with the exact solutions for the limiting sharp interface problem, and examined them through self-consistency. Subject to the radius of curvature limitation, it was established that the interface could be stretched by orders of magnitude without significant loss of accuracy, even in physically delicate situations. On the other hand, even a 10% change in surface tension resulted in dramatic changes in the evolution of the interface.

In this paper, our primary aim is to show that in two dimensions a range of sharp interface problems with distinct patterns can be computed using the phase field equations. A secondary objective is to verify that the interface can be stretched with quantitative accuracy when the computations are truly higher dimensional (instead of radially symmetric equations). In the higher-dimensional case, the issue of interface stability is also relevant, so that enlarging ϵ is predicated on the expectation that it does not significantly alter stability properties. We confirm this in both the planar and spherical cases, and again we use self-consistency and comparison with exact solutions.

We begin by considering planar traveling waves for the phase field equations within the modified Stefan limit. Since the velocity of the traveling waves for the sharp interface problem is known [CCh] from the analytic solution, we compare our computations with the exact results. The traveling wave is then perturbed with a sine wave so that the stability properties can be examined in the context of the sharp interface problem. We find that a typical unstable mode in the sharp interface problem is also unstable in the phase field equations.

In §3 we consider the problem of the critical radius, which is an unstable equilibrium in solidification [Ch] and we obtain quantitative agreement with the analytical results. Anisotropic surface tension is then considered as we observe the change in interface shape as a function of both equilibrium and dynamical anisotropy. In equilibrium, these results can be compared with well-established results such as the Wulff construction approach [Wu], [Ta], [CH].

In §§4–6 we demonstrate that a broad spectrum of sharp interface problems can be approximated by the phase field model in the distinguished scaling limits as indicated in [Ca1] and [Ca2]. Section 4 features the limit of motion by mean curvature in which the interface is often characterized by reduction of curvature by becoming more circular and then shrinking until extinction. The extinction time from a circle is readily calculated analytically so that quantitative agreement of the numerical computations is verified along with the qualitative.

In §5 we consider solidification in the case of the single-needle crystal. The computations result in a single needle that moves at essentially constant velocity. Furthermore, this velocity is independent of the initial conditions. This is consistent with the known experimental [GS], [SG], and theoretical [BP], [L], and [KKL] results.

Finally, in §6, we consider solidification under conditions that favor more stable growth, so that the faceted crystal growth is observed in the anisotropic situation. It is noteworthy that a completely smooth set of equations with smooth initial data render faceted shapes, e.g., cubic. The results obtained are consistent with those obtained from the classical Wulff construction methods.

Throughout this study we use finite difference methods [CL], [CS2] with a fixed grid to isolate the issues that are of specific interest. In principle, a combination of phase field methods and adaptive grids with finite elements should provide similar accuracy at a lower cost.

Some of the other numerical studies of solidification include [LF], [SS], [K], and [RT].

2. Plane fronts, stability, and the emergence of single-needle dendrites. We study first the traveling wave solutions for the phase field equations (1.6), (1.7), the existence of which was established in [CN]. Next, we perturb the planar fronts to examine the stability properties of the interface (for which there are no analytical results). In particular, we present the growth of needle-type crystals from perturbations. These computations bridge the gap between the initial Mullins–Sekerka instability [MS] and the steady-state dendrites [BP] that evolve from them.

We consider (1.6′), (1.7′) in the distinguished limit of the surface tension and kinetics model (1.1′)–(1.3′), i.e., ϵ approaches zero with all other variables fixed. For the sharp interface problem, one can verify the existence [CCh], [DHOX] of the following traveling wave solutions

with velocity v^* and $u(t, \infty) = u_{\text{cool}}$:

$$u(t,x) = \begin{cases} u_{\text{cool}} + e^{-v^*(x-v^*t)/D} & x > v^*t, \\ u_{\text{cool}} + 1 & x \le v^*t, \end{cases} \tag{2.1}$$

$$v^* = \frac{-1}{\alpha d_0}(u_{\text{cool}} + 1). \tag{2.2}$$

To ensure the positivity of the velocity v^*, one must assume that

$$u_{\text{cool}} + 1 < 0. \tag{2.3}$$

Note that the velocity v^* and the temperature at the interface $u_{\text{cool}} + 1$ (and in fact for all x in the solid region, $x \le v^*t$) are both determined by the temperature at ∞, i.e., u_{cool}. Also, the latent heat is just unity for our temperature scale.

To state the analogous problem for the phase field equations (1.6′), (1.7′), one must impose conditions on φ as well as on u. A natural set of conditions [CN] is

$$\varphi(-\infty) = \varphi^\epsilon_\infty, \qquad \varphi(\infty) = \varphi^\epsilon_\infty, \tag{2.4}$$

$$u(-\infty) = u_{\text{cool}} + 1, \qquad u(\infty) = u_{\text{cool}}, \tag{2.5}$$

in terms of the moving coordinate $z := x - vt$ where v is to be determined. Here, the values $\varphi^\epsilon_{\pm\infty}$ must satisfy the compatibility condition (1.8).

In terms of the moving coordinates, the phase field equations have the form

$$\epsilon^2\varphi_{zz} = \alpha\epsilon^2 v\varphi_z + \frac{1}{2}(\varphi - \varphi^3) + \frac{\epsilon}{3d_0}u = 0, \tag{2.6}$$

$$Du_{zz} + v\left(u_z + \frac{1}{2}\varphi_z\right) = 0. \tag{2.7}$$

It was proven in [CN] that there exists a unique solution of (2.6), (2.7) subject to (2.4), (2.5) for small ϵ, and the velocity v (which depends on ϵ) approaches v^* given by (2.2). The far-field temperature u_{cool} not only determines the velocity, but the other boundary conditions in (2.4), (2.5) as well [CN]. In the limit of $\epsilon \to 0$, the temperature u in (2.6), (2.7) converges to the temperature (2.1) of the sharp interface model uniformly with respect to the distance measure given by the moving coordinate z. Other analyses of traveling waves for phase field equations in other scaling limits have been performed in [Wi], [BS], and [LBT].

An important question that is not resolved by the theoretical results is the rate at which the velocity $v(\epsilon)$ converges to v^* as ϵ approaches zero. Stated differently, the physically realistic value of ϵ is on the order of Angstroms, whereas, in practical computations, one would need to make ϵ larger by orders of magnitude.

Hence our first goal is to determine if the computation of plane waves is still reliable in the above situation. If so, by taking values of ϵ, which are small but still much larger than the true physical value, the front velocities and stability properties should not differ significantly from the velocity of the sharp interface model.

In our experiments we set the parameters to be $D = 1.0, \alpha = 1.0, d_0 = 0.01$, and $u_\infty = -1.05$, which yield a theoretical velocity $v^* = 5.0$. We then examined the nature of the convergence to the exact solution of the sharp interface model by halving ϵ as shown in Table 1.

We perform the same computation with each value of ϵ, and we examine the relative error of the interface

$$\frac{x(\text{theoretical}) - x(\text{experimental})}{x(\text{theoretical})}$$

at a characteristic point ($t = 0.0051$). Note that while ϵ is cut in half between experiments 1 and 2, the relative error in the interface position is reduced to one-fourth. Similarly, the relative error in velocity is reduced from 0.543 for $\epsilon = 0.00495$ to 0.093 for $\epsilon = 0.00247$. Between experiments 2 and 3, the relative error in the interface is similarly reduced. Since the approximations used in determining velocity are less accurate than those of the interface, there appears to be a finite limit to the relative error in velocity.

TABLE 1
Relative error with different values of ϵ.

Experiment	ϵ	Relative error in interface at $t = 0.00551$	Relative error in velocity at $t = 0.0051$	Maximum relative error in velocity
1	0.00495	0.162	0.543	0.911
2	0.00247	0.048	0.093	0.353
3	0.00124	0.015	0.081	0.135
4	0.00062	0.005	0.033	0.037

In earlier work [CS1], [CS2], we studied plane fronts in the distinguished limit of the classical Stefan model (there are no traveling waves in this case), using a one-dimensional formulation. The significant difference between one- and two-dimensional computations necessitates the testing of plane fronts and traveling waves in the actual two spatial dimensions. In our $2d$ experiments, we reproduce the exact classical Stefan results with a relative error of 0.0008 with 200 mesh points and $\epsilon = \triangle x$. The two sets of computations ($1d$ and $2d$) agree to the first 12 digits, thereby confirming the absence of extraneous grid effects in $2d$.

Hence, our basic conclusions for the $1d$ traveling waves [CS1], [CS2] in the surface tension and kinetics limit remain valid within the $2d$ context. The overall φ profile is essentially identical with the $1d$ calculations. The boundary conditions $\varphi_{\pm}$ are determined by (2.4) in correspondence with (1.8). The φ-level curves are all parallel to the interface and φ is approximately given by the function $\tanh(\frac{x-vt}{2\epsilon})$ as indicated by the theoretical results [CN]. The transition layer, is thus $\mathcal{O}(\epsilon)$ as in the $1d$ case. More specifically, if we take $\varphi = \pm.9$ as the cutoff in the transition layer, then the transition layer has a width 6ϵ; for cutoff $\varphi = \pm.99$ it is 10ϵ. Of course, we know from the theoretical results that the order ϵ correction to φ is crucial in the selection of the interface velocity, so that a correct interface velocity is confirmation of φ profile to order ϵ .

It is also noteworthy that the numerical error does not cause shape instability of the planar front, unlike the perturbation discussed below. This is consistent with the phase field theory since the stability properties of (1.6), (1.7) are the same as those of (1.1)–(1.3) to leading order [J], and the latter can be expected to be stable for perturbations with wavelengths that are on the size of the mesh used. The precise conditions are given in [CCh] and [J].

Next, we consider a planar wave whose interface is perturbed by a sinusoidal function, so that the interface location is given by

$$x(y) = a + b \cos my.$$

The parameters and boundary conditions remain the same as in experiment 1 with the initial temperature set at $u_\infty + 1$ in the solid with exponential decay to the boundary in the x-direction.

In Fig. 2.1 we show snapshots of the time evolution of the interface at $t = 0.0$, 0.00367, 0.00826, 0.01286, 0.01745, 0.022041, and 0.03122. In this experiment, $m = 1$, $a = 0.21$, and $b = 0.1485$. It can be clearly observed that the initial perturbation evolves into a needle-type shape.

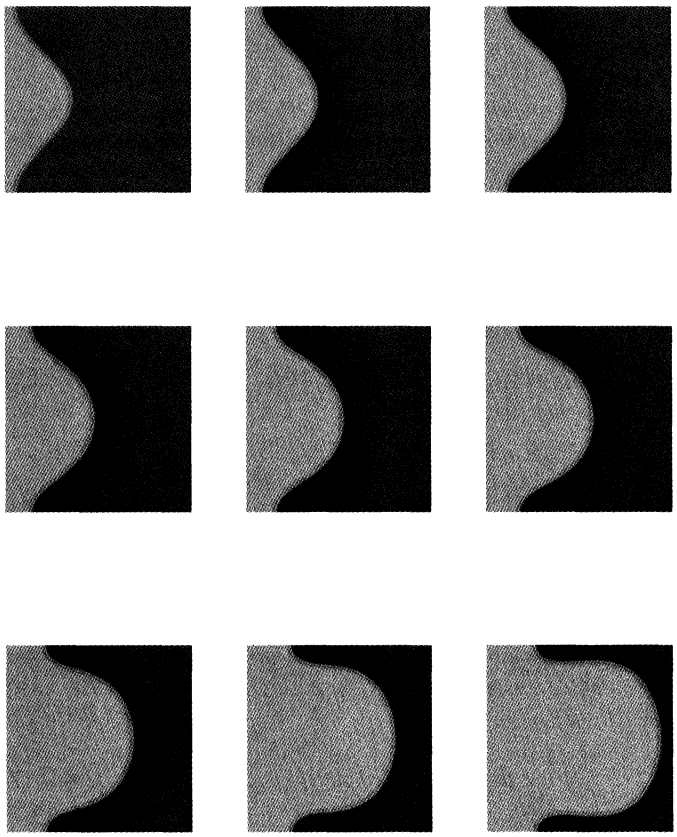

FIG. 2.1. *Single-needle crystal growth due to instability of a planar front. Initial interface at* $x = 0.21 + 0.1485 \cos y$. *Parameters are* $D = 1.0$, $\alpha = 1.0$, $d_0 = 0.01$, *and* $u_\infty = -1.05$, *which yield a Stefan planar front velocity* $v^* = 5.0$.

Hence the development of instabilities where one expects them on physical and theoretical grounds, and the absence of extraneous instabilities due to numerical error, indicate the suitability of using phase field equations to study interfaces.

It was noted in [CS1], [CS2] that there are questions of optimization in choosing ϵ with respect to the mesh spacing Δx. For a fixed grid, practical constraints impose a lower bound on Δx. For a given Δx, the question of the optimal choice of ϵ is more subtle. If ϵ is too small compared to Δx, then the surface tension, which is proportional to $\int (\nabla\varphi \cdot n)^2 dx$, will not be calculated accurately since there will be too few grid points in the interfacial region. This is easily illustrated with the tanh function that approximates φ, so that surface tension is essentially proportional to $\int \operatorname{sech}^2(r/2\epsilon) dr$. Recalling that the transition layer is about six to ten ϵ, depending on the precise cutoff point, a grid spacing of about $\Delta x = \epsilon$ would result in six to ten grid points on the interfacial region. Clearly, any fewer than six points would mean that the surface tension is not accurately computed. Since surface tension is crucial for the stability properties of the interface and this integral also has a key role in determining the $\mathcal{O}(\epsilon)$ terms in the solution, this is an important constraint.

Alternatively, if ϵ is too large, then (a) it diffuses the interface so that geometries with radii of curvatures smaller than ϵ would not be captured, and (b) the $\mathcal{O}(\epsilon)$ dynamics becomes a more significant factor limiting the quantitative accuracy of the interface velocity, as indicated by the asymptotic analysis.

In the two-dimensional problems we found the optimal value of the ratio $\frac{\epsilon}{\Delta x}$ to be $0.75 \leq \frac{\epsilon}{\Delta x} \leq 1.1$, as in the $1d$ problems. This is not very surprising in view of the asymptotic analysis, in which the size of ϵ is significant primarily in the direction perpendicular to the interface.

For the remainder of this paper we will use the ratio $\epsilon/\Delta x = 1$. Performing the same empirical optimization in some of the low symmetry examples implies a similar range for $\epsilon/\Delta x$.

The computation in Figs. 2.1, 3.1, 4.1, 5.1, 6.2, and 6.3 were done using a CRAY YMP with 200 meshpoints per side. Computations performed with 400 meshpoints were very similar, though much more costly. We use the same type of explicit schemes as in [CS1] and [CS2] and similar timescales. The timestep in all cases is the largest allowed by numerical stability considerations. The numerical runs continued until complete solidification or melting.

3. The critical radius and unstable equilibrium. A well-known instability in materials science is the critical radius [Ch, p. 67] in which a solid sphere with the sum of principal curvatures equal to κ_0 is in equilibrium with its melt at temperature u_0 with

$$u_0 = -d_0\kappa_0. \tag{3.1}$$

Under suitable conditions, e.g., Dirichlet boundary conditions, and ℓ, K^{-1} sufficiently small, a perturbation of the sphere to a larger one results in complete solidification and, analogously, for melting (see [CS2] for more discussion). The numerical computations assuming spherical symmetry confirmed this unstable equilibrium and showed that a small change in κ or σ produces a dramatic difference (melting to freezing or vice versa), while a large change in ϵ only produces a small change in velocity.

We study this problem now in the fully two-dimensional geometry (without imposing spherical symmetry), and we find that the spherical geometry is preserved. The values of K, ℓ, etc. are identical to those reported in [CS2], and again there is a 12-digit agreement between the one-dimensional and two-dimensional results for the location of the interface. Again, this confirms the absence of artificial grid effects.

Thus the two-dimensional calculations confirm the existence of this physical instability without causing artificial numerical instabilities nor necessitating the use of explicit equations of motion for the interface. Furthermore, in Fig. 3.1 we illustrate the results obtained when the initial interface is the perturbed circle $r = 0.3(1 + \frac{1}{3}\cos 8\theta)$. The parameters correspond to a critical radius $r_0 = 0.01732$, and, as predicted by (1.5), the interface evolves to a spherical shape and continues to freeze.

The introduction of anisotropy with respect to a fixed angle in the surface tension changes (3.1) into

$$\kappa_0 = -[s]_E u_0/(\sigma(\theta) + \sigma''(\theta)). \tag{3.2}$$

This expression for the curvature implies that the equilibrium shape is a dilation of the Wulff region. Figure 3.2 depicts the Wulff crystal for pivalic acid. This will be discussed in greater detail within the context of crystal growth in §5.

The $2d$ computations on the critical radius and the perturbed circle (Fig. 3.1) are also useful in demonstrating that grid effects do not introduce artificial anisotropy. In particular, the grid effects would be most pronounced for the critical radius problem since the initial configuration is borderline between melting and freezing, so that any extraneous effects would be magnified.

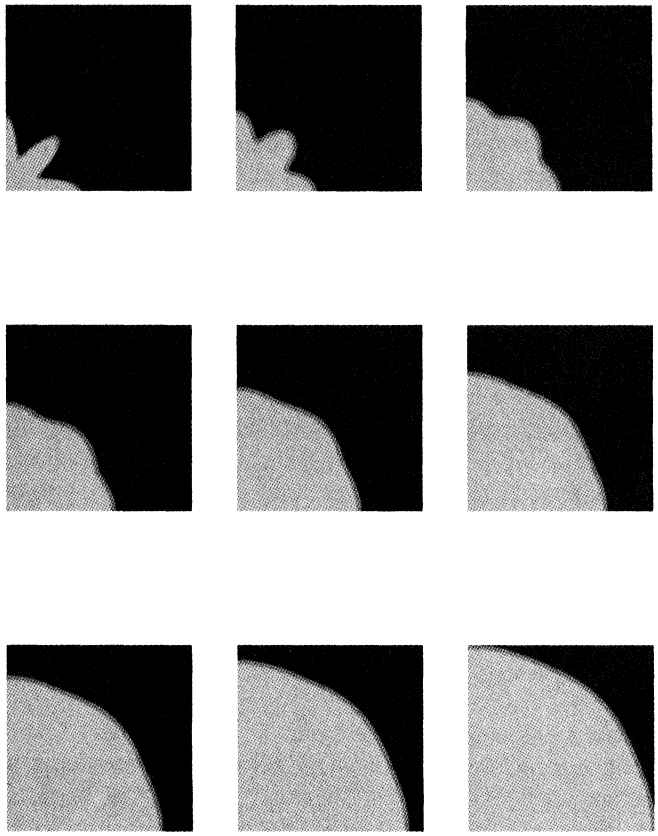

FIG. 3.1. *Stability of perturbations in the case of unstable equilibrium at critical radius. Initial interface at* $r = 0.3(1 + \frac{1}{3}\cos 8\theta)$. *Parameters are* $\alpha = 1.0$, $D = 1.0$, $\ell = 0.01$, $[s]_E = 4$, $\epsilon = 0.005$, *and* $\sigma = 0.034651$, *with critical radius* $r_0 = 0.01732$.

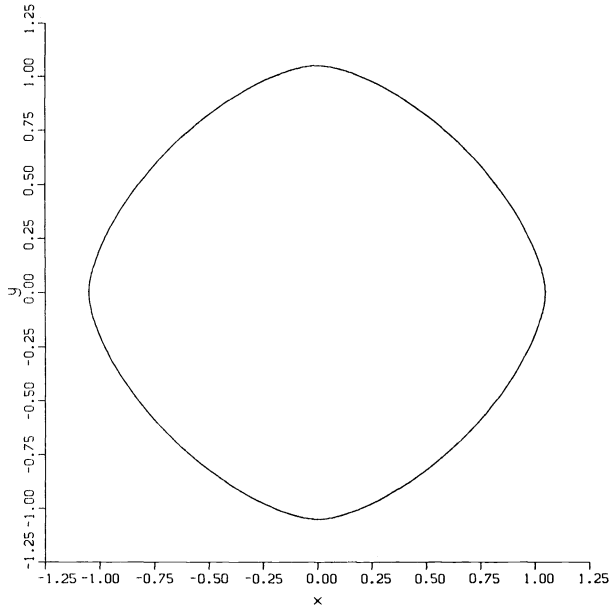

FIG. 3.2. *Wulff crystal for pivalic acid.*

4. The single-needle crystal. In §§4–6 we use the phase field equations to study a spectrum of problems that involve different physical parameters and behavior. One set of numerical experiments (see Figs. 3.1, 4.1, 5.1, and 6.3) are performed with identical initial conditions to illustrate the wide range of applicability.

The first of these is the single-needle crystal solidification at high velocities. Anisotropy is generally regarded as important for this problem as both σ and α vary with respect to orientation angle, θ. A series of physical experiments [SG], [GS] indicate that the role of anisotropy is to select the direction of the growth rather than to determine the shape or velocity of the tip. (However, other measurements, with samples that are not as pure as those used by [GS] suggest that the anistropy of these materials is much closer.) For example, the extent of anisotropy in the surface tension is ten times greater for pivalic acid than succinonitrile, yet the shape and dimensionless velocity (as a function of undercooling) are essentially identical [GS]. In earlier work [CL], the anisotropy in σ has been studied. In these numerical experiments, we study the effects of dynamic anisotropy, which is not as well understood in terms of the physical experiments. As a precise physical form for dynamical anisotropy has not been established, we use a (phenomenological) function that is strongly anisotropic along the diagonal. In particular,

$$\alpha^{-1} = \begin{cases} \alpha_0 + (1-\alpha_0)\left(\cos \frac{4\pi}{\sqrt{2}} d\right)^4 & \text{if } \frac{-\sqrt{2}}{8} < d < \frac{\sqrt{2}}{8}, \\ \alpha_0 & \text{otherwise,} \end{cases} \tag{4.1}$$

where d is the distance to the diagonals (between $\hat{x}$ and $\hat{y}$ axes). Note that the dynamic anisotropy will not generally have a form such as (1.5′), which arises from the second derivatives in the Laplacian.

In a part of the interface in which the temperature and curvature do not vary significantly, the velocity is given by

$$v \cong -\alpha^{-1}(\text{const}), \tag{4.2}$$

so that the diagonal is the preferred direction of growth. Figure 4.1 displays a time sequence in which the initial condition is a circle that is strongly perturbed by a sine function with values of $\alpha_0 = 0.1$. The growth is chiefly in the preferred direction. The diagonal was chosen as the preferred direction to ensure that anisotropic growth would not be the result of grid effects. In fact, the absence of anisotropic growth when α^{-1} is isotropic indicates that grid effects are not significant.

There is considerable experimental [SG], [GS], [DG] and theoretical evidence [BP], [KKL], [L] that suggests that the velocity of the single needle should be constant. This is confirmed by our numerical experiments, even though only linear interpolation is used to determine both the interface location and its velocity.

Furthermore, this velocity is found to be independent of the initial conditions, which is consistent with the experimental and theoretical results cited above. Figure 4.2 depicts the convergence to a selected velocity from distinct initial conditions. The velocity 44.13 is constant to within 0.62%.

5. Faceted crystal growth. The geometric patterns and facets that arise from crystal growth have posed intriguing questions for many years. A very early scheme to describe the equilibrium interface is known as the Wulff construction [Wu], which will be described later in this section. The propagation of facets and the development and elimination of corners has been studied extensively in recent decades from the minimal surfaces and related approaches [Ta].

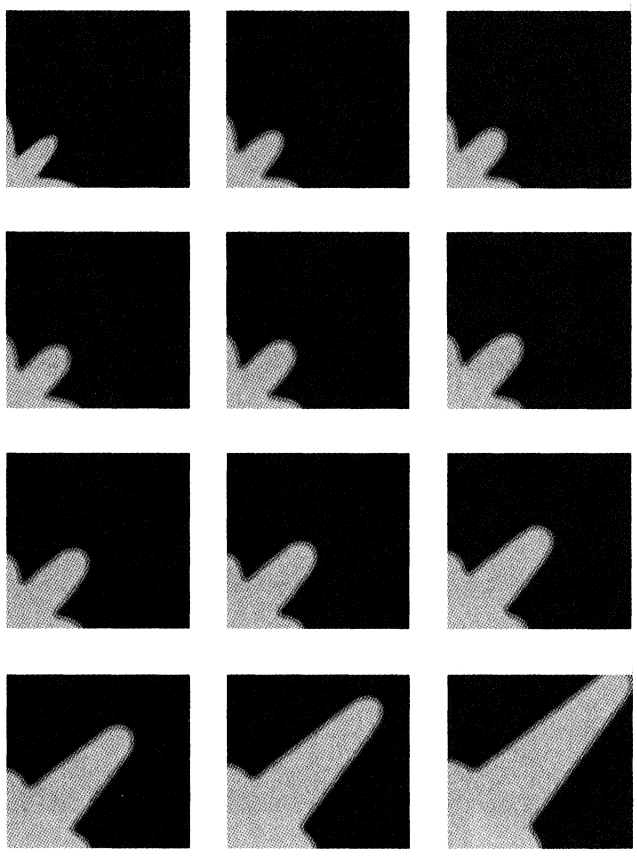

FIG. 4.1. *Single-needle crystal growth due to anisotropic mobility* (4.1) *with* $\alpha_0 = 0.1$. *Initial interface at* $r = 0.3(1 + \frac{1}{3}\cos 8\theta)$. *Parameters are* $D = 1.0$, $\ell = 0.01$, $[s]_E = 4$, $\epsilon = 0.005$, *and* $\sigma = 0.034641$.

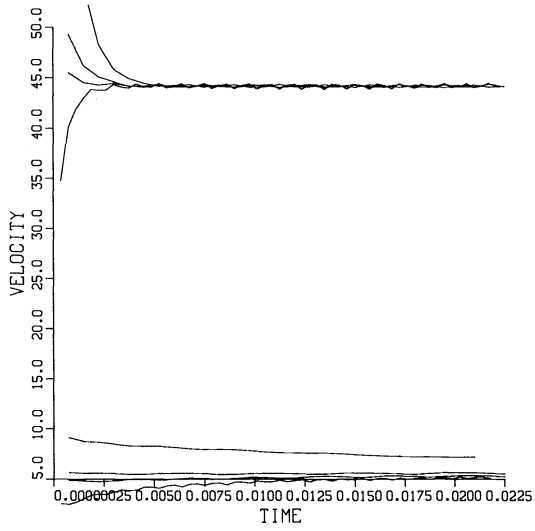

FIG. 4.2. *Tip and axis velocities of needle crystals obtained with different initial interfaces. Needle crystal tip velocity convergence to a constant independent of initial interface. Initial interfaces at* $r = 0.3$, $r = 0.3(1 + \frac{1}{3}\cos m(\theta - \frac{\Pi}{4}))$ *and* $r = 0.3(1 + \frac{1}{3}\cos m\theta)$ *for* $m = 4, 8$. *Parameters are* $D = 1.0$, $\ell = 0.01$, $[s]_E = 4$, $\epsilon = 0.005$, *and* $\sigma = 0.034641$.

In such studies, the corners are explicitly part of the numerical scheme. The evolution of faceted crystal growth poses a particularly strong challenge for a smooth set of parabolic equations, such as the phase field. Given a smooth initial data (e.g., first frame of Fig. 5.1), a material with anisotropy must eventually develop corners and facets and must propagate along planar fronts dictated by the geometry and anisotropy.

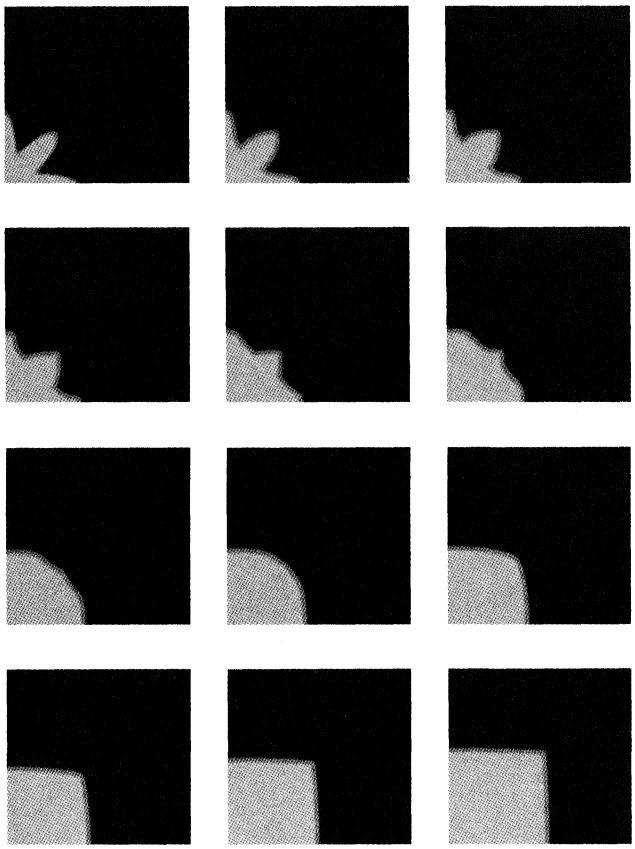

FIG. 5.1. *Faceted crystal growth due anisotropic mobility* $[\alpha^{-1} = .065(1 + 0.818 \cos 4(\theta - \frac{\pi}{4}))]$ *is the angle between interface normal and x-axis. Initial interface at* $r = 0.3(1 + \frac{1}{3} \cos 8\theta)$. *Parameters are* $D = 1$, $\ell = 0.01$, $[s]_E = 4$, $\epsilon = 0.005$, *and* $\sigma = .03464$.

The anisotropy in the phase field equations can involve both $\alpha(\theta)$ and $\sigma(\theta)$, where θ is now defined to be the angle between the normal to the interface and the x-axis, i.e.,

$$\cos\,\theta = \frac{\nabla\bar{\varphi}}{|\nabla\varphi|} \cdot \hat{x}. \tag{5.1}$$

We study the anisotropy by assuming σ and/or α are of the form

$$\sigma(\theta) = \sigma_0[1 + \delta_\sigma \cos\, M(\theta - \theta_\sigma)], \tag{5.2}$$

$$\alpha^{-1}(\theta) = \alpha_0^{-1}[1 + \delta_\alpha \cos\, M(\theta - \theta_\alpha)], \tag{5.3}$$

where M is an integer ($M = 4$ for cubic anisotropy), $\delta_\sigma, \delta_\alpha \in \mathbb{R}^+$ are the amplitudes of the anisotropies, and $\theta_\sigma, \theta_\alpha$ are the "preferred" angles. The latter will be defined more precisely below.

The phase field equations we study are then (1.6′), (1.7′) with d_0 and α given by (1.5′), (5.2), (5.3). In the asymptotic limit as ϵ approaches zero, the solutions to these phase field

equations are governed to leading order by those of (1.1′), (1.2′), (1.5), (1.5′). Since these dimensionless equations are related to the fully dimensional equations by simple substitution, every parameter in our system including those involving anisotropy, e.g., δ_σ, can be obtained directly from experimental data. Of course, we wish to "stretch out" the parameter ϵ, as discussed earlier, for computational convenience.

Next, we consider the issue of preferred direction, which is similar for the phase field and sharp interface models, in view of the remarks above. Consider the sharp interface problem (1.1′), (1.2′), (1.5), (1.5′) in equilibrium so that temperature is constant. Then (1.5), (1.5′) implies that (for some constant C^2)

$$\kappa = \frac{C^2}{\sigma(\theta) + \sigma''(\theta)}, \tag{5.4}$$

$$\sigma(\theta) + \sigma''(\theta) = \sigma_0[1 - (M^2 - 1)\delta_\sigma \cos M(\theta - \theta_\sigma)]. \tag{5.5}$$

Hence, if we assume that δ_σ satisfies $(M^2 - 1)\delta_\sigma < 1$, then the curvature has its maximum when $\theta = \theta_\sigma$. For cubic anisotropy ($M = 4$) with $\theta_\sigma := \frac{\pi}{4}$ this means that the equilibrium shape of the interface is such that the solid protrudes further in the diagonal directions.

This brief illustration is one implication of the Wulff construction [Wu] and can be obtained from the Cahn–Hoffman [CH] $\overline{\xi}$ vector approach or the Herring spheres approach. Note that when $\sigma + \sigma''$ changes sign, then one has facets in the equilibrium shape as a consequence of missing angles or orientations. The values of δ_σ for two materials used in dendritic experiments are 0.05 for pivalic acid and 0.005 for succinonitrile [GS].

The dynamical situation is more complicated even if the kinetic term αd_0 in (1.6) is neglected completely. On the other hand, in a limiting case in which curvature is neglected and $\alpha \neq 0$, one can acquire a basic understanding of the effects of this kinetic term. This analysis amounts to a comparison of velocities of planar fronts with different orientations, so that (1.5), (1.5′) imply

$$v \simeq \frac{C^2}{\alpha(\theta)[\sigma(\theta) + \sigma''(\theta)]}. \tag{5.6}$$

Once again, for small δ_σ and δ_α, and $\theta_\sigma = \theta_\alpha$, the velocity is maximum at $\theta = \theta_\sigma = \theta_\alpha$. Hence in the cubic case ($M = 4$, $\theta_\sigma = \theta_\alpha = \frac{\pi}{4}$), the growth is fastest in the diagonal directions.

These two calculations illustrate the following expectations. An initially spherical solid with cubic anisotropy will tend to grow fastest in the diagonal directions. If the boundary conditions are such that equilibrium is reached (e.g., appropriate Neumann conditions), then the interface will correspond to the Wulff shape, which is shown in Fig. 3.2, i.e., a square with rounded corners. Note that while the equilibrium result (5.4) is exact, the dynamic result (5.6) is only suggestive since the temperature will not be exactly constant and curvature is not precisely zero. Furthermore, one has a natural expectation that the dynamics will be less stable than equilibrium, thereby exaggerating growth in the favored directions. Thus it is possible that the dynamical problem will have facets for smaller anisotropies than those required by the vanishing of the denominator of (5.6), which would be the condition for "corners" or missing angles in equilibrium according to the Wulff construction.

While we consider the usual case in which $\theta_\sigma = \theta_\alpha$, it is worth noting that some materials exhibit dynamical anisotropy with a different preferred direction than that of the equilibrium.

In our numerical computations, we study a material with anisotropy given by (5.2) or (5.3) (with $\delta_\sigma = 0.05$ or $\delta_\alpha = .818$ and $M = 4$ and $\theta_\sigma = \frac{\pi}{4}$ or $\theta_\alpha = \frac{\pi}{4}$.). Note that the dynamic anisotropy appears to be larger, but the coefficient of δ_σ is multiplied by $M^2 - 1 = 15$. Our

value of δ_σ corresponds exactly to that reported by [GS] for pivalic acid. The computations show that a material with such anisotropy will evolve into a shape with four-fold symmetry, regardless of the initial pattern. In particular, Fig. 5.1 displays 12 frames in the phase field computations (1.6′), (1.7′) using (5.3) (i.e., with $d_0(\theta)$ defined by (1.5′). Similar results are obtained with (5.2). The fact that such different sources of anisotropy (5.2) versus (5.3) result in very similar patterns is an important physical conclusion that is not obvious from the form of the equations. The initial shape is the same perturbed circle used in the formation of the single-needle dendrite. By frame 3 of Fig. 5.1, this interface develops some corners and facets, some of which correspond to the favored directions discussed above, while others form as an immediate consequence of the initial conditions. In frames 3–9, these latter facets are gradually eliminated at the expense of the dominant facets distinguished by (5.4) and (5.6). In the last few frames (i.e., 10–12) these dominant planes become extended until they meet at the $x - y$ diagonal with a slightly smoothed-out right angle. The solidification then continues without any change in shape.

A rigorous result [So] has established that an interface moving in accordance with (1.3′) alone, with constant u, would retain the anisotropic shape. While there are no rigorous results for the full set of equations involved in solidification, our numerics show that this is indeed the case for the phase field equations. Since these equations are asymptotically governed by (1.1′)–(1.3′) to leading order, the same conclusion remains valid for the sharp interface problem.

6. Motion by mean curvature. The problem of motion by mean curvature (see [Br] and references contained therein) is to determine a $(d-1)$-dimensional surface (or curve) $\Gamma_s(t)$ in $\Omega \subset \mathbb{R}^d$, such that the (normal) velocity, $v(t,x)$, at each point on the surface satisfies

$$v(t,x) = -\alpha^{-1}\kappa(t,x), \tag{6.1}$$

where κ is again the sum of principal curvatures and α^{-1} is a constant or a function of orientation angle.

A closely related problem is to find the level set

$$\Gamma(t) := \{x \in \Omega : \varphi(t,x) = 0\}, \tag{6.2}$$

where φ is a solution to the single parabolic equation

$$\alpha\epsilon^2\varphi_t = \epsilon^2\Delta\varphi + \frac{1}{2}(\varphi - \varphi^3). \tag{6.3}$$

Equation (6.3), which was introduced by Cahn and Allen [Ca], [AC] in the context of antiphase boundaries is a limiting case of the phase field equations. As the latent heat ℓ approaches zero, while the initial and boundary conditions imposed on u are also zero, the phase field equations (1.6′), (1.7′) have solutions that are governed by those of (6.3) and consequently (6.1) to leading order. Thus the leading order asymptotics for (1.6′), (1.7′) is just a special case of (1.5) in which $u = 0$ [Ca2]. In recent years, the connections with materials science through the phase field equations have stimulated a resurgence of interest in the mathematical theory of (6.3) and other regularizations of (6.1) [BK], [MSc], [GG]. From a formal analysis it is clear that an initial interface of the form of frame 1 in Fig. 6.3 will tend to approach a circle and then shrink until extinction. The time of extinction from a circle is easily calculated.

Our numerical calculations consist of studying (1.6), (1.7) in the limit of small ℓ, with zero boundary and initial conditions for u, and the standard conditions of φ described in (2.10) so that $\varphi_+ = +1$ on the (exterior) liquid and $\varphi_- = -1$ in the (interior) solid in this case. In our first experiment we compared the numerical results with a theoretical solution. We took $\alpha = 1$, $\ell = 0$, zero boundary and initial conditions for u and the initial solid seed to be a circle of radius 0.3. The theoretical solution gives a circle with radius $r(t) = (0.09 - 2t)^{1/2}$, which has an extinction time $T_0 = 0.045$.

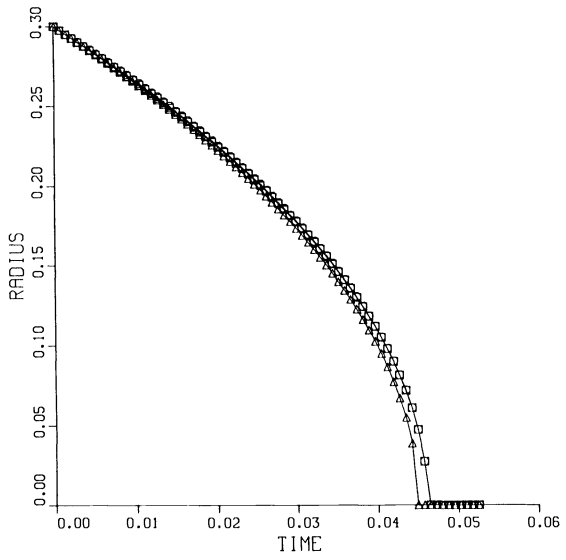

FIG. 6.1. *Motion by mean curvature. Computed and theoretical interface locations for a circular initial interface. Exact radius is* $r(t) = (0.09 - 2t)^{1/2}$, $0 \le t \le 0.045$. *Parameters are* $D = 1.0$, $\ell = 0$, $[s]_E = 4$, $\epsilon = 0.005$, *and* $\sigma = 0.866025$.

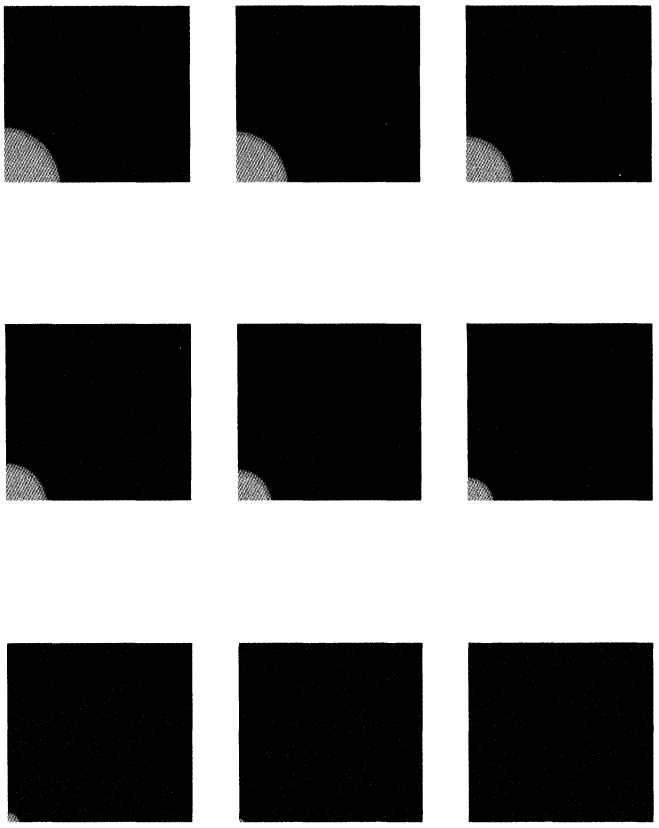

FIG. 6.2. *Motion by mean curvature. Crystal evolution corresponding to the computation of Fig.* 6.1.

In Fig. 6.1 we depict the computed and theoretical radius of the circle as a function of time. There is an agreement of two or more digits up to $t = 0.0345$ and the accuracy deteriorates approaching T_0 as expected. The computational extinction time is between 0.04575 and 0.0465. Figure 6.2 depicts the evolution at times

$$t = 0.0, 0.00675, 0.01425, 0.02175, 0.02925, 0.03675,$$
$$0.04425, 0.04565, 0.0465.$$

The initial condition in frame 1 of Fig. 6.3 is identical to those that we used for faceted crystals and stable solidification. In frames 1–4, the interface moves toward a circle (frame 5) with a radius that is approximately that of the perturbed circle in frame 1. The interface acts in a way to minimize the surface tension during this phase. The surface tension in (6.3) or (1.7) is determined to leading order by the coefficients of $\Delta\varphi$ and the $\frac{1}{2}(\varphi - \varphi^3)$ term.

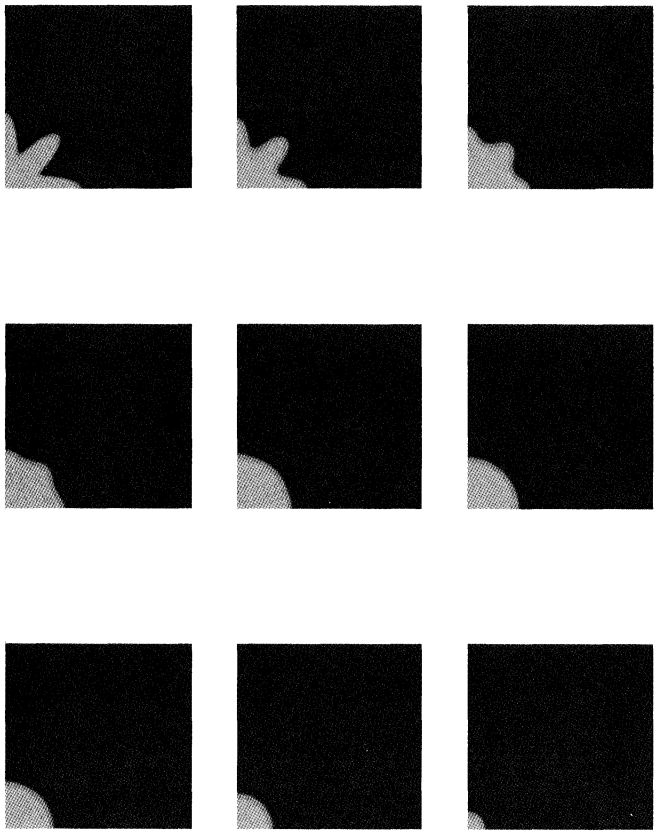

FIG. 6.3. *Motion by mean curvature. Crystal evolution for initial interface* $r = 0.3(1 + \frac{1}{3}\cos 8\theta)$. *Parameters are the same as in Figs.* 6.1 *and* 6.2.

The anisotropic analog of (6.1) involves replacing the constant α by a function of orientation angle as discussed earlier in the single-needle or faceted-crystal growth cases. Note that the anisotropy involved in the surface tension is not relevant in this limit since σ cancels in the asymptotics. In the anisotropic case the evolution of the interface is similar except that the convergence of the interface is toward the appropriate Wulff shape rather than the sphere.

THREE-DIMENSIONAL ADAPTIVE MESH REFINEMENT FOR HYPERBOLIC CONSERVATION LAWS*

JOHN BELL†, MARSHA BERGER‡, JEFF SALTZMAN§, AND MIKE WELCOME†

Abstract. A local adaptive mesh refinement algorithm for solving hyperbolic systems of conservation laws in three space dimensions is described. The method is based on the use of local grid patches superimposed on a coarse grid to achieve sufficient resolution in the solution. A numerical example computing the interaction of a shock with a dense cloud in a supersonic inviscid regime is presented. Detailed timings are given to illustrate the performance of the method in three dimensions.

Key words. adaptive methods, mesh refinement

AMS subject classifications. 65M06, 65M50, 76N15

1. Introduction.

Advanced finite difference methods, by themselves, are unable to provide adequate resolution of three-dimensional phenomena without overwhelming currently available computer resources. High-resolution three-dimensional modeling requires algorithms that focus the computational effort where it is needed. In this paper we describe an extension of the adaptive mesh refinement (AMR) algorithm for hyperbolic conservation laws originally developed in [2], [3] to three space dimensions. AMR is based on a sequence of nested grids with finer and finer mesh spacing in both time and space. These fine grids are recursively embedded in coarser grids until the solution is sufficiently resolved. An error estimation procedure automatically estimates the accuracy of the solution, and grid generation procedures dynamically create or remove rectangular fine grid patches. Special difference equations are used at the interface between coarse and fine grid patches to insure conservation. This is all handled without user intervention by the AMR program.

Two-dimensional versions of the AMR algorithm described here have been used to solve fluid flow problems in a variety of settings and have enabled the study of fluid flow phenomena not previously possible. For example, the extra resolution provided by AMR enabled the computation of a Kelvin–Helmholtz type instability along the slip line in a study of Mach reflection off an oblique wedge [2] and aided in the resolution of the weak von Neumann paradox in shock reflection [7]. When combined with a multifluid capability, the algorithm was used to compute the interaction of a supernova remnant with an interstellar cloud [8] and to categorize refraction patterns when a shock hits an oblique material interface [13]. When extended to use body-fitted coordinates, AMR was used to study diffraction of a shock over an obstacle [11]. In each of these cases the use of adaptive mesh refinement reduced the cost of the computation by more than an order of magnitude. The improved efficiency associated with using AMR may make similar flows in three dimensions computationally tractable.

There are several alternative approaches to focusing computational effort in three-dimensional flows. One approach uses a logically rectangular grid with moving grid points that adjust to the flow [11], [9]. There are several difficulties with this approach. First, it is hard

to implement a three-dimensional high-resolution integration scheme for moving rectilinear grids. In our approach the integration scheme need only be defined for uniform rectangular grids; this avoids the complexity and computational cost associated with metric coefficients in the moving grid approach. Furthermore, in three dimensions it is extremely difficult to effectively cluster points to capture unsteady phenomena while maintaining a grid with sufficient smoothness in both space and time to permit effective computation. Even if acceptable grid motion can be determined, the entire computation is usually performed with a fixed number of gridpoints throughout the computation. In contrast, the local grid refinement approach dynamically adjusts the number of zones to match the requirements of the computation. The timestep used in moving mesh codes is also limited by the smallest cell size unless additional work is done by solving the equations implicitly or using techniques that allow each cell to evolve with its own timestep.

Another approach to three-dimensional computations uses adaptive unstructured grids [1], [14]. Unstructured grids offer the most flexibility in optimally placing the gridpoints. They can treat general geometries in a simple uniform way. They also offer a possibility of anisotropic refinement, as might be used for Navier–Stokes boundary layer calculations. However, we favor the use of locally uniform refined patches (the basis for AMR, described later) for their accuracy and wave propagation properties. The development of discretization techniques that avoid degradation for strong shocks on highly irregular meshes remains an open issue. Our use of uniform grids allows us to directly use much of the high resolution difference scheme methodology developed for this flow regime. Uniform patches also have low overhead, both from the computational and the storage point of view. The extra information that is needed, in addition to the actual solution values, is proportional to the number of grids rather than the total number of grid points.

An indication of the robustness of the mesh refinement algorithm is that very few changes were required in extending it from two to three dimensions. However, time-dependent three-dimensional computations push the limits of current machine resources, both in terms of memory and CPU time. For this reason, particular care was taken in the implementation, and a better grid generation algorithm was used to increase the overall efficiency of the code.

The starting point for this paper is the version of AMR presented in [2] and we assume the reader is familiar with that paper. In §2 we describe the differences in the three-dimensional mesh refinement algorithm which have to do with the grid generation algorithm and the error estimator. In §3 we describe the operator split integration scheme used in the numerical experiment. In particular, this section clarifies the interaction of the grid refinement and operator split boundary conditions on patched grids while maintaining conservation at grid interfaces. We include a brief section on implementation since some simple changes that produce much cleaner code have been incorporated. We are also rewriting the code in a hybrid of C++ and FORTRAN. The results of a numerical experiment of a shock-cloud interaction modeling the laboratory experiments of Haas and Sturtevant [12] are presented in §5. Detailed timings are presented as well as memory usage and grid statistics demonstrating that AMR offers significant savings of computational resources and can be an important tool in the study of three-dimensional fluid dynamics.

2. The adaptive mesh refinement algorithm. AMR uses a nested sequence of logically rectangular meshes to solve a partial differential equation (PDE). In this work, we assume the domain is a single rectangular parallelepiped although it may be decomposed into several coarse grids. With the new grid generator described below, grids at the same level of refinement do not overlap. We require that the discrete solution be independent of the particular decomposition of the domain into subgrids. Grids must be properly nested, i.e., a fine grid should be at least one cell away from the boundary of the next coarser level unless it is touching

the boundary of the physical domain. However, a fine grid can cross a coarser grid boundary and still be properly nested. In this case, the fine grid has more than one parent grid. This is illustrated in Fig. 1 in two dimensions. (This set of grids was created for a problem with initial conditions specifying a circular discontinuity.)

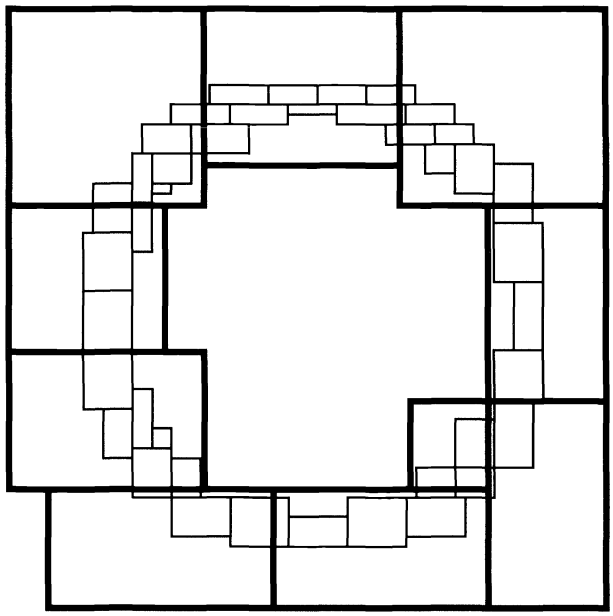

FIG. 1. *A coarse grid with two levels of refined grids. The grids are properly nested, but may have more than one parent grid.*

AMR contains five relatively separate components. The *error estimator* uses Richardson extrapolation to estimate the local truncation error; this determines where the solution accuracy is insufficient. The *grid generator* creates fine grid patches covering the regions needing refinement. *Data structure* routines manage the grid hierarchy allowing access to the individual grid patches as needed. *Interpolation* routines initialize a solution on a newly created fine grid and provide the boundary conditions for integrating the fine grids. *Flux correction* routines insure conservation at grid interfaces by modifying the coarse grid solution for coarse cells that are adjacent to a fine grid.

When all these components are assembled, a typical integration step proceeds as follows. The integration steps on different grids are interleaved so that before advancing a grid, all the finer level grids have been integrated to the same time. One coarse grid cycle is then the basic unit of the algorithm. The variable r denotes the mesh refinement factor in both space and time (typically 4), and $level$ refers to the number of refinements (the coarsest grid is at level 0). The regridding procedure is done every few steps, so any particular step may or may not

involve regridding.

```
Recursive Procedure Integrate (lev)
   Repeat r^lev times
      Regridding time? - error estimation and grid generation
                                 for level lev grids and finer
      step Δt_lev on all grids at level lev
      if (lev+1) grids exist
      then begin
              integrate (lev+1)
              conservation_fixup(lev, lev+1)
           end
   end.

lev = 0  (* coarsest grid level *)
Integrate (level)
```

Single Coarse Grid Integration Cycle

All of these steps are described fully in [2], with the exception of the new grid generation algorithm.

2.1. Grid generation. The grid generation algorithm takes a list of coarse grid points tagged as needing refinement and groups them in clusters. Fine grids are then defined by fitting the smallest possible rectangle around each cluster. The grid generator should produce efficient grids, i.e., rectangles containing a minimum number of cells that are not tagged, without creating a large number of small grids with poor vector performance and excessive boundary overhead.

The grid generator described in [2] uses a simple bisection algorithm. If a single enclosing rectangle is too inefficient, it is bisected in the long direction, the tagged points are sorted into their respective halves, and new enclosing rectangles are calculated. The efficiency is measured by taking the ratio of tagged points to all points in a new fine grid. The procedure is repeated recursively if any of the new rectangles is also inefficient. Since this algorithm uses no geometric information from the tagged points, it often results in too many tiny subgrids and is followed by a merging step. Unfortunately, this results in overlapping grids. Since the memory usage in three-dimensional calculations is at a premium, we want to avoid overlapping. Furthermore, we expect that there will be large numbers of grids in three dimensions which makes the merging step costly.

We now use a new clustering algorithm that uses a combination of signatures and edge detection. Both techniques are common in the computer vision and pattern recognition literature. After much experimentation, described in [4], we settled on what amounts to a "smart bisection" algorithm. Instead of cutting an inefficient rectangle in half, we look for an "edge" where a transition from a flagged point region to a nonflagged one occurs. The most prominent such transition represents a natural line with respect to which the original grid can be partitioned.

We describe the procedure in two dimensions for purposes of illustration. First, the signatures of the flagged points are computed in each direction. Given a continuous function $f(x, y)$, the horizontal and vertical signatures Σ_x and Σ_y are defined as

$$\Sigma_x = \int_y f(x, y)\, dy$$

and

$$\Sigma_y = \int_x f(x, y)\, dx,$$

respectively. For discrete binary images, this is just the sum of the number of tagged points in each row and column. If either signature contains a zero value, then clearly a rectangle can be partitioned into two separate clusters in the appropriate direction. If not, an edge is found by looking for a zero crossing in the second derivative of the signature. If there is more than one such zero crossing, the largest one determines the location for the partitioning of the rectangle. If two zero crossings are of equal strength, we use the one closest to the center of the old rectangle to prevent the formation of long thin rectangles with poor vectorization. This procedure is also applied recursively if the resulting rectangles do not meet the efficiency criterion, with the exception that if no good partition is found and the efficiency is at least 50%, the rectangle is accepted; otherwise, it is bisected in the long direction as a last resort. In computational experiments in two space dimensions, for the same level of accuracy the new algorithm reduces the CPU time by approximately 20%.

Figure 2 illustrates the entire procedure on a sample set of points. The first column on each side is the signature, and next to it is the second derivative. After each partitioning of the points, a new enclosing rectangle is calculated around the tagged points. In this figure, after three steps, the fine grids are acceptably efficient and the procedure stops.

2.2. Error estimation. The second improvement over the basic approach in [2] is the addition of a purely spatial component to the error estimation process to supplement Richardson extrapolation. In Richardson extrapolation, the data on the grid where the error is being estimated is coarsened and then integrated for a timestep. That result is then compared to the result of integrating first and then coarsening. For smooth solutions, the difference in these two results is proportional to the truncation error of the scheme. The motivation for including an additional error measure is to identify structures that are missed by the averaging process associated with the coarsening in the Richardson extrapolation. For example, in gas dynamics a slow-moving or stationary contact surface generates little or no error in the Richardson extrapolation process. In fact, the integrator is not generating any error in this case. However, failure to tag the contact will cause it to be smeared over a coarser grid. The error associated with deciding whether or not to refine the contact surface is associated only with the spatial resolution of the discontinuity, not with errors in integration. Should the contact need to be refined later (for example, if it interacts with another discontinuity), the initial conditions are no longer available to provide higher resolution. For certain special cases a similar phenomenon can also occur for shocks. These problems can be avoided by providing the error estimation routine with the unaveraged grid data so that spatial resolution can also be measured.

Along with the addition of a purely spatial component to the error estimation, we also directly control the process of tagging (and untagging) cells for refinement. For example, a user can insist that only a certain part of the domain is of interest and that the error estimator should be ignored if it says refinement is needed outside of the interesting regions. Similarly, it can force refinement in a particular region independent of the error estimation result.

3. Integration algorithm. For the computational examples presented in §5, we use an operator-split second-order Godunov integration scheme. However, the particular form of the integration scheme is independent of the remainder of the AMR shell. Other integration methods and, in fact, other hyperbolic systems can be easily inserted into the overall AMR framework. The only requirement for the integration scheme is that it be written in flux form, i.e.,

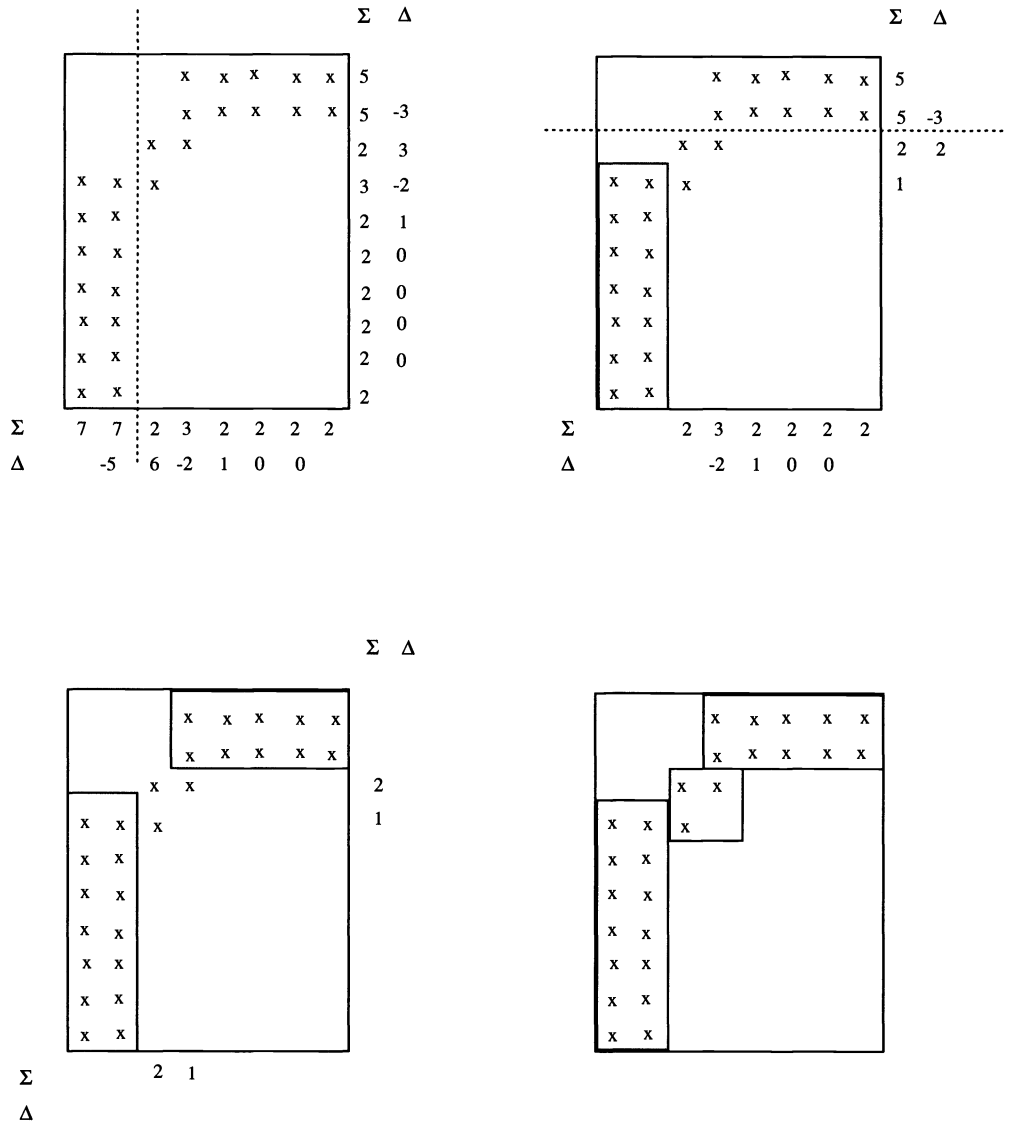

FIG. 2. *The signature arrays* Σ_x, Σ_y *and the second derivatives* Δ_x, Δ_y *used to partition the clusters.*

$$U_{ijk}^{n+1} = U_{ijk}^{n} - \Delta t \left(\frac{F_{i+1/2,j,k} - F_{i-1/2,j,k}}{\Delta x} + \frac{G_{i,j+1/2,k} - G_{i,j-1/2,k}}{\Delta y} + \frac{H_{i,j,k+1/2} - H_{i,j,k-1/2}}{\Delta z} \right), \tag{1}$$

where F, G, H are the numerical fluxes in the x, y, z directions, respectively. In its current form, these numerical fluxes are assumed to be explicitly computable from the values in cell ijk and a localized collection of its neighbors, as is typical of conventional explicit finite difference methods. When the integrator is invoked, it is provided with data on the grid to be integrated as well as sufficient boundary data (based on the scheme's stencil) to advance the solution on the given grid. No special stencils are used at fine/coarse interfaces. Instead, coarse

grid data is linearly interpolated to the fine grid resolution to provide a border of boundary cells, which is provided to the integrator along with the grid data itself. After the integration step, fluxes are adjusted to insure conservation at grid interfaces.

When operator splitting is used with local grid patches, the only thing to note is that extra boundary cells must be integrated during the first sweep to provide accurate boundary values for subsequent sweeps. For example, for a scheme with four points to the side in the stencil, four entire rows of dummy cells along the top and bottom of the grid must be advanced in the x sweep, so that four points are available for the y sweep at the next stage. For very small grids, this additional boundary work can dominate the computational cost of advancing a grid (particularly for difference methods having a broad stencil such as the Godunov algorithm we are using). This additional boundary work, as well as the vectorization issues, places a premium on generating large but efficient grids during regridding.

As an example, if one $60 \times 60 \times 60$ grid were replaced by two $30 \times 60 \times 60$ grids, both grids would redundantly integrate the overlapping boundary cells. This causes approximately 4% of the total computation to be redundant.

4. Implementation. Two simple decisions had a large impact on the implementation of AMR. The first concerned the organization and separation of the problem-dependent and problem-independent parts of the AMR code. The problem-dependent parts include the particular hyperbolic systems to be solved (and a suitable integration scheme), the initial and boundary conditions, the problem domain, and the error estimation routines. When a new problem is being set up, the changes required to the code are localized to a small number of subroutines. The integration subroutine advances the solution of the particular differential equations for a single timestep on a rectangular subgrid and returns fluxes that are required to insure conservation at coarse-fine boundaries. Consequently, adapting an existing integration module for use with the AMR algorithm is routine. The remainder of the AMR shell treats the data in terms of conserved variables where the number of variables is specified as a parameter. Thus, the data structures, memory management, grid generation algorithms, the logic controlling the timestepping and subcycling on subgrids, interior boundary conditions, and the interfacing between grids that insure conservation are completely divorced from the particular system being solved.

The second implementation detail that simplified the programming of AMR and resulted in much cleaner code than in [2] is the use of a global integer index space covering the domain. These integers are used in describing the location of the grids. Based on the initial (user-specified) domain, given in floating point numbers, an integer lattice based on the number of cells in each dimension (nx, ny, and nz) is determined. The domain may then be partitioned into several coarse grids, each located in subcubes with indices between (1, 1, 1) and (nx, ny, nz). If the refinement ratio is r between level l and level $l+1$, then the fine grid cells corresponding to coarse grid cell i, j, k are $r \cdot i + p_i, r \cdot j + p_j, r \cdot k + p_k$, where the $0 \le p_{i,j,k} \le r - 1$. This completely eliminates round-off error problems that would otherwise require careful coding to determine whether two grids overlap or whether a coarse grid is a parent to a fine grid.

We are currently rewriting the AMR algorithm in C++ with calls to FORTRAN routines for the numerically intensive parts. By constructing the appropriate classes we are able to define a grid calculus in which the computation of intersections and, in fact, the entire regridding process is greatly simplified. Using the built-in macro preprocessor, we are able to implement a large portion of the code in a dimension-independent manner with the dimension as a compile time parameter. With the data hiding inherent in C++ we are able to implement AMR in such a way that the underlying data representation is restricted to a few model dependent classes. Changing the data representation, such as to a sparse data representation for a multifluid version

of the code, would be restricted to the member functions of these classes. Since the majority of the run time for AMR is spent integrating large rectangular meshes, the overhead experienced by doing the data management in C++ is just a few percent over an implementation done entirely in FORTRAN. Further optimization of the most important member functions reduces the running time to a few percent less than the pure FORTRAN code.

5. Numerical example. To test the performance of the three-dimensional AMR algorithm, we have modeled the interaction of a Mach 1.25 shock in air hitting an ellipsoidal bubble of Freon-22. The case being modeled is analogous to one of the experiments described by Haas and Sturtevant [12]. The Freon is a factor of 3.0246 more dense than the surrounding air, which leads to a deceleration of the shock as it enters the cloud and a subsequent generation of vorticity that dramatically deforms the bubble.

The computational domain is a rectangular region with length (x) 22.5 cm and width (y) and height (z) of 8.9 cm. The major axis of the bubble is 3.5 cm and is aligned with the z-axis. The minor axes are 2.5 cm with circular cross sections of the bubble in the $x - y$ plane. The bubble is centered at the point $(x, y, z) = (10 \text{ cm}, 0 \text{ cm}, 0 \text{ cm})$. The shocked fluid is placed at points less than or equal to 14.5 cm in the x direction. The shock moves in the direction of increasing x. We use the operator split second-order Godunov method of [6], with Strang splitting. Reflecting boundary conditions are set on the constant z and constant y planes. The inflow and outflow velocities on the constant x planes, as well as the interior fluid velocities, are set so the frame of reference is shifted to one in which the post-shock velocity is zero in order to minimize the x extent of the problem. The numerics preserve a four-fold symmetry in y and z, so we only compute on a quarter of the physical domain. (We have reflected the data in the renderings so that the entire domain is shown.)

We use a simplified treatment of the equations of multifluid gas dynamics. The features of this method include using a single fluid solver, advecting only one additional quantity, and solving a set of equations in conservation form.

We use a γ-law equation of state for each gas with $\gamma_a = 1.4$ for air and $\gamma_f = 1.25$ for Freon. Mixtures of the two gases are modeled with an equation of state defined using both γ's,

$$\Gamma_c = \frac{1}{\frac{f}{\gamma_f} + \frac{(1-f)}{\gamma_a}}$$

for sound speeds, and

$$\Gamma_e = 1 + \frac{1}{\frac{f}{\gamma_f - 1} + \frac{(1-f)}{\gamma_a - 1}}$$

for energy. Here, Γ_c is used to compute an effective sound speed for the mixture with

$$c = \sqrt{\frac{\Gamma_c p}{\rho}}, \tag{2}$$

and f is the mass fraction of the Freon. The harmonic average used to compute Γ_c, used by Colella, Ferguson, and Glaz for multifluid computations [5], expresses the net volume change of a mixture of the gases in terms of their individual compressibilities. The sound speed defined by (2) is used in the integration routine for defining characteristic speeds and for approximate solution of the Riemann problem. We also assume that the two components of a mixed fluid cell are at the same pressure. Pressure is computed from density and internal

energy using Γ_e, namely,

$$p = (\Gamma_e - 1)\,\rho\, e.$$

The harmonic average used to compute Γ_e insures that mixing of the two fluids at the same pressure does not result in a pressure and internal energy change of the composite fluid.

We ran the AMR algorithm with an initial coarse grid of $80 \times 16 \times 16$ with two levels of refinement, each by a factor of four, for 100 coarse grid timesteps. The integration used six conserved quantities (mass, momentum, energy, and mass of Freon). The addition of this extra conserved variable besides the usual five found in three-dimensional gas dynamics does not change the AMR structure. The error estimation procedure was modified so that the finest level grids (level 3) only existed in a neighborhood of the bubble and so that acoustic waves away from the bubble were not refined once the incident shock was well past the bubble. The computation was performed on a Cray-2 and required about 20 hours of CPU time. In Fig. 3, we show volume renderings of the density field at four times during the evolution of the cloud. For the renderings, we interpolated all the data onto a uniformly fine grid. The effective result of the volume rendering is to yield an isosurface of the interface between air and Freon. The earliest frame is shortly after the incident shock has completely passed through the bubble. The bubble evolution qualitatively agrees with the experimental results of Haas and Sturtevant. The dominant features of the flow are a strong jet coming from the back of the bubble and the unstable evolution of the roll-up of the outer portion of the bubble.

During the computation, a total of 1.77×10^9 cells were advanced by the integration routine (not including boundary advancements required by operator splitting) for an effective time of 40 μ-seconds per zone including all of the AMR overhead. Figures 4 and 5 present a more detailed breakdown of the algorithm performance. Figure 4 shows a histogram of the dimensions of the level 3 grids during the entire calculation. In this figure, each dimension is counted separately in adding up the total number of grids of a given size. For this computation the maximum grid dimension was limited to 50 and most grids were at least 24 cells wide in each direction. This was done to limit an individual grid size to 125000 zones times six variables per zone. Since the integration algorithm is operator split and each dimension determines the vector length for one step, this gives a measure of the quality of the grids.

Figure 5 shows the number of level 3 cells as a function of time and indicates a growth in memory requirements as the solution complexity grows. The maximum memory required at any point during the run was 22.6 Mwords.

Independent measurements of the integration algorithm on a single large grid $160 \times 64 \times 64$ indicated a time of 30 μ-seconds per zone. Thus, the additional boundary work, smaller vector lengths and AMR overhead increased the time per zone by 33%. However, to achieve the same resolution, a uniform grid $1280 \times 256 \times 256$ would be required. Such a computation would require 500 Mwords of storage and 1100 hours of CPU time. The net speedup with AMR is a factor of 55.

Although it is difficult to predict in advance, only 40 of the 80 zones in the x direction played a significant role in the computation. The difficulty in prediction of the extent of the problem is shown by cruder mesh calculations, which indicated a larger computation region. An outflow boundary condition to handle the reflected shock off of the bubble could have eliminated a region of length 40 zones in the x direction. Such a computation would require 251 Mwords of storage and 560 hours of CPU time. Alternatively, we estimate that with a carefully designed, exponentially stretched computation mesh, the fixed grid computational cost also could be halved; however, such an approach also requires substantial knowledge of the solution in designing the mesh. Thus, even from a conservative viewpoint, AMR reduced the computational cost by more than a factor of 20 for this problem.

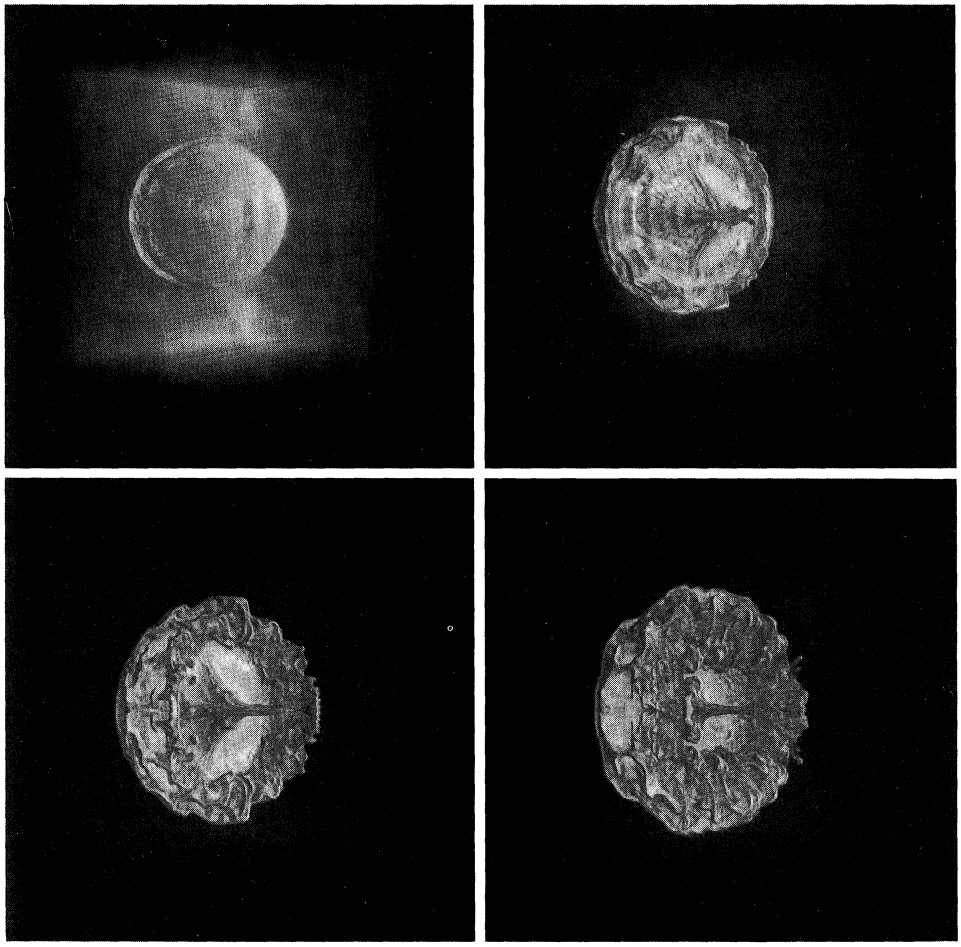

FIG. 3. *Volume renderings of the density during the evolution of the bubble after being hit with a shock wave.*

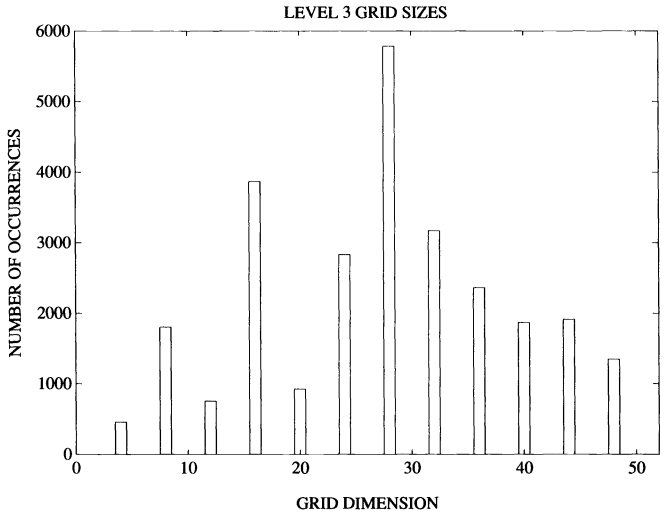

FIG. 4. *Histogram of the linear dimensions of all the level* 3 *grids.*

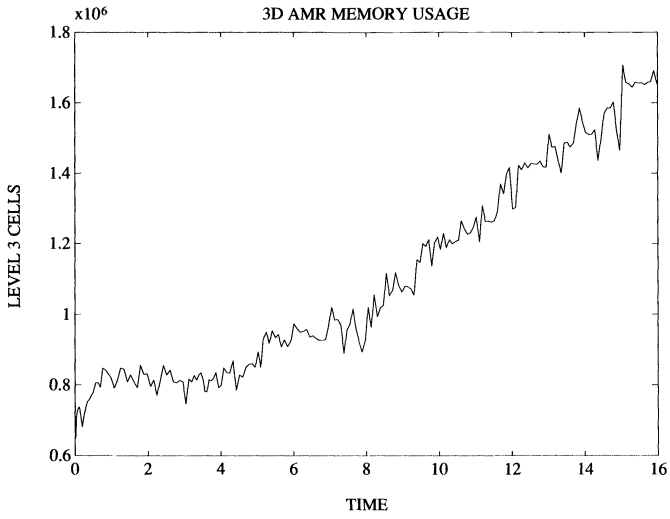

FIG. 5. *The number of level 3 cells as a function of time during the calculations.*

Of course, the performance of AMR is highly problem dependent. For some problems the cost reduction may be greater and for some problems it may be less. However, AMR will be cost effective as long as the average number of coarse cells per timestep that require the finest level of refinement throughout the computation is less than 75% of the total number. Although sophisticated grid placement strategies can reduce the advantage of using AMR, these strategies require considerable knowledge of the solution to be effective and may add considerable difficulties to problem setup. AMR provides a high level of performance while making problem setup routine.

STABILITY OF THE PARTITIONED INVERSE METHOD FOR PARALLEL SOLUTION OF SPARSE TRIANGULAR SYSTEMS*

NICHOLAS J. HIGHAM† AND ALEX POTHEN‡

Abstract. Several authors have recently considered a parallel method for solving sparse triangular systems with many right-hand sides. The method employs a partition into sparse factors of the product form of the inverse of the coefficient matrix. It is shown here that while the method can be unstable, stability is guaranteed if a certain scalar that depends on the matrix and the partition is small and that this scalar is small when the matrix is well conditioned. Moreover, when the partition is chosen so that the factors have the same sparsity structure as the coefficient matrix, the backward error matrix can be taken to be sparse.

AMS subject classifications. primary 65F05, 65F50, 65G05

1. Introduction.

The method of choice for solving triangular systems on a serial computer is the substitution algorithm. Several approaches have been suggested for parallel solution. Implementations of substitution for distributed memory architectures are described by Heath and Romine [12] and Li and Coleman [15], and a short survey of this work is given by Gallivan, Plemmons, and Sameh [9, §3.5.2] (see also [11, §6.4.4]). Implementations of substitution for sparse matrices on shared memory architectures are investigated by Rothberg and Gupta [20]. Algorithms that are not based on substitution are surveyed by Gallivan, Plemmons, and Sameh [9, §3.5], Heller [13], and Ortega and Voigt [16]. A new method has been developed recently for the parallel solution of sparse triangular systems with many right-hand sides when these vectors are not necessarily available at the same time [1]–[3], [8]. The method involves representing the inverse of the coefficient matrix as a product of sparse factors, and can be explained as follows.

If $L \in \mathbb{R}^{n\times n}$ is lower triangular, we can write $L = L_1 L_2 \dots L_n$, where L_k differs from the identity matrix only in the kth column:

$$L_k = \begin{bmatrix} I_{k-1} & & & & \\ & l_{kk} & & & \\ & l_{k+1,k} & 1 & & \\ & \vdots & & \ddots & \\ & l_{nk} & & & 1 \end{bmatrix}. \tag{1.1}$$

The factorization of L can be partitioned

$$L = G_1 G_2 \dots G_m, \tag{1.2}$$

where $1 \le m \le n$ and

$$G_k = L_{i_k} L_{i_k+1} \dots L_{i_{k+1}-1}, \qquad 1 = i_1 < i_2 < \cdots < i_{m+1} = n+1. \tag{1.3}$$

Note that G_k is the lower triangular matrix equal to the identity except for columns $i_k, \ldots, i_{k+1}-1$, which equal the corresponding columns of $L_{i_k}, \ldots, L_{i_{k+1}-1}$, respectively. Defining $\overline{G}_k = G_k(:, i_k : i_{k+1} - 1)$ (using the colon notation from [11]) we have the relation

$$L = G_1 G_2 \ldots G_m = [\overline{G}_1, \overline{G}_2, \ldots, \overline{G}_m], \tag{1.4}$$

which we will use later. Equation (1.2) yields the partitioned, product-form representation

$$L^{-1} = H_m H_{m-1} \ldots H_1, \qquad H_k = G_k^{-1}. \tag{1.5}$$

For a sparse matrix L, the idea behind the "partitioned inverse method" is to choose the partition (1.2) so that (1.5) represents L^{-1} as a short product of sparse factors. Then $Lx = b$ is solved by forming

$$x = H_m H_{m-1} \ldots H_1 b, \tag{1.6}$$

and the advantage is that x can be computed in m serial steps of parallel matrix–vector multiplication. Thus on a massively parallel SIMD computer such as the Connection Machine CM-2, only m communication steps involving the router are necessary in the algorithm. The scalar multiplications in each product $x_k = H_k x_{k-1}$ (where $x_0 = b$) can be done concurrently in time proportional to v, where v is the maximum number of elements of H_k assigned to a processor, and the additions can be done in logarithmic time [1]. The two extreme cases are $m = n$, which gives a modified version of forward substitution (or forward substitution itself if L has unit diagonal), and $m = 1$, for which the method forms $x = L^{-1} \times b$. For a sparse matrix L we would not take $m = 1$, because $H_1 = L^{-1}$ is usually much denser than L [7, §12.6]. Rather, we would like to minimize m subject to the condition that each factor H_k can be stored in the same space as G_k, since m is the number of serial steps in the parallel evaluation of x. Since we are assuming that many right-hand sides are to be processed, we can afford to spend some computational effort in constructing the partition (1.2).

Algorithms for finding a *best no-fill partition* (1.2) are described in [1]–[3]; such a partition has the smallest possible number of factors (the minimum value of m) subject to the requirement that each G_k is invertible in place. A matrix X is *invertible in place* if $(X^{-1})_{ij} = 0$ whenever $x_{ij} = 0$ for any assignment of (nonzero) numerical values to the nonzeros in X. Note that L_k in (1.1) is invertible in place, so a partition with $m = n$ is always a no-fill partition. When L is sparse, a best no-fill partition could have $m \ll n$. Partitions that incur some fill-in have also been investigated [3].

Algorithms are also given in [1] and [2] for finding a *best reordered partition*: this is a no-fill partition with the fewest factors over all lower triangular matrices PLP^T, where P is a permutation matrix. Let $F = L + L^T$ denote the *filled matrix* corresponding to a Cholesky factor. It is well known that if L is the Cholesky factor of a symmetric positive definite matrix A whose nonzero elements are algebraically independent, then the adjacency graph of F is chordal. By exploiting chordality, very efficient algorithms for computing best reordered partitions in time and space linear in the order of the matrix (rather than the number of nonzeros) can be designed for a Cholesky factor L [1], [19]. Furthermore, algorithms for finding a partition with the fewest factors over all permutations P such that the permuted matrix PFP^T has the same structure as the filled matrix F have also been designed [17], [18]. Note that, in this case, the permutation may change the structure of L, and hence the permutation P has to be applied to A *before* it is factored.

The numerical stability of the partitioned inverse method has not been studied in previous work, either theoretically or in numerical experiments. The numerical stability is clearly questionable because when $m = 1$ (which gives the best no-fill partition for a dense matrix)

the method computes $x = L^{-1} \times b$, and a numerical example in [6, §4] shows that this evaluation need not be backward stable. To answer the question of stability we have done an error analysis of the partitioned inverse method; this analysis is presented in §2. In §3 we describe some numerical experiments that illustrate the analysis and confirm the possible numerical instability of the method.

Our main findings are as follows.

(1) In general, the partitioned inverse method does not satisfy the componentwise backward and forward error bounds enjoyed by the substitution algorithm (namely, (2.1) and (2.2)).

(2) Normwise stability depends on a quantity ρ, defined in (2.13), which is a function of the matrix L and the partition, and which can be arbitrarily large. Specifically, the computed solution $\widehat{x}$ to $Lx = b$ satisfies $(L + \Delta L)\widehat{x} = b$, where $\|\Delta L\|_\infty$ is bounded in (2.12); the relative error $\|x - \widehat{x}\|_\infty / \|x\|_\infty$ is bounded in (2.19). If ρ is of order 1, which is guaranteed if L is well conditioned, the partitioned inverse method is both normwise backward stable and normwise forward stable.

(3) If L is sparse and each G_k is invertible in place (as is guaranteed by a best no-fill or best reordered partition), then the backward error matrix ΔL mentioned in (2) can be taken to have the same sparsity structure as L.

Another way to summarize the stability of the partitioned inverse method is to say that the method is only conditionally stable, with the backward error dependent on the condition number of L. The partitioned inverse method therefore provides another example, to add to those discussed by Demmel [4], of how parallelism can conflict with stability.

In future work we intend to examine how particular sparsity structures and other special properties of L affect the stability of the partitioned inverse method.

2. Error analysis. In this section we give an error analysis of the partitioned inverse method for solving $Lx = b$. To keep the analysis general we will not make any assumptions about sparsity. As our model of floating point arithmetic we take

$$\begin{aligned} fl(x \pm y) &= x(1+\alpha) \pm y(1+\beta), \qquad |\alpha|, |\beta| \le u, \\ fl(x \text{ op } y) &= (x \text{ op } y)(1+\delta), \qquad |\delta| \le u, \quad \text{op} = *, /, \end{aligned}$$

where u is the unit roundoff. This model admits machines that lack a guard digit in addition and subtraction. We place a hat over a variable to indicate a computed quantity.

For later comparison we summarise what can be said about the substitution algorithm. The computed $\widehat{x}$ satisfies (see, for example, [22, p. 150] or [14])

$$(L + \Delta L)\widehat{x} = b, \qquad |\Delta L| \le \big((n+1)u + O(u^2)\big)|L|. \tag{2.1}$$

(Absolute values and inequalities are interpreted componentwise for matrices.) This result shows that there is a componentwise tiny backward error matrix ΔL that has the same sparsity structure as L. From (2.1) it is easy to obtain the forward error bound

$$\frac{\|x - \widehat{x}\|_\infty}{\|x\|_\infty} \le (n+1)u \,\mathrm{cond}(L, x) + O(u^2), \tag{2.2}$$

which contains the Bauer–Skeel condition number

$$\mathrm{cond}(L, x) = \frac{\| \, |L^{-1}||L||x| \, \|_\infty}{\|x\|_\infty}.$$

This bound may be weakened to

$$\frac{\|x - \widehat{x}\|_\infty}{\|x\|_\infty} \le (n+1)u\kappa_\infty(L) + O(u^2), \tag{2.3}$$

where $\kappa_\infty(L) = \|L\|_\infty \|L^{-1}\|_\infty$. Our aim is to see how close the partitioned inverse method comes to achieving the ideal bounds (2.1) and (2.2). Note that if L is sparse, the constant $n+1$ in (2.1)–(2.3) can be replaced by $p+1$, where p is the maximum number of nonzeros per row over all the rows of L. Similarly, the constants c_k that we define below to equal the partition widths can be redefined to take account of sparsity.

First, we consider the computation of the factors $H_k = G_k^{-1}$ of L^{-1} (from L). Because of its special structure, G_k is formed without error, and we assume that G_k^{-1} is computed by one of the several stable methods described by Du Croz and Higham in [6] (for example, its columns may be computed one at a time by forward substitution). For each of these methods applied to G_k, precisely one of the following two residual bounds holds, depending on the method:

$$|\widehat{H}_k G_k - I| \le \bigl(c_k u + O(u^2)\bigr)|\widehat{H}_k||G_k|, \tag{2.4}$$

$$|G_k \widehat{H}_k - I| \le \bigl(c_k u + O(u^2)\bigr)|G_k||\widehat{H}_k|, \tag{2.5}$$

where $c_k = i_{k+1} - i_k + 1$. Each residual bound implies the forward error bound

$$|\widehat{H}_k - G_k^{-1}| \le c_k u |H_k||G_k||H_k| + O(u^2). \tag{2.6}$$

(Since we are working to first order, $\widehat{H}_k$ and H_k are interchangeable in all the bounds.)

Applying standard error analysis of matrix–vector products [11, p. 66] to (1.6) we obtain

$$\widehat{x} = (\widehat{H}_m + \Delta_m)(\widehat{H}_{m-1} + \Delta_{m-1}) \dots (\widehat{H}_1 + \Delta_1) b, \tag{2.7}$$

where

$$|\Delta_k| \le \bigl(c_k u + O(u^2)\bigr)|\widehat{H}_k|. \tag{2.8}$$

If the inner products that occur in the matrix–vector products are evaluated using the fan-in algorithm for summation, then the constant c_k in (2.8) can be replaced by $\log_2 c_k$. We can rewrite (2.7) as $(L + \Delta L)\widehat{x} = b$, where

$$L + \Delta L = (H_1 + E_1)^{-1}(H_2 + E_2)^{-1} \dots (H_m + E_m)^{-1}, \tag{2.9}$$

with

$$E_k = \Delta_k + (\widehat{H}_k - H_k). \tag{2.10}$$

Now we consider the sparsity of ΔL. First, we note that if H_k is computed by forward substitution, then, by (2.1), its jth column $\widehat{h}_j$ satisfies $(G_k + F_k^{(j)})\widehat{h}_j = e_j$, where e_j is the jth unit vector and $|F_k^{(j)}| \le \bigl((n+1)u + O(u^2)\bigr)|G_k|$, so that $F_k^{(j)}$ has the same sparsity structure as G_k. It follows that if G_k is invertible in place, then $\widehat{H}_k$ (whose jth column is that of $(G_k + F_k^{(j)})^{-1}$) has the same sparsity structure as G_k. The same is true for any of the stable methods in [6] because, as explained there, these methods all incur essentially the same rounding errors. Next, we observe that by (2.8), Δ_k has the same sparsity structure as $\widehat{H}_k$, and, therefore, if G_k is invertible in place, then $(H_k + E_k)^{-1} = (\widehat{H}_k + \Delta_k)^{-1}$ has the same sparsity structure as G_k. From (2.9) and the structural relation $L = G_1 G_2 \dots G_m$, we conclude that *if each G_k is invertible in place then the backward error matrix ΔL has the same sparsity structure as L*. It remains to bound ΔL.

From (2.9) we have

$$\Delta L = -\sum_{k=1}^{m} H_1^{-1} \dots H_{k-1}^{-1} \cdot H_k^{-1} E_k H_k^{-1} \cdot H_{k+1}^{-1} \dots H_m^{-1} + O(u^2),$$

so that

$$|\Delta L| \le \sum_{k=1}^{m} |H_1^{-1} \dots H_{k-1}^{-1}| \cdot |H_k^{-1} E_k H_k^{-1}| \cdot |H_{k+1}^{-1} \dots H_m^{-1}| + O(u^2).$$

If (2.4) holds, then, from (2.8) and (2.10),

$$\begin{aligned} |H_k^{-1} E_k H_k^{-1}| &= |H_k^{-1} \Delta_k H_k^{-1} + H_k^{-1}(\widehat{H}_k H_k^{-1} - I)| \\ &\le c_k u |H_k^{-1}||H_k||H_k^{-1}| + c_k u |H_k^{-1}||H_k||G_k| + O(u^2) \\ &= 2c_k u |G_k||H_k||G_k| + O(u^2), \end{aligned}$$

and precisely the same bound is obtained if we use (2.5).

Define $d_n = 2 \max_k c_k$. To obtain a convenient bound for ΔL we use (1.4), together with the observation that since $|G_k||H_k||G_k|$ differs from the identity only in columns $i_k, \dots, i_{k+1} - 1$, it can be treated like $|G_k|$ when we invoke (1.4). We have

$$\begin{aligned} |\Delta L| &\le d_n u \sum_{k=1}^{m} |G_1| \dots |G_{k-1}| \cdot |G_k||H_k||G_k| \cdot |G_{k+1}| \dots |G_m| + O(u^2) \\ &\le d_n u \sum_{k=1}^{m} \big[|\overline{G}_1|, \dots, |\overline{G}_{k-1}|, \overline{|G_k||H_k||G_k|}, |\overline{G}_{k+1}|, \dots, |\overline{G}_m| \big] + O(u^2) \\ &\le d_n u \big((m-1)|L| + \sum_{k=1}^{m} [0, \dots, 0, \overline{|G_k||H_k||G_k|}, 0, \dots, 0] \big) + O(u^2) \\ &= d_n u \big((m-1)|L| + \sum_{k=1}^{m} |G_k||H_k||G_k| - (m-1)I \big) + O(u^2). \end{aligned} \tag{2.11}$$

This bound is not of the form (2.1) that holds for substitution, because of the summation term. If $m = 1$, the bound is $|\Delta L| \le 2(n+1)u|L||L^{-1}||L| + O(u^2)$. When $m = n$, the relation $|L_k||L_k^{-1}||L_k| \le 3|L_k|$ allows us to simplify the bound to $|\Delta L| \le 4(n+2)u|L| + O(u^2)$, which is of the same form as in (2.1).

Taking norms in (2.11) we obtain

$$\|\Delta L\|_\infty \le d_n u (m - 1 + \rho) \|L\|_\infty + O(u^2), \tag{2.12}$$

where

$$\rho = \frac{\big\| \sum_{k=1}^{m} |G_k||G_k^{-1}||G_k| - (m-1)I \big\|_\infty}{\|L\|_\infty}. \tag{2.13}$$

The scalar $\rho \ge 1$ might be loosely described as a growth factor for the partitioned inverse method, although it is not related to the growth factor in Gaussian elimination. For any $m < n$, ρ can be arbitrarily large, but for $m = n$ it is easy to show that $\rho \le 3$. Under scaling of the system, ρ behaves as follows: if $D_1 = \operatorname{diag}(d_i)$ and $D_2 = \operatorname{diag}(e_i)$ are nonnegative diagonal matrices and we scale $Lx = b \to (D_1 L D_2) \cdot (D_2^{-1} x) = D_1 b$, then

$$\rho \to \overline{\rho} = \frac{\big\| \sum_{k=1}^{m} D_1^{(k)} |G_k||G_k^{-1}||G_k| D_2^{(k)} - (m-1)I \big\|_\infty}{\|D_1 L D_2\|_\infty},$$

where $D_1^{(k)} = \operatorname{diag}(1, \dots, 1, d_{i_k}, \dots, d_n)$ and $D_2^{(k)} = \operatorname{diag}(1, \dots, 1, e_{i_k}, \dots, e_{i_{k+1}-1}, 1, \dots, 1)$ (recall that i_k is defined in (1.3)). This expression suggests that ρ is fairly insensitive to the scaling of the rows and columns of L.

We see from (2.12) that if L and the partition are such that ρ is of order one, then the partitioned inverse method is normwise backward stable; that is, the computed solution $\widehat{x}$ solves a system obtained by making a tiny normwise perturbation to L. Using (2.12), the sparse backward error property noted earlier can be expressed as follows. Define $Z \in \mathbb{R}^{n\times n}$ by

$$z_{ij} = \begin{cases} 1 & \text{if } l_{ij} \neq 0, \\ 0 & \text{otherwise.} \end{cases} \tag{2.14}$$

Then, if each G_k is invertible in place,

$$(L + \Delta L)\widehat{x} = b, \qquad |\Delta L| \leq \big(d_n u(m - 1 + \rho)\|L\|_\infty + O(u^2)\big)Z, \tag{2.15}$$

where the matrix inequality both bounds Δl_{ij} and shows that ΔL has the same sparsity structure as L.

Two useful upper bounds can be obtained for ρ. By examining the form of the matrix whose norm is the numerator in (2.13), it is easy to show that $\rho \leq m \max_k \kappa_\infty(G_k)$. From the relation

$$\begin{aligned} G_k^{-1} &= G_{k+1} \ldots G_m L^{-1} G_1 \ldots G_{k-1} \\ &= G_{k+1} \ldots G_m \begin{bmatrix} I_{i_k-1} & 0 \\ 0 & L^{-1}(i_k\!:\!n, i_k\!:\!n) \end{bmatrix}, \end{aligned}$$

we have $\|G_k^{-1}\|_\infty \leq \max(1, \|L\|_\infty)\max(1, \|L^{-1}\|_\infty)$. As ρ is invariant under scalar multiplication of L, we can assume, without loss of generality, that $\|L\|_\infty = 1$, and hence we have, for all partitions,

$$\rho \leq m\kappa_\infty(L).$$

We conclude that the normwise backward error for the partitioned inverse method is bounded by a multiple of $\kappa_\infty(L)u$. Although this bound may be very weak when L is ill conditioned, it shows that *if L is well conditioned then the partitioned inverse method is guaranteed to be normwise backward stable.*

It is interesting to note that dependence of the backward error on the condition number occurs also in block LU factorization [5]. Another example of this dependence is a parallel triangular system solver analysed by Sameh and Brent [21], for which a backward error result with $\|\Delta L\| \leq c_n u\kappa^2(L)\|L\|$ is obtained. It seems to be a rule of thumb that if we attempt to improve the parallelism of Gaussian elimination or substitution, we will achieve only conditional stability, with the backward error potentially proportional to some function of the condition number.

Now we turn to the forward error. One way to obtain a forward error bound is to expand the equation $\widehat{x} = (H_m + E_m)(H_{m-1} + E_{m-1}) \ldots (H_1 + E_1)b$, which follows from (2.7) and (2.10). For $m = 1$, this leads to the bound

$$\begin{aligned} \frac{\|x - \widehat{x}\|_\infty}{\|x\|_\infty} &\leq 2(n+1)u \frac{\| \, |L^{-1}||L||L^{-1}||b| \, \|_\infty}{\|x\|_\infty} + O(u^2) \\ &\leq 2(n+1)u\,\theta \| \, |L^{-1}||L| \, \|_\infty + O(u^2), \end{aligned} \tag{2.16}$$

where

$$\theta = \frac{\| \, |L^{-1}||b| \, \|_\infty}{\|L^{-1}b\|_\infty} \geq 1. \tag{2.17}$$

The scalar θ can be regarded as a measure of forward stability for the $L^{-1}b$ method. Note that θ is large only when there is a lot of cancellation through subtraction in the product $L^{-1}b$. Gill, Murray, and Wright [10, §4.7.2] analyse the $L^{-1}b$ method under the simplifying assumption that the computed inverse is the correctly rounded inverse. Their forward error bound from a normwise analysis is proportional to $\kappa_\infty(L)(\|L^{-1}\|_\infty\|b\|_\infty/\|x\|_\infty)$, and so is consistent with our bound.

For general m, a more useful bound is obtained by manipulating the backward error result. Since $(L+\Delta L)\widehat{x}=b$ implies $|x-\widehat{x}|\le|L^{-1}||\Delta L||\widehat{x}|$, we obtain from (2.11)

$$\frac{\|x-\widehat{x}\|_\infty}{\|x\|_\infty}\le d_n u\frac{\left\|\left((m-1)|L^{-1}||L|+|L^{-1}|\left(\sum_{k=1}^m|G_k||H_k||G_k|-(m-1)I\right)\right)|x|\right\|_\infty}{\|x\|_\infty}+O(u^2). \tag{2.18}$$

The summation term precludes this bound from matching the ideal bound (2.2), but (2.18) does share with (2.2) the very desirable property that it is independent of the row scaling of the system. We can weaken (2.18) to obtain

$$\frac{\|x-\widehat{x}\|_\infty}{\|x\|_\infty}\le d_n u(m-1+\rho)\kappa_\infty(L)+O(u^2), \tag{2.19}$$

where ρ is the growth factor in (2.13) (of course, this bound could have been obtained directly using (2.12)). Hence if ρ is of order one, then the partitioned inverse method satisfies a bound of the form (2.3), that is, it is normwise forward stable.

3. Numerical experiments. We describe two numerical experiments that illustrate the error analysis and confirm the potential instability of the partitioned inverse method. Our experiments were performed in Matlab, which has unit roundoff $u\approx 1.1\times 10^{-16}$. Statistics that we report include

$$\begin{aligned}\text{nberr}&=\min\{\epsilon:|b-L\widehat{x}|\le\epsilon\|L\|_\infty ee^T|\widehat{x}|\},\\ \text{sberr}&=\min\{\epsilon:|b-L\widehat{x}|\le\epsilon\|L\|_\infty Z|\widehat{x}|\},\\ \text{cberr}&=\min\{\epsilon:|b-L\widehat{x}|\le\epsilon|L||\widehat{x}|\},\end{aligned}$$

and

$$\text{ferr}=\frac{\|x-\widehat{x}\|_\infty}{\|x\|_\infty},$$

where $e=(1,1,\dots,1)^T$ and Z is defined in (2.14). The quantity nberr is the usual normwise backward error, written in a way that shows its connection with the "sparse normwise backward error" sberr. From (2.12) it follows that, to first order, nberr $\le d_n u(m-1+\rho)$, and, if each G_k is invertible in place, sberr satisfies the same bound, by (2.15). The componentwise backward error cberr is $O(u)$ for substitution, by (2.1). We mention that in both experiments, modifying the backward errors nberr, sberr, and cberr to include a b term (thus allowing b to be perturbed in the definition of backward error) changes the backward errors by at most a factor 2.

In our first experiment $L=R^T$, where $V=QR$ is a QR factorization of the 15×15 Vandermonde matrix with (i,j) element $((j-1)/(n-1))^{i-1}$, and $b=Le$. This linear system is taken from [6, §4]. We solved the system $Lx=b$ by using the partitioned inverse method with "fixed-width" partitions (1.3) having $i_{k+1}=i_k+p$, for several values of p. Results are reported in Table 3.1; since L is dense, nberr $\approx$ sberr, so we do not give the sberr values. We see that as p increases, the normwise backward error increases and the algorithm loses

backward stability. In these examples, both (2.12) and (2.18) are a factor $\approx 10^3$ from being equalities for $p \geq 4$, and the bound $\rho \leq m \max_k \kappa_\infty(G_k)$ is clearly very weak. The ideal forward error bounds (2.2) and (2.3) are 6.43e−4 and 3.87e−3, respectively; ferr exceeds both values for $p \geq 6$, so the algorithm also loses forward stability. The quantity θ in (2.17) has the value $\theta = 3.60\text{e}11$, so the bound (2.16) predicts forward instability when $m = 1$, but is a factor $\approx 10^8$ from being an equality. We also solved $Lx = c$, where $c = (-1, 1, -1, 1, \ldots)^T$, and the result for $p = 15$ is reported in the last line of Table 3.1. Here, $\theta = 1$, and, as predicted by (2.16), the algorithm performs in a forward stable manner; the tiny backward error is not predicted by our analysis.

TABLE 3.1
Dense system $Lx = b$, $n = 15$.

$\kappa_\infty(L) = 2.18\text{e}12$, $\text{cond}(L, x) = 3.62\text{e}11$

p	m	nberr	ferr	ρ	$\max_k \kappa_\infty(G_k)$
1	15	0.00	2.04e−6	3.00	8.38e6
2	8	4.98e−18	5.68e−6	2.65e1	1.55e7
4	4	5.77e−16	4.94e−4	1.49e3	9.51e8
6	3	2.14e−14	4.36e−3	3.62e4	9.51e8
8	2	9.10e−14	8.42e−3	5.68e5	1.03e11
10	2	4.73e−13	7.34e−3	2.04e6	1.41e10
12	2	6.63e−13	1.11e−2	2.72e6	3.83e9
15	1	6.60e−13	1.13e−2	2.78e6	2.18e12
	$Lx = c$, $\text{cond}(L, x) = 3.90\text{e}4$				
15	1	9.07e−23	8.78e−11	2.78e6	2.18e12

In our second experiment L is a 20×20 matrix with 58 nonzeros; the entries and their locations were chosen randomly and then manipulated "by hand" to produce interesting behaviour. The inverse of L has 93 nonzeros. We solved the system $Lx = b$, where $b = Le$, using five different partitions. Partition A corresponds to forming $\widehat{x} = L^{-1} \times b$ ($m = 1$), Partition B has $m = 2$ with $G_1 = L_1 L_2 \ldots L_{14}$ and $G_2 = L_{15} \ldots L_{20}$, Partition C is a best no-fill partition, Partition D is a best reordered partition, and Partition E gives a variant of forward substitution ($m = n$). (Recall that Partition D corresponds to a partition of a symmetric permutation of L that preserves its lower triangular structure.) In Table 3.2 we report the backward errors and ρ (the system is too ill conditioned for us to determine the forward errors, but the computed solutions probably have no correct digits).

TABLE 3.2
Sparse system $Lx = b$, $n = 20$.

$\kappa_\infty(L) = 2.69\text{e}28$, $\text{cond}(L, x) = 1.47\text{e}16$

Partition $(i_1, i_2, \ldots, i_{m+1})$	nberr	sberr	cberr	ρ
A: (1,21)	5.49e−9	4.26e−6	2.47e−1	7.36e19
B: (1,15,21)	1.83e−14	4.26e−6	9.48e−2	1.06e14
C: (1,2,3,4,11,12,13,19,21)	4.03e−24	1.55e−14	6.96e−14	5.67e3
D: (1,5,9,11,17,19,21)	4.93e−24	1.55e−14	6.96e−14	5.67e3
E: (1,2,3,...,21)	7.27e−24	3.80e−17	1.70e−16	3.00

The results confirm two properties suggested by the analysis.

(1) For partitions in which the factors are not invertible in place (Partitions A and B in the table), the sparse backward error can greatly exceed the normwise backward error.

(2) Even a best no-fill partition can yield sparse or componentwise backward errors appreciably larger than those for substitution.

We have been unable to construct a numerical example where the sparse backward error is large even when ρ is small, which the analysis suggests may be possible for partitions where the factors are not invertible in place. Our limited experience with the partitioned inverse method suggests that, like substitution, it frequently achieves surprisingly small forward and backward errors in practice. However, in view of the possible instability it is wise to compute one of the backward errors and make an *a posteriori* test for stability. Alternatively, if many right-hand sides are to be handled, it may be preferable to compute ρ or estimate its upper bound $m\kappa_\infty(L)$ before solving the systems. If any of these tests reveal or predict instability, substitution could be used instead.

Acknowledgements. We thank Des Higham for suggesting improvements to the manuscript.

TWO-LEVEL LOCAL REFINEMENT PRECONDITIONERS FOR NONSYMMETRIC AND INDEFINITE ELLIPTIC PROBLEMS*

RICHARD E. EWING†, SVETOZARA I. PETROVA‡, AND PANAYOT S. VASSILEVSKI§

Abstract. Preconditioners of optimal order for nonselfadjoint and indefinite elliptic boundary value problems discretized on grids with local refinement are constructed. The proposed technique utilizes solution of a discrete problem on a uniform coarse grid; then, the reduced problem is handled by a generalized conjugate gradient (GCG) method. The reduced problem is coercive if the initial coarse mesh is sufficiently fine and is local, solving only for the unknowns on the subdomains where local refinement has been introduced. The reduced problem can be preconditioned by a preconditioner for the symmetric positive definite matrix arising from the symmetric and coercive principal part of the original bilinear form restricted to the subdomains containing local refinement. This problem also utilizes a uniform grid. In the numerical tests, the recent algebraic multilevel (AMLI) preconditioners [Axelsson and Vassilevski, *SIAM J. Numer. Anal.*, 27 (1990), pp. 1569–1590; Saad and Schultz, *SIAM J. Sci. Statist. Comput.*, 7 (1986), pp. 856–869], which are of optimal order for selfadjoint and coercive elliptic problems, were used.

Key words. indefinite problems, nonsymmetric problems, optimal order preconditioner, local refinement, two-level method, generalized conjugate gradients, elliptic problems

AMS subject classifications. 65F10, 65N20, 65N30

1. Introduction.

Recently much interest has been devoted to the construction of preconditioners for solving discretized elliptic and parabolic problems on grids with local refinement (for example, see the so-called fast adaptive composite (FAC) grid method of McCormick [20], McCormick and Thomas [22], Mandel and McCormick [19], and the monograph by McCormick [21]. Also, a symmetrized version of the FAC grid-method was proposed in Bramble, Ewing, Pasciak, and Schatz [9] and studied further in Ewing, Lazarov, and Vassilevski [15] for elliptic problems and in Ewing, Lazarov, Pasciak, and Vassilevski [13] for parabolic problems with local refinement in time and space. These methods have been also generalized to the case of multilevel local refinement by Widlund [29], Dryja and Widlund [12], Ewing, Lazarov, and Vassilevski [14], and Vassilevski, Petrova, and Lazarov [28]. The additive version of the multigrid method as proposed by Bramble, Pasciak, and Xu [10] is also suitable for multilevel local refinement.

Another approach, based on the two-level method of Bank and Dupont [7] and studied further in Axelsson and Gustafsson [3], was successfully exploited in Ewing and Vassilevski [17] in the context of local refinement methods for two-level and multilevel grids. In the present paper, we extend one of the two-grid preconditioners (the so-called two-level block Gauss–Seidel preconditioner) to the case of nonsymmetric and possibly indefinite finite element discretization matrices. The extension is based on the paper of Vassilevski [26] and uses the fact observed by Schatz [25] that, within a certain subspace, the bilinear form corresponding to our elliptic problem is coercive. In matrix notation, this means that the coefficient matrix of the discrete problem has a Schur complement that has a positive definite symmetric part. In the context of local refinement, this Schur complement is obtained by first solving the original problem discretized by an initial uniform coarse grid. Hence, this Schur complement is related to the unknowns corresponding to the grids in the subdomains where we have introduced

local refinement. This is again a problem with similar discretization to the original problem, but now in uniformly refined subregions. The difference with the result from Vassilevski [26] is in the preconditioner derived for the reduced Schur complement that is based on preconditioners for the principal symmetric and coercive part of the original bilinear form restricted to the subdomains where we have uniformly refined grid. This means that we do not have to precondition the symmetric positive definite principal part of the original matrix of the problem in the entire domain with complicated grid with local refinement (as the method from Vassilevski [26] would have required), but only its restriction to the subdomains with uniformly refined grid.

In the present paper, we prove that the reduced problem can be preconditioned in a generalized conjugate gradient (GCG) method by any preconditioner for the symmetric and coercive principal part of the bilinear form restricted to the subdomains where we have introduced local refinement. By exploiting the technique from Axelsson and Vassilevski [6] (see also [5]), we can allow the coarse-grid solvers to be somewhat inexact; but this is not discussed further in this paper.

The outline of the paper is as follows. In §2, we introduce the problem and formulate the preconditioner. The convergence properties of the preconditioner are studied in §3. Finally, in §4, a number of numerical tests that illustrate our theory are presented.

2. Construction of the preconditioner. Let Ω be a given two-dimensional (2D) polygon or a three-dimensional (3D) polytope, and let Γ_N be a given part of the boundary $\partial\Omega$ on which Neumann boundary conditions are imposed. We assume that the Dirichlet portion, $\Gamma_D = \partial\Omega \backslash \Gamma_N$, is a nontrivial part of $\partial\Omega$. We denote by $W_2^j(\Omega)$ the standard L^2-based Sobolev spaces on Ω.

We consider the second-order boundary value problem in a variational setting. Given $f \in L^2(\Omega)$ and $g_N \in W_2^{-1/2}(\Gamma_N)$, find $u \in W_2^1(\Omega)$ such that

$$
\begin{aligned}
a(u,\phi) &\equiv \int_\Omega \left[\sum_{i,j} k_{i,j}(x) \frac{\partial u}{\partial x_i} \frac{\partial \phi}{\partial x_j} + (\mathbf{b}\cdot\nabla u)\phi + c_0 u\phi \right] dx \\
&= \int_\Omega f\phi dx + \int_{\Gamma_N} g_N \phi d\Gamma \quad \text{for all } \phi \in W_2^1(\Omega), \qquad \phi = 0 \text{ on } \Gamma_D,
\end{aligned} \tag{2.1}
$$

and $u = 0$ on Γ_D.

The bounded measurable coefficients $k_{i,j}(x)$ define a symmetric matrix that is assumed to be uniformly positive definitive for $x \in \bar{\Omega}$. We also assume that c_0 is a measurable and bounded function and that the vector field $\mathbf{b}$ is sufficiently smooth.

The principal symmetric and coercive part of $a(\cdot,\cdot)$ is

$$
a_0(u,\phi) = \int_\Omega \sum_{i,j} k_{i,j} \frac{\partial u}{\partial x_i} \frac{\partial \phi}{\partial x_j} dx. \tag{2.2}
$$

We discretize the boundary value problem above on an initial coarse mesh $\tilde{\omega}$. For definiteness, we consider the case of triangular grids for a polygonal domain Ω. The finite element discretization space $\tilde{V} \subset W_2^1(\Omega)$ is assumed to be spanned by piecewise linear functions that are continuous in Ω and vanish on Γ_D. The nodes (vertices of triangles that do not lie on Γ_D) define the initial (coarse) grid $\tilde{\omega}$. We denote by $\tilde{h}$ the discretization parameter on $\tilde{\omega}$. The discrete finite element problem reads: find $u_{\tilde{h}} \in \tilde{V}$ such that for all $\phi \in \tilde{V}$, we have

$$
a(u_{\tilde{h}}, \phi) = \int_\Omega f\phi dx + \int_{\Gamma_N} g_N \phi d\Gamma.
$$

Let $\{\tilde{\phi}_i\}_{i=1}^{\tilde{n}}$ be a standard nodal basis for $\tilde{V}$. Then we can compute the corresponding stiffness matrix $\tilde{A}$,

$$\tilde{A} = \left\{a\left(\tilde{\phi}_j, \tilde{\phi}_i\right)\right\}_{i,j=1}^{\tilde{n}}$$

and formulate the finite element problem as a linear algebraic system

$$\tilde{A}\tilde{\mathbf{x}} = \tilde{\mathbf{b}},$$

where $\tilde{\mathbf{x}}$ is the coefficient vector of $u_{\tilde{h}}$ expanded in terms of the basis $\{\tilde{\phi}_i\}_{i=1}^{\tilde{n}}$ and

$$\tilde{\mathbf{b}} = \left(\int_\Omega f\tilde{\phi}_i dx + \int_{\Gamma_N} g_N\tilde{\phi}_i d\Gamma\right)_{i=1}^{\tilde{n}}.$$

In general, we may not be satisfied by the solution $u_{\tilde{h}}$ on the coarse mesh $\tilde{\omega}$. Thus, after a proper a posteriori analysis, one may decide to refine the mesh. This process can be repeated successively. In practice, the refinement will usually take place only in certain subregions where the currently computed approximate solution has a large gradient. We study the following model situation. Let $\Omega_1 \subset \Omega$ be a subregion where we introduce a finer mesh ω_1. We assume that Ω_1 is covered by coarse-grid elements. The refinement is performed by subdividing any coarse-grid element in Ω_1 into a fixed number of congruent ones. At the interfaces that arise between the refined and unrefined elements, we have to introduce so-called "slave" nodes. The values of the functions at these nodes in the corresponding fine finite element space $V \supset \tilde{V}$ are obtained by interpolation (linear interpolation between the vertices of the adjacent coarse-grid element that is not refined). This means that the values at these nodes are not degrees of freedom. We denote the finer grid (also called the composite grid) obtained in this manner by ω. We have $\omega_1 = \Omega_1 \cap \omega$; that is, ω_1 consists of all the nodes (old nodes and those added in the refinement) in Ω_1. The fine-grid space can also be defined as follows:

$$V = \tilde{V} + V_0^{(1)},$$

where $V_0^{(1)}$ is the standard finite element space of piecewise linear functions in Ω_1 that vanish on the interfaces between Ω_1 and the unrefined part of Ω. Let $\{\phi_i\}_{i=1}^n$ be the standard nodal basis in V. Then one can consider the following hierarchical basis in V:

$$\left\{\hat{\phi}_i\right\}_{i=1}^n \equiv \left\{\tilde{\phi}_i\right\}_{i=1}^{\tilde{n}} \cup \{\phi_i\}_{i=\tilde{n}+1}^n.$$

We compute the stiffness matrices with respect to the above hierarchical basis, obtaining

$$A = \left\{a\left(\hat{\phi}_j, \hat{\phi}_i\right)\right\}_{i,j=1}^n, \qquad A_0 = \left\{a_0\left(\hat{\phi}_j, \hat{\phi}_i\right)\right\}_{i,j=1}^n.$$

Our ultimate requirement is the following:

(I) Problems on the standard, possibly uniform, grids can be solved efficiently; for example, there exists a standard efficient software code for such solution processes.

In our case, such grids will be $\tilde{\omega}$, ω_1, and any grid obtained by uniform refinement of any of their regular parts. For example, we can think of rectangular subgrids. We now partition the composite-grid matrices into the following natural two-by-two block forms:

$$A = \begin{pmatrix} \tilde{A} & G \\ F & H \end{pmatrix} \begin{matrix} \}\tilde{\omega}, \\ \}\omega\backslash\tilde{\omega}, \end{matrix} \qquad A_0 = \begin{pmatrix} \tilde{A}_0 & G_0 \\ F_0 & H_0 \end{pmatrix} \begin{matrix} \}\tilde{\omega}, \\ \}\omega\backslash\tilde{\omega}. \end{matrix}$$

We note that, since we use hierarchical basis functions, the first block on the diagonal of A or (A_0) is just $\tilde{A}$ (respectively, $\tilde{A}_0$), the coarse-grid matrix. We will need the Schur complements

$$W = H - F\tilde{A}^{-1}G \quad \text{and} \quad W_0 = H_0 - F_0\tilde{A}_0^{-1}G_0. \tag{2.3}$$

Our next goal will be to construct a preconditioner for W, the reduced Schur form of A. To do this we will need the stiffness matrix

$$A_0^{(1)} = \left\{a_{0,\Omega_1}\left(\hat{\phi}_j, \hat{\phi}_i\right)\right\}_{x_i, x_j \in \omega_1}.$$

This is the stiffness matrix corresponding to the symmetric and coercive bilinear form $a_0(\cdot,\cdot)$ restricted to Ω_1; it is defined in the subregion Ω_1 using the finite element space $V_0^{(1)}$ of functions that vanish on the interfaces between Ω_1 and the unrefined part of Ω. We similarly have the hierarchical block form

$$A_0^{(1)} = \begin{pmatrix} \tilde{A}_0^{(1)} & G_0^{(1)} \\ F_0^{(1)} & H_0^{(1)} \end{pmatrix} \begin{matrix} \}\tilde{\omega}_1, \\ \}\omega_1 \backslash \tilde{\omega}_1. \end{matrix}$$

Here $\tilde{\omega}_1$ and ω_1 are the coarse and fine grids in Ω_1, respectively. Note that $\omega_1 \backslash \tilde{\omega}_1 = \omega \backslash \tilde{\omega}$. We note that, in the computation, the hierarchical basis stiffness matrices are used only implicitly, cf. Yserentant [32] or Bank, Dupont, and Yserentant [8].

We also need the Schur complement

$$W_0^{(1)} = H_0^{(1)} - F_0^{(1)}\tilde{A}_0^{(1)^{-1}}G_0^{(1)}. \tag{2.4}$$

Note that $W_0^{(1)}$ is symmetric and positive definite.

Consider now the composite-grid problem

$$A\mathbf{x} = \mathbf{b},$$

where

$$\mathbf{x} = \begin{bmatrix} \tilde{\mathbf{x}} \\ \mathbf{x}_2 \end{bmatrix} \begin{matrix} \}\tilde{\omega}, \\ \}\omega \backslash \tilde{\omega}, \end{matrix} \qquad \mathbf{b} = \begin{bmatrix} \tilde{\mathbf{b}} \\ \mathbf{b}_2 \end{bmatrix} \begin{matrix} \}\tilde{\omega}, \\ \}\omega \backslash \tilde{\omega}, \end{matrix}$$

which, after a coarse-grid solution, is reduced to

$$W\mathbf{x}_2 = \tilde{\mathbf{b}}_2 = \mathbf{b}_2 - F\tilde{A}^{-1}\tilde{\mathbf{b}}. \tag{2.5}$$

We will precondition W in a GCG method, e.g., the method from Axelsson [2] or the generalized minimal residual (GMRES) method from Saad and Schultz [24]. The construction of the preconditioner $Z^{(1)}$ for W is given below.

Let $M^{(1)}$ be a symmetric positive definite (s.p.d.) preconditioner of $A_0^{(1)}$ such that, for some positive constants d_0 and d_1, we have

$$d_0\mathbf{v}^{(1)^T}M^{(1)}\mathbf{v}^{(1)} \le \mathbf{v}^{(1)^T}A_0^{(1)}\mathbf{v}^{(1)} \le d_1\mathbf{v}^{(1)^T}M^{(1)}\mathbf{v}^{(1)} \tag{2.6}$$

for all $\mathbf{v}^{(1)}$ corresponding to the nodes in ω_1. Then $Z^{(1)}$ is defined through the relation

$$M^{(1)^{-1}} = \begin{bmatrix} * & * \\ * & Z^{(1)^{-1}} \end{bmatrix} \begin{matrix} \}\tilde{\omega}_1, \\ \}\omega_1 \backslash \tilde{\omega}_1. \end{matrix} \tag{2.7}$$

Thus, to solve the system

$$Z^{(1)}\mathbf{v}_2^{(1)} = \mathbf{b}_2^{(1)},$$

we solve the larger system

$$M^{(1)}\mathbf{v}^{(1)} = \begin{bmatrix} 0 \\ \mathbf{b}_2^{(1)} \end{bmatrix} \begin{matrix} \}\tilde{\omega}_1, \\ \}\omega_1\backslash\tilde{\omega}_1, \end{matrix}$$

and then $\mathbf{v}_2^{(1)} = Z^{(1)^{-1}}\mathbf{b}_2^{(1)}$ is the second block component of $\mathbf{v}^{(1)}$,

$$\mathbf{v}^{(1)} = \begin{bmatrix} * \\ \mathbf{v}_2^{(1)} \end{bmatrix} \begin{matrix} \}\tilde{\omega}_1, \\ \}\omega_1\backslash\tilde{\omega}_1. \end{matrix}$$

We recall that ω_1 is a standard, uniform grid. We see that solving systems with the preconditioner $Z^{(1)}$ is based on solving systems with the preconditioner $M^{(1)}$ for $A_0^{(1)}$ on a standard, uniform grid; we assumed in (I) that this can be efficiently realized. Also note that, to compute the actions of the Schur complement W, we need to solve a coarse-grid problem with $\tilde{A}$, again on a standard, uniform grid.

3. Convergence properties of the preconditioner. At first we study the properties of the Schur complement W given in (2.3). We use the notation that $|\cdot|_{s,\Omega}$ and $\|\cdot\|_{s,\Omega}$ denote the seminorms in the Sobolev space $W_2^s(\Omega)$. We need the following result, which is the essence of many iterative methods for nonsymmetric and/or indefinite elliptic problems; cf., e.g., Mandel [18] for multigrid methods for nonsymmetric problems, Yserentant [33] for hierarchical basis methods for nonsymmetric and indefinite problems, Cai and Widlund [11] for certain additive domain decomposition methods, and the general approaches developed in Xu and Cai [31] for additive preconditioners, and Xu [30] for his multiplicative version. This result was also used in Vassilevski [26] where iterative methods in a subspace (orthogonal to a coarse-grid finite element space) were proposed.

LEMMA 3.1. *Assume the following approximation property for the coarse-grid finite element space $\tilde{V}$: given $f \in L^2(\Omega)$, consider the adjoint problem: find $v \in W_2^1(\Omega)$, $v = 0$ on Γ_D, such that*

$$a(\phi, v) = (f, v) \qquad \text{for all } \phi \in W_2^1(\Omega), \quad \phi = 0 \quad \text{on } \Gamma_D. \tag{3.1}$$

We make the assumption that for some accuracy level $\epsilon > 0$, there exists a function $\tilde{\phi} \in \tilde{V}$ such that

$$\left|v - \tilde{\phi}\right|_{1,\Omega} \leq \epsilon |f|_{0,\Omega}. \tag{3.2}$$

Consider the space

$$H = \left\{ w \in W_2^1(\Omega),\ w = 0 \text{ on } \Gamma_D \text{ and } a\left(w, \tilde{\phi}\right) = 0 \quad \text{for all } \tilde{\phi} \in \tilde{V} \right\}.$$

Then, the following properties of the bilinear form $a(\cdot, \cdot)$ hold:

$$a(w, w) \geq (1 - 0(\epsilon))a_0(w, w) \quad \text{for all } w \in H$$

and

$$a(v, w) \leq (1 + 0(\epsilon))\sqrt{a_0(v, v)}\sqrt{a_0(w, w)} \quad \text{for all } w \in H,$$

and all $v \in W_2^1(\Omega)$, $v = 0$ on Γ_D.

Proof. As already mentioned, this result can be found in one form or another in many papers. In the present form (which is suitable for our application) it was proved in Vassilevski [26]. For completeness we provide the proof here also.

For simplicity, we assume that $\Gamma_D = \partial\Omega$. We follow the standard method of "duality argument" (due to Aubin [1] and Nitsche [23], and used in Schatz [25], Mandel [18], Yserentant [33] and, more recently, in Cai and Widlund [11], Vassilevski [26], Xu and Cai [31], and Xu [30]). If v is the solution of the corresponding adjoint problem (3.1), and for any $w \in H$, we have

$$\begin{aligned}(w, f) &= a(w, v)\\ &= a\left(w, v - \tilde{\phi}\right) \quad \text{for all } \tilde{\phi} \in \tilde{V}\\ &= a_0\left(w, v - \tilde{\phi}\right) + \int_\Omega (\mathbf{b}\cdot\nabla w + c_0 w)\left(v - \tilde{\phi}\right)\\ &\le a_0\left(w, v - \tilde{\phi}\right) + c\|w\|_1 \left|v - \tilde{\phi}\right|_0\\ &\le c|w|_1 \left|v - \tilde{\phi}\right|_1,\end{aligned}$$

where we have used the boundedness of the vector field $\mathbf{b}$, the coefficient matrix $[k_{i,j}]$, and c_0. Since $\tilde{\phi} \in \tilde{V}$ is arbitrary, using (3.2), we obtain,

$$(w, f) \le c|w|_1 \inf\left\{\left|v - \tilde{\phi}\right|_1,\ \tilde{\phi} \in \tilde{V}\right\} \le c\epsilon|w|_1\,|f|_0.$$

Thus for $f = w$, we obtain

$$|w|_0 \le c\epsilon|w|_1 \le c\epsilon\sqrt{a_0(w, w)} \tag{3.3}$$

by using the coercivity of $a_0(\cdot,\cdot)$, the principal symmetric part of the bilinear form $a(\cdot,\cdot)$. Then, using integration by parts ($\mathbf{b}$ has been assumed to be sufficiently smooth) and (3.3), we see that

$$\begin{aligned}a(w, w) &= a_0(w, w) + \int_\Omega \left(c_0 - \frac{1}{2}\mathrm{div}\mathbf{b}\right) w^2\\ &\ge a_0(w, w) - \left|c_0 - \frac{1}{2}\mathrm{div}\mathbf{b}\right|_\infty |w|_0^2\\ &\ge \left[1 - O(\epsilon^2)\right] a_0(w, w),\end{aligned}$$

which is the first desired inequality. The second inequality is again obtained through integration by parts. We have

$$\begin{aligned}a(w, v) &= a_0(w, v) + \int_\Omega [(\mathbf{b}\cdot\nabla w)v + c_0 wv]\\ &= a_0(w, v) - \int_\Omega w\ \mathrm{div}(\mathbf{b}v) + \int_\Omega c_0 wv\\ &\le a_0(w, v) + c|w|_0\,|v|_1\\ &\le [1 + 0(\epsilon)]\sqrt{a_0(w, w)}\sqrt{a_0(v, v)},\end{aligned}$$

where we have used (3.3), the coercivity of $a_0(\cdot,\cdot)$, and the Schwarz inequality. □

Consider now the hierarchical block-matrix forms of A and A_0:

$$A = \begin{bmatrix} \tilde{A} & G \\ F & H \end{bmatrix} \begin{matrix} \}\tilde{\omega}, \\ \}\omega\backslash\tilde{\omega}, \end{matrix} \quad \text{and} \quad A_0 = \begin{bmatrix} \tilde{A}_0 & G_0 \\ F_0 & H_0 \end{bmatrix} \begin{matrix} \}\tilde{\omega}, \\ \}\omega\backslash\tilde{\omega}. \end{matrix}$$

As already noted, the first blocks equal the corresponding coarse-grid stiffness matrices since we use hierarchical basis functions. The blocks $\tilde{A}$ and $\tilde{A}_0$ are the stiffness matrices at the initial (coarse) discretization level.

The coefficient vector of a function $\tilde{v} \in \tilde{V} \subset V$ with respect to the hierarchical basis in V has the block form,

$$\begin{bmatrix} \tilde{\mathbf{v}} \\ 0 \end{bmatrix} \begin{matrix} \}\tilde{\omega}, \\ \}\omega\backslash\tilde{\omega}. \end{matrix}$$

Then, if $w \in V$ has a coefficient vector

$$\mathbf{w} = \begin{bmatrix} \tilde{\mathbf{w}} \\ \mathbf{w}_2 \end{bmatrix} \begin{matrix} \}\tilde{\omega}, \\ \}\omega\backslash\tilde{\omega}, \end{matrix}$$

and

$$a(w, \tilde{v}) = 0 \quad \text{for all } \tilde{v} \in \tilde{V},$$

we have

$$\begin{bmatrix} \tilde{\mathbf{v}} \\ 0 \end{bmatrix}^T A \begin{bmatrix} \tilde{\mathbf{w}} \\ \mathbf{w}_2 \end{bmatrix} = 0.$$

Thus

$$\tilde{\mathbf{v}}^T \left(\tilde{A}\tilde{\mathbf{w}} + G\mathbf{w}_2 \right) = 0 \quad \text{for all } \tilde{\mathbf{v}}.$$

This implies that

$$\tilde{\mathbf{A}}\tilde{\mathbf{w}} + G\mathbf{w}_2 = 0.$$

Having this in mind, we see that the space

$$H = \left\{ w \in V : a\left(w, \tilde{\phi}\right) = 0 \quad \text{for all } \tilde{\phi} \in \tilde{V} \right\}$$

in matrix-vector form can be written as

$$H = \left\{ \mathbf{w} : \tilde{\mathbf{A}}\tilde{\mathbf{w}} + G\mathbf{w}_2 = 0 \right\}.$$

Next we state the following main result from Vassilevski [26].

LEMMA 3.2. *There exist two positive constants* $\gamma_1 = 1 - O(\epsilon)$ *and* $\gamma_2 = 1 + O(\epsilon)$ *such that, under the approximation property stated in Lemma* 3.1, *the following spectral equivalence relations between the Schur complements* W *of* A *and* $W_0 = H_0 - F_0\tilde{A}_0^{-1}G_0$ *of* A_0 *hold*:

$$\mathbf{v}_2^T W \mathbf{w}_2 \geq \gamma_1 \mathbf{v}_2^T W_0 \mathbf{v}_2 \quad \textit{for all } \mathbf{v}_2 \in \mathbb{R}^{\tilde{n}}$$

and

$$\mathbf{v}_2^T W \mathbf{w}_2 \le \gamma_2 \left(\mathbf{v}_2^T W_0 \mathbf{v}_2\right)^{1/2} \left(\mathbf{w}_2^T W_0 \mathbf{w}_2\right)^{1/2} \quad \textit{for all } \mathbf{v}_2, \mathbf{w}_2 \in \mathbb{R}^{\tilde{n}}.$$

Proof. From Lemma 3.1, we have

$$\mathbf{v}^T A \mathbf{v} \ge \gamma_1 \mathbf{v}^T A_0 \mathbf{v} \tag{3.4}$$

for any $\mathbf{v} = \begin{bmatrix} \tilde{\mathbf{v}} \\ \mathbf{v}_2 \end{bmatrix}_{\omega\setminus\tilde{\omega}}^{\tilde{\omega}}$ in the subspace H satisfying $\tilde{A}\tilde{\mathbf{v}} + G\mathbf{v}_2 = 0$; here $\gamma_1 = 1 - O(\epsilon)$. Since $A\mathbf{v} = \begin{bmatrix} 0 \\ W_{\mathbf{v}_2} \end{bmatrix}$, the inequality above implies that

$$\mathbf{v}_2^T W \mathbf{v}_2 \ge \gamma_1 \inf_{\tilde{\mathbf{v}}} \mathbf{v}^T A_0 \mathbf{v} = \gamma_1 \mathbf{v}_2^T W_0 \mathbf{v}_2.$$

From Lemma 3.1, we also have that

$$\mathbf{v}^T A \mathbf{w} \le \hat{\gamma}_2 \left(\mathbf{v}^T A_0 \mathbf{v}\right)^{1/2} \left(\mathbf{w}^T A_0 \mathbf{w}\right)^{1/2},$$

where $\hat{\gamma}_2 = 1 + O(\epsilon)$, for arbitrary vectors $\mathbf{v} = \begin{bmatrix} \tilde{\mathbf{v}} \\ \mathbf{v}_2 \end{bmatrix}\Big\}_{\omega\setminus\tilde{\omega}}^{\tilde{\omega}}$ and all $\mathbf{w} = \begin{bmatrix} \tilde{\mathbf{w}} \\ \mathbf{w}_2 \end{bmatrix}\Big\}_{\omega\setminus\tilde{\omega}}^{\tilde{\omega}}$ from the subspace H, satisfying $\tilde{A}\tilde{\mathbf{w}} + G\mathbf{w}_2 = 0$. Then we have

$$\begin{aligned}
\mathbf{v}_2^T W \mathbf{w}_2 &= \mathbf{v}^T A \mathbf{w} \\
&\le \hat{\gamma}_2 \left(\inf_{\tilde{\mathbf{v}}} \mathbf{v}^T A_0 \mathbf{v}\right)^{1/2} \left(\mathbf{w}^T A_0 \mathbf{w}\right)^{1/2} \\
&\le \hat{\gamma}_2 \left(\mathbf{v}_2^T W_0 \mathbf{v}_2\right)^{1/2} \left(\mathbf{w}^T A_0 \mathbf{w}\right)^{1/2} \\
&\le \hat{\gamma}_2 / \sqrt{\gamma_1} \left(\mathbf{v}_2^T W_0 \mathbf{v}_2\right)^{1/2} \left(\mathbf{w}_2^T W \mathbf{w}_2\right)^{1/2}
\end{aligned}$$

from (3.4). We set $\mathbf{v}_2 = \mathbf{w}_2$ in this inequality, and thus obtain

$$\left(\mathbf{w}_2^T W \mathbf{w}_2\right)^{1/2} \le \hat{\gamma}_2 / \sqrt{\gamma_1} \left(\mathbf{w}_2^T W_0 \mathbf{w}_2\right)^{1/2}.$$

Substituting the last inequality in the preceding one, we get

$$\mathbf{v}_2^T W \mathbf{w}_2 \le \hat{\gamma}_2^2 / \gamma_1 \left(\mathbf{v}_2^T W_0 \mathbf{v}_2\right)^{1/2} \left(\mathbf{w}_2^T W_0 \mathbf{w}_2\right)^{1/2}.$$

Denoting $\gamma_2 = \hat{\gamma}_2^2 / \gamma_1 = 1 + O(\epsilon)$, we thus obtain the second desired inequality. □

We next need the following result.

LEMMA 3.3 (Strengthened Cauchy Inequality, cf. Axelsson and Gustafsson [3] or Bank and Dupont [7]). *There exists a constant* $\gamma \in (0, 1)$ *such that*

$$a_0\left(\phi, \tilde{\phi}\right) \le \gamma \left(a_0(\phi, \phi)\right)^{1/2} \left(a_0\left(\tilde{\phi}, \tilde{\phi}\right)\right)^{1/2}$$

for all $\tilde{\phi} \in \tilde{V}$ *and all* $\phi \in V$ *that satisfy* $\phi|_{\tilde{\omega}} = 0$. *In matrix notation, we have*

$$\mathbf{v}_2^T F_0 \tilde{\mathbf{v}} \le \gamma \left(\mathbf{v}_2^T H_0 \mathbf{v}_2\right)^{1/2} \left(\tilde{\mathbf{v}}^T \tilde{A}_0 \tilde{\mathbf{v}}\right)^{1/2}$$

for all vectors $\mathbf{v}_2 \in \mathbb{R}^{n-\tilde{n}}$, $\tilde{\mathbf{v}} \in \mathbb{R}^{\tilde{n}}$. *In general, the constant* γ *depends only on the shape of the elements, also on* $\tilde{h}/h$ *(the ratio of the coarse grid over the fine grid) and on the local ellipticity constant* σ *defined as follows*:

$$\sigma = \sup_{T \in \tilde{\mathcal{J}}} \frac{\mu_2(T)}{\mu_1(T)};$$

here $\mu_1(T)$ *and* $\mu_2(T)$ *are the bounds of the expression*

$$\mu_1(T)|\xi|^2 \leq \sum_{i,j} k_{i,j}(x)\xi_i\xi_j \leq \mu_2(T)|\xi|^2 \quad \text{for all } x \in T \in \tilde{\mathcal{J}}.$$

In particular, this means that γ *remains bounded away from unity, independent of the possible jumps of the coefficients if these occur only across edges of elements from* $\tilde{\mathcal{J}}$ *(the set of initial coarse triangles). The asymptotic behavior of* γ *in terms of* $\tilde{h}/h$ *is (cf., e.g., Vassilevski* [27])

$$\gamma^2 = 1 - \begin{cases} C\dfrac{1}{1+\log\frac{\tilde{h}}{h}} & \text{for 2D domain } \Omega, \\ C\frac{h}{\tilde{h}}, & \text{for 3D domain } \Omega. \end{cases}$$

We assume throughout this paper that the aspect ratio, $\tilde{h}/h$, *is bounded.*

A corollary from Lemma 3.3 is the following lemma (cf. Axelsson and Gustafsson [3]).

LEMMA 3.4. *The following inequality holds*:

$$\mathbf{v}_2^T H_0 \mathbf{v}_2 \leq \frac{1}{1-\gamma^2}\mathbf{v}^T A_0 \mathbf{v} \quad \text{for all } \mathbf{v} = \begin{bmatrix} \tilde{\mathbf{v}} \\ \mathbf{v}_2 \end{bmatrix} \begin{matrix} \}\tilde{\omega}, \\ \}\omega\backslash\tilde{\omega}. \end{matrix}$$

Proof. We have, using the strengthened Cauchy inequality,

$$\begin{aligned} \mathbf{v}^T A_0 \mathbf{v} &= \mathbf{v}_2^T H_0 \mathbf{v}_2 + \tilde{\mathbf{v}}^T \tilde{\mathbf{A}}_0 \tilde{\mathbf{v}} + 2\mathbf{v}_2^T F_0 \tilde{\mathbf{v}} \\ &\geq \mathbf{v}_2^T H_0 \mathbf{v}_2 + \tilde{\mathbf{v}}^T \tilde{\mathbf{A}}_0 \tilde{\mathbf{v}} - 2\gamma \left(\mathbf{v}_2^T H_0 \mathbf{v}_2\right)^{1/2} \left(\tilde{\mathbf{v}}^T \tilde{\mathbf{A}}_0 \tilde{\mathbf{v}}\right)^{1/2} \\ &= (1-\gamma^2)\mathbf{v}_2^T H_0 \mathbf{v}_2 + \left[\gamma\sqrt{\mathbf{v}_2^T H_0 \mathbf{v}_2} - \sqrt{\tilde{\mathbf{v}}^T \tilde{\mathbf{A}}_0 \tilde{\mathbf{v}}}\right]^2 \\ &\geq (1-\gamma^2)\mathbf{v}_2^T H_0 \mathbf{v}_2, \end{aligned}$$

which is the desired inequality. □

We also need the following basic lemma (cf. Ewing and Vassilevski [17]).

LEMMA 3.5. *The following inequalities between the Schur complement* $W_0^{(1)} = H_0^{(1)} - F_0^{(1)} \tilde{A}_0^{(1)^{-1}} G_0^{(1)}$ *of* $A_0^{(1)}$ *(see* (2.4)*), the Schur complement* W_0 *of* A_0 *(see* (2.3)*), and the block* H_0 *of* A_0 *hold*:

$$\mathbf{v}_2^T W_0 \mathbf{v}_2 \leq \mathbf{v}_2^T W_0^{(1)} \mathbf{v}_2 \leq \mathbf{v}_2^T H_0 \mathbf{v}_2 \leq \frac{1}{1-\gamma^2}\mathbf{v}_2^T W_0 \mathbf{v}_2 \quad \text{for all } \mathbf{v}_2 \in \mathbb{R}^{n-\tilde{n}}.$$

Proof. By a main property of Schur complements of s.p.d. matrices, we have,

$$\begin{aligned}
\mathbf{v}_2^T W_0 \mathbf{v}_2 &= \inf_{\tilde{\mathbf{v}}} \begin{bmatrix} \tilde{\mathbf{v}} \\ \mathbf{v}_2 \end{bmatrix}^T A_0 \begin{bmatrix} \tilde{\mathbf{v}} \\ \mathbf{v}_2 \end{bmatrix} \\
&\le \inf_{\tilde{\mathbf{v}}} \left\{ \begin{bmatrix} \tilde{\mathbf{v}} \\ \mathbf{v}_2 \end{bmatrix}^T A_0 \begin{bmatrix} \tilde{\mathbf{v}} \\ \mathbf{v}_2 \end{bmatrix} : \tilde{\mathbf{v}} = \begin{bmatrix} \tilde{\mathbf{v}}^{(1)} \\ 0 \end{bmatrix} \begin{matrix} \}\tilde{\omega}_1 \\ \}\tilde{\omega}\backslash\tilde{\omega}_1 \end{matrix} \right\} \\
&= \inf_{\tilde{\mathbf{v}}^{(1)}} \begin{bmatrix} \tilde{\mathbf{v}}^{(1)} \\ \mathbf{v}_2 \end{bmatrix}^T A_0^{(1)} \begin{bmatrix} \tilde{\mathbf{v}}^{(1)} \\ \mathbf{v}_2 \end{bmatrix} \\
&= \mathbf{v}_2^T W_0^{(1)} \mathbf{v}_2.
\end{aligned}$$

We have, by Lemma 3.4,

$$\mathbf{v}_2^T H_0 \mathbf{v}_2 \le \frac{1}{1-\gamma^2} \mathbf{v}^T A_0 \mathbf{v},$$

and hence

$$\mathbf{v}_2^T H_0 \mathbf{v}_2 \le \frac{1}{1-\gamma^2} \inf_{\tilde{\mathbf{v}}} \mathbf{v}^T A_0 \mathbf{v} = \frac{1}{1-\gamma^2} \mathbf{v}_2^T W_0 \mathbf{v}_2.$$

Finally, noting that $H_0 = H_0^{(1)}$ and

$$\mathbf{v}_2^T W_0^{(1)} \mathbf{v}_2 = \mathbf{v}_2^T \left(H_0^{(1)} - F_0^{(1)} \tilde{A}_0^{(1)^{-1}} G_0^{(1)} \right) \mathbf{v}_2 \le \mathbf{v}_2^T H_0 \mathbf{v}_2,$$

the proof is complete. □

Now we can prove our main result.

THEOREM 3.6. *The preconditioning matrix $Z^{(1)}$ induced by the preconditioner $M^{(1)}$ for $A_0^{(1)}$ (see (2.6) and (2.7)), is spectrally equivalent to the reduced Schur matrix W of A, and the following spectral equivalence relations hold:*

$$\begin{aligned}
&\mathbf{v}_2^T W \mathbf{w}_2 \le d_1 \gamma_2 \left(\mathbf{v}_2^T Z^{(1)} \mathbf{v}_2 \right)^{1/2} \left(\mathbf{w}_2^T Z^{(1)} \mathbf{w}_2 \right)^{1/2} \quad \text{for all } \mathbf{v}_2, \mathbf{w}_2 \in \mathbb{R}^{n-\tilde{n}}, \\
&\mathbf{v}_2^T W \mathbf{v}_2 \ge (1-\gamma^2) d_0 \gamma_1 \mathbf{v}_2^T Z^{(1)} \mathbf{v}_2 \quad \text{for all } \mathbf{v}_2 \in \mathbb{R}^{n-\tilde{n}}.
\end{aligned}$$

The constants γ_1 and γ_2 are from Lemma 3.2; *the constants d_0 and d_1 are from* (2.6), *and $\gamma \in (0, 1)$ is the constant from the strengthened Cauchy inequality from Lemma* 3.3.

Proof. We have, from (2.6), noting that $Z^{(1)}$ is a Schur complement of $M^{(1)}$,

$$d_0 \mathbf{v}_2^T Z^{(1)} \mathbf{v}_2 \le \mathbf{v}_2^T W_0^{(1)} \mathbf{v}_2 \le d_1 \mathbf{v}_2^T Z^{(1)} \mathbf{v}_2 \quad \text{for all } \mathbf{v}_2 \in \mathbb{R}^{n-\tilde{n}}.$$

Then the proof simply follows from Lemma 3.2, the above inequalities, and Lemma 3.5. □

COROLLARY 3.7. *The generalized conjugate gradient methods, e.g., those from Axelsson* [2], *or the* GMRES method *from Saad and Schultz* [24], *applied to solve the reduced system* (2.5) *with W as a coefficient matrix using $Z^{(1)}$ as a preconditioning matrix, have an asymptotic convergence factor that depends only on the constant $(\gamma_2/\gamma_1)(1-\gamma^2)^{-1}\kappa$, where $\kappa = d_1/d_0$ is the condition number of $M^{(1)^{-1}} A_0^{(1)}$.*

Remark 1. The approximation property of the coarse finite element space $\tilde{V}$ assumed in Lemma 3.2 is ensured, for example, if the adjoint problem (3.1) has certain (very weak) regularity, say, for some $\alpha > 0$ and any $f \in L^2(\Omega)$ the solution v of (3.1) belongs to $W_2^{1+\alpha}(\Omega)$.

Then we can let $\epsilon = O(\tilde{h}^{\alpha})$ in (3.2), where $\tilde{h}$ is the coarse-grid discretization parameter. We also note that the ratio $\gamma_2/\gamma_1 = 1 + O(\epsilon) = 1 + O(\tilde{h}^{\alpha})$ in this case. Hence, the convergence properties of the preconditioner $Z^{(1)}$ are asymptotically the same (if $\tilde{h}$ is sufficiently small) as if the original problem was assumed symmetric. We also remark that $1/(1-\gamma^2)$ is bounded when $\tilde{h}/h$ is bounded.

4. Numerical experiments. In this section we present numerical results for the bilinear form

$$a(u,\varphi) = \int_{\Omega} k\nabla u \cdot \nabla\varphi dx + \int_{\Omega} (\mathbf{v}\cdot\nabla u)\varphi dx - \lambda \int_{\Omega} u\varphi dx.$$

Here Ω is the unit square. We impose homogeneous Dirichlet boundary conditions on the boundaries $\{x = 0\}$ and $\{y = 0\}$ and homogeneous natural boundary conditions on $\{x = 1\}$ and $\{y = 1\}$.

We test the following problems.

Problem 1 (symmetric and positive definite bilinear form). This case corresponds to the bilinear form $a_0(\cdot,\cdot)$ from (2.2) with $k = 1 + x^2 + y^2$, i.e., $\mathbf{v} = 0$ and $\lambda = 0$.

Problem 2 (nonsymmetric bilinear form). The coefficients are

1. $v_1 = -\cos\theta(x\cos\theta + y\sin\theta)$,
   $v_2 = -\sin\theta(x\cos\theta + y\sin\theta)$,
2. $v_1 = -10\cos\theta(x\cos\theta + y\sin\theta)$,
   $v_2 = -10\sin\theta(x\cos\theta + y\sin\theta)$,

where θ is 45°; in this case, $\lambda = 0$ and $k = 1 + x^2 + y^2$.

Problem 3 (symmetric but possibly indefinite bilinear form). This case corresponds to a Helmholtz-like equation, i.e., $k = 1 + x^2 + y^2$ and $\mathbf{v} = 0$. We test this problem with $\lambda = 10, 50, 500$.

For all problems, the exact solution is

$$u(x,y) = x\left(1 - \frac{1}{2}x\right) y\left(1 - \frac{1}{2}y\right).$$

In the discretization, we use the finite element methods with piecewise linear elements on isosceles right-angled triangles. The results are listed in Tables 1–6 where N_c is the number of nodes in the initial coarse grid coordinate, i.e., the initial mesh size is $h_c = 1/N_c$. The subregion Ω_1 where the local refinement is introduced is chosen to be the northeast 1/16 part of the whole domain Ω and the local refinement is done with parameter $n_0 = h_c/h_f = 2, 4, 8$, where h_f is the grid size in the subdomain Ω_1.

We solve the corresponding reduced discrete problems (2.5) where the right-hand side vector $\mathbf{b}$ corresponds to the exact solution $u(x, y)$ above. We use the GCG method from Axelsson [2] with a stopping criterion

$$\Delta = \mathbf{r}_2^T \mathbf{r}_2 < \epsilon, \qquad \epsilon = 10^{-12},$$

where $\mathbf{r}_2$ is the residual vector and the parameters iter and arfac in the tables are, respectively, the number of iterations and the average reduction factor for reaching the above accuracy, i.e.,

$$\text{arfac} = \left(\sqrt{\frac{\Delta}{\Delta_0}}\right)^{1/\text{iter}},$$

where $\Delta_0 = \mathbf{r}_2^{(0)^T} \mathbf{r}_2^{(0)}$ and $\mathbf{r}_2^{(0)}$ is the initial residual vector.

For problems in the subregion we use the AMLI preconditioner (algebraic multilevel preconditioner) from Axelsson and Vassilevski [4] as modified in Vassilevski [27]. We also indicate in Tables 2–6 whether $\tilde{A}$ and W are positive definite (coercive) or not.

From the numerical results presented, we see that the proposed extension of the iterative refinement methods from Ewing and Vassilevski [16], [17] works as predicted by the theory. If the coarse-grid space $\tilde{V}$ gives more accurate approximation to the considered boundary value problem, i.e., when N_c is larger, we see that the GCG method has better convergence properties in the sense that the number of iterations (iter) decreased for a fixed $n_0 = h_c/h_f = 2, 4, 8$.

For the case in Table 6, for $N_c = 8$, $n_0 = 2, 4, 8$ and $\lambda = 500$, we obtain noncoercive Schur complement W. However, it turns out that the GCG method, after a short starting phase, performs as in the coercive case. This behavior can be explained as in Yserentant [33]. This is due to the fact that the GCG method is also convergent when we have a number of eigenvalues (but not too many) with negative real part. The number of such eigenvalues depends only on λ (if the discretization is sufficiently accurate) and is independent of the preconditioner used.

We also observe from Tables 4, 5, and 6 that the method is not very sensitive with respect to λ. We get about the same number of iterations for $\lambda = 10$, 50, and 500 in the case when the Schur complement W is coercive.

FAST BAND-TOEPLITZ PRECONDITIONERS FOR HERMITIAN TOEPLITZ SYSTEMS*

RAYMOND H. CHAN† AND PING TAK PETER TANG‡

Abstract. This paper considers the solutions of Hermitian Toeplitz systems where the Toeplitz matrices are generated by nonnegative functions f. The preconditioned conjugate gradient method with well-known circulant preconditioners fails in the case when f has zeros. This paper employs Toeplitz matrices of fixed bandwidth as preconditioners. Their generating functions g are trigonometric polynomials of fixed degree and are determined by minimizing the maximum relative error $\|(f-g)/f\|_\infty$. It is shown that the condition number of systems preconditioned by the band-Toeplitz matrices are $O(1)$ for f, with or without zeros. When f is positive, the preconditioned systems converge at the same rate as other well-known circulant preconditioned systems. An a priori bound of the number of iterations required for convergence is also given.

Key words. Toeplitz matrix, generating function, preconditioned conjugate gradient method, Chebyshev approximation, Remez algorithm

1. Introduction.

In this paper, we consider solutions of n-by-n Hermitian Toeplitz systems $A_n x = b$ by the preconditioned conjugate gradient method. The Toeplitz matrices A_n are assumed to be generated by 2π-periodic continuous real-valued functions f defined on $[-\pi, \pi]$, i.e., the entries of A_n are given by the Fourier coefficients of f:

$$[A_n]_{j,k} = \frac{1}{2\pi}\int_{-\pi}^{\pi} f(x)e^{-i(j-k)x}dx \quad \forall 0 \le j,k < n.$$

We emphasize that the generating function f is given in some applications of Toeplitz systems. Typical examples are the kernels of the Wiener–Hopf equations, see Gohberg and Fel'dman [12, p. 82], the spectral density functions in stationary stochastic process, see Grenander and Szegö [14, p. 171], and the point-spread functions in image deblurring, see Oppenheim [16, p. 200].

If the generating function f is positive, the preconditioned conjugate gradient method with circulant preconditioners has proved to be a successful method—the preconditioned systems converge superlinearly when f is smooth, see, for instance, Chan and Strang [3] and Chan and Yeung [5]. However, these circulant preconditioners do not work in general when f has zeros. A specific example is the one-dimensional discrete Laplacian given by the tridiagonal matrix trid$[-1, 2, -1]$. Its generating function is $f(x) = 4\sin^2 x$, which has a zero at $x = 0$. The corresponding Strang circulant preconditioner, see [17], is actually singular. (See also the numerical results in §4 for the performance of the T. Chan [8] circulant preconditioner in the case where f has zeros.)

Recently, Chan [4] proposed using band-Toeplitz matrices $B_{n,\ell}$ as preconditioners for f that has zeros. These preconditioners are constructed by matching their generating function g with f at those zeros of f. It is proved that if the order of the zero of f is 2ℓ, then the condition number $\kappa(A_n)$ of A_n is $O(n^{2\ell})$, whereas $\kappa(B_{n,\ell}^{-1}A_n)$ is $O(1)$. However, when f is positive, the band-Toeplitz preconditioned systems converge much slower than those preconditioned by circulant preconditioners.

Our main aim in this paper is to design band-Toeplitz preconditioners that work when f has zeros and yet their preconditioned systems converge at the same rate as the circulant

preconditioned systems even when f is positive. Our idea is to increase the bandwidth of the band-Toeplitz preconditioner to get extra degrees of freedom, which enable us not only to match the zeros in f but also to minimize the relative error $||(f-g)/f||_\infty$. The minimizer g is found by a version of the Remez algorithm proposed by Tang [18]. The algorithm also computes the minimum relative error, which ultimately gives an a priori bound on the number of iterations required for convergence.

We note that the band-Toeplitz preconditioner we proposed has bandwidth ℓ that depends only on the order of the zeros of f and is independent of n, the size of the matrix. Hence for any vector x, $B_{n,\ell}^{-1}x$ can be obtained by band solver in $O(\ell^2 n)$ operations. In contrast, solution of circulant systems requires $O(n \log n)$ operations. We remark that in [15], Ku and Kuo have considered using products of lower- and upper-triangular band-Toeplitz matrices as preconditioners. Their resulting preconditioners are in general non-Toeplitz and hence are different from ours.

The outline of the paper is as follows. In §2, we analyze the convergence rate of our preconditioned systems $B_{n,\ell}^{-1}A_n$ in terms of the generating functions g of B_n and f of A_n. In §3, we describe the Remez algorithm and how it is applied to construct the generating function g and hence the preconditioner $B_{n,\ell}$. In §4, we present numerical results that confirm our analysis in §2. In §5, we discuss the use of regularization, a technique that is relevant in computations corresponding to f having zeros and especially when n is large. Finally, concluding remarks are given in §6.

2. Convergence analysis. In this section, we analyze the convergence rate of the preconditioned conjugate gradient method in terms of the generating functions f and g.

We first note that if f is nonnegative, then A_n is always positive definite.

LEMMA 2.1. *Let $f_{\min}$ and $f_{\max}$ be the minimum and maximum of f in $[-\pi, \pi]$. If $f_{\min} < f_{\max}$, then for all $n > 0$,*

$$f_{\min} < \lambda_i(A_n) < f_{\max}, \quad i = 1, \ldots, n,$$

where $\lambda_i(A_n)$ is the ith eigenvalue of A_n. In particular, if $f \geq 0$, then A_n are positive definite for all n.

The proof of the lemma can be found in Chan [4]. Next we give a bound on the condition number of the preconditioned systems.

THEOREM 2.2. *Let f be the generating function of A_n and let g be the generating function of a band-Toeplitz matrix $B_{n,\ell}$:*

$$g(x) = \sum_{j=-(\ell-1)}^{\ell-1} b_j e^{ijx}, \qquad b_j = \bar{b}_{-j}.$$

Then, if

$$\left\| \frac{f-g}{f} \right\|_\infty = h < 1,$$

then $B_{n,\ell}$ is positive definite and

$$\kappa(B_{n,\ell}^{-1}A_n) \leq \frac{1+h}{1-h}, \qquad n = 1, 2, 3, \ldots.$$

Proof. By assumption, we have

$$f(x)(1-h) \leq g(x) \leq f(x)(1+h) \quad \forall x \in [-\pi, \pi].$$

Clearly, $g(x)$ is nonnegative. In particular, by Lemma 2.1, $B_{n,\ell}$ is positive definite for $n = 1, 2, 3, \ldots$. Since A_n and $B_{n,\ell}$ are Toeplitz matrices, we have

$$u^* A_n u = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(x) \left| \sum_{j=0}^{n-1} u_j e^{ijx} \right|^2 dx$$

and

$$u^* B_n u = \frac{1}{2\pi} \int_{-\pi}^{\pi} g(x) \left| \sum_{j=0}^{n-1} u_j e^{ijx} \right|^2 dx$$

for an arbitrary (complex) n-vector $u^* = [u_0, u_1, \ldots, u_{n-1}]$, see Grenander and Szegö [14]. Hence, we get

$$(1) \qquad (1-h) u^* A_n u \le u^* B_n u \le (1+h) u^* A_n u.$$

Since $B_{n,\ell}$ is also positive definite, we finally have

$$\kappa(B_{n,\ell}^{-1} A_n) \le \frac{1+h}{1-h}. \qquad \square$$

By standard error analysis of the conjugate gradient method, see, for instance, Axelsson and Barker [1, p. 14], we conclude that the number of iterations required for convergence is bounded by

$$\frac{1}{2} \left(\frac{1+h}{1-h} \right) \log \left(\frac{1}{\tau} \right) + 1,$$

where τ is the tolerance. Since h is given explicitly in the Remez algorithm, we have an a priori bound on the number of iterations required for convergence.

3. Construction of preconditioner by the Remez algorithm. In this section, we describe how we construct our band-Toeplitz preconditioner. For ease of presentation, we assume the matrix A_n is real symmetric. Handling the complex Hermitian case will become clear once the symmetric case is explained. Since A_n is symmetric, its generating function f is even, in addition to being 2π-periodic and continuous. It suffices to consider f on $[0, \pi]$. The generating function of a band-Toeplitz matrix $B_{n,\ell}$,

$$B_{n,\ell} = \begin{pmatrix} b_0 & b_1 & \cdots & b_{\ell-1} & & & & \\ b_1 & \ddots & \ddots & & \ddots & & & \\ \vdots & \ddots & \ddots & \ddots & & \ddots & & \\ b_{\ell-1} & & \ddots & \ddots & \ddots & & \ddots & \\ & \ddots & & \ddots & \ddots & \ddots & & b_{\ell-1} \\ & & \ddots & & \ddots & \ddots & \ddots & \vdots \\ & & & \ddots & & \ddots & \ddots & b_1 \\ & & & & b_{\ell-1} & \cdots & b_1 & b_0 \end{pmatrix}$$

is given by

$$g(x) = b_0 + b_1(2\cos(x)) + b_2(2\cos(2x)) + \cdots + b_{\ell-1}(2\cos((\ell-1)x)).$$

Thus, in the case where $f > 0$ on $[0, \pi]$, determining the optimal P is a standard linear minimax approximation problem:

$$\text{minimize}_{p_0, p_1, \ldots, p_{\ell-1}} \|1 - P(x)\|_\infty ,$$

where

$$P(x) = \sum_{j=0}^{\ell-1} p_j \phi_j(x), \quad \phi_0 = 1/f(x) \quad \text{and} \quad \phi_j(x) = 2\cos(jx)/f(x) \quad \text{for } j > 0.$$

Note that $P = g/f$. This optimal P (and hence g) can be obtained by a standard Remez algorithm (see Cheney [10], for example). We, however, use the version proposed by Tang [18], which can be extended to handle the case when $f(x_0) = 0$ for some $x_0 \in [0, \pi]$. We now describe this version of the Remez algorithm briefly; after that, the extension will also be explained.

Given $\phi_0(x) = 0$, and $\phi_j(x) = 2\cos(jx)/f(x)$, $j = 1, \ldots, \ell - 1$, we are to solve

Problem $\mathcal{P}$.

$$\text{Minimize} \quad h \text{ subject to } \quad h \geq s\left(1 - \sum_{j=0}^{\ell-1} p_j \phi_j(x)\right), \quad (s, x) \in \{-1, 1\} \times [0, \pi].$$

One can think of Problem $\mathcal{P}$ as a linear programming problem (by, say, replacing $[0, \pi]$ by a finite set of points). The dual of this problem is given by the following.

Problem $\mathcal{D}$.

$$\text{Maximize} \quad \sum_{s,x} s \cdot r_{s,x} \text{ subject to } \quad r_{s,x} \geq 0, \quad \text{and} \quad \sum_{s,x} r_{s,x} \phi_j(x) s = 0, \quad j = 0, 1, \ldots, \ell-1.$$

It is observed in [18] that even without discretizing the domain $[0, \pi]$, the Simplex algorithm can be applied to Problem $\mathcal{D}$. The preconditioners in the next section are obtained by this computation.

Now, suppose that $f(x_0) = 0$. In practice, x_0 is often known. Because $f \geq 0$ (lest A_n has negative eigenvalues for large enough n), we have $f'(x_0) = 0$ also. Suppose that $f''(x_0) \neq 0$, then we would determine P by imposing the constraint $g(x_0) = 0$, that is,

$$p_0 + 2\sum_{j=1}^{\ell-1} p_j \cos(jx_0) = 0.$$

This linear constraint on the coefficients p_j's can be naturally added to Problem $\mathcal{P}$ and translated to its dual form in Problem $\mathcal{D}$. In general, the case when $f^{(k)}(x_0) = 0$ for $k = 0, 1, \ldots, m$ can be handled by the constraints $g^{(k)}(x_0) = 0$ for $k = 0, 1, \ldots, m - 1$.

We note that when A_n is complex Hermitian, f will not be even necessarily (but still continuous real-valued and 2π-periodic). The domain of approximation becomes $[-\pi, \pi]$ and the approximant will be trigonometric polynomials with sin and cos. Similar constraints can be imposed when $f(x_0) = 0$ for some x_0.

Let us end the section by discussing the computational cost of our method. As pointed out in [18], the number of Simplex iterations needed to determine g is proportional to ℓ. In

practice, all of our experiments took less than 2ℓ iterations. Moreover, after an initial LU decomposition of an ℓ-by-ℓ matrix, each Simplex iteration requires only a modification to the decomposition after a rank-1 change. The total effort for location g is $O(\ell^3)$. We stress the fact that g is independent of n. Thus, as long as f is fixed and a sufficient bandwidth ℓ is reached, the entries for $B_{n,\ell}$ are determined for all n.

In each iteration of the preconditioned conjugate gradient method, we have to compute matrix vector multiplications of the form $A_n x$ and $B_{n,\ell}^{-1} y$. We note that $A_n x$ can be computed in $O(n \log n)$ operations by first embedding A_n into a $2n$-by-$2n$ circulant matrix and then perform the multiplication by the Fast Fourier Transform (see Strang [17]). The vector $z = B_{n,\ell}^{-1} y$ can be obtained by solving the banded system $B_{n,\ell} z = y$ with any band solvers, see, for instance, Golub and Van Loan [13], or Wright [19] for a parallel one. Typically, we will decompose $B_{n,\ell}$ into some triangular factors and then solve the system by a backward and forward solve. The cost of obtaining the triangular factors is $O(\ell^2 n)$, and each subsequent solve will cost $O(\ell n)$, as the triangular factors will also be banded.

Recall that the number of iterations is independent of the size of the matrix n; we therefore conclude that the total complexity of our method is $O(n \log n + \ell^2 n)$.

4. Numerical results. In this section, we compare the convergence rate of the band-Toeplitz preconditioner with a circulant preconditioner on five different generating functions. They are $\cosh x$, $x^4 + 1$, $1 - e^{-x^2}$, $(x - 1)^2(x + 1)^2$, and x^4. The first two functions are positive while the others have either one or two distinct zeros. The matrices A_n are formed by evaluating the Fourier coefficients of the generating functions.

We note that when $f(x) = 1 - e^{-x^2}$, its Fourier coefficients cannot be evaluated exactly. In this case, we approximate them by

$$\begin{aligned} a_j &= \frac{1}{2\pi} \int_{-\pi}^{\pi} f(x) e^{-ijx} dx \\ &\approx \frac{1}{2n} \sum_{k=0}^{2n-1} f\left(\frac{k\pi}{n} - \pi\right) e^{-ij(k\pi/n - \pi)}, \quad j = 0, \pm 1, \pm 2, \ldots, \end{aligned}$$

where the last expression is evaluated by using the Fast Fourier Transform.

In our tests, the vector of all ones is the right-hand side vector, the zero vector is the initial guess and the stopping criterion is $||r_q||_2 / ||r_0||_2 \leq 10^{-7}$, where r_q is the residual vector after q iterations. All computations are done by Matlab on a Sun workstation. Tables 1–5 show the number of iterations required for convergence with different choices of preconditioners. In the tables, I denotes that no preconditioner is used, C is the T. Chan circulant preconditioner [8], and $B_{n,\ell}$ is the band-Toeplitz preconditioner with half-bandwidth ℓ.

We note that for the cases when the f's are positive, our preconditioners, with half-bandwidths four to five, work as well as the circulant preconditioners. In the cases when the f's have zeros, our preconditioned systems still converge at a rate that is independent of the sizes of the matrices. For the circulant preconditioned systems, however, the numbers of iterations required grow as the sizes of the matrices increase.

5. Regularization. We note that when f has zeros, the system of equations $A_n x = b$ will become very ill conditioned when n is large. Thus the usefulness of the solution x can be in doubt even though we can solve for it quickly using our preconditioners. In this case, one can employ the technique of regularization to alleviate the problem. One approach is to solve the appended least squares problem:

$$\min_x \left\| \begin{bmatrix} A_n \\ \mu P_n \end{bmatrix} x - \begin{bmatrix} b \\ 0 \end{bmatrix} \right\|_2 .$$

Here μ is the regularization parameter and the n-by-n matrix P_n is the regularization operator that tries to smooth the solution x to a certain degree. Choosing P_n as the $2k$th difference operator will force the solution to have a small $2k$th derivative. We note that the corresponding P_n will be a banded Hermitian matrix with half-bandwidth $k + 1$. Typical choices of P_n are the n-by-n identity matrix and the one-dimensional discrete Laplacian matrix. Choosing the regularization parameter μ, on the other hand, is usually not a trivial problem. One may need to solve the least squares problem for several values of μ to determine the best one; see Eldén [11].

The solution to the least squares problem can be obtained by solving the normal equation:

$$(A_n^2 + \mu^2 P_n^2)x = A_n b.$$

An obvious choice of preconditioners for the normal equation is the band matrix $B_{n,\ell}^2 + \mu^2 P_n^2$. Its half-bandwidth is $\max(2\ell - 1, 2k + 1)$. By using (1), we can easily show that

$$\kappa\left\{(B_{n,\ell}^2 + \mu^2 P_n^2)^{-1}(A_n^2 + \mu^2 P_n^2)\right\} \leq \left(\frac{1+h}{1-h}\right)^2.$$

In contrast, even if C_n is a good circulant preconditioner for A_n, the matrix $C_n^2 + \mu^2 P_n^2$ will no longer be circulant. However, we remark that regularization techniques using other circulant preconditioners have been considered in Chan, Nagy, and Plemmons [7].

6. Concluding remarks. By understanding the Toeplitz preconditioner from the point of view of minimax approximation of the corresponding generating functions, we can construct band-Toeplitz preconditioners that offer fast convergence rates even when the matrix to be preconditioned has a generating function with a zero. Moreover, our preconditioner with modest bandwidth is also an excellent choice for f without a zero. We emphasize that for a given f, the entries of the preconditioners are unchanged as n increases. Thus, we need to invoke the Remez algorithm once for each f. We note, moreover, that the Cholesky factors of $B_{n,\ell}$ can be used to build the Cholesky factors of $B_{n+1,\ell}$. That can reduce the cost of factorization of the band-Toeplitz preconditioner. Finally, we remark that our preconditioner can also be adapted easily to give a good preconditioner for Toeplitz-plus-band systems of the form $(A_n + D_n)x = b$, where D_n is an arbitrary band matrix. Toeplitz-plus-band systems appear in solving Fredholm integral-differential equations, see Delves and Mohamed [9, p. 343] and, in signal processing literature, see Carayannis, Kalouptsidis, and Manolakis [2].

For such systems, direct Toeplitz solvers and the preconditioned conjugate gradient method with circulant preconditioners will not work. However, one can use $B_{n,\ell} + D_n$ as a preconditioner and use the proof mentioned in Chan and Ng [6] to derive basically the same result that we have in Theorem 2.2, namely that

$$\kappa\left\{(B_{n,\ell} + D_n)^{-1}(A_n + D_n)\right\} \leq \frac{1+h}{1-h}.$$

Hence the number of iterations required for convergence is still fixed independent of the size of the matrices. Since $B_{n,\ell} + D_n$ is a band matrix, the system $(B_{n,\ell} + D_n)x = y$ can still be solved efficiently by band solvers for any vector y.

SOME REMARKS ON A MULTIGRID PRECONDITIONER*

JINCHAO XU† AND JINSHUI QIN†

Abstract. This paper is devoted to a class of multilevel preconditioners developed in [*Math Comp.*, 55 (1990), pp. 1–22] by Bramble, Pasciak, and Xu and in the Ph.D. thesis of Xu at Cornell University, Ithaca, NY, 1989. A simple proof is given for optimal estimation of the conditioning. A derivation of matrix representations and a description of efficient implementation techniques are also given. Some modified preconditioners are proposed combining the hierarchical basis method. Numerical examples are also given that compare various preconditioners discussed in this paper.

Key words. finite element, hierarchical basis, multigrid, preconditioner

1. Introduction.

We consider the following model boundary-value problem:

$$\begin{aligned} -\Delta U &= F \quad \text{in } \Omega, \\ U &= 0 \quad \text{on } \partial\Omega, \end{aligned} \tag{1.1}$$

where $\Omega \subset \mathbb{R}^d$ is a polyhedral domain.

Let $H^1(\Omega)$ be the standard Sobolev space consisting of square integrable functions with square integrable derivatives of first order and let $H_0^1(\Omega)$ be a subspace of $H^1(\Omega)$ consisting of functions that vanish on $\partial\Omega$ (in an appropriate sense). Clearly, $U \in H_0^1(\Omega)$ is the solution of

$$a(U, \chi) = (F, \chi) \quad \forall\, \chi \in H_0^1(\Omega), \tag{1.2}$$

where

$$(F, \chi) = \int_\Omega F\chi dx \quad \text{and} \quad a(U, \chi) = \int_\Omega \nabla U \cdot \nabla \chi dx. \tag{1.3}$$

We approximate the above problem by finite element discretizations on a quasi-uniform triangulation $\mathcal{T}$ of Ω. We assume that the triangulation $\mathcal{T}$ is constructed by a successive refinement process. That is, $\mathcal{T} = \mathcal{T}_j$ for some $j > 1$ and $\mathcal{T}_k$ for $k \leq j$ are a nested sequence of quasi-uniform triangulations, which consist of simplexes $\mathcal{T}_k = \{\tau_k^i\}$ of size h_k for $k = 1, \ldots, j$ such that $\Omega = \cup_i \tau_k^i$, where the quasi-uniformity constants are independent of k (cf. Ciarlet [6]). These triangulations should be nested in the sense that any simplex $\tau_{k-1}^i \in \mathcal{T}_{k-1}$ can be written as a union of some simplexes of $\{\tau_k^i\} \in \mathcal{T}_k$. We further assume that there is a constant $\eta > 1$, independent of k, such that h_k is proportional to η^{-k}. In the two-dimensional case, for example, the finer grid is obtained by connecting the midpoints of the edges of the triangles of the coarser grid with $\mathcal{T}_1$ being the initial triangulation.

Corresponding to each triangulation $\mathcal{T}_k$, a finite element space $\mathcal{M}_k$ is defined by

$$\mathcal{M}_k = \{v \in H_0^1(\Omega) : v|_\tau \in \mathcal{P}_1(\tau) \quad \forall\, \tau \in \mathcal{T}_k\},$$

where $\mathcal{P}_1$ is the space of linear polynomials. As a result, we have a nested sequence of subspaces as follows:

$$\mathcal{M}_1 \subset \mathcal{M}_2 \subset \cdots \subset \mathcal{M}_j.$$

*Received by the editors May 15, 1990; accepted for publication (in revised form) March 16, 1993. This work was supported in part by the National Science Foundation.

†Department of Mathematics, Pennsylvania State University, University Park, Pennsylvania 16802 (xu@math.psu.edu or qin@math.psu.edu).

We shall drop the subscript j and denote $\mathcal{M} = \mathcal{M}_j$ for the finest space.[1] The finite element discretization on the space $\mathcal{M}$ for (1.2) is finding a solution $u \in \mathcal{M}$ such that

$$a(u, v) = (F, v) \quad \forall\, v \in \mathcal{M}. \tag{1.4}$$

For each k, $\mathcal{M}_k$ has a natural nodal basis $\{\phi_i^k\}_{i=1}^{n_k}$ ($n_k = \dim \mathcal{M}_k$) that satisfies

$$\phi_i^k(x_l^k) = \delta_{il} \quad \forall\, i, l = 1, \ldots, n_k, \tag{1.5}$$

where $\{x_l^k : l = 1, \ldots, n_k\} \equiv \mathcal{N}_k$ is the set of all interior nodal points of the triangulation $\mathcal{T}_k$ on which $\mathcal{M}_k$ is defined. By means of the nodal basis functions on the finest $\mathcal{M}$, (1.4) is reduced to the following algebraic system:

$$A\alpha = b, \tag{1.6}$$

where

$$A = ((\nabla\phi_i, \nabla\phi_l))_{n\times n},\ \alpha = (\alpha_i)_{i=1}^n \quad \text{and} \quad b = ((F, \phi_i))_{i=1}^n \tag{1.7}$$

(with $n = n_j$), and A is often called the stiffness matrix, which is symmetric and positive definite.

It is well known that the condition number of A is $O(h^{-2})$, and hence (1.6) is an ill-conditioned system. Thus preconditioners (used with the preconditioned conjugate gradient method) are often constructed for its solution. What we shall study in this paper is a class of multilevel preconditioners (in the form of functional operators) proposed in [2] and [10].

Since the publication of [2], [10], there are a number of works devoted to the improvements of the estimate of the conditioning. One improvement was made by Zhang [14]. The optimal estimate was first proved by Oswald [9] using Besov space technique. Alternative proofs of the optimal estimate have been given recently by Bramble and Pasciak [1], Bornemann and Yserentant [3], and Xu [11]. In this paper, we shall present a simple proof for such an estimate.

The preconditioners in [2], [10] were presented in terms of functional operators. In this paper we shall show that their matrix representations can be written as follows:

$$B = \sum_{k=1}^{j} h_k^{2-d} T_k T_k^t, \tag{1.8}$$

where h_k is the meshsize of $\mathcal{T}_k$ and $T_k \in \mathbb{R}^{n\times n_k}$ is the representation matrix of the nodal basis $\{\phi_i^k\}$ for $\mathcal{M}_k$ in terms of the nodal basis $\{\phi_i\}$ for $\mathcal{M}$ (for $k \le j$ since $\mathcal{M}_k \subset \mathcal{M}$). More precisely,

$$\Phi_k = \Phi T_k,$$

where

$$\Phi_k = (\phi_1^k, \ldots, \phi_{n_k}^k), \qquad \Phi = (\phi_1, \ldots, \phi_n). \tag{1.9}$$

The preconditioner B given by (1.8) depends entirely on the transformation matrices between the nodal bases in different levels. For this reason we shall call this preconditioner *the multilevel nodal basis* preconditioner.

[1] Throughout this paper, if a subscript or superscript is j, it will often be dropped from the notation without further explanation.

The simple algebraic structure of (1.8) makes it easy to implement the preconditioner that is the basis for a very simple and efficient implementation technique for the preconditioner presented in this paper.

Another purpose of this paper is to introduce some modified preconditioners. The first example will be a Gauss–Seidel version of (1.8) as follows:

$$B = \sum_{k=1}^{j} T_k G_k T_k^t, \tag{1.10}$$

where G_k is the symmetric Gauss–Seidel iterative matrix obtained from the stiffness matrix on $\mathcal{M}_k$, namely, $A_k = ((\nabla\phi_i^k, \nabla\phi_l^k))_{n_k \times n_k}$. Numerical experiments show that this preconditioner results in a much smaller condition number than (1.8).

Another modified preconditioner we propose is related to an algorithm developed by Yserentant [12] that is often called the hierarchical basis preconditioner. The hierarchical basis preconditioner is quite similar to (1.8) and, in fact, can be derived from (1.8) by eliminating certain n_{k-1} columns from each T_k. Based on such an observation, the hierarchical basis preconditioner can be slightly modified to improve its efficiency. The implementation techniques for (1.8) can also be applied directly to hierarchical basis preconditioner and its modified version.

For convenience of exposition, we shall use MNB (*multilevel nodal basis*) or GS-MNB for the preconditioner (1.8) or (1.10), and HB for the hierarchical basis preconditioner.

The outline of the remainder of the paper is as follows. In the next section, the preconditioner proposed in [2], [10] is reviewed; §3 contains the derivation of expression (1.8); §4 is devoted to the implementation of the algorithms; and §5 discusses the hierarchical basis preconditioner, some variants of (1.8), and a few numerical examples that compare the performances of different algorithms.

2. Multilevel preconditioners and optimal conditioning estimates. In this section, we shall give a brief description of the multilevel preconditioners to be studied in this paper and then present a proof on their conditioning. Even though the theory holds in more general cases, the focus in this paper is only on its applications to finite element equations with quasi-uniform triangulations.

We first need to introduce some linear operators on the finite element functional spaces. For distinction, we will use boldface letters to denote these operators. In contrast, notation for matrices is not boldface unless otherwise specified.

With respect to the L^2 inner product $(\cdot, \cdot)$ (given by (1.3)), for each k we define operators $\boldsymbol{A}_k : \mathcal{M}_k \mapsto \mathcal{M}_k$ and $\boldsymbol{Q}_k : \mathcal{M} \mapsto \mathcal{M}_k$ by

$$(\boldsymbol{A}_k u, v) = a(u, v), \quad (\boldsymbol{Q}_k u, v) = (u, v), \quad u \in \mathcal{M}, v \in \mathcal{M}_k. \tag{2.1}$$

The operator $\boldsymbol{A}_k$(which is symmetric positive definite) may be regarded as a discretization of the elliptic operator $-\Delta$ on $\mathcal{M}_k$ and $\boldsymbol{Q}_k$ is the standard orthogonal L^2 projection.

Again we denote $\boldsymbol{A} = \boldsymbol{A}_j$. By definition, problem (1.4) is equivalent to

$$\boldsymbol{A}u = f$$

for some appropriate $f \in \mathcal{M}$. One of the preconditioners for $\boldsymbol{A}$ proposed in [2], [10] is given by

$$\boldsymbol{B}v = \sum_{k=1}^{j} h_k^{2-d} \sum_{i=1}^{n_k} (v, \phi_i^k)\phi_i^k, \qquad v \in \mathcal{M}. \tag{2.2}$$

It is easy to see that $\boldsymbol{B}$ is symmetric positive definite with respect to L^2 inner product.

The effectiveness of the preconditioner $\boldsymbol{B}$ is measured by the condition number of $\boldsymbol{BA}$, denoted by $\kappa(\boldsymbol{BA})$, which is the ratio of its maximum eigenvalue to the minimum one. We have the following theorem.

THEOREM 2.1. *There exists a constant C independent of k or j such that*

$$\kappa(\boldsymbol{BA}) \leq C.$$

The constant C appearing in the estimate in Theorem 2.1 behaves like $O(h_1^{-2})$, where h_1 is the size of triangulation $\mathcal{T}_1$. This is usually not a problem since h_1 is often of unit size in practical computations. Nevertheless, if h_1 is considerably small, the preconditioner can be modified by solving the problem on $\mathcal{M}_1$ exactly:

$$\boldsymbol{B}v = \boldsymbol{A}_1^{-1}\boldsymbol{Q}_1 + \sum_{k=2}^{j} h_k^{2-d} \sum_{i=1}^{n_k} (v, \phi_i^k)\phi_i^k \tag{2.3}$$

for which the relative condition number is independent of h_1 (cf. [10]).

A slightly more general preconditioner is also given in [2]:

$$\boldsymbol{B}_R = \sum_{k=1}^{j} \boldsymbol{R}_k \boldsymbol{Q}_k, \tag{2.4}$$

where $\boldsymbol{R}_k : \mathcal{M}_k \mapsto \mathcal{M}_k$ are symmetric positive definite operators satisfying

$$c_0 \lambda_k^{-1} \|v\|^2 \leq (\boldsymbol{R}_k v, v) \leq c_1 \lambda_k^{-1} \|v\|^2 \quad \forall\, v \in \mathcal{M}_k,$$

where $\|\cdot\|^2 = (\cdot, \cdot)$. It can be shown that Theorem 2.1 also holds for (2.4).

Using the techniques in [2], [10], the proof of Theorem 2.1 follows directly from the following.[2]

PROPOSITION 2.2. *There exist positive constants c_0 and c_1 such that*

$$c_0 \|v\|^2_{H^1(\Omega)} \leq \sum_{k=1}^{\infty} \|(\boldsymbol{Q}_k - \boldsymbol{Q}_{k-1})v\|^2_{H^1(\Omega)} \leq c_1 \|v\|^2_{H^1(\Omega)} \quad \forall\, v \in H_0^1(\Omega).$$

The above proposition can be derived from Oswald [9] and we shall present a new proof of this result in the rest of this section.

The proof to be presented can also be found in Xu [11] and the idea is similar to a proof in Bramble and Pasciak [1]. The main ingredient in our analysis is the fractional Sobolev space.

The fractional Sobolev space $H_0^{m+\sigma}(\Omega)$ ($m = 0, 1$ and $0 < \sigma < 1$) is defined by the completion of $C_0^\infty(\Omega)$ in the following norm:

$$\|v\|_{H^{m+\sigma}(\Omega)} = \left(\|v\|^2_{H^m(\Omega)} + |v|^2_{H^{m+\sigma}(\Omega)}\right)^{1/2},$$

where

$$|v|^2_{H^{m+\sigma}(\Omega)} = \sum_{|\alpha|=m} \int_\Omega \int_\Omega \frac{|D^\alpha v(x) - D^\alpha v(y)|^2}{|x - y|^{d+2\sigma}} dx\, dy.$$

[2]Here we assume there are infinitely many number of levels of nested triangulations. The result is more general than the case of finite number of levels.

For $\alpha \in (0, 1]$, we define $H^{-\alpha}(\Omega) = (H_0^{\alpha}(\Omega))^*$, the dual of $H_0^{\alpha}(\Omega)$.

The following inverse inequalities (cf. [4], [10]) hold:

$$\|v\|_{H^{1+\sigma}(\Omega)} \lesssim h_k^{-\sigma}\|v\|_{H^1(\Omega)}, \qquad \|v\|_{H^s(\Omega)} \lesssim h_k^{-s}\|v\| \quad \forall\, v \in \mathcal{M}_k, \tag{2.5}$$

where $\sigma \in (0, \frac{1}{2})$ and $s \in [0, 1]$.

Let $\boldsymbol{P}_k : H_0^1(\Omega) \mapsto \mathcal{M}_k$ be the H^1 projection defined by

$$(\nabla \boldsymbol{P}_k u, \nabla v_k) = (\nabla u, \nabla v_k) \quad \forall\, u \in H_0^1(\Omega),\, v_k \in \mathcal{M}_k.$$

It follows from the standard finite element approximation theory that

$$\|v - \boldsymbol{P}_k v\|_{H^{1-\alpha}(\Omega)} \lesssim h_k^{\alpha}\|v\|_{H^1(\Omega)} \quad \forall\, v \in H_0^1(\Omega) \tag{2.6}$$

for some constant $\alpha \in (0, 1]$ (depending on the domain Ω).

It is well known that (cf. Bramble and Xu [5])

$$\|v - \boldsymbol{Q}_k v\| + h_k\|\boldsymbol{Q}_k v\|_{H^1(\Omega)} \lesssim h_k\|v\|_{H^1(\Omega)} \quad \forall\, v \in H_0^1(\Omega). \tag{2.7}$$

By interpolation, we have (for $\sigma \in (0, 1)$, $\sigma \neq \frac{1}{2}$)

$$\|\boldsymbol{Q}_k v\|_{H^{\sigma}(\Omega)} \lesssim \|v\|_{H^{\sigma}(\Omega)} \quad \forall\, v \in H_0^1(\Omega). \tag{2.8}$$

The first ingredient in our proof is the so-called strengthened Cauchy inequality. This result is similar to the corresponding result by Yserentant [12] for his hierarchical basis preconditioner. A constructive proof of this inequality may be found in Xu [11], and the proof presented here is a modification of a proof of Bramble and Pasciak [1].

LEMMA 2.3. *There is a constant $\gamma \in (0, 1)$ and a positive constant C such that*

$$(\nabla u_i, \nabla v_j) \le C\gamma^{|i-j|}\|\nabla u_i\|\,\|\nabla v_j\| \quad \forall\, u, v \in H_0^1(\Omega),\, i, j \ge 1,$$

where $u_i = (\boldsymbol{Q}_i - \boldsymbol{Q}_{i-1})u$ and $v_j = (\boldsymbol{Q}_j - \boldsymbol{Q}_{j-1})v$.

Proof. Let $D_i = \partial/\partial x_i$. Obviously $D_i : H_0^1(\Omega) \mapsto L^2(\Omega)$ is continuous, and by duality, so is $D_i : L^2(\Omega) \mapsto H^{-1}(\Omega)$. By interpolation, for $\alpha \in (0, \frac{1}{2})$, $D_i : H^{1-\alpha}(\Omega) \mapsto H^{-\alpha}(\Omega)$ is also continuous. Consequently, $\|\nabla v\|_{H^{-\alpha}(\Omega)} \lesssim \|v\|_{H^{1-\alpha}(\Omega)}$, for $v \in H_0^1(\Omega)$. Therefore (without loss of generality, we assume that $j \ge i$),

$$(\nabla u_i, \nabla v_j) \lesssim \|\nabla u_i\|_{H^{\alpha}(\Omega)}\|\nabla v_j\|_{H^{-\alpha}(\Omega)} \lesssim \|u_i\|_{H^{1+\alpha}(\Omega)}\|v_j\|_{H^{1-\alpha}(\Omega)}.$$

It follows from the inverse inequality (2.5) that

$$(\nabla u_i, \nabla v_j) \lesssim h_i^{-\alpha}\|u_i\|_{H^1(\Omega)}h_j^{-(1-\alpha)}\|v_j\| \lesssim (\eta^{\alpha})^{j-i}h_j^{-1}\|u_i\|_{H^1(\Omega)}\|v_j\|.$$

An application of (2.7) then completes the proof with $\gamma = \eta^{\alpha}$. □

We are now in a position to present the proof for Proposition 2.2.

Denote $\tilde{\boldsymbol{Q}}_k = \boldsymbol{Q}_k - \boldsymbol{Q}_{k-1}$ and $v_i = (\boldsymbol{P}_i - \boldsymbol{P}_{i-1})v$. It follows from (2.5), (2.8), and (2.6) that

$$\|\tilde{\boldsymbol{Q}}_k v_i\|_{H^1(\Omega)}^2 \lesssim \lambda_k^{\alpha}\|\tilde{\boldsymbol{Q}}_k v_i\|_{H^{1-\alpha}(\Omega)}^2 \lesssim \lambda_k^{\alpha}\|v_i\|_{H^{1-\alpha}(\Omega)}^2 \lesssim \lambda_k^{\alpha}h_i^{2\alpha}\|v_i\|_{H^1(\Omega)}^2.$$

Let $i \wedge j = \min(i, j)$; we have

$$\begin{aligned}
&\sum_{k=1}^{\infty} \|(\boldsymbol{Q}_k - \boldsymbol{Q}_{k-1})v\|^2_{H^1(\Omega)} \\
&\quad \le c_1 \|v\|^2_{H^1(\Omega)} \\
&\quad = \sum_{k=1}^{\infty} \sum_{i,j=k}^{\infty} (\nabla \tilde{\boldsymbol{Q}}_k v_i, \nabla \tilde{\boldsymbol{Q}}_k v_j) \\
&\quad \lesssim \sum_{i,j=1}^{\infty} \sum_{k=1}^{i\wedge j} (\nabla \tilde{\boldsymbol{Q}}_k v_i, \nabla \tilde{\boldsymbol{Q}}_k v_j) \\
&\quad \lesssim \sum_{i,j=1}^{\infty} \sum_{k=1}^{i\wedge j} \lambda_k^{\alpha} h_i^{\alpha} h_j^{\alpha} \|v_i\|_{H^1(\Omega)} \|v_j\|_{H^1(\Omega)} \\
&\quad \lesssim \sum_{i,j=1}^{\infty} \lambda_{i\wedge j}^{\alpha} h_i^{\alpha} h_j^{\alpha} \|v_i\|_{H^1(\Omega)} \|v_j\|_{H^1(\Omega)} \\
&\quad \lesssim \sum_{i,j=1}^{\infty} \gamma^{\alpha|i-j|} \|v_i\|_{H^1(\Omega)} \|v_j\|_{H^1(\Omega)} \\
&\quad \lesssim \sum_{i=1}^{\infty} \|v_i\|^2_{H^1(\Omega)}.
\end{aligned}$$

On the other hand, by the strengthened Cauchy inequality

$$\begin{aligned}
\|v\|^2_{H^1(\Omega)} &= \sum_{i,j=1}^{\infty} (\nabla \tilde{\boldsymbol{Q}}_i v, \nabla \tilde{\boldsymbol{Q}}_j v) \\
&\lesssim \sum_{i,j=1}^{\infty} \gamma^{|i-j|} \|\tilde{\boldsymbol{Q}}_i v\|_{H^1(\Omega)} \|\tilde{\boldsymbol{Q}}_j v\|_{H^1(\Omega)} \\
&\lesssim \sum_{i=1}^{\infty} \|\tilde{\boldsymbol{Q}}_i v\|^2_{H^1(\Omega)}.
\end{aligned}$$

This completes the proof of Proposition 2.2.

3. Preconditioners in terms of matrices. The preconditioners in the form of (2.2) are convenient for theoretical analysis. But for numerical implementation, a matrix form is more desirable. In this section, we shall derive the corresponding preconditioning matrix that can be applied directly to the system (1.6). For a more systematic approach, we refer to Xu [11].

In this section, we shall use $(\cdot, \cdot)$ for the usual L^2 product and $\langle \cdot, \cdot \rangle$ for the usual Euclidean inner product of vectors in any Euclidean spaces.

To relate the functional operator to matrix, for a given operator $\boldsymbol{R} : \mathcal{M} \mapsto \mathcal{M}$, let $\boldsymbol{R}_m$ be the $n \times n$ matrix [3] representation of $\boldsymbol{R}$ satisfying

$$\langle \boldsymbol{R}_m \mu, \nu \rangle = (\boldsymbol{R} u, v), \qquad u, v \in \mathcal{M},$$

[3] Please note an abuse of notation here; a boldface with subscript m, e.g., $\boldsymbol{R}_m$, denotes a matrix.

where $\mu = (\mu_i) = (u(x_i^j)) \in \mathbb{R}^n$ and $v = (v_i) = (v(x_i^j)) \in \mathbb{R}^n$. $\boldsymbol{R}_m$ may be called the matrix representation of the operator $\boldsymbol{R}$.

The above definition of the matrix representation is a little different from the usual definition for a matrix corresponding to a linear operator on a linear vector space. The advantage of this definition can be seen from the following lemma.

LEMMA 3.1. *The matrix representation of A (defined by (2.1) for $k = j$) is just the usual stiffness matrix A given by* (1.7).

The proof of the above lemma is straightforward by definition. The unusual property of our matrix representation of operators is that the product of two operators does not quite correspond to the product of their matrices.

LEMMA 3.2. *For any two operators $\boldsymbol{R}, \boldsymbol{S}$ on $\mathcal{M}$,*

$$(\boldsymbol{R} + \boldsymbol{S})_m = \boldsymbol{R}_m + \boldsymbol{S}_m, \qquad (\boldsymbol{RS})_m = \boldsymbol{R}_m M^{-1} \boldsymbol{S}_m$$

with M being the mass matrix (which is symmetric positive definite) given by

$$M = ((\phi_i, \phi_l))_{n\times n}. \tag{3.1}$$

Proof. The first identity is obvious by definition. To see the second one, for any $u, v \in \mathcal{M}$, we introduce a mapping $E : \mathbb{R}^n \mapsto \mathcal{M}$ defined by

$$E\mu = \sum \mu_i \phi_i.$$

Thus $u = E\mu$ if $\mu_i = u(x_i)$ and $v = Ev$ if $v_i = v(x_i)$. Let $E^* : \mathcal{M} \mapsto \mathbb{R}^n$ be the adjoint of E, namely,

$$\langle E^* u, v\rangle = (u, Ev).$$

Obviously, both E^* and E are isomorphisms. By definition, one can easily check that

$$\boldsymbol{R}_m = E^* \boldsymbol{R} E, \qquad E^* E = M.$$

Consequently,

$$(\boldsymbol{RS})_m = E^* \boldsymbol{R} S E = E^* \boldsymbol{R} E (E^* E)^{-1} E^* S E = \boldsymbol{R}_m M^{-1} \boldsymbol{S}_m.$$

This proves the second identity. □

In order to see what $\boldsymbol{B}_m$ is, by Lemma 3.2, it suffices to obtain $(\boldsymbol{B}_k)_m$ for each k, where

$$\boldsymbol{B}_k v = \sum_{i=1}^{n_k} (v, \phi_i^k)\phi_i^k, \qquad v \in \mathcal{M}. \tag{3.2}$$

To do this, taking $u, v \in \mathcal{M}$, we have

$$(\boldsymbol{B}_k u, v) = \sum_{i=1}^{n_k} (u, \phi_i^k)(v, \phi_i^k) = \langle \alpha, \beta\rangle, \tag{3.3}$$

where $\alpha = ((u, \phi_1^k), \ldots, (u, \phi_{n_k}^k))^t$ and $\beta = ((v, \phi_1^k), \ldots, (v, \phi_{n_k}^k))^t$.

Note that, with Φ_k and Φ given by (1.9), $u = \Phi\mu$ and $\Phi_k = \Phi T_k$. Hence

$$\begin{aligned}\alpha &= \int_\Omega u \Phi_k^t dx = \int_\Omega \Phi \mu T_k^t \Phi^t dx \\ &= \int_\Omega T_k^t (\Phi^t \Phi)\mu dx = T_k^t \left(\int_\Omega \Phi^t \Phi dx\right)\mu.\end{aligned}$$

Observing that $\int_\Omega \Phi^t \Phi dx$ is exactly the mass matrix M defined by (3.1), we then get

$$\alpha = T_k^t M \mu$$

and, similarly, $\beta = T_k^t M \nu$. Combining these identities with (3.3) yields

$$\begin{aligned}(\boldsymbol{B}_k u, v) &= \langle T_k^t M\mu, T_k^t M\nu\rangle \\ &= \langle M T_k T_k^t M\mu, \nu\rangle,\end{aligned}$$

which means that

$$(\boldsymbol{B}_k)_m = M T_k T_k^t M.$$

Therefore, by (2.2), (3.2), and Lemma 3.2,

$$\boldsymbol{B}_m = \sum_{k=1}^{j} h_k^{2-d} (\boldsymbol{B}_k)_m = MBM, \tag{3.4}$$

where

$$B = \sum_{k=1}^{j} h_k^{2-d} T_k T_k^t. \tag{3.5}$$

Let λ_0 and λ_1 be the minimum and maximum eigenvalue of $\boldsymbol{BA}$, respectively,

$$\lambda_0(\boldsymbol{A}v, v) \le (\boldsymbol{BA}v, v) \le \lambda_1(\boldsymbol{A}v, v) \quad \forall\, v \in \mathcal{M}.$$

By the definition of the matrix representation

$$\lambda_0\langle \boldsymbol{A}_m \nu, \nu\rangle \le \langle (\boldsymbol{BA})_m \nu, \nu\rangle \le \lambda_1 \langle \boldsymbol{A}_m \nu, \nu\rangle \quad \forall\, \nu \in \mathbb{R}^n.$$

The above expression involves the matrix representation of a product of operators. By Lemma 3.2,

$$(\boldsymbol{BA})_m = \boldsymbol{A}_m M^{-1} \boldsymbol{B}_m M^{-1} \boldsymbol{A}_m.$$

Applying Lemma 3.1 then yields

$$(\boldsymbol{BA})_m = ABA,$$

where B is given by (3.5). Hence

$$\lambda_0\langle A\nu, \nu\rangle \le \langle BA\nu, \nu\rangle \le \lambda_1 \langle A\nu, \nu\rangle \quad \forall\, \nu \in \mathbb{R}^n.$$

Consequently,

$$\kappa(BA) = \kappa(\boldsymbol{BA}).$$

In summary, we have the following theorem.

THEOREM 3.3. *The matrix B given by* (3.5) *is a preconditioner of the stiffness matrix A such that*

$$\kappa(BA) \le C.$$

Corresponding to (2.3), we can have the following more refined preconditioner:

$$B = T_1 A_1^{-1} T_1^t + \sum_{k=2}^{j} h_k^{2-d} T_k T_k^t.$$

More generally, A_1^{-1} may be replaced by a preconditioner of A_1.

4. On the implementation. In this section, we shall discuss some techniques for the implementation of the preconditioner B given by (3.5).

As the preconditioner is applied with the preconditioned conjugate gradient method, it suffices to consider the computation of, for $\alpha \in \mathbb{R}^n$, $B\alpha$ and $\langle B\alpha, \alpha\rangle$ as follows:

$$B\alpha = \sum_{k=1}^{j} h_k^{2-d} T_k T_k^t \alpha, \qquad \langle B\alpha, \alpha\rangle = \sum_{k=1}^{j} h_k^{2-d} \langle T_k^t \alpha, T_k^t \alpha\rangle. \tag{4.1}$$

The implementation of the above computations was also discussed in the earlier paper [2]. But the current version of the algorithm allows us to discuss this issue in a more straightforward way. If, for $k \le l$, T_k^l denotes the matrix that transforms the nodal basis of $\mathcal{M}_k$ to the nodal basis of $\mathcal{M}_l$, the following relation is then obvious by definition:

$$T_l^l = I, \qquad T_k^l = T_{l-1}^l T_k^{l-1}, k < l.$$

Let, for $1 \le l \le j$,

$$B_l = \sum_{k=1}^{l} h_k^{2-d} T_k^l (T_k^l)^t.$$

By definition $B = B_j$ and

$$B_l = h_l^{2-d} I + T_{l-1}^l B_{l-1} (T_{l-1}^l)^t.$$

We shall use the above recurrence relation to compute the action of B. Assume that m_l is the number of operations that are needed to compute the action $B_l\alpha_l$ for $\alpha_l \in \mathbb{R}^{n_l}$. By the identity

$$B_l\alpha_l = h_l^{2-d}\alpha_l + T_{l-1}^l [B_{l-1}(T_{l-1}^l)^t \alpha_l],$$

we get, for some constant $c_0 > 0$,

$$m_l \le m_{l-1} + c_0 n_l$$

from which we conclude that

$$m_j \le m_1 + c_0 \sum_{l=2}^{j} n_l \le c_1 n$$

for some positive constant c_1. This means that the action of B_j can be carried out within $O(n)$ operations.

In summary, we have the following algorithm.

AN ALGORITHM FOR COMPUTING $B\alpha$ AND $\langle B\alpha, \alpha\rangle$

$\alpha_j = \alpha$; $c = h_j^{2-d}\langle \alpha, \alpha\rangle$;
for $l = j - 1 : 1$,
  $\alpha_l = T_l^{l+1}\alpha_{l+1}$; $c = c + h_l^{2-d}\langle \alpha_l, \alpha_l\rangle$;
end
$\langle B\alpha, \alpha\rangle = c$;
$\beta_1 = \alpha_1$;
for $l = 2 : j$,
  $\beta_l = h_l^{2-d}\alpha_l + T_{l-1}^l \beta_{l-1}$;
end
$B\alpha = \beta_j$.

As discussed above, the number of operations needed in the above algorithm is $O(n)$. We also note that all the vectors α_l for $1 \le l \le j$ need to be stored, but the whole storage space for these vectors is also only $O(n)$.

5. Other variants and numerical examples. In this section, we shall discuss several other methods that are related to our main algorithm. We shall first present a preconditioner by means of Gauss–Seidel iteration. We shall then have a look at the relationship between the preconditioner (1.8) and the hierarchical basis preconditioner. By comparing these two methods, a modified preconditioner will be proposed. Finally, some numerical examples will be presented.

5.1. Gauss–Seidel-type algorithms. By the more general version of the multigrid preconditioner (2.4), $\boldsymbol{R}_k$ are operators that are free to choose. Choosing $\boldsymbol{R}_k = h_k^2 \boldsymbol{I}$ that is related to the damped Jacobi iteration, we get the preconditioner and hence (3.5). It is well known that the Gauss–Seidel iteration often has better performance than the Jacobi method. In our case, a Gauss–Seidel algorithm can be obtained by choosing $\boldsymbol{R}_k$ from the symmetric Gauss–Seidel iteration as follows:

$$B_g = \sum_{k=1}^{j} T_k G_k T_k^t,$$

where $G_k = (D_k + U_k)^{-1} D_k (D_k + L_k)^{-1}$ from the decomposition of the stiffness matrix $A_k = D_k + L_k + U_k$ with D_k being the diagonal, L_k the lower triangle, and U_k the upper triangle of A_k.

By comparing their asymptotical theoretical estimates, B_g is spectrally equivalent to the B in (1.8). However, our numerical experiments seem to indicate that B_g results in much smaller condition numbers.

5.2. Hierarchical basis preconditioner. Since the hierarchical basis preconditioner only works well for one- or two-dimensional problems (cf. [8], [11]), the following discussion is then confined in a two-dimensional problem. The so-called hierarchical functions are defined in $\mathcal{M}_1$ by the nodal basis of $\mathcal{M}_1$ and in $\mathcal{M}_k$, for $k = 2, \ldots, j$, by the hierarchical basis functions of $\mathcal{M}_{k-1}$, together with those nodal basis functions $\{\phi_i^k\}$ of $\mathcal{M}_k$ that correspond to the nodes in $\mathcal{N}_k \setminus \mathcal{N}_{k-1}$. It is easy to see that the set of all the hierarchical basis functions on $\mathcal{M}$ indeed form a basis for $\mathcal{M}$.

Let $S \in \mathbb{R}^{n \times n}$ be the matrix that transforms the nodal basis into hierarchical basis, namely,

$$\Psi = \Phi S,$$

where Ψ is an n row vector whose components are hierarchical basis functions and Φ is an n row vector whose components are nodal basis functions. In terms of S, the hierarchical basis preconditioner [12] can be represented by

$$H = SS^t.$$

Following [12] and [10], we let $S_k \in \mathbb{R}^{n \times (n_k - n_{k-1})}$ be the matrix that represents the part of hierarchical basis on $\mathcal{M}_k$ in terms of nodal basis in $\mathcal{M}$, then we have $S = (S_1, \ldots, S_j)$ and

$$H = \sum_{k=1}^{j} S_k S_k^t. \tag{5.1}$$

Notice that S_k is a submatrix of T_k; hence we have

$$\langle H\alpha, \alpha \rangle \leq \langle B\alpha, \alpha \rangle \quad \forall\, \alpha \in \mathbb{R}^n. \tag{5.2}$$

A more detailed discussion of the relationship between the MNB preconditioner and the HB preconditioner can be found in Xu [10], [11] and in Yserentant [13]. We note that the

action of H is slightly easier to compute than that of B, but, from the theoretical estimates as well as numerical experiments, B is much better than H as far as the resulting condition numbers are concerned. We would also like to mention that in three-dimensional or higher cases, the HB preconditioner deteriorates (cf. Ong [8]), but the MNB preconditioner does not.

5.3. A modified preconditioner. In view of the inequality (5.2), we introduce the following modified preconditioner:

$$\hat{H} = \sum_{k=1}^{j-1} S_k S_k^t + I. \tag{5.3}$$

It is trivial to see that

$$\langle H\alpha, \alpha\rangle \leq \langle \hat{H}\alpha, \alpha\rangle \leq \langle B\alpha, \alpha\rangle \quad \forall\, \alpha \in \mathbb{R}^n.$$

The preconditioner in (5.3) is obtained by a very slight change from the HB preconditioner, but as we shall see from the numerical experiments, it is much better than the HB preconditioner and sometimes even better than the MNB preconditioner. Notice that, in terms of computational complexity, $\hat{H}$ is quite close to H. For convenience, we use MHB to stand for the modified hierarchical basis preconditioner.

5.4. Some numerical examples. In this subsection, we shall report some numerical experiments that compare the performances of the various preconditioners discussed above.

Our numerical examples will be for the problem (1.1) with piecewise linear finite element discretizations as described in §1. The equation we need to solve is (1.6).

For a given preconditioner B of A, to solve (1.6), we consider the equivalent system of (1.6):

$$BAx = Bb.$$

The conjugate gradient method may be applied to the above system and the resultant algorithm is a preconditioned conjugate gradient method. The effectiveness of the preconditioned conjugate gradient algorithm is measured by the condition number of the preconditioned matrix:

$$\kappa(BA) = \frac{\lambda_{\max}(BA)}{\lambda_{\min}(BA)},$$

where B is any preconditioner mentioned above and $\lambda_{\max}(BA)$ and $\lambda_{\min}(BA)$ are the maximum and minimum eigenvalue of BA, respectively. These eigenvalues are calculated by the standard power method and inverse power method. In the inverse power method, the corresponding systems can be solved effectively by the conjugate gradient method since BA is a well-conditioned matrix.

We have tested the MNB, HB, and MHB preconditioners on three different domains: (a) unit square; (b) slit domain; (c) irregular polygon. All the multilevel triangulations will be determined by the first triangulation $\mathcal{T}_1$ as all the other triangulations will be obtained by connecting the midpoints of the edges of the triangles from the previous coarse mesh. The first triangulations for different domains are shown in Fig. 1 (with broken lines).

The numerical results are shown in Figs. 2–4 for square, slit, and irregular polygon domains, respectively. The correspondences between pictures with different preconditioners are as follows:

$$\kappa(HA) : -\cdot-\cdot-, \quad \kappa(\hat{H}A) : \text{———}, \quad \kappa(BA) : - - --, \quad \kappa(B_gA) : \cdots\cdots.$$

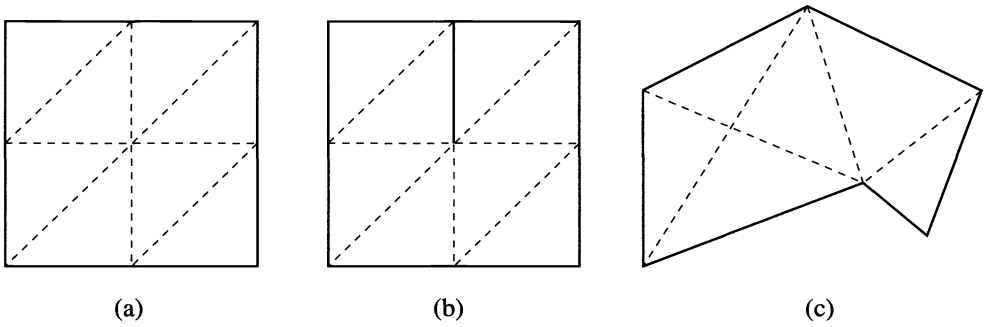

FIG. 1. *Three different test regions.*

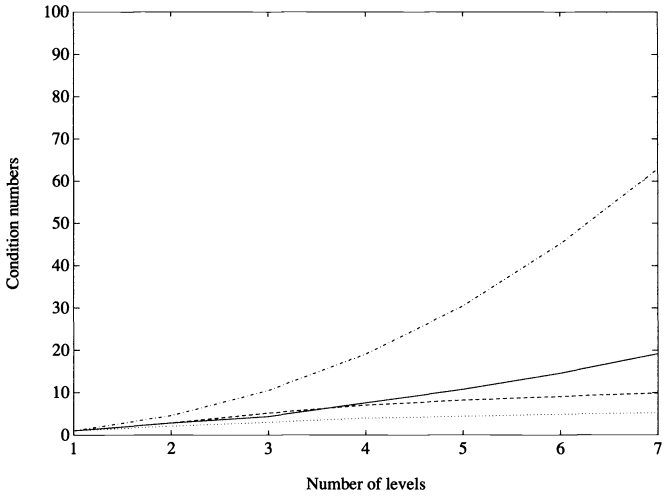

FIG. 2. *Square domain.*

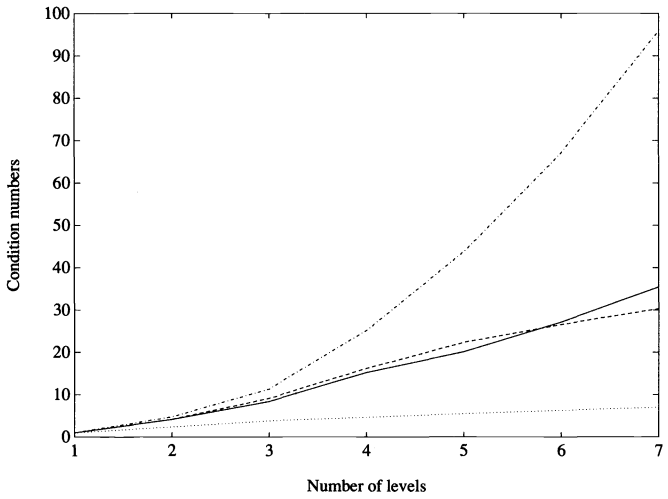

FIG. 3. *Slit domain.*

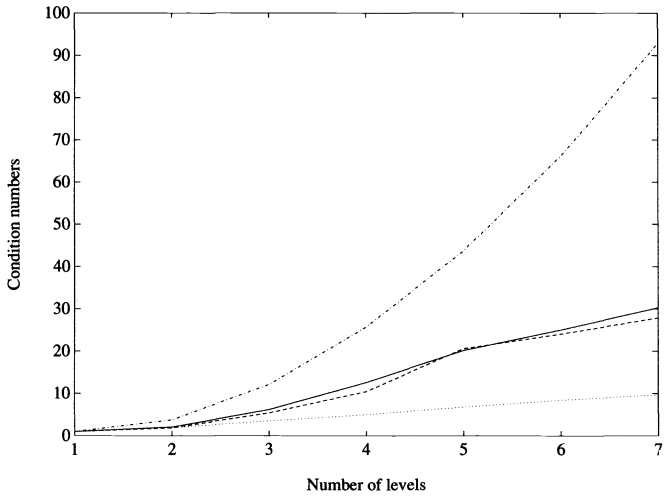

FIG. 4. *Irregular polygon.*

As shown by the pictures, MNB, GS-MNB, and MHB preconditioners result in much smaller condition numbers than the HB preconditioner, and GS-MNB gives the smallest condition number. It is most interesting to compare MHB with HB and MNB. In terms of computational complexity, the difference between MHB and HB is negligible, but the resultant condition numbers differ considerably. Note also that the behaviors of $\kappa(\hat{H}A)$ and $\kappa(BA)$ are quite close.

FAST ADAPTIVE METHODS FOR THE FREE-SPACE HEAT EQUATION*

JOHN STRAIN†

Abstract. Standard numerical methods for the heat equation in two or more space dimensions are excellent if it is necessary to follow the evolution in great detail through many small timesteps. This paper presents efficient and accurate new adaptive methods that solve the free-space heat equation with *large* timesteps. These methods combine the fast Gauss transform with an adaptive refinement scheme that represents the solution as a continuous piecewise polynomial, to a user-specified degree of accuracy. The same approach is extended to solve inhomogeneous problems and to solve the heat equation in moving domains with boundaries. In problems with boundaries, it allows the use of accurate boundary representations without requiring difficult product integration formulas or precluding fast evaluation schemes. Numerical experiments in two space dimensions show these methods to be accurate and efficient, especially for highly nonuniform or discontinuous initial data or when substantial accuracy is required.

Key words. heat equation, heat potentials, fast algorithms, adaptive methods, crystal growth

1. Introduction.

It is often necessary to solve the free-space heat equation

$$\begin{aligned} u_t &= \Delta u \quad \text{in} \quad \mathbf{R}^2 \\ u &= f \quad \text{at} \quad t = 0 \end{aligned} \tag{1}$$

with a difficult initial temperature field f: We suppose that f vanishes at infinity, is globally Lipschitz but not necessarily C^1, and varies rapidly over only a small portion of its support. One needs values of u at arbitrary points, not on a regular grid.

In this paper, we present efficient and accurate new numerical methods for solving this problem. These methods are *accurate* in the sense that the user can specify a precision ϵ, and the solution is then produced within error ϵ (relative to $|u|_\infty$). The work required increases as ϵ decreases, as it must, but these methods are *efficient* in the sense that they attempt to represent u with as few degrees of freedom as possible, adapting those degrees of freedom to fit u. These methods are efficient in another sense as well; the work required to go from $u(x, t)$ to $u(x, t + \Delta t)$ is proportional to the number of degrees of freedom required and *decreases* as Δt increases. (For explicit numerical methods, the work required *increases* as Δt increases, and for implicit methods, it is superlinear in the number of degrees of freedom.)

Our methods are based on the exact evolution formula

$$u(x, t + \Delta t) = \frac{1}{\pi \delta} \int_{\mathbf{R}^2} e^{-|x-y|^2/\delta} u(y, t)\, dy, \qquad \delta = 4\Delta t. \tag{2}$$

We begin by projecting the initial temperature field f onto a finite-dimensional space of piecewise polynomial interpolants, chosen adaptively to resolve f within error ϵ. Then we use Hermite expansions to evaluate $u(x, \Delta t)$ via (2) efficiently, again within error ϵ, and project $u(x, \Delta t)$ onto another adaptively chosen finite-dimensional space that resolves it within error ϵ. This process can be repeated at each timestep, or the Hermite expansion coefficients can be updated to simply evaluate u at any desired time $t \geq \Delta t$. The first approach is more applicable to inhomogeneous problems, the second approach more efficient.

The techniques used here can also be used to solve the more general problem

$$u_t = \Delta u + F(x,t) \quad \text{in } \Omega \subset \mathbf{R}^2$$

$$\alpha u + \beta \frac{\partial u}{\partial n} = g \quad \text{on } \partial\Omega \tag{3}$$

$$u = f \quad \text{at } t = 0,$$

with Ω a possibly time-dependent subset of the plane having a bounded C^2 boundary $\partial\Omega$, n the outward unit normal to $\partial\Omega$, and α, β, g, f, and F C^2 functions on their domains.

We first discuss the inhomogeneous free-space problem

$$u_t = \Delta u + F(x,t) \quad \text{in } \mathbf{R}^2$$

$$u = f \quad \text{at } t = 0 \tag{4}$$

as an example of the technique employed on (3). We solve (4) by Duhamel's principle and evaluate the resulting integral by the trapezoidal rule; this is second-order accurate in Δt. Simpson's rule gives a fourth-order method, and higher-order methods are similarly easy to construct.

The organization of the paper is as follows. In §2, we derive the Hermite expansion of the heat kernel and truncation error estimates. Next, in §3, we describe how we project a given function f onto a finite-dimensional subspace, which resolves it within error ϵ relative to $|f|_\infty = \max|f|$. In §4, we describe how to combine these two techniques to solve the homogeneous free-space heat equation (1), and in §5 we extend the method to the inhomogeneous equation (4). In §6 we sketch how to solve (3), using our method and heat potential theory; details will be given in a later publication. Numerical experiments are presented in §7 and conclusions in §8.

2. Hermite expansions. The purpose of this section is to describe how certain moments of $u(x,t)$ suffice to evaluate $u(x,t+\Delta t)$ at any point x within an error tolerance ϵ. We use the explicit evolution formula [5]

$$u(x,t+\Delta t) = \frac{1}{\pi\delta}\int_{\mathbf{R}^2} e^{-|x-y|^2/\delta} u(y,t)\,dy, \qquad \delta = 4\Delta t \tag{5}$$

for the bounded solution u of (1).

The heat kernel (with $\delta = 1$ for simplicity) is a real-analytic function of $y \in \mathbf{R}^2$, so we can expand it in a two-dimensional Taylor series:

$$h(x-y) = e^{-|x-y|^2} = \sum_{\alpha \geq 0} \frac{1}{\alpha!} h_\alpha(x) y^\alpha. \tag{6}$$

Here $\alpha = (\alpha_1, \alpha_2)$ is a multi-index with integer components, $\alpha! = \alpha_1!\alpha_2!$; we say that $\alpha \geq 0$ if $\alpha_i \geq 0$ for each $i = 1, 2$, and $y^\alpha = y_1^{\alpha_1} y_2^{\alpha_2}$. The Taylor coefficients are given by

$$h_\alpha(x) = D_y^\alpha h(x-y)\big|_{y=0} = (-1)^{|\alpha|} D_x^\alpha h(x), \tag{7}$$

where $|\alpha| = \alpha_1 + \alpha_2$ and

$$D_y^\alpha = \left(\frac{\partial}{\partial y_1}\right)^{\alpha_1} \left(\frac{\partial}{\partial y_2}\right)^{\alpha_2}.$$

Since the variables x_1 and x_2 are separated in $h(x)$, we have

$$h_\alpha(x) = h_{\alpha_1}(x_1)h_{\alpha_2}(x_2),$$

where each one-variable function $h_n(x)$ is given by

$$\begin{aligned} h_n(x) &= (-1)^n \left(\frac{d}{dx}\right)^n e^{-x^2} \\ &= H_n(x)e^{-x^2}, \end{aligned} \tag{8}$$

and H_n is the usual Hermite polynomial. We will need two facts from [11]. First, the two-term recursion

$$H_{n+1}(x) = 2xH_n(x) - 2nH_{n-1}(x),$$

with $H_0(x) = 1$ and $H_1(x) = 2x$. Second, Cramer's inequality

$$|H_n(x)| \le K2^{n/2}\sqrt{n!}e^{x^2/2},$$

where K is less than 1.09. Hence

$$\frac{1}{\alpha!}|h_\alpha(x)| \le K^2\frac{2^{|\alpha|/2}}{\sqrt{\alpha!}}. \tag{9}$$

The "tail" left after truncating the series (6) after terms with every $\alpha_i \le p$ is bounded uniformly in x by

$$\sum_{\text{some } \alpha_i > p} \frac{1}{\alpha!}|h_\alpha(x)||y^\alpha| \le K^2 \sum_{\text{some } \alpha_i > p} \frac{2^{|\alpha|/2}}{\sqrt{\alpha!}} r^{|\alpha|} = O\left(\frac{2er^2}{p+2}\right)^{(p+1)/2} \tag{10}$$

if $|y_i| \le r$ for $i = 1, 2$, by Stirling's formula. This decreases very rapidly as p increases. Thus the kernel $h(x - y)$ can be approximated by a $(p + 1)^2$-term truncated Taylor series when $|y_i| \le r$, with an error that decreases rapidly as p, increases uniformly in x.

This expansion was used in [6] and [10] to evaluate the two-dimensional discrete Gauss transform

$$G_\delta f(t_i) = \sum_{j=1}^{N} f_j e^{-|t_i - s_j|^2/\delta}, \qquad i = 1, 2, 3, \ldots, M, \tag{11}$$

with $t_i, s_j \in \mathbf{R}^2$, $\delta > 0$, $|t|^2 = t_1^2 + t_2^2$, in $O(N + M)$ time. (In [6], δ was a constant; [10] extended the algorithm to cover the situation when $\delta = \delta_i$ or $\delta = \delta_j$.)

Now rescale and shift this formula with an arbitrary δ and a center of expansion c; we get

$$h\left(\frac{x-y}{\sqrt{\delta}}\right) = h\left(\frac{x-c-(y-c)}{\sqrt{\delta}}\right) = \sum_{\alpha \ge 0} \frac{1}{\alpha!} h_\alpha\left(\frac{x-c}{\sqrt{\delta}}\right)\left(\frac{y-c}{\sqrt{\delta}}\right)^\alpha, \tag{12}$$

and the error in truncating after terms with $\alpha_i \le p$ is given by (10) if $|y_i - c_i| \le r\sqrt{\delta}$. Hence $e^{-|x-y|^2/\delta}$ is well represented by a truncated Taylor series in y when y lies in a square with center c and side $2r\sqrt{\delta}$.

