Special Issue on Iterative Methods in Numerical Linear Algebra

This issue of *SISC* is dedicated to papers that were presented at the Colorado Conference on Iterative Methods, which was held in Breckenridge, Colorado, April 5–9, 1994. This was the ninth in the series of Copper Mountain Conferences, the third dedicated to general iterative methods, and the first held outside Copper Mountain. Although the two locations are less than 20 miles apart, Breckenridge offered a new setting complete with an historic mining town that was established over a century ago.

The meeting was attended by approximately 180 mathematicians from all over the world who presented 115 talks on a broad range of subjects. The talks were organized into morning and afternoon sessions leaving the afternoons free for informal discussions. Loosely grouped by topic, the sessions included

Domain Decomposition (8 talks)
Nonlinear Problems (7 talks)
Integral Equations and Inverse Problems (4 talks)
Eigenvalue Problems (3 talks)
Nonsymmetric System Solvers (16 talks)
Parallel Computation (16 talks)
Iterative Method Theory (4 talks)
Software and Programming Environments (4 talks)
ODE Solvers (4 talks)
Student Papers (3 talks)
Multigrid and Multilevel Methods (12 talks)
Applications (11 talks)
Preconditioners (7 talks)
Teoplitz and Circulant Matrix Solvers (3 talks)
Saddle Point Problem Solvers (3 talks)

In addition, two evening workshops were held on

Recent Progress in Iterative Software (5 talks)
Robust Iterative Methods (5 talks)

A special effort was made to bring students to the meeting. The vehicle for this was the Student Paper Competition, which was funded by the National Science Foundation. Students were asked to submit an original research paper consisting primarily of their own work and limited to 10 pages in length. The winners were chosen by a panel of judges taken from the program committee. Ten excellent papers were submitted, which made the judges' job difficult but gratifying. This year's winners were

First place: Johannas Tausch, Colorado State University, *"Equivalent Preconditioners for Boundary Element Methods"*;
Second place: Lina Hemmingsson, Uppsala University, *"Analysis of Semi-Toeplitz Preconditioners for First-Order PDE's"*;
Third place: Qing He, Arizona State University, *"Parallel Algorithms for Unconstrained Optimizations by Multisplitting."*

The winners presented their papers in a special session just prior to the conference banquet.

Due to the generosity of the NSF we were able to provide travel expenses, lodging, and registration for the three winners and lodging and registration for all contestants who were able to attend. Lodging and registration expenses were provided to a number of other students. In all, 22 students were given support.

This special issue contains a set of papers that represent a broad range of topics. The issue begins with a paper by Toh and Trefethen on fast calculation of pseudospectra of matrices, followed by a paper by Eisenstat and Walker on inexact Newton methods. Then, a group of six papers are concerned with preconditioned iterative methods. The first of this group, by Elman and Silvester, develops multilevel preconditionings for the Navier–Stokes equations that yield a condition independent of the mesh parameter. Also notable in this group are two student papers, one by Lina Hemmingsson and the other by Johannas Tausch. The next group of five papers involves multigrid methods either explicitly or as a preconditioning strategy. The first of this group, by Meza and Tuminaro, describes a multigrid preconditioner for semiconductor equations. This exemplifies the many talks at the meeting devoted to iterative methods applied to real world problems. The last paper in this group, by Henson, Limber, McCormick, and Robinson, develops a multilevel method for image reconstruction and is followed by two other papers on iterative solution of integral equations. The next two papers are concerned with parallel computing issues and are representative of the large number of talks on parallel computing at the meeting. The final three papers represent a cross section of new ideas in iterative methods.

I would like to thank the following members of the program committee for their help in editing this special issue.

Howard Elman
Anne Greenbaum
Seymour Parter
Homer Walker
Roland Freund
Steve McCormick
Nick Trefethen

Through their efforts, the articles contained in this special issue were carefully refereed and brought to print on schedule.

I would like to extend a special thanks to Fred Howes of the Applied Mathematical Sciences Program of the Department of Energy for generous support of this meeting. Without his help, this meeting could not have taken place. Special thanks also go to Mike Steuerwalt of the NSF Computational Mathematics Program for his generous support of the Student Paper Competition.

As this issue goes to press, planning for the next conference in this series is in its final stages. It will be held in Copper Mountain, Colorado, April 9–13, 1996 and will again focus on general iterative methods. It is our hope that the lively interaction and fine quality of presentations and papers that have marked previous meetings can be duplicated at the upcoming meeting.

CALCULATION OF PSEUDOSPECTRA BY THE ARNOLDI ITERATION*

KIM-CHUAN TOH† AND LLOYD N. TREFETHEN‡

Abstract. The Arnoldi iteration, usually viewed as a method for calculating eigenvalues, can also be used to estimate pseudospectra. This possibility may be of practical importance, because in applications involving highly nonnormal matrices or operators, such as hydrodynamic stability, pseudospectra may be physically more significant than spectra.

Key words. Arnoldi, Lanczos, pseudospectra, numerical range, hydrodynamic stability

AMS subject classifications. 65F15, 47A12

1. Introduction.

Large-scale nonsymmetric matrix eigenvalue problems, which typically arise via discretization of non-self-adjoint differential or integral operators, are commonly solved numerically by the Arnoldi iteration and its variants [1], [8], [18], [25]. In this paper we explore the possibility that the Arnoldi iteration can also be used for the estimation of pseudospectra. Such an idea was first proposed by Nachtigal, Reichel, and Trefethen [17] and Freund [7], and methods much closer to those of the present paper have been presented by Ruhe in talks at the Householder (1993) and St. Girons (1994) symposia on linear algebra [23]. Recent developments indicate that in some applications, the pseudospectra of a matrix or operator may be more significant physically than its spectrum (see §7). Since calculation of pseudospectra is much more expensive than calculation of spectra, this suggests that it may be desirable to develop methods for determining them iteratively.

The idea investigated here is that the pseudospectra of a matrix A can be approximated by those of the Hessenberg matrices constructed by an Arnoldi iteration. In the version of this paper originally submitted for publication [30], we made use of the $n \times n$ Hessenberg matrices H_n (see the next section for definitions). However, Tom Manteuffel recommended to us that it might be advantageous to consider instead the $(n+1) \times n$ Hessenberg matrices $\tilde{H}_n$, as is done, for example, in [13]. Meanwhile, this is also the idea that Axel Ruhe has been investigating. In the end we have decided to present experiments here for both H_n and $\tilde{H}_n$, while giving greater attention to the latter. For the examples we have computed, the distinction between the two makes little difference in practice, but $\tilde{H}_n$ has theoretical advantages (monotonic convergence) and also conceptual appeal, because it bypasses the usual consideration of Ritz values or "Arnoldi eigenvalue estimates." Thus we find ourselves exploring a new way of interpreting approximations not only of pseudospectra but also of spectra, one that may be of interest even in the special case of the Lanczos iteration for symmetric matrices.

For any $\epsilon \geq 0$, the ϵ-pseudospectrum of a matrix A is defined by

$$\Lambda_\epsilon(A) = \{z \in \mathbf{C} : \ \|(zI - A)^{-1}\| \geq \epsilon^{-1}\}, \tag{1}$$

with the convention $\|(zI - A)^{-1}\| = \infty$ if $z \in \Lambda(A)$, the spectrum of A [32]. If $\|\cdot\|$ is the 2-norm, an equivalent definition is

*Received by the editors May 18, 1994; accepted for publication (in revised form) April 10, 1995. This work was supported by NSF grant DMS-9116110 and DOE grant DE-FG02-94ER25199.

$$\Lambda_\epsilon(A) = \{z \in \mathbf{C} : \sigma_{\min}(zI - A) \le \epsilon\}, \tag{2}$$

where $\sigma_{\min}(zI - A)$ denotes the smallest singular value of $zI - A$. Either definition makes it clear that the pseudospectra of a matrix are a family of nested subsets of C, with $\Lambda_0(A) = \Lambda(A)$. They can be computed most straightforwardly by evaluating $\sigma_{\min}(zI - A)$ on a grid of values in the complex z-plane, then sending the result to a contour plotter. S.-H. Lui has shown that this straightforward algorithm can be speeded up by a factor of five to ten by a preliminary reduction of A to Hessenberg form followed by inverse iteration combined with continuation [12]. Variants of this procedure involve triangular instead of Hessenberg reduction or Lanczos instead of inverse iteration. Such ideas apply to our matrices H_n and $\tilde{H}_n$ as well as A, and thus have little bearing on the relative speedup to be gained via Arnoldi iterations, so we shall not give details.

If A is normal (has a complete set of orthogonal eigenvectors), then $\Lambda_\epsilon(A)$ is just the closed ϵ-neighborhood of $\Lambda(A)$, but if A is far from normal, $\Lambda_\epsilon(A)$ may be much larger. These are the cases where difficulties are likely to arise if one tries to use the spectrum $\Lambda(A)$ to estimate quantities such as $\|A^n\|$, $\|e^{tA}\|$, or $\|f(A)\|$. Better estimates can often be obtained from the pseudospectra using methods such as Cauchy integrals, the Laplace transform, or the Kreiss matrix theorem [21], [32]–[34].

2. The Arnoldi iteration. Let A be a real or complex $m \times m$ matrix, and let $\|\cdot\|$ denote the 2-norm. A complete unitary reduction of A to upper Hessenberg form might be written $A = QHQ^*$ or $AQ = QH$. The idea of the Arnoldi iteration is to compute the successive steps of this reduction columnwise, starting from the condition that the first column of Q is a prescribed vector q_1 with $\|q_1\| = 1$. Let Q_n be the $m \times n$ matrix whose columns are the first n columns of Q,

$$Q_n = \left[\begin{array}{c|c|c|c} & & & \\ q_1 & q_2 & \cdots & q_n \\ & & & \end{array}\right], \tag{3}$$

and let $\tilde{H}_n$ be the $(n+1) \times n$ upper-left section of H,

$$\tilde{H}_n = \begin{pmatrix} h_{11} & & \cdots & h_{1n} \\ h_{21} & h_{22} & & \vdots \\ & \ddots & \ddots & \\ & & h_{n,n-1} & h_{nn} \\ & & & h_{n+1,n} \end{pmatrix}. \tag{4}$$

Then we have

$$AQ_n = Q_{n+1}\tilde{H}_n, \tag{5}$$

and the nth column of this equation can be written $Aq_n = h_{1n}q_1 + \cdots + h_{nn}q_n + h_{n+1,n}q_{n+1}$. The Arnoldi iteration is the modified Gram–Schmidt iteration that implements this $(n+1)$-term recurrence relation:

```
$q_1$ = arbitrary ($\|q_1\| = 1$)
for $n = 1, 2, 3, \ldots$
    $v = Aq_n$
    for $j = 1$ to $n$
        $h_{jn} = q_j^* v$
        $v = v - h_{jn} q_j$
    $h_{n+1,n} = \|v\|$
    $q_{n+1} = v / h_{n+1,n}$
```

The vectors $\{q_j\}$ form orthogonal bases of the successive *Krylov subspaces* generated by A and q_1,

$$\mathcal{K}_n = \langle q_1, Aq_1, \ldots, A^{n-1}q_1 \rangle = \langle q_1, q_2, \ldots, q_n \rangle \subseteq \mathbf{C}^m.$$

As a practical matter the iteration can be implemented with the aid of a "black box" procedure for computing the matrix–vector products Aq_n, which can be designed to take advantage of sparsity or other structure of A.

The product $Q_n^* Q_{n+1}$ is equal to the $n \times (n+1)$ identity, i.e., the $n \times (n+1)$ matrix with 1 on the main diagonal and 0 elsewhere. Therefore $Q_n^* Q_{n+1} \tilde{H}_n$ is the $n \times n$ Hessenberg matrix obtained by removing the last row of $\tilde{H}_n$,

$$H_n = \begin{pmatrix} h_{11} & & \cdots & h_{1n} \\ h_{21} & h_{22} & & \vdots \\ & \ddots & \ddots & \\ & & h_{n,n-1} & h_{nn} \end{pmatrix}. \tag{6}$$

From (5) we can accordingly derive the formula

$$H_n = Q_n^* A\, Q_n. \tag{7}$$

Though they differ in only one row, H_n and $\tilde{H}_n$ are entirely different objects. To highlight the difference, it is helpful to extend $\tilde{H}_n$ to the $m \times n$ matrix $\hat{H}_n$ consisting of the first n columns of H:

$$\hat{H}_n = \begin{pmatrix} h_{11} & & \cdots & h_{1n} \\ h_{21} & h_{22} & & \vdots \\ & \ddots & \ddots & \\ & & h_{n,n-1} & h_{nn} \\ & & & h_{n+1,n} \\ 0 & & & 0 \\ \vdots & & & \vdots \\ 0 & & & 0 \end{pmatrix}. \tag{8}$$

The matrices $\tilde{H}_n$ and $\hat{H}_n$ are identical except for the presence of $m - (n+1)$ additional rows of zeros in the latter, and thus they have, for example, the same rank, norm, and singular values.

We can interpret H_n and $\hat{H}_n$ as follows. With respect to the basis $\{q_1, q_2, \ldots\}$, $\hat{H}_n$ represents the action of A on $\mathcal{K}_n$, whereas H_n represents the same operation followed by an orthogonal projection back into $\mathcal{K}_n$. Since the domain and range of H_n are the same, it makes sense to speak of the eigenvalues of H_n; but since $\hat{H}_n$ has distinct domain and range, it does not make sense to speak of its eigenvalues.

3. Estimation of pseudospectra and numerical range. We propose that in many cases, for sufficiently large n, some of the pseudospectra of A can be reasonably approximated by the corresponding pseudospectra of H_n or $\tilde{H}_n$:

$$\Lambda_\epsilon(A) \approx \Lambda_\epsilon(H_n) \approx \Lambda_\epsilon(\tilde{H}_n). \tag{9}$$

For $n \ll m$, the computation of $\Lambda_\epsilon(H_n)$ or $\Lambda_\epsilon(\tilde{H}_n)$ will be $O((m/n)^3)$ times faster than that of $\Lambda_\epsilon(A)$. Note that in considering $\Lambda_\epsilon(\tilde{H}_n)$, we are dealing with the ϵ-pseudospectrum of a rectangular matrix. This set can be defined just as for square matrices by (1), with I now denoting a rectangular version of the identity and $(zI - A)^{-1}$ denoting the pseudoinverse. Equivalently, it can be defined by (2). As far as we know, pseudospectra of rectangular matrices have not been discussed before. However, the smallest singular value of $\tilde{H}_n$ has been considered in work by Meza, for example, on iterative solution of ill-conditioned systems of equations [16].

We are not aware of very satisfactory theorems to justify the approximation $\Lambda_\epsilon(A) \approx \Lambda_\epsilon(H_n)$. On the other hand the approximations $\Lambda_\epsilon(A) \approx \Lambda_\epsilon(\tilde{H}_n)$ converge monotonically (cf. (3.21) of [16] and Thm. 3.1 of [13]).

THEOREM 1. *Let an $m \times m$ matrix A be unitarily similar to a Hessenberg matrix H, and let $\tilde{H}_n$ denote the $(n+1) \times n$ section* (4). *(In particular, $\tilde{H}_n$ might be computed by an Arnoldi iteration, with arbitrary restarts in case a zero subdiagonal element $h_{n+1,n}$ is encountered.) Then for any z we have*

$$\sigma_{\min}(zI - \tilde{H}_1) \ge \sigma_{\min}(zI - \tilde{H}_2) \ge \sigma_{\min}(zI - \tilde{H}_3) \ge \cdots \ge \sigma_{\min}(zI - A), \tag{10}$$

and, consequently, for any $\epsilon \ge 0$,

$$\Lambda_\epsilon(\tilde{H}_1) \subseteq \Lambda_\epsilon(\tilde{H}_2) \subseteq \Lambda_\epsilon(\tilde{H}_3) \subseteq \cdots \subseteq \Lambda_\epsilon(A). \tag{11}$$

Proof. Since $zI - \tilde{H}_n$ and $zI - \hat{H}_n$ differ only by rows of zeros, they have the same singular values, and we may replace $\tilde{H}_n$ in (10) by $\hat{H}_n$. Since $zI - A$ and $zI - H$ are unitarily similar, they too have the same singular values, and we may replace A in (10) by H. Since $\hat{H}_n$ is simply the first n columns of H, (10) now follows directly from the characterization $\sigma_{\min}(A) = \min_{\|x\|=1} \|Ax\|$. By (2), this implies (11). □

It is interesting to compare Theorem 1 with the more familiar interpretation of Arnoldi and Lanczos iterations. Conventionally, a set of n Ritz values are considered at step n, and one is faced with the problem of estimating how close they may be to eigenvalues of A. In Theorem 1, there are no Ritz values. However, it may be noted that Ritz values can be defined as the points z at which $\sigma_{\min}(zI - H_n)$ achieves a local minimum (namely, zero). An analogue for the rectangular case would be to consider the points at which $\sigma_{\min}(zI - \tilde{H}_n)$ achieves a local minimum. It follows from (10) that this minimum value will be equal to zero if and only if z is an eigenvalue of A corresponding to an eigenvector that lies in the Krylov subspace $\mathcal{K}_n$.

Besides pseudospectra, it is well known that an Arnoldi iteration also may provide estimates of the numerical range (= field of values) of A, which we denote by $W(A)$. Now it is H_n that we most naturally make use of:

$$W(A) \approx W(H_n). \tag{12}$$

gain we have monotonic convergence (cf. Thm. 3.1 of [13]).

THEOREM 2. *Let A and H be as in Theorem* 1, *and let H_n denote the $n \times n$ section* (6). *Then*

$$W(H_1) \subseteq W(H_2) \subseteq W(H_3) \subseteq \cdots \subseteq W(A). \tag{13}$$

Proof. This is an easy consequence of the definition $W(A) = \{x^*Ax : \|x\| = 1\}$. □

4. Numerical experiments. We now turn to numerical examples computed in MATLAB. Consider first the $m \times m$ "Kahan matrix"

$$A = \begin{pmatrix} 1 & -c & -c & -c & -c \\ & s & -sc & -sc & -sc \\ & & s^2 & -s^2c & -s^2c \\ & & & \ddots & \vdots \\ & & & & s^{m-1} \end{pmatrix}, \tag{14}$$

where $s^{m-1} = 0.1$ and $s^2 + c^2 = 1$. Matrices of this type were proposed by Kahan to illustrate that QR factorization with column pivoting is not a fail-safe method of numerical rank determination [8], [11]. Pseudospectra of this matrix, for $m = 32$, were plotted in [32].

In Fig. 1, we take $m = 64$ and consider Arnoldi approximations $\Lambda_\epsilon(H_n)$ to $\Lambda_\epsilon(A)$ with $n = 5, 10, 15, 20$. At each of these steps, the figure shows the approximate numerical range and the ϵ-pseudospectra for $\epsilon = 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}$. In this and all of our numerical experiments, the initial vector q_1 is random (independent normally distributed entries).

To the eye, at least, the convergence of $\Lambda_\epsilon(H_n)$ to $\Lambda_\epsilon(A)$ in Fig. 1 is compelling. At $n = 5$, the Arnoldi iteration has not learned much of value, but by $n = 10$, recognizable approximations have begun to emerge. At $n = 20$ the approximations are excellent. Since the cost of an SVD grows cubically with the dimension of the matrix, and 1000 or more SVDs are involved in making one of these plots, calculations of pseudospectra even for these small matrices can be time-consuming, and if $n = 64$ can be replaced by $n = 20$, the savings will be a factor of around 30.

Note that, as is typical in cases of extreme nonnormality, the convergence of the eigenvalues of H_n to those of A in Fig. 1 is slow. The eigenvalues are too ill conditioned to be easily resolved. This is just the sort of problem where eigenvalues are likely to be of limited physical significance and where pseudospectra may provide a useful alternative. For a discussion of the physical significance of pseudospectra, including transient evolution phenomena, the effect of small perturbations, and the notion of "pseudo-resonance" in highly nonnormal systems, see [34].

Figure 2 shows the same computation, for the same matrix, except now the approximations are based on the rectangular Hessenberg matrix $\tilde{H}_n$. Broadly speaking, the approximations are about as good as in Fig. 1. Notice that there are no longer any Ritz values in the plot, which might be considered conceptually advantageous. On the other hand, in dealing with a matrix whose behavior was close to normal in some parts of the complex plane and far from normal in others, it might certainly be convenient to have Ritz values.

Not every matrix behaves as nicely as in Figs. 1 and 2. In Fig. 3 we consider the 64×64 "Grcar matrix," a Toeplitz matrix with -1 on the subdiagonal and 1 on the main diagonal and on the first three superdiagonals. This time, Arnoldi approximations based on $\tilde{H}_n$ at steps 10, 20, 30, and 40 are plotted, and only at $n = 40$ is reasonable convergence of the pseudospectra beginning to be evident. Although $(40/64)^3 \approx 0.24$ is still substantially less than 1, this is

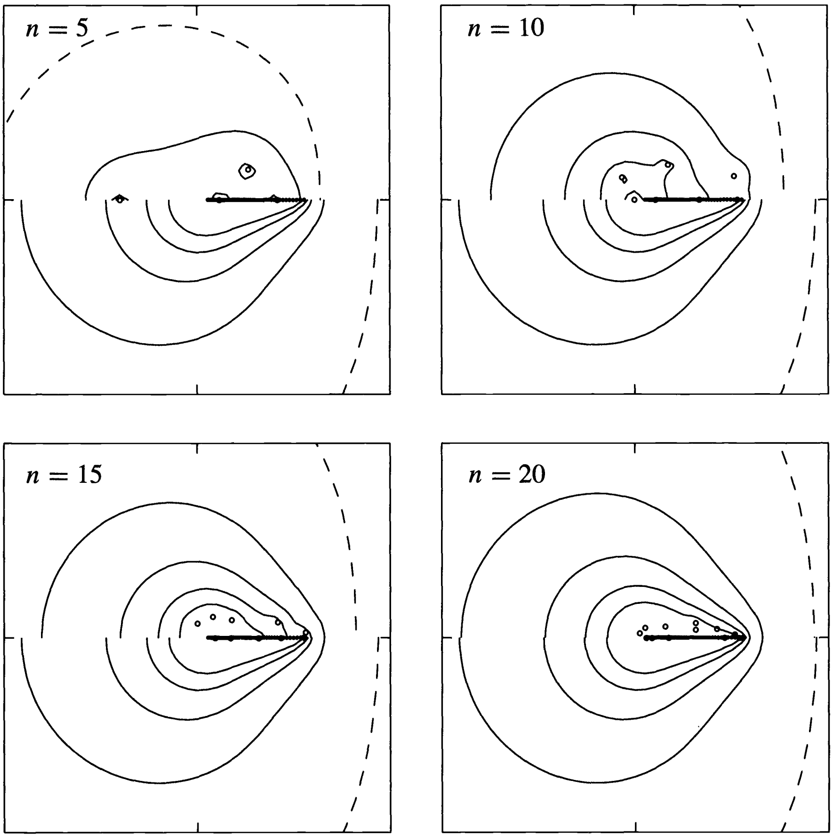

FIG. 1. *ϵ-pseudospectra of the* 64 × 64 *Kahan matrix* (14) *compared with those of four Arnoldi approximations* H_n ($\epsilon = 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}$). *The upper half of each plot corresponds to* $\Lambda_\epsilon(H_n)$, *and the lower half to* $\Lambda_\epsilon(A)$. *The dashed curves represent an analogous comparison of the numerical ranges* $W(H_n)$ *and* $W(A)$. *The small dots are the eigenvalues of* A *in the lower half-plane (hard to distinguish; they appear like a solid interval on the real axis), and the small circles are the eigenvalues of* H_n *in the upper half-plane (Ritz values). The real and imaginary axes are marked by ticks in each plot; the axis limits are* $-1.8 \leq \Re z \leq 1.8$, $-1.8 \leq \Im z \leq 1.8$.

a case where there is probably little to be gained in approximating $\Lambda_\epsilon(A)$ by $\Lambda_\epsilon(\tilde{H}_n)$ (or $\Lambda_\epsilon(H_n)$, whose performance is about the same).

Figures 2 and 3 represent two of the thirteen examples of highly nonnormal matrices considered in [32]. We have plotted Arnoldi approximations to pseudospectra for all of these and find that the Kahan matrix exhibits the best convergence and the Grcar matrix among the worst. Based on these examples alone, one would probably conclude that the Arnoldi approach to calculation of pseudospectra holds some promise but is not completely convincing.

However, the matrices of [32] are not typical of the large-scale problems that arise in practice. For these special matrices, selected for their dramatic pseudospectra, the nonnormality is such that all m eigenvalues are strongly coupled to one another. In applications, it is more typical for a small number of eigenvalues to be dominant and not strongly coupled to the others, with the behavior of the pseudospectra in the vicinity of these eigenvalues being of primary interest. In such cases Arnoldi approximations may perform better.

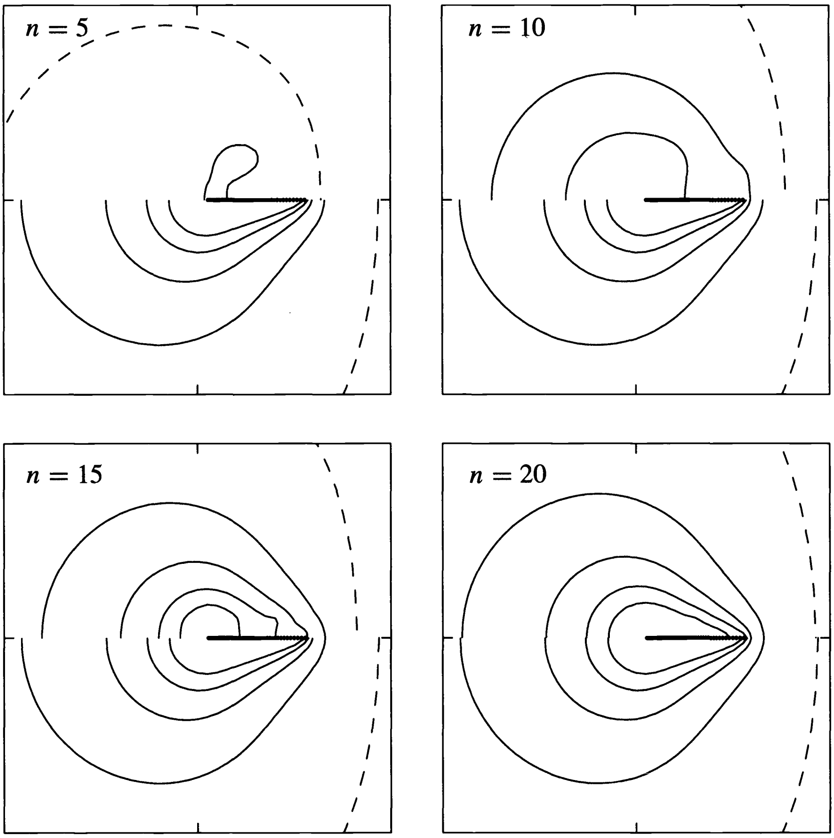

FIG. 2. *Same as Fig.* 1, *but now the curves in the upper half of each plot correspond to* $\Lambda_\epsilon(\tilde{H}_n)$ *instead of* $\Lambda_\epsilon(H_n)$. *Since the Ritz values have no simple connection to* $\tilde{H}_n$, *they are no longer shown. The dashed curves still correspond to* $W(H_n)$ *and* $W(A)$.

Figure 4 presents an example of this kind. Here A is the 64 × 64 bidiagonal matrix defined by

$$a_{k,k+1} = a_{k,k} = k^{-1/2}. \tag{15}$$

We can think of this as a prototype of a highly nonnormal compact operator and imagine that it is the behavior of the spectrum and pseudospectra away from the origin that is of interest. The convergence in this part of the complex plane is excellent. Moreover, it would be nearly as fast even if m were much larger than 64. For an example like this, the payoff in estimating pseudospectra iteratively could be huge.

5. Modified Arnoldi iterations. The large-scale matrices that arise most often in applications are of a kind different from all of our examples so far. These are discretizations of differential operators, which are not compact. As in Fig. 4, it is the behavior near a few leading eigenvalues that is of greatest interest, but the rest of the spectrum will typically extend to ∞ in the complex plane.

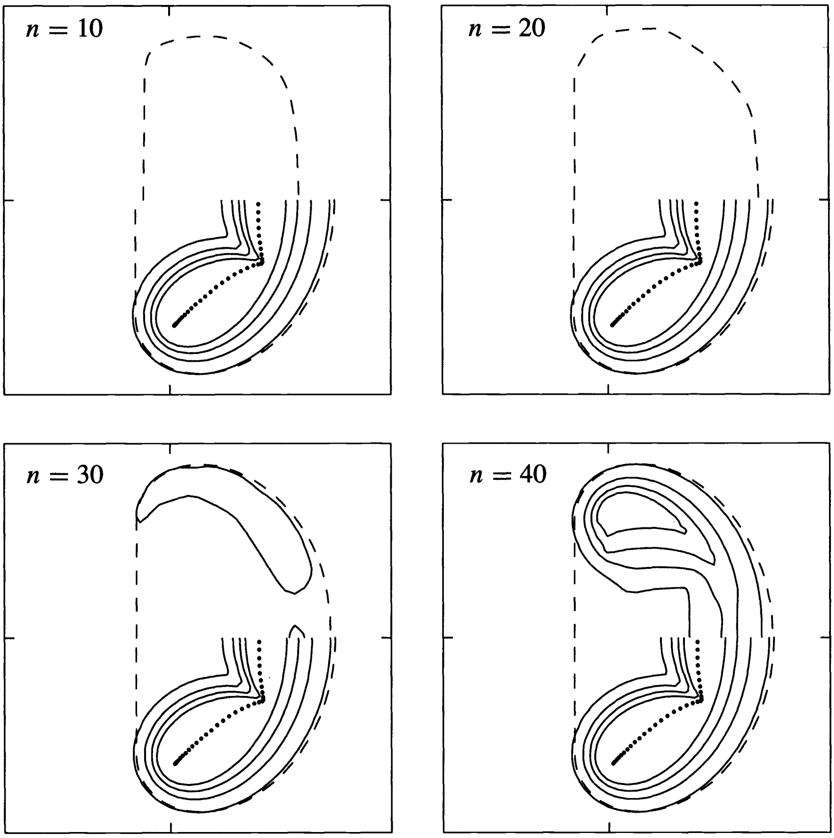

FIG. 3. *Same as Fig. 2, except for the pentadiagonal Grcar matrix of dimension $m = 64$. The axis limits are* $-3 \le \Re z \le 4$, $-3.5 \le \Im z \le 3.5$.

It is well known that a pure Arnoldi iteration may be ineffective in cases of this kind. As an example, consider another bidiagonal matrix defined by

$$a_{k,k} = -0.3k, \qquad a_{k,k+1} = 1. \tag{16}$$

Here the spectral and pseudospectral behavior near the origin should be largely unaffected by whether the dimension is 64 or 64,000. A pure Arnoldi iteration will have difficulty nonetheless, and the difficulty will increase with the dimension. This is illustrated in Fig. 5a, with $m = 64$, where we see quite disappointing convergence to the pseudospectra near $z = 0$.

Solutions to this problem have been proposed by a number of authors. One approach is to suppress the part of the spectrum far from the origin by an ancillary linear process such as a Chebyshev iteration or some other polynomial filter. Such ideas have been investigated by Chatelin and her colleagues and by Saad, Scott, Sorensen, and others [6], [9], [17], [24], [25], [27], [29]. A more powerful possibility, when it is feasible, is to modify the problem with the use of matrix inverses, in effect working with rational functions of A rather than just polynomials. Variations on this theme go by names such as shift-and-invert Arnoldi and rational Krylov iteration, and have been investigated by Ruhe, Saad, and Spence, among others [15], [22], [23], [25]. To be effective, such methods depend on the assumption that inverting A (i.e., solving a system $Ax = b$) is cheaper than the computation of main interest. This

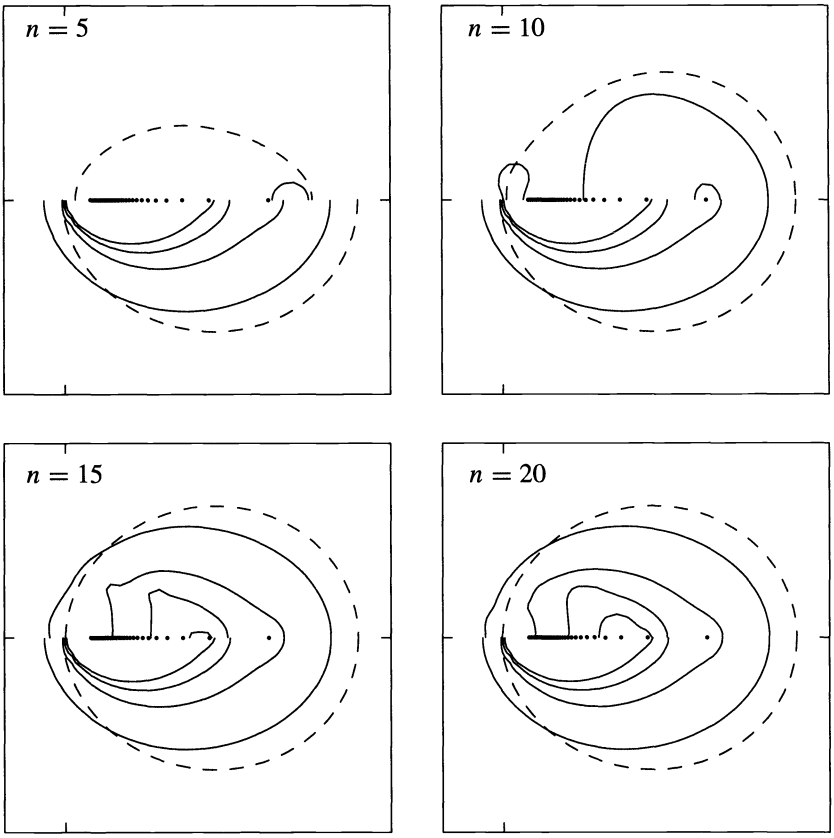

FIG. 4. *Same as Fig. 2 but for the bidiagonal matrix* (15), *a prototype of a compact operator. The axis limits are* $-0.3 \le \Re z \le 1.6$, $-0.95 \le \Im z \le 0.95$.

assumption is satisfied by many sparse eigenvalue problems, since sparsity can often be better taken advantage of for systems of equations than eigenvalues. It is amply satisfied in many calculations of pseudospectra, since these computations are even more expensive. Finally, an intermediate class of acceleration methods is based on preconditioning the eigenvalue problem by inverses not of A itself but of more easily inverted approximations $M \approx A$. This is the idea behind Davidson's method [4], [5] and related methods developed more recently by Meerbergen, Van der Vorst, and others [14], [25], [28].

We shall not attempt a systematic comparison of the uses for estimating pseudospectra of the various acceleration and preconditioning methods that have been proposed. Instead, we shall consider just the simplest modified Arnoldi process to give an idea of the great speedups that may be achieved by these methods. Figure 5b is a repetition of Fig. 5a in which the Arnoldi iteration has been replaced by an "inverse Arnoldi" iteration carried out with A^{-1} instead of A. This entails a solution of a system of equations involving A at each step, but this is a minor matter since A is bidiagonal. The result is a Hessenberg matrix H_n that approximates A^{-1}, and it is the pseudospectra of H_n^{-1} that we plot as approximations to those of A. Since H_n^{-1} is square, the plot also shows its eigenvalues.

Figure 5b shows excellent agreement of $\Lambda_\epsilon(H_n^{-1})$ and $\Lambda_\epsilon(A)$. Evidently the inverse-Arnoldi idea is highly effective for this problem. We take this as illustrative of the kind

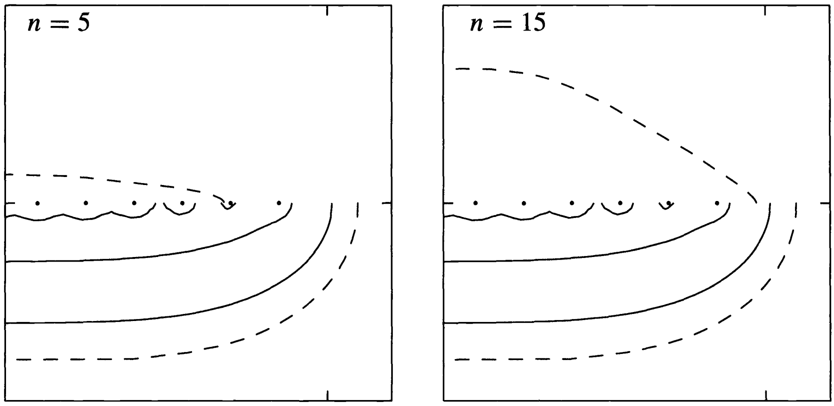

Fig. 5A. *Same as Fig.* 2 *but for the bidiagonal matrix* (16), *a prototype of an unbounded operator. The axis limits are* $-2 \le \Re z \le 0.4$, $-1.2 \le \Im z \le 1.2$.

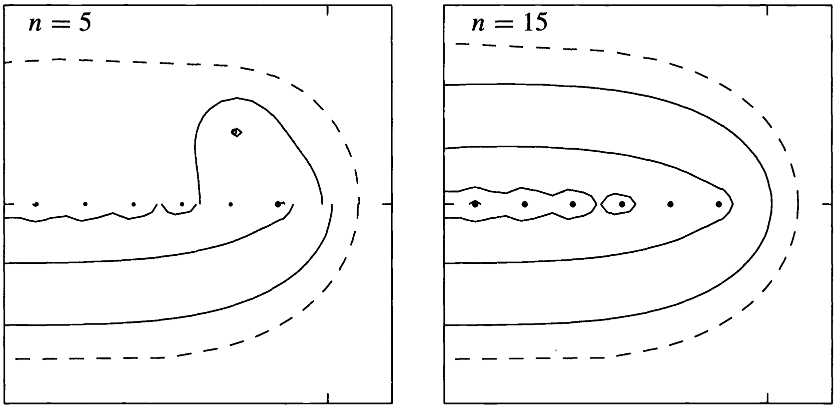

Fig. 5B. *Repetition of Fig.* 5a *with the Arnoldi iteration replaced by an inverse-Arnoldi iteration based on* A^{-1} *instead of* A. *The plot shows pseudospectra and eigenvalues of* H_n^{-1}.

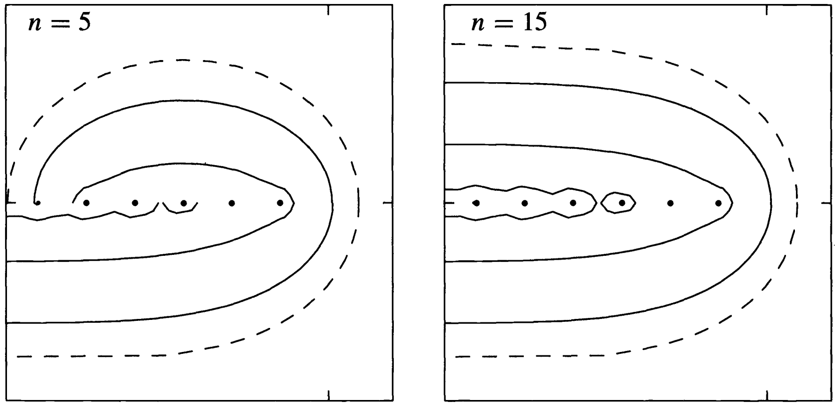

Fig. 5C. *Repetition of Fig.* 5a *with the Arnoldi iteration replaced by a projection of* A *onto the invariant subspace associated with the* n *eigenvalues of maximal real part.*

of gains that may be achieved by acceleration techniques in cases where A is invertible at reasonable cost. More sophisticated algorithms of this kind (based on $\tilde{H}_n$, not just H_n) are currently under development by Ruhe [23].

6. Projection onto an invariant subspace. There is another, more elementary, trick that we must not fail to mention. The calculation of pseudospectra is expensive, much more so than the calculation of a single eigenvalue decomposition. It follows that when the latter is affordable, much may be gained by simply calculating an eigenvalue decomposition of A, then projecting it onto the subspace of $\mathbf{C}^m$ spanned by certain eigenvectors. In typical applications these might be the eigenvectors associated with a subset of eigenvalues of A of maximal real part. This idea may be useful even when no Arnoldi iterations are in store; it is used, for example, in [20].

The mechanics of such a projection are as follows. We have already noted after (8) that if Q is an $m \times n$ matrix with orthonormal columns, then Q^*AQ represents the projection of A onto the column space of Q. Suppose now that we start with an $m \times n$ matrix V whose columns are selected eigenvectors of A, satisfying $AV = VD$ for some $n \times n$ diagonal eigenvalue matrix D. If $V = QR$ is a QR decomposition of V, with Q of dimension $m \times n$ and R of dimension $n \times n$, then we have $Q^*V = R$ and $Q = VR^{-1}$ and therefore

$$Q^*AQ = Q^*AVR^{-1} = Q^*VDR^{-1} = RDR^{-1}. \tag{17}$$

Thus RDR^{-1} (upper triangular) is the matrix representation of the projection of A onto the subspace spanned by the selected eigenvectors.

Figure 5c illustrates that for the example (16), this eigenvalue projection idea gives highly accurate pseudospectra. Despite its triviality, this trick can save a great deal of work. For example, an eigenvalue decomposition of a matrix of dimension 300 is a straightforward matter, whereas computing pseudospectra of such a matrix is a major project on most machines available today. If the dimension can be reduced to 30 by eigenvalue projection, the calculation of pseudospectra becomes easy.

Figure 6, following the format of Fig. 5, presents a less contrived example. Consider the convection-diffusion operator

$$\mathcal{L}u = u'' + u', \qquad u(0) = u(d) = 0 \tag{18}$$

acting on the interval $[0, d\,]$ (in the Hilbert space $L^2[0, d\,]$). The spectrum of this operator is a discrete, unbounded subset of the negative real axis, but, as discussed in [21], the pseudospectra are large regions in the left half-plane shaped approximately like parabolas. Taking $d = 40$, suppose we want to determine these pseudospectra in the neighborhood of the origin determined by the axis limits in Fig. 6. As discussed in [21], an efficient procedure is to construct a discretization matrix A based on Chebyshev spectral differentiation (we omit details). Unfortunately, for an accurate picture, the dimension of A has to be on the order of 100, making the calculation of the pseudospectra quite time-consuming, and if we wanted results in a larger region of the complex plane, matters would get worse. The figure shows that the inverse-Arnoldi idea works reasonably well here. Since A is dense, the eigenvalue projection idea is even better, and with $n = 40$ it produces a perfect picture with ten times less computing than would be involved in treating the full matrix with $m = 100$.

The dashed curves in Fig. 6, corresponding to the boundary of the numerical range, are worth a comment. Note that in Figs. 6b and 6c, we appear to have convincing convergence of the numerical range estimates in the upper half of the plot, but no dashed mirror image appears

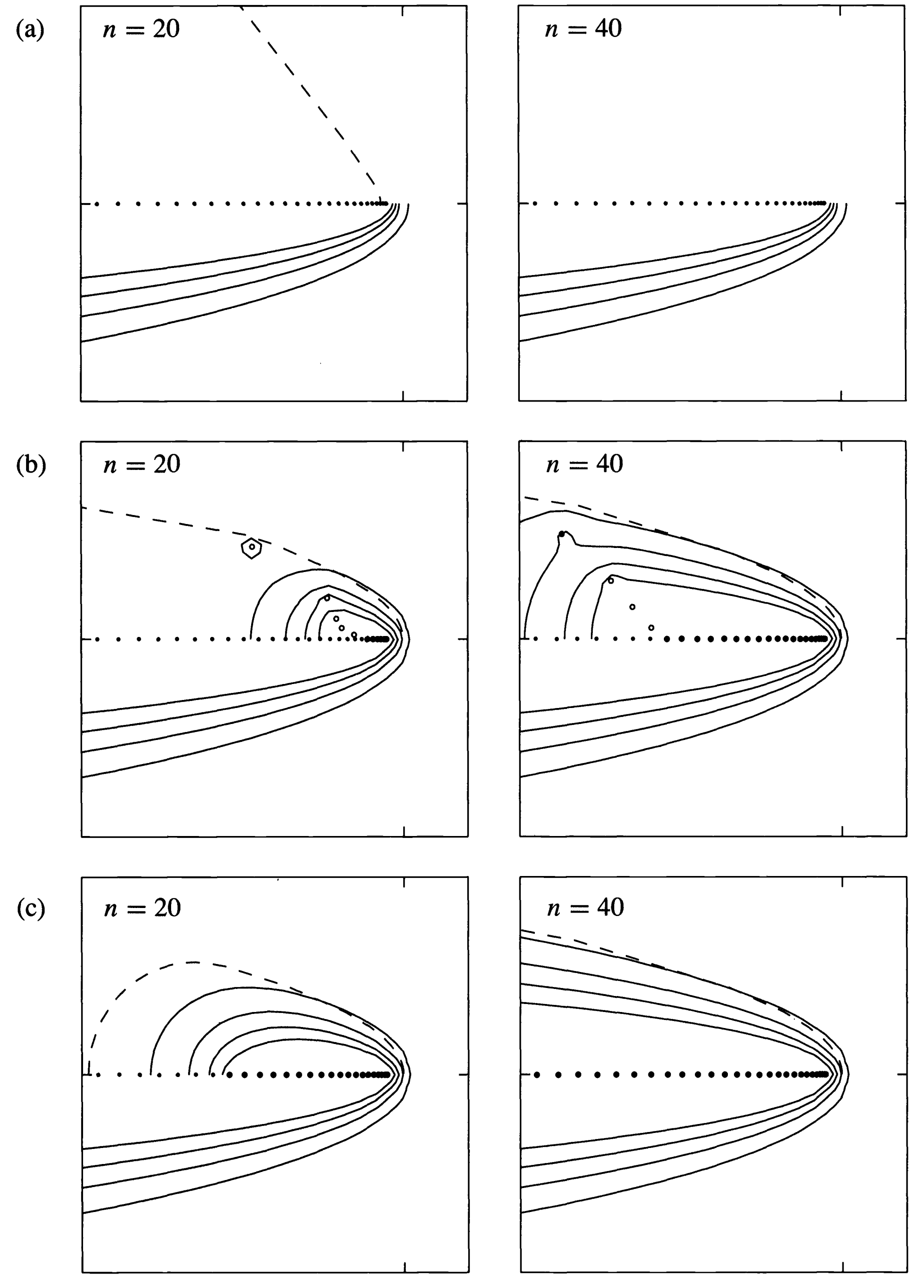

FIG. 6. *Same as Fig. 5, but for a* 100 × 100 *Chebyshev spectral approximation to the convection-diffusion operator* (18). *The axis limits are* $-5 \leq \Re z \leq 1$, $-3 \leq \Im z \leq 3$.

in the lower half. The explanation is that the actual 100 × 100 spectral differentiation matrix considered here has some huge "outlier" eigenvalues of size 1.2×10^4. These eigenvalues are artifacts of the discretization, with no relevance to the convection-diffusion operator $\mathcal{L}$, but they make the numerical range of A much larger than the axis scales of the figure. Thus the numerical range estimates in the upper half of Fig. 6 are no good at all, strictly speaking, for the matrix A being approximated. As it happens, however, they are excellent approximations to the numerical range of the operator $\mathcal{L}$. This stroke of good fortune is more than just coincidence, but of course one would have to be cautious about counting on such effects in applications.

For larger problems than those illustrated in this paper, a combination of the Arnoldi iteration and eigenvalue projections might be advantageous. A matrix of dimension 5000, for example, might be projected to dimension 100 by the Arnoldi iteration, whereupon an eigenvalue decomposition might be used to project further to a matrix of dimension 50, whose pseudospectra could then be plotted quickly by the methods proposed by Lui [12]. In such a sequence, the speedup over a naive calculation of pseudospectra might be on the order of many thousands.

7. Discussion. In this paper we have proposed that the iterative algorithms that have been developed for calculating spectra of large matrices may also be useful for estimating pseudospectra. If the matrix is a sparse approximation of a differential operator, the gains to be achieved by rational variants of the Arnoldi algorithm may be very great. If the matrix is dense, other acceleration devices may play a role, and surprisingly good results can be achieved by the simple method of computing the eigenvalue decomposition of A, then projecting onto an invariant subspace associated with a subset of the eigenvalues.

We have made no attempt to explain why our methods approximate pseudospectra as well as they do, beyond the lower bound on $\Lambda_\epsilon(A)$ of Theorem 1. An upper bound on $\Lambda_\epsilon(A)$ has been developed by Ruhe [23], but it appears to be far from sharp in practice.

It should be emphasized that the idea of using Arnoldi iterations for purposes more general than the calculation of eigenvalues is not new. The Arnoldi iteration potentially has relevance in all kinds of matrix problems where A is too big to deal with directly, but where there is reason to expect that the essential behavior can be captured by a low-dimensional projection. The example that has received the most attention is the use of Krylov subspaces to approximate e^{tA} [6], [10], [26]. Of course, the approximation of pseudospectra is not unrelated to the approximation of e^{tA}, since the ultimate purpose of estimating pseudospectra is often to obtain better insight into the behavior of $\|e^{tA}\|$ than the spectrum alone provides.

In closing, we would like to make two remarks.

Our first observation concerns the uses of Arnoldi iterations and the uses of spectra. The examples of this paper have shown that in cases of pronounced nonnormality, the behavior of a Krylov subspace iteration may be more closely tied to the pseudospectra of a matrix or operator than to its spectrum. A curious parallel of this statement is the recent discovery that in applications involving pronounced nonnormality, what is ultimately of physical interest may also be tied more closely to the pseudospectra than to the spectrum. In particular this is true of problems of hydrodynamic instability of fluid flows in a pipe or a channel, where traditional eigenvalue methods fail to explain the instabilities that are observed in practice, but pseudospectra do much better [2], [3], [19], [31], [34]. In our view, these two parallel statements about spectra and pseudospectra form a natural pair. In highly nonnormal problems, the Arnoldi iteration may indeed not be effective at determining eigenvalues, but we should not wish it to be. The information that it does acquire may be deeper and more valuable. It will be interesting to see whether this vision of broader uses of Arnoldi iterations in applications comes to fruition in upcoming years.

Our second remark is addressed to all those who use nonsymmetric Krylov subspace iterations or who produce software for such computations. For the present, due to the great variety of iterations and preconditioners that have been found to be useful, computations of this kind almost invariably involve an element of exploration. We believe that such explorations can be carried out far more effectively if the user habitually produces plots, not just numbers. Such plots might show Ritz values, lemniscates, pseudospectra of H_n, pseudospectra of $\tilde{H}_n$, eigenvalues of perturbed matrices, or other things—tastes differ, and at this time no one choice seems clearly superior to all others. But we firmly believe it is a mistake to plot nothing at all, or to plot nothing but Ritz values. The habit of looking at plots leads almost unconsciously to new questions and new understanding. Matrices and operators have personalities, which may be revealed with surprising economy by a few curves on the computer screen.

Acknowledgments. We are greatly indebted to Tom Manteuffel for his good advice, which has had a fundamental impact on this paper, and to Axel Ruhe for sharing with us his unpublished report [23]. We are also grateful to Anne Greenbaum for numerous technical suggestions.

CHOOSING THE FORCING TERMS IN AN INEXACT NEWTON METHOD*

STANLEY C. EISENSTAT[†] AND HOMER F. WALKER[‡]

Abstract. An inexact Newton method is a generalization of Newton's method for solving $F(x) = 0$, $F : \mathbb{R}^n \to \mathbb{R}^n$, in which, at the kth iteration, the step s_k from the current approximate solution x_k is required to satisfy a condition $\|F(x_k) + F'(x_k)s_k\| \le \eta_k\|F(x_k)\|$ for a "forcing term" $\eta_k \in [0, 1)$. In typical applications, the choice of the forcing terms is critical to the efficiency of the method and can affect robustness as well. Promising choices of the forcing terms are given, their local convergence properties are analyzed, and their practical performance is shown on a representative set of test problems.

Key words. forcing terms, inexact Newton methods, Newton iterative methods, truncated Newton methods, Newton's method, iterative linear algebra methods, GMRES

AMS subject classifications. 65H10, 65F10

1. Introduction.

Suppose that $F : \mathbb{R}^n \to \mathbb{R}^n$ is continuously differentiable in a neighborhood of $x_* \in \mathbb{R}^n$ for which $F(x_*) = 0$ and $F'(x_*)$ is nonsingular. Suppose further that F' is Lipschitz continuous at x_* with constant λ, i.e.,

$$\|F'(x) - F'(x_*)\| \le \lambda\|x - x_*\| \tag{1.1}$$

for x near x_*, where $\|\cdot\|$ denotes some norm on $\mathbb{R}^n$ and the induced norm on $\mathbb{R}^{n\times n}$.

An *inexact Newton method* (Dembo, Eisenstat, and Steihaug [4]) is an extension of classical Newton's method for approximating x_* formulated as follows:

Algorithm IN: Inexact Newton Method [4]

```
LET $x_0$ BE GIVEN.
FOR $k = 0$ STEP 1 UNTIL "CONVERGENCE" DO:
    FIND **some** $\eta_k \in [0, 1)$ AND $s_k$ THAT SATISFY
(1.2)        $\|F(x_k) + F'(x_k)s_k\| \le \eta_k\|F(x_k)\|$.
    SET $x_{k+1} = x_k + s_k$.
```

Note that (1.2) expresses both a certain reduction in the norm of $F(x_k) + F'(x_k)s$, the local linear model of F, and a certain accuracy in solving the *Newton equation* $F'(x_k)s = -F(x_k)$, the exact solution of which is the *Newton step.* In many applications, notably Newton iterative or truncated Newton methods[1], each η_k is specified first, and then an s_k is determined so that (1.2) holds. The role of η_k is, then, to force $\|F(x_k) + F'(x_k)s_k\|$ to be small in a particular way; accordingly, η_k is often called a *forcing term.*

The local convergence of an inexact Newton method is controlled by the forcing terms. Some specific illustrative results are the following (see Dembo, Eisenstat, and Steihaug [4]): Under the present assumptions, if x_0 is sufficiently close to x_* and $0 \le \eta_k \le \eta_{\max} < 1$ for each k, then $\{x_k\}$ converges to x_* q-linearly in the norm $\|\cdot\|_*$, defined by $\|v\|_* \equiv \|F'(x_*)v\|$ for

It was done in part during a visit to the Computational and Applied Mathematics Department and the Center for Research on Parallel Computation, Rice University.

[1] These are implementations of Newton's method in which iterative linear algebra methods are used to solve the Newton equation approximately.

$v \in \mathbb{R}^n$, with asymptotic rate constant no greater than $\eta_{\max}$. Furthermore, if $\lim_{k\to\infty} \eta_k = 0$, then the convergence is q-superlinear, and if $\eta_k = O(\|F(x_k)\|)$, then the convergence is q-quadratic.[2]

In addition to controlling local convergence, there is another important issue associated with the forcing terms. Away from a solution, F and its local linear model may disagree considerably at a step that closely approximates the Newton step. Thus choosing η_k too small may lead to *oversolving* the Newton equation, by which we mean imposing an accuracy on an approximation of the Newton step that leads to significant disagreement between F and its local linear model. Oversolving may result in little or no decrease in $\|F\|$ and, therefore, little or no progress toward a solution. Moreover, in applications such as Newton iterative or truncated Newton methods, in which additional accuracy in solving the Newton equation requires additional expense, it may entail pointless costs; a less accurate approximation of the Newton step may be both cheaper and more effective.

Our purpose is to propose choices of the forcing terms that achieve desirably fast local convergence and also tend to avoid oversolving. All of the proposed choices incorporate information about F but are scale independent in that they do not change if F is multiplied by a constant.

In §2, we outline the proposed choices and analyze the local convergence of Algorithm IN that results from them; we also note some practical safeguards that improve performance. In §3, we discuss numerical experiments. The algorithm used in the experiments is a special case of Algorithm IN and is outlined in §3.1. The test problems are described in §3.2. An example of oversolving is given in §3.3, with additional observations and examples in §3.4. Summary test results are shown in §3.5. A summary discussion is given in §4.

Preliminaries. We define some useful constants and formulate several elementary results. Set $M \equiv \max\left\{\|F'(x_*)\|, \|F'(x_*)^{-1}\|\right\}$. For $\delta > 0$, define

$$N_\delta(x_*) \equiv \{x \in \mathbb{R}^n : \|x - x_*\| < \delta\},$$

and let $\delta_* > 0$ be sufficiently small that

1. F is continuously differentiable and F' is nonsingular on $N_{\delta_*}(x_*)$,
2. $\|F'(x)^{-1}\| \le 2M$ for $x \in N_{\delta_*}(x_*)$,
3. inequality (1.1) holds for $x \in N_{\delta_*}(x_*)$,
4. $\delta_* < 2/(\lambda M)$.

LEMMA 1.1. *If $x \in N_{\delta_*}(x_*)$ and if s is such that $x_+ \equiv x + s \in N_{\delta_*}(x_*)$, then*

$$\|F(x_+) - F(x) - F'(x)s\| \le \lambda\left(2\|x - x_*\| + \frac{\|s\|}{2}\right)\|s\|.$$

Proof. Setting $x(t) \equiv x + ts$ for $0 \le t \le 1$, we have

$$\begin{aligned}
\|F(x_+) - F(x) - F'(x)s\| &= \left\|\int_0^1 F'(x(t))\,s\,dt - F'(x)\,s\right\| \\
&\le \left\|\int_0^1 \left[F'(x(t)) - F'(x_*)\right]dt - \left[F'(x) - F'(x_*)\right]\right\| \|s\| \\
&\le \left(\int_0^1 \lambda\left[\|x - x_*\| + t\|s\|\right]dt + \lambda\|x - x_*\|\right)\|s\| \\
&= \lambda\left(2\|x - x_*\| + \frac{\|s\|}{2}\right)\|s\|. \qquad \square
\end{aligned}$$

[2] See, e.g., Dennis and Schnabel [6, §§2.3 and 3.1] for definitions of the types of convergence referred to throughout this paper.

LEMMA 1.2. *There is a* $\mu > 0$ *such that*

$$\frac{1}{\mu}\|x - x_*\| \le \|F(x)\| \le \mu\|x - x_*\|$$

whenever $x \in N_{\delta_*}(x_*)$.

Proof. With Lemma 1.1, we have

$$\begin{aligned}\|F(x)\| &\le \|F'(x_*)(x - x_*)\| + \|F(x) - F(x_*) - F'(x_*)(x - x_*)\| \\ &\le M\|x - x_*\| + \frac{\lambda}{2}\|x - x_*\|^2 \le \left(M + \frac{\lambda\delta_*}{2}\right)\|x - x_*\|\end{aligned}$$

and

$$\begin{aligned}\|F(x)\| &\ge \|F'(x_*)(x - x_*)\| - \|F(x) - F(x_*) - F'(x_*)(x - x_*)\| \\ &\ge \frac{1}{M}\|x - x_*\| - \frac{\lambda}{2}\|x - x_*\|^2 \ge \left(\frac{1}{M} - \frac{\lambda\delta_*}{2}\right)\|x - x_*\|.\end{aligned}$$

The lemma follows with $\mu \equiv \max\left\{M + \lambda\delta_*/2, (1/M - \lambda\delta_*/2)^{-1}\right\}$. □

LEMMA 1.3. *If* $x \in N_{\delta_*}(x_*)$ *and* $\|F(x) + F'(x)\,s\| \le \eta\|F(x)\|$ *for some* s *and* $\eta \in [0, 1)$, *then* $\|s\| \le 4M\|F(x)\|$.

Proof. We have

$$\begin{aligned}\|s\| &\le \|F'(x)^{-1}\|\,\|F'(x)\,s\| \\ &\le 2M\big(\|F(x)\| + \|F(x) + F'(x)\,s\|\big) \\ &\le 2M(1 + \eta)\|F(x)\| \le 4M\|F(x)\|. \quad \square\end{aligned}$$

LEMMA 1.4. *There is a* $B > 0$ *such that if* $x \in N_{\delta_*}(x_*)$, s *and* $\eta \in [0, 1)$ *are such that* $\|F(x) + F'(x)\,s\| \le \eta\|F(x)\|$, *and* $x_+ \equiv x + s \in N_{\delta_*}(x_*)$, *then*

$$\|F(x_+)\| \le \big(\eta + B\|F(x)\|\big)\|F(x)\|.$$

Proof. With Lemmas 1.1–1.3, we have that

$$\begin{aligned}\|F(x_+)\| &\le \|F(x) + F'(x)\,s\| + \|F(x_+) - F(x) - F'(x)\,s\| \\ &\le \eta\|F(x)\| + \lambda\left(2\|x - x_*\| + \frac{\|s\|}{2}\right)\|s\| \\ &\le \eta\|F(x)\| + \lambda\big(2\mu\|F(x)\| + 2M\|F(x)\|\big)\cdot 4M\|F(x)\| \\ &= \big(\eta + B\|F(x)\|\big)\|F(x)\|,\end{aligned}$$

where $B \equiv 8\lambda M(\mu + M)$. □

2. The proposed choices. In the analysis in this section, we use the Lipschitz constant λ in (1.1) and the constants M, δ_*, μ, and B introduced in the preliminaries in §1. We also let δ be such that $0 < \delta \le \delta_*/(1 + 4\mu M)$ and note the following consequence of Lemmas 1.2 and 1.3.

PROPOSITION 2.1. *If $x \in N_\delta(x_*)$ and $\|F(x) + F'(x)s\| \le \eta\|F(x)\|$ for some s and $\eta \in [0, 1)$, then $x + s \in N_{\delta_*}(x_*)$.*

We assume for convenience that Algorithm IN continues indefinitely without termination and that $F(x_k) \neq 0$ for all k. Note that if $x_k \in N_{\delta_*}(x_*)$, then $F'(x_k)$ is nonsingular and, therefore, suitable s_k and x_{k+1} exist for any $\eta_k \in [0, 1)$. Our standing assumptions on F and x_* are those made in the first paragraph of §1.

Our first choice is the following.

Choice 1: Given $\eta_0 \in [0, 1)$, choose

$$\eta_k = \frac{\|F(x_k) - F(x_{k-1}) - F'(x_{k-1})s_{k-1}\|}{\|F(x_{k-1})\|}, \qquad k = 1, 2, \ldots, \tag{2.1}$$

or

$$\eta_k = \frac{\Big|\|F(x_k)\| - \|F(x_{k-1}) + F'(x_{k-1})s_{k-1}\|\Big|}{\|F(x_{k-1})\|}, \qquad k = 1, 2, \ldots. \tag{2.2}$$

Note that η_k given by either (2.1) or (2.2) directly reflects the agreement between F and its local linear model at the previous step. The choice (2.2) may be more convenient to evaluate than (2.1) in some circumstances. Since it is at least as small, local convergence will be at least as fast as with (2.1); however, if it is significantly smaller, then it may be more difficult to find a suitable step in some applications and perhaps risk greater oversolving as well.

THEOREM 2.2. *Under the standing assumptions on F and x_*, if x_0 is sufficiently near x_*, then $\{x_k\}$ produced by Algorithm IN with $\{\eta_k\}$ given by Choice 1 remains in $N_{\delta_*}(x_*)$ and converges to x_* with*

$$\|x_{k+1} - x_*\| \le \beta\|x_k - x_*\|\|x_{k-1} - x_*\|, \qquad k = 1, 2, \ldots, \tag{2.3}$$

for a constant β independent of k.

Remark. It follows immediately from (2.3) that the convergence is q-superlinear and two-step q-quadratic. As in the case of the classical secant method, it also follows that the convergence is of r-order $(1 + \sqrt{5})/2$; see, e.g., Stoer and Bulirsch [14, p. 293] for the argument.

Proof. It suffices to prove the theorem with $\{\eta_k\}$ given by (2.1).

Suppose that $\eta_0 \in [0, 1)$ is given. Let τ be such that $\eta_0 < \tau < 1$, and let $\epsilon > 0$ be sufficiently small that $\eta_0 + B\epsilon \le \tau$, $\big[8\lambda M(\mu + M) + B\big]\epsilon \le \tau$, and $\epsilon < \delta/\mu$. Note that if $x \in N_{\delta_*}(x_*)$ and $\|F(x)\| \le \epsilon$, then $x \in N_\delta(x_*)$ by Lemma 1.2.

Let $x_0 \in N_\delta(x_*)$ be sufficiently near x_* that $\|F(x_0)\| \le \epsilon$. Since $x_0 \in N_\delta(x_*)$, we have $x_1 \in N_{\delta_*}(x_*)$ by Proposition 2.1. Also, by Lemma 1.4,

$$\begin{aligned} \|F(x_1)\| &\le \big(\eta_0 + B\|F(x_0)\|\big)\|F(x_0)\| \le \big(\eta_0 + B\epsilon\big)\|F(x_0)\| \\ &\le \tau\|F(x_0)\| \le \|F(x_0)\| \le \epsilon, \end{aligned} \tag{2.4}$$

and, hence, $x_1 \in N_\delta(x_*)$.

As an inductive hypothesis, suppose that, for some $k \ge 1$, we have $x_k \in N_\delta(x_*)$, $x_{k-1} \in N_\delta(x_*)$, $\|F(x_k)\| \le \epsilon$, and $\|F(x_{k-1})\| \le \epsilon$. Then $x_{k+1} \in N_{\delta_*}(x_*)$ by Proposition 2.1, and

Lemmas 1.1–1.3 give

$$\begin{aligned}\eta_k &= \frac{\|F(x_k) - F(x_{k-1}) - F'(x_{k-1})\, s_{k-1}\|}{\|F(x_{k-1})\|} \\ &\le \frac{\lambda\big(2\|x_{k-1} - x_*\| + \|s_{k-1}\|/2\big)\|s_{k-1}\|}{\|F(x_{k-1})\|} \\ &\le \frac{\lambda\big(2\mu\|F(x_{k-1})\| + 2M\|F(x_{k-1})\|\big)\cdot 4M\|F(x_{k-1})\|}{\|F(x_{k-1})\|} \\ &= 8\lambda M(\mu + M)\|F(x_{k-1})\|.\end{aligned}$$

Then Lemma 1.4 implies

$$\begin{aligned}\|F(x_{k+1})\| &\le \big(\eta_k + B\|F(x_k)\|\big)\|F(x_k)\| \\ &\le \Big[8\lambda M(\mu + M)\|F(x_{k-1})\| + B\|F(x_k)\|\Big]\|F(x_k)\| \\ &\le \big[8\lambda M(\mu + M) + B\big]\epsilon\|F(x_k)\| \le \tau\|F(x_k)\|.\end{aligned} \tag{2.5}$$

Thus $\|F(x_{k+1})\| \le \tau\|F(x_k)\| \le \epsilon$ and, hence, $x_{k+1} \in N_\delta(x_*)$.

It follows from this induction that $\{x_k\} \subset N_\delta(x_*) \subset N_{\delta_*}(x_*)$. Furthermore, (2.4) and (2.5) give $\|F(x_{k+1})\| \le \tau\|F(x_k)\|$ for each $k \ge 0$; hence, $F(x_k) \to 0$ and, by Lemma 1.2, $x_k \to x_*$ as well.

To show (2.3), we note that (2.4) and (2.5) give, for $k \ge 1$, $\|F(x_k)\| \le \|F(x_{k-1})\|$ and

$$\begin{aligned}\|F(x_{k+1})\| &\le \Big[8\lambda M(\mu + M)\|F(x_{k-1})\| + B\|F(x_k)\|\Big]\|F(x_k)\| \\ &\le \big[8\lambda M(\mu + M) + B\big]\|F(x_{k-1})\|\,\|F(x_k)\|.\end{aligned}$$

With Lemma 1.2, this implies (2.3) with $\beta \equiv \mu^3\big[8\lambda M(\mu + M) + B\big]$. □

One possible way to obtain faster local convergence while retaining the potential advantages of (2.1) and (2.2) is to raise those expressions to powers greater than one. A particular possibility that we considered in our numerical experiments is squaring those expressions. We note without proof that this leads to local convergence with

$$\|x_{k+1} - x_*\| \le \beta \max\left\{\|x_{k-1} - x_*\|^2, \|x_k - x_*\|\right\}\|x_k - x_*\|, \quad k = 1, 2, \ldots,$$

which implies that $x_k \to x_*$ r-quadratically. However, this possibility was not as successful in our experiments as the other choices proposed here, and we do not consider it further.

Our second choice is the following.

Choice 2: Given $\gamma \in [0, 1]$, $\alpha \in (1, 2]$, and $\eta_0 \in [0, 1)$, choose

$$\eta_k = \gamma\left(\frac{\|F(x_k)\|}{\|F(x_{k-1})\|}\right)^\alpha, \quad k = 1, 2, \ldots. \tag{2.6}$$

The choice (2.6) does not directly reflect the agreement between F and its local linear model, as does Choice 1. However, the experiments in §3 show that it results in little oversolving in practice, and the following theorem shows that it offers attractive local convergence.

THEOREM 2.3. *Under the standing assumptions on F and x_*, if x_0 is sufficiently near x_*, then $\{x_k\}$ produced by Algorithm IN with $\{\eta_k\}$ given by Choice 2 remains in $N_{\delta_*}(x_*)$ and converges to x_*. If $\gamma < 1$, then the convergence is of q-order α. If $\gamma = 1$, then the convergence is of r-order α and of q-order p for every $p \in [1, \alpha)$.*

Proof. Suppose that $\eta_0 \in [0, 1)$ is given and let $\epsilon > 0$ be sufficiently small that $\eta_0 + B\epsilon \leq \eta_0^{1/\alpha}$ and $\epsilon < \delta/\mu$. Note that if $x \in N_{\delta_*}(x_*)$ and $\|F(x)\| \leq \epsilon$, then $x \in N_\delta(x_*)$ by Lemma 1.2.

Let $x_0 \in N_\delta(x_*)$ be sufficiently near x_* that $\|F(x_0)\| \leq \epsilon$. As an inductive hypothesis, suppose that, for some $k \geq 0$, we have $x_k \in N_\delta(x_*)$, $\|F(x_k)\| \leq \epsilon$, and $\eta_k \leq \eta_0$. Since $x_k \in N_\delta(x_*)$, we have $x_{k+1} \in N_{\delta_*}(x_*)$ by Proposition 2.1. Also, by Lemma 1.4,

$$\begin{aligned}\|F(x_{k+1})\| &\leq \big(\eta_k + B\|F(x_k)\|\big)\|F(x_k)\| \\ &\leq \big(\eta_0 + B\epsilon\big)\|F(x_k)\| \leq \eta_0^{1/\alpha}\,\|F(x_k)\|.\end{aligned} \tag{2.7}$$

Then $\|F(x_{k+1})\| \leq \eta_0^{1/\alpha}\,\epsilon \leq \epsilon$, and it follows that $x_{k+1} \in N_\delta(x_*)$. Furthermore, (2.7) gives

$$\eta_{k+1} = \gamma\big(\|F(x_{k+1})\|/\|F(x_k)\|\big)^\alpha \leq \gamma\eta_0 \leq \eta_0.$$

It follows from this induction that $\{x_k\} \subset N_\delta(x_*) \subset N_{\delta_*}(x_*)$. Furthermore, (2.7) gives $\|F(x_{k+1})\| \leq \eta_0^{1/\alpha}\,\|F(x_k)\|$ for each $k \geq 0$; hence, $F(x_k) \to 0$ and, by Lemma 1.2, $x_k \to x_*$ as well.

It remains to show the desired rates of convergence. Note that, for $k > 0$, (2.7) and (2.6) give

$$\|F(x_{k+1})\| \leq \left[\gamma\left(\frac{\|F(x_k)\|}{\|F(x_{k-1})\|}\right)^\alpha + B\|F(x_k)\|\right]\|F(x_k)\|. \tag{2.8}$$

First, suppose that $\gamma < 1$ and set $\rho_k \equiv \|F(x_k)\|/\|F(x_{k-1})\|^\alpha$ for $k > 0$. From (2.8) and (2.7), we have $\rho_{k+1} \leq \gamma\rho_k + B\|F(x_k)\|^{2-\alpha} \leq \gamma\rho_k + B\|F(x_0)\|^{2-\alpha}$ for $k > 0$, and it follows inductively that

$$\rho_{k+1} \leq \gamma^k\rho_1 + \left(\sum_{j=0}^{k-1}\gamma^j\right)B\|F(x_0)\|^{2-\alpha} \leq \rho_1 + \frac{B}{1-\gamma}\|F(x_0)\|^{2-\alpha}.$$

Thus $\{\rho_k\}$ is uniformly bounded. Consequently, $F(x_k) \to 0$ with q-order α, and it follows from Lemma 1.2 that $x_k \to x_*$ with q-order α as well.

Now, suppose that $\gamma = 1$. We first show that the convergence is of q-order p for $p \in [1, \alpha)$. For $k > 0$, (2.8) gives

$$\begin{aligned}\|F(x_{k+1})\| &\leq \left[\left(\frac{\|F(x_k)\|}{\|F(x_{k-1})\|}\right)^\alpha + B\|F(x_k)\|\right]\|F(x_k)\| \\ &= \left[\left(\frac{\|F(x_k)\|}{\|F(x_{k-1})\|}\right)^{\alpha-p}\frac{\|F(x_k)\|}{\|F(x_{k-1})\|^p} + B\|F(x_k)\|^{2-p}\right]\|F(x_k)\|^p.\end{aligned} \tag{2.9}$$

For each $k > 0$, set $\sigma_k \equiv \|F(x_k)\|/\|F(x_{k-1})\|^p$ and recall that (2.7) gives $\|F(x_k)\| \leq \eta_0^{1/\alpha}\,\|F(x_{k-1})\|$, whence $\|F(x_k)\| \leq \eta_0^{k/\alpha}\,\|F(x_0)\|$. Then for $k > 0$, (2.9) implies

$$\sigma_{k+1} \leq \eta_0^{1-p/\alpha}\sigma_k + B\eta_0^{k(2-p)/\alpha}\|F(x_0)\|^{2-p} \leq \xi\sigma_k + \xi^k C,$$

where $\xi \equiv \eta_0^{1-p/\alpha}$ and $C \equiv B\|F(x_0)\|^{2-p}$. It follows inductively that

$$\sigma_{k+1} \le \xi^k \left(\sigma_1 + kC\right),$$

and, hence,

$$\|F(x_{k+1})\| \le \xi^k \left(\sigma_1 + kC\right) \|F(x_k)\|^p.$$

Since $\xi^k \left(\sigma_1 + kC\right) \to 0$ as $k \to \infty$, we conclude that $F(x_k) \to 0$ with q-order p and, by Lemma 1.2, $x_k \to x_*$ with q-order p as well.

Still assuming $\gamma = 1$, we now show that $x_k \to x_*$ with r-order α. By Lemma 1.2, it suffices to show that $\|F(x_k)\| \to 0$ with r-order α; we shall prove the somewhat stronger result that $\tau_k \equiv \|F(x_k)\|/\|F(x_{k-1})\| \to 0$ with r-order α.

It follows from the results above that $\tau_k \to 0$. Then there is a k_0 such that $(2\tau_{k_0+1})^{(\alpha-1)} + 2B\|F(x_{k_0})\| \le 1$. For convenience, we re-index if necessary so that $k_0 = 0$. Then $(2\tau_1)^{(\alpha-1)} + 2B\|F(x_0)\| \le 1$, which implies $D \equiv 1/(2\tau_1) > 1$. Set $\beta_k \equiv D\tau_k$ for $k \ge 0$. Note that $\beta_1 = 1/2$. It suffices to show that $\beta_k \to 0$ with r-order α.

We claim that $\beta_k \le \beta_1^{\alpha^{k-1}}$ for $k = 1, 2, \ldots$, from which it follows that $\beta_k \to 0$ with r-order α. The claim clearly holds for $k = 1$. Suppose that it holds up to some $k \ge 1$. Then Lemma 1.4 implies

$$\|F(x_{k+1})\| \le \left(\tau_k^\alpha + B\|F(x_k)\|\right) \|F(x_k)\|,$$

whence

$$\tau_{k+1} \le \tau_k^\alpha + B\tau_k \ldots \tau_1 \|F(x_0)\|.$$

From this, we obtain

$$\begin{aligned}
\beta_{k+1} &\le D^{1-\alpha}\beta_k^\alpha + \frac{B\|F(x_0)\|}{D^{k-1}}\beta_k \cdots \beta_1 \\
&\le D^{1-\alpha}\left(\beta_1^{\alpha^{k-1}}\right)^\alpha + B\|F(x_0)\|\beta_1^{(\alpha^{k-1}+\cdots+1)} \\
&\le \left(D^{1-\alpha} + B\|F(x_0)\|/\beta_1\right)\beta_1^{\alpha^k} \\
&= \left[(2\tau_1)^{\alpha-1} + 2B\|F(x_0)\|\right]\beta_1^{\alpha^k} \le \beta_1^{\alpha^k},
\end{aligned}$$

and the proof is complete. □

It is possible to show local convergence for Algorithm IN when $\{\eta_k\}$ is given by Choice 2 with $\gamma > 1$, provided η_0 is sufficiently small. However, Choice 2 with $\gamma > 1$ was not competitive in our experiments.

2.1. Practical safeguards. Although the forcing term choices given above are usually effective in avoiding oversolving, we have observed in experiments that they occasionally become too small far away from a solution. There is a particular danger of the Choice 1 forcing terms becoming too small; indeed, an η_k given by (2.1) or (2.2) can be undesirably small because of either a very small step or coincidental very good agreement between F and its local linear model. In our experiments, we observed relatively few occasions on which the Choice 2 forcing terms became undesirably small; however, this did occur.

We introduce safeguards here that are intended to prevent the forcing terms from becoming too small too quickly. The rationale is that if large forcing terms are appropriate at some point, then subsequent forcing terms should not be allowed to become much smaller until this has been justified over several iterations. These are not claimed to be the most effective safeguards that might be devised for general use or even for the test problems used in our experiments. However, they were consistently effective in our tests, more so than several other possibilities that we tried, and they serve to demonstrate the usefulness of safeguards.

For each choice, we restrict η_k to be no less than a certain minimum value, but only if that minimum value is above a threshhold. The minimum value is determined by raising η_{k-1} to a power associated with the rate of convergence of the (unsafeguarded) choice. The threshhold that we use here is .1; this is clearly somewhat arbitrary but was effective in our experiments. Note that, in each case, the minimum value eventually drops below the threshhold whenever there is convergence to a solution. Thus the safeguards eventually become inactive whenever there is convergence, and the asymptotic convergence is that for the unsafeguarded choice given by the theorems above.

For Choice 1, the safeguard is the following:

Choice 1 *safeguard:* Modify η_k by $\eta_k \leftarrow \max\{\eta_k, \eta_{k-1}^{(1+\sqrt{5})/2}\}$ whenever $\eta_{k-1}^{(1+\sqrt{5})/2} > .1$.

For perspective, recall from the remark after Theorem 2.2 that the convergence of (2.3) implies convergence of r-order $(1+\sqrt{5})/2$. For Choice 2, the safeguard is the following:

Choice 2 *safeguard:* Modify η_k by $\eta_k \leftarrow \max\{\eta_k, \gamma\eta_{k-1}^{\alpha}\}$ whenever $\gamma\eta_{k-1}^{\alpha} > .1$.

Finally, we note that, away from a solution, it may be possible for each of the proposed choices to be greater than one. Accordingly, it may be necessary in practice to impose an additional safeguard to make sure that $\eta_k \in [0, 1)$ for each k, as in the algorithm in §3.1 below that was used in our experiments.

3. Numerical experiments. In this section, we report on numerical experiments with the forcing term choices outlined in §2, modified with the safeguards given in §2.1. In the experiments, for computational convenience, we always used η_k given by (2.2) for Choice 1. For Choice 2, we used $\gamma = 1, .9, .5$ and $\alpha = 2, (1+\sqrt{5})/2$. The latter value of α results in an order of convergence roughly comparable to that for Choice 1; see Theorem 2.3 and the remark after Theorem 2.2. For a broader comparison, we also included the following representative forcing term choices:

1. the choice $\eta_k = 10^{-1}$, which requires modestly accurate approximations of Newton steps and results in local q-linear convergence in the norm $\|\cdot\|_*$.
2. the choice $\eta_k = 10^{-4}$ used by Cai, Gropp, Keyes, and Tidriri [3], which requires uniformly close approximations of Newton steps for all k and results in fast local q-linear convergence in the norm $\|\cdot\|_*$.
3. the choice $\eta_k = 1/2^{k+1}$ of Brown and Saad [2]. This choice results in local q-superlinear convergence and allows relatively inaccurate approximations of Newton steps for small k, when x_k may not be near x_*; however, it incorporates no information about F.
4. the choice $\eta_k = \min\{1/(k+2), \|F(x_k)\|\}$ of Dembo and Steihaug [5]. This choice results in q-quadratic local convergence and also may allow relatively inaccurate approximations of Newton steps for small k. It incorporates some information about F; however, it does not reflect the agreement of F and its local linear model and, in addition, depends on the scale of F.

3.1. The algorithm. A globalized inexact Newton algorithm was necessary because initial approximate solutions were not always near a solution. We used Algorithm INB of

Eisenstat and Walker [7, §6]. This is an inexact Newton method globalized by backtracking, which we write here as follows.

Algorithm INB: Inexact Newton Backtracking Method [7]

```
LET $x_0$, $\eta_{\max} \in [0, 1)$, $t \in (0, 1)$, AND $0 < \theta_{\min} < \theta_{\max} < 1$ BE GIVEN.
FOR $k = 0$ STEP 1 UNTIL "CONVERGENCE" DO:
    CHOOSE AN **initial** $\eta_k \in [0, \eta_{\max}]$ AND $s_k$ SUCH THAT
        $\|F(x_k) + F'(x_k)\, s_k\| \leq \eta_k \|F(x_k)\|$.
    WHILE $\|F(x_k + s_k)\| > [1 - t(1 - \eta_k)]\|F(x_k)\|$ DO:
        CHOOSE $\theta \in [\theta_{\min}, \theta_{\max}]$.
        UPDATE $s_k \longleftarrow \theta s_k$ AND $\eta_k \longleftarrow 1 - \theta(1 - \eta_k)$.
    SET $x_{k+1} = x_k + s_k$.
```

Note that Algorithm INB requires $\eta_k \in [0, \eta_{\max}]$ for each initial η_k. For the safeguarded choices in §2, this necessitates the additional safeguard $\eta_k \leftarrow \min\{\eta_k, \eta_{\max}\}$.

Theorem 6.1 of Eisenstat and Walker [7] states that if $\{x_k\}$ generated by Algorithm INB has a limit point x_* such that $F'(x_*)$ is invertible, then $F(x_*) = 0$ and $x_k \rightarrow x_*$. Furthermore, in this case, the initial η_k and s_k are accepted without modification for all sufficiently large k; it follows in particular that the asymptotic convergence to x_* is determined by the initial η_k's.

In implementing Algorithm INB, we first chose each initial η_k (with $\eta_0 = 1/2$ for Choices 1 and 2) and then determined an initial s_k by approximately solving the Newton equation using GMRES(m), the restarted GMRES method of Saad and Schultz [12], with restart value $m = 20$. Products of $F'(x_k)$ with vectors were evaluated analytically in some cases and approximated by finite differences of F-values in others; see §3.2. When finite-difference approximations were used, a second-order central difference was used to evaluate the initial residual at the beginning of each cycle of 20 GMRES steps, and subsequently first-order forward differences were used within the cycle. This selective second-order differencing gave essentially the same accuracy as if central differences had been used throughout, but at much lower cost (see Turner and Walker [16]).

The parameters used were $\eta_{\max} = .9$, $t = 10^{-4}$, $\theta_{\min} = 1/10$, and $\theta_{\max} = 1/2$. The norm was the Euclidean norm $\|\cdot\|_2$. In the while-loop, each θ was chosen to minimize over $[\theta_{\min}, \theta_{\max}]$ the quadratic $p(\theta)$ for which $p(0) = g(0)$, $p'(0) = g'(0)$, and $p(1) = g(1)$, where $g(\theta) \equiv \|F(x_k + \theta s_k)\|_2^2$. Convergence was declared when either $\|F(x_k)\|_2 \leq 10^{-12}\|F(x_0)\|_2$ or $\|s_k\|_2 \leq 10^{-12}$. These tight stopping tolerances allowed asymptotic convergence behavior to become evident.[3] Failure was declared when one of the following occurred: (1) k reached 200 without convergence, (2) an initial s_k was not found in 1000 GMRES(20) iterations, or (3) ten iterations of the while-loop failed to produce an acceptable step. All computing was done in double precision on Sun Microsystems workstations using the Sun Fortran compiler.

3.2. The test problems.

The test set consisted of four PDE problems and two integral equation problems. The PDE problems are all elliptic boundary value problems posed on $\Omega \equiv [0, 1] \times [0, 1] \subseteq \mathbb{R}^2$.

3.2.1. A PDE problem.

The problem is

$$\Delta u + u^3 = 0 \text{ in } \Omega, \qquad u = 0 \text{ on } \partial\Omega.$$

[3] In some applications, less stringent convergence tolerances are commonly used. As a result, asymptotic convergence behavior may not be very important, and it may be appropriate to use forcing terms that are not asymptotically increasingly demanding, such as constant forcing terms that give adequately fast q-linear convergence.

This problem has multiple solutions, but only one that is positive everywhere (McKenna [10], Schaaf [13]). These properties appear to be shared by the discretized problem, and finding the everywhere-positive solution can be difficult without a good initial approximate solution. Discretization was by the usual centered differences on a 100 × 100 uniform grid, so that $n = 10^4$. The discretized problem was preconditioned on the right using a fast Poisson solver from FISHPACK (Swartztrauber and Sweet [15]). Products of F' with vectors were evaluated analytically. The initial approximate solution was a discretization of $u_0(x) \equiv \kappa x_1(1 - x_1)x_2(1 - x_2)$, which should lead to the everywhere-positive solution for large κ. Two test cases were considered: $\kappa = 100$ and $\kappa = 1000$. For the latter value, the initial approximate solution is farther from the solution and the problem is harder.

3.2.2. The (modified) Bratu problem. The problem is

$$\Delta u + \kappa \frac{\partial u}{\partial x_1} + \lambda e^u = 0 \text{ in } \Omega, \qquad u = 0 \text{ on } \partial\Omega.$$

The actual Bratu (or Gelfand) problem has $\kappa = 0$; see, e.g., Glowinski, Keller, and Reinhart [8] or the description by Glowinski and Keller in the collection of nonlinear model problems assembled by Moré [11, pp. 733–737]. As κ and λ grow, solving the Newton equations for the discretized problem becomes harder for GMRES(20). Discretization and preconditioning were as in §3.2.1. Products of F' with vectors were evaluated analytically. The initial approximate solution was zero. Two test cases were considered: $\kappa = \lambda = 10$ and $\kappa = \lambda = 20$.

3.2.3. The driven cavity problem. The problem is

$$(1/Re)\Delta^2\psi + \frac{\partial\psi}{\partial x_1}\frac{\partial}{\partial x_2}\Delta\psi - \frac{\partial\psi}{\partial x_2}\frac{\partial}{\partial x_1}\Delta\psi = 0 \quad \text{in } \Omega,$$

$$\psi = 0 \quad \text{and} \quad \frac{\partial\psi}{\partial n} = g \quad \text{on } \partial\Omega,$$

where $g(x_1, x_2) = 1$ if $x_2 = 1$ and $g(x_1, x_2) = 0$ if $0 \leq x_2 < 1$. This is a widely used test problem; see, e.g., Brown and Saad [2] or Glowinski, Keller, and Reinhart [8]. The numerical problem becomes harder as the Reynolds number Re increases. Discretization was by piecewise-linear finite elements on a uniform 63 × 63 grid[4], so that $n = 3969$. The discretized problem was preconditioned on the right using a fast biharmonic solver of Bjørstad [1]. Products of F' with vectors were approximated with finite differences. The initial approximate solution was zero. Two test cases were considered: $Re = 100$ and $Re = 500$.

3.2.4. The porous medium equation. The problem considered here is

$$\Delta\left(u^2\right) + d\frac{\partial}{\partial x_1}(u^3) + f = 0 \quad \text{in } \Omega,$$

with $u = 1$ on the bottom and left sides of Ω and $u = 0$ on the top and right sides. This is more or less a steady-state special case of a general problem considered by van Duijn and de Graaf [17]. Discretization was by the usual centered differences on a 64 × 64 uniform grid, so that $n = 4096$. The discretized problem was preconditioned on the right using the tridiagonal part of the Jacobian. Products of F' with vectors were evaluated analytically. The function f was a point source of magnitude 50 at the lower left grid point. The initial approximate solution was a discretization of $u_0(x) \equiv 1 - x_1x_2$ on the interior grid points, which tended to require more backtracking for negative d and to cause more oversolving for positive d. Two test cases were considered: $d = 50$ and $d = -50$.

[4] We thank P. N. Brown for providing the code for this.

3.2.5. An integral equation. The problem, from Kelley and Northrup [9], is

$$cu(x)^2 - \frac{1}{2}\int_0^1 \cos(yu(x))u(y)\,dy + \frac{1}{2}\sin 1 - c = 0, \quad x \in [0,1].$$

Clearly, $u(x) \equiv 1$ is always a solution, and there exist other solutions for at least some values of c. The discretized problem was determined by approximating integrals using 20-point Gaussian quadrature[5] over 20 subintervals of $[0, 1]$, so that $n = 400$. No preconditioning was necessary. Products of F' with vectors were approximated with finite differences. The initial approximate solution was a discretization of $u_0(x) \equiv 1 + \kappa \cos 9\pi x$. One test case was considered: $c = \kappa = 1.25$.

3.2.6. The Chandrasekhar H-equation. The problem is

$$u(x) - \frac{1}{1 - Lu(x)} = 0, \quad x \in [0,1],$$

where

$$Lu(x) \equiv \frac{c}{2}\int_0^1 \frac{xu(\xi)}{x+\xi}\,d\xi.$$

This problem arises in radiative transfer problems; see, e.g., the description by Kelley in the Moré problem collection [11, pp. 737–739]. The continuous problem is singular at $c = 1$, and so is the discretized problem considered here with discretization as in §3.2.5. The discretized problem becomes more difficult to solve as $c \to 1$ but is still tractable at $c = 1$. As in §3.2.5, no preconditioning was necessary. Products of F' with vectors were approximated with finite differences. The initial approximate solution was zero. Three test cases were considered: $c = .5$, $c = .999$, and $c = 1$.

3.3. An example of oversolving. Algorithm INB with the Dembo–Steihaug [5] choice $\eta_k = \min\{1/(k+2), \|F(x_k)\|_2\}$ was applied to the driven cavity problem with $Re = 500$. The results are shown in Fig. 3.1, in which the logarithms of the norms of F and its local linear model are plotted as dotted and solid curves, respectively, versus the numbers of GMRES(20) iterations. (Most of the F-values used for Figs. 3.1–3.4 would not normally be available but were computed for these illustrations.) Triangles indicate the start of new inexact Newton steps. In this example, $\eta_k = \|F(x_k)\|_2$ for each $k > 0$; the safeguard value $\eta_k = 1/(k+2)$ was never invoked for $k > 0$.

In Fig. 3.1, gaps between the solid and dotted curves indicate oversolving. Note that once oversolving begins, there is virtually no further reduction in $\|F\|_2$ until the beginning of the next inexact Newton step; thus further GMRES(20) iterations represent wasted effort. Note also the vertical discontinuity in the dotted curve at the end of the fourth inexact Newton step (after 45 GMRES(20) iterations); this indicates a reduction of the initial inexact Newton step through backtracking.

To show the benefits gained by reducing oversolving, we applied Algorithm INB with η_k given by the safeguarded Choice 1 to the same problem. The results are shown in Fig. 3.2. Note that oversolving is almost eliminated and there are no step reductions through backtracking. Also, the total number of GMRES(20) iterations is 221, compared to 327 in the previous case. However, the number of inexact Newton steps is 12, compared to 10 previously.

[5] We thank C. T. Kelley for providing the code for this.

3.4. Additional observations and examples. In an algorithm such as the implementation of Algorithm INB used here, choosing a very small forcing term may risk more than needless expense in obtaining an unnecessarily accurate solution of the Newton equation. First, if oversolving results, then disagreement between F and its local linear model may require significant work from the globalization procedure or even cause it to fail. In the example in §3.3, the choice $\eta_k = \min\{1/(k+2), \|F(x_k)\|_2\}$ required one backtracking, while the safeguarded Choice 1 did not. We observed a more dramatic example involving the PDE problem of §3.2.1 with $\kappa = 1000$. With the safeguarded Choice 1, the iterates from Algorithm INB converged to the everywhere-positive solution in 40 GMRES(20) iterations; two backtracks were required. With the choice $\eta_k = \min\{1/(k+2), \|F(x_k)\|_2\}$, 164 GMRES(20) iterations and 11 backtracks were necessary; furthermore, convergence was to a solution other than the everywhere-positive solution. Such convergence to a "wrong" solution may or may not be undesirable per se, but it does indicate the potentially serious effects of disagreement between F and its local linear model.

Second, unless special care is taken, a very small forcing term may require more residual reduction than an iterative linear solver such as GMRES can accurately deliver, especially when products of F' with vectors are approximated with finite differences. Recall from §3.1 that our implementation of Algorithm INB uses selective second-order differencing to obtain essentially the same accuracy as if second-order differences were used throughout. Using the safeguarded Choice 2 forcing terms with $\alpha = 2$ and $\gamma = .9$, we applied this implementation to the driven cavity problem with $Re = 500$; the results are shown in Fig. 3.3. There is no evidence of inaccuracy in GMRES(20), and 218 iterations were required for successful termination. However, when the implementation was changed to use only first-order forward

differences throughout, we obtained the results in Fig. 3.4. Note the increase in the linear residual norm curve (the solid curve) just after iteration 200. The linear residual norm values used for this curve were evaluated directly at the beginning of each GMRES(20) cycle and then maintained recursively within the cycle; the observed increase occurs after the direct evaluation at iteration 200 and indicates that the recursively maintained values have become inaccurate. We note also that the number of GMRES(20) iterations required for termination has increased to 232.

3.5. Summary test results. In Table 3.1, we summarize the results of applying Algorithm INB to all test problem cases described in §3.2. In Table 3.2, we summarize the results over the PDE problem cases only. The results for the PDE problems are broken out in a separate table not only because these problems constitute an important problem class but also because the characteristic performance of Algorithm INB on these problems differed from that on the integral equations. On the integral equations, and on the H-equation in particular, GMRES(20) was so effective that the effects of different forcing term choices tended to be obscured. In most cases, only one to three GMRES(20) iterations were required for each inexact Newton step, and the linear residual norm was often reduced by several orders of magnitude in a single iteration. On the PDE problems, many more GMRES(20) iterations were typically required for each inexact Newton step, with only modest linear residual norm reduction per GMRES(20) iteration. Thus the PDE problems gave a somewhat more refined view of the effects of different forcing term choices.

The first three columns of Tables 3.1 and 3.2 give geometric means of the numbers of linear iterations (GMRES(20) iterations), inexact Newton steps, and "function evaluation equivalents," where, for each test case, we define the number of "function evaluation

equivalents" to be the sum of the numbers of linear iterations, backtracks, and inexact Newton steps. The number of linear iterations is the same as the number of products of F' with vectors; if these products were always approximated by first-order forward differences, then the number of "function evaluation equivalents" would be equal to the number of function evaluations. This number provides a rough relative measure of overall work for the test problems used here. It would be a less suitable measure, e.g., if there were additional costs associated with beginning a new inexact Newton step, such as initializing a new preconditioner. The fourth column gives numbers of backtracks over all test cases, i.e., numbers of step-reductions in the while-loop in Algorithm INB. The fifth column gives numbers of instances of convergence to a "wrong" solution, i.e., convergence to a solution other than the everywhere-positive solution in the PDE problem of §3.2.1 or to a solution other than $u \equiv 1$ in the integral equation problem of §3.2.5. As noted previously, convergence to a "wrong" solution illustrates the potentially serious effects of disagreement between F and its local linear model. The sixth column gives the number of failures over all test cases. If failure occurred in a test case, then that case was not included in the statistics for columns 1–5; consequently, those statistics are not fully comparable to those for which all runs were successful.

One sees from Tables 3.1 and 3.2 that the best overall performances were from Choice 1 and from Choice 2 with $\gamma = .9$ and $\gamma = 1$. Taking $\gamma = .5$ in Choice 2 resulted in significantly less efficiency with $\alpha = 2$; in addition, it led to increased numbers of backtracks with $\alpha = 2$ and to one failure and one instance of convergence to a "wrong" solution with $\alpha = (1+\sqrt{5})/2$, which suggest less robustness when γ is as small as .5. The other choices included in the tests were notably less effective.

Among Choice 1 and Choice 2 with $\gamma = .9$ and $\gamma = 1$, Choice 2 with $\gamma = 1$ and $\alpha = (1 + \sqrt{5})/2$ placed first in every category except mean numbers of inexact Newton steps; thus this choice might be judged the winner. However, its margin of superiority was slight: for example, in "function evaluation equivalents," the best and worst means for these choices differ by less than 4% over all problems and by less than 5% over the PDE problems. Furthermore, there was considerable variance in the relative performance and ranking of these choices among the individual test cases.

The results for Choice 2 illustrate that more aggressive choices of the forcing terms, i.e., choices that are smaller or result in faster asymptotic convergence, may decrease the number of inexact Newton steps up to a point but, through oversolving, may also lead to more linear iterations, more backtracking, and less robustness. Less aggressive choices, on the other hand, may reduce the number of linear iterations up to a point and improve robustness but may also result in increased numbers of inexact Newton steps.

4. Summary discussion.

We have outlined forcing term choices that result in desirably fast local convergence and also tend to avoid oversolving the Newton equation, i.e., imposing an accuracy on an approximation of the Newton step that leads to significant disagreement between F and its local linear model. The choices, along with theoretical support and practical safeguards, are given in §2. Practical performance on a representative set of test problems is discussed in §3.

Choice 1 directly reflects the agreement between F and its local linear model at the previous step. It results in a certain q-superlinear local convergence; see Theorem 2.2 and the following remark for precise statements. Choice 2 does not directly reflect the agreement between F and its local linear model; however, it performed effectively in our tests. Furthermore, it can give up to q-quadratic local convergence (see Theorem 2.3), and the parameters α and γ appearing in it allow flexibility that may be useful in applications.

The best performances in our tests were from Choice 1 and from Choice 2 with $\gamma = .9$ and $\gamma = 1$. (With Choice 2, the values $\alpha = 2$ and $\alpha = (1 + \sqrt{5})/2$ were used in the tests. The latter value was chosen to give convergence roughly comparable to that for Choice 1.) Of these choices, Choice 2 with $\gamma = 1$ and $\alpha = (1 + \sqrt{5})/2$ could be considered most effective in these tests, but only by a small margin; any of these choices might be best for a particular application.

The numerical results in §3 illustrate that, in a globalized Newton iterative or truncated Newton method such as the implementation of Algorithm INB used here, oversolving resulting from inappropriately small forcing terms not only may incur unnecessary expense in solving the Newton equation but also may place significant demands on the globalization and even cause it to fail. In addition, unless special care is taken, very small forcing terms may call for more residual reduction than the iterative linear solver can accurately obtain, especially when finite differences are used to approximate products of F' with vectors. Conversely, choosing larger forcing terms may reduce oversolving and avoid inaccuracy in the iterative linear solver but increase the number of the inexact Newton steps required for convergence.

FAST NONSYMMETRIC ITERATIONS AND PRECONDITIONING FOR NAVIER–STOKES EQUATIONS*

HOWARD ELMAN[†] AND DAVID SILVESTER[‡]

Abstract. Discretization and linearization of the steady-state Navier–Stokes equations gives rise to a nonsymmetric indefinite linear system of equations. In this paper, we introduce preconditioning techniques for such systems with the property that the eigenvalues of the preconditioned matrices are bounded independently of the mesh size used in the discretization. We confirm and supplement these analytic results with a series of numerical experiments indicating that Krylov subspace iterative methods for nonsymmetric systems display rates of convergence that are independent of the mesh parameter. In addition, we show that preconditioning costs can be kept small by using iterative methods for some intermediate steps performed by the preconditioner.

1. Introduction.

Consider the steady-state *Navier–Stokes problem*: given data $\mathbf{f}$, find the velocity $\mathbf{u}$ and pressure p satisfying

$$\begin{aligned} -\nu\nabla^2\mathbf{u} + \frac{1}{2}\mathbf{u}(\operatorname{div}\mathbf{u}) + \mathbf{u}\cdot\nabla\mathbf{u} + \operatorname{grad} p &= \mathbf{f} \qquad \text{in } \Omega \\ \operatorname{div}\mathbf{u} &= 0 \end{aligned} \tag{1.1}$$

subject to boundary conditions, typically, specified velocity $\mathbf{u} = \mathbf{g}$ on $\partial\Omega$; $\Omega \subset \mathbf{R}^2$ or $\Omega \subset \mathbf{R}^3$. Here, the scalar ν is the inverse of the Reynolds number or the ratio of convection to diffusion in the system. In the diffusion dominated case, ($\nu \to \infty$) (1.1) tends to a linear self-adjoint system of equations known as the *Stokes problem.*

There are two ways of calculating solutions to the system (1.1). A popular approach is to compute "true" steady-state solutions of the time-dependent Navier–Stokes equations. There are many ways to do this: one way is to make use of the "characteristics" associated with the hyperbolic part of the Navier–Stokes operator via a Lagrange–Galerkin approach (for example, see [13]). The associated transpose-diffusion splitting leads to absolutely stable temporal discretizations so that large time steps can be taken. At each time step, a symmetric indefinite matrix system corresponding to a time-discretized Stokes-like system must be solved. These systems can be solved efficiently by iterative methods, for example, if a multigrid solver is used to precondition the primary (Laplacian) operator. There are, however, a number of disadvantages to the time-dependent approach. Simple time discretization methods based on the l_2-projection onto the discretely divergence-free subspace [10] have an $O(h)$ CFL restriction on the time step, which impinges on efficiency. On the other hand, absolutely stable schemes like the method of backward characteristics are known to be sensitive to implementation issues (e.g., the need to perform quadrature; see [13]). Even with fixed grids, efficiency is often limited by the costs associated with interpolation.

In this work, we consider the alternative approach of attacking the system (1.1) directly. Applying a fixed point (or Picard) iteration, the system (1.1) reduces to solving a sequence of

linear Oseen problems of the following form: given some velocity field $\mathbf{w}$, find the velocity $\mathbf{u}$ and pressure p satisfying

$$-\nu\nabla^2\mathbf{u} + \frac{1}{2}\mathbf{u}(\operatorname{div}\mathbf{w}) + \mathbf{w}\cdot\nabla\mathbf{u} + \operatorname{grad} p = \mathbf{f} \qquad \text{in } \Omega \tag{1.2}$$
$$\operatorname{div}\mathbf{u} = 0$$

subject to the same boundary conditions.

For this methodology to be effective it is necessary to solve the discrete versions of (1.2) efficiently. Finite element discretization of (1.2) leads to the matrix problem

$$\begin{pmatrix} \nu A + N & B^t \\ B & O \end{pmatrix}\begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}, \tag{1.3}$$

where $A = A^t$ represents diffusion (for example, $-\nabla^2$) and hence is a positive definite matrix of order n_u; N represents convection ($\frac{1}{2}\operatorname{div}\mathbf{w} + \mathbf{w}\cdot\nabla$); and the $n_p \times n_u$ matrix B represents the coupling between the discrete velocity u and the pressure p. Note that the representation of the quadratic convection term in (1.1) ensures that if velocity is specified everywhere on the boundary then $N = -N^t$; that is, the discrete form of the convection operator is *skew-symmetric* [10, p. 53]. Note that with these boundary conditions the system (1.3) is singular; pressure is only unique up to a (hydrostatic) constant. We assume in the following analysis that the pressure solution is uniquely specified in this case, e.g., by insisting that its mean is zero.

Working in a conventional mixed finite element framework, we will further assume that the underlying velocity and pressure approximations are *(div-)stable* (see, e.g., [2, p. 57], [10, pp. 10ff], and [19]); i.e., defining a mesh parameter h, a velocity space $\mathbf{V}_h$, and a pressure space P_h, there exist constants γ, Γ, independent of h, such that

$$\gamma^2 \le \frac{(p, BA^{-1}B^t p)}{(p, Qp)} \le \Gamma^2 \qquad \forall p \in P_h\,. \tag{1.4}$$

Here, Q is the pressure mass matrix, or alternatively the Grammian matrix of basis functions defining P_h. The lower bound γ is the so-called *inf–sup* constant. The relation (1.4) is crucial to the success of iterative solvers for solving discrete Stokes problems because it implies that, using a quasi-uniform mesh, the Schur complement $BA^{-1}B^t$ has a condition number bounded independently of h. It is also known from our previous work [16] that when $\nu \to \infty$, "optimal" preconditioners for the Laplacian subblocks give rise to "optimal" preconditioners for the Stokes problem in the sense that the spectra of the underlying discrete operators are contained in small clusters, which are bounded independently of h. A consequence of this is that the asymptotic convergence rate, with respect to the preconditioned residual norm, of Krylov subspace methods applied to discrete Stokes problems is also independent of h.

In this paper, we derive analogous results for eigenvalues in the general Oseen case. We introduce two preconditioners for the Oseen problem such that, for any value $0 < \nu < \infty$, the eigenvalues of the preconditioned Oseen operator are bounded independently of the mesh size. These observations apply to arbitrary discretizations satisfying (1.4). In addition, in a series of numerical experiments we show that these bounds on eigenvalues are predictive of the performance of Krylov subspace iterative methods for solving the preconditioned Oseen equations. Of course, it is well known that when convection dominates (i.e., when ν is "small" relative to h and $\|\mathbf{w}\|$), the standard Galerkin approximation deteriorates. Oscillations in the discrete velocity are apparent if the local mesh Reynolds number $Re^h = h\|\mathbf{w}\|/\nu$ is greater than unity. In such situations, the addition of streamwise diffusion to the discrete system is known to give added stability, both theoretically and numerically; see [3] and [12]. In our experiments, we demonstrate the effectiveness of the ideas using both a standard Galerkin discretization on a set of quasi-uniform grids and a streamline-upwind scheme on a set of uniform grids.

The remainder of the paper is divided into three sections. Our main theoretical results are presented in §2, and results of numerical experiments confirming and augmenting the theoretical analysis are given in §3. In §4, we consider more practical preconditioning strategies and present a perturbation analysis and additional numerical experiments demonstrating their effectiveness.

2. Preconditioning strategies. In this section, we introduce two preconditioning techniques for (1.1) and present an analysis showing that the spectra of the preconditioned systems are bounded independently of the discretization mesh size h. Throughout the section, we will be concerned with the eigenvalues of preconditioned matrices; these matrices can be viewed as being of the form $\mathcal{A}\mathcal{M}^{-1}$, where $\mathcal{A}$ is the original matrix and $\mathcal{M}$ is the preconditioner. Equivalently, we are concerned with the solution of the generalized eigenvalue problem $\mathcal{A}v = \lambda\mathcal{M}v$. All the matrices in question are implicitly parameterized by h. For simplicity, we state our results under the assumption that B of (1.3) has full rank.

The first idea is derived from a method developed in [14], [16], [20] for the discrete Stokes equations, where the coefficient matrix has the form

$$\begin{pmatrix} A & B^t \\ B & O \end{pmatrix}. \tag{2.1}$$

Consider the preconditioner

$$\begin{pmatrix} A & 0 \\ 0 & Q \end{pmatrix}$$

for (2.1). The eigenvalues of the preconditioned operator are then given by the solution to the generalized eigenvalue problem

$$\begin{pmatrix} A & B^t \\ B & O \end{pmatrix}\begin{pmatrix} u \\ p \end{pmatrix} = \lambda \begin{pmatrix} A & 0 \\ 0 & Q \end{pmatrix}\begin{pmatrix} u \\ p \end{pmatrix}. \tag{2.2}$$

One solution is $\lambda = 1$, of multiplicity $n_u - n_p$, for which the eigenvectors have the form $\binom{u}{0}$ where $Bu = 0$; i.e., u is "discretely divergence free." The remaining eigenvalues come from the solution of the quadratic equation $\lambda(\lambda - 1) = \mu$, where μ is a generalized eigenvalue of the Schur complement associated with (2.1),

$$BA^{-1}B^t p = \mu Qp. \tag{2.3}$$

Equivalently,

$$\lambda = \frac{1 \pm \sqrt{1+4\mu}}{2}. \tag{2.4}$$

Since (1.4) implies that as $h \to 0$ the solutions to (2.3) remain bounded above and below, it follows that the eigenvalues of (2.2) are also bounded. The preconditioned conjugate residual method can then be used to solve (2.1), with a convergence rate independent of h [14], [16].

A natural generalization for the discrete Oseen equations uses the block preconditioner

$$\begin{pmatrix} F & 0 \\ 0 & \frac{1}{\nu}Q \end{pmatrix}, \tag{2.5}$$

where $F = \nu A + N$. As above, the generalized eigenvalues for

$$\begin{pmatrix} F & B^t \\ B & O \end{pmatrix}\begin{pmatrix} u \\ p \end{pmatrix} = \lambda \begin{pmatrix} F & 0 \\ 0 & \frac{1}{\nu}Q \end{pmatrix}\begin{pmatrix} u \\ p \end{pmatrix} \tag{2.6}$$

are either $\lambda = 1$ or (2.4), where μ is now a solution to the generalized eigenvalue problem

$$Sp = \mu\left(\frac{1}{\nu}Q\right)p, \tag{2.7}$$

with $S = BF^{-1}B^t$, the Schur complement for the discrete Oseen operator. The following result, which generalizes the analysis for the Stokes operator in [19], provides a bound.

THEOREM 1. *The eigenvalues of the generalized Schur complement problem* (2.7) *for the Oseen operator are contained in a rectangular box in the right half plane whose borders are bounded independently of h.*

Proof. Let $C = B\left(\frac{F^{-1}+F^{-t}}{2}\right)B^t$ denote the symmetric part of S, and let $R = B\left(\frac{F^{-1}-F^{-t}}{2}\right)B^t$ denote its skew-symmetric part, so that $S = C + R$. By Bendixson's theorem ([17, p. 418]), any eigenvalue μ of the problem (2.7) satisfies

$$\min_p \frac{(p, Cp)}{(p, \frac{1}{\nu}Qp)} \le \mathrm{Re}(\mu) \le \max_p \frac{(p, Cp)}{(p, \frac{1}{\nu}Qp)}, \qquad |\mathrm{Im}(\mu)| \le \max_p \frac{|(p, Rp)|}{(p, \frac{1}{\nu}Qp)}. \tag{2.8}$$

To construct bounds on these Rayleigh quotients, it will be convenient to refer to $S_\infty = BA^{-1}B^t$, the Schur complement for the Stokes operator. For the symmetric part C in (2.8), we use the relation

$$\frac{(p, Cp)}{(p, \frac{1}{\nu}Qp)} = \frac{(p, Cp)}{(p, \frac{1}{\nu}S_\infty p)}\,\frac{(p, S_\infty p)}{(p, Qp)}. \tag{2.9}$$

In light of (1.4), we need only consider the first quotient on the right in (2.9). Note that

$$\begin{aligned} \frac{F^{-1}+F^{-t}}{2} &= F^{-1}\left(\frac{F+F^t}{2}\right)F^{-t} \\ &= (\nu A + N)^{-1}(\nu A)(\nu A - N)^{-1} \\ &= A^{-1/2}\left(\nu I - \frac{1}{\nu}\tilde{N}^2\right)^{-1} A^{-1/2}, \end{aligned} \tag{2.10}$$

where $\tilde{N} = A^{-1/2}NA^{-1/2}$. Consequently,

$$\frac{(p, Cp)}{(p, \frac{1}{\nu}S_\infty p)} = \frac{(p, BA^{-1/2}(\nu I - \frac{1}{\nu}\tilde{N}^2)^{-1}A^{-1/2}B^t p)}{(p, \frac{1}{\nu}BA^{-1}B^t p)} = \frac{(v, (I - \frac{1}{\nu^2}\tilde{N}^2)^{-1}v)}{(v, v)},$$

where $v = A^{-1/2}B^t p$. But $\tilde{N}$ is skew-symmetric, so that the eigenvalues of $-\tilde{N}^2$ are real and nonnegative. Moreover, since N and A are first-order and second-order operators, respectively, the eigenvalues of $\tilde{N}$ are uniformly bounded in modulus by a constant δ that is independent of h [5]. Therefore, the spectrum of $I - \frac{1}{\nu^2}\tilde{N}^2$ is contained in the interval $\left[1, 1 + \delta^2/\nu^2\right]$, or, equivalently,

$$\frac{\nu^2}{\delta^2 + \nu^2} \le \frac{(p, Cp)}{(p, \frac{1}{\nu}S_\infty p)} \le 1.$$

Combining this with (1.4) and (2.9) gives

$$\frac{\gamma^2\nu^2}{\delta^2 + \nu^2} \le \frac{(p, Cp)}{(p, \frac{1}{\nu}Qp)} \le \Gamma^2.$$

For the skew-symmetric part R in (2.8), the analogue of (2.9) is

$$\frac{(p, Rp)}{(p, \frac{1}{\nu}Qp)} = \frac{(p, Rp)}{(p, \frac{1}{\nu}S_\infty p)} \, \frac{(p, S_\infty p)}{(p, Qp)} \, ,$$

and as in (2.10), we have

$$\frac{F^{-1} - F^{-t}}{2} = -A^{-1/2} \, (\nu I + \tilde{N})^{-1} \, \tilde{N} \, (\nu I - \tilde{N})^{-1} \, A^{-1/2}.$$

Therefore

$$\frac{(p, Rp)}{(p, \frac{1}{\nu}S_\infty p)} = -\frac{\nu(v, \tilde{N}v)}{(v, (\nu^2 I - \tilde{N}^2)v)} \, , \tag{2.11}$$

where $v = (\nu I - \tilde{N})^{-1} A^{-1/2} B^T p$. The skew-symmetric matrix $\tilde{N}$ admits a decomposition of the form $\tilde{N} = iU\Lambda U^H$, where Λ is a real diagonal matrix and U is unitary. Consequently, $\tilde{N}^2 = -U\Lambda^2 U^H$, and the modulus of the Rayleigh quotient on the right side of (2.11) can be expressed in the form

$$\frac{\nu \, |(w, \Lambda w)|}{(w, (\nu^2 I + \Lambda^2)w)} \, .$$

This is bounded by

$$\max_{-\delta \le \lambda \le \delta} \frac{\nu|\lambda|}{\nu^2 + \lambda^2} = \max_{0 \le \lambda \le \delta} \frac{\nu\lambda}{\nu^2 + \lambda^2} \, .$$

It follows from elementary calculus that this maximum is $\frac{1}{2}$, obtained when $\lambda = \nu$, giving

$$\frac{|(p, Rp)|}{(p, \frac{1}{\nu}Qp)} \le \frac{\Gamma^2}{2} \, . \qquad \square$$

Corollary 1 follows immediately from Theorem 1 and (2.4).

COROLLARY 1. *The eigenvalues of the discrete Oseen operator preconditioned by* (2.5) *consist of* $\lambda = 1$ *of multiplicity* $n_u - n_p$, *together with four sets consisting of points of the form* $1 + (a \pm bi)$ *and* $-a \pm bi$. *These sets can be enclosed in two rectangular regions that are symmetric with respect to* $\mathrm{Re}\,(\lambda) = \frac{1}{2}$, *whose borders are bounded independently of* h.

The inclusion regions for these eigenvalues consist of the image of the box $\left[\frac{\gamma^2\nu^2}{\delta^2+\nu^2}, \Gamma^2\right] \times \left[-\frac{\Gamma^2}{2}, \frac{\Gamma^2}{2}\right]$ under the mapping $\mu \mapsto \lambda(\mu)$ given by (2.4). It can be shown that the rectangular regions of this result are contained in

$$\left[\frac{1 + s_{\min}}{2}, \frac{1 + s_{\max}}{2}\right] \times [-t, t] \quad \text{and} \quad \left[\frac{1 - s_{\max}}{2}, \frac{1 - s_{\min}}{2}\right] \times [-t, t]$$

in the right and left half sides, respectively, of the complex plane, where

$$s_{\min} = \left(1 + \frac{4\gamma^2\nu^2}{\delta^2 + \nu^2}\right)^{1/2}, \qquad s_{\max} = \left[\frac{1}{2}\left(1 + 4\Gamma^2 + \sqrt{1 + 8\gamma^2 + 20}\,\right)\right]^{1/2},$$

$$t = \frac{\Gamma^2}{\left(1 + \frac{4\gamma^2\nu^2}{\delta^2+\nu^2}\right)^{1/2}} \, .$$

The fact that the eigenvalues for the preconditioned system derived from (2.5) lie on both sides of the imaginary axis is a potential disadvantage of this idea. An alternative that avoids this problem is the block triangular operator

$$\begin{pmatrix} F & B^t \\ 0 & -\frac{1}{\nu}Q \end{pmatrix}. \tag{2.12}$$

For this choice, the preconditioned eigenvalue problem is

$$\begin{pmatrix} F & B^t \\ B & O \end{pmatrix}\begin{pmatrix} u \\ p \end{pmatrix} = \lambda \begin{pmatrix} F & B^t \\ 0 & -\frac{1}{\nu}Q \end{pmatrix}\begin{pmatrix} u \\ p \end{pmatrix}. \tag{2.13}$$

Again, one solution is $\lambda = 1$, now of multiplicity n_u. If $\lambda \neq 1$, then premultiplying the first block row of (2.13) by BF^{-1} and using the relation $Bu = -\lambda(\frac{1}{\nu}Q)p$ leads to equation (2.7) for the other eigenvalues. Thus, we have the following result.

THEOREM 2. *The eigenvalues of the discrete Oseen operator preconditioned by* (2.12) *consist of* $\lambda = 1$ *together with the generalized eigenvalues of* S *in* (2.7). *Therefore, the eigenvalues are bounded independently of* h.

Remark 1. Use of either preconditioning operator (2.5) or (2.12) entails the computation of the action of F^{-1} at each step of an iterative procedure. F is a discrete convection-diffusion operator and applying F^{-1} to a vector using direct methods will be expensive. An alternative is to replace this computation with an approximation obtained by iterative solution of the convection-diffusion equation. We will examine this approach in §4.

Remark 2. Both preconditioners also require the action of Q^{-1}, which may also be expensive, depending on the choice of pressure discretization. In this case, however, it is known that Q can be replaced by some approximation $\hat{Q}$ without affecting asymptotic convergence properties; only the constants γ and Γ of (1.4) change [21]. In the experiments discussed in §§3 and 4, we replace Q with a diagonal matrix consisting of the main diagonal of Q.

3. Numerical results I: Exact convection-diffusion solves. In this section, we present the results of numerical experiments indicating that the analysis of §2 is predictive of the performance of iterative methods for solving (1.3). Computations were performed using MATLAB 4.1 on a variety of computing platforms.

Our test problem is a "leaky" two-dimensional lid-driven cavity problem in a square domain $(-1 \leq x \leq 1 : -1 \leq y \leq 1)$. The boundary conditions are $u_x = u_y = 0$ on the three fixed walls $(x = -1, y = -1, x = 1)$, and $u_x = 1, u_y = 0$ on the moving wall $(y = 1)$. The hydrostatic pressure is not explicitly specified, so that all the linear equation systems we solve below are singular with a one-dimensional nullspace. The convective "wind" is a circular vortex as illustrated in Fig. 1, and is given by

$$\begin{aligned} w_x &= 2y(1 - x^2), \\ w_y &= -2x(1 - y^2). \end{aligned}$$

The fact that there is no dominant flow direction makes this a challenging test problem. Note that in the corners and in the center of the flow region the driving flow is stagnant.[1]

Unless otherwise specified, we consider values of the viscosity parameter ν between 1 and 1/100. When $\nu = 1$ we have diffusion dominated (essentially Stokes) flow, whereas as

[1] This is actually not a linearization of the Navier–Stokes equations since $\mathbf{w}$ and $\mathbf{u}$ do not satisfy the same boundary conditions; this fact does not affect the demonstration of the solution algorithms. Also, note that $\operatorname{div}\mathbf{w} = 0$ so that the term $\frac{1}{2}\mathbf{u}(\operatorname{div}\mathbf{w})$ in (1.2) is identically zero.

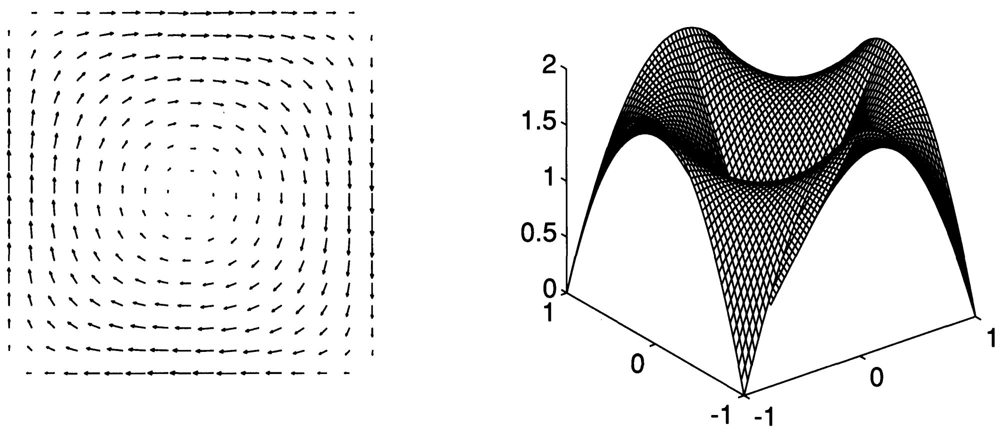

FIG. 1. *Magnitude and direction of the convecting flow.*

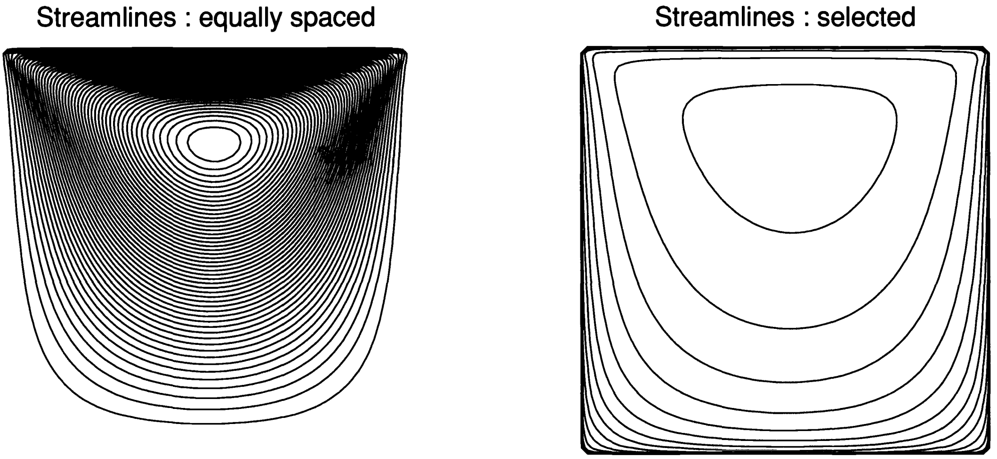

FIG. 2. *Uniform* 64 × 64 *grid*: $\nu = 1$.

$\nu \to 0$ the flow becomes dominated by the "wind." Typical flow solutions are illustrated in Figs. 2 and 3. Note that as the viscosity is decreased, the center of primary recirculation moves to the right (the Stokes flow solution is perfectly symmetric about the line $x = 0$), and secondary vortices are generated in the two bottom corners.

To discretize (1.2), we take a finite element subdivision based on $n \times n$ grids of rectangular elements. Bearing in mind the nature of the flow solution being computed, we present results for two representative discretizations here: a conventional Galerkin approach using a quasi-uniform sequence of grids and a streamline-upwind method using uniform grids of square elements of size $h = 2/n$. In either case, the mixed finite element used was the div-stable "Taylor–Hood" method based on continuous bilinear pressure with a continuous bilinear velocity field defined on four element macroelements (see, e.g., [10, p. 30]).

For the Galerkin discretization, the quasi-uniform grids are chosen to resolve the details of the flow in the four corners of the domain: they are symmetric about $x = 0$ and $y = 0$, and in each quadrant the grid lines become more dense near the boundary. The 64 × 64 grid is shown in the pressure solution plot in Fig. 4. The analytic pressure solution is singular at the top corners where the imposed velocity is discontinuous.

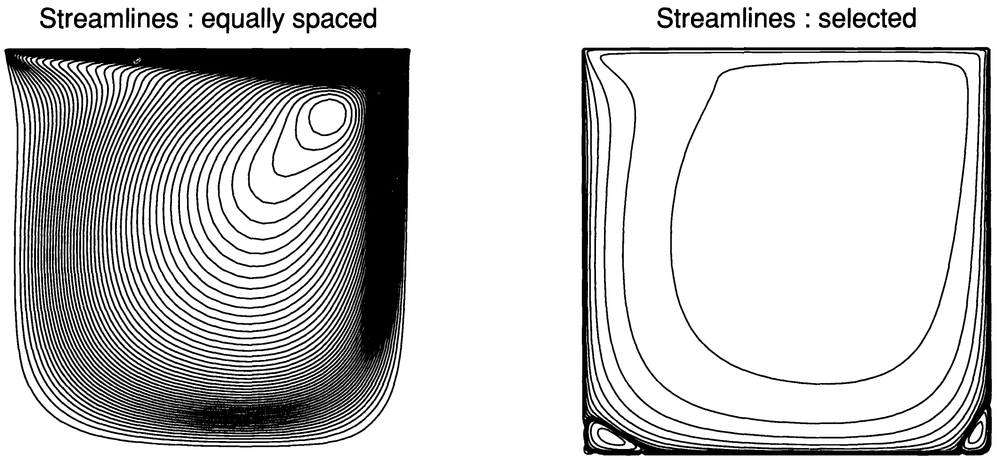

FIG. 3. *Nonuniform* 64 × 64 *grid*: $\nu = 1/100$.

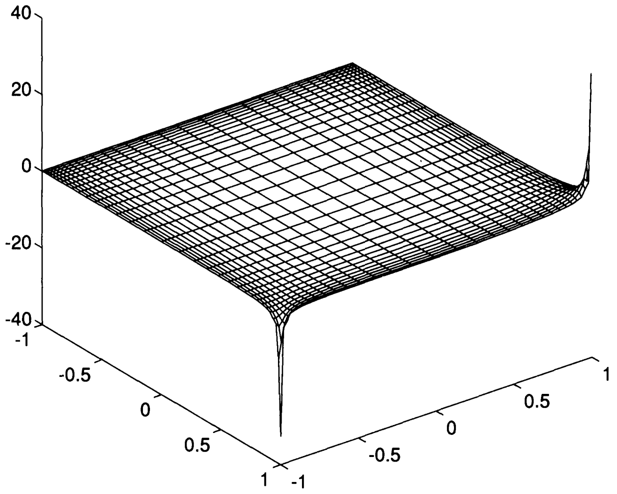

FIG. 4. *Pressure solution for* $\nu = 1/10$.

The streamline-upwind discretization is as described in [12, p. 185]. In this case, the block convection-diffusion operator F is perturbed by a symmetric positive semidefinite matrix $A_{\mathbf{w}}$. That is, $F = -\nu\Delta_h + A_{\mathbf{w}} + N$, where Δ_h is the discrete Laplacian obtained from the usual Galerkin formulation. $A_{\mathbf{w}}$ is the discrete form of a stabilizing term $\alpha\ (\mathbf{w}\cdot\nabla\mathbf{u}, \mathbf{w}\cdot\nabla\mathbf{v})$ that adds $\alpha \equiv O(h)$ diffusion along the streamlines. For our experiments with streamline upwinding, we took $\alpha = h/4$. Note that the perturbation does not affect the skew-symmetric part of the convection-diffusion operator, so that the analysis of §2 holds; only the definition of the "diffusion matrix" A is changed, from $-\Delta_h$ to $-\Delta_h + \frac{1}{\nu}A_{\mathbf{w}}$.

We first consider the bounds of Theorem 1. Table 1 shows the extreme real parts and maximum imaginary parts of the generalized eigenvalues (2.7) of the Schur complement operator, for $\nu = 1/10$ and $1/100$ with the streamline-upwind discretization, on three meshes. The small changes in all values are in accordance with the analysis, although it appears that finer meshes would be needed to produce constant values. The analysis also shows that the

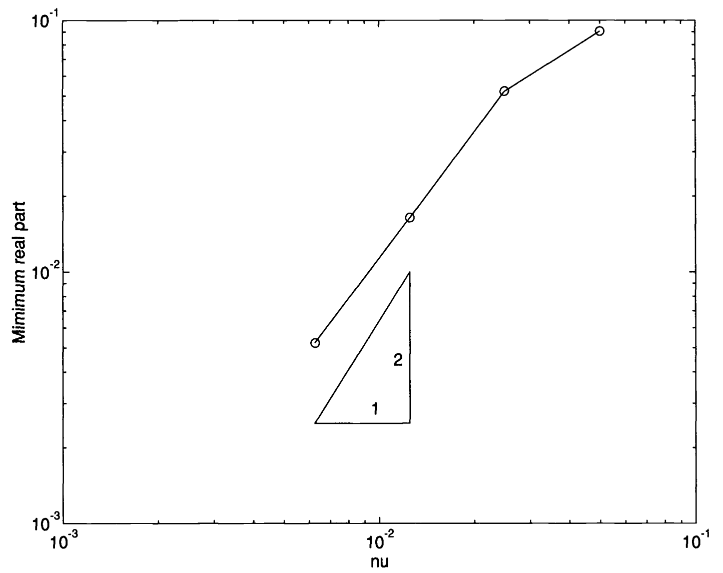

FIG. 5. *Minimum real parts of eigenvalues of the Schur complement, for streamline-upwind discretization on a* 64×64 *grid.*

real parts and largest imaginary parts of the eigenvalues are bounded independently of ν; the bound for the smallest real part is proportional to ν^2. The data in Table 1 are in agreement with the upper bounds. Figure 5 plots the smallest real parts on a logarithmic scale for the streamline-upwind discretization on a 64×64 grid and $\nu = 1/20$, $1/40$, $1/80$, and $1/160$. The results indicate that the lower bound is also tight.

We test the preconditioners here with two Krylov subspace methods for solving nonsymmetric systems: the generalized minimum residual method (GMRES) [15] and a simple implementation of the quasi-minimum residual method (QMR) [8] based on coupled two-term recurrences without look-ahead. GMRES demonstrates the performance of the preconditioners with the optimal (with respect to the residual norm) Krylov subspace solver. This method is impractical for large problems because its work and storage requirements grow with the iteration count; QMR is a nonoptimal alternative that avoids this difficulty. Some additional experiments with restarted GMRES are presented in §4. In all cases we use right-oriented preconditioning, and our convergence criterion is a reduction of 10^{-6} in the l_2-norm of the residual. The action of F^{-1} and F^{-t} is computed using the LU-factorization in MATLAB. We start from a zero initial guess. Using random initial guesses gave comparable iteration counts in all cases.

We first discuss the performance of GMRES. Table 2 shows the iteration counts obtained for three values of ν using the block triangular preconditioner (2.12) in the case of Galerkin approximation on the quasi-uniform grid sequence, and Table 3 shows the iteration counts for uni-

TABLE 2

form grids with streamline-upwind discretization. The results suggest that grid-independent convergence is observed even on relatively coarse grids if the flow is diffusion dominated, that is, eigenvalues are indeed predictive of performance. If convection dominates (as ν tends to zero), then the iteration counts increase, as might be expected from the analytic bounds of §2. For the smallest value of ν considered here, $1/50$, the iteration counts grow as the mesh is refined; although for fine enough grids the counts become close to constant. We believe that for "small" ν, the asymptotic grid independence will be visible only for sufficiently fine grids.

GMRES with the block diagonal preconditioner (2.5) gives an identical picture. Indeed, we find that for the grid sizes and values of ν in Tables 2 and 3 (only $n \leq 64$ was tested), GMRES requires precisely $2k - 1$ iterations to reach the tolerance where k is the iteration count from Table 2 or 3. Moreover, the behavior of GMRES using (2.5) mirrors its behavior with the triangular preconditioning, in the sense that the odd iterates at step $2i - 1$ are close to those obtained in the triangular case at step i, and the norms of the even iterates stagnate. A rigorous explanation for this behavior can be given by relating the optimal polynomials implicitly generated by GMRES. In particular, it follows from the analysis in [6] that for a particular starting guess (not zero), the ith GMRES polynomial for the triangular case is identical to the $(2i - 1)$st GMRES polynomial for the diagonal case.

Tables 4 and 5 show analogous iteration counts for QMR. The tables contain data for both the triangular and (in parentheses for $n \leq 64$) diagonal preconditioners. Note that the iteration counts in the first three rows of Tables 4 and 5 are close to the corresponding entries of Tables 2 and 3, respectively; i.e., the performance in QMR is close to optimal. Results for $\nu = 1/100$ are included to get a sense of the behavior of the preconditioners as ν becomes small; it appears that the asymptotic behavior is not seen for the grid sizes used.

Note that the cost per step of the block triangular preconditioner is only slightly higher than that of the block diagonal preconditioner (only an extra multiplication by B^t is needed); hence (2.12) is more efficient. However, for the Stokes problem ($\nu \to \infty$), the preferred choice of preconditioner is less obvious since the inherent symmetry is destroyed if (2.12) is used in place of (2.5).

$\nu = 1/100$	76 (157)	133 (249)	190 (382)	229

Remark 3. In addition to the implementation of QMR with a coupled two-term recurrence (QMR$_2$) discussed above, we tested a version without look-ahead based on a three-term recurrence (QMR$_3$) [7], and the definitive (Fortran) implementation of a two-term QMR with look-ahead (QMR$_2^*$) from the QMRPAK directory in Netlib. For the preconditioners discussed above, the performances of the three variants were virtually identical. However, with the inexact preconditioners of the next section, we found QMR$_2$ to be much more robust than QMR$_3$.

4. Numerical results II: Inexact convection-diffusion solves. The dominant costs of the preconditioners of §§2 and 3 come from applying the action of F^{-1}, and for QMR, F^{-t}, to some vector v at each step of the iteration. In this section, we show that this operation can be replaced by an inexpensive one derived from an approximation to F^{-1}, with little degradation of performance of the Krylov subspace methods. The idea is to replace the preconditioning operators (2.5) and (2.12) with

$$(4.1) \qquad \begin{pmatrix} \hat{F} & 0 \\ 0 & \frac{1}{\nu}Q \end{pmatrix} \quad \text{and} \quad \begin{pmatrix} \hat{F} & B^t \\ 0 & -\frac{1}{\nu}Q \end{pmatrix},$$

respectively, where $\hat{F} \approx F$. Our choice of $\hat{F}$ will be implicitly determined by the use of iterative methods to compute approximate solutions to the systems $Fw = v$ and $F^t w = v$, although the methodology is not restricted to this choice. We will refer to the preconditioners that use the exact action of F^{-1} as the *exact* versions, and those based on approximations as in (4.1) as *inexact* versions.

Some insight into the effects of the inexact preconditioners is derived from matrix perturbation theory. Let $Q_\nu = \frac{1}{\nu}Q$. The preconditioned matrix for the exact block diagonal preconditioner (2.5) is

$$\mathcal{A}_D = \begin{pmatrix} F & B^t \\ B & O \end{pmatrix} \begin{pmatrix} F & 0 \\ 0 & Q_\nu \end{pmatrix}^{-1} = \begin{pmatrix} I & B^t Q_\nu^{-1} \\ BF^{-1} & 0 \end{pmatrix},$$

and that derived from the inexact version is

$$\hat{\mathcal{A}}_D = \begin{pmatrix} F & B^t \\ B & O \end{pmatrix} \begin{pmatrix} \hat{F} & 0 \\ 0 & Q_\nu \end{pmatrix}^{-1} = \mathcal{A}_D + \mathcal{E}_D,$$

where, with $E = \hat{F} - F$,

$$\mathcal{E}_D = -\begin{pmatrix} E\hat{F}^{-1} & 0 \\ BF^{-1}E\hat{F}^{-1} & 0 \end{pmatrix}.$$

Similarly, the preconditioned matrices for the exact and inexact block tridiagonal preconditioners (2.12) satisfy $\hat{\mathcal{A}}_T = \mathcal{A}_T + \mathcal{E}_T$, where

$$\mathcal{A}_T = \begin{pmatrix} I & 0 \\ BF^{-1} & BF^{-1}B^t Q_\nu^{-1} \end{pmatrix}, \qquad \mathcal{E}_T = -\begin{pmatrix} E\hat{F}^{-1} & E\hat{F}^{-1}B^t Q_\nu^{-1} \\ BF^{-1}E\hat{F}^{-1} & BF^{-1}E\hat{F}^{-1}B^t Q_\nu^{-1} \end{pmatrix}.$$

We have the following bounds on the eigenvalues of the preconditioned systems using inexact preconditioners.

THEOREM 3. *If* $\mathcal{A}_D = \mathcal{V}_D \Lambda_D \mathcal{V}_D^{-1}$ *is diagonalizable, then for any eigenvalue* $\mu \in \sigma(\hat{\mathcal{A}}_D)$,

$$\min_{\lambda \in \sigma(\mathcal{A}_D)} |\lambda - \mu| \leq \|E\hat{F}^{-1}\|_\infty \kappa_\infty(\mathcal{V}_D) \max(1, \|BF^{-1}\|_\infty).$$

If $\mathcal{A}_T = \mathcal{V}_T \Lambda_T \mathcal{V}_T^{-1}$ *is diagonalizable, then for any eigenvalue* $\mu \in \sigma(\hat{\mathcal{A}}_T)$,

$$\min_{\lambda \in \sigma(\mathcal{A}_T)} |\lambda - \mu| \leq \|E\hat{F}^{-1}\|_\infty \kappa_\infty(\mathcal{V}_T)\, (1 + \|B^t Q^{-1}\|_\infty) \max(1, \|BF^{-1}\|_\infty).$$

Proof. The result is an immediate consequence of the Bauer–Fike theorem [9, p. 342], which states that for diagonalizable $\mathcal{A} = \mathcal{V}\Lambda\mathcal{V}^{-1}$, any $\mu \in \sigma(\mathcal{A} + \mathcal{E})$ satisfies $\min_{\lambda \in \sigma(\mathcal{A})} |\lambda - \mu| \leq \kappa(\mathcal{V})\, \|\mathcal{E}\|$, where $\|\cdot\|$ is any l_p-norm. □

Thus, if $\hat{F}$ is a good enough approximation to F, i.e., if enough inner iterations are used, then $\|E\hat{F}^{-1}\|$ will be small and the eigenvalues of $\hat{\mathcal{A}}_D$ and $\hat{\mathcal{A}}_T$ will be close to those of $\mathcal{A}_D$ and $\mathcal{A}_T$, respectively. We state the result in terms of the l_∞-norm only because the bounds then have a simple form.

Remark 4. We have computed the condition numbers $\kappa(\mathcal{V})$ for $\mathcal{A}_T$ and found them to be large, on the order of 10^3 or higher, for the three values of ν, with streamline upwinding and $h = 1/16$. However, the presence of $\kappa(\mathcal{V})$ in these bounds is an artifact of the proof of the Bauer–Fike theorem; there are more subtle analyses ([9, pp. 344ff]), as well as bounds that do not require diagonalizable matrices [11]. We have observed that the eigenvalues of $\mathcal{A}_T$ are insensitive to perturbations, and we believe that the presence of $\kappa(\mathcal{V})$ is pessimistic. This supposition is supported by the experimental results described below.

To demonstrate that inexact preconditioning is effective, we consider versions of it based on two line-oriented splittings of F. The first uses a *horizontal line Gauss–Seidel relaxation*: Let $F = H - R$ denote a horizontal line Gauss–Seidel splitting of the block convection-diffusion operator F derived from the one-line natural left-to-right, bottom-to-top ordering of the velocity grid. Thus, H is a block lower triangular matrix consisting of the block diagonal of F (a tridiagonal matrix) together with the strict block lower triangular part of F. (See [18], [22] for further details.) The horizontal line Gauss–Seidel method for $Fw = v$ performs the iteration

$$w_0 = 0, \quad w_{i+1} = w_i + H^{-1}(v - Fw_i).$$

For k steps of this iteration, the approximating matrix is $\hat{F} = F(I - (H^{-1}R)^k)^{-1}$.

It has been observed that the performance of relaxation methods of this type can be improved if the sweep direction follows the underlying direction of flow [4]. Our benchmark problem has a circular flow, so that no simple line relaxation can mimic the flow direction throughout Ω. A slightly more sophisticated idea is to use an *alternating line relaxation.* For this, let $F = V - T$ denote a vertical line Gauss–Seidel splitting of F; that is, if P is a permutation matrix associated with the mapping from the natural horizontal line ordering of grid points to the natural vertical line ordering, then P^TVP is the block lower triangular part of P^TFP. One iteration of alternating line relaxation consists of two line Gauss–Seidel steps, one using the horizontal splitting, followed by one using the vertical splitting:

$$w_0 = 0, \quad w_{i+1/2} = w_i + H^{-1}(v - Fw_i), \quad w_{i+1} = w_{i+1/2} + V^{-1}(v - Fw_{i+1/2}).$$

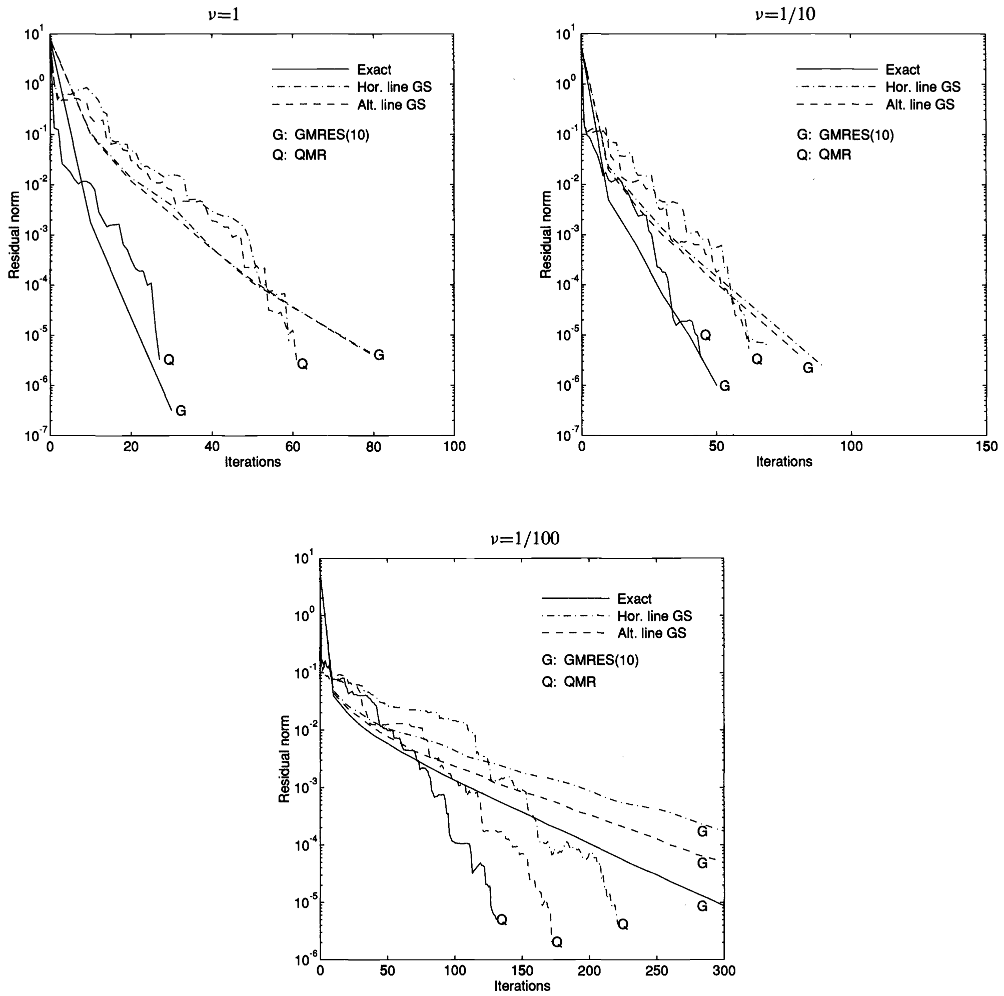

FIG. 6. *Performance of block tridiagonal inexact preconditioners for* 32 × 32 *grid.*

Figure 6 shows results of using the inexact block tridiagonal preconditioners with a version of GMRES with restarts every ten steps (denoted GMRES(10)) and with QMR. The test problem is discretized by streamline upwinding on a 32 × 32 grid. Results for inexact block diagonal preconditioners were similar, except that, as with the exact preconditioners, convergence was slower. We used four steps of horizontal line relaxation or two steps of alternating line relaxation, so that both inexact preconditioners perform four sweeps. The figure also shows the performance of the exact preconditioner, whose cost per step is significantly more expensive. For example, with an $n \times n$ velocity grid, direct solution using a bandsolver requires $O(n^4)$ operations, whereas each inner iteration is an $O(n^2)$ computation. We see that the use of inexact preconditioners in place of the exact versions leads to little degradation of performance of the Krylov subspace methods. For example, in the convection-dominated case $\nu = 1/100$, QMR with alternating line relaxation requires roughly 25% more iterations than with the exact preconditioner. For the diffusion dominated case $\nu = 1$, roughly three times as many outer iterations are required with the inexact preconditioners, which still leads to a less costly computation. Not surprisingly, alternating relaxation is more effective than horizontal relaxation, especially for convection-dominated problems. We remark that our goal here is only to demonstrate "proof-of-concept"; many other techniques for approximating the action of F^{-1} are possible, for both diffusion-dominated and convection-dominated flow. See, for example, [1], [4], [14], [16], [20].

Remark 5. Although we do not make a detailed comparison of Krylov subspace methods, we briefly comment on the behavior of the two choices used here. QMR requires twice as many preconditioned matrix–vector products per step as GMRES(10), and since matrix–vector products are the dominant cost, each QMR step is roughly twice as expensive. Thus, these results indicate that GMRES(10) is more efficient than QMR for large ν, but QMR becomes more effective as convection becomes dominant. The storage requirements of the two methods are comparable.

Acknowledgments. We thank Oliver Ernst, Roland Freund, and Marlis Hochbruck for providing us with Matlab versions of QMR.

ANALYSIS OF SEMI-TOEPLITZ PRECONDITIONERS FOR FIRST-ORDER PDES*

LINA HEMMINGSSON† AND KURT OTTO†

Abstract. A semi-Toeplitz preconditioner for nonsymmetric, nondiagonally dominant systems of equations is studied. The preconditioner solve is based on a fast modified sine transform. As a model problem we study a system of equations arising from an implicit time discretization of a scalar hyperbolic partial differential equation (PDE). Analytical formulas for the eigenvalues and the eigenvectors of the preconditioned system are derived. The convergence of a minimal residual iteration is shown to depend only on the spatial grid ratio and not on the number of unknowns.

Key words. first-order PDE, finite difference discretization, preconditioner, spectral analysis, convergence

AMS subject classifications. 65F10, 65N22

1. Introduction.

We are interested in solving systems of first-order partial differential equations (PDEs) such as the Euler equations and the Maxwell equations. For the Euler equations, we are mainly interested in the case when there are different time scales present in the problem, and the fastest time scale does not have to be resolved. An important application is almost incompressible flow [4], [5], where the sound waves in the medium are much faster than the motion of the fluid. For an explicit discretization in time, the restriction on the time step due to the Courant–Friedrichs–Lewy criterion becomes too severe. For the Maxwell equations, we intend to consider complicated geometries such that the smallest grid cell in the space discretization restricts the time step considerably in an explicit time discretization. Therefore, we use an implicit time discretization. This leads to a system of equations

$$Au = b, \tag{1}$$

which has to be solved at each time step. A is nonsymmetric, and since the time step is large compared to the space step, it is also strongly nondiagonally dominant.

In this paper we examine theoretically the convergence properties when we apply a minimal residual iteration to (1), utilizing a semi-Toeplitz preconditioner. Such preconditioners have been shown to be well suited in a domain decomposition setting of the problem [8].

2. The model problem.

2.1. The differential equation.

In [7] we consider a scalar two-dimensional equation with variable coefficients. Here we will restrict our presentation to constant coefficients in order to be able to derive theoretical properties of the preconditioned system.

$$\frac{\partial u}{\partial t} + \frac{\partial u}{\partial x_1} + \frac{\partial u}{\partial x_2} = g, \quad 0 < x_1 \leq 1, \quad 0 < x_2 \leq 1, \quad t > 0. \tag{2}$$

Problem (2) is well posed if we prescribe $u(0, x_2, t)$, $u(x_1, 0, t)$, and $u(x_1, x_2, 0)$.

2.2. Discretization.

Introduce a uniform grid as

$$x_{d,j} = jh_d, \quad j = 0, \ldots, m_d, \quad h_d = 1/m_d, \quad d = 1, 2.$$

†Department of Scientific Computing, Uppsala University, Box 120, S-751 04 Uppsala, Sweden (lina@tdb.uu.se and kurt@tdb.uu.se).

Let $u_{j,k}$ denote the approximate solution at the point $(x_{1,j}, x_{2,k})$. Now we discretize equation (2) in time using the trapezoidal rule with time step Δt:

$$\frac{u^{n+1} - u^n}{\Delta t} + \tfrac{1}{2}\sum_{d=1}^{2}\left(\left(\frac{\partial u}{\partial x_d}\right)^{n+1} + \left(\frac{\partial u}{\partial x_d}\right)^{n}\right) = \tfrac{1}{2}(g^{n+1} + g^n).$$

For the spatial derivatives, we use second-order centered differences in the interior of the domain and one-sided first-order differences at the outflow boundaries. We define the following quantities:

$$\kappa_d \equiv \frac{\Delta t}{h_d}, \quad d = 1, 2,$$

$$u^n = \begin{pmatrix} u^n_{1,1} & u^n_{2,1} & \cdots & u^n_{m_1,1} & u^n_{1,2} & \cdots & u^n_{m_1,m_2} \end{pmatrix}^T,$$

and finally write the equations as

$$Au^{n+1} \equiv (I_{m_2} \otimes A_1 + \kappa_2 A_2 \otimes I_{m_1})u^{n+1} = b, \tag{3}$$

where b contains known quantities, and A_1 and A_2 are defined by

$$A_1 = \begin{pmatrix} 4 & \kappa_1 & & & \\ -\kappa_1 & 4 & \kappa_1 & & \\ & \ddots & \ddots & \ddots & \\ & & -\kappa_1 & 4 & \kappa_1 \\ & & & -2\kappa_1 & 4 + 2\kappa_1 \end{pmatrix}, \tag{4}$$

$$A_2 = \begin{pmatrix} 0 & 1 & & & \\ -1 & 0 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & -1 & 0 & 1 \\ & & & -2 & 2 \end{pmatrix}.$$

3. Iterative methods. The matrix A defined in (3) is extremely sparse, with five nonzero diagonals and semibandwidth m_1. Modern CG-like iterative methods are well suited for nonsymmetric systems of equations. In this paper we consider minimal residual iterations [3], which in each iteration satisfy

$$\|r^{(i)}\|_2 = \min_{p_i \in \mathcal{P}_i,\, p_i(0)=1} \|p_i(M^{-1}A)r^{(0)}\|_2,$$

where $\mathcal{P}_i$ is the set of all polynomials of degree i, M is the left preconditioner, $r^{(i)} \equiv M^{-1}(Au^{(i)} - b)$, and $u^{(i)}$ denotes the approximation of u obtained at iteration i. If $M^{-1}A$ is diagonalizable we obtain

$$\frac{\|r^{(i)}\|_2}{\|r^{(0)}\|_2} \le \mathrm{cond}_2(W_{M^{-1}A}) \min_{p_i \in \mathcal{P}_i,\, p_i(0)=1} \max_{1 \le \ell \le n} |p_i(\lambda_\ell)| \equiv \mathrm{cond}_2(W_{M^{-1}A}) \cdot \varepsilon_i, \tag{5}$$

where $W_{M^{-1}A}$ is the eigenvector matrix and λ_ℓ are the eigenvalues of $M^{-1}A$. From (5) we conclude that we will have finite termination in n iterations, where n is the number of distinct eigenvalues to the preconditioned system. Moreover, if we can precondition our system in such a way that the eigenvalues of $M^{-1}A$ are contained in k dense clusters, we have a good approximation to the solution in k iterations. Clustering of the eigenvalues may be even more important than a condition number improvement [1], [2], and [12]. In §4 we define a preconditioner that yields a highly clustered spectrum. Since the iterative method includes the solution of

$$Mx = y \tag{6}$$

in each step, we must have a fast solver for this system. The preconditioner solve defined in this paper is based on a fast modified sine transform developed in [6].

4. Preconditioning. Consider the semi-Toeplitz preconditioner M defined by

$$M = I_{m_2} \otimes \hat{A}_1 + \kappa_2 A_2 \otimes I_{m_1}, \quad \hat{A}_1 = \begin{pmatrix} 4 & \kappa_1 & & \\ -\kappa_1 & \ddots & \ddots & \\ & \ddots & \ddots & \kappa_1 \\ & & -\kappa_1 & 4 \end{pmatrix}. \tag{7}$$

In [7] it is shown that M can be decomposed as

$$M = (I_{m_2} \otimes S_{m_1}) T (I_{m_2} \otimes S_{m_1}^H),$$

where T is block tridiagonal with diagonal blocks

$$T = I_{m_2} \otimes \Lambda_1 + \kappa_2 A_2 \otimes I_{m_1},$$

where

$$\Lambda_1 = \operatorname{diag}(\lambda_{1,1}, \ldots, \lambda_{1,m_1}), \quad \lambda_{1,j} = 4 + 2i\kappa_1 \cos\left(\frac{j\pi}{m_1+1}\right). \tag{8}$$

S_{m_1} is the modified sine matrix defined by

$$S_{m_1}(j,k) = \sqrt{\frac{2}{m_1+1}}\, i^{j+k+1} \sin\left(\frac{jk\pi}{m_1+1}\right), \quad j,k = 1,\ldots,m_1. \tag{9}$$

By rearranging the unknowns, the solution of

$$Tx = y$$

decouples into m_1 independent tridiagonal systems of order m_2. In [6] it is shown how the modified sine transforms can be evaluated using Fourier transforms of vectors $y \in C^{\frac{m_1+1}{2}}$. By symmetry we can also reduce the intermediate solution of the tridiagonal systems to the solution of only the first $\frac{m_1+1}{2}$ systems.

To sum up this section we present the different steps in the solution of (6):

- m_2 Fourier transforms of vectors $y \in C^{\frac{m_1+1}{2}}$,
- $\frac{m_1+1}{2}$ solutions of tridiagonal systems of order m_2,
- m_2 Fourier transforms of vectors $y \in C^{\frac{m_1+1}{2}}$.

5. Spectral analysis. By defining

$$E \equiv A - M = I_{m_2} \otimes E_1,$$

where E_1 is defined by

$$E_1 = \begin{pmatrix} 0 & \cdots & 0 & 0 & 0 \\ \vdots & & \vdots & \vdots & \vdots \\ 0 & \cdots & 0 & 0 & 0 \\ 0 & \cdots & 0 & -\kappa_1 & 2\kappa_1 \end{pmatrix},$$

we get

$$M^{-1}A = I + M^{-1}(I_{m_2} \otimes E_1). \tag{10}$$

Otto [9] shows how to compute the eigenvalues and the eigenvectors of (10) when M is a semicirculant preconditioner, i.e., each block is circulant. We use a similar technique here. We will make use of a lemma in [9], which we restate for readability. Let $\mathcal{E}(a, b)$ denote the closed ellipse centered at the origin with semimajor axis b oriented along the imaginary axis and semiminor axis a. Also, let $\mathcal{E}^+(a, b)$ denote the region $\{z | z \in \mathcal{E}(a, b) \text{ and } \Re e(z) \geq 0\}$.

LEMMA 5.1. *The eigenvalues* $\lambda_{2,k}$, $k = 1, \ldots, m_2$, *of* A_2 *satisfy*

- $\lambda_{2,k} \neq \lambda_{2,j}, \quad k \neq j,$
- $\lambda_{2,k} \in \mathcal{E}^+(4m_2^{-3/4}, 2 + 4m_2^{-3/2})$.