This suggests a natural way to evaluate the integral

$$G_\delta f(x) = \frac{1}{\pi\delta}\int_{\mathbf{R}^2} e^{-|x-y|^2/\delta} f(y)\, dy.$$

Suppose f has compact support. Cover the support of f with nonoverlapping square cells C of side $2r\sqrt{\delta}$ and centers c. In each cell, expand the heat kernel about the cell center using (12);

$$G_\delta f(x) = \frac{1}{\pi} \sum_C \sum_{\alpha \geq 0} C_\alpha h_\alpha \left(\frac{x-c}{\sqrt{\delta}} \right), \tag{13}$$

where

$$C_\alpha = \frac{1}{\delta \alpha!} \int_C \left(\frac{y-c}{\sqrt{\delta}} \right)^\alpha f(y)\, dy. \tag{14}$$

The variables x and y are now separated, so we have decomposed the calculation into two simpler pieces; first, we evaluate the moments C_α for each cell C and for $\alpha_i = 0, 1, \ldots, p$, and then we sum the Hermite series (13) for each point where $G_\delta f(x)$ is to be evaluated. The numerical error in the approximation of $G_\delta f$ by this procedure comes from two sources: first, truncation of the Hermite series, and second, quadrature error in evaluating C_α numerically. We have already discussed the truncation error; the quadrature error will be discussed in the next section.

We can speed up the evaluation considerably, when δ is small, by dropping negligible contributions from cells distant from the point of evaluation x. The contribution from a distant cell C' is bounded by

$$\frac{1}{\pi\delta} \int_{C'} e^{-|x-y|^2/\delta} |f(y)|\, dy \leq \frac{1}{\pi\delta} |f|_\infty |C'| e^{-|x-x_0|^2/\delta},$$

where x_0 is the closest point in C' to x and $|C'|$ is the area of C'. Thus only a fixed number of cells within a distance $O(\sqrt{\delta})$ need to be kept, for any fixed precision. Our next step is to evaluate C_α.

3. Adaptive refinement. The purpose of adaptive refinement is to know a function within ϵ as efficiently as possible. Numerically, we know a function f within ϵ if we can evaluate it at any point x with an error that is less than $\epsilon |f|_\infty$ and a cost that depends only on ϵ.

The Hermite expansion of §2 enables us to evaluate $u(x, t + \Delta t)$ at any point x, not just on a fixed set of grid points. The cost per evaluation is fixed, because each evaluation is independent of the others. Thus we are in the following situation: We have a function, f say, and we can evaluate it at any point for fixed cost per evaluation. How can we best approximate f by piecewise polynomials within error $\epsilon |f|_\infty$? For our applications, f is not very smooth initially, so refinement in space seems a reasonable approach. Thus we use a fixed low degree d of polynomial interpolation and refine the interpolation grid wherever f is not accurately represented. We use a triangular grid and approximate f by degree-d interpolation over each triangle; the degree is selected by the user. When we evaluate the moments C_α, we have to integrate f times powers over cells C. It is convenient if each triangle of our triangulation lies completely within a single cell C. We begin with the simplest such triangulation, which is the one formed by cutting each cell C into two isosceles right triangles and subdividing until f is accurate within ϵ.

Thus we use the following method to construct the adaptive approximation of f; we begin by dividing each cell C into two right triangles and constructing the degree-d interpolant to f at the $(d+1)(d+2)/2$ nodes shown in Fig. 1.

Now we stack all the triangles and sweep through, testing whether each triangle requires subdivision. To test a triangle, we evaluate f at each node that would be produced by bisecting

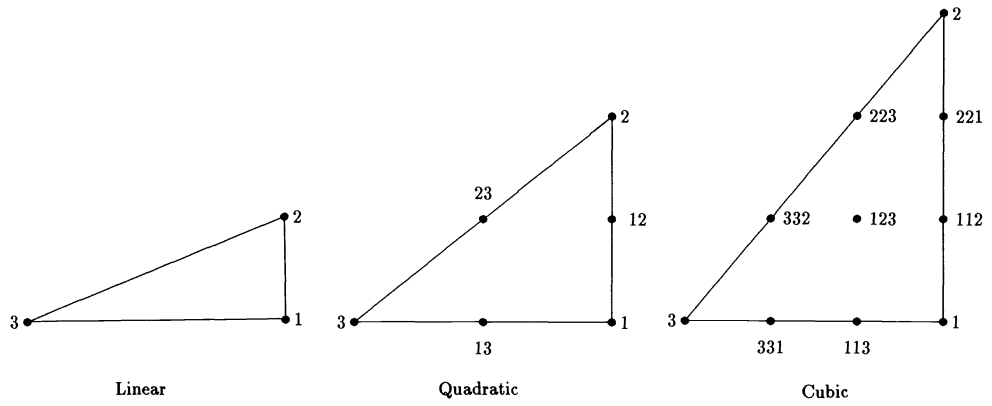

FIG. 1. *Nodes for degree-d interpolation on triangles for* $d = 1, 2,$ *and* 3.

the longest side, as shown in Fig. 2. This requires one evaluation for $d = 1$, three for $d = 2$, and six for $d = 3$; all these values are used if the triangle is subdivided. We also evaluate the degree-d interpolant at the same nodes and compute the maximum difference between the two sets of values. If f is within ϵ (relative to the maximum value of $|f|$ so far encountered) of the interpolant at the new nodes, the triangle is accepted. Otherwise, the triangle is subdivided by Mitchell's newest-node bisection method [8], maintaining compatibility by subdividing neighbors as necessary, and the new triangles are stacked. We then repeat the procedure until the stack is finished.

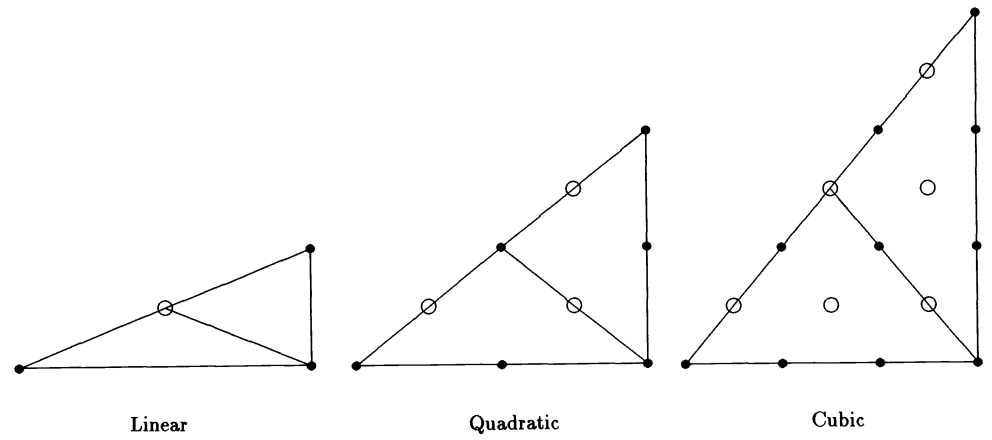

FIG. 2. *New nodes produced when the base is bisected are circled.*

Mitchell's subdivision procedure assigns one vertex of each triangle in the initial triangulation as a "peak" and the side opposite the peak as the base. (In our case, the initial triangulation consists of isosceles right triangles and the peak is the vertex at the right angle, opposite the hypotenuse.) Then it subdivides triangles by dividing the base and the neighboring triangle opposite the peak, with the new vertex being assigned as the peak of each of the four new triangles created by the subdivision. Compatibility is maintained by always subdividing compatible pairs of triangles; if the neighbor opposite the peak is not compatibly subdivisible, it is itself divided recursively until compatibility is maintained. An example is shown in Fig. 3.

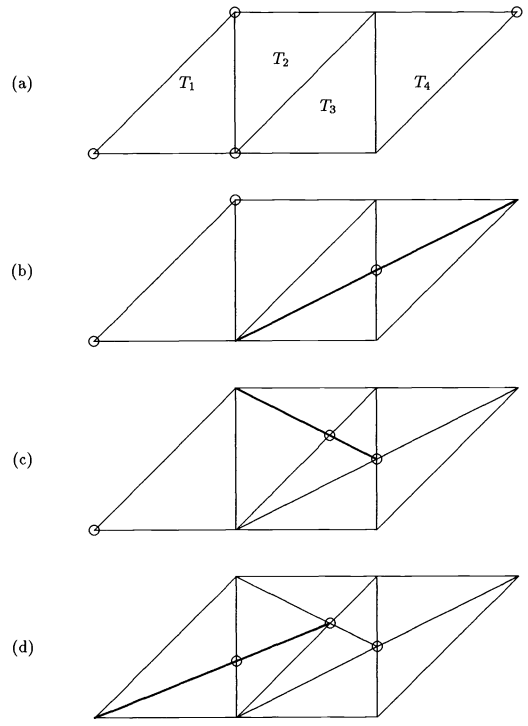

FIG. 3. *An example of Mitchell's recursive newest-node bisection* [8]. *Triangle T_1 is flagged for subdivision, but the peak of its neighbor T_2 (indicated by circle) does not lie opposite T_1. Hence we must refine T_2 and its neighbor T_3. Similarly, the peak of T_3 does not lie opposite T_2, so we must refine T_4 and T_3. The peak of T_4 lies opposite T_3, so the recursion stops here. We then divide triangles backwards in pairs as shown in* (b) *through* (d), *until we have divided the triangle T_1 we originally wanted to divide. The subdivided triangulation is shown in* (d).

Once a triangulation is constructed, we have enough information about f to solve the heat equation to accuracy ϵ after time Δt has elapsed. We need only to use the interpolant of f on the adapted triangulation to evaluate $(p+1)^2$ of the moments C_α within relative error ϵ. This requires integrating the interpolant times $((x-c)/\sqrt{\delta})^\alpha$ over each triangle lying in cell C with center c.

This task is simpler if we put the interpolant, on each triangle, in the shifted and scaled Cartesian form

$$\tilde{f}(x) = \sum_{|\beta| \le d} F_\beta \left(\frac{x-c}{\sqrt{\delta}} \right)^\beta .$$

This requires considerable hand calculation, because $\tilde{f}$ is most naturally expressed in barycentric coordinates as in [3], and the expressions for the Cartesian coefficients F_β can become quite complicated for quadratic or cubic interpolation. The expressions for F_β are given in the Appendix.

Next we need to calculate the approximate moments

$$\begin{aligned} \tilde{C}_\alpha &= \frac{1}{\alpha!\delta} \int_C \left(\frac{y-c}{\sqrt{\delta}} \right)^\alpha \tilde{f}(y)\, dy \\ &= \sum_{T \subset C} \frac{1}{\alpha!\delta} \int_T \left(\frac{y-c}{\sqrt{\delta}} \right)^\alpha \tilde{f}(y)\, dy \end{aligned} \tag{15}$$

using the piecewise polynomial interpolant. Here we have split up the integral over C into a sum of integrals $\tilde{T}_\alpha$, say, over the triangles T contained in C.

Now consider the evaluation of

$$\tilde{T}_\alpha = \frac{1}{\alpha!\delta} \int_T \left(\frac{y-c}{\sqrt{\delta}} \right)^\alpha \tilde{f}(y)\, dy \tag{16}$$

$$= \sum_{|\beta| \le d} F_\beta \frac{1}{\alpha!\delta} \int_T \left(\frac{y-c}{\sqrt{\delta}} \right)^{\beta+\alpha} dy. \tag{17}$$

We need only evaluate triangle moments

$$T_\gamma = \frac{1}{\gamma!\delta} \int_T \left(\frac{x-c}{\sqrt{\delta}} \right)^\gamma dx$$

for $\gamma_i = 0, 1, 2, \ldots, p+d$. Note that while c may not lie in T and δ may be small, we nevertheless have $T \subset C$ and thus $|x_i - c_i| \le r\sqrt{\delta}$ for $x \in T$, where r is a fixed constant. Hence evaluating T_γ and adding up values with coefficients is not a numerically unstable process.

To evaluate T_γ, we first translate and scale T to simplify the notation, then use the Divergence Theorem and recursion. Write $\gamma = (i, j)$ and $x = (x, y)$. Then

$$T_\gamma = T_{ij} = \frac{1}{i!j!} \int_{T'} x^i y^j \, dxdy,$$

where $T' = (T - c)/\sqrt{\delta}$ is a shifted and scaled version of T.

Let v_1, v_2, and v_3 be the vertices of T', arranged in counterclockwise order, and let $v_4 = v_1$. Then by the Divergence Theorem,

$$T_{ij} = \sum_{k=1}^{3} T_{ijk},$$

where explicit parametrization of the line segment $\overline{v_k v_{k+1}}$ gives

$$T_{ijk} = \int_0^1 (y_{k+1} - y_k) \frac{x^{i+1}}{(i+1)!} \frac{y^j}{j!} \, d\theta.$$

Here $(x, y) = v = \theta v_{k+1} + (1-\theta) v_k$ and $v_k = (x_k, y_k)$. Integrating by parts gives a recurrence relation

$$T_{ijk} = \Lambda \left[\frac{x_k^{i+1}}{(i+1)!} \frac{y_k^{j+1}}{(j+1)!} \right] - \frac{\Lambda x_k}{\Lambda y_k} T_{i-1,j+1,k}.$$

Here Λ is the forward difference operator $\Lambda x_k = x_{k+1} - x_k$. We can use this recurrence to compute T_{ijk} for $i, j = 0, 1, 2, \ldots, q = p + d$ if we start with values for T_{0jk} for $j = 0, 1, 2, \ldots, 2q$. Integrating by parts again produces initial values for the recurrence:

$$T_{0jk} = \Lambda \left[x_k \frac{y_k^{j+1}}{(j+1)!} \right] - \frac{\Lambda x_k}{\Lambda y_k} \Lambda \left[\frac{y_k^{j+2}}{(j+2)!} \right].$$

Note that (a) it is efficient to precompute and store the values $x_k^i/i!$ and $y_k^j/j!$, which are used repeatedly, and (b) $T_{ijk} = 0$ when $\Lambda y_k = 0$ (so there is no difficulty with dividing by zero). This concludes the evaluation of T_{ijk} and hence of C_α.

4. The homogeneous problem. We now combine the tools described in §§2 and 3 to construct methods for solving the homogeneous free-space heat equation

$$u_t = \Delta u \quad \text{in } \mathbf{R}^2, \tag{18}$$

$$u(x, 0) = f(x), \tag{19}$$

with f a bounded function that vanishes at infinity. The unique bounded solution u satisfies the semigroup property [5]

$$u(x, t + \Delta t) = \frac{1}{\pi\delta} \int_{\mathbf{R}^2} e^{-|x-y|^2/\delta} u(y, t)\, dy, \tag{20}$$

with $\delta = 4\Delta t$.

Method 1. Taking $t = 0$ and $\Delta t = t$ gives

$$u(x, t) = \frac{1}{\pi\delta} \int_{\mathbf{R}^2} e^{-|x-y|^2/\delta} f(y)\, dy, \qquad \delta = 4t, \tag{21}$$

which represents u at any time t in terms of the convolution of a Gaussian with scale $\delta = 4t$ with the initial temperature field f. Let us suppose that we want to know $u(x, t)$ within relative error ϵ at a sequence of times $t = 0, \Delta t, 2\Delta t, \ldots, N\Delta t = T$, and Δt is not too small. (If Δt is very small and we wish to know u at every step, explicit adaptive finite difference or finite element methods are excellent.)

Let $\delta = 4\Delta t$ and let us first evaluate $u(x, \Delta t)$. We replace f by a piecewise polynomial $\tilde{f}$ constructed, as in §3, to approximate f within $\epsilon|f|_\infty/2$. Then we use $\tilde{f}$ to evaluate the moments $\tilde{C}_\alpha$ defined in (15) for $0 \le \alpha_i \le p$ for each cell. We can now evaluate $u(x, \Delta t)$ by (21) within error ϵ relative to $|f|_\infty$, by a truncated Hermite series

$$u(x, t + \Delta t) = \frac{1}{\pi} \sum_C \sum_{\alpha \ge 0}^{p} C_\alpha h_\alpha \left(\frac{x - c}{\sqrt{\delta}} \right) + E,$$

where the error E comes from several sources; first, the error due to replacing f by $\tilde{f}$, which is bounded by $\epsilon|f|_\infty/2$ by the maximum principle [5]; second, the error due to truncating each Hermite series at $\alpha_i = p$, and third, the error due to ignoring distant cells. These add up to

$$\frac{\epsilon|f|_\infty}{2} + O\left(\frac{2er^2}{p+2} \right)^{(p+1)/2} |f|_\infty + O\left(e^{-4r^2 I^2} \right) |f|_\infty, \tag{22}$$

which can be easily made less than ϵ by choice of p and the cutoff distance once r and N are fixed.

Thus we can evaluate $u(x, \Delta t)$ at any point x. Method 1 is distinguished by the way in which we evaluate u at later times. In principle, a separate computation should be required for each time at which we wish to evaluate u, because the moments C_α depend on t through δ. However, C_α is homogeneous of degree $-1 - |\alpha|/2$ in δ;

$$C_\alpha = \frac{1}{\alpha!\delta} \int_C \left(\frac{y - c}{\sqrt{\delta}} \right)^\alpha f(y)\, dy.$$

Thus $C_\alpha(2\delta) = 2^{-(2+|\alpha|)/2} C_\alpha(\delta)$ if we make the dependence on δ explicit. Once we have $C_\alpha(\delta)$, therefore, we can evaluate $u(x, t)$ with relative error less than ϵ at any time $t \ge \Delta t$,

simply by scaling the coefficients and evaluating. More precisely,

$$u(x,t) = \frac{1}{\pi} \sum_{C} \sum_{\alpha \geq 0}^{p} \left(\frac{t}{\Delta t} \right)^{-(2+|\alpha|)/2} C_\alpha h_\alpha \left(\frac{x-c}{\sqrt{4t}} \right) + E,$$

where $E \leq \epsilon |f|_\infty$. The need to include more cells C in the sum as t increases, due to spreading of the Gaussians, is more than counterbalanced by the fewer coefficients required: C_α is effectively reduced exponentially as $\delta = 4t$ increases.

The scaling of coefficients used in Method 1 was developed in [10] for evaluating the discrete Gauss transform with target-dependent scales.

Method 1 is highly efficient and accurate. It requires a substantial investment of effort at the beginning of the calculation to construct the triangulation and approximate f (especially if f is not very smooth), but evaluation of u gets less and less expensive as time goes by. Moreover, the space required for the triangulation can be reused for other purposes as soon as the coefficients are evaluated and stored. Method 1 is useful whenever the homogeneous free-space heat equation is to be solved for rough data and not too small times.

Two fundamental properties of the heat equation influence this method. First, the increasing smoothness and decreasing variation of $u(x,t)$ as t increases means that it takes fewer and fewer degrees of freedom to represent u within a fixed relative precision ϵ. A typical example is shown in Figs. 4 and 5. In Fig. 4, we display the triangulation needed to resolve

$$f(x) = \sum_{k_1=1}^{10} \sum_{k_2=1}^{10} \cos(k_1(x_1 - \bar{x}_1)) \cos(k_2(x_2 - \bar{x}_2)) e^{-(k_1(x_1-\bar{x}_1))^2 - (k_2(x_2-\bar{x}_2))^2}$$

(where $\bar{x}_1$ and $\bar{x}_2$ are randomly chosen, for each k_1 and k_2, on $[-1, 1]$) within error $\epsilon = 10^{-2}$ relative to $|f|_\infty$, using linear interpolation. Figure 5 displays the triangulation needed to resolve the solution $u(x,t)$ with initial data $f(x)$, at $t = 0.1$, to the same relative precision. The triangulation began with a 6×6 grid of square cells on $[-3, 3]^2$ in both cases; f required 2910 triangles while u required only 608, a reduction in the number of degrees of freedom by almost 5. The smallest triangle for f is 2^{-6} on a side, while at $t = 0.1$, the smallest triangle is 2^{-3}. Thus smoothing by heat flow speeds up later stages of the calculation.

The other property of the heat equation, the spreading support of its solutions, is less benign though hardly malignant. Even though f has compact support, $u(x,t)$ will not have compact support for any $t > 0$, because heat flows instantaneously (though in small amounts) to infinity. Thus if we begin by representing f by a piecewise polynomial on $B = [-R, R]^2$, say, where $|f| \leq \epsilon$ outside B, the support of u will spread and $|u|$ will eventually be greater than ϵ outside B. No fixed region can be used for computing u for arbitrarily long times, because eventually significant heat flows to infinity.

Method 2. We now describe another method for solving (18), with slightly different aims. Method 2 is better suited to solving inhomogeneous problems and extends more easily to solving problems on domains with boundaries and variable-coefficient and nonlinear problems.

The basic idea of Method 2 is simply to restart Method 1 at each step. (More generally, we could restart every few steps.) The advantage in this is that data like inhomogeneous terms and boundaries can more easily enter the evolution.

More precisely, we carry out Method 1 to construct the coefficients C_α of $u(x, \Delta t)$. Then we apply the adaptive refinement strategy again, with $u(x, \Delta t)$ in place of $f(x)$. Thus we construct a new triangulation on which $u(x, \Delta t)$ is equal to a piecewise polynomial of degree d, within error $\epsilon |u(\cdot, \Delta t)|_\infty$. We then repeat the construction of the C_α's with $u(x, \Delta t)$ in place of f, and we then can evaluate $u(x, 2\Delta t)$. We repeat this process, going from real-space

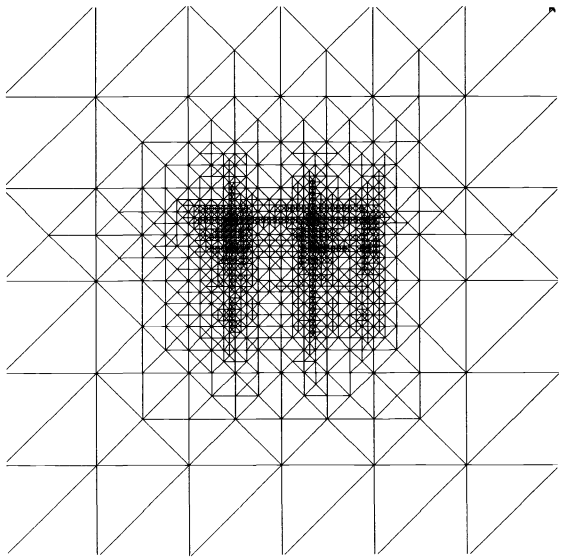

FIG. 4. *Initial triangulation for sum of* 100 *scaled and randomly shifted terms of*

$$u_1(x,t) = \frac{e^{1/4T-1/4}}{\sqrt{T}} \cos\left(\frac{x}{T}\right) e^{-x^2/T},$$

where $T = 1 + 4t$, *resolved to error* $\epsilon = 10^{-2}$ *relative to* $|u_1|_\infty$ *with linear interpolation. The triangulation began with a* 6×6 *grid of square cells on* $[-3, 3]$. *This required* 2910 *triangles and* 1468 *nodes, with minimum side length* $2^{-6.5}$ *times the maximum side length.*

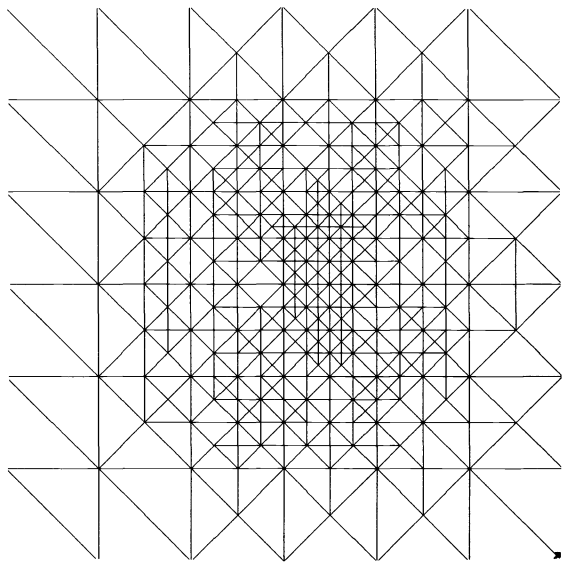

FIG. 5. *Triangulation for* 100 *terms of* u_1 *at* $t = 0.1$, *with* $\epsilon = 10^{-2}$ *and linear interpolation. The increasing smoothness of the solution is reflected in the larger triangles used to represent it; only* 608 *triangles are needed here, with* 317 *nodes and minimum side length* $2^{-3.5}$ *times the maximum side length.*

values sufficient to resolve $u(x, n\Delta t)$ to the coefficients for $u(x, (n+1)\Delta t)$ and back again, at each timestep.

A disadvantage of Method 2 is that in the worst case we commit error ϵ *at each step*; thus if we want to go N steps to time T, and *guarantee* a final error $\leq \epsilon$, we have to commit error $\epsilon' = \frac{\epsilon}{N}$ at each step. Fortunately, this estimate is quite pessimistic, because the error committed at one time is high frequency and therefore decays rapidly under the heat flow. Hence errors do not accumulate to this extent in practice.

There are several ways to deal with the problem of spreading support and they lead to a subdivision of Method 2.

Method 2.1 is the simplest. Here we plan to compute up to some final time T, determine R so that $|u(x,t)| \leq \epsilon$ outside $[-R, R]^2$ for $0 \leq t \leq T$, then compute on the fixed domain $[-R, R]^2$. Either R can be determined experimentally or the exact representation (18) for u can be used to bound R a priori. Suppose $|f| \leq \epsilon |f|_\infty$ when $|x| \geq \rho$. Then within error $\epsilon |f|_\infty$,

$$u(x,t) = \frac{1}{\pi\delta} \int_{|y|\leq\rho} e^{-|x-y|^2/\delta} f(y)\, dy, \qquad \delta = 4\Delta t.$$

If $|x| \geq R$ where $R \geq \rho$, then

$$|u(x,t)| \leq \frac{\rho^2}{\delta} e^{-(R-\rho)^2/\delta} |f|_\infty.$$

We can make this $\leq \epsilon$ for $0 \leq t \leq T$ with $R = \rho + O(\sqrt{T \log(\epsilon T)})$, so R grows rather slowly with T. This a priori bound is rather crude, however, and it is usually far cheaper to run the code once with $\Delta t = T$ and large ϵ (which costs very little), measure the maximum of $|u|$ near the boundary, and increase R until a suitable value is found. Note that increasing R adds to the outer regions of the computational domain, where u is small and smooth and therefore needs little refinement, hence adds very little to the cost of the calculation.

Method 2.2 is almost as simple as Method 2.1; here, we compute on a changing computational box $B(t) = [a_1(t), b_1(t)] \times [a_2(t), b_2(t)]$, outside of which $|f| \leq \epsilon$ initially. At each step, we expand $B(t)$ adaptively to include all regions in which $|u| > \epsilon$. This is done by computing the max of $|u|$ over each side and adding one cell at a time until satisfied.

This method is adaptive in a way that fits well with our general approach. It is not foolproof (as Method 2.1 with an a priori estimate would be), but in practice works very well. It achieves a small savings over Method 2.1 at a small additional cost in algorithmic complexity.

Method 2.3, like 2.2, expands the domain as necessary. But Method 2.2 adds cells, so the cost goes up; in Method 2.3, we simply scale up the size of each cell by increasing δ until cells of size $2r\sqrt{\delta}$ cover the region on which $|u| > \epsilon$. Thus we look at the solution on a larger spatial scale to take advantage of its increased smoothness and take larger timesteps accordingly. The spatial and temporal scalings are related by the natural scaling law of the heat equation; time = space squared.

This method achieves roughly constant cost, but at the price of varying the timestep. Thus we have to use interpolation in time if we want to know u at a specific time. Another disadvantage is that Method 2.3 does not easily extend to inhomogeneous problems, where the solution does not necessarily become smoother as time goes by.

Method 3 speeds up the evaluation of u by transforming the sum of $(2I+1)^2$ Hermite series into a single Taylor series for each cell, using a technique developed in [6]. We have

$$u(x,t) = \sum_C \sum_{\alpha\geq 0} C_\alpha h_\alpha \left(\frac{x-c}{\sqrt{\delta}}\right).$$

We can transform this to a single Taylor series in the cell B in which x lies, say,

$$u(x,t) = \sum_{\beta \geq 0} B_\beta \left(\frac{x-b}{\sqrt{\delta}} \right)^\beta,$$

where b is the center of B. To do this, we simply calculate the Taylor coefficients

$$\begin{aligned} B_\beta &= \frac{(\sqrt{\delta})^{|\beta|}}{\beta!} D_b^\beta u(b,t) \\ &= \frac{1}{\beta!} \sum_C \sum_{\alpha \geq 0} C_\alpha (\sqrt{\delta})^{|\beta|} D_b^\beta h_\alpha \left(\frac{b-c}{\sqrt{\delta}} \right). \end{aligned}$$

But $h_\alpha = (-D)^\alpha e^{-|x|^2}$, by definition, so

$$B_\beta = \frac{(-1)^{|\beta|}}{\beta!} \sum_C \sum_{\alpha \geq 0} C_\alpha h_{\alpha+\beta} \left(\frac{b-c}{\sqrt{\delta}} \right). \tag{23}$$

This sum can be truncated with an error bound similar to that for the original series. Thus u can be expressed as a local Taylor series in each cell, with coefficients depending on the Hermite coefficients C_α for nearby cells and the Hermite functions of the center-to-center vectors.

The advantage of this is that each evaluation of u costs only $O(p+1)^2$ arithmetic operations, rather than $O((2I+1)(p+1))^2$, which can be one or two orders of magnitude larger. Since most of the computational effort is spent on evaluating u, this is a considerable savings.

As in [6], there is a break-even point, a number of evaluations per cell below which it is not efficient to transform u to a Taylor series. This point depends on the degree of refinement necessary in the given cell, hence is not known a priori. However, it can be estimated from the behavior of u in the cell in the previous timestep or directly from the rate of decay of the Hermite coefficients.

However, another advantage is that when u is given by a truncated Taylor series, the coefficents C_α for the next time level are trivial to compute. For cell C, we have

$$\begin{aligned} C_\alpha &= \int_C \left(\frac{x-c}{\sqrt{\delta}} \right)^\alpha \sum_{\beta \leq p} B_\beta \left(\frac{x-c}{\sqrt{\delta}} \right)^\beta dx \\ &= \sum_{\beta \leq p} B_\beta \frac{r^{|\alpha+\beta|+2}(1-(-1)^{\alpha_1+\beta_1+1})(1-(-1)^{\alpha_2+\beta_2+1})}{(\alpha_1+\beta_1+1)(\alpha_2+\beta_2+1)} \end{aligned} \tag{24}$$

since the sides of C are $2r\sqrt{\delta}$ long. Thus it is unnecessary, as far as u is concerned, to retriangulate. Of course, inhomogeneous terms and layer potentials will still need to be approximated on a triangulation.

By substituting (23) into (24), we also get an expression for the new C_α's in terms of the old C_α's, which allows us to evolve u completely in transform space and makes it unnecessary to return to real space at every step.

5. The inhomogeneous case. We now generalize one of the methods, Method 2.1, to solve the inhomogeneous free-space heat equation

$$\begin{aligned} u_t &= \Delta u + F(x,t) \quad \text{in } \mathbf{R}^2, \\ u(x,0) &= f(x), \end{aligned} \tag{25}$$

where F has compact support in x for each t. The evolution formula corresponding to (20) is Duhamel's principle [5, p. 196]

$$u(x,t+\Delta t) = \frac{1}{\pi\delta}\int_{\mathbf{R}^2} e^{-|x-y|^2/\delta} u(y,t)\,dy + \int_t^{t+\Delta t} \frac{1}{\pi\sigma}\int_{\mathbf{R}^2} e^{-|x-y|^2/\sigma} F(y,s)\,dy\,ds \tag{26}$$

with $\delta = 4\Delta t$ as usual and $\sigma = 4(t+\Delta t - s)$.

Let us begin by discretizing the time integral. The integrand is a smooth function of s, so the trapezoidal rule

$$\int_t^{t+\Delta t} g(s)\,ds = \frac{\Delta t}{2}(g(t+\Delta t)+g(t)) + O(\Delta t^3)$$

is globally second-order accurate. Moreover, when $s \to t+\Delta t$, the integrand approaches $F(x,t+\Delta t)$. Thus we have

$$u(x,t+\Delta t) = \frac{1}{\pi\delta}\int_{\mathbf{R}^2} e^{-|x-y|^2/\delta}\left[u(y,t)+\frac{\Delta t}{2}F(y,t)\right]dy + \frac{\Delta t}{2}F(x,t+\Delta t) + O(\Delta t^3).$$

Thus $u(x,t+\Delta t)$ can be found by Method 2.1, if we simply replace $u(y,t)$ by $u(y,t) + \frac{1}{2}\Delta t F(y,t)$ in the construction of the triangulation and the evaluation of the moments, and afterward add $\frac{1}{2}\Delta t F(x,t+\Delta t)$. Since we commit $O(\Delta t^3)$ error at each of $N = \frac{T}{\Delta t}$ steps, the final error in u up to time T is $O(\Delta t^2)$.

Higher-order methods are easy to construct, but slightly more expensive per timestep. Several sets of coefficients must be stored, and updated (by the technique of Method 1) after each step. These higher-order methods are important, however, because our approach is efficient when Δt is *large*; thus we need a higher order of accuracy to capture variations in F. Hence this approach is suited to F varying rapidly in x but not in t.

A fourth-order method, for example, can be based on Simpson's rule:

$$\int_{t-\Delta t}^{t+\Delta t} \frac{\Delta t}{3}\left[g(t-\Delta t)+4g(t)+g(t+\Delta t)\right] + O(\Delta t^5).$$

This leads to two possible methods, depending on whether or not it is convenient to evaluate F at half timesteps. If not, for example, we get

$$u(x,t+\Delta t) = \frac{1}{2\pi\delta}\int_{\mathbf{R}^2} e^{-|x-y|^2/2\delta}\left[u(y,t-\Delta t)+\frac{\Delta t}{3}F(y,t-\Delta t)\right]dy + \frac{4\Delta t}{3\pi\delta}\int_{\mathbf{R}^2} e^{-|x-y|^2/\delta}F(y,t)\,dy + \frac{\Delta t}{3}F(x,t+\Delta t) + O(\Delta t^5).$$

The final error after N steps of this method is $O(\Delta t^4)$.

6. Domains with boundaries. The methods we are developing in this paper find perhaps their best application in the solution of the heat equation on domains with (possibly time-dependent) boundaries. To do this, we use the classical theory of layer potentials for the heat equation described in [9] and more recently in [2]. The key operators in this theory are the layer potentials

$$Sg(x,t) = \int_0^t \int_{\Gamma(t')} G(x-x', t-t')g(x,t')\,dx'\,dt',$$

$$Dg(x,t) = \int_0^t \int_{\Gamma(t')} \frac{\partial G}{\partial n'}(x-x', t-t')g(x,t')\,dx'\,dt',$$

$$D^*g(x,t) = \int_0^t \int_{\Gamma(t')} \frac{\partial G}{\partial n}(x-x', t-t')g(x,t')\,dx'\,dt',$$

taken over a time-dependent boundary $\Gamma(t)$. Here G is the heat kernel $G(x,t) = (4\pi t)^{-1}e^{-|x|^2/4t}$ and g is a function defined on $\Gamma(t)$ for each t. Various boundary conditions for the heat equation can be transformed into Volterra integral equations on $\Gamma(t)$, with operators like S, D, or D^*, by representing the solution of the heat equation as a sum of layer potentials.

In this section, we describe briefly how our methods can be used to evaluate Sg. The basic idea is that layer potentials are solutions of inhomogeneous problems like the one treated in the previous section, but with distributions rather than smooth functions on the right-hand side as forcing terms. Sg, for example, solves

$$\begin{aligned} u_t &= \Delta u + \mu, \\ u(x,0) &= 0, \end{aligned} \tag{27}$$

where μ is the *measure* that assigns density g concentrated on $\Gamma(t)$. The double layer potential Dg has the normal derivative of a measure on the right-hand side.

Clearly this observation does not allow one to evaluate layer potentials with standard numerical methods that mostly require point values. Our methods, however, require only the ability to integrate the inhomogeneous term against a piecewise polynomial. The singularity in time of the kernel G turns out to complicate the integration slightly, requiring a straightforward asymptotic calculation.

Let us consider the single layer potential $u = Sg$. Since u satisfies (27), the evolution formula (26) gives

$$\begin{aligned} u(x,t) = {} & \frac{1}{\pi\delta}\int_{\mathbf{R}^2} e^{-|x-y|^2/\delta}u(y, t-\Delta t)\,dy \\ & + \int_{t-\Delta t}^t \int_{\Gamma(t')} \frac{e^{-|x-y|^2/4(t-t')}}{4\pi(t-t')}g(y,t')\,dy\,dt'. \end{aligned} \tag{28}$$

The integrand in the time integral is singular; it becomes infinite as t' approaches t. Thus a standard integration formula like the trapezoidal rule will not achieve its usual order of accuracy. A standard technique for eliminating this difficulty is *product integration*; to apply product integration, one extracts an analytic form for the singularity of

$$\tilde{g}(x,t') = \int_{\Gamma(t')} \frac{e^{-|x-y|^2/4(t-t')}}{4\pi(t-t')}g(y,t')\,dy$$

as t' approaches t from below. Say, $\tilde{g}(x,t') \sim \phi(x,t')$ as $t' \uparrow t$. Then we construct an integration rule by interpolating $\tilde{g}(x,t')/\phi(x,t')$ and integrating the resulting polynomial

times $\phi(x, t')$ exactly. Such a rule will achieve the order of accuracy of the interpolation used. Of course, ϕ must be simple enough that ϕ times a polynomial can be integrated exactly or very accurately, by some trick.

Thus we need the asymptotic behavior of $\tilde{g}$ as $t' \uparrow t$. When x lies on $\Gamma(t)$, a simple calculation shows that

$$\tilde{g}(x, t') \sim \frac{1}{\sqrt{4\pi(t - t')}} g(x, t) \quad \text{as } t' \uparrow t.$$

This square-root singularity is consistent with the usual parabolic scaling of the heat equation. It is derived by approximating $\Gamma(t')$ by its tangent line, estimating the error, and Taylor expanding. The technique is fairly standard [1].

When x does not lie on $\Gamma(t)$, however, approximation by the tangent line gives the wrong answer, because it neglects the curvature of $\Gamma(t)$. A better approach is to approximate $\Gamma(t)$ by the osculating circle or parabola; the result depends only on the curvature of $\Gamma(t)$, so either will do. We omit the details and state the result.

Assume x_0 is the closest point on $\Gamma(t)$ to x and let $D = |x - x_0|$. Let R be the radius of curvature of $\Gamma(t)$ at x_0 and ρ be the distance from x to the center of curvature. Then, if $\rho > 0$,

$$\tilde{g}(x, t') \sim \sqrt{\frac{R}{\rho}} \frac{1}{\sqrt{4\pi(t - t')}} e^{-D^2/4(t-t')} g(x_0, t)$$

as $t' \uparrow t$.

We now have the asymptotic behavior of the integrand. The next step is to write the time integral as

$$\int_{t-\Delta t}^{t} \frac{e^{-D^2/4(t-t')}}{\sqrt{4\pi(t - t')}} h(x, t')\, dt'$$

$$h(x, t') = \int_{\Gamma(t')} \frac{e^{(D^2 - |x-y|^2)/4(t-t')}}{\sqrt{4\pi(t - t')}} g(y, t')\, dy$$

so that $h(x, t') \to \sqrt{R/\rho}\, g(x_0, t)$ as $t' \uparrow t$. Now h is a nice smooth function, so we replace it by its linear interpolant

$$\tilde{h}(x, t') = \frac{t - t'}{\Delta t} h(x, t - \Delta t) - \frac{t - \Delta t - t'}{\Delta t} h(x, t)$$

and carry out the time integral exactly. This gives

$$\int_{t-\Delta t}^{t} \frac{e^{-D^2/4(t-t')}}{\sqrt{4\pi(t - t')}} \tilde{h}(x, t')\, dt'$$

$$= \sqrt{\frac{\Delta t}{4\pi}} e^{-D^2/\delta} \left[\Gamma_0\left(-\frac{1}{2}, \frac{D^2}{\delta}\right) - \Gamma_0\left(-\frac{3}{2}, \frac{D^2}{\delta}\right) \right] \sqrt{\frac{R}{\rho}} g(x_0, t) \tag{29}$$

$$+ \sqrt{\frac{\Delta t}{4\pi}} \Gamma_0\left(-\frac{3}{2}, \frac{D^2}{\delta}\right) \int_{\Gamma(t-\Delta t)} \frac{e^{-|x-y|^2/\delta}}{\sqrt{\pi\delta}} g(y, t - \Delta t)\, dy + O(\Delta t^{5/2}).$$

Here Γ_0 is the normalized incomplete gamma function defined by

$$\Gamma_0(a, \xi) = e^{\xi} \xi^{-a} \int_{\xi}^{\infty} e^{-z} z^{a-1}\, dz \qquad a < 0.$$

We now have an approximate evolution formula

$$u(x,t+\Delta t) = \frac{1}{\pi\delta}\int_{\mathbf{R}^2} e^{-|x-y|^2/\delta}u(y,t)\,dy + W_1(x,t)g(x_0,t+\Delta t) + W_2(x,t)\int_{\Gamma(t)} \frac{e^{-|x-y|^2/\delta}}{\sqrt{\pi\delta}}g(y,t)\,dy,$$

accurate to $O(\Delta t^{5/2})$. Here W_0 and W_1 are given in (29) as functions of x, Δt, and $\Gamma(t)$. To evaluate u by this formula, we need to find the nearest point x_0 on $\Gamma(t+\Delta t)$ to x and estimate the curvature and normal of $\Gamma(t+\Delta t)$ at x_0. Finding the nearest point can be done efficiently by binning pieces of $\Gamma(t+\Delta t)$ and searching bins.

To evaluate u, we also need to evaluate the "Gauss transform on a curve" defined by

$$\Gamma_\delta g(x) = \int_\Gamma \frac{e^{-|x-y|^2/\delta}}{\sqrt{\pi\delta}}g(y)\,dy.$$

This can be approximated adaptively by the Hermite expansion technique used for the homogeneous case. We begin by representing Γ and g as piecewise polynomials of degree d, within accuracy ϵ. To do this, we first lay down a coarse grid on Γ (parametrized by $s \in [0,1]$, say), and construct piecewise polynomial interpolants to the coordinate functions of Γ and to g at meshpoints s_j equispaced in $[0,1]$. In the style of §3, we now refine our representation of Γ adaptively whenever the polynomial interpolation fails to represent either Γ or g accurately. The result is a representation

$$\Gamma = \cup_j \Gamma_j + O(\epsilon),$$
$$g = \tilde{g} + O(\epsilon),$$

where Γ_j is an element; if we use linear interpolation, for example, Γ_j is a line segment.

Now we apply the expansion technique of §2. Lay down cells C of size $2r\sqrt{\delta}$ to cover Γ, and expand the contribution of $\Gamma \cap C$ as a series about the cell center c. We find

$$\Gamma_\delta g(x) = \sum_C \sum_{\alpha\geq 0} C_\alpha h_\alpha\left(\frac{x-c}{\sqrt{\delta}}\right) + E$$

with $E = O(\epsilon)$ and

$$C_\alpha = \frac{1}{\sqrt{\pi\delta}}\int_{\Gamma\cap C}\left(\frac{y-c}{\sqrt{\delta}}\right)^\alpha \tilde{g}(y)\,dy$$
$$= \frac{1}{\sqrt{\pi\delta}}\sum_{\Gamma_j\subset C}\int_{\Gamma_j}\left(\frac{y-c}{\sqrt{\delta}}\right)^\alpha \tilde{g}(y)\,dy,$$

where $\Gamma = \cup\Gamma_j$. (In order to have Γ divided into elements each of which lies in a single cell C, we perform a further subdivision of Γ by cutting any element crossing more than one cell.) This Hermite series can be truncated with the usual bounds.

We now have to evaluate integrals of the form

$$\int_{\Gamma_j}\left(\frac{y-c}{\sqrt{\delta}}\right)^\alpha \tilde{g}(y)\,dy,$$

where $\tilde{g}$ is a polynomial. If we use linear interpolation, the recurrence relation for doing this was developed in §3. Otherwise, similar but more complicated recurrence relations can be developed, or Gauss–Legendre integration of sufficiently high order can be used.

A major advantage of the present approach is that we are able to use high-order approximations of Γ without having to integrate Gaussians over such approximations. The difficulty of carrying out these calculations has been a major stumbling block in the construction of high-order product integration schemes, both for the heat equation and the Laplace equation. With the current approach, one needs only to integrate powers over polynomial curve elements, a technique that can always be carried out. This advantage was observed but not developed in [6]. The fast multipole method [7] can be used in a similar way to eliminate the necessity of product integration in potential theory for the Laplace equation. This approach seems likely to be particularly useful in three-dimensional problems, where product integration is more difficult.

The remainder of the calculation is straightforward; we present some preliminary numerical results in §7. We have described only the single layer potential, but the analysis of the double layer potential is quite similar. The jump in the double layer potential across the boundary complicates matters surprisingly little.

7. Numerical experiments. In this section, we describe the results of codes written for the homogeneous problem and the single layer potential. The codes were written in standard FORTRAN 77 and run on a SUN SPARCstation 1+ with the optimizer flag `-O`, using double-precision arithmetic. The timings reported are usually reproducible within 1 or 2%, which is sufficient for our purposes.

First, we implemented Method 2.1 for the homogeneous problem, checking the numerical results against exact solutions for three sets of exact temperature fields; each is produced by shifting, scaling, and summing a basic solution. We put

$$u(x, y, t) = \sum_{k_1=1}^{K} \sum_{k_2=1}^{K} u_j(k_1(x - x_{k_1}), k_1^2 t) u_j(k_2(y - y_{k_2}), k_2^2 t),$$

where x_{k_1} and y_{k_2} are random uniformly distributed on $[-1, 1]$. The three basic solutions are given by

$$u_1(x, t) = \frac{e^{1/4T} e^{-1/4}}{\sqrt{T}} \cos\left(\frac{x}{T}\right) e^{-x^2/T}$$

where $T = 1 + 4t$,

$$u_2(x, t) = \begin{cases} \max(1 - |x|, 0) & \text{if } t = 0, \\ \Lambda^2[\frac{1}{2}(x-1)\operatorname{erf}((x-1)/\sqrt{4t}) + \sqrt{t/\pi} e^{-(x-1)^2/4t}] & \text{if } t > 0, \end{cases}$$

where $\Lambda f(x) = f(x + 1) - f(x)$, and

$$u_3(x, t) = \begin{cases} \chi_{[-1,1]}(x) & \text{if } t = 0, \\ \frac{1}{2}[\operatorname{erf}((x+1)/\sqrt{4t}) - \operatorname{erf}((x-1)/\sqrt{4t})] & \text{if } t > 0, \end{cases}$$

where $\chi_{[-1,1]}(x)$ is zero for $|x| > 1$ and 1 otherwise. The first solution is smooth with K^2 sharp peaks of scales from 1 to $\frac{1}{K}$, and decays exponentially at infinity. The second is piecewise linear, continuous, Lipschitz, and piecewise smooth but not C^1 at $t = 0$. The third is discontinuous in x at $t = 0$ but smooth and sharply varying for $t > 0$. We used our method to compute u for ten timesteps equispaced from 0 to 1, beginning each triangulation with a 14×14 grid of square cells on the domain $[-7, 7]^2$ and using linear, quadratic, and cubic

interpolation with various error tolerances ϵ. We took $K = 10$, so each solution u_j varies over scales from 1 to 0.1. We used $p = 6$ and $I = 2$ to achieve error $\epsilon = 10^{-2}$ relative to $|u|_\infty$ at each step.

Table 1 reports the errors and times produced by Method 2.1 on these three temperature fields. Several conclusions can be drawn from Table 1. The method achieves the requested accuracy in every case. The time required for accuracy ϵ scales roughly like ϵ^{-1} for linear, $\epsilon^{-2/3}$ for quadratic, and $\epsilon^{-1/2}$ for cubic interpolation, as it should.

For purposes of comparison, the standard explicit nonadaptive finite difference method

$$u_{ij}^{n+1} = u_{ij}^n + \frac{\Delta t}{h^2}(\Lambda_i^2 + \Lambda_j^2)u_{i-1,j-1}^n$$

on a square $N \times N$ grid requires time $O(\epsilon^{-2})$ to attain accuracy ϵ. Indeed, this method has error $O(\Delta t + h^2)$ and is stable if $\Delta t \leq h^2/4$, so decreasing the error by a factor of 4 requires halving h and reducing Δt by 4. Since this method requires $O(h^{-2})$ work per step, we see that decreasing the error by a factor of 4 requires 16 times as much work, corresponding to $O(\epsilon^{-2})$. A fourth-order explicit method would need $O(\epsilon^{-1})$ work to achieve error less than ϵ.

Our method is relatively unfazed by nonsmooth or discontinuous initial temperature fields as long as they are bounded. It resolves the discontinuity as well as it can, and ends up with a very good approximation except on a very small area. The small area where the interpolant is inaccurate does not affect the total error, essentially because the heat equation is stable in L^1 as well as L^∞.

TABLE 1

Times and errors for the homogeneous free-space heat equation. Column N_0/N_1 displays the number of triangles in the triangulation at $t = 0$ and at $t = 1$, T is the total computing time for ten steps from $t = 0$ to $t = 1$, and E is the maximum error, divided by the maximum of the solution. Results for lower-degree interpolation with small ϵ, shown with dashes, were too time consuming and were omitted.

One feature that is not apparent from the tables is that evaluation of u is more costly than evaluation of the coefficients. Typically the code spends 80% of its time evaluating u and only 20% evaluating coefficients. This is partly due to inefficiency; the refinement test we use wastes many evaluations of u when the grid is almost completed. We plan to address this admittedly minor point in future improvements.

Finally, we present some preliminary numerical results for the evaluation of the single layer potential

$$Sg(x,t) = \int_0^t \int_{\Gamma(t')} \frac{e^{-|x-y|^2/4(t-s)}}{4\pi(t-s)} g(y,s)\,dy\,ds.$$

In order to compute the error, we took a very simple case with $g = 1$ and $\Gamma(t)$ a stationary circle with center (0, 0) and radius 1.1. (Of course, we coded the method for a general curve and density.) We computed Sg on an adaptive grid using N steps until $t = 1$, setting $\epsilon = 10^{-1}$ initially and reducing ϵ by a factor of 4 for each successive calculation. The triangulation with $\epsilon = 10^{-1}$ is shown in Fig. 6 at $t = 1$; the triangulation for this problem changes little over time.

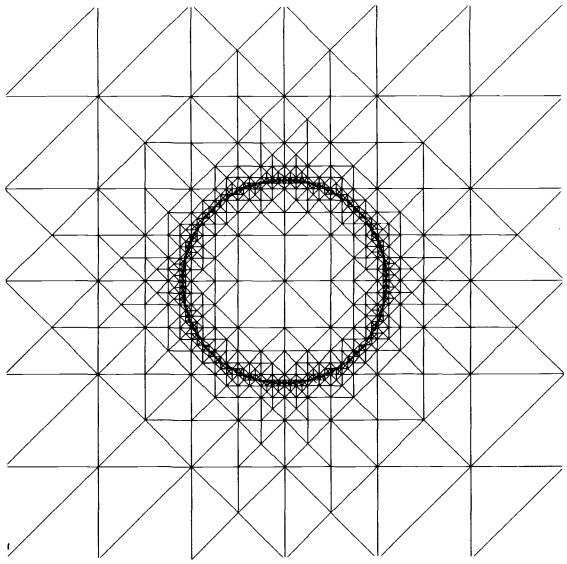

FIG. 6. *Triangulation for the single layer potential of unit density on a circle with center* (0, 0) *and radius* 1.1. *Here* $\epsilon = 10^{-2}$ *and* $t = 0.1$. *The smallest triangle has sides of length* 2^{-5} *times the maximum side length and there are* 1232 *triangles with* 5581 *nodes in the box* $[-3, 3]$. *The maximum level of subdivision was* 10. *The dotted circle is the curve* $\Gamma(t)$; *it is resolved to accuracy* $\epsilon' = 10^{-3}$ *with* 120 *line segments, subdivided further to have each line segment lie in a single cell.*

Table 2 presents numerical results for this calculation with $N = 10, 20, 40$ steps and cubic interpolation. T is the total computing time, E is the maximum error, divided by the maximum of the solution, and N_T is the number of triangles at $t = 1$.

TABLE 2

Times and errors for the single-layer heat potential; T is the total computing time for N steps from $t = 0$ *to* $t = 1$, *and E is the maximum error, divided by the maximum of the solution.*

Δt	h	p	I	N_T	T	E
0.1	1.33	8	1	218	79	.58−1
0.05	0.923	10	2	520	1104	.15−1
0.025	0.632	11	2	1220	6694	.37−2

We conclude that the method is expensive but accurate; perhaps its best feature is the elimination of product integration.

8. Conclusions. We have described an efficient adaptive approach to several heat flow problems that arise in physics. The simplest is the homogeneous free-space heat equation, for which we constructed several methods. All are based on the Hermite expansion of the heat kernel, combined with an adaptive triangulation scheme that represents a given function f as a piecewise polynomial within an error $\epsilon|f|_\infty$. Another key ingredient is the idea of writing the solution as a *function* that can be evaluated at any point, rather than a set of values to be interpolated.

We then demonstrated how to construct methods for the inhomogeneous case, using Duhamel's principle, and how to evaluate layer potentials. We treated layer potentials as inhomogeneous problems with distributional right-hand sides and treated the time singularities by product integration. The Hermite expansion is highly useful here, because it makes it unnecessary to carry out product integration in space. Thus even for high-order curve representations such as cubic splines, we still need only to evaluate integrals of *monomials* over the curve; we do not have to integrate Gaussians over a cubic spline curve, which is very difficult or impossible to do exactly. The Hermite series approach also combines the accuracy of product integration with the speed of the fast algorithm; usually product integration and fast algorithms do not marry well, because fast algorithms depend on processing the source independently of the location of the target then evaluating. In this case, the product integration simply *postmultiplies* the output of the fast summation technique.

Numerical results show these methods to be efficient and accurate. They perform particularly well in spatially rough problems where considerable accuracy is required.

The present techniques are formulated for the heat equation. It is shown in [4] how to extend fast techniques for the heat equation to nonlinear parabolic problems, and a similar technique works for variable-coefficient linear problems. Thus the techniques presented in this paper seem likely to be broadly applicable.

Appendix A. Cartesian coefficients. The polynomial of degree d that interpolates given values of a function f at the nodes shown in Fig. 1 (for $d = 1, 2, 3$) is usually expressed in terms of the barycentric coordinates $\lambda_1(x, y), \lambda_2(x, y), \lambda_3(x, y)$ defined by

$$\begin{aligned} \lambda_1 + \lambda_2 + \lambda_3 &= 1, \\ x_1\lambda_1 + x_2\lambda_2 + x_3\lambda_3 &= x, \\ y_1\lambda_1 + y_2\lambda_2 + y_3\lambda_3 &= y, \end{aligned} \tag{30}$$

with $(x_i, y_i) = v_i$ the vertices of the triangle. The barycentric coordinates of a point v can be computed in terms of the components x and y of v, by

$$\lambda_i = a_i x + b_i y + c_i, \tag{31}$$

by solving (30).

The $(d + 1)(d + 2)/2$ nodes required for interpolation of degree d are shown in Fig. 1. The interpolants of degrees $d = 1, 2, 3$ at these nodes are given by [3]

$$f(x) = \sum_{i=1}^{3} \lambda_i f(v_i) \qquad (d = 1),$$

$$f(x) = \sum_{i=1}^{3} \lambda_i(2\lambda_i - 1) f(v_i) + \sum_{i<j} 4\lambda_i\lambda_j f(v_{ij}) \qquad (d = 2),$$

$$f(x) = \frac{1}{2}\sum_{i=1}^{3} \lambda_i(3\lambda_i - 1)(3\lambda_i - 2) f(v_i) + \frac{9}{2}\sum_{i\neq j} \lambda_i\lambda_j(3\lambda_i - 1) f(v_{iij}) + 27 \sum_{i<j<k} \lambda_i\lambda_j\lambda_k f(v_{ijk}) \qquad (d = 3).$$

The numbering of the nodes is shown in Fig. 1 and follows [3].

In the linear case, it is straightforward to transform from barycentric to Cartesian coordinates:

$$f(x, y) = (a \cdot f)x + (b \cdot f)y + (c \cdot f),$$

where $a \cdot f = \sum_{i=1}^{3} a_i f(v_i)$, and so forth.

For the quadratic case, we find after some tedious calculations that

$$f(x, y) = \sum_{|\alpha| \le 2} F_\alpha x^\alpha = F_{20}x^2 + F_{11}xy + F_{02}y^2 + F_{10}x + F_{01}y + F_{00},$$

where the Cartesian coefficients F_{ij} are given by

$$F_{20} = \sum_{i=1}^{3} 2a_i^2 f_i + \sum_{i<j} 4a_i a_j f_{ij},$$

$$F_{11} = \sum_{i=1}^{3} 4a_i b_i f_i + \sum_{i<j} 4(a_i b_j + a_j b_i) f_{ij},$$

$$F_{02} = \sum_{i=1}^{3} 2b_i^2 f_i + \sum_{i<j} 4b_i b_j f_{ij},$$

$$F_{10} = \sum_{i=1}^{3} 2a_i(4c_i - 1) f_i + \sum_{i<j} 4(a_i c_j + a_j c_i) f_{ij},$$

$$F_{01} = \sum_{i=1}^{3} 2b_i(4c_i - 1) f_i + \sum_{i<j} 4(b_i c_j + b_j c_i) f_{ij},$$

$$F_{00} = \sum_{i=1}^{3} 2c_i(2c_i - 1) f_i + \sum_{i<j} 4c_i c_j f_{ij}.$$

Here we have abbreviated $f_i = f(v_i)$, $f_{ij} = f(v_{ij})$, and so forth.

The calculations for the cubic case are even more tedious and lead to

$$\begin{aligned} f(x, y) &= \sum_{|\alpha| \le 3} F_\alpha x^\alpha \\ &= F_{30}x^3 + F_{21}x^2 y + F_{12}xy^2 + F_{03}y^3 \\ &\quad + F_{20}x^2 + F_{11}xy + F_{02}y^2 + F_{10}x + F_{01}y + F_{00}, \end{aligned}$$

with

$$F_{30} = \frac{9}{2}\sum_{i=1}^{3} a_i^3 f_i + \frac{27}{2}\sum_{i \ne j} a_i^2 a_j f_{iij} + 27a_1a_2a_3 f_{123},$$

$$\begin{aligned} F_{21} &= \frac{27}{2}\sum_{i=1}^{3} a_i^2 b_i f_i + \frac{27}{2}\sum_{i \ne j} a_i(a_i b_j + 2b_i a_j) f_{iij} \\ &\quad + 27(a_1a_2b_3 + a_1b_2a_3 + b_1a_2a_3) f_{123}, \end{aligned}$$

$$\begin{aligned} F_{12} &= \frac{27}{2}\sum_{i=1}^{3} b_i^2 a_i f_i + \frac{27}{2}\sum_{i \ne j} b_i(b_i a_j + 2a_i b_j) f_{iij} \\ &\quad + 27(b_1b_2a_3 + b_1a_2b_3 + a_1b_2b_3) f_{123}, \end{aligned}$$

$$F_{03} = \frac{9}{2}\sum_{i=1}^{3} b_i^3 f_i + \frac{27}{2}\sum_{i\neq j} b_i^2 b_j f_{iij} + 27 b_1 b_2 b_3 f_{123},$$

$$F_{20} = \frac{9}{2}\sum_{i=1}^{3} a_i^2(3c_i - 1) f_i + \frac{9}{2}\sum_{i\neq j} a_i(3a_i c_j + (6c_i - 1)a_j) f_{iij}$$

$$+ 27(a_1 a_2 c_3 + a_1 c_2 a_3 + c_1 a_2 a_3) f_{123},$$

$$F_{11} = 9\sum_{i=1}^{3} a_i b_i(3c_i - 1) f_i + \frac{9}{2}\sum_{i\neq j}(6a_i b_i c_j + a_i(6c_i - 1)b_j + b_i(6c_i - 1)a_j) f_{iij}$$

$$+ 27(c_1(a_2 b_3 + a_3 b_2) + c_2(a_1 b_3 + a_3 b_1) + c_3(a_1 b_2 + a_2 b_1)) f_{123},$$

$$F_{02} = \frac{9}{2}\sum_{i=1}^{3} b_i^2(3c_i - 1) f_i + \frac{9}{2}\sum_{i\neq j} b_i(3b_i c_j + (6c_i - 1)b_j) f_{iij}$$

$$+ 27(b_1 b_2 c_3 + b_1 c_2 b_3 + c_1 b_2 b_3) f_{123},$$

$$F_{10} = \frac{1}{2}\sum_{i=1}^{3} a_i(27c_i^2 - 18c_i + 2) f_i + \frac{9}{2}\sum_{i\neq j}(a_i(6c_i - 1)c_j + c_i(3c_i - 1)a_j) f_{iij}$$

$$+ 27(a_1 c_2 c_3 + c_1 a_2 c_3 + c_1 c_2 a_3) f_{123},$$

$$F_{01} = \frac{1}{2}\sum_{i=1}^{3} b_i(27c_i^2 - 18c_i + 2) f_i + \frac{9}{2}\sum_{i\neq j}(b_i(6c_i - 1)c_j + c_i(3c_i - 1)b_j) f_{iij}$$

$$+27(b_1 c_2 c_3 + c_1 b_2 c_3 + c_1 c_2 b_3) f_{123},$$

$$F_{00} = \frac{1}{2}\sum_{i=1}^{3} c_i(3c_i - 1)(3c_i - 2) f_i + \frac{9}{2}\sum_{i\neq j} c_i(3c_i - 1)c_j f_{iij} + 27 c_1 c_2 c_3 f_{123}.$$

A NONLINEAR VARIATIONAL PROBLEM FOR IMAGE MATCHING*

YALI AMIT†

Abstract. Minimizing a nonlinear functional is presented as a way of obtaining a planar mapping that matches two similar images. A smoothing term is added to the nonlinear functional to penalize discontinuous and irregular solutions. One option for the smoothing term is a quadratic form generated by a linear differential operator. The functional is then minimized using the Fourier representation of the planar mapping. With this representation the quadratic form is diagonalized. Another option is a quadratic form generated via a basis of compactly supported wavelets. In both cases, a natural approximation scheme is described. Both quadratic forms are shown to impose the same smoothing. However, in terms of the finite dimensional approximations, it is easier to accommodate local deformations using the wavelet basis.

1. Introduction.

Let F and G be smooth functions on the two-dimensional unit square I^2, and let $\phi(x)$ be a mapping of the unit square into itself, such that $G(x) = F(\phi(x))$. It is clear that if F and G have the same range, many such mappings exist, most of which would be highly discontinuous and degenerate and not very interesting. However, if the mapping $\phi(x)$ is a smooth diffeomorphism of the unit square onto itself, then the extremal points of F would be mapped via ϕ^{-1} onto the extremal points of G, level curves would be mapped onto level curves, etc. Heuristically speaking, the graphs of F and G considered as surfaces would have similar topographies. Conversely, if F and G have similar topographies, then it should be possible to find a smooth and locally nondegenerate mapping ϕ such that $F(\phi(x))$ is close to G in some sense.

To illustrate this idea, consider the images in Fig. 1, which are x-rays of two different hands. If we consider the images as some smooth function sampled at the points of the pixel lattice, we obtain two functions that indeed have very similar topographies. This would be the case with any two images of some fixed organ of the body of two different patients, or of the same patient obtained at different times, provided that these images came from the same type of imaging device. Consequently, there should exist a smooth and locally nondegenerate mapping ϕ that transforms one image, called the *template*, into the other image, called the *data*, via composition. The mapping ϕ would automatically match between the corresponding parts of the two images. See, for example, Fig. 1 where the various parts of the hand such as the tips of the fingers or the joints are correctly matched.

One of the first attempts dealing with the issue of image matching can be traced to Horn and Schnuck [5] and Huang and Tsai [6] in the context of optical flow and movement compensation calculations for sequences of images. These ideas were further developed by Nagel [10] and Terzopoulos [11]. In Bajcy and Kovacic [2] these ideas were applied to the issue of matching medical images of similar organs, such as MRI images of the brain. Here the matching is not intended to calculate movement, but to automate the analysis of medical images. This second problem is also more difficult in that large deformations may occur, as opposed to relatively small deformations in image sequences.

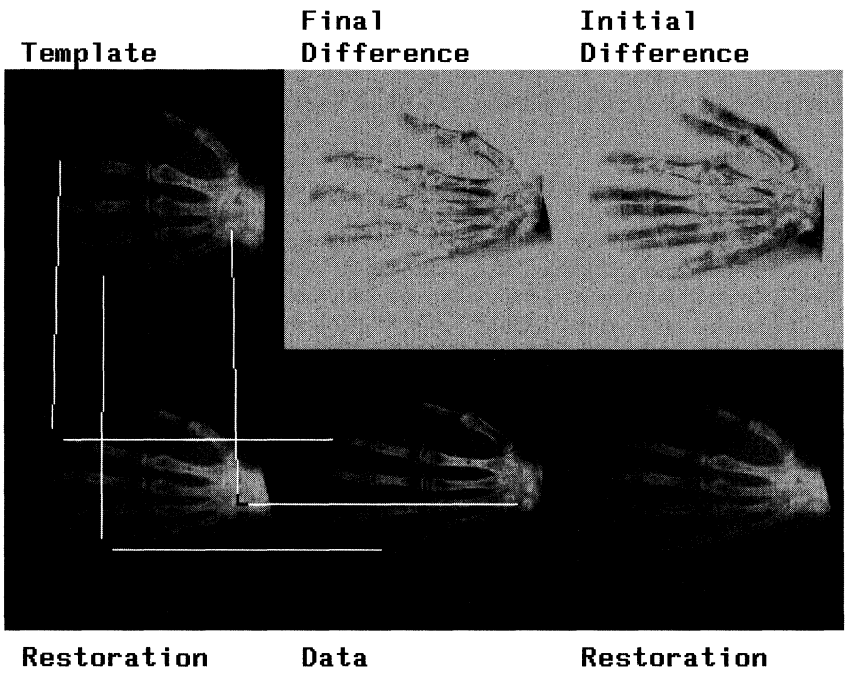

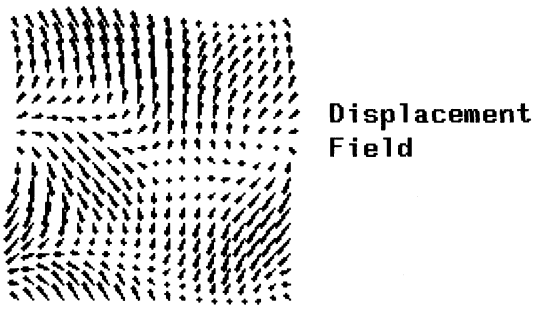

FIG. 1. *The template corresponds to the function F and the data to the function G. The restoration was done using the Fourier method. The white lines show the matching induced by the displacement field. A point x in the data is connected via the restoration to the point $x + \overline{U}(x)$ from which it obtained its grey level value. The final difference image shows $1 - |F(x + \overline{U}(x)) = G(x)|$ and the initial difference image shows $1 - |F(x) - G(x)|$.*

The question is how to find the mapping ϕ. We have addressed this problem by minimizing the following functional:

$$I(U) = \frac{1}{2}\int_{T^2} |F(x + U(x)) - G(x)|^2 dx, \tag{1}$$

where $U(x) = \phi(x) - x$ is the displacement field and T^2 is the unit torus. Minimizing I over some set of vector fields provides a mapping $\phi(x) = x + U(x)$ of the torus into itself, such that $F \circ \phi(x)$ is close in the mean square norm to G.

It should be noted that the periodic domain is chosen for the sake of notational and computational convenience. It takes care of the problem of what to do when $x + U(x)$ is not

in I^2. Another possibility is that F is defined on some large domain D that includes I^2. Then one would want to minimize over mappings from I^2 into D.

To rule out the discontinuous and irregular solutions to this minimization problem, it is possible to introduce a smoothing or regularizing term, thus obtaining a new functional

$$J(U) = \alpha \mathcal{E}(U, U) + \frac{1}{2} \int |F(x + U(x)) - G(x)|^2 dx, \tag{2}$$

where $\mathcal{E}$ is a bilinear form penalizing nonsmooth functions. In all our applications, $\mathcal{E}$ was taken to be a Hilbertian norm equivalent to one of the Sobolev norms. Since the domain under consideration is two dimensional, taking the Sobolev norm to be of order greater or equal to two will ensure that the solutions are continuous. Higher-order Sobolev norms will, of course, introduce additional smoothness. This approach was first described in a statistical setting by Amit, Grenander, and Piccioni [1].

The functional J is nonlinear and may have many global and local minima. In the sequel we will be interested mainly in finding local minima of J close to the initial point $U(x) \equiv 0$ *that corresponds to the identity map*. The nondegeneracy of the mapping $\hat{\phi}$ generated by a local minimizer $\hat{U}$ is then ensured by the fact that it is close to the identity map so that its Jacobian is nonzero at most points.

There are several major differences between the work mentioned above and the approach presented here. First, we do not use a data term derived from intensity conservation assumptions originally suggested by Horn and Schnuck [5], which is equivalent to linearizing the functional I as described at the end of §2. It appears that the linearized problem will not capture larger deformations (see Fig. 2).

Second, the solution of the variational problem is obtained by parametrizing the unknown function in terms of its coefficients with respect to either the Fourier basis or some wavelet basis, thus allowing for a coarse-to-fine or multiresolution approach. This was indeed suggested in [11] using multigrid techniques, which may be appropriate for the linearized equations that have a unique solution and are known to be efficiently soluble using multigrid techniques. However, given that the nonlinear functional is to be used, and that this nonlinear functional is not convex, it is not clear how well the classical multigrid approach will perform. The coarse level displacement is calculated using only the information of a smooothed version of the data on that same coarse grid, and there is some risk of information being lost. Moreover, when moving to finer grids, a bilinear interpolation is used that may not be smooth enough and that may introduce unnatural deformations.

Setting the problem in terms of an orthonormal basis directly incorporates interpolation through the basis functions. The smoothing operator is automatically written in diagonal form in terms of the basis chosen. Thus using the description in terms of a basis expansion, and solving first for low-frequency coefficients, gradually increasing the number can be thought of as a multigrid method translated onto the finest grid. Although some computational speed is lost, the advantage is that all the data is used to drive the algorithm.

The level of smoothness versus locality can be controlled by the choice of wavelet basis. Since the problem at hand is not really governed by physical fluid dynamical or elasticity laws, there is no special advantage in using the Laplacian as a smoothing operator. The existence of fast transforms for these bases makes the algorithm computationally feasible.

In §2 the smoothing term $\mathcal{E}$ is set to be a quadratic form generated by a linear differential operator. The approximations are then described together with minimization procedure. The basic idea is to diagonalize the differential operator using the Fourier basis and to solve the problem in the spectral domain.

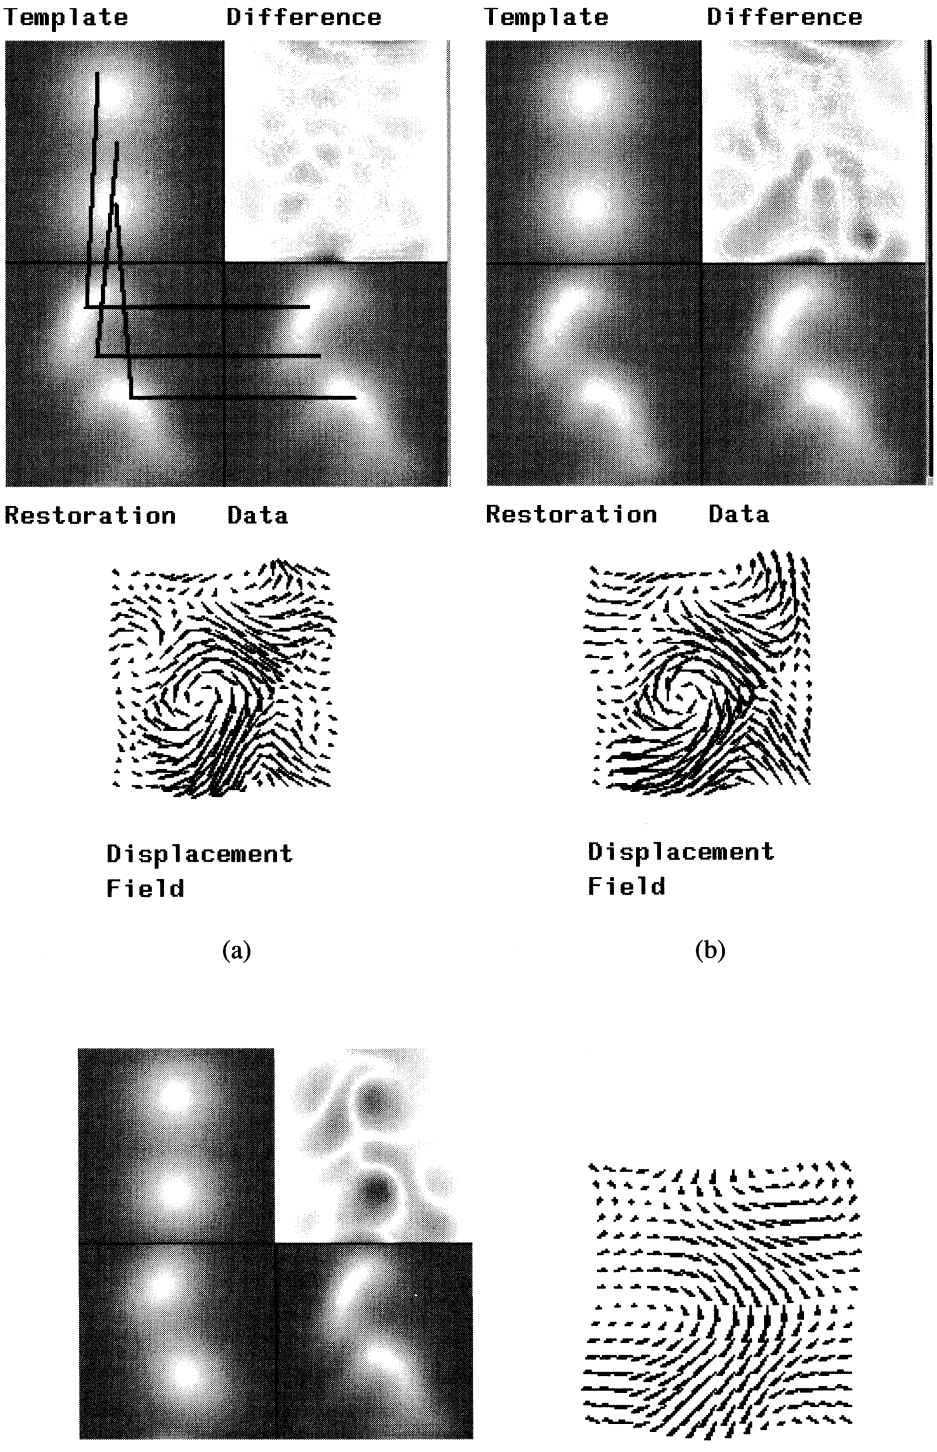

FIG. 2. *A transformation constructed with the Fourier basis was initially applied to the template to generate the data.* (a) *was done using the Fourier basis.* (b) *was done using the wavelet basis.* (c) *was done using the linearized equations.*

In §3 an alternative smoothing term is suggested. This time $\mathcal{E}$ is directly given in a diagonal form using a wavelet basis instead of the Fourier basis. The eigenvalues are set so as to ensure the same type of smoothing.

In §4 the experiments are described, and the performance of the two approaches is compared.

2. A nonlinear partial differential equation. Consider the bilinear form

$$B(f, g) = \frac{1}{2}\int_{T^2} (\Delta + \varepsilon)^2 f(x) \cdot g(x)dx,$$

where Δ denotes the Laplacian with periodic boundary conditions. This bilinear form defines a Hilbertian norm equivalent to the standard Sobolev norm on $H = H^2(T^2)$. Set $\varepsilon(U, U) = B(U^{(1)}, U^{(1)}) + B(U^{(2)}, U^{(2)})$ in (2). With this choice of the bilinear form in the functional J, the Euler equation for the minimizer is the following nonlinear partial differential equation (PDE):

$$\alpha(\Delta + \varepsilon)^2 U^{(1)} = (G(x) - F(x + U(x)))\frac{\partial F}{\partial x_1}(x + U(x)),$$
$$\alpha(\Delta + \varepsilon)^2 U^{(2)} = (G(x) - F(x + U(x)))\frac{\partial F}{\partial x_2}(x + U(x)).$$

The parameter α determines the relative weight of the regularizing term. Since the issue of the choice of α is not addressed here, we set $\alpha = 1$. This is the parameter used in the experiments as well.

For the purpose of numerical solutions, it is, of course, necessary to find finite-dimensional approximations to the functional J. Since the spectral decomposition of Δ is known, it is convenient to write J in the spectral domain and then approximate it coordinatewise. Let λ_{kl}, ϕ_{kl} denote the eigenvalues and eigenvectors of Δ, then

$$\lambda_{kl} = (2\pi)^2(k^2 + l^2) + \varepsilon \quad \text{and} \quad \phi_{kl}(x_1, x_2) = e^{2\pi i(kx_1 + lx_2)},$$

and the functional J can be rewritten as

$$J(U) = \sum_{k,l=-\infty}^{\infty} \lambda_{kl}^2((u_{kl}^{(1)})^2 + (u_{kl}^{(2)})^2)$$
$$+ \int \left[F\left(x_1 + \sum u_{kl}^{(1)}\phi_{kl}(x), x_2 + \sum u_{kl}^{(2)}\phi_{kl}(x)\right) - G(x)\right]^2 dx$$
$$= \Gamma(u^{(1)}, u^{(2)}) + q(u^{(1)}, u^{(2)}),$$

where $u_{kl}^{(i)} = \int U^{(i)}(x)\phi_{kl}(x)dx$. The vector $(u^{(1)}, u^{(2)}) \in \ell_2 \times \ell_2$, is simply the coordinate vector of $(U^{(1)}, U^{(2)})$ with respect to the basis ϕ_{kl} of $L_2(T^2)$. We write $(u^{(1)}, u^{(2)}) = \pi(U^{(1)}, U^{(2)})$. Note that $q(u^{(1)}, u^{(2)}) = I(U^{(1)}, U^{(2)})$ with I as in (1).

The finite dimensional approximations of the functional are obtained by taking the sums in the linear term and those in the integrand between $-(N-1)$ and N. The approximation is therefore obtained by restricting the argument of J to the space $H_N \times H_N$, where $H_N = \operatorname{span}\{\phi_{kl}\}_{k,l=-(N-1)}^{N}$. The dimension of the approximate space H_N is $(2N)^2$ and $\pi(H_N \times H_N) = R^{(2N)^2} \times R^{(2N)^2}$.

Let J_N denote the approximate functional on $H_N \times H_N$. Each of the finite dimensional functionals is positive and continuous. Moreover, $J_N(U) \to \infty$ as $U \to \infty$ and therefore has at least one global minimum. Let S_N be the set of global minima of J_N.

THEOREM. *Let $U_N \in S_N$ for $N = 1, 2, \ldots$. Then U_N has a convergent subsequence in $H \times H$, which converges to a global minimum of J.*

Proof. Consider $H \times H$ with the Hilbertian norm defined by $\mathcal{E}(\cdot, \cdot)$. Since $H \times H$ is compactly imbedded in $C(T^2) \times C(T^2)$, $|U_N - U|_{H\times H} \to 0$ implies uniform convergence that, in turn, implies that $G(x + U_N(x)) \to G(x + U(x))$, as $N \to \infty$. Since G and F are bounded, it follows from the dominated convergence theorem that $I(U_N) \to I(U)$. Clearly, $\mathcal{E}(U_N, U_N) \to \mathcal{E}(U, U)$, so that J is continuous in H.

Now $J_N(U_N)$ is a positive monotonically decreasing sequence so that it converges to some value L. Moreover, since U_N is the global minimum of J in $H_N \times H_N$, and since $\cup_{N=1}^{\infty}(H_N \times H_N)$ is dense in $H \times H$, it follows from the continuity of J that $L = \inf_{U\in H\times H} J(U)$.

Since $|U_N|_{H\times H} = \mathcal{E}(U_N, U_N) < J_N(U_N) < J_1(U_1)$ for all $N = 1, 2, \ldots$ the sequence U_N is weakly compact. Let U_{N_k} be a subsequence that converges weakly to some $U \in H \times H$. Again, since H is compactly embedded in $C(T^2)$, U_{N_k} converges in the uniform norm to U as $k \to \infty$. As above, this implies that $I(U_{N_k}) \to I(U)$. Together with the fact that $J(U_{N_k})$ converges, we conclude that $\mathcal{E}(U_{N_k}, U_{N_k})$ converges to $L - I(U)$ as $k \to \infty$.

Now since the norm function is lower semicontinuous in the weak topology, we have $\mathcal{E}(U, U) \le L - I(U)$, and since L is the infimum, we have $\mathcal{E}(U, U) + I(U) = L$ and $\mathcal{E}(U, U) = \lim_{k\to\infty} \mathcal{E}(U_{N_k}, U_{N_k})$. This, together with the weak convergence of U_{N_k} to U, implies strong convergence in H. Finally, since $J(U) = L$, it is a global minimum of J. □

Observe that by using the same arguments as above, it is possible to show that the set of global minima of J is compact in H.

Practical considerations. In practice, the template and the data are images and are given only on a discrete pixel lattice of equally spaced points $x_{\alpha\beta}$, $\alpha, \beta = 0, \ldots, L-1$ in I^2. The unknown displacement field U is given in terms of its array of values at the points of the lattice, which will also be denoted by U. We write $U_{\alpha\beta} = U(x_{\alpha\beta})$ for all $\alpha, \beta = 0, \ldots, L-1$. The approximate functional J_N now has the form

$$J_N(U) = \sum_{k,l=-(N-1)}^{N} \lambda_{kl}((u_{kl}^{(1)})^2 + (u_{kl}^{(2)})^2) + \frac{1}{L^2}\sum_{\alpha,\beta=0}^{L-1}\left[F(x_{\alpha\beta} + U_{\alpha\beta}) - G(x_{\alpha\beta})\right]^2. \tag{3}$$

The array $u_{k,l}$, $k, l = -(N-1), \ldots, N$ is the discrete Fourier transform of the array U, i.e.,

$$u_{kl}^{(i)} = \frac{1}{L^2}\sum_{\alpha,\beta=0}^{L-1} U_{\alpha\beta}^{(i)}\phi_{kl}(x_{\alpha\beta}),$$

and we write $u^{(i)} = \pi(U^{(i)})$. Since F is actually given only on the lattice, and $x_{\alpha\beta} + U_{\alpha\beta}$ may not lie on the lattice, it is possible either to truncate to the nearest point or to use a linear interpolation between the four nearest points. The resolution of the pixel lattice is the finest, so that these corrections are negligible.

We have not tried to find the global minimum of the approximating functional. Instead, we have done gradient descent starting at initial point zero. In other words, the following ordinary differential equation (ODE) in $R^{(2N)^2} \times R^{(2N)^2}$ was solved.

$$\begin{aligned}\frac{du_{kl}^{(i)}(t)}{dt} &= -\lambda_{kl}u_{kl}^{(i)} \\ &\quad -\frac{1}{L^2}\sum_{\alpha,\beta=0}^{L-1}\left[F(x_{\alpha\beta} + U_{\alpha\beta}(t)) - G(x_{\alpha\beta})\right]\frac{\partial F}{\partial x_i}(x_{\alpha\beta} + U_{\alpha\beta}(t))\phi_{kl}(x_{\alpha\beta}).\end{aligned} \tag{4}$$

Writing

$$Z_{\alpha\beta}^{(i)}(t) = \left[F(x_{\alpha\beta} + U_{\alpha\beta}(t)) - G(x_{\alpha\beta})\right] \frac{\partial F}{\partial x_i}(x_{\alpha\beta} + U_{\alpha\beta}(t)), \tag{5}$$

the second term in (4) is simply $(\pi(Z^{(i)}(t)))_{kl}$. The choice of initial point zero is motivated by the fact that the mapping generated by the solution is expected to be in some neighborhood of the identity map. The symmetric difference approximation of the derivatives of F was used.

It was found that minimizing all $2(2N)^2$ coefficients at once for large N is not the best approach. It might be preferable to start out in a low-dimensional space and gradually to increase the dimension until the desired maximum dimension is reached. The initial point in each space is then taken as the local minimum obtained in the previous space. This procedure is also faster. Heuristically, this can be interpreted as matching global features in low-dimensional spaces and moving on to the finer details as the dimension increases.

The algorithm is described as follows.

(i) Set $N = 0$, initial condition $u(0) = 0$.

(ii) Find local minimum $\hat{u}_N$ for J_N, starting from $u(0)$.

(iii) Set $N \to N + 1$ and $u_{kl}^{(i)}(0) = \begin{cases} (\hat{u}_N^{(i)})_{kl} & \text{for } -N < k, l \leq N, \\ 0 & \text{otherwise.} \end{cases}$

(iv) Go to (ii).

Step (ii) is carried out by a simple Euler method.

(a) Fix time step dt, set $t = 0$.

(b) Generate $U(t)$ from $(u^{(1)}(t), u^{(2)}(t))$-inverse DFT, $U^{(i)} = \pi^{-1}(u^{(i)})$ or

$$U_{\alpha\beta}^{(i)}(t) = \sum_{k,l=-N+1}^{N} u_{kl}^{(i)}(t)\phi_{kl}(x_{\alpha\beta}), \qquad \alpha, \beta = 0, \ldots, L-1.$$

(c) Carry out quadrature (in (4)) for each eigenvector ϕ_{kl}-DFT, $V^{(i)}(t) = \pi(Z^{(i)}(t))$ or

$$V_{kl}^{(i)}(t) = \frac{1}{L^2} \sum_{\alpha,\beta=0}^{L-1} F(x_{\alpha\beta} + U_{\alpha\beta}(t)) \frac{\partial F}{\partial x_i}(x_{\alpha\beta} + U_{\alpha\beta}(t))\phi_{kl}(x_{\alpha\beta}).$$

(d) Add the linear term and carry out Euler step.

$$u_{kl}^{(i)}(t+1) = u_{kl}^{(i)}(t) - dt \cdot \left[V_{kl}^{(i)}(t) + \lambda_{kl} u_{kl}^{(i)}(t)\right].$$

If difference is smaller than tolerance, set $\hat{u}_N = u(t+1)$ and go to (iii).

(e) Go to (b).

The time-consuming parts of the algorithm are steps (b) and (c). One option is to apply a fast Fourier transform (FFT) and an inverse FFT. The dimensions of these FFTs are determined by the size of the pixel lattice on which F and G are defined, i.e., 128×128 or 256×256. However, when N is very small, or when the dimensions of the pixel lattice are not powers of two, it may be faster to actually carry out the quadrature in step (c) for those frequencies that are being updated and to carry out the summation in step (b) for all points (α, β) on the lattice.

In some cases it is possible to carry out the quadrature in (c) on a coarser lattice than the original pixel lattice; then, of course, the summation in (b) is only done for the points on the coarse lattice. This is particularly true when F and G are smooth functions. This is related to the multigrid approach suggested in [11]. However, in [11] the number of unknowns is

equal to the number of points used and this seems to be insufficient. This is also the case for the pseudospectral methods described below. In the experiments described here the algorithm did not produce much improvement for $N > 10$, and at low frequencies the coarse lattice quadrature method is indeed faster than the FFT method.

In some experiments it was useful to actually smooth out the template and the data through some low-pass filter (see Figs. 3 and 4). This tends to single out global topological features and eliminate local ones. In this case the coarse lattice quadrature is very appropriate. For images 128×128, one could work with a 16×16 lattice for the first four or five frequencies and get good results.

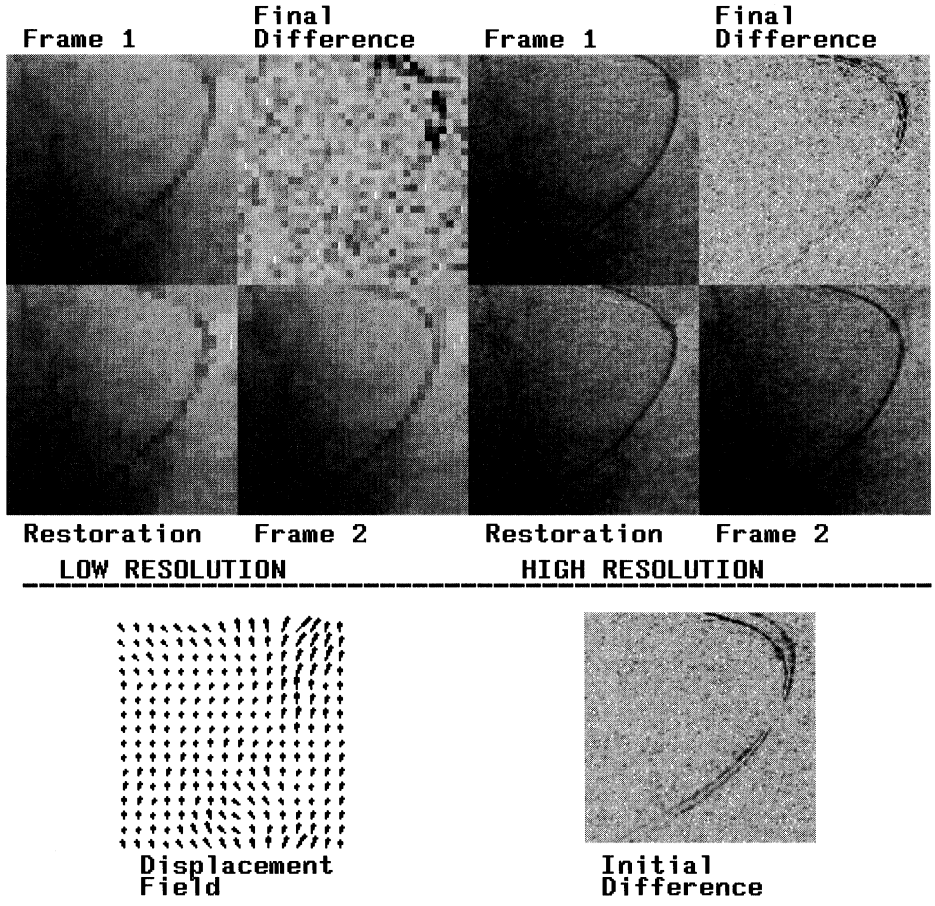

FIG. 3. *Frames* 1 *and* 2 *are two subsequent pictures from an x-ray of a catheter inserted into an artery. Frame* 1 *is used as the template and Frame* 2 *as the data. The displacement field is found by using the wavelet method at the low resolution, and then applied to the high-resolution template (Frame* 1*). The black line in the restoration is almost perfectly aligned with the black line in the second frame.*

If the full lattice has $L \times L$ pixels and the coarser lattice has $K \times K$ pixels, the number of floating-point multiplications used in this method is of order $K^2 \cdot N^2$, with N being the number of frequencies, whereas using the full FFT would be approximately $L^2 \cdot \log L^2$. Thus, depending on the number of frequencies to be used, it is possible to choose which is the most appropriate. As a rule, K, the number of quadrature points, should be greater than N, the

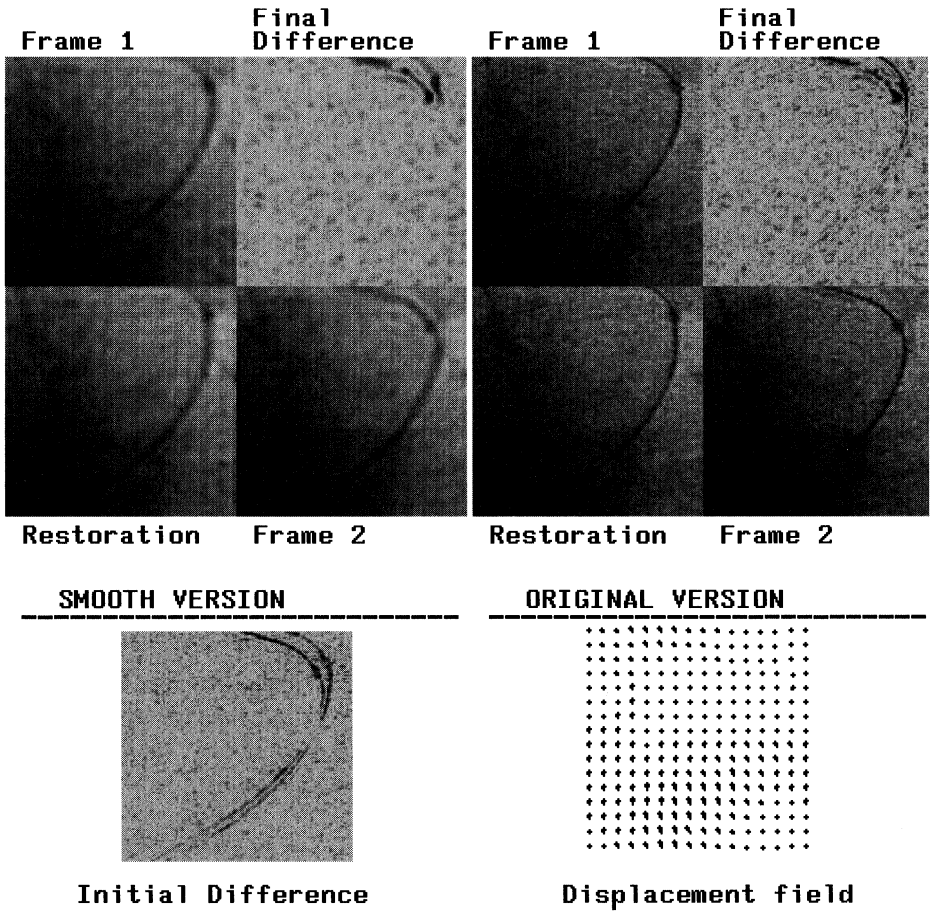

FIG. 4. *The same setting as in Fig.* 3. *The restoration is done using the Fourier basis. The line in the restoration is not aligned at the upper right-hand corner.*

number of frequencies being solved. For high frequencies the coarse lattice approximation is therefore not suitable, in which case it is clearly advantageous to use the FFT.

Another method is the pseudo-spectral method described by Gottlieb, Hussaini, and Orszag in [4]. Since one does not expect to solve, say, for $N > K$ (namely, the solution that is assumed to be in $H_K \times H_K$) using the periodic version of the sampling theorem, one can write

$$U^{(i)}(x) = \sum_{\alpha,\beta=0}^{K-1} U_{\alpha\beta}^{(i)} S_{\alpha\beta}(x),$$

where $S_{\alpha\beta}(x)$ are trigonometric polynomials and $x_{\alpha\beta}$, $\alpha, \beta = 0, \ldots, K-1$ are equally spaced points on the unit square called the collocation points. Thus

$$\Delta^2 U^{(i)}(x) = \sum_{\alpha,\beta=0}^{K-1} U_{\alpha\beta}^{(i)} \Delta^2 S_{\alpha\beta}(x).$$

If the quadrature in (3) is carried out on the $K \times K$ lattice of collocation points, then the

gradient descent equation has the form

$$\frac{dU_{(i)\gamma\delta}(t)}{dt} = -\sum_{\alpha\beta} U^{(i)}_{\alpha\beta}(t)(\Delta^2+\varepsilon)S_{\alpha\beta}(x_{\gamma\delta}) - \left[F(x_{\gamma\delta}+U_{\gamma\delta}(t)) - G(x_{\gamma\delta})\right]\frac{\partial F}{\partial x_i}(x_{\gamma\delta}+U_{\gamma\delta}(t)),$$

for $\gamma, \delta = 0, \ldots, K-1$. Now since the minimization is taking place in the space domain, the coupling between the equations occurs in the smoothing term and not in the data term. The derivatives of the functions S at all collocation points can be calculated off-line and stored as a matrix.

The discrete time iterations for this ODE require only one time-consuming step, the summation, as opposed to the previous schemes that had two time-consuming steps. If a $K \times K$ lattice of collocation points is used, the number of floating-point multiplications is approximately K^4.

The disadvantage of this method lies in the fact that the number of frequencies being updated is equivalent to the number of collocation points used. Thus if only very low frequencies are to be updated, very few collocation points are used and they are insufficient to obtain a good result. On the other hand, if more collocation points are used, the solution obtained involves higher frequencies at the start and this might be undesirable. There is also no natural way to gradually increase the dimension of approximation.

As mentioned in the Introduction, a further possibility would be to linearize the functional by substituting $F(x) + \nabla F(x) \cdot U(x)$ for $F(x + U(x))$ in $I(U)$. Then we obtain a quadratic form in $U(x)$, or in the coefficients u_{kl}, which has a unique minimum. The Euler equations for this functional are precisely those suggested by Horn and Schnuck [5]:

$$\alpha(\Delta+\varepsilon)^2 U^{(1)} + (\nabla F \cdot U)\frac{\partial F}{\partial x_1} = (G(x)-F(x))\frac{\partial F}{\partial x_1},$$
$$\alpha(\Delta+\varepsilon)^2 U^{(2)} + (\nabla F \cdot U)\frac{\partial F}{\partial x_2} = (G(x)-F(x))\frac{\partial F}{\partial x_2}.$$

Experiments with this option have not led to satisfactory results; see §4 and Fig. 2.

The disadvantage of the various spectral methods described above is the use of the Fourier basis whose functions have global support. This makes local changes in U or in the mapping ϕ difficult to achieve. A very attractive alternative is the wavelet basis.

3. The wavelet method. Using a periodic wavelet basis obtained from certain types of compactly supported wavelets, it is possible to rewrite the functional J in such a way that the same regularization is achieved with a different bilinear form. First, a brief survey of various results regarding these wavelets. For a detailed description of the discrete wavelet transform used in the experiments see the Appendix.

Periodic wavelets. Let ψ be a compactly supported wavelet as constructed by Daubechies in [3] with support in $[-R, R]$. Let ϕ be the corresponding function that generates the multiresolution analysis. Observe that ϕ has compact support on $[0, 2R]$. Define $\psi^P_{nk}(x) = 2^{n/2}\sum_{l=-\infty}^{\infty}\psi(2^n(x-l)-k)$, and $\phi^P_{nk}(x) = 2^{n/2}\sum_{l=-\infty}^{\infty}\phi(2^n(x-l)-k)$ for $0 \le x \le 1$. All the functions with superscript P are periodic with period 1, and if $k = 2^n$, then $\psi^P_{nk} = \psi^P_{n0}$, similarly for ϕ^P. The number of terms in these sums is determined by the support of ψ and is bounded by $2R$. For $n > r = \log_2 R + 1$ there are at most two terms in the sum.

For small n the functions ψ^P_{nk} cannot be expressed as scales and shifts of $\psi^P_{00}(x) \equiv \psi^P$. However, for $n > r$, we have $\psi^P_{(n+1)k}(x) = \sqrt{2}\psi^P_{n0}(2x-k)$, where the argument is considered modulo 1 or on the unit circle. Moreover, the family of functions ψ^P_{nk} for $n = 0, 1, \ldots$ and

$k = 0, 1, \ldots, 2^n - 1$ together with the function $\phi_{00}^P \equiv \mathbf{1}$ form an orthonormal basis. Let $V_0 = \text{span}\{\phi_{00}^P\}$ (i.e., the constant functions) and $W_n = \text{span}\{\psi_{nk}^P\}_{k=0}^{2^n-1}$. Using the fact that the ordinary wavelet basis spans $L_2(R)$, it is not hard to verify that

$$L_2(T^1) = V_0 \oplus \oplus_{n=1}^{\infty} W_n,$$

where T^1 is the one-dimensional torus. All that is necessary is to extend a periodic function f to a function $F \in L^2(R)$ by making $2R$ copies to the right and to the left of the unit interval and leaving the rest zero. Expanding F in the ordinary wavelet basis, we find that the part supported on [0, 1] can be given in terms of the functions $\mathbf{1}$ and ψ_{nk}^P; see [9, Chap. III, §11].

By [3] for sufficiently large R, the functions ψ and ϕ are twice differentiable and the first two moments of ψ are zero. Hence by [9, Chap. II, Thm. 8], $f \in H_2(T)$ if and only if

$$C(f, f) = f_{00}^2 + \sum_{n=1}^{\infty} \sum_{k=0}^{2^n-1} f_{nk}^2 (1 + 4^{2n}) < \infty,$$

where $f_{00} = \int f(x)dx$ and $f_{nk} = \int f(x)\psi_{nk}^P(x)dx$. This implies, via the closed graph theorem, that the Hilbert norm $C(f, f)$ defined above is equivalent to the Sobolev norm.

In two dimensions let

$$\Phi_{nkl}^P(x) = \phi_{nk}^P(x_1)\phi_{nl}^P(x_2), \qquad \Psi_{nkl}^{P,a}(x) = \phi_{nk}^P(x_1)\psi_{nl}^P(x_2),$$
$$\Psi_{nkl}^{P,b}(x) = \psi_{nk}^P(x_1)\phi_{nl}^P(x_2), \qquad \Psi_{nkl}^{P,c}(x) = \psi_{nk}^P(x_1)\psi_{nl}^P(x_2).$$

Let V_0 denote the constant functions and

$$W_n^{(a)} = \text{span}\left\{\Psi_{nkl}^{P,a}\right\}_{k,l=0}^{2^n-1}, \qquad n = 1, \ldots, \infty,$$

similarly for b and c. Setting $W_n = W_n^{P,a} \oplus W_n^{P,b} \oplus W_n^{P,c}$, we can show that

$$L_2(T^2) = V_0 \oplus \oplus_{n=1}^{\infty} W_n.$$

As in one dimension, $f \in H^2(T^2)$ if and only if

$$C(f, f) = f_{00}^2 + \sum_{n=1}^{\infty} \sum_{k,l=0}^{2^n-1} (1 + 4^{2n}) \left((f_{nkl}^{(a)})^2 + (f_{nkl}^{(b)})^2 + (f_{nkl}^{(c)})^2 \right) < \infty,$$

where $f_{nkl}^{(a)} = \int f(x)\psi_{nkl}^{P,a}(x)dx$, similarly for b and c. Consequently, it is possible to redefine $\varepsilon(U, U)$ in the functional J as $C(U^{(1)}, U^{(1)}) + C(U^{(2)}, U^{(2)})$ to obtain the same regularization as before. Now the finite dimensional spaces are given by

$$H_N = V_0 \oplus \oplus_{n=0}^{N-1} W_n.$$

Thus the regularization on the infinite dimensional space is the same as in the Fourier method; however, the sequence of approximations is different, and hence should lead to different types of solutions.

Observe that H_N is of dimension $2^N \times 2^N$. Moreover, for $f \in H_N$, the coefficients can be arranged in a $2^N \times 2^N$ array C so that $C_{00} = f_0$ and

$$C_{kl} = \begin{cases} f_{nkl}^{(a)} & \text{for } 2^n \le k < 2^{n+1} \quad \text{and } 0 \le l < 2^n, \\ f_{nkl}^{(b)} & \text{for } 0 \le k < 2^n \quad \text{and } 2^n \le l < 2^{n+1}, \\ f_{nkl}^{(c)} & \text{for } 2^n \le k < 2^{n+1} \quad \text{and } 2^n \le l < 2^{n+1}, \end{cases}$$

for $n = 1, \ldots, N - 1$.

Practical considerations. The algorithm itself proceeds very much like the one described in the previous section except that the Fourier transform is replaced by the two-dimensional wavelet transform. In practice, we are working with discrete data so that we use the discrete two-dimensional wavelet transform developed by Mallat in [8].

This transform takes the data D given on a discrete $2^N \times 2^N$ lattice as representing the coefficients of some function $f \in H_N$ on the unit square with respect to the functions Φ^P_{Nkl}, $k, l = 0, \ldots, 2^N - 1$. Think of f as an interpolation between the data values D_{ij} given on the discrete lattice using the compactly supported functions Φ^P_{nkl}. As above, the function f can be decomposed into its coefficients with respect to the wavelet basis. Let C denote this new $2^N \times 2^N$ array of coefficients, and write $C = W(D)$. Mallat [8] provides a very simple and fast algorithm for calculating $W(D)$, the forward wavelet transform, and $W^{-1}(C)$, the inverse wavelet transform. For the sake of completeness this is described in detail in the Appendix.

Now the algorithm described previously is modified as follows. Let $u^{(i)}$ describe the wavelet coefficients of $U^{(i)}$, i.e., $u^{(i)} = W(U^{(i)})$. In step (iii) we now have

$$u^{(i)}_{kl}(0) = \begin{cases} (\hat{u}_N)_{kl} & \text{for } 0 \le k, l < 2^N - 1, \\ 0 & \text{for } 2^N \le k < 2^{N+1} \quad \text{or} \quad 2^N \le l < 2^{N+1}. \end{cases}$$

In other words, when increasing the level of approximation $3 \cdot 2^N$ zeros are added for each component of the displacement field. In step (b) we have $U^{(i)}(t) = W^{-1}(u^{(i)}(t))$ and in step (c) $V^{(i)}(t) = W(Z^{(i)}(t))$ with $Z^{(i)}(t)$ as in (5). In step (d) the eigenvalues λ_{kl} are replaced by $\eta_{kl} = 1 + 4^{2n}$ for $2^n \le k < 2^{n+1}$, $0 \le l < 2^n$, or $0 \le k < 2^n$, $2^n \le l < 2^{n+1}$, or $2^n \le k < 2^{n+1}$, $2^n \le l < 2^{n+1}$.

In this approach the smoothing term is, of course, decoupled as before. In addition, since at higher frequencies ψ_{nk} have small support, the data parts of the equations are only *locally coupled.* This is in contrast to the Fourier approach in which *all* the equations are coupled through the data part.

This points to a clear advantage of the wavelet approach. It allows for local updates in problematic regions where the difference between $F(x + U(x))$ and $G(x)$ is still large, which has a relatively small effect on other regions where the difference is small.

The periodic setting we have chosen greatly facilitates the discrete algorithm by eliminating the need to store extra boundary terms at each level. Thus the size of the transformed data at each level of resolution is precisely that of the original data.

In practice we have used $R = 3$, which does not generate a wavelet smooth enough to apply the above-mentioned theorems; however, it performed well enough for our purposes.

The wavelet algorithm was tried using only the discrete transform. Due to its speed and ease of implementation there was no need to try the quadrature method for low-frequency coefficients. Moreover, instead of smoothing the data G and the template F as in the Fourier method, we take a lower resolution version of both, which consists of smoothing and sampling at the coarser grid (see the Appendix). The field U is found on the coarser grid. This field is then interpolated to the fine grid through the inversion formula (6) in the Appendix with the y coefficients set to zero (see Fig. 3). Again, this is similar to multigrid techniques; however, we did not apply it to a cascade of grids or continue the algorithm at the fine grid. This was merely a way to help the algorithm to "see" similar topological structures.

4. Description of experiments. In the first experiment (Fig. 1), the transformation between one x-ray of a hand, the template, to another, the data, is found and is used to automatically identify the location of important landmarks of the hand in the data image. The white lines connect points in the template to the points they are mapped to by the displacement field.

In this case, the tip of the index finger was successfully located in the data, whereas the tip of the little finger was slightly misplaced. The restoration has definitely succeeded in correcting the widths of the fingers and the palm. Observe that the fingers in the template are wider than those in the data, as is the palm of the hand. The absolute value of the initial difference between the images is shown as compared to the absolute value of the difference between the restoration image and the data. The black area indicates large differences.

In the second experiment (Fig. 5), the restoration on the right represents the result using a fixed dimension, whereas the restoration on the left used a sequence of increasing dimensions. The maximum dimension used was $N = 7$. Using the increasing dimension method not only produces a better result, but is also much faster when the Fourier transform is calculated via quadrature only for the frequencies being updated.

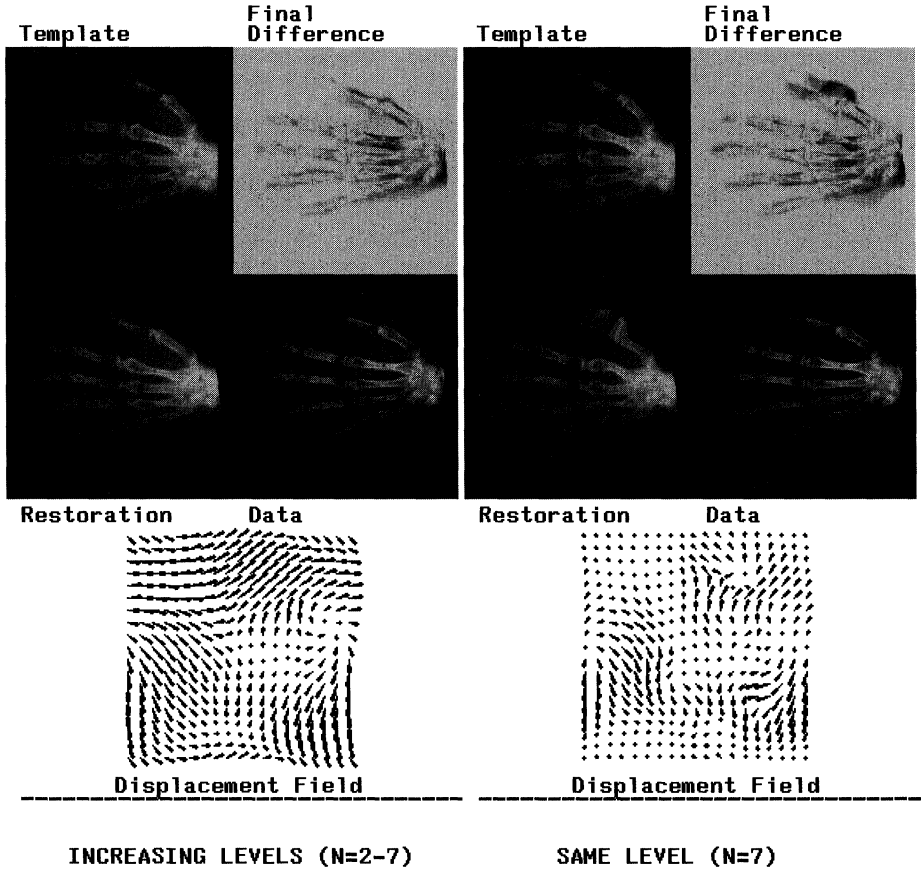

FIG. 5. *The restoration was done using the Fourier method. Using* (a) *increasing levels of approximation starting at* $N = 2$ *up to* $N = 7$, *and* (b) *using a fixed level* $N = 7$.

In the third experiment, we use a synthetic image consisting of two "humps" for the template F. The data G was created by composing F with some field U. The field U was generated by drawing the coefficients of the Fourier basis from independent Gaussian random variables with variances $1/\lambda_{nm}$, for $-9 \leq n,\ m \leq 10$. On the left in Fig. 2, we have the restoration process using the Fourier basis and on the right using the wavelet basis. Observe

that the final field obtained by both methods is very similar. Again, it is possible to see that the topological landmarks — the maxima, the saddle points, etc. — are mapped into each other by the field U. At the bottom we have the restoration using the linearized equations. These did not do nearly as well in spite of the fact that the mean square error in the equation was down to 10^{-5}.

The fourth experiment (Fig. 6) shows what happens when we attempt to use a template with the wrong topological features (Template 2) as compared to the correct template (Template 1). The data in this case was the same as in the previous two pictures with added independently and identically distributed Gaussian noise of variance 0.2, when the grey level values are scaled to the interval [0, 1]. Even though the restoration using the wrong template is fairly good, the displacement field is highly irregular when compared to the displacement field obtained by using the correct template. This might indicate a method of determining which of several possible templates corresponds to the objects in the noisy image.

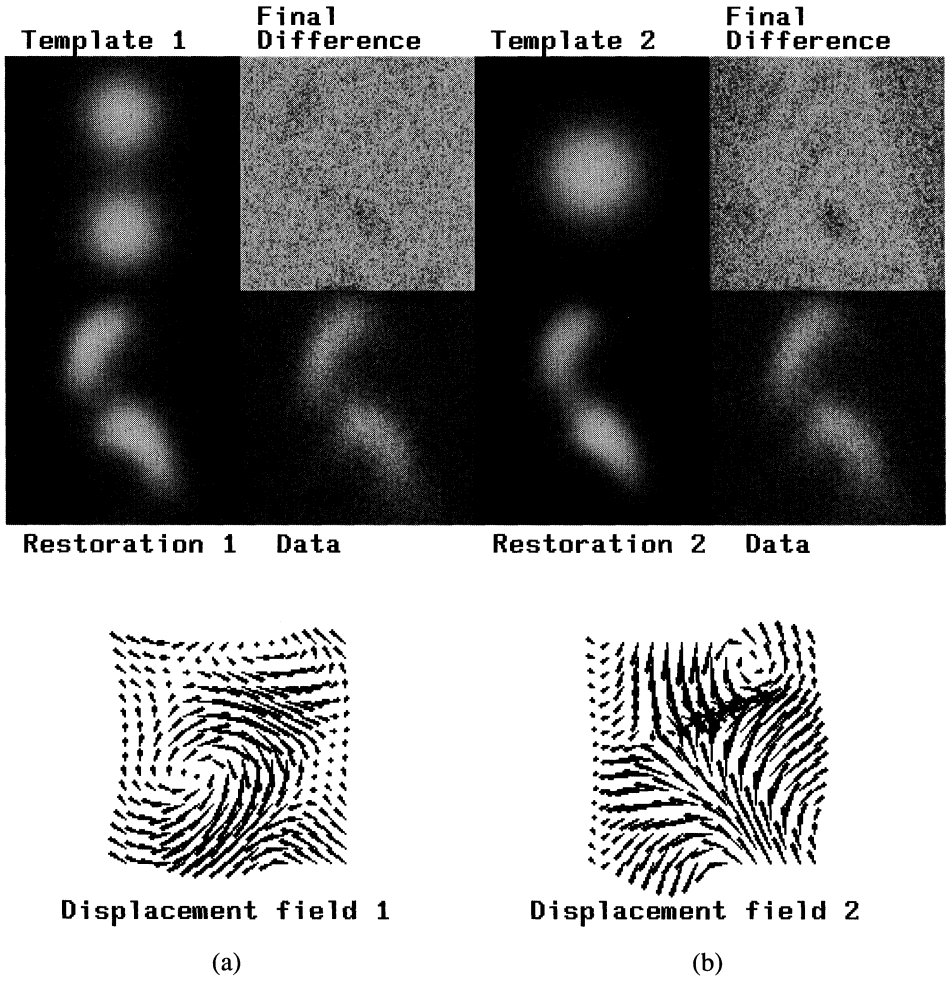

FIG. 6. *Gaussian independently and identically distributed noise was added to the data. In* (a) *the correct template was used, and in* (b) *a different template was used (one hump instead of two).*

The fifth experiment illustrates the possible advantages of the wavelet basis. The template F is a subimage from a sequence of x-rays of a catheter that has been inserted into a coronary

artery. The data G is the corresponding subimage of the x-ray that follows in the sequence. The idea is to use the algorithm to find the movement of the catheter between the two images. In this experiment the template F is larger than what is actually seen in the image. In other words, the function F is defined outside the unit square. When $x + U(x)$ lies outside the unit square, the value of F is taken from that point and not from the corresponding point on the torus. Thus we did not wrap around when composing the template with the mapping. This allows the algorithm to find possible movement *in and out* of the frame under consideration, and is, of course, much better adapted to the issue of movement compensation between consecutive movie frames.

Figure 3 shows the result using the wavelet basis. On the left side are the low resolution versions of the template, Frame 1, and of the data, Frame 2, together with the restoration obtained by using these lower resolution versions in the algorithm. On the right side are the original Frame 1 and Frame 2 together with the restoration obtained by using the displacement field from the low-resolution calculation. Most of the movement between these two consecutive frames has occurred in the upper right-hand corner and, indeed, the restoration has found that movement. Observe that in the low-resolution versions the black lines are widened and thus begin to overlap. This is what generates a gradient for the algorithm to proceed along.

Figure 4 shows the result of using the Fourier basis. The smooth version is on the right and the high resolution is on the left. Observe that this time the change in the upper right-hand corner was not found by the restoration procedure. Apparently, the wavelet basis performed better due to its ability to create a local change in the field without affecting other parts of the image.

In this experiment both the data *and* the template images are quite noisy. In the Fourier method the Fourier transforms of the template and the data are low-pass filtered and retransformed to the original space domain. They are, therefore, much smoother than in the wavelet case where a low-resolution version of the two is used, i.e., a low-pass filter that is not retransformed to the original resolution. This explains why the final low-resolution difference image in Fig. 3 is much noisier than the corresponding smooth version difference image in Fig. 4.

It should be noted that this movement analysis of the catheter is done without any preprocessing of the images to find the line or edge corresponding to the catheter. The algorithm was "helped" only by having it run on the low-resolution transform of the images. In such a way the "canyons" corresponding to the lines become wide valleys that overlap and enable the algorithm to draw them into one another. In other words, if the high resolution images are used, small changes of the field do not produce a better mean square error because the error along both canyons remains the same. Thus there is no clear gradient in any direction. On the other hand when the "valleys" overlap, the direction in which the field could reduce the error is clear.

In the sixth experiment (Fig. 7), we tried to find the movement between two subsequent frames of x-rays of the coronary arteries themselves. The direction of movement varies between different parts of the frame and the wavelet method managed to accommodate these local changes. In this experiment the actual difference between the two frames is compared to the actual difference between the restoration and Frame 2. The grey levels indicate values close to zero. Black or white values indicate large differences.

5. Conclusion. We have presented a nonlinear functional whose minimizers represent the mapping that transforms one image or function into another. The minimizers make sense only in so far as the two functions considered as surfaces have similar topographies, so that one function may be considered as a template for the other.

The functional is regularized using two different choices of a bilinear form. The first form is generated by a differential operator and has a spectral representation using the Fourier basis.

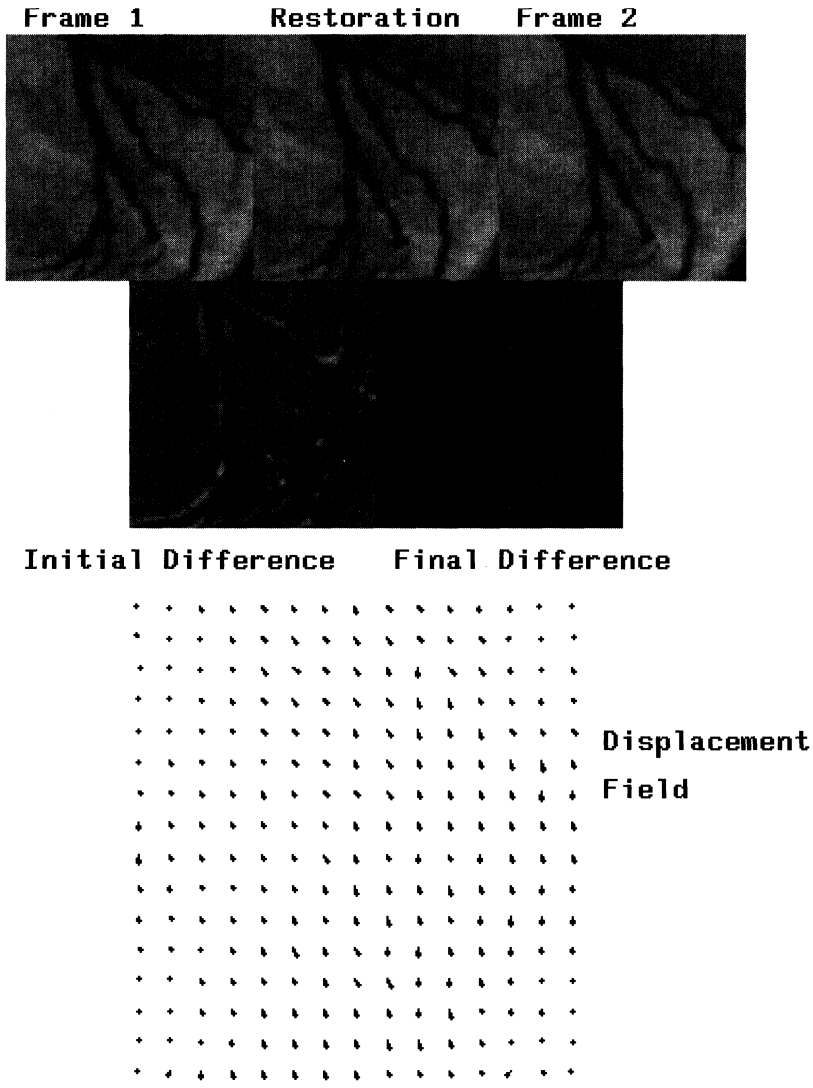

FIG. 7. *Frames* 1 *and* 2 *are two subsequent pictures from an x-ray movie of the coronary arteries. The displacement field corresponds to the movement between the two frames. The initial difference and the final difference pictures represent the actual difference. Grey values are close to zero and white and black values correspond to large differences. The restoration was done using the wavelet method.*

The second form is directly defined in the spectral domain using a wavelet basis of compact support. Both bilinear forms generate the same type of regularization, namely, they constrain the solutions to the same Sobolev space.

The variational problem is solved in terms of the expansion coefficients of the unknown map in terms of the chosen basis. The solution starts at low frequency and gradually moves up. The experimental results clearly indicate that the wavelet basis is more flexible and permits local changes in the mapping.

Appendix. For the sake of completeness we briefly describe the discrete wavelet transform so that the interested reader can code it without further reading. We start with the one-dimensional case.

Let $N = 2^n$ and let $x^{(0)} = (x_0, \ldots, x_{N-1})$ be the data. Given two vectors $g = (g_0, \ldots, g_{2R-1})$, and $h = (h_0, \ldots, h_{2R-1})$, let $\tilde{x} = h * x^{(0)}$ and $\tilde{y} = g * x^{(0)}$, i.e.,

$$\tilde{x}_k = \sum_{j=0}^{2R-1} h_j x_{[(k+j) \bmod N]}, \qquad \tilde{y}_k = \sum_{j=0}^{2R-1} g_j x_{[(k+j) \bmod N]},$$

for $k = 0, \ldots, N-1$. Now set $x_i^{(1)} = \tilde{x}_{2i}$ and $y_i^{(1)} = \tilde{y}_{2i}$ for $i = 0, \ldots, N/2-1$. Alternatively, we write $x^{(1)} = H_n x^{(0)}$ and $y^{(1)} = G_n x^{(0)}$, where H_n, G_n are linear mappings from R_N to $R^{N/2}$. As long as $N > 2R$, it is possible to write the $N/2 \times N$ matrix for G_n as follows:

$$G_n = \begin{pmatrix} g_0 & g_1 & g_2 & g_3 & \cdots & g_{2R-3} & g_{2R-2} & g_{2R-1} & 0 & 0 & \ldots & 0 & 0 \\ 0 & 0 & g_0 & g_1 & \ldots & \ldots & \ldots & g_{2R-3} & g_{2R-2} & g_{2R-1} & \ldots & 0 & 0 \\ & & & \vdots & & & & & & & & & \\ g_2 & g_3 & \ldots & \ldots & \ldots & g_{2R-1} & 0 & 0 & 0 & 0 & \ldots & g_0 & g_1 \end{pmatrix}.$$

The $N/2 \times N$ matrix for H_n is given in the same way using the vector h. (Observe that we have indexed the matrices according to the log of the dimension.) This is the first level of the transform. Using the properties of multiresolution analysis and other techniques (see [3] and [8]) it is possible to find vectors g and h with the following properties.

(i) $\sum_{i=0}^{2R-1} g_i = 0$ and $\sum_{i=0}^{2R-1} h_i = \sqrt{2}$,
(ii) $g_i = (-1)^n h_{2R-1-i}$,
(iii) $H_n^t H_n + G_n^t G_n = I$,
(iv) $H_n G_n^t = 0$.

The first item implies that the H_n matrix is a smoothing operator and that the G_n matrix is a difference operator. The third item is the inversion formula. The fourth item is an orthogonality condition. Given two vectors x, y of length $N/2$, then the corresponding vectors in the full resolution space are orthogonal, i.e., $\langle H_n^t x, G_n^t y \rangle = 0$.

The second level of the transform is given by $x_i^{(2)} = h * x_{2i}^{(1)}$ and $y_i^{(2)} = g * x_{2i}^{(1)}$, for $i = 0, \ldots, N/4 - 1$. $y^{(1)}$ remains unchanged. Thus, at each level, the smoothed version $x^{(i)}$, which is of length 2^{n-i}, is decomposed into yet a smoother version $x^{(i+1)}$ and the difference component $y^{(i+1)}$ both of length 2^{n-i-1}. Clearly, this procedure comes to an end at step $i = n$, where $x^{(n)}$ and $y^{(n)}$ are scalars. The sequence of vectors $x^{(1)}, \ldots, x^{(n)}$ are called *lower resolution versions* of the original vector $x^{(0)}$.

From the inversion formula it follows that

$$x^{(i)} = H_{n-i}^t H_{n-i-1}^t \cdots H_1^t x^{(n)} + \sum_{l=i}^{n-1} H_{n-i}^t \cdots H_{n-l+1}^t G_{n-l}^t y^{(l)}.$$

In Daubechies [3], numbers for the vectors h and g are calculated so as to satisfy the four conditions listed above (see [3, p. 980]). Moreover, Daubechies shows that the wavelet corresponding to these numbers satisfies certain smoothness conditions. In terms of the inversion formula above this means that if we set $x^{(n)} = 1$ and $y^{(j)} = 0$ for $j = 1, \ldots, n$, then the vectors

$$x^{(i)} = H_{n-i}^t H_{n-i-1}^t \cdots H_1^t \mathbf{1}$$

for small values of i are smooth. It should be noted that since we are working here in the periodic setting, $x^{(0)}$ would be constant.

In two dimensions the wavelet transform is constructed using the one-dimensional operators described above. An initial $N \times N$ matrix $x^{(0)}$ is decomposed into four components. First, the one-dimensional transform is carried out on the columns, $A = H_n x^{(0)}$ and $B = G_n x^{(0)}$, where A, B are $N/2 \times N$ matrices. Then the one-dimensional transform is carried out on the rows of A and B or on the columns of A^t and B^t, and we obtain

$$x^{(1)} = H_n A^t = H_n (H_n x^{(0)})^t, \qquad y_a^{(1)} = G_n A^t = G_n (H_n x^{(0)})^t,$$
$$y_b^{(1)} = H_n B^t = H_n (G_n x^{(0)})^t, \qquad y_c^{(1)} = G_n B^t = G_n (G_n x^{(0)})^t.$$

The low-resolution version of $x^{(0)}$ is $x^{(1)}$. The transform continues by operating on $x^{(1)}$ with the matrices G_{n-1}, H_{n-1}. Finally, the inversion formula has the form

$$x^{(0)} = G_n^t (G_n^t y_c^{(1)} + H_n^t y_b^{(1)})^t + H_n^t (G_n^t y_a^{(1)} + H_n^t x^{(1)})^t. \tag{6}$$

Acknowledgments. I would like to express my gratitude to David Gottlieb for his suggestions and encouragement.

A REFORMULATION OF THE PARTIAL LEAST SQUARES REGRESSION ALGORITHM*

P. J. YOUNG†

Abstract. A new algorithm for partial least squares regression is introduced that is shown to be equivalent to, and more efficient than, the current algorithms. In addition, the new algorithm works explicitly in terms of the factor loadings and is therefore particularly useful when interpretation of the factors is required.

Key words. partial least squares, latent variables, factor loadings

AMS subject classifications. primary 62J99; secondary 62H20, 62H25, 62J05

1. Introduction. In the notation of Helland [2], we assume that we have k variables recorded on n subjects, $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_k)$, where $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_k$ are n-dimensional vectors, often referred to as the independent variables. Also available is an associated n-dimensional vector, $\mathbf{y}$, which we shall call the dependent variable. Until mentioned again it is assumed that the means $\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_k$ and $\bar{y}$ have been subtracted from the data $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_k$, and $\mathbf{y}$.

In linear regression we attempt to predict the values of the dependent variable using a linear combination of the independent variables, i.e., $\hat{\mathbf{y}} = \mathbf{X}\beta$ for some k-dimensional vector β. If we then define $\mathbf{S} = \mathbf{X}'\mathbf{X}$ and $\mathbf{s} = \mathbf{X}'\mathbf{y}$, then the ordinary least squares estimate of β is $\mathbf{S}^{-1}\mathbf{s}$.

Unfortunately, problems arise with $\mathbf{S}$ being singular if there is collinearity between the independent variables. This is frequently the case when large numbers of independent variables are available on relatively few subjects. Typically, examples of this are found in the social sciences [4] and the use of infrared spectroscopy data [1]. Use of the Moore–Penrose generalised inverses does not often lead to a unique solution [8], and selecting the appropriate variables from a large pool of variables is not an easy task.

There are three methods of overcoming the problem of collinearity which are currently used [6]. The first, partial least squares (PLS) regression [9] is the focus of this paper and is considered at length later. The second method, ridge regression, overcomes singularity of $\mathbf{S}$ by replacing it by $(\mathbf{S} + k\mathbf{I})$, where k is a scalar known as the ridge parameter. Ridge regression is known to lead to biased parameter estimates. However, it is also known to have better mean squared error properties if the ridge parameter is chosen correctly. Unfortunately, to date, no satisfactory method of selection of the ridge parameter has been proposed and the selection of the ridge parameter is carried out using subjective methods. A more detailed explanation of ridge regression is given by Smith and Campbell [7].

The final method is principal component (PC) regression. In PC regression linear combinations of the original variables are formed and used instead of the original variables. The point to note here is that because the new factors, or latent variables, are only linear combinations of the original variables, PC regression is still a method of linear regression.

The advantage of PC regression lies in the way in which the factor loadings are selected. These are selected sequentially, by maximising the variance of each factor such that it is mutually orthogonal to all the previous factors. These conditions are equivalent to using the eigenvectors $\mathbf{S}$ as factor loadings, with the eigenvalues being the corresponding variances.

*Received by the editors July 27, 1992; accepted for publication (in revised form) March 12, 1993. This research was supported by a Science and Engineering Research Council research studentship held at the University of Kent, United Kingdom.

†Department of Applied Statistics, University of Reading, PO box 238, Earley Gate 3, Whiteknights road, Reading RG6 2AL, United Kingdom (SNSYOUPH@uk.ac.reading).

The advantage of using PC regression is that if there is collinearity in the data, then the last few PC will have zero variance and can be discarded.

The idea of using latent variables is not just restricted to PCs. Two points to note are that, first, the importance of any of the PCs in the subsequent linear regression depends on more than just their variance. Second, the PCs are formed without reference to **s**. In PLS the factors are formed by sequentially maximising the canonical correlation between the latent variables and **y**, whilst keeping the different latent variables uncorrelated. PLS regression therefore has two advantages over PC regression. First, the order of the latent variables is known, and second, it usually requires fewer latent variables in any stepwise inclusion [2]. One criticism of using latent variable methods is that they use all the original variables. For this reason it is often desirable to see the factor loading explicitly so that the factors can be interpreted [3]. Alternatively, having access to the factor loadings may be useful in the detection of outliers [5].

2. PLS regression. PLS revolves around the central decomposition of **X**.

$$\mathbf{X} = \mathbf{t}_1\mathbf{p}_1' + \mathbf{t}_2\mathbf{p}_2' + \cdots + \mathbf{t}_A\mathbf{p}_A' + \mathbf{E}_A. \tag{1}$$

The $\mathbf{t}_a$'s are n-dimensional vectors, which are referred to as the "score vectors," while the $\mathbf{p}_a$'s are k-dimensional vectors, known as the "loading vectors." The $n \times k$ matrix $\mathbf{E}_A$ is a residual matrix, which is intended to be small in some sense. The basis of the PLS algorithm is that the relationship between **X** and **y** is carried through the score vectors, so that

$$\mathbf{y} = \mathbf{t}_1 q_1 + \mathbf{t}_2 q_2 + \cdots + \mathbf{t}_A q_A + \mathbf{f}_A, \tag{2}$$

where the q_a's are scalars and $\mathbf{f}_A$ is a residual vector.

There are a multitude of ways in which **X** could be decomposed, as in (1). There are two restrictions that are of interest here. First, the $\mathbf{t}_a$'s are forced to be mutually orthogonal, and second, the $\mathbf{p}_a$'s are forced to be mutually orthogonal. Using both restrictions has a unique solution [2]. Interestingly, the algorithms derived from assuming either the loadings or the scores to be orthogonal have been shown to be equivalent by Helland [2]. Here we will only consider the so-called original PLS algorithm, derived from assuming the $\mathbf{t}_a$'s to be orthogonal, which is by far the simpler of the two algorithms to use.

2.1. The original PLS algorithm. Initially, we define $\mathbf{E}_0 = \mathbf{X}$ and $\mathbf{f}_0 = \mathbf{y}$. The following items are then iteratively defined in the following sequence, starting with the so-called weight vector

$$\mathbf{w}_a = \mathbf{E}_{a-1}'\mathbf{f}_{a-1}, \tag{3.1}$$

$$\mathbf{t}_a = \mathbf{E}_{a-1}\mathbf{w}_{a-1}, \tag{3.2}$$

$$\mathbf{p}_a = (\mathbf{E}_{a-1}'\mathbf{t}_a)/(\mathbf{t}_a'\mathbf{t}_a), \tag{3.3}$$

$$q_a = \frac{\mathbf{f}_{a-1}'\mathbf{t}_a}{\mathbf{t}_a'\mathbf{t}_a} = \frac{\mathbf{w}_a'\mathbf{w}_a}{\mathbf{t}_a'\mathbf{t}_a}, \tag{3.4}$$

$$\mathbf{E}_a = \mathbf{E}_{a-1} - \mathbf{t}_a\mathbf{p}_a', \tag{3.5}$$

$$\mathbf{f}_a = \mathbf{f}_{a-1} - \mathbf{t}_a q_a. \tag{3.6}$$

The above algorithm does not explicitly give the factor loadings and the following procedure is needed for the prediction of a new observation. Because cross-validation is usually used to determine A, the number of factors required [2], this procedure is often used even if there are

no additional observations to classify. For additional observations with an outcome y_0 and covariates $(x_1, x_2, \ldots, x_k)$, we define $\mathbf{e}_0 = (x_1, x_2, \ldots, x_k)'$ and the predicted value of y_0 is

$$\hat{y}_0 = \bar{y} + \sum_{a=1}^{A} t_{a,0} q_a, \tag{4}$$

where $t_{a,0} = \mathbf{e}_{a-1}\mathbf{w}_a$ and $\mathbf{e}_a = \mathbf{e}_{a-1} - \mathbf{t}_{a,0}\mathbf{p}_a$.

Alternatively, the factor loadings can be explicitly calculated. Let $\mathbf{b}_i$ be the vector of factor loadings for the ith factor, then the predicted values of the dependent variable, $\hat{\mathbf{y}}$, is given by

$$\hat{\mathbf{y}} = \bar{\mathbf{y}} + \beta_1 \mathbf{X}\mathbf{b}_1 + \beta_2 \mathbf{X}\mathbf{b}_2 + \cdots + \beta_A \mathbf{X}\mathbf{b}_A = \bar{\mathbf{y}} + \mathbf{X}\mathbf{c}_A,$$

where β_i's are calculated by ordinary least squares regression [8] and $\mathbf{c}_A = \beta_1 \mathbf{X} + \beta_2 \mathbf{X} + \cdots + \beta_A \mathbf{X}$ is the vector of regression coefficients using A factors. Then as the regression coefficients and factor loadings are interchangeable quantities

$$\mathbf{c}_a = \mathbf{W}_a(\mathbf{P}_a'\mathbf{W}_a)^{-1}\mathbf{q}_a, \tag{5}$$

where $\mathbf{q}_a = (q_1, q_2, \ldots, q_a)'$, $\mathbf{W}_a = (\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_a)$, and $\mathbf{P}_a = (\mathbf{p}_1, \mathbf{p}_2, \ldots, \mathbf{p}_a)$. Fortunately, it has been shown that $\mathbf{P}_a'\mathbf{W}_a$ is bidiagonal, with all diagonal entries equal to one [5], which is of help in the computation stage (see §5).

3. Reformulation of the original PLS algorithm. We define $\mathbf{U}_0 = \mathbf{I}$

$$\mathbf{U}_{a+1} = \mathbf{U}_a \left[\mathbf{I} - \frac{(\mathbf{U}_a'\mathbf{s})(\mathbf{U}_a'\mathbf{s})'(\mathbf{U}_a'\mathbf{S}\mathbf{U}_a)}{(\mathbf{U}_a'\mathbf{s})(\mathbf{U}_a'\mathbf{S}\mathbf{U}_a)(\mathbf{U}_a'\mathbf{s})} \right] \tag{6}$$

for $i = 1, 2, \ldots, k$. The Helland algorithm given in (3)–(8) is equivalent to the following.

$$\mathbf{w}_a = \mathbf{U}_{a-1}'\mathbf{s}, \tag{7.1}$$

$$\mathbf{t}_a = \mathbf{X}\mathbf{U}_{a-1}\mathbf{U}_{a-1}'\mathbf{s}, \tag{7.2}$$

$$\mathbf{p}_a = \frac{(\mathbf{U}_{a-1}'\mathbf{S}\mathbf{U}_{a-1})(\mathbf{U}_{a-1}'\mathbf{s})}{(\mathbf{U}_{a-1}'\mathbf{s})'(\mathbf{U}_{a-1}'\mathbf{S}\mathbf{U}_{a-1})(\mathbf{U}_{a-1}'\mathbf{s})}, \tag{7.3}$$

$$\mathbf{q}_a = \frac{(\mathbf{U}_{a-1}'\mathbf{s})'(\mathbf{U}_{a-1}'\mathbf{s})}{(\mathbf{U}_{a-1}'\mathbf{s})'(\mathbf{U}_{a-1}'\mathbf{S}\mathbf{U}_{a-1})(\mathbf{U}_{a-1}'\mathbf{s})}, \tag{7.4}$$

$$\mathbf{E}_a = \mathbf{X}\mathbf{U}_a, \tag{7.5}$$

$$\mathbf{f}_a = \mathbf{y} - \mathbf{X}\sum_{i=0}^{a-1} \frac{(\mathbf{U}_i\mathbf{U}_i'\mathbf{s})(\mathbf{U}_i'\mathbf{s})'(\mathbf{U}_i'\mathbf{s})}{(\mathbf{U}_i'\mathbf{s})'(\mathbf{U}_i'\mathbf{S}\mathbf{U}_i)(\mathbf{U}_i'\mathbf{s})}. \tag{7.6}$$

The proof of equivalence given below is dependent on the following lemma and is proved in the Appendix.

LEMMA. $\mathbf{U}_a = \mathbf{U}_i\mathbf{U}_a \forall i \leq a$.

Proof of equivalence. Proof is by induction. First, the forms of (7.5) and (7.6) are assumed to be true. Then, using (3.1),

$$\mathbf{w}_a = \mathbf{U}_{a-1}'\mathbf{s} - \mathbf{U}_{a-1}'\mathbf{S}\sum_{i=0}^{a-2} \frac{(\mathbf{U}_i\mathbf{U}_i'\mathbf{s})(\mathbf{U}_i'\mathbf{s})'(\mathbf{U}_i'\mathbf{s})}{(\mathbf{U}_i'\mathbf{s})'(\mathbf{U}_i'\mathbf{S}\mathbf{U}_i)(\mathbf{U}_i'\mathbf{s})}.$$

Now, using the lemma,

$$\mathbf{w}_a = \mathbf{U}'_{a-1}\mathbf{s} - \mathbf{U}'_{a-1}\sum_{i=0}^{a-2}\mathbf{U}'_{i+1}\mathbf{S}\frac{(\mathbf{U}_i\mathbf{U}'_i\mathbf{s})(\mathbf{U}'_i\mathbf{s})'(\mathbf{U}'_i\mathbf{s})}{(\mathbf{U}'_i\mathbf{s})'(\mathbf{U}'_i\mathbf{S}\mathbf{U}_i)(\mathbf{U}'_i\mathbf{s})},$$

and from (6)

$$\mathbf{w}_a = \mathbf{U}'_{a-1}\mathbf{s} - \mathbf{U}'_{a-1}\sum_{i=0}^{a-2}\left[\mathbf{U}'_i\mathbf{S}\frac{(\mathbf{U}_i\mathbf{U}'_i\mathbf{S})(\mathbf{U}'_i\mathbf{S})(\mathbf{U}'_i\mathbf{S})}{(\mathbf{U}'_i\mathbf{s})(\mathbf{U}'_i\mathbf{S}\mathbf{U}_i)(\mathbf{U}_i\mathbf{s})} - \frac{(\mathbf{U}'_i\mathbf{S}\mathbf{U}_i)(\mathbf{U}8_i\mathbf{s})(\mathbf{U}'_i\mathbf{s})'\mathbf{U}'_i\mathbf{S}(\mathbf{U}_i\mathbf{U}'_i\mathbf{s})(\mathbf{U}'_i\mathbf{s})'(\mathbf{U}'_i\mathbf{s})}{(\mathbf{U}'_i\mathbf{s})'(\mathbf{U}'_i\mathbf{S}\mathbf{U}_i)(\mathbf{U}'_i\mathbf{s})^2}\right] = \mathbf{U}'_{a-1}\mathbf{s}.$$

Using (3.2)–(3.4), the derivation of (7.2)–(7.4) is then trivial. Using (3.5) and (6), the form of (7.5) is easily verified as

$$\mathbf{E}_a = \mathbf{X}\mathbf{U}_{a-1}\left[\mathbf{I} - \frac{(\mathbf{U}'_{a-1}\mathbf{s})(\mathbf{U}'_{a-1}\mathbf{s})'(\mathbf{U}'_{a-1}\mathbf{S}\mathbf{U}_{a-1})}{(\mathbf{U}'_{a-1}\mathbf{s})'(\mathbf{U}'_{a-1}\mathbf{S}\mathbf{U}_{a-1})(\mathbf{U}'_{a-1}\mathbf{s})}\right] = \mathbf{X}\mathbf{U}_a,$$

and, finally, the form of (7.6) is also easily verified.

In order to complete the induction process it is only necessary to show that (7.5) and (7.6) hold for a trivial example. Consider $a = 0$, we know that $\mathbf{E}_0 = \mathbf{X}$, $\mathbf{f}_0 = \mathbf{y}$, and $\mathbf{U}_0 = \mathbf{I}$, in which case (7.5) and (7.6) are clearly correct. Hence equivalence of the algorithms is shown.

4. Implementation of the new algorithm. Although theoretically more simple, the above form of the algorithm is not practical. The regression equation is defined as

$$\hat{\mathbf{y}} = \bar{\mathbf{y}} + q_1\mathbf{X}\mathbf{b}_1 + q_2\mathbf{X}\mathbf{b}_2 + \cdots + q_A\mathbf{X}\mathbf{b}_A. \tag{8}$$

In the case where $\mathbf{b}_a = \mathbf{U}_a\mathbf{U}'_a\mathbf{s}$, consider the following:

$$\mathbf{U}_{a+1} = \mathbf{U}_a\left[\mathbf{I} - \frac{\mathbf{U}'_a\mathbf{s}\mathbf{s}'\mathbf{U}_a\mathbf{U}'_a\mathbf{S}\mathbf{U}_a}{(\mathbf{U}_a\mathbf{U}'_a\mathbf{s})'\mathbf{S}(\mathbf{U}_a\mathbf{U}'_a\mathbf{s})}\right] = \left[\mathbf{I} - \frac{\mathbf{b}_a\mathbf{b}'_a\mathbf{S}}{\mathbf{b}'_a\mathbf{S}\mathbf{b}_a}\right]\mathbf{U}_a.$$

Therefore,

$$\mathbf{U}_{a+1} = \prod_{i=1}^{a}\left(\mathbf{I} - \frac{\mathbf{b}_i\mathbf{b}'_i\mathbf{S}}{\mathbf{b}'_i\mathbf{S}\mathbf{b}_i}\right),$$

but it is known that $\mathbf{b}'_i\mathbf{S}\mathbf{B}_j = 0$ if $i \neq j$. Hence

$$\mathbf{U}_{a+1} = \mathbf{I} - \sum_{i=1}^{a}\left(\frac{\mathbf{b}_i\mathbf{b}'_i\mathbf{S}}{\mathbf{b}'_i\mathbf{S}\mathbf{b}_i}\right) = \mathbf{U}_a - \frac{\mathbf{b}_a\mathbf{b}'_a\mathbf{S}}{\mathbf{b}'_a\mathbf{S}\mathbf{b}_a}.$$

Therefore,

$$\begin{aligned}\mathbf{b}_{a+1} &= \mathbf{U}_{a+1}\mathbf{U}'_{a+1}\mathbf{S} = \mathbf{U}_{a+1}\mathbf{U}'_a\mathbf{s} - \mathbf{U}_{a+1}\mathbf{S}\mathbf{b}_a q_{a+1}\\ &= \left[\mathbf{I} - \frac{\mathbf{b}_a\mathbf{b}'_a\mathbf{S}}{\mathbf{b}'_a\mathbf{S}\mathbf{b}_a}\right]\mathbf{U}_a\mathbf{U}'_a\mathbf{s} - \mathbf{U}_{a+1}\mathbf{S}\mathbf{b}_a q_{a+1} = -\mathbf{U}_{a+1}\mathbf{S}\mathbf{b}_a q_{a+1}\\ &= -\left[\mathbf{I} - \frac{\mathbf{b}_a\mathbf{b}'_a\mathbf{S}}{\mathbf{b}'_a\mathbf{S}\mathbf{b}_a}\right]\mathbf{U}_a\mathbf{S}\mathbf{b}_a q_{a+1} = -\prod_{i=1}^{a}\left[\mathbf{I} - \frac{\mathbf{b}_i\mathbf{b}'_i\mathbf{S}}{\mathbf{b}'_i\mathbf{S}\mathbf{b}_i}\right]\mathbf{S}\mathbf{b}_a q_{a+1}\end{aligned}$$

remembering that $\mathbf{b}_i'\mathbf{S}\mathbf{B}_j = 0$ for $i \neq j$.

$$\mathbf{b}_{a+1} = \left[\left(\sum_{i=1}^{a} \frac{\mathbf{b}_i\mathbf{b}_i'\mathbf{S}}{\mathbf{b}_i'\mathbf{S}\mathbf{b}_i}\right) - I\right]\mathbf{S}\mathbf{b}_a q_{a+1}. \tag{9}$$

The new algorithm is then defined as follows.

Initially, obtain $\mathbf{S}$, $\mathbf{s}$, and define $\mathbf{g}_0 = \mathbf{S}\mathbf{s}$, $\mathbf{h}_0 = \mathbf{s}'\mathbf{S}\mathbf{s}$, and $q_1 = \mathbf{s}'\mathbf{s}/\mathbf{s}'\mathbf{S}\mathbf{s}$, then iteratively find

$$\mathbf{b}_{a+1} = \left(\sum_{i=0}^{a} \frac{\mathbf{b}_i(\mathbf{g}_i'\mathbf{g}_a)}{h_i} - \mathbf{g}_a\right) q_{a+1}, \tag{10}$$

and store $\mathbf{g}_{a+1} = \mathbf{S}\mathbf{b}_{a+1}$, $\mathbf{h}_{a+1} = \mathbf{b}_a'\mathbf{S}\mathbf{b}_a$, $\mathbf{q}_{a+2} = \mathbf{b}_{a+1}'\mathbf{s}/h_{a+1}$, and, of course $\mathbf{b}_{a+1}$.

5. Relative efficiency of the algorithms. If we consider the cost of the of the original PLS algorithm in terms of flops then we see that (3.1)–(3.3) are all matrix–vector multiplications each using nk flops. In addition, (3.3) requires an additional $n + 1$ flops for the scalar product of, and division by, $t_a't_a$. For (3.4) there is another scalar product requiring n flops and one extra for the scaling by $t_a't_a$. The vector-by-vector multiplications in (3.5) of $t_a p_a'$ require nk flops. For (3.6) only n flops are required. This gives a total of $4nk + 3n + 2$ flops per iteration. Therefore, if A factors are used, a total of

$$A(4nk + 3n + 2) \tag{11}$$

flops are required.

However, it is necessary to explicitly obtain the factor loadings. This requires the calculation and inversion of $\mathbf{P}_a'\mathbf{W}_a$, which is an $a \times a$ matrix. As the matrix is bidiagonal with all diagonal entries equal to one, we need only calculate the $a - 1$ off-diagonal entries which uses $k(a - 1)$ flops. The inversion itself is trivial using the Gauss–Jordan method which requires $a - 1$ flops. Postmultiplication by $\mathbf{q}_a$ requires $\frac{1}{2}a(a + 1)$ flops as the inverse is triangular. Finally, the premultiplication by $\mathbf{W}_a$ needs a^2 flops, which gives a total of $\frac{3}{2}a^2 + a(k + \frac{3}{2}) - (k + 1)$ flops. So, as A factors are required, an additional

$$\frac{1}{2}(A^3 + A^2k + 3A^2 - Ak) \tag{12}$$

flops will be required.

The new algorithm requires the multiplication of $\mathbf{g}_i'\mathbf{g}_a$, which takes k flops. This is then divided by h_i, and is then premultiplied by $\mathbf{b}_i$ using k flops. The procedure is repeated a times so that $a(2k + 1)$ are used. This vector is then scaled by q_{a+1} using another k_{a+1} flops. All that remains is to find $\mathbf{g}_{i+1}$, which needs k^2 flops, h_{i+1}, which requires k flops, and q_{i+2}, which uses another $k + 1$ flops. Hence a total of $a(2k + 1) + k^2 + 3k$ flops are required. Assuming that A factors are required, then

$$A\left(k^2 + Ak + 4k + \frac{1}{2}A + \frac{3}{2}\right) \tag{13}$$

flops are required.

We consider only the dominant terms of (11) and (13) for a large problem. For (11) the dominant term is $4Ank$, while for (13) it is $Ak^2 + A^2k$. Hence the ratio of the relative efficiency of the old method to the new is $4n/(A + k)$. If we then consider the cost of calculating the factor loadings in the old algorithm, the dominant term in (12) is $\frac{1}{2}(A^3 + A^2k)$, which alters the ratio of relative efficiency to $4n/(A + k) + A/2k$.

Appendix. Proof of lemma. The proof is in two parts. In the first part it is shown by induction that $\mathbf{U}_a\mathbf{U}_a = \mathbf{U}_a$. Assuming this to be true for $a = i$, consider $a = i + 1$. First, denoting

$$\mathbf{V}_{i+1} = \frac{(\mathbf{U}_i'\mathbf{s})(\mathbf{U}_i'\mathbf{s})'(\mathbf{U}_i'\mathbf{S}\mathbf{U}_i)}{(\mathbf{U}_i'\mathbf{s})'(\mathbf{U}_i'\mathbf{S}\mathbf{U}_i)(\mathbf{U}_i'\mathbf{s})},$$

it can be seen that

$$\mathbf{U}_{i+1}\mathbf{U}_{i+1} = \mathbf{U}_i[\mathbf{I} - \mathbf{V}_{i+1}]\mathbf{U}_i[\mathbf{I} - \mathbf{V}_{i+1}] = \mathbf{U}_i\mathbf{U}_i - \mathbf{U}_i\mathbf{V}_{i+1}\mathbf{U}_i - \mathbf{U}_i\mathbf{U}_i\mathbf{V}_{i+1} + \mathbf{U}_i\mathbf{V}_{i+1}\mathbf{U}_i\mathbf{V}_{i+1},$$

but, as $\mathbf{U}_i\mathbf{U}_i = \mathbf{U}_i$, it follows that $\mathbf{V}_{i+1}\mathbf{U}_i = \mathbf{V}_{i+1}$, and it is then easy to see that $\mathbf{U}_{i+1}\mathbf{U}_{i+1} = \mathbf{U}_{i+1}$. Hence all that remains is to show that $\mathbf{U}_a\mathbf{U}_a = \mathbf{U}_a$ hold for a trivial example, for which we consider $a = 0$, where $\mathbf{U}_0 = \mathbf{I}$.

We now note that $\mathbf{U}_a = \mathbf{U}_{a-1}(\mathbf{I} - \mathbf{V}_a)$ so that

$$\begin{aligned}\mathbf{U}_a &= (\mathbf{I} - \mathbf{V}_1)(\mathbf{I} - \mathbf{V}_2)\cdots(\mathbf{I} - \mathbf{V}_i)(\mathbf{I} - \mathbf{V}_{i+1})\cdots(\mathbf{I} - \mathbf{V}_a) = \mathbf{U}_i(\mathbf{I} - \mathbf{V}_{i+1})\cdots(\mathbf{I} - \mathbf{V}_a)\\ &= \mathbf{U}_i\mathbf{U}_i(\mathbf{I} - \mathbf{V}_{i+1})\cdots(\mathbf{I} - \mathbf{V}_a) = \mathbf{U}_i\mathbf{U}_a.\end{aligned}$$

A NOVEL TWO-GRID METHOD FOR SEMILINEAR ELLIPTIC EQUATIONS*

JINCHAO XU†

Abstract. A new finite element discretization technique based on two (coarse and fine) subspaces is presented for a semilinear elliptic boundary value problem. The solution of a nonlinear system on the fine space is reduced to the solution of two small (one linear and one nonlinear) systems on the coarse space and a linear system on the fine space. It is shown, both theoretically and numerically, that the coarse space can be extremely coarse and still achieve asymptotically optimal approximation. As a result, the numerical solution of such a nonlinear equation is not significantly more expensive than the solution of one single linearized equation.

Key words. elliptic boundary value problem, finite elements, two-grid

AMS subject classifications. 65M60, 65N15, 65N30

1. Introduction. In this paper, we shall present a new discretization technique for semilinear elliptic equations based on finite element spaces defined on two grids of different sizes. Methods along this direction have been studied in a recent paper [1] for linear (nonsymmetric or indefinite) and especially nonlinear elliptic partial equations. (See also references cited in [1] for other methods for nonlinear elliptic equations.) As for nonlinear equations, the idea in [1] is basically to use a coarse space to produce a rough approximation of the solution, and then use it as the initial guess for one Newton iteration on the fine grid. This procedure involves a nonlinear solve on the coarse space and a linear solve on the fine space. A remarkable fact about this simple approach is, as shown in [1], that the coarse mesh can be quite coarse and still maintain an optimal approximation. The purpose of this paper is to make a further refinement in the aforementioned process by solving one more linear equation on the *coarse* space. This additional correction step (which needs very little extra work) improves the accuracy of the algorithms in [1] up to one or two orders. The fact that a further coarse grid correction *after* the fine grid correction can actually improve the accuracy appears to be of great theoretical interest.

The rest of the paper is organized as follows. Section 2 is devoted to the standard finite element discretization for a model semilinear equation. Section 3 contains the new algorithm of the paper with error analysis. Section 4 gives a simple numerical example.

2. Preliminaries. Given a bounded domain $\Omega \subset \mathbb{R}^d$ $(d = 1, 2, 3)$, we assume that $\partial\Omega$ is either smooth or convex and piecewise smooth. Let $\mathcal{W}_p^m(\Omega)$ be the standard Sobolev space with a norm $\|\cdot\|_{m,p}$ given by $\|v\|_{m,p}^p = \sum_{|\alpha|\le m} \|D^\alpha v\|_{L^p(\Omega)}^p$. For $p = 2$, we denote $\mathcal{H}^m(\Omega) = \mathcal{W}_2^m(\Omega)$ and $\mathcal{H}_0^1(\Omega)$ to be the subspace of $\mathcal{H}^1(\Omega)$ consisting of functions with vanishing trace on $\partial\Omega$. $\|\cdot\|_m = \|\cdot\|_{m,2}$ and $\|\cdot\| = \|\cdot\|_{0,2}$. The following Sobolev inequalities are well known:

(2.1) $\|u\|_{0,p} \lesssim \|u\|_1 \quad (d = 2 \quad \text{and} \quad 1 \le p < \infty) \quad \text{and} \quad \|u\|_{0,6} \lesssim \|u\|_1 \quad (d = 3),$

where the notation "$\lesssim$" is equivalent to "$\le C$" for some positive constant C.

We consider the following semilinear equation:

$$-\Delta u + f(x, u) = 0, \quad x \in \Omega, \quad u|_{\partial\Omega} = 0. \tag{2.2}$$

Here the function f is sufficiently smooth. For brevity, we shall drop the dependence of variable x in $f(x, u)$ in the following exposition.

We assume that the above equation has at least one solution $u \in \mathcal{H}_0^1(\Omega) \cap \mathcal{H}^2(\Omega)$ and the linearized operator $L_u \equiv -\Delta + f'(u)$ is nonsingular. As a result of this assumption, $L_u : \mathcal{H}^2(\Omega) \cap \mathcal{H}_0^1(\Omega) \mapsto \mathcal{L}_2(\Omega)$ is a bijection and satisfies

$$\|w\|_2 \le C_0 \|L_u w\| \quad \forall\, w \in \mathcal{H}^2(\Omega) \cap \mathcal{H}_0^1(\Omega)$$

for some constant C_0 depending on u.

Given $h \in (0, 1)$, we assume that $V_h \subset \mathcal{H}_0^1(\Omega)$ is a piecewise linear finite element space defined on a quasi-uniform triangulation (with a meshsize h) of Ω satisfying

$$\inf_{\chi \in V_h} \{\|v - \chi\|_{0,p} + h\|v - \chi\|_{1,p}\} \lesssim h\|v\|_{2,p} \quad \forall\, v \in \mathcal{W}_p^2(\Omega) \cap \mathcal{H}_0^1(\Omega),\ 1 \le p \le \infty.$$

The standard finite element discretization of (2.2) is to find $u_h \in V_h$ so that

$$(\nabla u_h, \nabla \chi) + (f(u_h), \chi) = 0 \quad \forall\, \chi \in V_h. \tag{2.3}$$

It can be proven that (cf. [1] and the references cited therein) if h is sufficiently small, the above equation has a (locally unique) solution u_h satisfying

$$\|u - u_h\|_{0,p} + h\|u - u_h\|_{1,p} \le C(\|u\|_{2,p})h^2 \quad \forall\, 2 \le p < \infty \tag{2.4}$$

and

$$\|u - u_h\|_{0,\infty} \le C(\|u\|_{2,\infty})h^2 |\log h|, \qquad \|u - u_h\|_{1,\infty} \le C(\|u\|_{2,\infty})h.$$

LEMMA 2.1. *There exists a constant $\delta > 0$ such that for any $v \in \mathcal{H}_0^1(\Omega) \cap \mathcal{L}_\infty(\Omega)$ with $\|u - v\|_{0,\infty} \le \delta$, the following statements are valid.*

1. *The operator $L_v \equiv -\Delta + f'(v) : \mathcal{H}_0^1(\Omega) \cap \mathcal{H}^2(\Omega) \mapsto \mathcal{L}_2(\Omega)$ is bijective and there exists a constant $C = C(\delta)$, so that*

$$\|w\|_2 \le C(\delta)\|L_v w\| \quad \forall\, w \in \mathcal{H}_0^1(\Omega) \cap \mathcal{H}^2(\Omega).$$

2. *If h is sufficiently small, there exists a constant $c = c(\delta)$ such that*

$$\sup_{\chi \in V_h} \frac{a_v(w_h, \chi)}{\|\chi\|_1} \ge c(\delta)\|w_h\|_1 \quad \forall\, w_h \in V_h,$$

where

$$a_v(w_h, \chi) = (\nabla w_h, \nabla \chi) + (f'(v)w_h, \chi). \tag{2.5}$$

Proof. Since f is smooth, we have

$$\|f'(u) - f'(v)\|_{0,\infty} \le C_1\|u - v\|_{0,\infty} \le C_1\delta$$

for some constant C_1 depending on f and u. Thus

$$\|(L_u - L_v)w\| = \|(f'(u) - f'(v))w\| \le \|f'(u) - f'(v)\|_{0,\infty}\|w\| \le C_1\delta\|w\|_2,$$

and, if $\delta \le (2C_0C_1)^{-1}$,

$$\|w\|_2 \le C_0\|L_u w\| \le C_0(\|L_v w\| + \|(L_u - L_v)w\|) \le C_0\|L_v w\| + \tfrac{1}{2}\|w\|_2.$$

The first statement is then justified with $C = 2C_0$.

The assumption that L_u is nonsingular implies that

$$\sup_{\chi \in V_h} \frac{a_u(w_h, \chi)}{\|\chi\|_1} \ge c_0\|w_h\|_1 \quad \forall\, w_h \in V_h$$

for some constant c_0 and sufficiently small h. But

$$a_v(w_h, \chi) \ge a_u(w_h, \chi) - C_1\delta\|w_h\|_1\|\chi\|_1.$$

The second statement then follows with $c = c_0/2$ for $\delta \le c_0/(2C_1)$. □

3. Two-grid algorithms based on the Newton method. In this section, we shall present the main algorithm of this paper. The basic ingredient in our approach is another finite element space V_H ($\subset V_h \subset \mathcal{H}_0^1(\Omega)$) defined on a coarser quasi-uniform triangulation (with meshsize $H > h$) of Ω. Note that all the results for V_h in the previous section are valid for V_H if H is sufficiently small.

Setting $a_H(v, \phi) = a_{u_H}(v, \phi)$ (see (2.5)), the main algorithm of the paper is as follows.

ALGORITHM A1. Find $u_h^* = u_H + e_h + e_H$ such that

1. $u_H \in V_H$, $(\nabla u_H, \nabla\phi) + (f(u_H), \phi) = 0 \quad \forall\, \phi \in V_H$;
2. $e_h \in V_h$, $a_H(e_h, \chi) = -(f(u_H), \chi) - (\nabla u_H, \nabla\chi) \quad \forall\, \chi \in V_h$;
3. $e_H \in V_H$, $a_H(e_H, \phi) = -\frac{1}{2}(f''(u_H)e_h^2, \phi) \quad \forall\, \phi \in V_H$.

The new feature of the above algorithm mainly lies in step 3 where a further coarse grid correction is performed. We notice that the linearized operator used in this step is based on the first coarse grid approximation u_H (instead of the more accurate $u_H + e_h$). As we shall see later, such a correction indeed improves the accuracy of the approximation.

Corresponding to the form $a_H(\cdot, \cdot)$, we define a projection $P_H : \mathcal{H}_0^1(\Omega) \mapsto V_H$ by

$$a_H(\phi, P_H v) = a_H(\phi, v) \quad \forall\, \phi \in V_H, v \in \mathcal{H}_0^1(\Omega).$$

By Lemma 2.1, it can be easily shown that there exists $H_0 > 0$, if $H \le H_0$, P_H is well defined and satisfies for $k = 1, 2$

$$\|w - P_H w\| + H\|w - P_H w\|_1 \le C(H_0)H^k\|w\|_k \quad \forall\, w \in \mathcal{H}_0^1(\Omega) \cap \mathcal{H}^k(\Omega). \tag{3.1}$$

We begin our analysis for Algorithm A1 with a simple lemma.

LEMMA 3.1. *For any* $\chi \in V_h$

$$a_H(u_H + e_h, \chi) = (-f(u_H) + f'(u_H)u_H, \chi), \tag{3.2}$$

$$\begin{aligned} a_H(u_h^*, \chi) = {} & (-f(u_H) + f'(u_H)u_H - \tfrac{1}{2}f''(u_H)e_h^2, \chi) \\ & + \tfrac{1}{2}(f''(u_H)e_h^2, \chi - P_H\chi). \end{aligned} \tag{3.3}$$

Proof. The first equality follows directly for the definition of u_H and e_h. Again, by the definition of P_H and e_H,

$$a_H(e_H, \chi) = a_H(e_H, P_H\chi) = -\tfrac{1}{2}(f''(u_H)e_h^2, P_H\chi).$$

Adding this to the first equality then leads to the second one. □

LEMMA 3.2. *If* $u \in \mathcal{W}_p^2(\Omega)$ *with* $p > 2$ *for* $d = 2$ *and* $p = \frac{12}{5}$ *for* $d = 3$, *then*

$$\|u_h - (u_H + e_h)\|_1 \lesssim H^4.$$

Proof. It follows from (2.3) that

$$a_H(u_h, \chi) = -(f(u_h), \chi) + (f'(u_H)u_h, \chi),$$

which, together with (3.2), gives

$$a_H(u_h - (u_H + e_h), \chi) = (f(u_H) - f(u_h) + f'(u_H)(u_h - u), \chi) = (b(u_h - u_H)^2, \chi).$$

Here we have

$$b = -\int_0^1 (1-t)f''(u_H + t(u_h - u_H))dt.$$

By assumption and (2.4), it is easy to see that b is a uniformly (with respect to both H and h) bounded function on $\bar{\Omega}$. Using the Hölder inequality and (2.1), we then deduce that

$$((u_h - u_H)^2, \chi) \le \|(u_h - u_H)^2\|_{0,\frac{p}{2}}\|\chi\|_{0,\frac{p}{p-2}} \lesssim \|u_h - u_H\|_{0,p}^2\|\chi\|_1.$$

It follows from Lemma 2.1 and (2.4) that

$$\|u_h - (u_H + e_h)\|_1 \lesssim \|u_h - u_H\|_{0,p}^2 \lesssim H^4. \qquad \square$$

The estimate in Lemma 3.2, essentially contained in [1], is already quite remarkable because of the high power on the coarse meshsize H. But more remarkable estimates will be seen in the next theorem.

THEOREM 3.1. *If* $u \in \mathcal{W}_4^2(\Omega)$ *is the solution of* (2.2) *and* $u_h \in V_h$ *is the solution of* (2.3) (*satisfying* (2.4)), *then*

$$\|u_h - u_h^*\|_1 \lesssim H^5, \qquad \|u_h - u_h^*\| \lesssim H^6.$$

Consequently,

$$\|u - u_h^*\|_1 \lesssim h + H^5, \quad \|u - u_h^*\| \lesssim h^2 + H^6.$$

Proof. By the definition of u_h and the Taylor expansion, we have

$$\begin{aligned} a_H(u_h, \chi) = (&-f(u_H) + f'(u_H)u_H - \tfrac{1}{2}f''(u_H)(u_h - u_H)^2, \chi) \\ &+(O(u_h - u_H)^3, \chi), \end{aligned}$$

which, together with (3.3), gives that for any $\chi \in V_h$,

$$\begin{aligned} a_H(u_h - u_h^*, \chi) = &-\tfrac{1}{2}(f''(u_H)(e_h^2 - (u_h - u_H)^2), \chi) + \tfrac{1}{2}(f''(u_H)e_h^2, \chi - P_H\chi) \\ &+(O(u_h - u_H)^3, \chi). \end{aligned}$$

By the Hölder inequality and (2.1)

$$\begin{aligned}(e_h^2 - (u_h - u_H)^2, \chi) &\le \|(u_h - (u_H + e_h))(e_h + u_h - u_H)\|_{0,\frac{5}{6}} \|\chi\|_{0,6} \\ &\le \|u_h - (u_H + e_h)\|_{0,3} \|e_h + u_h - u_H\|_{0,2} \|\chi\|_{0,6} \\ &\le \|u_h - (u_H + e_h)\|_1 (\|e_h\| + \|u_h - u_H\|) \|\chi\|_1.\end{aligned}$$

It follows from (2.4) and Lemma 3.2 that

$$(e_h^2 - (u_h - u_H)^2, \chi) \le H^6 \|\chi\|_1.$$

By the Schwarz inequality and Lemma 3.2,

$$(f''(u_H) e_h^2, (I - P_H)\chi) \lesssim \|e_h\|_{0,4}^2 \|(I - P_H)\chi\| \lesssim H^4 \|(I - P_H)\chi\|.$$

By the Hölder inequality, (2.4), and (2.1),

$$(O(u_h - u_H)^3, \chi) \lesssim \|(u_h - u_H)^3\|_{0,\frac{6}{5}} \|\chi\|_{0,6} \lesssim \|u_h - u_H\|_{0,4}^3 \|\chi\|_1 \lesssim H^6 \|\chi\|_1.$$

Consequently,

$$a_H(u_h - u_h^*, \chi) \lesssim H^6 \|\chi\|_1 + H^4 \|(I - P_H)\chi\|. \tag{3.4}$$

This, together with Lemma 2.1 and (3.1), immediately implies the first estimate of the theorem. To derive the estimate in $\mathcal{L}_2(\Omega)$ norm, we use a duality argument by considering the auxiliary problem: Find $w \in \mathcal{H}_0^1(\Omega) \cap \mathcal{H}^2(\Omega)$ so that

$$-\Delta w + f'(u_H) w = u_h - u_h^*.$$

By Lemma 2.1, there exists $H_0 > 0$ and $C(H_0) > 0$, so that if $H \le H_0$,

$$\|w\|_2 \le C(H_0) \|u_h - u_h^*\|.$$

Then, if $w_h \in V_h$ is the nodal value interpolation of w, we have

$$\|u_h - u_h^*\|^2 = a_H(u_h - u_h^*, w) = a_H(u_h - u_h^*, w - w_h) + a_H(u_h - u_h^*, w_h).$$

Note that

$$a_H(u_h - u_h^*, w - w_h) \lesssim \|u_h - u_h^*\|_1 \|w - w_h\|_1 \lesssim H^5 h \|w\|_2 \lesssim H^6 \|u_h - u_h^*\|.$$

It follows from (3.4) that

$$\begin{aligned}a_H(u_h - u_h^*, w_h) &\lesssim H^6 \|w_h\|_1 + H^4 \|(I - P_H) w_h\| \\ &\lesssim H^6 \|w\|_2 + H^4 (\|(I - P_H) w\| + H \|w - w_h\|_1) \\ &\lesssim H^6 \|w\|_2 \lesssim H^6 \|u_h - u_h^*\|.\end{aligned}$$

The second estimate of the theorem then follows. □

Comparing Theorem 3.1 with Lemma 3.2, we find that one coarse grid correction leads to a one-order improvement in $\mathcal{H}^1(\Omega)$ norm and possibly a two-order improvement in $\mathcal{L}_2(\Omega)$ norm.

According to Theorem 3.1, to obtain the asymptotically optimal accuracy, it suffices to take $H = O(h^{1/3})$ for both $\mathcal{L}_2(\Omega)$ and $\mathcal{H}^1(\Omega)$ norms (for $\mathcal{H}^1(\Omega)$ norm, it even suffices to take $H = O(h^{1/5})$). As a result, the dimension of V_H can be much smaller than the dimension

of V_h, and thus the dominated part of the work in Algorithm A1 is the solution of the linear system in step 2.

With a standard treatment near the boundary where it is curved, the estimates corresponding to Theorem 3.1 for Algorithm A1 for elements of degree r are as follows:

$$\|u_h - u_h^*\|_1 \lesssim H^{2r+3}, \qquad \|u_h - u_h^*\| \lesssim H^{2r+4}.$$

Thus

$$\|u - u_h^*\|_1 \lesssim h^r + H^{2r+3}, \qquad \|u - u_h^*\| \lesssim h^{r+1} + H^{2r+4}.$$

A proper choice of meshsizes would be $h = O(H^{2+2/(r+1)})$ (or even $h = O(H^{2+3/r})$).

For most practical purposes, Algorithm A1, which involves only one Newton iteration on the fine grid, is sufficient for applications. Nevertheless, a more dramatic result can be derived if one more Newton iteration is performed on the fine grid.

ALGORITHM A2. Find $\tilde{u}_h = u_h^* + e^h$ such that
1. $u_h^* \in V_h$ is obtained by Algorithm A1.
2. $e^h \in V_h$, $a_{u_h^*}(e^h, \chi) = -(f(u_h^*), \chi) - (\nabla u_h^*, \nabla\chi) \quad \forall\, \chi \in V_h$.

For this algorithm, we can prove that, if $u \in W_4^2(\Omega)$, then

$$\|u_h - \tilde{u}_h\|_1 \lesssim H^{12} |\log h|^{\frac{1}{2}}.$$

In fact, by Taylor expansion, we have

$$a_{u_h^*}((u_h - \tilde{u}_h), \chi) = (O(u_h - u_h^*)^2, \chi).$$

For $d = 2$, using the well-known inequality that $\|\chi\|_{0,\infty} \lesssim |\log h|^{1/2} \|\chi\|_1$, we deduce that

$$(O(u_h - u_h^*)^2, \chi) = \|u_h - u_h^*\|^2 \|\chi\|_{0,\infty} \lesssim \|u_h - u_h^*\|^2 \|\chi\|_1 |\log h|^{\frac{1}{2}} \lesssim H^{12} |\log h|^{\frac{1}{2}} \|\chi\|_1.$$

The desired estimate for $d = 2$ then follows. The proof for $d = 3$ depends on the $L_p(\Omega)$ estimates of $u_h - u_h^*$, and the technical details will be omitted here.

It is also possible to make an additional coarse grid correction in Algorithm A2 to further improve the estimate, but we suspect such an improvement will not be that important since the order of H is already so high.

One final remark is that the technique presented in this paper extends naturally to other discretization methods such as finite difference and spectral methods.

4. A numerical example. In this section we present a simple numerical result to demonstrate the efficiency of our proposed schemes. Our model problem is

$$-\Delta u + u^3 = f(x) \quad \text{in } \Omega \quad \text{and} \quad u = 0 \quad \text{on } \partial\Omega.$$

Here Ω is the unit square $(0, 1) \times (0, 1)$ and f is so chosen that $u = \sin \pi x \sin \pi y$ is the exact solution. The domain Ω is divided into families T_H and T_h of quadrilaterals, and $V_H, V_h \subset H_0^1(\Omega)$ are linear spaces of piecewise continuous bilinear functions defined on T_H and T_h, respectively.

On the coarse grid level, we solve the nonlinear problem by the Newton iteration. (Because of its small size, this nonlinear system takes very little time to solve compared to the larger linear systems.) The fine grid linearized equations (which are symmetric positive definite for this example) are solved by the conjugate gradient method or multigrid method. We take $h = H^4$ with $H = \frac{1}{4}$. Notice that $\dim V_h = 65,025$ while $\dim V_H = 49$. The numerical results are shown in Table 1.

TABLE 1
Errors in $\mathcal{H}^1$ and $\mathcal{L}_2$ norms.

	$\mathcal{H}^1$-norm	$\mathcal{L}_2$-norm
$u - u_H$	5.01E−1	3.19E−02
$u - (u_H + e_h)$	7.90E−3	1.45E−04
$u - (u_H + e_h + e_H)$	7.87E−3	3.19E−05
$u - u_h$	7.87E−3	7.85E−06

DATA ANALYSIS, MATRIX DECOMPOSITIONS, AND GENERALIZED INVERSE*

AGNAR HÖSKULDSSON†

Abstract. An approach to data analysis and matrix analysis is presented with the aid of a general algorithm to carry out data analysis, matrix decompositions, and computation of the generalized inverse. The algorithm represents a novel approach to common numerical and statistical analysis of data. It allows users to specify their views on data so that the solution may reflect the importance of different parts of data. The algorithm provides a unified method to analyze data, to decompose the matrix similar to the singular value decomposition, and to compute the generalized inverse. It is a fast and efficient way to handle numerical questions like solving linear equations or determining the rank of a matrix. The algorithm allows views on the column vectors, row vectors, and on both rows and columns. Different views on the data give different decompositions or solutions. Stopping rules are presented that can be used to identify the noise level in data. Some basic modelling questions are treated and applied to typical situations found in practice.

Key words. linear equations, rank of matrix, decomposition, generalized inverse

1. Introduction.

The solution of linear equations and the decomposition of matrices are now fundamental techniques in many applied sciences. Excellent textbooks have been written on these topics, both from a numerical point of view (see, e.g., [1]) and from a statistical point of view (see, e.g., [2] and [3]). One can state that these theories have been extensively studied, and there are now good algorithms available for performing linear numerical analysis such as solving linear equations, computing eigenvalues and vectors of matrices, and handling similar matrix problems.

Modern measurement equipment often produces a large amount of data. In modern chemical laboratories it is common that the data matrices collected from the measurements are large, often containing more than 100 rows or columns. Matrices containing 100 or 200 rows and a similar number of columns are "medium"-sized matrices in many chemical laboratories. These matrices are usually of low rank. We often see matrices of size 100 times 100 or larger, but of rank only 10 or even less. For example, in these cases we can easily compute the singular value decomposition (SVD) of the matrix. But experience with these solutions has shown that they often do not function well. The reason is that the results are often very unstable. In statistics it is called "instability due to overfitting." In numerical analysis the phenomenon is well known in the case of polynomial approximation: If we choose too high a degree of the polynomial in order to get good fit to the data points, the estimated polynomial will tend to fluctuate between the data points. The approximation may be good at the data points, but can be very bad between the points. Experience with these large models has shown that what is important is that one gets a stable solution. The exact numerical solutions give good fit or description, but when applied they often give unstable and uncertain predictions. For example, a stable solution should, from a practical point of view, be almost equally good in terms of fit as the exact numerical solution, but have good performance when it is applied.

We present here an algorithm for solving linear equations and linear decomposition of matrices, which has been found efficient in handling large data matrices. The solutions arrived at by the algorithm have been found to be stable and function well from the point of view of the user, i.e., providing an almost equally good solution as the exact one, but giving more precise predictions.

If a large data matrix $\mathbf{A}$ is given and it turns out to be of low rank, the linear equation $\mathbf{Ax} = \mathbf{b}$ is often solved by computing the generalized inverse $\mathbf{A}^\dagger$ by the SVD, and one works further with the solution $\mathbf{x} = \mathbf{A}^\dagger\mathbf{b}$. But this is usually not a good way to compute the solution vector. The reason is that SVD does not take into consideration the right-hand-side vector $\mathbf{b}$. If $\mathbf{b}$ projects onto the subspace associated with the small singular values of $\mathbf{A}$, the solution vector can be very bad or even useless, although there may be a solution given by the present algorithm that functions well. Similarly, the results of an SVD may not be easy to interpret for the user, because the criteria for SVD may not be the important ones for the user.

The present algorithm reduces at each step the matrix $\mathbf{A}$ by rank one. The result, if all components are extracted, is a decomposition of $\mathbf{A}$ of a kind that looks like SVD:

$$\mathbf{A} = \lambda_1\mathbf{u}_1\mathbf{v}_1{}' + \lambda_2\mathbf{u}_2\mathbf{v}_2{}' + \cdots.$$

But in the present algorithm the vectors $(\mathbf{u}_i)$ and $(\mathbf{v}_i)$ need not be orthogonal vectors. The properties of these vectors depend on the criteria used.

In many applied situations we have views or expectations concerning the results we obtain from the mathematical model. For example, if we wish to estimate the maximum of a quadratic surface that fits the given data, we have certain expectations concerning the results. We wish the maximum value to be well determined and the quadratic surface to fit well to data. Often the data follow approximately a quadratic surface in the neighbourhood of the maximum, while data points far away from maximum may not be adequately described by a second-order model. In such situations one may have to choose between a good description of data and a good determination of the maximum. In situations like that it can be useful to be able to specify that the algorithm should take into account the way we look at data. It is actually quite common that we have an attitude concerning the way in which data should be viewed. In neural networks, e.g., a_{ij} is sometimes the weight that goes from node i to node j in the network. If the values in a row are small, we want the solution vector not to depend much on such small values. Similarly, in geology substantial measurement values may be more important than samples with small values. In these situations we would like the results to take into account these views or preferences.

The algorithm presented here allows the user to specify the way he looks at the data. The views are formulated as criteria for determining weights on columns, or on rows, or on both columns and rows. Thus the user specifies a criterion for determining a vector $\mathbf{w}$ that states how the columns of $\mathbf{A}$ should be treated. Similarly, the user can specify a criterion for determining a vector $\mathbf{z}$, that states how the rows should be looked at. The fundamental idea of the present algorithm is that the user specifies criteria for determining $\mathbf{w}_i$, how columns should be treated, and $\mathbf{z}_i$, how rows should be treated, such that $\mathbf{w}_i$ and $\mathbf{z}_i$ reflect the views we have on the given data. The algorithm then orthogonalizes $\mathbf{A}$ with respect to these given choices, $\mathbf{z}_i'\mathbf{A}_j = \mathbf{0}$ and $\mathbf{A}_j\mathbf{w}_i = \mathbf{0}$ for $j \geq i$. This means that we, at each step, extract as much as possible from the given data and adjust the data so that they do not depend on what already has been selected. This means that we select "the best possible" at each step, and we stop when there is nothing more to fetch from data. This means that the algorithm is good at identifying the noise level in data, i.e., the situation where we cannot select more useful results from data. One can ask, "What about the numerical accuracy of the algorithm?" The answer is that, if the data are appropriately scaled from the beginning, we identify the noise level (where we stop) long before there are problems with the numerical accuracy.

The algorithm has been applied to numerous data from practice. What is the experience from these cases? The general experience is that the algorithm functions better than corresponding traditional approaches. This holds especially for large matrices of low rank. But in many cases it can be difficult for the user to know when to stop in the algorithm. Therefore,

we give some criteria and guidelines that we have found useful in determining when to stop in the algorithm.

The present algorithm is a decomposition of the coefficient matrix $\mathbf{A}$ into rank-one components according some choices of the criterion vectors $\mathbf{w}_i$ and $\mathbf{z}_i$. For special choices of $\mathbf{w}_i$ and $\mathbf{z}_i$ one can arrive at most decompositions found in numerical analysis and statistics, but it is not the purpose of the present paper to show that. However, we will point out some cases in which the connection may be of interest.

The emphasis here is on a unified approach to data analysis, matrix decompositions, and computation of the generalized inverse. The practical situation may or may not dictate the approach to choose. The algorithm and a stopping criterion identify the noise level, and we arrive at a decomposition that in a certain sense reflects the views on data as well as possible.

Since the algorithm is very fast and contains at most as many steps as the number of columns or rows in $\mathbf{A}$, we frequently find that scientists like to see more than one decomposition before they decide upon which to use. The scientist looks at different measures of quality and sizes and at several plots; on the basis of these, one decides which decomposition to use.

There are two situations considered in this paper. In the first situation we have only a given data matrix $\mathbf{A}$. In the second one, we need to solve a linear equation $\mathbf{Ax} = \mathbf{b}$. The algorithm is the same for both. In the case of a linear equation one more set of equations needs to be computed, namely, the present solution vector (step 6^o in the algorithm).

2. Notation. Let $\mathbf{A}$ be a rectangular matrix, an n-times-k matrix. We will write

$$\mathbf{A} = (\mathbf{a}_j) = (\mathbf{a}^i) = (a_{ij}).$$

Here $\mathbf{a}_j$ is the jth column vector of $\mathbf{A}$, $\mathbf{a}^i$ the ith row vector and a_{ij} is element number (i, j). A decomposition of $\mathbf{A}$ into rank-one components can be written as

$$\begin{aligned} \mathbf{A} &= \lambda_1 \mathbf{u}_1 \mathbf{v}_1' + \lambda_2 \mathbf{u}_2 \mathbf{v}_2' + \cdots \\ &= \mathbf{U}\Lambda\mathbf{V}'. \end{aligned} \tag{1}$$

Here $\mathbf{U} = (\mathbf{u}_i)$ is a matrix with n rows, $\Lambda = \operatorname{diag}(\lambda_i)$, a diagonal matrix with λ_i in the ith, diagonal and $\mathbf{V} = (\mathbf{v}_i)$ a matrix with k rows. The number of components in (1) is equal to the number of columns in $\mathbf{U}$, Λ, and $\mathbf{V}$. The last equality of (1) follows from the rules of matrix multiplication. When a new set of $(\lambda_i, \mathbf{u}_i, \mathbf{v}_i)$ is computed in the algorithm below, we will sometimes say that we are "extracting a component from $\mathbf{A}$." Note that if $\mathbf{A}$ is of full rank and $n > k$, the number of terms in (1) is equal to k. Thus, e.g., $\mathbf{U}$ will be an n-times-k matrix like $\mathbf{A}$, which shows that there is a lot of indeterminacy in (1). We utilize this indeterminacy to compute the decomposition reflecting the problem in question. $\mathbf{A}'$ and $\mathbf{v}'$ denote the transposes of $\mathbf{A}$ and $\mathbf{v}$, respectively.

3. Scaling of data values. If the units for different parts of data deviate much, it may be necessary to scale the data values. If we are using a criterion for columns, we consider the variation in the numbers $(\mathbf{a}_1'\mathbf{a}_1), \ldots, (\mathbf{a}_k'\mathbf{a}_k)$. If these values are very different, the data values in $\mathbf{A}$ should be scaled. It is common to scale the data values such that $\mathbf{a}_i'\mathbf{a}_i = 1$. Similarly, if we are using a row criterion, it may be necessary to scale the rows. If all values are given in the same units, scaling of data is not needed. For example, if all values are concentrations with values between 0 and 1, scaling is not needed. If the rank is low, one should be careful with scaling data. In order to show the problems involved, suppose that $\mathbf{A}$ has rank two and $\mathbf{u}_1'\mathbf{u}_2 = 0$ in the decomposition (1). Then we get

$$\mathbf{A}'\mathbf{A} = \lambda_1^2(\mathbf{u}_1'\mathbf{u}_1)\mathbf{v}_1\mathbf{v}_1' + \lambda_2^2(\mathbf{u}_2'\mathbf{u}_2)\mathbf{v}_2\mathbf{v}_2'.$$

Scaling $\mathbf{A}$ such that the diagonal elements of $\mathbf{A}'\mathbf{A}$ consist of ones means that there are constraints on the $\mathbf{v}$-vectors. If we know $\mathbf{\Lambda}$ and $\mathbf{U}$, $\mathbf{v}_2$ can be derived from $\mathbf{v}_1$. Thus scaling of columns puts constraints on the $\mathbf{v}$-vectors and if we have only a few $\mathbf{v}$-vectors, we may not be able to use the interpretations that the plots of $\mathbf{v}$-vectors suggest.

4. The singular value decomposition. The singular value decomposition (SVD) is the most used decomposition method in practice. Since the decompositions generated by the present algorithm are of a type similar to the SVD, it is useful to look closer at it. It is a decomposition (1), where the vectors $(\mathbf{u}_i)$ and $(\mathbf{v}_i)$ are chosen to be orthogonal,

$$\mathbf{u}_i'\mathbf{u}_j = 0 \quad \text{and} \quad \mathbf{v}_i'\mathbf{v}_j = 0 \quad \text{for } i \neq j$$

and

$$\mathbf{u}_i'\mathbf{u}_i = 1 \quad \text{and} \quad \mathbf{v}_i'\mathbf{v}_i = 1.$$

The vectors $(\mathbf{u}_i)$ and $(\mathbf{v}_i)$ are the eigenvectors to the eigenvalue problems

$$\mathbf{A}'\mathbf{A}\mathbf{v}_i = \lambda_i^2\mathbf{v}_i \quad \text{and} \quad \mathbf{A}\mathbf{A}'\mathbf{u}_i = \lambda_i^2\mathbf{u}_i.$$

The singular values (λ_i) have the appealing interpretation

$$\lambda_1^2 = \max \|\mathbf{A}\mathbf{w}\|^2 = \max \|\mathbf{A}'\mathbf{z}\|^2 = \max(\mathbf{z}'\mathbf{A}\mathbf{w})^2 \tag{2}$$

for $\|\mathbf{w}\| = 1$ and $\|\mathbf{z}\| = 1$, $\mathbf{w}$ a k vector and $\mathbf{z}$ an n vector.

Here $\|\mathbf{w}\|$ denotes the length of a vector $\mathbf{w}$. The solutions to (2) are given by $\mathbf{w} = \mathbf{v}_i$ and $\mathbf{z} = \mathbf{u}_i$. This means that the first pair, $\mathbf{u}_1$ and $\mathbf{v}_1$, is a set of n-vector and k-vector that gives maximal rank-one reduction, λ_1^2, of $\mathbf{A}$,

$$\operatorname{tr}(\mathbf{A}'\mathbf{A}) = \lambda_1^2 + \lambda_2^2 + \lambda_3^2 + \cdots. \tag{3}$$

$\lambda_1^2 = (\mathbf{u}_1'\mathbf{A}\mathbf{v}_1)^2$ is the maximal size of all possible rank-one reductions of $\mathbf{A}$. The next set $(\mathbf{u}_2, \mathbf{v}_2)$ is selected to be orthogonal to $\mathbf{u}_1$ and $\mathbf{v}_1$, respectively, and gives a maximal reduction in $\mathbf{A}$, λ_2^2, i.e., the largest possible second term in (3). (Here $\operatorname{tr}(\mathbf{A}'\mathbf{A})$ denotes the trace of a matrix $\mathbf{A}'\mathbf{A}$.) This interpretation of the SVD is important and easy to understand.

Most technical literature uses the SVD to determine the generalized inverse, because it has a very simple form,

$$\mathbf{A}^\dagger = 1/\lambda_1\mathbf{v}_1\mathbf{u}_1' + 1/\lambda_2\mathbf{v}_2\mathbf{u}_2' + \cdots. \tag{4}$$

But, as mentioned earlier, in many situations it need not be the proper generalized inverse to use, because the situation may dictate another generalized inverse.

5. The basic algorithm. The basic algorithm is somewhat complicated because it allows judgement of rows, columns, or both. We suppose that we have some view or criterion of treating column vectors $(\mathbf{a}_i)$ of $\mathbf{A}$. $(\mathbf{w}_i)$-vectors reflect this view. Similarly, some principle or view determines $(\mathbf{z}_i)$, which states how to look at the row vectors of $\mathbf{A}$.

Let $\mathbf{A}_o = \mathbf{A}$, $\mathbf{x}_o = \mathbf{0}$ and let $\mathbf{E}_o = \mathbf{I}_k$ and $\mathbf{B}_o = \mathbf{I}_n$, where $\mathbf{I}_k$ and $\mathbf{I}_n$ are the identity matrices of size k and n, respectively. The steps of the algorithm are as follows:

For $i = 1, 2, \ldots$

1°. **Determine criterion vector for columns.**

Choose the k-vector $\mathbf{w}_i$ that reflects how columns of $\mathbf{A}$ should be treated.

2°. **Determine criterion vector for rows.**
Choose the n-vector $\mathbf{z}_i$ that reflects how rows of $\mathbf{A}$ should be treated.

3°. **Compute components.**
Compute

$$\mathbf{u}_i = \mathbf{A}_{i-1}\mathbf{w}_i, \qquad \mathbf{v}_i = \mathbf{A}_{i-1}{}'\mathbf{z}_i, \quad \text{and} \quad \lambda_i = 1/(\mathbf{z}_i{}'\mathbf{A}_{i-1}\mathbf{w}_i).$$

4°. **Rank-one reduction of A.**

$$\mathbf{A}_i = \mathbf{A}_{i-1} - \lambda_i \mathbf{u}_i \mathbf{v}_i{}'.$$

5°. **Compute the transformation vectors.**

$$\mathbf{r}_i = \mathbf{E}_{i-1}\mathbf{w}_i, \qquad \mathbf{s}_i = \mathbf{B}_{i-1}\mathbf{z}_i,$$

Update the transformation matrices.

$$\mathbf{E}_i = \mathbf{E}_{i-1} - \lambda_i \mathbf{r}_i \mathbf{v}_i{}', \qquad \mathbf{B}_i = \mathbf{B}_{i-1} - \lambda_i \mathbf{s}_i \mathbf{u}_i{}'.$$

6°. **In case of solving a linear equation, $\mathbf{Ax} = \mathbf{b}$.**
Compute the improved solution vector.

$$\mathbf{x}_i = \mathbf{x}_{i-1} + \lambda_i(\mathbf{b}'\mathbf{s}_i)\mathbf{r}_i = \lambda_1(\mathbf{b}'\mathbf{s}_1)\mathbf{r}_1 + \cdots + \lambda_i(\mathbf{b}'\mathbf{s}_i)\mathbf{r}_i.$$

7°. **Determine if a new iteration should be carried out**. Determine from the criteria used if a new iteration is to be carried out. In that case set i to $i + 1$ and start from 1°.

Discussion of the algorithm. We shall now discuss the individual steps in the algorithm.

1°. We suppose that there is a criterion that determines $\mathbf{w}_i$. The criterion states how we look at the columns of $\mathbf{A}$. If the user does not specify such a column criterion, we choose $\mathbf{w}_i = \mathbf{v}_i$.

2°. Similarly, we suppose that there is a criterion that determines $\mathbf{z}_i$, which shows how rows should be looked at. If the user does not specify such a row criterion, we choose $\mathbf{z}_i = \mathbf{u}_i$.

3°. The vectors $\mathbf{u}_i$ and $\mathbf{v}_i$ are the resulting vectors,

$$\mathbf{u}_i = \mathbf{A}_{i-1}\mathbf{w}_i = \mathbf{a}_i w_{1i} + \mathbf{a}_2 w_{2i} + \cdots$$

and

$$\mathbf{v}_i = \mathbf{A}_{i-1}{}'\mathbf{z}_i = \mathbf{a}^1 z_{1i} + \mathbf{a}^2 z_{2i} + \cdots.$$

These vectors are the best we can select from $\mathbf{A}$ and the value of a common criterion is $1/\lambda_i = \mathbf{z}_i{}'\mathbf{A}_{i-1}\mathbf{w}_i$. The larger the numerical value of this common criterion is, the better are the vectors $\mathbf{u}_i$ and $\mathbf{v}_i$. If the value is zero, we cannot reduce $\mathbf{A}$ more by using the given criteria.

4°. Here we reduce $\mathbf{A}$ by the vectors selected. That it always gives a rank-one reduction of $\mathbf{A}$, when $\mathbf{z}_i{}'\mathbf{A}_{i-1}\mathbf{w}_i$ is different from zero, is a well-known theorem of Laplace. If all possible vectors are selected, we get (1).

5°. The transformation vectors $\mathbf{r}_i$ and $\mathbf{s}_i$ are needed in order to compute the generalized inverse that is associated with the decomposition. The vector $\mathbf{r}_i$ is determined so that $\mathbf{u}_i = \mathbf{A}\mathbf{r}_i$ and $\mathbf{r}_i$ is a linear combination of $\mathbf{w}_1, \ldots, \mathbf{w}_i$. We write

$$\begin{aligned}\mathbf{u}_i = \mathbf{A}\mathbf{r}_i &= \mathbf{A}_{i-1}\mathbf{w}_i = \mathbf{A}_{i-2}(\mathbf{I} - \lambda_{i-1}\mathbf{w}_{i-1}\mathbf{v}_{i-1}{}')\mathbf{w}_i \\ &= \mathbf{A}(\mathbf{I} - \lambda_1\mathbf{w}_1\mathbf{v}_1{}')\cdots(\mathbf{I} - \lambda_{i-1}\mathbf{w}_{i-1}\mathbf{v}_{i-1}{}')\mathbf{w}_i = \mathbf{A}\,\mathbf{E}_{i-1}\mathbf{w}_i.\end{aligned}$$

For

$$\mathbf{E}_{i-1} = (\mathbf{I} - \lambda_1 \mathbf{w}_1 \mathbf{v}_1{}') \cdots (\mathbf{I} - \lambda_{i-1} \mathbf{w}_{i-1} \mathbf{v}_{i-1}{}')$$

we can write

$$\mathbf{E}_i = \mathbf{E}_{i-1}(\mathbf{I} - \lambda_i \mathbf{w}_i \mathbf{v}_i{}') = \mathbf{E}_{i-1} - \lambda_i \mathbf{r}_i \mathbf{v}_i{}'.$$

Similarly, $\mathbf{s}_i$ is determined so that $\mathbf{v}_i = \mathbf{A}'\mathbf{s}_i$ and $\mathbf{s}_i$ is a linear combination of $\mathbf{z}_1, \ldots \mathbf{z}_i$. An expansion of $\mathbf{A}_{i-1}$ given by

$$\begin{aligned}\mathbf{A}_{i-1} &= (\mathbf{I} - \lambda_{i-1} \mathbf{u}_{i-1} \mathbf{z}_{i-1}{}')\mathbf{A}_{i-2} \\ &= (\mathbf{I} - \lambda_{i-1} \mathbf{u}_{i-1} \mathbf{z}_{i-1}{}') \cdots (\mathbf{I} - \lambda_1 \mathbf{u}_1 \mathbf{z}_1{}')\mathbf{A} = \mathbf{B}_{i-1}{}'\mathbf{A}\end{aligned}$$

gives similarly the equation of $\mathbf{s}_i$ and the recursive one for $\mathbf{B}_i$.

6°. In the case where we are solving a linear equation, we use this step. The vector $\mathbf{x}_i$ is an estimate of the linear least squares solution $\mathbf{x} = (\mathbf{A}'\mathbf{A})^\dagger \mathbf{A}'\mathbf{b}$, when i terms are used in the expansion of $\mathbf{x}$.

The algorithm works with three pairs of vectors. The vectors $(\mathbf{w}_i)$ and $(\mathbf{z}_i)$ are determined from the criteria given by the practical problem in question. $(\mathbf{u}_i)$ and $(\mathbf{v}_i)$ reduce $\mathbf{A}$ by rank one, and $(\mathbf{r}_i)$ and $(\mathbf{s}_i)$ reduce $\mathbf{A}^\dagger$ by rank one. When $\mathbf{w}_i$ or $\mathbf{z}_i$ are selected, they can be scaled to be of length one. In the algorithm we do not scale $\mathbf{u}_i$ or $\mathbf{v}_i$. The scaling is taken care of by the constant λ_i. This is done in order to secure numerical stability of the algorithm. All computations in the algorithm are products and inner products except the computation of λ_i. This means that the algorithm can be programmed to give very precise numerical results.

In the case of SVD the $(\mathbf{w}_i)$ are the eigenvectors to the eigenvalue problem $\mathbf{A}'\mathbf{A}\mathbf{w} = \lambda\mathbf{w}$. In that case, $\mathbf{w}_i = \mathbf{v}_i = \mathbf{r}_i$ and $\mathbf{u}_i = \mathbf{z}_i = \mathbf{s}_i$ apart from a scaling constant. Note that in the SVD, $\mathbf{u}$- and $\mathbf{v}$-vectors are scaled to be of length one, while in the present algorithm they are not. See below what criterion gives SVD.

6. Geometric properties of the vectors. The vectors in the algorithm have the following geometric properties.

PROPERTY 1. $\mathbf{z}_i$ *is orthogonal to later* $\mathbf{A}$*-matrices,*

$$\mathbf{z}_i{}'\mathbf{A}_j = \mathbf{0} \quad \textit{for } i \leq j. \tag{5}$$

PROPERTY 2. $\mathbf{z}_i$ *is orthogonal to later* $\mathbf{u}$*-vectors,*

$$\mathbf{z}_i{}'\mathbf{u}_j = \mathbf{0}, \qquad i < j. \tag{6}$$

PROPERTY 3. $\mathbf{w}_i$ *is orthogonal to later* $\mathbf{A}$*-matrices,*

$$\mathbf{A}_j\mathbf{w}_i = \mathbf{0}, \qquad i \leq j. \tag{7}$$

PROPERTY 4. $\mathbf{w}_i$ *is orthogonal to later* $\mathbf{v}$*-vectors,*

$$\mathbf{w}_i{}'\mathbf{v}_j = \mathbf{0}, \qquad i < j. \tag{8}$$

PROPERTY 5. $(\mathbf{s}_i)$ *and* $(\mathbf{u}_i)$ *are mutually orthogonal,*

$$\mathbf{s}_i{}'\mathbf{u}_j = \mathbf{0} \quad \textit{and} \quad \mathbf{s}_i{}'\mathbf{u}_i = 1/\lambda_i, \qquad i \neq j. \tag{9}$$

PROPERTY 6. $(\mathbf{r}_i)$ *and* $(\mathbf{v}_i)$ *are mutually orthogonal,*

$$\mathbf{r}_i'\mathbf{v}_j = \mathbf{0}, \quad \mathbf{r}_i'\mathbf{v}_i = 1/\lambda_i \quad \textit{for } i \neq j. \tag{10}$$

PROPERTY 7. *If* $(\mathbf{w}_i)$ *is chosen such that it is in the range of* $\mathbf{A}_{i-1}'$, $(\mathbf{w}_i)$ *are mutually orthogonal*

$$\mathbf{w}_i'\mathbf{w}_j = \mathbf{0} \quad \textit{for } i \neq j.$$

PROPERTY 8. *The generalized inverse of* $\mathbf{A}$ *can be computed as*

$$\begin{aligned} \mathbf{A}^\dagger &= \lambda_1\mathbf{r}_1\mathbf{s}_1' + \lambda_2\mathbf{r}_2\mathbf{s}_2' + \cdots \\ &= \mathbf{R}\Lambda\mathbf{S}'. \end{aligned} \tag{11}$$

These properties are proved in Appendix 1.

Properties 1 and 3 are the most basic properties. They show that the reduction of $\mathbf{A}$ can be viewed such that $\mathbf{A}$ is adjusted for the actual choices of $\mathbf{w}_i$ and $\mathbf{z}_i$. The rows of $\mathbf{A}$ are made orthogonal to $\mathbf{w}_i$ and columns of $\mathbf{A}$ are made orthogonal to $\mathbf{z}_i$. Usually $\mathbf{w}_i$ is chosen to be in the range of $\mathbf{A}_{i-1}'$, which gives orthogonal set $(\mathbf{w}_i)$. By symmetry, if $\mathbf{z}_i$ is chosen in the range of $\mathbf{A}_{i-1}$, the set $(\mathbf{z}_i)$ becomes an orthogonal set of vectors. Note that the coefficients (λ_i) in (11) differ from the corresponding ones in (4), because the vectors $(\mathbf{r}_i)$ and $(\mathbf{s}_i)$ are not scaled to be of unit length.

In terms of matrices, Properties 5 and 6 can be written as

$$\mathbf{R}'\mathbf{V} = \Lambda^{-1} \quad \text{and} \quad \mathbf{S}'\mathbf{U} = \Lambda^{-1},$$

where $\mathbf{R} = (\mathbf{r}_i)$, $\mathbf{V} = (\mathbf{v}_i)$, $\mathbf{S} = (\mathbf{s}_i)$, $\mathbf{U} = (\mathbf{u}_i)$, and $\Lambda^{-1} = \text{Diag}(1/\lambda_i)$.

7. The quality of solutions: Example 1. We shall here consider some questions concerning the quality of solutions derived from the decompositions arrived at by the algorithm. We shall discuss the question of quality in the light of a small example. We suppose that the situation is that there is given a set of linear equations, $\mathbf{Ax} = \mathbf{b}$. The data are given as follows.

$$\mathbf{A} = \begin{matrix} -101.00001 & 98.00001 & 101.00002 \\ -99.00001 & 102.00001 & 99.00002 \\ 98.99999 & -101.99999 & -98.99998 \\ 100.99999 & -97.99999 & -100.99998 \end{matrix}, \quad \mathbf{b} = \begin{matrix} 98.00002 \\ 102.00002 \\ -101.99998 \\ -97.99998 \end{matrix}.$$

Here $\mathbf{A}$ has approximately the rank two ($\mathbf{a}_3 \approx -\mathbf{a}_1$). But the exact numerical solution can be computed and it is given by $\mathbf{x} = (1, 1, 1)$. Although this example is small, it is representative for the situations in which large data matrices are involved. If we use the column criterion (17) below and no row criterion, the solution vector $\mathbf{x}_i$ obtains the following values in the algorithm.

Solution vector $\mathbf{x}_i$ at iterations 1 – 3:

1	2	3
−0.33326669332267	0.00000000000287	1.00000000013348
0.33346669333867	0.99999999999445	1.00000000000000
0.33326669332268	0.00000000000844	1.00000000013349

Here we would normally select as a solution the one obtained at the second iteration, $\mathbf{x}_2$. We note that the solution $\mathbf{x}_3$ is close to the exact solution, while $\mathbf{x}_2$ differs much from the exact solution. When should we select as exact a solution as possible, and when should we select as stable a solution as possible? In cases where we have a technical construction and the coefficients are exact numbers derived from the given construction, we should select the exact solution. But in most cases in practice the coefficients are uncertain. In these cases we should select as good a solution as possible. There are three aspects of a good solution that we shall consider here.

I. *Sizes of criteria used.*

(1) Size of the column criterion.

(2) Size of the row criterion.

(3) The combined criteria, $\mathbf{z}_i'\mathbf{A}_{i-1}\mathbf{w}_i$.

Interpretation of (3) is similar to the one in the case of the SVD, i.e., the variation extracted by the row and column criteria. In the example above $\mathbf{z}_3'\mathbf{A}_2\mathbf{w}_3 = 2^*10^{-10}$. This shows that the third component, $(\lambda_3, \mathbf{u}_3, \mathbf{v}_3)$, is not explaining any variation in data.

II. *Sizes of results.*

(1) Residuals, $\mathbf{A}_{i-1}$ or $\mathbf{A}\mathbf{x}_i - \mathbf{b}$.

(2) Size of reduction in $\mathbf{A}$ and/or $\mathbf{b}$ due to the rank-one reduction.

(3) Size of extracted matrices, $\mathbf{A} - \mathbf{A}_i$ and $(\mathbf{A} - \mathbf{A}_i)^\dagger$.

Here the elements of $\mathbf{A}\mathbf{x}_2 - \mathbf{b}$ are less than or equal to 10^{-5}. Thus $\mathbf{x}_2$ gives sufficiently small error estimates. The precision of the solution vector $\mathbf{x}_i$ can be expressed in terms of $((\mathbf{A} - \mathbf{A}_i)'(\mathbf{A} - \mathbf{A}_i))^\dagger$, see Appendix 2. Since the rank of $\mathbf{A}$ is approximately two, the inverse increases extremely, when adding the third component. This means that $\mathbf{x}_3$ is a very unstable solution.

III. *Measures of performance.*

(1) Total prediction variance,

(a) $\|\mathbf{A}_i\|_F{}^2\|(\mathbf{A} - \mathbf{A}_i)^\dagger\|_F{}^2$, (b) $\|\mathbf{A}\mathbf{x}_i - \mathbf{b}\|^2\|(\mathbf{A} - \mathbf{A}_i)^\dagger\|_F{}^2$.

(2) Total prediction error variance,

(a) $\|\mathbf{A}_i\|_F{}^2(1 + \|(\mathbf{A} - \mathbf{A}_i)^\dagger\|_F{}^2)$, (b) $\|\mathbf{A}\mathbf{x}_i - \mathbf{b}\|^2(1 + \|(\mathbf{A} - \mathbf{A}_i)^\dagger\|_F{}^2)$.

(3) The H-index,

(a) $\|\Delta\mathbf{A}_i\|_F{}^2/\|\Delta\mathbf{A}_i{}^\dagger\|_F{}^2$, (b) $\|\Delta(\mathbf{A}\mathbf{x}_i)\|^2/\|\Delta\mathbf{A}_i{}^\dagger\|_F{}^2$.

Since the size of $(\mathbf{A} - \mathbf{A}_2)^\dagger$ is small, while that of $(\mathbf{A} - \mathbf{A}_3)^\dagger$ is very large, $\mathbf{x}_3$ when it is applied, will have very bad performance.

The formulas (a) refer to the case in which we have only $\mathbf{A}$, while (b) refers to the case of solving a linear equation. The motivation for these three measures is given in Appendix 2. Note that in the algorithm $\mathbf{A}_i$ is the residual matrix, when i components have been extracted, while $(\mathbf{A} - \mathbf{A}_i)$ represents what has been extracted.

8. Criteria based on columns only. In many situations we wish to select only $\mathbf{w}_i$. This happens when there are not big differences from row to row in $\mathbf{A}$. In many statistical analyses the rows of $\mathbf{A}$ can be viewed as repeated samples and thus expected to be of approximately same size. If we have no special information or theory on the variation of the row, it is natural to seek only to determine $\mathbf{w}_i$.

In this case we have

$$\mathbf{u}_i = \mathbf{A}_{i-1}\mathbf{w}_i, \qquad \mathbf{z}_i = \mathbf{s}_i = \mathbf{u}_i, \quad \text{and} \quad \mathbf{v}_i = \mathbf{A}_{i-1}{}'\mathbf{u}_i.$$

From Property 2 we get that $(\mathbf{u}_i)$ are mutually orthogonal:

$$\mathbf{u}_i{}'\mathbf{u}_j = 0 \qquad \text{for } i \neq j,$$

and from the definition of λ_i we get

$$\lambda_i = 1/(\mathbf{u}_i'\mathbf{u}_i). \tag{12}$$

Since $\mathbf{A}_{i-1}'\mathbf{u}_i = \mathbf{A}'\mathbf{u}_i$, it follows that $\mathbf{s}_i = \mathbf{u}_i$. The size H_i of the reduction in $\mathbf{A}$ is given by

$$\begin{aligned} H_i &= \operatorname{tr}[(\lambda_i\mathbf{u}_i\mathbf{v}_i')(\lambda_i\mathbf{u}_i\mathbf{v}_i')'] = \lambda_i^2(\mathbf{u}_i'\mathbf{u}_i)(\mathbf{v}_i'\mathbf{v}_i) = (\mathbf{v}_i'\mathbf{v}_i)/(\mathbf{u}_i'\mathbf{u}_i) \\ &= (\mathbf{u}_i'\mathbf{u}_i)\|\mathbf{A}_{i-1}'\mathbf{A}_{i-1}\mathbf{w}_i\|^2/(\|\mathbf{A}_{i-1}\mathbf{w}_i\|^2)^2. \end{aligned} \tag{13}$$

If $\mathbf{w}_i$ is any eigenvector of $\mathbf{A}_{i-1}'\mathbf{A}_{i-1}$ of unit length, H_i will be equal to $(\mathbf{u}_i'\mathbf{u}_i) = \mathbf{z}_i'\mathbf{A}_{i-1}\mathbf{w}_i$. Often the $\mathbf{w}$-vector will be close to an eigenvector of $\mathbf{A}_{i-1}'\mathbf{A}_{i-1}$, and therefore H_i will be approximately the squared size of the $\mathbf{u}$-vector. Also H_i is invariant to the scale of $\mathbf{w}_i$, and thus $\mathbf{w}_i$ can always be chosen to be of length one.

It is often convenient to work with the algorithm in terms of the positive definite matrix associated with $\mathbf{A}$, namely, $\mathbf{A}'\mathbf{A}$, i.e., not to compute the vectors $\mathbf{u}_i$. This is the case when we want to work with the normal equations only: $\mathbf{A}'\mathbf{A}\mathbf{x} = \mathbf{A}'\mathbf{b}$. The algorithm can now be formulated as follows:

0°. **Compute** $\mathbf{Q} = \mathbf{A}'\mathbf{A}$ and let $\mathbf{Q}_o = \mathbf{Q}$.

1°. **Determine** $\mathbf{w}_i$.
Select $\mathbf{w}_i$, e.g., according to some criterion.

2°. **Compute components**.

$$\mathbf{v}_i = \mathbf{Q}_{i-1}\mathbf{w}_i \quad \text{and} \quad \lambda_i = 1/(\mathbf{w}_i'\mathbf{Q}_{i-1}\mathbf{w}_i).$$

3°. **Rank-one reduction of** $\mathbf{Q}$.

$$\mathbf{Q}_i = \mathbf{Q}_{i-1} - \lambda_i\mathbf{v}_i\mathbf{v}_i'.$$

4°. **Compute the transformation vector**.

$$\mathbf{r}_i = \mathbf{E}_{i-1}\mathbf{w}_i.$$

Update the transformation matrix.

$$\mathbf{E}_i = \mathbf{E}_{i-1} - \lambda_i\mathbf{r}_i\mathbf{v}_i'.$$

5°. **In case of solving a linear equation,** $\mathbf{Ax} = \mathbf{b}$.
Compute the improved solution vector, $\mathbf{q} = \mathbf{A}'\mathbf{b}$,

$$\mathbf{x}_i = \mathbf{x}_{i-1} + \lambda_i(\mathbf{q}'\mathbf{r}_i)\mathbf{r}_i = \lambda_1(\mathbf{q}'\mathbf{r}_1)\mathbf{r}_1 + \cdots + \lambda_i(\mathbf{q}'\mathbf{r}_i)\mathbf{r}_i.$$

6°. **Determine if a new iteration should be carried out**.
If a new component is to be selected, $i \to i + 1$ and go to 1°.

This form of the algorithm is based on the properties that the $\mathbf{u}$-vectors are orthogonal and that λ_i is given by (12). If the matrix $\mathbf{A}'\mathbf{A}$ is fully reduced, we have

$$\mathbf{A}'\mathbf{A} = \lambda_1\mathbf{v}_1\mathbf{v}_1' + \lambda_2\mathbf{v}_2\mathbf{v}_2' + \cdots,$$

$$(\mathbf{A}'\mathbf{A})^\dagger = \lambda_1\mathbf{r}_1\mathbf{r}_1' + \lambda_2\mathbf{r}_2\mathbf{r}_2' + \cdots.$$

This form of the algorithm is useful if we are updating the decomposition with a new row of $\mathbf{A}$, or analyzing the dependence of the decomposition on one or more rows. This follows from

$$\mathbf{A}'\mathbf{A} = \mathbf{a}^1\mathbf{a}^{1\prime} + \mathbf{a}^2\mathbf{a}^{2\prime} + \cdots + \mathbf{a}^n\mathbf{a}^{n\prime}. \tag{14}$$

Using (14) and the above form of the algorithm makes it easy to update the decomposition when a new row is added to $\mathbf{A}$. If $\mathbf{a}^{n+1}$ is a new row, we compute the new $\mathbf{Q}$-matrix as $\mathbf{Q} = \mathbf{A}'\mathbf{A} + \mathbf{a}^{n+1}\mathbf{a}^{n+1\prime}$ and start from 1° in the modified algorithm.

8.1. Some criteria based on A only. In order to simplify the notation we shall drop the indices associated with each step in the algorithm. We are to determine a vector $\mathbf{w}$ such that

$$\mathbf{u} = \mathbf{A}\mathbf{w} = w_1\mathbf{a}_1 + w_2\mathbf{a}_2 + \cdots + w_k\mathbf{a}_k$$

has some desirable properties or characteristics. There are some views that are common in practice that we will review.

8.1.1. Variation in u. One view is to determine $\mathbf{w}$ such that the variation in the values in the $\mathbf{u}$-vector has some properties. One is to require that the length of $\mathbf{u}$ is as large as possible for $|\mathbf{w}| = 1$. This is the criterion of the SVD. The power method, see [3], can be used to determine $\mathbf{w}$, because it gives one eigenvector at a time.

8.1.2. Selection of variables. Frequently, each column in the data table contains repeated measurements of a given physical magnitude. In practice we say that we have a variable and the column represents measurements of the variable at different instances. A basic question is often, "Which variables (columns) are important?" In our setup it corresponds to choosing $\mathbf{w}$ to be a unit vector having zeros at all coordinates except one, which is equal to 1. The coordinate equal to 1 corresponds to the variable that is selected. Let $\mathbf{w}$ be given by

$$\mathbf{w}' = (0, 0, \ldots, 0, 1, 0, \ldots)$$

with 1 at the jth coordinate. With this notation we have

$$\mathbf{u} = \mathbf{a}_j, \quad \mathbf{v}' = (\mathbf{a}_j'\mathbf{a}_1, \mathbf{a}_j'\mathbf{a}_2, \ldots) \quad \text{and} \quad \lambda = 1/(\mathbf{a}_j'\mathbf{a}_j).$$

This gives H_j of (13) equal to

$$H_j = [(\mathbf{a}_j'\mathbf{a}_1)^2 + (\mathbf{a}_j'\mathbf{a}_2)^2 + \cdots + (\mathbf{a}_j'\mathbf{a}_k)^2]/(\mathbf{a}_j'\mathbf{a}_j). \tag{15}$$

In [4] the H-principle, the Heisenberg principle of mathematical modelling, is formulated and applied to different modelling tasks. According to the H-principle we should consider

$$\begin{aligned} &\{\text{size of reduction in } \mathbf{A}\}\{\text{size of the } \mathbf{u}\text{-vector}\} \\ &= H_j(\mathbf{u}_j'\mathbf{u}_j) \\ &= (\mathbf{a}_j'\mathbf{a}_1)^2 + (\mathbf{a}_j'\mathbf{a}_2)^2 + \cdots + (\mathbf{a}_j'\mathbf{a}_k)^2. \end{aligned} \tag{16}$$

Thus the criterion of determining a column of $\mathbf{A}$ is

$$\underset{j}{\text{maximize}}\,[(\mathbf{a}_j'\mathbf{a}_1)^2 + (\mathbf{a}_j'\mathbf{a}_2)^2 + \cdots + (\mathbf{a}_j'\mathbf{a}_k)^2] \quad \text{for} \quad j = 1, 2, \ldots, k. \tag{17}$$

The intuitive argument for criterion (17) is that the size of the reduction of $\mathbf{A}$, H_j, does not depend on the length of the $\mathbf{u}$-vector, only on its direction (H_j does not change if $\mathbf{u}$ is replaced by $c\mathbf{u}$, where c is a constant different from zero). Thus if we only use (15) as a criterion, the risk is that we select a column that is small and will "blow up" (15) because it is small. On the other hand, a large $\mathbf{u}$-vector need not be good to "explain" the remaining columns in the $\mathbf{A}$-matrix. The criterion (17) is balancing these two opposite points of view on the modelling task.

In the literature there have been many suggestions of how to select columns. An interesting one is the concept of "pure variables," see [5]. The basic idea is to consider σ_i/m_i, where σ_i is the standard deviation of the values in the ith column and m_i the average value (where m_i is close to zero, it is replaced by $(m_i + \epsilon)$). The purest variable is the one where this is smallest. When a pure variable has been selected, the $\mathbf{A}$-matrix is adjusted for the selected column, as in the present algorithm. The disadvantage of the concept of pure variables is that a pure variable need not be good in explaining other variables. Thus the concept of pure variables should be modified in a way similar to the way in which we treated the reduction H_j due to a variable.

8.1.3. w as weight coefficients. It was shown in the algorithm that the rows of reduced **A** become orthogonal to the **w**-vectors that have been selected. Sometimes the data or the situation dictates some weights that are appropriate to use. In [6] the concept of a marker is introduced, which is a row of **A** that is "important" and appropriate to use as relative weights. Another choice of **w** consists of ones, $\mathbf{w} = (1, 1, \ldots, 1)$. Here we are actually centering the rows of **A** because all rows in reduced **A**'s will have sum zero.

Criteria other than those mentioned above can be used. Also the above criteria can be mixed. For example, it sometimes happens that in the selection of variables once some variables have been selected, none of the remaining ones are doing a good job, though we are clearly not at the noise level. In these cases it can be advantageous to start selecting **w** according to the variation in **u** like, e.g., the eigenvectors of the reduced **A** matrix (eigenvector of $\mathbf{A}_{i-1}'\mathbf{A}_{i-1}$).

We shall now consider more closely the case when **A** is not of full rank and we are selecting variables. Suppose that j variables have been selected and $\mathbf{A}_j$ is judged to be zero. To simplify the notation, we will suppose that it is the first j columns of **A** that have been chosen. Let **A** be partitioned as $\mathbf{A} = (\mathbf{A}_1, \mathbf{A}_2)$, where $\mathbf{A}_1$ is the first j columns of **A**. If **V** is partitioned in a similar way, $\mathbf{V}' = (\mathbf{V}_1', \mathbf{V}_2')$, where $\mathbf{V}_1$ is j times j, we get from $\mathbf{A} = \mathbf{UDV}'$,

$$\mathbf{A}_1 = \mathbf{UDV}_1' \quad \text{and} \quad \mathbf{A}_2 = \mathbf{UDV}_2'. \tag{18}$$

Here **U** has j orthogonal columns. We are here selecting columns and $(\mathbf{DV}_1')$ is upper triangular with 1 in its diagonal. Thus here the algorithm is numerically equivalent to the well-known QR algorithm in numerical analysis. Equation (18) also shows how the last columns of **A** depend on the first j ones:

$$\mathbf{A}_2 = \mathbf{A}_1\mathbf{V}_1'^{-1}\mathbf{V}_2'.$$

8.2. Selection of $\mathbf{w}_i$ in case of linear equations. The choice of **w** is one of the most extensively studied problems in numerical analysis and theoretical statistics. In numerical analysis it has been studied in relation to "conjugate" and "steepest descent" methods, see [7]. In statistics it is known as variable or component selection, see [8], [9], and [11]. We shall only mention here how the H-principle suggests that we choose **w**. Similar to (16), we should consider

$$\{\text{reduction in variation in } \mathbf{b}\}\{\text{size of the } \mathbf{u}\text{-vector}\}. \tag{19}$$

The reduction in variation in **b** is $(\mathbf{b}'\mathbf{u})^2/(\mathbf{u}'\mathbf{u})$ (the squared length of the projection of **b** onto **u**). Thus (19) becomes

$$[(\mathbf{b}'\mathbf{u})^2/(\mathbf{u}'\mathbf{u})](\mathbf{u}'\mathbf{u}) = (\mathbf{b}'\mathbf{u})^2 = (\mathbf{b}'\mathbf{Aw})^2. \tag{20}$$

Thus the H-principle suggests choosing **w** so that it maximizes (20), which has the solution

$$\mathbf{w} = \mathbf{A}'\mathbf{b}/\|\mathbf{A}'\mathbf{b}\|. \tag{21}$$

This choice of **w** is the criterion of partial least squares (PLS) regression, see [12]. The intuitive argument for (19) is the same as for (16). With this choice of **w** they become orthogonal, $\mathbf{w}_i\mathbf{w}_j = 0$ for $i \neq j$.

Example 1, cont.

We shall look at the properties of the solution shown earlier, where **w** was chosen as given in (21). If **w** in (21) is inserted in (20), we get $(\mathbf{b}'\mathbf{Aw})^2 = \|\mathbf{A}'\mathbf{b}\|^2$. Let us look more closely at Table 1.

TABLE 1

i	Size of column criterion $\|\mathbf{A}_{i-1}'\mathbf{b}\|$	Combined criteria $\mathbf{z}_i'\mathbf{A}_{i-1}\mathbf{w}_i$	Prediction variance	Prediction error variance
1	69282.035074038	119999.990401923	$0.01110667\ 10^{-7}$	15.99360064
2	19.5919995419	24.000001920	$0.00000695\ 10^{-7}$	0.0000000004
3	0.0000000003	0.000000000	$0.10097420\ 10^{-7}$	0.0000000101

The first two columns tell us how much we are selecting at each step of the algorithm. And we see that at the third step we are actually not selecting anything. The last two columns are approximate estimates of variances, when the linear model is applied. Generally, we select the number where they are smallest. We see that they are smallest at the second step, $i = 2$. This table therefore confirms the previous conclusion that we should carry out only two steps (iterations) in the algorithm. □

The approach given by (19) to (21) identifies the projection of $\mathbf{b}$ onto the linear column space of $\mathbf{A}$. If there is a very high degree of collinearity in the column space of $\mathbf{A}$, then this approach may not be the best approach. If large portions of columns of $\mathbf{A}$ depend linearly on the other columns of $\mathbf{A}$, it can be beneficial to identify the "good" linearly independent columns and use the approach given by (19) to (21) on these columns instead of the whole of $\mathbf{A}$. The reason for this is that $\mathbf{w}$ in (21) involves the linear combination of all columns in $\mathbf{A}$, and one can show that the redundant columns may worsen the quality of the solution. We shall here consider how to choose "good" columns of $\mathbf{A}$ using the criteria (19) and (20). Let $\mathbf{w} = (0, \ldots, 0, 1, 0, \ldots)$, where the jth element of $\mathbf{w}$ contains one and others are zero. Then $\mathbf{Aw} = \mathbf{a}_j$ and the criterion (20) becomes

$$\text{maximize } (\mathbf{b}'\mathbf{a}_j)^2 \quad \text{for} \quad j = 1, \ldots, k. \tag{22}$$

Thus the procedure here is to determine the column giving the maximum value of (22). We shall see how this functions for the small example we have considered.

Table 2, which is similar to Table 1, follows:

TABLE 2

Col	Size of column criterion $\|\mathbf{A}_{i-1}'\mathbf{b}\|$	Combined criteria $\mathbf{z}_i'\mathbf{A}_{i-1}\mathbf{w}_i$	Prediction variance	Prediction error variance
2	40016.0000000008	40016.0000000004	$0.0000000000003\ 10^{-6}$	$0.0004\ 10^{-6}$
3	0.0000000004	35.9856057581	$0.0000012351853\ 10^{-6}$	$0.0004\ 10^{-6}$
1	0.0000000004	0.0000000004	$0.1312664544592\ 10^{-6}$	$0.1313\ 10^{-6}$

From the table we see that when we have selected the second column very little is left in data. Thus the results here suggest that only column number 2 should be used. □

9. Criteria based on rows only. Criteria that are the same or similar to the ones we have discussed previously can be used for the rows. But frequently we have different views on rows than on columns. We often expect some rows to be more important than some other rows. This can often be formulated in terms of weights determined by the row.

When there is given a criterion for rows only, we choose only the vectors $(\mathbf{z}_i)$. We have

$$\mathbf{v}_i = \mathbf{A}_{i-1}'\mathbf{z}_i, \quad \mathbf{w}_i = \mathbf{r}_i = \mathbf{v}_i, \quad \text{and} \quad \mathbf{u}_i = \mathbf{A}_{i-1}\mathbf{w}_i.$$

From Property 4 it follows that $(\mathbf{v}_i)$ are orthogonal:

$$\mathbf{v}_i'\mathbf{v}_j = 0 \quad \text{for } i \neq j.$$

From the definition of λ_i we get

$$\lambda_i = 1/\mathbf{v}_i'\mathbf{v}_i.$$

The size of the reduction in $\mathbf{A}$, which is similar to H_i of (13), is here given as

$$H_i = (\mathbf{u}_i'\mathbf{u}_i)/(\mathbf{v}_i'\mathbf{v}_i) = (\mathbf{v}_i'\mathbf{v}_i)\|\mathbf{A}_{i-1}\mathbf{A}_{i-1}'\mathbf{z}_i\|^2/[\|\mathbf{A}_{i-1}'\mathbf{z}_i\|^2]^2.$$

If $\mathbf{z}_i$ is any eigenvector of $\mathbf{A}_{i-1}\mathbf{A}_{i-1}'$ of unit length, the size of the reduction will be $(\mathbf{v}_i'\mathbf{v}_i) = \mathbf{z}_i'\mathbf{A}_{i-1}\mathbf{w}_i$. Thus one can state that the size of the reduction when $\mathbf{z}_i$ is close to an eigenvector is approximately equal to $(\mathbf{v}_i'\mathbf{v}_i)$.

9.1. Sizes. An important type of choice of $\mathbf{z}_i$ is the size of rows of $\mathbf{A}$. An example is to let $\mathbf{z}_i$ be the length of rows of $\mathbf{A}$:

$$\mathbf{z}' = (\|\mathbf{a}^1\|, \|\mathbf{a}^2\|, \ldots, \|\mathbf{a}^n\|). \tag{23}$$

A way to look at $\mathbf{z}$ is provided in the following equation:

$$\mathbf{z}'\mathbf{z} = \|\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{A}\mathbf{A}') = a_{11}^2 + a_{21}^2 + \cdots + a_{nk}^2.$$

Thus the squared length of $\mathbf{z}$ is equal to the sum of squares of the data that is present at each step of the algorithm.

Sometimes we want $\mathbf{v}_i$ to be one of the "important" rows of $\mathbf{A}$. For example, we may want $\mathbf{v}_i$ to be the row that has the largest value in $\mathbf{A}$. This can be achieved by setting $\mathbf{z}_i = (0, \ldots, 0, 1, 0, \ldots)$ with the index of one being the number of the row containing the largest value in $\mathbf{A}$.

9.2. Weights. Sometimes parts of data carry more information than other parts. This is often solved by defining $\mathbf{z}$ to be equal to one for the important part of data and smaller than one for other parts. In control theory, e.g., see [13], this kind of scaling is fundamental to most applications. There typically exponential decaying weights are used. But it is more natural to let the data themselves define the weights. We shall look at how the type of weights can be defined. Suppose that $\mathbf{a}^n$ is the important row (or the most "recent" row). If rows are close to $\mathbf{a}^n$, they will be given weight one, and weight less than one, if the rows differ much from $\mathbf{a}^n$. (Another view is to use the correlation coefficient between a row and $\mathbf{a}^n$ as criterion.) This can be achieved by defining for the vector $\mathbf{z} = (z_1, \ldots, z_n)$:

$$z_j = 1 \quad \text{for } \|\mathbf{a}^j - \mathbf{a}^n\| < c,$$
$$z_j = c/\|\mathbf{a}^j - \mathbf{a}^n\| \quad \text{for } \|\mathbf{a}^j - \mathbf{a}^n\| > c$$

for some constant c. There are other ways to define $\mathbf{z}$ that reflect views on the rows of $\mathbf{A}$. For example, there can be a "target," and we may want to use the same views on the rows as we treated the columns in the case of linear equations, where the $\mathbf{b}$-vector was the "target" vector.

10. Criteria based on rows and columns. All the criteria mentioned above can be combined and used on both rows and columns. A possible complication is the constant

$$1/\lambda_i = (\mathbf{z}_i'\mathbf{A}_{i-1}\mathbf{w}_i). \tag{24}$$

This must be different from zero in order for the algorithm to reduce the rank of $\mathbf{A}_{i-1}$ by one. Values of (24) close to or equal to zero indicate that there is nothing more to select in the sense that the two criteria are not able to select components from $\mathbf{A}_{i-1}$. The criteria treated above will be discussed later in this paper.

11. Stopping rules. When this algorithm is used, the basic question concerns when one should stop. The algorithm stops automatically at $i = n$ or $i = k$, whichever is smallest. But usually one should stop earlier. There is, however, no unique answer to this question. It depends on the problem one is trying to solve. When dealing with engineering construction where the coefficients $\mathbf{A} = (a_{ij})$ and $\mathbf{b} = (b_i)$ are uniquely determined, the maximal number of iterations should be carried out. But in most applied sciences these coefficients are uncertain. In these cases it is important to obtain a "stable" solution. There are three aspects we can consider when evaluating the results. They are sizes, predictions, and crossvalidation. We shall consider them closer.

11.1. Sizes. If the criteria that are being used have very small values, it indicates that we have selected all that can be selected. We can also look at the elements of $(\mathbf{A} - \mathbf{A}_i)$ or $(\mathbf{A}\mathbf{x}_i - \mathbf{b})$. If all of them are small, there is no need to continue the iterations. This aspect is discussed in more detail in the study of the (Flow Injection Analysis) data (§15).

11.2. Predictions. It is always good to look at the measures of predictions, both the (total) prediction variance and the (total) prediction error variance. From the point of view of prediction, we should choose the number of components (iterations) where they are at their smallest. Usually the two measures give approximately the same number of components. The H-index is a measure that the H-principle is trying to maximize. It is the ratio {decrease in residual variation}/{increase in model variance}. If the H-index gets small compared to the values of the H-index for the first components, it indicates that the prediction ability is getting small and therefore it is time to stop extracting components.

11.3. Crossvalidation. In this approach some 10 to 15% of data are left out. Initially, these values are estimated by the average values. If only column criterion is used, a_{ij} is estimated by a_j, where a_j is the average value of the jth column. Similarly, if only row criterion is used, we estimate a_{ij} by a_i. If both row and column criteria are used, we estimate a_{ij} by $a_j + a_i - a$, where a is the average over all data values. The decomposition $\mathbf{A}_i$ is computed using these estimated values. The steps in the crossvalidation are as follows:

(1) Delete randomly 10 to 15% of the data values. Compute $\mathbf{A}_i$. Replace the estimated a_{ij}-values by those from $\mathbf{A}_i$. Compute a new $\mathbf{A}_i$. Repeat this procedure until $\mathbf{A}_i$ does not change.

(2) We compute the PRESS value,

$$\text{PRESS} = \Sigma(a_{ij} - \mathbf{A}_i(i, j))^2. \tag{25}$$

The sum in (25) is over the left-out values, and $\mathbf{A}_i(i, j)$ are the corresponding values in $\mathbf{A}_i$.

(3) Repeat (1) and (2) a number of times, e.g., $N = 100$ times.

(4) Compute the average of the N PRESS values for fixed i:

$$\text{PRESS}_i = \Sigma \text{ PRESS/N}. \tag{26}$$

(5) Repeat (1) to (4) for $i = 1, 2, \ldots$. Then we choose the number of components i that gives the smallest value of (26).

The basic idea of crossvalidation is to determine the number of components needed to determine unknown data values. The experience with large numbers of data tables indicates that the number of components may be slightly underestimated by this procedure. Note that if the PRESS value is used to estimate residual variance for given numbers of components, it should be divided by the appropriate number of degrees of freedom.

This is an empirical approach, and it is useful, if the data table is not large. Where there are large data tables, this approach may be time consuming to carry out on the computer.

In the case of linear equations the theoretical formula corresponding to the crossvalidation procedure (25) and (26) is given by (A.2.5) in Appendix 2. If we assume the standard assumptions in linear regression analysis, one may show that (see [4]) requiring (A.2.5) to be as small as possible is equivalent to requiring

$$(\mathbf{b}'\mathbf{u}_i)^2/(\mathbf{u}_i'\mathbf{u}_i) > \sigma^2 n/(n-i), \tag{27}$$

where σ^2 is the residual variance. It can be estimated by

$$\sigma^2 \approx \|\mathbf{A}\mathbf{x}_i - \mathbf{b}\|^2/(n-i).$$

The interpretation of (27) is that, if it is not satisfied, we are generating more noise than the variation we are explaining. Thus (27) represents an upper bound on the number of components that should be used, i.e., if (27) is not satisfied, the component should not be extracted. Experience has shown that (27) is generally better for estimating the number of components than the crossvalidation steps (1)–(5). (There can, however, be problems with this method, as, for example, when the estimate of σ^2 tends to zero because of overfitting and where an estimate of σ^2 must be obtained by crossvalidation.)

12. Some guidelines concerning choice of criteria. The algorithm has been applied to many data from practice. In this section we shall discuss our experiences concerning the choice of criteria. The criteria treated in this paper are as follows:

(a) $\mathbf{w}_i$ is the eigenvector associated with the largest eigenvalue of the eigenvalue problem $\mathbf{A}_{i-1}'\mathbf{A}_{i-1}\mathbf{w}_i = \lambda_i \mathbf{w}_i$.

(b) $\mathbf{w}_i = (0, \ldots, 0, 1, 0, \ldots)$, where the index of 1 is the column number, which maximizes $\max((\mathbf{a}_j'\mathbf{a}_1)^2 + (\mathbf{a}_j'\mathbf{a}_2)^2 + \cdots + (\mathbf{a}_j'\mathbf{a}_k)^2)$.

(c) $\mathbf{w}_i = \mathbf{a}^j$ is an important row in $\mathbf{A}_{i-1}$.

(d) $\mathbf{w}_i = (0, \ldots, 0, 1, 0, \ldots)$, where the index of 1 is the column number of the column, which contains largest element a_{ij} in $\mathbf{A}_{i-1}$ (we can also choose the column that is the largest in size).

(e) $\mathbf{w}_i = (\|\mathbf{a}_1\|, \ldots, \|\mathbf{a}_k\|)$.

(f) $\mathbf{w} = \mathbf{w}_i = (w_1, w_2, \ldots)$ with $w_j = 1$ for $\|\mathbf{a}_j - \mathbf{a}_k\| < c$, and $w_j = c/\|\mathbf{a}_j - \mathbf{a}_k\|$ for $\|\mathbf{a}_j - \mathbf{a}_k\| > c$.

In the case of a linear equation $\mathbf{A}\mathbf{x} = \mathbf{b}$:

(g) $\mathbf{w}_i = \mathbf{A}_{i-1}'\mathbf{b}/\|\mathbf{A}_{i-1}'\mathbf{b}\|$

(h) $\mathbf{w}_i = (0, \ldots, 0, 1, 0, \ldots)$, where the index of 1 is the number of the column giving the maximum of $(\mathbf{b}'\mathbf{a}_j)^2$.

Here we have formulated the criteria as column criteria. Similar criteria can be obtained for rows by changing column and row indices. (Note that $\mathbf{w}_i$ need not be scaled to be of unit length. But we recommend doing so, when $\mathbf{w}_i$ has been selected in order to prevent numerical instability in the algorithm.) One set of the vectors $(\mathbf{w}_i)$ and $(\mathbf{z}_i)$ should be orthogonal. The criteria (a), (b), (c), (d), (g), and (h) all give orthogonal $\mathbf{w}$-vectors. In the case where we are reducing a matrix $\mathbf{A}$, the criteria (a) and (b) are proper ones according to the H-principle, where an optimal balance between residual variance and model variance is determined. Similarly, (g) and (h) are the criteria determined by the H-principle when we are solving a linear equation. If the columns are of approximately equal size, the criteria (b), (g), and (h) are numerically very stable and can be applied to large matrices containing hundreds or thousands of rows and columns. In many cases $\mathbf{w}$ is determined according to (a), (b), (g), or (h), while $\mathbf{z}$ is used to determine the weights that should be used. The weights may be defined from the given applied situation. They may also be derived from one's expectation of data. What happens if $\mathbf{w}_i$ is selected according to (a) and $\mathbf{z}_i$ according to (e)? Well, $(\mathbf{w}_i)$ will be orthogonal and only $\mathbf{u}_1$

will be the same as $\mathbf{u}_1$ in SVD. It means that at each step we select $\mathbf{u}_i$ to be of maximal length, but we weigh the rows, and rows having large length will be more important than small ones. This may be important when we want rows with small values to be scaled down.

It is the author's opinion that the row and column criteria should be selected such that they reflect the views one has on the data.

13. Discussion. The algorithm presented here can be used in many fields of applied sciences. Here we shall discuss some practical aspects of the algorithm.

13.1. Statistics. In the statistical analysis of data the rows are usually considered as repeated samples. In these cases we are mainly interested in the columns. For example, in stepwise regression we determine "good" **w**-vectors. Program packages such as SAS, BMDP, SPSS, and others, contain a large collection of criteria for determining **w**, all of which are different from the choices treated here. These program packages allow a weight vector **z** to take into account differences between rows (samples). This weight vector is independent of the data, and the same at each step (iteration) in our setup. In general it is better to let data themselves determine appropriate weight vectors, in our case the **z**-vectors.

13.2. Biology. Biologists, in their field work, often work with a certain number of species. For example, a biologist may have, say, 51 samples of species. The species are given, but they can be measured in many ways. The main features of the 51 species can be supplemented by different kinds of chemical measurements. New measurements on the 51 species mean that the data table is expanded by new columns representing the new measurements (as opposed to many situations in statistics, where new measurements mean new rows). Here the biologist has certain views on the 51 species that **z**-vectors can represent, while the columns are further information on the given set of species. In these cases the biologist may wish to treat the rows in much the same way that the statistician treats the columns; columns, on the other hand, may be treated as rows. An example of this situation is shown in [14].

13.3. Archaeology and analytic chemistry. In archaeology some excavations are rich in materials while other are scarce. One row of the data table can represent the amounts of different types of materials found at a given location. That the quality of data is different at different locations is often solved by "closing the data table," i.e., scaling the rows to get sum equal to 1 each. The values in a row thus represent the percentage of each type found at that location. In analytical chemistry this approach is also often used. The argument for this scaling of original data is that one is mainly interested in the relative proportions in each sample (row). But this type of scaling often has several complications. In chemistry, for example, some proportions are so small that they are below the detection level. And scaling values to sum to 1 may cause some undesirable side effects, such as overemphasizing samples that are at the noise level. See, e.g., [15]. It will be better to let the data define the weights of samples through the **z**-vectors.

13.4. Neural networks. In some neural networks a_{ij} represents the weight of the link between neuron j to neuron i. In such neural networks the rows of **A** that contain only small values carry very little information. In the analysis such rows should be weighed down, or perhaps not used at all. Sometimes this is solved by defining a threshold value for coefficients in a row, see [16]. But this is not a proper way to handle "small effects," when the phenomenon is continuous. It is better to introduce a weight vector **z** if the data indicate that there is a need for one.

14. Plots. Plots of appropriate vectors are useful in order to learn the variation in data. The most useful plots involving the vectors in the algorithm are the following ones.

(a) $\mathbf{b}$ *versus* $\mathbf{u}_i$. *Added variable plots.* They show how the new component relates to the right-hand-side vector when solving linear equations. The plots should show some degree of linearity. If the scatter plot does not show any kind of linearity, it indicates that the component and later ones should not be used.

(b) $\mathbf{u}_i$ *versus* $\mathbf{u}_j$. *Score plots.* They show how the components vary. They are useful in detecting outliers and groups in data.

(c) $\mathbf{v}_i$ *versus* $\mathbf{v}_j$. *Loading plots.* They show how the variables vary. They are useful in detecting special variables and groups of variables.

(d) $\mathbf{r}_i$ *versus* $\mathbf{r}_j$. *Transformation plots.* They show how the score values are computed. They are useful in detecting the influence of variables and groups of variables.

Reference [17] is a good tutorial paper on the interpretation of plots of the above type.

15. Example 2: FIA data. We shall consider a data table from analytical chemistry. It is a data table derived from flow injection analysis (FIA). FIA is popular in chemical laboratories, because a high degree of automation can be used and because the data collection happens over a relatively short period of time, see [18]. We shall here consider a data table that has 41 rows and 241 columns. One row in the data table is an observed spectrum and the columns are the time points where registration takes place. The contents of the data table are the concentrations of the chemical substance that is being analyzed. The data table considered here has $41 \times 241 = 9881$ data values and all of them are between zero and one. Table 3 gives the ten largest singular values associated with $\mathbf{A}$ that is a 41-times-241 matrix. The numerical

TABLE 3

No. i	Singular value λ_i	Cumulative Percentage $\Sigma^i \lambda_j^2 / \Sigma \lambda_j^2$	Size $\|\mathbf{A}_{i-1}\|_F$	Largest element in $\mathbf{A}_i$, $\max(\|a_{ij}\|)$
1	21.0829379	98.5371	21.2388612	0.142489
2	2.3627405	99.7747	2.5688423	0.034013
3	1.0047351	99.9985	1.0081708	0.006078
4	0.0607094	99.9993	0.0831609	0.003875
5	0.0293583	99.9995	0.0568340	0.003520
6	0.0272765	99.9996	0.0486641	0.002379
7	0.0193580	99.9997	0.0403012	0.002372
8	0.0124964	99.9998	0.0353476	0.001878
9	0.0111743	99.9998	0.0330650	0.001744
10	0.0097538	99.9998	0.0311196	0.001335

precision of the individual data values in an FIA analysis is approximately 0.006. This means that the measured data values are given with an uncertainty of ± 0.003. Thus, from a practical point of view, the rank of $\mathbf{A}$ is at most 10. The size of a matrix is given by

$$\|\mathbf{A}_i\|_F = [\mathrm{tr}(\mathbf{A}_i{}'\mathbf{A}_i)]^{1/2}.$$

Note that $\|\mathbf{A}_o\|_F = 21.2388612$ is the size of the original matrix $\mathbf{A}$. From Table 3 we see that the size of the residual matrix after 10 steps is not zero. This is due to the existence of so many elements (in this case, 9881). Also the singular values do not approach zero as one would expect, $\lambda_{20} = 0.0057$, $\lambda_{30} = 0.0045$, $\lambda_{40} = 0.0031$, and $\lambda_{41} = 0.0030$. The last column in Table 3 gives the largest element in the reduced $\mathbf{A}$-matrix, $\mathbf{A}_i$, when the ith component has been subtracted from $\mathbf{A}_{i-1}$. We see that the last value in that column is well below the numerical precision of the measurements.

The SVD of this data table is not especially interesting from the point of view of the chemist. The important parts of the data table are those points where the concentrations are large. An important question is: "At what time points would it be sufficient to measure the

chemical process? The problem can be phrased as: "What are 'good' columns?" And if we know them, can we compute the remaining columns?" This problem is important, not because we want to limit the number of measurements, but because in FIA analysis we get many tables, and it is difficult to compare the tables when they are so large. The measurement equipment gives us 9881 data values for each experiment, but we want to reduce that data, when storing data and when comparing results from experiments. One way to handle this problem is to select columns according to the criterion (17). The results are shown in Table 4. This table

TABLE 4

No. i	Column number	Criterion (17)	Size $\|\mathbf{A}_{i-1}\|_F$	Largest element $\max(\|a_{ij}\|)$
1	91	3146.692156845	21.238861	0.19597
2	127	2.050383374	3.153601	0.03967
3	73	0.036819414	1.096335	0.00785
4	157	0.000000740	0.099461	0.00729
5	109	0.000000229	0.075478	0.00408
6	47	0.000000047	0.058675	0.00263
7	139	0.000000015	0.050093	0.00261
8	231	0.000000014	0.044776	0.00204
9	61	0.000000003	0.043120	0.00201
10	226	0.000000002	0.039775	0.00167

shows that we can select 10 columns, which can represent the remaining 231 columns with the desired numerical accuracy. We see that the value of criterion (17) is very small for the tenth component compared with the first one. We notice that criterion (17) is already very small at step number 4, where column number 157 is selected. The first impression is that only three components should be selected. If 10 components are selected, the resulting matrix will be 41 times 10. The same procedure can in principle be used on the rows of this new matrix to give a 10-times-10 matrix that is able to reproduce the original data matrix. Similar analysis can be carried out selecting the spectra (rows) instead of columns (time points).

When we look at the data table, large spectra (rows) are more important than the small ones. Here the size of a row is the length of the row vector

$$\|\mathbf{a}^i\| = \left(\sum_j {a_{ij}}^2\right)^{1/2}. \tag{28}$$

In Table 5 we consider both criterion (17) and the maximization of (28). We determine the column that gives maximal value of (17). The coordinates of $\mathbf{w}$ are equal to zeros except for the one that corresponds to the index of the maximum, where it has value one. Similarly, $\mathbf{z}$ has zeros except for the index that gives the maximum value of (28), where it has value 1. The results of the decomposition are given in Table 5. From the table we see that when selecting the first component, the time (column) number 91 has the most predictive power and spectrum (row) number 1 is the largest among the 41 spectra. The last column shows that we can manage with at most 10 components. Note that the size of $\mathbf{A}$ need not decrease, when it is reduced by rank one. In Table 5 the size of $\mathbf{A}$ slightly increases at the fifth, eighth, and tenth components, respectively. This is due to our working with two independent criteria, which when applied may give a slight increase in the size of $\mathbf{A}$, although $\mathbf{A}$ is always reduced by rank one. This happens often when we have reached the noise level in data. It is basically due to the fact that the vectors $(\mathbf{u}_i)$ and $(\mathbf{v}_i)$ are not a set of orthogonal vectors when we have both column and row criteria. Experience with many data tables has shown that we may need more components when we use criteria for both columns and rows than if we use only a criterion for one of them.

TABLE 5

No. i	Column number	Criterion (17)	Row j	Row size $\|\mathbf{a}^j\|$	Size $\|\mathbf{A}_{i-1}\|_F$	Largest element $\max(\|a_{ij}\|)$

We shall study more closely the decomposition derived from (17), where the main results were given in Table 4. Some descriptive measures are given in Table 6. We see that the common

TABLE 6

Number	Column number	$\mathbf{z}_i'\mathbf{A}_{i-1}\mathbf{w}_i$	$\lambda_i^2\|\mathbf{u}_i\|^2\|\mathbf{v}_i\|^2$	Cumulative %	$\|(\mathbf{A}-\mathbf{A}_i)^\dagger\|_F^2$
1	91	7.1330268	441.14402307	97.7953	0.374423
2	127	0.2345104	8.74325000	99.7335	2.428226

7	139	0.0000294	0.00050444	99.9996	329.757384
8	231	0.0000935	0.00014557	99.9996	356.663916
9	61	0.0000097	0.00027722	99.9996	533.998761
10	226	0.0000111	0.00014826	99.9997	640.703899

criterion $\mathbf{z}_i'\mathbf{A}_{i-1}\mathbf{w}_i$ is already small for the fourth component. (Note that this criterion has a similar interpretation to that of the singular values. Since the smallest singular value is 0.0030, we notice that the value of this criterion at the fourth component is smaller than the smallest singular value.) The total variation in $\mathbf{A}$, $\|\mathbf{A}\|_F^2$, is at each step reduced by $\lambda_i^2\|\mathbf{u}_i\|^2\|\mathbf{v}_i\|^2$. The size of this reduction is given in the next column, and the cumulative percentage in the following one. We see that the first component accounts for 97.7953% of the variation in $\mathbf{A}$. Already the first three components account for 99.9978%. When we select the fourth component, the size of the inverse, $\sum^i \lambda_j\mathbf{r}_j\mathbf{s}_j$, increases from 6.459474 to 89.363820. All of these measures indicate that only three components should be used. In Table 7 the predictive measures associated with this decomposition are given. Table 7 confirms that only three components should be extracted from $\mathbf{A}$ because the prediction variances are smallest at the third component. The prediction variances increase 100 times when going from three to four components. Also the H-index, the last column, shows that components number 4 and up have no predictive abilities. These results conform well to the chemical knowledge of data.

As mentioned above, we could have chosen the corresponding row (spectra) criterion and selected the three spectra that can represent the remaining 38 spectra and carried out a similar analysis.

A similar analysis, like that shown in Tables 6 and 7, can be carried out for the decompositions shown in Tables 3 and 5. For the decomposition in Table 5 we get results analogous to the ones in Table 6 and 7.

For a chemist there is much more information in Tables 4 and 5 than in Table 3, because the chemist has a more direct interpretation of Tables 4 and 5 than of Table 3. But everything

TABLE 7

Number	Column number	$\|\mathbf{A}_i\|^2\|(\mathbf{A}-\mathbf{A}_i)^\dagger\|^2$	$\|\mathbf{A}_i\|^2(1+\|(\mathbf{A}-\mathbf{A}_i)^\dagger\|^2)$	$\|\Delta\mathbf{A}_i\|_F{}^2/\|\Delta\mathbf{A}_i^\dagger\|_F{}^2$
1	91	1.3942469	11.3394475	3146.69215684526

can be used to represent the original matrix or to compute a generalized inverse. The SVD is popular, because one gets maximal reduction in the variation of $\mathbf{A}$ at each step. But as Table 4 shows, the decomposition according to the criterion (17) gives almost the same size of reduction. The general experience is that decompositions using (17) require only very few more components than does the SVD to get the same size of reduction in variation.

If all computations in this example were carried out in one run on a computer, it would take approximately 300 Mflops. Thus on a modern workstation or PC these computations can be carried out in seconds or minutes, depending on the size of the computer.

16. Conclusions. We have presented here an approach for solving standard matrix problems such as determining the rank of a matrix, solving linear equations, and computing the generalized inverse. This methodology allows "tailoring" a mathematical model to the practical situation. The approach is given in terms of a general algorithm to decompose a data matrix into rank-one components. The algorithm can reflect different views on rows, on columns, or on both rows and columns. If the criteria used are based on the H-principle of mathematical modelling and data are initially appropriately scaled, the algorithm has been found efficient and numerically stable even for very large matrices containing hundreds or thousands of rows and columns. The algorithm is easy to implement in matrix languages such as MATLAB, GLIM, MATEMATICA, SASIML, and other similar languages. The main advantage of this approach is that the noise level can be appropriately identified. The algorithm is important for scientists who want more nuanced decompositions of data tables that reflect their theories on data than those provided by standard numerical methods.

Appendix 1. Here we shall prove that the vectors have the geometric properties stated in the text.

PROPERTY 1. $\mathbf{z}_i$ *is orthogonal to later* $\mathbf{A}$*-matrices,*

$$\mathbf{z}_i'\mathbf{A}_j = \mathbf{0} \quad \textit{for } i \le j. \tag{A.1.1}$$

Proof. Expressing $\mathbf{A}_j$ in terms of earlier $\mathbf{A}$-matrices we get

$$\begin{aligned}\mathbf{A}_j &= \mathbf{A}_{j-1} - \lambda_j \mathbf{u}_j \mathbf{v}_j' \\ &= \mathbf{A}_{j-1} - \lambda_j \mathbf{A}_{j-1}\mathbf{w}_j\mathbf{v}_j' \\ &= \mathbf{A}_{j-1}(\mathbf{I} - \lambda_j \mathbf{w}_j\mathbf{v}_j') \\ &= \mathbf{A}_{j-1}\mathbf{Q}_o \\ &= \mathbf{A}_i\mathbf{Q}_1.\end{aligned}$$

Here $\mathbf{Q}_o$ and $\mathbf{Q}_1$ are matrices that are not used. From

$$\mathbf{z}_i'\mathbf{u}_i = 1/\lambda_i \quad \text{and} \quad \mathbf{z}_i'\mathbf{A}_i = \mathbf{z}_i'\mathbf{A}_{i-1} - \lambda_i(\mathbf{z}_i'\mathbf{u}_i)\mathbf{v}_i' = \mathbf{v}_i' - \mathbf{v}_i' = \mathbf{0}$$

(A.1.1) follows. □

PROPERTY 2. $\mathbf{z}_i$ *is orthogonal to later* $\mathbf{u}$*-vectors,*

$$\mathbf{z}_i'\mathbf{u}_j = 0, \qquad i < j. \tag{A.1.2}$$

Proof. Follows from (A.1.1) and the definition of $\mathbf{u}_j$. □

PROPERTY 3. $\mathbf{w}_i$ *is orthogonal to later* $\mathbf{A}$*-matrices,*

$$\mathbf{A}_j\mathbf{w}_i = \mathbf{0}, \qquad i \leq j. \tag{A.1.3}$$

Proof. The iteration is performed in a way similar to the way in which the proof of Property 1 was performed:

$$\begin{aligned}\mathbf{A}_j &= \mathbf{A}_{j-1} - \lambda_j\mathbf{u}_j\mathbf{z}_j'\mathbf{A}_{j-1} = (\mathbf{I} - \lambda_j\mathbf{u}_j\mathbf{z}_j)\mathbf{A}_{j-1} \\ &= \mathbf{Q}\mathbf{A}_i,\end{aligned}$$

where $\mathbf{Q}$ is some matrix that is not used. Equation (A.1.3) follows now from

$$\mathbf{w}_i'\mathbf{v}_i = 1/\lambda_i \quad \text{and} \quad \mathbf{A}_i\mathbf{w}_i = \mathbf{A}_{i-1}\mathbf{w}_i - \lambda_i\mathbf{u}_i(\mathbf{w}_i'\mathbf{v}_i) = \mathbf{u}_i - \mathbf{u}_i = \mathbf{0}. \quad \square$$

PROPERTY 4. $\mathbf{w}_i$ *is orthogonal to later* $\mathbf{v}$*-vectors,*

$$\mathbf{w}_i'\mathbf{v}_j = 0, \qquad i < j. \tag{A.1.4}$$

Proof. The proof follows from (A.1.3) and the definition of $\mathbf{v}_j$. □

PROPERTY 5. $(\mathbf{s}_i)$ *and* $(\mathbf{u}_i)$ *are mutually orthogonal,*

$$\mathbf{s}_i'\mathbf{u}_j = 0 \quad \textit{and} \quad \mathbf{s}_i'\mathbf{u}_i = 1/\lambda_i, \quad i \neq j. \tag{A.1.5}$$

Proof. Consider $i = j = 1$. We get

$$\begin{aligned}\mathbf{u}_1 &= \mathbf{A}\mathbf{w}_1 = \mathbf{A}\mathbf{r}_1 \quad \text{or} \quad \mathbf{r}_1 = \mathbf{w}_1. \\ \mathbf{v}_1 &= \mathbf{A}'\mathbf{z}_1 = \mathbf{A}'\mathbf{s}_1 \quad \text{or} \quad \mathbf{s}_1 = \mathbf{z}_1.\end{aligned}$$

This gives

$$\mathbf{s}_1'\mathbf{u}_1 = \mathbf{z}_1'\mathbf{A}\mathbf{w}_1 = 1/\lambda_1.$$

For $i = 2$ and $j = 1$, we get

$$\mathbf{v}_2 = \mathbf{A}_1'\mathbf{z}_2 = \mathbf{A}'(\mathbf{I} - \lambda_1\mathbf{z}_1\mathbf{u}_1')\mathbf{z}_2 \quad \text{or} \quad \mathbf{s}_2 = (\mathbf{I} - \lambda_1\mathbf{z}_1\mathbf{u}_1')\mathbf{z}_2.$$

This gives

$$\mathbf{u}_1'\mathbf{s}_2 = (\mathbf{u}_1' - \lambda_1(\mathbf{u}_1'\mathbf{z}_1)\mathbf{u}_1')\mathbf{z}_2 = (\mathbf{u}_1' - \mathbf{u}_1')\mathbf{z}_2 = 0.$$

For $i = j = 2$ we get from Property 1,

$$\mathbf{u}_2'\mathbf{s}_2 = \mathbf{w}_2'\mathbf{A}_1'\mathbf{s}_2 = \mathbf{w}_2\mathbf{A}_1'(\mathbf{I} - \lambda_1\mathbf{z}_1\mathbf{u}_1')\mathbf{z}_2 = \mathbf{w}_2'\mathbf{A}_1'\mathbf{z}_2 = 1/\lambda_2.$$

Higher indices are proved along the lines of the proofs of Properties 1 and 3. □

PROPERTY 6. $(\mathbf{r}_i)$ *and* $(\mathbf{v}_i)$ *are mutually orthogonal,*

$$\mathbf{r}_i'\mathbf{v}_j = 0, \quad \mathbf{r}_i'\mathbf{v}_i = 1/\lambda_i \quad \textit{for } i \neq j. \tag{A.1.6}$$

Proof. The proof is shown in a way similar to that of Property 5. □

PROPERTY 7. *If* $(\mathbf{w}_i)$ *is chosen such that it is in the range of* $\mathbf{A}_{i-1}'$, $(\mathbf{w}_i)$ *are mutually orthogonal,*

$$\mathbf{w}_i'\mathbf{w}_j = 0 \quad \textit{for } i \neq j.$$

Proof. Let $i < j$. That $\mathbf{w}_j$ is in the range of $\mathbf{A}_{j-1}'$ means that there is a vector $\mathbf{q}_j$ such that $\mathbf{w}_j = \mathbf{A}_{j-1}'\mathbf{q}_j$. This gives

$$\mathbf{w}_i'\mathbf{w}_j = (\mathbf{A}_{j-1}\mathbf{w}_i)'\mathbf{q}_j = 0,$$

by Property 3. □

PROPERTY 8. *The generalized inverse of* $\mathbf{A}$ *can be computed as*

$$\begin{aligned}\mathbf{A}^\dagger &= \lambda_1\mathbf{r}_1\mathbf{s}_1' + \lambda_2\mathbf{r}_2\mathbf{s}_2' + \cdots \\ &= \mathbf{R}\Lambda\mathbf{S}'.\end{aligned} \tag{A.1.7}$$

Proof. The equation $\mathbf{A}\mathbf{A}^\dagger\mathbf{A} = \mathbf{A}$ follows from Properties 5 and 6. □

Note that if only column criterion is given, the vectors $(\mathbf{u}_i)$ will be orthogonal, and similarly if we have only a row criterion, $(\mathbf{v}_i)$ will be orthogonal.

Appendix 2. Predictive performance measures. In this section we shall consider more closely the performance measures suggested in this paper. The set of linear equations $\mathbf{A}\mathbf{x} = \mathbf{b}$ suggests that there is given a linear model,

$$b = a_1x_1 + a_2x_2 + \cdots + a_kx_k = \mathbf{a}'\mathbf{x}.$$

Suppose that $\mathbf{a}_o = (a_{o1}, a_{o2}, \ldots, a_{ok})$ is a new row. We estimate the new b-value, b_o, by inserting this new vector in the equation, giving

$$b_o = a_{o1}x_1 + a_{o2}x_2 + \cdots + a_{ok}x_k = \mathbf{a}_o'\mathbf{x}.$$

The important question is now: "What variation can be expected for b_o, when the coefficients $\mathbf{x}$ are uncertain?" The answer is given in standard textbooks in statistics, see, e.g., [19]. Assuming the usual assumptions in linear regression analysis, it follows that the variance of b_o can be computed as

$$\text{Var}\,(b_o) = \sigma^2\mathbf{a}_o'(\mathbf{A}'\mathbf{A})^\dagger\mathbf{a}_o \approx \|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2\mathbf{a}_o'(\mathbf{A}'\mathbf{A})^\dagger\mathbf{a}_o/(n-k). \tag{A.2.1}$$

We see that the variance consists of two parts, the residual variation $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2$, and the model variance $\mathbf{a}_o'(\mathbf{A}'\mathbf{A})^\dagger\mathbf{a}_o$. The model variance is due to the uncertainty of the vector $\mathbf{x}$. The model variance depends on the specific $\mathbf{a}_o$ that is used. But when we compare one situation to another,

$\text{tr}((\mathbf{A}'\mathbf{A})^\dagger)$ gives a fairly good impression on the size of the model variance. Therefore, when we compare solution vectors, we compare what we call the *total prediction variance*:

$$\|\mathbf{Ax} - \mathbf{b}\|^2 \text{tr}((\mathbf{A}'\mathbf{A})^\dagger) \approx \|\mathbf{Ax} - \mathbf{b}\|^2 \|\mathbf{A}^\dagger\|_F{}^2. \tag{A.2.2}$$

In the present algorithm, $\mathbf{A}_i$ is the residual matrix and $(\mathbf{A} - \mathbf{A}_i)$ is the extracted part. With this notation (A.2.2) becomes

$$\|\mathbf{Ax}_i - \mathbf{b}\|^2 \|(\mathbf{A} - \mathbf{A}_i)^\dagger\|_F{}^2. \tag{A.2.3}$$

In case we are only reducing $\mathbf{A}$, a similar line of argument suggests that we consider

$$\|\mathbf{A}_i\|_F{}^2 \|(\mathbf{A} - \mathbf{A}_i)^\dagger\|_F{}^2 \tag{A.2.4}$$

to be an analogous measure of total prediction variance.

If we have a value of the right-hand-side, $\mathbf{b}$, we may want to compare b and b_o. Usually b is what is observed and b_o is the computed value according to the model. One may similarly show that the variance of the difference is given by

$$\text{Var}\,(b - b_o) = \sigma^2(1 + \mathbf{a}_o'(\mathbf{A}'\mathbf{A})^\dagger \mathbf{a}_o) \approx \|\mathbf{Ax} - \mathbf{b}\|^2 (1 + \mathbf{a}_o'(\mathbf{A}'\mathbf{A})^\dagger \mathbf{a}_o)/(n - k). \tag{A.2.5}$$

As in (A.2.3), we determine the *total prediction error variance* to be

$$\|\mathbf{Ax} - \mathbf{b}\|^2 (1 + \|(\mathbf{A} - \mathbf{A}_i)^\dagger\|_F{}^2) \tag{A.2.6}$$

in the case of reducing $\mathbf{A}$, it is analogous to (A.2.4):

$$\|\mathbf{A}_i\|_F{}^2 (1 + \|(\mathbf{A} - \mathbf{A}_i)^\dagger\|_F{}^2). \tag{A.2.7}$$

For further details on (A.2.1) and (A.2.5) see [4].

The H-principle is concerned with obtaining a balance between the improvement in fit, $\boldsymbol{\Delta}(\mathbf{Ax}_i - \mathbf{b}) = \boldsymbol{\Delta}Ax_i$, and the increase in model variance $\boldsymbol{\Delta}(\mathbf{A}_i{}^\dagger)$. The H-principle tries to get at each step of the algorithm as large a value as possible for the H-index, where the H-index for linear equations is

$$\|\boldsymbol{\Delta}(\mathbf{Ax}_i)\|^2 / \|\boldsymbol{\Delta}\mathbf{A}_i{}^\dagger\|_F{}^2$$

and for reducing $\mathbf{A}$ it is

$$\|\boldsymbol{\Delta}\mathbf{A}_i\|_F{}^2 / \|\boldsymbol{\Delta}\mathbf{A}_i{}^\dagger\|_F{}^2.$$

For a more precise treatment of the H-principle, see [4]. We compute these measures from

$$\begin{aligned}
\boldsymbol{\Delta}Ax_i &= \lambda_i(\mathbf{b}'\mathbf{s}_i)\mathbf{r}_i, & \|\boldsymbol{\Delta}(\mathbf{Ax}_i)\|^2 &= \lambda_i{}^2(\mathbf{b}'\mathbf{s}_i)^2(\mathbf{r}_i'\mathbf{r}_i).\\
\boldsymbol{\Delta}A_i &= \lambda_i \mathbf{u}_i \mathbf{v}_i', & \|\boldsymbol{\Delta}\mathbf{A}_i\|_F{}^2 &= \lambda_i{}^2(\mathbf{u}_i'\mathbf{u}_i)(\mathbf{v}_i'\mathbf{v}_i).\\
\boldsymbol{\Delta}A_i^\dagger &= \lambda_i \mathbf{r}_i \mathbf{s}_i', & \|\boldsymbol{\Delta}\mathbf{A}_i{}^\dagger\|_F{}^2 &= \lambda_i{}^2(\mathbf{r}_i'\mathbf{r}_i)(\mathbf{s}_i'\mathbf{s}_i).
\end{aligned}$$

Acknowledgment. The author wishes to thank Carsten Ridder, Chemical Laboratory A, Danish Technical University, for supplying small, medium, and large data matrices as well as many useful discussions.

A HIGHER-ORDER GODUNOV METHOD FOR MULTIDIMENSIONAL IDEAL MAGNETOHYDRODYNAMICS*

ANDREW L. ZACHARY†, ANDREA MALAGOLI‡, AND PHILLIP COLELLA§

Abstract. The authors present a higher-order Godunov method for the solution of the two- and three-dimensional equations of ideal magnetohydrodynamics (MHD). This work is based both on a suitable operator-split approximation to the full multidimensional equations, and on a one-dimensional Riemann solver. This Riemann solver is sufficiently robust to handle the nonstrictly hyperbolic nature of the MHD equations and the presence of local linear degeneracies. Results from a set of test problems show that this operator-split methodology has no problems handling any of the three MHD waves, yet resolves shocks to three or four computational zones. The advantages and limitations of this method are discussed.

Key words. magnetohydrodynamics (MHD), Godunov methods, hyperbolic systems, finite difference equations

AMS subject classifications. 65M06, 35L665, 3504, 76W05

1. Introduction.

Conservative, finite-difference schemes based on higher-order Godunov methods have proven very effective at computing discontinuous solutions to hyperbolic systems of conservation laws. Several examples of such schemes are available for the equations of hydrodynamics (van Leer [23], Roe [20], Harten, Lax, and van Leer [13], and Colella and Woodward [9]) and have been used extensively to simulate highly supersonic flows in aerodynamics and astrophysics. For a comparative review of some of these methods, see, e.g., Woodward and Colella [24]. An extension of Godunov methods to general systems of hyperbolic conservation laws has been suggested by Bell, Colella, and Tragenstein [3], hereinafter refered to as BCT, who have also discussed modifications to the basic method when the systems have points at which they are no longer strictly hyperbolic. At these locations, some of the eigenvalues of the linearized matrix are identical and the corresponding eigenvectors become degenerate.

In this paper, we present a new, multidimensional scheme for the equations of ideal MHD, which is based on a higher-order Godunov method specially developed to treat the degeneracies that occur in these equations. Our formulation is a direct extension of the method developed by Zachary and Colella [25], but with several modifications and amendments that have proven necessary when testing the algorithm on a variety of one- and two-dimensional problems. The core of the problem is to construct an appropriate solution of a local, linearized Riemann problem along the ray $\frac{x}{t} = 0$ at the boundary between two adjacent cell edges. This solution is then used to compute the flux $\mathbf{F}^G(\mathbf{U}_R, \mathbf{U}_L)$, the generalized Engquist–Osher [12] flux for our system of conservation laws (see BCT [3] for details).

Although this approach has several computational advantages over finding the solution to the complete nonlinear Riemann problem, it does have two major difficulties that require special attention. First, the equations of ideal MHD involve seven characteristics that can become mutually degenerate in several ways. Each type of degeneracy requires a different,

special treatment. Second, linearized Riemann solvers are known to fail in some extreme situations, even if the underlying physical problem admits a solution. Einfeldt et al. [11] have shown, for example, that certain types of hydrodynamic Riemann solvers fail to compute strong rarefaction waves correctly. Based on the experience obtained by computing a large set of test problems, we have incorporated an algorithm in our Riemann solver that detects and classifies the occurrence of degeneracies and strong rarefactions. This Riemann solver is so sufficiently robust that we have used it as the basis of a multidimensional scheme.

Following common procedures for higher-order methods, e.g., the piecewise parabolic method (PPM) and MUSCL schemes, the most natural way to extend our Riemann solver to two or three dimensions is by operator-splitting, in which a fully multidimensional step is achieved by combining a sequence of one-dimensional steps in alternating directions. However, the use of operator-splitting for the MHD equations cannot be achieved in a straightforward way, because the condition $\nabla \cdot \mathbf{B} = 0$ introduces cross-coupling between the spatial directions. In this paper we have still adopted an operator-split scheme, because of its relative simplicity, and we have written the MHD equations in a particular nonconservation form that makes them suitable for operator-splitting. The condition $\nabla \cdot \mathbf{B} = 0$ is further enforced by performing a projection (see, e.g., Brackbill and Barnes [4]) at the end of each timestep. A fully unsplit, multidimensional method will be developed at a later stage following the ideas of Colella [8].

In §2, we present an extensive description of the one-dimensional, higher-order Godunov method. We also briefly discuss our particular form of the operator-split MHD equations, and then we provide a detailed look at the Riemann solver. Finally, in §3, we present and discuss the results from our extensive series of one- and two-dimensional test problems.

2. The operator-split higher-order Godunov method. Zachary and Colella [25] describe a higher-order Godunov method designed for purely one-dimensional MHD equations. As with similar higher-order methods, e.g., PPM, MUSCL, BCT, this method has two parts: a predictor step that traces characteristics to determine time-centered values of the solution extrapolated to each cell edge from each of the left and right cell centers; and, a corrector step in which fluxes are computed at the cell edge and differenced to update the conserved quantities at the cell centers. These fluxes are computed using an approximate Riemann solver, using as input the left and right states obtained in the predictor step. In an earlier paper, we showed that our Riemann solver was sufficiently robust to handle the wave interactions present in a set of one-dimensional test problems. When these techniques are extended to a fully multidimensional set of MHD equations, they must handle a much wider range of wave phenomena. As a consequence, we have been led to make a number of modifications in our earlier solver to deal with these new interactions. Specifically, we must: account for terms of the form $\partial B_x/\partial x$ that arise from the operator-splitting; handle degeneracies that commonly arise in multidimensional studies, but which rarely occur in purely one-dimensional test problems; refine the treatment of rarefaction waves; and, finally, modify the predictor step to preserve monotonic gradients in both the characteristic fields and in the primitive variables. Since this solver differs significantly from the version described earlier, we present a detailed description of it below.

Before we begin our discussion, we make one general comment about our method. Many finite-difference algorithms such as MacCormack's method, Lax–Wendroff, and flux-corrected transport work only with $\mathbf{U}$, the conserved variables. Our experience with a higher-order Godunov method has led us to work with $\mathbf{U}$, as well as with the primitive variables $\mathbf{W} = [\rho, u_x, u_y, u_z, B_x, B_y, B_z, p]^t$. There are several reasons for our choice. First, working in $\mathbf{W}$-space provides the simplest possible expressions for the right and left eigenvectors. Using these representations reduced the complexity and improved the performance of the resulting computer code. Second, our algorithm must preserve positivity in the density and the pressure. When the predictor or the corrector step used conserved variables, we found there was a broad

range of conditions under which our Riemann solver produced a negative pressure. As our section below on rarefaction waves makes clear, switching to primitive variables fixed most, but not all, of the cases under which either the pressure or the density became negative.

2.1. Operator-split equations of MHD. The full set of equations for multidimensional hydrodynamics naturally splits into a set of one-dimensional equations with no cross-coupling. Unfortunately, this statement is not true for the equations of MHD; the restriction $\nabla\cdot\mathbf{B} = 0$ naturally induces some cross-coupling between the different directions. In this section, we present a set of one-dimensional equations for MHD that is suitable for operator-splitting. We begin with the full set of equations written as:

$$\frac{\partial \rho}{\partial t} + \nabla\cdot(\rho\mathbf{u}) = 0, \tag{1a}$$

$$\frac{\partial \rho u_x}{\partial t} + \frac{\partial}{\partial x}\left(\rho u_x^2 + p + \frac{B_{\perp,x}^2}{8\pi}\right) + \nabla\cdot\left(\mathbf{u}_{\perp,x} u_x \rho\right) - \frac{1}{4\pi}\left(\mathbf{B}_{\perp,x}\cdot\nabla\right) B_x = 0, \tag{1b}$$

$$\frac{\partial \rho u_y}{\partial t} + \frac{\partial}{\partial y}\left(\rho u_y^2 + p + \frac{B_{\perp,y}^2}{8\pi}\right) + \nabla\cdot\left(\mathbf{u}_{\perp,y} u_y \rho\right) - \frac{1}{4\pi}\left(\mathbf{B}_{\perp,y}\cdot\nabla\right) B_y = 0, \tag{1c}$$

$$\frac{\partial \rho u_z}{\partial t} + \frac{\partial}{\partial z}\left(\rho u_z^2 + p + \frac{B_{\perp,z}^2}{8\pi}\right) + \nabla\cdot\left(\mathbf{u}_{\perp,z} u_z \rho\right) - \frac{1}{4\pi}\left(\mathbf{B}_{\perp,z}\cdot\nabla\right) B_z = 0, \tag{1d}$$

$$\frac{\partial \mathbf{B}}{\partial t} + \nabla\cdot(\mathbf{u}\mathbf{B} - \mathbf{B}\mathbf{u}) = 0, \tag{1e}$$

$$\frac{\partial(\rho E)}{\partial t} + \nabla\cdot(\rho\mathbf{u}E + \mathbf{u}p) + \sum_{i=1}^{3}\frac{\partial}{\partial x}\left(u_{x_i}\frac{B_{\perp,x_i}^2}{8\pi}\right) - \frac{1}{4\pi}\sum_{i=1}^{3}\frac{\partial}{\partial x_i} B_{x_i}\left(\mathbf{B}_{\perp,x_i}\cdot\mathbf{u}\right) = 0, \tag{1f}$$

$$\nabla\cdot\mathbf{B} = 0. \tag{1g}$$

The right-hand side of these equations differs from the conservation form of the equations by terms of the form $\nabla\cdot\mathbf{B}(\ldots)$, where the terms inside the parentheses are not differentiated. Our reason for using this form was to minimize the extent to which various terms in the discrete evolution operators in each of the coordinate directions in the operator split algorithm would have to sum to zero due to the divergence-free constraint on the magnetic field. The use of this nonconservation form is similar to the common practice, in incompressible flow calculations, of using advective differencing of the velocity fields, rather than conservative differencing (see, for example, Bell, Colella, and Glaz [1]). Also, it has been shown by Brackbill and Barnes [4] that using the nonconservation form of the momentum equations reduces the effect of magnetic monopole forces on the dynamics of the system. In the above equations, we have used the following notation:

$$\rho E = \frac{1}{2}\rho u^2 + \frac{p}{\gamma - 1} + \frac{B^2}{8\pi},$$

$$\mathbf{B}_{\perp,x_i} = \mathbf{B} - B_{x_i}\hat{\mathbf{e}}_i,$$

$$\mathbf{u}_{\perp,x_i} = \mathbf{u} - u_{x_i}\hat{\mathbf{e}}_i,$$

$$\nabla\cdot\left(\mathbf{q}_{\perp,x_i} a\right) = \sum_{i\neq j}\frac{\partial}{\partial x_j}(q_{x_j} a) = \nabla_{\perp,x_i}(\mathbf{q}a),$$

$$\mathbf{q}_{\perp,x_i}\cdot\nabla a = \sum_{i\neq j} q_j\frac{\partial a}{\partial x_j} = \left(\mathbf{q}\cdot\nabla_{\perp,x_i}\right) a.$$

With the equations written in this form, it is immediately apparent that a nonconservative, one-dimensional, operator-split set will be

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u_x}{\partial x} = 0, \tag{2a}$$

$$\frac{\partial \rho u_x}{\partial t} + \frac{\partial}{\partial x}\left(\rho u_x^2 + p + \frac{B_{\perp,x}^2}{8\pi}\right) = 0, \tag{2b}$$

$$\frac{\partial \rho u_y}{\partial t} + \frac{\partial}{\partial x}\left(u_x u_y \rho\right) - \frac{B_x}{4\pi}\frac{\partial B_y}{\partial x} = 0, \tag{2c}$$

$$\frac{\partial \rho u_z}{\partial t} + \frac{\partial}{\partial x}\left(u_x u_z \rho\right) - \frac{B_x}{4\pi}\frac{\partial B_z}{\partial x} = 0, \tag{2d}$$

$$\frac{\partial B_x}{\partial t} = 0, \tag{2e}$$

$$\frac{\partial B_y}{\partial t} + \frac{\partial}{\partial x}\left(u_x B_y - u_y B_x\right) = 0, \tag{2f}$$

$$\frac{\partial B_z}{\partial t} + \frac{\partial}{\partial x}\left(u_x B_z - u_z B_x\right) = 0, \tag{2g}$$

$$\frac{\partial (\rho E^{1D})}{\partial t} + \frac{\partial}{\partial x}\left(\rho u_x E^{1D} + u_x p + u_x \frac{B_{\perp,x}^2}{8\pi}\right) - \frac{1}{4\pi}\frac{\partial}{\partial x} B_x \left(B_y u_y + B_z u_z\right) = 0. \tag{2h}$$

Note that we have not completely eliminated terms of the form $\partial B_x/\partial x$; they appear in the B_y, B_z, and ρE evolution equations. However, since $\partial B_x/\partial t = 0$, we can formally treat them as source terms.

The one-dimensional equations are all of the form

$$\frac{\partial \mathbf{U}^{1D}}{\partial t} + \frac{\partial \mathbf{F}^{1D}}{\partial x} + \mathbf{A}(\mathbf{U}^{1D})\frac{\partial \mathbf{H}(\mathbf{U}^{1D})}{\partial x} = 0, \tag{3}$$

where $\mathbf{U}^{1D} = [\rho, \rho u_x, \rho u_y, \rho u_z, B_x, B_y, B_z, \rho E^{1D}]^T$. On a one-dimensional row of cells, our discretization of these equations has the following form:

$$\begin{aligned} \mathbf{U}_i^{n+1} = \mathbf{U}_i^n &+ \frac{\Delta t}{\Delta x}\left(\mathbf{F}\left(\mathbf{U}_{i-1/2}^{n+1/2}\right) - \mathbf{F}\left(\mathbf{U}_{i+1/2}^{n+1/2}\right)\right) \\ &+ \frac{\Delta t}{\Delta x}\mathbf{A}\left(\frac{1}{2}\left(\mathbf{U}_{i+1/2}^{n+1/2} + \mathbf{U}_{i-1/2}^{n+1/2}\right)\right)\cdot\left(\mathbf{H}\left(\mathbf{U}_{i-1/2}^{n+1/2}\right)\mathbf{H}\left(\mathbf{U}_{i+1/2}^{n+1/2}\right)\right), \end{aligned} \tag{4}$$

where by $\mathbf{U}$ we mean $\mathbf{U}^{1D}$. By adding the contribution of B_x^2 back into the energy, we arrive at an evolution operator for the conserved quantities, $\mathbf{U}$. We denote this evolution operator by $(\mathbf{L}_x^{\Delta t}\mathbf{U}^n)_i - \mathbf{U}_i^{n+1}$. Similarly, we can define operators $\mathbf{L}_y^{\Delta t}$ and $\mathbf{L}_z^{\Delta t}$ for the one-dimensional equations in the y and z directions.

We can extend these one-dimensional operators to act on the full two- or three-dimensional grid of data,

$$\begin{aligned} \left(\mathcal{L}_x^{\Delta t}\mathbf{U}\right)_{i,j,k} &= \left(\mathbf{L}_x^{\Delta t}\mathbf{U}_{\cdot,j,k}\right)_i, \\ \left(\mathcal{L}_y^{\Delta t}\mathbf{U}\right)_{i,j,k} &= \left(\mathbf{L}_y^{\Delta t}\mathbf{U}_{i,\cdot,k}\right)_j, \\ \left(\mathcal{L}_z^{\Delta t}\mathbf{U}\right)_{i,j,k} &= \left(\mathbf{L}_z^{\Delta t}\mathbf{U}_{i,j,\cdot}\right)_k. \end{aligned} \tag{5}$$

Our full operator-split scheme is given by

$$\mathbf{U}_{i,j,k}^{n+1} = \left(\mathcal{L}_x^{\Delta t}\mathcal{L}_y^{\Delta t}\mathcal{L}_z^{\Delta t}\mathcal{L}_z^{\Delta t}\mathcal{L}_y^{\Delta t}\mathcal{L}_x^{\Delta t}\mathbf{U}^n\right)_{i,j,k}, \tag{6}$$

where we have used symmetric Strang splitting to obtain an overall evolution that is second-order accurate in time provided the individual one-dimensional operators are second-order accurate.

2.2. The predictor step: tracing characteristics. As in other higher-order Godunov methods, we predict states at the zone interface by tracing characteristics. To trace characteristics, we must first construct an approximate gradient $\Delta\mathbf{W}$ for each primitive variable in each zone. There are two alternate ways to construct this gradient: construct $\Delta\mathbf{W}$ by either monotonizing each primitive variable or by monotonizing each characteristic field. In a purely hydrodynamic model, the monotonized central difference algorithm used in van Leer [23] and Colella [7] gives good results. This approximation, which we subsequently refer to as the MUSCL gradient, follows the first approach and monotonizes each primitive variable separately, perhaps with some nonlinear flattening algorithm. In a series of experiments with the MHD code on one-dimensional test problems, using this form of the gradient introduced moderate amplitude (5–10%) fluctuations at shocks, compound waves, and certain types of rarefaction waves. These oscillations occur because under some conditions the MUSCL gradient is too steep. The usual cure—the flattening algorithm of [7]—when applied to the seven MHD variables, does not fix the problem.

The other approach, discussed in [3] and [8] for general systems of conservation laws, monotonizes each characteristic field separately. Unfortunately, this technique does not guarantee that the resulting gradient will be monotonic in each primitive variable. Rather than use either approach independently, we have adopted a modified hybrid of the two. This hybrid could be thought of as a MUSCL gradient combined with a highly sophisticated flattening algorithm.

Our method begins by computing eigenvalues, eigenvectors, and structure coefficients at each zone center. Zachary and Colella [25] give expressions for the eigenvalues and eigenvectors and we do not repeat them here. The structure coefficients, κ_{lm}, are the gradient of each wave speed in the direction of a characteristic field

$$\kappa_{lm} = (\nabla\lambda_l)\cdot\mathbf{r}_m. \tag{7}$$

We then form the following differences:

$$\begin{aligned}
\Delta^-\mathbf{W} &= (\mathbf{W}_i - \mathbf{W}_{i-1}) = \sum \alpha_k^-\mathbf{r}_k,\\
\Delta^+\mathbf{W} &= (\mathbf{W}_{i+1} - \mathbf{W}_i) = \sum \alpha_k^+\mathbf{r}_k,\\
\Delta^c\mathbf{W} &= \frac{1}{2}(\mathbf{W}_{i+1} - \mathbf{W}_{i-1}) = \sum \alpha_k^c\mathbf{r}_k,\\
\Delta^m\mathbf{W} &= \sum \alpha_k^m\mathbf{r}_k.
\end{aligned} \tag{8}$$

The expressions Δ^-, Δ^+, and Δ^c correspond to backward, forward, and centered differences, respectively. The final difference, Δ^m, is the monotonized, fourth-order difference used in the MUSCL algorithm.

We combine these differences to construct a fourth-order monotonized gradient by monotonizing each characteristic field independently. That is, we write $\Delta\mathbf{W}$ as

$$\Delta\mathbf{W} = \sum \overline{\alpha}_k\mathbf{r}_k, \tag{9}$$

where

$$\overline{\alpha}_k = \begin{cases} \min(\gamma|\alpha_k^-|, \gamma|\alpha_k^+|, |\alpha_k^c|, |\alpha_k^m|) \times \text{sign}(\alpha_k^c) & \text{if } \alpha_k^- \alpha_k^+ > 0, \\ 0 & \text{otherwise.} \end{cases} \tag{10}$$

The expansion coefficients α_k^m from the MUSCL gradient enforce monotonicity in each variable.

For strictly hyperbolic systems $\gamma = 2$, however, if an eigenvector is locally linearly degenerate, we use $\gamma = 1$. As in BCT, we detect local linear degeneracy through the structure coefficients. That is, at meshpoint i and for a given characteristic k, whenever

$$\kappa_{kk,i-1}\kappa_{kk,i} < 0 \quad \text{or} \quad \kappa_{kk,i+1}\kappa_{kk,i} < 0, \tag{11}$$

we assume the corresponding eigenvector is linearly degenerate.

Using the monotonized expansion coefficients, we approximate the states at $\mathbf{W}_{i+1/2,L}^{n+1/2}$ and $\mathbf{W}_{i-1/2,R}^{n+1/2}$ by tracing each characteristic forward or backward from zone center. Following the discussion in BCT, we write

$$\begin{aligned} \mathbf{W}_{i+1/2,L}^{n+1/2} &= \mathbf{W}_i^n + \frac{1}{2}\sum_{\lambda_k>0} \overline{\alpha}_k \left(1 - \frac{\Delta x}{\Delta t}\lambda_k\right)\mathbf{r}_k, \\ \mathbf{W}_{i-1/2,R}^{n+1/2} &= \mathbf{W}_i^n - \frac{1}{2}\sum_{\lambda_k<0} \overline{\alpha}_k \left(1 + \frac{\Delta x}{\Delta t}\lambda_k\right)\mathbf{r}_k. \end{aligned} \tag{12}$$

Finally, the predicted states, $\mathbf{W}_L$ and $\mathbf{W}_R$, are modified by the presence of source terms. These source terms can originate from: external forces, i.e., gravity; geometry, i.e., spherical or cylindrical coordinates; or $\partial B_x/\partial x$. Written in strict conservation form, the equations of MHD are each of the form

$$\frac{\partial \mathbf{U}}{\partial t} + \nabla\cdot\mathbf{F} = S(\mathbf{U}), \tag{13}$$

where $S(\mathbf{U})$ represents sources terms. However, we have chosen to perform the characteristic analysis in Lagrangian or primitive variables, $\mathbf{W}$. In the $\mathbf{W}$-basis, (13) becomes

$$\frac{\partial \mathbf{W}}{\partial t} + \mathbf{A}(\mathbf{W})\cdot\frac{\partial \mathbf{W}}{\partial x} = S(\mathbf{W}). \tag{14}$$

The matrix $\mathbf{A}(\mathbf{W})$ is

$$\mathbf{A}(\mathbf{W}) = \left[\frac{\partial \mathbf{U}}{\partial \mathbf{W}}\right]^{-1}\frac{\partial \mathbf{F}}{\partial \mathbf{W}}.$$

Some straightforward algebra shows that the source terms must be transformed according to the rule

$$S(\mathbf{W}) = \left[\frac{\partial \mathbf{U}}{\partial \mathbf{W}}\right]^{-1} S(\mathbf{U}). \tag{15}$$

Assume for the moment that the only source terms come from the incorrect representation of $\partial B_x/\partial x$ in the $\mathbf{B}_\perp$ and in the ρE equations. Then we have

$$S(\mathbf{U}) = \left(0, 0, 0, 0, u_y\frac{\partial B_x}{\partial x}, u_z\frac{\partial B_x}{\partial x}, \frac{\mathbf{u}_\perp\cdot\mathbf{B}_\perp}{4\pi}\frac{\partial B_x}{\partial x}\right)^T.$$

Using (15) to express $S(\mathbf{W})$ in terms of $S(\mathbf{U})$, we find that

$$S(\mathbf{W}) = \left(0, 0, 0, 0, u_y \frac{\partial B_x}{\partial x}, u_z \frac{\partial B_x}{\partial x}, 0\right)^T.$$

In the $\mathbf{W}$-representation, $\partial B_x/\partial x$ changes only the $\mathbf{B}_\perp$-equations, and not the pressure equation.

2.3. The corrector step. We seek solutions to the system of conservation laws

$$\frac{\partial \mathbf{u}}{\partial t} + \nabla \cdot \mathbf{F} = 0. \tag{16}$$

As required by the Godunov methodology, we must compute the flux $\mathbf{F}^G(\mathbf{U}_R, \mathbf{U}_L)$ evaluated along the ray $\frac{x}{t} = 0$ in the Riemann problem solution to the above equation with initial conditions

$$\mathbf{U}(x, t = 0) = \begin{cases} \mathbf{U}_L & x \leq 0, \\ \mathbf{U}_R & x > 0. \end{cases} \tag{17}$$

As mentioned in [25], any general solution technique for the MHD version of (16) faces two serious difficulties. First, the MHD wave speeds are not strictly hyperbolic. The loss of strict hyperbolicity at a point means that the analytic structure of the weak solutions is generally unknown in the neighborhood of that point. Second, the genuinely nonlinear waves can be locally linearly degenerate. It is much more difficult to determine the correct entropy satisfying discontinuities for modes with local linear degeneracies.

To deal with these problems, the starting point for our methodology is a high-order Godunov method developed by BCT. We take the BCT point of view and treat the equations of MHD as a hyperbolic system of conservation laws whose weak solutions are uniquely determined by entropy conditions, such as those described in Liu [17] for these systems. The questions surrounding whether this general approach will produce the correct weak solutions are far from settled; some of these issues are discussed in BCT. The algorithm described by BCT is an extension of the Engquist–Osher [12] flux to general systems of conservation laws and is sufficiently robust to handle the nonstrictly hyperbolic nature of the MHD equations. In the exposition that follows, we rely on BCT for the higher-order solution of the Riemann problem.

As discussed in [25], we do not need the entire solution to the Riemann problem. Indeed, the full solution may not be well defined for nonstrictly hyperbolic systems, so it is sufficient to develop the solution as a series of approximations to the full Riemann problem along the ray $\frac{x}{t} = 0$. In the next subsection, we describe the basic structure of our Riemann solver without any of the modifications needed to deal with rarefaction waves or with eigenvector degeneracies. As in the previous section on tracing characteristics, we continue to work in $\mathbf{W}$-space.

2.3.1. The Riemann solver. At each interface, we expand the jump $\mathbf{W}_R - \mathbf{W}_L$ in terms of a linearly independent set of eigenvectors $\overline{\mathbf{R}}_k$, i.e.

$$\mathbf{W}_R - \mathbf{W}_L = \sum_k \alpha_k \overline{\mathbf{R}}_k. \tag{18}$$

We determine $\overline{\mathbf{R}}_k$ from $\mathbf{W}_e = \frac{1}{2}(\mathbf{W}_R + \mathbf{W}_L)$, and let $\overline{\mathbf{R}}_k = \mathbf{r}_k(\mathbf{W}_e)$ be the kth right eigenvector of $D\mathbf{F}$ at $\mathbf{W}_e$.

With these expansion coefficients, we define two intermediate states that "bound" the entropy wave. These states are defined as

$$\mathbf{W}_L^* = \mathbf{W}_L + \sum_{\lambda^-} \alpha_k \mathbf{r}_k, \qquad \mathbf{W}_R^* = \mathbf{W}_R - \sum_{\lambda^+} \alpha_k \mathbf{r}_k. \tag{19}$$

The λ^- waves move backward and the λ^+ waves move forward with respect to the entropy wave.

At each of the four states $\mathbf{W}_L$, $\mathbf{W}_L^*$, $\mathbf{W}_R^*$, and $\mathbf{W}_R$, we compute eigenvalues for all seven MHD waves. From these eigenvalues, we can construct

$$\bar{\lambda}_0^* = \frac{1}{2}\left(\lambda_{0,L}^* + \lambda_{0,R}^*\right),$$

which is the average advective velocity at the starred states. The sign of $\bar{\lambda}_0^*$ gives an unambiguous determination of the upwind state. If $\bar{\lambda}_0^* \geq 0$, then the upwind state lies to the left of the entropy wave, while if $\bar{\lambda}_0^* < 0$, it lies to the right.

In our previous paper, we used the structure coefficients and the wave speeds at the left- and right-hand states and the two intermediate states to construct a cubic Hermite interpolating polynomial for each eigenvalue. We interpolated λ^- waves from $\lambda(\mathbf{W}_L)$ and $\lambda(\mathbf{W}_L^*)$ and λ^+ waves from $\lambda(\mathbf{W}_R)$ to $\lambda(\mathbf{W}_R^*)$. We used the resulting set of interpolants, $\bar{\lambda}_k$, to detect sonic points along each wave path.

In this study, we find that in the presence of large gradients, the structure coefficients can often become so large that they make the Hermite polynomial useless. These large structure coefficients occur when there are substantial changes in density and pressure between $\mathbf{W}_e$, the point at which we know the eigenvectors, and $\mathbf{W}_{L,R}$, or $\mathbf{W}_{L,R}^*$, where we compute $\nabla\lambda_k$. To circumvent this difficulty, we use a simple linear interpolation of the wave speeds from $\mathbf{W}_L$ to $\mathbf{W}_L^*$ and from $\mathbf{W}_R$ to $\mathbf{W}_R^*$. Changing to a linear, rather than a cubic, interpolation does not alter any of our results.

BCT derived a generalized version of the Engquist–Osher flux suitable for systems of nonstrictly hyperbolic equations. Ignoring for the moment the treatment of degenerate waves, and assuming that $\mathbf{U}_L$ is the upwind state, the BCT extension of the Engquist–Osher flux is

$$\mathbf{F}^{EO}(\mathbf{U}_L, \mathbf{U}_R) = \mathbf{F}(\mathbf{U}_L) + \sum_{k=1}^{K} \left(\int_0^{\alpha_k} \min(\bar{\lambda}_k, 0) d\alpha \right) \cdot \bar{\mathbf{R}}_k. \tag{20}$$

As BCT discuss, the integral terms in (20) add a nonnegative dissipation to each of the characteristic modes in the expansion of $\mathbf{U}_R - \mathbf{U}_L$.

Unfortunately, this generalization is unsuitable for multidimensional MHD because the terms of the form $\partial B_x/\partial x$ require special treatment, and because some terms in the flux must be differenced as gradients and some terms as divergences. We, therefore, adopt an alternative formulation of the Engquist–Osher flux. This alternative formulation was presented but not derived in Zachary and Colella [25]. We now discuss the origin of our flux formulation.

Our motivation is the scalar case, for which

$$\begin{aligned} F^{EO} &= f(u_L) + \int_{u_L}^{u_R} \min(a(u), 0) du \\ &= f(u_L) + \int_{u_L}^{u_R} \chi(u) a(u) du, \end{aligned} \tag{21}$$

where $a(u)$ is the wave speed along the path $u_R - u_L$, and $\chi(u)$ is the characteristic function

$$\chi(u) = \begin{cases} 1 & \text{if } a(u) < 0, \\ 0 & \text{if } a(u) > 0. \end{cases}$$

This can be written as the sum of terms of the form

$$\int_{u^p}^{u^{p+1}} a(u)du = f(u^{p+1}) - f(u^p), \tag{22}$$

where $a < 0$ for all $u \in [u^p, u^{p+1}]$, and

$$\begin{aligned} a(u^p) = 0 \quad &\text{or} \quad u^p = u_L, \\ a(u^{p+1}) = 0 \quad &\text{or} \quad u^{p+1} = u_R. \end{aligned} \tag{23}$$

A simple formula for F^{EO} is then given by

$$F^{EO} = f(u_L) + \sum_{s=1}^{S} (-1)^s f(u^s), \tag{24}$$

where $q = \text{sign}(u_R - u_L)$, $qu^1 < qu^2 < \cdots < qu^S$, and u^s satisfies either $a(u^s) = 0$ or

$$\begin{aligned} a(u^1) = 0 \quad u^1 = u_L, \\ a(u^S) = 0 \quad u^S = u_R. \end{aligned}$$

We can use (24) as the starting point for systems. Given the approximate parameterization of the wave curves in §2 of BCT, we can define the Engquist–Osher flux for systems of equations as follows:

$$\mathbf{F}^{EO} = \mathbf{F}(\mathbf{W}_L) + \sum_{k=1}^{K} \sum_{s=1}^{S(k)} \mathbf{F}(\mathbf{W}_k^s)(-1)^s, \tag{25}$$

where

$$\begin{aligned} \mathbf{W}_k &= \mathbf{W}_L + \sum_{k'<k} \overline{\alpha}_{k'} \mathbf{R}_{k'}, \\ \mathbf{W}_k^s &= \mathbf{W}_k + \alpha_k^s \mathbf{R}_k. \end{aligned} \tag{26}$$

Also, $q\alpha_k^1 < q\alpha_k^2 < \cdots < q\alpha_k^S$, and $q = \text{sign}(\overline{\alpha}_k)$. Finally, α_k^s satisfies

$$\begin{aligned} \overline{\lambda}_k(\alpha_k^s) = 0 \quad & 2 \le s \le S(k) - 1, \\ \overline{\lambda}_k(\alpha_k^1) \le 0 \quad & \alpha_k^1 = 0, \\ \overline{\lambda}_k(\alpha_k^{S(k)}) \le 0 \quad & \alpha_k^{S(k)} = \overline{\alpha}_k, \end{aligned} \tag{27}$$

and $\overline{\lambda}_k(\alpha)$ is the linear approximation to the wave speed given above.

The advantage of this approach is that various subpieces of the flux can be defined, as might be required for quasi-conservative differencing. If $\mathbf{F} = \mathbf{Q}_1 + \mathbf{Q}_2$, then $\mathbf{Q}_i$ can be defined as

$$\mathbf{Q}_i^{EO} = \mathbf{Q}_i(\mathbf{W}_l) + \sum_{k=1}^{K} \sum_{s=0}^{S} \mathbf{Q}_i(\mathbf{W}_k)(-1)^s. \tag{28}$$

Then $\mathbf{Q}_1$ could be differenced as a divergence, while $\mathbf{Q}_2$ could be differenced as a gradient, as might be required in a spatially varying geometry.

2.3.2. Rarefaction waves. Rarefaction waves cause problems for most Riemann solvers. Even the fully nonlinear Riemann solver in PPM needs special modification to deal with rarefaction waves, and most other Riemann solvers simply treat rarefaction waves as if they were rarefaction shocks. Our technique of expanding the discontinuity at each zone interface in terms of eigenvectors at a single reference state also does not correctly handle rarefaction waves. In fact, Einfeldt et al. [11] show that there exist initial conditions for strong rarefaction waves under which any linear Riemann solver must fail. With this failure in mind, we have modified our Riemann solver whenever we detect a strong rarefaction. Our detection criterion is simply that if

$$v_f(\mathbf{W}_e) < \lambda_0(\mathbf{W}_R) - \lambda_0(\mathbf{W}_L), \tag{29}$$

where v_f is the velocity of the fast magnetosonic wave, then we assume there is a strong rarefaction wave at this interface. Using the procedures in Einfeldt et al., particularly, equations (4.4) and (4.5), we recompute the flux as

$$\mathbf{F}^G(\mathbf{W}_R, \mathbf{W}_L) = \frac{b^+\mathbf{F}(\mathbf{W}_R) - b^-\mathbf{F}(\mathbf{W}_L)}{b^+ - b^-} + \frac{b^+ \cdot b^-}{b^+ - b^-}(\mathbf{U}_R - \mathbf{U}_L). \tag{30}$$

Here, $b^+ = \max(\lambda_R^+, \lambda_e^+, 0)$ and $b^- = \min(\lambda_L^-, \lambda_e^-, 0)$; see [11] for details. This particular representation of the Godunov flux is positively conservative.

Rarefaction waves also pose problems for our algorithm since we use density rather than specific volume as an independent variable. (Using specific volume rather than density poses similar problems at compressions.) These problems arise when estimating the density at intermediate states, particularly at $\mathbf{W}^*_{L,R}$. When we construct $\mathbf{W}^*_L$ or $\mathbf{W}^*_R$, if

$$\rho(\mathbf{W}^*_L) < \rho(\mathbf{W}_L) \quad \text{or} \quad \rho(\mathbf{W}^*_R) < \rho(\mathbf{W}_R),$$

then we interpolate in specific volume rather than in density on that particular side of the entropy wave. Using the eigenvectors in [25], we note that a change in basis from ρ to τ only changes the density components of the right and left eigenvectors. The only nonzero density component of a left eigenvector belongs to the entropy wave, and since the left eigenvectors determine the expansion coefficients, only the expansion coefficient for the entropy wave, α_0, changes under this change in basis. Note, however, that α_0 is never used by construction. We simply keep track of the appropriate representation for the right eigenvectors on each side of the entropy wave. The rest of our method for constructing the Engquist–Osher flux remains unchanged.

2.3.3. Degenerate waves. The MHD equations are nonstrictly hyperbolic because there are points with degenerate eigenvalues. At these points, the wave ordering that applies in strictly hyperbolic systems no longer holds and two or more wave speeds coincide. In MHD, the eigenvalues become degenerate in two distinct limits: if $B_x = 0$ and if $\mathbf{B}_\perp = 0$. In the first limit, the Alfven and the slow magnetosonic wave travel at the same speed as the entropy wave, resulting in a five-fold degeneracy. In the second limit, there are three different degeneracies that can occur depending upon the values of the Alfven velocity, v_{ax}, and the sound velocity c_s. When $v_{ax} > c_s$, the fast magnetosonic and the Alfven wave are degenerate, while when $v_{ax} < c_s$, the Alfven wave and the slow magnetosonic wave are degenerate, and finally when $v_{ax} = c_s$, all three waves are mutually degenerate. In each limit, and for each subcase, the algorithm must detect any degeneracy and then take appropriate action.

It is important here to clarify the exact meaning of such degeneracies and why they are peculiar to MHD. According to the definition given by Lax [15], two or more waves are considered to be degenerate when their values coincide, resulting in a loss of strict hyperbolicity.

In this case it may happen that the eigenvectors corresponding to the orginally distinct eigenvalues become essentially parallel, resulting in an eigenvector deficiency like those considered in BCT. Also, Lax [16] defines a wave to be linearly degenerate when $(\nabla\lambda_k)\cdot\mathbf{r}_k = 0$, where $\mathbf{r}_k$ is the right eigenvector corresponding to the kth characteristic field. This is the case, for example, for the entropy and Alfven waves.

We emphasize that with our choice of eigenvectors (Zachary and Colella [25]), the degeneracy of the eigenvalues does not also imply a deficiency in the eigenvectors. We always have a set of complete, linearly independent eigenvectors spanning the phase space. The same situation already occurs in the equations for pure three-dimensional hydrodynamics: the entropy wave has in fact a three-fold degeneracy that is related to the transport of entropy and shear, and there are three linearly independent eigenvectors associated with it. In pure hydrodynamics, the three-fold degeneracy always occurs, and is independent of the value of the physical variables. Therefore, purely hydrodynamics equations can still be viewed as a strictly hyperbolic system, and it can be shown that the Engquist–Osher formulation [12] does compute fluxes that satisfy the entropy condition. In MHD, however, waves that are genuinely nonlinear in the sense of Lax [16] (specifically, the fast and slow magnetosonic waves) do become linearly degenerate when their eigenvalues coincide with those of already linearly degenerate waves, i.e., the entropy and Alfven waves. If this condition happens anywhere along the wave-path of integration between the left and right states, then the Engquist–Osher formulation may fail and the entropy condition may not be satisfied. When this happens, we need to modify our scheme and apply a different type of dissipation, as described below.

The first task in dealing with degeneracies is detecting them. Analytically, two eigenvectors are degenerate whenever their corresponding eigenvalues coincide. It is rare, however, that eigenvalues will, numerically, be exactly equal; therefore we have adopted here the BCT detection algorithm. The BCT algorithm was designed with the idea in mind to identify points in a general system of hyperbolic conservation laws at which eigenvectors become parallel and the corresponding expansion coefficients are no longer reliable. However, the same approach can be utilized more generally to detect loss of strict hyperbolicty, independent of the fate of the eigenvectors. As already mentioned, our construction of the MHD eigenvectors insures that when the eigenvalues coincide, the corresponding eigenvectors are not deficient, but an originally genuinely nonlinear wave may become linearly degenerate. We adopt the BCT idea that two eigenvectors are degenerate whenever the difference in their eigenvalues at $\mathbf{W}_e$ is less than some fraction of the difference in the predicted variation of the eigenvalues over the wave path. Specifically, we say that two eigenvectors are degenerate whenever

$$|\lambda_l^e - \lambda_m^e| \le c \sum_k |\alpha_k(\kappa_{kl} - \kappa_{km})|. \tag{31}$$

(Here, as elsewhere, we use $c = 0.1$.)

The eigenvector degeneracy detection criterion in (31) fails in the limit $B_x/\mathbf{B}_\perp \to 0$, where the Alfven and slow magnetosonic waves become degenerate, but where the structure coefficients are independent of B_x. (We define $\kappa_{lm} = (\nabla\lambda_l)\cdot\mathbf{r}_m$, but there is no component of $\mathbf{r}_m$ along B_x.) We, therefore, adopt an alternative criterion, empirically derived, which states that the eigenvectors corresponding to the Alfven and slow magnetosonic waves become degenerate whenever

$$\frac{|v_{ax}^e|}{v_f^e} \le c^2 \frac{\left(\mathbf{B}_\perp^2(\mathbf{W}_e) + \mathbf{B}_\perp^2(\mathbf{W}_L) + \mathbf{B}_\perp^2(\mathbf{W}_R)\right)^{1/2}}{|B_x(W_e)|}, \tag{32}$$

where v_{ax}^e and v_f^e are, respectively, the Alfven velocity and fast mode velocity at $\mathbf{W}_e$.

The linear Riemann solver described in the previous sections breaks the full Riemann problem into two distinct parts, with each part corresponding to waves that move forward or backward with respect to the entropy wave. Accordingly, we treat all waves that are degenerate with the entropy wave as if they were additional entropy waves. Recall that from (19), entropy waves are not included in the construction of $\mathbf{W}^*_{L,R}$, nor are they incorporated in the computation of the flux.

Any other changes in the flux computation depend upon whether the eigenvector degeneracy is associated with a change in the sign of the wave speed along the wave path. Assume that the eigenvalues λ^e_l and λ^e_m satisfy (31), and assume that $\bar{\lambda}^*_0 > 0$, so that the reference state is $\mathbf{W}_L$. Let

$$\lambda^{\max}_{lm} = \max(\lambda^L_l, \lambda^{L^*}_l, \lambda^L_m, \lambda^{L^*}_m)$$

and

$$\lambda^{\min}_{lm} = \min(\lambda^L_l, \lambda^{L^*}_l, \lambda^L_m, \lambda^{L^*}_m).$$

When $\lambda^{\min}$ and $\lambda^{\max}$ have the same sign, (25) remains unchanged. When $\lambda^{\min}_{lm}$ and $\lambda^{\max}_{lm}$ have opposite signs, then we assume that the eigenvector degeneracy is associated with a transonic wave. In this case, we replace the flux correction terms in (25) with a dissipative term from Rusanov's [21] scheme. More exactly, the added flux correction term is

$$\mathbf{F}^{EO} = \mathbf{F}(\mathbf{W}_L) - \frac{1}{2}\nu \sum_{k=l,m} \alpha_k \overline{\mathbf{R}}_k + \sum_{k\neq l,m} \sum_{s=1}^{S(k)} \mathbf{F}(\mathbf{W}^s_k)(-1)^s, \tag{33}$$

where $\nu = \max(|\lambda^{\max}_{lm}|, |\lambda^{\min}_{lm}|)$. Although this description of a Rusanov-type dissipation assumes that only two waves were degenerate, it is easily generalized to include the case where many different waves are degenerate.

Note that if (32) is true, and the Alfven and slow waves are degenerate, then it is possible for waves to be degenerate across the entropy wave. In that case, the definitions for $\lambda^{\min}$ and $\lambda^{\max}$ simply look at the wavespeeds at $\mathbf{W}_L$ and $\mathbf{W}_R$, without considering the wavespeeds at the intermediate states.

2.4. Insuring $\nabla\cdot\mathbf{B} = 0$. The problem of preserving $\nabla\cdot\mathbf{B} = 0$ to the highest possible accuracy, possibly even to machine accuracy, is a crucial one for discretized versions of the MHD equations. While the continuum equations insure that an initially solenoidal magnetic field will remain solenoidal when evolving in time, the discretized equations do not. As a consequence, numerical solutions of the MHD equations can generate magnetic monopole forces that strongly affect the dynamics of the fluid (See, e.g., Brackbill and Barnes [4]). Writing the equations in variables other than the magnetic field, like the vector potential or the magnetic flux function, partially solves the problem. This approach, however, has two drawbacks: it requires a staggered mesh, and the equations are not in a form suitable for characteristic analysis.

In our code we have used a centered, finite-difference scheme based on primitive variables because this scheme is the natural choice for higher-order Godunov methods. Our choice means that $\nabla\cdot\mathbf{B} = 0$ is preserved only to the truncation error of the method. In principle, that truncation error could be $O(1)$, since we are computing solutions in the presence of discontinuities. To deal with that problem, we follow the prescription in [4], remove the nonsolenoidal part of $\mathbf{B}$, and then apply a Hodge projection to $\mathbf{B}$ at the end of each timestep. First solve the Poisson equation for the potential ϕ

$$\nabla^2\phi + \nabla\mathbf{B} = 0, \tag{34}$$

then the new solenoidal magnetic field is defined by $\mathbf{B} = \mathbf{B} - \nabla\phi$. Here we used second-order central difference approximations for the gradient and divergence operators. This numerical form of the Hodge projection leads to nonstandard discretizations of the Laplacian. However, the resulting linear equations can be solved efficiently and accurately using interative methods, e.g., multigrid (see Bell, Colella, and Howell [2]). It is worth noting that, for the two-dimensional problems presented in this paper, we did not find any noticeable difference regardless of whether or not we applied a projection.

3. Numerical results. We have tested our algorithm on a variety of MHD problems in one and two dimensions to check the consistency and robustness of our method under different conditions on the physical variables. Each problem tests different features of the code, such as its behavior in special limiting conditions, e.g., in the purely hydrodynamic limit, or its ability to track discontinuities. Our testing procedure has been particularly useful as we tuned the degeneracy detection algorithm, which is a crucial component of our Riemann solver.

All computations described below were performed on a Cray Y-MP8e/8128-4 at the Cray Research, Inc., data center in Eagan, Minnesota, and on a Cray Y-MP8/464 at the NASA Center for Computational Sciences (NCCS) in Greenbelt, Maryland. At the moment, the current version of the code, including all the test and corrections for degeneracy, the construction of two different sets of eigenvectors for each meshpoint, and the modifications for rarefaction waves, takes 15 μs per cell in one dimension and twice that in two dimensions. In other words, the algorithm does approximately 32,000 meshpoints/s in two dimensions. Our timestep was set by the Courant–Friedrichs–Lewy (CFL) stability condition

$$\Delta t = \sigma \max_{i,j} \left(\frac{\Delta x_i}{|u_{x,i}| + v_{f,i}}, \frac{\Delta y_i}{|u_{y,j}| + v_{f,j}} \right), \tag{35}$$

where σ is the Courant number, and the maximum is taken over $i = 1, \ldots, N_x$, $j = 1, \ldots, N_y$. All the calculations were done using a Courant number $\sigma = 0.8$ without any artificial viscosity.

3.1. One-dimensional problems. Our suite of one-dimensional problems includes benchmarks commonly used to test numerical algorithms: the Sod shock tube problem [22], the Brio and Wu problem [5], and the strong version of the Sod shock tube problem [5]. In addition, we have studied the strong rarefaction problems considered by Einfeldt et al. [11]. Each problem tests a different aspect of the Riemann solver. The Sod shock tube problem tests the solver in the purely hydrodynamic limit, the Brio and Wu problem stresses our handling of linear degeneracies and compound waves, while the strong version of the Brio and Wu problem accents our handling of large-amplitude shock waves. Finally, the Einfeldt et al. problems test our ability to detect and handle strong rarefaction waves.

As mentioned above, the Sod shock tube is a purely hydrodynamical Riemann problem in which the initial condition consists of two uniform states $\mathbf{W}_L$ and $\mathbf{W}_R$ separated by a discontinuity. The gas polytropic index is $\gamma = 1.4$, and the initial conditions are

$$\mathbf{W}_L(x < 0) = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 1 \end{bmatrix}, \qquad \mathbf{W}_R(x > 0) = \begin{bmatrix} .125 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0.1 \end{bmatrix}.$$

The numerical solution has been obtained for 100 grid points (with $\Delta x = 1$) and is shown in Fig. 1 after 50 timesteps (Δt being given by the CFL condition). The shock discontinuity is well resolved within three grid points. The contact discontinuity is slightly more diffused, which is expected since we have not used a detection algorithm (see [9]). Also, there is a small undershoot at the base of the rarefaction wave that is a peculiar feature of how our linearized solver treats rarefaction waves. This undershoot can be partially eliminated by adding a quadratic artificial viscosity to our scheme of the type described by BCT. In Fig. 2 we show a comparison between the density profile at the same timestep as computed by our method and by the PPM method of Colella and Woodward [9]. Both solutions are very similar, with the main difference being the undershoot discussed above; one can see that the contact discontinuity is better represented by the PPM code that used a contact detection algorithm.

In Fig. 3 we present the results of the Brio and Wu [5] problem, which is an MHD analogue of the Sod shock tube problem. The initial configuration is the same as the Sod shock tube problem, but with $\gamma = 2$; the initial magnetic field is $By_l = \sqrt{4\pi}$, $By_r = -\sqrt{4\pi}$, and $Bx = 0.75\sqrt{4\pi}$. Here we have used a grid of 800 points and 400 timesteps. The solution is in excellent agreement with the one obtained by Brio and Wu [5] using a Riemann solver written specifically for this problem. Again, we note that our method introduces a small perturbation at rarefaction waves. This perturbation does not affect the solution seriously and was previously noted also by Zachary and Colella [25]. On the other hand, all the shocks are extremely sharp and do not show any post-shock oscillations. In Fig. 4 we present the last of our set of Riemann problems, the strong version of the magnetized Sod shock tube problem that was also discussed by [5]. Here we set $B_x = 0$, $P_L = 1000$, $\gamma = \frac{5}{3}$, and all the other parameters as before. The solution is very well behaved even in this extreme case, and we note that we could solve this problem with a $\gamma \neq 2$, while the Brio and Wu solver could not.

Our final one-dimensional test problem is drawn from the strong rarefaction problems discussed by Einfeldt et al. [11]. In our earlier discussion of the Riemann solver, we noted that conditions exist under which any linear Riemann will fail, even if the underlying physical problem admits a solution. We have implemented a strong rarefaction wave detection algorithm that automatically applies additional dissipation whenever the Riemann solver fails. In Fig. 5 we show the results for the problem defined as $1-2-0-3$ in [11]. This problem consists of two strong rarefaction waves moving symmetrically in opposite directions. With an adiabatic index $\gamma = 1.4$, the initial conditions are

$$\mathbf{W}_L(x<0) = \begin{bmatrix} 1 \\ -2 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0.4 \end{bmatrix}, \qquad \mathbf{W}_R(x>0) = \begin{bmatrix} l \\ 2 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0.4 \end{bmatrix}.$$

From the analysis in [11], these initial conditions have a physical solution, but the solution is not linearizable.

3.2. Two-dimensional problems. Among the various two-dimensional test cases that we have tried, we present here two particularly interesting ones: a spherically symmetric explosion in a uniformly magnetized medium and the compressible version of the Orszag–Tang vortex (see Dahlburg and Picone [10] and Picone and Dahlburg [19]). Both problems develop interesting wave patterns and shocks that propagate in all directions, and therefore

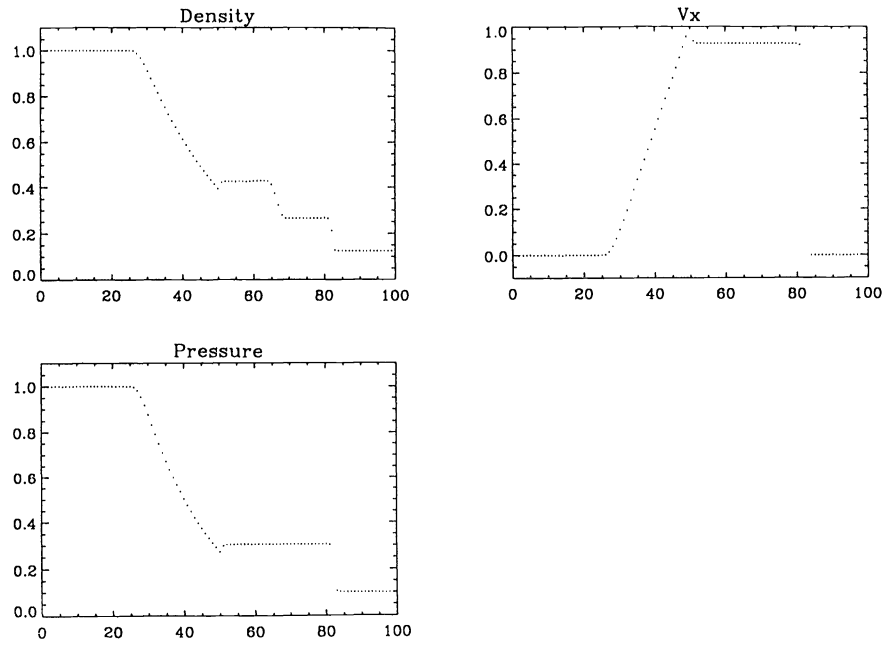

FIG. 1. *The solution to the Sod shock tube problem on a uniform mesh with* 100 *grid points is shown after* 50 *timesteps. The size of the timestep was controlled by the* CFL *condition with* CFL *number of* 0.8.

they are very useful tests of the two-dimensional properties of our code. One of the main differences between the purely one-dimensional problems and the two-dimensional problems is that the magnetic field **B** varies in the direction of spatial integration in each of the one-dimensional sweeps of the operator-split method. This introduces extra source terms in the equations and may give rise to a new set of degeneracies that are not present in the purely one-dimensional problems (see the discussion in the previous section).

3.2.1. Spherical explosion. The explosion is driven by a spherical region (with $r = 0.1$) with a large overpressure. The initial density and pressure are $\rho = 1$, $P_e = 1$, and the overpressure is $P_i = 100$. We have tried three different values of the initially uniform magnetic field: $B_y = 0$, $B_y = 10$, and $B_y = 100$. Our computation mesh is a cartesian uniform grid with 120 points in each direction. This problem is identical to the one described by Kössl, Müller, and Hillebrandt [14], and we have used their results as a qualitative comparison. In Figs. 6, 7, and 8, we show the contour plots of density, thermal pressure, magnetic pressure, and kinetic energy for the three cases in which $B_y = 0$, $B_y = 10$, and $B_y = 100$. For $B_y = 0$ (Fig. 6), there is one spherically symmetric hydrodynamical shock wave that propagates outward. This solution is essentially identical to the one obtained with other purely hydrodynamical codes, e.g., PPM. For $B_y = 10$, the shock wave is still mostly spherically symmetric, but it becomes slightly elongated in the direction of the magnetic field.

For $B_y = 100$, the explosion becomes highly anisotropic: there is essentially no displacement of gas in the direction transverse to the magnetic field, and two hydrodynamical shocks propagate in the parallel direction. In this highly magnetized fluid, the slow magnetosonic wave speed is almost equal to the sound speed, and the fast wave speed is almost equal to the Alfven velocity. Several weak magnetosonic waves are radiated transverse to the magnetic field as an initial transient until total pressure equilibrium is reached at the center. While

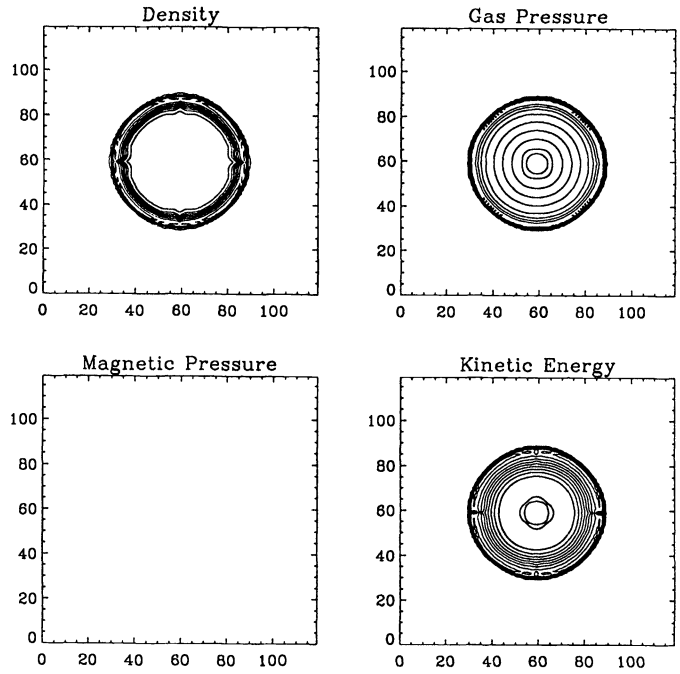

FIG. 6. *The solution to the spherically symmetric explosion problem in the hydrodynamic limit* $By_0 = 0$ *is shown on a mesh with* 120*-by-*120 *grid points after* 48 *timesteps. For each variable, there are* 20 *equally spaced contour levels. A* CFL *condition of* 0.8 *was used. No artificial viscosity or flattening was applied.*

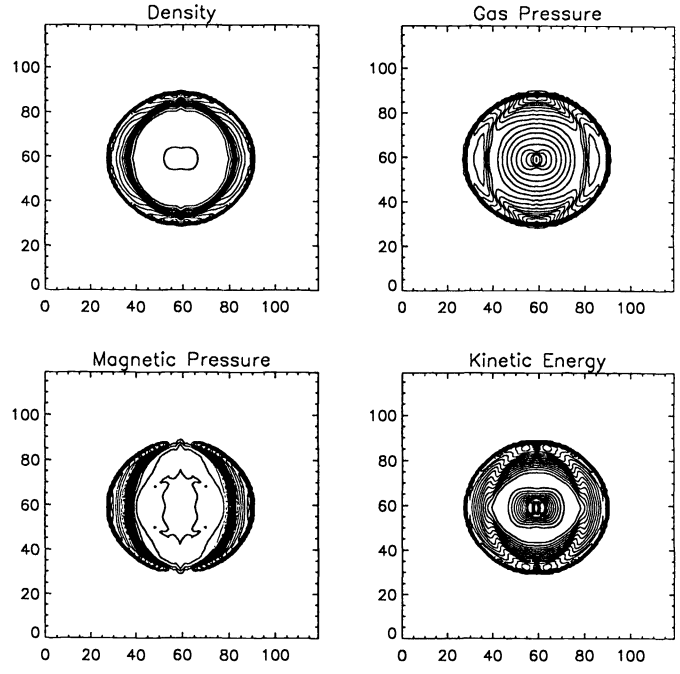

FIG. 7. *The solution to the spherically symmetric explosion problem with an initial field* $By_0 = 10$ *is shown after* 48 *timesteps. All the other conditions are the same as in Fig.* 6.

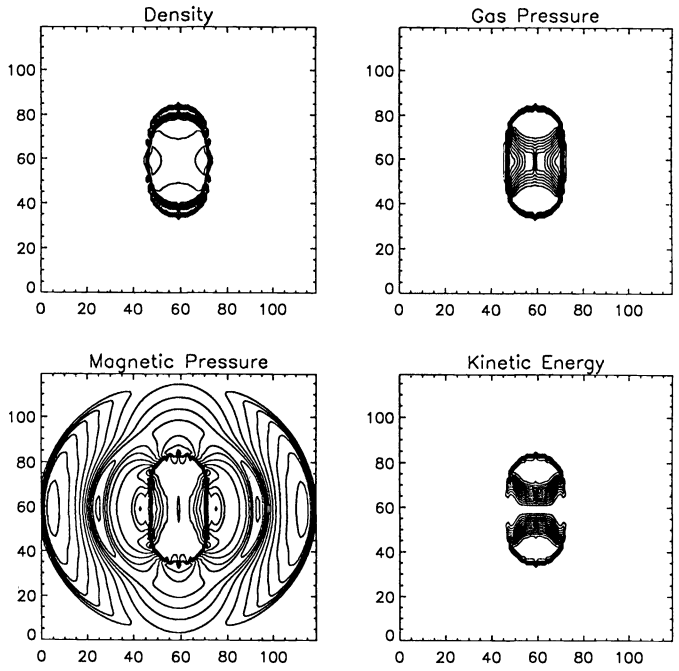

FIG. 8. *The solution to the spherically symmetric explosion problem with an initial field* $By_0 = 100$ *is shown after* 48 *timesteps. All the other conditions are the same as in Fig.* 6.

the results are in good agreement with the results of [14], we see that the waves and shocks look very sharp and clean with little or no oscillations. The strong steepening of the profiles generates the step-like irregularities that appear in the contour lines near the strong discontinuities. These irregularities are a well-known feature of higher-order Godunov methods (see Woodward and Colella [24]). A flattening algorithm and a quadratic artificial viscosity will cure this effect and prevent the appearance of low-amplitude nonphysical oscillations.

3.2.2. Orszag–Tang vortex. In the second numerical example, we studied the evolution of a compressible Orszag–Tang vortex system like the ones described by Dahlburg and Picone [10], [19]. This problem has been introduced by Orszag and Tang [18] as a simple model to study the evolution of MHD turbulence, and it has been generalized by Dahlburg and Picone [10] for the case of a fully compressible medium. We have selected this problem to test how our two-dimensional code treats the interactions between the several shock waves generated as the vortex system evolves. The initial conditions have a periodic structure containing X-points in both the velocity and the magnetic field. The velocity and magnetic fields have different modal structures. We selected an initially uniform pressure and density based on the value of the average Mach number. The initial configuration is as follows: we choose a cartesian uniform grid with periodic boundaries and 192-by-192 grid points. The fields are given as in [19]:

$$\rho(x, y, t = 0) = \rho_0,$$
$$P(x, y, t = 0) = P_0,$$
$$\mathbf{v}(x, y, t = 0) = -\sin(y)\hat{\mathbf{x}} + \sin(x)\hat{\mathbf{y}},$$
$$\mathbf{B}(x, y, t = 0) = -\sin(y)\hat{\mathbf{x}} + \sin(2x)\hat{\mathbf{y}},$$

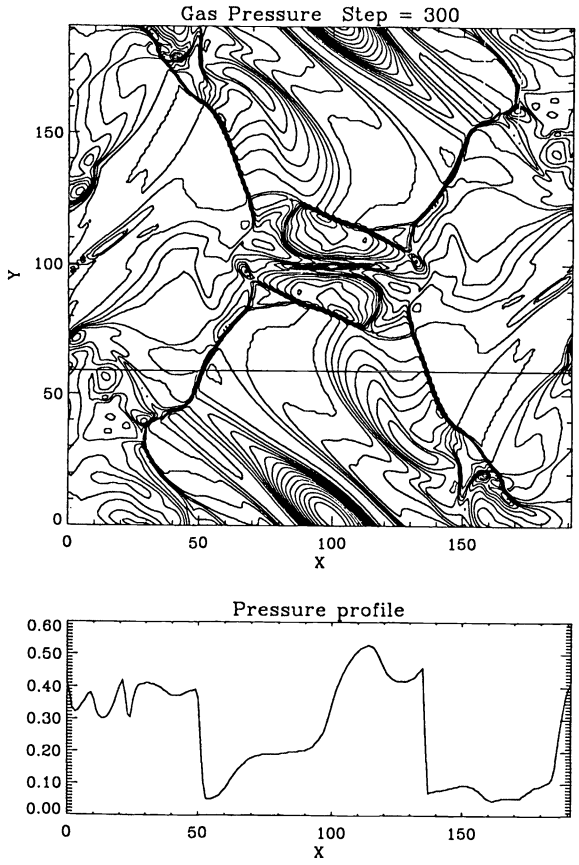

FIG. 9. *The evolution of the compressible Orszag–Tang vortex system for the case with initial Mach number* $M_0 = 1$ *and initial* $\beta = \frac{10}{3}$. *The solution was computed on a periodic cartesian mesh with* 192*-by-*192 *zones and is shown after* 300 *timesteps (approximately* 2 *Alfven transit times). The upper plot shows equally spaced contour levels of the thermal pressure. There are several shock fronts that propagate at transverse directions with respect to the grid and eventually interact. The lower plot shows the pressure profile along the solid line at* $Y = 60$. *There are two sharp jumps clearly visible where the solid line intersects the two strong shock fronts.*

where $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$ are unit vectors in the x and y directions. The initial average Mach number is given by $M^2 = \rho_0 |\mathbf{V}_0| / (\gamma P_0)$, where $|\mathbf{V}|_0$ is the initial root mean square (rms) value of the velocity. The initial average β, i.e., the ratio of thermal and magnetic pressure, is $\beta = 8\pi P_0 \, |\mathbf{B}^2|$.

We examined the case with $M = 1.0$ and $\beta = \frac{10}{3}$. In Fig. 9 we present the contour profiles of the thermal pressure after 300 timesteps. The plot shows the pressure profile along the solid line at $y = 60$, and it shows how the shocks remain sharply defined within a few grid points even in two dimensions. There are several shock fronts that propagate at different angles with respect to the grid, and which interact until the vortex system decays and gives rise to small-scale structures. The dynamics of the decay appears to closely match the one described in Dahlburg and Picone [10], even though we are not using exactly the same initial conditions. We note that in our code, the decay of the vortex system is determined by the numerical viscosity and resistivity that is built into the dissipation mechanism of the code. The similarity between our results and the results of Dahlburg and Picone, who use physical dissipation, therefore suggests that the numerical dissipation indeed provides a good model for the physical diffusive processes at subgrid scales. This conjecture, which deserves further

experiments, has been advanced also for the case of hydrodynamic turbulence by, for example, Cattaneo et al. [6].

4. Discussion and conclusions. We have derived an explicit, second-order Godunov method for the equations of ideal MHD in two and three spatial dimensions. Our approach contains many of the same elements applied successfully to ideal, compressible hydrodynamics. Most of the general techniques that improve the behavior of Godunov methods in hydrodynamics, such as flattening and artificial viscosity, carry over to our code. Our main innovation is the construction of an approximate, linearized Riemann solver. This Riemann solver detects and handles the degeneracies that occur in ideal MHD, and is well behaved for physically acceptable states. By well behaved we mean that the Riemann solver does not produce nonphysical states like, for example, negative pressures and densities in the presence of strong rarefaction waves.

To apply the one-dimensional characteristic analysis to the formulation of the Riemann problem, we rewrote the equations in quasi-conservative form. That is, we handle the terms containing derivatives of the magnetic field component parallel to each spatial direction, $\partial B_x/\partial x$ and $\partial B_y/\partial y$, as source terms, not as fluxes. In general coordinates, we split the terms in the equations into different components: some that must be treated as divergences, some as gradients, and some as pure source terms. Our particular quasi-conservative formulation is well suited to the operator-split methodology on which we based our code. At each timestep, we solve two sets of one-dimensional equations, one set for each spatial direction. These equations are not the same as the purely one-dimensional equations because they contain source terms arising from the Maxwell equation $\nabla\cdot\mathbf{B} = 0$. Furthermore, we wrote the momentum equations in such a way that the condition $\nabla\cdot\mathbf{B} = 0$ applies exactly to the continuum equations, even if it does not apply to the discretized version. For the examples we have considered, our approach appears to suppress the occurrence of monopole forces that would lead to unphysical dynamics. In cases where our basic difference approximation does not suffice to maintain the divergence-free condition of the magnetic field, we have the option of applying a Hodge decomposition to the magnetic field at each timestep to eliminate the monopole component.

The code achieves high resolution and accuracy in the presence of strongly discontinuous solutions. This high performance has some limitations, however. Because performing a Riemann solve is computationally expensive, and because the time advance of the solution is limited by the CFL condition, our code is best suited to studying transient phenomena that involve the propagation and interaction of shock discontinuities and MHD waves. While the current formulation of the code can already be used to study a wide variety of problems, there are good reasons to construct a fully unsplit Godunov scheme for the MHD equations. We expect that an unsplit method will be more appropriate when studying systems with strongly sheared fields, and that generally such an approach will improve the advection of the solenoidal magnetic field. This problem is analogous to the advection of the velocity field in an incompressible medium. Colella [8] discusses a general method of constructing unsplit methods that make use of the multidimensional wave propagation properties of the solution to construct the Godunov fluxes. We believe that the same approach will work also for the equations of MHD, and that our Riemann solver will be the base of one such scheme. As usual, the final answer must rely on numerical experiments.

COMPUTING LARGE SPARSE JACOBIAN MATRICES USING AUTOMATIC DIFFERENTIATION*

BRETT M. AVERICK†‡, JORGE J. MORÉ‡, CHRISTIAN H. BISCHOF‡, ALAN CARLE†§, AND ANDREAS GRIEWANK‡

Abstract. The computation of large sparse Jacobian matrices is required in many important large-scale scientific problems. Three approaches to computing such matrices are considered: hand-coding, difference approximations, and automatic differentiation using the ADIFOR (automatic differentiation in Fortran) tool. The authors compare the numerical reliability and computational efficiency of these approaches on applications from the MINPACK-2 test problem collection. The conclusion is that ADIFOR is the method of choice, leading to results that are as accurate as hand-coded derivatives, while at the same time outperforming difference approximations in both accuracy and speed.

1. Introduction. The solution of large-scale nonlinear problems often requires the computation of the Jacobian matrix $f'(x)$ of a mapping $f : \mathbb{R}^n \to \mathbb{R}^m$. This computation is required, for example, in constrained optimization, parameter identification, sensitivity analysis, and the solution of systems of stiff differential and algebraic equations. In this paper, we consider three approaches to computing large, sparse Jacobian matrices: function differences, hand coding, and automatic differentiation.

The most popular approach is to use *function differences* (FD) to approximate the Jacobian matrix. The ith column of $f'(x)$ can be approximated by first-order accurate *forward differences* and by second-order accurate *central differences*,

$$\frac{f(x + h_i e_i) - f(x)}{h_i}, \qquad \frac{f(x + h_i e_i) - f(x - h_i e_i)}{2h_i},$$

respectively, where h_i is a suitably chosen parameter and e_i is the ith unit vector. Computing derivatives by differences has the advantage that only the function is needed as a black box; however, the accuracy of such derivative approximations is hard to assess. The choice of the difference parameter h_i can be a source of difficulty for many problems, in particular if the problem is highly nonlinear or if the function is noisy. A small stepsize h_i is needed to suitably approximate the derivatives, yet it may lead to numerical cancellation and the loss of accuracy.

The potential inaccuracies of difference approximations can be avoided if one is able to supply derivative code. One approach is to *hand code* a subroutine to evaluate $f'(x)$.

In addition to being accurate, hand coding usually produces efficient code. However, this approach is often time consuming and error prone, especially if the function is complicated. In particular, new coding effort is required whenever the function is modified.

Another way to obtain Jacobian matrices is by using symbolic manipulation packages such as Maple, Reduce, Macsyma, or Mathematica. Given a string describing the definition of a function, symbolic manipulation packages provide algebraic expressions for derivatives expressed in terms of the independent variables. Symbolic differentiation is a powerful technique, but quickly runs into resource limitations when applied to even moderately sized problems (described by 100 lines of code, say). Hence we will not consider it further.

Still another way to obtain derivative code is through *automatic differentiation* (AD). AD techniques rely on the fact that every function, no matter how complicated, is executed on a computer as a (potentially very long) sequence of elementary operations such as additions, multiplications, and elementary functions such as the trigonometric and exponential functions. By applying the chain rule to the composition of those elementary operations, one can compute derivative information for f exactly and in a completely mechanical fashion. The perceived disadvantage of AD techniques is that they are not able to handle large problems. In particular, there seems to be a perception that AD techniques are not able to compute large sparse Jacobian matrices either accurately or efficiently. The main purpose of this paper is to dispel this perception.

In §§2 and 3, we review three approaches to computing sparse Jacobian matrices: hand coding, difference approximations, and automatic differentiation using the ADIFOR tool. The rest of the paper uses several of the MINPACK-2 test problems to compare these approaches. The test problems are described in §4, and computational results are presented in §§5 and 6. We conclude that ADIFOR is the method of choice, leading to results that are as accurate as hand-coded derivatives, while at the same time outperforming difference approximations in both accuracy and speed.

2. Computing sparse Jacobian matrices. Computing the Jacobian matrix $f'(x)$ of a mapping $f : \mathbb{R}^n \to \mathbb{R}^m$ can be a difficult task when $f'(x)$ is large and sparse, particularly if a sparse data structure is used. One potential difficulty lies in the need to place elements of $f'(x)$ into the correct positions of the sparse data structure once they have been computed. For many problems, however, it is relatively easy to develop code for evaluating the Jacobian-vector product $f'(x)v$ for any $x, v \in \mathbb{R}^n$ since there is no dependence on data structure. In this section, we discuss the compressed Jacobian technique for computing sparse Jacobian matrices.

We assume that code is available for evaluating the Jacobian-vector product. It is often possible to write such code by hand, but as we shall see in the next section, it is also possible to generate this code with AD tools. If $f'(x)v$ code is not available, the Jacobian-vector product can be approximated by

$$f'(x)v \approx \frac{f(x + h_v v) - f(x)}{h_v}$$

for some difference parameter h_v.

Each column of $f'(x)$ can be obtained by choosing v to be the corresponding Cartesian basis vector. This can be extremely inefficient as it requires the computation of n Jacobian-vector products or in the case of a difference approximation, n function evaluations. To avoid this inefficiency, we *partition* the columns of $f'(x)$ into groups such that columns in a group do not have nonzeros in the same row position. For example, if a function $f : \mathbb{R}^4 \to \mathbb{R}^5$ has a

Jacobian matrix $f'(x)$ with the structure (symbols denote nonzeros, and zeros are not shown)

$$f'(x) = \begin{pmatrix} \bigcirc & & & \\ \bigcirc & & & \diamond \\ & \triangle & & \diamond \\ & \triangle & \square & \\ & \triangle & \square & \end{pmatrix},$$

then columns 1 and 2 can be placed in one group, while columns 3 and 4 can be placed in another group. This partitioning identifies *structurally orthogonal* columns of $f'(x)$, that is, columns whose inner product is zero, independent of x.

Given a partitioning of $f'(x)$ into p groups, each group consisting of structurally orthogonal columns, we can determine $f'(x)$ with p evaluations of $f'(x)v$. For each group we compute $f'(x)v$, where $v_i = 1$ if the i-th column is in the group, and $v_i = 0$ otherwise. In the above example, we would compute $f'(x)v_i$ for $v_1 = e_1 + e_2$ and $v_2 = e_3 + e_4$, and obtain

$$f'(x)v_1 = \begin{pmatrix} \bigcirc \\ \bigcirc \\ \triangle \\ \triangle \\ \triangle \end{pmatrix}, \qquad f'(x)v_2 = \begin{pmatrix} \diamond \\ \diamond \\ \square \\ \square \end{pmatrix},$$

at the cost of only two evaluations of $f'(x)v$ (versus four for the naive approach). Because of the structural orthogonality property, we can uniquely extract all entries of the Jacobian matrix from the Jacobian-vector products.

When Jacobian-vector products $f'(x)v_i$ are computed by hand-coded programs, it is usually advantageous to calculate them simultaneously to avoid the reevaluation of common expressions. This is the motivation for the *compressed Jacobian* approach where we assemble the vectors v_i into an $n \times p$ matrix V and compute $f'(x)V$. Clearly, the advantages of computing the compressed Jacobian tend to increase with p. Figure 2.1 illustrates the difference between the sparsity structure of $f'(x)$ and the sparsity structure of the compressed Jacobian $f'(x)V$ for the inverse elastic rod (IER) problem from the MINPACK-2 collection (see §4).

Curtis, Powell, and Reid (CPR) [11] were the first to note that a partitioning of the columns into p structurally orthogonal groups allows the approximation of the Jacobian matrix by function differences with p function evaluations. In the CPR algorithm, the groups are formed one at a time by scanning the columns in the natural order and including a column in the current group if it has not been included in a previous group and if it does not have a nonzero in the same row position as another column already in the group.

Coleman and Moré [10] showed that the partitioning problem could be analyzed as a *graph coloring* problem and that, by looking at the problem from the graph coloring point of view, it is possible to improve the CPR algorithm by scanning the columns in a carefully selected order. Coleman, Garbow, and Moré [9], [8] describe software for the partitioning problem. Given a representation of the sparsity structure of $f'(x)$, these algorithms produce a partitioning of the columns of $f'(x)$ into p structurally orthogonal groups. For many sparsity patterns, p is small and independent of n. For example, if the sparsity structure has bandwidth β, then $p \leq \beta$. We also note that discretization of an infinite-dimensional problem also leads to sparsity patterns where p is independent of the meshsize.

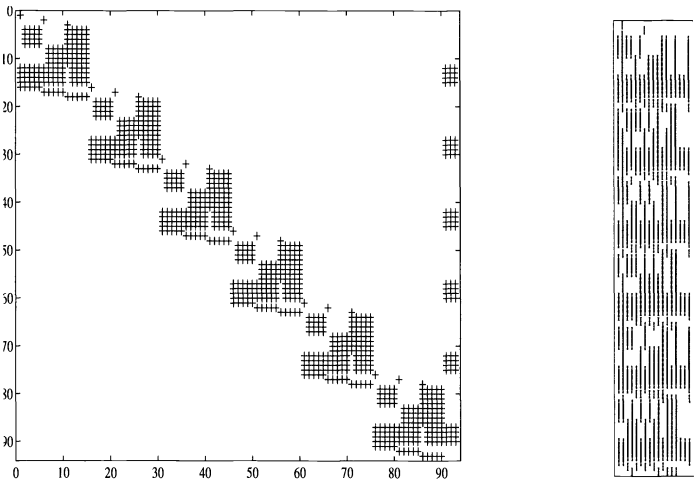

FIG. 2.1. IER *Jacobian sparsity (left) and* IER *compressed sparsity (right).*

3. AD and the ADIFOR tool. AD [17] is a chain rule-based technique for evaluating the derivatives of functions defined by computer programs with respect to their input variables. There are two basic modes of AD, which are usually referred to as *forward* and *reverse*. As discussed in [12], the reverse mode is closely related to adjoint methods and has a very low operation count for gradients. However, its potentially large memory requirement has been a serious impediment to its application in large-scale scientific computing. When there are several independent and dependent variables, the operation count for evaluating the Jacobian matrix may be lowest for certain mixed strategies [15] rather than for the forward or reverse mode. AD can also be extended to the accurate evaluation of second and higher derivatives [3], [7], [13]. A comprehensive collection on the theory, implementation, and some earlier applications can be found in [14].

In contrast to the approximation of derivatives by function differences, AD incurs no truncation error. Hence, at least for noniterative and branch-free codes, the resulting derivative values are usually obtained with the working accuracy of the original function evaluation. In contrast to fully symbolic differentiation, both operations count and storage requirement can be a priori bounded in terms of the complexity of the original function code.

The ADIFOR[1] tool [2], [4], [5] provides AD of programs written in Fortran 77. Given a Fortran subroutine (or collection of subroutines) describing a function, and an indication of which variables in parameter lists or common blocks correspond to independent and dependent variables with respect to differentiation, ADIFOR produces Fortran 77 code that allows the computation of the derivatives of the dependent variables with respect to the independent variables. ADIFOR employs a hybrid of the forward and reverse modes of AD. The resulting decrease in complexity compared with an implementation based entirely on the forward mode is usually substantial.

In contrast to some earlier AD implementations [16], the source translator ADIFOR was designed from the outset with large-scale codes in mind. The facilities of the ParaScope Fortran environment [6] control flow and data dependence flow information. ADIFOR produces portable Fortran 77 code and accepts almost all of Fortran 77; in particular, arbitrary calling sequences, nested subroutines, common blocks, and equivalences. The ADIFOR-generated

[1]For questions and information about ADIFOR e-mail `adifor-request@mcs.anl.gov`.

code tries to preserve vectorization and parallelism in the original code. It also employs a consistent subroutine naming scheme that allows for code tuning, the use of domain-specific knowledge, and the exploitation of vendor-supplied libraries. It should be stressed that ADIFOR uses data flow analysis information to determine the set of variables that require derivative information in addition to the dependent and independent ones. This approach allows for an intuitive interface and greatly reduces the storage requirements of the derivative code.

ADIFOR produces code to compute the Jacobian-vector product $f'(x)v$ or the compressed Jacobian matrix $f'(x)V$. The directional derivative $f'(x)v$ can be evaluated without forming the Jacobian matrix explicitly and thus potentially at a much lower computational cost. The operations count for this calculation is bounded by three times that of f; actual run time ratios vary depending on the implementation, the computing platform, and the nature of f. The compressed Jacobian matrices can be computed by exploiting the same graph coloring techniques discussed in §2. As already pointed out, the advantages of computing the compressed Jacobian matrix increase with p because it allows the reuse of expressions. ADIFOR-generated code reuses these expressions automatically; this is not possible with difference approximations and may not be done in a hand-coded subroutine to evaluate $f'(x)V$.

4. Test problems. In this section, we describe the problems used in comparing the different approaches for computing a sparse Jacobian matrix. The descriptions are brief since the problems are part of the MINPACK-2 test problem collection[2]; the current version of this collection is described by Averick, Carter, Moré, and Xue [1]. For each problem, the MINPACK-2 test collection contains subroutines that define the sparsity pattern of $f'(x)$ and evaluate $f(x)$ and $f'(x)V$ for any $V \in \mathbb{R}^{n\times p}$.

These problems are representative of computational problems found in applications. Collocation and finite differences are used to discretize these problems so as to obtain systems of nonlinear equations $f(x) = 0$, where $f : \mathbb{R}^n \to \mathbb{R}^n$ is a nonlinear mapping with a sparse Jacobian matrix $f'(x)$.

Flow in a channel (FIC). The analysis of fluid injection through one side of a long vertical channel leads to the boundary value problem

$$\begin{aligned} u'''' &= R[u'u'' - uu'''], \qquad 0 \le t \le 1, \\ u(0) = u'(0) &= 0, \quad u(1) = 1, \quad u'(1) = 0, \end{aligned}$$

where u is the potential function, u' is the tangential velocity, and R is the Reynolds number of the fluid.

Discretization of this problem by a k-stage collocation method, with $k = 4$, leads to a system of $n = 8n_h$ equations, where n_h is the number of subintervals in the collocation scheme. In this problem there is a maximum of nine nonzeros per row, independent of n_h.

Swirling flow between disks (SFD). The analysis of steady flow of a viscous, incompressible, axisymmetric fluid between two rotating, infinite coaxial disks, located at $t = 0$ and $t = 1$, yields the boundary value problem

$$\begin{aligned} \epsilon f'''' + ff''' + gg' = 0, \quad \epsilon g'' + fg' + f'g = 0, \qquad 0 \le t \le 1, \\ f(0) = f'(0) = f(1) = f'(1) = 0, \quad g(0) = \Omega_0, \quad g(1) = \Omega_1, \end{aligned}$$

where f' is radial velocity, g is angular velocity (Ω_0 and Ω_1 are the angular velocities of the infinite disks), and $0 \le \epsilon \ll 1$ is a viscosity parameter.

[2]Software for the MINPACK-2 test problem collection is available by anonymous ftp from `info.mcs.anl.gov`; current contents are in the file `pub/MINPACK-2/README`.

Discretization of this problem by a k-stage collocation method, with $k = 4$, leads to a system of $n = 14n_h$ equations, where n_h is the number of subintervals in the collocation scheme. In this problem there is a maximum of 14 nonzeros per row, independent of n_h.

Incompressible elastic rods (IER). The shape of a thin incompressible elastic rod, clamped at the origin and acted on by a vertical force Q, a horizontal force P, and torque M is described by the solution of the boundary value problem

$$\theta'(s) = Qx(s) - Py(s) + M, \quad x'(s) = \cos[\theta(s)], \quad y'(s) = \sin[\theta(s)],$$
$$x(0) = y(0) = \theta(0) = 0,$$

where θ is the local angle of inclination, and s is the arc length along the rod. We need to determine Q, P, and M such that $x(\cdot)$, $y(\cdot)$, and $\theta(\cdot)$ solve this boundary value problem and satisfy the boundary conditions $x(1) = a$, $y(1) = b$, $\theta(1) = c$.

Discretization by a k-stage collocation method, with $k = 4$, leads to a system of $n = 15n_h + 3$ equations, where n_h is the number of subintervals in the collocation scheme. The sparsity structure of the Jacobian and compressed Jacobian matrix for $n_h = 6$ are shown in Figure 2.1. The nonzeros in the last three columns correspond to the variables Q, P, and M. In this problem there is a maximum of 17 nonzeros per row, independent of n_h. Since there are 17 columns in the compressed Jacobian matrix, the coloring is optimal.

Solid fuel ignition (SFI). This problem arises in the analysis of a thermal reaction process dependent upon a balance between chemically generated heat addition and heat transfer by conduction in a rigid material. A steady-state model of this process can be described in terms of the solution u_λ of the boundary value problem

$$-\Delta u(x) = \lambda \exp[u(x)], \quad x \in \Omega, \qquad u(x) = 0, \quad x \in \partial\Omega,$$

where Δ is the Laplace operator, Ω is a domain in $\mathbb{R}^2$ with boundary $\partial\Omega$, and $\lambda \in \mathbb{R}$.

Discretization of this problem by finite differences on the unit square leads to a system of $n = n_x n_y$ equations, where n_x and n_y are the number of interior gridpoints in the coordinate directions, respectively. For this problem there is a maximum of five nonzeros per row, independent of n_x and n_y.

Flow in a driven cavity (FDC). The steady flow of a viscous incompressible fluid in a planar region Ω is described in terms of a stream function by the boundary value problem

$$\Delta^2\psi - R\Big[(\partial_y\psi)(\partial_x\Delta\psi) - (\partial_x\psi)(\partial_y\Delta\psi)\Big] = 0,$$
$$\psi(\xi_1, \xi_2) = \partial_x\psi(\xi_1, \xi_2) = 0, \qquad \partial_y\psi(\xi_1, \xi_2) = \begin{cases} 1 & \text{if } \xi_2 = 1, \\ 0 & \text{if } 0 \le \xi_2 < 1. \end{cases}$$

Discretization by finite differences on the unit square leads to a system of $n = n_x n_y$ equations, where n_x and n_y are the number of interior grid points in the coordinate directions, respectively. The Jacobian matrix has a maximum of 13 nonzeros per row independent of n_x and n_y.

5. Accuracy. We first compare the accuracy of the Jacobian matrix produced by ADIFOR, with the accuracy of the function difference approximation. As the standard, we take the Jacobian matrix included with the MINPACK-2 test problem collection. We measure both the absolute error and the relative error,

$$\max_{ij} \left\{ |\partial_{i,j} f(x) - a_{ij}(x)| \right\}, \qquad \max_{ij} \left\{ \frac{|\partial_{i,j} f(x) - a_{ij}(x)|}{\max\{|\partial_{i,j} f(x)|, |a_{ij}(x)|\}} \right\},$$

respectively, where $\partial_{i,j} f(x)$ is the derivative produced by the MINPACK-2 software, and $a_{i,j}(x)$ is either the difference approximation or the ADIFOR Jacobian matrix.

The results presented in Table 5.1 were obtained on a Solbourne 5E/902 in double-precision IEEE arithmetic. For these results, we evaluated the Jacobian matrices at a random vector with elements in the interval [0,1] and used a value of $h_i = 10^{-8}$ for all the variables. We do not claim that this choice is optimal, but for these problems, this choice produces reasonably accurate results. In general, the accuracy of an approximation with differences of function values depends on the choice of the difference parameters h_i, but even with an optimal choice of difference parameter, we can expect a difference approximation that is accurate only up to half the number of possible significant digits.

TABLE 5.1
Accuracy of ADIFOR *and function differences.*

		Absolute Error		Relative Error	
Problem	N	FD	ADIFOR	FD	ADIFOR
FIC	96	2.9×10^{-6}	1.4×10^{-14}	5.6×10^{-1}	9.5×10^{-16}
SFD	98	2.5×10^{-8}	0.0	1.0	0.0
IER	93	4.4×10^{-8}	0.0	1.6×10^{-1}	0.0
SFI	100	9.7×10^{-8}	0.0	3.8×10^{-8}	0.0
FDC	100	3.2×10^{-6}	3.5×10^{-14}	5.6×10^{-6}	5.4×10^{-14}

The results in Table 5.1 clearly indicate the superior accuracy of ADIFOR as compared with function differences. In terms of absolute error, ADIFOR and hand-coded Jacobians agree up to 16 significant digits, while function differences offer at most half that accuracy.

The same type of observation can be made for the relative error. However, relative error can be misleading if the Jacobian elements are sufficiently small. For FIC and IER, the relative error is usually of order 10^{-7}, but for small Jacobian entries, it may be of order 10^{-1}. In the case of SFD, function differences show a relative error of one. This is due to entries where the derivative value is of order 10^{-13} but function differences yield zero. Note, however, that ADIFOR accurately computes these small elements.

6. Timing. We now compare the time required to compute a sparse Jacobian matrix by all three approaches. The timing information was obtained for double-precision computations on a Solbourne 5E/902 and an IBM RS6000/580 workstation. Since we are interested in large problems, we used problems with n variables where n ranges between 14, 000 and 160, 000. Similar results were obtained on smaller problems.

Figure 6.1 shows the ratio of the run times for difference approximations to the Jacobian matrix to ADIFOR-generated derivative code. These results clearly show that the ADIFOR-generated code is faster than the difference approximations in all cases and that the performance advantage is more pronounced on the IBM than on the Solbourne. This can be explained by noting that the Solbourne has a true scalar processor, whereas the IBM employs a pipelined superscalar chip that performs well on the vector operations that constitute the bulk of the ADIFOR-generated derivative code.

In general, we expect ADIFOR to perform best if the number of groups p is large because the advantages of computing the compressed Jacobian matrix increase with p. This is borne out by our results. The performance of ADIFOR for small p tends to depend on the particular problem.

Note that the run time ratios in Figure 6.1 are independent of n. This can be explained by noting that the run time is proportional to the number of groups p associated with the sparsity structure; for these problems, p does not depend on the size n of the Jacobian matrix.

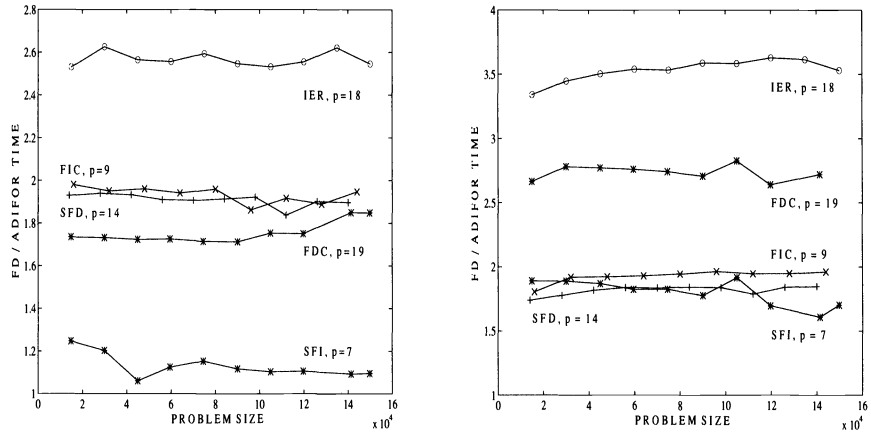

FIG. 6.1. FD *vs.* ADIFOR *timings on the Solbourne (left) and the* IBM *(right).*

The timing comparison of the ADIFOR-generated code with the hand-coded Jacobian matrix appears in Figure 6.2. We see that the ADIFOR-generated Jacobian code performs somewhat worse than the hand-coded Jacobian matrix, but not by a margin of more than roughly 2.5.

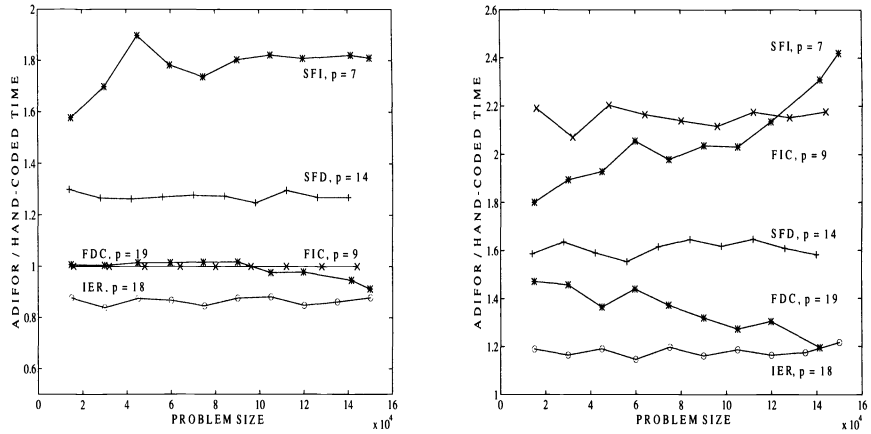

FIG. 6.2. ADIFOR *vs. hand-code timings on the Solbourne (left) and the* IBM *(right).*

Last, Table 6.1 puts these these timings in perspective by comparing the time for computing the Jacobian matrices (FD, ADIFOR, and MINPACK) with the time required to partition the columns into structurally orthogonal groups (DSM), and the time required to convert the compressed Jacobian matrix into a sparse matrix format (FDJS). Subroutines for these tasks are described by Coleman, Garbow, and Moré [8], [9]. Subroutine DSM takes the sparsity pattern of the Jacobian matrix and produces a partitioning of the columns of $f'(x)$ into p structurally orthogonal groups, while subroutine FDJS converts the compressed Jacobian matrix into a sparse matrix format. Columns N, NNZ, and P show the dimension, number of nonzeros in the Jacobian, and number of groups, respectively, for each of the problems.

Table 6.1 shows that the time required by DSM is significant when compared with the time required to compute a Jacobian matrix by either ADIFOR or the hand-coded MINPACK

subroutines. This is justified for most problems because DSM needs to be called only once for each sparsity pattern. Moreover, the runtime of DSM only depends on the sparsity pattern, not on the expense of evaluating the function or Jacobian matrix.

TABLE 6.1
Detailed Solbourne timings.

				Time (seconds)				
Problem	N	NNZ	P	DSM	FD	ADIFOR	MINPACK	FDJS
SFI	14884	73932	7	2.38	1.35	0.93	0.59	.19
FIC	16000	123987	9	2.62	5.23	2.55	1.46	.35
SFD	14000	154981	14	3.79	5.48	2.69	2.08	.43
IER	15003	158000	18	6.14	7.43	2.77	3.16	.48
FDC	14884	191056	19	9.11	11.71	6.53	6.50	.54

We also note that the runtime of FDJS is small compared with the other times in Table 6.1 and is proportional to the number of nonzeros in the Jacobian. This was to be expected because FDJS converts the compressed Jacobian matrix into a column-oriented sparse matrix format, but does not perform any arithmetic operations. We also note that the time required by FDJS becomes less significant as the number of groups p increases.

7. Conclusions. We conclude that ADIFOR-derived derivatives are certainly superior to difference approximations. Not only does the AD approach not suffer from truncation error, but its ADIFOR incarnation delivers code that outperforms divided differences by a factor of up to 3.5. The other attraction of ADIFOR is that one can generate derivative code at the touch of a button, whereas the development of a derivative code by hand is tedious and time consuming. Whether the effort involved in computing a Jacobian by hand is worth the modest speedup that we have observed here obviously depends on the application, but from our perspective it is not.

Acknowledgments. We would like to thank Richard Carter for many stimulating discussions and Jack Dongarra for the use of the IBM RS-6000.

SPECIAL SECTION ON ITERATIVE METHODS IN NUMERICAL LINEAR ALGEBRA

The 1992 Copper Mountain Conference on Iterative Methods in Numerical Linear Algebra was the seventh conference in the Copper Mountain series and the second devoted to general iterative methods. It was attended by approximately 190 mathematicians from all corners of the world. The meeting, held April 9–14, 1992, took place at the Copper Mountain Resort, which is located 70 miles west of Denver, in the heart of Colorado's famous Summit County ski region. The setting of the conference was a cluster of buildings nestled at the base of the resort's ski hill. Morning and evening sessions were scheduled, leaving afternoons open for informal discussions and recreation.

During the five days of the meeting, 109 talks on current research were presented. These talks were organized by content and grouped into sessions. Session topics included the Theory of Iterative Methods (two sessions), Nonsymmetric Systems (four), Preconditioning Strategies (two), Parallel Implementations (three), Applications (four), Multigrid and Multilevel Methods (three), Domain Decomposition (two), Eigenvalue Problems (two), Integral Equations, Nonlinear Systems (two), Indefinite and Complex Matrix Problems, Collocation Matrices, and Software. In addition, there were workshops devoted to Scientific Computing in C^{++} and Common Software Standards.

On the first day of the conference each participant was provided with a two-volume set of Preliminary Proceedings, which contained either a short paper or an abstract by each of the scheduled speakers. Of those, 49 speakers submitted complete papers to this special issue of the *SIAM Journal on Scientific Computing* (*SISC*). This and the next issue of *SISC* contain the results of the refereeing process. They represent a rich mix of papers on a wide variety of topics related to iterative methods.

The following twelve papers represent the conference. The first three deal with general iterative algorithms. The second and third involve quasi-minimal residual algorithms, a subject that inspired much discussion at the meeting. Papers 4 and 5 analyze interesting theoretical aspects of iterative methods. Papers 6 through 9 deal with precondition strategies. Papers 10 through 12 explore the implications for iterative methods of parallel computing environments.

In the next issue the last twelve papers again represent the conference. The first seven of these deal with multigrid or multilevel algorithms. The first of these is a very interesting paper that uses the tools of classical iterative methods to analyze and compare many well-known algorithms. The second and third papers also contribute to the development of the theory of multigrid and multilevel algorithms. Papers 4 through 6 are concerned with domain decomposition methods, which, incidentally, fall into the structure developed in the first paper. The final six papers in this group discuss iterative methods in the context of specific applications and represent the many fine application-specific talks presented at the conference.

A special effort was made to bring students to the meeting. The vehicle for this effort was a Student Paper Competition in which students were asked to submit an original research paper consisting primarily of their own work. We were fortunate enough to be able to provide all student authors participating in this competition with free lodging and registration. Out of thirteen submissions, three winners were selected. First place went to Xian-Zhong Guo from the University of Maryland for his work, *"The Algebraic Hierarchical Basis Multigrid Method."* Second place was awarded to Marlis Hochbruck from the University of Karlsruhe, Germany, for her paper, *"On the Use of Two QMR Algorithms for Solving Singular Systems and Applications in the Markov Chain Modeling."* Third place honors were awarded to Andrew Lumsdaine from MIT for the paper, *"Accelerating Dynamic Iteration Methods with Application to Semiconductor Device Simulation."* All winners were awarded a travel stipend,

and their papers were presented at a special session devoted to the Student Paper Competition.

We would like to thank the following members of the program committee for their help in editing this special issue. They are: Steve Ashby, Howard Elman, Roland Freund, Anne Greenbaum, Seymour Parter, Paul Saylor, Homer Walker, and Olof Widlund. Through their efforts, the articles contained in this special issue were carefully refereed and brought to print on schedule.

We would also like to extend a special thanks to Fred Howes of the Applied Mathematical Sciences Program of the Department of Energy for generous support of this meeting. Without his help, this meeting could not have taken place.

As this issue goes to press, planning for the next conference in this series is in its final stages. It will be called the Colorado Conference on Iterative Methods and will be held April 4–9, 1994, in Breckenridge, Colorado. Plans again include a special journal issue in *SISC*. It is our hope that the lively interaction and the fine quality of presentations and papers that have marked the previous meetings can be duplicated at the upcoming meeting.

RESIDUAL SMOOTHING TECHNIQUES FOR ITERATIVE METHODS*

LU ZHOU† AND HOMER F. WALKER†

Abstract. An iterative method for solving a linear system $Ax = b$ produces iterates $\{x_k\}$ with associated residual norms that, in general, need not decrease "smoothly" to zero. "Residual smoothing" techniques are considered that generate a second sequence $\{y_k\}$ via a simple relation $y_k = (1-\eta_k)y_{k-1}+\eta_k x_k$. The authors first review and comment on a technique of this form introduced by Schönauer and Weiss that results in $\{y_k\}$ with monotone decreasing residual norms; this is referred to as *minimal residual smoothing*. Certain relationships between the residuals and residual norms of the biconjugate gradient (BCG) and quasi-minimal residual (QMR) methods are then noted, from which it follows that QMR can be obtained from BCG by a technique of this form; this technique is extended to generally applicable quasi-minimal residual smoothing. The practical performance of these techniques is illustrated in a number of numerical experiments.

Key words. iterative linear algebra methods, Krylov subspace methods, residual smoothing methods, GMRES, CGS, Bi-CGSTAB methods, QMR methods

AMS subject classification. 65F10

1. Introduction.

In recent years, there has been a great deal of interest in iterative methods for solving a general nonsymmetric linear system

$$Ax = b,$$

where $A \in \mathbb{R}^{n\times n}$ and $x, b \in \mathbb{R}^n$. The quality of the iterates $\{x_k\}$ produced by a method is often judged by the behavior of $\{\|r_k\|\}$, where $r_k = b - Ax_k$; in particular, it is usually desirable that $\{\|r_k\|\}$ converge "smoothly" to zero.

In the widely used generalized minimal residual (GMRES) method [13], each x_k is characterized by

$$\|b - Ax_k\|_2 = \min_{x\in x_0+\mathcal{K}_k(r_0,A)} \|b - Ax\|_2,$$

where $\|\cdot\|_2$ is the Euclidean norm and the *Krylov subspace* $\mathcal{K}_k(r_0, A)$ is defined by

$$\mathcal{K}_k(r_0, A) = \text{span}\left\{r_0, Ar_0, \ldots, A^{k-1}r_0\right\}.$$

For GMRES, then, $\{\|r_k\|_2\}$ converges to zero optimally among all *Krylov subspace methods*, for which $x_k \in x_0 + \mathcal{K}_k(r_0, A)$. Other methods, such as biconjugate gradient (BCG) [12], [4] and conjugate gradient squared (CGS) [15], have certain advantages over GMRES but often exhibit very irregular residual-norm behavior. This irregular behavior has provided an incentive for the development of methods that have similar advantages but produce better behaved residual norms, such as the biconjugate gradient stabilized (Bi-CGSTAB) methods [10], [17] and methods based on the quasi-minimal residual (QMR) approach [2], [3], [6]–[8].

Another approach to generating well-behaved residual norms has been pursued in [14] and [18]. In this approach, an auxiliary sequence $\{y_k\}$ is generated from $\{x_k\}$ by a relation

$$\begin{aligned} &y_0 = x_0, \\ &y_k = (1 - \eta_k)y_{k-1} + \eta_k x_k, \qquad k = 1, 2, \ldots, \end{aligned} \tag{1.1}$$

in which each η_k is chosen to minimize $\|b - A((1-\eta)y_{k-1} + \eta x_k)\|_2$ over $\eta \in \mathbb{R}$, i.e.,

$$\eta_k = -\frac{s_{k-1}^T(r_k - s_{k-1})}{\|r_k - s_{k-1}\|_2^2}, \tag{1.2}$$

where $s_{k-1} = b - Ay_{k-1}$. (A weighted Euclidean norm is allowed in [18], but this is not important here.) The resulting residuals $s_k = b - Ay_k$ clearly have monotone decreasing Euclidean norms, and $\|s_k\|_2 \leq \|r_k\|_2$ for each k.

Our purpose here is to explore residual smoothing techniques of the form (1.1). In §2, we elaborate briefly on the particular technique of [14] and [18] described above, which we refer to here as *minimal residual smoothing* (MRS). In §3, we first note that the residuals and residual norms of the QMR and BCG methods are related in certain ways, from which it follows that QMR can be obtained from BCG by a technique of the form (1.1). We then extend this to a *quasi-minimal residual smoothing* (QMRS) technique applicable to any iterative method.[1] We describe a number of illustrative numerical experiments in §4 and discuss conclusions in §5.

A notational convention: When helpful, we denote iterates and residuals associated with a particular method by superscripts indicating that method.

2. Minimal residual smoothing. Assuming we have some iterative method that generates iterates $\{x_k\}$ and corresponding residuals $\{r_k\}$, we formulate the MRS technique of [14], [18] as follows:

ALGORITHM 2.1. Minimal residual smoothing [14], [18].

INITIALIZE: SET $s_0 = r_0$ AND $y_0 = x_0$.

ITERATE: FOR $k = 1, 2, \ldots,$ DO:

COMPUTE x_k AND r_k.
COMPUTE η_k by (1.2).
SET $s_k = s_{k-1} + \eta_k(r_k - s_{k-1})$ AND $y_k = y_{k-1} + \eta_k(x_k - y_{k-1})$.

There is a potential numerical difficulty with Algorithm 2.1. In practice, when the performance of an iterative method has become degraded through numerical error, the computed value of r_k can differ significantly from $b - Ax_k$. When this happens, the value of s_k computed in Algorithm 2.1 can differ significantly from $b - Ay_k$. Algorithm 2.2 below is a mathematically equivalent variation that does not suffer this difficulty provided an accurate value of Ap_k is available for each $p_k = x_k - x_{k-1}$, which is very often the case. In Algorithm 2.2, both s_k and y_k are determined directly from p_k and Ap_k; in particular, r_k is not involved in the computation at all. The intermediate quantities u_k and v_k are maintained so that, after the updating in the final step, we have $r_k = s_k - u_k$ and $x_k = y_k + v_k$. The comparative practical behavior of Algorithms 2.1 and 2.2 is illustrated in §4.1.

ALGORITHM 2.2. Minimal residual smoothing.

INITIALIZE: SET $s_0 = r_0$, $y_0 = x_0$, AND $u_0 = v_0 = 0$.

ITERATE: FOR $k = 1, 2, \ldots,$ DO:

COMPUTE $p_k = x_k - x_{k-1}$ AND Ap_k.
SET $u_k = u_{k-1} + Ap_k$ AND $v_k = v_{k-1} + p_k$.
COMPUTE $\eta_k = s_{k-1}^T u_k / u_k^T u_k$.
SET $s_k = s_{k-1} - \eta_k u_k$ AND $y_k = y_{k-1} + \eta_k v_k$.
UPDATE $u_k \leftarrow (1 - \eta_k)u_k$ AND $v_k \leftarrow (1 - \eta_k)v_k$.

[1] This should not be confused with the QMR squared method, designated QMRS in [8].

In MRS, each s_k is the vector of minimal Euclidean norm along the line containing s_{k-1} and r_k. There is an obvious extension, viz., inductively determining s_k as the vector of minimal Euclidean norm in the affine subspace containing s_{k-1} and $r_k, \ldots, r_{k-\ell}$ for some ℓ. This extension can be implemented reasonably economically (in $O(\ell n) + O(\ell^2)$ arithmetic operations for each k). However, there is no guarantee of improvement, and, in experiments that we carried out, it was not more effective than basic MRS in reducing the residual norm.

3. Quasi-minimal residual smoothing.

3.1. How QMR smoothes BCG. We first develop certain relationships between the QMR and BCG residuals and their norms. We recall the BCG method as follows:

ALGORITHM 3.1.1. Biconjugate gradient method [12], [4].

INITIALIZE:

CHOOSE x_0 AND SET $q_0 = r_0 = b - Ax_0$.
CHOOSE $\tilde{r}_0 \neq 0$, AND SET $\tilde{q}_0 = \tilde{r}_0$.

ITERATE: FOR $k = 1, 2, \ldots,$ DO:

COMPUTE $\delta_k = \tilde{r}_{k-1}^T r_{k-1} / \tilde{q}_{k-1}^T A q_{k-1}$ AND SET $x_k = x_{k-1} + \delta_k q_{k-1}$.
SET $r_k = r_{k-1} - \delta_k A q_{k-1}$ AND $\tilde{r}_k = \tilde{r}_{k-1} - \delta_k A^T \tilde{q}_{k-1}$.
COMPUTE $\gamma_k = \tilde{r}_k^T r_k / \tilde{r}_{k-1}^T r_{k-1}$.
SET $q_k = r_k + \gamma_k q_{k-1}$ AND $\tilde{q}_k = \tilde{r}_k + \gamma_k \tilde{q}_{k-1}$.

We consider the basic QMR method obtained from the general method in [7] by omitting diagonal scaling and using the classical nonsymmetric Lanczos process [11] *without* look-ahead. To discuss this, we note that $r_0, \ldots, r_{k-1}$ generated by Algorithm 3.1.1 clearly form a basis of $\mathcal{K}_k(r_0, A)$. Set $V_k = (v_1, \ldots, v_k)$ with $v_i = r_{i-1}/\rho_{i-1}$ and $\rho_{i-1} = \|r_{i-1}\|_2$ for each i. The columns of V_k also form a basis of $\mathcal{K}_k(r_0, A)$, and any $x \in x_0 + \mathcal{K}_k(r_0, A)$ can be written as

$$x = x_0 + V_k z, \qquad z \in \mathbb{R}^k. \tag{3.1.1}$$

By the nonsymmetric Lanczos process, we have

$$AV_k = V_{k+1} H_k, \tag{3.1.2}$$

where $H_k \in \mathbb{R}^{(k+1)\times k}$ is tridiagonal. From (3.1.2), the residual for x in (3.1.1) is

$$\begin{aligned} b - Ax &= r_0 - AV_k z = r_0 - V_{k+1} H_k z \\ &= V_{k+1}(\rho_0 e_1 - H_k z), \end{aligned} \tag{3.1.3}$$

where $e_1 = (1, 0, \ldots, 0)^T \in \mathbb{R}^{k+1}$. The kth QMR iterate is defined by $x_k^{\mathrm{QMR}} = x_0 + V_k z_k$, where z_k satisfies

$$\|\rho_0 e_1 - H_k z_k\|_2 = \tau_k \equiv \min_{z \in \mathbb{R}^k} \|\rho_0 e_1 - H_k z\|_2.$$

For later reference, we recall from [7] that

$$\|r_k^{\mathrm{QMR}}\|_2 \leq \sqrt{k+1}\, \tau_k. \tag{3.1.4}$$

In [7], the upper bound $\sqrt{k+1}\, \tau_k$ is used in a preliminary test for termination in QMR. We comment further on it below.

To develop the desired relationships between QMR and BCG, we note that $q_0, \ldots, q_{k-1}$ generated by Algorithm 3.1.1 also form a basis of $\mathcal{K}_k(r_0, A)$. Set

$$Y_k = (\delta_1 q_0, \ldots, \delta_k q_{k-1})$$

and

$$G_{k+1} = \begin{pmatrix} \rho_0 & & & \\ & \rho_1 & & \\ & & \ddots & \\ & & & \rho_k \end{pmatrix}.$$

We assume that Algorithm 3.1.1 can successfully carry out the kth step, in which case $\delta_1, \ldots, \delta_k$ are all nonzero and the columns of Y_k form a basis of $\mathcal{K}_k(r_0, A)$. From Algorithm 3.1.1, we have

$$AY_k = V_{k+1} G_{k+1} \bar{H}_k, \tag{3.1.5}$$

where

$$\bar{H}_k = \begin{pmatrix} 1 & & & \\ -1 & 1 & & \\ & \ddots & \ddots & \\ & & -1 & 1 \\ & & & -1 \end{pmatrix} \in \mathbb{R}^{(k+1)\times k}.$$

Since the columns of Y_k are a basis for $\mathcal{K}_k(r_0, A)$, we can write $x \in x_0 + \mathcal{K}_k(r_0, A)$ as $x = x_0 + Y_k \bar{z}$ for $\bar{z} \in \mathbb{R}^k$. Then from (3.1.5), we have

$$\begin{aligned} b - Ax &= r_0 - AY_k \bar{z} = r_0 - V_{k+1} G_{k+1} \bar{H}_k \bar{z} \\ &= V_{k+1} \left[G_{k+1} (e_1 - \bar{H}_k \bar{z}) \right]. \end{aligned} \tag{3.1.6}$$

Comparing (3.1.3) and (3.1.6), one easily verifies that

$$\tau_k = \min_{z \in \mathbb{R}^k} \| \rho_0 e_1 - H_k z \|_2 = \min_{\bar{z} \in \mathbb{R}^k} \| G_{k+1} (e_1 - \bar{H}_k \bar{z}) \|_2. \tag{3.1.7}$$

The least-squares problem on the right-hand side of (3.1.7) is easily solved. Setting $\bar{z} = (\zeta_1, \zeta_2, \ldots, \zeta_k)^T$ gives

$$\tau_k^2 = \min_{\bar{z} \in \mathbb{R}^k} \rho_0^2 (1 - \zeta_1)^2 + \rho_1^2 (\zeta_1 - \zeta_2)^2 + \cdots + \rho_{k-1}^2 (\zeta_{k-1} - \zeta_k)^2 + \rho_k^2 \zeta_k^2.$$

With a change of variables $\xi_0 = 1 - \zeta_1, \xi_1 = \zeta_1 - \zeta_2, \ldots, \xi_{k-1} = \zeta_{k-1} - \zeta_k, \xi_k = \zeta_k$, we have

$$\tau_k^2 = \min_{\sum_{i=0}^k \xi_i = 1} \sum_{i=0}^k \rho_i^2 \xi_i^2.$$

The unique minimizer is given by

$$\xi_i = \frac{\frac{1}{\rho_i^2}}{\sum_{j=0}^k \frac{1}{\rho_j^2}}, \quad i = 0, 1, \ldots, k,$$

and so

$$\tau_k = \sqrt{\frac{1}{\sum_{j=0}^{k} \frac{1}{\rho_j^2}}}.$$

Then the upper bound in (3.1.4) is

$$\sqrt{k+1}\,\tau_k = \sqrt{\frac{1}{\frac{1}{k+1}\sum_{j=0}^{k} \frac{1}{\rho_j^2}}}, \tag{3.1.8}$$

and it follows from (3.1.6) that the QMR residual vector is

$$r_k^{\mathrm{QMR}} = V_{k+1}(\rho_0\xi_0, \ldots, \rho_k\xi_k)^T = \frac{1}{\sum_{j=0}^{k} \frac{1}{\rho_j^2}} \sum_{i=0}^{k} \frac{1}{\rho_i^2} r_i^{\mathrm{BCG}}. \tag{3.1.9}$$

These results are of interest in their own right. We summarize them in the following theorem and then discuss some consequences.

THEOREM 3.1. *With* $\rho_i = \|r_i^{\mathrm{BCG}}\|_2$ *for* $i = 0, \ldots, k$, *the* QMR *residual* r_k^{QMR} *is given by* (3.1.9) *as a convex combination of the* BCG *residuals* $r_0^{\mathrm{BCG}}, \ldots, r_k^{\mathrm{BCG}}$. *The upper bound* $\sqrt{k+1}\,\tau_k$ *on* $\|r_k^{\mathrm{QMR}}\|_2$ *in* (3.1.4) *is given by* (3.1.8) *as the square root of the harmonic mean of* $\rho_0^2, \ldots, \rho_k^2$.

Equation (3.1.9) gives considerable insight into how QMR produces relatively smoothly decreasing (if not monotonically decreasing) residual norms. If $\|r_k^{\mathrm{BCG}}\|_2$ is small for some k, then r_k^{BCG} is given large weight in the convex combination (3.1.9) and $\|r_k^{\mathrm{QMR}}\|_2$ is small. If subsequent BCG residual norms increase, then the effect of this increase is mollified by relatively small weights in (3.1.9) and any increase in $\|r_k^{\mathrm{QMR}}\|_2$ is correspondingly small. These observations are borne out in Experiments 3 and 4 in §4.2 below, in which each QMR residual norm is roughly comparable to the best BCG residual norm obtained so far.

It follows from (3.1.8) that the upper bound $\sqrt{k+1}\,\tau_k$ on $\|r_k^{\mathrm{QMR}}\|_2$ is greater than or equal to $\min_{j=0,\ldots,k} \|r_j^{\mathrm{BCG}}\|_2$, with equality if and only if $\|r_0^{\mathrm{BCG}}\|_2 = \cdots = \|r_k^{\mathrm{BCG}}\|_2$. In fact, this upper bound can be a significant overestimate of $\|r_k^{\mathrm{QMR}}\|_2$, e.g., when A is nearly symmetric. Indeed, if A were symmetric, then the nonsymmetric Lanczos process would become the symmetric process, the vectors r_i^{BCG} would be mutually orthogonal, and we would have $\|r_k^{\mathrm{QMR}}\|_2 = \tau_k$ from (3.1.9).

From (3.1.9), we immediately obtain

$$\begin{aligned} r_k^{\mathrm{QMR}} &= \frac{\tau_k^2}{\tau_{k-1}^2} r_{k-1}^{\mathrm{QMR}} + \frac{\tau_k{}^2}{\rho_k^2} r_k^{\mathrm{BCG}}, \\ x_k^{\mathrm{QMR}} &= \frac{\tau_k^2}{\tau_{k-1}^2} x_{k-1}^{\mathrm{QMR}} + \frac{\tau_k^2}{\rho_k^2} x_k^{\mathrm{BCG}}. \end{aligned} \tag{3.1.10}$$

This has two useful consequences: First, since $\tau_k^2/\tau_{k-1}^2 + \tau_k^2/\rho_k^2 = 1$, we conclude that *the* QMR *method is obtained from the* BCG *method by a smoothing technique of the form* (1.1).[2] We generalize this technique in §3.2 below. Second, (3.1.10) gives a convenient and economical way of obtaining the QMR iterates and residuals from BCG. We note, however, that

[2]This is also implicit in results in [8] derived in a different manner. A different but equivalent way of determining the QMR iterates from BCG is also given in [8, §3].

if r_k^{BCG} and $b - Ax_k^{\mathrm{BCG}}$ differ significantly because of numerical error, then, as with Algorithm 2.1, r_k^{QMR} and $b - Ax_k^{\mathrm{QMR}}$ computed by (3.1.10) can also differ significantly. In this case, an analogue of Algorithm 2.2 obtained by applying the general Algorithm 3.2.2 below should perform better. In §4.2, we describe an experiment in which (3.1.10) performs poorly while the mathematically equivalent implementation of Algorithm 3.2.2 performs satisfactorily.

3.2. General quasi-minimal residual smoothing. Suppose we have some iterative method that generates iterates $\{x_k\}$ and corresponding residuals $\{r_k\}$. Since the difference of any two residuals is in the range of A, we can find for each $k \geq 1$ a w_k such that $r_{k-1} - r_k = Aw_k$. Define $Y_k = (w_1, \ldots, w_k)$ and $\rho_i = \|r_i\|_2$ for $i = 0, \ldots, k$. With V_{k+1}, G_{k+1}, and $\bar{H}_k$ as in §3.1, we again have (3.1.5), and so (3.1.6) holds for $x = x_0 + Y_k\bar{z}$, $\bar{z} \in \mathbb{R}^k$. It follows as before that

$$\tau_k \equiv \min_{\bar{z}\in\mathbb{R}^k} \|G_{k+1}(e_1 - \bar{H}_k\bar{z})\|_2 = \sqrt{\frac{1}{\sum_{j=0}^{k} \frac{1}{\rho_j^2}}}, \tag{3.2.1}$$

and, for the minimizing $\bar{z}$, we have, as in (3.1.9),

$$s_k \equiv V_{k+1}\left[G_{k+1}(e_1 - \bar{H}_k\bar{z})\right] = \frac{1}{\sum_{j=0}^{k} \frac{1}{\rho_j^2}} \sum_{i=0}^{k} \frac{1}{\rho_i^2} r_i. \tag{3.2.2}$$

In analogy with (3.1.10), we can use (3.2.2) to define "smoothed" residuals and iterates by

$$s_k = \frac{\tau_k^2}{\tau_{k-1}^2} s_{k-1} + \frac{\tau_k^2}{\rho_k^2} r_k, \qquad y_k = \frac{\tau_k^2}{\tau_{k-1}^2} y_{k-1} + \frac{\tau_k^2}{\rho_k^2} x_k,$$

and we can determine τ_k simply by $1/\tau_k^2 = 1/\tau_{k-1}^2 + 1/\rho_k^2$. This leads to the following algorithm.

ALGORITHM 3.2.1. Quasi-minimal residual smoothing.

INITIALIZE: SET $s_0 = r_0$, $y_0 = x_0$, AND $\tau_0 = \rho_0 = \|r_0\|_2$.

ITERATE: FOR $k = 1, 2, \ldots,$ DO:

COMPUTE x_k AND r_k.

SET $\rho_k = \|r_k\|_2$ AND DEFINE τ_k by $1/\tau_k^2 = 1/\tau_{k-1}^2 + 1/\rho_k^2$.

SET $s_k = (\tau_k^2/\tau_{k-1}^2)s_{k-1} + (\tau_k^2/\rho_k^2)r_k$ AND $y_k = (\tau_k^2/\tau_{k-1}^2)y_{k-1} + (\tau_k^2/\rho_k^2)x_k$.

In this algorithm, as in Algorithm 2.1, the divergence of r_k and $b - Ax_k$ through numerical error can cause s_k and $b - Ay_k$ to differ significantly. We formulate a mathematically equivalent algorithm analogous to Algorithm 2.2 that should avoid this difficulty provided an accurate value of Ap_k is available for each $p_k = x_k - x_{k-1}$.

ALGORITHM 3.2.2. Quasi-minimal residual smoothing.

INITIALIZE: SET $s_0 = r_0$, $y_0 = x_0$, $u_0 = v_0 = 0$, AND $\tau_0 = \rho_0 = \|r_0\|_2$.

ITERATE: FOR $k = 1, 2, \ldots,$ DO:

COMPUTE $p_k = x_k - x_{k-1}$ AND Ap_k.

SET $u_k = u_{k-1} + Ap_k$ AND $v_k = v_{k-1} + p_k$.

SET $\rho_k = \|s_{k-1} - u_k\|_2$ AND DEFINE τ_k BY $1/\tau_k^2 = 1/\tau_{k-1}^2 + 1/\rho_k^2$.

SET $s_k = s_{k-1} - (\tau_k^2/\rho_k^2)u_k$ AND $y_k = y_{k-1} + (\tau_k^2/\rho_k^2)v_k$.

UPDATE $u_k \leftarrow (1 - (\tau_k^2/\rho_k^2))u_k$ AND $v_k \leftarrow (1 - (\tau_k^2/\rho_k^2))v_k$.

It would be trivial to incorporate a diagonal scaling matrix

$$\Omega_{k+1} = \operatorname{diag}(\omega_0, \ldots, \omega_k) \in \mathbb{R}^{(k+1)\times(k+1)}$$

into the above developments, as is typically done in deriving QMR-type methods. In place of (3.2.1) and (3.2.2), we would then have

$$\tau_k \equiv \min_{\bar{z}\in\mathbb{R}^k} \|\Omega_{k+1}G_{k+1}(e_1 - \bar{H}_k\bar{z})\|_2 = \sqrt{\frac{1}{\sum_{j=0}^{k}\frac{1}{\omega_j^2\rho_j^2}}},$$

and, for the minimizing $\bar{z}$,

$$s_k \equiv V_{k+1}\Omega_{k+1}^{-1}\left[\Omega_{k+1}G_{k+1}(e_1 - \bar{H}_k\bar{z})\right] = \frac{1}{\sum_{j=0}^{k}\frac{1}{\omega_j^2\rho_j^2}}\sum_{i=0}^{k}\frac{1}{\omega_i^2\rho_i^2}r_i.$$

Algorithms 3.2.1 and 3.2.2 would be modified by replacing each occurrence of ρ_k^2 by $\omega_k^2\rho_k^2$. Similar remarks hold for the developments in §3.1.

As in Theorem 3.1, each s_k generated by Algorithms 3.2.1 and 3.2.2 is given by (3.2.2) as a convex combination of $r_0, \ldots, r_k$. Also, (3.2.1) and (3.2.2) imply immediately an analogue of (3.1.4) and (3.1.8), i.e.,

$$\|s_k\|_2 \le \sqrt{k+1}\,\tau_k = \sqrt{\frac{1}{\frac{1}{k+1}\sum_{j=0}^{k}\frac{1}{\rho_j^2}}}.$$

The remarks in the two paragraphs following Theorem 3.1, with appropriate changes, are valid here.

We mention the possibility of applying Algorithms 3.2.1 and 3.2.2 repeatedly to produce increasingly "smoothed" residuals and iterates. However, in an experiment that we performed, applying these algorithms twice to a BCG sequence (i.e., applying them once to a QMR sequence) showed no practical advantages.

In the case of the CGS method, Algorithms 3.2.1 and 3.2.2 can be applied in a straightforward way; however, we note an interesting alternative in this specific case. We write the CGS method as follows:

ALGORITHM 3.2.3. Conjugate gradient squared method [15].

INITIALIZE:
CHOOSE x_0 AND SET $p_0 = u_0 = r_0 = b - Ax_0$ AND $v_0 = Ap_0$.
CHOOSE $\tilde{r}_0$ SUCH THAT $\rho_0 = \tilde{r}_0^T r_0 \neq 0$.

ITERATE: FOR $k = 1, 2, \ldots,$ DO:
COMPUTE $\sigma_{k-1} = \tilde{r}_0^T v_{k-1}$, $\alpha_{k-1} = \rho_{k-1}/\sigma_{k-1}$, AND
$q_k = u_{k-1} - \alpha_{k-1}v_{k-1}$.
SET $x_k = x_{k-1} + \alpha_{k-1}(u_{k-1} + q_k)$ AND $r_k = r_{k-1} - \alpha_{k-1}A(u_{k-1} + q_k)$.
SET $\rho_k = \tilde{r}_0^T r_k$, $\beta_k = \rho_k/\rho_{k-1}$, $u_k = r_k + \beta_k q_k$,
$p_k = u_k + \beta_k(q_k + \beta_k p_{k-1})$, AND $v_k = Ap_k$.

We define auxiliary iterates and residuals as follows: For $k = 0, 1, \ldots,$ set

$$\begin{aligned} \hat{x}_{2k} &= x_k, & \hat{x}_{2k+1} &= x_k + \alpha_k u_k, \\ \hat{r}_{2k} &= r_k, & \hat{r}_{2k+1} &= r_k - \alpha_k A u_k. \end{aligned} \tag{3.2.3}$$

It is not hard to verify that, if we apply Algorithms 3.2.1 and 3.2.2 (modified, if necessary, to incorporate diagonal scaling) to the iterates $\{\hat{x}_k\}$ and residuals $\{\hat{r}_k\}$, then the resulting method is equivalent to the "transpose-free" QMR-like method derived from CGS in [6]. This is *not* the same as the method obtained by the straightforward application of Algorithms 3.2.1 and 3.2.2 to CGS; in §4.3, we illustrate the practical performance of these two ways of applying QMRS to CGS. This equivalence may help to explain experiments in [3] and also Experiments 5 and 6 in §4.3 below, in which residual norms from the method of [6] are roughly comparable to the best CGS residual norms obtained so far. (However, an example is given in [8] in which CGS diverges while the method of [6] converges.)

One can similarly obtain the QMRCGSTAB method of [3] by applying Algorithms 3.2.1 and 3.2.2 to Bi-CGSTAB [17]. Indeed, in addition to iterates $\{x_k\}$ and residuals $\{r_k\}$, Bi-CGSTAB produces $\{s_k, p_k, \alpha_k, \omega_k\}$ such that

$$x_k = x_{k-1} + \alpha_k p_k + \omega_k s_k,$$
$$s_k = r_{k-1} - \alpha_k A p_k, \qquad r_k = s_k - \omega_k A s_k.$$

In this case, we define auxiliary iterates and residuals by

$$\hat{x}_{2k} = x_k, \qquad \hat{x}_{2k+1} = x_k + \alpha_{k+1} p_{k+1},$$
$$\hat{r}_{2k} = r_k, \qquad \hat{r}_{2k+1} = s_{k+1},$$

for $k = 0, 1, \ldots$. Then the method obtained by applying Algorithms 3.2.1 and 3.2.2 (modified to incorporate diagonal scaling, if necessary) to $\{\hat{x}_k\}$ and $\{\hat{r}_k\}$ is equivalent to QMRCGSTAB.

4. Numerical experiments. We report on numerical experiments that illustrate the performance of the algorithms discussed previously. The test problem used in all but one of the experiments is a discretization of

$$\begin{aligned} \Delta u + cu + d\frac{\partial u}{\partial x} &= f \quad \text{in } D, \\ u &= 0 \quad \text{on } \partial D, \end{aligned} \tag{4.1}$$

where $D = [0, 1] \times [0, 1]$ and c and d are constants. In the experiments outlined here, we took $f \equiv 1$ and used a 100×100 mesh of equally spaced discretization points in D, so that the resulting linear systems were of dimension 10,000. Discretization was by the usual second order centered differences. Preconditioning, when used, was with a fast Poisson solver from FISHPACK [16]. In all experiments, computing was done in double precision on Sun Microsystems workstations.

4.1. Comparing Algorithms 2.1 and 2.2. We compared the numerical performance of the mathematically equivalent MRS Algorithms 2.1 and 2.2 in the following two experiments.

Experiment 1. This was a controlled experiment in which we artificially simulated the numerical breakdown of a convergent algorithm through exponential error growth. In each simulation, we first generated random[3] A and b and computed $x_* = A^{-1}b$ using a direct method; then, for $k = 0, \ldots, k_{\max}$, we generated $x_k = x_* + 2^{-k}u_k$ for random u_k, computed $r_k = b - Ax_k$, and perturbed $x_k \leftarrow x_k + \epsilon(k/k_{\max})^\nu v_k$ and $r_k \leftarrow r_k + \epsilon(k/k_{\max})^\nu w_k$ for random

[3]Here, "random" means having components that are sampled independently from a normal distribution with zero mean and unit variance. Random normal components were generated using the URAND subroutine from [5] followed by a Box–Muller transformation; see [5, p. 247]. In the particular experiment reported in Fig. 1, the seed 2468 was used in URAND.

v_k and w_k and fixed $\epsilon > 0$ and positive integer ν. We plotted $\log_{10} \|s_k\|_2$ and $\log_{10} \|b - Ay_k\|_2$ versus k for both Algorithms 2.1 and 2.2 in a number of trials. Typical results (with $n = 10$, $\epsilon = 10^2$, $\nu = 10$, and $k_{\max} = 50$) are shown in Fig. 1. Note that in Fig. 1, the solid curve is actually a superposition of the curves for $\log \|s_k\|_2$ and $\log \|b - Ay_k\|_2$ generated by Algorithm 2.2; they are visually indistinguishable. In contrast, the corresponding curves for Algorithm 2.1 diverge strongly.

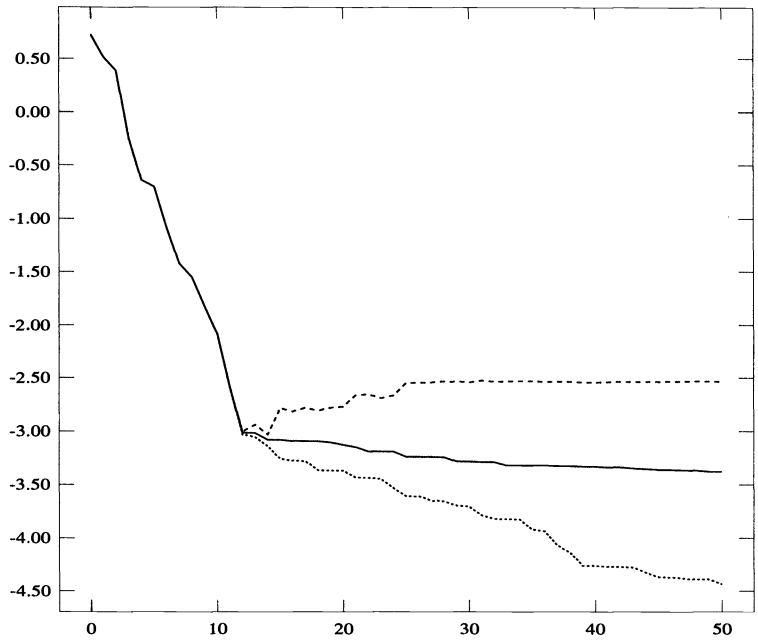

FIG. 1. *Residual norms versus the number of iterations for Experiment* 1. *Solid curve*: $\log_{10} \|s_k\|_2$ *and* $\log_{10} \|b - Ay_k\|_2$ *for Algorithm* 2.2; *dotted curve*: $\log_{10} \|s_k\|_2$ *for Algorithm* 2.1; *dashed curve*: $\log_{10} \|b - Ay_k\|_2$ *for Algorithm* 2.1.

Experiment 2. In this, we applied BCG without preconditioning to problem (4.1) with $c = d = 50$. For insight here and in Experiment 3 below, we first plotted $\log_{10} \|r_k^{\mathrm{BCG}}\|_2$ and $\log_{10} \|b - Ax_k^{\mathrm{BCG}}\|_2$ versus k in Fig. 2. Note the divergence of $\|r_k^{\mathrm{BCG}}\|_2$ and $\|b - Ax_k^{\mathrm{BCG}}\|_2$ beyond about $k = 280$; this is apparently due to rounding errors introduced in earlier iterations when $\|r_k^{\mathrm{BCG}}\|_2$ was very large. We next plotted $\log_{10} \|s_k\|_2$ and $\log_{10} \|b - Ay_k\|_2$ versus k for both Algorithms 2.1 and 2.2. The results are shown in Fig. 3, in which the graphs of $\log_{10} \|b - Ay_k\|_2$ for Algorithm 2.1 (solid curve) and for Algorithm 2.2 (long-dashed curve) are nearly superimposed. Note that for Algorithm 2.2, the values of $\log_{10} \|s_k\|_2$ stay fairly close to the values of $\log_{10} \|b - Ay_k\|_2$ in the later iterations, while for Algorithm 2.1, the values of $\log_{10} \|s_k\|_2$ are wrongly forced downward by the (inaccurate) decreasing values of $\|r_k^{\mathrm{BCG}}\|_2$. In view of the superior performance of Algorithm 2.2, it was used to implement MRS in the remaining experiments discussed below.

4.2. Smoothing methods for BCG. We compared the performance of BCG, QMR, and MRS applied to BCG on problem (4.1) in the two experiments below. In these, MRS was implemented as in Algorithm 2.2, and the QMR iterates and their residuals were generated from the BCG iterates and residuals using either (3.1.10) or a mathematically equivalent implementation of Algorithm 3.2.2. Caution: Comments below regarding the numerical

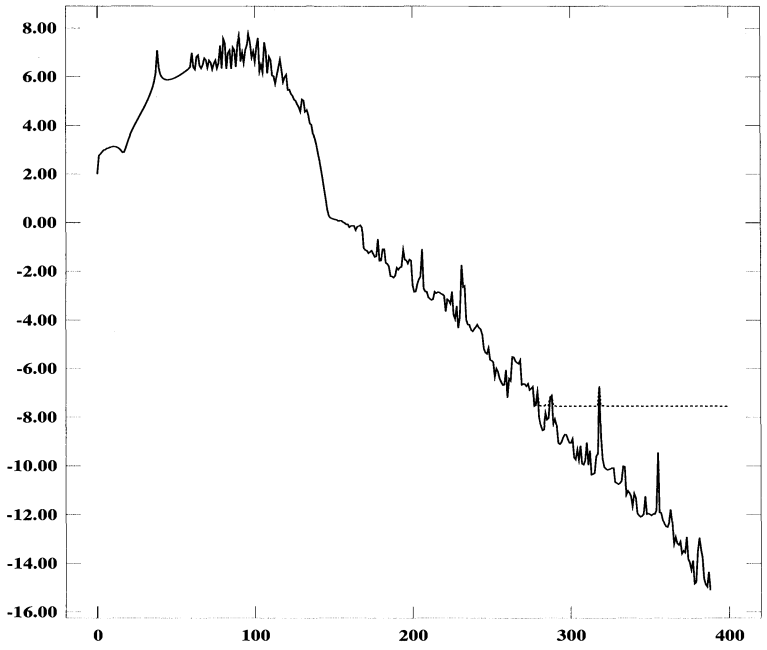

FIG. 2. *Recursive and true* BCG *residual norms versus the number of iterations for Experiments* 2 *and* 3. *Solid curve*: $\log_{10} \|r_k^{\mathrm{BCG}}\|_2$; *dotted curve*: $\log_{10} \|b - Ax_k^{\mathrm{BCG}}\|_2$.

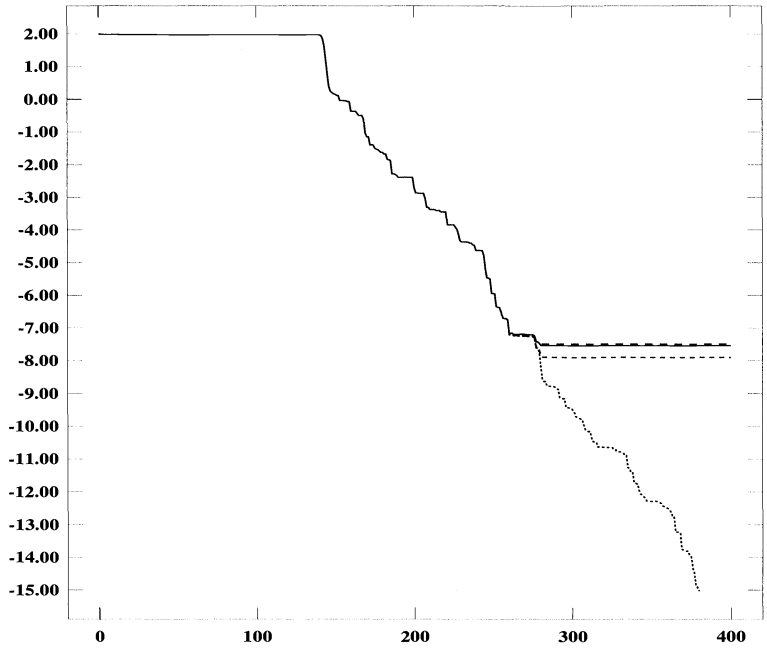

FIG. 3. *Residual norms versus the number of iterations for Experiment* 2. *Solid curve and nearly superimposed long-dashed curve*: $\log_{10} \|b - Ay_k\|_2$ *for Algorithms* 2.1 *and* 2.2; *dotted curve*: $\log_{10} \|s_k\|_2$ *for Algorithm* 2.1; *short-dashed curve*: $\log_{10} \|s_k\|_2$ *for Algorithm* 2.2.

accuracy of QMR iterates are *not* intended to apply to the general QMR method of [7], which uses the look-ahead Lanczos process; they only pertain to the soundness of (3.1.10) and Algorithm 3.2.2 applied to the BCG iterates.

Experiment 3. As in Experiment 2, we considered problem (4.1) with $c = d = 50$, without preconditioning. We first compared the accuracy of (3.1.10) and Algorithm 3.2.2 for obtaining QMR iterates from BCG iterates. The results, which are analogous to those in Fig. 3, are shown in Fig. 4, in which the graphs of $\log_{10} \|b - Ax_k^{\mathrm{QMR}}\|_2$ for (3.1.10) (solid curve) and for Algorithm 3.2.2 (long-dashed curve) are nearly indistinguishable. The remarks made in Experiment 2 about Fig. 3 are valid here, with the appropriate changes. In view of the superior performance of Algorithm 3.2.2, it was used instead of (3.1.10) or Algorithm 3.2.1 in the remaining experiments reported below, except where noted.

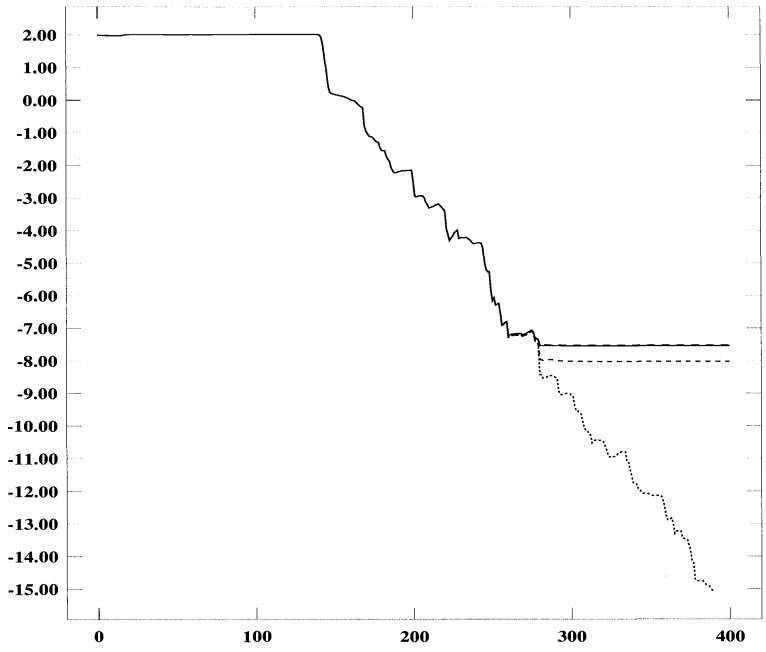

FIG. 4. *Residual norms versus the number of iterations for Experiment* 3. *Solid curve and nearly indistinguishable long-dashed curve*: $\log_{10} \|b - Ax_k^{\mathrm{QMR}}\|_2$ *for* (3.1.10) *and Algorithm* 3.2.2; *dotted curve*: $\log_{10} \|r_k^{\mathrm{QMR}}\|_2$ *for* (3.1.10); *short-dashed curve*: $\log_{10} \|r_k^{\mathrm{QMR}}\|_2$ *for Algorithm* 3.2.2.

We next compared the performance of BCG, QMR, and MRS applied to BCG on this problem. The results are shown in Fig. 5. Note that the solid curve in Fig. 5 is the *recursive* residual value $\log_{10} \|r_k^{\mathrm{BCG}}\|_2$, rather than the *true* value $\log_{10} \|b - Ax_k^{\mathrm{BCG}}\|_2$; cf. Fig. 2. Both QMR and MRS were very effective in smoothing the BCG iterates. Although fine details are hard to make out in parts of Fig. 5, the performance of QMR and MRS was, in fact, very similar over all iterations; of course, the MRS residual norms were monotone decreasing while those of QMR, although trending downward fairly smoothly, were not. Note that both QMR and MRS very effectively stabilized the iterates and residuals at about the point of greatest *true* residual reduction of BCG.

Experiment 4. We applied the three methods with preconditioning to problem (4.1) with $c = d = 100$. The preconditioning resulted in relatively well-behaved BCG residual norms, and QMR and MRS applied to BCG performed very similarly. There was no evidence of numerical error. The results are shown in Fig. 6.

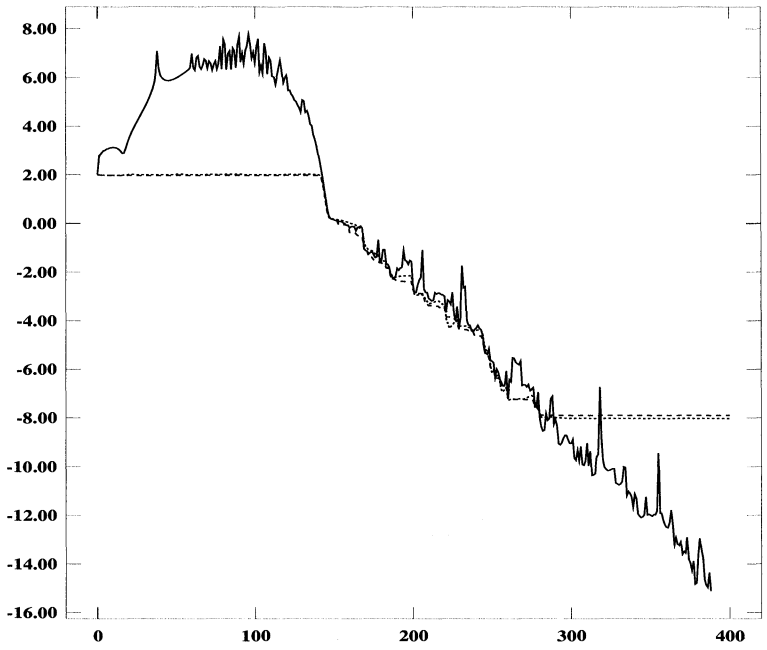

FIG. 5. *Residual norms versus the number of iterations for Experiment* 3. *Solid curve*: $\log_{10} \|r_k^{\mathrm{BCG}}\|_2$; *dotted curve*: $\log_{10} \|r_k^{\mathrm{QMR}}\|_2$; *dashed curve*: $\log_{10} \|s_k\|_2$ *for* MRS *Algorithm* 2.2 *applied to the* BCG *iterates*.

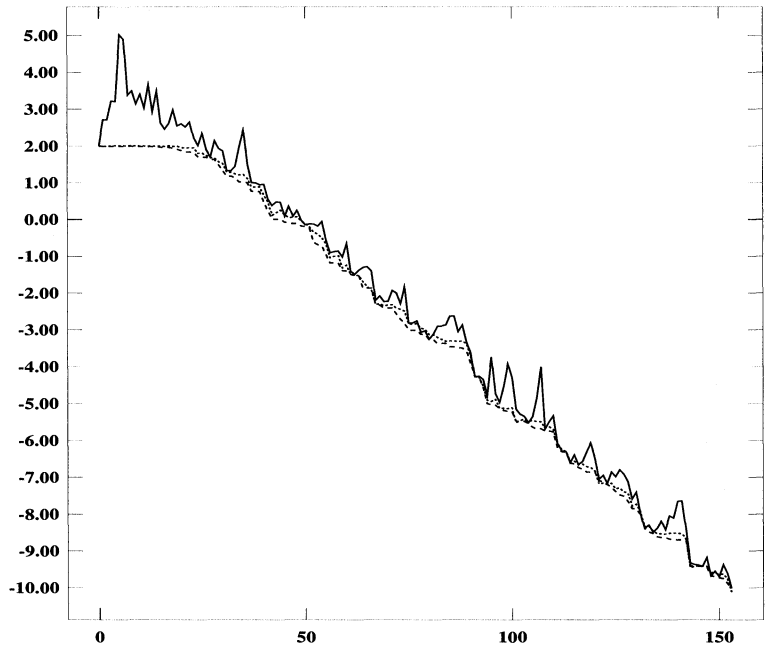

FIG. 6. *Residual norms versus the number of iterations for Experiment* 4. *Solid curve*: $\log_{10} \|r_k^{\mathrm{BCG}}\|_2$; *dotted curve*: $\log_{10} \|r_k^{\mathrm{QMR}}\|_2$; *dashed curve*: $\log_{10} \|s_k\|_2$ *for* MRS *Algorithm* 2.2 *applied to the* BCG *iterates*.

4.3. Smoothing methods for CGS. In the two experiments below, we compared the performance on problem (4.1) of CGS, the "transpose-free" QMR-like method of [6] (referred to as TFQMR below), CGS with QMRS, and CGS with MRS. We implemented TFQMR by applying QMRS to $\{\hat{x}_k\}$ and $\{\hat{r}_k\}$ defined in (3.2.3); see §3.2. The implementation of CGS with QMRS was straightforward.

Experiment 5. We applied the methods without preconditioning to problem (4.1) with $c = d = 5$. The results are given in Fig. 7. The three smoothing methods very effectively smoothed the very ill-behaved CGS residuals and performed roughly the same, although MRS tended to give slightly smaller residual norms than the other two methods. Although not shown in Fig. 7, significant divergence of $\|r_k^{\mathrm{CGS}}\|_2$ and $\|b - Ax_k^{\mathrm{CGS}}\|_2$ began at about iteration 262 and, as in Experiment 3 and Fig. 5, all three smoothing methods effectively stabilized the iterates and residuals at about the point of greatest *true* CGS residual reduction.

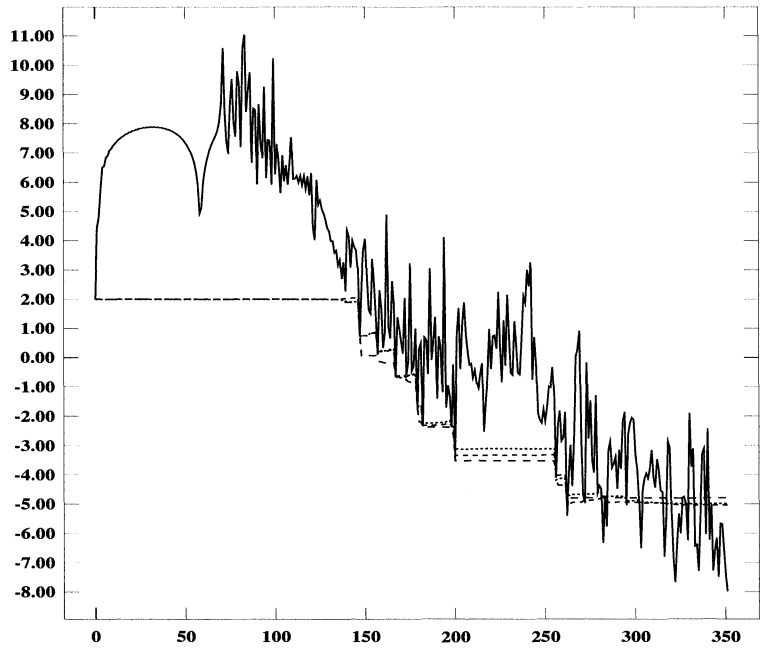

FIG. 7. *Residual norms versus the number of iterations for Experiment* 5. *Solid curve*: $\log_{10}\|r_k^{\mathrm{CGS}}\|_2$; *dotted curve*: $\log_{10}$ *of the* TFQMR *residual norms*; *short-dashed curve*: $\log_{10}\|s_k\|_2$ *for* QMRS *Algorithm* 3.2.2 *applied to the* CGS *iterates*; *long-dashed curve*: $\log_{10}\|s_k\|_2$ *for* MRS *Algorithm* 2.2 *applied to the* CGS *iterates*.

Experiment 6. We applied the methods with preconditioning to problem (4.1) with $c = d = 50$. Because r_k^{CGS} and $b - Ax_k^{\mathrm{CGS}}$ remained very close throughout this experiment, we used Algorithm 3.2.1 rather than Algorithm 3.2.2. The results are given in Fig. 8. It is evident that all three smoothing methods worked very effectively, especially in stabilizing the iterates and residuals once the limits of residual reduction were reached. It is also notable how similarly QMRS and MRS behaved, although MRS ultimately gave the smallest residual norms of all methods.

5. Summary and conclusions. We have focused on two residual smoothing techniques of the general form (1.1), minimum residual smoothing (MRS) and quasi-minimal residual smoothing (QMRS). The former generates from given iterates a sequence of auxiliary iterates with monotone decreasing residual norms that are no greater than those of the original sequence. The latter generates auxiliary iterates with residual norms that typically decrease

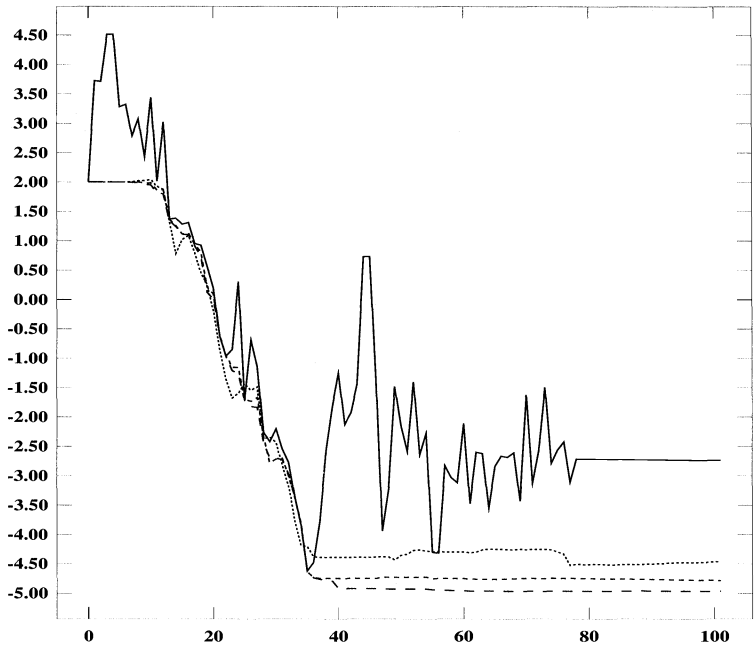

FIG. 8. *Residual norms versus the number of iterations for Experiment* 6. *Solid curve*: $\log_{10} \|r_k^{\mathrm{CGS}}\|_2$; *dotted curve*: $\log_{10}$ *of the* TFQMR *residual norms*; *short-dashed curve*: $\log_{10} \|s_k\|_2$ *for* QMRS *Algorithm* 3.2.1 *applied to the* CGS *iterates*; *long-dashed curve*: $\log_{10} \|s_k\|_2$ *for* MRS *Algorithm* 2.2 *applied to the* CGS *iterates*.

fairly smoothly, if not necessarily monotonically. It also provides insight into the workings of QMR-type methods and, in particular, indicates how they are related to and smooth the residual norms of underlying methods such as BCG and CGS.

These residual smoothing techniques provide important practical tools. Their performance is illustrated in a number of numerical experiments in §4; these indicate that both MRS and QMRS are reliable and very effective in smoothing the residuals of the underlying method when applied as in Algorithms 2.2 and 3.2.2, respectively. The performance of MRS and QMRS was roughly similar in our experiments. However, the MRS residual norms were monotone decreasing while those of QMRS, although typically trending fairly smoothly downward, were not; also, the MRS residual norms were often, although not always, slightly smaller than the QMRS residual norms and, in some cases, tended to remain a little more stable in the final iterations. On the basis of work to date, we have some preference for MRS over QMRS for general use.

Having smoothly decreasing or monotone decreasing residual norms may be of real importance or just a nicety, depending on the application. In fact, this can always be achieved trivially just by saving the best iterate obtained so far; in some of our experiments, MRS and QMRS did not produce significantly smaller residual norms than this simple technique. Thus the good behavior of the MRS and QMRS residual norms alone may not always be enough to justify their use. However, a strongly compelling reason for using MRS or QMRS with methods such as BCG and CGS is their effectiveness in stabilizing the iterates and residuals once the limits of residual reduction have been reached. This is perhaps most clearly seen in Figs. 5 and 7, in which the recursive residuals generated by the underlying method continue to decrease long after they have lost accuracy, while the MRS and QMRS residuals become stable and remain fairly accurate. In addition to helping to avoid misleading results, this stabilizing effect could be useful in obtaining further accuracy from the method. Indeed, one might be

able to detect the onset of stability and restart the method with a fresh, more accurate residual, thereby making further accurate residual reduction possible. We have successfully carried out this strategy in experiments.

We conclude by noting recent related work. In [9] it is shown that iterates produced by certain pairs of "orthogonal error" methods can be related through (1.1), extending Theorem 4.2 of [18, p. 78]. In [1], it is assumed that two sequences $\{x'_k\}$ and $\{x''_k\}$ are given, and an auxiliary sequence is generated by

$$y_k = (1 - \eta_k)x'_k + \eta_k x''_k,$$

where η_k is chosen to minimize the residual at y_k. If a single sequence $\{x_k\}$ is given, then the choice $x'_k = y_{k-1}, x''_k = x_k$ gives MRS as a special case. Many other possibilities are explored in [1], and the possibility is raised of combining given $\{x_k^{(1)}\}, \ldots, \{x_k^{(m)}\}$ to produce $\{y_k\}$ by

$$y_k = \eta_k^{(1)} x_k^{(1)} + \cdots + \eta_k^{(m)} x_k^{(m)}, \qquad \sum_{i=1}^{m} \eta_k^{(i)} = 1. \tag{5.1}$$

In [1], it is suggested that the $\eta_k^{(i)}$'s be chosen to minimize the residual at y_k, but more general choices may be useful. For example, the QMR squared method of [8] can be obtained from the CGS iterates and certain auxiliary quantities through a relation of the form (5.1) in which $x_k^{(1)} = y_{k-1}$; see (4.11) of [8, p. 9].

AN IMPLEMENTATION OF THE QMR METHOD BASED ON COUPLED TWO-TERM RECURRENCES*

ROLAND W. FREUND† AND NOËL M. NACHTIGAL‡

Abstract. Recently, the authors proposed a new Krylov subspace iteration, the quasi-minimal residual (QMR) algorithm, for solving non-Hermitian linear systems. In the original implementation of the QMR method, the Lanczos process with look-ahead is used to generate basis vectors for the underlying Krylov subspaces. In the Lanczos algorithm, these basis vectors are computed by means of three-term recurrences. It has been observed that, in finite-precision arithmetic, vector iterations based on three-term recursions are usually less robust than mathematically equivalent coupled two-term vector recurrences.

This paper presents a look-ahead algorithm that constructs the Lanczos basis vectors by means of coupled two-term recursions. Some implementation details are given, and the look-ahead strategy is described. A new implementation of the QMR method, based on this coupled two-term algorithm, is proposed. A simplified version of the QMR algorithm without look-ahead is also presented, and the special case of QMR for complex symmetric linear systems is considered. Results of numerical experiments comparing the original and the new implementations of the QMR method are reported.

Key words. Krylov subspace iteration, quasi-minimal residual method, non-Hermitian matrices, coupled two-term recurrences, look-ahead techniques, complex symmetric matrices

AMS subject classifications. 65F10, 65N22

1. Introduction.

Recently, we proposed a new Krylov subspace method, the quasi-minimal residual (QMR) algorithm [9], for the iterative solution of general nonsingular non-Hermitian systems of linear equations

$$Ax = b. \tag{1.1}$$

The QMR method is closely related to the classical biconjugate gradient (BCG) algorithm due to Lanczos [17]. The BCG method aims at generating approximate solutions for (1.1) that satisfy a Galerkin condition. Unfortunately, for non-Hermitian matrices A, such iterates need not always exist, and this is the source of one of the two possible breakdowns—triggered by division by 0—that can occur during each iteration step of BCG. The second breakdown is equivalent to the possible breakdown—also triggered by division by 0—of the nonsymmetric Lanczos process [16]. In finite-precision arithmetic, it is unlikely that one encounters exact breakdowns in the BCG algorithm. However, near-breakdowns can occur, which can cause a buildup of round-off in successive iterations. Another problem with BCG is the lack of a residual minimization property for its iterates, which leads to a typically erratic convergence behavior, with wild oscillations in the residual norm.

The QMR method offers remedies for these problems. It generates iterates that are defined by a quasi minimization of the residual norm, rather than a Galerkin condition. This eliminates the oscillations and leads to a smooth and nearly monotone convergence behavior. In contrast to BCG, a QMR iterate always exists at each iteration step, and this excludes breakdowns caused by nonexistent iterates. Moreover, possible breakdowns in the underlying Lanczos

process are prevented by using look-ahead techniques. Therefore, except for the rare event of an incurable breakdown, breakdowns cannot occur in the QMR method.

In the original QMR algorithm [9], an implementation of the Lanczos method with look-ahead is used to generate basis vectors for the underlying Krylov subspaces. In the Lanczos process, these basis vectors are generated by means of three-term recurrences. It turns out that, in finite-precision arithmetic, these three-term vector iterations are usually less robust than mathematically equivalent coupled two-term vector recurrences. In this paper, we present a general look-ahead algorithm based on coupled two-term recursions for constructing basis vectors of Krylov subspaces. Based on this algorithm we then propose a new implementation of the QMR method.

We stress that the better numerical behavior of coupled two-term recurrences is not a characteristic of QMR only, and that this phenomenon was also observed for other Krylov subspace methods. For instance, Joubert [15] remarked that BCG, which is based on coupled two-term recurrences, is more robust than the mathematically equivalent Lanczos/Orthodir and Lanczos/Orthores algorithms, which are both based on three-term vector recursions. Indeed, Lanczos/Orthodir and Lanczos/Orthores often converge considerably slower than BCG, or they even diverge, while BCG converges; we refer the reader to [18] for numerical examples that illustrate this phenomenon. Finally, we remark that the standard implementation of the classical conjugate gradient (CG) method of Hestenes and Stiefel [14] is also based on coupled two-term recurrences. Reid [20] mentions that this version of CG is "preferable on computational grounds" to an equivalent three-term implementation of CG. Woźniakowski [24] presents numerical examples for which an implementation of CG based on two-term recurrences generates approximate solutions to a higher accuracy than does a three-term version of CG.

The remainder of the paper is organized as follows. In §2, we briefly review the Lanczos process and the original QMR algorithm. In §3, we present a sketch of the proposed look-ahead procedure for constructing Lanczos vectors by means of coupled two-term recurrences. In §4, we discuss the look-ahead strategy for this algorithm, and in §5, we give some implementation details. Next we combine the coupled two-term procedure with the QMR approach. In §6, we outline the resulting implementation for the general case of QMR with look-ahead. In §7, we present a simplified version of the QMR algorithm without look-ahead. In §8, we consider a variant of QMR for the special case of complex symmetric linear systems. In §9, we report results of numerical experiments comparing the original and the new implementations of the QMR method. Finally, in §10, we make some concluding remarks.

Throughout the paper, all vectors and matrices are allowed to have real or complex entries. As usual, $M^T = [m_{kj}]$ and $M^H = [\overline{m}_{kj}]$ denote the transpose and the conjugate transpose, respectively, of the matrix $M = [m_{jk}]$. We use $\sigma_{\max}(M)$ and $\sigma_{\min}(M)$ for the largest and smallest singular value of M, respectively. The vector norm $\|x\| := \sqrt{x^H x}$ is always the Euclidean norm and $\|M\| := \sigma_{\max}(M)$ is the corresponding matrix norm. We denote by

$$\mathcal{P}_n := \{\varphi(\lambda) \equiv \gamma_0 + \gamma_1\lambda + \cdots + \gamma_n\lambda^n \mid \gamma_0, \gamma_1, \ldots, \gamma_n \in \mathbb{C}\}$$

the set of all complex polynomials of degree at most n. The nth Krylov subspace of $\mathbb{C}^N$ generated by $c \in \mathbb{C}^N$ and the $N \times N$ matrix B is defined by

$$K_n(c, B) := \operatorname{span}\{c, Bc, \ldots, B^{n-1}c\},$$

and we will make use of the fact that

$$K_n(c, B) = \{\varphi(B)c \mid \varphi \in \mathcal{P}_{n-1}\}.$$

Furthermore, it is always assumed that A is an $N \times N$ matrix, singular or nonsingular.

Finally, we remark that, for complex matrices, there are two equivalent formulations of the Lanczos process, using either A^T or A^H. In this paper, we have chosen the formulation with A^T, for two reasons. First, it avoids complex conjugation of the scalars in some of the recurrence relations, and, second, the recursions reduce immediately for the special case of complex symmetric matrices.

2. The QMR algorithm. In this section, we briefly describe the QMR method and its original implementation [9]. We remark that, in [9], QMR was proposed for nonsingular linear systems (1.1). Freund and Hochbruck [8] showed that the QMR method can also be applied to singular square systems, and that it always generates well-defined iterates. However, as discussed in [8], these iterates converge to a meaningful solution of (1.1) only for consistent systems with coefficient matrices of index 1. An important special case for which these conditions are satisfied is consistent singular systems with a one-dimensional null space, i.e.,

$$b \in \{Ax \mid x \in \mathbb{C}^N\} \quad \text{and} \quad \dim\{x \in \mathbb{C}^N \mid Ax = 0\} = 1. \tag{2.1}$$

In this paper, we always consider the QMR method for the general case of $N \times N$ linear systems, with singular or nonsingular coefficient matrices A.

2.1. Krylov subspace methods. Let $x_0 \in \mathbb{C}^N$ be an arbitrary initial guess for the linear system (1.1), and denote by $r_0 := b - Ax_0$ the corresponding residual vector. An iterative scheme for solving (1.1) is called a *Krylov subspace method* if, for any choice of x_0, it produces approximate solutions of the form

$$x_n \in x_0 + K_n(r_0, A), \qquad n = 1, 2, \ldots . \tag{2.2}$$

Clearly, the design of a Krylov subspace algorithm consists of two main parts: the construction of suitable basis vectors for the Krylov subspaces $K_n(r_0, A)$ in (2.2) and the choice of the actual iterates x_n. The QMR method is an example of a Krylov subspace iteration, where the basis vectors are generated by means of the nonsymmetric Lanczos process, and the iterates are characterized by a QMR property. Next, we describe these two main ingredients of QMR.

2.2. The Lanczos process. The Lanczos method is started with two vectors

$$v_1 = r_0/\rho_1, \quad \text{where } \rho_1 = \|r_0\|, \tag{2.3}$$

and an arbitrary second starting vector

$$w_1 \in \mathbb{C}^N \quad \text{with } \|w_1\| = 1. \tag{2.4}$$

It then produces two sequences of vectors

$$\{v_j\}_{j=1}^n \quad \text{and} \quad \{w_j\}_{j=1}^n, \tag{2.5}$$

such that, for $n = 1, 2, \ldots,$

$$\begin{aligned} \operatorname{span}\{v_1, v_2, \ldots, v_n\} &= K_n(v_1, A), \\ \operatorname{span}\{w_1, w_2, \ldots, w_n\} &= K_n(w_1, A^T), \end{aligned} \tag{2.6}$$

and the two sets are biorthogonal or block biorthogonal, i.e.,

$$W_n^T V_n = D_n, \tag{2.7}$$

where D_n is a diagonal or block-diagonal matrix. Here, and in the sequel, we denote by

$$V_n := [\, v_1 \quad v_2 \quad \cdots \quad v_n \,] \quad \text{and} \quad W_n := [\, w_1 \quad w_2 \quad \cdots \quad w_n \,] \tag{2.8}$$

the matrices containing the Lanczos vectors $\{v_j\}_{j=1}^n$ and $\{w_j\}_{j=1}^n$ as columns. We remark that the conditions (2.6)–(2.7) determine the vectors (2.5) only up to scaling. Throughout this paper, we always scale the Lanczos vectors to have unit length

$$\|v_n\| = \|w_n\| = 1, \qquad n = 1, 2, \ldots . \tag{2.9}$$

The crucial point of the Lanczos process is that vectors satisfying (2.6)–(2.7) can be constructed by means of short vector recursions. In the classical Lanczos algorithm [16], the vectors are generated using simple three-term recurrences:

$$\begin{aligned} \tilde{v}_{n+1} &= Av_n - v_n\mu_n - v_{n-1}\nu_n, \\ \rho_{n+1} &= \|\tilde{v}_{n+1}\|, \qquad v_{n+1} = \tilde{v}_{n+1}/\rho_{n+1}, \end{aligned} \tag{2.10}$$

$$\begin{aligned} \tilde{w}_{n+1} &= A^T w_n - w_n\mu_n - w_{n-1}(\nu_n\rho_n/\xi_n), \\ \xi_{n+1} &= \|\tilde{w}_{n+1}\|, \qquad w_{n+1} = \tilde{w}_{n+1}/\xi_{n+1}, \end{aligned} \tag{2.11}$$

where

$$\mu_n = w_n^T A v_n / w_n^T v_n, \qquad \nu_n = \xi_n w_n^T v_n / w_{n-1}^T v_{n-1}. \tag{2.12}$$

In this case, the matrix D_n in (2.7) is diagonal and nonsingular:

$$D_n = \operatorname{diag}(\delta_1, \delta_2, \ldots, \delta_n), \quad \text{where } \delta_j := w_j^T v_j \neq 0. \tag{2.13}$$

Furthermore, we note that, by using the notation introduced in (2.8), the recurrence relations (2.10)–(2.11) for the first $n+1$ Lanczos vectors $\{v_j\}_{j=1}^{n+1}$ and $\{w_j\}_{j=1}^{n+1}$ can be written compactly in matrix form:

$$AV_n = V_{n+1}H_n, \tag{2.14}$$

$$A^T W_n = W_{n+1}\Gamma_{n+1}^{-1} H_n \Gamma_n. \tag{2.15}$$

Here, H_n is an $(n+1) \times n$ tridiagonal matrix, and

$$\Gamma_n := \operatorname{diag}(\gamma_1, \gamma_2, \ldots, \gamma_n), \quad \text{where } \gamma_j := \begin{cases} 1 & \text{if} \quad j = 1, \\ \gamma_{j-1}\rho_j/\xi_j & \text{if} \quad j > 1, \end{cases} \tag{2.16}$$

is a diagonal scaling matrix with positive diagonal entries. Finally, for later use, we note that all subdiagonal elements of H_n are nonzero, and therefore

$$\operatorname{rank} H_n = n. \tag{2.17}$$

Unfortunately, in the classical Lanczos algorithm, breakdowns cannot be excluded. Indeed, by (2.12), division by 0 will occur during the construction of v_{n+1} and w_{n+1} if $w_n^T v_n = 0$, but $w_n \neq 0$ and $v_n \neq 0$. Parlett, Taylor, and Liu [19] were the first to devise a practical modification of the Lanczos procedure that uses look-ahead to skip over possible *exact breakdowns* ($w_n^T v_n = 0$) or *near-breakdowns* ($w_n^T v_n$ is nonzero, but small in some sense). The QMR algorithm is based on a different implementation of the look-ahead Lanczos method, recently

developed by Freund, Gutknecht, and Nachtigal [7]. Next, we briefly sketch this look-ahead Lanczos procedure.

As in the classical Lanczos algorithm, two sequences of Lanczos vectors $\{v_j\}_{j=1}^n$ and $\{w_j\}_{j=1}^n$ are generated, starting with (2.3) and (2.4). Again, we will use the matrix notation V_n and W_n defined in (2.8). As before, these vectors satisfy (2.6)–(2.7), but now D_n is generally only a block-diagonal matrix, with $l := l(n)$ square blocks of dimension h_j, $j = 1, 2, \ldots, l$, on the diagonal. More precisely, we have

$$D_n = \operatorname{diag}(D^{(1)}, D^{(2)}, \ldots, D^{(l)}), \quad \text{where } D^{(j)} := (W^{(j)})^T V^{(j)}. \tag{2.18}$$

Here, the matrices $V^{(j)}$ and $W^{(j)}$, $j = 1, 2, \ldots, l$, are defined by partitioning V_n and W_n into blocks, according to the look-ahead steps taken:

$$V_n = \begin{bmatrix} V^{(1)} & V^{(2)} & \cdots & V^{(l)} \end{bmatrix} \quad \text{and} \quad W_n = \begin{bmatrix} W^{(1)} & W^{(2)} & \cdots & W^{(l)} \end{bmatrix}. \tag{2.19}$$

We remark that the matrices $V^{(j)}$ and $W^{(j)}$ are of size $N \times h_j$, and they contain as their columns the Lanczos vectors constructed in the jth look-ahead step. The integer h_j is called the length of the jth look-ahead step, and l in (2.18)–(2.19) is the number of look-ahead steps that were performed during the first n steps of the Lanczos process. For later use, we introduce some further notation. For $j = 1, 2, \ldots$, we denote by n_j the index of the first vectors of the blocks $V^{(j)}$ and $W^{(j)}$ in (2.19); hence, we have

$$V^{(j)} = \begin{bmatrix} v_{n_j} & v_{n_j+1} & \cdots \end{bmatrix} \quad \text{and} \quad W^{(j)} = \begin{bmatrix} w_{n_j} & w_{n_j+1} & \cdots \end{bmatrix}. \tag{2.20}$$

Note that the indices n_j satisfy

$$1 =: n_1 < n_2 < \cdots < n_l \leq n < n_{l+1}. \tag{2.21}$$

The vectors v_{n_j} and w_{n_j} are called *regular*, while the remaining vectors in the blocks $V^{(j)}$ and $W^{(j)}$ are called *inner*. We remark that, in view of (2.7) and (2.18), the regular vectors are biorthogonal to all previous Lanczos vectors, i.e.,

$$w_i^T v_{n_j} = w_{n_j}^T v_i = 0 \quad \text{for all } i = 1, 2, \ldots, n_j - 1, \tag{2.22}$$

while the inner vectors in the jth blocks $V^{(j)}$ and $W^{(j)}$ are biorthogonal to all Lanczos vectors from the previous blocks, but not necessarily to the Lanczos vectors in the jth blocks. Finally, we note that, in (2.18), the blocks $D^{(j)}$, $j = 1, 2, \ldots, l-1$, are all nonsingular, while the last block $D^{(l)}$ is nonsingular if $n_{l+1} = n + 1$, i.e., if v_{n+1} and w_{n+1} are constructed as regular vectors.

In the look-ahead algorithm, the Lanczos vectors (2.5) are again generated using only short vector recurrences, which now involve vectors from the last two blocks $V^{(l)}$, $V^{(l-1)}$ and $W^{(l)}$, $W^{(l-1)}$, instead of just v_n, v_{n-1} and w_n, w_{n-1}, as in the classical algorithm. For example, v_{n+1} is computed by means of the relations

$$\begin{aligned} \tilde{v}_{n+1} &= A v_n - V^{(l)} \mu_n - V^{(l-1)} \nu_n, \\ \rho_{n+1} &= \|\tilde{v}_{n+1}\|, \qquad v_{n+1} = \tilde{v}_{n+1}/\rho_{n+1}, \end{aligned} \tag{2.23}$$

where $\mu_n \in \mathbb{C}^{h_l}$ and $\nu_n \in \mathbb{C}^{h_{l-1}}$ are suitably chosen coefficient vectors. The second Lanczos vector w_{n+1} is obtained similarly. As before, the recurrence relations for the Lanczos vectors can be summarized in the form (2.14)–(2.15). Here, H_n is now a block-tridiagonal matrix with l square blocks on the diagonal, where the jth block has dimension $h_j \times h_j$, $j = 1, 2, \ldots, l$.

In addition, H_n is also an upper Hessenberg matrix. Furthermore, (2.16) and (2.17) remain valid, and ρ_j and ξ_j in (2.16) are scaling factors used to ensure the normalization (2.9) of the Lanczos vectors; see (2.23).

We would like to stress that the look-ahead strategy (see [7] and also §4 below) is such that the algorithm performs mostly standard Lanczos steps, i.e., look-ahead steps of length $h_j = 1$ with blocks $V^{(j)}$ and $W^{(j)}$ that consist of only single Lanczos vectors. True look-ahead steps, i.e., steps of size $h_j > 1$, are only used to avoid exact and near-breakdowns. Typically, except for contrived examples, only few true look-ahead steps occur, and their size is usually small, mostly $h_j = 2$. We note that, if only steps of length $h_j = 1$ are performed, then the look-ahead Lanczos algorithm reduces to the classical algorithm. Finally, we remark that so-called incurable breakdowns [23], [13] can occur in the Lanczos process. Such breakdowns cannot be remedied by look-ahead, and indeed, in such a case, the look-ahead Lanczos algorithm would build a block of size $h_l = \infty$. Fortunately, incurable breakdowns are extremely rare, and they do not present a problem in practice.

The look-ahead Lanczos algorithm is intimately connected with formally orthogonal polynomials; see, e.g., [13], [7]. In particular, we will use the fact that each pair of Lanczos vectors v_j and w_j can be expressed in the form

$$v_j = \phi_{j-1}(A)v_1 \quad \text{and} \quad w_j = \gamma_j \phi_{j-1}(A^T)w_1, \tag{2.24}$$

where $\phi_{j-1} \in \mathcal{P}_{j-1}$ is of exact degree $j-1$ and $\gamma_j > 0$ is defined in (2.16).

For further details and properties of the look-ahead Lanczos algorithm, we refer the reader to [7].

2.3. The QMR property. In the QMR method, the vectors $\{v_j\}_{j=1}^n$ generated by the look-ahead Lanczos algorithm are used as a basis for the Krylov subspace $K_n(r_0, A)$ in (2.2). The nth QMR iterate x_n is then defined by

$$x_n = x_0 + V_n z_n, \tag{2.25}$$

where $z_n \in \mathbb{C}^n$ is the unique solution of the least-squares problem

$$\| f_{n+1} - \Omega_{n+1} H_n z_n \| = \min_{z \in \mathbb{C}^n} \| f_{n+1} - \Omega_{n+1} H_n z \|. \tag{2.26}$$

Here

$$f_{n+1} := \omega_1 \rho_1 \cdot [1 \quad 0 \quad \cdots \quad 0]^T \in \mathbb{R}^{n+1}, \tag{2.27}$$

with ρ_1 given in (2.3), and

$$\Omega_{n+1} := \operatorname{diag}(\omega_1, \omega_2, \ldots, \omega_{n+1}), \quad \omega_j > 0, \quad j = 1, 2, \ldots, n+1, \tag{2.28}$$

is an arbitrary diagonal weighting matrix. Note that, in view of (2.17) and (2.28), the $(n+1) \times n$ matrix $\Omega_{n+1} H_n$ has full rank n. This guarantees that there always exists a unique solution of (2.26). Furthermore, we remark that the standard choice for the weights in (2.28) is

$$\omega_j = 1 \quad \text{for all } j. \tag{2.29}$$

However, there are instances (see [11]) where the use of different weights is crucial, and therefore we formulate the QMR method in the general setting (2.28).

From (2.25), (2.14), (2.27), and (2.3), it follows that the residual vector $r_n := b - Ax_n$ corresponding to x_n satisfies

$$r_n = V_{n+1} \Omega_{n+1}^{-1} \left(f_{n+1} - \Omega_{n+1} H_n z_n \right). \tag{2.30}$$

Hence, in view of (2.26), the nth QMR iterate x_n is characterized by a minimization of the second factor in (2.30); this is just the *quasi-minimal residual* property. The relation (2.30) shows that the scaling (2.29) is very natural, in the sense that all columns of $V_{n+1}\Omega_{n+1}^{-1}$ in the representation (2.30) of r_n are treated equally. We remark that the QMR iterates x_n can be easily updated from step to step. Due to the block-tridiagonal structure of H_n, this update can be implemented with only short recurrences; see [9] for details. Finally, we note that the QMR property can be used to derive convergence results for the QMR method; we refer the reader to [9] and [6].

3. A coupled two-term procedure with look-ahead. In this section, we consider a different approach to constructing the Lanczos vectors. The basic idea is to break up the three-term recurrences in the Lanczos process into coupled two-term recurrences, by using (in addition to the Lanczos vectors) a suitable second set of basis vectors for the underlying Krylov subspaces. In §9, we will illustrate that QMR based on this coupled two-term procedure has better numerical properties than the original implementation of QMR based on three-term recurrences.

3.1. The general setting. In the following, let $\{v_j\}_{j=1}^n$ and $\{w_j\}_{j=1}^n$ always denote the sequence of vectors generated by the look-ahead Lanczos algorithm as described in §2.2. We assume that we are also given a second set of basis vectors

$$\{p_j\}_{j=1}^n \quad \text{and} \quad \{q_j\}_{j=1}^n \tag{3.1}$$

for the Krylov subspaces $K_n(v_1, A)$ and $K_n(w_1, A^T)$. More precisely, we consider vectors (3.1) that, in analogy to (2.24), are of the form

$$p_j = \psi_{j-1}(A)v_1 \quad \text{and} \quad q_j = \gamma_j\psi_{j-1}(A^T)w_1, \tag{3.2}$$

where $\gamma_j > 0$ is given by (2.16), and $\psi_{j-1} \in \mathcal{P}_{j-1}$ is of exact degree $j-1$ with the same leading coefficient as the polynomial ϕ_{j-1} in (2.24). To distinguish between the two bases, we will often refer to the Lanczos vectors $\{v_j\}_{j=1}^n$ and $\{w_j\}_{j=1}^n$ as the *V–W sequence* and to the vectors (3.1) as the *P–Q sequence*.