From Lemma 5.1 we conclude that there exists a nonsingular matrix V_2 such that

$$V_2^{-1} A_2 V_2 = \Lambda_2 = \mathrm{diag}(\lambda_{2,1}, \ldots, \lambda_{2,m_2}).$$

By defining

$$D \equiv (V_2^{-1} \otimes S_{m_1}^H) M (V_2 \otimes S_{m_1}),$$

where S_{m_1} is the modified sine matrix of order m_1 defined in (9), we get

$$\begin{aligned} D &= (V_2^{-1} \otimes S_{m_1}^H)(I_{m_2} \otimes \hat{A}_1 + \kappa_2 A_2 \otimes I_{m_1})(V_2 \otimes S_{m_1}) \\ &= I_{m_2} \otimes S_{m_1}^H \hat{A}_1 S_{m_1} + \kappa_2 V_2^{-1} A_2 V_2 \otimes I_{m_1} = I_{m_2} \otimes \Lambda_1 + \kappa_2 \Lambda_2 \otimes I_{m_1}, \end{aligned}$$

where Λ_1 is defined in (8). From Lemma 5.1 we get that

$$\Re e(\lambda_{1,j} + \kappa_2 \lambda_{2,k}) = 4 + \kappa_2 \Re e(\lambda_{2,k}) \geq 4,$$

which implies that $I_{m_2} \otimes \Lambda_1 + \kappa_2 \Lambda_2 \otimes I_{m_1}$ is nonsingular, i.e., M^{-1} exists. Hence,

$$D = I_{m_2} \otimes \Lambda_1 + \kappa_2 \Lambda_2 \otimes I_{m_1} = \mathrm{diag}(D_1, \ldots, D_{m_2}),$$

where

$$D_k = \mathrm{diag}(d_\nu),$$

$$d_\nu = 4 + 2i\kappa_1 \cos\left(\frac{j\pi}{m_1+1}\right) + \kappa_2 \lambda_{2,k}, \qquad \begin{cases} \nu = (k-1)m_1 + j, \\ k = 1, \ldots, m_2, \\ j = 1, \ldots, m_1, \end{cases} \tag{11}$$

and the spectral decomposition of M^{-1} becomes

$$M^{-1} = (V_2 \otimes S_{m_1}) D^{-1} (V_2^{-1} \otimes S_{m_1}^H).$$

Now consider the matrix W given by

$$\begin{aligned} W &= (V_2 \otimes I_{m_1})^{-1} M^{-1} E (V_2 \otimes I_{m_1}) \\ &= (I_{m_2} \otimes S_{m_1}) \mathrm{diag}(D_1^{-1}, \ldots, D_{m_2}^{-1})(I_{m_2} \otimes S_{m_1}^H E_1) \\ &= \mathrm{diag}(S_{m_1} D_1^{-1} S_{m_1}^H E_1, \ldots, S_{m_1} D_{m_2}^{-1} S_{m_1}^H E_1) \equiv \mathrm{diag}(W_1, \ldots, W_{m_2}). \end{aligned}$$

As W is a similarity transformation of $M^{-1}E$ and W is block diagonal, the eigenvalues of $M^{-1}E$ are equal to the eigenvalues of W_k, $k = 1, \ldots, m_2$. Due to the sparse structure of E_1, W_k only has two nonzero columns,

$$W_k = \begin{pmatrix} 0 & \cdots & 0 & W_k(1, m_1 - 1) & W_k(1, m_1) \\ 0 & \cdots & 0 & W_k(2, m_1 - 1) & W_k(2, m_1) \\ \vdots & & \vdots & \vdots & \vdots \\ 0 & \cdots & 0 & W_k(m_1, m_1 - 1) & W_k(m_1, m_1) \end{pmatrix}, \tag{12}$$

where

$$\begin{aligned} W_k(\ell, m_1 - 1) &= -\kappa_1 \sum_{j=1}^{m_1} S_{m_1}(\ell, j) d_\nu^{-1} S_{m_1}^H(j, m_1) \\ &= -\kappa_1 i^{\ell - m_1} \Phi_{m_1,\ell}(\tfrac{4+\kappa_2\lambda_{2,k}}{2}, \kappa_1), \\ W_k(\ell, m_1) &= 2\kappa_1 \sum_{j=1}^{m_1} S_{m_1}(\ell, j) d_\nu^{-1} S_{m_1}^H(j, m_1) \\ &= 2\kappa_1 i^{\ell - m_1} \Phi_{m_1,\ell}(\tfrac{4+\kappa_2\lambda_{2,k}}{2}, \kappa_1), \qquad \ell = 1, \ldots, m_1, \end{aligned} \tag{13}$$

where $\nu = (k-1)m_1 + j$, d_ν is defined in (11) and

$$\Phi_{k,\ell}(\alpha, \beta) = \frac{2}{m_1 + 1} \sum_{j=1}^{m_1} F_{k,\ell}\left(\frac{j\pi}{m_1+1}\right), \tag{14}$$

$$F_{k,\ell}(\theta) = \frac{\sin(k\theta)\sin(\ell\theta)}{2\alpha + 2i\beta\cos(\theta)}, \qquad k, \ell = 1, \ldots, m_1, \tag{15}$$

where α is a complex number with $\Re e(\alpha) > 0$, and $\beta > 0$ is real. We now show how to evaluate the sums in (14). Using this result we can then compute the sums defined in (13).

LEMMA 5.2. *$\Phi_{k,\ell}(\alpha, \beta)$ defined in* (14) *can be evaluated by*

$$\Phi_{k,\ell}(\alpha, \beta) = \frac{i}{\beta}\left(\frac{z^{k+\ell} - z^{|k-\ell|}}{z - z^{-1}} + \frac{(z^k - z^{-k})(z^\ell - z^{-\ell})}{z - z^{-1}} \frac{z^{2m_1+2}}{1 - z^{2m_1+2}}\right),$$

where

$$z = i\left(\tfrac{\alpha}{\beta} - \sqrt{1 + \left(\tfrac{\alpha}{\beta}\right)^2}\right)$$

and the principal branch of the square root function is employed.

Proof. By periodicity we get

$$\Phi_{k,\ell}(\alpha,\beta) = \frac{1}{m_1+1}\sum_{j=0}^{2m_1+1} F_{k,\ell}\left(\tfrac{j\pi}{m_1+1}\right), \quad k,\ell = 1,\ldots,m_1.$$

$F_{k,\ell}$ is C^1 and 2π-periodic, implying

$$F_{k,\ell}(\theta) = \sum_{q=-\infty}^{\infty} c_q e^{iq\theta}, \quad c_q = \frac{1}{2\pi}\int_0^{2\pi} e^{-iq\theta}F_{k,\ell}(\theta)d\theta.$$

The Poisson summation formula yields

$$\Phi_{k,\ell}(\alpha,\beta) = \sum_{q=-\infty}^{\infty} 2c_{q(2m_1+2)} = 2c_0 + \sum_{q=1}^{\infty} 2c_{-q(2m_1+2)} + 2c_{q(2m_1+2)}.$$

Using the Euler identities in (15) gives

$$\begin{aligned} F_{k,\ell}(\theta) &= -\frac{1}{4}\frac{(e^{ik\theta}-e^{-ik\theta})(e^{i\ell\theta}-e^{-i\ell\theta})}{2\alpha+i\beta(e^{i\theta}+e^{-i\theta})} \\ &= \frac{e^{i(k-\ell)\theta}+e^{i(\ell-k)\theta}-e^{i(k+\ell)\theta}-e^{-i(k+\ell)\theta}}{8\alpha+4i\beta(e^{i\theta}+e^{-i\theta})}. \end{aligned}$$

By making the substitution $z = e^{i\theta}$ we get

$$c_q = -\frac{i}{4\beta}\frac{1}{2\pi i}\oint_C \frac{z^{k-\ell-q}+z^{\ell-k-q}-z^{k+\ell-q}-z^{-k-\ell-q}}{(z-z_1)(z-z_2)}dz, \tag{16}$$

where C is the positively oriented unit circle and

$$z_1 = i\left(\tfrac{\alpha}{\beta}-\sqrt{1+\left(\tfrac{\alpha}{\beta}\right)^2}\right), \quad z_2 = i\left(\tfrac{\alpha}{\beta}+\sqrt{1+\left(\tfrac{\alpha}{\beta}\right)^2}\right), \tag{17}$$

where $|z_1| < 1$ and $|z_2| > 1$. Hence, z_1 is within C while z_2 is not. Note that $z_2 = z_1^{-1}$.

Two types of integrals arise, which can be evaluated using the residue theorem.

- $p \geq 0$, $I_1 = \frac{1}{2\pi i}\oint_C \frac{z^p}{(z-z_1)(z-z_2)}dz = \frac{z_1^p}{z_1-z_2} = \frac{z_1^p}{z_1-z_1^{-1}}$,
- $p \geq 1$, $I_2 = \frac{1}{2\pi i}\oint_C \frac{z^{-p}}{(z-z_1)(z-z_2)}dz = \frac{z_1^{-p}}{z_1-z_2} + \frac{1}{(p-1)!}\varphi^{(p-1)}(0)$.

Here $\varphi^{(p-1)}(0)$ denotes the $(p-1)$th derivative of $\varphi(z)$ at $z = 0$, where $\varphi(z)$ is defined by

$\varphi(z) = \frac{1}{(z-z_1)(z-z_2)} = \frac{1}{z_1-z_2}\left((z-z_1)^{-1}-(z-z_2)^{-1}\right)$, yielding

$\varphi^{(p-1)}(z) = \frac{1}{z_1-z_2}(p-1)!(-1)^{p-1}\left((z-z_1)^{-p}-(z-z_2)^{-p}\right)$, and hence

$$I_2 = \frac{z_1^{-p}}{z_1-z_1^{-1}} + \frac{(-1)^{p-1}}{z_1-z_1^{-1}}\left((-z_1)^{-p}-(-z_2)^{-p}\right) = \frac{z_1^p}{z_1-z_1^{-1}}.$$

Using this result in (16) yields

$$\begin{cases} c_0 = \frac{i}{2\beta}\left(\frac{z_1^{k+\ell}-z_1^{|k-\ell|}}{z_1-z_1^{-1}}\right), & \\ c_{-q(2m_1+2)} = \frac{i}{4\beta}\left(\frac{z_1^{k+\ell}+z_1^{-k-\ell}-z_1^{k-\ell}-z_1^{\ell-k}}{z_1-z_1^{-1}}\right)z_1^{q(2m_1+2)}, & k,\ell = 1,\dots,m_1, \\ c_{q(2m_1+2)} = c_{-q(2m_1+2)}. & \end{cases}$$

Since $|z_1| < 1$, we get

$$\sum_{q=1}^{\infty}(z_1^{2m_1+2})^q = \frac{z_1^{2m_1+2}}{1-z_1^{2m_1+2}},$$

which gives

$$\sum_{q=1}^{\infty} 2c_{-q(2m_1+2)} + 2c_{q(2m_1+2)} = \frac{i}{\beta}\frac{z_1^{k+\ell}+z_1^{-k-\ell}-z_1^{k-\ell}-z_1^{\ell-k}}{z_1-z_1^{-1}}\frac{z_1^{2m_1+2}}{1-z_1^{2m_1+2}}.$$

Summing up, we conclude that

$$\Phi_{k,\ell}(\alpha,\beta) = \frac{i}{\beta}\left(\frac{z_1^{k+\ell}-z_1^{|k-\ell|}}{z_1-z_1^{-1}} + \frac{(z_1^k-z_1^{-k})(z_1^\ell-z_1^{-\ell})}{z_1-z_1^{-1}}\frac{z_1^{2m_1+2}}{1-z_1^{2m_1+2}}\right),$$

where z_1 is defined in (17), which completes the proof. □

Thus, by Lemma 5.2 and the facts that $\Re e(4+\kappa_2\lambda_{2,k}) > 0$ and $\kappa_1 > 0$, we can find analytical expressions for $W_k(\ell, m_1-1)$ and $W_k(\ell, m_1)$ defined in (13). The characteristic equation for W_k defined in (12) is

$$\begin{aligned} 0 &= \det(\lambda I_{m_1} - W_k) \\ &= \lambda^{m_1-2}\begin{vmatrix} \lambda - W_k(m_1-1,m_1-1) & -W_k(m_1-1,m_1) \\ -W_k(m_1,m_1-1) & \lambda - W_k(m_1,m_1) \end{vmatrix} \\ &= \lambda^{m_1-1}\left(\lambda - i\kappa_1\Phi_{m_1,m_1-1}(\tfrac{4+\kappa_2\lambda_{2,k}}{2},\kappa_1) - 2\kappa_1\Phi_{m_1,m_1}(\tfrac{4+\kappa_2\lambda_{2,k}}{2},\kappa_1)\right). \end{aligned}$$

Hence, W_k only has one nonzero eigenvalue λ_k, given by

$$\begin{aligned} \lambda_k &= i\kappa_1\Phi_{m_1,m_1-1}(\tfrac{4+\kappa_2\lambda_{2,k}}{2},\kappa_1) + 2\kappa_1\Phi_{m_1,m_1}(\tfrac{4+\kappa_2\lambda_{2,k}}{2},\kappa_1) \\ &= -z_k^2\frac{1-z_k^{2m_1-2}}{1-z_k^{2m_1+2}} + 2iz_k\frac{1-z_k^{2m_1}}{1-z_k^{2m_1+2}}, \end{aligned}$$

where

$$z_k = i\left(\tfrac{4+\kappa_2\lambda_{2,k}}{2\kappa_1} - \sqrt{1+\left(\tfrac{4+\kappa_2\lambda_{2,k}}{2\kappa_1}\right)^2}\right). \tag{18}$$

We summarize this result in a theorem.

THEOREM 5.3. *The matrix $M^{-1}A$, where M and A are defined in* (7) *and* (3), *has $(m_1-1)m_2$ eigenvalues that are identically one. The remaining m_2 eigenvalues μ_k are given by*

$$\mu_k = 1 - z_k^2\frac{1-z_k^{2m_1-2}}{1-z_k^{2m_1+2}} + 2iz_k\frac{1-z_k^{2m_1}}{1-z_k^{2m_1+2}}, \quad k = 1,\dots,m_2, \tag{19}$$

where z_k is defined in (18).

As the dimension of the nullspace of E is $(m_1 - 1)m_2$, it is clear that the eigenvalue zero of $M^{-1}E$ has $(m_1 - 1)m_2$ linearly independent eigenvectors. Hence, we know that a minimal residual iteration will converge in at most $m_2 + 1$ iterations. We now derive the eigenvectors of $M^{-1}A$.

THEOREM 5.4. *Assume that the nontrivial eigenvalues λ_k, $k = 1, \ldots, m_2$, defined in* (18), *are nonzero. Then the matrix $M^{-1}A$ has a nonsingular eigenvector matrix*

$$W_{M^{-1}A} = (V_2 \otimes I_{m_1})\operatorname{diag}(U_1, \ldots, U_{m_2}).$$

Here V_2 is the eigenvector matrix of A_2 and U_k is given by

$$U_k = \left[e_1, \ldots, e_{m_1-2}, (2e_{m_1-1} + e_{m_1})/\sqrt{5}, u^{(k)}/\|u^{(k)}\|_2\right], \quad k = 1, \ldots, m_2,$$

where e_j denotes the jth canonical column vector and

$$u_\ell^{(k)} = i^\ell(z_k^\ell - z_k^{-\ell}), \quad \ell = 1, \ldots, m_1,$$

where z_k is defined in (18).

Proof. In the proof of Theorem 5.3 we derived the formula

$$(V_2 \otimes I_{m_1})^{-1} M^{-1} E (V_2 \otimes I_{m_1}) = \operatorname{diag}(W_1, \ldots, W_{m_2}),$$

where the eigenvalues of W_k are λ_k and zero with multiplicity $m_1 - 1$. The first $m_1 - 2$ columns of W_k are identically zero, and combining (13) and Lemma 5.2 yields

$$\left.\begin{aligned} W_k(\ell, m_1 - 1) &= \frac{i^{-m_1+1} z_k^{m_1+1}}{1 - z_k^{2m_1+2}} i^\ell (z_k^\ell - z_k^{-\ell}) \\ W_k(\ell, m_1) &= -2W_k(\ell, m_1 - 1). \end{aligned}\right\}, \quad \ell = 1, \ldots, m_1,$$

We now investigate the eigenvector matrix U_k of W_k. Due to the structure of W_k we conclude that $\left\{\{e_j\}_{j=1}^{m_1-2}, (2e_{m_1-1} + e_{m_1})/\sqrt{5}\right\} \in \operatorname{null}(W_k)$. Consequently, those $m_1 - 1$ orthonormal vectors are eigenvectors of W_k corresponding to the eigenvalue zero. The assumption $\lambda_k \neq 0$ implies that the corresponding eigenvector $u^{(k)} \notin \operatorname{null}(W_k)$. Thus, W_k has m_1 linearly independent eigenvectors. From $0 < |z_k| < 1$ it follows that column $m_1 - 1$ of W_k is nonzero. Furthermore, the structure of W_k implies that column $m_1 - 1$ is an eigenvector corresponding to λ_k. By rescaling the column we can choose

$$u_\ell^{(k)} = i^\ell(z_k^\ell - z_k^{-\ell}), \quad \ell = 1, \ldots, m_1,$$

as the nontrivial eigenvector to W_k. We then obtain

$$U_k^{-1} W_k U_k = \Lambda_k = \operatorname{diag}(0, \ldots, 0, \lambda_k), \quad k = 1, \ldots, m_2.$$

Now the matrix $W_{M^{-1}A} \equiv (V_2 \otimes I_{m_1})\operatorname{diag}(U_1, \ldots, U_{m_2})$ is nonsingular and

$$\begin{aligned} &W_{M^{-1}A}^{-1} M^{-1} A W_{M^{-1}A} \\ &= I + \left(\operatorname{diag}(U_1, \ldots, U_{m_2})\right)^{-1} (V_2 \otimes I_{m_1})^{-1} M^{-1} E (V_2 \otimes I_{m_1}) \operatorname{diag}(U_1, \ldots, U_{m_2}) \\ &= I + \operatorname{diag}(U_1^{-1}, \ldots, U_{m_2}^{-1}) \operatorname{diag}(W_1, \ldots, W_{m_2}) \operatorname{diag}(U_1, \ldots, U_{m_2}) \\ &= I + \operatorname{diag}(\Lambda_1, \ldots, \Lambda_{m_2}), \end{aligned}$$

i.e., $W_{M^{-1}A}$ is the eigenvector matrix of $M^{-1}A$. □

From Theorem 5.6 it is easy to establish that the assumption in Theorem 5.4 is valid, when m_1 and m_2 are sufficiently large. To compare the condition of the eigenvectors for A and $M^{-1}A$, we define the *condition number reduction*

$$\psi \equiv \mathrm{cond}_2(W_{M^{-1}A})\big/\mathrm{cond}_2(W_A), \tag{20}$$

where W_A is the eigenvector matrix of A. Following the technique in [9] ψ can be estimated. Under the same assumption as in Theorem 5.4 we obtain

$$\psi \le \psi_0 = \max_{1\le k\le m_2} \|U_k\|_2 \cdot \max_{1\le k\le m_2} \|U_k^{-1}\|_2 \Big/ \mathrm{cond}_2(V_1), \tag{21}$$

where V_1 is the eigenvector matrix of A_1 defined in (4). Therefore, we determine $\|U_k\|_2$ and $\|U_k^{-1}\|_2$.

THEOREM 5.5. *Under the same assumption as in Theorem* 5.4,

$$\left.\begin{aligned} \|U_k\|_2 &= \left(1+\sqrt{1-a_k}\right)^{1/2} \\ \|U_k^{-1}\|_2 &= \left(1-\sqrt{1-a_k}\right)^{-1/2} \end{aligned}\right., \qquad k = 1, \ldots, m_2,$$

where

$$a_k = \frac{\frac{1}{5}|z_k^{m_1-1} - z_k^{-m_1+1}|^2 + \frac{4}{5}|z_k^{m_1} - z_k^{-m_1}|^2 - \frac{4}{5}\Im m\left((z_k^{m_1-1} - z_k^{-m_1+1})(\bar{z}_k^{m_1} - \bar{z}_k^{-m_1})\right)}{\dfrac{|z_k|^2 - |z_k|^{2m_1+2}}{1-|z_k|^2} + \dfrac{|z_k|^{-2} - |z_k|^{-2m_1-2}}{1-|z_k|^{-2}} - 2\Re e\left(\dfrac{z_k\bar{z}_k^{-1} - (z_k\bar{z}_k^{-1})^{m_1+1}}{1 - z_k\bar{z}_k^{-1}}\right)}.$$

Proof. To derive the results we examine the eigenvalues of $U_k^H U_k$. Using the notation in Theorem 5.4, we define the auxiliary vectors $w^{(k)}$, $k = 1, \ldots, m_2$

$$w_\ell^{(k)} = u_\ell^{(k)}\big/\|u^{(k)}\|_2, \quad \ell = 1, \ldots, m_1 - 2,$$

$$w_{m_1-1}^{(k)} = \left(\tfrac{2}{\sqrt{5}}u_{m_1-1}^{(k)} + \tfrac{1}{\sqrt{5}}u_{m_1}^{(k)}\right)\big/\|u^{(k)}\|_2.$$

Exploiting the orthonormality of the first $m_1 - 1$ columns of U_k yields

$$U_k^H U_k = \begin{pmatrix} I_{m_1-1} & w^{(k)} \\ (w^{(k)})^H & 1 \end{pmatrix}.$$

The characteristic polynomial $P_k(\lambda)$ of $U_k^H U_k$ satisfies

$$\begin{aligned} (1-\lambda)P_k(\lambda) &= (1-\lambda)\det(U_k^H U_k - \lambda I_{m_1}) \\ &= \begin{vmatrix} I_{m_1-1} & 0 \\ -(w^{(k)})^H & 1-\lambda \end{vmatrix} \begin{vmatrix} (1-\lambda)I_{m_1-1} & w^{(k)} \\ (w^{(k)})^H & 1-\lambda \end{vmatrix} \\ &= \begin{vmatrix} (1-\lambda)I_{m_1-1} & w^{(k)} \\ 0 & (1-\lambda)^2 - (w^{(k)})^H w^{(k)} \end{vmatrix} \\ &= (1-\lambda)^{m_1-1}\left((1-\lambda)^2 - \|w^{(k)}\|_2^2\right). \end{aligned}$$

Thus,

$$P_k(\lambda) = (1-\lambda)^{m_1-2}\left((1-\lambda)^2 - \|w^{(k)}\|_2^2\right).$$

Consequently, the eigenvalues of $U_k^H U_k$ are one with multiplicity $m_1 - 2$ and

$$\begin{aligned}\lambda_{k,1} &= 1 + \|w^{(k)}\|_2,\\ \lambda_{k,2} &= 1 - \|w^{(k)}\|_2.\end{aligned}$$

We obtain

$$\left.\begin{aligned}\|U_k\|_2 &= \big(\max(1, \lambda_{k,1}, \lambda_{k,2})\big)^{1/2} = (1 + \|w^{(k)}\|_2)^{1/2}\\ \|U_k^{-1}\|_2 &= \big(\max(1, \lambda_{k,1}^{-1}, \lambda_{k,2}^{-1})\big)^{1/2} = (1 - \|w^{(k)}\|_2)^{-1/2}\end{aligned}\right., \quad k = 1, \dots, m_2.$$

It now remains to derive a formula for $\|w^{(k)}\|_2$. From the definition of $w^{(k)}$ and Theorem 5.4 it follows that

$$\begin{aligned}\|w^{(k)}\|_2^2 &= \sum_{\ell=1}^{m_1-1} |w_\ell^{(k)}|^2 = \|u^{(k)}\|_2^{-2}\big(\tfrac{1}{5}|2u_{m_1-1}^{(k)} + u_{m_1}^{(k)}|^2 + \sum_{\ell=1}^{m_1-2} |u_\ell^{(k)}|^2\big)\\ &= 1 - \|u^{(k)}\|_2^{-2}\big(\tfrac{1}{5}|u_{m_1-1}^{(k)}|^2 + \tfrac{4}{5}|u_{m_1}^{(k)}|^2 - \tfrac{4}{5}\Re e(u_{m_1-1}^{(k)}\bar{u}_{m_1}^{(k)})\big)\\ &= 1 - \|u^{(k)}\|_2^{-2}\Big(\tfrac{1}{5}|z_k^{m_1-1} - z_k^{-m_1+1}|^2 + \tfrac{4}{5}|z_k^{m_1} - z_k^{-m_1}|^2\\ &\qquad -\tfrac{4}{5}\Im m\big((z_k^{m_1-1} - z_k^{-m_1+1})(\bar{z}_k^{m_1} - \bar{z}_k^{-m_1})\big)\Big).\end{aligned}$$

By contradiction one can derive that $z_k \neq \bar{z}_k$. This and $|z_k| \neq 1$ makes $\|u^{(k)}\|_2^2$ computable from the geometric series

$$\begin{aligned}\|u^{(k)}\|_2^2 &= \sum_{\ell=1}^{m_1} |u_\ell^{(k)}|^2 = \sum_{\ell=1}^{m_1} (\bar{z}_k^\ell - \bar{z}_k^{-\ell})(z_k^\ell - z_k^{-\ell})\\ &= \sum_{\ell=1}^{m_1} |z_k^2|^\ell + |z_k^{-2}|^\ell - (z_k\bar{z}_k^{-1})^\ell - (\bar{z}_k z_k^{-1})^\ell\\ &= \frac{|z_k|^2 - |z_k|^{2m_1+2}}{1 - |z_k|^2} + \frac{|z_k|^{-2} - |z_k|^{-2m_1-2}}{1 - |z_k|^{-2}} - 2\Re e\Big(\frac{z_k\bar{z}_k^{-1} - (z_k\bar{z}_k^{-1})^{m_1+1}}{1 - z_k\bar{z}_k^{-1}}\Big),\end{aligned}$$

which completes the proof. □

From Theorem 5.3 we derive the following asymptotic result.

THEOREM 5.6. *Assume that*

$$\Delta t = ch_1^\alpha, \quad 0 < \alpha < 1, \quad c > 0, \tag{22}$$

and

$$m_1 = \left\lceil \frac{m_2(1 + 2m_2^{-\frac{3}{2}})}{\phi} \right\rceil, \quad 0 < \phi < 1, \tag{23}$$

where $\lceil \frac{a}{b} \rceil$ *denotes the closest integer greater than or equal to* $\frac{a}{b}$. *In the limit* $m_1 \to \infty$, *the* m_2 *eigenvalues of* $M^{-1}A$ *that are different from one all reside on a curve* $\mu(\gamma)$

$$\mu(\gamma) = 2 - 2\gamma^2 + 2\sqrt{1 - \gamma^2} - 2i\gamma\big(1 + \sqrt{1 - \gamma^2}\big), \quad -\phi \le \gamma \le \phi. \tag{24}$$

Proof. Define ζ_k as

$$\zeta_k \equiv \tfrac{4+\kappa_2\lambda_{2,k}}{2\kappa_1}, \qquad k = 1, \ldots, m_2.$$

By (22) we get

$$\zeta_k = \frac{2h_1}{ch_1^\alpha} + \frac{h_1}{2h_2}\lambda_{2,k} = 2c^{-1}m_1^{\alpha-1} + w_k,$$

where

$$w_k = \tfrac{m_2}{2m_1}\lambda_{2,k}. \tag{25}$$

Lemma 5.1 together with (25) yields

$$w_k \in \mathcal{E}^+\big(2\tfrac{m_2^{\frac{1}{4}}}{m_1}, \tfrac{m_2}{m_1}(1+2m_2^{-\frac{3}{2}})\big), \qquad k = 1, \ldots, m_2.$$

By (23) $m_2 < m_1$ and $\frac{m_2}{m_1}(1+2m_2^{-\frac{3}{2}}) \leq \phi$ yielding

$$w_k \in \mathcal{E}^+(2\tfrac{m_2^{\frac{1}{4}}}{m_1}, \phi) \in \mathcal{E}^+(2m_1^{-\frac{3}{4}}, \phi).$$

Now define

$$\epsilon = c^{-1}m_1^{\alpha-1} + \delta_k m_1^{-\frac{3}{4}}, \quad 0 \leq \delta_k \leq 1,$$

which gives

$$\zeta_k = 2\epsilon + i\gamma_k, \quad -\phi \leq \gamma_k \leq \phi. \tag{26}$$

For $m_1 \gg 1$ we have $0 < \epsilon \ll 1$, and (26) combined with (18) and a Taylor expansion yields

$$z_k = i\big(\zeta_k - \sqrt{1+\zeta_k^2}\big) = 2i\epsilon - \gamma_k - i\sqrt{1-\gamma_k^2} + \frac{2\epsilon\gamma_k}{\sqrt{1-\gamma_k^2}} + \mathcal{O}(\epsilon^2).$$

We obtain

$$z_{k,\infty} \equiv \lim_{m_1\to\infty} z_k = -\gamma_k - i\sqrt{1-\gamma_k^2}, \quad -\phi \leq \gamma_k \leq \phi. \tag{27}$$

For m_1 sufficiently large there is a positive constant c_k such that

$$|z_k|^2 = 1 - \frac{4\epsilon}{\sqrt{1-\gamma_k^2}} + \mathcal{O}(\epsilon^2) < 1 - c_k m_1^{\alpha-1}.$$

Thus, we get $|z_k|^{2m_1} \to 0$, which together with (19) gives

$$\lim_{m_1\to\infty} \mu_k = 1 - z_{k,\infty}^2 + 2iz_{k,\infty}, \quad k = 1, \ldots, m_2. \tag{28}$$

By inserting (27) in (28) and exploiting the fact that $-\phi \leq \gamma_k \leq \phi$, we conclude that the eigenvalues of $M^{-1}A$ that are different from one all lie on the curve $\mu(\gamma)$ defined by (24). □

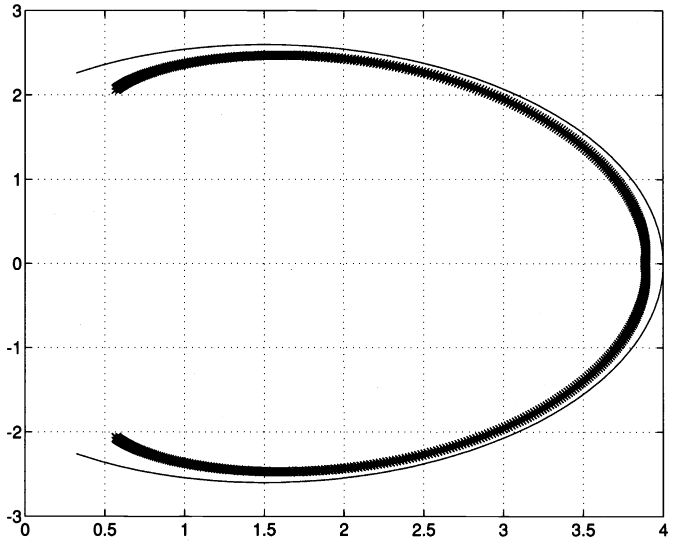

FIG. 1. *Asymptotic spectrum (solid line) and eigenvalues (stars) for $\alpha = 0.99$, $c = 100$, $\phi = 0.99$, and $m_2 = 505$.*

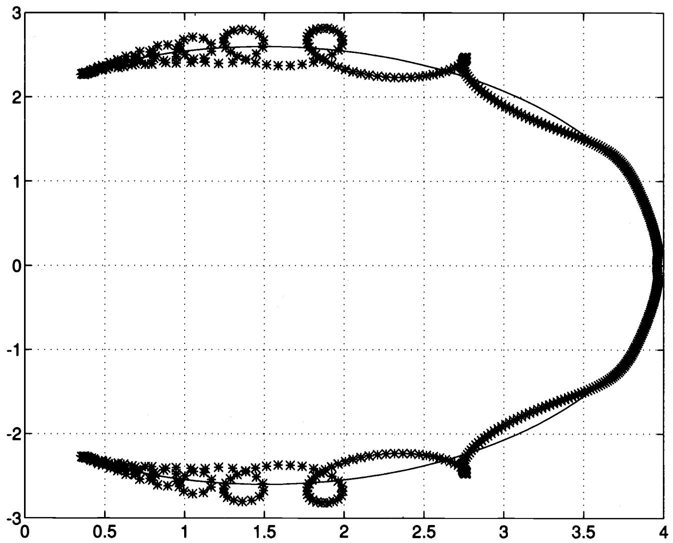

FIG. 2. *Asymptotic spectrum (solid line) and eigenvalues (stars) for $\alpha = 0.1$, $c = 10$, $\phi = 0.99$, and $m_2 = 505$.*

From Theorem 5.6 we see that when Δt is defined by (22), the eigenvalues stay bounded and are well separated from the origin as the problem size increases. If time accuracy is not required, as in steady-state computations, it is preferable to choose the time step almost independently of the space step, i.e., $\alpha \approx 0$. For time-accurate computations, the time step should be almost proportional to the space step, i.e., $\alpha \approx 1$. In Figs. 1 and 2 we show how well the asymptotic formula (24) agrees with the eigenvalues for large problems.

Numerical experiments show that $\mathrm{cond}_2(W_{M^{-1}A})$ grows rapidly with m_2. However, in Figs. 3 and 4 we note that the upper bound ψ_0 of the condition number reduction is favorable. For all values of α and the spatial grid ratio ϕ examined, ψ_0 is less than 0.1 and decreases when

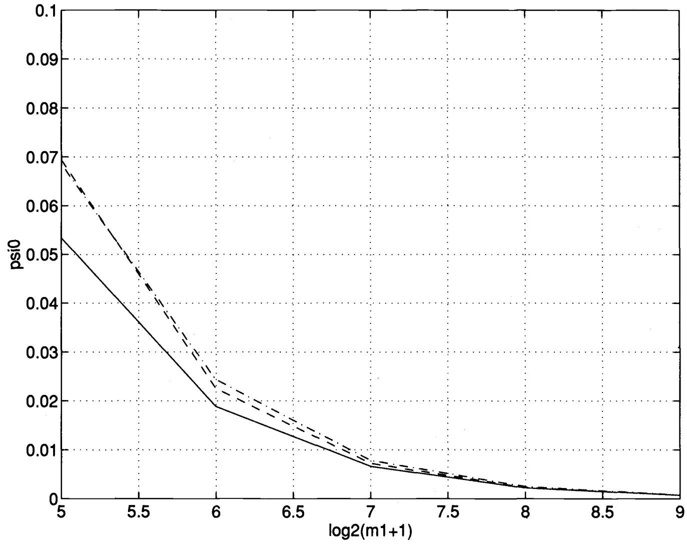

FIG. 3. *The bound* ψ_0 *for* $\alpha = 0.99$ *and* $c = 100$. *The solid line represents* $\phi = 0.99$, *the dashed line* $\phi = 0.75$, *and the dash-dot line* $\phi = 0.5$.

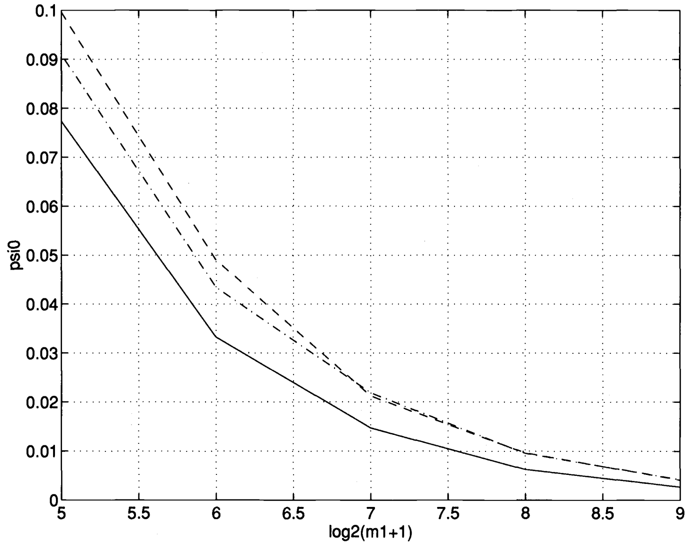

FIG. 4. *The bound* ψ_0 *for* $\alpha = 0.1$ *and* $c = 10$. *The solid line represents* $\phi = 0.99$, *the dashed line* $\phi = 0.75$, *and the dash-dot line* $\phi = 0.5$.

the problem size increases. The conclusion is that the semi-Toeplitz preconditioner improves the condition of the eigenvectors to the iteration matrix.

6. Convergence properties. In this section we determine the *asymptotic convergence factor* ρ defined by

$$\rho \equiv \lim_{i\to\infty} \varepsilon_i^{1/i}, \tag{29}$$

where ε_i is defined in (5). We enclose the asymptotic spectrum μ, defined in (24), in a circle $\mathcal{C}(4, R)$ and use the general result from [10]. Here $\mathcal{C}(c, R)$ denotes the circle with center c and radius R.

LEMMA 6.1. *The circle $\mathcal{C}(4, R)$, where R is defined by*

$$R = |\mu(\pm\phi) - 4| = \sqrt{8 + 12\phi^2 - 8\sqrt{1-\phi^2}},$$

encloses the asymptotic spectrum μ defined in (24).

Proof. Define $r(\gamma)$ as the distance between 4 and $\mu(\gamma)$. Then

$$\begin{aligned} r^2 &= \left(-2 - 2\gamma^2 + 2\sqrt{1-\gamma^2}\right)^2 + \left(2\gamma(1+\sqrt{1-\gamma^2})\right)^2 \\ &= 8 + 12\gamma^2 - 8\sqrt{1-\gamma^2} \end{aligned}$$

and

$$\frac{d^2r^2}{d\gamma^2} = 24 + \frac{8}{(1-\gamma^2)^{3/2}} > 0.$$

Hence, r^2 obtains its maximum value at the endpoints, yielding $r(\gamma) \le R$, which proves the lemma. □

THEOREM 6.2. *For $0 < \phi < \frac{\sqrt{8}}{3}$ the asymptotic convergence factor ρ satisfies*

$$\rho \le \frac{\sqrt{2 + 3\phi^2 - 2\sqrt{1-\phi^2}}}{2} < 1.$$

Proof. For $0 < \phi < \frac{\sqrt{8}}{3}$ we obtain $8 + 12\phi^2 < 8 + 12 \cdot \frac{8}{9} = 8\sqrt{1 - \frac{8}{9}} + 16 < 8\sqrt{1-\phi^2} + 16$, and consequently $\sqrt{8 + 12\phi^2 - 8\sqrt{1-\phi^2}} < 4$. Using Lemma 6.1 and the general result in [10] yields

$$\rho \le \frac{R}{4} = \frac{\sqrt{2 + 3\phi^2 - 2\sqrt{1-\phi^2}}}{2} < 1. \qquad \square$$

In Figs. 5 and 6 we display the asymptotic convergence factor as a function of ϕ. In the same figures we present the residual reduction $\tilde{\rho}$, defined by

$$\tilde{\rho} \equiv \left(\frac{\|r^{(i)}\|_2}{\|r^{(0)}\|_2}\right)^{1/i}, \tag{30}$$

for different problem sizes using generalized minimal residual (GMRES) [11] with $i = 20$.

Figs. 7 and 8 show the actual number of iterations obtained from restarted GMRES(20) for different problem sizes. The iteration has converged when $\|r^{(i)}\|_2/\|M^{-1}b\|_2$ is less than 10^{-6}.

From Figs. 5–8 we observe that the convergence seems to depend only on the spatial grid ratio ϕ and not on the number of unknowns. Finally, in Figs. 9 and 10 we present the arithmetic speedup using GMRES(20) and the semi-Toeplitz preconditioner compared to the unpreconditioned system (3). Clearly, the speedup is large for large problems, and it is also

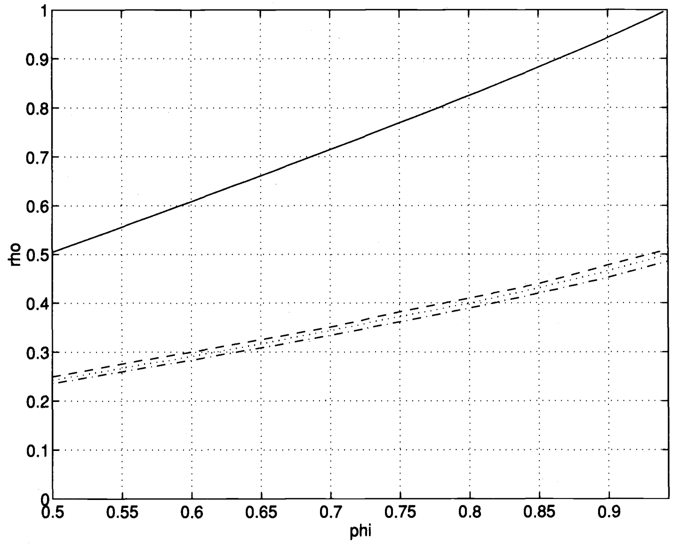

FIG. 5. *The solid line represents the asymptotic convergence factor for $\alpha = 0.99$ and $c = 100$. The residual reduction is plotted for $m_1 = 127$ (dashed), $m_1 = 255$ (dotted), and $m_1 = 511$ (dash-dot).*

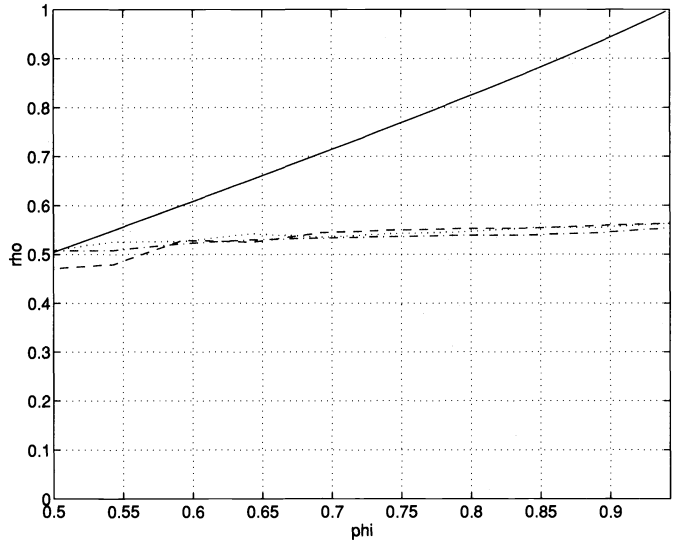

FIG. 6. *The solid line represents the asymptotic convergence factor for $\alpha = 0.1$ and $c = 10$. The residual reduction is plotted for $m_1 = 127$ (dashed), $m_1 = 255$ (dotted), and $m_1 = 511$ (dash-dot).*

greater than one for small problems. Notice that lowering ϕ yields a gain in speedup. We conclude that the semi-Toeplitz preconditioner results in a significant improvement.

7. Conclusions. We have studied semi-Toeplitz preconditioners and minimal residual iterations to solve block tridiagonal systems of equations. Analytical formulas for the eigenvalues and the eigenvectors of the preconditioned system are derived. It is numerically verified that the eigenvector matrix to the preconditioned system is better conditioned than its unpreconditioned counterpart. We have also shown that in the limit $m_d \to \infty$, the eigenvalues of the

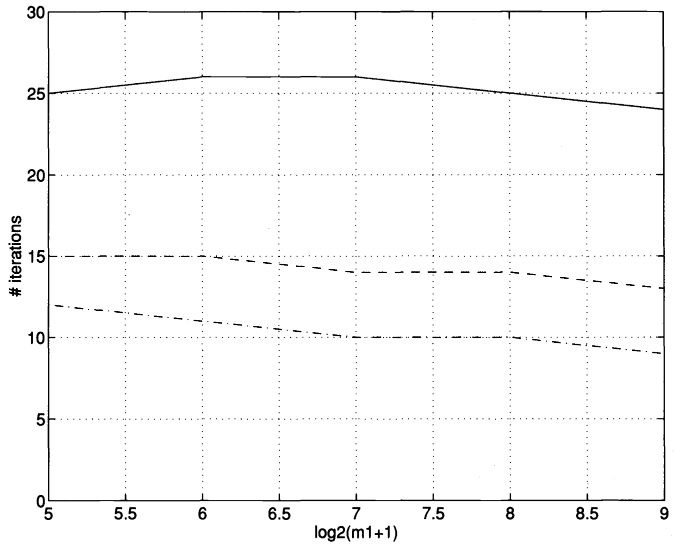

FIG. 7. *Number of iterations for* $\alpha = 0.99$ *and* $c = 100$. *The solid line represents* $\phi = 0.99$, *the dashed line* $\phi = 0.75$, *and the dash-dot line* $\phi = 0.5$.

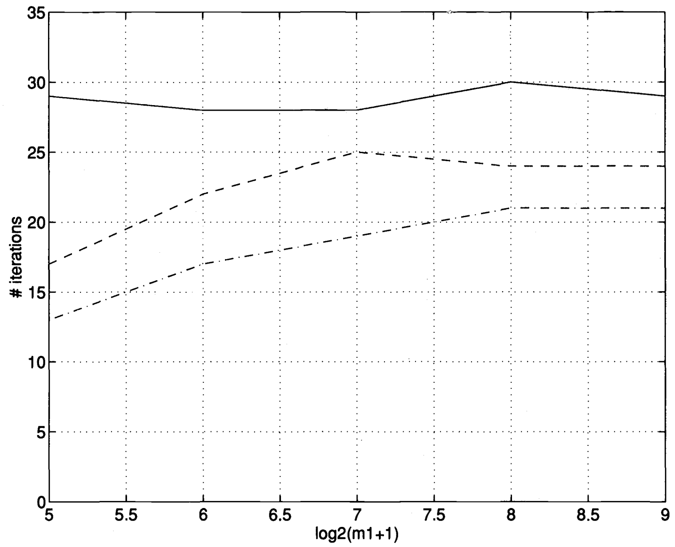

FIG. 8. *Number of iterations for* $\alpha = 0.1$ *and* $c = 10$. *The solid line represents* $\phi = 0.99$, *the dashed line* $\phi = 0.75$, *and the dash-dot line* $\phi = 0.5$.

preconditioned system all lie on a curve. The eigenvalues stay bounded and are well separated from the origin, independently of the problem size. From this eigenvalue distribution we derive upper bounds of the asymptotic convergence factor. These bounds have been corroborated numerically. Finally, we show empirically that the number of iterations does not grow when we increase the number of unknowns. This leads to a substantial arithmetic speedup compared to the unpreconditioned system.

ODE RECURSIONS AND ITERATIVE SOLVERS FOR LINEAR EQUATIONS*

ALFRED A. LORBER†, GRAHAM F. CAREY†, AND WAYNE D. JOUBERT‡

Abstract. Timestepping to a steady-state solution is increasingly applied in engineering and scientific applications as a means for solving equilibrium problems. In the present work we examine the relation between the recursion in timestepping algorithms for semidiscrete systems of ODEs and certain types of iterative methods for solving discretized systems of equilibrium PDEs. We consider, in particular, the possibility of accelerating the ODE approach using recursions that are not time accurate together with parameter selection based on the theory of iterative methods. As one example, we take the parameters arising from the Chebyshev-type iterative methods and use them in a two-stage Runge–Kutta scheme. A comparison study for a representative steady-state diffusion problem indicates a dramatic improvement in convergence and efficiency. We remark that this approach can be trivially incorporated into existing time-integration codes to significant advantage. This yields a hybrid adaptive approach in a single code.

Key words. iterative methods, ODE solvers, Runge–Kutta, time-accurate solutions, steady-state solutions

AMS subject classifications. 65F10, 65L06

1. Introduction.

It is well known that certain simple explicit integrators may be identified with corresponding iterative methods in certain applications. For example, the forward Euler integration scheme for unsteady diffusion can be easily related to the point Jacobi iteration for the steady-state problem. The purpose of this study is twofold: first to investigate the connection between the solution of systems of linear equations by iterative methods and the steady-state integration of a related class of evolution PDEs by timestepping methods, and second to exploit this relationship to accelerate the ODE approach by improved parameter selection. This then permits an adaptive hybrid strategy in which either time accurate solutions or steady solutions can be computed efficiently by changing parameters in a single algorithm and code.

In engineering applications ODE integrators are increasingly being used to timestep a linear or nonlinear ODE system to steady state. This may be done in two ways: values of the solution may be obtained for intermediate time values that correspond to the actual physical solution at those intermediate times (time-accurate); alternatively, intermediate solution approximations may be obtained that have no relation to the physical solution at actual intermediate times (non-time-accurate). This strategy is not only convenient in the sense that the same algorithm or code is used for both classes of problems, but, particularly for nonlinear problems, the time-iterative algorithms may exploit the physics of the evolution problem to produce a more robust algorithm [1].

The preceding remarks notwithstanding, it is more common to obtain the steady-state solution directly using a linear system solver. Iterative solvers are particularly attractive for large-scale systems arising from discretized PDEs. The iterates produced by such solvers can be compared with intermediate solution approximations produced by the ODE recursion. Of course, usually the iterates do not correspond to time-accurate solutions, though they may for some iterative methods and problem classes. For nonlinear ODE problems, iterative linear solvers may be used to solve linearizations of the ODE problem at incremental steps toward the steady-state solution (see, e.g., [3]). Similarly, continuation techniques may be applied to

general nonlinear (or linear) problems by embedding them within a nonlinear ODE problem and applying ODE solvers. In such cases, the continuation parameter can be interpreted as a "time-like variable" for the associated nonlinear ODE.

The theory of ODE solvers has mainly focused on issues of accuracy (with respect to time), stiffness, and stability. The interest in timestepping the transient problem to get a steady-state solution is relatively little studied in its own right, but is being increasingly used (particularly in engineering computations for nonlinear problems with complex physics where different rate processes may occur and this feature can be exploited [5]). On the other hand, there is an extensive theoretical foundation on iterative methods (see, e.g., [17], [18], [20]). This includes analysis of convergence behavior, stopping tests, and other properties of the various iterative methods. More importantly, in the present context, it provides an analysis of parameter selection for "parameter-dependent" methods such as Chebyshev and for adaptively selecting relaxation factors. These analytical results can be exploited to derive improved ODE recursions as shown later. Moreover, an existing ODE scheme can be easily modified to a hybrid form that permits faster steady-state solutions through appropriate parameter selection. These ideas are similar to those used with ODE exponential fitting methods. This also implies that in a given calculation the parameters can be adapted so that, for instance, the early transient is computed time-accurately, then the steady state is computed using a local time-inaccurate scheme with appropriate parameters, and finally the transient "off-design" behavior can be examined time-accurately.

The outline of the present paper is as follows: in §2 we consider a simple class of linear evolution equations and give the exact integral solution involving the exponential matrix. This motivates the discussion of time-accurate and steady-state behavior. The problem of integrating semidiscrete ODE systems of this form is then introduced and several standard ODE methods are listed together with a brief discussion of approximations of the exponential. Using these properties, the relationship between the ODE recursion and iterative schemes is examined in §§4 and 5. In particular, we list here a number of different iterative methods and identify corresponding ODE recursions. The special case of polynomial preconditioners and Chebyshev-type methods follow in §6. A modified Runge–Kutta scheme is then developed using the Chebyshev iterative parameters and applied to a diffusion problem in §§7 and 8. This demonstrates the main ideas and indicates the value of this new hybrid approach.

2. Evolution equations. To motivate the approach let us begin with the simple time-dependent problem

$$u'(t) = f(t) - A(t)(u(t)) \equiv R(t, u(t)), \quad t \geq 0, \qquad u(0) = u_0. \tag{1}$$

Here, $u : \mathbb{R}^+ \to V$, and $A : \mathbb{R}^+ \times V \to V$ is a linear or nonlinear operator for some linear space V (see [14]). When f and A are independent of t, then the steady-state solution of (1) is defined by $u' = R(\cdot, u) = 0$.

In the case when A is linear and satisfies certain standard conditions, the solution to (1) is given uniquely by

$$u(t) = e^{-At}u_0 + \int_0^t e^{-As} f(t-s)ds. \tag{2}$$

If furthermore f is independent of time and the integration is successful, then the solution can be simply expressed as

$$u(t) \quad = \quad u_0 + A^{-1}[I - e^{-At}](f - Au_0). \tag{3}$$

If we introduce the residual $r(t) \equiv R(t, u(t))$ in (1), then (3) can be rewritten equivalently as

$$u(t) \quad = \quad u_0 + A^{-1}[I - e^{-At}]r(0), \tag{4}$$

which implies

$$r(t) = e^{-At} r(0). \tag{5}$$

For this case, when A is nonsingular with eigenvalues having positive real part, then as $t \to \infty$, $e^{-At} \to 0$. Thus $u(t) \to u_0 + A^{-1} r(0) = u_0 + e^{(0)} = u_\infty$, where u_∞ denotes the solution to the steady-state problem and $e^{(0)}$ denotes the initial error $e^{(0)} = u_0 - u_\infty$ measured relative to the steady-state solution. Furthermore, setting $t = t_n$ and $\Delta t_n = t_n - t_{n-1}$ for a timestep in (3) and (5), we obtain

$$u(t_n) = u(t_{n-1}) + A^{-1}[I - e^{-A\Delta t_n}](f - Au(t_{n-1})) \tag{6}$$

and

$$r(t_n) = e^{-A\Delta t_n} r(t_{n-1}). \tag{7}$$

Hence a discrete set of values $\{u(t_n)\}$ can be computed using (6). As $n \to \infty$ the sequence converges to the steady-state solution u_∞. Similarly, the residual sequence $\{r(t_n)\}$ converges to zero. For illustrative purposes we have selected a problem that can be integrated exactly (although in computation the exponential operator would still need to be evaluated, possibly by a Padé approximation), and A^{-1} appears on the right side. This result serves to motivate our approach.

Thus, the incremental time-stepping recursion (6) may be viewed as a form of iterative method that converges to the steady-state solution $u_\infty = A^{-1} f$ as $n \to \infty$. Obviously, the process is "time exact" in the sense that computed intermediate values $\{u(t_n)\}$ are precisely the transient solution of the evolution problem at corresponding times $\{t_n\}$. In practice, the system (1) is integrated approximately in which case the ODE integrator generates a sequence of approximations u_n to $u(t_n)$ with corresponding residuals r_n. If the timestep Δt_n is sufficiently small, then $u_n \sim u(t_n)$ with $u(t_n) = u_n + O((\Delta t)^p)$ where p is the order ($p = 1$ for a first-order-in-time scheme, etc.). Different numerical schemes may be used and these would lead to different classes of recursions for an iteration to compute an approximation to u_∞. Of particular interest is the case where V is finite dimensional, so A is a matrix. This is frequently the case for approximate solution of PDEs.

The convergence of these integration schemes toward u_∞ may be improved by relaxing the requirement of time-accuracy and increasing the size of the timestep. Certain stability conditions on the timestep still may apply, but even these may be "occasionally" violated during the recursion without destroying convergence. In fact, different local timesteps may be taken for the components of a vector $u(t)$. The method is no longer an ODE integrator in the usual sense but can still be viewed as an iteration for u_∞. Standard iterative methods for solving systems are not developed in this way. Nevertheless, the approach of time-stepping to a steady state and related ideas in continuation theory are extensively used in engineering practice with considerable success. Part of the focus of the present work is the relationship between the corresponding iterative recursions obtained by these approaches. From this relationship we show by means of an example with RK integration how iteration theory can be exploited to obtain faster convergence from the time-stepping recursion.

3. ODE solvers. Let us now consider some specific classes of methods for solving (1). We construct approximations $\{u_i\}$ of u at the times $\{t_i\}$, where $0 = t_0 < t_1 \cdots < t_n \cdots \leq \infty$. Standard ODE solvers attempt to determine u_i by using approximate values of u at previous times, as well as evaluations of $R(\cdot, \cdot)$. ODE solvers may be classified as follows (e.g., [19]).

First, set $\Delta t_i = \Delta t$ as a constant "parameter." The linear multistep methods are defined by

$$\sum_{i=0}^{k_1} \alpha_i u_{n-i} = \Delta t \sum_{i=0}^{k_2} \beta_i R(t_{n-i}, u_{n-i}) \tag{8}$$

for some k_1, k_2, and for $\alpha_0 \neq 0$. The method is an explicit method if and only if $\beta_0 = 0$. This method can be easily generalized to cases where not all Δt_i are the same. If all α_i are zero except α_0 and one other, then numerical quadrature rules may be used in order to construct a specific method, such as the forward Euler scheme $u_n = u_{n-1} + (\Delta t) r_{n-1}$ or, in terms of residuals, $r_n = (I - \Delta t A) r_{n-1}$. On the other hand, if only one β_i is nonzero, numerical differentiation formulas may be employed. Note that in order for the method to be exact when u is (pointwise) constant independent of time, we must have $\sum \alpha_i = 0$.

A second well known class of methods, which we consider in more detail later, is the Runge–Kutta (RK) family, which can be expressed in the form

$$u_n = u_{n-1} + \sum_{i=1}^{s} b_i \kappa_i, \tag{9a}$$

with

$$\kappa_i = \Delta t R \left(t_{n-1} + c_i \Delta t, u_{n-1} + \sum_{j=1}^{i-1} a_{ij} \kappa_j \right), \tag{9b}$$

where $c_i = \sum_{j=1}^{i-1} a_{ij}$ ($c_1 = 0$), and s is the number of stages in the method. The coefficients b_i and a_{ij} are chosen so that the coefficients of the increasing powers of Δt in a Taylor series expansion of the right- and left-hand sides of (9a) agree exactly up to a desired order. Under reasonable assumptions, this means that a certain order of accuracy is obtained as $\Delta t \downarrow 0$. Other properties are of interest as well, such as the behavior of the method if Δt is too large: a method is said to be unconditionally stable if $u_i \to u_\infty$ as $i \to \infty$, for any u_0, regardless of the size of Δt.

Now let us briefly review some familiar forms of these methods for the case where f and A are constant (for later convenient comparison with corresponding iterative methods, we express these directly in terms of the residuals):[1]

$$\begin{array}{ll}
\text{forward Euler} & r_n = [I - (\Delta t A)] r_{n-1}, \\
\text{backward Euler} & r_n = [I + (\Delta t A)]^{-1} r_{n-1}, \\
\text{Crank–Nicolson} & r_n = [I - (\frac{\Delta t}{2} A)][I + (\frac{\Delta t}{2} A)]^{-1} r_{n-1}, \\
\text{Runge–Kutta second order} & r_n = [I - (\Delta t A) + \frac{1}{2}(\Delta t A)^2] r_{n-1}, \\
\text{Runge–Kutta third order} & r_n = [I - (\Delta t A) + \frac{1}{2}(\Delta t A)^2 - \frac{1}{6}(\Delta t A)^3] r_{n-1}, \\
\text{Runge–Kutta fourth order} & r_n = [I - (\Delta t A) + \frac{1}{2}(\Delta t A)^2 - \frac{1}{6}(\Delta t A)^3 \\
 & \quad + \frac{1}{24}(\Delta t A)^4] r_{n-1}.
\end{array} \tag{10}$$

It is common to investigate these schemes from the standpoint of stability: if $r_n = g(\Delta t A) r_{n-1}$, then $r_n \to 0$ as $n \to \infty$ is assured if $|g(\Delta t \lambda_i)| < 1$ for each eigenvalue $\lambda_i \in \sigma(A)$. This analysis is valid as long as g is a rational function. Instead of beginning

[1] Here, we give RK methods in which the order p is equal to the number of stages s. In general, $p \leq s$.

with a method and then determining where $|g| < 1$, an alternate approach is to use the spectral properties of A to determine better coefficients for the method. This approach will be considered later in this study.

Each of the above examples in (10) can be identified as an approximation of the form $r_n \doteq e^{-\Delta t A} r_{n-1}$ for (7). Specifically, we seek approximations of the exponential of the form

$$e^{-A\Delta t} \doteq I - AG_{\Delta t} \tag{11}$$

(or $G_{\Delta t} \doteq A^{-1}[I - e^{-A\Delta t}]$) for some computable operator $G_{\Delta t}$. Then

$$r_n = [I - AG_{\Delta t}]r_{n-1} \tag{12a}$$

or

$$u_n = u_{n-1} + G_{\Delta t} r_{n-1}. \tag{12b}$$

These ideas can also be related to the Padé approximations of the exponential by rational functions. Similar concepts arise in semigroup theory (e.g., see [14]).

The backward Euler and Crank–Nicolson schemes in (10) are implicit and unconditionally stable for all Δt: in this case we can consider $\Delta t \to \infty$ in (11) and (12) so that $G_{\Delta t}$ then approximates A^{-1}. The other schemes are explicit and there is a maximum possible stepsize Δt for stability. Usually, the approximation $G_{\Delta t}$ is constructed to give the highest possible accuracy in the sense of asymptotic rate with respect to Δt, and within a given class of methods. However, the size of the stability region will also vary with the $G_{\Delta t}$ form chosen.

4. Iterative solvers and ODE integrators. Iterative linear solvers involve recursions and hence have a similar structure to the ODE recursions above. When solving linear equations directly by iterative methods, an approximation of zero in (11) is sought instead of an approximation to the exponential. That is, for linear iterative solvers an operator F_n analogous to $G_{\Delta t}$ in (12) is needed such that the approximation $I - AF_n \doteq 0$ holds in some sense. In this case, since $r_n = [I - AF_n]r_{n-1}$ and $\|r_n\| \le \|I - AF_n\| \cdot \|r_{n-1}\|$, making $\|I - AF_n\|$ small in turn makes $\|r_n\|$ small. We then obtain an iteration process defined by

$$u_n = u_{n-1} + F_n r_{n-1}, \tag{13}$$

which can be compared with (12). An alternate formulation is obtained by writing $u_n = u_{n-1} + K_n c_n$, where the columns of K_n are a basis for some space and c_n is chosen so that u_n is as close to u as possible [8].

It is clearly desirable that F_n be an approximation of A^{-1} in some sense. The most simple choice is $F_n = I$, leading to the *basic iterative method*

$$u_n = u_{n-1} + r_{n-1}. \tag{14}$$

Clearly, the more A departs from the identity, the worse the choice of $F_n = I$, so while this choice is simple and obviously inexpensive, we anticipate that convergence of (14) may be slow. Other choices of F_n that lead to faster iterative schemes are possible, leading to various combinations of preconditioners with iterative acceleration techniques. Examples of these will be discussed in the next section. In fact, an important issue is the selection of parameters to accelerate convergence, and this is central to the current work. In fact, drawing a relationship between ODE solvers in (12) and iterative solvers in (13) immediately suggests two avenues for the development of improved methods. First, ODE solvers may be modified to give the steady-state solution faster by abandoning time-accuracy and making the best choice of parameters for accelerating convergence to the steady state rather than embracing accuracy. Second, iterative linear solvers may be modified to give time-accurate intermediate solutions by modifying the given solver to approximate the exponential instead of approximating zero. In each case, the result is a "hybrid" solver with software that can provide both time-accurate evolution solutions and efficient steady-state solutions.

When A is linear and independent of time, a linear solver may be preferable for determining the steady-state solution. However, when A is nonlinear or dependent on t, it may be more desirable to use ODE recursions to get the steady-state solution, since the predictability of the solution based on a linearization of A at the current time is more tenuous. In fact, in some applications an artificial transient term is added to convert the problem to a time-dependent ODE form that can then be integrated to steady state.

5. Polynomial methods and recursion equivalence. In this section we describe some specific relationships between iterative linear solvers for matrix A and ODE solvers that lead to an approach for parameter selection. This discussion is loosely based on the summary of iterative linear solvers in [8]. We remark, however, that our analysis applies to more general operators A.

An effective choice of the operators F or G is given by a polynomial in the matrix A. Linear solvers of this class are known as *polynomial* or *Krylov subspace methods.* A generalization of this is the class of *preconditioned polynomial methods*: for some matrix Q that approximates A, we let $F = q_{n-1}(Q^{-1}A)Q^{-1}$. Likewise, left, right, or two-sided preconditioning could be considered by using $F = Q_R^{-1}q_{n-1}(Q_L^{-1}AQ_R^{-1})Q_L^{-1}$ for appropriate Q_L and Q_R where $Q_L^{-1}AQ_R^{-1} \doteq I$.

The most fundamental polynomial method for solving linear equations is the extrapolated basic iterative method, for which $F = \alpha I$, for some α. Typically, α is chosen to minimize the spectral radius of $I - AF = I - \alpha A$. The recursion for this iterative linear solver is identical to that for Euler's ODE scheme, where $F = G$ with the timestep given by $\Delta t = \alpha$. The method with $\alpha = 1$ is simply referred to as the (unextrapolated) basic iterative method.

The extrapolated basic iterative method may be coupled with preconditioning by writing $F = \alpha Q^{-1}$. Of course, the resulting iterative method does not generally now yield time-accurate solutions. It can be interpreted as yielding time-accurate solutions with Euler's method for a modified ODE where the operator A is replaced by the operator AQ^{-1} with f replaced by $Q^{-1}f$ and again $\Delta t = \alpha$. For example, let us decompose A into diagonal and strictly lower and upper triangular parts as $A = A_D + A_L + A_U$, and set $Q = A_D$. For $\alpha = 1$, Jacobi's method for solving linear equations is obtained. When α is varied from 1, then a relaxation form of the Jacobi iteration is obtained. More generally, if $Q = \Omega$ where Ω is diagonal, the iterative method can be interpreted as corresponding to the use of a modified Euler method in which different timesteps are used at different points in the physical domain.

When the basic iterative method is applied with a preconditioning of $Q = \frac{1}{\omega}A_D + A_L$, then the SOR method is obtained, with the special case of $\omega = 1$ being the Gauss–Seidel method. As pointed out in [17], this method also is equivalent to a first-order, time-accurate method for the operator $A_D^{-1}A$, where ω is interpreted as the timestep and is chosen to be near zero. The ad hoc SOR method [4] employs different values of ω at different grid points in the mesh. This can be expressed in the form $Q = \Omega^{-1}A_D + A_L$ where Ω is diagonal and can also be seen to give time-accurate solutions for the operator $(\Omega/\Delta t)A_D^{-1}A$, where Δt is the timestep. Conversely, this scheme can be interpreted as an ODE-type method that is not time-accurate for operator A and that uses varying timesteps for different components; i.e., for the PDE problem this would correspond to local timesteps at different parts of the physical domain. Similarly, chaotic relaxation techniques [2] may be viewed as an extreme form of

ODE scheme that applies timesteps at various locations in the physical domain according to some ordering, yielding solutions, which, in general, are not time-accurate.

The SSOR preconditioner $Q = \frac{\omega}{2-\omega}(\frac{1}{\omega}A_D + A_L)A_D^{-1}(\frac{1}{\omega}A_D - A_U)$ used with the basic iterative method also corresponds to a first-order, time-accurate method applied to operator $A_D^{-1}A$, using timestep $\omega(2-\omega)$; again, ω must be chosen near zero to give good time-accuracy. Furthermore, when A is a property-A matrix [18], the incomplete Cholesky and modified incomplete Cholesky preconditioners have the same form for Q, except that A_D is replaced with a diagonal matrix of the pivots; this preconditioner with the basic iterative method may again be interpreted equivalently as an ODE solver that uses different timesteps over a spatial discretization of a physical domain.

Other preconditioners can be interpreted similarly in the context of ODE solvers; for example, [17] describes the relationship between the Peaceman–Rachford preconditioner and the Crank–Nicolson method. Similarly, the ADI solvers may be related to operator-split ODE integration schemes. Finally, multigrid methods may be used as linear solvers by seeking appropriate multigrid approximations of zero, while the work by Jesperson [7] may be seen as an attempt to form multigrid approximations to the exponential. Pardhanani [11] has developed similar multigrid schemes for semidiscrete ODE systems.

6. Polynomial methods to enhance ODE solvers. The purpose of this section is to explore new ODE-type methods that may be derived using known results on polynomial approximations. Following [8], polynomial methods for solving linear equations may be divided into two categories: *Chebyshev-type methods*, for which the polynomial q_{n-1} is independent of r_0 and is usually based on the theory of polynomials in the complex plane, and *conjugate gradient-type methods*, for which q_{n-1} is based on r_0, typically through inner-product information. A third class of *hybrid* or *adaptive* methods mixes the approaches, usually to supplement the Chebyshev-type method with spectral estimates for A from the conjugate gradient component of the algorithm.

Chebyshev-type methods generally attempt to make $P_n(z) = 1 - zq_{n-1}(z)$, for z complex, approximate zero on some $\Sigma \supseteq \sigma(A)$ (the spectrum of A), or alternatively on its boundary $\partial\Sigma$. The approximation is usually done either in the ℓ^∞ norm (preferable) or the ℓ^2 norm. A wide range of methods has been developed for this problem. Of particular interest are those for which Σ is an ellipse. Here, if an ellipse containing $\sigma(A)$ can be described, a corresponding $P_n(z)$ may be determined that is parameterized by variables that describe the ellipse. This is done in §7.

Similarly, many Chebyshev-type methods may be modified immediately to approximate e^{-tz} instead of zero on Σ or $\partial\Sigma$, yielding new methods for obtaining time-accurate ODE solutions. In particular, we may minimize $\sup_{z\in\Sigma}|e^{-\Delta tz} - (I - zF(z))|$, where F is a polynomial and $\sigma(A) \subseteq \Sigma \subseteq \mathbb{C} \setminus \{0\}$. This approach corresponds to constructing iterative linear equation solvers of the Chebyshev type for which $\sup_{z\in\Sigma}|(I - zF(z))|$ is minimized. This technique has the advantage over conjugate gradient-type methods in that it requires fewer inner products, which may be advantageous on certain parallel computers. A more general Chebyshev-type approach is to minimize some other norm of the function $e^{-\Delta tz} - (I - zF(z))$ over Σ, such as a least-squares norm.

On the other hand, conjugate gradient-type methods for solving $Au = f$ can be viewed as a special case of *projection methods*, defined by the relations

$$u_n \in u_0 + \mathbf{R}_n, \qquad e_n = u_n - u \perp \mathbf{L}_n \tag{15}$$

for some linear spaces $\mathbf{L}_n$ and $\mathbf{R}_n$. When $\mathbf{L}_n = B\mathbf{R}_n$ for some matrix B and, furthermore, if B is Hermitian positive definite (HPD), then the orthogonality condition causes $\|e_n\|_B$ to be minimized, where $\|v\|_B = \sqrt{v^*Bv}$. To find time-accurate solutions to the ODE problem,

(15) may be generalized to

$$u_n \in u_0 + \mathbf{R}_n, \qquad u_n - u(t) = -A^{-1}[r_n - e^{-At}r_0] \perp \mathbf{L}_n. \tag{16}$$

Again, if $\mathbf{L}_n = B\mathbf{R}_n$ for HPD B, then $\|A^{-1}[r_n - r(t)]\|_B$ is minimized.

Letting L_n and R_n be matrices whose columns form a basis for $\mathbf{L}_n$ and $\mathbf{R}_n$, respectively, we obtain from (16) and (4)

$$u_n = u_0 + R_n[L_n^* R_n]^{-1} L_n^* A^{-1}[I - e^{-At}]r_0. \tag{17}$$

Unfortunately, the quantity $L_n^* A^{-1} e^{-At} r_0$ typically is not known; thus, it must be approximated, e.g., by replacing A in e^{-At} with a projection of A available from the method.

When the method is a polynomial method, $\mathbf{R}_n = K_n(r_0, A) \equiv \operatorname{span}\{A^i r_0\}_{i=0}^{n-1}$, which is the Krylov space. Two important choices of $\mathbf{L}_n$ are $\mathbf{L}_n = A^* A K_n(r_0, A)$, which gives rise to the GMRES linear solver and related methods, and $\mathbf{L}_n = A^* K_n(\tilde{r}_0, A^*)$, $(\tilde{r}_0 = r_0)$, which gives rise to the biconjugate gradient method and related methods.

We now derive a time-accurate ODE solver based on the biconjugate gradient approach. The biconjugate gradient method generates matrices R_n and $\tilde{R}_n \equiv A^{-*} L_n$ whose columns form bases for $K_n(r_0, A)$ and $K_n(\tilde{r}_0, A^*)$, respectively, such that $\tilde{R}_n^* A R_n = D_n$ is diagonal and $\tilde{R}_n^* A^2 R_n = T_n$ is tridiagonal. Let us assume that $R_n = [\, R_{n-1} \quad v_n \,]$ and $\tilde{R}_n = \left[\, \tilde{R}_{n-1} \quad \tilde{v}_n \,\right]$ for each n. Using the approximation $D_n^{-1} \tilde{R}_n^* A(A)^i R_n \doteq (D_n^{-1} T_n)^i$, $i \geq 0$ (which is exact when $i < 2$ or when R_n and $\tilde{R}_n$ are square and nonsingular), we obtain

$$\begin{aligned} u_n &= u_0 + R_n D_n^{-1} \tilde{R}_n^* A [z^{-1} - z^{-1} e^{-zt}]_{z=A} R_n \beta e_1 \\ &\doteq u_0 + R_n [z^{-1} - z^{-1} e^{-zt}]_{z=D_n^{-1} T_n} \beta e_1 \end{aligned} \tag{18}$$

for some $\beta \neq 0$, since $R_n e_1$ is proportional to r_0. This algorithm may be implemented by evaluating the analytic function $[z^{-1} - z^{-1} e^{-zt}]$ applied to the matrix $D_n^{-1} T_n$ using, for example, a Jordan decomposition of the matrix. The result is a biconjugate gradient-type ODE solver for obtaining time-accurate solutions. Similarly, in [6] a time-accurate ODE solver is developed based on the GMRES approach.

It should be noted that these different approaches, whether Chebyshev-type or CG-type, can be modified so that the polynomials generated yield higher-order ODE solvers. This can be done by putting constraints on the derivatives of the polynomial P_n at zero. The inverse problem of adapting a time-accurate ODE integrator to an improved iterative recursion may also be addressed. In the next section we consider this approach for the RK ODE schemes and then apply the resulting scheme in a numerical experiment.

7. A modified RK scheme. In this section we construct a RK ODE recursion based on applying ideas from iterative linear system solvers to the problem of finding steady-state solutions to a (possibly nonlinear) ODE. Using the notation introduced in (10), the two-stage RK methods for constants A and f can be conveniently expressed as the residual recursion

$$r_n = g(\Delta t A) r_{n-1}, \tag{19}$$

where

$$g(\Delta t A) = I - \gamma_1(\Delta t A) + \gamma_2(\Delta t A)^2. \tag{20}$$

Comparing (19) and (20) with (9) for $s = 2$, we have $\gamma_1 = b_1 + b_2$ and $\gamma_2 / b_2 = c_2 = a_{21}$ (see also [13]).

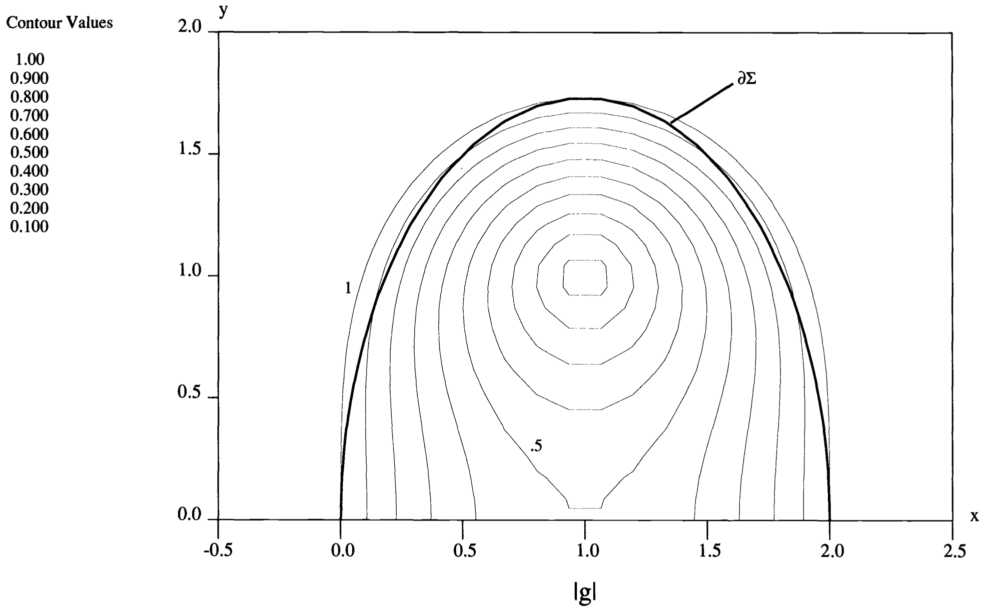

FIG. 1. *Stability region: second-order, two-stage RK, and the associated boundary of (elliptical region)* Σ.

Second-order accuracy is obtained when γ_1 and γ_2 are set equal to 1 and $\frac{1}{2}$, respectively, and the RK2 scheme in (10) is recovered. If instead we set only $\gamma_1 = 1$ and allow γ_2 to be free, the resulting scheme is only first-order accurate. However, γ_2 can now be chosen to enhance convergence to the steady state and thereby create an improved iterative recursion. The idea extends immediately to higher-order RK formulas and to other methods.

For a method of given order, the size of the timestep, and hence the effectiveness of an ODE integrator, can be measured by analyzing the stability domain of the method. In §3, we saw that stability is assured if $|g(\Delta t\lambda_i)| < 1$ for each eigenvalue $\lambda_i \in \sigma(A)$. That is, the stability domain corresponds to the region in the complex plane $(\mathrm{Re}\,(\Delta t\lambda)\,, i\mathrm{Im}\,(\Delta t\lambda))$ for which $|g(\Delta t\lambda)| < 1$.

The stability domain for the second-order scheme above ($\gamma_1 = 1$, $\gamma_2 = \frac{1}{2}$) is shown in Fig. 1. Here, we have plotted the contours $|g(\zeta)| = .1, .2, \ldots, 1$ in the upper-half complex plane. If instead only γ_1 is specified, then γ_2 can be chosen to increase the size of the stability domain. This, in turn, may lead to a larger stepsize and accelerate "convergence" of the recursion to the steady state. Moreover, in view of the correspondence noted in §5, we can appeal to parametric selection criteria from the theory of iterative methods to determine an optimal value of γ_2.

Here, we investigate selecting values for γ_2 based on the properties of Chebyshev-type polynomial iterative methods discussed in §6. These methods were seen to maximize residual reduction per iteration on $\Sigma \supseteq \sigma(A)$ as measured by a suitable norm. To produce iteration polynomials $P_n(z)$ with characteristics similar to those of the RK methods being considered, we choose Chebyshev-based iteration polynomials for which Σ is an ellipse passing through the origin and centered at coordinate $(d, 0)$ with foci at $(d \pm c, 0)$. These iteration polynomials are given by

$$P_n(z) = \frac{T_n\left(\frac{z-d}{c}\right)}{T_n\left(\frac{-d}{c}\right)}, \tag{21}$$

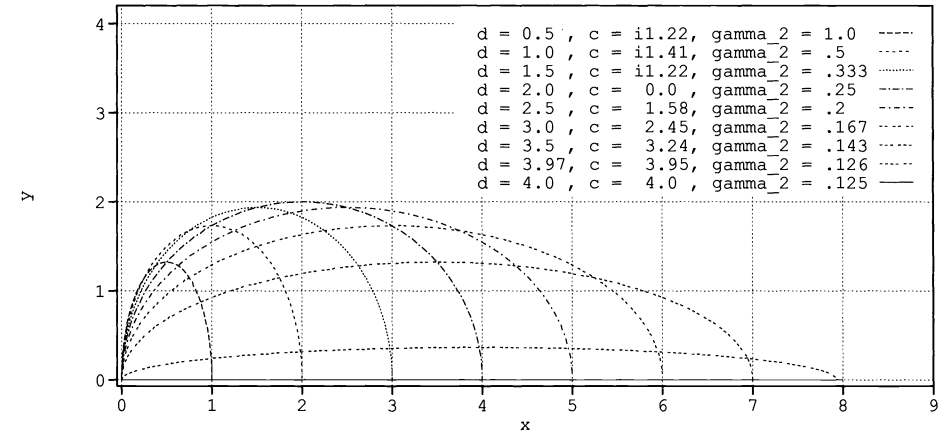

FIG. 2. *Boundaries of elliptical domains* Σ *and corresponding* γ_2 *for representative values of* d *and* c.

where c can be either pure real or pure imaginary [10]. Here n is the degree of the polynomial and T_n are Chebyshev polynomials of the first kind. For the two-stage RK example considered here, the quadratic Chebyshev polynomial is

$$T_2(z) = -1 + 2z^2, \tag{22}$$

so that in (21)

$$P_2(z) = 1 - \frac{4dz}{-c^2 + 2d^2} + \frac{2z^2}{-c^2 + 2d^2}. \tag{23}$$

Since we want the polynomial g in (20) to correspond to the iteration polynomial in (23), this implies

$$\gamma_1 = \frac{4d}{-c^2 + 2d^2} \quad \text{and} \quad \gamma_2 = \frac{2}{-c^2 + 2d^2}. \tag{24}$$

For instance, for the second-order scheme (10) with $\gamma_1 = 1$ and $\gamma_2 = \frac{1}{2}$ in (24),

$$d = 1, \qquad c = \pm i\sqrt{2}. \tag{25}$$

Obviously, substituting for c and d in (23) and sketching the level contours of $P_2(z)$ again yields the plot in Fig. 1. Note that as expected, the stability domain contains the elliptical domain Σ with center and foci defined by (25) and sketched in Fig. 1.

If, instead, the desired accuracy is relaxed to first order by setting $\gamma_1 = 1$, then (24) generates an alternative method for selecting γ_2. We then have

$$c = \pm\sqrt{2d\,(d-2)} \quad \text{and} \quad \gamma_2 = \frac{1}{2d}, \tag{26}$$

where d may be chosen based on knowledge of $\sigma(A)$. A set of ellipses corresponding to representative values of d and c are sketched in Fig. 2. The ellipses are defined for values of d between 0 and 4 and, in general, as d increases the ellipses become increasingly elongated in the positive real direction. At $d = 0$, $c = 0$ and the ellipse degenerates to a point. For $0 < d < 2$, c is imaginary and the semimajor axes are parallel to the imaginary axis. At

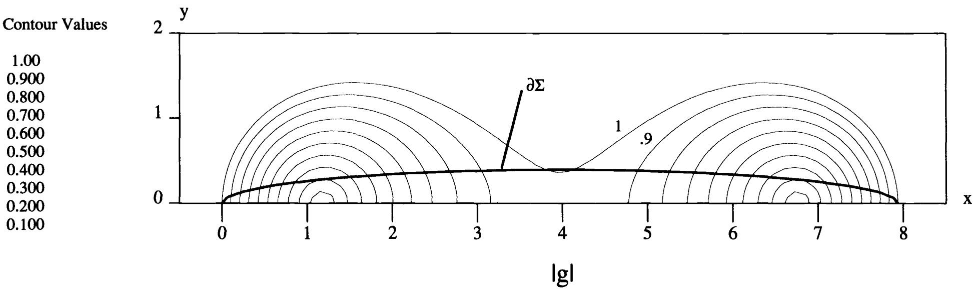

FIG. 3. *Stability region: first-order, two-stage RK* ($\gamma_1 = 1.0, \gamma_2 = .1260$), *and the associated boundary of* (*elliptical region*) Σ.

$d = 2$, $c = 0$ and the ellipse is a circle. For $2 \leq d < 4$, c is real and the semimajor axes are parallel to the real axis. At $d = c = 4$, the ellipse degenerates to a slit of length 8. Increasing d beyond 4 generates γ_2 values for which the stability regions have a detached lobe. Hence d (and therefore γ_2) can be selected to accelerate convergence for a given class of problems. This is illustrated in the next section for a representative diffusion problem. Since the eigenvalues are real and positive for this problem, the coefficients c, d may be chosen so that the ellipse is stretched along the real axis. For example, let us choose $d = 3.97$ for which $c = 3.95$. This should produce a stability region enclosing a highly elongated ellipse centered at $(3.97, 0)$, extending to $(7.93, 0)$. The resulting stability region is indicated in Fig. 3, and we see the expected shape is obtained. Since the domain is significantly extended in the x-direction, these coefficients should give excellent convergence results for systems whose eigenvalues are purely real. Indeed, since the domain is nearly four times longer along the x-axis than that for the second-order scheme in Fig. 1, we can increase the timestep accordingly and would expect a near fourfold acceleration in convergence to the steady state for such problems. Note that in order to produce stability regions that extend in the imaginary direction, imaginary values of c can be used, as was seen in Fig. 2 for $0 < d < 2$. If there are pure imaginary eigenvalues, then part of the imaginary axis should be contained in the stability region. This can be accomplished by selecting parameters γ_1, γ_2 based on the Van der Houwen polynomials rather than the Chebyshev polynomials [12], [16]. Finally, Faber polynomials can be used to enclose domains of arbitrary shape [15]. Next we demonstrate the effectiveness of the stability region shown in Fig. 3 for a representative diffusion problem.

8. Numerical example: Diffusion to steady state. As a numerical example, we use the two-stage RK scheme to solve the model diffusion problem

$$\frac{\partial u}{\partial t} = -\Delta u \quad \text{on} \quad \Omega = [0, 1] \times [0, 1] \tag{27}$$

with $u = 0$ on sides $x = 0, 1$, $y = 0$ and $u = 100$ on side $y = 1$. The RK scheme used is given by (9) with $s = 2$, $b_1 = 0$, $b_2 = 1$, and $c_2 = a_{21} = \gamma_2$ where the values of b_i have been chosen to enhance vector computations [9]. For spatial discretization we use second-order, central differences over a regular, uniform 41×41 grid. The initial iterate corresponds to $u = 0$ in the interior. The timestep is determined using a linear von Neumann stability analysis, which gives $\Delta t_{\max} = .5d/(\frac{1}{\Delta x^2} + \frac{1}{\Delta y^2})$, where $\Delta x = \Delta y = .025$ for this problem and $(d, 0)$ is the coordinate of the center of the associated ellipse.

The convergence histories for the residual iterates are compared in Fig. 4 for the second-order accurate scheme and the first-order accurate scheme with $d = 3.97$ ($\gamma_2 = .1260$) in

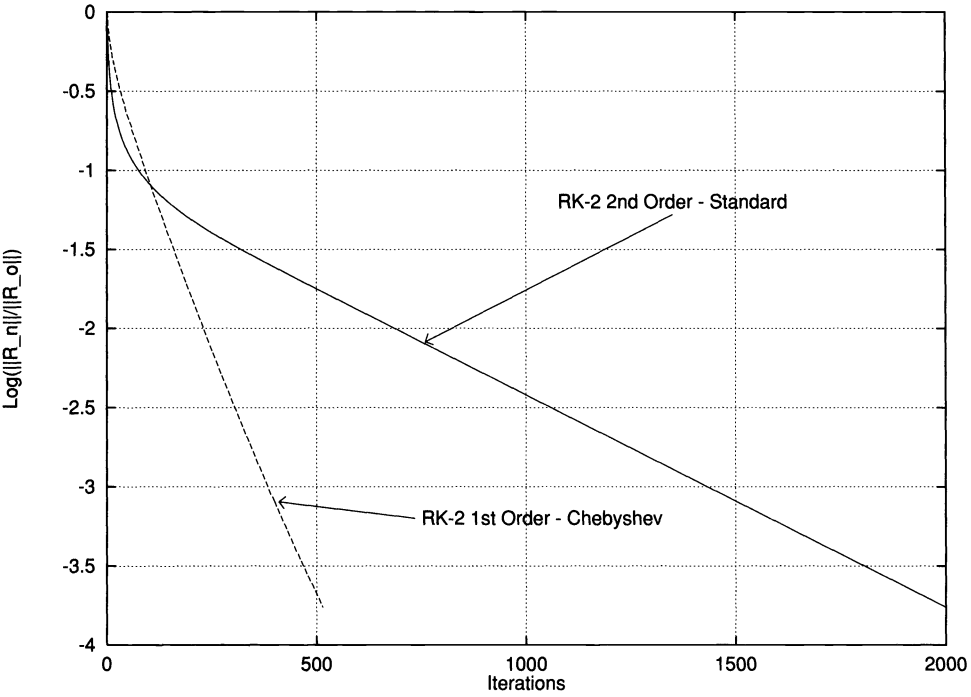

FIG. 4. *Convergence history for a diffusion equation. Standard and modified two-stage RK* 41 × 41 *grid.*

the Chebyshev-based method. It is seen that the Chebyshev-based parameters provide the expected fourfold improvement in the convergence rate.

9. Concluding remarks. As the above diffusion example indicates, the use of parameters chosen from iterative theory for Chebyshev-type methods produces a dramatic improvement in the convergence behavior for a representative two-stage RK scheme. These ideas are currently being extended and applied to nonlinear viscous flow applications and preliminary results have been excellent [9]. We remark, however, that some care should be exercised with regard to the nonlinear problem when multiple steady-state solutions arise. Clearly, choice of a scheme that is not time-accurate does correspond simply to an iterative recursion and there is no guarantee that a specific desired steady state will be obtained rather than another valid solution state. There are now numerous instances in engineering analysis where timestepping to a steady state is being advocated over other solution strategies. The present approach exploits parameter selection based on the equivalence to iterative recursion and the choice of best iteration parameters. This may accelerate the convergence of the recursion significantly as seen here. It is easy to "retrofit" the timestepping code to this form. Moreover, simply by use of a logical flag the algorithms may be selected for time-accurate analysis or faster convergence to steady state. In some situations it may even be desirable to use a hybrid scheme in which the early transient behavior is first monitored using the parameters corresponding to the high-order time-accurate scheme and then the parameters adaptively changed to correspond to the time-inaccurate recursion for fast steady-state solution. Of course, it is also tacitly assumed that a steady-state solution exists. Problems with periodic unsteady solutions must be accommodated using time-accurate integration. Finally, we remark that the approach here can be applied by introducing artificial transient terms for equilibrium equations and in conjunction with nonlinear continuation techniques. Conversely, in some instances it may be possible to modify an iterative solver and code to generate time-accurate transient solutions.

Acknowledgments. We would like to express our appreciation to the reviewers for their helpful suggestions.

SOLUTION OF DENSE SYSTEMS OF LINEAR EQUATIONS IN THE DISCRETE-DIPOLE APPROXIMATION*

JUSSI RAHOLA†

Abstract. The discrete-dipole approximation (DDA) is a method for calculating the scattering of light by an irregular particle. The DDA has been used, for example, in calculations of optical properties of cosmic dust. In this method the particle is approximated by interacting electromagnetic dipoles. Computationally the DDA method includes the solution of large dense systems of linear equations where the coefficient matrix is complex symmetric. In this work, the linear systems of equations are solved by various iterative methods. QMR was found to be the best iterative method in this application. It converged in only a few more iterations than the full generalized minimal residual (GMRES) method. When the discretization of the particle was refined, the number of iterations remained constant even without preconditioning. The matrix–vector product in the iterative methods can be computed with the fast Fourier transform or the fast multipole algorithm. These algorithms make it feasible to solve dense linear systems of hundreds of thousands of unknowns.

1. Introduction.

Light scattering calculations are widely applied in the astrophysics community. In many applications, it is necessary to be able to compute how an irregular dust grain scatters light. The scattering of light by individual dust grains seems to explain the optical properties of atmosphereless solar system bodies, such as the moon. This application of scattering calculations is described, for example, in Lumme and Rahola [20].

Purcell and Pennypacker [22] developed a method to compute the scattering of light by a particle of any shape. This method was later refined by Draine [7], who also called it the discrete-dipole approximation (DDA). The DDA is a rather crude way to discretize the integral equations that govern scattering. However, the DDA seems to work well in practice. The considerations for solving linear systems given here are not limited to the DDA, but apply also to other formulations of scattering calculations.

The DDA leads to a system of linear equations with a dense complex symmetric coefficient matrix. In previous studies, this system was usually solved by the conjugate gradient method applied to the normal equations. Lumme and Rahola [20] applied the quasi-minimal residual (QMR) method [13] to this problem and obtained a gain in performance.

The most time-consuming part in any iterative method for dense linear systems is the matrix–vector product. In the DDA algorithm, Goodman, Draine, and Flatau [16] showed how the fast Fourier transform (FFT) can be used in computing the matrix–vector product in some regular cubical geometries. Another fast method for computing the matrix–vector product is the fast multipole method [23], [17], [4], which we will apply to the DDA problem.

In §2, we will give the equations governing scattering and will review some of the properties of the coefficient matrix. In §3, several iterative methods will be tested. Section 4 describes various methods of computing the matrix–vector product. Section 5 shows how the fast multipole algorithm can be applied to the DDA problem.

2. The scattering equations.

In the DDA, the scatterer is approximated by interacting electric dipoles in an incident electromagnetic plane wave field that propagates with wave vector $\mathbf{k}$ and wave number $k = |\mathbf{k}|$. A harmonic time dependence $\exp(-i\omega t)$ is assumed. The dipole moments $\mathbf{p}_i$ and thus the electric fields $\mathbf{E}_i$ radiated by the dipoles are unknown.

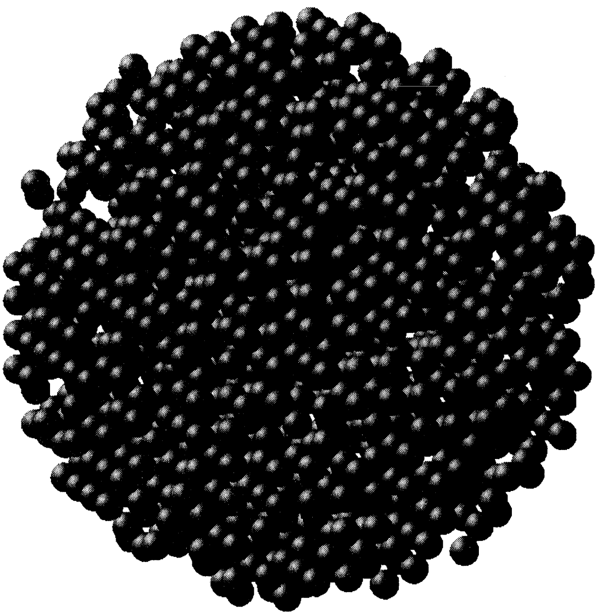

FIG. 1. *An example of a pseudosphere where a number of particles have been removed.*

At each dipole position $\mathbf{r}_i$, the electric field is determined by the incoming field $\mathbf{E}_i^0 = \mathbf{E}^0 \exp(i\mathbf{k} \cdot \mathbf{r}_i)$ plus the field radiated by the other dipoles. Thus the electric field at the dipoles can be solved from

$$\mathbf{E}_i = \mathbf{E}_i^0 + k^3\alpha \sum_{j \neq i}^{N_{\text{dip}}} \mathbf{T}_{ij} \cdot \mathbf{E}_j, i = 1, \ldots, N_{\text{dip}}, \tag{1}$$

where α is the polarizability of a single dipole. Each dipole is thought to represent a spherical volume of radius r_0. The polarizability of the dipole is connected to the index of refraction of the particle m and the dimensionless size parameter $x_0 = kr_0$ as given in [20]. The dipole interaction tensor (or dyadic) is given by

$$\begin{aligned} \mathbf{T}_{ij} &= \frac{e^{i\rho_{ij}}}{\rho_{ij}^3}(\rho_{ij}^2 + i\rho_{ij} - 1)\mathbf{1} + \frac{e^{i\rho_{ij}}}{\rho_{ij}^3}(-\rho_{ij}^2 - 3i\rho_{ij} + 3)\hat{\mathbf{r}}_{ij}\hat{\mathbf{r}}_{ij}, \\ \rho_{ij} &= k|\mathbf{r}_i - \mathbf{r}_j|, \end{aligned} \tag{2}$$

where $\mathbf{I}$ is the unit dyadic and $\hat{\mathbf{r}}_{ij}\hat{\mathbf{r}}_{ij}$ is the symmetric dyadic formed from the interdipole unit vectors $\hat{\mathbf{r}}_{ij} = (\mathbf{r}_i - \mathbf{r}_j)/|\mathbf{r}_i - \mathbf{r}_j|$.

The DDA is also called the coupled dipole method or the digitized Green function method. It can also be derived from a volume integral equation describing scattering. In [19], the DDA is compared with another computational technique, the method of moments, which better estimates the effect of the singularity of the free space dyadic Green function.

In our calculations, the two main geometries for the dipoles were a pseudospherical cluster of dipoles or a particle generated by the diffusion-limited aggregation process. The pseudospheres are generated by taking all the dipoles in a regular lattice that are within a given radius from the origin. An example of a pseudosphere from which a number of particles have been removed is given in Fig. 1. The diffusion-limited aggregation process builds fractal clusters by a three-dimensional random walk. A sample particle is given in Fig. 2.

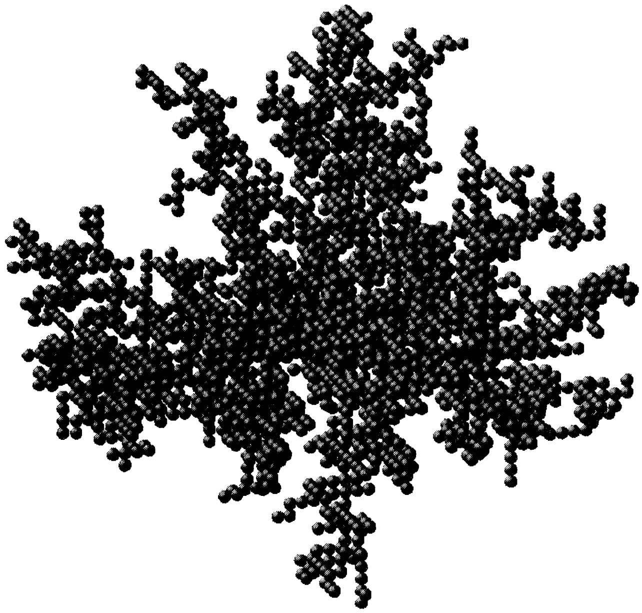

FIG. 2. *A particle generated by the diffusion-limited aggregation process.*

The equations (1) form a system of linear equations in the unknowns $\mathbf{E}_i$ where the coefficient matrix is complex symmetric. The right-hand side vector is given by the incident field $\mathbf{E}_i^0$. The coefficient matrix is full as each dipole interacts with all the other dipoles.

If we have N_{dip} dipoles, the system of linear equations has $3N_{\text{dip}}$ unknowns, because we need to determine the components of the electric field in the x, y, and z directions. When calculating the scattering of light by particles a few microns across, we typically need 1000–100,000 dipoles, giving rise to huge linear systems.

The spectrum of the matrix is shown in Fig. 3. Note that most of the eigenvalues lie on a line segment. This fact will be important in analyzing the convergence of iterative solvers.

3. Comparison of iterative solvers. A modern recipe for solving dense linear algebra systems is given by Edelman in his survey [8]: use a preconditioned iterative method that accesses the matrix only by matrix–vector multiplication and look for fast approximate methods for computing the matrix–vector product. Thus iterative methods can be used not only with sparse matrices but also with dense matrices. Actually, for very large dense problems, iterative methods are the only plausible solution methods. For an introduction to iterative methods, see [14].

In this work, several iterative methods were implemented and tested. The convergence of these methods depends on the geometry of the dipoles, the index of refraction m, and the size parameter x_0. The following methods are used: QMR, GMRES, conjugate gradient applied to the normal equations (CGNR), biconjugate gradient (BCG), conjugate gradient squared (CGS), and biconjugate gradient stabilized (BiCGStab). These methods belong to the family of Krylov-subspace methods, which access the matrix through matrix–vector multiplications. For a description of the methods, see [1]. We used the complex symmetric versions of QMR and BCG, which only need one matrix–vector multiplication per iteration [13]. Figure 4 shows the convergence of these methods in a typical small problem. The horizontal axis shows the number of matrix–vector products so it is roughly proportional to the CPU time. In the figure, the memory length of GMRES was 20.

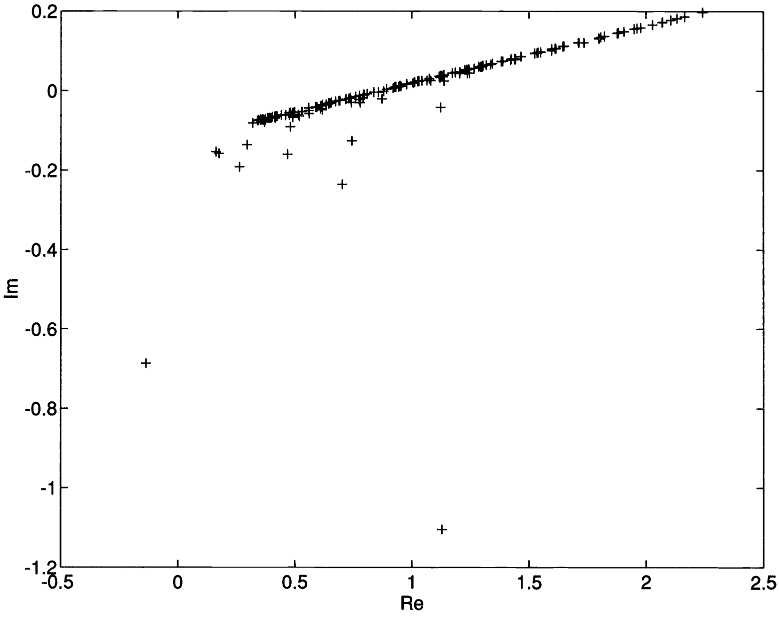

FIG. 3. *Spectrum of the linear system arising in the DDA calculations.*

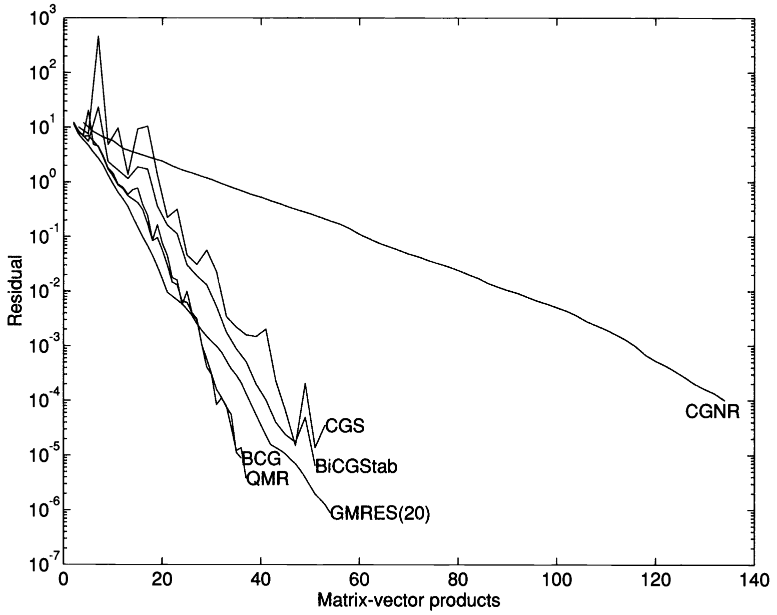

FIG. 4. *Convergence of various iterative methods.*

In bigger systems, CGS had trouble converging, and the residuals of BCG started to oscillate. CGNR was slower than the most efficient methods roughly by a factor of four. Figure 5 shows a comparison of QMR with GMRES using several memory lengths and with full GMRES. The different GMRES versions are converging with a linear rate after an initial sublinear phase. The full GMRES and QMR seem to find a superlinear rate of convergence,

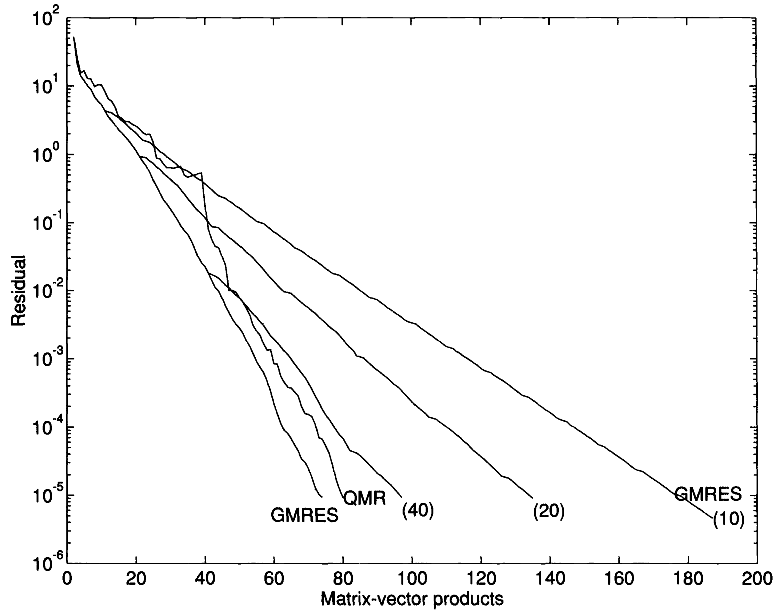

FIG. 5. *A comparison of QMR and GMRES with different memory lengths and with full GMRES.*

TABLE 1

The table shows the number of iterations for QMR (N_{iter}) and the elapsed CPU time in seconds (t) needed to reduce the initial residual by 10^{-5} when the same particle is discretized with different number of dipoles (N_{dip}) and with different size parameters (x_0) associated with each dipole. The number of unknowns is three times the number of dipoles N_{dip}.

N_{dip}	x_0	N_{iter}	t
32	0.3	6	0.23
136	0.188	7	0.46
304	0.144	7	1.52
1064	0.0947	7	3.3
2330	0.0731	7	10
5232	0.0555	7	21
10048	0.0448	7	37
20336	0.0355	7	91
137376	0.01875	7	562

but this may be just a better adaptation to the spectrum. The three iteration phases, sublinear, linear, and superlinear, are typically found when using Krylov-subspace methods [21].

QMR converges with only a few more iterations that full GMRES, which is optimal in the sense that it computes a minimal residual solution. However, full GMRES needs all the previously computed iterates and can thus be time and memory consuming. QMR is based on short recurrences and can be implemented efficiently. QMR was chosen to be the iterative method in the production version of this code.

Table 1 shows the number of QMR iterations needed to reduce the initial residual by a factor of 10^{-5} when the same particle is discretized with increasing resolution. This means that each dipole corresponds to a smaller volume, whose radius is given by the size parameter x_0. The geometry is a filled pseudosphere. The reported CPU time is on a Convex C3840 at the Center for Scientific Computing. The FFT was used to compute the matrix–vector product.

The number of iterations was remarkably constant. Note that in this simulation the index of refraction was smaller than in the earlier figures, resulting in faster convergence.

In the astrophysical calculations, the interest is in the scattering of light by micron-scale particles, leading to dipole configurations of tens or hundreds of thousands of dipoles. In practical calculations even smaller accuracies in the solution of the linear systems are acceptable because orientational averages of the results are taken.

An ideal iterative method for non-Hermitian matrices would have some minimization property and could be implemented using only a few of the latest iterates. Faber and Manteuffel have proved an important theorem for unsymmetric iterations [11], [12], which we state here in the form given in [14].

THEOREM 3.1. *Except for a few anomalies, ideal CG-like methods whose iterates are characterized by a minimal residual or an orthogonal residual property and that can be implemented based on short vector recursions exist only for matrices of the special form*

$$A = e^{i\theta}(T + \sigma I), \tag{3}$$

where T is Hermitian, $\theta \in \mathbb{R}$, $\sigma \in \mathbb{C}$.

In the DDA case, the spectrum of the coefficient matrix lies on a line except for a few eigenvalues, as visualized in Fig. 3. This structure of the spectrum probably accounts for the good performance of QMR. We plan to analyze the convergence of QMR and relate the spectrum of the coefficient matrix to the spectrum of the underlying continuous integral operator.

4. Calculating the matrix–vector product. The performance of iterative solvers for dense linear equations is determined by the number of iterations and the time it takes to multiply the coefficient matrix by a vector.

There are two evident ways to compute the matrix–vector product. The first one is simply to form the coefficient matrix and to keep it in memory. This is indeed the fastest way to calculate the matrix–vector product for small to medium-size matrices. For example, if half a gigabyte of central storage is available, dense matrices up to 7000 × 7000 elements can be stored using single precision. The second method, used for larger matrices, is to either store the matrix in the disk ("out of core") or recompute the matrix elements whenever necessary.

In order to be able to solve large dense linear systems one has to make use of the "all large dense matrices are structured" hypothesis [8], according to which nature does not just randomly throw n^2 numbers at us. Instead, there is some structure in most dense coefficient matrices and we must find an algorithm that exploits this structure.

In this paper, we have applied two fast methods, the FFT and the fast multipole method to compute the matrix–vector product.

Goodman, Draine, and Flatau [16] showed how to use the FFT in conjunction with the DDA. If the dipoles occupy positions in a regular cubical lattice and the lattice dimensions are doubled in each dimension, the matrix–vector multiplication reduces into a 3-D convolution. This convolution can be calculated using a 3-D FFT.

The use of FFT is not limited to cubical arrays of dipoles. The lattice spacings and extents can be different in different dimensions. Not all the lattice positions need to be occupied; the artificial dipoles affect only the performance of the Fourier transform. The size of the FFT is determined by first finding a lattice so that all the dipoles sit on that lattice. The smallest rectangular part of the lattice containing all the dipoles is taken as the computational lattice.

The use of the Fourier transform is very efficient if the dipoles are packed together in a dense and regular way. On the other hand, if the dipoles form a sparse dendrite-like particle generated, for example, by the diffusion-limited aggregation process, many artificial dipoles are needed in order to be able to use the FFT and the method slows down [20].

5. The fast multipole algorithm. The fast multipole method [23], [17], [4] is an efficient method to compute the electric potential of a system of N charges or multipoles. It can also be used in the solution of integral equations of potential theory [23], [24]. The fast multipole method was initially used in simulations where Coulomb or gravitational potential is used. In this paper we will apply the fast multipole method to compute the matrix–vector multiplication in electromagnetic scattering in three dimensions.

The brute force method of computing the interactions of N particles or the evaluation of a full matrix in integral equation computations requires $\mathcal{O}(N^2)$ operations. The full fast multipole method is a rather complicated algorithm that can achieve $\mathcal{O}(N)$ complexity in the solution of the Laplace equation or with the Coulomb or gravitational potential, and $\mathcal{O}(N \log N)$ complexity in the electromagnetic scattering case, i.e., in the solution of the Helmholz equation. For 2-D systems, the break-even point between the direct method and the fast multipole algorithm can be as low as 100 particles. In 3-D calculations, the break-even point is much larger, typically in the range 1000–10,000. An example of 3-D fast multipole computations using the Coulomb potential was given in [26].

For 2-D electromagnetic scattering problems, the fast multipole method was given in [9]. The 3-D version was given in [5], which formulates the scattering problem using a boundary integral equation. The DDA is related to a volume-integral equation. Thus we use different expansions of the potential than those found in [5].

5.1. The multipole and local expansions. Here we shall develop the multipole and local expansions for the dipole potential and show how the electric field and thus the matrix–vector product can be computed from these potentials. Here the matrix–vector product should be viewed as follows: given x, the current guess for the electric field caused by the dipoles, Ax gives the combined field of all the other dipoles at all the dipole positions. The electric field and the dipole moment of a dipole are related by $\mathbf{p}_i = k^3\alpha\mathbf{E}_i$.

The vector potential generated by an oscillating electric dipole at position $\mathbf{r}_i$ with dipole moment $\mathbf{p}_i$ is given by [18]

$$\phi(\mathbf{r}) = -ik\mathbf{p}_i \frac{e^{ik|\mathbf{r}-\mathbf{r}_i|}}{|\mathbf{r}-\mathbf{r}_i|}. \tag{4}$$

The electric field due to this potential is given by

$$\mathbf{E}(\mathbf{r}) = \frac{i}{k}\nabla \times (\nabla \times \phi(\mathbf{r})). \tag{5}$$

The expansion of the Green function occurring in the potential (4) in spherical coordinates is [18]

$$\frac{e^{ik|\mathbf{r}-\mathbf{r}_i|}}{|\mathbf{r}-\mathbf{r}_i|} = \begin{cases} 4\pi ik \displaystyle\sum_{n=0}^{\infty}\sum_{m=-n}^{n} h_n^{(1)}(kr)j_n(kr_i)Y_n^m(\theta,\phi)\left[Y_n^m(\theta_i,\phi_i)\right]^*, & r > r_i, \\ 4\pi ik \displaystyle\sum_{n=0}^{\infty}\sum_{m=-n}^{n} h_n^{(1)}(kr_i)j_n(kr)Y_n^m(\theta,\phi)\left[Y_n^m(\theta_i,\phi_i)\right]^*, & r < r_i. \end{cases} \tag{6}$$

The function $h_n^{(1)}$ is the spherical Hankel function of the first kind, j_n is the spherical Bessel function, and Y_n^m are the spherical harmonics.

In the fast multipole algorithm we need a multipole expansion, which can be used if we are evaluating the potential in a point that is further away from the origin than any of the dipoles. We also need a local expansion that is valid when all the dipoles are further away from the origin than the evaluation point.

The multipole coefficients of a collection of N_{dip} dipoles are given by

$$\text{(7)} \qquad \mathbf{M}_{nm} = \sum_{i=1}^{N_{\text{dip}}} \mathbf{p}_i j_n(kr_i) \left[Y_n^m(\theta_i, \phi_i)\right]^* .$$

The multipole expansion of the potential in terms of the multipole coefficients is

$$\text{(8)} \qquad \phi(\mathbf{r}) = 4\pi k^2 \sum_{nm} \mathbf{M}_{nm} h_n^{(1)}(kr) Y_n^m(\theta, \phi).$$

The local coefficients of a collection of N_{dip} dipoles are given by

$$\text{(9)} \qquad \mathbf{L}_{nm} = \sum_{i=1}^{N_{\text{dip}}} \mathbf{p}_i h_n^{(1)}(kr_i) \left[Y_n^m(\theta_i, \phi_i)\right]^* .$$

The local expansion of the potential is

$$\text{(10)} \qquad \psi(\mathbf{r}) = 4\pi k^2 \sum_{nm} \mathbf{L}_{nm} j_n(kr) Y_n^m(\theta, \phi).$$

When we are using the potential expansions in practice, the summations over n are truncated at a value N, while the summation over m is from $-n$ to n. For the expansion (8), N must be greater than kR, where $R = \max r_i$. For the expansion (10), N must be greater than kR_1, where R_1 is the maximum distance where $\psi(\mathbf{r})$ is going to be evaluated [25].

When given a potential (8) or (10) in terms of the multipole or local coefficients, we must be able to compute the electric field caused by this potential. For the multipole potential case, let us mark

$$\text{(11)} \qquad \gamma = h_n^{(1)}(kr) Y_n^m(\theta, \phi).$$

Now the electric field due to the multipole potential is given by

$$\text{(12)} \qquad \mathbf{E}(\mathbf{r}) = 4\pi i k \sum_{nm} \left\{ \mathbf{M}_{nm} \cdot \nabla\nabla\gamma + k^2 \gamma \mathbf{M}_{nm} \right\},$$

where $\nabla\nabla\gamma$ is a symmetric second-rank tensor whose representation is given in spherical coordinates by

$$\text{(13)} \qquad \begin{pmatrix} \frac{\partial^2 \gamma}{\partial r^2} & \frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial \gamma}{\partial \theta}\right) & \frac{1}{\sin\theta}\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial \gamma}{\partial \phi}\right) \\ \frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial \gamma}{\partial \theta}\right) & \frac{1}{r^2}\frac{\partial^2 \gamma}{\partial \theta^2} + \frac{1}{r}\frac{\partial \gamma}{\partial r} & \frac{1}{r^2}\frac{\partial}{\partial \theta}\left(\frac{1}{\sin\theta}\frac{\partial \gamma}{\partial \phi}\right) \\ \frac{1}{\sin\theta}\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial \gamma}{\partial \phi}\right) & \frac{1}{r^2}\frac{\partial}{\partial \theta}\left(\frac{1}{\sin\theta}\frac{\partial \gamma}{\partial \phi}\right) & \frac{1}{r^2 \sin^2\theta}\frac{\partial^2 \gamma}{\partial \phi^2} + \frac{1}{r}\frac{\partial \gamma}{\partial r} + \frac{\cos\theta}{r^2 \sin\theta}\frac{\partial \gamma}{\partial \theta} \end{pmatrix}.$$

The electric field due to the local potential is computed similarly.

5.2. Translations. In the fast multipole algorithm we need to translate the origin of a multipole or a local expansion and also to switch between multipole and local expansions. The translation formulas are based on the addition theorems for spherical wave functions [15], [27], [6]. They are stated here in a form that uses the Clebsch–Gordan or Wigner coefficients $C_{m_1 m_2 m}^{j_1 j_2 j}$ [2].

In the translation formulas, we use coefficients $c_{n\nu}^{m\mu p}$ defined by

$$c_{n\nu}^{m\mu p} = (-1)^m i^{n-\nu+p} \sqrt{\frac{4\pi(2n+1)(2\nu+1)}{2p+1}} C_{000}^{\nu n p} C_{\mu,-m,\mu-m}^{\nu n p}. \tag{14}$$

The first transformation is used to translate the origin of a multipole expansion. The new origin is given in spherical coordinates by (r_0, θ_0, ϕ_0),

$$\mathbf{M}'_{nm} = \sum_{\nu=0}^{\infty} \sum_{\mu=-\nu}^{\nu} \mathbf{M}_{\nu\mu} \sum_p c_{n\nu}^{m\mu p} j_p(kr_0) Y_p^{\mu-m}(\theta_0, \phi_0). \tag{15}$$

The second transformation is used to switch between a multipole and a local expansion

$$\mathbf{L}'_{nm} = \sum_{\nu=0}^{\infty} \sum_{\mu=-\nu}^{\nu} \mathbf{M}_{\nu\mu} \sum_p c_{n\nu}^{m\mu p} h_p^{(1)}(kr_0) Y_p^{\mu-m}(\theta_0, \phi_0). \tag{16}$$

Finally, this transformation is used to translate the origin of a local expansion

$$\mathbf{L}'_{nm} = \sum_{\nu=0}^{\infty} \sum_{\mu=-\nu}^{\nu} \mathbf{L}_{\nu\mu} \sum_p c_{n\nu}^{m\mu p} j_p(kr_0) Y_p^{\mu-m}(\theta_0, \phi_0). \tag{17}$$

In the above formulas, the summation over p takes the values $n+\nu$, $n+\nu-2, \ldots, \max(|m-\mu|, |n-\nu|)$. The translations are exact, but in practice they are truncated in a similar way as the potential expansions.

The above transformations are quite expensive to compute, especially when the order of the multipole expansion is high. Rokhlin [25] and Epton and Dembart [10] have developed a theory for the diagonal forms of the translation operators. The principal tool is the far-field signature function defined by

$$\hat{\phi}_{\mathbf{a}}(\mathbf{s}) = \lim_{r\to\infty} \left[\phi(\mathbf{a} + r\mathbf{s}) e^{-ikr} kr\right], \tag{18}$$

where $\mathbf{a}$ is the center of the expansion and $\mathbf{s}$ is a unit vector. This function can be directly constructed for the field of a collection of dipoles. On the other hand, given an expansion of the form (8), the truncated far-field signature function is given by

$$\hat{\phi}_{\mathbf{a},N}(\mathbf{s}) = 4\pi k^2 \sum_{n=0}^{N} \sum_{m=-n}^{n} \mathbf{M}_{nm} Y_n^m(\theta, \phi)/i^{n+1}, \tag{19}$$

where θ and ϕ are the spherical coordinates of $\mathbf{s}$.

The translation formula for the far-field signature function is [10]

$$\hat{\phi}_{\mathbf{b}}(\mathbf{s}) = e^{ik(\mathbf{b}-\mathbf{a})\,\mathbf{s}} \hat{\phi}_{\mathbf{a}}(\mathbf{s}), \tag{20}$$

where $\mathbf{b}$ is the new origin.

A truncated function describing the far-field behavior of the local expansion $\psi(\mathbf{r})$ is defined by

$$\hat{\psi}_{\mathbf{a},N'}(\mathbf{s}) = 4\pi k^2 \sum_{n=0}^{N'} \sum_{m=-n}^{n} \mathbf{L}_{nm} Y_n^m(\theta, \phi)/i^{n+1}. \tag{21}$$

The far-field signature function can be transformed into $\hat{\psi}_{\mathbf{c},N'}(\mathbf{s})$ by

$$\hat{\psi}_{\mathbf{c},N'}(\mathbf{s}) = M_L(\mathbf{s}, \mathbf{c} - \mathbf{b})\hat{\phi}_{\mathbf{b},N}(\mathbf{s}), \tag{22}$$

where

$$M_L(\mathbf{s}, \mathbf{r}) = \sum_{n=0}^{L}(2n + 1)i^n h_n^{(1)}(kr)P_n(\mathbf{s} \cdot \hat{\mathbf{r}}). \tag{23}$$

Here $L \geq N + N'$, P_n is the Legendre polynomial, and $\hat{\mathbf{r}}$ is the unit vector in the direction $\mathbf{r}$.

The function $\hat{\psi}_{\mathbf{c}}(\mathbf{s})$ obeys the translation theorem

$$\lim_{L \to \infty} \hat{\psi}_{\mathbf{d},L}(\mathbf{s}) = e^{ik(\mathbf{d}-\mathbf{c})\cdot\mathbf{s}}\hat{\psi}_{\mathbf{c},N}(\mathbf{s}). \tag{24}$$

In practice, the functions $\hat{\phi}_{\mathbf{a}}(\mathbf{s})$ and $\hat{\psi}_{\mathbf{b}}(\mathbf{s})$ are represented by a discrete set of K^2 points on the unit ball, where $K \approx kR_{\max}$ and $R_{\max}$ is the largest computational box in the fast multipole algorithm whose multipole and local expansions are used [25].

5.3. The fast multipole algorithm. The fast multipole algorithm describes an economical way of computing the electromagnetic interactions between the dipoles. The interactions between nearby dipoles are computed directly; the distant interactions are computed using truncated multipole and local expansions. In the algorithm, the computational domain is adaptively divided into boxes. The interaction between dipoles in two distant boxes is computed by forming the multipole expansions of the dipoles in the boxes, transforming the expansions into local expansions with respect to the origin of the other box, and evaluating the local expansions at the dipole positions.

The fast multipole algorithm organizes the evaluation of the dipole interactions so that the computations are made using the coarsest refinement level possible and maintaining a rigorous error bound. The number of terms used in the multipole calculations is determined by the size of the particle and is practically independent of the precision of the computations [25].

We will review the fast multipole algorithm as given in [4]. We shall be working with computational boxes b containing some number of dipoles. Each box is either a *parent box* if it is further divided in the algorithm or a *childless box*. *Colleagues* are adjacent boxes at the same refinement level. Each box has at most 26 colleagues.

The algorithm is given here in terms of the translation formulas (15)–(17). In an actual implementation, the diagonal forms of the translation theorems should be used.

ALGORITHM 5.1 (the fast multipole algorithm).

1. Refine the computational domain adaptively into boxes. If a box contains more than s dipoles, it is subdivided into eight child boxes.
2. Form the multipole coefficients (7) for each childless box. For each parent box, use (15) to translate the origin of the multipole expansions of each child to the center of the parent box and add the expansions to get the multipole expansion of the parent box.
3. For each childless box b, compute directly the interactions between the dipoles in b with the other dipoles in b and with the dipoles in the childless boxes that are adjacent to b.
4. For each box b, convert the multipole expansions of those children of colleagues of b's parent that are well separated from b into a local expansion about b's center using (16) and adding them up.
5. For each childless box b, using (12) at each dipole position calculate the electric field due to the multipole expansion of all descendants of b's colleagues whose parents are adjacent to b but who are not adjacent to b themselves.

6. If the multipole expansion of box b' was used at box b during stage 5, form the local expansion coefficients (9) of b at the center of b'.

7. For each parent box b, shift the center of the local expansion obtained in stages 4 and 6 to the center of b's children using (17).

8. For each childless box, calculate at all dipole positions the electric field due to the local expansion from stage 7 and add the contributions from stages 3 and 5 to get the full electric field caused by all the other dipoles.

At this point, we have limited practical experiences with the fast multipole methods. The current version that does not use the diagonal forms of the translation formulas becomes faster than direct calculations when using on the order of 10,000 dipoles. The calculations can be optimized by tabulating the values of the special functions. A lot of computing time is spent calculating the transformations (15)–(17) or their corresponding diagonal forms. There are only a fixed number of possible translations. The multipole-to-multipole translations are always from the child boxes to their parent box; the local-to-local translations are from a parent box to its children. There are 189 possible multipole-to-local translations in each refinement level, as indicated in [26]. These can be precomputed and tabulated.

6. Conclusion. We have presented an efficient way to solve the dense systems of linear equations arising in the discrete-dipole approximation. The recipe consists of using an efficient iterative method and calculating the matrix–vector products using a fast algorithm. In this project we chose QMR as the iterative method and showed how to apply the FFT and fast multipole techniques in this setting.

The same procedure can be applied in other electromagnetic scattering calculations where the physics are described by a volume integral equation.

The FFT gives by far the best method when the computational geometry is dense so that not very many artificial dipoles need to be used in the FFT algorithm. We plan to optimize the fast multipole method and compare its performance with the direct method and the FFT algorithm in a forthcoming study.

As the iterative methods converged in relatively few iterations, no preconditioning was considered necessary. A preconditioner could be built by running some inner iteration and computing the matrix–vector multiplication with the fast multipole algorithm using fewer terms in the multipole and local expansions.

In the scattering calculations, the same system of linear equations is solved many, maybe over one hundred, times. The convergence of the iterative solver could be speeded up by using a block version of QMR, as described in [3].

Acknowledgment. I would like to thank Kari Lumme for an introduction to the astrophysical problem and for his comments in applying the methods described here. Olavi Nevanlinna has provided important comments about the convergence of the iterative solvers and Olli Serimaa has given invaluable help with the special functions and the potential expansions. I would also like to thank the anonymous referees for their constructive comments.

EQUIVARIANT PRECONDITIONERS FOR BOUNDARY ELEMENT METHODS*

JOHANNES TAUSCH†

Abstract. In this paper we propose and discuss two preconditioners for boundary integral equations on domains that are nearly symmetric. The preconditioners under consideration are equivariant; that is, they commute with a group of permutation matrices. Numerical experiments demonstrate their efficiency for the GMRES method.

Key words. preconditioners, integral equations, boundary element methods

AMS subject classifications. 65F10, 65R20, 65N38

1. Introduction. In the past few years symmetry-exploiting methods have become a popular topic in numerical linear algebra. Of special interest are linear systems that come from discretizing an integral equation defined on a domain with geometrical symmetries. These problems inherit the structure of the underlying group of symmetry transformations when the discretization is done in an appropriate way. By making use of this structure, it is possible to significantly reduce the amount of work involved in solving these systems.

Of course, this method will fail when the symmetry is destroyed by perturbing the domain slightly. Figures 1 and 2 show what kind of domains we have in mind. However, we expect that the symmetric and the perturbed problems are somewhat close to each other and that it is possible to take advantage of this situation as well.

Here we present an approach to how this can be achieved. We propose two preconditioners for the iterative solution of the discretized equation that have the structure of the related symmetry.

Now let us outline this paper. After a brief overview of boundary element methods and iterative methods for the linear system associated with the integral equation in §§2 and 3, we discuss in §4 symmetry reduction methods. In the following we will describe the preconditioners used. In §5 a preconditioner is constructed by discretizing the integral equation on a nearby symmetric surface. Section 6 contains a preconditioner that is the solution of a minimization problem. Some results of numerical experiments are presented in §7.

2. Boundary integral methods. Consider the linear integral equation

$$\lambda\rho(x) + \mathcal{K}\rho(x) = g(x), \qquad x \in \mathcal{B}, \tag{1}$$

with the boundary integral operator

$$\mathcal{K}\rho(x) = \int_{\mathcal{B}} k(x, y)\rho(y)\, d\mathcal{B}(y) \tag{2}$$

defined on a linear space of functions on $\mathcal{B}$, which is denoted by X.

We are interested in the case when $\mathcal{B}$ is a closed and compact surface in the three-space $\mathcal{B} \subset \mathbb{R}^3$. Equations like (1) arise from solving Laplace's equation on a domain with boundary $\mathcal{B}$, in which case the kernel $k(x, y)$ is weakly singular.

One of the standard approaches for solving (1) numerically is the collocation method. The idea here is to seek an approximation of the solution ρ in an n-dimensional linear subspace $X_n \subset X$ spanned by basis functions $\{\phi_i\}_{i\in\mathcal{N}}$, where $\mathcal{N} = \{1, \ldots, n\}$.

*Received by the editors May 18, 1994; accepted for publication (in revised form) February 2, 1995. This work was supported by the National Science Foundation grant DMS-9403392.

†Department of Mathematics, Colorado State University, Fort Collins, CO 80523 (Tausch@Math.Colostate.Edu).

In general, the solution of the integral equation (1) will not be a member of X_n, and therefore a function in this subspace cannot solve the equation at all points on the surface. Instead, one forces the unknown function ρ_n to satisfy (1) at least at points $\{p_i\}_{i\in\mathcal{N}} \subset \mathcal{B}$, which are called collocation points.

If ρ_n is written as a linear combination of the basis functions $\rho_n = \sum c_i\phi_i$, then the collocation method yields a linear system for the coefficients $x = (c_1, \ldots, c_n)^T$ of the following form:

$$Ax = b, \tag{3}$$

where the entries of the matrix are given by

$$A(i, j) = \lambda\phi_j(p_i) + (\mathcal{K}\phi_j)(p_i) \tag{4}$$

and the right-hand side is given by

$$b(i) = g(p_i)\,.$$

If the collocation points are chosen in a way such that the interpolation problem

$$\text{find } \rho_n \in X_n \text{ such that } \rho(p_i) = \rho_n(p_i) \quad \text{for } i \in \mathcal{N}$$

is uniquely solvable for all functions $\rho \in X$, then the system (3) is nonsingular.

Typically, the subspace X_n consists of functions that are piecewise polynomial on a triangulation of $\mathcal{B}$; this has been extensively studied by Atkinson [3]. For estimates of the discretization error $|\rho_n - \rho|$ we refer to the vast literature on numerical methods for integral equations; see, e.g., [4] or [13].

3. GMRES. The matrix of the collocation method in (3) is, in general, dense and nonsymmetric. A classic approach for solving (3) is the multigrid method; see, for instance, [12] or [13]. This technique works well when the operator $\mathcal{K}$ in the integral equation (1) is compact. If the boundary is only piecewise smooth, then this assumption is often violated and the multigrid iteration may perform poorly or may even diverge [5].

Only recently other iterative methods, like conjugate gradients and Krylov suuspace methods, have been studied in connection with boundary integral equations; see, e.g., [8] and [19]. One of these methods is the GMRES method of Saad and Schultz [14].

A well-known technique to improve the convergence of iterative methods is preconditioning; see, e.g., [11]. The idea here is to multiply the linear system $Ax = b$, with the inverse of a nonsingular matrix L, the preconditioner, and to solve the equivalent linear system $L^{-1}Ax = L^{-1}b$. Alternatively, one can transform the unknown x to $Lx = y$ and solve $AL^{-1}y = b$. Note that the products $L^{-1}A$ or AL^{-1} are actually never formed—this would be too costly. Instead, in each step of the iteration an additional linear system with the preconditioner has to be solved. Hence it should be possible to do this efficiently. To get an overall saving, the preconditioner should also decrease the number of steps involved in solving the proposed problem.

A good choice for a preconditioner is a matrix that factors A in the form $L^{-1}A = I + B$ where the norm of the remainder $\|B\|_2$ is small. Then the eigenvalues of the preconditioned matrix $L^{-1}A$ cluster around unity and yield a small condition number.

Another suitable preconditioner is a matrix L that factors A to a low-rank perturbation of the identity; i.e., $L^{-1}A = I + R$. Here R denotes a low-rank matrix: $rk(R) = p \ll n$ and no assumption must be made about the norm of R. In this case the preconditioned GMRES iteration terminates after at most p steps with the exact solution.

4. Equivariance. We are interested in the structure of the system matrix in (3) when the surface $\mathcal{B}$, on which the integral equation (1) is to be solved, has symmetries. That is, $\mathcal{B}$ is left invariant under a group Γ of isometries such as rotations and reflections. Each isometry $\gamma \in \Gamma$ gives rise to a linear operator $\Pi_\gamma : X \to X$ mapping the function $f \in X$ on $f \circ \gamma^{-1} \in X$. The operators $\{\Pi_\gamma : \gamma \in \Gamma\}$ defined in this way form a group under the usual multiplication of operators, which is isomorphic to the group of isometries. Henceforth we will use the same symbol for both groups.

Moreover, suppose the kernel of the integral operator $\mathcal{K}$ in (2) depends only on the distance of the two points x and y; i.e.,

$$k(x, y) = \tilde{k}(|x - y|)\,.$$

This situation is typical when equation (1) comes from an integral reformulation of a boundary value problem. Using a change of variables, it is straightforward that such an integral operator commutes with the action of an element in Γ; i.e.,

$$\mathcal{K}\Pi_\gamma = \Pi_\gamma \mathcal{K}\,. \tag{5}$$

In general, an operator $\mathcal{K}$ with the property (5) is called *equivariant with respect to the group action* Γ, or simply Γ*-equivariant.*

In order to be able to exploit the structure of the continuous problem, the discretization must not destroy the symmetry. It is required that the basis functions and the collocation points remain invariant under the action of the group. This is the content of our assumption.

ASSUMPTION 4.1. *The group* Γ *defines a group of permutations on the indices*

$$\gamma\colon (1, \ldots, n) \mapsto (\gamma 1, \ldots, \gamma n),$$

where the action of the group element γ *on the index* i *is defined by*

$$\Pi_\gamma \phi_i = \phi_{\gamma i}$$

and

$$\gamma p_i = p_{\gamma i}.$$

Moreover, the group of permutations is isomorphic to Γ.

The permutations on the indices in turn induce permutation matrices P_γ in the usual way:

$$(P_\gamma b)(i) = b(\gamma^{-1} i)$$

for a vector $b \in \mathbb{R}^n$. Using the equivariance of $\mathcal{K}$ and the above-defined group actions we obtain for the matrix entries in (4):

$$A(\gamma^{-1}i, j) = (\mathcal{K}\phi_j)(p_{\gamma^{-1}i}) = (\Pi_\gamma \mathcal{K}\phi_j)(p_i) = (\mathcal{K}\Pi_\gamma \phi_j)(p_i) = (\mathcal{K}\phi_{\gamma j})(p_i) = A(i, \gamma j)\,.$$

Hence we see that the matrix A has the three equivalent properties:

$$A(\gamma^{-1}i, j) = A(i, \gamma j) \qquad \forall i, j \in \mathcal{N}, \gamma \in \Gamma, \tag{6}$$

$$A(i, j) = A(\gamma i, \gamma j) \qquad \forall i, j \in \mathcal{N}, \gamma \in \Gamma, \tag{7}$$

$$P_\gamma A = A P_\gamma, \qquad \gamma \in \Gamma\,. \tag{8}$$

Equation (8) is the discrete analogue to equation (5), and, consequently, a matrix with property (8) is called Γ-equivariant. For the following, let us denote an equivariant matrix by L.

The most prominent examples of this class are the circulant matrices, which are equivariant with respect to the cyclic group $\mathbf{Z}_n$. In this case the group action is given by $\gamma i = (\gamma + i) \bmod n$ for $\gamma \in \mathbf{Z}_n$ and $i \in \mathcal{N}$ [7]. It is well known that linear systems with circulant matrices can be solved efficiently by means of the discrete Fourier transform.

It is possible to generalize this idea to arbitrary equivariant matrices. The key here lies in the irreducible representations of the group Γ; for an introduction to representation theory we refer to [15]. The irreducible representations determine a sparse and unitary matrix F—the generalized Fourier matrix—which factors L in the form $L = F^H \widehat{L} F$, with $\widehat{L}$ being a block diagonal matrix. Since F is a unitary matrix, its inverse is given by the Hermitian transpose; i.e., $F^{-1} = F^H$. Instead of solving the linear system $Lx = b$, the equivalent system $\widehat{L}\widehat{x} = \widehat{b}$ with right-hand side $\widehat{b} = Fb$ and unknown $\widehat{x} = Fx$ is solved and then the solution x is recovered from $\widehat{x}$ via the inverse transformation $x = F^H\widehat{x}$.

The diagonal blocks of $\widehat{L}$ can be computed with n^2 floating point operations, the transformations $\widehat{b} = Fb$, and $x = F^H\widehat{x}$ can be done in $\#(\Gamma)n$ flops. Thus the overhead compares to one matrix–vector multiplication and is negligible, considering that L is a full matrix. The major savings in computational effort comes from the fact that a number of small systems are solved as opposed to one big system in the unreduced case. The size of these systems decreases with the order of the group.

For more details about this generalization of the Fourier transform we refer to [16]. An earlier description of symmetry reduction using projections can be found in [1] and [10]. The approach presented there yields equivalent subsystems. Applications to boundary element methods with numerical results are in [2] and in [20].

5. Preconditioner derived from a nearby symmetric surface. In the next two sections we describe two preconditioners to handle problems defined on domains that are close to a domain with geometrical symmetries.

The first preconditioner is obtained by discretizing the integral equation on the symmetric surface. As it was pointed out in the previous section, this yields an equivariant matrix, which can be inverted efficiently.

Let us briefly discuss how this preconditioner is constructed. Usually surfaces are represented via parameterizations. Since we want to include piecewise smooth surfaces, it is convenient to use a piecewise linear (PL) manifold for the domain of the parameterization. Here we recall the definition found in Georg [9]: A *PL-manifold* is a finite collection $\mathcal{S}_{PL}$ of closed triangles in $\mathbb{R}^3$, each having affinely independent vertices $T_i = [v_0^i, v_1^i, v_2^i]$, $i = 1, \dots, J$. In addition, we require the following.

1. The intersection of two triangles in $\mathcal{S}_{PL}$ is empty or a vertex or an edge.
2. Each edge is common to exactly two triangles.

We assume that it is possible to parameterize the symmetric as well as the perturbed surface with the same PL-manifold. Then our discretization scheme can be described as follows:

1. Find a symmetry-respecting PL-manifold $\mathcal{S}_{PL}$ and parameterizations (i.e., piecewise smooth isomorphisms) $m : \mathcal{S}_{PL} \to \mathcal{B}$ and $\tilde{m} : \mathcal{S}_{PL} \to \tilde{\mathcal{B}}$ of the symmetric and the perturbed surface, respectively.

2. Define a set of basis functions $\{\psi_1, \dots, \psi_n\}$ on $\mathcal{S}_{PL}$. Lifting them to the surfaces $\mathcal{B}$ and $\tilde{\mathcal{B}}$ via $\psi_i = \phi_i \circ m$ and $\psi_i = \tilde{\phi}_i \circ \tilde{m}$ produces basis functions $\{\phi_1, \dots, \phi_n\}$ and $\{\tilde{\phi}_1, \dots, \tilde{\phi}_n\}$. Note that the basis on $\mathcal{B}$ must respect the symmetry in the sense of our assumption.

3. Define collocation points $\{q_1, \dots, q_n\}$ on $\mathcal{S}_{PL}$ and map them to the two surfaces: $p_i = m(q_i)$ and $\tilde{p}_i = \tilde{m}(q_i)$.

Applying the collocation method, we obtain the two nonsingular matrices L and A arising from the symmetric and the unsymmetric problem, respectively. The matrix L is only a good preconditioner when the quantity $\|A - L\|$ is small. In [17] it is shown that this is in fact true when the parameterizations and their first few derivatives are close to each other.

The use of the above preconditioner has a significant drawback. Usually the assembly of the system matrix is the most costly part of a boundary element technique. Our method requires two matrices—one for the symmetric and one for the perturbed problem. Even though only a fraction of matrix entries have to be determined in the equivariant case, the savings in the iteration may not justify the extra calculation of the preconditioner.

This objection, however, does not apply for situations where the perturbed surface differs from the symmetric surface only on a small piece. In this case the respective basis functions and the collocation points are identical except for a few, which implies that only a few rows and columns of A have to be updated to obtain the preconditioner. In other words, A is a low-rank perturbation of L or $L^{-1}A$ is a low-rank perturbation of the identity. This in turn implies that the number of steps in the GMRES iteration of $L^{-1}A$ is bounded by this rank.

In the next section we introduce a preconditioner that does not depend on additional surface integrations.

6. An optimal preconditioner. Our next goal is to find an equivariant matrix L so that the product $L^{-1}A$ is as close to the identity as possible. In other words, the preconditioner has to minimize the quantity $\left\|L^{-1}(A - L)\right\|$ in a consistent matrix norm. An upper bound for this number can be obtained easily. Setting $B = A - L$, we estimate

$$\left\|L^{-1}B\right\| = \left\|(A - B)^{-1}B\right\| = \left\|(I - A^{-1}B)^{-1}A^{-1}B\right\| \leq \frac{\left\|A^{-1}B\right\|}{1 - \left\|A^{-1}B\right\|}.$$

Since the right-hand side of this inequality is monotonically increasing with $\left\|A^{-1}B\right\|$, it is straightforward to minimize $\|B\| = \|A - L\|$. Thus we require that our preconditioner solves the following minimization problem:

$$L \equiv \min\{\|A - L\| : L \text{ is } \Gamma\text{-equivariant}\}\ . \tag{9}$$

We will show that this problem is trivially solvable in the Frobenius norm: to obtain the optimal preconditioner, one has to average over the orbits of the group action on the indices. This construction can be viewed as a generalization of T. Chan's circulant preconditioner for Toeplitz systems [6]. Here this idea is extended to any finite group. More formally, we have Theorem 6.1.

THEOREM 6.1. *The matrix defined by*

$$L(i, j) = \frac{1}{\#\Gamma}\sum_{\gamma\in\Gamma} A(\gamma i, \gamma j) \tag{10}$$

is Γ*-equivariant and is the optimal solution of the minimization problem* (9) *in the Frobenius norm. In matrix notation, the optimal preconditioner has the form*

$$L = \frac{1}{\#\Gamma}\sum_{\gamma\in\Gamma} P_{\gamma^{-1}} A P_{\gamma}. \tag{11}$$

Before we give the proof of the above theorem, we need some simple notions of a group acting on a set of integers.

Consider the index i in the index set $\mathcal{N}$. We denote the set $\mathrm{Orb}(i) := \{\gamma i : \gamma \in \Gamma\}$ the *orbit* of the group action on the index i. The set $\mathcal{N}$ can be viewed as the disjoint union of its orbits. A subset $\mathcal{S} \subset \mathcal{N}$ that contains exactly one element from each orbit is called a *selection* of indices. The *isotropy subgroup* of the index i consists of the group elements that leave i fixed; i.e.,

$$\mathrm{Fix}(i) = \{\gamma \in \Gamma : \gamma\, i = i\}\,.$$

If the isotropy subgroup of an index is trivial, i.e., $\mathrm{Fix}(i) = \{e\}$, then the size of the orbit containing i is equal to the group order. If there are fixed points in the group action then the size of the orbit is given by $\#\mathrm{Orb}(i) = \#\Gamma / \#\mathrm{Fix}(i)$.

Now we are able to prove the above theorem.

Proof. Let L be an arbitrary Γ-equivariant matrix. The main idea of the proof is to rearrange the summation in the Frobenius norm

$$\|A - L\|_F^2 = \sum_{i' \in \mathcal{N}} \sum_{j' \in \mathcal{N}} \left(A(i', j') - L(i', j')\right)^2$$

so that the orbits of $L(i, j)$ stand together. We write the index j' as the product of a group element and an index from a selection, i.e., $j' = \gamma j$ for a $\gamma \in \Gamma$ and $j \in \mathcal{S}$. When summing up over all $\gamma \in \Gamma$ and $j \in \mathcal{S}$ there might be repetitions due to fixed points in the group action. To account for that we have to divide by the order of the isotropy subgroup. Thus we obtain

$$\begin{aligned}\|A - L\|_F^2 &= \sum_{i' \in \mathcal{N}} \sum_{\gamma \in \Gamma} \sum_{j \in \mathcal{S}} \frac{1}{\#\mathrm{Fix}(j)} \left(A(i', \gamma j) - L(i', \gamma j)\right)^2 \\ &= \sum_{i \in \mathcal{N}} \sum_{\gamma \in \Gamma} \sum_{j \in \mathcal{S}} \frac{1}{\#\mathrm{Fix}(j)} \left(A(\gamma i, \gamma j) - L(\gamma i, \gamma j)\right)^2 .\end{aligned}$$

In the last step we have set $i = \gamma^{-1} i'$, which changes only the sequence of the summation. Finally, using the equivariance of L, we get

$$\|A - L\|_F^2 = \sum_{i \in \mathcal{N}} \sum_{j \in \mathcal{S}} \frac{1}{\#\mathrm{Fix}(j)} \sum_{\gamma \in \Gamma} \left(A(\gamma i, \gamma j) - L(i, j)\right)^2 .$$

The above expression consists of uncoupled optimization problems for the $L(i, j)$. The optimal solution can be obtained by minimizing each term

$$\sum_{\gamma \in \Gamma} \left(A(\gamma i, \gamma j) - L(i, j)\right)^2 .$$

This yields equation (10):

$$L(i, j) = \frac{1}{\#\Gamma} \sum_{\gamma \in \Gamma} A(\gamma i, \gamma j)\,.$$

It is easy to see that L is equivariant. Equation (11) can be verified by pre- and postmultiplying with canonical basis vectors. □

Computing one entry $L(i, j)$ by formula (10) takes $\#\Gamma$ additions. Since the matrix L is determined by the indices $i \in \mathcal{S}$ and $j \in \mathcal{N}$ this adds up to n^2 floating point operations for the whole matrix. Thus the calculation of the optimal preconditioner costs approximately about as much as one single matrix–vector multiplication. This is clearly an advantage over the preconditioner of the previous section, because no costly surface integrations have to be done.

TABLE 1
Iteration results for the second kind equation on the ellipsoid.

	No precond.		Opt. precond.

48	11	.050	5	.0055
192	10	.042	5	.0095
768	11	.048	6	.0083

Note that the matrix constructed in the above theorem is not always nonsingular. However, if A is positive, i.e., $\langle Ax, x\rangle > 0$ for $x \neq 0$, then the preconditioner is positive as well, as it is shown in the following calculation:

$$\langle Lx, x\rangle = \frac{1}{\#\Gamma}\sum_{\gamma\in\Gamma}\langle P_{\gamma^{-1}}AP_\gamma x, x\rangle = \frac{1}{\#\Gamma}\sum_{\gamma\in\Gamma}\langle AP_\gamma x, P_\gamma x\rangle .$$

Here we have used that the permutations P_γ form a group of orthogonal matrices; thus $P_{\gamma^{-1}} = P_\gamma^{-1} = P_\gamma^T$. The last expression is positive when $x \neq 0$ by the positivity of A.

This generalizes an analogous result for circulant matrices [18].

7. Some numerical results.

7.1. Second kind equations. In the following we present some numerical results using the optimal preconditioner described above. The first examples deal with the integral equation

$$2\pi\rho(x) + \int_{\mathcal{B}} \frac{\partial}{\partial n_y}\left(\frac{1}{|x-y|}\right)\rho(y)d\mathcal{B}(y) + (2\pi - \Omega(x))\rho(x) = g(x),$$

which comes from solving Laplace's equation on a domain with boundary surface $\mathcal{B}$. Here $\Omega(x)$ denotes the solid angle of $\mathcal{B}$ at the point x, which is 2π when the surface is smooth at x. The linear systems come from collocating with functions that are piecewise constant on a triangulation of the parameter space.

The GMRES iteration was continued until the 2-norm of the residual was reduced by the factor 10^{-15}. The tables show the number of iterations (its) as well as the average reduction factor of the residual in each step (δ) for various refinements of the grid (N denotes the number of triangles). The parameters its and δ are compared for the original and the preconditioned system.

The domain in the first example is the ellipsoid $(x/1.1)^2 + (y/1.05)^2 + z^2 = 1$. The parameterizing $\mathcal{S}_{PL}$-manifold is the unit cube, which induces a group action of order 48 on the indices. This group action was used to construct the preconditioner as in our theorem (10). The results of the experiments are shown in Table 1. In the middle column are the results of the iteration applied on the original system; in the right column are the respective numbers for the preconditioned system.

The second domain is a cube, with one side perturbed by a quadratic surface; see Fig. 1. Due to the edges, the number of steps of the unpreconditioned iteration is higher than in the previous example with a smooth surface. Note, however, that the increase of steps in the preconditioned method is not so significant. The numerical results are displayed in Table 2.

In the third example (a cube with a small cube removed in one corner, cf. Fig. 2) the preconditioner performed poorly. This is due to the fact that the derivatives of the parameterizations are not nearby, yielding boundary integral operators that are not close in some norm. The results are shown in Table 3.

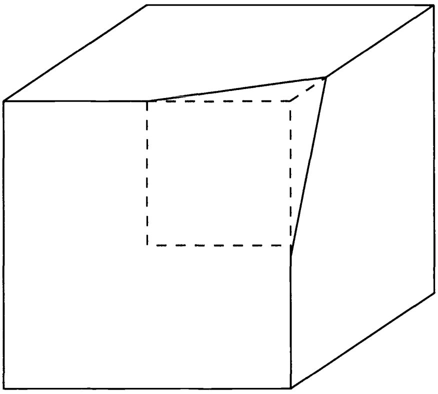

FIG. 1. *The perturbed cube.*

7.2. First kind equations. In the above numerical examples the preconditioner reduced the number of steps in the iteration significantly; however, the unpreconditioned iteration converges reasonably fast as well, especially in the case of the ellipsoid. This is due to the well-posed nature of second kind equations (1) with compact operators.

This picture changes when first kind equations are to be solved. Equations of this type are of great importance for boundary element methods. We experimented with the single layer operator from potential theory, which is defined by

$$\mathcal{S}\rho(x) = \int_{\mathcal{B}} \frac{1}{|x-y|}\, \rho(y)\, d\mathcal{B}(y)\,.$$

Since this operator is compact, its inverse is not bounded and the equation $\mathcal{S}\rho = g$ is ill posed. When a discretization technique is applied then the number of GMRES iterations will increase with the refinement of the mesh.

The experiments suggest that our preconditioners work well especially for first kind equations. Compare with the results of Table 4, which were obtained by discretizing the perturbed cube of Fig. 1 in the same way as for the double layer equation.

As expected, the number of iterations increases as the grid is refined. This is also the case when the preconditioner is used; however, the increase is much slower. The two preconditioners that we have discussed perform almost equally well as in the case of the double layer equation.

Surprisingly, we obtained good performance for the single layer equation even on the domain of Fig. 2, where preconditioning of the double layer equation failed; see Table 5. This behavior may be attributed to the higher sensitivity of the double layer operator to perturbations of the surface. We will investigate this in our future work [17].

Acknowledgment. The author would like to thank his Ph.D. advisors Dr. Eugene Allgower and Dr. Kurt Georg for the help and guidance during this study.

PERFORMANCE ISSUES FOR ITERATIVE SOLVERS IN DEVICE SIMULATION*

QING FAN†, P. A. FORSYTH‡, J. R. F. MCMACKEN§, AND WEI-PAI TANG‡

Abstract. Due to memory limitations, iterative methods have become the method of choice for large scale semiconductor device simulation. However, it is well known that these methods suffer from reliability problems. The linear systems that appear in numerical simulation of semiconductor devices are notoriously ill conditioned. In order to produce robust algorithms for practical problems, careful attention must be given to many implementation issues. This paper concentrates on strategies for developing robust preconditioners. In addition, effective data structures and convergence check issues are also discussed. These algorithms are compared with a standard direct sparse matrix solver on a variety of problems.

Key words. device simulation, iterative solver, preconditioning, ordering, drop tolerance, fill level

AMS subject classifications. 65F10, 78A35

1. Introduction. The increasing demands for more accurate semiconductor device modeling have pushed the development of numerical methods into a new era. One of these new developments is the study of techniques for the solutions of very large ill-conditioned sparse linear systems. In the past, software developers favored the use of sparse direct methods. These solvers could be treated as black box modules, since a reliable solution could (almost) always be obtained. However, the memory requirements of these direct methods make them impractical for large scale simulations. Consequently, attention has shifted to the use of iterative methods.

During the past decade, there has been considerable interest in Krylov subspace acceleration coupled with various preconditioning techniques. A great deal of effort [2], [26], [34], [36], [39], [19] has been devoted to developing iterative acceleration methods, while *robust* preconditioners have received less attention, mainly because of inherent theoretical difficulties. However, a good preconditioner is necessary for a robust iterative algorithm. Many workers have observed that a superior preconditioner can boost performance by an order of magnitude [5], [40], while a better acceleration technique may only improve the performance by 10–30%. In [5] and [34], various new developments in iterative methods for device simulation have been summarized.

Although iterative methods seem to be the only practical choice for large scale simulations, direct methods are still used in many situations. This is because many existing iterative methods may fail to converge when the matrix is very ill conditioned and careful attention is not given to many implementation issues.

The objective of this article is to investigate several issues which are important for the performance of iterative methods in device simulation. In particular, our emphasis will be on construction of an effective preconditioner. Both level-based and drop tolerance preconditioners [16] will be tested. A new two-step preconditioner, which treats the electric potential terms in the Jacobian in a very accurate manner, will also be developed. The alternate block factorization (ABF) technique, which will be shown to be equivalent to block scaling, has been suggested as a preconditioner for device simulation problems. The ABF preconditioner will

be compared to the above methods. Some other issues which will also be addressed include the ordering of the unknowns [14], [16], [12], the choice of acceleration method, and the convergence check criteria. All these methods were tested in a commercially available drift-diffusion device simulator [31] which uses full Newton iteration for solution of the nonlinear algebraic equations.

2. CHORDV and test problems. CHORD System V [31] is a semiconductor device simulator which uses fully coupled Newton iteration to solve a variety of carrier transport models. In this paper, we are concerned with the traditional two-carrier, drift-diffusion equations: Poisson's equation and the electron and hole current continuity equations.

$$\nabla^2\psi + \frac{q}{\epsilon}(p - n + N_D - N_A) = 0,$$

$$\frac{\partial n}{\partial t} = \frac{1}{q}\nabla \cdot J_n - R,$$

$$-\frac{\partial p}{\partial t} = \frac{1}{q}\nabla \cdot J_p - R.$$

Here, ψ is the electrostatic potential, p, n the hole and electron concentrations, J_n, J_p the corresponding current densities, N_D, N_A the ionized donor and acceptor concentrations, and R the net recombination. Using the drift-diffusion approximation, we can write the electron and hole currents as

$$J_n = -q\mu_n n\nabla\psi + qD_n\nabla n,$$

$$J_p = -q\mu_p p\nabla\psi - qD_p\nabla p,$$

where μ_n, μ_p and D_n, D_p are the carrier mobility and diffusion coefficients. These expressions are combined to yield a system of three equations in three unknowns (ψ,n,p). Our carrier mobility models are taken from Nishida and Sah [32] and include components due to lattice vibration, ionized impurities, surface scattering, and velocity saturation. The recombination term includes Shockley–Read–Hall, Auger, and impact ionization. We convert the diffusion coefficients to effective mobilities using the Einstein relation.

The three equations are discretized across a two-dimensional (2D) domain using box integration [35] applied to a nonorthogonal grid. Box integration can also be viewed as a finite volume-type method [3]. In the finite volume approach, the differential equations are integrated over finite volumes, and the volume integrals are converted to surface integrals. Consider the grid node i and its neighbors j. We begin by constructing perpendicular bisectors of the grid to develop a control volume. Note that this approach restricts us to using grid meshes which are Delauney triangulations.

Next we assume that the electric field and current are constant across each face of the polygon as well as all physical properties. Using a finite volume method, the discrete Poisson equation is

$$\sum_j \left[\frac{h_j^+ + h_j^-}{l_j}\right][\psi_j - \psi_i] + \frac{q}{\epsilon}[p_i - n_i + N_{Di} - N_{Ai}]\sum_j \left[a_j^+ + a_j^-\right] = 0$$

where l_j is the distance from node i to node j (see Fig. 2.1).

Backward Euler timestepping is used, and consequently, the discrete electron continuity equation becomes

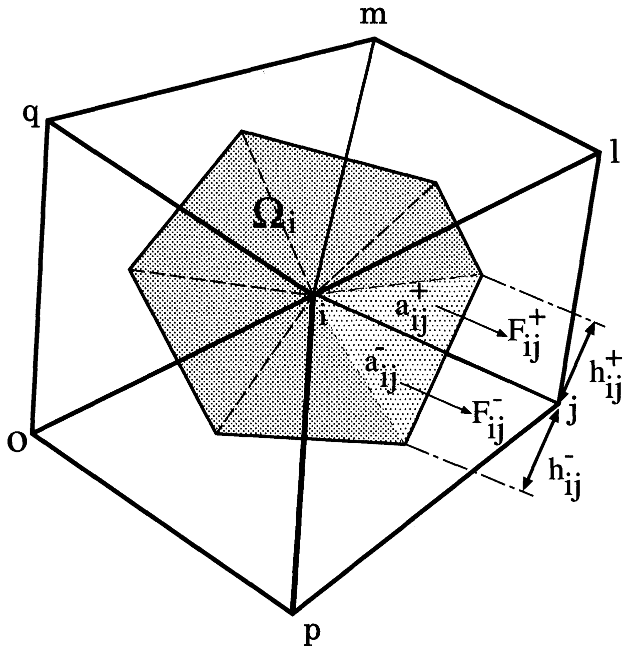

FIG. 2.1. *Box integration scheme for discretization.*

$$\frac{1}{q}\sum_j \left[h_j^+ + h_j^-\right][J_n \cdot \hat{\eta}_{ij}]_j^{k+1} - \left[[R_i]^{k+1} + \frac{n_i^{k+1} - n_i^k}{\Delta t}\right]\sum_j \left[a_j^+ + a_j^-\right] = 0$$

where $\hat{\eta}_{ij}$ is the outward pointing normal to Ω_i along the face between node i and node j. The Scharfetter–Gummel approximation for current density [37] is given by

$$[J_n \cdot \hat{\eta}_{ij}]_j^{k+1} = -q\frac{\phi_T \mu_n}{l_j}\left[n_i^{k+1}B(-\delta\psi_j^{k+1}/\phi_T) - n_j^{k+1}B(\delta\psi_j^{k+1}/\phi_T)\right]$$

where

$$B(x) = \frac{x}{\exp x - 1},$$

$$\delta\psi_j = \psi_j - \psi_i,$$

and ϕ_T is the thermal voltage. Thus, the resulting discrete form of the electron continuity equation is

$$\frac{1}{q}\sum_j \left[h_j^+ + h_j^-\right] - q\frac{\phi_T \mu_n}{l_j}\left[n_i^{k+1}B(-\delta\psi_j^{k+1}/\phi_T) - n_j^{k+1}B(\delta\psi_j^{k+1}/\phi_T)\right]$$

$$-\left[[R]_i^{k+1} + \frac{n_i^{k+1} - n_i^k}{\Delta t}\right]\sum_j \left[a_j^+ + a_j^-\right] = 0.$$

A similar expression may be developed for the hole continuity equation.

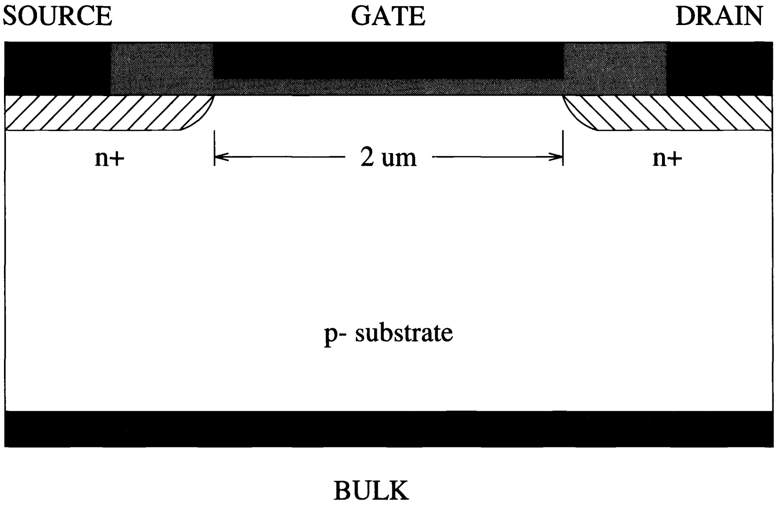

FIG. 2.2. *An n-channel MOSFET.*

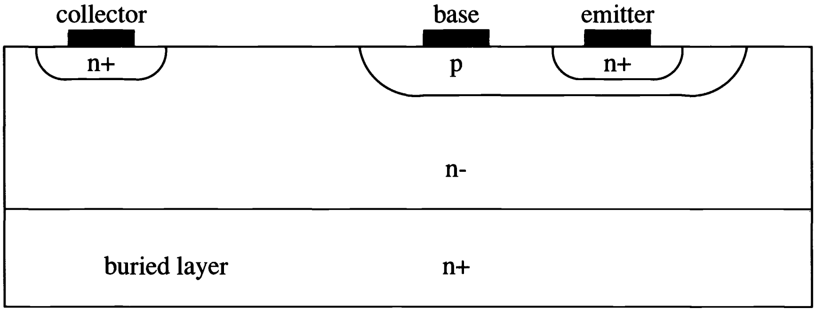

FIG. 2.3. *A bipolar junction transistor.*

In CHORD, the transport model is solved using Newton iteration. Given a set of equations with residuals r_k, associated with unknowns x_k, we linearize the system about a point x_k and solve the linear system $J_k(x_{k+1} - x_k) = J_k \Delta x_k = -r(x_k)$ where J_k is the Jacobian matrix formed by computing partial derivatives of r_k. In our case, x_k is typically the vector of unknowns (ψ, n, p). Our solution estimate is then updated by the Newton step Δx_k and the process repeated until the system is converged. In this paper, we will focus on iterative methods for solving the linear system.

Two typical semiconductor models, metal-oxide-semiconductor field-effect transistor (MOSFET) and bipolar junction transistor (BJT), are used for testing purposes. The n-channel MOSFET device is a simplified self-aligned n-channel MOSFET with a 2um drawn channel length and a 25nm thick gate insulator (see Fig. 2.2). The source and drain are 0.25um abrupt junctions in a lightly doped p-type substrate ($5.0e + 15$ cm^{-3}). There is no channel implant. We assume an ideal structure with no oxide charge or interface charge. The MOSFET problem has 15587 unknowns.

The second device is a bipolar junction transistor (see Fig. 2.3) that is an active three-terminal device which can be used as an amplifier or switch. There are areas of applications in which the bipolar transistor is superior to MOSFET, such as in high-power devices and in high-speed logics for high-performance computers. This device is a simple vertical *npn* transistor formed by two ion-implant steps and a thermal anneal, an $n+$ buried layer is used to reduce the parasitic collector resistance. The BJT problem has 13758 unknowns.

Three sets of test problems were developed based on the two device structures. In the MOSA test set, the MOSFET source and substrate were grounded and the drain held at 5.0V while the gate bias was swept from 0.0V to 10.0V in 0.5V increments. In MOSB, the gate was fixed at 1.0V while the drain was swept from 0.0V to 10.0V, again in 0.5V steps. In the final problem, BJT, a single bias point (zero on emitter, base, and collector) was applied to the bipolar junction transistor.

Each of these subproblems requires many Newton steps, which in turn requires many Newton solves. Consequently, each test problem exercises the matrix solution algorithm over many different Newton iterations and values of the source-drain voltage. Consequently, the total time for the entire test problem is a good indication of the robustness and reliability of the matrix solver over a wide range of situations.

The Newton iteration convergence criteria used in these problems was a relative one. Given the Newton step Δx_i and solution estimate x_i, the iteration was stopped when the relative error $|\Delta x_i / x_i|$ was less than 0.001 for all variables. To avoid numerical inaccuracies, this test was skipped if $|x_i| < 10^{-7}$. This situation is most often found with minority carrier concentrations. For our problems, values of this magnitude do not contribute to the solution.

3. Inner iteration convergence criteria. The complete solution process in a device simulation consists of an inner and an outer iteration. The outer iteration is the nonlinear Newton method. If the Jacobian is solved using an iterative method, then the convergence tolerance must be specified. For the first few Newton steps, the nonlinear residual in (4.2) is quite large. Therefore, a large residual reduction in the linear iteration is needed for an accurate Δx (where x is the vector of unknowns). After the Newton iteration reaches a certain accuracy, the nonlinear residual becomes smaller. The update Δx only affects the last few digits of the final solution. As a result, the relative residual reduction requirement for the solution of the Jacobian can be lowered.

Although at first sight this seems to be contrary to the usual approach suggested in, for example, [18], where a loose tolerance is used at the initial stages of the Newton iteration, and a tighter tolerance is used at the final stages, this can be understood as follows. An inner iteration convergence tolerance of reducing the l_2 residual by 10^{-3} is sufficient, at least in our experience, to ensure quadratic convergence of the Newton iteration, as convergence is approached. Therefore, this tolerance is to be considered quite tight. However, we have found that a loose tolerance for the initial Newton iterations, which are far away from the solution, often results in divergence of the Newton iteration. This problem can sometimes be cured by using an even tighter inner iteration tolerance for the initial Newton iterations. A similar effect has been observed when using Newton iteration for the incompressible Navier–Stokes equations [11]. In the fluid dynamics case, it can be argued that a loose tolerance will result in large mass balance errors (the mass balance equation is linear for incompressible flow), and hence makes the iteration unstable. We suspect that in the device simulation case, the electric potential equation must be solved quite accurately, or else the iteration will tend to diverge.

In this work, a dynamic switch of the linear convergence criteria is implemented in the linear solver. Initially, the convergence requirement is that the initial l_2 residual be reduced by 10^{-6}. After the *nonlinear* residual is reduced below 10^{-3} (compared to the initial *nonlinear* residual), the linear residual reduction switches to 10^{-3}. This dynamic switch can generally save 10–15% of the CPU time.

4. Block data structure and scaling. Since device simulation involves a system of coupled partial differential equations, it is natural to exploit the block structure of the Jacobian in order to obtain a good preconditioner. Two methods that use this concept are the ABF [4] and the modified singular perturbation (MSP) [41].

For the purposes of illustration, assume that the device model in question is a drift-diffusion model having three coupled partial differential equations. If the Jacobian equations are ordered so that all the electric potential equations are grouped first, followed by the electron conservation equations, and then the hole conservation equations, and the unknowns are ordered so that all the electric potentials are first, then the electron concentrations, and finally the hole concentrations, then the Jacobian matrix can be partitioned as

$$J = \begin{bmatrix} J_{\phi\phi} & J_{\phi n} & J_{\phi p} \\ J_{n\phi} & J_{nn} & J_{np} \\ J_{p\phi} & J_{pn} & J_{pp} \end{bmatrix} \tag{4.1}$$

where J_{ij}, $i, j = \phi, n, p$ denotes the block of derivatives of the equation for electric potential, electron conservation, or hole conservation, with respect to the electric potential, electron concentration, or hole concentration. Then the ABF preconditioner is

$$D^{-1} = \begin{bmatrix} D_{\phi\phi} & D_{\phi n} & D_{\phi p} \\ D_{n\phi} & D_{nn} & D_{np} \\ D_{p\phi} & D_{pn} & D_{pp} \end{bmatrix}^{-1}$$

where D_{ij} is the diagonal matrix of J_{ij}. More recently, the approximate block elimination (ABE) has been proposed which uses an incomplete 3×3 block factorization of the original block structured Jacobian [40].

In this paper, another kind of block structure of the Jacobian matrix is used. The unknown variables at each physical grid node are grouped together to form an $m \times m$ block matrix, where m is the number of grid nodes. In general, the diagonal block elements of this block Jacobian may have different sizes since the number of unknowns for each node varies. This is due to the fact that different models are used in different device materials and at the device contacts. The motivation for explicitly considering the block structure is the following.

All the nonzero blocks are regarded as dense. Consequently, we need only to specify the sparsity pattern for the nonzero blocks. As a result, the integer space needed for specifying the structure of the block sparse matrix is an order of magnitude less compared to the original scalar sparse matrix (assuming that the average number of unknowns per node is at least three). This block structure will be more attractive when the semiconductor model becomes more sophisticated, since typically, more detailed physics requires more equations per node. Our study [9] indicates that one of the basic operations in iterative methods, namely matrix vector multiplication, takes less time if a block data structure is used compared to the scalar case. It is clear that the cache hit ratio will be higher in the block case.

More importantly, the new block structure can allow us to reduce the strong coupling between unknowns associated with a single grid node before the iterative process and other preconditioning steps begin. If we order the unknowns and equations so that all equations and unknowns associated with a node are ordered consecutively, then

$$J = \begin{bmatrix} J_{11} & J_{12} & \cdots & J_{1n} \\ J_{21} & J_{22} & \cdots & J_{2n} \\ & & \ddots & \\ J_{n1} & J_{n2} & \cdots & J_{nn} \end{bmatrix}$$

where J_{ii} are typically $1 \times 1, 2 \times 2, \ldots, 7 \times 7$ block matrices. For drift-diffusion models, the number of unknowns in each block may vary. Usually, there are three unknowns (ψ, n, p), but if the computational domain contains an oxide, then only the electric potential equation

TABLE 4.1
Block scaling at ground bias point, where N is the number of unknowns.

Test (N)	Methods applied	Total linear iterations	Total linear CPU time
MOSA	ABF	1723	1697.67
(15583)	Two step	73	465.04
BJT	ABF	Not converged	
(13758)	Two step	117	523.54

is solved (with ψ as an unknown) in the oxide region, since it is assumed that there are no charge carriers in an oxide. Some of the examples in this work contain oxides. In addition, at contacts, it is sometimes convenient to impose an additional boundary condition in terms of the total current. This total current is added to the list of unknowns at a contact node. However, in this paper, none of the examples have this additional electric current unknown. The maximum size of J_{ii} is then usually four, with minimum size being 1×1. Recall that at each Newton step we need to solve the equation

$$J\Delta x = -r \tag{4.2}$$

where J is the Jacobian, Δx is the vector of updates, and r is the residual vector.

First, a block scaling is applied to equation (4.2). The scaling matrix

$$S = \begin{bmatrix} J_{11}^{-1} & 0 & \cdots & 0 \\ 0 & J_{22}^{-1} & \cdots & 0 \\ & & \ddots & \\ 0 & 0 & \cdots & J_{nn}^{-1} \end{bmatrix}$$

is multiplied on both sides of equation (4.2). The preconditioned Krylov space method is then applied to the scaled matrix equation

$$SJ\Delta x = Sr.$$

Note that this scaling step is equivalent to applying the ABF preconditioner if a permutation is applied. The difference here is that a further preconditioning process will be applied to the scaled system. The improvement in using a block scaling followed by further preconditioning is significant compared to using block scaling alone.

Table 4.1 shows the difference in performance if a further preconditioning step is taken. Two Jacobian matrices were generated at intermediate Newton iterations from MOSA and BJT. The two-step preconditioner uses a block scaling followed by the best preconditioned BI-CGSTAB method which will be described in more detail in following sections. Table 4.1 shows the total number of solver iterations for all Newton iterations, as well as the total number of unknowns N. Clearly, block scaling (ABF) alone is not sufficient for a robust technique.

5. Preconditioning issues. Preconditioned Krylov subspace methods are the standard iterative methods for device simulation. However, much of the past research has concentrated on the behavior of different acceleration methods [1], [5], [7], [22], [25], [28], [29], [34]. Many authors have observed that GMRES, CGS, and Bi-CGSTAB are the relatively robust choices among the many. Both CGS and Bi-CGSTAB are BCG-type methods, but are now more widely used than the original BCG algorithm. Bi-CGSTAB seems to be a good choice

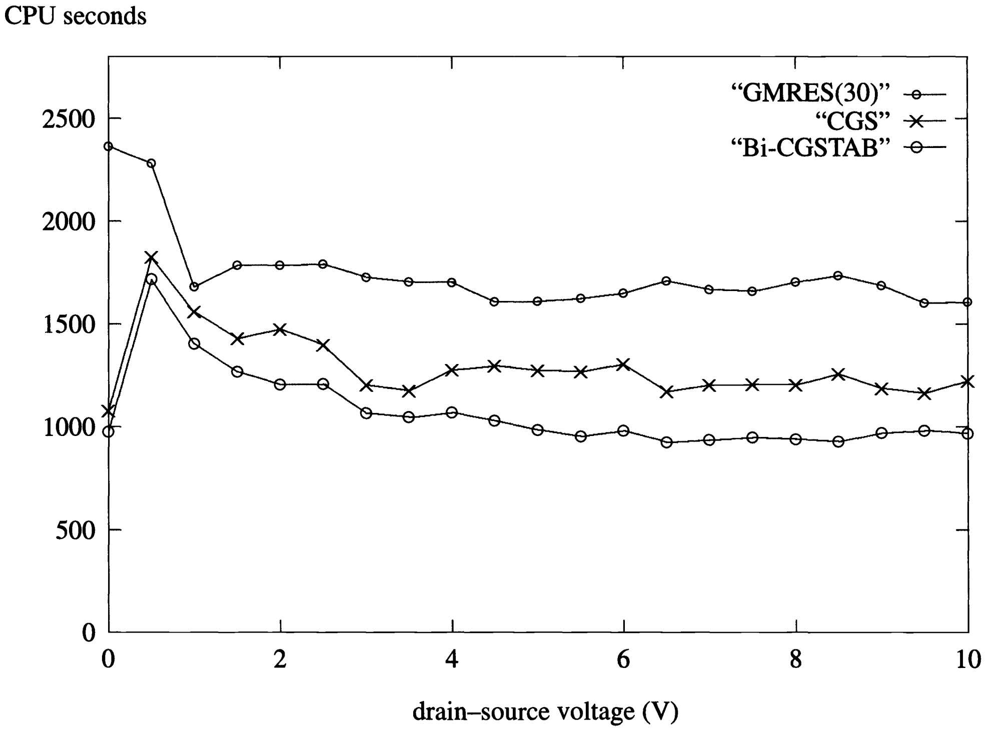

FIG. 5.1. *Comparison of various acceleration methods* (5.1).

from among the BCG methods, since convergence is rapid and less prone to the wild residual oscillations of CGS. QMR [26] is a newly developed Krylov subspace method which has very smooth convergence behavior. Thusfar, we have carried out only limited testing using the QMR method, and it is too soon to draw firm conclusions about the performance of QMR compared to Bi-CGSTAB or GMRES.

In particular, we found that Bi-CGSTAB is generally the most robust method. For example, Fig. 5.1 shows the total CPU times for the MOSB problem with an $ILU(1)$ preconditioner at various values of the drain-source voltage. Clearly, Bi-CGSTAB is the most efficient acceleration method. Tests for other problems showed a similar trend. Consequently, all computations will be carried out using Bi-CGSTAB for the remainder of this paper.

For completeness, we give the preconditioned Bi-CGSTAB algorithm below.

(LU represents the incomplete factorization of matrix A, and $\overline{Aq}$ is a vector.)

$$\begin{array}{rcl}
r_0 & = & b - Ax_0 \\
\hat{\omega}_0 & = & \beta = \alpha_0 = 1 \\
\overline{Aq}_0 & = & q_0 = 0 \\
\textbf{For} & & i = 1, 2, \ldots \\
 & & \hat{\beta} = (r_0, r_{i-1}); \quad \omega_i = (\hat{\beta}/\beta)(\bar{\omega}_{i-1}/\alpha_{i-1}) \\
 & & \beta = \hat{\beta} \\
 & & q_i = r_{i-1} + \omega_i(q_{i-1} - \alpha_{i-1}\overline{Aq}_{i-1}) \\
 & & \bar{q}_i = (LU)^{-1} q_i
\end{array}$$

```
        $\overline{Aq}_i = A\bar{q}_i$
        $\hat{\omega}_i = \hat{\beta}/(r_0, \overline{Aq_i})$
        $s = r_{i-1} - \hat{\omega}_i \overline{Aq}_i$
        $\bar{s} = (LU)^{-1}s$
        $t = A\bar{s}$
        $\alpha_i = (L^{-1}t, L^{-1}s)/(L^{-1}t, L^{-1}t)$
        $x_i = x_{i-1} + \hat{\omega}\bar{q}_i + \alpha_i \bar{s}$
        if $x_i$ accurate enough, then quit
        $r_i = s - \alpha_i t$
    End
```

In this paper, we will concentrate on the issues related to incomplete LU preconditioners, since these are regarded as among the most robust for semiconductor simulations [5], [29].

Before we pursue the different issues in constructing a good preconditioner, a block graph representation of the Jacobian is useful. If we view the grid node v_i as the node of a graph representing the block sparse matrix and map the nonzero block element J_{ij} to an edge connecting the two nodes v_i, v_j, the block sparse Jacobian

$$J = \begin{bmatrix} J_{11} & J_{12} & \cdots & J_{1n} \\ J_{21} & J_{22} & \cdots & J_{2n} \\ & & \ddots & \\ J_{n1} & J_{n2} & \cdots & J_{nn} \end{bmatrix} \tag{5.1}$$

can be represented by a graph form. During the factorization process, new nonzero block elements will be introduced. A notion of "fill level" can be introduced to each position of the block matrix. We initially define

$$\text{level}_{ij}^{(0)} = \begin{cases} 0, & \text{if } J_{ij} \neq 0, \\ \infty, & \text{otherwise.} \end{cases} \tag{5.2}$$

The nonzero block elements then have a fill level 0. As the elimination proceeds, fill will be introduced. At the kth step of the elimination, the fill levels are given by [16]

$$\text{level}_{ij}^{(k)} := \min\left(\text{level}_{ik}^{(k-1)} + \text{level}_{kj}^{(k-1)} + 1, \text{level}_{ij}^{(k-1)}\right).$$

In other words, the fill level of a fill is the length of the shortest path between nodes v_i and v_j through the nodes eliminated before v_i and v_j [27]. The fill level is commonly used to decide the sparsity pattern of an ILU factorization.

5.1. Ordering. The matrix ordering affects the computational efficiency of a matrix solver in many ways. For direct methods, a good ordering technique is essential in order to minimize the amount of fill. In parallel (or vector) processing, ordering again plays a crucial rule. A number of studies have examined the effect of matrix ordering on the quality of preconditioners for iterative methods based on an incomplete factorization [8], [14], [16], [23], [24], [33], [21]. In [14], [16], and [17] evidence was presented to demonstrate that matrix ordering can have a profound effect on the quality of preconditioners. A heuristic method was developed that was shown to produce good matrix ordering. Unfortunately, some of the techniques for an effective ordering developed in [14], [16], and [17] can only be applied to scalar sparse matrices. The ordering generated by these new algorithms may destroy the block pattern we employed here. However, the graph-based orderings (where we view each block of the Jacobian as a node in the graph) can handle the block matrix (5.1) naturally.

The algorithm for generating a scalar ILU preconditioner can be directly extended to the block case. The block incomplete LU factorization can then be interpreted as a graph elimination process [27]. The graph representation of (5.1) is in fact the graph of the grid used to discretize the device. Note that most of the grid generation algorithms in semiconductor simulation involve some kind of refinement process. Consequently, the ordering of the grid nodes can be very scattered. In addition, after the refinement the resulting grid is usually unstructured. Consequently, there is no obvious natural way to order the grid nodes. The reverse Cuthill–McKee (RCM) ordering [27] originally was proposed as a good technique for reducing the profile of a sparse matrix. The basic idea of this ordering algorithm is to construct the level set from a starting node of the graph representing the sparse matrix. The reverse order of the level set will produce a small profile. We can also view the RCM ordering as a generalized natural ordering of an unstructured grid. For a rectangular grid, RCM ordering is the diagonal ordering of the mesh, if a corner node is chosen as the starting node. This ordering algorithm can be generalized to the block Jacobian case, in an obvious way.

RCM ordering is known as an effective ordering [23], [24] for ILU preconditioning in many applications. The standard RCM ordering can produce a poor ordering (for an iterative solver) if the problem is anisotropic. A revised version for a weighted graph can alleviate this problem [12]. A comparison of an ILU method which uses the original ordering and the RCM ordering was carried out for MOSA test set. Figure 5.2 gives the total CPU time required to obtain the steady state solution for various values of the drain-source voltage for MOSA, using the original ordering (ORI), RCM ordering (RCM), and, for comparison, the time for a direct solver (SPARSPAK) [10] is also shown. Here an ILU(0) preconditioner is used with Bi-CGSTAB acceleration. On average, RCM ordering reduces the total CPU time by about 30–40% compared to the original ordering. Consequently, in the following, RCM ordering will be used unless otherwise noted.

5.2. Sparsity pattern. The key step during the incomplete LU factorization process is to determine the sparsity pattern of the L and U. To find the optimal sparsity pattern for the ILU factorization is a much more difficult task than the solution of the Jacobian itself. Typically, some simple heuristics are used to determine if a fill element will be discarded. The common strategies are the following.

1. By a drop tolerance, $ILU(\varepsilon)$. A drop tolerance method discards numerically "small" values of fills. There are many possible drop tolerance criteria [16]. Let $a_{ij}^{(0)}$ be the (scalar) entry of the original Jacobian matrix and $a_{ij}^{(k)}$ be the element of the submatrix that remains after $(k-1)$ steps of the incomplete factorization. A possible drop tolerance method is

$$|a_{ij}^{(k)}| < \varepsilon\sqrt{|a_{ii}^{(0)}a_{jj}^{(0)}|}. \tag{5.3}$$

For symmetric systems, this is the same criteria as in [42]. Note that since the Jacobian matrix is not symmetric positive definite, we do not use the diagonal modification suggested in [30]. Even for symmetric positive definite problems, the diagonal modification usually results in a slow method [20].

It is probably not a good idea to extend the drop tolerance approach to the block case. The elements in each of the small block matrices of the Jacobian in device simulation often vary by many orders of magnitude ($10^{10} - 10^{16}$). One large entry in a block element may result

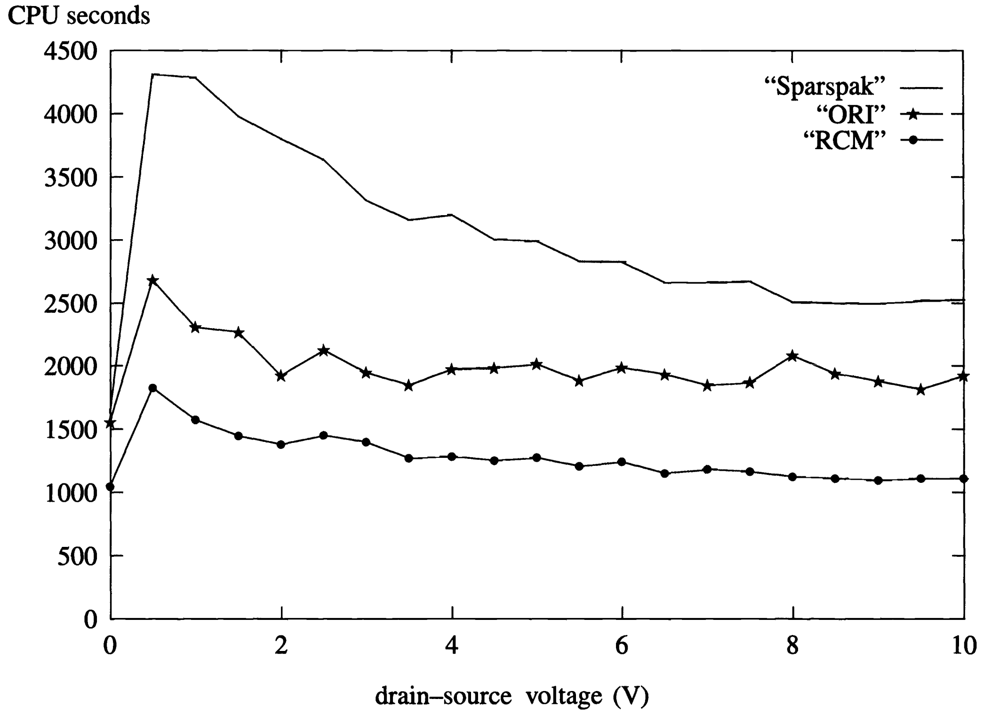

FIG. 5.2. *Comparison of direct solver (Sparspak) and iterative solver, RCM ordering (RCM) and ORI ordering (ORI). ILU(0) preconditioner and Bi-CGSTAB acceleration were used in the iterative solver.*

in keeping the entire fill block, which may not be desirable. Consequently, the drop tolerance method will be applied to each individual element in the Jacobian matrix in the following. A similar approach was used in [42].

In general, we have found that a drop tolerance incomplete factorization is not an effective technique for semiconductor device simulations. The characteristics of the Jacobian in this particular application cause problems for a drop tolerance approach. As we mentioned earlier, the elements in the Jacobian matrix can differ by a factor of 10^{14}. Several variables with very different scales coexist in the same submatrix. A small element may not imply insignificant influence on the solution. This effect has also been seen when applying a drop tolerance incomplete factorization to incompressible Navier–Stokes problems [13]. In this case, the drop tolerance worked well for small Reynolds numbers, but was very poor for high Reynolds numbers. This indicates that at high Reynolds numbers, the fluid flow problem is inherently poorly scaled, and so it becomes difficult to determine appropriate drop tolerance criteria. We believe that a similar effect occurs in device simulation. Of course, since the Jacobian itself is very ill conditioned, we can expect that dropping terms in an incomplete factorization (whatever drop strategy is used) may cause large changes in the solution, and hence result in a poor preconditioner.

The drop tolerance method (applied with criteria (5.3) to each element of the Jacobian) was compared with use of a two-stage method (to be described in the following section). Table 5.1 shows the total CPU time required for the matrix solve, the number of iterations, and the storage required (for a single value of the source-drain voltage), for various values of the drop tolerance ε. Both incomplete factorization and preconditioning cost are increasing as ε decreases.

TABLE 5.1

Drop tolerance compared to two step. Device MOSFET is tested at one representative bias point from MOSB test set. Device BJT is tested at the ground state.

Test (N)	Methods applied	Total linear iterations	Total linear CPU time	Kilo bytes
MOSB	Two step	131	820.52	8702
	$\varepsilon = 0.5$	1099	3195.84	5281
(15583)	$\varepsilon = 0.1$	999	3638.57	5838
	$\varepsilon = 0.01$	570	3951.03	9130
	$\varepsilon = 0.001$	391	6273.49	14273
BJT	Two step	117	523.54	7897
	$\varepsilon = 0.5$	1439	3700.06	4280
(13758)	$\varepsilon = 0.1$	1226	3320.64	4580
	$\varepsilon = 0.01$	1029	3505.31	6177
	$\varepsilon = 0.001$	579	2980.67	8867

Table 5.1 indicates that decreasing ε further for the MOSB problem will result in an increase in total CPU cost due to the expensive incomplete factorization stage. For problem BJT, the total CPU cost is still decreasing as ε decreases, but the final entry in Table 5.1 ($\varepsilon = .001$) indicates that the storage required for the drop tolerance incomplete factorization is larger than the storage required for the two-step method, and the drop tolerance approach is more than five times slower than the two-step method.

In general, the drop tolerance preconditioner is between six and ten times slower than the two-step preconditioner. It is clear that, for the same amount of storage, the two-step method is far superior to the drop tolerance approach.

2. By fill level, $ILU(\ell)$. The fill block $J_{ij}^{(k)}$ at the kth step of the factorization will be discarded if

$$\text{level}_{ij}^{(k)} > \ell.$$

It is clear that the larger the level ℓ the better the preconditioner. When $\ell = n$, a complete factorization is obtained. However, large values of ℓ will be too expensive in terms of storage for 3D problems. Our experiments indicate that the performance (in terms of total CPU time) stops improving after $\ell = 2$ even for 2D problems.

For the level approach, only one symbolic factorization is needed for the entire simulation as long as the grid does not change. The sparsity patterns of the incomplete factorization are the same for different Newton steps or timesteps. As a result, the numerical and symbolic factorization can be separated to make the factorization process more efficient. This contrasts with the drop tolerance incomplete factorization, since a different sparsity pattern will result when the Jacobian changes. Therefore, the incomplete factorization process is more expensive for a drop tolerance preconditioner. The level approach is not only easy to implement, it is even more efficient for the block Jacobian case. Indeed, the symbolic factorization phase in this case costs only a very small fraction of symbolic factorization cost if the Jacobian was not considered as a block matrix.

Table 5.2 shows the total CPU times for the MOSA test set at various levels of fill of the ILU. The improvement from level zero to level one is significant. However, the improvement in going to levels higher than one is marginal. We also list a detailed record of a typical simulation in Fig. 5.3 (for a single value of the source-drain voltage). We can see that the number of iterations is monotone decreasing as the level increases. However, the amount of fill for the preconditioner becomes larger as the level of fill increases. Therefore, the higher cost for each iteration will eventually outweigh the reduction in number of iterations. Note

TABLE 5.2
Comparison of levels 0, 1, 2, 3, *and* 4, *MOSA test.*

Method	Newton iter #	Linear iter #	Total CPU linear time	Total CPU time	Kilo bytes
Level(0)	13	178	701.33	898.18	6648
Level(1)	12	111	510.02	681.79	7391
Level(2)	12	85	485.42	670.90	8702
Level(3)	12	83	558.10	729.52	10116
Level(4)	12	70	580.68	768.87	11498
Sparspak	12	12	1658.10	1852.57	20234

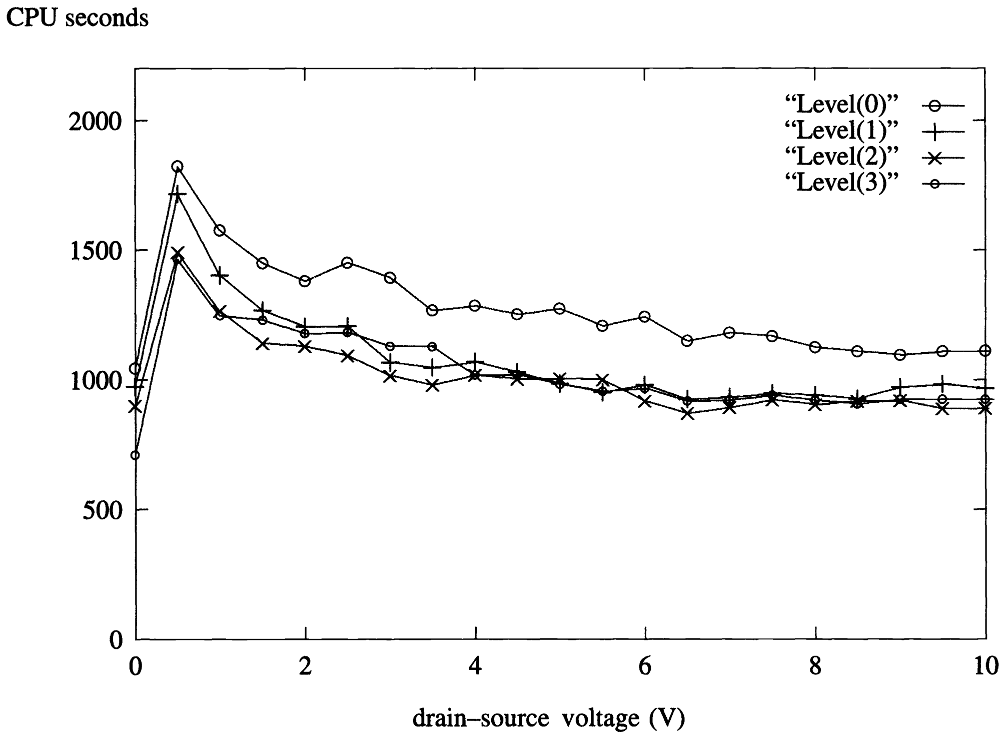

FIG. 5.3. *Comparison of levels* 0, 1, 2, *and* 3 *using one-step preconditioner in Bi-CGSTAB acceleration and RCM ordering, MOSA test.*

from Table 5.2 the level(0) test requires one more Newton iteration than other tests. This is because the Jacobian iterations are not precisely the same for all the tests, due to the finite convergence tolerance for the inner iteration. In the case of the level(0) tests, this results in an extra Newton iteration before the nonlinear convergence test is satisfied.

3. **By the combination of both,** $ILU(\ell, \varepsilon)$. A fill entry is dropped if

$$\text{level}^{(k)}_{ij} > \ell \quad \text{or} \quad |J_{ij}| < \varepsilon.$$

This is a useful heuristic for many applications [16]. However, since the drop tolerance approach by itself does not appear to be very useful in this application, we will not pursue this method further.

5.3. Two-step preconditioner. As we can see from the experiments of the previous sections, when the accuracy of the factorization (by using a higher level fill or a smaller drop tolerance) improves, the number of iterations required for convergence decreases. However, the improvement in the number of iterations will not compensate for the higher cost of each iteration after a certain point. The best combination of the strategies thus far is to use RCM ordering plus ILU(1) or ILU(2). For a 3D problem, the ILU(2) approach may require too much storage. In the following, we will use an ILU(1) factorization unless otherwise noted.

Let L_J and U_J be the incomplete factorization of the Jacobian matrix J. The techniques used in the previous sections attempt to reduce the difference

$$\|J - L_J U_J\|.$$

The basic assumption of this method is that if this difference is small, then the solution y of the preconditioning step

$$L_J U_J y = p \tag{5.4}$$

will be close to the solution of

$$Jx = p.$$

Alternatively, we can use the following criteria for producing an effective preconditioner. Denote M_j a preconditioner of J and y the solution of

$$M_j y = p.$$

A better preconditioner M_j means a smaller residual of

$$r = Jy - p. \tag{5.5}$$

When $r = 0$, a perfect preconditioner is obtained. Therefore a refined preconditioner or a two-step preconditioner can be developed as follows.

For the purposes of illustration, assume that the variables are ordered as in (4.1). After we solve the equation (5.4), the residual r in (5.5) is calculated. Let $J_{\phi\phi}$ be the diagonal block element for the potential variable in (4.1) and r_ϕ be the part of residual in (5.5) corresponding to the electric potential equations. The equation

$$J_{\phi\phi} \Delta y_\phi = r_\phi \tag{5.6}$$

is solved. This problem is much smaller and better conditioned. Let $\Delta y = [\Delta y_\phi, 0, 0]^T$, i.e., only the potential variables become updated. Then, the refined solution $\tilde{y} = y - \Delta y$ is used as the solution for the new two-step preconditioner M_t such that

$$M_t \tilde{y} = p.$$

It is easy to see that the new residual

$$\tilde{r} = J\tilde{y} - p$$

will have

$$\tilde{r}_\phi = 0.$$

* Two-step preconditioner with ILU(1).

$^+$ Drop tolerance ILU(ε), where ε = drop tolerance.

In other words, the two-step preconditioner has more accurate electric potential solution. Consider a case where the drift flow of holes and electrons dominates the diffusion flux. In this case, as the mesh size is reduced, the electric potential derivatives in the Jacobian will dominate the hole and electron concentration derivatives. Essentially, this is because in this situation, the electric potential is an elliptic-type variable, while the hole and electron concentrations are hyperbolic-type variables.

For the range of 2D problems we have tested so far, we have found that use of a direct solve of equation (5.6) is quite efficient. In other words, $J_{\phi\phi}$ is factored once, and equation (5.6) is solved by a forward and back solve each iteration. We use minimum degree ordering [10] for the initial complete factorization of $J_{\phi\phi}$ (this system is much smaller than the original Jacobian). Of course, for larger 3D problems, it may be more efficient to use an iterative method to solve equation (5.6).

Note that the two-step method is similar to the combinative technique used in [6]. Tables 5.3 and 5.4 present some detailed comparisons between the one-step and two-step precondi-

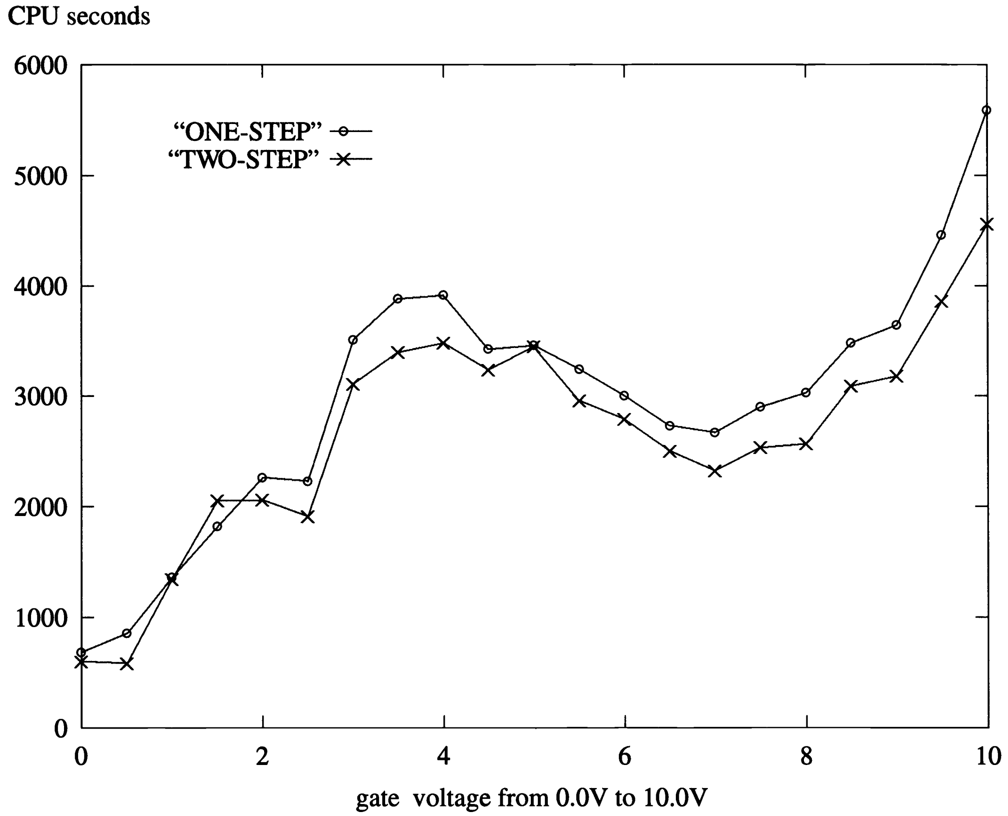

FIG. 5.4. *Comparison of one-step and two-step preconditioners.*

tioners for MOSA, MOSB, and BJT. We can see that the total number of linear iterations is reduced significantly with the two-step preconditioner. Figure 5.4 lists the CPU time comparison for a complete test run for test MOSA. The ILU(1) with Bi-CGSTAB acceleration is used for both one-step and two-step preconditioners. Block RCM ordering is applied. Of course, the new preconditioner is more expensive than the single step preconditioner. However, the larger reduction in the number of iterations compensates for the extra cost in each iteration.

In Table 5.4, we present a detailed performance comparison between many different techniques. (Note that the CPU clock is only accurate to within 5%.) It is clear that a careful implementation of the preconditioned Krylov space method is very important for performance. Although some extra memory is needed for the small system (5.6) (see the comparison in Table 5.3), the total memory requirement for the two-step preconditioner is still competitive with a direct method.

6. Conclusion. We emphasize that these conclusions are based on many different test cases, with widely varying bias voltages. In the course of our tests, we have solved several thousand device simulation Jacobians. Consequently, we are concerned with the best overall performance, not just isolated cases.

In agreement with previous work, we have found Bi-CGSTAB acceleration to be generally superior to either CGS or GMRES methods for device simulation Jacobians.

A generally robust iterative method for a wide range of tests used

- block scaling of the Jacobian and right-hand side,

- a block RCM ordering of the unknowns,
- block ILU preconditioning (level(1) or level(2) appeared to be a good choice),
- Bi-CGSTAB acceleration.

We found that it was important to treat the Jacobian as a block system, i.e., all the unknowns associated with a node remain tightly coupled together during the ordering and preconditioning steps. A similar effect has been observed in petroleum reservoir simulation [38]. In particular, if block scaling is not used, we have found that convergence is problematic in many cases.

Use of a two-step preconditioner which uses the usual block ILU as a first stage, followed by a more accurate treatment of the electric potential terms was slightly faster (in terms of CPU time) than the block ILU factorization by itself. More importantly, the two-step preconditioner typically reduced the number of iterations required for a solve by about one-half. Consequently, if we measure robustness by the number of iterations required, the two-stage preconditioner is more robust than the block ILU factorization by itself. If the matrix is very ill conditioned, the two-step preconditioner is more reliable than the one-step technique.

Tests using a drop tolerance method based on the scalar values of the Jacobian matrix indicated that this approach was not very robust. This is likely due to the large variation in the magnitudes of the Jacobian entries typical of device simulation. In this case, it becomes difficult to define *small* in terms of fill entry size in a meaningful way. A similar effect was observed for high Reynolds number Navier–Stokes flows [13]. However, it may be that a different choice for drop tolerance criteria would produce better results.

A MULTIGRID PRECONDITIONER FOR THE SEMICONDUCTOR EQUATIONS*

JUAN C. MEZA† AND RAY S. TUMINARO‡

Abstract. A multigrid preconditioned conjugate gradient algorithm is introduced into a semiconductor device modeling code DANCIR. This code simulates a wide variety of semiconductor devices by numerically solving the drift-diffusion equations. The most time-consuming aspect of the simulation is the solution of three linear systems within each iteration of the Gummel method. The original version of DANCIR uses a conjugate gradient iteration preconditioned by an incomplete Cholesky factorization. In this paper, we consider the replacement of the Cholesky preconditioner by a multigrid preconditioner. To adapt the multigrid method to the drift-diffusion equations, interpolation, projection, and coarse grid discretization operators need to be developed. These operators must take into account a number of physical aspects that are present in typical devices: wide-scale variation in the partial differential equation (PDE) coefficients, small-scale phenomena such as contact points, and an oxide layer. Additionally, suitable relaxation procedures must be designed that give good smoothing numbers in the presence of anisotropic behavior. The resulting method is compared with the Cholesky preconditioner on a variety of devices in terms of iterations, storage, and run time.

Key words. multigrid, semiconductors, drift-diffusion

1. Introduction.

Currently most integrated circuits are designed in a "trial and error" fashion. That is, prototypes are built and improved via experimentation and testing. In the near future it may be possible to significantly reduce the cost of building new devices by using computer simulations to shorten the design cycle. To accurately perform these complex simulations in three dimensions, however, new algorithms and high performance computers are necessary.

In this paper we discuss the use of multigrid preconditioning in conjunction with a conjugate gradient algorithm inside a semiconductor device modeling code DANCIR [7]. DANCIR is a three-dimensional semiconductor device simulator capable of computing the solution of the steady-state, drift-diffusion equations. The solution of the drift-diffusion equations involves the solution of a large nonlinear set of equations that arise from the spatial discretization of the drift-diffusion equations on a rectangular grid. These nonlinear equations are solved using Gummel's method, which requires three symmetric linear systems to be solved within each Gummel iteration. It is the solution of these linear systems that comprises the dominant computational cost of a simulation. The original version of DANCIR uses an incomplete Cholesky preconditioned conjugate gradient algorithm to solve these linear systems. Unfortunately, this algorithm has a number of disadvantages: (1) it can take many iterations to converge or it may not converge at all in some cases, (2) it can require a significant amount of computing time, and (3) it is not very parallelizable.

In this study we consider an alternate solution method based on a multigrid preconditioner. The multigrid method uses iterations on a hierarchy of grids to accelerate the convergence on the finest grid. The method requires interpolation, projection, and discretization operators for the different grids to be defined. Developing these operators in the context of the drift-diffusion equations requires some care due to the presence of greatly varying physical phenomena including wide-scale variation in PDE coefficients and small-scale phenomena such as contact

points. In both cases, the development of operator-dependent interpolation and projection is essential for improving the performance. Further, the presence of certain device characteristics such as oxide layers requires some care to ensure that the different operators and the grid hierarchy adequately approximate the PDE on all levels. Finally, the presence of a severely stretched grid gives rise to anisotropic phenomena that requires a suitable relaxation procedure.

The paper is organized as follows. Section 2 describes the drift-diffusion equations that are most commonly used to model semiconductor devices. We also present the numerical methods currently used in a particular simulation code developed at Sandia National Laboratories. In §3 we describe the multigrid preconditioner as well as some of the choices necessary to implement this algorithm for the drift-diffusion equations. In §4, the resulting method is compared with the incomplete Cholesky preconditioner on a variety of devices in terms of iterations, storage, and run time. We conclude in §5 with a summary of our results.

2. The drift-diffusion equations. The drift-diffusion model for semiconductor device modeling consists of a set of three coupled, nonlinear PDEs: the potential equation plus two continuity equations, one each for the electron and hole current densities. For a complete derivation of the equations the reader can consult a variety of references, for example, [9], [11], [13].

The potential or Poisson equation is given by

$$\epsilon \nabla \cdot E = -\epsilon \nabla^2 \psi = \rho, \tag{2.1}$$

where ϵ is the scalar permittivity of the semiconductor, ψ is the electric potential, and $E = -\nabla \psi$ is the electric field. The total electric charge density ρ is given by

$$\rho = q(p - n + N_D - N_A), \tag{2.2}$$

where q is the elementary charge, n is the density of free electrons, p is the density of holes, N_D is the density of donor impurities, and N_A is the density of acceptors.

The continuity equations for the electron and hole currents can be stated as

$$\frac{\partial n}{\partial t} - \nabla \cdot (\mu_n n E + D_n \nabla n) - R = 0, \tag{2.3}$$

$$\frac{\partial p}{\partial t} + \nabla \cdot (\mu_p p E - D_p \nabla p) - R = 0, \tag{2.4}$$

where μ_n and μ_p are the electron and hole mobilities, respectively, D_n and D_p are the diffusion coefficients, and R is a term that accounts for the recombination and generation of electrons and holes. The mobilities and the recombination-generation term are functions of various physical and semi-empirical parameters and are usually modeled through a variety of sophisticated methods (see, for example, [11]).

2.1. Scaling of variables. The wide range in magnitude of both the dependent and independent variables creates difficulties in the numerical solution process. Independent variables such as the concentrations of impurity dopings N_D and N_A range from 10^{13} to 10^{19} carriers per cubic centimeter. Dependent variables such as the carrier densities n and p can range from 10^3 to 10^{19} carriers per cubic centimeter. The difficulties associated with the wide range in the magnitude of the dependent variables can be circumvented to a certain extent by employing different variables. However it has been noted by Polak [12] that changing variables amounts to trading high variability in the dependent variables for increased nonlinearity in the equations.

In the DANCIR code, the carrier concentrations are scaled by using the Slotboom variables u and v:

$$n = n_{ie} \exp\left(\frac{q\psi}{kT}\right) u, \tag{2.5}$$

$$p = n_{ie} \exp\left(\frac{-q\psi}{kT}\right) v, \tag{2.6}$$

where n_{ie} is the effective intrinsic carrier concentration, k is the Boltzmann constant, and T is the bulk material temperature.

One of the advantages of using the Slotboom variables is that the current continuity equations assume the form of Poisson equations facilitating the numerical solution process. Using the Slotboom scaling the current densities can be written as

$$J_n = kT\mu_n n_{ie} \exp(q\psi/kT)\nabla u, \tag{2.7}$$

$$J_p = -kT\mu_p n_{ie} \exp(-q\psi/kT)\nabla v. \tag{2.8}$$

The resulting steady-state, drift-diffusion equations can then be expressed as

$$f_1(\psi, u, v) = \epsilon\nabla^2\psi + q\left[n_{ie}e^{\frac{-q\psi}{kT}} v - n_{ie}e^{\frac{q\psi}{kT}} u + N_D - N_A\right] = 0, \tag{2.9}$$

$$f_2(\psi, u, v) = \nabla\cdot\left[kT\mu_n n_{ie}e^{\frac{q\psi}{kT}}\nabla u\right] + R = 0, \tag{2.10}$$

$$f_3(\psi, u, v) = \nabla\cdot\left[kT\mu_p n_{ie}e^{\frac{-q\psi}{kT}}\nabla v\right] + R = 0. \tag{2.11}$$

2.2. Nonlinear equations. If the functions f_1, f_2, and f_3 are defined by equations (2.9)–(2.11) then the nonlinear system of equations arising from the spatial discretization of the drift-diffusion equations can be written more compactly as $F(\psi, u, v) = [f_1, f_2, f_3]^T = 0$. The DANCIR code uses Gummel's method [6] (also known as nonlinear block Gauss–Seidel) to solve this nonlinear equation. One Gummel iteration consists of solving f_2 for u, f_3 for v, and then f_1 for ψ. Gummel's method has the advantage of only having to solve three linear systems at each iteration. The disadvantage is that convergence can be quite slow in certain circumstances, for example in high voltage situations.

In practice, the solution of the steady-state, drift-diffusion equations is accomplished by solving a series of continuation steps where each continuation step is in turn a steady-state problem. The initial steady-state or equilibrium problem solved is that of the device with no external voltages applied. The potential at the contacts is then incremented until the desired voltage is reached at the contacts. The initial estimate for the potential is computed by solving a nonlinear potential equation. The DANCIR code uses a Newton method for this calculation because the Jacobian is symmetric in this special case, thereby not incurring any extra expense for storage over the Gummel iteration.

2.3. Linear equations. Within each Gummel iteration, three linear systems of equations must be solved. As we mentioned above, the use of the Slotboom variables transforms the continuity equations for the electron and hole currents into a set of self-adjoint PDEs. The linear systems resulting from the discretization are therefore symmetric and positive definite. The particular method used in the original version of the DANCIR code is a preconditioned

conjugate gradient method with an incomplete Cholesky factorization used as the preconditioner [4]. The solution of these linear systems usually constitutes the dominant amount of work, so any improvement in this part of the code would have a significant effect on the overall performance.

In the remainder of this paper, we discuss the replacement of this preconditioner by a multigrid preconditioner and make comparisons between the two preconditioners.

3. Multigrid preconditioner. The multigrid algorithm is a fast and efficient method for solving the systems of equations that arise from many PDE applications. We give only a brief sketch of one type of multigrid algorithm. Detailed descriptions of more general multigrid algorithms can be found in [3], [5].

One iteration of a simple multigrid "V" cycle consists of smoothing the error using a relaxation technique (such as Gauss–Seidel), "solving" an approximation to the smooth error equation on a coarse grid, interpolating the error correction to the fine grid, and finally adding the error correction into the approximation (and perhaps performing some additional relaxation steps). An important aspect of the multigrid method is that the coarse grid solution can be approximated by recursively using the multigrid idea. That is, on the coarse grid, relaxation is performed to reduce high frequency errors followed by the projection of a correction equation on yet a coarser grid, and so on. Thus, the multigrid method corresponds to a series of relaxation iterations on a hierarchy of grids with different mesh sizes followed by the use of a direct solver on the coarsest grid (which is usually a fairly small grid). We summarize one iteration of this procedure in Fig. 1.

It is important to note that when the multigrid method is used as a preconditioner within the conjugate gradient method, it is necessary that the preconditioner be symmetric. This can be accomplished in the above procedure by choosing the postrelaxation ("relax2" in Fig. 1) as the transpose of the prerelaxation ("relax" in Fig. 1) [8]. The Jacobi iteration is one smoother that has this property when it is used for prerelaxation and postrelaxation. Another smoother combination with this property consists of using red-black Gauss–Seidel for prerelaxation and black-red Gauss–Seidel for postrelaxation.

To complete the definition of the above method, we will define a grid hierarchy, grid transfer operators, a coarse grid discretization scheme, and a specific relaxation method.

3.1. Grid hierarchy. In the DANCIR code, the discretization mesh used consists of a tensor product grid of one-dimensional arrays. In defining a grid hierarchy for the multigrid method, we consider only coarsening by a factor of 2 to facilitate code development. It should be noted that in order to carry out this procedure it is necessary to restrict the size of the fine grid.

Specifically, for two-dimensional simulations, the fine grid must contain $(2^k m+1) \times (2^j n+1)$ points where $\max(k, j)$ defines the number of levels in the hierarchy and $(m+1) \times (n+1)$ is the size of the coarsest grid. For the case $k \geq j$, the grid hierarchy is defined as follows:

$$\begin{aligned}
\mathcal{G}_0 &: 2^k m+1 \times 2^j n+1, \\
\mathcal{G}_1 &: 2^{(k-1)} m+1 \times 2^{(j-1)} n+1, \\
&\vdots \\
\mathcal{G}_j &: 2^{(k-j)} m+1 \times n+1, \\
&\vdots \\
\mathcal{G}_k &: m+1 \times n+1.
\end{aligned}$$

Though this scheme is straightforward, some care must be taken due to certain device characteristics such as the presence of an oxide layer as well as the contacts. This difficulty will be discussed after defining the grid transfer operators and the coarse grid discretization.

3.2. Grid transfer operators. In simple multigrid codes it is quite common to use linear interpolation for second-order problems and full weighting or half weighting for projection [3]. In most cases these simple grid transfer operators are sufficient and the resulting multigrid scheme works quite well. However, when the PDE coefficients vary greatly (or contain a discontinuity), these choices for the grid transfer operators may not be sufficient. To illustrate this point consider the simple PDE

$$(w(x)\, u_x\,)_x = f(x), \qquad 0 < x < 1, \tag{3.1}$$

with Dirichlet boundary conditions at $x = 0$ and $x = 1$ and

$$w(x) = \begin{cases} \varepsilon & x < .5, \\ 1 & x \geq .5. \end{cases}$$

If linear interpolation (or even higher-order interpolation) is used to obtain the value of u at $x = .5$, the resulting quantity $w(x)u_x$ will in general be discontinuous. Since this term is differentiated, it is quite clear that this discontinuity is undesirable. That is, interpolating such that u is smooth (i.e., u_x is constant) at the interpolation point is not the right criterion. Instead, we need to take into account the function $w(x)$. One possibility (see [14] or [1]) is to require that the term $w(x)u_x$ be constant at the interpolated points. This results in an interpolation formula of the form

$$u(x) = \frac{w(x-\frac{h}{2})u(x-h) + w(x+\frac{h}{2})u(x+h)}{w(x+\frac{h}{2}) + w(x-\frac{h}{2})} \tag{3.2}$$

for the above example on a uniform grid (with mesh spacing h on the fine grid). This formula can be verified by observing that when it is used, the central difference approximations to $w(x)u_x$ at $x - \frac{h}{2}$ and $x + \frac{h}{2}$ are equal. It should be noted that the above interpolation operator could have been defined in simply algebraic terms. Specifically, when (3.1) is discretized in a standard way the resulting difference operator is tridiagonal. To solve this tridiagonal system, a procedure called cyclic reduction can be used [4]. This procedure is essentially Gaussian elimination with a special elimination ordering of the points. The first step corresponds to eliminating all the even numbered points (where the points are numbered sequentially along the line). If we make an analogy between the multigrid algorithm and cyclic reduction, the interpolation algorithm corresponds to one step in the back solve of cyclic reduction.

Generalization of the interpolation procedure given above to two- or three-dimensional PDEs is not obvious because the exact analogy with cyclic reduction is no longer possible.

In this work we consider the following interpolation procedure in two dimensions.

1. Split the finite difference operator on $\mathcal{G}_l$, A_l, into matrices corresponding to the x and y derivatives as well as the 0th order terms:

$$A_l = A_l^x + A_l^y + G_l.$$

2. Average the derivative operators in the direction orthogonal to the derivative

$$\tilde{A}_l^x(j) = \frac{1}{4}A_l^x(j-1) + \frac{1}{2}A_l^x(j) + \frac{1}{4}A_l^x(j+1),$$

where $A_l^x(j)$ is the x derivative operator for level l on horizontal line j of the grid.

3. Interpolate in the x direction. For points where the coarse and fine grid coincide, use injection. For points in between two coarse grid points use the one-dimensional procedure outlined above in conjunction with $\tilde{A}_l^x(i)$. Specifically, set the interpolated value at (i, j) such that

$$\{\tilde{A}_l^x(j)u\}_i = 0,$$

where u is the vector of interpolated values corresponding to line j of the grid. This essentially corresponds to the back solve step of cyclic reduction applied to $\tilde{A}_l^x(j)$. It is important to note that at this point the operator u is defined on every other horizontal line.

4. Repeat the procedure in the y direction for the horizontal lines that have not yet been defined in the previous x interpolation. In particular, for fine grid points that are surrounded by four coarse grid points, use the interpolated values from the x interpolation.

Effectively, this procedure corresponds to performing the interpolation in one direction after another using one-dimensional difference operators defined from the original difference operator. The overall procedure is similar to that in [1], where they use an arithmetic average of the harmonic averages (as opposed to the harmonic average of the arithmetic averages) to define the interpolation operator.

For the projection operator we simply use the transpose of the interpolation scheme. Given that the difference operator is symmetric, this is a quite natural way to define a weighted projection operator. Using this projection on a one-dimensional problem corresponds to performing the forward elimination step of a cyclic reduction procedure on the tridiagonal discretization matrix.

3.3. Coarse grid discretizations. In typical multigrid codes, there are two ways of obtaining PDE discretizations for the coarser grids. One reliable technique, Galerkin coarsening, uses the interpolation and projection operators.

While this procedure works well for two- and three-dimensional problems, it has several disadvantages. For example, when standard interpolation and projection operators are used the Galerkin procedure may result in a larger difference stencil on coarser grids. Thus the programmer would have to write new codes for the coarse grid discretization as well as incur an extra storage penalty.

An alternative to the Galerkin procedure is to use an averaging procedure to generate PDE coefficients in conjunction with the differencing scheme used on the fine grid. There are many possible averaging procedures. In this work, we use a scheme based on the one-dimensional Galerkin operator. Specifically, when a Galerkin procedure is used in conjunction with the operator-dependent interpolation and projection on (3.1), the resulting coarse grid operator is equivalent to the reduced operator obtained with one step of cyclic reduction. For (3.1), this

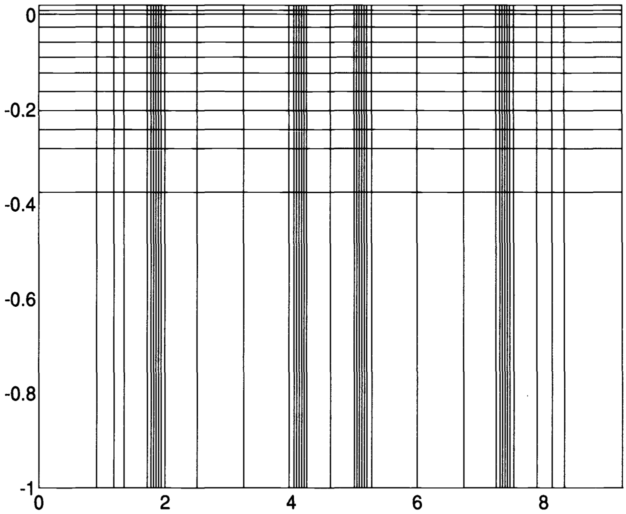

FIG. 2. *Grid obtained by keeping every eighth line from a typical MOSFET grid.*

coarse grid operator is equivalent to a three-point difference operator that corresponds to using the fine grid difference scheme on the coarse grid in conjunction with the PDE coefficients

$$\tilde{w}(x) = \frac{2\ w(x+h)\ w(x-h)}{w(x+h) + w(x-h)}.$$

For higher-dimensional problems we first split the finite difference operator into different terms. A standard averaging procedure is used to approximate the constant term G_l on the coarse grid. For the derivative terms, we first form averages (e.g., $\tilde{A}_l^x(i)$) as for the interpolation. Then, we use a cyclic reduction procedure on the one-dimensional problems in each of the different coordinate directions to generate approximations to the PDE coefficients on the coarser grid. Overall, the resulting procedure can be viewed as an approximation to the reduced equations of cyclic reduction (or the Galerkin coarsening) where the operator has first been split into component terms, the cyclic reduction procedure has been applied, and then the terms are regrouped to form the coarse grid discretization.

3.4. Relaxation method. There are two major possibilities for the relaxation method: point relaxation and line relaxation. It is well known in the multigrid community that line relaxation (or semicoarsening) should be adopted when the method is applied to anisotropic problems. That is, while standard point relaxation methods sufficiently smooth the error for the Poisson equation, their performance is quite poor for severely anisotropic problems. If, however, line relaxation is used instead of the point relaxation, it is once again possible to obtain good multigrid convergence rates even for anisotropic problems. We omit the details and refer the reader to [3], where a Fourier analysis is given illustrating this phenomenon. In our case, the highly stretched grid (e.g., Fig. 2) is a source of anisotropic phenomena.[1] Thus, we have implemented red-black Gauss–Seidel as well as red-black alternating line Gauss–Seidel for prerelaxation and black-red point and line Gauss–Seidel for postrelaxation. Additionally, we have implemented local Gauss–Seidel procedures to take into account the physics of the simulation. In particular, the majority of the difficulties for the smoother are caused by the

[1] It is not clear whether line relaxation would be necessary with another grid structure. That is, if the sole source of the anisotropic behavior is the grid, it may not be necessary to use line relaxation.

FIG. 3. *One-dimensional grid hierarchy.*

top of the device (near the contacts, oxide layer, and doped regions). The local Gauss–Seidel procedures consist of performing red-black (point or alternating line) Gauss–Seidel on the residual equation restricted to the domain covering the upper one-fourth of the device. This local procedure is usually used after the standard relaxation procedure to improve the smoother in the upper part of the device (at only one-fourth the cost of the global procedure).

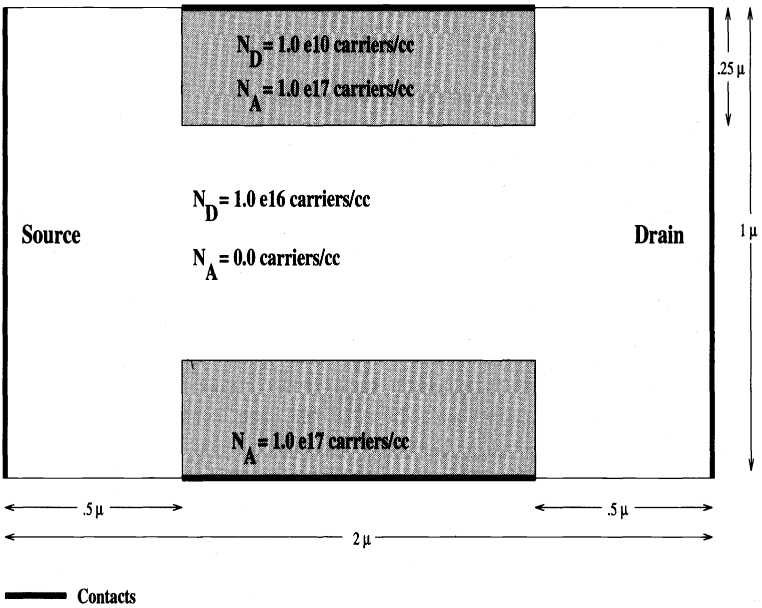
3.5. Contact points and oxide layer. In defining the grid hierarchy no particular attention has been given to device characteristics such as the oxide layer and the contact points present in many devices. It is entirely possible that the location of the boundary between the oxide and the interior or the boundary between a contact point and the interior could differ between the fine and coarse grids. For example, consider the one-dimensional hierarchy of three grids shown in Fig. 3. If we have a contact region (denoted in bold) that covers two points on the fine grid, then it effectively becomes smaller on the next coarser grid. To prevent this phenomenon, there are two possible solutions. One option is to choose the grid hierarchy in conjunction with the contacts (and oxide) such that the boundaries of these regions remain in place. The other possibility, which we consider, is to keep the grid hierarchy but to modify the discretization and the right-hand side on the coarse grid such that the location of the contact boundary is maintained. For example, the matrix equation corresponding to the fine grid above

$$\begin{pmatrix} 1 &&&&&&&& \\ & 1 &&&&&&& \\ && -2 & 1 &&&&& \\ && 1 & -2 & 1 &&&& \\ &&& 1 & -2 & 1 &&& \\ &&&& 1 & -2 & 1 && \\ &&&&& 1 & -2 & 1 & \\ &&&&&& 1 & -2 & \\ &&&&&&&& 1 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ u_5 \\ u_6 \\ u_7 \\ u_8 \\ u_9 \end{pmatrix} = \begin{pmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \\ b_5 \\ b_6 \\ b_7 \\ b_8 \\ b_9 \end{pmatrix}$$

has the same solution at the odd points as

$$\begin{pmatrix} 1 &&&& \\ & \mathbf{-3} & \mathbf{1} && \\ & 1 & -2 & 1 & \\ && 1 & -2 & \\ &&&& 1 \end{pmatrix} \begin{pmatrix} u_1 \\ u_3 \\ u_5 \\ u_7 \\ u_9 \end{pmatrix} = \begin{pmatrix} b_1 \\ \mathbf{2b_3 + b_4} \\ b_4 + 2b_5 + b_6 \\ b_6 + 2b_7 + b_8 \\ b_9 \end{pmatrix}.$$

Notice that the main change is the second equation (discretization and right-hand side projection). This procedure corresponds to cyclic reduction and can also be motivated by truncation error arguments. The main point is that the operator-dependent schemes automatically take care of these situations to maintain a proper coarse grid approximation. Of course, this example is one dimensional and in higher dimensions it will not be possible to have an exact representation on the coarse grid. However, by using the operator-dependent grid transfers and discretizations we need not worry too much about the grid hierarchy with respect to the oxide and the contacts. Further, any small degradations in the coarse discretization (for example,



N_D = 1.0 e10 carriers/cc
N_A = 1.0 e17 carriers/cc
N_D = 1.0 e16 carriers/cc
N_A = 0.0 carriers/cc

near the corners of an oxide region) will in general not cause great difficulties for a conjugate gradient routine (because the problem areas will be of very low rank).

4. Algorithm summary. To summarize, the numerical algorithm used for the nonlinear equations is the Gummel iteration. Gummel's method requires three linear system solutions. For these a conjugate gradient algorithm is used in conjunction with a multigrid preconditioner. Finally, within the multigrid preconditioner, Gauss–Seidel is used as a smoother with red-black sweeps for prerelaxation and black-red for postrelaxation. It should be noted that it is possible to use multigrid as a solver instead of a preconditioner (i.e., without the conjugate gradient iterations). However, in our experiments we found that the multigrid preconditioned conjugate gradient code outperformed the use of just multigrid. We believe that there are two primary reasons for this:

- The presence of small-scale effects such as small contacts and doping regions that disappear on the coarse grid degrade the multigrid coarse grid operator.
- The interpolation, projection, and coarse grid scheme used are a bit simplistic. These choices were made partially because they were easy to incorporate into a large already-existing program with fairly complicated data structures and a simplistic scheme for handling nonrectangular grids (resulting from the oxide region). Unfortunately these procedures do not handle the corners of the oxide very well.

While these low-rank degradations can make the multigrid convergence slower, they do not greatly affect the conjugate gradient procedure.

5. Numerical results. A two-dimensional version of the multigrid algorithm described in the previous section was incorporated into the DANCIR code. To evaluate the multigrid scheme, a number of experiments have been performed on a variety of devices. Before illustrating these results we briefly describe the devices used in the comparison.

5.1. Junction field effect transistor (JFET). The first model used consists of a JFET depicted in Fig. 4. The simulation is started with zero volts on all of the contacts. Once

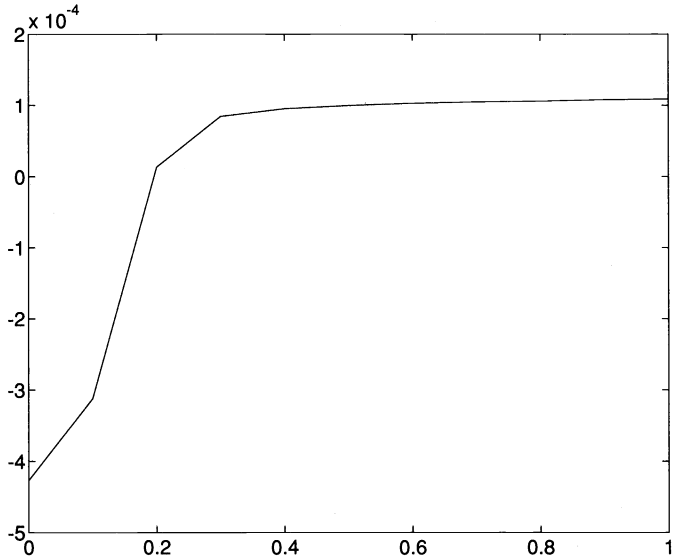

FIG. 5. *Current–voltage characteristics for JFET.*

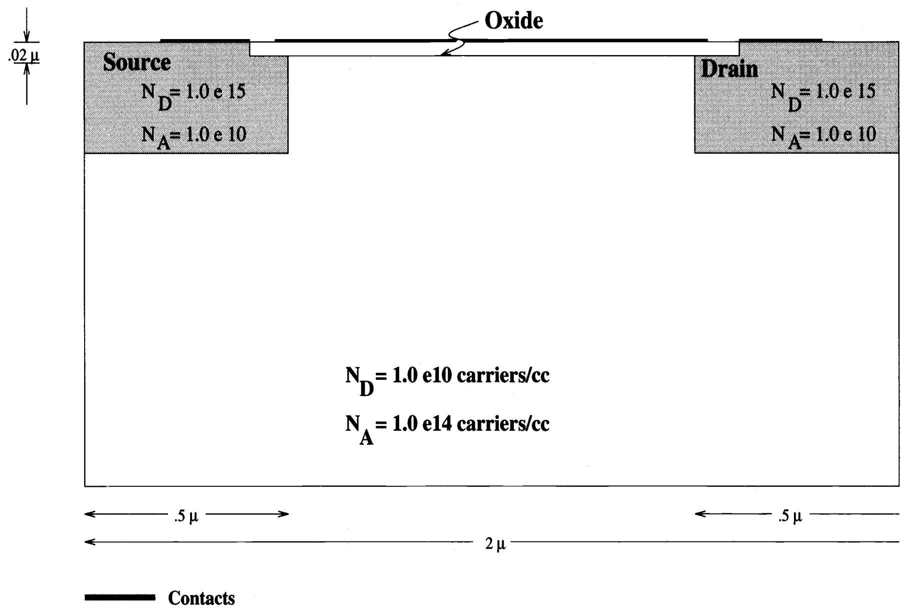

FIG. 6. *MOSFET1 device.*

the equilibrium solution is computed, the voltage on the bottom and top contacts is gradually incremented (and the corresponding steady-state solutions are computed) until the final contact voltage is reached (1.0 volts). After this stage the drain contact voltage is incremented until it attains a value of 1.0 volts. The current–voltage characteristics (computed with the DANCIR/MG code) are displayed in Fig. 5.

5.2. MOSFET1. The second test problem consists of a simple MOSFET device depicted in Fig. 6. In this case the simulation starts at equilibrium. The gate contact is first incremented to 5.5 volts and finally the drain value is incremented to 2.5 volts.

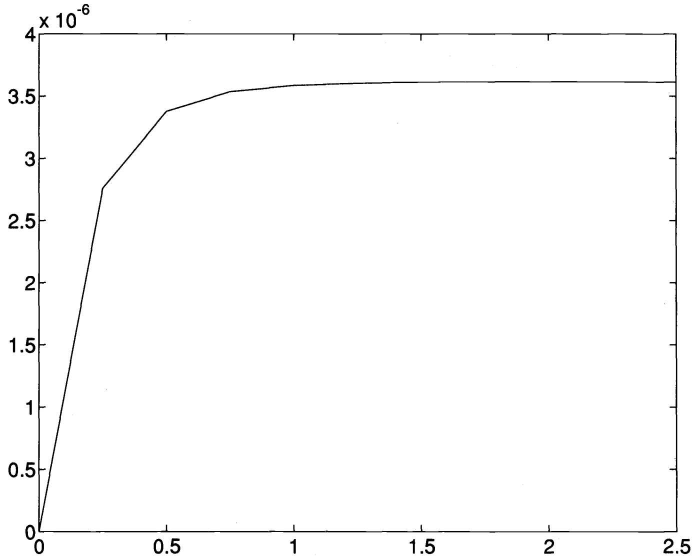

FIG. 7. *Current–voltage characteristics for MOSFET1.*

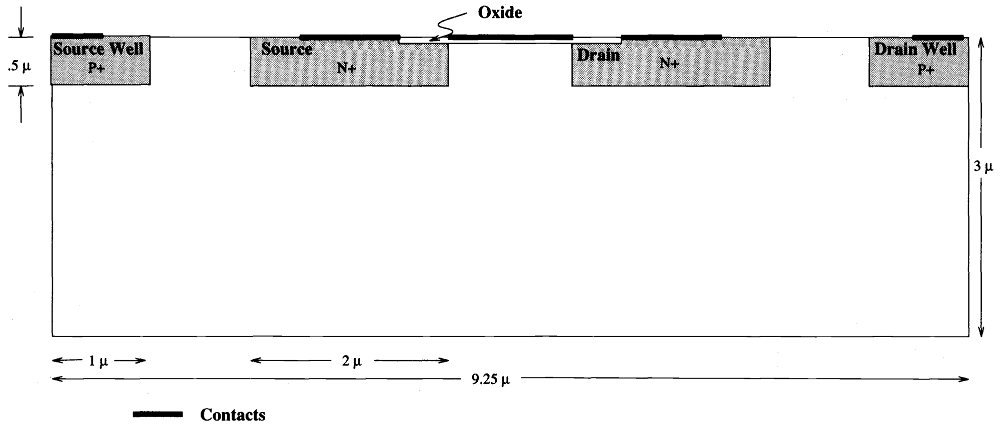

FIG. 8. *MOSFET2 device.*

The current–voltage characteristics (computed with the DANCIR/MG code) are displayed in Fig. 7.

5.3. MOSFET2. This final device is our most complex device and corresponds to a 1.25μ N-channel MOSFET that has been used at Sandia for testing purposes. This device is depicted in Fig. 8. In this case the simulation starts at equilibrium. The gate contact is first incremented to 5.5 volts and finally the drain value is incremented to 2.5 volts.

The current–voltage characteristics (computed with the DANCIR/MG code) are displayed in Fig. 9. These characteristics are standard for this device.

In Tables 1–3 we illustrate the total number of iterations for the conjugate gradient method and the CPU time corresponding to an entire simulation where the conjugate gradient iterations for each linear solve terminate when the residual is reduced by 10^{-9}. In parenthesis we indicate the average number of conjugate gradient iterations per linear solve. It should be noted that a less strict convergence criterion for the linear subiterations is not considered in this paper.

While a milder criteria may be more efficient for the overall nonlinear problem,[2] our focus is to compare linear solvers where it is best if both simulations (multigrid and incomplete Cholesky preconditioned) follow the same nonlinear path. In Tables 1–4 the notation MG(#1X, #2Y, #3) indicates that the multigrid preconditioner uses #1 pre- and postrelaxation iterations[3] of the "X" (P for point or L for alternating line) Gauss–Seidel procedure and #2 pre- and postrelaxation iterations of the "Y" (P for point or L for alternating line) local Gauss–Seidel procedure on each grid in the #3 level hierarchy. All of the ILU results correspond to ILU(0), which has the same sparsity pattern as the original finite difference matrix.[4] As Tables 1–4 illustrate, the multigrid code with point relaxation is ineffective for the harder problems (though it works quite well on the JFET problem). On the other hand, the multigrid with line relaxation can be a very effective solver because it requires far fewer iterations than the corresponding ILU preconditioned code and because the overall run time is much better than the ILU code even

[2] In our experience, we have found that it can often be more efficient to perform just a few multigrid sweeps for the two carrier equations. However, it is necessary to solve somewhat accurately the Poisson equation for the potential. This is due to the fact that the potential is exponentiated in the Gummel iteration. Thus, if the potential is not accurate (and these inaccuracies are amplified due to exponentiation), the nonlinear path taken by the Gummel iteration can be suboptimal.

[3] Actually, the postrelaxation operator is the transpose of the prerelaxation operator. Thus, the prerelaxation operator uses red-black Gauss–Seidel while the postrelaxation operator uses black-red Gauss–Seidel.

[4] The original DANCIR code allows for ILU(1), ILU(2), etc. Over a wide variety of numerical experiments, we have found that the total run time is usually about the same using ILU(1) as opposed to ILU(0) (though the number of iterations is less using ILU(1)).

though the cost per iteration is greater. Specifically, for the larger grid JFET problem and the smaller grid MOSFET1 and MOSFET2 problems the multigrid code is between a factor of two and four times faster than the ILU code. More importantly, the number of iterations per linear solve is relatively independent of the grid size when using the multigrid preconditioner while it grows for the ILU scheme.[5] Thus, the savings associated with multigrid are even greater for larger grids.

In terms of storage, our multigrid scheme requires slightly more storage than the ILU method. Specifically, the ILU scheme requires the storage of the ILU preconditioner ($3n$ for five-point symmetric difference operators where n is the number of grid points). In the multigrid scheme, we need additional storage for the coarse grid versions of the matrix, the solution, and the right-hand side ($\approx 3n/4$ for the coarse matrices and $\approx 2n/4$ for the coarse solutions and right-hand sides). Thus, the ILU requires an additional $3n$ values while multigrid requires an additional $5n/4$ values. However, in our multigrid implementation we also store $2(4n/3)$ intermediate values for interpolation and projection operators and $2(4n/3)$ intermediate values for the factorization of the line solver.

We conclude this section by illustrating the total CPU time for each device simulation in Table 4. By comparison with the earlier tables, the reader can verify that the conjugate gradient iteration dominates the calculation and thus the multigrid savings are significant with respect to the entire simulation time.

6. Conclusions. We have incorporated a multigrid preconditioner into a semiconductor device modeling code. To do this, a multigrid scheme was developed that could be used in cases that exhibited highly variable PDE coefficients and anisotropic behavior. In addition, special consideration had to be taken with respect to certain device characteristics such as oxide layers and small contact regions. The resulting scheme is fast, parallel, and requires far fewer iterations than the ILU scheme that it replaced. In our sample problems we improved the performance by a factor of between 2 and 4 over the ILU preconditioner. Extensions to the three-dimensional case are straightforward and planned for the future.

Finally, we note that while we have used a multigrid solver for the linear equations that arise within Gummel's method, there are potentially much greater savings if the Gummel technique can be replaced by a nonlinear multigrid iteration. We have not pursued this, but we hope that this study will give insight into this possibility.

MULTIGRID WAVEFORM RELAXATION ON SPATIAL FINITE ELEMENT MESHES: THE DISCRETE-TIME CASE*

JAN JANSSEN† AND STEFAN VANDEWALLE‡

Abstract. The efficiency of numerically solving time-dependent partial differential equations on parallel computers can be greatly improved by computing the solution on many time levels simultaneously. The theoretical properties of one such method, namely the discrete-time multigrid waveform relaxation method, are investigated for systems of ordinary differential equations obtained by spatial finite-element discretisation of linear parabolic initial-boundary value problems. The results are compared to the corresponding continuous-time results. The theory is illustrated for a one-dimensional and a two-dimensional model problem and checked against results obtained by numerical experiments.

Key words. parabolic partial differential equations, waveform relaxation, multigrid, linear multistep methods

AMS subject classifications. 65F10, 65L05, 65M55, 65M60

1. Introduction. We consider the numerical solution of a linear parabolic initial-boundary value problem, spatially discretised by a conforming Galerkin finite-element method. This leads to a linear system of ordinary differential equations (ODEs), see e.g. [10], [20],

$$B\dot{u} + Au = f \ , \quad u(0) = u_0 \ , \quad t > 0 \ , \tag{1.1}$$

with B the symmetric positive definite mass matrix, A the stiffness matrix, and $u(t) = (u_1(t), u_2(t), \dots, u_d(t))^t$ the unknown solution vector.

In [10] we considered solving (1.1) with the continuous-time multigrid waveform relaxation method. This method is based on waveform relaxation, a highly parallel technique for solving very large systems of ODEs [12], [15]. It is accelerated by using multigrid, a very efficient method for solving elliptic partial differential equations, see e.g. [1], [4], [24]. The continuous-time waveform relaxation method differs from standard ODE solvers in that it computes a solution along a continuous time interval. It requires the analytical solution of certain ODEs and the exact continuous representation of certain functions. The method is therefore mainly of theoretical interest. In an actual implementation of the method, the algorithm is replaced by a discrete-time algorithm. That is, functions are represented discretely as vectors defined on successive time levels, and the ODEs are solved by using standard time-stepping techniques.

The resulting *discrete-time multigrid waveform relaxation method* belongs to the class of parabolic multigrid methods. These are multigrid methods for time-dependent problems designed to operate on grids extending in space and time. Other examples of such methods are the time-parallel multigrid method [3], [7] and the space–time multigrid method [8]. These methods are highly efficient on parallel computers, possibly outperforming parallel implementations of standard time-stepping methods by orders of magnitude [9], [23]. Their convergence characteristics as iterative solvers are often similar to the convergence characteristics of multigrid methods for stationary problems, although different parabolic multigrid methods may have very different robustness characteristics. The waveform method, in par-

ticular, was shown to be very robust across a wide range of time-discretisation schemes. We refer to [8], [22] for a further discussion.

In this paper, we continue our study of the multigrid waveform relaxation method for systems of the form (1.1). In particular, we analyse the effect of time discretisation when linear multistep formulae are used. The structure of this paper is similar to the structure of [10]. In §2, we analyse the spectral properties of certain operators that arise in the formulation of the waveform relaxation methods. After a brief review of some definitions and properties of linear multistep methods in §3, we investigate the convergence of the discrete-time standard waveform relaxation method (§4) and of its two-grid acceleration (§5), both on finite and infinite time intervals. For systems of the form (1.1) with $B = I$, the discrete-time waveform method and its multigrid variant have been investigated in [14], [16], [17], [21]. Our results are qualitatively very similar, and generalise the ones found in these references. In §6, we perform a model problem analysis for a one-dimensional and two-dimensional model problem. Finally, in §7, extensive numerical results are reported.

2. Spectral properties of a special operator. We will show in §§4 and 5 that the discrete-time waveform relaxation method and its two-grid acceleration can be written as successive approximation schemes of the form

$$u_\tau^{(\nu)} = \mathcal{H}_\tau u_\tau^{(\nu-1)} + \varphi_\tau \,. \tag{2.1}$$

We use subscript τ-notation to denote vectors or sequences, e.g. $u_\tau^{(\nu)} = \{u_i^{(\nu)}\}_{i=0}^{N-1}$, where N is the (possibly infinite) number of components. Each component is a d-vector, and will typically approximate the solution of the system of d differential equations (1.1) at a given time level. Operator $\mathcal{H}_\tau$ is a linear discrete convolution operator with matrix-valued kernel h_τ,

$$(\mathcal{H}_\tau u_\tau)_j = (h_\tau \star u_\tau)_j = \sum_{i=0}^{j} h_{j-i} u_i \,, \quad j = 0, \ldots, N-1 \,.$$

The convergence properties of operator $\mathcal{H}_\tau$ will be analysed in the spaces of $\mathbb{C}^d$-valued p-summable sequences of length N, $l_p(N; \mathbb{C}^d)$, or $l_p(N)$ for short. These are Banach spaces with norms given by

$$||u_\tau||_p = \begin{cases} \sqrt[p]{\sum_{i=0}^{N-1} ||u_i||^p} & 1 \le p < \infty, \\ \sup\limits_{0 \le i < N} \{||u_i||\} & p = \infty, \end{cases} \tag{2.2}$$

with $||\cdot||$ any usual $\mathbb{C}^d$ vector norm. Recall that the iterative scheme (2.1) is convergent if and only if the spectral radius of $\mathcal{H}_\tau$, denoted by $\rho(\mathcal{H}_\tau)$, is smaller than one. The spectral radius is defined as the largest value ρ for which $|\lambda| > \rho$ implies that $\lambda - \mathcal{H}_\tau$ has a bounded inverse. When N is finite, it equals the magnitude of the largest eigenvalue of $\mathcal{H}_\tau$.

2.1. Spectral radius on finite time intervals.

LEMMA 2.1. *Consider $\mathcal{H}_\tau$ as an operator in $l_p(N)$, with $1 \le p \le \infty$ and N finite. Then, $\mathcal{H}_\tau$ is a bounded operator and*

$$\rho(\mathcal{H}_\tau) = \rho(h_0) = \rho(\mathbf{H}_\tau(\infty)) \,, \tag{2.3}$$

with $\mathbf{H}_\tau(z) = \sum_{i=0}^{N-1} h_i z^{-i}$ the discrete Laplace transform of h_τ.

Proof. Since $\mathcal{H}_\tau$ is a linear operator in a finite-dimensional space, boundedness of $\mathcal{H}_\tau$ follows. The operation $\mathcal{H}_\tau u_\tau$ can be represented in standard linear algebra notation as a matrix-vector product,

$$\begin{bmatrix} h_0 & & & & & \\ h_1 & h_0 & & & & \\ h_2 & h_1 & h_0 & & & \\ \cdot & \cdot & \cdot & \cdot & & \\ \cdot & \cdot & \cdot & \cdot & \cdot & \\ h_{N-1} & \cdot & \cdot & h_2 & h_1 & h_0 \end{bmatrix} \begin{bmatrix} u_0 \\ u_1 \\ \cdot \\ \cdot \\ \cdot \\ u_{N-1} \end{bmatrix} . \tag{2.4}$$

The spectral radius of operator $\mathcal{H}_\tau$ equals the spectral radius of the $N \times N$-block lower triangular Toeplitz matrix in (2.4). By consequence, $\rho(\mathcal{H}_\tau) = \rho(h_0)$. The second equality follows immediately. □

2.2. Spectral radius on infinite time intervals.

LEMMA 2.2. *Suppose $h_\tau \in l_1(\infty)$, and consider $\mathcal{H}_\tau$ as an operator in $l_p(\infty)$, with $1 \le p \le \infty$. Then, $\mathcal{H}_\tau$ is bounded and*

$$\rho(\mathcal{H}_\tau) = \max_{|z|\ge 1} \rho(\mathbf{H}_\tau(z)) \tag{2.5}$$

$$= \max_{|z|=1} \rho(\mathbf{H}_\tau(z)) , \tag{2.6}$$

with $\mathbf{H}_\tau(z) = \sum_{i=0}^{\infty} h_i z^{-i}$ the discrete Laplace transform of h_τ.

The outline of our proof is very similar to the one given in [16, Thm. 3.1]. Yet, here, it is phrased in terms of general convolution operators. A similar line of arguments is implied in the proof of [14, Prop. 9]. The proof is based on the discrete version of the Paley–Wiener theorem [13]. This theorem states that the solution of a discrete Volterra convolution equation $x_\tau + h_\tau \star x_\tau = f_\tau$, with $f_\tau \in l_p(\infty)$ and $h_\tau \in l_1(\infty)$ is bounded in $l_p(\infty)$ if and only if $\det(I + \mathbf{H}_\tau(z)) \neq 0$ for $|z| \ge 1$, with $\mathbf{H}_\tau(z)$ the discrete Laplace transform of h_τ.

Proof. The boundedness of $\mathcal{H}_\tau$ follows from the fact that $l_1 \star l_p \subset l_p$. Indeed, applying Young's inequality for discrete convolution products [6, p. 198] yields

$$||\mathcal{H}_\tau u_\tau||_p \le ||h_\tau||_1 \, ||u_\tau||_p .$$

By definition, the spectral radius of $\mathcal{H}_\tau$ is the smallest value of ρ for which $|\lambda| > \rho$ implies that $\lambda - \mathcal{H}_\tau$ has a bounded inverse in $l_p(\infty)$. Consider

$$\lambda u_\tau - \mathcal{H}_\tau u_\tau = \lambda u_\tau - h_\tau \star u_\tau = f_\tau ,$$

with $f_\tau \in l_p(\infty)$. Suppose $\lambda \neq 0$, then this can be rewritten as a convolution equation

$$u_\tau - \frac{1}{\lambda} h_\tau \star u_\tau = \frac{1}{\lambda} f_\tau .$$

By the Paley–Wiener theorem, it follows that u_τ is bounded if and only if

$$\det\left(I - \frac{1}{\lambda}\mathbf{H}_\tau(z)\right) \neq 0 \quad \text{for} \quad |z| \ge 1 ,$$

or, equivalently,

$$\rho(\mathcal{H}_\tau) = \sup_{|z|\ge 1} \rho(\mathbf{H}_\tau(z)) .$$

Note that $\mathbf{H}_\tau(z)$ is analytic for $|z| > 1$, including $z = \infty$, and, since $h_\tau \in l_1(\infty)$, it is continuous for $|z| \geq 1$. Also, the spectral radius satisfies the maximum principle. Hence, we obtain (2.5) and (2.6). □

Remark 2.1. In the case of $d = 1$, this lemma corresponds to a well-known spectral property of semi-infinite Toeplitz operators [18, Thm. 2.1].

In $l_2(\infty)$, an analogous result holds for the norm.

LEMMA 2.3. *Suppose $h_\tau \in l_1(\infty)$, and consider $\mathcal{H}_\tau$ as an operator in $l_2(\infty)$. Denote by $||\cdot||_2$ the l_2-norm (2.2) with $||\cdot||$ the standard Euclidean vector norm. Then,*

$$||\mathcal{H}_\tau||_2 = \max_{|z|\geq 1} ||\mathbf{H}_\tau(z)|| \tag{2.7}$$

$$= \max_{|z|=1} ||\mathbf{H}_\tau(z)||\,, \tag{2.8}$$

with $\mathbf{H}_\tau(z)$ the discrete Laplace transform of h_τ.

Proof. The proof is based on Parseval's relation for vector-valued l_2-sequences,

$$||u_\tau||_2 := ||\{u_i\}_{i=0}^{\infty}||_2 = \left\| \sum_{i=0}^{\infty} u_i z^{-i} \right\|_{H_2} ,$$

where $||\cdot||_{H_2}$ is the norm in the Hardy–Lebesgue space of square integrable functions analytic outside the unit disk,

$$||f(z)||_{H_2} = \sup_{r>1} \left(\frac{1}{2\pi} \int_0^{2\pi} ||f(re^{i\theta})||^2 d\theta \right)^{1/2} .$$

The Parseval relation for the scalar case can be found, e.g., in [25, p. 41]. By definition of operator norm and by Parseval's relation, we have

$$||\mathcal{H}_\tau||_2 = \sup \frac{||\mathcal{H}_\tau u_\tau||_2}{||u_\tau||_2} = \sup \frac{||\mathbf{H}_\tau(z)\tilde{u}_\tau(z)||_{H_2}}{||\tilde{u}_\tau(z)||_{H_2}} ,$$

with $\tilde{u}_\tau(z)$ the discrete Laplace transform of u_τ. $||\mathcal{H}_\tau||_2$ can be seen to be equal to $\sup_{|z|\geq 1} ||\mathbf{H}_\tau(z)||$. (For the technical details of this last step, we refer to the proof of a very similar theorem, [2, Thm. 2.2], which deals with operator norms of Fourier multipliers.) Consideration of the analyticity and continuity of $\mathbf{H}_\tau(z)$ leads to (2.7) and (2.8). □

Remark 2.2. From (2.3) and (2.5), it follows that the spectral radius of $\mathcal{H}_\tau$ on finite time intervals is smaller than the spectral radius of $\mathcal{H}_\tau$ on infinite time intervals.

3. Some linear multistep formulae.

3. Some linear multistep formulae. For the reader's convenience, we recall the general linear multistep formula for calculating the solution to the ODE $\dot{y} = f(t, y)$ with $y(0) = y_0$, see e.g. [11, p. 11],

$$\frac{1}{\tau} \sum_{j=0}^{k} \alpha_j y_{n+j} = \sum_{j=0}^{k} \beta_j f_{n+j} \,. \tag{3.1}$$

In this formula, α_j and β_j are real constants, and τ denotes a constant step size. We shall assume that k starting values $y_0, y_1, \ldots, y_{k-1}$ are given.

DEFINITION 3.1. *The characteristic polynomials of the linear multistep method are given by*

$$a(z) = \sum_{j=0}^{k} \alpha_j z^j \quad \textit{and} \quad b(z) = \sum_{j=0}^{k} \beta_j z^j \,.$$

Throughout this paper we adhere to some common assumptions. The linear multistep method is irreducible: $a(z)$ and $b(z)$ have no common roots; the linear multistep method is consistent: $a(1) = 0$ and $a'(1) = b(1)$; the linear multistep method is zero-stable: all roots of $a(z)$ are inside the closed unit disk and every root with modulus one is simple. For future reference, we also define the stability region of a linear multistep method, and the related notion of $A(\alpha)$-stability, see e.g. [5], [11].

DEFINITION 3.2. *The stability region S consists of those $\mu \in \bar{\mathbb{C}}$ for which the polynomial $a(z) - \mu b(z)$ (around $\mu = \infty$: $\mu^{-1}a(z) - b(z)$) satisfies the root condition: all roots satisfy $|z_j| \leq 1$ and those of modulus one are simple.*

DEFINITION 3.3. *A multistep method is called*

(i) *$A(\alpha)$-stable, $0 < \alpha < \frac{\pi}{2}$, if $S \supset \Sigma_\alpha = \{z : |\mathrm{Arg}(-z)| < \alpha,\ z \neq 0\}$*

(ii) *A-stable if S contains the left-half complex plane.*

4. The waveform relaxation method. The continuous-time waveform relaxation method for solving initial value problem (1.1) is defined by the splittings $B = M_B - N_B$, $A = M_A - N_A$, and the iteration scheme

$$M_B \dot{u}^{(\nu)} + M_A u^{(\nu)} = N_B \dot{u}^{(\nu-1)} + N_A u^{(\nu-1)} + f\ , \tag{4.1}$$

with $u^{(\nu)}(0) = u_0$. We assume the splitting is such that M_B is invertible. This iterative scheme can be written in explicit form as $u^{(\nu)} = \mathcal{K}u^{(\nu-1)} + \varphi$. The convergence properties of iteration operator $\mathcal{K}$, the *continuous-time waveform relaxation operator*, have been studied in [10]. They are expressed in terms of the matrix

$$\mathbf{K}(z) = (zM_B + M_A)^{-1}(zN_B + N_A)\ . \tag{4.2}$$

It was shown on finite and infinite time intervals, respectively, and with $i = \sqrt{-1}$, that

$$\rho(\mathcal{K}) = \rho(\mathbf{K}(\infty)) \quad \text{and} \quad \rho(\mathcal{K}) = \sup_{\mathrm{Re}(z)\geq 0} \rho(\mathbf{K}(z)) = \sup_{\xi\in\mathbb{R}} \rho(\mathbf{K}(i\xi))\ . \tag{4.3}$$

4.1. The discrete-time waveform relaxation operator. Application of linear multistep formula (3.1) to the continuous-time iteration scheme (4.1) leads to

$$\begin{aligned} &\frac{1}{\tau}\sum_{j=0}^{k} \alpha_j M_B u_{n+j}^{(\nu)} + \sum_{j=0}^{k} \beta_j M_A u_{n+j}^{(\nu)} \\ &\quad = \frac{1}{\tau}\sum_{j=0}^{k} \alpha_j N_B u_{n+j}^{(\nu-1)} + \sum_{j=0}^{k} \beta_j N_A u_{n+j}^{(\nu-1)} + \sum_{j=0}^{k} \beta_j f_{n+j}\ , \quad n \geq 0\ . \end{aligned} \tag{4.4}$$

We do not iterate on the k starting values, i.e., $u_j^{(\nu)} = u_j^{(\nu-1)} = u_j$, for $j < k$. In the remainder of the text we shall concentrate on the use of implicit methods, i.e., $\beta_k \neq 0$. Equation (4.4) can then be solved uniquely for every n if and only if the following condition is satisfied:

$$\frac{\alpha_k}{\beta_k} \notin \sigma\left(-\tau M_B^{-1} M_A\right)\ , \tag{4.5}$$

where $\sigma(\cdot)$ denotes the spectrum. Further on we shall refer to this condition as the discrete solvability condition.

Iteration (4.4) can be rewritten as $u_\tau^{(\nu)} = \mathcal{K}_\tau u_\tau^{(\nu-1)} + \varphi_\tau$. Because we do not iterate on the starting values, we use a slightly different subscript τ-notation here than the one in (2.1), that is,

$$u_\tau = \{u_{k+i}\}_{i=0}^{N-1}\ . \tag{4.6}$$

(Alternatively, we could have used negative indices to denote the time levels associated with the k starting values, as is done in [13], [14]. This, however, would require some shifting in the indices of formulae (3.1) and (4.4).) The precise expression for φ_τ can be calculated following the lines of [17, p. 536–537]. It depends on the values of $f_n, n \geq 0$ and on the starting values u_n, $n < k$. In order to determine the nature of $\mathcal{K}_\tau$, the *discrete-time waveform relaxation operator*, we rewrite (4.4) using $e_n^{(\nu)} = u_n^{(\nu)} - u_n$. Here, u_n is the exact solution of ODE (1.1) when discretised using the linear multistep method. This gives

$$\frac{1}{\tau}\sum_{j=0}^{k}\alpha_j M_B e_{n+j}^{(\nu)} + \sum_{j=0}^{k}\beta_j M_A e_{n+j}^{(\nu)} = \frac{1}{\tau}\sum_{j=0}^{k}\alpha_j N_B e_{n+j}^{(\nu-1)} + \sum_{j=0}^{k}\beta_j N_A e_{n+j}^{(\nu-1)}\ , \quad n \geq 0\,.$$

With $C_j = \frac{1}{\tau}\alpha_j M_B + \beta_j M_A$, and $D_j = \frac{1}{\tau}\alpha_j N_B + \beta_j N_A$, this becomes

$$\sum_{j=0}^{k} C_j e_{n+j}^{(\nu)} = \sum_{j=0}^{k} D_j e_{n+j}^{(\nu-1)}\ , \quad n \geq 0\,. \tag{4.7}$$

Note that $e_j^{(\nu)} = e_j^{(\nu-1)} = 0$, $j < k$. When we combine the first N equations, i.e., the equations for the unknowns on time steps $k, \ldots, N+k-1$, and after introducing vector $E^{(\nu)} = [e_k^{(\nu)} e_{k+1}^{(\nu)} \ldots e_{N+k-1}^{(\nu)}]^t$, we get

$$E^{(\nu)} = C^{-1} D\, E^{(\nu-1)}\,. \tag{4.8}$$

Matrices C and D are $N \times N$-block lower triangular matrices with $k+1$ constant diagonals. The blocks on the jth diagonal are given respectively by C_{k-j} and D_{k-j}. It follows immediately that matrix $C^{-1}D$ is a $N \times N$-block lower triangular Toeplitz matrix. Hence, $\mathcal{K}_\tau$ is a discrete linear convolution operator on the l_p-space of vectors or sequences of length N. The jth component of the matrix-valued discrete convolution kernel k_τ equals the (constant) submatrix on the jth lower block diagonal of $C^{-1}D$.

In the theory we shall need the discrete Laplace transform of the convolution kernel. It can be found by discrete Laplace-transforming equation (4.7). If $\tilde{e}_\tau^{(\nu)}(z)$ denotes the transform of $e_\tau^{(\nu)}$, we obtain

$$\tilde{e}_\tau^{(\nu)}(z) = \mathbf{K}_\tau(z)\tilde{e}_\tau^{(\nu-1)}(z)\,,$$

with the discrete-time waveform relaxation matrix given by

$$\mathbf{K}_\tau(z) = (a(z)M_B + \tau b(z)M_A)^{-1}(a(z)N_B + \tau b(z)N_A)\,. \tag{4.9}$$

By comparison to (4.2) the following relation results:

$$\mathbf{K}_\tau(z) = \mathbf{K}\left(\frac{1}{\tau}\frac{a}{b}(z)\right)\,. \tag{4.10}$$

Note that (4.10) still holds when $\frac{a}{b}(z)$ is set to ∞ in the case of $b(z) = 0$. (In this case $a(z) \neq 0$, since the characteristic polynomials have no common roots.)

4.2. Convergence analysis.

4.2.1. Convergence on finite time intervals.

THEOREM 4.1. *Assume that condition* (4.5) *is satisfied, and consider $\mathcal{K}_\tau$ as an operator in $l_p(N)$, with $1 \leq p \leq \infty$ and N finite. Then, $\mathcal{K}_\tau$ is bounded and*

$$\rho(\mathcal{K}_\tau) = \rho\left(\mathbf{K}\left(\frac{1}{\tau}\frac{\alpha_k}{\beta_k}\right)\right)\,. \tag{4.11}$$

Proof. The theorem follows from Lemma 2.1 and the observation that

$$\lim_{z\to\infty} \mathbf{K}_\tau(z) = \lim_{z\to\infty} \mathbf{K}\left(\frac{1}{\tau}\frac{a}{b}(z)\right) = \mathbf{K}\left(\frac{1}{\tau}\frac{\alpha_k}{\beta_k}\right). \qquad \square$$

4.2.2. Convergence on infinite time intervals. The following lemma deals with the boundedness of the discrete-time waveform relaxation operator $\mathcal{K}_\tau$. It is proved using a matrix-valued version of Wiener's inversion theorem [13, p. 446] and [16, p. 577], which is stated here for the reader's convenience.

THEOREM 4.2 (WIENER'S INVERSION THEOREM). *Given a matrix-valued sequence A_τ such that $A_\tau \in l_1(\infty)$, assume that*

$$\det \sum_{i=0}^{\infty} A_i z^{-i} \neq 0$$

for $|z| \geq 1$. Setting $\sum_{i=0}^{\infty} B_i z^{-i} = \left(\sum_{i=0}^{\infty} A_i z^{-i}\right)^{-1}$, we have $B_\tau \in l_1(\infty)$.

LEMMA 4.3. *If $\sigma(-\tau M_B^{-1} M_A) \subset \operatorname{int} S$, then $\mathcal{K}_\tau$ is bounded in $l_p(\infty)$.*

Proof. It is sufficient to prove that the kernel k_τ of the discrete convolution operator $\mathcal{K}_\tau$ is an l_1-sequence. To this end, consider first the l_1-sequence

$$\alpha_k M_B + \tau\beta_k M_A,\ \alpha_{k-1} M_B + \tau\beta_{k-1} M_A, \ldots, \alpha_0 M_B + \tau\beta_0 M_A,\ 0,\ 0, \ldots.$$

Its discrete Laplace transform equals the matrix function $z^{-k}(a(z)M_B + \tau b(z)M_A)$. By Wiener's theorem, we have that the inverse, $(a(z)M_B + \tau b(z)M_A)^{-1} z^k$, is the transform of another l_1-sequence, say r_τ, if

$$\det(a(z)M_B + \tau b(z)M_A) \neq 0 \text{ for } |z| \geq 1. \tag{4.12}$$

Next, consider the l_1-sequence

$$s_\tau = \alpha_k N_B + \tau\beta_k N_A,\ \alpha_{k-1} N_B + \tau\beta_{k-1} N_A, \ldots, \alpha_0 N_B + \tau\beta_0 N_A,\ 0,\ 0, \ldots,$$

the discrete Laplace transform of which is given by $z^{-k}(a(z)N_B + \tau b(z)N_A)$. The convolution of r_τ and s_τ is another l_1-sequence, which can be seen to be equal to the kernel k_τ. Indeed, the discrete Laplace transform of $r_\tau \star s_\tau$ is identical to $\mathbf{K}_\tau(z)$. As a result, it follows that $\mathcal{K}_\tau$ is bounded if (4.12) is satisfied.

Suppose there is a z with $|z| \geq 1$ such that

$$\det(a(z)M_B + \tau b(z)M_A) = 0. \tag{4.13}$$

Then necessarily $b(z) \neq 0$. (If $b(z) = 0$ then $a(z) \neq 0$, because $a(z)$ and $b(z)$ have no common roots. Since M_B is assumed to be invertible, equality (4.13) cannot hold.) Hence, we obtain

$$\det\left(\frac{a}{b}(z)M_B + \tau M_A\right) = 0,$$

and therefore $\frac{a}{b}(z) \in \sigma(-\tau M_B^{-1} M_A)$. Since $|z| \geq 1$, it follows that $-\tau M_B^{-1} M_A$ has an eigenvalue which is not an interior point of S. This contradicts the assumption of the lemma. Hence, (4.12) is satisfied. $\square$

Remark 4.1. Condition $\sigma(-\tau M_B^{-1} M_A) \subset \operatorname{int} S$ implies the discrete solvability condition (4.5). Indeed, since $\frac{\alpha_k}{\beta_k} = \frac{a}{b}(\infty)$, it follows that $\frac{\alpha_k}{\beta_k} \notin \operatorname{int} S$, and, therefore, $\frac{\alpha_k}{\beta_k} \notin \sigma(-\tau M_B^{-1} M_A)$.

Remark 4.2. Condition $\sigma(-\tau M_B^{-1} M_A) \subset \operatorname{int} S$ implies that all poles of $\mathbf{K}(z)$ are in the interior of the scaled stability region $\frac{1}{\tau} S$.

THEOREM 4.4. *Assume* $\sigma(-\tau M_B^{-1} M_A) \subset \operatorname{int} S$, *and consider* $\mathcal{K}_\tau$ *as an operator in* $l_p(\infty)$, *with* $1 \leq p \leq \infty$. *Then,*

$$\rho(\mathcal{K}_\tau) = \sup\{\rho(\mathbf{K}(z)) | \tau z \in \mathbb{C} \setminus \operatorname{int} S\} \tag{4.14}$$

$$= \sup_{\tau z \in \partial S} \rho(\mathbf{K}(z)) \,. \tag{4.15}$$

Proof. As $\sigma(-\tau M_B^{-1} M_A) \subset \operatorname{int} S$, it follows that $k_\tau \in l_1(\infty)$. Lemma 2.2 yields

$$\rho(\mathcal{K}_\tau) = \max_{|z|\geq 1} \rho(\mathbf{K}_\tau(z)) = \max_{|z|\geq 1} \rho\left(\mathbf{K}\left(\frac{1}{\tau}\frac{a}{b}(z)\right)\right) .$$

By definition of the stability region,

$$\bar{\mathbb{C}} \setminus \operatorname{int} S = \left\{\frac{a}{b}(z) : |z| \geq 1\right\} ,$$

and thereby (4.14) follows. Equality (4.15) is obtained by the maximum principle. Note that we write "sup" instead of "max," since the maximum may be approached at infinity. □

In $l_2(\infty)$, a similar result holds for the norm by application of Lemma 2.3.

THEOREM 4.5. *Assume* $\sigma(-\tau M_B^{-1} M_A) \subset \operatorname{int} S$, *and consider* $\mathcal{K}_\tau$ *as an operator in* $l_2(\infty)$. *Denote by* $||\cdot||_2$ *the* l_2*-norm* (2.2) *with* $||\cdot||$ *the standard Euclidean vector norm. Then,*

$$||\mathcal{K}_\tau||_2 = \sup\{||\mathbf{K}(z)|| : \tau z \in \mathbb{C} \setminus \operatorname{int} S\} \tag{4.16}$$

$$= \sup_{\tau z \in \partial S} ||\mathbf{K}(z)|| \,. \tag{4.17}$$

Analogous to the discussion in [17, Thm. 4.2], we can make the following note.

Remark 4.3. When the assumption in the above theorems is violated, a weaker condition may be satisfied: $\sigma(-\tau M_B^{-1} M_A) \subset \operatorname{int} S_{\gamma\tau}$, where $S_{\gamma\tau}$ consists of all μ for which $a(e^{-\gamma\tau}z) - \mu b(e^{-\gamma\tau}z)$ (around $\mu = \infty$: $\mu^{-1}a(e^{-\gamma\tau}z) - b(e^{-\gamma\tau}z)$) satisfies the root condition. The analysis then can be redone using an exponentially scaled norm,

$$||u_\tau||_\gamma = ||\{u_i\}||_\gamma = ||\{e^{-\gamma\tau i} u_i\}|| \,. \tag{4.18}$$

The norm in the right-hand side is a standard p-norm (2.2). With this change of norm, the suprema in Theorems 4.4 and 4.5 have to be taken over all τz in $\mathbb{C} \setminus \operatorname{int} S_{\gamma\tau}$, or, after application of the maximum principle, over $\partial S_{\gamma\tau}$.

4.3. Discrete-time versus continuous-time results. The continuous-time results (4.3) are regained when we let $\tau \to 0$ in the convergence formulae for operator $\mathcal{K}_\tau$. For finite time intervals, we have

$$\lim_{\tau\to 0} \rho(\mathcal{K}_\tau) = \lim_{\tau\to 0} \rho\left(\mathbf{K}\left(\frac{1}{\tau}\frac{\alpha_k}{\beta_k}\right)\right) = \rho(\mathbf{K}(\infty)) = \rho(\mathcal{K}) .$$

A similar result is found for infinite time intervals. Note that the tangent to ∂S in the origin of the complex plane is the imaginary axis, for any consistent linear multistep method. As such, the boundary of the scaled stability region $\partial(\frac{1}{\tau} S)$ tends to the imaginary axis when $\tau \to 0$. Consequently,

$$\lim_{\tau\to 0} \rho(\mathcal{K}_\tau) = \lim_{\tau\to 0} \sup_{\tau z \in \partial S} \rho(\mathbf{K}(z)) = \sup_{\xi \in \mathbb{R}} \rho(\mathbf{K}(i\xi)) = \rho(\mathcal{K}) .$$

Furthermore, for a fixed time step τ, we can prove the following theorem for $A(\alpha)$-stable linear multistep methods (see Definition 3.3). The theorem is closely related to [14, Prop. 9], where multigrid waveform relaxation on finite-difference grids is analysed. We reformulate the proof, using our notations, for completeness.

THEOREM 4.6. *Assume $\sigma(-\tau M_B^{-1}M_A) \subset \Sigma_\alpha$. Consider $\mathcal{K}_\tau$ as an operator in $l_p(\infty)$ and $\mathcal{K}$ as an operator in $L_p(0,\infty)$, with $1 \leq p \leq \infty$. Then,*

(i) *if the linear multistep method is A-stable, then $\rho(\mathcal{K}_\tau) \leq \rho(\mathcal{K})$;*

(ii) *if the linear multistep method is $A(\alpha)$-stable, then*

$$\rho(\mathcal{K}_\tau) \leq \sup_{z\in\Sigma_\alpha^c} \rho(\mathbf{K}(z)) = \sup_{z\in\partial\Sigma_\alpha^c} \rho(\mathbf{K}(z)) \,, \tag{4.19}$$

with $\Sigma_\alpha^c = \mathbb{C} \setminus \Sigma_\alpha = \{z : |\text{Arg}(z)| \leq \pi - \alpha\}$.

Proof. Part (i) is a special case of (ii) with $\alpha = \pi/2$, combined with the second equality of (4.3). For part (ii), we notice that we may apply Theorem 4.4 since $\sigma(-\tau M_B^{-1}M_A) \subset \Sigma_\alpha \subset$ int S. Therefore,

$$\rho(\mathcal{K}_\tau) = \max_{|z|\geq 1} \rho\left(\mathbf{K}\left(\frac{1}{\tau}\frac{a}{b}(z)\right)\right) . \tag{4.20}$$

If the multistep method is $A(\alpha)$-stable, then $\frac{a}{b}(z) \in \Sigma_\alpha^c$ for $|z| \geq 1$. Combining the latter with (4.20) yields the inequality of (4.19). The equality is obtained by the maximum principle. □

5. The multigrid waveform relaxation method. The splittings of matrices B and A used in actual computations typically correspond to Gauss–Seidel or weighted Jacobi splittings. Each iteration defined by (4.1) can then be computed as the solution of d ordinary differential equations, each in a single unknown. The resulting iteration can be accelerated by using the multigrid principle, in a very similar way as the standard pointwise relaxation methods are accelerated when solving elliptic partial differential equations.

The continuous-time two-grid waveform relaxation scheme is sketched below. We refer to [10] for a more elaborate description. The algorithm uses two nested grids, a coarse grid Ω_H and a fine grid Ω_h. Grid functions are mapped from the one grid to the other by a prolongation (or interpolation) operator ($p : \Omega_H \to \Omega_h$) and a restriction operator ($r : \Omega_h \to \Omega_H$). The discretisation on the fine grid is defined by the matrices B_h and A_h, the discretisation on the coarse grid by B_H and A_H. One iteration transforms iterate $u^{(\nu-1)}$ into $u^{(\nu)}$ in three steps.

(i) Presmoothing. Set $x_h^{(0)} = u^{(\nu-1)}$ and perform ν_1 fine-grid waveform relaxation steps: for $\nu = 1, 2, \ldots, \nu_1$, solve

$$M_{B_h}\dot{x}_h^{(\nu)} + M_{A_h}x_h^{(\nu)} = N_{B_h}\dot{x}_h^{(\nu-1)} + N_{A_h}x_h^{(\nu-1)} + f_h \ , \ \text{with} \ x_h^{(\nu)}(0) = u_0 \, . \tag{5.1}$$

(ii) Coarse-grid correction. Calculate the defect

$$d_h = B\dot{x}_h^{(\nu_1)} + A_h x_h^{(\nu_1)} - f_h \, .$$

Solve the coarse-grid defect equation

$$B_H\dot{v}_H + A_H v_H = rd_h, \ \text{with} \ v_H(0) = 0 \, ,$$

and correct,

$$\bar{x}_h = x_h^{(\nu_1)} - pv_H \, .$$

(iii) Postsmoothing. Set $x_h^{(0)} = \bar{x}_h$ and perform ν_2 fine-grid waveform relaxation steps (5.1). Set $u^{(\nu)} = x_h^{(\nu_2)}$.

This two-grid cycle can be written as $u^{(\nu)} = \mathcal{M}u^{(\nu-1)} + \varphi$, where $\mathcal{M}$ is called the *continuous-time two-grid waveform relaxation operator*. The convergence formulae of $\mathcal{M}$ as an iteration operator resemble those of the standard waveform relaxation method. More precisely, in [10] we find for the finite and for the infinite time-interval case, respectively,

$$(5.2) \qquad \rho(\mathcal{M}) = \rho(\mathbf{M}(\infty)) \quad \text{and} \quad \rho(\mathcal{M}) = \sup_{\mathrm{Re}(z)\geq 0} \rho(\mathbf{M}(z)) = \sup_{\xi\in\mathbb{R}} \rho(\mathbf{M}(i\xi)) \,.$$

$\mathbf{M}(z)$, the continuous-time two-grid waveform relaxation matrix, is given by

$$\mathbf{M}(z) = \mathbf{K}^{\nu_2}(z)(I - p(zB_H + A_H)^{-1}r(zB_h + A_h))\mathbf{K}^{\nu_1}(z) \,,$$

with $\mathbf{K}(z)$ the fine-grid matrix given in (4.2). We recall from [10, Rem. 4.1] the following important remark.

Remark 5.1. In the case of a Gauss–Seidel (or weighted Jacobi) splitting of A_h and B_h, $\mathbf{K}(z)$ and $\mathbf{M}(z)$ are respectively the Gauss–Seidel (or weighted Jacobi) iteration matrix and the two-grid iteration matrix for the system $(zB_h + A_h)u_h = f_h$.

In the following, the discrete-time variant of this *two-grid* waveform relaxation method is theoretically investigated. We refer to the Appendix for a similar convergence study of the *multigrid* waveform relaxation method. The latter is defined by solving the coarse-grid defect equation using one or more similar two-grid waveform relaxation cycles, and applying this idea recursively.

5.1. The discrete-time two-grid waveform relaxation operator. We discretise the equations of the continuous-time two-grid cycle using a linear multistep method with a fixed time step τ. As before, we assume that we do not iterate on the k given starting values. The discrete-time two-grid cycle defines a linear operator $\mathcal{M}_\tau$, which satisfies

$$(5.3) \qquad u_\tau^{(\nu)} = \mathcal{M}_\tau u_\tau^{(\nu-1)} + \varphi_\tau \quad \text{and} \quad e_\tau^{(\nu)} = \mathcal{M}_\tau e_\tau^{(\nu-1)} \,,$$

where $e_\tau^{(\nu)}$ is the error of the νth iterate. Our notation is again similar to (4.6). $\mathcal{M}_\tau$ is called the *discrete-time two-grid waveform relaxation operator*.

The second equation of (5.3) can be reformulated similar to how we arrived at (4.8),

$$(5.4) \qquad E^{(\nu)} = (C_h^{-1}D_h)^{\nu_2}(I - PF_H^{-1}RF_h)(C_h^{-1}D_h)^{\nu_1}E^{(\nu-1)} \,.$$

Here, $E^{(\nu)} = [e_k^{(\nu)}e_{k+1}^{(\nu)} \dots e_{N+k-1}^{(\nu)}]^t$. Matrices C_h, D_h, F_H and F_h are $N \times N$-block lower triangular matrices with $k+1$ constant diagonals. The blocks of the jth diagonal equal $(C_h)_{k-j}$, $(D_h)_{k-j}$, $(F_H)_{k-j}$, and $(F_h)_{k-j}$, respectively, with

$$(C_h)_j = \frac{1}{\tau}\alpha_j M_{B_h} + \beta_j M_{A_h} \,, \quad (D_h)_j = \frac{1}{\tau}\alpha_j N_{B_h} + \beta_j N_{A_h} \,,$$

and

$$(F_H)_j = \frac{1}{\tau}\alpha_j B_H + \beta_j A_H \,, \quad (F_h)_j = \frac{1}{\tau}\alpha_j B_h + \beta_j A_h \,.$$

Matrices P and R are block diagonal with constant diagonal blocks equal to matrices p and r, respectively. I is the identity matrix of dimension $d \times N$. The resulting discrete-time two-grid cycle is well defined, if and only if the following conditions hold:

$$(5.5) \qquad \frac{\alpha_k}{\beta_k} \notin \sigma(-\tau M_{B_h}^{-1}M_{A_h}) \quad \text{and} \quad \frac{\alpha_k}{\beta_k} \notin \sigma(-\tau B_H^{-1}A_H) \,.$$

We shall refer to (5.5) as the discrete solvability conditions for the two-grid algorithm.

It can be seen that the matrix premultiplying $E^{(\nu-1)}$ in (5.4) is a lower triangular block Toeplitz matrix. This implies that $\mathcal{M}_\tau$ is a discrete linear convolution operator. The discrete Laplace transform of its matrix-valued kernel can be found by transforming the equations of the discrete-time two-grid cycle. It is denoted by $\mathbf{M}_\tau(z)$, the discrete-time two-grid waveform relaxation matrix, and equals

$$\mathbf{M}_\tau(z) = \mathbf{K}_\tau{}^{\nu_2}(z)\,\mathbf{C}_\tau(z)\,\mathbf{K}_\tau{}^{\nu_1}(z)\,,$$

with $\mathbf{K}_\tau(z)$ given by (4.9) and $\mathbf{C}_\tau(z)$ given by

$$I - p\,(a(z)B_H + \tau b(z)A_H)^{-1}\,r\,(a(z)B_h + \tau b(z)A_h)\,.$$

Matrix $\mathbf{M}_\tau(z)$ satisfies a similar relation as $\mathbf{K}_\tau(z)$ does in (4.10):

$$\mathbf{M}_\tau(z) = \mathbf{M}\left(\frac{1}{\tau}\frac{a}{b}(z)\right)\,. \tag{5.6}$$

5.2. Convergence analysis. The convergence analysis of operator $\mathcal{M}_\tau$ is very similar to the convergence analysis of the standard waveform relaxation operator $\mathcal{K}_\tau$.

5.2.1. Convergence on finite time intervals.

THEOREM 5.1. *Assume that conditions* (5.5) *are satisfied, and consider $\mathcal{M}_\tau$ as an operator in $l_p(N)$, with $1 \le p \le \infty$ and N finite. Then, $\mathcal{M}_\tau$ is bounded and*

$$\rho(\mathcal{M}_\tau) = \rho\left(\mathbf{M}\left(\frac{1}{\tau}\frac{\alpha_k}{\beta_k}\right)\right)\,. \tag{5.7}$$

Proof. The theorem follows from Lemma 2.1 and (5.6):

$$\rho(\mathcal{M}_\tau) = \rho(\mathbf{M}_\tau(\infty)) = \rho\left(\mathbf{M}\left(\frac{1}{\tau}\frac{a}{b}(\infty)\right)\right) = \rho\left(\mathbf{M}\left(\frac{1}{\tau}\frac{\alpha_k}{\beta_k}\right)\right)\,. \qquad \square$$

5.2.2. Convergence on infinite time intervals. We first prove the boundedness of $\mathcal{M}_\tau$, i.e., we prove the two-grid equivalent of Lemma 4.3.

LEMMA 5.2. *Assume $\sigma(-\tau M_{B_h}^{-1}M_{A_h}) \cup \sigma(-\tau B_H^{-1}A_H) \subset \operatorname{int} S$. Then, $\mathcal{M}_\tau$ is bounded in $l_p(\infty)$.*

Proof. It is sufficient to prove that the kernel of $\mathcal{M}_\tau$ belongs to $l_1(\infty)$. We shall analyse each of the factors in the formula for $\mathbf{M}_\tau(z)$ separately.

We have, from the proof of Lemma 4.3, that $\mathbf{K}_\tau(z)$ is the discrete Laplace transform of an l_1-sequence, say q_τ, if

$$\det\left(a(z)M_{B_h} + \tau b(z)M_{A_h}\right) \neq 0\,,\quad |z| \ge 1\,. \tag{5.8}$$

Consider the l_1-sequence

$$\alpha_k B_H + \tau\beta_k A_H,\ \alpha_{k-1}B_H + \tau\beta_{k-1}A_H, \ldots, \alpha_0 B_H + \tau\beta_0 A_H,\ 0,\ 0, \ldots.$$

Its transform is given by $z^{-k}(a(z)B_H + \tau b(z)A_H)$. By Wiener's inversion theorem, $(a(z)B_H + \tau b(z)A_H)^{-1}z^k$ is the transform of an l_1-sequence, say w_τ, if

$$\det(a(z)B_H + \tau b(z)A_H) \neq 0\,,\quad |z| \ge 1\,. \tag{5.9}$$

Next, consider the l_1-sequences

$$\begin{aligned} i_\tau &= I,\ 0, \ldots, 0,\ 0,\ 0, \ldots,\\ v_\tau &= \alpha_k B_h + \tau\beta_k A_h,\ \alpha_{k-1}B_h + \tau\beta_{k-1}A_h, \ldots, \alpha_0 B_h + \tau\beta_0 A_h,\ 0,\ 0, \ldots. \end{aligned}$$

I is the $d \times d$ identity matrix. Their transforms are given, respectively, by

$$I \qquad \text{and} \qquad z^{-k}\left(a(z)B_h + \tau b(z)A_h\right).$$

Now, consider the sequence

$$\underbrace{q_\tau \star q_\tau \star \cdots \star q_\tau}_{\nu_2 \text{ times}} \star \left(i_\tau - p\, w_\tau \;\star\; r\, v_\tau \right) \star \underbrace{q_\tau \star q_\tau \star \cdots \star q_\tau}_{\nu_1 \text{ times}} . \tag{5.10}$$

If conditions (5.8) and (5.9) are satisfied, it follows that this sequence is in l_1. (l_1 is closed under convolution and addition. The multiplication of an l_1-sequence by a matrix is an l_1-sequence.) The discrete Laplace transform of sequence (5.10) equals $\mathbf{M}_\tau(z)$, hence the sequence equals the kernel of $\mathcal{M}_\tau$. To conclude, $\mathcal{M}_\tau$ is bounded under conditions (5.8) and (5.9).

Suppose one of these conditions is violated. That is to say, there is a z with $|z| \geq 1$ such that $\det(a(z)M_{B_h} + \tau b(z)N_{B_h}) = 0$ or $\det(a(z)B_H + \tau b(z)A_H) = 0$. That would mean that $\frac{a}{b}(z) \in \sigma(-\tau M_{B_h}^{-1}M_{A_h}) \cup \sigma(-\tau B_H^{-1}A_H)$. Since $|z| \geq 1$ this violates the assumption of the lemma. □

Remark 5.2. The assumption of Lemma 5.2 implies the two-grid discrete solvability conditions (5.5).

Remark 5.3. The assumption of Lemma 5.2 implies that all poles of $\mathbf{M}(z)$ are inside the scaled stability region $\frac{1}{\tau}S$.

THEOREM 5.3. *Assume $\sigma(-\tau M_{B_h}^{-1}M_{A_h}) \cup \sigma(-\tau B_H^{-1}A_H) \subset \operatorname{int} S$, and consider $\mathcal{M}_\tau$ as an operator in $l_p(\infty)$, with $1 \leq p \leq \infty$. Then,*

$$\rho(\mathcal{M}_\tau) = \sup\{\rho(\mathbf{M}(z)) | \tau z \in \mathbb{C} \setminus \operatorname{int} S\} \tag{5.11}$$

$$= \sup_{\tau z \in \partial S} \rho(\mathbf{M}(z)). \tag{5.12}$$

Proof. The proof is a direct consequence of Lemma 2.2, and is similar to the proof of Theorem 4.4. □

Application of Lemma 2.3 yields the following result for the l_2-norm of $\mathcal{M}_\tau$.

THEOREM 5.4. *Assume $\sigma(-\tau M_{B_h}^{-1}M_{A_h}) \cup \sigma(-\tau B_H^{-1}A_H) \subset \operatorname{int} S$, and consider $\mathcal{M}_\tau$ as an operator in $l_2(\infty)$. Denote by $||\cdot||_2$ the l_2-norm* (2.2) *with $||\cdot||$ the standard Euclidean vector norm. Then,*

$$||\mathcal{M}_\tau||_2 = \sup\{||\mathbf{M}(z)|| : \tau z \in \mathbb{C} \setminus \mathit{int}\, S\} \tag{5.13}$$

$$= \sup_{\tau z \in \partial S} ||\mathbf{M}(z)||. \tag{5.14}$$

Remark 5.4. If the assumption of the former theorems is violated, but the weaker condition $\sigma(-\tau M_{B_h}^{-1}M_{A_h}) \cup \sigma(-\tau B_H^{-1}A_H) \subset \operatorname{int} S_{\gamma\tau}$ holds, then we can formulate a remark analogous to Remark 4.3.

5.3. Discrete-time versus continuous-time results. The relation between the two-grid operators $\mathcal{M}_\tau$ and $\mathcal{M}$ is similar to the relation between $\mathcal{K}_\tau$ and $\mathcal{K}$. More precisely, for both finite and infinite intervals,

$$\lim_{\tau \to 0} \rho(\mathcal{M}_\tau) = \rho(\mathcal{M}).$$

We also state the two-grid equivalent of Theorem 4.6, without proof.

THEOREM 5.5. *Assume $\sigma(-\tau M_{B_h}^{-1}M_{A_h}) \cup \sigma(-\tau B_H^{-1}A_H) \subset \Sigma_\alpha$. Consider $\mathcal{M}_\tau$ as an operator in $l_p(\infty)$ and $\mathcal{M}$ as an operator in $L_p(0, \infty)$, with $1 \leq p \leq \infty$. Then,*

with $\Sigma_\alpha^c = \mathbb{C} \setminus \Sigma_\alpha = \{z : |\mathrm{Arg}(z)| \le \pi - \alpha\}$.

6. Model problem analysis.

6.1. A one-dimensional model problem. In order to clarify the convergence behaviour of the waveform relaxation methods, we shall start with a very simple and small model problem, the one-dimensional heat equation on the unit interval,

$$\frac{\partial \mathbf{u}}{\partial t} - \frac{\partial^2 \mathbf{u}}{\partial x^2} = 0 \,, \quad x \in [0,1] \,. \tag{6.1}$$

Dirichlet boundary and initial conditions are chosen such that the solution equals $\mathbf{u}(x,t) = \sin(\pi x)\exp(-\pi^2 t)$. The problem is discretised using linear finite elements on a mesh Ω_h with mesh size $h = 1/16$.

We consider the Gauss–Seidel waveform relaxation algorithm and the two-level method, with one red/black Gauss–Seidel presmoothing step, a similar postsmoothing step, standard coarsening ($H = 2h$), and linear interpolation. The restriction is defined in the standard way for finite-element multigrid methods, i.e., $r = p^t$. For both waveform algorithms, we analyse the use of different time-discretisation formulae, with a constant time step $\tau = 1/100$. In particular, we consider the trapezoidal rule or Crank–Nicolson (CN) method, and the backward differentiation formulae (BDF) of order 1 up to 5. The spectral radii of the finite and infinite time-interval operators for the standard and for the two-level algorithm are reported in Tables 6.1 and 6.2, respectively. The results were computed by direct numerical evaluation of formulae (4.11) and (4.15), and (5.7) and (5.12). The tables also present values of convergence factors, observed with an implementation of the methods, using 1000 time steps. An oscillatory initial approximation to the solution was chosen in order to excite all possible error frequencies. The measured values correspond very well to the theoretical, infinite-interval spectral radii. This effect is explained in more detail in §7.1.

These results can be understood by looking at the *spectral picture* [21, p. 107], which facilitates a graphical inspection of convergence. In the spectral picture a set of contour lines of the function $\rho(\mathbf{K}(z))$ or $\rho(\mathbf{M}(z))$ is plotted for z in a region of the complex plane close to the complex origin. On top of this picture, the scaled stability boundary of the linear multistep methods can be plotted. Figures 6.1 and 6.2 display contour lines of $\rho(\mathbf{K}(z))$ and $\rho(\mathbf{M}(z))$ (for

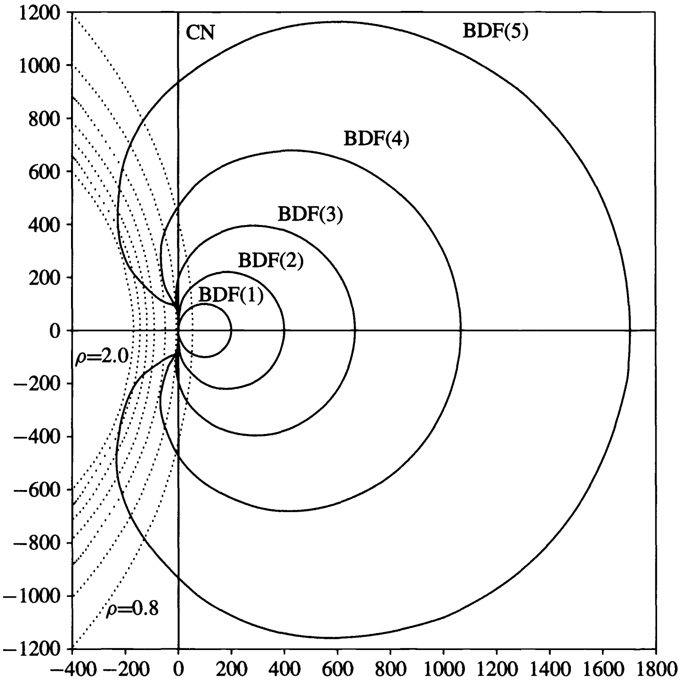

FIG. 6.1. *Spectral picture and graphical convergence test for* (6.1) ($\rho(\mathbf{K}(z))$, $h = 1/16$, $\tau = 1/100$).

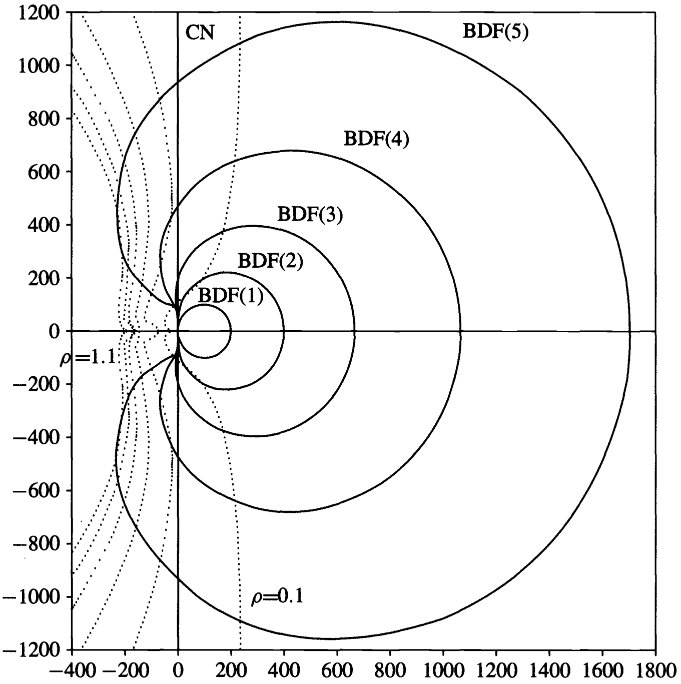

FIG. 6.2. *Spectral picture and graphical convergence test for* (6.1) ($\rho(\mathbf{M}(z))$, $h = 1/16$, $\tau = 1/100$).

values 0.8, 1.0, 1.2, 1.4, 1.6, 1.8, 2.0 and for values 0.1, 0.3, 0.5, 0.7, 0.9, 1.1, respectively) for the model problem, together with the scaled stability region boundaries of the CN and BDF methods.

The values of the finite-interval spectral radii can be estimated by checking the values of the functions at the points on the real axis given by $\frac{1}{\tau}\frac{\alpha_k}{\beta_k}$ (which are not shown in the picture). With increasing order of the BDF methods, these points move to the right. Indeed, $\frac{\alpha_k}{\beta_k}$ equals 1 (BDF(1)), 3/2 (BDF(2)), 11/6 (BDF(3)), 25/12 (BDF(4)), and 137/60 (BDF(5)). A value of 2 is found for the CN method.

The values of the infinite-interval spectral radii can be estimated by taking the maximum of $\rho(\mathbf{K}(z))$ or $\rho(\mathbf{M}(z))$ over the plotted scaled stability region boundaries. The infinite-length discrete-time waveform methods are convergent for the CN method and the low-order BDF methods. Divergence is observed for some high-order methods. In general, the spectral radius increases with increasing order of the BDF method. This was to be expected from Theorems 4.6 and 5.5, and the knowledge that the BDF methods are $A(\alpha)$-stable with $\alpha = 90°$ (BDF(1), BDF(2)), $\alpha = 88°$ (BDF(3)), $\alpha = 73°$ (BDF(4)), and $\alpha = 51°$ (BDF(5)). Note also that the maximum of $\rho(\mathbf{K}(z))$ over $\frac{1}{\tau}\partial S$ is found at the origin for CN, BDF(1), and BDF(2). Hence, the equality of the corresponding values in Table 6.1.

6.2. A two-dimensional model problem. Next, we study the two-dimensional heat equation on the unit square,

$$\frac{\partial \mathbf{u}}{\partial t} - \frac{\partial^2 \mathbf{u}}{\partial x^2} - \frac{\partial^2 \mathbf{u}}{\partial y^2} = 0\,, \quad (x, y) \in [0,1] \times [0,1]\,, \tag{6.2}$$

completed with Dirichlet boundary conditions and an initial condition. The analytical solution equals $\mathbf{u}(x, y, t) = 1 + \sin(\pi x/2)\sin(\pi y/2)\exp(-\pi^2 t/2)$. The problem is discretised on a regular triangular mesh with linear elements, and on a regular rectangular mesh with bilinear elements. We will analyse convergence of the two-level method, with one four-colour Gauss–Seidel presmoothing step, a similar postsmoothing step, standard coarsening ($H = 2h$), and linear interpolation. The restriction is again defined by $r = p^t$, which leads to a seven-point formula in the linear element case, and a nine-point formula in the bilinear element case.

It is no longer practical to use a direct numerical evaluation of $\rho(\mathbf{M}(z))$ to study convergence characteristics. Instead, we can resort to Remark 5.1, which relates $\rho(\mathbf{M}(z))$ to the analysis of a standard two-grid method for a simple elliptic problem. The latter can be analysed efficiently using a classical Fourier mode analysis as introduced by Brandt in [1]. Fourier analysis shows that, under certain conditions, matrix $\mathbf{M}(z)$ is spectrally equivalent to a block-diagonal matrix whose diagonal blocks are matrices of size at most four by four. The general form of these four-by-four matrices can be derived by studying the action of the different multigrid operators on certain sets of four related exponential or sinusoidal Fourier modes. The spectral properties of $\mathbf{M}(z)$ are then calculated easily. We refer to the above reference, and to [19] and [24] for an in-depth discussion of the classical Fourier mode analysis. In the present paper we have closely followed the guidelines laid out in [24, Chap. 7].

Figure 6.3 shows the spectral picture for linear finite elements with h=1/32. In the computation we used exponential Fourier modes. They led to an exact value of the spectral radius in the case of periodic boundary conditions. A slight modification to the standard exponential mode analysis was applied to cater for the Dirichlet boundary conditions, a modification described in [24, p. 111]. Figure 6.4 shows a similar picture for bilinear elements on a grid with h=1/32. The nature of the stencil in the bilinear element case is such that a sinusoidal Fourier mode analysis is possible, see [19, §7.1]. The sinusoidal mode analysis leads automatically to the correct value of the spectral radius in the case of a problem with Dirichlet boundary conditions.

In Tables 6.3 and 6.4 we present two-grid spectral radii for the finite-length and infinite-length waveform operators, together with two-grid convergence factors computed numerically using an oscillatory initial approximation and 1000 time steps. As for the one-dimensional problem, there is again a good agreement between the theoretical infinite-length spectral radii and the experimental convergence factors.

7. Numerical experiments.

7.1. The one-dimensional model problem.

In this section, we shall clarify the relation between the finite and infinite time-interval spectral radii. To this end, we solve (6.1) using the Gauss–Seidel waveform method with BDF(2) and BDF(5) time discretisation, with constant time step $\tau = 1/100$ on 100 time levels ($N = 100$). (Note that a similar analysis could be done for the two-level method and/or for larger values of N. It would lead to similar conclusions and insights.)

Let $d_\tau^{(\nu)}$ denote the discrete defect or residual in the νth iteration. The convergence factor of the νth iteration is then defined by

$$\rho^{(\nu)} = ||d_\tau^{(\nu)}||_2/||d_\tau^{(\nu-1)}||_2 . \tag{7.1}$$

In Fig. 7.1 successive convergence factors are plotted for the first 400 waveform Gauss–Seidel iterations, when BDF(2) discretisation is used. These factors appear to remain more or less constant for a large number of iterations. The height of the plateau matches the value obtained in Table 6.1 for infinite time intervals, i.e., 0.962. Eventually, the plateau in Fig. 7.1 is left, and the factors start to decrease. Ultimately, they start to rise again and reach the value 1. This is for purely technical reasons, because at that time the solution has converged within the finite-precision arithmetic of the implementation. A similar plot is given in Fig. 7.2 for the BDF(5) discretisation. Here, the evolution is much more erratic. The results clearly indicate divergence for a large number of iterations. After a sufficient number of iterations, the convergence factors decrease below 1, and the iteration starts to converge rapidly.

This behaviour can be explained by examining the *time-level convergence factors*. These factors are similar to the standard convergence factors (7.1), but are evaluated for each time level separately,

$$\rho_k^{(\nu)} = ||d_k^{(\nu)}||_2/||d_k^{(\nu-1)}||_2 .$$

In Fig. 7.3, we plotted such time-level convergence factors for the BDF(2) method (for $\nu = 10$, $\nu = 100$, $\nu = 200$, and $\nu = 300$). The factor measured at the first time level equals

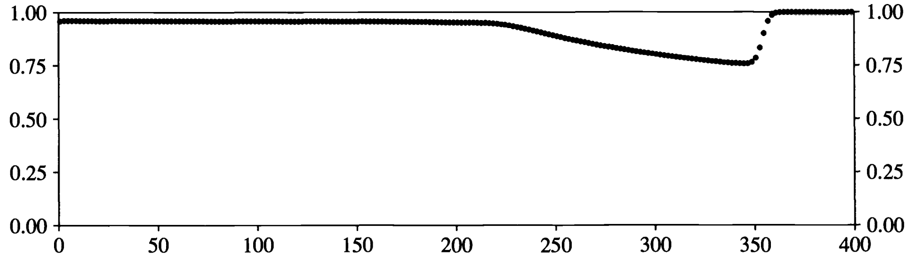

FIG. 7.1. *Convergence factors* $\rho^{(\nu)}$ *as a function of* ν *(BDF(2) method).*

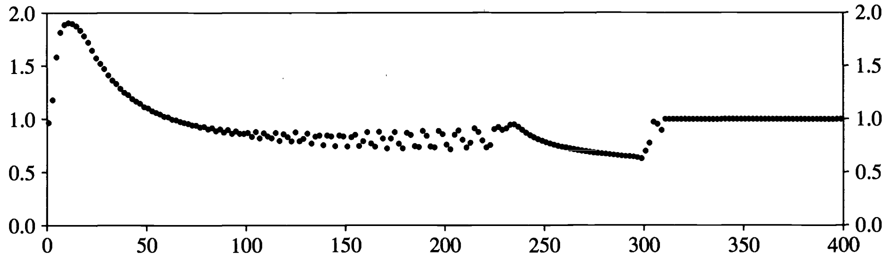

FIG. 7.2. *Convergence factors* $\rho^{(\nu)}$ *as a function of* ν *(BDF(5) method).*

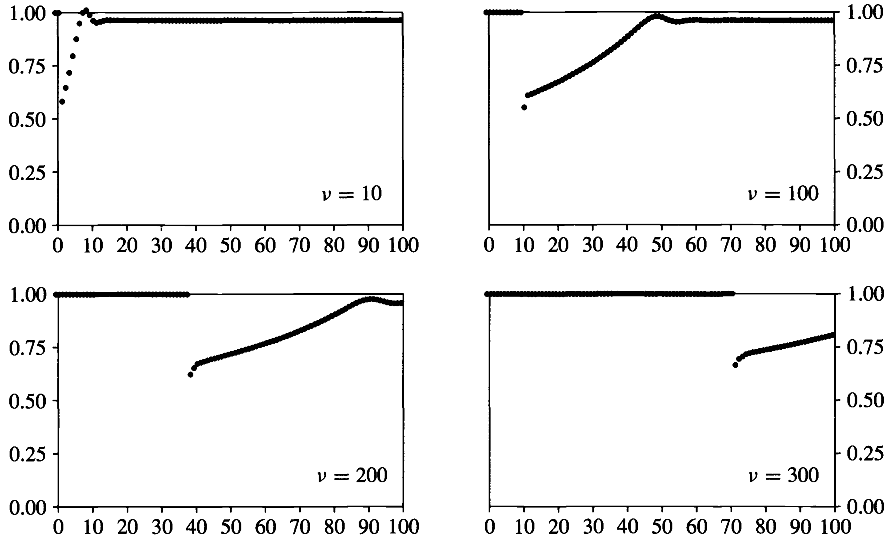

FIG. 7.3. *Time-level convergence factors* $\rho_k^{(\nu)}$ *as a function of k (BDF(2) method).*

0.548, exactly equal to the value predicted by the finite time-interval analysis in Table 6.1. The convergence factors at the next time levels increase, and eventually become constant. The height of the plateau matches the spectral radius value for infinite time intervals. As more iterations are applied, the plateau is forced out of the time window and the corresponding convergence factors decrease.

In Fig. 7.4, we have plotted time-level convergence factors for the BDF(5) method (for $\nu = 1$, $\nu = 5$, $\nu = 50$, and $\nu = 100$). Again, we observe that the factor at the first time level corresponds to the value predicted by the finite time-interval analysis (0.414). The pictures illustrate the onset of oscillations which rapidly explode. As more iterations are applied, the

region of divergent behaviour moves to the right, and is forced out of the time window. From then on, the iteration converges rapidly.

7.2. The two-dimensional problem. We discretise (6.2) using linear basis functions (triangular elements) or bilinear basis functions (rectangular elements) on a mesh with equal mesh size in x- and y-direction. The resulting system of ODEs is solved using Gauss–Seidel and multigrid waveform relaxation for $t \in [0, 1]$. In the latter we applied V-cycles and W-cycles, with one presmoothing and one postsmoothing step of four-colour Gauss–Seidel type. We use standard coarsening down to a mesh with size $h = 1/2$, seven-point prolongation (linear basis functions), and nine-point prolongation (bilinear basis functions). The restriction operator is defined as $r = p^t$.

In Tables 7.1 and 7.2 we report *averaged convergence factors.* These are defined as the average of $\rho^{(\nu)}$ over the region of nearly constant behaviour. The dashes ("–") in the tables indicate that the corresponding method showed divergence over a large number of iterations. Both tables illustrate the dependence of the convergence on the nature of the time-discretisation method.

In Tables 7.3–7.8, we report averaged convergence factors obtained with W-cycles for different values of the mesh-size parameters, and for different discretisation schemes. We observe a dependence of the actual convergence factors on h and τ. For the Crank–Nicolson and BDF(2) methods, these factors appear to be bounded by a constant, smaller than one, independent of the mesh size.

For a constant value of h, we expect the convergence factors to converge to the continuous-time results when τ decreases, see §§4.3 and 5.3. This behaviour is recognised clearly for the CN method in Tables 7.3 and 7.6. Due to the shape of the stability regions of the BDF(2) and BDF(4) methods, it takes a much smaller value of τ before the discrete-time convergence factors tend to the continuous-time ones, see Tables 7.4, 7.5, 7.7, and 7.8. For a constant value of τ, we observe an initial increase of the convergence factor when h decreases. For sufficiently small h the convergence factor starts to decrease again. This behaviour is similar to what is observed when the multigrid waveform relaxation method is used to solve the ODEs obtained by spatial finite-difference discretisation of a parabolic problem. We refer to [21, §3.5] for an intuitive explanation, and to [22] for a discussion based on an exponential Fourier mode analysis.

Appendix. Analysis of the multigrid waveform relaxation operators. We consider the case where we have a hierarchy of grids, $\Omega_{h_0} \subset \Omega_{h_1} \subset \cdots \subset \Omega_{h_l}$, a set of prolongation operators $p_{h_i}^{h_{i+1}} : \Omega_{h_i} \longrightarrow \Omega_{h_{i+1}}$, $0 \le i \le l-1$, a set of restriction operators, $r_{h_{i+1}}^{h_i} : \Omega_{h_{i+1}} \longrightarrow \Omega_{h_i}$, $0 \le i \le l-1$, and discretisation matrices B_{h_i} and A_{h_i}, $0 \le i \le l$. The multigrid algorithm differs from the two-grid cycle in that the coarse-grid defect equation is approximately solved by an application of γ two-grid cycles, an idea that is further extended recursively. (The classical V- and W-cycles correspond to $\gamma = 1$ and $\gamma = 2$, respectively.) In the continuous-time case this leads to an iteration of the form $u^{(\nu)} = \mathcal{M}_{h_l} u^{(\nu-1)} + \varphi$. In the discrete-time case we end up with an iteration operator which we denote by $(\mathcal{M}_{h_l})_\tau$.

Both iterative schemes can be analysed in exactly the same way as the two-grid cycles have been analysed. A Laplace-transform argument is used in the continuous-time case, whereas the discrete-time case is treated by using a discrete Laplace-transform method. Proceeding as before, we can derive the symbol of the continuous-time multigrid waveform relaxation method, $\mathbf{M}_{\mathbf{h_l}}(z)$. The latter takes a particularly simple form under the natural assumption that the semidiscretised PDE operators are invertible. In that case we can apply the following Lemma.

LEMMA A.1. *Let $B\dot{u} + Au = f$ have a unique solution, and let it be solved approximately by γ steps of a consistent waveform method: $u^{(k)} = \mathcal{M}u^{(k-1)} + \varphi$ with $u^{(0)}(t) = 0$. Then, the γth iterate can be represented as $u^{(\gamma)} = (I - \mathcal{M}^\gamma)u$.*

Under the above assumption, the multigrid symbol becomes

$$\mathbf{M}_{\mathbf{h_l}}(z) = \begin{cases} \mathbf{K}_{\mathbf{h_l}}^{\nu_2}(z)\left(I - p_{h_{l-1}}^{h_l}\left(I - \mathbf{M}_{\mathbf{h_{l-1}}}^{\gamma}(z)\right)\mathbf{L}_{\mathbf{h_{l-1}}}^{-1}(z) r_{h_l}^{h_{l-1}} \mathbf{L}_{\mathbf{h_l}}(z)\right)\mathbf{K}_{\mathbf{h_l}}^{\nu_1}(z)\,, & \\ & l \neq 1, \\ \mathbf{K}_{\mathbf{h_1}}^{\nu_2}(z)\left(I - p_{h_0}^{h_1}\mathbf{L}_{\mathbf{h_0}}^{-1}(z) r_{h_1}^{h_0}\mathbf{L}_{\mathbf{h_1}}(z)\right)\mathbf{K}_{\mathbf{h_1}}^{\nu_1}(z)\,, & l = 1, \end{cases}$$

where $\mathbf{L}_{\mathbf{h_i}}(z) = zB_{h_i} + A_{h_i}$ and $\mathbf{K}_{\mathbf{h_i}}(z) = (zM_{B_{h_i}} + M_{A_{h_i}})^{-1}(zN_{B_{h_i}} + N_{A_{h_i}})$. Note that $\mathbf{M}_{\mathbf{h_l}}(z)$ is technically more complicated when the assumption is violated. In that case, it does not involve the factor $\mathbf{L}_{\mathbf{h_{l-1}}}^{-1}(z)$.

Remark A.1. Let $\mathbf{K}_{\mathbf{h_i}}(z)$ correspond to a Gauss–Seidel or weighted Jacobi splitting. Then, $\mathbf{M}_{\mathbf{h_l}}(z)$ is the multigrid iteration operator for the elliptic problem $(zB_{h_l} + A_{h_l})u_{h_l} = f_{h_l}$; compare [4, p. 162] and [19, p. 46].

As in [10], the continuous-time convergence theorems can be formulated in terms of this symbol. The ideas behind the proofs are identical to the ones behind the corresponding proofs in the above reference, and therefore omitted.

THEOREM A.2. *The multigrid waveform relaxation operator $\mathcal{M}_{h_l}$ is a bounded operator in $C[0, T]$ and*

$$\rho(\mathcal{M}_{h_l}) = \rho\left(\mathbf{M}_{\mathbf{h_l}}(\infty)\right) . \tag{A.2}$$

THEOREM A.3. *Assume that all eigenvalues of $M_{B_{h_i}}^{-1} M_{A_{h_i}}$, $1 \le i \le l$, and $B_{h_0}^{-1} A_{h_0}$ have positive real parts, and consider $\mathcal{M}_{h_l}$ as an operator in $L_p(0, \infty)$ with $1 \le p \le \infty$. Then, $\mathcal{M}_{h_l}$ is a bounded operator with spectral radius*

$$\rho(\mathcal{M}_{h_l}) = \sup_{\mathrm{Re}(z) \ge 0} \rho\left(\mathbf{M}_{\mathbf{h_l}}(z)\right) = \sup_{\xi \in \mathbb{R}} \rho\left(\mathbf{M}_{\mathbf{h_l}}(i\xi)\right) . \tag{A.3}$$

Following the line of arguments of §5.1, we can derive the discrete-time symbol

$$(\mathbf{M}_{\mathbf{h_l}})_\tau(z) = \mathbf{M}_{\mathbf{h_l}}\left(\frac{1}{\tau}\frac{a}{b}(z)\right) .$$

The discrete-time convergence theorems are immediate extensions of Theorems 5.1 and 5.3. The proofs are very similar.

THEOREM A.4. *Assume $\frac{\alpha_k}{\beta_k} \notin \bigcup_{i=1}^{l} \sigma(-\tau M_{B_{h_i}}^{-1} M_{A_{h_i}}) \cup \sigma\left(-\tau B_{h_0}^{-1} A_{h_0}\right)$, and consider $(\mathcal{M}_{h_l})_\tau$ as an operator in $l_p(N)$, with $1 \le p \le \infty$ and N finite. Then, $(\mathcal{M}_{h_l})_\tau$ is a bounded operator and*

$$\rho((\mathcal{M}_{h_l})_\tau) = \rho\left(\mathbf{M}_{\mathbf{h_l}}\left(\frac{1}{\tau}\frac{\alpha_k}{\beta_k}\right)\right) . \tag{A.4}$$

THEOREM A.5. *Assume $\bigcup_{i=1}^{l} \sigma(-\tau M_{B_{h_i}}^{-1} M_{A_{h_i}}) \cup \sigma(-\tau B_{h_0}^{-1} A_{h_0}) \subset \mathrm{int}\, S$, and consider $(\mathcal{M}_{h_l})_\tau$ as an operator in $l_p(\infty)$, with $1 \le p \le \infty$. Then,*

$$\rho((\mathcal{M}_{h_l})_\tau) = \sup\{\rho(\mathbf{M}_{\mathbf{h_l}}(z)) | \tau z \in \mathbb{C} \setminus \mathrm{int}\, S\} = \sup_{\tau z \in \partial S} \rho(\mathbf{M}_{\mathbf{h_l}}(z)) . \tag{A.5}$$

IMPLICIT EXTRAPOLATION METHODS FOR MULTILEVEL FINITE ELEMENT COMPUTATIONS*

MICHAEL JUNG† AND ULRICH RÜDE‡

Abstract. Extrapolation methods for the solution of partial differential equations are commonly based on the existence of error expansions for the approximate solution. Implicit extrapolation, by contrast, is based on applying extrapolation indirectly, by using it on quantities like the residual. In the context of multigrid methods, a special technique of this type is known as τ-extrapolation. For finite element systems this algorithm can be shown to be equivalent to higher order finite elements. The analysis is local and does not use global expansions, so that the implicit extrapolation technique may be used on unstructured meshes and in cases where the solution fails to be globally smooth. Furthermore, the natural multilevel structure can be used to construct efficient multigrid and multilevel preconditioning techniques. The effectivity of the method is demonstrated for heat conduction problems and problems from elasticity theory.

Key words. finite elements, extrapolation, multigrid, elasticity

1. Introduction.

Multigrid methods have been shown to be very efficient solvers for elliptic partial differential equations (PDE). In this paper we are concerned with the so-called τ-extrapolation multigrid method (see Brandt [6] and Hackbusch [7]), which is an extension of conventional multigrid that can improve the accuracy of the numerical result by implicitly using higher order approximations.

In contrast to conventional extrapolation methods for partial differential equations, as described in Marchuk and Shaidurov [15] and Blum, Lin, and Rannacher [4], the τ-extrapolation algorithm is based on an *implicit* application of Richardson's deferred approach to the limit. We do not take linear combinations of computed approximations, but extrapolate the *residuals* of different levels. This is equivalent to forming a linear combination of the stiffness matrices and right-hand sides. The precise meaning of this will be explained in detail later.