From (2.24) and (3.2), we conclude that, for each $n = 1, 2, \ldots,$

$$p_n = v_n - \sum_{i=1}^{n-1} p_i u_{in}, \tag{3.3}$$

$$q_n = w_n - \sum_{i=1}^{n-1} q_i u_{in}(\gamma_n/\gamma_i), \tag{3.4}$$

with suitable coefficients $u_{in} \in \mathbb{C}$, $i = 1, 2, \ldots, n-1$. Similarly, in view of (2.23), (2.24), (3.2), and (2.16), we have

$$\tilde{v}_{n+1} = Ap_n - \sum_{i=1}^{n} v_i l_{in}, \quad \rho_{n+1} = \|\tilde{v}_{n+1}\|, \quad v_{n+1} = \tilde{v}_{n+1}/\rho_{n+1}, \tag{3.5}$$

$$\tilde{w}_{n+1} = A^T q_n - \sum_{i=1}^{n} w_i l_{in}(\gamma_n/\gamma_i), \quad \xi_{n+1} = \|\tilde{w}_{n+1}\|, \quad w_{n+1} = \tilde{w}_{n+1}/\xi_{n+1}, \tag{3.6}$$

with suitable coefficients $l_{in} \in \mathbb{C}$, $i = 1, 2, \ldots, n$. Note that (3.3)–(3.6) are coupled recurrences for generating the P–Q and V–W sequences: first, p_n and q_n are computed by means

of (3.3)–(3.4), and then, the next Lanczos pair v_{n+1} and w_{n+1} is obtained from (3.5)–(3.6). Of course, it remains to specify the actual choice of the P–Q sequence. In order to minimize work and storage of previous vectors, the goal here is to select these vectors such that the recurrences (3.3)–(3.6) are as short as possible.

In addition to (2.8), it will be convenient to use the notation

$$P_n := [\, p_1 \quad p_2 \quad \cdots \quad p_n \,] \quad \text{and} \quad Q_n := [\, q_1 \quad q_2 \quad \cdots \quad q_n \,].$$

The recurrences (3.3)–(3.6) for the vectors $\{p_j\}_{j=1}^{n}$, $\{q_j\}_{j=1}^{n}$, $\{v_j\}_{j=1}^{n+1}$, and $\{w_j\}_{j=1}^{n+1}$ can then be written compactly in matrix form:

$$V_n = P_n U_n, \qquad A P_n = V_{n+1} L_n, \tag{3.7}$$

$$W_n = Q_n \Gamma_n^{-1} U_n \Gamma_n, \quad A^T Q_n = W_{n+1} \Gamma_{n+1}^{-1} L_n \Gamma_n. \tag{3.8}$$

Here, U_n is an upper triangular matrix and L_n is an upper Hessenberg matrix given by

$$U_n := \begin{bmatrix} 1 & u_{12} & \cdots & u_{1n} \\ 0 & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & u_{n-1,n} \\ 0 & \cdots & 0 & 1 \end{bmatrix} \quad \text{and} \quad L_n := \begin{bmatrix} l_{11} & l_{12} & \cdots & l_{1n} \\ \rho_2 & l_{22} & & \vdots \\ 0 & \rho_3 & \ddots & \vdots \\ \vdots & \ddots & \ddots & l_{nn} \\ 0 & \cdots & 0 & \rho_{n+1} \end{bmatrix}, \tag{3.9}$$

respectively, and Γ_n is the diagonal matrix defined in (2.16). Note that, by eliminating P_n in (3.7), we obtain

$$A V_n = V_{n+1} L_n U_n. \tag{3.10}$$

By comparing (3.10) with (2.14), it follows that

$$H_n = L_n U_n, \tag{3.11}$$

i.e., the matrices (3.9) define a factorization of the block-tridiagonal Hessenberg matrix H_n generated by the look-ahead Lanczos algorithm.

Recall from (2.7) and (2.18) that the Lanczos vectors are block biorthogonal. These biorthogonality relations determine the coefficients l_{in} in (3.5)–(3.6). For example, consider the case that v_{n+1} and w_{n+1} are constructed as regular vectors. Then, in view of (2.22), we have the condition $W_n^T v_{n+1} = 0$, which, by (3.5), is equivalent to

$$0 = W_n^T A p_n - \sum_{i=1}^{n} W_n^T v_i l_{in}. \tag{3.12}$$

Using (2.7), (2.8), and the first equation in (3.8), we deduce from (3.12) that

$$\begin{bmatrix} l_{1n} \\ \vdots \\ l_{nn} \end{bmatrix} = D_n^{-1} \Gamma_n U_n^T \Gamma_n^{-1} Q_n^T A p_n. \tag{3.13}$$

Recall from (2.18), (2.16), and (3.9) that the matrices D_n^{-1}, Γ_n, and U_n^T are block diagonal, diagonal, and lower triangular, respectively. Hence the relation (3.13) implies that the vector $Q_n^T A p_n$ determines the length of the recurrences (3.5)–(3.6). In particular, in order to obtain recursions that are as short as possible, the P–Q sequence should be chosen such that the vector

$Q_n^T A p_n$ has as many leading zeros as possible. The same conclusion also holds for the case that v_{n+1} and w_{n+1} are constructed as inner vectors.

Motivated by this discussion, we require that the vectors in the P–Q sequence be A-biorthogonal or block A-biorthogonal, in the sense that the matrix

$$E_n := Q_n^T A P_n \tag{3.14}$$

should be diagonal or block diagonal. Note that the vector $Q_n^T A p_n$ is just the nth column of E_n. Furthermore, we remark that $q_n^T A P_n$, the nth row of E_n, has the same zero structure as $Q_n^T A p_n$. This is a consequence of relation (3.16) in the following lemma, which we will also need later on.

LEMMA 3.1. *Let* $\{v_i\}_{i=1}^n$, $\{w_i\}_{i=1}^n$ *and* $\{p_i\}_{i=1}^n$, $\{q_i\}_{i=1}^n$ *be vectors satisfying* (2.24) *and* (3.2), *respectively, and let* $\Gamma_n = \operatorname{diag}(\gamma_1, \gamma_2, \ldots, \gamma_n)$. *Let* D_n *and* E_n *be the matrices given by* (2.7) *and* (3.14), *respectively. Then*

$$D_n \Gamma_n = (D_n \Gamma_n)^T, \tag{3.15}$$

$$E_n \Gamma_n = (E_n \Gamma_n)^T. \tag{3.16}$$

Proof. Using the polynomial representation (2.24) for the V–W vectors and the fact that polynomials in a matrix commute, we obtain

$$w_i^T v_j \gamma_j = \gamma_i w_1^T \phi_{i-1}(A) \phi_{j-1}(A) v_1 \gamma_j = \gamma_j w_1^T \phi_{j-1}(A) \phi_{i-1}(A) v_1 \gamma_i = w_j^T v_i \gamma_i$$

and thus (3.15). The relation (3.16) follows similarly. □

3.2. The coupled algorithm without look-ahead. Next, we briefly consider the case that the V–W sequence consists of the vectors generated by the classical Lanczos algorithm without look-ahead. Recall from (2.13) that here the matrix D_n in (2.7) is diagonal, and that the Lanczos vectors are biorthogonal:

$$w_j^T v_n = \begin{cases} 0 & \text{if } j \neq n, \\ \delta_n \neq 0 & \text{if } j = n. \end{cases} \tag{3.17}$$

Suppose that it is possible to construct the vectors in the P–Q sequence such that the matrix E_n in (3.14) is also diagonal:

$$E_n = \operatorname{diag}(\epsilon_1, \epsilon_2, \ldots, \epsilon_n), \quad \text{where } \epsilon_j := q_j^T A p_j \neq 0. \tag{3.18}$$

By (3.14) and (3.18), the P–Q vectors are then A-biorthogonal:

$$q_j^T A p_n = \begin{cases} 0 & \text{if } j \neq n, \\ \epsilon_n \neq 0 & \text{if } j = n. \end{cases} \tag{3.19}$$

With (2.13), (3.9), and (3.19), we deduce from (3.13) that

$$l_{in} = 0, \quad i = 1, 2, \ldots, n-1, \quad \text{and} \quad l_{nn} = \beta_n := \epsilon_n / \delta_n. \tag{3.20}$$

Furthermore, by multiplying (3.3) from the left by $q_j^T A$ and by using (3.19), (3.6), and (3.17), we obtain that, for $j = 1, 2, \ldots, n-1$,

$$\begin{aligned} 0 = q_j^T A p_n &= q_j^T A v_n - \epsilon_j u_{jn} \\ &= (A^T q_j)^T v_n - \epsilon_j u_{jn} \\ &= \xi_{j+1} w_{j+1}^T v_n - \epsilon_j u_{jn}. \end{aligned} \tag{3.21}$$

With (3.17), it follows from (3.21) that

$$u_{in} = 0, \quad i = 1, 2, \ldots, n-2, \quad \text{and} \quad u_{n-1,n} = \xi_n \delta_n / \epsilon_{n-1}. \tag{3.22}$$

In view of (3.20) and (3.22), all but the last terms vanish in each of the sums in (3.3)–(3.6), and hence (3.3)–(3.6) reduces to a coupled two-term procedure for generating the P–Q and V–W sequences.

The nth iteration of the resulting algorithm can be summarized as follows.

ALGORITHM 3.2 (nth iteration of the coupled algorithm without look-ahead).

1. If $\epsilon_{n-1} = 0$, then stop.
   Otherwise, compute $\delta_n = w_n^T v_n$.
   If $\delta_n = 0$, then stop.
2. Compute

$$\begin{aligned} p_n &= v_n - p_{n-1}(\xi_n \delta_n / \epsilon_{n-1}), \\ q_n &= w_n - q_{n-1}(\rho_n \delta_n / \epsilon_{n-1}). \end{aligned}$$

3. Compute $\epsilon_n = q_n^T A p_n$, $\beta_n = \epsilon_n / \delta_n$, and set

$$\begin{aligned} \tilde{v}_{n+1} &= A p_n - v_n \beta_n, \quad \rho_{n+1} = \|\tilde{v}_{n+1}\|, \\ \tilde{w}_{n+1} &= A^T q_n - w_n \beta_n, \quad \xi_{n+1} = \|\tilde{w}_{n+1}\|. \end{aligned}$$

4. If $\rho_{n+1} = 0$ or $\xi_{n+1} = 0$, then stop.
   Otherwise, set

$$v_{n+1} = \tilde{v}_{n+1} / \rho_{n+1}, \quad w_{n+1} = \tilde{w}_{n+1} / \xi_{n+1}.$$

We remark that the vectors in the P–Q and V–W sequences are, up to scaling, just the search directions and the residual vectors generated by the BCG method [17], [4]. In particular, Algorithm 3.2 can be viewed as the nth iteration of a rescaled version of BCG, where the computation of the BCG iterates is omitted.

In exact arithmetic, one of the termination checks in steps 1 or 4 of the coupled two-term procedure will be satisfied after at most N iterations. Normally, the algorithm stops due to $\rho_{n+1} = 0$ or $\xi_{n+1} = 0$, and then the procedure has constructed a basis for the invariant subspaces $K_n(v_1, A)$ or $K_n(w_1, A^T)$, respectively. This is called regular termination. If $\epsilon_{n-1} = 0$ or $\delta_n = 0$ occurs, then the algorithm has to be stopped to avoid division by 0. This is referred to as an exact breakdown. Recall from §2.2 that $\delta_n = 0$ signals a breakdown in the classical Lanczos algorithm. Note that, like BCG, the coupled two-term procedure now has a second source of breakdown, namely, the case $\epsilon_{n-1} = 0$. It can be shown that the condition $\epsilon_{n-1} = 0$ corresponds to a breakdown in the BCG algorithm due to an nth iterate not being defined by the Galerkin condition.

In finite-precision arithmetic, exact breakdowns are rather unlikely. However, near-breakdowns, where δ_n or ϵ_{n-1} is nonzero, but small in some sense, may occur, leading to numerical instabilities in subsequent iterations. Next, we sketch a coupled two-term procedure that uses look-ahead in the construction of both the V–W and P–Q sequences to avoid exact and near-breakdowns.

3.3. The general algorithm with look-ahead. For describing the look-ahead in the V–W sequence, we will use the notations (2.18)–(2.21) introduced in §2.2. In particular, the integer $l := l(n)$ denotes the number of look-ahead steps that were performed during the construction of the first n vectors $\{v_i\}_{i=1}^n$ and $\{w_i\}_{i=1}^n$ in the V–W sequence, and the n_j's in (2.21) are the indices of the regular vectors. Recall that, by (2.7) and (2.18), the V–W vectors satisfy the block-biorthogonality conditions

$$(W^{(i)})^T V^{(j)} = \begin{cases} 0 & \text{if } i \neq j, \\ D^{(j)} & \text{if } i = j, \end{cases} \qquad i, j = 1, 2, \ldots, l. \tag{3.23}$$

Here, the blocks $D^{(j)}$ are all nonsingular, except for possibly $D^{(l)}$. However, we have that necessarily

$$D^{(l)} \text{ is nonsingular, if } n_{l+1} = n + 1. \tag{3.24}$$

Next, we introduce similar notations for describing the look-ahead in the P–Q sequence. We denote by $k := k(n)$ the number of look-ahead steps that were performed during the construction of the first $n-1$ vectors $\{p_i\}_{i=1}^{n-1}$ and $\{q_i\}_{i=1}^{n-1}$ in the P–Q sequence. In analogy to (2.19), we partition these vectors into blocks, according to the look-ahead steps taken:

$$P_{n-1} = \left[P^{(1)} \quad P^{(2)} \quad \cdots \quad P^{(k)} \right] \quad \text{and} \quad Q_{n-1} = \left[Q^{(1)} \quad Q^{(2)} \quad \cdots \quad Q^{(k)} \right]. \tag{3.25}$$

Recall from (3.14) that the P–Q vectors are constructed to be block A-biorthogonal. More precisely, we have

$$E_{n-1} = \operatorname{diag}(E^{(1)}, E^{(2)}, \ldots, E^{(k)}),$$

or, equivalently,

$$(Q^{(i)})^T A P^{(j)} = \begin{cases} 0 & \text{if } i \neq j, \\ E^{(j)} & \text{if } i = j, \end{cases} \qquad i, j = 1, 2, \ldots, k. \tag{3.26}$$

Here, the blocks $E^{(j)}$ are nonsingular, except for possibly the last block $E^{(k)}$. In analogy to (2.21), we denote by m_j the indices of the first vectors of the blocks $P^{(j)}$ and $Q^{(j)}$ in (3.25). Hence, for $j = 1, 2, \ldots, k$, we have

$$P^{(j)} = \left[p_{m_j} \quad p_{m_j+1} \quad \cdots \quad \right] \quad \text{and} \quad Q^{(j)} = \left[q_{m_j} \quad q_{m_j+1} \quad \cdots \quad \right]. \tag{3.27}$$

Furthermore, the indices m_j satisfy

$$1 =: m_1 < m_2 < \cdots < m_k < n \leq m_{k+1}. \tag{3.28}$$

We remark that, by (3.26) and (3.27), the vectors p_{m_j} and q_{m_j} are A-biorthogonal to all previous P–Q vectors, i.e.,

$$q_i^T A p_{m_j} = q_{m_j}^T A p_i = 0 \quad \text{for all } i = 1, 2, \ldots, m_j - 1.$$

Therefore, using the same notation as for the V–W sequence, we refer to the vectors p_{m_j} and q_{m_j} as *regular* vectors, while the remaining vectors in (3.27) are called *inner*. Finally, it turns out that, in (3.26), the last block $E^{(k)}$ has to be nonsingular, if p_n and q_n are constructed as regular vectors. This means that, in analogy to (3.24),

$$E^{(k)} \text{ is nonsingular, if } m_{k+1} = n. \tag{3.29}$$

After these preliminaries, we can now sketch the actual algorithm. Let $n \geq 1$, and assume that we have already generated the first $n-1$ vectors $\{p_i\}_{i=1}^{n-1}$ and $\{q_i\}_{i=1}^{n-1}$ of the P–Q sequence, and the first n vectors $\{v_i\}_{i=1}^{n}$ and $\{w_i\}_{i=1}^{n}$ of the V–W sequence.

First, the next pair of P–Q vectors, p_n and q_n, is constructed, using the recurrences (3.3)–(3.4). Here, the coefficients u_{in} need to be chosen such that p_n satisfies the corresponding A-biorthogonality conditions (3.26). We note that, in view of (3.16), the A-biorthogonality relations for the vector q_n are then also fulfilled. With (3.6) and (3.23), one readily verifies that

$$q_i^T A v_n = (A^T q_i)^T v_n = 0 \quad \text{for all } i = 1, 2, \ldots, n_l - 2.$$

By rewriting this in terms of the blocks $Q^{(j)}$, we obtain that

$$(Q^{(j)})^T A v_n = 0 \quad \text{for all } j = 1, 2, \ldots, k^\star - 1, \tag{3.30}$$

where $k^\star := k^\star(n)$ is given by

$$k^\star = \max\left\{ j \;\middle|\; 1 \leq j \leq k \text{ and } m_j \leq \max\{1, n_l - 1\} \right\}. \tag{3.31}$$

The orthogonality conditions (3.30), together with (3.26), imply that, in (3.3), we have $u_{in} = 0$ for all $i < m_{k^\star}$. Thus the recurrences (3.3)–(3.4) reduce to

$$p_n = v_n - \sum_{i=m_{k^\star}}^{n-1} p_i u_{in}, \tag{3.32}$$

$$q_n = w_n - \sum_{i=m_{k^\star}}^{n-1} q_i u_{in} (\gamma_n / \gamma_i). \tag{3.33}$$

Now we need to determine the coefficients u_{in} for $m_{k^\star} \leq i \leq n-1$. This is done by enforcing the remaining A-biorthogonality conditions (3.26) for p_n and the vectors q_i, namely,

$$q_i^T A p_n = 0 \quad \text{for all } i = m_{k^\star}, m_{k^\star} + 1, \ldots, m^\star. \tag{3.34}$$

Here, $m^\star := n-1$ if p_n and q_n are constructed as regular vectors, and $m^\star := m_k - 1$ otherwise. Note that, in view of (3.28), we always have $m_k - 1 \leq m^\star$. First, we consider (3.34) for the indices i in the range $m_{k^\star} \leq i \leq m_k - 1$. Using (3.32) and (3.26), we deduce from (3.34) that

$$U_{m_{k^\star}:m_k-1,n} = (\operatorname{diag}(E^{(k^\star)}, \ldots, E^{(k-1)}))^{-1} \left[Q^{(k^\star)} \quad \cdots \quad Q^{(k-1)} \right]^T A v_n. \tag{3.35}$$

Here, and in the sequel, we use the notation

$$M_{i:j,n} := [\, m_{in} \quad m_{i+1,n} \quad \cdots \quad m_{jn} \,]^T$$

for vectors consisting of successive elements of the nth column of the matrix $M = [\, m_{ij} \,]$. If p_n and q_n are constructed as regular vectors, then we also have to ensure that (3.34) holds for i with $m_k \leq i \leq n-1$, and this gives

$$U_{m_k:n-1,n} = (E^{(k)})^{-1} (Q^{(k)})^T A v_n. \tag{3.36}$$

We remark that, by (3.29), the matrix $E^{(k)}$ in (3.36) is necessarily nonsingular since the vectors p_n and q_n are regular. If p_n and q_n are constructed as inner vectors, then $m^\star = m_k - 1$,

and (3.34) yields no conditions for the choice of the coefficients u_{in} with $m_k \le i < n-1$. In this case, we set

$$u_{in} = \zeta_{in} \quad \text{for } i = m_k, m_k+1, \ldots, n-1, \tag{3.37}$$

where $\zeta_{in} \in \mathbb{C}$ can be chosen arbitrarily. Finally, if p_n and q_n are regular, we update the "regular" indices (3.28) by setting $m_{k+1} := n$ and $k := k+1$. This completes the construction of the p_n and q_n vectors.

In a second step, we now compute the next pair of V–W vectors, v_{n+1} and w_{n+1}, using the recurrences (3.5)–(3.6). Here, we have to determine the coefficients l_{in} such that v_{n+1} satisfies the corresponding biorthogonality conditions (3.23). Note that, in view of (3.15), the relations (3.23) for w_{n+1} are then fulfilled automatically. We proceed similar to the construction of p_n and q_n. By using (3.26) and the fact that the columns of the matrices Q_i and W_i span the same space, it is easily verified that

$$(W^{(j)})^T A p_n = 0 \quad \text{for all } j = 1, 2, \ldots, l^\star - 1, \tag{3.38}$$

where $l^\star := l^\star(n)$ is given by

$$l^\star = \max\left\{ j \;\middle|\; 1 \le j \le l \text{ and } n_j \le m_k \right\}. \tag{3.39}$$

From (3.38), we conclude that the recurrences (3.5)–(3.6) reduce as follows:

$$\tilde{v}_{n+1} = A p_n - \sum_{i=n_{l^\star}}^{n} v_i l_{in}, \tag{3.40}$$

$$\tilde{w}_{n+1} = A^T q_n - \sum_{i=n_{l^\star}}^{n} w_i l_{in} (\gamma_n/\gamma_i). \tag{3.41}$$

The recurrence coefficients l_{in} in (3.40)–(3.41) are determined by enforcing the remaining biorthogonality conditions (3.23) for the vectors v_{n+1} and w_i, $n_{l^\star} \le i \le n$. This gives

$$L_{n_{l^\star}:n_l-1,n} = (\operatorname{diag}(D^{(l^\star)}, \ldots, D^{(l-1)}))^{-1} \left[W^{(l^\star)} \quad \ldots \quad W^{(l-1)} \right]^T A p_n. \tag{3.42}$$

Moreover, if v_{n+1} and w_{n+1} are constructed as regular vectors, then

$$L_{n_l:n,n} = (D^{(l)})^{-1} (W^{(l)})^T A p_n. \tag{3.43}$$

Note that, by (3.24), the matrix $D^{(l)}$ in (3.43) is necessarily nonsingular since v_{n+1} and w_{n+1} are regular. If v_{n+1} and w_{n+1} are built as inner vectors, then we set

$$l_{in} = \eta_{in} \quad \text{for } i = n_l, n_l+1, \ldots, n, \tag{3.44}$$

where $\eta_{in} \in \mathbb{C}$ can be chosen arbitrarily. Finally, if v_{n+1} and w_{n+1} are regular, then we update the indices (2.21) by setting $n_{l+1} := n+1$ and $l := l+1$.

The resulting coupled procedure for generating the P–Q and V–W sequences can be sketched as follows.

ALGORITHM 3.3 (Coupled algorithm with look-ahead).

0. Choose $v_1, w_1 \in \mathbb{C}^N$ with $\|v_1\| = \|w_1\| = 1$.
   Set $V^{(1)} = v_1$, $W^{(1)} = w_1$, $D^{(1)} = w_1^T v_1$.
   Set $k = 1, m_k = 1, l = 1, n_l = 1$.

For $n = 1, 2, \ldots,$ do:

1. Determine $k^\star$ from (3.31).
2. Decide whether to construct p_n and q_n as regular or inner vectors and go to step 3 or 4, respectively.
3. Compute p_n and q_n by means of (3.35)–(3.36) and (3.32)–(3.33).
   Set $m_{k+1} = n$, $k = k + 1$, $P^{(k)} = Q^{(k)} = \emptyset$ and go to step 5.
4. Compute p_n and q_n by means of (3.35), (3.37), and (3.32)–(3.33).
5. Set
$$P^{(k)} = \left[P^{(k)} \quad p_n \right], \quad Q^{(k)} = \left[Q^{(k)} \quad q_n \right], \quad E^{(k)} = (Q^{(k)})^T A P^{(k)}.$$
6. Determine $l^\star$ from (3.39).
7. Decide whether to construct v_{n+1} and w_{n+1} as regular or inner vectors and go to step 8 or 9, respectively.
8. Compute $\tilde{v}_{n+1}$ and $\tilde{w}_{n+1}$ by means of (3.42)–(3.43) and (3.40)–(3.41).
   Set $n_{l+1} = n + 1$, $l = l + 1$, $V^{(l)} = W^{(l)} = \emptyset$ and go to step 10.
9. Compute $\tilde{v}_{n+1}$ and $\tilde{w}_{n+1}$ by means of (3.42), (3.44), and (3.40)–(3.41).
10. Compute $\rho_{n+1} = \|\tilde{v}_{n+1}\|$ and $\xi_{n+1} = \|\tilde{w}_{n+1}\|$.
    If $\rho_{n+1} = 0$ or $\xi_{n+1} = 0$, then stop.
    Otherwise, set
$$v_{n+1} = \tilde{v}_{n+1}/\rho_{n+1}, \quad w_{n+1} = \tilde{w}_{n+1}/\xi_{n+1},$$
$$V^{(l)} = \left[V^{(l)} \quad v_{n+1} \right], \quad W^{(l)} = \left[W^{(l)} \quad w_{n+1} \right], \quad D^{(l)} = (W^{(l)})^T V^{(l)}.$$

We remark that Algorithm 3.3 reduces to the coupled two-term procedure described in § 3.2 if all vectors in the P–Q and V–W sequences are built as regular vectors. Note that in this case, we have $k(n) = n - 1$, $n_{k^\star} = n - 1$, $l(n) = n$, and $n_{l^\star} = n$ for all n.

4. The look-ahead strategy. As described in §3.2, there are two possible breakdowns in the coupled two-term procedure without look-ahead: one associated with the V–W sequence, and another associated with the P–Q sequence. In particular, Algorithm 3.2 will encounter an exact breakdown in the V–W sequence if $w_n^T v_n = 0$, or in the P–Q sequence if $q_{n-1}^T A p_{n-1} = 0$. The exact breakdowns of the two sequences are not independent of each other, as was pointed out by Gutknecht in [12]. For a full description of the structure and coupling of the exact breakdowns, we refer the reader to [12] and [2], and the references given there. However, in practice one is also concerned with avoiding near-breakdowns; that is, situations when $w_n^T v_n$ or $q_{n-1}^T A p_{n-1}$ are not exactly zero, but are small in some sense.

In the coupled procedure with look-ahead, which we sketched in §3.3, exact and near-breakdowns in the P–Q, respectively V–W, sequence are prevented by building the next pair of vectors p_n and q_n, respectively v_{n+1} and w_{n+1}, as inner vectors. In this section, we describe the look-ahead strategy that is used to decide in steps 2 and 7 of Algorithm 3.3 whether vectors are constructed as regular or inner vectors.

Recall from §2.2 that the vectors $\{v_i\}_{i=1}^{n+1}$ and $\{w_i\}_{i=1}^{n+1}$ in the look-ahead Lanczos algorithm satisfy a block three-term recurrence that can be written compactly as (2.14)–(2.15). By eliminating V_n and W_n in (3.7) and (3.8), one obtains a similar recurrence relation for the vectors $\{p_i\}_{i=1}^{n}$ and $\{q_i\}_{i=1}^{n}$ of the P–Q sequence:

$$A P_{n-1} = P_n U_n L_{n-1} \quad \text{and} \quad A^T Q_{n-1} = Q_n \Gamma_n^{-1} U_n L_{n-1} \Gamma_{n-1}. \tag{4.1}$$

By using the A-biorthogonality of p_n and q_n, it is easy to show that the recurrences for the P–Q sequence are also three-term recurrences, or, in the general case, block three-term recurrences. We note that, in (4.1), the matrix $U_n L_{n-1}$ of recurrence coefficients is obtained by multiplying the factors L_{n-1} and U_n from the decompositions (3.11) of H_{n-1} and H_n, respectively, in reverse order. This was first remarked by Rutishauser [21] for the special case of no look-ahead, and recently by Gutknecht [12], for the general case.

The look-ahead strategy consists of monitoring breakdowns in the two sequences independently. For the V–W sequence, the criteria used are the same as those proposed in [7]:

$$\sigma_{\min}(D^{(l)}) \geq \text{ eps}, \tag{4.2}$$

$$n(A) \geq \sum_i \left|(L_n U_n)_{in}\right|, \tag{4.3}$$

$$n(A) \geq \sum_i \frac{\gamma_n}{\gamma_i} \left|(L_n U_n)_{in}\right|, \tag{4.4}$$

where eps is machine epsilon, and $n(A)$ is an estimate for the norm of A. The Lanczos vectors v_{n+1} and w_{n+1} are built as regular vectors only if all three of the above checks are satisfied. The check (4.2) ensures that the diagonal blocks $D^{(j)}$ are nonsingular, while the checks (4.3)–(4.4) ensure that the size of the coefficients μ_n and ν_n in (2.23) and in the corresponding relation for $\tilde{w}_{n+1}$ do not exceed an estimate $n(A)$ for the norm of A. The first condition is needed since the inverse of $D^{(l)}$ appears in μ_n, while the second and third conditions attempt to ensure that the components from $K_n(r_0, A)$ and from $K_n(w_1, A^T)$ do not dominate the Av_n and $A^T w_n$ terms, respectively. Another motivation for these checks is as follows. The symmetric Lanczos process for Hermitian matrices A generates tridiagonal matrices H_n that satisfy

$$\|H_n\| \leq \|A\| \quad \text{for all } n. \tag{4.5}$$

For the classical nonsymmetric Lanczos algorithm, the relation (4.5) does not hold in general. Indeed, formally, we have $\|H_n\| = \infty$ if a breakdown occurs. As David Day has pointed out to us,[1] an "ideal" look-ahead Lanczos procedure would ensure that (4.5) also holds for non-Hermitian matrices. The criteria (4.3)–(4.4) can be viewed as a cheap way of modeling the conditions (4.5). We remark that the checks (4.3)–(4.4) take advantage of the normalization (2.9) of the Lanczos vectors.

For the P–Q sequence, the criteria are similar: the diagonal blocks $E^{(j)}$ must be nonsingular, and the size of the last columns of $U_n L_{n-1}$ and of $\Gamma_n^{-1} U_n L_{n-1} \Gamma_{n-1}$ must not exceed the estimate $n(A)$ for the norm of A. Singularity of $E^{(k)}$ is once again checked from its smallest singular value:

$$\sigma_{\min}(E^{(k)}) \geq \text{ eps}.$$

However, for the second and third checks, it is no longer sufficient to compute just the norm of the last column of the matrices of recurrence coefficients, as the vectors p_n and q_n are not normalized to unit length. Instead, one must check

$$n(A)\|p_n\| \geq \sum_i \left|(U_n L_{n-1})_{i,n-1}\right| \|p_i\| \tag{4.6}$$

and

$$n(A)\|q_n\| \geq \sum_i \frac{\gamma_{n-1}}{\gamma_i} \left|(U_n L_{n-1})_{i,n-1}\right| \|q_i\|. \tag{4.7}$$

[1] Private communication, Berkeley, March 1992.

This means that the look-ahead strategy for the P–Q sequence requires the computation of the two norms $\|p_n\|$ and $\|q_n\|$ at each step, work that would otherwise not be needed by the algorithm. Once again, the vectors p_n and q_n are built as regular vectors only if all three of the above checks are satisfied. We remark that the look-ahead strategy presented here builds regular vectors in preference to inner vectors and will therefore build as few inner vectors as possible.

Finally, we note that other look-ahead strategies are also possible. For example, Gutknecht [12] proposed a look-ahead strategy that assumes that the near-breakdowns encountered in the two sequences have the same structure as the exact breakdowns. We have chosen to monitor the two sequences independently; nevertheless, our strategy will recover the exact-breakdown structure if only exact breakdowns are considered.

5. Implementation details. In this section, we discuss some of the details of an implementation of Algorithm 3.3. The nth iteration of Algorithm 3.3 updates the matrices E_{n-1}, L_{n-1}, U_{n-1}, P_{n-1}, Q_{n-1}, V_n, W_n, and D_n, to E_n, L_n, U_n, P_n, Q_n, V_{n+1}, W_{n+1}, and D_{n+1}, respectively. We are interested in obtaining an implementation that requires only two inner products per iteration to compute all the coefficients of the recurrence formulas. Recall that the look-ahead strategy (4.6)–(4.7) for the P–Q sequence and the normalization (2.9) require a total of four norm computations, so that the implementation will require two inner products and four norms per iteration.

Let us introduce the auxiliary matrices

$$F_n = W_n^T A P_n \quad \text{and} \quad \tilde{F}_n = Q_n^T A V_n,$$

whose columns are needed in (3.42)–(3.43) and (3.35)–(3.36). It turns out that these two matrices are essentially the transpose of each other.

LEMMA 5.1. *The matrices F_n and $\tilde{F}_n$ satisfy $F_n \Gamma_n = (\tilde{F}_n \Gamma_n)^T$.*

Proof. The proof is similar to the proof of Lemma 3.1. □

At the beginning of each iteration, we will have available the $n \times (n-1)$ matrix $F_{1:n,1:n-1}$, which we will update to $F_{1:n+1,1:n}$.

To compute the coefficients u_{in} needed in (3.32)–(3.33), $\tilde{F}_{1:n-1,n}$ is obtained by Lemma 5.1. The vectors p_n and q_n are then computed from (3.32)–(3.33). To obtain E_n from E_{n-1}, the diagonal term $q_n^T A p_n$ is computed directly, requiring one inner product. Then, using

$$F_n = W_n^T A P_n = \Gamma_n U_n^T \Gamma_n^{-1} Q_n^T A P_n = \Gamma_n U_n^T \Gamma_n^{-1} E_n, \tag{5.1}$$

the remainder of the last row of E_n is computed from E_{n-1}, $F_{n,1:n-1}$, and U_{n-1}. The last column of E_n is obtained by symmetry, using (3.16) from Lemma 3.1. One then computes $F_{1:n,n}$, using (5.1) and the new column $E_{1:n,n}$. The vectors v_{n+1} and w_{n+1} are then computed from (3.40)–(3.41).

Next, we consider the update of D_{n+1} from D_n. The diagonal term $w_{n+1}^T v_{n+1}$ is once again computed directly, thus requiring the second inner product per iteration. Next, using

$$\begin{aligned} F_n &= W_n^T A P_n = W_n^T V_{n+1} L_n \\ &= D_n L_{1:n,1:n} + l_{n+1,n} D_{1:n,n+1} [\,0 \quad \cdots \quad 0 \quad 1\,], \end{aligned} \tag{5.2}$$

the remainder of the last column of D_{n+1} is computed from D_n, F_n, and L_n. The last row of D_{n+1} is obtained by symmetry, using (3.15) from Lemma 3.1. One then computes $F_{n+1,1:n}$, using (5.2) and the new row $D_{n+1,1:n+1}$.

Thus, the coupled Lanczos Algorithm 3.3 requires the computation of two inner products and four vector norms per iteration. We conclude this section by noting that, in Algorithm 3.3,

the choice of the inner recurrence coefficients (3.37) and (3.44) is arbitrary. In our implementation of the algorithm, we used

$$\begin{aligned} u_{n-1,n} &= 1, \\ u_{n-2,n} &= 1 \quad \text{when } m_k \leq n-2, \\ u_{in} &= 0 \quad \text{for } i = m_k, \ldots, n-3, \\ l_{nn} &= 1, \\ l_{n-1,n} &= 1 \quad \text{when } n_l \leq n-1, \\ l_{in} &= 0 \quad \text{for } i = n_l, \ldots, n-2, \end{aligned}$$

for the inner-vector recurrence coefficients.

6. An implementation of QMR with look-ahead. We now return to linear systems (1.1) and the QMR method. In this section, we propose an implementation of the QMR method based on the coupled two-term look-ahead Algorithm 3.3.

Recall that the nth QMR iterate x_n is defined by (2.25)–(2.26) in terms of the matrices V_n and H_n generated by the look-ahead Lanczos algorithm. In the original implementation of QMR, the solution z_n of the least-squares problem (2.26) is computed by means of a QR decomposition of the matrix $\Omega_{n+1}H_n$.

Here we consider the case that the Lanczos vectors are constructed using the coupled two-term Algorithm 3.3. Recall that Algorithm 3.3 yields as a by-product the factors L_n and U_n in the decomposition (3.11) of H_n. Using the factorization (3.11) and setting $y_n := U_n z_n$, we can rewrite the definition (2.25)–(2.26) of x_n as follows:

$$x_n = x_0 + V_n U_n^{-1} y_n, \tag{6.1}$$

where y_n is the unique solution of the least-squares problem

$$\| f_{n+1} - \Omega_{n+1} L_n y_n \| = \min_{y \in \mathbb{C}^n} \| f_{n+1} - \Omega_{n+1} L_n y \|. \tag{6.2}$$

Here, as before, f_{n+1} is given by (2.27) and Ω_{n+1} is defined in (2.28). We remark that the least-squares problem (6.2) is actually cheaper to solve than the original one (2.26). The reason is that the matrix L_n in (6.2) has fewer nonzero elements than H_n in (2.26). For example, if no look-ahead steps are taken, then H_n is tridiagonal, while L_n is a lower bidiagonal matrix. This special case will be considered in more detail in §7. We remark that, typically, the coefficient matrix $\Omega_{n+1}L_n$ of (6.2) is better conditioned than the matrix $\Omega_{n+1}H_n$ in (2.26). Consequently, the least-squares problem (6.2) usually can be solved to higher accuracy than the original one (2.26); see the examples in §9. This is another advantage of the coupled two-term implementation of QMR.

As discussed in [9], solutions of least-squares problems of the type (6.2) can be easily updated from step to step, using the QR decomposition of $\Omega_{n+1}L_n$,

$$\Omega_{n+1} L_n = Q_n^H \begin{bmatrix} R_n \\ 0 \end{bmatrix}, \tag{6.3}$$

where Q_n is a unitary $(n+1) \times (n+1)$ matrix, and R_n is a nonsingular upper triangular $n \times n$ matrix. With this, the least-squares problem (6.2) becomes

$$\begin{aligned} \min_{y \in \mathbb{C}^n} \| f_{n+1} - \Omega_{n+1} L_n y \| &= \min_{y \in \mathbb{C}^n} \left\| Q_n^H \left(Q_n f_{n+1} - \begin{bmatrix} R_n \\ 0 \end{bmatrix} y \right) \right\| \\ &= \min_{y \in \mathbb{C}^n} \left\| Q_n f_{n+1} - \begin{bmatrix} R_n \\ 0 \end{bmatrix} y \right\|. \end{aligned}$$

For y_n this gives:

$$y_n = R_n^{-1} t_n, \quad \text{where } t_n = \begin{bmatrix} \tau_1 \\ \vdots \\ \tau_n \end{bmatrix}, \quad \begin{bmatrix} t_n \\ \tilde{\tau}_{n+1} \end{bmatrix} := Q_n f_{n+1}. \tag{6.4}$$

Finally, we note that it is possible to update the QMR iterate at each step, as was done in the original QMR algorithm. Full implementation details were given in [9, §4], and we will not repeat them here. The point is that the QMR iterates have an update formula of the form

$$x_n = x_{n-1} + d_n \tau_n. \tag{6.5}$$

Here, τ_n is given by (6.4), and d_n is an auxiliary search direction defined as the last column of the matrix $V_n U_n^{-1} R_n^{-1} = P_n R_n^{-1}$, which appears in (6.1) after inserting y_n from (6.4). The vectors d_n are also updated with short recurrences: the recurrence for d_n involves only as many vectors as the recurrence for v_{n+1}. For full details of the update procedure for d_n, we refer the reader to [9].

The basic outline of the resulting implementation of QMR based on the coupled two-term Algorithm 3.3 is then as follows.

ALGORITHM 6.1 (QMR based on coupled recurrences).

0. Choose $x_0 \in \mathbb{C}^N$ and set $r_0 = b - Ax_0$, $\rho_1 = \|r_0\|$, $v_1 = r_0/\rho_1$.
   Choose $w_1 \in \mathbb{C}^N$ with $\|w_1\| = 1$.

For $n = 1, 2, \ldots$, do:

1. Perform the nth iteration of the coupled two-term Algorithm 3.3.
   This yields matrices L_n, P_n, U_n, and V_{n+1}, which satisfy (3.7).
2. Update the QR factorization (6.3) of $\Omega_{n+1} L_n$ and the vector t_n in (6.4).
3. Update the QMR iterate x_n by means of (6.5).
4. If x_n has converged, then stop.

In [9], various properties of the QMR method are given. For example, it is shown how existing BCG iterates can be easily recovered from the QMR process and how estimates for the QMR residual norms can be obtained at no extra costs. We would like to stress that these properties also hold true for the particular implementation of QMR sketched in Algorithm 6.1. Finally, recall from (2.29) that we recommend the use of unit weights $\omega_j = 1$ in $\Omega_{n+1} = \operatorname{diag}(\omega_1, \omega_2, \ldots, \omega_{n+1})$.

7. An implementation of QMR without look-ahead. In this section, we present the simplification of Algorithm 6.1 to the case where no look-ahead is used. We also briefly address the issue of preconditioning.

Let M be a given nonsingular $N \times N$ matrix that approximates in some sense the coefficient matrix A of (1.1). Suppose further that M is decomposed as

$$M = M_1 M_2. \tag{7.1}$$

Then, one applies the QMR algorithm to the system

$$A' y' = b', \tag{7.2}$$

where $A' = M_1^{-1} A M_2^{-1}$, $b' = M_1^{-1} b$, and $x' = M_2 x$. It is easy to see that the linear systems (1.1) and (7.2) are equivalent, and that one can transform back from the iterates x'_n and the

residuals r'_n of the system (7.2) to the iterates x_n and the residuals r_n of the system (1.1). For example, while applying QMR to the preconditioned system (7.2), it is possible to write the resulting algorithm in terms of the quantities corresponding to the original system (1.1); this is what is done below.

We now present a version of the QMR algorithm based on the coupled Algorithm 3.2, which does not have look-ahead. We remark that in this case, by (3.22) and (3.20), the matrix U_n in (3.9) is upper bidiagonal, and L_n is a lower bidiagonal matrix. We also implement preconditioning, as discussed above. The resulting QMR algorithm is as follows.

ALGORITHM 7.1 (QMR based on coupled recurrences without look-ahead).

0. Choose $x_0 \in \mathbb{C}^N$ and set $r_0 = b - Ax_0$.
   Compute $\rho_1 = \|M_1^{-1} r_0\|$ and set $v_1 = r_0/\rho_1$.
   Choose $w_1 \in \mathbb{C}^N$ with $\|M_2^{-T} w_1\| = 1$.
   Set $p_0 = q_0 = d_0 = 0$, $c_0 = \epsilon_0 = \xi_1 = 1$, $\vartheta_0 = 0$, $\eta_0 = -1$.

For $n = 1, 2, \ldots,$ do:

1. If $\epsilon_{n-1} = 0$, then stop.
   Compute $\delta_n = w_n^T M^{-1} v_n$. If $\delta_n = 0$, then stop.

2. Compute

$$p_n = M^{-1} v_n - p_{n-1}(\xi_n \delta_n / \epsilon_{n-1}),$$
$$q_n = M^{-T} w_n - q_{n-1}(\rho_n \delta_n / \epsilon_{n-1}).$$

3. Compute $\epsilon_n = q_n^T A p_n$, $\beta_n = \epsilon_n / \delta_n$, and set

$$\tilde{v}_{n+1} = Ap_n - v_n \beta_n, \qquad \rho_{n+1} = \|M_1^{-1} \tilde{v}_{n+1}\|,$$
$$\tilde{w}_{n+1} = A^T q_n - w_n \beta_n, \qquad \xi_{n+1} = \|M_2^{-T} \tilde{w}_{n+1}\|.$$

4. Compute

$$\vartheta_n = \frac{\omega_{n+1} \rho_{n+1}}{\omega_n c_{n-1} |\beta_n|}, \quad c_n = \frac{1}{\sqrt{1 + \vartheta_n^2}}, \quad \eta_n = -\eta_{n-1} \frac{\rho_n c_n^2}{\beta_n c_{n-1}^2},$$
$$d_n = p_n \eta_n + d_{n-1} (\vartheta_{n-1} c_n)^2, \quad x_n = x_{n-1} + d_n.$$

5. If $\rho_{n+1} = 0$ or $\xi_{n+1} = 0$, then stop.
   Otherwise, set

$$v_{n+1} = \tilde{v}_{n+1} / \rho_{n+1}, \quad w_{n+1} = \tilde{w}_{n+1} / \xi_{n+1}.$$

As pointed out in §3.2, the vectors computed in steps 2 and 3 of Algorithm 7.1 are rescaled versions of vectors used in BCG. Freund and Szeto [11] used this connection to derive an implementation of QMR without look-ahead that is directly based on BCG. Their Algorithm 3.1 in [11] and Algorithm 7.1 are mathematically equivalent.

8. QMR for complex symmetric matrices. In this section, we briefly discuss the application of the QMR Algorithm 7.1 to the solution of complex symmetric linear systems, i.e., systems with

$$A = A^T \in \mathbb{C}^{N \times N}.$$

We note that the QMR approach was originally proposed by Freund in [5] for exactly this class of linear systems. We stress that the implementation of complex symmetric QMR in [5] is based on the three-term Lanczos recurrence. Here we present a different implementation based on coupled two-term recursions.

The benefit of applying a Lanczos method to complex symmetric systems is that the underlying Lanczos algorithm simplifies naturally. Recall that in the coupled Algorithm 3.3, the second starting vector w_1 is arbitrary. In the case of a symmetric matrix, if w_1 is chosen equal to v_1, then it is easy to show that $w_n = v_n$ and $q_n = p_n$ for all n. Thus, the recurrences for w_n and q_n can be eliminated, saving roughly half the amount of work and storage.

However, we remark that, in contrast to the Lanczos algorithm for Hermitian matrices where breakdowns are excluded, the Lanczos process for complex symmetric also requires look-ahead to avoid exact and near-breakdowns. This is discussed in detail in [5].

The only other issue in the case of complex symmetric systems is that the preconditioner M in (7.1) must also be symmetric, i.e.,

$$M = M_1 M_2 = (M_1 M_2)^T = M^T. \tag{8.1}$$

For example, this is always guaranteed if the decomposition (7.1) is "symmetric" in the sense that

$$M_2 = M_1^T. \tag{8.2}$$

However, we stress that the condition (8.2) is not necessary, and M_1 and M_2 can be arbitrary matrices satisfying (8.1). We remark that standard preconditioning techniques, such as incomplete factorization, yield symmetric preconditioners (8.1) when applied to symmetric matrices A.

In this case, one can apply the QMR Algorithm 7.1 to the resulting preconditioned system. Once again writing everything in terms of the quantities corresponding to the original system (1.1), one obtains the following iteration.

ALGORITHM 8.1 (QMR without look-ahead for complex symmetric systems).

0. Choose $x_0 \in \mathbb{C}^N$ and set $r_0 = b - Ax_0$.
   Compute $\rho_1 = \|M_1^{-1} r_0\|$ and set $v_1 = r_0/\rho_1$.
   Set $p_0 = d_0 = 0$, $c_0 = \epsilon_0 = 1$, $\vartheta_0 = 0$, $\eta_0 = -1$.

For $n = 1, 2, \ldots$, do:

1. If $\epsilon_{n-1} = 0$, then stop.
   Compute $\delta_n = v_n^T M^{-1} v_n$. If $\delta_n = 0$, then stop.
2. Compute
$$p_n = M^{-1} v_n - p_{n-1}(\rho_n \delta_n / \epsilon_{n-1}).$$
3. Compute $\epsilon_n = p_n^T A p_n$, $\beta_n = \epsilon_n/\delta_n$, and
$$\tilde{v}_{n+1} = Ap_n - v_n \beta_n, \quad \rho_{n+1} = \|M_1^{-1} \tilde{v}_{n+1}\|.$$
4. Compute
$$\vartheta_n = \frac{\omega_{n+1}\rho_{n+1}}{\omega_n c_{n-1} |\beta_n|}, \quad c_n = \frac{1}{\sqrt{1+\vartheta_n^2}}, \quad \eta_n = -\eta_{n-1} \frac{\rho_n c_n^2}{\beta_n c_{n-1}^2},$$
$$d_n = p_n \eta_n + d_{n-1}(\vartheta_{n-1} c_n)^2, \quad x_n = x_{n-1} + d_n.$$

5. If $\rho_{n+1} = 0$, then stop.
   Otherwise, set

$$v_{n+1} = \tilde{v}_{n+1}/\rho_{n+1}.$$

9. Numerical experiments. In this section, we present a few numerical examples. We compare the original and the new implementation of the QMR algorithm, as well as illustrate an application of the coupled QMR algorithm to the solution of complex symmetric linear systems.

In Figs. 9.1–9.3 below, we always show the true relative residual norm $\|r_n\|/\|r_0\|$ plotted versus the iteration index n. All examples were run on a Sun SparcStation 2 using double precision, with machine epsilon of order $\mathcal{O}(10^{-16})$. In all cases, we used unit weights $\omega_j = 1$ for all j in the least-squares problems (6.2), respectively (2.26).

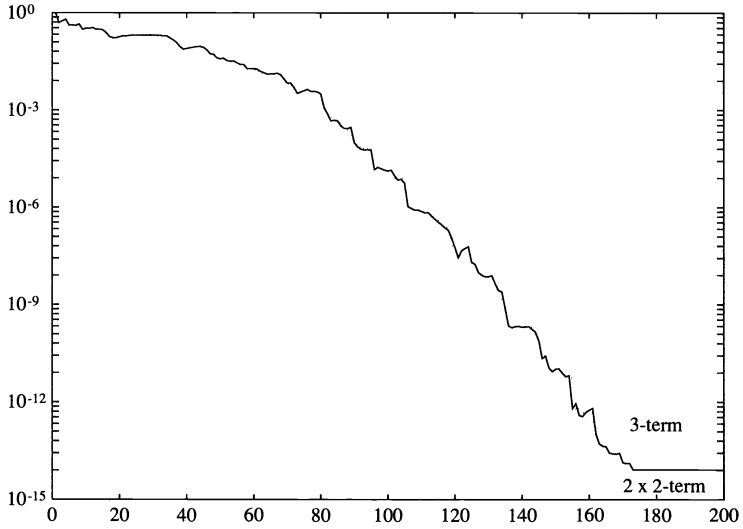

FIG. 9.1. *Convergence curves for Example* 9.1.

Example 9.1. This example is taken from [1] and is meant to illustrate the typical behavior that can be expected from the new implementation of QMR when compared to the original implementation. We consider the partial differential equation

$$Lu = f \quad \text{on } (0, 1) \times (0, 1), \tag{9.1}$$

where

$$Lu := -\frac{\partial}{\partial x}\left(e^{-xy}\frac{\partial u}{\partial x}\right) - \frac{\partial}{\partial y}\left(e^{xy}\frac{\partial u}{\partial y}\right)$$
$$+20(x+y)\frac{\partial u}{\partial x} + 20\frac{\partial}{\partial x}((x+y)u) + \frac{1}{1+x+y}u,$$

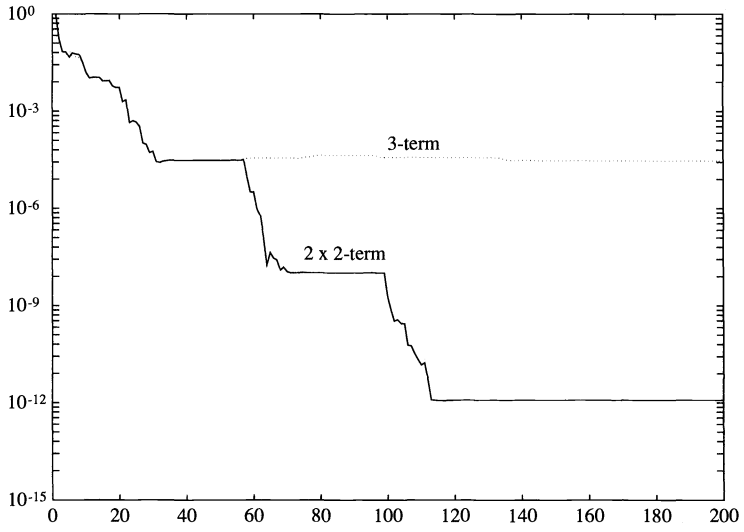

FIG. 9.2. *Convergence curves for Example* 9.2.

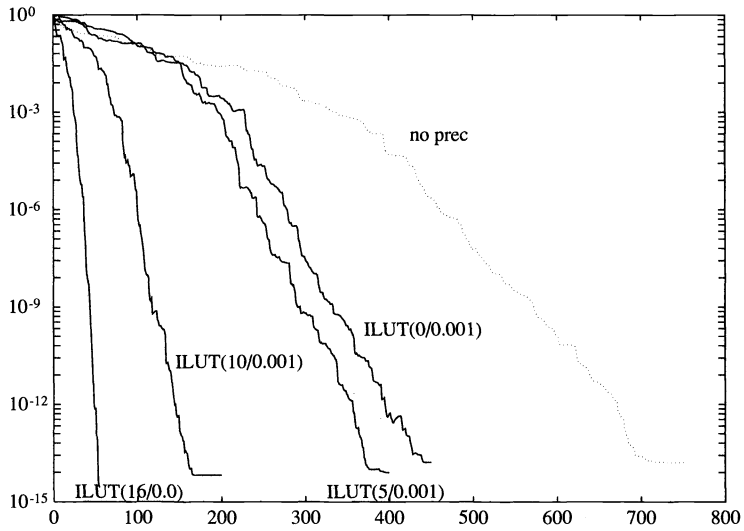

FIG. 9.3. *Convergence curves for Example* 9.3.

with Dirichlet boundary conditions $u = 0$. We discretized (9.1) using centered differences on a 30×30 grid with mesh size $h = \frac{1}{31}$. This leads to a linear system $Ax = b$, where A is a nonsymmetric matrix of order $N = 900$ with 4380 nonzero entries. We ran the original and the new implementations of QMR, both with look-ahead and with the same starting conditions, until the true residual norm $\|r_n\|$ was not reduced any further. The vectors b and w_1 were

random vectors, the initial guess x_0 was zero, and the example was run without preconditioning. The original QMR algorithm is plotted in Fig. 9.1 with a dotted line; it stagnated at `6.7e-14`, and it built six look-ahead blocks of size 2. The coupled QMR algorithm is plotted in Fig. 9.1 with a solid line; it stagnated at `8.3e-15`, and it built four blocks of size 2 in the V–W sequence and seven blocks of size 2 in the P–Q sequence. Recall from §6 that the coupled two-term QMR algorithm solves the least-squares problem (6.2) with coefficient matrix L_n, while the original three-term implementation is based on the least-squares problem (2.26) with coefficient matrix H_n. The Euclidean condition numbers of these matrices at step $n = 165$, respectively $n = 173$, when the original QMR algorithm, respectively the coupled QMR algorithm, begins to stagnate, are $\mathrm{cond}(L_n) =$ `5.2e+03` and $\mathrm{cond}(H_n) =$ `7.3e+03` for both $n = 165$ and $n = 173$. Thus the least-squares problem (6.2) is slightly better conditioned than (2.26).

The behavior in Example 9.1 seems to be fairly typical, in that usually the new implementation is better than the original implementation, but the difference is not very large. However, there are cases where the coupled implementation is significantly better than the original QMR implementation. The next example is of this type.

Example 9.2. This is a linear system that arises in performance modeling of multiprocessor systems, using Petri-net analysis. In such applications, one obtains large sparse singular matrices A with null spaces of dimension 1, and one needs to compute a nontrivial basis vector for this null space. This leads to a linear system of the form $Ax = 0$, and thus condition (2.1) is satisfied. We used a matrix A of size $N = 3663$ with 23397 nonzero elements. The vector b was zero, while the initial guess x_0 and the starting vector w_1 were both random. The linear system is a difficult one, and iterative methods do not converge easily without preconditioning. We used the variant described in [9] of Saad's ILUT preconditioner [22], with no additional fill-in allowed and a drop tolerance of `0.001`, which generated a preconditioning matrix M with 23397 elements. The original QMR algorithm is plotted in Fig. 9.2 with a dotted line; it stagnated at `2.9e-05`, and it built two blocks of size 2. On the other hand, the new implementation, plotted in Fig. 9.2 with a solid line, stagnated at `1.2e-12`, and it built one block of size 2 in the V–W sequence and three blocks of size 2 in the P–Q sequence. The Euclidean condition numbers of the coefficient matrices L_n and H_n of the least-squares problems (6.2) and (2.26) at step $n = 58$, when the original QMR algorithm begins to stagnate, are $\mathrm{cond}(L_{58}) =$ `4.5e+06` and $\mathrm{cond}(H_{58}) =$ `2.4e+10`. At step $n = 113$, when the coupled QMR algorithm begins to stagnate, we have $\mathrm{cond}(L_{113}) =$ `4.9e+06` and $\mathrm{cond}(H_{113}) =$ `3.8e+10`. Thus the least-squares problem (6.2) is considerably better conditioned than (2.26).

Example 9.3. Here A is the complex symmetric YOUNG1C matrix from the Harwell–Boeing test collection of sparse matrices [3]. The matrix arises in a scattering problem in aerodynamics research; it is of dimension $N = 841$ with 4089 nonzero elements. We ran Algorithm 8.1 without look-ahead, with various complex symmetric ILUT preconditioners. In all cases, the iteration was started with the same random vector for b and zero initial guess x_0. This system is also a difficult one, and, if not preconditioned, the QMR algorithm requires around 700 iterations to reach the stagnation level of `2.5e-14`; the corresponding convergence curve is plotted in Fig. 9.3 with a dotted line. However, the ILUT preconditioner is quite effective in this example, especially at higher levels of allowed fill-in and/or drop tolerance. In Fig. 9.3, we show, in order of solid lines from right to left, ILUT with no additional fill-in and `0.001` drop tolerance (2375 nonzero elements), ILUT with five additional fill-in and `0.001` drop tolerance (5171 nonzero elements), ILUT with 10 additional fill-in and `0.001` drop tolerance (9320 nonzero elements), and finally ILUT with 16 additional fill-in and `0.0` drop tolerance (13329 nonzero elements). As can be seen, all variants reach roughly the same stagnation level, around `1.0e-14`. However, as shown in Table 9.1, they do so in

TABLE 9.1
Total execution times (secs) for Example 9.3, average of five runs.

Preconditioner	no prec	ILUT 0/0.001	ILUT 5/0.001	ILUT 10/0.001	ILUT 16/0.0
Iterations	750	450	400	200	55
Time (secs)	144.5	111.4	123.3	75.9	44.4

fewer and fewer iterations, and, in fact, for this example, the additional time spent computing the denser preconditioners was almost always made up by faster convergence.

10. Concluding remarks. We presented a new look-ahead algorithm for constructing Lanczos vectors based on coupled two-term recurrences instead of the usual three-term recurrences. We then discussed a new implementation of the QMR algorithm, using the coupled process to build the basis for the Krylov space. While the theoretical results derived for the original algorithm carry over to the new one, the latter was shown in examples to have better numerical properties. We also briefly covered an implementation of the new QMR method without look-ahead, as well as the application of the QMR algorithm to the solution of complex symmetric linear systems, where the underlying Lanczos process naturally simplifies. Finally, an extended version of this paper, with a more detailed implementation section, is available as a RIACS Technical Report [10].

FORTRAN 77 codes for the proposed coupled-two term look-ahead procedure and the resulting new implementation of the QMR algorithm can be obtained electronically from the authors (freund@research.att.com and na.nachtigal@na-net.ornl.gov). We note that FORTRAN 77 codes for the original implementation of QMR and the underlying look-ahead Lanczos algorithm are available from netlib by sending an email message consisting of the single line "send lalqmr from linalg" to netlib@ornl.gov or netlib@research.att.com.

Acknowledgments. The authors wish to acknowledge the fruitful discussions held with Martin Gutknecht and Tedd Szeto. Marlis Hochbruck and Uwe Seidel provided the matrix for Example 9.2.

A QUASI-MINIMAL RESIDUAL VARIANT OF THE BI-CGSTAB ALGORITHM FOR NONSYMMETRIC SYSTEMS*

T. F. CHAN†, E. GALLOPOULOS‡, V. SIMONCINI§, T. SZETO†, AND C. H. TONG¶

Abstract. Motivated by a recent method of Freund [*SIAM J. Sci. Comput.*, 14 (1993), pp. 470–482], who introduced a quasi-minimal residual (QMR) version of the conjugate gradients squared (CGS) algorithm, a QMR variant of the biconjugate gradient stabilized (Bi-CGSTAB) algorithm of van der Vorst that is called QMRCGSTAB, is proposed for solving nonsymmetric linear systems. The motivation for both QMR variants is to obtain smoother convergence behavior of the underlying method. The authors illustrate this by numerical experiments that also show that for problems on which Bi-CGSTAB performs better than CGS, the same advantage carries over to QMRCGSTAB.

Key words. conjugate gradients, Lanczos algorithm, iterative methods, BCG, CGS, QRM, Bi-CGSTAB, nonsymmetric linear systems

1. Introduction.

In this note we propose a variation of the Bi-CGSTAB algorithm of van der Vorst [18] for solving the linear system

$$Ax = b, \tag{1}$$

where A is a nonsymmetric sparse matrix of order n.

Various attempts have been made in the last forty years to extend the highly successful conjugate gradient (CG) algorithm to the nonsymmetric case [4]. One such natural extension is what is currently called the biconjugate gradient algorithm (BCG) [9], [1]. Although BCG is still quite competitive today, it also has several well-known drawbacks. Among these are (i) the need for matrix-vector multiplications with A^T (which can be inconvenient as well as doubling the number of matrix-vector multiplications compared to CG for each increase in the degree of the underlying Krylov subspace), (ii) the possibility of breakdowns, and (iii) erratic convergence behavior.

Many recently proposed methods can be viewed as improvements over some of these drawbacks of BCG. The most notable of these is the ingenious CGS method proposed by Sonneveld [14], which cures the first drawback mentioned above by computing the square of the BCG polynomial without requiring A^T. Hence when BCG converges, CGS is an attractive, faster converging alternative. However, this relation between the residual polynomials also causes CGS to behave even more erratically than BCG, particularly in near-breakdown situations for BCG [8], [18]. These observations led van der Vorst [18] to introduce Bi-CGSTAB, a more smoothly converging variant of CGS. The main idea is to form a product of the BCG

polynomial with another, locally defined polynomial. The Bi-CGSTAB method was further refined by Gutknecht [7] to handle complex matrices and also lead to better convergence for the case of complex eigenvalues. Nevertheless, although the Bi-CGSTAB algorithms were found to perform very well compared to CGS in many situations, there are cases where convergence is still quite erratic (see, for example, §4 and [12]).

In a recent paper [3], Freund proposed a new version of CGS, called TFQMR, which "quasi-minimizes" [6] the residual in the space spanned by the vectors generated by the CGS iteration. Numerical experiments show that in most cases TFQMR retains the good convergence features of CGS while correcting its erratic behavior. The transpose-free nature of TFQMR, its low computational cost, and its smooth convergence behavior make it an attractive alternative to CGS. On the other hand, since the square of the residual polynomial for BCG is still in the space being quasi-minimized, in many practical examples CGS and TFQMR converge in about the same number of steps. We note however that in contrast to CGS, the asymptotic behavior of TFQMR has been analyzed [2]. It is also well known that the CGS residual polynomial can be quite polluted by round-off error [16]. One possible remedy would be to combine TFQMR with a look-ahead Lanczos technique as was done for the original QMR method [5]. In this paper, we take an alternative approach by deriving quasi-minimum residual extensions to Bi-CGSTAB. We call the basic method QMRCGSTAB and illustrate its smoothed convergence by means of numerical experiments.

It may appear redundant to combine the local minimization in Bi-CGSTAB with a global quasi-minimization. However, our view is that the local minimization is secondary in nature and is only used as a way of generating residual polynomials in the appropriate Krylov subspace over which the residual is being quasi-minimized. In fact, this view allows us some flexibility in modifying the local minimization step in Bi-CGSTAB, which leads to other quasi-minimal residual variants. Although we use extensively notation introduced in [18] for algorithm Bi-CGSTAB, for the sake of brevity we refer to that paper for a description of the method.

2. The QMRCGSTAB algorithm. The algorithm proposed in this paper is inspired by TFQMR in that it applies the quasi-minimization principle to the Bi-CGSTAB method, in the same way that TFQMR is derived from CGS. During each step of Bi-CGSTAB, the following vector relations hold:

$$s_i = r_{i-1} - \alpha_i A p_i, \qquad r_i = s_i - \omega_i A s_i, \tag{2}$$

where α_i is the same as the analogous coefficient in BCG, and ω_i is chosen by a local steepest descent principle. Note that x_i is completely determined by α_i and ω_i. Instead, our algorithm uses Bi-CGSTAB to generate the vectors p_i and s_i, but chooses x_i by quasi-minimizing the residual over their span. Let $Y_k = \{y_1, y_2, \ldots, y_k\}$, where $y_{2l-1} = p_l$ for $l = 1, \ldots, [(k+1)/2]$ and $y_{2l} = s_l$ for $l = 1, \ldots, [k/2]$ ($[k/2]$ is the integer part of $k/2$). In the same way, let $W_{k+1} = \{w_0, w_1, \ldots, w_k\}$ with $w_{2l} = r_l$ for $l = 0, \ldots, [k/2]$ and $w_{2l-1} = s_l$ for $l = 1, \ldots, [(k+1)/2]$. We also define $\{\delta_1, \delta_2, \ldots, \delta_k\}$, as $\delta_{2l} = \omega_l$ for $l = 1, \ldots, [(k+1)/2]$ and $\delta_{2l-1} = \alpha_l$ for $l = 1, \ldots, [(k+1)/2]$. In this case, for each column of W_{k+1} and Y_k, (2) may be written as

$$A y_j = (w_{j-1} - w_j)\delta_j^{-1}, \qquad j = 1, \ldots, k, \tag{3}$$

or, using matrix notation,

$$A Y_k = W_{k+1} E_{k+1},$$

where E_{k+1} is a $(k+1) \times k$ bidiagonal matrix with diagonal elements δ_j^{-1} and lower diagonal elements $-\delta_j^{-1}$.

It can easily be checked that the degree of the polynomials corresponding to the vectors r_i, s_i, and p_i are $2i$, $2i-1$, and $2i-2$, respectively. Therefore, $\text{span}(Y_k) = \text{span}(W_k) = K_{k-1}$, where K_k is the Krylov subspace of degree k generated by r_0. The main idea in QMRCGSTAB is to look for an approximation to the solution of (1), using the Krylov subspace K_{k-1}, in the form

$$x_k = x_0 + Y_k g_k \quad \text{with } g_k \in \mathbb{R}^n.$$

Hence, we may write the residual $r_k = b - Ax_k$ as

$$r_k = r_0 - AY_k g_k = r_0 - W_{k+1} E_{k+1} g_k.$$

Using the fact that the first vector of W_{k+1} is indeed r_0, it follows that

$$r_k = W_{k+1}(e_1 - E_{k+1} g_k),$$

where e_1 is the first vector of the canonical basis. Since the columns of W_{k+1} are not normalized, it was suggested in [3] to use a $(k+1) \times (k+1)$ scaling matrix Σ_{k+1}=diag$(\sigma_1, \ldots, \sigma_{k+1})$, with $\sigma_i = \|w_i\|$, to make the columns of W_{k+1} to be of unit norm. Then

$$r_k = W_{k+1}\Sigma_{k+1}^{-1}\Sigma_{k+1}(e_1 - E_{k+1}g_k) = W_{k+1}\Sigma_{k+1}^{-1}(\sigma_1 e_1 - H_{k+1}g_k) \tag{4}$$

with $H_{k+1} = \Sigma_{k+1} E_{k+1}$.

The quasi-minimal residual approach consists of the minimization of $\|\sigma_1 e_1 - H_{k+1} g\|$ for some $g \in \mathbb{R}^k$. In §3 we introduce a variant of QMRCGSTAB that generates W_{k+1} with pairwise orthogonal columns.

The least squares minimization of $\|\sigma_1 e_1 - H_{k+1} g\|$ is solved using QR decomposition of H_{k+1}. This is done in an incremental manner by means of Givens rotations. Since H_{k+1} is lower bidiagonal, only the rotation of the previous step is needed. We refer to [3] for a detailed description of the QR decomposition procedure.

The pseudocode for the QMRCGSTAB algorithm is as follows, in which the Givens rotations used in the QR decomposition are written out explicitly:

ALGORITHM QMRCGSTAB(A, b, x_0, ϵ)
(1) Initialization
$r_0 = b - Ax_0$
choose $\tilde{r}_0$ such that $(\tilde{r}_0, r_0) \neq 0$
$p_0 = v_0 = d_0 = 0$
$\rho_0 = \alpha_0 = \omega_0 = 1$; $\tau = \|r_0\|$, $\theta_0 = 0$, $\eta_0 = 0$
(2) for $k = 1, 2, \ldots$ do
$\rho_k = (\tilde{r}_0, r_{k-1})$; $\beta_k = (\rho_k \alpha_{k-1})/(\rho_{k-1}\omega_{k-1})$
$p_k = r_{k-1} + \beta_k(p_{k-1} - \omega_{k-1} v_{k-1})$
$v_k = Ap_k$
$\alpha_k = \rho_k/(\tilde{r}_0, v_k)$
$s_k = r_{k-1} - \alpha_k v_k$
(2.1) First quasi-minimization and update iterate
$\tilde{\theta}_k = \|s_k\|/\tau$; $c = 1/\sqrt{1+\tilde{\theta}_k^2}$; $\tilde{\tau} = \tau\tilde{\theta}_k c$
$\tilde{\eta}_k = c^2 \alpha_k$
$\tilde{d}_k = p_k + \frac{\theta_{k-1}^2 \eta_{k-1}}{\alpha_k} d_{k-1}$
$\tilde{x}_k = x_{k-1} + \tilde{\eta}_k \tilde{d}_k$

(2.2) compute t_k, ω_k and update r_k

$t_k = As_k$

$\omega_k = (s_k, t_k)/(t_k, t_k)$

$r_k = s_k - \omega_k t_k$

(2.3) Second quasi-minimization and update iterate

$\theta_k = \|r_k\|/\tilde{\tau}$; $c = 1/\sqrt{1+\theta_k^2}$; $\tau = \tilde{\tau}\theta_k c$

$\eta_k = c^2\omega_k$

$d_k = s_k + \frac{\tilde{\theta}_k^2\tilde{\eta}_k}{\omega_k}\tilde{d}_k$

$x_k = \tilde{x}_k + \eta_k d_k$

If x_k is accurate enough, then quit

(3) end

To check the convergence, the estimate $\|\hat{r}_k\| \leq \sqrt{k+1}|\tau|$ was used, where $\hat{r}_k$ denotes the QMRCGSTAB residual at step k [3].

Note that the cost per iteration is slightly higher than for Bi-CGSTAB, since two additional inner products are needed to compute the elements of Σ_{k+1}. A more detailed discussion on computational costs is given in §4.

3. Some variants of QMRCGSTAB. The use of quasi-minimization in the "product algorithms" (such as CGS and Bi-CGSTAB) introduces some flexibility. For example, the underlying product algorithm need not be constrained to generate a residual polynomial that has small norm since, presumably, the quasi-minimization step will handle that. Instead, the basic iteration can be viewed as only generating a set of vectors spanning the Krylov subspace over which the quasi-minimization is applied. This leads us to several variants of QMRCGSTAB, which we will briefly describe. Note however that only one of these variants will be used in the numerical experiments.

We make two observations on the QMRCGSTAB method:

1. It is not crucial that the steepest descent step reduces the norm of the residual as long as it increases the degree of the Krylov subspace associated with W_{k+1}.
2. If W_{k+1} were orthogonal, then quasi-minimization becomes true minimization of the residual.

Therefore, it is natural to choose ω_i to make W_{k+1} "more orthogonal." For example, one can choose ω_i to make r_i orthogonal to s_i and W_k pairwise orthogonal. This leads to the formula:

$$\omega_i = \frac{(s_i, s_i)}{(s_i, t_i)},$$

which replaces the corresponding formula in Algorithm QMRCGSTAB. We call this variant QMRCGSTAB2. We note that since the inner-product (s_i, s_i) is already needed to compute $\tilde{\theta}_i$, we save one inner product compared to QMRCGSTAB.

We also note that similarly to Bi-CGSTAB, both QMRCGSTAB and QMRCGSTAB2 break down if $(s_i, t_i) = 0$, which is possible if A is indefinite (in fact it is always true if A is skew symmetric). This is an additional breakdown condition over that of BCG. One possible strategy to overcome this is to set a lower bound for the quantity $|(s_i, t_i)|$. However, for matrices with large imaginary parts, Gutknecht [7] observed that Bi-CGSTAB does not perform well because the steepest descent polynomials have only real roots and thus cannot be expected to approximate the spectrum well. In principle, it is possible to derive a quasi-minimal residual version of Gutknecht's variant of Bi-CGSTAB, but we shall not pursue that here.

4. Numerical experiments. We next compare the performance of the QMRCGSTAB variants with that of Bi-CGSTAB, TFQMR, and CGS.

Table 1 shows the cost per step of the methods under discussion, excluding the cost for computing the residual norm which is the same for all methods.

TABLE 1
Cost per step for each method.

	Inner products	DAXPY operations	Matrix-vector multiplications
Bi-CGSTAB	4	6	2
CGS	2	7**	2
QMRCGSTAB	6	8	2
QMRCGSTAB2	5	8	2
TFQMR	4	10	2

In the sequel we present experiments to show that QMRCGSTAB indeed achieves a smoothing of the residual compared to Bi-CGSTAB. Note however that, because the Bi-CGSTAB method already improves the erratic residual convergence of BCG, the effect of QMRCGSTAB is not as impressive as the one of TFQMR on the residual of CGS.

Unless stated otherwise, in all examples, the right-hand side b was generated as a random vector with values distributed uniformly in (0, 1), and the starting vector x_0 was taken to be zero. All matrices arising from a partial differential operator were obtained using centered, second-order finite differences. The methods were compared on the basis of the number of iterations necessary to achieve relative residual $\|r_k\|/\|r_0\| < 10^{-8}$ with $r_k = b - Ax_k$ being the true residual. Hence, the figures were built with the abscissae representing the number of iterations and the ordinates representing $\|r_k\|/\|r_0\|$ graded with a logarithmic scale. Experiments were conducted using a Beta test version of Matlab 4.0 [10] running on a Sun Sparc workstation.

Example 1. This example was taken from [14] and corresponds to the discretization of the convection-diffusion operator

$$L(u) = -\varepsilon \triangle u + \cos(\alpha) u_x + \sin(\alpha) u_y \tag{5}$$

on the unit square with homogeneous Dirichlet conditions on the boundary and parameters $\varepsilon = 0.1$ and $\alpha = -30°$, using 40 grid points per direction, yielding a matrix of order $n = 1600$. Figure 1 shows the convergence histories, from which we can see the smoothing effect of quasi-minimization on the CGS and Bi-CGSTAB residuals. We see that Bi-CGSTAB and its smoothed counterparts converge slightly faster than CGS and TFQMR, with QMRCGSTAB2 showing the best performance by a small margin.

Example 2. This example was taken from [17] and corresponds to the discretization of

$$-(Du_x)_x - (Du_y)_y = 1 \tag{6}$$

on the unit square with homogeneous boundary conditions. We used a coarser grid than the one considered in [17]; that is, 50 grid points per direction yielding a matrix of order $n = 2500$. Parameter D takes the value $D = 10^5$ in $0 \le x, y \le 0.75$, $D = 0.1$ in $0.75 < x, y \le 1$, and $D = 1$ everywhere else. Left diagonal preconditioning was applied. In [17], this matrix was used to illustrate the better convergence of Bi-CGSTAB over CGS. We see from Fig. 2 that this advantage carries over to the smoothed versions. Furthermore, even though the matrix is symmetric positive definite and hence CG is applicable, as shown in Fig. 2, the method

**Strictly speaking, one of the operations is a simple vector addition. This must be taken into account if floating point operations were to be counted.

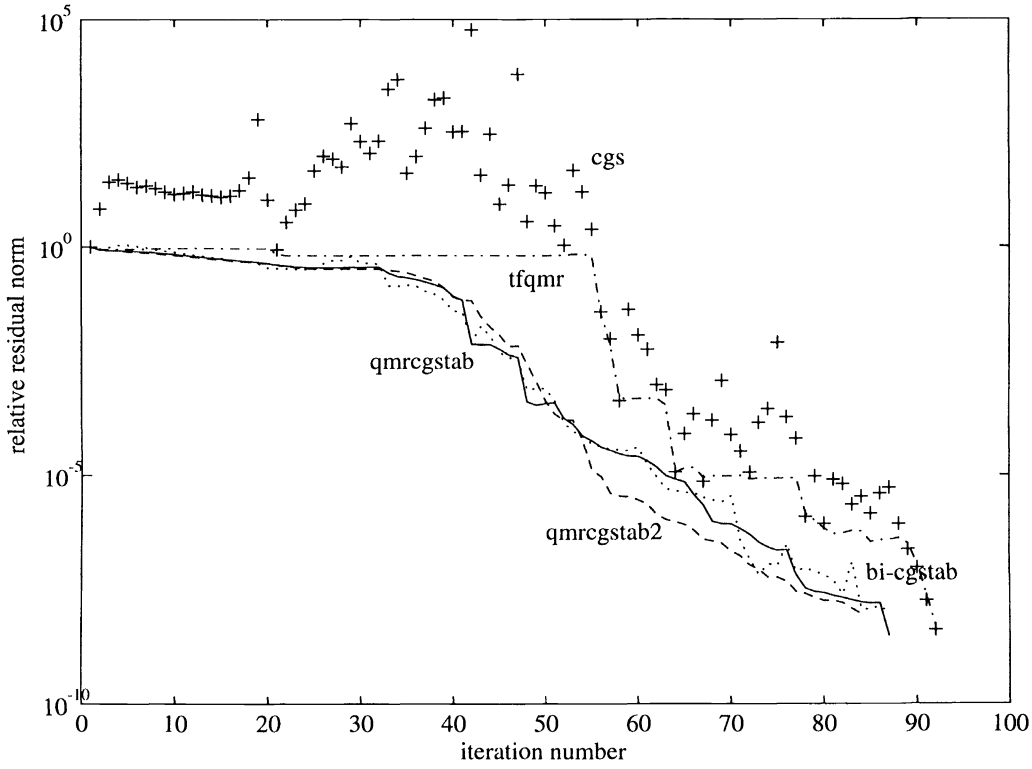

FIG. 1. *Example* 1: *Two-dimensional convection-diffusion operator* (5).

stagnates. This is due to the fact that for this operator, the computed direction vectors of CG methods rapidly lose orthogonality [16]. We note that to make cost comparisons meaningful, the CG curve was plotted so that each "iteration" corresponds to two true CG iterations, i.e., two matrix-vector multiplications.

Example 3. This example comes from the discretization of the convection-diffusion equation

$$L(u) = -\Delta u + \gamma(xu_x + yu_y) + \beta u \tag{7}$$

on the unit square where $\gamma = 100$, $\beta = -100$, for a 63×63 grid, yielding a matrix of order $n = 3969$. No preconditioning was used. In this example, we see the CGS-based methods converge a little faster than Bi-CGSTAB and QMRCGSTAB, but the pairwise orthogonal variant, QMRCGSTAB2, is the fastest. See Fig. 3.

Example 4. Figure 4 shows the results of a three-dimensional version of Example 3 without preconditioning:

$$L(u) = -\Delta u + \gamma(xu_x + yu_y + zu_z) + \beta u \tag{8}$$

on the unit cube where $\beta = -100$, and $\gamma = 50$ for a $15 \times 15 \times 15$ grid, yielding a matrix of order $n = 3375$.

We note that in this example the improvement caused by Bi-CGSTAB over CGS and TFQMR is impressive. Therefore it is not surprising that there is only little additional improvement brought by the variants proposed in this paper. We note that for this operator, the

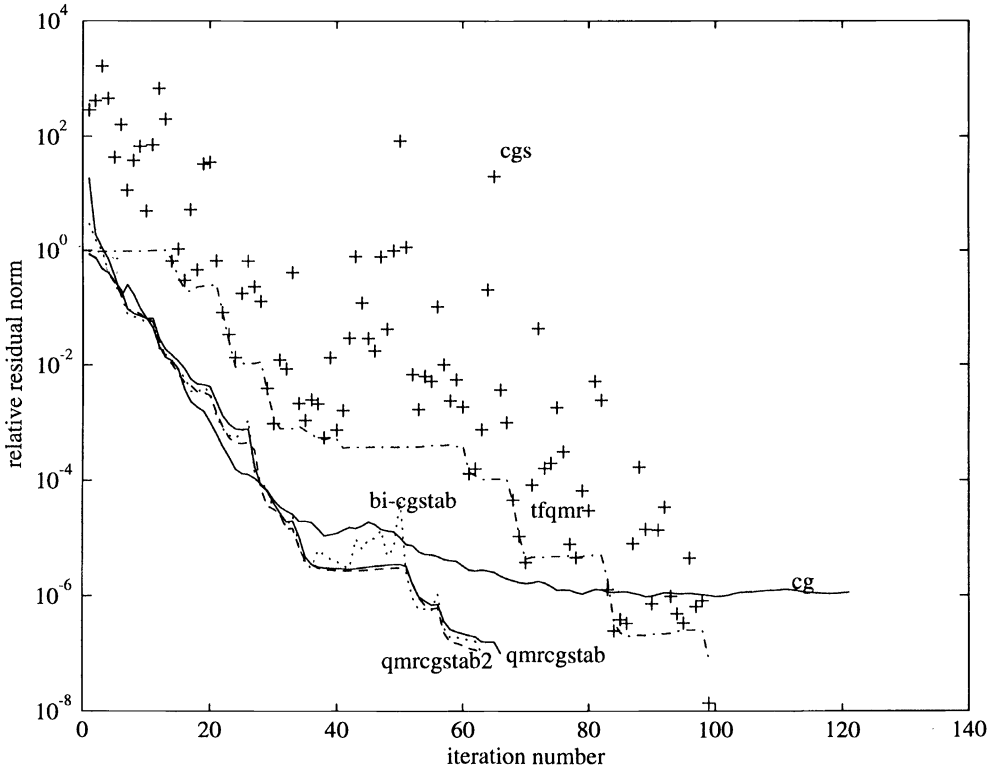

FIG. 2. *Example* 2: *Two-dimensional operator with discontinuous coefficients. Every point on the* CG *curve refers to two CG iterations.*

use of centered differences and large values of γ are unfavorable for Bi-CGSTAB-type methods, since the resulting matrices would have pronounced skew-symmetric components and eigenvalues with large imaginary parts [7]; different discretization methods would be more attractive [13].

Example 5. The next example illustrates how all methods can be affected by the conditioning of the generated polynomial. Matrix A is a modification of an example presented in [11],

$$A = I_{n/2} \otimes \begin{pmatrix} \epsilon & 1 \\ -25 & 100 \end{pmatrix}, \tag{9}$$

i.e., A is an $n \times n$ block diagonal matrix with 2×2 blocks and $n = 40$. We chose $b = (1\ 0\ 1\ 0\ \cdots)^T$ and $\tilde{r}_0 = r_0$. For such a b the norm of the resulting BCG polynomial satisfies $\|\varphi_n\| = \mathcal{O}(\epsilon^{-1})$. Thus, $\|\varphi_n^2\| = \mathcal{O}(\epsilon^{-2})$ in the squared methods and we can foresee numerical problems when ϵ is small.

Each entry of Table 2 shows (i) the number of correct digits, d, in the relative residual obtained after running each algorithm until the relative residual dropped below 10^{-8} but without exceeding 20 matrix vector multiplications, and (ii) in parentheses, the number of matrix vector multiplications, mv, that is a number, not greater than 20, needed to achieve a relative residual of 10^{-d}.

In exact arithmetic, finite termination occurs after the second BCG polynomial φ_2 is computed in both the CGS and Bi-CGSTAB algorithms. We see from Table 2 that all methods

† Iterations stopped when division by zero was encountered.

behave equally well for $\epsilon = 1.0$. As ϵ decreases, round-off error causes CGS and TFQMR, which are based on squaring, to fail or not to converge within the expected time. Furthermore, both CGS and TFQMR lose about twice as many digits as Bi-CGSTAB and its quasi-minimal variants. We also mark the instances of the quasi-minimal variants whose residuals stagnate before the maximum number of iterations has been reached. We note that although the example is contrived, it does justify the implementation of a QMRCGSTAB-type method.

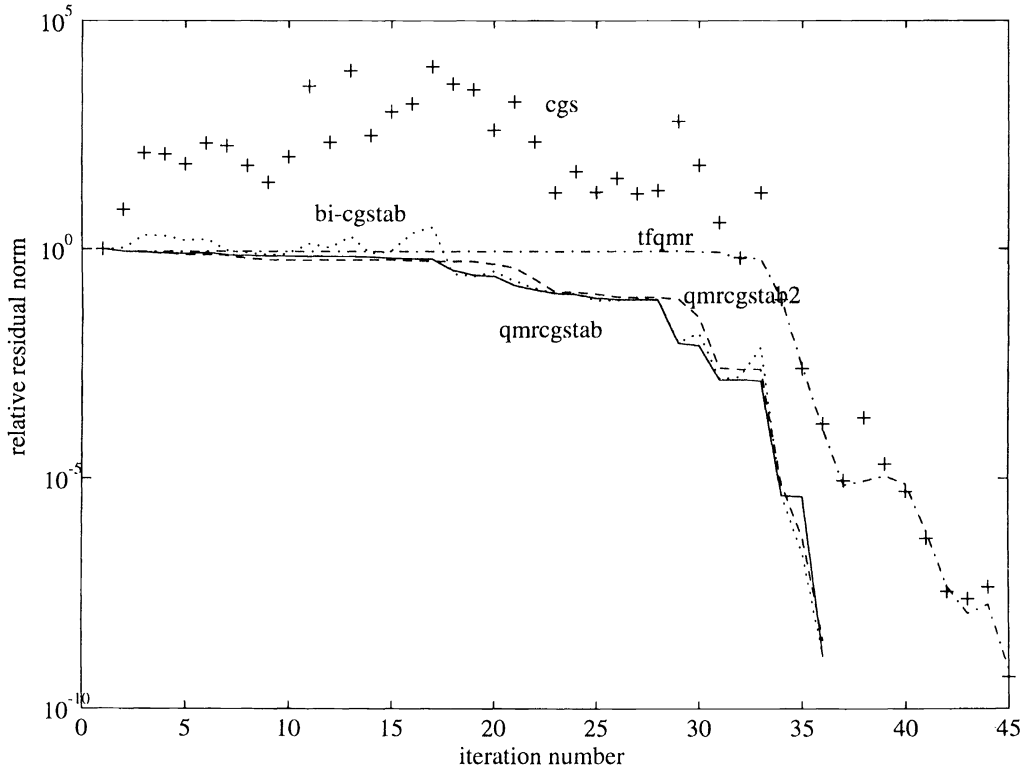

FIG. 4. *Example* 4: *Three-dimensional convection-diffusion operator* (8).

We finally observe that experiments using several of the methods discussed herein, albeit using another naming convention, were presented in [15].

5. Conclusions and future work. We have derived two QMR variants of Bi-CGSTAB. Our motivation for these methods was to inherit any potential improvements on performance that Bi-CGSTAB offers over CGS, while at the same time to provide a smoother convergence behavior. We have shown numerically that this is indeed true for many realistic problems. Although in their present form, the two proposed methods still suffer from some numerical problems, they have many desirable properties: they are transpose-free, they use short recurrences, they make efficient use of matrix-vector multiplications, and they demonstrate smooth convergence behavior.

MAX-MIN PROPERTIES OF MATRIX FACTOR NORMS*

A. GREENBAUM† AND L. GURVITS‡

Abstract. Given a set of real matrices $C_0, C_1, \ldots, C_k$, conditions are considered under which the equality

$$\min_{\alpha_1,\ldots,\alpha_k} \max_{\|w\|=1} \left\| \left(C_0 + \sum_{i=1}^{k} \alpha_i C_i \right) w \right\| = \max_{\|w\|=1} \min_{\alpha_1,\ldots,\alpha_k} \left\| \left(C_0 + \sum_{i=1}^{k} \alpha_i C_i \right) w \right\|$$

holds. It is shown that if the matrices C_i, $i = 0, 1, \ldots, k$ are normal and commute with one another, then the equality holds. In particular, this implies that if $C_i = A^i$ or $C_i = A^{k-i}$, where A is a normal matrix, then the equality holds. An example is given to show that the equality may fail for noncommuting matrices, when $k > 1$. It is shown that the equality holds for arbitrary matrices if $k = 1$.

1. Introduction. The following problem arises in the analysis of iterative methods for solving linear systems and computing eigenvalues. To solve a linear system, $Ax = b$, given an initial guess x^0 for the solution, the generalized minimal residual (GMRES) method [7] generates approximate solutions x^k, $k = 1, 2, \ldots$ of the form

$$x^k = x^0 + \sum_{i=1}^{k} \alpha_{ik} A^{i-1} r^0,$$

where $r^0 \equiv b - Ax^0$ is the initial residual. The residual vectors $r^k \equiv b - Ax^k$ are of the form

$$r^k = r^0 - \sum_{i=1}^{k} \alpha_{ik} A^i r^0,$$

and the coefficients $\alpha_{1k}, \ldots, \alpha_{kk}$ are chosen to make the 2-norm of r^k as small as possible. A bound on the 2-norm of the residual at any step k is given by

$$\|r^k\| \le \min_{\alpha_1,\ldots,\alpha_k} \left\| I - \sum_{i=1}^{k} \alpha_i A^i \right\| \cdot \|r^0\|.$$

The question arises as to whether this bound is ever attained; that is, whether there is an initial residual r^0, such that

$$\min_{\alpha_1,\ldots,\alpha_k} \left\| \left(I - \sum_{i=1}^{k} \alpha_i A^i \right) r^0 \right\| = \min_{\alpha_1,\ldots,\alpha_k} \left\| I - \sum_{i=1}^{k} \alpha_i A^i \right\| \cdot \|r^0\|.$$

In other words, we have the following max-min problem: Is the inequality

$$\max_{\|r^0\|=1} \min_{\alpha_1,\ldots,\alpha_k} \left\| \left(I - \sum_{i=1}^{k} \alpha_i A^i \right) r^0 \right\| \le \min_{\alpha_1,\ldots,\alpha_k} \max_{\|r^0\|=1} \left\| \left(I - \sum_{i=1}^{k} \alpha_i A^i \right) r^0 \right\| \tag{1}$$

actually an equality?

A similar question arises in analyzing the Arnoldi method [1] for computing eigenvalues. Given an initial vector q with $\|q\| = 1$, the Arnoldi iteration constructs a sequence of monic polynomials P_k, $k = 1, 2, \ldots$ whose coefficients are chosen to minimize $\|p_k(A)q\|$ over all monic polynomials p_k of degree k. The roots of these polynomials are taken as approximate eigenvalues of the matrix A. The question arises as to whether, for each k, there is an initial vector q such that the monic polynomial P_k constructed by the Arnoldi process also minimizes $\|p_k(A)\|$. A similar max-min statement of the problem asks if the inequality

$$\max_{\|q\|=1} \min_{\alpha_1,\ldots,\alpha_k} \left\| \left(A^k - \sum_{i=1}^{k} \alpha_i A^{k-i} \right) q \right\| \leq \min_{\alpha_1,\ldots,\alpha_k} \max_{\|q\|=1} \left\| \left(A^k - \sum_{i=1}^{k} \alpha_i A^{k-i} \right) q \right\| \tag{2}$$

is actually an equality.

In this paper, we consider a somewhat more general question: Given an arbitrary sequence of real matrices $C_0, C_1, \ldots, C_k$, under what circumstances will the equality

$$\min_{\alpha_1,\ldots,\alpha_k} \max_{\|w\|=1} \left\| \left(C_0 + \sum_{i=1}^{k} \alpha_i C_i \right) w \right\| = \max_{\|w\|=1} \min_{\alpha_1,\ldots,\alpha_k} \left\| \left(C_0 + \sum_{i=1}^{k} \alpha_i C_i \right) w \right\| \tag{3}$$

hold? It is shown that if the matrices C_i, $i = 0, 1, \ldots, k$ are normal and commute with one another, then (3) holds. This result has actually been known for some time, in a slightly different form [6, p. 292]. We include a proof of the result here, since it is not widely known in the numerical analysis community and we point out how our theorem is equivalent to an established result in approximation theory. In particular, this implies that if $C_i = A^i$ or $C_i = A^{k-i}$, where A is a normal matrix, then the equality holds. This generalizes some known results showing that equality holds in (1) and (2) when the matrix A is normal [2], [4], [5]. An example is given to show that (3) may fail for noncommuting matrices, when $k > 1$. It is shown that the equality (3) holds for arbitrary matrices if $k = 1$. The question of whether equality holds in (1) and (2) when $k > 1$ remains open, as does the question of more general conditions on the matrices $C_0, C_1, \ldots, C_k$ that would ensure that (3) holds.

Throughout this paper, we assume that the matrices and vectors appearing in our max-min statements and related theorems are real (though, of course, the eigenvalues and eigenvectors of these matrices may be complex). We will use the notation $A > 0$ to mean that the symmetric matrix A is positive definite. For a vector w, $\|w\|$ will always denote the 2-norm, and for a matrix A, $\|A\|$ will denote the corresponding matrix norm, $\max_{\|w\|=1} \|Aw\|$.

The next section gives the main theorems and examples.

2. Main theorems. The first theorem gives conditions under which some linear combination of given symmetric matrices is positive definite.

THEOREM 2.1. *Let $A_1, \ldots, A_k$ be real n-by-n symmetric matrices. There exist scalars $\alpha_1, \ldots, \alpha_k$ such that*

$$\sum_{i=1}^{k} \alpha_i A_i > 0 \tag{4}$$

if and only if for every set $\{w_1, \ldots, w_m\}$, $m \leq n$, of real nonzero orthogonal n-vectors ($w_p \cdot w_j = 0$, for $p \neq j$), there is an i such that

$$\sum_{j=1}^{m} \langle A_i w_j, w_j \rangle \neq 0. \tag{5}$$

If the symmetric matrices $A_1, \ldots, A_k$ commute: $A_i A_j = A_j A_i$, $i, j = 1, \ldots, k$, then there exist scalars $\alpha_1, \ldots, \alpha_k$ for which (4) *holds if and only if for every individual real nonzero n-vector w, there is an i such that*

$$\langle A_i w, w \rangle \neq 0. \tag{6}$$

Proof. To see the necessity of (5), note that if, for some orthogonal set $\{w_1, \ldots, w_m\}$, we have

$$\sum_{j=1}^{m} \langle A_i w_j, w_j \rangle = 0$$

for all i, then also

$$\sum_{j=1}^{m} \left\langle \sum_{i=1}^{k} \alpha_i A_i w_j, w_j \right\rangle = \operatorname{tr}\left(W^T \left(\sum_{i=1}^{k} \alpha_i A_i \right) W \right) = 0$$

for any $\alpha_1, \ldots, \alpha_k$, where W is the matrix whose columns are $w_1, \ldots, w_k$. But since every principal submatrix of a positive definite matrix is positive definite, this implies that $\sum_{i=1}^{k} \alpha_i A_i$ cannot be positive definite.

To see the sufficiency of (5), suppose that no linear combination $\sum_{i=1}^{k} \alpha_i A_i$ is positive definite. Then the linear subspace spanned by $A_1, \ldots, A_k$ and the convex cone of positive definite matrices can be separated. That is, there is a symmetric matrix B such that

$$\operatorname{tr}\left(B \sum_{i=1}^{k} \alpha_i A_i \right) = 0 \tag{7}$$

for all $\alpha_1, \ldots, \alpha_k$ and

$$\operatorname{tr}(BP) > 0 \tag{8}$$

for all positive definite matrices P. Write B in the form $B = QDQ^T$, where D is the diagonal matrix of eigenvalues of B and Q is the orthogonal matrix of eigenvectors. Then (8) implies that

$$\operatorname{tr}(QDQ^T P) = \operatorname{tr}(D\, Q^T P Q) > 0. \tag{9}$$

Since the diagonal elements of $Q^T P Q$ can be any positive numbers, (9) implies that the diagonal elements of D are nonnegative, with at least one of these being positive. But from (7) it follows that

$$\operatorname{tr}(BA_i) = \operatorname{tr}(QDQ^T A_i) = \operatorname{tr}((QD^{1/2})^T A_i (QD^{1/2})) = 0$$

for all i. Taking $w_1, \ldots, w_m$ to be the nonzero columns of $QD^{1/2}$, this says

$$\sum_{j=1}^{m} w_j^T A_i w_j = 0,$$

which contradicts (5).

The second part of the theorem can be proved similarly, using the fact that if the matrices $A_1, \ldots, A_k$ commute, then they can be simultaneously diagonalized. That is, there exists an orthogonal matrix Q such that

$$A_i = Q\Lambda_i Q^T, \quad QQ^T = Q^T Q = I, \quad \Lambda_i = \operatorname{diag}(\lambda_{i1}, \ldots, \lambda_{in}).$$

Again, the necessity of (6) is clear, and to see that it is sufficient, we note that if no linear combination of $A_1, \ldots, A_k$ and hence of $\Lambda_1, \ldots, \Lambda_k$ is positive definite, then there is a diagonal matrix $D = \operatorname{diag}(d_1, \ldots, d_n)$ such that

$$\operatorname{tr}\left(D \sum_{i=1}^{k} \alpha_i \Lambda_i\right) = 0, \tag{10}$$

for all $\alpha_1, \ldots, \alpha_k$ and

$$\operatorname{tr}(DP) > 0 \tag{11}$$

for all positive definite diagonal matrices P. From (11) it follows that the diagonal elements of D are nonnegative, with at least one being positive. Define w to be the vector $(\sqrt{d_1}, \ldots, \sqrt{d_n})^T$. From (10) we have for each i,

$$\operatorname{tr}(D\Lambda_i) = \sum_{j=1}^{n} d_j \lambda_{ij} = \langle \Lambda_i w, w \rangle = 0,$$

which contradicts (6). □

The second part of Theorem 2.1 is really a result about vectors rather than matrices: Given a set of n-vectors, $\phi^{(1)}, \ldots, \phi^{(k)}$ (corresponding to the diagonal matrices $\Lambda_1, \ldots, \Lambda_k$ in the theorem), there is a linear combination of these vectors that has all positive elements if and only if for every set of nonnegative numbers $w_1^2, \ldots, w_n^2$, not all zero, there is an i such that

$$\sum_{j=1}^{n} \phi_j^{(i)} w_j^2 \neq 0.$$

In this form, the second part of Theorem 2.1, as well as Theorem 2.3, which is given later, are known. See, for example, [6]. We include proofs of these theorems here for completeness.

We now use Theorem 2.1 to establish conditions under which the optimal coefficients $\alpha_1, \ldots, \alpha_k$ on both sides of equality (3) are zero.

THEOREM 2.2. *Let $C_1, \ldots, C_k$ be real square matrices such that each pair $(C_i + C_i^T)$ and $(C_j + C_j^T)$ commute. Suppose*

$$\min_{\alpha_1, \ldots, \alpha_k} \max_{\|w\|=1} \left\| \left(I + \sum_{i=1}^{k} \alpha_i C_i\right) w \right\| = 1. \tag{12}$$

Then

$$\max_{\|w\|=1} \min_{\alpha_1, \ldots, \alpha_k} \left\| \left(I + \sum_{i=1}^{k} \alpha_i C_i\right) w \right\| = 1. \tag{13}$$

Proof. For a given vector w, we have

$$\min_{\alpha_1,\ldots,\alpha_k} \left\| \left(I + \sum_{i=1}^{k} \alpha_i C_i \right) w \right\| = 1$$

if and only if $\langle C_i w, w\rangle = 0$ for all i; i.e., if and only if $\langle (C_i + C_i^T)w, w\rangle = 0$ for all i. Suppose (13) does not hold. Then for any vector $w \neq 0$ there is an i such that

$$\langle (C_i + C_i^T)w, w\rangle \neq 0.$$

From Theorem 2.1, there is a linear combination

$$\sum_{i=1}^{k} \alpha_i (C_i + C_i^T)$$

that is positive definite. For ϵ sufficiently small, then,

$$\left\| I - \epsilon \sum_{i=1}^{k} \alpha_i C_i \right\|^2 = \left\| I - \epsilon \sum_{i=1}^{k} \alpha_i (C_i + C_i^T) \right\| + \mathcal{O}(\epsilon^2) < 1,$$

which contradicts the assumption (12). □

Theorem 2.2 is now used to establish certain conditions under which equality (3) holds.

THEOREM 2.3. *Let $C_0, C_1, \ldots, C_k$ be nonsingular normal matrices that commute. Then*

$$\min_{\alpha_1,\ldots,\alpha_k} \max_{\|w\|=1} \left\| \left(C_0 + \sum_{i=1}^{k} \alpha_i C_i \right) w \right\| = \max_{\|w\|=1} \min_{\alpha_1,\ldots,\alpha_k} \left\| \left(C_0 + \sum_{i=1}^{k} \alpha_i C_i \right) w \right\|. \tag{14}$$

Proof. Suppose $\hat{\alpha}_1, \ldots, \hat{\alpha}_k$ minimize $\|C_0 + \sum_{i=1}^{k} \alpha_i C_i\|$. We can assume without loss of generality that this minimal norm is 1. We will consider two cases.

1. First, suppose all singular values of $U \equiv C_0 + \sum_{i=1}^{k} \hat{\alpha}_i C_i$ are equal. Then U is a real orthogonal matrix and it commutes with each matrix C_i. The same holds for the inverse matrix U^T. We can write

$$\min_{\alpha_1,\ldots,\alpha_k} \left\| C_0 + \sum_{i=1}^{k} \alpha_i C_i \right\| = \min_{\beta_1,\ldots,\beta_k} \left\| U^T \left(C_0 + \sum_{i=1}^{k} (_i a \hat{\alpha}_i + \beta_i) C_i \right) \right\|$$

$$= \min_{\beta_1,\ldots,\beta_k} \left\| I + \sum_{i=1}^{k} \beta_i U^T C_i \right\| = 1.$$

Because the matrices C_i are normal and commute with each other and with U and U^T, each pair $(U^T C_i + C_i^T U)$ and $(U^T C_j + C_j^T U)$ commute. Therefore, from Theorem 2.2, we have

$$\max_{\|w\|=1} \min_{\beta_1,\ldots,\beta_k} \left\| \left(I + \sum_{i=1}^{k} \beta_i U^T C_i \right) w \right\| = 1,$$

and from this the desired result follows.

2. Now suppose some singular values are less than 1. We can write the real Schur decomposition of each matrix C_i in the form

$$C_i = Q D_i Q^T, \qquad Q Q^T = Q^T Q = I,$$

where each D_i is a block diagonal matrix with 1-by-1 or 2-by-2 blocks on the main diagonal. It suffices to consider the block diagonal matrices D_i. Define $\hat{D} \equiv D_0 + \sum_{i=1}^{k} \hat{\alpha}_i D_i$, and order the elements so that $\hat{D}$ is of the form

$$\hat{D} = \begin{pmatrix} U & 0 \\ 0 & K \end{pmatrix},$$

where U is, say, a t-by-t matrix whose eigenvalues are all equal to 1 in magnitude and K is an $(n-t)$-by-$(n-t)$ matrix whose eigenvalues are all less than 1 in magnitude. Note that each matrix D_i has this same block structure

$$D_i = \begin{pmatrix} D_{i1} & 0 \\ 0 & D_{i2} \end{pmatrix},$$

since any off-diagonal block X in D_i would have to satisfy the homogeneous Sylvester equation: $UX - XK = 0$ in order that D_i and $\hat{D}$ commute. Since the spectrum of U does not intersect the spectrum of K, this equation has only the trivial solution $X = 0$. We can write

$$\begin{aligned} \min_{\alpha_1,\ldots,\alpha_k} \left\| D_0 + \sum_{i=1}^{k} \alpha_i D_i \right\| &= \min_{\beta_1,\ldots,\beta_k} \left\| D_0 + \sum_{i=1}^{k} (\hat{\alpha}_i + \beta_i) D_i \right\| \\ &= \min_{\beta_1,\ldots,\beta_k} \left\| \begin{pmatrix} U & 0 \\ 0 & K \end{pmatrix} + \sum_{i=1}^{k} \beta_i \begin{pmatrix} D_{i1} & 0 \\ 0 & D_{i2} \end{pmatrix} \right\|. \end{aligned} \tag{15}$$

Since $\|U\| > \|K\|$, the same coefficients $\beta_1, \ldots, \beta_k$ that minimize the norm of the matrix in (15) (namely, $\beta_i = 0$, $i = 1, \ldots, k$) also minimize the norm of the upper left t-by-t block, and we have

$$\min_{\beta_1,\ldots,\beta_k} \left\| U - \sum_{i=1}^{k} \beta_i D_{i1} \right\| = 1.$$

Since the singular values of the minimal norm matrix of this form are all equal to 1 and since the matrices D_{i1} are normal and commute with each other, it now follows from part 1 that there is a t-vector $\hat{w}$ with $\|\hat{w}\| = 1$ such that

$$\min_{\beta_1,\ldots,\beta_k} \left\| U - \sum_{i=1}^{k} \beta_i D_{i1} \right\| = \min_{\beta_1,\ldots,\beta_k} \left\| \left(U - \sum_{i=1}^{k} \beta_i D_{i1} \right) \hat{w} \right\|.$$

Defining $\tilde{w}$ to be the n-vector whose first t elements are equal to those of $\hat{w}$ and whose remaining elements are zero, we find

$$\min_{\alpha_1,\ldots,\alpha_k} \left\| D_0 + \sum_{i=1}^{k} \alpha_i D_i \right\| = \min_{\alpha_1,\ldots,\alpha_k} \left\| \left(D_0 + \sum_{i=1}^{k} \alpha_i D_i \right) \tilde{w} \right\|,$$

from which the desired result follows. □

Stated in terms of vectors, Theorem 2.3 states the following. Let f denote the vector consisting of the eigenvalues of C_0, and let $g^{(1)}, \ldots, g^{(k)}$ denote the vectors consisting of the eigenvalues of $C_1, \ldots, C_k$. The left-hand side of (14) is the distance between f and the closest vector to f in the infinity norm from the space G spanned by $g^{(1)}, \ldots, g^{(k)}$. The right-hand side of (14) is the difference between f and the closest vector to f in some weighted L_2 norm

from the space G. The weights are the squared components of the vector w in the direction of each eigenvector of C_i. With this notation, Theorem 2.3 can be stated as follows.

There exists a vector w in R^n with $\|w\|_2 = 1$ such that

$$\min_{g \in G} \|f - g\|_\infty = \|f - \bar{g}\|_\infty = \|f - \bar{g}\|_w = \min_{g \in G} \|f - g\|_w,$$

where $\|v\|_w^2 \equiv \sum_{i=1}^n v_i^2 w_i^2$.

A more general version of this theorem can be deduced from [6, p. 292]. Corollary 1 in that reference states that for any p, q with $1 < p < q \leq \infty$, the vector $\bar{g}$ minimizes some weighted L_q norm of $f - g$ if and only if it minimizes some weighted L_p norm of $f - g$. To obtain the additional result that $\|f - \bar{g}\|_\infty = \|f - \bar{g}\|_w$, we must use the fact that $|f_i - \bar{g}_i|$ attains its maximum value at each of the points i for which w_i is nonzero [6, p. 302]. These facts form the basis of Lawson's algorithm for computing L_∞ approximations by solving a sequence of weighted L_2 (or L_k) approximation problems [3].

Note that the assumption of commutativity in the second part of Theorem 2.1, and hence in Theorems 2.2 and 2.3, is necessary. Consider, for example, the symmetric matrices

$$A_1 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad A_2 = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}. \tag{16}$$

For any vector w, we have

$$\langle A_1 w, w \rangle = w_1^2 - w_2^2, \qquad \langle A_2 w, w \rangle = w_1^2 + 2w_1 w_2 - w_2^2,$$

and if the first inner product is zero and w_1 and w_2 are not both zero, then the second inner product cannot be zero. Yet there is no linear combination of A_1 and A_2 that is positive definite. We have

$$\min_{\alpha_1, \alpha_2} \|I + \alpha_1 A_1 + \alpha_2 A_2\| = 1,$$

but for any vector w,

$$\min_{\alpha_1, \alpha_2} \|(I + \alpha_1 A_1 + \alpha_2 A_2) w\| = 0.$$

In the next lemma we consider general real m-by-n matrices $C_0, C_1, \ldots, C_k$. Suppose $\hat{\alpha}_1, \ldots, \hat{\alpha}_k$ minimize

$$\left\| C_0 + \sum_{i=1}^k \alpha_i C_i \right\|.$$

Define $\hat{C} \equiv C_0 + \sum_{i=1}^k \hat{\alpha}_i C_i$ and write the singular value decomposition of $\hat{C}$ as

$$\hat{C} = U \Sigma V^T,$$

where U is an m-by-m real orthogonal matrix, V is an n-by-n real orthogonal matrix, and Σ is an m-by-n matrix of the form

$$\Sigma = \begin{pmatrix} \sigma_1 & & & \\ & \cdot & & \\ & & \cdot & \\ & & & \sigma_n \\ 0 & \cdot & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot \\ 0 & \cdot & \cdot & 0 \end{pmatrix} \quad \text{or} \quad \Sigma = \begin{pmatrix} \sigma_1 & & & 0 & \cdot & 0 \\ & \cdot & & \cdot & \cdot & \cdot \\ & & \cdot & \cdot & \cdot & \cdot \\ & & & \sigma_m & 0 & \cdot & 0 \end{pmatrix}$$

accordingly as $m \geq n$ or $m \leq n$. Assume that the singular values σ_i, $i = 1, \ldots, \min\{m, n\}$ satisfy

$$\sigma_1 = \cdots = \sigma_t > \sigma_{t+1} \geq \cdots,$$

and let V_t be the n-by-t matrix consisting of the first t columns of V, while $V_{t+1:n}$ is the n-by-$(n-t)$ matrix consisting of columns $t+1$ through n of V.

The following lemma is used to prove Theorem 2.5, but it is also of significant interest in itself.

LEMMA 2.4. *Using the above notation, the coefficients* $\hat{\alpha}_1, \ldots, \hat{\alpha}_k$ *that minimize*

$$\left\| C_0 + \sum_{i=1}^{k} \alpha_i C_i \right\| \tag{17}$$

also minimize

$$\left\| \left(C_0 + \sum_{i=1}^{k} \alpha_i C_i \right) V_t \right\|. \tag{18}$$

Proof. Suppose $\hat{\alpha}_1, \ldots, \hat{\alpha}_k$ do not minimize (18). Then there are coefficients $\tilde{\alpha}_1, \ldots, \tilde{\alpha}_k$ such that

$$\left\| \left(C_0 + \sum_{i=1}^{k} \tilde{\alpha}_i C_i \right) V_t \right\| < \left\| \left(C_0 + \sum_{i=1}^{k} \hat{\alpha}_i C_i \right) V_t \right\|.$$

We will show that for sufficiently small values of ϵ, the coefficients $(1-\epsilon)\hat{\alpha}_i + \epsilon\tilde{\alpha}_i$ satisfy

$$\left\| C_0 + \sum_{i=1}^{k} ((1-\epsilon)\hat{\alpha}_i + \epsilon\tilde{\alpha}_i) C_i \right\| < \left\| C_0 + \sum_{i=1}^{k} \hat{\alpha}_i C_i \right\|,$$

which contradicts the assumption that $\hat{\alpha}_1, \ldots, \hat{\alpha}_k$ minimize (17).

For any ϵ in $(0, 1)$ we have

$$\begin{aligned} \left\| \left(C_0 + \sum_{i=1}^{k} ((1-\epsilon)\hat{\alpha}_i + \epsilon\tilde{\alpha}_i) C_i \right) V_t \right\| &\leq (1-\epsilon) \left\| \left(C_0 + \sum_{i=1}^{k} \hat{\alpha}_i C_i \right) V_t \right\| \\ &\quad + \epsilon \left\| \left(C_0 + \sum_{i=1}^{k} \tilde{\alpha}_i C_i \right) V_t \right\| < \sigma_1 - \mathcal{O}(\epsilon). \end{aligned} \tag{19}$$

For sufficiently small ϵ, we also have

$$\begin{aligned} \left\| \left(C_0 + \sum_{i=1}^{k} ((1-\epsilon)\hat{\alpha}_i + \epsilon\tilde{\alpha}_i) C_i \right) V_{t+1:n} \right\| &\leq (1-\epsilon) \left\| \left(C_0 + \sum_{i=1}^{k} \hat{\alpha}_i C_i \right) V_{t+1:n} \right\| \\ &\quad + \epsilon \left\| \left(C_0 + \sum_{i=1}^{k} \tilde{\alpha}_i C_i \right) V_{t+1:n} \right\| < \sigma_{t+1} + \frac{1}{2}(\sigma_1 - \sigma_{t+1}). \end{aligned} \tag{20}$$

Define the matrix $K \equiv (K_1, K_2)$ by

$$K_1 = U^T \left(C_0 + \sum_{i=1}^{k} ((1-\epsilon)\hat{\alpha}_i + \epsilon\tilde{\alpha}_i) C_i \right) V_t$$

$$= (1-\epsilon)\sigma_1 \begin{pmatrix} I \\ 0 \end{pmatrix} + \epsilon U^T \left(C_0 + \sum_{i=1}^{k} \tilde{\alpha}_i C_i \right) V_t,$$

$$K_2 = U^T \left(C_0 + \sum_{i=1}^{k} ((1-\epsilon)\hat{\alpha}_i + \epsilon\tilde{\alpha}_i) C_i \right) V_{t+1:n}$$

$$= (1-\epsilon) \begin{pmatrix} 0 \\ \Sigma_{t+1:n} \end{pmatrix} + \epsilon U^T \left(C_0 + \sum_{i=1}^{k} \tilde{\alpha}_i C_i \right) V_{t+1:n},$$

where $\Sigma_{t+1:n} \equiv \operatorname{diag}(\sigma_{t+1}, \ldots, \sigma_n)$. We would like to show that $\|K\| < \sigma_1$ or, equivalently, that the matrix

$$\sigma_1^2 I - K^T K = \begin{pmatrix} \sigma_1^2 I - K_1^T K_1 & -K_1^T K_2 \\ -K_2^T K_1 & \sigma_1^2 I - K_2^T K_2 \end{pmatrix} \tag{21}$$

is positive definite. From (19) and (20) it follows that the diagonal blocks are positive definite, so it suffices to show that

$$(\sigma_1^2 I - K_1^T K_1) - K_1^T K_2 (\sigma_1^2 I - K_2^T K_2)^{-1} K_2^T K_1 > 0.$$

It is easy to check that

$$\|K_1^T K_2 (\sigma_1^2 I - K_2^T K_2)^{-1} K_2^T K_1\| = \mathcal{O}(\epsilon^2),$$

while the eigenvalues of $\sigma_1^2 I - K_1^T K_1$ are of order ϵ. For sufficiently small ϵ, then, the matrix (21) is positive definite, and this gives the desired contradiction. □

Using this lemma and Theorem 2.2 we can now prove equality (3) for general matrices, when $k = 1$.

THEOREM 2.5. *Let C_0 and C_1 be arbitrary real m-by-n matrices. Then*

$$\min_{\alpha} \max_{\|w\|=1} \|(C_0 + \alpha C_1) w\| = \max_{\|w\|=1} \min_{\alpha} \|(C_0 + \alpha C_1) w\|. \tag{22}$$

Proof. We will use induction on the number of columns n. If $n = 1$, the result is clearly true. Assume it is true for matrices with $n-1$ columns, and now consider matrices with n columns. Suppose $\hat{\alpha}$ minimizes $\|C_0 + \alpha C_1\|$. Define $\hat{C} \equiv C_0 + \hat{\alpha} C_1$ and write the singular value decomposition of $\hat{C}$ as

$$\hat{C} = U \Sigma V^T,$$

where U, V, and Σ are as defined earlier. Assume that the singular values $\sigma_i, i = 1, \ldots, \min\{m, n\}$ satisfy

$$\sigma_1 = \cdots = \sigma_t > \sigma_{t+1} \geq \cdots,$$

and let V_t be the n-by-t matrix consisting of the first t columns of V, while $V_{t+1:n}$ is the n-by-$(n-t)$ matrix consisting of columns $t+1$ through n of V.

We will consider two cases. In the first case, assume that $t < n$. According to the lemma, $\hat{\alpha}$ minimizes

$$\|(C_0 + \alpha C_1)V_t\|,$$

and so, by the induction hypothesis,

$$\|(C_0 + \hat{\alpha}C_1)V_t\| = \max_{\|w\|=1} \min_{\alpha} \|(C_0 + \alpha C_1)V_t w\|.$$

If $\hat{w}$ is the t-vector for which this maximum is attained and if we define the n-vector $\tilde{w}$ to be $V_t\hat{w}$, then we have the desired result

$$\|C_0 + \hat{\alpha}C_1\| = \min_{\alpha} \|(C_0 + \alpha C_1)\tilde{w}\|.$$

Now suppose $t = n$. We can assume without loss of generality that $\sigma_1 = 1$, and then we have

$$\min_{\alpha} \|C_0 + \alpha C_1\| = \min_{\beta} \|U^T(C_0 + (\beta + \hat{\alpha})C_1)V\|$$

$$= \min_{\beta} \left\| \begin{pmatrix} I \\ 0 \end{pmatrix} + \beta \begin{pmatrix} U_n^T C_1 V \\ \\ U_{n+1:m}^T C_1 V \end{pmatrix} \right\| = 1,$$

where U_n consists of the first n columns of U and $U_{n+1:m}$ consists of columns $n+1$ through m of U. The same coefficient β that minimizes the norm of the entire matrix also minimizes the norm of the top n-by-n block of this matrix and so we have

$$\min_{\beta} \|I + \beta U_n^T C_1 V\| = 1.$$

From Theorem 2.2 it now follows that

$$\max_{\|w\|=1} \min_{\beta} \|(I + \beta U_n^T C_1 V)w\| = 1$$

and hence that (22) holds. □

Special cases of this theorem, as well as Theorem 2.3, were derived independently and proved in a different way by Joubert [5].

3. Further discussion. Extensive numerical testing of the inequalities in (1) and (2) for a variety of matrices suggests that they are, indeed, equalities. Theorem 2.5 proves this is so for $k = 1$, but we have been unable to prove (or disprove) this result for $k > 1$. The example (16) shows that the proof must rely on special properties of polynomials, since the result is not true for arbitrary noncommuting matrices, even if they are normal.

Acknowledgment. The authors thank Nick Trefethen for pointing out that the results of Theorem 2.3 are equivalent to known results about vector approximation and for indicating where these could be found in the literature.

GMRES/CR AND ARNOLDI/LANCZOS AS MATRIX APPROXIMATION PROBLEMS*

ANNE GREENBAUM† AND LLOYD N. TREFETHEN‡

Abstract. The GMRES and Arnoldi algorithms, which reduce to the CR and Lanczos algorithms in the symmetric case, both minimize $\| p(A)\, b \|$ over polynomials p of degree n. The difference is that p is normalized at $z = 0$ for GMRES and at $z = \infty$ for Arnoldi. Analogous "ideal GMRES" and "ideal Arnoldi" problems are obtained if one removes b from the discussion and minimizes $\| p(A) \|$ instead. Investigation of these true and ideal approximation problems gives insight into how fast GMRES converges and how the Arnoldi iteration locates eigenvalues.

Key words. GMRES, CR, Arnoldi, Lanczos, matrix approximation problem, normal matrix

1. Introduction.

Since the 1950s it has been recognized that matrix iterative methods are naturally connected with approximation theory. The most familiar connections are between polynomial approximation and the numerous iterative methods that make use of Krylov subspaces, including the Richardson, Chebyshev, conjugate gradient, biconjugate gradient, CGNR, GMRES, CGS, Bi-CGSTAB, and QMR iterations. Sometimes rational approximation problems also arise, notably in the analysis of ADI iterations, circulant-preconditioned Toeplitz iterations, and Krylov subspace algorithms via Padé approximation. Recent references on these matters include [4], [8], [16], [25].

The approximation problems that are discussed in the linear algebra literature almost invariably involve scalar functions defined on subsets of the complex plane or, if the matrix A is symmetric, the real axis. The set in question is the spectrum $\Lambda(A)$ or an estimate of the spectrum. If A is normal, such reductions are sometimes exact in the sense that the behavior of the matrix iteration is determined exactly by the properties of the approximation problem. If A is not normal, however, they are always approximate. GMRES, for example, does not exactly solve any known approximation problem in the complex plane, when A is not normal. Between the approximation problem and the convergence of the matrix iteration there is a gap of size $\kappa(V)$, the condition number of a matrix of eigenvectors of A. When $\kappa(V)$ is large, predictions based on the approximation problem may have little bearing on the actual convergence of the matrix algorithm [16], [25].

The purpose of this paper is to explore a different kind of approximation problem that can also be associated with iterative linear algebra, involving matrices instead of scalars. Instead of asking how small a polynomial $p(z)$ can be on the set $\Lambda(A)$, we ask how small the norm $\| p(A) \|$ can be. Matrix approximation questions are implicit in much of the literature of matrix iterations; we certainly do not claim to be the first to consider them. However, they have received no discussion in print that we are aware of. We believe it is important to investigate these problems if one's goal is an understanding of matrix iterations that does not depend upon hidden assumptions of near-normality. At the same time, the consideration of matrix approximation problems preserves a familiar feature of scalar approximation problems, the removal from the analysis of the effects of the starting vector. Since most of the phenomena

of greatest interest in iterative linear algebra depend mainly on the matrix, not the starting vector, this is a valuable simplification for most applications.

We shall concentrate on two algorithms for nonsymmetric matrix problems: GMRES, which solves systems of equations $Ax = b$, and Arnoldi, which computes eigenvalues of A. Our matrix approximation analogues of these processes are called the "ideal GMRES" and "ideal Arnoldi" problems. Mathematically, the new result presented here is a proof of the existence and uniqueness of ideal GMRES and Arnoldi approximants. (Existence is trivial, but uniqueness is surprisingly tricky.) In the final section we propose five questions whose answers might further advance our understanding of matrix iterations.

2. GMRES and Arnoldi. Throughout this paper N and $n < N$ are integers, A is an $N \times N$ matrix,[1] b is an N-vector, $\| \cdot \|$ is the 2-norm, and

$$P_n = \{\text{polynomials of degree} \le n \text{ with } p(0) = 1\},$$

$$P^n = \{\text{monic polynomials of degree } n\}.$$

The difference between P_n and P^n is that P_n is normalized at $z = 0$ and P^n at $z = \infty$.

GMRES [4], [23] is an algorithm that solves the following approximation problem[2] successively for $n = 1, 2, 3 \ldots$.

GMRES APPROXIMATION PROBLEM. *Find $p_* \in P_n$ such that*

$$\| p_*(A)b \| = \text{minimum}. \tag{1}$$

An equivalent statement is

$$b \approx \langle Ab, A^2b, \ldots, A^nb \rangle, \tag{1'}$$

where "$y \approx V$" denotes the problem of finding the best approximation with respect to $\| \cdot \|$ to the point y in the space V. This characterization of GMRES is well known. To explain it one notes that GMRES finds a vector x_n in the Krylov subspace $\mathcal{K}_n = < b, Ab, \ldots, A^{n-1}b >$ such that the residual $r_n = b - Ax_n$ has minimal norm over all $x \in \mathcal{K}_n$. This vector x_n can be represented in the form $x_n = q(A)b$ for some polynomial $q(z)$ of degree $n - 1$, and (1) comes upon writing $r_n = p_*(A)b$ with $p_*(z) = 1 - zq(z) \in P_n$.

The Arnoldi iteration [1], [4], [20]–[22] is an algorithm that solves the analogous problem involving P^n instead of P_n.

ARNOLDI APPROXIMATION PROBLEM *Find $p^* \in P^n$ such that*

$$\| p^*(A)b \| = \text{minimum}. \tag{2}$$

Equivalently,

$$A^nb \approx \langle b, Ab, \ldots, A^{n-1}b \rangle. \tag{2'}$$

The vector b is no longer the right-hand side of a system of equations, but an arbitrary initial vector. This characterization is also known, but perhaps not as widely known as it should be.[3] It can be readily proved as a consequence of the usual formulation of the Arnoldi process in terms of orthogonality. The Arnoldi iteration "finds p^*" in the sense that it constructs a Hessenberg matrix H_n of which p^* is the characteristic polynomial.

[1] Nothing essential changes if we take $N = \infty$ and let A be a bounded operator.

[2] We have assumed that the initial guess for the iteration is $x_0 = 0$. Arbitrary initial guesses can be handled by an easy modification.

[3] See Theorem 1 of [22]. The symmetric (Lanczos) case of this result was stated by Lanczos himself [11, p. 34] and also appears as Corollary 12-3-7 of [18], unfortunately with a typographical error.

If A is real and symmetric, the GMRES and Arnoldi iterations reduce to the conjugate residual (CR) and Lanczos iterations, respectively. Everything said in this paper about GMRES applies also to CR, and everything said about Arnoldi applies also to Lanczos.

A comparison of (1) and (2) suggests that from an approximation point of view, the difference between the GMRES and Arnoldi algorithms is slight. This analogy is rarely brought out in accounts of these algorithms, partly for historical reasons and partly because the usual applications of the two algorithms are different. Whereas GMRES is applied to solve systems of equations $Ax = b$, so that (1) comes quickly to mind as a description of it, the Arnoldi iteration is traditionally thought of as a method for estimating eigenvalues of A. The "Arnoldi eigenvalue estimates"[4] at step n are the eigenvalues of H_n, that is, the roots of p^*. But what the Arnoldi iteration actually does is solve (2); its connection with eigenvalues is indirect and approximate.

The formulations (1) and (2) provide elegant proofs of certain well-known properties of the GMRES and Arnoldi iterations. For example, one sees immediately from (1) and (2) that both of these iterations are essentially invariant under changes of scale ($A \to \alpha A, \alpha \in \mathbf{C}$) and under unitary similarity transformations ($A \to UAU^*$, $U^* = U^{-1}$). The Arnoldi iteration is also translation-invariant ($A \to A + \alpha I, \alpha \in \mathbf{C}$), since ∞ is translation-invariant, but GMRES is not, since 0 is not [11]. In these statements and throughout this paper, we ignore the effects of rounding errors.

3. Ideal GMRES and ideal Arnoldi. The GMRES and Arnoldi iterations depend on the starting vector b. However, one may remove b from the discussion and pose the following "ideal" approximation problems.

IDEAL GMRES APPROXIMATION PROBLEM. *Find $q_* \in P_n$ such that*

$$\|q_*(A)\| = \text{minimum}. \tag{3}$$

Equivalently,

$$I \approx \langle A, A^2, \ldots, A^n \rangle. \tag{3'}$$

IDEAL ARNOLDI APPROXIMATION PROBLEM. *Find $q^* \in P^n$ such that*

$$\|q^*(A)\| = \text{minimum}. \tag{4}$$

That is,

$$A^n \approx \langle I, A, \ldots, A^{n-1} \rangle. \tag{4'}$$

Whereas (1) and (2) are vector approximation problems, (3) and (4) involve matrices. Procedures for computing these polynomials, either actual or in our imaginations, might be called ideal GMRES and ideal Arnoldi algorithms. Some computations of this kind are discussed in §6.

We believe that studying these idealized problems may be a fruitful way to gain insight into the properties of Krylov subspace iterations in linear algebra. Our reasoning is as follows. The behavior of a GMRES or Arnoldi iteration is determined by two things: A and b. However, though the special properties of b are occasionally important, more often the features that one cares about do not differ very much from one choice of b to another. It is the properties of A

[4]The roots of p^* are Ritz values of A with respect to the Krylov subspace (2'). The roots of p_* have been called "pseudo-Ritz values" [4] and "roots of kernel polynomials" [14]. The Ritz values lie in the field of values of A, and the pseudo-Ritz values lie in the inverse of the field of values of A^{-1}; see [14].

that usually decide between an iteration that converges in 10 steps and one that requires 100 or 1000 (which in practice means it is time to look for a better preconditioner). By passing from (1)–(2) to (3)–(4) we disentangle this matrix essence of the process from the distracting effects of the initial vector and end up with a pair of elegant mathematical problems in the bargain.

The solutions to (1)–(2) and (3)–(4) are related by the following bounds. The proof of this theorem is easy; the four inequalities follow from the minimality properties (1), (3), (2), and (4), respectively.

THEOREM 1. *The true and ideal* GMRES *polynomials are related by*

$$\frac{\|p_*(A)b\|}{\|b\|} \leq \|q_*(A)\| \leq \|p_*(A)\|, \tag{5}$$

and the true and ideal Arnoldi polynomials are related by

$$\frac{\|p^*(A)b\|}{\|b\|} \leq \|q^*(A)\| \leq \|p^*(A)\|. \tag{6}$$

These two pairs of bounds are identical in form, but from the point of view of applications, the nature of the relationship between (4) and (2) is quite different from that between (3) and (1). The purpose of GMRES is to solve (1), not (3). The relevance of (3) is that it gives an upper bound on how slow the convergence may be, thanks to (5), and if the right-hand side b is "random enough," one may expect that this bound may be close to sharp. For an Arnoldi iteration aimed at estimating eigenvalues, the logic is reversed. One can take the view that the essence of the process by which an Arnoldi iteration locates eigenvalues is the solution not of (2) but of (4). The iteration solves (2) because that is what is computationally tractable, but the implicit hope is that if b is "random enough," the solution to (2) will be a good approximation to the solution to (4). It would be interesting to investigate how this point of view can be related to the existing theory of convergence of the Arnoldi iteration as developed by Saad [20], [22].

The ideal Arnoldi polynomial q^* might be called the degree n *Chebyshev polynomial of* A, in analogy to the notion in approximation theory of a Chebyshev polynomial of a subset of the complex plane, which is a monic polynomial that achieves minimal sup-norm on that set.[5] Another way to view q^* is as a *pseudo-annihilating polynomial* for A, i.e., a monic polynomial that maps A to a matrix of norm $\epsilon \approx 0$. According to the usual definition, an annihilating polynomial is a polynomial that annihilates A exactly. This is a fragile concept, however, ill posed with respect to perturbations of A and with little quantitative force. Krylov subspace iterations in numerical linear algebra are founded on the observation that for practical purposes, a pseudo-annihilating polynomial with parameter $\epsilon = 10^{-10}$ or 10^{-20} is as useful as an exact annihilating polynomial and may be of vastly lower degree.

4. The special case when A is normal. When A is normal, problems (1)–(4) reduce to standard problems of approximation theory. For any vector b we have

$$p(A)b = \sum_{j=1}^{N} \omega_j p(\lambda_j) v_j, \qquad \omega_j = v_j^T b,$$

where $\{\lambda_j\}$ and $\{v_j\}$ are a set of eigenvalues and corresponding orthonormal eigenvectors of A, and therefore

$$\|p(A)b\| = \left(\sum_{j=1}^{N} |\omega_j|^2 |p(\lambda_j)|^2 \right)^{1/2}.$$

[5] See Chapter 16 of [9]. This analogy becomes an identity if A is normal; see §4.

Thus the Arnoldi and GMRES problems (1)–(2) are equivalent to weighted least-squares approximation problems in the complex plane: find an appropriately normalized polynomial $p(z)$ that has minimal weighted 2-norm on $\Lambda(A)$ with respect to the discrete weight function $\{|\omega_j|^2\}$. As for the ideal Arnoldi and GMRES problems (3)–(4), the identity

$$\| p(A) \| = \sup_{\lambda \in \Lambda(A)} |p(\lambda)|$$

(for normal matrices only) shows that they are are equivalent to Chebyshev approximation problems in the complex plane: find a polynomial that has minimal supremum norm on $\Lambda(A)$. In particular, the ideal Arnoldi polynomial q_* is exactly the same as the Chebyshev polynomial for the set $\Lambda(A)$, mentioned in the last section.

Both weighted least-squares and Chebyshev approximation problems in the complex plane are well understood and discussed in many books. Existence and uniqueness of best approximations are easily proved (we defer a precise statement to the next section). In the Chebyshev case the computation of best approximations can be carried out by various methods such as linear programming, variations of the Remes algorithm, the Lawson algorithm, or other ideas; see [24] and the references therein. In the least-squares case the computation of best approximants is a matter of routine linear algebra. One can use a QR decomposition, for example, and that is exactly what GMRES does.

There are two reasons to pay special attention to the case in which A is normal. First, some matrices are normal or close enough to normal that the results one obtains are sometimes applicable in practice. In particular, the CR and Lanczos iterations fall in this category since symmetric matrices are normal. Second, most people's intuitions about the behavior of matrices are based on the normal case [26]. By studying how the normal case differs from the general case we obtain a valuable check on our intuitions.

5. Existence and uniqueness. We return now to problems (1)–(4) for matrices A that are arbitrary, i.e., not necessarily normal. The most fundamental questions to be asked about (1)–(4) are those of existence and uniqueness. For (1) and (2) the answers to both are straightforward and well known. For (3) and (4), existence is straightforward but uniqueness is not. So far as we are aware, though this seems surprising, the uniqueness of the solutions to (3) and (4) is a new result.

THEOREM 2. *The optimal polynomials p_*, p^*, q_*, q^* all exist. Provided that the minima in* (1)–(4) *are nonzero, and provided in the cases of* GMRES *and ideal* GMRES *that A is nonsingular, they are unique.*

Proof. Consider the formulations (1′)–(4′). In each case we have a problem of the form $y \approx V$, where V is a finite-dimensional subspace of a vector space W and $y \in W$. (For (1) and (2), V and W are spaces of N-vectors, whereas for (3) and (4) they are spaces of $N \times N$ matrices; generically we can speak of "vectors" in either case.) Existence of a closest point $v \in V$ to y follows by a standard compactness argument that can be found in any book on approximation theory. See, for example, [2, p. 20] or [13, p. 17].

The question of uniqueness of the polynomials p_*, p^*, q_*, q^* can be divided into two parts:

(a) Is the closest point $v \in V$ to y unique?

(b) Does it have a unique representation as a linear combination of the n vectors indicated in (1′)–(4′)?

Part (b) can be dispatched as follows. What we have to show is that the n vectors in question are linearly independent. Consider first the ideal Arnoldi problem (4′), and suppose to the contrary that $I, A, \ldots, A^{n-1}$ are linearly dependent. Then by multiplying by a power of A if necessary we can find a linear combination of them that is zero and in which the coefficient

of A^{n-1} is nonzero. Thus $A^{n-1} \in \langle I, A, \ldots, A^{n-2} \rangle$, which implies $A^n \in \langle A, A^2, \ldots, A^{n-1} \rangle$ and therefore $\|q^*(A)\| = 0$, contradicting the assumption that the minimum in (4) is nonzero. An analogous argument applies to (2′). For the GMRES problem (3′), suppose $A, A^2, \ldots, A^n$ are linearly dependent, which by a similar argument implies $A^n \in \langle A, A^2, \ldots, A^{n-1} \rangle$ and thus again $\|q^*(A)\| = 0$. If the constant term of q^* is nonzero, then dividing by that constant term yields a properly normalized GMRES polynomial q_* with $\|q_*(A)\| = 0$. On the other hand if the constant term is zero, then since A is nonsingular we can multiply by A^{-1} one or more times until it becomes nonzero. An analogous argument applies to (1′).

This brings us to part (a) of the proof of uniqueness. For problems (1′) and (2′) the uniqueness of v follows by another standard result in approximation theory, since the vector norm $\|\cdot\|$ is strictly convex. See, for example, [2, p. 23] or [13, p. 17]. The *matrix* norm $\|\cdot\|$, however, is not strictly convex, and, in general, matrix best approximation problems posed in this norm do not have unique solutions [6], [27]. The following proof of uniqueness for (3′) and (4′) depends on the special property that these problems concern approximation by matrix polynomials, not by arbitrary linear combinations of matrices.

Consider first the ideal Arnoldi problem (4). Suppose that q_1 and q_2 are two distinct solutions to (4), and let the minimal norm they attain be

$$\|q_1(A)\| = \|q_2(A)\| = C.$$

If we define $q(z) = \frac{1}{2}(q_1(z) + q_2(z))$, then $\|q(A)\| \le C$, so we must have $\|q(A)\| = C$ since q_1 and q_2 are minimal. Let $w_1, \ldots, w_J$ be a set of maximal right singular vectors for $q(A)$, i.e., a set of orthonormal vectors with

$$\|q(A)w_j\| = C, \qquad 1 \le j \le J,$$

with J as large as possible. For each w_j we must have

$$\|q_1(A)w_j\| \;=\; \|q_2(A)w_j\| \;=\; C$$

and

$$q_1(A)w_j \;=\; q_2(A)w_j,$$

for otherwise, by the strict convexity of the vector norm $\|\cdot\|$, we would have $\|q(A)w_j\| < C$. Thus

$$(q_2 - q_1)(A)w_j = 0, \qquad 1 \le j \le J.$$

Now since $(q_2 - q_1)(z)$ is not identically zero, we can multiply it by a scalar and a suitable power of z to obtain a monic polynomial $\Delta q \in P^n$ such that

$$\Delta q(A)w_j = 0, \qquad 1 \le j \le J.$$

For $\epsilon \in (0, 1)$, consider now the polynomial $q_\epsilon \in P^n$ defined by the convex linear combination

$$q_\epsilon(z) \;=\; (1-\epsilon)q(z) + \epsilon\, \Delta q(z).$$

If $w_{J+1}, \ldots, w_N$ denote the remainder of a set of N singular vectors of $q(A)$, with corresponding singular values $C > \sigma_{J+1} \ge \cdots \ge \sigma_N \ge 0$, then we have

$$\|q_\epsilon(A)w_j\| \;\le\; \begin{cases} (1-\epsilon)C & (1 \le j \le J), \\ (1-\epsilon)\sigma_{J+1} + \epsilon\,\|\Delta q(A)\| & (J+1 \le j \le N). \end{cases}$$

The first row is $< C$ for arbitrary ϵ, and the second row is $< C$ for sufficiently small ϵ, since $\sigma_{J+1} < C$. Since the singular vectors $w_1, \ldots, w_N$ form an orthonormal basis for $\mathbf{R}^N$, this implies that $\|q_\epsilon(A)\| < C$ for sufficiently small ϵ, contradicting the assumption that q_1 and q_2 are minimal.

For the ideal GMRES problem (3), the argument is the same except that from $q_2 - q_1$ we need to construct $\Delta q \in P_n$ rather than $\Delta q \in P^n$. If the constant term of $q_2 - q_1$ is nonzero, we do this by dividing by that term. If it is zero, we make use of the assumption that A is nonsingular and multiply by a suitable power of z^{-1}. □

6. Computations. If A is normal, the ideal Arnoldi and GMRES polynomials q^* and q_* are simply Chebyshev polynomials for the set $\Lambda(A)$, as noted in §4, and can be computed by various algorithms. If A is not normal, however, we know of no simple algorithm that is guaranteed to compute q^* and q_*. For simplicity, from now on we shall consider the ideal GMRES polynomial q_*; our remarks carry over straightforwardly to the ideal Arnoldi problem.

We have found that in many cases, q_* can be computed by using an optimization code to determine an initial vector b, with $\|b\| = 1$, for which $\|p_*(A)b\|$ is maximal at the prescribed step n. From Theorem 1 we have

$$\|p_*(A)b\| \leq \|q_*(A)\| \leq \|p_*(A)\| \tag{7}$$

for any b with $\|b\| = 1$. If a choice of b can be found for which $\|p_*(A)b\| = \|p_*(A)\|$, it follows that $p_* = q_*$. It is not known whether such a b always exists, but we conjecture that it does (see the first question of the next section). Maximizing the left-hand side of (7) seems to be easier in practice than minimizing the right-hand side, presumably because the latter problem is nonsmooth. We have carried out our computations using the Matlab optimization routine `fminu` [15] coupled with a GMRES subprogram to compute $\|p_*(A)b\|$ for a given vector b. Although several attempts with different initial guesses b are often required for the optimization code to succeed, it usually does so eventually.

Figure 1 illustrates the behavior of the ideal vs. true GMRES polynomials by a simple example—a matrix of Lenferink and Spijker [12], [26]. This is a nonnormal tridiagonal matrix of the form $\texttt{tridiag}((i+1)^{-1}, -3-2i, i+1)$, $i = 1, \ldots, N$. For the Lenferink–Spijker matrix of order $N = 16$, we computed the ideal GMRES polynomials q_* of degree 1 through 15 as well as the true GMRES polynomials p_* for five different random initial vectors. The thick curve in the figure represents the norms $\|q_*(A)\|$ as a function of n, and the thinner curves represent $\|p_*(A)b\|$ for the various vectors b. The GMRES curves lie below the ideal GMRES curve, as they must, but exhibit qualitatively the same shape. Our experiments have not been sufficiently extensive to draw conclusions about how GMRES and ideal GMRES convergence curves compare in general.

It is interesting to note that while the norm of the ideal GMRES polynomial for this problem decreases strictly monotonically, this does not always happen. For many problems, $\|q_*(A)\|$ remains exactly equal to 1 for a number of steps before it begins to decrease. The case $n = 1$ of this phenomenon is fully understood: one can show that $\|q_*(A)\| < 1$ at step 1 if and only if the field of values of A lies in an open half-plane with respect to the origin in $\mathbf{C}$ (see [3] and [16, §6]). For some problems, $\|q_*(A)\| = 1$ for steps 1 through $N-1$. This happens frequently with random matrices, for example. For such problems there is a right-hand side vector b for which the GMRES algorithm makes no progress whatsoever until step N.

A difference we have observed between the ideal GMRES polynomials for normal and nonnormal matrices is the following. If A is normal, then $q_*(A)$ must have at least $n+1$ equal maximal singular values. This follows from the fact that the degree n Chebyshev polynomial for a set in the complex plane always takes on its maximum absolute value in at least $n+1$

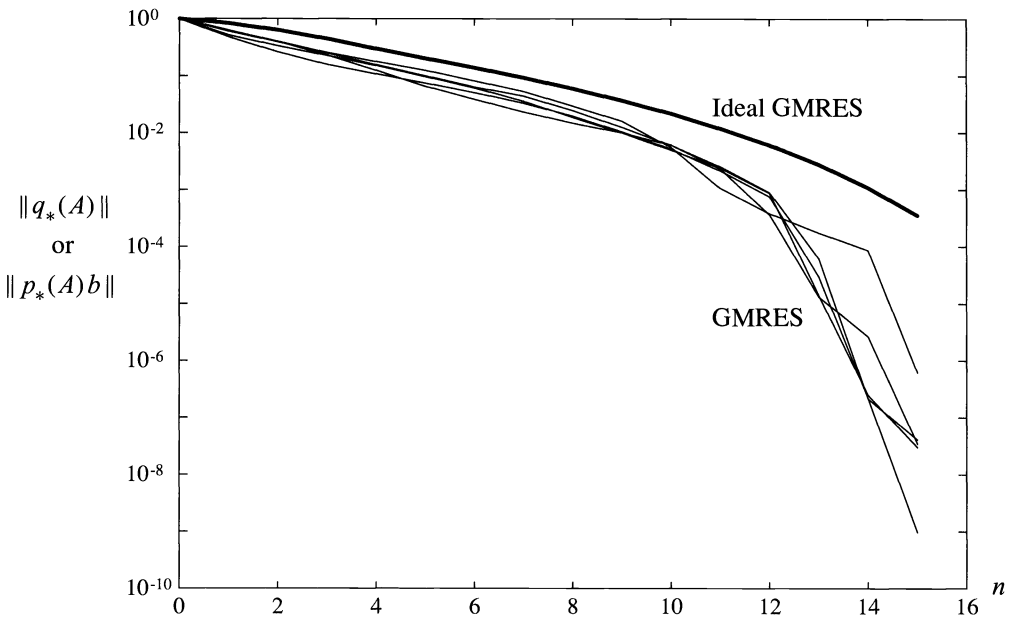

FIG. 1. *Convergence curves for the* 16 × 16 *Lenferink–Spijker matrix. The upper curve corresponds to ideal* GMRES *and the lower curves to standard* GMRES *with five different random initial vectors b.*

distinct points. In contrast, when A is not normal, our experiments indicate that after the initial phase with $\|q_*(A)\| = 1$ just mentioned, $q_*(A)$ usually has only one maximal singular value.

7. Open questions. Our work on ideal GMRES and Arnoldi approximations has raised more questions than it has answered. We shall close with a list of five questions that we consider particularly interesting. In each of the following, A is a matrix, b is a vector normalized by $\|b\| = 1$, and the *convergence curve* is the curve of $\|p_*(A)b\|$ or $\|q_*(A)\|$ as a function of the step number n. The questions are posed for GMRES, but they all have Arnoldi analogues.

1. *Is the envelope attained*? Theorem 1 asserts that the GMRES convergence curve lies below the ideal GMRES convergence curve, as illustrated in Fig. 1. Given n, does there exist an initial vector b such that these two curves intersect at step n, i.e., such that $\|p_*(A)b\| = \|q_*(A)\|$? The answer is known to be yes for symmetric matrices [5] and more generally for normal matrices [6], [10], and for arbitrary matrices at step $n = 1$ [6], [10]. It is also yes in the "generic" nonnormal case in which the maximal singular value of $q_*(A)$ is simple. Whether it is yes in all cases is not known. If it is, then the ideal GMRES convergence curve can be described as the upper envelope of the GMRES convergence curves corresponding to all initial vectors b.

2. *How close is the average case to the worst case*? Assuming that the envelope is attained in the sense above, there is still the question of how closely the GMRES and ideal GMRES convergence curves agree for typical starting vectors. If A is normal, it is easily argued that two agree typically to within a factor on the order of $\sqrt{N}$. We do not know what can be said for general A.

3. *What convergence curves are possible*? At step n, $\|q_*(A)\|$ must be at least as small as $\min_{1\le k\le n-1} \|q_k(A)\| \, \|q_{n-k}(A)\|$, where q_k denotes the ideal GMRES polynomial for A at step k. Geometrically this means that the ideal GMRES convergence curve is convex when plotted on a logarithmic scale. Are all convergence curves that satisfy this convexity constraint

possible? If not, how can one characterize those convergence curves that are possible?

4. *Can any matrix be simulated by a normal matrix*? Short of a full characterization of convergence curves, one may naturally ask if the possibilities for normal matrices are more restricted than for nonnormal matrices. In other words, are there convergence curves that can only be generated by a nonnormal matrix? For standard GMRES the answer has recently been proved to be no; any sequence $\| p_*(A)b \|$ as a function of n can be duplicated by another sequence $\| p_*(\tilde{A})b \|$ where $\tilde{A}$ is normal—in fact, unitary [7]. For ideal GMRES, the answer is unknown.

5. *Is there a variant of Lawson's algorithm for ideal* GMRES *approximation*? In our experience the "brute force" use of a general optimization program such as `fminu` to compute p_*, as described in the last section, is neither efficient nor reliable. As an alternative we have found that one can sometimes maximize the left-hand side of (7) by means of an iteration modeled on Lawson's algorithm, which is a method of iteratively reweighted least squares that has been proved convergent for problems of scalar L^∞ approximation [19]. We have obtained good results this way in many cases, but have not succeeded in developing a method of this kind that converges consistently (and consequently we will not provide details here). Can a matrix variant of Lawson's algorithm with guaranteed convergence be devised for the ideal GMRES problem?

Acknowledgments. We are happy to acknowledge discussions with Michael Overton, who showed us how the ideal Arnoldi and GMRES problems relate to more general problems of minimization of singular values of functions of matrices [17].

ALTERNATING DIRECTION PRECONDITIONING FOR NONSYMMETRIC SYSTEMS OF LINEAR EQUATIONS*

GERHARD STARKE†

Abstract. Preconditioning strategies based on the application of the alternating direction implicit (ADI) method to large systems of linear equations of the form

$$(H + V)\mathbf{u} = \mathbf{f},$$

where both H and V can be "easily inverted," are presented and analyzed. Besides other applications, such systems arise naturally from finite difference discretizations of two-dimensional elliptic boundary value problems. The emphasis here is on the case where H and V are nonsymmetric.

The use of alternating direction preconditioning is especially attractive for massively parallel computers since, during each iteration, a large number of tridiagonal systems must be solved simultaneously. Numerical experiments are presented comparing ADI with other preconditioners for some examples of discretized nonselfadjoint elliptic boundary value problems including nonseparable cases.

Key words. ADI, nonsymmetric linear systems, elliptic boundary value problems, preconditioning, parallel computing

AMS subject classifications. 65F10, 65N30

1. Introduction.

We consider systems of linear equations of the form

$$(H + V)\mathbf{u} = \mathbf{f}, \tag{1.1}$$

where H and V are large, sparse, and, in general, nonsymmetric matrices. Moreover, both H and V are assumed to be "easily invertible," in the sense that the solution of linear systems with H and V is cheap compared to the solution of the original system (1.1). Such linear systems arise in connection with Lyapunov and Sylvester matrix equations in control theory and from finite difference and finite element discretizations of elliptic boundary value problems.

Our purpose in this paper is to study the use of the alternating direction implicit (ADI) method, which was originally proposed by Peaceman and Rachford [23] in 1955, as a preconditioning technique for Krylov subspace methods for *nonsymmetric* linear systems. It turns out that this leads to a very effective preconditioner, especially for two-dimensional elliptic difference equations. For separable nonselfadjoint elliptic equations, it can be shown that the number of iterations required to achieve a certain accuracy is proportional to $O(h^{-1/2})$ as $h \to 0$ for the stationary ADI method. Moreover, using l different parameters in a cyclic fashion, the iteration count can be reduced to $O(h^{-1/4})$ for $l = 2$ and to $O(\log h^{-1})$ for $l = \log h^{-1}$ similarly to the selfadjoint case. ADI preconditioning can, in contrast to many other techniques, e.g., symmetric successive overrelaxation (SSOR) or fast direct solvers, be implemented on a variety of parallel architectures in a straightforward way.

The idea to use ADI as a preconditioner goes back to the 1960s. In 1961, D'Yakonov [7] studied the combination of ADI and the Chebyshev method in an inner-outer iteration fashion. To solve symmetric positive definite linear systems, ADI was used as a preconditioner for the conjugate gradient method and was studied by Wachspress ([32, pp. 214], see also [33]). There, a number of steps of the ADI method, applied to a model problem (e.g., the Poisson equation), were used to precondition more general diffusion equations. Chin, Manteuffel, and de Pillis

*Received by the editors May 18, 1992; accepted for publication (in revised form) April 6, 1993. This work, done while the author was visiting the Institute for Mathematics and its Applications at the University of Minnesota during the first three months of 1992, was supported by the Alexander-von-Humboldt-Stiftung.

†Institut für Praktische Mathematik, Universität Karlsruhe, Englerstrasse 2, 76128 Karlsruhe, Germany (starke@ipmsun1.mathematik.uni-karlsruhe.de).

used ADI as a preconditioner for nonsymmetric systems that arise from convection-diffusion problems. Recently, a number of papers focused on the performance of the ADI method on different parallel architectures (for a survey and a list of references, see Johnsson, Saad, and Schultz [19]). A new approach to alternating direction preconditioning on multiprocessors for symmetric positive definite systems was presented by Jiang and Wong [18].

Our approach to the construction of an ADI preconditioner for nonsymmetric systems of the form (1.1) is motivated by the one in Chin, Manteuffel, and de Pillis [3]. There, the stationary ADI method is used to precondition the Chebyshev iteration, i.e., instead of solving the original system (1.1), the left preconditioned system

$$(V + \psi I)^{-1}(H + \varphi I)^{-1}(H + V)\mathbf{u} = (V + \psi I)^{-1}(H + \varphi I)^{-1}\mathbf{f}$$

or the right preconditioned system

$$(H + V)(V + \psi I)^{-1}(H + \varphi I)^{-1}\mathbf{v} = \mathbf{f}\,, \qquad \mathbf{u} = (V + \psi I)^{-1}(H + \varphi I)^{-1}\mathbf{v}$$

are considered. In §2 this type of *alternating direction preconditioning* will be introduced and generalized to higher degree, i.e., using polynomials

$$p_l(H) = (H + \varphi_1 I)\cdots(H + \varphi_l I)\,, \qquad q_l(V) = (V + \psi_1 I)\cdots(V + \psi_l I)$$

instead of $H + \varphi I$, $V + \psi I$, respectively. Furthermore, we point out relations between the preconditioned matrices and corresponding ADI iteration operators. After that, in §3, we discuss the question of how to choose the parameters $\varphi_1, \ldots, \varphi_l$ and $\psi_1, \ldots, \psi_l$ to get a well-preconditioned system. Convergence bounds for Krylov subspace methods (which exist, e.g., for the generalized minimal residual (GMRES) and the quasi-minimal residual (QMR) algorithms) will be used to show that it is a good idea to choose the parameters in such a way that the spectral radius of the associated ADI iteration operator is minimized. If H and V commute, this leads to a classical minimization problem for rational functions, the so-called "rational Zolotarev problem" (see, e.g., [27]). In the noncommutative case, only weaker bounds based on norm estimates are possible.

From §4 on, we will restrict ourselves to the *model problem* of *finite difference* discretizations of second-order elliptic equations on *rectangular two-dimensional domains* to illustrate our analysis and to test our techniques. We will, however, allow *nonseparable* and *nonselfadjoint* problems. Following Elman and Schultz ([12], see also Elman [10]), we consider elliptic equations of the type

$$-(au_x)_x - (bu_y)_y + cu_x + (cu)_x + du_y + (du)_y + eu = f \tag{1.2}$$

on a rectangular region $\Omega \subseteq \mathbb{R}^2$ (let, without loss of generality, Ω be the unit square $(0, 1) \times (0, 1)$) with Dirichlet boundary conditions on $\partial\Omega$. The functions $a(x, y)$, $b(x, y)$, $c(x, y)$, and $d(x, y)$ are assumed to be in $C^1(\Omega) \cap C(\overline{\Omega})$ and $e(x, y)$ to be continuous on $\overline{\Omega}$. The discretization of this elliptic boundary value problem by finite differences on an $n \times n$ grid leads to a linear system of the form (1.1), where H and V are the parts of the difference operator that arise from the derivatives in the x- and in y-direction, respectively. Both matrices, H and V, are usually large and sparse with a very regular structure. For example, if we use centered differences for the second-order terms as well as for the first-order terms, then H is a block diagonal matrix with tridiagonal blocks $H_{ii} \in \mathbb{R}^{n,n}$, $i = 1, \ldots, n$, and V is a block tridiagonal matrix where the blocks are diagonal matrices of order n.

It was already observed by Peaceman and Rachford in [23] that, for the solution of Poisson's equation on a rectangle, parameters for the ADI method can be found such that the

number of operations that is necessary to approximate the solution to a given accuracy is of the order $O(n^2 \log n)$ ($\log n$ is the required number of ADI iterations, each of which consists of the solution of n tridiagonal systems of order n). In §4, we will show that the same complexity can be achieved for general separable elliptic problems, i.e., if we have

(1.3)
$$a(x, y) \equiv a(x),\ b(x, y) \equiv b(y),\ c(x, y) \equiv c(x),\ d(x, y) \equiv d(y),\ e(x, y) = e_1(x) + e_2(y),$$

in (1.2). In practice, however, we might not want to increase the degree of the ADI preconditioner with n. Instead, it is often sufficient to choose $l = 2$, which already leads to an iteration count of $O(n^{1/4})$.

A lot of research has been done in the last 30 years to apply the alternating direction idea to more general problems than (1.2). Alternating direction methods in three dimensions were studied by Douglas [5], and the application to mixed finite element methods was discussed by Douglas, Durán, and Pietra [6]. Mixed derivatives in (1.2) can be treated with the technique proposed by Beam and Warming [1]. The use of the ADI method for the numerical solution of Navier–Stokes equations is described in Beam and Warming [2]; a variant for nonlinear variational problems is described in Glowinski [16]. The ADI method as an iterative method for the solution of Lyapunov matrix equations has been investigated by Wachspress in [34] (see also [17] for the application of the techniques presented in this paper to such matrix equations).

Fast direct algorithms for the solution of separable elliptic equations that also require $O(n^2 \log n)$ operations have been designed in the last 20 years (see, e.g., Swarztrauber [29] for block cyclic reduction, which is also applicable to nonselfadjoint problems). For nonseparable (and nonselfadjoint) problems, preconditioning by a "nearby" separable problem that is solved by a fast direct method was studied by Concus and Golub [4], Widlund [36], and Elman and Schultz [12].

Our motivation for this work is the fact that the ADI method is especially attractive for parallel computers. In contrast to other preconditioners that are currently used in this context, such as SSOR or the above mentioned fast methods, this technique has the advantage of being very easy and straightforward to (massively) parallelize on a variety of architectures. In each iteration, we first perform operations (multiplication by tridiagonal matrices and solving tridiagonal systems) independently on each column of the grid, and then, in the second half of the iteration, we do the same independently on each row. An architecture that seems to be perfectly suited for this method is the arrangement of the processors in a two-dimensional grid. There is, however, a bottleneck in the transfer between the half-steps since we must switch from rowwise to columnwise communication or vice versa. Techniques to overcome this problem on different multiprocessor architectures are discussed in Johnsson, Saad, and Schultz [19]. In any case, routines for the efficient solution of a large number of independent tridiagonal systems are now available in software libraries on parallel machines (see [30, Chap. 11] for the CM-5).

Finally, in §5, we present numerical experiments for some examples of discretized elliptic boundary value problems, including nonselfadjoint and nonseparable cases. Besides comparing ADI to other preconditioners, we will also use different Krylov subspace methods as acceleration schemes.

2. Alternating direction preconditioning. In this section we will show how to construct effective preconditioners, based on the ADI method, for linear systems of the form (1.1). Let us first consider the stationary case $l = 1$ that was studied earlier by Chin, Manteuffel, and de Pillis in [3]. Their preconditioning strategy has the form

$$(V + \psi I)^{-1}(H + \varphi I)^{-1}(H + V)\mathbf{u} = (V + \psi I)^{-1}(H + \varphi I)^{-1}\mathbf{f} \tag{2.1}$$

(left preconditioning) or

$$(H+V)(V+\psi I)^{-1}(H+\varphi I)^{-1}\mathbf{v}=\mathbf{f}\,,\qquad \mathbf{u}=(V+\psi I)^{-1}(H+\varphi I)^{-1}\mathbf{v} \tag{2.2}$$

(right preconditioning).

When using one of the Krylov subspace methods for nonsymmetric systems (like biconjugate gradient (Bi-CG), conjugate gradient squared (CGS), QMR, GMRES), the goal is to get the preconditioned problem "as close as possible" to the identity operator, in the sense that the eigenvalues of the operator approximate a positive constant. This can be motivated heuristically by the fact that the preconditioned operator being close to the identity means, roughly speaking, that we have already "inverted most" of the linear system. This will be discussed, in more detail, in terms of error bounds for Krylov subspace methods in §3.

Our aim is to choose the parameters φ and ψ in such a way that the spectrum of the preconditioned matrix

$$\Omega_1 := \sigma((V+\psi I)^{-1}(H+\varphi I)^{-1}(H+V)) = \sigma((H+V)(V+\psi I)^{-1}(H+\varphi I)^{-1}) \tag{2.3}$$

is as close as possible to a positive constant. The following theorem provides a connection between the distance of the preconditioned matrix to the identity and the spectral radius of the ADI iteration operator, which is given by

$$(V+\psi I)^{-1}(H-\psi I)(H+\varphi I)^{-1}(V-\varphi I)$$

(see [27]).

THEOREM 2.1. *With the constant $c=\varphi+\psi$, we have*

$$\max\{|1-c\tau| : \tau\in\Omega_1\} = \rho((H+\varphi I)^{-1}(H-\psi I)(V+\psi I)^{-1}(V-\varphi I))\,. \tag{2.4}$$

Proof. The relation (2.4) follows directly from

$$\begin{aligned} &I-(\varphi+\psi)(V+\psi I)^{-1}(H+\varphi I)^{-1}(H+V)\\ &=(V+\psi I)^{-1}(H+\varphi I)^{-1}(H-\psi I)(V-\varphi I)\,, \end{aligned} \tag{2.5}$$

and

$$\begin{aligned} &I-(\varphi+\psi)(H+V)(V+\psi I)^{-1}(H+\varphi I)^{-1}\\ &=(H-\psi I)(V-\varphi I)(V+\psi I)^{-1}(H+\varphi I)^{-1}\,. \end{aligned} \tag{2.6}$$

□

It will turn out to be important for the analysis of this ADI preconditioning technique that, from (2.5) and (2.6), instead of multiplying a vector $\mathbf{x}$ with the preconditioned matrix, one can compute

$$\mathbf{x}-(V+\psi I)^{-1}(H+\varphi I)^{-1}(H-\psi I)(V-\varphi I)\mathbf{x} \tag{2.7}$$

in the case of left preconditioning and

$$\mathbf{x}-(H-\psi I)(V-\varphi I)(V+\psi I)^{-1}(H+\varphi I)^{-1}\mathbf{x} \tag{2.8}$$

for right preconditioning, respectively. It is obvious that this requires exactly the same amount of work as the application of the preconditioned operator to $\mathbf{x}$. This implies that we could as well implement the preconditioner in this way as acceleration of the ADI iterative method.

Because of this representation of the ADI preconditioned matrix as a rational function in H and V, we will also use the term *rational preconditioning*.

In what follows, we restrict our attention to preconditioning from the right as in (2.2). Rational preconditioners of higher order can be constructed in the following way. Let the polynomials $p_l(z) = (z+\varphi_1)\cdots(z+\varphi_l)$ and $q_l(z) = (z+\psi_1)\cdots(z+\psi_l)$ be given, then the operator

$$I - q_l(-H)p_l(-V)[q_l(V)]^{-1}[p_l(H)]^{-1} \tag{2.9}$$

is the natural generalization of (2.2). Note that, for the construction of these alternating direction preconditioners, we did not make any assumption on commutativity of the matrices H and V.

3. Convergence bounds. Convergence bounds for conjugate gradient (CG)-like methods for nonsymmetric systems usually involve the size of the residual polynomial on the spectrum of the (preconditioned) operator. For example, for the GMRES algorithm (see Saad and Schultz [25]), if the corresponding coefficient matrix A can be diagonalized such that $A = T\Lambda T^{-1}$, one obtains

$$\frac{\|\mathbf{r}_m\|_2}{\|\mathbf{r}_0\|_2} \le \|T\|_2 \, \|T^{-1}\|_2 \min_{\Phi_m \in \Pi_m, \Phi_m(0)=1} \max_{z\in\sigma(A)} |\Phi_m(z)| \, . \tag{3.1}$$

Here, Π_m denotes the polynomials of degree $\le m$. A weaker bound for the error reduction that also involves

$$\min_{\Phi_m \in \Pi_m, \Phi_m(0)=1} \max_{z\in\sigma(A)} |\Phi_m(z)| \tag{3.2}$$

holds, under certain assumptions, for the QMR algorithm by Freund and Nachtigal [15]. If A is not diagonalizable, then similar bounds are valid that involve derivatives at certain eigenvalues (where the corresponding Jordan blocks have size > 1). A convergence result that depends on the size of $\Phi_m(z)$ and $\Phi_m'(z)$ was shown for the transpose-free QMR method proposed by Freund in [14] (see [13, Thm. 6]). In any case, the convergence of these iterative methods is governed by (3.2).

Since, for nonnormal matrices, the condition number $\|T\|_2 \, \|T^{-1}\|_2$ (or the corresponding expression for the QMR bound) can be quite large, it is important that convergence bounds are known that are not based on eigenvalues. These bounds are based on polynomial approximations on sets containing the spectrum of A like the ε-pseudo-spectra (see [22, Thm. 4]) or the field of values (see [9, Thm. 1]). We will not pursue this further and instead will follow the approach based on (3.1).

Our goal is to choose the parameters φ and ψ in such a way that

$$\min_{\Phi_m \in \Pi_m, \Phi_m(0)=1} \max_{z\in\Omega} |\Phi_m(z)| \tag{3.3}$$

with

$$\begin{aligned} \Omega_1 &= \sigma((H+\varphi I)^{-1}(H+V)(V+\psi I)^{-1}) \\ &= 1 - \sigma((H+\varphi I)^{-1}(H-\psi I)(V-\varphi I)(V+\psi I)^{-1}) \end{aligned}$$

(see (2.3)) is as small as possible. In the case that Ω_1 is a real interval (which is fulfilled, for example, if the eigenvalues of H and V are real and H and V commute), this leads to the problem

$$\min_{\varphi,\psi} \rho((H+\varphi I)^{-1}(H-\psi I)(V-\varphi I)(V+\psi I)^{-1}) \, , \tag{3.4}$$

i.e., minimizing the spectral radius of the corresponding ADI iteration matrix. If Ω_1 is not contained on the real line, and if we do not have any further information about the shape of Ω_1, our aim is still to choose φ and ψ in such a way that Ω_1 is as far away from the origin as possible. This again leads to (3.4). We remark that, for complex Ω_1, it is not rigorously justified that choosing the parameters φ and ψ in this way leads to the best possible Ω_1 for (3.3). Instead, it might be advantageous to minimize the largest imaginary part of Ω_1, although this would lead to a smaller distance to the origin. It was actually observed by Chin, Manteuffel, and de Pillis [3] that choosing the parameters according to (3.4) does not necessarily lead to the best (overall) convergence for ADI accelerated by the Chebyshev iteration in the case of complex spectra. For simplicity, we will, however, determine φ and ψ from (3.4). Analogously, for $l > 1$, (2.9) leads to

$$\min_{p_l, q_l \in \Pi_l} \rho([p_l(H)]^{-1} q_l(-H)\, p_l(-V)[q_l(V)]^{-1}) \,. \tag{3.5}$$

If H and V commute, we can transform H and V simultaneously into Schur form (see, e.g., Marcus and Minc [21, p. 77]), i.e., there exists a unitary matrix U such that $U^H H U$ and $U^H V U$ are both upper triangular. This assumption about commutativity is fulfilled, e.g., for discretized elliptic boundary value problems if the differential operator is separable (see (1.3)), and for Lyapunov and Sylvester matrix equations. Under these circumstances, we have

$$\begin{aligned}
&\rho([p_l(H)]^{-1} q_l(-H)\, p_l(-V)[q_l(V)]^{-1}) \\
&= \rho([U^H p_l(H) U]^{-1} U^H q_l(-H) U U^H p_l(-V) U [U^H q_l(V) U]^{-1}) \\
&\le \max_{\lambda \in \sigma(V)} \left| \frac{p_l(-\lambda)}{q_l(\lambda)} \right| \max_{\mu \in \sigma(H)} \left| \frac{q_l(-\mu)}{p_l(\mu)} \right|
\end{aligned}$$

leading to the rational minimization problem

$$\min_{p_l, q_l \in \Pi_l} \left[\max_{\lambda \in \sigma(V)} \left| \frac{p_l(-\lambda)}{q_l(\lambda)} \right| \max_{\mu \in \sigma(H)} \left| \frac{q_l(-\mu)}{p_l(\mu)} \right| \right] . \tag{3.6}$$

If $\sigma(V)$ and $\sigma(H)$ are replaced by arbitrary compact subsets of the complex plane, this is the so-called rational Zolotarev problem. For different approaches to this approximation problem, see [27] and references therein. The results in [27], and the numerical experiments in §5 of this paper, indicate that the main improvement of the convergence rate takes place when we use two parameters instead of one, especially for nonsymmetric problems. Explicit formulas for the optimal parameters for $l = 2$ are known for special regions, e.g., rectangles, enclosing $\sigma(H)$ and $\sigma(V)$ (see, again, [27]). On the other hand, these parameters can also be computed cheaply in many situations using minimization procedures. It is also possible to use the generalized Leja points discussed in [27] that solve the rational Zolotarev problem in an asymptotic sense. ADI with these Leja points as parameters could then be combined with the adaptive Chebyshev iteration [20] or iterative methods based on Faber polynomials (see [8] and [28]).

In the noncommutative case we can still get bounds for the location of the spectrum of the preconditioned operator using norm estimates. Obviously,

$$\rho([p_l(H)]^{-1} q_l(-H)\, p_l(-V)[q_l(V)]^{-1}) \le \|[p_l(H)]^{-1} q_l(-H)\|_2 \, \|p_l(-V)[q_l(V)]^{-1}\|_2 \,.$$

If H and V are symmetric, we have

$$\|[p_l(H)]^{-1} q_l(-H)\|_2 = \rho([p_l(H)]^{-1} q_l(-H)) = \max_{\mu \in \sigma(H)} \left| \frac{q_l(-\mu)}{p_l(\mu)} \right|$$

and

$$\|p_l(-V)[q_l(V)]^{-1}\|_2 = \rho(p_l(-V)[q_l(V)]^{-1}) = \max_{\lambda \in \sigma(V)} \left| \frac{p_l(-\lambda)}{q_l(\lambda)} \right| ,$$

which again leads to the rational expression (3.6) as an upper bound for the spectral radius of the ADI operator. It should be remarked that these norm estimates for the noncommutative case depend on the fact that we apply the ADI preconditioner in the form (2.9), i.e., in such a way that the terms with H and V are separated.

If H and V are nonsymmetric (and do not commute), then only much weaker results can be obtained. For the case $l = 1$, with real parameters φ and ψ, we get

$$\|(H+\varphi I)^{-1}(H-\psi I)\|_2^2 = \max_{\|\mathbf{x}\|_2=1} \frac{\|(H-\psi I)\mathbf{x}\|_2^2}{\|(H+\varphi I)\mathbf{x}\|_2^2}$$

$$= \max_{\|\mathbf{x}\|_2=1} \frac{\mathbf{x}^T(H^T-\psi I)(H-\psi I)\mathbf{x}}{\mathbf{x}^T(H^T+\varphi I)(H+\varphi I)\mathbf{x}} = \max_{\|\mathbf{x}\|_2=1} \frac{\|H\mathbf{x}\|_2^2 - \psi\mathbf{x}^T(H+H^T)\mathbf{x} + \psi^2}{\|H\mathbf{x}\|_2^2 + \varphi\mathbf{x}^T(H+H^T)\mathbf{x} + \varphi^2}$$

$$\le \max_{\|\mathbf{x}\|_2=1} \frac{\|H\mathbf{x}\|_2 - 2\psi \min \mathrm{Re}W(H) + \psi^2}{\|H\mathbf{x}\|_2 + 2\varphi \min \mathrm{Re}W(H) + \varphi^2} \le \frac{\|H\|_2^2 - 2\psi \min \mathrm{Re}W(H) + \psi^2}{\|H\|_2^2 + 2\varphi \min \mathrm{Re}W(H) + \varphi^2},$$

where $W(H)$ and $W(V)$ denote the field of values of the matrices H and V. Analogously, we obtain

$$\|(V-\varphi I)(V+\psi I)^{-1}\|_2^2 \le \frac{\|V\|_2^2 - 2\varphi \min \mathrm{Re}W(V) + \varphi^2}{\|V\|_2^2 + 2\psi \min \mathrm{Re}W(V) + \psi^2},$$

which leads to

$$\begin{aligned} &\rho((H+\varphi I)^{-1}(H-\psi I)(V-\varphi I)(V+\psi I)^{-1}) \\ &\le \frac{\|H\|_2^2 - 2\psi \min \mathrm{Re}W(H) + \psi^2}{\|H\|_2^2 + 2\varphi \min \mathrm{Re}W(H) + \varphi^2} \cdot \frac{\|V\|_2^2 - 2\varphi \min \mathrm{Re}W(V) + \varphi^2}{\|V\|_2^2 + 2\psi \min \mathrm{Re}W(V) + \psi^2}. \end{aligned} \tag{3.7}$$

4. Application to elliptic boundary value problems. We now apply the bounds derived in the last section to the elliptic boundary value problem (1.2). We use centered difference approximations for all the derivatives, which means that the operators H and V are defined by

$$\begin{aligned} [Hu]_{i,j} &= (a_{i,j+1/2} + a_{i,j-1/2})u_{i,j} - a_{i,j+1/2}u_{i,j+1} - a_{i,j-1/2}u_{i,j-1} \\ &\quad + [(c_{i,j} + c_{i,j+1})u_{i,j+1} - (c_{i,j} + c_{i,j-1})u_{i,j-1}]h/2 + e_{i,j}u_{i,j}h^2/2, \\ [Vu]_{i,j} &= (b_{i+1/2,j} + b_{i-1/2,j})u_{i,j} - b_{i+1/2,j}u_{i+1,j} - b_{i-1/2,j}u_{i-1,j} \\ &\quad + [(d_{i,j} + d_{i+1,j})u_{i+1,j} - (d_{i,j} + d_{i-1,j})u_{i-1,j}]h/2 + e_{i,j}u_{i,j}h^2/2, \end{aligned} \tag{4.1}$$

where $h = 1/(n+1)$. Let the numbers $\underline{a}, \overline{a}, \underline{b}, \overline{b}, \overline{c}$, and $\overline{d}$ be given such that

$$0 < \underline{a} \le a(x,y) \le \overline{a}, \quad 0 < \underline{b} \le b(x,y) \le \overline{b},$$
$$|c(x,y)| \le \overline{c}, \quad |d(x,y)| \le \overline{d}$$

on $(0,1) \times (0,1)$. With these bounds we obtain, for any matrix representation of the difference operators defined by (4.1),

(4.2)

$$\begin{aligned} \mathrm{Re}\sigma(H) \subseteq \mathrm{Re}W(H) \subseteq \sigma((H+H^T)/2) \subseteq [2\underline{a}(1-\cos\pi h), 2\overline{a}(1+\cos\pi h)] =: [\alpha_H, \beta_H], \\ \mathrm{Re}\sigma(V) \subseteq \mathrm{Re}W(V) \subseteq \sigma((V+V^T)/2) \subseteq [2\underline{b}(1-\cos\pi h), 2\overline{b}(1+\cos\pi h)] =: [\alpha_V, \beta_V], \\ \mathrm{Im}\sigma(H) \subseteq \mathrm{Im}W(H) \subseteq \sigma(i(H-H^T)/2) \subseteq [-2h\overline{c}, 2h\overline{c}] =: [-\gamma_H, \gamma_H], \\ \mathrm{Im}\sigma(V) \subseteq \mathrm{Im}W(V) \subseteq \sigma(i(V-V^T)/2) \subseteq [-2h\overline{d}, 2h\overline{d}] =: [-\gamma_V, \gamma_V]. \end{aligned}$$

In what is to follow, we will also use

$$\alpha := \min\{\alpha_H, \alpha_V\} = 2\min\{\underline{a}, \underline{b}\}(1 - \cos \pi h) ,$$
$$\beta := \max\{\beta_H, \beta_V\} = 2\max\{\overline{a}, \overline{b}\}(1 + \cos \pi h) ,$$
$$\gamma := \max\{\gamma_H, \gamma_V\} = 2h \max\{\overline{c}, \overline{d}\} .$$

Note that $\alpha = O(h^2)$ and $\gamma = O(h)$ for $h \to 0$.

We are interested in the location of the eigenvalues of the preconditioned operator as $h \to 0$. It can be shown that the matrices H and V can be transformed into real symmetric matrices if $h\overline{c} < 1$ and $h\overline{d} < 1$, respectively. This implies that, for sufficiently small h, the spectra of H and V will be contained on the real line, more precisely,

$$\sigma(H) \subseteq [\alpha, \beta] , \qquad \sigma(V) \subseteq [\alpha, \beta] .$$

Let us first investigate the separable case, i.e., we assume that (1.3) is fulfilled. In this case, it is well known that H and V commute (see [31, §7.3] and [27] for a different point of view in terms of matrix equations). Let φ^* and ψ^* denote the optimal ADI parameters with respect to $\sigma(H)$ and $\sigma(V)$ (see the following section for questions on how to find these parameters); then, for $\varphi = \psi = \sqrt{\alpha\beta}$, we have

$$\max_{\lambda\in\sigma(V)} \left|\frac{\lambda - \varphi^*}{\lambda + \psi^*}\right| \max_{\mu\in\sigma(H)} \left|\frac{\mu - \psi^*}{\mu + \varphi^*}\right| \le \max_{\lambda\in\sigma(V)} \left|\frac{\lambda - \sqrt{\alpha\beta}}{\lambda + \sqrt{\alpha\beta}}\right| \max_{\mu\in\sigma(H)} \left|\frac{\mu - \sqrt{\alpha\beta}}{\mu + \sqrt{\alpha\beta}}\right|$$
$$\le \max_{z\in[\alpha,\beta]} \left|\frac{z - \sqrt{\alpha\beta}}{z + \sqrt{\alpha\beta}}\right|^2 = \left(\frac{\sqrt{\beta} - \sqrt{\alpha}}{\sqrt{\beta} + \sqrt{\alpha}}\right)^2 .$$

Hence, by (2.3), we have, for sufficiently small h, for the spectrum Ω_1 of the ADI preconditioned operator,

$$\Omega_1 \subseteq \left[1 - \left(\frac{\sqrt{\beta} - \sqrt{\alpha}}{\sqrt{\alpha} + \sqrt{\beta}}\right)^2 , 1 + \left(\frac{\sqrt{\beta} - \sqrt{\alpha}}{\sqrt{\alpha} + \sqrt{\beta}}\right)^2\right] = \left[\frac{4\sqrt{\alpha\beta}}{(\sqrt{\alpha} + \sqrt{\beta})^2}, \frac{\alpha + \beta}{(\sqrt{\alpha} + \sqrt{\beta})^2}\right] .$$

By straightforward computation of the size of the associated Chebyshev polynomial, this leads to

$$\min_{\Phi_m\in\Pi_m, \Phi_m(0)=1} \max_{z\in\Omega_1} |\Phi_m(z)|$$
$$\le \frac{2(\sqrt{\beta} - \sqrt{\alpha})^{2m}}{[(\sqrt{\beta} + \sqrt{\alpha})^2 + \sqrt{8}(\alpha\beta)^{1/4}(\alpha + \beta)^{1/2}]^m + [(\sqrt{\beta} + \sqrt{\alpha})^2 - \sqrt{8}(\alpha\beta)^{1/4}(\alpha + \beta)^{1/2}]^m}$$
$$\approx 1 - [(4 - \sqrt{2})m + \sqrt{2}m^2] \left(\frac{\alpha}{\beta}\right)^{1/2}$$

Using (3.1), we observe that, to ensure that the residual norm is reduced by a factor of ε,

$$(4 - \sqrt{2})m + \sqrt{2}m^2 \le \left(\frac{\beta}{\alpha}\right)^{1/2} \left(1 - \frac{\varepsilon}{\|T\|_2 \, \|T^{-1}\|_2}\right)$$

must be fulfilled. Since $\alpha = O(h^2)$, this implies that the number of GMRES iterations m is proportional to $n^{1/2}$ (compared to n if we use ADI as an iteration scheme). Similarly, for $l = 2$, if $p_2^*, q_2^* \in \Pi_2$ are the optimal polynomials for (3.6), then

$$\max_{\lambda\in\sigma(V)} \left|\frac{p_2^*(-\lambda)}{q_2^*(\lambda)}\right| \max_{\mu\in\sigma(H)} \left|\frac{q_2^*(-\mu)}{p_2^*(\mu)}\right|$$

$$\leq \max_{z\in[\alpha,\beta]} \left| \frac{z^2 - \sqrt{2}(\alpha\beta)^{1/4}(\alpha+\beta)^{1/2}z + \alpha\beta}{z^2 + \sqrt{2}(\alpha\beta)^{1/4}(\alpha+\beta)^{1/2}z + \alpha\beta} \right|^2 = \left(\frac{(\alpha+\beta)^{1/2} - \sqrt{2}(\alpha\beta)^{1/4}}{(\alpha+\beta)^{1/2} + \sqrt{2}(\alpha\beta)^{1/4}} \right)^2 .$$

Hence, for the spectrum Ω_2 of the corresponding preconditioned system, we have

$$\Omega_2 \subseteq \left[1 - \left(\frac{(\alpha+\beta)^{1/2} - \sqrt{2}(\alpha\beta)^{1/4}}{(\alpha+\beta)^{1/2} + \sqrt{2}(\alpha\beta)^{1/4}} \right)^2 , 1 + \left(\frac{(\alpha+\beta)^{1/2} - \sqrt{2}(\alpha\beta)^{1/4}}{(\alpha+\beta)^{1/2} + \sqrt{2}(\alpha\beta)^{1/4}} \right)^2 \right]$$

$$= \left[\frac{4\sqrt{2}(\alpha\beta)^{1/4}(\alpha+\beta)^{1/2}}{[(\alpha+\beta)^{1/2} + \sqrt{2}(\alpha\beta)^{1/4}]^2}, \frac{2[\sqrt{\alpha}+\sqrt{\beta}]^2}{[(\alpha+\beta)^{1/2} + \sqrt{2}(\alpha\beta)^{1/4}]^2} \right].$$

In the same way as for $l = 1$, we derive that the number of GMRES iterations m needed to reduce the error by a given factor is proportional to $n^{1/4}$ (compared to $n^{1/2}$ if we use two-parameter ADI as an iteration scheme). Generally, if we use $l = 2^k$ optimal parameters, the number of required iterations is of the order $n^{1/2^k}$ for the ADI method and of the order $n^{1/2^{k+1}}$ for GMRES (or CG in the symmetric case) with ADI preconditioner. If we choose $l = \log n$ parameters for a problem of size n, it is even possible to bound the number of ADI cycles (and the number of GMRES steps using this ADI preconditioner of degree $l = \log n$) by a constant. This means that we are able to get the same asymptotic operation count of $O(n^2 \log n)$ as we can with fast direct methods.

Let us investigate the nonseparable case when the elliptic equation is selfadjoint. At the end of §3, we showed that

$$\rho([p_l(H)]^{-1} q_l(-H) p_l(-V)[q_l(V)]^{-1}) \leq \max_{\lambda\in\sigma(V)} \left| \frac{p_l(-\lambda)}{q_l(\lambda)} \right| \max_{\mu\in\sigma(H)} \left| \frac{q_l(-\mu)}{p_l(\mu)} \right|$$

also holds under these circumstances. Using the above analysis, this implies that the spectrum of the ADI preconditioned matrix for $l = 1$, Ω_1, is contained in a circle with center 1 and radius

$$\left(\frac{\sqrt{\beta} - \sqrt{\alpha}}{\sqrt{\beta} + \sqrt{\alpha}} \right)^2 = 1 - O(h) \text{ for } (h \to 0) .$$

Therefore, the number of required ADI iterations is of the order n, and, using this bound, the same order is obtained for GMRES with ADI preconditioning. Analogously, for $l = 2$, the number of iterations is proportional to $n^{1/2}$, and, using $l = \log n$ parameters, an iteration count of $\log n$ is achievable. Again, the above norm estimates for the noncommutative case are only valid because we apply the ADI preconditioner in the form (2.9) such that the terms with H and V are separated. If we use the cyclic form of ADI (as an iterative scheme or as preconditioner), the situation is different. In fact, Price and Varga [24] constructed an example of a diffusion equation, where the cyclic ADI method with two parameters fails to converge. Using the technique by Widlund [35] of appropriately scaling the diffusion equation or, equivalently, varying the ADI parameters with the space variables, it is possible to bound the number of iterations by $O(\log n)$ also for the cyclic ADI version.

In the nonselfadjoint (and nonseparable) case, using the bounds (4.2) in (3.7), we obtain

$$\rho((H + \varphi I)^{-1}(H - \psi I)(V - \varphi I)(V + \psi I)^{-1})$$

$$\leq \frac{(\beta+\gamma)^2 - 2\alpha\psi + \psi^2}{(\beta+\gamma)^2 + 2\alpha\varphi + \varphi^2} \cdot \frac{(\beta+\gamma)^2 - 2\alpha\varphi + \varphi^2}{(\beta+\gamma)^2 + 2\alpha\psi + \psi^2}.$$

This quantity is minimized for $\varphi = \psi = \beta + \gamma$, leading to

$$\rho((H+\varphi I)^{-1}(H-\psi I)(V-\varphi I)(V+\psi I)^{-1}) \leq \left(\frac{\beta+\gamma-\alpha}{\beta+\gamma+\alpha}\right)^2.$$

Using this bound, no improvement of the $O(n^2)$ dependence of the number of iterations for GMRES, applied directly to $(H+V)\mathbf{u} = \mathbf{f}$, can be guaranteed. Our numerical experiments, however, indicate that ADI preconditioning works as well in the separable case as it works for many nonseparable examples.

5. Numerical experiments. This final section contains numerical experiments carried out for certain examples of elliptic boundary value problems (1.2) including nonselfadjoint and nonseparable cases. In all the examples and for all preconditioners, we will precondition from the right. All the tables show the number of iterations that is needed to reduce the Euclidean norm of the starting residual by a factor of 10^{-6}. The entries of the right-hand side of the matrix problem are chosen randomly with coefficients uniformly distributed in the interval $[-1, 1]$; the initial guess is always the zero matrix.

Example 1. We first consider the Poisson equation, i.e., $a(x, y) = b(x, y) \equiv 1$ and $c(x, y) = d(x, y) = e(x, y) \equiv 0$.

The following conclusions can be drawn from a glance at Table 5.1. First, ADI *can* obviously be accelerated significantly by the CG method. Note that the additional work per iteration step of CG with ADI(l) preconditioning compared to ADI(l) consists in two scalar products of vectors of size n^2, which we may assume to be a fraction of the work required for the matrix-vector multiplication and tridiagonal linear system solving. Second, the convergence becomes significantly faster as we increase the number of parameters. The work for one iteration step of CG with ADI(2) preconditioning is essentially twice as much as for CG with ADI(1) preconditioning (actually a little less since the CG scalar products are only computed once). But the number of required CG/ADI(2) iterations is less than half the CG/ADI(1) iteration counts and remains almost constant as the number of unknowns increases (actually, the dependency of the number of iterations on $n^{1/4}$ can be observed quite nicely). While the step from two to four parameters still pays for the ADI iteration, this is not the case when using ADI as a preconditioner.

TABLE 5.1
Iteration counts for Example 1.

h	CG	ADI(1)	ADI(2)	ADI(4)	CG ADI(1)	CG ADI(2)	CG ADI(4)
1/16	39	32	7	3	15	6	3
1/32	77	70	11	4	21	7	3
1/64	157	139	16	4	28	9	4
1/128	309	255	20	6	46	12	5

Example 2. Let us now turn to the nonsymmetric (but still separable) problem

$$-\Delta u + \tau(xu_x + yu_y) + \eta u = f \tag{5.1}$$

in $(0, 1)\times(0, 1)$ with Dirichlet boundary conditions. This is Example 6.1 in [14] and is obtained from (1.2) if we set $a(x, y) = b(x, y) \equiv 1$, $c(x, y) = \frac{\tau}{2}x$, $d(x, y) = \frac{\tau}{2}y$, and $e(x, y) \equiv \eta - \tau$.

The linear system, resulting from discretization by central differences, is symmetrizable when $\frac{\tau}{2}h \leq 1$; otherwise we get (some) complex eigenvalues. For our experiments, we did not only use different preconditioners (ADI(1), ADI(2), block SSOR and a fast Fourier transform (FFT)-based fast Poisson solver (FPS)) but also different acceleration schemes; in particular, GMRES (without restarts) [25], CGS [26], and TFQMR (transpose-free QMR) [14]. We first choose $\tau = \eta = 200$. Figures 5.1 and 5.2 show the convergence behavior for different iterative methods and different preconditioners, respectively. The relative residual norm $\|\mathbf{r}\|/\|\mathbf{r}_0\|$ is plotted versus computational work. The latter is measured in units equivalent to the number of operations required for one half-step of the ADI iteration, i.e., the solution of n tridiagonal systems of order n plus n matrix-vector products with matrices of size n.

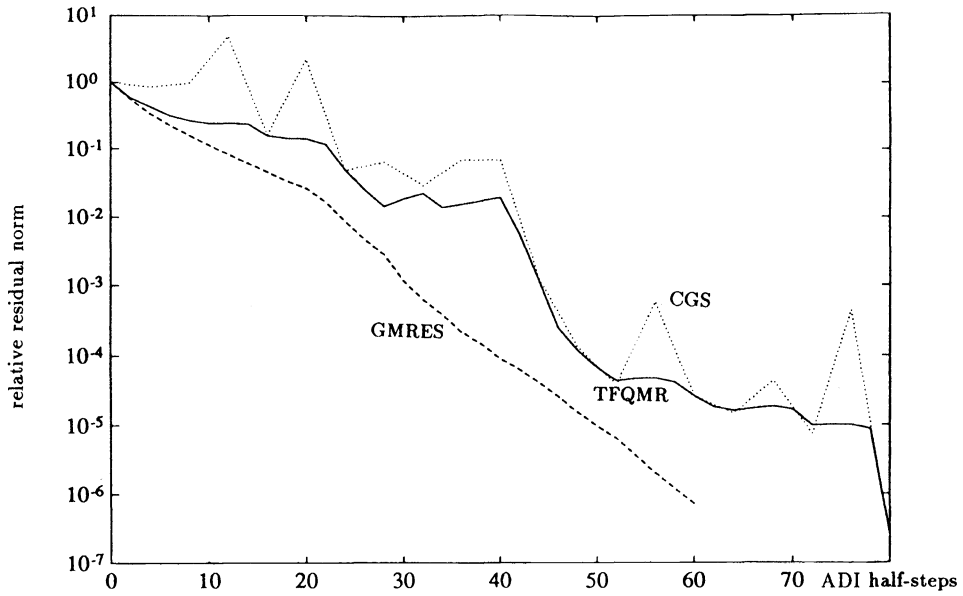

FIG. 5.1. *Example* 2 ($h = 1/64$) : ADI(1) *preconditioning, different iterative methods.*

From Table 5.2 and Fig. 5.1, we see that, although all the methods seem to work well with ADI preconditioning, using GMRES gives the fastest convergence (note that one step of GMRES involves only one multiplication, while one CGS iteration requires two multiplications with the preconditioned matrix). However, since, for the full GMRES algorithm, the number of SAXPY operations and inner products per GMRES step is growing linearly with the iteration count, this part of the computation amounts to a significant part of the work. Although the behavior of the residual norm is much more erratic, CGS reaches the desired accuracy after about the same time as TFQMR. (The amount of work is about the same for one CGS iteration and two TFQMR iterations.)

Let us now turn to the performance of the different preconditioners (see Tables 5.2, 5.3, and 5.4 and Fig. 5.2). Since (block) SSOR preconditioning involves the same amount of work per iteration as ADI(1), the results show that SSOR is preferable for any size of h in this example. Obviously, the results obtained by using an FPS as preconditioner are not satisfactory in this example (note that not only is the iteration count higher, but also that each iteration step requires more operations).

The iteration counts in Tables 5.2, 5.3, and 5.4 should be sufficient to illustrate that the dependence of the rate of convergence on the preconditioner is essentially the same for

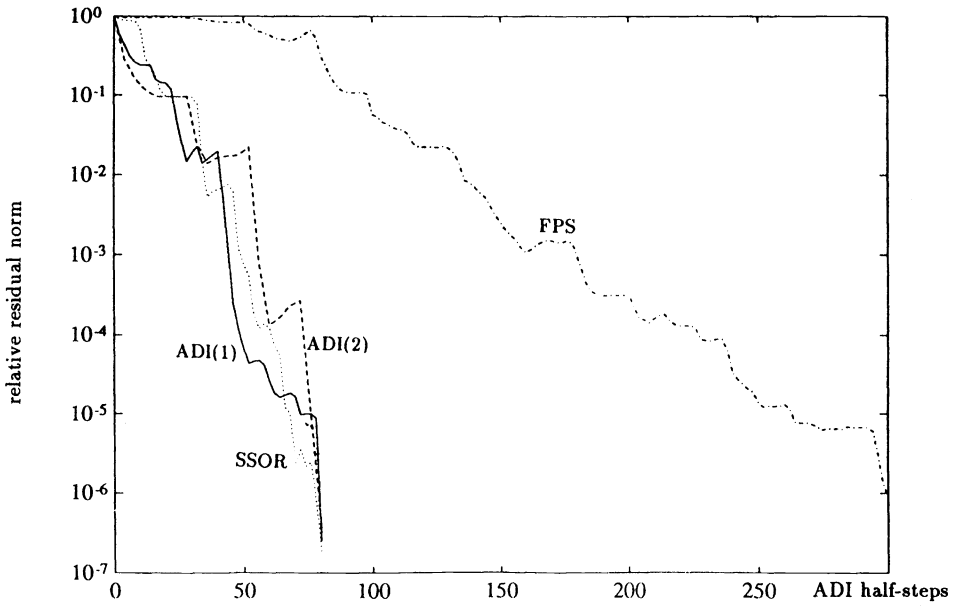

FIG. 5.2. *Example* 2 ($h = 1/64$) : TFQMR, *different preconditioners.*

1/128	502	47	24	64	160

GMRES, CGS, and TFQMR. From now on, we will restrict ourselves to TFQMR as our basic iterative method.

The results in Table 5.5 were obtained for the same example with the choice of parameters as in [14, Ex. 6.1] ($\tau = 100$ and $\eta = -200$) to show that ADI preconditioning also works well if the linear system has (some) eigenvalues in the left half-plane. Note that, as h gets smaller, the iteration count for the unpreconditioned method increases much faster than the one for ADI(1). On the other hand, preconditioning by an FPS and, for some h, also SSOR did not show any signs of convergence at all after a reasonable number of iterations.

1/128	842	104	—	—

Example 3. Let us now turn to the nonseparable problem

$$-\Delta u + \tau y(1 - x^2)u_x - \tau x(1 - y^2)u_y = f,$$

which has the physical interpretation of modelling circular flow of a fluid around a point (see Elman and Golub [11]). To derive this equation from the general formulation (1.2), we set $a(x, y) = b(x, y) = 1, c(x, y) = \frac{\tau}{2}y(1 - x^2), d(x, y) = -\frac{\tau}{2}x(1 - y^2)$, and $e(x, y) = 0$. Again, we consider the elliptic differential equation on $(0, 1) \times (0, 1)$ with Dirichlet boundary conditions. For $\tau = 200$, the convergence behavior is illustrated in Table 5.6 and Fig. 5.3.

TABLE 5.6
TFQMR *iteration counts for Example* 3, $\tau = 200$.

h	No prec.	ADI(1)	ADI(2)	SSOR	FPS
1/16	76	19	15	102	109
1/32	133	40	26	78	132
1/64	235	82	24	62	124
1/128	466	123	30	80	131

Example 4. In our final example, we look at the nonseparable equation

$$-(e^{-2xy}u_x)_x - (e^{-2xy}u_y)_y + \tau(xu_x + yu_y) = f,$$

where we also have variable diffusion coefficients. The corresponding computational results are shown in Table 5.7 and Fig. 5.4. We see that while SSOR does not lead to convergence at all, ADI preconditioning still works quite well.

6. Conclusions. In this paper, we have studied, both analytically and numerically, the performance of ADI preconditioning for finite difference discretizations of elliptic boundary value problems in two dimensions. One of the advantages of this approach is that it can be easily parallelized on a variety of architectures. For separable, not necessarily selfadjoint, problems, we proved that the number of iterations required to reduce the norm of the residual by a certain factor is proportional to $h^{-1/2}$ if we use ADI(1) preconditioning and is proportional to $h^{-1/4}$ for ADI(2). In our numerical experiments we compared these ADI preconditioners

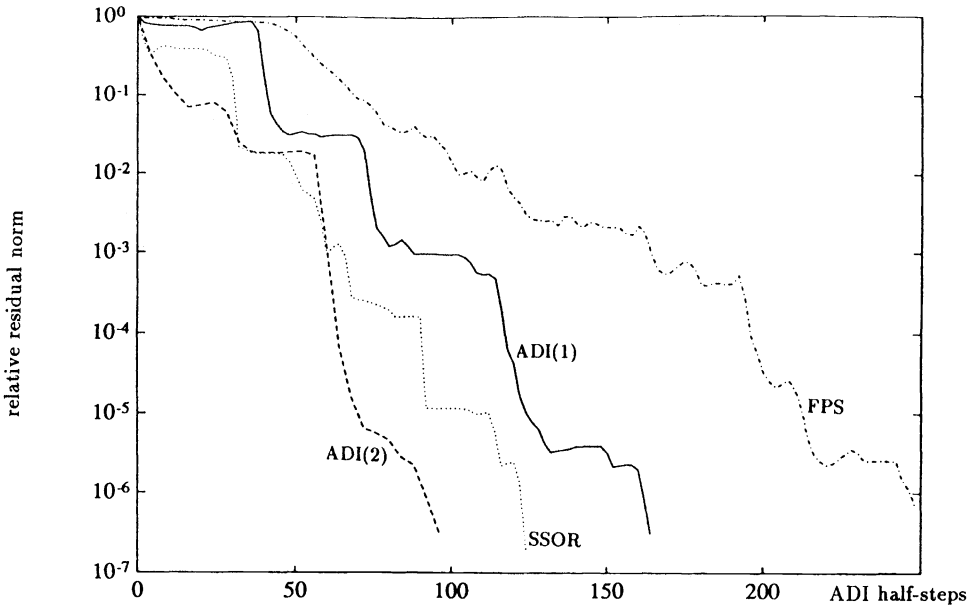

FIG. 5.3. *Example* 3 ($h = 1/64$): TFQMR, *different preconditioners.*

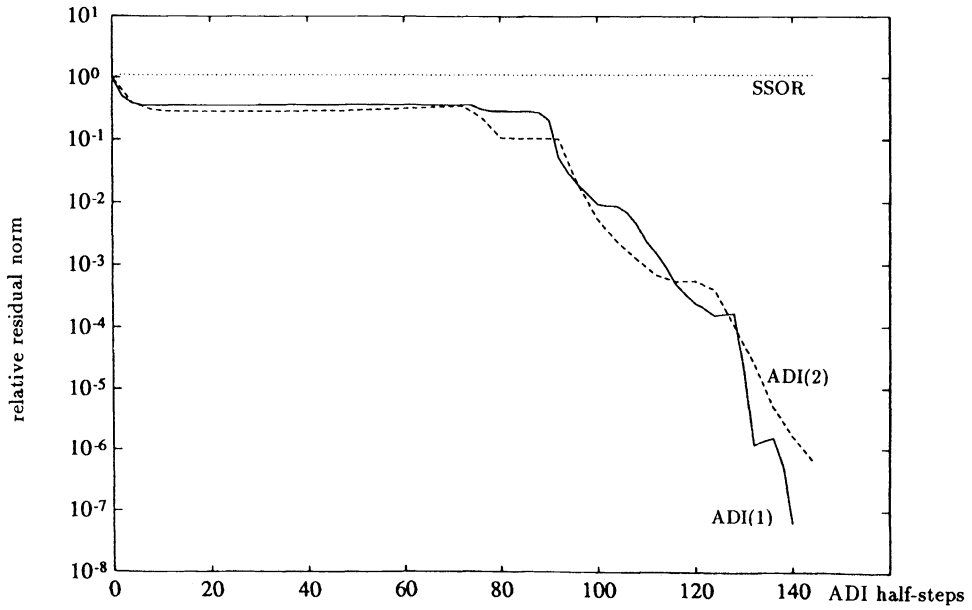

FIG. 5.4. *Example* 4 ($h = 1/64$): TFQMR, *different preconditioners.*

with other approaches for a number of different iterative methods. These numerical results illustrate the analysis which implies that, at least for small h, ADI(2) should be preferred to ADI(1). Moreover, ADI frequently performs better than preconditioning by SSOR or an FPS. This is particularly true for SSOR for small h or for problems where the underlying matrix has large imaginary eigenvalue components.

SEMICIRCULANT PRECONDITIONERS FOR FIRST-ORDER PARTIAL DIFFERENTIAL EQUATIONS*

SVERKER HOLMGREN† AND KURT OTTO†

Abstract. This paper considers solving time-independent systems of first-order partial differential equations (PDEs) in two space dimensions using a conjugate gradient (CG)-like iterative method. The systems of equations are preconditioned using semicirculant preconditioners. Analytical formulas for the eigenvalues and the eigenvectors are derived for a scalar model problem with constant coefficients. The main problems in constructing and analyzing the numerical methods are caused by the numerical boundary conditions required at the outflow boundaries. It is proved that, when the grid ratio is less than one, the spectrum asymptotically becomes two finite curve segments that are independent of the number of gridpoints. The same type of result for a time-dependent problem has previously been established. For the restarted generalized minimal residual (GMRES) iteration, a slight reduction of the grid ratio from one substantially improves the convergence rate. This is also predicted by an asymptotic analysis of the eigenvalues.

1. Introduction.

In this paper we consider solving first-order PDEs in two space dimensions. The systems of equations arising are solved using a CG-like iterative method combined with semicirculant preconditioners. Eventually we intend to use the methods presented here in the process of solving the Euler and Navier–Stokes equations.

We first give a brief description of semicirculant preconditioners. Then we present scalar model problems with constant coefficients. We mainly consider a steady-state hyperbolic equation, but results for a related time-dependent problem are included for comparison. For the model problems we give analytical formulas for the eigenvalues of the preconditioned coefficient matrices. The eigenvectors of the steady-state problem are also studied.

Using a grid in which the number of gridpoints in one space direction is greater than in the other, it is proved [Otto92] that the spectrum for the time-dependent model problem asymptotically resides on two finite curve segments in the complex plane. The curves are well separated from zero and independent of the quotient κ between the time- and space-steps. These results should be compared to those presented in [HoOtto91]. There Holmgren and Otto analyze a similar model problem, but with periodic boundary conditions in one space direction and the same number of gridpoints in both directions. The results for that problem imply that the spectrum is independent of the number of gridpoints, but that $\max_i |\lambda_i| / \min_i |\lambda_i| = \mathcal{O}(\sqrt{\kappa})$.

Generalizing the results in [Otto92], we are able to prove that asymptotically the spectrum for the steady-state problem resides on the same curve segments as for the time-dependent problem, provided a weak artificial viscosity is added in one space direction. Also, the grid ratio must be less than one to guarantee a bounded spectrum. This is the main topic of this paper. The theoretical arguments are verified by numerical experiments.

2. Notation.

We solve

$$M^{-1}Bu = M^{-1}b\,, \tag{1}$$

where M is the preconditioner matrix. The matrix B arises from a discretization of a system of n_c PDEs in two space dimensions using a standard five-point operator. The solution is

*Received by the editors May 18, 1992; accepted for publication (in revised form) April 23, 1993. This work was supported by the Swedish National Board for Industrial and Technical Development (NUTEK).

†Department of Scientific Computing, Uppsala University, Box 120, S-751 04 Uppsala, Sweden (sverker@tdb.uu.se, kurt@tdb.uu.se).

unknown in $m_1 \times m_2$ gridpoints, hence u has $n = n_c m_1 m_2$ components. The only restriction on the difference approximation at the boundaries is that it must not be wider than the five-point operator used in the interior. The matrix B is assumed to have the following structure:

$$B = \mathrm{trid}_{k,m_2}(B_{k,-1}, B_{k,0}, B_{k,1}), \tag{2}$$

where

$$\begin{aligned} B_{k,-1} &= \mathrm{diag}_{j,m_1}(v_{j,k,-2}), \\ B_{k,0} &= \mathrm{trid}_{j,m_1}(v_{j,k,-1}, v_{j,k,0}, v_{j,k,1}), \\ B_{k,1} &= \mathrm{diag}_{j,m_1}(v_{j,k,2}). \end{aligned}$$

Here $v_{j,k,r}$, $r = -2, \ldots, 2$, are $n_c \times n_c$ matrices. Hence, $\sim 5n_c n$ memory cells are required to store B, and $\sim 10n_c n$ arithmetic operations are required to perform the matrix-vector multiplication $y = Bx$. Above, we have used the notation

$$\mathrm{diag}_{j,m}(\beta_j) = \begin{pmatrix} \beta_1 & & & \\ & \ddots & & \\ & & \ddots & \\ & & & \beta_m \end{pmatrix}, \quad \mathrm{trid}_{j,m}(\alpha_j, \beta_j, \gamma_j) = \begin{pmatrix} \beta_1 & \gamma_1 & & \\ \alpha_2 & \ddots & \ddots & \\ & \ddots & \ddots & \gamma_{m-1} \\ & & \alpha_m & \beta_m \end{pmatrix}.$$

We will also denote circulant tridiagonal and periodic tridiagonal matrices by

$$\mathrm{ctrid}_m(\alpha, \beta, \gamma) = \begin{pmatrix} \beta & \gamma & & \alpha \\ \alpha & \ddots & \ddots & \\ & \ddots & \ddots & \gamma \\ \gamma & & \alpha & \beta \end{pmatrix}, \quad \mathrm{ptrid}_{j,m}(\alpha_j, \beta_j, \gamma_j) = \begin{pmatrix} \beta_1 & \gamma_1 & & \alpha_1 \\ \alpha_2 & \ddots & \ddots & \\ & \ddots & \ddots & \gamma_{m-1} \\ \gamma_m & & \alpha_m & \beta_m \end{pmatrix}.$$

The Kronecker product, denoted by $\otimes$, will be used extensively. The mth-order Fourier matrix F_m is given by

$$[F_m]_{j,k} = m^{-1/2} \cdot \omega_m^{(j-1)(k-1)}, \qquad j, k = 1, \ldots, m,$$

where $\omega_m \equiv \exp(i2\pi/m)$.

3. Semicirculant preconditioners. For a more complete discussion on semicirculant preconditioners and some numerical results, see [HoOtto91], [Holm93], and [Otto93]. Circulant preconditioners are discussed in [TChan88], [RChSt89], [RChan89], [RChJin91], and [TChOl92]. A semicirculant preconditioner M for B is defined by

$$M = \mathrm{ptrid}_{k,m_2}(M_{k,-1}, M_{k,0}, M_{k,1}), \tag{3}$$

where

$$M_{k,-1} = I_{m_1} \otimes \rho_{k,-2}, \quad M_{k,0} = \mathrm{ctrid}_{m_1}(\rho_{k,-1}, \rho_{k,0}, \rho_{k,1}), \quad M_{k,1} = I_{m_1} \otimes \rho_{k,2}.$$

Here $\rho_{k,r}$ are $n_c \times n_c$ matrices. When $\rho_{1,-2}$ and $\rho_{m_2,2}$ are zero, M is nonperiodic block-tridiagonal just like B. However, the diagonal blocks in M are circulant matrices, whereas the corresponding blocks in B are tridiagonal. Notice that the preconditioning matrix M is almost as sparse as B, and it is completely described by the $5m_2$ $n_c \times n_c$ matrices $\rho_{k,r}$. Different choices of these parameters result in different preconditioners. In this paper we use

$$\rho_{k,r} = \frac{1}{m_1} \sum_{j=1}^{m_1} \tilde{v}_{j,k,r}, \quad k = 1, \ldots, m_2, \quad r = -2, \ldots, 2. \tag{4}$$

The matrix entries $\tilde{v}_{j,k,r}$, $j = 1, \ldots, m_1$, $k = 1, \ldots, m_2$, $r = -2, \ldots, 2$, form the matrix $\tilde{B}$ corresponding to the difference approximation of the original problem, but with periodic boundary conditions in the x_1-direction. Most of the entries $\tilde{v}_{j,k,r}$ will be equal to the entries $v_{j,k,r}$ in the matrix B. Especially, $\rho_{1,-2}$ and $\rho_{m_2,2}$ become zero, and consequently M becomes block-tridiagonal. The choice of parameters for circulant and semicirculant preconditioners is discussed in [TChan88], [Tyr92], and [HoOtto91].

The reason for introducing circulant matrices in the preconditioner is that such matrices are diagonalized by using discrete Fourier transforms, which are performed by the fast Fourier transform (FFT) algorithm. The derivation of the preconditioner solve is based on the observation that M^{-1} may be written as

$$M^{-1} = (I_{m_2} \otimes F_{m_1} \otimes I_{n_c}) \big(\text{ptrid}_{k,m_2}(M_{k,-1}, \Lambda_k, M_{k,1})\big)^{-1} (I_{m_2} \otimes F_{m_1}^* \otimes I_{n_c}), \tag{5}$$

where $\Lambda_k = \text{diag}_{j,m_1}(\Lambda_{j,k})$ and $\Lambda_{j,k} = \rho_{k,0} + \omega_{m_1}^{(j-1)} \rho_{k,1} + \omega_{m_1}^{-(j-1)} \rho_{k,-1}$. Details are given in [HoOtto91]. In [Holm93] some savings in arithmetics, generalizations, and parallel implementations are discussed. An algorithmic formulation of the preconditioner solve follows:

PRECONDITIONER SOLVE

for $k = 1$ to $n_c m_2$ do (in parallel):
    Perform an FFT of length $m_1/2$.
endfor
for $j = 1$ to $m_1/2 + 1$ do (in parallel):
    Solve a (possibly periodic) block-tridiagonal system of equations
    with blocksize $n_c \times n_c$ and $n_c m_2$ unknowns.
endfor
for $k = 1$ to $n_c m_2$ do (in parallel):
    Perform an FFT of length $m_1/2$.
endfor

For the implementation used in this paper, $\sim 6 n_c n$ memory cells are required to store the factorized reduced systems and for workspace. To form the preconditioner and to factorize the reduced systems $\sim (32 n_c^2 - 16 n_c + 3) n$ arithmetic operations are required. Each preconditioner solve requires $\sim (5 \log_2 m_1 + 24 n_c + 2) n$ arithmetic operations. Both the memory requirement and the arithmetic complexity is increased if m_1 is not a power of two, since the discrete Fourier transforms are then computed according to the *fractional* Fourier transform algorithm [BaSw91]. The semicirculant framework can be extended to three space dimensions; see [Holm93] and [Otto93]. The three-dimensional preconditioner solve is based on FFT methods in two dimensions and the solution of block-tridiagonal systems in the third dimension.

In [Otto93] and [Holm93] standard incomplete LU (ILU) and block ILU preconditioners are considered for the type of problems presented in the next section. Analysis of the spectra for the preconditioned systems shows [Otto93] that no significant improvement is obtained compared to the unpreconditioned system. Furthermore, some preconditioners exhibit stability problems [Holm93]. For large, nondiagonally dominant problems the convergence properties are poor. The conclusion is that ILU and block ILU preconditioners are not beneficial for the problems of interest here.

4. The model problems. We present a hyperbolic model problem in both a time-dependent and a steady-state setting. The time-dependent problem is analyzed in [Otto92]. We present it here since it is instructive to compare the coefficient matrices and the results for the two problem settings.

The time-dependent problem. We consider the scalar ($n_c = 1$) two-dimensional problem

$$\frac{\partial u}{\partial t} + \frac{\partial u}{\partial x_1} + \frac{\partial u}{\partial x_2} = g, \tag{6}$$

on the unit square for $t > 0$. Here $u(0, x_2, t)$, $u(x_1, 0, t)$, $u(x_1, x_2, 0)$, and g are chosen so that the analytical solution is known. The time discretization is performed using the second-order accurate trapezoidal rule. The space discretization is performed on a uniform grid with $(m_1+1) \times (m_2+1)$ gridpoints, where the space-steps are given by $h_d = 1/m_d$, $d = 1, 2$. Let $u_{j,k}$ denote the approximate solution at the point (jh_1, kh_2), $j = 0, \ldots, m_1$, $k = 0, \ldots, m_2$. Observe that $u_{0,k}$ for $k = 0, \ldots, m_2$ and $u_{j,0}$ for $j = 0, \ldots, m_1$ are given directly by the boundary conditions for the PDE problem. This means that we have to solve for $m_1 \times m_2$ unknowns in each time-step. The spatial derivatives in (6) are approximated using second-order accurate centered differences in the interior of the domain. For the numerical boundary conditions required at the outflow boundaries, we use one-sided differences. Now define $\kappa_1 \equiv \Delta t/h_1$ and $\kappa_2 \equiv \Delta t/h_2$, where Δt is the time-step. The solution vector is defined as $u^N = (u^N_{1,1}\ u^N_{2,1}\ \ldots\ u^N_{m_1,1}\ u^N_{1,2}\ \ldots\ u^N_{m_1,m_2})^T$. Introducing the discretizations in (6) yields the following system of equations for the unknowns at time level $N+1$:

$$(I_{m_2} \otimes B_1 + \kappa_2 B_2 \otimes I_{m_1}) u^{N+1} = b. \tag{7}$$

Here b contains known quantities and

$$B_1 = \begin{pmatrix} 4 & \kappa_1 & & & \\ -\kappa_1 & 4 & \kappa_1 & & \\ & \ddots & \ddots & \ddots & \\ & & -\kappa_1 & 4 & \kappa_1 \\ & & & -2\kappa_1 & 4+2\kappa_1 \end{pmatrix},$$

$$B_2 = \begin{pmatrix} 0 & 1 & & & \\ -1 & 0 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & -1 & 0 & 1 \\ & & & -2 & 2 \end{pmatrix}.$$

The steady-state problem. Here we consider the steady-state version of (6):

$$\frac{\partial u}{\partial x_1} + \frac{\partial u}{\partial x_2} = g. \tag{8}$$

The boundary conditions are of the same form as for the time-dependent problem. The boundary data and g are again chosen so that the analytical solution is known. The space discretization is performed on the same type of grid as for the time-dependent problem, and the derivatives in the PDE are approximated using centered differences in the interior of the domain. However, we add a weak artificial viscosity in the x_1-direction. The difference operator in the interior is given by

$$D_{0,x_1} + D_{0,x_2} - \frac{\gamma}{2} h_1^{2-\alpha} D_{+,x_1} D_{-,x_1}, \tag{9}$$

where $D_{+,x_1} u_{j,k} = h_1^{-1}(u_{j+1,k} - u_{j,k})$, $D_{-,x_1} u_{j,k} = D_{+,x_1} u_{j-1,k}$, and finally $D_{0,x_1} = \frac{1}{2}(D_{+,x_1} + D_{-,x_1})$. The constants α and γ are chosen so that $\alpha \in [0, 1)$ and $\gamma \in (0, 1)$. The order of accuracy for this operator is $2 - \alpha$ in the x_1-direction and 2 in the x_2-direction.

Adding artificial viscosity is customary when using centered differences for flow problems. Normally, a stronger artificial viscosity like the difference operator $f(\nabla u)\gamma_1 h_1 D_{+,x_1} D_{-,x_1} + \gamma_2 h_1^3 (D_{+,x_1} D_{-,x_1})^2$ is added. The function f is large when the gradient of u is large, i.e., in a shock, and small otherwise. It would be interesting to perform the analysis using an artificial viscosity of the form $\gamma_2 h_1^3 (D_{+,x_1} D_{-,x_1})^2$, which preserves second-order accuracy. However, we have not yet pursued this approach. Artificial viscosity could also be added in the x_2-direction. The solution method presented here would still be defined, and reasonably the performance should be enhanced.

For the numerical boundary conditions we again use one-sided differences. The difference operators at the outflow boundaries are given by

$$\begin{aligned} D_{-,x_1} + D_{0,x_2}, &\quad j = m_1, \quad k = 1, \ldots, m_2 - 1, \\ D_{-,x_1} + D_{-,x_2}, &\quad j = m_1, \quad k = m_2, \\ D_{0,x_1} + D_{-,x_2} - \frac{\gamma}{2} h_1^{2-\alpha} D_{+,x_1} D_{-,x_1}, &\quad k = m_2, \quad j = 1, \ldots, m_1 - 1. \end{aligned}$$

Define the grid ratio β and δ by

$$\beta \equiv h_1/h_2\,, \qquad \delta \equiv \gamma h_1^{1-\alpha}.$$

We then have the following system of equations:

$$Bu \equiv (I_{m_2} \otimes \hat{B}_1 + \beta B_2 \otimes I_{m_1})u = b. \tag{10}$$

Here b again contains known quantities and

$$\hat{B}_1 = \begin{pmatrix} 2\delta & 1-\delta & & & \\ -1-\delta & 2\delta & 1-\delta & & \\ & \ddots & \ddots & \ddots & \\ & & -1-\delta & 2\delta & 1-\delta \\ & & & -2 & 2 \end{pmatrix}.$$

The difference between the two problem settings lies in the difference between B_1 and $\hat{B}_1$. The study of the steady-state problem was initiated by an examination of the quotient between the diagonal and off-diagonal entries in these matrices. When the number of gridpoints is large, the steady-state problem is closely related to a time-dependent problem with $\kappa_1 = \frac{2}{\delta} = 2\gamma^{-1} h_1^{\alpha-1}$. Asymptotically the matrix $\hat{B}_1$ approaches the "true" wave propagation matrix. This is not the case for the standard form of artificial viscosity with $\alpha = 1$, since the main diagonal does not vanish.

5. Two lemmas. In this section we state two fundamental lemmas. The first lemma concerns the location of the eigenvalues of the matrix B_2. Let $\mathcal{E}(a, b)$ denote the closed ellipse centered at the origin with semimajor axis b oriented along the imaginary axis and semiminor axis a. Also let $\mathcal{E}^+(a, b)$ denote the region $\{z | z \in \mathcal{E}(a, b) \text{ and } \Re e(z) \geq 0\}$.

LEMMA 1. *The eigenvalues $\lambda_{k,2}$ of B_2 satisfy*:

(i) $\lambda_{k,2} \neq \lambda_{j,2}\,, \quad k \neq j.$

(ii) $\lambda_{k,2} \in \mathcal{E}^+(4m_2^{-3/4}, 2 + 4m_2^{-3/2})\,, \quad k = 1, \ldots, m_2.$

(iii) $\lambda_{k,2} > \ln(m_2)/m_2$ *when* $\Im m(\lambda_{k,2}) = 0.$

The proof is based on difference equation theory and is available in [Otto92].

Lemma 2 concerns the evaluation of certain sums in the proof of Theorem 2.

LEMMA 2. *Assume that $d \geq 1$. Let ζ denote a complex number satisfying*

$$\zeta \notin \mathcal{E}\left(\frac{d-1}{2}, \frac{d+1}{2}\right) \quad \text{and} \quad \Re e(\zeta) > 0\,.$$

Then

$$\sigma_p \equiv m_1^{-1} \sum_{j=1}^{m_1} \frac{\omega_{m_1}^{p(j-1)}}{2\zeta + \omega_{m_1}^{(j-1)} - d\omega_{m_1}^{-(j-1)}} = s_p + r_p\,, \qquad p = -m_1 + 1, \ldots, m_1 - 1,$$

where

$$s_p = \frac{(-dz^{-1})^p}{z + dz^{-1}}, \quad p < 0,$$

$$s_p = \frac{z^p}{z + dz^{-1}}, \quad p \geq 0,$$

$$r_p = \frac{z^p}{z + dz^{-1}} \cdot \frac{z^{m_1}}{1 - z^{m_1}} + \frac{(-dz^{-1})^p}{z + dz^{-1}} \cdot \frac{(-d^{-1}z)^{m_1}}{1 - (-d^{-1}z)^{m_1}},$$

and

$$z = -\zeta + \sqrt{d + \zeta^2}.$$

The proof is available in [Otto93]. It is based on the Poisson summation formula, residue theory, and geometric series.

6. The steady-state problem. A semicirculant preconditioner, with parameters chosen according to (4), for the coefficient matrix in (10) is given by

$$M = I_{m_2} \otimes \hat{C}_1 + \beta B_2 \otimes I_{m_1}, \tag{11}$$

where

$$\hat{C}_1 = \mathrm{ctrid}_{m_1}(-1 - \delta, 2\delta, 1 - \delta).$$

Theorem 1 establishes the existence of M^{-1} for all finite grids.

THEOREM 1. *The matrix M is diagonalizable and nonsingular.*

Proof. Since $\hat{C}_1$ is a circulant matrix we have

$$F_{m_1}^* \hat{C}_1 F_{m_1} = \Lambda_1 = \mathrm{diag}_{j,m_1}(\lambda_{j,1}), \qquad \lambda_{j,1} = 2\delta + (1 - \delta)\omega_{m_1}^{(j-1)} - (1 + \delta)\omega_{m_1}^{-(j-1)}.$$

From Lemma 1 we conclude that there exists a nonsingular matrix V_2 diagonalizing B_2, i.e.,

$$V_2^{-1} B_2 V_2 = \Lambda_2 = \mathrm{diag}_{k,m_2}(\lambda_{k,2}).$$

This implies

$$\begin{aligned}(V_2^{-1} \otimes F_{m_1}^*) M (V_2 \otimes F_{m_1}) &= (V_2^{-1} \otimes F_{m_1}^*)(I_{m_2} \otimes \hat{C}_1 + \beta B_2 \otimes I_{m_1})(V_2 \otimes F_{m_1}) \\ &= I_{m_2} \otimes F_{m_1}^* \hat{C}_1 F_{m_1} + \beta V_2^{-1} B_2 V_2 \otimes I_{m_1} \\ &= I_{m_2} \otimes \Lambda_1 + \beta \Lambda_2 \otimes I_{m_1} \equiv \Lambda.\end{aligned}$$

Thus, M is diagonalizable. The eigenvalues of M are the diagonal entries of Λ, i.e., $\lambda_{j,1} + \beta\lambda_{k,2}$, $k = 1, \ldots, m_2$, $j = 1, \ldots, m_1$. We prove by contradiction that these eigenvalues are nonzero. Assume that $\lambda_{j,1} + \beta\lambda_{k,2} = 0$ for some j and k. Then we have

$$\begin{aligned}0 &= 2\delta + (1 - \delta)\omega_{m_1}^{(j-1)} - (1 + \delta)\omega_{m_1}^{-(j-1)} + \beta\lambda_{k,2} \\ &= 2\delta\big(1 - \cos((j-1)2\pi/m_1)\big) + \beta\Re e(\lambda_{k,2}) \\ &\quad + i\big(2\sin((j-1)2\pi/m_1) + \beta\Im m(\lambda_{k,2})\big).\end{aligned}$$

Now $\delta, \beta > 0$ and $\Re e(\lambda_{k,2}) \geq 0$ according to Lemma 1. Then the only possibility is $j = 1$, $\Re e(\lambda_{k,2}) = 0$, and $\Im m(\lambda_{k,2}) = 0$. But $\lambda_{k,2} = 0$ contradicts Lemma 1, and consequently the assumption is false. □

The convergence analysis in §8, for GMRES applied to (1), is based on the spectral decomposition of $M^{-1}B$. For the rest of this section, we therefore examine the eigenvalues and the eigenvectors of $M^{-1}B$. Now define the error matrix $E \equiv B - M$. Observe that $E = I_{m_2} \otimes E_1$, where

$$E_1 = \hat{B}_1 - \hat{C}_1 = \begin{pmatrix} 0 & 0 & \cdots & 0 & 0 & 1+\delta \\ 0 & 0 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & & \vdots & \vdots & \vdots \\ \vdots & \vdots & & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & 0 & 0 \\ -1+\delta & 0 & \cdots & 0 & -1+\delta & 2-2\delta \end{pmatrix}. \tag{12}$$

We obtain

$$M^{-1}B = M^{-1}(M+E) = I + M^{-1}E. \tag{13}$$

Theorem 2 provides analytical formulas relating the eigenvalues of $M^{-1}E$ to the eigenvalues of B_2.