We show that one step of multigrid τ-extrapolation for piecewise linear C^0 finite element (FE) methods is equivalent to using quadratic elements. This can be derived as a consequence of asymptotic error expansions for the numerical integration of the FE stiffness matrices, as shown in Rüde [20]. Here we will follow a different approach and show that the quadratic stiffness matrix and the stiffness matrix which is implicitly constructed by τ-extrapolation for linear elements coincide. Therefore the system solved by τ-extrapolation is equivalent to using quadratic elements. Furthermore, we show the asymptotically optimal convergence of a multigrid solution of the extrapolated system.

Our experimental framework is the *Finite Element Multi-Grid Package* (FEMGP) (see Steidten and Jung [22]) developed at the Technische Universität Chemnitz-Zwickau for the solution of elliptic and parabolic problems arising in the computation of magnetic and thermomechanical fields. We focus on self-adjoint second-order linear elliptic partial differential equations, using the heat conduction equation and the equations of elasticity as typical model problems. The equivalence of τ-extrapolation to higher order finite elements justifies its use even for unstructured meshes as produced with FEMGP; see also the results on τ-extrapolation-based higher order adaptive methods by McCormick and Rüde [16].

2. Finite element discretizations of the boundary value problem. We consider two-dimensional second-order elliptic boundary value problems:

$$\text{(1)} \qquad \text{Find } u \in V_0 \text{ such that } \quad a(u,v) = \langle F, v\rangle \quad \text{for all } v \in V_0,$$

with a symmetric, V_0-elliptic, and V_0-bounded bilinear form $a(.,.)$; $\langle .,.\rangle : V_0^* \times V_0 \to \mathbb{R}^1$ is the duality pairing, V_0^* denotes the space which is dual to V_0, and $F \in V_0^*$ is a linear and bounded functional on V_0. Later we will describe more precisely which bilinear forms we want to investigate.

Let us first describe some finite element discretizations of problem (1). The starting point of the discretization process is a coarse triangular mesh $\mathcal{T}_1$. Then we generate a sequence of nested triangular meshes $\mathcal{T}_k = \{\delta_k^{(r)},\ r \in \mathcal{J}_k\}$, $k = 1,2,\dots,l$, $\mathcal{J}_k = \{1,2,\dots,R_k\}$, where R_k denotes the number of triangles of the triangulation $\mathcal{T}_k$. We suppose that we obtain the triangulation $\mathcal{T}_l$ by dividing all triangles $\delta_{l-1}^{(r)}$, $r \in \mathcal{J}_{l-1}$, into four congruent subtriangles $\delta_l^{(r)}$. The nodes of the triangulations are numbered *hierarchically*, i.e., $P^{(1)}, P^{(2)}, \dots, P^{(\overline{N}_1)}, P^{(\overline{N}_1+1)}, \dots, P^{(\overline{N}_2)}, \dots, P^{(\overline{N}_{k-1}+1)}, \dots, P^{(\overline{N}_k)}, \dots, P^{(\overline{N}_{l-1}+1)}, \dots, P^{(\overline{N}_l)}$, where $P^{(\overline{N}_{k-1}+1)}, \dots, P^{(\overline{N}_k)}$ are the nodes of $\mathcal{T}_k$ that do not belong to $\mathcal{T}_{k-1}$ (but are naturally also nodes of $\mathcal{T}_{k+1}, \dots, \mathcal{T}_l$).

Corresponding to each triangulation $\mathcal{T}_k$, $k = 1,2,\dots,l-1$, we define the finite element subspaces $V_k \subset V_0$ as

$$\text{(2)} \qquad V_k = V_k^{L,N} = \operatorname{span}\{p_k^{(i)} \ : \ i = 1,2,\dots,N_k\},$$

where the trial functions $p_k^{(i)}$ are piecewise linear functions such that $p_k^{(i)}$ is linear in all triangles of $\mathcal{T}_k$, they are continuous, and they satisfy the relations $p_k^{(i)}(x_1^{(j)}, x_2^{(j)}) = 1$ for $i = j$, $p_k^{(i)}(x_1^{(j)}, x_2^{(j)}) = 0$ for $i \neq j$, $i,j = 1,2,\dots,N_k$. Here $(x_1^{(j)}, x_2^{(j)})$ denotes the coordinates of the node $P^{(j)}$, and N_k is the number of nodes belonging to $\Omega \cup \Gamma_N$, where Γ_N is the part of the boundary $\partial\Omega$ on which natural boundary conditions are given.

The finite element subspace corresponding to the finest triangulation $\mathcal{T}_l$ we define, only formally for now, by

$$\text{(3)} \qquad V_l = \operatorname{span}\{\tilde{p}_l^{(i)},\ i = 1,2,\dots,N_l\}.$$

For the specific choice of the functions $\tilde{p}_l^{(i)}$ we consider four possibilities. The first one is the usual *nodal basis*, i.e., we set $\tilde{p}_l^{(i)} = p_l^{(i)}$, where the functions $p_l^{(i)}$ are defined in the same way as the functions $p_k^{(i)}$, $k = 1,2,\dots,l-1$. Consequently, we obtain the FE subspace

$$\text{(4)} \qquad V_l = V_l^{L,N} = \operatorname{span}\{p_l^{(i)},\ i = 1,2,\dots,N_l\}.$$

As a second possibility we use the *two-level h-hierarchical basis*, i.e.,

$$\text{(5)} \quad V_l = V_l^{L,H} = \operatorname{span}\{p_{l-1}^{(i)},\ i = 1,\dots,N_{l-1}\} \cup \operatorname{span}\{p_l^{(i)},\ i = N_{l-1}+1,\dots,N_l\}.$$

Additionally, to these two approaches we also introduce FE subspaces spanned by piecewise quadratic functions $q_{l-1}^{(i)}$. These functions are polynomials of degree 2 in all triangles of $\mathcal{T}_{l-1}$, they are continuous, and they satisfy the relations $q_{l-1}^{(i)}(x_1^{(j)}, x_2^{(j)}) = 1$ for $i = j$, $q_{l-1}^{(i)}(x_1^{(j)}, x_2^{(j)}) = 0$ for $i \neq j$, $i,j = 1,2,\dots,N_l$. Using these functions we can define the usual *quadratic nodal basis* as

$$\text{(6)} \qquad V_l = V_l^{Q,N} = \operatorname{span}\{q_{l-1}^{(i)},\ i = 1,2,\dots,N_l\},$$

and the *two-level p-hierarchical basis* as

$$(7)\quad V_l = V_l^{Q,H} = \text{span}\{p_{l-1}^{(i)},\ i = 1, \dots, N_{l-1}\} \cup \text{span}\{q_{l-1}^{(i)},\ i = N_{l-1}+1, \dots, N_l\ \}.$$

The sequence of FE subspaces V_k, $k = 1, 2, \dots, l$, where V_l stands for $V_l^{L,N}$, $V_l^{L,H}$, $V_l^{Q,N}$, or $V_l^{Q,H}$, respectively, results in a sequence of finite element schemes:

$$(8)\qquad \text{Find } u_k \in V_k \text{ such that } \quad a(u_k, v_k) = \langle F, v_k \rangle \quad \text{for all } v_k \in V_k.$$

The determination of the unknown function u_k is equivalent to the solution of the system

$$(9)\qquad K_k^{L,N} \underline{u}_k = \underline{f}_k^{L,N}$$

of the algebraic finite element equations, where for $k = 1, 2, \dots, l-1$,

$$(10)\qquad \underline{u}_k = [u_k^{(i)}]_{i=1,2,\dots,N_k} \quad \leftrightarrow u_k = \sum_{i=1}^{N_k} u_k^{(i)} p_k^{(i)},$$

$$(11)\qquad K_k^{L,N} = [K_k^{L,N,(ij)}]_{i,j=1,2,\dots,N_k}\ , \quad K_k^{L,N,(ij)} = a(p_k^{(j)}, p_k^{(i)}), \quad \text{and}$$

$$(12)\qquad \underline{f}_k^{L,N} = [f_k^{L,N,(i)}]_{i=1,2,\dots,N_k} \quad , \quad f_k^{L,N,(i)} = \langle F, p_k^{(i)} \rangle.$$

For $k = l$ the stiffness matrix K_l and the load vector $\underline{f}_l$ are defined in the same way, and we set only the functions $\tilde{p}_l^{(i)}$ instead of the functions $p_l^{(i)}$. Depending on the concrete choice of the functions $\tilde{p}_l^{(i)}$ (see the possibilities (4)–(7)), we get the stiffness matrices $K_l = K_l^{L,N}$, $K_l^{L,H}$, $K_l^{Q,N}$, or $K_l^{Q,H}$ and the load vectors $\underline{f}_l = \underline{f}_l^{L,N}$, $\underline{f}_l^{L,H}$, $\underline{f}_l^{Q,N}$, or $\underline{f}_l^{Q,H}$ respectively.

Next we specify the bilinear form $a(.,.)$. In the following we will consider bilinear forms which are defined by

$$(13)\qquad a(u, v) = \int_\Omega (A\nabla_x u, \nabla_x v)\, dx,$$

where A is a symmetric, positive definite (2×2)-matrix,

$$(14)\qquad \nabla_x = \left(\frac{\partial}{\partial x_1} \ \ \frac{\partial}{\partial x_2} \right)^T,$$

and $(.,.)$ denotes the Euclidian scalar product in the space $\mathbb{R}^2$. Such bilinear forms arise from the derivation of the weak formulation of heat conduction problems. Let us suppose that the entries of the matrix A are piecewise constant functions, i.e., constant in each triangle $\delta_{l-1}^{(r)}$, $r \in \mathcal{J}_{l-1}$. In this paper we will not discuss the variable coefficient case.

Next we prove an interesting relation among the matrices $K_{l-1}^{L,N}$, $K_l^{L,H}$, and $K_l^{Q,H}$, which is useful for the investigation of the convergence properties of a multigrid algorithm with extrapolation.

LEMMA 2.1. *Let $K_{l-1}^{L,N}$, $K_l^{L,H}$, and $K_l^{Q,H}$ be defined by the bilinear form* (13) *as described above, where the entries of the matrix $A(x)$ in the bilinear form are constant in each triangle $\delta_{l-1}^{(r)} \in \mathcal{T}_{l-1}$. Then the relation*

$$(15)\qquad K_l^{Q,H} = \frac{4}{3} K_l^{L,H} - \frac{1}{3} \tilde{K}_{l-1}$$

holds, where

$$\tilde{K}_{l-1} = \begin{pmatrix} K_{l-1}^{L,N} & 0 \\ 0 & 0 \end{pmatrix}.$$

Proof. Recall the definition of the stiffness matrices

$$K_{l-1}^{L,N} = [K_{l-1}^{L,N,(ij)}]_{i,j=1,2,\dots,N_{l-1}}, \quad K_{l-1}^{L,N,(ij)} = a(p_{l-1}^{(j)}, p_{l-1}^{(i)}), \tag{16}$$

$$K_l^{L,H} = [K_l^{L,H,(ij)}]_{i,j=1,2,\dots,N_l}, \tag{17}$$

$$K_l^{L,H,(ij)} = \begin{cases} a(p_{l-1}^{(j)}, p_{l-1}^{(i)}) & \text{for} \quad i,j = 1,2,\dots,N_{l-1}, \\ a(p_l^{(j)}, p_{l-1}^{(i)}) & \text{for} \quad j = N_{l-1}+1, N_{l-1}+2, \dots, N_l,\ i = 1,2,\dots,N_{l-1}, \\ a(p_{l-1}^{(j)}, p_l^{(i)}) & \text{for} \quad j = 1,2,\dots,N_{l-1},\ i = N_{l-1}+1, N_{l-1}+2, \dots, N_l, \\ a(p_l^{(j)}, p_l^{(i)}) & \text{for} \quad i,j = N_{l-1}+1, N_{l-1}+2, \dots, N_l\,, \end{cases}$$

$$K_l^{Q,H} = [K_l^{Q,H,(ij)}]_{i,j=1,2,\dots,N_l}, \tag{18}$$

$$K_l^{Q,H,(ij)} = \begin{cases} a(p_{l-1}^{(j)}, p_{l-1}^{(i)}) & \text{for} \quad i,j = 1,2,\dots,N_{l-1}, \\ a(q_{l-1}^{(j)}, p_{l-1}^{(i)}) & \text{for} \quad j = N_{l-1}+1, N_{l-1}+2, \dots, N_l,\ i = 1,2,\dots,N_{l-1}, \\ a(p_{l-1}^{(j)}, q_{l-1}^{(i)}) & \text{for} \quad j = 1,2,\dots,N_{l-1},\ i = N_{l-1}+1, N_{l-1}+2, \dots, N_l, \\ a(q_{l-1}^{(j)}, q_{l-1}^{(i)}) & \text{for} \quad i,j = N_{l-1}+1, N_{l-1}+2, \dots, N_l. \end{cases}$$

All these stiffness matrices have the structure

$$K_l = \begin{pmatrix} K_{l,vv} & K_{l,vm} \\ K_{l,mv} & K_{l,mm} \end{pmatrix}, \tag{19}$$

where $K_{l,vv}$ corresponds to the nodes of the triangulation $\mathcal{T}_{l-1}$, $K_{l,mm}$ corresponds to the new nodes in the triangulation $\mathcal{T}_l$, and $K_{l,mv}$, $K_{l,vm}$ are the coupling blocks.

From the definitions (16)–(18) of the matrix elements we see that

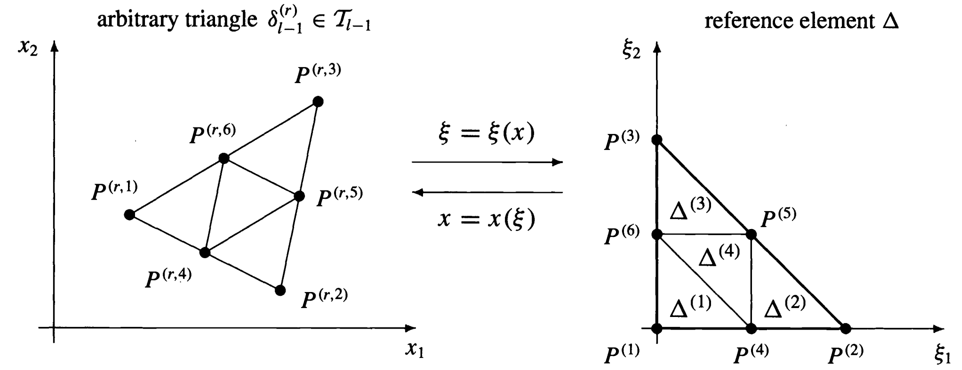
$$\frac{4}{3}K_l^{L,H} - \frac{1}{3}\tilde{K}_{l-1} = \begin{pmatrix} K_{l-1}^{L,N} & \frac{4}{3}K_{l,vm}^{L,H} \\ \frac{4}{3}K_{l,mv}^{L,H} & \frac{4}{3}K_{l,mm}^{L,H} \end{pmatrix} \tag{20}$$

and

$$K_l^{Q,H} = \begin{pmatrix} K_{l-1}^{L,N} & K_{l,vm}^{Q,H} \\ K_{l,mv}^{Q,H} & K_{l,mm}^{Q,H} \end{pmatrix}. \tag{21}$$

Taking into account that these matrices are symmetric, we have to prove that

$$\frac{4}{3}K_{l,vm}^{L,H} = K_{l,vm}^{Q,H} \quad \text{and} \quad \frac{4}{3}K_{l,mm}^{L,H} = K_{l,mm}^{Q,H}.$$



$$P^{(r,1)} = P^{(r,1)}(x_1^{(r,1)}, x_2^{(r,1)}),\qquad P^{(1)} = P^{(1)}(0,0),$$
$$P^{(r,2)} = P^{(r,2)}(x_1^{(r,2)}, x_2^{(r,2)}),\qquad P^{(2)} = P^{(2)}(1,0),$$
$$P^{(r,3)} = P^{(r,3)}(x_1^{(r,3)}, x_2^{(r,3)})\qquad P^{(3)} = P^{(3)}(0,1)$$

FIG. 1. *The mapping between the reference element Δ and an arbitrary element $\delta^{(r)}_{l-1}$.*

To do this we introduce some notation. The transformation $x = x(\xi)$,

$$\begin{aligned} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} &= \begin{pmatrix} x_1^{(r,2)} - x_1^{(r,1)} & x_1^{(r,3)} - x_1^{(r,1)} \\ x_2^{(r,2)} - x_2^{(r,1)} & x_2^{(r,3)} - x_2^{(r,1)} \end{pmatrix} \begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix} + \begin{pmatrix} x_1^{(r,1)} \\ x_2^{(r,1)} \end{pmatrix} \\ &= J^{(r)}_{l-1} \begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix} + \begin{pmatrix} x_1^{(r,1)} \\ x_2^{(r,1)} \end{pmatrix}, \end{aligned} \tag{22}$$

realizes the mapping of the reference element $\Delta = \{(\xi_1, \xi_2) : 0 \le \xi_1 \le 1,\ 0 \le \xi_2 \le 1,\ \xi_1 + \xi_2 \le 1\}$ onto an element $\delta^{(r)}_{l-1}$ of the triangulation $\mathcal{T}_{l-1}$ (see Fig. 1).

On the reference element Δ we define six shape functions φ_α, $\alpha = 1, 2, \ldots, 6$. In the case of the h-hierarchical basis we have

$$\begin{aligned} \tilde{\varphi}_1(\xi_1, \xi_2) &= \varphi_1(\xi_1, \xi_2) = 1 - \xi_1 - \xi_2, \\ \tilde{\varphi}_2(\xi_1, \xi_2) &= \varphi_2(\xi_1, \xi_2) = \xi_1, \\ \tilde{\varphi}_3(\xi_1, \xi_2) &= \varphi_3(\xi_1, \xi_2) = \xi_2, \\ \tilde{\varphi}_4(\xi_1, \xi_2) &= \varphi_4(\xi_1, \xi_2) = \begin{cases} 2\xi_1 & \text{in} \quad \Delta^{(1)}, \\ 2 - 2\xi_1 - 2\xi_2 & \text{in} \quad \Delta^{(2)}, \\ 0 & \text{in} \quad \Delta^{(3)}, \\ 1 - 2\xi_2 & \text{in} \quad \Delta^{(4)}, \end{cases} \\ \tilde{\varphi}_5(\xi_1, \xi_2) &= \varphi_5(\xi_1, \xi_2) = \begin{cases} 0 & \text{in} \quad \Delta^{(1)}, \\ 2\xi_2 & \text{in} \quad \Delta^{(2)}, \\ 2\xi_1 & \text{in} \quad \Delta^{(3)}, \\ 2\xi_1 + 2\xi_2 - 1 & \text{in} \quad \Delta^{(4)}, \end{cases} \\ \tilde{\varphi}_6(\xi_1, \xi_2) &= \varphi_6(\xi_1, \xi_2) = \begin{cases} 2\xi_2 & \text{in} \quad \Delta^{(1)}, \\ 0 & \text{in} \quad \Delta^{(2)}, \\ 2 - 2\xi_1 - 2\xi_2 & \text{in} \quad \Delta^{(3)}, \\ 1 - 2\xi_1 & \text{in} \quad \Delta^{(4)}, \end{cases} \end{aligned} \tag{23}$$

(0.5, 0.5)	−2	−2	2	2	−2	−2

and in the case of the p-hierarchical basis,

$$\begin{aligned}
&\tilde\varphi_1(\xi_1,\xi_2) = \varphi_1(\xi_1,\xi_2),\quad \tilde\varphi_2(\xi_1,\xi_2) = \varphi_2(\xi_1,\xi_2),\quad \tilde\varphi_3(\xi_1,\xi_2) = \varphi_3(\xi_1,\xi_2),\\
&\tilde\varphi_4(\xi_1,\xi_2) = \psi_4(\xi_1,\xi_2) = 4\xi_1(1-\xi_1-\xi_2),\\
&\tilde\varphi_5(\xi_1,\xi_2) = \psi_5(\xi_1,\xi_2) = 4\xi_1\xi_2,\\
&\tilde\varphi_6(\xi_1,\xi_2) = \psi_6(\xi_1,\xi_2) = 4\xi_2(1-\xi_1-\xi_2)\,.
\end{aligned} \tag{24}$$

In order to calculate the elements of the stiffness matrices we need the derivatives of the shape functions. For the h-hierarchical functions we get the partial derivatives given in Table 1.

For the computation of the matrix elements in the case of the p-hierarchical basis we use the following quadrature rule:

$$\int_\Delta \psi(\xi_1,\xi_2)\,d\xi \approx \sum_{k=1}^{3}\frac{1}{6}\,\psi(\xi^{(k)}) = \frac{1}{6}\left(\psi(0.5,0)+\psi(0,0.5)+\psi(0.5,0.5)\right), \tag{25}$$

which is exact for quadratic polynomials on Δ. Therefore we present in Table 2 the values of the partial derivatives of the functions ψ_4, ψ_5, and ψ_6 in the quadrature points $(0.5, 0)$, $(0, 0.5)$, and $(0.5, 0.5)$.

First we prove $\frac{4}{3}K^{L,H}_{l,mm} = K^{Q,H}_{l,mm}$. We have

$$\begin{aligned}
a(\tilde p^{(j)}_l,\tilde p^{(i)}_l) &= \int_\Omega \left(A\nabla_x\tilde p^{(j)}_l, \nabla_x\tilde p^{(i)}_l\right) dx\\
&= \sum_{r\in\omega^{(ij)}}\int_{\delta^{(r)}_{l-1}} \left(A\nabla_x\tilde p^{(j)}_l, \nabla_x\tilde p^{(i)}_l\right) dx,
\end{aligned} \tag{26}$$

where

$$\omega^{(ij)} = \left\{r\in\mathcal{J}_{l-1} : \tilde p^{(i)}_l \not\equiv 0 \text{ and } \tilde p^{(j)}_l \not\equiv 0 \text{ on } \delta^{(r)}_{l-1}\right\}.$$

Obviously, the index sets $\omega^{(ij)}$ are the same for both the h-hierarchical functions $\tilde{p}_l^{(i)} = p_l^{(i)}$ and the p-hierarchical functions $\tilde{p}_l^{(i)} = q_{l-1}^{(i)}$, $i = N_{l-1}+1, \dots, N_l$. Using the mapping to the reference element, it follows that

$$a(\tilde{p}_l^{(j)}, \tilde{p}_l^{(i)}) = \sum_{r\in\omega^{(ij)}} \int_\Delta \Big(A(J_{l-1}^{(r)})^{-T}\nabla_\xi \tilde{p}_l^{(j)}(x(\xi)), (J_{l-1}^{(r)})^{-T}\nabla_\xi \tilde{p}_l^{(i)}(x(\xi))\Big)\, |\det J_{l-1}^{(r)}|\, d\xi$$

$$= \sum_{r\in\omega^{(ij)}} \int_\Delta \Big(B\nabla_\xi \tilde{p}_l^{(j)}(x(\xi)), \nabla_\xi \tilde{p}_l^{(i)}(x(\xi))\Big)\, d\xi,$$

with $B = (J_{l-1}^{(r)})^{-1}A(J_{l-1}^{(r)})^{-T}|\det J_{l-1}^{(r)}|$. Note that the entries of A, $J_{l-1}^{(r)}$, and $|\det J_{l-1}^{(r)}|$ are constants.

For $j = i$ and $\tilde{p}_l^{(i)} = p_l^{(i)}$, that is, for the h-hierarchical basis, we have

$$(27)\qquad a(p_l^{(i)}, p_l^{(i)}) = \sum_{r\in\omega^{(ii)}} \sum_{k\in I(\alpha^{(r)})} \int_{\Delta^{(k)}} \left(B\nabla_\xi \varphi_{\alpha^{(r)}}, \nabla_\xi \varphi_{\alpha^{(r)}}\right) d\xi$$

$$= \sum_{r\in\omega^{(ii)}} \sum_{k\in I(\alpha^{(r)})} \frac{1}{8}\left(B\nabla_\xi \varphi_{\alpha^{(r)}}|_{\Delta^{(k)}}, \nabla_\xi \varphi_{\alpha^{(r)}}|_{\Delta^{(k)}}\right),$$

where $\alpha^{(r)}$ is the local number of the node $P^{(i)}(x_1^{(i)}, x_2^{(i)})$ in the triangle $\delta_{l-1}^{(r)}$, i.e.,

$$a^{(r)} = 4, 5, \text{ or } 6, \quad \text{and} \quad I(\alpha^{(r)}) = \left\{k \in \{1,2,3,4\} : \varphi_{\alpha^{(r)}} \not\equiv 0 \text{ on } \Delta^{(k)}\right\}.$$

Obviously, $I(4) = \{1,2,4\}$, $I(5) = \{2,3,4\}$, and $I(6) = \{1,3,4\}$. Therefore, in all the cases, we have exactly three terms.

If we use quadrature rule (25), we obtain for the case of the p-hierarchical basis

$$(28)\qquad a(q_{l-1}^{(i)}, q_{l-1}^{(i)}) = \sum_{r\in\omega^{(ii)}} \int_\Delta \left(B\nabla_\xi \psi_{\alpha^{(r)}}, \nabla_\xi \psi_{\alpha^{(r)}}\right) d\xi$$

$$= \sum_{r\in\omega^{(ii)}} \sum_{k=1}^{3} \frac{1}{6}\left(B\nabla_\xi \psi_{\alpha^{(r)}}(\xi^{(k)}), \nabla_\xi \psi_{\alpha^{(r)}}(\xi^{(k)})\right),$$

where $\xi^{(k)}$ are the quadrature nodes of formula (25).

Now we compare the summands in the sums over k in (27) and (28). If we examine the values of the partial derivatives $\partial\varphi_{\alpha^{(r)}}/\partial\xi_1$, $\partial\varphi_{\alpha^{(r)}}/\partial\xi_2$ in the triangles $\Delta^{(k)}$ and the values of the derivatives $\partial\psi_{\alpha^{(r)}}/\partial\xi_1$, $\partial\psi_{\alpha^{(r)}}/\partial\xi_2$ in the quadrature nodes (see Tables 1 and 2) then we can see that these summands differ only by the factor $\frac{4}{3}$. Therefore, we have

$$\frac{4}{3}a(p_l^{(i)}, p_l^{(i)}) = a(q_{l-1}^{(i)}, q_{l-1}^{(i)}) \qquad \text{for} \qquad i = N_{l-1}+1, \dots, N_l.$$

For $i \neq j$, $i, j = N_{l-1}+1, \dots, N_l$, we obtain

$$(29)\qquad a(q_{l-1}^{(j)}, q_{l-1}^{(i)}) = \sum_{r\in\omega^{(ij)}} \int_\Delta \left(B\nabla_\xi \varphi_{\beta^{(r)}}, \nabla_\xi \varphi_{\alpha^{(r)}}\right) d\xi,$$

where $\beta^{(r)}$ and $\alpha^{(r)}$ are the local numbers of the nodes $P^{(j)}$ and $P^{(i)}$ in the triangle $\delta_{l-1}^{(r)}$, respectively. Using again the quadrature formula (25) and the results from Table 2 we have

$$(30)\qquad a(q_{l-1}^{(j)}, q_{l-1}^{(i)}) = \begin{cases} \displaystyle\sum_{r\in\omega^{(ij)}} -\frac{1}{3}\left(B\begin{pmatrix}0\\2\end{pmatrix}, \begin{pmatrix}2\\2\end{pmatrix}\right) & \text{for} \quad \begin{matrix}\beta^{(r)}=4, \alpha^{(r)}=5,\\ \beta^{(r)}=5, \alpha^{(r)}=4,\end{matrix} \\ \displaystyle\sum_{r\in\omega^{(ij)}} \frac{1}{3}\left(B\begin{pmatrix}0\\2\end{pmatrix}, \begin{pmatrix}2\\0\end{pmatrix}\right) & \text{for} \quad \begin{matrix}\beta^{(r)}=4, \alpha^{(r)}=6,\\ \beta^{(r)}=6, \alpha^{(r)}=4,\end{matrix} \\ \displaystyle\sum_{r\in\omega^{(ij)}} -\frac{1}{3}\left(B\begin{pmatrix}2\\2\end{pmatrix}, \begin{pmatrix}2\\0\end{pmatrix}\right) & \text{for} \quad \begin{matrix}\beta^{(r)}=5, \alpha^{(r)}=6,\\ \beta^{(r)}=6, \alpha^{(r)}=5.\end{matrix} \end{cases}$$

For the h-hierarchical basis we get, with $I(\beta^{(r)}, \alpha^{(r)}) = I(\beta^{(r)}) \cap I(\alpha^{(r)})$,

$$\begin{aligned} a(p_l^{(j)}, p_l^{(i)}) &= \sum_{r\in\omega^{(ij)}} \sum_{k\in I(\beta^{(r)},\alpha^{(r)})} \int_{\Delta^{(k)}} \left(B\nabla_\xi \varphi_{\beta^{(r)}}, \nabla_\xi \varphi_{\alpha^{(r)}}\right) d\xi \\ (31)\qquad &= \sum_{r\in\omega^{(ij)}} \sum_{k\in I(\beta^{(r)},\alpha^{(r)})} \frac{1}{8}\left(B\nabla_\xi \varphi_{\beta^{(r)}}|_{\Delta^{(k)}}, \nabla_\xi \varphi_{\alpha^{(r)}}|_{\Delta^{(k)}}\right) \end{aligned}$$

$$= \begin{cases} \displaystyle\sum_{r\in\omega^{(ij)}} -\frac{1}{4}\left(B\begin{pmatrix}0\\2\end{pmatrix}, \begin{pmatrix}2\\2\end{pmatrix}\right) & \text{for} \quad \begin{matrix}\beta^{(r)}=4, \alpha^{(r)}=5,\\ \beta^{(r)}=5, \alpha^{(r)}=4,\end{matrix} \\ \displaystyle\sum_{r\in\omega^{(ij)}} \frac{1}{4}\left(B\begin{pmatrix}0\\2\end{pmatrix}, \begin{pmatrix}2\\0\end{pmatrix}\right) & \text{for} \quad \begin{matrix}\beta^{(r)}=4, \alpha^{(r)}=6,\\ \beta^{(r)}=6, \alpha^{(r)}=4,\end{matrix} \\ \displaystyle\sum_{r\in\omega^{(ij)}} -\frac{1}{4}\left(B\begin{pmatrix}2\\2\end{pmatrix}, \begin{pmatrix}2\\0\end{pmatrix}\right) & \text{for} \quad \begin{matrix}\beta^{(r)}=5, \alpha^{(r)}=6,\\ \beta^{(r)}=6, \alpha^{(r)}=5.\end{matrix} \end{cases}$$

Comparing (30) and (31) we see that $\frac{4}{3}a(p_l^{(j)}, p_l^{(i)}) = a(q_{l-1}^{(j)}, q_{l-1}^{(i)})$. Consequently, we have shown that

$$(32)\qquad \frac{4}{3}K_{l,mm}^{L,H} = K_{l,mm}^{Q,H}\,.$$

It remains to prove $\frac{4}{3}K_{l,vm}^{L,H} = K_{l,vm}^{Q,H}$. For $j = N_{l-1}+1, N_{l-1}+2, \ldots, N_l$, $i = 1, 2, \ldots, N_{l-1}$ we have

$$\begin{aligned} (33)\qquad a(p_l^{(j)}, p_{l-1}^{(i)}) &= \sum_{r\in\omega^{(ij)}} \int_\Delta (B\nabla_\xi \varphi_{\beta^{(r)}}, \nabla_\xi \varphi_{\alpha^{(r)}})\, d\xi \\ &= \sum_{r\in\omega^{(ij)}} \sum_{k\in I(\beta^{(r)})} \frac{1}{8}\left(B\nabla_\xi \varphi_{\beta^{(r)}}|_{\Delta^{(k)}}, \nabla_\xi \varphi_{\alpha^{(r)}}|_{\Delta^{(k)}}\right) \end{aligned}$$

and

$$\begin{aligned} (34)\qquad a(q_{l-1}^{(j)}, p_{l-1}^{(i)}) &= \sum_{r\in\omega^{(ij)}} \int_\Delta (B\nabla_\xi \psi_{\beta^{(r)}}, \nabla_\xi \varphi_{\alpha^{(r)}})\, d\xi \\ &= \sum_{r\in\omega^{(ij)}} \sum_{k=1}^{3} \frac{1}{6}\left(B\nabla_\xi \psi_{\beta^{(r)}}(\xi^{(k)}), \nabla_\xi \varphi_{\alpha^{(r)}}(\xi^{(k)})\right)\,. \end{aligned}$$

From Tables 1 and 2 we see again that the summands in the sums over k differ only by the factor $\frac{4}{3}$. Hence, $\frac{4}{3}a(p_l^{(j)}, p_{l-1}^{(i)}) = a(q_{l-1}^{(j)}, p_{l-1}^{(i)})$, i.e.,

$$(35)\qquad \frac{4}{3}K_{l,vm}^{L,H} = K_{l,vm}^{Q,H}\,,$$

and in an analogous way

$$\frac{4}{3}K_{l,mv}^{L,H} = K_{l,mv}^{Q,H}\,. \tag{36}$$

Combining the relations (20), (21), (32), (35), and (36) we obtain the statement of the lemma. □

In Lemma 2.2 we formulate the corresponding property for the right-hand side.

LEMMA 2.2. *Let*

$$\langle F, v\rangle = \int_\Omega f v\, dx + \int_{\Gamma_N} g_2 v\, ds\,,$$

where f is a piecewise constant function, i.e., constant over all triangles $\delta_{l-1}^{(r)} \in \mathcal{T}_{l-1}$, and g_2 a piecewise constant function, i.e., constant over $\partial\delta_{l-1}^{(r)} \cap \partial\Omega$. Then the following relation holds:

$$\underline{f}_l^{Q,H} = \frac{4}{3}\underline{f}_l^{L,H} - \frac{1}{3}\underline{\tilde{f}}_{l-1}\,, \qquad \underline{\tilde{f}}_{l-1} = \begin{pmatrix} \underline{f}_{l-1}^{L,N} \\ 0 \end{pmatrix}. \tag{37}$$

Proof. We have defined

$$\underline{f}_{l-1}^{L,N} = [f_{l-1}^{L,N,(i)}]_{i=1,2,\ldots,N_{l-1}}\,, \quad f_{l-1}^{L,N,(i)} = \langle F, p_{l-1}^{(i)}\rangle,$$

$$\underline{f}_l^{L,H} = [f_l^{L,H,(i)}]_{i=1,2,\ldots,N_l}\,, \quad f_l^{L,H,(i)} = \begin{cases} \langle F, p_{l-1}^{(i)}\rangle & \text{for} \quad i = 1,\ldots,N_{l-1}, \\ \langle F, p_l^{(i)}\rangle & \text{for} \quad i = N_{l-1}+1,\ldots,N_l\,, \end{cases}$$

$$\underline{f}_l^{Q,H} = [f_l^{Q,H,(i)}]_{i=1,2,\ldots,N_l}\,, \quad f_l^{Q,H,(i)} = \begin{cases} \langle F, p_{l-1}^{(i)}\rangle & \text{for} \quad i = 1,2,\ldots,N_{l-1}, \\ \langle F, q_{l-1}^{(i)}\rangle & \text{for} \quad i = N_{l-1}+1,\ldots,N_l\,. \end{cases}$$

Consequently,

$$\frac{4}{3}\underline{f}_l^{L,H} - \frac{1}{3}\underline{\tilde{f}}_{l-1} = \begin{pmatrix} \underline{f}_{l-1}^{L,N} \\ \frac{4}{3}\underline{f}_{l,m}^{L,H} \end{pmatrix} \quad \text{and} \quad \underline{f}_l^{Q,H} = \begin{pmatrix} \underline{f}_{l-1}^{L,N} \\ \underline{f}_{l,m}^{Q,H} \end{pmatrix}. \tag{38}$$

First we prove

$$\frac{4}{3}\int_\Omega f p_l^{(i)}\, dx = \int_\Omega f q_{l-1}^{(i)}\, dx \tag{39}$$

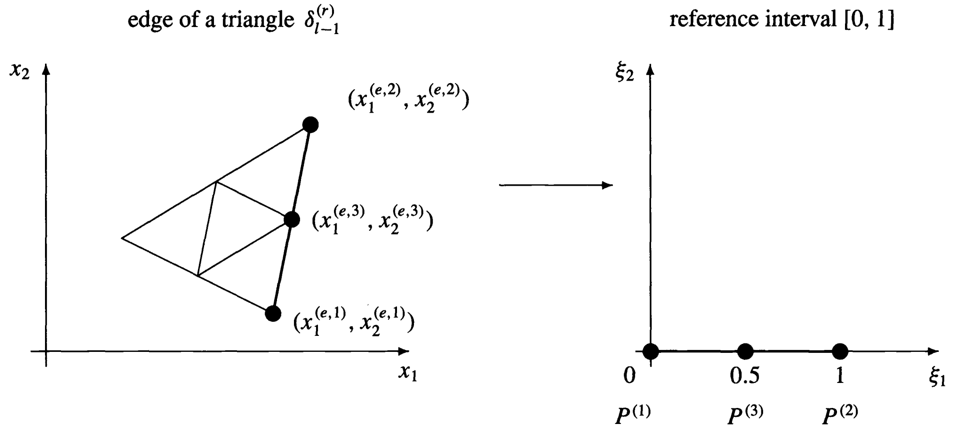
for $i = N_{l-1}+1,\ldots,N_l$. Using the notation from the proof of Lemma 2.1 we have

$$\begin{aligned} \int_\Omega f p_l^{(i)}\, dx = \sum_{r\in\omega^{(i)}} \int_{\delta_{l-1}^{(r)}} f p_l^{(i)}\, dx &= \sum_{r\in\omega^{(i)}} \int_\Delta f p_l^{(i)}(x(\xi))|\det J_{l-1}^{(r)}|\, d\xi \\ &= \sum_{r\in\omega^{(i)}} \sum_{k\in I(\alpha^{(r)})} \int_{\Delta^{(k)}} f\varphi_{\alpha^{(r)}}(\xi)|\det J_{l-1}^{(r)}|\, d\xi\,, \end{aligned}$$

where

$$\omega^{(i)} = \{r \in \mathcal{J}_{l-1} \;:\; p_l^{(i)} \not\equiv 0 \;\text{ on }\; \delta_{l-1}^{(r)}\},$$

$$I(\alpha^{(r)}) = \{k \in \{1,2,3,4\} \;:\; \varphi_{\alpha^{(r)}} \not\equiv 0 \;\text{ on }\; \Delta^{(k)}\},$$



edge of a triangle $\delta_{l-1}^{(r)}$

FIG. 2. *The mapping between an edge of a triangle and the reference interval* [0, 1].

and $\alpha^{(r)}$ is the local number of the node $P^{(i)}$ in the triangle $\delta_{l-1}^{(r)}$. Computing the integrals over $\Delta^{(k)}$ we obtain

$$\int_\Omega f p_l^{(i)}\, dx = \sum_{r\in\omega^{(i)}} \sum_{k\in I(\alpha^{(r)})} \frac{1}{24} f\,|\det J_{l-1}^{(r)}| = \sum_{r\in\omega^{(i)}} \frac{1}{8} f\,|\det J_{l-1}^{(r)}|\,, \tag{40}$$

and using the quadrature formula (25) it follows that

$$\int_\Omega f q_{l-1}^{(i)}\, dx = \sum_{r\in\omega^{(i)}} \sum_{k=1}^{3} \frac{1}{6} f \psi_{\alpha^{(r)}}(\xi^{(k)})|\det J_{l-1}^{(r)}| = \sum_{r\in\omega^{(i)}} \frac{1}{6} f\,|\det J_{l-1}^{(r)}|\,, \tag{41}$$

i.e., the integrals in (40) and (41) differ by the factor $\frac{4}{3}$.

Next we show that

$$\frac{4}{3} \int_{\Gamma_N} g_2 p_l^{(i)}\, ds = \int_{\Gamma_N} g_2 q_{l-1}^{(i)}\, ds \tag{42}$$

for $i = N_{l-1} + 1, \ldots, N_l$. We have

$$\int_{\Gamma_N} g_2 p_l^{(i)}\, ds = \sum_{e\in E_{l-1}} \int_{\Gamma_{N,l-1}^{(e)}} g_2 p_l^{(i)}\, ds\,,$$

where $\Gamma_{N,l-1}^{(e)}$ is an edge of a triangle $\delta_{l-1}^{(r)}$, $r \in \mathcal{J}_{l-1}$, which is a part of the boundary Γ_N. We transform the last integral into an integral over the reference interval [0, 1].

This transformation is described by

$$\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} x_1^{(e,2)} - x_1^{(e,1)} \\ x_2^{(e,2)} - x_2^{(e,1)} \end{pmatrix} \xi_1 + \begin{pmatrix} x_1^{(e,1)} \\ x_2^{(e,1)} \end{pmatrix}$$

(see Fig. 2). On the reference interval the piecewise linear shape function $\varphi_3(\xi_1)$ is defined as follows:

$$\varphi_3(\xi_1) = \begin{cases} 2\xi_1 & \text{in} \quad [0, \frac{1}{2}), \\ 2 - 2\xi_1 & \text{in} \quad [\frac{1}{2}, 1], \end{cases}$$

and for the quadratic shape function $\psi_3(\xi_1)$ we have $\psi_3(\xi_1) = -4\xi_1^2 + 4\xi_1$.

With $\sigma = [(x_1^{(e,2)} - x_1^{(e,1)})^2 + (x_2^{(e,2)} - x_2^{(e,1)})^2]^{0.5}$ we obtain

$$\int_{\Gamma_N} g_2 p_l^{(i)}\, ds = \sum_{e \in E_{l-1}} \int_{\Gamma_{N,l-1}^{(e)}} g_2 p_l^{(i)}\, ds$$

$$(43) \qquad = \sum_{e \in E_{l-1}} \left\{ \int_0^{0.5} g_2 2\xi_1 \sigma\, d\xi_1 + \int_{0.5}^1 g_2 (2 - 2\xi_1)\sigma\, d\xi_1 \right\}$$

$$= \sum_{e \in E_{l-1}} g_2 \sigma \left\{ \frac{1}{4} + \frac{1}{4} \right\} = \sum_{e \in E_{l-1}} \frac{1}{2} g_2 \sigma$$

and

$$(44) \qquad \int_{\Gamma_N} g_2 q_{l-1}^{(i)}\, ds = \sum_{e \in E_{l-1}} \int_{\Gamma_{N,l-1}^{(e)}} g_2 q_{l-1}^{(i)}\, ds$$

$$= \sum_{e \in E_{l-1}} \int_0^1 g_2(-4\xi_1^2 + 4\xi_1)\sigma\, ds = \sum_{e \in E_{l-1}} \frac{2}{3} g_2 \sigma\,.$$

Again, both integrals differ only by the factor $\frac{4}{3}$. Combining the relations (38), (39), and (42) we get the statement of the lemma. □

THEOREM 2.3. *Under the assumptions of Lemmas* 2.1 *and* 2.2 *the FE systems of algebraic equations*

$$\left(\frac{4}{3}K_l^{L,H} - \frac{1}{3}\tilde{K}_{l-1}\right)\underline{u}_l^H = \left(\frac{4}{3}\underline{f}_l^{L,H} - \frac{1}{3}\tilde{\underline{f}}_{l-1}\right) \qquad \textit{and} \qquad K_l^{Q,H}\underline{u}_l^H = \underline{f}_l^{Q,H}$$

have the same solution.

Proof. The proof follows immediately from Lemmas 2.1 and 2.2. □

An analogous result can be proved for the FE systems in the nodal basis. Before we show this property, we state a lemma.

LEMMA 2.4. *Between the p-hierarchical and the quadratic nodal shape functions on the reference element it holds that*

$$(45) \qquad \Phi_\Delta^H = \Phi_\Delta^N S_\Delta\,,$$

where

$$S_\Delta = [S_\Delta^{(\alpha\beta)}]_{\alpha,\beta=1,\dots,6}\,, \quad S_\Delta^{(\alpha\beta)} = \begin{cases} 1 & \textit{for} \quad \alpha = \beta, \\ \frac{1}{2} & \textit{for} \quad (\alpha,\beta) = (4,1),(4,2), \\ & \qquad (\alpha,\beta) = (5,2),(5,3), \\ & \qquad (\alpha,\beta) = (6,3),(6,1), \\ 0 & \textit{otherwise}\,; \end{cases}$$

$$\Phi_\Delta^H = (\varphi_1(\xi_1,\xi_2),\ \varphi_2(\xi_1,\xi_2),\ \varphi_3(\xi_1,\xi_2),\ \psi_4(\xi_1,\xi_2),\ \psi_5(\xi_1,\xi_2),\ \psi_6(\xi_1,\xi_2)),$$

$$\Phi_\Delta^N = (\psi_1(\xi_1,\xi_2),\ \psi_2(\xi_1,\xi_2),\ \psi_3(\xi_1,\xi_2),\ \psi_4(\xi_1,\xi_2),\ \psi_5(\xi_1,\xi_2),\ \psi_6(\xi_1,\xi_2)),$$

with

$$(46) \qquad \begin{aligned} &\varphi_1(\xi_1,\xi_2) = 1 - \xi_1 - \xi_2\,, \quad \varphi_2(\xi_1,\xi_2) = \xi_1\,, \quad \varphi_3(\xi_1,\xi_2) = \xi_2\,, \\ &\psi_1(\xi_1,\xi_2) = 2\xi_1^2 + 2\xi_2^2 - 3\xi_1 - 3\xi_2 + 4\xi_1\xi_2 + 1\,, \\ &\psi_2(\xi_1,\xi_2) = 2\xi_1^2 - \xi_1\,, \quad \psi_3(\xi_1,\xi_2) = 2\xi_2^2 - \xi_2\,, \\ &\psi_4(\xi_1,\xi_2) = 4\xi_1(1 - \xi_1 - \xi_2)\,, \quad \psi_5(\xi_1,\xi_2) = 4\xi_1\xi_2\,, \\ &\psi_6(\xi_1,\xi_2) = 4\xi_2(1 - \xi_1 - \xi_2)\,. \end{aligned}$$

Proof. A simple calculation leads to

$$\begin{aligned}\varphi_1(\xi_1,\xi_2) &= \psi_1(\xi_1,\xi_2) + 0.5\ (\psi_4(\xi_1,\xi_2) + \psi_6(\xi_1,\xi_2)),\\ \varphi_2(\xi_1,\xi_2) &= \psi_2(\xi_1,\xi_2) + 0.5\ (\psi_4(\xi_1,\xi_2) + \psi_5(\xi_1,\xi_2)),\\ \varphi_3(\xi_1,\xi_2) &= \psi_3(\xi_1,\xi_2) + 0.5\ (\psi_5(\xi_1,\xi_2) + \psi_6(\xi_1,\xi_2)),\end{aligned}$$

and therefore (45) holds. □

LEMMA 2.5. *For the p-hierarchical and the quadratic nodal basis the relation*

$$\Phi_l^H = \Phi_l^N S_l \tag{47}$$

holds, where

$$\Phi_l^H = (p_{l-1}^{(1)}, p_{l-1}^{(2)}, \ldots, p_{l-1}^{(N_{l-1})}, q_{l-1}^{(N_{l-1}+1)}, \ldots, q_{l-1}^{(N_l)}), \tag{48}$$

$$\Phi_l^N = (q_{l-1}^{(1)}, q_{l-1}^{(2)}, \ldots, q_{l-1}^{(N_l)}), \tag{49}$$

$$S_l = [S_l^{(ij)}]_{i,j=1,2,\ldots,N_l}, \tag{50}$$

$$S_l^{(ij)} = \begin{cases} 1 & \textit{for } i = j,\ i,j = 1,2,\ldots,N_l,\\ \frac{1}{2} & \textit{for } j = i_1 \textit{ and } j = i_2,\ N_{l-1} < i \le N_l, \textit{ where } P^{(i)} \textit{ is the}\\ & \textit{midpoint of that edge which is given by the vertices}\\ & P^{(i_1)} \textit{ and } P^{(i_2)} \textit{ of a triangle of } \mathcal{T}_{l-1},\\ 0 & \textit{otherwise.}\end{cases} \tag{51}$$

Proof. The FE functions are defined element by element, i.e.,

$$\tilde{p}_l^{(i)}(x) = \begin{cases} \tilde{p}_\alpha^{(r)}(x) = \tilde{\varphi}_\alpha(\xi(x)), & x \in \delta_{l-1}^{(r)},\ r \in B_i,\\ 0 & \text{otherwise,}\end{cases}$$

where $\tilde{p}_l^{(i)}$ stands for one function from (48) or (49), $\tilde{\varphi}_\alpha$ stands for the corresponding shape function on the reference element Δ, i.e., for the corresponding function of (46), and $B_i = \{r \in \mathcal{J}_{l-1} : P^{(i)} \in \bar{\delta}_{l-1}^{(r)}\}$. Thus the statement of the lemma follows from Lemma 2.4 immediately. □

THEOREM 2.6. *Under the assumptions of Lemmas* 2.1 *and* 2.2 *the FE systems of algebraic equations*

$$\left(\frac{4}{3}K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}\right)\underline{u}_l^N = \left(\frac{4}{3}\underline{f}_l^{L,N} - \frac{1}{3}\tilde{\underline{f}}_{l-1}\right) \quad \textit{and} \quad K_l^{Q,N}\underline{u}_l^N = \underline{f}_l^{Q,N}$$

have the same solution.

Proof. Using Lemma 2.5 we get for arbitrary vectors $\underline{u}_l,\ \underline{v}_l \in \mathbb{R}^{N_l}$

$$(K_l^{Q,H}\underline{u}_l, \underline{v}_l) = a(\Phi_l^H\underline{u}_l, \Phi_l^H\underline{v}_l) = a(\Phi_l^N S_l\,\underline{u}_l, \Phi_l^N S_l\,\underline{v}_l) = (S_l^T K_l^{Q,N} S_l\,\underline{u}_l, \underline{v}_l)$$

and

$$(\underline{f}_l^{Q,H}, \underline{v}_l) = \langle F, \Phi_l^H\underline{v}_l\rangle = \langle F, \Phi_l^N S_l\,\underline{v}_l\rangle = (S_l^T\underline{f}_l^{Q,N}, \underline{v}_l).$$

Therefore we have

$$K_l^{Q,H} = S_l^T K_l^{Q,N} S_l\,, \quad K_l^{Q,N} = S_l^{-T} K_l^{Q,H} S_l^{-1}, \tag{52}$$

$$\underline{f}_l^{Q,H} = S_l^T\underline{f}_l^{Q,N}, \quad \underline{f}_l^{Q,N} = S_l^{-T}\underline{f}_l^{Q,H}\,. \tag{53}$$

Furthermore, from Yserentant [24] we know that

$$K_l^{L,H} = S_l^T K_l^{L,N} S_l \quad \text{and} \quad \underline{f}_l^{L,H} = S_l^T \underline{f}_l^{L,N} \,. \tag{54}$$

From (52), (54), Lemma 2.1, and Lemma 2.2 it follows that

$$K_l^{Q,N} = S_l^{-T} K_l^{Q,H} S_l^{-1} \;=\; S_l^{-T} \left(\frac{4}{3} K_l^{L,H} - \frac{1}{3} \tilde{K}_{l-1} \right) S_l^{-1}$$

$$= \frac{4}{3} S_l^{-T} (S_l^T K_l^{L,N} S_l \,) S_l^{-1} - \frac{1}{3} S_l^{-T} \tilde{K}_{l-1}\, S_l^{-1} \;=\; \frac{4}{3} K_l^{L,N} - \frac{1}{3} \tilde{K}_{l-1} \tag{55}$$

and

$$\underline{f}_l^{Q,N} = S_l^{-T} \underline{f}_l^{Q,H} \;=\; S_l^{-T} \left(\frac{4}{3} \underline{f}_l^{L,H} - \frac{1}{3} \underline{\tilde{f}}_{l-1} \right)$$

$$= \frac{4}{3} S_l^{-T} S_l^T \underline{f}_l^{L,N} - \frac{1}{3} S_l^{-T} \underline{\tilde{f}}_{l-1} \;=\; \frac{4}{3} \underline{f}_l^{L,N} - \frac{1}{3} \underline{\tilde{f}}_{l-1} \,. \qquad \square \tag{56}$$

3. Multilevel algorithms with extrapolation. In this section we analyze a multigrid (MG) algorithm using FE discretizations with piecewise *linear* functions and an implicit extrapolation step. The iterates of this algorithm converge to the solution which we get by an FE discretization of problem (1) with piecewise *quadratic* functions. Additionally, we will use this algorithm as a preconditioner in the preconditioned conjugate gradient (PCCG) method.

First we introduce some notation.

- Smoothing procedure. Presmoothing $G_l^V(\underline{u}_l^{N,(j)}, K_l^{L,N}, \underline{f}_l^{L,N})$:

  Let the initial guess $\underline{u}_l^{N,(j)} = (\underline{u}_{l,v}^{N,(j)}, \underline{u}_{l,m}^{N,(j)})^T$ be given.

  Set $\underline{u}_{l,v}^{N,(j+1)} = \underline{u}_{l,v}^{N,(j)}$ and compute an approximate solution $\tilde{\underline{z}}_{l,m}$ of the system

$$K_{l,mm}^{L,N} \underline{z}_{l,m} = \underline{f}_{l,m}^{L,N} - K_{l,mv}^{L,N} \underline{u}_{l,v}^{N,(j+1)} - K_{l,mm}^{L,N} \underline{u}_{l,m}^{N,(j)} \tag{57}$$

  by means of an iterative method, starting with the zero-vector. We suppose that the error transmission operator of the method is of the type $M_{l,m} = (I_{l,m} - B_{l,mm}^{-1} K_{l,mm}^{L,N})$. Set $\underline{u}_l^{N,(j+1)} = (\underline{u}_{l,v}^{N,(j+1)}, \underline{u}_{l,m}^{N,(j)} + \tilde{\underline{z}}_{l,m})^T$.

  Postsmoothing $G_l^N(\underline{u}_l^{N,(j)}, K_l^{L,N}, \underline{f}_l^{L,N})$:

  We use the same algorithm; however, we suppose that the error transmission operator of the iterative method for solving the system (57) is of the type $M_{l,m} = (I_{l,m} - B_{l,mm}^{-T} K_{l,mm}^{L,N})$, so that the overall multigrid iteration operator becomes symmetric.
- Interpolation.

$$I_{l-1}^l \,:\, \mathbb{R}^{N_{l-1}} \to \mathbb{R}^{N_l} \,, \qquad I_{l-1}^l = \begin{pmatrix} I_{l,v} \\ S_{l,mv} \end{pmatrix} , \tag{58}$$

  where

$$(I_{l-1}^l)^{(ij)} = \begin{cases} 1 & \text{for } i = j,\ i,j = 1,2,\dots,N_{l-1}, \\ \frac{1}{2} & \text{for } j = i_1 \text{ and } j = i_2,\ N_{l-1} < i \le N_l, \text{ where } P^{(i)} \text{ is the} \\ & \text{midpoint of that edge which is given by the vertices} \\ & P^{(i_1)} \text{ and } P^{(i_2)} \text{ of a triangle from } \mathcal{T}_{l-1}, \\ 0 & \text{otherwise.} \end{cases} \tag{59}$$

- Restrictions.

$$I_l^{l-1} : \mathbb{R}^{N_l} \to \mathbb{R}^{N_{l-1}}, \quad I_l^{l-1} = (I_{l-1}^l)^T = (I_{l,v} \quad S_{l,mv}^T), \tag{60}$$

$$I_l^{l-1,inj} : \mathbb{R}^{N_l} \to \mathbb{R}^{N_{l-1}}, \quad I_l^{l-1,inj} = (I_{l,v} \quad 0). \tag{61}$$

Now we formulate the multigrid algorithm.

ALGORITHM 1. Let an initial guess $\underline{u}_l^{N,(k,0)}$ be given.

1. Presmoothing:

$$\underline{u}_l^{N,(k,1)} = G_l^V(\underline{u}_l^{N,(k,0)}, K_l^{L,N}, \underline{f}_l^{L,N}). \tag{62}$$

2. Coarse-grid correction.
   (a) Computation of the defect:

$$\underline{d}_{l-1}^{(k)} = \frac{4}{3} I_l^{l-1}(\underline{f}_l^{L,N} - K_l^{L,N}\underline{u}_l^{N,(k,1)}) - \frac{1}{3}(\underline{f}_{l-1}^{L,N} - K_{l-1}^{L,N} I_l^{l-1,inj}\underline{u}_l^{N,(k,1)}). \tag{63}$$

   (b) Solution of the system:

$$K_{l-1}^{L,N}\underline{w}_{l-1}^{(k)} = \underline{d}_{l-1}^{(k)} \tag{64}$$

   by means of μ iteration steps of a usual multigrid ($(l-1)$-grid) algorithm (see, e.g., [7]) which starts with the zero-vector and returns an approximate solution $\underline{\tilde{w}}_{l-1}^{(k)}$.

   (c) Computation of the correction:

$$\underline{u}_l^{N,(k,2)} = \underline{u}_l^{N,(k,1)} + I_{l-1}^l \underline{\tilde{w}}_{l-1}^{(k)}. \tag{65}$$

3. Postsmoothing:

$$\underline{u}_l^{N,(k,3)} = G_l^N(\underline{u}_l^{N,(k,2)}, K_l^{L,N}, \underline{f}_l^{L,N}). \tag{66}$$

Set $\underline{u}_l^{N,(k+1,0)} = \underline{u}_l^{N,(k,3)}$.

Before we present an alternative formulation of this algorithm, we analyze the smoothing step and the computation of the defect.

- The essential operation in the smoothing step is the approximate solution of system (57). Obviously, we can replace equation (57) by

$$\frac{4}{3}K_{l,mm}^{L,N}\underline{z}_{l,m} = \frac{4}{3}\underline{f}_{l,m}^{L,N} - \frac{4}{3}K_{l,mv}^{L,N}\underline{u}_{l,v}^{N,(j+1)} - \frac{4}{3}K_{l,mm}^{L,N}\underline{u}_{l,m}^{N,(j)}\ . \tag{67}$$

  Using the relations (55) and (56) in the proof of Theorem 2.6 we get the equivalence of relation (67) to

$$K_{l,mm}^{Q,N}\underline{z}_{l,m} = \underline{f}_{l,m}^{Q,N} - K_{l,mv}^{Q,N}\underline{u}_{l,v}^{N,(j+1)} - K_{l,mm}^{Q,N}\underline{u}_{l,m}^{N,(j)}\ . \tag{68}$$

- Step 2(a) in Algorithm 1 can be formulated in terms of the quadratic nodal basis. We have

$$\frac{4}{3} I_l^{l-1}(\underline{f}_l^{L,N} - K_l^{L,N} \underline{u}_l^{N,(k,1)}) - \frac{1}{3}(\underline{f}_{l-1}^{L,N} - K_{l-1}^{L,N} I_l^{l-1,inj} \underline{u}_l^{N,(k,1)})$$

$$= I_l^{l-1}\left[\left(\frac{4}{3}\underline{f}_l^{L,N} - \frac{1}{3}\underline{\tilde{f}}_{l-1}\right) - \left(\frac{4}{3}K_l^{L,N} - \tilde{K}_{l-1}\right)\underline{u}_l^{N,(k,1)}\right] \tag{69}$$

$$= I_l^{l-1}(\underline{f}_l^{Q,N} - K_l^{Q,N} \underline{u}_l^{N,(k,1)}).$$

Because of the equivalence of the relations (57) and (68) we can replace in Algorithm 1 the smoothing steps (62) and (66) by the equivalent steps

$$\underline{u}_l^{N,(k,1)} = G_l^V(\underline{u}_l^{N,(k,0)}, K_l^{Q,N}, \underline{f}_l^{Q,N}) \quad \text{and} \quad \underline{u}_l^{N,(k,3)} = G_l^N(\underline{u}_l^{N,(k,2)}, K_l^{Q,N}, \underline{f}_l^{Q,N}).$$

Furthermore, we can see from equation (69) that the computation of the defect (63) is equivalent to

$$\underline{d}_{l-1}^{(k)} = I_l^{l-1}(\underline{f}_l^{Q,N} - K_l^{Q,N} \underline{u}_l^{N,(k,1)}).$$

Therefore, Algorithm 1 can be interpreted as a multigrid algorithm for solving the system $K_l^{Q,N} \underline{u}_l = \underline{f}_l^{Q,N}$ of algebraic finite element equations resulting from a discretization with piecewise quadratic functions.

We can also formulate Algorithm 1 in terms of the h- or p-hierarchical basis. Because of

$$\underline{u}_l^{N,(j)} = S_l \underline{u}_l^{H,(j)}, \text{ i.e., } \underline{u}_{l,v}^{N,(j)} = \underline{u}_{l,v}^{H,(j)}, \quad \underline{u}_{l,m}^{N,(j)} = S_{l,mv} \underline{u}_{l,v}^{H,(j)} + \underline{u}_{l,m}^{H,(j)},$$

with S_l defined in (50), $\underline{f}_{l,m}^{L,H} = \underline{f}_{l,m}^{L,N}$, and $K_{l,mm}^{L,H} = K_{l,mm}^{L,N}$, it follows from (67) that

$$\frac{4}{3} K_{l,mm}^{L,H} \underline{z}_{l,m} = \frac{4}{3} \underline{f}_{l,m}^{L,H} - \frac{4}{3} K_{l,mv}^{L,N} \underline{u}_{l,v}^{H,(j+1)} - \frac{4}{3} K_{l,mm}^{L,N}(S_{l,mv} \underline{u}_{l,v}^{H,(j)} + \underline{u}_{l,m}^{H,(j)}).$$

Taking into account that we set $\underline{u}_{l,v}^{H,(j+1)} = \underline{u}_{l,v}^{H,(j)}$ in the smoothing procedure defined at the beginning of this section and that $K_{l,mv}^{L,H} = K_{l,mv}^{L,N} + K_{l,mm}^{L,N} S_{l,mv}$ is valid (see also relation (54)) we get

$$\frac{4}{3} K_{l,mm}^{L,H} \underline{z}_{l,m} = \frac{4}{3} \underline{f}_{l,m}^{L,H} - \frac{4}{3} K_{l,mv}^{L,H} \underline{u}_{l,v}^{H,(j+1)} - \frac{4}{3} K_{l,mm}^{L,H} \underline{u}_{l,m}^{H,(j)} \tag{70}$$

or the equivalent relation,

$$K_{l,mm}^{Q,H} = \underline{f}_{l,m}^{Q,H} - K_{l,mv}^{Q,H} \underline{u}_{l,v}^{H,(j+1)} - K_{l,mm}^{Q,H} \underline{u}_{l,m}^{H,(j)}. \tag{71}$$

Using the relation (54) a simple calculation leads to the equivalence of the coarse-grid correction step in Algorithm 1,

$$\underline{u}_l^{N,(k,2)} = \underline{u}_l^{N,(k,1)} + I_{l-1}^l(I_{l-1} - M_{l-1}^{\mu})(K_{l-1}^{L,N})^{-1} I_l^{l-1}\left[\left(\frac{4}{3}\underline{f}_l^{L,N} - \frac{1}{3}\underline{\tilde{f}}_{l-1}\right)\right.$$
$$\left. - \left(\frac{4}{3}K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}\right)\underline{u}_l^{N,(k,1)}\right],$$

to the coarse-grid correction step

$$\underline{u}_l^{H,(k,2)} = \underline{u}_l^{H,(k,1)}$$
$$+ \tilde{I}_{l-1}^l(I_{l-1} - M_{l-1}^{\mu})(K_{l-1}^{L,N})^{-1}\left[\underline{f}_{l-1}^{L,N} - \left(K_{l-1}^{L,N} \underline{u}_{l,v}^{H,(k,1)} - \frac{4}{3} K_{l,vm}^{L,H} \underline{u}_{l,m}^{H,(k,1)}\right)\right] \tag{72}$$

in the h-hierarchical basis, where $\tilde{I}^{l}_{l-1}\underline{v}_{l-1} = (\underline{v}_{l-1} \quad 0)^T$ for all $\underline{v}_{l-1} \in \mathbb{R}^{N_{l-1}}$, I_{l-1} is the identity operator in the space $\mathbb{R}^{N_{l-1}}$, and M_{l-1} denotes the error transmission operator of the $(l-1)$-grid method for solving the coarse-grid system (64). In the p-hierarchical basis this becomes

$$\begin{aligned}\underline{u}_l^{H,(k,2)} &= \underline{u}_l^{H,(k,1)} \\ &+ \tilde{I}^{l}_{l-1}(I_{l-1} - M^{\mu}_{l-1})(K^{L,N}_{l-1})^{-1}\left[\underline{f}^{L,N}_{l-1} - \left(K^{L,N}_{l-1}\underline{u}^{H,(k,1)}_{l,v} - K^{Q,H}_{l,vm}\underline{u}^{H,(k,1)}_{l,m}\right)\right].\end{aligned} \tag{73}$$

Instead of using the initial guess $\underline{u}_l^{N,(k,0)}$, we set $\underline{u}_l^{H,(k,0)} = S_l^{-1}\underline{u}_l^{N,(k,0)}$ and replace the smoothing steps by the equivalent steps

$$G_l^V(\underline{u}_l^{H,(j)}, K_l^{L,H}, \underline{f}_l^{L,H}), \quad G_l^N(\underline{u}_l^{H,(j)}, K_l^{L,H}, \underline{f}_l^{L,H}) \qquad \text{or}$$

$$G_l^V(\underline{u}_l^{H,(j)}, K_l^{Q,H}, \underline{f}_l^{Q,H}), \quad G_l^N(\underline{u}_l^{H,(j)}, K_l^{Q,H}, \underline{f}_l^{Q,H})$$

as well as the coarse-grid correction step by the step (72) or (73), respectively. Thus we obtain the formulation of Algorithm 1 in the h- and p-hierarchical basis.

According to these interpretations we can formulate Algorithm 1 in a more abstract form. If we use a decomposition of the FE space V_l, i.e.,

$$V_l = V_l^{Q,N} = V_l^{Q,H} = V_{l-1} + T_l \ , \qquad T_l = \operatorname{span}\{q^{(i)}_{l-1}\ , \ i = N_{l-1}+1, \ldots, N_l\} \tag{74}$$

we get the following equivalent algorithm.

ALGORITHM 1′. Let an initial guess $u_l^{(k,0)} \in V_l$ be given.

1. Presmoothing.

$$\begin{aligned}&\text{Determine} \quad u_l^{(k,1)} \in u_l^{(k,0)} + T_l \ : \|u_l^{(k,1)} - u_{l,*}^{(k,1)}\| \le \rho_1 \|u_l^{(k,0)} - u_{l,*}^{(k,1)}\| \\ &\text{where} \quad u_{l,*}^{(k,1)} \in u_l^{(k,0)} + T_l \ : a(u_{l,*}^{(k,1)}, v) = \langle F, v\rangle \quad \text{for all } v \in T_l\,.\end{aligned} \tag{75}$$

2. Coarse-grid correction.

$$\begin{aligned}&\text{Determine} \quad u_l^{(k,2)} \in u_l^{(k,1)} + V_{l-1} : \|u_l^{(k,2)} - u_{l,*}^{(k,2)}\| \le \rho_2 \|u_l^{(k,1)} - u_{l,*}^{(k,2)}\| \\ &\text{where} \quad u_{l,*}^{(k,2)} \in u_l^{(k,1)} + V_{l-1} : a(u_{l,*}^{(k,2)}, v) = \langle F, v\rangle \quad \text{for all } v \in V_{l-1}.\end{aligned} \tag{76}$$

3. Postsmoothing.

$$\begin{aligned}&\text{Determine} \quad u_l^{(k,3)} \in u_l^{(k,2)} + T_l \ : \|u_l^{(k,3)} - u_{l,*}^{(k,3)}\| \le \rho_3 \|u_l^{(k,2)} - u_{l,*}^{(k,3)}\| \\ &\text{where} \quad u_{l,*}^{(k,3)} \in u_l^{(k,2)} + T_l \ : a(u_{l,*}^{(k,3)}, v) = \langle F, v\rangle \quad \text{for all } v \in T_l\,.\end{aligned} \tag{77}$$

Set $u_l^{(k+1,0)} = u_l^{(k,3)}$.

Depending on the choice of the basis in the space V_l we get from Algorithm 1′ the multigrid algorithm for solving the FE system of algebraic equations in terms of the piecewise quadratic nodal basis or the p-hierarchical basis.

In [21], Schieweck has proved the following convergence result for this type of multigrid algorithm:

$$\|u_l^{(k+1,0)} - u_l\| \le \eta\, \|u_l^{(k,0)} - u_l\|\,, \tag{78}$$

where

$$\eta = \rho_2 + (1-\rho_2)[\rho_1 + (1-\rho_1)\gamma][\rho_3 + (1-\rho_3)\gamma]\,, \tag{79}$$

$\|.\|^2 = a(.,.)$, and u_l is the solution of the problem

$$\text{find } u_l \in V_l \ : \ a(u_l, v_l) = \langle F, v_l\rangle \quad \text{for all} \quad v_l \in V_l\,,$$

and γ is the constant in the strengthened Cauchy inequality

$$|a(v_l, w_{l-1})| \le \gamma \|v_l\| \, \|w_{l-1}\| \quad \text{for all} \quad v_l \in T_l, \ \text{for all} \quad w_{l-1} \in V_{l-1}\,. \tag{80}$$

Using this result we can prove the following convergence theorem for Algorithm 1.

THEOREM 3.1. *Let the smoothing procedures, the restriction, and the interpolation operators be defined as at the beginning of this section and let the assumptions of Lemmas* 2.1 *and* 2.2 *be fulfilled. Then the following occur.*

(i) *The iterates of Algorithm* 1 *converge to the solution which we get by an FE discretization of problem* (1) *with piecewise quadratic functions.*

(ii) *The convergence estimate*

$$\|\underline{u}_l^{(k+1,0)} - \underline{u}_l\|_* \le \eta \|\underline{u}_l^{(k,0)} - \underline{u}_l\|_* \tag{81}$$

holds, where $\|.\|_*^2 = ((\frac{4}{3}K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}).,.)$ *and* $\underline{u}_l$ *is the solution of the system of algebraic FE equations*

$$\left(\frac{4}{3}K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}\right)\underline{u}_l = \left(\frac{4}{3}\underline{f}_l^{L,N} - \frac{1}{3}\underline{\tilde{f}}_{l-1}\right).$$

The convergence rate η *depends on the number of iteration steps for solving the systems* (57), *on the convergence rate of the* $(l-1)$*-grid algorithm used in step* 2(b), *and on the constant in the strengthened Cauchy inequality* (80).

Proof.

(i) This follows from the interpretation of Algorithm 1 as a multigrid algorithm for solving the FE system $K_l^{Q,N}\underline{u}_l = \underline{f}_l^{Q,N}$, immediately.

(ii) The convergence estimate (81) follows from estimate (79), because Algorithm 1 is equivalent to Algorithm 1′.

From [1] we know that the matrices $K_{l,mm}^{L,N}$ and $K_{l,mm}^{Q,N}$ have a condition number which is independent of the discretization parameter. Therefore ρ_1 and ρ_3 in (75) and (77), respectively, do not depend on the discretization parameter. If additionally the convergence rate of the $(l-1)$-grid algorithm for solving the system (64) is independent of the discretization parameter h_{l-1}, then we get an h_l-independent convergence rate η of Algorithm 1. □

Remark 3.1. The strengthened Cauchy inequality (80) for various bilinear forms $a(.,.)$ was analyzed by many authors [1], [2], [5], [9], [12], [14], [21], [23]. Maitre and Musy [14] calculated the constant γ for bilinear forms corresponding to scalar partial differential equations of second order. Jung [9] and Jung, Langer, and Semmler [12] studied the dependence of γ on the Poisson ratio for linear elasticity problems in two and three dimensions.

Remark 3.2. For different bilinear forms, the dependence of ρ_1 and ρ_3 on problem-specific parameters is studied in [9], [12], and [21].

Remark 3.3. The statements of Theorem 3.1 can also be proved for Algorithm 1 applied to FE equations resulting from the discretization of plane linear elasticity problems. To get these results we must prove the statements of Lemmas 2.1 and 2.2 for the related matrices $K_l^{L,H}$, $K_{l-1}^{L,N}$, and $K_l^{Q,H}$. These proofs are similar to the proofs given in §2. In §4 we will show some numerical experiments for plane linear elasticity problems.

Remark 3.4. We can also use Algorithm 1 as a preconditioner. The starting point is the PCCG method for solving the system of algebraic equations

$$\left(\frac{4}{3}K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}\right)\underline{u}_l = \left(\frac{4}{3}\underline{f}_l^{L,N} - \frac{1}{3}\underline{\tilde{f}}_{l-1}\right) . \tag{82}$$

Since the matrix of the system of equations (82) is only used for matrix by vector multiplications within the PCCG method it is not necessary to assemble the matrix $\left(\frac{4}{3}K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}\right)$. Also, the right-hand side is needed for the computation of the defect in the initial step of the PCCG method only. Therefore, we can perform all operations of the PCCG method using the matrices $K_l^{L,N}$, $K_{l-1}^{L,N}$ and the right–hand sides $\underline{f}_l^{L,N}$ and $\underline{f}_{l-1}^{L,N}$. A priori we choose the matrix $\tilde{C}_l = \left(\frac{4}{3}K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}\right)$ as preconditioner and solve the preconditioning systems $\tilde{C}_l\underline{w}_l = \underline{r}_l$ within the PCCG algorithm by means of Algorithm 1. This approach we can interpret as a preconditioning with the matrix

$$C_l = \left(\frac{4}{3}K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}\right)\left(I_l - M_l^m\right)^{-1} , \tag{83}$$

where M_l^m is the error transmission operator of Algorithm 1. We have to check whether the matrix C_l is symmetric and positive definite. In [11] some conditions for the smoothing procedures, the restriction, and the interpolation operators are given, which guarantee these properties. It is easy to verify these conditions for our case.

4. Numerical results. In this section we want to demonstrate that the iterates of Algorithm 1 converge to the FE solution which we would obtain by a discretization of problem (1) with piecewise quadratic functions. Furthermore, we show that the convergence rate of Algorithm 1 is independent of the discretization parameter. We compare Algorithm 1 with a multigrid algorithm applied to FE equations resulting from a discretization with quadratic elements.

The primary purpose of these experiments is to demonstrate the validity of our previous analysis and to show that it leads to efficient algorithms. This, however, means that the algorithms are not necessarily optimal from a more pragmatic point of view. For example, our stopping criterion (see (85) below) forces the algorithm to compute solutions much better than truncation error accuracy. Our goal is not to compute an acceptable solution at minimal cost, but to show the numerical equivalence of the algorithmic variants discussed above.

For the same reason we have introduced the smoothing procedure (62) which is restricted to the fine-grid nodes excluding nodes belonging to the coarser grid. With this smoother the different algorithms converge to exactly the same result. In practice, a τ-extrapolation algorithm may be more efficient when used with regular multigrid smoothing. This, however, would introduce perturbations that change the solution and is therefore not studied here, because a careful analysis similar to Hackbusch [7] or Rüde [17] is beyond the scope of the present paper. For an analysis of various multigrid τ-extrapolation algorithms and interesting numerical experiments with different smoothing procedures we also refer the reader to Bernert [3].

Finally, we remark that our full multigrid strategy could be improved by using τ-extrapolation to compute the coarser level solutions and then use higher order interpolation to find a

TABLE 3

7	16129	8192	1.892 sec	2.851 sec

more accurate initial guess for each new level. This has not been implemented for reasons of simplicity.

All algorithms have been implemented within the multigrid package FEMGP [10], [22]. The computations were performed on a PC 80486 (33 MHz) using the LAHEY-Fortran compiler.

Let us first consider the problem: find $u \in H_0^1(\Omega)$ such that

$$\int_\Omega (A\nabla_x u, \nabla_x v)\,dx = \int_\Omega f v\,dx \tag{84}$$

holds for all $v \in H_0^1(\Omega)$, where $\Omega = (0,1)\times(0,1)$, $A = \left(\begin{smallmatrix}4 & 4\\ 4 & 5\end{smallmatrix}\right)$, and $f = \pi^2(9\sin\pi x\sin\pi y - 8\cos\pi x\cos\pi y)$. The exact solution of this problem is $u = \sin\pi x\sin\pi y$.

In §3 we have seen that we can give equivalent formulations of Algorithm 1 in terms of the quadratic nodal basis, the h-hierarchical basis, and the p-hierarchical basis, respectively. A detailed analysis of the arithmetical work needed for the generation of the stiffness matrices and right-hand sides as well as for a matrix by vector multiplication shows that the implementation of Algorithm 1 in terms of the linear nodal basis or the equivalent algorithm in the p-hierarchical basis will lead to the best algorithms with respect to the necessary CPU-time (see also [13]). For example, for the generation of the matrices and right-hand sides, we need

$K_{l-1}^{L,N}$, $K_l^{L,N}$, $\underline{f}_{l-1}^{L,N}$, $\underline{f}_l^{L,N}$:	67 R_{l-1} additions and 51 R_{l-1} multiplications,
$K_l^{L,H}$, $\underline{f}_l^{L,H}$:	105 R_{l-1} additions and 169 R_{l-1} multiplications,
$K_l^{Q,N}$, $\underline{f}_l^{Q,N}$, $K_{l-1}^{L,N}$:	111 R_{l-1} additions and 146 R_{l-1} multiplications,
$K_l^{Q,H}$, $\underline{f}_l^{Q,H}$:	81 R_{l-1} additions and 120 R_{l-1} multiplications,

where R_{l-1} denotes the number of triangles in the triangulation $\mathcal{T}_{l-1}$. Table 3 demonstrates this for the linear nodal basis and the p-hierarchical basis.

Now we compare Algorithm 1 with the equivalent Algorithm 1′ in terms of the p-hierarchical basis, in the following, which is called Algorithm 1′(H, Q). Within Algorithm 1 and Algorithm 1′(H, Q) we used for the presmoothing (62) two iteration steps of the lexicographically forward Gauss–Seidel method, one iteration step of an $(l-1)$-grid algorithm for solving the coarse-grid system (64), and two iteration steps of the lexicographically backward Gauss–Seidel method for the postsmoothing (66). The initial guess was obtained by a full multigrid strategy using, on the levels $k = 1, 2, \dots, l-1$, a usual multigrid algorithm for solving the corresponding FE equations in the linear nodal basis, i.e., we performed within these k-grid algorithms two W-cycles with two Gauss–Seidel steps lexicographically forward in the presmoothing step and two Gauss–Seidel steps lexicographically backward in the postsmoothing step. For the k-grid algorithms, $k = 1, 2, \dots, l-1$, we observed a convergence rate of

TABLE 4

0.085. The iteration of Algorithm 1 or Algorithm $1'(H, Q)$ is terminated when the defect criterion

$$\frac{\left\| \left(\frac{4}{3}\underline{f}_l^{L,N} - \frac{1}{3}\underline{\tilde{f}}_{l-1}\right) - \left(\frac{4}{3}K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}\right)\underline{u}_l^{N,(k+1,0)} \right\|}{\left\| \left(\frac{4}{3}\underline{f}_l^{L,N} - \frac{1}{3}\underline{\tilde{f}}_{l-1}\right) - \left(\frac{4}{3}K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}\right)\underline{u}_l^{N,(0,0)} \right\|} \leq 10^{-4} \tag{85}$$

or

$$\|\underline{f}_l^{Q,N} - K_l^{Q,N}\underline{u}_l^{N,(k+1,0)}\| \leq 10^{-4} \, \|\underline{f}_l^{Q,N} - K_l^{Q,N}\underline{u}_l^{N,(0,0)}\| \tag{86}$$

is fulfilled, where $\| \, . \, \|$ denotes the Euclidian norm in the space $\mathbb{R}^{N_l}$, and where $\underline{u}_l^{N,(0,0)}$ is the initial guess. In Table 4 the number of iterations and the CPU time needed by the application of Algorithm 1 and Algorithm $1'(H, Q)$ are given. The results show that the number of iterations is independent of the discretization parameter. In this example the constant in the strengthened Cauchy inequality (80) is 0.98. With the observed convergence rate of 0.085 of the $(l-1)$-grid method and this constant in the strengthened Cauchy inequality we conclude that the bound on the convergence rate of Algorithm 1 cannot be better than 0.96. Note that for the Laplace operator the constant would be $\sqrt{2/3}$ (see Maitre and Musy [14]) and would therefore lead to much less pessimistic and obviously also more realistic convergence estimates.

If we use one iteration step of Algorithm 1 as preconditioner in the PCCG method for solving the system

$$\left(K_l^{L,N} - \frac{1}{3}\tilde{K}_{l-1}\right)\underline{u}_l = \left(\underline{f}_l^{L,N} - \frac{1}{3}\underline{\tilde{f}}_{l-1}\right), \tag{87}$$

we get an algorithm with better convergence, the so-called MG(1)-PCCG method (see also Remark 3.4). The iteration of the MG(1)-PCCG method is again terminated when the criterion (85) is fulfilled.

Finally, we compare the discretization errors $\|u - u_l^L\|_1$ and $\|u - u_l^Q\|_1$ in the H^1-norm (see Table 5). Here u_l^L denotes the FE solution obtained by means of Algorithm 1, and u_l^Q the FE solution by a discretization with piecewise quadratic functions. We remark that in our example the right-hand side f is not constant on triangles $\delta_{l-1}^{(r)}$, which we had assumed in the proof of Theorems 2.3 and 2.6. Therefore, in our example the right-hand sides $\left(\frac{4}{3}\underline{f}_l^{L,N} - \frac{1}{3}\underline{\tilde{f}}_{l-1}\right)$ and $\underline{f}_l^{Q,N}$ are not identical. But the discretization errors are almost the same.

As a second example we consider a linear elasticity problem: find the displacement field $u = (u_1, u_2)^T \in V_0$, such that

&\left.+\frac{1}{2}\left(\frac{\partial u_1}{\partial x_2}+\frac{\partial u_2}{\partial x_1}\right)\left(\frac{\partial v_1}{\partial x_2}+\frac{\partial v_2}{\partial x_1}\right)\right]dx=\int_{\Gamma_N} g_{2,1}v_1+g_{2,2}v_2\,ds
\end{aligned}
$$

holds for all test functions $v \in V_0$.

Here $g_2 = (g_{2,1}, g_{2,2})^T$ denotes the surface tractions, E is Young's elasticity modulus, and ν is the Poisson ratio. The space V_0 is defined by $V_0 = \{v \in [H^1(\Omega)]^2 : v_1(x) = v_2(x) = 0 \text{ on } \Gamma_D\}$ and $\partial\Omega = \bar{\Gamma}_D \cup \bar{\Gamma}_N$, $\Gamma_D \cap \Gamma_N = \emptyset$. The domain Ω is given in Fig. 3 and Fig. 4 shows the triangulation $\mathcal{T}_4$ and the contour of the domain with its deformation.

Again we compare the CPU time needed for the generation of the FE systems in the nodal basis of piecewise linear functions and in the p-hierarchical basis.

Furthermore, we give results concerning the application of Algorithm 1 and its use as a preconditioner in the PCCG method. In the algorithms we use the same components as in the first example. We mention here that the constant in the strengthened Cauchy inequality (80) is relatively large, namely $\gamma = 0.94$ (see [12]), and therefore the convergence of Algorithm 1 is poor. For the $(l-1)$-grid method, which is used to solve the coarse-grid problem, we observed a convergence rate of 0.371. Therefore the bound on the convergence rate for Algorithm 1 cannot be better than 0.93.

In Tables 6 and 7 we summarize some results for Algorithm 1, Algorithm $1'(H, Q)$, and the MG(1)-PCCG method for the systems (87).

Finally, we compare the energy of the FE solutions obtained by the application of Algorithm 1 and Algorithm $1'(H, Q)$. From Table 8 we see that we have in both cases the same FE solution.

5. Conclusions. We have shown that multigrid τ-extrapolation can be interpreted as an implicit method to form higher order FE stiffness matrices. This is not only of theoretical interest, but leads to an efficient higher order multilevel solution technique for PDEs. In particular, this extrapolation technique can be used on unstructured meshes.

The resulting algorithm is competitive with multilevel methods that use higher order elements directly. The convergence rate and numerical work per iteration are comparable, but the algorithm has the advantage of a possibly simpler structure. In particular, the τ-extrapolation method is easy to incorporate into existing low-order methods, because it differs from the basic algorithm for linear elements only by a slight modification of the fine-to-coarse restriction process.

The alternative analysis for τ-extrapolation given in Rüde [20] is based on asymptotic expansions for quadrature rules over the triangle, and shows that the method can be generalized when the coefficients are not piecewise constant. In this case the linear combination of the stiffness matrices constitute an appropriate numerical quadrature formula for the quadratic stiffness matrix. This analysis also opens up the possibility of generalizing this technique for more than one extrapolation step. These methods would then be equivalent to polynomial finite elements of degree $p > 2$. Some preliminary results for these extensions are contained in Rüde [17], [18], [19].

Acknowledgment. We would like to thank the referees for many helpful comments.

ON RED-BLACK SOR SMOOTHING IN MULTIGRID*

IRAD YAVNEH†

Abstract. Optimal relaxation parameters are obtained for red-black Gauss–Seidel relaxation in multigrid solvers of a family of elliptic equations. The resulting relaxation schemes are found to retain very high efficiency over an appreciable range of coefficients of the elliptic differential operator, yielding simple, inexpensive, and fully parallelizable smoothers in many situations where less cost-effective block- and alternating-direction schemes are commonly used.

Key words. multigrid, SOR, red-black Gauss–Seidel

AMS subject classifications. 65N12, 65N55

1. Introduction.

An important part of multigrid algorithms for the solution of discretized elliptic boundary-value problems is relaxation, whose purpose is to *smooth* the current error in the approximation, i.e., to efficiently reduce all error Fourier components that cannot be approximated on the coarser grids employed. For definite elliptic operators, the *smoothing factor* (defined below) normally provides an excellent prediction of the convergence factor that the two-grid cycle can achieve.

A well-known technique for improving the convergence properties of relaxation, when it is used as an iterative solver, is relaxation parameters (over- or under-relaxation). In the context of multigrid solution, where the main role of relaxation is to smooth the error rather than reduce it, it has been observed that such modifications are not cost-effective in many situations, particularly when applied to Gauss–Seidel relaxation (e.g., [1, §3.4], [5, §9.2]). (Of course, in other relaxation schemes a relaxation parameter may be essential for smoothing, such as the necessary damping in Jacobi relaxation.) For example, some improvement in the smoothing properties of Gauss–Seidel relaxation has been shown with slight over-relaxation in the case of the two-dimensional Laplace operator, but the two additional floating-point operations required rendered this modification ineffective [5].

It is a fundamental observation that any local relaxation process must lose its efficiency as the operator becomes anisotropic. Standard treatments of this problem are global methods, such as incomplete LU decomposition and line (or plane) relaxation or semi coarsening (or both), sometimes together with alternating-direction relaxation [2], [5], [7], [9], [10]. Frequently, the resulting solver is far more expensive (per relaxation sweep) than the usual solver which employs point relaxation and standard coarsening. This is especially true in parallel computation, where the more elaborate methods cannot always be implemented efficiently.

In making the analyses that led to the conclusions that (a) over-relaxation is inefficient, and (b) elaborate methods are necessary for anisotropic operators, a significant "middle ground" has often been neglected. Thus, while it is true that over-relaxation is not particularly helpful for the two-dimensional (2D) Poisson problem, and also that special measures are required when the ratio of coefficients differs from 1 by several orders of magnitude, it will be shown that relaxation parameters are quite useful when the anisotropy is moderate. This is also true in the case of isotropic operators in higher dimensions.

We consider scalar elliptic partial differential operators of the type

$$L = \sum_{i=1}^{n} c_i \partial_{x_i^2}^2 \,, \qquad \sum_{i=1}^{n} c_i = 1 \,, \tag{1}$$

on a rectangular periodic domain, where c_i $(i = 1, \dots, n)$ are real positive constants. The discretization of L is assumed to be the usual second-order accurate central differences involving only nearest neighbors (producing a $2n+1$-point "star"). Throughout this study, $n \geq 2$ is assumed. We denote the set of coordinate indices by $\mathcal{I} = \{1, \dots, n\}$, the position labels by a vector of integers $\mathbf{k} = (k_1, \dots, k_n)$, and the meshsize by h. A square mesh is assumed for simplicity, but rectangular-mesh problems are trivially reduced to equivalent square-mesh problems by replacing the coefficients c_i with $\tilde{c}_i = c_i (\frac{\tilde{h}}{h_i})^2$, where h_i is the meshsize corresponding to c_i, and $\tilde{h}$ is chosen such that $\sum_{i=1}^{n} \tilde{c}_i = 1$. For the square mesh,

$$x_i = hk_i \,, \qquad i \in \mathcal{I} \,.$$

We compute optimal relaxation parameters for Gauss–Seidel relaxation in red-black ordering. In §2 we analyze the case where only one relaxation sweep is performed between coarse-grid corrections. In §3 we consider the case of several relaxation sweeps. In §4 results of two-level analyses are obtained and compared to the smoothing-factor values, and numerical tests are reported for problems with varying coefficients and varying grid-spacing. The results are summarized and conclusions are drawn in §5.

2. Single relaxation sweep.

2.1. Smoothing analysis. "Pattern" relaxation methods, such as red-black Gauss–Seidel have been studied and analyzed extensively in the context of multigrid algorithms. (See especially [5], and also, e.g., [1], [3], [7], [8], and [10].) We describe the smoothing analysis here briefly.

It is a well-known observation for Gauss–Seidel relaxation of five-point star operators (in two dimensions) in red-black order, that two-dimensional subspaces of error Fourier components are invariant. This result immediately generalizes to $2n+1$-point star operators in n dimensions. Specifically, this relaxation couples each Fourier component $\exp(i\mathbf{k} \cdot \theta)$ only with $\exp(i\mathbf{k} \cdot \tilde{\theta})$, where

$$\theta = (\theta_1, \dots, \theta_n) \,, \qquad \tilde{\theta} = (\tilde{\theta}_1, \dots, \tilde{\theta}_n) \,, \tag{2}$$

$$-\pi < \theta_i \leq \pi \,, \tag{3}$$

and

$$\tilde{\theta}_i = \theta_i - \operatorname{sign}(\theta_i)\pi \,, \tag{4}$$

$i \in \mathcal{I}$. Here sign(0) is defined as -1. θ_i can really assume discrete values only, but, for convenience in obtaining h-independent upper bounds, below we assume that θ_i can take on any value in $(-\pi, \pi]$.

DEFINITION 1. *An element θ_i of mode θ is* smooth *if it satisfies*

$$-\frac{\pi}{2} < \theta_i \leq \frac{\pi}{2} \,.$$

Otherwise it is rough.

DEFINITION 2. *A Fourier mode θ is smooth if all its elements θ_i are smooth. Otherwise it is rough.*

We shall denote the set of smooth θ's by Θ_s and the set of rough θ's by Θ_r.

Fourier modes that are rough on the fine grid cannot be approximated on the twice-coarser grid that is assumed to provide the coarse-grid correction, since they alias with other components. Hence, they need to be treated efficiently by relaxation on the fine grid. Evidently, all pairs $(\theta, \tilde{\theta})$ consist of either two rough modes or one rough and one smooth mode. Without loss of generality, it will be our convention that $\tilde{\theta}$ is always rough.

The relaxation operator, $S(\theta, \tilde{\theta}) = \{s_{ij}\}$, is a two-by-two matrix which gives the amplitude of error Fourier components $(\exp(i\theta \cdot \mathbf{k}), \exp(i\tilde{\theta} \cdot \mathbf{k}))^T$ after one full relaxation sweep, when multiplied by their amplitudes before the sweep. It can be obtained by multiplying the operators of the two weighted-Jacobi half-sweeps performed over the black points (defined as gridpoints for which the sum of the indices k_i is odd) and the red points (whose index-sums are even). Now, a sweep over the black points amplifies components of black-point errors by the weighted-Jacobi symbol s_ω (see (6)–(7) below), without affecting the red-point errors, and vice versa. And since red-point and black-point error components can be expressed as sums and differences of the pairs of Fourier components, each half-sweep operator can be written as a two-by-two matrix. These are given by

$$\frac{1}{2}\begin{pmatrix} s_\omega(\theta)+1 & s_\omega(\tilde{\theta})-1 \\ s_\omega(\theta)-1 & s_\omega(\tilde{\theta})+1 \end{pmatrix} \quad \text{and} \quad \frac{1}{2}\begin{pmatrix} s_\omega(\theta)+1 & -s_\omega(\tilde{\theta})+1 \\ -s_\omega(\theta)+1 & s_\omega(\tilde{\theta})+1 \end{pmatrix}$$

for the red-point and black-point relaxation half-sweeps, respectively. Now, S is given by their product:

(5)
$$S = \frac{1}{4}\begin{pmatrix} [s_\omega(\theta)+1]^2 + [s_\omega(\tilde{\theta})-1][1-s_\omega(\theta)] & [s_\omega(\theta)+1][1-s_\omega(\tilde{\theta})] + s_\omega(\tilde{\theta})^2 - 1 \\ [s_\omega(\tilde{\theta})+1][1-s_\omega(\theta)] + s_\omega(\theta)^2 - 1 & [s_\omega(\tilde{\theta})+1]^2 + [s_\omega(\tilde{\theta})-1][1-s_\omega(\theta)] \end{pmatrix}.$$

Here, the weighted Jacobi relaxation symbols are given by

$$s_\omega(\theta) = 1 - \omega(1-C), \qquad s_\omega(\tilde{\theta}) = 1 - \omega(1+C), \tag{6}$$

where

$$C = \sum_{i=1}^{n} c_i \cos\theta_i, \tag{7}$$

and ω is the relaxation parameter. In the special case of $\omega = 1$, $s_1(\theta) = -s_1(\tilde{\theta}) = C$, and S is simplified appreciably.

In relaxation operators for which the Fourier components are eigenfunctions (such as damped Jacobi relaxation for the present problem), S is a scalar, and the smoothing factor μ is naturally defined as the largest absolute value of S over the space of rough modes. μ must give some information on the asymptotic reduction of rough error components by the relaxation, but the other parts of the multigrid cycle are idealized. This motivation led to the following highly successful extension to general S, introduced in [1] and [5] (see also [7], [8], and [10]): apply S and then annihilate the smooth modes, while leaving the rough modes unchanged, by projecting on the space of rough modes. When S is a two-by-two matrix, the projection operator Q, which acts as the idealized coarse-grid operator, is given by

$$Q = \begin{pmatrix} q(\theta) & 0 \\ 0 & q(\tilde{\theta}) \end{pmatrix}, \tag{8}$$

where $q = 0$ for a smooth argument and 1 otherwise. (Hence, our rough-$\tilde{\theta}$ convention implies $q(\tilde{\theta}) = 1$.) The smoothing factor μ, when a single relaxation sweep is performed between successive coarse-grid corrections, is defined by

$$\mu = \sup_h \max_\theta \rho(QS)\,, \tag{9}$$

where ρ denotes spectral radius. The implication of the *supremum* is that θ is allowed *any* value in $(-\pi, \pi]$. This will henceforth be implicitly assumed, and $\sup_h$ will be omitted for brevity.

Let

$$\mu^{(s)} = \max_{\theta\in\Theta_s} \rho(QS)$$

and

$$\mu^{(r)} = \max_{\theta\in\Theta_r} \rho(QS).$$

Note that $\mu = \max(\mu^{(s)}, \mu^{(r)})$. Our object is to find ω_{opt}, the relaxation parameter which minimizes μ, yielding μ_{opt}. In particular, μ_{opt} must obviously satisfy

$$\mu_{\text{opt}} \le \mu_{(\omega=1)} = (1 - c_{\min})^2 < 1\,, \tag{10}$$

where

$$0 < c_{\min} \overset{\text{def}}{=} \min_{i\in\mathcal{I}} c_i \le 0.5\,.$$

($\mu_{(\omega=1)}$ is derived in, e.g., [5] and [7] for $n = 2$ and in [10] for general n. The latter inequality is due to the fact that we are only considering $n \ge 2$.)

2.2. Derivation of ω_{opt}. For $\theta \in \Theta_s$, $q(\theta)$ vanishes as noted, leaving

$$\mu^{(s)} = \max_{\theta\in\Theta_s} |s_{22}|\,. \tag{11}$$

Now, $\theta \in \Theta_s$ implies by (7) that C can take on any value between 0 (when all components of θ equal $\frac{\pi}{2}$) and 1 (when all components of θ equal zero). Hence, (5), (6), and (11) yield after rearrangement

$$\mu^{(s)} = \frac{1}{2} \max_{C\in[0,1]} \left|\omega^2(C^2 + C) - 2\omega(1 + C) + 2\right|\,. \tag{12}$$

In order to find the maximum of the right-hand side of (12) over C in the relevant range, we must check the endpoints, $C = 0$ and $C = 1$, and the point at which the derivative with respect to C vanishes. Setting $C = 0$ yields $|\omega - 1|$. This implies, by (10), $0 < \omega_{\text{opt}} < 2$. Setting $C = 1$ yields $(\omega - 1)^2$, which is smaller than $|\omega - 1|$ in this range of ω. Equating the derivative with respect to C to zero yields after rearrangement $0.125|\omega^2 + 4\omega - 4|$, at $C = (2 - \omega)/2\omega$. This C is in [0, 1] so long as $2/3 \le \omega \le 2$. Indeed, it will be established below (Observation 4) that we are only interested in the range $1 \le \omega < 2$. For this range of ω we therefore have the following observation.

OBSERVATION 1. *For* $1 \le \omega < 2$,

$$\mu^{(s)} = 0.125(\omega^2 + 4\omega - 4)\,,$$

and $\mu^{(s)}$ *is consequently a monotonically increasing function of* ω *in* $[1, 2)$.

Proof.

$$0.125|\omega^2+4\omega-4|-|\omega-1|=0.125(\omega-2)^2>0\,. \qquad \square$$

For $\theta\in\Theta_r$, Q is the identity matrix, so $QS=S$, whose eigenvalues are given by

$$\lambda_{1,2}^{(r)}=\frac{1}{2}\left[s_{11}+s_{22}\pm\sqrt{(s_{11}-s_{22})^2+4s_{12}s_{21}}\right]. \tag{13}$$

Substitution from (5) and (6) yields

$$\begin{aligned} s_{11}+s_{22} &= \omega^2C^2-2(\omega-1)\,,\\ s_{11}-s_{22} &= \omega C(2-\omega)\,,\\ 4s_{12}s_{21} &= C^2\omega^4(C^2-1)\,, \end{aligned}$$

and hence

$$\lambda_{1,2}^{(r)}=\frac{1}{2}\left[\omega^2C^2-2(\omega-1)\pm\omega C\sqrt{\omega^2C^2-4(\omega-1)}\right]. \tag{14}$$

Now, $\theta\in\Theta_r$ implies that at least one of θ's components is rough (by Definition 2), but also that at least one of its components is smooth, else $\tilde{\theta}$ would be smooth, by (4), in contradiction to our convention. Hence, by (7), the relevant range of C in (14) is given by

$$|C|\le C_{\max}\overset{\text{def}}{=}1-c_{\min}\,. \tag{15}$$

Here, $C=C_{\max}$ is obtained when all of θ's components vanish, except that which corresponds to $c_{\min}$, which equals $-\frac{\pi}{2}$. Note that

$$0.5\le C_{\max}<1\,. \tag{16}$$

Note also in (14) that $\lambda_1(C)=\lambda_2(-C)$, so it suffices to consider nonnegative values of C, and this will be assumed henceforth for convenience.

OBSERVATION 2. *Denote*

$$D_\omega(C)=\omega^2C^2-4(\omega-1)\,, \tag{17}$$

and let $\bar{D}_\omega=D_\omega(C_{\max})$. Then,

$$\mu^{(r)}=|\omega-1|\,, \tag{18}$$

if $\bar{D}_\omega\le 0$, and

$$\mu^{(r)}=\frac{1}{2}\left[\omega^2C_{\max}^2-2(\omega-1)+\omega C_{\max}\sqrt{\omega^2C_{\max}^2-4(\omega-1)}\right], \tag{19}$$

if $\bar{D}_\omega\ge 0$.

Proof. If $\bar{D}_\omega<0$, then $\lambda_{1,2}^{(r)}$ are complex, and

$$|\lambda_1^{(r)}|=|\lambda_2^{(r)}|=\frac{1}{2}\left\{[\omega^2C^2-2(\omega-1)]^2-\omega^2C^2D_\omega(C)\right\}^{1/2}=|\omega-1|\,, \tag{20}$$

independently of C. And (20) clearly holds also when $\bar{D}_\omega=0$. On the other hand, whenever $D_\omega(C)\ge 0$ then, perforce, also $\omega^2C^2-2(\omega-1)\ge 0$. Hence, only the "+" sign in front of the square root in (14) needs to be considered when seeking the root that is larger in absolute value. Moreover, in this case the corresponding root is evidently a monotonically increasing function of C. By (15), this completes the proof. □

This yields the following observation.

OBSERVATION 3. *For $\bar{D}_\omega > 0$, $\mu^{(r)}$ is a monotonically decreasing function of ω.*

Proof. Differentiation of (19) with respect to ω yields after rearrangement

$$\frac{\partial \mu^{(r)}}{\partial \omega} = \frac{1}{\sqrt{\bar{D}_\omega}} \left[\sqrt{\bar{D}_\omega}(\omega C_{\max}^2 - 1) + C_{\max}(\bar{D}_\omega + \omega - 2) \right]. \tag{21}$$

Evidently, a necessary condition for this derivative to vanish is

$$\bar{D}_\omega(\omega C_{\max}^2 - 1)^2 = C_{\max}^2(\bar{D}_\omega + \omega - 2)^2,$$

which more algebra reduces to

$$(\omega - 1)(C_{\max}^2 - 1) = 0.$$

Now, substituting $C_{\max} = 1$ into (21) indeed makes the derivative vanish, but that is outside the range of $C_{\max}$, by (16). On the other hand, putting $\omega = 1$ yields for the derivative the negative value of $2(C_{\max}^2 - 1)$. Hence, the derivative is negative for all relevant values of $C_{\max}$. □

Now we have the following observation.

OBSERVATION 4.

$$1 \leq \omega_{\text{opt}} < 2.$$

That is, μ_{opt} is obtained by over-relaxation.

Proof. The obvious upper bound has already been established. To derive the lower bound we first note that when $\omega = 1$,

$$\mu^{(r)} = C_{\max}^2 \geq 0.25 > 0.125 = \mu^{(s)}.$$

(See (16) and Observation 1.) Hence, $\mu = \mu^{(r)}$ at $\omega = 1$, and the proof follows now from Observation 3 and the fact that $\bar{D}_\omega$ is positive for $\omega < 1$. □

We can now establish sharp bounds on ω_{opt} and μ_{opt}, by choosing ω such that $\bar{D}_\omega = 0$.

THEOREM 2.1.

$$\omega_{\text{opt}} < \omega_{ub} = \frac{2}{1 + \sqrt{1 - C_{\max}^2}},$$

and

$$\mu_{\text{opt}} < \mu_{ub} \stackrel{\text{def}}{=} \mu_{(\omega=\omega_{ub})} = 0.125(\omega_{ub}^2 + 4\omega_{ub} - 4) = \frac{1 + C_{\max}^2}{2\left(1 + \sqrt{1 - C_{\max}^2}\right)^2}.$$

Hence,

$$\mu_{\text{opt}} \leq 1 - \sqrt{8c_{\min}} + O(c_{\min}).$$

Proof. When $\omega = \omega_{ub}$, $\bar{D}_\omega = 0$ and $\mu^{(r)} = \omega_{ub} - 1 < \mu^{(s)}$ (see Observations 1 and 2). The upper bounds now follow from Observations 1 and 4. The final estimate is verified straightforwardly by substituting $1 - c_{\min}$ for $C_{\max}$, and finding that it applies to μ_{ub}. Indeed, this estimate can easily be shown to be an equality. □

COROLLARY 2.2. *$\bar{D}_\omega > 0$ when $\omega = \omega_{\text{opt}}$.*

Note that the upper-bound values of ω, which are shown below to be nearly optimal, are precisely of the form of the corresponding optimal values when SOR is used as a solver [6], but with $C^2_{\max}$ (the smoothing factor of red-black Gauss–Seidel) replacing the spectral radius of the Gauss–Seidel iteration matrix. Furthermore, it can easily be shown that

$$\frac{1 - \sqrt{1 - C^2_{\max}}}{1 + \sqrt{1 - C^2_{\max}}},$$

which is of the form of the optimal convergence factor for SOR when used as a solver (with the same substitution), is a lower bound on μ_{opt}.

Comparing μ_{opt} to $\mu_{(\omega=1)}$ in (10), we find that the former grows far more slowly as $c_{\min}$ decreases than the latter. This implies that employing over-relaxation allows point Gauss–Seidel relaxation in red-black ordering to retain high efficiency over a much larger range of coefficients c_i than the usual relaxation (see Fig. 2).

There seems to be no simple way to express ω_{opt} and μ_{opt} explicitly, although some implicit relations (whose simple proofs are omitted) are given below. However, Figs. 1 and 2 compare the optimal and upper-bound values of ω and μ, respectively, and demonstrate that the upper-bound values provide excellent approximations (see also below). This is also tested in numerical examples in §4.

Some implicit relations for ω_{opt} and μ_{opt} are

- ω_{opt} is the only $\omega \in [1, 2)$ which yields

  $$\mu^{(r)} = \mu^{(s)} (= \mu_{\text{opt}}),$$

  producing an equation for ω_{opt} in terms of $C_{\max}$, obtained from (19) and Observation 1.
- Let ω_{ub} and μ_{ub} be the upper-bound values corresponding to some particular $C^2_{\max}$. Then they are equal to the optimal values, ω_{opt} and μ_{opt}, which correspond to

  $$\tilde{C}^2_{\max} = C^2_{\max} + \frac{(\omega_{ub} - 2)^4}{64\omega^2_{ub}\mu_{ub}}.$$

  The smallness of the last term (especially as $C_{\max}$ tends to 1, and ω_{ub} to 2) plus the moderate sensitivity of ω_{opt} (and μ_{opt}) to variations in $C_{\max}$, which is verified by differentiation of the above-mentioned implicit equation, imply that the upper-bound values are close to the optimal values. This derivation is omitted, as the result is more clearly evident in Figs. 1 and 2.

3. Several relaxation sweeps. Unlike methods of relaxation for which Fourier components are eigenfunctions, the smoothing factor of red-black Gauss–Seidel relaxation depends on the number of sweeps performed between successive coarse-grid corrections. Let ν denote the number of sweeps. Then the smoothing factor is naturally defined by [1] and [5]

$$\mu = \left[\sup_h \max_\theta \rho(QS^\nu) \right]^{1/\nu}. \tag{22}$$

Since, for $\theta \in \Theta_r$, Q is the identity matrix, we have the following observation.

OBSERVATION 5. *$\mu^{(r)}$ is independent of ν.*

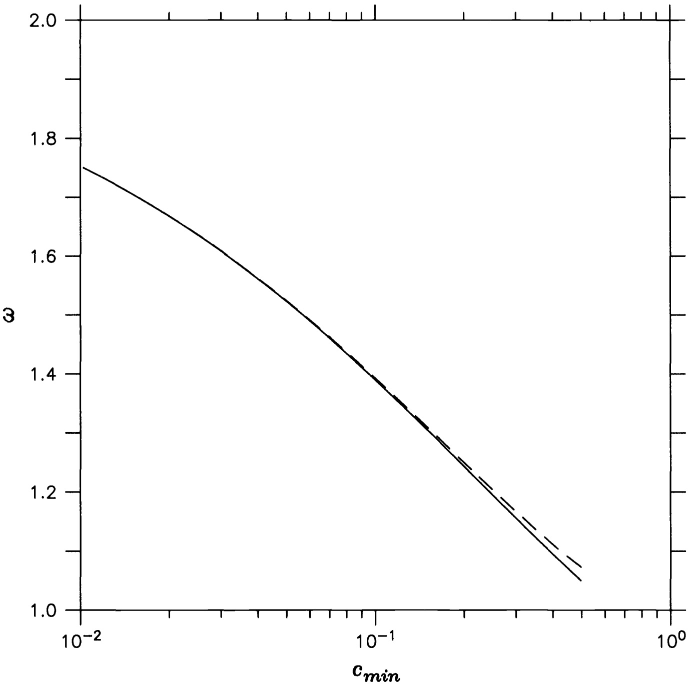

FIG. 1. ω_{opt} *(solid) and* ω_{ub} *(dashes) as a function of* $c_{\min}$.

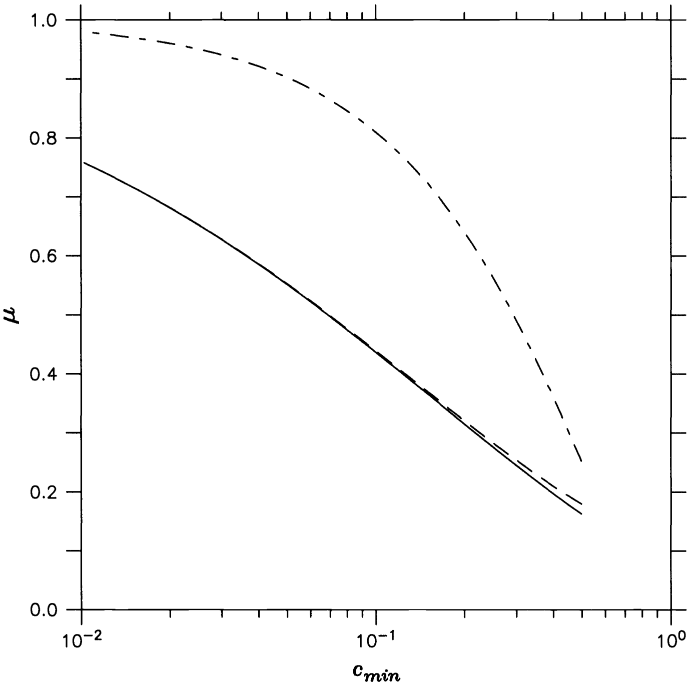

FIG. 2. μ_{opt} *(solid),* μ_{ub} *(dashes) and* $\mu_{(\omega=1)}$ *(alternating dashes) as a function of* $c_{\min}$.

Now denote

$$S^{\nu} = \{s_{ij}^{(\nu)}\}.$$

Then, we have the following observation.

OBSERVATION 6.

$$\mu^{(s)} = \max_{C \in [0,1]} |s_{22}^{(\nu)}|. \tag{23}$$

As ν is increased, $s_{22}^{(\nu)}$ has more and more terms, and we resort to numerical calculation in order to obtain $\mu^{(s)}$, and consequently μ. Figures 3 and 4 show ω_{opt} and μ_{opt} for $\nu = 1, 2, 3$. It is seen that there is some deterioration in performance (per relaxation sweep) when the number of sweeps performed between coarse-grid corrections is increased (as is generally the case with no over-relaxation too). However, this effect diminishes as $c_{\min}$ becomes small. Also, optimal ω is smaller for larger ν, but it is demonstrated below that this effect should be ignored in practical use, and ω_{ub} given in Theorem 2.1 is a very good working value.

4. Two-level analyses and numerical tests. The predictions of the smoothing analysis were compared with two-level analyses (which here predict the two-level performance exactly), and with results of numerical calculations. In all the examples, bi-linear interpolation was used for prolongation and its adjoint full-weighting operator for residual-restriction, with vertex-centered discretization and standard coarsening. Bi-cubic interpolation was also tested, with results that were usually slightly better only in the more isotropic cases, and somewhat worse otherwise.

Example 1. Analyses with the full two-level operator (two-level analyses, e.g., [1, §4.1], [10]) were carried out for the two-dimensional problem with several values of $c_{\min}$. The results are summarized in Table 1, which shows two-level convergence factors per relaxation sweep, denoted μ^{tl}. The values of ω compared are ω_{ub} from Theorem 2.1, ω_{opt} (Fig. 3), and ω_{best}, which denotes the over-relaxation parameter that yielded the best two-level results obtained. The sixth column shows the prediction of the smoothing analysis, using ω_{opt} (Fig. 4), and the seventh column shows the usual $\omega = 1$ performance. It is seen that there are only very minor differences between the results with the different near-optimal over-relaxation parameters, and that ω_{ub} is a very good working value. Indeed, in some cases it yields even better results than the optimum predicted by the smoothing analysis. In all cases over-relaxation yielded a large improvement in performance, but of course the relative gain (measured by the ratios of $\log \mu^{tl}$) is greater as $c_{\min}$ is smaller. The last two columns show the asymptotic error-reduction factor per cycle obtained by V cycles with two prerelaxation sweeps and one postrelaxation sweep per level for the problem

$$u_{xx} + u_{yy} + \epsilon u_{zz} = 0,$$

on a triply-periodic cube. Here, $\epsilon = 2c_{\min}/(1 - c_{\min})$. The finest resolution was 64^3 and five levels were employed. The initial field was random with uniform distribution. The right-hand side was set to 0, and 100 cycles were performed, renormalizing the solution after every cycle so as to avoid roundoff errors. (Of course, due to the linearity of the problem, the asymptotic convergence factors are independent of the choice of right-hand side function.) An appreciable improvement in performance is obtained by using the over-relaxation parameter ω_{ub}, which becomes more marked for smaller $C_{\min}$. For example, convergence using ω_{ub} is about twice as fast for $C_{\min} = 0.2$ and more than two and a half times as fast for $C_{\min} = 0.1$.

Example 2. V(1,1) cycles were implemented for the Poisson problem in three dimensions with the same specifications as in Example 1. Asymptotic error-reduction factors per cycle

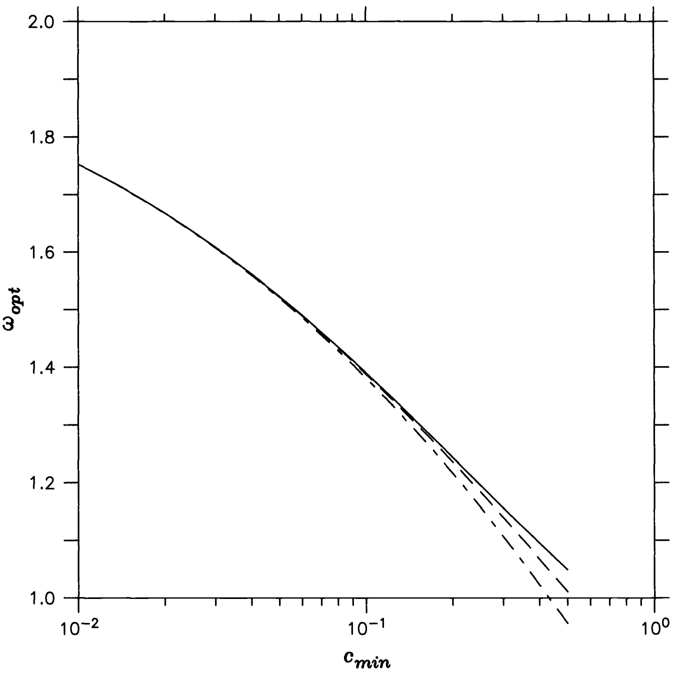

FIG. 3. *ω_{opt} as a function of c_{min}, with one (solid), two (dashes), and three (alternating dashes) relaxation sweeps ν between successive coarse-grid corrections.*

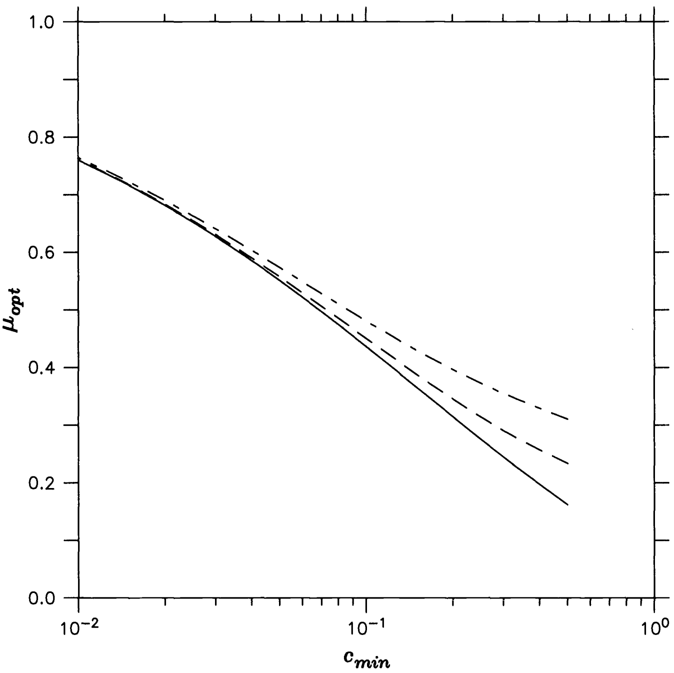

FIG. 4. *μ_{opt} as a function of c_{min}, with one (solid), two (dashes), and three (alternating dashes) relaxation sweeps ν between successive coarse-grid corrections.*

TABLE 1

Comparison of two-level analysis error-reduction factors (per relaxation sweep) using several values of over-relaxation parameter ω: ω_{ub} of Theorem 2.1, ω_{opt} of Fig. 3, and ω_{best}—the over-relaxation parameter which yielded the best two-level results. In the sixth column is the smoothing-analysis prediction of Fig. 4, and the seventh column shows the usual $\omega = 1$ performance. ν denotes the number of relaxation sweeps performed between successive coarse-grid corrections. The last two columns show the error-reduction factor per cycle obtained by V(2,1) cycles using $\omega = \omega_{ub}$ and $\omega = 1$, respectively (see text for details).

$c_{\min}$	ν	$\mu^{tl}_{\omega_{ub}}$	$\mu^{tl}_{\omega_{\mathrm{opt}}}$	$\mu^{tl}_{\omega_{\mathrm{best}}}$	μ_{opt}	μ^{tl}_{1}	$V(2,1)_{\omega_{ub}}$	$V(2,1)_1$

	2	0.272	0.277	0.262	0.277	0.444		
	3	0.315	0.361	0.302	0.345	0.444		
$\frac{1}{5}$	1	0.313	0.316	0.308	0.315	0.640	0.088	0.293
	2	0.354	0.347	0.345	0.345	0.640		
	3	0.378	0.397	0.373	0.397	0.640		
$\frac{1}{10}$	1	0.426	0.437	0.425	0.437	0.810	0.222	0.552
	2	0.445	0.450	0.442	0.451	0.810		
	3	0.487	0.481	0.480	0.481	0.810		

TABLE 2

Asymptotic error-reduction factors (E.R.F.) per V(1,1) cycle for the Poisson problem in three dimensions. In comparison, a V(2,1) cycle with $\omega = 1$ yields an error-reduction factor of 0.150 (see Table 1).

ω	E.R.F
1.	0.240
1.146 (ω_{ub})	0.128
1.114 (ω_{opt})	0.147
1.164 (ω_{best})	0.113

are compared in Table 2 for over-relaxation parameters 1, ω_{ub}, ω_{opt}, and ω_{best}. Even in this fully isotropic problem over-relaxation yields a significant improvement. ω_{ub} is slightly better than ω_{opt}, as ω_{best} is somewhat larger than predicted (as was the case for $c_{\min} = 1/3$ shown in Table 1). In comparison, a V(2,1) cycle with $\omega = 1$ (which is of course more expensive then the over-relaxed V(1,1) cycles even in the case of the simple Poisson operator) yielded an error-reduction factor 0.150 (see Table 1)—slightly worse than the 0.128 factor obtained with ω_{ub} which appears in Table 2.

Example 3. Since smoothing here is a local process, it seems natural to vary the over-relaxation parameter in space as a function of $c_{\min}$, so as to maintain locally-optimal smoothing throughout the domain. We tested this approach in this and the next examples. V(2,1) and V(2,2) cycles were implemented for the variable-coefficient two-dimensional ($n = 2$) problem

$$(1 + \epsilon \sin x)u_{xx} + (1 + \epsilon \sin y)u_{yy} = 0\,, \tag{24}$$

and three-dimensional ($n = 3$) problem

$$(1 + \epsilon \sin x)u_{xx} + (1 + \epsilon \sin y)u_{yy} + (1 + \epsilon \sin z)u_{zz} = 0\,. \tag{25}$$

The domain of solution was a square (cube) of side 2π. In the three-dimensional problem the same specifications as in Examples 1 and 2 were used. In the two-dimensional problem we solved both with periodic and Dirichlet boundary conditions. The latter were homogeneous, to avoid roundoff errors, and again 100 cycles were implemented. The finest resolution in the two-dimensional problem was 128^2 (127^2 not including boundary points in the Dirichlet problem), and six levels were employed. The error-reduction factors per cycle are shown

TABLE 3

in Tables 3 and 4 for various values of ϵ, which determine the anisotropy, with $\omega = 1$ and $\omega = \omega_{ub}$ locally. Evidently, over-relaxation improves the usability of point relaxation very significantly. Indeed, in three dimensions, even moderate anisotropy necessitates over-relaxation for obtaining a useful algorithm.

Example 4. In a commonly used discretization for planetary flow simulations on the sphere, the gridlines lie along lines of latitude and longitude, and the grid is thus anisotropic near the poles. If the meshsizes in a two-dimensional problem are chosen to be equal at the equator, then their ratio elsewhere is approximately $\cos\phi$, where ϕ is the latitude (ranging from 0 at the equator to $\pm\pi/2$ at the poles). For the two-dimensional Poisson equation, this implies an equivalent anisotropy of approximately

$$c_{\min} \approx \frac{\cos^2\phi}{1+\cos^2\phi}\,.$$

One can apply more relaxation sweeps in regions that are far from the equator, but at some stage line relaxation (along latitude lines) is used. Over-relaxation can be employed to reduce the region where line relaxation needs to be used, while also reducing the number of sweeps that need to be performed where point relaxation is used. A particular example occurs in the shallow-water equations, especially when semi-Lagrangian discretization is used. The principal part of the matrix operator is then normally composed of three Laplace operators. In [4], over-relaxation is introduced for this problem, with the result that the total work spent on line relaxation is reduced to about 1/3, while the total work spent on point relaxation remains about the same (with less sweeps per latitude-line on the average, but more lines to sweep over). Here, V(ν, ν) cycles are employed, where ν is varied according to latitude, given some desired convergence factor. Line relaxation is used (with $\nu = 1$) whenever point relaxation would require $\nu > 4$ for the desired convergence rate. The relative gain quoted is not sensitive to the required convergence factor. These tests were performed at a resolution of 128 by 65 points along lines of latitude and longitude, respectively.

5. Concluding remarks. Optimal over-relaxation parameters for red-black Gauss–Seidel in multigrid algorithms were calculated for (1), and an upper bound, which was shown to provide a good working value, was established in Theorem 2.1. Employing over-relaxation is always more cost-effective than the usual red-black Gauss–Seidel in three dimensions or higher. In two dimensions over-relaxation is also better, unless the operator is very isotropic.

The extra cost required for over-relaxing, assuming that the optimal parameters are precomputed and stored, is about one or at most two operations per gridpoint. This may not be negligible in the case of the Laplace operator in two dimensions, but is quite unimportant in almost any relevant "real" problem.

The relative gain in using over-relaxation, compared to the usual relaxation, grows rapidly as the problem becomes more anisotropic. But of course the overall efficiency of the solver then decreases even when over-relaxation is used. Hence, full robustness can only be achieved by more elaborate global techniques, which are also more expensive (sometimes *much* more expensive on parallel machines). However, when the anisotropy is known to be moderate (perhaps only in part of the domain, as in Example 4—solution on a sphere), SOR should be employed. An example of this is large-scale, stably stratified planetary flows (e.g., quasi-geostrophic equations), where $c_{\min}$ will usually be about an order of magnitude smaller than 1 at worst.

Varying the relaxation parameter in space as a function of the anisotropy was found to perform well, especially if the over-relaxation parameters are precomputed and stored. One can then also use the prediction of μ_{ub} to choose the number of sweeps performed in various regions, as was done in Example 4 [4].

Acknowledgment. The author would like to thank John Ruge for his valuable contribution, and Bruno Welfert for pointing out the similarity of the present upper-bound over-relaxation parameter to the classical value.

MULTILEVEL IMAGE RECONSTRUCTION WITH NATURAL PIXELS*

VAN EMDEN HENSON†, MARK A. LIMBER‡, STEPHEN F. MCCORMICK§, AND BRUCE T. ROBINSON¶

Abstract. The sampled Radon transform of a two-dimensional (2D) function can be represented as a continuous linear map $A : L_2(\Omega) \to \mathbf{R}^N$, where $(Au)_j = \langle u, \psi_j \rangle$ and ψ_j is the characteristic function of a strip through Ω approximating the set of line integrals in the sample. The image reconstruction problem is: given a vector $\mathbf{b} \in \mathbf{R}^N$, find an image (or density function) $u(x, y)$ such that $Au = \mathbf{b}$. In general there are infinitely many solutions; we seek the solution with minimal 2-norm, which leads to a matrix equation $B\mathbf{w} = \mathbf{b}$, where B is a square dense matrix with several convenient properties. We analyze the use of Gauss–Seidel iteration applied to the problem, observing that while the iteration formally converges, there exists a *near null space* into which the error vectors migrate, after which the iteration stalls. The null space and near null space of B are characterized in order to develop a multilevel scheme. Based on the principles of the multilevel projection method (PML), this scheme leads to somewhat improved performance. Its primary utility, however, is that it facilitates the development of a PML-based method for *spotlight tomography*, that is, local grid refinement over a portion of the image in which features of interest can be resolved at finer scale than is possible globally.

Key words. tomography, Radon transform, multigrid

AMS subject classifications. 92C55, 44A12, 65R10, 65N55

1. Introduction.

In this paper, we consider a model of transmission and emission tomography and an associated image reconstruction technique. The reconstruction technique approximates a minimum norm solution to an underdetermined linear inversion problem, based on an infinite-dimensional formulation of the tomographic inversion problem. This formulation of the problem avoids the traditional square pixel discretization of the image space and leads to a smaller, but dense, matrix problem (compared to traditional algebraic reconstruction techniques). This approach leads to what have been termed "natural pixels" in [1], and the "optimal grid" in [10].

Following the development of the natural pixel discretization, we consider solution techniques for the resulting linear system. In particular, we employ Gauss–Seidel iteration, analyze its performance, and then introduce a multilevel projection method (PML) for accelerating convergence.

2. Image reconstruction and the Radon transform.

We formulate the image reconstruction from projection problems in a general setting, but concentrate on a parallel beam geometry, for which we have implemented our ideas. The basic idea in tomography is that an object is subjected to a dose of radiation, either by passing X-rays through the object, or (if the object is a living patient) by administering a radiopharmaceutical. The amount of radiation leaving the object can be measured, compared with the original amount, and the difference is a measurement of the attenuation (transmission tomography) or activity (emission tomography) within the object. In parallel beam geometry, the data is collected in collimated bins, so that any activity detected in a particular bin can be attributed to the strip emanating perpendicularly out of the detector, with width equal to that of the bin.

To model this apparatus, let $u(x, y)$ be a function of the spatial variables x and y describing the activity in the object. Typically this is some physical quantity, such as the material density

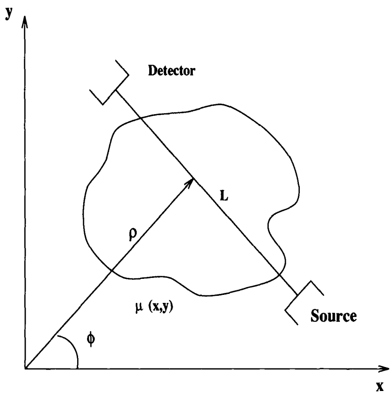

FIG. 1. *The geometry of the Radon transform.*

of the subject. The vector **f** represents the projection data. The data acquisition is modeled by

$$Au = \begin{pmatrix} \int_{\mathbf{R}^2} u(x,y)\psi_1(x,y)dxdy \\ \vdots \\ \int_{\mathbf{R}^2} u(x,y)\psi_N(x,y)dxdy \end{pmatrix} = \begin{pmatrix} f_1 \\ \vdots \\ f_N \end{pmatrix} = \mathbf{f}, \tag{1}$$

where the function ψ_k is the characteristic function of the kth strip through the image, within which passes (or emanates) the energy collected by the kth detector. For this to be well defined, we restrict our function space to be $L_2(\Omega)$, where Ω is a compact subset of $\mathbf{R}^2$, called the *image space*. Thus,

$$(Au)_j = \langle \psi_j, u \rangle$$

defines a continuous linear map $A : L_2(\Omega) \to \mathbf{R}^N$. The basic problem of computer assisted tomography is to reconstruct the image $u(x, y)$ from a collection of measured strip integrals, collected at various angles. When this problem can be solved, it is done through some approximate inversion of the Radon transform, which is defined as follows.

Let $u(x, y)$ be a function defined on the region $\Omega \in \mathbf{R}^2$. Letting L denote any line in $\mathbf{R}^2$, the set of line integrals of $u(x, y)$, along all possible lines L, is a function of two variables, and is known as the *Radon transform* of $u(x, y)$, provided the integral exists. Formally,

$$[Ru](\rho, \phi) = \int_L u(x,y)ds = \int u(x,y)\delta(x\cos\phi + y\sin\phi - \rho)dxdy,$$

where δ is the Dirac delta function. The line L is parametrized by

$$\rho = x\cos\phi + y\sin\phi, \tag{2}$$

where ρ is the signed distance from the origin and ϕ is an angle measured counter-clockwise from the positive x-axis. Thus, (2) determines the equation of a line in the xy-plane normal to the unit vector $\vec{\xi} = (\cos\phi, \sin\phi)^T$. Figure 1 shows the geometry of the Radon transform of a function $u(x, y)$ in terms of this parameterization.

Viewing the Radon transform as an operator, the image reconstruction problem can be cast as $Ru = f$, where f represents the collection of measured line integrals. Given **f**, a finite sampling of f, we model the problem $Ru = f$ with $Au = \mathbf{f}$, since each of the strip integrals $\langle \psi_j, u \rangle$ approximates a collection of line integrals, for those lines falling within the strip. Hence, the data **f** forms a sampling of the continuous Radon transform. We will refer to the set of strip integrals (1) as the *strip averaged* Radon transform.

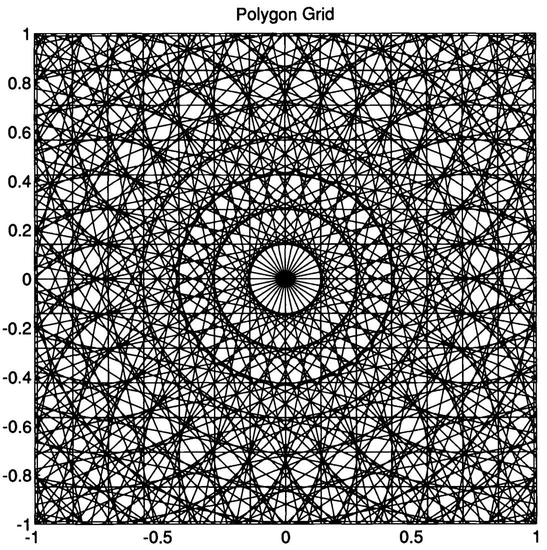

FIG. 2. *A representative grid of polygons. The optimal solution is constant on each polygon. This particular optimal grid corresponds to having* 16 *detector bins of uniform width for each of* 20 *angles, taken at regular angular intervals between* 0 *and* π.

3. Optimal grid discretization. Suppose there are M angles ϕ_j for $j = 1 : M$, such that $\phi_1 = 0 < \phi_2 < \phi_3 < \cdots < \phi_M < \pi$, and that at each angle ϕ_j there are $n(j)$ strips, or detector bins. Then $N = \sum_{j=1}^{M} n(j)$ gives the total number of data points. Suppose the image space Ω is some convex, compact region in $\mathbf{R}^2$, and assume that for the jth angle the $n(j)$ strips are parallel, nonoverlapping, and entirely cover Ω. Let $\psi_\ell(x, y)$ be the characteristic function of the ℓth strip. Then the discrete strip averaged Radon transform is the map $A : L_2(\Omega) \to \mathbf{R}^N$ defined in equation (1).

Assuming the system $Au = \mathbf{f}$ is consistent, it is underdetermined; that is, since A is a linear mapping from an infinite-dimensional space $L_2(\Omega)$ to the finite-dimensional space $\mathbf{R}^N$, the null space of A, $NS(A)$, is infinite-dimensional. If there are any solutions to $Au = \mathbf{f}$, there are infinitely many. We must select some representative solution image u from the infinite number of feasible images. The minimum norm solution to the equation $Au = \mathbf{f}$ is given by $u(x, y) = A^*\mathbf{w}$, where $\mathbf{w}$ solves the $N \times N$ system

$$AA^*\mathbf{w} = \mathbf{f}.$$

We write this system as $B\mathbf{w} = \mathbf{f}$ and concentrate on efficient methods to solve it. Note that forming $A^*\mathbf{w}$ corresponds to *backprojecting* the vector $\mathbf{w}$ over the image space.

A simple formula can be used to construct the matrix B. Note that $A^* : \mathbf{R}^N \to L_2(\Omega)$ is defined by

$$[A^*\mathbf{w}](x, y) = \sum_{i=1}^{N} w_i \psi_i(x, y). \tag{3}$$

Since the ψ_i are characteristic functions, we observe from equation (3) that the optimal image u is piecewise constant on the set of polygons defined by the intersections of the strips, at all angles. This set of polygons we term the *optimal grid*, as shown in Fig. 2.

The (i, j)th entry of B can be determined by computing the jth entry of $B\mathbf{e}_i$ where $\mathbf{e}_i$ is the ith standard basis vector in $\mathbf{R}^N$. Specifically,

$$(B\mathbf{e}_i)_j = \left(AA^*\mathbf{e}_i\right)_j = (A\psi_i(x, y))_j = \int_\Omega \psi_i(x, y)\psi_j(x, y)dxdy = \langle\psi_i, \psi_j\rangle.$$

Thus, B is an $N \times N$ matrix with entries

$$b_{ij} = \langle\psi_i, \psi_j\rangle. \tag{4}$$

We immediately have the following theorem.

THEOREM 1. *The $N \times N$ matrix B is nonnegative, symmetric, positive semidefinite with positive diagonal entries, $b_{ii} > 0$.*

Proof. This follows immediately since $\psi_k \geq 0$, $B = AA^*$, $\langle u, AA^*u\rangle = \langle A^*u, A^*u\rangle$, and $b_{ii} = \langle\psi_i, \psi_i\rangle$. □

Since we will employ iterative methods, it is important to identify those vectors that may cause difficulty in the iteration process. That is, we seek to characterize the eigenvectors of $\mathbf{R}^N$ that are associated with small nonzero eigenvalues of B. Such eigenvectors have the property that $B\mathbf{w}$ is small (in norm) compared to $\mathbf{w}$, and error vectors of this nature have residuals that are small compared to the error. We refer to them as vectors in the *near null space*, and assert that their presence in the error causes slow convergence. The near null space will be studied in §4.2. For now, we are concerned with characterizing the null space of B, which is just the null space of AA^*:

$$NS(B) = NS(AA^*) = NS(A^*). \tag{5}$$

For this characterization we need the following definition.

DEFINITION. *A vector* $\mathbf{w} \in \mathbf{R}^N$ *is said to be* constant by angle *if, upon writing*

$$\mathbf{w} = \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \\ \vdots \\ \mathbf{v}_M \end{bmatrix}, \qquad \mathbf{v}_j \in \mathbf{R}^{n(j)}, \qquad \mathbf{v}_j = \begin{bmatrix} \alpha_1^j, \\ \alpha_2^j, \\ \vdots \\ \alpha_{n(j)}^j \end{bmatrix},$$

then $\alpha_i^j = \alpha_{i+1}^j$, $i = 1, \ldots, n(j) - 1$, *for* $j = 1 : M$.

Using this definition, we may show the following.

THEOREM 2. *A vector* $\mathbf{w} \in \mathbf{R}^N$ *is in* $NS(B)$ *if and only if* $\mathbf{w}$ *is constant by angle and the elements of* $\mathbf{w}$ *sum to zero*; *that is,* $\sum_{i=1}^N w_i = 0$.

Proof. Let $\{\hat\psi_k(x, y) | k = 1 : M\}$ be the set of strips that contain the point (x, y). There is one such strip from each projection angle. Let $\{\hat w_k | k = 1 : M\}$ be the set of coefficients associated with those strips. Clearly, if $\mathbf{w}$ is constant by angle and sums to zero, it is in $NS(B)$, since

$$[A^*\mathbf{w}](x, y) = \sum_{i=1}^N w_i\psi_i(x, y) = \sum_{k=1}^M \hat w_k\hat\psi_k(x, y) = 0.$$

Conversely, suppose $\mathbf{w} \in NS(A^*)$ so that

$$\sum_{i=1}^N w_i\psi_i(x, y) = 0 \quad \forall(x, y) \in \Omega.$$

Writing $\mathbf{w}$ as in the definition of constant by angle, that is,

$$\mathbf{w} = [\mathbf{v}_1^T, \ldots, \mathbf{v}_M^T]^T, \quad \mathbf{v}_j \in \mathbf{R}^{n(j)}, \quad \mathbf{v}_j = [\alpha_1^j, \ldots, \alpha_{n(j)}^j]^T,$$

then the objective is to show that for the jth projection angle, the subvector $\mathbf{v}_j \in \mathbf{R}^{n(j)}$ is constant. Without loss of generality, we show only that $\mathbf{v}_1$ is constant.

Denote the jth strip at the first angle as Ω_j. Consider the partitioning of the image space Ω into the set of polygons determined by the intersections of all strips at all angles *except the first.* Clearly, for each j, the boundary between Ω_j and Ω_{j+1} intersects the interior of at least one of these polygons. Hence, it is possible to select two points, $(x_1, y_1) \in \Omega_j$ and $(x_2, y_2) \in \Omega_{j+1}$, such that the line segment joining (x_1, y_1) and (x_2, y_2) lies entirely in one strip emanating from each of the other angles. That is, the line segment lies entirely in each of the strips $\Omega_{k_2}, \ldots, \Omega_{k_M}$.

By construction,

$$\begin{aligned} 0 = [A^*\mathbf{w}](x_1, y_1) - [A^*\mathbf{w}](x_2, y_2) &= \left(\alpha_j^1 - \alpha_{j+1}^1\right) + \sum_{\ell=2}^{M} w_{k_\ell} \left(\psi_{k_\ell}(x_1, y_1) - \psi_{k_\ell}(x_2, y_2)\right) \\ &= \alpha_j^1 - \alpha_{j+1}^1 \end{aligned}$$

since $\psi_j(x_1, y_1)$, $\psi_{j+1}(x_2, y_2)$, $\psi_{k_\ell}(x_1, y_1)$, and $\psi_{k_\ell}(x_2, y_2)$ all equal 1. It then follows that $\alpha_j^1 = \alpha_{j+1}^1$. That is, $\mathbf{w}$ is constant by angle.

Finally, since $\mathbf{w} \in NS(A^*)$, it must be that the terms sum to zero, because

$$A^*\mathbf{w}(x, y) = \sum_{k=1}^{M} \alpha_1^k = 0. \qquad \Box$$

An immediate corollary is the following.

COROLLARY 1. *The dimension of the nullspace of B is $M - 1$, where M is the number of projection angles. A basis for $NS(B)$ is*

$$\begin{aligned} \mathbf{w}_1 &= [\vec{1}, -\vec{1}, \vec{0}, \ldots, \vec{0}], \\ \mathbf{w}_2 &= [\vec{0}, \vec{1}, -\vec{1}, \vec{0}, \ldots, \vec{0}], \\ &\vdots \\ \mathbf{w}_{M-1} &= [\vec{0}, \ldots, \vec{0}, \vec{1}, -\vec{1}], \end{aligned}$$

where each constant vector $\vec{1} \in \mathbf{R}^{n(j)}$.

4. Gauss–Seidel relaxation on $B\,\mathbf{w} = \mathbf{f}$. Many iterative methods are available for solving equations in B, and, indeed, many have been applied to the general image reconstruction problem [1], [9], [18], [19], [20], [24]. Here we consider Gauss–Seidel iteration, one sweep of which may be stated as: *For $j = 1 : N$, modify the jth component of the vector* $\mathbf{w}$ *such that the jth component of the resulting residual vanishes.* The jth correction is given by

$$\mathbf{w} \leftarrow \mathbf{w} + \frac{1}{b_{jj}} \langle \mathbf{e}_j, \mathbf{f} - B\mathbf{w} \rangle \mathbf{e}_j.$$

A more common formulation arises from splitting B in terms of its diagonal, upper triangular, and lower triangular parts, giving $B = D - L - U$. Then the $(n + 1)$st sweep may be written as

$$\mathbf{w}^{(n+1)} = P_G \mathbf{w}^{(n)} + \mathbf{g},$$

where $\mathbf{g} = (D - L)^{-1}\mathbf{f}$ is a fixed vector and $P_G = (D - L)^{-1}U$ is known as the Gauss–Seidel *iteration matrix.* Letting $\mathbf{w}^*$ be any vector that solves $B\mathbf{w} = \mathbf{f}$, we may write an *error vector* defined as $\mathbf{z}^{(n)} = \mathbf{w}^{(n)} - \mathbf{w}^*$. It is easy to see that $\mathbf{z}^{(n+1)} = P_G\mathbf{z}^{(n)}$ and, hence, $\mathbf{z}^{(n+1)} = (P_G)^n\mathbf{z}^{(0)}$. Convergence of the iteration to $\mathbf{w}^*$ is guaranteed if the spectral radius $\rho(P_G)$ is less than 1.

The matrix B, however, is rank deficient, so that if any solutions exist, then infinitely many solutions exist, and the iteration does not converge under all initial guesses. However, measured in the *energy seminorm*

$$|||\mathbf{x}||| = \langle B\mathbf{x}, \mathbf{x}\rangle^{1/2},$$

Gauss–Seidel cannot diverge.

THEOREM 3. *The energy seminorm of the error does not increase under Gauss–Seidel iteration on* $B\mathbf{w} = \mathbf{f}$. *That is,* $|||\mathbf{z}^{(n+1)}||| \leq |||\mathbf{z}^{(n)}|||$.

Proof. A direct proof follows from the easily derived relation

$$|||\mathbf{z}^{(n+1)}||| = |||\mathbf{z}^{(n)}||| - \frac{\langle \mathbf{e}_j, B\mathbf{z}^{(n)}\rangle^2}{b_{jj}}. \qquad \square \tag{6}$$

Gauss–Seidel applied to $B\mathbf{w} = \mathbf{f}$ cannot diverge in the energy sense, but to understand when it actually converges we first examine the related Kaczmarz iteration, applied to $Au = \mathbf{f}$.

Proof of the following may be found in [13], [18], and [25].

THEOREM 4. *Let* $L : H_1 \to H_2$ *be a continuous linear operator, where* H_1 *is a Hilbert space and* H_2 *is an* N*-dimensional Hilbert space with orthonormal basis* $\{v_1, v_2, \ldots, v_N\}$. *Let* $g \in H_2$ *be given, and suppose that* $Lu = g$ *has a solution. Suppose* $u^{(0)} \in$ *range*(L^*), *and define the sequence* $u^{(k)}$ *generated by the Kaczmarz iteration by*

```
Set $u \leftarrow u^{(k)}$.
For $j = 1 : N$,
    Determine $s$ such that $\langle v_j, L(u + sL^*v_j) - g\rangle = 0$.
    Set $u \leftarrow u + sL^*v_j$.
Set $u^{(k+1)} \leftarrow u$.
```

Then $u^{(k)}$ *converges, as* $k \to \infty$, *to the minimum norm solution of* $Lu = g$.

Kaczmarz iteration applied to $Au = \mathbf{f}$ uses $H_1 = L_2(\Omega)$, $H_2 = \mathbf{R}^N$ with orthonormal basis $\{\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_N\}$, and

$$s = \frac{\langle \mathbf{e}_j, \mathbf{f} - Au\rangle}{\langle \mathbf{e}_j, AA^*\mathbf{e}_j\rangle}. \tag{7}$$

Proof of the following may be found in [20] or [25].

THEOREM 5. *Let* $\mathbf{w}^{(0)}$ *be any vector in* $\mathbf{R}^N$, *and let* $\mathbf{w}^{(k,j)}$, *for* $j = 1 : N$ *and* $k = 1, 2, \ldots,$ *be the vector resulting from the* j*th step of the* k*th sweep of Gauss–Seidel iteration on* $B\mathbf{w} = \mathbf{f}$, *using* $\mathbf{w}^{(0)}$ *as the initial guess. Then the image* $A^*\mathbf{w}^{(k,j)}$ *is just the image* $u^{(k,j)}$ *resulting from the* j*th step of the* k*th sweep of the Kaczmarz iteration applied to* $Au = \mathbf{f}$ *with initial guess* $u^{(0)} = A^*\mathbf{w}^{(0)}$.

An immediate consequence of this theorem is the following.

COROLLARY 2. *Let* $\mathbf{w}^{(0)}$ *be any vector in* $\mathbf{R}^N$, *and let* $\{\mathbf{w}^{(k)}\}$ *be the sequence of vectors produced by Gauss–Seidel iteration on* $B\mathbf{w} = \mathbf{f}$. *If* $Au = \mathbf{f}$ *has a solution, then the sequence* $A^*\mathbf{w}^{(k)}$ *converges, as* $k \to \infty$, *to the minimum norm solution of* $Au = \mathbf{f}$.

4.1. Numerical performance. We use the positron emission problem, as in PET and SPECT, for our model problem in developing the iterative methods presented here. Such

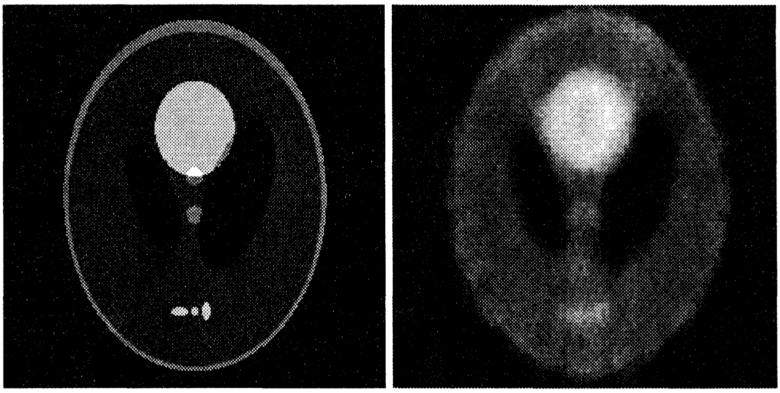

FIG. 3. *An "exact" image is shown on the left, and a reconstructed image is shown on the right. The reconstruction geometry uses data collected in* 64 *bins of uniform width along each of* 20 *angles. The* 20 *angles are equispaced at angular intervals of* $\Delta\phi = \pi/20$ *in the interval* $[0, \pi)$. *Twenty-five sweeps of Gauss–Seidel iteration were used to reconstruct the image.*

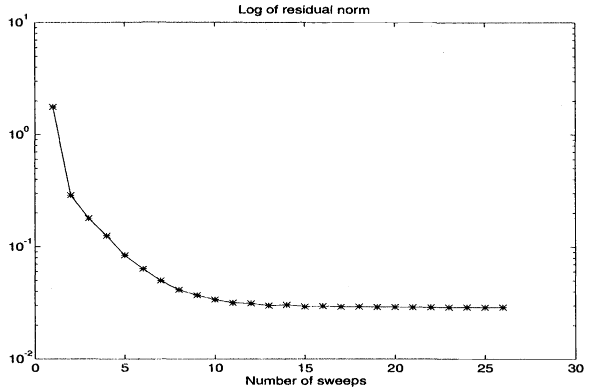

FIG. 4. *Performance of the Gauss–Seidel iteration on* $B\mathbf{w} = \mathbf{f}$ *is displayed by plotting the logarithm of* $\|\mathbf{f} - B\mathbf{w}^{(n)}\|_2$ *as a function of n, the number of iteration sweeps. Twenty-five sweeps of Gauss–Seidel iteration were used to reconstruct the image.*

applications are characterized by relatively small values of N and M, so that we are dealing with fairly small computational problems. Typically, the number of bins per angle, N, is less than 100, as is the number of angles, M. Accordingly, our numerical experiments use $N = 16, 32, 64$, and $M = 10, 20, 64$. Here we report on one such test, which is very representative of the performance characteristics we have observed.

Figure 3 displays an "exact" image, the Shepp–Logan phantom [23], from which a set of values for the right-hand side vector $\mathbf{f}$ is constructed. In generating the vector $\mathbf{f}$ we used $N = 64$ and $M = 20$. Twenty-five sweeps of Gauss–Seidel on $B\mathbf{w} = \mathbf{f}$ produce the reconstructed image shown in 3.

Qualitatively, one can argue that the procedure produces a good reconstruction, in that most of the identifiable features of the original image are present. Since, in general, the exact image is unknown, we use the residual $\mathbf{f} - B\mathbf{w}$ as a numerical indication of how well the method solves the problem. Figure 4 displays the logarithm of $\|\mathbf{f} - B\mathbf{w}^{(n)}\|_2$ as a function of n, the number of iteration sweeps. Noteworthy is the fact that the first few sweeps result in significant reduction in the norm of the residual, but that the improvement per

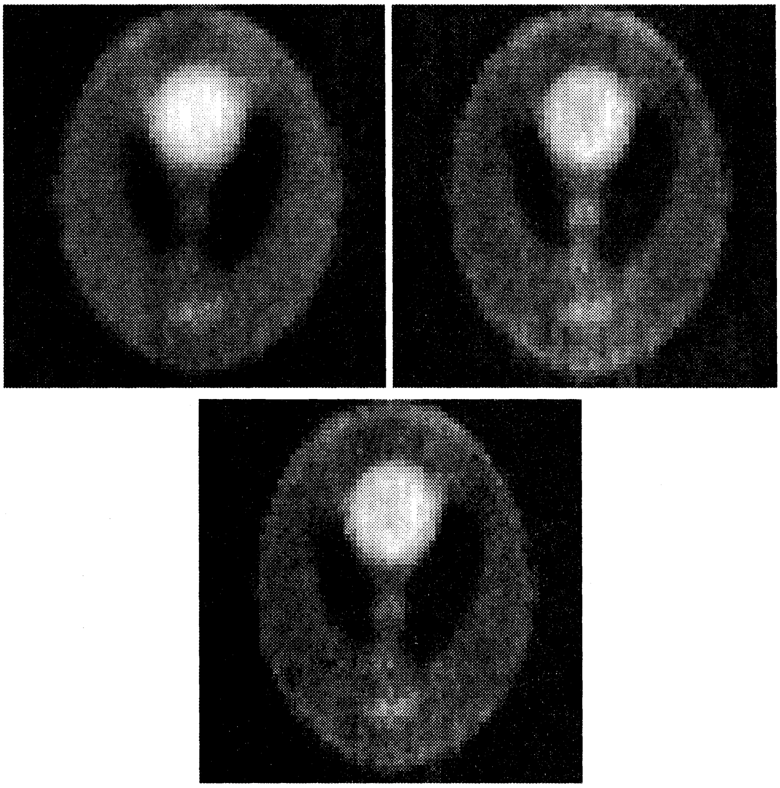

FIG. 5. *Reconstructions of the image from Fig.* 3 *using* 1, 2, *and* 4 *Gauss–Seidel sweeps are displayed clockwise from the upper left. It is difficult to distinguish these reconstructions, and even more difficult to determine which is "best."*

sweep declines until (after approximately 10 sweeps) the residual norm remains essentially unchanged.

This behavior, of rapid improvement in the residual norm over the course of several sweeps followed by stagnation of the residual norm, is characteristic of many iteration methods. In the field of partial differential equations, this numerical "stalling" often occurs because relaxation eliminates the oscillatory components of the error rapidly, but is ineffectual on the remaining smooth components of the error. The stalling phenomenon is often eliminated through the use of multigrid algorithms. Shortly we will develop a multigrid method for the problem $B\mathbf{w} = \mathbf{f}$, in an attempt to address the numerical stalling. Before doing so, however, we wish to make two observations.

First, the stalling phenomenon is often unrelated to the quality of the reconstructed image when the quality is measured by the subjective standard of "looking good." While this measure is hard to quantify, and therefore not so useful to the mathematician or engineer, it is the ultimate measure applied by the end user, for example, the radiologist tasked with treating a patient. It is important to note that the reconstructed images frequently *look* good after only one or two iteration sweeps, while the numerical stalling is not apparent until much later. Figure 5 shows reconstuctions of the "exact" image of Fig. 3 as they appear after 1, 2, and 4 sweeps. While subtle differences are apparent in the reconstructions, all are "good." Indeed, it is difficult to differentiate the reconstructions after 4 sweeps and 25 sweeps (Fig. 3). For this reason, the residual norm may not be the appropriate indicator of reconstruction quality.

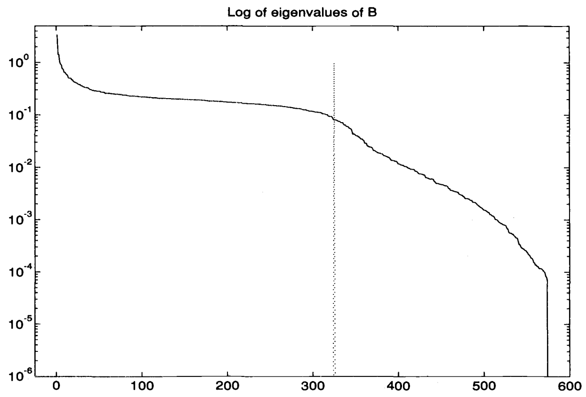

FIG. 6. *The logarithms of the eigenvalues of a typical matrix B are shown. $M = 20$ angles are used, so that the null space of B has dimension* 15. *The eigenvalues between index* 1 *and index* 325 *are the "good" modes, while those between* 326 *and* 573 *are the* near null space eigenvalues.

4.2. Mode analysis. The second observation we make is that it is possible to examine the performance of the Gauss–Seidel iteration on individual components of the error. For numerical partial differential equations this is often done by way of Fourier analysis [4]. However, Fourier analysis is not particularly useful in this setting, because the Fourier modes are not eigenfunctions of the continuum operator, nor are discrete Fourier modes eigenvectors of either the matrix B or the iteration matrix P_G.

The approach we take is somewhat empirical in nature: we examine the eigenvalues and corresponding eigenvectors of the matrix B. Since B is singular with rank $N - M + 1$, we know that zero is an eigenvalue of multiplicity $M - 1$. We are not concerned with eigenvectors corresponding to the zero eigenvalues, as they have no impact on the norm of the residual or on the reconstruction itself (their backprojections vanish).

Slow convergence of the iteration implies that the correction given by the iteration is insufficient. Since the size of the correction to the jth unknown is determined by the jth entry in the residual, then slow convergence implies that the residual is "small" compared to the error. Indeed, this has been shown to be the case for many familiar iteration schemes [3]. Since B applied to the error gives the residual, troublesome components are thus errors consisting essentially of the eigenvectors associated with the small nonzero eigenvalues of B, the near null space components.

Figure 6 displays a plot of the eigenvalues of a representative B matrix, which is typical of the spectra of all matrices we have examined. The geometry for this case has $M = 20$ angles and $N = \sum_{j=1}^{20} n(j) = 592$ total detectors. The set of eigenvalues is divided into three groups: the zero eigenvalues, the large nonzero eigenvalues, and the group of small eigenvalues λ_k whose amplitudes decay rapidly with increasing index k. The last 19 eigenvalues, λ_{574} through λ_{592}, are zero, and the associated eigenvectors form $NS(B)$. The vertical dashed line in the figure marks the division between the "good" eigenvalues (λ_1 through λ_{325}) and the eigenvalues with rapidly decaying magnitude (λ_{326} through λ_{573}), whose associated eigenvectors form the near null space. These near null space eigenvectors are the "slow" modes that stall performance.

We show this empirically in the following way. Representative modes are selected from the "good" and near null space segments of the spectrum. Each such mode is used as the right-hand side of $B\mathbf{w} = \mathbf{f}$. Gauss–Seidel relaxation is then applied, with an initial guess of 0, to solve the equation. Two important observations are obtained in this way. First, by computing the norm of the residual at the end of each sweep, we may determine the convergence factor for

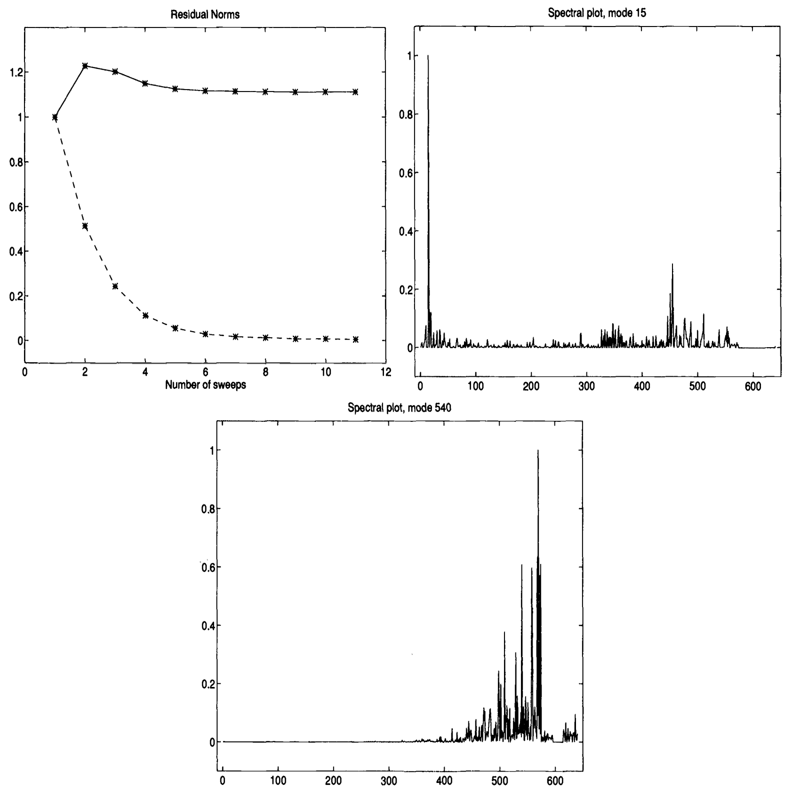

FIG. 7. *The residual norms are shown* (*top left*) *for Gauss–Seidel applied to* $B\mathbf{w} = \mathbf{f}$ *using eigenvectors as the right-hand side. Observe that for mode* 15 (*dashed line*) *the iteration converges well, while for mode* 540 *the iteration stalls immediately. The spectral densities of the vectors resulting from one relaxation sweep is shown for mode* 15 (*top right*) *and mode* 540 (*bottom*).

each mode. Second, after one sweep of Gauss–Seidel, we compute the projection of the current approximation in the directions of all the eigenvectors of B, and plot the resulting magnitudes against the eigenvalue index. This results in a "power spectral density" of the latest iterate. Since the initial error in such an experiment is in the direction of a single eigenvector (the right-hand side), such a spectral density plot tells us to what extent the iteration mixes modes, and if the iteration excites some of the modes, to which part of the spectrum they belong.

Figure 7 shows a typical set of results of these experiments. On the top left are residual norms, as a function of iteration sweeps, for two eigenvectors. The dashed line shows the residual norms for the eigenvector corresponding to λ_{15}, a typical "good" mode, while the solid line gives the residual norms for the eigenvector corresponding to λ_{540}, a typical near null space mode. In the top right is shown the power spectral density plot after one sweep with the 15-mode as the right-hand side, while on the bottom is the corresponding spectral density plot for the 540-mode.

The results shown in Figure 7 support our assertion regarding the modes. That is, the iteration attenuates "good" error modes rapidly, while the iteration stalls on near null space error modes. In addition, we see that there is mode mixing in the spectral density plots for both cases, but that it is much more pronounced in the case of mode 540. In both cases, though, the excitation of extraneous modes occurs predominantly in the near null space band.

Finally, the images resulting from backprojecting modes 15 and 540 are shown in Fig. 8, and again they are typical cases. The backprojected "good" modes generally appear as smooth,

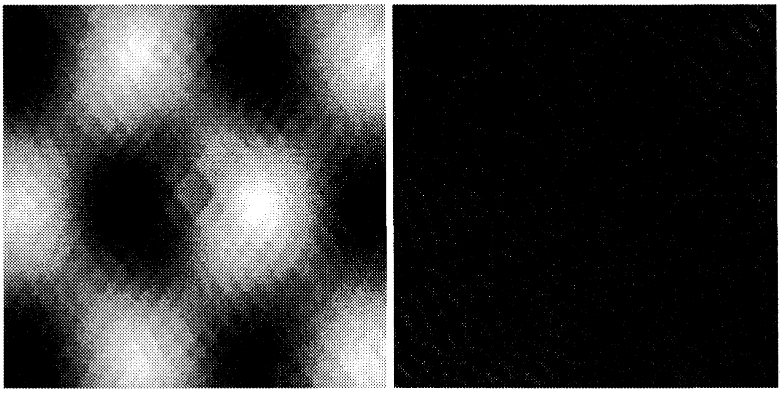

FIG. 8. *The images corresponding to backprojecting mode* 15 (*left*) *and mode* 540 (*right*) *are shown. The "good" mode is a gently undulating surface, while the near null space mode is nearly black.*

highly geometric structures in image space, often as gently undulating surfaces. The backprojected near null space modes, as the name implies, are almost invisible. They often show distinct geometric characteristics, such as narrow subparallel striping, or isolated spikes in nearly flat images.

At this stage we have a good idea what the Gauss–Seidel method achieves. Further, we have a fairly complete picture of where and why it stalls. We next develop multilevel methods for solving $B\mathbf{w} = \mathbf{f}$. We do this for three reasons. First, we believe that if the nature of the near null space modes can be accurately determined, it may be possible to design a "coarse grid correction" to treat the bad modes of the error. That is, we may be able to find a grid on which the bad modes can be annihilated efficiently. Hence, we may hope to achieve multigrid acceleration on this problem. Since the bad modes are not characterized by physical smoothness, like they are in model multigrid problems, standard coarsening is not likely to be very effective. As with other applications that do not possess standard smoothness properties, we must be careful to use what we know about these bad components to devise a coarsening process that closely matches them. Our first attempt is based on the presumption that, at certain scales (e.g., when the number of angles is small compared to the resolution within projections), they must be smooth within projections. We base our multigrid scheme on this idea. A second and equally important reason for using multigrid is our anticipation of the spotlight tomography problem, introduced in the final section of this paper. Finally, the correct isolation of these modes that occurs naturally and efficiently in multilevel processing may pave the way for treating them by an individualized regularization process that is better tailored to the computational objectives.

5. Multilevel image reconstruction.

5.1. Multilevel projection methods (PML). Designing a multigrid method for a new problem is a difficult task, especially when the application is far removed from the classical multigrid setting of elliptic PDEs. Multigrid has been extended to a wide variety of such problems, with varying degrees of success [6], [17], [22]; multigrid design in such instances is generally a lengthy and difficult process.

The multilevel projection methodology (PML) was developed to provide a simpler, systematic approach to multilevel algorithm design [15]. A basic tenet of PML design is that only the appropriate subspaces in which the problem is to be set need to be determined. The problem is discretized by orthogonal projections, and the projection operators in turn lead to the correct choices for intergrid transfer operators, relaxation techniques, and coarsening schemes.

To briefly describe the fundamentals of PML, let H_1 and H_2 be Hilbert spaces and $L : H_1 \to H_2$ be a linear operator. The continuum problem is to find $u \in H_1$ such that $Lu - f = 0$. *Discretization by projections* is accomplished as follows.

Let S^h be a finite-dimensional subspace of H_1, and let $P^{S^h} : H_1 \to S^h$ be an orthogonal projection of H_1 onto S^h, where the superscript h refers to a discretization parameter. We also require a finite-dimensional subspace $T^h \subset H_2$, and an orthogonal projection $P^{T^h} : H_2 \to T^h$, as well as mappings $P_{S^h} : S^h \to H_1$ and $P_{T^h} : T^h \to H_2$.

The projection operators are used to generate a discrete operator $L^h : S^h \to T^h$ by projecting the action of the continuum operator L onto the subspaces, that is, the discretized problem becomes $P^{T^h} L(P^{S^h} u) = 0$, for $u \in H_1$. This allows us to define the discrete operator for the problem by

$$L^h u^h - f^h = 0, \quad \text{for } u^h \in S^h, \qquad \text{where} \qquad L^h \equiv P^{T^h} L P^{S^h} \text{ and } f^h = P^{T^h} f.$$

We pause here to show that the strip pixel discretization developed earlier is in fact a discretization by projection.

THEOREM 6. *For each $j = 1 : M$, let Ω be exactly partitioned into $n(j)$ parallel nonoverlapping strips and let $N = \sum_{j=1}^{M} n(j)$. Number the strips from 1:N and let $\psi_j(x, y)$ be the characteristic function of the jth strip. Let S^h be the subspace of the Hilbert space $H_1 = L_2(\Omega)$ spanned by the set*

$$\{\psi_j\}_{j=1}^{N}.$$

Then the matrix equation

$$B\mathbf{w} = \mathbf{f}$$

is a discretization by projections of the problem $Au = \mathbf{f}$, where A is the strip-averaged Radon transform (1) *and B is the $N \times N$ matrix with entries $b_{jk} = \langle \psi_j, \psi_k \rangle$.*

Proof. We define the various subspaces of the discretization as follows. H_1 and S^h are defined in the statement of the theorem. Note that (3) implies that $S^h = \text{range}\{A^*\}$. We take $H_2 = \mathbf{R}^N$ and define the subspace T^h to be H_2. Since $H_2 = T^h = \mathbf{R}^N$, we may take $P^{T^h} = I_N$, the $N \times N$ identity matrix. The discrete equation will then be $AP^{S^h} u = \mathbf{f}$, where $P^{S^h} u$ is the orthogonal projection of $u(x, y)$ onto S^h, so

$$P^{S^h} u = \sum_{k=1}^{N} w_k \psi_k(x, y) = A^{h*}\mathbf{w}$$

for some $\mathbf{w} \in \mathbf{R}^N$. Since P^{S^h} is an orthogonal projection, we must have $(u - P^{S^h} u) \perp \psi_j$ for every $\psi_j \in S^h$. Hence, for $j = 1 : N$,

$$\begin{aligned} 0 &= \left\langle u - P^{S^h} u, \psi_j \right\rangle \\ &= \left\langle u - \sum_{k=1}^{N} w_k \psi_k, \psi_j \right\rangle \\ &= \left\langle u, \psi_j \right\rangle - \sum_{k=1}^{N} w_k \left\langle \psi_k, \psi_j \right\rangle. \end{aligned}$$

Thus, if $P^{S^h} u = A^{h*}\mathbf{w}$ is an orthogonal projection of $u(x, y)$ into S^h, then the vector $\mathbf{w}$ must satisfy

$$[\langle u, \psi_1 \rangle \ \langle u, \psi_2 \rangle, \dots, \langle u, \psi_N \rangle]^T = B\mathbf{w}. \tag{8}$$

But the left-hand side of (8) is just Au, so $\mathbf{w}$ must solve $Au = B\mathbf{w}$, and the projection-discretized form of $Au = \mathbf{f}$ is just $B\mathbf{w} = \mathbf{f}$. □

Henceforth, to keep track of the level we are examining, we use the notation $B^h\mathbf{w}^h = \mathbf{f}^h$, where B^h is the matrix defined by (4). We also adopt superscripts for use with the characteristic functions of the strips, e.g., ψ^h_k.

An important observation to be made here is that it is not necessary to know the projection operators explicitly if the *condition* of orthogonal projection adequately defines the discrete operator L^h.

Now we can examine how the PML method makes use of discretization by projections to build a two-level solver. Let $P^{S^{2h}}$ and $P^{T^{2h}}$ be projection operators mapping the continuum spaces H_1 and H_2 into "coarse grid" subspaces $S^{2h} \subset S^h \subset H_1$ and $T^{2h} \subset T^h \subset H_2$. The coarse grid operator is given by $L^{2h} = P^{T^{2h}} L P^{S^{2h}}$.

The two main components of any multigrid problem are relaxation and coarse grid correction. The PML approach defines relaxation by decomposing the spaces S^h and T^h into sums (which need not be direct sums) of m subspaces

$$S^h = \sum_{\ell=1}^{m} S^h_\ell \qquad \text{and} \qquad T^h = \sum_{\ell=1}^{m} T^h_\ell .$$

Any element of S^h can be written as a linear combination (not necessarily unique!) of the elements of S^h_ℓ:

$$u^h = \sum_{\ell=1}^{m} \alpha_l u^h_{(\ell)}, \quad \text{where } u^h_{(\ell)} \in S^h_\ell .$$

The ℓth relaxation step is defined by adding to the current approximation u^h an element of the subspace S^h_ℓ such that the projection of the residual into T^h_ℓ vanishes. A relaxation sweep is made by performing the relaxation step for all m subspaces. Hence, *relaxation by projections* is defined by

```
Relaxation:    $u^h \leftarrow G^h(u^h)$
    For $\ell = 1, 2, \ldots, m$
        1. Determine $u^h_{(\ell)} \in S^h_\ell$ such that $P^{T^h_\ell} L^h(u^h + u^h_{(\ell)}) - f^h = 0$.
        2. Set $u^h \leftarrow u^h + u^h_{(\ell)}$.
```

In standard multigrid, coarse grid correction is performed by restricting the residual equation to the coarse grid, solving for the error, interpolating the error to the fine grid, and adding it to the fine grid approximation. This basic process is also what PML does, though in an abstract way that is guided by the discretization. Given the coarse level subspaces $S^{2h} \subset S^h \subset H_1$ and $T^{2h} \subset T^h \subset H_2$, together with the associated projection operators, the aim is to determine an element of the coarse space S^{2h} that, when added to the current approximation u^h, satisfies the projection of the residual equation onto T^{2h}. Thus, *coarse grid correction by projections* is written as

```
Coarse grid correction: $u^h \leftarrow C^h(u^h)$
    1. Determine $u^{2h} \in S^{2h}$ such that

        $P^{T^{2h}} \left( L(P^{S^h} u^h + P^{S^{2h}} u^{2h}) - f^h \right) = 0.$

    2. Set $u^h \leftarrow u^h + u^{2h}$.
```

Relaxation and coarse grid correction together form a two-level PML method that is given by

```
Two-level PML method:    $u^h \leftarrow PML^h(u^h)$
    • $u^h \leftarrow G^h(u^h)$.
    • $u^h \leftarrow C^h(u^h)$.
```

The two-level PML algorithm can be converted into a multilevel scheme in just the same way that standard multigrid schemes are developed from two-grid schemes: the exact solver in the coarse grid correction is replaced by a recursive call $u^{2h} \leftarrow PML^{2h}(u^{2h})$, leading to a PML V-cycle, for example.

6. PML image reconstruction.

6.1. Discretization and intergrid transfers. Applying PML to equations in A is somewhat subtle [15], primarily because of the need to treat both projection (Radon transform) and image spaces, but with the optimal pixel discretization, applying PML to equations in $B = AA^*$ may be more direct. We have already shown that $B^h \mathbf{w}^h = \mathbf{f}^h$ is a discretization by projections of the problem $Au = \mathbf{f}$ onto S^h and T^h. It is easy to define coarse subspaces S^{2h} and T^{2h} in a manner that leads to a useful multilevel algorithm.

Let S^h be the span of the N strip pixels ψ_j^h, where the h is some parameter that indicates the level of the discretization (e.g., h may be the width of the widest strip pixel). Suppose for simplicity that there is an even number of strip pixels for each of the M views, and that we number the strips from ψ_1^h to ψ_N^h in a way so that two adjacent strips on any view are always numbered consecutively. Then a useful subspace S^{2h} can be constructed according to

$$(9) \qquad S^{2h} = \operatorname{span}\left\{\psi_k^{2h}\right\}_{k=1}^{N/2} \qquad \text{where} \qquad \psi_k^{2h} = \psi_{2k-1}^h + \psi_{2k}^h .$$

Thus, each strip pixel in the coarse subspace is the union of two adjacent fine space strip pixels. This may be viewed in physical terms as widening the aperture of the detectors, or bins.

With these coarse space strip pixels, we find that $A^{2h^*}\mathbf{w}^{2h} = \sum_{j=1}^{N/2} w_j^{2h} \psi_j^{2h}$, from which we easily obtain $A^{2h} : S^{2h} \to \mathbf{R}^{N/2}$ by $\left(A^{2h}u\right)_i = \langle \psi_i^{2h}, u \rangle$. This in turn leads us to the projection discretized coarse level problem $B^{2h}\mathbf{w}^{2h} = \mathbf{f}^{2h}$, where $B^{2h} = A^{2h}A^{2h^*}$ is an $N/2 \times N/2$ matrix with entries $b_{ij}^{2h} = \langle \psi_i^{2h}, \psi_j^{2h} \rangle$.

The multilevel scheme requires interlevel transfer operators to map grid functions between the coarse and fine levels, and a basic tenet of PML is that these operators are defined implicitly. That is, $P_{S^h}^{S^{2h}} : S^h \to S^{2h}$ and $P_{S^{2h}}^{S^h} : S^{2h} \to S^h$ are defined by

$$P_{S^{2h}} = P_{S^h} P_{S^{2h}}^{S^h}, \qquad \text{and} \qquad P^{S^{2h}} = P_{S^h}^{S^{2h}} P^{S^h}.$$

Analogous transfers can be defined for the subspaces $T^{2h} \subset T^h \subset H_2$.

To determine the intergrid transfer operators $P_{S^h}^{S^{2h}}$ and $P_{S^{2h}}^{S^h}$, we begin with a simple observation based on the definition of the coarse space strips ψ_k^{2h}.

LEMMA 1. *The operators $A^h : S^h \to T^h$ and $A^{2h} : S^{2h} \to T^{2h}$ are related by*

$$A^{2h} = P_{S^h}^{S^{2h}} A^h$$

where $P_{S^h}^{S^{2h}}$ is an $N/2 \times N$ matrix given by

$$P_{S^h}^{S^{2h}} = \begin{pmatrix} 1 & 1 & & & & & \\ & & 1 & 1 & & & \\ & & & & \ddots & \ddots & \\ & & & & & & 1 & 1 \end{pmatrix}.$$

Furthermore, the adjoint operators $A^{h^*} : T^h \to S^h$ and $A^{2h^*} : T^{2h} \to S^{2h}$ are related by

$$A^{2h^*} = A^{h^*} \left(P_{S^h}^{S^{2h}}\right)^T .$$

Proof. Let the coarse grid strip pixel ψ_k^{2h} be the union of adjacent fine grid strip pixels given by $\psi_k^{2h} = \psi_{2k-1}^h + \psi_{2k}^h$, for $k = 1 : N/2$. Then

$$\langle \psi_k^{2h}, u\rangle = \langle \psi_{2k-1}^h + \psi_{2k}^h, u\rangle = \langle \psi_{2k-1}^h, u\rangle + \langle \psi_{2k}^h, u\rangle = (1 \quad 1)\begin{pmatrix} \langle \psi_{2k-1}^h, u\rangle \\ \langle \psi_{2k}^h, u\rangle \end{pmatrix}.$$

The first assertion of the lemma follows by partitioning the vector $A^h u$ into blocks consisting of pairs of adjacent entries and forming the matrix $P_{S^h}^{S^{2h}}$ by placing, for $k = 1 : N/2$, the block $(1 \quad 1)$ in the $(2k-1)$st and $(2k)$th positions of the kth row of an $N/2 \times N$ zero matrix. Matrix vector multiplication then yields $A^h u$.

The second assertion is established by

$$\begin{aligned} A^{2h*}\mathbf{w}^{2h} &= \begin{pmatrix} \psi_1^{2h} & \psi_2^{2h} & \cdots & \psi_{N/2}^{2h} \end{pmatrix} \mathbf{w}^{2h} \\ &= \begin{pmatrix} \psi_1^h + \psi_2^h & \psi_3^h + \psi_4^h & \cdots & \psi_{N/2-1}^h + \psi_{N/2}^h \end{pmatrix} \mathbf{w}^{2h} \\ &= \left[A^{h*} \left(P_{S^h}^{S^{2h}} \right)^T \right] \mathbf{w}^{2h}. \qquad \square \end{aligned}$$

The second part of the lemma verifies that the operator $P_{S^h}^{S^{2h}}$ gives a consistent definition to the adjoint of the coarse space operator A^{2h}, showing that $A^{2h*} = (P_{S^h}^{S^{2h}} A^h)^* = A^{h*}(P_{S^h}^{S^{2h}})^T$. Thus we may define $P_{S^{2h}}^{S^h} = (P_{S^h}^{S^{2h}})^T$. Combining this with the observation that $B^{2h} = A^{2h}A^{2h*} = P_{S^h}^{S^{2h}} A^h A^{h*} P_{S^{2h}}^{S^h} = P_{S^h}^{S^{2h}} B^h P_{S^{2h}}^{S^h}$, we find that the standard variational conditions of multigrid are satisfied by this discretization [5].

6.2. Relaxation. Following the principles of PML, we select sets of m subspaces S_ℓ^h and T_ℓ^h whose unions equal S^h and T^h, respectively. The most obvious choice is to select $m = N$ and $S_\ell^h = \operatorname{span}\{\psi_\ell^h\}$, that is, each subspace is the span of an individual strip pixel.

LEMMA 2. *Let $S_\ell^h = \operatorname{span}\{\psi_\ell^h\}$ and $T_\ell^h = \operatorname{span}\{\mathbf{e}_\ell^h\}$ for $\ell = 1 : N$, where $\mathbf{e}_\ell^h$ is the ℓ^{th} standard basis vector in T^h. Then the PML relaxation on $A^h u^h = \mathbf{f}^h$ is implemented by performing point Gauss–Seidel iteration on the matrix equation $B^h\mathbf{w}^h = \mathbf{f}^h$.*

Proof. The ℓth step of PML relaxation consists of finding that value of α satisfying

$$P_\ell^{T^h}\left(AP^{S^h}(u^h + \alpha\psi_\ell^h) - \mathbf{f}^h\right) = 0,$$

where u^h is the current approximation to the solution, and then modifying the approximation by $u^h \leftarrow u^h + \alpha\psi_\ell^h$. Now $\psi_\ell^h = A^{h*}\mathbf{e}_\ell^h$, and since $P^{S^h}u^h \in S^h$, then we know that $P^{S^h}u^h = A^{h*}\mathbf{w}^h$ for some $\mathbf{w}^h \in T^h$. Hence we seek α such that

$$\begin{aligned} 0 &= P_\ell^{T^h}\left(A^h(A^{h*}\mathbf{w}^h + \alpha A^{h*}\mathbf{e}_\ell^h) - \mathbf{f}^h\right) \\ &= P_\ell^{T^h} B^h(\mathbf{w}^h + \alpha\mathbf{e}_\ell^h) - f_\ell^h. \end{aligned}$$

Noting that $P_\ell^{T^h}$ is accomplished by forming the inner product with $\mathbf{e}_\ell^h$, then α must satisfy

$$(\mathbf{e}_l^h)^T(B^h\mathbf{w}^h + \alpha B^h\mathbf{e}_\ell^h) = f_\ell,$$

whose solution is given by

$$\alpha = \frac{1}{b_{\ell\ell}}(f_\ell^h - \mathbf{b}_\ell^T\mathbf{w}^h),$$

where $\mathbf{b}_\ell^T$ is the ℓth row of B^h. Hence, the ℓth step of the PML relaxation is

$$\mathbf{w}_\ell^h \leftarrow \mathbf{w}_\ell^h + \frac{1}{b_{\ell\ell}}(f_\ell^h - \mathbf{b}_\ell^T \mathbf{w}^h),$$

which is precisely the correction of the ℓth step of Gauss–Seidel applied to $B^h \mathbf{w}^h = \mathbf{f}^h$. □

6.3. Coarse grid correction. Like relaxation, coarse grid correction in the PML approach is defined by the selection of the subspaces and the implicit intergrid transfer operators. For the problem $Au = \mathbf{f}$, it is performed by finding the element $u^{2h} \in S^{2h}$ that satisfies

$$P^{T^{2h}}\left(A(P^{S^h}u^h + P^{S^{2h}}u^{2h}) - \mathbf{f}^h\right) = 0, \tag{10}$$

where u^h is the current approximation in the fine space S^h. The correction is then given by $u^h \leftarrow u^h + u^{2h}$. Note that

$$P^{T^{2h}} A P^{S^h} u^h = P_{S^h}^{S^{2h}} P^{T^h} A P^{S^h} u^h = P_{S^h}^{S^{2h}} B^h \mathbf{w}^h$$

where $A^{h*}\mathbf{w}^h$ represents $P^{S^h}u^h$. We also know that since $u^{2h} \in S^{2h}$, there is a vector $\mathbf{y}^{2h} \in T^{2h}$ such that $u^{2h} = A^{2h*}\mathbf{y}^{2h}$. Hence, $P^{T^{2h}} A P^{S^{2h}} u^{2h} = B^{2h}\mathbf{y}^{2h}$. Noting also that $P^{T^{2h}}\mathbf{f} = P_{S^h}^{S^{2h}}\mathbf{f}$, then (10) becomes

$$P_{S^h}^{S^{2h}} B^h \mathbf{w}^h + B^{2h}\mathbf{y}^{2h} - P_{S^h}^{S^{2h}} \mathbf{f}^h = 0.$$

The correction step is thus $\mathbf{w}^h \leftarrow \mathbf{w}^h + P_{S^{2h}}^{S^h}\mathbf{y}^{2h}$. Hence, with the operators we have constructed, the PML coarsening step for this problem is formally the same as conventional multigrid:

1. Set $\mathbf{f}^{2h} = P_{S^h}^{S^{2h}}(\mathbf{f}^h - B^h\mathbf{w}^h)$.
2. Solve $B^{2h}\mathbf{y}^{2h} = \mathbf{f}^{2h}$.
3. Correct the approximation by $\mathbf{w}^h \leftarrow \mathbf{w}^h + P_{S^{2h}}^{S^h}\mathbf{y}^h$.

Of course, as with any multigrid algorithm, in practice the exact solve on the coarse grid is replaced by a recursion, so that the only time an exact solution is computed is on the coarsest subspace. To form such a recursion in the strip pixel PML setting, we need only continue defining coarser spaces S^{jh}, for $j = 1, 2, \ldots$. This is done by taking the strip pixels that generate the new subspace to be the pairwise union of strip pixels in the current subspace, just as was done to produce S^{2h} from S^h. Once this is done, a PML V-cycle can be defined in the usual way.

```
PML V-cycle:    $\mathbf{w}^h \leftarrow PMLV(\mathbf{w}^h, B^h, \mathbf{f}^h)$
1. Relax $\nu_1$ times on $B^h\mathbf{x}^h = f^h$ with initial guess $\mathbf{w}^h$.
2. If $S^h$ represents the coarsest level, go to 3. Otherwise:
    (a) $\mathbf{f}^{2h} \leftarrow P_{S^h}^{S^{2h}}(f^h - B^h\mathbf{w}^h)$
    (b) $\mathbf{w}^{2h} \leftarrow 0$.
    (c) $\mathbf{w}^{2h} \leftarrow PMLV(\mathbf{w}^{2h}, B^{2h}, \mathbf{f}^{2h})$
    (d) $\mathbf{w}^h \leftarrow \mathbf{w}^h + P_{S^{2h}}^{S^h}\mathbf{w}^{2h}$.
3. Relax $\nu_2$ times on $B^h\mathbf{x}^h = f^h$ with initial guess $\mathbf{w}^h$.
```

6.4. Numerical performance. Figures 9 and 10 display two examples of the image reconstructions obtained with the PMLV algorithm. The pair of images in Fig. 9 were obtained using 20 views with 32 detectors per view, and restricting the image to lie in the unit square. The data were generated by projecting the exact image on the left, while the reconstruction of the image by PMLV is shown on the right. The reconstruction was made using 3 PMLV cycles with 2 relaxation sweeps on the downward leg of the V and one relaxation sweep on

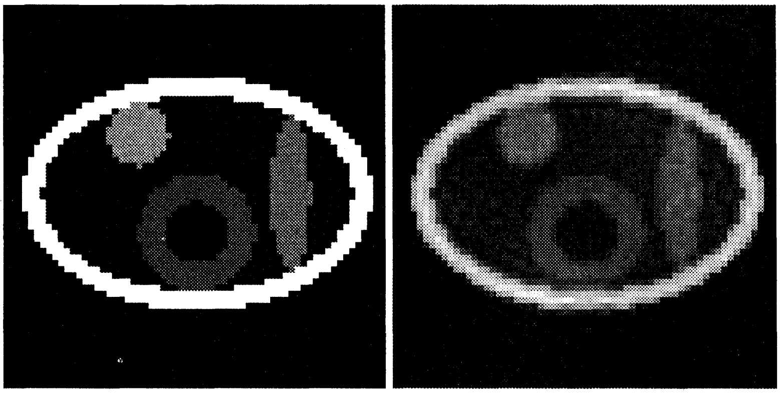

FIG. 9. *The performance of the PMLV method may be observed by comparing the actual (left) and reconstructed (right) images of a "brain phantom." The reconstruction was obtained using* 3 *PMLV cycles with* 2 *relaxation sweeps on the downward leg of the V and one relaxation sweep on the upward leg. The image on the left was used to generate the data used in the reconstruction, with* 20 *angles and* 32 *detectors per angle.*

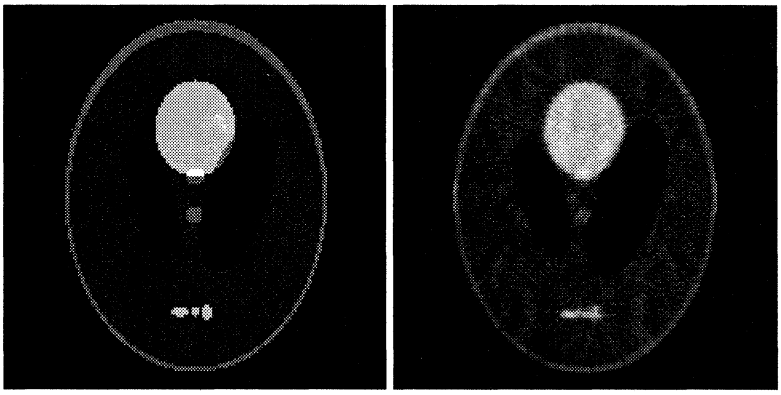

FIG. 10. *The reconstruction on the right was obtained using the multilevel method from data generated from the image on the left, using* 64 *angles and* 64 *detectors per angle. The reconstruction was obtained using* 3 *PMLV cycles with* 2 *relaxation sweeps on the downward leg of the V and one relaxation sweep on the upward leg.*

the upward leg. The Shepp–Logan phantom was used for the reconstruction in Fig. 10, which was obtained from 64 views with 64 detectors per view. Again, the image on the left was used to generate data for the multilevel reconstruction (right), which was made from 3 PMLV (2,1)-cycles.

To compare the performance of PMLV and Gauss–Seidel, let the work entailed by one sweep of Gauss–Seidel on the finest level be one work unit (WU), which is an $O(N^2)$ operation. Computation of the residual requires approximately one WU. The work required for one PMLV-cycle, using $\nu_1 + \nu_2$ sweeps of Gauss–Seidel on each level, is then bounded by

$$(\nu_1 + \nu_2 + 1)\left(1 + \frac{1}{4} + \frac{1}{16} + \cdots\right) \approx \frac{4}{3}(\nu_1 + \nu_2 + 1).$$

PMLV was applied to several reconstruction problems, using several different geometries. The performance of the algorithm in all tests was similar, and may be summarized by examining the results of a typical suite of experiments. In these tests the parameters $\nu_1 = 2$ and $\nu_2 = 1$ give the number of iteration sweeps, respectively, descending and ascending through the

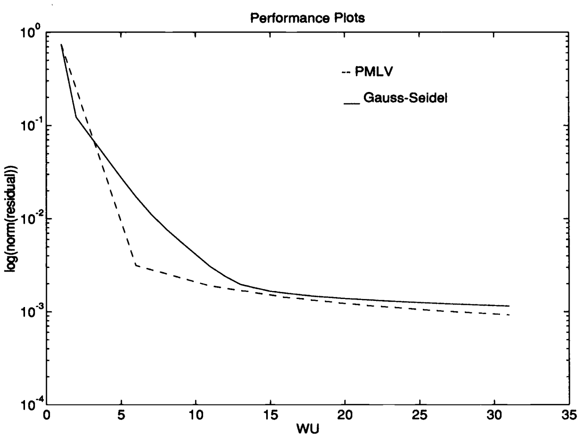

FIG. 11. *Comparison of the performance of Gauss–Seidel and PMLV. The logarithm of the residual norm is plotted as a function of the number of work units required to attain it.*

V-cycle. Hence, one V-cycle requires approximately $\frac{16}{3}$ WUs. The problem was coarsened to the coarsest possible level, giving one strip per view and a problem of size $M \times M$ at the coarsest level. Figure 11 compares the typical performance of Gauss–Seidel to the PMLV algorithm for a problem with 32 detectors over 20 angles.

It is clear from Fig. 11 that, even for this relatively small problem, PMLV initially outperforms Gauss–Seidel. However, continued iteration of Gauss–Seidel eventually achieves similar results at similar costs. We believe this is due largely to the fact that the bad modes do not possess the physical smoothness characteristic of bad modes in elliptic PDE problems, so that coarsening by row-lumping within projections does not entirely succeed at eliminating the bad modes. We think that this may be caused by the problem entering a scale regime where there is close coupling between the projections. This is likely to mean that a special lumping of rows is needed, where the oscillatory but possibly regular pattern of these components across angles is taken into account. Note that the slopes at the right end of the curves indicate that further iteration may favor PMLV. However, it is important to recall that the ultimate goal is quality image reconstruction, and that the residual norm may not be a reliable measure of success. It is also important to recall the ill-posed nature of reconstruction. Consider the problem $B\mathbf{w} = \mathbf{f}$, whose exact solution (in the least squares sense) is

$$\mathbf{w} = B^{\dagger}\mathbf{f},$$

where $B^{\dagger}$ is the pseudoinverse of B. In terms of the singular value decomposition $B = U\Sigma V^T$, the solution $\mathbf{w}$ can be expressed as

$$\mathbf{w} = \left[\sum_{i=1}^{r} \frac{1}{\sigma_i}\mathbf{v}_i\mathbf{u}_i^T\right]\mathbf{f} = \sum_{i=1}^{r} \frac{1}{\sigma_i}\mathbf{v}_i\langle\mathbf{u}_i, \mathbf{f}\rangle,$$

where the σ_i's are the singular values, $\mathbf{u}_i$ and $\mathbf{v}_i$ (the left and right singular vectors of B) are the columns of U and V, and $r = \operatorname{rank}(B)$. If there is *measurement noise* in the data, so that instead of $\mathbf{f}$ the data are $\mathbf{f} + \varepsilon$, then solution components corresponding to small singular values will magnify this noise. These are the components in the near null space that are slow to be recovered. Thus, continued iteration after the procedure stalls in an attempt to recover these slow components has the potential to corrupt the solution with magnified noise [11], [19].

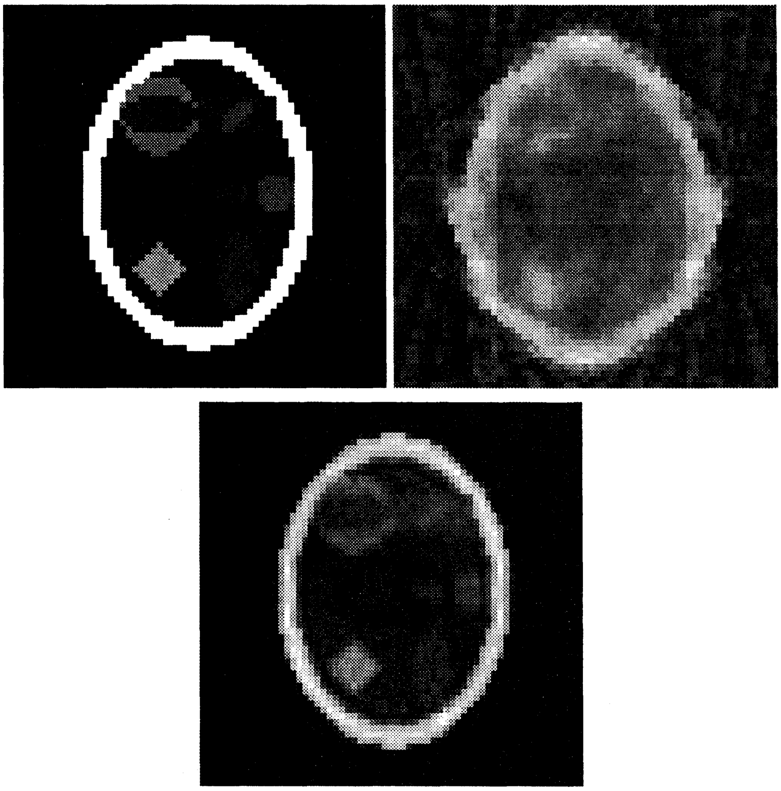

FIG. 12. *Exact image (top left), minimum norm solution (top right), and PMLV solution (bottom).*

Experiments have shown, in fact, that it is possible to drive the residual norm to zero, finding one of the solutions to the linear system, and have reconstructed images that are of poor subjective quality, perhaps worse than that of early iterates. Figure 12, for example, displays an exact image and two reconstructions of the data for that image. One reconstruction is made by computing $\mathbf{w} = B^{\dagger}\mathbf{f}$, while the other is made by running three PMLV cycles. The residual norms are 1.8×10^{-13} (pseudoinverse) and 4×10^{-4} (PMLV), but it can be seen that PMLV has produced a somewhat better reconstruction.

Such problems require some form of regularization to prevent the ill-posedness from completely corrupting the approximation. One way to do this [18] is to stop iterating when the algorithm begins to stall. An ad hoc approach to this is to measure the difference between successive residual norms, and stop iterating when a tolerance is achieved. A potentially more effective stopping criterion exists [20], based on a newly developed convergence theory for multilevel algorithms [7], but this is beyond the scope of interest here.

7. Spotlight image reconstruction. Often, one desires high resolution in a certain region of the image, for example, where a tumor is suspected. Discretizing the entire image space at a fine resolution may be impractical, as this leads to extremely large systems of equations. An attractive alternative is to discretize the region of special interest at a fine resolution and the remaining image space at a coarser resolution, leading to a *composite grid* problem. This is called *spotlighting* the region of interest. Numerous multigrid methods have been developed for handling composite grid problems [2], [16], [21]. One such method that we develop in the next section is a consequence of PML methodology.

7.1. Fast adaptive composite grid (FAC). The spotlight tomography problem is essentially a composite grid problem, in which an operator equation $Lu = f$ must be solved on a composite grid $\Omega^{\underline{h}}$ comprised of a global coarse grid Ω^{2h} and one or more local refinement grid Ω^h (the refinement grid may itself be a composite grid, which permits recursive refinement). Fast adaptive composite grid methods (FAC) were developed [14], [16] in order to utilize multigrid technology to treat such problems efficiently. It comes from the PML methodology by simply restricting the fine grid subspaces to local collections of detectors.

FAC succeeds because it handles the composite grid as a nested sequence of regular grids that can be treated independently using virtually any regular grid method. The key ingredients lie in having appropriate representations of the operator and intergrid transfer operators. Thus, grid functions u must be representable on the composite, global, and refinement grids ($u^{\underline{h}}$, u^{2h}, u^h), and operators must exist to transfer grid functions between these grids ($I_{\underline{h}}^h : \Omega^{\underline{h}} \to \Omega^h$, $I_{\underline{h}}^{2h} : \Omega^{\underline{h}} \to \Omega^{2h}$, $I_h^{\underline{h}} : \Omega^h \to \Omega^{\underline{h}}$, and $I_{2h}^{\underline{h}} : \Omega^{2h} \to \Omega^{\underline{h}}$). Finally, it is critical that the operator L be representable on these grids ($L^{\underline{h}}$, L^{2h}, L^h). In general, the details of these operators and representations can be developed in a straightforward fashion once the grids are defined; the details, however, are very technical and can be found in [12], [14], and [16]. Once the operators and grids are defined, FAC proceeds in the following two-step sequence:

Step 1: *Set* $f^{2h} \leftarrow I_{\underline{h}}^{2h}(f^{\underline{h}} - L^{\underline{h}}u^{\underline{h}}), \quad u^{2h} \leftarrow (L^{2h})^{-1} f^{2h}, \quad u^{\underline{h}} \leftarrow u^{\underline{h}} + I_{2h}^{\underline{h}} u^{2h}.$

Step 2: *Set* $f^{h} \leftarrow I_{\underline{h}}^{h}(f^{\underline{h}} - L^{\underline{h}}u^{\underline{h}}), \quad u^{h} \leftarrow (L^{h})^{-1} f^{h}, \quad u^{\underline{h}} \leftarrow u^{\underline{h}} + I_{h}^{\underline{h}} u^{h}.$

Despite this formal definition, FAC need not utilize exact solvers on the global coarse grid or the refinement patch. Historically, FAC has been used predominantly with iterative methods [14].

7.2. The spotlight grid. We utilize FAC methodology to devise a discretization for the spotlight tomography problem. We begin with a global grid Ω^{2h} generated by the natural pixels ψ_j^{2h}. We next add a refinement grid Ω^h by forming strips ψ_j^h. For each view we choose pairs of strips whose union conforms exactly to one of the global strips. As a very simple example, consider the discretization given by three views, each consisting of four strip pixels (Fig. 13, left). The resulting global (coarse grid) operator is the 12 × 12 matrix $B_{2h,2h}$, the matrix whose (j, k)th entry is $b_{jk}^{2h} = \langle \psi_j^{2h}, \psi_k^{2h} \rangle$. The refinement grid Ω^h is formed by partitioning one strip from each view into two strips. Hence ψ_2^{2h} generates ψ_1^h and ψ_2^h. Similarly, strips 3 and 4 on the refinement grid are a partition of ψ_7^{2h}, and ψ_{11}^{2h} generates refinement strips 5 and 6 (Fig. 13, right). The refinement strips ψ_k^h generate a refinement patch operator $B_{h,h}$, formed in the usual manner by $b_{jk}^h = \langle \psi_j^h, \psi_k^h \rangle$, giving a 6 × 6 matrix in the simple example. The composite grid $\Omega^{\underline{h}}$ formed in this manner is shown at the bottom of Fig. 13.

The basic assumption of the discretization, that the unknown image is a linear combination of the strip functions, is unchanged. The total number of strips is $N = N_{2h} + N_h$, the sum of the number of strips on the global grid and the refinement patch. Hence, the image $u = A^{\underline{h}*}\mathrm{w}$ is given by (3) where $\psi_j = \psi_j^{2h}$ if $1 \le j \le N_{2h}$ and $\psi_j = \psi_{j-N_{2h}}^h$ if $N_{2h} < j \le N$. We can define the composite grid version of $A^{\underline{h}}$ by $(Au)_j = \langle \psi_j, u \rangle$ using the same ordering of the ψ_j's. The discretized composite grid operator $B_{\underline{h},\underline{h}}$ may then be computed in the standard way, by $B_{\underline{h},\underline{h}} = A^{\underline{h}}A^{\underline{h}*}$, and it has, as its (j, k)th entry, the element $b_{jk}^{\underline{h}} = \langle \psi_j, \psi_k \rangle$. This method accounts for the interaction of the refinement grid with the global coarse grid, including the inner products between the fine strips and coarse strips. In fact, this leads to a natural

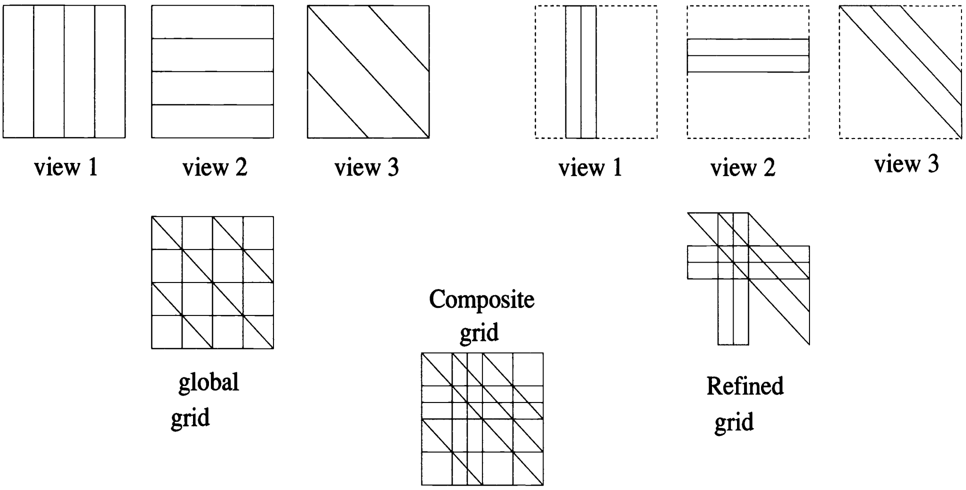

FIG. 13. *The global grid Ω^h (bottom left) is generated by strips from three views (top left), while the refinement patch (bottom right) is generated by finer strips from the three views (top right). The union of all strips generates the composite grid (bottom center).*

partitioning of the composite grid operator as

$$B_{\underline{h},\underline{h}} = \begin{pmatrix} B_{2h,2h} & B_{2h,h} \\ B_{h,2h} & B_{h,h} \end{pmatrix}.$$

We observe that by the ordering of the ψ_j's and the definition of $A^{\underline{h}*}$ we are led to a natural definition of the composite grid unknown, namely $u^{\underline{h}} = (\mathbf{w}^{2h} \quad \mathbf{w}^h)^T$. Naturally, we must have a compatible composite grid data vector $\mathbf{f}^{\underline{h}} = (\mathbf{f}^{2h} \quad \mathbf{f}^h)^T$. Conceivably, the coarse grid data and the refinement data could be acquired in separate recordings, but it is more likely that a single data set be generated, from which the coarse and refinement data are derived. The composite grid problem $B_{\underline{h},\underline{h}}\mathbf{w}^{\underline{h}} = \mathbf{f}^{\underline{h}}$ then becomes

$$\begin{pmatrix} B_{2h,2h} & B_{2h,h} \\ B_{h,2h} & B_{h,h} \end{pmatrix} \begin{pmatrix} \mathbf{w}^{2h} \\ \mathbf{w}^h \end{pmatrix} = \begin{pmatrix} \mathbf{f}^{2h} \\ \mathbf{f}^h \end{pmatrix}. \tag{11}$$

7.3. FAC implementation. It can be shown [14], [20] that FAC in this setting is equivalent to applying two steps of *block* Gauss–Seidel iteration to the system (11). That is, FAC takes the two-step form:

Step 1: *Set* $\mathbf{w}^{2h} \leftarrow B^{-1}_{2h,2h}(\mathbf{f}^{2h} - B_{2h,h}\mathbf{w}^h).$

Step 2: *Set* $\mathbf{w}^{h} \leftarrow B^{-1}_{h,h}(\mathbf{f}^{h} - B_{h,2h}\mathbf{w}^{2h}).$

These steps are formal, of course, since we know that $B_{2h,2h}$ is singular. In fact, we take $\mathbf{w} \leftarrow B^{-1}\mathbf{f}$ to mean "solve $B\mathbf{w} = \mathbf{f}$," which need not be done with exact solvers. In principle we may apply any method to these subproblems: ART, filtered backprojection, Fourier methods. A natural choice is an iterative method, such as Gauss–Seidel or multigrid. Noting that each of the steps are solving a "residual" equation on one of the grids, this process may be viewed as one of multilevel correction.

The composite grid operator $B_{\underline{h},\underline{h}}$ possesses a host of useful and interesting properties [20], related to a family of useful properties generated by the discretization method and inherent

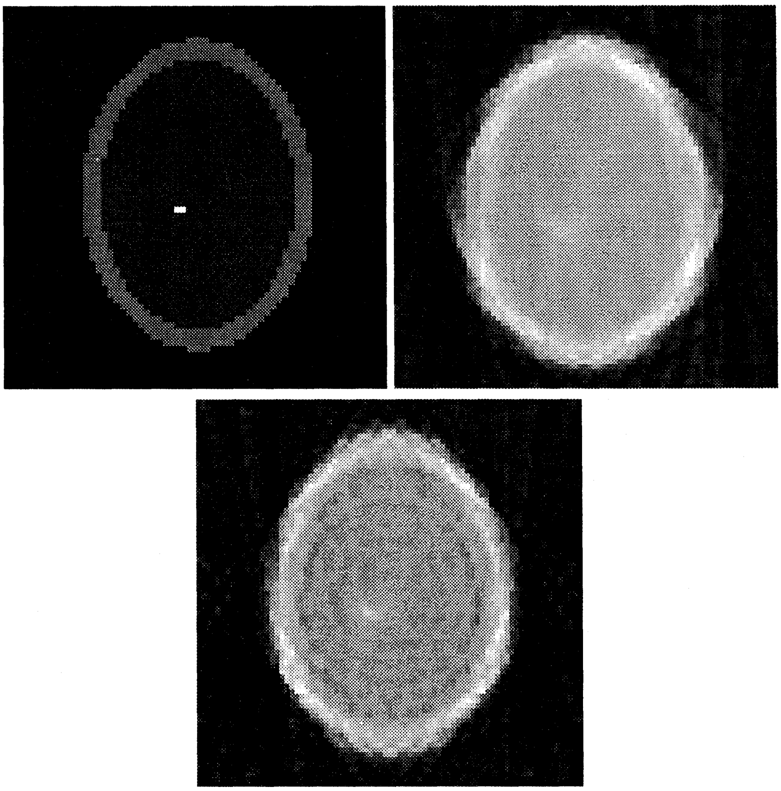

FIG. 14. *The "exact" image used to generate data for the spotlight tomography problem is shown on the top left. In the top right is shown the PML reconstruction on the global coarse grid* Ω^{2h}*, using data generated for* 20 *angles with* 32 *strips per angle. On the bottom is the spotlight reconstruction, generated using data for strips half the width of the global coarse grid, over the central region of the image.*

in the global and local operators $B_{2h,2h}$ and $B_{h,h}$. Space limitations do not permit elaboration here, nor is there room for a performance analysis. A rigorous treatment of the method, including a performance assessment, is forthcoming [8], [20].

We demonstrate the promise of the spotlight method with a simple example. A "brain" phantom is generated, consisting of a uniform grey region within the skull (high-density elliptical ring). Embedded in the grey region is a small square high-density region. Data is generated by integrating the product of this image with the characteristic functions of the strips representing a 20 angle, 32 bins-per-angle discretization. The square of high density has width equal to one half the width of the individual strips making up the global coarse grid. The "exact" image is shown on the left of Fig. 14, while the global coarse grid reconstruction is shown on the top right.

A single-level refinement region is generated by refining one half of the strips in the center of the set for each angle, using strips of half the width of those on the global coarse grid. The reconstructed image using the spotlight method with one cycle of FAC is shown on the bottom of Fig. 14. Both the global coarse grid and refinement grid portions of the composite grid were solved using three V-cycles, each with two relaxation sweeps on the downward leg and one relaxation sweep on the upward leg. The high-density region, which does not show in the global coarse grid reconstruction, appears in the spotlight reconstruction. This is demonstrated a bit more clearly in Fig. 15, in which only the central region of each of the reconstructions is shown.

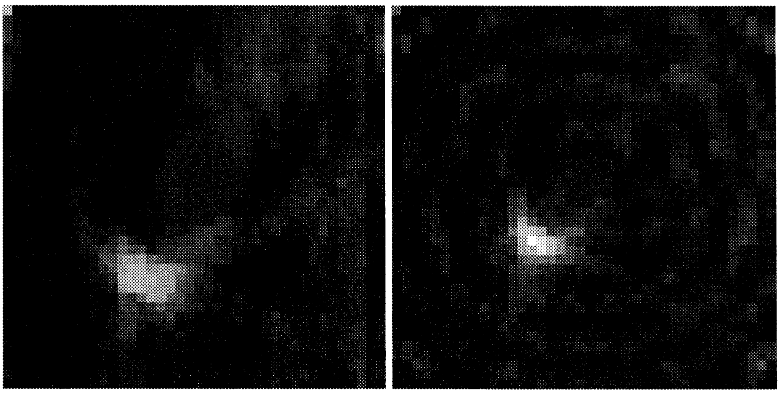

FIG. 15. *The central portions of global coarse grid (left) and spotlight (right) reconstructions of Fig. 14 are shown in this figure. The image reconstructed from the composite grid data clearly shows the object of interest, while the global coarse grid image fails to resolve it.*

We chose this example because of its clarity for the reader. However, it does not really illustrate the practical benefits of FAC because it costs essentially the same as would solving the globally refined problem. In practice, we envision that FAC will be used for spotlighting smaller features of the image, and to much finer detail. That is, rather than refining one half of the strips on each angle by splitting them once, we foresee refining a much smaller region, such as one tenth of the strips along each angle, to a resolution four or eight times that of the global coarse grid. In such settings the benefits of spotlighting would be very substantial.

8. Concluding remarks. The results presented here are encouraging, in that they demonstrate that multilevel methodology can be applied to the image reconstruction problem with some hope of success. The benefits of multilevel reconstruction, the way we have developed it, remain somewhat limited, although we do see images of quality equal to those produced by Gauss–Seidel, achieved at somewhat lower cost.

We believe that this limitation may stem from restricting the coarsening to be within projections. That is, we have reduced only the number of detectors per angle, not the number of angles themselves. Evidence gathered by examining the near null space components suggests that angle coarsening is essential for efficiency at coarse grain resolution, which multigrid methods always face. This is currently being explored.

The results presented here show great promise in the area of spotlight tomography, for cases where a finer resolution image is needed over portions of the image space. It is not feasible to compute entire images at the fine resolution, since such problems lead to extremely large, dense systems. As the simple example shows, however, PML can be used to formulate the spotlight problem to use FAC technology in a way that may lead to practical algorithms.

GMRES AND INTEGRAL OPERATORS*

C. T. KELLEY† AND Z. Q. XUE†

Abstract. In this paper we show how the properties of integral operators and their approximations are reflected in the performance of the GMRES iteration and how these properties can be used to smooth the GMRES iterates by an implicit application of Nyström interpolation, thereby strengthening the norm in which convergence takes place. The smoothed iteration has very similar properties to Broyden's method. We present an example to illustrate the ideas.

Key words. integral equations, GMRES iteration, Broyden's method

AMS subject classifications. 65F10, 65J10, 65R20

1. Introduction. In this paper we consider the performance of the GMRES [27] iteration for linear equations of the form

$$Au = u - Ku = f \tag{1.1}$$

with K a compact operator on a separable Hilbert space H. An example of such an operator is an integral operator on $H = L^2[0, 1]$ of the form

$$Ku(x) = \int_0^1 k(x, y)u(y)\, dy \tag{1.2}$$

where k is continuous.

Our setting is that of [15] where issues similar to those raised in this paper were considered in the context of Broyden's method [4] for linear and nonlinear equations. Broyden's method has also been considered as a linear equation solver in [5], [12], [13], [25], and [20]. Let H be a separable real Hilbert space and let $X \subset H$ be a Banach space such that the inner product $(\cdot, \cdot)$ in H is continuous from $X \times X \to R$. This implies that there is C_X such that

$$\|u\|_H \leq C_X \|u\|_X \tag{1.3}$$

for all $u \in X$. Let $K \in \mathcal{COM}(H, X)$, which is the space of compact operators from H to X. Of course, we may also regard K as an element of $\mathcal{COM}(H)$, which is the space of compact operators on H. In the context of the integral operator (1.2) with continuous k, $H = L^2[0, 1]$, $X = C[0, 1]$, and $C_X = 1$.

Algorithms such as GMRES and Broyden's method, which depend on notions of orthogonality, could use the Hilbert space inner product of H to solve equations in which the right-hand side $f \in X$. However, a convergence theory based entirely on a Hilbert space formulation would show that the resulting sequence is convergent in the topology of H but not necessarily in that of the Banach space X in which the problem may have been originally posed. Hence, we face an apparent conflict between the topology in which the problem was posed and the inner product (and hence Hilbert space) nature of the algorithm. This issue was resolved in [15] in the context of Broyden's method. For the linear equations context of this paper the result of [15] is that the Broyden iterations converge q-superlinearly in the topology of X provided $K \in \mathcal{COM}(H, X)$ and $f \in X$.

Nyström interpolation [24], i.e., replacing an approximate solution u by $\bar{u} = f + Ku$, can be used to create approximations accurate in stronger norms than the original [17] to improve the overall accuracy of a discrete approximation [28] and as a method for smoothing an intergrid transfer in multilevel schemes [1], [3], [14]. We have the first purpose in mind here. Following GMRES with a Nyström interpolation would, as we shall see, result in accuracy in the X-norm. The cost, however, would be an additional application of K.

The purpose of this paper is to show how GMRES can be modified to incorporate Nyström interpolation at a very small cost in both computational effort and algorithmic complexity. The result is an algorithm that has the simultaneous X and H convergence property of Broyden's method. The example we give in §4 compares GMRES, both with and without Nyström interpolation, and Broyden's method as primary solvers and not in the context of a multilevel method, where they could be either used as coarse mesh solvers or as the primary solver in a nested iteration approach. The reasons for this are that the independence of our results to mesh size can best be illustrated if the solvers perform the same task for each mesh. The merits of our implicit Nyström interpolation carry over to the multilevel situation, enabling coarse mesh solvers to be accurate in the appropriate discrete X-norm, which is important for the convergence theory.

Throughout this paper we assume that A is a nonsingular linear operator on H and X. We consider convergence rate estimates of the form

$$\|r_k\|_H \leq \tau_k \|r_0\|_H, \tag{1.4}$$

where $r_k = f - Au_k$, and the sequence of real numbers $\{\tau_k\}$ converges to zero and is independent of the right-hand side f of (1.1).

Rates of convergence of the form (1.4) can be derived from resolvent integration [21], [22] for any K such that $I - K$ has bounded inverse and 1 is in the unbounded component of the resolvent set of K. If K is compact, more precise information can be obtained. In fact the GMRES iterates converge r-superlinearly to the solution in a way that is independent of the right-hand side. This means that the sequence $\{\tau_k\}$ converges q-superlinearly to zero; i.e.,

$$\lim_{k\to\infty} \frac{\tau_{k+1}}{\tau_k} = 0.$$

In the case of normal or diagonalizable (similar to normal) compact operators a q-superlinearly convergent sequence $\{\tau_k\}$ can be directly related to spectral properties of K in a very simple way. In [18] assumptions on the rate of decay of the spectrum were used for this. In order to illustrate how the smoothing properties of K might influence the convergence rate, below we present a slight extension of the result in [18]. While this result follows from the general theory in [22], we believe that its direct and brief proof is worth inclusion. We denote by $\kappa_H(A)$ the H-norm condition number of A;

$$\kappa_H(A) = \|A\|_H \|A^{-1}\|_H.$$

THEOREM 1.1. *Let H be a separable Hilbert space, $K \in \mathcal{COM}(H)$, let $A = I - K$ be nonsingular, and let S be a nonsingular bounded operator on H such that*

$$L = SKS^{-1}$$

is normal. Let $\{\lambda_i\}$ be the eigenvalues of A ordered so that

$$|\lambda_i - 1| \geq |\lambda_{i+1} - 1| \quad \textit{for } i \geq 1; \tag{1.5}$$

then for all $k \geq 1$ the GMRES residuals r_k satisfy

$$\|r_k\| \leq \kappa_H(S)\|r_0\|2^k \prod_{i=1}^{k} |1 - \lambda_i^{-1}|. \tag{1.6}$$

Proof. For $k = 1, \ldots$ define

$$p_k(z) = \prod_{i=1}^{k}(1 - \lambda_i^{-1}z). \tag{1.7}$$

Since $p_k(0) = 1$ for all k we have [27]

$$\|r_k\|_H \leq \kappa_H(S)\|r_0\|_H \sup_m |p_k(\lambda_m)|. \tag{1.8}$$

For k fixed, $p_k(\lambda_m) = 0$ for $1 \leq m \leq k$. For $m > k$,

$$\begin{aligned} |p_k(\lambda_m)| &\leq \prod_{i=1}^{k} |1 - \lambda_i^{-1}\lambda_m| = \prod_{i=1}^{k} |\lambda_i^{-1}||\lambda_i - \lambda_m| \\ &\leq \prod_{i=1}^{k} |\lambda_i^{-1}|(|\lambda_i - 1| + |1 - \lambda_m|) \leq \prod_{i=1}^{k} |\lambda_i^{-1}|2|\lambda_i - 1| \\ &= 2^k \prod_{i=1}^{k} |1 - \lambda_i^{-1}|. \end{aligned}$$

This completes the proof. □

Since $\lambda_i \to 1$, the sequence

$$\tau_k = 2^k \prod_{i=1}^{k} |1 - \lambda_i^{-1}|$$

is q-superlinearly convergent. If, say, K is normal (so $S = I$) and the eigenfunctions of K are smooth, then the rate of convergence of λ_i to one reflects both the smoothness of the kernel k and the convergence rate of the sequence $\{\tau_k\}$.

2. Convergence in a stronger norm.

In this section we show how, given a rate estimate like (1.4) for the sequence of residuals, the GMRES iteration can be modified to produce a sequence that converges with the same rate in the norm of X. This will lead to a modified form of GMRES that uses information at hand to perform Nyström interpolation implicitly without the need for an additional application of the operator K. Proposition 2.1 is a coupling of the convergence rate derived above with the standard smoothing result for Nyström interpolation [2]. We provide the simple proof to help clarify the ideas.

PROPOSITION 2.1. *Let $\{u_k\}$ be the sequence of GMRES iterates. Assume that* (1.4) *holds for some sequence $\{\tau_k\}$. Let $\bar{u}_k = u_k + r_k$. Then*

$$\|\bar{u}_k - u^*\|_X \leq \|K\|_{\mathcal{L}(H,X)}\kappa_H(A)\tau_k\|u_0 - u^*\|_X. \tag{2.1}$$

Proof. First note that (1.4) implies that

$$\|u_k - u^*\|_H \leq \tau_k\kappa_H(A)\|u_0 - u^*\|_H. \tag{2.2}$$

Since

$$\bar{u}_k = u_k + r_k = f + K u_k,$$

continuity of K as a map from H to X implies that

$$\|\bar{u}_k - u^*\|_X = \|K(u_k - u^*)\|_X \le \|K\|_{\mathcal{L}(H,X)} \|u_k - u^*\|_H.$$

This completes the proof. □

The interpolant $\bar{u}_k$ is as easy to compute as u_k upon exit from the main loop in GMRES. An algorithmic description of GMRES follows.

ALGORITHM 2.1. *Algorithm* gmres(u, f, A, ϵ)

```
1. $r = f - Au$, $v_1 = r/\|r\|_H$, $\rho = \|r\|_H$, $\beta = \rho$, $k = 1$
2. While $\rho > \epsilon \|b\|_H$ do
   (a) $v_{k+1} = Av_k$
       for $j = 1, \dots, k$
         i. $h_{jk} = (v_{k+1}, v_j)$
         ii. $v_{k+1} = v_{k+1} - h_{jk} v_j$
   (b) $h_{k+1,k} = \|v_{k+1}\|_H$
   (c) $v_{k+1} = v_{k+1}/\|v_{k+1}\|_H$
   (d) $e_1 = (1, 0, \dots, 0)^T \in R^{k+1}$
       Minimize $\|\beta e_1 - H_k y\|_{R^{k+1}}$ to obtain $y \in R^k$
   (e) $\rho = \|\beta e_1 - H_k y\|_{R^{k+1}}$
   (f) $k = k + 1$
3. $u_k = u_0 + V_k y$
```

In step 3 $V_k : R^k \to H$ is defined by

$$V_k y = \sum_{j=1}^{k} y_j v_j.$$

We can use the fact that

$$r_k = f - Au_k = V_{k+1}(\beta e_1 + H_k y) = r_0 + V_{k+1} H_k y$$

to recover $\bar{u}_k$ with no additional operator–vector products involving A. In fact if $z = H_k y$ and we define a vector

$$w = (w_1, w_2, \dots, w_{k+1})^T \in R^{k+1}$$

by $w_i = z_i + y_i$ for $1 \le i \le k$ and $w_{k+1} = z_{k+1}$, we have

$$\bar{u}_k = \bar{u}_0 + V_{k+1} w, \tag{2.3}$$

which can simply replace the computation of u_k in step 3 of gmres. We will refer to the resulting algorithm as *smoothed GMRES*. Note that smoothed GMRES differs from GMRES only in the final output, where (2.3) is used to compute the final result.

As an algorithm for the solution of linear compact fixed point problems, smoothed GMRES shares two properties with Broyden's method. Both converge superlinearly to the solution in the topologies of both H and X and both require storage of the iteration history. Older implementations of Broyden's method require storage of two vectors for each iteration, [10], [23], [7]. However recent work for linear [9] and nonlinear [16] problems show how to use only a single vector, making the two algorithms competitive.

3. Discrete problems. While we state and prove our results in the infinite-dimensional setting they apply equally well when K is an approximation of some compact operator and X and H are both R^N for some N with different norms, say, discrete approximations of L^2 (for H) and L^∞ or C^l (for X) norms.

To illustrate this point, consider the integral operator defined by (1.2). A standard approximation by an N-point quadrature rule would lead to the discrete problem

$$u_i - \sum_{j=1}^{N} k(x_i, x_j) w_j = f(x_i), \tag{3.1}$$

where $\{x_i\}$ and $\{w_i\}$ are the nodes and weights of the quadrature rule. Assume that f and k are l times continuously differentiable. Define H to be R^N with the inner product

$$(u, v)_H = \sum_{j=1}^{N} u_j v_j w_j$$

and associated norm

$$\|u\|_H = \left(\sum_{j=1}^{N} u_j^2 w_j \right)^{1/2}.$$

We give $C^l[0, 1]$ the norm

$$\|u\|_{C^l} = \|u\|_\infty + \|d^l u/dx^l\|_\infty.$$

If we replace $\|d^l u/dx^l\|_\infty$ with a lth divided difference we may define an approximate C^l norm on R^N. If X is R^N with such an approximate C^l norm, then the matrix

$$K_{ij} = k(x_i, x_j) w_j$$

satisfies, with C independent of N

$$\|Ku\|_X \le C \|u\|_H,$$

and the development in the above section may be applied for each level of discretization N with the constants in the estimates being independent of N.

For example, if $l = 1$, and the nodes of quadrature rule are $\{ih\}_{i=0}^{N-1}$ with $h = 1/(N-1)$, we may define the divided difference $D_1 u \in R^{N-1}$ by

$$(D_1 u)_i = (u_{i+1} - u_i)/h \tag{3.2}$$

and the X-norm by

$$\|u\|_X = \|u\|_\infty + \|D_1 u\|_\infty.$$

In §4 we present an example showing how smoothed GMRES can capture the smoothing properties of the Broyden iteration that are missed by GMRES alone.

4. Example. As an example we consider the source iteration operator from linear transport theory [19], [26]. We will describe the equation and its discretization only briefly and refer to [19] and [26] for more details. We consider the equation

$$\mu \frac{\partial \psi}{\partial x}(x, \mu) + \psi(x, \mu) = \frac{c(x)}{2} \int_{-1}^{1} \psi(x, \mu') \, d\mu' \tag{4.1}$$

for $x \in (0, \tau)$ with boundary conditions

$$\psi(0, \mu) = F_l(\mu), \quad \mu > 0; \qquad \psi(\tau, \mu) = F_r(\mu), \quad \mu < 0. \tag{4.2}$$

In (4.1) and (4.2) the intensity ψ is the unknown real valued function of x and μ. $\tau < \infty$, $c \in C([0, \tau])$, and F_l and F_r are given continuous real valued functions of μ. It is known [6] that the boundary value problem (4.1)–(4.2) has a unique solution if $0 \leq c(x) < 1$.

The intensity can be computed directly once the flux

$$f(x) = \frac{1}{2}\int_{-1}^{1} \psi(x, \mu')\, d\mu' \tag{4.3}$$

is known. By integrating forward ($\mu > 0$) and backward ($\mu < 0$) in x we derive the integral equation for f,

$$f(x) - \int_0^{\tau} k(x, y) f(y)\, dy = g(x) \tag{4.4}$$

where

$$k(x, y) = \frac{1}{2} E_1(|x - y|) c(y),$$

$$E_1(|x - y|) = \int_0^1 \exp\left(\frac{-|x - y|}{\nu}\right) \frac{d\nu}{\nu},$$

and

$$g(x) = \frac{1}{2}\int_0^1 \exp\left(\frac{-x}{\nu}\right) F_l(\nu)\, d\nu$$
$$+\frac{1}{2}\int_0^1 \exp\left(\frac{-(\tau - x)}{\nu}\right) F_r(-\nu)\, d\nu.$$

It is known [6], [8] that the integral operator K in (4.4) has spectral radius < 1 and hence (4.4) has a unique solution. It is also easy to see from the formula for k that K maps L^2 into any of the spaces

$$X_\epsilon^l = C[0, 1] \cap C^l[\epsilon, 1].$$

By examining the formula for g we see that the solution $f \in C[0, 1]$ is infinitely differentiable in compact subsets of $(0, 1]$ and hence lies in any of the spaces X_ϵ^l.

We discretize (4.4) with the standard *discrete ordinates* approximation to (4.1), which is not a direct approximation of (4.4) by a quadrature rule at all. We approximate the integral in (4.1) by a 20-point double Gaussian quadrature rule (10-point Gaussian quadratures on each of the intervals $(-1, 0)$ and $(0, 1)$) in line with the analysis in [26] and then integrate forward and backward with the Crank–Nicolson scheme on a spatial mesh with N points. The convergence theory developed in [19] and [26] implies that the discrete form K of the integral operator satisfies

$$\|Ku\|_{l,\epsilon} \leq M(l, \epsilon)\|u\|_H$$

for some $M(k, \epsilon)$, which is independent of the spatial mesh. Here $\|\cdot\|_H$ denotes the scaled Euclidean norm

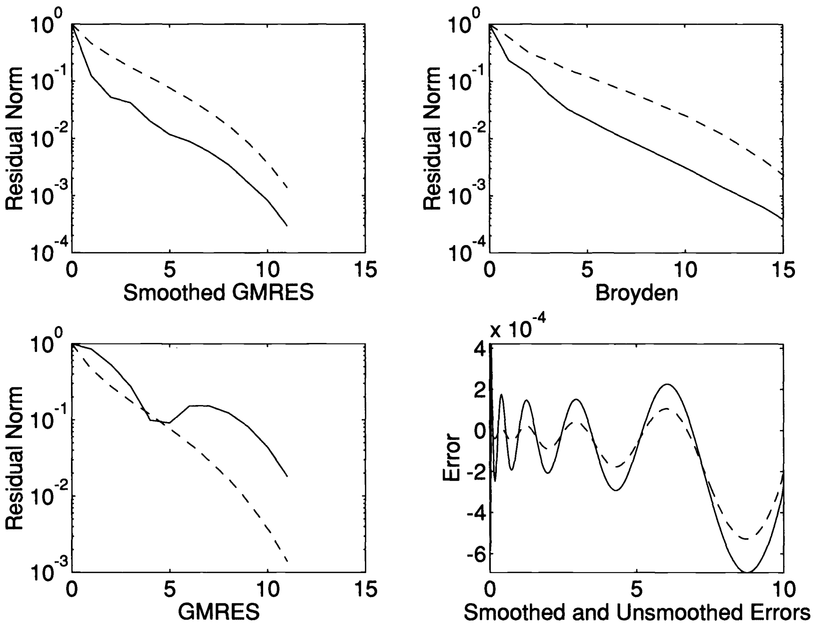

FIG. 4.1. $N = 401$.

$$\|u\|_H = \left(\frac{1}{N}\sum_{j=1}^{N} u_j^2\right)^{1/2},$$

and the discrete X_ϵ^l norms are given by

$$\|u\|_{l,\epsilon} = \|u\|_\infty + \|D_1^l u_\epsilon\|_\infty. \tag{4.5}$$

In (4.5) the operator D_1 is defined by (3.2) and u_ϵ is the vector defined by

$$(u_\epsilon)_i = \begin{cases} 0, & ih \le \epsilon, \\ u_i, & ih > \epsilon. \end{cases}$$

We set $F_l(\mu) = 1$, $F_r(\mu) = 0$ for all μ, and $\tau = 10$. We set $c(x) = \exp(-x/100)$, which is a special case of the class considered in [11]. We performed three sets of computations for $N = 401$, $N = 801$, and $N = 1601$. We used the initial iterate $u_0 = 0$ and solved the equation with GMRES, smoothed GMRES, and Broyden's method. We terminated the iteration when the discrete H-norm residual had been reduced by a factor of $5/(N-1)^2$. We used the solution with $N = 6401$ (terminated when the H-norm residual had been reduced by a factor of 10^{-12} as a representation of the exact solution). We computed the discrete X_ϵ^l-norms with $\epsilon = .025$.

For $N = 401$ (Fig. 4.1), $N = 801$ (Fig. 4.2), and $N = 1601$ (Fig. 4.3) we plot relative residual norms as functions of the iteration number in both the discrete X_ϵ^1-norm (solid line) and the discrete H-norm (dashed line). In each figure there are plots of residual histories for both GMRES and smoothed GMRES (SGMRES). In those plots the dashed line is the H-norm relative residual for both GMRES and SGMRES. The solid line is the relative residual norm in X_ϵ^1, which we computed directly in GMRES by explicitly computing the residual and its X_ϵ^1-norm or by using (2.3). We also plot the error in the final result as a function of $x \in [0, \tau]$ for smoothed (dashed line) and unsmoothed (solid line) GMRES. One can clearly see the

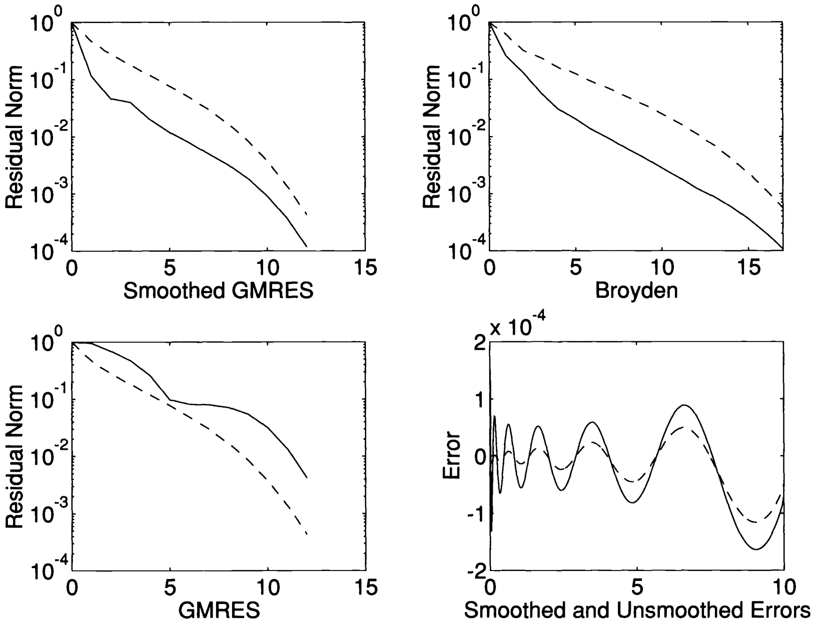

FIG. 4.2. $N = 801$.

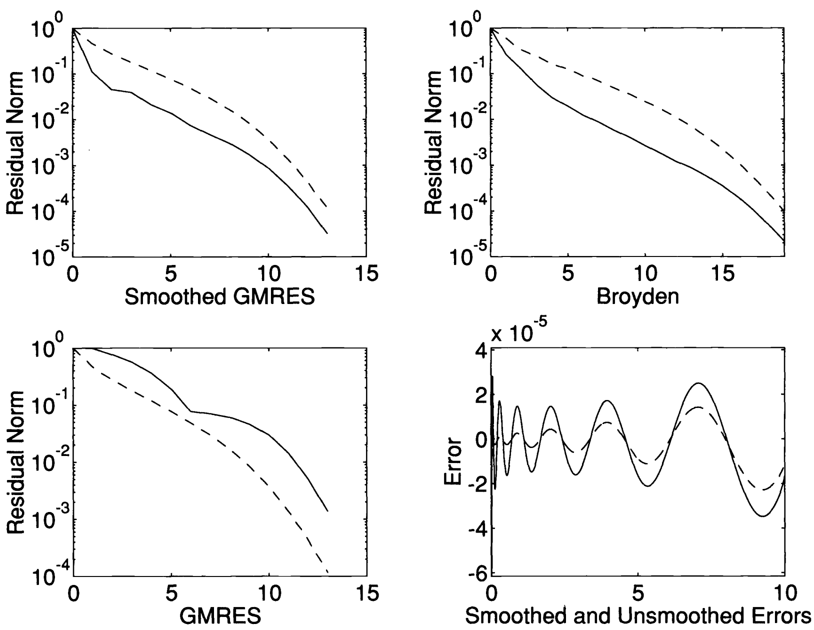

FIG. 4.3. $N = 1601$.

effects of the smoothing especially near $x = 0$ where the errors of the unsmoothed solution oscillate much more strongly.

To show how the smoothing affects the results in other norms, we present in Table 4.1 the norms of the errors in the discrete L^∞, X_ϵ^1, X_ϵ^2, and X_ϵ^3 norms for GMRES and SGMRES. One can see from these tables that the effect of the Nyström interpolation becomes more dramatic as the differentiability in the norms increases.

TABLE 4.1
Errors in various norms.

	$N = 401$		$N = 801$		$N = 1601$	
Norm	GMRES	SGMRES	GMRES	SGMRES	GMRES	SGMRES
H	3.1865e-4	2.3279e-4	7.6028e-5	4.8816e-5	1.7326e-5	9.8239e-6
L^∞	6.9223e-4	5.2749e-4	1.6349e-4	1.1584e-4	6.1573e-5	2.2828e-5
X_ϵ^1	4.0814e-2	8.0632e-3	7.0348e-3	1.2897e-3	3.1247e-3	3.9660e-4
X_ϵ^2	1.9878e+0	2.4950e-1	5.3146e-1	3.0577e-2	2.2838e-1	1.1983e-2
X_ϵ^3	8.3956e+1	7.5656e+0	2.5227e+1	1.6119e+0	9.2401e+0	8.5306e-1

The computations illustrate how the smoothed GMRES iteration gives better performance in the X_ϵ^1-norm. The curves for the various values of m are quite similar, indicating that the infinite-dimensional analysis can be observed numerically. Note also that the X_ϵ^1 and H relative residuals for the Broyden iteration, which requires more work than GMRES, are very close, in line with the theory in [15].

The tables and figures were created with MATLAB version 4.0a on a Sun SPARC 20 model 61 workstation running SUN OS 4.1.3.

ITERATIVE METHODS FOR TOTAL VARIATION DENOISING*

C. R. VOGEL† AND M. E. OMAN‡

Abstract. Total variation (TV) methods are very effective for recovering "blocky," possibly discontinuous, images from noisy data. A fixed point algorithm for minimizing a TV-penalized least squares functional is presented and compared with existing minimization schemes. A variant of the cell-centered finite difference multigrid method of Ewing and Shen is implemented for solving the (large, sparse) linear subproblems. Numerical results are presented for one- and two-dimensional examples; in particular, the algorithm is applied to actual data obtained from confocal microscopy.

Key words. total variation, denoising, image reconstruction, multigrid methods, confocal microscopy, fixed point iteration

AMS subject classifications. 65F10, 65N55

1. Introduction. The problem of denoising, or estimating an underlying function from error-contaminated observations, occurs in a number of important applications, particularly in probability density estimation and image reconstruction. Consider the model equation

$$z = u + \epsilon, \tag{1.1}$$

where u represents the desired true solution, ϵ represents error, and z represents the observed data. A number of approaches can be taken to estimate u. These include spline smoothing (see [18]), filtering using Fourier and wavelet transforms, and total variation (TV)-based denoising. Figure 1 illustrates the qualitative differences between these various approaches on a simple one-dimensional test case. It is not the goal of this paper to carry out an exhaustive comparison of TV with standard denoising methods. For that, see [15] and the analysis in [5]. Suffice it to say that TV denoising is extremely effective for recovering "blocky," possibly discontinuous, functions from noisy data. It *is* the goal of this paper to present a new algorithm for TV denoising and to compare it with some existing TV-based methods.

In their seminal paper on TV denoising, Rudin, Osher, and Fatemi [15] considered the constrained minimization problem

$$\min_u \int_\Omega |\nabla u|\, dx \quad \text{subject to} \quad \|u - z\|^2 = \sigma^2, \tag{1.2}$$

where the parameter σ describes the magnitude of the error ϵ in the data in the model equation (1.1). Here Ω is a bounded, convex region in d-dimensional space, $|\cdot|$ denotes the Euclidean norm in R^d, and $\|\cdot\|$ denotes the norm on $L^2(\Omega)$.

Here we will consider a closely related problem—the minimization of the TV-penalized least squares functional

$$f(u) = \frac{1}{2}\|u - z\|^2 + \alpha\, J_\beta(u), \tag{1.3}$$

where

$$J_\beta(u) = \int_\Omega \sqrt{|\nabla u|^2 + \beta^2}\, dx \tag{1.4}$$

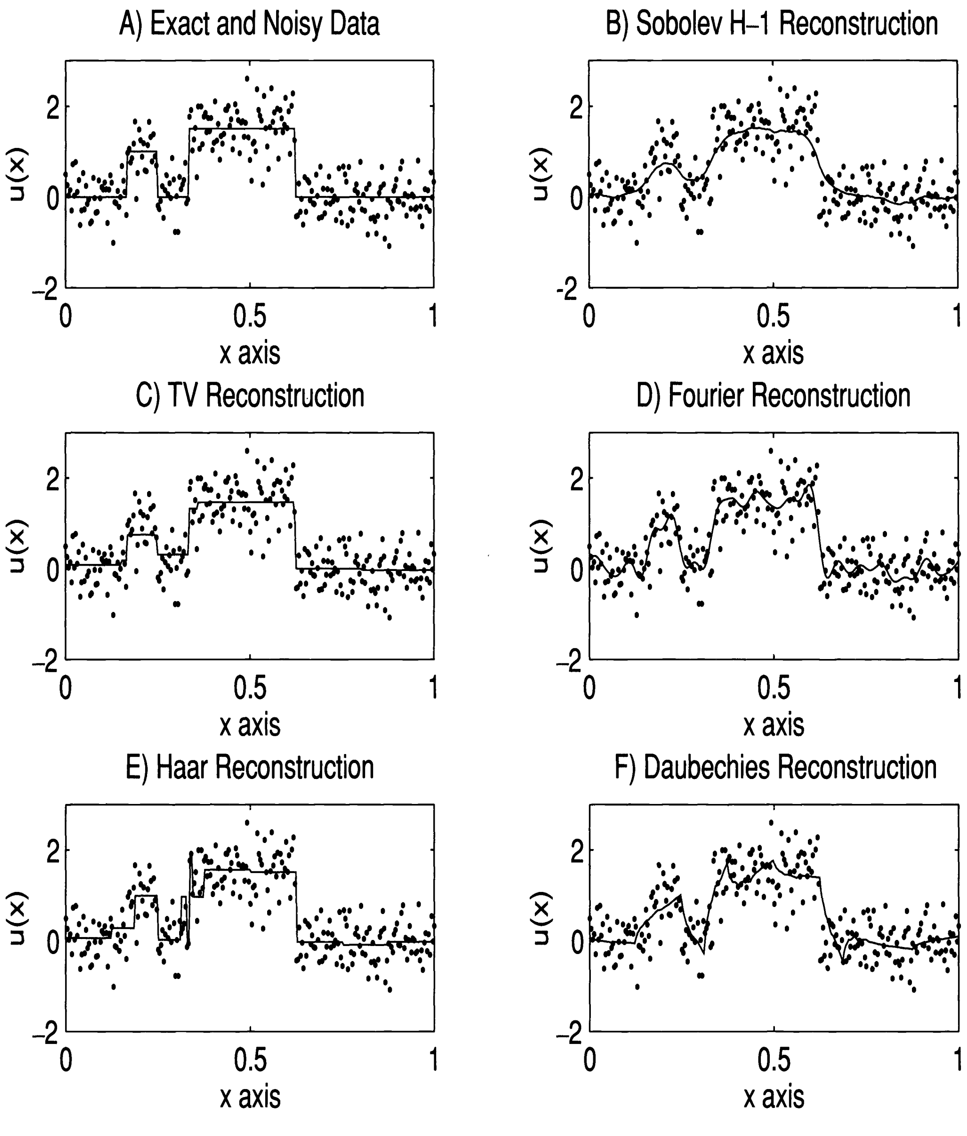

FIG. 1. *Denoised reconstructions obtained using a variety of filtering techniques. Dotted lines represent noisy data. Solid line in subplot A is the exact solution. Solid lines in subplots B–F are reconstructions. Reconstructions E and F were obtained using Haar and Daubechies's wavelets, respectively. See* §4 *for details.*

and α and β are (typically small) positive parameters. The parameter α controls the trade-off between goodness of fit to the data, as measured by $\|u - z\|$, and the variability of the solution, measured by $J_\beta(u)$. When $\beta = 1$, $J_\beta(u)$ represents the surface area of the graph of u, while $\beta = 0$ gives the total variation of u.

When $\beta = 0$, TV-penalized least squares can be viewed as a penalty method (see [11]) to solve the constrained problem (1.2). The penalty parameter α in (1.3) is inversely proportional to the Lagrange multiplier for (1.2). This penalty approach is standard in the inverse problems community and is commonly referred to as Tikhonov regularization. Provided the parameters are selected appropriately, the solutions obtained by these two methods are identical. However, from a computational standpoint, unconstrained problems are much easier to implement than constrained problems.

To solve their constrained minimization problem, Rudin, Osher, and Fatemi applied artificial time evolution. In the context of the unconstrained problem (1.3), this amounts to assuming u is a function of time t (as well as space) and then time-integrating the differential equation

$$\frac{\partial u}{\partial t} = -g(u), \quad t > 0, \tag{1.5}$$

$$u = u^{(0)}, \quad t = 0, \tag{1.6}$$

to steady state. Here $g(u)$ denotes the gradient (derivative with respect to u) of the TV-penalized least squares functional (1.3), and $u^{(0)}$ is an initial guess for the solution. Formally, g is a nonlinear elliptic partial differential operator with homogeneous Neumann boundary conditions

$$g(u) = u - \alpha \nabla \cdot \left(\frac{\nabla u}{\sqrt{|\nabla u|^2 + \beta^2}} \right) - z, \quad x \in \Omega, \tag{1.7}$$

$$\frac{\partial u}{\partial n} = 0, \quad x \in \partial\Omega. \tag{1.8}$$

After spatial discretization, Rudin, Osher, and Fatemi applied explicit (forward Euler) time marching to obtain a gradient descent scheme. In the context of (1.5), this approach yields

$$u^{(k+1)} = u^{(k)} - \tau_k \, g(u^{(k)}), \quad k = 0, 1, \ldots. \tag{1.9}$$

A line search (see [4]) can be added to select the step size τ_k in a manner that gives sufficient decrease in the objective functional in (1.3) to guarantee convergence to a minimizer. This gives the method of steepest descent (see [11]). While numerical implementation is straightforward, steepest descent has rather undesirable asymptotic convergence properties that can make it very inefficient. Obviously, one can apply other standard unconstrained optimization methods with better convergence properties, like the nonlinear conjugate gradient method or Newton's method. These methods converge rapidly near a minimizer *provided the objective functional depends smoothly on u.* When $\beta = 0$, the term J_β in (1.3) is not differentiable. For small values of β, the near nondifferentiability of the objective functional results in a loss of robustness and efficiency for higher-order methods like Newton's method.

In this paper we introduce an alternative approach to minimizing (1.3) that we call "lagged diffusivity fixed point iteration," denoted by FP. At a minimizer, $g(u) = 0$ or, equivalently,

$$u + \alpha \, L(u) u = z, \tag{1.10}$$

where $L(u)$ is the diffusion operator whose action on a function v is given by

$$L(u)v = -\nabla \cdot \left(\frac{1}{\sqrt{|\nabla u|^2 + \beta^2}} \nabla v \right). \tag{1.11}$$

FP iteration can be expressed as

$$\left(1 + \alpha \, L(u^{(k)})\right) u^{(k+1)} = z, \quad k = 0, 1, \ldots. \tag{1.12}$$

Note that at each iteration one must solve a linear diffusion equation, whose diffusivity depends on the previous iterate $u^{(k)}$, to obtain the new iterate $u^{(k+1)}$. In our numerical experiments, we have observed global convergence of FP iteration. We suspect this is true in general because the mapping $u \mapsto L(u)u$ is monotone (see [9]). Hence, there appears to be no need for a "globalization" procedure like a line search to guarantee convergence, as is the case with standard optimization methods. In addition, this method exhibits rapid linear convergence for a broad range of the parameters α and β.

In the following section, we discuss the mathematical structure of the TV-penalized least squares functional (1.3) and the equations that arise in its minimization. Section 3 deals with numerical implementation issues like discretization, stopping criteria, and iterative methods to solve (large, sparse) linear systems. In the final section we present a numerical comparison of FP iteration with Newton's method and steepest descent. Results of a numerical study of the effects of various parameters (e.g., α and β in (1.3)) are also presented in this section. Finally, we apply FP iteration to denoise actual data obtained from a confocal scanning microscope [19].

2. Mathematical structure. In this section we discuss the mathematical structure of the TV-penalized least squares functional (1.3) and the implications of this structure for numerical methods. An analysis of a similar functional,

$$\frac{1}{2}\|Ku - z\|^2 + \alpha J_\beta(u), \tag{2.1}$$

has been carried out in [1], where K is a compact linear operator mapping $L^p(\Omega)$ into $L^2(\Omega)$, with $1 \le p < d/(d-1)$. d is the spatial dimension. This analysis relies on the relative compactness of sets of the form

$$\{u \in L^p(\Omega) : \|u\|_p + J_\beta(u) \le B\}, \tag{2.2}$$

where B is a fixed constant, in $L^p(\Omega)$.

Perhaps the most important difference in the analysis of (1.3) is the fact that sets of the form (2.2) are *not* relatively compact in $L^2(\Omega)$ for dimensions $d > 1$. Following §2 of [1], define the functional

$$Q(u, \vec{v}) = \int_\Omega \left[\frac{1}{2}(u-z)^2 - \alpha\, u\, \nabla \cdot \vec{v} + \alpha\beta\sqrt{1 - |\vec{v}|^2}\right] dx. \tag{2.3}$$

Also define

$$f(u) = \sup_{\vec{v} \in \mathcal{V}} Q(u, \vec{v}), \tag{2.4}$$

where

$$\mathcal{V} = \{\vec{v} \in C_0^\infty(\Omega; R^d) : |\vec{v}(x)| \le 1\}. \tag{2.5}$$

For u sufficiently smooth (say, in $C^1(\Omega)$), this coincides with the functional in (1.3)–(1.4). We wish to find $u^* \in L^2(\Omega)$ for which

$$f(u^*) = \inf_{u \in L^2(\Omega)} f(u). \tag{2.6}$$

THEOREM 2.1. *Problem* (2.6) *has a unique solution.*

Proof. Note that $f(u)$ is L^2-coercive; i.e., $f(u) \to \infty$ whenever $\|u\|_2 \to \infty$. This combined with the weak compactness of closed balls in $L^2(\Omega)$ and the weak lower-semicontinuity of f yields existence. Uniqueness follows from the strict convexity of the L^2 norm. □

While we have not yet been able to rigorously establish this fact, it appears that the minimizer is stable with respect to perturbations in the data z and the parameters α and β. This has the following implications:

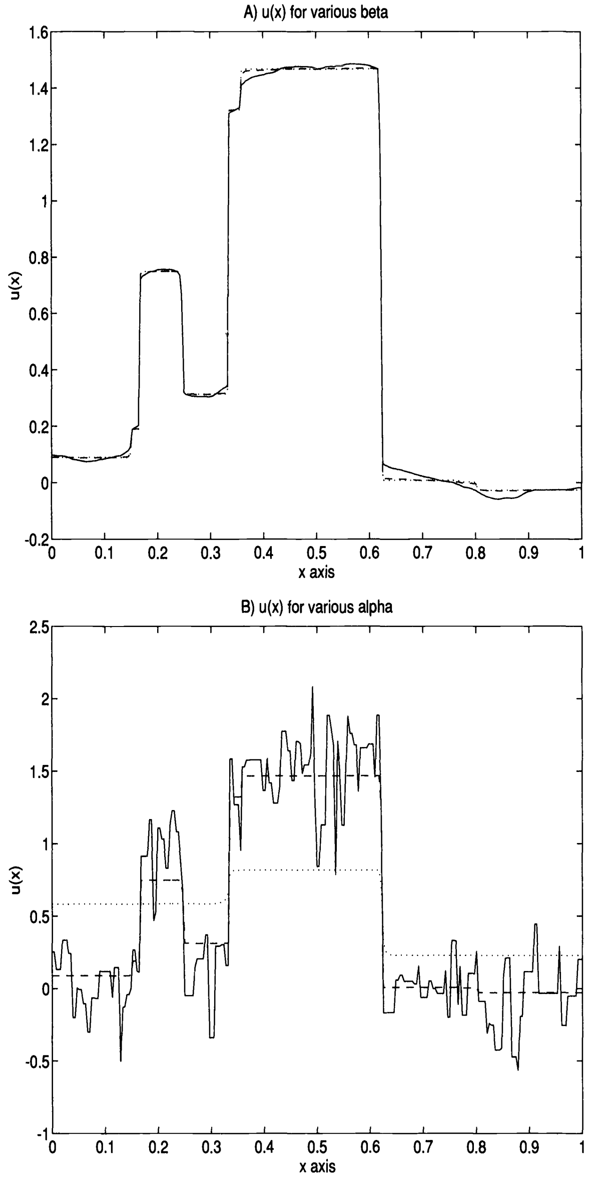

FIG. 2. *Subplot A shows TV reconstructions for various β's with fixed α = 0.01. Solid line corresponds to $\beta = .1$, dashed line to $\beta = .01$, and dotted line to $\beta = 10^{-6}$. Subplot B shows reconstructions for various α's with fixed $\beta = 10^{-4}$. Solid line corresponds to $\alpha = .001$, dashed line to $\alpha = .01$, and dotted line to $\alpha = .1$. See* §4 *for details.*

(i) Taking β small but positive in (1.3) gives minimizers that are close (in an L^2 sense) to minimizers obtained with $\beta = 0$. This is illustrated in Fig. 2A.

(ii) As $\alpha \rightarrow 0$, the minimizer $u = u_\alpha$ in (1.3) tends to the (noisy) data z. On the other hand, as α becomes large, u_α tends to the mean value of z. This is illustrated in Fig. 2B.

We next examine the operators arising in the minimization of (1.3). Taking the first Gateaux derivative in the direction v and assuming u and v are smooth, one obtains the gradient

$$\langle g(u), v\rangle = \int_\Omega \left((u-z)v + \alpha\left(\frac{\nabla u \cdot \nabla v}{\sqrt{|\nabla u|^2+\beta^2}}\right)\right) dx. \tag{2.7}$$

Similarly, one obtains the Hessian

$$\langle H(u)v, w\rangle = \int_\Omega \left(vw + \alpha\frac{\nabla v \cdot \nabla w}{(|\nabla u|^2+\beta^2)^{3/2}}\right) dx. \tag{2.8}$$

The quadratic approximation

$$f(u+s) = f(u) + \langle g(u), s\rangle + \frac{1}{2}\langle H(u)s, s\rangle + o(\|s\|^2) \tag{2.9}$$

is the basis for the analysis of standard optimization methods. In particular, the spectrum of the Hessian $H(u)$ determines the asymptotic convergence rate of the methods of steepest descent and the (nonlinear) conjugate gradient method (see [11]). One obtains local quadratic convergence for Newton's method assuming that $H(u)$ is Lipschitz continuous and has a bounded inverse (see [4]). The size of the convergence region is proportional to the inverse of the Lipschitz constant and the bound on the inverse. Note that if $\beta = 0$ and ∇u vanishes anywhere in Ω, then $f(u)$ is not differentiable. This is a consequence of the nondifferentiability of the Euclidean norm. This difficulty is overcome when $\beta > 0$, but the Lipschitz constant behaves like β^{-3} when β is small. This explains the deterioration in the performance of Newton's method observed in §4 for small values of β.

Again assuming sufficient smoothness and applying Green's identity (integration by parts) in (2.7), one obtains

$$\begin{aligned}\langle g(u), v\rangle &= \int_\Omega \left((u-z) - \alpha\nabla\cdot\left(\frac{\nabla u}{\sqrt{|\nabla u|^2+\beta^2}}\right)\right) v\, dx \\ &+\alpha\int_{\partial\Omega}\frac{\nabla u\cdot n}{\sqrt{|\nabla u|^2+\beta^2}} ds,\end{aligned} \tag{2.10}$$

where n is the outward unit normal to the boundary $\partial\Omega$. Consequently, a minimizer for (1.3) is a weak solution to the nonlinear second-order elliptic PDE

$$g(u) \stackrel{\text{def}}{=} u - \alpha\nabla\cdot\left(\frac{\nabla u}{\sqrt{|\nabla u|^2+\beta^2}}\right) - z = 0, \quad x \in \Omega, \tag{2.11}$$

$$\frac{\partial u}{\partial n} = 0, \quad x \in \partial\Omega. \tag{2.12}$$

This can be expressed in operator form

$$A(u)u = (1+\alpha L_\beta(u))u = z, \tag{2.13}$$

where

$$L_\beta(u)v = -\nabla\cdot\left(\kappa_\beta(u)\nabla v\right) \tag{2.14}$$

and

$$\kappa_\beta(u) = \frac{1}{\sqrt{|\nabla u|^2+\beta^2}}. \tag{2.15}$$

Note that the operator L_β is symmetric and positive semidefinite. Its null space consists of the constant functions. The diffusivity $\kappa_\beta(u)$ is bounded above by $\frac{1}{\beta}$ and below by zero.

Finally, observe that the Hessian is related to the operators $A(u)$ and $L_\beta(u)$ by

$$\begin{aligned} H(u) &= 1 + \alpha L_\beta(u) + \alpha L'_\beta(u)u \\ &= A(u) + \alpha L'_\beta(u)u, \end{aligned} \tag{2.16}$$

where $'$ denotes differentiation with respect to u.

3. Numerical implementation. Any discretization of (1.3) should allow for very sharp gradients without introducing spurious oscillations in the solution u. We have implemented several finite element methods (which are based on (2.7)) with piecewise linear basis functions and the first-order accurate finite difference scheme described in [15] (based on (2.11)–(2.12)). The resulting discrete systems are quite similar. These schemes yield discrete Hessians H, cf. (2.8), and matrix operators A, cf. (2.13), which are symmetric and positive definite (SPD) and sparse—tridiagonal in one space dimension and block tridiagonal in two dimensions. Let $\mathbf{u}$ and $\mathbf{z}$ denote the vectors (mesh functions) obtained from the discretization of u and z, respectively. Also, denote by $f(\mathbf{u})$, $\mathbf{g}(\mathbf{u})$, $H(\mathbf{u})$, and $A(\mathbf{u})$, respectively, the discretization of the objective functional (1.3), its gradient, Hessian, and the operator A in (2.13).

What follows is a generic algorithm for the minimization of $f(\mathbf{u})$. The superscript (k) denotes iteration count. Let $\mathbf{u}^{(0)}$ be an initial guess. For $k = 0, 1, \ldots,$

1. Compute a descent direction $\mathbf{d}^{(k)}$ for f at $\mathbf{u}^{(k)}$.
2. $\mathbf{u}^{(k+1)} = \mathbf{u}^{(k)} + \lambda^* \mathbf{d}^{(k)}$, where

$$\lambda^* = \text{argmin}_{\lambda>0} f(\mathbf{u}^{(k)} + \lambda \mathbf{d}^{(k)}).$$

3. Check stopping criteria.

For the method of steepest descent, $\mathbf{d}_{SD}^{(k)} = -\mathbf{g}^{(k)} \overset{\text{def}}{=} -\mathbf{g}(\mathbf{u}^{(k)})$, while for Newton's method,

$$\mathbf{d}_N^{(k)} = -H(\mathbf{u}^{(k)})^{-1}\mathbf{g}^{(k)}. \tag{3.1}$$

Note that the line search in step 2 may be replaced by a trust region method [4]. Either "globalization" technique will guarantee convergence to the minimizer of f.

For our FP iteration, steps 1 and 2 are combined. One obtains $\mathbf{u}^{(k+1)}$ directly by solving the linear system

$$A(\mathbf{u}^{(k)})\mathbf{u}^{(k+1)} = \mathbf{z}. \tag{3.2}$$

Setting $\mathbf{d}_{FP}^{(k)} = \mathbf{u}^{(k+1)} - \mathbf{u}^{(k)}$ yields

$$\begin{aligned} \mathbf{d}_{FP}^{(k)} &= -A(\mathbf{u}^{(k)})^{-1}\left(A(\mathbf{u}^{(k)})\,\mathbf{u}^{(k)} - z\right) && (3.3)\\ &= -A(\mathbf{u}^{(k)})^{-1}\, g(\mathbf{u}^{(k)}). && (3.4) \end{aligned}$$

The second equality follows from (2.11) and (2.14). Hence FP iteration is of quasi-Newton form, and existing convergence theory in [4] can be applied. Since the matrix $A(\mathbf{u})$ is SPD with its minimum eigenvalue bounded away from zero, each of the $\mathbf{d}_{FP}^{(k)}$'s is a descent direction, and global convergence can be guaranteed by "globalization," i.e., appropriate step size control. In our computational experiments, we have not found globalization to be necessary. Comparing (3.1) and (3.3) and observing that the term $\alpha L'_\beta(u)u$ in (2.16) does not vanish, the asymptotic convergence rate is linear.

The following stopping criteria are standard (see [4]). δ_1, δ_2, and δ_3 are user-defined tolerances, $k_{\max}$ is an iteration limit, and $\|\cdot\|$ denotes the ℓ^2 norm.

$$\|\mathbf{u}^{(k+1)} - \mathbf{u}^{(k)}\| \leq \delta_1, \tag{3.5}$$

$$\|\mathbf{g}^{(k+1)})\| \leq \delta_2, \tag{3.6}$$

$$f(\mathbf{u}^{(k)}) - f(\mathbf{u}^{(k+1)}) \leq \delta_3 \, \|\mathbf{u}^{(k+1)} - \mathbf{u}^{(k)}\|, \tag{3.7}$$

$$k \geq k_{\max}. \tag{3.8}$$

Solving the linear systems. With both Newton's method (cf. (3.1)) and FP iteration (cf. (3.2)), one must solve a sparse SPD linear system at each iteration. In one space dimension, these systems are tridiagonal and can be solved directly in $\mathcal{O}(n)$ operations, where n is the order of the system. In two space dimensions, these systems are block tridiagonal. Direct banded system solvers, which have complexity $\mathcal{O}(n^{3/2})$, may be applied. One may also apply a variety of iterative methods, like preconditioned conjugate gradient (PCG) methods (see [2], [10]) and multigrid methods (see [12] and the references therein).

For certain linear SPD systems arising in the discretization of elliptic PDEs, one can achieve $\mathcal{O}(n)$ complexity with multigrid methods [12]. Our early multigrid implementations, which were based on standard finite difference or finite element discretizations and standard intergrid transfer operators, yielded very disappointing results when u was not smooth. This seems to be due to properties of the diffusion coefficient $\kappa_\beta(u)$; cf. equation (2.15). For nonsmooth u of bounded variation, $\kappa_\beta(u)$ is not smooth. Moreover, on the set (having Lebesgue measure zero) where u is discontinuous, $\kappa_\beta(u)$ vanishes.

To overcome these difficulties, we employed a cell-centered finite difference (CCFD) discretization (see [7] and the references therein). To solve the resulting linear systems, we applied a variant of the multigrid algorithm developed by Ewing and Shen [8]. While pure multigrid iterations were considered in [8], we applied a PCG iteration with a CCFD-based multigrid method as a preconditioner. See [17] for implementation details. Numerical results appear in the following section.

4. Numerical results. In this section we first present a numerical comparison of FP iteration, Newton's method, and steepest descent applied to minimize the TV-penalized least squares functional (1.3). Results are also presented that illustrate the effects of varying the parameters α and β on these methods.

First consider the one-dimensional test problem of denoising the data presented in Fig. 1. The exact (noise-free) solution is

$$u_{\text{exact}}(x) = \chi_{[1/6,1/4]} + \frac{3}{2}\chi_{[1/3,5/8]}, \tag{4.1}$$

where $\chi_{[a,b]}$ denotes the indicator function for the interval $a \leq x \leq b$. The data was generated by evaluating u_{exact} at $N = 257$ equispaced points in the interval $0 \leq x \leq 1$ and adding pseudorandom, uncorrelated error (so-called "discrete white noise") $\{\epsilon_i\}_{i=1}^N$ having a Gaussian distribution with mean 0 and variance σ^2 selected so the noise-to-signal ratio

$$\sqrt{\frac{E(\sum_{i=1}^N \epsilon_i^2)}{\sum_{i=1}^N u(x_i)^2}} = 0.5. \tag{4.2}$$

Here $E(\cdot)$ denotes mathematical expectation. Subplot C shows the minimizer of theTV-penalized least squares functional (1.3). Subplot B shows the minimizer of a related H^1-penalized least squares functional, which is commonly used in data smoothing (see [18])

$$\|u - z\|^2 + \lambda \int_\Omega |\nabla u|^2 \, dx. \tag{4.3}$$

Here the penalty term is the square of the Sobolev H^1 seminorm. It does not allow discontinuous minimizers. On the other hand, it is easy to compute minimizers and is appropriate for denoising smooth functions. Subplot D was obtained by Fourier transforming the data, applying a low pass filter, and then applying the inverse transform. Subplots E and F were created with the aid of the software package `wavethresh`, as documented by Nason and Silverman [14]. Each of these reconstructions was obtained by applying a wavelet transform to the data, applying the universal filter of Donoho and Johnstone [6], and then applying an inverse wavelet transform. In Subplot E, Haar wavelets are used in the transformations (see [16] or [13] for a discussion of Haar wavelets). These wavelets are generated by a discontinuous mother wavelet and are of regularity level 1 (see [14]). This reconstruction clearly maintains the discontinuities of the true image; however, there appear to be extraneous effects similar to ringing that are not a part of the original image. Subplot F uses Daubechies's "extremal phase" wavelets (see [3]), which have regularity level 2 (see [14]). Here, both smoothing and ringing effects are apparent. In all cases, the filter parameters were selected so that

$$\sum_{i=1}^{N} (u(x_i) - z_i)^2 / N \approx \sigma^2. \tag{4.4}$$

Figure 2 shows the qualitative effects of varying the parameters α and β on the minimizer of the TV-penalized least squares functional (1.3). In subplot A, the fixed $\alpha = 0.01$ is selected so (4.4) is satisfied, and β is varied. Larger values of β have the effect of "rounding off sharp edges" in the reconstructions. In subplot B, $\beta = 10^{-2}$ is fixed and α is varied. Solutions tend to be piecewise constant. Larger values of α have the effect of reducing the number of piecewise constant regions.

Figure 3 illustrates the convergence behavior of the various methods for minimizing (1.3), as measured in the ℓ_1 norm of the gradient. In each case, the initial guess was taken to be the zero solution; i.e., $\mathbf{u}^{(0)} = 0$, and $\alpha = 0.01$. Subplots A and B also show the effect of varying the parameter β on the performance of Newton's method with a line search and FP iteration. Note that the Newton iteration converges rapidly for relatively large values of β. However, as β decreases, the performance decreases markedly. The line search restricts the size of steps in order to maintain a steady decrease in $f(\mathbf{u}^{(k)})$, but quadratic convergence is not attained until a very large number of iterations have been performed. See the discussion in §2 for an explanation. FP performance also drops off as β decreases, but unlike Newton's method, the drop off is gradual and there is no dramatic change as β becomes very small. Subplot C illustrates performance of the method of steepest descent. There is a substantial decrease in the norm of the gradient in the first few iterations, but after that the decrease is extremely slow. A thousand steepest descent iterations were required to obtain reconstructions comparable to those obtained with four or five Newton or FP iterations.

Figure 4 shows FP performance as measured by the objective functional (1.3). Note that $f(\mathbf{u}^{(k)})$ decreases monotonically.

Finally, we present a two-dimensional example from confocal microscopy (see [19]). The images in subplots A and B of Fig. 5 show rod-shaped bacteria on a stainless steel surface. The vertical axis represents recorded light intensity, while the horizontal axes represent scaled

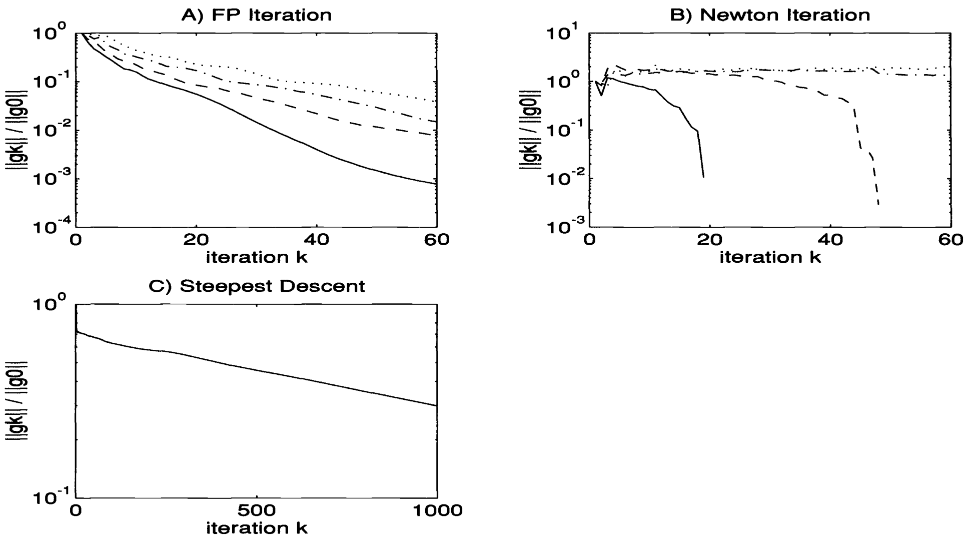

FIG. 3. *Performance of methods measured by the scaled ℓ_1 norm of the gradient $\|\mathbf{g}^{(k)}\|_1/\|\mathbf{g}^{(0)}\|_1$. $\alpha = 0.01$ is fixed throughout. Subplot C shows steepest descent performance for $\beta = 1$ only. Subplot A shows FP performance for $\beta = 1$ (solid line), $\beta = 0.1$ (dashed line), $\beta = 10^{-2}$ (dashed-dotted line), and $\beta = 10^{-3}$ (dotted line). Subplot B shows Newton performance for $\beta = 1$ (solid line), $\beta = 0.1$ (dashed line), $\beta = 10^{-2}$ (dashed-dotted line), and $\beta = 10^{-3}$ (dotted line).*

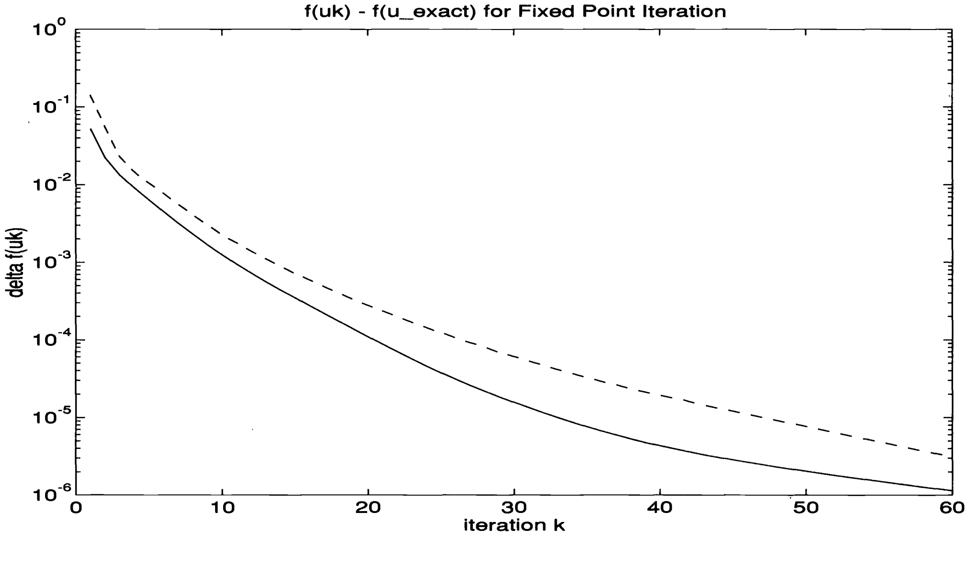

FIG. 4. *Performance of fixed point iteration measured by $f(\mathbf{u}^{(k)}) - f(\mathbf{u}^*)$, where $\mathbf{u}^*$ is the minimizer of f. Solid line is for $\beta = 1$ and dashed line is for $\beta = 0.1$. α is fixed at* 0.01.

pixel locations on a 64 × 64 grid. Figure 5A is an actual image recorded with a scanning confocal microscope. Figure 5B shows a TV reconstruction obtained from the FP algorithm with our CCFD multigrid PCG method used to solve the linear systems at each fixed point iteration. The actual computations were performed on a 256 × 256 pixel grid, with $n \approx 65,000$ unknowns. So that fine details are not obscured, only the upper left hand 64 × 64 subgrid is actually displayed. Parameter values are $\alpha = \beta = .01$.

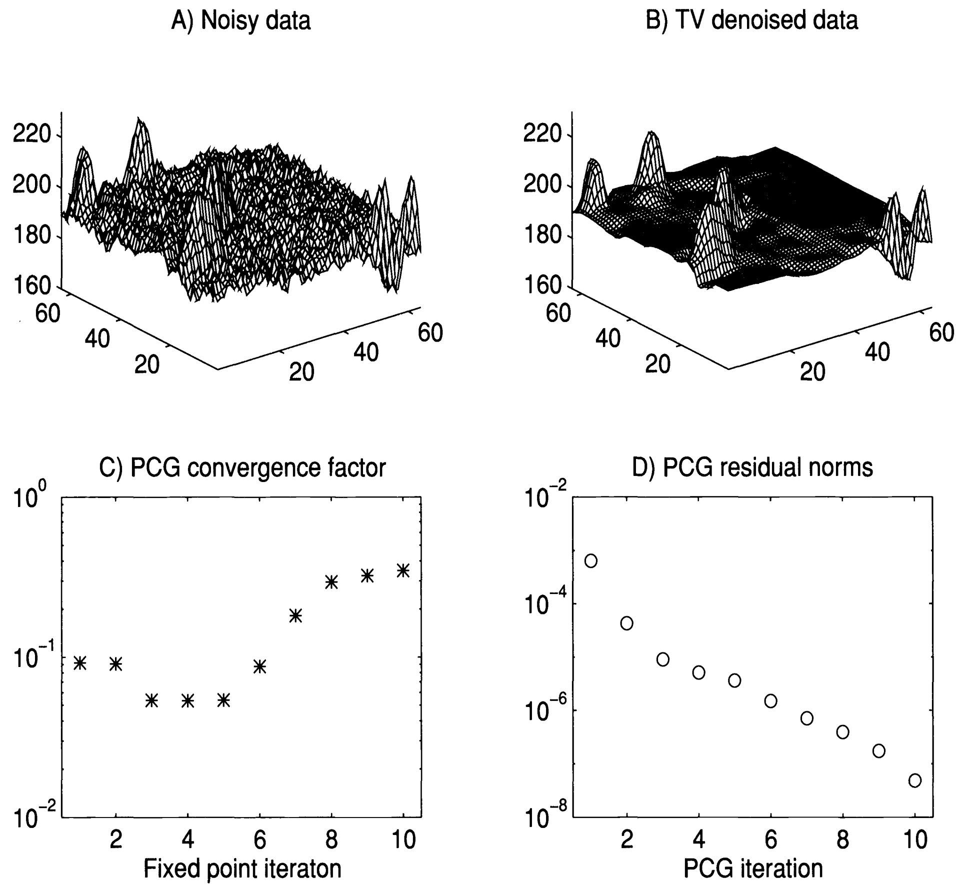

FIG. 5. *Subplot A shows a scanning confocal microscope image of rod-shaped bacteria on a stainless steel surface. Subplot B shows a TV reconstruction obtained using FP iteration. Subplots C and D illustrate performance of the linear system solver.*

Subplots C and D describe the performance of the CCFD multigrid PCG linear system solver. Subplot D shows the norms of residuals $\mathbf{r}_j = \mathbf{z} - A\mathbf{u}_j$ as a function of PCG iteration count at FP iteration 10. $A = A(\mathbf{u}^{(10)})$ is fixed throughout for this subplot. Define the PCG convergence factor to be the ratio $\rho_j = \|\mathbf{r}_j\|/\|\mathbf{r}_{j-1}\|$. Subplot C shows the geometric mean of the convergence factors, $\bar{\rho} = \exp(\sum_j^m \ln \rho_j/m)$, as a function of FP iteration count.

Finally, we note that far fewer that 10 fixed point iterations and 10 PCG iterations per FP iteration were required to obtain comparable denoised images. The purpose of the large number of iterations was to demonstrate the asymptotic convergence properties of the linear iterative method.

MIGRATION OF VECTORIZED ITERATIVE SOLVERS TO DISTRIBUTED-MEMORY ARCHITECTURES*

CLAUDE POMMERELL† AND ROLAND RÜHL‡

Abstract. Distributed-memory parallel processors (DMPPs) can deliver peak performance higher than vector supercomputers while promising a better cost-performance ratio. Programming, however, is harder than on traditional vector systems, especially when problems necessitating unstructured solution methods are considered. A class of such applications, with large resource requirements, is the numerical solution of partial differential equations (PDEs) on nonuniformly refined three-dimensional finite element discretizations. Porting an application of this class from vector and shared-memory parallel machines to DMPPs involves some fundamental algorithm changes, such as grid decomposition, mapping, and coloring strategies. In addition, no standardized language interface is available to ease the efficient parallelization and porting among DMPPs and between vector computers and DMPPs.

This article describes how PILS—an existing package for the iterative solution of large unstructured sparse linear systems of equations on vector computers—was ported to DMPPs, using the parallelizing Fortran compiler Oxygen. Two DMPPs, namely an Intel Paragon and a Fujitsu AP1000, were used to evaluate the performance of the generated parallel program quantitatively. The results indicate how an application should be designed to be portable among supercomputers of different architecture. Several language and architecture features are essential for such a porting process and ease the parallelization of similar applications drastically.

Key words. distributed-memory parallel processing, large-scale scientific computing, iterative solvers, parallelizing compilers, inspector-executor, unstructured sparse matrix computations

1. Introduction.

Recent development in VLSI technology has made distributed-memory parallel processors (DMPPs) attractive alternatives to vector supercomputers. DMPPs offer high peak performance for relatively low investment in computer hardware: powerful microprocessors can be used to build a DMPP processing element (PE) with only few integrated circuits. By connecting many such PEs together in a communication network, it is easy to achieve at least the same peak performance as featured by today's most powerful vector supercomputers.

Unfortunately, DMPPs are still much less comfortable to program. Programming comfort cannot be quantified as precisely as peak performance, but it is clear that more user efforts are required to implement efficient and portable programs. While early research in scientific parallel processing concentrated on isolated parallel algorithms and specialized architectures, many current projects aim to mitigate this lack of general programmability. Approaches include new software technology—like parallel algorithms, operating systems (OS) and parallelizing compilers—and new hardware designs, in particular more powerful DMPP interconnection networks. Portability among DMPPs and, even more, portability between DMPPs and vector supercomputers is often ignored.

In this article, we trace a way to extend the portability of a software package from vector computers to DMPPs, in the hope of providing a guideline for similar ports. Our project is a step toward the full parallelization of existing applications that are based on large and unstructured two- and three-dimensional finite element discretizations.

The article is organized as follows. After defining the project goal and rising the associated questions more precisely, we will introduce the hardware platforms and the two software packages PILS [29] and Oxygen [32] used in our study. We will then discuss additions to the

numerical library PILS that enable an efficient parallelization with the parallelizing compiler Oxygen and conclude with a summary of our measurements on two selected DMPPs.

2. Goal of this project. The distinction between the two classes of supercomputers is far less rigid than it may appear from the above. Pipelined vector operations and parallel computations on distributed memory are two orthogonal architectural concepts to exploit parallelism. Distributed-memory parallel vector processors or superpipelined processors with large caches on a shared-memory bus are examples of hybrid combinations featured in commercial supercomputers available today. If an application proves to be portable from single vector processors to distributed-memory scalar parallel processors, one can safely assume that it will also achieve reasonable efficiency on a supercomputer of hybrid architecture. For the sake of clarity, we distinguish between single vector processors (which we call vector computers) and distributed-memory scalar parallel processors (which we call DMPPs), keeping in mind all variations in between.

The interest of the research community in DMPPs has led all leading vector supercomputer manufacturers to develop new supercomputers that are based on distributed-memory architectures. For many applications, however, DMPP operating systems and compilers are still incapable of assisting the user in obtaining a reasonable fraction of the machine's peak performance, in a way comparable with what can be expected on vector computers. Closing this gap faces many unsolved problems. Among others, the following three questions have yet to be answered.

- How difficult is the migration of existing vector supercomputer application codes to DMPPs, and by what techniques can parallelism expressed for vector operations be translated into parallel computations on data structures in distributed memories?
- How much can the system software (OS and compiler) ease the above migration, and how efficiently could a standardized software interface (for instance, a programming language like High Performance Fortran (HPF) [18]) support the implementation of scientific applications that are portable to both types of high performance architectures?
- How should large-scale applications be designed to achieve high performance on both vector and parallel supercomputers in a portable way?

It is easier to answer the questions above for applications requiring only highly structured computations, like dense matrix linear algebra, or finite element and difference methods applied to structured grids. In fact several research groups have defined Fortran-like languages and implemented compilers to allow portable coding of these applications. The definition of HPF is an attempt to standardize these efforts. The portability on a whole spectrum of architectures has been proven for some of these languages (see for instance [14]).

We are concerned with more unstructured computations, like linear algebra on general sparse matrices, or finite element or finite volume methods applied to nonuniformly refined grids. For this application class some software support must be provided at run-time; standard compile-time dependence analysis techniques fail when control-flow depends on run-time information. If we want to avoid "manual" intervention in the application code, run-time support should either be provided by the OS or by the compiler's run-time library. The three problems above have been discussed by only a few research groups [5], [21].

Strictly speaking, almost any unstructured solution method to a given scientific problem can be substituted by a structured method that is more easily parallelizable, but generally also more resource intensive. With many real-world problems, however, using a less powerful method induces a severe loss that cannot be offset even by massive parallelism. While there are many options to solve a particular problem, the only *efficient* solution method may require unstructured computations. Many publications reporting close to peak performance on some problem in fact use outdated regularly structured methods, and it would be faster to solve the same problem with a state-of-the-art unstructured method running at workstation performance.

This article tries to answer the three questions above for the existing vector supercomputer code PILS, a software Package of Iterative Linear Solvers targeted to the solution of very large, unstructured sparse, unsymmetric, ill-conditioned systems of linear equations. The package is used routinely in finite element-based applications on a range of sequential and vector supercomputers, and we want to extend this portability to DMPPs and among DMPPs. We have parallelized PILS using the compiler Oxygen. The performance of the generated parallel program is evaluated on two DMPP systems, namely the Intel Paragon [19] and the Fujitsu AP1000 [20].

A fully automatic parallelization of such a code would be impossible, just like today's highly mature vectorizing compilers are incapable of achieving high performance on a naive sequential implementation of such an application. Instead, carefully designed data structures together with additional hints to the compiler (usually in the form of directives) are necessary to exploit the architectural features of vector computers. We try to exploit the same restructuring effort in a highly vectorized application and substitute a parallelizing compiler for DMPPs, together with some additional tuning.

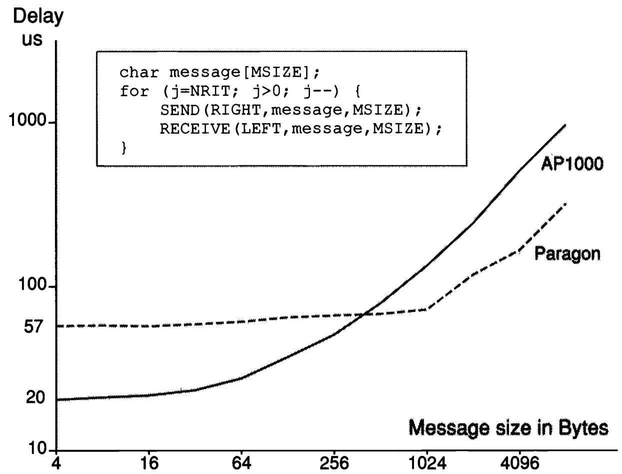
Our self-imposed restrictions include that modifications to the original application are kept to a minimum, so that the code stays fully compatible and compilable on vector computers. Except for the performance gain, the user should not be able to distinguish whether the application runs on a single processor or in parallel on the DMPP. Along with that, most communications are generated transparently by the parallelizing compiler, which hides the underlying message-passing architecture as far as possible.

Many recent studies investigate DMPP implementations of iterative solvers for linear systems. Almost all of these publications aim at a much simpler goal. Most authors consider only regularly structured problems, like 5-point finite difference discretizations of simple PDEs. The resulting matrices do not need a general sparsity data structure; all operations on them can be treated much more efficiently as addition, scaling, and positional shifts on smaller dense matrices. Furthermore, most authors do not consider preconditioning, except possibly for diagonal scaling. Good preconditioners often increase the convergence speed of an iterative method more drastically than parallelization, and many real-world ill-conditioned problems just cannot be solved by unpreconditioned iterative methods. On the other hand, good preconditioners, like approximate factorizations, are more difficult to parallelize than any other component of iterative solvers. Finally, many authors consider only symmetric positive-definite systems, for which conjugate gradients, but also weaker methods like successive over relaxation (SOR) or Jacobi iteration converge well. Despite significant new developments in the last few years, no single unsymmetric variant of conjugate gradients can be seen as universally successful on ill-conditioned unsymmetric linear systems, so that high flexibility in the choice of methods and preconditioners is required.

3. Background.

3.1. Target platforms. We have ported PILS to five different DMPPs: the CM-5 from Thinking Machines, the NEC Cenju-2 and Cenju-3, the Fujitsu AP1000, and the Intel Paragon. Results in this article are only drawn from the latter two.

3.1.1. Intel Paragon. The Intel Paragon XP/S 5+ features Intel i860 XP processors connected in a rectangular mesh. PEs operate at 50 MHz and contain 16 Kbyte data and instruction caches. The maximum bandwidth from cache to floating point unit is 800 Mbytes/s. Hardware communication bandwidth between any two nodes is 200 Mbytes/s full duplex. For this article, parallel measurements were taken on a machine with 32 Mbytes local PE memory,



```
char message[MSIZE];
for (j=NRIT; j>0; j--) {
    SEND(RIGHT,message,MSIZE);
    RECEIVE(LEFT,message,MSIZE);
}
```

FIG. 1. *Execution time of neighbor-to-neighbor communications in the (virtual) torus topology of* AP1000 *and Paragon for various message sizes. Both systems are configured as* 4 × 8 *tori. We use tagged communication operations as specified in the code segment above.*

whereas sequential measurements were performed on a single PE of another (much smaller) machine with 128 Mbytes.

As C compiler and back end to Oxygen, the PGI compiler version 4.5 was used under a beta release of operating system OSF AD 1.2.

The communication library of the Paragon is build on top of OSF. This provides a high functionality (like support of standard UNIX I/O library functions), but requires expensive context switches and thereby affects the utilization of the underlying communication hardware.

3.1.2. Fujitsu AP1000. An AP1000 consists of a collection of processors and a Sun-4 host. Each AP1000 PE consists of a 25 MHz Sparc with FPU, 16 Mbytes DRAM, and 128 Kbytes direct mapped cache memory. Three communication networks are available: the Torus network (T-net) for point-to-point communication between PEs, the Broadcast network (B-net) for host-to-PE communication, and the Synchronization network (S-net) for barrier synchronization. A detailed description of the AP1000 system can be found in [20].

For all our measurements we used the AP1000 OS CellOS1.1, with the Sun-C compiler SC1.0 as back end for Oxygen.

Each processor runs only a relatively primitive microkernel that supports communication to the host and to other processors. The host connects to the outside world and provides general I/O.

3.1.3. Basic measurements. We showed in [2], [3] that the speedup of DMPP programs strongly depends on the DMPP's *communication/computation ratio.*

To determine communication performance, we measure execution time of neighbor-to-neighbor communications in the (virtual) torus topology for various message sizes. Figure 1 compares such measurements on Paragon and AP1000. Both machines are configured as 4 × 8 tori.

The performance of floating point operations is difficult to predict on complex computer architectures, as it depends strongly on the location of the operands in the memory hierarchy. We have therefore measured T_c, the time required to compute a double-precision multiply add operation as in DAXPY, for in-cache and out-of-cache operands. Table 1 shows the results

TABLE 1

Measurements of computation speed (in C-compiled DAXPYs) on the two systems. For comparisons we also include measurements for several Sparc-based workstations, namely Sun SparcStations 1+, 2, *and* 10–41.

	T_c (μs)				
	Paragon	AP1000	SS1+	SS2	SS10
In cache	0.27	1.15	1.93	0.87	0.24
Out of cache	1.14	1.91	2.25	1.18	0.58

for the two DMPPs. Note that code generated by the Paragon C compiler even for the simple DAXPY loop does not run close to peak performance.

3.2. PILS. PILS implements a large number of iterative methods, preconditioners, and other variants for iterative solvers and provides a high degree of flexibility, like automatic adaptation to a more robust preconditioned iterative method whenever the solver that is usually fastest fails to converge. The library is integrated into a number of applications, including several semiconductor device simulators, where the solution of hundreds of ill-conditioned linear systems of similar sparsity structure dominates the overall execution time. PILS and its client applications have been used regularly over four years now, at several dozens of academic and industrial sites.

PILS runs on a number of different platforms, from workstations to supercomputers, including Convex, Cray, Fujitsu, and NEC vector computers. The sparse matrix data structures in PILS are optimized for the use of vector computers.

This section describes those features of PILS that are relevant for our project. Interested readers are referred to [29] for an overview of algorithms and applications, [30] for a performance analysis, and [27] for ample detail on algorithms and implementation.

3.2.1. Colored jagged diagonals based on a partitioning by matchings. Nonzero entries of the sparse matrix are stored in so-called "jagged diagonals" [33], a data structure in which matrix–vector products can be computed with a few long vector operations, even if the number of nonzeros per row or column is small. Every operation on a row-oriented jagged diagonal (where row indices are given implicitly by the storage order, and column indices are stored explicitly in an index vector) accesses one of the argument vectors (on the right-hand side of an assignment) through indirect addressing, using a vector-gather routine.

Column-oriented jagged diagonal operations update a vector by addressing it indirectly both on the left- and the right-hand side of an assignment, requiring vector-gather and vector-scatter routines. To avoid write conflicts in this scatter, the entries in the index vector must be unique. This is obtained through a reordering of the nonzeros resulting from a partitioning by matchings in the associated graph. PILS uses a combination of row- and column-oriented jagged diagonals to save storage on structurally symmetric parts of the matrix and to make transposed matrix–vector multiplication as efficient as matrix–vector multiplication without transposition. Transposed matrix–vector products are important in some of the iterative methods, and are inefficient with many other sparse matrix formats.

The rows of the sparse matrix are further symmetrically permuted into blocks, such that the blocks comprising the diagonal are zero everywhere except on the diagonal itself. This allows for a vectorized solution of sparse triangular systems, which is important for fast no-fill incomplete factorization preconditioners. Such a block structure is obtained after coloring the associated graph of the matrix into sets of independent vertices. Every color block of each triangle of the sparse matrix is stored in separate jagged diagonals.

3.2.2. Language usage for portable vectorization. To meet the requirement for the data structuring and flexibility, PILS is mainly implemented in C++. Because of the existence of a translator to C [37], C++ is available on all machines with a C compiler, including all vector supercomputers. Unfortunately, the code generated by vectorizing C compilers, if available at all, is generally slower than code generated by vectorizing Fortran compilers. For this reason, the most time-critical, vectorizable parts of PILS are written in Fortran. These Fortran parts consist of 46 simple loops and four nested loops. Although they account for only six percent of the total code size, these loops take over 99 percent of the solver's run-time in a typical application and are fully vectorized. The compilation system inserts for each machine the appropriate compiler directives, allowing the vectorizing compiler associative rearrangements of global summations, or asserts that index vectors used on the left-hand side of an assignment are unique and safe for scatter operations.

In particular, all linear algebra operations are handled by these critical loops. Addition, scaling, componentwise multiplication, copying, and zeroing of vectors as well as inner products are among the simple Fortran loops.[1] Sparse matrix operations are supported through several more complicated loops that use indexed addressing and deeper nesting.

The C++ part of PILS constructs data structures, interprets specifications to set up the correctly parametrized solution method, and interfaces with the outside world (e.g., a client application), converting external formats into internal data structures if required. Within the solution process in a preconditioned iterative method, C++ controls the program flow, calls linear algebra routines, and checks convergence through vector norms, but never accesses directly the entries of any of the vectors involved in the iteration. In the computation of sparse matrix–vector products, as well as in the application of no-fill incomplete factorization preconditioners, a C++ program segment guides through the data structure, but the final computation involving the argument and result vectors is performed by Fortran segments.

3.2.3. PILS client applications. Typical client applications for PILS require the solution of many linear systems in which the matrices have different numerical values but only one or a few sparsity structures. These matrices arise, e.g., in the discretization of nonlinear PDEs into a system of nonlinear equations. Every iteration of a Newton solver for this nonlinear system requires the solution of a linear system of equations. Similarly, the solution of time-dependent PDEs calls for the solution of one or more linear systems at each time step. Semiconductor device simulation, our target application [16], requires the solution of up to several hundreds or even thousands of linear systems within the modeling of a system of time-dependent nonlinear PDEs on nonuniformly refined two- or three-dimensional finite element grids. For large simulations, the time to solve linear systems accounts for more than 95 percent of the overall execution time.

As the sparsity structure of the matrices is reused many times, the initialization cost for data structures is amortized over several numerical solver runs. The time used in the inherently sequential algorithms to build vectorizable data structures is negligible in comparison to their benefits.

The linear systems occurring in device simulation can be very ill conditioned. Occasionally, iterative methods preconditioned by standard fast no-fill incomplete factorization preconditioners fail to converge. In such a case, PILS adapts to more robust preconditioners, like approximate factorizations with numerical dropping of fill entries based on a threshold tolerance. Unfortunately, these robust preconditioners offer little room for vectorization or parallelism and run essentially in scalar mode.

3.3. Oxygen. Oxygen is a parallelizing Fortran compiler for DMPPs. It accepts Fortran 77 and compiler directives and generates parallel C code with communication primitives

[1] Note that the collection does not consist only of BLAS1 routines [23]. Most critical loops perform combined operations that allow a more efficient usage of caches, vector registers, and chainable pipelines.

for execution on DMPPs. Originally designed as part of the K2 project [1], the compiler has been ported to several platforms. For a list of such platforms and for an evaluation of the efficiency of Oxygen-generated parallel programs, the interested reader is referred to [31].

Several compilation systems with similar (or more) functionality than Oxygen have been developed recently [40], [24], [17], [22], [13], [41], [6]. Such compilers provide programming comfort and ease program portability on DMPPs and often target automatic parallelization of existing "dusty deck" sequential Fortran programs. As a result of those efforts the HPF standard has evolved [18], which essentially defines a set of Fortran annotations to distribute data and parallelize loops on DMPPs. In all the above systems, distributed data can be accessed through what is commonly referred to as a *global name space*. This means that any processor's reference to an element of a distributed data structure is handled by the compiler, transparently to the user; the compiler inserts communication primitives in the generated DMPP program to allow such remote data references.

For this study, Oxygen serves only as a tool to ease the parallelization of PILS, without making use of its automatic parallelization capabilities. While simple programs like dense linear algebra codes such as LINPACK can be parallelized automatically in an efficient way [26], it is commonly believed that strong user interaction is required to parallelize PILS-like codes, even on simpler parallel architectures such as shared-memory multiprocessors.

The Oxygen input language features a global name space much like HPF. In contrast to the above-mentioned compilers of languages that had some influence on the HPF definition, and also in contrast to the first HPF compilers commercially available (e.g., the HPF subset compiler from Applied Parallel Research [4]), Oxygen includes several features that make it especially well suited for supporting the parallelization of unstructured computations in general and PILS in particular:

- Oxygen directives include constructs to dynamically distribute data and control flow in parallel programs.
- Run-time analysis supports a global name space even in program segments that include arbitrarily nested dependencies on elements of distributed arrays.
- Not only remote fetches, but also *remote updates* of distributed data, are allowed. That is, we do not restrict ourselves to the "owner-computes rule."
- All processors in Oxygen-generated parallel programs execute duplicates of the sequential part and synchronize only implicitly through local communications as required by data exchanges.

Some of the above features are supported also by few other experimental systems (for instance, remote updates by ARF [40]). However, for the DMPP parallelization of PILS, *all* these features are crucial.

3.3.1. Programming paradigm. Most of the systems mentioned above support a global name space primarily through compile-time analysis. The user can specify data distributions in the input language, and the compiler then distributes operations on distributed data by using, for instance, the owner-computes rule; i.e., only the PE that allocates a data item is allowed to change it. To a limited extent, some of the above systems (for instance Fortran D and ARF) support the global name space also through run-time analysis. For code segments for which the compiler cannot statically determine from where to fetch nonlocal data (for instance, when sparse matrix data structures are used), the compiler generates two execution phases: a so-called *inspector* and an *executor*. The inspector preprocesses execution to find out about nonlocal data accesses. The executor performs the actual computation and uses communication patterns constructed by the inspector to fetch nonlocal data. Such run-time analysis introduces significant overhead in execution time. However, many important applications that require such run-time analysis have two important characteristics: (1) the critical code segments are invoked repeatedly, for instance as computational kernels of an iterative solution method; (2) the critical code segments can be *start-time scheduled*; i.e., although control flow depends on run-time information, once a communication pattern has been computed, it can be reused for repeated execution of a given segment.

Oxygen supports a global name space primarily at run-time. It also generates two execution phases for critical code segments: *symbol handlers* and executors. We do not denote the preprocessing phase as inspector because the symbol handler has more functionality: while inspectors can only handle a single level of indirect array accesses, the symbol handler correctly preprocesses code segments with multiple nesting levels of dependencies on nonlocal data. The compiler generates several preprocessor *slices* [10], i.e., symbol-handler iterations that generate communication patterns either for the following symbol-handler iteration or for the executor. Oxygen's run-time analysis is also more powerful in saving communication patterns: driven by compiler directives, for a given code segment, several communication patterns can be saved; communication patterns are stored symbolically, such that preprocessing can be avoided even when a computational kernel is applied to different data (for instance by calling a subroutine with different parameters), as long as the data structures have identical shape. Note that the generation of recursive inspectors has recently also been investigated by other research groups [6], [7].

Oxygen lets the user decide where computation on distributed data is carried out, and both remote fetches and updates of nonlocal data are allowed. Therefore, the input language not only includes directives for data distribution but also for loop distribution. Both data and loops can be distributed dynamically using a user-defined mapping computed at run-time. Unless specified differently by the user, variables are replicated (and not part of the global name space), and sequential code is executed on all processors. Many of the above other systems imply global synchronizations at the end of parallel loops by restricting execution of sequential program parts to one processor or by using collective communication statements to orchestrate nonlocal data accesses. Oxygen generates parallel programs where PEs synchronize only implicitly through the use of local communication primitives (i.e., nonblocking sends and blocking receives) for nonlocal data exchange.

4. Porting PILS with Oxygen. If the linear solver is the main time-consuming operation within an application implemented using PILS, we can obtain a notable benefit by parallelizing only PILS, without touching the client application. Parts with significant parallelism are already marked in PILS as vectorizable parts. These critical loops, mentioned in §3.2.2, are parallelized by Oxygen.

The client application should preferably run sequentially and not see a difference between a sequential or a parallel version of the PILS library. Because of the large memory requirements of a typical client application, and because of necessary OS support, we decided on the AP1000 to run the client application and the mostly sequential parts of PILS that construct data structures on the AP1000 host. On the Paragon, any PE can take the role of the host, since virtual memory and standard UNIX I/O library routine calls are also supported on compute nodes. We decided that Paragon PE 0 both executes the sequential control code and its share of the parallelized code. An alternative model, where one particular PE executes *only* sequential code, was discarded because—for increased parallel efficiency—Oxygen requires the underlying machine to feature a number of processors computable as a power of two. To simplify the following discussion we call Paragon PE 0 as well as the AP1000 host *controller*.

The separation of the numerically intensive, time-consuming part of PILS coded in Fortran and the more complex control and interfacing part coded in C++ led us to the following parallelization strategy:

- All C++ code is executed on the controller.
- All Fortran routines are annotated with parallelization directives and compiled by Oxygen into parallel subroutines to be executed on the PEs.
- Controller and PEs communicate via a remote procedure call interface. This interface requires an additional software layer between C++ and Fortran that determines which parameters to send from controller to PEs on subroutine invocation, and which parameters to return at the end of the routine's parallel execution.

We will now describe the parallelization of the numerically intensive time-consuming Fortran source on the PEs and then explain how the remote procedure call interface was optimized to avoid expensive controller/PE communications.

4.1. Parallelizing the Fortran part. The numerically intensive part of PILS consists of linear algebra operations on vectors and sparse matrices. As mentioned in §3.2.1, matrices are stored in colored jagged diagonals. The part of this data structure that describes the sparsity structure consists mainly of indices for nonzero entries and remains constant while an application is solving many linear systems with the same sparsity structure. The numerical part of the data structure, with one particular instance of values for the nonzero entries, remains constant over the whole iterative algorithm that solves one particular system of linear equations. The average number of nonzeros per row in the matrices ranges typically between five and twenty-two, and there are typically between five and twenty vectors involved in the iteration process. Both matrices and vectors thus have to be distributed for memory and execution-time efficiency.

Matrices can be distributed in a way that they are read only locally during the solution of one linear system. Distributed vectors are accessed remotely and updated in each iteration. We declare them as distributed Fortran arrays, so that remote accesses to vector elements are supported by Oxygen's global name space.

All vectors share the same dynamic distribution in all fifty subroutines. A distribution vector specifying ownership of vector elements (i.e., which element is allocated on which PE) is defined in data distribution directives when vectors are declared. The distribution vector is initialized by the controller/PE interface when the solver starts executing.

The same dynamic partitioning and mapping is also used for simple loops. This makes efficient parallelization of many Fortran routines defining vector–vector operations rather simple, as no linear operation on vectors requires communication. Since Oxygen does not enforce global synchronization at the end of loops, PEs compute fully asynchronously on these operations. Only a few such routines (for instance, the computation of a dot product) require global reduction operations.

The indirect addressing within sparse matrix–vector products constitutes the major challenge. The same operations that require vector-gather routines on a vector computer (see §3.2.1) need remote memory fetching on a DMPP. Oxygen handles these transparently by generating appropriate messages for accesses to the global name space. Since the indirect addresses are not known at compile-time, the communication patterns can only be generated at run-time. As the same patterns are required many times (there are one or two matrix–vector products per iteration, and several tens of iterations to solve a linear system), the executor can reuse communication patterns, and the time-consuming symbol handler is performed only once.

Vector-computer scatter routines writing to an indexed array correspond to remote updates on a DMPP. These operations can be parallelized efficiently only because Oxygen does *not* restrict computation to the owner of a data item. The generation of remote update messages is just as transparent and efficient as remote fetching.

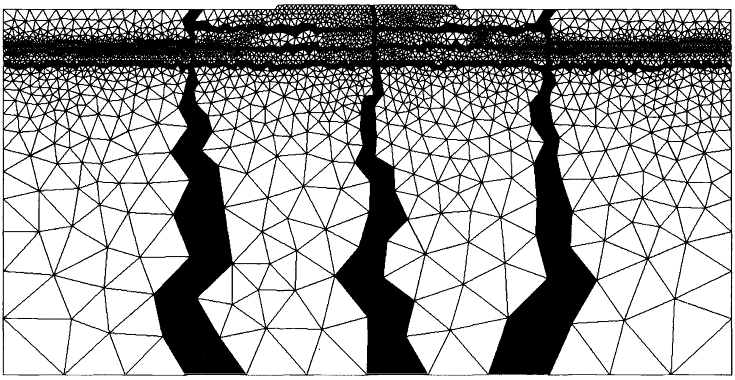


FIG. 2. *Two-dimensional geometric mapping of a refined discretization grid to a* 4 × 4 *processor interconnection network. All elements* (*triangles*) *whose corners are assigned to different processor are drawn in black. White lines crossing black strips correspond to graph edges that require communication; local edges are drawn as black lines.*

4.2. Mapping for locality. Any simple-minded assignment of vector entries to processors would degrade performance disastrously, as almost all indirectly addressed entries would result in remote accesses, and every processor would have to communicate with every other processor. The *mapping problem* for finite element meshes consists of partitioning vectors (and matrix rows and columns) in a way that each processor owns an approximately equal number of entries (for load balancing) and a maximum number of accesses are local. Moreover, a minimum number of other processors should be accessed for remote fetching or updating, and these processors should be at minimum distance in the communication network (thus reducing transfer latency and network contention). The development of heuristics for this (NP-hard) mapping problem is currently a field of active research, and beyond the scope of a parallelizing compiler, but the possibility of defining a dynamic mapping using a distribution list allows us to add problem-specific mapping heuristics to our code.

We selected a two-dimensional geometric mapping heuristic that we had good experience with in an earlier related project [28] and that is well adjusted to the two-dimensional network topologies of both the Paragon and the AP1000. The heuristic proceeds as follows on n vertices mapped to a $p_v \times p_h$ torus or mesh of processors: First, vertices are sorted according to their x-coordinate in the physical discretization grid. This sorted list of vertices is partitioned by $(p_v - 1)$ vertical cut lines into p_v sets of n/p_v vertices each, and each of these sets is assigned to one column of the mesh of processors. Then each set is sorted again according to the y-coordinate and partitioned by $(p_h - 1)$ horizontal cut lines into p_h sets, and each of these sets is assigned to one processor of this column. This algorithm has a time complexity of $O(n \log n)$ and can be used in the sequential part on the controller, as it does not dominate over other algorithms in the construction of the colored jagged diagonal data structure. Figure 2 shows how the discretization grid of the smallest of our test cases was mapped on 16 processors arranged in a 4 × 4 mesh.

Recently, new mapping heuristics such as recursive spectral bisection [35] have been shown to reduce the total number of edges that are cut by processor boundaries. We refrain from such techniques because the eigenvalue computations required in these algorithms would clearly dominate over all other operations in the construction of the PILS data structures. The normal procedure would be to move these computations off line to a separate mapping program whose result is read from the file before starting the parallel program. This would conflict too much with our goal to parallelize PILS transparently from its client application.

4.3. Coloring. Incomplete factorization preconditioners rely on the solution of sparse triangular systems of linear equations. In the case of fast preconditioners with no fill (like ILU or its faster variant D-ILU), the sparsity structure of the triangular matrices for the preconditioner coincides with the corresponding triangle of the system matrix.

The solution of triangular systems imposes higher sequentiality than matrix–vector multiplication. In a lower triangular system $Lx = b$, for instance, the ith entry of the solution vector x_i depends on the calculation of the previous entries, x_j with $j < i$. Apparently, this would impose a synchronization point (with data exchange through communication) for each row. However, sparsity in L reduces the dependencies: x_i depends only on x_j if ℓ_{ij} is nonzero. *Coloring* is a technique to exploit this sparsity in order to construct higher parallelism in triangular system solvers.

Coloring is already used in PILS to vectorize triangular system solvers (see §3.2.1) and is integrated into the colored jagged diagonal data structure. The solution of a triangular system with c colors now results in $(c - 1)$ self-synchronizing data exchanges, adding up to $(2c - 2)$ communication points for a D-ILU preconditioned matrix–vector product. The typical number of colors is around 7 for our two-dimensional grids and around 12 for our three-dimensional grids.

Even if perfect load balance in vector–vector operations and unpreconditioned matrix–vector multiplication is achieved by mapping an equal number of vector entries to each processor, the coloring introduces some imbalance within the processing of each single color. The *balanced greedy coloring heuristic* [28] achieves an equal distribution of each color, at the expense of increasing the total number of colors. As this type of coloring would require certain modifications in the code that handles the jagged diagonal sparse matrix data structure, we refrained from this additional tuning.

4.4. The controller/PE interface. The controller/PE interface replaces Fortran subroutine calls in the C++ PILS source code with a remote procedure call (RPC) interface. It first passes all parameters required for the parallel execution of the subroutine to the PEs, then initiates the start of the corresponding compiler-parallelized routine on the PEs, and finally, after the parallelized routine's execution, the interface collects results necessary on the controller for further execution of the solver. Parameters to be passed include scalars, vectors, and sparse matrices.

For best performance, matrix assembly should be performed in parallel on the PEs. However, as most client applications assemble their matrices outside of PILS, we provide a mechanism to load the matrix from the controller to the PEs, so that the entire client application can run on the controller without necessarily having to be parallelized as well. Correct parallel execution does not require the matrix to be loaded for each parallel matrix–vector operation. As already mentioned above, the matrix is only read accessed and can therefore be loaded only once for each linear system.

Controller-to-PE distribution of vectors jeopardizes efficient parallel execution of any vector operation, if read access to a vector during such operation requires the controller to distribute the vector to the PEs. Iterative solvers spend most of their time updating vectors. Because the PILS source was optimized such that the most time-consuming code was implemented in Fortran, most vector accesses take place *in the Fortran code*; i.e., the controller never overwrites a vector during the iterative solver's execution. Most dependencies from the Fortran subroutines to the controlling C++ code are due to data items involved in control flow decisions, such as the computation of a convergence criterion.

The above observation allows for heavy optimization of the controller-to-PE communication protocol: if indeed a vector is only modified by the Fortran subroutines, it must be distributed to the PEs only once; any future subroutine accessing the same vector will operate on the same data kept resident in the PE memory after the subroutines finish execution.

However, without major changes in the controlling PILS C++ source, it is difficult to decide statically whether any valid vector copy exists on the PEs or whether such a vector should be (re)initialized by the controller/PE interface. Our measurements in §5 show that such a decision can be made efficiently at run-time by the controller/PE interface. As part of that interface we have implemented on the PEs a *controller/PE cache*, which dynamically allocates and downloads from the controller copies of vectors accessed in parallelized Fortran subroutines. Whenever the cache on the PEs finds a valid memory-resident copy of a vector it does not download the vector from the controller.

For result vectors and scalars that are used in the controller code after they are modified by a parallelized Fortran subroutine, the PEs are forced to invalidate the corresponding entry in the controller/PE cache. Such a decision is done statically as part of the controller/PE interface code.

On some platforms controller/PE communications are rather expensive. On the AP1000, for instance, PEs are attached to the host via a VME interface, which is much slower than interprocessor communication channels.

The following two strategies were chosen to further optimize the interface. First, only few parallelized Fortran subroutines actually return data to the controller. These are mostly vector dot products used in the iterative algorithm to compute scalars and control termination. Therefore, the execution of most subroutines can be *pipelined*, which reduces PE idle times due to controller-to-PE latency *and* PE idle times due to interprocessor communication. Oxygen does not introduce global synchronizations at the end of most parallel loops. Second, the controller/PE cache is also implemented on the controller to reduce protocol overhead between controller and PEs. The controller itself computes which data need to be distributed; the PEs take in parallel the same decision about which data need to be received from the controller.

4.5. Visualization. To summarize our porting strategy, we visualize in Fig. 3 different execution phases of a PILS application running in parallel on a 2×4 Paragon system. For the visualization, PILS was instrumented to drive the performance analysis tool ParaGraph [15], which is part of the Paragon programming environment. The following different phases of execution are shown together in a "Task Gantt Chart" [12]: sequential execution of C++ code on PE 0, parallel (and asynchronous) execution of Fortran routines, and the run-time analysis introduced by Oxygen during the first PILS iteration.

The symbol-handler overhead only appears in the first iteration. Later iterations save execution time by reusing communication patterns. Further overhead in the first iteration on PE 0 is due to sequential operations like preconditioner setup. The asynchronous overlapping of computation in different processors is clearly visible during colored preconditioned matrix–vector multiplications using gather and scatter remote accesses.

5. Experimental results.

5.1. Test environment. Our benchmark suite consists of six linear systems extracted from real semiconductor device simulations. These problems are selected to display the variety of problem sizes and complexities within typical large device simulations. Most of our problems are based on three-dimensional discretizations, as two-dimensional device simulation problems are often small enough to be solved more efficiently with sparse direct solvers.

Standard device simulation solves the drift-diffusion equations, a set of three PDEs in three variables. Depending on the operating mode, the discretized equations are solved separately

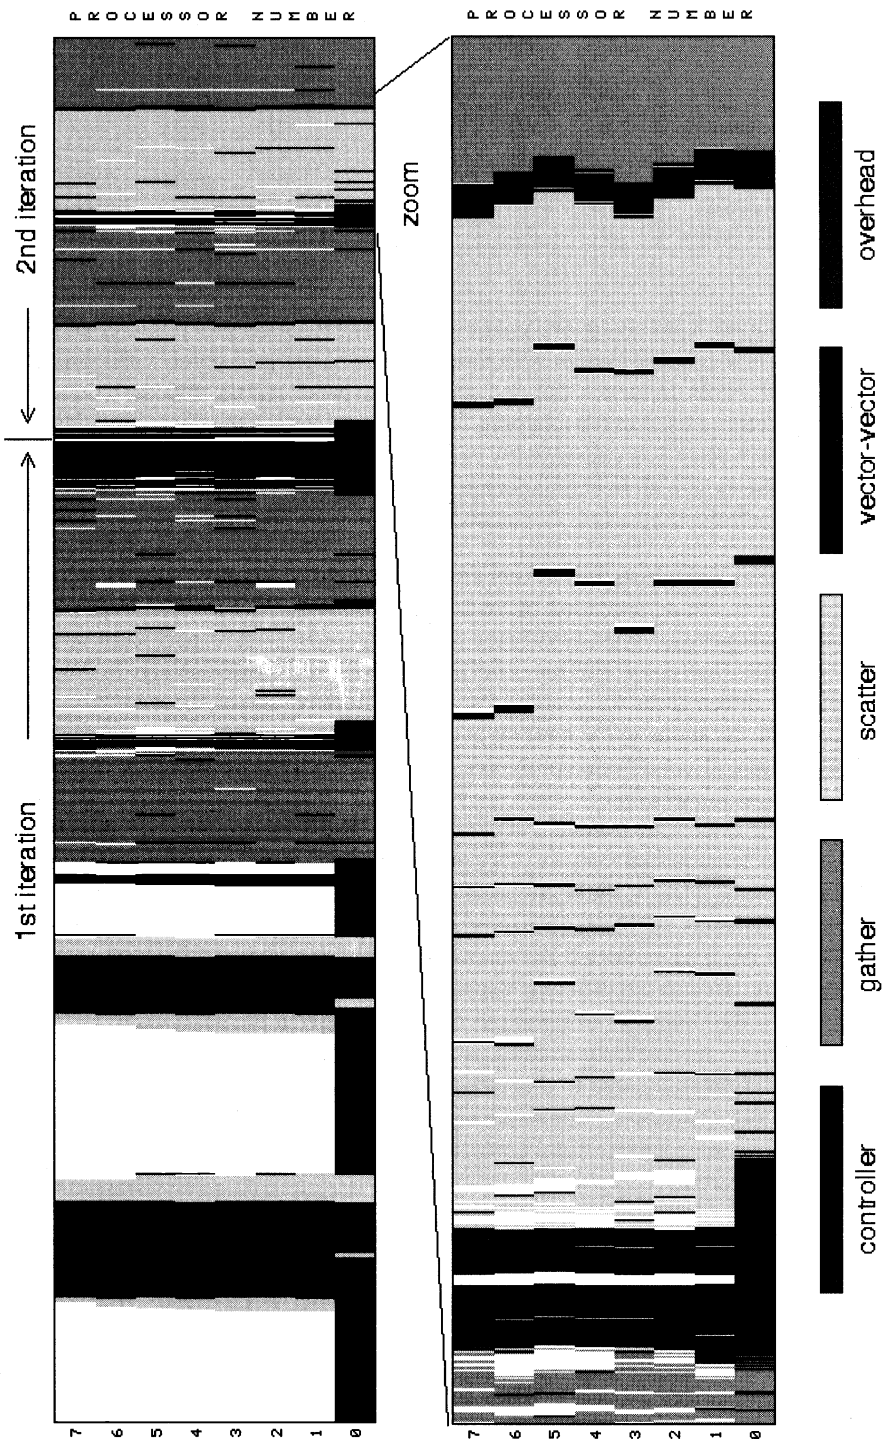

FIG. 3. *The parallel execution of PILS is visualized using Task Gantt charts of ParaGraph. Different execution phases of PILS running on a* 2 × 4 *Paragon are shown in different shades of gray. We distinguish controller execution, Oxygen symbol-handler overhead, and actual parallel computation of different PILS library routines. The top Gantt chart depicts the first and most of the second Bi-CGSTAB iteration; the bottom chart zooms into the solution of a sparse triangular system within a preconditioned matrix–vector multiplication.*

("Gummel iteration"), involving one unknown per discretization grid point, or all three PDEs are assembled in a coupled system with three unknowns per grid point. Grid dimensionality and number of PDEs influence the density of the sparse matrix and the connectivity for partitionings as those used in the mapping. Table 2 summarizes the characteristics of our test problems. Matrix density is conveniently expressed as the number of nonzero entries per row. Unless otherwise noted, all benchmarks are done using Bi-CGSTAB as the iterative solution method, preconditioned by a D-ILU preconditioner in split position.