THEOREM 2. *Let $\lambda_{k,2}$, $k = 1, \ldots, m_2$, denote the eigenvalues of B_2. Define ζ_k and d by*

$$\zeta_k \equiv \frac{\delta}{1-\delta} + \frac{\beta\lambda_{k,2}}{2(1-\delta)} \quad \text{and} \quad d \equiv \frac{1+\delta}{1-\delta}.$$

Then the matrix $M^{-1}E$ has the eigenvalue zero with multiplicity at least $m_2(m_1 - 2)$, and $2m_2$ eigenvalues given by

$$\lambda^{(SC)}_{(1,m_1),k} = \frac{2 - (2-d^{-1})z_k + R_1(z_k) \pm \sqrt{-(4d^{-1} - d^{-2})z_k^2 - 4(2-d^{-1})z_k - 4(d-1) + R_2(z_k)}}{2(z_k + dz_k^{-1})},$$

$$k = 1, \ldots, m_2,$$

where

$$\begin{aligned}
R_1(z_k) &= \big((d-1)z_k^{-1} + 2 - z_k\big)\frac{z_k^{m_1}}{1-z_k^{m_1}} + \big((d^{-1}-1)z_k + 2 + dz_k^{-1}\big)\frac{(-d^{-1}z_k)^{m_1}}{1-(-d^{-1}z_k)^{m_1}}, \\
R_2(z_k) &= \big(-6d^{-1}z_k^2 - (12-4d^{-1})z_k - 8d + 6 - 2d^{-1} + (4d-4)z_k^{-1} - 4dz_k^{-2}\big)\frac{z_k^{m_1}}{1-z_k^{m_1}} \\
&\quad + \big(-(6d^{-1} - 2d^{-2})z_k^2 - (12 - 8d^{-1})z_k - 8d + 10 + 4dz_k^{-1}\big)\frac{(-d^{-1}z_k)^{m_1}}{1-(-d^{-1}z_k)^{m_1}} \\
&\quad + \big(z_k^2 - 4z_k - 2d + 6 + (4d-4)z_k^{-1} + (d-1)^2 z_k^{-2}\big)\Big(\frac{z_k^{m_1}}{1-z_k^{m_1}}\Big)^2 \\
&\quad + \big((d^{-1}-1)^2 z_k^2 + (4d^{-1} - 4)z_k - 2d + 6 + 4dz_k^{-1} + d^2 z_k^{-2}\big)\Big(\frac{(-d^{-1}z_k)^{m_1}}{1-(-d^{-1}z_k)^{m_1}}\Big)^2 \\
&\quad + \big(-(2 + 6d^{-1})z_k^2 - (8 - 4d^{-1})z_k - 12d + 4 - 2d^{-1} \\
&\qquad + (8d-4)z_k^{-1} - (2d^2 + 6d)z_k^{-2}\big)\frac{z_k^{m_1}}{1-z_k^{m_1}} \cdot \frac{(-d^{-1}z_k)^{m_1}}{1-(-d^{-1}z_k)^{m_1}},
\end{aligned}$$

and finally

$$z_k = -\zeta_k + \sqrt{d + \zeta_k^2}.$$

Proof. First we construct a sparse block-diagonal matrix having the same eigenvalues as $M^{-1}E$. Using the notation from Theorem 1 we introduce

$$D = (I_{m_2} \otimes \Lambda_1 + \beta \Lambda_2 \otimes I_{m_1})^{-1} = \mathrm{diag}_{k,m_2}(D_k),$$

where

$$D_k = \mathrm{diag}_{j,m_1}(d_{j,k}) = \mathrm{diag}_{j,m_1}\left((2\delta + (1-\delta)\omega_{m_1}^{(j-1)} - (1+\delta)\omega_{m_1}^{-(j-1)} + \beta\lambda_{k,2})^{-1}\right).$$

Employing the transformation of M from Theorem 1, the spectral decomposition of M^{-1} becomes

$$M^{-1} = (V_2 \otimes F_{m_1}) D (V_2^{-1} \otimes F_{m_1}^*).$$

We now consider the matrix T given by

$$\begin{aligned} T &= (V_2 \otimes I_{m_1})^{-1} M^{-1} E (V_2 \otimes I_{m_1}) \\ &= (V_2^{-1} \otimes I_{m_1})(V_2 \otimes F_{m_1}) D (V_2^{-1} \otimes F_{m_1}^*)(I_{m_2} \otimes E_1)(V_2 \otimes I_{m_1}) \\ &= (I_{m_2} \otimes F_{m_1}) \mathrm{diag}_{k,m_2}(D_k)(I_{m_2} \otimes F_{m_1}^* E_1) = \mathrm{diag}_{k,m_2}(T_k), \end{aligned}$$

where $T_k = F_{m_1} D_k F_{m_1}^* E_1$. Since $M^{-1}E$ and T are similar, and T is block-diagonal, the eigenvalues of $M^{-1}E$ equal the eigenvalues of T_k, $k = 1, \ldots, m_2$.

Due to the structure of E_1 displayed in (12), we see that T_k has only three nonzero columns $t_{p,1}$, t_{p,m_1-1}, t_{p,m_1}, $p = 1, \ldots, m_1$. Performing the matrix multiplication and using the periodicity $\omega_{m_1}^{(p \pm m_1)} = \omega_{m_1}^{p}$, we obtain

$$\begin{aligned} t_{p,1} &= m_1^{-1} \sum_{j=1}^{m_1} \omega_{m_1}^{p(j-1)} (-1+\delta) d_{j,k} \\ &= -m_1^{-1} \sum_{j=1}^{m_1} \frac{\omega_{m_1}^{p(j-1)}}{\frac{2\delta+\beta\lambda_{k,2}}{1-\delta} + \omega_{m_1}^{(j-1)} - \frac{1+\delta}{1-\delta}\omega_{m_1}^{-(j-1)}} = -\sigma_p, \\ t_{p,m_1-1} &= t_{p,1} = -\sigma_p, \\ t_{p,m_1} &= m_1^{-1} \sum_{j=1}^{m_1} \left(\omega_{m_1}^{(p-1)(j-1)}(1+\delta) + \omega_{m_1}^{p(j-1)}(2-2\delta)\right) d_{j,k} \\ &= m_1^{-1} \sum_{j=1}^{m_1} \frac{d\omega_{m_1}^{(p-1)(j-1)} + 2\omega_{m_1}^{p(j-1)}}{\frac{2\delta+\beta\lambda_{k,2}}{1-\delta} + \omega_{m_1}^{(j-1)} - \frac{1+\delta}{1-\delta}\omega_{m_1}^{-(j-1)}} = d\sigma_{p-1} + 2\sigma_p, \end{aligned}$$

where

$$\sigma_p = m_1^{-1} \sum_{j=1}^{m_1} \frac{\omega_{m_1}^{p(j-1)}}{2\zeta_k + \omega_{m_1}^{(j-1)} - d\omega_{m_1}^{-(j-1)}}.$$

Using the periodicity $\sigma_{p \pm m_1} = \sigma_p$, the characteristic equation for T_k becomes

$$0 = \det(\lambda I - T_k) = \lambda^{m_1-3}\begin{vmatrix} \lambda - t_{1,1} & -t_{1,m_1-1} & -t_{1,m_1} \\ -t_{m_1-1,1} & \lambda - t_{m_1-1,m_1-1} & -t_{m_1-1,m_1} \\ -t_{m_1,1} & -t_{m_1,m_1-1} & \lambda - t_{m_1,m_1} \end{vmatrix}$$

$$= \lambda^{m_1-3}\begin{vmatrix} \lambda + \sigma_1 & \sigma_1 & -d\sigma_0 - 2\sigma_1 \\ \sigma_{-1} & \lambda + \sigma_{-1} & -d\sigma_{-2} - 2\sigma_{-1} \\ \sigma_0 & \sigma_0 & \lambda - d\sigma_{-1} - 2\sigma_0 \end{vmatrix}$$

$$= \lambda^{m_1-2}\big(\lambda^2 - ((d-1)\sigma_{-1} + 2\sigma_0 - \sigma_1)\lambda + d(\sigma_0^2 - \sigma_{-1}^2 - \sigma_1\sigma_{-1} + \sigma_0\sigma_{-2})\big).$$

Thus, T_k has at most two nonzero eigenvalues

$$\lambda^{(SC)}_{(1,m_1),k} = \frac{(d-1)}{2}\sigma_{-1} + \sigma_0 - \frac{\sigma_1}{2} \pm$$
$$\sqrt{\frac{\sigma_1^2}{4} - (d-1)\sigma_0^2 + \frac{(d+1)^2}{4}\sigma_{-1}^2 + \frac{(d+1)}{2}\sigma_1\sigma_{-1} - \sigma_1\sigma_0 - d\sigma_0\sigma_{-2} + (d-1)\sigma_0\sigma_{-1}}.$$

Now

$$\zeta_k = \frac{\delta}{1-\delta} + \frac{\beta\lambda_{k,2}}{2(1-\delta)} = \frac{d-1}{2} + \frac{\beta\lambda_{k,2}}{2(1-\delta)},$$

and due to Lemma 1 we get $\Re e(\zeta_k) \geq (d-1)/2 > 0$, and $\Re e(\zeta_k) > (d-1)/2$ when $\Im m(\zeta_k) = 0$. From Lemma 2 we then obtain formulas for σ_p. Inserting those formulas into the equation above and rearranging terms, the final formulas for $\lambda^{(SC)}_{(1,m_1),k}$ follow. □

We now determine the eigenvectors of $M^{-1}B$.

THEOREM 3. *Assume that there are constants $\eta_1 \geq \eta_2 > 0$ and $\eta_3 > 0$ such that $\eta_1 \geq |\lambda^{(SC)}_{(1,m_1),k}| \geq \eta_2$ and $|\lambda^{(SC)}_{1,k} - \lambda^{(SC)}_{m_1,k}| \geq \eta_3$. Then the matrix $M^{-1}B$ has a nonsingular eigenvector matrix*

$$W_{M^{-1}B} = (V_2 \otimes I_{m_1})\mathrm{diag}_{k,m_2}(\hat{U}_k).$$

V_2 is the eigenvector matrix of B_2. The columns $\hat{u}^{(j),k}$ of $\hat{U}_k$ are given by

$$\begin{aligned} \hat{u}^{(1),k} &= u^{(1),k}/\|u^{(1),k}\|_2, \\ \hat{u}^{(j),k} &= e_j, \quad j = 2, \ldots, m_1 - 2, \\ \hat{u}^{(m_1-1),k} &= (e_1 - e_{m_1-1})/\sqrt{2}, \\ \hat{u}^{(m_1),k} &= u^{(m_1),k}/\|u^{(m_1),k}\|_2. \end{aligned}$$

The vector e_j denotes the jth canonical vector. The entries of $u^{(1,m_1),k}$ are given by

$$u_p^{(1,m_1),k} = \frac{\lambda^{(SC)}_{(1,m_1),k}(1 - (-d^{-1}z_k)^{m_1}) + 1}{(z_k + dz_k^{-1})(1 - z_k^{m_1})(1 - (-d^{-1}z_k)^{m_1})} z_k^p$$
$$+ \frac{\lambda^{(SC)}_{(1,m_1),k}(1 - z_k^{m_1}) - z_k^{m_1}}{(z_k + dz_k^{-1})(1 - z_k^{m_1})(1 - (-d^{-1}z_k)^{m_1})}(-d^{-1}z_k)^{m_1-p},$$
$$p = 1, \ldots, m_1,$$

where z_k is defined in Theorem 2.

Proof. Lemma 1 yields that V_2 is nonsingular. In Theorem 2 we derived

$$(V_2 \otimes I_{m_1})^{-1} M^{-1} E (V_2 \otimes I_{m_1}) = \mathrm{diag}_{k,m_2}(T_k),$$

where the eigenvalues of T_k are $\lambda_{1,k}^{(SC)}$, $\lambda_{m_1,k}^{(SC)}$, and zero with multiplicity $m_1 - 2$. Only columns $t^{(1)}$, $t^{(m_1-1)}$, $t^{(m_1)}$ of T_k are nonzero and $t^{(1)} = t^{(m_1-1)}$.

We now investigate the eigenvector matrix $\hat{U}_k$ of T_k. Due to the structure of T_k, we conclude that $\left\{\{e_j\}_{j=2}^{m_1-2}, (e_1 - e_{m_1-1})/\sqrt{2}\right\} \in \mathrm{null}(T_k)$. Consequently, those $m_1 - 2$ orthonormal vectors are eigenvectors of T_k corresponding to the eigenvalue zero.

The assumption $|\lambda_{1,k}^{(SC)} - \lambda_{m_1,k}^{(SC)}| \geq \eta_3$ implies that the corresponding eigenvectors $u^{(1),k}$ and $u^{(m_1),k}$ are linearly independent. Furthermore, $|\lambda_{(1,m_1),k}^{(SC)}| \geq \eta_2$ leads to $u^{(1,m_1),k} \notin \mathrm{null}(T_k)$. Thus, T_k has m_1 linearly independent eigenvectors. Using the assumption $|\lambda_{(1,m_1),k}^{(SC)}| \geq \eta_2$, $\sigma_0 \neq 0$, and the formulas for the entries of T_k given in Theorem 2, the two nontrivial eigenvectors become

$$u_p^{(1,m_1),k} = \lambda_{(1,m_1),k}^{(SC)} \sigma_p + d(\sigma_0 \sigma_{p-1} - \sigma_{-1}\sigma_p), \qquad p = 1, \ldots, m_1.$$

By substituting σ_p with formulas from Lemma 2, the formulas for $u^{(1,m_1),k}$ follow. We then obtain

$$\hat{U}_k^{-1} T_k \hat{U}_k = \Lambda_k = \mathrm{diag}_{m_1}(\lambda_{1,k}^{(SC)}, 0, \ldots, 0, \lambda_{m_1,k}^{(SC)}), \qquad k = 1, \ldots, m_2.$$

Now the matrix $W_{M^{-1}B} = (V_2 \otimes I_{m_1})\mathrm{diag}_{k,m_2}(\hat{U}_k)$ is nonsingular and

$$\begin{aligned} W_{M^{-1}B}^{-1} M^{-1} B W_{M^{-1}B} &= I + \mathrm{diag}_{k,m_2}(\hat{U}_k)^{-1}(V_2 \otimes I_{m_1})^{-1} M^{-1} E (V_2 \otimes I_{m_1}) \mathrm{diag}_{k,m_2}(\hat{U}_k) \\ &= I + \mathrm{diag}_{k,m_2}(\hat{U}_k^{-1}) \mathrm{diag}_{k,m_2}(T_k) \mathrm{diag}_{k,m_2}(\hat{U}_k) = I + \mathrm{diag}_{k,m_2}(\Lambda_k), \end{aligned}$$

i.e., $W_{M^{-1}B}$ is the eigenvector matrix of $M^{-1}B$. □

Later (in Corollary 1) it is established that the assumptions in Theorem 3 are valid, when m_1 and m_2 are sufficiently large. Later we will study the condition number reduction $\psi \equiv \mathrm{cond}_2(W_{M^{-1}B}) / \mathrm{cond}_2(W_B)$, where W_B is the eigenvector matrix of B. For the moment we just state the following theorem.

THEOREM 4. *Under the same assumptions as in Theorem* 3,

$$\psi \leq \psi_0 = \max_{1 \leq k \leq m_2} \|\hat{U}_k\|_2 \cdot \max_{1 \leq k \leq m_2} \|\hat{U}_k^{-1}\|_2 \Big/ \mathrm{cond}_2(\hat{V}_1),$$

where $\hat{V}_1$ *is the eigenvector matrix of* $\hat{B}_1$.

Proof. We obtain

$$\begin{aligned} \mathrm{cond}_2(W_{M^{-1}B}) &= \|W_{M^{-1}B}\|_2 \|W_{M^{-1}B}^{-1}\|_2 \\ &= \|(V_2 \otimes I_{m_1})\mathrm{diag}_{k,m_2}(\hat{U}_k)\|_2 \|\mathrm{diag}_{k,m_2}(\hat{U}_k^{-1})(V_2^{-1} \otimes I_{m_1})\|_2 \\ &\leq \|V_2 \otimes I_{m_1}\|_2 \|V_2^{-1} \otimes I_{m_1}\|_2 \|\mathrm{diag}_{k,m_2}(\hat{U}_k)\|_2 \|\mathrm{diag}_{k,m_2}(\hat{U}_k^{-1})\|_2 \\ &= \mathrm{cond}_2(V_2) \cdot \max_{1 \leq k \leq m_2} \|\hat{U}_k\|_2 \cdot \max_{1 \leq k \leq m_2} \|\hat{U}_k^{-1}\|_2. \end{aligned}$$

We also have $W_B = V_2 \otimes \hat{V}_1$ implying

$$\begin{aligned} \mathrm{cond}_2(W_B) &= \|V_2 \otimes \hat{V}_1\|_2 \|V_2^{-1} \otimes \hat{V}_1^{-1}\|_2 = \|V_2\|_2 \|\hat{V}_1\|_2 \|V_2^{-1}\|_2 \|\hat{V}_1^{-1}\|_2 \\ &= \mathrm{cond}_2(V_2) \cdot \mathrm{cond}_2(\hat{V}_1). \end{aligned}$$

Employing these results yields

$$\psi = \frac{\operatorname{cond}_2(W_{M^{-1}B})}{\operatorname{cond}_2(W_B)} \le \max_{1\le k\le m_2} \|\hat{U}_k\|_2 \cdot \max_{1\le k\le m_2} \|\hat{U}_k^{-1}\|_2 \Big/ \operatorname{cond}_2(\hat{V}_1) \equiv \psi_0. \qquad \square$$

Using the information on the spectrum of B_2 given in Lemma 1 and a condition on the grid, it is possible to give asymptotic expressions for the eigenvalues of $M^{-1}E$.

THEOREM 5. *Assume that*

$$0 < \alpha < 1$$

and

$$\frac{m_2(1+2m_2^{-3/2})}{m_1(1-\gamma m_1^{\alpha-1})} \le \varphi\,, \qquad \varphi < 1.$$

Then, in the limit $m_1, m_2 \to \infty$, the nonzero eigenvalues of $M^{-1}E$ approach two curve segments given by

$$\lambda_1^{(SC)}(\theta) = \frac{2-\sqrt{1-\theta^2}+i\theta-\sqrt{-3+6\theta^2-4\sqrt{1-\theta^2}+i\theta(4+6\sqrt{1-\theta^2})}}{4\sqrt{1-\theta^2}},$$
$$-\varphi \le \theta < 0,$$
$$\lambda_1^{(SC)}(\theta) = \frac{2-\sqrt{1-\theta^2}+i\theta+\sqrt{-3+6\theta^2-4\sqrt{1-\theta^2}+i\theta(4+6\sqrt{1-\theta^2})}}{4\sqrt{1-\theta^2}},$$
$$0 \le \theta \le \varphi,$$

$$\lambda_\infty^{(SC)}(\theta) = \bar{\lambda}_1^{(SC)}(\theta)\,, \quad -\varphi \le \theta \le \varphi.$$

Proof. Using $\delta = \gamma m_1^{\alpha-1}$ and $\beta = m_2/m_1$, ζ_k can be rewritten

$$\zeta_k = \frac{\gamma m_1^{\alpha-1}}{1-\gamma m_1^{\alpha-1}} + \frac{m_2\lambda_{k,2}}{2m_1(1-\gamma m_1^{\alpha-1})} \equiv \frac{\gamma m_1^{\alpha-1}}{1-\gamma m_1^{\alpha-1}} + w_k.$$

Exploiting that $\lambda_{k,2} \in \mathcal{E}^+(4m_2^{-3/4}, 2+4m_2^{-3/2})$ yields

$$w_k \in \mathcal{E}^+\left(\frac{2m_2^{1/4}}{m_1(1-\gamma m_1^{\alpha-1})}, \frac{m_2(1+2m_2^{-3/2})}{m_1(1-\gamma m_1^{\alpha-1})}\right), \qquad k = 1, \ldots, m_2.$$

By assumption we have $m_2/m_1 \le \varphi(1-\gamma m_1^{\alpha-1})/(1+2m_2^{-3/2}) < 1$ yielding

$$\frac{2m_2^{1/4}m_1^{-1}}{1-\gamma m_1^{\alpha-1}} < \frac{2m_1^{-3/4}}{1-\gamma m_1^{\alpha-1}},$$

which implies $w_k \in \mathcal{E}^+(2m_1^{-3/4}/(1-\gamma m_1^{\alpha-1}), \varphi)$. Thus,

$$\zeta_k = \epsilon + i\theta_k\,, \qquad -\varphi \le \theta_k \le \varphi,$$
$$\epsilon = \frac{\gamma m_1^{\alpha-1} + 2\delta_k m_1^{-3/4}}{1-\gamma m_1^{\alpha-1}}\,, \qquad 0 \le \delta_k \le 1.$$

For $m_1 \gg 1$ we have $0 < \epsilon \ll 1$, and a Taylor expansion yields

$$z_k = -\zeta_k + \sqrt{d+\zeta_k^2} = -\epsilon - i\theta_k + \sqrt{d-\theta_k^2+\epsilon^2+i2\epsilon\theta_k}$$
$$= \sqrt{d-\theta_k^2} - i\theta_k - \epsilon + \frac{i\epsilon\theta_k}{\sqrt{d-\theta_k^2}} + \mathcal{O}(\epsilon^2).$$

Using $d = (1+\gamma m_1^{\alpha-1})/(1-\gamma m_1^{\alpha-1})$ we obtain $z_{k,\infty} \equiv \lim_{m_1\to\infty} z_k = \sqrt{1-\theta_k^2} - i\theta_k$ and

$$|z_k|^2 = d\left(1 - \frac{2\epsilon}{\sqrt{d-\theta_k^2}}\right) + \mathcal{O}(\epsilon^2)$$
$$= 1 - \frac{2\gamma m_1^{\alpha-1}}{1-\gamma m_1^{\alpha-1}}\left(\frac{1}{\sqrt{d-\theta_k^2}} - 1\right) - \frac{4\delta_k m_1^{-3/4}}{(1-\gamma m_1^{\alpha-1})\sqrt{d-\theta_k^2}} + \mathcal{O}(m_1^{\alpha-1}\epsilon + \epsilon^2).$$

We now determine $\lim_{m_1\to\infty} R_\ell(z_k)$, $\ell = 1, 2$. First consider the case $\theta_k^2 > 0$. Choose $\theta_0^2 > 0$ arbitrarily small. For m_1 sufficiently large we have $2\gamma m_1^{\alpha-1}/(1-\gamma m_1^{\alpha-1}) \le \theta_0^2/2$. For $\theta_0^2 \le \theta_k^2 \le \varphi^2$, we obtain

$$\frac{\theta_0^2}{2} + d - 1 = \frac{\theta_0^2}{2} + \frac{2\gamma m_1^{\alpha-1}}{1-\gamma m_1^{\alpha-1}} \le \theta_0^2 \le \theta_k^2,$$

implying

$$\frac{1}{\sqrt{d-\theta_k^2}} - 1 \ge \frac{1}{\sqrt{1-\theta_0^2/2}} - 1 \ge 1 - \sqrt{1-\frac{\theta_0^2}{2}} \ge \frac{\theta_0^2}{4}.$$

This yields

$$|z_k|^2 \le 1 - 2\gamma m_1^{\alpha-1}\frac{\theta_0^2}{4} + \mathcal{O}(m_1^{\alpha-1}\epsilon + \epsilon^2) = 1 - \frac{\gamma\theta_0^2}{2}m_1^{\alpha-1} + \mathcal{O}(m_1^q),$$
$$q = \max\left(2\alpha - 2, \alpha - \frac{7}{4}, -\frac{3}{2}\right).$$

$0 < \alpha < 1$ leads to $\alpha - 1 > q$ implying

$$\lim_{m_1\to\infty}\left(1 - \frac{\gamma\theta_0^2}{2}m_1^{\alpha-1} + \mathcal{O}(m_1^q)\right)^{m_1/2} = 0,$$

and consequently $\lim_{m_1\to\infty} z_k^{m_1} = 0$. This and $d^{-1} \le 1$ implies $\lim_{m_1\to\infty}(-d^{-1}z_k)^{m_1} = 0$, which yields

$$\lim_{m_1\to\infty} R_1(z_k) = \lim_{m_1\to\infty} R_2(z_k) = 0.$$

Now consider the case $\theta_k = 0$. We obtain $\Im m(w_k) = \Im m(\lambda_{k,2}) = 0$ and

$$\zeta_k = \frac{\gamma m_1^{\alpha-1}}{1-\gamma m_1^{\alpha-1}} + w_k = \epsilon,$$

and consequently $d = 1 + 2\gamma m_1^{\alpha-1}/(1-\gamma m_1^{\alpha-1}) = 1 + 2\epsilon - 2w_k$. This yields

$$|z_k| = -\epsilon + \sqrt{1 + 2\epsilon - 2w_k + \epsilon^2} = -\epsilon + (1+\epsilon)\sqrt{1 - 2w_k(1+\epsilon)^{-2}}$$

$$\leq -\epsilon + (1+\epsilon)\big(1 - w_k(1+\epsilon)^{-2}\big) = 1 - \frac{w_k}{1+\epsilon}$$

$$= 1 - \frac{m_2\lambda_{k,2}}{2m_1(1-\gamma m_1^{\alpha-1})} \Big/ \left(1 + \frac{\gamma m_1^{\alpha-1}}{1-\gamma m_1^{\alpha-1}} + \frac{m_2\lambda_{k,2}}{2m_1(1-\gamma m_1^{\alpha-1})}\right)$$

$$= 1 - \frac{m_2\lambda_{k,2}}{2m_1} \Big/ \left(1 + \frac{m_2\lambda_{k,2}}{2m_1}\right) = \frac{1}{1 + m_2\lambda_{k,2}/(2m_1)}.$$

Using $\lambda_{k,2} > \ln(m_2)/m_2$ from Lemma 1, we obtain

$$|z_k|^{m_1} \leq \frac{1}{\big(1 + \ln(m_2)/(2m_1)\big)^{m_1}} \leq \frac{1}{1 + \ln(m_2)/2}$$

implying

$$\lim_{m_1\to\infty} |z_k|^{m_1} \leq \lim_{m_2\to\infty} \frac{1}{1 + \ln(m_2)/2} = 0.$$

$|z_k| \leq 1$ leads to $|-d^{-1}z_k| \leq d^{-1} \leq 1 - \gamma m_1^{\alpha-1}$ implying $\lim_{m_1\to\infty} |-d^{-1}z_k|^{m_1} = 0$. This yields

$$\lim_{m_1\to\infty} R_1(z_k) = \lim_{m_1\to\infty} R_2(z_k) = 0.$$

With $\lim_{m_1\to\infty} d = 1$, we now obtain

$$\lim_{m_1\to\infty} \lambda^{(SC)}_{(1,m_1),k} = \frac{2 - z_{k,\infty} \pm \sqrt{-3z_{k,\infty}^2 - 4z_{k,\infty}}}{2(z_{k,\infty} + z_{k,\infty}^{-1})}$$

$$= \frac{2 - \sqrt{1-\theta_k^2} + i\theta_k \pm \sqrt{-3 + 6\theta_k^2 - 4\sqrt{1-\theta_k^2} + i\theta_k(4 + 6\sqrt{1-\theta_k^2})}}{4\sqrt{1-\theta_k^2}}.$$

Exploiting $-\varphi \leq \theta_k \leq \varphi$ and distinguishing the branch cut of the square root function, we can conclude that the nonzero eigenvalues of $M^{-1}E$ approach the two curve segments, $\lambda_1^{(SC)}(\theta)$ and $\lambda_\infty^{(SC)}(\theta)$. □

We restate the following corollary originally established in [Otto92].

COROLLARY 1. *It holds that*

$$1 + \lambda_1^{(SC)}(-\varphi) = \chi_1 + \mathcal{O}(\sqrt{1-\varphi}),$$

$$1 + \lambda_1^{(SC)}(0) = \frac{5 + \sqrt{7}i}{4},$$

$$1 + \lambda_1^{(SC)}(\varphi) = \chi_2 + \mathcal{O}(\sqrt{1-\varphi}),$$

$$\frac{15}{28} < |1 + \lambda_1^{(SC)}(\theta)| < 1 + \frac{\sqrt{5}+\sqrt{7}}{4\sqrt{1-\varphi^2}}, \qquad -\varphi \le \theta \le \varphi,$$

$$\frac{5}{14} < |\lambda_1^{(SC)}(\theta)| < \frac{\sqrt{5}+\sqrt{7}}{4\sqrt{1-\varphi^2}}, \qquad -\varphi \le \theta \le \varphi,$$

$$\lim_{m_1 \to \infty} |\lambda_{1,k}^{(SC)} - \lambda_{m_1,k}^{(SC)}| \ge \frac{\sqrt{7}}{2}, \qquad k = 1, \ldots, m_2,$$

where

$$\chi_1 \equiv \frac{4+2i}{5},$$

$$\chi_2 \equiv \frac{2+i}{2\sqrt{1-\varphi^2}} + \frac{7+4i}{10}.$$

Proof. The formulas for $1 + \lambda_1^{(SC)}(0)$ and $1 + \lambda_1^{(SC)}(\pm\varphi)$ are directly derived from the formula for $\lambda_1^{(SC)}(\theta)$ and Taylor expansions. Using the triangle inequality, we obtain

$$|\lambda_1^{(SC)}(\theta)| \le \frac{|2 - \sqrt{1-\theta^2} + i\theta| + \sqrt{|-3(\sqrt{1-\theta^2} - i\theta)^2 - 4(\sqrt{1-\theta^2} - i\theta)|}}{4\sqrt{1-\theta^2}}$$

$$\le \frac{\sqrt{5 - 4\sqrt{1-\theta^2}} + \sqrt{3+4}}{4\sqrt{1-\theta^2}} < \frac{\sqrt{5}+\sqrt{7}}{4\sqrt{1-\varphi^2}},$$

and consequently

$$|1 + \lambda_1^{(SC)}(\theta)| < 1 + \frac{\sqrt{5}+\sqrt{7}}{4\sqrt{1-\varphi^2}}.$$

Introducing $\epsilon = \sqrt{1-\theta^2}$, $0 < \epsilon \le 1$, we get

$$|1 + \lambda_1^{(SC)}(\theta)| \ge \frac{|2 + 3\sqrt{1-\theta^2} + i\theta| - \sqrt{|-3 + 6\theta^2 - 4\sqrt{1-\theta^2} + i\theta(4 + 6\sqrt{1-\theta^2})|}}{4\sqrt{1-\theta^2}}$$

$$= \frac{\sqrt{5 + 12\sqrt{1-\theta^2} + 8(1-\theta^2)} - (25 + 24\sqrt{1-\theta^2})^{1/4}}{4\sqrt{1-\theta^2}}$$

$$= \frac{\sqrt{5 + 12\epsilon + 8\epsilon^2} - \sqrt{5}(1 + \frac{24}{25}\epsilon)^{1/4}}{4\epsilon} \ge \frac{\sqrt{5 + 12\epsilon + 8\epsilon^2} - \sqrt{5}(1 + \frac{6}{25}\epsilon)}{4\epsilon}$$

$$\ge \frac{6\sqrt{5}}{25} > \frac{15}{28}.$$

We also obtain

$$|\lambda_1^{(SC)}(\theta)| \ge \frac{\sqrt{|-3 + 6\theta^2 - 4\sqrt{1-\theta^2} + i\theta(4 + 6\sqrt{1-\theta^2})|} - |2 - \sqrt{1-\theta^2} + i\theta|}{4\sqrt{1-\theta^2}}$$

$$= \frac{(25 + 24\epsilon)^{1/4} - \sqrt{5 - 4\epsilon}}{4\epsilon} \ge \frac{\sqrt{5}(1 + \frac{6\epsilon}{25} - \frac{54\epsilon^2}{625}) - \sqrt{5}(1 - \frac{2\epsilon}{5} - \frac{2\epsilon^2}{25} - \frac{4\epsilon^3}{125})}{4\epsilon}$$

$$= \left(\frac{4}{25} + \frac{5\epsilon^2 - \epsilon}{625}\right)\sqrt{5} > \frac{5}{14}.$$

Finally, we have

$$\lim_{m_1\to\infty} |\lambda_{1,k}^{(SC)} - \lambda_{m_1,k}^{(SC)}| = \left| \frac{\sqrt{-3z_{k,\infty}^2 - 4z_{k,\infty}}}{z_{k,\infty} + z_{k,\infty}^{-1}} \right|$$

$$= \frac{\sqrt{|-3 + 6\theta_k^2 - 4\sqrt{1-\theta_k^2} + i\theta_k(4 + 6\sqrt{1-\theta_k^2})|}}{2\sqrt{1-\theta_k^2}}$$

$$= \frac{(25 + 24\epsilon_k)^{1/4}}{2\epsilon_k} \geq \frac{\sqrt{7}}{2}, \qquad k = 1, \ldots, m_2. \qquad \square$$

We make the following important observations:

(i) In the limit $m_1, m_2 \to \infty$, the restriction on the grid can be reduced to $\beta = m_2/m_1 = \varphi < 1$.

(ii) The curves $\lambda_{1,\infty}^{(SC)}(\theta)$, and hence the estimates in Corollary 1, are independent of α and γ.

(iii) The convergence of the eigenvalues $\lambda_{(1,m_1),k}^{(SC)}$ to the curves $\lambda_{1,\infty}^{(SC)}(\theta)$ essentially depends on that $d = (1 + \gamma m_1^{\alpha-1})/(1 - \gamma m_1^{\alpha-1}) \to 1$ and $R_{1,2}(z_k) \to 0$. Depending on the choice of parameters, these processes occur with different relative speed.

(iv) The interesting case $\alpha = 0$ is excluded from the theorem, since the remainder terms $R_1(z_k)$ and $R_2(z_k)$ will not vanish as $m_1 \to \infty$. This means that $\lambda_{(1,m_1),k}^{(SC)}$ will not converge to $\lambda_{1,\infty}^{(SC)}(\theta)$.

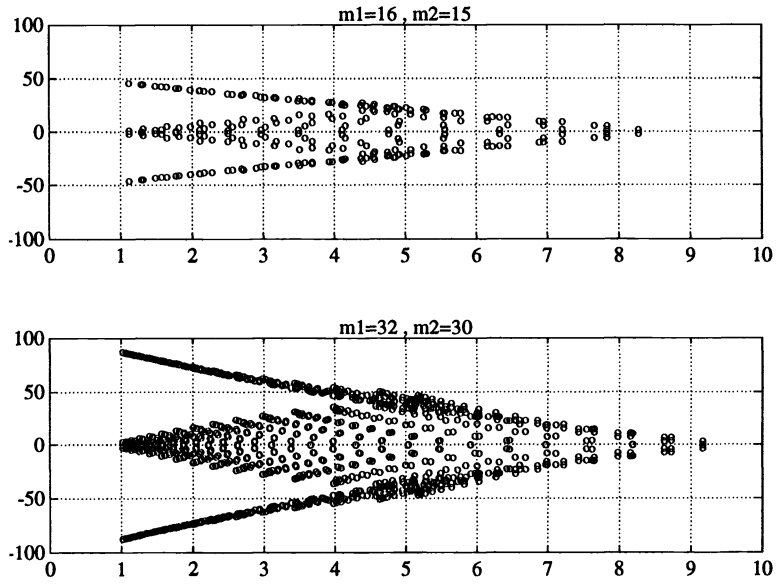

FIG. 1. *Spectra for B when* $\alpha = 0.1$ *and* $\gamma = 0.5$.

In Fig. 1 we show spectra of the unpreconditioned coefficient matrix B for two problem sizes. The parameters chosen for the artificial viscosity are $\alpha = 0.1$ and $\gamma = 0.5$. It is clear that the spectrum of B grows approximately linearly with the number of gridpoints in the fastest growing space direction, since B is a discretization of a first-order differential

operator. In Theorem 5 we have proved that this growth is removed by using the semicirculant preconditioner M. In Figs. 2–4 we show numerically computed spectra for three different choices of parameters. For each parameter set, the eigenvalues of $M^{-1}B$ for two different problem sizes are plotted together with the asymptotic curves $1 + \lambda_{1,\infty}^{(SC)}(\theta)$. The eigenvalues are computed using the formula in Theorem 2, where we have used "exact" eigenvalues of B_2. For all spectra below, we have used $\beta = \frac{15}{16} = 0.9375$. Hence, the curves $1 + \lambda_{1,\infty}^{(SC)}(\theta)$ (which are *not* straight lines) are identical in all graphs. We note that:

(i) The multiplicity of the eigenvalue at 1 is 3720 for the 64×60 problems and 244800 for the 512×480 problems.

(ii) For $\alpha = 0.9$, $R_{1,2}(z_k)$ converges to zero much faster than d converges to one. Hence, the spectrum quickly becomes two "simple" curves, which slowly converge to $1 + \lambda_{1,\infty}^{(SC)}(\theta)$.

(iii) For $\alpha = 0.1$, $R_{1,2}(z_k)$ converges to zero slower than d converges to one. Hence, the spectrum centers around $1 + \lambda_{1,\infty}^{(SC)}(\theta)$, but the oscillations of $R_{1,2}(z_k)$ are still present in the spectrum for the large problem.

(iv) For $\alpha = 0$, $R_{1,2}(z_k)$ will not converge to zero. However, in Fig. 4 we see that the spectrum is contained in a finite region well separated from zero, even for large problems. We have so far not been able to prove this.

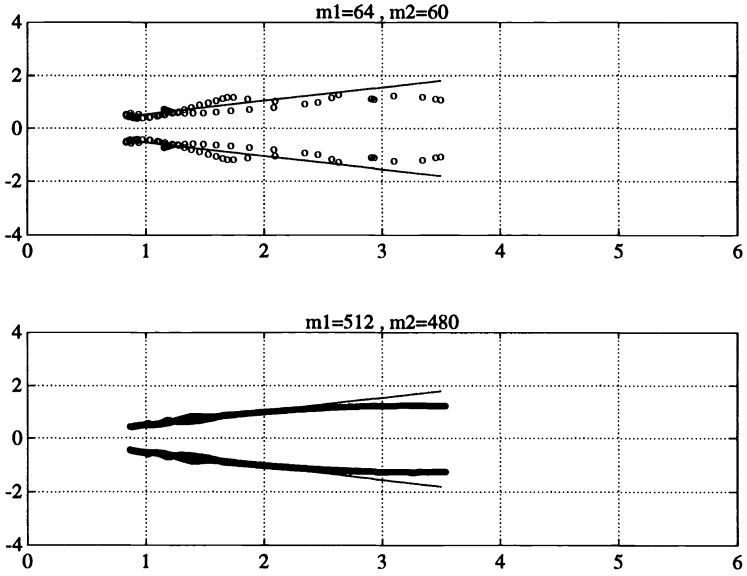

FIG. 2. *Spectra for* $M^{-1}B$ *when* $\alpha = 0.9$ *and* $\gamma = 0.05$.

7. The time-dependent problem. For comparison we restate here the results from [Otto92] using the theorems in §6. A semicirculant preconditioner, with parameters chosen as prescribed in (4), for the coefficient matrix in (7) is given by

$$M = I_{m_2} \otimes C_1 + \kappa_2 B_2 \otimes I_{m_1}, \tag{14}$$

where

$$C_1 = \text{ctrid}_{m_1}(-\kappa_1, 4, \kappa_1).$$

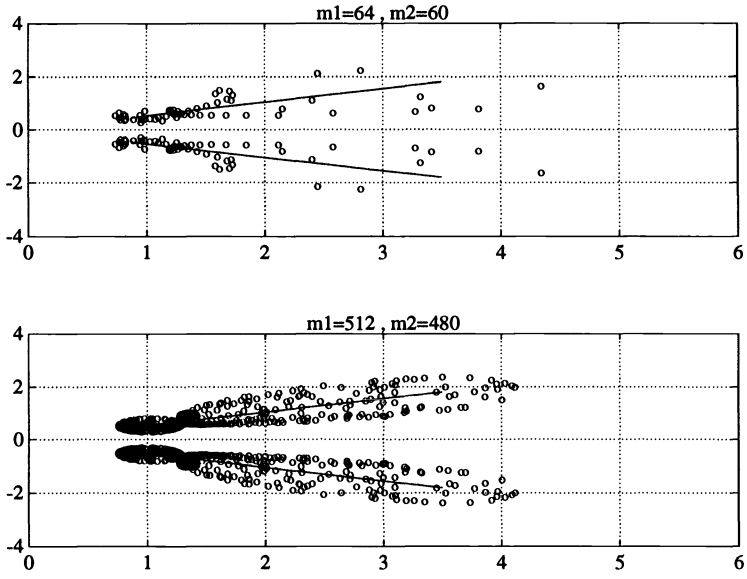

FIG. 3. *Spectra for* $M^{-1}B$ *when* $\alpha = 0.1$ *and* $\gamma = 0.5$.

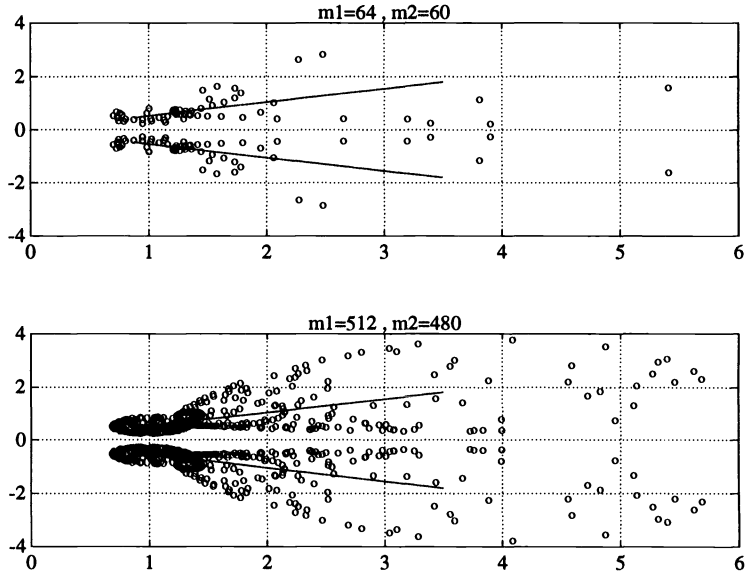

FIG. 4. *Spectra for* $M^{-1}B$ *when* $\alpha = 0$ *and* $\gamma = 0.5$.

We again define the error matrix $E \equiv B - M$. Now put $d = 1$ and define ζ_k by

$$\zeta_k \equiv \frac{4 + \kappa_2 \lambda_{k,2}}{2\kappa_1},$$

where $\lambda_{k,2}$ are the eigenvalues of B_2. Now Theorem 2 applies to this problem too. With some technical changes in the proof, Theorem 5 is also applicable provided

$$\Delta t = ch_1^{\alpha}, \quad 0 < \alpha < 1, \quad c > 0,$$

and

$$\frac{m_2(1+2m_2^{-3/2})}{m_1} \le \varphi\,, \qquad \varphi < 1.$$

The case $\alpha = 0$ could be allowed, since the remainder terms would be bounded.

8. Convergence rate. We solve (1) using GMRES(ℓ), i.e., the restarted GMRES iteration [SaadSch86]. If GMRES is not restarted it is a minimal residual iteration [FrGoNa91]. Hence, in iteration i we have

$$\|r_i\|_2 = \min_{p_i \in \mathcal{P}_i,\ p_i(0)=1} \|p_i(M^{-1}B)r_0\|_2,$$

where $r_i \equiv M^{-1}(Bu_i - b)$ and u_i is the approximation of u computed in iteration i. Since $M^{-1}B$ is diagonalizable by Theorem 3, we obtain

$$\frac{\|r_i\|_2}{\|r_0\|_2} \le \mathrm{cond}_2(W_{M^{-1}B}) \cdot \min_{p_i \in \mathcal{P}_i,\ p_i(0)=1} \max_{1 \le \ell \le n} |p_i(\lambda_\ell)| \equiv \mathrm{cond}_2(W_{M^{-1}B}) \cdot \varepsilon_i, \tag{15}$$

where $W_{M^{-1}B}$ is the eigenvector matrix and λ_ℓ the eigenvalues of $M^{-1}B$. $\mathcal{P}_i$ is the set of all polynomials of maximal degree i. For our model problems Theorem 2 yields that $\{\lambda_\ell\}_{\ell=1}^n = \{1\} \cup \{1 + \lambda^{(SC)}_{(1,m_1),k}\}_{k=1}^{m_2}$. It is normal to define the *asymptotic convergence factor* ϱ by

$$\varrho \equiv \lim_{i \to \infty} \varepsilon_i^{1/i}. \tag{16}$$

The points χ_1 and χ_2 defined in Corollary 1 determine a circle $\mathcal{C}(c, q)$ with center on the positive real axis. Here c denotes the distance from the origin to the center, and q is the radius. In Fig. 5 the curves $1 + \lambda^{(SC)}_{1,\infty}(\theta)$ are plotted for $\varphi = \frac{15}{16}$. The points $\chi_1, \bar{\chi}_1, \chi_2, \bar{\chi}_2$ are denoted by an asterisk (*), and the circle $\mathcal{C}(c, q)$ is drawn as a dotted line.

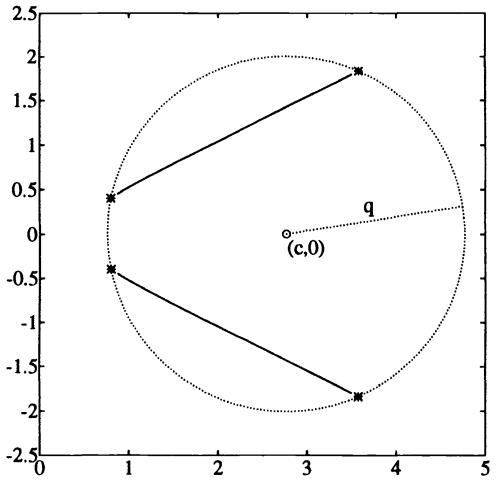

FIG. 5. *Circle* $\mathcal{C}(c, q)$.

Convincing results from numerical experiments [Otto92] corroborate that the curves $1 + \lambda^{(SC)}_{1,\infty}(\theta)$ lie inside $\mathcal{C}(c, q)$, i.e.,

$$|1 + \lambda^{(SC)}_{1,\infty}(\theta) - c| < q\,, \quad -\varphi \le \theta \le \varphi\,, \quad \varphi < 1. \tag{17}$$

In [Saad81] it is shown that, if the spectrum of $M^{-1}B$ is enclosed by $\mathcal{C}(c,q)$ then $\varrho \leq \frac{q}{c}$. Exploiting this result we can prove that, for sufficiently large problems, ϱ is bounded by a quantity less than one.

THEOREM 6. *Presume that the assumptions in Theorem* 5 *are fulfilled and* (17) *holds. Then for* $\epsilon > 0$ *arbitrarily small, there are integers* $\bar{m}_1(\epsilon)$ *and* $\bar{m}_2(\epsilon)$ *such that* ϱ *is bounded by*

$$\varrho < \varrho_\epsilon(\varphi) = \left(\frac{1 + (\frac{40}{225} + \frac{116}{25}\epsilon + \frac{36}{25}\epsilon^2)\sqrt{1-\varphi^2}}{1 + \frac{616}{225}\sqrt{1-\varphi^2}} \right)^{1/2},$$

when $m_1 > \bar{m}_1(\epsilon)$ *and* $m_2 > \bar{m}_2(\epsilon)$.

Proof. The proof follows the technique presented in [Otto92]. Using $\tau \equiv \sqrt{1-\varphi^2}$, $0 < \tau \leq 1$, we have

$$\chi_1 = \frac{4+2i}{5}, \qquad \chi_2 = \left(\tau^{-1} + \frac{7}{10}\right) + \left(\frac{1}{2}\tau^{-1} + \frac{4}{10}\right) i.$$

The circle $\mathcal{C}(c,q)$ is uniquely determined by $q^2 = \big(\Re e(\chi_1) - c\big)^2 + \big(\Im m(\chi_1)\big)^2 = \big(\Re e(\chi_2) - c\big)^2 + \big(\Im m(\chi_2)\big)^2$, which results in

$$c = \frac{25 + 36\tau - 3\tau^2}{4\tau(10-\tau)}, \qquad q = \sqrt{c^2 - \frac{8}{5}c + \frac{4}{5}}.$$

A simple analysis of c yields

$$c^{-1} \leq \frac{\frac{58}{25}\tau}{1 + \frac{616}{225}\tau} \leq \frac{18}{29}.$$

After some careful analysis we obtain

$$\frac{q^2}{c^2} = 1 - \frac{8}{5}c^{-1} + \frac{4}{5}c^{-2} = 1 - \frac{32\tau(10-\tau)(25+16\tau-\tau^2)}{5(25+36\tau-3\tau^2)^2} \leq \frac{1 + \frac{40}{225}\tau}{1 + \frac{616}{225}\tau},$$

implying that $q < c$. Choose $\epsilon > 0$ arbitrarily small. According to Theorem 5 and (17), there exist $\bar{m}_1(\epsilon)$ and $\bar{m}_2(\epsilon)$ such that, the spectrum of $M^{-1}B$ is enclosed by $\mathcal{C}(c, q+\epsilon)$ when $m_1 > \bar{m}_1$ and $m_2 > \bar{m}_2$. Some algebra yields

$$\frac{(q+\epsilon)^2}{c^2} < \frac{q^2}{c^2} + \left(2\epsilon + \frac{18}{29}\epsilon^2\right) \frac{\frac{58}{25}\tau}{1 + \frac{616}{225}\tau} \leq \frac{1 + (\frac{40}{225} + \frac{116}{25}\epsilon + \frac{36}{25}\epsilon^2)\tau}{1 + \frac{616}{225}\tau},$$

and the desired result follows. □

Directly we establish that, for $0 < \epsilon < (\sqrt{1417} - 29)/18 \approx 0.48$, $\varrho_\epsilon(\varphi) < 1$. So there is a margin to enclose the spectrum, when the number of gridpoints is large but still finite.

We now study the upper bound ψ_0 of the condition number reduction ψ defined in Theorem 4. Figure 6 shows ψ_0 for problems of size $2^p \times \frac{15}{16}2^p$, $p = 4, \ldots, 10$. The solid line represents problems with $\alpha = 0.9$ and $\gamma = 0.05$, the dashed line represents $\alpha = 0.1$ and $\gamma = 0.5$, and finally the dashed-dotted line represents $\alpha = 0$ and $\gamma = 0.5$. We see that for increasing problem size, ψ_0 is less than one and decreases dramatically for all values of α examined. Thus, the condition number in estimate (15) is lower for the preconditioned system than for the unpreconditioned system. Also, the gain increases with problem size. So it is clear that

applying the semicirculant preconditioner improves *both* the spectrum *and* the behavior of the eigenvectors of the iteration operator. On the other hand, Theorem 4 yields

$$(18)\quad \mathrm{cond}_2(W_{M^{-1}B}) \le \psi_0 \cdot \mathrm{cond}_2(V_2 \otimes \hat{V}_1) = \max_{1\le k\le m_2} \|\hat{U}_k\|_2 \cdot \max_{1\le k\le m_2} \|\hat{U}_k^{-1}\|_2 \cdot \mathrm{cond}_2(V_2).$$

An analysis shows that $\max_{1\le k\le m_2} \|\hat{U}_k^{-1}\|_2 \to \infty$ when $m_1, m_2 \to \infty$. However, numerical experiments indicate that this growth is slow, whereas $\mathrm{cond}_2(V_2)$ grows significantly with m_2. This is expected since V_2 is the eigenvector matrix of B_2, which corresponds to a discretization of a PDE lacking eigenfunctions. Therefore, the upper bound of $\mathrm{cond}_2(W_{M^{-1}B})$ grows mainly due to the "degenerate" eigenvectors of B_2.

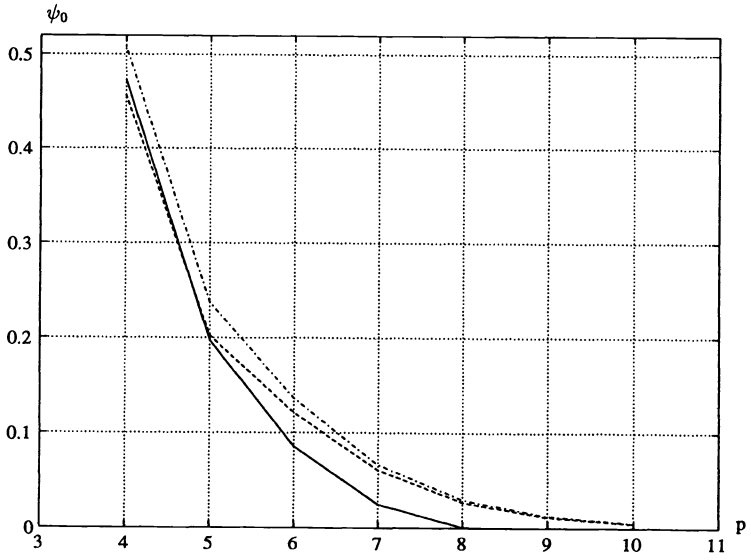

FIG. 6. ψ_0 *as a function of problem size.*

In Fig. 7 the solid line is the graph of the function $\varrho_0(\beta)$, which is the upper bound of ϱ and is defined in Theorem 6, in the limit $m_1, m_2 \to \infty$. The figure also shows the empirically derived convergence factors using the GMRES(20) iteration for some problems where $\alpha = 0.9$ and $\gamma = 0.05$. The symbols $\times$, $\circ$, and $*$ mark problems with $128 \times 128\beta$, $256 \times 256\beta$, $512 \times 512\beta$ unknowns, respectively. We see that, at least for large problems, a substantial improvement in the convergence factor is achieved when reducing β from 1 to ~ 0.9. Hence, we do not have to use many more points in the x_1-direction than in the x_2-direction to attain good convergence. The relatively high convergence factor, for small problems and low grid ratios, seems to be an effect of the finite problem size. Also, the growing upper bound of $\mathrm{cond}_2(W_{M^{-1}B})$ for increasing problem size seems to have little effect on the convergence factor. For practical computations, the bound on the asymptotic convergence factor derived in Theorem 6 governs the convergence.

For nonnormal matrices there is, to our knowledge, no theory that reduces the study of convergence for polynomial iterations with the matrix $M^{-1}B$ to a study of polynomials at $\mathcal{O}(n)$ "easily" computable points such as the eigenvalues $\{\lambda_i\}_{i=1}^n$. No strict convergence estimates are available for "closely nonnormal" or "asymptotically nonnormal" coefficient matrices.

9. Numerical experiments. We show the number of GMRES(6) iterations required to attain $\|r_i\|_2/\|r_0\|_2 \le 10^{-6}$ for the steady-state problem. The initial guess is $u_0 = 0$, and

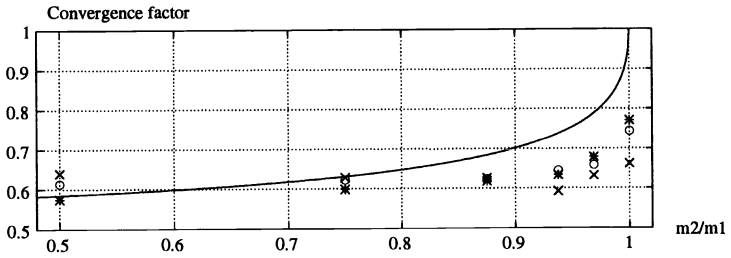

FIG. 7. *The convergence factor as a function of* $\beta = m_2/m_1$.

problems of size $2^p \times \frac{15}{16}2^p$, $p = 4, \ldots, 9$, are studied. We present the results for the same parameter sets as in Figs. 2–4. The solid line represents problems with $\alpha = 0.9$ and $\gamma = 0.05$, the dashed line represents $\alpha = 0.1$ and $\gamma = 0.5$, and finally the dashed-dotted line represents $\alpha = 0$ and $\gamma = 0.5$.

In Fig. 8 we see that for $\alpha > 0$, the number of iterations required does not grow with problem size for large problems. Similar results for the time-dependent problem presented in [Otto92] show that the number of iterations is indeed independent of problem size and κ. Note that also for $\alpha = 0$, there is no large growth in the number of iterations when the problem size is increased.

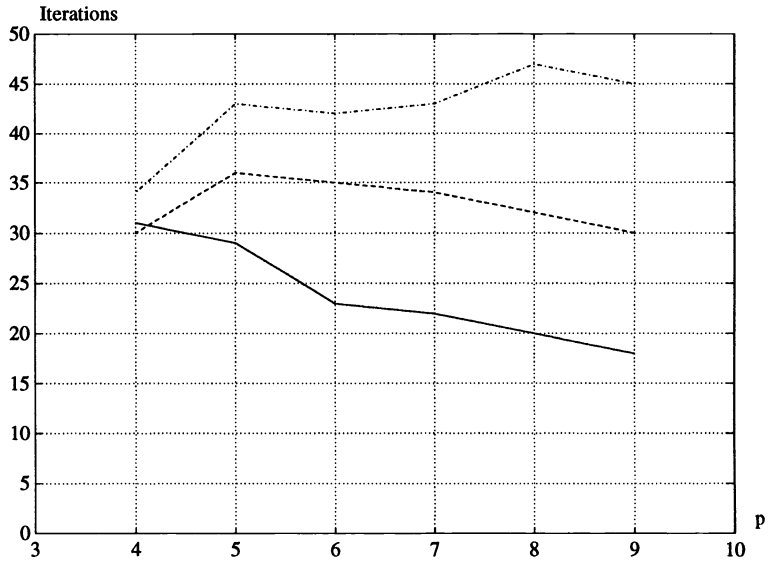

FIG. 8. *The number of* GMRES(6) *iterations required.*

We have also used other iterative methods such as CGS [Sonne89] and transpose-free quasi-minimal residual (TFQMR) [Freund91]. The performance (in terms of the number of matrix-vector multiplies and preconditioner solves) for these methods is similar to the performance for GMRES(6). The restarting length 6 gives a storage requirement for GMRES, which is comparable to those of CGS and TFQMR.

Each preconditioner solve requires quite a large number of arithmetic operations. Hence, we compare the performance obtained when using the semicirculant preconditioner to the performance without preconditioner. In Fig. 9 we show the speedup in CPU time obtained on

a Sun-4/470 using the semicirculant preconditioner combined with the GMRES(6) iteration compared to the unpreconditioned iteration. Again, problems of size $2^p \times \frac{15}{16}2^p$, $p = 4, \ldots, 9$, are studied. It is clear that the speedup is large for large problems. Note that the speedup is greater than one also for small problems. Heuristically, we expect the speedup to grow as $\mathcal{O}(m/\log_2 m)$, when $m = m_1 \approx m_2$ is large.

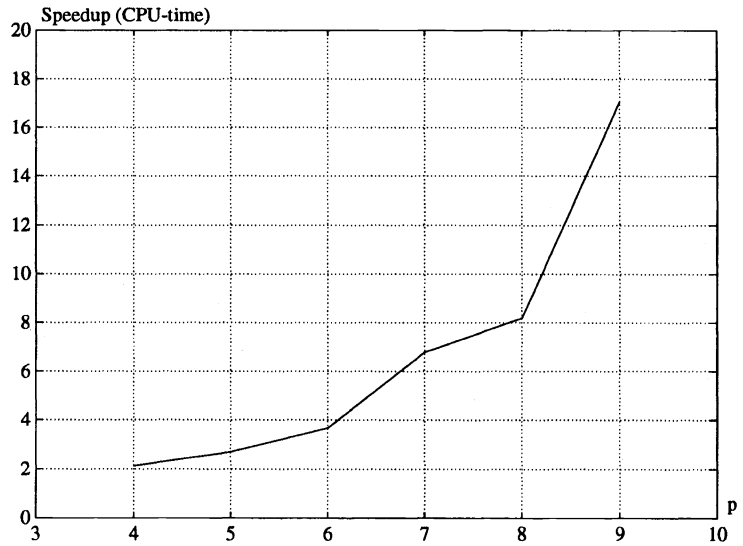

FIG. 9. *CPU time speedup as a function of problem size.*

10. Conclusions. We have used the restarted GMRES iteration combined with a semicirculant preconditioner for solving systems of equations arising from a time-independent hyperbolic PDE in two space dimensions. In the discretization a weak artificial viscosity is added in the x_1-direction. The numerical results indicate that the number of iterations required to solve the systems is independent of problem size. If no preconditioner is used, the number of iterations grows with problem size.

We have proved that, provided the ratio β of gridpoints in the x_2-direction to gridpoints in the x_1-direction is less than one, the spectrum of the preconditioned coefficient matrix asymptotically resides on two finite curve segments separated from zero. The spectrum of the unpreconditioned system asymptotically grows linearly with the number of gridpoints in the x_1-direction. Also, we have demonstrated that the eigenvectors of the preconditioned system are "improved" compared to the unpreconditioned system. The condition number of the eigenvector matrix is dramatically reduced. For practical computations, we have found that the convergence for the GMRES iteration is governed by a bound derived only from properties of the spectrum of the preconditioned coefficient matrix.

ON ADAPTIVE WEIGHTED POLYNOMIAL PRECONDITIONING FOR HERMITIAN POSITIVE DEFINITE MATRICES*

BERND FISCHER† AND ROLAND W. FREUND‡

Abstract. The conjugate gradient algorithm for solving Hermitian positive definite linear systems is usually combined with preconditioning in order to speed up convergence. In recent years, there has been a revival of polynomial preconditioning, motivated by the attractive features of the method on modern architectures. Standard techniques for choosing the preconditioning polynomial are based only on bounds for the extreme eigenvalues. Here a different approach is proposed that aims at adapting the preconditioner to the eigenvalue distribution of the coefficient matrix. The technique is based on the observation that good estimates for the eigenvalue distribution can be derived after only a few steps of the Lanczos process. This information is then used to construct a weight function for a suitable Chebyshev approximation problem. The solution of this problem yields the polynomial preconditioner. In particular, polynomial preconditioners associated with Bernstein–Szegö weights are studied. Results of numerical experiments are reported.

1. Introduction.

One of the most powerful iterative schemes for solving Hermitian positive definite linear systems

$$Ax = b \tag{1.1}$$

is the conjugate gradient (CG) algorithm of Hestenes and Stiefel [16], especially when it is combined with preconditioning [5]. In recent years, there has been much interest in polynomial preconditioning. The basic idea is as follows: instead of solving the original system (1.1) by the CG algorithm, the CG iteration is applied either to

$$\psi(A)Ax = \psi(A)b \tag{1.2}$$

(left preconditioning) or to

$$A\psi(A)y = b, \qquad x = \psi(A)y \tag{1.3}$$

(right preconditioning). Here ψ is a suitably chosen polynomial of small degree. Moreover, it is required that none of the zeros of ψ coincides with an eigenvalue of A. This guarantees that the preconditioned systems (1.2) and (1.3) are both equivalent to (1.1).

Polynomial preconditioning goes back to the 1950s. It seems that Lanczos [21] was the first to mention the idea; interestingly, his paper is never referenced. Stiefel [28] used polynomial preconditioning techniques to accelerate eigenvalue computations. Rutishauser [25] proposed an inner-outer iteration process, with CG as the outer iteration and the Chebyshev semi-iterative method [14] as the inner recursion. The motivation for his approach was to reduce roundoff in the classical CG algorithm. In the 1980s, starting with the work of Johnson,

Micchelli, and Paul [18], there has been a revival of Rutishauser's method and polynomial preconditioning in general; see [2], [9], [23], [26], and the references given there. The main reason for this renewed interest is that polynomial preconditioning is an attractive technique on vector and parallel computers; see, e.g., [27]. Each CG iteration involves the computation of inner products, which constitutes a bottleneck on many modern architectures. Polynomial preconditioning reduces the number of CG iterations and thus the total number of inner products, since the preconditioning step itself, i.e., multiplication by the preconditioner $\psi(A)$, does not require inner products.

For the Chebyshev iteration in Rutishauser's method, estimates α and β for the smallest and largest eigenvalues of A are needed. Often, good upper bounds β can be obtained easily, using simple techniques such as Gershgorin's theorem [26]. It is far more difficult to estimate the smallest eigenvalue. Saad [26] proposed a polynomial preconditioning technique that only requires an upper bound for the largest eigenvalue, while the trivial bound $\alpha = 0$ is used for the smallest eigenvalue of the positive definite matrix A. His technique is based on least-squares polynomials associated with the family of Jacobi weights [29]. Ideally, one would choose the weight function in the Jacobi class such that CG for the preconditioned systems (1.2) and (1.3) converges as fast as possible. However, the problem of finding such an optimal Jacobi weight is not addressed in [26]. Another way to avoid the computation of α and β is to use the CG polynomial itself as preconditioner. This approach was investigated by O'Leary [23]. The disadvantage of this technique is that the preconditioned system is not guaranteed to be positive definite. Ashby, Manteuffel, and Otto [2] demonstrated in a variety of numerical examples that the effectiveness of Chebyshev and least-squares polynomial preconditioners depends on the eigenvalue distribution of the coefficient matrix A.

Another option is to construct polynomial preconditioners via weighted Chebyshev approximation problems. This was proposed by Freund [9] who also suggested a heuristic for adapting the weight function to the eigenvalue distribution of A. The technique exploits the observation that eigenvalue distributions of Hermitian matrices can be surprisingly well estimated, using only a few steps of the Lanczos method. Actually, spectral estimation based on the Lanczos process is a widely used technique in applications; see, e.g., [24] and the references given there. The obtained estimated eigenvalue distribution is then used to construct a weight function, and finally the polynomial preconditioner is computed by solving the corresponding approximation problem.

In this paper, we further study polynomial preconditioning based on weighted Chebyshev approximation problems. In particular, we investigate the use of Bernstein–Szegö weights [29]. For such weights, the solutions of the associated approximation problems are known explicitly. Therefore, the construction of preconditioning polynomials based on Bernstein–Szegö weights does not involve the numerical solution of an approximation problem.

The remainder of this paper is organized as follows. In §2, we recall some basic properties of CG, and we discuss Chebyshev polynomial preconditioning. In §3, we present our approach to polynomial preconditioning based on weighted Chebyshev approximation problems, and we propose a procedure for obtaining a suitable weight function from the Lanczos process. This technique involves the construction of a monotone interpolant. In §4, we briefly describe a procedure for monotone piecewise cubic interpolation. In §5, we consider polynomial preconditioners based on Bernstein–Szegö weights. In §6, results of numerical experiments are reported. Finally, in §7, we make some concluding remarks.

Throughout the paper, it is always assumed that A in (1.1) is a Hermitian positive definite $N \times N$ matrix, with real or complex entries. As usual, M^H denotes the conjugate transpose of a matrix M, and the vector norm $\|x\| = \sqrt{x^H x}$ is the Euclidean norm. Finally, we denote by

$$\mathcal{P}_n := \{\varphi(\lambda) \equiv \sigma_0 + \sigma_1\lambda + \cdots + \sigma_n\lambda^n \mid \sigma_0, \sigma_1, \ldots, \sigma_n \in \mathbb{C}\}$$

the set of all complex polynomials of degree at most n.

2. CG and Chebyshev polynomial preconditioning. In this section, we collect some basic facts about CG, and we review Chebyshev polynomial preconditioning.

2.1. The CG algorithm. Let $x_0 \in \mathbb{C}^N$ be any initial guess for the solution of (1.1), and let $r_0 := b - Ax_0$ be the associated residual vector. The CG algorithm generates iterates of the form

$$x_n = x_0 + \chi_n(A)r_0, \quad \text{where } \chi_n \in \mathcal{P}_{n-1}, \quad n = 1, 2, \ldots . \tag{2.1}$$

The corresponding residual vectors are given by

$$r_n = \phi_n(A)r_0, \quad \text{where } \phi_n(\lambda) \equiv 1 - \lambda\chi_n(\lambda). \tag{2.2}$$

In exact arithmetic, the CG algorithm terminates after a finite number of steps with the exact solution $x_L = A^{-1}b$ of (1.1). In the sequel, L always denotes this termination index. We remark that L is just the minimal number of components in any expansion of r_0 into orthonormal eigenvectors v_j of A, and thus we have

$$r_0 = \sum_{j=1}^{L} \sigma_j v_j, \quad \text{where } \sigma_j \neq 0 \quad \text{for all } j. \tag{2.3}$$

In particular, $L \leq N$. In the following, we always assume that the vectors v_j have been scaled such that $\sigma_j > 0$ in (2.3). Furthermore, we denote by λ_j the eigenvalues corresponding to the eigenvectors v_j in (2.3), and thus we have

$$Av_j = \lambda_j v_j. \tag{2.4}$$

Since the number of terms in the representation (2.3) is minimal, it follows that the λ_j's are distinct. From now on, we assume that they are numbered in increasing order:

$$\lambda_1 < \lambda_2 < \cdots < \lambda_L. \tag{2.5}$$

The CG iterates are optimal, in the sense that $r_n^H A^{-1} r_n$ is minimal for all possible iterates of the form (2.1). This minimization property can be shown to be equivalent to the following orthogonality relations:

$$r_n^H r_k = 0 \quad \text{for all} \quad n, k = 0, 1, \ldots, L, \ n \neq k. \tag{2.6}$$

Using (2.2), (2.3), and (2.4), we can rewrite (2.6) in the form

$$\langle \phi_n, \phi_k \rangle = 0 \quad \text{for all } n, k = 0, 1, \ldots, L, \ n \neq k,$$

where

$$\langle \phi_n, \phi_k \rangle := r_0^H \phi_n(A)\phi_k(A)r_0 = \sum_{j=1}^{L} \sigma_j^2 \phi_n(\lambda_j)\phi_k(\lambda_j). \tag{2.7}$$

We remark that—even for complex Hermitian A—all CG polynomials ϕ_n have real coefficients, and hence no complex conjugation of ϕ_n is needed in (2.7).

It is well known (see, e.g., [13]) that the CG method and the Lanczos process [20] for tridiagonalizing A are mathematically equivalent. Using this connection, it can be shown that, for each fixed $n \in \{1, 2, \ldots, L\}$, the residual polynomials $\phi_0, \phi_1, \ldots, \phi_n$ are also orthogonal with respect to the inner product induced by J_n. Here, J_n denotes the $n \times n$ tridiagonal matrix generated by the first n steps of the Lanczos process. Before we state these orthogonality relations, we introduce some more notation. Let $n \in \{1, 2, \ldots, L\}$ be fixed, and let $\theta_j := \theta_j^{(n)}$, $j = 1, 2, \ldots, n$, denote the eigenvalues of J_n. The θ_j's are called the nth Ritz values of A. They are all distinct, and we assume that they are numbered in increasing order:

$$\theta_1 < \theta_2 < \cdots < \theta_n. \tag{2.8}$$

Let s_j be a set of corresponding orthonormal eigenvectors, i.e.,

$$J_n s_j = \theta_j s_j, \qquad \|s_j\| = 1.$$

Moreover, we assume that the s_j's are normalized such that their first components, $\tau_j := e_1^H s_j$, are all real and nonnegative. Here, e_1 denotes the first unit vector in $\mathbb{R}^n$. With these notations, the orthogonality relations can be stated as follows:

$$\langle \phi_i, \phi_k \rangle_n = 0 \quad \text{for all } i, k = 0, 1, \ldots, n, \ i \neq k,$$

where

$$\langle \phi_i, \phi_k \rangle_n := e_1^H \phi_i(J_n)\phi_k(J_n)e_1 = \sum_{j=1}^{n} \tau_j^2 \phi_i(\theta_j)\phi_k(\theta_j). \tag{2.9}$$

From now on, we assume that α and β are given real numbers satisfying

$$0 \leq \alpha \leq \lambda_1 \quad \text{and} \quad \lambda_L \leq \beta. \tag{2.10}$$

The condition (2.10) guarantees that the eigenvalues (2.5) of A and all Ritz values (2.8) are contained in the interval $[\alpha, \beta]$. In the sequel, we will make frequent use of the linear transformation

$$t := \ell(\lambda) \equiv \frac{2\lambda - (\beta + \alpha)}{\beta - \alpha}, \tag{2.11}$$

which maps $[\alpha, \beta]$ onto the unit interval $[-1, 1]$. In particular, it will turn out to be convenient to rewrite, by means of (2.11), the inner products (2.7) and (2.9) in terms of $[-1, 1]$. We set $\hat{t}_j := \ell(\lambda_j)$ and $t_j := \ell(\theta_j)$. From (2.7) and (2.9), we obtain

$$\begin{aligned} \langle \phi_n, \phi_k \rangle &= \sum_{j=1}^{L} \sigma_j^2 \phi_n(\lambda_j)\phi_k(\lambda_j) \\ &= \sum_{j=1}^{L} \sigma_j^2 \phi_n(\ell^{-1}(\hat{t}_j))\phi_k(\ell^{-1}(\hat{t}_j)) =: \int_{\mathbb{R}} \phi_n(\ell^{-1}(t))\phi_k(\ell^{-1}(t))\, d\sigma(t) \end{aligned} \tag{2.12}$$

and

$$\begin{aligned} \langle \phi_i, \phi_k \rangle_n &= \sum_{j=1}^{n} \tau_j^2 \phi_i(\theta_j)\phi_k(\theta_j) \\ &= \sum_{j=1}^{n} \tau_j^2 \phi_i(\ell^{-1}(t_j))\phi_k(\ell^{-1}(t_j)) =: \int_{\mathbb{R}} \phi_i(\ell^{-1}(t))\phi_k(\ell^{-1}(t))\, d\tau(t), \end{aligned} \tag{2.13}$$

respectively. The distribution functions $\sigma(t)$ and $\tau(t)$ in the Riemann–Stieltjes integrals defined in (2.12) and (2.13) are step functions, and they are given by

$$\sigma(t) \equiv \sum_{j=1}^{L} \sigma_j^2 H(t - \hat{t}_j), \quad \text{where } H(t) \equiv \begin{cases} 1 & \text{for } t \geq 0, \\ 0 & \text{otherwise,} \end{cases} \tag{2.14}$$

and

$$\tau(t) \equiv \sum_{j=1}^{n} \tau_j^2 H(t - t_j), \tag{2.15}$$

respectively.

We now turn to polynomial preconditioning. For simplicity, we will focus only on right preconditioning (1.3), but all statements in this paper essentially remain true for left preconditioning (1.2). From now on, it is always assumed that $p > 1$ is a given integer, and we consider preconditioning polynomials $\psi \in \mathcal{P}_{p-1}$ in (1.3).

2.2. Chebyshev polynomial preconditioning. The standard approach for the design of preconditioners is to choose the polynomial ψ in (1.3) such that $A\psi(A)$ is, in some sense, as close as possible to the identity matrix I. For instance, one could attempt to minimize the Euclidean norm $\|I - A\psi(A)\|$. However, the solution of this problem would require the knowledge of all eigenvalues of A. Therefore, one usually substitutes for the spectrum of A an interval $[\alpha, \beta]$ that is known to contain all eigenvalues of A. In addition, it is required that $\alpha > 0$. This approach then leads to a Chebyshev approximation problem on the interval $[\alpha, \beta]$. After rewriting, by means of the transformation $\ell(\lambda)$ in (2.11), this problem in terms of the unit interval $[-1, 1]$, we obtain the Chebyshev approximation problem

$$\min_{\varphi \in \mathcal{P}_p:\, \varphi(\zeta)=1} \; \max_{t \in [-1,1]} |\varphi(t)|. \tag{2.16}$$

Here, $\zeta := \ell(0)$ and $\varphi(\ell(\lambda)) \equiv 1 - \lambda\psi(\lambda)$. It is well known that the optimal solution φ_p of (2.16) is just the suitably scaled pth Chebyshev polynomial of the first kind, T_p, and we have

$$\varphi_p(t) \equiv \frac{T_p(t)}{T_p(\zeta)}. \tag{2.17}$$

Note that the spectrum of the preconditioned matrix $A\psi_p(A)$ is contained in the interval

$$[\alpha_p, \beta_p], \quad \text{where } \alpha_p := 1 - \frac{1}{|T_p(\zeta)|} \quad \text{and} \quad \beta_p := 1 + \frac{1}{|T_p(\zeta)|}. \tag{2.18}$$

As in (2.2), let $r_{np} = \phi_{np}(A)r_0$ denote the residual vector obtained after np steps of CG applied to the original system (1.1). Similarly, let $r_n^{(\mathrm{P})} = \phi_n^{(\mathrm{P})}(A\psi_p(A))r_0$ be the nth residual vector generated by CG applied to the preconditioned system (1.3). In view of the optimality properties of the CG algorithm, we have

$$\begin{aligned} r_{np}^H A^{-1} r_{np} &= \min_{\phi \in \mathcal{P}_{np}:\, \phi(0)=1} (\phi(A)r_0)^H A^{-1} (\phi(A)r_0) \\ &\leq (\phi_n^{(\mathrm{P})}(A\psi_p(A))r_0)^H A^{-1} (\phi_n^{(\mathrm{P})}(A\psi_p(A))r_0) = (r_n^{(\mathrm{P})})^H A^{-1} r_n^{(\mathrm{P})}. \end{aligned}$$

As a result, n steps of CG applied to (1.3) can at best give the same residual vector as np steps of CG applied to (1.1). Therefore, Chebyshev polynomial preconditioning is indeed best possible, provided that the residual polynomials ϕ_{np} and $\phi_n^{(\mathrm{P})}$ satisfy

$$\phi_{np}(\lambda) \equiv \phi_n^{(\mathrm{P})}(\lambda\psi_p(\lambda)). \tag{2.19}$$

Next, we show that (2.19) is fulfilled if the distribution function $\sigma(t)$ defined in (2.14) corresponds to the worst-case distribution for the interval $[-1, 1]$.

The function $\sigma(t)$ is a step function with jumps at the translated eigenvalues $\hat{t}_j = \ell(\lambda_j)$ of A. For our discussion, we treat $\sigma(t)$ as a continuous function, and we denote by

$$\delta(t) \equiv \frac{d\sigma(t)}{dt} \tag{2.20}$$

the associated density function. Actually, since the dimension N of A (and thus L) is usually large, the step function "looks like" a continuous function; see Fig. 3.1 for an example. From potential theory, it is known that the worst-case distribution is just the equilibrium distribution, and for the case of the unit interval, it is given by

$$\sigma^{(\mathrm{E})}(t) \equiv \arcsin t, \qquad t \in [-1, 1]. \tag{2.21}$$

Furthermore, the orthogonal polynomials with respect to the corresponding inner product are the Chebyshev polynomials of the first kind, and we have, for all integers n, $k \geq 0$, $n \neq k$,

$$\int_{-1}^{1} T_n(t)T_k(t)\delta^{(\mathrm{E})}(t)\,dt = 0, \quad \text{where } \delta^{(\mathrm{E})}(t) \equiv \frac{1}{\sqrt{1-t^2}}. \tag{2.22}$$

We remark that (2.22) can be evaluated by means of Gaussian quadrature. This gives

$$\int_{-1}^{1} T_n(t)T_k(t)\delta^{(\mathrm{E})}(t)\,dt = \sum_{j=1}^{L} \hat{\sigma}_j^2 T_n(\hat{t}_j)T_k(\hat{t}_j), \qquad n, k < L.$$

In other words, for the distribution function defined by (2.21) the CG residuals correspond to Chebyshev polynomials. We remark that in this case the standard error bounds for the CG iterates are sharp; see [15]. Finally, we show that for the worst-case distribution (2.21) the relation (2.19) is satisfied, and hence Chebyshev polynomial preconditioning is optimal in this case.

LEMMA 2.1. *Let ℓ_p denote the linear mapping that maps $[\alpha_p, \beta_p]$ (cf. (2.18)) onto the unit interval $[-1, 1]$, and let $\zeta_p := \ell_p(0)$. Let $\phi_{np}(\lambda) \equiv T_{np}(\ell(\lambda))/T_{np}(\zeta)$ and $\phi_n^{(\mathrm{P})}(\lambda) \equiv T_n(\ell_p(\lambda))/T_n(\zeta_p)$ be the shifted and normalized Chebyshev polynomial on $[\alpha, \beta]$ and $[\alpha_p, \beta_p]$, respectively. Then the identity* (2.19) *is satisfied.*

Proof. From (2.18) and (2.17) one readily obtains

$$\phi_n^{(\mathrm{P})}(\lambda\psi_p(\lambda)) \equiv \frac{T_n(T_p(\ell(\lambda)))}{T_n(T_p(\zeta))}.$$

Equation (2.19) then follows from the well-known identity $T_{np}(t) \equiv T_n(T_p(t))$. □

3. Weighted polynomial preconditioning. As discussed in the previous section, Chebyshev polynomial preconditioning is optimal for matrices A, for which the function $\sigma(t)$ in (2.14) is the worst-case distribution. However, in practice, linear systems, especially those arising in the numerical treatment of partial differential equations, have eigenvalue distributions that are far from the worst case. For those, Chebyshev polynomial preconditioning is not optimal. Furthermore, it is known [1] that repeated application of Chebyshev polynomials will transform any given distribution into the worst-case distribution. This behavior is also reflected in Chebyshev polynomial preconditioning. If A has a favorable eigenvalue distribution, then the eigenvalue distribution of the preconditioned system is usually much closer to the worst case.

In this section, we propose a heuristic for adapting the preconditioning polynomial to the actual eigenvalue distribution of A.

3.1. Weighted Chebyshev approximation problems. Instead of (2.16), we now consider weighted Chebyshev approximation problems of the form

$$\min_{\varphi\in\mathcal{P}_p:\,\varphi(\zeta)=1}\ \max_{t\in[-1,1]}\ |w(t)\varphi(t)|, \quad \text{where } \zeta = \ell(0). \tag{3.1}$$

Here, w is a continuous weight function on the unit interval $[-1, 1]$, and it is always assumed that $w(t) > 0$ on the open interval $(-1, 1)$. Standard results from approximation theory (see, e.g., [22]) guarantee that there exists a unique optimal polynomial φ_p for (3.1). In general, φ_p is not known explicitly, and one needs to solve (3.1) numerically, for example, using the Remez algorithm; see, e.g., [22], [12]. Note that, for $w(t) \equiv 1$, the problem (3.1) reduces to (2.16), and the scaled Chebyshev polynomial (2.17) is the solution of (3.1).

The idea now is to use—instead of the Chebyshev polynomial (2.17)—the optimal solution φ_p of (3.1) as a polynomial preconditioner, where the weight function w is chosen based on an estimate for the density δ of the eigenvalue distribution of A.

It remains to give a heuristic for the choice of the weight function w in (3.1). If the estimated density δ of A happens to be the worst-case density $\delta^{(\mathrm{E})}$ defined in (2.22), then the solution of (3.1) should yield the optimal preconditioner for the worst case. As shown in §2, Chebyshev polynomials are optimal in this case. Therefore, the weight function should be constructed such that $w(t) \equiv 1$ if $\delta(t) \equiv 1/\sqrt{1-t^2}$. Motivated by this consideration, we propose the choice

$$w(t) \equiv \sqrt{\delta(t)\sqrt{1-t^2}}, \tag{3.2}$$

where $\delta(t)$ is an estimate for the eigenvalue density defined in (2.20). We stress that the connection between w and δ in (3.2) is very natural. Indeed, it is known that, for certain families of densities δ, the weighted L_2-approximation problem

$$\min_{\varphi\in\mathcal{P}_p:\,\varphi(\zeta)=1}\ \int_{-1}^{1} |\varphi(t)|^2\delta(t)\,dt$$

and the weighted Chebyshev approximation problem (3.1) with w given by (3.2) have the same optimal solution φ_p. For example, this is true for the worst-case density $\delta^{(\mathrm{E})}$ and for the more general class of densities associated with Bernstein–Szegö polynomials; this was first observed by Bernstein [3].

3.2. Estimating the distribution function. Usually, a good estimate for the eigenvalue distribution σ in (2.14) can be derived from the quantities generated by relatively few steps of the Lanczos process. Actually, since the Lanczos algorithm is equivalent to CG, we can extract all necessary information from a few steps of the CG algorithm applied to the original system (1.1).

Suppose we run CG for n steps. The process then has generated the entries of the $n \times n$ tridiagonal Lanczos matrix J_n. The Ritz values θ_j for J_n and the first component τ_j of the corresponding orthonormal eigenvectors define the inner product $\langle\cdot,\cdot\rangle_n$ in (2.9). It can be shown that $\langle\cdot,\cdot\rangle_n$ and the inner product $\langle\cdot,\cdot\rangle$ in (2.7) have the same moments up to degree $2n-1$, i.e., for all real polynomials ϕ of degree at most $2n-1$, it holds that

$$\langle 1, \phi\rangle_n = \langle 1, \phi\rangle.$$

This condition implies, roughly speaking, that the distribution $\tau(t)$ of the Ritz values has to be close to the eigenvalue distribution $\sigma(t)$. This statement can be made more precise, in the sense of the following theorem due to Karlin and Shapley [19, Thm. 22.2].

THEOREM 3.1. *Let $\sigma(t)$ and $\tau(t)$ denote the distribution functions defined in* (2.14) *and in* (2.15), *respectively. Then the difference function $\sigma(t) - \tau(t)$, if not identically zero, has exactly $2n - 1$ sign changes in the interval* $[-1, 1]$.

Next, we illustrate this result for the case of Example 6.1 described in §6. We only consider the case $h = \frac{1}{64}$, which leads to a matrix A of order $N = 3844$. In Fig. 3.1, the "continuous-looking" curve is the eigenvalue distribution $\sigma(t)$ of A, while the step function is the Ritz-value distribution $\tau(t)$ obtained after $n = 10$ steps of the CG algorithm. Note that the horizontal and vertical steps of $\tau(t)$ intersect $\sigma(t)$ exactly 19 times in $[-1, 1]$, in accordance with Theorem 3.1.

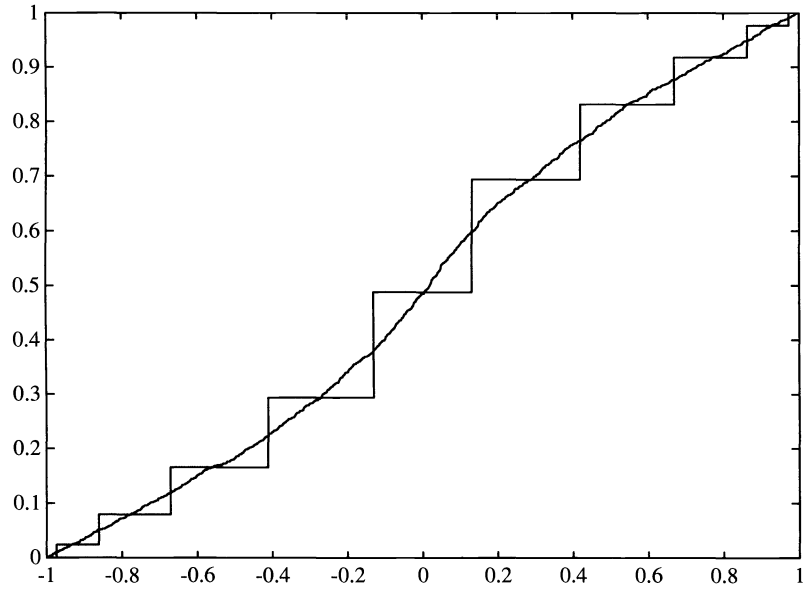

FIG. 3.1. *Distribution $\tau(t)$ of the Ritz values corresponding to $n = 10$ and eigenvalue distribution $\sigma(t)$ for Example* 6.1 *with $h = \frac{1}{64}$.*

We remark that, in Fig. 3.1, the midpoints of the vertical steps of $\tau(t)$ are very good approximations to points on the unknown curve $\sigma(t)$. This behavior is rather typical, and it was also observed by others [24, p. 6]. This suggests using interpolation at the vertical midpoints of $\tau(t)$ to construct an estimate, denoted by $f(t)$ in the sequel, for the true eigenvalue distribution $\sigma(t)$.

More precisely, we proceed as follows. First, we need to choose numbers α and β that satisfy (2.10). We stress that the lower bound α is only required to be nonnegative. In particular, the trivial choice $\alpha = 0$ is feasible, and this is one of the strengths of our approach. Of course, if there are better lower bounds for the smallest eigenvalue at hand, one should use these. However, we stress that overestimating the smallest eigenvalue may slow down the convergence rate. Typically, the largest Ritz value θ_n is a good approximation for the largest eigenvalue of A, and therefore we usually set $\beta := \theta_n$. This choice is not critical. Indeed, if there are a few eigenvalues larger than β, the preconditioning polynomial amplifies them, and the CG iteration will rapidly suppress components corresponding to these large eigenvalues.

Once α and β are chosen, we define the interpolating points by setting

$$t_j := \begin{cases} -1 & \text{for } j = 0, \\ \ell(\theta_j) & \text{for } j = 1, 2, \ldots, n-1, \\ 1 & \text{for } j = n, \end{cases}$$

and

$$\vartheta_j := \begin{cases} 0 & \text{for } j = 0, \\ \tau_j^2/2 + \sum_{i=1}^{j-1} \tau_i^2 & \text{for } j = 1, 2, \ldots, n-1, \\ 1 & \text{for } j = n. \end{cases}$$

Here, $\ell(\lambda)$ is again the linear map given by (2.11). Finally, the estimated distribution is then chosen as a monotone function $f \in C^1[-1, 1]$ satisfying

$$f(t_j) = \vartheta_j, \qquad j = 0, 1, \ldots, n. \tag{3.3}$$

4. Monotone piecewise cubic interpolation. One obvious choice for the interpolating function f is a monotone piecewise cubic interpolant. In this section, we briefly describe how to construct such a function. We follow the derivation of Fritsch and Carlson [11] and Fritsch and Butland [10].

Let $-1 = t_0 < t_1 < \cdots < t_n = 1$ and $0 = \vartheta_0 < \vartheta_1 < \cdots < \vartheta_n = 1$ be given. The goal is to construct a piecewise cubic function $f \in C^1[-1, 1]$ such that $f(t_i) = \vartheta_i$, $i = 0, 1, \ldots, n$, and f is monotone on $[-1, 1]$. To this end, one expresses f, on any subinterval $[t_i, t_{i+1}]$, in terms of the derivatives $d_i = f'(t_i)$, $i = 0, 1, \ldots, n$, as described in [11]. This leads to the representation

$$f(t) \equiv \left(\frac{d_i + d_{i+1} - 2\Delta_i}{h_i^2}\right)(t - t_i)^3 + \left(\frac{-2d_i - d_{i+1} + 3\Delta_i}{h_i}\right)(t - t_i)^2 + d_i(t - t_i) + \vartheta_i,$$

where $h_i := t_{i+1} - t_i$ and $\Delta_i := (\vartheta_{i+1} - \vartheta_i)/h_i$, $i = 0, 1, \ldots, n-1$.

By construction, any choice of the free parameters d_i leads to a function $f \in C^1[-1, 1]$ that fulfills (3.3). The remaining step is to adjust the d_i's such that f is monotone on $[-1, 1]$.

Note that the d_i's are not uniquely determined, and various choices have been discussed in the literature. Here, we use a formula proposed by Brodlie [4] and Fritsch and Butland [10]:

$$d_i := \begin{cases} \dfrac{\Delta_{i-1}\Delta_i}{\xi_i\Delta_i + (1 - \xi_i)\Delta_{i-1}} & \text{for } \Delta_{i-1}\Delta_i > 0, \\ 0 & \text{otherwise,} \end{cases} \qquad i = 1, 2, \ldots, n-1, \tag{4.1}$$

where $\xi_i := (h_{i-1} + 2h_i)/(3(h_{i-1} + h_i))$. In addition to (4.1), we still need to choose the boundary conditions d_0 and d_n. Since, in our case, no information about the derivatives at the endpoints is available, we select a weak version of the so-called "not-a-knot" condition; see De Boor [6, p. 54]. Here one chooses d_0 and d_n such that f is twice continuously differentiable on $[t_0, t_2)$ and $(t_{n-2}, t_n]$, respectively. One obtains

$$\begin{aligned} d_0 &= \frac{h_0}{h_1}\big(3\Delta_1 - (2d_1 + d_2)\big) + 3\Delta_0 - 2d_1, \\ d_n &= \frac{h_{n-1}}{h_{n-2}}\big(3\Delta_{n-2} - (2d_{n-1} + d_{n-2})\big) + 3\Delta_{n-1} - 2d_{n-1}. \end{aligned} \tag{4.2}$$

However, this special choice of d_0 and d_n does not necessarily produce a monotone f on the subintervals $[t_0, t_1]$ and $[t_{n-1}, t_n]$, respectively. Note that the additional requirements $d_0 \in [0, 3\Delta_0]$ and $d_n \in [0, 3\Delta_{n-1}]$ will lead to a monotone function. Thus, if, for example, d_0 (computed by (4.2)) turns out to be negative or bigger than $3\Delta_0$, we simply set $d_0 = 0$ or $d_0 = 3\Delta_0$, respectively.

We would like to mention that FORTRAN codes for the described procedures are available in NETLIB (PCHIP package).

Finally, in analogy to (2.20), we set

$$\delta(t) \equiv f'(t), \tag{4.3}$$

where f is the computed monotone interpolant, and we define the weight function $w(t) \equiv w(t; f)$ by (3.2). Note that $w(t; f)$ is continuous on $[-1, 1]$. The desired polynomial preconditioner is then obtained by solving the resulting weighted Chebyshev approximation problem (3.1) numerically, using the Remez algorithm. One might ask why we did not use the simpler approach of constructing f as a monotone piecewise linear or quadratic interpolant. In both cases, the resulting weight function $w(t; f)$ would no longer be continuous in general. As a result, the standard Remez algorithm, which requires that the weight function is continuous, could not be used for solving (3.1). Therefore, we did not pursue the use of linear or quadratic interpolants.

5. Bernstein–Szegö weight functions. The approach described so far consists of two steps: first, one approximates the distribution function, and second, the polynomial preconditioner is obtained by solving the resulting approximation problem (3.1) numerically. In this section, we propose a different procedure that eliminates the second step. The idea is to restrict the weight functions to a class for which the solution of the Chebyshev problem (3.1) is known explicitly. We consider three classes of weight functions that fulfill this requirement.

Let ρ_k be any real polynomial of degree k with $\rho_k(t) > 0$ on $[-1, 1]$, and define

$$s_0(t) \equiv 1, \quad s_{1/2}(t) \equiv \sqrt{1+t}, \quad s_1(t) \equiv \sqrt{1-t^2}.$$

Then (3.1) can be solved explicitly for the so-called Bernstein–Szegö weight functions

$$w_j(t) \equiv \frac{s_j(t)}{\sqrt{\rho_k(t)}}, \qquad j \in \left\{0, \frac{1}{2}, 1\right\};$$

see Szegö [29], Freund [8], and the references given therein. More precisely, the solution φ_p of (3.1) with respect to w_j, $j \in \{0, \frac{1}{2}, 1\}$, is explicitly known for $p \geq p_j$, where

$$p_j = \begin{cases} 0 & \text{if } j = 1 \text{ and } k = 0, \\ \lfloor (k+1)/2 - j \rfloor & \text{otherwise.} \end{cases}$$

For convenience, in the sequel, we allow ρ_k to have simple zeros at the endpoints ± 1, i.e., the cases $j = 0, \frac{1}{2}$ are now included in the case $j = 1$. Therefore, we will only investigate weight functions of the form

$$w(t) \equiv w_1(t) \equiv \frac{\sqrt{1-t^2}}{\sqrt{\rho_k(t)}}. \tag{5.1}$$

From (4.3), (3.2), and (5.1), it follows that

$$f(x) \equiv \int_{-1}^{x} \delta(t)\, dt \equiv \int_{-1}^{x} \frac{w(t)^2}{\sqrt{1-t^2}}\, dt \equiv \int_{-1}^{x} \frac{\sqrt{1-t^2}}{\rho_k(t)}\, dt. \tag{5.2}$$

It remains to choose the polynomial ρ_k in (5.2) such that f fulfills the interpolatory conditions $f(t_j) = \vartheta_j$ stated in (3.3). Note that any f defined by (5.2) is "automatically" monotone on $[-1, 1]$, and that $f(-1) = 0$.

It turns out to be advantageous to express ρ_k in terms of its zeros:

$$\rho_k(t) \equiv a_{m+1} \prod_{j=1}^{m} (t - a_j) \prod_{j=1}^{l} (t - z_j)(t - \overline{z}_j), \qquad k = m + 2l.$$

Here, a_j, $j = 1, 2, \ldots, m$, are the real zeros, and $z_j = x_j + iy_j$, $y_j > 0$, $j = 1, 2, \ldots, l$, are the complex zeros in the upper half-plane. The partial-fractions expansion of (5.2) reads

$$\begin{aligned} f(x) &\equiv \frac{1}{a_{m+1}} \left(\sum_{j=1}^{m} A_j \int_{-1}^{x} \frac{\sqrt{1 - t^2}}{t - a_j} \, dt + \sum_{j=1}^{l} \int_{-1}^{x} \frac{(B_j t + C_j)\sqrt{1 - t^2}}{(t - z_j)(t - \overline{z}_j)} \, dt \right) \\ &\equiv F(x; a_1, \ldots, a_{m+1}, x_1, \ldots, x_l, y_1, \ldots, y_l), \end{aligned} \tag{5.3}$$

where

$$A_j = \frac{1}{\rho_k'(a_j)}, \qquad j = 1, 2, \ldots, m,$$

$$B_j t + C_j \equiv \frac{\rho_k'(\overline{z}_j)(t - \overline{z}_j) + \rho_k'(z_j)(t - z_j)}{\rho_k'(z_j)\rho_k'(\overline{z}_j)}, \qquad j = 1, 2, \ldots, l.$$

It is readily verified that all integrals in (5.3) have an explicit antiderivative. We omit these routine, but somewhat lengthy, calculations.

Now the interpolation conditions (3.3), together with the positivity requirement

$$\rho_k > 0 \quad \text{on} \quad (-1, 1), \tag{5.4}$$

lead to the following nonlinear interpolation problem with constraints:

Find real numbers $a_1, \ldots, a_{m+1}, x_1, \ldots, x_l, y_1, \ldots, y_l$ such that

$$\begin{aligned} F(t_j; a_1, \ldots, a_{m+1}, x_1, \ldots, x_l, y_1, \ldots, y_l) &= \vartheta_j, \qquad j = 1, 2, \ldots, n, \\ |a_j| &\geq 1, \qquad j = 1, 2, \ldots, m, \\ \operatorname{sgn}(a_{m+1}) &= (-1)^m \prod_{j=1}^{m} \operatorname{sgn}(a_j), \\ y_j &> 0, \qquad j = 1, 2, \ldots, l. \end{aligned} \tag{5.5}$$

Apart from the sign conditions, the problem (5.5) can be viewed as a nonlinear system of n equations in $k + 1 = m + 1 + 2l$ unknowns. Therefore, a natural choice of the polynomial degree is $k = n - 1$. Also, we would like to mention that (5.5) does not address the problem of the possible occurrence of multiple zeros at ± 1. However, in our experiments, we never encountered such multiple zeros.

The success of any nonlinear solver applied to (5.5) depends strongly on good starting values. We now describe a linear procedure for computing starting values. In view of (5.2), we have

$$\rho_k(x) f'(x) \equiv \sqrt{1 - x^2}$$

and, consequently,

$$(\rho_k(x) f(x))' \equiv \rho_k(x)' f(x) + \sqrt{1-x^2}. \tag{5.6}$$

By integrating (5.6) and using $f(-1) = 0$, we obtain the identity

$$\rho_k(x) f(x) \equiv \int_{-1}^{x} \rho_k(t)' f(t)\, dt + g(x), \tag{5.7}$$

where $g(x) \equiv \int_{-1}^{x} \sqrt{1-t^2}\, dt$. Now we parametrize ρ_k in the form

$$\rho_k(x) \equiv \sum_{j=0}^{k} b_j x^j, \quad \text{with } b_j \in \mathbb{R}, \tag{5.8}$$

and we set

$$\gamma_j(x;\, f) \equiv \int_{-1}^{x} t^{j-1} f(t)\, dt.$$

Then, the relation (5.7) can be rewritten as follows:

$$\sum_{j=0}^{k} b_j \left(x^j f(x) - j\gamma_j(x;\, f)\right) \equiv g(x). \tag{5.9}$$

We consider (5.9) only at the interpolation points $x = t_j$, $j = 1, 2, \ldots, n$. Together with the positivity condition (5.4), we obtain the following semi-infinite problem for computing the unknown coefficients $b_0, b_1, \ldots, b_n$ in (5.8):

Find real numbers b_j, $j = 0, 1, \ldots, k$, such that

$$\begin{aligned} G(t_i;\, b_0, \ldots, b_k) &= 0, \qquad i = 1, 2, \ldots, n, \\ \sum_{j=0}^{k} b_j x^j &> 0, \qquad x \in (-1, 1), \end{aligned} \tag{5.10}$$

where

$$G(t_i;\, b_0, \ldots, b_k) := \sum_{j=0}^{k} b_j \left(t_i^j \vartheta_i - j\gamma_j(t_i;\, f)\right) - g(t_i).$$

Note that problem (5.10) is linear, but there are infinitely many constraints. In addition, we must evaluate the integrals γ_j, which involve the unknown function f. To this end, we approximate f by a monotone piecewise cubic function S, as described in §4. Clearly, the resulting integrals $\gamma_j(x;\, S)$ are easy to compute.

A standard approach for solving semi-infinite problems is to replace the infinitely many constraints by a finite number, say M. Finally, after relaxing the interpolatory conditions slightly, we obtain the following linear programming problem:

Find real numbers b_j, $j = 0, 1, \ldots, k$, such that

$$\begin{aligned} \sum_{i=1}^{n} G(t_i;\, b_0, \ldots, b_k) &= \min!, \\ G(t_i;\, b_0, \ldots, b_k) &\geq 0, \quad i = 1, 2, \ldots, n, \\ \sum_{j=0}^{k} b_j \xi_i^j &> 0, \quad \xi_i \in (-1, 1), \quad i = 1, 2, \ldots, M. \end{aligned} \tag{5.11}$$

Here ξ_i, $i = 1, 2, \ldots, M$, are given distinct points in $(-1, 1)$. In our experiments, we always chose the ξ_i's as Chebyshev knots.

It is not hard to check that the feasible set of (5.11) is not empty, and hence (5.11) always has a solution $\rho_k^*(t; M) \equiv \sum_{j=0}^{k} b_j^* t^j$. The second parameter M indicates that ρ_k^* depends on the number M of positivity constraints. Unfortunately, it is possible that $\rho_k^*(t; M)$ has zeros in $(-1, 1)$. Here, one basically has to distinguish between the cases that $\rho_k^*(t; M)$ has one zero μ in the first (respectively, last) interval $(-1, \xi_1)$ (respectively, $(\xi_M, 1)$), or two zeros μ_1, μ_2 in (ξ_i, ξ_{i+1}), $i \in \{0, 1, \ldots, M\}$, where $\xi_0 := -1$ and $\xi_{M+1} := 1$. Such zeros cannot be used as starting values for the nonlinear problem (5.5). Therefore, we replace μ by -1 or 1, and the real zeros μ_1 and μ_2 by the complex zeros $z = (\mu_1 + \mu_2)/2 + i\varepsilon$ and $\overline{z}$, where ε is some small positive number. Notice that

$$(t - \mu_1)(t - \mu_2) - (t - z)(t - \overline{z}) = \frac{1}{4}(\mu_1 - \mu_2)^2 + \varepsilon^2 < |\xi_i - \xi_{i+1}|^2 + \varepsilon^2.$$

For sufficiently large M and sufficiently small ε, this "substitution of zeros" perturbs $\rho_k^*(t; M)$ only slightly.

In our experiments, we always chose $M := 200$. The corresponding linear solution $\rho_k^*(t; M)$ always yielded a good starting guess for the nonlinear solver applied to (5.5). In fact, quite frequently, the solution of (5.11) was such a good approximation that there was no need for applying the nonlinear solver.

6. Examples. In this section, we discuss some practical implementation details of the preconditioned CG method, and we describe some numerical examples.

6.1. Implementation. The basic outline of our preconditioned CG algorithm is as follows.

ALGORITHM 6.1 (Outline of CG with polynomial preconditioning).

1. *Start*: *choose* $x_0 \in \mathbb{C}^N$ *and compute* $r_0 = b - Ax_0$.
2. *Estimate the distribution function*:
   - *Perform n steps of the Lanczos algorithm starting with* $q_0 = r_0/\|r_0\|$.
   - *Compute the Lanczos distribution function* $\tau(t)$ *given by* (2.15).
   - *Set up the interpolation problem* (3.3).
3. *Determine the polynomial preconditioner* ψ_p :
   - *Compute the monotone piecewise cubic interpolant, as described in* §4.
   - *Either solve the associated weighted Chebyshev approximation problem* (3.1), *or compute the Bernstein–Szegö weight function, as described in* §5.
4. *Iterate*: *apply the CG method to the polynomial preconditioned system* $A\psi_p(A)y = b$.

Recall from (2.14) that the distribution function $\sigma(t)$ depends on the eigenvalues of A and the starting guess x_0. Therefore, in step 4 of Algorithm 6.1, we start the CG method with x_0, rather than the iterate x_n that can be constructed from quantities generated by the n Lanczos iterations in step 2. It is worth noticing that the n matrix-vector products with A, which are computed in the course of the n Lanczos steps, can be reused for the first $\lfloor n/p \rfloor$ iterations with the preconditioned CG method in step 4. However, this requires the storage of all $n + 1$ Lanczos vectors $q_0, q_1, \ldots, q_n$ generated in step 2.

In each step of the preconditioned CG algorithm, we must compute a matrix-vector product of the form $A\psi_p(A) \cdot v$. To this end, in our implementation, we represent the polynomial $\lambda\psi_p(\lambda)$ in Newton-form

$$\lambda\psi_p(\lambda) \equiv c_0 + \sum_{j=1}^{p} c_j \prod_{k=0}^{j-1}(\lambda - \xi_k). \tag{6.1}$$

Here, the interpolation points ξ_k are chosen as Chebyshev points shifted to the interval $[\alpha, \beta]$, and they are ordered using van der Corput's sequence. This leads to a stable implementation for computing $A\psi_p(A) \cdot v$, even for polynomials ψ_p of high degree; see, for example, [7]. Finally, the evaluation of $A\psi_p(A) \cdot v$ is performed by a Horner scheme applied to (6.1).

6.2. Performance. In all our examples, we use coefficient matrices A that result from a finite-difference discretization of the diffusion equation

$$-\frac{\partial}{\partial x}\left(\mu\frac{\partial u}{\partial x}\right) - \frac{\partial}{\partial y}\left(\nu\frac{\partial u}{\partial y}\right) = g \tag{6.2}$$

on the unit square in $\mathbb{R}^2$ with Dirichlet–Neumann boundary conditions. Equations of this type arise, for example, in connection with groundwater flow problems; see [17].

In order to ensure continuity of fluid flux even for highly discontinuous coefficient functions μ and ν, one uses the following five-point stencil:

$$-\eta_{i-1,j}u_{i-1,j} - \eta_{ij}u_{i+1,j} - \kappa_{i,j-1}u_{i,j-1} - \kappa_{ij}u_{i,j+1} + \rho_{ij}u_{ij} = h^2 g_{ij},$$

where h is the distance between adjacent nodes. Moreover, we set

$$\eta_{ij} = \delta(\mu_{ij};\, \mu_{i+1,j}),$$

$$\kappa_{ij} = \delta(\nu_{ij};\, \nu_{i,j+1}),$$

where

$$\delta(c;\, d) = \begin{cases} 2cd/(c+d) & \text{if } c + d \neq 0\,, \\ 0 & \text{otherwise,} \end{cases}$$

and

$$\rho_{ij} = \begin{cases} \eta_{i-1,j} + \eta_{ij} + \kappa_{i,j-1} + \kappa_{ij} & \text{if this sum} \neq 0, \\ 1 & \text{otherwise.} \end{cases}$$

Neumann boundary conditions are enforced by setting appropriate η and κ to zero.

We have tested the preconditioned CG method extensively for different cases. Here, we present three examples that show the typical behavior of the various polynomial preconditioners.

In addition to the Chebyshev polynomial preconditioner and the weighted Chebyshev preconditioner, we also implemented a preconditioner based on least-squares polynomials. For the latter, the Chebyshev norm in problem (3.1) is substituted by a weighted L_2-norm

$$\min_{\varphi \in \mathcal{P}_p:\, \varphi(\zeta)=1} \int_{-1}^{1} \varphi(t)^2 w(t)\, dt. \tag{6.3}$$

We have used the Legendre weight $w(1) \equiv 1$. For this special case the solution of (6.3) can be found in [18] (see also [2]).

All three examples were run for two different step sizes h: first with $h = \frac{1}{64}$ and then with half the step size $h = \frac{1}{128}$. In the following, numbers without brackets always correspond to $h = \frac{1}{64}$, while numbers for $h = \frac{1}{128}$ are given in brackets. For instance, the matrix in Example 6.1 is of order $N = 3844$ [15876] if $h = \frac{1}{64}$ $\left[\frac{1}{128}\right]$.

In all examples, the initial vector $x_0 = 0$ is chosen, and the right-hand side b is a random vector with entries $\in [-1, 1]$. The algorithm is stopped as soon as the kth residual satisfies $\|r_k\|/\|r_0\| \leq 10^{-10}$ $[10^{-6}]$. All computations were carried out in double-precision arithmetic, i.e., with approximately 16 significant decimal digits.

For the definition of μ and ν, we decompose the unit square into four parts, $R0$, $R1$, $R2$, and $R3$, as indicated in Fig. 6.1.

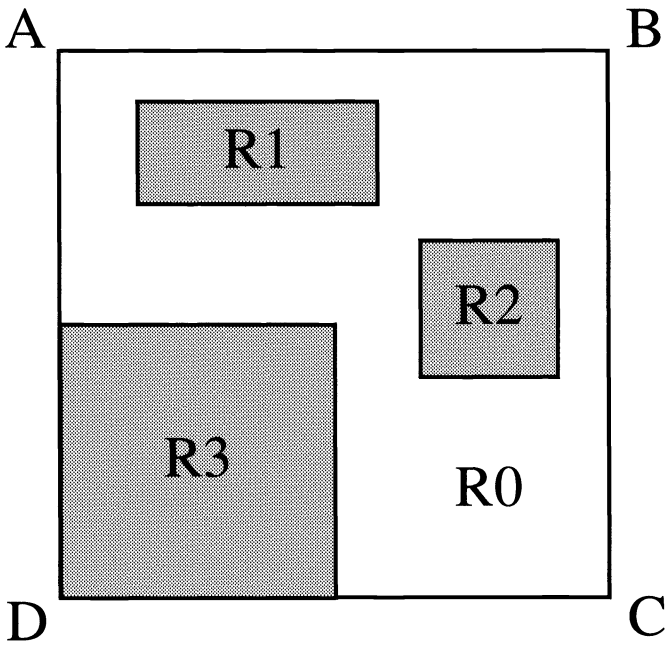

FIG. 6.1. *Decomposition of the unit square.*

In step 2 of Algorithm 6.1, we always performed $n = 20$ Lanczos steps. Note that, in this case, the Bernstein–Szegö preconditioner is then known explicitly for $p \geq 9$, where p is the degree of $t\psi_p(t)$. The weighted Chebyshev preconditioner (referred to as Remez or Bernstein, respectively) and the least-squares polynomial preconditioner (referred to as Legendre) are computed for the interval $[0, \theta_n]$, where θ_n is the largest Ritz value. The Chebyshev polynomial preconditioner (referred to as Chebyshev) is based on the "true" spectrum $[\lambda_1, \lambda_L]$.

Example 6.1. Here we consider (6.2) with $\mu \equiv \nu \equiv 1$ on $R0 \cup R1 \cup R2 \cup R3$ and Dirichlet boundary condition $u \equiv$ const on $\overline{AB}$, $\overline{BC}$, $\overline{CD}$, and $\overline{DA}$. Note that, in this case, (6.2) just reduces to Poisson's equation. The order of the resulting system is $N = 3844$ [15876], and the Euclidean condition number of A is about 1600 [6560]. The CG method, without any preconditioning, converged after 229 [286] steps. The iteration counts for the various polynomial preconditioners are listed in Table 6.1.

For the case $p = 5$ and $h = \frac{1}{64}$, the Chebyshev polynomial $T_5(t)/T_5(\zeta)$ (dashed line), the solution $\varphi_5(t)$ of (3.1) (solid line), and the functions $\pm d_5/w(t)$ (dotted lines) are plotted

in Fig. 6.2. The number d_5 denotes the minimal deviation of problem (3.1) with corresponding Bernstein–Szegö weight function. The Chebyshev polynomial is based on [0.005, 7.995] and $\varphi_5(t)$ is based on [0, 7.995]. The underlying distribution function $\sigma(t)$ is shown in Fig. 3.1.

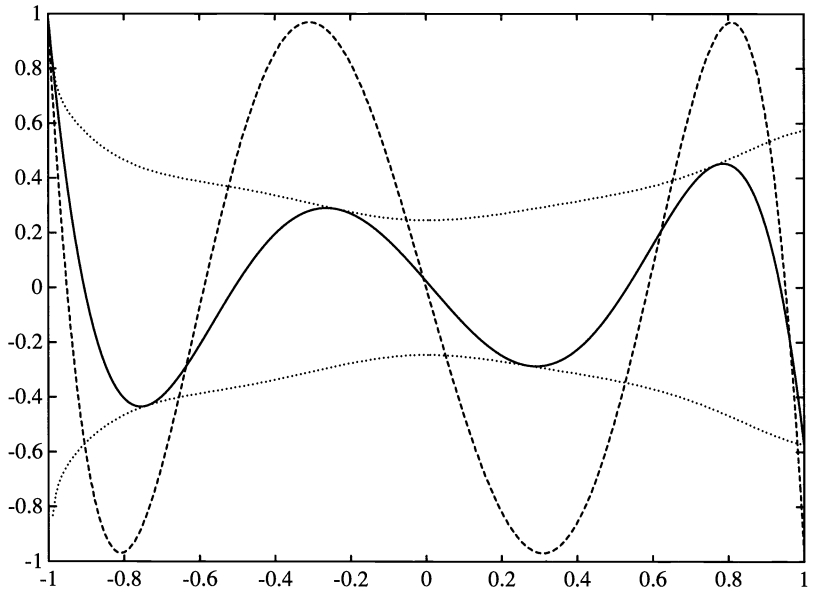

FIG. 6.2. *Chebyshev polynomial, weighted Chebyshev polynomial, and Bernstein–Szegö weight function for Example* 6.1 *and* $p = 5$.

Example 6.2. In this example, we choose continuous nonconstant coefficient functions in (6.2). More precisely, we set $\mu(x, y) \equiv \nu(x, y) \equiv x + y$ on $R0 \cup R1 \cup R2 \cup R3$. Furthermore, we have Dirichlet boundary conditions on $\overline{DA}$ and no-flow Neumann boundary conditions on $\overline{AB}$, $\overline{BC}$, and $\overline{CD}$. The matrix A has been symmetrically scaled to have unit main diagonal. The order of A is $N = 4032$ [16256], and the condition number of A is about 21000 [56180]. The CG method, without any preconditioning, converged after 370 [569] steps. The iteration counts for the various polynomial preconditioners are listed in Table 6.2.

Example 6.3. In this example, the coefficient functions in (6.2) are highly discontinuous. They have different values on all four components of the unit square:

TABLE 6.2
Polynomial preconditioning for Example 6.2.

p	5		10		15	
Bernstein	–	[–]	54	[65]	35	[49]

Legendre	198	[300]	141	[211]	115	[172]

$$\mu(x, y) \equiv \nu(x, y) \equiv \begin{cases} 1 & \text{for } (x, y) \in R0, \\ 1000 & \text{for } (x, y) \in R1, \\ 0 & \text{for } (x, y) \in R2, \\ 100 & \text{for } (x, y) \in R3. \end{cases}$$

Again, we choose Dirichlet boundary conditions on $\overline{DA}$ and no-flow Neumann boundary conditions on $\overline{AB}$, $\overline{BC}$, and $\overline{CD}$. The matrix A has been symmetrically scaled to have unit main diagonal. The order of A is $N = 4032$ [16256], and the condition number of A is about 450000 [1905837]. The unpreconditioned CG method converged after 395 [678] steps. The iteration counts for the various polynomial preconditioners are listed in Table 6.3.

TABLE 6.3

The results demonstrate the effectiveness of the proposed weighted "Bernstein–Szegö" and "Remez" polynomial preconditioners. Moreover, they show that these preconditioners are usually superior to the other considered preconditioners. In particular, both preconditioners perform very well for ill-conditioned problems. Furthermore, we note that, for the case $h = \frac{1}{128}$, the "Bernstein–Szegö" preconditioner is consistently better than the "Remez" preconditioner.

7. Concluding remarks. On modern architectures, it is attractive to combine the CG algorithm with polynomial preconditioning. In this paper, we have presented an approach for adapting polynomial preconditioners to the actual eigenvalue distribution of the coefficient matrix of the linear system. Our technique is based on the observation that good estimates for the eigenvalue distribution can be derived after only a few steps of the Lanczos process. We then use this information to construct a weight function for a suitable Chebyshev approximation problem. The solution of this problem yields the polynomial preconditioner. We have explored the use of Bernstein–Szegö weights.

We have presented some numerical examples that demonstrate the effectiveness of the proposed polynomial preconditioner. Our results suggest that the adaptive weighted polynomial preconditioner is superior to other polynomial preconditioners.

Acknowledgment. We would like to thank Youcef Saad for bringing reference [21] to our attention.

A ROBUST GMRES-BASED ADAPTIVE POLYNOMIAL PRECONDITIONING ALGORITHM FOR NONSYMMETRIC LINEAR SYSTEMS*

WAYNE JOUBERT†

Abstract. In this study a hybrid generalized minimal residual (GMRES) / polynomial preconditioning algorithm for solving nonsymmetric systems of linear equations is defined. The algorithm uses the results from cycles of restarted GMRES to form an effective polynomial preconditioner, typically resulting in decreased work requirements. The algorithm has the advantage over other hybrid algorithms in that its convergence behavior is well understood: the new algorithm converges for all starting vectors if and only if restarted GMRES converges. The results of numerical experiments with the algorithm are presented.

Key words. iterative methods, nonsymmetric linear systems, GMRES, polynomial preconditioning

AMS subject classification. 65F10

1. Introduction.

A desirable method for solving the linear system

$$Au = b, \tag{1}$$

where $A \in \mathbb{C}^{N\times N}$ is nonsingular, is the minimal residual method

$$u^{(n)} = u^{(0)} + q_{n-1}(A)r^{(0)}, \quad \deg q_{n-1} \le n-1, \quad q_{n-1} \text{ such that } ||r^{(n)}|| \text{ minimized}, \tag{2a}$$

or, alternatively,

$$u^{(n)} \in u^{(0)} + \mathbf{K}_n(r^{(0)}, A), \qquad Ar^{(n)} \perp \mathbf{K}_n(r^{(0)}, A), \tag{2b}$$

where $\{u^{(i)}\}_{i\ge 0}$ denote the iterates, $r^{(i)} = b - Au^{(i)}$ denotes the associated residuals, $\mathbf{K}_n(v, A) = \text{span}\{A^i v\}_{i=0}^{n-1}$ is the associated Krylov space, and $||\cdot||$ is the standard 2-norm of vectors. We also let $P_n(z) = 1 - zq_{n-1}(z)$, so that $r^{(n)} = P_n(A)r^{(0)}$, which condition identifies (2a), (2b) as a polynomial method.

When A is Hermitian positive definite (HPD) or possesses a similar property, the polynomial q_{n-1} may be determined by only n matrix-vector products $A \cdot v$ along with $2n$ inner products. This fact leads to effective iterative methods such as the conjugate residual method. On the other hand, to form q_{n-1} in the general case requires at least $n^2/2$ inner products, a requirement that appears insurmountable and that renders standard iterative methods such as full GMRES for performing (2) prohibitively costly due to long recurrence relations [2], [3], [12], and [9, §2.5].

A typical remedy to the order-n^2 work problem is to restart (2) periodically every s iterations. This is the basis of the GMRES(s) algorithm, for example, [18]; see [11] for a survey of restarted methods. Choosing s large improves the convergence of the method; however, an increased average work per iteration results (see [10]).

A further remedy to the long recurrence problem comes in the form of hybrid methods. These methods typically apply GMRES until sufficient information is extracted from A, typically in the form of eigenvalue information, so that an effective polynomial method such as polynomial preconditioning or Chebyshev acceleration may be applied based on this information (see, e.g., [15], [1], [16]). This approach has the advantage of using short recurrences

for the sections of the algorithm not using GMRES. On the other hand, the composite nature of these algorithms often makes it difficult to prove rigorous convergence results for the algorithms or to predict their behavior compared to other iterative methods.

In this study, an alternative hybrid algorithm is proposed. For this algorithm, the basic framework of restarted GMRES is maintained, but for each restart cycle the $(s-1)$ degree polynomial that would normally be calculated by (2) is optionally replaced by a polynomial preconditioner of the same degree that is based on information from previous GMRES cycles. The new algorithm has the advantage of converging for exactly the same class of matrices as restarted GMRES, and often at significantly less cost. The savings are even greater on parallel machines and other architectures for which inner product computations are particularly expensive.

The remainder of this paper is organized as follows. In §2 we consider the theoretical feasibility of replacing GMRES cycles with polynomial preconditioning. Then in §3 the new algorithm is defined. In §4 the results of numerical experiments are presented.

2. The feasibility of polynomial preconditioning. In this section we consider the relative convergence behavior of (2) compared to the best fixed polynomial preconditioning that can be applied to solve (1). We assume throughout that A is nonsingular.

We begin with definitions of basic convergence bounds for polynomial methods. Following [10], for $\mathbb{K}$ denoting the reals $\mathbb{R}$ or the complex numbers $\mathbb{C}$, and $A \in \mathbb{K}^{N\times N}$ and $n \geq 0$, let

$$\psi_{n,\mathbb{K}}(A) = \sup_{\substack{r\in\mathbb{K}^N \\ r\neq 0}} \inf_{\substack{\deg P_n \leq n \\ P_n(0)=1}} \frac{||P_n(A)r||}{||r||} = \sup_{\substack{r^{(0)}\in\mathbb{K}^N \\ r^{(0)}\neq 0}} \frac{||r^{(n)}||}{||r^{(0)}||},$$

$$\varphi_{n,\mathbb{K}}(A) = \inf_{\substack{\deg P_n \leq n \\ P_n(0)=1}} \sup_{\substack{r\in\mathbb{K}^N \\ r\neq 0}} \frac{||P_n(A)r||}{||r||},$$

where $r^{(n)}$ refers to the nth residual generated by the minimal residual method (2), and $P_n(z) = 1 - zq_{n-1}(z)$ is a polynomial over $\mathbb{C}$. When the field $\mathbb{K}$ is omitted in the notation, it is assumed to be $\mathbb{C}$. Here and throughout, $||v|| = \sqrt{v^*v}$, where v^* denotes the conjugate transpose of v, and $||M||$ denotes the induced matrix norm.

The quantities $\psi_{n,\mathbb{K}}(A)$ and $\varphi_{n,\mathbb{K}}(A)$ are bounds that denote the possible residual norm decrease for two particular polynomial methods. They differ in the following important respect. The first quantity gives a sharp bound for the convergence of GMRES or any other algorithm implementing (2). In this case the polynomial P_n is chosen as a function of $r^{(0)}$. On the other hand, the second quantity denotes the performance of the best polynomial preconditioner (defined here as q_{n-1}) that is chosen independent of $r^{(0)}$ and that must be effective for all such vectors in $\mathbb{K}^N$. The main concern of this section is the relationship between these two quantities; in particular, it is of interest to determine when they are equal.

Basic results on these quantities are set forth in [10]. Of interest to us here are the following properties for $A \in \mathbb{K}^{N\times N}$:

(i) $0 \leq \psi_{n,\mathbb{K}}(A) \leq \varphi_{n,\mathbb{K}}(A) \leq 1$ for all n.

(ii) $\psi_{0,\mathbb{K}}(A) = \varphi_{0,\mathbb{K}}(A) = 1$, while $\psi_{n,\mathbb{K}}(A) = \varphi_{n,\mathbb{K}}(A) = 0$ for any n satisfying $n \geq d(A) = \min\{\deg P : P \text{ monic}, P(A) = 0\}$.

(iii) When $A \in \mathbb{R}^{N\times N}$, $\psi_{n,\mathbb{R}}(A) \leq \psi_{n,\mathbb{C}}(A)$, while $\varphi_{n,\mathbb{R}}(A) = \varphi_{n,\mathbb{C}}(A)$.

(iv) For fixed n, $\psi_{n,\mathbb{K}}(A)$ and $\varphi_{n,\mathbb{K}}(A)$ are each continuous in A.

(v) $\psi_{n,\mathbb{K}}(A)^2 = \sup_{r\in\mathbb{K}^N} F_n(r)$ holds for $A \in \mathbb{K}^{N\times N}$, where $F_n(r)$ is defined to be zero for r satisfying $d(r, A) < n$ and elsewhere $F_n(r)$ is defined to be

$$1 - r^* A K_n(r, A)[K_n(r, A)^* A^* A K_n(r, A)]^{-1} K_n(r, A)^* A^* r / r^* r. \tag{3}$$

Here, $d(v, A) = \min\{\deg P : P \text{ monic}, P(A)v = 0\}$ denotes the degree of a vector, and $K_n(v, A) = \begin{bmatrix} v & Av & \dots & A^{n-1}v \end{bmatrix}$ is the standard Krylov basis matrix. Note that $F_n(r^{(0)}) = ||r^{(n)}||^2/||r^{(0)}||^2$, where $r^{(n)}$ is defined by (2), which gives the square of the residual decrease from n steps of GMRES applied to a vector.

(vi) The map F_n of (3) is the zero map when $d(A) \le n$. Otherwise it is continuous, and in fact it is C^∞ on the complement of the closed measure-zero set $\{r : d(r, A) < n\}$, where F_n is considered as a map on $\mathbb{R}^{2N}$. The latter fact follows directly from the fact that $F_n(r)$ is a rational function of the entries of $\operatorname{Re} r$ and $\operatorname{Im} r$.

From the standpoint of iterative methods, it is desirable that one or both of the following conditions be satisfied.

Condition 1. For given $A \in \mathbb{K}^{N\times N}$, $\psi_{s,\mathbb{K}}(A) < 1 \Leftrightarrow \varphi_{s,\mathbb{K}}(A) < 1$. If this property holds, then a convergent polynomial preconditioner of degree $s - 1$ necessarily exists (in the sense that $\varphi_{s,\mathbb{K}}(A) < 1$) if and only if GMRES($s$) is guaranteed to converge for all $r^{(0)} \in \mathbb{K}^N$.

Condition 2. For given $A \in \mathbb{K}^{N\times N}$, $\psi_{s,\mathbb{K}}(A) = \varphi_{s,\mathbb{K}}(A)$. If this stronger condition holds, then not only does a convergent polynomial preconditioner exist if and only if GMRES(s) must converge, but one exists that has the same convergence bound $||r^{(ms)}||/||r^{(0)}|| \le \psi_s(A)^m$ as GMRES(s).

It is not clear whether generally $\psi_{n,\mathbb{K}}(A) = \varphi_{n,\mathbb{K}}(A)$. However, the following results do hold.

THEOREM 1. *For* $\mathbb{K} = \mathbb{R}$ *or* $\mathbb{C}$, *and* $A \in \mathbb{K}^{N\times N}$, $\psi_{1,\mathbb{K}}(A) = \varphi_{1,\mathbb{K}}(A)$.

Proof. Let P be a minimizing polynomial for $\varphi_{1,\mathbb{K}}(A)$. As shown in [10], it is possible to choose P with coefficients in $\mathbb{K}$.

We first show that for any nonzero $\alpha \in \mathbb{K}$, there exists nonzero v within V, V here defined to be the eigenspace (over $\mathbb{K}$) associated with the maximal eigenvalue of $P(A)^*P(A)$, such that $\operatorname{Re}\alpha^* v^* A^* P(A)v \ge 0$. Note that for any v and α, and any $\epsilon > 0$, $||[P(A) + \epsilon\alpha A]v||^2 = ||P(A)v||^2 + 2\epsilon \operatorname{Re}[\alpha^* v^* A^* P(A)v] + \epsilon^2|\alpha|^2||Av||^2$. If the result is false, then for some α, $\operatorname{Re}\alpha^* v^* A^* P(A)v < 0$ for all nonzero $v \in V$, in which case there exists $\tilde{c}_1 > 0$ with $2\operatorname{Re}\alpha^* v^* A^* P(A)v \le -\tilde{c}_1||P(A)v||^2$ for all $v \in V$.

Let $\tilde{P}(z) = P(z) + \epsilon\alpha z$ and $w = v\cos\theta + v^\perp \sin\theta$, $v \in V$, $v^\perp \in V^\perp$, $||v|| = ||v^\perp|| = 1$. We seek to show for some ϵ, $||\tilde{P}(A)w|| < ||P(A)||$ for all w, a contradiction to P being a minimizer. Note that

$$\begin{aligned}
||\tilde{P}(A)w||^2 &= \cos^2\theta||\tilde{P}(A)v||^2 + 2\cos\theta\sin\theta \operatorname{Re} v^*\tilde{P}(A)^*\tilde{P}(A)v^\perp + \sin^2\theta||\tilde{P}(A)v^\perp||^2 \\
&= \cos^2\theta||P(A)v||^2 + 2\epsilon\cos^2\theta \operatorname{Re}\alpha^* v^* A^* P(A)v \\
&\quad + 2\epsilon\cos\theta\sin\theta \operatorname{Re}[\alpha v^* P(A)^* A v^\perp + \alpha^* v^* A^* P(A)v^\perp] \\
&\quad + \sin^2\theta||P(A)v^\perp||^2 + 2\epsilon\sin^2\theta \operatorname{Re}\alpha^* v^{\perp *} A^* P(A)v^\perp + \mathcal{O}(\epsilon^2).
\end{aligned}$$

Thus there exist constants c_2, c_3, c_4, and c_5 (with $c_5 > 0$, such that the condition $||P(A)v^\perp||^2 \le ||P(A)v||^2 - c_5$ is satisfied, by definition of V), such that for any v, $v^\perp$ as defined above, $||\tilde{P}(A)w||^2$ is bounded by

$$\begin{aligned}
&\cos^2\theta(1 - \epsilon\tilde{c}_1)||P(A)v||^2 + \epsilon c_2\cos\theta\sin\theta + \epsilon c_3\sin^2\theta + \sin^2\theta||P(A)v^\perp||^2 + \epsilon^2 c_4 \\
&\quad \le ||P(A)v||^2 - \epsilon c_1\cos^2\theta + \epsilon c_2\cos\theta\sin\theta + \epsilon c_3\sin^2\theta - c_5\sin^2\theta + \epsilon^2 c_4,
\end{aligned}$$

where $c_1 = \tilde{c}_1||P(A)||^2$. It is sufficient to find $\epsilon > 0$ such that for all θ,

$$\epsilon(-c_1\cos^2\theta + c_2\cos\theta\sin\theta + c_3\sin^2\theta) - c_5\sin^2\theta + \epsilon^2 c_4 < 0.$$

But the left-hand side of this inequality equals

$$-c_5 \sin^2\theta + \epsilon^2 c_4 - \epsilon c_1 + \epsilon \sin\theta(c_1 \sin\theta + c_2 \cos\theta + c_3 \sin\theta)$$
$$\leq -c_5 \sin^2\theta + \epsilon^2 c_4 - \epsilon c_1 + \epsilon c_6 \sin\theta$$

for some c_6, for all θ. Letting $z = \sin\theta$ yields the quadratic $-c_5 z^2 + \epsilon c_6 z + (\epsilon^2 c_4 - \epsilon c_1)$, which can be made negative for all real z by choosing ϵ sufficiently small.

This establishes that for any $\alpha \in \mathbb{K}$ there exists a nonzero $v \in V$ such that $\mathrm{Re}\,\alpha^* v^* A^* \cdot P(A)v \geq 0$. We now show that for any $c \in \mathbb{K}$ there is nonzero $v \in V$ such that $\mathrm{Re}[c^* v^* A^* P(A)v] = 0$. Otherwise, letting $\alpha = \pm c$ yields v_1, $v_2 \in V$ such that $\mathrm{Re}[c^* v_1^* A^* P(A)v_1] > 0$ and $\mathrm{Re}[c^* v_2^* A^* P(A)v_2] < 0$. Note v_1 and v_2 must be linearly independent; otherwise, $v_1 = \xi v_2$, $\xi \in \mathbb{K}$, yields $v_1^* A^* P(A)v_1 = |\xi|^2 v_2^* A^* P(A)v_2$, a contradiction. Setting $v_t = t v_1 + (1-t)v_2$, $0 \leq t \leq 1$, yields by a continuity argument some t such that $\mathrm{Re}[c^* v_t^* A^* P(A)v_t] = 0$, giving the result.

Let $\underline{V}$ be a matrix whose columns form a basis over $\mathbb{K}$ of V. We have shown for any $c \in \mathbb{K}$ there exists nonzero $u \in \mathbb{K}^{\mathrm{DimV}}$ such that $\mathrm{Re}[c^* u^* \underline{V}^* A^* P(A)\underline{V}u] = 0$. When $\mathbb{K} = \mathbb{R}$, take $c = 1$ to give $r = \underline{V}u \neq 0$ with $r^* A^* P(A)r = 0$. When $\mathbb{K} = \mathbb{C}$, we have shown $0 \in F(H(c^* \underline{V} A^* P(A)\underline{V}))$ for any $c \in \mathbb{C}$, where $H(M) = (M + M^*)/2$ denotes the Hermitian part of a matrix M and $F(M) = \{x^* M x : x \in \mathbb{C}^N, ||x|| = 1\}$ the field of values [8]. This implies that $0 \in F(\underline{V} A^* P(A)\underline{V})$: otherwise, by the convexity of the field of values, there exists $c = e^{i\theta}$ such that $H(c^* \underline{V} A^* P(A)\underline{V})$ is positive definite, i.e., $0 \notin F(H(c^* \underline{V} A^* P(A)\underline{V}))$. Thus there exists nonzero $r = \underline{V}u \in V$ such that $r^* A^* P(A)r = 0$.

Thus, for either the real or complex case, $Ar \perp P(A)r$ for nonzero $r \in V$. It is easily seen that this $P(z) = 1 - z q_0(z)$ satisfies (2b) for this r, and in fact $\psi_{1,\mathbb{K}}(A)^2 \geq ||P(A)r||^2/||r||^2 = ||P(A)||^2 \geq \varphi_{1,\mathbb{K}}(A)^2$. □

THEOREM 2. *For $A \in \mathbb{R}^{N\times N}$, $\psi_{2,\mathbb{R}}(A) < 1 \Leftrightarrow \varphi_{2,\mathbb{R}}(A) < 1$.*

Proof. Let $n = 2$. It is clear from (3) that $\psi_{n,\mathbb{R}}(A) < 1$ implies that for all real v satisfying $d(v, A) \geq n$ and $||v|| = 1$, $v^* A K_n(v, A) \neq 0$. The same is true when $d = d(v, A) < n$ and $||v|| = 1$: in this case, we have

$$0 = v^* v - v^* A K_d(v, A)[K_d(v, A)^* A^* A K_d(v, A)]^{-1} K_d(v, A)^* A^* v,$$

so that $0 \neq v^* A K_d(v, A)$, a subvector of $v^* A K_n(v, A)$. Defining

$$\mathcal{F}_{n,\mathbb{K}}(A) = \{v^* A K_n(v, A) : v \in \mathbb{K}^N, ||v|| = 1\} \subseteq \mathbb{K}^n$$

for $A \in \mathbb{K}^{N\times N}$, we thus have that $0 \notin \mathcal{F}_{n,\mathbb{R}}(A)$. According to [7, p. 86], $\mathcal{F}_{2,\mathbb{R}}(A)$ is convex in $\mathbb{R}^2$ when $N \geq 3$.

When $N \leq 2$, $\psi_{2,\mathbb{R}}(A) = \varphi_{2,\mathbb{R}}(A) = 0$. When $N \geq 3$, since $0 \notin \mathcal{F}_{n,\mathbb{R}}(A)$, by the Hahn–Banach theorem there is a hyperplane through zero that does not intersect $\mathcal{F}_{2,\mathbb{R}}(A)$. Letting $c = [c_1\ c_2]^T$ denote the appropriate normal vector to this hyperplane, we have that $c^* \mathcal{F}_{2,\mathbb{R}}(A)$ consists only of positive numbers. Thus $c_1 v^* A v + c_2 v^* A^2 v$ is bounded above zero for all real v satisfying $||v|| = 1$. Now let $P(z) = 1 - \alpha(c_1 z + c_2 z^2)$. Then $||P(A)v||^2/||v||^2 = 1 - 2\alpha v^*(c_1 A v + c_2 A^2)v/v^* v + \alpha^2 ||(c_1 A v + c_2 A^2)v||^2/v^* v$ which, for α sufficiently small, is bounded beneath one for all nonzero v. □

THEOREM 3. *For $A \in \mathbb{R}^{N\times N}$ HPD, $\psi_{n,\mathbb{R}}(A) = \varphi_{n,\mathbb{R}}(A)$.*

Proof. See [4]. □

THEOREM 4. *For $\mathbb{K} = \mathbb{R}$ or $\mathbb{C}$ and $A \in \mathbb{K}^{N\times N}$ normal, $\psi_{n,\mathbb{K}}(A) = \varphi_{n,\mathbb{K}}(A)$.*

Proof. See [5] for an alternate proof for the $\mathbb{K} = \mathbb{R}$ case. If $n \geq d(A)$ then we are done. Otherwise for $r, s \in \mathbb{K}^N$ and $\epsilon > 0$ small, let

$$r' = (1 - \epsilon^2)^{1/2} r + \epsilon s = (1 - \epsilon^2/2)r + \epsilon s + \mathcal{O}(\epsilon^4)$$

with $d(r, A) \geq n$. Also let $||r|| = ||s|| = 1$ and $r \perp s$, so $||r'|| = 1$. Let P_r be the least squares polynomial (2a), (2b) of degree not greater than n associated with r, and let $K_r = K_n(r, A)$, $K_s = K_n(s, A)$. Note that $P_r(A)r = r - AK_r[K_r^*A^*AK_r]^{-1}K_r^*A^*r$, and P_r is a polynomial over $\mathbb{K}$. Note also that:

(i) $K_{r'} \equiv K_n(r', A) = (1 - \epsilon^2/2)K_r + \epsilon K_s + \mathcal{O}(\epsilon^3)$;

(ii) $K_{r'}^*A^*AK_{r'} = (1-\epsilon^2)K_r^*A^*AK_r + \epsilon K_r^*A^*AK_s + \epsilon K_s^*A^*AK_r + \epsilon^2 K_s^*A^*AK_s + \mathcal{O}(\epsilon^3)$;

(iii) $[K_{r'}^*A^*AK_{r'}]^{-1} = (1 + \epsilon^2)K_r^*A^*AK_r^{-1}$
$-\epsilon K_r^*A^*AK_r^{-1}[K_r^*A^*AK_s + K_s^*A^*AK_r]K_r^*A^*AK_r^{-1}$
$+\epsilon^2 K_r^*A^*AK_r^{-1}[K_r^*A^*AK_s + K_s^*A^*AK_r]$
$\cdot K_r^*A^*AK_r^{-1}[K_r^*A^*AK_s + K_s^*A^*AK_r]K_r^*A^*AK_r^{-1}$
$-\epsilon^2 K_r^*A^*AK_r^{-1}[K_s^*A^*AK_s]K_r^*A^*AK_r^{-1} + \mathcal{O}(\epsilon^3)$.

Then, since $s - AK_s[K_r^*A^*AK_r]^{-1}K_r^*A^*r = P_r(A)s$, we have after some manipulation

$$F_n(r') = [r^*P_r(A)^*P_r(A)r] + 2\epsilon \operatorname{Re}[s^*P_r(A)^*P_r(A)r]$$
$$+\epsilon^2\Big[s^*P_r(A)^*P_r(A)s - r^*P_r(A)^*P_r(A)r - [K_r^*A^*P_r(A)s + K_s^*A^*P_r(A)r]^*$$
$$\cdot[K_r^*A^*AK_r]^{-1}[K_r^*A^*P_r(A)s + K_s^*A^*P_r(A)r]\Big] + \mathcal{O}(\epsilon^3).$$

If r is a (global) maximizer for F_n (and thus a local maximizer), then F_n is smooth near r, so we must have

$$\text{(4a)} \qquad \operatorname{Re} s^*P_r(A)^*P_r(A)r = 0,$$

$$\text{(4b)} \qquad \begin{aligned} &s^*P_r(A)^*P_r(A)s - r^*P_r(A)^*P_r(A)r \\ &\quad - [K_r^*A^*P_r(A)s + K_s^*A^*P_r(A)r]^*[K_r^*A^*AK_r]^{-1} \\ &\quad \cdot [K_r^*A^*P_r(A)s + K_s^*A^*P_r(A)r] \leq 0 \end{aligned}$$

for any $s \perp r$.

Now $\operatorname{Re} s^*P_r(A)^*P_r(A)r = 0$ for any $s \perp r$. If $\mathbb{K} = \mathbb{R}$, then $s^*P_r(A)^*P_r(A)r = 0$; otherwise, by replacement of s with the quantity (is), we obtain $\operatorname{Im} s^*P_r(A)^*P_r(A)r = 0$, and thus $s^*P_r(A)^*P_r(A)r = 0$ for all $s \perp r$. Thus $P_r(A)^*P_r(A)r$ is a scalar multiple of r, namely,

$$P_r(A)^*P_r(A)r = \frac{r^*P_r(A)^*P_r(A)r}{r^*r}r.$$

Thus r is a (right) singular vector of $P_r(A)$.

If r is a maximal singular vector (in the sense that its associated singular value is maximal among the singular values), then for all $v \in \mathbb{K}^N$,

$$\varphi_{n,\mathbb{K}}(A) \leq \frac{||P_r(A)v||}{||v||} \leq \frac{||P_r(A)r||}{||r||} = \psi_{n,\mathbb{K}}(A) \leq \varphi_{n,\mathbb{K}}(A),$$

and thus P_r is a minimizer for $\varphi_{n,\mathbb{K}}(A)$ and we are done. Otherwise, there exists $s \perp r$ a maximal singular vector for $P_r(A)$, and r is not a maximal singular vector.

Since A is normal, then $A = U\Lambda U^*$, with U unitary and Λ diagonal. Then U^*r is an eigenvector of $\Lambda^*\Lambda$, and is thus composed of a linear combination of standard unit basis vectors e_{i_j}, and similarly U^*s is composed of a set of vectors e_{i_k} all distinct from e_{i_j}. Since then r and s are contained in the linear spans of distinct (orthogonal) eigenspaces of A, it follows that $A^l r \perp A^m s$ for any l, m. Then (4b) reduces to

$$s^*P_r(A)^*P_r(A)s - r^*P_r(A)^*P_r(A)r \leq 0$$

or

$$r^* P_r(A)^* P_r(A) r \geq s^* P_r(A)^* P_r(A) s$$

which contradicts the maximality of s over r. □

The results of this section have the following significance. In certain cases such as when A is normal, a fixed polynomial preconditioning of degree $(s-1)$ exists independent of $r^{(0)}$, which has the same convergence bound as a cycle of GMRES(s). In such cases it is reasonable to seek a polynomial preconditioner to replace (2) so that inner products need not be computed. Of course, since (2) finds the best polynomial for each $r^{(0)}$, the *average* behavior of (2) may be better than the average behavior of the best polynomial preconditioner, though the worst case behavior for a cycle applied to a given vector is the same.

It is not clear whether $\psi_{n,\mathbb{K}}(A) = \varphi_{n,\mathbb{K}}(A)$ holds for general A, though numerical experiments suggest that it does hold for cases other than A normal and $n = 1$. The exact behavior of these functions is an open area of research.

The algorithm presented in §3 takes advantage of the cases when a fixed polynomial preconditioning of degree s can be found that yields a convergence rate as good as that of the restarted GMRES algorithm with restart frequency s.

3. Definition of the hybrid algorithm. We wish to define a modification of the restarted GMRES algorithm that allows for alternate means of calculating the polynomial P_n of (2) besides the least squares minimization of (2a), (2b).

To make use of the relevant inner product information from the Krylov spaces obtained from GMRES cycles in the history of a run, we define a fixed polynomial basis to be used to represent the Krylov space at each cycle. The use of a fixed polynomial basis simplifies the recording of Krylov space inner products for each cycle. In particular, we define the polynomials $\{p_i\}_{i=0}^{s}$ that are fixed independent of the cycle number, and use these to represent the Krylov space of each cycle by the matrix $\mathcal{P}_{s+1}(r) = [p_0(A)r \ldots p_s(A)r]$ and the associated inner product matrix $\mathcal{P}_{s+1}(r)^* \mathcal{P}_{s+1}(r)$. Means of choosing the polynomials so that the basis is well conditioned are described in [11]. Here we employ Chebyshev polynomials which possess a three-term recurrence.

The idea of the algorithm is as follows: given $r^{(ms)}$, the Krylov basis vectors $\mathcal{P}_{s+1}(r^{(ms)})$ may be generated, and then a decision can be made as to whether $r^{(ms+s)}$ is calculated by (2) or alternatively by some polynomial preconditioner represented in the basis $\mathcal{P}_{s+1}(r^{(ms)})$. The polynomial preconditioner may be based on information from the history of the run, in particular, the previous cycles that were performed in GMRES mode (2).

The structure of the algorithm is shown below. Here m denotes the cycle number, $\mathcal{S}$ denotes the set of cycles performed in GMRES mode, and the parameter t is a user-supplied tolerance, $0 \leq t \leq 1$.

1. Initialize. $m \leftarrow 0$.
2. Perform the stopping test.
3. Compute $r^{(s)}$ via a cycle of GMRES. $m \leftarrow 1$.
4. Determine well-conditioned basis polynomials $\{p_i\}$.
5. Determine $\mathcal{P}_{s+1}(r^{(0)})^* \mathcal{P}_{s+1}(r^{(0)})$ from the GMRES Arnoldi vector information from the first cycle (see below). Initialize $\mathcal{S} \leftarrow \{0\}$.
6. Perform the stopping test.
7. Select a polynomial preconditioner q, based on the information in $\{\mathcal{P}_{s+1}(r^{(is)})^* \cdot \mathcal{P}_{s+1}(r^{(is)})\}_{i \in \mathcal{S}}$, and represented in the basis $\{p_i\}$.
8. Compute $\tilde{r}^{(ms+s)} = [I - Aq(A)]r^{(ms)}$ and its norm.
9. Test: If $||\tilde{r}^{(ms+s)}||/||r^{(ms)}|| \leq [\max_{i \in \mathcal{S}} ||r^{(is+s)}||/||r^{(is)}||] \cdot (1-t) + [1] \cdot (t)$, then set $r^{(ms+s)} = \tilde{r}^{(ms+s)}$; else, add m to $\mathcal{S}$, calculate the inner products

$\mathcal{P}_{s+1}(r^{(ms)})^*\mathcal{P}_{s+1}(r^{(ms)})$, and then compute $r^{(ms+s)}$ via the minimal residual method (2) using the existing basis vectors $\mathcal{P}_{s+1}(r^{(ms)})$.

10. Form $u^{(ms+s)}$ corresponding to $r^{(ms+s)}$.
11. Increment m; go to 6.

The details of executing the minimal residual component of step 9 are found in [11]. In particular,

$$u^{(ms+s)} = u^{(ms)} + \mathcal{P}_s(r^{(ms)})[\mathcal{P}_s(r^{(ms)})^* A^* A \mathcal{P}_s(r^{(ms)})]^{-1} \mathcal{P}_s(r^{(ms)})^* A r^{(ms)},$$

$$r^{(ms+s)} = r^{(ms)} - A\mathcal{P}_s(r^{(ms)})[\mathcal{P}_s(r^{(ms)})^* A^* A \mathcal{P}_s(r^{(ms)})]^{-1} \mathcal{P}_s(r^{(ms)})^* A r^{(ms)}.$$

The parameter t controls how good the polynomial preconditioner is required to be in order to be used. If $t = 0$, then the polynomial preconditioner applied to the current cycle must do at least as well as the worst GMRES cycle in the history of the run; t set closer to 1 allows a worse preconditioner to be tolerated, while any $t < 1$ insures convergence unless GMRES(s) can stagnate for this matrix (i.e., $\psi_{s,\mathbb{K}}(A) = 1$). This equivalence of the convergence behavior of the new method to that of GMRES(s) assumes, of course, that the Krylov basis for each cycle is well conditioned; for a full discussion of such considerations, see [11].

The calculation of the inner product information of step 5 from the GMRES information of that first cycle requires a more detailed description. Let $AQ_s = Q_{s+1}H_{s+1}$, where H_{s+1} is the upper Hessenberg matrix from the Arnoldi sequence of the first GMRES cycle, with Q_{s+1} the associated matrix of Arnoldi vectors, $Q_{s+1}^* Q_{s+1} = I$. We seek a new basis $\tilde{Q}_s \equiv \mathcal{P}_s(r^{(0)})$ such that $A\tilde{Q}_s = \tilde{Q}_{s+1}T_{s+1}$, where T_{s+1} is upper Hessenberg (for the Chebyshev basis case, tridiagonal) and defines the set of recurrences associated with $\{p_i\}$ (see [11] for complete details). Let $\tilde{Q}_{s+1} = Q_{s+1}\tilde{T}$, so that $\tilde{T}$ is the change of basis matrix. We seek $\tilde{Q}_{s+1}^* \tilde{Q}_{s+1} = \tilde{T}^* \tilde{T}$. Note $\tilde{T}$ is upper triangular. After some manipulation we have

$$\tilde{T}T_{s+1} = H_{s+1}\begin{bmatrix} I_s \\ 0 \end{bmatrix}^* \tilde{T}\begin{bmatrix} I_s \\ 0 \end{bmatrix},$$

where I_s is the identity. By applying the standard unit basis vector e_i to the right side of each side of the equation, we obtain a recursion for the columns of $\tilde{T}$. Specifically, we let $\tilde{t}_i = \tilde{T}e_i$ and $T_{s+1} = \{t_{i,j}\}$, and then

$$t_{i+1,i}\tilde{t}_{i+1} = H_{s+1}\begin{bmatrix} I_s \\ 0 \end{bmatrix}^* \tilde{t}_i - \sum_{j=1}^{i} t_{j,i}\tilde{t}_j.$$

Finally, $\tilde{t}_1$ is a multiple of e_1 based on the scaling relationship between the initial basis vectors $Q_{s+1}e_1$ and $\tilde{Q}_{s+1}e_1$.

It should be emphasized that the algorithm presented thus far makes no restriction on the type of preconditioner used. Any type of preconditioner may be applied, and the mechanism of the algorithm insures that if the residual decrease is not adequate, then the cycle can be completed using GMRES. Furthermore, the cost of the algorithm when in GMRES mode is only slightly greater (about one SAXPY operation per step) than a standard GMRES-type algorithm for computing (2), due to the computation of $\tilde{r}^{(ms+s)}$.

We now define a particular preconditioner to be used in this study. This preconditioner is based on the inner product information from past GMRES cycles of the run and approximates the minimizing polynomial of $\varphi_{s,\mathbb{K}}(A)$.

Given a set of vectors $\{r_i\} \subseteq \mathbb{K}^N$, for $A \in \mathbb{K}^{N\times N}$, it is assumed that the inner product information contained in the matrices $K_{s+1}(r_i, A)^* K_{s+1}(r_i, A)$ is known. Then we note

$$\inf_{e_1^*c=1} \sup_{r_i} \frac{||K_{s+1}(r_i, A)c||}{||r_i||} \leq \inf_{e_1^*c=1} \sup_{r\in\mathbb{K}^N} \frac{||K_{s+1}(r, A)c||}{||r||}$$
$$= \inf_{P_s(0)=1} \sup_{r\in\mathbb{K}^N} \frac{||P_s(A)r||}{||r||} = \varphi_{s,\mathbb{K}}(A),$$

where $P_s(z) = \sum_{i=0}^{s}(e_{i+1}^*c)z^i$. Since each $F_i(c) = ||K_{s+1}(r_i, A)c||/||r_i||$ is convex (and in fact F_i^2 is quadratic), the function $F(c) = \sup_i F_i(c)$ is convex. Optimization routines may be used to find the minimizer of F numerically. Furthermore, when the set $\{r_i\}$ is sufficiently expanded, $\inf_{e_1^*c=1} F(c)$ becomes closer to $\varphi_{s,\mathbb{K}}(A)$.

The algorithm considered here, then, uses a polynomial based on the minimizer of $F = \sup_i F_i$, which yields a polynomial that in some sense is optimal for all previous GMRES cycles.

Let us consider for a moment the computational cost of this algorithm. Following the analysis techniques of [10], let w_{mv}, w_{sax}, and w_{dot} represent the computational cost on a given computer of the matrix-vector product $A \cdot v$, SAXPY $y \leftarrow y + \alpha x$, and dot product u^*v, respectively. The cost for an s-step cycle in polynomial preconditioning mode using Chebyshev basis polynomials is $[sw_{mv} + w_{\text{dot}} + (4s + 2)w_{\text{sax}}]$, while a cycle in GMRES mode adds $[(s + 1)(s + 2)/2]w_{\text{dot}} + (s + 1)w_{\text{sax}}$ to this. The number of cycles to converge to $||r^{(ms)}||/||r^{(0)}|| \leq \zeta$ is approximately $\log(\zeta)/\log((1 - t)\varphi_{s,\mathbb{K}}(A) + t)$, assuming $0 \leq t \leq 1$ for this analysis, since $||r^{(ms+s)}|| \leq ((1 - t)\varphi_{s,\mathbb{K}}(A) + t)||r^{(ms)}||$ is assured. If l cycles in GMRES mode are required, then the total work for solution is approximately

$$l\left[\frac{(s + 1)(s + 2)}{2}w_{\text{dot}} + (s + 1)w_{\text{sax}}\right]$$
$$+[sw_{mv} + w_{\text{dot}} + (4s + 2)w_{\text{sax}}]\frac{\log(\zeta)}{\log[(1 - t)\varphi_{s,\mathbb{K}}(A) + t]}. \tag{5}$$

For comparison purposes we consider the case when A is HPD. Then $\varphi_{s,\mathbb{K}}(A)$ may be approximated using Chebyshev polynomials to yield

$$\varphi_{s,\mathbb{K}}(A) \doteq \frac{1}{\cosh\left(s \log\left(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\right)\right)}, \tag{6}$$

where $\kappa = ||A|| \cdot ||A^{-1}||$ is the condition number of A. This approximation is most valid when the spectrum $\sigma(A)$ does not have large gaps.

For the purpose of this analysis we assume l is fixed independently of κ; this may not hold in practice, depending in part on the strategy used to determine the preconditioner. Let $s = c\kappa^{\xi}$ and assume κ is large. Now, if $\xi \geq \frac{1}{2}$, then (5) grows at least as fast as a multiple of κ. Otherwise, when $0 < \xi < \frac{1}{2}$, we expand by Taylor series for κ large and after some manipulation and dropping of low order terms, we obtain from (5) the estimated asymptotic total cost,

$$w_\infty \equiv ls^2\frac{w_{\text{dot}}}{2} + \frac{\kappa}{s}[w_{mv} + 4w_{\text{sax}}]\frac{\log\zeta^{-1}}{2(1-t)}$$
$$= lc^2\kappa^{2\xi}\frac{w_{\text{dot}}}{2} + \frac{\kappa^{1-\xi}}{c}[w_{mv} + 4w_{\text{sax}}]\frac{\log\zeta^{-1}}{2(1-t)}. \tag{7}$$

It is clear that setting $\xi = \frac{1}{3}$ minimizes the maximal exponent of κ and thus the growth rate of this quantity. In this case, s grows at a rate proportional to $\kappa^{1/3}$, and the total work estimate

w_∞ grows at a rate proportional to $\kappa^{2/3}$. Under these assumptions, minimizing the asymptotic total work estimate (7) over choices of the constant c yields after some manipulation

$$s = \left[\frac{w_{mv} + 4w_{\text{sax}}}{2w_{\text{dot}}} \frac{\log \zeta^{-1}}{l(1-t)} \kappa \right]^{1/3},$$

$$w_\infty = \frac{3}{2}(l w_{\text{dot}})^{1/3} \left[(w_{mv} + 4w_{\text{sax}}) \frac{\log \zeta^{-1}}{2(1-t)} \right]^{2/3} \kappa^{2/3}.$$

These results show that for the HPD case under these assumptions, it is desirable to let the restart frequency s for this algorithm grow in proportion to $\kappa^{1/3}$ to get best performance, and the resulting total work required (measured in vector operations) grows in proportion to $\kappa^{2/3}$.

This compares favorably with a total work growth rate proportional to κ for standard restarted GMRES with the best choice of s (see [10]), while it is not as good as the conjugate residual method whose growth rate is proportional to $\kappa^{1/2}$ due to its short recurrence. In other words, the new method under the given assumptions is able to recover part of the effective performance of short recurrence methods.

The algorithm presented here is similar to the hybrid GMRES algorithm of [16] but has significant differences. Both algorithms apply a cycle of GMRES to the linear problem and use the resulting polynomial as a preconditioner. However, if the polynomial is not adequate, the algorithm of [16] increases the value of s, in an attempt to form a better polynomial. On the other hand, the algorithm presented here keeps s fixed but uses more GMRES cycles to improve the preconditioner.

4. Numerical experiments. We now present the results of numerical experiments with the new algorithm. For these experiments we consider the model problem

$$-u_{xx}(x, y) - u_{yy}(x, y) + Du_x(x, y) = g(x, y) \quad \text{on } \Omega = [0, 1]^2,$$

$$u(x, y) = 1 + xy \quad \text{on } \partial\Omega.$$

Here D is constant, and g is chosen so that the true solution is $u(x, y) = 1 + xy$ on Ω. Five-point central differencing is applied, with uniform mesh spacing $h = 1/n_h$ in each direction. No preconditioning is used.

The mesh size for these experiments is $h = \frac{1}{128}$. Initial guess $u^{(0)} = 0$ is used, and a vector of random entries is used for b. In practice, a random vector may be used for $u^{(0)}$, as described in [16]. The stopping test $||r^{(n)}||/||r^{(0)}|| < \zeta = 10^{-8}$ is used.

The experiments are run in double precision on a Sun 4/330 Sparcstation with 25 Mhz clock speed. The optimization to find the polynomial preconditioner is performed by the GRG2 package of [13], [14], which uses a generalized reduced gradient technique for convex optimization. For each run, the approximation to the best polynomial for the previous cycle is used as the initial guess to the next call of the optimizer package to find an improved value.

The timings in Tables 1–6 are in seconds and the optimizer time is not counted. The case of $t = -\infty$ denotes the case when GMRES mode forced for every cycle. In these instances, the least squares polynomial (2) is used for each cycle, and the method reduces to the GMRES/Chebyshev basis algorithm described in [11], which typically gives the same iterates as standard GMRES at reduced cost. The performance values for these instances are indicative of the performance for the standard restarted GMRES algorithm for these cases.

Several conclusions may be drawn from these results (cf. [16], [17]):

1. In most cases only a couple of GMRES cycles are required to form an adequate preconditioner.

2. The run times for the new method are typically better than those for the pure GMRES method (denoted by $t = -\infty$), sometimes by as much as a factor of three, which is a substantial savings. This is coupled with the fact that the GMRES/Chebyshev basis algorithm [11] used here for the $t = -\infty$ case is up to twice as fast as the standard Arnoldi-based GMRES implementation, leading to solution time reductions of up to a factor of six.

3. It is easier to determine a good polynomial when s is chosen larger. This is consistent with the results of [16]. Of course, if $s = d(A) = d(r^{(0)}, A)$, then the polynomial from the first cycle matches the spectrum of A exactly (in exact arithmetic).

4. For the cases for which only one GMRES cycle is performed, the result of the algorithm applied here is identical to that of the hybrid algorithm of [16], assuming the value of s is forced to be fixed for that algorithm. For the cases for which more than one GMRES cycle is performed, the algorithms are different. In these cases, the polynomial P_s from the first cycle of GMRES is found by this algorithm to be inadequate, and if used would lead to slower convergence or to divergence (cf. [17]). This is because a single GMRES cycle may yield insufficient information to insure that $||P_s(A)r||/||r|| \leq 1$ for all r, even though $||P_s(A)r^{(0)}||/||r^{(0)}|| \leq 1$ is imposed. Such problems may occur when $r^{(0)}$ lacks a representative distribution of eigencomponents. In such cases, the algorithm of [16] with fixed s may diverge.

5. In the HPD cases, many GMRES cycles are required to obtain an effective polynomial. This is due in part to the fact that for the HPD case it is especially critical to estimate the smallest eigenvalue accurately, which is difficult. Furthermore, the polynomial preconditioner used here does not take advantage of the fact that for the HPD case, effective polynomials may be found based solely on the endpoints of the spectrum. Therefore, the algorithm spends a large amount of time making the polynomial small throughout the interior of the spectrum. On the other hand, when the matrix is nonnormal, the behavior of polynomials on the spectrum is less determinative of the convergence behavior of the polynomial preconditioner, and the approach used here has greater merit.

6. For these problems, $s = 20$ generally gave the best timings. This indicates a tradeoff between choosing s large to keep small the required number of GMRES cycles for the preconditioner calculation, and choosing s small to avoid the need to do even a single very large GMRES cycle. Furthermore, the aspect of GMRES which makes its average performance better than its worst case performance may be more pronounced when s is large.

7. These experiments do not shed light on the growth rate of the best value of s as the problem size grows, since only one problem size is used. The earlier asymptotic analysis suggests that at least for the HPD case, the best value of s grows for larger problem sizes. However, this may not always occur in practice due to such factors as superlinear convergence of GMRES due to gaps in the spectrum of A, or the need for differing numbers of GMRES cycles as the problem size grows, factors not accounted for in the model given earlier.

8. Though the timings for the new algorithm are generally less than those for the $t = -\infty$ (pure GMRES(s)) case, the difference is not as dramatic as might be expected. This is because more overall cycles are often required by the hybrid algorithm: the true minimal residual algorithm for each cycle has an *average* performance which may be better than the average performance of a good polynomial preconditioner, though the worst case bounds may be the same. The reasons for this are a topic of further study.

Next, in Table 7 the execution times for the convex optimizer are compared to the total run times, for the $s = 20$ case shown in Table 2.

It should be emphasized that this study does not fully investigate the issue of fast convex minimization algorithms for this problem. Alternate algorithms might give faster results; this is a topic for further research. On the other hand, it can be expected that for sufficiently large problems, the time for the optimization relative to the time for the rest of the algorithm will be small, since the optimization does not require the use of long vectors of size N. Thus, for many practical problems, an extremely fast minimizer may not be necessary.

The optimization times shown in Table 2 are fairly small compared to the total time, except for the HPD ($Dh = 0$) case. Even for the $s = 60$ case, the optimizer time did not exceed approximately 20% of the total time, except for the HPD case. On the other hand, when A is HPD, as noted earlier, many cycles are executed in GMRES mode, requiring a large number of calls to the optimizer to revise the preconditioner. One possible remedy to avoid

TABLE 7
Optimizer times / total times (seconds); case of $s = 20$.

Meth \ Dh:	0	2^{-3}	2^{-2}	2^{-1}	2^{0}	2^{1}	2^{2}	2^{3}	2^{4}	2^{5}
$t = .2$	407/1131	10/456	5/267	8/200	5/168	5/148	7/129	8/130	10/160	7/243
$t = .5$	2055/2614	6/452	5/260	7/193	5/164	5/144	7/125	8/126	10/156	7/235

such cases is to set an upper limit on the number of optimizations done, and when this number is exceeded the algorithm could revert to using standard restarted GMRES for every cycle. In any case, it should be emphasized that performing even a few optimizations yields a better polynomial than the simple first-cycle polynomial, which is employed by the fixed-s version of the algorithm of [16].

In short, the algorithm shows benefit in terms of CPU savings over restarted GMRES, particularly for large values of s. Even greater savings may be expected on computer architectures such as distributed memory machines for which inner product operations are particularly costly.

5. Conclusions. In this paper we have shown results on the effectiveness of replacing GMRES with a polynomial preconditioning, defined an algorithm for safely adapting between GMRES and polynomial preconditioning, and defined a new preconditioning which approximates the minimax polynomial preconditioning for a given matrix.

The algorithm is shown to be effective compared to restarted GMRES for a number of cases. Further research is needed to shed more light on the behavior of polynomial methods for nonsymmetric problems.

A COMPARISON OF PRECONDITIONED NONSYMMETRIC KRYLOV METHODS ON A LARGE-SCALE MIMD MACHINE*

JOHN N. SHADID† AND RAY S. TUMINARO‡

Abstract. Many complex physical processes are modeled by coupled systems of partial differential equations (PDEs). Often, the numerical approximation of these PDEs requires the solution of large sparse nonsymmetric systems of equations. In this paper the authors compare the parallel performance of a number of preconditioned Krylov subspace methods on a large-scale multiple instruction multiple data (MIMD) machine. These methods are among the most robust and efficient iterative algorithms for the solution of large sparse linear systems. In this comparison, the focus is on parallel issues associated with preconditioners within the generalized minimum residual (GMRES), conjugate gradient squared (CGS), biconjugate gradient stabilized (Bi-CGSTAB), and quasi-minimal residual CGS (QMRCGS) methods. Conclusions are drawn on the effectiveness of the different schemes based on results obtained from a 1024 processor nCUBE 2 hypercube.

1. Introduction.

A wide variety of complex physical systems are modeled by three-dimensional partial differential equations (PDEs). Often, numerical formulations of these PDE problems give rise to systems of large sparse nonsymmetric equations. Unfortunately, the slow asymptotic performance and large storage requirements of direct solvers make them impractical for the increasingly larger systems that scientists need to solve. For these systems robust and fast iterative solvers must be used.

In this paper, we focus on performance and implementation issues for preconditioned Krylov methods on large-scale multiple instruction multiple data (MIMD) machines. These machines utilize many independent processors, each with their own local memory and a message-passing capability for communicating between processors. The Krylov methods we consider (GMRES, CGS, Bi-CGSTAB, and QMRCGS) are relatively easy to program and work well on a wide variety of meaningful problems. A number of highly parallel preconditioners are implemented including classical methods such as Jacobi, Gauss–Seidel, and polynomial preconditioners, as well as more sophisticated (though sometimes more problematic) preconditioners such as multigrid and multilevel filtering. Based on results obtained on a 1024 processor nCUBE 2, a number of general conclusions are drawn about the effectiveness of the underlying Krylov methods as well as the parallel performance of the preconditioners.

2. Iterative solvers.

Krylov algorithms are among the fastest and most robust iterative solvers for a wide variety of applications (e.g., computational fluid dynamics). In this paper, a representative group of nonsymmetric Krylov solvers are considered: conjugate gradient squared (CGS) [26], biconjugate gradient stabalized (Bi-CGSTAB) [29], generalized minimum residual method, (GMRES) [21], and a transpose-free variant of the quasi-minimum residual method (QMR) [8] referred to in this paper as QMRCGS.

The basic process in each of the Krylov solvers is the projection of the original set of equations onto a subspace. The resulting set of equations is then solved and the subspace

solution is used to correct the solution to the original problem. The Bi-CGSTAB, CGS, and QMRCGS methods are based on the Lanczos biorthogonalization method. Their corresponding projection operators are computed using short recurrence relations. Unfortunately, the resulting projection operator is not orthogonal. By contrast, GMRES is based on the Arnoldi method. Its projection operator is much more expensive to compute (in terms of time and storage) as short recurrences cannot be used. However, the corresponding projection operator is orthogonal. To avoid excessive growth in storage and computations, a restarted version of GMRES is considered. Specifically, the iteration is terminated after a modest number of steps and then reinitiated using the previous solution as an initial guess. We note that all the methods considered in this paper are transpose-free schemes. In many engineering applications, the matrix-vector product corresponds to a complex and lengthy set of subroutines (where the the matrix is not explicitly stored). Thus, methods that do not require the use of the transpose of a matrix are more generally applicable. Figures 1–4 depict preconditioned (see §3) versions of CGS, Bi-CGSTAB, GMRES, and QMRCGS methods corresponding to our implementations.

```
CGS(x_0, A, b )
    r_0 = b − Ax_0;    q_0, p_{-1} = 0;
    Choose r̃_0 so that r_0^T r̃_0 ≠ 0;
    ρ_{-1} = 1;    n = 0;
    while (not converged) do
        ρ_n = r̃_0^T r_n;    β = ρ_n / ρ_{n-1};
        u = r_n + βq_n;
        p_n = u + β(q_n + βp_{n-1});
        Solve: M p̂ = p_n;        /* M is the preconditioning matrix. */
        v = A p̂;
        α = ρ_n / (r̃_0^T v);
        q_{n+1} = u − αv;
        Solve: M û = (u + q_{n+1});
        r_{n+1} = r_n − αA û;
        x_{n+1} = x_n + α û;
        n = n + 1;
    end
end
```

2.1. Parallel issues. In this comparison we report on the relative performance of parallel solvers developed for systems of equations arising from PDE discretizations on regular two-dimensional domains. Specifically, parallelization is accomplished by spatially decomposing the computational domain and assigning subdomains to individual processors. Each processor updates only those variables internal to its subdomain. In addition to these internal variables, each processor contains internal boundary components. The internal boundaries are copies of components that are updated on other processors, but which are needed to compute local operations. Currently, we have implemented only rectangular subdomains. In this case, each processor contains an extra border around its subdomain that contains the additional variables. Similar to the variables, the discrete equations are also partitioned among the processors. In particular, the matrix is stored using a parallel generalization of the standard modified sparse row (MSR) format [20]. This format requires that two arrays be maintained: one array to store the nonzeros of the matrix and the other array to describe their location. A parallel version of this format is defined as follows. Let us assume (for clarity of presentation) that $\frac{N}{P}$ variables have been assigned to P processors. We decompose the matrix into P submatrices (each with $\frac{N}{P}$ rows) such that each processor is assigned a submatrix whose nonzero columns correspond

```
Bi-CGSTAB(x_0, A, b)
    r_0 = b − Ax_0;    v_0, p_0 = 0;
    Choose r̃_0 so that r_0^T r̃_0 ≠ 0;
    ρ_0, α, ω_0 = 1;    n = 1;
    while (not converged) do
        ρ_n = r̃_0^T r_{n−1};    β = (ρ_n/ρ_{n−1})(α/ω_{n−1});
        p_n = r_{n−1} + β(p_{n−1} − ω_{n−1} v_{n−1});
        Solve: M p̂ = p_n;        /* M is the preconditioning matrix. */
        v_n = A p̂;
        α = ρ_n/(r̃_0^T v_n);
        s = r_{n−1} − α v_n;
        Solve: M ŝ = s;
        t = A ŝ;
        ω_n = (t^T s)/(t^T t);
        x_n = x_{n−1} + α p̂ + ω_n ŝ;
        r_n = s − ω_n t;
        n = n + 1;
    end
end
```

to the variables stored in the processor. Each submatrix is then stored using an MSR format in conjunction with a local numbering of the variables. More details of the distributed sparse matrix and the subdomain partitioning can be found in [24].

The majority of the solvers are implemented using only basic linear algebra subroutine (BLAS) kernels such as dot products and vector addition routines (supplied and optimized by the vendor, nCUBE). Additionally, a matrix-vector kernel is needed. Since this kernel is only a few lines long, it was written in assembly code (with the help of the vendor). Our implementation of this kernel runs at 1.3 Mflops per node. This performance for an indirectly addressed sparse matrix-vector multiply compares well with the maximum nCUBE 2 double

QMRCGS(x_0, A, b)

FIG. 4. QMRCGS *Algorithm.*

precision computation rate of about 2.5 Mflops per node[1] [23], [24]. The only communication procedures are a local exchange border routine (used by the sparse matrix-vector multiply requiring four messages to be exchanged per processor) and a global summation routine (used in the dot product algorithm requiring $\log_2(P)$ messages to be exchanged per processor on a hypercube with P total processors).

Parallel versions of Bi-CGSTAB, CGS, and the QMRCGS require only parallel implementations of the above-mentioned kernels. However, for GMRES the orthogonalization procedure needs to be reevaluated. Typically, GMRES orthogonalization is performed by a modified Gram–Schmidt process on scalar and vector computers. This choice is motivated by the superior stability properties of the modified scheme relative to the classical Gram–Schmidt method. However, from a parallel efficiency perspective, the classical Gram–Schmidt algorithm is superior. Specifically, $m \log_2 P$ messages per processor are needed to orthogonalize

[1] Unless noted otherwise, the results we present are for double precision computations using the assembly-coded matrix-vector multiply routine.

a vector with respect to m previous vectors by a modified Gram–Schmidt method. In contrast, the classical Gram–Schmidt method requires only $\log_2 P$ messages per processor (though these messages are now of size m). For large Krylov subspace dimensions, m, this difference can be significant. Both orthogonalization schemes have been implemented on the nCUBE 2.

Finally, we note that redundant work is performed (on all processors) in our implementation of the Hessenberg solver. That is, each processor performs the plane rotations corresponding to the factorization of the Hessenberg matrix along with the resulting triangular solve. Though this might appear to be inefficient, the actual time required for these operations is insignificant (for example less than .3% of the total solution time for the results given in Table 1, §4) and thus there is no advantage in parallelizing this step.

3. Preconditioners. It is well known that the overall performance of Krylov methods can be substantially improved when one uses preconditioning [6]. The basic idea is that instead of solving the system $Ax = b$, the system $AM^{-1}y = b$ is solved where M^{-1} is an approximation to A^{-1} and is easily computed. Since only matrix-vector products are needed, it is not necessary to explicitly form AM^{-1} (only a subroutine to solve $Mv = y$ is needed). We note that the preconditioning described here corresponds to "right" preconditioning and that it is also possible to precondition on the "left" (i.e., $M^{-1}A$). In this paper, only right preconditioning is considered as the comparisons are somewhat more straightforward. Specifically, when left preconditioning is used the computed residual corresponds to a preconditioned residual. Thus, if convergence is based on the size of the residual, changing the preconditioner effectively changes the convergence criteria.

Currently, a wide variety of preconditioners are available. The proper choice of preconditioner is both computer (or architecture) dependent as well as problem dependent. This research continues in a number of areas. It is, therefore, impossible to give a complete survey of all preconditioners. Instead, we attempt to investigate some of the more common preconditioners currently in use. It is expected that further advances in preconditioners will yield improvements in terms of both robustness and performance.

3.1. Local preconditioners. In this section we consider preconditioners that use information only within a local neighborhood to update the value of the solution at a grid point. This local data dependency is the result of the numerical approximation method (e.g., finite difference or finite element techniques) as well as the particular iterative procedure that is used as a preconditioner.

Classical iterative schemes. Two classical schemes are considered in this paper: Jacobi and Gauss–Seidel. Jacobi preconditioning amounts to rescaling the matrix and is thus easily parallelizable. For Gauss–Seidel, however, the ordering of the points must be considered. On sequential computers, points are often updated in an order that corresponds to counting across the rows of the grid (natural ordering). On vector and parallel machines this ordering is inefficient due to data dependencies. Instead, a "multicolor" ordering of the grid points is used that partitions the grid points into disjoint sets [1], [31]. These sets are selected so that update operations for each grid point are independent of all other grid points in the same set; thus points within a set can be updated in parallel. Of course, different orderings imply different numerical convergence properties. Thus, there is often a tradeoff between parallelism and rate of convergence.

Polynomial preconditioners. These methods use a polynomial expansion in the matrix A to approximate A^{-1}. Since these methods require only the standard matrix-vector kernel, no new communication routines are necessary to produce a parallel polynomial preconditioner. The major difficulty is choosing the polynomial coefficients properly. One choice based on

$$\min_{\alpha_i's} \; ||I - P(A)A||_2, \tag{1}$$

where

$$M^{-1} = P(A) = \sum_{i=0}^{n} \alpha_i A^i$$

leads to the least squares polynomial. The α's are easily approximated when an approximation to the convex hull of the spectrum of A, $\sigma(A)$, is available (e.g., within GMRES) [18]. Since the convex hull is not always easily available, we approximate (1) by assuming that all the eigenvalues of A lie on the real axis between 0 and $||A||_\infty$. When A is close to symmetric positive definite (SPD), this approximation is quite good.

A second choice for the $\alpha's$ corresponds to first defining

$$G \equiv I - \frac{1}{\beta} A \tag{2}$$

and using a truncated Neumann series

$$A^{-1} = \frac{1}{\beta}(I - G)^{-1} \approx \frac{1}{\beta} \sum_{i=0}^{n} G^i \tag{3}$$

[7], [30]. To ensure convergence of the infinite series, β must be chosen so that the spectral radius of G is less than one. For a real positive definite matrix A, this corresponds to

$$\beta > \frac{1}{2} \max_{\lambda \in \sigma(A)} \frac{|\lambda|^2}{\mathrm{Re}(\lambda)}, \tag{4}$$

where $\mathrm{Re}(\lambda)$ is the real part of λ. When A is SPD, (4) reduces to $\beta > \frac{\lambda_{\max}}{2} \approx \frac{||A||_\infty}{2}$. Rather than computing β from (4) for the nonsymmetric case, we use $\beta = 1.1||A||_\infty/2$, and have found this suitable for a wide range of problems.

Finally, we note that in our implementation, a row sum scaling is first performed (i.e., $a_{ij} = a_{ij} / \sum_{j=1}^{N} ||a_{ij}||$) before the polynomial preconditioner is constructed for the resulting matrix.[2]

3.2. Global preconditioners. Global preconditioners use information across the domain to update each point. In PDE discretizations this corresponds to using information from distant grid points to update an unknown. Since A^{-1} is dense in most applications (i.e., the solution at a point depends on information from all points), it is not surprising that global schemes often converge in many fewer iterations than local ones. Unfortunately, global preconditioners are often much harder to implement and have a somewhat more limited range of applicability. In this paper, we discuss alternating line Gauss–Seidel, incomplete LU factorization (ILU), multigrid, and multilevel filtering.

Alternating line Gauss–Seidel. We consider the alternating line Gauss–Seidel method [31]. Specifically, the grid is colored into red and black horizontal lines and one iteration of line Gauss–Seidel is performed. The procedure is then repeated with vertical lines. To update a line, a matrix containing all coupling within that line is factored. For five-point discretization of a single PDE this corresponds to factoring a tridiagonal matrix. Thus, a series of tridiagonal (or block tridiagonal) matrices must be solved in one direction and then solved in the other direction. Our parallel implementation proceeds as follows. Consider a

[2]Row sum scaling is explicitly performed on the matrix before using all of the preconditioners except the Jacobi scheme (where diagonal scaling is already incorporated) and the multigrid method where consistent scaling must be used on different grid levels to properly implement multigrid.

$p \times p$ array of processors that corresponds to an $n \times n$ computational grid. We perform p line solves in parallel (assuming $n \geq 2p$) until all the line solves in the x direction are complete. We then repeat the procedure for the y direction solves. Thus, each line solve is assigned p processors. A multitude of parallel tridiagonal algorithms have been studied [10], [13]. In our implementation we use block cyclic reduction. This algorithm proceeds by eliminating all the even unknowns within a line. The remaining unknowns are renumbered and the resulting even unknowns are eliminated. This process is repeated until only two unknowns remain (which can be solved directly). Since each of the $\log_2 n$ stages in the elimination process requires two messages to be communicated, a total of $2 \log_2 n$ messages are sent during the process. It should be noted that our implementation of the tridiagonal solvers is fairly crude. In part, this explains the poor results that are presented in §4. In particular, a number of issues must be addressed to improve the tridiagonal solver: the slower serial performance of cyclic reduction, inactive processors, and high communication requirements. There are, of course, many other possibilities for solving tridiagonal systems in parallel. One could keep a full line in each processor and solve all the tridiagonals in parallel. However, this approach would require a matrix transpose algorithm to perform the line solves in the other direction as well as require that the grid has sufficiently many points in each direction (e.g., at least 2048 grid lines in each direction when using a system with 1024 processors). Overall, we believe that improvements can be made to our tridiagonal solver (perhaps even by a factor of three or more). Even with significant improvements, however, the line scheme would still lag behind the other preconditioners (see §4).

ILU. We consider incomplete factorization as a preconditioner [15]. An incomplete factorization can be thought of as performing a Gaussian elimination procedure without storing all of the elements (i.e., restricting the fill-in). In our implementation we require the approximate LU factors to have the same sparsity pattern as in A. Most ILU schemes use a natural ordering of the unknowns.[3] Since standard ILU does not parallelize well, we consider a local ILU method (LILU) in which the boundary interface values for each subdomain are taken as known quantities. Each processor then appends a set of boundary interface equations to its local sparse matrix. These equations have unit diagonal with a right-hand side corresponding to the boundary interface value. An ILU factorization is performed on the expanded matrix and the triangular solves are used to generate an approximate inverse within each subdomain. It should be noted that the LILU method requires the same type of communication as the polynomial preconditioners, i.e., at each iteration updated interface values from neighboring processors must be communicated. One disadvantage of this approach is that the resulting preconditioner may yield slower convergence as it now uses information only within its subdomain. More sophisticated techniques that globally couple the interface equations exist (e.g., [25], [27]). We are currently investigating these approaches.

Multigrid. Multigrid methods are among the fastest iterative solvers for elliptic PDE problems [3]. One iteration of a simple multigrid V cycle consists of smoothing steps (e.g., Jacobi, Gauss–Seidel) along with projection and interpolation operations on a hierarchy of grids with different mesh sizes. In our Krylov solvers we use one multigrid V cycle as a preconditioner (recursively coarsening the grid down to a 4×4 grid). Coarse grid discretizations are obtained using the same scheme (in fact the same subroutine) as for the fine grid and storing the coarse grid operators using the MSR format. Within the V cycle, bilinear interpolation and full weighting restriction is used to transfer between grids. Unless otherwise stated, it should be assumed that one Gauss–Seidel iteration is used before and another Gauss–Seidel

[3] Multicolor orderings are also possible. However, the overall convergence is often much less reliable for hard problems than with the natural ordering scheme [4].

iteration is used after the coarse grid correction.[4]

Multilevel filtering. Motivated by the success of multigrid and hierarchical basis preconditioners, the multilevel filtering preconditioner [14] (similar to the BPX preconditioner, see [2]) approximately decomposes the residual into different frequency components, selectively scales these components, and then recombines them to form the preconditioned residual. In particular, a projection operator is used to project the residual onto a series of coarser grids. The projected residual on each grid is then scaled by differing amounts. This scaling represents an approximate inverse in Fourier space and is chosen optimally for the Poisson equation. Finally, the residual components are interpolated and combined to form the preconditioned residual. From an implementation perspective, multilevel filtering corresponds to a multigrid V cycle where the relaxation operation is replaced by a subroutine that scales the right-hand side, and the projection and interpolation operators are applied to the right-hand side (as opposed to the residual and solution).

In both the multigrid and the multilevel filtering preconditioners, each grid is processed in sequence. Each grid is partitioned among the processors corresponding to a particular decomposition of the domain. On coarser grids (where there are fewer grid points than processors) the subdomain assigned to a processor may not contain grid points. In this case the processor simply performs redundant work, in parallel, to the useful work proceeding on other processors. It should be noted that when a binary reflected Gray code is used in conjunction with the multigrid algorithm, not only are adjacent subdomains assigned to neighboring processors, but on coarse grids (with fewer points than processors) it is possible to shuffle the data (using nearest neighbor communication) so that only nearest neighbor communication is needed to exchange boundary information between those processors that contain valid grid points. This is due to the extra interconnections present on a hypercube that are not available on a mesh-connected architecture [5].

4. Numerical results. The remainder of this paper considers the performance of the solvers and preconditioners, discussed in the previous sections, on massively parallel machines. In this examination we focus on two questions:

- Which methods and preconditioners are best suited to parallel machines?
- What performance can be expected from current massively parallel MIMD machines?

To perform this evaluation, a number of test problems have been solved. In the process of our numerical experiments, a significant effort has been made to accurately reflect the relative performance of the different schemes. That is, numerous tests and variants (different algorithms, implementations, and convergence criteria) have been examined in an effort not to favor any one method over another. However, given the nature of the task, these results (as with any comparisons of this kind) should only be taken as an approximate guide of expected performance on similar problems. A 1024 processor nCUBE 2 hypercube was used for all of the tests. This machine is a distributed-memory MIMD machine with 4 Mbytes of memory per node and a maximum double precision computation rate of about 2.5 Mflops per node. We describe below the four test problems used in this paper.

PROBLEM 1.

$$-\frac{\partial^2 u}{\partial x^2}+\frac{\partial u}{\partial x}+(1+y^2)\left(-\frac{\partial^2 u}{\partial y^2}+\frac{\partial u}{\partial y}\right)=f(x,y) \tag{5}$$

defined on the unit square with Dirichlet boundary conditions and right-hand side such that

$$u(x,y)=e^{x+y}+x^2(1-x)^2\ln(1+y^2). \tag{6}$$

[4]Numerous experiments were performed with different smoother combinations. For isotropic problems, two Gauss–Seidel iterations are typically among the most efficient. Only one V cycle was chosen for preconditioning. Obviously, as more V cycles are used, the more the method behaves like pure multigrid.

This convection-diffusion PDE is taken from [28] and is discretized using central differences. The resulting algebraic system is positive definite and represents a relatively easily solved nonsymmetric system.

PROBLEM 2.

$$(7)\quad -[b(x,y)u_x]_x - [c(x,y)u_y]_y + [b(x,y)\ c(x,y)u]_x + [d(x,y)u]_y + e(x,y)u = f$$

defined on the unit square with

$$\begin{aligned} b(x,y) &= e^{-xy}, & c(x,y) &= \beta(x+y), \\ d(x,y) &= \gamma(x+y), & e(x,y) &= (1+xy)^{-1}, \\ \beta &= .01, & \gamma &= .01, \end{aligned}$$

Dirichlet boundary conditions and right-hand side such that the solution is given by

$$(8)\qquad u(x,y) = xe^{xy}\sin(\pi x)\sin(\pi y).$$

This PDE is anisotropic in that the amount of diffusion varies significantly in the different coordinate directions. In addition, by varying the magnitude of the γ parameter it is possible to produce a more strongly convected system. The problem is taken from [26] and is discretized via central differences.

PROBLEM 3.

$$(9)\quad \begin{aligned} \frac{\partial^2\Omega}{\partial x^2} + \mathrm{Ax}^2\frac{\partial^2\Omega}{\partial y^2} &= \Pi_1\frac{\partial\Phi}{\partial x} + \Pi_2\frac{\partial\Phi}{\partial y}, \\ \frac{\partial^2\Psi}{\partial x^2} + \mathrm{Ax}^2\frac{\partial^2\Psi}{\partial y^2} &= \frac{-\mathrm{Ax}^2}{4}\Omega, \\ \mathrm{Ax}\frac{\partial\Psi}{\partial y}\frac{\partial\Phi}{\partial x} - \mathrm{Ax}\frac{\partial\Psi}{\partial x}\frac{\partial\Phi}{\partial y} &= \frac{\partial^2\Phi}{\partial x^2} + \mathrm{Ax}^2\frac{\partial^2\Phi}{\partial y^2}. \end{aligned}$$

This PDE system corresponds to the incompressible Navier–Stokes and thermal energy equations (given in stream-vorticity formulation) describing buoyancy-induced natural convection in an inclined two-dimensional rectangular cavity over the computational domain $(-1, 1) \times (-1, 1)$. In the above equations,

$$(10)\qquad \Pi_1 \equiv -\mathrm{Ax}\frac{\mathrm{Ra}\cos\Theta}{2}, \qquad \Pi_2 \equiv (\mathrm{Ax})^2\frac{\mathrm{Ra}\sin\Theta}{2},$$

where Ax is the aspect ratio of a rectangular cavity, Θ is the angle of inclination, and Ra is the Rayleigh number. In this formulation the Prandtl number has been assumed to be infinite so that the inertial terms in the momentum equation can be neglected. In our specific example problem, we take $\mathrm{Ax} = 1$, $\Theta = \frac{\pi}{2}$, and $\mathrm{Ra} = 10^3$. Dirichlet boundary conditions are used for the stream function, Ψ, a mixed Dirichlet/Neumann condition for temperature, Φ, and a first-order approximation of the stream function-vorticity relationship at the boundary is used for the vorticity boundary conditions (see [22]). A discrete nonlinear set of equations is obtained using central difference approximations. The resulting nonlinear system is solved by Newton's method requiring a series of linear subproblems to be solved. As the Rayleigh number is increased the system becomes more strongly convected and nonlinear.

PROBLEM 4.

$$(11)\qquad -\frac{\partial^2 u}{\partial x^2} - \frac{\partial^2 u}{\partial y^2} + \gamma\left(x^2\frac{\partial u}{\partial x} + y^2\frac{\partial u}{\partial y}\right) - \beta u = f(x,y)$$

defined on the unit square with Dirichlet boundary conditions and right-hand side such that the vector of all ones is the exact solution. This problem is discretized using centered differences on a uniform mesh, the parameter $\gamma = 100$, and the parameter β is varied to make the problem more indefinite.

4.1. Krylov solvers. In this subsection we focus on the four Krylov solvers. Due to the large number of possible preconditioner/solver combinations, we limit ourselves to polynomial preconditioning and use the notation LSn to denote an n term least-squares polynomial expansion. A similar notation is used for the Neumann series. Studies of the various preconditioners are deferred to the next section.

Before comparing Krylov solvers, it is necessary to first address two algorithmic issues associated with the GMRES method. The first issue (unique to the parallel environment) is the choice of orthogonalization procedure: classical Gram–Schmidt or modified Gram–Schmidt. The second issue corresponds to choosing the Krylov subspace size so that the convergence rate and the time per iteration are balanced to yield the fastest overall solution time (see §2). Figure 5 illustrates the GMRES results using both modified and classical Gram–Schmidt orthogonalization with a variety of subspace sizes for Problem 1. The results shown in the figure are typical of GMRES behavior. Specifically, we have not encountered a PDE problem that required significantly fewer GMRES iterations using modified Gram–Schmidt as opposed to classical Gram–Schmidt.[5] Thus, when comparing CPU times, the classical Gram–Schmidt procedure requires less time per iteration and therefore outperforms the modified Gram–Schmidt procedure (1.5 times faster for $m = 150$ in Fig. 5). Unless otherwise stated, the GMRES results in the remainder of the paper correspond to using classical orthogonalization. When we wish to distinguish between the two schemes, we use the notation GMRES^{C} and GMRES^{M} to denote the use of classical and modified Gram–Schmidt, respectively. While our examples do not indicate a need for a more stable orthogonalization procedure, it may be worthwhile to consider some combination of classical and modified Gram–Schmidt to obtain better stability properties without significantly increasing the time per iteration. We, however, do not pursue this topic any further.

Unfortunately, the situation is not as clear for the choice of Krylov subspace size. In particular, the optimal size is problem dependent, preconditioner dependent, and grid size dependent. Thus, it is difficult to find a nearly optimal subspace dimension without experimentation. For the problem corresponding to Fig. 5, the optimal subspace size is approximately 50 for the least-squares preconditioner, while the Neumann series works best with a subspace size of 90. From our experience we have generally found that a Krylov subspace size of 64 works well on a variety of problems. However, there are some situations that require bigger subspace sizes to reduce CPU time and in some cases to obtain convergence. In the remainder of the comparison we attempt to present representative results for the restarted GMRES method by selecting appropriate values for m.

We now consider the performance of the different Krylov algorithms using representative preconditioners. In these examples we select the initial guess as the zero vector and take the $\tilde{r}_0$ vector as a random vector in the CGS, Bi-CGSTAB, and QMRCGS methods. To determine convergence we require the residual normalized by $||A||_\infty$ to be less than 10^{-6}. This choice was influenced by the nonlinear problem, since requiring a significant reduction in the initial residual can be problematic when the initial guess is quite accurate. In the CGS and Bi-CGSTAB solvers we use the naturally occurring $||r||_2$ measure of the residual, and in the GMRES method we use the estimate suggest by Saad and Schultz [21]. In QMRCGS, we use

[5] It is possible, however, to create linear systems illustrating the superior numerical properties of modified Gram–Schmidt.

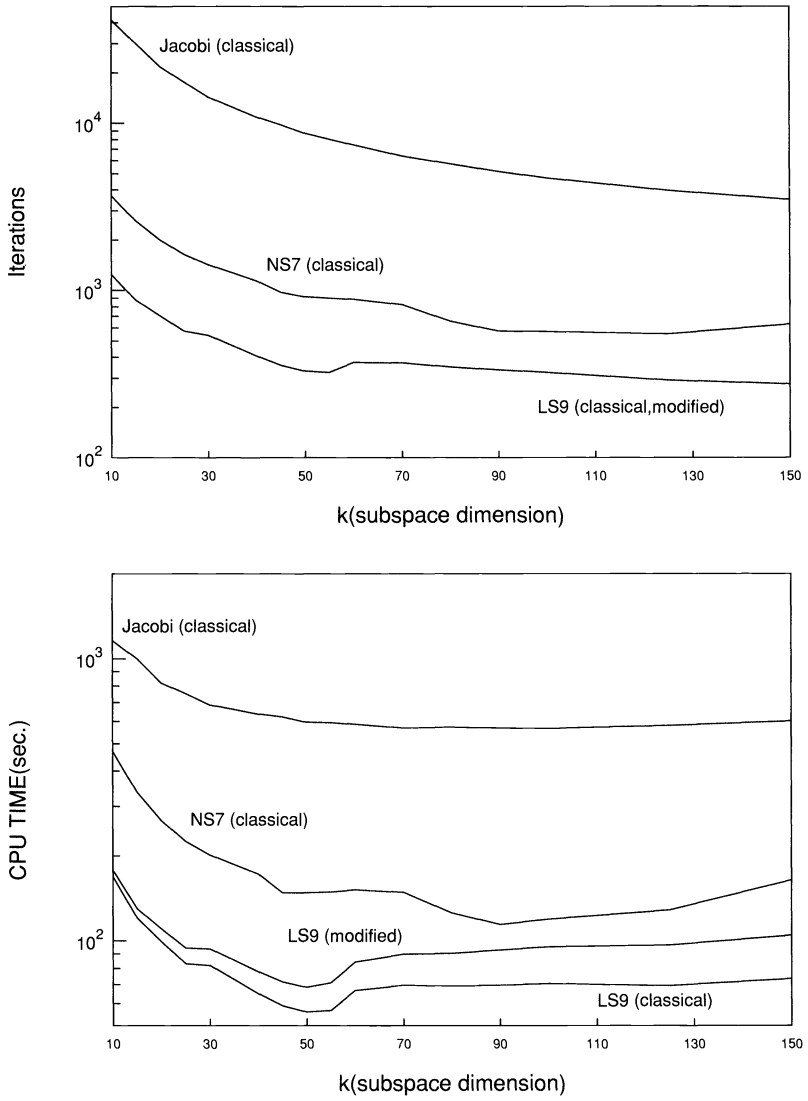

FIG. 5. *Convergence of* GMRES *for Problem* 1 *on a* 256 × 256 *grid with* 256 *processors.*

the bound $||r_m|| \leq \sqrt{m+1}\tau_m$ to estimate this quantity at the mth iteration as suggested by Freund [8]. After satisfying the above criteria we compute the value of the true residual to verify convergence of the solver.

In Tables 1–4 we present timings for the four parallel Krylov methods on the different PDE test problems. The times given in the tables correspond to the time needed for the solution algorithm as well as the scaling. However, it should be noted that the time to create the matrices (whose entries are computed locally in parallel on each processor) is insignificant. With the possible exception of GMRES using modified Gram–Schmidt orthogonalization, all the solvers are highly parallelizable. In Table 1, speedups are given corresponding to Problem 1. Most of the solvers attain speedups between 5 and 6 where speedup is defined relative to the 128-processor run time as

$$S_p = \frac{T_{128}}{T_p}$$

and T_p is the time required using p processors. These speedups compare quite favorably with the theoretical maximum of 8 (especially when one takes into account that the grid size is quite modest compared to a three-dimensional application). Unfortunately, the GMRES method using modified Gram–Schmidt attains a speedup of only 2.6 due to the large number of message startups. In the remainder of the tables we consider only the classical GMRES method. It should also be noted that the QMRCGS, CGS, and the Bi-CGSTAB methods are rather sensitive to roundoff error. As a consequence, the number of iterations required for convergence changes as the number of processors changes. This behavior explains the apparent superlinear speedup shown in Table 1. If the speedups for CGS and Bi-CGSTAB are calculated using the time per iteration (instead of entire solution time), the superlinear speedups do not appear.

In terms of overall solver performance GMRES is usually the slowest. In fact, it is often two or three times slower than the other methods. Additionally, large Krylov subspace sizes are sometimes needed to obtain any convergence. For example, in Table 3 the solution times are given for the nonlinear convection problem with increasing Rayleigh numbers. Increasing the Rayleigh number effectively makes the problem more nonlinear and more convective in nature. Even for the smaller Rayleigh numbers, a Krylov subspace size greater than 100 is needed to obtain convergence in a reasonable number of iterations. Furthermore, for a Rayleigh number of 5×10^4, convergence is still not obtained using a Krylov subspace size of 175. That is, the GMRES method is not only slower, but it often does not converge when the subspace size is not large enough. We should note, however, that the time differential between GMRES and the other solvers drops substantially (see Table 10) as more effective preconditioners are used.

For many problems we have observed that the Bi-CGSTAB method is slightly faster than both the CGS and the QMRCGS schemes. However, there are situations where Bi-CGSTAB performs noticeably worse. For example, in Table 4, we see that the Bi-CGSTAB method deteriorates as the magnitude of β is increased. This increase in β effectively makes more of the eigenvalues associated with the discrete operator negative. The net result is that all the methods degrade as β increases. However, the degradation is most pronounced with the Bi-CGSTAB scheme. Similar behavior is observed in Table 2 where Bi-CGSTAB is almost a factor of two slower than QMRCGS for $\gamma = 100.0$. In this case, the large value of γ produces an unstable discretization. While this instability does not greatly affect CGS and QMRCGS, it causes a large deterioration in the Bi-CGSTAB performance. Though unstable discretizations should generally be avoided, this example illustrates the greater sensitivity of the Bi-CGSTAB method to the specific nature of the equations.

Overall, there is no clear winner between the iterative solvers. For the most part, the GMRES method is the slowest. Typically, Bi-CGSTAB is slightly faster than CGS and QMRCGS (though it can sometimes be a lot slower on some hard problems). Finally, the run times of CGS and QMRCGS are usually quite close and in the worst case are only slightly longer than the fastest overall run time.

4.2. Preconditioning. The overall performance of a variety of preconditioners is depicted in Tables 5–8 using the Bi-CGSTAB method.[6] In the tables, the following notations are used for different preconditioners: Jac, Jacobi; RBGS, red-black Gauss–Seidel; mg[rbgs1], V cycle multigrid with one pre- and post-Gauss–Seidel sweep; mf, multilevel filtering; LILU,

[6]Only the Bi-CGSTAB method is used to simplify the presentation. The Bi-CGSTAB results are representative of preconditioner performance. However, it should be noted that the performance of the GMRES method is usually improved more substantially by preconditioning than the other schemes.

local ILU; and lineGS, alternating red-black line Gauss–Seidel. The time for the Jacobi preconditioned system essentially corresponds to the time for just using Bi-CGSTAB without preconditioning since the time required to diagonally scale the matrix is insignificant. While the results vary significantly, it is still possible to draw some general conclusions. The most important of these is that preconditioning *does* strongly influence the overall solution time. Overall, the global multilevel schemes frequently provide the "best" performance boost. In particular, the multigrid and multilevel filtering schemes often reduce solution times drastically when compared to local schemes (even though they require more communication and are somewhat more difficult to efficiently parallelize). This reduction is evident in Table 5 where the run time for Problrm 1 drops from 961.3 to 66.0 seconds when comparing Jacobi versus multigrid preconditioning on 64 processors.[7] Unfortunately, the parallel efficiency associated with multigrid preconditioning can be rather low on problems with small grids. For example, the time per iteration using multigrid preconditioning in Table 7 is quite high relative to that for Jacobi. This is essentially due to the inherent inefficiency associated with processing the coarse grids. Additionally, multilevel methods attain their speed by making assumptions about the underlying structure and behavior of the differential operator (e.g., that the PDE operator is elliptic). Even for elliptic problems with irregular behavior, the performance can drop off significantly unless more "specialized" techniques can be incorporated (e.g., near boundaries, interfaces, boundary layers, singularities, etc.). Therefore, it is not surprising that the multiple level methods do not perform well on problems such as Problem 2 (Table 6) for large γ and Problem 4 for large β (Table 8). Further line relaxation techniques are often used to produce more robust multigrid algorithms. Unfortunately, implementation of an efficient parallel tridiagonal solver (see §3) is quite difficult. Thus, the resulting multigrid method with line relaxation is slow (see Table 6, $\gamma \leq 1.0$) as the time per iteration is large. We are currently looking into some promising new multigrid algorithms which make use of semicoarsening techniques (see [16] and [17]) to produce a more efficient parallel robust multigrid method.

Although local preconditioners are sometimes much slower than the multilevel schemes, their performance is much more uniform over a wider range of problems; they are easier to implement for a broad class of problems; and they can still reduce the overall run time by a substantial amount. For example, in Tables 6–8, it is apparent that a number of the local schemes perform well in comparison with the standard multilevel methods on these difficult problems. In addition, from Table 5 it is clear that as the number of processors increases, the

[7] There is some debate as to whether multigrid is best used alone or as a preconditioner. In this paper, we ignore this debate and simply illustrate the multigrid preconditioning results.

CPU time reduction relative to the local methods decreases for a fixed size problem. This decrease in relative performance is due to the higher communication costs associated with the global exchange of information at each iteration for the global preconditioners. In this sense the local methods can be seen to scale more effectively to large number of processors for a fixed size computational problem.

Among local preconditioners, least-squares polynomials perform the best over a wide range of problems despite the simplified criteria used to determine the polynomial coefficients (see §3.1). This can be seen in Tables 5–8 as well as in Fig. 6 where the time and number of

iterations for Problem 1 are given as a function of polynomial degree. As Fig. 6 illustrates, the use of high-order polynomials greatly reduces the total iterations (and hence the number of global inner products). This reduction, however, comes at the cost of increasing the number of local matrix-vector operations. Thus, the overall performance is a function of the cost differential between local matrix-vector computations and global inner products. On massively parallel machines such as the nCUBE2, the matrix-vector product is relatively inexpensive and hence high-order polynomial preconditioners are often effective. In the parallel computing environment it is definitely an advantage to have the ability to easily alter the balance of local and global data flow to suit parallel machines with differing computation/communication characteristics. Additionally, we remark that the polynomial preconditioners generally outperform Gauss–Seidel preconditioning. This is partially a function of code optimization and partially a function of communication requirements. In particular, an assembly coded matrix-vector multiply routine is used for the polynomial methods, but only a standard C code is used for the Gauss–Seidel routines. In the optimization of the sparse matrix-vector routine, the best standard C code performed at about .8 Mflops and the assembly code ran at 1.3 Mflops per node. There are essentially three reasons that we believe it is justified to use of the assembly coded matrix-vector multiply routine in our results. The first and possibly the most important reason is that all the preconditioned solvers benefit. This is evident from Table 5 where we present results for the nonassembly coded results with the optimized assembly code. It is apparent that the use of assembly code has not significantly changed the relative performance of the various preconditioners. In addition, the matrix-vector kernel is a very simple routine that can be easily optimized. And finally, highly optimized versions of standard format sparse matrix-vector multiplies are now being developed for specific machines by vendors [12]. In terms of communication overhead, polynomial methods do not require any type of multicoloring and, therefore, incur fewer costly message startups per iteration than does Gauss–Seidel preconditioning.

Finally, we discuss the local ILU method that lies somewhere between a local and a global preconditioner. The classic ILU scheme is among the most popular preconditioners on serial machines. This scheme is relatively easy to implement and can be designed so that the amount of work per iteration (which is closely tied to the amount of fill-in) can be controlled by a few simple parameters. In this way, it is possible to adjust the ILU scheme according to the difficulty of the problem being solved. It is often the case that on some difficult problems, only the ILU preconditioner will yield satisfactory results. Unfortunately, the classical ILU algorithm (using natural ordering) does not parallelize well, and so we use the local ILU method discussed in §3. Since this LILU scheme ignores coupling between grid points that reside on different processors, one might expect that its convergence rate would be slower than standard ILU. However, in many problems this convergence degradation is quite small. In Table 9 we illustrate this effect using different numbers of subdomains (processors). From the table it is clear that the convergence degradation of the LILU preconditioner on this problem is only slight and is more than offset by the high degree of parallelism. By comparison with the polynomial preconditioners (see Table 10), the resulting LILU speedups are respectable. While the overall run time is competitive with unoptimized polynomial preconditioners, its performance is somewhat mediocre compared to the highly optimized polynomial schemes. However, if one optimizes the LILU it should run quite competitively with the other methods. Unfortunately, this optimization is fairly difficult.

We conclude our evaluation by considering the performance of the nCUBE 2 using these solvers on large problems. In particular, we wish to determine the megaflops and *scaled* speedups that one can expect to obtain using these highly parallel solvers and preconditioners on parallel machines. Specifically, *scaled* speedup is defined as

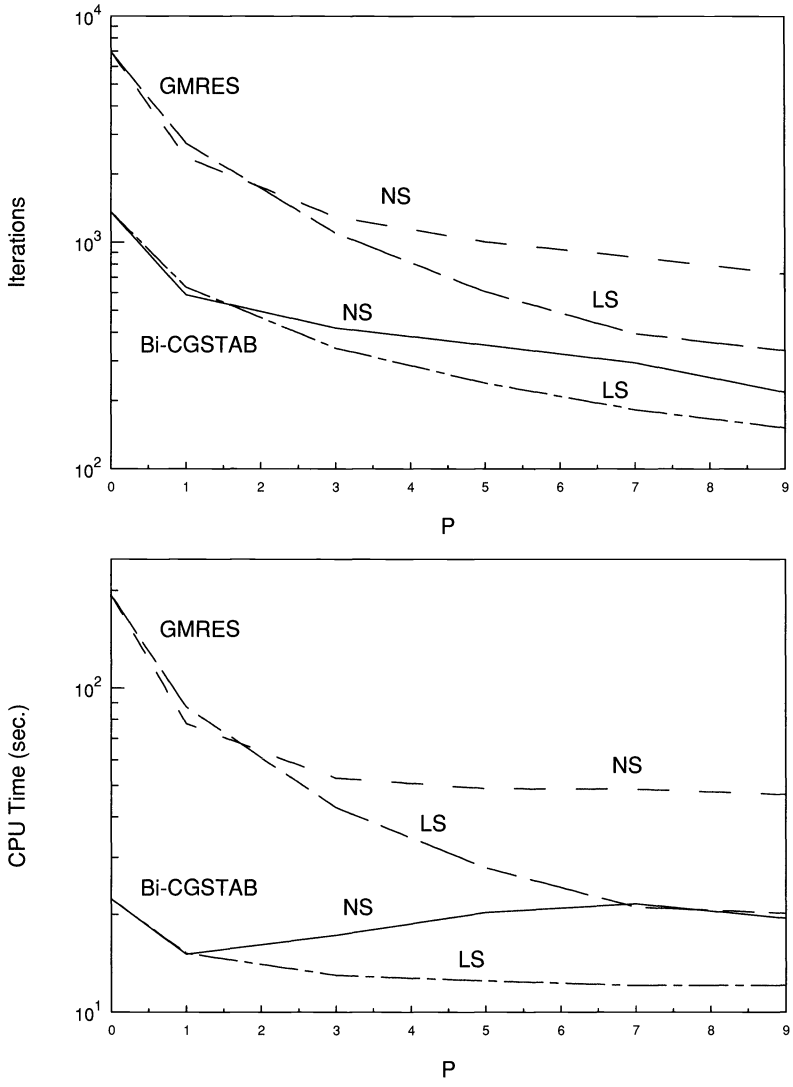

FIG. 6. *Convergence of* GMRES *and* Bi-CGSTAB *for Problem* 1 *on a* 1024 × 1024 *grid with* 1024 *processors varying the degree* (P) *of the polynomial preconditioner.*

$$S_p^* = \frac{pT_1}{T_p},$$

where T_p is the time required to complete one iteration of the problem with $p * n$ unknowns using p processors [11]. From Table 10 we see that extremely high scaled speedups are obtained for all of the solvers. The majority of the methods and preconditioners achieve speedups of

over 900 out of a possible 1024. Even the majority of the multilevel preconditioners that make heavy use of coarse grids (and so are somewhat less efficient on parallel machines) achieve speedups over 700. In fact, only the multilevel methods that use the the line relaxation have poor speedups. Consequently, the majority of the solvers/preconditioners sustain computation rates of over 1 gigaflop and nearly 2 gigaflops for the GMRES method. This compares quite favorably with the vendors maximum computation rating of about 2.5 gigaflops for double precision calculations.

5. Conclusions. We have considered the performance of a variety of preconditioners and Krylov subspace solvers on massively parallel machines. These methods are among the fastest algorithms on serial and vector computers. An implementation of the Krylov solvers and preconditioners was developed on a 1024 processor nCUBE 2. Using this implementation in conjunction with a selection of PDE problems, a number of performance tests were conducted. Based on these experiments, it is apparent that the Krylov solvers are in fact highly parallel. Each method yields scaled speedups over 900 (when used with a highly parallel preconditioner). With respect to numerical convergence, we have found that preconditioning is much more important with these nonsymmetric methods than with the classical CG algo-

rithm. Overall, it appears that multilevel preconditioners offer the largest payoff in terms of convergence rate. In this context, we have shown that algorithmic issues are still important on large-scale parallel machines and that Mflops do not necessarily tell the entire story. Unfortunately, multilevel schemes can be hard to program and often their exceptional performance is somewhat problem dependent.

Among local schemes, polynomial methods (in particular high-order least-squares polynomials) significantly accelerate the convergence of the Krylov solvers enabling fast solution times. These methods combine ease of implementation with the flexibility to alter the balance between local and global data flow requirements. For the most part, all the preconditioners discussed in this paper are highly parallel with the exception of the classical ILU and to some extent the line relaxation. For the line relaxation, it may be possible to improve performance with a better parallel implementation of the block parallel cyclic reduction or by alternative algorithms that perform a similar function but make better use of parallel processors. For the ILU schemes, it is possible to use domain decomposition techniques to maintain parallelism. In this context we feel that some combination of domain decomposition with globally coupled interface equations and LILU should be explored for large-scale MIMD machines.

Acknowledgment. We would like to thank S. R. Wheat and the SUNMOS team for assistance with determining experimental floating-point operation rates for the LILU and lineGS preconditioners.

MEMORY ASPECTS AND PERFORMANCE OF ITERATIVE SOLVERS*

CLAUDE POMMERELL† AND WOLFGANG FICHTNER‡

Abstract. In many scientific computing problems, the overall execution time is dominated by the time to solve very large linear systems. Quite often, the matrices are unsymmetric and ill conditioned, with an irregular sparsity structure reflecting the irregular refinement in the discretization grid. With increasing problem size and problem dimension, direct solvers cannot be used because of the huge memory requirements. The performance of preconditioned iterative solvers is largely dominated by memory-related aspects like size, bandwidth, and indirect addressing speed.

This article summarizes the experience of the authors on the relationship between memory aspects and performance in real applications in the domain of very large scale integration (VLSI) device simulation. The authors analyze storage requirements of direct and iterative solvers on a statistical data set, and demonstrate performance variations due to memory-related architectural features on a number of computers ranging from workstations to Cray, NEC, and Fujitsu supercomputers for typical and ill-conditioned linear systems, using different iterative methods and preconditioners.

The experiments are done using PILS, a package of iterative linear solvers. PILS implements a large number of iterative methods and preconditioners and allows them to be combined in a flexible way.

AMS subject classifications. 65Y20, 65F10

1. Introduction.

The solution of large systems of linear equations is one of the main operations inside many large-scale scientific applications. As problem sizes increase, the linear solver often dominates the total execution time. Sparsity of the system matrix must be exploited to achieve acceptable efficiency. Irregular sparsity patterns and ill-conditioned linear systems induce further complexity on the choice of methods and implementations.

There are two basic approaches used to solve large sparse linear systems. *Direct methods* use (explicitly or implicitly) a factorization of the matrix, where the factors are easily invertible (e.g., triangular matrices). *Iterative methods* construct a sequence of approximations that converges to the solution and stop when a given tolerance is achieved. In §4.1, we analyze the storage requirements of both approaches on a larger set of practical cases. We analyze their dependence on the dimensionality of the problem and point out the infeasibility of direct methods on very large problems. In the rest of this paper, we focus only on iterative solvers.

The performance of scientific codes is usually measured in Mflops (millions of floating-point operations per second). Our benchmarks in §4.2 show the Mflops performance of our preferred preconditioned iterative solver over a range of machines from workstations to supercomputers. Using a set of problems of different sizes, we explain why performance does not necessarily increase with problem size.

The use of Mflops may be reasonable for applications where a given algorithm is known to be the "best" and "fastest." It is questionable for solvers targeted towards ill-conditioned and irregular sparse matrices, as there is no single algorithm that is the fastest for all problems (even not for all problems among a restricted class, such as the one described in §2). Different algorithms use a different number of operations to achieve the same result. Also, the same number of flops requires a different number and different kinds of memory accesses, which

better suit one architecture or another. We illustrate these variations of the performance by using different iterative methods in §4.3 and different preconditioners in §4.4.

Periodically, we stumble over certain very ill-conditioned linear systems that standard preconditioned iterative solvers cannot solve. We have developed several parametrized sets of preconditioners to solve these difficult problems. In §4.5, we illustrate how the parameters of these robust solvers affect their speed and their storage requirements.

The experiments in §4 are preceded by an overview of the methods and our context. Section 2 summarizes the need for linear solvers in our application, semiconductor device simulation. Section 3 lists those features of the methods, preconditioners, and data structures that are essential for this study. It also introduces PILS, our software package used both as a test bed for studies like this and as a solver library for production runs.

2. Context. The present study is part of a large project to analyze and construct new VLSI semiconductor devices (diodes, transistors, memory cells, thyristors, sensors). Numerical semiconductor device simulation predicts the behavior of such structures by solving a set of three transient partial differential equations (PDEs), the so-called drift-diffusion equations [34], over a one-, two- or three-dimensional domain [4]. This system consists of Poisson's equation and two continuity equations for the two carriers in semiconductors, electrons and holes. The drift-diffusion equations relate the values of the electrostatic potential and the two carrier concentrations.

The discretization of these PDEs leads to a system of nonlinear equations that is then solved by damped Newton methods [3], [7] or block variants thereof. Each Newton iteration requires the solution of a system of linear equations. Several tens of linear systems typically must be solved in stationary simulations and several hundreds or even thousands in transient simulations.

Modern device simulators use irregularly refined finite-element grids, where the grid density in the simulated domain may vary over several orders of magnitude. The number of grid points varies between 1,000 and 20,000 for two-dimensional (2-D) simulations and between 15,000 and 100,000 for three-dimensional (3-D) simulations. The number of unknowns in the corresponding linear systems is up to three times as large.

The system of PDEs is known to be extremely nonlinear due to the coupling of the physical variables in these equations. The linear systems are unsymmetric and tend to be very ill conditioned. Because of their huge resource requirements, both in storage and computation time, device simulators must run on high-performance architectures. The linear solver time is dominating; it takes more than 95% of the total execution time [17]. The irregularity of the discretization grid leads to an irregular sparsity structure for the matrices. This makes the task of vectorizing and parallelizing the solver algorithms considerably more difficult than for regular (e.g., finite difference) discretizations.

For further details about device simulation, please consult [18].

3. PILS. PILS is a software package of iterative linear solvers designed to meet the requirements for solving large linear systems as they occur in applications like device simulation. PILS implements a large number of iterative methods, preconditioners, and other variants for iterative solvers, and runs on a large range of platforms from workstations to supercomputers. It concentrates on methods and preconditioners suited for very ill-conditioned unsymmetric systems and on the efficient exploitation of high-performance architectures.

In this section, we will only discuss those aspects of PILS and its algorithms that are relevant for the present study. More about PILS, its requirements, its features, its structure and implementation, and its applications can be found in [27]. The methods, preconditioners, and data structures are covered in detail in [25].

3.1. Iterative methods. The set of iterative methods implemented in PILS currently includes conjugate gradients (CG) [19] (for symmetric positive-definite systems only), conjugate gradients applied to the normal equations (CGNR) [19], (restarted) generalized conjugate residuals (GCR) [11], (truncated) Orthomin [35], (restarted) generalized minimal residuals (GMRES) [30], biconjugate gradients (BiCG) [12], conjugate gradients squared (CGS) [31], Bi-CGSTAB [32], and BiCGStab2 [16].

CG applied to symmetric and positive definite systems converges monotonically, has a constant and low storage overhead, uses the minimum number of matrix-vector products to reach a residual norm within a tolerance, and cannot break down in divisions by zero. The other methods can be used for unsymmetric systems as well, but at the price of losing one or more of these four properties. CGNR is usually much slower than the other methods. GCR(∞), Orthomin(∞), and GMRES(∞) need the minimum number of matrix-vector products to minimize the residual, but must store another vector at every iteration. In practice, the methods in this family are usually restarted (GCR(ℓ), GMRES(ℓ)) or truncated (Orthomin(ℓ)). Unfortunately, the limited storage versions usually require many more iterations. Breakdowns do occur sometimes in GCR and Orthomin, but not in GMRES (which is otherwise algebraically equivalent to GCR). BiCG has constant and low storage requirements, but has an irregular convergence behavior. If BiCG converges, CGS usually converges much faster, but its convergence behavior is also much more erratic. Bi-CGSTAB and BiCGStab2 are usually about as fast as CGS, but have a smoother (yet not monotonic) convergence behavior. The methods in the BiCG family can break down, but breakdowns are quite infrequent and can usually be fixed by restarting the method.

Table 1 lists the storage requirements and the types of operations involved.

TABLE 1

Storage overhead and (average) operation count per iteration for the different iterative methods. n is the problem size, k is the number of iterations needed for convergence, ℓ is the truncation or restarting parameter. Minor terms are ignored (assuming that $n \gg k^2 \gg \ell^2$).

Method	Storage overhead (extra values to store)	Operations per iteration			
		Matrix-vector products	Transposed matrix-vector products	Vector dot products	Linear operations on vectors
CG	$2n$	1	–	2	6
CGNR	$2n$	1	1	2	6
Orthomin(∞) / GCR(∞)	$(2k+1)\,n$	1	–	$\frac{1}{2}k+2.5$	$k+4.5$
GMRES(∞)	kn	1	–	$\frac{1}{2}k+1.5$	$k+3.5$
Orthomin(ℓ)	$(2\ell+1)\,n$	1	–	$\ell+2$	$2\ell+4$
GCR(ℓ)	$(2\ell+1)\,n$	1	–	$\frac{1}{2}\ell+2$	$\ell+4$
GMRES(ℓ)	ℓn	1	–	$\frac{1}{2}\ell+1$	$\ell+3$
BiCG	$4n$	1	1	2	10
CGS	$6n$	2	–	2	12
Bi-CGSTAB	$4n$	2	–	4	12
BiCGStab2	$7n$	2	–	4.5	18.5

3.2. Preconditioners. Preconditioning significantly improves the convergence speed of all the methods above. A *preconditioned* iterative method solves the linear system $[Q_1^{-1}AQ_2^{-1}][Q_2x] = [Q_1^{-1}b]$. The preconditioner $Q = Q_1Q_2$ is chosen such that iterative methods converge in substantially fewer iterations than on the original system $Ax = b$. Generally, a preconditioner is an approximation to the matrix that is more or less inexpensive to construct and to invert.