5.2. Parallel reduction operations and convergence. Iterative solvers are sensitive to rounding errors in the computation of vector dot products. Any parallel implementation of such a reduction operation must modify the summation order with respect to the sequential operation. Since floating-point addition is not associative, even a slight change in the summation order induces a different rounding of the result. In an iterative solver, these rounding variations propagate up to variations in the total number of iterations required to solve a given problem (for very sensitive ill-conditioned problems, such variations may even result in divergence or algorithmic breakdown [27]).

Vector dot products are executed in parallel on a DMPP by summing up globally local dot products on the local partial vectors. Oxygen substitutes tuned library calls for these global summations. Unfortunately, the summation order in these manufacturer-provided library routines typically depends on the number of processors of the underlying machine configuration.

In Table 3 we have collected the number of iterations required for both serial and parallel solver runs. Due to the different sequences of summations when computing vector dot products, the required number of iterations to achieve a given precision (here 10^{-10}) with the parallelized solver may be both smaller or larger than for the serial program run. In order to avoid misinterpretations due to this effect, whenever the measurements presented in this section should demonstrate the efficiency of our parallelization strategy, we refer to only one iteration of the iterative solver. Total execution times are shown only when different solution methods are compared.

5.3. Execution time and speedups per iteration. The total execution time of PILS can roughly be decomposed into three components: (1) execution time of the compute intensive Fortran code, (2) distribution of the matrix from controller to PEs, and (3) overhead of the controller/PE RPC interface. The first component is depicted in Table 4; measurements of the second and third components are summarized in Table 5.

Table 4 summarizes execution times and speedups measured for one iteration running on one Paragon and one AP1000 processor, respectively, on both a SparcStation 1+ and a SparcStation 2, and running in parallel on Paragon and AP1000 systems of different sizes. The parallel execution times refer to the Fortran code only; i.e., no controller/PE communication overhead is included. On the one hand, parallel performance depends on the structure of the problem: larger systems like DR15C achieve high speedups, because the relative importance of the communication overhead decreases. On the other hand, different communication

performance of the underlying DMPP strongly influences speedup measurements. As also shown in Fig. 1 and Table 1, for short messages, the ratio of communication to computation performance is approximately eight times smaller on the AP1000 than on the Paragon. It is therefore not surprising that the highest speedups could be measured on the AP1000. The lower message latency also lets the AP1000 outperform a Paragon with the same number of processors on moderately sized problems.

The major reason for the measured differences on the Paragon and the AP1000 is the different communication performance of the two systems. In order to quantify how important low communication startup latencies are for the efficient distributed-memory parallel execution of PILS, we have depicted in Fig. 4 the total number of PE-to-PE messages communicated in an 8 × 8 AP1000 as a function of the message size for the complete solution of each

TABLE 5

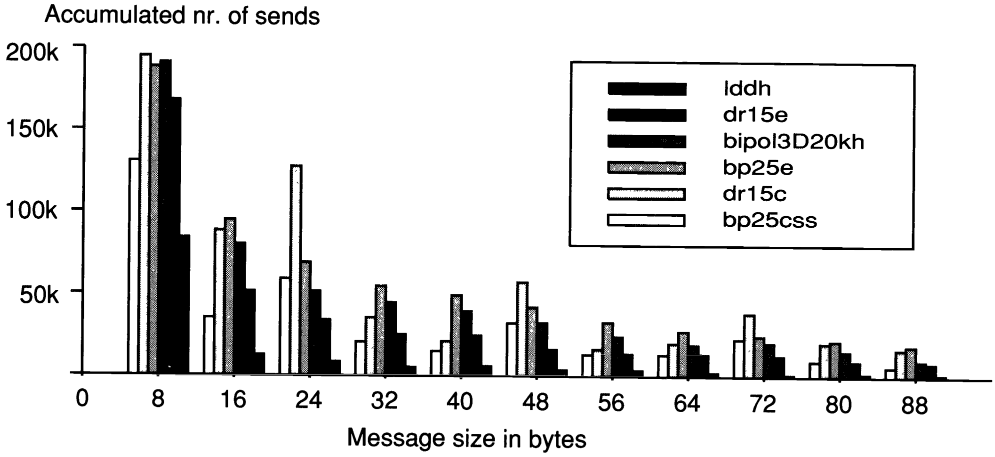

FIG. 4. *Distribution of message sizes for parallel execution on an* 8 × 8 AP1000 *system.*

of the six problems. From this figure it is obvious that very often only small messages are communicated. Since the compiler is able to pack messages optimally at run-time, this distribution only depends on the partitioning strategy and the resulting data dependencies.

5.4. Introducing global synchronizations. Most of the compilation systems mentioned in §3.3 generate collective communication statements at the end of each parallel loop. Therefore at any such point an implicit synchronization of all PEs takes place. When an Oxygen-generated parallel program is executed, only PEs that need to exchange data implicitly synchronize by blocking-receive statements.

To demonstrate what impact global synchronizations have on the overall performance in Table 6 we compare PE execution times per iteration on one hand running an example problem (DR15C) without synchronizations on several Paragon configurations, and on the other hand running the same code with an additional synchronization at the end of each parallel loop. Performance degrades quickly with increasing number of processors. This is partially because

TABLE 6

PE execution times per. iteration (in seconds) without and with global synchronizations introduced after every parallel Fortran loop of the program running on several Paragon configurations.

Paragon configuration	Without synchronization	With synchronization
2×2	1.799	2.269
2×4	1.022	1.765
4×4	0.616	1.630
4×8	0.368	1.626
8×8	0.285	1.830

TABLE 7

Execution time (in seconds) of various variants of methods for one particular problem on 64 processors of an Intel Paragon and a Fujitsu AP1000. *The numbers in parentheses indicate speedup over a single processor. This problem is too large to fit on a single* AP1000 *processor, so we extrapolated the* AP1000 *speedup from SparcStation measurements.*

Method	Preconditioner	Iterations	Time (Speedup)

synchronizations *per se* cost a lot of time (e.g., 600 μs on 32 processors), but also because asynchronously operating PEs can overlap different computation phases (cf. Fig. 3).

5.5. Variants of iterative methods. Table 7 details some other variants of iterative solvers in PILS. For all these experiments, the linear system DR15C was solved to a relative residual norm of 10^{-10}. We compare execution times on 64 processors of an Intel Paragon and a Fujitsu AP1000.

Our experience on other machines has shown that Bi-CGSTAB [38], split preconditioned with a D-ILU factorization, is the fastest iterative method on most of the linear systems occurring in semiconductor device simulation. It appears to be the fastest solver in our DMPP version as well; this is why we chose split D-ILU preconditioned Bi-CGSTAB for all other measurements in this article, and as a reference for the following comparison of other methods. The present section just highlights a few aspects of the methods that appear to be relevant for the parallelization; the interested reader is referred to [27] for further details.

BiCG [11] requires transposed matrix–vector products, which is often an impediment in a parallel implementation. The good speedup here is due to the partitioning by matchings in the jagged diagonal data structure of PILS, and to remote updates in the code generated by Oxygen. Conjugate Gradients Squared (CGS) [36] has a very similar structure to Bi-CGSTAB, which explains the similarity in the parallelization results. GMRES(∞) [34] requires a minimum number of matrix–vector multiplications, at the expense of memory and other operations. In particular, GMRES requires many dot products of vectors. These global reduction operations are a well-known bottleneck in parallel implementations. High message latencies make this bottleneck more visible on the Paragon. The dot-product bottleneck can be reduced by grouping more global reduction operations together or by restarting the method every few iterations (10 in our experiment), but most of these kinds of variants of GMRES appear to lose some numerical stability and convergence speed, and this can be devastating on ill-conditioned problems.

The most popular preconditioners perform an approximate factorization of the original system matrix A into a product of two sparse triangular matrices $A \approx LU$. If $L + U$ has the same sparsity structure as A, a preconditioned matrix–vector product requires twice as many computations as an unpreconditioned product. Our favorite preconditioner is D-ILU, a variant of incomplete factorizations in which all off-diagonal entries of the triangular factors coincide (modulo a diagonal multiplier) with the off-diagonal nonzeros of the original matrix. When D-ILU is used in split position (that is, every preconditioned matrix–vector product applies the operator $L^{-1}AU^{-1}$ to a vector), Eisenstat's trick [8] saves almost half of the computations for a preconditioned matrix–vector product. The savings are only one quarter in right or left preconditioning (using the operators $AU^{-1}L^{-1}$ or $U^{-1}L^{-1}A$, respectively). Classical ILU preconditioning [25], [9] modifies all nonzero entries on unstructured matrices as ours, so that Eisenstat's savings cannot be refunded. The SSOR preconditioner has the same general structure as D-ILU, and thus achieves the same parallelization effect.

Note that the most powerful preconditioner in PILS, an approximate factorization with a numerical threshold, is too finely grained for an efficient parallelization on today's DMPPs. In some large device simulations, a few among several hundreds of linear systems are so ill conditioned that they require this more robust preconditioner. This preconditioner runs mostly in scalar mode on vector computers. In our programming paradigm, it can run sequentially on the controller. A fully distributed parallelization would be severely restricted in this case.

Nested iterative solvers are another alternative for very ill conditioned linear systems that resist standard preconditioning. A preconditioned iterative method (Bi-CGSTAB or GMRES in our examples) is used to precondition another iterative method (Generalized Conjugate Residuals (GCR) in the examples). The inner method is again preconditioned by split D-ILU. The first of the nested solvers listed in Table 7 is equivalent to GMRESR(10) [39]; it uses ten inner iterations for each outer iteration. The inner method of our second nested solver iterates only to a relative tolerance of 10^{-2} or terminates if this inner tolerance cannot be achieved within ten iterations.

6. Conclusions. With the results of §5, and at least for packages similar to PILS, i.e., applications based on finite elements and unstructured sparse matrix computations, we can now answer the three main questions asked at the beginning of this project:

- How difficult is the migration of existing vector supercomputer application codes to DMPPs?
- How much can compilers ease this migration?
- How should applications be designed to keep portability among vector and parallel architectures?

In our case, the migration was possible due to several features of both the application code and the supporting parallelizing compiler.

The clear separation of Fortran code for numerically intensive computing and C++ code for the more complex control-flow decisions was a key feature of PILS allowing us to successfully use the parallelization strategy outlined in §4.4. The fact that two different languages are used to implement both parts is not important; what allowed us to reduce host/PE traffic significantly was the relatively few data dependencies between the two code parts. PILS has been used in several applications, including some semiconductor device simulators. In these applications it was used as a library; i.e., the surrounding application used PILS library calls to solve a linear system of equations stored in memory. The main lesson for the user of similar packages (already optimized for vector supercomputers) is to access main data structures if possible exclusively using library calls provided by the underlying package. The less data traffic exists between the surrounding application and the library, the easier our parallelization strategy could be applied. On the other hand, the package developer should include a set of library routines that cover all reasonable uses of the data, so that uncontrolled direct access to the main data structures can be avoided.

Several features of Oxygen are crucial for the efficient parallelization of PILS: (1) general global name space support at run-time, (2) support of remote fetches and *remote updates* of distributed data (i.e., no "owner computes"), (3) replication of sequential parts of the program execution, and (4) avoidance of global synchronizations by synchronizing processors only locally through the use of local communications as required by data exchanges. None of the other compilation systems listed in §3.3 supports all four of these features.

The general opinion of the DMPP operating system research and development community seems to favor a hostless programming paradigm. We agree that in contrast to host-based machines like the AP1000, on machines like the Paragon, this paradigm offers more elegance and potential to overcome the host I/O bottleneck. However, unless full I/O support is provided on at least some selected PEs of the system (including a large physical and even larger virtual memory), a strategy as outlined in §4.4 for the parallelization of PILS could not be applied to such a hostless system. On the Paragon, which supports virtual memory on all PEs, the lack of physical memory on the controlling PE accounts for longer execution times when solving large problems.

In addition, as we have already done in [2], [3], we must again advocate *balanced* DMPP architectures. Applications like PILS can only be parallelized efficiently on DMPPs if the underlying architecture supports performing computation and communication engines equally well. For host-based DMPPs, the host can be incorporated into the overall parallel application, and thus host communication speed is equally essential. The communication time for message sizes required by a given application should be of the same order of magnitude as the time to consume the message contents in computations. As shown in Fig. 4, the compiler generated parallel code with many small-message exchanges between processors (due to application requirements, not due to compiler restrictions). Therefore, the efficient execution of PILS depends strongly on the communication startup latency featured by the underlying DMPP architecture. A DMPP's communication latency, its communication bandwidth, and its local computation performance should be balanced to support efficient parallel execution of applications similar to PILS.

Acknowledgments. Access to AP1000 machines of various sizes was provided by the Fujitsu Parallel Computing Research Facilities in Kawasaki, Japan. We would like to thank T. Horie from Fujitsu Laboratories Ltd. for his support. We are grateful to M. Vollmer from Intel SSD for providing us access to the above-described Paragon system in Beaverton, OR. We thank W. M. Coughran, K. Decker, and W. Sawyer for their careful proofreading.

A SIMPLE PARALLEL ALGORITHM FOR POLYNOMIAL EVALUATION*

LEI LI†, JIE HU‡, AND TADAO NAKAMURA‡

Abstract. In this paper, we show a simple parallel algorithm for polynomial evaluation. By this method, we only need $2N/p + \log_2 p$ steps on p processors (where $p \leq O(N^{1/2})$) to evaluate a polynomial of degree N on an SIMD computer or an MIMD computer, which is a decrease of $\log_2 p$ steps as compared with the p-order Horner method [S. Lakshmivarahan and S. K. Dhall, *Analysis and Design of Parallel Algorithms*, McGraw-Hill, New York, 1990], and also a decrease of $(2 \log_2 p)^{1/2}$ steps as compared with some other algorithms on an MIMD computer [J. I. Munro and M. Paterson, *J. Comput. System Sci.*, 7 (1973), pp. 189–198, K. Maruyama, *IEEE Trans. Comput.*, C-22 (1973), pp. 2–5]. The new algorithm is simple in structure and easy to implement.

Key words. parallel algorithm, polynomial evaluation

AMS subject classification. MR65

1. Introduction.

As a basic subroutine, the polynomial evaluation of degree N is often used in many parallel iterative computations. For an SIMD computer, Estrin's algorithm [2] needs $T = 2(\log_2 N + 1)$ steps when using $p = [N/2]$ processors; here $[x]$ is an integer satisfying the inequality $x \leq [x] < x+1$. And the p-order Horner method needs $T = 2N/p + 2 \log_2 p$ steps when using p processors [1]. For an MIMD computer, the number of steps can be further decreased but the algorithms become extremely complex to implement. For example, Munro and Paterson [3] and Maruyama [4] proved that $p = N$, $T \leq \log_2 N + (2 \log_2 N)^{1/2} + O(1)$, and when $p = N^{1/2}$, $T \leq 2N/p + \log_2 p + (2 \log_2 p)^{1/2} + O(1)$. Muraoka applied the method of folding and realized $T \leq 1.44 \log_2 N + O(1)$ when using N processors [1]. Even when there is an infinite number of processors, Kosaraju [5] derived a lower bound for $T(N)$ by giving the inequality $T(N) \geq \log_2 N + (2 \log_2 N)^{1/2} - (\log_2 N)^{1/4} - C$, where the constant $C > 0$.

In this paper, we present a simple parallel algorithm for evaluating a polynomial of degree N on an SIMD computer or an MIMD computer. This algorithm needs $T \leq 2N/p + \log_2 p$ steps when using $p \leq O(N^{1/2})$ processors.

2. Algorithm.

Let $f(x)$ be a polynomial of degree N,

$$f(x) = \sum_{i=0}^{N} a_i x^i, \tag{1}$$

and $N + 1 = KL$. Suppose the number of processors $p = L + 1$. First we divide the $N + 1$ items of $f(x)$ into L groups; i.e.,

$$f(x) = \sum_{i=0}^{L-1} b_i x^{iK},$$

where

$$b_i = a_{iK} + a_{iK+1}x + \cdots + a_{iK+K-1}x^{K-1} \quad \text{for } i = 0, 1, \ldots, L - 1. \tag{2}$$

Therefore the new algorithm can be obtained as follows:

*Received by the editors June 29, 1994; accepted for publication (in revised form) December 23, 1994.

†Department of Information System Engineering, Aomori University, Aomori, 030 Japan (lilei@auvax.aomori-u.ac.jp).

‡Graduate School of Information Science, Tohoku University, Sendai, 980 Japan (tadao@archi.is.tohoku.ac.jp).

(a) First, compute $b_0, b_1, \ldots, b_{L-1}$ in parallel using L processors by the vector Horner method. We know $2(K-1)$ steps are needed.

(b) Next, serially compute $x^K, x^{2K}, \ldots, x^{(L-1)K}$.

Now, let us show how to compute each x^{iK} by the fast power method. Suppose $2^r \leq K < 2^{r+1}$; then K can be expressed in binary form:

$$K = d_0 + d_1 * 2 + d_2 * 2^2 + \cdots + d_r * 2^r,$$

where $d_i \in (0, 1), i = 0, 1, \ldots, r-1, d_r = 1$. Then x^K can be written as follows:

$$x^K = x^{d0}(x^{d1}(x^{d2} \ldots (x^{dr-1}(x^{dr})^2)^2 \ldots)^2)^2; \tag{3}$$

therefore x^K can be computed serially in $2r(\leq 2[\log_2 K])$ steps using one processor. Furthermore using $L-2$ multiplications, we can get

$$x^{iK} \quad \text{for } i = 2, 3, \ldots, L-1. \tag{4}$$

(c) And last, compute the inner product

$$b_0 + b_1 x^K + b_2 x^{2K} + \cdots + b_{L-1} x^{(L-1)K} \tag{5}$$

in parallel using L processors. We know that at most $1 + [\log_2 L]$ steps are needed.

3. The analysis of time complexity. Now let us turn to analyze the number of steps of the new algorithm for an MIMD computer. Note that expressions (2)–(4) can be computed in the following parallel way. We compute (2) by using L processors, and compute (3) and (4) by using one processor in parallel. Finally we can compute (5) by using L processors. Thus, the whole process can be computed in parallel in

$$\begin{aligned} T &\leq \max(2K-2, 2\log_2 K + L - 2) + 2 + \log_2 L \\ &= \begin{cases} 2K + \log_2 L & \text{when } L \leq 2K - 2\log_2 K, \\ L + \log_2 K + \log_2(N+1) & \text{when } L > 2K - 2\log_2 K \end{cases} \end{aligned}$$

steps. Let

$$Y_1 = f(L) = 2K + \log_2 L = 2(N+1)/L + \log_2 L \quad (\text{where } L \leq 2K - 2\log_2 K);$$

then the derived function of Y_1 is

$$\begin{aligned} Y_1' &= -2(N+1)/L^2 + 1/\ln 2 * 1/L \\ &= 1/L * (\log_2 e - 2(N+1)/L) < 0. \end{aligned}$$

Thus function Y_1 is monotone decreasing. Similarly, let

$$\begin{aligned} Y_2 = g(L) &= L + \log_2 K + \log_2(N+1) \\ &= L - \log_2 L + 2\log_2(N+1) \quad (\text{where } L > 2K - 2\log_2 K); \end{aligned}$$

then the derived function of Y_2 is

$$Y_2' = 1 - \log_2 e * 1/L > 0,$$

and so Y_2 is monotone increasing. Therefore the number of steps takes the minimum $T = 2K + \log_2 L$ when $L = 2K - 2\log_2 K$. Now we can get the following conclusion.

THEOREM 1. *For an MIMD computer, a polynomial of degree N(where $N+1 = KL$) can be computed in $T = 2K + \log_2 L$ steps at most when using $L+1$ processors, where $L \leq 2K - 2\log_2 K$. And when $L = 2K - 2\log_2 K$, T takes the minimum.*

For an SIMD computer, it is easy to use our method. When $p_0, p_1, \ldots, p_{L-1}$, then do addition. We can let p_L do addition by plus zero. So, we obtain an SIMD algorithm for polynomial evaluation with $T \leq 2K + \log_2 L$, $L \leq K - 2\log_2 K$. Therefore, we can get the following:

$$\text{For an SIMD computer,} \quad T \leq 2N/p + \log_2 p, \quad p < O(N^{1/2}).$$

$$\text{For an MIMD computer,} \quad T \leq 2N/p + \log_2 p, \quad p \leq O(N^{1/2}).$$

4. Conclusion. A simple parallel algorithm for evaluating a polynomial of degree N is presented in this paper. This method needs $2N/p + \log_2 p$ parallel steps on $p \leq O(N^{1/2})$ processors and has decreased by $\log_2 p$ steps and $(2\log_2 p)^{1/2}$ steps as compared with the p-order Horner method [1] and some MIMD methods [3], [4], respectively. The new method is also simple on structure and easy to implement.

A BLOCK QMR METHOD FOR COMPUTING MULTIPLE SIMULTANEOUS SOLUTIONS TO COMPLEX SYMMETRIC SYSTEMS*

WILLIAM E. BOYSE† AND ANDREW A. SEIDL†

Abstract. The solution of complex symmetric indefinite systems of equations where multiple solutions are required is considered. The quasi-minimum residual (QMR) method, ideally suited for these matrices, is generalized using the block Lanczos algorithm to solve multiple solutions simultaneously. This modification alone is shown, through numerical examples involving large sparse matrices from finite element discretization of Maxwell's equations, to accelerate the convergence by a factor almost as great as the number of simultaneous solutions. A natural convergence criterion for this method is presented that is shown to be as effective as, and easier to compute than, the usual equation residual. Finally, a numerical comparison of the classical incomplete Cholesky and a variant of the ILU(T) preconditioners is given showing superior performance by the latter.

Key words. QMR, complex symmetric matrices, block Lanczos algorithm, preconditioner, Maxwell's equations

AMS subject classifications. 65F10, 65N22

1. Introduction. Electromagnetic scattering applications require the solution of large matrix equations for many right-hand side vectors. Typically these vectors correspond to the numerous angles for which the simulated radar return is desired, i.e., monostatic radar cross section (RCS). When using a boundary integral equation method (aka method of moments [12]) the system matrix is general, complex, and dense. For these systems, an LU factorization is performed and the multiple solutions are generated by forward reduction and back substitution. However, when finite element methods are used to model scattering from large three-dimensional objects [1], [7], [6] they produce matrices much too large for direct factorization.

Using the finite element method to discretize Maxwell's equations in differential form necessitates the solution of large sparse complex symmetric indefinite matrices for many right-hand side vectors using iterative methods. This is by far the dominant computational task in all such scattering codes.

Recently an iterative solver of particular merit was developed which specifically addresses the complex symmetric indefinite nature of these matrices [8]. The quasi-minimum residual (QMR) method is theoretically superior to the biconjugate gradient (BCG) method for these problems and exhibits a nearly monotonically decreasing convergence behavior.

In this paper, we generalize the QMR algorithm to solve multiple right-hand side vectors simultaneously as was done for the conjugate gradient (CG) method in [14], [15]. This involves utilization of the block rather than the point Lanczos algorithm and of course the requisite matrix rather than scalar arithmetic. For the application considered, this modification alone results in an acceleration of convergence by a factor almost as great as the number of simultaneous solutions [4]. A natural convergence criterion for this method is also presented and is shown to be equal to the usual equation residual in effectiveness.

Further convergence acceleration is achieved by using an appropriate preconditioner. Both the "classical" incomplete Cholesky preconditioner and a variant of the ILU(T) [17], [18], [3] preconditioner are implemented and evaluated on a scattering problem.

The outline of this paper is as follows. In §2, we present the block version of the QMR algorithm for complex symmetric matrices and the natural convergence criterion. Arguments are given for the potential speedup of convergence by using the block algorithm. In §3,

*Received by the editors June 29, 1994; accepted for publication (in revised form) September 20, 1994.

†Lockheed Palo Alto Research Laboratories, 3251 Hanover Street, Palo Alto, CA 94304-1191 (boyse@lmsc.lockheed.com, seidl@lmsc.lockheed.com).

numerical examples are shown illustrating the effectiveness of the natural convergence criterion and the effects of preconditioning and blocksize on the convergence rate as applied to large finite element problems. Finally, in §4, we draw some conclusions and comment on parallel applications.

2. Block QMR method. The QMR method, based on the Lanczos algorithm, has a natural generalization to the simultaneous solution of multiple right-hand sides in the block Lanczos algorithm. Converting the QMR algorithm to block form requires generalizing vectors and scalars into matrices and deriving a block QR decomposition used in the solution process. The noncommutative nature of matrices requires that all the algebra used in the derivation respect this restriction. The algorithm described and notation used follow [8] with modifications as needed.

We will call the symmetric indefinite bilinear form

$$\langle x, y\rangle_Q = \sum_k x_k y_k, \tag{1}$$

where x and y are complex vectors, the "quasi" inner product. It differs from the usual inner product in that neither constituent is conjugated. With respect to this form, a complex symmetric matrix is "quasi–self-adjoint," i.e.,

$$\langle Ax, y\rangle_Q = \langle x, Ay\rangle_Q. \tag{2}$$

This permits the formal generalization of techniques developed for real symmetric matrices to complex symmetric matrices, as in the derivation of the BCG algorithm from the CG algorithm. In the remainder of the paper, the prefix of quasi will refer to an operation with respect to the bilinear form in (1).

The block QMR algorithm used addresses the solution of a system of equations involving a complex symmetric indefinite matrix

$$\mathbf{A}x = b, \tag{3}$$

where **A** is an n-by-n matrix, and x and b are n-by-m matrices. In this case, the m columns of b are m right-hand side vectors and the m columns of x are their corresponding solution vectors.

2.1. Symmetric block Lanczos recursion. Let x_0 be an initial guess at the solution, which may be zero. The symmetric block Lanczos algorithm is then

Initialization:

$$r_0 = b - Ax_0 \tag{4}$$

$$v_0 = 0 \tag{5}$$

$$\tilde{v}_1 = r_0 \tag{6}$$

For k = 1, 2, 3, . . .

$$v_k\beta_k = \tilde{v}_k \tag{7}$$

$$\tilde{v}_{k+1} = Av_k - v_{k-1}\beta_k^T \tag{8}$$

$$\alpha_k = v_k^T \tilde{v}_{k+1} \tag{9}$$

$$\tilde{v}_{k+1} = \tilde{v}_{k+1} - v_k\alpha_k \tag{10}$$

where α_k and β_k are m-by-m matrices, v_k and $\tilde{v}_k$ are n-by-m matrices, and the superscript T denotes the transpose. The operation described by (7) is the quasi-QR decomposition of $\tilde{v}_k$, where $\tilde{v}_k$ is written as a quasi-unitary matrix v_k times an upper triangular matrix β_k. This decomposition is computed using the modified Gram–Schmidt process using the quasi inner product. The Lanczos algorithm is due to Pissanetzky [16] and differs from [8] in that the computation of α_k in (9) is performed after the partial orthogonalization of Av_k in (8).

The matrix V_k is defined to be the aggregate of the columns of the individual v_j's for $j = 1, \dots, k$,

$$V_k = \begin{bmatrix} v_1 & v_2 & \dots & v_k \end{bmatrix}, \tag{11}$$

and the $k+1$-by-k block tridiagonal matrix $\tilde{T}^k$ is defined by

$$\tilde{T}_k = \begin{bmatrix} \alpha_1 & \beta_2^T & & & \\ \beta_2 & \alpha_2 & & & \\ & & \ddots & & \\ & & & \alpha_{k-1} & \beta_k^T \\ & & & \beta_k & \alpha_k \\ & & & & \beta_{k+1} \end{bmatrix}. \tag{12}$$

The Lanczos algorithm thus provides the block tridiagonal representation of the matrix A in terms of V_k,

$$AV_k = V_{k+1}\tilde{T}_k, \tag{13}$$

where the columns of V_k are a quasi-orthonormal basis for the Krylov subspace generated by all the right-hand side vectors

$$\mathrm{K}_k = \mathrm{Span}\{A^j \operatorname{col}_i(b - Ax_0) | 0 \le j \le k-1, 1 \le i \le m\}, \tag{14}$$

where $\operatorname{col}_i(b)$ is the ith column of b.

2.2. Block QMR algorithm. At iteration k we seek an approximate solution x_k of the form

$$x_k = x_0 + V_k z_k, \tag{15}$$

where z_k is a $k \cdot m$-by-m complex matrix. That is, each column of $x_k - x_0$ lies in the Krylov subspace K_k (14).

The equation residual for this approximate solution is given by

$$\begin{aligned} r_k &= b - Ax_k & (16)\\ &= b - Ax_0 - AV_k z_k & (17)\\ &= r_0 - AV_k z_k & (18)\\ &= v_1\beta_1 - V_{k+1}\tilde{T}_k z_k. & (19) \end{aligned}$$

Let Ω_k be a $k \cdot m$-by-$k \cdot m$ block diagonal weight matrix

$$\Omega_k = \mathrm{Diag}(\omega_1, \omega_2, \dots, \omega_k), \tag{20}$$

where ω_i is an m-by-m matrix to be defined later. The residual may then be written

$$r_k = V_{k+1}\Omega_{k+1}^{-1}\left[\omega_1 e_1 \beta_1 - \Omega_{k+1}\tilde{T}_k z_k\right], \tag{21}$$

where e_1 is the n-by-m matrix which is zero except for the first m rows, which are the m-by-m identity matrix. This represents each column of the residual matrix as a linear combination of the columns of $V_{k+1}\Omega_{k+1}^{-1}$.

Suppose for a moment that all quantities are in fact real, that $m = 1$, and that Ω_{k+1} is the identity matrix. Then V_k would be a unitary matrix, not just quasi-unitary. The minimum residual solution could then be obtained by minimizing the Euclidean norm of the coefficients of the columns of V_k, i.e., minimizing

$$\|\omega_1 e_1 \beta_1 - \Omega_{k+1}\tilde{T}_k z_k\|. \tag{22}$$

For the complex symmetric case, the QMR algorithm mimics this solution by also minimizing these coefficients, where the block diagonal weighting matrix Ω_{k+1} is chosen so that the columns of $V_{k+1}\Omega_{k+1}^{-1}$ are each of unit Euclidean norm. In light of (20) this may be accomplished by defining

$$\omega_k \quad = \quad \mathrm{Diag}(\|\mathrm{col}_i(v_k)\|). \tag{23}$$

The block QMR algorithm chooses z_k so that

$$\|\mathrm{col}_i(\omega_1 e_1 \beta_1 - \Omega_{k+1}\tilde{T}_k z_k)\| \tag{24}$$

is a minimum independent for $i = 1, \ldots, m$. The natural convergence criterion for this method is the maximum of the minima attained in (24) and is termed the quasi residual.

This minimization is accomplished using the QR decomposition [11], where a unitary matrix Q_{k+1} is determined so that

$$\begin{aligned} Q_{k+1}\Omega_{k+1}\tilde{T}_k \quad &= \quad \begin{bmatrix} R_k \\ 0 \end{bmatrix} \\ &= \quad \begin{bmatrix} \zeta_1 & \eta_2 & \theta_3 & & \\ & \zeta_2 & \eta_2 & \ddots & \\ & & \ddots & \ddots & \theta_k \\ & & & \ddots & \eta_k \\ & & & & \zeta_k \\ & & & & 0 \end{bmatrix}, \end{aligned} \tag{25}$$

where R_k is upper triangular as shown. This factorization is stable for indefinite matrices under consideration.

The matrix Q_{k+1} is updated from the previous iteration by setting

$$Q_{k+1} = \begin{bmatrix} I_{(k-1)m} & 0 \\ 0 & Q(a_k, b_k, c_k, d_k) \end{bmatrix} \begin{bmatrix} Q_k & 0 \\ 0 & I_m \end{bmatrix}, \tag{26}$$

where

$$Q(a_k, b_k, c_k, d_k) = \begin{bmatrix} a_k & b_k \\ c_k & d_k \end{bmatrix} \tag{27}$$

is a $2m$-by-$2m$ unitary matrix written as four m-by-m blocks, and I_m is the m-by-m identity matrix.

A problem equivalent to minimizing (24) may then be written as minimizing

$$\left\|\mathrm{col}_i\left(Q_{k+1}\omega_1 e_1 \beta_1 - \begin{bmatrix} R_k \\ 0 \end{bmatrix} z_k\right)\right\| \tag{28}$$

for $i = 1, \ldots, m$. This is easily done by defining

$$\tilde{t}_{k+1} = Q_{k+1}\omega_1 e_1 \beta_1 = \begin{bmatrix} t_k \\ \tilde{\tau}_{k+1} \end{bmatrix}, \tag{29}$$

where $\tilde{\tau}_{k+1}$ is an m-by-m matrix, and setting

$$z_k = R_k^{-1}\, t_k. \tag{30}$$

The quasi residual QRES_k is computed directly from the quantity $\tilde{\tau}_{k+1}$ as

$$\text{QRES}_k = \max_i \|\text{col}_i(\tilde{\tau}_{k+1})\|. \tag{31}$$

This will be compared with the equation residual

$$\text{RES}_k = \max_i \|\text{col}_i(Ax_k - b)\| \tag{32}$$

as an equivalent convergence criterion. Note that when using these criteria all the simultaneous solutions will satisfy the convergence tolerance individually.

2.3. Block QMR algorithm. The block algorithm closely follows that given in [8]. It is worth noting that Freund's algorithm makes no use of multiplicative commutivity of scalars in its derivation and therefore resembles the current algorithm for which lack of commutivity for matrices must be respected.

Initialization:

$$\begin{aligned}
v_0 = p_0 = p_{-1} &= 0 && (33)\\
c_0 = b_{-1} = b_0 &= 0 && (34)\\
a_0 = d_{-1} = d_0 &= I_m && (35)\\
\tilde{v}_1 &= b - Ax_0 && (36)\\
v_1\beta_1 &= \tilde{v}_1 && (37)\\
\omega_1 &= \text{Diag}\{\|\text{col}_i(v_1)\|\} && (38)\\
\tilde{\tau}_1 &= \omega_1\beta_1 && (39)
\end{aligned}$$

For k = 1, 2, 3, . . .

$$\begin{aligned}
\tilde{v}_{k+1} &= Av_k - v_{k-1}\beta_k^T && (40)\\
\alpha_k &= v_k^T\tilde{v}_{k+1} && (41)\\
\tilde{v}_{k+1} &= \tilde{v}_{k+1} - v_k\alpha_k && (42)\\
v_{k+1}\beta_{k+1} &= \tilde{v}_{k+1} && (43)\\
\omega_{k+1} &= \text{Diag}\{\|\text{col}_i(v_{k+1})\|\} && (44)\\
\theta_k &= b_{k-2}\omega_{k-1}\beta_k^T && (45)\\
\eta_k &= a_{k-1}d_{k-2}\omega_{k-1}\beta_k^T + b_{k-1}\omega_k\alpha_k && (46)\\
\tilde{\zeta}_k &= c_{k-1}d_{k-2}\omega_{k-1}\beta_k^T + d_{k-1}\omega_k\alpha_k && (47)
\end{aligned}$$

Next, a $2m$-by-$2m$ unitary matrix $Q(a_k, b_k, c_k, d_k)$ is computed such that

$$Q(a_k, b_k, c_k, d_k)\begin{bmatrix} \tilde{\zeta}_k \\ \omega_{k+1}\beta_{k+1} \end{bmatrix} = \begin{bmatrix} \zeta_k \\ 0 \end{bmatrix} \tag{48}$$

where ζ_k is upper triangular. Then,

$$p_k = (v_k - p_{k-1}\eta_k - p_{k-2}\theta_k)\,\zeta_k^{-1} \tag{49}$$

$$\tau_k = a_k\tilde{\tau}_k \tag{50}$$

$$x_k = x_{k-1} + p_k\tau_k \tag{51}$$

$$\tilde{\tau}_{k+1} = c_k\tilde{\tau}_k \tag{52}$$

Here, a_*, b_*, c_*, d_* α_*, β_*, θ_*, η_*, ζ_*, $\tilde{\zeta}_*$, ω_*, τ_*, and $\tilde{\tau}_*$ are all m-by-m matrices with ζ_* and β_* upper triangular. The terms p_*, v_*, $\tilde{v}_*$, and x_* are n-by-m matrices. Equations (37) and (43) are quasi-QR decompositions of the right-hand side matrix in each equation.

At the end of each iteration, the quasi residual is computed and compared with a given convergence limit. The equation residual RES_k may also be computed, either directly or by accumulating in another work matrix [8].

Aside from the obvious matrix arithmetic and quasi-QR factorizations, the main difference between this and Freund's algorithm is the QR factorization in (48). In the point algorithm, this is just a complex Givens rotation of the form

$$Q = \begin{bmatrix} c_j & \overline{s_j} \\ -s_j & c_j \end{bmatrix}. \tag{53}$$

The generalization to the block algorithm necessitates a more general form, (48), which then affects the rest of the algorithm. This factorization is computed using a conventional QR decomposition algorithm [11] of rank $2 \cdot m$ and then partitioning the matrix into four m-by-m submatrices.

2.4. Convergence improvement. O'Leary [14] showed that the effect on the convergence rate of the block CG algorithm, with blocksize of m, was to remove the deleterious effects of the $m - 1$ smallest eigenvalues. Specifically, she showed that while the worse-case convergence rate of the point CG algorithm is determined by the condition number, i.e., ratio of largest to smallest eigenvalue, the worse-case convergence of the block algorithm is determined by the ratio of the largest to mth smallest eigenvalue, and thus is no worse and possibly much better. Theoretically, this could be of great benefit when there are a few small eigenvalues that slow the convergence rate. O'Leary also observed significant convergence acceleration of eigenvalue computations using a block algorithm and randomly generated initial vectors.

A heuristic argument for the convergence advantages of the block algorithm over the point algorithm is given by a comparison of the Krylov subspaces used in the approximations.

In the point algorithm, we have

$$x_k - x_0 \in \text{Span}\{A^j\,(b - Ax_0) | 0 \le j \le k-1\}. \tag{54}$$

Thus, the exact vector $x^* - x_0$ is approximated in a subspace of dimension k. However, in the block algorithm, we have

$$\text{col}_l(x_k - x_0) \in \text{Span}\{A^j\,\text{col}_i(b - Ax_0) | 0 \le j \le k-1, 1 \le i \le m\} \tag{55}$$

for each $l = 1, \ldots, m$. In this case, the approximating subspace has dimension $m \cdot k$, or m times as great as the corresponding point algorithm. The larger dimension of the subspace should provide a better approximation and thus more rapid convergence. The ideal limit of convergence improvement would be a reduction in the number of iterations by a factor of m, exactly corresponding to the increase in dimension of the approximating subspace.

The word "should" must be emphasized because the behavior of this algorithm in real applications is dependent on the right-hand side vectors. Just because the Krylov subspace is larger in the block rather than the point algorithm does not necessarily imply that the approximation will be better. The Krylov subspaces corresponding to the individual right-hand side vectors may not provide good approximations to solutions other than their corresponding one. In extreme cases, the right-hand sides might be linearly dependent, which would cause the presented algorithm to fail completely because the QR decomposition (37) would be singular.

While it is easy to concoct examples that will defeat the block algorithm, it is of most interest to determine what practical problems are amenable to this approach. In the next section, we will show, through a numerical example, real acceleration due entirely to the block Lanczos method as applied to the iterative solution of large finite element problems.

3. Numerical example. The application for which this technique was developed is called the hybrid finite element method (HFEM) [2], [5]. In this method, finite elements are used to discretize Maxwell's equations in differential form in and around the scatterer while a scattering integral equation is used on a smooth enclosing surface, where the fields themselves are smooth, to terminate the finite element mesh and provide the exact near field radiation condition.

The finite element implementation utilizes a scalar and vector potential formulation [1] for the electric field and second-order Lagrangian tetrahedral elements. It is essentially a 3-D vector Helmholtz formulation. The mesh is terminated on a surface of revolution where the integral equation is applied to ensure a radiating solution [13].

The discretization of the integral equation represents the equivalent electric $\vec{J} = \hat{n} \times \vec{H}$ and magnetic $\vec{M} = -\hat{n} \times \vec{E}$ currents using 1-D Hermite-cubic finite elements along the generator and Fourier modes azimuthally for each of the two orthogonal polarizations on the surface, where $\hat{t}$ is directed along the generator from pole to pole, and $\hat{\phi}$ is directed azimuthally. These basis functions are then nearly orthogonal, with only basis functions of the same polarization, same azimuthal mode, and belonging to the same Hermite element having a nonzero inner product.

In this application, the computational task is to solve the finite element boundary value problem, where $\hat{n} \times \vec{E} = -\vec{M}_k$, on the surface of revolution for each of the basis functions $\vec{M}_k$ representing the magnetic current on this surface. Once these multiple solutions are generated, the scattering problem is reduced to one involving only the efficient boundary integral equation.

The scatterer used for this example is a 10λ-by-10λ-by-$1/10\lambda$ perfectly conducting plate, where λ is the wavelength in a vacuum, enclosed in a surface of revolution resembling a thick traditional (round) pizza crust. The volume between the plate and the outer surface was discretized yielding 270,000 complex finite element degrees of freedom. The finite element matrix is real symmetric, since there is no lossy material present, and the right-hand side vectors are complex.

Two symmetric preconditioners are evaluated on this example. The first is the "classical" incomplete Cholesky (IC), where no fill is allowed. The second is an IC variant of the ILU(T) method [17], [18], [3], called IC(T), where the usual factorization algorithm is applied and "small" elements are dropped from each row of the factor as it is generated. Here "small" refers to size compared with the diagonal entry and was adjusted so that the "classical" IC and IC(T) factorizations have approximately the same number of nonzeros and thus require the same computer time to apply. This makes for a fair comparison of the two methods. Minimum degree ordering [10] is used for both preconditioners, which are applied symmetrically.

All timing tests were performed on a SUN Sparcstation rated at 3.8 double precision Megaflops (LINPACK). The algorithms, of course, all utilize double precision arithmetic.

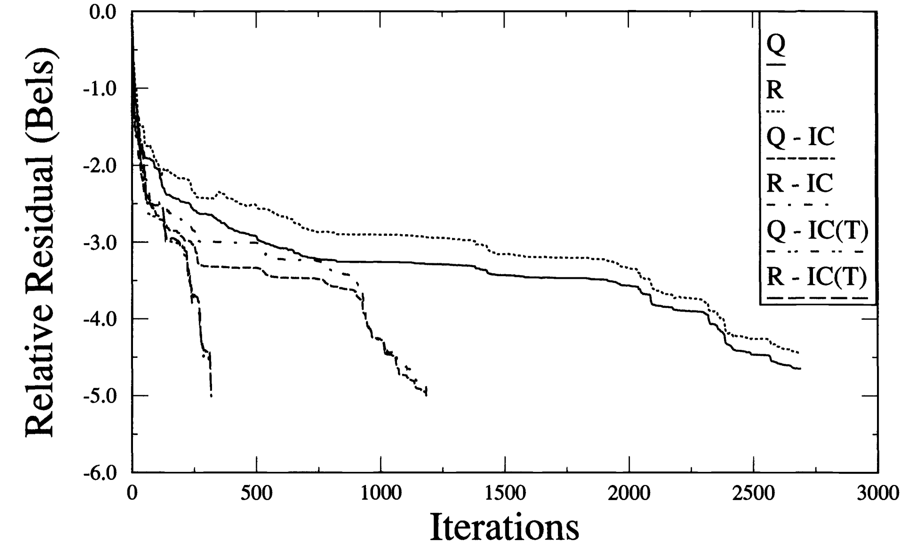

FIG. 1. *Preconditioner comparison: Quasi and equation residuals.*

While the scattering problem was too large to run to completion on the SUN, these convergence tests were completed.

Figure 1 shows the preconditioner evaluation while solving just one right-hand side vector. Convergence was defined by $Q \leq -5.0$, with iterations cut off at 1% of the rank of the matrix. The curves labeled "Q*" are the relative quasi residual while those labeled "R*" are the relative equation residual, both in Bels (the base 10 logarithm of the residuals),

$$\begin{aligned} Q &= \log_{10}\left|\frac{\text{QRES}_k}{\text{QRES}_0}\right|, \\ R &= \log_{10}\left|\frac{\text{RES}_k}{\text{RES}_0}\right|. \end{aligned} \tag{56}$$

The curves labeled Q and R show the convergence without preconditioning, Q-IC and R-IC show the convergence using the IC preconditioner, while Q-IC(T) and R-IC(T) show those using the IC(T) preconditioner.

Note that the quasi residuals are all slightly below but closely follow the equation residual. This is typical behavior experienced in running this code over the last four years. In practice, the quasi residual provides a reliable convergence criterion and eliminates both the computation and storage [8] needed to monitor the usual equation residual.

The case without preconditioning was terminated at 2700 iterations without quite reaching the -5.0 convergence criterion (-4.65). The case with IC preconditioning converged in 1184 iterations. Although this is less than half the number of iterations required with no preconditioning, each iteration is twice as expensive. A preconditioner, whose number of nonzeros is the same as the original matrix, must reduce the number of iterations by a factor of 2 just to break even, which the IC preconditioner barely achieved.

However, the IC(T) preconditioning converged in only 318 iterations. This is approximately one-ninth of the number with no preconditioning and reduced the wall clock time to solution by a factor greater than 4. Again, this is the typical behavior these preconditioners have exhibited on a wide range of problems, and the IC(T) is the only one used in practice.

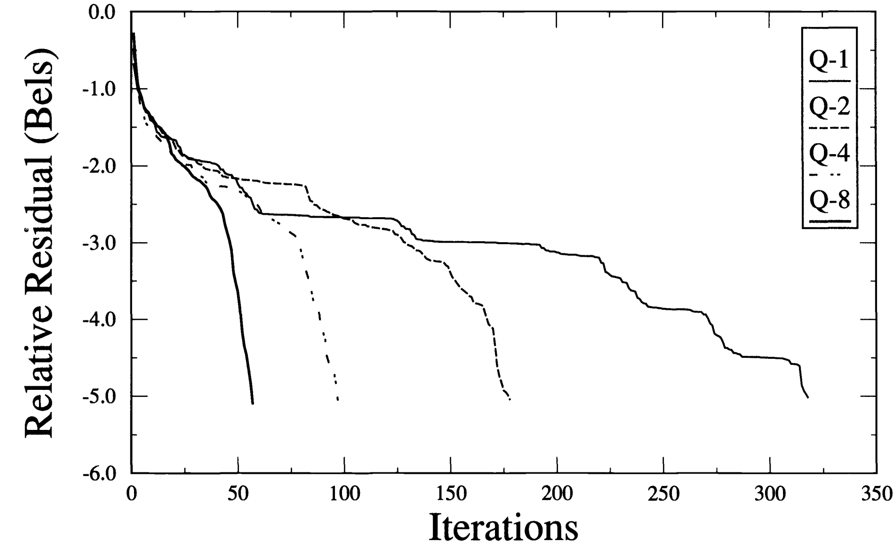

FIG. 2. *Blocksize comparison.*

Figure 2 shows the effects of varying the number of simultaneous solutions. Only the quasi residuals are shown, since they are the criterion used in practice; preconditioning using the IC(T) method and blocksizes of 1, 2, 4, and 8 are compared.

The case for 1 solution, the same as curve "Q-IC(T)" in Fig. 1, shows convergence in 318 iterations. Solving for 2 solutions simultaneously required 178 iterations—57% of the iterations required for 1 solution and close to the ideal limit of 50%. Solving for 4 solutions simultaneously took 97 iterations, 30% of that required for 1 solution, compared with the ideal limit of 25%. Finally, solving 8 solutions simultaneously required only 57 iterations, or 18% of that required for one solution, compared with the ideal limit of 12.5%.

Note that in the early convergence history, 50 to 100 iterations in Fig. 2, the convergence for one solution appears better than the convergence for two simultaneous solutions. This is caused by slower convergence for right-hand side number two only and the fact that the maximum of the residuals for right-hand sides one and two is plotted. When solving multiple simultaneous solutions, the residual for any single right-hand side will never exceed the residual obtained when that right-hand side is iterated individually.

The wall clock time per solution provides another important measure of the effectiveness of this technique. Figure 3 shows the elapsed time per solution relative to the time for one solution without preconditioning. Note that the use of the classical IC preconditioner did not affect the solution time significantly. Although convergence was accelerated, it was not enough to overcome the added computation of applying the preconditioner at each iteration. In contrast to this, the IC(T) preconditioner had a major beneficial effect on solution times, as did increasing the blocksize.

It should be noted that as blocksize m increases, the relative cost of the algorithm increases due to the m-by-m and n-by-m matrix arithmetic. These operations, however, are all BLAS3 calls, which are highly optimized on most computers capable of seriously running a problem of this size.

As a second example, a perfectly conducting sphere of radius 1 meter covered with two hemispherical shells of dielectric material 1/16 meter thick was illuminated by an 80 MHz plane wave. The electrical parameters of one shell were $\epsilon_r = 2 + \imath$ and $\mu_r = 1$, while those

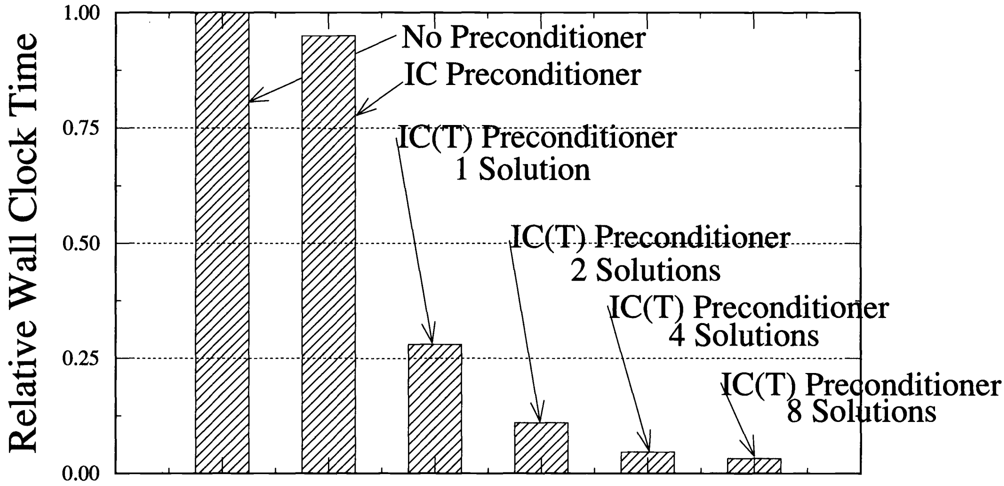

FIG. 3. *Relative solution time comparison.*

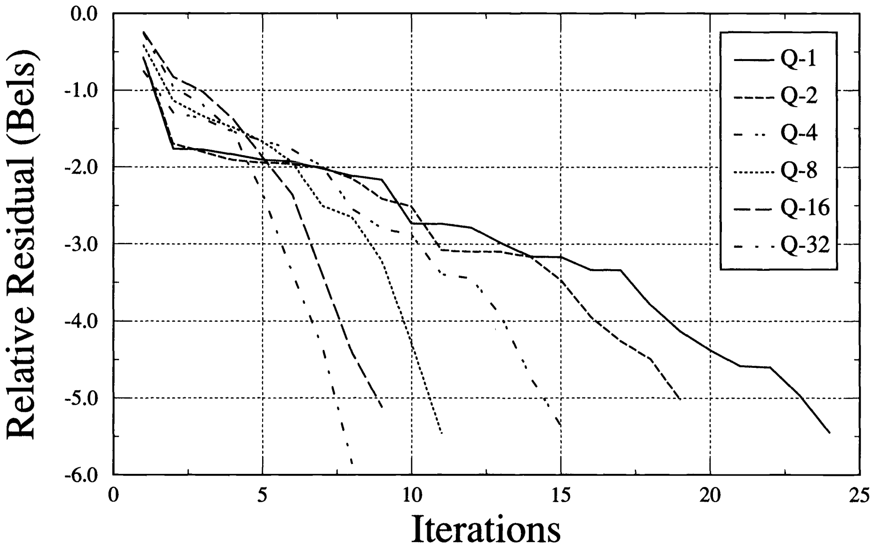

FIG. 4. *Convergence results for dielectric coated conducting sphere.*

of the other were $\mu_r = 2 + \imath$ and $\epsilon_r = 1$. The discretization of this problem yielded 10,556 unknowns. Due to the lossy materials, the matrix was complex symmetric.

Figure 4 shows the effect of varying the blocksize from 1 to 32, using the IC(T) preconditioner as usual. In this case, the convergence acceleration with increased blocksize is not as dramatic as in the previous example. This is not uncommon for problems this small where convergence is achieved in only a few iterations [3], [4].

4. Discussion. There are many topics of interest relative to this iterative method that we have not addressed. The issues of dealing with possible linear dependencies in the Krylov subspace bases, incorporating look ahead [9] into the block algorithm, and deflating the linear systems that converge before the others are not treated. Our emphasis has been on developing the basic algorithm and evaluating its behavior on our problems.

This preconditioned block QMR method has been the solver of choice for our finite element work for about four years. Applied primarily to large problems, $\sim$ 100, 000+ unknowns, it has been both reliable and effective.

Although the large example shown here uses a real matrix for computational expediency, the performance on complex matrices, generated either with impedance boundary conditions or the inclusion of lossy material, is just as good or better. In fact when the loss is removed from the material in the second example, the convergence for one right-hand side increases from 24 to 47 iterations. This behavior is typical and not unexpected.

The computation of the IC(T) preconditioner uses the algorithms given in [16], is adapted to use files on disk, and is very fast. The preconditioner used in the rank 270,000 problem took only 10 minutes elapsed time on a 3.8 MFLOP Sun workstation (compared with hours for the block QMR to complete). Since this factorization is potentially unstable for indefinite matrices, there were some initial concerns about stability. To date we have not experienced any problem attributable to instability in this calculation. We do, however, monitor the maximum and minimum pivots used in the factorization as a measure of stability.

For large problems, several factors must be balanced for optimal solution times. Increasing the blocksize accelerates convergence but also increases the memory requirements of the block QMR algorithm and increases the computational burden due to the matrix arithmetic. Computing a "less incomplete" preconditioner, by decreasing the definition of "small" in the algorithm, also accelerates convergence but increases the cost of computing and applying the preconditioner. These factors are highly dependent on the computer used and must be optimized in situ.

The dominant computational task in this method is the sparse matrix multiply and preconditioner application. In this area, too, the block algorithm shows great potential. As found in [15] and observed by us, using the block algorithm provides another dimension that may be used for parallelization.

Our preliminary work on a Cray Y-MP has shown that both the sparse matrix multiply and preconditioner applications are "embarrassingly" parallel, exhibiting a speedup of almost 8 times when solving 8 simultaneous solutions using 8 processors. This is especially significant for the preconditioner application since its recursive nature severely limits parallelization. Combining this speedup with the convergence acceleration of solving multiple simultaneous solutions means significant reductions in wall clock times per solution are possible.

While this solver performs exceedingly well in our application, the convergence acceleration due to multiple simultaneous solutions is dependent on the sparse matrix, the right-hand side vectors, and the choice of initial guesses. In what other situations block solvers will perform equally well is not yet known. Preliminary testing of a sparsely preconditioned block GMRES solver for general dense complex matrices shows convergence acceleration with increased blocksize, but not yet as much as reported here.

Acknowledgment. The authors would like to thank Noel Nachtigal for helpful discussions about this method and for his encouragement to publish this material, and the reviewers whose thoroughness greatly improved this manuscript.

SOLVING LINEAR INEQUALITIES IN A LEAST SQUARES SENSE*

R. BRAMLEY† AND B. WINNICKA†

Abstract. In 1980, S.-P. Han [*Least-Squares Solution of Linear Inequalities*, Tech. Report TR–2141, Mathematics Research Center, University of Wisconsin–Madison, 1980] described a finitely terminating algorithm for solving a system $Ax \leq b$ of linear inequalities in a least squares sense. The algorithm uses a singular value decomposition of a submatrix of A on each iteration, making it impractical for all but the smallest problems. This paper shows that a modification of Han's algorithm allows the iterates to be computed using QR factorization with column pivoting, which significantly reduces the computational cost and allows efficient updating/downdating techniques to be used. The effectiveness of this modification is demonstrated, implementation details are given, and the behaviour of the algorithm discussed. Theoretical and numerical results are shown from the application of the algorithm to linear separability problems.

1. Introduction.

Let $A \in \Re^{m \times n}$ be an arbitrary real matrix, and let $b \in \Re^m$ be a given vector. A familiar problem in computational linear algebra is to solve the system $Ax = b$ in a least squares sense, that is, to find an x^* minimizing $||Ax - b||$. Here and throughout this paper, $\|\cdot\|$ refers to the two-norm. Such an x^* solves the *normal equations* $A^T(Ax - b) = 0$, and the optimal residual $r^* = b - Ax^*$ is unique (although x^* need not be). The least squares problem is usually interpreted as corresponding to multiple observations, represented by the rows of A and b, on a vector of data x. The observations may be inconsistent, and in this case a solution is sought that minimizes the norm of the residuals. More information about linear least squares problems and solution techniques can be found in [9], [15], [4].

A less familiar problem to numerical linear algebraists is to solve systems of linear *inequalities* $Ax \leq b$ in a least squares sense, but the motivation is similar: if a set of observations places upper or lower bounds on linear combinations of variables, we want to find x^* minimizing $||(Ax - b)_+||$, where the ith component of the vector v_+ is the maximum of zero and the ith component of v. However, potential applications extend beyond simple data analysis, and include linear separability problems. That application requires finding a hyperplane that best separates two point sets; when the two sets are not linearly separable, a hyperplane that correctly separates the largest number of points is desired. Although an $\mathcal{L}_1$-norm formulation using linear programming seems more natural for this problem, the $\mathcal{L}_2$-norm formulation described here provides comparable solutions.

When the system $Ax \leq b$ is consistent, that is, when a solution exists that satisfies all the inequalities, then phase I of any standard linear programming method can find it. Furthermore when the system is not consistent, linear programming can identify that case, but does not directly provide an "optimal" solution. Other methods developed for solving linear inequalities include an unusual algorithm by Stewart [14], which defines a function that diverges in a direction that converges to a solution of the inequalities; if no solution exists, the function converges to a unique minimum.

One way of solving the problem is to state it as the quadratic programming problem in (x, z)

*Received by the editors May 23, 1994; accepted for publication (in revised form) December 19, 1994. This work was supported by NSF grant CDA–9223008.

†Computer Science Department, Indiana University, 215 Lindley Hall, Bloomington, IN 47405-4101 (bramley@cs.indiana.edu).

$$(1) \qquad (\mathrm{QP}) = \begin{cases} \min \frac{1}{2} z^T z, \\ \text{subject to } Ax - b \leq z. \end{cases}$$

However, there are serious numerical difficulties with solving a quadratic programming problem that has a singular objective function; furthermore, most methods require an active-set strategy that can be difficult to implement, particularly when it is necessary to decide which entries to drop from the active set. The analogue of an active set for the algorithm described in this paper is automatically determined without difficult decisions of when to drop a constraint. In particular, the *numerical* determination of the active set consists of a test against zero, without the need to introduce machine- or problem-dependent tolerances.

The only algorithm specifically designed for solving arbitrary systems of linear inequalities in a least squares sense was developed by S.-P. Han [6]. That algorithm requires finding the minimum-norm least squares (equality) solution to systems $A_I x = b_I$, where A_I is a submatrix of A consisting of some rows of A. This implies that a singular-value decomposition or a complete orthogonal decomposition of A_I is required on every iteration. Both of these decompositions are relatively expensive to compute, and there are currently no effective update/downdate methods that allow the reuse of work performed on a previous iteration. This paper will show that a minor modification of Han's algorithm allows an implementation using a QR factorization with column pivoting instead, and both the robustness and finite termination of Han's algorithm are retained.

Section 2 of this paper defines notation and reviews some basic properties of least squares solutions for linear inequalities, most of which can be found in [6]. Section 3 outlines Han's algorithm and §4 presents and validates the minor change in the convergence proof that allows QR with column pivoting to be used. Section 5 gives implementation details and testing results. As an illustration of how the algorithm can be used in an application area, §§6 and 7 examine the linear separability problem. Linear separability problems start with two sets of experimental data points, where the points in one set have a certain property and the points in the other do not. A hyperplane that best separates the two point sets is found and then used to classify future data points as having or not having the relevant property.

2. Basics of systems of linear inequalities. This section summarizes some fundamental properties of linear inequalities from Han's technical report, and proofs of the results can be found in [6]. Let $A \in \Re^{m \times n}$ be an arbitrary real matrix, and let $b \in \Re^m$ be a given vector. No relation is assumed between m and n, and the matrix A can be rank deficient, ill conditioned, or even the zero matrix. Let the rows of A be denoted a_i^T, $i = 1, \ldots, m$. We want to find an $x \in \Re^n$ solving the system

$$(2) \qquad Ax \leq b$$

in some sense. System (2) is interpreted componentwise, so we want $a_i^T x \leq b_i$ for all $i = 1, \ldots, m$. Possibly no such x exists. As an example, consider the system

$$A = \begin{bmatrix} 1 & 0 \\ -1 & 0 \end{bmatrix}, b = \begin{pmatrix} 1 \\ -2 \end{pmatrix},$$

which is equivalent to $x_1 \leq 1$ and $x_1 \geq 2$. In these cases, we want a *least squares* solution, which we now define. Given a vector $v \in \Re^l$, define its positive part as the vector $v_+ \in \Re^l$ with components given by $v_+^i = \max\{0, v^i\}$. A least squares solution to (2) is any vector x that minimizes

$$(3) \qquad f(x) = \frac{1}{2} \|(Ax - b)_+\|^2.$$

Analogous to the linear equality case, we can also define the (necessarily unique) x of minimum norm that solves $x = \text{argmin } \|(Ax - b)_+\|$, but the method analyzed here does not provide a minimum-norm solution. For example when $m < n$ and A is full rank, the method finds one of the infinite number of possible solutions, but which one depends on the starting point. Also, the function $f(x)$ is convex, continuously differentiable, and piecewise quadratic. Differentiating gives the analogue of the normal equations.

PROPOSITION 2.1. *$x^* \in \Re^n$ solves* (2) *if and only if $A^T(Ax^* - b)_+ = 0$.*

The proposition follows immediately from the convexity of f and the relation $\nabla f(x) = A^T(Ax - b)_+$.

Keeping in mind the similarity of Proposition 2.1 and the normal equations for equality linear least squares problems, we define the residual vector as $z = (Ax - b)_+$. This residual is zero if and only if the system of inequalities is consistent and x is a solution. Furthermore, by noting the equivalence of (2) and the quadratic programming problem (1), which is convex, we have the following proposition.

PROPOSITION 2.2. *For any matrix $A \in \Re^{m \times n}$ and vector $b \in \Re^n$, a least squares solution to* (2) *exists. The optimal residual vector $z^* = (Ax^* - b)_+$ is unique, and x is a least squares solution if and only if $(Ax - b)_+ = z^*$.*

Finally, we note that the gradient of f is globally Lipschitz of order 1, with a Lipschitz constant of $\|A\|^2$.

PROPOSITION 2.3. $\|\nabla f(x) - \nabla f(y)\| \leq \|A\|^2 \|x - y\|$, *for all $x, y \in \Re^n$.*

Again the proof is straightforward, using the relation $\nabla f(x) = A^T(Ax^* - b)_+$. Note, however, that the Hessian of f fails to exist at points where $a_i^T x = b_i$ for any $i = 1, 2, \ldots, m$.

3. Outline of Han's algorithm. Two notations are needed for the statement of Han's algorithm. First, $G^\dagger$ denotes the pseudoinverse of the matrix G [13]. In practice, all that is needed is the action of $G^\dagger$ on a vector f, not the linear operator itself in explicit form. The vector $G^\dagger f$ is the minimum-norm, least squares solution to the problem of minimizing $||Gy - f||$, and can be computed by a QR factorization when G is full rank, or by singular value or complete orthogonal decomposition otherwise. See [4, Chap. 5] for details on computing these and other factorizations for linear least squares.

Second, let $I \subseteq \{1, 2, \ldots, m\}$ be an index set. Then A_I is the submatrix of A consisting of rows with indices in I. With this definition, $A_I \in \Re^{|I| \times n}$, where $|I|$ is the cardinality of I. The vector b_I can be defined similarly. Using this notation, the algorithm follows.

ALGORITHM 3.1. Let $A \in \Re^{m \times n}$, $b \in \Re^m$, a starting point $x^0 \in \Re^n$, and $\epsilon > 0$ be given.

```
Initialize:
    • Set $k = 0$ (Iteration number)
    • Set $r^0 = b - Ax^0$
    • Set $I = \{i : a_i^T x^0 \geq b_i\} = \{i : r_i^0 \leq 0\}$ (Set of active indices)
    • Set $\rho^0 = ||r_I^0||$ (initial residual norm)
Iterate: While ($\rho^k > \epsilon$)
    • $d^k = A_I^\dagger r_I^k$
    • $\lambda = \text{argmin } f(x^k + \lambda d^k)$, where $f(x)$ is defined by equation (3)
    • $x^{k+1} = x^k + \lambda d^k$
    • $r^{k+1} = b - Ax^{k+1}$
    • $I = I_{k+1} = \{i : a_i^T x^{k+1} \geq b_i\}$ (New set of active indices)
    • $\rho^{k+1} = ||(r^{k+1})_I||$
    • $k = k + 1$
```

Superscripts in the above algorithm indicate the iteration number. Note that I and λ depend on k also, but for clarity, we omit the k when examining a single step of the algorithm. The exact line search for λ is computationally reasonable, since $\theta(\lambda) = f(x^k + \lambda d^k)$ is piecewise quadratic, convex, and continuous; we can simply search through the knot points to isolate an interval on which $\theta(\lambda)$ is quadratic, then interpolate. Numerical testing shows that the algorithm is in fact sensitive to the line-search procedure, and it is worthwhile to consider other methods.

The fundamental result Han established about this algorithm is that it converges in a finite number of steps to some minimizer of (3). The proof relies on the following properties, which are readily verified.

PROPOSITION 3.1. *For any matrix $A \in \Re^{m\times n}$ and vector $b \in \Re^n$, let $f(x)$ be given by* (3), *$x = x^k$, $d = d^k$, and $I = I(x^k)$. Then*

1. *$\nabla f(x) = -A_I^T A_I d$, so $d^T \nabla f(x) = \|A_I d\|^2$, and d is a descent direction for $f(x)$.*
2. *d is the minimum norm least squares solution to the problem: minimize $\|A_I d - r_I\|$.*

4. A more efficient version of Han's algorithm. To make this algorithm practical, d^k needs to be computed by means of a cheaper factorization of A_I. Han's algorithm uses the pseudoinverse to define d^k in order to limit the growth of the component of x^k in the null space of A_I. As mentioned in the introduction, we now show that this can be relaxed, allowing cheaper computation of d^k. Omitting the superscript k temporarily, let $d_{\rm svd} = A_I^\dagger r_I$. The general least squares solution to $A_I d = r_I$ is given by $d = d_{\rm svd} + (I - A_I^\dagger A_I)y$ for $y \in \Re^n$. Note that $(I - A_I^\dagger A_I)y$ is in the null space of A_I, so that $A_I d = A_I d_{\rm svd}$. This is critical since, with one exception, the proof of finite termination in [6] involves only the quantity $A_I d$, not d. Before addressing that exception, we recall a result of Golub and Pereyra [5].

THEOREM 4.1. *Let G be an $m \times n$ matrix, and let $GP = Q\hat{R}$ be the QR with column-pivoting factorization of G. Partition*

$$\hat{R} = \begin{bmatrix} R_1 & R_2 \\ 0 & 0 \end{bmatrix}, \tag{4}$$

where R_1 is $r \times r$, upper triangular, and invertible, and R_2 is $r \times n-r$. Let $y_{\rm svd}$ be the minimum-norm least squares solution to the problem: minimize $\|Gy - f\|$, let $Q^T f = (c^T, g^T)^T$, where $c \in \Re^r$, and set

$$y = P\begin{pmatrix} R_1^{-1}c \\ 0 \end{pmatrix}. \tag{5}$$

Then $\|y\|^2 \le (1 + \|R_1^{-1}R_2\|^2)\|y_{\rm svd}\|^2$.

The application of this result to the linear inequality algorithm tells us that using QR factorization with column pivoting to compute the search direction d will always provide a d that is bounded by a constant times the norm of $d_{\rm svd}$, where the constant does not depend on x or the iteration number k.

THEOREM 4.2. *Let d be computed in Han's algorithm using QR factorization with column pivoting. Then there is $C_R \ge 0$ such that $\|d\| \le C_R\|d_{\rm svd}\|$ independently of the iteration number k.*

Proof. For a given index set I, let R_1 and R_2 be the factors defined by applying Theorem 4.1 to the problem: minimize $\|A_I d - r_I\|$. Let $C_I = \sqrt{(1 + \|R_1^{-1}R_2\|^2)}$, and let $C_R = \max\{C_I\}$, where the maximum is taken over all possible index sets I. Since the number of such index sets is finite, C_R is well defined. The result follows immediately from the last Theorem. □

We now prove the main convergence result needed.

THEOREM 4.3. *Let the sequences of vectors x^k and d^k be computed using Algorithm 3.1, with d^k computed using QR factorization with column pivoting on A_I. Then either the algorithm stops after a finite number of iterations, or*

$$\lim_{k\to\infty} \nabla f(x^k) = 0. \tag{6}$$

Proof. If the algorithm stops after a finite number of iterations there is nothing further to prove. Suppose it takes an infinite number of iterations. Then for all steps, A_I is a nonempty matrix, since $I = \phi$ if and only if x^k is a solution. Initially we drop the superscripts k, and consider one step of the algorithm. Since ∇f is continuous and globally Lipschitz with a Lipschitz constant of $\|A\|^2$, from the mean value theorem [11, Thm. 8.3.1]

$$\begin{aligned} f(x+\lambda d) - f(x) &= \lambda \int_0^1 d^T \nabla f(x + t\lambda d) dt \\ &= \lambda \int_0^1 d^T [\nabla f(x+t\lambda d) - \nabla f(x)] dt + \lambda d^T \nabla f(x) \\ &\le \lambda \int_0^1 \|d\| \|\nabla f(x+t\lambda d) - \nabla f(x)\| dt + \lambda d^T \nabla f(x) \\ &\le \lambda \|A\|^2 \int_0^1 \lambda \|d\|^2 t dt + \lambda d^T \nabla f(x), \end{aligned} \tag{7}$$

and so

$$f(x+\lambda d) \le f(x) + \lambda d^T \nabla f(x) + \frac{\|A\|^2}{2} (\lambda \|d\|)^2. \tag{8}$$

As a function of λ, the right-hand side of the above bound has a minimum at

$$\hat{\lambda} = \frac{-d^T \nabla f(x)}{\|A\|^2 \cdot \|d\|^2}. \tag{9}$$

Substituting this value of λ in (8) and using $d^T \nabla f(x) = -d^T A_I^T A_I d$, we get

$$f(x+\hat{\lambda} d) - f(x) \le -\frac{1}{2} \left[\frac{d^T \nabla f(x)}{\|A\| \cdot \|d\|} \right]^2 \le -\frac{1}{2} \left[\frac{\|A_I d\|^2}{\|A\| \cdot \|d\|} \right]^2. \tag{10}$$

Note that if the component of d that lies in the null space of A_I becomes arbitrarily large, the upper bound above can go to zero. However, from Theorem 4.2 $\|d\| \le C_R \|d_{\text{svd}}\|$, where C_R is independent of the iteration number. Since $d_{\text{svd}} \in$ range (A_I^T), $d_{\text{svd}} = A_I^\dagger A_I d$, and so

$$\|d\| \le C_R \|A_I^\dagger A_I d_{\text{svd}}\| \le C_R \|A_I^\dagger\| \cdot \|A_I d_{\text{svd}}\| \le C \|A_I d_{\text{svd}}\|, \tag{11}$$

where $C = \left(\max_I \|A_I^\dagger\|\right) C_R$. Substituting this bound on d into (10) gives

$$f(x+\hat{\lambda} d) - f(x) \le -\frac{1}{2C\|A\|^2} \|A_I d\|^2. \tag{12}$$

Since the stepsize λ is chosen by an exact line search,

$$f(x) - f(x+\lambda d) \ge f(x) - f(x+\hat{\lambda} d) \ge \frac{1}{2C\|A\|^2} \|A_I d\|^2. \tag{13}$$

The last inequality holds for all iterations, and since $f(x^k)$ is monotone decreasing and bounded below by zero,

$$\sum_{k=0}^{\infty}\left[f(x^k) - f(x^k + \lambda d^k)\right] \geq \frac{1}{2C\|A\|^2}\sum_{k=0}^{\infty}\|A_{I^k} d_k\|^2 \tag{14}$$

is a finite sum, so $A_{I^k}d^k \rightarrow 0$ as $k \rightarrow \infty$ and hence $\nabla f(x^k) = -A_{I^k}^T A_{I^k} d^k \rightarrow 0$ as $k \rightarrow \infty$. □

The rest of Han's proofs, which are not reproduced here, still apply to the modified algorithm, since they only rely on $A_I d$, not d. His arguments in particular show that of the two alternatives in Theorem 4.3, the second alternative (equation (6)) cannot occur. It is worthwhile to compare those results with related ones. As early as 1965, Katznelson [8] established finite termination of an algorithm for solving piecewise linear systems of equations that arise in circuits. More recently Li and Swetits [10] have established finite termination for solving systems of the form $\Phi(x) = Q^T[(Ax+b)_+ + (Cx+d)] = 0$ (c.f. the gradient of $f(x)$). In both cases, they relied on the assumption that within each polyhedral set created by the hyperplanes $H_i = \{x : a_i^T x = b_i\}$, the gradient of Φ is nonsingular. This corresponds to the case where $A_I^T A_I$ is nonsingular for all index sets I. The key idea is that within each polyhedral set the function is quadratic, and so if the kth iterate lands in the polyhedral set containing the (necessarily unique) minimum, Newton's iteration converges in one step. Since there are a finite number of such polyhedral sets, it is a matter of showing that if an infinite number of the iterates lie in a single polyhedral set, they must converge to a point in the set. The unicity of solutions to $\nabla\Phi(x)d = -\Phi$ allows this by assuring that the iterates remain bounded.

Han's method applies a Gauss–Newton approach to the same problem, and restricts the choice of search directions d^k to minimum-norm solutions, in order to have zero growth in the null-space component of A_{I^k}. The key idea used in this paper is that some growth in that null space is allowed, provided that it is uniformly bounded over all of the polyhedral sets, that is, over all choices of index set I. This result is important because it allows applying the algorithm to large systems, and the recent development of efficient and reliable orthogonal factorization methods for sparse systems allows it to be applied to the kind of systems that frequently arise in applications. Furthermore, methods for computing QR factorization with some form of pivoting on parallel machines allow implementation on modern high-performance computers.

5. Numerical characteristics of the algorithm. This section summarizes results of numerical testing, and further details can be found in [2]. The algorithm has been implemented in Matlab©,[1] with four ways of generating search directions: the singular value decomposition (SVD), a complete orthogonal factorization (COF), QR factorization with column pivoting (QR), and QR factorization with updating and downdating of the factors (UD), which is used only when it is numerically safe.

The implementation defines the active set exactly as given in Algorithm 3.1. By contrast, active-set strategies in quadratic programming methods for (1) involve tolerances and can require numerical determination of ranks of submatrices.

The number of iterations required is sensitive to the line search, since stopping short or overshooting a hyperplane boundary gives a different index set. Two line-search methods have been tested: a search through the knot points for the piecewise quadratic line-search function followed by quadratic interpolation, and a binary search method.

Table 1 shows the mean ratios of flops and iterations for 200 random problems of orders 80 × 40, 40 × 80, and 400 × 15. The flops computed are the total flops required, not just those

in finding the search direction or performing the line search. The third and fourth columns compare using an SVD to using QR with column pivoting, and show that for all problem sizes, SVD is significantly more expensive, even though fewer iterations are required by SVD, especially for the 40 × 80 problem size. This makes intuitive sense because, in this case, many of the submatrices A_I don't have full column rank. Finding the search direction via QR with column pivoting can introduce components from the null space of A_I, components that may have to be removed by later iterations when the index set changes, and which can introduce numerical instability. However, even when requiring 3 times more iterations, the QR-based method takes fewer flops; less than one-tenth as many in some cases. The fifth and sixth columns show the ratios when QR with column pivoting is used, but this time comparing the two line-search methods. This shows that the two methods are close in cost, but for overdetermined problems binary search is slightly cheaper. Because binary search is easily coded and evaluating the line-search function at a given point requires only the computationally inexpensive task of forming matrix–vector products with A, this suggests it is the preferred method.

Table 2 compares the number of flops for four search direction methods: COF, SVD, QR, and UD. The ratios of the first three to the last one are given, since UD was found most often to be the most efficient method for overdetermined problems. Although the average cost of COF for underdetermined problems is slightly more than for UD, the geometric mean of 0.94 shows that COF is cheaper for a larger number of problems. In this case the subproblems tend to have a large null space for A_I, and eliminating that component as COF does significantly reduces the number of iterations. So although on a given iteration COF is more expensive, its overall cost can be reduced.

The conclusions from these experiments are that using a binary line-search method is cheaper than a quadratic interpolation as often as not, and altering the algorithm to select the search direction with a QR factorization is an important improvement for the $m \geq n$ case. When $n \gg m$ and the extra freedom introduced in null(A_I) could potentially cause numerical difficulties, COF is preferred.

Figure 1 shows the maximum iterations needed for random problems with varying m and n. In all cases no more than $1 + \max(m, n)$ iterations were needed, and the largest number of iterations occurs when $m \approx 2n$, which may be from having twice as many halfspaces as variables, and so finding the correct index set takes several steps. When $m \gg 2n$, few iterations are needed, since there are generally enough active rows to give an impetus in the directions imposed by rows not currently active, but which are active at the solution. Finally,

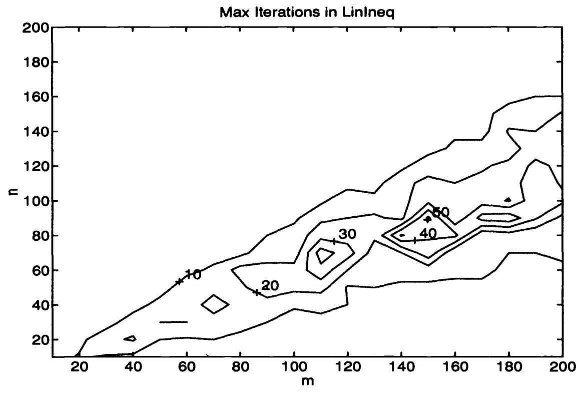

FIG. 1. *Maximum iterations required for m × n problems.*

when $m < n$, only 1–3 iterations are required, since the number of degrees of freedom exceeds the number of "constraints" imposed by the system.

6. Application to the linear separability problem. The linear separability problem is the one of finding a best hyperplane that separates two point sets $\mathcal{A}$ and $\mathcal{B}$ in $\Re^n$. Let $\mathcal{A}$ and $\mathcal{B}$ have m and k points, respectively, and let A and B be matrices with rows giving the coordinates of the points in $\mathcal{A}$ and $\mathcal{B}$. We want to find $w \in \Re^n$ and a scalar γ so that $Aw \leq \gamma e_m$ and $Bw > \gamma e_k$, where $e_i \in \Re^i$ is a vector of all ones.

Clearly not all sets $\mathcal{A}$ and $\mathcal{B}$ can be separated by a hyperplane, so we want to find a hyperplane that is optimal by having fewest points incorrectly classified as belonging to $\mathcal{A}$ or $\mathcal{B}$. This can be approximated as the least squares inequality problem

$$\begin{aligned} Aw - \gamma e_m &\leq -e_m, \\ -Bw + \gamma e_k &\leq -e_k. \end{aligned} \tag{15}$$

This formulation specifies that all the points lie outside of the "slab" $H = \{x : \gamma - 1 \leq w^T x \leq \gamma + 1\}$, guarding against the case when all the data points line up on a hyperplane, in which case the least squares problem (15) with zero on the right-hand side gives a trivial solution $(w, \gamma) = 0$. In [1], Bennett and Mangasarian formulate this problem in terms of the $\mathcal{L}_1$-norm: minimize

$$\frac{1}{m}\sum_{i=1}^{m}\left(-a_i^T w + \gamma + 1\right)_+ + \frac{1}{k}\sum_{j=1}^{k}\left(b_j^T w - \gamma + 1\right)_+ \tag{16}$$

and then solve it as the linear programming problem: minimize over (w, γ, y, z) the function $(y^T e_m)/m + (z^T e_k)/k$ subject to the constraints $Aw - \gamma e_m + y \geq e_m$, $-Bw + \gamma e_k + z \geq e_k$, and $y, z \geq 0$.

The normalization of terms of the objective function by $1/m$ and $1/k$ assures that nontrivial solutions (w, γ) exist. A similar result holds for the least squares formulation (15).

THEOREM 6.1. *Suppose the two point sets $\mathcal{A}$ and $\mathcal{B}$ have m and k points, respectively, and $m, k > 0$. Then the least squares formulation of* (15) *has the trivial solution $w = 0$ if and only if*

$$\sum_{i=1}^{m} a_i = \alpha \sum_{j=1}^{k} b_j \tag{17}$$

for some constant α.

Proof. Suppose that the least squares solution of (15) has $w = 0$, let $\tilde{w} = (w^T, \gamma)^T$, and let

$$G = \begin{bmatrix} A & -e_m \\ -B & e_k \end{bmatrix}, \quad g = \begin{pmatrix} -e_m \\ -e_k \end{pmatrix}. \tag{18}$$

Then

$$\begin{aligned} \|(G\tilde{w} - g)_+\|^2 &= \left\| \begin{pmatrix} (1-\gamma)e_m \\ (1+\gamma)e_k \end{pmatrix}_+ \right\|^2 \\ &= \begin{cases} m(1-\gamma)^2, & \text{if } \gamma < -1, \\ k(1+\gamma)^2, & \text{if } \gamma > 1, \\ m(1-\gamma)^2 + k(1+\gamma)^2, & \text{if } -1 \leq \gamma \leq 1. \end{cases} \end{aligned} \tag{19}$$

Furthermore, the active index set I is

$$I = \begin{cases} \{1, 2, \ldots, m\}, & \gamma < -1, \\ \{m+1, m+2, \ldots, m+k\}, & \gamma > 1, \\ \{1, 2, \ldots, m+k\}, & -1 \leq \gamma \leq 1. \end{cases} \tag{20}$$

From the normal equations, $G^T(G\tilde{w} - g)_+ = 0$. If $\gamma < -1$, this implies

$$0 = \begin{pmatrix} A^T(1-\gamma)e_m \\ -m(1-\gamma) \end{pmatrix} = (1-\gamma)\begin{pmatrix} \sum_{i=1}^m a_i \\ -m \end{pmatrix} \tag{21}$$

and so $m = 0$, a contradiction. Similarly, if $\gamma > 1$, this implies

$$0 = \begin{pmatrix} -B^T(1+\gamma)e_k \\ k(1+\gamma) \end{pmatrix} = (1+\gamma)\begin{pmatrix} -\sum_{j=1}^k b_j \\ k \end{pmatrix} \tag{22}$$

and so $k = 0$, again a contradiction. So $-1 \leq \gamma \leq 1$, in which case

$$0 = \begin{pmatrix} A^T(1-\gamma)e_m - B^T(1+\gamma)e_k \\ -m(1-\gamma) + k(1+\gamma) \end{pmatrix} = \begin{pmatrix} (1-\gamma)\sum_{i=1}^m a_i - (1+\gamma)\sum_{j=1}^k b_j \\ \gamma(m+k) + (k-m) \end{pmatrix}.$$

If $|\gamma| = 1$, the last component implies that one of m or k is zero. So $|\gamma| < 1$, and the theorem holds with $\alpha = (1+\gamma)/(1-\gamma)$. □

It is easy to check condition (17) before beginning computations, and perturbing any entry of G will avoid the trivial solution. By contrast, in the $\mathcal{L}_1$-norm minimizing method of [1], only the objective function for the linear program needs scaling. However, that formulation only guarantees that nontrivial solutions exist, but it does not assure that a linear programming program will find such a nontrivial solution. In any case, the condition in (17) has so far only occurred in artificially created problems.

In testing the linear programming and least squares methods, after (w, γ) are found a secondary minimization on γ is performed to improve the solution. The next proposition shows that the inequality least squares problem will translate the separating hyperplane to where the sum of residual violations is balanced; this is not a criterion of the original linear separability problem, and is the reason we follow the iterations with the secondary minimization.

PROPOSITION 6.2. *Let (w, γ) be a least squares solution to the system* (15). *The sum of residuals corresponding to point set $\mathcal{A}$ equals the sum of residuals corresponding to point set $\mathcal{B}$.*

Proof. From the normal equations for (15),

$$\begin{bmatrix} A^T & -B^T \\ -e_m^T & e_k^T \end{bmatrix} \begin{pmatrix} Aw - (\gamma - 1)e_m \\ -Bw + (\gamma + 1)e_k \end{pmatrix}_+ = 0. \tag{23}$$

The last scalar equation from above gives

$$e_m^T(Aw - (\gamma - 1)e_m)_+ = e_k^T(-Bw + (\gamma + 1)e_k)_+ \tag{24}$$

or equivalently

$$\sum_{i=1}^{m} \left[a_i^T w - (\gamma - 1)\right]_+ = \sum_{j=1}^{k} \left[-b_j^T w + (\gamma + 1)\right]_+ , \tag{25}$$

which is the statement of the proposition. □

The one-dimensional minimization is easily carried out by searching through the knot points defined by $\gamma_i = a_i^T w$ and $\gamma_j = b_j^T w$ and adds little to the overall computation costs. This usually improves the solution by a few data points for two-dimensional test problems, but is much less effective for higher-dimensional problems. Intuitively, in the two-dimensional case minimizing on γ varies one-third of the variables, while for a 9- or 13-dimensional problem, only one-tenth or one-fourteenth of the variables are being changed.

7. Performance on test databases. The linear separability methods have been tested on the Wisconsin Breast Cancer and Cleveland Heart Disease Databases [3]. Here the goal is to provide a linear predictor that can be used to distinguish between benign and malignant tumors in the first database, and patients at risk or not at risk of heart attack in the second database.

Both data sets are available from the University of California–Irvine Repository of Machine Learning Databases and Domain Theories [11]. The first data set consists of 551 points, 346 from set $\mathcal{A}$ (corresponding to benign tumors) and 205 from set $\mathcal{B}$ (corresponding to malignant tumors). Each data point has 9 components, corresponding to experimental measurements. The second data set consists of 297 points, 137 from set $\mathcal{A}$ (corresponding to a negative diagnosis) and 160 from set $\mathcal{B}$ (corresponding to a positive diagnosis).

We discarded data samples that had missing measurements. As in [1], the data were divided randomly into a training group consisting of two-thirds of the data points, and a testing group consisting of the remaining one-third of the data. The best separating hyperplane was found by applying the inequality least squares solver using the training group of data, and then

TABLE 3
Percent of incorrectly classified points for two databases.

Database	Data Group	Ls Sq w/o γ Min	Ls Sq w γ Min	Lin Progr
Cancer	Training	3.19	2.64	3.01
	Testing	4.24	3.80	2.56
Heart	Training	14.75	13.84	15.23
	Testing	15.76	15.96	16.53

the effectiveness of the hyperplane was tested on the remaining testing group of data. This was repeated ten times, with different partitionings into training and testing sets. For the first data set, the inequality solver required seven or eight iterations each time and spent an average of 92% of its flops in finding the search direction. For the second data set, five or six iterations were needed each time and an average of 95% of the flops were spent in finding the search direction.

Table 3 shows the results both with and without the secondary minimization on γ, along with similar results from [1]. The results are not strictly comparable since that work used 566 data points from the Wisconsin Cancer Database and 197 data points from the Cleveland Heart Disease Database, but the comparison suggests that the inequality least squares method provides a solution similar to that of a linear programming method. This is unexpected because the two-norm solution given by inequality least squares can heavily weight outlying data points while the one-norm solution given by the linear programming method weights outlying data points less. However, these results show that for realistic problems the inequality least squares solution is qualitatively competitive.

8. Summary and future work. A computationally efficient implementation of Han's algorithm for solving linear inequalities in a least squares sense has been presented, and has been shown convergent by minor modifications to his convergence proofs. The effectiveness of this change in the algorithm's implementation has been demonstrated, and it has been tested on randomly generated and linear separability problems. The results indicate that with the new implementation, this linear inequalities solution method is a worthwhile addition to a computational scientist's toolkit.

Current work includes applying this method to the graph-partitioning problem for parallel computing (see [7] for a survey of this problem and solution methods). This works in phases: given a graph corresponding to a physical mesh, first find the "deepest" set of nodes by a breadth-first search from the boundary nodes. Two nodes that are furthest apart in the deepest set are selected as initial $\mathcal{A}$ and $\mathcal{B}$ points, and the sets are grown outwards using a constrained breadth-first search. A separating hyperplane is then found to better define those sets, followed possibly by a few steps of simulated annealing to further improve the partitioning. This avoids finding eigenvalues or singular values of the Laplacian of a sparse matrix, and uses only fast graph algorithms and a relatively low-cost linear inequality solver.

The most interesting work remaining is a proof of convergence within $\max(m, n) + 1$ iterations, or a counterexample. Since QR factorization with column pivoting takes $\mathcal{O}(mn^2)$ work in the dense case, this would provide a polynomial upper bound on the algorithm. A linear programming problem can be stated as a system of inequalities [6], so this algorithm would be another polynomial method for linear programming. Furthermore, the subproblems generated by the inequality least squares algorithm have condition numbers no worse than that of the original data, since at each step a decomposition is performed on a submatrix of A (condition number for least squares problems is defined as the ratio of largest to smallest nonzero singular values). Interior point methods for linear programming have subproblems that become increasingly ill conditioned as the iterates converge. So if the conjectured upper bound on the number of iterations holds, this algorithm provides a numerically stable, polynomial time algorithm for linear programming.

ON THE EFFECTS OF USING THE GRASSMANN–TAKSAR–HEYMAN METHOD IN ITERATIVE AGGREGATION–DISAGGREGATION*

TUĞRUL DAYAR† AND WILLIAM J. STEWART‡

Abstract. Iterative aggregation–disaggregation (IAD) is an effective method for solving finite nearly completely decomposable (NCD) Markov chains. Small perturbations in the transition probabilities of these chains may lead to considerable changes in the stationary probabilities; NCD Markov chains are known to be ill-conditioned. During an IAD step, this undesirable condition is inherited by the coupling matrix and one confronts the problem of finding the stationary probabilities of a stochastic matrix whose diagonal elements are close to 1. In this paper, the effects of using the Grassmann–Taksar–Heyman (GTH) method to solve the coupling matrix formed in the aggregation step are investigated. Then the idea is extended in such a way that the same direct method can be incorporated into the disaggregation step. Finally, the effects of using the GTH method in the IAD algorithm on various examples are demonstrated, and the conditions under which it should be employed are explained.

Key words. Markov chains, decomposability, stationary probability, aggregation–disaggregation, Gaussian elimination, sparsity schemes

1. Introduction.

NCD Markov chains are irreducible stochastic matrices that can be ordered so that the matrix of transition probabilities has a block structure in which the nonzero elements of the off-diagonal blocks are small compared with those of the diagonal blocks. Such matrices often arise in queueing network analysis, large scale economic modeling, and computer systems performance evaluation. We have

$$P_{n\times n} = \begin{array}{c} \\ \left(\begin{array}{cccc} P_{11} & P_{12} & \cdots & P_{1N} \\ P_{21} & P_{22} & \cdots & P_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ P_{N1} & P_{N2} & \cdots & P_{NN} \end{array}\right) \end{array} \quad \tag{1.1}$$

$$\begin{array}{cccc|c} n_1 & n_2 & \cdots & n_N & \\ \hline P_{11} & P_{12} & \cdots & P_{1N} & n_1 \\ P_{21} & P_{22} & \cdots & P_{2N} & n_2 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ P_{N1} & P_{N2} & \cdots & P_{NN} & n_N \end{array} .$$

The subblocks P_{ii} are square, of order n_i, with $n = \sum_{i=1}^{N} n_i$. Let the stationary distribution of P, π (i.e., $\pi P = \pi$, $\|\pi\|_1 = 1$), be partitioned conformally with P such that $\pi = (\pi_1, \pi_2, \ldots, \pi_N)$. Each π_i, $i = 1, 2, \ldots, N$ is a row vector having n_i elements. Let $P = \mathrm{diag}(P_{11}, P_{22}, \ldots, P_{NN}) + E$. The quantity $\|E\|_\infty$ is referred to as the *degree of coupling* and it is taken to be a measure of the decomposability of the matrix (see [5]). If it was zero, then P would be reducible.

NCD Markov chains that appear in applications are quite large and sparse, possibly having more than thousands of states. For such large chains, direct methods can generate immense fill-in during the triangularization phase of the solution process, and due to storage limitations they become impractical. Moreover, when the system is nearly completely decomposable, there are eigenvalues close to 1, and the poor separation of the unit eigenvalue implies a slow rate of convergence for standard matrix iterative methods [12]. IAD methods do not suffer from these limitations [7], [23].

The idea in IAD methods is to observe the system in isolation in each of the diagonal blocks as if the system is completely decomposable (see [15]) and to compute the stationary probability distribution of each diagonal block. However, there are two problems with this approach. First, since the diagonal blocks are substochastic, the off-diagonal probability mass must somehow be incorporated into the diagonal blocks. Second, the probabilities obtained by this approach are conditional probabilities, and this condition has to be removed by weighing each probability subvector by the probability of being in that group of states. Only if these two problems are overcome can one form the stationary distribution of the Markov chain by weighing the subvectors and pasting them together.

For the transition probability matrix P, the stochastic complement of P_{ii} [8] is

$$S_{ii} = P_{ii} + P_{i*}(I - P_i)^{-1}P_{*i},$$

where

P_{i*} : $n_i \times (n - n_i)$ matrix is composed of the ith row of blocks of P with P_{ii} removed,

P_{*i} : $(n - n_i) \times n_i$ matrix is composed of the ith column of blocks of P with P_{ii} removed,

P_i : $(n - n_i) \times (n - n_i)$ is the principal submatrix of P with ith row and ith column of blocks removed.

Each stochastic complement is the stochastic transition probability matrix of a smaller irreducible Markov chain obtained by observing the original process in the corresponding block of states. The conditional stationary probability vector of the ith block is $\pi_i/\|\pi_i\|_1$ and it may be computed by solving $(\pi_i/\|\pi_i\|_1)S_{ii} = \pi_i/\|\pi_i\|_1$ (see [8] for details). However, each stochastic complement has an embedded matrix inversion that may require excessive computation. An alternative solution technique is to approximate S_{ii} by accumulating the off-diagonal mass P_{i*} into the diagonal block P_{ii} on a row-by-row basis. There are various ways in which this can be done [21]. Thereafter, an approximation to the conditional stationary vector of the block of states may be found by solving the corresponding linear system as before.

To determine the probability of being in a certain block of states, one needs to construct the so-called coupling matrix that shrinks each block down to a single element, forming an $N \times N$ irreducible stochastic matrix. This is accomplished by first replacing each row of each block by the sum of elements in that block row. The sum of elements of row k of P_{ij} gives the probability of leaving state k of block i and entering into block j. Therefore, the operation to be performed for each block is $P_{ij}e$. In what follows, e is a column vector of 1's whose length is determined by the context in which it is used. Moreover, each column vector $P_{ij}e$ must be reduced to a scalar. The total probability of leaving block i to enter into block j may be determined by summing the elements of $P_{ij}e$ after each element of this vector has been multiplied by the probability of being in that state (given that the system is in block i). These multiplicative constants may be obtained from the stationary vector elements; they are the components of $\pi_i/\|\pi_i\|_1$. Hence, the ijth element of the coupling matrix is given by $c_{ij} = (\pi_i/\|\pi_i\|_1)P_{ij}e$. The stationary vector of the coupling matrix gives the stationary probability of being in each one of the block of states. In other words, the weighing factors mentioned before are the elements of the stationary vector of the coupling matrix. However, the stationary vector itself is needed to form the coupling matrix. Since the aim is to compute the stationary vector, one can approximate the coupling matrix by using an approximate stationary vector and improve on the approximate solution iteratively [21].

Without further ado, the IAD algorithm is provided. Convergence analysis of the algorithm appears in [17]. Additional discussion may be found in [21] and [2].

The generic iterative aggregation–disaggregation (IAD) algorithm.

1. Let $\pi^{(0)} = (\pi_1^{(0)}, \pi_2^{(0)}, \ldots, \pi_N^{(0)})$ be a given initial approximation to the solution. Set $k = 1$.

2. Construct the coupling matrix $C^{(k-1)}$

$$c_{ij}^{(k-1)} = \frac{\pi_i^{(k-1)}}{\|\pi_i^{(k-1)}\|_1} P_{ij} e.$$

3. Solve the eigenvector problem

$$\xi^{(k-1)} C^{(k-1)} = \xi^{(k-1)}, \quad \|\xi^{(k-1)}\|_1 = 1$$

for $\xi^{(k-1)} = (\xi_1^{(k-1)}, \xi_2^{(k-1)}, \dots, \xi_N^{(k-1)})$.

4. (a) Compute the row vector

$$z^{(k)} = \left(\xi_1^{(k-1)} \frac{\pi_1^{(k-1)}}{\|\pi_1^{(k-1)}\|_1}, \xi_2^{(k-1)} \frac{\pi_2^{(k-1)}}{\|\pi_2^{(k-1)}\|_1}, \dots, \xi_N^{(k-1)} \frac{\pi_N^{(k-1)}}{\|\pi_N^{(k-1)}\|_1} \right).$$

(b) Solve the N systems of equations

$$\pi_i^{(k)} = \pi_i^{(k)} P_{ii} + \sum_{j>i} z_j^{(k)} P_{ji} + \sum_{j<i} \pi_j^{(k)} P_{ji}$$

for $\pi_i^{(k)}$, $\quad i = 1, 2, \dots, N$.

5. Test $\pi_i^{(k)}$ for convergence. If the desired accuracy is attained, then stop and take $\pi_i^{(k)}$ as the stationary probability vector of P. Else set $k = k + 1$ and go to step 2.

In the IAD algorithm, steps 2 and 3 form the aggregation step and step 4(b), which is essentially a block Gauss–Seidel iteration, forms the disaggregation step. In step 2, $\pi_i^{(k-1)}/\|\pi_i^{(k-1)}\|_1$ is an approximation of the stationary distribution of the stochastic complement of P_{ii}. The weighing factors $(\|\pi_1\|_1, \|\pi_2\|_1, \dots, \|\pi_N\|_1)$ are approximated by $\xi^{(k-1)}$ in step 3. Each iteration of the IAD algorithm reduces the residual error (i.e., $\|\pi(I - P)\|$) by a factor of $\|E\|$ (see [14], p. 80).

The next section discusses how a modified version of Gaussian elimination may be used to enforce stability in the solution of the coupling matrix. In §3, the idea is extended so that it can be used in a nonsingular system of equations with a substochastic coefficient matrix. Section 4 discusses certain implementation issues, and §5 provides numerical experiments with the IAD algorithm on NCD Markov chains.

2. Solving the coupling matrix. The coupling matrix is an irreducible stochastic matrix of order N; that is, each of its two dimensions is equal to the number of blocks in the NCD Markov chain, and all states form a single communicating class. The goal is to solve the singular system $\xi^{(k)} C^{(k)} = \xi^{(k)}$ subject to $\|\xi^{(k)}\|_1 = 1$, which is termed the normalization equation. Essentially, each row of $C^{(k)}$ is a linear combination of the others, and inclusion of the normalization equation enables one to replace the redundant equation, thus achieving full rank in the set of equations. Being an irreducible stochastic matrix, the coupling matrix has a unique unit eigenvalue. All other $N - 1$ eigenvalues are close to 1. The distance of these other eigenvalues to 1 depends on the degree of coupling.

A careful inspection reveals that one can solve the equivalent transposed system

$$(I - C^{(k)})^T (\xi^{(k)})^T = 0, \qquad \|\xi^{(k)}\|_1 = 1. \tag{2.1}$$

The justification for considering this form of the problem is the following. (2.1) is the conventional form in which a (homogeneous) linear system of equations is expressed: the coefficient matrix postmultiplied by the unknown vector equals the (zero) right-hand side. Besides, there are already existing algorithms that may be used with this form of a linear system. But most importantly, as it is explained later in §4, a row-wise sparse storage implementation will spend extra time in the substitution phase of the nontransposed system of equations.

$(I - C^{(k)})^T$ is a singular M-matrix (see [1]) with 0 column sums, and the unique null vector of unit 1-norm is sought. For such a matrix, Gaussian elimination (GE) preserves column diagonal dominance throughout its computation so that the multiplier element at each step is bounded by 1 thereby eliminating the need for pivoting. This follows from the fact that the pivot element at a given step has the largest magnitude among all elements that lie in the unreduced part of its respective column. Note that the same argument would be valid for the original system of equations if $C^{(k)}$ was doubly stochastic.

It is well known that since $C^{(k)}$ is a perturbation of the identity matrix, all its nonunit eigenvalues are close to 1. Due to this fact, iterative methods tend to converge slowly. On the other hand, certain stability issues need to be addressed if direct methods are used. As it is shown next, ordinary GE is not stable in the presence of rounding errors on a coupling matrix whose diagonal elements are close to 1.

Example. Consider the following irreducible stochastic matrix:

$$P = \begin{pmatrix} \frac{1}{3} & \frac{2}{3} - \alpha & \alpha \\ \frac{3}{4} - \alpha & \frac{1}{4} & \alpha \\ \alpha & \alpha & 1 - 2\alpha \end{pmatrix}.$$

Assuming α is small, P is clearly NCD. Additionally, the degree of coupling is 2α. Now, suppose 2α is less than machine epsilon (smallest representable positive floating-point number ϵ such that $1 + \epsilon > 1$). Let $\pi^{(k)} > 0$. Then, the coupling matrix is rounded to

$$C^{(k)} = \begin{pmatrix} 1 & \alpha \\ 2\alpha & 1 \end{pmatrix}.$$

Note that the coupling matrix is not stochastic. Therefore, the matrix $(I - C^{(k)})^T$ is rounded to

$$(I - C^{(k)})^T = \begin{pmatrix} 0 & -2\alpha \\ -\alpha & 0 \end{pmatrix}.$$

Hence, it is necessary to apply some sort of pivoting strategy in order to proceed with GE. Otherwise, the algorithm breaks down contrary to the general belief that GE applied to stochastic matrices is always stable. Before going any further, this issue should be explained some more.

It is possible for an irreducible NCD Markov chain ordered as described in (1.1) to have zero blocks. Consequently, the coupling matrix of such a chain at any iteration has zeros in locations corresponding to zero blocks in the transition probability matrix. However, the zeros in the coupling matrix occur in just the right places so that the coupling matrix is still irreducible [8]. Keeping this in mind, the situation that causes GE to break down occurs when the pivot element at a given step of GE is zero in the matrix $(I - C^{(k)})^T$ during the kth iteration of the IAD algorithm. A sufficient condition for the failure of GE during the aggregation step is to have a transition probability matrix with a degree of coupling less than machine epsilon. In this case, all diagonal elements in $(I - C^{(k)})^T$ will be zero, as in the example, and GE will fail in the first step.

The advocated approach to finding a remedy for this situation is the GTH algorithm described in [4] and the direct method discussed in [16]. The original GTH algorithm emerges from probabilistic arguments, and it is shown that the stationary distribution of a Markov chain can be calculated using only nonnegative numbers and avoiding subtraction operations.

This algorithm achieves significantly greater accuracy than other algorithms described in the literature [11], [5] since there is no loss of significant digits due to cancellation [6]. Interestingly, the inspiration for the algorithm presented in [16], which is specifically for the solution of NCD Markov chains, is the GTH algorithm. In a recent paper [10], it is shown that the stationary probability vector of an $N \times N$ irreducible Markov chain stored in floating-point form is close to its exact stationary vector. In other words, even if one has an algorithm that does not introduce any errors by itself, the best that can be done is to compute the stationary vector of an $N \times N$ Markov chain with an entrywise relative error of only about $2Nu$ of the exact stationary vector. In fact, the relative error incurred by each element of the floating-point stationary vector is about $2Nu$, where u is the unit roundoff (i.e., the maximum relative error in approximating a real number by its nearest floating-point number). This result follows from the fact that the perturbation introduced by storing the matrix in floating-point form is of order unit roundoff. Moreover, in the same paper it is proven that if GTH is employed in the solution process of this $N \times N$ Markov chain, the relative error in each entry of the stationary vector will be of order N^3u. It should be remarked that the entrywise relative error in the stationary vector for the GTH algorithm is independent of the structure of the matrix and the magnitude of its elements.

The following lemma shows that the GTH way of calculating the pivot element may also be applied to the transposed system of equations (2.1). It is this form of the equations in which multipliers are bounded by 1, and it will be demonstrated by numerical experiments that the type of implementation chosen (i.e., transposed versus nontransposed system of equations) has no effect on the accuracy of the results obtained.

LEMMA. Let $A = I - P^T$, where P is a stochastic matrix, and

$$A = \begin{pmatrix} a_{11} & v^T \\ u & A_{22} \end{pmatrix}.$$

Then $e^T A = 0$ and $e^T u = -a_{11}$. If

$$L_1 A = \begin{pmatrix} a_{11} & v^T \\ 0 & \tilde{A}_{22} \end{pmatrix},$$

where

$$L_1 = \begin{pmatrix} 1 & 0 \\ -u/a_{11} & I \end{pmatrix}, \qquad L_1^{-1} = \begin{pmatrix} 1 & 0 \\ u/a_{11} & I \end{pmatrix},$$

then $\tilde{A}_{22}$ (like A) is a singular M-matrix having 0 column sums.

Proof. We have

$$e^T A = e^T (L_1^{-1} L_1) A = 0,$$

$$e^T L_1^{-1} = (1, 1, \dots, 1) \begin{pmatrix} 1 & 0 \\ u/a_{11} & I \end{pmatrix} = (0, 1, \dots, 1),$$

$$(0, 1, \dots, 1)(L_1 A) = 0 \;\Rightarrow\; e^T \tilde{A}_{22} = 0.$$

Other steps may be shown similarly. Note that the lemma is also valid for the negation of any generator matrix. □

The properties of a singular M-matrix coupled with the GTH idea of avoiding subtractions and negative numbers suggests the following modification to GE. At each step of GE, rather than calculating the pivot element in the usual way, one can correct the pivot by replacing it with the negated sum of the off-diagonal elements in the unreduced part of the same column as the pivot. When one mentions the GTH method, it is this approach used in calculating the pivot elements that is implied.

3. Using the GTH method in the disaggregation step. In a given iteration, the disaggregation step of the IAD method uncouples the NCD Markov chain to obtain a new estimate for the stationary distribution. As indicated in [21], in order to achieve an even better approximation of π, at the $(k+1)$st iteration of the IAD algorithm, one solves

$$(I - P_{ii}^T)(\pi_i^{(k+1)})^T = b_i, \tag{3.1}$$

where $\pi_i^{(k+1)}$ is the $(k+1)$st approximation of π_i and $b_i^T = \sum_{j<i} \pi_j^{(k+1)} P_{ji} + \sum_{j>i} z_j^{(k+1)} P_{ji}$ for $i = 1, 2, \ldots, N$ (see step 4(b) of the IAD algorithm).

P_{ii} is a strictly substochastic matrix of order n_i, and $b_i \neq 0$, which gives a nonhomogeneous system of linear equations with a nonsingular coefficient matrix. Had the coefficient matrix been stochastic, the same GTH technique that is utilized in solving the coupling matrix could be clearly employed. In order to be able to use the GTH technique in solving the diagonal block system, first certain modifications must be made. These modifications involve adding one more equation and augmenting the matrix with b_i to put the system into the form

$$W_i^T (\pi_i^{(k+1)}, \hat{\pi}_i^{(k+1)})^T = 0, \tag{3.2}$$

where

$$W_i^T = \begin{array}{c} \begin{array}{cc} n_i & 1 \end{array} \\ \left(\begin{array}{cc} I - P_{ii}^T & b_i \\ w_i^T & \hat{w}_i \end{array} \right) \end{array} \begin{array}{c} \\ n_i \\ 1 \end{array},$$

$w_i = P_{i*}e$, $\hat{w}_i = -b_i^T e$, and $\hat{\pi}_i^{(k+1)}$ is introduced so that the solution vector has as many columns as the coefficient matrix. In other words, $(w_i^T, \hat{w}_i)$ sums up the columns of W_i^T to 0. The values of $\hat{w}_i$ and $\hat{\pi}_i^{(k+1)}$ are irrelevant, because just as in (2.1) one has a singular system with $n_i + 1$ equations, and after W_i^T is reduced to upper-triangular form, the last row will be all 0's. Hence, the reduction needs to be carried out for only n_i steps. What needs to be done for the computation of $(\pi_i^{(k+1)})^T$ is to use the first n_i elements of column $n_i + 1$ in the upper-triangular matrix as the right-hand side in the back substitution phase.

It is not possible to put GE to use in the disaggregation step in the previous example in §2 or in similar problems on the diagonal blocks for which $\|P_{i*}\|_\infty < \epsilon$. Under the given condition, $I - P_{ii}^T$ is a singular matrix in floating-point form; however, the vector b_i is still nonzero, and therefore the system of equations in (3.2) is inconsistent. On the other hand, GTH computes w_i^T in W_i^T by using the nonzero elements in P_{i*} and forms the pivot by summing off-diagonal entries in the unreduced part of the same column as the pivot. Hence, GTH may be applied to solve such blocks.

4. Implementation considerations. As mentioned before, NCD Markov chains that arise in real-life applications are generally large and sparse. This necessitates the design and employment of sparse storage schemes, which essentially store only the nonzero elements of the transition probability/rate matrix.

So far, the application of the GTH (and GE, for that matter) algorithm to systems (2.1) and (3.1) is considered. (3.1) is written in the form of (3.2) so that it has a singular M-matrix with 0 column sums as its coefficient matrix just as in (2.1). Now, the alternative nontransposed systems of equations may be written. The system that corresponds to (2.1) is given by

$$\xi^{(k)}(I - C^{(k)}) = 0, \qquad \|\xi^{(k)}\|_1 = 1. \tag{4.1}$$

Similarly, the equivalent of (3.2) is

$$(\pi_i^{(k+1)}, \hat{\pi}_i^{(k+1)})W_i = 0. \tag{4.2}$$

Define

Scheme 1. The transposed systems of equations in (2.1) and (3.2).

Scheme 2. The nontransposed systems of equations in (4.1) and (4.2).

Unless otherwise specified, reductions mean row reductions (i.e., the addition of a multiple of a lower-indexed row to a higher-indexed row) in a given system of equations. The last assumption is that the coefficient matrices are supplied to both schemes in the nontransposed version. This is a fairly reasonable assumption, since the matrices are usually generated by following the possible transitions from a given state, implying a row-wise generation.

The advantage of reducing the coefficient matrices in Scheme 1 rather than the ones in Scheme 2 to upper-triangular form is twofold:

- the multiplier elements at each step of the reduction are bounded by 1 and
- only the upper-triangular matrix needs to be stored during the reduction process.

Although the multipliers in Scheme 2 are not necessarily bounded by 1, the growth factor still cannot be greater than 1 as indicated in [22]. However, if row reductions are carried out in Scheme 2, both the upper-triangular matrix and the lower-triangular matrix, which contains the multipliers, have to be stored during the triangularization process. The reason is that if row reductions are performed on the nontransposed coefficient matrix, the LU decomposition will provide a nonsingular lower-triangular matrix and a singular upper-triangular matrix that has 0's in the last row. Although the decomposition is premultiplied by the stationary vector, one only has to carry out a single substitution phase (see [9], p. 724) just as in the transposed system of equations (but this time involving the lower-triangular matrix), thereby making it necessary to store both the lower and the upper-triangular matrix during the reduction. One cure that comes to mind is to store only the upper-triangular matrix during the reduction process and to reconstruct the multiplier matrix after the reduction is over. Though quite straightforward, this solution is inefficient due to the superfluous operations performed in calculating the multipliers for the second time. On the other hand, Scheme 1 calls for the transposition of the coefficient matrix before executing GE or GTH.

What follows is a discussion of the effects of the two implementation schemes on a *semisystematic row-wise sparse storage format* (see [13]). A row-wise sparse storage format is a data structure that stores the nonzero elements in the coefficient matrix row by row. Semisystematic means the elements of row i precede those of row $i + 1$, but the elements within a given row need not be ordered. Together with the real value of each nonzero element, the column index of the element is stored as well. Hence, two arrays of the same length, one real and the other integer, are needed. Last, in order to have access to the rows, the starting location of each row has to be stored in an integer array. To facilitate the computation of the number of nonzero elements per row, an extra element whose value is equal to the total number of nonzero elements plus 1 is appended to this array.

The GE algorithm, no matter which scheme is chosen, may be implemented using delayed updates, which means at step k all reductions on row $k + 1$ may be carried out and the row compacted and stored before the algorithm continues in the next step with the update of the next row. The property of the GE algorithm that makes this efficient implementation possible is that reduction on a given row requires the addition of appropriate multiples of lower-indexed rows to it. Hence, there is no data dependency between a row to be reduced and higher-indexed rows in GE. The importance of this idea lies in the fact that it is sufficient to fully expand only the row to be updated at a given step, whereas all other rows with higher indices can still be held in compact form. However, this is no longer applicable when GTH is used in Scheme 1, since all updates due to a row must be finished before the algorithm proceeds with the next step. This situation is dictated by the new way of calculating the pivot elements. In the GTH algorithm, the pivot element is formed by summing the most recently updated elements that lie below the pivot, which implies a dependency of data between the pivot row and the higher-indexed rows. Since storage is limited, one possibility is to expand each row that is operated on, update it, and finally store it back in the appropriate location. The drawback is that this sequence of operations on a row, depending on the fill-in, most probably causes other elements in sparse storage to be shifted around the data structure (extra nonzero entries are likely to occur after a row update). Consequently, it is safe to assume that GTH, with such an implementation, spends more time doing memory reads and writes for larger chains. As pointed out in §2, there is a slight difference in the way the single substitution phase in Schemes 1 and 2 is implemented in the GTH algorithm when a row-wise sparse storage format is used. In the substitution phase, Scheme 2 calls for the solution of a homogeneous linear system in which the stationary vector is postmultiplied by the lower-triangular matrix obtained from the LU decomposition. The substitution is accomplished by accessing a different column of the lower-triangular matrix at each step. This situation makes it necessary to have a doubly nested loop in the code for accessing the elements of the columns. On the other hand, the substitution phase of Scheme 1 requires the solution of a homogeneous linear system in which the stationary vector is premultiplied by an upper-triangular matrix. This being so, the substitution phase of Scheme 1 conforms nicely to a row-wise sparse storage implementation, and, therefore, it may be handled in a single loop that accesses a row of the upper-triangular matrix at each step. In the actual implementation, the normalization equation (i.e., $\|\pi\|_1 = 1$) is used to discard the last equation and form a nonzero right-hand side in both schemes.

A suggestion made by G. W. Stewart [18] as a compromise between the high accuracy of GTH and the implementation efficiency of GE is the following. Rather than performing a correction on the pivot element at each step of GTH, the suggestion is that a pivot should be corrected only when cancellation would produce an inaccurate pivot. For the systems arising in the IAD algorithm, cancellation seems to occur at quite predictable places. Specifically, for the coupling matrix $C^{(k)}$, cancellation occurs in the computation of the diagonal elements of $I - C^{(k)}$. The suggested cure is to compute the diagonal elements of $I - C^{(k)}$ from the off-diagonal elements at the start and to use GE thereafter. For the solution of the diagonal blocks, cancellation is most likely to occur in the computation of the last pivot element. In this case the recommendation is that GE should be applied to the augmented system in (3.2) (or (4.2)), and only the last pivot should be computed by summing the off-diagonal probability mass as in GTH. It is expected that using the suggested scheme in the IAD algorithm will result in a competitive solver (with the GTH method in terms of relative accuracy and with the GE method in terms of total time spent in the IAD algorithm). Results of experiments with this scheme are discussed in §5.

An alternative storage scheme is one that keeps the unused array elements in the form of a linked list (basically, a freepool). In this case, an extra integer array, which, for each nonzero element, stores the location of the next nonzero element in the same row, is required. If a given element is the last in its row, then the corresponding pointer may be set to 0. Though this scheme circumvents the problem of moving array elements back and forth in memory, it introduces overhead due to the manipulation of the freepool. Note that just as in the ordinary row-wise sparse storage format, all elements in a row may be kept ordered according to their column indices in this last implementation. Finally, it should be pointed out that the effect of using a column-wise sparse storage format with Scheme 2 is the same as using a row-wise sparse storage format with Scheme 1 and vice versa.

Although not as costly as the extra reads and writes due to the discussed implementation problems, GTH has $N - k$ extra additions at step k of the elimination procedure, amounting to $\sum_{k=1}^{N-1}(N - k) = N(N - 1)/2$ extra operations in the solution of the coupling matrix. Similarly, there are $n_i(n_i - 1)/2$ extra additions in the solution of the ith diagonal block. Clearly, this is an upper bound. Since these extra addition operations are performed only on nonzero elements in a sparse storage implementation, the actual overhead may be smaller. Moreover, because of the need to introduce one more row to the linear system, extra $n_i + 1$ locations are used during the solution of each P_{ii} in the disaggregation step. Last, in order to form the $(n_i + 1)$st equation during the disaggregation step, a number of additions equal to the number of nonzero elements in P_{i*} are performed. If extra memory locations are available, these N matrix–vector multiplications may be performed at the outset and the resulting vectors stored for future use.

Note that both programming difficulties and overhead storage (arrays to store the indices of nonzero array elements and pointers between elements) increase with the sophistication of the storage scheme. Together with the row-wise sparse storage format, experiments with the sparse storage format proposed by Knuth (see [13] for a brief explanation), which provide equally fast access to columns and rows of a matrix, are conducted. For each nonzero element, in addition to having a pointer to the next nonzero element in the same row, there is an additional pointer to the next nonzero element in the same column. Obviously, there are two arrays that keep the locations of the first nonzero element in each row and each column, respectively. However, as remarked earlier, extra time will be spent for obtaining memory elements from and returning memory elements to the freepool with this kind of implementation. With Knuth's sparse storage format, there is no need to transpose the matrix because rows may be treated as columns and columns as rows. Although one may be inclined to think that Knuth's sparse storage format is more advantageous than the row-wise sparse storage format, due to the overhead of handling the freepool, numerical experiments suggest that Knuth's format is likely be useful only if implemented in a programming language that provides primitives for pointers to memory.

If some information about the structure of the coefficient matrix is available, then another possibility may be to employ a two-dimensional banded storage structure. As for GE, the row-wise sparse storage format with Scheme 1 is recommended.

Keeping in mind that memory is much slower than CPU, one must evaluate the significance of extra operations performed and excess time spent in a sparse storage implementation as opposed to the increased stability and accuracy that accrue from GTH in the context of real-life applications.

5. Numerical results. Experiments with the IAD algorithm are carried out in sparse storage on a SUN SPARC station 2. All routines used are part of the software package MARCA (Markov Chain Analyzer) (see [20]). The routines are written in FORTRAN and compiled in both double-precision and quadruple-precision floating-point arithmetic. For each problem solved, the residual error and the relative error in the solution are computed. The relative error is computed as $\|\pi - \tilde{\pi}\|_2/\|\pi\|_2$, where π is the quadruple-precision solution and $\tilde{\pi}$ is the double-precision solution obtained by the IAD algorithm. Both π and $\tilde{\pi}$ are normalized so that their 1-norms are unity. The residual error is computed as $\|(I - P^T)\tilde{\pi}^T\|_2$, which theoretically is 0 if $\pi = \tilde{\pi}$. See Table 1.

TABLE 1
Notation for parameters of numerical methods.

n	Order of the stochastic transition matrix P
n_z	Number of nonzero elements in the matrix
N	Number of strongly connected components
nzb	Number of nonzero blocks
$Iter$	Number of iterations required to get a residual norm of less than 10^{-15}
T_{total}	Total time spent in the IAD algorithm, (in CPU seconds)
Err_{res}	$\|(I - P^T)\tilde{\pi}^T\|_2$
Err_{rel}	$\|\pi - \tilde{\pi}\|_2/\|\pi\|_2$
γ	Decomposability parameter
M_{agg}	Method used in aggregation phase
M_{disagg}	Method used in disaggregation phase

GTH_1	Sparse Grassmann–Taksar–Heyman algorithm using Scheme 1

The problem associated with GE, when NCD Markov chains with a degree of coupling less than machine epsilon are to be solved, has already been shown. Therefore, the emphasis is on problems with a degree of coupling larger than machine epsilon in order to see how GE and GTH behave comparatively in this case. Experiments are performed with implementation Schemes 1 and 2 on the row-wise sparse storage format used in MARCA. The GTH implementation of Scheme 1 is accomplished by shifting contents of arrays rather than using the alternative with the freepool. See Table 2.

The first problem appears quite frequently in the literature. Although the order of the matrix considered in this problem is quite small, it is still instructive to examine the effects of using the IAD algorithm on such a problem. The second problem investigated is a real-life example and had been studied with a variety of parameters in the past. The scheme suggested by G. W. Stewart [18] in §4 is implemented, and the outcome of the related experiments are discussed following the presentation of the numerical results.

The decomposability parameter γ (in Table 1) is input by the user; it is used to determine the strongly connected components in the transition matrix by simply ignoring the elements that are less than the suggested value. Therefore, γ may be taken as an approximation of the degree of coupling. If the matrix is not already in the form (1.1), then symmetric permutations are used to put it into the form in which the diagonal blocks form the strongly connected aggregates.

5.1. Test Problem 1. The first problem that is considered is the 8×8 Courtois matrix [3] with all row sums equal to 1. The degree of coupling for this matrix is 0.001.

5.2. Test Problem 2. The second problem considered appears in [19]. It represents a time-shared, multiprogrammed, paged, virtual memory computer system modeled as a closed queueing network (see Fig. 1).

The system consists of a number of users using the terminals, a central processing unit (CPU), a secondary memory device (SMD), and a filing device (FD). The degree of multiprogramming in the system at any given time is $\eta = \eta_0 + \eta_1 + \eta_2$, where η_0, η_1, η_2 are, respectively, the number of processes in the CPU, SMD, and FD queues at that moment. Furthermore, η_t represents the number of processes currently being generated at the terminals but not yet transmitted to the CPU for execution. λ is the mean generation time of processes by users working on the terminals. The mean service rate of the CPU depends on η and is given by $\mu_0(\eta)$. The processes that leave the CPU proceed to the SMD, to the FD, and back to the terminals with probabilities p_1, p_2, $1 - p_1 - p_2$, respectively. The mean service rate at the SMD is given by μ_1 and at the FD by μ_2. All arrival and service rates are exponential. Note that it is not possible to apply analytical techniques to solve the above model since the CPU execution time depends on the degree of multiprogramming.

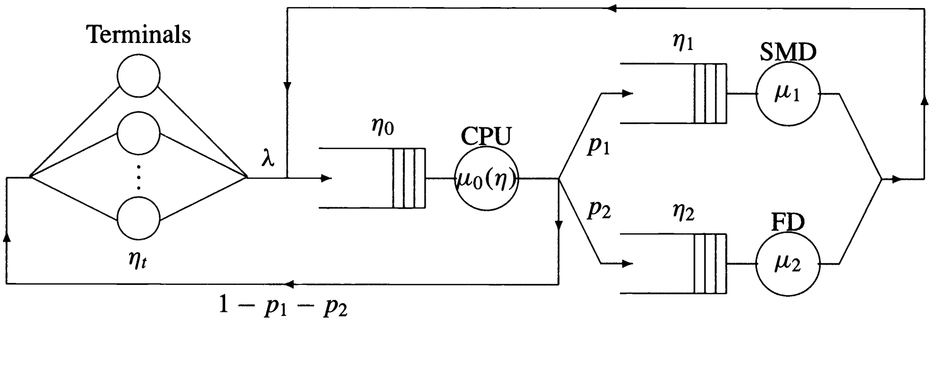

FIG. 1. *An interactive computer system.*

Given the necessary parameters, MARCA generates the transition probability matrix corresponding to the specific queueing system under consideration. Experiments with different combinations of parameters are carried out because the effect of making the transition probability matrix larger and closer to the identity matrix so that it is almost decomposable is to be observed. The generated matrix has a block tridiagonal structure with a small percentage of nonzero elements. It must be remarked that this type of matrix is frequently encountered in queueing network analysis.

(a) For the first example, the following parameters are chosen:

$$\begin{aligned} \eta_t + \eta &= 3, \\ \lambda &= (10^{-4})\eta_t, \\ p_1\mu_0(\eta) &= 100(\eta/128)^{1.5}, \\ p_2\mu_0(\eta) &= 0.05, \\ 1 - p_1 - p_2 &= 0.002, \\ \mu_1 &= 0.2, \\ \mu_2 &= 1/30. \end{aligned}$$

In all problems considered, both IAD with GE and IAD with GTH converged (see $Iter$ in Table 1) with a residual of order machine epsilon regardless of the implementation scheme chosen. For each problem, the number of iterations taken by both methods is the same.

However, the relative error in IAD with GE is much larger than that of IAD with GTH in the first small problem (see Table 3) where IAD with GTH has a relative error almost of order machine epsilon. It is presumed this is due to the smaller size of the systems solved in this problem. The first test problem has a small coefficient matrix giving rise to a coupling matrix of size 3 × 3. Similarly, the largest system solved in the disaggregation step of the IAD algorithm is of size 3 × 3. Consequently, one expects to lose a relative accuracy of roughly 2 digits in this problem when IAD is used with GTH. The results confirm that IAD with GTH performs even better than the expectations, and only a single digit of accuracy is lost. However, as in the second problem, there are cases where the GTH algorithm does not achieve its worst-case bound due to statistical effects in rounding error accumulation although the matrices solved are considerably larger (see Tables 4, 8, 10, 12, and 14). Moreover, just as indicated in [10], it is possible to improve the entrywise relative error in the GTH algorithm even further by forming the pivot element in higher precision (quadruple precision for the given system parameters).

As expected, the number of iterations taken to achieve the prespecified tolerance criterion decreases as the decomposability parameter becomes smaller for a given problem. Among the problems considered, when the decomposability parameter is greater than or equal to 10^{-6}, IAD with GE provided results in which 3 to 5 digits of accuracy are lost (see Tables 3, 5, 9, 11, 13, and 15). An observation regarding the results of the second test problem is the difference between T_{total}'s for implementation Schemes 1 and 2 (see Tables 9, 11, 13, 15, and 16). First, although it is not the case for the second problem, the nonzero structure of a nonsymmetric matrix changes if the matrix is transposed, thus totally affecting the reduction process. Second, both methods in Scheme 2 store the multipliers, and thus they spend extra time. Finally, remember that Scheme 1 implementation of GTH is accomplished by shifting data around in memory, which is a very time-consuming process.

The results of the modified scheme (suggested by G. W. Stewart) are quite competitive with those of IAD with GTH for the first small problem (see Table 17). However, there are examples (Test Problem 2, parts (b), (c), (e), (f), (g)) with varying degrees of decomposability for which the modified scheme does not provide a relative error that is competitive with the relative error in IAD with GTH (see Tables 6, 7, 11, 13, and 15). However, it is never larger than the relative error in IAD with GE (see Table 17). The timing of the modified scheme is almost as good as that of IAD with GE even for the larger test cases.

6. Conclusion. In this paper, the computation of the stationary probability vectors of ill-conditioned NCD Markov chains is considered. The GTH method, which avoids subtractions, is a much more stable version of GE. For that reason, it is a good candidate to be used in the two-level IAD algorithm. Experiments on several problems are carried out, applying this

TABLE 17
Results for modified scheme (transposed version).

Problem	*Iter*	T_{total}	Err_{res}	Err_{rel}
1	4	0.04	$0.621E-16$	$0.423E-15$

2(h)	3	2.71	$0.399E-16$	$0.273E-15$

idea versus GE in the IAD technique. The GTH approach to calculating the pivot element by taking the negated sum of the off-diagonal elements in the unreduced part of the pivot column proves to be valuable for singular M-matrices with 0 column sums, and it is shown to be quite effective on the problems of interest.

The GTH idea is employed to solve the linear systems of equations formed in both the aggregation and disaggregation steps of the IAD algorithm. For the first small problem considered, we observed that the relative error in IAD with GE is much larger than that of IAD with GTH, whose relative error is fixed in the order of machine epsilon. In all cases, the size of the systems solved provides an estimation for the worst case bound on the relative error for IAD with GTH. Additionally, just as explained in §4, it was not surprising to see IAD with GTH take on the order of 10 times as much time as IAD with GE for the larger chains in the second test problem. A modified scheme suggested by G. W. Stewart, which essentially performs diagonal correction on pivots only when there is a suspected loss in significance, seems to work very well in the IAD algorithm for small NCD Markov chains. The scheme possesses the good relative accuracy property of GTH and the convenient implementation of GE. However, for larger matrices, it is frequently no better than GE (while never being worse than GE) in terms of relative accuracy. It is also verified for IAD with GE that a significant difference between the relative error and the residual error is a clear indication of an ill-conditioned problem.

In conclusion, ordinary GE should definitely be avoided in both steps of the iterative IAD algorithm when solving NCD chains with a degree of coupling less than machine epsilon. However, if an approximation to the stationary vector of a large NCD Markov chain is sought in a short time, IAD with GE may be used. On the contrary, if relative error in the stationary vector of the NCD chain is deemed as of utmost importance, then IAD with GTH has to be recommended. However, we do recommend IAD with GE when the decomposability parameter for a given problem is greater than or equal to 10^{-6}. Only 3 to 5 digits of accuracy were lost in such problems considered. A compromise between GE and GTH seems to be the modified scheme suggested by G. W. Stewart. Examination of several sparse storage formats for both GTH and GE has indicated one disadvantage of the GTH method. The time to execute the IAD algorithm on large irreducible NCD Markov chains tends to be longer when the GTH method is used in the aggregation and disaggregation steps of the iterative solver. Memory requirement of the GTH algorithm is generally slightly higher than that of GE; nevertheless this mostly depends on the sparse storage format chosen. One last remark would be to direct attention to the possibility of exploiting the inherent parallelism in the formation of the coupling matrix. Similarly, parallel implementation of the solution of N nonsingular systems in the disaggregation step needs to be investigated.

MOVING MESH METHODS FOR PROBLEMS WITH BLOW-UP*

CHRIS J. BUDD†, WEIZHANG HUANG‡, AND ROBERT D. RUSSELL§

Abstract. In this paper we consider the numerical solution of PDEs with blow-up for which scaling invariance plays a natural role in describing the underlying solution structures. It is a challenging numerical problem to capture the qualitative behaviour in the blow-up region, and the use of nonuniform meshes is essential. We consider moving mesh methods for which the mesh is determined using so-called *moving mesh partial differential equations* (MMPDEs). Specifically, the underlying PDE and the MMPDE are solved for the blow-up solution and the computational mesh simultaneously. Motivated by the desire for the MMPDE to preserve the scaling invariance of the underlying problem, we study the effect of different choices of MMPDEs and monitor functions. It is shown that for suitable ones the MMPDE solution evolves towards a (moving) mesh which close to the blow-up point automatically places the mesh points in such a manner that the ignition kernel, which is well known to be a natural coordinate in describing the behaviour of blow-up, approaches a constant as $t \to T$ (the blow-up time). Several numerical examples are given to verify the theory for these MMPDE methods and to illustrate their efficacy.

Key words. blow-up solution, moving mesh, scaling invariance

1. Introduction.

Many mathematical idealizations of physical models have the property that they develop singularities in a finite time T. Examples are the blow-up of the solutions of models describing combustion in chemicals or chemotaxis in cellular aggregates and the formation of shocks in the inviscid Burgers' equation and the space-charge equations. Such a singularity often represents an important change in the properties of the model, such as the ignition of a heated gas mixture, and it is important that it should be accurately reproduced by a numerical computation.

When a singularity forms, changes occur on increasingly small length scales and, as the time T is approached, on increasingly smaller timescales. If a numerical method with a *fixed* mesh is used to reproduce such behaviour then its accuracy will diminish significantly when the length scale of the singularity approaches the spacing between mesh points. In some cases this will lead to numerical solutions which differ qualitatively from the underlying analytic solution. Indeed, examples can be found where a computation on a fixed mesh misses the blow-up entirely, or where the numerical solution blows up over the whole region even though the analytic solution develops a singularity at a single point [AB94].

To compute such singular behaviour accurately, it is essential to use a numerical method which adapts the spatial mesh as the singularity develops. Ideally, the numerical method will reproduce the singularity sufficiently accurately as $t \to T$ to mimic the asymptotic behaviour of the solution. A feature of a wide class of PDEs (partial differential equations) which makes this feasible is that the spatial structure of the singularity evolves in a fairly simple manner, often independent of any local structure in the initial conditions. Provided that the adaptive method can reproduce this simple asymptotic behaviour, there is reason to hope that a numerical scheme can be designed to perform accurately for all times $t < T$.

One class of problems which have this feature is the semilinear parabolic equations describing the blow-up of the temperature of a reacting medium, such as a burning gas. The

simplest equations describing such blow-up have the form

$$(1.1)\qquad u_t = u_{xx} + f(u), \quad u(0,t) = u(1,t) = 0, \quad u(0,x) = u_0(x),$$

where $f(u)$ is any convex function of u such that $f(u) \to \infty$ as $u \to \infty$. In this paper we shall consider the cases of $f(u) = u^p$, $f(u) = e^u$, and slightly more general problems. It is well known [FM85] that if $u_0(x)$ is "sufficiently large" and has a single nondegenerate maximum, then there is a blow-up time $T < \infty$ and a unique blow-up point x^* such that

$$(1.2)\qquad u(x^*, t) \to \infty \quad \text{as } t \to T$$

and

$$(1.3)\qquad u(x,t) \to u(x,T) < \infty \quad \text{if } x \neq x^*.$$

(If $t > T$ the solution becomes infinite everywhere.) Close to x^*, the solution $u(x,t)$ develops an isolated peak which becomes narrower, tending to zero width, as $t \to T$. A derivation and general study of these systems is given in [BE89].

The computation of the solutions of (1.1) is important for several reasons. First, although very simple, the formation of the singularities in this problem is typical of that of a wide class of PDEs modelling many differing physical phenomena. Second, a great deal is known about the analytic structure of the solutions of (1.1) for t close to T and x close to x^*, and thus they make excellent problems for testing the performance of and verifying the analysis for the numerical methods used in their solution. Third, having numerical methods which are faithful to the underlying asymptotics of the PDEs raises the possibility of solving very difficult problems for which the analytic structure is unknown, and then using the resulting numerical solutions to lend insight into this structure. Of course this can in turn motivate derivation of further theoretical results.

Existing adaptive numerical methods for solving (1.1) are described in [Cho81], [LPSS86], [BK88], [Ber89], and [BDS93]. These are either based upon closely exploiting the known analytic structure of the singularity or on an adaptive procedure which requires an increasingly larger number of mesh points to model the developing singularity as $t \to T$. In contrast, we shall describe here an elegant set of methods for solving (1.1) which use the dynamic gridding algorithms described in [HRR94b]. These MMPDE (moving mesh PDE) methods are based upon equidistributing a monitor function, say $M(u, u_x, u_{xx})$, which relies on no a priori knowledge of the solution to the PDE u, although an analysis of scaling properties of the PDE does lead to certain optimal choices of M. We shall show that these methods have the significant property that they reproduce the dynamical nature of the development of the singularity. In particular, there is a natural rescaling of the spatial coordinate close to the singularity which is automatically captured by the moving mesh method.

The asymptotic scaling of the singularity was first observed formally by [Dol85]. A full proof is given in [BB92]. They showed that for x close to x^* and t close to T there was a natural spatial coordinate, the so-called *ignition kernel* μ, where

$$(1.4)\qquad \mu(x,t) = (x - x^*)\left[(T-t)|\log(T-t)|\right]^{-\frac{1}{2}}.$$

In [BK88] the original PDE is recast in terms of the closely related "similarity" variable

$$(1.5)\qquad \zeta = \mu \ \log^{\frac{1}{2}}(T-t),$$

which is derived from a scaling invariance of the original PDE, and the resulting scaled PDE is then solved by using a static regridding algorithm. In contrast, we show that the MMPDE solution evolves towards a (moving) mesh which close to the singularity automatically places the mesh points $x_i(t)$ in such a manner that $\mu(x_i, t)$ approaches a constant as $t \to T$. In this way, the MMPDE methods naturally inherit the correct spatial structure of the singularity.

The paper is organized as follows. In §2 we introduce the blow-up problems and describe the asymptotic form of solutions close to blow-up. In §3 we introduce the MMPDE method for determining the mesh coordinate transformation used to solve these problems. Motivated by the desire to preserve scaling invariance, we consider the effect of different choices of the MMPDE and monitor function M. In §4 we show that in fact the "approximate" similarity solution behaviour of (1.1) is preserved by suitable choices of M, using techniques for the discrete analysis which mimic the previous analyses for the continuous case. In §5 we give numerical examples to verify the theory for these MMPDE methods and illustrate their efficacy. Finally, in §6 we state some conclusions and briefly discuss a more general framework under current investigation.

2. Structure of blow-up solutions for PDEs. We now consider the form of the solutions of the semilinear parabolic PDE

$$\begin{aligned} &u_t = u_{xx} + u^p, \quad p > 1, \\ &u(0,t) = u(1,t) = 0, \\ &u(x,0) = u_0(x) > 0. \end{aligned} \tag{2.1}$$

As well as looking at the asymptotic form of the solutions close to blow-up we also consider some of the underlying principles which lead to these solutions. These principles can then be used as a guide to the numerical method and also to study other related equations.

It has been shown by several authors, e.g., [FM85], that if $u_0(x)$ is sufficiently large and positive and has a single nondegenerate maximum, then (1.2) and (1.3) hold. The point x^* and the time T depend subtlely upon $u_0(x)$ but, remarkably, the solution $u(x,t)$ itself is almost independent of u_0 provided that x and t are close to x^* and T, respectively. The blow-up profile takes the form of an isolated spike of increasingly narrow width and has been studied by [Dol85] and [BK88]. The behaviour of this spike may be described as follows.

THEOREM 2.1. *Let $\beta = \frac{1}{p-1}$ and let $\mu(x,t)$ be defined by*

$$\mu = (x - x^*)\left[(T-t)(\alpha - \log(T-t))\right]^{-\frac{1}{2}} \tag{2.2}$$

where α is a constant which depends on $u_0(x)$.

(i) *If $x(t)$ is taken to keep $\mu(x,t)$ constant, then the solution $u(x,t)$ to* (2.1) *satisfies*

$$(T-t)^\beta u(x,t) \to \beta^\beta \left[1 + \frac{\mu^2}{4p\beta}\right]^{-\beta} \quad \text{as } t \to T. \tag{2.3}$$

(ii) *If $|x - x^*|$ is small but fixed and independent of t, then*

$$u(x,t) \to u(x,T) = \left[4p\beta^2 \frac{|\alpha - 2\log|x-x^*||}{|x-x^*|^2}\left(1 + O(|x-x^*|)^2\right)\right]^\beta \tag{2.4}$$

as $t \to T$.

We observe that the expressions (2.3) and (2.4) coincide if we set μ to be large. The expression (2.3) describes the evolution of the blow-up peak in terms of the "ignition kernel" μ. This variable was first identified by [Dol85], and is a natural variable to describe the spatial structure of blow-up. A remarkable feature of the numerical methods we shall describe is that close to x^* the moving mesh is placed precisely at those points for which μ is constant.

The starting point for deriving these expressions is a natural scaling invariance of the solutions of (2.1) (in the absence of boundary conditions). In particular, the equation is invariant under the scaling

$$\left\{\begin{array}{l}(T-t)\to\lambda(T-t),\\ u\to\frac{1}{\lambda^\beta}u,\\ x\to\lambda^{\frac{1}{2}}x\end{array}\right. \tag{2.5}$$

for any positive λ. A similarity solution of (2.1) is any solution which is invariant under this scaling. Many interesting PDEs, including problems leading to blow-up (see below), have a scaling invariance similar to (2.5).

Motivated by (2.5) we recast (2.1) in terms of *similarity variables* $w(s,y)$, y, and s defined by

$$\left\{\begin{array}{l}s=-\log(T-t),\\ w(s,y)=(T-t)^\beta u(x,t),\\ y=(x-x^*)(T-t)^{-1/2}\end{array}\right. \tag{2.6}$$

to give the partial differential equation

$$w_s=w_{yy}-\frac{1}{2}yw_y+w^p-\beta w \tag{2.7}$$

supplemented with

$$w_y(s,0)=0 \text{ and } w(s,y)\to 0 \text{ as } |y|\to\infty. \tag{2.8}$$

The latter condition is necessary to match the boundary conditions satisfied by the solutions of the unscaled problem.

A similarity solution of the original PDE is a steady state (i.e., s independent) solution of (2.7) which also satisfies (2.8). These solutions were originally proposed as solutions of (2.1), but in fact, the only bounded, nonzero steady state solution of (2.7) is

$$w(s,y)=\beta^\beta, \tag{2.9}$$

which fails to satisfy (2.8). However, if we consider a set of points $x(t)$ such that $y(x,t)$ is fixed, then by using energy arguments Giga and Kohn [GK85] show that

$$(T-t)^\beta u(x,t)\to\beta^\beta, \tag{2.10}$$

so that the function (2.9) is an attractor for solutions of (2.7) over compact sets in y.

To calculate a solution of (2.7) which corresponds to a solution of (2.1) we consider instead a perturbation of the similarity solution by setting

$$w(s,y)=f\left(\frac{y}{g(s)}\right)\equiv f(z) \tag{2.11}$$

where f and g satisfy the conditions

$$\left\{\begin{array}{l}f(z)\to 0 \text{ as } |z|\to\infty,\\ g(s)\to\infty \text{ as } s\to\infty,\\ \frac{g'}{g}\to 0 \text{ as } s\to\infty.\end{array}\right. \tag{2.12}$$

The derivation of these conditions is given in [BK88]. Substituting into (2.7) gives

$$-\frac{g'}{g}zf_z - g^{-2}f_{zz} + \frac{1}{2}zf_z + \beta f - f^p = 0 \tag{2.13}$$

which, for large s, reduces to the first-order equation

$$\frac{1}{2}zf_z + \beta f - f^p = 0 \tag{2.14}$$

with solution

$$f(z) = \left[\frac{1}{\beta} + cz^2\right]^{-\beta}, \tag{2.15}$$

where c is a constant which without loss of generality may be set to 1. The reduction of problem (2.1) from a second-order equation (2.7) to a first-order Hamilton-Jacobi one (2.14) is a crucial feature of blow-up problems, see [GV93]. The function g, giving the spreading rate, can be derived formally by making an expansion of the function w in powers of $\frac{1}{s}$ and matching terms. This implies that g^{-2}, $\frac{g'}{g}$, and s^{-1} should all be of the same order for $s >> 1$. The details of this derivation are given in [BK88] and [Dol85] and give

$$g(s) = \left[4\beta^2 p(s+\alpha)\right]^{\frac{1}{2}} \tag{2.16}$$

where α is a constant which depends (weakly) upon the initial conditions. Combining (2.15) with (2.16) and taking s large gives (2.3).

The derivation given here is formal and is closely related to an analysis of the behaviour of the numerical scheme described in §4. A more precise derivation of the result (2.3) describing the shape of the blow-up peak follows from a centre-manifold reduction of the solutions of (2.7) and is given in [BB92], [FK92], and [HV93]. These papers also give a rigorous derivation of (2.4), although this equation follows formally from taking the large μ limit of (2.3) and matching to a steady state solution.

A useful conclusion from (2.3) is the natural relationship between the various scalings involved in the solution of the blow-up problem. In particular, if we consider $\tau = (T - t)$ to be the local "timescale" for blow-up, then the corresponding scale for u is

$$U = \frac{1}{\tau^\beta}, \tag{2.17}$$

and the length scale for x is

$$X = \left[\tau(\alpha - \log\tau)\right]^{1/2}. \tag{2.18}$$

Furthermore, the scale for u_x is approximately given by

$$u_x \approx \frac{U}{X} = \left[\tau^{1+2\beta}(\alpha - \log\tau)\right]^{-1/2}. \tag{2.19}$$

These scales are useful in deciding the choice of an appropriate numerical method. For example, (2.18) gives an indication of the correct mesh spacing close to the blow-up point.

The scaling invariance (2.5) plays a crucial role in the analysis of (2.1). Although the solution of the PDE is not self-similar, it is close to being self-similar and moreover converges to the self-similar solution $w = \beta^\beta$ on any compact interval in the similarity variable y.

Such scaling invariance and associated self-similar and approximately self-similar solution behaviour is found in many other equations describing blow-up and for completeness we list some of these here. Further examples of semilinear and quasi-linear PDEs related to (2.1) include the Kassoy problem [Kas77], [Gel63]

$$u_t = u_{xx} + e^u, \tag{2.20}$$

and porous-medium reaction-diffusion equations

$$u_t = (|u_x|^\sigma u_x)_x + e^u \tag{2.21}$$

and

$$u_t = (u^\alpha u_x)_x + u^p, \tag{2.22}$$

which are analyzed in [BDG93] and in [GP91], respectively. Furthermore, the nonlinear Schrödinger equation [LPSS86]

$$i\psi_t + \Delta\psi + |\psi|^{2\sigma}\psi = 0 \tag{2.23}$$

is an example of a hyperbolic PDE for which blow-up occurs in R^N if $N \geq 2$, and this has been used to model focusing in lasers.

The similarity variables for (2.20) and (2.21) are

$$\begin{cases} w(s, y) = \log(T - t) + u(x, t), \\ y = x(T - t)^{-\frac{1}{\sigma+2}}, \end{cases} \tag{2.24}$$

and with this change of variables (2.20) and (2.21) reduce to PDEs similar to (2.7), which can be analyzed in an analogous way. Remarkably, the corresponding solution is approximately self-similar if $\sigma = 0$ and exactly self-similar if $\sigma > 0$. Similar behaviour to that in (2.1) is observed for (2.22) with $\alpha > 0$, where

$$y = x(T - t)^{-\frac{1}{2}[1+\alpha/(p-1)]}. \tag{2.25}$$

The behaviour of the nonlinear Schrödinger equation is less well understood, but it is invariant under various scalings. In particular, it has a natural set of similarity variables given by

$$\begin{cases} y = \frac{r}{L(t)}, \\ \tau = \int_0^t \frac{ds}{L}, \\ u(y, \tau) = L^{1/\sigma}\psi, \end{cases} \tag{2.26}$$

where $r = |x|$ and $L(t)$ can be chosen in various ways. These follow from the scaling invariance of solutions given by

$$\psi(x, t) \to \lambda^{-1/\sigma}\psi\left(\frac{x}{\lambda}, \frac{t}{\lambda^2}\right). \tag{2.27}$$

In [LPSS86] extensive use is made of this rescaling in calculating the solution of (2.23) numerically. Self-similar solutions arise when $L(t) = (T - t)^{1/2}$, as in the previous problems, and numerical evidence for the existence of such solutions has been obtained.

It is clear from this brief discussion that the scaling invariance of (2.1) and (2.20) - (2.23) plays a key role in determining the dynamical solution behaviour. This strongly implies that numerical methods which respect this invariance should be more effective in reproducing the dynamics than those which do not. Such methods must necessarily employ moving meshes to allow for rescalings in both space and the solution. We now consider these.

3. Moving mesh PDEs with scaling invariance. The class of methods which we propose for solving (1.1) are the moving mesh PDE methods described in [HRR94a] and [HRR94b]. For these the function $u(x,t)$ is discretized to give the solution values $u_i(t)$ defined on a moving mesh $x_i(t)$, $i = 0, \dots, N$. The boundary conditions in (1.1) give $u_0 = u_N = 0$ and $x_0 = 0$, $x_N = 1$. The mesh $x_i(t)$ is defined in terms of a differentiable mesh transformation $x(\xi, t)$: $[0,1] \to [0,1]$, where x is the physical coordinate and ξ is the computational coordinate such that

$$x_i(t) = x\left(\frac{i}{N}, t\right). \tag{3.1}$$

In the continuous formulation, the constraint

$$\frac{\partial x}{\partial \xi} > 0 \tag{3.2}$$

assures that the mesh transformation is well defined for fixed t, and the discrete analogue is that mesh crossing does not occur. For the MMPDE approach, a new partial differential equation for $x(\xi, t)$, called the moving mesh PDE, is solved simultaneously with the original PDE for $u(x,t)$. The underlying strategy for determining $x(\xi,t)$ is to require *equidistribution* of a positive *monitor function*, say $M(u, u_x, u_{xx})$, so that

$$\int_0^x M dy = \xi \int_0^1 M dy. \tag{3.3}$$

Equivalently, differentiating this identity gives

$$\frac{\partial}{\partial \xi}\left(M \frac{\partial x}{\partial \xi}\right) = 0, \; x(0,t) = 0, \; x(1,t) = 1. \tag{3.4}$$

A mesh (or a coordinate transformation) is said to be *equidistributed* when (3.4) holds. It is convenient in practice not to enforce exact equidistribution upon a mesh but to instead solve an MMPDE for which it tends toward an equidistributed state. This has the advantages that a simple initial mesh (such as a uniform one) can be used, the process produces stable meshes with less risk of mesh crossing than if (3.3) were enforced, and combined with a smoothing approach it reduces the problem (associated, for example, with the schemes proposed in [LPSS86]) of placing so many points close to the developing singularity that resolution is lost elsewhere. Of the various MMPDEs proposed in [HRR94a], we consider the two labelled MMPDE4 and MMPDE6. These are, respectively,

$$\tau \frac{\partial}{\partial \xi}\left(M \frac{\partial \dot{x}}{\partial \xi}\right) = -\frac{\partial}{\partial \xi}\left(M \frac{\partial x}{\partial \xi}\right) \tag{MMPDE4}$$

and

$$\tau \frac{\partial^2 \dot{x}}{\partial \xi^2} = -\frac{\partial}{\partial \xi}\left(M \frac{\partial x}{\partial \xi}\right). \tag{MMPDE6}$$

Here, $\dot{x}$ denotes $\frac{\partial x}{\partial t}|_{\xi \text{ fixed}}$ and τ is a small parameter which acts to relax the mesh to the equidistributed state. Note that MMPDE6 is the second derivative with respect to ξ of the integro-differential equation

$$\tau \dot{x} = -\left(\int_0^x M dx - \xi \int_0^1 M dx\right). \tag{3.5}$$

It is worth remarking that many previous moving mesh equations can be regarded as variants of or discrete approximations of these MMPDEs. (See, e.g., [HL89] for MMPDE6; see also [HRR94a] and [HRR94b].)

If we apply moving mesh PDE methods to solve a PDE with an underlying scaling invariance, then as the underlying PDE and the MMPDE are solved simultaneously to determine both the solution u and the mesh x, it is desirable that the scaling invariance of the underlying PDE be preserved. For (2.1) this requires that MMPDE4 or MMPDE6 be invariant under the scaling (2.5). The parameter τ and the monitor function M can indeed be suitably chosen to meet this requirement. Assuming that the solution $u(x, t)$ to (2.1) is positive for $x \in (0, 1)$ and $t \geq 0$, MMPDE6 can be made invariant under the scaling (2.5) if τ is taken as a dimensionless constant and

$$M(u) = u^{p-1}. \tag{3.6}$$

However, regardless of the choice of M, τ cannot be constant if MMPDE4 is to be invariant under (2.5) (although we can obtain an invariance if τ is chosen adaptively).

This difference between MMPDE6 and MMPDE4 becomes important when we consider the timescales under which the mesh adapts to follow the structure of the solution. An inspection of MMPDE4 and MMPDE6 shows that each has a natural timescale T_{mesh} for adapting the mesh towards an equidistributed mesh. For MMPDE4 $T_{\text{mesh}} = O(\tau)$ and for MMPDE6 $T_{\text{mesh}} = O(\frac{\tau}{M})$. If T_{mesh} is significantly greater than the natural timescale for the evolution of the solution structure, then the mesh cannot adapt rapidly enough to follow the solution structure and is to all intents and purposes fixed. As we showed in §2, the natural timescale for the evolution of the blow-up peak is $O(T - t)$. Hence, if

$$T - t << \tau, \tag{3.7}$$

then MMPDE4 will not be able to evolve the mesh rapidly enough to follow the evolution of the peak. In contrast, if we look at MMPDE6 with M as in (3.6), then $\frac{\tau}{M} = \frac{\tau}{u^{p-1}} = \tau(T - t)$. Hence the timescale for the evolution of the mesh is always a factor τ smaller than the natural timescale of the underlying problem, and MMPDE6 will continue to evolve the mesh for t close to T. This is a direct consequence of the scaling invariance of MMPDE6 under this choice of monitor function. Other choices of monitor function (for example, arclength) do not share this property, and we will study this in more detail in §4.

For the numerical computation, PDE (2.1) is transformed in terms of the computational coordinate ξ and discretized by central finite differences on a uniform mesh in the computational domain. That is, (2.1) is first transformed into the quasi-Lagrangian form

$$\begin{cases} \dot{u} - \frac{u_\xi}{x_\xi}\dot{x} = \frac{1}{x_\xi}\left(\frac{u_\xi}{x_\xi}\right)_\xi + u^p, \\ u(0, t) = u(1, t) = 0, \end{cases} \tag{3.8}$$

and discretization gives the equation

$$\dot{u}_i - \frac{u_{i+1} - u_{i-1}}{x_{i+1} - x_{i-1}}\dot{x}_i = \frac{2}{x_{i+1} - x_{i-1}}\left(\frac{u_{i+1} - u_i}{x_{i+1} - x_i} - \frac{u_i - u_{i-1}}{x_i - x_{i-1}}\right) + u_i^p, \tag{3.9}$$

$i = 1, \ldots, N - 1$ and $u_0 = u_N = 0$. Similar finite difference equations can be obtained for discretizations of MMPDEs 4 and 6.

It is well known that for moving mesh methods, some sort of smoothing of the mesh is often necessary in order to obtain nonoscillatory, reasonably accurate solutions (e.g., see [DD87], [FVZ90], and [HRR94b]). In [DD87], Dorfi and Drury use a technique which smooths the node concentration defined by $\frac{1}{x_{i+1}-x_i}$. In [VBFZ89], Verwer et al. prove that smoothing the node concentration is basically equivalent to smoothing the monitor function over all points. To maintain the local structure of the underlying difference equations, we use the technique employed in [HRR94b]. Specifically, the values of the smoothed monitor function $\tilde{M}$ at nodes are defined by

$$\tilde{M}_i = \frac{\sum_{k=i-i_p}^{i+i_p} M_k \left(\frac{\gamma}{\gamma+1}\right)^{|k-i|}}{\sum_{k=i-i_p}^{i+i_p} \left(\frac{\gamma}{\gamma+1}\right)^{|k-i|}}, \tag{3.10}$$

where $M_i \equiv M(\xi_i, t)$, i_p is a nonnegative integer, and γ is a positive constant. The summations in (3.10) are understood to contain only elements with indices in the range between 0 and N. Notice that the replacement of M_i by $\tilde{M}_i$ is basically equivalent to using a smoother monitor function, and $i_p = 0$ corresponds to the nonsmoothing case. Values of the parameters γ and i_p need to be selected for these moving mesh PDE methods. In our experience (also see [HRR94b]), the choice of γ is fairly insensitive and can generally be fixed. In this paper, we use $\gamma = 2$. The value for i_p usually is taken as 0, 1, 2, 3, or 4.

The final forms for the discrete moving mesh equations for MMPDE4 and MMPDE6 are

$$\begin{aligned} &\tau\left(\tilde{M}_{i+\frac{1}{2}}(\dot{x}_{i+1} - \dot{x}_i) - \tilde{M}_{i-\frac{1}{2}}(\dot{x}_i - \dot{x}_{i-1})\right) \\ &= -\left(\tilde{M}_{i+\frac{1}{2}}(x_{i+1} - x_i) - \tilde{M}_{i-\frac{1}{2}}(x_i - x_{i-1})\right), \end{aligned} \tag{3.11}$$

and

$$\tau\left(\dot{x}_{i+1} - 2\dot{x}_i + \dot{x}_{i-1}\right) = -\left(\tilde{M}_{i+\frac{1}{2}}(x_{i+1} - x_i) - \tilde{M}_{i-\frac{1}{2}}(x_i - x_{i-1})\right), \tag{3.12}$$

$i = 1, \dots, N-1$ supplemented with $x_0 = 0$, $x_N = 1$, where $\tilde{M}_{i+\frac{1}{2}} := (\tilde{M}_i + \tilde{M}_{i+1})/2$. We note that the smoothing process maintains the dimension of the monitor function, which will become important when we consider rescalings of the equations.

4. Analysis of the solutions of the moving mesh equations.

We now analyze the solution behaviour for the discretization of problem (2.1), using the discrete version of MMPDE6 together with the monitor function given by (3.6). The analysis will be in two parts. First, we shall solve MMPDE6 exactly assuming that $u(x, t)$ is as described in §2. This will, in effect, determine the "optimum" mesh for such a problem. Second, we shall analyze the solutions of the coupled finite difference equations (3.9) and (3.12), assuming exact time integration, and compare the solutions with those obtained in the continuous case.

4.1. Analysis of the moving mesh equations.

Integrating MMPDE6 with respect to ξ, we know that the mesh transformation $x(\xi, t)$ satisfies the equation

$$-\tau\dot{x}_\xi = Mx_\xi + \theta(t) \tag{4.1}$$

where $\theta(t)$ is an integral constant which will be determined by the boundary conditions for $x(\xi, t)$. Indeed, integrating (4.1) with respect to ξ we have

$$-\tau\dot{x}(\xi, t)|_{\xi=0}^{1} = \int_0^1 Mx_\xi d\xi + \theta(t). \tag{4.2}$$

Then, from the boundary conditions

$$x(0,t) = x(1,t) - 1 = 0, \tag{4.3}$$

(4.2) implies that

$$\theta(t) = -\int_0^1 M dx. \tag{4.4}$$

Because the function $u(x,t)$ has a sharp peak, the integral above is asymptotically dominated by the contribution from the peak. It follows from (3.6) and (2.3) that within the blow-up region M has the asymptotic form

$$M = \frac{\beta}{(T-t)\left[1+\frac{\mu^2}{4p\beta}\right]}, \tag{4.5}$$

where $\mu(x,t)$ is defined in (2.2). If we take ϵ to be a small (fixed) positive value, we then have that

$$\begin{aligned} \theta(t) &\approx -\int_{x^*-\epsilon}^{x^*+\epsilon} \frac{\beta}{(T-t)\left[1+\frac{\mu^2}{4p\beta}\right]} dx \\ &\approx -\frac{\beta[\alpha-\log(T-t)]^{1/2}}{(T-t)^{1/2}} \int_{-\epsilon[\alpha-\log(T-t)]^{-1/2}(T-t)^{-1/2}}^{\epsilon[\alpha-\log(T-t)]^{-1/2}(T-t)^{-1/2}} \frac{dy}{1+\frac{y^2}{4p\beta}}. \end{aligned} \tag{4.6}$$

As $t \to T$ the limits in the above integral tend to $\pm\infty$ so that

$$\begin{aligned} \theta(t) &\approx -\frac{\beta[\alpha-\log(T-t)]^{1/2}}{(T-t)^{1/2}} \int_{-\infty}^{\infty} \frac{dy}{1+\frac{y^2}{4p\beta}} \\ &\approx -\frac{\pi\beta\sqrt{4p\beta}[\alpha-\log(T-t)]^{1/2}}{(T-t)^{1/2}}. \end{aligned} \tag{4.7}$$

The contribution to $\theta(t)$ from the range outside that considered will be of $O(1)$ in time and will be asymptotically dominated by the estimate in (4.7). It then follows that within the blow-up region (4.1) reads as

$$-\tau \dot{x}_\xi = \frac{\beta}{(T-t)(1+\frac{\mu^2}{4p\beta})} x_\xi - \frac{\pi\beta\sqrt{4p\beta}[\alpha-\log(T-t)]^{1/2}}{(T-t)^{1/2}}. \tag{4.8}$$

The definition of $\mu(x,t)$ in (2.2) suggests an ansatz for the mesh behaviour of the form

$$x(\xi,t) = x^* + (T-t)^{1/2}[\alpha - \log(T-t)]^{1/2} z(\xi). \tag{4.9}$$

Substituting this into (4.8) gives

$$-\tau z_\xi \left[-\frac{1}{2} + O\left(\frac{1}{\log(T-t)}\right)\right] = \frac{\beta z_\xi}{1+\frac{z^2}{4p\beta}} - \pi\beta\sqrt{4p\beta}. \tag{4.10}$$

The choice of the monitor function to be u^{p-1} ensures that the left-hand side and the first term of the right-hand side of (4.1) have the same scale in $(T-t)$. The term $O\left(\frac{1}{\log(T-t)}\right)$ on the left-hand side of (4.10) emphasizes the difference between an exactly self-similar and an approximately self-similar solution. Since $z(\xi)$ should be finite in the blow-up region, the left-hand side term is small compared with the first term on the right-hand side if $\tau << 1$ and therefore can be dropped. Hence, to the approximation of order τ we obtain an asymptotic equation within the blow-up region as

$$\frac{\beta z_\xi}{1+\frac{z^2}{4p\beta}} - \pi\beta\sqrt{4p\beta} = 0 \tag{4.11}$$

or

$$\beta\sqrt{4p\beta}\,\tan^{-1}\left(\frac{z}{2\sqrt{p\beta}}\right) = \pi\beta\sqrt{4p\beta}(\xi-\xi^*), \tag{4.12}$$

where we have assumed that $z = 0$ when $\xi = \xi^*$, i.e., blow-up occurs at the point $x^* = x(\xi^*, T)$.

Equation (4.12) describes the distribution of the mesh points within the peak, and the boundary conditions (4.3) determine ξ^*. From (4.9) these two conditions correspond in the limit of large $|z|$, i.e.,

$$\begin{cases} z \to -\infty, & \text{as } \xi \to 0, \\ z \to +\infty, & \text{as } \xi \to 1, \end{cases} \tag{4.13}$$

implying

$$\xi^* = \frac{1}{2}. \tag{4.14}$$

Our choice of M implies that the terms of order τ will be consistently small inside the blow-up peak.

Combining these results, we deduce that the mesh function x is given by

$$x(\xi,t) = x^* + 2\sqrt{\beta p}(T-t)^{1/2}[\alpha - \log(T-t)]^{1/2}\,\tan\left(\pi(\xi-\frac{1}{2})\right) + O(\tau) \tag{4.15}$$

so that

$$\frac{x(\xi,t)-x^*}{(T-t)^{1/2}[\alpha-\log(T-t)]^{1/2}\,\tan\pi(\xi-\frac{1}{2})} \to 2\sqrt{\beta p} \text{ as } t \to T. \tag{4.16}$$

Substituting this into the expression for $u(x,t)$ gives

$$u(\xi,t) = (T-t)^{-\beta}\beta^{\beta}[\cos(\pi(\xi-1/2))]^{2\beta}. \tag{4.17}$$

This expression for u in the computational domain may be easily checked against numerical calculations.

The above analysis only applies for mesh points within the peak. However, as $\xi \to 0$ or $\xi \to 1$ the mesh points must eventually tend to 0 and 1, respectively, and close to $\xi = 0$ they correspond to points where $u(x,t)$ is not changing rapidly and hence is bounded as $t \to T$. If we fix x, then as $t \to T$,

$$u(\xi,t) \to \left[\frac{8\beta^2 p\,|\log|x-x^*||}{(x-x^*)^2}\right]^{\beta} + O(x-x^*)^2. \tag{4.18}$$

Thus,

$$\int_0^x u^{1/\beta} \approx 8\beta^2 p \int_0^x \frac{|\log|x - x^*||}{(x - x^*)^2} \approx 8\beta^2 p \frac{|\log|x - x^*||}{(x - x^*)^2}. \tag{4.19}$$

Similarly, from (4.11),

$$\int_0^1 u^{1/\beta} = \theta(t) \approx \frac{\beta\pi\sqrt{4p\beta}\,[\alpha - \log(T - t)]^{1/2}}{(T - t)^{1/2}}, \tag{4.20}$$

so that an equidistributed mesh will give

$$\int_0^x u^{1/\beta} \approx \theta(t)\xi, \tag{4.21}$$

and hence

$$8\beta^2 p \frac{|\log|x - x^*||}{(x - x^*)^2} \approx \frac{\beta\pi\sqrt{4p\beta}\,[\alpha - \log(T - t)]^{1/2}\xi}{(T - t)^{1/2}}. \tag{4.22}$$

After some manipulation we find that this is precisely the form that (4.16) takes as $\xi \to 0$ (or indeed as $\xi \to 1$).

We observe from (4.15) and (4.22) that x is close to x^* if ξ lies in the interval $[\epsilon, 1 - \epsilon]$ where $\epsilon = (T - t)^{1/2}[\alpha - \log(T - t)]^{1/2}$. Outside this interval, x rapidly tends to 0 or 1. The implications of this analysis are that if $\Delta\xi$ is the mesh spacing in the computational domain, then a significant number of mesh points will be away from the peak only if

$$\Delta\xi < (T - t)^{1/2}[\alpha - \log(T - t)]^{1/2}. \tag{4.23}$$

A similar calculation can be made for the arclength monitor function

$$M = \sqrt{1 + u_x^2}. \tag{4.24}$$

Indeed, when u_x is large, $M \approx u_x$, and we have from (4.1), (4.4), and (4.9) that

$$\begin{aligned} &-\tau z_\xi \left[-\tfrac{1}{2} + O\left(\tfrac{1}{\log(T-t)}\right)\right] [\alpha - \log(T - t)]^{1/2} (T - t)^{\beta - 1/2} \\ &= \frac{2\beta^{\beta+1}|z|z_\xi}{4p\beta(1+\frac{z^2}{4p\beta})^{\beta+1}} + \Theta, \end{aligned} \tag{4.25}$$

where Θ is a constant. Thus, when $\tau[\alpha - \log(T - t)]^{1/2}(T - t)^{\beta-1/2} << 1$, for which we require $p < 3$ and τ to be fixed and small, then within the blow-up region the mesh equation is asymptotic to

$$\frac{2\beta^{\beta+1}|z|z_\xi}{4p\beta(1 + \frac{z^2}{4p\beta})^{\beta+1}} + \Theta = 0, \tag{4.26}$$

which leads to

$$u(\xi, t) = (T - t)^{-\beta}\beta^\beta \left[1 - 2|\xi - \xi^*|\right]. \tag{4.27}$$

However, when $\tau[\alpha - \log(T - t)]^{1/2}(T - t)^{\beta-1/2} >> 1$, which occurs when $p > 3$ and t is sufficiently close to T, then the left-hand side of (4.25) dominates over other terms and then there exists no solution satisfying the resulting asymptotic equation and the matching conditions (4.13). This implies that the mesh (or the coordinate transformation) cannot take the form (4.9) and hence is not "optimal" when $\tau[\alpha - \log(T-t)]^{1/2}(T-t)^{\beta-1/2} >> 1$. Indeed, in this case the timescale for the mesh evolution is greater than $T-t$ and the mesh ceases to evolve. To be precise, this occurs when

$$\tau(T-t)^{\beta-1/2} = \tau(T-t)^{(3-p)/2(p-1)} = \tau u_{\max}^{(p-3)/2} >> 1. \tag{4.28}$$

Finally we note that the above analysis is general and can also be applied to MMPDE4. Since the argument is quite similar, we omit it here but refer the reader to the discussion in §3.

4.2. The analysis of the discrete equations. We now turn our attention to an analysis of the discretizations (3.9) and (3.12) of the PDEs for blow-up and mesh evolution. We show that these equations admit a discrete solution which evolves in an "approximately self-similar" manner very closely related to that of the solution described in §2. Although we do not prove that this discrete solution is an attractor, the numerical calculations given in §5 strongly imply that it is, and the asymptotic predictions of this section agree with the observations in §5. (We emphasize at this point that the numerical solution may have a slightly different blow-up time from the analytical solution. However, as we are interested in the dynamics close to blow-up rather than the blow-up time itself we shall treat the blow-up times of the analytic and numerical methods as the same.)

Since the discrete equations have the same scaling invariance as the continuous ones, it is reasonable to consider a discrete solution in terms of similarity variables closely related to those in (2.6), namely

$$\begin{cases} w_i = (T-t)^{\beta} u_i, \\ y_i(s) = (x_i - x^*)(T-t)^{-1/2}, \\ s = -\log(T-t). \end{cases} \tag{4.29}$$

In these similarity variables we consider solutions with w_i independent of time. Substituting into (3.9) gives

$$\begin{aligned} &\beta w_i + \tfrac{w_{i+1}-w_{i-1}}{y_{i+1}-y_{i-1}}\left(\tfrac{1}{2}y_i - \dot{y}_i\right) \\ &= \tfrac{2}{y_{i+1}-y_{i-1}}\left(\tfrac{w_{i+1}-w_i}{y_{i+1}-y_i} - \tfrac{w_i-w_{i-1}}{y_i-y_{i-1}}\right) + w_i^p. \end{aligned} \tag{4.30}$$

The equation (4.30) is essentially a discretization of (2.7) on the nonuniform mesh $\{y_i\}$ and must also satisfy a discrete form of the boundary conditions (2.8). Like (2.7) it also possesses discrete "similarity solutions" for which both w_i and y_i are independent of time, and these solutions satisfy a discretization of the steady state of (2.7). However, this latter equation has only one solution which does not grow exponentially with y, and that is the constant solution, which does not satisfy the boundary conditions. (We note that $w_i \equiv \beta^{\beta}$ is also a solution of (4.30).) Provided that the mesh $\{y_i\}$ is sufficiently fine we will expect that the (nonconstant) discrete solutions of the steady state of (4.30) should approximate their continuous counterparts and also grow rapidly with i. Such solutions will not then match the boundary conditions. We can conclude from this reasoning that (4.30) is unlikely to have a steady state solution and that we should instead seek a solution which, like its analytical counterpart, is approximately self-similar rather than self-similar. We can compute these as in §2 by setting

$$y_i(s) = g(s)z_i \tag{4.31}$$

where z_i is independent of time and the function g satisfies (cf. (2.12))

$$g(s) \to \infty \text{ and } \frac{g'}{g} \to 0 \text{ as } s \to \infty. \tag{4.32}$$

Substituting into (4.30) and letting $s \to \infty$, we have

$$\beta w_i + \frac{w_{i+1} - w_{i-1}}{z_{i+1} - z_{i-1}} \frac{z_i}{2} = w_i^p. \tag{4.33}$$

This is a centred difference discretization of (2.14), and hence, provided the mesh $\{z_i\}$ is sufficiently regular,

$$w_i = \left(\frac{1}{\beta} + z_i^2\right)^{-\beta} + \epsilon_i, \tag{4.34}$$

where ϵ_i is a small error which decreases with the number of mesh points. As before, the form of g for large s can be derived from formal scaling arguments which give

$$g(s) = c[\alpha + s]^{1/2}. \tag{4.35}$$

We can repeat the arguments in [BK88] to deduce the value of the constant c which, to within a small error similar to ϵ_i, is consistent with (2.16). This demonstrates that an approximately self-similar solution for the numerical scheme (4.30) exists which has the correct dependence upon z_i and hence upon x_i. Finally, we evaluate z_i. The moving mesh equation (3.12) gives

$$\begin{aligned} &-\tau(\dot{x}_{i+1} - 2\dot{x}_i + \dot{x}_{i-1}) \\ &= \tfrac{1}{2}(u_{i+1}^{p-1} + u_i^{p-1})(x_{i+1} - x_i) - \tfrac{1}{2}(u_i^{p-1} + u_{i-1}^{p-1})(x_i - x_{i-1}), \end{aligned} \tag{4.36}$$

which has first integral

$$-\tau(\dot{x}_{i+1} - \dot{x}_i) = \frac{1}{2}(u_{i+1}^{p-1} + u_i^{p-1})(x_{i+1} - x_i) + \theta(t). \tag{4.37}$$

Substituting for z_i and w_i we have after some manipulation that

$$\begin{aligned} &\tfrac{\tau}{2}(z_{i+1} - z_i)\left(1 + O(\tfrac{1}{s})\right) \\ &= \tfrac{1}{2}(w_{i+1}^{p-1} + w_i^{p-1})(z_{i+1} - z_i) + \tfrac{(T-t)^{1/2}}{g(s)}\theta(t). \end{aligned} \tag{4.38}$$

Choosing θ appropriately and using (4.34), this is a centred difference discretization of (4.10), and hence z_i is a discrete approximation to $z(\xi)$ given in (4.9).

We conclude that the discrete form of the PDE coupled with MMPDE6 admits an approximately self-similar solution for which both the mesh x_i and the function u_i are consistent approximations to the mesh $x(\xi, t)$ and function $u(\xi, t)$ calculated in §4.1. Provided that this solution is (like its analytic counterpart) an attractor for a wide class of initial data, then the numerical method given will faithfully reproduce the dynamics of the blow-up peak for all times up to the blow-up time. In particular, the asymptotic estimates given in §4.1 will be reproduced in the numerical calculations. It is difficult to analyze analytically whether the solution is an attractor, and we do not attempt it here.

5. Numerical examples. We now present some numerical calculations for several blow-up problems using MMPDE4 and MMPDE6. These calculations support the analysis of §§3 and 4 and also illustrate the effect of smoothing the monitor function M. For these calculations we take $u_0(x) = 20 \sin(\pi x)$.

After spatial discretization, the resulting ODE systems are solved using the double precision version of the stiff ODE solver DASSL [Pet82]. The time integration uses the backward differentiation formulas (BDF), wherein an approximate Jacobian is computed by DASSL internally using finite differences. The relative and absolute local time-stepping error tolerances

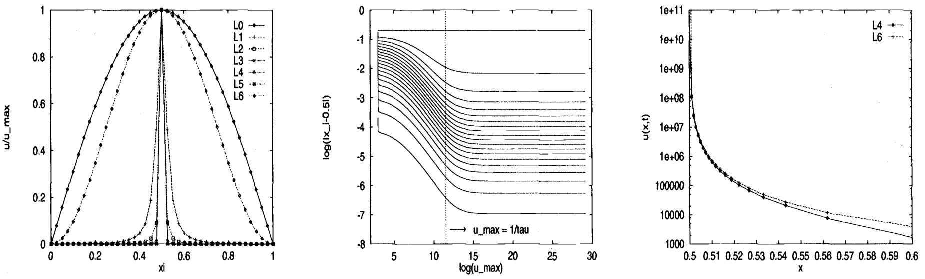

FIG. 1 (1a, 1b, *and* 1c *from the left*). *MMPDE4 without smoothing is used for solving* (2.1) *with* $p = 2$. *In Figs.* 1a *and* 1c $L0$: *initial solution*, $L1 : u_{\max} = 10^8$, $L2 : u_{\max} = 10^9$, $L3 : u_{\max} = 10^{10}$, $L4 : u_{\max} = 10^{11}$, $L5 : u_{\max} = 5 \times 10^{11}$, $L6$: *the asymptotic solution.*

(in a root-mean-square norm) are chosen as rtol $= 10^{-8}$ and atol $= 10^{-8}$, respectively. Unless stated otherwise, we use a uniform mesh (in x) initially with $N = 40$ and take $\tau = 10^{-5}$. As pointed out in [HRR94a] and [HRR94b], the choice of value for the time correction parameter τ is not critical and can generally be fixed to be a small positive value.

5.1. Calculations using MMPDE4. The analysis in §3 indicates that MMPDE4 ceases to evolve the mesh when the timescale of the blow-up is less than τ, i.e., when

$$(T - t) < \tau. \tag{5.1}$$

Since $u(x^*, t) \approx (T - t)^{-\beta}$, the mesh ceases to evolve when

$$u(x^*, t) > \tau^{-\beta}, \tag{5.2}$$

after which MMPDE4 gives a nonuniform but essentially *fixed* mesh. The results of [AB94] show that if $p > 2$, u_i will blow up at only one point and if $p = 2$ it will blow up at three points, but the blow-up is asymptotically dominated by the growth at one point.

To confirm these results we integrate (2.1) when $p = 2$ coupled with MMPDE4 using the monitor function given by (3.6). Blow-up occurs at $T = 0.082291$ and $x^* = \frac{1}{2}$ so that the maximum value occurs at u_{20}. In Fig. 1a we present a graph of the scaled discrete solution values $\{\frac{u_i}{u_{20}}\}$ for $u_{20} = 10^8$, 10^9, 10^{10}, 10^{11}, 5×10^{11}, and in Fig. 1b we show the corresponding mesh, plotting $\log |x_i - \frac{1}{2}|$ against $\log(u_{20})$. From the second figure it is clear that the mesh evolves until $u_{20} \approx \frac{1}{\tau}$ and is then fixed. The results of Fig. 1a show convergence of the normalized solution to a delta function, demonstrating that, effectively, it is only u_{20} which is blowing up. In Fig. 1c we plot the approximation for $u(x, t)$ when $u_{20} = 10^{11}$ and compare it with the asymptotic function $u(x, t)$ given in (2.3). It is clear that it approximates the limiting asymptotic function rather well (except at the blow-up point), showing that the mesh generated by MMPDE4 leads to an accurate approximation to $u(x, t)$ away from the point of blow-up and the behaviour of $u(x, T)$ is well approximated in this range. Indeed, at the point when MMPDE4 ceases to evolve the mesh, the mesh point nearest $\frac{1}{2}$ is given by

$$x_i = \frac{1}{2} + O(\Delta\xi \tau^{1/2} \log^{1/2} \tau), \tag{5.3}$$

where $\Delta\xi$ is the mesh spacing in the computational domain. Thus MMPDE4 gives an accurate picture of the evolution of the solution in the region $[0, \frac{1}{2} - O(\Delta\xi\tau^{1/2}\log^{1/2}\tau)] \cup [\frac{1}{2} + O(\Delta\xi\tau^{1/2}\log^{1/2}\tau), 1]$, but it will not resolve the structure in the remaining blow-up region.

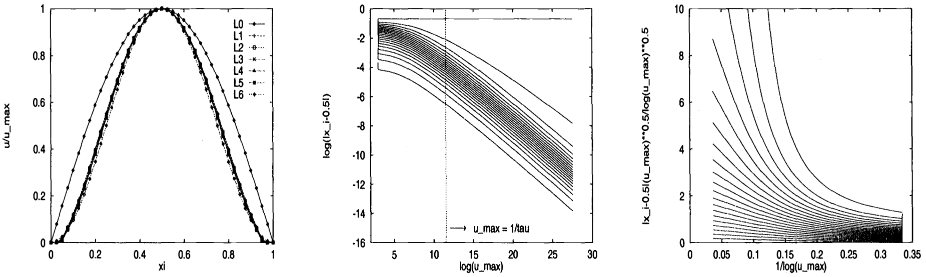

FIG. 2 (2a, 2b, *and* 2c *from the left*). *MMPDE*6 *without smoothing is used for solving* (2.1) *with* $p = 2$. *In Fig.* 2a *L*0: *initial solution*, $L1 : u_{\max} = 10^8$, $L2 : u_{\max} = 10^9$, $L3 : u_{\max} = 10^{10}$, $L4 : u_{\max} = 10^{11}$, $L5 : u_{\max} = 5\times 10^{11}$, *L*6: *the asymptotic solution.*

5.2. Calculations using MMPDE6. The analysis given in §§3 and 4 indicates that (in contrast to MMPDE4) using MMPDE6 with the monitor function given by (3.6) should give an accurate resolution of the blow-up peak. A calculation of the evolution of the PDE gives a blow-up time of $T = 0.082283$ when $p = 2$. The scaled solution $\{\frac{u_i}{u_{20}}\}$ for $u_{20} = 10^8,\ 10^9,\ 10^{10},\ 10^{11},\ 5\times 10^{11}$, is given in Fig. 2a together with the theoretical scaled solution $\cos^2\pi(\xi - \frac{1}{2})$ where $\xi = i\Delta\xi$ (cf. (2.10) and (4.17)). It is clear from the figure that there is close agreement between the predicted and computed curves implying that the solution calculated in §4.2 is indeed an attractor. Figure 2b shows a graph of $\log|x_i - \frac{1}{2}|$ as a function of $\log u_{\max}$ with clear evidence that each of the mesh points (apart from those close to the boundary) evolves in the same (approximately self-similar) manner. To confirm that the mesh behaves precisely as predicted in §4, we give a graph in Fig. 2c of $\frac{|x_i-\frac{1}{2}|}{(T-t)^{1/2}|\log(T-t)|^{1/2}}$ as a function of $|\log(T - t)|^{-1}$, where we use the estimate $T - t = \frac{1}{u_{20}}$. According to formula (4.16),

$$\frac{|x_i - \frac{1}{2}|}{(T - t)^{1/2}|\log(T - t)|^{1/2}} \approx \sqrt{8}\,\tan\pi\left(\xi_i - \frac{1}{2}\right)\left[1 - \frac{1}{2}\frac{\alpha}{|\log(T - t)|}\right] \tag{5.4}$$

as $|\log(T - t)| \to \infty$. Thus, for each i we expect to obtain a graph which is asymptotically linear in $|\log(T - t)|^{-1}$ and converges to $\sqrt{8}\,\tan\pi(\xi_i - \frac{1}{2})$ with slope $-\frac{1}{2}\alpha\sqrt{8}\,\tan\pi(\xi_i - \frac{1}{2})$. The figure clearly shows that this is the case, and we estimate α to be 7.

Thus MMPDE6 accurately reproduces the evolution of the peak profile; however, with 40 mesh points $x_{39} - \frac{1}{2} \approx 35.94(T - t)^{1/2}|\log(T - t)|^{1/2}$ so that $x_{39} = 0.500966$ when $u_{20} = 10^{11}$. Thus, the mesh points are concentrated in the blow-up region, so that the solution away from the peak is poorly resolved.

If smoothing as described in §3 is introduced, the resulting form of $\frac{u_i}{u_{20}}$ for the same value of $u_{\max}$ is given in Fig. 3a. In this case, the blow-up is slightly delayed to $T = 0.082319$. Now, the scaled discrete solution $\{\frac{u_i}{u_{20}}\}$ no longer approaches a constant curve, but instead, slowly approaches the delta function which would be obtained using a uniform mesh. This is because smoothing tends to place fewer points in the peak and more points away from the peak. Nevertheless, we see from Fig. 3b that the mesh points close to the peak evolve in a manner similar to those in Fig. 2b. Hence, whilst these points are close to the blow-up point, the analysis of §4 still applies and the value of u_i will be close to $u(x_i, t)$. Thus, although smoothing does not precisely align the mesh along the level curves of the function μ in (4.16), it still gives an accurate resolution of the structure of the peak.

The resolution of the peak in the two cases is made apparent in Figs. 4a and 4b, which plot $\frac{u_i}{u_{20}}$ as a function of $\log|x_i - \frac{1}{2}|$ for $u_{20} = 10^9,\ 10^{10}, 10^{11},\ 5\times 10^{11}$ for the unsmoothed

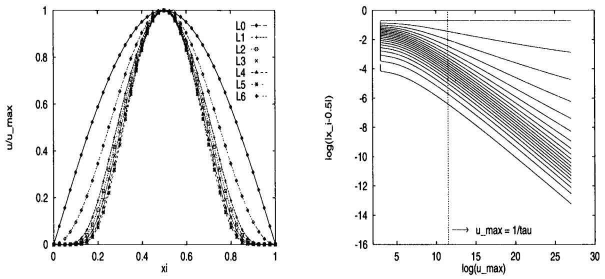

FIG. 3 (3a *and* 3b *from the left*). *MMPDE6 with smoothing* ($i_p = 2$) *is used for solving* (2.1) *with* $p = 2$. *In Fig.* 3a *L0: initial solution, L1* : $u_{\max} = 10^8$, *L2* : $u_{\max} = 10^9$, *L3* : $u_{\max} = 10^{10}$, *L4* : $u_{\max} = 10^{11}$, *L5* : $u_{\max} = 5 \times 10^{11}$, *L6: the asymptotic solution which is valid only for the unsmoothed case.*

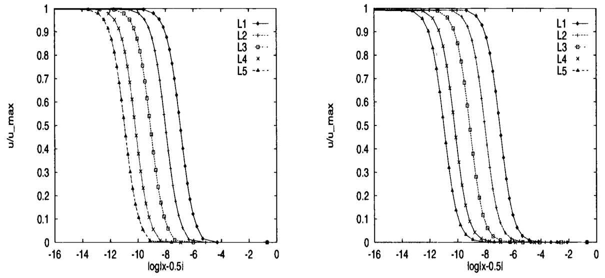

FIG. 4 (4a *and* 4b *from the left*). *MMPDE6 is used for solving* (2.1) *with* $p = 2$. *Fig.* 4a *is for the case without smoothing and Fig.* 4b *for that with smoothing* ($i_p = 2$). *In the figures, L1* : $u_{\max} = 10^8$, *L2* : $u_{\max} = 10^9$, *L3* : $u_{\max} = 10^{10}$, *L4* : $u_{\max} = 10^{11}$, *L5* : $u_{\max} = 5 \times 10^{11}$.

and smoothed meshes, respectively. The coordinate $\log |x_i - \frac{1}{2}|$ is used to stretch the length scale close to the peak so that its structure can be seen more easily. The two figures are almost identical, confirming that smoothing does not affect the accuracy of the resolution of the peak for these values of u (although presumably it would for much larger values). As a further test of the accuracy of the schemes the graphs in Figs. 4a and 4b can be compared with the graph of the function

$$\frac{u}{u_{\max}} = \left[1 + \frac{(x - \frac{1}{2})^2}{8(T - t)(\alpha - \log(T - t))}\right]^{-1} \tag{5.5}$$

where $u_{\max} \equiv (T - t)^{-1}$. Indeed, the value of $\alpha = 7$ estimated earlier gives a good fit for each of the curves.

Although smoothing is not necessary when $p = 2$, it becomes essential when dealing with more severe nonlinearities, as unsmoothed moving mesh equations can tend to introduce oscillations in solutions away from singularities by placing too few points there (e.g., see [VBFZ89]). We see this by taking $p = 5$, $M = u^4$, and using an initial mesh equidistributed with respect to the initial solution $u(x, 0) = 20 \sin(\pi x)$. Figure 5a shows the computed value of $\left(\frac{u_i}{u_{\max}}\right)^4$ plotted as a function of ξ in the case of no smoothing for $u_{\max}^5 = 10^8, 10^9, 10^{10}, 10^{11}$, and 10^{12}. These computed solutions approximate $\cos^2 \pi(\xi - \frac{1}{2})$ for $u_{\max}^5 = 10^{11}$, but deviate from it, due to mesh oscillations, when $u_{\max}^5 > 10^{11}$. In contrast, the smoothed solution (obtained with $i_p = 4$) does not oscillate and still retains enough points near the blow-up point to give good resolution in the peak, where for reference purposes we also give the asymptotic solution $\cos^2 \pi(\xi - \frac{1}{2})$ which applies only for the nonsmooth moving mesh case (see Fig. 5b).

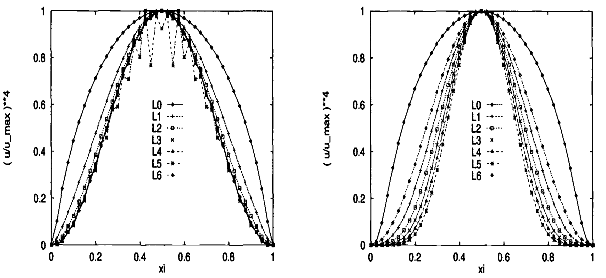

FIG. 5 (5a *and* 5b *from the left*). *MMPDE6 is used for solving* (2.1) *with* $p = 5$. *In Fig.* 5a (*without smoothing*), *L0: initial solution,* $L1 : u^5_{\max} = 10^8$, $L2 : u^5_{\max} = 10^9$, $L3 : u^5_{\max} = 10^{10}$, $L4 : u^5_{\max} = 10^{11}$, $L5 : u^5_{\max} = 10^{12}$, *L6: the asymptotic solution. In Fig.* 5b (*with smoothing* ($i_p = 4$)), *L0: initial solution,* $L1 : u^5_{\max} = 10^9$, $L2 : u^5_{\max} = 10^{10}$, $L3 : u^5_{\max} = 10^{11}$, $L4 : u^5_{\max} = 10^{12}$, $L5 : u^5_{\max} = 10^{13}$, *L6: the asymptotic solution which is valid only for the unsmoothed case.*

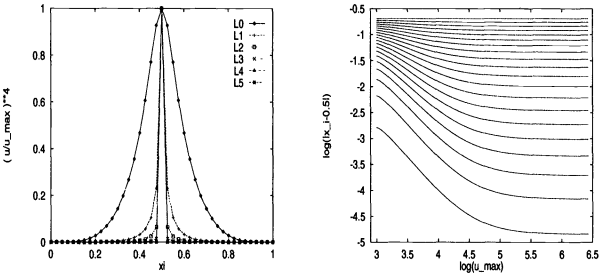

FIG. 6 (6a *and* 6b *from the left*). *MMPDE6 with smoothing* ($i_p = 4$) *and the arclength monitor function is used for solving* (2.1) *with* $p = 5$. *In Fig.* 6a, *L0: initial solution,* $L1 : u^5_{\max} = 10^{10}$, $L2 : u^5_{\max} = 10^{11}$, $L3 : u^5_{\max} = 10^{12}$, $L4 : u^5_{\max} = 10^{13}$, $L5 : u^5_{\max} = 10^{14}$, *L6: the asymptotic solution.*

It is interesting to repeat the calculations for $p = 5$ using the common choice of the arclength monitor function $M = \sqrt{1 + u_x^2}$ [HRR94b]. The results of §4 indicate that the mesh will cease to evolve when $\tau u_{\max}^{(p-3)/2} >> 1$, which in this case occurs when $u_{\max} >> 1/\tau$. In Figs. 6a and 6b we present the resulting computed solution for different values of $u^5_{\max}$ and the evolution of the mesh (with smoothing $i_p = 4$), respectively. We see clearly that the mesh ceases to evolve in this case. The value of $u_{\max}$ at which this occurs is, in fact, rather smaller than the value predicted above. This is a result of the smoothing we have employed.

5.3. Exponential nonlinearities. We can easily extend the results of the previous subsections to the case of an exponential nonlinearity, such as for the equation

$$u_t = u_{xx} + e^u \tag{5.6}$$

and its generalization

$$u_t = (|u_x|^\sigma u_x)_x + e^u, \tag{5.7}$$

using the monitor function $M(u) = e^u$. It is well known [Dol85] that close to the blow-up point the solutions of (5.6) have an approximately self-similar solution of the form

$$u(x,t) \sim -\log(T-t) - \log\left(1 + \frac{x^2}{4(T-t)\log(T-t)}\right). \tag{5.8}$$

The solutions of (5.7) are, in contrast, self-similar such that

$$u(x,t) \sim -\log(T-t) + W\left(\frac{x}{(T-t)^{1/(\sigma+2)}}\right), \tag{5.9}$$

where for small σ the function W has the form

$$W(\zeta) = -\log\left(1 + \frac{1}{2}\left(\frac{\sigma}{2}\right)^{1-\sigma}\zeta^2\right) \tag{5.10}$$

(see [BG94]). Using an analysis identical to that given earlier we may derive the following formal result.

PROPOSITION 5.1. *Let $M(u) = e^u$.*

(i) *If $\sigma = 0$, then an equidistributed mesh transformation is given by*

$$x(\xi,t) = x^* + (4(T-t)\log(T-t))^{1/2}\tan^{-1}\left(\pi\left(\xi - \frac{1}{2}\right)\right), \tag{5.11}$$

$$\frac{e^{u(\xi,t)}}{e^{u(\frac{1}{2},t)}} \to \cos^2\pi\left(\xi - \frac{1}{2}\right). \tag{5.12}$$

(ii) *Let*

$$f(x) \equiv \int_0^x \frac{dx}{1+y^{\sigma+2}}, \quad F \equiv 2f(\infty). \tag{5.13}$$

If $\sigma > 0$, σ small, then

$$x(\xi,t) = x^* + \left(2(T-t)\left(\frac{2}{\sigma}\right)^{1-\sigma}\right)^{1/(\sigma+2)} f^{-1}\left[F\left(\xi - \frac{1}{2}\right)\right], \tag{5.14}$$

$$\frac{e^{u(\xi,t)}}{e^{u(\frac{1}{2},t)}} \to \frac{1}{1+\left(f^{-1}\left[F(\xi - \frac{1}{2})\right]\right)^2}. \tag{5.15}$$

Computations with the exponential nonlinearity raise issues similar to those discussed earlier, especially with regard to smoothing. For example, if $\sigma = 0$ then a calculation with $u_0(x) = 5\sin(\pi x)$ and no smoothing is successful when $u_{\max} < 15$ ($e^{u_{\max}} < 3 \times 10^6$), giving a close approximation to the asymptotic results, but it becomes unstable for larger values of u. We illustrate this in Fig. 7a, giving $e^{u_i - u_{\max}}$ for $u_{\max} = 10, 11.6, 13.33, 15, 16.6$. A graph of the resulting mesh in Fig. 7b shows the oscillations in the mesh points at the boundary even more dramatically. In Figs. 7c and 7d we give the corresponding results with smoothing, taking $i_p = 4$.

It is interesting to compare the functions $u(x,t)$ computed in these cases, and in Figs. 7e and 7f we present graphs of $e^{u-u_{\max}}$ as a function of the physical coordinate x for $u_{\max} = 10, 11.6, 13.33, 15, 16.6$ for both the unsmoothed and smoothed cases, respectively. These graphs are nearly identical, except that the peak is smoother in Fig. 7f. Figure 8 gives the results of the same calculation on a fixed, uniform mesh. We conclude again that smoothing greatly improves the method without losing the advantages of mesh adaption.

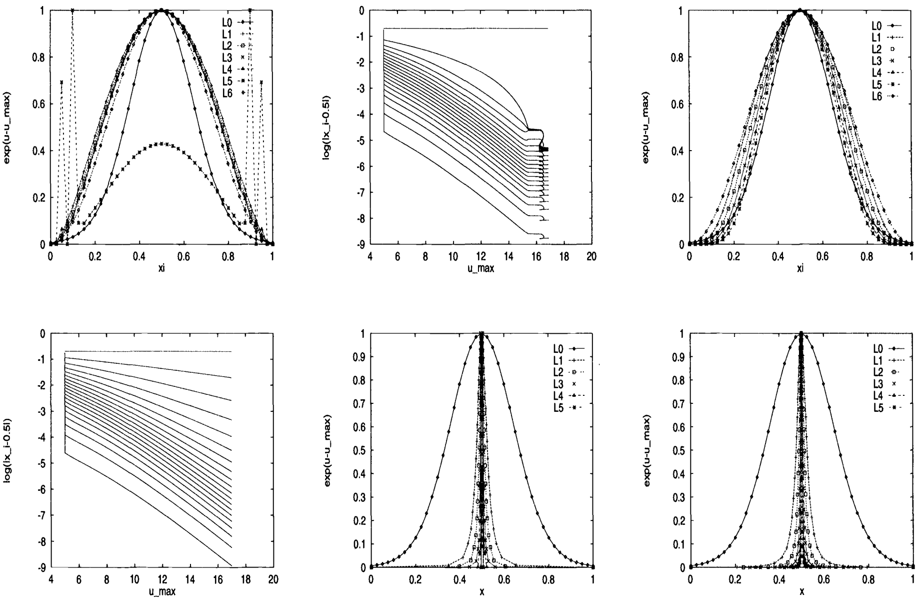

FIG. 7 (7a, 7b, 7c, 7d, 7e, *and* 7f *from the top left*). *MMPDE*6 *is used for solving* (5.6). *Figures* 7a, 7b, *and* 7e *are for the case without smoothing and Figs.* 7c, 7d, *and* 7f *are for that with smoothing* ($i_p = 4$). *In the figures, L*0*: initial solution,* $L1 : u_{\max} = 10$, $L2 : u_{\max} = 11.6$, $L3 : u_{\max} = 13.33$, $L4 : u_{\max} = 15$, $L5 : u_{\max} = 16.6$, *L*6*: the asymptotic solution which is valid only for the unsmoothed case.*

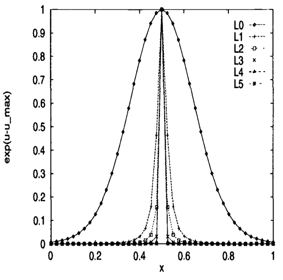

FIG. 8. *A fixed, uniform mesh is used for solving* (5.6). *L*0*: initial solution,* $L1 : u_{\max} = 10$, $L2 : u_{\max} = 11.6$, $L3 : u_{\max} = 13.33$, $L4 : u_{\max} = 15$, $L5 : u_{\max} = 16.6$.

5.4. Degenerate parabolic equations. To show the ability of the MMPDE methods to handle different types of blow-up, we conclude this section with the application of the MMPDE methods to a problem that has not been as extensively analyzed as (2.1) or (2.20). We consider the degenerate parabolic problem

$$xu_t = u_{xx} + 15u^2 \tag{5.16}$$

subject to the boundary conditions $u(0, t) = u(1, t) = 0$. This problem has been studied theoretically and numerically in [Flo91] and [SF90]. It is shown in [Flo91] that a distinct feature of the blow-up for (5.16) from that for nondegenerate problems (e.g., (1.1)) is that the solution blows up at the boundary $x = 0$. In contrast to that for nondegenerate problems, the blow-up behaviour for degenerate problems like (5.16) is as yet not well understood.

The results obtained with MMPDE6 and smoothing ($i_p = 2$) are shown in Figs. 9a–9e. In the computation, we have used $u_0(x) = 4x(1-x)$ and $M = u^{3/2}$, which is chosen so that the

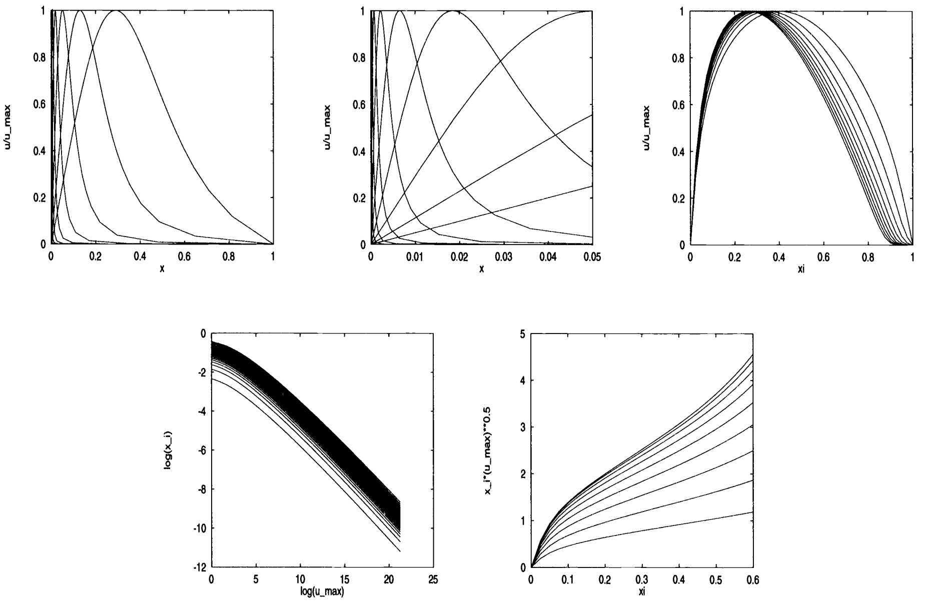

FIG. 9 (9a, 9b, 9c, 9d, *and* 9e *from the top left*). *MMPDE*6 *with smoothing* ($i_p = 2$) *is used for solving* (5.16). *Figure* 9b *is the magnification of the left portion of Fig.* 9a.

extended system consisting of the physical PDE and the MMPDE preserves the underlying scaling invariance of (5.16). The results show the blow-up at the boundary $x = 0$. Our computation gives a blow-up time of $T \approx 0.056015$, which is close to the value obtained in [SF90] with a so-called peak-tracking strategy. The computation required roughly 36.7 seconds of CPU time on an SGI R3000 Indigo.

6. Conclusions and comments. In this paper we have considered PDEs which model blow-up problems for which scaling invariance plays a natural role in describing the underlying solution structures. When one computes the solutions to such problems, adaptive mesh methods are virtually unavoidable. It is useful to interpret such numerical methods as discretizations (on a uniform mesh) of the PDEs rewritten in terms of a computational coordinate transformation. This transformation can in turn be defined through an MMPDE [HRR94b] which is determined by equidistribution with respect to a monitor function M. It is natural to seek a monitor function which preserves the scaling invariance; note that this does not require detailed knowledge of the solution behaviour itself. The scaling invariance is then preserved by the discretization, i.e., by the actual moving mesh method which is implemented. To our knowledge, this is the first instance in which rigorous analysis has been used to motivate the choice of specific monitor functions. For the blow-up problems with known detailed solution behaviour, the solutions are only approximate similarity solutions, and, quite remarkably, their structure is also preserved by the discrete equations when suitable monitor functions are chosen. As a result, with relatively few mesh points the analytic structure of the blow-up solutions can be accurately computed in a very efficient way. We briefly present some computations (without accompanying analysis) for a degenerate parabolic problem whose solution has not been extensively analyzed.

A comparison of our approach for blow-up problems with those of others is outside the scope of this paper. Nevertheless, we have tried to emphasize the naturalness of our method for automatically picking up the self-similar coordinate and to demonstrate the ease with which these problems can often be solved with little a priori knowledge.

This is not to say that the moving mesh methods are without pitfalls, however. It is important to use proper monitor functions, and examples are given where the popular choice of arclength fails to perform adequately. The MMPDEs must also be implemented with care. For example, in Figs. 1a and 1b MMPDE4 with fixed τ fails to give the proper blow-up structure when the solution becomes sufficiently large, and the question of whether or not to use mesh smoothing, and if so, the judicious choice of one, are issues with no simple resolution. The blow-up problems considered here are part of a larger framework of PDEs having similarity solutions for which MMPDEs with suitable monitor functions preserve the scaling invariance, and we are in the process of developing a theory for such problems.

HIGH-ACCURACY FINITE-DIFFERENCE SCHEMES FOR LINEAR WAVE PROPAGATION*

DAVID W. ZINGG†, HARVARD LOMAX‡, AND HENRY JURGENS†

Abstract. Two high-accuracy finite-difference schemes for simulating long-range linear wave propagation are presented: a maximum-order scheme and an optimized scheme. The schemes combine a seven-point spatial operator and an explicit six-stage low-storage time-march method of Runge-Kutta type. The maximum-order scheme can accurately simulate the propagation of waves over distances greater than five hundred wavelengths with a grid resolution of less than twenty points per wavelength. The optimized scheme is found by minimizing the maximum phase and amplitude errors for waves which are resolved with at least ten points per wavelength, based on Fourier error analysis. It is intended for simulations in which waves travel under three hundred wavelengths. For such cases, good accuracy is obtained with roughly ten points per wavelength.

Key words. finite-difference schemes, wave propagation, phase error, high accuracy

AMS subject classifications. 65M05, 76-08, 78-08

1. Introduction.

In the past few years, interest has grown in time-domain numerical simulations of linear wave phenomena using finite-difference or related methods. Applications include electromagnetic [12, 13, 20], acoustic [3, 6, 14], and elastic waves [10, 11]. It is generally recognized that in order to avoid excessively fine meshes for many practical problems, high-order discretizations are required. Consequently, many high-order differencing methods have been developed for problems involving wave phenomena [1, 4, 5, 7, 10].

Furthermore, optimized or spectral-like finite-difference schemes have been proposed which can provide improvements in accuracy over high-order schemes with the same computational effort [8, 9]. In an optimized finite-difference scheme, the error behavior over a range of spatial wavenumbers is optimized according to some criterion, usually based on Fourier error analysis. This contrasts with conventional schemes, which generally maximize the order of accuracy, i.e., the order of the leading error term. Detailed studies of optimized schemes have been performed by Lele [9] and Holberg [8], who optimized the spatial operator only. Sguazzero, Kindelan, and Kamel [11] have developed optimized fully discrete schemes based on Holberg's spatial operators. Tam and Webb [15] present an optimized scheme which consists of a seven-point centered-difference operator in space combined with a four-step time-marching method of the Adams-Bashforth type.

In this paper, we present two fully discrete finite-difference schemes for linear wave propagation: a maximum-order scheme and an optimized scheme. The schemes are suitable for problems requiring high accuracy with relatively large distances of travel. Both schemes combine a seven-point spatial operator and an explicit six-stage time-march method of the Runge-Kutta type. The spatial operator is divided into an antisymmetric component, i.e., a centered difference operator, and a symmetric component or filter. The optimized scheme is developed by minimizing the maximum phase and amplitude errors obtained using Fourier error analysis for waves which are resolved with at least ten points per wavelength.

The maximum-order scheme and the optimized scheme are presented in the next two sections. The two schemes are then analyzed and compared. Next, their stability is discussed and numerical boundary schemes are presented. After presenting the results of some numerical experiments, we conclude with a discussion of some of the considerations involved in choosing a difference scheme for a given problem.

2. Maximum-order scheme. We consider first the spatial difference operator, which is divided into an antisymmetric component, i.e., a centered difference operator, and a symmetric component, or filter, which provides dissipation of high wavenumber modes. The grid is uniform with $x_j = j\Delta x$. The function values at the grid nodes are $u_j = u(x_j)$. For the linear convection equation with a positive phase speed, the first derivative of u at node j is approximated as

$$(1)\quad \begin{aligned}(\delta_x u)_j = \frac{1}{\Delta x}[&(d_3 - a_3)u_{j-3} + (d_2 - a_2)u_{j-2} + (d_1 - a_1)u_{j-1} + d_0 u_j \\ &+ (d_1 + a_1)u_{j+1} + (d_2 + a_2)u_{j+2} + (d_3 + a_3)u_{j+3}],\end{aligned}$$

where the a_i are the coefficients of the antisymmetric component and the d_i are the coefficients of the filter. The maximum order of accuracy possible for this operator is sixth-order. This is obtained with $a_1 = 3/4$, $a_2 = -3/20$, $a_3 = 1/60$, $d_0 = d_1 = d_2 = d_3 = 0$. With a nonzero value of d_0, fifth-order accuracy is obtained with $d_1 = -3d_0/4$, $d_2 = 3d_0/10$, $d_3 = -d_0/20$.

Since the time-marching method described below is unstable for pure imaginary eigenvalues, a nonzero value of d_0 is required. We have chosen $d_0 = 0.1$. Although this introduces some amplitude error, the amplitude error of the fully discrete scheme is generally less than the phase error, as will be shown later. Furthermore, the resulting operator produces dissipation for high wavenumber components of the solution which are not propagated accurately.

In order to apply this spatial operator to a hyperbolic system of equations in the form

$$(2)\quad \frac{\partial \mathbf{u}}{\partial t} + \frac{\partial(\mathbf{Au})}{\partial x} = 0,$$

the operator must be split into the antisymmetric part, δ_x^a (with the a_i coefficients), and the symmetric part, δ_x^s (with the d_i coefficients). The spatial derivative in equation (2) is approximated as

$$(3)\quad \frac{\partial(\mathbf{Au})}{\partial x} \approx \delta_x^a \mathbf{Au} + \delta_x^s |\mathbf{A}|\mathbf{u}$$

where

$$|\mathbf{A}| = \mathbf{X}|\Lambda|\mathbf{X}^{-1}$$

and $\mathbf{X}$ is the matrix of right eigenvectors and Λ the matrix of eigenvalues of $\mathbf{A}$.

The time-marching method is an explicit six-stage method of the following form:

$$(4)\quad \begin{aligned} u_{n+\alpha_1}^{(1)} &= u_n + h\alpha_1 f_n, \\ u_{n+\alpha_2}^{(2)} &= u_n + h\alpha_2 f_{n+\alpha_1}^{(1)}, \\ u_{n+\alpha_3}^{(3)} &= u_n + h\alpha_3 f_{n+\alpha_2}^{(2)}, \\ u_{n+\alpha_4}^{(4)} &= u_n + h\alpha_4 f_{n+\alpha_3}^{(3)}, \\ u_{n+\alpha_5}^{(5)} &= u_n + h\alpha_5 f_{n+\alpha_4}^{(4)}, \\ u_{n+1} &= u_n + h f_{n+\alpha_5}^{(5)}, \end{aligned}$$

where $u_n = u(t_n)$, h is the time step, and

$$f^{(k)} = \frac{du^{(k)}}{dt}.$$

With $\alpha_5 = 1/2$, this method is second-order accurate. With $\alpha_5 = 1/2, \alpha_4 = 1/3, \alpha_3 = 1/4, \alpha_2 = 1/5, \alpha_1 = 1/6$, it produces sixth-order accuracy for linear homogeneous ordinary differential equations. In [19], this six-stage method is shown to be more accurate than the classical fourth-order Runge-Kutta method when combined with the above spatial operator for both homogeneous and inhomogeneous linear problems. The extra stages were accounted for by performing the comparison for an equal number of derivative function evaluations. Furthermore, the six-stage method requires less computer memory than the classical fourth-order Runge-Kutta method.

3. Optimized scheme. Optimized finite-difference schemes are obtained by dropping the requirement of maximum order of accuracy and selecting the resulting free parameters to achieve some desired error behavior. The spatial operator given in (1) is at least first-order accurate if

$$d_0 + 2d_1 + 2d_2 + 2d_3 = 0 \tag{5}$$

and

$$a_1 + 2a_2 + 3a_3 = \frac{1}{2}. \tag{6}$$

A value of $d_0 = 0.1$ was selected based on stability considerations and the need for high wavenumber damping, as discussed above. Therefore, by reducing the order of accuracy of the spatial operator to first order, four free parameters are obtained. The time-march method, (4), is at least second-order accurate as long as $\alpha_5 = 0.5$. With this constraint, four free parameters are available in the time-march method as well. Consequently, eight parameters are available to optimize the fully discrete scheme.

The present optimized scheme was developed to minimize the maximum error for waves resolved with at least ten grid points per wavelength (*PPW*) for Courant numbers less than or equal to one. There are numerous ways to find such an optimized scheme. We used the following approach. First, we determined the optimal spatial operator for the specified wavenumber range in one dimension. Using this spatial operator, we then optimized the time-march method at a Courant number of one, also in one dimension. The resulting coefficients are listed below:

$$\begin{gathered} a_1 = 0.7599613, \quad a_2 = -0.1581220, \quad a_3 = 0.01876090, \\ d_0 = 0.1, \quad d_1 = -0.07638461, \quad d_2 = 0.03228961, \quad d_3 = -0.005904994, \\ \alpha_1 = 0.168850, \quad \alpha_2 = 0.197348, \quad \alpha_3 = 0.250038, \quad \alpha_4 = 0.333306, \quad \alpha_5 = 0.5. \end{gathered} \tag{7}$$

4. Fourier error analysis. In order to analyze finite-difference schemes for wave propagation problems, we consider the linear convection equation [16], given in one dimension by

$$\frac{\partial U}{\partial t} + c\frac{\partial U}{\partial x} = 0, \tag{8}$$

where $U = U(x,t)$ and c, the phase speed, is a positive real constant. With an initial condition given by

$$U(x,0) = U_0 \exp(i\kappa x), \tag{9}$$

the exact solution on an infinite domain is

$$U(x,t) = U_0 \exp[i\kappa(x - ct)], \tag{10}$$

where κ is the spatial wavenumber. Assuming a solution in the form

$$U(x,t) = u(t)\exp(i\kappa x) \tag{11}$$

and replacing the spatial derivative appearing in (8) by a numerical approximation, the following ordinary differential equation is obtained:

$$\frac{du}{dt} = -ic\kappa^* u = \lambda u, \tag{12}$$

where κ^* is the numerical (or modified) wavenumber, which depends on the spatial operator, and $\lambda = -ic\kappa^*$.

This ordinary differential equation can be numerically advanced in time using a time-march method. For linear time-march methods, the characteristic polynomial has one or more roots, σ, which are functions of λh, where h is the time step. We consider here only methods which produce one σ root. The numerical solution to (12) is then

$$u_n = U_0\sigma^n, \tag{13}$$

where $u_n = u(t_n) = u(nh)$. Writing $\sigma = R\exp(i\phi)$, the numerical solution to (8) is thus

$$U_{\text{num}}(x,t) = U_0R^n\exp[i(\kappa x + n\phi)]. \tag{14}$$

This numerical solution can differ from the exact solution in both amplitude and phase. We can rewrite the numerical solution as

$$U_{\text{num}}(x,t) = U_0R^n\exp[i\kappa(x - c^*t)], \tag{15}$$

where c^* is the numerical phase speed given by $c^* = \phi/\kappa h$. Comparing (15) with (10), we define the normalized error components as

$$er_a = |\sigma| - 1 = R - 1, \tag{16}$$

$$er_p = \frac{c^*}{c} - 1 = -\frac{\phi}{c\kappa h} - 1, \tag{17}$$

where er_a and er_p denote amplitude and phase error, respectively.

In one dimension, the error resulting from a given numerical scheme depends on the product $z = \kappa\Delta x$ where Δx is the grid spacing and the Courant number is $C = ch/\Delta x$. In two or three dimensions, the error has a further dependence on the direction of propagation. The two-dimensional linear convection equation is given by

$$\frac{\partial U}{\partial t} + c\cos\theta\frac{\partial U}{\partial x} + c\sin\theta\frac{\partial U}{\partial y} = 0. \tag{18}$$

This equation governs a plane wave convecting a scalar U with speed c along a straight line making an angle θ with respect to the x-axis. On a square grid, when the same difference operator is used to approximate the two spatial derivatives in (8), the two-dimensional numerical wavenumber κ^*_{2d} can be written as

$$\kappa^*_{2d}(z,\theta) = \cos\theta\kappa^*_{1d}(z\cos\theta) + \sin\theta\kappa^*_{1d}(z\sin\theta), \tag{19}$$

where κ^*_{1d} is determined from the one-dimensional analysis.

For the spatial operator given in (1), the numerical wavenumber is given by

$$
\begin{aligned}
i\kappa^* = \frac{1}{\Delta x}[d_0 + 2(d_1 \cos z + d_2 \cos 2z + d_3 \cos 3z) \\
+ 2i(a_1 \sin z + a_2 \sin 2z + a_3 \sin 3z)].
\end{aligned} \tag{20}
$$

For the time-marching method (4), σ is given by

$$
\sigma = 1 + \lambda h + \beta_2(\lambda h)^2 + \beta_3(\lambda h)^3 + \beta_4(\lambda h)^4 + \beta_5(\lambda h)^5 + \beta_6(\lambda h)^6, \tag{21}
$$

where

$$
\begin{gathered}
\beta_2 = \alpha_5, \quad \beta_3 = \alpha_5\alpha_4, \quad \beta_4 = \alpha_5\alpha_4\alpha_3, \\
\beta_5 = \alpha_5\alpha_4\alpha_3\alpha_2, \quad \beta_6 = \alpha_5\alpha_4\alpha_3\alpha_2\alpha_1.
\end{gathered}
$$

The procedure for determining the errors for given values of z, θ, and C proceeds as follows. First, κ^*_{2d} must be calculated from (19) with κ^*_{1d} determined from (20). The parameter λ is then found using $\lambda = -ic\kappa^*$. Equation (21) is used to determine σ, which then produces the phase and amplitude errors from (16) and (17).

Figures 1 and 2 show the numerical phase speed and amplitude at a Courant number of unity in one dimension for the following three fully discrete finite-difference schemes: (1) second-order centered differences in space with fourth-order Runge-Kutta time marching (designated RK4C2 on the figures), (2) fourth-order centered differences with fourth-order Runge-Kutta time marching (designated RK4C4) and (3) the maximum-order spatial scheme given by (1) with $d_0 = 0.1$ and the time-marching method given by (4) with the values of the coefficients which produce the maximum order (designated maximum-order). Care must be taken in assessing schemes at individual values of θ and C. However, for the schemes considered here, the errors in the practical range of wavenumbers are generally largest for $\theta = 0^o$ and decrease with decreasing Courant number.

Lele [9] defines the resolving efficiency of a scheme as the fraction of the domain $0 \leq z \leq \pi$ for which the errors lie below a specified tolerance. Table 1 shows the resolving efficiency of the three schemes above for four different values of error tolerance e. In all three cases, the phase error is larger than the amplitude error and hence the resolving efficiency is determined by the phase error. Note that as the error tolerance decreases, the higher-order schemes become relatively more efficient. For example, at the largest error tolerance shown, the resolving efficiency of the maximum-order scheme is less than twice that of scheme RK4C4 while, at the smallest tolerance, the maximum-order scheme has almost three times the resolving efficiency of scheme RK4C4. The parameter $z = \kappa\Delta x$ is related to the number of points per wavelength by which a given wave is resolved through the relation $PPW = 2\pi/z$. Table 2 shows the PPW required to produce errors below the specified error tolerance values.

The procedure used to develop the optimized scheme is not sufficient to guarantee that the maximum error obtained over the specified wavenumber range in one dimension is not exceeded at nonzero values of θ. However, in the present case, the maximum phase and amplitude errors are obtained at $\theta = 0^o$ at a Courant number of unity. These errors are shown in Figures 3 and 4 in comparison with the maximum-order scheme for $0 \leq z \leq \pi/5$. The errors produced by the optimized scheme are bounded by 2×10^{-5} while the maximum-order scheme produces errors up to 4×10^{-4}. For the range $0.4 \leq z \leq 0.7$, the optimized scheme gives much smaller errors than the maximum-order scheme. This corresponds roughly to 9 to 16 PPW. For larger wavenumbers the advantage is reduced, while for smaller wavenumbers, the maximum-order scheme is more accurate.

Table 3 shows the resolving efficiency r and required PPW values for the optimized scheme with the four error tolerances as in the preceding tables. The advantage of the optimized

scheme is largest at the "design" error tolerance 2×10^{-5}. For this error tolerance, it produces 1.6 times the resolving efficiency of the maximum-order scheme and four times the resolving efficiency of the fourth-order scheme. For error tolerances below 2×10^{-5}, the optimized

scheme is substantially inferior to the maximum-order scheme. For higher values of error tolerance, the advantage of the optimized scheme is reduced in comparison with both the maximum-order scheme and the fourth-order scheme.

Another useful approach for assessing finite-difference schemes for wave propagation is to determine the *PPW* required to maintain global phase and amplitude errors below a specified level as a function of the number of wavelengths travelled. The global amplitude error is given by

$$Er_a = \left| 1 - |\sigma(z, C)|^{\frac{2\pi n_w}{Cz}} \right|, \tag{22}$$

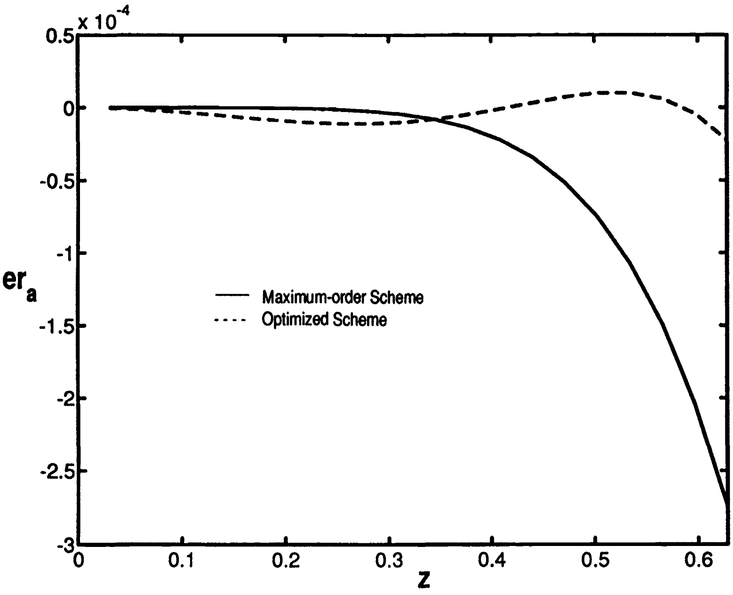

FIG. 4. *Amplitude error for the maximum-order scheme and the optimized scheme.*

TABLE 3
Resolving efficiency and PPW required for optimized scheme.

	e =			
	10^{-5}	2×10^{-5}	10^{-4}	3×10^{-3}
r	0.05	0.20	0.22	0.32
PPW	40	10	9	6

where n_w is the number of wavelengths travelled. The global phase error is

$$Er_p = \frac{2\pi n_w}{Cz}|\phi(C, z) + Cz|. \tag{23}$$

Figure 5 shows the *PPW* required to maintain Er_a and Er_p less than 0.1. The maximum-order scheme can accurately simulate the propagation of waves over distances greater than five hundred wavelengths with a grid resolution of less than twenty points per wavelength. This is less than half of the *PPW* required by the combination of fourth-order centered differences and fourth-order Runge-Kutta time marching. In three dimensions, this translates to more than eight times fewer grid nodes. The optimized scheme is superior for simulations in which waves travel under three hundred wavelengths. For such cases, good accuracy is obtained with roughly ten points per wavelength. In [21] several other finite-difference schemes are compared on this basis.

5. Stability and numerical boundary schemes. From Fourier analysis, the maximum-order fully discrete scheme is stable up to a Courant number of roughly 1.5 in one dimension and the optimized scheme is unconditionally unstable. Stability by Fourier analysis is a necessary condition for Lax-Richtmyer stability. However, the instability of the optimized scheme is very mild and we now show that on a finite domain asymptotic (or time) stability is achieved. Consider a semidiscrete approximation to (8) obtained by dividing the domain into

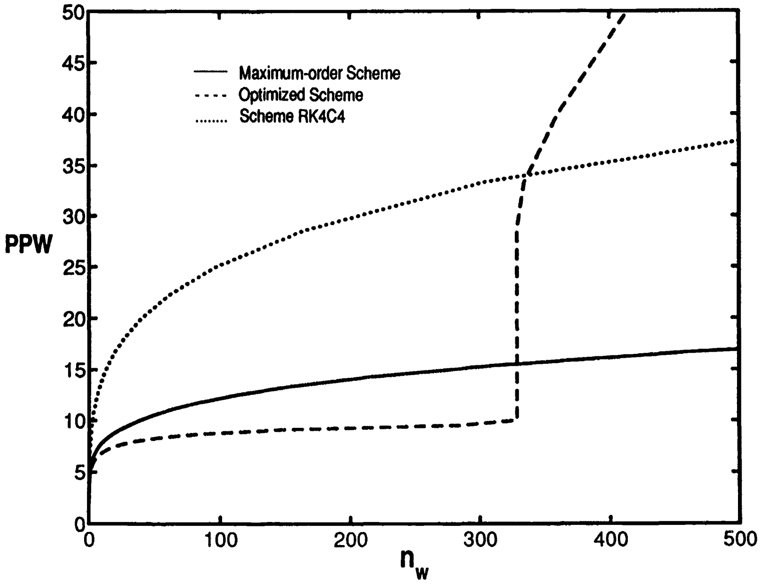

FIG. 5. *PPW requirements for the maximum-order scheme, the optimized scheme, and the combination of fourth-order centered differences and fourth-order Runge–Kutta time marching.*

M subintervals of length $\Delta x = 1/M$ and approximating the spatial derivative in the interior by (1). At the inflow boundary, the derivative is approximated by [18]:

$$(24)\qquad \begin{aligned} (\delta_x u)_1 &= \frac{1}{60\Delta x}[-12u_0 - 65u_1 + 120u_2 - 60u_3 + 20u_4 - 3u_5],\\ (\delta_x u)_2 &= \frac{1}{60\Delta x}[6.6u_0 - 51.6u_1 + 34u_2 - 12u_3 + 39u_4 - 19.6u_5 + 3.6u_6]. \end{aligned}$$

These operators are fifth-order accurate and hence do not compromise the global accuracy of the method. At the outflow boundary, the difference operators for the last three points in the grid are formed using fifth-order space extrapolation together with the interior differencing scheme. The space extrapolation can be written in the form

$$(25)\qquad (1 - E^{-1})^p u_{M+1} = 0,$$

where the shift operator E is defined by $Eu_j = u_{j+1}$ and the order of the approximation is $p - 1$. When this approach is applied to hyperbolic systems, flux-vector splitting is required near boundaries [20].

The semidiscrete form can be written as

$$(26)\qquad \frac{d\mathbf{u}}{dt} = \tilde{\mathbf{A}}\mathbf{u}, \qquad \text{where} \qquad \tilde{\mathbf{A}} = \frac{c}{\Delta x}\mathbf{A},$$

$\mathbf{u} = [u_1, u_2, \ldots, u_{M-1}, u_M]^T$. Figure 6 shows the eigenvalues of $\mathbf{A}$ for the maximum-order and optimized spatial schemes with $M = 100$. Each scheme produces two boundary-condition-dependent eigenvalues [2] but these lie in the left half-plane and hence do not pose a problem. These eigenvalue spectra both lie well within the stability contours of the respective time-marching methods, as shown in Figure 7, and thus the fully discrete methods are asymptotically stable at a Courant number of unity.

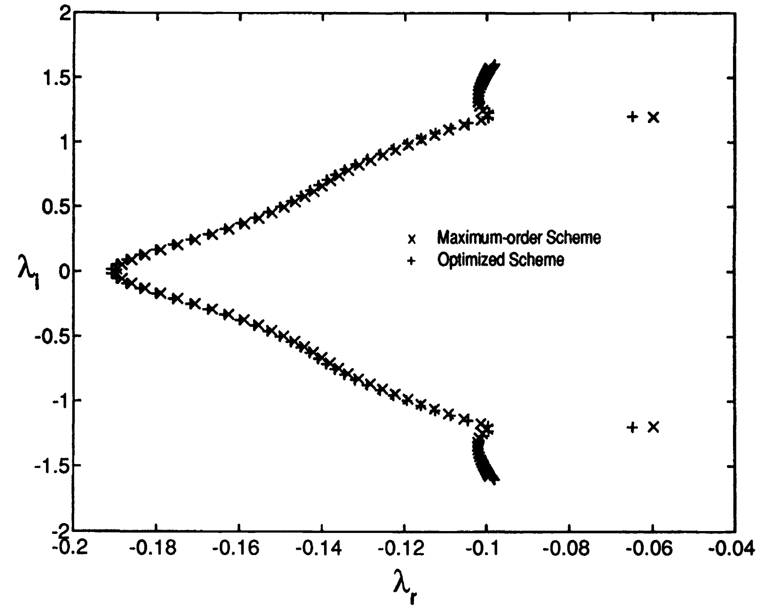

FIG. 6. *Eigenvalue spectra of semidiscrete operators.*

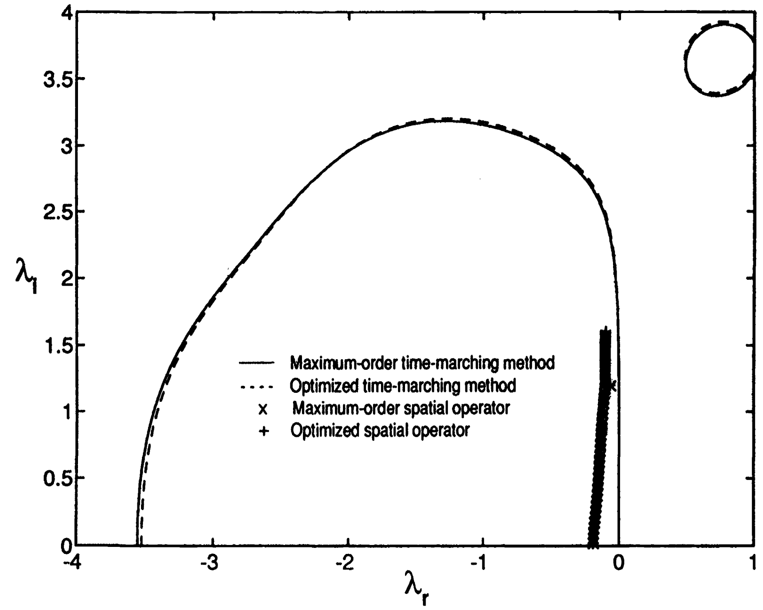

FIG. 7. *Stability contours of the time-marching methods.*

Asymptotic stability is a necessary condition for Lax-Richtmyer stability but it is not sufficient. Thus we now consider the amplification matrix **G** given by

$$\mathbf{G} = \mathbf{I} + C\mathbf{A} + \beta_2(C\mathbf{A})^2 + \beta_3(C\mathbf{A})^3 + \beta_4(C\mathbf{A})^4 + \beta_5(C\mathbf{A})^5 + \beta_6(C\mathbf{A})^6. \quad (27)$$

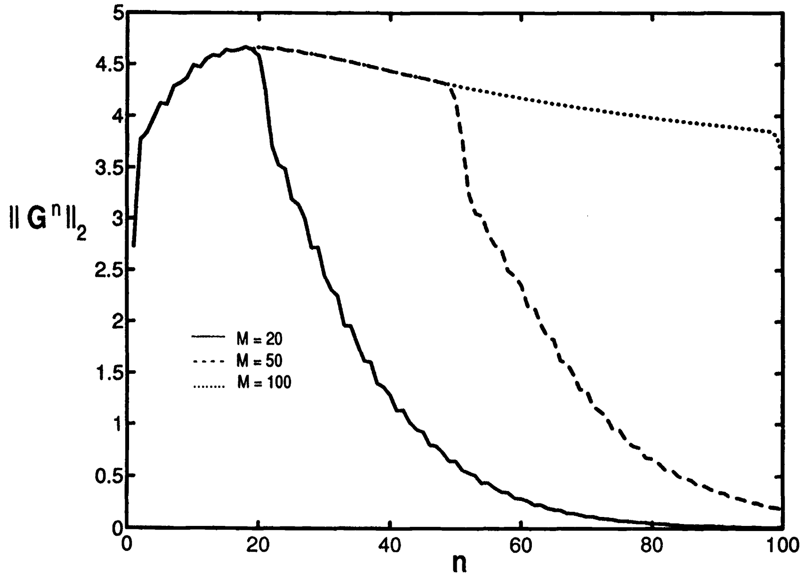

FIG. 8. *Variation of the L_2-norm of the amplification matrix of the maximum-order scheme.*

A necessary and sufficient condition for stability of a fully discrete finite-difference scheme is that there exists a constant $K \geq 1$ such that

$$\|(\mathbf{G}(\Delta x, h))^n\| \leq K \tag{28}$$

for all $n \geq 0$, $0 \leq nh \leq T$ with T fixed. For hyperbolic problems, the Courant number must be kept constant as n is increased. Figure 8 shows $\|\mathbf{G}^n\|_2$ for the maximum-order scheme for three different values of M and a Courant number of unity. Figure 9 shows similar results for the optimized scheme. In both cases, $\|\mathbf{G}^n\|_2$ is clearly bounded and hence both schemes appear to be stable. This is consistent with the results of [20], in which both schemes were used for simulations of electromagnetic waves with no evidence of instability. However, a singular value decomposition of $\mathbf{G}^n$ shows that the growth in $\|\mathbf{G}^n\|$ shown in Figure 9 is associated with the numerical boundary scheme at the inflow boundary. This obscures the very slow growth of the unstable modes of the optimized scheme, which is revealed if the numerical boundary scheme at inflow is removed. Nevertheless, Figure 9 provides some reassurance that the instability causes no immediate difficulties. As shown in Figure 4, the maximum value of $|\sigma|$ predicted using Fourier analysis is 1.00002 at a Courant number of unity. Since $1.00002^{34,000} < 2$, the scheme can safely be used for well over 34,000 time steps without the solution exhibiting any instability. However, the optimized scheme is not intended for such long simulations since the maximum-order scheme becomes more accurate if the distance travelled becomes very large, as shown in Figure 5.

6. Numerical experiments. We now consider several numerical experiments in order to further compare the four schemes discussed above. The one-dimensional linear convection equation with $c = 1$ is solved with periodic boundary conditions on the domain $0 \leq x \leq 1$. The initial condition is given by a Gaussian-modulated cosine function as follows:

$$U(x, 0) = (\cos \kappa x)e^{-0.5[(x-0.5)/\sigma_g]^2}$$

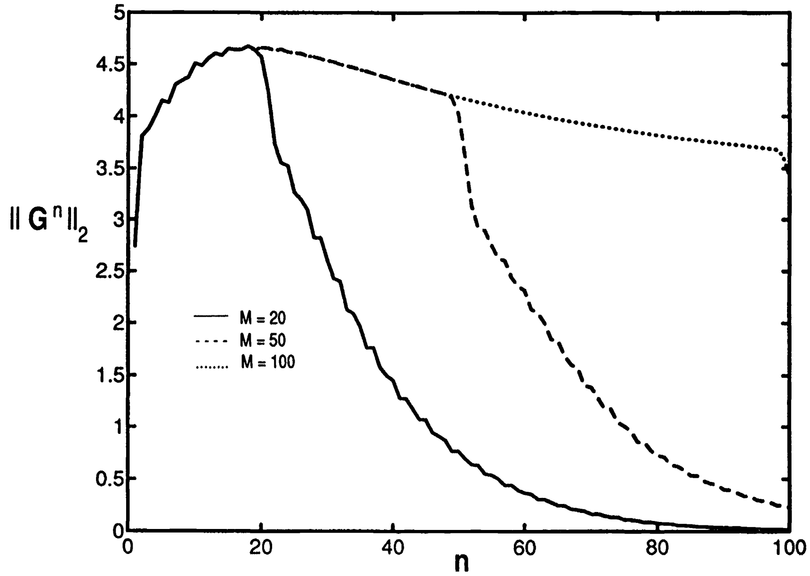

FIG. 9. *Variation of the L_2-norm of the amplification matrix of the optimized scheme.*

with various values of σ_g and κ. For the present schemes, the errors in the practical range of wavenumbers are generally largest at $\theta = 0^o$ and decrease with decreasing Courant number. Therefore, one-dimensional numerical experiments with a Courant number of unity represent the worst case.

For the first experiment, we consider a Gaussian ($\kappa = 0$) with $\sigma_g = 0.04$. The grid is uniform with 100 points across the domain. Figure 10 shows the result after 100 time steps with a Courant number of unity, i.e., at $t = 1$. The exact solution is identical to the initial condition. The solution produced by scheme RK4C2 is poor, while the other schemes are very accurate. After 1000 time steps, the solution produced by RK4C4 is inadequate for many purposes, while the maximum-order and optimized schemes remain very accurate, as shown in Figure 11.

Figures 12–15 compare the maximum-order and optimized schemes for Gaussian initial conditions with four different values of σ_g. The results are again shown for $C = 1$ and $t = 1$. The figures show the difference between the computed solution and the exact solution. For $\sigma_g = 0.04$ and $\sigma_g = 0.03$, the L_2-norm of the error produced by the optimized scheme is less than half of that produced by the maximum-order scheme. For $\sigma_g = 0.02$ the improvement from the optimized scheme is reduced and for $\sigma_g = 0.05$ the optimized scheme produces more error than the maximum-order scheme.

These results can be better understood by considering the normalized power spectra of these Gaussians, which are shown in Figure 16. These spectra show the wavenumber content of the Gaussians as a function of z based on a 100-point grid. They can be compared with Figures 3 and 4, which show the numerical errors also as a function of z. For example, Figures 3 and 4 show that the optimized scheme is much more accurate than the maximum-order scheme for roughly $0.4 \leq z \leq 0.7$. With $\sigma_g = 0.05$, there is virtually no content in this region and hence the optimized scheme is inferior to the maximum-order scheme since it produces more error at low wavenumbers. For $\sigma_g = 0.04$ and $\sigma_g = 0.03$, there is some content in the range $0.4 \leq z \leq 0.7$ and little content at higher wavenumbers. Consequently, the error is dominated by these modes and the optimized scheme is superior. Finally, for $\sigma_g = 0.02$, the

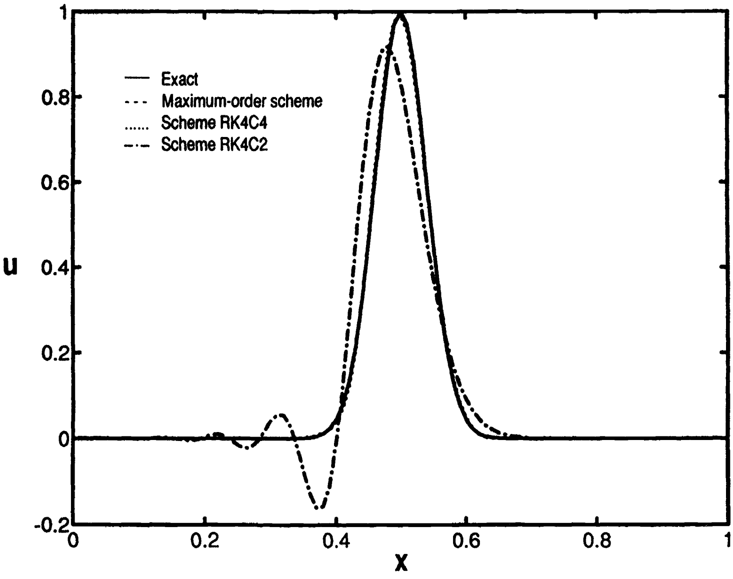

FIG. 10. *Solution at* $t = 1$.

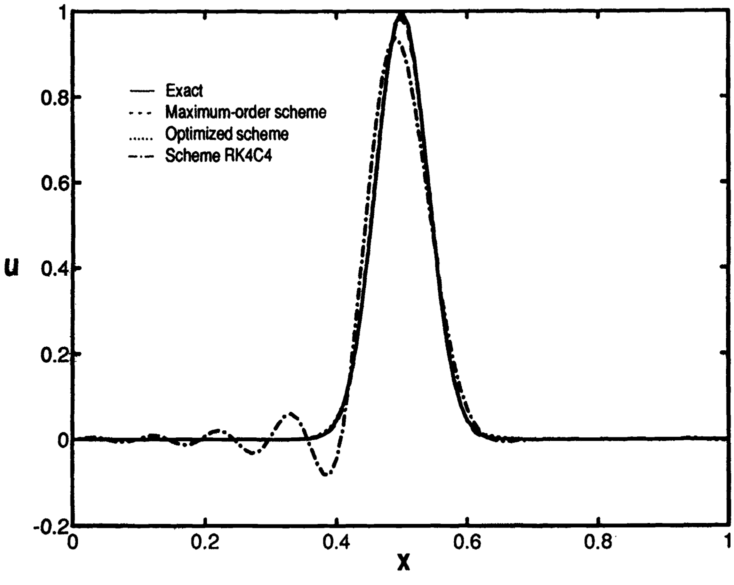

FIG. 11. *Solution at* $t = 10$.

error is dominated by wavenumbers with $z > 0.7$ and thus the optimized scheme is not much superior to the maximum-order scheme.

The gains produced by the optimized scheme for Gaussians are quite modest, even for $\sigma_g = 0.03$ and $\sigma_g = 0.04$. This occurs because Gaussians always have considerable low wavenumber content, which is convected more accurately by the maximum-order scheme. The optimized scheme is more effective for functions with a narrower bandwidth. Figures 17–19 show results for Gaussian-modulated cosine functions with $\sigma_g = 0.1$ and $\kappa = 24\pi$,

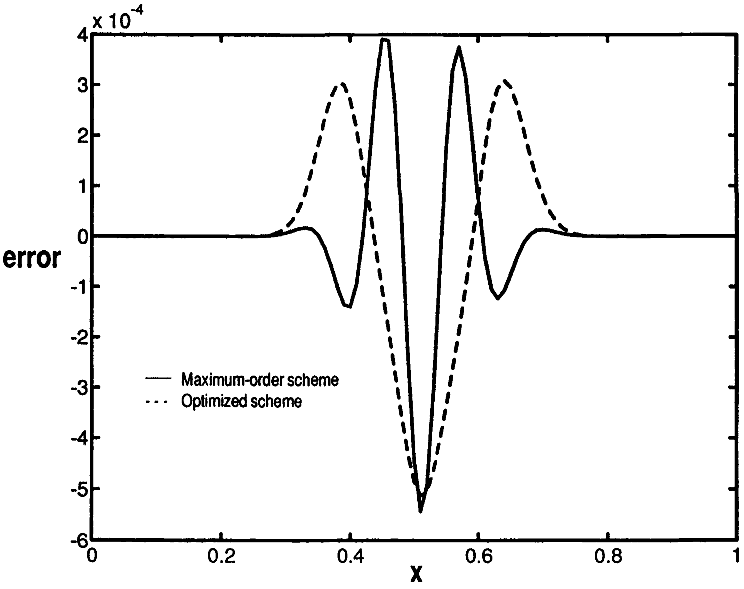

FIG. 12. *Error for* $\sigma_g = 0.05$.

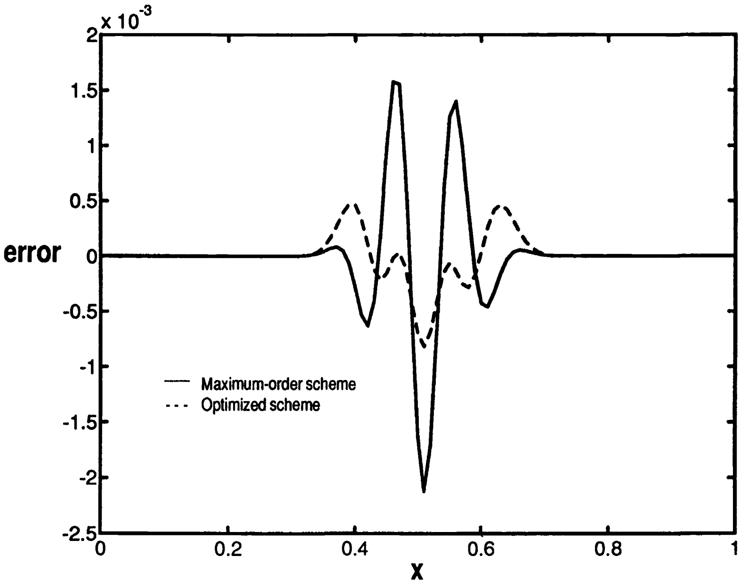

FIG. 13. *Error for* $\sigma_g = 0.04$.

32π, and 40π, on a 200-point grid. The results are shown after 200 time steps at a Courant number of unity, i.e., at $t = 1$. The corresponding normalized power spectra are shown in Figure 20. In each case, these functions have considerable spectral content in the range for which the optimized scheme is superior. For $\kappa = 32\pi$, the L_2-norm of the error produced by the optimized scheme is more than ten times less than that produced by the maximum-order scheme.

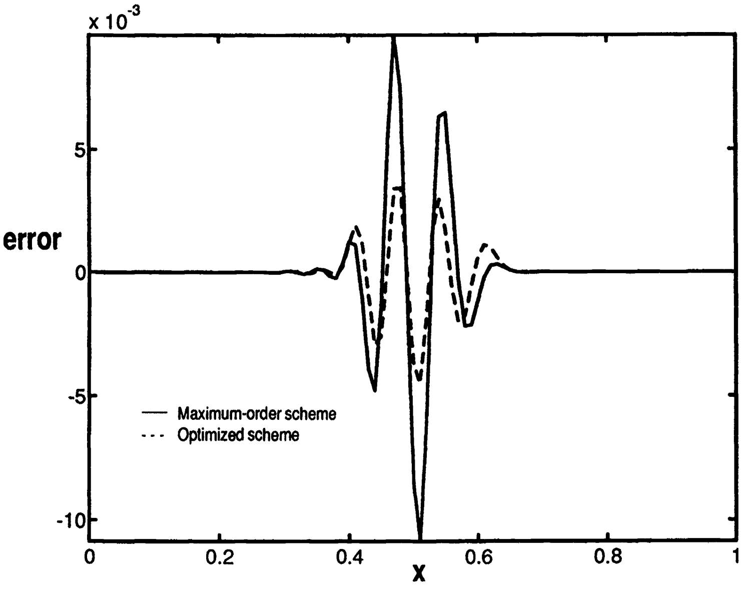

FIG. 14. *Error for* $\sigma_g = 0.03$.

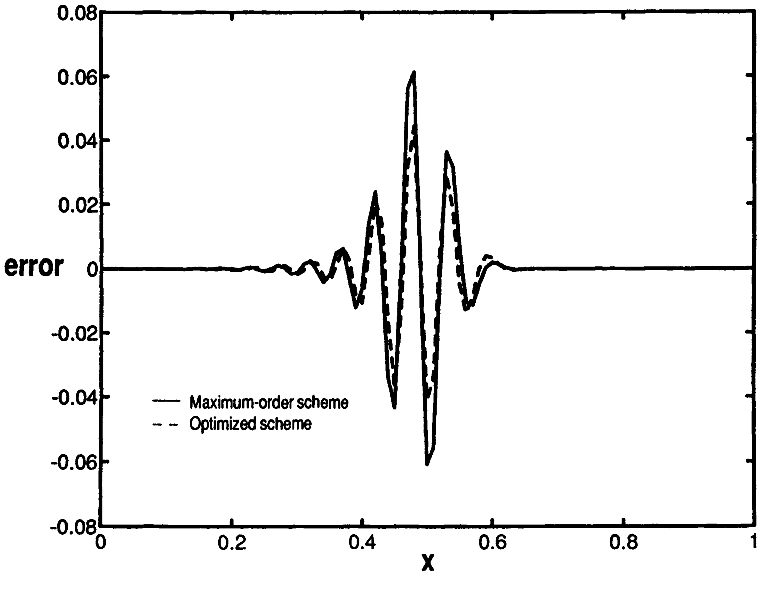

FIG. 15. *Error for* $\sigma_g = 0.02$.

7. Discussion. In this section, we discuss some considerations in selecting and developing finite-difference schemes for wave propagation problems. Initially an error tolerance must be determined. This is based on two factors: (1) the level of accuracy required of the simulation in order to produce meaningful results and (2) an estimate of the largest distance a wave will travel during the simulation. Next an estimate must be made of the shortest wavelength which must be accurately resolved. This is also based on the accuracy requirements of the sim-

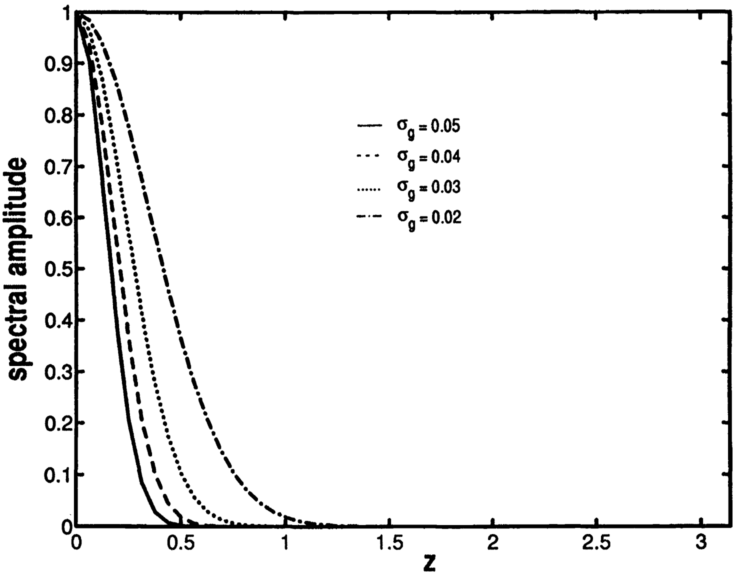

FIG. 16. *Normalized power spectra of Gaussians.*

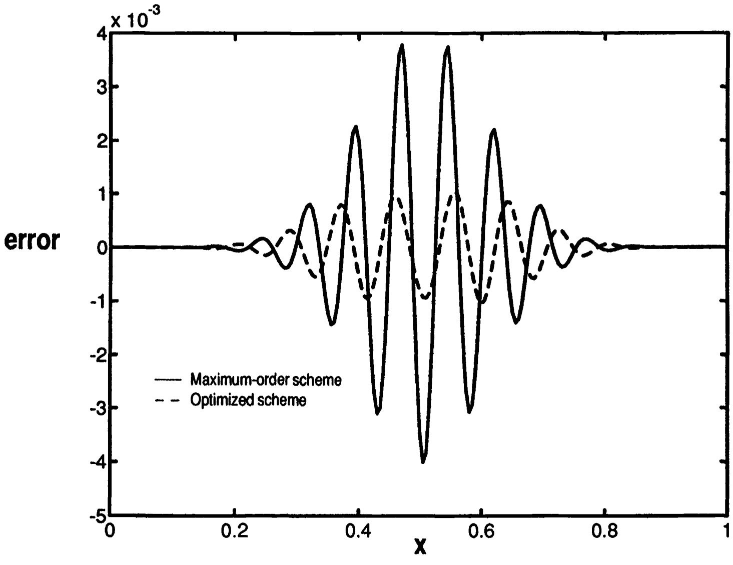

FIG. 17. *Error for* $\kappa = 24\pi$.

ulation. For a given scheme, the grid spacing can then be determined to produce the required accuracy in phase and amplitude for the shortest wavelength of interest based on Fourier error analysis. The grid resolution must be sufficient to satisfy the accuracy requirements for the worst combination of Courant number and propagation direction.

The compromise involved in optimizing a scheme is clearly revealed in Figure 5. For small distances of travel, the optimized scheme is superior but as the distance is increased the maximum-order scheme eventually requires fewer *PPW*. [21] includes a scheme similar to

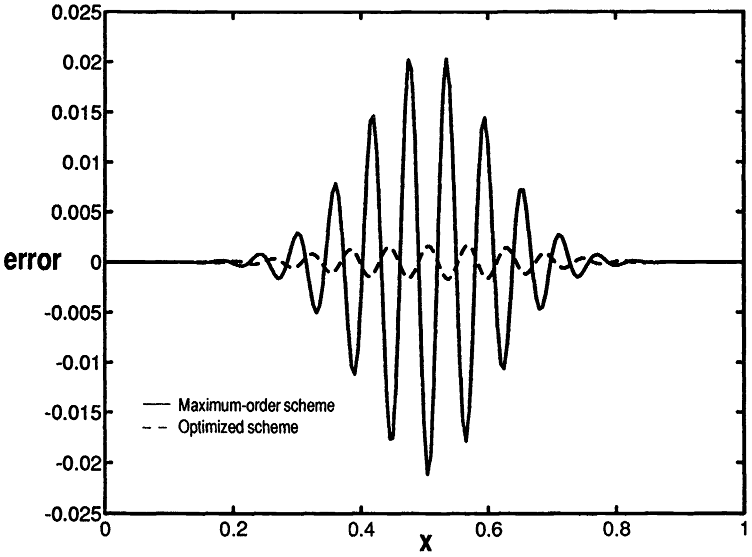

FIG. 18. *Error for* $\kappa = 32\pi$.

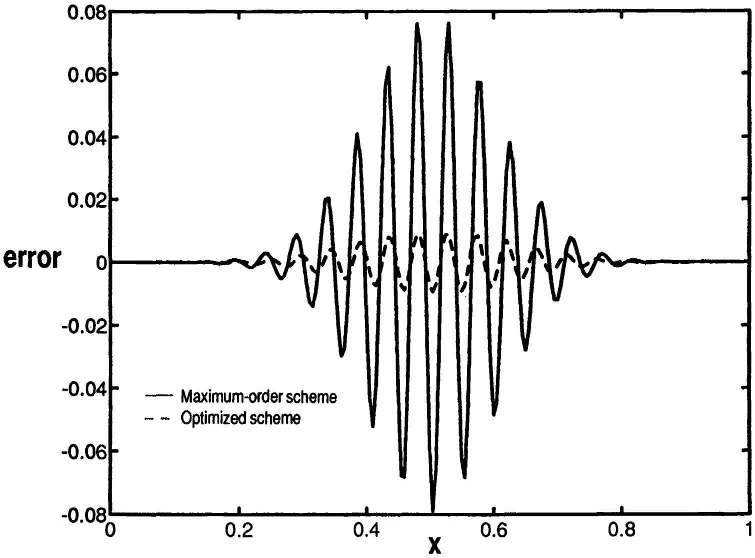

FIG. 19. *Error for* $\kappa = 40\pi$.

that presented here which is optimized for waves resolved with at least 7.5 *PPW*. This scheme is slightly superior to the present optimized scheme for distances of travel less than roughly 75 wavelengths but is inferior for longer distances.

For some wave propagation applications, it is essential that the numerical scheme produce no dissipation, i.e., no amplitude error. The schemes presented here are inappropriate for such problems. However, for most problems it is sufficient that the amplitude error be less than or comparable to the phase error. Furthermore, the damping of high wavenumber modes produced by the present schemes can be helpful in some applications [17]. If reduced dissipation is

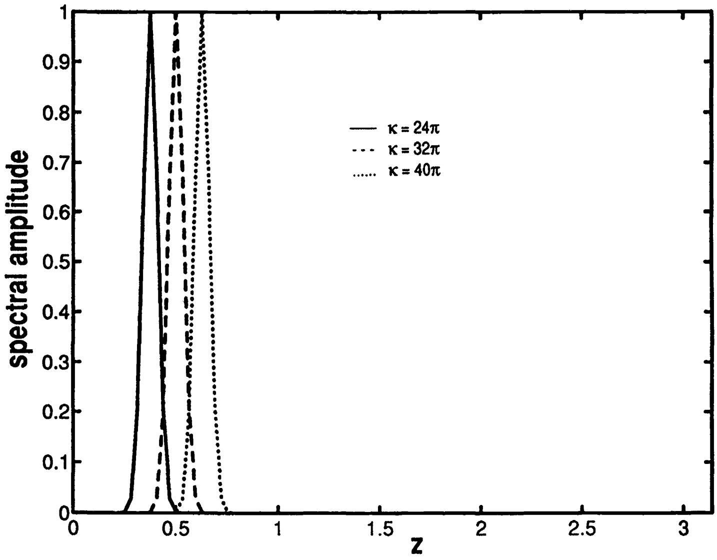

FIG. 20. *Normalized power spectra of Gaussian-modulated cosine functions.*

desired, the present spatial scheme can be used without the filter. Fourth-order Runge-Kutta time marching should then be used for stability.

8. Conclusions. The two finite-difference schemes presented here provide a promising option for simulating long-range propagation of linear waves. Potential applications include electromagnetics and acoustics. Both schemes combine a seven-point spatial operator and an explicit six-stage low-storage time-marching method of the Runge-Kutta type. The optimized scheme was developed by minimizing the maximum phase and amplitude errors for waves which are resolved with at least ten points per wavelength. The maximum-order scheme can accurately simulate the propagation of waves over distances greater than five hundred wavelengths with a grid resolution of less than twenty points per wavelength. The optimized scheme is intended for simulations in which waves travel under three hundred wavelengths. For such cases, good accuracy is obtained with roughly ten points per wavelength. Future work will address the application of these schemes to complex geometries.

A NONLINEAR, SUBGRIDSCALE MODEL FOR INCOMPRESSIBLE VISCOUS FLOW PROBLEMS*

WILLIAM J. LAYTON†

Abstract. We consider a nonlinear subgridscale model of the Navier-Stokes equations resulting in a Ladyzhenskaya-type system. The difference is that the power "p" and scaling coefficient $\mu(h) \doteq O(h^\sigma)$ do not arise from macroscopic fluid properties and can be picked to ensure both L^∞-stability and yet be of the order of the basic discretization error in smooth regions. With a properly scaled p-Laplacian-type artificial viscosity one can construct a higher-order method which is just as stable as first-order upwind methods.

Key words. high Reynolds number, subgridscale model, Ladyzhenskaya model

AMS subject classifications. Primary 76M10; Secondary 65N30

1. Introduction. Consider the approximate solution of steady, incompressible, viscous flow problems, as described by the Navier-Stokes equations for the velocity $\mathbf{u} : \Omega \subset \mathbb{R}^d \to \mathbb{R}^d (d = 2, 3)$ and the pressure $\lambda : \Omega \to \mathbb{R}$:

$$(1.1) \qquad -\operatorname{Re}^{-1}\Delta\mathbf{u} + \mathbf{u}\cdot\nabla\mathbf{u} + \nabla\lambda = \mathbf{f} \text{ in } \Omega, \quad \nabla\cdot\mathbf{u} = 0 \text{ in } \Omega,$$

subject to the usual no-slip boundary condition and normalization condition for λ:

$$(1.2) \qquad \mathbf{u} = 0 \text{ on } \partial\Omega, \ \int_\Omega \lambda dx = 0.$$

In (1.1), (1.2) Ω is a bounded, polygonal domain in $\mathbb{R}^d$, Re is the Reynolds number, λ is the fluid pressure, and $\mathbf{u}$ is the fluid velocity. To fix ideas we consider a (centered) finite element discretization of (1.1), (1.2) with a global (or outer) meshwidth (meaning maximum d-simplex diameter) "h."

We also specifically consider herein the case of "high" Reynolds numbers. For Re high enough, the equilibrium problem (1.1), (1.2) loses its stability. Thus, in this report large Re will be understood to mean *large with respect the number of degrees of freedom available for the approximation of* (1.1), (1.2). Thus $0 < \operatorname{Re}^{-1} \leq O(h)$ will be the case considered.

In fluid flow problems, considerable energy in the flow can be contained in "eddies, vortices/solution scales," etc. which are not large enough to be represented on a computationally feasible grid. It is common practice for such problems to employ either a specialized discretization such as [16, 19, 28, 29] or some sort of "subgridscale" (SGS) model to represent these effects on the grid, at least in some averaged sense. The goal is to remove the "excess energy" from the large (resolved) eddies and to return some energy to the large eddies when the eddy moves into a region with smaller local meshwidth. One common approach (others are certainly possible; see Dubois, Jauberteau, and Temam [10] and Heywood and Rannacher [17]) is to obtain closure in the resulting set of SGS averaged equations via a judicious combination of continuum mechanical principles and phenomenology. Often this approach results in the same effect as beginning with, for example, an algebraic turbulence model, such as studied in Gunzburger and Turner [14], and setting the characteristic length scale $\ell(x)$ to be the local meshwidth $h(x)$; for this approach see, e.g., Leslie and Quarini [23]. Thus, SGS modelling, while unavoidable in many applications, can be highly arguable.

*Received by the editors January 31, 1994; accepted for publication (in revised form) October 5, 1994. This work was partially supported by NSF grant 9400057.

†Institute for Computational Mathematics and Applications, Department of Mathematics, University of Pittsburgh, Pittsburgh, PA 15260 (WJL@VMS.CIS.PITT.EDU).

This paper takes a much more modest approach, not linked to either phenomenology or (alas) mechanics, but having similar motivation and goals. To motivate the present proposal consider first the usual $O(h)$ upwind/artificial viscosity approximation to (1.1), (1.2). This may be considered to be the most successful, although crudest, SGS model in practical calculations. Effects smaller than one mesh cell are spread to $O(\sqrt{h})$ distance thus resolvable on the outer mesh. It "stabilizes" both the discretization and the resulting linear system and does not alter the graph norm error (H^1 for velocities, L^2 for pressures) when using linear elements. Although (1.1), (1.2) does not satisfy a maximum principle,[1] the upwind/artificial viscosity discretization does control "wiggles" since L^∞-stability of the upwind approximation is easily proven using discrete Sobolev inequalities:

$$\sup_{0<\mathrm{Re}<\infty} \|\mathbf{u}^h\|_{L^\infty} \leq C(\Omega, f)h^{-\frac{d}{2}}|lnh|^{1-\frac{1}{d}}, \ d = \dim(\Omega) = 2, 3. \tag{1.3}$$

(The Navier-Stokes equations do possess singular solutions which are not in $L^\infty_{\mathrm{loc}}(\Omega)$ on small sets, Boisvert and Ames [4], so the constant on the right-hand side of (1.3) must $\to \infty$ as $h \to 0$ if the method is convergent.) Further, other mathematical support for some advantages of using upwind/artificial viscosity discretizations can be given [12, 13, 28, 29].

From the point of view of this paper, an SGS model should share these good attributes while at least partially overcoming the well-documented accuracy and resolution shortcomings of upwinding and first-order artificial viscosity. Therefore, relevant criteria include the following.

(i) The approximate solution should satisfy the same L^∞-stability bound (1.3) as the upwind method.

(ii) For degree k velocity elements and in smooth flow regions, the model should involve an $O(h^k)$ or $O(h^{k+1})$ perturbation from a consistent variational formulation.

(iii) Mathematical support for the agreeable effects of the model should be possible (at least for "model" problems).

(iv) The additional terms arising from the SGS model should be "stabilizing" for the algebraic system in the sense of adding contractive terms. This plays the role of removing "excess energy" from the large eddies.

To obtain a bound of the form (1.3) via the Sobolev embedding theorem, only three parameters are available: d the dimension of Ω, m the order of the derivative, and p the L^p-norm in which smoothness is measured. d is fixed at $\dim(\Omega)$ (2 or 3) and m may be considered fixed at 2 (not wishing to increase the order of (1.1) for the usual reasons). Thus, only p is available, leading to a p-Laplacian! An additional, nonlinear, artificial viscosity term of the form

$$AV_p(\mathbf{u}^h, \mathbf{v}) := \mu(h)(|\nabla\mathbf{u}^h|^{p-2}\nabla\mathbf{u}^h, \nabla\mathbf{v})$$

is thus suggested, where $(\cdot, \cdot)$ and $\|\cdot\|$ denote the usual $(L^2(\Omega))^d$ inner product and norm. For μ fixed (e.g., $\mu(h) \leq 0(h^\sigma)$, $\sigma =$ polynomial degree $(X^h) + 1$), taking $2 \leq p < \infty$ large enough will satisfy the conditions (i)-(iv) above.

The above form of "h" is taken to simplify the analysis somewhat. If meshwidths are highly variable then $AV_p(\cdot, \cdot)$ should be modified appropriately to use the correct local meshwidth:

$$AV_p(\mathbf{u}^h, \mathbf{v}) = \sum_{\substack{\text{all triangles} \\ e}} \int_e \mu \text{ (diameter } (e))|\nabla\mathbf{u}^h|^{p-2}\nabla\mathbf{u}^h : \nabla\mathbf{v}dx,$$

[1] Similarity solutions are known with point singularities [4]. The singular set in space-time of solutions to the Navier-Stokes equation has $1 - D$ Hausdorff dimension zero [6], so it is thin.

with $\mu(h)$ given by the following formula. Choose $p > \frac{d}{2}$ and $(k+1) \leq \sigma \leq p-1$ if $d=2$ and $(k+1) \leq \sigma \leq \frac{3}{2}(p-1)$ if $d=3$. Pick (μ_0 = constant and h = local meshwidth)

$$\mu(h) = \mu_0 |lnh|^{-(\frac{d-1}{d})(p-1)} h^{\sigma}. \tag{1.4}$$

This choice is motivated in Lemma 2.2, §2, but optimality of (1.4) can only be determined by more testing. Note that we may choose σ as large as we want (for example σ = polynomial degree of finite element space +1) by taking p correspondingly large: $p > \frac{2}{3}\sigma + 1$ in three dimensions.

The need for agreeable SGS models is even more acutely felt when the (nonlinear or linearized) discrete Navier-Stokes equations are solved using a multilevel method. For example, the finest mesh may indeed be sufficient to resolve solution scales. However, those same scales can possibly be troublesome on coarser meshes. This can be potentially troublesome for a two-level or multilevel discretization of nonlinear problems when the coarse mesh approximation should be in the ball of attraction for Newton's method for the fine mesh problem. (These promising methods were used already in 1935 by Southwell [27]. Their mathematical validation has recently been pioneered by Xu [31] for elliptic boundary value problems, and then generalized to the Navier-Stokes equations in [19-21].) The "Navier-Stokes plus p-Laplacian" equations were originally proposed by Ladyzhenskaya [18] as an alternate model for fluids with large stresses. In our view, the Ladyzhenskaya alteration is *quite* promising as an SGS model with (1.4) when not justified as a macroscopic fluid model. Finite element error analysis of this model was carried out in Du and Gunzburger [7-9] under a global uniqueness (small data) condition. The preliminary analysis given herein thus complements that of [7-9] in that we give error analysis in §3 for high Re with respect to solutions of (1.1) with $\mu = \mu(h) \to 0$ as $h \to 0$.

2. Preliminaries and max-norm stability. We consider the nonlinear SGS method: seek $(\mathbf{u}^h, \lambda^h) \in (X^h, Q^h)$ satisfying

$$AV_p(\mathbf{u}^h, \mathbf{v}) + \mathrm{Re}^{-1}(\nabla \mathbf{u}^h, \nabla \mathbf{v}) + b(\mathbf{u}^h, \mathbf{u}^h, \mathbf{v}) - (\lambda^h, \nabla \cdot \mathbf{v}) + (q, \nabla \cdot \mathbf{u}^h) = (f, \mathbf{v}) \tag{2.1}$$

for all $(\mathbf{v}, q) \in (\mathbf{x}^h, \mathbf{Q}^h)$, where $AV_p(\cdot,\cdot)$ is given, as indicated in the introduction, by

$$AV_p(\mathbf{u}, \mathbf{v}) := \mu(h)(|\nabla \mathbf{u}|^{p-2} \nabla \mathbf{u}, \nabla \mathbf{v}).$$

Here $p = 2$ corresponds to usual linear artificial viscosity, and $b(\mathbf{u}, \mathbf{v}, \mathbf{w})$ is the usual skew-symmetrized trilinear form:

$$b(\mathbf{u}, \mathbf{v}, \mathbf{w}) := \frac{1}{2} \int_{\Omega} [\mathbf{u} \cdot \nabla \mathbf{v} \cdot \mathbf{w} - \mathbf{u} \cdot \nabla \mathbf{w} \cdot \mathbf{v}] dx.$$

We shall assume that $\mathbf{X}^h$ satisfies the usual inverse and discrete Sobolev inequalities. In particular, for $d = 2, 3$ and all $\mathbf{v} \in \mathbf{X}^h$ (where $\|\cdot\|$ is the L^2-norm),

$$\|\mathbf{v}\|_{L^\infty} \leq C|ln(h)|^{1-\frac{1}{d}} h^{-(\frac{d-2}{2})} \|\nabla \mathbf{v}\|. \tag{2.2}$$

Additionally, we shall need the $L^p - L^2$-type inverse inequality which follows.

LEMMA 2.1. *Let θ_0 be the minimum angle in the triangulation and $M^k = \{v(x) : v(x)|_e \in \mathcal{P}_k(e)$ for all $e \in \Pi^h(\Omega)\}$, $\mathcal{P}_k$ being the polynomials of degree $\leq k$. Then, for ∇^h the element-wise defined gradient operator, there is a $C = C(\theta_0, p, k)$ such that for $2 \leq p < \infty$, $d = 2, 3$ and all $v \in M^k$,*

$$\|\nabla^h v\|_{L^p(\Omega)} \leq C h^{\frac{d}{2}(\frac{2-p}{p})} \|\nabla^h v\|. \tag{2.3}$$

Proof. First a local version of (2.3) is proven by a scaling argument, using the technique of Dupont and Scott [11]. Let $\hat{e}$ denote the reference element. First consider the affine map $\mathbf{x} = h_e\tilde{\mathbf{x}} + \mathbf{b}$ mapping e to an element $\tilde{e}$ the size of the reference element $\hat{e}$.

A change of variables gives immediately that $\|\nabla v\|_{L^2(e)} = h_e^{(d-2)/2}\|\tilde{\nabla} v\|_{L^2(\tilde{e})}$ (well known) and $\|\tilde{\nabla} v\|_{L^p(\tilde{e})} = h_e^{(p-d)/p}\|\nabla v\|_{L^p(e)}$ (completely analogous). The effect of the shape distortion between $\tilde{e}$ and $\hat{e}$ is accounted for by a compactness argument (following [11]) which contributes a constant $C = C(\theta_0, k)$. Finally, norm equivalence implies $\|\hat{\nabla} v\|_{L^p(\hat{e})} \leq C(p,k,d)\|\hat{\nabla} v\|_{L^2(\hat{e})}$. These combine to yield

$$\|\nabla v\|_{L^p(e)} \leq Ch^{\frac{d}{2}(\frac{2-p}{p})}\|\nabla v\|_{L^2(e)}.$$

The global bound is obtained by the Cauchy-Schwarz inequality as follows. Let $p > 2$ be an integer. Then,

$$\begin{aligned}
\|\nabla^h v\|_{L^p} :&= \left[\sum_e \|\nabla v\|^p_{L^p(e)}\right]^{\frac{1}{p}} \leq Ch^{\frac{d}{2}(\frac{2-p}{p})}\left[\sum_e \|\nabla v\|^p_{L^2(e)}\right]^{1/p} \\
&= Ch^{\frac{d}{2}(\frac{2-p}{p})}\left[\sum_e \|\nabla v\|_{L^2(e)}\|\nabla v\|^{p-1}_{L^2(e)}\right]^{\frac{1}{2}} \leq (C.B.S.\text{ ineq.}) \\
&\leq Ch^{\frac{d}{2}(\frac{2-p}{p})}\|\nabla v\|^{\frac{1}{p}}_{L^2(\Omega)}\left[\sum_e \|\nabla v\|^{p-1}_{L^2(e)}\right]^{\frac{1}{p}} \\
&\text{repeat } p-3 \text{ more times } \leq Ch^{\frac{d}{2}(\frac{2-p}{p})}\|\nabla^h v\|_{L^2(\Omega)}.
\end{aligned}$$

This proves the result for the $2 \leq p < \infty$ integer. The case of noninteger p follows by interpolation. □

LEMMA 2.2 (max-norm stability). *Let $S^h(\Omega)$ satisfy the inverse estimates* (2.2) *and* (2.3). *Then the following holds.*

(i) Linear artificial viscosity. *If $p = 2$ and $\mu(h) = \mu_0 h$, then u^h satisfies $(\mu_0 h + \mathrm{Re}^{-1})\|\nabla u^h\|_0 \leq C\|f\|_{-1}$ so that*

$$\|\mathbf{u}^h\|_{L^\infty} \leq C(k,\Omega)\left(\mu_0 + \frac{\mathrm{Re}^{-1}}{h}\right)^{-1} h^{\frac{-d}{2}}|lnh|^{1-\frac{1}{d}}\ \|\mathbf{f}\|_{-1}.$$

(ii) Nonlinear artificial viscosity. *Let* $\mathrm{Re}^{-1} \leq Ch$. *If $p > \frac{d}{2}$, $\mu = \hat{\mu}h^\sigma$ with $\sigma \leq \frac{d}{2}(p-1)$ (i.e., $p \geq \frac{2\sigma}{d} + 1$), then*

$$\|\mathbf{u}^h\|_{L^\infty} \leq C(k,p,\Omega)\cdot\mu_0^{-\frac{1}{p-1}}h^{-\frac{d}{2}}\|\mathbf{f}\|^{\frac{1}{p-1}}_{W^{q,-1}}.$$

Remark. This suggests choosing $\hat{\mu} = 0(|lnh|^{-((d-1)/d)(p-1)})$, which gives the formula (1.4) of the introduction.

Proof. Set $\mathbf{v} = \mathbf{u}^h$ and $q = \lambda^h$ in (2.1):

$$\mu h^\sigma \int_\Omega |\nabla\mathbf{u}^h|^{p-2}|\nabla\mathbf{u}^h|^2 dx + \mathrm{Re}^{-1}\|\nabla\mathbf{u}^h\|^2_{L^2} = (\mathbf{f},\mathbf{u}^h) \leq \|\mathbf{f}\|_{W^{q,-1}}\|\nabla\mathbf{u}^h\|_{L^p},$$

where $\frac{1}{p} + \frac{1}{q} = 1$. Thus

$$\mu_0 h^\sigma\|\nabla\mathbf{u}^h\|^{p-1}_{L^p} \leq \|\mathbf{f}\|_{W^{q,-1}} \quad \text{and} \quad \|\nabla\mathbf{u}^h\|_{L^p} \leq \mu_0^{-\frac{1}{p-1}}h^{-\frac{\sigma}{p-1}}\|\mathbf{f}\|^{\frac{1}{p-1}}_{W^{q,-1}}.$$

The Sobolev embedding theorem now implies that for $p > \frac{d}{2}$, $\|\mathbf{u}^h\|_{L^\infty} \leq C(\Omega)\|\nabla\mathbf{u}^h\|_{L^p}$ and the result follows. □

3. Error analysis for the Oseen problem. This section presents an error analysis of the SGS model discretized by the finite element method for a linearized Navier-Stokes problem. The error is calculated with respect to the solution of (1.1), unregularized. This analysis complements the finite element error analysis for the Ladyzhenskaya model (see Ladyzhenskaya [18]) of fluid flow in Du and Gunzburger [7-9] in that the former considers the nonlinear problem with the parameters μ and Re sufficiently small to ensure global uniqueness of solutions while herein we study $\mu = \mu(h) \to 0$ and Re large for a (linearized) Oseen problem. There is also other work on the pure (symmetric) p-Laplacian problem and a related creeping flow problem in Barrett and Liu [2, 3].

The Oseen problem is given as follows. For $\mathbf{U}(x, y)$ a smooth enough, known flow fluid with div $\mathbf{U} = 0$, we seek $\mathbf{u}(x, y)$ satisfying

$$\left\{\begin{array}{l} -\mathrm{Re}^{-1}\Delta\mathbf{u} + \mathbf{U}\cdot\nabla\mathbf{u} + \nabla\lambda = \mathbf{f} \text{ in } \Omega,\ \nabla\cdot\mathbf{u} = 0 \text{ in } \Omega, \\ \mathbf{u} = 0 \text{ on } \partial\Omega,\ \displaystyle\int_\Omega \lambda dx = 0. \end{array}\right. \tag{3.1}$$

Error analysis for (3.1) at all Reynolds numbers is possible using monotonicity techniques since the solution operator to (3.1) is monotone on the space

$$\mathbf{V} := \left\{\mathbf{v} \in \left(\overset{\circ}{H}{}^1(\Omega)\right)^d : \nabla\cdot\mathbf{v} = 0\right\}$$

of divergence-free functions, [12, 13].

The numerical method for (3.1) is as follows. Choose the velocity-pressure finite element spaces $(\mathbf{X}^h, Q^h)$ such that $\mathbf{X}^h \subset (\overset{\circ}{H}{}^1(\Omega))^d$, $Q^h \subset L_0^2(\Omega) := \{q \in L^2(\Omega) : \int_\Omega q dx = 0\}$ and they satisfy the inf-sup or Babuska-Brezzi condition:

$$\inf_{q^h\in Q^h} \sup_{v^h\in\mathbf{X}^h} \frac{\int_\Omega q^h \nabla\cdot\mathbf{v}^h dx}{\|q^h\|\ \|\nabla\mathbf{v}^h\|} = \beta^h > 0, \tag{3.2}$$

β^h being bounded away from zero uniformly in h. Examples of "good" spaces satisfying (3.2) are given in [12, 13]. The approximation is now defined by the following: seek $(\mathbf{u}^h, p^h) \in (\mathbf{X}^h, Q^h)$ satisfying for all $(\mathbf{v}, q) \in (\mathbf{X}^h, Q^h)$,

$$AV_p(\mathbf{u}^h, \mathbf{v}) + a(\mathbf{u}^h, \mathbf{v}) + b(\mathbf{U}, \mathbf{u}^h, \mathbf{v}) + (\lambda^h, \nabla\cdot\mathbf{v}) - (q, \nabla\cdot\mathbf{u}^h) = (\mathbf{f}, \mathbf{v}). \tag{3.3}$$

LEMMA 3.1 (max-norm stability). *Under the assumptions of Lemma* 2.2 *the solution* $\mathbf{u}^h$ *to* (3.3) *satisfies all the stability bounds of Lemma* 2.2. □

Since $AV_p(\cdot,\cdot)$ is associated with the "p-Laplacian," its monotonicity properties are documented in many places; see e.g. [2-4, 7-9, 24, 30]. These properties will now be summarized here; see the above references for proofs. Using the Riesz representation theorem, define the operator $T : \mathbf{X} \to \mathbf{X}'$ satisfying

$$(T(\mathbf{u}), \mathbf{v}) = (|\nabla\mathbf{u}|^{p-2}\nabla\mathbf{u}, \nabla\mathbf{v}) \quad \forall\mathbf{v} \in \mathbf{X}.$$

PROPOSITION 3.1. *Let* $p \geq 2$. *Then* T *satisfies for all* $\mathbf{u}, \mathbf{v} \in (\overset{\circ}{W}{}^{1,p}(\Omega))^d$,

$$(T(\mathbf{u}) - T(\mathbf{v}), \mathbf{u} - \mathbf{v}) \geq \zeta(\|\nabla(\mathbf{u} - \mathbf{v})\|_{L^p})\|\nabla(\mathbf{u} - \mathbf{v})\|_{L^p},$$

$$\|T(\mathbf{u}) - T(\mathbf{v})\|_{W^{-1,q}} \leq \Gamma(r)\|\nabla(\mathbf{u} - \mathbf{v})\|_{L^p},$$

for $\|\nabla\mathbf{u}\|_{L^p} \leq r$ *and* $\|\nabla\mathbf{v}\|_{L^p} \leq r$, *where* $\Gamma(r) = C(2p - 3)r^{p-2}$, *and* $\zeta(s) = C(\frac{1}{2})^{p-2}s^{p-1}$.

Proof. These bounds have been proven, for example, in [2, 3, 7-10, 24, 30]. □

The following is an easy consequence of strong monotonicity, [30], of T and the inf-sup condition.

PROPOSITION 3.2. *Let $p \geq 2$ and suppose $(\mathbf{X}^h, Q^h)$ satisfies* (3.2). *Then,*

(i) *The subspace $\mathbf{V}^h$ of discretely divergence-free functions*

$$\mathbf{V}^h := \left\{\mathbf{v}^h \in \mathbf{X}^h : (\mathbf{v}^h, q^h) = 0 \, \forall \, q^h \in Q^h\right\}$$

is well defined and nontrivial. Further, for $\mathbf{u} \in \mathbf{X}$ satisfying $\operatorname{div}(\mathbf{u}) = 0$,

$$\inf_{\mathbf{v} \in \mathbf{V}^h} \|\nabla(\mathbf{u} - \mathbf{v})\| \leq C\left(1 + \frac{1}{\beta_h}\right) \inf_{\mathbf{v} \in \mathbf{X}^h} \|\nabla(\mathbf{u} - \mathbf{v})\|.$$

(ii) *There is a well-defined continuous mapping $T_p^h : \mathbf{V}^{h'} \to \mathbf{V}^h$ satisfying*

$$(T_p^h(\mathbf{u}), \mathbf{v}) = A V_p(\mathbf{u}, \mathbf{v}) + \mathrm{Re}^{-1}(\boldsymbol{\nabla}\mathbf{u}, \nabla\mathbf{v}) + b(\mathbf{U}, \mathbf{u}, \mathbf{v}).$$

(iii) *$T_p^h(\cdot)$ satisfies the following: for all $\mathbf{u}, \mathbf{v} \in \mathbf{V}^h$,*

$$(T_p^h(\mathbf{u}) - T_p^h(\mathbf{v}), \mathbf{u}-\mathbf{v}) \geq C\mu(h)\zeta(\|\nabla(\mathbf{u}-\mathbf{v})\|_{L^p})\|\nabla(\mathbf{u}-\mathbf{v})\|_{L^p} + \mathrm{Re}^{-1}\|\nabla(\mathbf{u}-\mathbf{v})\|_{L^2}^2,$$

where $\zeta(\cdot)$ is given in Proposition 3.1.

Proof. Part (i) is from standard finite element convergence theory for the linear Stokes problem; see, for example, [12, 13] for a proof. Part (ii) follows immediately from the Riesz representation theorem. Part (iii) follows from Proposition 3.1 and the skew symmetry of $b(\cdot, \cdot, \cdot)$. □

COROLLARY 3.1. *Suppose $p \geq 2$ and* (3.3) *holds. The solution $(\mathbf{u}^h, \lambda^h)$ to* (3.1) *exists uniquely.*

Proof. Existence of $\mathbf{u}^h$ is equivalent to the solvability of $T_p^h(\mathbf{u}^h) = P^h f$ in $\mathbf{V}^h$ where P^h is the L^2 orthogonal projection $P^h : \mathbf{X}^h \to \mathbf{V}^h$. Existence and uniqueness of $T_p^h(\mathbf{u}^h) = P^h\mathbf{f}^h$ follows from Proposition 3.2 and Minty's lemma; see Minty [26]. Existence and uniqueness of λ^h then follows from the inf-sup condition exactly as for the Stokes problem; see [12, 13] for these arguments. □

THEOREM 3.1. *Suppose $(\mathbf{X}^h, Q^h)$ satisfies the inf-sup condition with constant β^h, and $\mathbf{X}^h$ satisfies the inverse estimates* (2.2) *and* (2.3). *Then, with $r = \|\nabla\mathbf{u}\|_{L^p}$,*

$$\begin{aligned}
&\mu(h)\| \nabla(\mathbf{u} - \mathbf{u}^h)\|_{L^p}^p + \mathrm{Re}^{-1}\|\nabla(\mathbf{u} - \mathbf{u}^h)\|^2 \\
&\quad\leq C\left(1 + \frac{1}{\beta_h}\right) \inf_{\mathbf{w} \in \mathbf{X}^h} \Big\{C(\mathbf{U})\|\mathbf{u} - \mathbf{w}\|^2 + \mathrm{Re}^{-1}\|\nabla(\mathbf{u} - \mathbf{w})\|^2 \\
&\qquad + \mu(h)\|\nabla(\mathbf{u} - \mathbf{w})\|_{L^p}^p + h^{d\left(\frac{2-p}{p}\right)}\mu(h)^2\|\nabla(\mathbf{u} - \mathbf{w})\|_{L^p}^2\Big\} \\
&\qquad + C\inf_{q \in Q^h} \|\lambda - q\|^2 + C\mathrm{Re}h^{d\left(\frac{2-p}{p}\right)}\mu(h)^2\|\nabla\mathbf{u}\|_{L^p}^{2p-2}.
\end{aligned} \tag{3.4}$$

Proof. The error bound is proven using Galerkin orthogonality, the inf-sup condition, and monotonicity of $T_p^h(\cdot)$ on $\mathbf{V}^h$. First the error equation is derived. Let $\mathbf{v} \in \mathbf{V}^h$ be arbitrary, then $\mathbf{u} \in \mathbf{X}$ satisfies

$$a(\mathbf{u}, \mathbf{v}) + A V_p(\mathbf{u}, \mathbf{v}) + b(\mathbf{U}; \mathbf{u}, \mathbf{v}) = (f, \mathbf{v}) - (\lambda - q^h, \nabla \cdot \mathbf{v}) + A V_p(\mathbf{u}, \mathbf{v})$$

for all $q^h \in Q^h$. Thus, with $\mathbf{e} = \mathbf{u} - \mathbf{u}^h$, for all $\mathbf{v} \in \mathbf{V}^h$,

$$\begin{aligned} AV_p(\mathbf{u}, \mathbf{v}) &- AV_p(\mathbf{u}^h, \mathbf{v}) + a(\mathbf{e}, \mathbf{v}) + b(\mathbf{U}, \mathbf{e}, \mathbf{v}) \\ &= AV(\mathbf{u}, \mathbf{v}) - (\lambda - q^h, \nabla \cdot \mathbf{v}). \end{aligned}$$

Let $\mathbf{w} \in \mathbf{V}^h$ be arbitrary and define $\phi = (\mathbf{w} - \mathbf{u}^h) \in \mathbf{V}^h$, $\eta = \mathbf{u} - \mathbf{w}^h$. Adding and subtracting terms as appropriate gives

$$\begin{aligned} AV_p(\mathbf{w}, \mathbf{v}) &- AV_p(\mathbf{u}^h, \mathbf{v}) + a(\phi, \mathbf{v}) + b(\mathbf{U}, \phi, \mathbf{v}) \\ &= -(\lambda - q^h, \nabla \cdot \mathbf{v}) - b(\mathbf{U}, \eta, \mathbf{v}) \\ &\quad -a(\eta, \mathbf{v}) + AV_p(\mathbf{w}, \mathbf{v}) - AV_p(\mathbf{u}, \mathbf{v}) + AV_p(\mathbf{u}, \mathbf{v}). \end{aligned}$$

Equivalently, for all $\mathbf{v} \in \mathbf{V}^h$,

$$\begin{aligned} (T_p^h(\mathbf{w}), \mathbf{v}) - (T_p^h(\mathbf{u}^h), \mathbf{v}) &= -(\lambda - q^h, \nabla \cdot \mathbf{v}) \\ &\quad -b(\mathbf{U}, \boldsymbol{\eta}, \mathbf{v}) - a(\boldsymbol{\eta}, \mathbf{v}) + AV_p(\mathbf{u}, \mathbf{v}) \\ &\quad +AV_p(\mathbf{u}, \mathbf{v}) - AV_p(\mathbf{w}, \mathbf{v}). \end{aligned}$$

Setting $\mathbf{v} = \phi$ (since $\phi \in \mathbf{V}^h$), using strong monotonicity on the left-hand side of the above equation and local-Lipschitz continuity on the right-hand side gives

$$\begin{aligned} C\mu\ (h)\zeta(\|\nabla\phi\|_{L^p})\|\nabla\phi\|_{L^p} &+ \mathrm{Re}^{-1}\|\nabla\phi\|^2 \\ \leq \|\lambda - q\|\,\|\nabla\phi\| &+ C(\mathbf{U})\|\boldsymbol{\eta}\|\,\|\nabla\phi\| \\ +\mathrm{Re}^{-1}\|\nabla\boldsymbol{\eta}\|\ \|\nabla\phi\| &+ AV_p(\mathbf{u}, \phi) \\ +\mu(h)\Gamma(r_1)\|\nabla(\mathbf{u} - \mathbf{w})\|_{L^p}&\|\nabla\mathbf{w}\|_{L^p}, \end{aligned}$$

where $r_1 = \max\{\|\nabla\mathbf{u}\|_{L^p},\ \|\nabla\mathbf{w}\|_{L^p}\}$.

Now $AV_p(\mathbf{u}, \phi) = \mu(h)(T(\mathbf{u}) - T(0), \phi) \leq \mu(h)\|T(\mathbf{u}) - T(0)\|_{W^{-1,q}}\|\phi\|_{W^{-1,p}} \leq \mu(h)$ $\Gamma(r_2)\|\nabla\mathbf{u}\|_{L^p}\|\nabla\phi\|_{L^p}$, with $r_2 = \|\mathbf{u}\|_{W^{1,p}}$. Thus,

$$AV_p(\mathbf{u}, \phi) \leq \mu(h)\Gamma(r_2)\|\nabla\mathbf{u}\|_{L^p}^{p-1}\|\nabla\phi\|_{L^p}.$$

Thus,

$$\begin{aligned} C\ \mu(h)\zeta(\|\nabla\phi\|_{L^p})\|\nabla\phi\|_{L^p} + C\mathrm{Re}^{-1}\|\nabla\phi\|^2 &\leq \|\lambda - q\|^2 + C(\mathbf{U})\|\boldsymbol{\eta}\|^2 \\ +\mathrm{Re}^{-1}\|\nabla\boldsymbol{\eta}\|^2 + \mu(h)\Gamma(r_2)\|\nabla\mathbf{u}\|_{L^p}^{p-1}\|\nabla\phi\|_{L^p} &+ \mu(h)\Gamma(r_1)\|\nabla\boldsymbol{\eta}\|_{L^p}\|\nabla\phi\|_{L^p}. \end{aligned}$$

To complete the error analysis note that since $\phi \in \mathbf{X}^h$, ϕ satisfies the inverse estimate (2.3). Indeed, $\|\nabla\phi\|_{L^p} \leq \gamma(h)\|\nabla\phi\|$ for all $\phi \in \mathbf{X}^h$, where $\gamma(h) = Ch^{\frac{d}{2}((2-p)/p)}$, so that

$$\begin{aligned} C\mu(h)\zeta(\|\nabla\phi\|_{L^p})\|\nabla\phi\|_{L^p} + C\mathrm{Re}^{-1}\|\nabla\phi\|^2 &\leq \|\lambda - q\|^2 + C(\mathbf{U})\|\boldsymbol{\eta}\|^2 \\ +\mathrm{Re}^{-1}\|\nabla\boldsymbol{\eta}\|^2 &+ C\mathrm{Re}\gamma^2(h, p)\mu(h)^2\Gamma^2(r_2)\|\nabla\mathbf{u}\|_{L^p}^{2p-2} \\ &+ C\mathrm{Re}\Gamma^2(r_1)\gamma^2(h)\mu(h)^2\|\nabla\boldsymbol{\eta}\|_{L^p}^2. \end{aligned}$$

Under the inf-sup condition an infimum over $\mathbf{V}^h$ may be replaced by a constant times an infimum over $\mathbf{X}^h$. Thus the result follows from the triangle inequality, the fact that at the infimum $r_1, r_2 \leq Cr_0$, and (since $\|\mathbf{f} + g\|_{L^p}^p \leq C(p)(\|\mathbf{f}\|_{L^p}^p + \|g\|_{L^p}^p)$)

$$\begin{aligned} \zeta(\|\nabla(\mathbf{u} - \mathbf{u}^h)\|_{L^p})\ &\|\nabla(\mathbf{u} - \mathbf{u}^h)\|_{L^p} \\ &\leq C\zeta(\|\nabla\phi\|_{L^p})\|\nabla\phi\|_{L^p} + 2C\zeta(\|\nabla\boldsymbol{\eta}\|_{L^p})\|\nabla\boldsymbol{\eta}\|_{L^p}. \qquad \square \end{aligned}$$

It is interesting to compare (3.4) with the usual error estimate for the (centered) Galerkin method. With a careful error analysis, the usual Galerkin approximation of the Oseen problem satisfies the error bound:

$$\begin{aligned}\mathrm{Re}^{-1}\|\nabla(\mathbf{u}-\mathbf{u}^h)\|^2 &\le C(1+\beta_h^{-1})\inf_{\mathbf{w}\in\mathbf{X}^h}\left\{\mathrm{Re}^{-1}\|\nabla(\mathbf{u}-\mathbf{w})\|^2+\|\mathbf{u}-\mathbf{w}\|^2\right\}\\ &\quad + C\mathrm{Re}\inf_{q\in Q^h}\|\lambda-q\|^2.\end{aligned} \tag{3.5}$$

Suppose, for example, the "Mini" element [13, p. 36] is used (equal order interpolation is optimal if $\mathrm{Re}^{-1} \le O(h)$, [19, 21]); then (3.5) predicts an error bound of the rough form $\|\nabla(\mathbf{u}-\mathbf{u}^h)\| \le C_1(\mathbf{u},\lambda)(h^2+\mathrm{Re}^2h^4)$, which is no better than $O(1)$ when $\mathrm{Re} = O(h^{-2})$. With the same reasoning (ignoring logarithm terms), the error bound (3.4) roughly states that (fixing $d = 3$, $\mu(h) = \mu_0 h^\sigma$, $p = \sigma + 1$) $h^\sigma\|\nabla(\mathbf{u}-\mathbf{u}^h)\|_{L^p}^p + \mathrm{Re}^{-1}\|\nabla(\mathbf{u}-\mathbf{u}^h)\|^2 \le C_2(\mathbf{u},\lambda)\left\{h^4+\mathrm{Re}^{-1}h^2+h^{2\sigma+1}+\mathrm{Re}h^{2\sigma-3+3/(\sigma+1)}\right\}$. For example, if $\mathrm{Re} = O(h^{-2})$ and $\sigma = 4$, this predicts $\|\nabla(\mathbf{u}-\mathbf{u}^h)\|^2 \le C_2(\mathbf{u},\lambda)h^{8/5}$.

Naturally the constants $C_{1,2}(\mathbf{u}, p)$ in the above rough estimates depend upon Re implicitly due to local fluid behavior. The centered scheme is well known to do a poor job localizing the errors in such cases. Approximate solutions are globally oscillating due to local solution effects in small regions. Hopefully, the formulations (2.1), (3.3) introduce sufficient viscosity in such regions to better localize the errors due to large derivatives of $\mathbf{u}$ and p. There is some experimental evidence of this in §4; see Figures 4.1-4.3.

4. An illustration. Due to the complexity of solutions to the Navier-Stokes equations and the ambiguity of the notion of "solution quality," it has become customary to test discretizations tailored to higher Reynolds number problems first upon singularly perturbed convection diffusion equations such as the following: seek $\phi(x, y)$ satisfying

$$\begin{aligned}&-\epsilon\Delta\phi + \mathbf{U}\cdot\nabla\phi + 2\phi = f \text{ in } \Omega, \quad \phi = \alpha \text{ on } \partial\Omega,\\ &0 < \epsilon << O(h), \ \nabla\cdot\mathbf{U} = 0 \text{ in } \Omega.\end{aligned} \tag{4.1}$$

Equation (4.1) satisfies a maximum principle (unlike the Navier-Stokes equations) and, due to the additional "$+2\phi$" term, a fairly complete asymptotic picture of solutions is available. Therefore, at least *lack* of "solution quality" is clearcut for (4.1)! Further, (4.1) also arises coupled to the Navier-Stokes equations as an energy equation [5], so it is interesting in its own right.

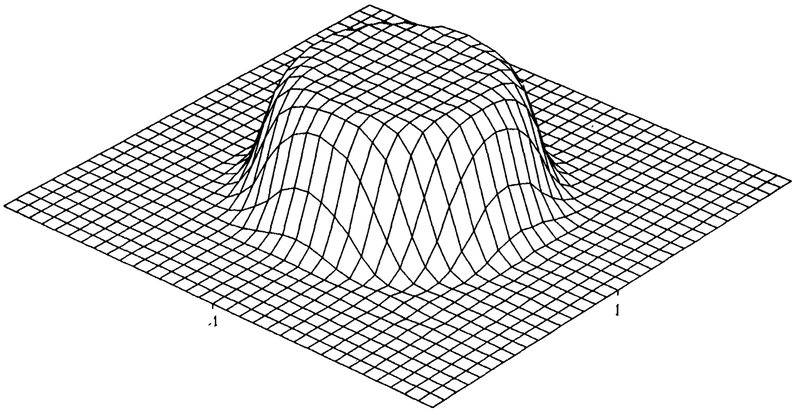

FIG. 4.1. *Approximate solution,* $\mu_0 = 1$, $p = 3$, $\sigma = 2$ *using linear elements.*

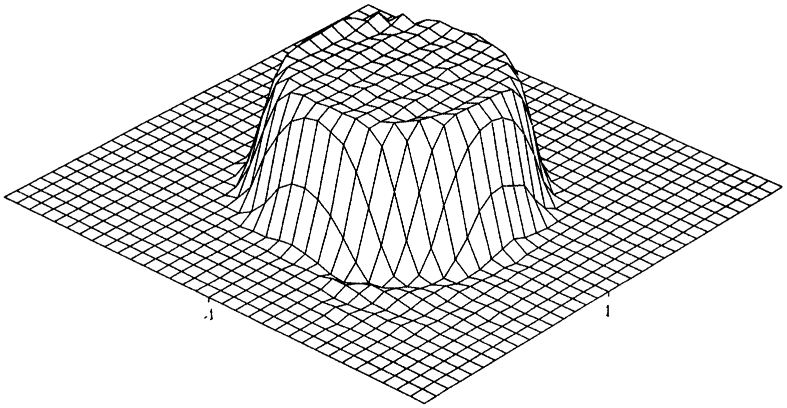

FIG. 4.2. *Approximate solution, $\mu_0 = 1$, $p = 5$, $\sigma = 3$, using linear elements.*

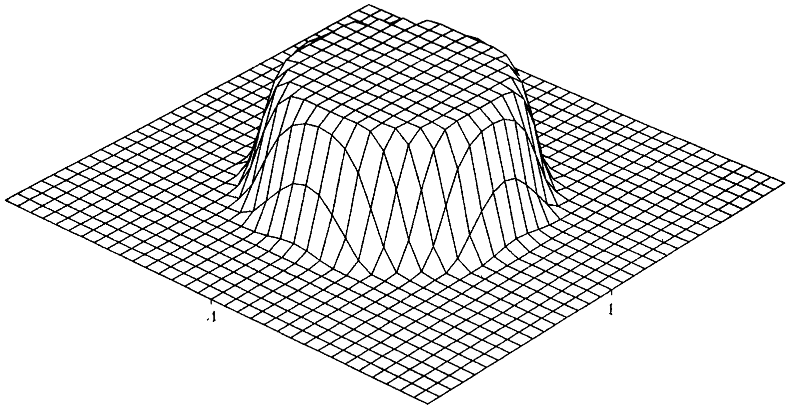

FIG. 4.3. *The (Linear interpolant of) an approximate solution, $\epsilon = .1h^2$, $h = \frac{1}{32}$ using $\mu_0 = 1$, $p = 5$, $\sigma = 3$, quadratic elements.*

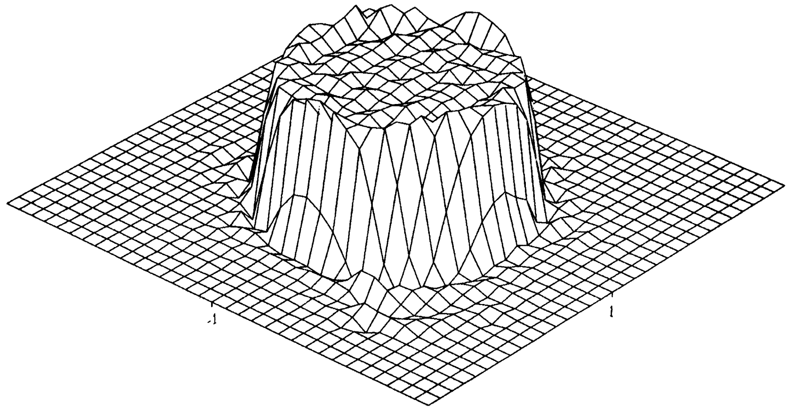

FIG. 4.4. *Usual FEM approximation, without nonlinear SGS terms.*

To illustrate the effect of the additional nonlinear artificial viscosity term upon "solution quality," we consider a rotating pulse problem of the form (4.1) approximated with linear and quadratic elements. The usual centered Galerkin formulation plus nonlinear artificial viscosity $AV_p(\cdot, \cdot)$ is used.

Example (internal flow, rotating pulse problem). We have

$$\Omega = (-1, 1) \times (-1, 1), \quad \mathbf{U} = (-yR(r),\ xR(r)),$$

where $r^2 = x^2 + y^2$, $R(r) = 0$ for $r \geq 1$ is a nonnegative C^1 function with $R(r) > 0$ for $r < 1$, $R(0) = 1$, so that $\nabla \cdot \mathbf{U} = 0$. We choose $\epsilon = .1h^2$, and $f \equiv 1$ if $r \leq \frac{1}{2}$, $f \equiv 0$ if $r > \frac{1}{2}$. This emulates a rotating flow inside a circular enclosure ($r \leq 1$). The true solution for ϵ small is a rotating "blob" or circular table with an $O(\sqrt{\epsilon})$ transition layer, $\phi \sim \frac{1}{2}$ if $r < \frac{1}{2}$ and $\phi \sim 0$ if $r > \frac{1}{2}$.

The same mesh was used for all tests: a uniform rectilinear mesh $h = \frac{1}{32}$, each square divided into two triangles by a line of slope -1. This mesh is *not* adapted to the circular symmetry of the convection field. The nonlinear equations were solved using a damped Newton method, and the linearizations, were solved using the conjugate gradient squared (CGS) method using an ILU_0 preconditioner; see Maubach [25] for a presentation of these methods. With a nonzero initial guess no difficulty was encountered. The only difficulty seen was in solving the linearized system arising from a zero initial guess. Specifically, with a zero initial guess for Newton's method, the first iterate is the solution of the usual (centered) Galerkin linear system. This *linear* system is much more sensitive and difficult to solve using standard preconditioners than all the remaining linear and nonlinear problems. Aside from using a nonzero initial guess or a better preconditioner, e.g., [22], another attractive possibility is to begin with a linear artificial viscosity approximation and "antidiffuse" using a few defect correction steps, where the $AV_p(\cdot, \cdot)$-nonlinearity only occurs in the residual calculation. This requires solving only a few (stable) linear systems with the same coefficient matrix. This combination has not yet been tested, but the practical success and theoretical support for this type of procedure in other similar contexts [1, 19] and Hemker and Koren [15, 16] suggest adapting it to the present one as well.

In the tests depicted in Figures 4.1-4.3, note the good quality of the approximate solutions (compare Figures 4.1, 4.2, and 4.3 to Figure 4.4) and the capturing of the transition regions in about $3h$ distance. With optimized parameter selections this could likely be further sharpened.

Acknowledgment. I thank J. Maubach for generously providing the examples in §4.

A NUMERICAL METHOD FOR THE INCOMPRESSIBLE NAVIER-STOKES EQUATIONS BASED ON AN APPROXIMATE PROJECTION*

ANN S. ALMGREN†, JOHN B. BELL†, AND WILLIAM G. SZYMCZAK‡

Abstract. In this method we present a fractional step discretization of the time-dependent incompressible Navier-Stokes equations. The method is based on a projection formulation in which we first solve diffusion-convection equations to predict intermediate velocities, which are then projected onto the space of divergence-free vector fields. Our treatment of the diffusion-convection step uses a specialized second-order upwind method for differencing the nonlinear convective terms that provides a robust treatment of these terms at a high Reynolds number. In contrast to conventional projection-type discretizations that impose a discrete form of the divergence-free constraint, we only approximately impose the constraint; i.e., the velocity field we compute is not exactly divergence-free. The approximate projection is computed using a conventional discretization of the Laplacian and the resulting linear system is solved using conventional multigrid methods. Numerical examples are presented to validate the second-order convergence of the method for Euler, finite Reynolds number, and Stokes flow. A second example illustrating the behavior of the algorithm on an unstable shear layer is also presented.

1. Introduction.

In this paper we develop a projection method for the incompressible Navier-Stokes equations

$$U_t + (U \cdot \nabla)U = \varepsilon \Delta U - \nabla p + F, \tag{1.1}$$

$$\nabla \cdot U = 0, \tag{1.2}$$

which is formally second-order accurate. Here U represents the velocity field, p represents the hydrodynamic pressure, and F represents any external forces. We denote the x and y components of velocity by u and v, respectively. The method presented here is based on the algorithms presented by Bell, Colella, and Glaz [1] and Bell, Colella, and Howell [2]. As in those papers, we use a second-order upwind method for the treatment of the nonlinear convective terms in (1.1). The algorithms presented in those papers were motivated by a desire to apply higher-order upwind methods developed for inviscid, compressible flow to the incompressible Navier-Stokes equations. In particular, they used a specialized version of the unsplit second-order Godunov methodology introduced for gas dynamics by Colella [9]. The upwind methodology provides a robust discretization of the convective terms that avoids any cell-Reynolds-number stability restriction for high Reynolds-number flow.

The focus of this paper is on the discretization of the projection. The original projection method developed by Chorin [6] defines the projection by defining discrete operators D and G, approximating divergence and gradient, which are skew adjoint; i.e.,

$$D = -G^T.$$

With this definition the discrete projection

$$\mathbf{P} = I - G(DG)^{-1}D$$

(with boundary conditions implicit in the boundary conditions of the flow problem) is a discrete orthogonal projection on the finite-dimensional space of vector fields defined on the mesh. In Chorin's formulation both pressure and velocity are specified at nodes and central differences are used for the definition of D and G. This results in an expanded five-point stencil for the discrete Laplacian, DG, that must be inverted to apply the projection. This expanded stencil produces a local decoupling of the mesh points with a 2^d-dimensional kernel for G where d is the dimension of the problem. Bell, Colella, and Glaz [1] use a discretization of the projection based on a finite element method due to Fortin [10] that uses pressure defined on cell centers with velocities given at nodes. This approach produces a more compact stencil but also generates a local decoupling of the grid and dim ker $G > 1$. Bell, Colella, and Howell [2] use a fully cell-centered analogue of Chorin's algorithm. This scheme exhibits a local decoupling, but in the presence of Dirichlet boundary conditions the cell-centered approximation eliminates the nonconstant elements in ker G.

Although the projections discussed above have been shown to be effective for solution of the incompressible Navier-Stokes equations, they exhibit a number of shortcomings as a result of the local grid decoupling. First, the schemes all use nonstandard discretizations of DG that require specialized iterative procedures that properly respect the stencil that is used. (See [2, 13] for a discussion of such a procedure.) For the schemes in which dim ker $G > 1$, the nonconstant elements in the kernel induce additional, artificial compatibility constraints similar to the physical condition

$$\int_{\partial\Omega} U \cdot \mathbf{n}\, ds = 0$$

on the boundary of the physical domain Ω. Local decoupling raises additional difficulties when more complex low Mach number processes are being modeled. Often in these cases a term that results from the additional physics, and is not in the range of the divergence operator, is added to the right-hand side of the Poisson equation for pressure. The presence of the additional source term can result in marked oscillations in the solution. Lai [16, 15] reports such oscillations when using projections with locally decoupled stencils for modeling low Mach number combustion. The approximate projection introduced here has successfully been used for this type of simulation; see [19].

The goal of the work reported here is to develop a projection that avoids the difficulties associated with locally decoupled stencils and is amenable to treatment by standard iterative methods. Several approaches have been proposed that address this issue. In a MAC discretization (cf. Harlow and Welch [11]), a discrete form of (1.2) is enforced in a context in which DG is the standard five-point finite difference Laplacian. However, in the MAC approach the components of velocity are not colocated, which makes the application of modern higher-order upwind techniques extremely cumbersome if not impossible. Strikwerda [20] proposes a regularized projection based on Chorin's original node-based algorithm. Strikwerda's method uses a skewed, higher-order third derivative perturbation to D and G to remove the local decoupling of Chorin's method. Colella [7] reports that although Strikwerda's algorithm is effective for homogeneous boundary conditions, noticeable anomalies arise from the asymmetry of the operators when inflow and outflow profiles are specified. Although the overall algorithm can be engineered around this shortcoming, the complexity of the method is considerably enhanced. In addition, the Strikwerda projection also generates a wide stencil requiring care in the treatment of boundary conditions.

We would like to develop a form of the projection compatible with a cell-centered discretization of velocity that avoids any local decoupling of the stencils, provides a symmetric discretization of the potential flow inherent in nonhomogeneous boundary conditions, and generates a linear system that fits the framework of conventional fast iterative techniques (e.g., multigrid) for second-order elliptic equations. The evidence to date suggests that this is not possible while simultaneously requiring that there is a discrete divergence D so that $DU = 0$ is satisfied. In this paper we will relax that condition and only require that $DU = O(h^2)$, where h is the mesh spacing. The approach will treat velocities as averages over grid cells and discretize pressure using a standard bilinear finite element discretization. We will show that relaxing the treatment of (1.2) does not have any deleterious effects on the stability or convergence properties of the algorithm; the advantages of the higher-order upwind methodology are retained and the complexity of the linear algebraic aspects of the method is substantially reduced.

In the next two sections we will review the basic fractional step scheme of Bell, Colella, and Glaz [1] and describe the discretization of the convection-diffusion step of the algorithm. The fourth section describes the approximation of the projection and briefly describes a multigrid algorithm for its solution. This section also contains a discussion of boundary conditions for the projection. In the fifth section we present computational results obtained with the method. The first sequence of results demonstrates second-order convergence of the algorithm for finite Reynolds number, Euler, and Stokes flows. The final example illustrates the application of the method to the computation of an unstable shear layer. The sixth section contains the conclusions.

2. Fractional step scheme. In this section we review the basic fractional step scheme used in the algorithm. In the presentation of the basic algorithm we will focus on homogeneous Dirichlet boundary conditions and no external forces. We will also assume that the mesh spacing on the base grid is uniform in the x- and y-directions, with $\Delta x = \Delta y = h$. These restrictions are not inherent limitations of the method; they have been adopted here for clarity of exposition. The reader is referred to [1, 4] for a more detailed description.

Our strategy for solving the system (1.1)-(1.2) is a fractional step scheme that has two parts: first we solve the advection-diffusion equations (1.1) without strictly enforcing the incompressibility constraint. Then, we project an intermediate vector field onto the space of discretely divergence-free vector fields.

For the diffusion-convection step we solve

$$\frac{U^* - U^n}{\Delta t} + [(U \cdot \nabla)U]^{n+\frac{1}{2}} = \varepsilon \Delta^h \left(\frac{U^n + U^*}{2} \right) - \nabla p^{n-\frac{1}{2}} \tag{2.1}$$

for the intermediate velocity U^*, where Δ^h is a second-order finite difference approximation to Δ. The pressure gradient is evaluated at $t^{n-1/2}$ and is treated as a source term in (2.1). (The pressure gradient is only computed at the 1/2-time levels.) The advection terms in (2.1), namely $[(U \cdot \nabla)U]^{n+1/2}$, are approximated at time $t^{n+1/2}$ to second-order in space and time using an explicit predictor-corrector scheme. This scheme uses only the available data at t^n; thus, the implicit part of (2.1) corresponds to two decoupled parabolic equation solves.

The velocity field U^* computed in the first step is not, in general, divergence-free. The projection step of the algorithm decomposes the result of the first step into a discrete gradient of a scalar potential and a discretely divergence-free vector field that correspond, respectively, to the new approximation to the pressure gradient and an update for the velocity. In particular, if $\mathbf{P}$ represents the composite grid projection then

$$\frac{U^{n+1} - U^n}{\Delta t} = \mathbf{P} \left(\frac{U^* - U^n}{\Delta t} \right), \tag{2.2}$$

$$\nabla p^{n+\frac{1}{2}} = \nabla p^{n-\frac{1}{2}} + (\mathbf{I} - \mathbf{P}) \left(\frac{U^* - U^n}{\Delta t} \right).$$

(Note that the vector field we project is not U^*; it is an approximation of U_t.)

3. Discretization of the diffusion-convection step. In this section we describe the algorithm for the diffusion-convection step in the fractional step scheme, namely (2.1). The algorithm is essentially the same as the second-order upwind method used by Bell, Colella, and Glaz [1]. Here, U^n_{ij} represents the value of the velocity field in cell B_{ij} at time t^n, and $Gp^{n-1/2}_{ij}$ represents the average value of ∇p in cell B_{ij} at time $t^{n-1/2}$. We note that although for the purposes of the projection the pressure is a bilinear function on each cell, we do not use that structure in the advection step. The algorithm is a predictor-corrector method. In the predictor, characteristic equations are used to extrapolate velocities to cell edges at the new half-time level $t^{n+1/2}$. In the corrector, the predicted values are used to compute a flux, which is then differenced to compute the advection terms. These two steps are described in more detail below.

Predictor. In the predictor we extrapolate the velocity and density to the cell edges at $t^{n+1/2}$ using a second-order Taylor series expansion. For edge $(i+\frac{1}{2}, j)$ this gives

$$U^{n+\frac{1}{2},L}_{i+\frac{1}{2},j} = U^n_{ij} + \frac{\Delta x}{2} U^n_{x,ij} + \frac{\Delta t}{2} U^n_{t,ij}$$

extrapolating from (i, j), and

$$U^{n+\frac{1}{2},R}_{i+\frac{1}{2},j} = U^n_{i+1,j} - \frac{\Delta x}{2} U^n_{x,i+1,j} + \frac{\Delta t}{2} U^n_{t,i+1,j}$$

extrapolating from $(i+1, j)$, with analogous formulae for the other edges. The differential equation (1.1) is then used to eliminate the time derivatives to obtain

$$U^{n+\frac{1}{2},L}_{i+\frac{1}{2},j} = U^n_{ij} + \left(\frac{\Delta x}{2} - \frac{u_{ij}\Delta t}{2}\right) U^n_{x,ij} - \frac{\Delta t}{2}(\widehat{vU_y})_{ij} + \frac{\Delta t}{2}\left(\varepsilon \Delta^h U^n_{ij} - Gp^{n-\frac{1}{2}}_{ij}\right), \tag{3.1}$$

$$\begin{aligned} U^{n+\frac{1}{2},R}_{i+\frac{1}{2},j} &= U^n_{i+1,j} - \left(\frac{\Delta x}{2} + \frac{u_{i+1,j}\Delta t}{2}\right) U^n_{x,i+1,j} \\ &\quad - \frac{\Delta t}{2}(\widehat{vU_y})_{i+1,j} + \frac{\Delta t}{2}\left(\varepsilon \Delta^h U^n_{i+1,j} - Gp^{n-\frac{1}{2}}_{i+1,j}\right). \end{aligned} \tag{3.2}$$

Here, Δ^h is the standard five-point finite difference approximation to the Laplacian. Equations (3.1)-(3.2) represent the final form of the predictor. Analogous formulae are used to predict values at each of the other edges of the cell. In evaluating these terms the first-order derivatives normal to the edge (in this case U_x) are evaluated using a monotonicity-limited fourth-order centered-difference slope approximation [8]. The limiting is done on the components of the velocity individually.