Most of the preconditioners in PILS can be viewed as incomplete LDU-factorizations. A complete factorization of the matrix A into the product of the unit lower triangular matrix L, the diagonal matrix D, and the unit upper triangular matrix U can be computed by

$$\forall i > j : l_{ij} = \frac{1}{d_{jj}} \left(a_{ij} - \sum_{k=1}^{i-1} l_{ik} d_{kk} u_{kj} \right), \tag{1}$$

$$\forall i < j : u_{ij} = \frac{1}{d_{ii}} \left(a_{ij} - \sum_{k=1}^{j-1} l_{ik} d_{kk} u_{kj} \right), \tag{2}$$

$$\forall i : d_{ii} = a_{ii} - \sum_{k=1}^{i-1} l_{ik} d_{kk} u_{ki}. \tag{3}$$

Incomplete factorizations are obtained by simplifying the factorization rules (1)–(3). Jacobi (or diagonal) preconditioning is the most radical simplification, approximating A by its diagonal only. Symmetric successive overrelaxation (SSOR) preconditioning ignores the summations in (1)–(3). D-ILU preconditioning ignores the summations in (1) and (2), but uses the complete summation for the diagonal in (3). ILU preconditioning [21], [11] uses all three formulae (1)–(3), but keeps the same sparsity structure as A; a zero in A imposes a zero in the same position of the ILU factors.[1] Table 2 summarizes the resource cost of these four preconditioners. The low cost in applying SSOR or D-ILU preconditioners results from a clever combination of the operations for a *preconditioned matrix-vector product*, known as the *Eisenstat trick* [10].

TABLE 2

Storage overhead and number of extra flops for the different no-fill incomplete factorization preconditioners. n is the problem size, m is the number of nonzeros in the original matrix. An unpreconditioned matrix-vector multiplication takes m multiplications and $(m - n)$ additions for a total of $(2m - n)$ flops.

Preconditioner	Storage overhead (extra values to store)	Computational overhead (flops)	
		Construction $Q :\approx A$ (once per linear system)	Application $w := Q^{-1}v$ (once or twice per iteration)
Jacobi	0	0	n
SSOR	0	0	$5n$
D-ILU	n	$\frac{3}{2}(m - n)$	$5n$
ILU	m	$O(m^2/n)$	$2m - n$

While the incomplete factorizations discussed above conserve the sparsity structure of the original matrix, other variants in PILS allow some limited fill of nonzero entries in the factors. ILU(k) uses a positional dropping criterion (based on the elimination tree, as suggested in [5]) to select fill entries; higher values of the integer parameter k allow for more fill. Another approximate factorization preconditioner in PILS uses numerical dropping with a drop tolerance τ and is referred to as ND(τ) [2], [13], [25], [27], [28], [37]; nonzero entries whose absolute value is smaller than the tolerance times the row or column maximum are dropped from the factorization. The overhead of these preconditioners depends, in a monotonic but nontrivial way, on their parameter.

[1] D-ILU is equivalent to ILU on sparsity structures resulting from tensor-product grids (or any other graph containing no triangles). Since many authors use only finite difference discretizations on such regular grids for their experiments, these two variants of no-fill incomplete LDU-factorizations are often confounded.

Nested iterative solvers form another class of preconditioners in PILS. Every iterative solver in PILS can be used to precondition another iterative method. This nesting can be taken to any level, and the innermost iterative method can again be preconditioned by an incomplete factorization. Nested iterative solvers using variants of GCR as the outer method and GMRES as the inner method have been introduced and analyzed under the name GMRESR by van der Vorst and Vuik [33]. Other variants for the inner method were investigated in [36].

We use incomplete factorizations mostly as a split preconditioner ($Q_1 = L$, $Q_2 = DU$) and nested solvers as a right preconditioner ($Q_1 = I$, $Q_2 = Q$).

3.3. Sparse matrix data structures. PILS applies a multicolor reordering (using a greedy coloring heuristic [1], [26]) to vectorize and parallelize the no-fill incomplete factorization preconditioners. A jagged diagonal sparse matrix structure [29] helps to vectorize sparse matrix-vector multiplication. To make transposed matrix-vector products (as needed in CGNR and BiCG) as efficient as regular matrix-vector products, the set of edges corresponding to each jagged diagonal forms a *matching* [23] in the graph representing the sparsity structure of the matrix. The data structure in PILS allows efficient and vectorizable preconditioned matrix-vector multiplication with the preconditioned matrix itself and its transpose. It stores the lower and the upper triangle of the matrix by color blocks, each block using jagged diagonals that form a *partitioning by matchings* of the corresponding edges of the associated graph.

Each iteration of the inner loops processing this data structure consists of one multiplication and one addition, together with five memory accesses. One of these memory accesses is indexed and requires gather/scatter operations on vector machines.

PILS uses different, specialized data structures for factorizations with parameter-controlled fill. Because of their higher complexity, operations on these data structures run essentially in sequential mode.

3.4. Application. PILS is fully integrated into several device simulators [6], [17], [18], [20], [22], and other applications, and has been used in many different problems over a period of more than two years. The options for PILS, usually controlled from the client application, can be modified externally even while the application is running. In case a given combination of a method and a preconditioner cannot solve a system within a given number of iterations, PILS can switch automatically to another (usually more resource intensive, but more stable) combination.

All the experiments presented in this paper were conducted using PILS and its monitoring options. The linear systems were extracted from real-life device simulations. They were selected to reflect the *typical* characteristics of linear systems in device simulation, including some very ill-conditioned cases.

4. Experiments. In §4.1, we analyze the effect that problem size and grid dimension have on the storage requirements of direct and iterative linear solvers. We then fix the solution approach (iterative solvers) and list, in §4.2, the Mflops rates of one particular preconditioned iterative method on a set of machines and on a representative set of linear systems. In §4.3, we select one typical linear system and analyze the speed and performance of several iterative methods applied to this problem (using the same preconditioner). We fix the iterative method in §4.4 and apply it with different preconditioners to that same typical system. In §4.5, we examine convergence speed and storage requirements of different preconditioners on a difficult, ill-conditioned linear system.

While §4.1 presents a statistical analysis on an impartially collected data set, the examples in §§4.2–4.5 were selected by hand as typical cases. Among the many thousands of linear systems we solved over the last years, we would be able to select examples for almost any

reasonable or unreasonable claim, such as the superiority of any given method over any other given method, or the particular quality of a machine. The reader must trust that our selection of examples truly reflects the *typical* behavior over the various applications in device simulation. An impartial statistical analysis on a significant data set would be too expensive, and large variances on the results would overshadow any of the observations that we point out in §§4.2–4.5.

Until now, our experience has been that the fastest linear solver for most problems in semiconductor device simulation is the Bi-CGSTAB method [32], split preconditioned with D-ILU [18], [27]. This method and preconditioner will therefore be used in those experiments where other things are varied.

4.1. Varying the approach. The alternatives to iterative solvers are sparse direct solvers. Direct solvers are often preferred over their iterative counterparts because of their reliability and predictability; they are numerically stable (at least if numerical pivoting is used) [8], and they take constant time and storage for a given sparsity structure (at least if numerical pivoting is not used). Solving for more than one right-hand side costs very little.

Most direct solvers are based on variants of Gaussian elimination. They construct a lower triangular matrix L and an upper triangular matrix U such that $LU = A$. The triangular factors L and U are also sparse, but usually more dense than the original matrix. Nonzeros in the factors appearing at zero positions of the original matrix are called *fill*. Reordering of the equations can reduce the amount of fill. The problem of computing the ordering that minimizes the fill is NP-complete. Heuristics like reverse Cuthill–McKee, nested dissection, or minimum degree and variants are used instead [14], [15]. Numerical stability, storage, efficiency, and parallelism are usually traded for one another [9].

The amount of fill increases superlinearly with the problem size and with the dimensionality of the problem. The fill for a matrix arising from a 3-D discretization is higher than for a matrix from a 2-D discretization with the same number of grid points. It is the combination of these two growth factors that makes the storage requirements of sparse direct solvers an issue when passing from 2-D to 3-D models.

Figure 1 compares the memory requirements for direct and iterative linear solvers. The fill was determined without actually performing the factorization on all the examples (no machine available to us has enough memory for the large 3-D cases), but an algorithm with minimal storage [5] was assumed, using nested dissection ordering [14] to reduce the fill. The analysis involved 224 nontrivial examples from device simulation,[2] using the matrices from the coupled Newton solution, and assuming 8-byte floating-point and 4-byte integer numbers.

In the double logarithmic plot of Fig. 1, the sample points for each of the assorted categories lie close to a line. We can thus state an empirical law of fill given by

$$s = \mu n^{\nu}, \tag{4}$$

where s is the amount of storage for a given number of unknowns n. Table 3 gives the values obtained from our empirical study.

The largest 2-D discretizations for semiconductor devices rarely exceed 10k grid points, and thus 30k unknowns for coupled linear systems (cf. §2). Direct solvers for such 2-D problems fit into 100 Mbytes of memory, which are usually available on departmental computers or in medium-size batch queues of supercomputers. On the other hand, iterative solvers for such 2-D problems fit into some 8 Mbytes available on any workstation. Direct solvers for

[2]Our data set used 172 2-D grids and 52 3-D grids for different kinds of semiconductor devices. In fact, these were all of the distinct nontrivial grids that were on disk at the Integrated Systems Laboratory of ETH on October 9, 1991. PILS was running inside the multidimensional device simulator SIMUL [20].

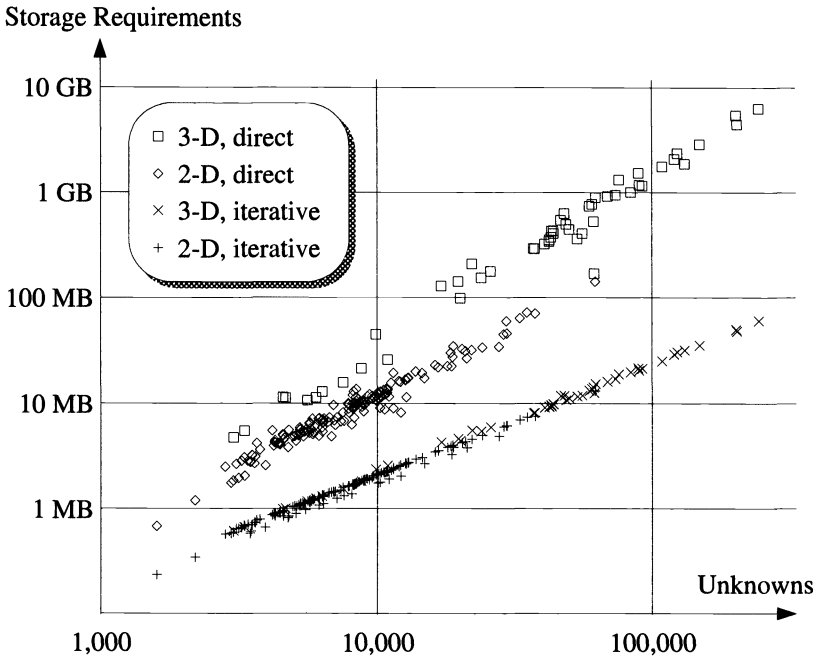

FIG. 1. *Sampled storage requirements for direct and iterative solvers.*

TABLE 3
Empirical values for the storage requirement formula (4).

Grid dimension	Type of solver	Factor μ [bytes/unknown]	Exponent ν
2-D	iterative	167	1.02
2-D	direct	63	1.32
3-D	iterative	156	1.04
3-D	direct	9	1.64

average size 3-D simulations can run only on very large computer memories, and no machine available today could accommodate truly large 3-D problems with several hundreds of thousands or even millions of grid points. Iterative solver storage requirements, even for 3-D problems, still increase linearly with problem size. At least for such large 3-D problems, there is no choice: direct methods are infeasible because of their storage requirements, and iterative solvers must be used.

The number of operations required to perform the factorization grows even faster than the storage requirements. Timing comparisons between the two choices show that for grid sizes above a certain crossover point, iterative methods are more efficient [18]. Such a comparison will always be biased, because it involves many parameters from the problem, the accuracy requirements, the implementation, and the platform, but the critical grid size is certainly much lower for 3-D than for 2-D.

4.2. Varying the machine. Table 4 reports the Mflops rates for one algorithm (split D-ILU preconditioned Bi-CGSTAB) when applied to the same set of problems on different machines. The differences in the performance clearly reflect the classes that these machines belong to: previous generation microprocessors, today's microprocessors, minisupercomputers, and supercomputers.

TABLE 4

Mflops rates for split D-ILU *preconditioned* Bi-CGSTAB *on different machines. Except for the Alliant, only one processor was used on each machine. Missing results indicate that the floating-point range, the virtual memory, or the maximum contiguously allocatable chunk of memory was too small on the machine at hand.*

Fujitsu VP2200	109.15	126.32		96.94	101.49

The problem size (i.e., the number of unknowns) increases from left to right in Table 4. The performance does not always improve with increasing problem size; rather, the opposite is more often the case. There are two reasons for this effect and both are related to memory access speed.

First of all, the average number of nonzeros per row differs in the five examples. The two problems on the left of Table 4 come from 2-D simulations, the other three come from 3-D simulations. Also, the first three problems involve one unknown per grid point, the two others involve three unknowns per point. More nonzeros per row lead to a higher percentage of indirect memory accesses (inside the sparse matrix operations), which are generally slower than the direct (and even sequential) accesses in the rest of the operations.

For problems with approximately the same number of nonzeros per row ("lddh" and "uvdih," "dr15c" and "mct70c"), a positive effect of problem size on performance can be observed for the six machines at the bottom of the table. On other machines, the performance still decreases, and this is because the cache hit ratio decreases.

Note also the difference in performance between the two variants of the Cray Y-MP architecture. The two machines have exactly the same processor and clock frequency, and differ only in their memory performance: the Y-MP 4D has 128 banks of fast 17ns ECL memory, while the more economical Y-MP M92 uses 64 banks of slower 60ns DRAM.

When iterative method and preconditioner are fixed, the Mflops rate does give an appreciation of the relative speed of different machines. However, problem size and matrix density have a significant effect on performance. This effect is not explained by the sole computation speed (or peak performance), but by various architectural features like memory bandwidth and cache size.

4.3. Varying the iterative method. Table 5 shows the performance of different iterative methods when used with the same preconditioner (split D-ILU), executed on the same machine (one processor of a Cray Y-MP 4D), and applied to the same problem (a typical, moderately ill-conditioned system with 46k unknowns taken from the 3-D simulation of a trench DRAM cell inside the simulator SECOND [17], [18]).

TABLE 5
Performance of different split D-ILU *preconditioned methods on one processor of a Cray* Y-MP 4D.

Method	Performance [Mflops]	Convergence [iterations]	Time [seconds]
CGNR	98	>400	–
Orthomin(∞) } GCR(∞) }	194	89	6.89
GCR(∞)	123	361	12.16
GMRES(∞)	188	89	5.15
Orthomin(10)	148	>400	–
GMRES(10)	116	388	12.24
BiCG	100	140	7.18
CGS	100	78	4.09
Bi-CGSTAB	103	65	3.43
BiCGStab2	110	65	3.53

The methods from the GMRES-family (including Orthomin, GCR, GMRES) deliver much higher Mflops rates than the biorthogonalization methods (BiCG, CGS, Bi-CGSTAB, BiCGStab2). This difference can be explained with the following reflection. Knowing that there are on average 21 nonzeros in each row of the particular matrix used for Table 5, and looking at the operation breakdown in Table 1, we see that more than half of the number of flops in the GMRES-like methods are spent in well-vectorized linear operations (vector additions, scaling, and inner products), and the rest are spent in operations involving indirect memory addressing (sparse matrix-vector products and preconditioning). The biorthogonalization methods, on the other hand, spend only around 20% of their flops in linear operations, and four times as many of their flops require gather/scatter memory access.

The important column in Table 5, however, is the last one, showing the time in seconds required to solve the system. Truncated or restarted variants of GMRES generally require more iterations than BCG variants on device simulation problems [18], [24]. Note that on a similar machine without hardware gather/scatter support, GMRES(∞) would certainly converge in less time than Bi-CGSTAB, provided that enough memory is available to store the 89 direction vectors.

4.4. Varying the preconditioner. Table 6 shows variations of the performance with different preconditioners for the same combination of an iterative method, a problem, and a machine.

At first glance, the goal of a preconditioner is to reduce the number of iterations that an iterative method needs to solve a linear system to a given accuracy. In practice, however, the goal is to minimize the time to find a solution. Constructing a preconditioner takes time, and applying this preconditioner in an iterative method slows down each single iteration. The choice of one particular preconditioner is a trade-off between this cost of individual operations and the effect of reducing the number of iterations.

Our experience over several years now has been that D-ILU preconditioning achieves the best trade-off for most cases. The linear system selected for Table 6 represents well this "typical" behavior.

TABLE 6

Performance of Bi-CGSTAB *with different preconditioners (in split position), on a Convex* C-220 *and on a Cray* Y-MP 4D *(one processor used). Note that for technical reasons, the Mflops rates are measured only in the iteration phase, and not in the preconditioner setup.*

Preconditioner	Performance [Mflops] C-220	Y-MP 4D	Number of iterations	Total time [seconds] C-220	Y-MP 4D
none	6.66	100	>400	–	–

TABLE 7

Performance of Bi-CGSTAB *split preconditioned with a numerical dropping factorization on different machines.*

Machine	Total solution time [seconds]	Time in factorization [percentage]
Sun-4/490	222	23%
Sun Sparc 10	108	23%
IBM RS/6000	402	16%
SGI Mips R3000	197	22%
SGI Mips R4000	91	26%
DEC Alpha	69	26%
HP 9000	55	21%
Convex C-220	163	45%
Convex C-3820	70	45%
Cray Y-MP M92	54	57%
Cray Y-MP 4D	39	59%
Fujitsu VP2200	31	48%

More effective preconditioners are usually more costly in both time and memory consumption and offer less room for vectorization and parallelization. Accordingly, the relative performance of different preconditioners varies from one machine to another. Since an approximate factorization with numerical dropping is sometimes needed to precondition very difficult linear systems, we have listed its performance on a selection of machines in Table 7. The factorization phase is almost exclusively scalar code with finely grained data-dependent control flow, and the iteration phase is partly vectorized.

Note that the picture is slightly distorted by the fact that, because of our previous experiences [18], we tuned the data structures in PILS to SSOR, D-ILU, and ILU preconditioners. Slightly higher performance would be possible with no preconditioning or with Jacobi preconditioning. Some fine-grained parallelism would be conceivable in the incomplete factorizations with fill, but has not been investigated yet.

4.5. Varying the storage consumption. Occasionally, linear systems arise for which most preconditioners do not achieve convergence in any iterative method. Within a device simulation run involving hundreds of linear solves, a single such ill-conditioned linear system is sufficient to preclude the entire simulation. We have devised robust preconditioners for this purpose. To prevent excessive loss of efficiency, our software uses fast preconditioners for all the other systems and switches automatically to a robust preconditioner when needed.

We will now analyze such a very ill-conditioned linear system. Standard preconditioners and methods can solve it only after a very high number of iterations or not at all. Our system

occurs in the solution of the hole continuity equation in the simulation of a UV diode on a strongly refined 2-D grid with more than 20k points.

Such a resilient case can be solved with an approximate factorization preconditioner using numerical dropping. The lower the drop tolerance τ, the more fill entries are allowed in the approximate factors and the fewer iterations are needed for convergence. On the other hand, more fill in the preconditioner increases the CPU time *per iteration*. Therefore, the plot of the total time to solve the system as a function of the storage requirements for ND(τ) (dotted curves in Figs. 2 and 3) is convex.

Similarly, certain nested iterative solvers can solve this problem in a reasonable amount of time. The higher the maximum number of inner iterations (the numbers inside the circles in Figs. 2 and 3) per outer iteration, the fewer outer iterations are needed. We used split D-ILU preconditioned Bi-CGSTAB as inner method and GCR(∞) as outer method for Figs. 2 and 3. GCR requires the storage of two more vectors for each iteration, so that the number of outer iterations dictates the storage requirements of the entire solver.

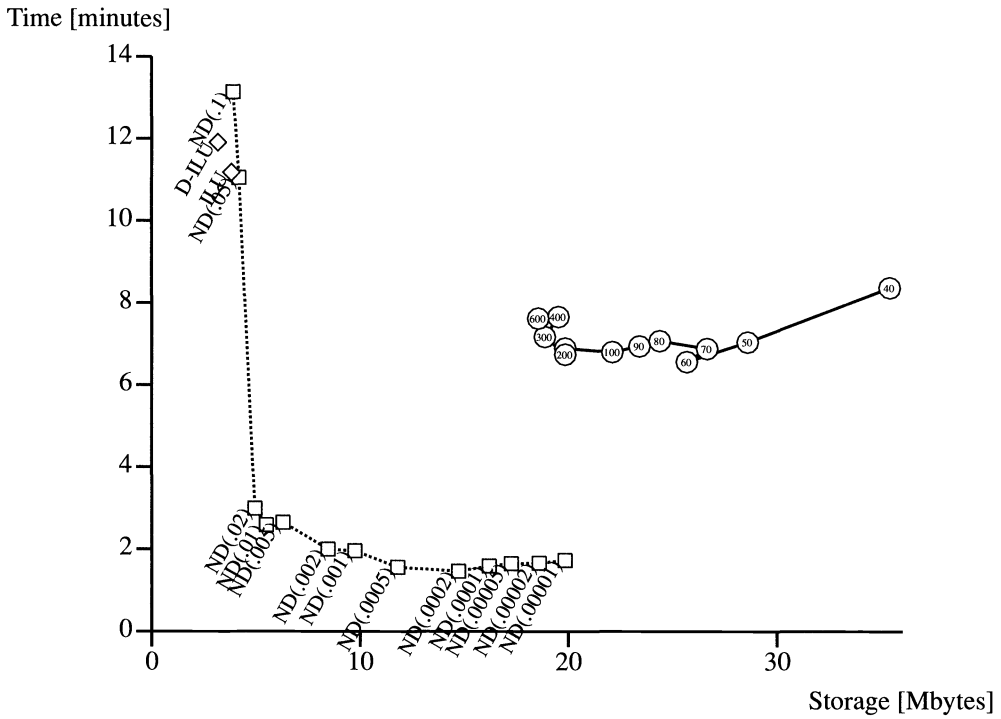

FIG. 2. *Storage size and solution time for an ill-conditioned linear system on a Convex* C-220 *(one processor). The square marks refer to different preconditioners used with* Bi-CGSTAB, *the dotted line following the marks of numerical dropping preconditioning with different drop tolerances. The solid line with the round marks refers to a nested iterative solver, with* GCR(∞) *as the outer method and split* D-ILU *preconditioned* Bi-CGSTAB *as the inner method.*

The experiments for Fig. 2 were done on a Convex C-220 and the experiments for Fig. 3 on a Cray Y-MP 4D (one processor). The set of experiments was exactly the same. The relative locations of the (dotted) curve for numerical dropping preconditioning and (solid) curve for nested iterative solvers are different for two reasons:

1. The ND(τ) preconditioner runs mainly in scalar mode. The performance ratio between vector and scalar code is much higher on the Cray than on the Convex, so that the ND(τ) preconditioned solvers are not as much faster than the others on the Cray.

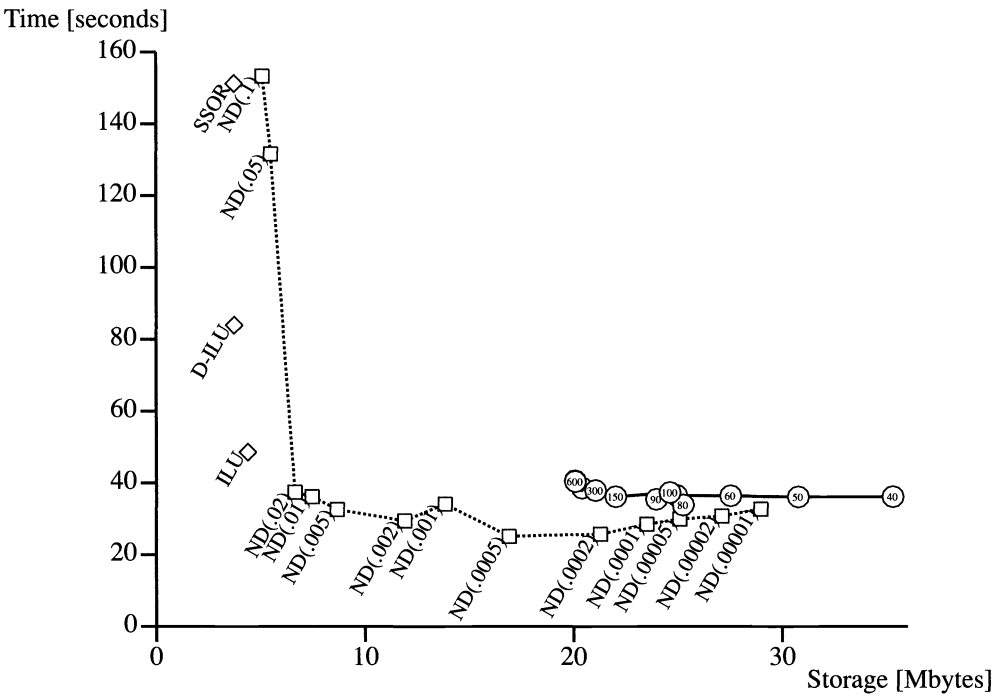

FIG. 3. *Storage size and solution time for an ill-conditioned linear system on a Cray* Y-MP 4D.

2. ND(τ) uses a considerable amount of integer storage. One integer takes 8 bytes on a Cray, but only 4 bytes on a Convex. Therefore, the preconditioner requires almost twice as much memory on the Cray, even if the number of fill entries is the same.

Also, the shape of the curves is not exactly the same. This is due to the differences in the floating-point formats on the two machines that lead to different rounding effects and sometimes ultimately to different iteration numbers.

5. Conclusions. The usefulness and the performance of preconditioned iterative solvers for numerically difficult large-scale applications with irregular structure is, to a great extent, governed by storage-related aspects.

The size of the memory requirements for direct sparse solvers limits their range of application for today's problem sizes and storage capacities. These requirements do not only increase superlinearly with problem size; the exponent of the leading term also increases with the dimensionality of the problem. Iterative solvers are much less restricted by storage limitations.

Mflops rates are of little help in evaluating different iterative methods. The fastest algorithms in terms of computation time do not always correspond to the methods with the highest performance numbers. Mflops do give acceptable figures with which to compare an iterative solver's performance on different machines, as long as the problem and the solution method are held constant.

The performance of iterative solvers does not necessarily increase with problem size. A growth in the problem complexity (dimension of the domain, number of PDEs, irregularity) leads to higher demands on the memory access. Memory aspects (latency, bandwidth, size), rather than pure computation speed, largely dominate the performance of iterative solvers on today's architectures.

Approximate factorizations with numerical dropping and nested iterative solvers are new preconditioners that are able to solve even very ill-conditioned linear systems. In essence, they trade memory for convergence speed. The solution time is always some convex function of the memory requirements, but the exact relations and the optimum value depend strongly on the characteristics of the machine.

Acknowledgments. The initial version of this article was submitted while the first author was still with the Integrated Systems Laboratory of ETH Zürich. The authors would like to express their gratitude to Henk van der Vorst and to Martin Gutknecht for their advice and cooperation concerning their latest iterative methods; to Marco Fillo and to Roland Rühl for their constructive proofreading; to Arno Liegmann for his generous help with the Cray benchmarks in Zürich and at Cray Research Inc. in Eagan MI; to Gernot Heiser and Frank Crawford for porting and benchmarking on the Fujitsu VP-2200 at Australian Supercomputer Technology in Sydney; to the computer centers of ETH in Zürich, EPF in Lausanne; and to CSCS in Manno for providing continued access to their Cray and NEC supercomputers; and especially to Cray Research for supporting our work over several years.

A PARALLEL VERSION OF A MULTIGRID ALGORITHM FOR ISOTROPIC TRANSPORT EQUATIONS*

T. MANTEUFFEL†, S. MCCORMICK†, J. MOREL‡, S. OLIVEIRA§, AND G. YANG†

Abstract. The focus of this paper is on a parallel algorithm for solving the transport equations in a slab geometry using multigrid. The spatial discretization scheme used is a finite element method called the modified linear discontinuous (MLD) scheme. The MLD scheme represents a lumped version of the standard linear discontinuous (LD) scheme. The parallel algorithm was implemented on the Connection Machine 2 (CM2). Convergence rates and timings for this algorithm on the CM2 and Cray-YMP are shown.

Key words. multigrid, parallel algorithms, transport equations

1. Introduction.

The description of the neutron transport problem is given in previous papers [1]–[3]. For steady state problems within the same energy group for the isotropic case (by isotropic we mean that the probability of scattering for the particles is the same for all directions), the transport equation in a slab geometry of slab width b becomes

$$\mu \frac{\partial \psi}{\partial x} + \sigma_t \psi = \frac{1}{2}\sigma_s \int_{-1}^{1} \psi(x, \mu') d\mu' + q(x, u), \tag{1.1}$$

for $x \in$ (0,b) and $\mu \in [-1,1]$. Here, $\psi(x, \mu)$ represents the flux of particles at position x traveling at an angle $\theta = \arccos(\mu)$ from the x-axis; $\sigma_t\, dx$ represents the expected number of interactions (absorptive or scattering) that a particle will have in traveling a distance dx; $\sigma_s\, dx$ represents the expected number of scattering interactions; $\sigma_a = \sigma_t - \sigma_s$ represents the expected number of absorptive interactions; and $q(x, \mu)$ represents the particle source. The boundary conditions prescribing particles entering the slab are

$$\psi(0, \mu) = g_0(\mu), \qquad \psi(b, -\mu) = g_1(\mu), \qquad \mu \in (0, 1). \tag{1.2}$$

This problem is difficult for conventional methods to solve in two cases of physical interest:

1. $\gamma = \frac{\sigma_s}{\sigma_t} = 1$ (pure scattering, no absorption);
2. $\frac{1}{\sigma_t} \ll$ b (optically dense).

In fact, as $\sigma_t \to \infty$ and $\gamma \to 1$, the problem becomes singularly perturbed.

Standard discrete approximations to (1.1) and (1.2) will have operators with condition numbers on the order of at least σ_t^2, regardless of the meshsize [1]. This phenomenon presents problems for numerical solution techniques in general and multigrid in particular. In this paper, the discretization used in the spatial dimension is a special finite element method called the modified linear discontinuous (MLD) scheme (described in the next section). To solve the linear system of equations, we use a suitable relaxation process, called two-cell μ-line relaxation, within a multigrid algorithm. The serial version of this algorithm was described

in [3] and the convergence properties were analyzed. It was shown that for $\gamma = 1$ (pure scattering), which is the case we examine in this paper, the algorithm yields a convergence factor on the order of $O((\frac{1}{\sigma_t h})^2)$ when $\sigma_t h \gg 1$ and $O((\sigma_t h)^3)$ when $\sigma_t h \ll 1$. For the two-angle case, it behaves like an exact solver. These convergence rates were proved for special cases in [3] and are substantiated by Fourier analysis in [12]. The Fourier analysis for multigrid based on red-black μ-line relaxation (with numerical results for both Jacobi and red-black Gauss–Seidel relaxation) is shown in [12]. The results show a close agreement between the Fourier analysis and the computational results presented here. The serial algorithm for the case in which $\gamma < 1$ is examined in [4]. The multigrid algorithms were compared to a version of the diffusion synthetic acceleration (DSA) method in [3] and [4]. It was shown to be faster than the DSA in all regimes.

Multigrid algorithms for the transport equations have been examined in [8]–[11]. The algorithm here takes advantage of the rank-1 form of the isotropic scattering operator in the implementation of the two-cell μ-line relaxation (see §3). In this form the two-cell μ-line relaxation is efficient, effective, and parallel. Together with efficient interpolation and restriction operators, this algorithm yields the rates mentioned above (for complete details see [3]). We also mention that a parallel implementation of the DSA algorithm was examined in [13].

In this paper we describe a parallel version of the algorithm. The main benefit of the single instruction multiple data (SIMD) architecture of the CM2 is attained at the relaxation step of the multigrid algorithm, where we take advantage of the structure of the matrix, matching the nonzero entries of very sparse matrices with the relevant processors.

An outline of the remainder of this paper is as follows. In §2 we describe the discretization scheme used. In §3 we show how to accomplish the inversion of the relaxation matrix to take advantage of the SIMD architecture on the CM2. In §4 we describe the multigrid scheme, the interpolation, and the restriction operators used. In §5 we discuss the storage and data structure. In §6 we develop the algorithm for the parallel relaxation and a few implementation details. In §7 we consider a few implementation details of our CM2 multigrid code. In §8 we report on convergence rates and compare these results with the Fourier analysis prediction. In §9 we show the timings obtained with our CM2 parallel codes and compare them with a sequential version of our algorithm on a Cray Y-MP. Finally, in §10 we make a few conclusions.

2. Modified linear discontinuous scheme. The angular discretization is accomplished by expanding the angular dependence in Legendre polynomials and is known as the S_N approximation when the first N Legendre polynomials are used. This results in a semidiscrete set of equations that resemble collocation at N Gauss quadrature points, μ_j, $j = 1, \ldots, N$, with weights w_j, $j = 1, \ldots, N$. Since the quadrature points and weights are symmetric about zero, we reformulate the problem in terms of the positive values, μ_j, $j = 1, \ldots, n$, where $n = \frac{N}{2}$. We define $\psi_j^+(x) = \psi(x, \mu_j)$ and $\psi_j^-(x) = \psi(x, -\mu_j)$ for $j = 1, \ldots, n$. The spatial discretization is accomplished by the MLD scheme, which uses elements that are linear across each cell and discontinuous in the upwind direction. In our grid representation, the variable $\psi_{ij}^{+(-)}$ denotes the flux of particles at position x_i in the direction μ_j ($-\mu_j$). Assuming γ=1, the nodal equations are

$$\frac{\mu_j}{\sigma_t}\frac{\psi^+_{i+\frac{1}{2},j} - \psi^+_{i-\frac{1}{2},j}}{h_i} + \psi^+_{i,j} = \sum_{k=1}^{n} \omega_k(\psi^+_{i,k} + \psi^-_{i,k}) + q^+_{i,j}, \tag{2.1}$$

$$2\frac{\mu_j}{\sigma_t}\frac{\psi^+_{i+\frac{1}{2},j} - \psi^+_{i,j}}{h_i} + \psi^+_{i+\frac{1}{2},j} = \sum_{k=1}^{n} \omega_k\left(\psi^+_{i+\frac{1}{2},k} + 2\psi^-_{i,k} - \psi^-_{i-\frac{1}{2},k}\right) + q^+_{i,j}, \tag{2.2}$$

$$\frac{\mu_j}{\sigma_t}\frac{\psi^-_{i-\frac{1}{2},j}-\psi^-_{i+\frac{1}{2},j}}{h_i}+\psi^-_{i,j}=\sum_{k=1}^{n}\omega_k(\psi^+_{i,k}+\psi^-_{i,k})+q^-_{i,j}, \tag{2.3}$$

and

$$2\frac{\mu_j}{\sigma_t}\frac{\psi^-_{i-\frac{1}{2},j}-\psi^-_{i,j}}{h_i}+\psi^-_{i-\frac{1}{2},j}=\sum_{k=1}^{n}\omega_k\left(\psi^-_{i-\frac{1}{2},k}+2\psi^+_{i,k}-\psi^+_{i+\frac{1}{2},k}\right)+q^-_{i,j}, \tag{2.4}$$

$j=1,\ldots,n$, $i=1,\ldots,m$, with boundary conditions

$$\psi^+_{\frac{1}{2},j}=g^+_{0,j},\quad \psi^-_{m+\frac{1}{2},j}=g^-_{1,j}, \tag{2.5}$$

$j=1,\ldots,n$.

In our model, $x_{i+1/2}$ and $x_{i-1/2}$ are cell edges, $x_i=\frac{1}{2}(x_{i+1/2}+x_{i-1/2})$ is the cell center, and $h_i=x_{i+1/2}-x_{i-1/2}$ is the cell width, $1\le i\le m$. Equations (2.1) and (2.3) are called balance equations and (2.2) and (2.4) are called edge equations. In block matrix form, (2.1)–(2.5) can be written, respectively, as

$$B_i\left(\underline{\psi}^+_{i+\frac{1}{2}}-\underline{\psi}^+_{i-\frac{1}{2}}\right)+\underline{\psi}^+_i=R(\underline{\psi}^+_i+\underline{\psi}^-_i)+\underline{q}^+_i, \tag{2.6}$$

$$2B_i\left(\underline{\psi}^+_{i+\frac{1}{2}}-\underline{\psi}^+_i\right)+\underline{\psi}^+_{i+\frac{1}{2}}=R\left(\underline{\psi}^+_{i+\frac{1}{2}}+2\underline{\psi}^-_i-\underline{\psi}^-_{i-\frac{1}{2}}\right)+\underline{q}^+_{i+\frac{1}{2}}, \tag{2.7}$$

$$B_i\left(\underline{\psi}^-_{i-\frac{1}{2}}-\underline{\psi}^-_{i+\frac{1}{2}}\right)+\underline{\psi}^-_i=R(\underline{\psi}^+_i+\underline{\psi}^-_i)+\underline{q}^-_i, \tag{2.8}$$

$$2B_i\left(\underline{\psi}^-_{i-\frac{1}{2}}-\underline{\psi}^-_i\right)+\underline{\psi}^-_{i-\frac{1}{2}}=R\left(\underline{\psi}^-_{i-\frac{1}{2}}+2\underline{\psi}^+_i-\underline{\psi}^+_{i+\frac{1}{2}}\right)+\underline{q}^-_{i-\frac{1}{2}}, \tag{2.9}$$

$$\underline{\psi}^+_{\frac{1}{2}}=\underline{g}^+_0,\ \underline{\psi}^-_{m+\frac{1}{2}}=\underline{g}^-_1, \tag{2.10}$$

$i=1,\ldots,m$. Here,

$$B_i=\begin{bmatrix}\frac{\mu_1}{\sigma_t h_i} & \cdots & 0\\ \vdots & \ddots & \vdots\\ 0 & \cdots & \frac{\mu_n}{\sigma_t h_i}\end{bmatrix}\text{ and }R=\begin{bmatrix}1\\ \vdots\\ 1\end{bmatrix}\begin{bmatrix}\omega_1 & \cdots & \omega_n\end{bmatrix}, \tag{2.11}$$

where $\mu_1,\mu_2,\ldots,\mu_n$ are the positive Gauss quadrature points, $w_1,w_2,\ldots,w_n$ are the Gauss quadrature weights, and $\underline{\psi}^{+(-)}_i$ is an n-vector: $\underline{\psi}^{+(-)}_i=(\psi^{+(-)}_{i1},\ldots,\psi^{+(-)}_{in})^T$.

In the computational grid, the inflow for positive angles is on the left of each cell and for the negative angles it is on the right. For a μ-line relaxation, the inflows of each cell are assumed to be known. This is the same as using the values of these variables from the previous iteration. Figure 1 shows the computational domain with $2m+1$ spatial points and n angles.

Consider cell i. In μ-line relaxation cell centers, $\underline{\psi}^+_i$ and $\underline{\psi}^-_i$, together with the outflow variables, $\underline{\psi}^-_{i-1/2}$ and $\underline{\psi}^+_{i+1/2}$, will be updated using the following matrix equation:

$$\begin{bmatrix} I+2B_i-R & -2R & -2B_i & R\\ 0 & I-R & -R & B_i\\ B_i & -R & I-R & 0\\ R & -2B_i & -2R & I+2B_i-R\end{bmatrix}\begin{bmatrix}\underline{\psi}^-_{i-\frac{1}{2}}\\ \underline{\psi}^+_i\\ \underline{\psi}^-_i\\ \underline{\psi}^+_{i+\frac{1}{2}}\end{bmatrix}=\begin{bmatrix}0\\ B_i\underline{\psi}^+_{i-\frac{1}{2}}\\ B_i\underline{\psi}^-_{i+\frac{1}{2}}\\ 0\end{bmatrix}+\begin{bmatrix}\underline{q}^-_{i-\frac{1}{2}}\\ \underline{q}^+_i\\ \underline{q}^-_i\\ \underline{q}^+_{i+\frac{1}{2}}\end{bmatrix}. \tag{2.12}$$

Solving this matrix equation corresponds to performing a μ-line relaxation. In our implementations we perform two-cell relaxations for the whole domain. In this kind of relaxation we consider pair of cells coupled together. This relaxation yields an error that is linear, independent of angle, and continuous across two cells up to $O(\frac{1}{\sigma_t h})$ accuracy when $\sigma_t h \gg 1$ [3]. Instead of updating four variables with a relaxation scheme, we update eight variables. For example, in Fig. 1, variables $\underline{\psi}^-_{i-1/2}$, $\underline{\psi}^-_i$, $\underline{\psi}^+_i$, $\underline{\psi}^-_{i+1/2}$, $\underline{\psi}^+_{i+1/2}$, $\underline{\psi}^-_{i+1}$, $\underline{\psi}^+_{i+1}$, and $\underline{\psi}^+_{i+3/2}$, will be updated. Notice that the inflow variables $\underline{\psi}^+_{i-1/2}$ and $\underline{\psi}^-_{i+3/2}$ will be used from the previous iteration.

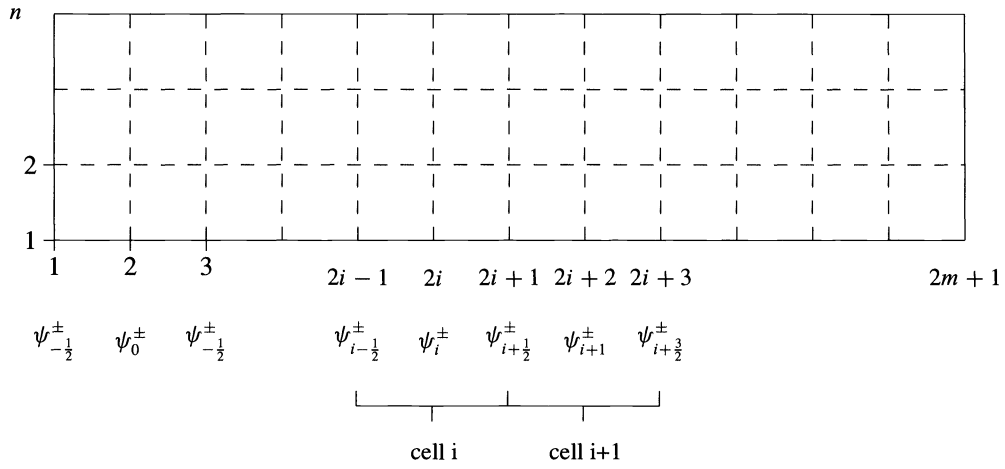

FIG. 1. *Computational grid.*

The two-cell μ-line relaxation involves inversion of the $8n \times 8n$ matrix

(2.13)
$$\begin{bmatrix}
I+2B_i-R & -2R & -2B_i & R & 0 & 0 & 0 & 0 \\
0 & I-R & -R & B_i & 0 & 0 & 0 & 0 \\
B_i & -R & I-R & 0 & -B_i & 0 & 0 & 0 \\
R & -2B_i & -2R & I+2B_i-R & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & I+2B_{i+1}-R & -2R & -2B_{i+1} & R \\
0 & 0 & 0 & -B_{i+1} & 0 & I-R & -R & B_{i+1} \\
0 & 0 & 0 & 0 & B_{i+1} & -R & I-R & 0 \\
0 & 0 & 0 & 0 & R & -2B_{i+1} & -2R & I+2B_{i+1}-R
\end{bmatrix}.$$

The order of variables for this matrix are

$$\underline{\psi} = \left(\underline{\psi}^-_{i-\frac{1}{2}}, \underline{\psi}^+_i, \underline{\psi}^-_i, \underline{\psi}^+_{i+\frac{1}{2}}, \underline{\psi}^-_{i+\frac{1}{2}}, \underline{\psi}^+_{i+1}, \underline{\psi}^-_{i+1}, \underline{\psi}^+_{i+\frac{3}{2}}\right)^T. \tag{2.14}$$

The right-hand side for the two-cell μ-line relaxation is given by

$$\left(0, B_i\underline{\psi}^+_{i-\frac{1}{2}}, 0, 0, 0, 0, B_{i+1}\underline{\psi}^-_{i+\frac{3}{2}}, 0\right)^T. \tag{2.15}$$

In our implementations we developed a multigrid scheme that uses either a block Jacobi relaxation or a block red-black Gauss–Seidel relaxation in parallel. For the Jacobi relaxation, all of the two-cell relaxations will be performed simultaneously for the whole domain. For red-black relaxation, we update half of the total number of cell-pairs during the first (red) stage of the algorithm and the other half during second (black) stage of the algorithm, each time skipping neighboring cell-pairs. To illustrate, Fig. 2 shows four cells. The even numbers represent the cell centers, the odd numbers represent the cell edges. For simplicity, we omitted the vertical lines (passing through each spatial grid point) that contain the Gauss quadrature points (angles). For a Jacobi type of relaxation process, variables at x points 5–9 will be updated at the same time as points 1–5. Each pair of cells will use the relaxation matrix just described. On a parallel machine like the CM2, red-black relaxation takes approximately twice as much CPU time as a Jacobi relaxation. This is partially offset by a better convergence rate (refer to the Fourier analysis in [12] and numerical results in §8).

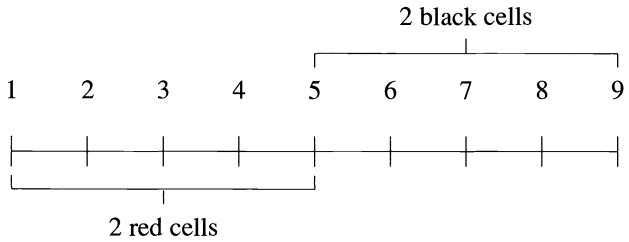

FIG. 2. *Red-black relaxation for four cells.*

3. Two-cell inversion. The inversion of the two-cell relaxation matrix can be done in a very suitable way for SIMD computers like the CM2. First, notice that the matrix can be written as the difference of an easily inverted matrix, which we call A, and a rank-four matrix, which we write as VW^T. The matrix A has a special structure that allows its inverse to be calculated basically in place. It is given by

(3.1)

$$A = \begin{bmatrix}
I+2B_i & 0 & -2B_i & 0 & & & & \\
0 & I & 0 & B_i & & & & \\
B_i & 0 & I & 0 & -B_i & & & \\
0 & -2B_i & 0 & I+2B_i & & & & \\
 & & & & I+2B_{i+1} & 0 & -2B_{i+1} & 0 \\
 & & & -B_{i+1} & 0 & I & 0 & B_{i+1} \\
 & & & & B_{i+1} & 0 & I & 0 \\
 & & & & 0 & -2B_{i+1} & 0 & I+2B_{i+1}
\end{bmatrix}_{(8n\times 8n)}$$

This is a block matrix with $n \times n$ blocks. Each nonzero block is diagonal. The rank-four matrix VW^T is defined by

$$V = \begin{bmatrix} \underline{2} & \underline{0} & \underline{0} & \underline{0} \\ \underline{1} & \underline{1} & \underline{0} & \underline{0} \\ \underline{1} & \underline{1} & \underline{0} & \underline{0} \\ \underline{0} & \underline{2} & \underline{0} & \underline{0} \\ \underline{0} & \underline{0} & \underline{0} & \underline{2} \\ \underline{0} & \underline{0} & \underline{1} & \underline{1} \\ \underline{0} & \underline{0} & \underline{1} & \underline{1} \\ \underline{0} & \underline{0} & \underline{2} & \underline{0} \end{bmatrix}_{(8n\times 4)} \tag{3.2}$$

and

$$W^T = \begin{bmatrix} -\frac{1}{2}\underline{w}^T & \underline{w}^T & 0 & \frac{1}{2}\underline{w}^T & 0 & 0 & 0 & 0 \\ \frac{1}{2}\underline{w}^T & 0 & \underline{w}^T & -\frac{1}{2}\underline{w}^T & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -\frac{1}{2}\underline{w}^T & \underline{w}^T & 0 & \frac{1}{2}\underline{w}^T \\ 0 & 0 & 0 & 0 & \frac{1}{2}\underline{w}^T & 0 & \underline{w}^T & -\frac{1}{2}\underline{w}^T \end{bmatrix}_{(4\times 8n)}, \tag{3.3}$$

where $\underline{1} = (1, 1, \ldots, 1)^T, \underline{0} = (0, 0, \ldots, 0)^T, \underline{2} = (2, 2, \ldots, 2)^T$, and $\underline{w}^T = (\omega_1, \omega_2, \ldots, \omega_n)$.

We can use the Sherman–Morrison formula to calculate the inverse of the two-cell μ-line relaxation matrix $M = A - VW^T$:

$$M^{-1} = A^{-1} + A^{-1}VE^{-1}W^TA^{-1}, \tag{3.4}$$

where $E = I - W^TA^{-1}V$. If $\underline{y}$ is an n-vector, we have $M^{-1}\underline{y} = (I + A^{-1}VE^{-1}W^T)A^{-1}\underline{y}$.

The connectivity of A is two interleaved 4×4 block matrices. Thus, inverting A amounts to solving $2n$ tridiagonal matrices, each of size 4×4, which can be done in parallel. Since all matrices are diagonal, and thus commute, we make use of the notation $\frac{M_1}{M_2} = M_1M_2^{-1}$. We have

$$A^{-1} = \begin{bmatrix} \frac{I}{D_i} & 0 & \frac{2B_i}{D_i} & 0 & \frac{2B_i^2}{D_iD_{i+1}} & 0 & \frac{4B_i^2B_{i+1}}{D_iD_{i+1}} & 0 \\ 0 & \frac{I+2B_i}{D_i} & 0 & \frac{-B_i}{D_i} & 0 & 0 & 0 & 0 \\ \frac{-B_i}{D_i} & 0 & \frac{I+2B_i}{D_i} & 0 & \frac{B_i+2B_i^2}{D_iD_{i+1}} & 0 & \frac{(B_i+2B_i^2)(2B_{i+1})}{D_iD_{i+1}} & \\ 0 & \frac{2B_i}{D_i} & 0 & \frac{I}{D_i} & 0 & 0 & 0 & \\ 0 & 0 & 0 & 0 & \frac{I}{D_{i+1}} & 0 & \frac{2B_{i+1}}{D_{i+1}} & 0 \\ 0 & \frac{(B_{i+1}+2B_{i+1}^2)2B_i}{D_iD_{i+1}} & 0 & \frac{B_{i+1}+2B_{i+1}^2}{D_iD_{i+1}} & 0 & \frac{I+2B_{i+1}}{D_{i+1}} & 0 & \frac{-B_{i+1}}{D_{i+1}} \\ 0 & 0 & 0 & 0 & \frac{-B_{i+1}}{D_{i+1}} & 0 & \frac{I+2B_{i+1}}{D_{i+1}} & 0 \\ 0 & \frac{4B_iB_{i+1}^2}{D_iD_{i+1}} & 0 & \frac{2B_{i+1}^2}{D_iD_{i+1}} & 0 & \frac{2Bi+1}{D_{i+1}} & 0 & \frac{I}{D_{i+1}} \end{bmatrix}, \tag{3.5}$$

where $B_i = \operatorname{diag}(\ldots, b_{ij}, \ldots)$, $D_i = \operatorname{diag}(\ldots, 1 + 2b_{ij} + 2b_{ij}^2, \ldots)$, and $b_{ij} = \frac{\mu_j}{\sigma_i h_i}$. The

matrix $E = I - W^T A^{-1} V$ is a 4×4 matrix of the form

$$I - W^T A_0^{-1} V = \begin{bmatrix} d_1 & 0 & a_{11} & b_1 \\ 0 & d_1 & c_1 & a_1 \\ a_{22} & b_2 & d_2 & 0 \\ c_2 & a_2 & 0 & d_2 \end{bmatrix}, \tag{3.6}$$

where

$$d_1 = 1 - 2\sum_{j=1}^{N} \frac{\omega_j + \omega_j b_{ij}}{d_{ij}}, \tag{3.7}$$

$$d_2 = 1 - 2\sum_{j=1}^{N} \frac{\omega_j + \omega_j b_{i+1j}}{d_{i+1j}}, \tag{3.8}$$

$$a_{11} = 2\sum_{j=1}^{N} \frac{\omega_j b_{ij} b_{i+1j} + \omega_j b_{ij}^2 b_{i+1j}}{d_{ij} d_{i+1j}}, \tag{3.9}$$

$$b_1 = -2\sum_{j=1}^{N} \frac{\omega_j b_{ij} + \omega_j b_{ij} b_{i+1j} + \omega_j b_{ij}^2 + \omega_j b_{ij}^2 b_{i+1j}}{d_{ij} d_{i+1j}}, \tag{3.10}$$

$$c_1 = -2\sum_{j=1}^{N} \frac{\omega_j b_{ij}^2 b_{i+1j}}{d_{ij} d_{i+1j}}, \tag{3.11}$$

$$a_1 = -2\sum_{j=1}^{N} \frac{\omega_j b_{ij}^2 + \omega_j b_{ij}^2 b_{i+1j}}{d_{ij} d_{i+1j}}, \tag{3.12}$$

$$a_{22} = -2\sum_{j=1}^{N} \frac{\omega_j b_{i+1j}^2 + \omega_j b_{ij} b_{i+1j}^2}{d_{ij} d_{i+1j}}, \tag{3.13}$$

$$b_2 = -2\sum_{j=1}^{N} \frac{\omega_j b_{ij} b_{i+1j}^2}{d_{ij} d_{i+1j}}, \tag{3.14}$$

$$c_2 = -2\sum_{j=1}^{N} \frac{\omega_j b_{i+1j} + \omega_j b_{ij} b_{i+1j} + \omega_j b_{i+1j}^2 + \omega_j b_{ij} b_{i+1j}^2}{d_{ij} d_{i+1j}}, \tag{3.15}$$

$$a_2 = -2\sum_{j=1}^{N} \frac{\omega_j b_{ij} b_{i+1j} + \omega_j b_{ij} b_{i+1j}^2}{d_{ij} d_{i+1j}}, \tag{3.16}$$

and E^{-1} is also a 4×4 matrix and can be calculated analytically. Its entries are shown in Appendix A.

4. Multigrid. To illustrate the multigrid scheme, we consider it in a two-grid form. Let L^h denote the fine grid operator, L^{2h} the coarse grid operator, and I_{2h}^h and I_h^{2h} the interpolation and restriction operators, respectively. Let ν_1 and ν_2 be small integers (e.g., $\nu_1 = \nu_2 = 1$), which determine the number of relaxation sweeps performed before and after the coarse grid correction. Then one multigrid $V(\nu_1, \nu_2)$ cycle is represented (in two-grid form) by the following:

1. Relax ν_1 times on $L^h u^h = f^h$.
2. Calculate the residual $r^h = f^h - L^h u^h$.
3. Solve approximately $L^{2h} u^{2h} = I_h^{2h} r^h$.
4. Replace $u^h \leftarrow u^h + I_{2h}^h u^{2h}$.
5. Relax ν_2 times on $L^h u^h = f^h$.

Our multigrid scheme is applied with regard to the spatial variable only. For a multilevel scheme in angle, see [7]. Figure 3 illustrates grid points on the fine grid and on the coarse grid after the a restriction operator is applied to the residual. The interpolation and restriction operators used here are based on the same finite element principle as in the derivation of the MLD scheme. They are defined as follows:

$$I_h^{2h} = \begin{bmatrix} S_{1,1} & S_{1,2} & & & & \\ & & S_{3,1} & S_{3,2} & & \\ & & & & \ddots & \ddots \\ & & & & S_{m-1,1} & S_{m-1,2} \end{bmatrix}, \tag{4.1}$$

where

$$S_{i,1} = \begin{bmatrix} I & 0 & 0 & 0 \\ 0 & \frac{h_i}{h_{i+1}+h_i} I & 0 & 0 \\ 0 & 0 & \frac{h_i}{h_{i+1}+h_i} I & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \text{ and } S_{i,2} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & \frac{h_{i+1}}{h_{i+1}+h_i} I & 0 & 0 \\ 0 & 0 & \frac{h_{i+1}}{h_{i+1}+h_i} I & 0 \\ 0 & 0 & 0 & I \end{bmatrix}$$

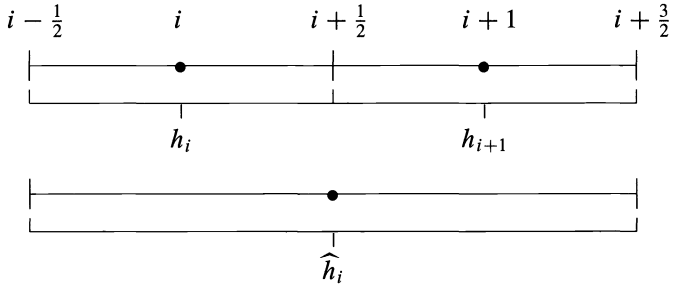

FIG. 3. *Fine and coarse grid.*

and

$$I_{2h}^{h} = \begin{bmatrix} T_{1,1} & & & & \\ T_{2,1} & & & & \\ & T_{1,3} & & & \\ & T_{2,3} & & & \\ & & \ddots & & \\ & & \ddots & & \\ & & & T_{1,m-1} & \\ & & & T_{2,m-1} & \end{bmatrix}, \tag{4.2}$$

where

$$T_{1,i} = \begin{bmatrix} I & 0 & 0 & 0 \\ 0 & \frac{2h_{i+1}+h_i}{h_{i+1}+h_i} I & 0 & \frac{-h_{i+1}}{h_{i+1}+h_i} I \\ \frac{h_{i+1}}{h_{i+1}+h_i} I & 0 & \frac{h_i}{h_{i+1}+h_i} I & 0 \\ 0 & \frac{2h_{i+1}}{h_{i+1}+h_i} I & 0 & \frac{h_i-h_{i+1}}{h_{i+1}+h_i} I \end{bmatrix}$$

and

$$T_{2,i} = \begin{bmatrix} \frac{h_{i+1}-h_i}{h_{i+1}+h_i} I & 0 & \frac{2h_i}{h_{i+1}+h_i} I & 0 \\ 0 & \frac{h_{i+1}}{h_{i+1}+h_i} I & 0 & \frac{h_i}{h_{i+1}+h_i} I \\ \frac{-h_i}{h_{i+1}+h_i} I & 0 & \frac{2h_i+h_{i+1}}{h_{i+1}+h_i} I & 0 \\ 0 & 0 & 0 & I \end{bmatrix}.$$

The order of variables for these operators is the same as in (2.14). The coarse grid operator, L^{2h}, is defined as

$$L^{2h} = I_{2h}^{h} L^{h} I_{h}^{2h},$$

where L^h is given by (2.6)–(2.9). The coarse grid operator L^{2h} has the same form as L^h, but on a new grid.

We use the notation $2h$ to indicate a coarse grid, although our grids are not really assumed to be uniform. In the general nonuniform case, the meshsize at cell i on the coarse grid is given by $\widehat{h_i} = h_{2i-1} + h_{2i}$.

5. Storage and data structure. Implementation of this scheme on the CM2 involves the following considerations.

- We assign one processor to each point (i.e., for each (x_i, μ_j) pair) in the computational mesh, assuming there are at least $(2m + 1)n$ processors. If we are using less than $(2m + 1)n$ physical processors, the CM2 will reuse the physical processors, creating virtual processors to store the additional grid points.
- Variables that are defined at different grid levels have an index that represents the grid level. We store these variables such that if they represent the same spatial and angular coordinate point, they will be assigned to the same processor even if their grid levels are distinct.

This avoids communication when data is accessed from different grid levels for a given spatial and angle coordinate variable. For example, variable $\underline{\psi}$ appears as ψ(:serial,:news,:news) in the code. Here, the first index represents the grid level, and the remaining indices represent spatial and angular coordinates.

• In the relaxation for the nonuniform grid (variable h), some processors will require products of variables that belong to different cells, as can be seen, for example, in any row of (3.5). In particular, look at the first row of this matrix. Even though this row will have its elements stored in a processor in the first cell of the two-cell pair, it uses data from both cells (i.e., $B_i^2 B_{i+1}$). To avoid extra complication in the parallel algorithm, we store these variables in the proper processors at the outset. For example, we have an array b that stores the values of matrix B for the first cell and an array $bp1$ that stores the values of matrix B for the second cell of the pair. In this way all the processors representing grid points of a two-cell pair will contain data from both cells of the pair.

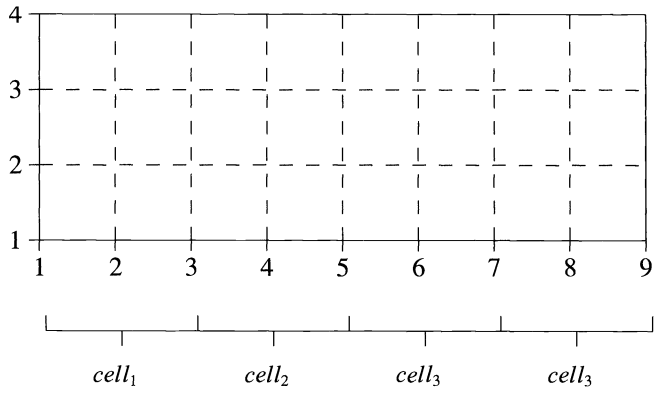

FIG. 4. *Computational mesh for four cells.*

Figure 4 illustrates the computational mesh for four cells (horizontal axis) and four angles (vertical axis). Vertical lines 1–5 represent the variables associated with $cell_1$ and $cell_2$, i.e.,

$$\left(\underline{\psi}^{+(-)}_{-\frac{1}{2}}, \underline{\psi}^{+(-)}_{1}, \underline{\psi}^{+(-)}_{\frac{3}{2}}, \underline{\psi}^{+(-)}_{2}, \underline{\psi}^{+(-)}_{\frac{5}{2}}\right),$$

while vertical lines 5–9 represent the variables associated with $cell_3$ and $cell_4$,

$$\left(\underline{\psi}^{+(-)}_{\frac{5}{2}}, \underline{\psi}^{+(-)}_{3}, \underline{\psi}^{+(-)}_{\frac{7}{2}}, \underline{\psi}^{+(-)}_{4}, \underline{\psi}^{+(-)}_{\frac{9}{2}}\right).$$

Processors represented by vertical lines 1–4 will contain all the information associated with $cell_1$ and $cell_2$, while processors represented by vertical lines 5–8 will contain all the information associated with $cell_3$ and $cell_4$. Consider $cell_1$ and $cell_2$. Array b contains the values of $b(i, j) = \mu(j)/(\sigma_t(cell_1)h(cell_1))$. Thus $bp(1,3) = bp(2,3) = bp(3,3) = bp(4,3)$. Array $bp1$ contains the values of $bp1(i, j) = \mu(j)/(\sigma_t(cell_2)h(cell_2))$. Thus $bp1(1,3) = bp1(2,3) = bp1(3,3) = bp1(4,3)$. However, $b(1, 1) \neq b(1, 2)$, $bp1(1, 1) \neq bp1(1, 2)$, and so on. The arrays b and $bp1$ are constant on the same subsets of the computational mesh. We also use some replication of data in a slightly different way for the mesh size variable h. The elements of array h contain the cellsize h_i, the array $hm1$ contains h_{i-1}, and the array $hp1$ contains h_{i+1}. These three arrays are constant on vertical lines in Fig. 4. This data structure is the same for all the grid levels, but with a different number of cells for each grid level.

• Some communication, of course, is necessary between processors. In fact, between the boundaries of every pair of cells we will have some shifting of data. For example, consider the variables (2.14) updated with the appropriate two-cell relaxation matrix ($cell_i$ and $cell_{i+1}$). Note that $\underline{\psi}^+_{i+3/2}$ will be updated by this matrix, but the variables $\underline{\psi}^-_{i+3/2}$ will be updated by the next two-cell pair relaxation matrix ($cell_{i+2}$ and $cell_{i+3}$). Again, consider Fig. 4. Vertical line 5 represents the variables $\underline{\psi}^{(+)(-)}_{5/2}$. The two-cell relaxation matrix for $cell_1$ and $cell_2$ will be stored on the processors associated with vertical lines 1–4. So, to update variables $\underline{\psi}^+_{5/2}$, the processors on line 5 will need to access data from line 4.

• In the CM2, conformable arrays (arrays with the same shape and size) are always stored in the same set of processors in the same order. To compute expressions like the elements of the matrix E in (3.6) without the need for communication, we store the variables w_j (a one-dimension array) as a two-dimension array that is conformable with array b (Fig. 4). Consequently, w is constant over horizontal lines in Fig. 4. Note that the elements of E^{-1} in (A.1) will also be conformable with variables w and b.

6. Relaxation in parallel. A two-cell relaxation step consists of applying M^{-1} (M is given by (2.13)) to a right-hand side vector that we call $\underline{y}$. What follows is the process to perform a two-cell relaxation step. If the current grid has k cells, then $\frac{k}{2}$ two-cell relaxations will be performed simultaneously for Jacobi, while $\frac{k}{4}$ two-cell relaxations steps will be performed in each of two stages for red-black Gauss–Seidel. Each two-cell relaxation can be performed through the following steps.

Step 1. Form $\underline{z} = A^{-1}\underline{y}$. This step is done at the same time for all the cells, using the matrix A^{-1} as shown in (3.5). To update any variable, the associated processor needs only one row of this matrix. For example, with the order of variables used and shown in (2.14), to update the variable $\underline{\psi}^+_i$, we need only the second row of A^{-1}; so, the processor that updates this variable needs only to store this row's entries. Note, though, that this row's entries will multiply data that are allocated in other processors. Through the use of the CM2 intrinsic function *eoshift*, we can perform a move of data in the x direction (index i), and then multiply by the appropriate entry of the matrix. To update all the variables, we thus have the following combination of shifts:

$$\psi^+_i = A_2\psi^+_i + A_1\psi^+_{i-\frac{1}{2}} + A_3\psi^+_{i+\frac{1}{2}} + A_4\psi^+_{i+1} + A_5\psi^+_{i+\frac{3}{2}}$$

for j =1, ..., n (at the same time). Here, A_1, A_2, A_3, A_4, and A_5 are the elements of the appropriate row. Note that processor (i, j) does not have variables other than the ones with indexes i, j. It will therefore use the CM2 intrinsic function *eoshift*[1] in the following way:

$$temp = \psi_{i+\frac{1}{2}} = eoshift(\psi_i, 1, 1),$$
$$\psi_{i+1} = eoshift(temp, 1, 1),$$

and so on. Each new shift will take advantage of the previous one. The big advantage of this step is that this updating occurs at the same time for all the processors, making this matrix multiplication a job that requires only eight communications. Note that for each cell the vector $\underline{z}$ has length $8n$.

Step 2. Form $VE^{-1}W^T\underline{z}$. In this step we take advantage of the fact that the $8n \times 8n$ matrix $VE^{-1}W^T$ can be written as the tensor product $F \otimes R = F \otimes \underline{1}\underline{w}^t$. Remember that $\underline{1}$ and $\underline{w}^t$ are n-vectors. The 8×8 matrix F is derived from a combination of rows and columns of the matrix E^{-1} and is given by

[1]The first argument of the *eoshift* function is the array name, the second is the array index that is going to be shifted, and the last is the stride of the shift.

$$(6.1)\quad F = \begin{bmatrix} 2 & 0 & & & & & & \\ 1 & 1 & & & & & & \\ 1 & 1 & & & & & & \\ 0 & 2 & & & & & & \\ & & 2 & 0 & & & & \\ & & 1 & 1 & & & & \\ & & 1 & 1 & & & & \\ & & 0 & 2 & & & & \end{bmatrix} E^{-1} \begin{bmatrix} \frac{1}{2} & 1 & 0 & -\frac{1}{2} & & & & \\ -\frac{1}{2} & 0 & 1 & \frac{1}{2} & & & & \\ & & & & \frac{1}{2} & 1 & 0 & -\frac{1}{2} \\ & & & & -\frac{1}{2} & 0 & 1 & \frac{1}{2} \end{bmatrix}.$$

Note that if the grids are nonuniform, the matrices E^{-1} and F will have their elements as arrays and will be different for each distinct pair of cells. Note that we can write $F \otimes \underline{1}\underline{w}^t = (I_8 \otimes \underline{1})F(I_8 \otimes \underline{w}^t)$, where I_8 is the 8×8 identity matrix. Thus, multiplication by the matrix $F \otimes \underline{1}\underline{w}^t$ can thus be done in three steps.

Step 2.1. Form $z^* = (I_8 \otimes \underline{w}^T)\underline{z}$. This step consists of a dot product of $\underline{w}^t$ and each n-vector that makes up the $8 \times n$-vector $\underline{z}$. Remember, vector $\underline{z}$ was obtained in Step 1 and $\underline{w}^t$ is an n-vector. So, first we multiply each entry of $\underline{w}^t$ by each corresponding entry of $\underline{z}$: $w_{ij} \times z_{ij}$ which is performed for all processors at the same time because $\underline{w}$ is conformable to $\underline{z}$. The i index for variable z_{ij} goes from 1 to 8 for each cell. The second stage of the dot product is to perform a summation in the angle index direction. This is done with the use of the CM2 intrinsic function *sum*. The vector $\underline{z}^*$ has length 8.

Step 2.2. Form $\underline{\eta} = \mathrm{F}\,\underline{z}^*$. This step is a multiplication of a vector by a matrix, and can be performed in the CM2 similar to the way Step 1 of this relaxation was performed. Depending on which point the processor is representing, it will have stored different rows of the matrix F. Its variables will be updated through the use of the CM2 intrinsic function *eoshift* only (in this case, 16 of them).

Step 2.3. Form $\Theta = (I_8 \otimes \underline{1})\underline{\eta}$. This spreads the result of Step 2.1 across all the angles (for all spatial points at the same time). This is done with the use of the CM2 intrinsic function *spread*.

Step 3. Form $A^{-1}\underline{\Theta}$ as in Step 1 and add the result to $\underline{z}$.

A special remark should be made here. It is not hard to see that Steps 2.2 and 2.3 can have their order interchanged. In fact, since all the CM2 processors will execute the same instruction simultaneously, unless instructed otherwise by the use of masks, we make use of this property of the algorithm. We spread vector z^* throughout all the angles represented by different processors. Since all the processors had the appropriate row elements of matrix F from the outset, we perform Step 2.2 last. This will make the use of masks necessary only for distinction between the processors regarding the kind of spatial point it represents, not the kind of angle.

It is easy to show that, if we take advantage of the structure of the various matrices and perform the matrix multiplication steps as described, the total operation count and the number of communications per processor for one relaxation sweep are both $O(n)$, more precisely $2(n-1)$. Details are given in [12].

7. Multigrid in parallel. The parallel relaxation process of the multigrid algorithm was explained in §6. For calculation of the residual on the finer grid, again we use the CM2 intrinsic function *eoshift*. For example, to calculate the residual at an edge grid point for a

negative angle, we use (2.4). Note that the processor that contains the variable $\psi^-_{i,j}$ will not contain other variables necessary for the calculation of the residual at this point. Therefore, we perform a move of data:

$$\psi^-_{i+\frac{1}{2}} = eoshift(\psi^-_i, 1, 1),$$
$$\psi^-_{i-\frac{1}{2}} = eoshift(\psi^-_i, 1, -1).$$

For calculation of the right-hand side of this equation, we perform a one-step multiplication for the conformable arrays w and ψ^+ (the same for ψ^-), and then, using the CM2 intrinsic function *sum*, we perform a summation in the angle direction for the resultant products.

After the residual is calculated, to solve for the error on the coarser grid, we have to estimate the residual on the coarser grid. This is done by multiplying r^h, residual on the fine grid by the restriction operator I^{2h}_h shown in (4.1). In some processors there will be no operation or communication at all, because as in §3 the grid level index is serial, and some processors will contain all the information they need. For example, for a negative angle at the left-hand side of a two-cell pair (negative angle outflow), the restriction consists of $r^{2h}_{i-1/2} = r^h_{i-1/2}$ (see the first row of (4.1)). This requires no communication.

For processors that represent cell centers on the coarse grid (second and third row of (4.1)), we use the CM2 intrinsic function *eoshift* in a way that is similar to what was done in Step 1 of relaxation.

$$temp\ 1 = r^h_{i+1} = eoshift(r^h_i, 1, 1),$$
$$temp2 = r^h_{i-1} = eoshift(r^h_i, 1, -1).$$

We then calculate the residual on the coarse grid

$$r^{2h}_i = \frac{hp1}{(hp1 + h)} temp1 + \frac{h}{(h + hp1)} temp2.$$

After forming r^{2h}, we perform parallel relaxation again, this time to estimate the error on the coarser grid (u^{2h}).

To use the coarser grid quantities to correct the solution on a finer grid, we multiply u^{2h} by the matrix I^h_{2h} shown in (4.2). This multiplication is performed similarly to the multiplication of r^h by I^{2h}_h.

8. Numerical results. The CM2 codes were run for different values of $\sigma_t h$ on the fine grid. In Tables 1 and 2 we chose these values to be the worst cases predicted by the Fourier analysis shown in [12]. All of the convergence factors (i.e., the ratio of Euclidean norms of the residuals before and after a multigrid V-cycle) shown here are for the case with no absorption ($\gamma = 1$). The results are shown for the two kinds of relaxation (Jacobi and red-black Gauss–Seidel) used in our multigrid scheme. The convergence factors shown for the CM2 codes were obtained for one V-cycle after five V-cycles. The convergence factors were close to the ones predicted by the Fourier analysis as Tables 1 and 2 show. Tables 1 and 2 show results for uniform grids for different number of angles, e.g., S_4 means four scattering angles (n=2) and so on. Table 3 shows convergence factors obtained for nonuniform grids; these grids were generated randomly with h varying between 1 and 100. Table 4 shows a comparison of three relaxation methods, discussed in the next section, and the behavior of the convergence factor for varying $\sigma_t h$ for a two-cell Jacobi ($V(1, 1)$ and $V(2, 2)$) or two-cell red-black Gauss–Seidel ($V(1, 1)$) relaxation. Note that the convergence factor appears to be $O((\frac{1}{\sigma_t h})^2)$ when $\sigma_t h \gg 1$

and $O((\sigma_t h)^3)$ when $\sigma_t h \ll 1$ for all three relaxation methods. To make a fair comparison between the different relaxations, we have to consider the difference in time spent to attain the above convergence factors. This will be analyzed in the next section.

TABLE 1

9. Timings. First, we show the cost behavior when we keep n constant (equal to one) and vary the spatial dimension m (Figs. 5 and 6 and Table 6). Second, we analyze the cost when n varies and the spatial dimension m is kept constant (Fig. 7). All the results shown in this section were measured for a $V(1,1)$ or $V(2,2)$ cycle. There are two codes, one for uniform grids and the other for nonuniform grids. The uniform grid code was used for the timings in this paper. However, similar results have been obtained with the nonuniform grid code, but with all of the timings roughly doubled. The sequential timings were measured using one processor of a Cray Y-MP, which has a vector architecture.

When we increase the number of grid points of the computational grid, we should have no increase on the time spent for our relaxation step on computers like the CM2 until all the processors are being used. However, in our multigrid relaxation scheme, the number of levels should be defined such that the coarsest grid consists of two cells. Hence the number of grid levels will always be $\log_2 \frac{m}{2}$; so, every time we double the number of cells (m) in our finest grid, we have new computations at the new added grid level since the grid level index is serial. This increase in time corresponds only to the new calculations. This can be observed in Fig. 5 for m between 2^6 and 2^9, specifically, where we notice that the increase in time when we double m is linearly proportional to $\log_2 m$, while after $m = 2^9$ there is a bigger increase in the slope of the graph every time we double m because the processors are saturated.

For our example, when m reaches the value of 2^{10}, we have begun to saturate the CM2. Here the number of grid points $(2m + 1)$ is 2049. When these timings were measured we used one sequencer, which consists of 2^{12} processors with 512 floating point units (FPU). Note that 2048 is four times the number of FPUs, where four is the vector-length at each FPU. This explains the beginning of increase for the slopes of the piecewise linear graph in Fig. 5, since we will be reusing these FPUs. Also, when we vary m between 2^{10} and 2^{11}, we are changing the number of grid points by 2048, which causes an even bigger increase on the slopes of Fig. 5. In fact, the timings will increase (disregarding the overhead) every time we further increase the number of cells $(2m + 1)$ by multiples of 2048 (the number of FPU $\times$ 4).

If we look at the timings and dimensions for larger m, the parallel code starts increasing its time proportionally to the increase of m, similarly to the way a sequential code does. Consider the points $m = 2^{15}(32768)$ and $m = 2^{16}(65536)$ in Fig. 6. This is explained by the fact that, for this range of m, every time we increase m we will be reusing FPUs.

Figure 7 shows the variation of cost when n changes. The multigrid in this paper was applied to the spatial variable m, so none of the increase in cost is due to the multilevel scheme used. The increase of cost here is due to the fact of using the CM2 intrinsic functions *sum* and

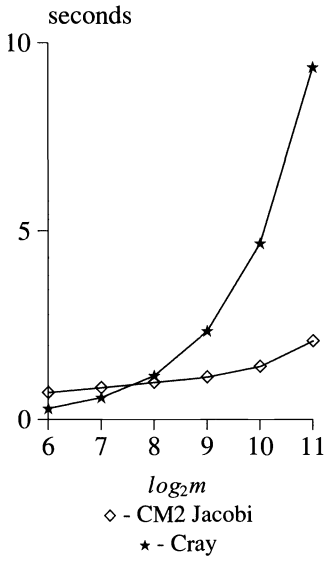

FIG. 5. *Timings for a V* (1, 1) *cycle for small m and n* = 1.

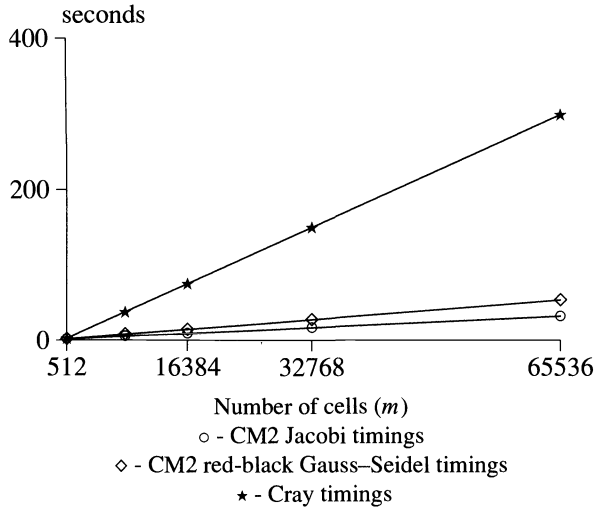

FIG. 6. *Timings for a V* (1, 1) *for large m and n* =*1.*

spread in the angular variable direction. This happens, for example, in Step 2 of the parallel relaxation. Of course, when we increase n to the point of reusing the FPUs, the time cost will increase similarly to the way it did when m increased.

Figure 6 also shows the additional time spent if we use a red-black Gauss–Seidel relaxation instead of a Jacobi. The timings for red-black Gauss–Seidel (V(1,1)) and Jacobi (V(1,1) and V(2,2)) two-cell relaxation are compared to the Cray timings on Table 6. The Cray timings were measured for a V(1,1) cycle. Note that since the code on the Cray is sequential, it is irrelevant for timing purposes whether we use the Jacobi or red-black Gauss–Seidel relaxation since both relaxations will take approximately the same time, $\frac{m}{2}$ sequential steps.

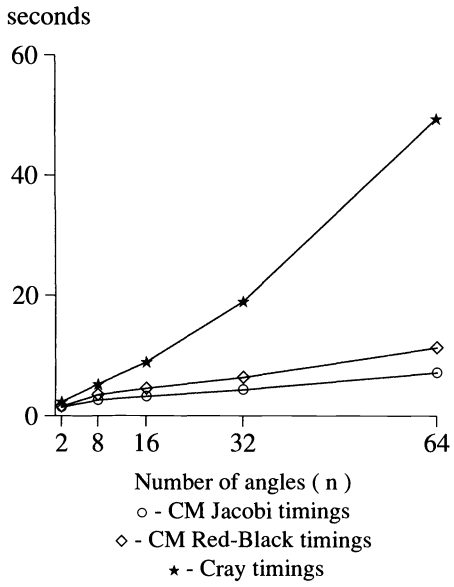

FIG. 7. *Timings for a* $V(1, 1)$ *cycle varying* (n) *and* $m = 512$.

TABLE 6

Timings for Jacobi ($V(1, 1)$ *and* $V(2, 2)$) *and red-black* ($V(1, 1)$) *on the* CM2 *and Cray* Y-MP. *S*4 *case*, $\sigma_t h = .1$.

m	Jacobi $V(1, 1)$	Red-black $V(1, 1)$	Jacobi $V(2, 2)$	Cray
512	1.19	1.78	1.69	2.9
1024	1.93	3.00	2.82	5.85
2048	2.78	4.54	4.35	11.71
4096	4.60	7.57	7.41	23.43
32768	31.00	53.53	52.69	187.5
65536	63.14	109.54	108.6	376.0

In the CM2 for the same number of V-cycles, the Jacobi relaxation in a $V(1, 1)$ cycle is much faster than the red-black Gauss–Seidel relaxation in a $V(1, 1)$ cycle, but its convergence factor is generally worse than the red-black $V(1, 1)$ convergence rate (Table 4). If we consider the Jacobi relaxation for the $V(2, 2)$ cycle, the timings will be slightly better than the red-black Gauss–Seidel $V(1, 1)$ cycle and the convergence factors in this case will be comparable. We show here that if the additional time used in doing a V-cycle with red-black Gauss–Seidel relaxation was used to perform more of the Jacobi V-cycles, the convergence factor (both $V(1, 1)$ and $V(2, 2)$) would be generally better.

For a fixed number of V-cycles, Table 7 compares Jacobi $V(1, 1)$ and $V(2, 2)$ with red-black Gauss–Seidel $V(1, 1)$. In this table we compare the convergence factors for each relaxation using the time for a red-black $V(1, 1)$ as the standard unit. For example, if red-black Gauss–Seidel $V(1, 1)$ took twice as long as Jacobi $V(1, 1)$, then two Jacobi $V(1, 1)$ cycles could be performed in the same time as one red-black $V(1, 1)$. Using the time for red-black $V(1, 1)$ as the standard unit of time, the proper convergence factor for Jacobi $V(1, 1)$ would be $(\rho_{j1})^2$. We define

t_{rb} = time for 1 $V(1, 1)$ cycle with red-black Gauss–Seidel relaxation,

t_{j1} = time for 1 $V(1, 1)$ cycle with Jacobi relaxation,

t_{j2} = time for 1 $V(2, 2)$ cycle with Jacobi relaxation.

TABLE 7

Comparison between Jacobi V(1, 1), *Jacobi* V(2, 2), *and red-black* V(1, 1) *convergence factors* (ρ_{j1}, ρ_{j2} *and* ρ_{rb1}) *for various values of* $\sigma_t h$ (S4 *case*).

$\sigma_t h$	$(\rho_{j1})^{\frac{t_{rb1}}{t_{j1}}}$	ρ_{rb1}	$(\rho_{j2})^{\frac{t_{rb1}}{t_{j2}}}$
10^{-5}	2.8×10^{-14}	3.3×10^{-10}	4.4×10^{-11}
10^{-4}	8.1×10^{-10}	2.8×10^{-7}	5.9×10^{-10}
10^{-3}	8.6×10^{-6}	7.2×10^{-5}	4.5×10^{-5}
10^{-2}	1.0×10^{-3}	4.3×10^{-3}	1.7×10^{-3}
10^{-1}	1.8×10^{-3}	8.0×10^{-3}	2.0×10^{-3}
1.	2.7×10^{-4}	1.1×10^{-3}	7.1×10^{-4}
10^{1}	2.4×10^{-7}	3.2×10^{-5}	1.0×10^{-5}
10^{2}	2.0×10^{-10}	2.5×10^{-7}	1.9×10^{-7}

Likewise we define the convergence factors ρ_{rb}, ρ_{j1}, and ρ_{j2}. The correct comparisons are

$$\rho_{rb} \quad \text{vs.} \quad (\rho_{j1})^{\frac{t_{rb}}{t_{j1}}} \quad \text{vs.} \quad (\rho_{j2})^{\frac{t_{rb}}{t_{j2}}}.$$

These comparisons are shown in Table 7. It is obvious that both Jacobi V(1,1) and V(2,2) are superior to red-black Gauss–Seidel. If we compare the Jacobi V(1,1) and V(2,2) relaxations, we conclude that Jacobi V(1,1) gives, in general, a better convergence factor in this parallel environment for the same CPU time.

10. Conclusions. In this paper we have shown a parallel algorithm for a multigrid scheme for solving the transport equations in slab geometry. This algorithm is suitable for SIMD computers and takes advantage of this kind of architecture during the different stages of the multigrid scheme. It was implemented on the CM2 and was much faster than a sequential version of the same algorithm on the Cray Y-MP (using only one processor), especially when comparing large gridsizes. For the relaxation step of the multigrid algorithm, we used the Sherman–Morisson formula and developed an efficient relaxation with the use of a few intrinsic functions on the CM2. The interpolation and restriction operations, for some grid points, were able to be performed without communication. The increase in the CPU time spent in a V-cycle when either one of the grid dimensions was increased was small before saturation. For the spatial dimension this increase is due to the addition of a new grid level, and for the angular dimension it is due to the use of the CM2 intrinsic functions. After saturation of the CM2 is reached, we have shown that the sharper increases in timings are caused by reuse of FPUs. In fact, when the CM2 becomes saturated, the parallel timings start doubling when one of the grid dimensions is doubled. This, of course, always happens in the sequential timings for any doubling of m or n.

The convergence rates attained per V-cycle were extremely good and matched theoretical results. We implemented three different kind of relaxations: Jacobi ($V(1, 1)$ and $V(2, 2)$) and red-black Gauss–Seidel $V(1,1)$ in two kinds of implementation each, uniform and nonuniform meshes. We have shown that in this context, the Jacobi $V(1,1)$-cycle was superior to Jacobi $V(2, 2)$-cycle and red-black Gauss–Seidel $V(1, 1)$-cycle. The timings for the nonuniform grid code do not appear in this paper, since they were obtained under a timesharing environment that was not reliably comparable to the uniform grid code executed under the dedicated environment. However, similar results and conclusions seem to hold, with the exception that all of the times are roughly doubled.

The results in this paper show the good performance of our parallel algorithms for solving the isotropic form of the transport equation on SIMD architectures. For the anisotropic scattering, we are developing an algorithm suitable for SIMD computers [12] using an angular multigrid developed in [7].

Appendix A. The inverse of the matrix E in (3.6) is given by

$$E^{-1} = \begin{bmatrix} e_{11} & e_{12} & e_{13} & e_{14} \\ e_{21} & e_{22} & e_{23} & e_{24} \\ e_{31} & e_{32} & e_{33} & e_{34} \\ e_{41} & e_{42} & e_{43} & e_{44} \end{bmatrix}, \tag{A.1}$$

where

ROTATING WAVES FROM HOPF BIFURCATIONS IN EQUATIONS WITH $O(2)$-SYMMETRY*

W. WU†, P. J. ASTON‡, AND A. SPENCE§

Abstract. This paper considers the problem of Hopf bifurcations that occur in equations with $O(2)$-symmetry on a solution that has the full $O(2)$-symmetry. It is well known that at such points, a path of standing waves and a path of rotating waves bifurcates. The standing waves are easily dealt with by restricting attention to a certain fixed point space and so the rotating wave solutions that arise are considered in detail. Efficient numerical methods for the detection and computation of these bifurcation points based on a block diagonalisation of the Jacobian are considered. Also described is a simple means of choosing the basis that gives rise to this block structure. Numerical methods for following the rotating wave branch away from the $O(2)$-symmetric solution are then described. The extension to infinite dimensions is considered briefly before a numerical example is presented.

Key words. rotating waves, $O(2)$-symmetry, Hopf bifurcations

AMS subject classifications. 34A34, 35B32, 65L99

1. Introduction.

For problems with $O(2)$-symmetry, it is well known that Hopf bifurcations on a path of solutions that have the full $O(2)$-symmetry give rise to paths of both standing waves and rotating (or travelling) waves. The form of the bifurcation equations at such a point has been studied in detail by Golubitsky, Stewart, and Schaeffer [7, Chap. XVII]. We consider this problem from a numerical viewpoint, concentrating on efficient methods for detecting such Hopf bifurcation points and then following the paths of rotating waves that occur. We do not consider the standing waves in detail because these solutions arise from a standard Hopf bifurcation in the subspace of functions that are symmetric with respect to the reflection in $O(2)$. Thus, standard methods for dealing with Hopf bifurcations can be employed to compute the branch of standing wave solutions (see, for example, [9]). However, the rotating wave solutions do not have this reflectional symmetry property; as a result, they cannot be isolated by restricting to a particular symmetric subspace of functions. Thus, special methods have to be developed to find these solutions and our approach is to reduce the problem to a steady-state equation to be solved for the rotating wave profile. This equation involves an additional variable, namely, the velocity of the wave. A phase condition for isolating a particular wave profile is an additional equation, which is introduced to match the extra velocity variable.

Rotating waves can also arise from bifurcations on steady-state branches of solutions with dihedral symmetry when the reflectional symmetry is broken. This situation has been analysed from an abstract point of view in [10] and from a numerical aspect in [2]. In this situation, however, the bifurcation is a nonstandard steady state bifurcation associated with a zero eigenvalue of the Jacobian, in contrast to the Hopf bifurcation in the present framework. Another difference between the two cases is that the bifurcation from an $O(2)$-symmetric solution has nonzero velocity on the rotating wave branch at the bifurcation, whereas, for the bifurcation from a branch with dihedral symmetry, the velocity is zero on the rotating wave branch at the bifurcation. This is due to the fact that an $O(2)$ symmetric solution can be considered as a rotating wave solution with arbitrary velocity; this is not true for a solution that does not have the full $O(2)$-symmetry.

There are three main aspects of this paper. Firstly, we construct a basis for the space, which gives rise to a block diagonalisation of the Jacobian matrix. This decomposition then

*Received by the editors November 27, 1991; accepted for publication (in revised form) March 12, 1993.

gives rise to efficient methods for the detection and computation of Hopf bifurcations. Finally, we consider the computation of the branch of rotating waves arising from the bifurcation.

The block diagonalisation of the Jacobian we consider is associated with the isotypic decomposition of the underlying Hilbert space [12], [1]. However, with this decomposition, there is always a problem in finding an appropriate basis for the block diagonalisation to occur in its simplest and most useful form. Healey [8] and Chang and Healey [3] essentially employ the known projection operators P_k onto the isotypic components and solve the equation

$$(P_k - I)\psi = 0$$

for the eigenfunctions ψ associated with the zero eigenvalue of the linear operator $P_k - I$. Murota and Ikeda [11] derive a transformation matrix that can be applied to any basis to give a basis that results in the block diagonal form of the Jacobian. However, in our case, these relatively complicated methods are not required since we are able to choose an appropriate basis as the eigenfunctions of a linear operator that arises naturally from the action of $O(2)$ on the Hilbert space.

The continuation package AUTO [5] will find rotating wave solutions of a restricted class of reaction-diffusion equations that arise from a Hopf bifurcation. However, in detecting these bifurcations, it deals with only the rather artificial case of fixing the velocity of the wave and allowing the period of the wave to vary.

The plan of the paper is as follows. In §2 we describe the block diagonalisation of the Jacobian and the simple way of finding a basis for the space that gives rise to this structure. In §3 we consider the Hopf bifurcation in more detail before describing methods for computing the bifurcating rotating waves in §4. In §5, we briefly consider the extension to the infinite-dimensional case and finally, we present a numerical example in §6.

2. Block diagonalisation. We consider time-dependent nonlinear problems of the form

$$\frac{du}{dt} + g(u, \lambda) = 0, \quad u \in X, \quad \lambda \in \mathbf{R}, \tag{2.1}$$

where X is an n-dimensional real Hilbert space equipped with an inner product $\langle \cdot, \cdot \rangle$ and $g : X \times \mathbf{R} \to X$ is a smooth nonlinear operator. We discuss the extension to the infinite-dimensional case in §6. We assume that g is equivariant with respect to an action of the group $O(2)$ on X, that is,

$$\gamma g(u, \lambda) = g(\gamma u, \lambda), \quad \forall \gamma \in O(2), \quad u \in X, \tag{2.2}$$

where $O(2)$ is the Lie group generated by rotations r_θ, $\theta \in \mathbf{R}$, and a reflection s, both of which satisfy the following relations for any α, $\beta \in \mathbf{R}$ (where $\mathbf{1}$ is the group identity element):

$$\begin{aligned} &r_{\alpha+2\pi} = r_\alpha, \quad r_{\beta+\alpha} = r_\beta r_\alpha = r_\alpha r_\beta, \\ &s^2 = r_0 = r_{2\pi} = \mathbf{1}, \quad s r_\alpha = r_{-\alpha} s. \end{aligned} \tag{2.3}$$

We also assume, without loss of generality [7, p. 31], that the inner product is $O(2)$-invariant, i.e.,

$$\langle \gamma x, \gamma y \rangle = \langle x, y \rangle \quad \forall x, y \in X, \ \gamma \in O(2). \tag{2.4}$$

For the sake of convenience, we assume the existence of a trivial steady-state solution path $(0, \lambda)$ so that

$$g(0, \lambda) = 0, \quad \lambda \in \mathbf{R}.$$

We are concerned with analysing the situation when a Hopf bifurcation occurs on this $O(2)$-symmetric trivial solution, with particular interest in the branch of rotating wave solutions that arises from such a bifurcation. In practice, Hopf bifurcations can often be found analytically in such situations. However, the theory also applies to problems with nontrivial $O(2)$-symmetric solutions such as are found in partial differential equation problems on a circular domain. Hopf bifurcations cannot be found analytically in such problems and so the numerical techniques we describe must be employed.

Rotating wave solutions of (2.1) are defined by

$$u(t) = r_{ct}x,$$

where $x \in X$ is independent of time and $c \in \mathbf{R}$ is the velocity of the wave. Substituting this form of solution into the original equation (2.1) leads to the "steady-state" equation

$$g(x, \lambda) + cAx = 0, \tag{2.5}$$

where A is the linear operator on X defined by

$$Ax := \frac{d}{d\theta} r_\theta x \Big|_{\theta=0}. \tag{2.6}$$

Because this operator A plays a central role in our theory, we now explore some of its properties.

LEMMA 2.1. (i) *For all* $\theta \in \mathbf{R}$,

$$\frac{dr_\theta}{d\theta} = r_\theta A, \quad r_\theta A = A r_\theta, \quad sA = -As. \tag{2.7}$$

(ii) *The linear operator* A^2 *is a symmetric linear operator on* X *with nonpositive eigenvalues.*

Proof. (i) These results are easily proved using the group relations (2.3).

(ii) Using the invariance property (2.4) of the inner product, we have that

$$\langle Ax, y\rangle = \frac{d}{d\theta}\langle r_\theta x, y\rangle \,|_{\theta=0} = \frac{d}{d\theta}\langle x, r_{-\theta} y\rangle \,|_{\theta=0} = -\langle x, Ay\rangle \tag{2.8}$$

giving $A^T = -A$, i.e., A is skew-symmetric. The stated properties of A^2 follow immediately from this fact. □

Let $\{\alpha_k, \ k = 0, 1, 2, \ldots, N\}$ be the distinct eigenvalues of A^2 and let the corresponding eigenspaces be

$$E_{\alpha_k} := \{\phi \in X : \ A^2\phi = \alpha_k \phi\}.$$

Elementary linear algebra gives

$$X = \sum_{k=0}^{N} \oplus E_{\alpha_k}.$$

We shall show later that this decomposition is very closely related to the isotypic decomposition of the Hilbert space and is the appropriate basis for the block diagonalisation of the Jacobian matrix.

The following results will frequently be used.

LEMMA 2.2. *The eigenspaces* E_{α_k}, $k = 0, 1, 2, \ldots, N$ *are invariant with respect to* A, $g_x(0, \lambda)$ *and* $O(2)$, *that is,*

$$A : E_{\alpha_k} \longrightarrow E_{\alpha_k}, \tag{2.9a}$$

$$g_x(0, \lambda) : E_{\alpha_k} \longrightarrow E_{\alpha_k}, \quad \lambda \in \mathbf{R}, \tag{2.9b}$$

$$\gamma : E_{\alpha_k} \longrightarrow E_{\alpha_k}, \quad \forall \gamma \in O(2). \tag{2.9c}$$

Proof. Property (2.9a) is easily verified. Differentiating the equivariance condition (2.2) for $\gamma = r_\theta$ with respect to θ and setting $\theta = 0$ gives

$$g_x(0, \lambda)A = Ag_x(0, \lambda), \quad \lambda \in \mathbf{R}. \tag{2.10}$$

Let $\phi \in E_{\alpha_k}$. Then

$$A^2 g_x(0, \lambda)\phi = g_x(0, \lambda)A^2\phi = \alpha_k g_x(0, \lambda)\phi,$$

which proves (2.9b). The relation

$$\gamma A^2 = A^2\gamma, \quad \gamma \in O(2),$$

which is derived from (2.7), is used to prove (2.9c) in a similar way. □

It is well known that the reflectional symmetry s can be used to decompose the space X into symmetric and antisymmetric subspaces as

$$X = X_s \oplus X_a,$$

where

$$X_s := \{x \in X : sx = x\}, \quad X_a := \{x \in X : sx = -x\}.$$

It follows from the last relation of (2.7) that $A : X_s \to X_a$ and $A : X_a \to X_s$, so both X_s and X_a are invariant under A^2. This enables the eigenspaces E_{α_k} to be decomposed as

$$E_{\alpha_k} = E^s_{\alpha_k} \oplus E^a_{\alpha_k}, \tag{2.11}$$

where

$$E^s_{\alpha_k} := E_{\alpha_k} \cap X_s, \quad E^a_{\alpha_k} := E_{\alpha_k} \cap X_a.$$

Note that $E^s_{\alpha_k}$ and $E^a_{\alpha_k}$ are also eigenspaces of A^2. It is easily verified that if $\alpha_k \neq 0$, then

$$E^a_{\alpha_k} = AE^s_{\alpha_k} \quad \text{and} \quad E^s_{\alpha_k} = AE^a_{\alpha_k} \tag{2.12}$$

so that if

$$E^s_{\alpha_k} = \text{span}\{\phi_1, \ldots, \phi_m\}, \tag{2.13a}$$

then

$$E^a_{\alpha_k} = \text{span}\{A\phi_1, \ldots, A\phi_m\}. \tag{2.13b}$$

The next result uses these eigenspaces to give the block diagonalisation of the Jacobian matrix $g_x(0, \lambda)$.

THEOREM 2.3. *If the basis of X is chosen to be the eigenvectors of A^2, then $g_x(0, \lambda)$ has the block diagonal structure*

$$g_x(0,\lambda) = \begin{bmatrix} B_0 & & & \\ & \cdot & & \\ & & \cdot & \\ & & & \cdot \\ & & & B_N \end{bmatrix}. \tag{2.14a}$$

In addition, for $\alpha_k \neq 0$, choosing (2.13) as bases of $E^s_{\alpha_k}$ and $E^a_{\alpha_k}$, leads to a further decomposition of the B_k block corresponding to E_{α_k} as

$$B_k = \begin{pmatrix} J_k & 0 \\ 0 & J_k \end{pmatrix}. \tag{2.14b}$$

Proof. The decomposition (2.14a) follows directly from (2.9b). The further two block decomposition (2.14b) also follows immediately from the splitting (2.13) and the fact that X_s and X_a are invariant with respect to $g_x(0, \lambda)$. It remains to prove that the two blocks are identical.

Let the two blocks of the Jacobian on the symmetric and antisymmetric subspaces of E_{α_k} be J^s and J^a, respectively. Then, relative to the basis (2.13a), which we assume is an orthogonal basis,

$$J^s_{i,j} = \frac{\langle \phi_i, g_x(0,\lambda)\phi_j \rangle}{\langle \phi_i, \phi_i \rangle}.$$

Similarly, relative to the basis (2.13b),

$$\begin{aligned} J^a_{i,j} &= \frac{\langle A\phi_i, g_x(0,\lambda)A\phi_j \rangle}{\langle A\phi_i, A\phi_i \rangle} \\ &= \frac{\langle A\phi_i, Ag_x(0,\lambda)\phi_j \rangle}{\langle A\phi_i, A\phi_i \rangle} \quad \text{using (2.10)} \\ &= \frac{\langle A^2\phi_i, g_x(0,\lambda)\phi_j \rangle}{\langle A^2\phi_i, \phi_i \rangle} \quad \text{using (2.8)} \\ &= \frac{\alpha_k \langle \phi_i, g_x(0,\lambda)\phi_j \rangle}{\alpha_k \langle \phi_i, \phi_i \rangle} \quad \text{since } \phi_i \in E_{\alpha_k} \\ &= J^s_{i,j}. \end{aligned}$$

This completes the proof. □

Clearly, the structure exhibited in the block decomposition of Theorem 2.3 is important for the numerical solution of the problem. However, before we consider the numerical implications, we establish the link between the eigenspaces E_{α_k} and the isotypic components of the Hilbert space.

A Hilbert space has an isotypic component associated with every (nonequivalent) irreducible representation of the group on the Hilbert space. In particular, the projection onto the isotypic component of a real Hilbert space associated with the irreducible representation τ_k of the compact Lie group Γ is

$$P_k = \frac{n_k}{d_k} \int_\Gamma \chi_k(\gamma)\gamma \, d\gamma,$$

where n_k is the dimension of τ_k, d_k is 1 for absolutely irreducible representations and $\chi_k(\gamma)$ is the trace of $\tau_k(\gamma)$. The irreducible representations of the group $O(2)$ are given by

(i) $\tau_0^+ : r_\theta = I,\ s = I,$

(ii) $\tau_0^- : r_\theta = I,\ s = -I,$

(iii) $\tau_k : r_\theta = \begin{bmatrix} \cos k\theta & \sin k\theta \\ -\sin k\theta & \cos k\theta \end{bmatrix}, \quad s = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \quad k \in \mathbf{Z}^+.$

We note that all of these irreducible representations are absolutely irreducible. The first step towards establishing the link is the following result.

THEOREM 2.4. *For all* $x \in X$,

(i) $A^2 P_k x = P_k A^2 x,\ k \in \mathbf{Z}^+,\ A^2 P_0^\pm x = P_0^\pm A^2 x,$

(ii) $A^2 P_0^+ x = 0,$

(iii) $A^2 P_0^- x = 0,$

(iv) $A^2 P_k x = -k^2 P_k x,\ k \in \mathbf{Z}^+.$

Proof. Result (i) follows immediately from the fact that r_θ and s commute with A^2, which follows from (2.7). We prove parts (ii) and (iii) together. Now

$$P_0^\pm = \frac{1}{4\pi}\int_0^{2\pi} r_\theta d\theta \pm \frac{1}{4\pi}\int_0^{2\pi} s r_\theta d\theta,$$

since $n_0^\pm = d_0^\pm = 1$, $\chi_0^\pm(r_\theta) = 1$, and $\chi_0^\pm(sr_\theta) = \pm 1$. Thus,

$$A^2 P_0^\pm = \frac{1}{4\pi}\int_0^{2\pi} A^2 r_\theta \pm A^2 s r_\theta d\theta$$

$$= \frac{1}{4\pi}\int_0^{2\pi} A^2 r_\theta \pm s A^2 r_\theta d\theta,$$

since A^2 commutes with s. From (2.7), we have

$$\frac{dr_\theta}{d\theta} = A r_\theta$$

and so

$$\frac{d^2 r_\theta}{d\theta^2} = A\frac{dr_\theta}{d\theta} = A^2 r_\theta.$$

Therefore,

$$A^2 P_0^\pm = \frac{1}{4\pi}\int_0^{2\pi} \left(\frac{d^2 r_\theta}{d\theta^2} \pm s\frac{d^2 r_\theta}{d\theta^2} \right) d\theta$$

$$= \frac{1}{4\pi}\left[\frac{dr_\theta}{d\theta} \pm s\frac{dr_\theta}{d\theta} \right]_0^{2\pi}$$

$$= 0$$

as required, since $\frac{dr_\theta}{d\theta}\,|_{\theta=2\pi} = \frac{dr_\theta}{d\theta}\,|_{\theta=0}$ $(= A)$.

Similarly, for part (iv) we have for $k \in \mathbf{Z}^+$ that

$$P_k = \frac{2}{4\pi}\left[\int_0^{2\pi} 2\cos k\theta\, r_\theta d\theta + \int_0^{2\pi} 0.s r_\theta d\theta \right]$$

$$= \frac{1}{\pi}\int_0^{2\pi} \cos k\theta\, r_\theta d\theta$$

and so

$$A^2 P_k = \frac{1}{\pi}\int_0^{2\pi} \cos k\theta \; A^2 r_\theta d\theta$$

$$= \frac{1}{\pi}\int_0^{2\pi} \cos k\theta \; \frac{d^2 r_\theta}{d\theta^2} d\theta$$

$$= -\frac{k^2}{\pi}\int_0^{2\pi} \cos k\theta \; r_\theta d\theta$$

$$= -k^2 P_k$$

using integration by parts twice. □

COROLLARY 2.5. *The only possible eigenvalues of* A^2 *are* 0 *and* $-k^2$ *for some* $k \in \mathbf{Z}^+$.

We can now establish the link between the eigenspaces of A^2 and the isotypic components of X in the following result.

THEOREM 2.6. *Let the isotypic components of* X *be* $V_0^{\pm} = P_0^{\pm} X$ *and* $V_k = P_k X$, $k \in \mathbf{Z}^+$. *Then*

(i) $E_0 = V_0^+ \oplus V_0^-$,

(ii) $E_{-k^2} = V_k$, $k \in \mathbf{Z}^+$.

Proof. (i) If $x \in V_0^{\pm}$, then $P_0^{\pm} x = x$ and so $A^2 x = 0$ by Theorem 2.4 (ii) and (iii), thus giving $V_0^+ \oplus V_0^- \subseteq E_0$. Conversely, suppose that $x \in E_0$, i.e., $A^2 x = 0$. Then for $k \in \mathbf{Z}^+$,

$$0 = P_k A^2 x = A^2 P_k x = -k^2 P_k x$$

by Theorem 2.4 (i), (iv), giving $P_k x = 0$ since $k \neq 0$. Thus, $x \in V_0^+ \oplus V_0^-$ since it has no component in any of the isotypic components V_k for $k \in \mathbf{Z}^+$. Therefore, $E_0 \subseteq V_0^+ \oplus V_0^-$. We thus conclude that $E_0 = V_0^+ \oplus V_0^-$.

(ii) As for part (i), if $x \in V_k$, then $P_k x = x$ and so $A^2 x = -k^2 x$ by Theorem 2.4 (iv), thus giving $V_k \subseteq E_{-k^2}$. Conversely, suppose that $x \in E_{-k^2}$. Then $A^2 x = -k^2 x$, so

$$-k^2 P_0^{\pm} x = P_0^{\pm} A^2 x = A^2 P_0^{\pm} x = 0$$

by Theorem 2.4 (i), (ii), and (iii), giving $P_0^{\pm} x = 0$ since $k \neq 0$. Similarly, for some $j \in \mathbf{Z}^+$,

$$-k^2 P_j x = P_j A^2 x = A^2 P_j x = -j^2 P_j x.$$

Thus, $P_j x = 0$ if $j \neq k$. Combining these results, we conclude that $x \in V_k$ and so $E_{-k^2} \subseteq V_k$. Thus, $V_k = E_{-k^2}$ as required.

Finally, by Theorem 3.3 of [1], the isotypic components V_k, $k \in \mathbf{Z}^+$ can be decomposed into symmetric and antisymmetric parts as

$$V_k = V_k^s \oplus V_k^a$$

with the property that $g_x(x, \lambda) : V_k^s \to V_k^s$ and $g_x(x, \lambda) : V_k^a \longrightarrow V_k^a$. This agrees with the decompositions of the B_k block into two blocks that act on the symmetric and antisymmetric subspaces. □

The numerical consequences of this block diagonalisation of the Jacobian are considered in the next section.

3. The Hopf bifurcation. Suppose that $(0, \lambda_0)$ is a Hopf bifurcation point at which

$$X_{\omega_0} := \text{Null}\{(g_x^0)^2 + \omega_0^2 I\} \neq 0, \quad \omega_0 \neq 0, \tag{3.1}$$

where $g_x^0 := g_x(0, \lambda_0)$. By [7, Chap. XVI, Prop. 1.4], generically X_{ω_0} is $O(2)$-simple. Since all the irreducible representations of $O(2)$ are absolutely irreducible, this implies that, generically

$$X_{\omega_0} = W_1 \oplus W_2, \tag{3.2}$$

where W_1 and W_2 are absolutely irreducible subspaces of X that are $O(2)$-isomorphic. We assume henceforth that (3.2) holds. Note that since W_1 and W_2 are isomorphic, their representations are equivalent. Hence, they are contained in the same isotypic component of the Hilbert space. As a result they are, by Theorem 2.6, also contained in the same eigenspace of A^2. However, we also assume that

$$X_{\omega_0} \cap E_0 = \{0\},$$

since the converse does not lead to (nontrivial) rotating wave solutions. This follows because $g : E_0 \times \mathbf{R} \to E_0$; thus any bifurcating periodic orbit remains in E_0 so that if it is a rotating wave solution, it must be a trivial one in the sense that $r_{ct}x = x$ for all time t. By Theorem 2.6, this excludes consideration of the isotypic components associated with the two one-dimensional irreducible representations and so (3.2) implies that dim $X_{\omega_0} = 4$, since W_1 and W_2 must have dimension 2, as they are irreducible.

When (3.1) and (3.2) hold, this clearly corresponds to a matrix block J_k in the decomposition (2.14b) having simple eigenvalues $\pm i\omega$ for some $k \in \mathbf{Z}^+$. It then follows from the choice of basis (2.13), which gives rise to the decomposition (2.14b), that

$$X_{\omega_0}^s := X_{\omega_0} \cap X_s = \text{span}\{\phi_1, \phi_2\},$$

where ϕ_1 and ϕ_2 satisfy

$$g_x^0 \phi_1 + \omega_0 \phi_2 = 0, \tag{3.3a}$$

$$g_x^0 \phi_2 - \omega_0 \phi_1 = 0. \tag{3.3b}$$

These equations are the real and imaginary parts of the complex eigenvalue equation. Since g_x^0 commutes with A (see (2.10)) and $A : X_s \to X_a$, it follows immediately from these equations that

$$X_{\omega_0}^a := X_{\omega_0} \cap X_a = \text{span}\{A\phi_1, A\phi_2\}.$$

This is not suprising in view of the choice of basis (2.13b) of $E_{\alpha_k}^a$. Clearly, $X_{\omega_0} = X_{\omega_0}^s \oplus X_{\omega_0}^a$.

In the next lemma, we highlight the relationship between the subspaces

$$X_{c_0}^{\pm} := \text{Null}\{g_x^0 \pm c_0 A\} \tag{3.4}$$

and the eigenspace X_{ω_0}.

LEMMA 3.1. *Suppose that $X_{\omega_0} \subset E_{-k_0^2}$ for some $k_0 \in \mathbf{Z}^+$. Then*

$$X_{\omega_0} = X_{c_0}^+ \oplus X_{c_0}^-,$$

where $c_0 = \omega_0/k_0$. *Moreover, there exists a* $\phi_0 \in X_{\omega_0}\backslash\{0\}$ *such that*

$$X^+_{c_0} = \text{span}\{\phi_0,\ A\phi_0\}, \tag{3.5a}$$

$$X^-_{c_0} = \text{span}\{S\phi_0,\ SA\phi_0\}. \tag{3.5b}$$

Proof. This result is based on the careful choice of ϕ_0. The appropriate function is

$$\phi_0 = k_0\phi_1 - A\phi_2, \tag{3.6}$$

where ϕ_1 and ϕ_2 are the eigenfunctions in $X^s_{\omega_0}$. Note that $\phi_1 \in X_s$ and $A\phi_2 \in X_a$ and so ϕ_0 is neither symmetric nor antisymmetric. Then,

$$\begin{aligned}(g^0_x + c_0A)\phi_0 &= (g^0_x + c_0A)(k_0\phi_1 - A\phi_2)\\ &= k_0g^0_x\phi_1 - g^0_xA\phi_2 + c_0k_0A\phi_1 - c_0A^2\phi_2\\ &= k_0g^0_x\phi_1 - Ag^0_x\phi_2 + c_0k_0A\phi_1 + c_0k_0^2\phi_2\\ &= -k_0\omega_0\phi_2 - \omega_0A\phi_1 + c_0k_0A\phi_1 + c_0k_0^2\phi_2\\ &= (c_0k_0 - \omega_0)(A\phi_1 + k_0\phi_2)\\ &= k_0^{-1}(c_0k_0 - \omega_0)A\phi_0,\end{aligned}$$

using the fact that g^0_x commutes with A (see (2.10)), the relation $A^2\phi_2 = -k_0^2\phi_2$, since $\phi_2 \in E_{-k_0^2}$ and the eigenvalue equations (3.3). Thus,

$$\phi_0 \in X^+_{c_0} \iff c_0 = \omega_0/k_0.$$

Given $\phi_0 \in X^+_{c_0}$, it follows immediately that $A\phi_0 \in X^+_{c_0}$ since A commutes with g^0_x and it is easily verified that ϕ_0 and $A\phi_0$ are linearly independent.

Finally, for any $\phi \in X^+_{c_0}$, $S\phi \in X^-_{c_0}$, since S commutes with g^0_x but anticommutes with A (see (2.7)). □

The block structure described in the previous section clearly has important numerical implications with regard to the detection and computation of the Hopf bifurcation points we are considering. Generally, in a discretised system of dimension N, the detection of a Hopf bifurcation requires the computation of *all* the eigenvalues of the nonsymmetric $N \times N$ Jacobian matrix, which requires $O(N^3)$ operations. For large N, this is often prohibitively expensive. However, in the situation we are considering, it is possible for any of the blocks J_k in the decomposition (2.14) to have imaginary eigenvalues. Hence, we need only compute the eigenvalues of the blocks J_k that are much smaller than the whole of the Jacobian matrix, thus reducing the computational expense considerably. The most efficient procedure for detecting a Hopf bifurcation is thus to construct each block J_k on the space $V_k \cap X_s$, where V_k is one of the isotypic components of the space X and apply standard methods for detecting Hopf bifurcations to this block. Also, each block depends only on the $O(2)$-symmetric solution and is independent of the other blocks. The computation of the eigenvalues of each block can therefore be performed in parallel, thus reducing the computational expense still further.

Once the Hopf bifurcation has been detected, standard methods can again be applied using the block J_k to compute the bifurcation point accurately [9].

4. The rotating waves. It follows immediately from the equivariance condition (2.2), that if (x, c, λ) is a rotating wave solution of (2.5), then so is $(r_\alpha x, c, \lambda)$ for all $\alpha \in [0, 2\pi)$,

giving rise to an *orbit* of solutions. To isolate a point on this orbit, a phase condition can be imposed to give the system

$$F(x, c, \lambda) := \begin{bmatrix} g(x, \lambda) + cAx \\ \langle \ell, x \rangle \end{bmatrix} = 0 \tag{4.1}$$

for some appropriate choice of $\ell \in X$ (see [2]). However, this extended system has a singular Jacobian at the Hopf bifurcation point and so is not the best choice when computing the bifurcating branch of rotating wave solutions. Adopting an idea in [4] we introduce the following extended system for the computation of rotating waves near the Hopf bifurcation point with $x = \epsilon\tilde{x}$

$$G(y, \epsilon) = 0, \quad G : Y \times \mathbf{R} \to Y,$$

$$G(y, \epsilon) := \begin{bmatrix} \epsilon^{-1} g(\epsilon\tilde{x}, \lambda) + cA\tilde{x} \\ \langle \ell_a, \tilde{x} \rangle \\ \langle \ell_s, \tilde{x} \rangle - 1 \end{bmatrix}, \quad \epsilon \neq 0, \tag{4.2a}$$

$$G(y, 0) := \begin{bmatrix} g_x(0, \lambda)\tilde{x} + cA\tilde{x} \\ \langle \ell_a, \tilde{x} \rangle \\ \langle \ell_s, \tilde{x} \rangle - 1 \end{bmatrix}, \quad \epsilon = 0, \tag{4.2b}$$

$$y = (\tilde{x}, c, \lambda) \in Y := X \times \mathbf{R}^2,$$

where $\ell_s \in X_s$ and $\ell_a \in X_a$. This system necessarily involves the velocity c. However, once the Hopf bifurcation has been detected, the initial velocity c_0 is known from Lemma 3.1.

For the next result, we require the left eigenvectors of $g_x^0 + c_0 A$, so we define

$$\text{Range}(g_x^0 + c_0 A) := \{x \in X, \ \psi_1 x = \psi_2 x = 0\}.$$

THEOREM 4.1. *Let $(x, \lambda) = (0, \lambda_0)$ be a Hopf bifurcation point at which $X_{\omega_0} \subset E_{-k_0^2}$ for some $k_0 \in \mathbf{Z}^+$ and let $y_0 = (\phi_0, c_0, \lambda_0)$, where ϕ_0 and c_0 are defined in Lemma* 3.1. *Choose $\ell_s \in X_s$ and $\ell_a \in X_a$ such that $G(y_0, 0) = 0$ and*

$$\langle \ell_a, A\phi_1 \rangle \neq 0, \tag{4.3}$$

where ϕ_1 is defined by (3.3). *If the nondegeneracy condition*

$$\begin{vmatrix} \langle \psi_1, A\phi_0 \rangle & \langle \psi_1, g_{x\lambda}^0 \phi_0 \rangle \\ \langle \psi_2, A\phi_0 \rangle & \langle \psi_2, g_{x\lambda}^0 \phi_0 \rangle \end{vmatrix} \neq 0 \tag{4.4}$$

holds, then $G_y^0 := G_y(y_0, 0)$ is nonsingular and hence, there exists a unique solution path $(y(\epsilon), \epsilon)$ of (4.2) *in $Y \times \mathbf{R}$.*

Proof. The Jacobian of the system (4.2) is given by

$$G_y(y, \epsilon) = \begin{bmatrix} g_x(\epsilon\tilde{x}, \lambda) + cA & A\tilde{x} & \frac{1}{\epsilon} g_\lambda(\epsilon\tilde{x}, \lambda) \\ \langle \ell_a, \cdot \rangle & 0 & 0 \\ \langle \ell_s, \cdot \rangle & 0 & 0 \end{bmatrix}.$$

Let $\Phi := (\alpha, \beta, \delta) \in Y$ satisfy

$$G_y^0 \Phi = 0. \tag{4.5}$$

Then the first equation of this system is

$$(g_x^0 + c_0 A)\alpha + \beta A\phi_0 + \delta g_{x\lambda}^0 \phi_0 = 0, \tag{4.6}$$

where $g_x^0 := g_x(0, \lambda_0)$, etc., since $\lim_{\epsilon \to 0} \frac{1}{\epsilon} g_\lambda(\epsilon\tilde{x}, \lambda) = g_{x\lambda}(0, \lambda)\tilde{x}$. Taking the inner product of this expression with ψ_1 and ψ_2 gives the two equations

$$\begin{bmatrix} \langle \psi_1, A\phi_0 \rangle & \langle \psi_1, g_{x\lambda}^0 \phi_0 \rangle \\ \langle \psi_2, A\phi_0 \rangle & \langle \psi_2, g_{x\lambda}^0 \phi_0 \rangle \end{bmatrix} \begin{bmatrix} \beta \\ \delta \end{bmatrix} = 0.$$

The nondegeneracy condition (4.4) then implies that $\beta = \delta = 0$. Thus, from (4.6) and (3.5a),

$$\alpha = \mu\phi_0 + \eta A\phi_0,$$

where $\mu, \eta \in \mathbf{R}$. Using the form of ϕ_0 given in (3.6), it is easily verified that $A\phi_0 = k_0(A\phi_1 + k_0\phi_2)$. Thus,

$$\alpha = k_0(\mu\phi_1 + \eta k_0 \phi_2) + (\eta k_0 A\phi_1 - \mu A\phi_2). \tag{4.7}$$

The first term of (4.7) is in X_s and the second term is in X_a, since $\phi_1, \phi_2 \in X_s$ and $A : X_s \to X_a$. The second and third equations of (4.5) are, therefore,

$$\begin{bmatrix} -\langle \ell_a, A\phi_2 \rangle & \langle \ell_a, k_0 A\phi_1 \rangle \\ \langle \ell_s, k_0\phi_1 \rangle & \langle \ell_s, k_0^2 \phi_2 \rangle \end{bmatrix} \begin{bmatrix} \mu \\ \eta \end{bmatrix} = 0.$$

Now $G(y_0, 0) = 0$ and this implies that $\langle \ell_a, \phi_0 \rangle = 0$ and $\langle \ell_s, \phi_0 \rangle = 1$, which in turn imply that $\langle \ell_a, A\phi_2 \rangle = 0$ and $\langle \ell_s, \phi_1 \rangle = 1$. Thus, the above matrix is nonsingular if and only if the nondegeneracy condition (4.3) holds, giving $\mu = \eta = 0$ and hence $\alpha = 0$ as well. Thus, $\Phi = 0$ and G_y^0 is nonsingular. The Implicit Function Theorem can then be applied to give the existence and uniqueness of the path of solutions $(y(\epsilon), \epsilon)$ of (4.2). □

Differentiating $G(y(\epsilon), \epsilon) = 0$ with respect to ϵ and evaluating at $\epsilon = 0$ gives

$$G_y^0 \dot{y}_0 + G_\epsilon^0 = 0, \tag{4.8}$$

where $G_\epsilon^0 := G_\epsilon(y_0, 0) = (\frac{1}{2} g_{xx}^0 \phi_0 \phi_0, 0, 0)^T$ and $\dot{y}_0 := \frac{dy(\epsilon)}{d\epsilon} |_{\epsilon=0}$. This equation can be solved for the tangent vector $\dot{y}_0$ to the path of rotating wave solutions, which can be used in continuation codes for starting out along the branch of solutions. Once the initial part of the branch has been followed, the rotating wave solutions could then be continued using the slightly smaller system (4.1) with $\ell = \ell_a$ if required.

It is possible to define a reflectional symmetry on the system (4.2). To see this, let

$$S \begin{bmatrix} \tilde{x} \\ c \\ \lambda \end{bmatrix} = \begin{bmatrix} s\tilde{x} \\ -c \\ \lambda \end{bmatrix}.$$

Then it is easily verified that

$$SG(y, \epsilon) = G(Sy, \epsilon)$$

using the invariance property (2.4) of the inner product. An immediate consequence of this property is that, for any value of ϵ, if $(\tilde{x}, c, \lambda)$ is a solution of (4.2), then $(s\tilde{x}, -c, \lambda)$ is also a solution. This new solution simply consists of a reflected wave rotating in the opposite direction.

Now we consider the symmetry properties of the rotating wave solutions. They clearly do not have the reflectional symmetry s. However, the isotypic component V_k is contained in the fixed point space X^{Z_k}, where Z_k is the cyclic group generated by $r_{2\pi/k}$. Thus, if $X_{\omega_0} \subset V_k$ for some k, then Theorem 4.1 holds restricting attention to the space $Y_k := X^{Z_k} \times \mathbf{R}^2$, resulting in a branch of solutions that are invariant under $r_{2\pi/k}$.

Finally, we show that the nondegeneracy condition (4.4) is essentially an eigenvalue crossing condition. For this, we assume that

$$X_{c_0}^{+} \cap \text{Range}(g_x^0 + c_0 A) = \{0\}. \tag{4.9}$$

Since ϕ_0 and $A\phi_0$ are basis vectors for $X_{c_0}^{+}$, this condition is equivalent to

$$\begin{vmatrix} \langle \psi_1, \phi_0 \rangle & \langle \psi_1, A\phi_0 \rangle \\ \langle \psi_2, \phi_0 \rangle & \langle \psi_2, A\phi_0 \rangle \end{vmatrix} \neq 0. \tag{4.10}$$

THEOREM 4.2. *Let $\sigma(\lambda) \pm i\omega(\lambda)$ be eigenvalues of $g_x(0, \lambda)$ satisfying $\sigma_0 := \sigma(\lambda_0) = 0$. If (4.9) holds, then the nondegeneracy condition (4.4) is satisfied if and only if $\dot{\sigma}_0 := \frac{d\sigma(\lambda)}{d\lambda}|_{\lambda=0} \neq 0$.*

Proof. Equating the real and imaginary parts of the eigenvalue equation gives

$$g_x(0, \lambda)\phi_1(\lambda) = \sigma(\lambda)\phi_1(\lambda) - \omega(\lambda)\phi_2(\lambda),$$

$$g_x(0, \lambda)\phi_2(\lambda) = \sigma(\lambda)\phi_2(\lambda) + \omega(\lambda)\phi_1(\lambda).$$

Differentiating these relations with respect to λ and setting $\lambda = 0$ gives

$$g_{x\lambda}^0\phi_1 + g_x^0\dot{\phi}_1 = \dot{\sigma}_0\phi_1 - \dot{\omega}_0\phi_2 - \omega_0\dot{\phi}_2, \tag{4.11a}$$

$$g_{x\lambda}^0\phi_2 + g_x^0\dot{\phi}_2 = \dot{\sigma}_0\phi_2 + \dot{\omega}_0\phi_1 + \omega_0\dot{\phi}_1. \tag{4.11b}$$

In order to introduce $\phi_0 = k_0\phi_1 - A\phi_2$, we multiply the first equation by k_0, operate on the second with A, and then add the two giving

$$g_{x\lambda}^0\phi_0 + g_x^0\dot{\phi}_0 = \dot{\sigma}_0\phi_0 - \frac{\dot{\omega}_0}{k_0}A\phi_0 - \frac{\omega_0}{k_0}A\dot{\phi}_0,$$

since $g_{x\lambda}^0$ commutes with A and $A\phi_0 = k_0(A\phi_1 + k_0\phi_2)$. Now $\omega_0 = c_0k_0$ by Lemma 3.1, so

$$g_{x\lambda}^0 + (g_x^0 + c_0A)\dot{\phi}_0 = \dot{\sigma}_0\phi_0 - \frac{\dot{\omega}_0}{k_0}A\phi_0.$$

Taking the inner product of this expression with ψ_j, $j = 1, 2$ gives

$$\langle \psi_j, \phi_0 \rangle \dot{\sigma}_0 - \frac{\dot{\omega}_0}{k}\langle \psi_j, A\phi_0 \rangle = \langle \psi_j, g_{x\lambda}^0\phi_0 \rangle,$$

which is two equations to be solved for $\dot{\sigma}_0$ and $\dot{\omega}_0$ giving

$$\dot{\sigma}_0 = \begin{vmatrix} \langle \psi_1, A\phi_0 \rangle & \langle \psi_1, g_{x\lambda}^0\phi_0 \rangle \\ \langle \psi_2, A\phi_0 \rangle & \langle \psi_2, g_{x\lambda}^0\phi_0 \rangle \end{vmatrix} \Big/ \begin{vmatrix} \langle \psi_1, \phi_0 \rangle & \langle \psi_1, A\phi_0 \rangle \\ \langle \psi_2, \phi_0 \rangle & \langle \psi_2, A\phi_0 \rangle \end{vmatrix}.$$

Because (4.9) holds, (4.10) also holds so that the denominator of this expression is nonzero. Thus, $\dot{\sigma}_0 \neq 0$ if and only if the numerator is nonzero, which is precisely condition (4.4). □

The condition $\dot{\sigma}_0 \neq 0$ in Theorem 4.2 is, of course, the familiar condition that the complex conjugate eigenvalues must actually *cross* the imaginary axis as λ passes through the Hopf bifurcation point at λ_0 so that a stable trivial solution loses stability at a Hopf bifurcation point.

5. Extension to infinite dimensions. In this section, we generalize our results to an infinite-dimensional case (cf. §6 of [2]). This enables us to deal with partial differential equations directly.

We assume that g is a C^2 mapping from $\tilde{X} \times \mathbf{R}$ into X, where $\tilde{X}$ and X are both real Hilbert spaces with $\tilde{X} \subset X$. We also assume that g_x is a Fredholm operator of index zero. We suppose that there is an action of $O(2)$ on X that is strongly continuous and that $\tilde{X}$ is an $O(2)$-invariant subspace of X, i.e., $\gamma x \in \tilde{X}, \forall \gamma \in O(2),\ x \in \tilde{X}$. The equivariance condition (2.2) then holds. We also assume that if $x \in \tilde{X}$, then $Ax \in X$, so that (2.5) defines a mapping from $\tilde{X} \times \mathbf{R}$ into X. Finally, we assume that the decomposition of X into eigenspaces of A^2 takes the form of an infinite sum of the finite-dimensional subspaces E_{-k^2}, $k = 0, 1, 2, \ldots$. This decomposition then gives a natural decomposition of $\tilde{X}$ also. All the results of the previous sections then hold for the infinite-dimensional case with minor changes.

6. Numerical results. We now apply the theory to a practical example. We consider the coupled pair of reaction-diffusion equations known as the Sel'kov model [6]:

$$u_t = d_1 u_{xx} + 1 - uv^2,$$
$$v_t = d_2 v_{xx} + p(uv^2 - v),$$

which we write in more general form as

$$U_t = G(U, d_1) = DU_{xx} + F(U),$$

where $U = \binom{u}{v}$, D is the diagonal matrix of diffusion coefficients, and $F(U)$ is the nonlinear reaction terms. We choose the diffusion coefficient d_1 as our bifurcation parameter. Let H^m be the Hilbert space of 2π-periodic functions whose derivatives up to and including the mth are square integrable, with inner product

$$\langle u, v \rangle_{H^m} := \frac{1}{2\pi} \int_0^{2\pi} u^{(m)}(x) v^{(m)}(x) + u(x)v(x)\, dx.$$

Then $G : H^2 \times H^2 \times \mathbf{R} \longrightarrow H^0 \times H^0$. We define an action of $O(2)$ on H^0 by

$$r_\alpha u(x) = u(x + \alpha), \quad \alpha \in [0, 2\pi), \quad su(x) = u(-x). \tag{6.1}$$

For this action, the inner product on H^m is $O(2)$-invariant and H^2 is an invariant subspace of H^0. Also G is equivariant with repect to the diagonal action on $H^0 \times H^0$ defined by

$$\gamma \begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} \gamma u \\ \gamma v \end{pmatrix} \quad \forall \gamma \in O(2).$$

In this example, the linear operator A has the form

$$A \begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} u_x \\ v_x \end{pmatrix} \tag{6.2}$$

and the eigenspaces of A^2 are

$$E_{-k^2} = (\text{span}\{\cos kx,\ \sin kx\})^2,\quad k \neq 0,$$

$$E_0 = (\text{span}\{1\})^2.$$

Clearly, the eigenspaces E_{-k^2} are four-dimensional for $k \neq 0$, giving rise to 4×4 blocks B_k in the decomposition of the Jacobian given by (2.14a). These blocks then decompose into 2×2 blocks (as in (2.14b)) on the symmetric and antisymmetric parts of the eigenspace E_{-k^2}. Using the definition of the reflectional symmetry s in (6.1), the symmetric subspace involves only the cosine functions, whereas the antisymmetric subspace involves only the sine functions. Thus, we know precisely the spaces that give rise to the block decomposition of the Jacobian.

As an example, we choose $d_2 = 4$, $p = 6$ and there is then a Hopf bifurcation from the trivial solution $u = v = 1$ at $d_1 = 1$ associated with the E_{-1} eigenspace for which $\omega_0 = c_0 = \sqrt{8}$. The symmetric eigenfunctions ϕ_1 and ϕ_2 at this point are given by

$$\phi_1 = \begin{pmatrix} (1+\sqrt{2})\cos x \\ 3\cos x \end{pmatrix}, \quad \phi_2 = \begin{pmatrix} (\sqrt{2}-1)\cos x \\ 3\cos x \end{pmatrix}.$$

With the linear operator A defined by (6.2), the corresponding antisymmetric eigenfunctions $A\phi_1$ and $A\phi_2$ are obtained from ϕ_1 and ϕ_2 by replacing $\cos x$ with $-\sin x$. The standing waves which bifurcate at this point can be computed by restricting attention to the subspace of symmetric functions (involving only the cosine functions) on which the Hopf bifurcation is standard. The usual methods can then be employed for switching onto the branch of standing waves. For computing the travelling waves, however, we require the function ϕ_0 defined by (3.6), which, for this example, is given by

$$\phi_0 = \begin{pmatrix} (1+\sqrt{2})\cos x + (\sqrt{2}-1)\sin x \\ 3(\cos x + \sin x) \end{pmatrix}.$$

By Theorem 4.1, we must choose the fixed vectors ℓ_s and ℓ_a so that they satisfy certain conditions. All these conditions are satisfied with

$$\ell_s = \begin{pmatrix} 0 \\ \frac{1}{3}\cos x \end{pmatrix}, \quad \ell_a = \begin{pmatrix} \sin x \\ \frac{1-\sqrt{2}}{3}\sin x \end{pmatrix}.$$

The system (4.2) can then be used to compute the branch of travelling waves.

The standing waves and travelling waves that bifurcate from the Hopf bifurcation point are shown in Fig. 1. The results are shown in terms of $\|U\|_2$, where U is defined by

$$U = \begin{pmatrix} u-1 \\ v-1 \end{pmatrix}$$

so that the trivial solution is $U = 0$. Figure 2 shows the variation in the velocity of the travelling waves along the branch together with the frequency of the standing waves.

Finally, we remark that the type of Hopf bifurcation we are considering will not occur generically in a single equation because the eigenspaces E_{-k^2} are then only two-dimensional. This is not sufficient to satisfy the generic condition (3.2), which requires a four-dimensional eigenspace of g_x^0 contained in E_{-k^2}. However, bifurcations to rotating wave solutions from nontrivial steady states are possible in this case, as in the Kuramoto–Sivashinsky equation (see [2]).

ERROR-MINIMIZING KRYLOV SUBSPACE METHODS*

RÜDIGER WEISS†

Abstract. Iterative methods for the solution of linear systems are usually controlled by the observation of the norm of the residual. In reality, the error should be controlled, but the error is not available. The residuals and the errors are connected by the condition number of the system matrix. If the system is well conditioned, the decrease of the errors is closely connected to the decrease of the residuals. For these cases, Krylov subspace methods that minimize the residuals in the Euclidean norm or in the energy norm are powerful solution techniques. If the system is ill conditioned, the residuals can decrease while the errors increase. For these systems, arising even from very simple and commonly used differential equations, iterative methods that minimize the residuals may require a large number of iterations to reduce the errors. The user may be misled to stop the iteration too early by small residuals. Two families of error-minimizing Krylov subspace methods are proposed to overcome these difficulties. Each of them is suited for different problem types.

Principles for the design of generalized cg methods that minimize the error are derived from the geometric convergence behavior of generalized cg methods. These methods use the transposed system matrix multiplied by the system matrix as the iteration matrix. By this technique a fast convergence is achieved for matrices with clustered singular values and scattered eigenvalues.

A class of Krylov subspace methods minimizing the error by using the simple transposed matrix as the iteration matrix is proposed. Various realization possibilities are inherent in these generalized minimum error methods. The methods are analyzed theoretically. Common and related properties with generalized conjugate gradient methods are presented. These techniques should be preferred if the eigenvalues are more clustered than the singular values. The first promising tests for one distinct method are presented.

AMS subject classifications. 65F10, 65F50, 40A05

1. Background.

The purpose of this paper is to present error-minimizing Krylov subspace methods for the solution of the linear system

$$Ax = b. \tag{1}$$

The matrix A is a real, square matrix of dimension n, i.e., $A \in \mathbb{R}^{n\times n}$, and $x, b \in \mathbb{R}^n$. In general, the matrix A is nonsymmetric and nonpositive definite. Let us assume A to be nonsingular.

We use the following notation for norms: Let Z be a symmetric, positive definite matrix; then the norm $||y||_Z$ of any vector $y \in \mathbb{R}^n$ is defined by $||y||_Z = \sqrt{y^T Z y}$. If Z is nonsymmetric and nonpositive definite, then $||y||_Z^2$ is mnemonic abbreviation for $y^T Z y$. $||y||_I$ is the Euclidean norm $||y||$.

Let $K_k(B, y) = \text{span}(y, By, \ldots, B^k y)$ be the Krylov space spanned by the matrix $B \in \mathbb{R}^{n\times n}$ and the vector $y \in \mathbb{R}^n$.

For any iterative method for the solution of (1) the residuals $r_k = Ax_k - b$ and the errors $e_k = x_k - x$ are connected by

$$r_k = Ae_k. \tag{2}$$

As a result of $||r_k|| = ||Ae_k|| \le ||A|| \cdot ||e_k||$ and $||e_k|| = ||A^{-1}r_k|| \le ||A^{-1}|| \cdot ||r_k||$, the following inequalities are valid:

$$\frac{1}{\kappa}\frac{||r_k||}{||r_0||} \le \frac{||e_k||}{||e_0||} \le \kappa\frac{||r_k||}{||r_0||} \le \kappa^2\frac{||e_k||}{||e_0||}, \tag{3}$$

*Received by the editors September 24, 1992; accepted for publication (in revised form) March 26, 1993.

†Numerikforschung für Supercomputer, Rechenzentrum der Universität Karlsruhe, Postfach 6980, 76128 Karlsruhe, Germany (weiss@rz.uni-karlsruhe.de).

where $\kappa = ||A|| \cdot ||A^{-1}||$ is the condition number of A. If κ is near to one, the norm of the relative residuals is strongly connected to the norm of the relative errors. In other words, if the residuals decrease sufficiently the errors will be reduced as well. For a large condition number the residuals can decrease while the norm of the errors either remains the same or even increases.

The next example shows that a separation of the norm of the errors from the norm of the residuals happens even for very simple and commonly used systems.

Example 1. Solve the following linear system resulting from the discretization of a one-dimensional Laplace equation:

$$\begin{pmatrix} 2 & -1 & 0 & \dots & 0 \\ -1 & \ddots & \ddots & \ddots & \vdots \\ 0 & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & -1 \\ 0 & \dots & 0 & -1 & 2 \end{pmatrix} \cdot x = \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix}.$$

The matrix has the eigenvalues $\lambda_k = 2 \cdot (1 - \cos \frac{k\pi}{n+1})$, where n is the dimension of the system and $1 \leq k \leq n$. Because the matrix is symmetric, the condition number is

$$\kappa = \frac{|\lambda_{\max}|}{|\lambda_{\min}|} = \frac{1 + \cos \frac{\pi}{n+1}}{1 - \cos \frac{\pi}{n+1}}.$$

The dimension of the system is 1000, resulting in a large condition number of approximately $4 \cdot 10^5$. The system was solved by the classical conjugate gradient (cg) method [8] and the GMRES method [11]. The starting guess is $x_0 = 0$. Figure 1 shows that the residuals decrease while the errors do not decrease for either method until 500 matrix-vector multiplications have been performed.

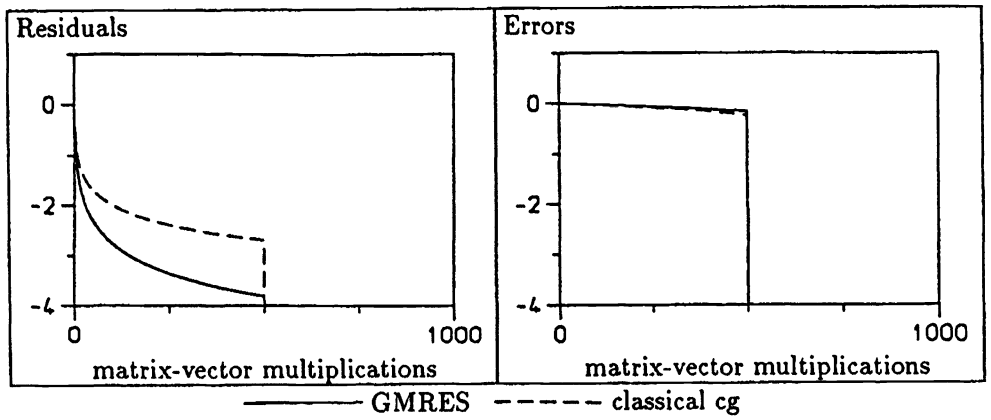

FIG. 1. *Norm of the relative residuals and errors of* GMRES *and classical cg (logarithmic scale).*

In the following sections we propose two remedies in order to obtain error-minimizing methods. The first technique is based on the iteration matrix $A^T A$ and generalized cg methods. The second technique uses the iteration matrix A^T and is a generalized Krylov subspace method.

2. Generalized conjugate gradient methods.

DEFINITION 1. *Let x_0 be any initial guess for the solution of the system $Ax = b$, $r_0 = Ax_0 - b$ the starting residual. The following recurrence is called a generalized cg method. Choose a preconditioning matrix P and calculate for $k \geq 1$ the residuals r_k and approximations x_k so that*

$$x_k \in x_0 + K_{k-1}(PA, Pr_0), \text{ with} \tag{4}$$

$$r_k^T Z r_{k-i} = 0 \tag{5}$$

for $i = 1, \ldots, \sigma_k$, where Z is an auxiliary, nonsingular matrix.

The method is called exact *if $\sigma_k = k$,* restarted *if $\sigma_k = (k-1) \bmod \sigma_{\text{res}} + 1$ with σ_{res} fixed,* truncated *if $\sigma_k = \min(k, \sigma_{\max})$ with $\sigma_{\max}$ fixed, and* combined *if the truncated method is restarted.*

From Definition 1 it follows directly for the residuals r_k and the errors $e_k = x_k - x$ that

$$r_k = \tilde{\Pi}_k(AP)r_0 = \sum_{i=1}^{k} \nu_{i,k}(AP)^i r_0 + r_0, \tag{6}$$

$$e_k = \tilde{\Pi}_k(PA)e_0 = \sum_{i=1}^{k} \nu_{i,k}(PA)^i e_0 + e_0, \tag{7}$$

where $\tilde{\Pi}_k$ is a polynomial of degree k with constant coefficient 1, i.e., $\tilde{\Pi}_k(0) = 1$.

If $Z = \bar{Z}AP$ and $\bar{Z}$ is symmetric, positive definite, then for exact and restarted methods (5) is equivalent to

$$\|r_k\|_{\bar{Z}} = \min_{\mu_{1,k},\ldots,\mu_{\sigma_k,k}} \left\| \sum_{i=1}^{\sigma_k} \mu_{i,k}(AP)^i r_{k-\sigma_k} + r_{k-\sigma_k} \right\|_{\bar{Z}}. \tag{8}$$

In this case the methods are called conjugate residual type methods or minimum residual methods.

If Z is symmetric, positive definite, then for exact and restarted methods (5) is equivalent to

$$\|\bar{r}_k\|_Z = \min_{\alpha_{1,k},\ldots,\alpha_{\sigma_k,k}} \left\| (AP)^{\sigma_k} r_{k-\sigma_k} + \sum_{i=1}^{\sigma_k} \alpha_{i,k}(AP)^{i-1} r_{k-\sigma_k} \right\|_Z, \tag{9}$$

where

$$\bar{r}_k = \frac{1}{\nu_{k,k}} r_k \tag{10}$$

is the pseudoresidual; see [12] and [14]. In this case the methods are called pseudoresidual methods.

The methods break down if division by zero occurs for the calculation of r_k. A breakdown may be curable, by modifying the algorithm [1], or incurable. We assume in the following that the algorithm does not break down.

LEMMA 2. *For any exact, generalized cg method*

$$r_k^T Z P^{-1} A^{-1} r_k = r_k^T Z P^{-1} A^{-1} \Pi_k(AP) r_0 \tag{11}$$

is satisfied for all matrix polynomials $\Pi_k(AP) = \sum_{i=1}^{k} \theta_i (AP)^i + I$ *(i.e.,* $\theta_1, \ldots, \theta_k$ *are arbitrary). This is especially true of*

$$r_k^T Z P^{-1} A^{-1} r_k = r_k^T Z P^{-1} A^{-1} r_j \,, \tag{12}$$

$$e_k^T A^T Z P^{-1} e_k = e_k^T A^T Z P^{-1} e_j \tag{13}$$

for $j = 0, \ldots, k$.

Proof. See [14]. □

The next investigations show some interesting facts concerning the geometric location of the residuals and the errors.

THEOREM 3. *The residuals* r_k *and the errors* e_k *of exact, generalized cg methods satisfy the following equations*:

$$\left\| r_k - \frac{\tilde{r}_j}{2} \right\|^2_{ZP^{-1}A^{-1}} = \frac{\|\tilde{r}_j\|^2_{ZP^{-1}A^{-1}}}{4}, \tag{14}$$

and

$$\left\| e_k - \frac{\tilde{e}_j}{2} \right\|^2_{A^T Z P^1} = \frac{\|\tilde{e}_j\|^2_{A^T Z P^{-1}}}{4} \tag{15}$$

for $j = 0, \ldots, k$ *with*

$$\tilde{r}_j = 2 \left(Z P^{-1} A^{-1} + (Z P^{-1} A^{-1})^T \right)^{-1} Z P^{-1} A^{-1} r_j, \tag{16}$$

$$\tilde{e}_j = 2 \left(Z P^{-1} + (Z P^{-1} A^{-1})^T A \right)^{-1} Z P^{-1} e_j. \tag{17}$$

In particular if $A^T Z P^{-1}$ *is symmetric, then*

$$\tilde{r}_j = r_j, \tag{18}$$

$$\tilde{e}_j = e_j. \tag{19}$$

Proof. By (12),

$$r_k^T Z P^{-1} A^{-1} (r_k - r_j) = 0.$$

Therefore,

$$r_k^T Z P^{-1} A^{-1} r_k - r_k^T Z P^{-1} A^{-1} r_j = 0.$$

From the definition (16) for $\tilde{r}_j$ follows

$$r_k^T Z P^{-1} A^{-1} r_k - \frac{1}{2} r_k^T Z P^{-1} A^{-1} A P Z^{-1} \left(Z P^{-1} A^{-1} + (Z P^{-1} A^{-1})^T \right) \tilde{r}_j = 0$$

and

$$r_k^T Z P^{-1} A^{-1} r_k \; - \; \frac{1}{2} r_k^T \left(Z P^{-1} A^{-1} + (Z P^{-1} A^{-1})^T \right) \tilde{r}_j + \frac{\|\tilde{r}_j\|^2_{ZP^{-1}A^{-1}}}{4} = \frac{\|\tilde{r}_j\|^2_{ZP^{-1}A^{-1}}}{4},$$

which is equivalent to

$$\left\| r_k - \frac{\tilde{r}_j}{2} \right\|^2_{ZP^{-1}A^{-1}} = \frac{\|\tilde{r}_j\|^2_{ZP^{-1}A^{-1}}}{4}.$$

Equation (15) follows by $r_j = Ae_j$. □

Equations (14) and (15) are quadratic forms and describe geometrical figures.

If $A^T ZP^{-1}$ is definite, then the residual r_k and the error e_k lie on hyperellipsoids. The lengths of the semiaxes of the hyperellipsoid for the residual are precisely the singular values of the matrix APZ^{-1} multiplied by $\|\tilde{r}_j\|_{ZP^{-1}A^{-1}}$. The lengths of the semiaxes of the hyperellipsoid for the error are precisely the singular values of the matrix $PZ^{-1}A^{-T}$ multiplied by $\|\tilde{e}_j\|_{A^T ZP^{-1}}$; see Fig. 2 for $j = 0$.

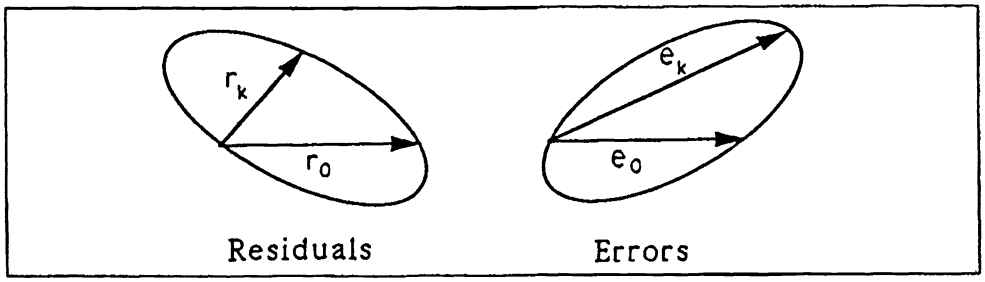

FIG. 2. *Residuals and errors if $A^T ZP^{-1}$ is definite.*

If $Z = AP$, then the residual r_k lies on an n-dimensional sphere; see Fig. 3 for $j = 0$. The norm of the residual is monotonically decreasing.

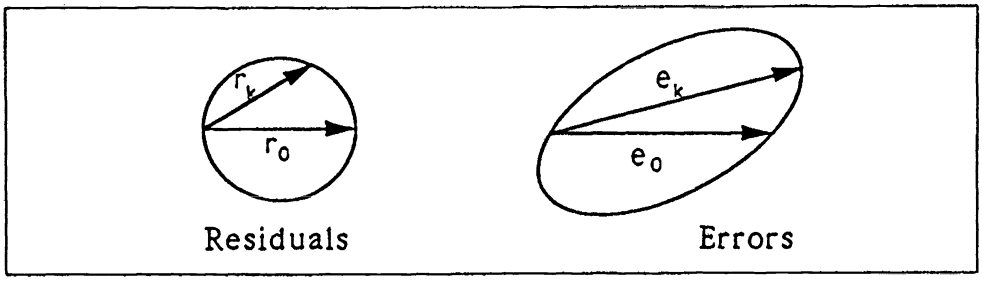

FIG. 3. *Residuals and errors if $Z = AP$.*

If $P = A^T Z$, then the error e_k lies on an n-dimensional sphere; see Fig. 4 for $j = 0$. The norm of the error is monotonically decreasing.

If $A^T ZP^{-1}$ is indefinite, then the geometric figures are not closed and in general the method does not converge; see Fig. 5 for $j = 0$.

The qualitative convergence behavior follows from Theorem 3 and the geometric interpretation. The speed of convergence depends on the eigenvalue distribution of the matrices AP and PA, respectively, which follows from the next lemma. Recall that the symmetric part of a matrix B is $\frac{1}{2}(B + B^T)$ and the skew-symmetric part is $\frac{1}{2}(B - B^T)$.

LEMMA 4. *If APZ^{-1} is positive real, i.e., the symmetric part of APZ^{-1} is positive definite,*

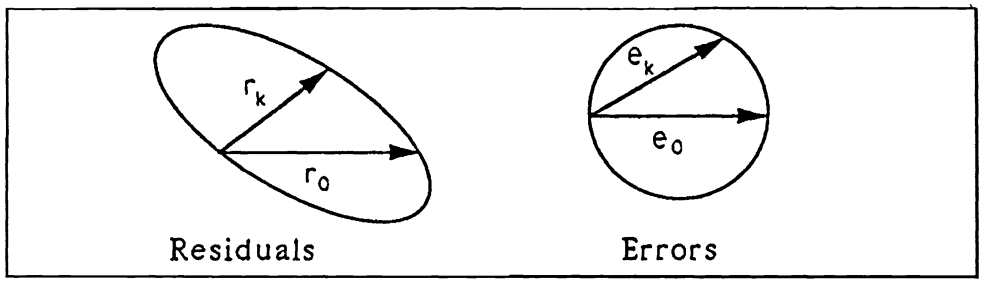

FIG. 4. *Residuals and errors if* $P = A^T Z$.

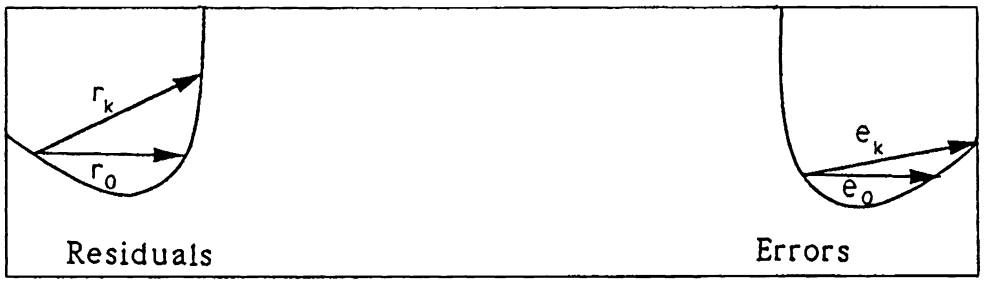

FIG. 5. *Residuals and errors if* $A^T Z P^{-1}$ *is indefinite.*

then

$$\|r_k\|_{ZP^{-1}A^{-1}} \leq \sqrt{1 + \frac{\rho^2(R)}{\mu_m^2}} \min_{\Pi_k} \|\Pi_k(AP)r_0\|_{ZP^{-1}A^{-1}}, \tag{20}$$

$$\|e_k\|_{A^T ZP^{-1}} \leq \sqrt{1 + \frac{\rho^2(R)}{\mu_m^2}} \min_{\Pi_k} \|\Pi_k(PA)e_0\|_{A^T ZP^{-1}} \tag{21}$$

holds for exact generalized cg methods. Π_k *is a polynomial of degree* k *with* $\Pi_k(0) = 1$. $\rho(R)$ *is the spectral radius of the skew-symmetric part* R *of* $ZP^{-1}A^{-1}$. μ_m *is the minimum eigenvalue of* M, *the symmetric part of* $ZP^{-1}A^{-1}$. *For residual-minimizing methods* ($Z = AP$)

$$\|r_k\| = \min_{\beta_1,\ldots,\beta_k} \left\| \sum_{i=1}^{k} \beta_i (AP)^i r_0 + r_0 \right\|. \tag{22}$$

For error-minimizing methods ($P = A^T Z$)

$$\begin{aligned} \|e_k\| &= \min_{\beta_1,\ldots,\beta_k} \left\| \sum_{i=1}^{k} \beta_i (PA)^i e_0 + e_0 \right\| \\ &= \min_{\beta_1,\ldots,\beta_k} \left\| \sum_{i=1}^{k} \beta_i (A^T ZA)^i e_0 + e_0 \right\| \end{aligned} \tag{23}$$

is valid.

Proof. See [14]. □

As

$$x^T APZ^{-1}x = x^T Z^{-T} P^T A^T x = y^T A^T ZP^{-1} y$$

with $y = PZ^{-1}x$ for all x, APZ^{-1} is positive real if and only if $A^T ZP^{-1}$ is positive real. Therefore Lemma 4, in fact, covers all converging cases following from Theorem 3 and the geometric interpretation. As a result of Theorem 3 and Lemma 4 the methods can be classified. In Table 1 the different conditions for the minimized items are collected.

TABLE 1
Various generalized cg methods.

Condition	Minimized Item	Method
$ZP^{-1} = I$ and		
A sym., pos. def.	$\|\|r_k\|\|_{A^{-1}}$	minimum energy norm
$ZP^{-1}A^{-1}$ sym., pos. def.	$\|\|r_k\|\|_{ZP^{-1}A^{-1}}$	minimum $ZP^{-1}A^{-1}$-residual
Z sym., pos. def.	$\|\|\tilde{r}_k\|\|_Z$	pseudoresidual
$Z = \tilde{Z}AP$ and		
$\tilde{Z}$ sym., pos. def.	$\|\|r_k\|\|_{\tilde{Z}}$	minimum $\tilde{Z}$-residual
$Z = AP$	$\|\|r_k\|\|$	minimum residual
$Z = A^{-T}\tilde{Z}P$ and		
$\tilde{Z}$ sym., pos. def.	$\|\|e_k\|\|_{\tilde{Z}}$	minimum $\tilde{Z}$-error
$P = A^T Z$	$\|\|e_k\|\|$	minimum error

For systems with clustered eigenvalues, i.e., a small condition number, the relative norm of the errors is closely connected to the relative norm of the residuals, and the speed of convergence is fast. For systems with a large condition number error-minimizing generalized cg methods ($P = A^T Z$) guarantee that the errors do not increase. These methods are techniques used to prevent the separation of the errors from the residuals.

The speed of convergence is dependent on the eigenvalue distribution of the iteration matrices AP for the residuals, PA for the errors, respectively. For error-minimizing generalized cg methods these matrices are $AA^T Z$ and $A^T ZA$. If the eigenvalues of $A^T ZA$ are clustered, then error-minimizing generalized cg methods guarantee a fast convergence. An investigation for the choice of Z in order to obtain a fast convergence on supercomputers is given in [15].

For Example 1 the eigenvalues of the matrix $A^T A$ are more scattered than the eigenvalues of A because the matrix is symmetric. Therefore an error-minimizing generalized cg method with $Z = I$ (Craig's method CGNE [2]) would prevent the separation of the residuals from the errors, but the convergence would be very slow. As regards the CPU time, this would become even worse because one iteration step needs two matrix-vector multiplications. For this example and many others the simple iteration matrix A or A^T would generate a faster convergence. In the next section we try to construct such methods that minimize the error.

3. Generalized minimum error methods. In this section we introduce our second technique: generalized minimum error methods that use $A^T P$ as the iteration matrix instead of using $A^T ZA$, as in the previous section. The technique is a generalization of a method proposed by Fridman [6] for symmetric, positive definite matrices.

The construction of the methods is based on the following lemma.

LEMMA 5. *Let* $y_i \in \mathbb{R}^n$, $q_i = A^T y_i$ *for* $i = k - \sigma_k, \ldots, k-1$ *and*

$$x_k = \sum_{i=k-\sigma_k}^{k-1} \gamma_{i,k} q_i + x_{k-\sigma_k}. \tag{24}$$

Then the error of $Ax_k - b$ is minimized in the Euclidean norm, i.e.,

$$||e_k|| = \min_{\gamma_{k-\sigma_k,k},\ldots,\gamma_{k-1,k}} \left\| \sum_{i=k-\sigma_k}^{k-1} \gamma_{i,k} q_i + x_{k-\sigma_k} - x \right\|, \tag{25}$$

by the solution $(\gamma_{k-\sigma_k,k}, \ldots, \gamma_{k-1,k})$ of the linear system

$$\sum_{i=k-\sigma_k}^{k-1} \gamma_{i,k} q_i^T q_j = b^T y_j - x_{k-\sigma_k}^T q_j, \tag{26}$$

$j = k - \sigma_k, \ldots, k-1$. The following orthogonalities are especially valid for $j = k - \sigma_k, \ldots, k-1$:

$$e_k^T q_j = 0. \tag{27}$$

Proof. The error $||e_k||$ is minimized if

$$\frac{1}{2} \frac{\partial}{\partial \gamma_{j,k}} ||e_k||^2 = e_k^T q_j = 0 \quad \text{for} \quad j = k - \sigma_k, \ldots, k-1,$$

with

$$\begin{aligned} e_k^T q_j &= (x_k - x)^T q_j \\ &= \sum_{i=k-\sigma_k}^{k-1} \gamma_{i,k} q_i^T q_j - x^T q_j + x_{k-\sigma_k}^T q_j \\ &= \sum_{i=k-\sigma_k}^{k-1} \gamma_{i,k} q_i^T q_j - b^T y_j + x_{k-\sigma_k}^T q_j = 0 \end{aligned}$$

following from (26). □

The q_i are update directions for the iterate x_k, and the y_i are auxiliary vectors needed for the computation of the coeffients $\gamma_{i,k}$. By means of Lemma 5 a whole family of error-minimizing Krylov subspace methods can be derived.

DEFINITION 6. *Let x_0 be any initial guess for the solution of the system $Ax = b$. Choose an auxiliary starting vector $y_0 \neq 0$, $q_0 = A^T y_0$. The following recurrence is called a generalized minimum error method* (GMERR). *Choose a preconditioning matrix P and calculate the following for $k \geq 1$:*

$$x_k = \sum_{i=k-\sigma_k}^{k-1} \gamma_{i,k} q_i + x_{k-\sigma_k}. \tag{28}$$

Choose $y_k \in K_k(PA^T, y_0)$ so that

$$q_k^T Z q_{k-i} = 0 \tag{29}$$

for $i = 1, \ldots, \bar{\sigma}_k$, where Z is an auxiliary, nonsingular matrix and

$$q_k = A^T y_k. \tag{30}$$

The $\gamma_{i,k}$ are determined from

$$||e_k|| = \min_{\gamma_{k-\sigma_k,k},\ldots,\gamma_{k-1,k}} \left\| \sum_{i=k-\sigma_k}^{k-1} \gamma_{i,k} q_i + e_{k-\sigma_k} \right\| . \tag{31}$$

The method is called exact *if* $\bar{\sigma}_k = k$, restarted *if* $\bar{\sigma}_k = (k-1) \bmod \sigma_{\text{res}} + 1$ *with* σ_{res} *fixed,* truncated *if* $\bar{\sigma}_k = \min(k, \sigma_{\max})$ *with* $\sigma_{\max}$ *fixed, and* combined *if the truncated method is restarted. The method is called* consistent *if* $\sigma_k = \bar{\sigma}_k$.

The coefficients $\gamma_{i,k}$ can be calculated by (26). If $ZA^T P = P^T AZ$, then the iterates q_k can be calculated by a simple three-term recurrence, and the methods are equivalent to the classical algorithm of Fridman [6]. The optimal choice of y_0 would be $y_0 = A^{-T} e_0 = A^{-T} A^{-1} r_0$ because then $q_0 = e_0$, and the solution is obtained in the first iteration step.

From Definition 6 follow directly

$$||e_k|| \leq ||e_{k-1}|| , \tag{32}$$

$$x_k \in x_0 + K_{k-1}(A^T P, q_0), \tag{33}$$

$$r_k \in r_0 + A\, K_{k-1}(A^T P, q_0), \tag{34}$$

$$q_k \in K_k(A^T P, q_0) . \tag{35}$$

From Definition 6 and condition (34) follow for the residuals and the errors:

LEMMA 7. *For* GMERRs *the following hold*:

$$e_k = \sum_{i=0}^{k-1} \nu_{i,k} (A^T P)^i q_0 + e_0, \tag{36}$$

$$r_k = \sum_{i=0}^{k-1} \nu_{i,k} A\, (A^T P)^i q_0 + r_0 . \tag{37}$$

Proof. The proof is trivial. □

From Lemma 7 the norm of the error can be estimated.

THEOREM 8. *For exact, consistent,* GMERRs *holds*

$$||e_k|| = \min_{\theta_0,\ldots,\theta_{k-1}} \left\| \sum_{i=0}^{k-1} \theta_i (A^T P)^i q_0 + e_0 \right\| . \tag{38}$$

Proof. Equation (38) follows directly from (31) and (36). □

From (38) it follows directly that for $P = ZA$ and $y_0 = Zr_0$ we also obtain the error-minimizing generalized cg methods of the previous section as GMERRs (see Lemma 4):

$$||e_k|| = \min_{\beta_1,\ldots,\beta_k} \left\| \sum_{i=1}^{k} \beta_i (A^T ZA)^i e_0 + e_0 \right\| . \tag{39}$$

Thus we have the following duality: The preconditioning matrix $P = ZA$ for GMERRs (see (39)) corresponds to the preconditioning matrix $P = A^T Z$ of generalized cg methods (see (23)).

The next theorem shows the interconnections of GMERRs to a one-dimensional minimization technique, the smoothing algorithm.

THEOREM 9. *If* $Z = I$, *then the calculation of* x_k *simplifies for exact, consistent* GMERRs *to*

$$x_k = x_{k-1} + \gamma_{k-1,k} q_{k-1}, \tag{40}$$

with

$$\gamma_{k-1,k} = \frac{b^T y_{k-1} - x_{k-1}^T q_{k-1}}{q_{k-1}^T q_{k-1}}. \tag{41}$$

Proof. The orthogonalities in Equation (29) simplify (26). Therefore, $\gamma_{k-i,j} = \gamma_{k-i,l}$ for all j and l, and the $\gamma_{k-i,k}$ can be calculated explicitly for $i = 1, \ldots, \sigma_k$ by

$$\begin{aligned}\gamma_{k-i,k} &= \frac{b^T y_{k-i} - x_0^T q_{k-i}}{q_{k-i}^T q_{k-i}} \\ &= \frac{b^T y_{k-i} - (\sum_{j=0}^{k-i-1} \gamma_{j,k-i} q_j + x_0)^T q_{k-i}}{q_{k-i}^T q_{k-i}}\end{aligned}$$

because of the orthogonalities

$$= \frac{b^T y_{k-i} - x_{k-i}^T q_{k-i}}{q_{k-i}^T q_{k-i}}.$$

Thus $x_k = x_0 + \sum_{i=0}^{k-1} \gamma_{i,k} q_i = x_{k-1} + \gamma_{k-1,k} q_{k-1}$. □

Equations (41) and (40) can be considered a smoothing algorithm to minimize the error. Schönauer introduced a smoothing algorithm to minimize the residual (see, e.g., [12]). In [14] it is shown that this algorithm transforms generalized cg methods that minimize the pseudoresidual to methods that minimize the residual. Gutknecht [7] gives the reverse of this smoothing algorithm, which is itself a smoothing algorithm. Zhou and Walker [16] show that a smoothing algorithm transforms the BCG method [3], [9] to the QMR method [5] and that it transforms the CGS method [13] to TFQMR [4].

If $\gamma_{k-1,k}$ is calculated according to (41), then the algorithm will be stable in the sense that x_k is depending only on values of the previous iteration step.

A GMERR can be implemented as shown in the following algorithm:

Algorithm I. *Let x_0 be any initial guess. Choose an auxiliary starting vector y_0 and calculate $q_0 = A^T y_0$. Choose δ and $\bar{\delta}$ accordingly. For $k \geq 1$ choose a preconditioning matrix P and calculate*:

$$\gamma_{k-1,k} = \frac{b^T y_{k-1} - x_{k-1}^T q_{k-1}}{\|q_{k-1}\|^2}, \tag{42}$$

$$\text{if } |\gamma_{k-1,k}| \leq \delta \text{ for } k > 1,$$

then restart

$$x_k = x_{k-1} + \gamma_{k-1,k} q_{k-1}, \tag{43}$$

$$\alpha_{i,k} = -\frac{q_{k-i}^T Z A^T P q_{k-1}}{\|q_{k-i}\|_Z^2}, \quad \text{for } i = 0, \ldots, \sigma_k \tag{44}$$

$$\bar{q}_k = A^T P q_{k-1} + \sum_{i=1}^{\sigma_k} \alpha_{i,k} q_{k-i}\,, \tag{45}$$

$$\text{if } \|\bar{q}_k\|_Z \leq \bar{\delta},$$

then restart

$$\phi_k = \frac{1}{\|\bar{q}_k\|_Z}, \tag{46}$$

$$q_k = \phi_k \bar{q}_k, \tag{47}$$

$$y_k = \phi_k \left(P q_{k-1} + \sum_{i=1}^{\sigma_k} \alpha_{i,k} y_{k-i} \right). \tag{48}$$

This implementation is an Arnoldi-like algorithm for q_k. If we calculate

$$\phi_k = \frac{1}{\sum_{i=1}^{\sigma_k} \alpha_{i,k}}$$

instead of (46), then Algorithm I resembles an ORTHORES algorithm. Without the restart function the algorithm would break down if $\bar{q}_k = 0$. An invariant subspace or the whole space would then be spanned, and the iteration would be restarted from the defect correction equation.

The algorithm is also restarted if the iterate x_k does not change sufficiently. By numerical engineering the value of δ has been optimized to $\delta = 3 \cdot 10^{-3} \|x_{k-1}\|$. Note that the iteration restarts from the defect correction equation so that the iterate x_k is decreasing, thus justifying the choice of δ.

4. Comparison of residual-minimizing/error-minimizing methods. We test the convergence behavior of the residual-minimizing method GMRES [11], the error-minimizing generalized cg method CGNE [2], and a GMERR method. The intention is to get a feeling for how GMERR methods behave in comparison with the corresponding GMRES methods and the error-minimizing cg methods. GMRES is an exact generalized cg method that minimizes the Euclidean norm of the residuals ($Z = A$, $P = I$). Correspondingly, we select the exact GMERR method with $Z = P = I$ according to Algorithm I with $\bar{\delta} = 10^{-8}$ (14 digits accuracy). For CGNE holds $P = A^T$, $Z = I$. For all methods we choose $x_0 = 0$, and for GMERR $y_0 = r_0$.

Example 1 (continuation). As predicted, CGNE behaves worse than do GMRES and GMERR because the eigenvalues of the iteration matrix are more scattered. Unfortunately, GMERR does not converge faster than GMRES, but for GMERR the norm of the residuals is connected to the norm of the errors. Thus the user is not misled by the residuals, see Fig. 6. The bad convergence is dependent on the bad starting vector $x_0 = 0$.

Examples MIT1–MIT8. The examples are taken from [10]. We omit the first example MIT1 because the system matrix is the unit matrix and the solution is obtained in the first iteration step. The examples "nail down the space of matrices at every corner" [10]. The dimension of the system is 40 for MIT2, MIT3, MIT4, MIT6, and MIT7. The dimension of the system is 400 for MIT5 and MIT8. The solution was prescribed by the random number generator, and the right-hand side was calculated accordingly.

MIT2: A is a random matrix of dimension 40. All methods are similarly bad (see Fig. 7).

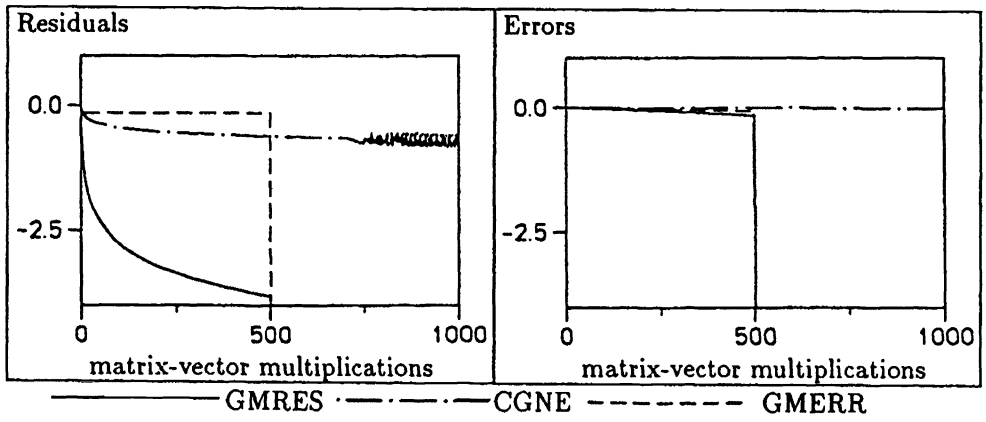

FIG. 6. *Norm of the relative residuals and errors of* GMRES, CGNE, *and* GMERR *for Example* 1 *(logarithmic scale).*

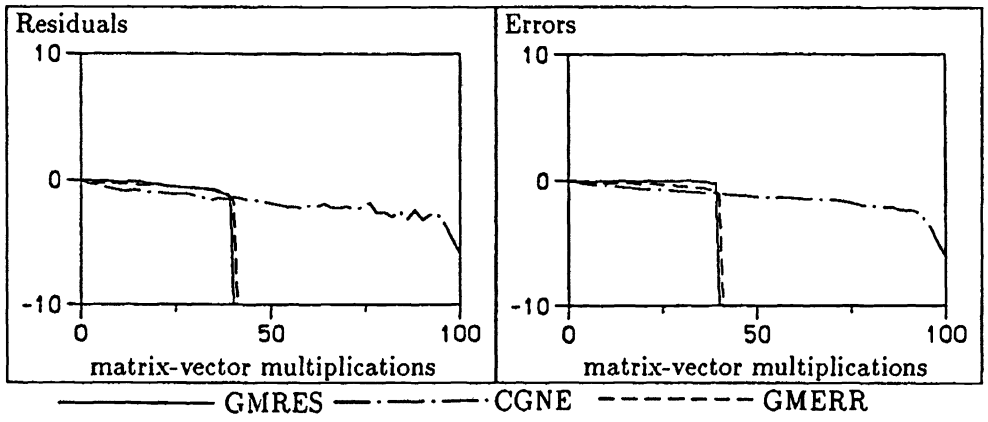

FIG. 7. *Norm of the relative residuals and errors of* GMRES, CGNE, *and* GMERR *for example* MIT2 *(logarithmic scale).*

MIT3: The matrix of MIT3 is

$$A = \begin{pmatrix} 0 & 1 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \ddots & 0 \\ 0 & & & \ddots & 1 \\ 1 & 0 & \dots & \dots & 0 \end{pmatrix}.$$

GMERR beats GMRES and gets the solution immediately because $q_0 = A^T y_0 = A^T r_0 = A^T A e_0 = e_0$ has an optimal direction. CGNE converges immediately because $A^T A = I$ (see Fig. 8). The eigenvalues of A are scattered and the eigenvalues of $A^T A$ are clustered. Therefore, CGNE should be better than GMERR. The opposite is true because of the artificial and special choice of A.

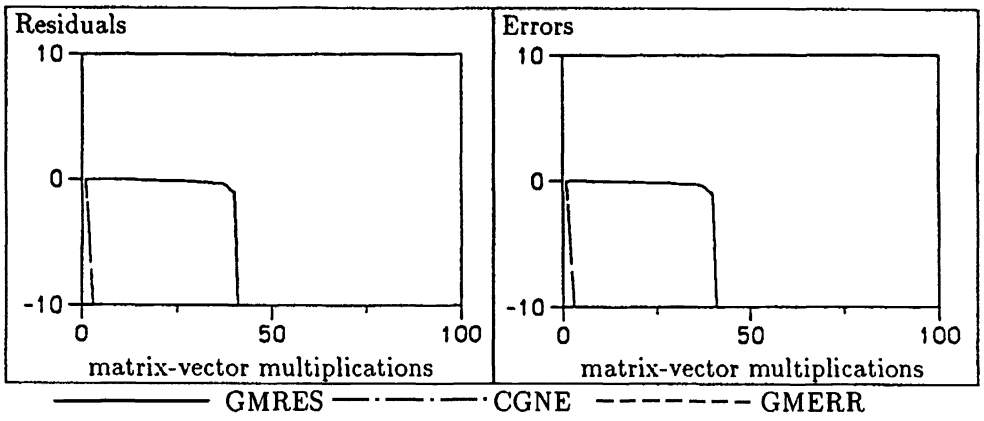

FIG. 8. *Norm of the relative residuals and errors of* GMRES, CGNE, *and* GMERR *for example* MIT3 *(logarithmic scale).*

The structure of the matrix for MIT4, MIT6, MIT7, and MIT8 is

$$A = \begin{pmatrix} A_1 & 0 & \dots & 0 \\ 0 & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \dots & 0 & A_{nn} \end{pmatrix}.$$

MIT4: $A_i = \begin{pmatrix} 1 & i-1 \\ 0 & 1 \end{pmatrix}$ The dimension is 40. GMRES is faster than GMERR and GMERR is faster than CGNE (see Fig. 9).

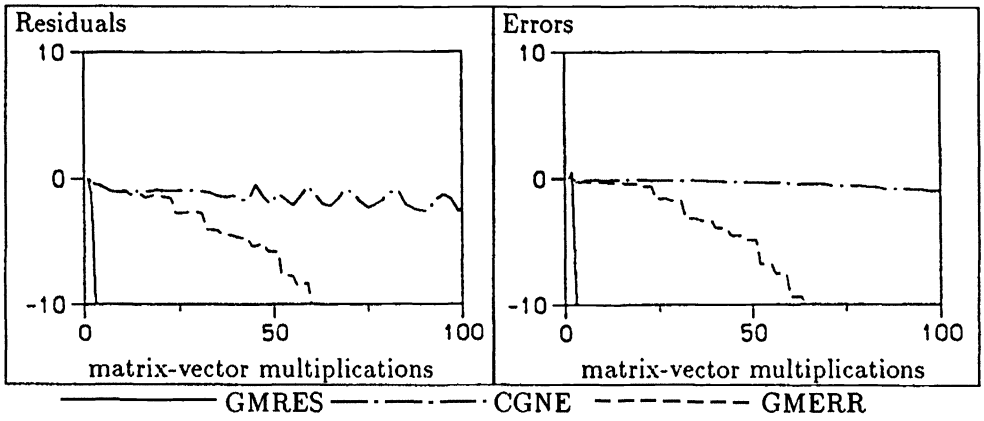

FIG. 9. *Norm of the relative residuals and errors of* GMRES, CGNE, *and* GMERR *for example* MIT4 *(logarithmic scale).*

MIT5:

$$A = \operatorname{diag}(\xi_1, \dots, \xi_n) \quad \text{with} \quad \kappa = \left(\frac{1 + \epsilon^{\frac{1}{2\sqrt{n}}}}{1 - \epsilon^{\frac{1}{2\sqrt{n}}}} \right)^2,$$

$\xi_i = 1 + \frac{1}{2}(y_i + 1)(\kappa - 1)$, $y_i = \cos\frac{(i-1)\pi}{n-1}$, and $\epsilon = 10^{-10}$. The dimension is 400. GMRES is faster than GMERR, and GMERR is faster than CGNE (see Fig. 10).

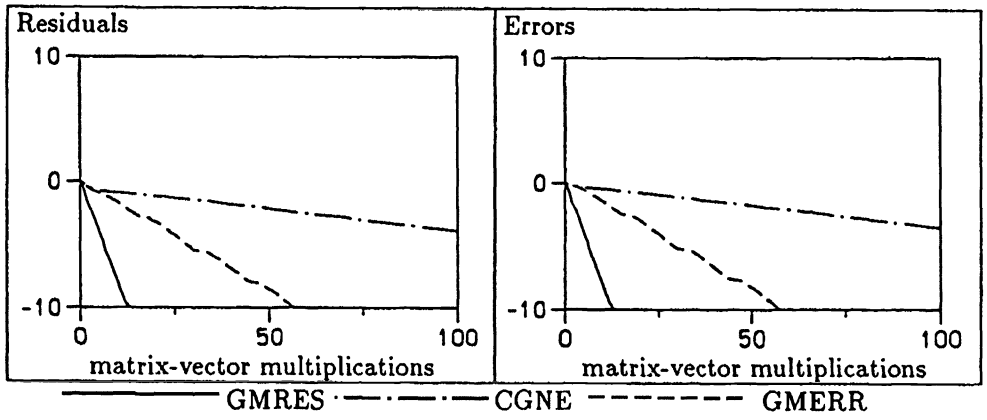

FIG. 10. *Norm of the relative residuals and errors of* GMRES, CGNE, *and* GMERR *for example* MIT5 *(logarithmic scale).*

MIT6: $A_i = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$. The dimension is 40. All methods are very fast because $A^2 = A^{2T} = -I$ and $AA^T = I$ (see Fig. 11).

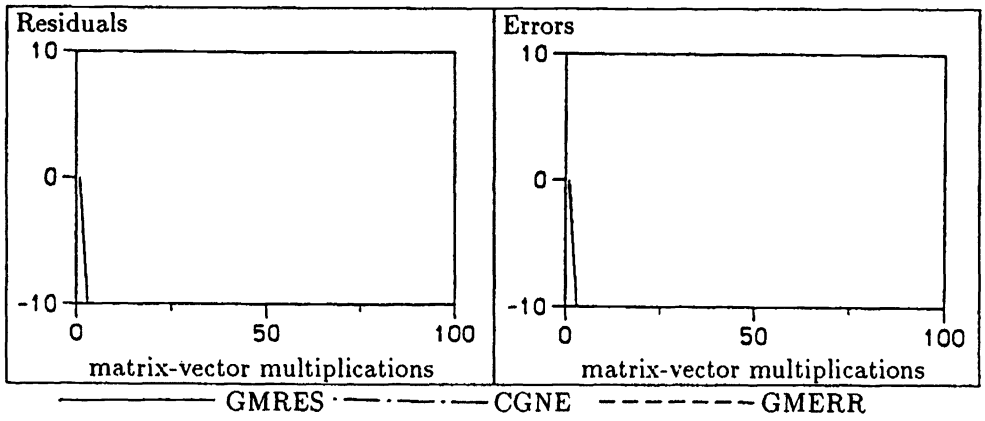

FIG. 11. *Norm of the relative residuals and errors of* GMRES, CGNE, *and* GMERR *for example* MIT6 *(logarithmic scale).*

MIT7: $A_i = \begin{pmatrix} 1 & i-1 \\ 0 & -1 \end{pmatrix}$. The dimension is 40. GMRES is very fast, GMERR is very slow, and CGNE is even worse (see Fig. 12).

MIT8:

$$A_i = \begin{pmatrix} \xi_i & \nu_i \\ 0 & \frac{\kappa}{\xi_i} \end{pmatrix} \quad \text{with} \quad \kappa = \left(\frac{1 + \epsilon^{\frac{\sqrt{nn}}{2}}}{1 - \epsilon^{\frac{\sqrt{nn}}{2}}} \right)^2,$$

$\xi_i = 1 + \frac{1}{2}(y_i + 1)(\kappa - 1)$, $y_i = \cos\frac{(i-1)\pi}{nn-1}$ and $\epsilon = 10^{-10}$. The dimension is 400. GMERR is twice as fast as GMRES; CGNE is as fast as GMERR (see Fig. 13).

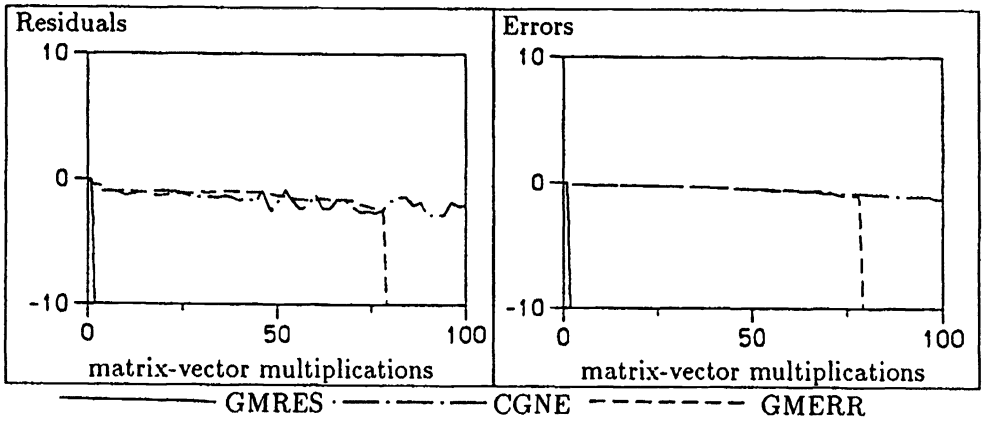

FIG. 12. *Norm of the relative residuals and errors of* GMRES, CGNE, *and* GMERR *for example* MIT7 *(logarithmic scale).*

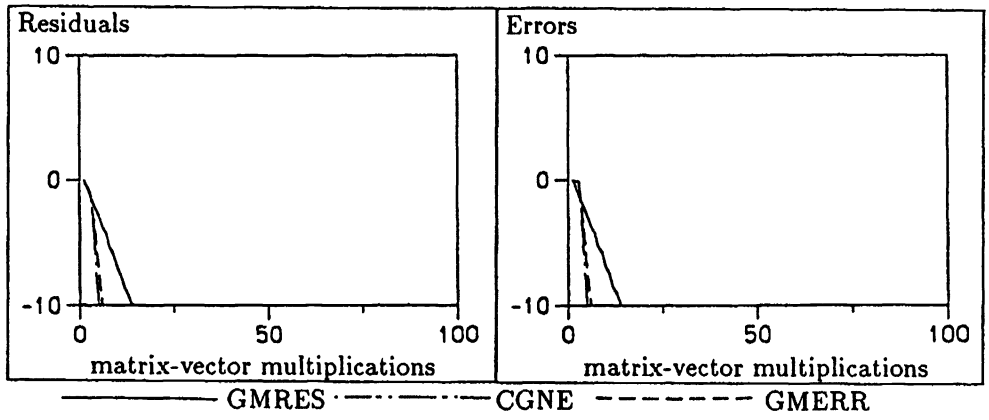

FIG. 13. *Norm of the relative residuals and errors of* GMRES, CGNE, *and* GMERR *for example* MIT8 *(logarithmic scale).*

For MIT2 and MIT6 GMRES and GMERR deliver comparable results. For MIT4, MIT5, and MIT7 GMRES is better; and for MIT3 and MIT8 GMERR beats GMRES. GMERR is better than CGNE for MIT4 and MIT5. For all other cases the two methods are comparable. In Table 2 the results are collected.

5. Outlook. The tests with the MIT examples indicate that exact, consistent GMERR according to Algorithm I is better than CGNE, and it is in some cases better than GMRES. But for more realistic problems, i.e., large problems arising from the discretization and linearization of partial differential equations, the exact methods are not feasible for storage requirements. Therefore, truncated and restarted versions have to be applied. While it was possible to optimize the restart and truncation parameters for GMRES-like methods, see e.g. [12], this optimization still lies ahead for GMERR methods. First tests indicate that this will be a more difficult task.

We further remark that GMERRs can be combined with generalized cg methods as we

TABLE 2
Comparison of GMRES, CGNE, *and* GMERR, *on a scale of* 1–3 (1=*best method*; 3=*worst method*).

Example	GMRES	CGNE	GMERR
MIT2	all methods bad		
MIT3	3	both 1	
MIT4	1	3	2
MIT5	1	3	2
MIT6	all methods good		
MIT7	1	both 3	
MIT8	3	both 1	

shall describe. For the biconjugate gradients (BCG) [3], [9] the double system $\hat{A}\hat{x} = \hat{b}$, i.e.,

$$\begin{pmatrix} A & 0 \\ 0 & A^T \end{pmatrix} \begin{pmatrix} x \\ x^* \end{pmatrix} = \begin{pmatrix} b \\ b^* \end{pmatrix},$$

is considered. b^* is arbitrary. The residuals have the form $\hat{r} = \binom{r}{r^*}$ and $Z = Z_B = \binom{0 \quad I}{I \quad 0}$. A generalized cg method is applied to this double system. As $Z_B \hat{A} = \hat{A}^T Z_B$, the method is exact for $\sigma = 2$, i.e., the sequence terminates automatically. Of course this doubling technique can be adapted to GMERRs in order to get terminating sequences. But we can also exploit this doubling differently. In the original BCG method the second sequence (*) is used only for the orthogonalization without exploitation of the iterates of the second sequence. But we can exploit the information of the second sequence for a generalized minimum error method especially because the iteration matrix of the second sequence is A^T as needed. Thus by modifying BCG slightly we obtain a generalized cg and a GMERR in parallel.

6. Conclusion. For problems with a single cluster of eigenvalues, i.e., in the symmetric case for well-conditioned problems, the errors decrease with the residuals, and the convergence of generalized cg methods is fast.

For problems with scattered eigenvalues, i.e., ill-conditioned problems in the symmetric case, the decrease of the residuals may be excellent while the errors do not decrease. As a consequence, we use error-minimizing methods. We have proposed two techniques. One is based on generalized cg methods with the iteration matrix $A^T Z A$, the other is based on GMERRs with the iteration matrix $A^T P$. We have shown various interconnections between the two techniques.

Because the speed of convergence is dependent on the eigenvalue distribution of the iteration matrix both techniques are suited for different problem types. The first is superior for scattered eigenvalues of the system matrix but more clustered eigenvalues of $A^T Z A$, i.e., for clustered singular values if $Z = I$. The second is preferable if the eigenvalues of $A^T Z A$, i.e., the singular values if $Z = I$, are more scattered than the eigenvalues of the system matrix.

POSITIVITY CONDITIONS FOR QUARTIC POLYNOMIALS*

GARY ULRICH† AND LAYNE T. WATSON‡

Abstract. Simple necessary and sufficient conditions that a quartic polynomial $f(z)$ be nonnegative for $z>0$ or $a\leq z\leq b$ are derived, and illustrated geometrically. The geometry provides considerable insight and suggests various approximations and computational simplifications. The theory is applied to monotone quintic spline interpolation, giving necessary and sufficient conditions and an algorithm for monotone Hermite quintic interpolation.

Key words. monotone quintic spline interpolation, nonnegative polynomial, polynomial interpolation, quintic Hermite interpolation

AMS subject classifications. 41A05, 65D05, 65D07

1. Introduction.

Consider the fourth degree polynomial with real coefficients,

$$f(z) = az^4 + bz^3 + cz^2 + dz + e, \tag{1}$$

where $ae \neq 0$ (the problem reduces to consideration of a cubic if $ae = 0$). This paper outlines conditions under which this polynomial has positivity, i.e., $f(z) \geq 0$ for every $z > 0$. This is a rather general condition since positivity on any fixed interval (u, v) can be directly related to positivity on the positive reals through the transformation

$$t = \frac{u + zv}{1 + z}.$$

The property of positivity has a number of important applications to mathematics and computer science, and to shape preserving polynomial approximations in particular. For example, Jury and Mansour [6] relate positivity to a number of problems in control theory. Fritsch and Carlson [4], who derived positivity conditions in the case of quadratic polynomials, use the result to construct monotone cubic spline interpolants. Schmidt and Heß [8] provided conditions for positivity of cubic polynomials and used their result to construct positive cubic splines with minimum curvature and complex rational cubic splines. For the case of the fourth degree polynomial, Jury and Mansour [6] use the discriminant of (1) along with other characteristic expressions from the theory of equations to derive an algorithm for verifying positivity of quartics. Their conditions are difficult to implement and provide no geometric insight into the underlying mathematical phenomena. Dougherty, Edelman, and Hyman [3] derive conditions for monotonicity and convexity of quintic Hermite interpolants, but

explicitly state only sufficient conditions. Our results are very similar to those of [3], but differ in that we give elegant sharp (necessary and sufficient) conditions for positivity of a quartic directly in terms of its coefficients, whereas [3] couches its sufficient conditions in terms of derivatives of Hermite quintics. We also give sharp conditions on the second derivatives, for given fixed first derivatives, such that a quintic Hermite interpolant is monotone; this question is not addressed by [3].

Some time ago, deBoor and Swartz [2] addressed monotone spline interpolation in general and the cubic case in detail, and monotonicity was also recently considered by Huynh [5] and Ulrich and Watson [11].

The present paper uses a simpler, but equivalent, form of the polynomial (1) to obtain positivity conditions which are as elegant as those available for the quadratic and cubic polynomials. The quartic polynomial is reparameterized to this simpler form in §2 where the regions of positivity are described and a formal proof of positivity is provided. The geometric characterization of positivity in §2 provides considerable insight, and easily leads to various approximate criteria and computational simplifications. Section 3 outlines the conditions used to test for positivity and provides some heuristics on constraining a nonpositive polynomial to be positive. Section 4 briefly describes applications of this result in polynomial interpolation.

All of the algebra in this paper was done with Mathematica [12], and thus algebraic derivations showing intermediate steps are not given here.

2. Regions of positivity. Consider the transformation used in [8], e.g.,

$$x^4 = \frac{a}{e} z^4.$$

This reparameterization should exist since a necessary condition for positivity of the polynomial (1) is that the coefficients a and e are both positive. The polynomial $f(z)/e$ then becomes

$$x^4 + ba^{-3/4}e^{-1/4}x^3 + ca^{-1/2}e^{-1/2}x^2 + da^{-1/4}e^{-3/4}x + 1,$$

which can be written as the polynomial

$$p(x;\alpha,\beta,\gamma) = x^4 + \alpha x^3 + \beta x^2 + \gamma x + 1, \tag{2}$$

where α, β, and γ are defined appropriately. This reparameterized polynomial has only three coefficients. In previous work on the quadratic and cubic equations, the regions of nonpositive roots were bounded by parametric curves corresponding to double roots of the polynomial. The same holds true for the quartic polynomial (2) above. A well-known result in the theory of equations is that double roots exist when the discriminant

$$\Delta = 4\left[c^2 - 3bd + 12ae\right]^3 - \left[2c^3 + 27ad^2 + 27b^2e - 9bcd - 72ace\right]^2$$

of the polynomial (1) is zero (a proof is given in [7]). Setting $\Delta = 0$ leads to the sixth order equation

$$\Delta = 4\left[\beta^2 - 3\alpha\gamma + 12\right]^3 - \left[72\beta + 9\alpha\beta\gamma - 2\beta^3 - 27\alpha^2 - 27\gamma^2\right]^2 = 0. \tag{3}$$

The discriminant for the quadratic and cubic polynomials was a second and fourth degree polynomial, respectively, and region inequalities could be represented and derived in a straightforward manner. In the case of the quartic, the discriminant is a sixth order polynomial and we see no way of approaching the problem directly; we will construct a geometric argument which utilizes the parametric form of the double root boundary. The presence of a double root (say t) implies that

$$p'(t) = 4t^3 + 3\alpha t^2 + 2\beta t + \gamma = 0 \quad \text{and} \quad 4p(t) - t\,p'(t) = \alpha t^3 + 2\beta t^2 + 3\gamma t + 4 = 0,$$

where the latter equation comes from the fact that $1/t$ is also a double root of $x^4\,p(1/x)$. Solving simultaneously for α and γ (for fixed β), we obtain parametric equations for $t \in (-\infty, \infty)$,

$$\alpha(t) = \frac{1 - \beta t^2 - 3t^4}{2t^3} \quad \text{and} \quad \gamma(t) = \frac{t^4 - \beta t^2 - 3}{2t}. \tag{4}$$

Symmetry clearly shows up in these parametric equations since $\alpha(-t) = -\alpha(t)$, $\gamma(-t) = -\gamma(t)$, $\alpha(1/t) = \gamma(t)$, and $\gamma(1/t) = \alpha(t)$. By applying curve tracing techniques, we can identify three distinct shapes (corresponding to zero, one, or two cusps on each component) for the double root curves as shown in Fig. 1 (important features of these curves are also labeled in the figure). Figure 2 shows the family of double root curves as β varies, plotting only the top portions.

The region of positivity for the quartic, like the quadratic and cubic, is bounded by the double root curve. Trying to prove this directly from (4), however, does not work out well. To prove this result, we employ the following theorem (from [1], [9]):

THEOREM 0. *The quartic polynomial $g(x)$ is nonnegative for all $x \geq 0$ if and only if there exist polynomials $u(x)$ and $v(x)$ such that*

$$g(x) = u^2(x) + x\,v^2(x).$$

Rewriting (2) as

$$p(x;\alpha,\beta,\gamma) = \left[x^2 + rx + s\right]^2 + x\left[(\alpha - 2r)x^2 + (\beta - (r^2 + 2s))x + (\gamma - 2rs)\right]$$

for some r and for $s = \pm 1$, then the above theorem implies that $p(x)$ is nonnegative for all $x \geq 0$ if and only if there exists real r such that

$$(\alpha - 2r)x^2 + (\beta - (r^2 + 2s))x + (\gamma - 2rs) \tag{5}$$

is a perfect square. If (5) is a nontrivial perfect square, the first and last coefficients must be positive. The values of r which make (5) a perfect square correspond to the roots of the quartic

$$q(r;\alpha,\beta,\gamma) = \left[\beta - (r^2 + 2s)\right]^2 - 4(\alpha - 2r)(\gamma - 2rs) = 0, \tag{6}$$
$$\text{where} \quad \alpha - 2r > 0 \quad \text{and} \quad \gamma - 2rs > 0.$$

(The limiting cases $\alpha - 2r = 0$ and $\gamma - 2rs = 0$ corresponding to $\beta - (r^2 + 2s) = 0$ are also possible and have trivial solutions, so we will not clutter the discussion by mentioning

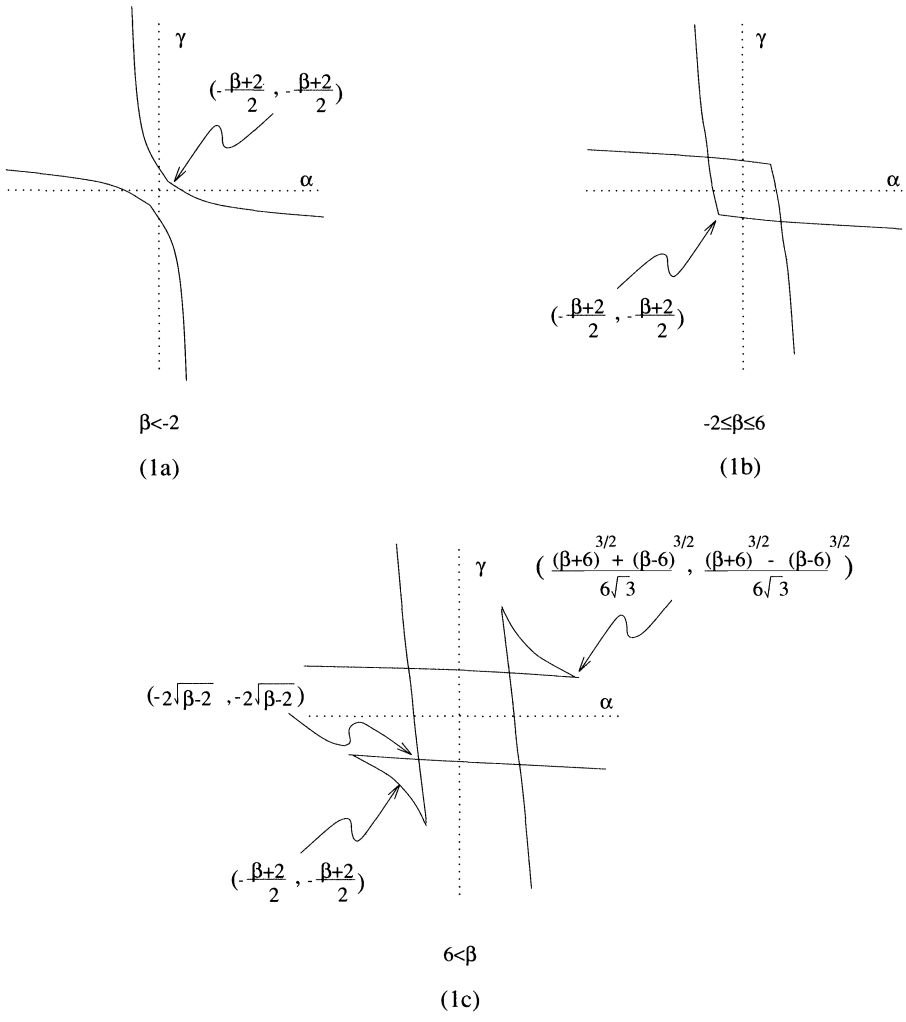

FIG. 1. *Parametric curves from* (4).

these special cases each time.) The discriminant of this quartic is proportional to (3), indicating that the quartic equations (2) and (6) have the same double root boundary; even though the double root boundary is the same for the two quartics (i.e., equations (2) and (6)), their parametric representations differ. Proceeding from (6), as was done from (2) to (4), gives parametric expressions $\alpha(r)$, $\gamma(r)$ in terms of a double root r of (6). Cleaner expressions result from writing the double root as $\pm\,\mathrm{sgn}(t)\,t$, where t is simply a parameter with restrictions obvious from the structure of the formulas. For $s = 1$ and $t^2 \geq 4$, a double root of (6) is $-\,\mathrm{sgn}(t)\,t$ and the corresponding boundary is parameterized as

$$\alpha(t) = \mathrm{sgn}(t)\left\{-2t + \frac{(t^2 - \beta + 2)}{4}\left[t + \sqrt{t^2 - 4}\right]\right\} \tag{7a}$$

and

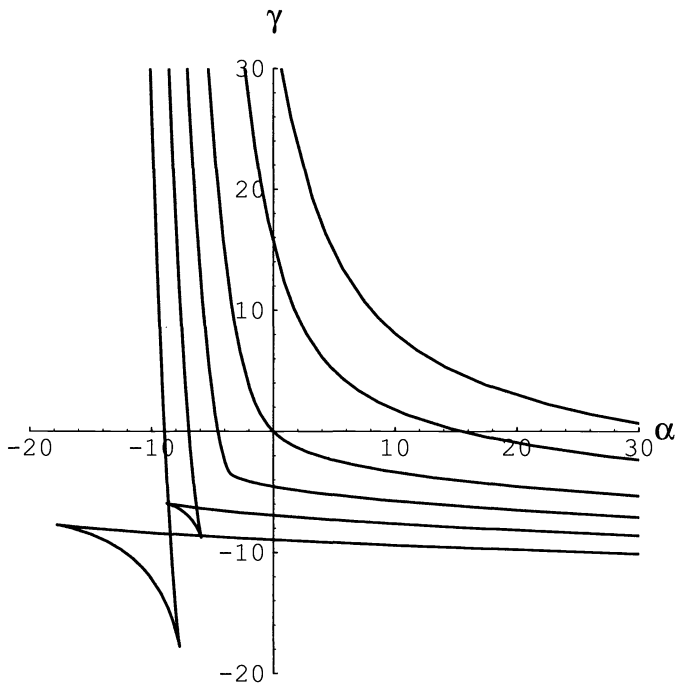

FIG. 2. *Top components of curves from* (4) *for* β=−20, −12, −2, 5, 12, 20 (*top to bottom*).

$$\gamma(t) = \operatorname{sgn}(t)\left\{-2t + \frac{(t^2-\beta+2)}{4}\left[t - \sqrt{t^2-4}\right]\right\}. \tag{7b}$$

This curve $(\alpha(t), \gamma(t))$ is the top half of the double root boundary in Fig. 1. The bottom half of the double root boundary corresponds to the double root $\operatorname{sgn}(t)\, t$ and parameterization $(-\alpha(t), -\gamma(t))$.

For $s = -1$ and $t \in (-\infty, \infty)$, the double root is t and the parametric representation of the top half of the double root boundary is

$$\alpha(t) = 2t + \frac{(t^2-\beta-2)}{4}\left[t + \sqrt{t^2+4}\right] \tag{8a}$$

and

$$\gamma(t) = -2t - \frac{(t^2-\beta-2)}{4}\left[t - \sqrt{t^2+4}\right]. \tag{8b}$$

The bottom half of the double root boundary corresponds to the double root t and parameterization $(-\gamma(t), -\alpha(t))$. The substitution of $w^2 = t^2 - 4$ in equation (7) would lead to equation (8), showing that these parameterizations are equivalent. For technical reasons that only become apparent much later, (7) is the cleanest form of the three parametrizations (4), (7), (8) to work with. Only equation (7) is needed for the proof of the following theorem concerning the region of positivity:

THEOREM 1. *For fixed* β, *the region of positivity for the quartic polynomial* (2) *is bounded below by the curve* Γ_β, *which is defined by* (7) *for* $t^2 \geq \max\{4, \beta - 2\}$. *In other words, for any* (α, γ), *the polynomial* $p(x; \alpha, \beta, \gamma)$ *has positivity if and only if there exist* (α^*, γ^*) *on* Γ_β *and* $\delta \geq 0$ *such that* $\alpha = \alpha^* + \delta$ *and* $\gamma = \gamma^* + \delta$.

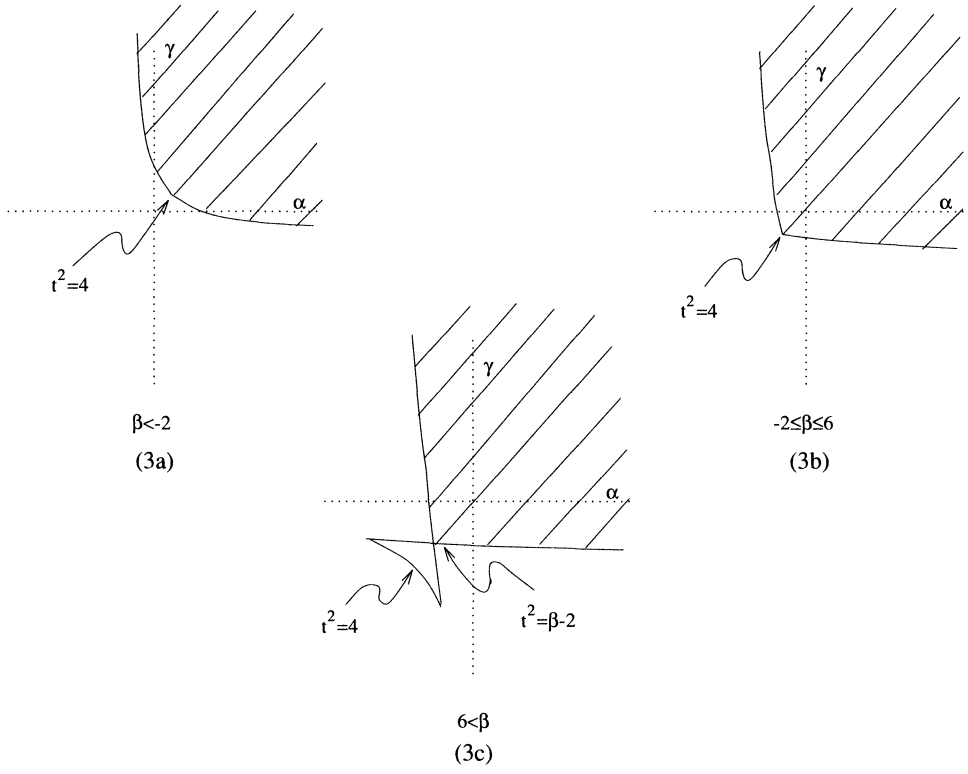

FIG. 3. *Regions of positivity for the quartic polynomial.*

Proof. For any given β, the region of positivity is depicted graphically in Fig. 3. In each case, the parametric curve Γ_β is convex; this is easily proved by looking at the signs of the first and second partial derivatives:

$$\frac{\partial \alpha^*}{\partial \gamma^*} = \frac{\sqrt{t^2-4}+t}{\sqrt{t^2-4}-t} < 0, \quad \text{for} \quad t^2 \geq \max\{4, \beta-2\},$$

$$\frac{\partial^2 \alpha^*}{\partial \gamma^{*2}} = \operatorname{sgn}(t) \frac{4\left(\sqrt{t^2-4}+t\right)}{\left(3t^2-6-\beta\right)\left(t^2-2-t\sqrt{t^2-4}\right)} > 0,$$

$$\text{for} \quad t^2 > \max\{4, \beta-2\} \geq \frac{\beta+6}{3}.$$

(An alternative argument for convexity is that the set of (α, β, γ) for which (2) is nonnegative for all $x \geq 0$ is convex, hence every constant β slice is convex, hence the bounding curve Γ_β must also be convex.) Assume for the moment that $s = 1$. For a fixed β, consider (α', γ') defined by

$$\alpha' = \alpha^*(t) + \delta, \qquad \gamma' = \gamma^*(t) + \delta,$$

for some value of $\delta \geq 0$ and for some t such that $t^2 > \max\{4, \beta-2\}$, and for $(\alpha^*(t), \gamma^*(t))$ given by equation (7). Since the parametric curve, Γ_β, is part of the

double root boundary of equation (6), and since $(\alpha^*(t), \gamma^*(t)) \in \Gamma_\beta$, then q from equation (6) with double root $-\operatorname{sgn}(t)\, t$ can be factored as

$$q(r; \alpha^*(t), \beta, \gamma^*(t)) = \big(r + \operatorname{sgn}(t)\, t\big)^2 \big(r^2 - 2\operatorname{sgn}(t)\, rt + 3t^2 - 2(\beta + 6)\big) \tag{9}$$

and $q(-\operatorname{sgn}(t)\, t; \alpha^*(t), \beta, \gamma^*(t)) = 0$. The double roots satisfy the conditions of equation (6). The other pair of roots,

$$\operatorname{sgn}(t)\, t \pm \sqrt{2(\beta + 6 - t^2)},$$

are complex when $t^2 > \beta + 6$, but do not make the lead and tail coefficients of (5) positive when they are real. Hence, the double roots $-\operatorname{sgn}(t)\, t$ are the only roots satisfying (6) and its side conditions along Γ_β.

We next show that if $p(x; \alpha, \beta, \gamma)$ has positivity, then so does $p(x; \alpha+\delta, \beta, \gamma+\delta)$ for any $\delta > 0$, i.e., moving northeast from a point of positivity (α, γ) preserves positivity. For simplicity, consider first the case of t negative, i.e., $t < \min\{-2, -\sqrt{\beta - 2}\}$ for which we have $\alpha^*(t) \le \gamma^*(t)$ and $q(t; \alpha^*(t), \beta, \gamma^*(t)) = 0$. It is obvious that $\alpha^*(t) - 2t > 0$ and $\gamma^*(t) - 2t > 0$, which means that the conditions of (6) are satisfied and $p(x; \alpha^*(t), \beta, \gamma^*(t))$ is nonnegative for positive x. Substituting $(\alpha', \beta, \gamma')$ into the function q yields

$$\begin{aligned} q(t; \alpha', \beta, \gamma') &= q(t; \alpha^*(t) + \delta, \beta, \gamma^*(t) + \delta) \\ &= q(t; \alpha^*(t), \beta, \gamma^*(t)) - 4\big[\delta(\alpha^*(t) + \gamma^*(t) - 4t) + \delta^2\big] \\ &= -4\big[\delta(\alpha^*(t) + \gamma^*(t) - 4t) + \delta^2\big]. \end{aligned} \tag{10}$$

When $\delta > 0$, this last term is negative since $\alpha^*(t) + \gamma^*(t) - 4t > 0$. Noting that the $\limsup_{r \to -\infty} q(r; \alpha', \beta, \gamma') = +\infty > 0$, it is clear that there exists a root, say $t' < t$, such that

$$q(t'; \alpha', \beta, \gamma') = 0, \quad \alpha' - 2t' > 0, \quad \gamma' - 2t' > 0.$$

Hence, $p(x; \alpha', \beta, \gamma')$ is nonnegative for positive x. Notice that this argument did not require starting on the double root boundary; it uses the fact that t is a root satisfying equation (6) for a given pair of coefficients, (α, γ), to show there exists a root t_δ which satisfies the equation for the pair $(\alpha + \delta, \gamma + \delta)$, for all $\delta > 0$.

For small $\delta < 0$, equation (10) indicates that the effect of the perturbation is to add a positive increment (in the form of a linear term) near the double roots so that they become complex. This has negligible effect on the other two roots which did not satisfy (6) so that, within a sufficiently small neighborhood below the double root boundary, the conditions of (6) are not satisfied. But this in turn proves that for any (α, γ) below the double root boundary, such that $\alpha < \gamma$, the conditions of (6) are not satisfied; if this were not true we could choose a $\delta > 0$ such that $(\alpha + \delta, \gamma + \delta)$ lay in the neighborhood just described, which would be a contradiction of the argument given in (10).

A similar analysis can be performed for positive t, i.e., $t > \max\{2, \sqrt{\beta - 2}\}$, with similar conclusions for $\alpha > \gamma$. Since Γ_β is convex, every (α, γ) in the region of

positivity can be reached from Γ_β through an appropriate choice of $(\alpha^*(t), \gamma^*(t))$ and $\delta > 0$.

We have shown that $p(x; \alpha, \beta, \gamma)$ has positivity for every (α, γ) above the curve Γ_β, and that for (α, γ) below Γ_β, $q(r; \alpha, \beta, \gamma)$ has no roots satisfying (6) for $s = 1$. Thus, all that remains to prove is that for (α, γ) below Γ_β, $q(r; \alpha, \beta, \gamma)$ has no roots satisfying (6) for $s = -1$.

So now assume $s = -1$, β is fixed, $\alpha' = \alpha^*(t) + \delta_1$, $\gamma' = \gamma^*(t) + \delta_2$, $t^2 > \beta + 2$, where $(\alpha^*(t), \gamma^*(t))$ is given by (8). Recall that the double root boundary described by (8) is the same as that given by (7), and thus Γ_β lies on the curve defined by (8). The double root t satisfies (6) if and only if $t^2 \geq \beta + 2$, so only those double roots need be considered. For double root t,

$$q(r; \alpha, \beta, \gamma) = (r - t)^2\big(r^2 + 2rt + 3t^2 + 12 - 2\beta\big),$$

and the other two roots are

$$-t \pm \sqrt{2(\beta - 6 - t^2)},$$

which are both complex since $t^2 > \beta + 2 > \beta - 6$. Therefore, the double root t is the only root satisfying (6) near the portion of Γ_β corresponding to $t^2 > \beta + 2$. Arguing as before, where now the sign of t does not matter, we conclude that $q(r; \alpha', \beta, \gamma')$ has a root satisfying (6) for any $\delta_1 > 0$ and $\delta_2 > 0$, but not for small $\delta_1 < 0$, $\delta_2 < 0$. If $q(r; \alpha, \beta, \gamma)$ had a root satisfying (6) for (α, γ) below Γ_β, then the analog of (10) would prove that $q(r; \alpha + \delta_1, \beta, \gamma + \delta_2)$ also had a root satisfying (6) for $(\alpha + \delta_1, \gamma + \delta_2)$ arbitrarily near and below the part of Γ_β corresponding to $t^2 > \beta + 2$, for appropriately chosen $\delta_1 > 0$, $\delta_2 > 0$. (It is always possible to choose such δ_i because Γ_β is convex and $\partial\gamma/\partial\alpha < 0$ along Γ_β.) Therefore we conclude that q has no roots satisfying (6) for (α, γ) below Γ_β. □

3. Positivity conditions. Verifying that a point (α, γ) lies above Γ_β is nontrivial using (7), and therefore computationally simple tests are sought for the positivity regions in Fig. 3. A continuity argument implies that the discriminant in (3) changes sign every time a double root boundary is crossed. This leads to the distribution of signs for Δ, in the three types of regions, as shown in Fig. 4. The conditions for positivity in the first case ($\beta < -2$) are simply

$$\Delta \leq 0 \quad \text{and} \quad \alpha + \gamma > 0. \tag{11}$$

For the second case, $-2 \leq \beta \leq 6$, we can use (11) as one of the conditions, but need another condition to cover the middle region with Δ positive. Linear bounds on (α, γ) could be used in this case, but a more compact representation is obtained by using a parabola,

$$\Lambda_1 \equiv (\alpha - \gamma)^2 - 16(\alpha + \beta + \gamma + 2) = 0, \tag{12}$$

which surrounds the positive middle region (see Fig. 5b). The algebra required to show that the parabola indeed lies below the curve Γ_β on the positive middle region is straightforward but tedious (because of convexity, it suffices to check the slopes at

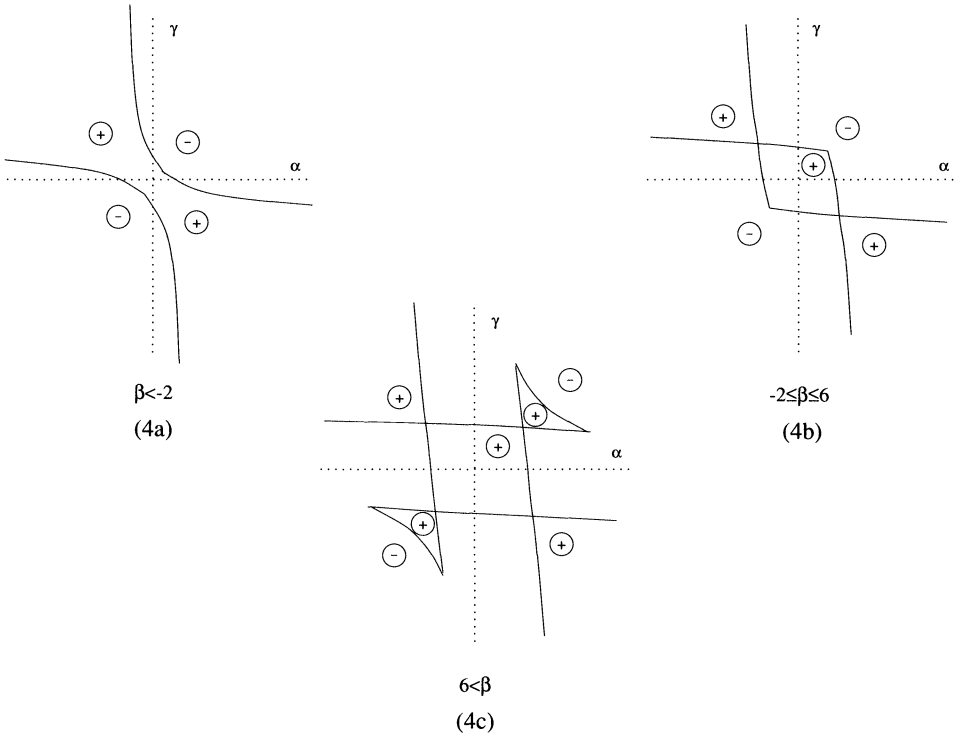

FIG. 4. *Sign distribution for the discriminant* Δ *of the quartic.*

the three points where Λ_1 intersects Γ_β). The resulting pair of conditions in the case of $-2 \leq \beta \leq 6$ are

$$\begin{aligned} &\Delta \leq 0 \quad \text{and} \quad \alpha + \gamma > 0 \\ &\qquad\quad \text{or} \\ &\Delta \geq 0 \quad \text{and} \quad \Lambda_1 \leq 0. \end{aligned} \tag{13}$$

In a similar way, a parabolic curve can be constructed to bound the middle region (see Fig. 5c) in the final case, $\beta > 6$, leading to the curve:

$$\Lambda_2 \equiv (\alpha - \gamma)^2 - \frac{4(\beta+2)}{\sqrt{\beta-2}}\left(\alpha + \gamma + 4\sqrt{\beta-2}\right) = 0. \tag{14}$$

This last case is more complicated than the previous one because the parabolic curve will not contain the tips of the cusp region for large β; however, noting that the cusp is always contained in the first quadrant leads to the following three positivity conditions corresponding to $\beta > 6$:

$$\begin{aligned} &\Delta \leq 0 \quad \text{and} \quad \alpha + \gamma > 0 \\ &\qquad\quad \text{or} \\ &\alpha > 0 \quad \text{and} \quad \gamma > 0 \\ &\qquad\quad \text{or} \\ &\Delta \geq 0 \quad \text{and} \quad \Lambda_2 \leq 0. \end{aligned} \tag{15}$$

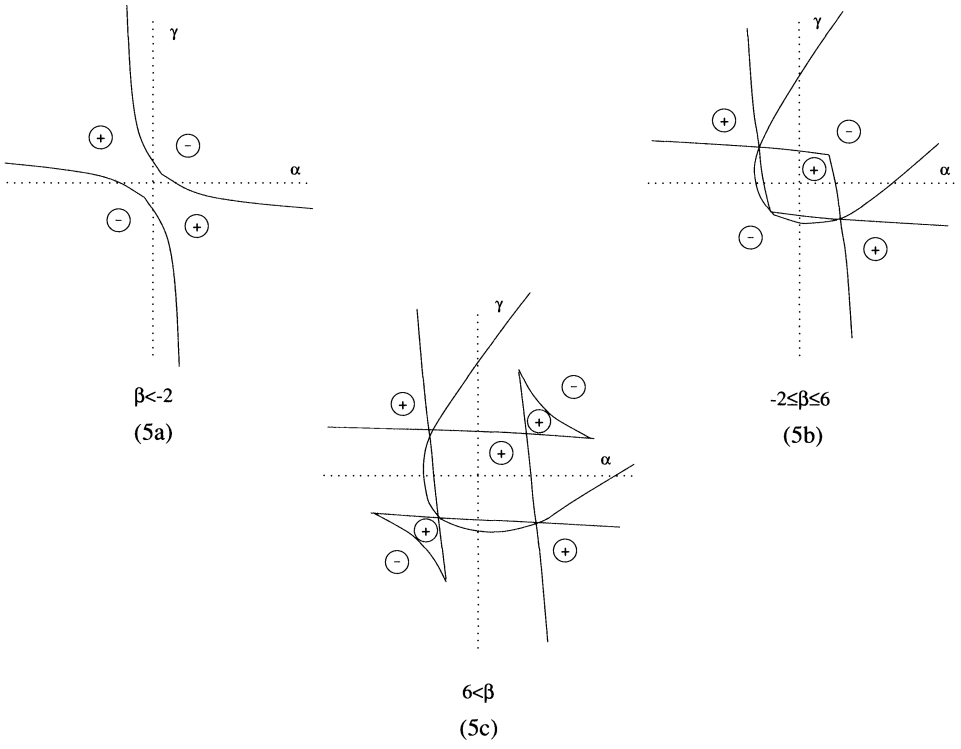

FIG. 5. *Positivity conditions for the quartic polynomial.*

A graphical depiction of these conditions is shown in Fig. 5 for the three cases. The theorem from §2 and these simple tests for positivity can be summarized in:

THEOREM 2. *Let* $f(z) = az^4 + bz^3 + cz^2 + dz + e$ *be a quartic polynomial with real coefficients and* $a > 0$, $e > 0$. *Define*

$$\alpha = ba^{-3/4}e^{-1/4}, \qquad \beta = ca^{-1/2}e^{-1/2}, \qquad \gamma = da^{-1/4}e^{-3/4},$$

$$\Delta = 4\left[\beta^2 - 3\alpha\gamma + 12\right]^3 - \left[72\beta + 9\alpha\beta\gamma - 2\beta^3 - 27\alpha^2 - 27\gamma^2\right]^2,$$

$$\Lambda_1 \equiv (\alpha-\gamma)^2 - 16(\alpha+\beta+\gamma+2), \qquad \Lambda_2 \equiv (\alpha-\gamma)^2 - \frac{4(\beta+2)}{\sqrt{\beta-2}}\left(\alpha+\gamma+4\sqrt{\beta-2}\right).$$

Then $f(z) \geq 0$ *for all* $z > 0$ *if and only if*

$$(1) \qquad \beta < -2 \quad \textit{and} \quad \Delta \leq 0 \quad \textit{and} \quad \alpha + \gamma > 0;$$

$$(2) \qquad -2 \leq \beta \leq 6 \quad \textit{and} \quad \begin{cases} \Delta \leq 0 \quad \textit{and} \quad \alpha + \gamma > 0 \\ \textit{or} \\ \Delta \geq 0 \quad \textit{and} \quad \Lambda_1 \leq 0; \end{cases}$$

$$(3) \qquad 6 < \beta \quad \textit{and} \quad \begin{cases} \Delta \leq 0 \quad \textit{and} \quad \alpha + \gamma > 0 \\ \textit{or} \\ \alpha > 0 \quad \textit{and} \quad \gamma > 0 \\ \textit{or} \\ \Delta \geq 0 \quad \textit{and} \quad \Lambda_2 \leq 0. \end{cases}$$

These conditions can be costly to implement and a set of simplified sufficient conditions can be used as a pretest for positivity. From Fig. 1, it should be clear that the following conditions are sufficient for positivity:

$$\text{(16)}\qquad \begin{aligned} &\text{(i)} \quad \alpha > -\frac{\beta+2}{2} \quad \text{and} \quad \gamma > -\frac{\beta+2}{2} \quad \text{for} \quad \beta \le 6; \\ &\text{(ii)} \quad \alpha > -2\sqrt{\beta-2} \quad \text{and} \quad \gamma > -2\sqrt{\beta-2} \quad \text{for} \quad \beta > 6. \end{aligned}$$

4. Applications. The initial motivation for this work was in the application of Hermite interpolation to construction of random number algorithms for arbitrary continuous distributions. Results from a previous paper [10] suggested that a fifth degree piecewise polynomial approximation could achieve accuracy comparable to that of an exact algorithm implemented in single precision for many common distributions. That same paper outlined an approach for constructing the piecewise polynomial interpolant but indicated that, even though the inverse cdf was monotone, piecewise interpolants using higher order polynomials might not be monotone. The problem of testing for monotonicity of cubic interpolants was solved by Fritsch and Carlson [4], of quartic interpolants by [8], and of quintic interpolants (sufficiency) by and [3] and [11]. Theorem 1 can be used in testing for monotonicity of the quintic interpolant as described below.

Suppose that a quintic interpolant is constructed on the interval (U_0, U_1) to match the ordinates and first and second derivatives of the function $f(U)$, e.g.,

$$\begin{aligned} X_0 &= f(U_0), \quad X_0' = f'(U_0), \quad X_0'' = f''(U_0), \\ X_1 &= f(U_1), \quad X_1' = f'(U_1), \quad X_1'' = f''(U_1). \end{aligned}$$

The fifth degree Hermite polynomial interpolant on (U_0, U_1) can be written as

$$\text{(17)}\qquad \begin{aligned} X(u) = \frac{1}{16}\Big\{ &\big[h^2(X_1'' - X_0'') - 3h(X_0' + X_1') + 3(X_1 - X_0)\big]u^5 \\ &+ \big[h^2(X_0'' + X_1'') - h(X_1' - X_0')\big]u^4 \\ &+ \big[-2h^2(X_1'' - X_0'') + 10h(X_0' + X_1') - 10(X_1 - X_0)\big]u^3 \\ &+ \big[-2h^2(X_0'' + X_1'') + 6h(X_1' - X_0')\big]u^2 \\ &+ \big[h^2(X_1'' - X_0'') - 7h(X_0' + X_1') + 15(X_1 - X_0)\big]u \\ &+ \big[h^2(X_0'' + X_1'') - 5h(X_1' - X_0') + 8(X_0 + X_1)\big]\Big\}, \end{aligned}$$

where $u = (U - \bar{U})/h$, $\bar{U} = (U_0 + U_1)/2$, and $h = (U_1 - U_0)/2$. The polynomial in (17) is monotone on (U_0, U_1) if and only if its derivative is nonnegative over the interval. Taking the derivative and using the transformation $u = \frac{z-1}{z+1}$ we obtain the test polynomial

$$\text{(18)}\qquad Bz^4 + 4(B - D)z^3 + 6(D - C - 2B - 2A + 5)z^2 + 4(A + C)z + A,$$

where $A = \frac{2hX_0'}{\nu}$, $B = \frac{2hX_1'}{\nu}$, $C = \frac{h^2X_0''}{\nu}$, $D = \frac{h^2X_1''}{\nu}$, and $\nu = (X_1 - X_0)$; the quintic in (17) is monotone if and only if (18) is nonnegative for $z > 0$. (The special case $AB = 0$

reduces to a cubic, and will not be considered further. Thus we assume $A > 0$, $B > 0$ henceforth.)

This quartic can be reparameterized to fit the form of equation (2) by defining

$$\alpha = \frac{4(B-D)}{A^{1/4}B^{3/4}}, \qquad \beta = \frac{6(D-C-2B-2A+5)}{A^{1/2}B^{1/2}}, \qquad \gamma = \frac{4(A+C)}{A^{3/4}B^{1/4}}. \tag{19}$$

Theorem 2 can be applied to these coefficient values to determine whether the polynomial in (17) is monotone. If the quintic is not monotone then we can adjust the derivative values to make it monotone over (U_0, U_1). One strategy is to scale the derivative vector $(X_0', X_1', X_0'', X_1'')$ by an appropriate factor $\rho \in (0,1)$, e.g.,

$$\rho\big(X_0', X_1', X_0'', X_1''\big),$$

which will always lead to monotonicity for ρ small enough. To see this, note that, after scaling, the coefficients in (19) become

$$\alpha = \frac{4(B-D)}{A^{1/4}B^{3/4}}, \qquad \beta = \frac{6\left(D-C-2B-2A+\frac{5}{\rho}\right)}{A^{1/2}B^{1/2}}, \qquad \gamma = \frac{4(A+C)}{A^{3/4}B^{1/4}},$$

and decreasing ρ increases β without affecting α or γ. The nature of the positivity regions is such that increasing β will eventually satisfy the conditions of Theorem 2, for fixed α and γ. In particular, equation (16ii) can be used to provide an approximate value for ρ, e.g., choose ρ as

$$\rho \approx \frac{120}{\sqrt{AB}(\delta^2+8) + 24(2A+2B+C-D)}, \quad \text{where } \delta = \min\{\alpha, \gamma\}.$$

A more satisfying strategy for constraining (17) to be monotone would involve adjusting only the second derivatives. For much of what follows, we will assume that the values of A and B are fixed. If a point $\eta_0 = (C_0, D_0)$ could be located within the interior of the monotonicity region, for fixed (A, B), then (17) would be monotone for (A, B, C^*, D^*), where

$$(C^*, D^*) = \rho\,(C, D) + (1-\rho)(C_0, D_0) \tag{20}$$

for sufficiently small ρ.

With fixed (A, B), using (19) and plotting $\Delta = \Delta(C, D) = 0$ in the (C, D) plane gives teardrop-shaped regions for the permissible values of (C, D) [3], [11]. The discussion below, based on [11], derives entirely from translating the positivity region in (α, β, γ) space to a region in (A, B, C, D) space.

We establish the notation $\eta = (C, D)$ for fixed (A, B), and consider the points (determined in conjunction with a previous paper [11] concerned with monotonicity of the quintic Hermite polynomial) defined by

$$
\begin{aligned}
\eta_1 = (C_1, D_1) = \Bigg(& \frac{-\sqrt{A}}{4}\left(7\sqrt{A} + 3\sqrt{B} + \sqrt{5\left(24 + 2\sqrt{AB} - 3(A+B)\right)}\right), \\
& \frac{\sqrt{B}}{4}\left(3\sqrt{A} + 7\sqrt{B} + \sqrt{5\left(24 + 2\sqrt{AB} - 3(A+B)\right)}\right)\Bigg), \\
\eta_2 = (C_2, D_2) = \Bigg(& \frac{-\sqrt{A}\left(6A + 3B - 15 + 2\sqrt{AB} - 4A^{3/4}B^{1/4}\right)}{3(\sqrt{A} + \sqrt{B}) - 4(AB)^{1/4}}, \\
& \frac{\sqrt{B}\left(3A + 6B - 15 + 2\sqrt{AB} - 4A^{1/4}B^{3/4}\right)}{3(\sqrt{A} + \sqrt{B}) - 4(AB)^{1/4}}\Bigg), \\
\eta_3 = (C_3, D_3) = \Bigg(& \frac{-\sqrt{A}}{4}\left(7\sqrt{A} + 3\sqrt{B} - \sqrt{5\left(24 + 2\sqrt{AB} - 3(A+B)\right)}\right), \\
& \frac{\sqrt{B}}{4}\left(3\sqrt{A} + 7\sqrt{B} - \sqrt{5\left(24 + 2\sqrt{AB} - 3(A+B)\right)}\right)\Bigg).
\end{aligned}
\tag{21}
$$

These points lie along the line $(\gamma = \alpha)$

$$
\sqrt{B}(A + C) = \sqrt{A}(B - D), \tag{22}
$$

and we will show that this line passes through the teardrop-shaped region of (C, D) values for which equation (17) is monotone, for fixed (A, B). Also consider Regions I and II, depicted in Fig. 6, showing values of A and B (both positive) over which the η_i will provide endpoints bounding the segment of (C, D) values along (22) for which the Hermite interpolant is monotone. Note that the Region II boundary is the same as the one defined in Fig. 4.2 of [3]. If we define $\alpha(\nu)$, $\beta(\nu)$, $\gamma(\nu)$ to be the coefficients in (19) evaluated at $\nu = \eta_1$, η_2, or η_3, then we can prove the following results:

THEOREM 3. *The coefficients in* (19) *exhibit the following properties*:

i. $\eta_2 = \eta_3$ *along the boundary between Regions* I *and* II;

ii. $\beta(\eta_1) > 6$ *over Regions* I *and* II;

iii. $\beta(\eta_2) \leq 6$ *over Region* I *and* $\beta(\eta_2) > 6$ *over Region* II;

iv. $\beta(\eta_3) \leq 6$ *over Region* I *and* $\beta(\eta_3) > 6$ *over Region* II;

v. $\alpha(\eta_1) = \gamma(\eta_1) = -2\sqrt{\beta(\eta_1) - 2}$;

vi. $\alpha(\eta_2) = \gamma(\eta_2) = -\dfrac{\beta(\eta_2) + 2}{2}$;

vii. $\alpha(\eta_3) = \gamma(\eta_3) = -2\sqrt{\beta(\eta_3) - 2}$.

The proof of these results involves tedious, but straightforward, algebra and therefore will not be given here. The points η_1, η_2, η_3 provide the endpoints to intervals

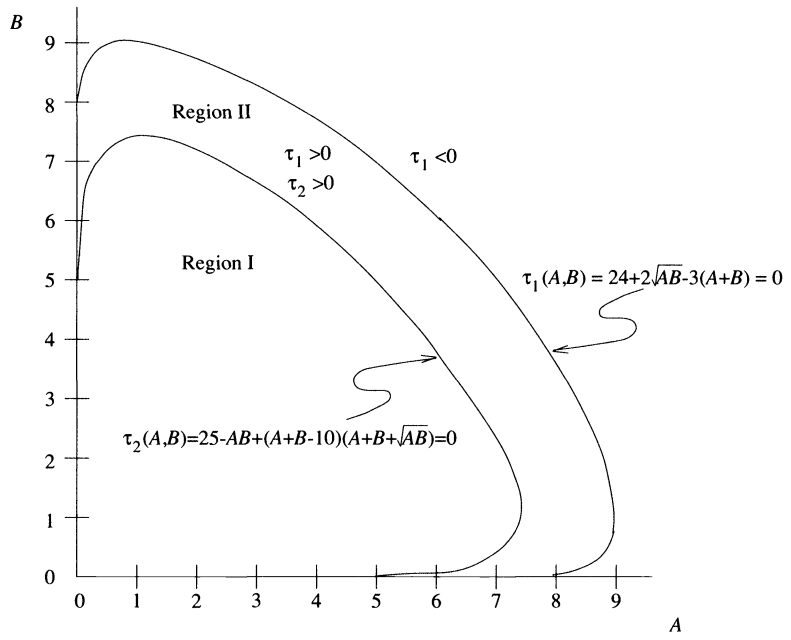

FIG. 6. *Boundary regions on* $\eta(A,B)$.

of monotonicity for η along the line given by equation (22). Note that η_1 and η_3 are complex for (A, B) beyond Region II, a reflection of the fact that equation (17) cannot be monotone for (A, B) outside of Regions I and II. The endpoint relationships can be summarized in the following theorem:

THEOREM 4. *Let* (A, B) *be fixed and contained within Region* I *or* II. *If* $\eta_0 = (C_0, D_0)$ *is any point on the line given by* (22), *then* (17) *is monotone for* (A, B, C_0, D_0) *if and only if*

i. (A, B) *is in Region* I *and* $\eta_0 = \rho\eta_1 + (1-\rho)\eta_2$ *for some* $\rho \in [0, 1]$, *or*
ii. (A, B) *is in Region* II *and* $\eta_0 = \rho\eta_1 + (1-\rho)\eta_3$ *for some* $\rho \in [0, 1]$.

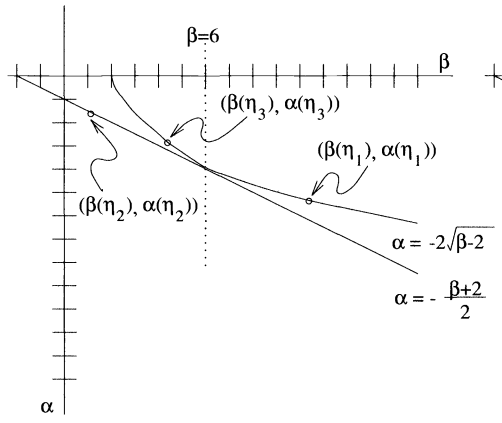
Proof. Sufficiency. Note first that $\alpha(\eta_0) = \gamma(\eta_0)$ since η_0 lies along the line given by (22). Consider first the case of (A, B) in Region II. According to (16), we need to show that $\alpha(\eta_0) \geq -2\sqrt{\beta(\eta_0) - 2}$. Clearly, for fixed (A, B), $\alpha(\eta)$ and $\beta(\eta)$ are affine in η so that (using Theorem 3)

$$\begin{aligned}\alpha(\eta_0) &= \rho\alpha(\eta_1) + (1-\rho)\alpha(\eta_3) = \rho\left(-2\sqrt{\beta(\eta_1) - 2}\right) + (1-\rho)\left(-2\sqrt{\beta(\eta_3) - 2}\right) \\ &\geq -2\sqrt{\left(\rho\beta(\eta_1) + (1-\rho)\beta(\eta_3)\right) - 2} \quad \text{by convexity of } -2\sqrt{x} \\ &= -2\sqrt{\beta(\eta_0) - 2}.\end{aligned}$$

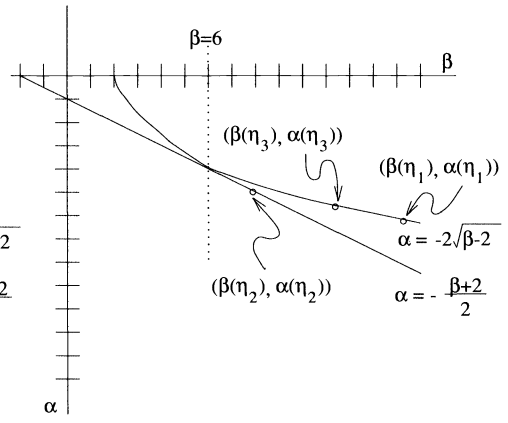
Figure 7b depicts the relationship established in the above inequality.

For the case of (A, B) in Region I, the proof is similar except that we have to consider the convex function defined by

$$\omega(x) = \begin{cases} -\dfrac{x+2}{2}, & x \leq 6; \\ -2\sqrt{x-2}, & x > 6. \end{cases}$$



(7a) (*A*,*B*) in region I.



(7b) (*A*,*B*) in region II.

FIG. 7. *Coefficients evaluated at η values.*

Again using Theorem 3 and (16), as Fig. 7a suggests, we have

$$\begin{aligned}\alpha(\eta_0) &= \rho\alpha(\eta_1) + (1-\rho)\alpha(\eta_2) = \rho\big(-2\sqrt{\beta(\eta_1)-2}\big) + (1-\rho)\left(-\frac{\beta(\eta_2)+2}{2}\right)\\ &= \rho\,\omega(\beta(\eta_1)) + (1-\rho)\omega(\beta(\eta_2))\\ &\geq \omega\big(\rho\beta(\eta_1) + (1-\rho)\beta(\eta_2)\big) \quad \text{by convexity of } \omega(x)\\ &= \omega(\beta(\eta_0)).\end{aligned}$$

Necessity. From Figs. 1 and 3 and Theorem 2, both the situations

$$\alpha(\eta_0) = \gamma(\eta_0) < -\frac{\beta(\eta_0)+2}{2}, \qquad \big(\beta(\eta_0) \leq 6\big),$$

and

$$\alpha(\eta_0) = \gamma(\eta_0) < -2\sqrt{\beta(\eta_0)-2}, \qquad \big(\beta(\eta_0) > 6\big),$$

correspond to nonmonotonicity of (17). These situations obtain precisely when $\rho \notin [0,1]$ for Region I (Fig. 7a) or $\rho \notin [0,1]$ for Region II (Fig. 7b), from the convexity of $\omega(x)$. This proves the necessity and completes the proof. □

By choosing η_0 as any point satisfying the conditions of Theorem 4, we obtain a point interior to the region of monotonicity. The adjustment described in (20) can then be used to constrain the quintic to be monotone. For (A,B) in Region II, a reasonable choice of η_0 is the average of the interval endpoints, η_1 and η_3, namely

$$\eta_0 = \left(-\frac{\sqrt{A}}{4}(7\sqrt{A}+3\sqrt{B}), \frac{\sqrt{B}}{4}(3\sqrt{A}+7\sqrt{B})\right). \tag{23}$$

Actually, this same point is interior to the monotonicity region for (A,B) in Region I as well since η_3 lies between η_1 and η_2 within Region I along the line given in (22).

We will summarize all of these results in algorithmic form. If $\nu = X_1 - X_0 < 0$, monotonically increasing is impossible, and if $\nu = 0$, the solution is $A = B = C = D = 0$. Assume $\nu > 0$ in the following, and that nominal values of A, B, C, D are given (obtained, e.g., by a C^4 quintic spline interpolant or finite difference approximations). The case where (A, B) lies outside of Regions I and II will be handled in the first and second steps of the algorithm.

Algorithm for constructing a monotone increasing Hermite quintic.

1. Set $A := \max\{0, A\}$, $B := \max\{0, B\}$. If $AB = 0$, use the simpler positivity criteria of [8] for cubics.
2. If $\tau_1(A, B) = 24 + 2\sqrt{AB} - 3(A+B) < 0$, then scale the derivative vector (X_0', X_1') until $\tau_1(A, B) > 0$.
3. Let $\eta = (C, D)$. If $\alpha(\eta)$, $\beta(\eta)$, and $\gamma(\eta)$ do not satisfy the conditions of Theorem 2, then find ρ such that $\alpha(\eta^*)$, $\beta(\eta^*)$, and $\gamma(\eta^*)$ do satisfy the conditions, where

$$\eta^* = \rho\eta + (1 - \rho)\eta_0, \qquad \rho \in (0, 1),$$

with η_0 defined in (23).

Following Huynh [5], Step 1 can be preceded by: Set $X_0' := \text{median}\left\{0, X_0', \frac{7\nu}{2h}\right\}$, $X_1' := \text{median}\left\{0, X_1', \frac{7\nu}{2h}\right\}$, and then compute (A, B). Step 2 can be replaced by a simpler sufficient condition which would scale the derivative vector till the first derivatives lie within the square imbedded within Region II (e.g., the square defined by $[0, 6] \times [0, 6]$). Yet another alternative to Step 2 would be to scale the derivatives X_0', X_1' back independently until $\tau_1(A, B) > 0$ [2], [3]. In a similar fashion, we can use the conditions in (16) to simplify verification of monotonicity of the quintic in Step 3 of the algorithm.

Note that the above algorithm is for a *single* monotone increasing Hermite quintic polynomial piece, and does not address at all the iterative adjustments required to achieve a monotone Hermite quintic *spline*. From Theorem 4 and (21) it is clear, however, that such an adjustment is always possible: for sufficiently small $(A, B) > 0$ the admissible (C, D) line segments are arbitrarily long. An efficient and robust computer algorithm for monotone Hermite quintic spline interpolation based on the teardrop regions of [11] will be the topic of a future paper.

5. Conclusion. Elegant necessary and sufficient conditions that a quartic polynomial $f(z)$ be nonnegative for $z > 0$ have been derived. Simple and computationally cheap sufficient conditions were deduced from the more general conditions. Important applications are to monotone quintic spline interpolation and the efficient generation of random variates from arbitrary continuous distributions. Applying the theory to monotone quintic interpolation, sharp necessary and sufficient conditions for monotonicity were derived. Simpler sufficient conditions for monotonicity were condensed into an algorithm suitable for quintic spline interpolation.

SPECIAL SECTION ON ITERATIVE METHODS IN NUMERICAL LINEAR ALGEBRA

The 1992 Copper Mountain Conference on Iterative Methods in Numerical Linear Algebra was the seventh conference in the Copper Mountain series and the second devoted to general iterative methods. It was attended by approximately 190 mathematicians from all corners of the world. The meeting, held April 9–14, 1992, took place at the Copper Mountain Resort, which is located 70 miles west of Denver, in the heart of Colorado's famous Summit County ski region. The setting of the conference was a cluster of buildings nestled at the base of the resort's ski hill. Morning and evening sessions were scheduled, leaving afternoons open for informal discussions and recreation.

During the five days of the meeting, 109 talks on current research were presented. These talks were organized by content and grouped into sessions. Session topics included the Theory of Iterative Methods (two sessions), Nonsymmetric Systems (four), Preconditioning Strategies (two), Parallel Implementations (three), Applications (four), Multigrid and Multilevel Methods (three), Domain Decomposition (two), Eigenvalue Problems (two), Integral Equations, Nonlinear Systems (two), Indefinite and Complex Matrix Problems, Collocation Matrices, and Software. In addition, there were workshops devoted to Scientific Computing in C^{++} and Common Software Standards.

On the first day of the conference each participant was provided with a two-volume set of Preliminary Proceedings, which contained either a short paper or an abstract by each of the scheduled speakers. Of those, 49 speakers submitted complete papers to this special issue of the *SIAM Journal on Scientific Computing* (*SISC*). This and the previous issue of *SISC* contain the results of the refereeing process. They represent a rich mix of papers on a wide variety of topics related to iterative methods.

In the previous issue the last twelve papers represent the conference. The first three deal with general iterative algorithms. The second and third involve quasi-minimal residual algorithms, a subject that inspired much discussion at the meeting. Papers 4 and 5 analyze interesting theoretical aspects of iterative methods. Papers 6 through 9 deal with precondition strategies. Papers 10 through 12 explore the implications for iterative methods of parallel computing environments.

In this issue the last twelve papers again represent the conference. The first seven of these deal with multigrid or multilevel algorithms. The first of these is a very interesting paper that uses the tools of classical iterative methods to analyze and compare many well-known algorithms. The second and third papers also contribute to the development of the theory of multigrid and multilevel algorithms. Papers 4 through 6 are concerned with domain decomposition methods, which, incidentally, fall into the structure developed in the first paper. The final six papers in this group discuss iterative methods in the context of specific applications and represent the many fine application-specific talks presented at the conference.

A special effort was made to bring students to the meeting. The vehicle for this effort was a Student Paper Competition in which students were asked to submit an original research paper consisting primarily of their own work. We were fortunate enough to be able to provide all student authors participating in this competition with free lodging and registration. Out of thirteen submissions, three winners were selected. First place went to Xian-Zhong Guo from the University of Maryland for his work, *"The Algebraic Hierarchical Basis Multigrid Method."* Second place was awarded to Marlis Hochbruck from the University of Karlsruhe, Germany, for her paper, *"On the Use of Two QMR Algorithms for Solving Singular Systems and Applications in the Markov Chain Modeling."* Third place honors were awarded to Andrew Lumsdaine from MIT for the paper, *"Accelerating Dynamic Iteration Methods with*

Application to Semiconductor Device Simulation." All winners were awarded a travel stipend, and their papers were presented at a special session devoted to the Student Paper Competition.

We would like to thank the following members of the program committee for their help in editing this special issue. They are: Steve Ashby, Howard Elman, Roland Freund, Anne Greenbaum, Seymour Parter, Paul Saylor, Homer Walker, and Olof Widlund. Through their efforts, the articles contained in this special issue were carefully refereed and brought to print on schedule.

We would also like to extend a special thanks to Fred Howes of the Applied Mathematical Sciences Program of the Department of Energy for generous support of this meeting. Without his help, this meeting could not have taken place.

As this issue goes to press, planning for the next conference in this series is in its final stages. It will be called the Colorado Conference on Iterative Methods and will be held April 4–9, 1994, in Breckenridge, Colorado. Plans again include a special journal issue in *SISC*. It is our hope that the lively interaction and the fine quality of presentations and papers that have marked the previous meetings can be duplicated at the upcoming meeting.

MULTILEVEL ALGORITHMS CONSIDERED AS ITERATIVE METHODS ON SEMIDEFINITE SYSTEMS*

MICHAEL GRIEBEL†

Abstract. For the representation of piecewise d-linear functions instead of the usual finite element basis, a generating system is introduced that contains the nodal basis functions of the finest level and of all coarser levels of discretization. This approach enables the author to work directly with multilevel decompositions of a function.

For a partial differential equation, the Galerkin scheme based on this generating system results in a semidefinite matrix equation that has in the one-dimensional (1D) case only about twice, in the two-dimensional (2D) case about 4/3 times, and in the three-dimensional (3D) case about 8/7 times as many unknowns as the usual system. Furthermore, the semidefinite system possesses not just one, but many solutions. However, the unique solution of the usual definite finite element problem can be easily computed from every solution of the semidefinite problem.

The author shows that modern multilevel algorithms can be considered as standard iterative methods over the semidefinite system. The conjugate gradient (CG) method for the semidefinite system is equivalent to the BPX- or MDS-preconditioned CG method for the linear system that arises from the usual finite element basis. The Gauss–Seidel iteration applied to the semidefinite system is equivalent to the multigrid (MG) method applied to the standard basis system. Consequently, the Gauss–Seidel-preconditioned CG method for the semidefinite system is equivalent to MG-CG for the standard basis system.

This paper includes results of numerical experiments regarding the condition number and the convergence rates of different iterative methods for the semidefinite system.

1. Introduction.

In recent years, different multilevel methods have been used extensively to obtain approximations to solutions of partial differential equations. Besides the multigrid method (see the references in [10], [13]) and the hierarchical basis multigrid method [3], multilevel methods for the preconditioning of the CG algorithm have also been developed, including the BPX-preconditioner of Bramble, Pasciak, and Xu [5], [21], its generalization multilevel diagonal scaling (MDS) (see [20], [25]), and the hierarchical basis preconditioner of Yserentant [22]. For a comparison of these preconditioners, see [23]. Another interesting type of multilevel preconditioner has been developed in [2]. Furthermore, preconditioners that make use of the multigrid method have been studied in [11].

Under rigorous assumptions on regularity and approximation properties, a convergence rate that is independent of the number of levels can be proved for multigrid methods. In contrast to this, two-level schemes have been proved to converge under weaker assumptions. The same is true for the preconditioner of Xu and, in the 2D case, of Yserentant. Here, no regularity assumptions are needed to prove a condition number of $O(k^2)$ for the preconditioned system, where k denotes the number of employed levels. Under strong regularity assumptions, a condition number estimate of $O(k)$ can be given. See the Appendix in [23].

Recently, Oswald [16]–[18], Xu [20], and Bornemann and Yserentant [4] showed that (even under weak assumptions) the condition number of the BPX-preconditioner is $O(1)$. Also, Zhang [25] gave an elegant proof for the condition number of the MDS operator, which is a slight generalization of BPX. It grows at most linearly with the number of levels in the

†Institut für Informatik, Technische Universität München, Arcisstraße 21, D-80290 München, Germany (griebel@informatik.tu-muenchen.de).

general case, and is bounded by a constant independent of the mesh sizes and number of levels under the H^2-regularity assumption. In this sense, multilevel methods are optimal.

In this paper we present a new approach to multilevel methods that abandons the usual basis approach in favor of generating functions that span the approximation space, but which are generally linearly dependent. The idea is to use the standard basis functions on *all* levels of discretization. The resulting Galerkin scheme therefore results in a redundant semidefinite system of linear equations that has multiple solutions, but each is equivalent to the unique solution of the standard basis approach. Fortunately, in many cases, the generalized condition number (i.e., the condition number of the matrix restricted to the orthogonal complement of its null space) of the semidefinite system matrix is of the order $O(1)$, and we will see that its singularity does not disrupt the iterative process that we use.

More specifically, there is no need for a basis of the approximation space if energy minimizing iteration methods like the CG method or Gauss–Seidel-type relaxations are used. In this case, even the use of a basis is an obstacle because smooth errors cannot be adequately attenuated by the standard basis functions. Acceleration of these methods can be gained only by quite complex techniques such as BPX-preconditioning or, in the multigrid context, by coarse grid corrections.

In contrast, the use of the generating system allows us to work directly with multilevel decompositions of functions. This gives additional freedom that is beyond the scope of the traditional basis approach and leads in a natural manner to accelerated algorithms. It is of special interest that standard iteration methods for the semidefinite system are equivalent to modern multilevel methods applied to the linear system that arises from the usual finite element basis.

We show that the BPX-preconditioner and its generalization MDS, together with the CG method, are just special implementations of the (diagonally scaled) CG iteration on the semidefinite system. Similarly, the HB-preconditioner can be interpreted in terms of the semidefinite system. Furthermore, we will show that the Gauss–Seidel iteration for the semidefinite system is equivalent to the multigrid method for the standard basis system. For Aitken's double sweep algorithm, which is also known as symmetric Gauss–Seidel (SGS) we obtain the standard (1,1)-MG-V-cycle. In this sense, our method and McCormick's approach of Unigrid and PML (multilevel projection method) are similar in spirit; see [14], [15]. Additionally, the HB-MG method can be explained easily in terms of the semidefinite system. If we use the Gauss–Seidel iteration as a CG-preconditioner for the semidefinite system, we obtain an algorithm that is equivalent to MG-CG for the standard basis system.

The outline of the remainder of this paper is as follows. In §2, we introduce the generating system, derive the semidefinite system of linear equations, and discuss its properties. In §3, we consider iterative methods on the semidefinite system. First, we study the diagonally preconditioned CG method. We show that it is equivalent to the BPX- or MDS-preconditioned CG method for the standard basis system. Then we demonstrate that the Gauss–Seidel iteration for the semidefinite system is equivalent to the multigrid method for the standard basis system. Furthermore, we show that the use of Gauss–Seidel relaxations as a preconditioner for the semidefinite system results in MG-CG for the standard basis system. Finally, the results of numerical experiments illustrating the theory of the earlier sections are given in §4. An extended version of this paper can be found in [7].

2. The semidefinite system. In this section, we introduce a generating system that replaces the usual finite element basis in the discretization of a boundary value problem of a partial differential equation. We then derive the associated semidefinite linear system and discuss its properties.

Consider a partial differential equation in d dimensions with a linear, second-order oper-

ator on the domain $\Omega = (0, 1)^d$, $d = 1, 2, \ldots$,

$$Lu = f \quad \text{on} \quad \Omega, \tag{1}$$

with appropriate boundary conditions and solution u. For reasons of simplicity, we restrict ourselves to homogeneous Dirichlet boundary conditions. Given an appropriate function space V, the problem can be expressed equivalently in its variational form: Find a function $u \in V$ with

$$a(u, v) = (f, v) \quad \forall\, v \in V. \tag{2}$$

(In the case of homogeneous Dirichlet boundary conditions, V would be the Sobolev space $H_0^1(\Omega)$.) Here, a: $V \times V \to V$ is a bounded, positive-definite, symmetric bilinear form and $(.\,,.)$ is the usual linear form for the right-hand side. Let $||.||_a := \sqrt{a(.\,,.)}$ denote the induced energy norm. We assume that V is complete with respect to $||.||_a$, which is true if $a(.\,,.)$ is H_0^1-elliptic. The Lax–Milgram lemma then guarantees the existence and uniqueness of the solution of (2). If we consider directly the energy functional $1/2 \cdot a(u, u) - (f, u)$, the problem can be stated alternatively as minimization of the energy in V.

2.1. Spaces, bases, and the generating system. Assume we are given a sequence of uniform, equidistant, nested grids,

$$\Omega_1 \subset \Omega_2 \subset \cdots \subset \Omega_{k-1} \subset \Omega_k, \tag{3}$$

on Ω with respective mesh sizes $h_l = 2^{-l}$, $l = 1, \ldots, k$, and an associated sequence of spaces of piecewise d-linear functions,

$$V_1 \subset V_2 \subset \cdots \subset V_{k-1} \subset V_k, \tag{4}$$

with dimensions

$$n_l := \dim(V_l) = (2^l - 1)^d, \qquad l = 1, \ldots, k. \tag{5}$$

Here, 1 denotes the coarsest and k the finest level of discretization. Consider also the sequence

$$N_1 \subset N_2 \subset \cdots \subset N_{k-1} \subset N_k \tag{6}$$

of sets of grid points $N_l = \{x_1, \ldots, x_{n_l}\}$ in the interior Ω_l, $l = 1, \ldots, k$.

The standard finite element basis that spans V_l on the equidistant grid Ω_l is denoted by B_l. It contains the nodal basis functions $\phi_i^{(l)}$, $i = 1, \ldots, n_l$, which are defined by

$$\phi_i^{(l)}(x_j) = \delta_{i,j}, \qquad x_j \in N_l. \tag{7}$$

Note that we use rectangular grids. Therefore, the 2D basis functions can be written as the product of two 1D basis functions for the different coordinate directions. The analogue is true for the 3D case, where the basis functions are written as the product of three 1D basis functions.

Any function $u \in V_k$ can be expressed uniquely by

$$u = \sum_{i=1}^{n_k} u_i^{(k)} \phi_i^{(k)}, \tag{8}$$

with the vector $u_k := (u_1^{(k)}, u_2^{(k)}, \ldots, u_{n_k}^{(k)})^T$ of nodal values.

In contrast to the basis approach expressed by the expansion in (8), we instead consider the set of functions E_k defined as the union of all the different nodal bases B_l for the levels $l = 1, \ldots, k$,

$$E_k = B_1 \cup B_2 \cup \cdots \cup B_{k-1} \cup B_k. \tag{9}$$

Clearly, because E_k is a linearly dependent set of functions, it is no longer a basis for V_k, but merely a generating system. See Fig. 1 for a simple 1D example.

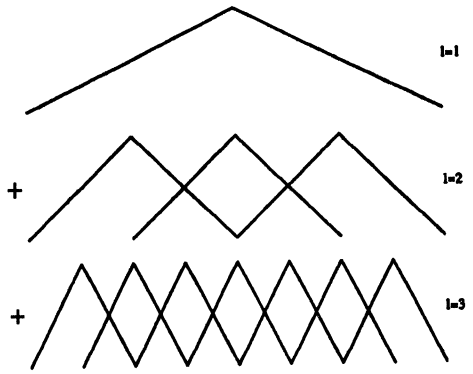

FIG. 1. *Functions of the generating system E_3 in the* 1D *case.*

In any case, an arbitrary function $u \in V_k$ can be expressed in terms of the generating system by

$$u = \sum_{l=1}^{k} \sum_{i=1}^{n_l} w_i^{(l)} \phi_i^{(l)}, \tag{10}$$

with the block vector $w_k^E := (w^{(1)}, w^{(2)}, \ldots, w^{(k)})^T$, were $w^{(l)} = (w_1^{(l)}, w_2^{(l)}, \ldots, w_{n_l}^{(l)})$, $l = 1, \ldots, k$. This represents a *level-wise decomposition* of u into functions $g^{(l)} \in V_l, l = 1, \ldots, k$, where

$$u = \sum_{l=1}^{k} g^{(l)}, \qquad g^{(l)} = \sum_{i=1}^{n_l} w_i^{(l)} \phi_i^{(l)}. \tag{11}$$

To simplify the notation, we will not distinguish explicitly between the functions u or $g^{(l)}$ and their vector representations u_k or $w^{(l)}$, but denote them by their vector representations only. Here and in the following, we denote representations in terms of the generating system E_k by the superscript E. The length of w_k^E is

$$n_k^E = \sum_{l=1}^{k} n_l, \tag{12}$$

which is in the 1D case about twice, in the 2D case about 4/3 times, and in the 3D case about 8/7 times larger than the length of the vectors for the basis representation above. This is due to the geometric rate of decrease of the number of grid points from fine to coarse levels, with

factors of 1/2, 1/4, and 1/8 for 1D, 2D, and 3D, respectively. The generalization of this concept to higher dimensions is straightforward.

Note that the representation of u in terms of E_k is not unique. In general, there exists an n_{k-1}^E-dimensional variety of level-wise decompositions of $u \in V_k$. However, for a given representation w_k^E of u in E_k, we can easily compute its unique representation u_k with respect to B_k. This transformation from w_k^E to u_k resembles a mapping $S_k^E : \mathbb{R}^{n_k^E} \to \mathbb{R}^{n_k}$, which can be described by the product

$$S_k^E = S_k^{k-1,E} \cdot S_{k-1}^{k-2,E} \cdot S_{k-2}^{k-3,E} \cdot \ldots \cdot S_3^{2,E} \cdot S_2^{1,E} = \prod_{l=k}^{2} S_l^{l-1,E} \tag{13}$$

of sparse triangular $(n_k^E - n_{l-1}^E) \times (n_k^E - n_{l-2}^E)$-matrices $S_l^{l-1,E}$. We then have

$$u_k = S_k^E w_k^E. \tag{14}$$

Let P_{l-1}^l be the d-linear interpolation (prolongation) operator that maps V_{l-1} to V_l, $l = k, \ldots, 2$. Let R_l^{l-1} be the restriction operator from V_l to V_{l-1} defined as the adjoint of P_{l-1}^l, $R_l^{l-1} = (P_{l-1}^l)^T$, $l = k, \ldots, 2$. The transformation matrices $S_l^{l-1,E}$, $l = k, \ldots, 2$ can be expressed by means of these intergrid transfer operators as

$$S_l^{l-1,E} = \begin{pmatrix} P_{l-1}^l & I_l & 0 \\ 0 & 0 & I_{k,l+1} \end{pmatrix}. \tag{15}$$

$I_{k,l+1}$ is the identity operator of dimension $\sum_{i=k}^{l+1} n_i$. Due to the generating system approach, these transformation matrices $S_l^{l-1,E}$ cannot be inverted uniquely. Nevertheless, the transposed matrices $(S_l^{l-1,E})^T$, $l = k, \ldots, 2$, are defined by

$$(S_l^{l-1,E})^T = \begin{pmatrix} R_l^{l-1} & 0 \\ I_l & 0 \\ 0 & I_{k,l+1} \end{pmatrix}. \tag{16}$$

Note that the identity relation in the basis representation B_k defines an equivalence relation $\equiv$ in E_k that is different from the simple vector equivalence. Thus, we can identify two different but equivalent representations in E_k of a function in V_k:

$$w_k^{E,1} \equiv w_k^{E,2} \Leftrightarrow_{\text{def}} S_k^E w_k^{E,1} = S_k^E w_k^{E,2}. \tag{17}$$

We see that two different representations $w_k^{E,1}$ and $w_k^{E,2}$ of u_k differ only by a vector $v_k^E = w_k^{E,1} - w_k^{E,2}$ that is in $\mathrm{Ker}(S_k^E)$, the kernel of S_k^E, i.e., $S_k^E v_k^E = 0$.

2.2. Linear systems. Using the nodal basis B_k, the Galerkin approach leads to the linear system of equations $L_k u_k = f_k$, where $(L_k)_{(i,j)} = a(\phi_i^{(k)}, \phi_j^{(k)})$ and $(f_k)_{(j)} = (f, \phi_j^{(k)})$, $i, j = 1, \ldots, n_k$. Alternatively, we can use the discrete energy functional $1/2 \cdot u_k^T L_k u_k - u_k^T f_k$ to describe the problem as energy minimization in the space V_k or $\mathbb{R}^{n_k}$, respectively. For the generating system E_k, the Galerkin approach leads to the system of equations

$$L_k^E w_k^E = f_k^E, \tag{18}$$

where

$$\begin{aligned} (L_k^E)_{(i,j)}^{(l_1,l_2)} &= a(\phi_i^{(l_1)}, \phi_j^{(l_2)}), \\ (f_k^E)_{(j)}^{(l_2)} &= (f, \phi_j^{(l_2)}), \end{aligned} \qquad l_1, l_2 = 1, \ldots, k, \quad i = 1, \ldots, h_{l_1}, \quad j = 1, \ldots, h_{l_2}. \tag{19}$$

Alternatively, we can use the discrete energy functional $1/2 \cdot (w_k^E)^T L_k^E w_k^E - (w_k^E)^T f_k^E$ to describe the problem as (nonunique) minimization in $\mathbb{R}^{n_k^E}$.

The system $L_k^E w_k^E = f_k^E$ has the following properties. The matrix L_k^E is semidefinite. It has the same rank as L_k. Thus $n_{k-1}^E = n_k^E - \text{rank}(L_k)$ eigenvalues are zero. The system is solvable because the right-hand side is constructed in a consistent manner. However, it does not have just one unique solution, but rather numerous different solutions. For two different solutions $w_k^{E,1}$ and $w_k^{E,2}$,

$$S_k^E w_k^{E,1} = S_k^E w_k^{E,2} = u_k \tag{20}$$

holds, where u_k is the unique solution of the system $L_k u_k = f_k$. Therefore, it is sufficient to compute just one solution of the enlarged semidefinite system to obtain via S_k^E the unique solution of the system $L_k u_k = f_k$.

Note that the enlarged matrix L_k^E contains the submatrices L_l that arise from the use of the standard basis B_l, $l = 1, \ldots, k$. A similar property holds for the right-hand sides. The matrix that stems from the hierarchical basis discretization is also contained in L_k^E. For the definition of the hierarchical basis, the resulting linear system, and further explanations, see [22].

Instead of using the bilinear form $a(.,.)$ and the linear form $(f,.)$, which involves explicit integration on all levels $l = 1, \ldots, k$, we can express L_k^E and f_k^E in a simple product-type representation that involves only the intergrid transfer operators P_{l-1}^l and R_l^{l-1}, $l = k, \ldots, 2$ and the discretizations of L and f on the finest level. Since the transformation from E_k to B_k is expressed by $u_k = S_k^E w_k^E$, we get

$$L_k^E = (S_k^E)^T L_k S_k^E, \qquad f_k^E = (S_k^E)^T f_k. \tag{21}$$

This can be interpreted as "semidefinite" preconditioning of the system $L_k u_k = f_k$. It is then easy to see that $\frac{1}{2} \cdot (w_k^E)^T L_k^E w_k^E - (w_k^E)^T f_k^E = \frac{1}{2} \cdot u_k^T L_k u_k - u_k^T f_k$.

Note that the matrix L_k^E is relatively densely populated. In practical applications, however, it is not necessary to know the matrix explicitly. Often only a matrix vector multiplication $L_k^E w_k^E$ is needed, which allows the product type representation (21) of L_k^E to be exploited, so that this matrix vector multiplication can be computed in $O(n_k^E) = O(n_k)$ operations.

Note further that the restriction operator R_l^{l-1} in the mapping $(S_k^E)^T$ is consistent with the Galerkin approach. If, for example, f_k in space V_k is given as $f_k = \sum_{i=1}^{n_k} (f, \phi_i^{(k)}) \phi_i^{(k)}$, then

$$R_k^{k-1} f_k = \sum_{i=1}^{n_{k-1}} (f, \phi_i^{(k-1)}) \phi_i^{(k-1)}. \tag{22}$$

This is an important fact that should be exploited in practical computations. The explicit calculation of the integral $(f,.)$ can be avoided on the coarser levels $l < k$. The linear combination of the coefficient values of f_k according to the restriction stencil is sufficient to reproduce the integral on the next coarser level. Consequently, if f_k on level k has been computed, then f_k^E can be gained easily using $(S_k^E)^T$.

Consider, as an example for the product type representation (21), the case of only two spaces V_{k-1}, V_k. Since the standard basis representation is computed from $w_k^E = (w^{(k-1)}, w^{(k)})^T$ by

$$u_k = \begin{pmatrix} P_{k-1}^k & I_k \end{pmatrix} \begin{pmatrix} w^{(k-1)} \\ w^{(k)} \end{pmatrix}, \tag{23}$$

then the system $L_k^E w_k^E = f_k^E$ can be rewritten as

$$\begin{pmatrix} R_k^{k-1} \\ I_k \end{pmatrix} L_k \begin{pmatrix} P_{k-1}^k & I_k \end{pmatrix} w_k^E = \begin{pmatrix} R_k^{k-1} \\ I_k \end{pmatrix} f_k, \tag{24}$$

and we see that

$$L_k^E = \begin{pmatrix} R_k^{k-1} L_k P_{k-1}^k & R_k^{k-1} L_k \\ L_k P_{k-1}^k & L_k \end{pmatrix}, \qquad f_k^E = \begin{pmatrix} R_k^{k-1} f_k \\ f_k \end{pmatrix}. \tag{25}$$

Note that $R_k^{k-1} L_k P_{k-1}^k$ is just the Galerkin coarse grid matrix L_{k-1}.

From this two-level example, we see that the system $L_k u_k = f_k$ arising from the finite element discretization using the basis B_k can instead be written in terms of the generating system E_k by the following steps:

Apply

$$\begin{pmatrix} R_k^{k-1} \\ I_k \end{pmatrix}$$

to both sides of the equation and set $u_k = \begin{pmatrix} P_{k-1}^k & I_k \end{pmatrix} w_k^E$.

In the first step, new equations are added to the system that are constructed from the original equations by forming linear combinations with the weights of the MG-restriction stencil. The second relation defines the new unknowns and their relation to the original unknowns. A natural two-level decomposition w_k^E of u_k is defined implicitly, which is not unique but nevertheless consistent with the Galerkin approach.

3. Iterative methods for the semidefinite system. In this section, we study iterative methods for the solution of the semidefinite system. We show that the diagonally preconditioned CG method is equivalent to the BPX- or MDS-preconditioned CG approach for the standard system using B_k. The generalized condition number of L_k^E is the same as for the BPX- or MDS-preconditioned matrix L_k. Therefore, proofs for the condition of BPX and MDS are directly valid for the semidefinite system. Results of work by Oswald, Zhang, Xu, Bornemann, and Yserentant for BPX establish a condition number of the order $O(1)$ for L_k^E. Furthermore, we show that the Gauss–Seidel (GS) method and its counterpart SGS are equivalent to multigrid methods for the standard system. A Gauss–Seidel-type relaxation itself can be used as preconditioner for the semidefinite system. This results in MG-CG for the standard basis system.

We want to achieve a solution of the semidefinite system $L_k^E w_k^E = f_k^E$. Because L_k^E is not invertible, we cannot use a conventional direct solver. Instead, we can consider basic iterations $w_k^E := w_k^E + C_k^E(f_k^E - L_k^E w_k^E)$ with positive-definite (or semidefinite) matrices C_k^E. We focus on the CG-type accelerations of such iterations where C_k^E is a diagonal matrix preconditioner. Furthermore, we study Gauss–Seidel-type relaxations, both as an iteration itself (with C_k^E as inverse of the lower triangular part of L_k^E) and as a preconditioner for the CG method.

It is well known that these methods iteratively reduce the energy of the system. They differ in the employed descent directions. While for the CG method the descent directions are based on the residual, the Gauss–Seidel iteration descends along the coordinate axes. It is well known that CG is sensitive to scaling, and that its convergence rate depends on the condition number of the system. On the other hand, Gauss–Seidel relaxations are invariant under scaling of the system. See [12] for further explanations on descent methods.

3.1. CG iteration for the semidefinite system. Here we consider the (diagonally preconditioned) CG method for the semidefinite system. The BPX-preconditioner of Bramble, Pasciak, and Xu and its generalization MDS applied to the standard basis system can be described directly in terms of E_k with simple diagonal matrices C_k^E of full rank n_k^E. This is also true of the HB-preconditioner introduced by Yserentant. It can be described with a simple diagonal matrix C_k^E of deficient rank n_k. If the functions of the generating system are properly scaled, then the C_k^E for BPX or MDS becomes the identity, and the CG method for the semidefinite system $L_k^E w_k^E = f_k^E$ is directly equivalent to BPX-CG or MDS-CG for the definite system $L_k u_k = f_k$. Otherwise, this scaling is done explicitly by the respective matrix C_k^E.

3.1.1. The residual and the CG iteration. In the CG method, a major task is to compute the residual

$$r_k^E = f_k^E - L_k^E w_k^E \tag{26}$$

of the semidefinite system for a given w_k^E. Here, the product type representation (21) of L_k^E and f_k^E can be exploited. We get

$$r_k^E = (S_k^E)^T f_k - (S_k^E)^T L_k S_k^E w_k^E \tag{27}$$

and, with $u_k = S_k^E w_k^E$ and $r_k = f_k - L_k u_k$, we have

$$r_k^E = (S_k^E)^T (f_k - L_k u_k) = (S_k^E)^T r_k. \tag{28}$$

Consider as an example once more the two-level case (23)–(25). The residual of the semidefinite system now reads

$$r_k^E = \begin{pmatrix} R_k^{k-1} f_k \\ f_k \end{pmatrix} - \begin{pmatrix} R_k^{k-1} L_k P_{k-1}^k w^{(k-1)} + R_k^{k-1} L_k w^{(k)} \\ L_k P_{k-1}^k w^{(k-1)} + L_k w^{(k)} \end{pmatrix}. \tag{29}$$

If we use the product-type representation (21) of L_k^E and f_k^E, we are able to implement the computation of the residual efficiently. We have

$$r_k^E = \begin{pmatrix} R_k^{k-1} \\ I_k \end{pmatrix} f_k - \begin{pmatrix} R_k^{k-1} \\ I_k \end{pmatrix} L_k \begin{pmatrix} P_{k-1}^k & I_k \end{pmatrix} \begin{pmatrix} w^{(k-1)} \\ w^{(k)} \end{pmatrix}, \tag{30}$$

and the same result is obtained if we first compute $u_k = P_{k-1}^k w^{(k-1)} + w^{(k)}$, then the fine level residual $r_k = f_k - L_k u_k$, then finally

$$r_k^E = \begin{pmatrix} R_k^{k-1} r_k \\ r_k \end{pmatrix}. \tag{31}$$

This avoids computing the expressions individually on the coarse and fine levels, which differ only by the coarse grid term R_k^{k-1}.

Note that all representations w_k^E in E_k of a given function u_k have exactly the *same residual vector* r_k^E. Therefore, even if our generating system allows many nonunique representations for a function u_k, it is unique with respect to the residual. In fact,

$$w_k^{E,1} \equiv w_k^{E,2} \Rightarrow L_k^E w_k^{E,1} = L_k^E w_k^{E,2}. \tag{32}$$

In the following, let C_k^E be a diagonal matrix. The central step in the CG method for solving $L_k^E w_k^E = f_k^E$ is the computation of the residual and its scalar product. With C_k^E-preconditioning, we must compute $(r_k^E)^T C_k^E r_k^E$. Since $r_k^E = (S_k^E)^T r_k$ (see (28)), then

$$(r_k^E)^T C_k^E r_k^E = r_k^T S_k^E C_k^E (S_k^E)^T r_k. \tag{33}$$

Hence, the C_k^E-preconditioned CG algorithm for solving $L_k^E w_k^E = f_k^E$ is equivalent to the CG algorithm with preconditioner $S_k^E C_k^E (S_k^E)^T$ for solving $L_k u_k = f_k$.

3.1.2. BPX- and related preconditioners. In the following, we show that the BPX-, MDS-, and HB-preconditioners can be expressed by the operator $S_k^E C_k^E (S_k^E)^T$ for appropriate diagonal matrices C_k^E. In [23], the finest level system $L_k u_k = f_k$ is treated by CG-accelerated iterations with a general selfadjoint, positive-definite preconditioning operator $C_k : V_k \to V_k$. Specific choices for C_k for the BPX- and HB-preconditioners were given by the respective matrices C_k^X and C_k^Y defined as follows:

$$C_k^X r_k = L_0^{-1} \sum_{i=1}^{n_0} (r_k, \phi_i^{(0)}) \phi_i^{(0)} + \sum_{l=1}^{k} \sum_{i=1}^{n_l} \frac{1}{d_i^{(l)}} (r_k, \phi_i^{(l)}) \phi_i^{(l)} \qquad \text{(BPX)}, \tag{34}$$

$$C_k^Y r_k = L_0^{-1} \sum_{i=1}^{n_0} (r_k, \phi_i^{(0)}) \phi_i^{(0)} + \sum_{l=1}^{k} \sum_{i=n_{l-1}+1}^{n_l} \frac{1}{d_i^{(l)}} (r_k, \phi_i^{(l)}) \phi_i^{(l)} \qquad \text{(HB)} \tag{35}$$

with the scaling factors $d_i^{(l)} = 4^l (1, \phi_i^{(l)})$. Yserentant suggested replacing the scaling factors $d_i^{(l)}$ by $\hat{d}_i^{(l)} = a(\phi_i^{(l)}, \phi_i^{(l)})$, which leads to the preconditioner C_k^Z defined as

$$C_k^Z r_k = L_0^{-1} \sum_{i=1}^{n_0} (r_k, \phi_i^{(0)}) \phi_i^{(0)} + \sum_{l=1}^{k} \sum_{i=1}^{n_l} \frac{1}{\hat{d}_i^{(l)}} (r_k, \phi_i^{(l)}) \phi_i^{(l)} \qquad \text{(MDS)}. \tag{36}$$

C_k^Z is further analyzed by Zhang in [25] as a multilevel diagonal scaling variant of the multilevel additive Schwarz method. This preconditioner can be expected to work in practice better than BPX for nonmodel problems since, with $\hat{d}_i^{(l)}$, it takes information into account that reflects more closely the properties of the problem. However, for elliptic problems with constant coefficients, MDS is equivalent to BPX up to a constant multiple.

Note that for our simplified case of Dirichlet boundary conditions, $V_0 = \{0\}$ and the term $L_0^{-1} \sum_{i=1}^{n_0} (r_k, \phi_i^{(0)}) \phi_i^{(0)}$ vanishes. For more general boundary conditions, a system with the level 0 discretization matrix L_0 must be solved here.

These preconditioners can now be expressed easily in terms of our semidefinite system $L_k^E w_k^E = f_k^E$. Computation of the residual $r_k^E = f_k^E - L_k^E w_k^E$ produces

$$r_k^E = (S_k^E)^T r_k = \begin{pmatrix} r^{(1)^T} & r^{(2)^T} & \dots & r^{(k-1)^T} & r^{(k)^T} \end{pmatrix}^T, \tag{37}$$

where

$$(r^{(l)})_i = (r_k, \phi_i^{(l)}) \phi_i^{(l)}, \quad l = k, \dots, 1, \quad i = 1, \dots, n_l. \tag{38}$$

The BPX- and HB- preconditioners resemble just a multiplication of the residual r_k^E of the enlarged system with the matrix C_k^E. For all preconditioners introduced above, this matrix C_k^E has diagonal form. The preconditioners differ only in the diagonal entries. Therefore, in terms of the enlarged system, BPX-, MDS-, or HB-preconditioning amounts to nothing but diagonal scaling of the residual.

For the BPX-preconditioner C_k^X, its analogue $C_k^{E,X}$ has full rank. In fact

$$C_k^{E,X} = \operatorname{diag}\left(\frac{1}{d_i^{(l)}}\right). \tag{39}$$

If the functions of our generating system use a special scaling, then $C_k^{E,X} = I_k^E$, and the BPX-preconditioner yields the usual CG method on the semidefinite system. This special scaling is expressed by

$$\bar{\phi}_i^{(l)} = h_l^{(2-d)/2}\phi_i^{(l)}, \quad l = k, \ldots, 1, \quad d = 1, 2, \ldots. \tag{40}$$

Note that in the 2D case no scaling is actually necessary.

Since the modified scaling factors $\hat{d}_i^{(l)} = a(\phi_i^{(l)}, \phi_i^{(l)})$ are used in the MDS scheme, we see that

$$C_k^{E,Z} = \operatorname{diag}\left(1/(L_k^E)_{(i,i)}^{(l,l)}\right). \tag{41}$$

Here, the MDS-preconditioner reduces to just a Jacobi-preconditioner for the semidefinite system (Jacobi-CG). If the functions of our generating system use a special scaling, then $C_k^{E,Z} = I_k^E$, and the MDS-preconditioner yields the usual CG method on the semidefinite system. This special scaling is expressed by

$$\hat{\phi}_i^{(l)} = a(\phi_i^{(l)}, \phi_i^{(l)})^{-1/2}\phi_i^{(l)}, \qquad l = k, \ldots, 1. \tag{42}$$

Note that Jacobi iteration on the semidefinite system alone does not generally converge, nor do the simple iterations based on BPX- or MDS-preconditioners. It is the combination of CG and preconditioning that makes the method properly (and quickly) converge.

For the HB-preconditioner C_k^Y, its analogue $C_k^{E,Y}$ has deficient rank. Only the n_k diagonal entries associated with the functions appearing in the hierarchical basis are nonzero. (They contain the inverse of the scaling factors $d_i^{(l)}$.) For further details, see [7] and [22].

If we want to express the resulting vector $C_k^{E,J} r_k^E$, $J \in \{X, Y, Z\}$ in terms of the basis B_k, we must multiply it by S_k^E, which amounts to the explicit level-wise summation of the BXP-, MDS-, or HB-preconditioner. However, using the generating system approach, this summation is avoided because of the direct, multilevel representation of the functions of V_k, implying that the summation is really done implicitly.

It is now possible to characterize the BPX-, MDS-, and HB-preconditioning in terms of B_k by the matrix notation

$$C_k^J = S_k^E C_k^{E,J} (S_k^E)^T, \qquad J \in \{X, Y, Z\}. \tag{43}$$

It is easy to see that the scalar products involved in the preconditioned CG methods for $L_k u_k = f_k$ and for $L_k^E w_k^E = f_k^E$ are the same. Since $r_k^E = (S_k^E)^T r_k$, then

$$(r_k)^T C_k^J r_k = (r_k^E)^T C_k^{E,J} r_k^E, \qquad J \in \{X, Y, Z\}. \tag{44}$$

We have seen that the use of the generating system, instead of the standard basis approach for the representation of the functions of V_k, allows an easy and simple description of the BPX-, MDS-, and HB-preconditioned CG method. The somewhat complicated form of the BPX-, MDS-, and HB-preconditioning reduces in E_k to simple diagonal scaling of the residual r_k^E. If we choose specially scaled generating functions in E_k, then C_k^E reduces to the identity matrix, which means that only the standard CG algorithm is performed on the associated semidefinite system.

3.1.3. Condition number considerations. Here we consider the condition number of the C_k^E-preconditioned semidefinite system. Of course, in general, the conventional condition number is infinity because L_k^E is singular. However, we will show here that the condition numbers of the preconditioned enlarged and original systems are the same, provided we use a generalized condition number that considers the preconditioned matrix restricted to the orthogonal complement of its null space. In fact, each eigenvalue of $C_k L_k$ is also an eigenvalue of $C_k^E L_k^E$, and the rest of the eigenvalues of $C_k^E L_k^E$ are zero. This holds for all symmetric, positive-definite preconditioning matrices C_k with $C_k^E = (S_k^E)^T C_k S_k^E$. It follows from considering the cases $e_k^E \in \text{Ker}(S_k^E)$ and $e_k^E \notin \text{Ker}(S_k^E)$ and from observing that the relation

$$C_k^E (S_k^E)^T L_k S_k^E e_k^E = \lambda_k^E e_k^E \tag{45}$$

implies the relation

$$S_k^E C_k^E (S_k^E)^T L_k e_k = \lambda_k^E e_k, \tag{46}$$

where $e_k = S_k^E e_k^E$. The generalized condition number that we use is given by

$$\kappa(C_k^E L_k^E) = \lambda_{\max}/\lambda_{\min}, \tag{47}$$

where $\lambda_{\max}$ denotes the largest eigenvalue of $C_k^E L_k^E$ and $\lambda_{\min}$ its smallest nonzero eigenvalue. We thus have

$$\kappa(C_k L_k) = \kappa(C_k^E L_k^E). \tag{48}$$

Note that $\kappa(C_k L_k)$ reduces to the usual definition of condition number.

Any results on the condition number of $C_k L_k$ therefore extend directly to the semidefinite, preconditioned matrix $C_k^E L_k^E$ provided C_k is symmetric, positive-definite, as is the case for the BPX-, and MDS-preconditioners. It has been shown by Oswald [16]–[18], Xu [20], Zhang [25], [26], and Bornemann and Yserentant [4] that the condition number of the BPX-preconditioner is of the order $O(1)$. So we may conclude that

$$\kappa(C_k^{E,J} L_k^E) = O(1), \qquad J \in \{X, Z\}. \tag{49}$$

Thus, if we use specially scaled functions in E_k, then $C_k^{E,J} = I_k^E$ and the semidefinite system matrix that now results from the Galerkin approach has a generalized condition number that is independent of k.

3.2. Gauss–Seidel iteration for the semidefinite system. Here we consider relaxation type iterations for the semidefinite system. We focus on the GS method and its counterpart SGS, and show that the multigrid method for the standard system can be interpreted as Gauss–Seidel-type iteration for the semidefinite system. The levels used in the multigrid scheme induce a block partitioning of the system, and switching from level to level corresponds to an outer block Gauss–Seidel iteration for the semidefinite system. The MG-smoothing steps resemble inner Gauss–Seidel iterations for each block. The multigrid V-cycle with one pre- and post-smoothing step by Gauss–Seidel iterations reduces to the SGS method, which is also known as Aitken's double sweep scheme. Other MG-cycle types can also be modeled by different orderings of the block Gauss–Seidel traversal. The case of multiple smoothing steps corresponds to multiple inner iterations. Furthermore, other smoothers can be incorporated in the block GS method as inner iterations, and the SGS iteration for the semidefinite system can be used itself as a preconditioner of the CG method.

As usual, we decompose the semidefinite matrix L_k^E by $L_k^E = F_k^E + G_k^E + (G_k^E)^T$, where F_k^E and G_k^E denote the diagonal and strictly lower triangular parts of L_k^E, respectively. Then the GS method is expressed by using $C_k^{E,GS} := (F_k^E + G_k^E)^{-1}$ and SGS is expressed by using $C_k^{E,SGS} := (F_k^E + G_k^E)^{-T} F_k^E (F_k^E + G_k^E)^{-1}$. Note that $F_k^E + G_k^E$ is generally not symmetric, but it is positive definite and invertible. In what follows, we order the unknowns level-wise starting with the coarsest level and the unknowns of each level are ordered lexicographically.

3.2.1. Gauss–Seidel and multigrid. Here we demonstrate that Gauss–Seidel-type relaxations for the semidefinite system are equivalent to the multigrid method for the standard system. Without loss of generality, we restrict ourselves for simplicity to the two-level case and consider the block system

$$\begin{pmatrix} R_k^{k-1} L_k P_{k-1}^k & R_k^{k-1} L_k \\ L_k P_{k-1}^k & L_k \end{pmatrix} \begin{pmatrix} w^{(k-1)} \\ w^{(k)} \end{pmatrix} = \begin{pmatrix} R_k^{k-1} f_k \\ f_k \end{pmatrix}. \tag{50}$$

The two-level block-partitioned Gauss–Seidel iteration (with some inner relaxation scheme like point Gauss Seidel) for the semidefinite system then proceeds as follows:

0. Choose some $w_k^{E,0} = (w^{(k),0}, w^{(k-1),0})^T$ as a starting value.
   For $i = 1$ to convergence:
   1. Relax on $L_k w^{(k),i-1} = f_k - L_k P_{k-1}^k w^{(k-1),i-1}$ to obtain $w^{(k),i}$.
   2. Relax on $L_{k-1} w^{(k-1),i-1} = R_k^{k-1} f_k - R_k^{k-1} L_k w^{(k),i}$ to obtain $w^{(k-1),i}$.

Consider now the well-known correction scheme (CS) form of the multigrid method. Here, instead of exact solving the coarse grid equation, we only iterate it. It consists of the following steps:

0. Choose some u_k^0 as a starting value.
   For $i = 1$ to convergence:
   1. Relax on $L_k u_k^{i-1} = f_k$ to obtain u_k^i.
   2. Set $u_{k-1}^{i-1} = 0$ and relax on $L_{k-1} u_{k-1}^{i-1} = R_k^{k-1}(f_k - L_k u_k^i)$ to obtain u_{k-1}^i.
   3. Form the correction $u_k^i = u_k^i + P_{k-1}^k u_{k-1}^i$.

It is easy to see that principally the same equations arise in both of these schemes. The coarse grid equations are exactly the same, and although the fine grid equations are not, their difference is compensated for in Step 3 of the CS scheme. This correction step performs just the analogue of the transformation S_k^E from the nonunique representation of the approximation of the solution in E_k to its unique representation in the standard basis B_k. Therefore, in the CS scheme, the approximation to the solution is represented after each coarse grid correction step in standard basis. This is not necessary for the block Gauss–Seidel scheme because it works directly with the nonunique representation based on the generating system.

Thus, the only difference between these two schemes is their representation. They are otherwise equivalent. The interpretation of the block entries of w_k^E is therefore clarified if the correction scheme of the multigrid method is kept in mind: In our two-level example we can see $w^{(k)}$ as some sort of implicit approximation of the solution on level k and $w^{(k-1)}$ as an implicit coarse grid correction to it. In this sense, our method and McCormick's approach of Unigrid and PML are in similar spirit; see [14], [15].

The V-cycle with one pre- and one post-smoothing step is equivalent to two Gauss–Seidel iterations for the semidefinite system, where the second step is performed in reversed ordering. This is just the well-known Aitken double sweep or SGS method. Multiple pre- and post-smoothing iterations can now be modeled by block sweeps over the semidefinite system with multiple inner iterations. Of course, other smoothers can also be applied in the inner iteration, and the outer block iteration can be reordered so that other MG-cycling strategies are implemented.

The Gauss–Seidel or SGS iteration can be considered as a method for the minimization of the energy functional, where the search directions are just the coordinate axes. Using the enlarged generating system, we can interpret the unknowns of the coarse grid equations of the multigrid method as additional coordinate axes which are given via $(S_k^E)^T$ as linear combinations of the fine grid coordinate axes. The coarse grid correction now gives additional search directions for the minimization of the energy, which makes multigrid fast to converge.

Furthermore, it is easy to see that the HB-MG method of [3] can be interpreted in the extended system as well: Iteration on the unknowns of $w^{(l)}, l = k, \ldots, 2$, which belong to grid points that are contained in the next coarser grid Ω_{l-1}, is simply omitted and its values are frozen there.

Note that we obtain the usual Gauss–Seidel iteration on the fine grid system by omitting iteration over the blocks that are associated with the coarser levels. This would mean that the associated values of w_k^E values are never changed. But if we transform the resulting solution to its standard basis representation, we obtain exactly the same result as for an iteration on the fine grid system only. For remarks on an estimate concerning the condition number of the SGS-preconditioned semidefinite matrix, we refer to [7].

4. Numerical experiments. Consider the simple model problem

$$\Delta u = f \quad \text{on} \quad \Omega = (0,1)^d, \qquad d = 1, 2, \tag{51}$$

with Dirichlet boundary conditions, where $\Delta = \sum_{i=1}^{d} \partial^2/\partial x_i^2$.

4.1. Eigenvalues and condition numbers. The numerically computed eigenvalues and generalized condition numbers of the semidefinite matrix L_k^E and the MDS-preconditioned semidefinite matrix $C_k^{E,Z} L_k^E$ are shown for the 1D case in Table 1. (The BPX-preconditioned matrix $C_k^{E,X} L_k^E$ has the same condition numbers and, up to the factor 2, the same eigenvalues.) Here, s and r denote the respective size and rank of the matrix.

TABLE 1
Eigenvalues and generalized condition numbers in the 1D *case.*

			L_k^E				$C_k^{E,Z} L_k^E$			
k	s	r	$\lambda_{\min}$	$\lambda_{\max}$	κ	$\frac{\kappa(k-1)}{\kappa(k)}$	$\lambda_{\min}$	$\lambda_{\max}$	κ	$\frac{\kappa(k-1)}{\tilde{\kappa}(k)}$
1	1	1	4.0000	4.0000	1.0000	-	1.0000	1.0000	1.0000	-
2	4	3	5.5279	14.472	2.6180	2.618	1.0000	2.0000	2.0000	2.0000
3	11	7	6.6046	31.206	4.7249	1.8048	1.0000	2.8666	2.8666	1.4333
4	26	15	7.1989	63.575	8.8312	1.8690	1.0000	3.4839	3.4839	1.2156
5	57	31	7.5073	127.77	17.019	1.9272	1.0000	3.9834	3.9834	1.1434
6	120	63	7.6642	255.88	33.386	1.9616	1.0000	4.3891	4.3891	1.1018
7	247	127	7.7433	511.94	66.114	1.9803	1.0000	4.7239	4.7239	1.0763
8	502	255	7.7831	1024.00	137.57	1.9900	1.0000	5.0029	5.0029	1.0591

Note that L_k^E has a generalized condition number of $O(h_k^{-1})$, which is by a factor h_k^{-1} better than the condition number of the standard basis matrix L_k. The diagonally preconditioned matrix $C_k^{E,Z} L_k^E$, however, has the constant 1.0 as the smallest eigenvalue and a very slowly growing largest eigenvalue. Its condition number actually behaves like $O(1)$.

Using Fourier analysis [19], it is easy to see that, with $N = 2^k, h_k = \frac{1}{N}$, the $N/2$th eigenvalue

$$\lambda_{N/2} = \frac{2}{h_k} \tag{52}$$

of L_k is also an eigenvalue of L_k^E. Since $C_k^{E,Z}$ has the diagonal entries $h_l/2$, $l = 1, \ldots, k$ (cf. (41)), it is clear that 1.0 is an eigenvalue of $C_k^{E,Z} L_k^E$. This is in fact the smallest nonzero eigenvalue of $C_k^{E,Z} L_k^E$, although we have yet to prove it. Applying Gerschgorin's theorem, it is easy to show that the largest eigenvalue $\lambda_{\max}$ of $C_k^{E,Z} L_k^E$ is bounded from above by a constant, which can be estimated to be 6.8284. This is due to the fact that, at least in the 1D case, the entries of the spectrally equivalent matrix $(C_k^{E,Z})^{1/2} L_k^E (C_k^{E,Z})^{1/2}$ decrease in a certain geometric progression.

For the 2D case, the condition number and the eigenvalues of the MDS-preconditioned matrix $C_k^{E,Z} L_k^E$ are shown in Table 2. (The BPX-preconditioner again results in the same condition numbers, although the eigenvalues are now multiplied by the factor 8/3.)

TABLE 2
Eigenvalues and generalized condition numbers for $C_k^{E,Z} L_k^E$ in the 2D case.

k	s	r	$\lambda_{\min}$	$\lambda_{\max}$	κ	$\frac{\kappa(k-1)}{\kappa(k)}$
1	1	1	1.0000	1.0000	1.0000	-
2	10	9	0.8232	1.6971	2.0615	2.0615
3	59	49	0.7690	2.2785	2.9629	1.4372
4	284	225	0.7548	2.7102	3.5906	1.2118
5	1245	961	0.7512	3.0576	4.0702	1.1336

Once again, using Fourier analysis, it can be shown that the eigenvalues

$$\lambda_{n_1,n_2} = \frac{2}{3}(4 - \cos(\pi n_1 h_k) - \cos(\pi n_2 h_k) - 2\cos(\pi n_1 h_k)\cos(\pi n_2 h_k)), \tag{53}$$

of L_k, $n_1 = 1, \ldots, N-1$, $n_2 = N/2$, and $n_2 = 1, \ldots, N-1$, $n_1 = N/2$, where $N = 2^k$, $h_k = 1/N$, are also eigenvalues of L_k^E. Since $C_k^{E,Z}$ is a diagonal matrix with the constant diagonal entries 3/8, it follows that $3/8 \cdot \lambda_{n_1,N/2}$ and $3/8 \cdot \lambda_{N/2,n_2}$ are eigenvalues of $C_k^{E,Z} L_k^E$. In fact (compare Table 2), the smallest eigenvalue of $C_k^{E,Z} L_k^E$ appears to be $3/8 \cdot \lambda_{(1,N/2)} = 3/8 \cdot \lambda_{(N/2,1)}$. (Again we have yet to prove this.) Hence,

$$\begin{aligned} \lambda_{\min}(C_k^{E,Z} L_k^E) &= \frac{1}{4}\left(4 - \cos(\pi h_k) - \cos\left(\frac{\pi h_k N}{2}\right) - 2\cos(\pi h_k)\cos\left(\frac{\pi h_k N}{2}\right)\right) \\ &= 1 - \frac{1}{4}\cos\left(\frac{\pi}{2^k}\right). \end{aligned} \tag{54}$$

The largest eigenvalue grows very moderately. However, Gerschgorin's theorem can no longer be used since the entries of $(C_k^{E,Z})^{1/2} L_k^E (C_k^{E,Z})^{1/2}$ no longer decrease geometrically for all rows. Note that in the 2D case the standard generating functions in E_k are already specially scaled with respect to h_l. $C_k^{E,Z}$ preconditioning results only in a scaling by the constant factor 3/8.

We now consider the SGS-CG approach. We computed the eigenvalues and generalized condition numbers of the preconditioned matrix $C_k^{E,SGS} L_k^E$. The results for the 1D case are shown in Table 3. Compared to the BPX- and MDS-preconditioner, the SGS-preconditioner improves the condition number roughly by a factor 4.

For the 2D case the condition number and eigenvalues of $C_k^{E,SGS} L_k^E$ are shown in Table 4.

Once more, the SGS-preconditioner improves the condition number by about a factor 4 and the formula $\kappa(C_k^{E,SGS} L_k^E) \approx 1 + 1/(4\lambda_{\min}(C_k^{E,Z} L_k^E))$ gives a good estimate of its upper bound.

4.2. Convergence factors and iteration steps. Here we study the convergence properties of the different preconditioned CG and GS methods. As shown in [1], the CG method needs at most $s = \text{int}\left[1/2\sqrt{\kappa}\ |ln(2/\varepsilon)| + 1\right]$ steps to reduce the energy of the initial error by a factor $\varepsilon \in (0, 1)$, where κ is the (generalized) condition number of the preconditioned matrix to be considered. The reduction factor after s steps can be estimated by the quantity $2 \cdot \rho_{cg}^s$, where $\rho_{cg} := (\sqrt{\kappa} - 1)/(\sqrt{\kappa} + 1)$ is the (worst-case) convergence factor. Note that, due to the sophisticated convergence properties of the CG method taking full advantage of the eigenvalue distribution of the preconditioned matrix, the upper bound $2 \cdot \rho_{cg}^s$ may be pessimistic.

We are able to derive estimates of the reduction factors from the computed condition numbers of the above tables. For example, in the case k=5, the generalized condition number of the MDS-preconditioner is close to 4.0 (compare Tables 1 and 2), so, we can expect a theoretical convergence factor of about 0.333. Also, since the generalized condition number of the SGS-preconditioner is about 1.25 (compare Tables 3 and 4), we can expect a convergence factor of about 0.0557. If we invest the additional work necessary for the Gauss–Seidel iterations on each level, we get an improvement of the convergence factor by a multiple of about 6.0.

For comparison, we performed numerical experiments to measure the number of CG steps necessary to reduce the L_2 norm of the residual r_k^E by the factors 10^{-2}, 10^{-4}, 10^{-6}, 10^{-8}, and 10^{-10} for the MDS-preconditioned and the SGS-preconditioned semidefinite system. The results are given in Tables 5 and 6. For the measurements, we directly computed r_k^E, the residual of the semidefinite system, which is related to the residual r_k by $(S_k^E)^T$, as in (28). Note that the SGS-preconditioner reduces the number of iteration steps roughly by a factor of 2.5 in comparison to the MDS-preconditioner.

These results should be compared to the performance of the simple iterative method associated with the respective preconditioner for which the worst-case convergence factor is

$$\rho(I_K^E - C_k^{E,J} L_k^E) = \max_i |1 - \lambda_i(C_k^{E,J} L_k^E)|, \qquad J \in \{Z, SGS\}, \tag{55}$$

where λ_i denotes the respective eigenvalues. We see from the Tables 1 and 2 directly that the

5	5	9	13	16	20	2	3	5	6	8

Jacobi iteration for the semidefinite system is divergent, with spectral radius is greater 1. Note that a damping parameter could be introduced to enforce convergence.

For the symmetric Gauss–Seidel iteration on the semidefinite system, which is equivalent to the (1,1)-MG-V-cycle for the standard system, we get

$$\rho_{sgs} = 1 - \lambda_{\min}(C_k^{E,SGS}L_k^E) = 1 - 1/\kappa(C_k^{E,SGS}L_k^E). \tag{56}$$

Since the generalized condition number is close to 1.25 (compare Tables 3 and 4), we can expect a theoretical convergence factor of about 0.2. If we invest the additional work necessary for the CG iteration to gain SGS-CG, we see that the convergence factor is improved by a multiple of about 3.588.

Tables 7 and 8 show the number of steps that were needed by the Gauss–Seidel and SGS iteration in numerical experiments to reduce the residual r_k^E by the factors 10^{-2}, 10^{-4}, 10^{-6}, 10^{-8}, and 10^{-10}. These iterations resemble directly a V-cycle with one post-smoothing step by (lexicographical) Gauss–Seidel and zero or one presmoothing step, respectively.

4.3. Efficiency considerations. To compare the different methods with respect to their efficiency, we restrict ourselves to the 2D model problem. BPX/MDS-CG is realized by a multigrid V-cycle followed by a CG step on the fine grid equations, where explicit smoothing iterations are omitted in the V-cycle. Note that smoothing now only takes place implicitly by simply (weighted) summing of the residuals on all levels. SGS-CG is implemented by a multigrid V-cycle with one pre- and one post-smoothing iteration (here we use lexicographical Gauss–Seidel) followed by a CG step on the fine grid equations.

Table 9 shows the number of operations per fine grid point needed by the major processes of the methods we consider. Operations $+$, $-$, $\times$, $/$, are all counted equal. Here, C_{gs} denotes the number of operations per grid point of one Gauss–Seidel smoothing iteration in the V-cycle, C_t denotes the number of operations per grid point that are necessary for the intergrid transfer operators in the V-cycle, and C_{cg} denotes the number of operations per grid point that are necessary for the CG method on the fine grid equations. Compare also [6] for the operation count of the different MG components and [1] for the CG operation count. The number, op, of operations per grid point for the different methods itself is then given in Table 10.

TABLE 9
2D *case*: *Number of operations per fine grid point for the major algorithmic processes.*

C_{gs}	C_t	C_{cg}
12	12	15

TABLE 10
2D *case*: *Number of operations per fine grid point for the different algorithms.*

	BPX-CG	SGS	SGS-CG
	$C_t + C_{cg}$	$2 \cdot C_{gs} + C_t$	$2 \cdot C_{gs} + C_t + C_{cg}$
op	27	36	51

The efficiency of these schemes is defined as the value

$$\text{eff} = -\text{op}/\ln(\rho), \tag{57}$$

which gives the number of operations per fine grid point necessary to reduce the norm of the residual at least by a factor e. For the case $k = 5$, Table 11 shows the theoretical convergence factors ρ_{th} and the resulting efficiencies derived from the condition numbers in Tables 2 and 4.

For comparison, we ran numerical tests and measured the average reduction factors after

enough steps, s, to reduce the residual by about $\varepsilon = 10^{-10}$. This average factor is defined to be

$$\rho_{\text{ave}} = \left(\frac{|r_k^{E,s}|_2}{|r_k^{E,0}|_2} \right)^{1/s} \approx \varepsilon^{1/s}. \tag{58}$$

For the results, see also Table 11.

TABLE 11
2D *case: Convergence factors and efficiencies for the different algorithms with* $k = 5$.

	BPX-CG	SGS	SGS-CG
ρ_{th}	0.333	0.200	0.0557
eff	24.58	22.37	17.66
ρ_{ave}	0.355	0.203	0.074
eff	26.06	22.58	19.68

All three methods considered perform comparably with respect to efficiency even though their convergence rates differ strongly. BPX-CG is slightly (by about a multiple of 1.15) less efficient than SGS, which in turn is slightly (by about a multiple of 1.15) less efficient than SGS-CG. This shows that it is possible to speed up multigrid somewhat by CG. Note, however, that multigrid allows other relaxation orderings and other choices for the number of pre- and post-smoothing steps that might allow for improvement in its efficiency. BPX-CG may also be improved by additional Gauss–Seidel iterations in the BPX-preconditioning process.

5. Concluding remarks. In this paper we have introduced the idea of using a generating system instead of the usual basis approach, which allows for the direct use of multilevel decompositions of a function. A Galerkin scheme based on the generating system results in a semidefinite matrix equation.

We showed that modern multilevel methods can be interpreted as standard iterative methods for the semidefinite system. The BPX- or MDS-preconditioner can be seen as simple diagonal scaling of the semidefinite system that resembles a Jacobi iteration step. Multigrid algorithms are equivalent to Gauss–Seidel iterations and can be used as preconditioners for CG as well, resulting in a substantial improvement of the convergence rate.

Of course, an efficient implementation of these methods must follow the traditional way that is already employed in the multigrid method. From this point of view, we have presented nothing really new. However, the interpretation of different multilevel methods in terms of a generating system as standard iteration techniques on a semidefinite system fully clarifies the relations and differences between them and provides a simple and natural approach to their general treatment. We believe that the development of new multilevel methods will be substantially simplified by this perspective.

Generalizations of the semidefinite system can be derived using coarse grid spaces other than the standard coarse grid spaces used here. For example, E_k can be enlarged to contain all possible coarse grid basis functions with respect to standard coarsening and semicoarsening in all coordinate directions, allowing multilevel methods to be derived for sparse grids [8], [9], [24].

ANALYSIS OF V-CYCLE MULTIGRID ALGORITHMS FOR FORMS DEFINED BY NUMERICAL QUADRATURE*

J. H. BRAMBLE†, C. I. GOLDSTEIN‡, AND J. E. PASCIAK‡

Abstract. The authors describe and analyze certain V-cycle multigrid algorithms with forms defined by numerical quadrature applied to the approximation of symmetric second-order elliptic boundary value problems. This approach can be used for the efficient solution of finite element systems resulting from numerical quadrature as well as systems arising from finite difference discretizations. The results are based on a regularity free theory and hence apply to meshes with local grid refinement as well as the quasi-uniform case. It is shown that uniform (independent of the number of levels) convergence rates often hold for appropriately defined V-cycle algorithms with as few as one smoothing per grid. These results hold even on applications without full elliptic regularity, e.g., a domain in R^2 with a crack.

Key words. multigrid methods, elliptic equations, finite elements, numerical quadrature

AMS subject classifications. 65F10, 65N30

1. Introduction.

In recent years, multigrid methods have been extensively used to efficiently solve the discrete equations that arise in the numerical approximation of partial differential equations (see [9], [14], [17] and references cited therein). In conjunction, there has been intensive research into the theoretical understanding of the convergence properties of these methods (cf. [1]–[3], [6], [11], [12], [14], [16], [17]). These results provide a uniform convergence rate (with respect to the number of grid levels) for the V-cycle algorithm in the case of full elliptic regularity and a quasi-uniform mesh. It was shown in [5], using a new general multigrid theory, that uniform estimates hold for the V-cycle algorithm, with only one smoothing per grid per iteration, even in the absence of full regularity and in the presence of mesh refinements. The results in [1]–[3], [5], [6], [11], [12], [14], [16], [17] were applied to the finite element method with stiffness matrix computed exactly.

In practice, the stiffness matrix is usually computed approximately using a suitable numerical quadrature. Furthermore, many standard finite difference schemes can be expressed in terms of the finite element method with a suitable quadrature rule. The V-cycle multigrid algorithm with numerical quadrature on each grid level was analyzed in [13]. In [13], the bilinear forms on the coarser grids were defined by using coarser grid quadrature. The results in [13] provide a uniform convergence rate for approximations of problems with full regularity utilizing a quasi-uniform mesh.

The purpose of the present paper is to show that the theoretical results in [5] yield a uniform convergence rate for the natural V-cycle multigrid algorithm that uses the fine grid quadrature to define the forms on all grid levels. These results hold with mesh refinements and for problems without full elliptic regularity (e.g., an L-shaped domain or a domain with a crack boundary). Uniform convergence estimates are also provided for a standard finite difference scheme.

The remainder of the paper is outlined as follows. In §2, we describe the theoretical multigrid framework in [5] and provide an abstract perturbation lemma. In §3, we consider

elliptic boundary value problems approximated by the finite element method with numerical quadrature. Using the perturbation lemma of §2 and the theory in [5], we prove uniform convergence results for corresponding multigrid V-cycle algorithms. This type of analysis is applied to finite difference multigrid in §4.

2. Abstract multigrid theory. We begin by briefly describing the general multigrid framework and results in [5]. We then provide a perturbation lemma that will be used to analyze the case of numerical quadrature.

Suppose we are given a nested sequence of finite dimensional vector spaces $M_1 \subseteq M_2 \subseteq \cdots \subseteq M_J$. Associated with this sequence, assume we are given additional subspaces, $\tilde{M}_k \subseteq M_k$, for $k = 2, 3, \ldots, J$. The multigrid algorithm will involve smoothing only on the subspaces $\{\tilde{M}_k\}$. Let $A(\cdot, \cdot)$ and $(\cdot, \cdot)$ be symmetric positive definite bilinear forms defined on $M_J \times M_J$ and let $\| \cdot \|_A$ and $\| \cdot \|$ denote the corresponding norms, respectively. We define a V-cycle multigrid algorithm for the solution of the problem: Given $f \in M_J$, find $u_J \in M_J$ satisfying

$$A(u_J, v) = (f, v) \quad \text{for all } v \in M_J. \tag{1}$$

The multigrid algorithm is defined in terms of auxiliary operators. For $k = 1, \ldots, J$, define the operator $A_k : M_k \to M_k$ by

$$(A_k w, v) \equiv A(w, v) \quad \text{for all } v \in M_k. \tag{2}$$

The operator A_k is clearly symmetric (in both the $A(\cdot, \cdot)$ and $(\cdot, \cdot)$ inner products) and positive definite. Let λ_k denote the largest eigenvalue of A_k. Also define the orthogonal projectors $P_k, Q_k : M_J \to M_k$ by

$$A(P_k w, v) = A(w, v) \quad \text{for all } v \in M_k,$$

and

$$(Q_k w, v) = (w, v) \quad \text{for all } v \in M_k.$$

It is easily seen that $Q_\ell A_k = A_\ell P_\ell$ if $\ell \leq k$. The operators $\tilde{A}_k$, $\tilde{P}_k$, and $\tilde{Q}_k$ are defined analogously by replacing M_k with $\tilde{M}_k$ above.

To introduce smoothing into the multigrid algorithm, we use "generic" smoothing operators $R_k : M_k \to \tilde{M}_k$, $k = 2, \ldots, J$, satisfying conditions (S.1)–(S.3) below. Let R_k^t denote the $(\cdot, \cdot)$ adjoint of R_k and set

$$K_k = I - R_k A_k$$

and

$$\bar{R}_k = (I - K_k^* K_k) A_k^{-1}.$$

Here $K_k^* = I - R_k^t A_k$ denotes the adjoint of K_k with respect to the $A(\cdot, \cdot)$ inner product. We set $R_1 = A_1^{-1}$, i.e., we solve on the coarsest space. Finally, set $T_k \equiv R_k Q_k A_J = R_k A_k P_k$. Note that $T_1 = P_1$.

We make the following three assumptions on R_k for $k = 2, \ldots, J$.

(S.1) There is a constant $C_R \geq 1$ that does not depend on k such that the smoothing procedure satisfies

$$\frac{\| u \|^2}{\lambda_k} \leq C_R(\bar{R}_k u, u) \quad \text{for all } u \in \tilde{M}_k. \tag{3}$$

Note that (3) holds with $C_R = 1$ for $k = 1$ since $\bar{R}_1 = A_1^{-1}$. The next assumption states that the smoothers must be properly scaled.

(S.2) There is a constant $\theta < 2$ not depending on k such that

$$A(T_k v, T_k v) \leq \theta A(T_k v, v) \quad \text{for all } v \in M_k. \tag{4}$$

The last assumption implies that $\tilde{M}_k$ is an invariant subspace under R_k^t.

(S.3) $R_k = R_k \tilde{Q}_k$.

Note that (S.3) is automatically satisfied for symmetric smoothers since the range of R_k is contained in $\tilde{M}_k$. Conditions (S.1)–(S.3) were shown to hold in [4] for smoothing operators corresponding to various Jacobi and Gauss–Seidel iterative procedures.

We next define the multigrid operator $B_J : M_J \to M_J$ by induction. For each $f \in M_J$, $B_J f$ is to approximate the solution $u_J = A_J^{-1} f$ of (1).

DEFINITION 2.1. *Define* $B_1 = A_1^{-1}$. *For* $k > 1$, $B_k g$ *for* $g \in M_k$ *is defined as follows*:

Step 1. *Set*

$$x = R_k^t g. \tag{5}$$

Step 2. *Set* $y = x + q$, *where* q *is given by*

$$q = B_{k-1} Q_{k-1}(g - A_k x). \tag{6}$$

Step 3. *Set* $B_k g = y + R_k(g - A_k y)$.

Definition 2.1 defines a symmetric V-cycle algorithm with one smoothing before and after the coarse grid correction (Step 2). As in [5], subsequent theorems hold for the W-cycle and other algorithms that use more than one iteration for the coarse grid correction. The results also hold for algorithms that use more smoothings per grid level as long as one alternates between R_k and R_k^t in Steps 1 and 3. This again results in a symmetric operator B_J [7]. Finally, an analogous contraction result holds for nonsymmetric cycling, where smoothing is only done either before or after the correction step, i.e., Step 1 or Step 3 is skipped.

The main convergence result proved in [5] for the multigrid operator B_J shows that, under suitable assumptions, the following estimate holds:

$$0 \leq A((I - B_J A_J)u, u) \leq \delta A(u, u) \quad \text{for all } u \in M_J, \tag{7}$$

where $\delta \in (0, 1)$ is independent of J. The proof of (7) in [5] was based on two conditions (as well as assumptions (S.1)–(S.3) on the smoother).

The first condition may be stated as follows:

(A.1) There is a constant $C_0 \geq 1$ satisfying

$$A(w, w) \leq C_0 \left[A(P_1 w, w) + \sum_{k=2}^{J} \frac{\| \tilde{A}_k \tilde{P}_k w \|^2}{\lambda_k} \right] \quad \text{for all } w \in M_J. \tag{8}$$

The second condition can be written as follows:

(A.2) There is a positive number $\epsilon < 1$ and a positive constant $\tilde{C}$ such that for $k = 2, \ldots, J$ and $l \leq k$,

$$\lambda_k^{-1} \| \tilde{A}_k \tilde{P}_k w \|^2 \leq (\tilde{C} \epsilon^{k-\ell})^2 A(w, w) \quad \text{for all } w \in M_\ell. \tag{9}$$

In this paper, we are interested in the behavior of the above conditions under perturbation of forms. To this end, let $A^E(\cdot, \cdot)$ be an alternative quadratic form on M_J and define the

operator A_k^E as above with $A(\cdot,\cdot)$ replaced by $A^E(\cdot,\cdot)$. Let λ_k^E denote the largest eigenvalues of A_k^E. We then have the following lemma.

LEMMA 2.1. *Assume that conditions* (A.1) *and* (A.2) *hold for* $A^E(\cdot,\cdot)$. *In addition, suppose that*

$$K_0 A(w,w) \le A^E(w,w) \le K_1 A(w,w) \quad \textit{for all } w \in M_J \tag{10}$$

and for some $\alpha > 0$,

$$|A^E(\phi,\psi) - A(\phi,\psi)| \le C\lambda_k^{-\alpha/2}\|\phi\|_A\|\psi\|_A \quad \textit{for all } \phi \in \tilde{M}_k,\ \psi \in M_k. \tag{11}$$

Finally, if $\lambda_k/\lambda_{k+1} \le \eta$ *for fixed* $\eta < 1$, *then conditions* (A.1) *and* (A.2) *hold for* $A(\cdot,\cdot)$.

Proof. We first note that condition (A.1) for $A(\cdot,\cdot)$ follows from (10) and Lemma 3.1 in [5]. We are thus left with proving that condition (A.2) holds.

By (10), it immediately follows that λ_k and λ_k^E are of comparable size. Let $w \in M_\ell$ with $1 \le \ell \le k$. Note that

$$\lambda_k^{-1} \parallel \tilde{A}_k \tilde{P}_k w \parallel^2 = \lambda_k^{-1}\left(\sup_{\phi\in\tilde{M}_k} \frac{|A(w,\phi)|}{\|\phi\|}\right)^2. \tag{12}$$

We clearly have that

$$\sup_{\phi\in\tilde{M}_k} \frac{\|A(w,\phi)\|}{\|\phi\|} \le \sup_{\phi\in\tilde{M}_k} \frac{|A^E(w,\phi)|}{\|\phi\|} + \sup_{\phi\in\tilde{M}_k} \frac{|A(w,\phi) - A^E(w,\phi)|}{\|\phi\|}. \tag{13}$$

Since condition (A.2) holds for $A^E(\cdot,\cdot)$, there exists a constant $\tilde{C}$ and a positive number $\epsilon < 1$ satisfying

$$(\lambda_k^E)^{-1} \sup_{\phi\in\tilde{M}_k} \frac{|A^E(w,\phi)|^2}{\|\phi\|^2} \le \tilde{C}\epsilon^{2k-2\ell} A(w,w). \tag{14}$$

By (11), the second term in (13) is bounded by

$$\frac{|A(w,\phi) - A^E(w,\phi)|}{\|\phi\|} \le C\lambda_k^{-\alpha/2} A(w,w)^{1/2} \frac{A(\phi,\phi)^{1/2}}{\|\phi\|}.$$

Using the definition of λ_k gives

$$\lambda_k^{-1} \sup_{\phi\in\tilde{M}_k} \frac{|A(w,\phi) - A^E(w,\phi)|^2}{\|\phi\|^2} \le C\lambda_k^{-\alpha} A(w,w). \tag{15}$$

The inequality (A.2) for $A(\cdot,\cdot)$ follows from (12)–(15). This completes the proof of the lemma. □

3. The finite element method with numerical integration. In this section we describe the finite element method with numerical quadrature for approximately solving elliptic boundary value problems. We then apply Definition 2.1 to define an efficient multigrid algorithm for solving the resulting system of equations. The main result (Theorem 3.1 below) shows that this multigrid algorithm has a convergence rate independent of the number of grid levels when a sufficiently accurate quadrature scheme is used. This accuracy condition is also required for the finite element error analysis of numerical integration (cf. [10]) and is referred to as the "patch test."

We employ standard notation for Sobolev spaces [15]. Let $H^s(\Omega)$ denote the Sobolev space of square-integrable functions on Ω with square-integrable derivatives up to order s, where s is a nonnegative integer. Let $\|\cdot\|_{H^s} \equiv \|\cdot\|_{H^s(\Omega)}$ denote the corresponding Sobolev norm. The inner product and norm on $L^2(\Omega) = H^0(\Omega)$ are denoted by $(\cdot,\cdot)_{L^2}$ and $\|\cdot\|_{L^2}$, respectively.

In the remainder of this paper, we let C, with or without subscript, denote a generic positive constant. It will take on different values in different places, but it will always be independent of the mesh parameters and the number of levels in the multigrid algorithm.

Let Ω be a bounded domain in R^d with polygonal boundary. We include the case when $\Omega \subset R^2$ is a domain with a crack. We consider the Dirichlet problem

$$\begin{aligned} Lu &= f \quad \text{in} \quad \Omega, \\ u &= 0 \quad \text{on} \quad \partial\Omega, \end{aligned} \tag{16}$$

where

$$Lv = -\sum_{i,j=1}^{2} \frac{\partial}{\partial x_i}\left(a_{ij}\frac{\partial v}{\partial x_j}\right).$$

We assume that the coefficients are in $C^{0,\alpha}(\Omega)$ for some α greater than zero. Furthermore, we assume that the coefficient matrix $\{a_{ij}(x)\}$ is symmetric positive definite with smallest eigenvalue bounded away from zero independently of $x \in \Omega$.

We consider the variational formulation of (16). Let $H_0^1(\Omega)$ denote the subset of $H^1(\Omega)$ consisting of functions with vanishing trace on $\partial\Omega$. The solution u of (16) satisfies

$$A^E(u, v) = (f, v)_{L^2} \quad \text{for all } v \in H_0^1(\Omega). \tag{17}$$

Here $A^E(\cdot,\cdot)$ is the generalized Dirichlet form given by

$$A^E(v, w) = \sum_{i,j=1}^{2} \int_\Omega a_{ij}\frac{\partial v}{\partial x_i}\frac{\partial w}{\partial x_j}\,dx. \tag{18}$$

The superscript E above indicates that the form is computed by exact integration. Subsequent forms will be defined by numerical quadrature.

We shall consider finite element spaces with a quasi-uniform mesh as well as mesh refinements. The quasi-uniform mesh partitioning is standard, but we include the details for completeness.

(i) *Quasi-uniform mesh.* To define the approximation spaces, we first define the underlying mesh partitioning. We assume that a unit size coarse finite element triangulation of the original domain Ω is given. Associated with the mesh partitioning, we are given a rule for refinement. For example, one triangle can be refined into four by connecting the midpoints of the edges.

The mesh triangulations $\{\mathcal{T}_k\}$ can be defined by induction. The coarse triangulation above provides $\mathcal{T}_1$. Given that a triangulation $\mathcal{T}_{k-1}$ has been defined, $\mathcal{T}_k$ is then defined by refining the triangles $\tau_k^i \in \mathcal{T}_{k-1}$ using the refinement rule. Thus each $\mathcal{T}_k$ consists of triangles $\{\tau_k^i\}$ such that $\bar{\Omega} = \cup_i \bar{\tau}_k^i$.

The finite element space M_k for each $k = 1, \ldots, J$ is defined to be a space of piecewise polynomial functions of degree $\leq K$ with respect to the triangulation $\mathcal{T}_k$. These functions are continuous on Ω and vanish on $\partial\Omega$. (We refer to [10] for comprehensive discussions of various specific finite element spaces.) We say the family of spaces $\{M_k\}$ has degree K. In the present example, each $\tilde{M}_k = M_k$, i.e., we smooth on all functions in M_k.

(ii) *General mesh refinement.* We also consider finite element approximations that utilize a locally refined mesh as described in [8]. Such mesh refinements are convenient for accurate modeling of problems with various types of singular behavior. We consider for simplicity the piecewise linear finite element space (i.e., $K = 1$), although we allow a very general form of refinement.

Following [8], we start with a coarse quasi-uniform triangulation. The refinement triangulation is defined in terms of a sequence of (open) mesh domains

$$\Omega_J \subseteq \Omega_{J-1} \subseteq \cdots \subseteq \Omega_1 = \Omega.$$

The only restrictions on the mesh domains $\{\Omega_k\}$ are that the boundary of Ω_k, for $k > 1$, consists of edges of mesh triangles in the triangulation $\mathcal{T}_{k-1}$ and that there is at least one edge of $\mathcal{T}_{k-1}$ contained in Ω_k. These mesh domains control the region of refinement. If τ_{k-1}^i is a triangle contained in Ω_k, then it is broken into four smaller triangles (in the triangulation $\mathcal{T}_k$) by the lines connecting the midpoints of the edges. Alternatively, if τ_{k-1}^i is in the complement of Ω_k, then it is not subdivided but is directly included into the triangulation $\mathcal{T}_k$. A simple example of this construction is the case of a unit square with local refinement near the corner. In this case we take $\Omega_k = \Omega$ for $k = 1, \ldots, j$ and $\Omega_k = (1 - 2^{j-k}, 1) \times (1 - 2^{j-k}, 1)$ for $k = j + 1, \ldots, J$.

The space M_k is defined to be the set of piecewise linear functions with respect to the triangulation $\mathcal{T}_k$ that are continuous on Ω and vanish on $\partial\Omega$. The continuity condition implies that the finer grid nodes on a coarse-fine boundary are "slave nodes" in the sense that the values of the function there are completely determined by the values of the function on the nearby coarse grid points. In this case, if $\Omega_{k-1} \neq \Omega_k$, then the subspace $\tilde{M}_k$ on which we smooth is a proper nonzero subspace of M_k. In fact, we define $\tilde{M}_k$ to be the functions in M_k that are zero outside of Ω_k. Thus we smooth on a given level just in the region where new nodes are being added in the refinement scheme. It is easy to see that the mesh corresponding to the space $\tilde{M}_k$ is quasi uniform of size $h_k \equiv 2^{-k+1}h_1$.

The finite element approximation, $u_J^E \in M_J$, to the solution of (16) is given by

$$A^E(u_J^E, v) = (f, v) \quad \text{for all } v \in M_J.$$

Here $(\cdot, \cdot)$ denotes the inner product in $L^2(\Omega)$. We will be interested in applying the multigrid algorithms and analysis to a perturbed form defined by numerical integration.

To define the form by numerical integration, we start with a numerical quadrature scheme Q_J^i over each element $\tau_J^i \in \mathcal{T}_J$. Consider the reference triangle τ and introduce the reference quadrature

$$\int_\tau \hat{\phi}(\hat{x})d\hat{x} \approx \sum_{\ell=1}^{L} w_\ell \hat{\phi}(b_\ell),$$

where the w_ℓ are positive weights and the $b_\ell \in \tau$ are quadrature points. The quadrature rule on each fine grid triangle τ_J^i is taken to be

$$\int_{\tau_J^i} \phi(x)dx \approx \sum_{\ell=1}^{L} w_{J,\ell}^i \phi(b_{J,\ell}^i) \equiv Q_J^i[\phi],$$

where $\phi(x) = \hat{\phi}(\hat{x})$ and the weights $w_{J,\ell}^i$ and quadrature points $b_{J,\ell}^i$ are defined in terms of the w_ℓ and b_ℓ by means of an affine mapping from τ_J^i onto τ that takes each x in τ_J^i into $\hat{x}$ in τ. We refer to [10] for detailed descriptions of numerical integration in connection with the finite element method.

We require that the above quadrature rule be exact when ϕ is a polynomial of degree $2K-2$. This is referred to as the patch test and is also a basic assumption used in finite element error analysis (see [10, §4.1], and references cited therein for specific examples).

The approximate form $A(v, w)$ is given by

$$A(v,w) = \sum_{\tau_J^l \in T_J} Q_J^l\left[\sum_{i,j=1}^{2}\left(a_{ij}\frac{\partial v}{\partial x_i}\frac{\partial w}{\partial x_j}\right)\right] \quad \text{for all } v, w \in M_J. \tag{19}$$

We present results for multigrid algorithms for computing the solution of the discrete problem: Find $u_J \in M_J$ satisfying

$$A(u_J, v) = F(v) \quad \text{for each } v \in M_J. \tag{20}$$

Here F is a linear functional defined on M_J. Typically, F is defined by using some form of numerical quadrature. The implementation of the algorithm developed in §2 can be used to solve (20) as well as problem (1) [6].

Assume that we have smoothing operators $R_k : M_k \to M_k$ satisfying (S.1)–(S.3) for each $k = 2, \ldots, J$. R_k may be defined in the same way as for the finite element method without numerical integration ([4], [14], [17]). Definition 2.1 provides a multigrid operator, $B_J : M_J \to M_J$, for which the following result holds.

THEOREM 3.1. *Assume that conditions* (S.1)–(S.3) *in* §2 *hold for the smoothing operators. Assume that a fixed quadrature scheme, which is exact on polynomials of degree* $2K-2$, *is used for every term defining* $A(\cdot,\cdot)$. *Let* B_J *be defined by Definition* 2.1. *Then* (7) *holds with* $\delta \in [0, 1)$ *independent of* J.

Proof. By Theorem 3.2 of [5], conditions (A.1) and (A.2) hold for $A^E(\cdot,\cdot)$. By Lemma 2.1, it suffices to verify (10) and (11). Since the same quadrature scheme was used for every term in defining $A(\cdot,\cdot)$, Theorem 4.1.2 of [10] implies that (10) holds.

We next show that (11) holds. Let ϕ and ψ be in $\tilde{M}_k$ and M_k, respectively. By definition, the support of ϕ is contained in Ω_k. Consequently,

$$|A^E(\phi,\psi) - A(\phi,\psi)| = \left|\sum_{i,j=1}^{2}\Bigg(\sum_{\tau_J^l \subseteq \Omega_k}\int_{\tau_J^l} a_{ij}\frac{\partial\phi}{\partial x_i}\frac{\partial\psi}{\partial x_j}\,dx - Q_J^l\left(a_{ij}\frac{\partial\phi}{\partial x_i}\frac{\partial\psi}{\partial x_j}\right)\Bigg)\right|. \tag{21}$$

Since $\tau_J^l \subseteq \Omega_k$, its diameter is bounded by h_k. Using the property that the quadrature is exact on polynomials of degree $2K-2$, a typical term in (21) can be written

$$\begin{aligned}&\int_{\tau_J^l} a_{ij}\frac{\partial\phi}{\partial x_i}\frac{\partial\psi}{\partial x_j}\,dx - Q_J^l\left(a_{ij}\frac{\partial\phi}{\partial x_i}\frac{\partial\psi}{\partial x_j}\right)\\ &= \int_{\tau_J^l}(a_{ij}(x)-\bar{a}_{ij})\frac{\partial\phi}{\partial x_i}\frac{\partial\psi}{\partial x_j}\,dx - Q_J^l\left((a_{ij}(x)-\bar{a}_{ij})\frac{\partial\phi}{\partial x_i}\frac{\partial\psi}{\partial x_j}\right).\end{aligned} \tag{22}$$

Here $\bar{a}_{ij}$ denotes the average value of a_{ij} on τ_J^l. We clearly have that the integral on the right-hand side of (22) is bounded by

$$Ch_k^{\alpha}\|a_{ij}\|_{C^{0,\alpha}(\tau_J^l)}\|\phi\|_{H^1(\tau_J^l)}\|\psi\|_{H^1(\tau_J^l)}.$$

Similarly, the quadrature in (22) is bounded by

$$Ch_k^{\alpha}\|a_{ij}\|_{C^{0,\alpha}(\tau_J^l)} \sum w_{J,m}^l \left|\frac{\partial\phi}{\partial x_i}(b_{J,m}^l)\right| \left|\frac{\partial\psi}{\partial x_j}(b_{J,m}^l)\right|$$

$$\leq Ch_k^{\alpha}\|a_{ij}\|_{C^{0,\alpha}(\tau_J^l)} \left(\sum w_{J,m}^l \left|\frac{\partial\phi}{\partial x_i}(b_{J,m}^l)\right|^2\right)^{1/2} \left(\sum w_{J,m}^l \left|\frac{\partial\psi}{\partial x_j}(b_{J,m}^l)\right|^2\right)^{1/2}$$

$$= Ch_k^{\alpha}\|a_{ij}\|_{C^{0,\alpha}(\tau_J^l)} \left\|\frac{\partial\phi}{\partial x_i}\right\|_{L^2(\tau_J^l)} \left\|\frac{\partial\psi}{\partial x_j}\right\|_{L^2(\tau_J^l)}.$$

We again used the exactness property of the quadrature rule in the last step. Combining the above inequalities and summing over τ_J^l, i, and j shows that

$$|A^E(\phi,\psi) - A(\phi,\psi)| \leq Ch_k^{\alpha}\|\phi\|_1\|\psi\|_1.$$

Equation (11) follows from the fact that $h_k \leq C\lambda_k^{-1/2}$. This completes the proof of the theorem. □

Remark 3.1. The hypothesis that the same quadrature was used on each term in the definition of $A(\cdot,\cdot)$ was only required to prove (10). Note that (11) holds even if different quadrature rules (satisfying the exactness property) are used on different terms. Moreover, (11) implies (10) in the quasi-uniform case if h_J is sufficiently small. In the refinement case, (11) implies (10) if h_1 is sufficiently small.

Remark 3.2. There is no difficulty in proving that (10) and (11) hold in the case of an operator with lower-order term with coefficient a provided that (i) the coefficient a is nonnegative and in $C^{0,\alpha}(\Omega)$ for some α greater than zero, and (ii) that the quadrature rule for this term has positive weights and is exact on constants.

One first proves that on any triangle τ_J^l in Ω_k, for $\phi \in \tilde{M}_k$ and $\psi \in M_k$,

$$\left|\int_{\tau_J^l} a\phi(\psi - \bar{\psi})\,dx\right| + \left|\tilde{Q}_J^l(a\phi(\psi - \bar{\psi}))\right| \leq ch_k\|\phi\|_{L^2(\tau_J^l)}\|\psi\|_{H^1(\tau_J^l)}.$$

Here, $\tilde{Q}^i{}_J$ is the quadrature used on the low-order term and $\bar{\psi}$ denotes the mean value of ψ on τ_J^l. Inequality (11) then easily follows from

$$\begin{aligned}\int_{\tau_J^l} a\phi\psi\,dx - \tilde{Q}_J^l(a\phi\psi) &= \int_{\tau_J^l} a\phi(\psi - \bar{\psi})\,dx - \tilde{Q}_J^l(a\phi(\psi - \bar{\psi})) \\ &\quad + \int_{\tau_J^l} a(\phi - \bar{\phi})\bar{\psi}\,dx - \tilde{Q}_J^l(a(\phi - \bar{\phi})\bar{\psi}) \\ &\quad + \int_{\tau_J^l} (a - \bar{a})\bar{\phi}\bar{\psi}\,dx - \tilde{Q}_J^l((a - \bar{a})\bar{\phi}\bar{\psi}).\end{aligned}$$

Thus, Theorem 3.1 holds for this case as well.

The multigrid algorithm defined by Definition 2.1 uses the fine grid quadrature to define the form on each of the subspaces. The sequence of stiffness matrices can be computed as follows. Let $N_k \equiv \dim(M_k)$ and let $\{\phi_k^i\}$, $i = 1,\ldots,N_k$ denote the standard nodal basis for M_k for each $k = 1,\ldots,J$. For $k = J$, we compute $A(\phi_J^i, \phi_J^j)$ directly from (19). If $k < J$, we express the basis functions for M_k as linear combinations of those for M_{k+1}. The number

of nonzero coefficients is bounded independent of k. Consequently, any stiffness matrix entry for the kth grid can be calculated from those of the $k+1$st grid with a fixed cost. This process is repeated, starting from the $J-1$st grid and descending to the coarsest grid. The total work is obviously bounded by a fixed multiple of the number of points on the finest grid.

Remark 3.3. An alternative multigrid algorithm can be defined as in [13] using numerical quadrature with respect to the kth grid to define the form on M_k. The resulting algorithm does not fit into the framework of [5] and uniform convergence results for the V-cycle algorithm were only proved in the case of full elliptic regularity [13].

Remark 3.4. Although the operator Q_{k-1} appears in the definition of the multigrid algorithm (Definition 2.1), it does not appear in the actual implementation provided that an appropriate choice of smoother is used, for example, Gauss–Seidel or Jacobi. This is discussed in detail in [5].

4. A finite difference application. In this section, we show that the stiffness matrix for a standard finite difference scheme in two spatial dimensions is equal to that from piecewise linear finite elements with an appropriate quadrature. Thus, we can apply Theorem 3.1 to obtain multigrid convergence estimates, independent of the number of grid levels, for variational multigrid methods applied to standard finite difference schemes.

We assume for simplicity that the domain Ω is a union of squares in a coarse square mesh with uniform mesh size h_1 with mesh lines with x_1,x_2 values that coincide with integer multiples of h_1. Ω need not be convex (e.g., Ω could be an L-shaped domain or slit domain). The coarse finite difference mesh is formed by the above-mentioned squares. Successively finer grids are formed by breaking each square into four subsquares in the obvious way. We will only consider the quasi-uniform case although the refinement case can be handled similarly provided that one uses the finite element quadrature to develop the finite difference schemes near the coarse/fine boundaries.

We employ the following finite difference notation. Set $\bar{\Omega}^h \equiv \{x_{\ell,m} \equiv (\ell h, mh) \in \bar{\Omega}\}$. Define $\Omega_h = \Omega \cap \bar{\Omega}_h$ and $\partial\Omega^h \equiv \bar{\Omega}^h \cap \partial\Omega$. Let S_h denote the set of grid functions on $\bar{\Omega}^h$ vanishing on $\partial\Omega^h$. If $V \in S_h$, then $V_{i,j}$ denotes the value of V at (ih, jh).

In this section, we take

$$Lu = -\frac{\partial}{\partial x_1} a \frac{\partial u}{\partial x_1} - \frac{\partial}{\partial x_2} b \frac{\partial u}{\partial x_2} + cu. \tag{23}$$

We assume that the coefficients a, b satisfy the conditions of the previous section. We further assume that c is nonnegative and in $C^{0,\alpha}(\Omega)$.

We consider the following standard five-point finite difference scheme approximating the solution of (16): For $F \in S_{h_J}$ find $U \in S_{h_J}$ satisfying

$$L_{h_J} U = F,$$

where $L_{h_J} : S_{h_J} \mapsto S_{h_J}$ is given by

$$\begin{aligned}(L_{h_J} V)_{i,j} = {} & a_{i+1/2,j}(V_{i,j} - V_{i+1,j}) + a_{i-1/2,j}(V_{i,j} - V_{i-1,j}) \\ & + b_{i,j+1/2}(V_{i,j} - V_{i,j+1}) + b_{i,j-1/2}(V_{i,j} - V_{i,j-1}) + h_J^2 c_{i,j} V_{i,j}.\end{aligned} \tag{24}$$

Here we have used the generic notation $f_{s,t}$ to denote the value of $f(sh_J, th_J)$.

Consider the triangulation $\{\tau_J^i\}$ that results from breaking each square of the Jth finite difference grid into two triangles (for example, along the positive sloping diagonal). Let M_J be the space of continuous piecewise linear functions with respect to this triangulation that vanish on $\partial\Omega$. We consider a finite element approximation that uses a different quadrature on each term in (23). Let τ_J^i be a typical triangle in $\{\tau_J^i\}$ and let:

1. b_1^i denote the midpoint of the edge that is parallel to the x_1 axis;
2. b_2^i denote the midpoint of the edge that is parallel to the x_2 axis;
3. $\tilde{b}_l^i$ for $l = 1, 2, 3$ denote the vertices of the triangle.

We use the following three quadrature schemes, respectively, for the three terms coming from (23):

$$\int_{\tau_J^i} \phi \, dx \approx \frac{h_J^2}{2} \phi(b_1^i),$$

$$\int_{\tau_J^i} \phi \, dx \approx \frac{h_J^2}{2} \phi(b_2^i),$$

$$\int_{\tau_J^i} \phi \, dx \approx \frac{h_J^2}{6} [\phi(\tilde{b}_1^i) + \phi(\tilde{b}_2^i) + \phi(\tilde{b}_3^i)].$$

Let $A(\cdot, \cdot)$ be the resulting quadratic form on the space M_J. It is straightforward to check that the stiffness matrix associated with this finite element numerical quadrature scheme is equal to the matrix associated with the finite difference operator L_{h_J}. Even though we have used different quadrature rules in defining $A(\cdot, \cdot)$, it is elementary to verify that (10) holds without any conditions on h_1 or h_J. Furthermore, these quadratures are exact on constants. Consequently, Remark 3.1 implies that Theorem 3.1 holds for the variational multigrid algorithm using the finite element subspace imbedding formulas to define the finite difference prolongation operators. This is a standard variational multigrid algorithm. We have the following theorem.

THEOREM 4.1. *The variational form of the multigrid algorithm with prolongation corresponding to finite element imbedding applied to the finite difference operator L_{h_J} with Gauss–Seidel smoothing converges with a reduction that is independent of the number of grid levels and unknowns.*

Remark 4.1. It is easy to check that the stiffness matrix for $A(\cdot, \cdot)$ is a five-point stencil on every grid level. The same is true for the coarser grid finite difference stencils developed in the variational multigrid scheme using the finite element prolongations.

ON THE MULTILEVEL ADAPTIVE ITERATIVE METHOD*

U. RÜDE†

Abstract. The *multilevel adaptive iterative method* is a technique for solving the sparse matrix equations that typically arise from partial differential systems. Its core consists of a relaxation scheme and an *active set strategy*. The active set is used to monitor where the iteration efficiently reduces the error. It is incrementally updated by exploiting the current solution and the matrix structure, and most arithmetic operations are restricted to it. The algorithm can be extended to a multilevel structure by additionally tracing the dependencies between unknowns on different levels. It improves the robustness and efficiency of classical multilevel methods; in particular, it is an almost ideal supplement to adaptive refinement techniques.

Key words. sparse matrices, iterative methods, multilevel methods, adaptivity

AMS subject classifications. 65F10, 65F50, 65N22, 65N50, 65N55

1. Introduction.

With the *multilevel adaptive iterative method* we introduce an algorithmic concept that improves both the robustness and efficiency of iterative sparse system solvers. In most iterative methods, the sequence of operations is determined a priori and depends neither on the particular matrix structure nor on the current approximation of the solution. For example, consider the case of a finite element mesh constructed by successive adaptive refinement. Typically, the refinement process is combined with nested iteration such that the initial guess for the solution can be obtained from the solution of the previous system (see Bai and Brandt [1], Bank [2], and McCormick [11]). The initial guess will be close to the new solution in large parts of the domain, while it may be far from the solution in regions where the mesh has been refined. A classical iterative method does not exploit this situation and will therefore be inefficient.

The core of the multilevel adaptive method consists of relaxation supplemented with an *active set strategy*, as introduced in Rüde [14]. In each elementary step, we select an unknown from the active set and perform a preliminary relaxation step at it. If the new value differs from the old value by more than a *characteristic tolerance*, the update is performed, but if the change is small, the old value is retained. In either case, the current unknown is removed from the active set, because a further relaxation step for the same unknown would not provide any new result. In the case where the update has been executed, a further relaxation of the same unknown gives exactly the same value, and if the update has been rejected, a new relaxation would also be rejected. If and only if the update has been performed, the active set must be supplemented by the *neighbors* of the current unknown. For all of these unknowns the residual has changed, and it must therefore be checked to determine whether they must be relaxed. Thus, the active set may grow and shrink to keep track of where the solution is changing. The basic relaxation is repeated until the active set becomes depleted. The sequence of operations in this algorithm depends on the matrix structure as well as on the current state of the iteration. Computational work is concentrated where it can efficiently improve the solution.

To make the algorithm practical, the critical tolerance must be selected and adapted appropriately. In §2, it will be shown that the speed of convergence is directly related to the tolerance parameter used, but that the tolerance parameter necessary to obtain a certain accuracy depends on the condition of the system. Thus, the effectivity of the method depends on whether it can be integrated with preconditioning techniques. In §3, we extend the method to a multilevel structure by introducing a nested system of subspaces. This structure can be

*Received by the editors May 18, 1992; accepted for publication (in revised form) November 2, 1992.

†Institut für Informatik, Technische Universität München, Arcisstr. 21, D-80290 München 9, Germany (ruede@informatik.tu-muenchen.de).

derived naturally in many cases that originate from the discretization of differential equations, but could also be obtained directly from the system matrix, as in the *algebraic multigrid method*; see Ruge and Stüben [17]. It will be shown that the active set strategy can be extended to the multilevel context by tracing dependencies between unknowns on different levels.

This extended algorithm is related to multilevel algorithms and can be shown to have asymptotically optimal convergence for many important special cases. The analysis relies on the theoretical foundation of either multigrid theory (see Hackbusch [8], McCormick [10]) or the theory of multilevel preconditioning (see Bramble, Pasciak, and Xu [3], Dryja and Widlund [6], Oswald [12], Yserentant [19]).

The following presentation focuses on the model case of a positive definite linear system as it arises in the finite element discretization of elliptic second-order partial differential equations. This allows us to explain the process as a minimization algorithm, simplifying the presentation and permitting a simple analysis based on the existing multilevel theory.

2. Adaptive relaxation. Consider the linear system

$$Ax = b, \tag{1}$$

where

$$A = (a_{i,j})_{1\le i,j\le n} \in \mathbb{R}^{n\times n}, \quad x = (x_i)_{1\le i\le n} \in \mathbb{R}^n, \quad b = (b_i)_{1\le i\le n} \in \mathbb{R}^n.$$

Assume that A is symmetric, positive definite, so that the solution of (1) is equivalent to finding the solution of

$$\min_{x\in\mathbb{R}^n}(x^T Ax - 2x^T b). \tag{2}$$

For each unknown i, define the set of its *neighbors* by

$$N(i) = \{j |\ j \neq i, a_{j,i} \neq 0\}, \tag{3}$$

that is the row indices of the nonzero entries in *column* i, excluding the diagonal. Due to symmetry, $N(i)$ is also the set of indices corresponding to nonzero entries in *row* i. The matrix is assumed to be *sparse*, that is, that the number of neighbors is small:

$$|N(i)| \le \bar{N} \ll n, \qquad 1 \le i \le n. \tag{4}$$

An *elementary relaxation* step for equation i consists of a modification of vector x by

$$x' = x + r_i, r_i = \tau_i e_i, \qquad \tau_i = a_{i,i}^{-1} e_i^T (b - Ax), \tag{5}$$

where e_i is the ith coordinate vector, (i.e., the ith column of the unit matrix) and $\tau_i = \tau_i(x)$ is called the *current scaled residual* of equation i (*dynamic residual*); see Brandt [4]. An elementary relaxation step for equation i can be understood as a coordinate descent for the ith coordinate direction applied to (2).

To evaluate the quality of an approximate solution we use the Euclidean norm, the maximum norm, or the *energy*-norm defined by

$$\|x\|_2 = \left(\frac{1}{n}\sum_{i=1}^{n} x_i^2\right)^{1/2}, \quad \|x\|_\infty = \max_{i=1,\dots,n} |x_i|, \quad \|x\|_E = (x^T Ax)^{1/2},$$

respectively. These norms will be used to measure the error $x - x^*$, $x^* = A^{-1}b$ of an approximate solution x. The effect of a basic relaxation step is described by the following lemma.

LEMMA 2.1. *Let $x - x^*$ be the error before, and $x' - x^*$ be the error after, a basic relaxation step for equation i. Then the energy norm of the error is reduced according to*

$$\|x - x^*\|_E^2 - \|x' - x^*\|_E^2 = a_{i,i}\tau_i^2.$$

Proof. It holds that

$$\begin{aligned}
&\|x - x^*\|_E^2 - \|x' - x^*\|_E^2 \\
&\quad = (x - x^*)^T A(x - x^*) - (x + r_i - x^*)^T A(x + r_i - x^*) \\
&\quad = -2r_i^T A(x - x^*) - r_i^T A r_i \\
&\quad = a_{i,i}\tau_i^2. \qquad \square
\end{aligned}$$

This lemma is exploited in the Gauss–Southwell method [18], where the equation with largest current residual is selected for relaxation in each step. This method is often too expensive, however, because it requires the determination of the maximal residual in each step.

In our algorithm we therefore use weaker conditions. Consider the sets

$$S(\tau, x) = \{i \mid \ |\tau_i(x)| \geq \tau\}.$$

If relaxation could be restricted to these sets, Lemma 2.1 would guarantee a lower bound on the reduction of the energy norm of the error in each elementary relaxation step. Unfortunately, the sets $S(\tau, x)$ are still too expensive to compute. Therefore, we will use *active sets* $\tilde{S}(\tau, x)$ that are computed more efficiently as supersets of $S(\tau, x)$: $\tilde{S}(\tau, x) \supset S(\tau, x)$.

These active sets are the basis of the *sequential adaptive relaxation algorithm* in Fig. 1, whose main loop consists of an elementary relaxation step and an update of the active set. The input for the algorithm in Fig. 1 is the initial guess x, the tolerance τ, and the current active set $\tilde{S}$. The assertions document that the algorithm will only perform properly if $\tilde{S}$ is indeed a superset of $S(\tau, x)$. If this is initially satisfied, it stays a *loop invariant.* On termination, the active set is empty implying that no residuals beyond the critical tolerance τ remain.

FIG. 1. *Sequential adaptive relaxation.*

An analogous active set strategy can be used in a simultaneous (Jacobi-style) relaxation. This may be useful if the algorithm is to be combined with other components that need

symmetric operators, such as the conjugate gradient method. In the remainder of this paper, however, we will focus on successive algorithms.

A simple argument (see Rüde [16]) shows that the work is directly proportional to the gain in energy. We state this as a lemma.

LEMMA 2.2. *Assume that algorithm* SequentialAdaptiveRelaxation *is started with initial guess x, tolerance τ, and active set $\tilde{S} \supset S(\tau, x)$. Let x' denote its result. Then the number, W, of passes through the main loop is bounded by*

$$W \leq |S| + \left(\|x - x^*\|_E^2 - \|x' - x^*\|_E^2\right) \frac{\bar{N}}{\tau^2 a_{\min}}, \tag{6}$$

where $\bar{N}$ is the maximal number of neighbors defined in (4) *and*

$$a_{\min} = \min_{i=1,\ldots,m} a_{i,i}.$$

Proof. See Proposition 3.2 in [16]. □

Lemma 2.2 shows that the work depends on the tolerance parameter τ. This raises the question of which values of τ are suitable. We prepare the answer to this question with another lemma that is often useful in the analysis of iterative methods. It relates the error with the gain in one step of the iteration (see Rüde [13]).

LEMMA 2.3. *Let a linear iteration*

$$x^{k+1} = Cx^k + b, \qquad k = 1, 2, 3, \ldots,$$

with $\|C\| \leq c < 1$ be given, and assume that x^* is its fixed point:

$$x^* = (I - C)^{-1} b.$$

Then

$$\|x^* - x^0\| \leq \frac{1}{1 - c} \|x^1 - x^0\|.$$

Proof. It holds that

$$\begin{aligned} \|x^* - x^0\| &= \left\| \sum_{k=1}^{\infty} (x^k - x^{k-1}) \right\| \\ &\leq \|x^1 - x^0\| \sum_{k=1}^{\infty} \|C^k\| \\ &\leq \frac{1}{1 - c} \|x^1 - x^0\|. \end{aligned}$$

□

We can now apply this lemma to the adaptive algorithm as follows.

THEOREM 2.4. *Let $D = \operatorname{diag}(A)$ be the diagonal part of A and assume that*

$$\|I - D^{-1}A\|_2 \leq c < 1. \tag{7}$$

Denote by x' the result of algorithm SequentialAdaptiveRelaxation *called with input $\tau > 0$ and $\tilde{S} \supset S(\tau, x)$. Then*

$$\|x' - x^*\|_2 \leq \frac{\tau}{1 - c}. \tag{8}$$

Proof. On termination, $\tau_i(x') \leq \tau$ for all i. Therefore, letting

$$\bar{r} = \sum_{i=1}^{n} r_i,$$

we get $\|\bar{r}\|_2 \leq \tau$. Now consider the iterative process

$$y^{k+1} = Cy^k$$

for $k = 0, 1, 2, \ldots$, and where $C = I - D^{-1}A$ and the initial value is $y^0 = x' - x^*$. Thus, $\bar{r} = -D^{-1}Ay^0$, and the first step in the iteration becomes $y^1 = y^0 + \bar{r}$. This is just Jacobi's method applied to $Ay = 0$. Lemma 2.3 then implies

$$||x' - x^*||_2 = ||y^0 - 0||_2 \leq \frac{1}{1-c}||y^1 - y^0||_2 = \frac{||\bar{r}||_2}{1-c} \leq \frac{\tau}{1-c}. \qquad \square$$

For the typical case of second-order elliptic equations, $c = 1 - O(h^2)$, where h is the meshsize. In this case, τ must be chosen as $O(h^2\epsilon)$, where ϵ is the desired accuracy. Lemma 2.2 shows that the computational complexity is $O(h^{-4})$, just as for the straightforward Jacobi or Gauss–Seidel iteration. Thus, adaptive relaxation has no better complexity than standard iterative methods. Instead, it should be perceived as a *device to augment an arbitrary iterative method* when some kind of nonuniformity makes a localization of the operations desirable.

In practical multilevel applications there are many situations where this is useful. The multigrid rate of convergence deteriorates in the case of singularities at reentrant corners. For the biharmonic equation discretized as a system of Laplace equations, difficulties at the boundary lead to a much reduced rate of convergence. In all these cases, *local relaxation* (see Brandt [5]) or adaptive relaxation recovers the optimal performance of multigrid algorithms, so that even simple V-cycles converge with full efficiency.

3. Multilevel adaptive iteration. In the multilevel context the situation is different because relaxation is only used as a smoother, not as a solver. A smoother need not eliminate the error, but only make it well approximated by a system with fewer unknowns.

To keep the presentation simple, we restrict the discussion to Galerkin algorithms where the coarse level equations are derived by the so-called Galerkin condition. Let us assume that we are given integers $n_1 \leq n_2 \leq \cdots \leq n_K = n$ and a sequence of spaces

$$\mathbb{R}^{n_k}, \qquad k = 1, 2, \ldots, n_K$$

with *projections* $P_k : \mathbb{R}^{n_{k+1}} \longrightarrow \mathbb{R}^{n_k}$, $k = 1, 2, \ldots, K-1$. Let $k \in \{1, 2, \ldots, K\}$ and define the product projection

$$\bar{P}_k = \prod_{\kappa=1}^{K-k} P_{K-\kappa}$$

that maps $\mathbb{R}^n$ to any of its subspaces $\mathbb{R}^{n_k}$. For $k = K$ we take this definition to mean $\bar{P}_K = I$, the identity on $\mathbb{R}^{n_K}$. The transpose P_k^T of P_k will be an *interpolation* operator. Similar to Griebel [7], we represent a vector $x \in \mathbb{R}^n$ *nonuniquely* as

$$x = \sum_{k=1}^{K} \bar{P}_k^T x_k,$$

where $x_k \in \mathbb{R}^{n_k}$, $k = 1, \ldots, K$. The minimization problem (2) then becomes

$$\min_{x_k \in \mathbb{R}^{n_k},\ k=1,\dots,K} \left(\left(\sum_{k=1}^{K} \bar{P}_k^T x_k \right)^T A \left(\sum_{k=1}^{K} \bar{P}_k^T x_k \right) - 2 \left(\sum_{k=1}^{K} \bar{P}_k^T x_k \right)^T b \right). \tag{9}$$

Multilevel algorithms usually focus on *one* level at a time, so that all but one x_k are kept fixed at any given time. This results in an equation for x_k of the form

$$\bar{P}_k A \bar{P}_k^T x_k = \bar{P}_k \left(b - A \sum_{\kappa=1,\ \kappa \neq k}^{K} \bar{P}_\kappa x_\kappa \right). \tag{10}$$

These systems are treated consecutively for $k = 1, \dots, K$. We are now interested in adaptive relaxation as an elementary process for each such level.

A complete theory of multilevel algorithms is beyond the subject of this paper. However, as an example of how theoretical results for multilevel algorithms can be used to analyze the multilevel adaptive iterative method, we derive some results based on a theorem of Zhang [20].

THEOREM 3.1. *Assume that the matrices A_k, $1 \le k \le K$, $A_K = A$, originate from a discretization of Poisson's equation on a nested sequence of uniformly refined, shape regular triangulations $\mathcal{T}_k$ of a plane, polygonal domain with linear elements. Further, let P_k^T be the (discrete representations of the) associated interpolation operators. Then there exist constants c_1, c_2, independent of K, such that for all $x \in \mathbb{R}^n$,*

$$\frac{c_1}{K} x^T A x \le x^T A \left(\sum_{\kappa=1}^{K} \bar{P}_k^T D_k^{-1} \bar{P}_k \right) A x \le c_2 x^T A x, \tag{11}$$

where $D_k = \operatorname{diag}(A_k)$ is the diagonal part of A_k. If the original problem has H^2-regularity, the lower bound can be improved to be independent of K.

Proof. See Theorem 3.1 of Zhang [20]. □

Theorem 3.1 has been proved only for the model case, so that our following argument is formally also restricted to this particular situation. Similar results for more general situations have been obtained by Bramble, Pasciak, and Xu [3], Dryja and Widlund [6], Oswald [12], and Yserentant [19], and can be applied in a similar fashion.

We define the *current scaled residual* of $x \in \mathbb{R}^n$ for any level $k = 1, 2, \dots, K$ as

$$\bar{r}_k = D_k^{-1} \bar{P}_k (b - Ax). \tag{12}$$

COROLLARY 3.2. *Under the hypothesis of Theorem* 3.1,

$$\|x - x^*\|_2 \le \frac{K}{c_1} \left\| \sum_{k=1}^{K} \bar{P}_k^T \bar{r}_k \right\|_2. \tag{13}$$

Proof. Theorem 3.1 implies that

$$\frac{c_1}{K} \le \frac{v^T A^{1/2} \left(\sum_{\kappa=1}^{K} \bar{P}_k^T D_k^{-1} \bar{P}_k \right) A^{1/2} v}{v^T v} \le c_2,$$

for all $v \in \mathbb{R}^n$. Thus the eigenvalues of the preconditioned matrix

$$\left(\sum_{\kappa=1}^{K} \bar{P}_k^T D_k^{-1} \bar{P}_k \right) A \tag{14}$$

satisfy

$$\rho\left(\sum_{k=1}^{K} \bar{P}_k^T D_k^{-1} \bar{P}_k A\right) \in \left[\frac{c_1}{K}, c_2\right].$$

Since

$$x - x^* = \left(\sum_{k=1}^{K} \bar{P}_k^T D_k^{-1} \bar{P}_k A\right)^{-1} \left(\sum_{k=1}^{K} \bar{P}_k^T \bar{r}_k\right),$$

then (13) follows. □

Theorem 3.1 can also be used to derive *lower bounds* on the L_2 error. Furthermore, bounds on the *energy norm* of the error can be constructed. Corollary 3.2 states that if the scaled residuals *on all levels* are small, then the error must be small. Therefore, we need not consider elementary relaxations with very small residuals. To obtain accuracy ϵ, relaxation need only reduce the residuals on each level to the point that they satisfy $\|\bar{r}_k\|_\infty \leq \epsilon_k$, where the ϵ_k are chosen such that

$$\sum_{k=1}^{K} \epsilon_k = O\left(\frac{\epsilon}{K}\right).$$

Thus, since adaptive relaxation can therefore be used with *large* critical tolerance values, we can now construct efficient solvers.

Unfortunately, the most straightforward idea of using adaptive relaxation directly for the preconditioned system (14) is not satisfactory. This difficulty arises because the preconditioned matrix is not sparse in the sense of (4). Analogous to a regular multilevel algorithm, we must instead use a *factored form*, where the levels are treated consecutively and independently, while trying to minimize the number of interlevel transfers. Fortunately, this can be implemented by the successive application of sequential adaptive relaxation to the systems of (10) for $k = 1, \ldots, K$.

This raises the question of how the active sets should be initialized on each level. For level k, we define

$$S_k(\bar{\tau}_k, x) = \left\{i | 1 \leq i \leq n_k,\ |e_i^T \bar{r}_k| > \bar{\tau}_k\right\}, \tag{15}$$

where $\bar{r}_k$ is the current scaled residual of level k as defined in (12). The trivial construction of a superset $\bar{S}_k \supset S_k(\bar{\tau}_k, x)$ is done by setting by $\bar{S}_k = \{1, 2, \ldots, n_k\}$, but this neglects useful information. To exploit locality, we should attempt to transfer information about the active sets between the levels. This is done essentially as if adaptive relaxation were applied to the semidefinite system (9); however, for efficiency, interlevel information is collected and transferred only when the algorithm actually switches between levels.

To give a concise description of the process we introduce the following notation. For a matrix

$$M = (\mu_{i,j}) \in \mathbb{R}^{m_1} \times \mathbb{R}^{m_2}$$

and a set $S \subset \{1, 2, \ldots, m_2\}$ of indices, let MS denote the set of indices defined by

$$MS = \{i |\ 1 \leq i \leq m_1,\ \exists j \in S : \mu_{i,j} \neq 0\}.$$

If sets are identified with Boolean vectors, MS denotes a Boolean matrix multiplication. In this notation, N, as defined in (3) and extended to be set-valued, could be written as $N = A - D$,

where D is the diagonal part of the system matrix A. Note that for two matrices A and B we only have $(AB)S \subset A(BS)$, not necessarily equality.

In Fig. 2 we display a generic multilevel adaptive iteration routine. The inner loop is precisely the adaptive relaxation applied on the different levels k. It is augmented with sets U_k and V_k to provide information where the relaxation causes changes that must be propagated to higher or lower levels. It is left unspecified whether "upward" or "downward" is selected. In either direction, the information accumulated in the set U_k (and V_k, respectively) is exploited to initialize the active set on the new level. These sets can also be used to *localize* the projection and interpolation operations. Furthermore, the set U (respectively, V) is updated so that information will be passed successively through all levels.

FIG. 2. *Multilevel adaptive iteration.*

Several different cycling strategies can be used. One possibility is a V-cycle, or W-cycle, as in classical multigrid methods. Additionally or alternatively, the number of elements in the active sets can be used to adapt the cycling strategy; see Rüde [16].

Certain variants of the above algorithm can be analyzed based on multigrid convergence theory. This possibility has been suggested by Leinen and Yserentant [9]. For this purpose, the adaptive relaxation on level k is slightly modified such that it can be interpreted as one or

more sweeps of regular, global relaxation on that level, perturbed by quantities of size $O(\bar{\tau}_k)$. The effect of one sweep of sequential adaptive relaxation starting with x_k and $\bar{\tau}_k$ on level k can therefore be described by

$$x' - x^* = \left((x - x^*) - \bar{P}_k^T (G_k \bar{P}_k A(x - x^*) + \mu_k)\right),$$

where G_k is the inverse of the lower triangular part of A_k and $\mu_k \in \mathbb{R}^{n_k}$ satisfies $\|\mu_k\|_\infty \leq \bar{\tau}_k$.

If a V-cycle with a single sweep of presmoothing is used, it suffices to argue that subsequent corrections within the same cycle cannot enlarge the error because all operators have norm smaller than 1. In particular, they cannot enlarge the μ_k perturbations, so that their total effect must be bounded by $\sum_{k=1}^{K} \bar{\tau}_k$. Thus, these variants of the multilevel adaptive iterative method have (almost) the same convergence properties as classical multigrid, but can be substantially cheaper.

The termination criterion in Fig. 2 guarantees that the final result will be accurate, provided the assumptions of Theorem 3.1 or their equivalents are satisfied. These assumptions assert that we have a suitable multilevel decomposition of the solution space, which, for classical multilevel algorithms, is the core feature that makes the algorithm work. The adaptive relaxation additionally improves robustness and efficiency.

Furthermore, and equally important, diagnostic information is automatically available within the algorithm. The relaxation within a level usually does not introduce large errors on other levels, because the corresponding components of the solution space are approximately orthogonal. If the orthogonality is severely violated, it becomes obvious in the performance of the algorithm. Cycling between levels will not efficiently reduce the size of the active sets, because removal of errors on one level feeds errors on another level. This indicates that the space decomposition is not optimal, the estimates of Theorem 3.1 are violated (or hold with large c_2/c_1 only), and thus also the error bound for the solution will be poor as determined by Corollary 3.2. In this case the setup of the multilevel hierarchy (that is the system of projection and prolongation operators) has not been successful and must be modified. With the adaptive iterative method, these troubles can be easily monitored. This makes the development of truly robust software possible.

Of course, the practical relevance of the *multilevel adaptive iterative method* depends on whether the necessary operations can be implemented efficiently. As discussed in Rüde [15], [16], this can be accomplished if *small sets* whose cardinality is bounded by a constant are implemented as lists. Typical small sets are $N(i)$. *Large sets*, like $\bar{S}$ or U and V must be represented by flags *and* lists. This is necessary so that the set operations can be performed efficiently.

4. Conclusions. The *multilevel adaptive iterative method* is a framework that can be modified and extended in many ways. The basic idea can be extended easily to nonsymmetric and even nonlinear problems. Moreover, the *multilevel adaptive iterative method* seems to be an almost ideal supplement of adaptive mesh refinement. Rüde [16] introduced a special mesh refinement technique, which is the so-called *virtual global grid*. Adaptive iteration by itself does not waste work for unknowns that are already well approximated by interpolation from a coarser grid. In this sense it can be shown that adaptive relaxation has the properties of an error estimator. This is exploited by the virtual global refinement technique. It relies on the adaptive iteration as a solver and error estimator. Grids are always refined globally; however, memory allocation for nodes is deferred until the node is really accessed and modified by an adaptive relaxation. Unknowns are therefore virtual entities that are physically created only when required by the algorithm. In this sense the multilevel adaptive iterative method can be seen as an algorithm to solve the linear systems when the number of levels tends to infinity

and where the solution process is driven only by the accuracy requirement. The fully adaptive multigrid method is thus a true partial differential equation solver.

Acknowledgment. The author thanks Steve McCormick and the referees for several helpful comments.

MULTIPLICATIVE SCHWARZ METHODS FOR PARABOLIC PROBLEMS*

XIAO-CHUAN CAI†

Abstract. The class of multiplicative Schwarz methods originated from the classical Schwarz alternating method. It has been shown to be one of the most powerful methods for solving finite element or finite difference elliptic problems. In this paper, these methods are extended to a class of singularly perturbed equations that are encountered when discretizing parabolic equations by implicit methods such as the backward Euler or Crank–Nicolson schemes. Several algorithms are discussed, including one-level, two-level, and multilevel overlapping methods. The authors also study how the convergence rates depend on the time and space discretization parameters, as well as subspace decomposition parameters such as the number of subregions and the number of levels to which the finite element space is decomposed. It is shown that in the presence of a fine enough coarse mesh space the algorithms are optimal for both symmetric and nonsymmetric problems, i.e., the convergence rates are independent of all these parameters in both two and three dimensions. If the coarse mesh space is dropped, the algorithms are still optimal but only if the timestep and the coarse mesh size satisfy certain relationships.

1. Introduction.

In a pioneer work of Lions [20] on domain decomposition methods, the classical Schwarz alternating algorithm [25] was extended successfully to a class of parabolic equations. The basic idea is to divide the region into several overlapping subregions and then to solve the parabolic problem in each subregion alternatively with boundary information from the neighboring subregions. In this paper, we further extend this idea to the case of many overlapping subregions, as well as to many levels of overlapping subregions. In this case, at each timestep many independent subproblems are being created. Thus parallel computers can be used more efficiently.

The focus of this paper is the study of the convergence rates and their dependence on the time and space discretization parameters on the subspace decomposition parameters, i.e., the number of subregions and the number of levels into which the finite element space is decomposed. Most of the techniques that we use in this paper are borrowed from the abstract theory of the additive and multiplicative Schwarz methods for elliptic equations; see, e.g., [3], [7], [8], [12], [13], and references therein. The additive version of some of the algorithms of this paper has previously been considered by the author in [4]. With a coarse mesh space, we show that under basically the same assumptions as for the additive Schwarz methods [4], the multiplicative algorithms converge with optimal rates that are independent of the time and space discretization parameters, the number of subregions, and the number of levels into which the space is decomposed. In contrast to the Schwarz methods for elliptic problems in which the coarse mesh space plays an essential role for the optimality, we prove that under the assumption that τ/H^2 is reasonably small, the algorithms remain optimal even if the coarse mesh space is eliminated. Here τ is on the order of the timestep size and H is the diameter of the largest substructure.

Some computational aspects of the algorithms have been studied extensively in the context of solving elliptic problems; see, e.g., the recent paper of Cai, Gropp, and Keyes [6]. Other domain decomposition based algorithms that deal with parabolic problems have recently been developed [2], [9], [10], [16], and [19], and references therein.

The paper is organized as follows. In the remainder of this section, we present the continuous and discrete parabolic equations and some of their basic properties. In §2, we discuss four overlapping decompositions of the finite element space, including a one-level decomposition, a two-level decomposition, and two multilevel decompositions and prove the uniformly boundedness of these decompositions. Four algorithms are introduced in §3 and their convergence rates are also analyzed. Finally, in §4, we apply these algorithms to some parabolic problems, including a time-dependent convection-diffusion equation. Throughout this paper, c and C, with or without subscripts, denote generic, strictly positive constants. Their values may be different at different occurrences, but are independent of the time and space discretization parameters, as well as the subspace decomposition parameters that will be introduced later as we move along.

Let $\Omega \subset R^d$ be a bounded polygonal region and $d = 2$, or 3. We are interested in the finite element solution of the following problem: Find $u \in H_0^1(\Omega)$, such that

$$d_\tau(u, \phi) \equiv \tau b(u, \phi) + (u, \phi) = (f, \phi) \quad \forall \phi \in H_0^1(\Omega). \tag{1}$$

Here $\tau > 0$ is a small number, which will be specified in §4 of this paper. The bilinear form $b(\cdot, \cdot)$ is defined as

$$b(u, v) = \sum_{i,j=1}^{d} \int_\Omega a_{ij}(x) \frac{\partial u}{\partial x_i} \frac{\partial v}{\partial x_j} dx + \sum_{i=1}^{d} \int_\Omega b_i(x) \frac{\partial u}{\partial x_i} v dx + \int_\Omega c(x) uv dx \tag{2}$$

and $(\cdot, \cdot)$ is the usual $L^2(\Omega)$ inner product. We assume that all coefficients are sufficiently smooth and the matrix $\{a_{ij}(x)\}$ is symmetric and uniformly positive definite. We also assume that the bilinear form $b(\cdot, \cdot)$ is bounded and positive definite, though not necessarily selfadjoint, i.e.,

(a) $|b(u, v)| \leq C\|u\|_{H_0^1(\Omega)} \|v\|_{H_0^1(\Omega)} \quad \forall u, v \in H_0^1(\Omega)$.

(b) $b(u, u) \geq c\|u\|^2_{H_0^1(\Omega)} \quad \forall u \in H_0^1(\Omega)$.

We use an $H_0^1(\Omega)$ equivalent norm, denoted by $\|\cdot\|_a$, defined by $a(u, v) = \frac{1}{2}(b(u, v)+b(v, u))$. In addition, we define the bilinear forms $a_\tau(u, v) = \frac{1}{2}(d_\tau(u, v) + d_\tau(v, u))$, which is symmetric positive definite, and $n_\tau(u, v) = \frac{1}{2}(d_\tau(u, v) - d_\tau(v, u))$, which is skewsymmetric. It is not difficult to see that the norm $\|\cdot\|_{a_\tau}$, defined by $a_\tau(\cdot, \cdot)$, is equivalent to the norm $(\|\cdot\|^2_{L^2(\Omega)} + \tau\|\cdot\|^2_{H_0^1(\Omega)})^{1/2}$. As an immediate consequence of the above assumptions, we have that the bilinear form $d_\tau(\cdot, \cdot)$ is bounded and positive definite in the $\|\cdot\|_{a_\tau}$ norm and that $n_\tau(\cdot, \cdot)$ is bounded: There exists a constant C, such that

$$| n_\tau(u, v) | \leq C\tau \|u\|_{H_0^1(\Omega)} \|v\|_{L^2(\Omega)} \quad \forall u, v \in H_0^1(\Omega).$$

It can be shown that $b(u, v)$ is $H^{1+\alpha}(\Omega)$-regular [17], [21]: For any $g \in L^2(\Omega)$ there exists a unique $u \in H^{1+\alpha}(\Omega) \cap H_0^1(\Omega)$, such that

$$b(v, u) = (g, v) \quad \forall v \in H_0^1(\Omega)$$

and

$$| u |_{H^{1+\alpha}(\Omega)} \leq C\|g\|_{L^2(\Omega)},$$

where α is at least $\frac{1}{2}$. We note that the convergence rates of some algorithms that are developed in this paper depend on the value α.

Let V^h be the usual piecewise linear conforming finite element subspace of $H_0^1(\Omega)$. The standard Galerkin approximation of (1) can then be defined by the following problem: Find $u_h^* \in V^h$, such that

$$d_\tau(u_h^*, \phi_h) = (f, \phi_h) \quad \forall \phi_h \in V^h. \tag{3}$$

In the next section, we shall formally introduce the space V^h and then decompose it into the sum of certain subspaces. Related multiplicative Schwarz methods will then be introduced to solve (3). The main purpose of this paper is the study of the convergence rates of these algorithms.

2. Overlapping decompositions and the stability analysis. In this section, we describe some uniformly overlapping subspace decompositions previously introduced by Dryja and Widlund [11], [14] for solving elliptic problems. These are the one-level, two-level, and multilevel overlapping decompositions. We will also show that these decompositions are uniformly, or nearly uniformly, bounded in the τ dependent norm $\|\cdot\|_{a_\tau}$. In the multilevel case, the uniformity is also with respect to the number of levels.

2.1. One- and two-level decompositions. Both decompositions have been discussed in [4], and the boundedness of the one-level decomposition is discussed only for the case $d = 2$. Here, we cover both $d = 2$ and 3.

Let $\{\Omega_i\}_{i=1}^M$ be a shape regular finite element triangulation, or a coarse mesh, of Ω and Ω_i has diameter of order H. In our second step, we further divide each substructure Ω_i into smaller simplices with diameter of order h. We assume that the resulting elements form a shape regular finite element subdivision of Ω. We call this the fine mesh or the h-level subdivision of Ω with mesh parameter h. Let us denote by $V^H \subset H_0^1(\Omega)$ and $V^h \subset H_0^1(\Omega)$ the continuous, piecewise linear function spaces, with zero trace on $\partial\Omega$, over the H-level and h-level subdivisions of Ω, respectively.

To obtain an overlapping decomposition, we extend each subregion Ω_i to a larger region Ω_i^{ext} such that $\Omega_i \subset \Omega_i^{\text{ext}} \subset \Omega$. Moreover, we assume that distance$(\partial\Omega_i^{\text{ext}} \cap \Omega, \partial\Omega_i \cap \Omega) \geq cH$ for all i. We suppose that $\partial\Omega_i^{\text{ext}}$ does not cut through any h-level elements.

Associated with the decomposition $\{\Omega_i^{\text{ext}}\}_{i=1}^M$, we define an undirected graph in which the nodes represent the extended subdomains and the edges intersections of the extended subdomains. This graph can be colored, using colors $1, \ldots, J$, such that no adjacent nodes have the same color. We regard the union of all subdomains with the same color as one subdomain (which is of course not simply connected), and denote them by $\Omega_1', \ldots, \Omega_J'$. We also denote $\Omega_0' = \Omega$ which has color 0. It is important to note that $J+1$, the number of colors, can be made to be independent of M, the number of substructures.

For each Ω_j', $1 \leq j \leq J$, we define $V_j = \{v \in V^h | \, v(x) = 0, \, x \bar{\in} \Omega_j'\} \subset V^h$. We also use the subspace $V_0 = V^H$. It is easy to see that we have two decompositions of V^h, i.e.,

$$V^h = V_1 + \cdots + V_J \tag{4}$$

and

$$V^h = V_0 + V_1 + \cdots + V_J, \tag{5}$$

which shall be referred as the one-level and two-level uniformly overlapping decompositions of V^h, or as the decomposition without and with the coarse mesh space, respectively.

It was proved in [4] that the two-level decomposition (5) is uniformly bounded in the $\|\cdot\|_{a_\tau}$ norm in both two- and three-dimensional spaces.

LEMMA 2.1. *There exists a constant C_0, such that for any $v \in V^h$, there exist $v_i \in V_i$, $v = v_0 + \cdots + v_J$, and*

$$\|v_0\|_{a_\tau}^2 + \sum_{i=1}^{J} \|v_i\|_{a_\tau}^2 \le C_0^2 \|v\|_{a_\tau}^2 \quad \forall v \in V^h. \tag{6}$$

Here the constant C_0 is independent of τ, h, and H.

If we drop the coarse mesh space V_0 from (5) and v_0 from the decomposition, the following estimate holds for both $d = 2$ and 3. The case $d = 2$ was discussed in [4].

LEMMA 2.2. *There exists a constant C_τ, such that for any $v \in V^h$, there exist $v_i \in V_i$, $v = v_1 + \cdots + v_J$, and*

$$\sum_{i=1}^{J} \|v_i\|_{a_\tau}^2 \le C\left(1 + \frac{\tau}{H^2}\right) \|v\|_{a_\tau}^2 \equiv C_\tau^2 \|v\|_{a_\tau}^2 \quad \forall v \in V^h, \tag{7}$$

where $C > 0$ is independent of τ, h, and H.

Proof. Let $\{\theta_i\}_{i=1}^J$ be a partition of unity and θ_i belongs to $C_0^\infty(\Omega_i' \cap \Omega)$. It can be chosen so that $|\nabla \theta_i|$ is bounded by C/H. Let I_h be the piecewise linear interpolation operator that uses the function values at the h-level nodes. For any $v \in V^h$, we let $v_i = I_h(\theta_i v) \in V_i$. For each subregion Ω_i', it is well known, in the sense of equivalent norms, that

$$|v_i|_{H_0^1(\Omega_i')}^2 = \sum ((\theta_i v)(x_l) - (\theta_i v)(x_m))^2 h^{d-2}, \tag{8}$$

where the sum is taken over all adjacent pairs of h-level nodal points in Ω_i'. Let $K \subset \Omega_i'$ be a single h-level triangle and x_l, $x_m \in \bar{K}$ be two of its vertices. Let $\bar{\theta}_{ilm} = (\theta_i(x_l) + \theta_i(x_m))/2$. We then have

$$\begin{aligned}(\theta_i v)(x_l) - (\theta_i v)(x_m) = (\theta_i(x_l) - \bar{\theta}_{ilm}) v(x_l) - (\theta_i(x_m) - \bar{\theta}_{ilm}) v(x_m) \\ + \bar{\theta}_{ilm}(v(x_l) - v(x_m)),\end{aligned}$$

which can be bounded from above by

$$C\left(\frac{h}{H} \max_{x \in \bar{K}} \{|v(x)|\}\right) + |v(x_l) - v(x_m)|.$$

By squaring this estimate, using the inequality $ab \le \frac{1}{2}(a^2 + b^2)$, summing over all $K \subset \Omega_i'$ and using (8), we obtain

$$\begin{aligned}|v_i|_{H_0^1(\Omega_i')}^2 &\le C\left(H^{-2} \sum_{K \subset \Omega_i'} \max_{x \in \bar{K}} \{|v(x)|^2\} \cdot h^d + |v|_{H^1(\Omega_i')}^2\right) \\ &\le C\left(H^{-2} \|v\|_{L^2(\Omega_i')}^2 + |v|_{H^1(\Omega_i')}^2\right).\end{aligned}$$

Therefore,

$$\sum_{i=1}^{J} \|v_i\|_{H_0^1(\Omega_i')}^2 \le C\left(H^{-2} \|v\|_{L^2(\Omega)}^2 + |v|_{H_0^1(\Omega)}^2\right) \le C H^{-2} \|v\|_{H_0^1(\Omega)}^2. \tag{9}$$

We refer to [4] for the L^2 estimate, i.e.,

$$\sum_{i=1}^{J} \|v_i\|^2_{L^2(\Omega_i')} \leq C\|v\|^2_{L^2(\Omega)}. \tag{10}$$

The proof follows immediately from the estimates (9) and (10). □

Remark 2.1. It is known that in the elliptic case, which corresponds to the use of the $\|\cdot\|_a$ norm in the estimate, if the coarse mesh space is dropped, a factor of $1/H^2$ would appear in the estimate and this makes this decomposition not so useful. However, as shown above, in the parabolic case, only a factor of τ/H^2 appears in the estimate and τ is usually in the order of the timestep size.

2.2. Multilevel decompositions. Following Dryja and Widlund [14] and Zhang [27], we let $\{\mathcal{T}^l\}_{l=0}^{L}$ be a nested sequence of triangulations of Ω, i.e., $\mathcal{T}^0 = \{\tau_i^0\}_{i=1}^{N_0}$ is the initial coarse triangulation and $\mathcal{T}^l = \{\tau_i^l\}(l = 1, \ldots, L)$ is defined by dividing each triangle of $\mathcal{T}^{l-1}$ into several triangles. We assume that all the triangulations are shape regular. Let $h_i^l = \operatorname{diam}(\tau_i^l)$, $h_l = \max_i\{h_i^l\}$, $H = \max_i h_i^0$, and $h = h_L$. We also assume that there exists $0 < r < 1$, such that h_l is proportional to Hr^l, for $l = 0, \ldots, L$. Let V^l be the usual conforming finite element space of continuous piecewise linear functions associated with the triangulation $\mathcal{T}^l$.

We construct L sets of overlapping subdomains $\{\hat{\Omega}_i^l\}_{i=1}^{J_l}, l = 1, 2, \ldots, L$; i.e., for each $1 \leq l \leq L$, we have

$$\Omega = \cup_{i=1}^{J_l} \hat{\Omega}_i^l.$$

Subdomains $\hat{\Omega}_i^l$ are defined as follows. Each triangle $\tau_i^{l-1}, i = 1, \ldots, N_l, l = 1, \ldots, L$, is extended to a larger region $\hat{\tau}_i^{l-1}$ so that

$$ch_i^{l-1} \leq \operatorname{dist}(\partial\hat{\tau}_i^{l-1} \cap \Omega, \partial\tau_i^{l-1} \cap \Omega) \leq Ch_i^{l-1}$$

aligning $\partial\hat{\tau}_i^{l-1}$ with the boundaries of level l triangles. For each l, we color the $\hat{\tau}_i^{l-1}$ by using J_l colors, such that all substructures of the same color are disjoint. Here J_l is a fixed constant depends only on the triangulations. On each level l, we group the extended subregions $\hat{\tau}_i^{j-1}$ by colors and obtain J_l sets of subregions. We denote by $\hat{\Omega}_i^l$ as the union of l-level extended subregions that share the same color $1 \leq i \leq J_l$. We denote $J = \max_l J_l$.

We define $V_i^l = \{v \in V^l |\ v(x) = 0,\ x \bar{\in} \hat{\Omega}_i^l\} \subset V^l$. Let $J_0 = 1$ and $V^0 = V_1^0 = V^H$. Thus, our finite element space $V^h = V^L$ can be represented as

$$V^L = V^0 + \sum_{l=1}^{L} V^l = V^0 + \sum_{l=1}^{L}\sum_{i=1}^{J_l} V_i^l \tag{11}$$

or

$$V^L = \sum_{l=1}^{L} V^l = \sum_{l=1}^{L}\sum_{i=1}^{J_l} V_i^l. \tag{12}$$

These two decompositions are referred to as the multilevel decomposition with and without a coarse mesh space, respectively. We note that the main difference between these two decompositions is that in (11) the coarsest mesh space is not decomposed into local subspaces. This works well if the degrees of freedoms involved in the coarse mesh problem are few. However, this is not always satisfied, especially for nonsymmetric problems where the coarse

mesh needs to be sufficiently fine. In the latter case, it is desirable to further decompose the coarse mesh problem and therefore (12) is sometimes more useful.

It is known that the decomposition with the coarse mesh (11) is uniformly bounded in the $\|\cdot\|_a$ norm, i.e., for any $v \in V^h$, there exist $v_i^l \in V_i^l$ such that

$$v = v^0 + \sum_{l=1}^{L} \sum_{i=1}^{J_l} v_i^l.$$

Moreover, there exists a constant $C > 0$, independent of the parameters h, H, and L, such that

$$\|v^0\|_a^2 + \sum_{l=1}^{L} \sum_{i=1}^{J_l} \|v_i^l\|_a^2 \le C\|v\|_a^2 \quad \forall v \in V^h.$$

We refer to [1], [14], [22], and [27] for the analysis and discussions of this bound.

To prove that the decomposition (11) is also uniformly bounded in the τ dependent norm $\|\cdot\|_{a_\tau}$, we need only to show that the same decomposition is uniformly bounded in the $L^2(\Omega)$ norm. Let us define Q^l as the usual L^2 projection

$$(Q^l v, \phi) = (v, \phi) \quad \forall v \in V^h \quad \forall \phi \in V^l$$

for $l = 0, \ldots, L$. For any given $v \in V^h$, let $v^0 = Q^0 v \in V^0$ and $v^l = Q^l v - Q^{l-1} v \in V^l$ for $l \ge 1$. It is easy to verify that

$$v = v^0 + v^1 + \cdots + v^l.$$

By using the fact that, for any $v \in V^h$ and $l \ge 1$,

$$\|(Q^l - Q^{l-1})v\|_{L^2(\Omega)}^2 = (v, (Q^l - Q^{l-1})v),$$

we establish the identity

$$\|Q^0 v\|_{L^2(\Omega)}^2 + \sum_{l=1}^{L} \|(Q^l - Q^{l-1})v\|_{L^2(\Omega)}^2 = \|v\|_{L^2(\Omega)}^2. \tag{13}$$

For each level $l \ge 1$, we define a partition of unity $\{\theta_i^l\}_{i=1}^{J_l}$ with $\theta_i^l \in H_0^1(\hat{\Omega}_i^l) \cap C_0^1(\hat{\Omega}_i^l \cap \Omega)$ such that $\sum_i \theta_i^l = 1$, $0 \le \theta_i^l \le 1$ and $|\nabla \theta_i^l| \le C/h_{l-1}$. Now, each $v^l = (Q^l - Q^{l-1})v$ can be further decomposed as

$$v^l = \sum_{i=1}^{J_l} v_i^l,$$

where $v_i^l = I_{h_l}(\theta_i^l v^l) \in V_i^l$, and where I_{h_l} is the piecewise linear interpolation operator from V^h to V^l. By using the second part of the proof of Lemma 4 of [4], we have that

$$\sum_{i=1}^{J_l} \|v_i^l\|_{L^2(\Omega)}^2 \le C\|v^l\|_{L^2(\Omega)}^2.$$

Therefore, by combining the above results, we obtain a decomposition

$$v = v^0 + \sum_{l=1}^{L} v^l = v^0 + \sum_{l=1}^{L} \sum_{i=1}^{J_l} v_i^l,$$

which is uniformly bounded in the $L^2(\Omega)$ norm, i.e.,

$$\|v^0\|^2_{L^2(\Omega)} + \sum_{l=1}^{L}\sum_{i=1}^{J_l} \|v_i^l\|^2_{L^2(\Omega)} \le C\|v\|^2_{L^2(\Omega)} \quad \forall v \in V^h,$$

where the constant $C > 0$ is independent of h, H, and L. As a consequence, we have proved the following lemma.

LEMMA 2.3. *For any $v \in V^h$, there exist $v_i^l \in V_i^l$, such that*

$$v = v^0 + \sum_{l=1}^{L}\sum_{i=1}^{J_l} v_i^l$$

and, moreover, there exists a constant C_0^{M}, independent of the parameters h, H, L, and τ, such that

$$\|v^0\|^2_{a_\tau} + \sum_{l=1}^{L}\sum_{i=1}^{J_l} \|v_i^l\|^2_{a_\tau} \le (C_0^{\mathrm{M}})^2\|v\|^2_{a_\tau} \quad \forall v \in V^h.$$

We now discuss the case when the coarse mesh space V^0 is dropped from the decomposition. In the analysis, we shall use the well-known approximation and boundedness properties of the operators $\{Q^l\}$, see e.g., [26], i.e., for any $v \in V^h$,

$$\|(Q^l - Q^{l-1})v\|^2_{L^2(\Omega)} \le Ch_l^2 a(v, v), \qquad l = 1, \ldots, L \tag{14}$$

and

$$\|Q^l v\|_a \le C\|v\|_a, \qquad l = 1, \ldots, L. \tag{15}$$

LEMMA 2.4. *For any $v \in V^h$, there exist $v_i^l \in V_i^l$, such that $v = \sum_{l=1}^{L}\sum_{i=1}^{J_l} v_i^l$ and*

$$\sum_{l=1}^{L}\sum_{i=1}^{J_l} \|v_i^l\|^2_{a_\tau} \le C\left(1 + \frac{\tau}{H^2}\right)\|v\|^2_{a_\tau} \equiv (C_\tau^{\mathrm{M}})^2\|v\|^2_{a_\tau} \quad \forall v \in V^h, \tag{16}$$

where $C > 0$ is independent of the parameters h, H, L, and τ.

Proof. For any given $v \in V^h$, we construct the multilevel overlapping decomposition as follows. Let $v^1 = Q^1 v$, $v^l = (Q^l - Q^{l-1})v$ for $l \ge 2$, and $v_i^l = I_{h_l}(\theta_i^l v^l)$ for $l = 1, \ldots, L$, $i = 1, \ldots, J_l$. These operators are linear, therefore

$$v = \sum_{l=1}^{L}\sum_{i=1}^{J_l} v_i^l.$$

We do the $H^1(\Omega)$ norm and $L^2(\Omega)$ norm estimates separately. For the $L^2(\Omega)$ estimate, by using the same arguments made for (13), we obtain

$$\sum_{l=1}^{L} \|v^l\|^2_{L^2(\Omega)} = \|v\|^2_{L^2(\Omega)}, \tag{17}$$

which, combined with the proof of Lemma 4 of [4], implies that

$$\sum_{l=1}^{L}\sum_{i=1}^{J_l} \|v_i^l\|^2_{L^2(\Omega)} \le C\|v\|^2_{L^2(\Omega)}. \tag{18}$$

We next examine the boundedness of the same decomposition described above in the $\|\cdot\|_a$ norm. We use the fact that

$$\sum_{l=1}^{L} \|v^l\|_a^2 \le C\|v\|_a^2 \quad \forall v \in V^h, \tag{19}$$

where the constant $C > 0$ is independent of the parameters h, H, and L. We refer to [1], [22], and [27] for the proofs and discussions.

Because of the estimate (6) of Dryja and Widlund [11], at each level $l \ge 2$, we have

$$|v_i^l|_{H_0^1(\hat{\Omega}_i^l)}^2 \le C\left(|v^l|_{H_0^1(\hat{\Omega}_i^l)}^2 + h_{l-1}^{-2}\|v^l\|_{L^2(\hat{\Omega}_i^l)}^2\right).$$

Here we used the fact that $\hat{\Omega}_i^l$ is the union of substructures of diameters on the order of h_{l-1}. Thus, by summing over $i = 1, \ldots, J_l$, and by using the approximation property (14), i.e., $\|v^l\|_{L^2(\Omega)}^2 \le Ch_{l-1}^2\|v^l\|_a^2$, we obtain

$$\sum_{i=1}^{J_l} \|v_i^l\|_a^2 \le C\left(\|v^l\|_a^2 + h_{l-1}^{-2}\|v^l\|_{L^2(\Omega)}^2\right) \le C\|v^l\|_a^2. \tag{20}$$

In the case $l = 1$, the desired estimate is known; see Lemma 8 of [4], i.e.,

$$\sum_{i=1}^{J_1} \|v_i^1\|_a^2 \le CH^{-2}\|v^1\|_a^2. \tag{21}$$

Therefore, the $\|\cdot\|_a$ estimate is accomplished by first adding (20), for $l = 2, \ldots, L$, and (21), and then using (19),

$$\sum_{l=1}^{L}\sum_{i=1}^{J_l} \|v_i^l\|_a^2 \le CH^{-2}\sum_{l=1}^{L} \|v^l\|_a^2 \le CH^{-2}\|v\|_a^2. \tag{22}$$

The proof of this lemma is completed by combining the results of the $L^2(\Omega)$ estimate (18) and the $H^1(\Omega)$ estimate (22). □

3. Schwarz algorithms and convergence rates analysis. In this section, we briefly describe the multiplicative Schwarz algorithms based on the various decompositions of V^h discussed in §2. The convergence rate of each algorithm is analyzed with the general Schwarz theory recently developed by Cai and Widlund [8].

3.1. Multiplicative Schwarz algorithms. Assuming that we have a set of triplets of $\{W_i, S_i, g_i \mid i = 1, \ldots, m\}$, where W_i are some subspaces of a normed linear space W, S_i some mappings from W to W_i, and $g_i \in W_i$, the multiplicative Schwarz algorithm can be described as follows.

ALGORITHM 3.1 (Multiplicative Schwarz $\{W_i, S_i, g_i\}$).
Given an initial guess $u^0 \in W$:
For $n = 0, 1, \ldots, n_{\max}$;
For $i = 1, \ldots, m$;
$u^{n+i/m} = u^{n+i-1/m} + (g_i - S_i u^{n+i-1/m})$.

It is not difficult to see that with the *error propagation* operator defined by

$$E = (I - S_m)\cdots(I - S_1)$$

and

$$g = (I - S_m)\cdots(I - S_2)g_1 + (I - S_M)\cdots(I - S_3)g_2 + \cdots + g_m,$$

then $u^{n+1} = Eu^n + g$. The convergence rate of the multiplicative Schwarz algorithm is thus determined by the spectral radus of the operator E. In an application, Algorithm 3.1 can also be used as a preconditioner for other conjugate gradient (CG)-type iterative methods, such as CG for symmetric positive definite problems, and generalized minimal residual (GMRES) [24], [15], or flexible GMRES (FGMRES) [23] for other cases. When it is used as a preconditioner, the actual system solved is the *transformed system* $(I - E)u = g$. We refer to [5], [6], [7], and [8] for discussion and comments on the numerical implementations.

In the rest of the paper, we take $W = V^h$ and W_i as one of the V_i or V_i^l defined in §2. Operators for subspaces V_i are defined as follows: For each $v \in V^h$, a unique $P_i v \in V_i$ is defined as the finite element solution of

$$d_\tau(P_i v, \phi) = d_\tau(v, \phi) \quad \forall \phi \in V_i.$$

Similarly, we can define P_i^l on V_i^l. We denote $g_i = P_i u_h^*$ and $g_i^l = P_i^l u_h^*$. We note that the g_i can be computed, without knowing the function u_h^* itself, by solving the finite element problems

$$d_\tau(g_i, \phi) = (f, \phi) \quad \forall \phi \in V_i. \tag{23}$$

Similarly, g_i^l can also be computed without knowing u_h^*.

ALGORITHM 3.2 (One-level multiplicative Schwarz). Run Algorithm 3.1 with an initial guess $u^0 \in V^h$ and $\{V_i, P_i, g_i \mid i = 1, \ldots, J\}$.

ALGORITHM 3.3 (Two-level multiplicative Schwarz). Run Algorithm 3.1 with an initial guess $u^0 \in V^h$ and $\{V_0, P_0, g_0, \text{ and } V_i, P_i, g_i \mid i = 1, \ldots, J\}$.

ALGORITHM 3.4 (Multilevel multiplicative Schwarz without a coarse mesh space). Run Algorithm 3.1 with an initial guess $u^0 \in V^h$ and

$$\{V_i^l, P_i^l, g_i^l \mid l = 1, \ldots, L,\ i = 1, \ldots, J_l\}.$$

ALGORITHM 3.5 (Multilevel multiplicative Schwarz with a coarse mesh space). Run Algorithm 3.1 with an initial guess $u^0 \in V^h$ and

$$\{V^0, P_0, g_0, \text{ and } V_i^l, P_i^l, g_i^l \mid l = 1, \ldots, L,\ i = 1, \ldots, J_l\}.$$

The convergence of these algorithms will be analyzed in §3.2. We note that the Algorithm 3.1 is a purely sequential algorithm; however, Algorithms 3.2–3.5 can be made highly parallel. This is due to the fact that each V_i (or V_i^l), except V_0 (or V^0), is the sum of several subspaces that are mutually orthogonal. Therefore the subproblem defined on V_i can be regarded as a set of independent sub-subproblems that can be solved in parallel. In Algorithms 3.2 and 3.4, the bottleneck step with V_0 (or V^0) is removed, as compared with their counterpart Algorithms 3.3 and 3.5. We show in the next subsection that the removal of the coarse mesh space does not degenerate by much the convergence rates for the class of parabolic problems under certain circumstances, although this is known to be not true for elliptic problems.

3.2. Convergence rates analysis. Let $E_{\text{A3.}i}$ be the error propagation operator for Algorithm $3.i$, $i = 1, \ldots, 5$. We estimate the norm of these operators by using a theorem of Cai and Widlund [8]. The proof of this theorem is technical; interested readers are referred to [8]

for details. To apply this theorem, we need only to verify certain properties of the subspaces related to the operator.

THEOREM 3.1 (Cai and Widlund). *Let W be a Hilbert space with inner product $v(\cdot,\cdot)$ and norm $\|\cdot\|_v = v(\cdot,\cdot)^{1/2}$. Suppose that W has a decomposition*

$$W = W_1 + \cdots + W_m, \tag{24}$$

where $W_1, \ldots, W_m$ are subspaces of W. Let the matrix $\mathcal{E} = \{\varepsilon_{ij}\}$ be defined by the strengthened Cauchy–Schwarz coefficients, where ε_{ij} is the smallest constant for which

$$|v(w_i, w_j)| \le \varepsilon_{ij}\|w_i\|_v\|w_j\|_v \quad \forall w_i \in W_i \quad \forall w_j \in W_j, \qquad i, j = 1, \ldots, m \tag{25}$$

holds. We assume that there are operators $T_i : W \to W_i$ that satisfy the following assumptions.

(i) *There exists a constant $\gamma > 0$ and parameters $\delta_i \ge 0$, such that $\sum_{i=1}^m \delta_i$ can be made sufficiently small, such that*

$$T_i + T_i^T - T_i^T T_i \ge \gamma T_i^T T_i - \delta_i I. \tag{26}$$

(ii) *There exists a constant $\bar{C}_0 > 0$, such that*

$$\sum_{i=1}^m T_i^T T_i \ge \bar{C}_0^{-2} I. \tag{27}$$

Here T_i^T is the adjoint operator of T_i given by $v(T_i^T u, v) = v(u, T_i v)$. Then, we have

$$\|(I - T_m)\cdots(I - T_1)\|_v \le \sqrt{1 - \bar{\gamma}\bar{C}_0^{-2}},$$

where

$$\bar{\gamma} = C\left(4(1+\gamma)^{-2}|\mathcal{E}|_{l^1}^2 + \left(\sum_{i=1}^m \delta_i\right)^2 + 1\right)^{-1}$$

and C is a positive constant.

In the remainder of this paper, we shall apply this theorem to the Hilbert space V^h equipped with the inner product $a_\tau(\cdot,\cdot)$, the decompositions (4), (5), (11), and (12) discussed in the previous section, and the operators P_i or P_i^l. Our main tasks include the verification of assumptions (i) and (ii) and the estimate of $|\mathcal{E}|_{l^1}$ for the four algorithms. The two assumptions required in Theorem 3.1 will be verified through the next two lemmas.

LEMMA 3.1. *For $i = 0, 1, \ldots, J$,*

$$P_i + P_i^T - P_i^T P_i \ge P_i^T P_i - \delta_i I \tag{28}$$

with $\delta_i = O(H)$, for $i \ge 1$, and $\delta_0 = CH^\alpha\sqrt{H^2/\tau + 1}$. Here $C > 0$ is independent of h, H, and τ. For $l = 1, \ldots, L$ and $i = 1, \ldots, J_l$,

$$P_i^l + (P_i^l)^T - (P_i^l)^T P_i^l \ge (P_i^l)^T P_i^l - \delta_i^l I \tag{29}$$

with $\delta_i^l = O(h_l)$.

The proof for P_0 can be obtained by applying Lemma 6 of [4] and the definition of P_0. A similar approach works for other mapping operators.

Remark 3.1. If the bilinear form $b(\cdot,\cdot)$ is selfadjoint and positive definite, then $\delta_i = 0$, for all $i = 0, \ldots, J$, and $\delta_i^l = 0$, for all $l = 1, \ldots, L$, $i = 1, \ldots, J_l$. $\gamma = 1.0$ in all cases.

Remark 3.2. For the one- and two-level methods, both summations

$$\sum_{i=1}^{J} \delta_i \le CJH \quad \text{and} \quad \delta_0 + \sum_{i=1}^{J} \delta_i \le C\left(H^{\alpha}\sqrt{\frac{H^2}{\tau}+1} + JH\right)$$

can made sufficiently small; therefore assumption (i) is verified. Note that the fact that J is independent of H is used here.

Remark 3.3. For the two multilevel algorithms, since h_l is proportional to Hr^l, the quantity

$$\sum_{l=1}^{L}\sum_{i=1}^{J_l} \delta_i^l \le C\frac{r}{1-r}\, JH$$

can be made sufficiently small if H is small. The extra member for the method with coarse mesh $H^{\alpha}\sqrt{H^2/\tau + 1}$ can also be made sufficiently small. Thus, assumption (i) is verified for the multilevel algorithms.

We next examine assumption (ii) for the four algorithms.

LEMMA 3.2. *The following four inequalities hold*:

$$\sum_{i=1}^{J} P_i^T P_i \ge C\left(1+\frac{\tau}{H^2}\right)^{-2} I = C_d^{-2}C_\tau^{-2} I, \tag{30}$$

$$P_0^T P_0 + \sum_{i=1}^{J} P_i^T P_i \ge CI = C_d^{-2}C_0^{-2} I, \tag{31}$$

$$\sum_{l=1}^{L}\sum_{i=1}^{J_l} (P_i^l)^T P_i^l \ge C\left(1+\frac{\tau}{H^2}\right)^{-2} I = C_d^{-2}(C_\tau^{\mathrm{M}})^{-2} I, \tag{32}$$

$$P_0^T P_0 + \sum_{l=1}^{L}\sum_{i=1}^{J_l} (P_i^l)^T P_i^l \ge CI = C_d^{-2}(C_0^{\mathrm{M}})^{-2} I, \tag{33}$$

where C_d *satisfies* $|d_\tau(u, v)| \le C_d \|u\|_{a_\tau} \|v\|_{a_\tau}$ *for any* $u, v \in V^h$.

Proof. The proofs for these four estimates are essentially the same, and we therefore only provide the proof of the second one. For any $v \in V^h$, by using the decomposition (4), the definition of mapping operators P_i, the Cauchy–Schwarz inequality, the uniformly boundedness of the decomposition (6) in the $\|\cdot\|_{a_\tau}$ norm, and the boundedness of $d_\tau(\cdot,\cdot)$, we have

$$\|v\|_{a_\tau}^2 \le d_\tau(v, v) = \sum_{i=0}^{J} d_\tau(v, v_i) = \sum_{i=0}^{J} d_\tau(P_i v, v_i)$$

$$\le C_d \sqrt{\sum_{i=0}^{J} \|P_i v\|_{a_\tau}^2}\sqrt{\sum_{i=0}^{J} \|v_i\|_{a_\tau}^2}$$

$$\le C_d C_0 \|v\|_{a_\tau} \sqrt{\sum_{i=0}^{J} \|P_i v\|_{a_\tau}^2}.$$

Therefore, removing the common term $\|v\|_{a_\tau}$ and squaring both sides, we obtain

$$C_d^{-2}C_0^{-2}\|v\|_{a_\tau}^2 \le \sum_{i=0}^{J} \|P_i v\|_{a_\tau}^2,$$

which is the desired proof. □

Remark 3.4. If $d_\tau(\cdot,\cdot)$ is symmetric positive definite, then $C_d = 1$.

We now discuss the bounds for $|\mathcal{E}|_{l^1}$. The cases for one- and two-level methods are simple. $|\mathcal{E}|_{l^1}$ is bounded by the maximum number of subregions that any given point in Ω belongs to. For example, for the box-decomposition of a rectangular region in the two-dimensional space, as in Fig. 1, the subregions can be colored such that $|\mathcal{E}|_{l^1} = 5$. In general, $|\mathcal{E}|_{l^1} \le J$ or $J+1$ for one- or two-level methods. In the multilevel cases, we need an estimate of Zhang [27],

$$a(v_i^{l_1}, v_j^{l_2}) \le C(r^d)^{|l_1-l_2|-1}\|v_i^{l_1}\|_a \|v_j^{l_2}\|_a \quad \text{for } l_1 \ne l_2 \quad \text{and} \quad \forall v_i^{l_1} \in V_i^{l_1}, \quad v_j^{l_2} \in V_j^{l_2}$$

and the following lemma.

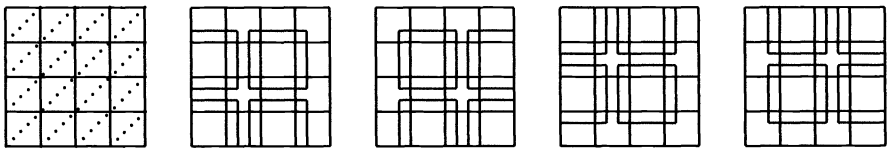

FIG. 1. *The coloring pattern of* 16 *fine grid overlapped subregions and a coarse grid region. Color* 0 *is for the global coarse grid. The extended subregions of the other colors are indicated by the dotted boundaries.*

LEMMA 3.3. *For* $l_1 \ne l_2$, *and any* $v_i^{l_1} \in V_i^{l_1}$, $v_j^{l_2} \in V_j^{l_2}$,

$$a_\tau(v_i^{l_1}, v_j^{l_2}) \le C(r^d)^{|l_1-l_2|-1}\|v_i^{l_1}\|_{a_\tau}\|v_j^{l_2}\|_{a_\tau},$$

where $C > 0$ *is independent of* h, H, L, *and* τ.

Proof. It suffices to show that, for $l_2 > l_1$,

$$(v_i^{l_1}, v_j^{l_2}) \le C(r^d)^{l_2-l_1-1}\|v_i^{l_1}\|_{L^2(\Omega)}\|v_j^{l_2}\|_{L^2(\Omega)}. \tag{34}$$

If the supporting regions $\hat{\Omega}_i^{l_1}$ and $\hat{\Omega}_i^{l_2}$ of $v_i^{l_1}$ and $v_j^{l_2}$ do not intersect, then (34) is trivial; otherwise, we have

$$(v_i^{l_1}, v_j^{l_2}) \le \|v_i^{l_1}\|_{L^2(\hat{\Omega}_i^{l_2})}\|v_j^{l_2}\|_{L^2(\Omega)}.$$

Let the triangle $K^{l_1} \in \mathcal{T}^{l_1}$ have vertices $y_1, \ldots, y_{d+1}$, and let $x_1, \ldots, x_k$ be all the nodal points of $\mathcal{T}^{l_2}$ in $\hat{\Omega}_i^{l_2}$. We can show that $k \le CJ_{l_2}(h_{l_2-1}/h_{l_2})^d$. Since $v_i^{l_1}$ is linear in $\hat{\Omega}_i^{l_2} \cap K^{l_1}$, we have

$$\|v_i^{l_1}\|_{L^2(\hat{\Omega}_i^{l_2}\cap K^{l_1})}^2 \le Ch_{l_2}^d \left(\sum_{1\le\sigma\le k, x_\sigma \in K^{l_1}} (v_i^{l_1}(x_\sigma))^2 \right)$$

$$\le Ck\, h_{l_2}^d \max_{x_\sigma \in K^{l_1}} \{|v_i^{l_1}(x_\sigma)|^2\}$$

$$\leq Ck\, h_{l_2}^d \sum_{\xi=1}^{d+1} (v_i^{l_1}(y_\xi))^2$$

$$\leq Ck \frac{h_{l_2}^d}{h_{l_1}^d} \|v_i^{l_1}\|^2_{L^2(K^{l_1})} \leq C \left(\frac{h_{l_2-1}}{h_{l_1}}\right)^d \|v_i^{l_1}\|^2_{L^2(K^{l_1})}.$$

By using the assumption that h_l is proportional to Hr^l, we obtain

$$\|v_i^{l_1}\|^2_{L^2(\hat{\Omega}_i^{l_2} \cap K^{l_1})} \leq C(r^d)^{l_2-l_1-1} \|v_i^{l_1}\|^2_{L^2(K^{l_1})}.$$

Summing over all $K^{l_1} \in \mathcal{T}^{l_1}$, we have

$$\|v_i^{l_1}\|^2_{L^2(\hat{\Omega}_i^{l_2})} \leq C(r^d)^{l_2-l_1-1} \|v_i^{l_1}\|^2_{L^2(\Omega)},$$

which proves the estimate (34). □

Applying Lemma 3.3 and using the fact that $1 + r^d + r^{2d} + \cdots \leq 1/(1-r^d)$, we see that $|\mathcal{E}|_{l^1}$ is uniformly bounded for both decompositions (11) and (12), independent of the number of levels L.

We now summerize the main convergence results for the four algorithms in the next theorem. The proof is a simple consequence of Theorem 3.1 and the lemmas of this section. Let $J = \max_l J_l$.

THEOREM 3.2. (a) *For Algorithm* 3.2, *there exists constants* $\tilde{c} > 0$ *and* $c = c(\tilde{c}) > 0$, *such that if* $\max\{H, H^\alpha \sqrt{H^2/\tau + 1}\} \leq \tilde{c}$, *then*

$$\|E_{\text{A3.2}}\|^2_{a_\tau} \leq 1 - \frac{c}{(1+J)^2 C_0^2}.$$

(b) *For Algorithm* 3.3, *there exist constants* $H_0 > 0$ *and* $c(H_0) > 0$, *such that if* $H \leq H_0$, *then*

$$\|E_{\text{A3.3}}\|^2_{a_\tau} \leq 1 - \frac{c}{(1+J)^2 C_\tau^2}.$$

Recall that $C_\tau^2 = C(1 + \tau/H^2)$.

(c) *For Algorithm* 3.4, *there exist constants* $H_0 > 0$ *and* $c(H_0) > 0$, *such that if* $H \leq H_0$, *then*

$$\|E_{\text{A3.4}}\|^2_{a_\tau} \leq 1 - \frac{c}{(1+J)^2 (C_\tau^{\text{M}})^2}.$$

Recall that $(C_\tau^{\text{M}})^2 = C(1 + \tau/H^2)$.

(d) *For Algorithm* 3.5, *there exists constants* $\tilde{c} > 0$ *and* $c = c(\tilde{c}) > 0$, *such that if* $\max\{H, H^\alpha \sqrt{H^2/\tau + 1}\} \leq \tilde{c}$, *then*

$$\|E_{\text{A3.5}}\|^2_{a_\tau} \leq 1 - \frac{c}{(1+\hat{c}^2)C} = 1 - \frac{c}{(1+\hat{c}^2)(C_0^{\text{M}})^2},$$

where $\hat{c} = J + H^\alpha \sqrt{1 + \frac{\tau}{H^2}} + JH$.

Here the constants c may be different in different occurrence.

Remark 3.5. As previously remarked, if the bilinear form $b(\cdot,\cdot)$ is symmetric positive definite, then the requirement that H be sufficiently small is not necessary, i.e., $H_0 = +\infty$.

Remark 3.6. In the nonsymmetric cases, when the coarse mesh size is $H \leq H_0$, the convergence is insured. Generally, the smaller H is, the faster the algorithm is.

Remark 3.7. These algorithms are often referred as algorithms with exact solvers, because all the subproblems defined in extended subregions, and the coarse mesh problem, are obtained by discretizing the original partial differential operator and then solved exactly by direct method. In practice, this is sometimes not necessary. A different differential operator can be used instead, and the linear systems need not be solved exactly; see discussions in [6], [7], and [8].

4. Applications to parabolic problems. In this section, we apply the algorithms developed in the previous sections to solve the following parabolic convection-diffusion problem: Find $u(x, t)$, such that

$$\begin{aligned} \tfrac{\partial u}{\partial t} + Lu &= f \qquad \text{in } \Omega \times [0, T], \\ u(x, t) &= 0 \qquad \text{on } \partial\Omega \times [0, T], \\ u(x, 0) &= u_0(x) \quad \text{in } \Omega, \end{aligned} \tag{35}$$

where $\Omega \subset R^2$. A weak formulation of (35) is: Find $u(x, t) \in H_0^1(\Omega)$, $u(x, 0) = u_0(x)$ in Ω, such that

$$\left(\frac{\partial u}{\partial t}, \phi\right) + b(u, \phi) = (f, \phi) \quad \forall \phi \in H_0^1(\Omega) \quad \forall t \in [0, T],$$

where the bilinear form $b(\cdot, \cdot)$ is the same as in (2). The existence and uniqueness of the solution of the weak parabolic convection-diffusion equation present no problems; see, e.g., [18]. Two time discretization schemes are considered, namely, a backward Euler scheme and a Crank–Nicolson scheme. The space variable is discretized by the piecewise linear finite element method. Let Δt_n be the nth timestep, M the number of steps, and $\sum_{n=1}^{M} \Delta t_n = T$. For the backward Euler–Galerkin scheme,

$$\left(\frac{u_h^n - u_h^{n-1}}{\Delta t_n}, \phi_h\right) + b(u_h^n, \phi_h) = (f, \phi_h) \quad \forall \phi_h \in V^h,$$

with $u_h^0(x, t) = u_0(x)$ and $n = 1, \ldots, M$. For the Crank–Nicolson–Galerkin scheme,

$$\left(\frac{u_h^n - u_h^{n-1}}{\Delta t_n}, \phi_h\right) + b\left(\frac{u_h^n + u_h^{n-1}}{2}, \phi_h\right) = (f, \phi_h) \quad \forall \phi_h \in V^h,$$

with $u_h^0(x, t) = u_0(x)$ and $n = 1, \ldots, M$. Both schemes lead to the following problem: For a given function $g_{n-1} \in H^{-1}(\Omega)$, find $w_h \in V^h$, such that

$$d_\tau(w_h, \phi_h) \equiv (w_h, \phi_h) + \tau b(w_h, \phi_h) = (g_{n-1}, \phi_h) \quad \forall \phi_h \in V^h, \tag{36}$$

where τ is the timestep parameter. The stability of both schemes is well understood; see, e.g., [18]. The algorithms discussed in the previous sections can thus be applied to the solution of (36) at each timestep. An obvious initial guess is the approximate solution obtained at the previous timestep. For the backward Euler–Galerkin scheme,

$$\begin{aligned} w_h &= u_h^n - u_h^{n-1}, \\ \tau &= \Delta t_n, \\ (g_{n-1}, \phi_h) &= \tau((f, \phi_h) - b(u_h^{n-1}, \phi_h)), \end{aligned}$$

and it is known that the truncation error is $O(\tau + h^2)$; therefore, it is reasonable to assume that τ is of order h^2 to maintain the balance of the time and space discretization errors. The factor τ/H^2 is thus $(h/H)^2$ bounded, and thus the algorithms without coarse mesh spaces are optimal. Similarly, for the Crank–Nicolson–Galerkin scheme,

$$\begin{aligned} w_h &= u_h^n - u_h^{n-1}, \\ \tau &= \tfrac{\Delta t_n}{2}, \\ (g_{n-1}, \phi_h) &= \tau(2(f, \phi_h) - b(u_h^{n-1}, \phi_h)), \end{aligned}$$

and since the truncation error is $O(\tau^2 + h^2)$, the factor τ/H^2 is approximately h/H^2. As long as this h/H^2 is kept reasonably small, the methods without coarse mesh spaces should also behave well.

In the rest of this section, we present some numerical results for model problems. We have only tested the one- and two-level methods; the numerical performance of the multilevel methods will be studied elsewhere. To specify our model problems, we give only the elliptic part of the parabolic operator. We consider the following linear second-order elliptic operator defined on $\Omega = [0, 1] \times [0, 1]$,

$$Lu = -\frac{\partial}{\partial x}\left(\xi \frac{\partial u}{\partial x}\right) - \frac{\partial}{\partial y}\left(\eta \frac{\partial u}{\partial y}\right) + \alpha \frac{\partial u}{\partial x} + \beta \frac{\partial u}{\partial y} + \gamma u,$$

with the homogenous Dirichlet boundary condition. The right-hand side is chosen so that the exact solution is $u = e^{xy} \sin(\pi x) \sin(\pi y)$. The coefficients are specified as follows.

Example 1. $\xi = 1$, $\eta = 1$, and $\alpha = \beta = \gamma = 0$.

Example 2. $\xi = 1 + x^2 + y^2$, $\eta = e^{xy}$, $\alpha = 5(x + y)$, $\beta = 1/(1 + x + y)$, and $\gamma = 0$.

The domain Ω is partitioned with two uniform triangular grids that have sizes h and H, respectively. The actual values of h and H are given in Tables 1 and 2. The overlapping subdomains are colored by using four colors as in Fig. 1 and the coarse grid has color 0. The differential operator is discretized by the usual five-point center finite difference method at both the coarse and fine levels. We assume that the timestep has the form

$$\tau = h^{\epsilon},$$

where $\epsilon = 0.25, 0.5, 1.0, 1.25$, and 1.5. All algorithms are accelerated by the GMRES method without restarting. The subdomain problems, as well as the coarse mesh problem, are solved exactly by a direct method. We present the iteration counts for GMRES that are required to solve (36). The iteration is stopped when the $\|r_i\|_2/\|r_0\|_2 \leq 10^{-5}$, where r_i is the preconditioned residual at the ith iteration. The initial guess is always zero.

TABLE 1

Iteration counts for solving the problems given in Examples 1 *and* 2. *The two-level method is used with the fine mesh size uniformly* $h = \frac{1}{128}$ *and the overlap is* $\frac{1}{8}$ *of* H.

	Example 1					Example 2				
$H\backslash\epsilon$	0.25	0.5	1.0	1.25	1.5	0.25	0.5	1.0	1.25	1.5 10pt
$\frac{1}{4}$	5	5	4	4	3	5	5	5	4	3
$\frac{1}{8}$	4	4	4	4	4	4	4	4	4	4
$\frac{1}{16}$	3	3	4	4	4	4	4	4	4	4

For the two-level method, we test various coarse grid sizes and the iteration numbers are given in Table 1. As predicted in the theory, the numbers are independent of H and τ(or ϵ).

TABLE 2

Iteration counts for solving the problems given in Examples 1 *and* 2. *The one-level method is used with a uniform fine mesh* $h = \frac{1}{128}$ *and the overlap is* $\frac{1}{8}$ *of* H. *The approximate ratio* τ/H^2 *is given as the subscript of the iteration number for Example* 1. *The ratios are the same for Example* 2 *and are therefore omitted.*

	Example 1					Example 2				
$H\backslash\epsilon$	0.25	0.5	1.0	1.25	1.5	0.25	0.5	1.0	1.25	1.5
$\frac{1}{4}$	$9_{(4.76)}$	$9_{(1.41)}$	$6_{(0.13)}$	$4_{(0.04)}$	$3_{(0.01)}$	11	10	7	5	4
$\frac{1}{8}$	$17_{(19.03)}$	$16_{(5.66)}$	$10_{(0.50)}$	$6_{(0.15)}$	$4_{(0.04)}$	20	19	12	8	6
$\frac{1}{16}$	$33_{(76.11)}$	$30_{(22.63)}$	$17_{(2.00)}$	$10_{(0.59)}$	$7_{(0.18)}$	39	38	22	14	10

If the coarse solve is dropped as in the one-level method, the iteration numbers become more sensitive to the ratio τ/H^2, as seen in Table 2, especially for the nonsymmetric problem. We see that if the ratio τ/H^2 is relatively small, the results are acceptable as compared with the cases that use a coarse mesh solve.

Acknowledgment. I would like to thank Professor Olof Widlund for many valuable discussions and comments on this paper.

DOMAIN DECOMPOSITION ALGORITHMS WITH SMALL OVERLAP*

MAKSYMILIAN DRYJA† AND OLOF B. WIDLUND‡

Abstract. Numerical experiments have shown that two-level Schwarz methods often perform very well even if the overlap between neighboring subregions is quite small. This is true to an even greater extent for a related algorithm, due to Barry Smith, where a Schwarz algorithm is applied to the reduced linear system of equations that remains after the variables interior to the subregions have been eliminated. In this paper, a supporting theory is developed.

Key words. domain decomposition, elliptic finite element problems, preconditioned conjugate gradients, Schwarz methods

AMS subject classifications. 65F10, 65N30, 65N55

1. Introduction.

Over the last decade, considerable interest has developed in Schwarz methods and other domain decomposition methods for partial differential equations; see, e.g., the proceedings of five international symposia [17]–[19], [34], [35]. A general theory has evolved and a substantial number of new algorithms has been designed, analyzed and tested numerically. Among them are *two-level, additive Schwarz* methods first introduced in 1987; see Dryja and Widlund [25], [28]–[30], [55]. For related work see also Bjørstad, Moe, and Skogen [1]–[3], Cai [10]–[12], Mathew [40]–[42], Matsokin and Nepomnyaschikh [43], Nepomnyaschikh [44], Skogen [47], Smith [48]–[52], and Zhang [58], [59]. As shown in Dryja and Widlund [30], a number of other domain decomposition methods, in particular those of Bramble, Pasciak, and Schatz [5], [6], can also be derived and analyzed using the same framework. Recent efforts by Bramble et al. [7] and Xu [56] have extended the general framework making a systematic study of multiplicative Schwarz methods possible. The multiplicative algorithms are direct generalizations of the original alternating method discovered more than 120 years ago by H. A. Schwarz [46]. For other recent projects, that also use the Schwarz framework, see Dryja, Smith, and Widlund [27] and Dryja and Widlund [32], [33].

When a two-level method is used, the restrictions of the discrete elliptic problem to overlapping subregions, into which the given region has been decomposed, are solved exactly or approximately. These local solvers form an important part of a preconditioner for a conjugate gradient method. In addition, to enhance the convergence rate, the preconditioner includes a global problem of relatively modest dimension.

Generalizations to more than two levels have also been developed; see, e.g., Bramble, Pasciak, and Xu [8], Dryja and Widlund [31], and Zhang [58]–[60]; here the families of domain decomposition methods and multigrid algorithms merge. Recently there has also been a considerable interest in nonsymmetric and indefinite problems; cf., e.g., Bramble, Leyk, and Pasciak [4], Cai [10]–[12], Cai, Gropp, and Keyes [13], Cai and Widlund [14], [15], Cai and Xu [16], and Xu [57]. However, in this paper, we work exclusively with two-level methods for positive definite, symmetric problems.

The main result of our early study of two-level Schwarz methods shows that the condition number of the operator, which is relevant for the conjugate gradient iteration, is uniformly bounded if the overlap between neighboring subregions is sufficiently generous in proportion to the diameters of the subregions.

Our current work has been inspired very directly by several series of numerical experiments that indicate that the rate of convergence is quite satisfactory even for a small overlap, and that the running time of the programs is often the smallest when the overlap is at a minimum. The number of conjugate gradient iterations is typically higher in such a case, but this can be compensated for by the fact that the local problems are smaller and therefore cheaper to solve; see, in particular, Bjørstad, Moe, and Skogen [2], Bjørstad and Skogen [3], Cai [10], [11], Cai, Gropp, and Keyes [13], and Skogen [47]. If the local problems are themselves solved by an iterative method, then a smaller overlap will give better conditioned local problems and therefore a higher rate of convergence; see Skogen [47] for a detailed discussion of this effect. All this work also shows that these algorithms are relatively easy to implement. Recent experiments by Gropp and Smith [37] for problems of linear elasticity provide strong evidence that these methods can be quite effective even for very ill-conditioned problems. In this paper, we show that the condition number of the preconditioned operator for the algorithm, introduced in 1987 by Dryja and Widlund [28], is bounded from above by const.$(1 + (H/\delta))$. Here H measures the diameter of a subregion and δ the overlap between neighboring subregions. We note that H/δ is a measure of the aspect ratio of the subregion common to two overlapping neighboring subregions.

We then turn our attention to a very interesting method, introduced in 1989 by Barry Smith [48], [51]. It is known as the *vertex space* (or *Copper Mountain*) algorithm. Numerical experiments, for problems in the plane, have shown that this method converges quite rapidly even for problems, which were originally very ill conditioned, even if the overlap is very modest; see Smith [48]. For additional work on variants of this method, see Chan and Mathew [20], [21], and Chan, Mathew, and Shao [22].

When Smith's algorithm is used, the given large linear system of algebraic equations, resulting from a finite element discretization of an elliptic problem, is first reduced in size by eliminating all variables associated with the interiors of the nonoverlapping *substructures* $\{\Omega_i\}$ into which the region has been subdivided. The reduced problem is known as the *Schur complement* system and the remaining degrees of freedom are associated with the set $\{\partial\Omega_i\}$ of substructure boundaries that form the interface Γ between the substructures. The preconditioner of this domain decomposition method, classified as a *Schwarz method on the interface* in Dryja and Widlund [30], is constructed from a coarse mesh problem, with the substructures serving as elements, and a potentially large number of local problems. The latter correspond to an overlapping covering of Γ, with each subset corresponding to a set of adjacent interface variables.

Smith's main theoretical result, given in [48], [51], is quite similar to that for the original two-level Schwarz method; the condition number of this domain decomposition algorithm is uniformly bounded for a class of second-order elliptic problems provided that there is a relatively generous overlap between neighboring subregions that define the subdivision of the domain decomposition method. In this paper, we show that the condition number of the iteration operator grows only in proportion to $(1 + \log(H/\delta))^2$. We note that even for a minimal overlap of just one mesh width h, this bound is as strong as those for the well-known iterative substructuring methods considered by Bramble, Pasciak, and Schatz [5], [6], Dryja [24], Dryja, Proskurowski, and Widlund [26], Smith [49], and Widlund [54]; cf. also Dryja, Smith, and Widlund [27]. We also note that the successful iterative substructuring methods for problems in three dimensions require the use of more complicated coarse subspaces and

that therefore Smith's method, considered in this paper, seems to offer an advantage.

2. Some Schwarz methods for finite element problems. As usual, we write our continuous and finite element elliptic problems as: Find $u \in V$, such that

$$a(u, v) = f(v) \quad \forall\, v \in V,$$

and, find $u_h \in V^h$, such that

$$a(u_h, v_h) = f(v_h) \quad \forall\, v_h \in V^h, \tag{1}$$

respectively. We assume that the bilinear form $a(u, v)$ is selfadjoint and elliptic and that it is bounded in $V \times V$. In the case of Poisson's equation, the bilinear form is defined by

$$a(u, v) = \int_\Omega \nabla u \cdot \nabla v \, dx. \tag{2}$$

We assume that Ω is a Lipschitz region in R^n, $n = 2, 3$, and that its diameter is on the order of 1. (We will follow Nečas [45] when defining Lipschitz regions and Sobolev spaces on Ω.) The bilinear form $a(u, v)$ is directly related to the Sobolev space $H^1(\Omega)$ that is defined by the seminorm and norm

$$|u|^2_{H^1(\Omega)} = a(u, u) \quad \text{and} \quad \|u\|^2_{H^1(\Omega)} = |u|^2_{H^1(\Omega)} + \|u\|^2_{L^2(\Omega)},$$

respectively. When we are considering subregions $\Omega_i \subset \Omega$, of diameter H, we use a different relative weight, obtained by dilation,

$$\|u\|^2_{H^1(\Omega_i)} = |u|^2_{H^1(\Omega_i)} + \frac{1}{H^2}\|u\|^2_{L^2(\Omega_i)}.$$

Whenever appropriate, we tacitly assume that the elements of $H^1_0(\Omega_i)$, the subspace of $H^1(\Omega_i)$ with zero trace on the boundary $\partial\Omega_i$, are extended by zero to $\Omega \setminus \Omega_i$.

To avoid unnecessary complications, we confine our discussion to Poisson's equation, to homogeneous Dirichlet conditions, and to continuous, piecewise linear finite elements and a polygonal region Ω triangulated using triangles or tetrahedra. It is well known that the resulting space $V^h \subset H^1_0(\Omega)$, i.e., it is conforming.

For the problem considered in an 1870 paper by H.A. Schwarz [46], two overlapping subregions Ω'_1 and Ω'_2 are used; the union of the two is Ω. There are two sequential, fractional steps of the iteration in which the approximate solution of the elliptic equation on Ω is updated by solving the given problem restricted to the subregions one at a time. The most recent values of the solution are used as boundary values on the part of $\partial\Omega'_i$ that is not a part of $\partial\Omega$.

The finite element version of the algorithm can conveniently be described in terms of projections $P_i : V^h \to V^h_i = H^1_0(\Omega'_i) \bigcap V^h$, defined by

$$a(P_i v_h, \phi_h) = a(v_h, \phi_h) \quad \forall \phi_h \in V^h_i. \tag{3}$$

It is easy to show that the error propagation operator of this multiplicative Schwarz method is

$$(I - P_2)(I - P_1).$$

This algorithm can therefore be viewed as a simple iterative method for solving

$$(P_1 + P_2 - P_2 P_1)u_h = g_h,$$

with an appropriate right-hand side g_h.

This operator is a polynomial of degree two and therefore not ideal for parallel computing since two sequential steps are involved. This effect is further pronounced if more than two subspaces are used. Therefore, it is often advantageous to collect subregions, which do not intersect, into groups; the subspaces of each group can then be regarded as one. The number of subspaces is thus reduced, and the algorithm becomes easier to parallelize. Numerical experiments with multiplicative Schwarz methods have also shown that the convergence rate often is enhanced if such a strategy is pursued; this approach is similar to a red-black or multicolor ordering in the context of classical iterative methods. In the case of an additive Schwarz method, this ordering only serves as a device to facilitate the analysis.

In the additive form of the algorithm, we work with the simplest possible polynomial of the projections: The equation

$$Pu_h = (P_1 + P_2 + \cdots + P_N)u_h = g_h' \tag{4}$$

is solved by an iterative method. Here $P_i : V \to V_i$, and $V = V_1 + \cdots + V_N$. Since the operator P can be shown to be positive definite, symmetric with respect to $a(\cdot, \cdot)$, the iterative method of choice is the conjugate gradient method. Equation (4) must also have the same solution as (1), i.e., the correct right-hand side must be found. This can easily be arranged; see, e.g., [29], [30], [55]. Much of the work, in particular that which involves the individual projections, can be carried out in parallel.

2.1. The Dryja–Widlund algorithm. We now describe the special additive Schwarz method introduced in Dryja and Widlund [28]; see also Dryja [25] and Dryja and Widlund [29]. We start by introducing two triangulations of Ω into nonoverlapping triangular or tetrahedral substructures Ω_i and into triangular or tetrahedral elements. We obtain the elements by subdividing the substructures. We always assume that the two triangulations are shape regular, see, e.g., Ciarlet [23], and, to simplify our arguments, that the diameters of all the substructures are on the order of H. In this algorithm, we use overlapping subregions obtained by extending each substructure Ω_i to a larger region Ω_i'. The overlap is said to be generous if the distance between the boundaries $\partial\Omega_i$ and $\partial\Omega_i'$ is bounded from below by a fixed fraction of H. We always assume that $\partial\Omega_i'$ does not cut through any element. We carry out the same construction for the substructures that meet the boundary except that we cut off the part of Ω_i' that is outside of Ω.

We remark that other decompositions are also of interest. In particular, the analysis in §4 extends immediately to the case when no degrees of freedom are shared between neighboring subregions. In this case the distance between $\partial\Omega_i'$ and $\partial\Omega_j'$ is just h for neighboring subregions. This additive Schwarz method corresponds to a block Jacobi preconditioner augmented by a coarse solver.

For this Schwarz method, the finite element space is represented as the sum of N+1 subspaces

$$V^h = V_0^h + V_1^h + \cdots + V_N^h.$$

The first subspace V_0^h is equal to V^H, the space of continuous, piecewise linear functions on the coarse mesh defined by the substructures Ω_i. The other subspaces are related to the subdomains in the same way as in the original Schwarz algorithm, i.e., $V_i^h = H_0^1(\Omega_i') \bigcap V^h$.

It is often more economical to use approximate rather than exact solvers for the problems on the subspaces. The approximate solvers are described in the following terms: Let $b_i(u, v)$ be an inner product defined on $V_i^h \times V_i^h$ and assume that there exists a constant ω such that

$$a(u, u) \leq \omega b_i(u, u) \quad \forall u \in V_i^h. \tag{5}$$

In terms of matrices, this inequality becomes a one-sided bound of the stiffness matrix corresponding to $a(\cdot,\cdot)$ and V_i^h, in terms of the matrix corresponding to the bilinear form $b_i(u,u)$.

An operator $T_i : V^h \to V_i^h$, which replaces P_i, is now defined by

$$b_i(T_i u, \phi_h) = a(u, \phi_h) \quad \forall \phi_h \in V_i^h. \tag{6}$$

It is easy to show that the operator T_i is positive semidefinite and symmetric with respect to $a(\cdot,\cdot)$ and that the minimal constant ω in (5) is $\|T_i\|_a$. Additive and multiplicative Schwarz methods can now be defined straightforwardly in terms of polynomials of the operators T_i. We note that if exact solvers, and thus the projections P_i, are used, then $\omega = 1$.

2.2. The Smith algorithm. Smith's method has previously been described in Smith [48], [51]. Let K be the stiffness matrix given by the bilinear form of (2). In the first step of this and many other domain decomposition methods, the unknowns of the linear system of equations

$$Kx = b$$

that correspond to the interiors of the substructures are eliminated. We now describe this procedure in some detail.

Let $K^{(i)}$ be the stiffness matrix corresponding to the bilinear form $a_{\Omega_i}(u_h, v_h)$, which represents the contribution of the substructure Ω_i to the integral $a_\Omega(u_h, v_h) = a(u_h, v_h)$. Let x and y be the vectors of nodal values that correspond to the finite element functions u_h and v_h, respectively. Then the stiffness matrix K of the entire problem can be obtained by using the *method of subassembly* defined by the formula

$$x^T K y = \sum_i x^{(i)T} K^{(i)} y^{(i)}.$$

Here $x^{(i)}$ is the subvector of nodal parameters associated with $\overline{\Omega}_i$, the closure of Ω_i. We represent $K^{(i)}$ as

$$\begin{pmatrix} K_{II}^{(i)} & K_{IB}^{(i)} \\ K_{IB}^{(i)T} & K_{BB}^{(i)} \end{pmatrix}.$$

Here we have divided the subvector $x^{(i)}$ into two, $x_I^{(i)}$ and $x_B^{(i)}$, corresponding to the variables that are interior to the substructure and those that are shared with other substructures, i.e., those associated with the nodal points of $\partial\Omega_i$. Since the interior variables of Ω_i are coupled only to other variables of the same substructure, they can be eliminated locally and in parallel. The resulting reduced matrix is a Schur complement and is of the form

$$S^{(i)} = K_{BB}^{(i)} - K_{IB}^{(i)T} K_{II}^{(i)-1} K_{IB}^{(i)}. \tag{7}$$

From this follows that the Schur complement, corresponding to the global stiffness matrix K, is given by S where

$$x_B^T S y_B = \sum_i x_B^{(i)T} S^{(i)} y_B^{(i)}. \tag{8}$$

If the local problems are solved exactly, what remains is to find a sufficiently accurate approximation of the solution of the linear system

$$S x_B = g_B. \tag{9}$$

It is convenient to rewrite (9) in variational form. Let $s_i(u_h, v_h)$ and $s(u_h, v_h)$ denote the forms defined by (7) and (8), respectively, i.e.,

$$s_i(u_h, v_h) = x_B^{(i)} S^{(i)} y_B^{(i)} \quad \text{and} \quad s(u_h, v_h) = x_B^T S y_B.$$

Equation (9) can then be rewritten as

$$s(u_h, v_h) = (g, v_h)_{L^2(\Gamma)} \quad \forall v_h \in V^h(\Gamma). \tag{10}$$

Here $\Gamma = \bigcup \partial\Omega_i \setminus \partial\Omega$.

Problem (10) will be solved by an iterative method of additive Schwarz type. The most important difference between this algorithm and that of the previous subsection is that we are now working with the trace space $H^{1/2}(\Gamma)$ instead of $H^1(\Omega)$; see §3 for a definition of $H^{1/2}(\Gamma)$.

It is well known that

$$x_B^{(i)T} S^{(i)} x_B^{(i)} = \min_{x_I^{(i)}} x^{(i)T} K^{(i)} x^{(i)}. \tag{11}$$

Therefore, if u_h is the minimal, *the discrete harmonic* extension of the boundary data represented by x_B, then

$$x_B^{(i)T} S^{(i)} x_B^{(i)} = |u_h|^2_{H^1(\Omega_i)}.$$

Smith's algorithm can now be described in terms of a subspace decomposition. We use the same coarse space as in the previous subsection, i.e., V^H, but we restrict its values to Γ. In the case when the original problem is two dimensional, we introduce one subspace for each interior edge and one for each vertex of the substructures. An edge space is defined by setting all nodal values, except those associated with the interior of the edge in question, to zero. Similarly, a vertex space is obtained by setting to zero all values at the nodes on Γ, which are at a distance greater than δ. For many more details and a discussion of implementation details, see Smith [48], [51].

In the case when the original problem is three dimensional, we introduce one subspace for each interior face, edge, and vertex. The elements of a face subspace vanish at all nodes on Γ that do not belong to the interior of the face. Similarly, an edge space is supported in the strips of width δ, which belong to the faces, that have this edge in common. Finally, a vertex space is defined in terms of the nodes on Γ that are within a distance δ of the vertex. We also again use the standard coarse space V^H.

2.3. Basic theory. To estimate the rate of convergence of our special, or any other, additive Schwarz methods, we need upper and lower bounds for the spectrum of the operator relevant in the conjugate gradient iteration. A lower bound can be obtained by using the following lemma; see, e.g., Dryja and Widlund [29], [33] or Zhang [60].

LEMMA 2.1. *Let T_i be the operators defined in* (6) *and let $T = T_0 + T_1 + \cdots + T_N$. Then*

$$a(T^{-1}u, u) = \min_{u=\sum u_i} \sum b_i(u_i, u_i), \qquad u_i \in V_i.$$

Therefore, if a representation, $u = \sum u_i$, can be found, such that

$$\sum b_i(u_i, u_i) \le C_0^2 a(u, u) \quad \forall u \in V^h,$$

then

$$\lambda_{\min}(T) \ge C_0^{-2}.$$

An upper bound for the spectrum of T is often obtained in terms of strengthened Cauchy–Schwarz inequalities between the different subspaces. Note that we now exclude the index 0; the coarse subspace is treated separately.

DEFINITION 1. *The matrix $\mathcal{E} = \{\varepsilon_{ij}\}$ is the matrix of strengthened Cauchy–Schwarz constants, i.e., ε_{ij} is the smallest constant for which*

$$|a(v_i, v_j)| \leq \varepsilon_{ij} \|v_i\|_a \|v_j\|_a \quad \forall v_i \in V_i \quad \forall v_j \in V_j \qquad i, j \geq 1 \tag{12}$$

holds.

The following lemma is easy to prove; see Dryja and Widlund [33].

LEMMA 2.2. *Let $\rho(\mathcal{E})$ be the spectral radius of the matrix $\mathcal{E}$. Then, the operator T satisfies*

$$T \leq \omega(\rho(\mathcal{E}) + 1)I.$$

For the particular algorithms considered in this paper, it is very easy to show that there is a uniform upper bound. In fact, by collecting and merging local subspaces that belong to nonoverlapping subregions, the number of subspaces, and $\rho(\mathcal{E})$, can be made uniformly bounded; see §4 for an alternative argument.

By combining Lemmas 2.1 and 2.2, we obtain the following theorem.

THEOREM 2.3. *The condition number $\kappa(T)$ of the operator T of the additive Schwarz method satisfies*

$$\kappa(T) \equiv \lambda_{\max}(T)/\lambda_{\min}(T) \leq \omega(\rho(\mathcal{E}) + 1)C_0^2.$$

In the multiplicative case, we need to provide an upper bound for the spectral radius, or norm, of the error propagation operator

$$E_J = (I - T_J) \ldots (I - T_0). \tag{13}$$

The following theorem is a variant of a result of Bramble, Pasciak, Wang, and Xu [7]; see also Cai and Widlund [15], Xu [56], or Zhang [60]. Note that this bound is also given in terms of the same three parameters that appear in Theorem 2.3.

THEOREM 2.4. *In the symmetric, positive definite case*

$$\|E_J\|_a \leq \sqrt{1 - \frac{(2 - \omega)}{(2\omega^2\rho(\mathcal{E})^2 + 1)C_0^2}}\,.$$

We note that this formula is useless if $\omega \geq 2$; since $\|I - T_i\|_a > 1$ if $\|T_i\|_a > 2$, the assumption that $\omega < 2$ is most natural. If we wish to use a multiplicative algorithm and ω is too large, we can scale the bilinear forms $b_i(\cdot, \cdot)$ suitably.

In this paper, our results are only formulated for additive algorithms. The corresponding bounds for the multiplicative variants can easily be worked out as applications of Theorem 2.4.

3. Technical tools. In this section, we collect a number of technical tools that are used to prove our main results. Some of these tools are quite familiar to specialists of the field. Others, to our knowledge, have not previously been used in the analysis of domain decomposition; see Il'in [38] for some similar inequalities.

As before, $\Omega \subset R^n$, n =2 or 3, is a bounded, polygonal region and $\{\Omega_i\}$ a nonoverlapping decomposition of Ω into substructures. To simplify our considerations, we now assume that the substructures are squares or cubes; see, e.g., Nečas [45] where simple maps and partions of unity are used to derive bounds for Lipschitz regions from bounds for such special regions;

if we can handle a corner of a square or cube, then we can analyze the general polygonal case. Our estimates, given in the next two sections, are developed for one substructure at a time; our arguments can be modified to make them valid for any shape regular substructure with a boundary consisting of a finite number of smooth curves or surfaces.

As before, let $\Gamma = \bigcup \partial\Omega_i \setminus \partial\Omega$. Let $\Gamma_{\delta,i} \subset \Omega_i$ be the set of points that is within a distance δ of Γ.

LEMMA 3.1. *Let u be an arbitrary element of $H^1(\Omega_i)$. Then*

$$\|u\|^2_{L^2(\Gamma_{\delta,i})} \leq C\,\delta^2\big((1 + H/\delta)|u|^2_{H^1(\Omega_i)} + 1/(H\delta)\|u\|^2_{L^2(\Omega_i)}\big).$$

Proof. We first consider a square region $(0, H) \times (0, H)$ in detail; the extension of the proof to the case of three dimensions is straightforward. Since

$$u(x, 0) = u(x, y) - \int_0^y \frac{\partial u(x, \tau)}{\partial y} d\tau,$$

we find, by elementary arguments, that

$$H\int_0^H |u(x, 0)|^2 dx \leq 2\int_0^H\int_0^H |u(x, y)|^2 dxdy + H^2\int_0^H\int_0^H \left|\frac{\partial u}{\partial y}\right|^2 dxdy.$$

Therefore,

$$H\int_0^H |u(x, 0)|^2 dx \leq 2\|u\|^2_{L^2(\Omega_i)} + H^2|u|^2_{H^1(\Omega_i)}.$$

Now consider the integral over a narrow subregion next to one of the sides of the square. Using similar arguments, we obtain

$$\int_0^H\int_0^\delta |u(x, y)|^2 dxdy \leq \delta^2|u|^2_{H^1(\Omega_i)} + 2\delta\int_0^H |u(x, 0)|^2 dx. \tag{14}$$

By combining this and the previous inequality, we obtain

$$\int_0^H\int_0^\delta |u(x, y)|^2 dxdy \leq \delta^2|u|^2_{H^1(\Omega_i)} + 2\delta\left(\frac{2}{H}\|u\|^2_{L^2(\Omega_i)} + H|u|^2_{H^1(\Omega_i)}\right)$$

as required.

The modifications necessary for the case of an arbitrary, shape regular substructure and the extension of the proof to the case of three dimensions are routine. □

LEMMA 3.2. *Let u_h be a continuous, piecewise quadratic function defined on the finite element triangulation and let $I_h u_h \in V^h$ be its piecewise linear interpolant on the same mesh. Then there exists a constant C, independent of h and H, such that*

$$|I_h u_h|_{H^1(\Omega_i)} \leq C|u_h|_{H^1(\Omega_i)}.$$

The same type of bounds hold for the L_2 and $H^{1/2}_{00}$ norms and it can also be extended, with different constants, to the case of piecewise cubic functions, etc.

Proof. It is elementary to show that,

$$|I_h u_h|^2_{H^1(\Omega_i)} \leq 2\big(|I_h u_h - u_h|^2_{H^1(\Omega_i)} + |u_h|^2_{H^1(\Omega_i)}\big).$$

Consider the contribution to the first term on the right-hand side from an individual element K. We obtain

$$|I_h u_h - u_h|^2_{H^1(K)} \leq Ch^2 |u_h|^2_{H^2(K)} \leq C|u_h|^2_{H^1(K)}$$

by using a standard error bound and an elementary inverse inequality for quadratic polynomials. The bound in L_2 follows from the linear independence of the standard finite element basis for the space of quadratic polynomials, see Ciarlet [23]. The bounds for the $H^{1/2}_{00}$ norm, which is further discussed later in this section, can be obtained by interpolation in Sobolev spaces; cf., e.g., Lions and Magenes [39, pp. 98–99]. We use the K-method and a norm, which is equivalent to the one given below,

$$\|u\|^2_{H^{1/2}_{00}} = \|u\|^2_{L_2} + \int_0^\infty t^{-2} K(t, u)^2 dt,$$

where

$$K(t, u) = \inf_{u=u_0+u_1} (\|u_0\|^2_{L^2} + t^2 \|u_1\|^2_{H^1_0})^{1/2}.$$

The crucial observation is that

$$K(t, I_h u_h) \leq C K(t, u_h),$$

To prove this estimate, consider an arbitrary decomposition $u_h = u_0 + u_1$ of a piecewise quadratic u_h. Let Q be the L_2-projection onto the space of piecewise quadratic finite elements. It is well known that Q is bounded in H^1 as well as L_2; see, e.g., Bramble and Xu [9]. Using the H^1 and L_2 bounds of I_h derived in this proof, we find that

$$K(t, I_h u_h)^2 \leq \|I_h Q u_0\|^2_{L^2} + t^2 \|I_h Q u_1\|^2_{H^1_0} \leq C(\|u_0\|^2_{L^2} + t^2 \|u_1\|^2_{H^1_0}).$$

The proof now follows easily. □

We now turn to the other auxiliary results needed in the analysis of Smith's algorithm. We begin by writing down a standard expression for the norm of $H^{1/2}$; see Chapters 1.3.2 and 1.5 of Grisvard [36] for a detailed discussion.

Let $I \subset R^1$ be an open interval of diameter H. Then

$$\|u\|^2_{H^{1/2}(I)} = \int_I \int_I \frac{|u(s) - u(t)|^2}{|s - t|^2} ds dt + \frac{1}{H} \|u\|^2_{L_2(I)}. \tag{15}$$

The relative weight of the two terms is obtained, by dilation, from the norm defined on a region of diameter 1.

It is well known that the extension by zero of the elements of $H^{1/2}(I)$ does not define a continuous map into $H^{1/2}(R^1)$; see Lemma 1.3.2.6 of Grisvard [36] or Lions and Magenes [39]. The largest subspace for which this extension operator is continuous is $H^{1/2}_{00}(I)$, which is defined in terms of the norm obtained by replacing the last term of (15) by

$$\int_I \frac{|u(s)|^2}{d(s)} ds. \tag{16}$$

Here $d(s)$ is the distance to the nearest end point of I.

In the case of a subset Ψ of the boundary of a three-dimensional region, the formula (15) is valid after replacing $|s - t|^2$ by $|s - t|^3$ and I by Ψ. However, for our purposes, it is more

convenient to use an alternative formula; see Dryja [24] and Nečas [45, Lemma 5.3, Chap. 2]. In the special case of a square with side H, the seminorm is defined by

$$(17)\quad \int_0^H \int_0^H \frac{\|u(s_1,.)-u(t_1,.)\|^2_{L_2}}{|s_1-t_1|^2} ds_1 dt_1 + \int_0^H \int_0^H \frac{\|u(.,s_2)-u(.,t_2)\|^2_{L_2}}{|s_2-t_2|^2} ds_2 dt_2.$$

To obtain the norm for the subspace $H_{00}^{1/2}((0,H)^2)$, we add a weighted norm

$$(18)\quad \int_0^H \int_0^H \frac{|u(s_1,s_2)|^2}{d(s)} ds_1 ds_2$$

just as in (16).

In addition to the space V^h, we will also use a coarser space V^δ, defined on a mesh with mesh size δ, in our proofs. We now formulate results that have been used extensively in work of this kind; see Dryja [24] or Bramble and Xu [9]. The first inequality of the lemma is given as Lemma 1 in Dryja [24]. The second is part of the proof of Lemma 4 in the same paper.

LEMMA 3.3. *Let I be an interval of length H. Then*

$$\|u_\delta\|^2_{L_\infty(I)} \le C(1+\log(H/\delta))\|u_\delta\|^2_{H^{1/2}(I)} \quad \forall u_\delta \in V^\delta.$$

Let I be an edge of a face Ψ of diameter H of a cube. Then

$$\|u_\delta\|^2_{L^2(I)} \le C(1+\log(H/\delta))\|u_\delta\|^2_{H^{1/2}(\Psi)} \quad \forall u_\delta \in V^\delta.$$

The next result gives a bound that is similar to the second formula of Lemma 3.3. However, the bound holds for all of $H^{1/2}$.

LEMMA 3.4. *Let $\Psi = (0,H)^2$ and let $\Psi_\delta = (0,H)\times(0,\delta)$. Then*

$$\|u\|^2_{L_2(\Psi_\delta)} \le C\delta(1+\log(H/\delta))\|u\|^2_{H^{1/2}(\Psi)} \quad \forall u \in H^{1/2}(\Psi).$$

The same result holds if we replace Ψ and Ψ_δ by $(0,H)$ and $(0,\delta)$, respectively.

Proof. We only provide a proof for the first of the two cases; the proof in the other case is completely analogous. Let $Q_\delta : L_2(\Psi) \to V^\delta$, be the L_2- projection. It is well known that $\|Q_\delta\|_{H^1(\Psi)}$ is bounded; see, e.g., Bramble and Xu [9]. Since, trivially, this operator is also bounded in L_2, it follows that $\|Q_\delta\|_{H^{1/2}(\Psi)}$ is bounded. By a standard argument,

$$(19)\quad \|u-Q_\delta u\|^2_{L_2(\Psi)} \le \delta C|u|^2_{H^{1/2}(\Psi)}.$$

We now only need to show that

$$(20)\quad \|Q_\delta u\|^2_{L_2(\Psi_\delta)} \le C\delta(1+\log(H/\delta))\|Q_\delta u\|^2_{H^{1/2}(\Psi)}.$$

To prove (20), we use the bound (14) derived in the proof of Lemma 3.1. Thus

$$\|Q_\delta u\|^2_{L_2(\Psi_\delta)} \le \delta^2|Q_\delta u|^2_{H^1(\Psi)} + 2\delta\int_0^H |Q_\delta u(x,0)|^2 dx.$$

By using an inverse inequality, the first term can be replaced by $\delta|Q_\delta u|^2_{H^{1/2}(\Psi)}$. The second term is estimated using Lemma 3.3. □

The final lemma will be used to estimate the weighted L_2 term in the $H_{00}^{1/2}$ norm.

LEMMA 3.5. *Let $u \in H^{1/2}(0,H)$. Then there exists a constant C, such that*

$$\int_\delta^H \frac{|u(s)|^2}{s} ds \le C(1+\log(H/\delta))^2\|u\|^2_{H^{1/2}(0,H)}.$$

Similarly, let $u \in H^{1/2}((0, H)^2)$. *Then there exists a constant* C, *such that*

$$\int_0^H \left(\int_\delta^H \frac{|u(s,t)|^2}{s} ds \right) dt \leq C(1 + \log(H/\delta))^2 \|u\|^2_{H^{1/2}((0,H)^2)}.$$

Proof. We begin by considering the first inequality. Let $Q_\delta : L_2(0, H) \to V^\delta(0, H)$, be the L_2-projection onto the finite element space with mesh size δ. We write $u = (u - Q_\delta u) + Q_\delta u$ and estimate each term separately. We first note that by a standard estimate,

$$\|u - Q_\delta u\|^2_{L_2(0,H)} \leq C\delta |u|^2_{H^{1/2}(0,H)}.$$

The bound for the first term is therefore obtained by noting that $s \geq \delta$ over the interval of integration.

The other term can be estimated by using the first bound of Lemma 3.3, which results in one logarithmic factor, and the observation that

$$\int_\delta^H \frac{|Q_\delta u|^2}{s} ds \leq \|Q_\delta u\|^2_{L_\infty} \int_\delta^H \frac{ds}{s},$$

from which the second logarithmic factor arises.

The second inequality follows by considering $u(s, t)$, a function of two variables, and applying the first inequality with respect to s. We then integrate with respect to t, change the order of integration, and use formula (17) to complete the proof. □

4. Analysis of the Dryja–Widlund algorithm. We now use the set $\Gamma_{\delta,i}$, previously introduced, to characterize the extent of the overlap. We assume that all $x \in \Omega_i$, which belong to at least one additional overlapping subregion Ω'_j, lie in $\Gamma_{\delta,i}$.

THEOREM 4.1. *In the case when exact solvers are used for the subproblems, the condition number of the additive Schwarz method satisfies*

$$\kappa(P) \leq C(1 + H/\delta).$$

The constant is independent of the parameters H, h, *and* δ.

We note that for the case of two subregions, it is easy to show that this result is sharp. It is routine to modify Theorem 4.1 to cover cases where inexact solvers are used.

Proof. The proof is a refinement of a result first given in Dryja and Widlund [28]; cf. [29] for a better discussion. The proof is equally valid for two and three dimensions. We first show that a constant upper bound for the spectrum of P can be obtained without the use of Lemma 2.2.

We note that P_i is also an orthogonal projection of $H^1(\Omega'_i) \bigcap V^h$ onto V_i. Therefore,

$$a(P_i u_h, u_h) \leq a_{\Omega'_i}(u_h, u_h).$$

Since, by construction, there is an upper bound, N_c, on the number of subregions to which any $x \in \Omega$ can belong, we have

$$\sum_{i=1}^N a_{\Omega'_i}(u_h, u_h) \leq N_c\, a(u_h, u_h).$$

In addition, we use the fact that the norm of P_0 is equal to one and obtain

$$\lambda_{\max}(P) \leq (N_c + 1).$$

The lower bound is obtained by using Lemma 2.1. A natural choice of u_0 is the L_2-projection $Q_H u_h$ of u_h onto V^H. As previously pointed out, this projection is bounded in L_2 as well as H^1 and there exists a constant, independent of h and H, such that

$$\|u_h - Q_H u_h\|_{L_2} \leq C\, H \|u_h\|_a. \tag{21}$$

Let $w_h = u_h - Q_H u_h$ and let $u_i = I_h(\theta_i w_h)$, $i = 1, \ldots, N$. Here I_h is the interpolation operator onto the space V^h and the $\theta_i(x)$ define a partition of unity, i.e., $\sum_i \theta_i(x) \equiv 1$. These functions are chosen as nonnegative elements of V^h. It is easy to see that

$$u_h = Q_H u_h + \sum u_i.$$

In the interior part of Ω_i, which does not belong to $\Gamma_{\delta,i}$, $\theta_i \equiv 1$. This function must decrease to 0 over a distance on the order of δ. It is easy to construct a partition of unity with $0 \leq \theta_i \leq 1$ and such that

$$|\nabla \theta_i| \leq \frac{C}{\delta}.$$

To use Lemma 2.1, we first estimate $a(u_i, u_i)$ in terms of $a(w_h, w_h)$. We consider the contribution from one substructure at a time and note that, trivially,

$$a_{\Omega_i \setminus \Gamma_{\delta,i}}(u_i, u_i) = a_{\Omega_i \setminus \Gamma_{\delta,i}}(w_h, w_h).$$

Let K be an element in $\Gamma_{\delta,i}$. Then, using the definition of u_i,

$$a_K(u_i, u_i) \leq 2a_K(\bar{\theta}_i w_h, \bar{\theta}_i w_h) + 2a_K(I_h((\theta_i - \bar{\theta}_i)w_h), I_h((\theta_i - \bar{\theta}_i)w_h)),$$

where $\bar{\theta}_i$ is the average of θ_i over the element K. Using the fact that the diameter of K is on the order of h and the bound on $\nabla\theta_i$, we obtain, after adding over all the relevant elements,

$$a_{\Gamma_{\delta,i}}(u_i, u_i) \leq 2a_{\Omega_i}(w_h, w_h) + \frac{C}{\delta^2}\|w_h\|^2_{L^2(\Gamma_{\delta,i})}.$$

We also need to estimate $a_{\Gamma_{\delta,i}}(u_j, u_j)$ for the j that correspond to neighboring substructures. This presents no new difficulties.

To complete the proof, we need to estimate $\|w_h\|^2_{L^2(\Gamma_{\delta,i})}$. We note that each $x \in \Omega$ is covered only a finite number of times by the subregions. We apply Lemma 3.1 to the function w_h, sum over i and use inequality (21) to complete the estimate of the parameter C_0^2 of Lemma 2.1. □

5. Analysis of the Smith method. A description of the reduction of the original linear system to one for the degrees of freedom on Γ, and of the algorithm, have been given in §2. We will now work in the $H^{1/2}(\Gamma)$ norm. The fact that this is a weaker norm than H^1 is reflected in a stronger bound than that of the previous section; better bounds of the components in the different subspaces can be obtained. There are many similarities between the two cases. Much of the analysis is again carried out one substructure at a time.

To show that we can work with $|u_h|^2_{H^{1/2}(\partial\Omega_i)}$ instead of $x_B^{(i)T} S^{(i)} x_B^{(i)}$, we must show that these norms are equivalent. We use (11) and the standard trace theorem to bound $|u_h|^2_{H^{1/2}(\partial\Omega_i)}$ from above by $x_B^{(i)T} S^{(i)} x_B^{(i)}$. The proof of the reverse inequality requires an extension theorem for finite element spaces given in Widlund [53]; see further discussion in Smith [51].

THEOREM 5.1. *In the case when exact solvers are used for the subproblems, the condition number of the vertex space method satisfies*

$$\kappa(P) \leq C(1 + \log(H/\delta))^2.$$

The constant is independent of the parameters H, h, and δ.

Proof. As in the proof of Theorem 4.1, there is no difficulty in establishing a uniform upper bound on the spectrum of P.

We now turn to the lower bound in the case where the original problem is two dimensional and thus the interface is of dimension one. To use Lemma 2.1, we have to decompose functions defined on Γ.

We use the $L_2(\Omega)$ projection onto V^H of the discrete harmonic function u_h, introduced in §2.2, to define the component of the coarse space. We only use the values on Γ. In addition, we use a partition of unity to represent the local space components. In the study of the local spaces, it is sufficient to consider one substructure Ω_i at a time. The partition of unity is based on simple, piecewise linear functions. Let $0 < t < H$ represent one of the edges of the boundary of this substructure and let $\theta_e(t)$ be a piecewise linear function that vanishes for t outside $(0, H)$, grows linearly to 1 at $t = \delta$, is equal to 1 for $\delta \leq t \leq H - \delta$, and drops to zero linearly over the interval $(H - \delta, H)$. In the decomposition, we choose $I_h(\theta_e w_h)$ as the component corresponding to this edge. As in the previous section, $u_0 = Q_H u_h$ and $w_h = u_h - Q_H u_h$ is the error of the L_2- projection. It follows from Lemma 3.2 that it is sufficient to estimate $\|v_e\|_{H_{00}^{1/2}(0,H)}$, where $v_e(t) = \theta_e(t) w_h(t)$. We note that we cannot use the weaker norm of $H^{1/2}(0, H)$ here; we must estimate the $H^{1/2}(\partial\Omega_i)$ norm of v_e extended by zero to the rest of the boundary, i.e., $\|v_e\|_{H_{00}^{1/2}(0,H)}$.

We first consider

$$\int_0^H \int_0^H \frac{|v_e(s) - v_e(t)|^2}{|s-t|^2} ds dt, \tag{22}$$

and then the additional term (16), which completes the definition of the relevant norm. We divide the interval $[0, H]$ into three parts, $[0, \delta]$, $[\delta, H - \delta]$, and $[H - \delta, H]$, and take the tensor product of $[0, H]$ with itself. The double integral (22) is then split into the sum of nine. By symmetry, only six different cases need to be considered. The integral over $[\delta, H - \delta] \times [\delta, H - \delta]$ is completely harmless. We now consider the diagonal term corresponding to the set $[0, \delta] \times [0, \delta]$ and use the identity

$$v_e(s) - v_e(t) \equiv \frac{s w_h(s) - t w_h(t)}{\delta} = \frac{(s+t)(w_h(s) - w_h(t))}{2\delta} + \frac{(s-t)(w_h(s) + w_h(t))}{2\delta}.$$

The integral corresponding to the first term is estimated by $\|w_h\|_{H^{1/2}}$ after noting that, for the relevant values of s and t, $|s + t|/2\delta \leq 1$.

The integral, corresponding to the second term, can be estimated by

$$1/\delta^2 \int_0^\delta \int_0^\delta |w_h(t)|^2 ds dt = 1/\delta \|w_h\|^2_{L^2(0,\delta)},$$

which, in turn, can be estimated appropriately by using Lemma 3.4.

The third diagonal double integral is estimated in exactly the same way.

We next estimate the off-diagonal double integrals. We note that for $0 \leq t \leq \delta$ and $\delta \leq s \leq H - \delta$,

$$v_e(s) - v_e(t) = w_h(s) - \frac{t}{\delta} w_h(t) = (w_h(s) - w_h(t)) + \frac{(\delta - t)}{\delta} w_h(t).$$

The first term gives an integral that can be estimated straightforwardly in terms of $|w_h|^2_{H^{1/2}(0,H)}$. What remains is the integral

$$\int_0^\delta \left(\int_\delta^H \frac{(\delta - t)^2}{\delta^2 (t - s)^2} ds \right) |w_h(t)|^2 dt.$$

We integrate with respect to s and find that the inner integral is bounded by $1/\delta$ and the double integral by

$$1/\delta \|w_h\|^2_{L^2(0,\delta)}. \tag{23}$$

The estimates of the other integrals can be carried out quite similarly. To complete the estimate of the $\|v_e\|_{H_{00}^{1/2}(0,H)}$, we consider

$$\int_0^H \left(\frac{|v_e(s)|^2}{s} + \frac{|v_e(s)|^2}{H-s} \right) ds.$$

For $s \in (0, \delta)$, and $s \in (H - \delta, H)$, we obtain contributions that can be estimated by the expression given in (23). For the integral over $(\delta, H - \delta)$, we use Lemma 3.5.

We next turn to the space associated with one of the vertices of Ω_i. We now use $\theta_v(t) = (\delta - |t|)/\delta$ to complete the partition of unity, i.e., we use $I_h(\theta_v w_h) = I_h(v_v)$. It follows from Lemma 3.2 that we can again ignore the interpolation operator I_h. We need to estimate

$$\int_{-\delta}^{\delta} \int_{-\delta}^{\delta} \frac{|v_v(s) - v_v(t)|^2}{|s-t|^2} ds dt$$

and

$$\int_{-\delta}^{\delta} \left(\frac{|v_v(s)|^2}{\delta - s} + \frac{|v_v(s)|^2}{s + \delta} \right) ds.$$

Considering the double integral, we note that

$$\frac{(\delta - |s|)w_h(s) - (\delta - |t|)w_h(t)}{\delta(s-t)} = \frac{w_h(s) - w_h(t)}{s-t} \left(1 - \frac{|s| + |t|}{2\delta} \right) - \frac{w_h(s) + w_h(t)}{2\delta} \frac{|s| - |t|}{s-t}.$$

Since $|1 - \frac{|s|+|t|}{2\delta}| \leq 1$ and $|\frac{|s|-|t|}{s-t}| \leq 1$, for relevant values of s and t, the two contributions to the integral can be estimated in terms of

$$|w_h|^2_{H^{1/2}(0,H)} \quad \text{and} \quad 1/\delta \|w_h\|^2_{L^2(0,\delta)},$$

respectively. Arguments, quite similar to those given above, complete the proof for the case of two dimensions.

We now turn to problems in three dimensions, i.e., the case where the interface Γ is two dimensional. In addition to the coarse space, we use three types of local subspaces associated with faces, and neighborhoods of edges and vertices, respectively. The diameter of the point set associated with a vertex subspace is on the order of δ. Similarly, the edge spaces include the degrees of freedom on Γ that are within a distance δ of the edge in question. We again construct a partition of unity associated with these sets. As before these functions are continuous, piecewise linear functions and their gradients are bounded by C/δ. The proof proceeds as in the case of two dimensions. We give only a few details. We use $\theta_e(t_1)\theta_e(t_2)$ to construct the contribution to the decomposition related to a face. Similarly, we use $\theta_e(t_1)\theta_v(t_2)$ as the part of the partition of unity associated with an edge. Using our formulas for θ_e and θ_v, we then show that the partition of unity is completed by adding functions that differ from zero only in small neighborhoods of the vertices. The estimates necessary for the use of Lemma 2.1 and the completion of this proof are then carried out as in the two-dimensional case. □

MULTILEVEL SCHWARZ METHODS FOR THE BIHARMONIC DIRICHLET PROBLEM*

XUEJUN ZHANG†

Abstract. The author considers the solution of the algebraic system of equations that result from the finite element discretization of the biharmonic equation. Some multilevel algorithms are designed and analyzed using a Schwarz framework. Both additive and multiplicative variants of the algorithms are considered and condition number estimates for the additive algorithms and the energy norm estimates for the error propagation operator of the multiplicative algorithms are given. It is noted that for a proper ordering, the iterative operators of the multiplicative algorithms correspond to the error propagation operators of certain V-cycle multigrid methods.

Key words. Schwarz methods, domain decomposition, multilevel methods, multigrid, preconditioned iterative methods, biharmonic problem, plate problem

AMS subject classifications. 65F10, 65N30, 65N55

1. Introduction.

We consider the biharmonic Dirichlet problem on a polygonal region in R^2. The solution is approximated by conforming finite elements. We design and analyze some multilevel methods for solving the resulting linear system. The additive variants of these methods can be considered as generalizations of the hierarchical basis method [23] and the multilevel additive Schwarz (MAS) method [10] designed previously for second-order elliptic problems. We adopt a Schwarz framework to study these methods. When the additive algorithms are used, an equivalent/preconditioned equation is solved by an iterative method such as the conjugate gradient method. We also consider some multiplicative variants of these algorithms and give condition number estimates for the additive variants and energy norm estimates for the error propagation operator of the multiplicative variants.

In this paper, we confine ourselves to the bicubic element discretization. We remark that similar ideas can be used for the Argyris and Bell elements V_A^h and V_B^h; see Ciarlet [7] for properties of these elements. Let $V_l = V_B^{h_l}$ be the Bell elements with respect to a nested triangulation $\mathcal{T}^l$. The new difficulty is that $V_l \not\subset V_{l-1}$, i.e., the subspaces $\{V_l\}$ are not nested. This difficulty can be overcome by using some tricks proposed in [24] for two-level domain decomposition algorithms. We will not further discuss this issue in this paper.

This paper is organized as follows. In §2, we consider the biharmonic problem and its finite element approximation by bicubic elements. We introduce a Schwarz framework in §3. We review some space decomposition and projection techniques, which are used to estimate the rate of convergence of the algorithms. In §4, we study the hierarchical basis (HB) algorithms for the biharmonic problem using an additive Schwarz framework, and we establish that the condition number $\kappa(P_{\mathrm{HB}})$ of the linear system with respect to the normalized hierarchical basis grows like $O(h^{-2})$. We then derive a more efficient algorithm by using additional vertex spaces in the space decomposition. This modified HB (MHB) algorithm costs almost the same as the HB algorithm, but has a condition number that grows like $O(|\log h|^2)$. In §5, we study the MAS method developed in Zhang [24]. This is an additive Schwarz method using a multilevel nodal basis decomposition. Optimal convergence properties of the algorithm are established. In §6, we consider some multilevel multiplicative Schwarz (MMS) algorithms and show that the energy norm of the error propagation operator is bounded by a constant less than one, independent of the number of levels. The MMS algorithm can also be considered as

a certain V-cycle multigrid algorithm and the MAS algorithm can be considered as a parallel multigrid algorithm. The MAS algorithm [10], [26] is quite similar to the BPX algorithm [21], [6]. The MMS and MAS algorithms are also related to, but different from, the fast adaptive composite (FAC) and parallel FAC (AFAC) algorithms developed in [11], [15], [16] and the algorithm studied in [3]. Those papers focused on the partial mesh refinement. In §7, we present some numerical results to verify our theory.

This paper is based in part on Chapter 5 of the author's thesis [24]. We note that recently Oswald [19] established a similar optimal convergence result for the MAS algorithm using Besov space theory.

2. Finite elements for the biharmonic equation.

2.1. The biharmonic problem. We are interested in solving the following biharmonic Dirichlet problem in a plane region: Find $u \in H^2(\Omega)$ such that

$$\begin{aligned} \Delta^2 u &= f \quad \text{in} \quad \Omega, \\ u &= g_0 \quad \text{on} \quad \partial\Omega, \\ \frac{\partial u}{\partial n} &= g_1 \quad \text{on} \quad \partial\Omega. \end{aligned}$$

For simplicity, we assume that Ω is a polygonal region and that $g_0 = g_1 = 0$. We consider the weak formulation: Find $u \in H_0^2(\Omega)$ such that

$$a(u, v) = (f, v) \quad \forall v \in H_0^2(\Omega),$$

where f is a bounded linear functional on $H_0^2(\Omega)$ and $a(u, v)$ is a symmetric, continuous, H_0^2-elliptic bilinear form. Two examples of such bilinear forms are

$$a(u, v) = \int_\Omega \Delta u \Delta v \, dx$$

and

$$a(u, v) = \int_\Omega \left\{ \Delta u \Delta v + (1 - \sigma) \left(2 \frac{\partial^2 u}{\partial x_1 \partial x_2} \frac{\partial^2 v}{\partial x_1 \partial x_2} - \frac{\partial^2 u}{\partial x_1^2} \frac{\partial^2 v}{\partial x_2^2} - \frac{\partial^2 u}{\partial x_2^2} \frac{\partial^2 v}{\partial x_1^2} \right) \right\} dx,$$

where $0 < \sigma < \frac{1}{2}$ is *Poisson's coefficient* of the plate. The first example arises in *fluid dynamics*, and the second provides a variational formulation of the *clamped plate problem*. By the Lax–Milgram theorem, the boundness and ellipticity imply the existence and uniqueness of the solution; cf. [12]. The methods studied in this paper can also be used for other symmetric, positive definite fourth-order problems, e.g.,

$$\Delta^2 u - \lambda \Delta u + \mu u = f, \qquad \lambda, \mu \geq 0.$$

The analysis would be similar to the case of the biharmonic equation.

2.2. The bicubic elements. For the biharmonic equation, the finite elements are all relatively complicated. In this paper, we confine ourselves to a simple case, the bicubic elements, known as the Bogner–Fox–Schmit rectangle. We assume that Ω is a union of rectangles.

We triangulate the domain Ω into nonoverlapping rectangles τ_i called elements; cf. Fig. 1. Let $Q_3 = \text{span}\{x^i y^j, 0 \leq i, j \leq 3\}$. The finite element space $V^h = V_{Q_3}^h$ is defined (cf. Fig. 2) by

$$V^h = \{v : v \in C^1(\Omega) \quad \text{and} \quad v|_{\tau_i} \in Q_3\}.$$

The degrees of freedom of this bicubic element are given by

$$\left\{ p(a_i),\ \frac{\partial p}{\partial x_1}(a_i),\ \frac{\partial p}{\partial x_2}(a_i),\ \frac{\partial^2 p}{\partial x_1 \partial x_2}(a_i) \right\},$$

where a_i is a vertex of an element. The finite element solution $u_h \in V^h$ satisfies

$$a(u_h, \phi_h) = f(\phi_h) \quad \forall \phi_h \in V^h.$$

Let $\mathcal{D}_1 = \{(0,0), (1,0), (0,1)\}$ and $\mathcal{D}_2 = \{(0,0), (1,0), (0,1), (1,1)\}$. We use the multi-indices notation to represent the order of derivatives. The nodal basis functions $\phi_i^\alpha(x)$ are defined by

$$\frac{\partial^{|\beta|}}{\partial x^\beta} \phi_i^\alpha(x_j) = \delta_{i,j}\delta_{\alpha,\beta}, \qquad \alpha, \beta \in \mathcal{D}_2.$$

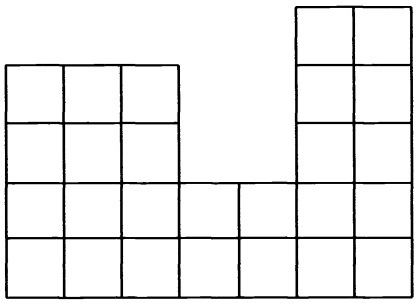

FIG. 1. *A uniform triangulation* $\mathcal{T}^1$, $h_x = h_y$.

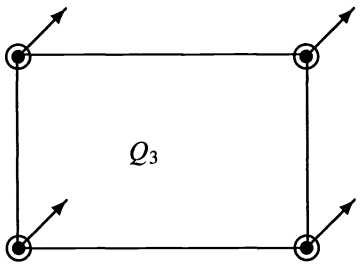

FIG. 2. *The bicubic elements.*

Representing u_h by the basis ϕ_i^α as

$$u_h = \sum_i \sum_{\alpha \in \mathcal{D}_2} x_i^\alpha \phi_i^\alpha,$$

we obtain a linear system

$$K_h x = b,$$

where $K_h = \{a(\phi_i^\alpha, \phi_j^\beta)\}$ and $b_i^\alpha = f(\phi_i^\alpha)$.

The stiffness matrix K_h is symmetric, positive definite. After a proper scaling, its condition number $\kappa(K_h)$ is on the order of h^{-4}. Since the linear system can be quite large, the condition number of K_h can also be very large, and solving the system can be very expensive.

2.3. Nested triangulations and subspaces. To construct and study multilevel algorithms, we need to define a sequence of nested rectangular triangulations $\{\mathcal{T}^l\}_{l=1}^L$. We start with a coarse triangulation $\mathcal{T}^1 = \{\tau_i^1\}_{i=1}^{N_1}$, where τ_i^1 represents an individual rectangle; cf. Fig. 1. The successively finer triangulations $\mathcal{T}^l = \{\tau_i^l\}_{i=1}^{N_l}$ are obtained by dividing the rectangles of the triangulation $\mathcal{T}^{l-1}$ into four rectangles (not necessarily of equal sizes). We denote by $h_x(\tau_i^l)$ and $h_y(\tau_i^l)$ the lengths of the edges of τ_i^l in the x and y directions, respectively, and we assume that all the triangulations are shape regular in the sense that $\min(h_x/h_y, h_y/h_x) \geq T_{\min}$, with $T_{\min} > 0$. Let $h_{li} = \text{diameter}(\tau_i^l)$, $h_l = \max_i h_{li}$, and $h = h_L$.

As a consequence of the shape regularity assumption, we know that there exist constants $C > 0$ and $0 < \gamma < 1$, such that if a rectangle τ_i^{l+k} of level $l+k$ lies in a rectangle τ_j^l of level l, then

$$\frac{\text{diam}(\tau_i^{l+k})}{\text{diam}(\tau_j^l)} \leq C\gamma^k.$$

For a uniform refinement, $\gamma = \frac{1}{2}$ and $C = 1$. We denote by $\mathcal{N}^l$ and $\mathcal{E}^l$ the sets of vertices and edges of $\mathcal{T}^l$ and by $\mathcal{E}^l(S)$ the edges of the subset S.

Let $V_l, l = 1, \ldots, L$, be the space of bicubic elements associated with the triangulation $\mathcal{T}^l$. The finite element problem can be rewritten in the new notation as: Find $u \in V_L$ such that

$$a(u, \phi) = f(\phi) \quad \forall \phi \in V_L. \tag{1}$$

We denote the nodal basis functions of V^l by $\phi_{li}^\alpha, i \in \mathcal{N}^l, \alpha \in \mathcal{D}_2$. Let $\Omega_i^l = \text{supp}\{\phi_{li}^\alpha\}$, $V_{li}^\alpha = \text{span}\{\phi_{li}^\alpha\}$ and $V_{li} = V_l \cap H_0^2(\Omega_i^l) = \sum_{\alpha \in \mathcal{D}_2} V_{li}^\alpha$. We note that for the bicubic element $\dim\{V_{li}\} = 4$.

3. A Schwarz framework. In this section, we review some tools for the study of Schwarz methods; see Dryja and Widlund [8], [9] and Matsokin and Nepomnyaschikh [14] for the additive methods and Bramble et al. [5] and Xu [22] for the multiplicative methods.

3.1. Additive Schwarz method. Consider the finite element problem: Find $u \in V$ such that

$$a(u, v) = (f, v) \quad \forall v \in V \quad \text{or} \quad Au = f. \tag{2}$$

Suppose that the finite element space V can be written as a sum of subspaces,

$$V = V_1 + V_2 + \cdots + V_N.$$

The projections $P_{V_i} : V \to V_i$ and $Q_{V_i} : V \to V_i$, are defined by

$$\begin{aligned} a(P_{V_i}u, \phi) &= a(u, \phi) \quad \forall \phi \in V_i, \\ (Q_{V_i}u, \phi) &= (u, \phi) \quad \forall \phi \in V_i. \end{aligned}$$

Let A_{V_i} be the restriction of A to the subspace V_i given by

$$(A_{V_i}u, v) = a(u, v) \quad \forall u, v \in V_i.$$

Based on the above space decomposition and projections, we define a preconditioner

$$B_{as}^{-1} = \sum_i A_{V_i}^{-1} Q_{V_i}$$

and an additive Schwarz operator

$$P_{as} = B_{as}^{-1}A = \sum_i P_{V_i}.$$

ALGORITHM 3.1 (AS ALGORITHM). Find the solution u to (2) by solving iteratively the additive Schwarz equation

$$P_{as}u_h = (P_{V_1} + P_{V_2} + \cdots + P_{V_N})u_h = f_{as} \equiv B_{as}^{-1}f. \tag{3}$$

We note that $f_{as} = B_{as}^{-1}f = \sum_i f_i$, where $f_i = A_{V_i}^{-1}Q_{V_i}f$ are the solutions for

$$a(f_i, \phi_h) = a(P_{V_i}u, \phi_h) = (f, \phi_h) \quad \forall \phi_h \in V_i. \tag{4}$$

It is easy to see that for f_i given by (4), the additive Schwarz equation (3), and the original finite element equation (2) are equivalent. The crucial issue is the condition number of the iteration operator P_{as}. From the definitions of B_{as} and P_{as}, we have $a(P_{as}^{-1}u, u) = (B_{as}u, v)$. The following lemma characterizes the extreme eigenvalues of P_{as}.

LEMMA 3.1. *Let V be a Hilbert space, V_i be subspaces of V and $V = \sum V_i$. Let P_{V_i} be the projections from V onto V_i, and $P = \sum_i P_{V_i}$. Then*

$$\lambda_{\min}(P) = \min_u \frac{a(u,u)}{a(P^{-1}u, u)} = \min_u \frac{a(u,u)}{\min\limits_{\sum u_i = u} \sum_i a(u_i, u_i)}, \qquad u_i \in V_i$$

and

$$\lambda_{\max}(P) = \max_u \frac{a(u,u)}{a(P^{-1}u, u)} = \max_u \frac{a(u,u)}{\min\limits_{\sum u_i = u} \sum_i a(u_i, u_i)}, \qquad u_i \in V_i.$$

Proof. See Lemma 3.1 in [26] for the proof. □

Remark. 3.1. If we can find constant C_1 and C_2 such that there exists a decomposition of $u = \sum_i u_i$ satisfying

$$C_1 \sum_i a(u_i, u_i) \le a(u,u) \quad \forall u \in V,$$

and for all $u \in V$ and for any decomposition of $u = \sum_i u_i$, we have

$$a(u,u) \le C_2 \sum_i a(u_i, u_i).$$

Then it follows from Lemma 3.1 that $\lambda_{\min}(P) \ge C_1$ and $\lambda_{\max}(P) \le C_2$. The first part is known as the Lions lemma; cf. Dryja and Widlund [8]–[10] and Nepomnyaschikh [17]. Similar results for the case $V = \oplus V_i$ can be found in Mandel and McCormick [13], where the "min" in the denominators is dropped, since the decomposition of a function is unique.

For $u, v \in V$, let $\cos(u, v) = a(u, v)/\|u\|_a\|v\|_a$. For V_1, V_2, two nontrivial subspaces of V, we define the cosine of the angle between V_1 and V_2 by

$$\cos(V_1, V_2) \stackrel{\text{def}}{=} \sup_{u_1 \in V_1, u_2 \in V_2} \cos(u_1, u_2). \tag{5}$$

Let $\theta_{ij} = \cos(V_i, V_j)$, $\Theta = \{\theta_{ij}\}$, and let $u = \sum_i u_i$, $u_i \in V_i$ be any decomposition of u. Then

$$a(u,u) = \sum_{i,j} a(u_i, u_j) \le \sum_{i,j} \theta_{ij}\|u_i\|_a\|u_j\|_a \le \|\Theta\|_2 \sum_i a(u_i, u_i).$$

Thus, $\lambda_{\max}(P) \le \rho(\Theta) = \|\Theta\|_2$.

3.2. Multiplicative Schwarz method. Algorithm 3.1 can be considered as a Jacobi method or simultaneous subspace correction. We can of course also define a Gauss–Seidel method or sequential subspace correction algorithm.

Consider solving (2) by the following procedure

ALGORITHM 3.2 (MS ALGORITHM). Let u^{old} be the current approximation. Compute

$$u_0 = u^{\text{old}}, \quad u_i = u_{i-1} + A_{V_i}^{-1} Q_{V_i}(f - Au_{i-1}), \quad i = 1, \ldots, N, \quad u^{\text{new}} = u_N.$$

It is easy to see that the error propagation operator is

$$E = (I - P_{V_N}) \cdots (I - P_{V_2}) \cdot (I - P_{V_1}).$$

In the case $V_i = \text{span}\{\phi_i\}$, $A_{V_i} = a(\phi_i, \phi_i)$, where ϕ_i is a nodal basis function, Algorithm 3.2 is the classical Gauss–Seidel algorithm.

In general, computing $A_{V_i}^{-1}$ (solving $A_{V_i} y = z$) is relatively expensive, and we can replace $A_{V_i}^{-1}$ by a preconditioner or a smoother R_i. Let $T_i = R_i Q_{V_i} A$. Then the corresponding error propagation operator is

$$E = (I - T_N) \cdots (I - T_2) \cdot (I - T_1).$$

The convergence rate is determined by $\|E\|_a$, the energy norm of E. We will derive bounds for $\|E\|_a$ using the properties of T_i and subspace V_i.

Let T_i, $i = 1, \ldots, N$ be symmetric, semipositive definite operators with respect to $a(\cdot, \cdot)$, and let $T = \sum_{i=1}^{N} T_i$. Let $E_0 = I$, $E_i = (I - T_i)E_{i-1}$, and $E = E_N$.

Let $\Theta_T = \{\theta_T^{ij}\}$, where $\theta_T^{ii} = 1$ and θ_T^{ij}, $i \neq j$ are given by

$$\theta_T^{i,j} = \sup_{u,v} \frac{a(T_i u, T_j v)}{a(T_i u, u)^{1/2} a(T_j v, v)^{1/2}}. \tag{6}$$

We note that when T_i are projections, definitions (6) and (5) are identical.

THEOREM 3.1. *Assume* $\|T_i\|_a \leq \omega < 2$. *Then*

$$1 - \frac{2\lambda_{\min}(T)}{2 - \omega + \lambda_{\min}(T)} \leq \|E\|_a \leq \sqrt{1 - (2 - \omega)\frac{\lambda_{\min}(T)}{\|\Theta_T\|_2^2}}.$$

The second inequality is a slightly modified version of a theorem given in Xu [22]. See [26] for a proof of Theorem 3.1.

Theorem 3.1 can be made more precise if $\dim(V_i) = 1$ and $T_i = P_{V_i}$ for all i. Let $\phi_i \in V_i$, $|\phi_i|_a = 1$, then $\cos(V_i, V_j) = |a(\phi_i, \phi_j)|$. Let $K = \{a(\phi_i, \phi_j)\}$. Then, K is a semidefinite matrix and $\Theta_T = \{\cos(V_i, V_j)\} = |K|$. Since, usually, $\{\phi_i\}$ are linearly dependent, the "stiffness matrix" K is usually singular and $\text{rank}(K) = \dim(V)$. Let $K = D - L - L^t$, where D is the diagonal of K and $-L$ and $-L^t$ are the strictly lower and upper triangular parts of K. Then, the $\|\Theta_T\|_2$ in Theorem 3.1 can be replaced by $\|(D - L)\|_2$; it is easy to see that $\|D - L\|_2 \leq \|\Theta_T\|_2$. Theorem 3.1 also provides an energy norm bound for the Gauss–Seidel method.

4. The HB methods.

4.1. Some interpolation operators. In this subsection, we state and prove some properties of certain interpolation operators defined on V_L.

Let $\Pi^l = \Pi^{h_l}$ be the standard nodal value interpolation operator defined by

$$\Pi^l u(x) = \sum_{i \in \mathcal{N}^l} \sum_{\alpha \in \mathcal{D}_2} D^\alpha u(x_i) \phi_{li}^\alpha(x). \tag{7}$$

LEMMA 4.1. *We have the following estimate for* Π^l:

$$|\Pi^l u - u|_{H^s} \le C h_l^{2-s} \left(\frac{h_l}{h_L}\right) |u|_{H^2} \le C 2^{l(s-2)} 2^{L-l} |u|_{H^2}, \quad u \in V_L, \quad s = 0, 1, 2.$$

Proof. This is Lemma 4.2.3 in [24]. □

Let $\tilde{\Pi}^l = \tilde{\Pi}^{h_l}$ be an interpolation operator defined by

$$\tilde{\Pi}^l u(x) = \sum_{i \in \mathcal{N}^l} \sum_{\alpha \in \mathcal{D}_1} D^\alpha u(x_i) \phi_{li}^\alpha(x).$$

We note that the mixed second derivative vanishes at level-ℓ grid points, that is, $D^{(1,1)} \tilde{\Pi}^l u(x) = 0$ for $x \in \mathcal{N}^l$. We note also that $\tilde{\Pi}^l p = p$ for p linear.

LEMMA 4.2. *Let* $\tilde{\Pi}^l$ *be the interpolation operator defined above. Then,*

$$|\tilde{\Pi}^l u - u|_{H^s} \le C h_l^{2-s} \left(1 + \log \frac{h_l}{h_L}\right)^{1/2} |u|_{H^2} \le C 2^{l(s-2)} (L-l)^{1/2} |u|_{H^2}, \quad u \in V_L, \quad s = 0, 1, 2.$$

Proof. This is Lemma 4.2.4 in [24]. We only sketch a proof here. Let $\tau \in \mathcal{T}^l$ be an element of level l and x_i, $1 \le i \le 4$, be its vertices. We have

$$\tilde{\Pi}^l u = \sum_{i=1}^{4} \sum_{|\alpha| \le 1} D^\alpha u(x_i) \phi_{li}^\alpha(x) \quad \forall x \in \tau.$$

We want to estimate $|u_h - \tilde{\Pi}^l u_h|_{H^s(\tau)}$. Note that $\tilde{\Pi}^l(p) = p$ for p linear. We can assume without loss of generality that

$$\{D^\alpha u\}_\tau \equiv \frac{\int_\tau D^\alpha u dx}{|\tau|} = 0, \ |\alpha| = 0, 1.$$

By the triangle inequality, we have

$$|\tilde{\Pi}^l u|_{H^s(\tau)} \le \sum_{i=1}^{4} \sum_{|\alpha| \le 1} |D^\alpha u(x_i)| |\phi_{li}^\alpha(x)|_{H^s(\tau)} \le \sum_{i=1}^{4} \sum_{|\alpha| \le 1} |u|_{W^{|\alpha|,\infty}(\tau)} |\phi_{li}^\alpha|_{H^s(\tau)}.$$

Using the fact that the basis functions are uniform to order 2, i.e.,

$$|\phi_{li}^\alpha(x)|_{W^{s,\infty}(\tau)} \le C h_l^{|\alpha|-s} \quad \text{and} \quad |\phi_{li}^\alpha(x)|_{H^s(\tau)} \le C h_l^{|\alpha|+1-s},$$

we get

$$|\tilde{\Pi}^l u|_{H^s(\tau)} \le C \left\{h_l^{1-s} |u|_{L^\infty(\tau)} + h_l^{2-s} |u|_{W^{1,\infty}(\tau)}\right\}.$$

Since $\{D^\alpha u\}_\tau = 0$, $|\alpha| = 0, 1$, we find that

$$|u|_{L^\infty(\tau)} \le C h_l |u|_{H^2(\tau)},$$
$$|u|_{W^{1,\infty}(\tau)} \le C \left(1 + \log\left(\frac{h_l}{h}\right)\right)^{1/2} |u|_{H^2(\tau)}.$$

The first inequality follows by the embedding $L^\infty \hookrightarrow H^2$ and a scaling argument. The second inequality follows from an application of Lemma 3 in the Appendix of Yserentant [23] to ∇u.

Using these inequalities in the estimate for $|\tilde{\Pi}^l u|_{H^s(\tau)}$, we obtain

$$|\tilde{\Pi}^l u|_{H^s(\tau)} \le C\left\{h_l^{2-s}|u|_{H^2(\tau)} + h_l^{2-s}\left(1+\log\left(\frac{h_l}{h_L}\right)\right)^{1/2}|u|_{H^2(\tau)}\right\}$$
$$\le Ch_l^{2-s}\left(1+\log\left(\frac{h_l}{h_L}\right)\right)^{1/2}|u|_{H^2(\tau)}.$$

By the triangle inequality and the vanishing mean values property of u, we have

$$|u-\tilde{\Pi}^l u|_{H^s(\tau)} \le |u|_{H^s(\tau)} + |\tilde{\Pi}^l u|_{H^s(\tau)} \le Ch_l^{2-s}\left(1+\log\left(\frac{h_l}{h_L}\right)\right)^{1/2}|u|_{H^2(\tau)}.$$

The lemma follows by summing over all $\tau \in \mathcal{T}^l$. □

It can be shown that the estimates in Lemmas 4.1 and 4.2 cannot be improved.

4.2. The HB method. We now study the HB method for the biharmonic problem. Let $\tilde{\mathcal{N}}^1 = \mathcal{N}^1$ and $\tilde{\mathcal{N}}^l = \mathcal{N}^l \setminus \mathcal{N}^{l-1}$ for $2 \le l \le L$, where $\mathcal{N}^l$ is the set of vertices of $\mathcal{T}^l$ as defined in §2.3. Let K_{HB} be the stiffness matrix with respect to the HB $\{\phi_{li}^\alpha\}_{\alpha\in\mathcal{D}_2, i\in\tilde{\mathcal{N}}^l, l\le L}$. To simplify the presentation, we assume that $h_1 = O(1)$, i.e., the coarse triangulation $\mathcal{T}^1$ is coarse enough. Therefore, the coarse stiffness matrix $K_1 = \{a(\phi_{1i}^\alpha, \phi_{1j}^\beta)\}$ can be replaced by D_1, the diagonal of K_1, and $\kappa(D_1^{-1}K_1)$ is small. In the general case, we need to solve the coarse problem exactly and the algorithms and analysis can be easily modified.

If we represent a function $u \in V_L$ by this HB as

$$u = \sum_{l=1}^{L}\sum_{i\in\tilde{\mathcal{N}}^l}\sum_{\alpha\in\mathcal{D}_2} x_{li}^\alpha \phi_{li}^\alpha,$$

then the extreme eigenvalues of K_{HB} can be estimated as follows:

$$\lambda_{\min}(K_{\mathrm{HB}}) = \min_x \frac{(K_{\mathrm{HB}}x, x)}{\|x\|_2^2} = \min \frac{|u|_{H^2}^2}{\|x\|_2^2},$$
$$\lambda_{\max}(K_{\mathrm{HB}}) = \max_x \frac{(K_{\mathrm{HB}}x, x)}{\|x\|_2^2} = \max \frac{|u|_{H^2}^2}{\|x\|_2^2}.$$

Note that $|\phi^{(0,0)}|_{H^2}^2 = O(h^{-2})$ and $|\phi^{(1,1)}|_{H^2}^2 = O(h^2)$. The unbalance between $\phi^{(1,1)}$ and $\phi^{(0,0)}$ implies that $\kappa(K_{\mathrm{HB}}) \ge ch^{-4}$. This suggests that we should use the normalized basis function (with respect to the energy norm), or equivalently a diagonal scaling technique. The diagonal scaling is inherent in the additive Schwarz method; therefore one does not need to keep track of scaling for different degrees of freedom. We will show that the simple diagonal scaling reduces the condition number to $O(h^{-2})$.

Let $\Pi^0 = 0$. By definition (7), we have

$$(\Pi^l - \Pi^{l-1})u = \sum_{i\in\tilde{\mathcal{N}}^l}\sum_{\alpha\in\mathcal{D}_2} x_{li}^\alpha \phi_{li}^\alpha.$$

It is easy to show that

$$|(\Pi^l - \Pi^{l-1})u|_{H^2}^2 \approx C\sum_{i\in\tilde{\mathcal{N}}^l}\sum_{\alpha\in\mathcal{D}_2}|x_{li}^\alpha|^2|\phi_{li}^\alpha|_{H^2}^2 \approx C\sum_{i\in\tilde{\mathcal{N}}^l}\sum_{\alpha\in\mathcal{D}_2}|x_{li}^\alpha|^2 h_l^{2|\alpha|-2}.$$

If we scale the basis functions such that $|\phi_{li}^{\alpha}|_{H^2}^2 = O(1)$, then

$$|(\Pi^l - \Pi^{l-1})u|_{H^2}^2 \approx \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} |x_{li}^{\alpha}|^2.$$

Thus,

$$\lambda_{\min}(K_{\mathrm{HB}}) = \min_x \frac{(K_{\mathrm{HB}}x, x)}{\|x\|_2^2} \approx \min_u \frac{|u|_{H^2}^2}{\sum_l |(\Pi^l - \Pi^{l-1})u|_{H^2}^2},$$

$$\lambda_{\max}(K_{\mathrm{HB}}) = \max_x \frac{(K_{\mathrm{HB}}x, x)}{\|x\|_2^2} \approx \max_u \frac{|u|_{H^2}^2}{\sum_l |(\Pi^l - \Pi^{l-1})u|_{H^2}^2}.$$

We will not discuss this direction further. Instead, we will use the additive Schwarz techniques to study this method. Based on the HB decomposition

$$V_L = V_1 + \sum_{l=2}^{L} \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} V_{li}^{\alpha},$$

we define a preconditioner

$$B_{\mathrm{HB}}^{-1} = A_{V_1}^{-1} Q_{V_1} + \sum_{l=2}^{L} \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha} A_{V_{li}^{\alpha}}^{-1} Q_{V_{li}^{\alpha}}$$

and an additive Schwarz operator

$$P_{\mathrm{HB}} = B_{\mathrm{HB}}^{-1} A = P_{V_1} + \sum_{l=2}^{L} \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} P_{V_{li}^{\alpha}}.$$

ALGORITHM 4.1 (HB). Find the solution u of the finite element problem (1) by solving iteratively the additive Schwarz equation

$$P_{\mathrm{HB}} u = f_{\mathrm{HB}} \stackrel{\mathrm{def}}{=} B_{\mathrm{HB}}^{-1} f.$$

We note that $f_{\mathrm{HB}} = B_{\mathrm{HB}}^{-1} f = \sum_l \sum_i \sum_{\alpha} f_{li}^{\alpha}$ and $f_{li}^{\alpha} = A_{V_{li}^{\alpha}}^{-1} Q_{V_{li}^{\alpha}} f$ are the solutions of

$$a(f_{li}^{\alpha}, \phi) = (f, \phi) \quad \forall \phi \in V_{li}^{\alpha}.$$

Since $\dim(V_{li}^{\alpha}) = 1$, it is easy to see that

$$P_{V_{li}^{\alpha}} v = \frac{a(v, \phi_{li}^{\alpha})}{a(\phi_{li}^{\alpha}, \phi_{li}^{\alpha})} \phi_{li}^{\alpha} \quad \text{and} \quad f_{li}^{\alpha} = \frac{f(\phi_{li}^{\alpha})}{a(\phi_{li}^{\alpha}, \phi_{li}^{\alpha})} \phi_{li}^{\alpha}.$$

If we replace P_{V_1} by $\sum_{i \in \mathcal{N}^1} \sum_{\alpha} P_{V_{1,i}^{\alpha}}$, then the above additive Schwarz equation can be written down explicitly as

$$\sum_{l=1}^{L} \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} \frac{a(u, \phi_{li}^{\alpha})}{a(\phi_{li}^{\alpha}, \phi_{li}^{\alpha})} \phi_{li}^{\alpha} = \sum_{l=1}^{L} \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} \frac{f(\phi_{li}^{\alpha})}{a(\phi_{li}^{\alpha}, \phi_{li}^{\alpha})} \phi_{li}^{\alpha}.$$

The corresponding linear system is

$$D^{-1} K_{\mathrm{HB}} x = D^{-1} b,$$

where $D = \operatorname{diag}(K_1, D_2, \ldots, D_L)$ or $D = \operatorname{diag}(D_1, D_2, \ldots, D_L)$, K_l is the stiffness matrix associated with $\{\phi_{li}^{\alpha}\}_{i \in \tilde{\mathcal{N}}^l}$, and $D_l = \operatorname{diag}(K_l)$.

LEMMA 4.3. *There exist constants C_1 and C_2 such that*

$$C_1 h^{-2} a(u,u) \le a(P_{\mathrm{HB}} u, u) \le C_2 a(u,u) \quad \forall u \in V^L.$$

The estimate cannot be improved, i.e., $c_1 h^{-2} \le \kappa(D^{-1} K_{\mathrm{HB}}) \le c_2 h^{-2}$.

Proof. Let $u_l = (\Pi^l - \Pi^{l-1})u$; it follows from Lemma 4.1 that

$$|u_l|_{H^2}^2 = |(\Pi^l - \Pi^{l-1})u|_{H^2(\Omega)}^2 \le C 4^{L-l} |u|_{H^2(\Omega)}^2.$$

It is easy to see that u_l can be represented uniquely as

$$u_l = \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} u_{li}^{\alpha}, \qquad u_{li}^{\alpha} \in V_{li}^{\alpha}.$$

By the inverse inequality and Lemma 4.1, we obtain

$$\begin{aligned} \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} |u_{li}^{\alpha}|_{H^2}^2 &\le C \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} h_l^{-4} |u_{li}^{\alpha}|_{L^2}^2 \le C h_l^{-4} |u_l|_{L^2}^2 \\ &\le C h_l^{-4} C h_l^4 \left(\frac{h_l}{h_L}\right)^2 |u|_{H^2}^2 \le C 4^{(L-l)} |u|_{H^2}^2. \end{aligned}$$

Summing over l gives

$$u_1 + \sum_{l=2}^{L} \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} |u_{li}^{\alpha}|_{H^2}^2 \le \sum_{l} C 4^{L-l} |u|_{H^2}^2 \le C 4^L |u|_{H^2}^2.$$

The lower bound follows from Lemma 3.1.

The upper bound, $a(P_{\mathrm{HB}}, u, u) \le C$, can be established by using certain strengthened Cauchy–Schwarz inequality. We will not give a proof here, since it follows easily from Theorem 5.1 and Remark 5.2 of the next section.

To show that the estimate is sharp, let $u = \phi_{Lj}^{(1,1)}$, $j \in \mathcal{N}^1$. The HB decomposition of u is given by

$$u = \sum_{l} \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} u_{li}^{\alpha}.$$

We have $u_{1j}^{(1,1)} = \phi_{1j}^{(1,1)}$, and note that $|\phi_{1j}^{(1,1)}|_{H^2}^2 = O(h_1^2)$ and $|u|_{H^2}^2 = |\phi_{Lj}^{(1,1)}|_{H^2}^2 = O(h_L^2)$. Thus

$$\sum_{l=1}^{L} \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} |u_{li}|_{H^2}^2 \ge |\phi_{1j}^{(1,1)}|_{H^2}^2 \ge C \left(\frac{h_1}{h_L}\right)^2 |u|_{H^2}^2 \ge C 4^L |u|_{H^2}^2.$$

It follows from Lemma 3.1 that $\lambda_{\min}(P_{\mathrm{HB}}) \le C h^{-2}$. □

Remark 4.1. In [20], Oswald studied the biharmonic problem approximated by composite finite elements consisting of piecewise quadratic Powell–Sabin elements and piecewise cubic elements of Clough–Tocher type. Using Besov space theory, Oswald established that the condition number of hierarchical multilevel methods grows like CL^2, which is significantly better than the case of bicubic element. This is because the second derivatives of the finite element function are not degrees of freedoms of the two composite finite elements considered by Oswald. In general, for symmetric elliptic problems of $2m$th order, if the degrees of freedom of the finite elements consists of function values and derivatives of order less than or equal to $m-1$, then, $\kappa(K_{\mathrm{HB}}) \le CL^2$.

4.3. A MHB method. To get better algorithms, we need to improve $\lambda_{\min}(P)$, the minimum eigenvalue of the iteration operator. If we use additional subspaces in the space decomposition, we have more freedom to choose the decomposition of a function $u \in V_L$ and by Lemma 3.1 we have a larger $\lambda_{\min}(P)$. Our approach is to add some additional vertex subspaces in the space decomposition. Using the space decomposition

$$V^L = V_1 + \sum_{l=2}^{L} \sum_{i \in \mathcal{N}^l} \sum_{\alpha \in \mathcal{D}_2} V_{li}^{\alpha} + \sum_{i \in \mathcal{N}^L} V_{Li}^{(1,1)},$$

we define a preconditioner

$$B_{\mathrm{MHB}}^{-1} = B_{\mathrm{HB}}^{-1} + \sum_{i \in \mathcal{N}^L} A_{V_{Li}^{(1,1)}}^{-1} Q_{V_{Li}^{(1,1)}}$$

and an additive Schwarz iteration operator

$$P_{\mathrm{MHB}} = B_{\mathrm{MHB}}^{-1} A = P_{\mathrm{HB}} + \sum_{i \in \mathcal{N}^L} P_{V_{Li}^{(1,1)}}.$$

ALGORITHM 4.2 (MHB). Find the solution u of the finite element equation (1) by solving the following additive Schwarz equation:

$$P_{\mathrm{MHB}} u = f_{\mathrm{MHB}},$$

where

$$f_{\mathrm{MHB}} = B_{\mathrm{MHB}}^{-1} f = f_{\mathrm{HB}} + \sum_{i \in \mathcal{N}^L} A_{V_{Li}^{(1,1)}}^{-1} Q_{V_{Li}^{(1,1)}} f = f_{\mathrm{HB}} + \sum_{i \in \mathcal{N}^L} \frac{f(\phi_{Li}^{(1,1)})}{a(\phi_{Li}^{(1,1)}, \phi_{Li}^{(1,1)})} \phi_{Li}^{\alpha}.$$

This algorithm costs a little more than the HB algorithm per iteration, since we need to compute the extra terms

$$P_{V_{Li}^{(1,1)}} u = \frac{a(u, \phi_{Li}^{(1,1)})}{a(\phi_{Li}^{(1,1)}, \phi_{Li}^{(1,1)})} \phi_{Li}^{(1,1)}, \qquad i = 1, \ldots, N_L$$

in each iteration. This requires N operations, where $N = N_L = \dim \mathcal{N}^L$. Compared with the cost for one multiplication Kx, which is about $144N$, this cost is small (less than 1% of the computation).

The following lemma provides a condition number estimates of P_{MHB}.

LEMMA 4.4. *There exist constants C_1 and C_2 such that*

$$C_1 |\log h|^{-2} a(u, u) \le a(P_{\mathrm{MHB}} u, u) \le C_2 a(u, u) \quad \forall u \in V^L.$$

Thus the condition number of the MHB *algorithm is $O(|\log h|^2) = O(L^2)$.*

Proof. We apply Lemma 3.1 to establish the lower bound. Let

$$u^{(1,1)} = \sum_{i \in \mathcal{N}^L} u_{xy}(x_i) \phi_{Li}^{(1,1)}.$$

It is easy to see that $u^{(1,1)}$ has the same mixed second derivatives as u, but has zero function values and first derivatives at the grid points $x \in \mathcal{N}^L$. Let $\Omega_i^L = \mathrm{supp}\{\phi_{Li}^{\alpha}\}$. Using the discrete norm estimates, $|u_{xy}(x_i)|^2 h^2 \le C|u|^2_{H^2(\Omega_i^L)}$, we obtain

$$\sum_{i \in \mathcal{N}^L} |u_{xy}(x_i) \phi_{Li}^{(1,1)}|^2_{H^2(\Omega)} \le \sum_{i \in \mathcal{N}^L} |u_{xy}(x_i)|^2 |\phi_{Li}^{(1,1)}|^2_{H^2(\Omega)} \le C \sum_{i \in \mathcal{N}^L} |u_{xy}(x_i)|^2 h^2$$

$$\le C \sum_{i \in \mathcal{N}^L} |u|^2_{H^2(\Omega_i^L)} \le C|u|^2_{H^2(\Omega)}.$$

Let $u_l = \tilde{\Pi}^l u - \tilde{\Pi}^{l-1} u$. Then,

$$u = u^{(1,1)} + \tilde{\Pi}^L u = \sum_{i \in \mathcal{N}^L} u_{xy}(x_i)\phi_{Li}^{(1,1)} + \sum_{l=1}^{L} u_l.$$

It is easy to check that

$$D^\alpha u_l(x_i) = 0, \qquad x_i \in \mathcal{N}^{l-1}, \quad \alpha \in \mathcal{D}_2.$$

Thus u_l can be uniquely represented as

$$u_l = \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} u_{li}^\alpha, \qquad u_{li}^\alpha \in V_{li}^\alpha.$$

By the inverse inequality and Lemma 4.2, we obtain

$$\sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} |u_{li}^\alpha|_{H^2}^2 \le C \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} h_l^{-4} |u_{li}^\alpha|_{L^2}^2 \le C h_l^{-4} |u_l|_{L^2}^2 \le C(L-l)|u|_{H^2}^2.$$

Combining the above two estimates, we get

$$\begin{aligned} &\sum_{i \in \mathcal{N}^L} |u_{xy}(x_i)\phi_{Li}^{(1,1)}|_{H^2}^2 + \sum_{l=1}^{L} \sum_{i \in \tilde{\mathcal{N}}^l} \sum_{\alpha \in \mathcal{D}_2} |u_{li}^\alpha|_{H^2}^2 \\ &\le \quad C|u|_{H^2}^2 + C \sum_{l=1}^{L} (L-l)|u|_{H^2}^2 \le CL^2 |u|_{H^2}^2, \qquad u_{li}^\alpha \in V_{li}^\alpha \end{aligned}$$

The lower bound follows from Lemma 3.1.

The upper bound, $a(P_{\mathrm{MHB}} u, u) \le Ca(u, u)$, follows from Theorem 5.1 and Remark 5.2 in the next section. □

5. MAS methods.

5.1. Algorithm. MAS methods for the biharmonic problem were designed and studied in [25] and [24]. They are generalizations of the two level domain decomposition methods also considered in [24]. In matrix form, they correspond to *multilevel block diagonal scaling*.

Let $\Omega_i^l = \mathrm{supp}\{\phi_{li}^\alpha\}$. The MAS method can be derived from the multilevel overlapping domain decomposition $\Omega = \cup_i \Omega_i^l$, using domain decomposition language; cf. [24]. In this paper, we work directly with the multilevel space decomposition.

Let $V_{li}^\alpha = \mathrm{span}\{\phi_{li}^\alpha\}$ and let $V_{li} = V_l \cap H_0^2(\Omega_i^l) = \sum_\alpha V_{li}^\alpha$ be defined as in §4. For uniform triangulations, $V_{li}^\alpha \perp V_{li}^\beta$, for $\alpha \ne \beta$, thus $V_{li} = \sum_\alpha V_{li}^\alpha$ is an orthogonal decomposition and $P_{V_{li}} u = \sum_\alpha P_{V_{li}^\alpha}$. The 4-by-4 local stiffness matrices $K_{li} = \{a(\phi_{li}^\alpha, \phi_{li}^\beta)\}$ are diagonal.

Based on the MAS space decomposition

$$V^h = V_1 + \sum_{l=2}^{L} \sum_{i \in \mathcal{N}^l} V_{li} \qquad \left(V_1 + \sum_{l=2}^{L} \sum_{i \in \mathcal{N}^l} \sum_{\alpha \in \mathcal{D}_2} V_{li}^\alpha \right),$$

we defined a preconditioner B_{MAS}^{-1}

$$B_{\mathrm{MAS}}^{-1} = A_{V_1}^{-1} Q_{V_1}^{-1} + \sum_{\ell \ge 2} \sum_{i \in \mathcal{N}^l} A_{V_{li}}^{-1} Q_{V_{li}} \qquad \left(A_{V_1}^{-1} Q_{V_1} + \sum_{\ell \ge 2} \sum_{i \in \mathcal{N}^l} \sum_{\alpha \in \mathcal{D}_2} A_{V_{li}^\alpha}^{-1} Q_{V_{li}^\alpha} \right)$$

and an additive Schwarz operator P_{MAS}

$$P_{\mathrm{MAS}} = B_{\mathrm{MAS}}^{-1} A = P_{V_1} + \sum_{\ell \geq 2} \sum_{i \in \mathcal{N}^l} P_{V_{li}} \qquad \left(P_{V_1} + \sum_{\ell \geq 2} \sum_{i \in \mathcal{N}^l} \sum_{\alpha \in \mathcal{D}_2} P_{V_{li}^{\alpha}} \right).$$

ALGORITHM 5.1 (MAS). Find the solution u_h of the finite element equation (1) by solving iteratively the equivalent equation:

$$P_{\mathrm{MAS}} u_h = f_{\mathrm{MAS}} \stackrel{\mathrm{def}}{=} B_{\mathrm{MAS}}^{-1} f. \tag{8}$$

Note that $f_{\mathrm{MAS}} = B_{\mathrm{MAS}}^{-1} f = \sum_l \sum_i f_{li}$, where $f_{li} = A_{V_{li}}^{-1} Q_{V_{li}} f$ are the solutions for the finite element problems

$$a(f_{li}, \phi_h) = a(P_{V_{li}} u, \phi_h) = f(\phi_h) \quad \forall \phi_h \in V_{li}. \tag{9}$$

It is easy to see that for f_{li} given by (9), equations (1) and (8) are equivalent. To find u_h, we first compute the right-hand side f_{MAS} by solving (9), and we then use the conjugate gradient (CG) method to solve the system (8). In each iteration, we need to compute $P_{V_{li}} v_h$ for a given $v_h \in V^h$ by solving the equation

$$a(P_{V_{li}} v_h, \phi_h) = a(v_h, \phi_h) \quad \forall \phi_h \in V_{li}.$$

This is a finite element equation on Ω_i^l with mesh size h_l, and $\dim(V_{li}) = 4$. Recall that for uniform triangulations, $V_{li}^{\alpha} \perp V_{li}^{\beta}$, for $\alpha \neq \beta$, and the local stiffness matrices $\{a(\phi_{li}^{\alpha}, \phi_{li}^{\beta})\}$ are diagonal, we have

$$P_{V_{li}} u = \sum_{\alpha} P_{V_{li}^{\alpha}} u = \sum_{\alpha} \frac{a(u, \phi_{li}^{\alpha})}{a(\phi_{li}^{\alpha}, \phi_{li}^{\alpha})} \phi_{li}^{\alpha}, \qquad f_{li} = \sum_{\alpha} \frac{f(\phi_{li}^{\alpha})}{a(\phi_{li}^{\alpha}, \phi_{li}^{\alpha})} \phi_{li}^{\alpha}.$$

If we assume that $h_1 = O(1)$, and we can replace P_{V_1} by $\sum_{i,\alpha} P_{V_{1i}^{\alpha}}$, then Algorithm 5.1 can be written explicitly as

$$\sum_{l=1}^{L} \sum_{i \in \mathcal{N}_l} \sum_{\alpha} \frac{a(u, \phi_{li}^{\alpha})}{a(\phi_{li}^{\alpha}, \phi_{li}^{\alpha})} \phi_{li}^{\alpha} = \sum_{l} \sum_{i \in \mathcal{N}_l} \sum_{\alpha} \frac{f(\phi_{li}^{\alpha})}{a(\phi_{li}^{\alpha}, \phi_{li}^{\alpha})} \phi_{li}^{\alpha}.$$

K_l is the stiffness matrix associated with V_l and D_l is the diagonal (block) part of K_l. Let Π^l be the prolongation operator (matrix representation of the interpolation operator from V_l to V_L), and let Π_l^t be the adjoint of Π_l. Equation (8) can then be written as a preconditioned linear system

$$B_L^{-1} K_L x = B_L^{-1} b,$$

where

$$B_L^{-1} = \Pi_1 K_1^{-1} \Pi_1^t + \Pi_2 D_2^{-1} \Pi_2^t + \cdots + \Pi_{L-1} D_{L-1}^{-1} \Pi_{L-1}^t + D_L^{-1}.$$

K_1^{-1} can be replaced by any good preconditioner B_1 of K_1; in particular, if $h_1 = O(1)$, then K_1 can be replaced by D_1.

Remark 5.1. For domains with complicated geometry, the use of the diagonal D_1^{-1} to replace K_1^{-1} is not recommended, since $\kappa(D_1^{-1} K_1)$ can be large.

For elements with relatively larger aspect ratio, the 4-by-4 local stiffness matrix $K_{li} = \{a(\phi_{li}^{\alpha}, \phi_{li}^{\beta})\}$ or $\mathrm{diag}(K_{li})^{-1} K_{li}$ may have large condition numbers. Therefore, we should not replace V_{li} by the sum of V_{li}^{α} in the space decomposition, and the local 4-by-4 problem $K_{li} x = b$ should be solved exactly. Replacing K_{li} by its diagonal can hurt the overall performance of the algorithm.

5.2. Condition number estimate. It is easy to establish that the MAS operator P_{MAS} satisfies

$$C_1 L^{-1} a(u,u) \le a(P_{\text{MAS}}u, u) \le C_2 L a(u,u). \tag{10}$$

Thus, $\kappa(P_{\text{MAS}}) \le CL^2$. For second-order problems, $\kappa(P_{\text{MAS}})$ can be bounded uniformly with respect to the number of levels; cf. [18], [26]. We now eliminate L from (10).

We first establish a "strengthened Cauchy–Schwarz" inequality.

LEMMA 5.1. *For $u_l \in V_l$ and $u_k \in V_k$, let*

$$u_l = \sum_{i\in\mathcal{N}^l}\sum_{\alpha} u_{li}^{\alpha}, \quad u_{li}^{\alpha} \in V_{li}^{\alpha}, \quad \text{and} \quad u_k = \sum_{j\in\mathcal{N}^k}\sum_{\alpha} u_{kj}^{\alpha}, \quad u_{kj}^{\alpha} \in V_{kj}^{\alpha}.$$

Then

$$\begin{aligned} a(u_l,u_k) &\le C\sqrt{\gamma}^{|k-l|}(h_l^{-2}\|u_l\|_{L^2})(h_k^{-2}\|u_k\|_{L^2}) \\ &\le C_{cs}\sqrt{\gamma}^{|k-l|}\left(\sum_{i\in\mathcal{N}^l}\sum_{\alpha}|u_{li}^{\alpha}|_{H^2}^2\right)^{1/2}\left(\sum_{i\in\mathcal{N}^k}\sum_{\alpha}|u_{ki}^{\alpha}|_{H^2}^2\right)^{1/2}. \end{aligned}$$

Proof. We assume $k > l$. For each element τ^l, we decompose u_k as (cf. Fig. 3)

$$u_k = u_{\text{out}} + u_B + u_{\text{in}} \overset{\text{def}}{=} \sum_{j\notin\mathcal{N}^k(\overline{\tau}^l)}\sum_{\alpha\in\mathcal{D}_2} u_{kj}^{\alpha} + \sum_{j\in\mathcal{N}^k(\partial\tau^l)}\sum_{\alpha\in\mathcal{D}_2} u_{kj}^{\alpha} + \sum_{j\in\mathcal{N}^k(\tau^l)}\sum_{\alpha\in\mathcal{D}_2} u_{kj}^{\alpha}.$$

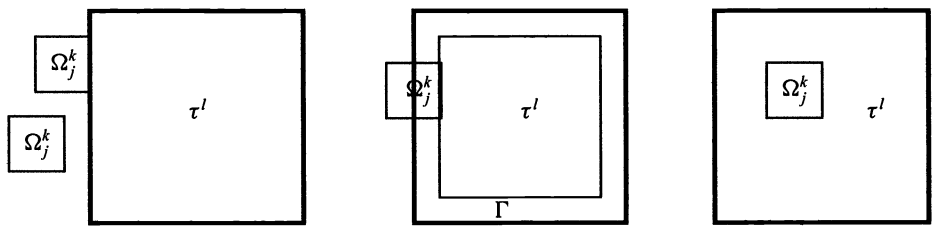

FIG. 3. *Three possible relations between Ω_j^k and τ^l.*

It is clear that, $a_{\tau^l}(u_l, u_{\text{out}}) = 0$, thus

$$a_{\tau^l}(u_l,u_k) = a_{\tau^l}(u_l,u_{in}) + a_{\tau^l}(u_l,u_B).$$

We estimate each term separately. Let $\Gamma = \tau^l \cap (\cup_{i\in\mathcal{N}^k(\partial\tau_k^l)}\Omega_i^k)$ be the union of smaller elements $\tau^k \in \mathcal{T}^k$ that touch the boundary of the larger element τ^l. We first estimate $a_{\tau^l}(u_l,u_B)$. Since $\text{supp}(u_B) = \Gamma$, we have

$$|a_{\tau^l}(u_l,u_B)| = |a_\Gamma(u_l,u_B)| \le |u_l|_{H^2(\Gamma)}|u_B|_{H^2(\Gamma)}.$$

Using inverse inequality, $|u_l|_{W^{2,\infty}(\tau^l)} \le Ch_l^{-1}|u_l|_{H^2(\tau^l)} \le Ch_l^{-3}\|u_l\|_{L^2(\tau^l)}$, we obtain

$$\begin{aligned} |u_l|_{H^2(\Gamma)} &\le |\Gamma|^{1/2}|u_l|_{W^{2,\infty}(\Gamma)} \le |\Gamma|^{1/2}|u_l|_{W^{2,\infty}(\tau^l)} \\ &\le C|\Gamma|^{1/2}h_l^{-3}\|u_l\|_{L^2(\tau^l)} \le C\sqrt{\gamma}^{k-l}h_l^{-2}\|u_l\|_{L^2(\tau^l)} \end{aligned}$$

and

$$|u_B|_{H^2(\Gamma)} \le Ch_k^{-2}\|u_B\|_{L^2(\Gamma)} \le Ch_k^{-2}\|u_k\|_{L^2(\tau^l)}.$$

Combining the above inequalities, we obtain

$$|a_{\tau^l}(u_l, u_B)| \le C\sqrt{\gamma}^{k-l}h_l^{-2}\|u_l\|_{L^2(\tau^l)}\, h_k^{-2}\|u_k\|_{L^2(\tau^l)}. \tag{11}$$

We now estimate $a_{\tau^l}(u_l, u_{in})$, integrate by parts, then use Schwarz inequality,

$$|a_{\tau^l}(u_l, u_{in})| = |(\Delta^2 u_l, u_{in})_{L_2(\tau^l)}| \le \|\Delta^2 u_l\|_{L^2(\tau^l)}\|u_{in}\|_{L^2(\tau^l)}.$$

It follows from the inverse inequality $|u_l|_{H^4(\tau^l)} \le h_l^{-4}\|u_l\|_{L^2(\tau^l)}$ that

$$\|\Delta^2 u_l\|_{L^2(\tau^l)} \le C|u_l|_{H^4(\tau^l)} \le Ch_l^{-4}\|u_l\|_{L^2(\tau^l)}.$$

Note that $\|u_{in}\|_{L^2(\tau^l)} \le C\|u_k\|_{L^2(\tau^l)}$, thus,

$$\begin{aligned} |a_{\tau^l}(u_l, u_{in})| &\le Ch_l^{-4}\|u_l\|_{L^2(\tau^l)}\|u_k\|_{L^2(\tau^l)} \\ &\le C\gamma^{2(k-l)}(h_l^{-2}\|u_l\|_{L^2(\tau^l)})\left(h_k^{-2}\|u_k\|_{L^2(\tau^l)}\right). \end{aligned} \tag{12}$$

Combining estimates (11) and (12), we obtain

$$|a_{\tau^l}(u_l, u_k)| \le C\sqrt{\gamma}^{k-l}\left(h_l^{-2}\|u_l\|_{L^2(\tau^l)}\right)\left(h_k^{-2}\|u_k\|_{L^2(\tau^l)}\right).$$

Summing over τ^l and using the Cauchy inequality, we obtain

$$\begin{aligned} a(u_l, u_k) &\le C\sqrt{\gamma}^{k-l}(h_l^{-2}\|u_l\|_{L^2(\Omega)})(h_k^{-2}\|u_k\|_{L^2(\Omega)}) \\ &\le C\sqrt{\gamma}^{k-l}h_l^{-2}\left(\sum_{i\in\mathcal{N}^l}\sum_{\alpha\in\mathcal{D}_2}\|u_{li}^\alpha\|_{L^2(\Omega)}^2\right)^{1/2} h_k^{-2}\left(\sum_{j\in\mathcal{N}^k}\sum_{\alpha\in\mathcal{D}_2}\|u_{kj}^\alpha\|_{L^2(\Omega)}^2\right)^{1/2}. \end{aligned}$$

The second inequality in the lemma follows from the fact that $\|u_{li}^\alpha\|_{L^2} \le h_l^2|u_{li}|_{H^2}$. □

The L^2 projection $Q_{V_h} : H^2(\Omega) \to V_h$ is defined by

$$(Q_{V_h}u, \phi)_{L^2(\Omega)} = (u, \phi)_{L^2(\Omega)} \quad \forall \phi \in V_h.$$

LEMMA 5.2. *We have the following estimates for* Q_{V_h}:

$$\begin{aligned} |Q_{V_h}u - u|_{H^s(\Omega)} &\le Ch^{2-s}|u|_{H^2(\Omega)}, \qquad s = 0, 1, 2, \\ |Q_{V_h}u|_{H^\sigma(\Omega)} &\le C|u|_{H^\sigma(\Omega)}, \qquad 0 \le \sigma \le 2. \end{aligned}$$

Proof. We construct a quasi-interpolation operator $\tilde{\Pi}_{V_h} : H_0^2(\Omega) \to V_h$ by

$$\tilde{\Pi}_{V_h}u = \sum_i u(x_i)\phi_i^{(0,0)} + \sum_i\sum_{\alpha\in\mathcal{D}_1}\{D^\alpha u\}_{\Omega_i}\phi_i^\alpha.$$

Here $\Omega_i = \operatorname{supp}\{\phi_i\}$ and $\{D^\alpha u\}_{\Omega_i} = (\int_{\Omega_i} D^\alpha u/|\Omega_i|)$. It can be shown, cf. Theorems 4.1.1 and 4.1.2 in [24], that

$$|\tilde{\Pi}_{V_h}u - u|_{H^s(\Omega)} \le Ch^{2-s}|u|_{H^2(\Omega)}. \tag{13}$$

By an inverse inequality and a property of Q_{V_h}, it follows that

$$
\begin{aligned}
|(Q_{V_h} - \tilde{\Pi}_{V_h})u|_{H^s(\Omega)} &\le Ch^{-s}\|(Q_{V_h} - \tilde{\Pi}_{V_h})u\|_{L^2(\Omega)} \\
&\le Ch^{-s}\|Q_{V_h}u - u\|_{L^2(\Omega)} + Ch^{-s}\|\tilde{\Pi}_{V_h}u - u\|_{L^2(\Omega)} \\
&\le 2Ch^{-s}\|\tilde{\Pi}_{V_h}u - u\|_{L^2(\Omega)} \le Ch^{2-s}|u|_{H^2(\Omega)}.
\end{aligned} \tag{14}
$$

The first part of the lemma follows from the inequalities (13), (14), and the triangle inequality. Taking $s = 2$ in the first inequality of the lemma and using the triangle inequality, we obtain

$$|Q_{V_h}u|_{H^2(\Omega)} \le |Q_{V_h}u - u|_{H^2(\Omega)} + |u|_{H^2(\Omega)} \le C|u|_{H^2(\Omega)}.$$

Note that $\|Q_{V_h}u\|_{L^2(\Omega)} \le \|u\|_{L^2(\Omega)}$. The second part of the lemma now follows from interpolation in Sobolev spaces. □

We will make the following regularity assumption.

Assumption 5.1. There exists a constant $\sigma > 0$ such that

$$|u|_{H^{2+\sigma}(\Omega)} \le C|\Delta^2 u|_{H^{-2+\sigma}(\Omega)}.$$

It is known that the assumption holds with $\sigma = 1$ for convex region. Blum and Rannacher [2] have shown that the assumption holds with $\sigma = 2$ for convex polygons with interior angles smaller than 126.28°.

Using the Aubin–Nitsche trick, it follows from Assumption 5.1 that the H^2-projection $P_{V_k} : H^2(\Omega) \to V_k$ satisfies

$$|(I - P_{V_k})u|_{H^{2-\sigma}(\Omega)} \le Ch_k^{\sigma}|(I - P_{V_k})u|_{H^2(\Omega)}. \tag{15}$$

LEMMA 5.3. *Assume that Assumption* 5.1 *holds. Let $Q_{V_l} : V_L \to V_l$ be the L^2 projection and let $u_k = (P_{V_k} - P_{V_{k-1}})u$. Then $Q_{V_l}u_k = 0$ for $l \ge k$ and*

$$|Q_{V_l}u_k|_{H^2(\Omega)} \le C\left(\frac{h_k}{h_l}\right)^{\sigma}|u_k|_{H^2(\Omega)} \le C_Q\gamma^{\sigma(k-l)}|u_k|_{H^2(\Omega)}, \qquad l \le k.$$

Proof. By an inverse inequality, the boundness of Q_{V_l} in the $H^{2-\sigma}$–norm, we obtain,

$$|Q_{V_l}u_k|_{H^2(\Omega)} \le Ch_l^{-\sigma}|Q_{V_l}u_k|_{H^{2-\sigma}(\Omega)} \le Ch_l^{-\sigma}|u_k|_{H^{2-\sigma}(\Omega)}.$$

The lemma follows by applying inequality (15) to the above inequality. □

We can now prove the following lemma.

LEMMA 5.4. *Assume that Assumption* 5.1 *holds. Then,*

$$\sum_{l=1}^{L}|(Q_{V_l} - Q_{V_{l-1}})u|^2_{H^2(\Omega)} \le C|u|^2_{H^2(\Omega)} \quad \forall u \in V_L.$$

The constant C is independent of L.

Proof. Let $u_k = (P_{V_k} - P_{V_{k-1}})u$. Then $u = \sum u_k$. Lemma 5.3 implies that $(Q_{V_l} - Q_{V_{l-1}})u_k = 0$, $k < l$ and

$$\sum_{l=1}^{L}|(Q_{V_l} - Q_{V_{l-1}})u|^2_{H^2} = \sum_{l=1}^{L}\left|(Q_{V_l} - Q_{V_{l-1}})\sum_{k=1}^{L}u_k\right|^2_{H^2}$$

$$
\begin{aligned}
&= \sum_{l=1}^{L} \left| \sum_{k=l}^{L} (Q_{V_l} - Q_{V_{l-1}}) u_k \right|_{H^2}^2 \\
&\le \sum_{l=1}^{L} \left\{ \sum_{k=l}^{L} |(Q_{V_l} - Q_{V_{l-1}}) u_k|_{H^2} \right\}^2 \\
&\le C_Q^2 \sum_{l=1}^{L} \left\{ \sum_{k=l}^{L} \gamma^{\sigma(k-l)} |u_k|_{H^2} \right\}^2 \\
&\le C_Q^2 C(\gamma, L) \sum_{k=1}^{L} |u_k|_{H^2}^2 = C_Q^2 C(\gamma, L) |u|_{H^2}^2 \le C_Q^2 C(\gamma) |u|_{H^2}^2.
\end{aligned}
$$

Here $C(\gamma, L) = (1 - \gamma^{\sigma L})^2/(1 - \gamma^{\sigma})^2$ and $C(\gamma) = 1/(1 - \gamma^{\sigma})^2$. □

THEOREM 5.1. *Assume that Lemma* 5.4 *holds. Then the* MAS *operator* P_{MAS} *satisfies*

$$C_1 a(u_h, u_h) \le a(P_{\text{MAS}} u_h, u_h) \le C_2 a(u_h, u_h) \quad \forall u_h \in V^h.$$

The constants are independent of $\{h_l\}$ *and* L.

Proof. Upper bound: Let $u \in V_L$ and let $\{u_{li}^{\alpha}\}$ be a decomposition of u, i.e.,

$$\sum_{l=1}^{L} \sum_{i \in \mathcal{N}^l} \sum_{\alpha} u_{li}^{\alpha} = u, \qquad u_{li}^{\alpha} \in V_{li}^{\alpha}.$$

Let $u_l = \sum_{i \in \mathcal{N}^l} \sum_{\alpha \in \mathcal{D}_2} u_{li}^{\alpha} \in V_{li}^{\alpha}$. It follows from Lemma 5.1 that

$$
\begin{aligned}
a(u, u) &= \sum_{l,k=1}^{L} a(u_l, u_k) \\
&\le C_{cs} \sum_{l,k=1}^{L} \sqrt{\gamma}^{|k-l|} \left(\sum_{i \in \mathcal{N}^l} \sum_{\alpha} |u_{li}^{\alpha}|_{H^2}^2 \right)^{1/2} \left(\sum_{j \in \mathcal{N}^k} \sum_{\alpha} |u_{kj}^{\alpha}|_{H^2}^2 \right)^{1/2} \\
&\le C_{cs} \frac{1 + \sqrt{\gamma}}{1 - \sqrt{\gamma}} \sum_{l=1}^{L} \sum_{i \in \mathcal{N}^l} \sum_{\alpha} |u_{li}^{\alpha}|_{H^2}^2.
\end{aligned}
$$

The upper bound follows from Lemma 3.1 and Remark 3.1.

Lower bound: Let $u_l = (Q_{V_l} - Q_{V_{l-1}})u$ and we further decompose u_l as

$$u_l = \sum_{i \in \mathcal{N}^l} \sum_{\alpha} u_{li}^{\alpha}, \qquad u_{li}^{\alpha} \in V_{li}^{\alpha}.$$

Using the inverse inequality $|u_{li}^{\alpha}|_{H^2(\Omega)}^2 \le C h_l^{-4} \|u_{li}^{\alpha}\|_{L^2(\Omega)}^2$, and Lemma 5.2, we obtain

$$\sum_{i \in \mathcal{N}^l} \sum_{\alpha} |u_{li}^{\alpha}|_{H^2(\Omega)}^2 \le C h_l^{-4} \sum_{i \in \mathcal{N}^l} \sum_{\alpha} \|u_{li}^{\alpha}\|_{L^2}^2 \le C h_l^{-4} \|u_l\|_{L^2}^2 \le C |u_l|_{H^2(\Omega)}^2.$$

Summing over l and using Lemma 5.4, we obtain

$$\sum_{l=1}^{L} \sum_{i \in \mathcal{N}^l} \sum_{\alpha} |u_{li}^{\alpha}|_{H^2(\Omega)}^2 \le C \sum_{l=1}^{L} |u_l|_{H^2(\Omega)}^2 \le C C(\gamma) |u|_{H^2(\Omega)}^2.$$

The lower bound now follows from Lemma 3.1. □

Remark 5.2. It is clear that

$$a(P_{\mathrm{HB}}u, u) \le a(P_{\mathrm{MAS}}u, u) \quad \text{and} \quad a(P_{\mathrm{MHB}}u, u) \le Ca(P_{\mathrm{MAS}}u, u).$$

Therefore, we have also obtained upper bounds for P_{HB} and P_{MHB}.

Remark 5.3. Recently, Oswald [19] also proved a similar result for the MAS algorithm. A discrete norm $|u|_O$ is defined by

$$|u|_O^2 = \inf_{\sum_l u_l = u} \sum_{l=1}^{L} h_l^{-4} \|u_l\|_{L^2}^2.$$

Oswald's approach is to use the Besov space theory to establish the following norm equivalency:

$$C_1|u|_O^2 \le |u|_{H^2(\Omega)}^2 \le C_2|u|_O^2. \tag{16}$$

Our proof for the lower bound follows an idea of Bramble and Pasciak [4]; see also Xu [22]. A more elementary approach for the lower bound is used in Zhang [26]: We first establish the result for domains with H^4-regularity. In the general case, we extend Ω to a larger convex domain $\tilde{\Omega}$, on which H^4-regularity holds. We then construct a decomposition of u with respect to $V^l(\Omega)$ from a decomposition of u with respect to $V^l(\tilde{\Omega})$. See [26] for a detailed discussion of the second-order case.

6. Multiplicative variants. In this section, we discuss some multiplicative variant of the multilevel Schwarz methods. They represent certain V-cycle multigrid methods.

Let $K^{ll} = \{a(\phi_{li}^{\alpha}, \phi_{lj}^{\beta})\}_{\alpha,\beta\in\mathcal{D}_2, i,j\in\mathcal{N}^l}$ be the stiffness matrix associated with triangulation $\mathcal{T}^l$. Let $K^{ll} = (D_l - L_l - L_l^t)$, where D_l, $-L_l$ are the diagonal and lower triangular parts of K^{ll}, respectively. Consider the problem

$$Au = f \quad \text{or} \quad K^{LL}x = b.$$

ALGORITHM 6.1 (MMS/MG-JACOBI). Let $u^{\mathrm{old}} \in V_L$ or x^{old} be the current approximation to the solution. Compute the new approximation by the following:

(1) Set $u_0 = u^{\mathrm{old}}$.

(2) For $l = 1, 2, \ldots, L$ compute

$$u_l = u_{l-1} + \eta(\textstyle\sum_{i,\alpha} A_{V_{li}^{\alpha}}^{-1} Q_{V_{li}^{\alpha}})(f - Au_{l-1}) = u_{l-1} + \eta(\textstyle\sum_{i,\alpha} P_{V_{li}^{\alpha}})(u - u_l),$$

where η is a damping factor such that $\|T_l\|_a \equiv \|\eta \sum_{i,\alpha} P_{V_{li}}^{\alpha}\|_a \le \omega < 2$.

(3) Set $u^{\mathrm{new}} = u_L$.

We order (α, i), $i \in \mathcal{N}^l$, $\alpha \in \mathcal{D}_2$, and represent it by one index i, $i = 1, \ldots, 4N_l$. Let $e_{li} = u - u_{li}$, $r_{li} = f - Au_{li} = Ae_{li}$.

ALGORITHM 6.2 (MMS/MG-SOR). Let $u^{\mathrm{old}} \in V_L$ be the current approximation.

(1) Set $u_{1,0} = u^{\mathrm{old}}$.

(2) For $\ell = 1, 2, \ldots, L$, compute

$u_{l,0} = u_{l-1,4N_{l-1}}$: the approximation of previous level (level ℓ-1).

For $i = 1, \ldots, 4N_l$ compute u_{li} by

$u_{li} = u_{l,i-1} + \omega A_{V_{li}}^{-1} Q_{V_{li}}(f - Au_{l,i-1}) = u_{l,i-1} + \omega P_{V_{li}} e_{l,i-1}$.

(3) Set $u^{\mathrm{new}} = u_{L,4N_L}$.

The case $\omega = 1$ corresponds to a Gauss–Seidel smoother and $1 < \omega < 2$ corresponds to a successive overrelaxation (SOR) smoother.

In matrix form, the algorithms can be written as

$$\begin{aligned} x_0 &= x^{\text{old}}, \\ x_l &= x_{l-1} + \Pi_l M_l^{-1} \Pi_l^t (b - K^{LL} x_{l-1}), \quad l = 1, \ldots, L, \\ x^{\text{new}} &= x_L, \end{aligned}$$

where $M_l^{-1} = \eta D_l^{-1}$ for weighted Jacobi smoother and $M_l^{-1} = (\frac{1}{\omega} D_l - L_l)^{-1}$ for a Gauss–Seidel/SOR smoother.

The corresponding error propagation operators are

$$E_J = \prod_{l=1}^{L} (I - T_l) \stackrel{\text{def}}{=} \prod_{l=1}^{L} \left(I - \eta \sum_{i \in N^l} \sum_{\alpha \in \mathcal{D}_2} P_{V_{li}^\alpha} \right), \tag{17}$$

$$E_\omega = \prod_{l=1}^{L} \prod_{i \in \mathcal{N}^l} \prod_{\alpha \in \mathcal{D}_2} (I - \omega P_{V_{li}^\alpha}). \tag{18}$$

The product in the above expressions can be arranged in any order; different orders correspond to different schemes. The operators E_J and E_ω correspond to the error propagation operators of V-cycle multigrid methods using damped Jacobi and Gauss–Seidel/SOR as smoothers, respectively.

Let ϕ_{li}^α be normalized basis functions, i.e., $|\phi_{li}^\alpha|_a = 1$. Then $\cos(V_{li}^\alpha, V_{kj}^\beta) = |a(\phi_{li}^\alpha, \phi_{kj}^\beta)|$. Let $K = \{a(\phi_{li}^\alpha, \phi_{kj}^\beta)\}$ and $\Theta = \{\cos(V_{li}^\alpha, V_{kj}^\beta)\}$. Then $\Theta = |K|$. The following lemma provides an estimate for $\|K\|_2$ and $\|\Theta\|_2$.

LEMMA 6.1. *There exists a constant $C > 0$ independent of L and h_l such that*

$$\|K\|_2 \le \|\Theta\|_2 \le C.$$

Proof. For simplicity, we assume that the triangulations are quasi uniform, thus $\gamma = \frac{1}{2}$. Let $\Omega_i^l = \text{supp}(\phi_{li}^\alpha) = \cup_{\tau^l \ni x_i^l} \tau^l$. We assume $l \le k$. There are three cases (cf. Fig 4).

(1) If $\Omega_i^l \cap \Omega_j^k = \emptyset$, then $\cos(V_{li}^\alpha, V_{kj}^\beta) = |a(\phi_{li}^\alpha, \phi_{kj}^\beta)| = 0$.

(2) If there exists an element $\tau^l \subset \Omega_i^l$ such that $\Omega_j^k \subset \tau^l \subset \Omega_i^l$, then

$$\begin{aligned} \cos(V_{li}^\alpha, V_{kj}^\beta) &= |a(\phi_{li}^\alpha, \phi_{kj}^\beta)| = |a_{\Omega_j^k}(\phi_{li}^\alpha, \phi_{kj}^\beta)| = |(\Delta^2 \phi_{li}^\alpha, \phi_{kj}^\beta)_{L^2(\Omega_j^k)}| \\ &\le C |\Delta^2 \phi_{li}^\alpha|_{L^2(\Omega_j^k)} |\phi_{kj}^\beta|_{L^2(\Omega_j^k)} \\ &\le C h_l^{-2} |\phi_{li}^\alpha|_{H^2(\Omega_j^k)} h_k^2 |\phi_{kj}^\beta|_{H^2(\Omega_j^k)} \\ &\le C 4^{-(k-l)} |\phi_{li}^\alpha|_{H^2(\Omega_j^k)} |\phi_{kj}^\beta|_{H^2(\Omega_j^k)} = C 4^{-(k-l)}. \end{aligned}$$

For fixed i, the number of Ω_j^k's that belong to this category is bounded by the number of Ω_j^k that intersect Ω_i^l. This number is bounded by

$$O\left(\frac{mes(\Omega_i^l)}{mes(\Omega_j^k)} \right) = O\left(\frac{h_l^2}{h_k^2} \right) = O(4^{k-l}).$$

(3) If i, j belong to neither the first case nor the second, then Ω_j^k must intersect some of the edges in $\mathcal{E}^l(\Omega_i^l)$, where $\mathcal{E}^l(\Omega_i^l)$ is the set of level-ℓ edges of Ω_i^l as defined in §2.3. For fixed

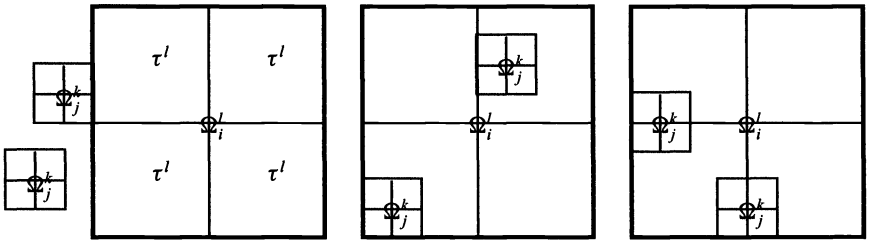

FIG. 4. *Three possible relations between* Ω_j^k *and* Ω_i^l.

i, the number of Ω_j^k that intersects some edges in $\mathcal{E}^l(\Omega_i^l)$ is bounded by $O(h_l/h_k) = O(2^{k-l})$. Note that $a(\phi_{kj}^\beta, \phi_{kj}^\beta) = 1$, and we have

$$\begin{aligned}
\cos(V_{li}^\alpha, V_{kj}^\beta) &= |a(\phi_{li}^\alpha, \phi_{kj}^\beta)| = |a_{\Omega_i^l \cap \Omega_j^k}(\phi_{li}^\alpha, \phi_{kj}^\beta)| \\
&\le |a_{\Omega_i^l \cap \Omega_j^k}(\phi_{li}^\alpha, \phi_{li}^\alpha)|^{1/2} |a(\phi_{kj}^\beta, \phi_{kj}^\beta)|^{1/2} \\
&\le mes(\Omega_i^l \cap \Omega_j^k)^{1/2} |\phi_{li}^\alpha|_{W^{2,\infty}(\Omega_i^l \cap \Omega_j^k)} \le Ch_k |\phi_{li}^\alpha|_{W^{2,\infty}(\Omega_i^l)} \\
&\le Ch_k h_l^{-1} |\phi_{li}^\alpha|_{H^2(\Omega_i^l)} = Ch_k h_l^{-1} \le C2^{-(k-l)}.
\end{aligned}$$

We partition $\Theta = \{\cos(V_{li}^\alpha, V_{kj}^\beta)\}_{i \in \mathcal{N}^l, j \in \mathcal{N}^k, \alpha, \beta \in \mathcal{D}_2, 1 \le l,k \le L}$ into L-by-L blocks,

$$\Theta = \{\Theta^{lk}\}_{1 \le l,k \le L},$$

where Θ^{lk} are $4N_l$-by-$4N_k$ matrices whose elements are given by

$$\Theta^{lk} = \{\Theta^{lk}(i, j)\}_{i \in \mathcal{N}^l, j \in \mathcal{N}^k, \alpha, \beta \in \mathcal{D}_2} = \{\cos(V_{li}^\alpha, V_{kj}^\beta)\}_{i \in \mathcal{N}^l, j \in \mathcal{N}^k, \alpha, \beta \in \mathcal{D}_2}.$$

We claim that

$$\|\Theta^{lk}\|_2 \le C\sqrt{2}^{(-|l-k|)}. \tag{19}$$

To prove this, we assume $l \le k$ and note that for fixed j, the number of Ω_i^l that intersect Ω_j^k is bounded uniformly. Thus the number of nonzeros in each column is bounded uniformly, i.e.;

$$\sum_{i \in \mathcal{N}^l} \sum_{\alpha} \operatorname{sign}(|a(\phi_{li}^\alpha, \phi_{kj}^\beta)|) \le N_0,$$

where N_0 depends only on the coarse triangulation $\mathcal{T}^1$. By a simple norm analysis, we can show that

$$\|\Theta^{lk}\|_2^2 \le N_0 \max_{i,\alpha} \|\mathrm{row}_{i,\alpha}(\Theta^{lk})\|_2^2.$$

We see that $\|\mathrm{row}_{i,\alpha}(\Theta^{lk})\|_2^2$ can be estimated as

$$\begin{aligned}
\|\mathrm{row}_{i,\alpha}(\Theta^{lk})\|_2^2 &= \sum_{j \in \mathcal{N}^k} \sum_{\beta} a(\phi_{li}^\alpha, \phi_{kj}^\beta)^2 \\
&= \left(\sum_{j \in \text{case 1}} + \sum_{j \in \text{case 2}} + \sum_{j \in \text{case 3}} \right) \sum_{\beta} a(\phi_{li}^\alpha, \phi_{kj}^\beta)^2 \\
&\le 0 + C4^{k-l} 4^{-2(k-l)} + C2^{k-l} 2^{-2(k-l)} \le C2^{-(k-l)}.
\end{aligned}$$

Thus

$$\|\Theta^{lk}\|_2 \le \sqrt{N_0}\max_{i,\alpha}\|\mathrm{row}_{i,\alpha}(\Theta^{lk})\|_2 \le C\sqrt{2}^{-(k-l)}.$$

If we replace Θ^{lk} by $\|\Theta^{lk}\|_2$, we get an L-by-L matrix $\tilde{\Theta} = \{\|\Theta^{lk}\|_2\}_{1\le lk\le L}$. The second part of the lemma follows from

$$\|\Theta\|_2 \le \|\tilde{\Theta}\|_2 \le \|\tilde{\Theta}\|_1 \le C\frac{\sqrt{2}+1}{\sqrt{2}-1}.$$

The first part of the lemma is trivial. □

The following theorem provides energy norm estimates for E_J and E_ω.

THEOREM 6.1. *There exist constants $\delta_J < 1$ and $\delta_\omega < 1$ such that*

$$\|E_J\|_a \le \delta_J, \quad \|E_\omega\|_a \le \delta_\omega, \quad 0 < \omega < 2.$$

The constants are independent of number of levels and the order of the product.

Proof. We first estimate $E_\omega = \prod_l \prod_i \prod_\alpha (I - \omega P_{V_{li}^\alpha})$. In this case, $T_i = \omega P_{V_{ij}^\alpha}$ for some subspace V_{ij}^α. Thus $T = \sum T_i = \omega P_{\mathrm{MAS}}$ and $\Theta_T = \omega\Theta = \omega|K|$. By Theorem 5.1, we know that $\lambda_{\min}(T) = \omega\lambda_{\min}(P_{\mathrm{MAS}})$ is uniformly bounded from below. On the other hand, it follows from Lemma 6.1 that $\|\Theta_T\|_2^2$ is uniformly bounded above. The estimate for $\|E_\omega\|_a$ now follows from Theorem 3.1.

We now estimate $E_J = \prod_l (I - \eta\sum_{i,\alpha} P_{V_{li}^\alpha})$. In this case, $T_l = \eta\sum_{i,\alpha} P_{V_{li}^\alpha}$ and $T = \sum T_l = \eta P_{\mathrm{MAS}}$. Thus $\lambda_{\min}(T) = \eta\lambda_{\min}(P_{\mathrm{MAS}})$ is uniformly bounded from below. To estimate $\|\Theta_T\|_2$, we note that

$$\begin{aligned}
a(T_l u, T_k v) &= \eta^2 \sum_{i,\alpha}\sum_{j,\beta} a(P_{V_{li}^\alpha} u, P_{V_{kj}^\beta} v)\\
&\le \eta^2 \sum_{i,\alpha}\sum_{j,\beta} \cos(V_{li}^\alpha, V_{kj}^\beta)|P_{V_{li}^\alpha} u|_a |P_{V_{kj}^\beta} v|_a\\
&\le \eta\|\Theta^{l,k}\|_2 \left(\eta\sum_{i,\alpha}|P_{V_{li}^\alpha} u|_a^2\right)^{1/2}\left(\eta\sum_{j,\beta}|P_{V_{kj}^\beta} v|_a^2\right)^{1/2}\\
&= \eta\|\Theta^{l,k}\|_2 a(T_l u, u)^{1/2} a(T_k v, v)^{1/2}.
\end{aligned}$$

By the definition of $\theta_T^{l,k}$ (cf. (6)), we have

$$\theta_T^{l,k} \le \eta\|\Theta^{l,k}\|_2 \le C\sqrt{2}^{(-|k-l|)}.$$

Therefore,

$$\|\Theta_T\|_2 \le \|\Theta_T\|_1 = \max_l \sum_k \theta_T^{l,k} \le C\frac{\sqrt{2}+1}{\sqrt{2}-1}.$$

The estimate for $\|E_J\|_a$ follows from Theorem 3.1. □

Theorem 6.1 implies that the V-cycle multigrid method, using damped Jacobi, Gauss–Seidel or SOR as smoother, has a rate of convergence that is independent of the number of levels and the order of product.

Similar techniques can be used to establish the convergence rate for the multiplicative HB algorithms (HB multigrid). We can show that the energy norms of the error propagation operators of the multiplicative variants of Algorithms 4.1 and 4.2 are bounded by $1 - Ch^2$ and $1 - C|\log h|^{-2}$, respectively. See [1] for more details about the multiplicative variants of Algorithm 4.1 for second-order elliptic problems.

7. Numerical experiments. In this section, we report on some numerical experiments with additive multilevel methods for the biharmonic problem. For comparison, we have also carried out experiments for the CG method and the Jacobi CG, a preconditioned CG method using a diagonal matrix as a preconditioner. These experiments were carried out for the biharmonic equation on a unit square with homogeneous Dirichlet boundary conditions

$$\begin{aligned} -\Delta^2 u &= f(x) \quad \text{in} \quad \Omega, \\ u = \frac{\partial u}{\partial n} &= 0 \quad \text{on} \quad \partial\Omega. \end{aligned} \tag{20}$$

We divide the domain Ω into 2×2 square elements τ_i^1, $i = 1, \ldots, 4$, and obtain a triangulation $\mathcal{T}^1 = \{\tau_i^1\}$. We then divide each τ_i^1 into 2×2 squares to obtain the triangulation $\mathcal{T}^2 = \{\tau_i^2\}$, etc. The length of an edge of τ_i^l is denoted by h_l, where $h_l = (\frac{1}{2})^l$. In all our experiments, we use the bicubic element. Let P_{NB}, P_{HB}, P_{MHB}, and P_{MAS} denote the linear operator (or matrix) obtained from the conventional nodal basis, the HB, the MHB, and the MAS methods, respectively. We use the preconditioned CG method to solve the corresponding linear systems.

In Tables 1–5, we present numerical results for these methods. The first column contains the number of levels, L, of the multilevel methods, the second column contains the total degrees of freedom N $(= 4(2^L - 1)^2)$. In the third, fourth, and fifth columns, we give the minimum eigenvalues, the maximum eigenvalues, and the condition numbers of the corresponding algorithms. These numbers are computed by the Lanczos methods (as a by-product of the CG computation). The sixth column gives the number of iterations required to decrease the l_2-norm of the residual of the preconditioned system by a factor of $\epsilon = 10^{-6}$.

TABLE 1
CG method using bicubic elements.

7	64516	0.971E–7	0.197E+1	0.202E+8	3313

We have shown that the condition number $\kappa(P_{NB}) = O(h^{-4}) = O(2^{-4L}) = O(16^{-L})$; this is clearly verified by Table 1. For $L = 1$, we have only one interior vertex and thus four degrees of freedom. The matrix is diagonal and has only three distinct eigenvalues and the CG algorithm converges in three steps. Note that the basis functions are not well scaled, $|\phi_{l,i}^{\alpha}|_a \neq \text{const}$. By normalizing the basis function or by using a diagonal scaling technique, the condition number can be improved. This is shown in Table 2.

TABLE 5
MAS method using bicubic elements.

Level	N	$\lambda_{\min}(P)$	$\lambda_{\max}(P)$	$\kappa(P)$	Iter.
1	4	0.100E+1	0.100E+1	0.100E+1	1
2	36	0.588E+0	0.188E+1	0.320E+1	10
3	196	0.471E+0	0.262E+1	0.557E+1	14
4	900	0.444E+0	0.327E+1	0.736E+1	17
5	3844	0.438E+0	0.379E+1	0.867E+1	18
6	15876	0.437E+0	0.422E+1	0.967E+1	19
7	64516	0.436E+0	0.458E+1	0.105E+2	20
8	260100	0.436E+0	0.486E+1	0.112E+2	20

In Table 3, we report on the results for the HB method. The theory suggest that the condition number $\kappa(P_{\mathrm{HB}}) = O(h^{-2}) = O(4^{-L})$. We see that the $\kappa(l+1)/\kappa(l) \approx 4$.

In Table 4, we report on the results for the MHB method. The condition number of P_{MHB} grows slowly as predicted by the theory.

Finally, in Table 5, we report on the results for the MAS method. The condition number of P_{MAS} is bounded (grows very slowly) as predicted by the theory. One can see that the smallest eigenvalues decrease very slowly and quickly approach a limiting value. This confirms our theory. As remarked in [23], the largest eigenvalues, although bounded in theory, increase as fast as they are allowed in the proof. In fact, for the first eight levels, the largest eigenvalues, thus the condition numbers, behave like $C\sqrt{L}$.

MULTILEVEL ALGORITHMS FOR CONSTRAINED COMPACT FIXED POINT PROBLEMS *

C. T. KELLEY† AND E. W. SACHS‡

Abstract. In this paper the authors extend the multilevel algorithm of Atkinson and Brakhage for compact fixed point problems and the projected Newton method of Bertsekas to create a fast multilevel algorithm for parabolic boundary control problems having bound constraints on the control. Results are extended from finite dimension on constraint identification. This approach permits both adaptive integration in time and inexact evaluation of the cost functional.

Key words. projected Newton method, constraint identification, collective compactness, parabolic optimal control problems

AMS subject classifications. 45G10, 47H17, 49K20, 49M15, 65H10, 65K10

1. Introduction.

In this paper, an expanded version of [15], we consider fast algorithms for solution of nonlinear equations that can be expressed in the form

$$u(t) = \mathcal{P}(\mathcal{K}(u))(t), \tag{1.1}$$

where $\mathcal{K}$ is a completely continuous map from $L^\infty(\Omega)$ to $C(\Omega)$ for some bounded $\Omega \subset R^n$, and $\mathcal{P}$ is the map on $C(\Omega)$ given by

$$\mathcal{P}(u)(t) = \begin{cases} u_{\min}(t) & \text{if } u(t) \le u_{\min}(t), \\ u(t) & \text{if } u_{\min}(t) \le u(t) \le u_{\max}(t), \\ u_{\max}(t) & \text{if } u(t) \ge u_{\max}(t), \end{cases} \tag{1.2}$$

for given $u_{\min}$ and $u_{\max}$ in $C(\Omega)$. The particular algorithm we consider is a generalization and synthesis of the Atkinson–Brakhage multilevel algorithm for compact fixed-point problems [3], [6], and the projected Newton method of Bertsekas [5] for bound constrained minimization problems.

A paradigm for problems of the form (1.1) is the Urysohn equation

$$\mathcal{K}(u)(t) = \int_\Omega k(t, s, u(s))\, ds. \tag{1.3}$$

Maps that are not easily expressible in this way, however, are the real target. In particular, we wish to develop an algorithm general enough to be applicable to boundary control problems for partial differential equations. The algorithms and assumptions in this paper provide fast local convergence for problems with continuous controls in one space dimension.

Our methods differ from previous multilevel approaches for such problems [10] in that the smoothing requirements on the approximate Fréchet derivatives at the various levels are relaxed, the results on identification of active indices from [5] can be extended, and the algorithm is a direct approximation of the projected Newton method and therefore quasi-Newton methods can be used to accelerate the convergence.

We are motivated by constrained parabolic optimal control problems in one space dimension. One such problem, a constrained version of the problem considered in [16], is to minimize

$$f(u) = \frac{1}{2}\int_0^1 (y(u;T,x) - z(x))^2\,dx + \frac{\alpha}{2}\int_0^T u^2(t)\,dt, \tag{1.4}$$

where $\alpha > 0$ is given and $y(t,x) = y(u;t,x)$ is the solution to the nonlinear parabolic problem

$$\begin{aligned} &y_t(t,x) = y_{xx}(t,x), \quad 0 < x < 1, \quad 0 < t < T, \\ &y(0,x) = y_0(x), \quad 0 < x < 1, \\ &y_x(t,0) = 0, \quad y_x(t,1) = g(y(t,1)) + u(t), \quad 0 < t < T. \end{aligned} \tag{1.5}$$

In this problem u is allowed to vary over the set

$$\mathcal{U} = \{u \in L^\infty([0,T]) \mid u_{\min}(t) \le u(t) \le u_{\max}(t), \text{ for a.e. } t \in [0,T]\}, \tag{1.6}$$

and the nonlinear function g is assumed to satisfy

$$g \in C^2(R), \qquad g', g'' \in L^\infty(R). \tag{1.7}$$

Such problems arise in metallurgy, for example [21].

The gradient of f in $L^2([0,T])$ is

$$(\nabla f(u))(t) = \alpha u(t) + d(t,1), \tag{1.8}$$

where $d(t,x)$ is the solution of the adjoint problem

$$\begin{aligned} &-d_t(t,x) = d_{xx}(t,x), \quad 0 < x < 1, \quad 0 < t < T, \\ &d(T,x) = y(T,x) - z(x), \quad 0 < x < 1, \\ &d_x(t,0) = 0, \quad d_x(t,1) = g'(y(t,1))d(t,1), \quad 0 < t < T. \end{aligned} \tag{1.9}$$

We let $\mathcal{K}$ be the map that takes u into $-d(t,1)/\alpha$. It is known [20] that $\mathcal{K}$ is completely continuous from $L^\infty([0,T])$ to $C([0,T])$, (and hence a completely continuous map on $C([0,T])$), and in fact is a continuous map from $L^p([0,T])$ to $C([0,T])$ for $p > 2$. Standard techniques in optimization [4] imply that a necessary condition for u^* to be a solution of the problem given by (1.4), (1.5), and (1.6), is that

$$u^* = \mathcal{P}(\mathcal{K}(u^*)).$$

In [16] we considered the unconstrained problem with $\mathcal{U}$ replaced by $C([0,T])$ and used DASSL [7] to perform the integration in time. The use of such an adaptive time integrator required weaker smoothing assumptions than that used in [10] on the maps that take discrete versions of u into those of d. Under these relaxed smoothing assumptions we showed how the Atkinson–Brakhage algorithm could be implemented with appropriate finite difference gradients to obtain fast convergence.

The purpose of this paper is to merge the work in [16] with the ideas in [5] to design a fast algorithm for constrained optimal control problems of the type described above. We extend the projected Newton method to the abstract setting of constrained compact fixed point problems. We generalize the convergence results and the results on identification of the intervals on which $u(t)$ attains its bounds. This latter result is an extension of some of the results in [17].

Once the analysis is complete we can apply the ideas in [16] directly to the problem given by (1.4)–(1.6) and produce a fast algorithm. The algorithm here differs from that proposed in [16] in that numerical Jacobians are not computed on coarse grids. Instead, generalized minimal residual (GMRES) [19] iteration is used to solve the coarse mesh linearized problems needed by the Atkinson–Brakhage iteration and a projected form of the Newton-GMRES iteration [8] is used to solve the coarse mesh problem itself. This modification, suggested for the first time in [12], makes the analysis of the algorithm proposed here simpler than the one from [16]. We conclude the paper with a report on some numerical results for constrained optimal control problems.

In the remainder of this section we briefly describe the projected Newton iteration of Bertsekas and our proposed algorithm for (1.1). We do not discuss the line search used in [5] to ensure global convergence since the focus of this paper is fast algorithms for local convergence. We take the position that the method from [5] is sufficient to obtain convergence from distant initial iterates on coarse meshes and that the solution so obtained can be interpolated to provide a good initial iterate on finer meshes.

The problem considered in [5] is to minimize a function f defined on a box in R^N

$$\mathcal{U}_N = \{u \in R^N \mid u^i_{\min} \le u^i \le u^i_{\max},\ 1 \le i \le N\}.$$

Here u^i denotes the ith component of the vector $u \in R^N$ and $u_{\min}, u_{\max} \in R^N$ are given. If f is differentiable there is a solution u^* and each solution satisfies the necessary condition

$$u = \mathcal{P}(u - \nabla f(u)) \tag{1.10}$$

where, similarly to (1.2) for the continuous problem,

$$(\mathcal{P}u)^i = \begin{cases} u^i_{\min} & \text{if } u^i \le u^i_{\min}, \\ u^i & \text{if } u^i_{\min} \le u^i \le u^i_{\max}, \\ u^i_{\max} & \text{if } u^i \ge u^i_{\max}. \end{cases}$$

The second-order sufficient condition for optimality of u^* is that (1.10) holds and that the matrix H given by

$$H = P_A + P_I \nabla^2 f(u^*) P_I$$

be positive definite. Here P_A is the projection

$$(P_A u)^i = \begin{cases} u^i & \text{if } (u^*)^i = u^i_{\max} \text{ and } (\nabla f(u^*))^i < 0, \\ u^i & \text{if } (u^*)^i = u^i_{\min} \text{ and } (\nabla f(u^*))^i > 0, \\ 0 & \text{otherwise,} \end{cases}$$

and $P_I = I - P_A$.

The iteration proposed in [5] is of the form

$$u_{n+1} = \mathcal{P}(u_n - \alpha_n H_n^{-1} \nabla f(u_n)), \tag{1.11}$$

where

$$H_n = P_{A,n} + P_{I,n} \nabla^2 f(u_n) P_{I,n},$$

α_n is selected by an Armijo type rule, and $P_{A,n}$ and $P_{I,n}$ are approximations to P_A and P_I, respectively. The construction of $P_{A,n}$ and $P_{I,n}$ in [5] ensures that in the iteration $P_{A,n} = P_A$

and $\alpha_n = 1$ for n sufficiently large. After the active set has been identified (when $P_{A,n} = P_A$) the iteration reduces to Newton's method on the inactive set and therefore local quadratic convergence holds. Crucial to the analysis in [5] is identification of the active set after finitely many iterations. This allows one to reduce the analysis of the limiting behavior of the iteration to that for Newton's method.

For problems with a continuum of constraints, such as the ones under consideration in this paper, identification of the active set after finitely many iterations is unlikely. To use the ideas of [5] one must change the algorithm to take this into consideration and change the analysis as well. In §2 we introduce notation and discuss the assumptions needed to make the estimate

$$\|u - u^*\|_X \leq K\|u - \mathcal{P}(\mathcal{K}(u))\|_X$$

for u sufficiently near u^* and some constant K. This estimate is trivial in the finite dimensional case if f is sufficiently smooth, u is an element of the sequence of iterates, and the active set has already been identified. In the infinite dimensional case considered here attention must be paid to the size of sets in which activity of the constraints is unclear. In §3 we show how the algorithm in [5] can be extented to take the continuum of constraints into account and prove a local convergence result. The results in these sections require only a modest smoothing assumption. We show how the Atkinson–Brakhage algorithm can be used to create a fast algorithm and present some numerical results in §4. The design of the fast algorithm requires a stronger compactness assumption than the results in the earlier sections.

2. The basic estimate. In this section we state our assumptions on the nonlinearity and show that for continuous u the error in the solution is proportional to the size of the nonlinear residual in a neighborhood of the solution. We work in the space of continuous functions on Ω, $C = C(\Omega)$ and also on $X = L^\infty(\Omega)$, where $\Omega \subset R^d$. We assume that $\mathcal{K}$ is a smooth map on X and seek to solve the constrained compact fixed point problem

$$\mathcal{F}(u) = u - \mathcal{P}(\mathcal{K}(u)), \tag{2.1}$$

where $\mathcal{P}$ is given by (1.2). We note that since $\mathcal{K}$ maps L^p to $C = C(\Omega)$, the point evaluation implicit in $\mathcal{P}$ is defined and therefore $\mathcal{F}$ is a well-defined map on X. The spaces X and C are both given the sup norm, which we denote by $\|\cdot\|_X$, and C is a closed subspace of X.

In keeping with the application to optimal control we will denote points in Ω by t. For $t \in \Omega$ we let U be given by

$$U(t) = \{u \in X \mid u_{\min}(t) \leq u(t) \leq u_{\max}(t)\},$$

where $u_{\min}, u_{\max} \in C$, and define the two point set

$$\partial U(t) = \{u_{\min}(t), u_{\max}(t)\}.$$

If $S \subset \Omega$ we let $S^c = \Omega \setminus S$ be the complement of S in Ω. If S and T are subsets of Ω we denote the symmetric difference by

$$S \Delta T = (S \cup T) \setminus (S \cap T).$$

Throughout this paper χ_S will denote the characteristic function of the set S and μ will denote Lebesgue measure on R^d. We will let $\mathcal{L}(X, Y)$ be the Banach space of bounded linear maps from a Banach space X to a Banach space Y and let $\mathcal{COM}(X)$ be the space of compact linear maps on X.

2.1. Differentiability, smoothing, and nonsingularity assumptions. We make the following differentiability assumption on $\mathcal{K}$.

Assumption 2.1. There is a solution $u^* \in C$ to (2.1) and a neighborhood $\mathcal{N} \subset X$ of u^* in which the $\mathcal{K}$ is Lipschitz continuously Fréchet differentiable in X and in C.

For future use we let γ be the Lipschitz constant for the map $\mathcal{K}$ and γ_1 the Lipschitz constant for the maps $\mathcal{K}'$.

Our smoothing assumptions are given in the following statements.

Assumption 2.2. There is $p \in [1, \infty)$ such that the family of maps $\{\mathcal{K}'(u)\}$, where $u \in \mathcal{N}$ is a uniformly bounded subset of $\mathcal{L}(L^p(\Omega), C)$. Let

$$\sup_{u \in \mathcal{N}} \|\mathcal{K}'(u)\|_{\mathcal{L}(L^p(\Omega), C)} = M_K. \tag{2.2}$$

An immediate consequence of these assumptions is stated in Proposition 2.1.

PROPOSITION 2.1. *For all measurable $S, T \subset \Omega$ and $u \in \mathcal{N}$*

$$\|\mathcal{K}'(u)(\chi_S - \chi_T)\|_C \leq M_K \mu(S \Delta T)^{1/p}.$$

We define active and inactive sets for u^* by

$$A^* = \{t \mid u^*(t) \in \partial U(t)\} \quad \text{and} \quad I^* = \{t \mid u^*(t) \in \operatorname{int}(U)(t)\}. \tag{2.3}$$

In (2.3) $\operatorname{int}(U)(t)$ is defined to be the interval

$$\operatorname{int}(U)(t) = (u_{\min}(t), u_{\max}(t)).$$

For a measurable subset S of Ω define

$$\mathcal{K}_S(u) = \chi_S \mathcal{K}(u^* + \chi_S(u - u^*))$$

and

$$\mathcal{G}_S(u) = u - \mathcal{K}_S(u).$$

Clearly, we have the following proposition.

PROPOSITION 2.2. *For all measurable $I \subset \Omega$ $\mathcal{G}_I$ is Lipschitz continuously Fréchet differentiable as a map on X and L^p. If I is closed, $\mathcal{G}_I$ is Lipschitz continuously Fréchet differentiable as a map on $C(I)$. Moreover there is M_1, independent of I, such that*

$$\|\mathcal{G}_I'(u)\|_{\mathcal{L}(C(I))}, \text{ (if } I \text{ is closed)}, \|\mathcal{G}_I'(u)\|_{\mathcal{L}(X)}, \|\mathcal{G}_I'(u)\|_{\mathcal{L}(L^p)} \leq M_1 \tag{2.4}$$

for all $u \in \mathcal{N}$.

In Proposition 2.2, the action of $\mathcal{G}_I'(u)$ on $w \in C(I)$ is understood to be given by extension of w to zero on $[0, T] \setminus I$, application of $\mathcal{G}_I'(u)$ to that extension, and restriction to I.

The next assumption is needed to make the extension of the projected Newton method described in [5] converge quadratically.

Assumption 2.3. $\mathcal{G}_{I^*}' = I - \chi_{I^*}\mathcal{K}'(u^*)\chi_{I^*}$ is a nonsingular map on X and on L^p. There are η_1 and M_2 such that for every $u \in \mathcal{N}$ and every measurable $I \subset \Omega$ such that $\|u - u^*\|_X < \eta_1$ and $\mu(I \Delta I^*) < \eta_1$ the map $\mathcal{G}_I'(u)$ is a nonsingular map on C, on X, and on L^p, and

$$\|\mathcal{G}_I'(u)^{-1}\|_{\mathcal{L}(C)}, \|\mathcal{G}_I'(u)^{-1}\|_{\mathcal{L}(X)}, \|\mathcal{G}_I'(u)^{-1}\|_{\mathcal{L}(L^p)} \leq M_2. \tag{2.5}$$

The most simple analog of the iteration (1.11) from [5] is

$$u_{n+1} = \mathcal{P}(u_n - A_n \mathcal{F}(u_n)), \tag{2.6}$$

where A_n is an approximation of $\mathcal{G}_{I^*}'(u^*)^{-1}$. Construction of an extension of (1.11) that has good L^∞ convergence properties requires a more complex iteration than that given in (2.6).

Fundamental to the local convergence analysis of any Newton-like algorithm is a bound of the error in terms of the size of $\mathcal{F}$. The remainder of this section is devoted to such an estimate.

2.2. Assumptions and results on sets A^* and I^*. The next two lemmas are simple consequences of the Lipschitz continuity of $\mathcal{K}$ and the convexity of U. Before stating them we recall some more notation. If $S \subset R^k$ for some k and $t \in R^k$, we denote the distance from t to S by

$$\text{dist}(t, S) = \inf\{s \in S \mid \|t - s\|_{R^k}\}.$$

Note that

$$\mathcal{G}(u) = \mathcal{G}_\Omega(u) = u - \mathcal{K}(u).$$

For $u \in C$ define

$$\Omega_\delta(u) = \{t \mid |\mathcal{G}(u)(t)| \geq \delta\}, \quad \text{and} \quad \Omega_\delta^* = \Omega_\delta(u^*) = \{t \mid |\mathcal{G}(u^*)(t)| \geq \delta\}. \tag{2.7}$$

We require the following trivial lemma.

LEMMA 2.3. *$\Omega_\delta^* \subset A^*$ for all $\delta > 0$.*

Proof. Since $u^*(t) = \mathcal{P}(\mathcal{K}(u^*))(t)$ either $\mathcal{G}(u^*)(t) = 0$ or $u^*(t) = \mathcal{P}(\mathcal{K}(u^*))(t) \neq (\mathcal{K}(u^*))(t)$. Hence if $t \in \Omega_\delta^*$ then $u^*(t)$ is the image under $\mathcal{P}$ of a point outside of U and therefore $u^*(t) \in \partial U$. This means that $t \in A^*$ as asserted. □

Recall that we denote by γ the Lipschitz constant for $\mathcal{K}$ in the set $\mathcal{N}$; therefore, $\bar{\gamma} = 1 + \gamma$ is the Lipschitz constant for $\mathcal{G}$ in $\mathcal{N}$. We have the following lemma.

LEMMA 2.4. *Assume that Assumption* 2.1 *holds. There is $\sigma_0 > 0$ such that if $u \in C$ satisfies*

$$\|u - u^*\|_X < \sigma \leq \sigma_0, \tag{2.8}$$

and $\delta > \bar{\gamma}\sigma$, then

$$\Omega_\delta(u) \subset \Omega_{\delta - \bar{\gamma}\sigma}^* \subset A^*.$$

Proof. Let $\sigma_0 < \delta/\bar{\gamma}$ be small enough so that that (2.8) implies that $u \in \mathcal{N}$. Note that for $t \in \Omega_\delta(u)$,

$$|\mathcal{G}(u^*)(t)| \geq |\mathcal{G}(u)(t)| - \bar{\gamma}\sigma \geq \delta - \bar{\gamma}\sigma > 0.$$

Hence $t \in \Omega_{\delta - \bar{\gamma}\sigma}^* \subset A^*$ and the proof is complete. □

Assumption 2.4. There is $\nu \in (0, 1)$ such that $u_{\max}(t) \geq u_{\min}(t) + \nu$ for all $t \in \Omega$. A^* is the closure of a finite union of disjoint open components. There is $c_0 > 0$ such that for all $\delta > 0$ the sets

$$E_\delta = \{t \in R^d \mid \text{dist}(t, \partial A^*) < \delta\}$$

are uniformly bounded in measure by

$$\mu(E_\delta) \leq c_0 \delta^d. \tag{2.9}$$

On each component of A^* either $u = u_{\max}$ or $u = u_{\min}$.

Moreover, there is c_1 such that

$$\begin{aligned} &|\mathcal{G}(u^*)(t)| \geq c_1 \text{dist}(t, \partial A^*) \quad \text{for all } t \in A^* \quad \text{and} \\ &\text{dist}(t, A^*) \leq c_1^{-1} \text{dist}(u^*(t), \partial U(t)) \quad \text{for all } t \in I^*. \end{aligned} \tag{2.10}$$

Note that (2.9) and the assertion that on each component of A^*, either $u = u_{\max}$ or $u = u_{\min}$ follow from the previous parts of the assumption if $d = 1$. For $d > 1$ they may be viewed as regularity conditions on the boundary of A^*.

LEMMA 2.5. *Let Assumptions* 2.1 *and* 2.4 *hold. Then there are* c_2 *and* δ_1 *such that if* $\delta \le \delta_1$, *then* $\Omega_\delta^* \subset A^*$ *and*

$$\mu(A^* \setminus \Omega_\delta^*) \le c_2 \delta^d. \tag{2.11}$$

Proof. Let

$$\delta_1 = \min(\delta_0, \delta_0/c_1),$$

where δ_0 and c_1 are from Assumption 2.4. By Lemma 2.3 $\Omega_\delta^* \subset A^*$. If $t \in A^* \setminus \Omega_\delta^*$, then $|\mathcal{G}(u^*)(t)| < \delta$ and $u^*(t) \in \partial U(t)$. Hence, by (2.10) from Assumption 2.4 for $\delta \le \delta_1 \le \delta_0$

$$\operatorname{dist}(t, \partial A) < \delta/c_1.$$

This implies that

$$A^* \setminus \Omega_\delta^* \subset E_{\delta/c_1}$$

and therefore, by (2.9) from Assumption 2.4,

$$\mu(A^* \setminus \Omega_\delta^*) \le c_0 c_1^{-d} \delta^d.$$

This completes the proof with $c_2 = c_0 c_1^{-d}$. □

Let $\sigma_1 = \min(\sigma_0, \delta_1/\bar{\gamma})/2$. Under all of our assumptions, for a given $u \in C$ such that $\|u - u^*\|_X < \sigma \le \sigma_1$, we have by Lemma 2.4 that

$$\Omega_{\delta_1}(u) \subset \Omega_{\delta_1/2}^* \subset A^*.$$

Define

$$\bar{I} = \{t \mid \mathcal{K}(u)(t) \in \operatorname{int}(U)(t)\} \cap I^*. \tag{2.12}$$

Since $A^* \cap I^* = \emptyset$, $\Omega_{\delta_2}^* \subset A^*$, and $\bar{I} \subset I^*$, we can decompose Ω into the disjoint union

$$\Omega = \Omega_{\delta_2}^* \cup \bar{I} \cup R(u), \tag{2.13}$$

where $\delta_2 = \delta_1/2$ and

$$R(u) = \Omega \setminus (\bar{I} \cup \Omega_{\delta_2}^*). \tag{2.14}$$

As a trivial corollary to Lemma 2.5 we obtain the following estimate.

COROLLARY 2.6. *Let Assumptions* 2.1 *and* 2.4 *hold. If* $u \in C$ *and* $\|u - u^*\|_X < \sigma_1$ *then*

$$\mu((R(u) \cup \bar{I}) \setminus I^*) = \mu(A^* \setminus \Omega_{\delta_2}^*) \le c_2 \delta_2^d.$$

The next lemma will enable us to estimate the size of $R(u)$.

LEMMA 2.7. *Let Assumption* 2.4 *hold. There is* c_3 *such that for all* $\delta > 0$

$$\mu\left(\{t \mid \operatorname{dist}(\mathcal{K}(u^*)(t), \partial U(t)) < \delta\}\right) \le c_3 \delta^d. \tag{2.15}$$

Proof. Let

$$S = \{t \mid \operatorname{dist}(\mathcal{K}(u^*)(t), \partial U(t)) < \delta\}.$$

If $t \in S \cap A^*$, then

$$\operatorname{dist}(\mathcal{K}(u^*)(t), \partial U(t)) = \operatorname{dist}(\mathcal{K}(u^*)(t), \mathcal{P}(\mathcal{K}(u^*)(t))) = |\mathcal{G}(u^*)(t)| < \delta$$

and hence, by (2.10) from Assumption 2.4, $\operatorname{dist}(t, \partial A^*) < \delta/c_1$. Hence $S \cap A^* \subset E_{\delta/c_1}$.

If $t \in S \cap I^*$ then (2.10) from Assumption 2.4 implies that $\text{dist}(t, A^*) < c_1^{-1}\delta$ and therefore $S \cap I^* \subset E_{\delta/c_1}$. Hence $S \subset E_{\delta/c_1}$ and therefore

$$\mu(S) \leq \mu(E_{\delta/c_1}) \leq c_0 c_1^{-d} \delta^d.$$

This completes the proof with $c_3 = c_0 c_1^{-d}$. □

LEMMA 2.8. *Let Assumptions* 2.1 *and* 2.4 *hold. Then if* $u \in C$ *is such that* $\|u - u^*\|_X \leq \sigma_1$ *and* $R(u)$ *is defined by* (2.14), *then*

$$\mu(R(u)) \leq c_3 \delta_2^d. \tag{2.16}$$

Proof. If $t \in R(u)$ then $|\mathcal{G}(u^*)(t)| < \delta_2$ because $R(u) \cap \Omega^*_{\delta_2} = \emptyset$. We divide the remainder of the proof into two cases. $t \in R(u)$ implies that $|\mathcal{G}(u^*)(t)| < \delta_2$ and that either (1) $\mathcal{K}(u^*)(t) \notin \text{int}(U)(t)$ or (2) $\mathcal{K}(u)(t) \notin \text{int}(U)(t)$ and $\mathcal{K}(u^*)(t) \in \text{int}(U)(t)$.

In case (1) $|\mathcal{G}(u^*)(t)| < \delta_2$ implies that $\text{dist}(\mathcal{K}(u^*)(t), \partial U(t)) < \delta_2$. In case (2), Lipschitz continuity implies that

$$|\mathcal{K}(u)(t) - \mathcal{K}(u^*)(t)| \leq \gamma \sigma_1$$

and hence, since $\mathcal{K}(u^*)(t) \in \text{int}(U)(t)$ in case (2),

$$\text{dist}(\mathcal{K}(u^*)(t), \partial U(t)) \leq \gamma \sigma_1 \leq \bar{\gamma} \sigma_1 \leq \delta_2.$$

These estimates imply that

$$R(u) \subset \{t \mid \text{dist}(\mathcal{K}(u^*)(t), \partial U(t)) < \delta_2\}$$

and therefore, by Lemma 2.7,

$$\mu(R(u)) \leq c_3 \delta_2^d.$$

This completes the proof. □

COROLLARY 2.9. *Let Assumptions* 2.1 *and* 2.4 *hold. Then if* $u \in X$ *is such that* $\|u - u^*\|_X \leq \sigma_1$, *then*

$$\mu(\bar{I} \Delta I^*) \leq (c_2 + c_3) \delta_2^d.$$

LEMMA 2.10. *Let Assumption* 2.1 *hold. Then if* $u \in X$ *is such that* $\|u - u^*\|_X < \sigma_1$, *then*

$$\mathcal{P}(\mathcal{K}(u)(t)) = u^*(t)$$

for all $t \in \Omega^*_{\delta_2}$, *and*

$$|u(t) - u^*(t)| \leq \|\mathcal{F}(u)\|_X$$

for all $t \in \Omega^*_{\delta_2}$.

Proof. Let $t \in \Omega^*_{\delta_2} \subset A^*$. Without loss of generality we may assume that $u^*(t) = u_{\max}(t)$ and $\mathcal{K}(u^*)(t) \geq u_{\max}(t) + \delta_2$. Since $\|u - u^*\| < \sigma_1$,

$$\mathcal{K}(u)(t) \geq \mathcal{K}(u^*)(t) - \gamma \sigma_1 \geq u_{\max}(t) + \delta_2 - \bar{\gamma} \sigma_1 > u_{\max}(t).$$

Hence $\mathcal{P}(\mathcal{K}(u))(t) = u_{\max}(t) = u^*(t)$. Therefore

$$|u(t) - u^*(t)| = |u(t) - \mathcal{P}(\mathcal{K}(u)(t))| = |\mathcal{F}(u)(t)| \leq \|\mathcal{F}(u)\|_X.$$

This completes the proof. □

2.3. The main estimate. Now we reduce δ_1 if necessary so that

$$(c_2 + c_3)\delta_2^d < \eta_1, \tag{2.17}$$

where η_1 is the bound in Assumption 2.3. This has the effect of reducing δ_2 and σ_1. By Corollary 2.9 this implies that $\mathcal{G}'_{\bar{I}}(u)$ satisfies (2.5).

We can now formally state and prove the main result in this section

THEOREM 2.11. *Let Assumptions* 2.1–2.4 *hold. There are* $\sigma_2 > 0$ *and* $K > 0$ *such that if* $u \in C$ *and* $\|u - u^*\|_X \le \sigma_2$, *then*

$$\|u - u^*\|_X \le K\|\mathcal{F}(u)\|_X.$$

Proof. We let $\sigma_2 = \sigma_1$ for now. We will reduce σ_2 as the proof progresses. Let $\sigma^* = \|u - u^*\|_X \le \sigma_2$ and let $\|\mathcal{F}(u)\|_X = \epsilon$. We will estimate σ^* in terms of ϵ in the course of the proof in a way that can be applied to show $\sigma^* = O(\epsilon)$.

Without loss of generality we assume that $\epsilon < \sigma^*$ as if that is not the case the lemma holds with $K = 1$. We decompose the projected gradient map into three parts

$$u - \mathcal{P}(\mathcal{K}(u)) = \chi_{\bar{I}}(u - \mathcal{P}(\mathcal{K}(u))) + \chi_{R(u)}(u - \mathcal{P}(\mathcal{K}(u))) + \chi_{\Omega^*_{\delta_2}}(u - \mathcal{P}(\mathcal{K}(u))).$$

Since $\mathcal{K}(u) = u^*$ on $\Omega^*_{\delta_2}$ by Lemma 2.10 and $\mathcal{P}\mathcal{K}(u) = \mathcal{K}(u)$ on $\bar{I}$ by definition, we have

$$u - \mathcal{P}\mathcal{K}(u) = \chi_{\bar{I}}(u - \mathcal{K}(u)) + \chi_{R(u)}(u - \mathcal{P}(\mathcal{K}(u))) + \chi_{\Omega^*_{\delta_2}}(u - u^*).$$

Let $e = u - u^*$, $e_I = \chi_{\bar{I}}e$, $e_R = \chi_{R(u)}e$, and $e_\delta = \chi_{\Omega^*_{\delta_2}}e$. Therefore $\|e_\delta\|_X \le \|\mathcal{F}(u)\|_X = \epsilon$ by Lemma 2.10. To analyze the sizes of e_I and e_R, we note that $\mathcal{K}$ is a Lipschitz continuous map from $L^p(\Omega)$ to X with Lipschitz constant M_K, where M_K is the bound on $\|\mathcal{K}'\|_{\mathcal{L}(L^p(\Omega),X)}$ from (2.2), Hence

$$\|\mathcal{K}(u) - \mathcal{K}(u^* + e_I)\|_X \le \gamma\|e_\delta\|_X + M_K\|e_R\|_{L^p} \le \gamma\epsilon + M_K\|e_R\|_{L^p}.$$

We write $\chi_{\bar{I}}(u - \mathcal{K}(u))$ as

$$\chi_{\bar{I}}(u - \mathcal{K}(u)) = \chi_{\bar{I}}(u - \mathcal{K}(u^* + e_I)) + \zeta_1(u) = \chi_{\bar{I}}\mathcal{G}_{\bar{I}}(u) + \zeta_1(u), \tag{2.18}$$

where

$$\zeta_1(u) = \chi_{\bar{I}}(\mathcal{K}(u^* + e_I) - \mathcal{K}(u^* + e_I + e_R + e_\delta)).$$

Recalling that

$$\|\mathcal{K}'(u)\|_{\mathcal{L}(L^p,X)} \le M_K$$

for all $u \in \mathcal{N}$ we have, since $\|e_R\|_{L^p} \le \|e_R\|_X \mu(R(u))^{1/p}$,

$$\begin{aligned} \|\zeta_1(u)\|_X &\le \gamma\|e_\delta\|_X + M_K\|e_R\|_{L^p} \\ &\le \gamma\epsilon + M_K\mu(R(u))^{1/p}\|e_R\|_X \le \gamma\epsilon + M_K\mu(R(u))^{1/p}\sigma^*. \end{aligned} \tag{2.19}$$

Hence, by (2.5),

$$\|e_I\|_X \le M_2\|\zeta_1(u)\|_X \le M_2(\gamma\epsilon + M_K c_3^d \delta_2^{d/p}\sigma^*). \tag{2.20}$$

For convenience we rewrite (2.20) as

$$\|e_I\|_X \le c_4(\epsilon + \delta_2^{d/p}\sigma^*), \tag{2.21}$$

where $c_4 = M_2 \max(\gamma, M_K c_3^d)$.

Now, reduce δ_1 if necessary so that

$$c_4\delta_2^{d/p} < 1/(8\gamma) \quad \text{and} \quad M_K(c_3\delta_2^d)^{1/p} < 1/8.$$

At this point we have shown that if δ_1 is sufficiently small, then $\|e_\delta\| \le \|\mathcal{F}(u)\|$

$$\|e_I\| \le c_4\|\mathcal{F}(u)\| + \sigma^*/(8\gamma).$$

We will obtain a similar estimate for $\|e_R\|_X$ and then apply these estimates to obtain the conclusion $\|e\|_X = O(\epsilon)$.

Let $\xi = \chi_{R(u)}\mathcal{F}(u)$. Letting $e_T = e_I + e_\delta$, we have

$$\|e_T\|_X \le (1 + c_4)\epsilon + \sigma^*/(8\gamma).$$

Since $u^* = \mathcal{P}(\mathcal{K}(u^*))$ we may write

$$e_R = \xi + \zeta_2(u),$$

where

$$\zeta_2(u) = \chi_{R(u)}(\mathcal{P}(\mathcal{K}(u^* + e_T + e_R)) - \mathcal{P}(\mathcal{K}(u^*))).$$

Since $\|e_R\|_X \le \sigma^*$,

$$\begin{aligned}
\|\zeta_2(u)\|_X &\le \gamma\|e_T\|_X + \|\mathcal{P}(\mathcal{K}(u^* + e_R)) - \mathcal{P}(\mathcal{K}(u^*))\|_X \\
&\le \gamma((1 + c_4)\epsilon + \sigma^*/(8\gamma)) + M_K\mu(R(u))^{1/p}\|e_R\|_X \\
&\le \gamma(1 + c_4)\epsilon + \sigma^*/8 + M_K(c_3\delta_2^d)^{1/p}\sigma^* \\
&\le \gamma(1 + c_4)\epsilon + \sigma^*/4.
\end{aligned} \tag{2.22}$$

Here we use the fact that $\mathcal{P}$ has Lipschitz constant 1 because it is a projection onto a convex set.

Noting that $\|\xi\|_X \le \|\mathcal{F}(u)\|_X = \epsilon$, we have that

$$\|e_R\|_X \le \epsilon + \|\zeta_2(u)\|_X \le K_2\epsilon + \sigma^*/4,$$

where $K_2 = 1 + \gamma(1 + c_4)$. Therefore

$$\|e\|_X = \sigma^* \le \|e_R\|_X + \|e_T\|_X \le (1 + c_4 + K_2)\epsilon + 3\sigma^*/4$$

and

$$\sigma^*/4 \le (1 + c_4 + K_2)\epsilon.$$

This completes the proof with $K = 4(1 + c_4 + K_2)$. □

3. The algorithm. In this section we describe our Newton-like iteration in broad terms. The details of an efficient implementation will be presented in §4. Our first task is to formulate the projected Newton iteration and analyze its convergence properties. Following that, it is easy to describe the class of algorithms that we implement.

Assume that the assumptions of Theorem 2.11 hold. Let $u_c \in C$ be such that $\|e_c\| < \sigma_2$, where $e_c = u_c - u^*$. We let

$$\|\mathcal{F}(u_c)\|_X = \delta_c.$$

Let $\bar{p} \in (0, 1)$. We define the sets

$$\begin{aligned} A_c &= \{t \mid \mathcal{P}(\mathcal{K}(u_c))(t) \neq \mathcal{K}(u_c)(t),\ |\mathcal{G}(u_c)(t)| \geq \delta_c^{\bar{p}}\}, \\ I_c &= \{t \mid \mathcal{P}(\mathcal{K}(u_c))(t) = \mathcal{K}(u_c)(t)\}, \\ R_c &= \{t \mid \mathcal{P}(\mathcal{K}(u_c))(t) \neq \mathcal{K}(u_c)(t),\ |\mathcal{G}(u_c)(t)| < \delta_c^{\bar{p}}\}. \end{aligned} \tag{3.1}$$

Note that the point evaluations required to to determine the sets A_c, I_c, and R_c are well defined since $u_c \in C$. Note also that I_c is a closed set because $u_{\min}$ and $u_{\max}$ are continuous.

Using (2.6) as an iteration would, as we shall see, not produce iterates that converge in the uniform norm. We use an evaluation of $\mathcal{K}$ to remedy this. We propose the iteration

$$\begin{aligned} u^{1/3} &= \chi_{A_c}\mathcal{P}\mathcal{K}(u_c) + \chi_{I_c \cup R_c} u_c, \\ u^{2/3} &= u^{1/3} - \mathcal{G}'_{I_c}(u^{1/3})^{-1}\mathcal{F}(u^{1/3}), \\ u_+ &= \mathcal{P}(\mathcal{K}(u^{2/3})). \end{aligned} \tag{3.2}$$

In the final form of the algorithm we advocate here, we will replace

$$\mathcal{G}'_{I_c}(u^{1/3})^{-1}\mathcal{F}(u^{1/3})$$

with an approximation of the action of $\mathcal{G}'_{I_c}(u^{1/3})^{-1}$ on $\mathcal{F}(u^{1/3})$ that can be evaluated efficiently. We note here that even though the intermediate iterate $u^{1/3}$ is not continuous on [0,T], it is everywhere defined and continuous on the set $I_c \cup R_c$, and particularly on the closed set I_c; and so methods for approximation of integral operators on the space of continuous functions are applicable to the approximation of the action of $\mathcal{G}'_{I_c}(u^{1/3})^{-1}$. We defer the construction of this approximation to §4, and in this section consider (3.2) and estimate $e^{2/3}$ in the L^p norm, where p is the exponent in Assumption 2.2. That estimate leads directly to a uniform estimate for $e_+ = u_+ - u^*$ by Assumption 2.2.

LEMMA 3.1. *Let Assumptions* 2.1–2.4 *hold. Let* σ_2 *and* K *be the constants from Theorem* 2.11. *Let* $u_c \in X$ *be such that*

$$\|e_c\|_X \leq \min\{\sigma_2, (1/2 + \gamma/K)^{-1/(1-\bar{p})}/\gamma, \nu/\gamma\} \tag{3.3}$$

then $A_c \subset A^*$ *and* $u^{1/3} = u^*$ *on* A_c.

Proof. Since $\delta_c \leq \gamma\|e_c\|_X$, (3.3) implies that

$$\delta^{1-\bar{p}} < (1/2 + \gamma/K)^{-1}. \tag{3.4}$$

Let $t \in A_c$, since

$$|\mathcal{G}(u^*)(t)| \geq |\mathcal{G}(u_c)(t)| - \gamma\|e_c\| \geq \delta_c^{\bar{p}} - \gamma\delta_c/K \geq \delta_c/2$$

by (3.4). Hence $A_c \subset A^*$ by Lemma 2.3.

To complete the proof, note that if $t \in A_c$ then $\mathcal{K}(u)(t) \in \partial U(t)$. As

$$|u^*(t) - \mathcal{P}(\mathcal{K}(u^*))(t)| = |\mathcal{P}(\mathcal{K}(u))(t) - \mathcal{P}(\mathcal{K}(u^*))(t)| \le \gamma \|e_c\|_X < \nu$$

we must have $u^*(t) = \mathcal{P}(\mathcal{K}(u))(t) = u^{1/3}(t)$ for $t \in A_c$. This completes the proof. □

The set R_c is small. This is made precise by the following lemma.

LEMMA 3.2. *Let Assumptions* 2.1–2.4 *and* (3.3) *hold. Then if* $u_c \in X$ *is such that*

$$\|e_c\|_X \le (\gamma K)^{-1/(1-\bar{p})}/\gamma, \tag{3.5}$$

then

$$\mu(R_c) \le c_3 3^d \delta_c^{\bar{p}/d},$$

where c_3 *is the constant from Lemma* 2.7.

Proof. By (3.3) $\|e_c\|_X < 1/\gamma$. Note that if $t \in R_c$, then $\mathcal{P}(\mathcal{K}(u_c))(t) \in \partial U(t)$ and also

$$\begin{aligned} |\mathcal{K}(u_c)(t) - \mathcal{P}(\mathcal{K}(u_c))(t)| &\le |\mathcal{G}(u_c)(t)| + |\mathcal{F}(u_c)(t)| \\ &\le \delta_c^{\bar{p}} + \delta_c \le 2\delta_c^{\bar{p}}. \end{aligned}$$

The last estimate follows from the assumption that $\|e_c\|_X < 1/\gamma$, which implies that $\delta_c < 1$. Therefore

$$\begin{aligned} R_c &\subset \{t \mid \operatorname{dist}(\mathcal{K}(u_c)(t), \partial U(t)) < 2\delta_c^{\bar{p}}\} \\ &\subset \{t \mid \operatorname{dist}(\mathcal{K}(u^*)(t), \partial U(t)) < 2\delta_c^{\bar{p}} + \bar{\gamma}\|e_c\|\} \\ &\subset \{t \mid \operatorname{dist}(\mathcal{K}(u^*)(t), \partial U(t)) < 2\delta_c^{\bar{p}} + \bar{\gamma}K\delta_c\} \\ &\subset \{t \mid \operatorname{dist}(\mathcal{K}(u^*)(t), \partial U(t)) < 3\delta_c^{\bar{p}}\}. \end{aligned}$$

The last estimate above follows from (3.5). The conclusion of the lemma is a direct application of Lemma 2.7. □

A_c will serve as the approximation to the active set. An immediate corollary of Lemmas 3.1 and 3.2 is a theorem on identification of the active set.

THEOREM 3.3. *Let Assumptions* 2.1–2.4 *and* (3.3) *hold. Assume that* $\delta_c < 1$. *Then there is* c_A *such that*

$$\mu(A^* \setminus A_c) \le c_A \delta_c^{\bar{p}/d}.$$

Proof. If $t \in A^* \setminus A_c$ then either $t \in R_c$ or $t \in I_c \cap A^*$. If $t \in I_c \cap A^*$ then $\mathcal{G}(u_c)(t) = \mathcal{F}(u_c)(t)$ and Assumption 2.4 implies

$$\begin{aligned} c_1 \operatorname{dist}(t, \partial A^*) &\le |\mathcal{G}(u^*)(t)| \le |\mathcal{G}(u_c)(t)| + \gamma\|e_c\|_X \\ &= |\mathcal{F}(u_c)(t)| + \gamma\|e_c\|_X \le \delta_c(1 + \gamma/K). \end{aligned}$$

This implies that

$$I_c \cap A^* \subset E_{c_1^{-1}\delta_c(1+\gamma/K)}$$

and therefore

$$\mu(I_c \cap A^*) \le c_0(c_1^{-1}\delta_c(1 + \gamma/K))^d.$$

This completes the proof as $A^* \setminus A_c \subset R_c \cup (I_c \cap A^*)$ with

$$c_A = c_3 + c_0(c_1^{-1}(1 + \gamma/K))^d. \qquad \square$$

The reader should compare the following lemma with (2.18) and (2.19) that used a similar decomposition of Ω to obtain a similar result.

LEMMA 3.4. *Let Assumptions* 2.1–2.4 *hold. Let* u_c *satisfy the assumptions of Lemma* 3.2. *Then* $|e^{1/3}(t)| \le |e_c(t)|$ *for all* $t \in \Omega$, *and there are* $w_c \in X$ *and* $K_w > 0$ *such that*

$$\|w_c\|_{L^p(\Omega)} \le K_w \|e_c\|_X \delta_c^{\bar{p}/(pd)}$$

and

$$\mathcal{F}(u^{1/3}) = \chi_{I_c} \mathcal{G}_{I_c}(u^* + \chi_{I_c} e^{1/3}) - w_c.$$

Proof. By Lemma 3.1, $\chi_{A_c} \mathcal{F}(u^{1/3}) = \chi_{A_c} e^{1/3} = 0$. Hence

$$\begin{aligned}\mathcal{F}(u^{1/3}) &= u^{1/3} - \mathcal{P}(\mathcal{K}(u^* + \chi_{I_c \cup R_c} e_c)) \\ &= \chi_{I_c \cup R_c}(u^{1/3} - \mathcal{P}(\mathcal{K}(u^* + \chi_{I_c \cup R_c} e_c))).\end{aligned}$$

By Lemma 3.2,

$$\|\chi_{R_c} \mathcal{F}(u^{1/3})\|_{L^p} \le c_5 \|e_c\|_X \delta_c^{\bar{p}/(pd)},$$

where

$$c_5 = (c_3 3^d)^{1/p}.$$

Similarly,

$$\|\mathcal{K}(u^* + \chi_{I_c} e_c + \chi_{R_c} e_c) - \mathcal{K}(u^* + \chi_{I_c} e_c)\|_X \le M_K \|e_c\|_X \mu(R_c)^{1/p} \le c_6 \|e_c\|_X \delta_c^{\bar{p}/(pd)},$$

where $c_6 = M_K c_5$. Hence if we let

$$w_c = \chi_{R_c} \mathcal{F}(u_c^{1/3}) + \chi_{I_c}(\mathcal{K}(u^* + \chi_{I_c} e_c + \chi_{R_c} e_c) - \mathcal{K}(u^* + \chi_{I_c} e_c)),$$

note that for any $f \in X$, $\|f\|_{L^p} \le \mu(\Omega)^{1/p} \|f\|_X$, and set $K_w = (1 + \mu(\Omega)^{1/p} M_K) c_5$, then the proof is complete. □

A trivial corollary of the proof is found in Theorem 3.5.

THEOREM 3.5. *Let Assumptions* 2.1–2.4 *hold. Let* $u_c \in C$ *satisfy the assumptions of Lemma* 3.2 *and assume that* $\|e_c\|_{L^p}, \|e_c\|_X < 1$. *Then there is* K_P *such that*

$$\|e^{2/3}\|_{L^p} \le K_P \|e_c\|_X^{1+(\bar{p}/pd)}, \tag{3.6}$$

and there is K_N *such that*

$$\|e_+\|_X \le K_N \|e_c\|_X^{1+(\bar{p}/pd)}. \tag{3.7}$$

Proof. By Lemma 3.4,

$$u^{2/3} = u^{1/3} - \mathcal{G}'_{I_c}(u^{1/3})^{-1} \mathcal{G}_{I_c}(u^* + \chi_{I_c} e^{1/3}) - \mathcal{G}'_{I_c}(u^{1/3})^{-1} w_c.$$

By Assumption 2.3, $\|\mathcal{G}'_{I_c}(u^{1/3})^{-1}\|_{L^p} \le M_2$ and hence by Lemma 3.4

$$\begin{aligned}\|\mathcal{G}'_{I_c}(u^{1/3})^{-1} w_c\|_{L^p} &\le M_2 K_w \|e_c\|_X \delta_c^{\bar{p}/(pd)} \\ &\le M_2 K_w \bar{\gamma}^{\bar{p}/(pd)} \|e_c\|_X^{1+(\bar{p}/pd)}.\end{aligned}$$

By standard estimates for Newton iterates and Assumption 2.3

$$\|e^{1/3} - \mathcal{G}'_{I_c}(u^{1/3})^{-1} \mathcal{G}_{I_c}(u^* + \chi_{I_c} e^{1/3})\|_X \le M_2 \bar{\gamma} \|e^{1/3}\|_X / 2.$$

Hence

$$\|e^{1/3} - \mathcal{G}'_{I_c}(u^{1/3})^{-1} \mathcal{G}_{I_c}(u^* + \chi_{I_c} e^{1/3})\|_{L^p} \le \mu(\Omega)^{1/p} M_2 \bar{\gamma} \|e^{1/3}\|_X / 2.$$

The first assertion therefore holds with

$$K_P = M_2 K_w \bar{\gamma}^{\bar{p}/(pd)} + \mu(\Omega)^{1/p} M_2 \bar{\gamma}/2.$$

The second assertion follows from Assumption 2.2 with

$$K_N = M_K K_P.$$

This completes the proof. □

The algorithms we implement replace $\mathcal{G}'_{I_c}(u_c)^{-1}$ in (3.2) with an approximation. The behavior of these algorithms is described by the next theorem, which is a direct consequence of Theorem 3.5.

THEOREM 3.6. *Let the assumptions of Theorem* 3.5 *hold and let* u_+ *be defined by*

$$\begin{aligned} u^{1/3} &= \chi_{A_c} \mathcal{P}\mathcal{K}(u_c) + \chi_{I_c \cup R_c} u_c, \\ u^{2/3} &= u^{1/3} - B_c^{-1} \mathcal{F}(u^{1/3}), \\ u_+ &= \mathcal{P}(\mathcal{K}(u^{2/3})), \end{aligned} \tag{3.8}$$

where

$$\|(B_c^{-1} - \mathcal{G}'_{I_c}(u^{1/3})^{-1})\|_{\mathcal{L}(X, L^p)} \le \rho_c.$$

Then there is $K_C > 0$ *such that*

$$\|e_+\|_X \le K_N \|e_c\|_X^{1+(\bar{p}/pd)} + K_C \rho_c \|e_c\|_X. \tag{3.9}$$

Proof. This follows directly from Theorem 3.5 with $K_C = M_K \gamma$. To see this, note that

$$\begin{aligned} \|e^{2/3}\|_{L^p} &\le K_P \|e_c\|_X^{1+(\bar{p}/pd)} + \rho \|\mathcal{F}(u^{1/3})\|_X \\ &\le K_P \|e_c\|_X^{1+(\bar{p}/pd)} + \gamma \rho_c \|e_c\|_X. \end{aligned}$$ □

Finally, we give an inexact variant of Theorem 3.5. The analysis is like that of the finite dimensional case [9].

THEOREM 3.7. *Let the assumptions of Theorem* 3.5 *hold and let* u_+ *be defined by*

$$\begin{aligned} u^{1/3} &= \chi_{A_c} \mathcal{P}\mathcal{K}(u_c) + \chi_{I_c \cup R_c} u_c, \\ u^{2/3} &= u^{1/3} + \tilde{s}, \\ u_+ &= \mathcal{P}(\mathcal{K}(u^{2/3})), \end{aligned} \tag{3.10}$$

where $\tilde{s} \in X \cap C(I_c)$ *and*

$$\|\mathcal{G}'_{I_c}(u^{1/3})\tilde{s} + \mathcal{F}(u^{1/3})\|_{L^p} \le \rho_c \|\mathcal{F}(u^{1/3})\|_X. \tag{3.11}$$

Then there is $K_I > 0$ *such that*

$$\|e_+\|_X \le K_N \|e_c\|_X^{1+(\bar{p}/pd)} + K_I \rho_c \|e_c\|_X. \tag{3.12}$$

In particular, if $\rho_c = \rho$ *is independent of* $u_c \in \mathcal{N}$, *we have q-linear convergence and if* $\rho_n \to 0$ *as* $n \to \infty$ *the convergence is q-superlinear.*

Proof. Note that

$$\begin{aligned} e^{2/3} = e^{1/3} &- \mathcal{G}'_{I_c}(u^{1/3})^{-1} \mathcal{F}(u^{1/3}) \\ &- \mathcal{G}'_{I_c}(u^{1/3})^{-1} (\mathcal{G}'_{I_c}(u^{1/3})\tilde{s} + \mathcal{F}(u^{1/3})). \end{aligned}$$

Hence, as in the proof of Theorem 3.5,

$$\|e^{2/3}\|_{L^p} \le K_P \|e_c\|_X^{1+(\bar{p}/pd)} + M_2 \rho_c \|\mathcal{F}(u^{1/3})\|_X$$
$$\le K_P \|e_c\|_X^{1+(\bar{p}/pd)} + M_2 \gamma \rho_c \|e_c\|_X.$$

Therefore

$$\|e_+\|_X \le M_K \|e^{2/3}\|_{L^p}$$
$$\le M_K (K_P \|e_c\|_X^{1+(\bar{p}/pd)} + M_2 \gamma \rho_c \|e_c\|_X).$$

Setting $K_I = M_K M_2 \gamma$ completes the proof. □

4. Implementation and an example. As in [16] we construct the operators B_c using a collectively compact sequence of approximations to $\mathcal{K}$. Recall that a family of maps $\{K_\alpha\}_{\alpha \in \Lambda} \subset \mathcal{L}(X, Y)$ is collectively compact if

$$\cup_{\alpha \in \Lambda} K_\alpha B$$

is precompact in Y for every bounded set $B \subset X$.

We incorporate an estimate of the set I_c using a "coarse mesh" approximation. We consider a sequence of approximations $\{\mathcal{K}_m\}$ to $\mathcal{K}$. We refer to the equation $u - \mathcal{P}(\mathcal{K}_m(u)) = 0$ as the equation for level m. Such approximations can be obtained, for example, by replacing the integral in (1.3) by a quadrature rule. Typically the problem at level m is equivalent to a finite dimensional problem of dimension N_m, say. Our compactness assumption is given below.

Assumption 4.1. The sequence of maps $\mathcal{K}_m$ converge strongly to $\mathcal{K}$ in $\mathcal{N}$ and the family $\{\mathcal{K}'_m(u)\}_{m \le \infty, u \in \mathcal{N}}$ is uniformly Lipschitz continuous as a family of maps from $\mathcal{N}$ to $\mathcal{L}(L^p, C)$ and is a collectively compact subset of $\mathcal{L}(X, C)$.

In Assumption 4.1, $\mathcal{K}_\infty = \mathcal{K}$. In the case of smooth nonlinearities, [2], [13], Assumption 4.1, solvability of $\mathcal{F}(u) = 0$, uniform Lipschitz continuity of the family $\{\mathcal{K}'_m(u)\}_{m \le \infty, u \in \mathcal{N}}$, and nonsingularity of $\mathcal{F}'(u^*)$ would imply that $u^m = \mathcal{K}_m(u^m)$ would have a solution for m sufficiently large and that $u^m \to u^*$ in X. In the nonsmooth case considered here we must assume that the approximate problems have solutions that converge to u^*.

Assumption 4.2. For m sufficiently large there is a solution to the fixed point problem $u^m = \mathcal{K}(u^m) \in C$. u^m converges uniformly to u^*.

Our algorithm, like the original Atkinson–Brakhage algorithm, [3], [6], or multigrid methods of the second kind [11], begins with a coarse level l for which the problem at that level is solved. The Atkinson–Brakhage approach uses low-level information to construct an approximate inverse B_l^L that is used to solve the problem at a higher level L. Our general scheme may be described in terms of the transition from a solution u^L at level L to a solution u^{L+1} for level $L + 1$. The initial iterate at level $L + 1$ is $u_0^{L+1} = u^L$. We apply the iteration (3.2) with $B_c = B_l^{L+1}$ until $\|\mathcal{F}_{L+1}(u^{L+1})\|_X \le \epsilon_{L+1}$, where ϵ_{L+1} is an estimate for truncation error at level $L + 1$. For a sufficiently fine coarse mesh one would hope to require only one iterate for each fine level L. Any necessary transfer of information between grids between levels can be done through Nyström interpolation [3] or directly by polynomial interpolation [14], [16].

The remaining issue is the construction of the maps B_l^L. We denote

$$\mathcal{G}_{l,S}(u) = I - \chi_S \mathcal{K}'_l(u) \chi_S$$

and let

$$I_l = \{t \mid \mathcal{K}(u^l) = \mathcal{P}(\mathcal{K}(u^l))\}.$$

We describe the action of $(B_l^L)^{-1}$ on a function v by the basic formula

$$(B_l^L)^{-1}v = v + \chi_{I_c}\chi_{I_l}\mathcal{G}'_{l,I_l}(u^l)^{-1}\chi_{I_l}\chi_{I_c}\mathcal{K}'_L(u_c)\chi_{I_c}v. \tag{4.1}$$

In (4.1) u_c is the current iterate at level L for the computation of u^L. Assumptions 2.2, 4.1, and 4.2 imply that B_l^L will satisfy the assumptions of Theorem 3.5 with ρ independent of L if the index of the lowest level, l, is sufficiently large. As with the original Atkinson–Brakhage iteration, (4.1) is an approximation to a two-term Neumann series expansion of $(\mathcal{G}'_L(u_c))^{-1}$.

In [16] the levels corresponded to piecewise linear approximations of the functions and the equations at the levels were equivalent to nonlinear equations for the values of the piecewise linear functions at the nodal points. The action of the fine mesh derivative $w = \mathcal{K}'(u_c)v$ was approximated by a difference quotient. The action of $(I - \mathcal{K}'_l(u^l))^{-1}$ was approximated by forming $I - \mathcal{K}'_l(u^l)$ as a matrix by numerically differentiating in coordinate directions, forming an LU factorization of the resulting matrix and storing the factors. Then w was projected onto the coarse mesh, the equation $(I - \mathcal{K}'_l(u^l))z = w$ was solved, and z extended to the fine mesh. The final approximation was $B_c^{-1}v = v - z$. Of course, a similar technique could be used for the constrainted problems considered here, setting

$$w = \chi_{I_l}\chi_{I_c}\mathcal{K}'_L(u_c)\chi_{I_c}v,$$

forming a matrix equivalent of $\mathcal{G}'_{l,I_l}$ and factoring it, and then using that factorization to compute $z = (\mathcal{G}'_{l,I_l})^{-1}w$. Instead, we follow the technique of [12] and use a GMRES [19] iteration with a discrete L^2 inner product to solve a finite dimensional problem associated with the linear system

$$\mathcal{G}'_{l,I_l}(u^l)z = w, \tag{4.2}$$

and then use interpolation to approximate the solution to (4.2). The matrix-vector products that are required by GMRES are done with a forward difference approximation to the action of the Fréchet derivative. As our assumptions on the family $\{\mathcal{K}_l\}$ will guarantee that the condition number of $I - \mathcal{K}'_l(u^l)$ is bounded independently of l, the results in [18] guarantee that the behavior of a GMRES iteration will be mesh independent in the sense of [1].

The theory in [16] allowed for inaccuracy in the evaluation of $\mathcal{K}_L$, which can be introduced, say, by the control of relative and absolute errors in adaptive integration codes or ordinary differential equation (ODE) codes like DASSL. In [16] we showed how one should adjust this accuracy to take into account the expected error $\|u^L - u^*\|_X$. That analysis can be incorporated here in a direct way in the evaluation of the difference approximations to directional derivatives $\mathcal{K}(u)'w$ that are required by both the Atkinson–Brakhage algorithm in the approximation of $\mathcal{K}'_L$ at the fine mesh level and the solution of (4.2) by Newton-GMRES iteration. In [16] the analysis was complicated by the numerical Jacobian, and additional accuracy was needed in the coarse mesh function evaluations. The use of GMRES eliminates some of that complexity. As in [16] the use of inaccurate function evaluations introduces an absolute error in the iteration. Making this absolute error smaller as the iteration progresses means that the convergence rate of the algorithm becomes r-linear.

Assume that the compact fixed point maps, $\mathcal{K}_m$, can be evaluated to a given absolute accuracy τ_m, with smaller values of τ_m resulting in a increase of the cost of the nonlinear function evaluation. In the case of the method of lines solution of a parabolic partial differential equation, for example, τ_m would be the absolute error tolerance given to the routine that performs the integration in time. Letting $h_m = O(\sqrt{\tau_m})$, we approximate the action of $\mathcal{K}'_m(u)$ on a vector w by the forward difference map

$$A_m(u, w) = \begin{cases} 0, & w = 0, \\ \|w\|_X \frac{\mathcal{K}(u + h_m w/\|w\|_X) - \mathcal{K}(u)}{h_m}, & w \neq 0. \end{cases}$$

$A_m(u, w)$, though nonlinear in w, approximates $\mathcal{K}_m'(u)w$ up to a relative error of $O(h_l)$. We have

$$\|A_m(u, w) - \mathcal{K}_m'(u)w\|_X \leq (\gamma/2)h_m\|w\|_X. \tag{4.3}$$

Hence $\mathcal{G}_{l,I_l}'(u^l)z$, which is used in the construction of the Atkinson–Brakhage approximate inverse, would be approximated by

$$G_l(u^l, z) = I - \chi_{I_l}A_l(u^l, \chi_{I_l}z).$$

The effect of this approximation is that in the evaluation of the action of the Atkinson–Brakhage approximate inverse given by (4.1), $w = \mathcal{K}_L'(u_c)\chi_{I_c}v$ is approximated by $A_L(u_c, v)$ and an error of $O(h_L\|v\|_X)$ is made. Then $z = \mathcal{G}_{l,I_l}'(u^l)^{-1}\chi_{I_l}\tilde{w}$ is approximated by $\tilde{z}$, where $\tilde{z}$ is computed by using GMRES to solve $\mathcal{G}_{l,I_l}'(u^l)\tilde{z} = \chi_{I_l}\tilde{w}$ with $G_l(u^l, z)$ used in the matrix-vector product routine whenever $\mathcal{G}_{l,I_l}'(u^l)z$ is requested and an approximate L^2 inner product used in the GMRES routine itself. We use the zero function as the initial iterate to GMRES and request a reduction in the residual by a factor of $\tilde{\rho}$. Following [8], we assume that the GMRES routine returns a vector that satisfies

$$\|G_l(u^l, \tilde{z}) - \chi_{I_l}\tilde{w}\|_{2,l} \leq \tilde{\rho}\|\chi_{I_l}\tilde{w}\|_{2,l}. \tag{4.4}$$

In (4.4), $\|\cdot\|_{2,l}$ is the norm associated with the approximate L^2 norm for level l. In our examples from control problems, $\|\cdot\|_{2,l} = \|\cdot\|_{L^2}$ and the functions at level l are piecewise linear. In the example from integral equations the approximate inner product is given by a quadrature rule. In either case there are $C_\infty > 0$ and $N_l \to \infty$ such that

$$N_l^{-1}\|\cdot\|_X \leq \|\cdot\|_{2,l} \leq C_\infty\|\cdot\|_X. \tag{4.5}$$

We can use (4.4) and (4.5) to obtain a uniform estimate

$$\|G_l(u^l, \tilde{z}) - \chi_{I_l}\tilde{w}\|_X \leq \tilde{\rho}N_lC_\infty\|\chi_{I_l}\tilde{w}\|_X. \tag{4.6}$$

Using (4.3) we have

$$\|G_l(u^l, \tilde{z}) - \mathcal{G}_l'(u^l)\tilde{z}\|_X \leq (\gamma h_l/2)\|\tilde{z}\|_X$$

and hence by Assumption 2.3, if $h_l \leq 2/(M_2\gamma)$,

$$\|\tilde{z}\|_X \leq \frac{M_2\|G_l(u^l, \tilde{z})\|_X}{1 - M_2\gamma h_l/2} \leq \frac{M_2}{1 - M_2\gamma h_l/2}\|\chi_{I_l}\tilde{w}\|_X(1 + \tilde{\rho}N_lC_\infty).$$

Hence if

$$\tilde{\rho}N_lC_\infty < 1 \text{ and } h_l \leq 1/(M_2\gamma), \tag{4.7}$$

we have

$$\|\tilde{z}\|_X \leq 4M_2\|\chi_{I_l}\tilde{w}\|_X.$$

Summarizing, if (4.7) holds, then

$$\|\mathcal{G}_l'(u^l)\tilde{z} - \chi_{I_l}\tilde{w}\|_X \leq (\tilde{\rho}N_lC_\infty + 2M_2\gamma h_l)\|\chi_{I_l}\tilde{w}\|_X.$$

This leads us to the rule to thumb that $h_l = O(\tilde{\rho}N_l)$ as a guide to selection of the accuracy required by a coarse mesh function evaluation. Also we get insight into the tolerances $\tilde{\rho}$ and $\tau_l = O(h_l)$ from (4.7).

If a Newton-GMRES [8] iteration is used, Theorem 3.7 and the analysis above provides guidance in the choice of h_c as a function of N_c and ρ_c, where ρ_c is the factor in (3.11). In the computations reported below, we set $\rho_c = \tilde{\rho} = .001$ with a view toward making $\tilde{\rho} N_l C_\infty$ and ρ_n small.

The overall effect of the GMRES approximations is to introduce a relative error of $O(\tilde{\rho} N_l + h_l + h_L)$ into the approximate Newton iteration and, if $\tilde{\rho} N_l + h_l + h_L$ is sufficiently small, the overall rate of r-linear convergence will be preserved. Approximating $\mathcal{F}_L$ will introduce an absolute error of τ_L and accordingly τ_L should be reduced as the grids are refined to approximate the expected truncation error. Note that it is not necessary to approximate $\mathcal{K}_L(u_c)$, which is used in the evaluation of $\mathcal{F}_L$, and the perturbations used in the approximation of $\mathcal{K}_L'$ to the same accuracy. We use an accuracy of τ_l for the perturbed evaluation since that does not change the size of the relative error in B_l^{-1}.

As in [16], for an example we consider maps $\mathcal{K}$ defined by

$$\mathcal{K}(u) = -d(t, 1)/\alpha,$$

where for $x \in (0, 1)$ and $t \in (0, T)$,

$$\begin{aligned} -d_t &= d_{xx} + f_2(t, x), \quad d(T, x) = y(T, x) - z(x), \\ d_x(t, 0) &= h_l(t), \quad d_x(t, 1) = h_r(t), \end{aligned}$$

(4.8)

$$\begin{aligned} y_t &= y_{xx} + f_1(t, x), \quad y(0, x) = y_0(x), \\ y_x(t, 0) &= g_l(t), \quad y_x(t, 1) = g_r(y(t, 1)) + q(t) + u(t) \end{aligned}$$

where the right-hand sides and boundary values can be used to specify a solution to the problem. Discretization in space was by piecewise linear finite elements. The mesh at level L consisted of the $L + 1$ points $\{i/L\}_{i=0}^{L}$. The functions $\mathcal{K}_L$ were evaluated by using DASSL to solve the systems of ODEs obtained by discretizing (4.8) in space and setting the absolute error to τ_L. The sets A_c, R_c, and I_c were specified as in (3.1) with $\bar{p} = \frac{1}{2}$.

In the computations we set the right-hand sides and boundary conditions so that the solution to (4.8) was

$$y(t, x) = (1 + xt)/(1 + x^2 t)$$

and

$$d(t, x) = \alpha(1 - x(2x(1 - t) - 1)^2)(1 - \exp(-(t - 1/4)^2)),$$

with

$$u^*(t) = \mathcal{P}(d(t, 1)/\alpha) = \mathcal{P}((1 - (1 - 2t)^2)(1 - \exp(-(t - 1/4)^2))).$$

We imposed constraints given by

$$u_{\max}(t) = 1 + 10(t - .5)^2 \quad \text{and} \quad u_{\min}(t) = t/4.$$

The solution to (1.1) is plotted in Figure 1. The solution is Lipschitz continuous but not differentiable. Hence we would expect piecewise linear approximations to be first-order accurate.

We have constructed the examples in such a way that tthe solution u^* does not depend on α. The reason for this was to isolate the ill conditioning that arises from small values of α in

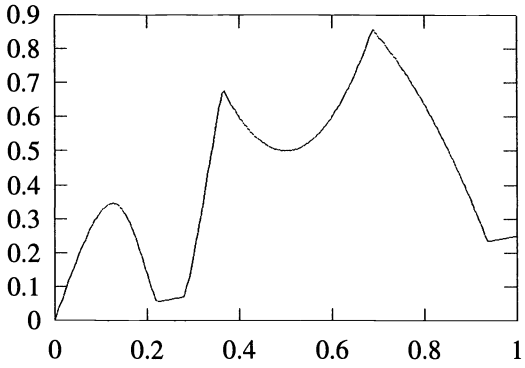

FIG. 1. *Plot of* u^*.

the operator and to make it possible to directly compare results for different values of α. We report results for $\alpha = 1, .5, .25, .1$. Since the Lipschitz constants of $\mathcal{K}$ are proportional to $1/\alpha$ and the solution of the linear equation for the step becomes very sensitive to high frequency perturbations of the solution for small α, one would expect that finer coarse meshes and more accurate initial iterates will be required for the smaller values of α. This is the case for both the Atkinson–Brakhage and Newton-GMRES forms of the algorithm.

The maps $\mathcal{K}_L$ were constructed exactly as reported in [16] and the absolute accuracy of the function evaluation at level L was $\tau_L = .001/L$, consistent with the expected first-order accuracy. In the forward differencing we used $h_l = .1/\sqrt{L}$. In the computations we used a coarse mesh of $N_l = l + 1$ points. Consistently with our requirement that $h_l = O(\tilde{\rho} N_l)$ we set $\tilde{\rho} = .01$. The iteration at the coarse mesh was terminated when $\|\mathcal{F}_l(u)\|_\infty < \epsilon_l = 10^{-4}$. The iteration at a higher mesh level L was terminated if $\|\mathcal{F}_L(u)\|_\infty < \epsilon_L = .01/L$. For both methods considered, projected Newton-GMRES and the Atkinson–Brakhage iteration, only one outer iterate was required for termination at the higher mesh levels. After that the mesh spacing was halved and the iteration continued. The initial iterate was

$$u_0 = \mathcal{P}(u(t) + \delta \sin(t)(t - .5)t).$$

δ controls the size of the initial iterate error and was reduced as α is reduced. The number of points in the coarse mesh N_l is increased as α is reduced.

In the tables that follow we report the norm ν_n of $\mathcal{F}_L$ at each iterate n and for the final iterate (n=1) at each level the ratio ν_1/ν_0 and the number of GMRES iterates I_G required for (3.11) to hold in the case of Newton-GMRES or needed to solve (4.2) in the case of the Atkinson–Brakhage iteration. In the header for each table we report α, δ, l, and the computation time T_C in seconds.

All computations were done on the CRAY Y-MP at the North Carolina Supercomputing Center running UNICOS 6.0. All codes were written in CRAY FORTRAN cft77 version 5.0.0.0. Computation times were taken from the output of the CRAY hardware performance monitor.

We report on two methods of solution. The first, reported in Tables 1–4, is a direct Newton-GMRES approach that satisfies (3.11) with a GMRES iteration, using $\rho_c = .001$.

In Tables 5–8, we report the results of the Atkinson–Brakhage algorithm using $\tilde{\rho} = .001$.

In both methods a fine mesh function evaluation was used to test for termination. A more efficient approach would be to see if the function norm at the next finer mesh has the predicted size of half the initial evaluation at the previous mesh. This would not avoid the

fine mesh function evaluation to test for termination at the finest and ultimate mesh. Hence at least four fine mesh function evaluations per level were done: one to compute $\mathcal{K}(u_c)$, one to compute $\mathcal{K}(u^{1/3})$, one to compute $u_+ = \mathcal{P}(\mathcal{K}(u^{2/3}))$, and one to test for termination. The Newton-GMRES required one additional fine mesh evaluation for each inner iterate, while the Atkinson–Brakhage method required a low accuracy (i.e., using τ_l instead of τ_L) fine mesh function evaluation to compute $\mathcal{K}_L'(u_c)$ via a difference in (4.1) and at most a few coarse mesh evaluations for the GMRES iteration. This accounts for the advantage in the Atkinson–Brakhage method, which, as the tables show, executes in roughly 60% of the time of Newton-GMRES. Note that for the computations reported in the tables that required more GMRES iterations in the inner iteration of Newton-GMRES, the advantage of the Atkinson–Brakhage method was larger. Having said that, the nested iteration form of Newton-GMRES is still a fast algorithm for compact fixed-point problems since the number of inner iterations required at each mesh level is bounded independently of the mesh size.

PRECONDITIONED RICHARDSON AND MINIMAL RESIDUAL ITERATIVE METHODS FOR PIECEWISE HERMITE BICUBIC ORTHOGONAL SPLINE COLLOCATION EQUATIONS*

BERNARD BIALECKI†

Abstract. The preconditioned Richardson and preconditioned minimal residual iterative methods are presented for the solution of linear equations arising when orthogonal spline collocation with piecewise Hermite bicubics is applied to a selfadjoint elliptic Dirichlet boundary value problem on a rectangle. For both methods, the orthogonal spline collocation discretization of Laplace's operator is used as a preconditioner. In the preconditioned Richardson method, an approximation of the optimal iteration parameter is computed from knowledge of spectral equivalence constants. Such a priori information is not required for the preconditioned minimal residual method. In each iteration of both methods, orthogonal spline collocation Poisson's problems are solved by a fast direct algorithm which employs fast Fourier transforms. An application of the preconditioned minimal residual method is also discussed for the solution of linear equations arising from the orthogonal spline collocation discretization of nonselfadjoint elliptic Dirichlet boundary value problems.

Key words. Dirichlet boundary value problem, orthogonal spline collocation, preconditioned iterative methods, Richardson method, minimal residual method, fast Fourier transforms

AMS subject classifications. 65N35, 65F10

1. Introduction.

Consider the Dirichlet boundary value problem

$$\begin{aligned} &Lu = f(x, y), \qquad (x, y) \in \Omega = (0, 1) \times (0, 1), \\ &u(x, y) = 0, \qquad (x, y) \in \partial\Omega, \end{aligned} \tag{1.1}$$

where L is the selfadjoint elliptic differential operator given by

$$Lu = -\frac{\partial}{\partial x}\left(a(x, y)\frac{\partial u}{\partial x}\right) - \frac{\partial}{\partial y}\left(b(x, y)\frac{\partial u}{\partial y}\right) + c(x, y)u. \tag{1.2}$$

(The homogeneous boundary condition in (1.1) is chosen to simplify the presentation.) Let $\{t_i\}_{i=0}^N$ be a uniform partition of $[0, 1]$ such that $t_i = ih$, where $h = \frac{1}{N}$. Let $\mathcal{M}_h$ be the space of piecewise Hermite cubics on $[0, 1]$ defined by

$$\mathcal{M}_h = \{v \in C^1[0, 1] : v|_{[t_i, t_{i+1}]} \in P_3, i = 0, \ldots, N-1, v(0) = v(1) = 0\},$$

where P_3 denotes the set of all polynomials of degree ≤ 3. Let V_h be the space of piecewise Hermite bicubics on $\overline{\Omega}$ defined by $V_h = \mathcal{M}_h \otimes \mathcal{M}_h$; that is, V_h is the set of all functions on $\overline{\Omega}$ that are finite linear combinations of products of the form $v(x)w(y)$, where $v, w \in \mathcal{M}_h$. Let $\{\xi_j\}_{j=1}^{2N}$ be the Gauss points in $(0, 1)$ given by

$$\xi_{2i+1} = t_i + h\frac{3 - \sqrt{3}}{6}, \quad \xi_{2i+2} = t_i + h\frac{3 + \sqrt{3}}{6}, \quad i = 0, \ldots, N-1,$$

and let $\mathcal{G}$ be the collection of Gauss points in Ω defined by $\mathcal{G} = \{(x, y) : x, y \in \{\xi_j\}_{j=1}^{2N}\}$. The piecewise Hermite bicubic orthogonal spline collocation solution to (1.1) is a function $u_h \in V_h$ such that

$$Lu_h(\xi) = f(\xi), \qquad \xi \in \mathcal{G}. \tag{1.3}$$

†Department of Mathematics, University of Kentucky, Lexington, Kentucky 40506 (bialecki@ms.uky.edu).

Sufficient conditions for the existence and uniqueness of u_h were given recently in [2], where the $O(h^3)$ rate of convergence of u_h to the exact solution u in the H^1-norm was also established.

When finite difference or finite element Galerkin methods are used to discretize (1.1), the resulting linear systems have symmetric, positive definite coefficient matrices. Such systems can be solved efficiently by the preconditioned Chebyshev or preconditioned conjugate gradient methods (see, for example, [3], and [14, §§6.2 and 8.4.1]) in which the discretization of the Laplacian plays the role of a preconditioner. In conjunction with alternating-direction methods, the idea of preconditioning finite difference linear systems was proposed by D'yakonov [6], and has been used by many researchers for the last three decades. For orthogonal spline collocation, the situation appears to be more complicated than that for a finite difference or a finite element Galerkin discretization, since even for Poisson's equation, the matrices arising from (1.3) are nonsymmetric. However, it was shown recently in [2] that the orthogonal spline collocation Laplace operator generating such matrices is selfadjoint and positive definite with respect to the discrete inner product, which is defined in terms of the composite Gauss–Legendre quadrature rule. Moreover, fast direct solvers based on fast Fourier transforms have been also developed in [1] for linear systems arising from the piecewise Hermite bicubic orthogonal spline collocation discretization of Poisson's equation. It is the purpose of this paper to discuss applications of these solvers to one-step preconditioned iterative methods for the solution of (1.3). Although the orthogonal spline collocation operator corresponding to this problem is not selfadjoint with respect to the discrete inner product, nevertheless it is spectrally equivalent to the orthogonal spline collocation Laplace operator. This spectral equivalence makes it possible to employ the preconditioned Richardson method and also the preconditioned minimal residual method that does not require a priori information for the selection of the iteration parameters.

Some recent works on preconditioned iterative methods for solving linear systems arising from discretizations of elliptic boundary value problems include [9] and [10]. In [9], the preconditioned conjugate gradient method applied to normal equations and the preconditioned Orthomin method were used for the solution of finite difference linear systems corresponding to nonselfadjoint elliptic boundary value problems. It was shown that the convergence rates of these methods were independent of the partition mesh size. In [10], the effect of boundary conditions was discussed on preconditioning discrete linear systems on the left and on the right. Conditions were given under which the condition numbers of the preconditioned matrices were uniformly bounded. It should be noted that preconditioned iterative methods based on spectrally equivalent operators have serious limitations. Even though the numbers of iterations in such methods are independent of the partition mesh size, they may still be quite large if the variations in the differential operator coefficients are large. This drawback of preconditioned iterative methods is characteristic of orthogonal spline collocation, finite difference, and finite element Galerkin discretizations.

A brief outline of this paper is as follows. The preconditioned Richardson and preconditioned minimal residual iterative methods for solving nonselfadjoint equations in a general Hilbert space framework are discussed in §2. These methods for solving the orthogonal spline collocation equations (1.3) are presented and analyzed in §3. In §4 an application of the preconditioned minimal residual method is considered for the solution of (1.3) when the differential operator L is nonselfadjoint. Finally, §5 contains results of numerical experiments and a brief discussion of these.

2. Preliminaries. In this section, following the approach of [14], we present the preconditioned Richardson and preconditioned minimal residual iterative methods for the solution of a nonselfadjoint positive definite linear operator equation in a general Hilbert space setting.

Let H be a finite dimensional Hilbert space over the field of real numbers and let $(\cdot, \cdot)$ and $\|\cdot\| = \sqrt{(\cdot, \cdot)}$ denote the inner product and norm in H, respectively. Let A be a linear operator from H into H. An operator A^* from H into H such that $(Av, w) = (v, A^*w)$ for all $v, w \in H$ is called the adjoint operator to A. The operator A is said to be *selfadjoint* if $A = A^*$. The operator A is said to be *positive definite* ($A > 0$) if $(Av, v) > 0$ for all nonzero $v \in H$. If A is selfadjoint and positive definite, then $\|v\|_A = \sqrt{(Av, v)}$ denotes the energy norm of $v \in H$ induced by A. The norm of the operator A is defined in the usual way, that is, $\|A\| = \sup_{x \neq 0} \|Ax\|/\|x\|$. If A and B are two linear operators from H into H, then $A \leq B$ means that $(Av, v) \leq (Bv, v)$ for all $v \in H$. In the following, E denotes the identity operator in H.

The following result plays an important role in establishing convergence rates of the iterative methods discussed in this paper.

LEMMA 2.1. *Assume that the linear operators A and B from H into H and the real numbers γ_i, $i = 1, 2, 3$, are such that*

$$B = B^* > 0, \quad \gamma_1 B \leq A \leq \gamma_2 B, \quad \gamma_1 > 0, \tag{2.1}$$

and

$$(A^* - A)B^{-1}(A - A^*) \leq 4\gamma_3^2 B, \qquad \gamma_3 \geq 0. \tag{2.2}$$

If

$$\overline{\tau} = \frac{2}{\gamma_1 + \gamma_2}(1 - \rho\kappa), \tag{2.3}$$

where

$$\rho = \frac{(1+\kappa)\gamma_2 - (1-\kappa)\gamma_1}{(1+\kappa)\gamma_2 + (1-\kappa)\gamma_1}, \qquad \kappa = \frac{\gamma_3}{\sqrt{\gamma_1\gamma_2 + \gamma_3^2}}, \tag{2.4}$$

then

$$\|E - \overline{\tau} D^{1/2} B^{-1} A D^{-1/2}\| \leq \rho \tag{2.5}$$

for any $D = S^*S$, where S is a linear nonsingular operator from H into H such that

$$SB^{-1}AS^{-1} = B^{-1/2}AB^{-1/2}. \tag{2.6}$$

Proof. Setting $\hat{A} = B^{-1/2}AB^{-1/2}$, it is easy to verify that

$$\|E - \tau D^{1/2} B^{-1} A D^{-1/2}\| = \|E - \tau \hat{A}\|, \qquad \tau \in \mathcal{R},$$

for any $D = S^*S$, where S satisfies (2.6). Since conditions (2.1) and (2.2) are equivalent to

$$\gamma_1 E \leq \hat{A} \leq \gamma_2 E, \qquad \|\hat{A} - \hat{A}^*\| \leq 2\gamma_3, \tag{2.7}$$

(2.5) follows from Lemma 4 in §6.4.2.2 of [14], where a certain bound on $\|E - \tau\hat{A}\|$ is minimized with respect to τ. □

It should be noted that the condition (2.6) is satisfied, for example, by $S = B^{1/2}(B^{-1}A)^l$, where l is a nonnegative integer.

It is important to observe that the formula (2.3) for $\overline{\tau}$ and the bound (2.5) are optimal in the sense that, if $A = A^*$, then

$$\min_{\tau} \|E - \tau D^{1/2} B^{-1} A D^{-1/2}\| = \left\| E - \frac{2}{\gamma_1' + \gamma_2'} D^{1/2} B^{-1} A D^{-1/2} \right\| = \frac{\gamma_2' - \gamma_1'}{\gamma_2' + \gamma_1'},$$

where γ_1' is the largest γ_1 such that $\gamma_1 B \leq A$, and γ_2' is the smallest γ_2 such that $A \leq \gamma_2 B$.

Let A be a linear nonsingular operator from H into H (A may be nonselfadjoint) and let $f \in H$. Assume that the equation

$$Au = f \tag{2.8}$$

is solved by the preconditioned Richardson (PR) method

$$B(u^{(k+1)} - u^{(k)}) = \tau r^{(k)}, \qquad k = 0, 1, \ldots, \tag{2.9}$$

where B is a nonsingular linear operator from H into H, τ is an iteration parameter to be selected, $u^{(0)} \in H$ is assumed to be given, and here and in what follows,

$$r^{(k)} = f - Au^{(k)}.$$

THEOREM 2.1. *Assume that A, B, and γ_i, $i = 1, 2, 3$, satisfy the assumptions of Lemma 2.1 and that $\bar{\tau}$ and ρ are given by (2.3) and (2.4), respectively. If $u^{(k)}$, $k = 1, \ldots,$ are generated by the* PR *method (2.9) with $\tau = \bar{\tau}$, then*

$$\|u^{(k)} - u\|_D \leq \rho^k \|u^{(0)} - u\|_D, \tag{2.10}$$

with $D = B$ and $D = A^* B^{-1} A$.

Proof. Using (2.8) and (2.9), it is easy to verify that

$$D^{1/2}(u^{(k+1)} - u) = (E - \tau D^{1/2} B^{-1} A D^{-1/2}) D^{1/2}(u^{(k)} - u),$$

and hence (2.10) follows easily from Lemma 2.1 on taking $S = B^{1/2}(B^{-1}A)^l$ with $l = 0, 1$. □

Let B be a nonsingular linear operator from H into H, and let D be an arbitrary linear operator from H into H such that $D = D^* > 0$. Consider solving (2.8) by the preconditioned one-step gradient method

$$B(u^{(k+1)} - u^{(k)}) = \tau_k r^{(k)}, \qquad k = 0, 1, \ldots, \tag{2.11}$$

where

$$\tau_k = \frac{(Dw^{(k)}, u - u^{(k)})}{(Dw^{(k)}, w^{(k)})}, \qquad Bw^{(k)} = r^{(k)}. \tag{2.12}$$

It should be noted that, for a given $u^{(k)}$, and $u^{(k+1)}$ defined by (2.11), (2.12) arises from minimizing $\|u^{(k+1)} - u\|_D$ with respect to τ_k. Therefore, if $u^{(k+1)}$ is computed from (2.11) with τ_k given in (2.12), then

$$\|u^{(k+1)} - u\|_D = \min_{\tau} \|(E - \tau D^{1/2} B^{-1} A D^{-1/2}) D^{1/2}(u^{(k)} - u)\|. \tag{2.13}$$

If $B = B^* > 0$ and $D = A^* B^{-1} A$, then (2.12) yields

$$\tau_k = \frac{(Aw^{(k)}, w^{(k)})}{(Aw^{(k)}, v^{(k)})}, \qquad Bw^{(k)} = r^{(k)}, \qquad Bv^{(k)} = Aw^{(k)}, \tag{2.14}$$

and the resulting method (2.11) can be regarded as the preconditioned minimal residual (PMR) method. It follows from (2.11) and (2.14) that the PMR method can be written in the following way:

$$
\begin{aligned}
&\text{Choose } u^{(0)} \in H, \text{ compute } r^{(0)} = f - Au^{(0)}, \text{ and solve } Bw^{(0)} = r^{(0)}.\\
&\text{For } k = 0, 1, \ldots,\\
&\qquad \text{Compute } z^{(k)} = Aw^{(k)}.\\
&\qquad \text{Solve } Bv^{(k)} = z^{(k)}.\\
&\qquad \text{Compute } \tau_k = (z^{(k)}, w^{(k)})/(z^{(k)}, v^{(k)}).\\
&\qquad \text{Compute } u^{(k+1)} = u^{(k)} + \tau_k w^{(k)}.\\
&\qquad \text{Compute } w^{(k+1)} = w^{(k)} - \tau_k v^{(k)}.
\end{aligned}
\tag{2.15}
$$

Clearly each iteration of the PMR method requires the solution of only one equation with the operator B.

THEOREM 2.2. *Assume that A, B, and γ_i, $i = 1, 2, 3$, satisfy the assumptions of Lemma 2.1 and that ρ is given by (2.4). If $u^{(k)}$, $k = 1, \ldots$, are generated by the PMR method (2.15), then*

$$
\|u^{(k)} - u\|_{A^*B^{-1}A} \le \rho^k \|u^{(0)} - u\|_{A^*B^{-1}A}. \tag{2.16}
$$

Proof. The inequality (2.16) follows easily from (2.13) with $D = A^*B^{-1}A$ and Lemma 2.1. □

The two methods described in this paper for the solution of (2.8) are referred to as the PR and PMR methods since they arise from applying the Richardson (R) method [15] and the minimal residual (MR) method [8], respectively, to the preconditioned operator equation

$$
\hat{A}\hat{u} = \hat{f}, \tag{2.17}
$$

where $\hat{A} = B^{-1/2}AB^{-1/2}$, $\hat{u} = B^{1/2}u$, $\hat{f} = B^{-1/2}f$. For example, the application of the MR method to (2.17) yields

$$
\hat{u}^{(k+1)} = \hat{u}^{(k)} + \hat{\tau}_k \hat{r}^{(k)}, \qquad \hat{r}^{(k)} = \hat{f} - \hat{A}\hat{u}^{(k)}, \qquad k = 0, 1, \ldots, \tag{2.18}
$$

where $\hat{u}^{(0)} \in H$ is given and

$$
\hat{\tau}_k = \frac{(\hat{A}\hat{r}^{(k)}, \hat{r}^{(k)})}{(\hat{A}\hat{r}^{(k)}, \hat{A}\hat{r}^{(k)})}. \tag{2.19}
$$

It is easy to verify that if $\hat{u}^{(k)}$ is generated by (2.18), (2.19), then $u^{(k)} = B^{-1/2}\hat{u}^{(k)}$ satisfies (2.11), (2.14).

The significance of the inequalities in (2.1) and (2.2) relating A and B becomes more transparent in view of their equivalence with the inequalities in (2.7). It is clear, for example, that γ_3 in the second inequality of (2.7) measures the size of the skew-symmetric part of the preconditioned operator $\hat{A}$.

It should be noted that the MR method applied to (2.17) is equivalent to the Orthomin(l) method [16] with $l = 0$. Of course, instead of using the MR method, one could apply to (2.17) the Orthomin(l), $l \ge 1$, or the generalized minimal residual (GMRES) method of [13], which is theoretically equivalent to the generalized conjugate residual method of [8]. Obviously

Thereom 2.2 remains valid for the Orthomin(l), $l \geq 1$, and the GMRES method, although these methods may converge faster than (2.16) seems to indicate. Since Orthomin(l) with large l and the GMRES method require, in general, significant amounts of work and storage per iteration, in this paper, we concentrate on the one-step PR and PMR methods, which, with a proper choice of the preconditioner B, have very modest work and storage requirements. Obviously, if A and B satisfy (2.1) and if, in addition, $A = A^*$, then (2.8) can be solved by the preconditioned conjugate gradient method [11] with B as a preconditioner, yielding (2.10) with $D = A$ and $2\rho_1^k$ in place of ρ^k, where $\rho_1 = (\sqrt{\gamma_2} - \sqrt{\gamma_1})/(\sqrt{\gamma_2} + \sqrt{\gamma_1})$ (see, for example, [14, §8.3.1]).

3. PR and PMR methods for orthogonal spline collocation. For the iterative methods of the previous section to be applicable to the solution of (1.3), results on spectral equivalence of elliptic orthogonal spline collocation operators must first be established.

3.1. Spectral equivalence of orthogonal spline collocation operators. It follows from Lemma 2.3 of [5] that any $v \in V_h$ is uniquely determined by its values on the set of Gauss points $\mathcal{G}$. Therefore V_h is a Hilbert space with the inner product $\langle \cdot, \cdot \rangle$ defined by

$$\langle v, w \rangle = \frac{h^2}{4} \sum_{\xi \in \mathcal{G}} (vw)(\xi), \qquad v, w \in V_h. \tag{3.1}$$

(The expression on the right-hand side in (3.1) arises by formally applying the composite Gauss–Legendre quadrature rule $\int_0^1 g(t)\,dt \approx (\frac{h}{2}) \sum_{j=1}^{M} g(\xi_j)$ with respect to each variable to the standard L^2-inner product $\int\int_\Omega (vw)(x, y)\,dxdy$.) Let L_h and Δ_h be the operators from V_h into V_h defined by

$$(L_h v)(\xi) = Lv(\xi), \qquad (\Delta_h v)(\xi) = \Delta v(\xi), \qquad \xi \in \mathcal{G}, \tag{3.2}$$

where L is given by (1.2) and Δ is the Laplacian. Obviously Δ_h is a special case of the operator L_h. It follows from Lemma 2.2 of [2] that $-\Delta_h$ is a selfadjoint and positive definite operator. The following theorem gives spectral equivalence results for the operators L_h and $-\Delta_h$.

THEOREM 3.1. *Assume that a is five times continuously differentiable in $\overline{\Omega}$ with respect to x, b is five times continuously differentiable in $\overline{\Omega}$ with respect to y, c is continuous in $\overline{\Omega}$, and that*

$$0 < \alpha \leq a(x, y),\ b(x, y) \leq \beta, \qquad (x, y) \in \overline{\Omega}. \tag{3.3}$$

Then

$$\left[\alpha + \frac{\gamma_*}{\lambda(h)} - C\eta(h)\right](-\Delta_h) \leq L_h \leq \left[\beta + \frac{\gamma^*}{\lambda(h)} + C\eta(h)\right](-\Delta_h), \tag{3.4}$$

$$(L_h^* - L_h)(-\Delta_h)^{-1}(L_h - L_h^*) \leq 4C^2\eta^2(h)(-\Delta_h), \tag{3.5}$$

where the positive constant C is independent of h, a, b, c, and where

$$\gamma_* = \min(0, \min_{(x,y)\in\overline{\Omega}} c(x, y)), \qquad \gamma^* = \max(0, \max_{(x,y)\in\overline{\Omega}} c(x, y)),$$

$$\lambda(h) = 24h^{-2}\frac{8 + \nu - \mu}{7 - \nu}, \qquad \nu = \cos(h\pi), \qquad \mu = \sqrt{43 + 40\nu - 2\nu^2}, \tag{3.6}$$

$$\eta(h) = h \max\left(\left\|\frac{\partial a}{\partial x}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial b}{\partial y}\right\|_{C(\overline{\Omega})}\right)$$

$$+h^2 \max\left(\left\|\frac{\partial^2 a}{\partial x^2}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^3 a}{\partial x^3}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^2 b}{\partial y^2}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^3 b}{\partial y^3}\right\|_{C(\overline{\Omega})}\right) \tag{3.7}$$

$$+h^3 \max\left(\left\|\frac{\partial^4 a}{\partial x^4}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^4 b}{\partial y^4}\right\|_{C(\overline{\Omega})}\right) + h^4 \max\left(\left\|\frac{\partial^5 a}{\partial x^5}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^5 b}{\partial y^5}\right\|_{C(\overline{\Omega})}\right).$$

Proof. Employing the approach used in the proof of Theorem 4.4 in [4] (see also the proof of Theorem 4.2 in [2]), it can be shown that

$$\langle L_h v, w\rangle = \mathcal{B}_h^{(1)}(v, w) + \mathcal{B}_h^{(2)}(v, w) + \langle c(x, y)v, w\rangle, \qquad v, w \in V_h, \tag{3.8}$$

where $\mathcal{B}_h^{(1)}$ and $\mathcal{B}_h^{(2)}$ are bilinear forms from $V_h \times V_h$ into R such that

$$\mathcal{B}_h^{(1)}(v, w) = \mathcal{B}_h^{(1)}(w, v), \tag{3.9}$$

$$\alpha\langle -\Delta_h v, v\rangle \le \mathcal{B}_h^{(1)}(v, v) \le \beta\langle -\Delta_h v, v\rangle, \tag{3.10}$$

$$|\mathcal{B}_h^{(2)}(v, w)| \le C\eta(h)\langle -\Delta_h v, v\rangle^{1/2}\langle -\Delta_h w, w\rangle^{1/2}, \tag{3.11}$$

where α, β, $\eta(h)$ are as in (3.3), (3.7), and the positive constant C is independent of h, a, b, c. Moreover, by Theorem 2.1 and Corollary 2.1 in [1],

$$\lambda(h)E \le -\Delta_h, \tag{3.12}$$

where $\lambda(h)$ is given in (3.6). Therefore (3.4) follows easily from (3.8) and (3.10)–(3.12).

For $w = (-\Delta_h)^{-1}(L_h - L_h^*)v$, (3.8), (3.9), and (3.11) give

$$\langle w, (L_h - L_h^*)v\rangle = \mathcal{B}_h^{(2)}(v, w) - \mathcal{B}_h^{(2)}(w, v) \le 2C\eta(h)\langle -\Delta_h v, v\rangle^{1/2}\langle w, (L_h - L_h^*)v\rangle^{1/2},$$

and hence

$$\langle w, (L_h - L_h^*)v\rangle \le 4C^2\eta^2(h)\langle -\Delta_h v, v\rangle,$$

which implies (3.5). □

3.2. PR and PMR methods. Let the operator L_h from V_h into V_h be defined by (3.2), and let $f_h \in V_h$ be such that $f_h(\xi) = f(\xi)$, $\xi \in \mathcal{G}$. Then (1.3) is equivalent to finding $u_h \in V_h$ such that

$$L_h u_h = f_h. \tag{3.13}$$

Assume that the assumptions of Theorem 3.1 are satisfied and that

$$c(x, y) > -2\pi^2\alpha, \qquad (x, y) \in \overline{\Omega}. \tag{3.14}$$

By Corollary 5.2 in [7], $\lambda(h) = 2\pi^2 + O(h^4)$, and hence

$$\alpha + \frac{\gamma_*}{\lambda(h)} = \alpha + \frac{\gamma_*}{2\pi^2} + O(h^4). \tag{3.15}$$

Therefore (3.4), (3.5), (3.7), (3.14), and (3.15) show that for h sufficiently small the operators $A = L_h$ and $B = -\Delta_h$ satisfy the assumptions of Lemma 2.1 in the Hilbert space $H = V_h$ with

$$\gamma_1 = \alpha + \frac{\gamma_*}{\lambda(h)} - C\eta(h), \quad \gamma_2 = \beta + \frac{\gamma^*}{\lambda(h)} + C\eta(h), \quad \gamma_3 = C\eta(h). \tag{3.16}$$

It follows from (2.9) that the PR method for (3.13) takes the form

$$-\Delta_h(u_h^{(k+1)} - u_h^{(k)}) = \bar{\tau}(f_h - L_h u_h^{(k)}), \qquad k = 0, 1, \ldots, \tag{3.17}$$

where $\bar{\tau}$ is defined by (2.3) with γ_1, γ_2, γ_3 of (3.16), and $u_h^{(0)} \in V_h$ is given. Using (2.8) of [12] and (3.2) of [5] it can be shown that there exist positive constants C_1 and C_2, independent of h, such that

$$C_1\|v\|_{H^1(\Omega)} \le \|v\|_{-\Delta_h} \le C_2\|v\|_{H^1(\Omega)}, \qquad v \in V_h. \tag{3.18}$$

Therefore it follows from (2.10) with $D = B$ that $u_h^{(k)}$ generated by (3.17) satisfies

$$\|u_h^{(k)} - u_h\|_{H^1(\Omega)} \le C\rho^k\|u_h^{(0)} - u_h\|_{H^1(\Omega)}, \tag{3.19}$$

where C is a positive constant independent of h, a, b, and c, and ρ is given by (2.4) with γ_1, γ_2, γ_3 of (3.16), and hence

$$\rho = \frac{\beta - \alpha + (\gamma^* - \gamma_*)/(2\pi^2)}{\beta + \alpha + (\gamma^* + \gamma_*)/(2\pi^2)} + O(h). \tag{3.20}$$

Equations (3.19) and (3.20) show that, for sufficiently small h, the convergence rate of the PR method applied to (3.13) is independent of h. It should be noted that the constant C appearing in (3.16) is not known explicitly, and hence the exact value of the parameter $\bar{\tau}$ given by (2.3) is not available. However, it is justifiable to take

$$\tilde{\tau} = \frac{2}{\alpha + \beta + (\gamma_* + \gamma^*)/(2\pi^2)}$$

in place of $\bar{\tau}$ in (3.17), since $\bar{\tau} = \tilde{\tau} + O(h)$. In fact, this was done in all of the numerical experiments involving the PR method and no noticeable deterioration of the convergence rate was observed.

It follows from (2.15) that the PMR method for solving (3.13) takes the form:

Choose $u_h^{(0)} \in V_h$, compute $r_h^{(0)} = f_h - L_h u_h^{(0)}$, and solve $-\Delta_h w_h^{(0)} = r_h^{(0)}$.

For $k = 0, 1, \ldots,$

$$\begin{aligned}
&\text{Compute } z_h^{(k)} = L_h w_h^{(k)}.\\
&\text{Solve } -\Delta_h v_h^{(k)} = z_h^{(k)}.\\
&\text{Compute } \tau_k = \langle z_h^{(k)}, w_h^{(k)}\rangle / \langle z_h^{(k)}, v_h^{(k)}\rangle.\\
&\text{Compute } u_h^{(k+1)} = u_h^{(k)} + \tau_k w_h^{(k)}.\\
&\text{Compute } w_h^{(k+1)} = w_h^{(k)} - \tau_k v_h^{(k)}.
\end{aligned} \tag{3.21}$$

To examine more closely the convergence rate of (3.21), we require the following result.

LEMMA 3.1. *Assume that the assumptions of Theorem* 3.1 *are satisfied. Then*

$$\left[\left(\alpha+\frac{\gamma_*}{2\pi^2}\right)^2+O(h)\right](-\Delta_h)\le L_h^*(-\Delta_h)^{-1}L_h \le\left[\left(\beta+\frac{\gamma^*}{2\pi^2}\right)^2+O(h)\right](-\Delta_h). \tag{3.22}$$

Proof. It is easy to see, by (3.8)–(3.11), that

$$\begin{aligned}\langle(-\Delta_h)^{-1}L_hv, L_hv\rangle &= \langle(-\Delta_h)^{-1}L_h^{(1)}v, L_h^{(1)}v\rangle \\ &\quad+\langle(-\Delta_h)^{-1}L_h^{(2)}v, L_h^{(2)}v\rangle+2\langle(-\Delta_h)^{-1}L_h^{(1)}v, L_h^{(2)}v\rangle,\end{aligned} \tag{3.23}$$

where

$$L_h^{(1)}=\left[L_h^{(1)}\right]^*, \qquad \delta_1(-\Delta_h)\le L_h^{(1)}\le\delta_2(-\Delta_h), \tag{3.24}$$

$$|\langle L_h^{(2)}v, w\rangle|\le C\eta(h)\langle-\Delta_hv, v\rangle^{1/2}\langle-\Delta_hw, w\rangle^{1/2}, \tag{3.25}$$

and $\delta_1=\alpha+\gamma_*/\lambda(h)$, $\delta_2=\beta+\gamma^*/\lambda(h)$. It follows from (3.24) that

$$\delta_1\left[L_h^{(1)}\right]^{-1}\le(-\Delta_h)^{-1}\le\delta_2\left[L_h^{(1)}\right]^{-1},$$

and hence

$$\delta_1^2\langle-\Delta_hv, v\rangle\le\langle(-\Delta_h)^{-1}L_h^{(1)}v, L_h^{(1)}v\rangle\le\delta_2^2\langle-\Delta_hv, v\rangle. \tag{3.26}$$

With $w=(-\Delta_h)^{-1}L_h^{(2)}v$, (3.25) implies that

$$\langle w, L_h^{(2)}v\rangle^{1/2}\le C\eta(h)\langle-\Delta_hv, v\rangle^{1/2},$$

and hence

$$0\le\langle(-\Delta_h)^{-1}L_h^{(2)}v, L_h^{(2)}v\rangle\le C^2\eta^2(h)\langle-\Delta_hv, v\rangle. \tag{3.27}$$

Using the Cauchy–Schwarz inequality, (3.26), and (3.27), we also obtain

$$\begin{aligned}|\langle(-\Delta_h)^{-1}L_h^{(1)}v, L_h^{(2)}v\rangle| &= |\langle(-\Delta_h)^{-1/2}L_h^{(1)}v, (-\Delta_h)^{-1/2}L_h^{(2)}v\rangle| \\ &\le C\delta_2\eta(h)\langle-\Delta_hv, v\rangle.\end{aligned} \tag{3.28}$$

Finally, (3.22) follows from (3.23), (3.26)–(3.28). □

If h is sufficiently small, then it follows from (2.16), (3.22), and (3.18) that the $u_h^{(k)}$ generated by (3.21) satisfy (3.19) with C independent of h, and ρ given by (3.20). Therefore, as was the case for the PR method, the convergence rate of the PMR method applied to (3.13) is independent of h.

3.3. Implementation and cost. Scaled standard Hermite basis functions $\{\phi_j\}_{j=0}^{2N+1}$ for the space of piecewise Hermite cubics on the partition $\{t_i\}_{i=0}^N$ of [0, 1] were used to implement the orthogonal spline collocation PR and PMR methods. For $i, j=0,\dots,N$, these basis functions are defined by

$$\phi_{2j}(t_i)=\delta_{i,j}, \quad \phi_{2j}'(t_i)=0, \quad \phi_{2j+1}(t_i)=0, \quad \phi_{2j+1}'(t_i)=h^{-1}\delta_{i,j},$$

where $\delta_{i,j}$ is the Kronecker delta. Clearly, if $v_h \in V_h$, then

$$v_h(x, y) = \sum_{i,j=0}^{2N+1} v_{i,j}\phi_i(x)\phi_j(y), \tag{3.29}$$

where

$$v_{2i,2j} = v_h(t_i, t_j), \qquad v_{2i+1,2j} = h\frac{\partial v_h}{\partial x}(t_i, t_j),$$

$$v_{2i,2j+1} = h\frac{\partial v_h}{\partial y}(t_i, t_j), \qquad v_{2i+1,2j+1} = h^2\frac{\partial^2 v_h}{\partial x \partial y}(t_i, t_j).$$

Hence any $v_h \in V_h$ is uniquely represented by either $\{v_h(\xi)\}_{\xi\in\mathcal{G}}$, the values of v_h on $\mathcal{G}$, or by $\{v_{i,j}\}_{i,j=0}^{2N+1}$, the expansion coefficients of (3.29). In both iterative methods, the successive iterates $u_h^{(k)}$ were represented in terms of their expansion coefficients $\{u_{i,j}^{(k)}\}_{i,j=0}^{2N+1}$. Collocation problems of the form $-\Delta_h v_h = w_h$, where $v_h, w_h \in V_h$, were solved by the fast Fourier transform solver of [1]. For a given $\{w_h(\xi)\}_{\xi\in\mathcal{G}}$, this solver requires $O(N^2 \ln N)$ arithmetic operations to produce $\{v_{i,j}\}_{i,j=0}^{2N+1}$. It is important to note that, for a given

$$\vec{v}_h = [v_{0,0}, \ldots, v_{0,2N+1}, \ldots, v_{2N+1,0}, \ldots, v_{2N+1,2N+1}]^T,$$

the evaluation of $\{v_h(\xi)\}_{\xi\in\mathcal{G}}$ involves multiplications of $\vec{v}_h$ by a matrix, which is the tensor product of $(2N+2) \times (2N+2)$ almost block diagonal matrices with four nonzero elements in each row. Therefore, the cost of such multiplications is $O(N^2)$. Similarly, for a given $\{v_{i,j}\}_{i,j=0}^{2N+1}$, $\{L_h v_h(\xi)\}_{\xi\in\mathcal{G}}$ is computed by multiplying $\vec{v}_h$ by four matrices each of which is the tensor product of $(2N+2) \times (2N+2)$ almost block diagonal matrices with four nonzero elements in each row. Therefore, the cost of one iteration in the orthogonal spline collocation PR or PMR method is $O(N^2 \ln N)$. It also follows from (3.19) and (3.20) that if $\|u_h^{(n)} - u_h\|_{H^1(\Omega)} = O(h^3)$ is to be guaranteed, then the number of iterations n should be proportional to $\ln N$. Thus the total cost of the orthogonal spline collocation PR or PMR method for solving (1.3) is $O(N^2 \ln^2 N)$.

4. Extension to nonselfadjoint boundary value problems. Consider the Dirichlet boundary value problem (1.1), where L is the elliptic differential operator given by

$$Lu = -\frac{\partial}{\partial x}\left(a(x, y)\frac{\partial u}{\partial x}\right) - \frac{\partial}{\partial y}\left(b(x, y)\frac{\partial u}{\partial y}\right) + d(x, y)\frac{\partial u}{\partial x} + e(x, y)\frac{\partial u}{\partial y} + c(x, y)u.$$

The corresponding orthogonal spline collocation problem is given by (1.3) or equivalently (3.13), where $(L_h v)(\xi) = Lv(\xi)$, $\xi \in \mathcal{G}$. The following theorem is a counterpart of Theorem 3.1.

THEOREM 4.1. *Assume that a and d are five times continuously differentiable in $\overline{\Omega}$ with respect to x, b and e are five times continuously differentiable in $\overline{\Omega}$ with respect to y, c is continuous in $\overline{\Omega}$, and that* (3.3) *is satisfied. Then*

$$\left(\alpha + \frac{\gamma_*}{\lambda(h)} - C\,[\eta(h) + \sigma(h)]\right)(-\Delta_h) \le L_h \le \left(\beta + \frac{\gamma^*}{\lambda(h)} + C\,[\eta(h) + \sigma(h)]\right)(-\Delta_h),$$

$$(L_h^* - L_h)(-\Delta_h)^{-1}(L_h - L_h^*) \le 4C^2\,[\delta + \eta(h) + \sigma(h)]^2\,(-\Delta_h),$$

where the positive constant C is independent of h, a, b, d, e, and c, and $\lambda(h)$ is given by (3.6), *$\eta(h)$ is given by* (3.7), *and*

$$\gamma_* = \min(0, \min_{(x,y)\in\overline{\Omega}} g(x, y)), \qquad \gamma^* = \max(0, \max_{(x,y)\in\overline{\Omega}} g(x, y)),$$

$$\sigma(h) = h \max\left(\|d\|_{C(\overline{\Omega})}, \|e\|_{C(\overline{\Omega})}\right)$$

$$+ h^2 \max\left(\left\|\frac{\partial d}{\partial x}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^2 d}{\partial x^2}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial e}{\partial y}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^2 e}{\partial y^2}\right\|_{C(\overline{\Omega})}\right)$$

$$+ h^3 \max\left(\left\|\frac{\partial^3 d}{\partial x^3}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^3 e}{\partial y^3}\right\|_{C(\overline{\Omega})}\right)$$

$$+ h^4 \max\left(\left\|\frac{\partial^4 d}{\partial x^4}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^5 d}{\partial x^5}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^4 e}{\partial y^4}\right\|_{C(\overline{\Omega})}, \left\|\frac{\partial^5 e}{\partial y^5}\right\|_{C(\overline{\Omega})}\right),$$

$$\delta = \max\left(\|d\|_{C(\overline{\Omega})}, \left\|\frac{\partial d}{\partial x}\right\|_{C(\overline{\Omega})}, \|e\|_{C(\overline{\Omega})}, \left\|\frac{\partial e}{\partial y}\right\|_{C(\overline{\Omega})}\right),$$

where $g(x, y) = c(x, y) - [(\partial d/\partial x)(x, y) + (\partial e/\partial y)(x, y)]/2$.

Proof. Rewriting Lu in the form

$$Lu = -\frac{\partial}{\partial x}\left(a(x, y)\frac{\partial u}{\partial x}\right) - \frac{\partial}{\partial y}\left(b(x, y)\frac{\partial u}{\partial y}\right)$$

$$+\frac{1}{2}\left[d(x, y)\frac{\partial u}{\partial x} + \frac{\partial}{\partial x}(d(x, y)u) + e(x, y)\frac{\partial u}{\partial y} + \frac{\partial}{\partial y}(e(x, y)u)\right] + g(x, y)u,$$

and using an approach similar to that in the proof of Theorem 3.1, it can be shown that

$$\langle L_h v, w\rangle = \sum_{i=1}^{4} \mathcal{B}_h^{(i)}(v, w) + \langle g(x, y)v, w\rangle,$$

where the bilinear forms $\mathcal{B}_h^{(1)}$ and $\mathcal{B}_h^{(2)}$ satisfy (3.9)–(3.11) and

$$\mathcal{B}_h^{(3)}(v, v) = 0, \qquad |\mathcal{B}_h^{(3)}(v, w)| \le C\delta\langle -\Delta_h v, v\rangle^{1/2}\langle -\Delta_h w, w\rangle^{1/2},$$

$$|\mathcal{B}_h^{(4)}(v, w)| \le C\sigma(h)\langle -\Delta_h v, v\rangle^{1/2}\langle -\Delta_h w, w\rangle^{1/2}.$$

The remainder of the proof is analogous to that of the proof of Theorem 3.1 and is therefore omitted. □

If

$$c(x, y) - \frac{1}{2}\left[\frac{\partial d}{\partial x}(x, y) + \frac{\partial e}{\partial y}(x, y)\right] > -2\pi^2\alpha, \qquad (x, y) \in \overline{\Omega},$$

then it follows from Theorem 4.1 that for h sufficiently small, the operators $A = L_h$ and $B = -\Delta_h$ satisfy the assumptions of Lemma 2.1. However, in contrast to the selfadjoint boundary value problem, the unknown $\gamma_3 = C[\delta + \eta(h) + \sigma(h)] = O(1)$, in general, and hence a good approximation to $\overline{\tau}$ of (2.3) is not readily available. Therefore, the PR method of (3.17) is not applicable for the solution of the orthogonal spline collocation problem corresponding to nonselfadjoint L. Nevertheless, this problem can be still solved by the PMR method (3.21) with the convergence rate given by (2.16).

5. Numerical experiments. The purpose of the numerical experiments was to verify the convergence rates of the PR and PMR orthogonal spline collocation methods rather than the accuracy of orthogonal spline collocation itself. Therefore the problem (1.1), (1.2) with

$$a(x, y) = e^{xy}, \quad b(x, y) = 1 + \sin(xy), \quad c(x, y) = 0, \quad u(x, y) = 10x(1 - x)y(1 - y),$$

was discretized by orthogonal spline collocation with piecewise Hermite bicubics that led to (1.3) with $u_h = u$. Starting with $u_h^{(0)} = 0$, for different values of the stepsize $h = \frac{1}{N}$, the PR method (3.17) and the PMR method (3.21) were used to compute sucessive iterates $u_h^{(k)}$ converging to u_h. Since (3.3) is satisfied with $\alpha = 1$ and $\beta = e$, following the discussion of §3.2, the iteration parameter $\bar{\tau}$ in (3.17) was replaced with $\tilde{\tau} = 2/(1 + e)$. Table 1 presents the discrete maximum norm errors

$$\varepsilon_N^{(k)} = \max_{0 \le i, j \le N} |(u_h - u_h^{(k)})(t_i, t_j)|$$

for both the PR and PMR methods. (The errors $\varepsilon_N^{(k)}$ were computed for convenience since the $H^1(\Omega)$ norm errors require the computation of integrals.)

TABLE 1
Errors $\varepsilon_N^{(k)}$ *in the* PR *and* PMR *methods.*

k	0	2	4	6	8
$\varepsilon_5^{(k)}$ in PR	.6	$.8 \times 10^{-1}$	$.1 \times 10^{-1}$	$.2 \times 10^{-2}$	$.3 \times 10^{-3}$
$\varepsilon_5^{(k)}$ in PMR	.6	$.2 \times 10^{-1}$	$.2 \times 10^{-2}$	$.2 \times 10^{-3}$	$.3 \times 10^{-4}$
$\varepsilon_{50}^{(k)}$ in PR	.6	$.8 \times 10^{-1}$	$.1 \times 10^{-1}$	$.2 \times 10^{-2}$	$.3 \times 10^{-3}$
$\varepsilon_{50}^{(k)}$ in PMR	.6	$.2 \times 10^{-1}$	$.2 \times 10^{-2}$	$.3 \times 10^{-3}$	$.4 \times 10^{-4}$

The obtained results show that the convergence rates of both methods were independent of h which confirms the theoretical results of §3.2. The numerical results also indicate, as expected, that the PMR method converges faster than the PR method, and hence is more efficient with respect to the number of arithmetic operations since each iteration of the PMR method requires about the same number of arithmetic operations as one iteration of the PR method. It should be noted that the PMR method does not have to converge faster than the PR method, due to the different paths taken by the PMR and PR methods. However, in practice, the PMR method usually does outperform the PR method.