The transverse derivative terms ($\widehat{vU_y}$ in this case) are evaluated by first extrapolating from above and below to construct edge states, using normal derivatives only, and then choosing between these states using the upwinding procedure defined below. In particular, we define

$$\widehat{U}^B_{i,j+\frac{1}{2}} = U^n_{ij} + \left(\frac{\Delta y}{2} - \frac{v_{ij}\Delta t}{2}\right) U_{y,ij},$$

$$\widehat{U}^T_{i,j+\frac{1}{2}} = U^n_{i,j+1} - \left(\frac{\Delta y}{2} + \frac{v_{i,j+1}\Delta t}{2}\right) U_{y,i,j+1},$$

where U_y are limited slopes in the y-direction, with similar formulae for the lower edge of B_{ij}. Using the upwinding procedure we first define the normal advective velocity on the edge:

$$\widehat{v}_{adv} = \begin{cases} \widehat{v}^B & \text{if } \widehat{v}^B > 0, \quad \widehat{v}^B + \widehat{v}^T > 0, \\ 0 & \text{if } \widehat{v}^B \le 0, \quad \widehat{v}^T \ge 0, \\ \widehat{v}^T & \text{otherwise.} \end{cases}$$

(We suppress the $i, j + \frac{1}{2}$ spatial indices on the bottom and top states here and in the next equation.) We now upwind U based on $\widehat{v}_{adv}$:

$$\widehat{U}_{i,j+\frac{1}{2}} = \begin{cases} \widehat{U}^B & \text{if } \widehat{v}_{adv} > 0, \\ \frac{1}{2}(\widehat{U}^B + \widehat{U}^T) & \text{if } \widehat{v}_{adv} = 0, \\ \widehat{U}^T & \text{if } \widehat{v}_{adv} < 0. \end{cases}$$

After constructing $\widehat{U}_{i,j-1/2}$ in a similar manner, we use these upwind values to form an approximation to the transverse derivative in (3.2):

$$\widehat{vU_y} \approx \frac{1}{2}(\widehat{v}_{i,j+\frac{1}{2}} + \widehat{v}_{i,j-\frac{1}{2}})(\widehat{U}_{i,j+\frac{1}{2}} - \widehat{U}_{i,j-\frac{1}{2}}).$$

Corrector. In the corrector we use the identical upwinding procedure to that used for the transverse derivatives to choose the appropriate states $U_{i+1/2,j}$ given the left and right states $U^{n+1/2,L}_{i+1/2,j}$ and $U^{n+1/2,R}_{i+1/2,j}$. We follow a similar procedure to construct $U_{i-1/2,j}$, $U_{i,j+1/2}$, and $U_{i,j-1/2}$. Finally, we use these values to form an approximation of the convective derivatives in (1.1)

$$uU_x + vU_y \approx \frac{1}{2}(u_{i+\frac{1}{2},j} + u_{i-\frac{1}{2},j})(U_{i+\frac{1}{2},j} - U_{i-\frac{1}{2},j}) + \frac{1}{2}(v_{i,j+\frac{1}{2}} + v_{i,j-\frac{1}{2}})(U_{i,j+\frac{1}{2}} - U_{i,j-\frac{1}{2}}).$$

The Godunov method is an explicit difference scheme and, as such, requires a time-step restriction. A linear, constant-coefficient analysis shows that for stability we must require

$$\max_{ij}\left(\frac{|u_{ij}|\Delta t}{\Delta x}, \frac{|v_{ij}|\Delta t}{\Delta y}\right) = \sigma \le 1,$$

where σ is the CFL number. The time-step restriction of the Godunov method is used to set the time step for the overall algorithm.

A weak nonlinear instability for $\sigma > 0.5$ has been observed [2]; it is believed to result from the use of the lagged pressure gradient in the predictor-corrector algorithm as described above. An alternate form of the corrector incorporates a MAC projection as in [2] to ensure that the edge velocities satisfy

$$D^{MAC}U = \frac{u_{i+1/2,j} - u_{i-1/2,j}}{\Delta x} + \frac{v_{i,j+1/2} - v_{i,j-1/2}}{\Delta y} = 0.$$

This projection is applied immediately before the construction of the convective derivatives and eliminates the instability for $.5 < \sigma \le 1$. Convergence results will be presented for calculations with and without the MAC projection.

Parabolic approximation. Once the advection terms are evaluated at every cell B_{ij}, to complete the solution of (2.1) we must solve the diffusion part of the system with the pressure and advective terms treated as source terms. For this step we use a standard five-point discretization of the Laplacian with a modification at the boundary that computes a second-order approximation of Laplacian that reflects the given boundary data. The resulting system for each velocity component is solved using multigrid.

4. Discretization of the projection. In this section we describe the numerical approximation of the projection. The projection is based on a finite element formulation. In particular, we consider the scalar pressure field to be a C^0 function that is a bilinear function over each cell; i.e., the pressure is in

$$S^h = M_0^1(x) \otimes M_0^1(y),$$

where $M_s^t(x)$ is the space of polynomials of degree t in the x-direction on each cell with C^s continuity at x-edges. For the velocity space we define

$$\mathbf{V}^h = \mathbf{V}^{h,x} \times \mathbf{V}^{h,y},$$

where $\mathbf{V}^{h,x} = M_{-1}^0(x) \otimes M_{-1}^1(y)$ and $\mathbf{V}^{h,y} = M_{-1}^1(x) \otimes M_{-1}^0(y)$; i.e., u is piecewise constant in x and a discontinuous linear function of y in each cell, with a similar form for v.

As noted above, our basic approximation represents U in terms of cell averages. The velocity space $\mathbf{V}^h$ contains additional functions that represent the linear variation within each cell. These additional degrees of freedom make $\mathbf{V}^h$ large enough to contain $\nabla\phi$ for $\phi \in S^h$. We establish a correspondence between these two representations by introducing an orthogonal decomposition of $\mathbf{V}^h$. In particular, for each $V \in \mathbf{V}^h$ we define a piecewise constant component

$$\overline{V}_{ij} = \frac{1}{Vol\ B_{ij}} \int_{B_{ij}} V\, d\mathbf{x}$$

and the variation

$$V^{\perp} = V - \overline{V}$$

so that for each cell B_{ij}, $\int_{B_{ij}} V^{\perp} d\mathbf{x} = 0$. By construction these two components are orthogonal in L^2, so they can be used to define a decomposition of $\mathbf{V}^h$ into two components

$$\mathbf{V}^h = \overline{\mathbf{V}}^h \oplus \mathbf{V}^{h\perp}, \tag{4.1}$$

where $\overline{\mathbf{V}}^h$ and $\mathbf{V}^{h\perp}$ represent the cell averages and the orthogonal linear variation, respectively. The decomposition of $\mathbf{V}^h$ induces a decomposition of $\nabla\phi$ for all $\phi \in S^h$; namely,

$$(\nabla\phi)_{ij} = (\overline{\nabla\phi})_{ij} + (\nabla\phi)_{ij}^{\perp},$$

where

$$G\phi_{ij} \equiv (\overline{\nabla\phi})_{ij} = \left(\frac{\phi_{i+1/2,j+1/2} + \phi_{i+1/2,j-1/2} - \phi_{i-1/2,j+1/2} - \phi_{i-1/2,j-1/2}}{2\Delta x}, \right.$$

$$\left. \frac{\phi_{i+1/2,j+1/2} + \phi_{i-1/2,j+1/2} - \phi_{i+1/2,j-1/2} - \phi_{i-1/2,j-1/2}}{2\Delta y} \right),$$

$$(\nabla\phi)_{ij}^{\perp} = (\phi_{i+\frac{1}{2},j+\frac{1}{2}} + \phi_{i-\frac{1}{2},j-\frac{1}{2}} - \phi_{i-\frac{1}{2},j+\frac{1}{2}} - \phi_{i+\frac{1}{2},j-\frac{1}{2}}) \left(\frac{y_{ij}}{\Delta x}, \frac{x_{ij}}{\Delta y} \right),$$

where $\phi_{i+1/2,j+1/2}$ represent the nodal values of ϕ. Here x_{ij} and y_{ij} are local variables, defined on each cell such that $x_{ij} = y_{ij} = 0$ at the center of B_{ij}, $x_{ij} = \pm\frac{1}{2}$ at the left and right edges of B_{ij}, and $y_{ij} = \pm\frac{1}{2}$ at the top and bottom edges of B_{ij}.

We now define a weak form of the projection on $\mathbf{V}^h$, based on a weak divergence on $\mathbf{V}^h$. In particular, we define a vector field V^d in $\mathbf{V}^h$ to be divergence-free if

$$\int_\Omega V^d \cdot \nabla\psi \, d\mathbf{x} = 0 \qquad \forall\psi \in S^h. \tag{4.2}$$

With this definition we can then project any vector field V onto a gradient $\nabla\phi$ and weakly divergence-free field V^d (with vanishing normal velocities on boundaries) by solving

$$\int_\Omega \nabla\phi(\mathbf{x}) \cdot \nabla\psi_{i+\frac{1}{2},j+\frac{1}{2}}(\mathbf{x}) \, d\mathbf{x} = \int_\Omega V \cdot \nabla\psi_{i+\frac{1}{2},j+\frac{1}{2}}(\mathbf{x}) \, d\mathbf{x} \qquad \forall\psi_{i+\frac{1}{2},j+\frac{1}{2}}(\mathbf{x}) \tag{4.3}$$

for

$$\phi(\mathbf{x}) = \sum_{i,j} \phi_{i+\frac{1}{2},j+\frac{1}{2}} \psi_{i+\frac{1}{2},j+\frac{1}{2}}(\mathbf{x})$$

and setting $V^d = V - \nabla\phi$. Here the ψ's are the standard basis functions for S^h; namely, $\psi_{i+1/2,j+1/2}(\mathbf{x})$ is the piecewise bilinear function having node values $\psi_{i+1/2,j+1/2} \cdot (\mathbf{x}_{k+1/2,\ell+1/2}) = \delta_{ik}\delta_{j\ell}$. We note that with a suitable normalization, the right-hand side of (4.3) defines a nodal value of the divergence of V at node $(i + \frac{1}{2}, j + \frac{1}{2})$; in particular, by using (4.3) we are implicitly defining the discrete divergence by

$$(DV)_{i+\frac{1}{2},j+\frac{1}{2}} = -\frac{1}{\overline{\psi}} \int_\Omega V \cdot \nabla\psi_{i+\frac{1}{2},j+\frac{1}{2}}(\mathbf{x}) \, d\mathbf{x}, \tag{4.4}$$

where $\overline{\psi} = \int_\Omega \psi_{i+1/2,j+1/2}(\mathbf{x}) \, d\mathbf{x}$.

When this approximate projection is applied in the context of our fractional step scheme, the vector field V to which the projection is applied is given by

$$V = \overline{V} \equiv \frac{U^* - U^n}{\Delta t}, \quad V^\perp = 0. \tag{4.5}$$

(In the predictor we have only determined the quantity $\overline{U}^*$, so we make the implicit assumption here that $U^{\perp,*} = U^{\perp,n}$.) In this case, since D operates on a "barred" vector, the divergence is simply

$$(D\overline{V})_{i+\frac{1}{2},j+\frac{1}{2}} = \frac{V^x{}_{i+1,j} + V^x{}_{i+1,j+1} - V^x{}_{i,j} - V^x{}_{i,j+1}}{2\Delta x} + \frac{V^y{}_{i,j+1} + V^y{}_{i+1,j+1} - V^y{}_{i,j} - V^y{}_{i+1,j}}{2\Delta y},$$

where V^x and V^y are the x- and y-components of V, respectively. With $\overline{V}$ defined by (4.5), $V^x = \frac{u^* - u^n}{\Delta t}$ and $V^y = \frac{v^* - v^n}{\Delta t}$. We solve (4.3) for ϕ to obtain an update for p; i.e.,

$$\phi(\mathbf{x}) = \delta p^n \equiv p^{n+\frac{1}{2}} - p^{n-\frac{1}{2}}.$$

For the purposes of the fractional-step scheme we then define

$$\overline{V}^{d} = \overline{V} - \overline{G\phi} \tag{4.6}$$

as the approximation of $\frac{\overline{U}^{n+1} - \overline{U}^{n}}{\Delta t}$ in (2.2).

The vector field $\overline{V}^{d}$ is only approximately divergence-free; i.e., $D\overline{V}^{d} \neq 0$ even in the weak sense of (4.2). The quantity that is weakly divergence-free is $V^d = V - \nabla\phi$; however, in general, $DV^{d^{\perp}} \neq 0$; consequently, $D\overline{V}^{d} \neq 0$. Effectively, what we have done in writing (4.6) is perform the vector field decomposition into a divergence-free component and the gradient of a scalar on $\mathbf{V}^h$ and project the weakly divergence-free component onto $\overline{\mathbf{V}}^{h}$ using the characterization of $\mathbf{V}^h$ given by (4.1).

In order to estimate the effect of only approximately enforcing discrete incompressibility we will rewrite the result of the projection as

$$\frac{\overline{U}^{*} - \overline{U}^{n}}{\Delta t} = \frac{U^{n+1} - U^{n}}{\Delta t} + \nabla \delta p^{n}, \tag{4.7}$$

$$DU^{n+1} = 0,$$

where we implicitly assume $DU^n = 0$, although $D\overline{U}^{n} \neq 0$. Since $D\overline{U}^{n} = -DU^{n^{\perp}}$, we can estimate how errors accumulate by examining the behavior of $U^{n^{\perp}}$. To accomplish this we break (4.7) into its component pieces:

$$\frac{\overline{U}^{*} - \overline{U}^{n}}{\Delta t} = \frac{\overline{U}^{n+1} - \overline{U}^{n}}{\Delta t} + \frac{U^{\perp, n+1} - U^{\perp, n}}{\Delta t} + \nabla(p^{n+\frac{1}{2}} - p^{n-\frac{1}{2}}).$$

If we then use the characterization of $\mathbf{V}^h$ given by (4.1), we obtain

$$\overline{U}^{n+1} = \overline{U}^{n} + \Delta t \left(\frac{\overline{U}^{*} - \overline{U}^{n}}{\Delta t} + Gp^{n-\frac{1}{2}} - Gp^{n+\frac{1}{2}} \right)$$

and

$$U^{n+1^{\perp}} = U^{n^{\perp}} + \Delta t ((\nabla p^{n-\frac{1}{2}})^{\perp} - (\nabla p^{n+\frac{1}{2}})^{\perp}) \approx U^{n^{\perp}} - \Delta t^2 (\nabla p_t^n)^{\perp}.$$

This evolution equation for $U^{\perp}$ places limits on the growth of $U^{\perp}$. The quantity $(\nabla p)^{\perp}$ is uniquely defined by the node values $p_{i+1/2, j+1/2}$. As long as the pressure remains sufficiently smooth in space and time, $U^{\perp}$ is well behaved as well and scales with $\Delta t \; h = \sigma h^2$. The factor of Δt comes from the evolution equation for $U^{\perp}$; the factor of h comes from the fact that for smooth ψ, $|(\nabla\psi)^{\perp}| \leq O(h)$. Thus $DU^n = 0$ guarantees that $D\overline{U}^{n} = O(h^2)$ as long as the CFL condition is enforced. We monitored $D\overline{U}$ for the convergence study presented in the next section and verified the second-order accuracy computationally.

The linear system associated with the solution of (4.3) is the standard bilinear finite element stiffness matrix for Poisson's equations. We solve this system using standard multigrid methods (see [5]); in particular, we use the standard V-cycle with Jacobi relaxation. This procedure reduces the residuals by approximately a factor of five per V-cycle.

The left-hand side of (4.3) is, in discrete form, a nine-point stencil approximating the Laplacian of ϕ. We note that it is possible, using a similar development, to construct an approximate projection in which the left-hand side of (4.3) is the standard five-point finite difference Laplacian. This construction is based on approximating pressure as a piecewise linear function on triangles. We define a triangulation of the domain by connecting lower-left corners of each grid cell to upper-right corners. With this definition we define $\mathbf{V}^h$ to

be piecewise constant functions on each triangle. As in the bilinear case, we establish the relationship between the projection and the upwind procedure by defining a decomposition of $\mathbf{V}^h$ similar to (4.1); namely,

$$\mathbf{V}^h = \overline{\mathbf{V}}^h \oplus \mathbf{V}^{h^\perp},$$

where $\overline{\mathbf{V}}^h$ is defined as before and $\mathbf{V}^{h^\perp}$ is piecewise constant on each triangle and averages to zero over each of the original rectangular grid cells. This alternate form also leads to an approximate projection in which the vector field decomposition is performed in $\mathbf{V}^h$ and the result is projected onto $\overline{\mathbf{V}}^h$; however, in this case (4.3) for ϕ gives

$$\frac{\phi_{i+3/2,j+1/2} + \phi_{i-1/2,j+1/2} + \phi_{i+1/2,j+3/2} + \phi_{i+1/2,j-1/2} - 4\phi_{i+1/2,j+1/2}}{h^2} = (DV)_{i+\frac{1}{2},j+\frac{1}{2}},$$

where $DV_{i+1/2,j+1/2}$ is defined as in (4.4). We have verified the second-order accuracy of the method with this five-point stencil and observed that the L_2-errors between calculations with different resolution using the five-point stencil differ by less than 2% from the errors shown in Tables 1 and 2.

Boundary conditions for the projection. For homogeneous boundary conditions we want $V^d \cdot \mathbf{n} = 0$ on $\partial\Omega$. This condition is enforced (weakly) by including ψ's that are nonzero on the boundary of Ω in S^h, which imposes a natural treatment of the boundary conditions for the Poisson equation. If we formally integrate (4.3) by parts we see that ϕ satisfies

$$\Delta\phi = DV \quad \text{on } \Omega,$$

$$\frac{\partial\phi}{\partial n} = V \cdot \mathbf{n} \quad \text{on } \partial\Omega.$$

For inflow and outflow, we want to specify $V^d \cdot \mathbf{n}$ on part of the boundary (inflow), which we will refer to as Γ_1, and have outflow on Γ_2. On the outflow face we want to impose the condition that there are no net forces accelerating the fluid parallel to the outflow face. In this simple setting we can accomplish this by setting $\phi = 0$ on Γ_2. Thus, for outflow we restrict S^h to include only those functions that vanish at points on Γ_2.

We do allow ψ's to have support on Γ_1, so we solve for ϕ's on Γ_1, as in the homogeneous boundary condition case; however, we must augment (4.3) with boundary terms to reflect the specified boundary data. In particular, we add a boundary term to (4.3) to obtain

$$\int_\Omega V \cdot \nabla\psi \, d\mathbf{x} = \int_\Omega \nabla\phi \cdot \nabla\psi \, d\mathbf{x} + \int_{\Gamma_1} \psi V^d \cdot \mathbf{n} \, ds.$$

We substitute the boundary conditions for V^d on Γ_1, subtract this quantity from the left-hand side, and proceed with the projection. As can be seen by formally integrating by parts, we now have

$$\frac{\partial\phi}{\partial n} = V \cdot \mathbf{n} - V^d \cdot \mathbf{n} \quad \text{on } \Gamma_1,$$

which enforces the desired condition. Note that the boundary condition for V^d is $V^d \cdot \mathbf{n} = (u_{in}^{n+1} - u_{in}^n)/\Delta t$, where u_{in} is the time-dependent inflow velocity.

5. Numerical results. In this section we first present numerical results to demonstrate the second-order convergence of the method presented here. We also apply the method to computation of a forced, unstable shear layer to illustrate the capabilities of the method in a more realistic setting.

For the convergence study we use the same initial data as was used in [1]. We initialize the data with a smooth velocity field

$$u(x, y) = -\sin^2(\pi x)\sin(2\pi y),$$

$$v(x, y) = \sin^2(\pi y)\sin(2\pi x),$$

in the unit square. The velocity satisfies homogeneous Dirichlet boundary conditions.

Calculations were run to $t = 0.5$ with $\Delta x = \Delta y = 1/2^n$ for $n = 4, 5, 6, 7, 8$. The time step was restricted by the stability criterion to be $\Delta t = .5\Delta x$, which approximates CFL $= 0.5$. To estimate the convergence rate, we find the L_2-norm of the difference between the velocity obtained on each grid and the velocity obtained on the next finer grid; then take $\log_2$ of the ratio of these norms. The convergence rates for velocity are given in Table 1 for the MAC-less predictor, and in Table 2 for the predictor that uses the MAC projection. (We also present, in Table 1, results for Stokes flow.)

The second set of calculations is a direct comparison with the experimental study of Ho and Huang [12] on the nonlinear instability of a forced shear layer. The forcing is introduced using an upstream perturbation based on the stability analysis of Monkewitz and Huerre [17]. We note that a number of other authors have also treated this problem; see, for example, Kuhl et al. [14], who include a survey of the other literature.

Our computations were performed on a 512 × 128 uniform grid, with $\varepsilon = 0$. In Figures 1 and 2 we present contours of vorticity for two cases corresponding to the fundamental perturbation frequency (ω_1) plus a subharmonic. The cases correspond to the first (ω_2) and second (ω_3) subharmonics, respectively. The largest perturbation amplitude was 1% for the fundamental with reduced amplitudes for the subharmonics as given in [17]. The numerical results show the instability of the shear layer and the downstream vortex merging pattern. The first case consists of a simple pairing; in the second case the vortices merge in groups of three with the latter two vortices merging first. The prediction of the correct merging patterns and the near periodicity of the results serve to validate the numerical method on a realistic flow problem.

We also compute the flow perturbed by the fundamental plus nine subharmonics. Computational results for this case are shown in Figure 3. In this case we see a substantially more complex pattern of merger, analogous to the broadly forced instability of this shear layer

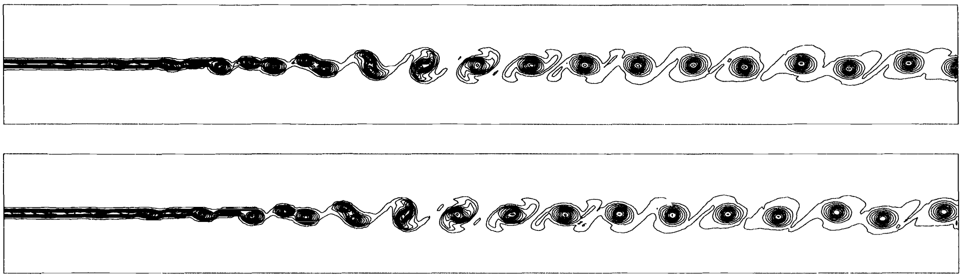

FIG. 1. $\omega_1 + \omega_2$ *forcing at times* T = 1333, 1369.

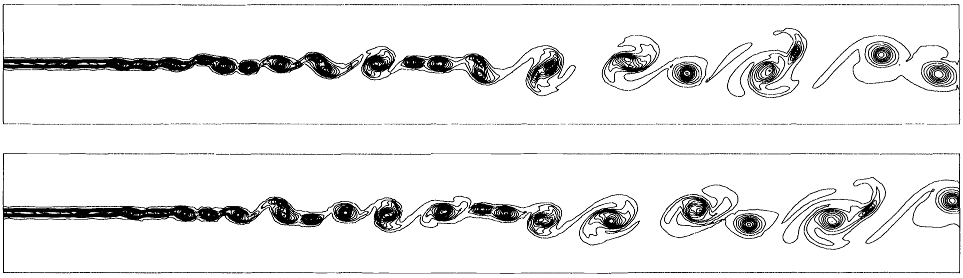

FIG. 3. *Ten frequency forcing forcing at times* T = 1281, 1351.

investigated by Oster and Wygnanski [18]. Although detailed comparisons for this case are beyond the scope of this paper, we note that the spreading rate in the computation agrees well with the experimental value of 11 degrees. Also note that we see no difficulties at inflow and outflow boundaries for either this case or the preceding cases.

6. Conclusions. Traditionally, projection methods for discretizing the time-dependent incompressible Navier-Stokes equations have exactly applied a discrete form of the projection; i.e., the velocity field returned from the projection satisfies a discrete constraint $DU = 0$ for some discrete divergence operator D. In this paper we have shown that this requirement can be relaxed. We have defined a projection based on a finite element construction that only enforces the divergence-free condition to second-order accuracy. The overall accuracy of the method is essentially no different than previous versions of the methodology that exactly imposed a discrete form of the constraint. By relaxing this requirement we have been able to define a projection for which the linear system that must be solved corresponds to a conventional discretization of the Laplacian but for which the velocities are cell-centered, enabling the use of modern upwind techniques for treating the advective derivatives.

This simplified projection is easily generalized to three dimensions and to variable density flows (see [3]). This generalization will be discussed in a forthcoming paper. We are also using this approach to develop an adaptive mesh version of the projection method. In this context we can exploit the similarity with standard finite element techniques in order to use iterative methods developed in the elliptic community for adaptivity.

RESURRECTING CORE SPREADING VORTEX METHODS: A NEW SCHEME THAT IS BOTH DETERMINISTIC AND CONVERGENT*

LOUIS F. ROSSI†

Abstract. A basic core spreading vortex scheme is inconsistent but can be corrected with a splitting algorithm, yielding a deterministic and efficient grid-free method for viscous flows. The splitting algorithm controls the consistency error by maintaining small vortex core sizes. Routine analysis will show that the core spreading method coupled to this splitting process is convergent in L^p spaces. Analysis of the linearized residual operator establishes the uniform convergence of this method when the exact flow field is known. A sequence of examples demonstrates the sensitivity of the method to numerical parameters as the computed solution converges to the exact solution. These experimental results agree with the linear convergence theory. Finally, direct comparisons between the traditional random walk vortex method and the new method indicate that the new method has several advantages while requiring the same computational effort.

Key words. vortex methods, vorticity dynamics, computational fluid dynamics, convergence theory

1. Introduction.

Core spreading algorithms have not been studied since 1985 when C. Greengard proved that the basic core spreading method would not converge [8]. There are many convergent methods for incorporating viscosity into vortex simulations, but none of them are as simple as a core spreading method. A core spreading algorithm is fully deterministic, allowing precise error control and faster convergence than stochastic methods. Also, these algorithms do not rely on operator splitting, the division of the Navier-Stokes equations into separate convective and diffusive processes. Furthermore, a core spreading method is fully localized and grid free, permitting fast parallel execution, free from flow geometry considerations. Neither the circulation redistribution schemes of Mas and Gallic nor the random walk methods of Chorin have both of these advantages [3], [14]. In this paper, we introduce a convergent core spreading vortex method that is both deterministic and localized.

While this new method is effective for unbounded flows, it was developed specifically for flows around general boundaries [15]. One weakness of the split-step techniques more commonly used for vortex methods is that they do not satisfy both normal and tangential boundary conditions at any given moment in the simulations except under very special conditions [3], [4], [5], [19]. Rather, they leapfrog from satisfying the normal flow condition to locally satisfying the tangential flow condition. Sethian has compiled a comprehensive bibliography on vortex methods covering these and other issues [18]. The new method is not a split-step method so it is possible to satisfy both boundary conditions using ideas similar to those of Chorin and Sethian though a thorough discussion of these methods is beyond the scope of this paper. This paper examines only the properties of this method for solving unbounded flows with the understanding that these may well be flows in the interior of some bounded region.

The basic core spreading method is corrected by introducing a process called "adaptive spatial refinement." This new vortex method is called the corrected core spreading vortex method (CCSVM). Since the width of each basis function, or blob, is the critical convergence parameter for a vortex method, it is necessary that blobs not grow too wide. Adaptive spatial refinement approximates a single vortex element or blob with several thinner blobs. While Lu and Ross investigated the possibility of using vortex splitting to approximate diffusive processes [13], the instantaneous reconfiguration of vortex elements has not been considered

as a method for reducing the core width. Surprisingly, it is possible to approximate any vortex element to any specified tolerance with a formation of arbitrarily thinner blobs. Thus, refinement is a technique for replacing one vortex element with many but has nothing to do with the physical process of a single region of vorticity splitting into several distinct regions. This technique has many similarities to the local regridding concepts introduced by Hou, Lowengrub, and Shelley, but core spreading with adaptive spatial refinement does not require the use of an underlying Eulerian coordinate system [11]. This paper establishes the linear convergence of CCSVM to the Navier-Stokes equations.

The work of Beale and Majda already establishes the full nonlinear convergence of the new method in the weaker L^p norms [2], but this paper will focus on the L^∞ (uniform) convergence of the CCSVM in the linear case. Goodman and Hou established uniform convergence of 2D vortex methods to Euler equations, but no such results exist for the Navier-Stokes equations partially due to the stochastic convergence properties of the more popular random walk method of modeling diffusion [7]. Uniform convergence is a more desirable result because it represents the maximum deviation from the exact solution anywhere in the domain. Also, the standard vortex method convergence theory expresses convergence in terms of the velocity field. By using a nonstandard approach, convergence can express itself as the difference between computed and exact vorticity fields. This result is developed by decoupling the velocity field from the vorticity field. The uniform convergence theory highlights two convergence parameters. The first parameter, l, is the maximum core width in the simulation. Hald used this parameter in his first inviscid convergence proof [9] and has continually appeared in subsequent vortex method analyses. If a vortex element or blob grows larger than l, the refinement scheme will replace it with several thinner elements. The other numerical parameter, α, controls the accuracy and frequency of the refinement process and is unique to CCSVM, though some associations can be drawn to parameters in other diffusive methods. More accurate and frequent refinement increases the total number of vortex elements in the simulation, as would be expected.

To control the problem size, many computational elements can be combined into a single one under certain circumstances in a process called "vortex fusion." It is clear that two blobs sharing the same location and core width could be replaced by a single blob with no change at all to the induced vorticity field. An efficient code would merge these two blobs without any loss of accuracy. Similarly, it can be shown that nearby elements with similar widths can be fused with small errors in the vorticity field. Thus, it is possible to reduce the problem size with precise error control. Since a thorough error analysis of this process is beyond the scope of this paper, only the fundamental results together with a demonstration will be presented in this paper. The full analysis, an explicit fusion algorithm, and detailed examples have been submitted for future publication [16].

In the last section, some examples will highlight the interplay between l and α as well as demonstrate the efficiency and accuracy of this new vortex method. To our knowledge, this is the first time precise measurements of vorticity field convergence have been measured in the uniform norm. These measurements show strong agreement with the linear convergence theory. Also, it will be shown that even a very conservative fusion scheme can increase the efficiency of the method considerably while inflicting a very small loss of accuracy. The ultimate implications are that this method is a fast, accurate and naturally adaptive method for viscous flow computations.

2. Formulation and algorithm.

2. Formulation and algorithm. This method is designed to simulate 2-D, unbounded, incompressible flows. Vortex methods attempt to approximate the vorticity dynamics equation

$$\frac{D\omega}{Dt} = \nu \nabla^2 \omega, \tag{1}$$

where $\frac{D}{Dt} = \partial_t + (\vec{u} \cdot \nabla)$. The velocity field $\vec{u}$ can be determined from the vorticity field using a Green's function. Essentially, one must solve the heat equation in a frame moving with the fluid. A vortex method accomplishes this by representing the full vorticity field as a sum of basis functions.

Unlike most vortex methods, CCSVM does not split the vorticity dynamics equation. Operator splitting breaks equation (1) into

$$\frac{D\omega}{Dt} = 0, \tag{2}$$

$$\partial_t \omega = \nu \nabla^2 \omega. \tag{3}$$

The first equation, the Euler equation, is approximated by a simple vortex method. Chorin handled the second equation by having each vortex undergo a random walk. There are many other ways of approximating diffusive processes without grids, but all involve operator splitting. Even though vortex methods converge to exact solutions of the Navier-Stokes equations when the operator is split, the numerical error will also include a splitting error not present in CCSVM. Furthermore, it is difficult to define concepts such as consistency and stability without keeping the operator intact. Hald notes in his original convergence proof that any distinction between the two properties is artificial [9].

To facilitate a future convergence theory, it is desirable to invent a method which is consistent with equation (1) without relying on operator splitting arguments. For solving the heat equation, Gaussian basis functions are advantageous:

$$\omega(\vec{x}) = \sum_{i=1}^{N} \frac{\gamma_i}{4\pi\sigma_i^2} \exp\left(-\frac{|\vec{x} - \vec{x}_i|^2}{4\sigma_i^2}\right), \tag{4}$$

where γ_i is the circulation of blob i and σ_i is the blob width. Though higher spatial accuracy is achieved with the kernels of Hald, Beale, and Majda, Gaussians maintain self-similarity while approximating the diffusive term in equation (1) [2], [10]. To capture equation (1), one must allow each vortex blob to move and diffuse with the flow, giving rise to the following dynamical system:

$$\dot{\vec{x}}_i = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix} \sum_{j=1}^{N} \frac{\gamma_i}{2\pi} \frac{\vec{x}_i - \vec{x}_j}{|\vec{x}_i - \vec{x}_j|^2} \left[1 - \exp\left(-\frac{|\vec{x}_i - \vec{x}_j|^2}{4\sigma_i^2}\right)\right], \tag{5}$$

$$\dot{\sigma_i^2} = \nu. \tag{6}$$

The first system, equation (5), arises from Stokes' theorem applied to equation (4). The whole blob will move with the velocity of the blob center. Later, it will be clear that this is the source of all consistency error. The second equation arises from solving the heat equation in a frame moving with the flow.

This system of ODEs is not new in the world of vortex methods. In 1985, Greengard demonstrated that it was inconsistent with the Navier-Stokes equations [8]. The reasons are more or less evident from a simple heuristic argument. The convergence parameter for a vortex method is the core size of the vortex elements. According to equation (6), the cores have sizes of at least $\sqrt{\nu T}$ at the end of the simulation. Hence, it is impossible to force the method to converge except under certain special circumstances discussed further in §3.1.

2.1. Reducing consistency error with adaptive spatial refinement. In order to maintain small blob sizes throughout the simulation, the basic core spreading scheme is coupled to adaptive spatial refinement. This refinement process splits any blob wider that l into a configuration of thinner blobs of width strictly less than l. With a practical and effective refinement process, the general convergence theory of Hald, Beale, Majda, and others asserts that CCSVM will have L^2 convergence of order l^2 when using Gaussian basis functions [2], [9].

However, the uniform norm is desired for many physical applications. Since both the calculated and the exact vorticity field decay exponentially, a uniform bound can be converted to an L^2 bound while the opposite is not true. Finally, a uniform stability result is necessary for the forthcoming uniform convergence theory. It will be shown that refinement induces uniformly bounded disturbances to the vorticity field as numerical parameters grow small.

The numerical parameter $\alpha \in [0, 1]$ controls the accuracy and stability of adaptive spatial refinement. The refinement process will approximate a single vortex element having width l with several blobs of width αl. Therefore, a refinement algorithm takes all vortex elements with core sizes greater than or equal to l and splits them into many, each of which is scaled by a factor of α.

The particular refinement process is somewhat arbitrary. Here, only 1-4 refinement, where one vortex blob splits into four, will be analyzed, but this program of analysis can be carried out for any "refined" configuration. The general strategy is to conserve as many moments as needed to constrain the free variables. To begin, a single vortex element with circulation γ and variance σ^2 will split into four identical vortices, each with a variance of $\alpha^2\sigma^2$. Without loss of generality, one can assume the original vortex is located at the origin. Conservation of the zeroth moment indicates the obvious: the new vortices must have the same circulation as the original. Conservation of the first moment along with the rotational symmetry of the system requires that each vortex have circulation $\frac{\gamma}{4}$ and be centered uniformly along a circle of radius r. Conservation of the second moment constrains the last variable

$$r = 2\sigma\sqrt{1-\alpha^2}. \tag{7}$$

Now, all of the free parameters of 1-4 refinement have been determined, and it is possible to explicitly describe CCSVM.

1. Approximate the exact initial vorticity distribution with vortex elements.
2. Numerically solve equations (5) and (6) to convect and spread each vortex element.
3. Split any element with $\sigma_i > l$ according to the 1-4 refinement process listed above with the refinement radius described in equation (7).
4. Repeat (2) and (3) until reaching time T.

As noted earlier, under the assumption that the field error induced by the refinement process is stable for $0 \leq t \leq T$, the previous work of other investigators such as Beale and Majda guarantees weak convergence of this algorithm. Also, one can see that this method is very similar to the more traditional random walk vortex method (RWVM). On the surface, it would appear that CCSVM and RWVM would require a similar number of numerical calculations given the same N. Experiments in §5 confirm that this is the case.

2.2. The stability of adaptive spatial refinement. While adaptive spatial refinement controls the core size of all elements in the simulation, it also induces small errors into the simulation because there will be a difference between the original vortex element and the new refined configuration. Fortunately, this error is a function of α and will converge to zero as α approaches unity. It is possible to make strict uniform estimates of this refinement-induced field error.

This estimate begins with a function expressing the pointwise difference between the unrefined and refined fields.

$$e(\vec{x}) = \frac{\gamma}{4\pi\sigma^2}\exp\left(-\frac{|\vec{x}|^2}{4\sigma^2}\right) - \sum_{i=1}^{4}\frac{\gamma}{16\pi\alpha^2\sigma^2}\exp\left(-\frac{|\vec{x}-\vec{x}_i|^2}{4\alpha^2\sigma^2}\right), \tag{8}$$

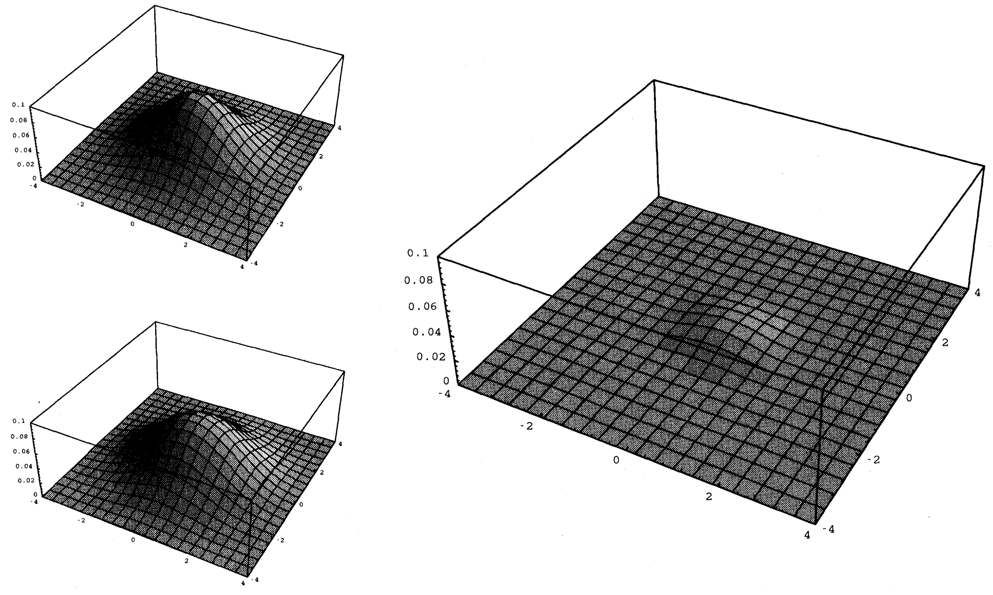

FIG. 1. *Adaptive spatial refinement with $\alpha = 0.8$. Upper left: Gaussian vortex before refinement. Lower left: Gaussian vortex after refinement. Right: difference between unrefined and refined vortices.*

where $\vec{x}_1 = \begin{bmatrix} r \\ 0 \end{bmatrix}$, $\vec{x}_2 = \begin{bmatrix} -r \\ 0 \end{bmatrix}$, $\vec{x}_3 = \begin{bmatrix} 0 \\ r \end{bmatrix}$, and $\vec{x}_4 = \begin{bmatrix} 0 \\ -r \end{bmatrix}$, and r comes from equation (7). Since the goal is to find a uniform norm, a scale transformation can be applied to all the spatial variables in this function as follows:

$$\frac{\vec{x}}{2\sigma} \rightarrow \hat{\vec{x}}. \tag{9}$$

Thus,

$$e(\hat{\vec{x}}) = \frac{\gamma}{4\pi\sigma^2}\left[\exp(-|\hat{\vec{x}}|^2) - \frac{1}{4\alpha^2}\sum_{i=1}^{4}\exp\left(-\frac{|\hat{\vec{x}} - \hat{\vec{x}}_i|^2}{\alpha^2}\right)\right]. \tag{10}$$

Detailed analysis of the term in [ ]'s will show that its maximum value is at the origin for realistically large ($\alpha > 0.43\ldots$) values of α.

Evaluating equation (10) at the origin, the uniform refinement error is

$$\|e(\hat{\vec{x}})\|_\infty = \frac{|\gamma|}{4\pi\sigma^2}\left[1 - \frac{1}{\alpha^2}\exp\left(\frac{\alpha^2 - 1}{\alpha^2}\right)\right]. \tag{11}$$

For any consistent method of initially assigning σ and γ to a vortex element, γ/σ^2 is bounded as the problem size grows. It is appropriate that this estimate only depends on the convergence parameter α and not l because l is strictly a measurement of blob width and does not control the refinement process. It is only when the total evolution of a system of vortex elements is analyzed that a relationship between l and α will emerge.

EXAMPLE 1 ($\alpha = 0.8$). *A vortex element with $\gamma = 1$ and $\sigma = 1$ undergoes refinement. Here, $\|e(\hat{\vec{x}})\|_\infty = 0.0087$, which is better than 40% improvement over $\alpha = 0.7$. The original vortex, the refined vortices, and the error between the two fields are shown in Fig.* 1.

This uniform bound applies to a single refinement event, but a vortex element may undergo many refinement events in its lifetime. The number of refinement events it will undergo is

FIG. 2. *A system of vortex elements undergoes adaptive spatial refinement n times in a uniform flow. Initially, there is only one vortex element located at the center. The distribution of 4^n vortex elements for $n = 0$ (left), $n = 2$ (middle), and $n = 4$ (right) obeys a double binomial distribution. The grid width is r.*

a function of l, α, the viscosity ν, and the total simulation time T. The time required for a vortex element to grow from a size $\sigma = \alpha l$ to size $\sigma = l$ shall be called "the viscous time step" and is denoted by Δt. After an element reaches a width of l, refinement occurs, and it is again reduced to size αl. Presumably, vortex elements shall go through $\frac{T}{\Delta t}$ of these cycles during a simulation. The viscous time step is determined from equation (6) to be

$$\Delta t = \frac{l^2(1-\alpha^2)}{\nu}. \tag{12}$$

Thus, the total number of refinement events, n, in a simulation of duration T is

$$n = \left[\frac{\nu T}{l^2(1-\alpha^2)}\right]. \tag{13}$$

Since refinement events are coupled to core spreading through viscosity, but not by the flow conditions, it is sufficient to analyze the stability of refinement when $\vec{u}$ is constant.

A stable refinement process is one that induces a controllably small error as the number of refinement events grows large. Therefore, one must consider the history of a single vortex element centered at the origin as spreads and splits many times. This vortex will generate a grid with spacing r from equation (7), but like a checkerboard, only even (odd) spaces will have vortex elements for n even (odd). Without loss of generality, one can assume that n is an even number. It follows from a block-walking argument that the distribution of 4^n children of the original vortex obeys a double binomial distribution [20]. More specifically, the number of vortex elements at position $x = \sqrt{2}r(i - j)$ and $y = \sqrt{2}r(i + j)$ is $\left(ni + \frac{n}{2}\right)\left(nj + \frac{n}{2}\right)$. For examples, see Fig. 2.

Thus, after n refinement events, the original element can be expressed as an array of elements with circulations

$$\gamma(x, y) = \gamma_0 \frac{1}{4^n}\left(ni + \frac{n}{2}\right)\left(nj + \frac{n}{2}\right). \tag{14}$$

This expression can also be interpreted as the probability density function (PDF) of two independent Bernoulli trials with $p = \frac{1}{2}$. In fact, this particular PDF corresponds to RWVM with step size $r = \sqrt{2\nu\Delta t}$ where Δt comes from equation (12). Thus, RWVM with Gaussian basis functions and CCSVM are equivalent when there are many computational elements. The crucial difference lies in the fact that CCSVM is deterministic, and one would only expect to observe differences in performance when the problem size is moderate or small.

The DeMoivre–Laplace theorem relates equation (14) to an exponential distribution for large n [6]:

$$\gamma(x, y) = \frac{\gamma_0}{2\pi\left(\frac{n}{4}\right)} \exp\left[-\frac{i^2 + j^2}{2\left(\frac{n}{4}\right)}\right] + O\left(\frac{1}{n}\right). \tag{15}$$

This approximation converges rather rapidly even for small values of n. Using equation (13) and substituting x and y into the left-hand side of equation (15), one obtains

$$\begin{aligned} \gamma(x, y) &= \gamma_0 \frac{8l^2(1-\alpha^2)}{4\pi\nu T} \exp\left[-\frac{x^2+y^2}{4\nu T}\right] + O[l^2(1-\alpha^2)] \\ &= (\sqrt{2}r)^2 \frac{\gamma_0}{4\pi\nu T} \exp\left[-\frac{x^2+y^2}{4\nu T}\right] + O[l^2(1-\alpha^2)] \end{aligned} \tag{16}$$

for discrete values of x and y. The total field is

$$\omega(\vec{x}) = \sum_{i,j} \gamma(\vec{r}_{i,j}) \frac{1}{4\pi\sigma^2} \exp\left(-\frac{|\vec{x} - \vec{r}_{i,j}|}{4\sigma^2}\right) \tag{17}$$

for $\sigma \in [\alpha l, l]$ and $\vec{r}_{i,j} = \sqrt{2}r\left[\begin{smallmatrix} i-j \\ i+j \end{smallmatrix}\right]$.

Adaptive spatial refinement is stable if this quantity is close to the exact solution for all time in the limit as $\alpha \to 0$ and $\alpha \to 1$. Each $\vec{r}_{i,j}$ can be said to lie in the center of a box $B_{i,j}$ of width $\sqrt{2}r$. These $B_{i,j}$ are the components of a grid (oriented 45^o to the mesh depicted in Fig. 2) naturally generated by refinement. Using this grid, one finds that equation (17) is a Riemann sum of a simpler expression,

$$\begin{aligned} &\omega(\vec{x}) - \frac{\gamma_0}{4\pi(\nu T + \sigma^2)} \exp\left[-\frac{|\vec{x}|^2}{4\pi(\nu T + \sigma^2)}\right] \\ &= \sum_{i,j} \gamma(\vec{r}_{i,j}) \frac{1}{4\pi\sigma^2} \exp\left(-\frac{|\vec{x} - \vec{r}_{i,j}|^2}{4\sigma^2}\right) \\ &\quad - \iint \frac{\gamma_0}{4\pi\nu T} \exp\left(-\frac{|\vec{s}|}{4\nu T}\right) \frac{1}{4\pi\sigma^2} \exp\left(-\frac{|\vec{x} - \vec{s}|}{4\sigma^2}\right) d\vec{s} \\ &= \frac{\gamma_0}{4\pi\nu T} \frac{1}{4\pi\sigma^2} \\ &\quad \cdot \sum_{i,j} \iint_{B_{i,j}} \left[\exp\left(-\frac{|\vec{r}_{i,j}|^2}{4\nu T} - \frac{|\vec{x} - \vec{r}_{i,j}|^2}{4\sigma^2}\right) - \exp\left(-\frac{|\vec{s}|^2}{4\nu T} - \frac{|\vec{x} - \vec{s}|}{4\sigma^2}\right)\right] d\vec{s} \\ &= \frac{\gamma_0}{\sigma^2} \sum_{i,j} \exp\left(-\frac{|\vec{x} - \xi_{i,j}|}{4\sigma^2}\right) \left[O(r^3) + O\left(\frac{r^4}{\sigma^2}\right)\right] \\ &= \frac{\gamma_0}{\sigma^2} [O(l\sqrt{1-\alpha^2}) + O(1-\alpha^2)], \end{aligned} \tag{18}$$

where $\xi_{i,j} \in B_{i,j}$. The higher-order error terms from the DeMoivre–Laplace theorem are neglected because error terms from the Taylor expansion are of lower order.

The term $\frac{\gamma_0}{\sigma^2}$ will not be scaled explicitly in this analysis, but is worthy of further discussion. Vortex elements must be initialized on a length scale of $d = l^p$ where $p < 1$ to accurately approximate the initial conditions. For instance, Hald in his second convergence paper chooses $p = \frac{1}{2}$ to balance error terms in his convergence analysis [9]. For a general p, $\frac{\gamma_0}{\sigma^2} = O\left[l^{2(1-p)}\right]$. One could also use the new parameter and set $d = r$, in which case $\frac{\gamma_0}{\sigma^2} = O(1-\alpha^2)$. For any of these choices, the term $\frac{\gamma_0}{\sigma^2}$ is arbitrarily small as $l \to 0$ and $\alpha \to 1$. So, to make this analysis as general as possible, $\frac{\gamma_0}{\sigma^2}$ will not be scaled explicitly.

Finally, the approximate field can be compared with the exact solution.

$$\omega(\vec{x}) = \frac{\gamma_0}{4\pi(\nu T + \sigma^2)} \exp\left[-\frac{|\vec{x}|^2}{4\pi(\nu T + \sigma^2)}\right] + O(l\sqrt{1-\alpha^2}) + O(1-\alpha^2)$$

$$(19) \qquad = \frac{\gamma_0}{4\pi\nu T} \exp\left[-\frac{|\vec{x}|^2}{4\pi\nu T}\right] + \frac{\gamma_0}{\sigma^2}\left[O(l\sqrt{1-\alpha^2}) + O(1-\alpha^2) + O(l^2)\right].$$

These error estimates apply for all points in the plane, implying that these estimates are uniform. This gives rise to the following theorem.

THEOREM 2.1. *A single vortex element initially having variance $\alpha^2 l^2$ and circulation γ will induce a uniform field error no greater than*

$$C\frac{\gamma_0}{\sigma^2}[l\sqrt{(1-\alpha^2)} + (1-\alpha^2) + l^2],$$

where C depends on T only.

Since the cumulative refinement error can be made arbitrarily small, this refinement error can be interpreted as controllably small numerical disturbances to an ordinary vortex method with Gaussian vortex elements of width l. That is, given any tolerance, the refinement error can be made uniformly small for any core size, l. This being the case, the previous work of other investigators such as Hald or Majda can be applied to this core spreading method.

3. Linear convergence theory. This convergence theory has advantages and disadvantages when compared with existing theory. The major disadvantage is that the flow field $\vec{u}$ is specified and ω is computed as if it were a passive scalar, linearizing equation (1). The greatest advantage of this theory is that it establishes full uniform convergence in ω to the exact solution. While this investigation focuses on vorticity dynamics, ω could represent the concentration of any passive scalar. It is assumed that the flow velocity $\vec{u}$ and all its derivatives are known and bounded everywhere.

While initial conditions cannot be totally ignored, this study will not include a thorough investigation of the initial approximation. It is assumed that the exact initial conditions, $\omega(\vec{x}, 0)$, are known and at least piecewise continuous. The operator $I\omega(\vec{x}, t) = \omega(\vec{x}, 0)$ merely projects the vorticity field onto its initial values. Also, it is assumed there is some consistent algorithm for assigning circulations to the initial configuration of vortex elements. For instance, if the vortices are initially laid out in a grid, each vortex might have circulation equal to the $\omega(\vec{x}, 0)$ at that point multiplied by the area of each grid cell. This or any other consistent method for assigning initial circulations has the property that the circulations are bounded as $N \to \infty$ for the startup configuration. Since circulations do not grow with this method, they remain bounded for the duration of the simulation, $0 \leq t \leq T$.

At any time, each vortex element can be thought to occupy a given area, A_i, not necessarily related to the core width. At $t = 0$, this area might be used to assign initial circulations. As the flow evolves and elements spread and split, this area will move with the flow. Since the flow is incompressible, the A_i's will never grow in area though they may decrease or redistribute themselves due to refinement. Furthermore, since the flow derivatives are bounded, these regions will retain their shapes locally as N grows large and the areas grow proportionally smaller. Later, this will be used to justify converting sums to Riemann integrals.

In studying the convergence of this method, a residual operator emerges,

$$(20) \qquad R\omega = \partial_t\omega + (\vec{u} \cdot \nabla)\omega - \nu\nabla^2\omega.$$

If ω^* refers to the exact solution and $\widehat{\omega}$ refers to a computed solution, uniform convergence in ω means $\|\omega^* - \widehat{\omega}\|_\infty \to 0$ as $l \to 0$ and $\alpha \to 1$. Inspired by the work of Isaacson and Keller [12], convergence is divided into two separate conditions. First,

$$\|R\widehat{\omega}\| \to 0 \tag{21}$$

as $l \to 0$ and $\alpha \to 1$. (Obviously, $R\omega^* = 0$ always.) This is called "Condition A." It is not quite the same as consistency, though it does measure the local truncation error because local truncation error is a concept restricted to a discrete set of points usually on a regular grid. The other condition is that

$$\|\omega(t = T)\| \le K \int_0^T \|R\omega\| dt \tag{22}$$

for any ω is some class of functions where K is independent of l and α. This condition (Condition B) looks suspiciously like another convergence property called stability, but it is not at all the same. In fact, Condition B is solely a property of the governing equations and not the numerical method used to solve them. By combining these two results and letting $\omega = \omega^* - \widehat{\omega}$, linear convergence is established. While one is free to choose any norm for this formalism, this paper shall focus on the L^∞ norm.

3.1. Condition A. Conventional treatments of local truncation error are not applicable for a vortex method because it is impossible to substitute the exact solution into a difference equation representing the numerical scheme. Thus, traditional concepts such as consistency do not apply. This problem can be resolved by substituting a numerical solution into the residual operator R.

$$\begin{aligned}
\partial_t\widehat{\omega} &= \sum_{i=0}^{N} \gamma_i \partial_{\sigma^2}\left[\frac{1}{4\pi\sigma_i^2}\exp\left(-\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2}\right)\right]\nu \\
&\quad + \sum_{i=0}^{N} \gamma_i \nabla_{\vec{x}_i}\left[\frac{1}{4\pi\sigma_i^2}\exp\left(-\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2}\right)\right]\cdot\vec{u}(\vec{x}_i) \\
&= \sum_{i=0}^{N} \frac{\gamma_i}{4\pi\sigma_i^4}\left(\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2} - 1\right)\exp\left(-\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2}\right)\nu \\
&\quad + \sum_{i=0}^{N} \frac{\gamma_i(\vec{x}-\vec{x}_i)}{8\pi\sigma_i^4}\exp\left(-\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2}\right)\cdot\vec{u}(\vec{x}_i), \\
\nabla\widehat{\omega} &= -\sum_{i=0}^{N} \frac{\gamma_i(\vec{x}-\vec{x}_i)}{8\pi\sigma_i^4}\exp\left(-\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2}\right), \\
\nu\nabla^2\widehat{\omega} &= \sum_{i=0}^{N} \frac{\gamma_i}{4\pi\sigma_i^4}\left(\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2} - 1\right)\exp\left(-\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2}\right)\nu.
\end{aligned}$$

Combining these terms, one obtains an expression for the residual:

$$R\widehat{\omega} = \sum_{i=0}^{N} \frac{\gamma_i(\vec{x}-\vec{x}_i)}{8\pi\sigma_i^4}\exp\left(-\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2}\right)\cdot[\vec{u}(\vec{x}_i) - \vec{u}(\vec{x})]. \tag{23}$$

Refinement-induced errors are not included here because they constitute arbitrarily small jump discontinuities in the time evolution. Therefore, it is more appropriate to incorporate these effects into Condition B in the next section.

From equation (23), it is possible to see why uncorrected core spreading fails to converge in most circumstances and why it will work in some special circumstances. Assuming particle trajectories are integrated exactly in time, the velocity deviations

$$(\vec{x} - \vec{x}_i) \cdot [\vec{u}(\vec{x}_i) - \vec{u}(\vec{x})] \simeq (\vec{x} - \vec{x}_i) D\vec{u}(\vec{x}_i)(\vec{x}_i - \vec{x})$$

across a vortex element centered at $\vec{x_i}$ are damped by the shape of the vortex element on the length scale equal to the core width. For CCSVM, this envelope scales on l while, for the uncorrected method, this envelope scales on $\sqrt{\nu t}$. As mentioned in §2, the core size for an uncorrected core spreading method is at least $\sqrt{\nu t}$. Therefore, it is impossible to make $R\widehat{\omega} \to 0$. Greengard presented this same result by finding that the uncorrected core spreading method converges to an equation different from Navier-Stokes [8]. In the case where flow deviations across every vortex element are orthogonal to the displacement from the center of the element, or, similarly, $D\vec{u}$ (the matrix of partial derivatives of $\vec{u}$) is strictly a rotation, this error is effectively zero.

EXAMPLE 2 (wherein core spreading does not need to be corrected). *To simulate the evolution of the vorticity field*

$$\frac{1}{4\pi} \exp\left(-\frac{x^2 + y^2}{4}\right),$$

the core spreading algorithm is employed using a single element with $\vec{x}_0 = \vec{0}$, $\sigma_0 = 1$, *and* $\gamma_0 = 1$. *Applying equations* (4)-(6), *the element will spread* ($\sigma_0 = 1 + \nu t$) *but not move. Furthermore, the induced flow across the single element is everywhere orthogonal to the displacement vector, hence the residual from equation* (23) *is exactly zero, corresponding to an exact solution to equation* (1).

However, a generic flow will not have the special property that flow deviations across the vorticity gradient will be zero, and so, will require corrections. Given that generic flows will require correction, core spreading corrected with adaptive spatial refinement will restrict the displacements over which velocity deviations can contribute to the residual. The extent to which refinement controls these deviations will reveal the dependence of the corrected method's accuracy on numerical parameters l and α.

Bounding $R\widehat{\omega}$ requires detailed analysis in many steps. First, equation (23) must be approximated by an integral. This integral is an anisotropic regularization of terms involving $\widehat{\omega}$ and the velocity field. This anisotropy is controlled by α while the smoothness of the regularization will depend on l. Finally, we found it necessary to include an artificial length scale, $d \simeq l^p$, to truncate the regularization, effectively introducing p into the convergence rate. Fortunately, p will only appear in higher-order terms and not affect the end result. Following this program without this artificial scale may be a valuable result in future investigations.

The first step in converting equation (23) into an integral is to extend the σ_i into a function $\sigma(\vec{x})$ such that $\alpha l \leq \sigma(\vec{x}) \leq l$ and $\sigma(\vec{x}_i) = \sigma_i$. There are many ways to construct this function. One might be to consider that each vortex blob position is contained in a small region, A_i, as discussed earlier, and $\sigma(\vec{x})$ is piecewise constant on these regions. Similarly, $\widehat{\widehat{\omega}}(\vec{x}) = \frac{\gamma_i}{|A_i|}$ on A_i.

In the limit $l \to 0$, the function $\widehat{\widehat{\omega}}(\vec{x}) \to \widehat{\omega}(\vec{x})$ almost everywhere. Unless otherwise noted, all integrals are evaluated over the entire real line. There are several relationships in addition to equation (4) which relate $\widehat{\omega}$ to convolutions.

$$\left\| \widehat{\omega}(\vec{x}) - \iint \frac{\widehat{\omega}(\vec{s})}{4\pi l^2} \exp\left(-\frac{|\vec{x} - \vec{s}|^2}{4l^2}\right) d\vec{s} \right\|_\infty = O(\|\nabla\widehat{\omega}\|, l),$$

$$\left\| \sum_{i=1}^{N} \frac{\gamma_i}{4\pi\sigma_i^2} \exp\left(-\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2}\right) - \iint \frac{\widehat{\omega}(\vec{s})}{4\pi\sigma^2(\vec{s})} \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4\sigma^2(\vec{s})}\right) d\vec{s} \right\|_\infty = O\left(\frac{1}{\sqrt{N}}\right).$$

Thus,

$$\begin{aligned} &\left\| \iint \frac{\widehat{\omega}(\vec{s})}{4\pi l^2} \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right) - \frac{\widehat{\omega}(\vec{s})}{4\pi\sigma^2(\vec{s})} \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4\sigma^2(\vec{s})}\right) d\vec{s} \right\|_\infty \\ &\qquad = O\left(\frac{1}{\sqrt{N}}\right) + O(\|\nabla\widehat{\omega}\|, l). \end{aligned} \tag{24}$$

Now,

$$\begin{aligned} &\frac{\widehat{\omega}(\vec{s})}{4\pi\sigma^2(\vec{s})} \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4\sigma^2(\vec{s})}\right) d\vec{s} \\ &\qquad = \frac{\widehat{\omega}(\vec{s})}{4\pi l^2} \left[1 + \frac{l^2-\sigma^2(\vec{s})}{\sigma^2(\vec{s})}\right] \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\left[1 + \frac{l^2-\sigma^2(\vec{s})}{\sigma^2(\vec{s})}\right]\right) d\vec{s}. \end{aligned} \tag{25}$$

However, the latter term in the exponential is close to unity when $|\vec{x}-\vec{s}|$ is close to zero.

$$\left| \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\left(\frac{l^2-\sigma^2(\vec{s})}{\sigma^2(\vec{s})}\right)\right] - 1 \right| \le \frac{|\vec{x}-\vec{s}|^2}{4l^2}\left(\frac{l^2-\sigma^2(\vec{s})}{\sigma^2(\vec{s})}\right). \tag{26}$$

Thus,

$$\begin{aligned} &\left\| \left(\iint_{\vec{s}<d} + \iint_{\vec{s}>d}\right) \frac{\widehat{\omega}(\vec{s})}{4\pi l^2} \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right) - \frac{\widehat{\omega}(\vec{s})}{4\pi\sigma(\vec{s})^2} \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4\sigma(\vec{s})^2}\right) d\vec{s} \right\|_\infty \\ &\le \left\| \iint_{\vec{s}<d} \frac{\widehat{\omega}(\vec{s})}{4\pi l^2} \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right) - \frac{\widehat{\omega}(\vec{s})}{4\pi l^2} \left[1 + \frac{l^2-\sigma^2(\vec{s})}{\sigma^2(\vec{s})}\right] \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4\sigma(\vec{s})^2}\right) d\vec{s} \right\| \\ &\quad + \|\widehat{\omega}\| \left(1+\alpha^{-2}\right) \exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right] \\ &\le \frac{\|\widehat{\omega}\|}{4\pi l^2} \frac{1-\alpha^2}{\alpha^2} \iint_{\vec{s}<d} \left(1 + \frac{|\vec{x}-\vec{s}|^2}{4l^2}\right) \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right) d\vec{s} \\ &\quad + \|\widehat{\omega}\| \left(1+\alpha^{-2}\right) \exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right] \\ &\le \|\widehat{\omega}\| \frac{1-\alpha^2}{\alpha^2} \left\{3 + \left[3 - \left(\frac{d}{l}\right)^2\right] \exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]\right\} \\ &\quad + \|\widehat{\omega}\| \left(1+\alpha^{-2}\right) \exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]. \end{aligned} \tag{27}$$

Allowing $d = l^p$ where $p < 1$, the exponential terms decay faster than any polynomial in l or α. So,

$$\begin{aligned} &\left\| \left(\iint_{\vec{s}<d} + \iint_{\vec{s}>d}\right) \frac{\widehat{\omega}(\vec{s})}{4\pi l^2} \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right) - \frac{\widehat{\omega}(\vec{s})}{4\pi\sigma(\vec{s})^2} \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4\sigma(\vec{s})^2}\right) d\vec{s} \right\|_\infty \\ &\qquad = O\left(1-\alpha^2\right). \end{aligned}$$

Therefore,

$$\left\| \iint \frac{\widehat{\omega}(\vec{s}) - \widehat{\widehat{\omega}}(\vec{s})}{4\pi l^2} \exp\left(-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right) d\vec{s} \right\|_\infty$$

$$= O\left(\frac{1}{\sqrt{N}}\right) + O(\|\nabla\widehat{\omega}\|, l) + O(1-\alpha^2). \tag{28}$$

This can be extended to the residual because the function

$$[\vec{u}(\vec{x}) - \vec{u}(\vec{s})] \cdot (\vec{s} - \vec{x})$$

is locally integrable. Hence,

$$\begin{aligned} R\widehat{\omega} &= \iint \frac{\widehat{\widehat{\omega}}(\vec{s})}{8\pi\sigma^4(\vec{s})} \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4\sigma^2(\vec{s})}\right] [\vec{u}(\vec{x}) - \vec{u}(\vec{s})] \cdot (\vec{s}-\vec{x}) d\vec{s} + O\left(\frac{1}{\sqrt{N}}\right) \\ &= \iint \frac{\widehat{\omega}(\vec{s})}{8\pi\sigma^4(\vec{s})} \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4\sigma^2(\vec{s})}\right] [\vec{u}(\vec{x}) - \vec{u}(\vec{s})] \cdot (\vec{s}-\vec{x}) d\vec{s} \\ &\quad + O\left(\frac{1}{\sqrt{N}}\right) + O(\|\nabla\widehat{\omega}\|, l) + O(1-\alpha^2). \end{aligned} \tag{29}$$

While $\|\widehat{\omega}\|$ and $\|\nabla\widehat{\omega}\|$ are bounded initially, nothing in this analysis asserts that their evolution is well behaved in the limit as $\alpha \to 1$ and $l \to 0$. However, similar analysis verifies that these two quantities are bounded as the numerical method converges. These issues are addressed in the appendices. Thus, for the rest of this section, it is assumed that the vorticity field and its gradients are bounded as the numerical parameters approach their limiting values.

Now, it is possible to analyze the residual operator

$$\begin{aligned} \|R\widehat{\omega}\|_\infty &= \left\| \left(\iint_{|\vec{s}|<d, |\vec{s}|>d} \right) \frac{\widehat{\omega}(\vec{s})}{8\pi\sigma^4(\vec{s})} \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4\sigma^2(\vec{s})}\right] [\vec{u}(\vec{x}) - \vec{u}(\vec{s})] \cdot (\vec{s}-\vec{x}) d\vec{s} \right\| \\ &\quad + O\left(\frac{1}{\sqrt{N}}\right) + O(\|\nabla\widehat{\omega}\|, l) + O(1-\alpha^2). \end{aligned} \tag{30}$$

The contributions to the residual are localized about $\vec{x}$ and the effects from $\vec{s} > d$ decay exponentially. Furthermore, the integrand for $\vec{x} < d$ can be decomposed into isotropic ($\sigma = l$) and anisotropic (σ varies in space) parts outside of the exponential. The expression $D\vec{u}$ is the matrix of partial derivatives of $\vec{u}$ and $\|D\vec{u}\|$ is the induced operator norm on L^∞.

$$\begin{aligned} \|R\widehat{\omega}\|_\infty \leq &\left\| \iint_{|\vec{s}|<d} \frac{\widehat{\omega}(\vec{s})}{8\pi l^4} \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4\sigma^2(\vec{s})}\right] [\vec{u}(\vec{x}) - \vec{u}(\vec{s})] \cdot (\vec{s}-\vec{x}) d\vec{s} \right\| \\ &+ \left\| \iint_{|\vec{s}|<d} \frac{\widehat{\omega}(\vec{s})}{8\pi l^4} \left(\frac{l^4 - \sigma^4(\vec{s})}{\sigma^4(\vec{s})}\right) \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4\sigma^2(\vec{s})}\right] [\vec{u}(\vec{x}) - \vec{u}(\vec{s})] \cdot (\vec{s}-\vec{x}) d\vec{s} \right\| \\ &+ \frac{\|\widehat{\omega}\| \, \|D\vec{u}\|}{2\alpha^4} \left[\left(\frac{d}{l}\right)^2 + 4\right] \exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right] \\ &+ O\left(\frac{1}{\sqrt{N}}\right) + O(\|\nabla\widehat{\omega}\|, l) + O(1-\alpha^2). \end{aligned} \tag{31}$$

The localization of the integral justifies a Taylor expansion of the vorticity field within the first term of equation (31). The second term can be bounded in terms of the vorticity field and the flow deviations.

$$
\begin{aligned}
&\|R\widehat{\omega}\|_\infty \\
&\quad\leq \left\| \iint_{|\vec{s}|<d} \frac{\widehat{\omega}(\vec{x}) + \nabla\widehat{\omega}(\vec{\xi}) \cdot (\vec{s}-\vec{x})}{8\pi l^4} \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4\sigma^2(\vec{s})}\right] \left[\vec{u}(\vec{x}) - \vec{u}(\vec{s})\right] \cdot (\vec{s}-\vec{x}) d\vec{s} \right\| \\
&\qquad + \|\widehat{\omega}\| \, \|D\vec{u}\| \frac{1}{8\pi l^4} \frac{1-\alpha^4}{\alpha^4} \iint_{|\vec{s}|<d} |\vec{x}-\vec{s}|^2 \exp\left(-\frac{|\vec{s}-\vec{x}|^2}{4l^2}\right) d\vec{s} \\
&\qquad + \frac{\|\widehat{\omega}\| \, \|D\vec{u}\|}{2\alpha^4} \left[\left(\frac{d}{l}\right)^2 + 4\right] \exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right] \\
&\qquad + O\left(\frac{1}{\sqrt{N}}\right) + O(\|\nabla\widehat{\omega}\|, l) + O(1-\alpha^2). \qquad (32)
\end{aligned}
$$

Within the first term of equation (31), the exponential can also be decomposed into isotropic and anisotropic parts. The anisotropic exponential is close to unity when α is close to unity as expected.

$$
\begin{aligned}
\|R\widehat{\omega}\|_\infty \leq &\left\| \iint_{|\vec{s}|<d} \frac{\widehat{\omega}(\vec{x})}{8\pi l^4} \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right] \right. \\
&\left. \times \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\left(\frac{l^2-\sigma^2(\vec{s})}{\sigma^2(\vec{s})}\right)\right] \left[\vec{u}(\vec{x}) - \vec{u}(\vec{s})\right] \cdot (\vec{s}-\vec{x}) d\vec{s} \right\| \\
&+ \left\| \iint_{|\vec{s}|<d} \frac{\nabla\widehat{\omega}(\vec{\xi}) \cdot (\vec{s}-\vec{x})}{8\pi l^4} \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4\sigma^2(\vec{s})}\right] \left[\vec{u}(\vec{x}) - \vec{u}(\vec{s})\right] \cdot (\vec{s}-\vec{x}) d\vec{s} \right\| \\
&+ \|\widehat{\omega}\| \, \|D\vec{u}\| \frac{1-\alpha^4}{2\alpha^4} \left\{4 - \left[\left(\frac{d}{l}\right)^2 + 4\right] \exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]\right\} \\
&+ \frac{\|\widehat{\omega}\| \, \|D\vec{u}\|}{2\alpha^4} \left[\left(\frac{d}{l}\right)^2 + 4\right] \exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right] \\
&+ O\left(\frac{1}{\sqrt{N}}\right) + O(\|\nabla\widehat{\omega}\|, l) + O(1-\alpha^2). \qquad (33)
\end{aligned}
$$

The anisotropic exponential in the first term of equation (33) can be approximated by 1 plus a small error which is bounded by the second term of its Taylor expansion.

$$
\begin{aligned}
\|R\widehat{\omega}\|_\infty \leq &\left\| \iint_{|\vec{s}|<d} \frac{\widehat{\omega}(\vec{x})}{8\pi l^4} \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right] \left[\vec{u}(\vec{x}) - \vec{u}(\vec{s})\right] \cdot (\vec{s}-\vec{x}) d\vec{s} \right\| \\
&+ \|\widehat{\omega}\| \, \|D\vec{u}\| \frac{d^2(1-\alpha^2)}{8\pi\alpha^4 l^6} \iint_{|\vec{s}|<d} |\vec{s}-\vec{x}|^2 \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right] d\vec{s} \\
&+ \frac{\|\nabla\widehat{\omega}\| \, \|D\vec{u}\|}{8\pi l^4} \iint_{|\vec{s}|<d} |\vec{s}-\vec{x}|^3 \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right] d\vec{s} \\
&+ \frac{\|\widehat{\omega}\| \, \|D\vec{u}\|}{2\alpha^4} \left\{4(1+\alpha^2)(1-\alpha^2) + \alpha^4 \left[\left(\frac{d}{l}\right)^2 + 4\right] \exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]\right\} \\
&+ O\left(\frac{1}{\sqrt{N}}\right) + O(\|\nabla\widehat{\omega}\|, l) + O(1-\alpha^2). \qquad (34)
\end{aligned}
$$

Finally, the velocity field is linearized about $\vec{x}$ in the first term. The remainder is bounded in terms of $H\vec{u}$, the Hessian.

$$
\begin{aligned}
\|R\widehat{\omega}\|_\infty \leq{}& \left\| \iint_{|\vec{s}|<d} \frac{\widehat{\omega}(\vec{x})}{8\pi l^4} \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right] \left[D\vec{u}(\vec{x})(\vec{x}-\vec{s})\right]\cdot(\vec{s}-\vec{x})d\vec{s} \right\| \\
&+ \frac{\|\widehat{\omega}\|\,\|H\vec{u}\|}{8\pi l^4} \iint_{|\vec{s}|<d} \exp\left[-\frac{|\vec{x}-\vec{s}|^2}{4l^2}\right] |\vec{s}-\vec{x}|^3 d\vec{s} \\
&+ \|\widehat{\omega}\|\,\|D\vec{u}\| \frac{(1-\alpha^2)}{2\alpha^4}\left(\frac{d}{l}\right)^2 \left\{4 - \left[\left(\frac{d}{l}\right)^2+4\right]\exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]\right\} \\
&+ \frac{3\|\nabla\widehat{\omega}\|\,\|D\vec{u}\|}{2} \left\{2\sqrt{\pi}l - \left[\frac{d^3}{l^2}\right]\exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]\right. \\
&\qquad \left. - 2d\exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right] - 2\sqrt{\pi}l\exp\left[-\frac{1}{8}\left(\frac{d}{l}\right)^2\right]\right\} \\
&+ \frac{\|\widehat{\omega}\|\,\|D\vec{u}\|}{2\alpha^4} \left\{4(1+\alpha^2)(1-\alpha^2) + \alpha^4\left[\left(\frac{d}{l}\right)^2+4\right]\exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]\right\} \\
&+ O\left(\frac{1}{\sqrt{N}}\right) + O(\|\nabla\widehat{\omega}\|, l) + O(1-\alpha^2).
\end{aligned}
\tag{35}
$$

Since the fluid is incompressible, $D\vec{u}$ has zero trace. Therefore, the first term of equation (35) is zero.

$$
\begin{aligned}
\|R\widehat{\omega}\|_\infty \leq{}& \frac{3\|\widehat{\omega}\|\,\|H\vec{u}\|}{2} \left\{2\sqrt{\pi}l - \left[\frac{d^3}{l^2}\right]\exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]\right. \\
&\qquad \left. -2d\exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right] - 2\sqrt{\pi}l\exp\left[-\frac{1}{8}\left(\frac{d}{l}\right)^2\right]\right\} \\
&+ \|\widehat{\omega}\|\,\|D\vec{u}\| \frac{(1-\alpha^2)}{2\alpha^4}\left(\frac{d}{l}\right)^2 \left\{4 - \left[\left(\frac{d}{l}\right)^2+4\right]\exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]\right\} \\
&+ \frac{3\|\nabla\widehat{\omega}\|\,\|D\vec{u}\|}{2} \left\{2\sqrt{\pi}l - \left[\frac{d^3}{l^2}\right]\exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]\right. \\
&\qquad \left. -2d\exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right] - 2\sqrt{\pi}l\exp\left[-\frac{1}{8}\left(\frac{d}{l}\right)^2\right]\right\} \\
&+ \frac{\|\widehat{\omega}\|\,\|D\vec{u}\|}{2\alpha^4} \left\{4\left[1+\alpha^2+\left(\frac{d}{l}\right)^2\right](1-\alpha^2)\right. \\
&\qquad \left. + \left[\alpha^4 - \left(\frac{d}{l}\right)^2(1-\alpha^2)\right]\left[\left(\frac{d}{l}\right)^2+4\right]\exp\left[-\frac{1}{4}\left(\frac{d}{l}\right)^2\right]\right\} \\
&+ O\left(\frac{1}{\sqrt{N}}\right) + O(\|\nabla\widehat{\omega}\|, l) + O(1-\alpha^2).
\end{aligned}
\tag{36}
$$

If $d = l^p$ where $p < 1$ then all but a few of these terms decay faster than any polynomial in l as $l \to 0$. The remaining terms are the true rate of uniform convergence for the corrected core spreading vortex method.

$$\|R\widehat{\omega}\|_\infty \le O\left(\frac{1}{\sqrt{N}}\right) + O(\|\widehat{\omega}\|, l) + O(\|\nabla\widehat{\omega}\|, l) + O[\|\widehat{\omega}\|, (1-\alpha^2)]$$

$$+O[\|\widehat{\omega}\|, (1-\alpha^2), l^{2(p-1)}]. \tag{37}$$

The artificial length scale d only enters into the fourth term which is of higher order than the previous three. While $\|\widehat{\omega}\|$ and $\|\nabla\widehat{\omega}\|$ are bounded initially, nothing in this analysis asserts that their evolution is well behaved in the limit as $\alpha \to 1$ and $l \to 0$. However, analysis of the growth of $\widehat{\omega}$ and $\nabla\widehat{\omega}$, similar to that of $R\widehat{\omega}$, proves that this is the case [15]. In this analysis, the growth of $\widehat{\omega}$ depends on $\nabla\widehat{\omega}$, but closure is achieved for the estimates of $\nabla\widehat{\omega}$. This establishes the following theorem.

THEOREM 3.1 (Condition A). *If $\widehat{\omega}$ is a solution to equations* (4), (5), *and* (6) *with a suitably stable refinement scheme to maintain core sizes between αl and l then the residual operator is at most $O(l) + O(1-\alpha^2)$ for large values of N.*

3.2. Condition B. In this section, it will be shown that any function can be uniformly bounded in terms of its response to the operator R. To facilitate this result, a new operator is defined:

$$L(t)f(\vec{x}(t), t) = -\nu \int_0^t \nabla^2 f(\vec{x}(s), s)ds, \tag{38}$$

where $\vec{x}$ is the position of a Lagrangian particle moving with a velocity $\vec{u}(\vec{x}(t), t)$. If $L(t)$ is restricted to a class of functions such that the function and all its derivatives are smaller than M, then $L(t)$ is bounded by νMT in the operator norm induced by L_∞.

By establishing a relationship between ω and $R\omega$ along Lagrangian trajectories, it is possible to obtain a uniform estimate. Since $\widehat{\omega}$ does not have classical time derivatives during refinement, we shall separate it into two parts:

$$\delta\widehat{\omega} = \widehat{\omega} - \widehat{\omega}^+, \tag{39}$$

where $\delta\widehat{\omega}$ is the difference between unrefined and refined $\widehat{\omega}$, and $\widehat{\omega}^+$ is the smoothly evolving difference between the two. Though $\delta\widehat{\omega}$ is not continuous in time, Theorem 2.1 establishes that the time integral of this quantity is uniformly bounded by quantities of order l^2, $1-\alpha^2$ and $l\sqrt{1-\alpha^2}$, all of which are of higher order than the error terms in $R\widehat{\omega}^+$. Thus, one only expects to apply Condition B to $\widehat{\omega}^+$ and ω.

$$\begin{aligned}
\omega(\vec{x}(T), T) &= e^{-L(T)}e^{L(T)}\omega(\vec{x}(T), T) \\
&= e^{-L(T)}\left[\int_0^T \frac{d}{dt}e^{L(t)}\omega(\vec{x}(t), t)dt + \omega(\vec{x}(0), 0)\right] \\
&= e^{-L(T)}\left[\int_0^T \frac{d}{dt}e^{L(t)}\omega(\vec{x}(t), t)dt + I\omega(\vec{x})\right] \\
&= e^{-L(T)}\left\{\int_0^T e^{L(t)}\left[\frac{D\omega}{Dt}(\vec{x}(t), t) - \nu\nabla^2\omega(\vec{x}(t), t)\right]dt + I\omega(\vec{x})\right\} \\
&= e^{-L(T)}\left[\int_0^T e^{L(t)}R\omega(\vec{x}(t), t)dt + I\omega(\vec{x})\right] \\
&= \int_0^T e^{L(t)-L(T)}R\omega(\vec{x}(t), t)dt + e^{-L(T)}I\omega(\vec{x}).
\end{aligned} \tag{40}$$

Thus, for any initial position,

$$|\omega(\vec{x}(T),T)| \leq e^{\nu MT}\left[\int_0^T |R\omega(\vec{x}(t),t)|dt + |I\omega(\vec{x})|\right]. \tag{41}$$

This pointwise estimate can be extended to yield the desired result.

THEOREM 3.2 (Condition B). *For any function ω with two continuous derivatives,*

$$\|\omega(\vec{x}(T),T)\|_\infty \leq e^{\nu MT}\left[\int_0^T \|R\omega(\vec{x}(t),t)\|_\infty dt + \|I\omega(\vec{x})\|_\infty\right].$$

3.3. *A* + *B* = Convergence. Combining Theorems 3.1 and 3.2, one obtains a uniform convergence estimate. From Theorem 3.2 and the linearity of R and I,

$$\begin{aligned}&\|\widehat{\omega}(\vec{x}(T),T) - \omega^*(\vec{x}(T),T)\|_\infty\\ &\quad\leq e^{\nu MT}\left[\int_0^T \|R\widehat{\omega}^+(\vec{x}(t),t) - R\omega^*(\vec{x}(t),t)\|_\infty dt + \|I\widehat{\omega}(\vec{x}) - I\omega^*(\vec{x})\|_\infty\right]\\ &\qquad+\|\delta\widehat{\omega}(T)\|_\infty.\end{aligned} \tag{42}$$

But, Theorem 3.1 asserts

$$\begin{aligned}&\|\widehat{\omega}(\vec{x}(T),T) - \omega^*(\vec{x}(T),T)\|_\infty\\ &\quad\leq e^{\nu MT}\left\{\int_0^T \left[O(l) + O(1-\alpha^2)\right]dt + \|I\widehat{\omega}(\vec{x}) - I\omega^*(\vec{x})\|_\infty\right\} + \|\delta\widehat{\omega}(T)\|_\infty.\end{aligned} \tag{43}$$

Since initially, no refinement has occurred, $\widehat{\omega}^+ = \widehat{\omega}$ at time zero. If refinement did occur initially, any error would be incorporated into $I\widehat{\omega}$ forming a new initial error, assuming that one is using a convergent scheme for approximating the initial conditions which is at least $O(l)$.

THEOREM 3.3 (convergence of improved core spreading method). *Assuming there existed an exact solution to equation* (1) *which is twice differentiable, the solution to equations* (4), (5), *and* (6) (*where $\vec{u}$ corresponds to the exact solution*) *with a suitable refinement algorithm will converge to this exact solution and*

$$\|\widehat{\omega}(\vec{x}(T),T) - \omega^*(\vec{x}(T),T)\|_\infty \leq O(l) + O(1-\alpha^2)$$

for $t \leq T$.

While this convergence rate appears modest, it is stronger than previous results in many ways. Previous findings are limited to velocity fields at particle positions. Convergence of the vorticity field itself is substantially weaker, and again, is only measured at particle positions. The above analysis determines a rate of convergence which is applicable to the vorticity field itself in the far stronger uniform norm. Of course, this result can be extended to the velocity field without loss of accuracy. This result will be verified experimentally in §5.

4. Efficiency and fusion. Since the computational complexity of a vortex method is $O(N^2)$, the feasibility of computing a flow to a prescribed accuracy hinges directly on the problem size, N. Clearly, two blobs sharing the same centroid and width can be merged into a single blob with no induced error in the vorticity field. "Vortex fusion" shall refer to the general process of merging many overlapping basis functions. The necessity of adaptive spatial refinement, discussed earlier, does not imply the existence of a fusion process. Rather, they are two separate mechanisms for solving two separate problems: one corrects consistency error while the other reduces the problem size. This section presents the basic theorems describing the uniform estimate for the induced fusion error without proof, leaving the details of this analysis to [16]. From these results, one will see that it is not necessary to rigorously examine all possible subsets of a configuration of vortex elements because the uniform estimate does not depend on the number of elements merged. Rather, it only depends on certain nondimensional parameters related to the separation and width of vortex elements in the simulation.

There are two error control parameters for vortex fusion based on a direct comparison between each individual vortex in the original group and the fused vortex. To begin, the vortices to be fused are labeled from 1 to n, where $n \leq N$, and have distinct circulations, widths, and positions. The post-fusion element shall be labeled 0. Also, it is necessary to assume that all γ_i's have the same sign for reasons discussed in [16]. The circulation, position, and width of the fused vortex is

$$\gamma_0 = \sum_{i=n}^{N} \gamma_i, \tag{44}$$

$$\vec{x}_0 = \sum_{i=n}^{N} \gamma_i \vec{x}_i, \tag{45}$$

$$4\gamma_0\sigma_0^2 = \sum_{i=n}^{N} \gamma_i(4\sigma_i^2 + |\vec{x}_i|^2). \tag{46}$$

For convenience, all positions will be translated to the center of mass of the original cluster of elements so that $\vec{x}_0 = 0$. Equation (46) constrains the fused blob width but does not play a key role in the uniform error bound, as do the others. Therefore, it may be possible to use other constraints in place of this one. The pointwise field error is

$$e(\vec{x}) = \frac{\gamma_0}{4\pi\sigma_0^2}\exp\left(-\frac{|\vec{x}|^2}{4\sigma_0^2}\right) - \sum_{i=1}^{n}\frac{\gamma_i}{4\pi\sigma_i^2}\exp\left(-\frac{|\vec{x}-\vec{x}_i|^2}{4\sigma_i^2}\right). \tag{47}$$

By isolating the appropriate length scales in the problem and studying the resulting expressions, it is possible to establish the following theorem.

THEOREM 4.1 (fusion error bound). *Suppose n vortex elements are fused into a single element with circulation, position, and width defined by equations* (44), (45), *and* (46). *Furthermore, assume that all circulations have the same sign and that*

$$\left(\frac{|\vec{x}_i|}{2\sigma_0}\right)^2 \leq R$$

and

$$b_1 \leq \left(\frac{\sigma_0}{\sigma_i}\right)^2 \leq b_2$$

for each vortex. Then, the uniform induced field error, $\|e(\hat{x})\|_\infty$, is no greater than

$$\frac{|\gamma_0|M}{4\pi\sigma_0^2},$$

where M is the maximum value of

$$\exp\left(-|\hat{x}|^2\right) - \frac{\sigma_0^2}{\sigma_i^2}\exp\left[-|\hat{x}-\hat{x}_i|^2\left(\frac{\sigma_0^2}{\sigma_i^2}\right)\right]$$

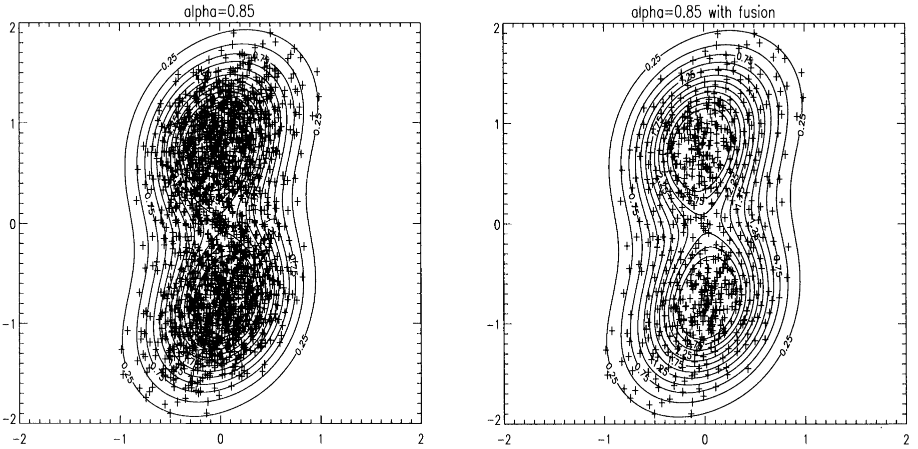

FIG. 3. *A demonstration of the efficacy of fusion. Vorticity field with element positions at* $t = 2.5$ *for* $\alpha = 0.85$ *in the experiment described in* §5.2 *without fusion* (*left*) *and with fusion* (*right*). *The absolute pointwise error between these two fields is less than* 0.06%, *while the problem size has been diminished by a factor of almost* 3.

restricted to the compact set of parameter space described by R, b_1, *and* b_2. *Thus,* $M \equiv M(R, b_1, b_2)$.

To find the value of M, it is not necessary to search the entire space $[0, R] \times [b_1, b_2]$ because further analysis reveals that these maximal values are only attained on two corners of this rectangle in parameter space. This is summarized in the second and final theorem describing these merger estimates.

THEOREM 4.2 (explicit determination of fusion error bound). *If*

$$\left(\frac{|\vec{x}_i|}{2\sigma_0}\right)^2 \leq R$$

and

$$b_1 \leq \left(\frac{\sigma_0}{\sigma_i}\right)^2 \leq b_2,$$

then the absolute maximal value of the uniform fusion error function

$$\exp\left(-|\hat{x}|^2\right) - \frac{\sigma_0^2}{\sigma_i^2} \exp\left[-|\hat{x} - \hat{x}_i|^2 \left(\frac{\sigma_0^2}{\sigma_i^2}\right)\right]$$

is achieved with parameter values of either (R, b_1) *or* (R, b_2). *Furthermore, this absolute maximum is attained when* $\vec{x}$ *is colinear with the origin and* $\vec{x}_i$.

The consequence of these theorems is that any number of same-signed vortex elements can be fused together provided they have sufficiently similar core widths and are in close proximity to each other relative to their core sizes. Furthermore, values of M can be tabulated easily by evaluating the function in Theorem 4.2 at two points. Together, these two results describe a fusion algorithm that can reduce the problem size of a given simulation [16]. Figure 3 presents a demonstration of this reduction for a simulation of two merging patches of vorticity discussed more thoroughly in §5.2.

5. Simulations, measurements, and comparisons. In this section, the new method is used to simulate two different flows. The first flow, a simple vortex patch, has an exact

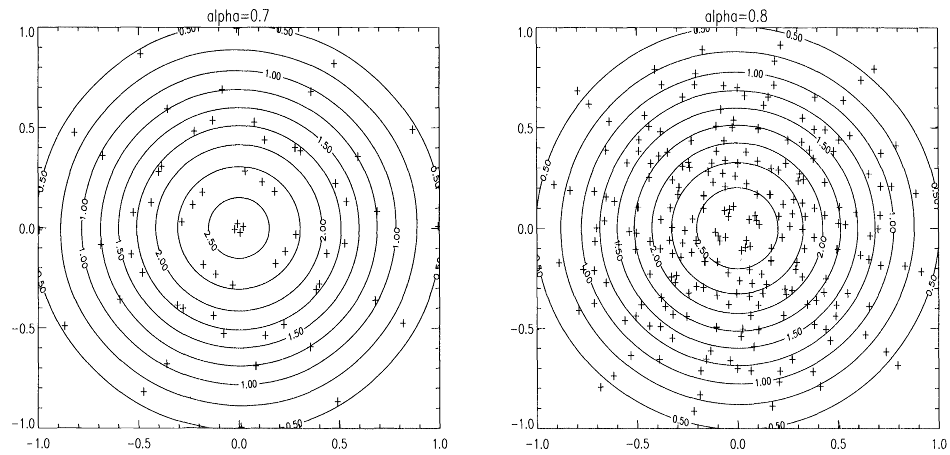

FIG. 4. *Vorticity field of a radially symmetric patch of vorticity with element positions at* $t = 1.0$ *for* $\alpha = 0.7$ *and* $\alpha = 0.8$.

analytic solution, and so can be used for a precise convergence study. Also, it can be argued that generic flows are composed of many simple vortex patches so that its performance in the simpler case can lend insight into its performance in more complicated settings. The second flow is more complicated but is also a good testing ground for a convergence study. As a second measurement of the method's performance, the results of CCSVM are analyzed to see whether or not they conserve certain integral invariants. Finally, one can directly compare CCSVM and RWVM by using them to solve the same problem on the same machine with the same total number of elements. As mentioned in §2.2, CCSVM and RWVM are equivalent in the limit as problem sizes grow infinitely large. However, this is never the case when solving a problem, so it is most meaningful to compare the two methods at moderate problem sizes.

5.1. A radially symmetric spreading patch of vorticity. The first example concerns the evolution of a single Gaussian blob. While seeming simple on the surface, this example could be said to be of fundamental importance because the analytical solution is known. Using this analytical solution, one can measure the uniform field error in numerical simulations to demonstrate the linear uniform convergence estimate from the previous section. Also, this simple example will demonstrate that refinement is a stable and locally adaptive process similar to the local regridding scheme of Hou, Lowengrub, and Shelley [11].

The initial field is expressed by a single vortex element ($\gamma = 5.0$, $\sigma = 0.2$) centered at the origin. The numerical parameter l is fixed at a reasonably small value of 0.25, and α is allowed to vary. The vortex positions and widths were updated using forward Cauchy-Euler with a small enough time step so that no variations in element positions were observed at the resolution of our printer. The flow was simulated with $T = 1$ and a large viscosity, $\nu = 0.1$, so that both convective and diffusive effects would be important. (Indeed, during the course of this simulation, the width of the exact solution nearly doubles.) In Fig. 4, one can see how the vortex elements split and adapt across streamlines to accurately express the solution with a length scale at or below l.

Earlier investigators noted that vortex methods for Euler equations lose accuracy after a finite period of time because flow deviations separate vortex elements until they cease to overlap. Hou, Lowengrub, and Shelley corrected this problem by introducing local regridding wherein vortex elements split under the action of flow deviations. Spreading and splitting provide a similar mechanism though they are dependent upon viscosity. In the uniform error

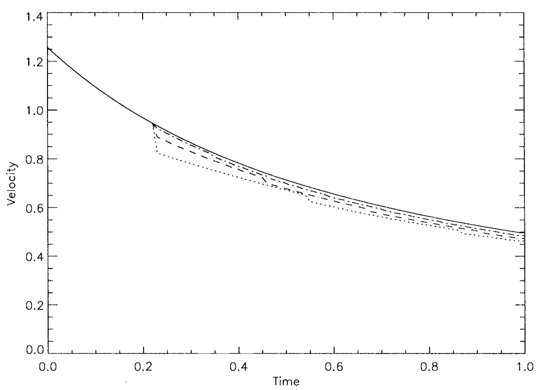

FIG. 5. *Radially symmetric patch of vorticity: velocity field at* (0,0.8) *at* $t = 1.0$ *for* $\alpha = 0.7$ (*dotted*), $\alpha = 0.8$ (*dashed*), $\alpha = 0.9$ (*dot-dashed*) *compared with the exact solution* (*solid*).

estimates of §3, the order of accuracy is actually determined to be $O(\|D\vec{u}\|l) + \ldots$ rather than just $O(l) + \ldots$. Viscosity does not enter into the error estimate because the corrected core spreading method solves the diffusion equation in the moving frame exactly. While $\vec{u}$ is not a numerical parameter it can be determined analytically and used in flow computation. This raises two issues. First, one could augment the adaptive spatial refinement process by allowing l to vary spatially with $D\vec{u}$ like $\|D\vec{u}\|l = \epsilon$ where ϵ is the new convergence parameter. Second, one could use refinement in an Euler code by allowing particles to split based on some measurement of strain during its evolution.

For this experiment, elements split more often and with greater accuracy as α grows larger. While somewhat counterintuitive, velocity measurements in Fig. 5 illustrate this increased accuracy. The refinement events can be seen as jumps in the velocity field. Refinement events begin after $t = 0.225$ because l is significantly larger than the initial core width. As $\alpha \to 1$, these jumps become more frequent but considerably smaller, demonstrating the stability of refinement.

Most importantly, a precise measurement of the uniform field error can be determined relative to the exact solution,

$$\tilde{\omega}(\vec{x}, t) = \frac{5}{4\pi(0.2^2 + 0.1t)} \exp\left(-\frac{|\vec{x}|^2}{4(0.2^2 + 0.1t)}\right). \tag{48}$$

Since l is fixed, one expects a linear profile in $1 - \alpha^2$. In Fig. 6, our results agree with this expectation. Variations at larger values of $1 - \alpha^2$ might be attributed to refinement error.

5.2. Two merging patches of vorticity. The next example is that of two blobs of the same sign placed in close proximity to one another. In the inviscid case, this experiment has been very popular because elements from opposite blobs would intertwine. In the viscous case, the blobs diffuse together at the center of the interaction, but the dynamics are still interesting. Other features of interest are the "tails" which form on the outer rim of the structure after long periods of time. We will illustrate the same concepts as in the first example, for a more challenging problem without an analytical solution. Once again, the initial conditions are simple and the algorithm will allow the problem size to expand to meet consistency requirements. Initially, there are two blobs, each with $\gamma = 5$ and $\sigma = 0.2$. In all simulations, the spatial accuracy is controlled by the parameter $l = 0.2$. (Elements larger than l split.) The elements are placed along the x-axis with a separation of 1.6, and the viscosity is 0.02. For $T = 2.5$, each blob will undergo about one quarter of a rotation about the origin, as seen in Fig. 7.

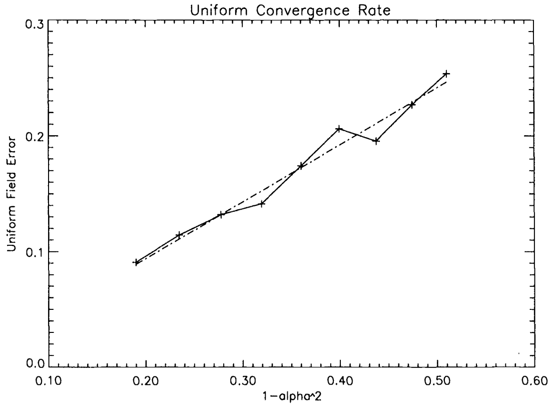

FIG. 6. *Radially symmetric patch of vorticity: uniform field error as a function of* $1 - \alpha^2$ *for* $\alpha = 0.7, 0.725, 0.75, 0.775, 0.8, 0.825, 0.85, 0.875, 0.9$ (*solid*) *and a least-squared linear fit* (*dot-dashed*).

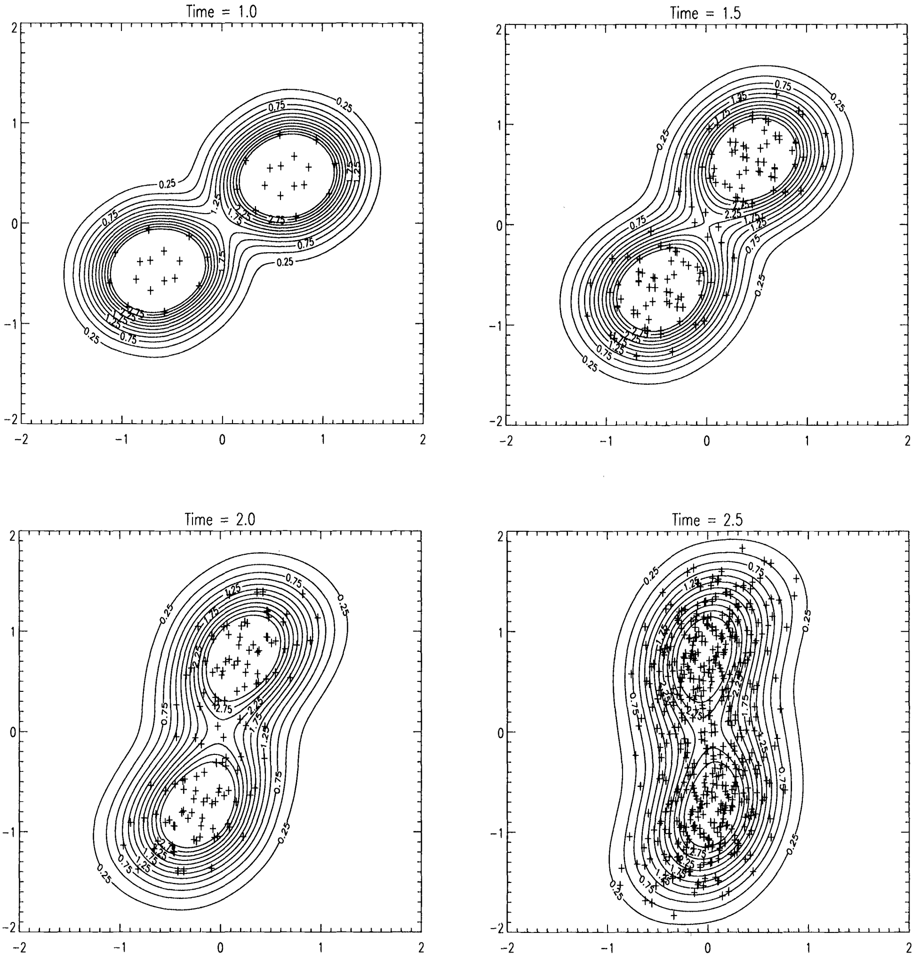

FIG. 7. *Two merging patches of vorticity: vorticity field with element positions at* $t = 1.0, 1.5, 2.0, 2.5$ *for* $\alpha = 0.8$.

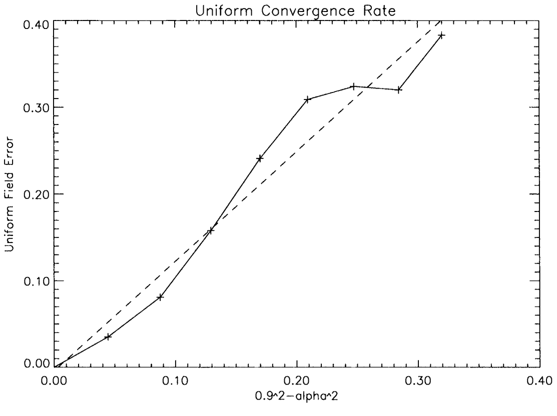

FIG. 8. *Two merging patches of vorticity: uniform field error as a function of* $(0.9)^2 - \alpha^2$ *for* $\alpha = 0.7$, 0.725, 0.75, 0.775, 0.8, 0.825, 0.85, 0.875, 0.9 (*solid*) *and a least-squared linear fit* (*dashed*).

As in the first example, the parameter α controls the relative accuracy of the method. This problem is more challenging because of the lower viscosity, greater flow deviations, and larger T. In Fig. 15 (left side only), it is clear that CCSVM naturally dedicates more elements where the vorticity is greatest. Since there is no analytic solution available, the uniform error is computed relative to the highest accuracy run at $\alpha = 0.9$. Still, the theory predicts a linear convergence in $(0.9)^2 - \alpha^2$ to this reference field and this is observed in Fig. 8.

While no analytic solution for this configuration is known, the dynamics of the second moment of this configuration,

$$\frac{d}{dt}\iint |\vec{x}|^2 \omega d\vec{x} = 4\nu \iint \omega d\vec{x}, \tag{49}$$

can be determined exactly [1]. Since vorticity is conserved, equation (49) has the exact solution

$$\iint |\vec{x}|^2 \omega d\vec{x} = 8 + 0.8t \tag{50}$$

for this particular two-vortex problem. This solution is compared with moments computed from CCSVM computations as a qualitative measurement of its accuracy. Even for the coarser value of $\alpha = 0.7$, the second moment of computed vorticity is difficult to distinguish from the exact value in Fig. 9 without adjusting the y-axis of the plot. Even so, the difference between the exact moment and the computed moment is due to the size of the time step used to advance the vortex positions rather than our method for reducing the Navier–Stokes equations to a finite system of ODEs. There is little difference between the various values of α. However, if the time step is reduced by a factor of 4, the second moments agree better even for the coarse value of $\alpha = 0.7$ (see Fig. 10).

Though this flow is relatively simple, it provides an example of how fusion can drastically improve computational efficiency. A fusion scheme using the principles in §4 will reduce the problem size during the simulation. In Fig. 3, one sees that the final problem size decreases from $N = 2048$ down to $N = 698$ with a very small loss of accuracy for $\alpha = 0.85$. Hence, fusion mediates the exponential growth caused by refinement to yield a very efficient and accurate method.

5.3. A comparative study with RWVM. To measure the strengths and weaknesses of CCSVM as a method for solving flow problems, both CCSVM and RWVM solved the previous problem on the same computer under the same conditions. These two programs are

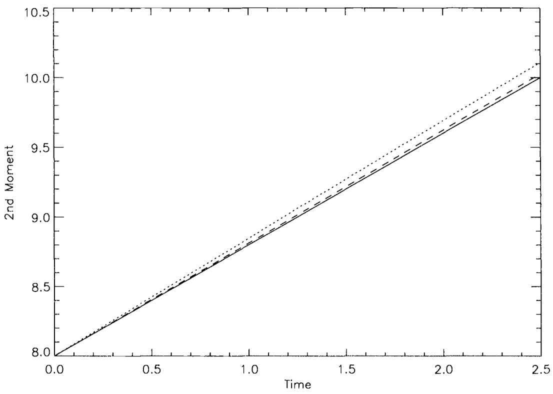

FIG. 9. *Second moment of merging pair at* $\alpha = 0.7$ (*dotted*), 0.8 (*dashed*), *and* 0.9 (*dot-dashed*) *with the exact value* (*solid*).

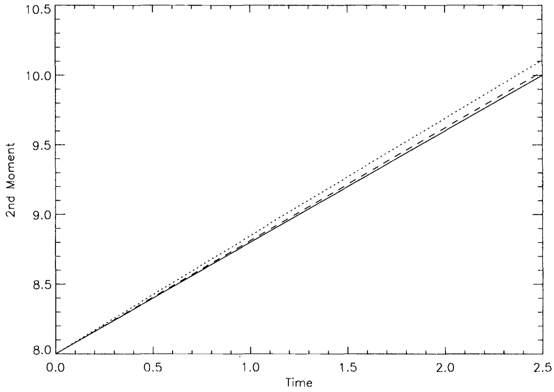

FIG. 10. *Second moment of merging pair at* $\alpha = 0.7$ *and* $\Delta t = 0.005$ (*dotted*) *and* 0.00125 (*dashed*) *with the exact value* (*solid*).

identical except for subroutines handling the diffusion. For CCSVM, elements spread and, if necessary, split. For RWVM, elements undergo random walks. Both programs were compiled with the same compiler settings on a Sparc 2 workstation without any special vectorization or parallelization. (Since both algorithms are fully parallelizable and vectorizable, specialized hardware is not likely to affect the outcome anyway.) Though both methods would have benefited from a fusion algorithm, this might have introduced some uncertainty into the experiment because fusion is geometry- and index-dependent. Thus, neither program used a fusion algorithm. Under these conditions, it was possible to directly compare these two algorithms.

The initial conditions for CCSVM were identical to those of the previous problem. For RWVM, $\frac{N}{2}$ vortex elements of width $l = 0.2$ and circulation $\frac{10}{N}$ were placed at $(0.8, 0)$, and the other $\frac{N}{2}$, having the same circulation and width, were placed at $(-0.8, 0)$. Thus, both methods began with the exact same initial conditions. Since the core sizes were the same, both methods had the same spatial accuracy during the convective step. Indeed, since both methods differed only in how they approximate the diffusive term, it was necessary to hold the core size constant to measure any differences in the methods.

Since the problem size for CCSVM changes with time and the time complexity is $O(N^2)$, a random walk algorithm with size $N = N_0$ should require the same amount of time as CCSVM with α chosen so that $\sqrt{\langle N^2 \rangle} = N_0$, where $\langle N^2 \rangle$ denotes the ensemble average of

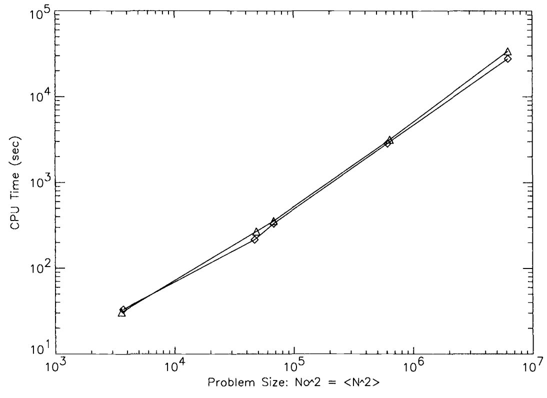

FIG. 11. *Two merging patches of vorticity: comparison of CPU time expended vs. square of problem size for RWVM (triangle) and CCSVM (diamond).*

N^2 over time. As predicted, both methods used about the same amount of computer time for a given problem size. Also, the relationship between N_0^2 and CPU time in Fig. 11 is linear for both methods as expected. If anything, the core spreading methods ran slightly faster, but one can safely say that both methods require roughly the same amount of computational effort.

Both methods conserve the zeroth moment, but only CCSVM conserves the first moment exactly. This is especially evident with smaller problem sizes as in Fig. 12. Using random walks when the problem size is low can result in very unphysical behavior. Even in larger simulations, regions of the flow that are approximated by a low particle density would be strongly affected by statistical noise [21]. Though both methods suffer from time integration errors when measuring their second moment, the random walk method appears to suffer more. Though both methods are convergent, CCSVM converges while conserving these important physical properties which are built into the algorithm. Figure 13 displays first and second moments for relatively large problems sizes.

The final comparison involves measuring the performance of both methods in terms of uniform error as a function of problem size. To eliminate any CCSVM bias, a random walk simulation using a large number of particles ($N = 5000$) was run on a Convex C-120 mini-supercomputer using a small step size ($\Delta t = 0.00125$) and treated as an exact solution for comparison with other data sets. The results, shown in Fig. 14, indicate that CCSVM has slightly better convergence properties than RWVM as measured by the L^∞ norm. For both methods, the accuracy as a function of problem size is similar to that observed by Sethian in his study of random walk vortex method performance while simulating boundary layer instability [17]. Moreover, using the random walk solution, one obtains the predicted $1 - \alpha^2$ linear rate of convergence. Even though both methods appear to indicate the same rate of convergence, CCSVM is more accurate for a given problem size and so produces better results given a fixed amount of computational resources, as can be seen in Fig. 15.

6. Conclusion. This paper introduces and analyzes a new vortex method with many attractive properties. Since both spreading and adaptive spatial refinement are local processes, this method is well suited for vector and parallel computation. These theoretical findings are sufficient to assure application-oriented investigators that certain uniform convergence properties will be achieved. The introduction of the numerical parameter α overshadows the importance of l for viscous computations once l is chosen to resolve given flow features. Finally, the exponential growth in the problem size can be controlled by the fusion process

analyzed in this paper. We demonstrated the accuracy and effectiveness of this method with nontrivial examples and found the results to be reassuring. Among these are measurements of the uniform error in the vorticity field in agreement with the derived theory.

While this paper attempts to analyze some important questions about spreading blob methods, there are still many unexplored areas to study. Only one stable refinement process is discussed in this paper, but many others are possible. Perhaps there is an optimal one in some sense. In proving linear convergence for CCSVM in L^∞, a full nonlinear uniform convergence proof introduces itself as the next challenge to investigators.

Nonetheless, linear convergence is still a useful result. Since uniform convergence of the vorticity field implies uniform convergence of the velocity field, one could view the full nonlinear residual operator as the linear theory R with a small perturbation as numerical parameters approach their limiting values.

Also, Condition A and Condition B can be applied to the convergence of other grid-free and gridded schemes. While these conditions were applied specifically to CCSVM, the general framework can be applied to any numerical method. Together, they form the basis for an alternative convergence theory.

While many investigators have methods for removing extraneous vortex elements from a simulation, fusion is a general, well-defined method for controlling the problem size. Maintaining efficient problem sizes during a vortex simulation is crucial because the natural action of viscosity is to increase the problem regardless of the method used. Furthermore, if one extends this work to bounded flows, vorticity will be shed from boundaries into the flow to satisfy the no-slip condition, increasing the problem size even more. Fusion is a natural way to recombine redundant elements while conserving several moments. Even without viscosity, Hou, Lowengrub, and Shelley have demonstrated the importance of splitting vortex elements to prevent the method from losing accuracy in finite time. As mentioned earlier in §5, it may be possible to adapt refinement to inviscid flows by computing flow deviations.

Acknowledgments. I would like to thank my advisor, Bruce Bayly, for suggesting this problem and giving me the freedom to pursue it. Also, I would like to acknowledge his friendship, advice, encouragement, and support. Furthermore, I revised this paper with the assistance of English Professor Thomas Miller during his fantastic Advanced Technical Writing Seminar, a summer course which proved to be an invaluable resource. The majority of the work in this paper was done at the University of Arizona's Program in Applied Mathematics.

FAST FOURIER TRANSFORM ACCELERATED FAST MULTIPOLE ALGORITHM*

WILLIAM D. ELLIOTT† AND JOHN A. BOARD, JR.†

Abstract. This paper describes an $\mathcal{O}(p^2 \log_2(p)N)$ implementation of the fast multipole algorithm (FMA) for N-body simulations. This method of computing the FMA is faster than the original, which is $\mathcal{O}(p^4N)$, where p is the number of terms retained in the truncated multipole expansion representation of the potential field of a collection of charged particles. The p term determines the accuracy of the calculation. The limiting $\mathcal{O}(p^4)$ computation in the original FMA is a convolution-like operation on a matrix of multipole coefficients. This paper describes the implementation details of a conversion of this limiting computation to linear convolution, which is then computed in the Fourier domain using the fast Fourier transform (FFT), based on a method originally outlined by Greengard and Rokhlin. In addition, this paper describes a new block decomposition of the multipole expansion data that provides numerical stability and efficient computation. The resulting $\mathcal{O}(p^2 \log_2(p))$ subroutine has a speedup of 2 on a sequential processor over the original method for $p = 8$, and a speedup of 4 for $p = 16$. The new subroutine vectorizes well and has a speedup of 3 on a vector processor at $p = 8$ and a speedup of 6 at $p = 16$.

1. Introduction. The Greengard–Rokhlin fast multipole algorithm (FMA) [6, 9] is an efficient and inherently parallel algorithm for computing the Coulomb (electrostatic) or Newtonian (gravitational) potential and forces in many-particle systems. The FMA is an $\mathcal{O}(N)$ solution to the N-body problem, which is a significant improvement in performance over the simpler but costly $\mathcal{O}(N^2)$ method of directly computing the potentials and forces between all pairwise combinations of particles. Applications of the FMA include simulations of molecular dynamics, astrophysical processes, and fluid dynamics, and many parallel implementations have been reported [1, 3, 4, 5, 7, 8, 13, 15, 16].

This paper describes an improvement to the FMA that applies to implementations on sequential or parallel machines. The improvement is a speedup of the limiting subroutine in the FMA by converting the computation to the Fourier domain, as described originally by Greengard and Rokhlin [10]. The speedup also applies to related algorithms, such as that of Barnes and Hut [2], when these are extended to include many terms in the multipole expansions.

Section 2 of the paper gives a brief overview of the FMA and describes the limiting multipole computation. Section 3 describes converting the limiting computation to the Fourier domain. To ensure a numerically stable and efficient computation, several optimizations are required on the basic Fourier domain computation; these improvements are described in §4. Section 5 reports results of running the FFT algorithm on a RISC processor and on a vector supercomputer.

2. Overview of the FMA. The FMA is described in detail in [6]. We use the language of electrostatics for our development, because electrostatic applications (such as molecular dynamics simulations) particularly benefit from the work herein (see §6). The algorithm begins with a hierarchical spatial decomposition of the computational cube that contains the particles

of interest into successively smaller cells. Each cell is split into eight child cells, allowing a hierarchical oct-tree representation of the simulation region. With a uniform distribution of charged particles, a uniform oct-tree is produced; the uniform case is assumed for this paper. Adaptive variants of the FMA exist for nonuniform particle distributions [5], and the FFT methods developed here apply equally to that case.

To improve the efficiency of the potential and force calculations, the FMA replaces most of the particle-to-particle interactions with cell-to-cell interactions by first representing the aggregate potential field of a group of charges in a cell with an equivalent multipole expansion. Interactions between cells are then computed by manipulating the coefficients of multipole expansions.

Multipole expansions corresponding to the cells at the lowest level of spatial decomposition (the leaf nodes of the oct-tree) are computed via (1). For a given leaf cell containing k particles, the position of the ith particle is given in spherical coordinates by $(\rho_i, \alpha_i, \beta_i)$. $\Phi(\mathbf{r})$ represents the aggregate potential field due to all k particles at any point $\mathbf{r} = (r, \theta, \phi)$ outside the given cell.The infinite multipole expansion describes the potential field exactly. The series is summed over the defined range of the order l $(0 \leq l \leq \infty)$ and degree m $(-l \leq m \leq l)$ of the spherical harmonic function $Y_l^m(\theta, \phi)$.[1] Outside this allowed range of values for l and m, Y_l^m is taken to be zero.

$$\Phi(\mathbf{r}) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \frac{M_l^m}{r^{l+1}} Y_l^m(\theta, \phi), \tag{1}$$

$$M_l^m = \sum_{i=1}^{k} q_i \rho_i^l Y_l^{*m}(\alpha_i, \beta_i). \tag{2}$$

The FMA next computes multipole expansions for all cells higher up the tree at all levels by translating the origins of the multipole expansions of the eight child cells of each parent cell to the center of the parent cell using a multipole-to-multipole (M2M) translation in an upward pass through the oct-tree.

We say that two cells A and B from the same or adjacent levels of the tree are *well separated* if they are sufficiently far apart so that the multipole series of A converges fairly rapidly at the center of B. Pragmatically, A and B are separated by at least two cell widths. Once all multipole expansions are computed at all levels, well-separated cells interact by multipole-to-local (M2L) translation. In M2L, a local Taylor series expansion of the cell A potential is formed, centered on cell B, to evaluate the potential at the particle sites in B due to all the particles in A. As B interacts with other well-separated cells, the results are accumulated into a single local (Taylor) series. During the downward pass of the algorithm, parents pass the Taylor series representing their far-field interactions to each of their children using local-to-local (L2L) translation; the series is recentered in each child box.

Although computing the cell-to-cell interactions is a complicated procedure compared with the simpler particle-to-particle $\frac{1}{r}$ computation, for a simulation with a large enough number of particles, the multipole-based cell-to-cell interactions will run faster. For details on the FMA, the reader is directed to [1, 3, 5, 7, 8, 13, 15, 16].

This paper will focus on the mathematics of the three cell-to-cell translations (M2M, M2L, and L2L), depicted in Figure 1. In particular, the M2L interaction between well-separated cells will be discussed because it is the performance limiting subroutine in the FMA computations.

[1] Consistent with Greengard and Rokhlin's notation [6], the spherical harmonic functions Y_l^m in this paper omit the standard normalization factor $\sqrt{(2l+1)/4\pi}$.

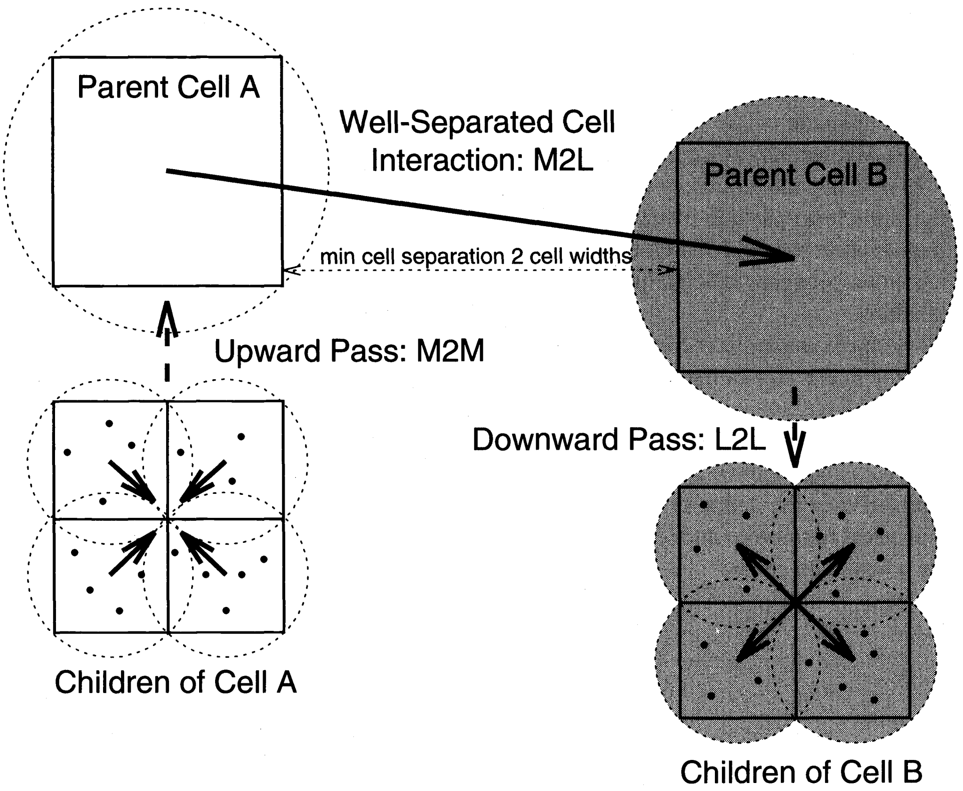

FIG. 1. *FMA multipole expansion translations. The children of cell A use the* M2M *translation to shift to the center of cell A the multipole expansions representing the far-field potential of the particles contained in them. The* M2L *translation allows well-separated cells to interact by creating a local (Taylor) series expansion of the far-field potential of distant cell A around the center of cell B. Using the* L2L *translation, cell B in turn shifts the center of the local expansion to the center of each of its children.*

2.1. Contribution to the FMA runtime of the M2L subroutine. In the FMA, the M2L translation, which is the interaction between well-separated cells, consumes the most runtime. The M2L subroutine dominates the runtime due to the number of cells in the oct-tree and the number of distant cells with which each cell must interact. If level 0 is the original simulation space, each level L of spatial decomposition creates 8^L new cells. The interaction list of each cell i contains all well-separated cells that have not already appeared in the interaction lists of i's parent. (The exact rule for assigning interaction lists is somewhat more complex; see [6].) Using a well-separated criteria of two cell widths puts as many as 189 peer-level and parent-level cells in the interaction list of any cell [16]. Figure 2 shows the total number of M2L interactions (or equivalently, calls to the M2L subroutine) at each level of spatial decomposition in the FMA. In contrast to the "horizontal" M2L interactions, the M2M and L2L translations are "vertical" between parent and children only, and thus are performed eight times at most for each cell. Although the M2L, M2M, and L2L routines have a similar runtime cost per call, the large number of M2L interactions causes that subroutine to dominate the FMA runtime.

Multipole expansions and the three translation operations acting on them in the FMA are exact in the limit of an infinite series. When truncated to a finite number of terms p, the relative error in the potential is bounded above by $(\frac{1}{2})^p$ as Greengard and Rokhlin proved [6].

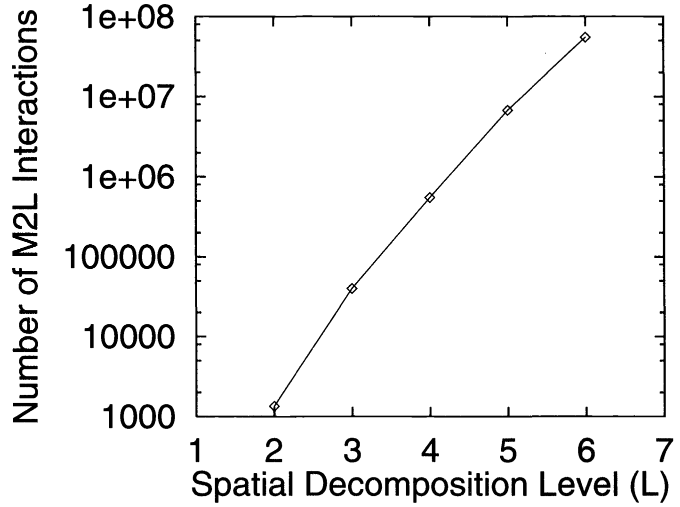

FIG. 2. M2L *interactions in the FMA. The plot shows the rapid growth in the number of* M2L *interactions, measured by the number of calls to the* M2L *subroutine, as the level of spatial decomposition increases to accommodate more particles.*

In practice, p is the linear dimension of a 2-D matrix of multipole expansion coefficients; there are a total of p^2 terms in the matrix. Each interaction between a pair of cells in the FMA requires the translation of the origin of a series representation of the electrostatic field; this in turn requires a double summation over all terms of the input multipole expansion coefficient matrix multiplied with a corresponding term in a weighting function matrix to produce each term in the output coefficient matrix (see (4) below). These operations yield $\mathcal{O}(p^4)$ complexity for the series translations.[2] These translations resemble 2-D discrete convolution, which is also $\mathcal{O}(p^4)$. The complexity of the operations on the multipole expansions, combined with the requirement to perform a large number of M2L translations for each cell, causes that part of the FMA to dominate the runtime over the accuracy range (values of p) of interest for molecular dynamics.

3. Conversion to Fourier domain. The convolution-like form of the computation and the expense of the M2L translation motivate the conversion of the operation to the Fourier domain using a 2-D FFT. In a technical report, Greengard and Rokhlin [10] described an FFT conversion of the FMA. Schmidt and Lee [15] anticipated an FFT conversion of the FMA as an optimization. Pan, Reif, and Tate [14] described a theoretical parallelized algorithm based on Greengard and Rokhlin's FFT conversion that could further improve the runtime of such an algorithm when parallelized. Here we describe the implementation considerations and performance of the FFT version of the FMA implemented in an existing version of FMA code developed by Board and Leathrum [4, 12]. To our knowledge this is the first published version of the implementation details of an FFT version of the FMA.

3.1. Description of the M2L translation. The M2L translation from a distant cell A to a local cell B, see (3), simultaneously translates the origin O of a truncated multipole expansion describing the potential field due to the particles in A to a new origin at point $O' = (\rho, \alpha, \beta)$ at the center of B and converts that expansion to a local Taylor series expansion about the new

[2] Greengard and Rokhlin have reported a method that takes advantage of symmetry to reduce many of the translations to $\mathcal{O}(p^2)$ [11].

origin:

$$\Phi(\mathbf{r}) = \Phi'(\mathbf{r}') = \sum_{l=0}^{p-1} \sum_{m=-l}^{l} \mathbf{M}_l^m \frac{Y_l^m(\theta, \phi)}{r^{l+1}} = \sum_{l'=0}^{p-1} \sum_{m'=-l'}^{l'} \mathbf{L}_{l'}^{m'} Y_{l'}^{m'}(\theta', \phi') r'^{l'}. \tag{3}$$

Within the error bound described in §2.1, the local expansion of the potential field at any arbitrary point (r', θ', ϕ') with respect to the new origin O' gives the same value for the potential due to A as the multipole expansion evaluated at the same point (r, θ, ϕ) described with respect to the old origin O, provided series convergence criteria are met. Cells from the same level of the tree separated by at least two cell-widths meet the series convergence criteria. Since the location of the evaluation point of the potential is arbitrary as far as the M2L translation is concerned, the translation can be viewed as an operation on only the coefficients of the input matrix of multipole expansion coefficients $\mathbf{M}_l^m$, using a matrix of translation coefficients $\mathbf{T}_{l,m,l',m'}^{M2L}$ as a weighting function, resulting in an output matrix of local expansion coefficients $\mathbf{L}_l^m$ as shown in (4) (using the notation of Schmidt and Lee [15]):

$$\mathbf{L}_{l'}^{m'} = \sum_{l,m} \mathbf{T}_{l,m,l',m'}^{M2L} \mathbf{M}_l^m, \tag{4}$$

$$\mathbf{T}_{l,m,l',m'}^{M2L} = \frac{(-1)^{l'+m} A_l^m A_{l'}^{m'}}{A_{l'+l}^{m'-m}} \frac{Y_{l'+l}^{*m'-m}(\alpha, \beta)}{\rho^{l'+l+1}}, \tag{5}$$

$$A_l^m = \frac{(-1)^{l+m}}{\sqrt{(l+m)!(l-m)!}}. \tag{6}$$

These input, output, and translation coefficient matrices are approximately half-filled, since the coefficients are zero outside the allowed range of l and m, where l is a nonnegative integer and $-l <= m <= l$. The spherical harmonic function $Y_l^m(\theta, \phi)$ equals zero for index values outside of this range.

3.2. Converting M2L to convolution form. Double summation over an input coefficient matrix multiplied by a weighting matrix resembles convolution. In fact the M2L computation resembles linear convolution with what can be considered a 4-D weighting function matrix $\mathbf{T}_{l,m,l',m'}^{M2L}$; the four dimensions are l, m, l', and m'. In order to reduce the complexity, weighting coefficients are needed that are not a function of all four indices but are a function only of the difference between the corresponding indices $l' - l$ and $m' - m$. In that case, the computation would be a convolution of the 2-D input coefficient matrix with a 2-D transfer function matrix we will call $\mathbf{H}_l^m$.

3.3. Warping the coefficients with the A_l^m function. Equations (7) and (8) show the 2-D transfer function $\mathbf{H}_l^m$ created by moving to the left side of (4) the terms of $\mathbf{T}_{l,m,l',m'}^{M2L}$ that depend on only l' and m' and grouping with $\mathbf{M}_l^m$ the terms that depend on only l and m. The result "warps" the input coefficient matrix with the A_l^m normalization function and produces a warped output coefficient matrix.[3] Of course, the output values must be unwarped with the A_l^m function before computing any potentials, but by using warped values, the double summation of input coefficients multiplied by transfer function coefficients is a 2-D linear convolution operation. We have

$$\left[(-1)^{-l'} \frac{\mathbf{L}_{-l'}^{m'}}{A_{-l'}^{m'}}\right] = \sum_{l,m} \left[\mathbf{H}_{-(l'-l)}^{m'-m}\right] \left[(-1)^m \mathbf{M}_l^m A_l^m\right], \tag{7}$$

[3] The A_l^m function used here differs slightly from that of Greengard and Rokhlin [6, 9].

$$[\mathbf{H}_l^m] = \frac{Y_l^{*m}(\alpha, \beta)}{A_l^m \rho^{l+1}}. \tag{8}$$

The equation in this form can be computed more quickly in the Fourier domain using the FFT of the respective matrices, as shown in (9)-(13). Defining the "warped" functions $y(l, m)$, $h(l, m)$, and $x(l, m)$, we perform the convolution computation $h \circledast x$ in the Fourier domain by element-by-element multiplication of the matrices $H(\omega_{-l}, \omega_m)$ and $X(\omega_l, \omega_m)$, resulting in the output matrix Fourier space matrix $Y(\omega_{-l}, \omega_m)$. The 2-D FFT of the coefficient matrices has a complexity $\mathcal{O}(p^2 \log_2(p))$, and the element-by-element multiplication of matrix elements has a complexity $\mathcal{O}(p^2)$. We have

$$y(l, m) = \left[(-1)^l \frac{\mathbf{L}_l^m}{A_l^m}\right], \tag{9}$$

$$h(l, m) = [\mathbf{H}_l^m] = \frac{Y_l^{*m}(\alpha, \beta)}{A_l^m \rho^{l+1}}, \tag{10}$$

$$x(l, m) = [(-1)^m \mathbf{M}_l^m A_l^m], \tag{11}$$

$$y(-l', m') = \sum_{l,m} h(-(l' - l), m' - m) x(l, m) = h(-l', m') \circledast x(l', m'). \tag{12}$$

With the equation in convolution form, the distinction between primed and unprimed values of l and m disappears, and the M2L translation can be done in the Fourier domain. We have

$$y(-l, m) = h(-l, m) \circledast x(l, m) \leftrightarrow Y(\omega_{-l}, \omega_m) = H(\omega_{-l}, \omega_m) X(\omega_l, \omega_m). \tag{13}$$

The $-l$ terms in the transfer function H and the output Y affect the alignment of those matrices in coefficient space. Specifically, the transfer function matrix and the output matrix both will be aligned with the input matrix in the m direction but reversed in the l direction. The FFT versions of the M2M and L2L translations, shown in the Appendix, are similar to the M2L equations.

4. Implementation considerations and enhancements. While the mathematics of §3 appear complete, there are several modifications required for actual computation of the FFT version of the M2L to achieve correctness and numerical stability. Also, to run efficiently enough to outperform the conventional method of calculating the M2L interaction at low p values, several optimizations are necessary. This section describes the modifications necessary for a correct and efficient implementation.

4.1. Linear convolution from FFT circular convolution. Computing the M2L translation in Fourier space using (13) introduces two side effects that do not occur in the original coefficient-space computation (3). First, to get the required linear convolution from FFT circular convolution requires zero padding, which increases the complexity of the computation. Nominally, zero padding will result in an FFT matrix of size $4p \times 2p$. $4p$ places are required in the m direction because the coefficients range from $m = -(p - 1)$ to $(p - 1)$ (including 0) at the widest point and from $l = 0$ to $(p - 1)$ at the highest point. The second side effect occurs when FFT convolution produces nonzero coefficients outside the allowed range of l and m ($l \geq 0$ and $|m| \leq l$); while the FFT method computes values over the full $4p \times 2p$ matrix, the conventional coefficient-space computation of the M2L translation needs to sum only over the allow ranges of l, m, l', and m'.

One problem associated with these side effects is the increase in runtime complexity of the computation. To illustrate, the FFT of an $N \times M$ matrix requires $\frac{NM}{2}(\log_2 N + \log_2 M)$ multiplications of complex numbers. For the zero padded $4p \times 2p$ matrix, then, the number of complex multiplications is $4p^2(2\log_2 p + 3)$ for each matrix. After the FFT, the element-by-element matrix multiplication requires $8p^2$ complex multiplications. In contrast, it can be shown that the original coefficient-space M2L computation requires $\frac{p^4+4p^3+5p^2+2p}{12}$ complex multiplications. The problem arises because typical values of p are low ($p \leq 16$), and the coefficient-space computations for those p values are less than the equivalent FFT computations using the full $4p \times 2p$ matrix.

Fortunately, half of the zero padding can be eliminated as follows. The wrap-around effect of FFT circular convolution in the m direction of an array $2p$ wide affects only those values that are outside of the allowed range of l and m anyway, allowing the FFT matrix to shrink down to $2p \times 2p$, which eliminates half of the zero padding in the m direction and still gives correct results. Furthermore, the 1-D FFT in the m direction contains significant redundancies due to the following relationships among the values of the coefficients with respect to m:

$$(14) \qquad M_l^{-m} = (-1)^m M_l^{*m}, \quad L_l^{-m} = (-1)^m L_l^{*m}.$$

This relationship applies to the multipole expansion coefficients and to the local expansion coefficients as well as the spherical harmonic function:

$$(15) \qquad Y_l^{-m}(\theta, \phi) = (-1)^m Y_l^{*m}(\theta, \phi).$$

When converted to the Fourier domain, this relationship results in half of the 1-D FFT coefficients in the m direction being equal to the complex conjugates of the other half. Significantly, this relationship holds even for the $2p \times 2p$ coefficient matrix described above subject to the wrap-around effect of circular convolution. Thus, one half of the FFT array in the m direction contains all of the information about the multipole expansion or local expansion coefficients. Therefore, only half the array need be computed and stored, saving memory and runtime. The values of the unused half of the Fourier-space array are needed only implicitly and only during the FFT and inverse FFT operations. With most of the zero padding in the m direction eliminated and redundant terms unstored, all of the information in the FFT matrix can be stored in a $p \times 2p$ block. All the zero padding in the l direction is still required.

Another problem arising from the side effects of FFT convolution is the need to zero out coefficients outside of the allowed range of l and m after the M2L translation is computed. This prevents the full FMA from being computed entirely in Fourier space. This situation does not occur in the coefficient-space computation because $Y_l^m(\theta, \phi)$ equals zero outside of the allowed values of l and m, a property which has the effect of zeroing out M2L output coefficients values with indices outside of this range. In practice, the coefficient-space method of computing the M2L translation requires summation only over the allowed range of l, m, l', and m'. However, a convolution of the multipole expansion coefficients computed in Fourier space does not include any consultation with a spherical harmonic function, and therefore does not restrict values in that way. Rather, the convolution "smears" the coefficient matrices, resulting in an output coefficient matrix that contains many nonzero values outside the allowable range of l and m. Figure 3 diagrams the smearing effect of convolving an input coefficient matrix with a transfer function matrix both containing values for $l = 0$ to 3 and $m = -l$ to l with l running in the vertical direction and m running in the horizontal direction. Any further convolution on the output matrix, to perform an L2L translation, for example (the next step of the FMA algorithm following M2L), will give incorrect values unless the nonzero coefficients at the out-of-bounds values of l and m are eliminated.

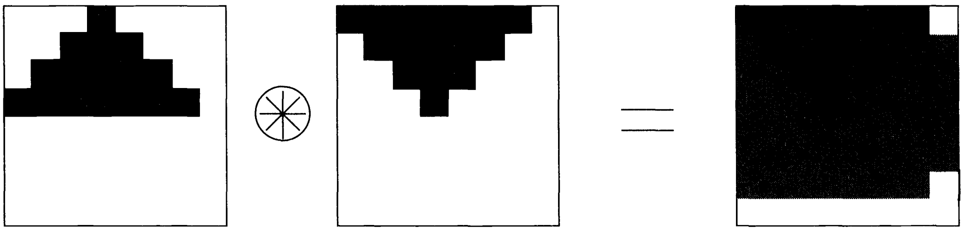

FIG. 3. *Convolution produces nonzero coefficients outside the allowed range of l and m. The figure shows input and output matrices for the* M2L *computation for $p = 4$ with the l values running in the vertical direction and the m values running in the horizontal direction. The dark regions show the nonzero values of the multipole expansion coefficient matrix and the transfer function matrix. In the output matrix, the dark regions show the locations of the desired data, within the allowed range of l and m, and the shaded regions show locations of nonzero values resulting from convolution that must be cleared.*

To zero out the coefficients where $l < 0$ or $|m| \geq l$, an element-by-element multiplication of the M2L coefficient-space output matrix with a mask matrix is required as follows:

$$\text{mask}(l, m) = \begin{cases} 1 & l \geq 0 \text{ and } -l \leq m \leq l, \\ 0 & \text{otherwise.} \end{cases} \tag{16}$$

Although this can be done in either coefficient space or Fourier space, it is much less expensive to do in coefficient space. This is because the operation is a direct multiplication of matrix elements in coefficient space but it is a convolution between the FFT of the above mask and the FFT of the matrix to be corrected. Incurring the overhead of converting out of Fourier space, multiplying and converting back to Fourier space is less expensive than convolving in Fourier space. This situation mirrors the reason for converting the M2L operation into Fourier space to start with, namely to avoid explicit convolution. The net result of the smearing effect of FFT convolution is that an inverse FFT (IFFT) must be performed on the M2L results prior to going on to perform L2L in Fourier space. In general, if all three operations, M2M, M2L, and L2L, are to be performed in Fourier space, an IFFT/multiply/FFT sequence must be performed between translations.

Although the coefficients must come out of Fourier space between translations to zero out the out-of-bounds coefficients, the results of each of the large number of M2L translations can be accumulated in Fourier space without any intermediate IFFT operations. This is important and valuable since the M2L is the most time-consuming portion of the FMA, and the repetition and accumulation reduces the overhead of converting the input multipole expansion coefficient matrix in and out of Fourier space to a small fraction of the M2L runtime. The transfer function matrix still requires an FFT for each M2L computation.

4.2. Numerical instability. Another difficulty in implementing the FFT version of the FMA is the numerical instability problem observed by Greengard and Rokhlin [10]. This instability comes from two sources. The first source is the nature of the warping operation on the multipole expansion and local expansion coefficients. These coefficients are warped with the A_l^m function, which ranges in magnitude from 1.0 to roughly $1/\sqrt{(2p)!}$. Thus, even for modest values of p, the range of magnitudes of values in the warped coefficient matrix exceeds the machine precision using double precision floating point numbers. The other source of instability arises when the dimensions of the problem are not scaled properly. The range of magnitudes due to r^n terms in the multipole expansion coefficients and the $1/\rho^n$ terms in the transfer function coefficients will cause numerical instability unless the dimensions in the problem are scaled to roughly within an order of magnitude of 1.0. Because the FFT operation produces a matrix of Fourier-space values that are linear combinations of the corresponding coefficient-space matrix values, combining input matrix values, which vary in magnitude, loses much of the information contained in the small magnitude numbers.

To make the algorithm numerically stable, Greengard and Rokhlin suggested a polynomial scaling scheme or a block decomposition of the coefficient matrices, and they implemented the polynomial scaling scheme. They reported comparable errors for the FFT and original versions of the FMA at $p = 8$ with single precision.

We implemented a block decomposition of the data for numerical stability and produced identical results to coefficient space computation out to $p = 32$ at double precision. We found that the block decomposition scheme provided many advantages including making the algorithms less sensitive to scaling and providing a speedup in performance by tailoring the size of the matrices to the nonzero values as described in the next section.

Block decomposition of the coefficient matrices in the l direction groups together coefficient values of proximate magnitude. This reduces the range of magnitudes input into the FFT function but requires several separate multiplications of matrix elements for each block. In other words, the block decomposition results in a large-grain convolution at the level of the coefficient blocks. In our implementation we selected a granularity of eight terms in the l direction (four coefficient terms and four zeros for padding) for each block to achieve a power of 2 for FFT efficiency and to reduce the numerical instability problems while keeping a large enough block size to minimize the block-level convolution. Figure 4 shows block-level decomposition for an example where $p = 16$. Each input block and transfer function block contains four rows of coefficients and four rows of zero padding. In the output blocks the smearing effect of convolution produces seven rows of useful data in the output blocks, except in the $l = 0$ to three block. We have demonstrated that this level of block decomposition of the coefficient matrices controls the numerical instability out to at least $p = 32$ for double precision data.

To demonstrate the numerical stability of the block decomposition scheme, we set up an experiment to compute the M2L translation between the two cells shown in Figure 5 with and without block decomposition at various scaling values, and we compared the results with coefficient-space computation. Each spherical, unit-radius cell contains 100 uniformly distributed particles. Each particle has a charge of -1.0 or 1.0, and the two values of charge occur with equal probability among the particles. The cell centers are separated by a distance of 4.0 along the vector $\vec{\rho}$, which leaves a cell diameter separation between the two cells. Because of the spherical symmetry, the results are essentially independent of the values of α and β. The results are shown in Figures 6 and 7 at single and double precision. The potential error for the N particles in cell B was computed by using (17) to compare the local expansion potential $\Phi^{\mathrm{B,local}}$ with the direct particle-to-particle potential Φ^{direct} computed at double precision. The theoretical worst-case error shown in the plots for this geometry is $\left(\frac{1}{2}\right)^p$. We have

$$\text{(17)} \qquad \text{Error} = \left(\frac{\sum_{i=1}^{N} (\Phi_i^{\mathrm{direct}} - \Phi_i^{\mathrm{B,local}})^2}{\sum_{i=1}^{N} (\Phi_i^{\mathrm{direct}})^2} \right)^{\frac{1}{2}} .$$

The s values in the plots indicate the values at which the dimensions of the cell and particle positions in Figure 5 were scaled. The scaling values were selected as powers of 2 in order to reflect the relative dimensions of cells encountered in the spatial decomposition of the FMA simulations region; at each level of decomposition, cells are cut in half in the x, y, and z directions to create eight child cells in the next level.

The single precision results with no block decomposition in Figure 6 show the polynomial scaling effect described by Greengard and Rokhlin [6, 9]. A scaling factor of 2–4 provides stability out to $p = 16$ by offsetting to some extent the $1/\sqrt{(2p)!}$ warping function with s^p

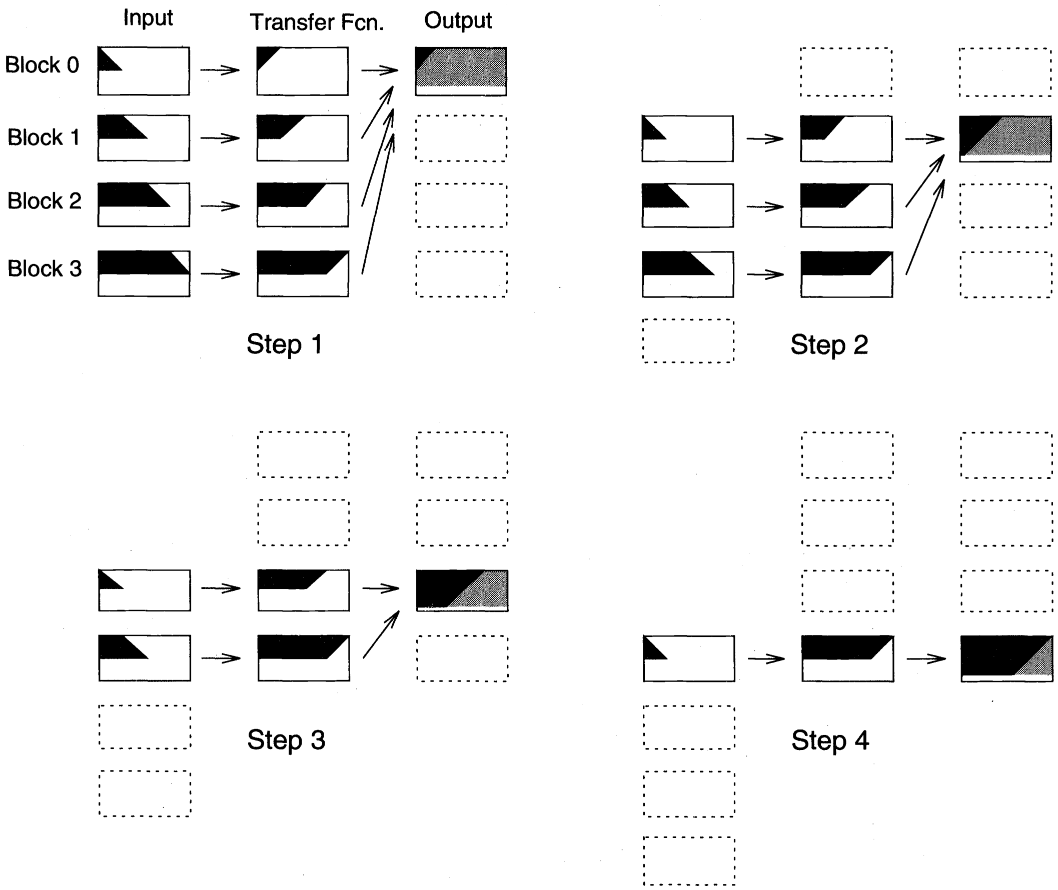

FIG. 4. *Large-grain convolution at the FFT block level. In this example* $p = 16$, *so decomposition of the coefficients into four blocks is required for numerical stability. Each input and transfer function block contains four rows of nonzero data corresponding to four* l *values. Only half of the coefficients are required in the* m *direction. The output blocks contain seven rows of useful data (except for block* 0) *plus some nonzero values shown in the shaded regions which are outside the allowed range of* l *and* m.

The block decomposition scheme provides stability over a wide range of geometry scales.*

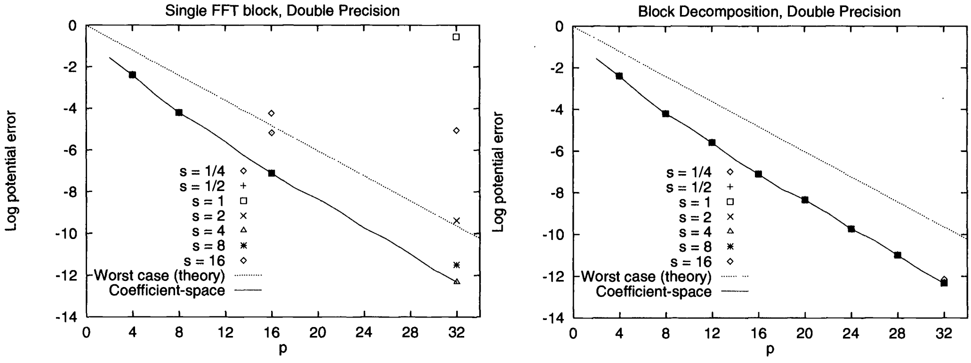

FIG. 7. *Results of the numerical stability experiment at double precision comparing the single block FFT computation of* M2L *(left) to the block decomposition scheme (right) with block size* 8. *Similar to the results in the previous figure, the block decomposition scheme provides stability over a wide range of geometry scales.*

polynomial scaling. The block decomposition method, on the other hand, is less sensitive to the scale of the geometry of the cells and particles and provides better stability over a wide range of scaling factors. Similarly, for the double precision case, the single block FFT provided stability when the geometries are carefully scaled, while the block decomposition FFT was stable over a wide range of scales. This block decomposition method thus allows all FMA translations to be computed at the scale determined by spatial decomposition, without rescaling each set of interactions.

4.3. More efficient block decomposition. In addition to improving the numerical stability, block decomposition provides a speedup opportunity due to the sparsity of the first few FFT array blocks. For example, in Figure 4, block 0 of the transfer function convolves only with input block 0. Both of these blocks could be as small as four units in width and when convolved together would still give the correct value of their contribution to output block 0. However, since block 0 of the input also convolves with the rest of the transfer function blocks, its width must be the full size p, which is 16 in the example of Figure 4. Block 0 of the transfer function, on the other hand, can be handled as if it is only four units wide, which is equivalent to making periodic replicas of the nonzero values of the transfer function block in the width of the full-size block.

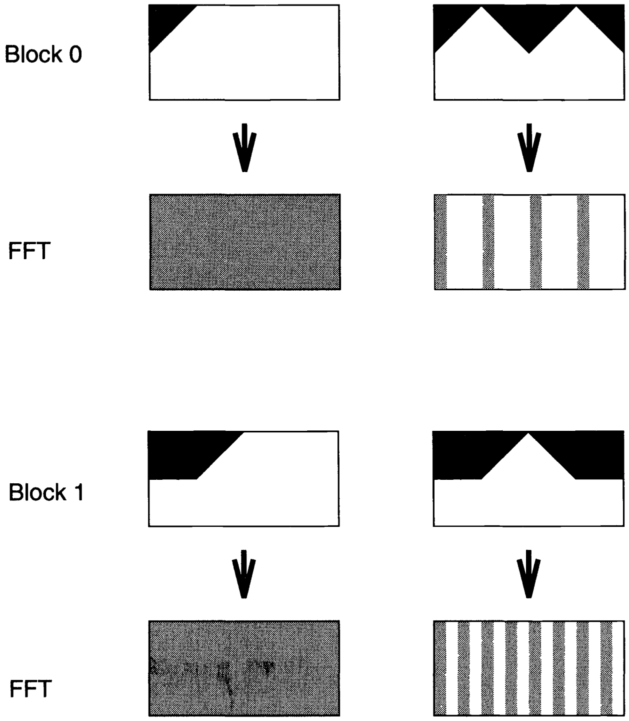

FIG. 8. *Simplifying the FFT of transfer function blocks. Blocks* 0 *and* 1 *from Figure* 5 *shown here handled as containing periodic replicas in the m direction to reduce the data required in the Fourier domain. Shaded areas of the Fourier transformed blocks show the locations of nonzero values.*

The advantage to modifying the effective transfer function block widths is in the Fourier transform of the block. As Figure 8 shows, the FFT of a function that is periodic in the m direction with a period that is a multiple of the FFT array length simplifies the FFT computation and produces fewer nonzero values for the subsequent matrix multiplication with the input blocks. Block 1 from Figure 4 can be treated in a similar fashion.

This modification to the transfer function block sizes improves the runtime of the FMA, because for each call to the M2L subroutine the transfer function is computed, transformed to the Fourier domain, and multiplied with a multipole expansion coefficient matrix. Shortening the effective width of the first few transfer function blocks lowers the computation count of the Fourier transforms and matrix multiplications involving those blocks.

The improved efficiency of the block decomposition method is clear from studying the operation count. Consider again the block decomposition in Figure 4 with $p = 16$. As described in §4.1, the fundamental size of the FFT matrix is $2p \times 2p$, although, because of the redundancy of the data in the m direction, only $p \times 2p$ are required for the matrix multiplication. The full width of the matrices in the m direction are required implicitly during FFT/IFFT operations, but only half of the matrices need to be stored. Furthermore, some of the blocks can be shortened (in Figure 4 the blocks 0 and 1) resulting in storage requirements diagrammed in Figure 9.

To analyze the operation count of the two principal computations in the M2L interaction, we consider the blocks to be twice their stored m direction width for the FFT, but equal to the stored width for the matrix multiplication. Since the full array is required in the m direction for the FFT, the nonstored values must be recovered from the stored values. Each block in

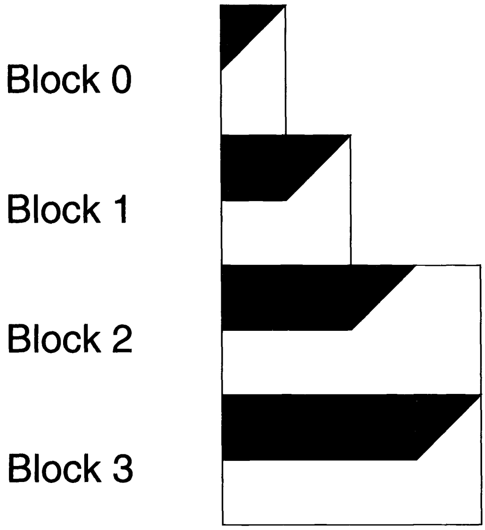

FIG. 9. *Storage requirements for shortened FFT blocks holding the transfer function coefficients. Dark regions show the location of the coefficients and light regions show zero padding.*

Figure 9 then requires $\frac{h(2w)}{2}(\log_2 h + \log_2 2w)$ complex multiply operations to compute the FFT, where h and w are the height and width of the individual block. The element-by-element matrix multiplication, on the other hand, requires only the information stored in the blocks; the remaining coefficients that make up the $2p \times 2p$ fundamental matrix are accounted for in the redundancy of the data or in the Fourier-space zeros of the periodic replica scheme described above. The number of complex multiplications for each block is simply hw.

As an example, dividing a coefficient matrix into four blocks and accumulating the computations required for the FFT of each block yields $p^2(\frac{11}{4}\log_2 p - \frac{1}{2})$ complex multiplications compared with $4p^2(\log_2 p + 1)$ computations for the FFT of the full $2p \times 2p$ matrix. The matrix multiplication requires slightly more computations for the block decomposition scheme because of the block-level convolution (Figure 4). For the case where the coefficients are decomposed into four blocks, $\frac{11}{4}p^2$ complex multiplications are required compared with $2p^2$ computations for the full matrix of $p \times 2p$ nonredundant values. For a concrete example, inserting $p = 16$ yields a total of 3,392 complex multiplications for the efficient block decomposition scheme which compares favorably to the 5,632 complex multiplications required for the FFT computation of M2L without block decomposition and 6,936 required for the original coefficient-space M2L computation. As is evident in §5 the operation count discussed above does not account for all of the speedup in the FFT method over the coefficient-space method. On one hand, for example, the regular locations of FFT block data allow more rapid computation on vector and pipelined machines. On the other hand, operations such as zeroing out the FFT matrix prior to each M2L uses nontrivial amounts of CPU time, and the extra memory usage required by the FFT version can result in more cache misses for large simulations run on machines with small caches. In general, however, the FFT version runs faster for any $p > 4$.

As an added benefit of the block decomposition method, p values other than powers of 2 can be selected with a smaller penalty in terms of extra zero padding. For example, $p = 12$ can be implemented with three blocks, each length 8 in the l direction. This eliminates the wasted zero padding in the l direction which would be required for a full 16×16 single block matrix to hold the $p = 12$ data.

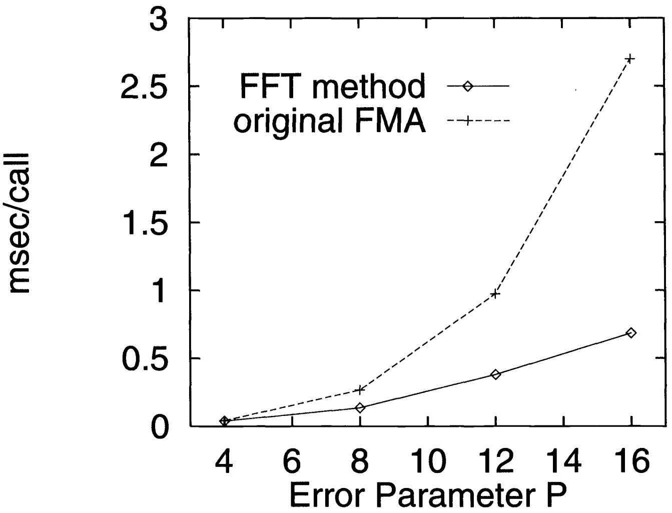

FIG. 10. M2L *subroutine performance comparison on IBM* RS-6000. *The msec/call times are an average reported by the UNIX prof utility running a simulation of* 20K *uniformly distributed charged particles.*

5. Implementation and results. Although it is possible to do the M2M and L2L translations in the Fourier domain as shown in the Appendix, our current implementation of the FFT version of the FMA does only the M2L translation in the Fourier domain. The M2M and L2L are done in coefficient space because their runtimes typically amount to only a few percent of the total. Also, the overhead of the FFT/IFFT conversion is amortized over fewer accumulated translations for M2M and L2L than for the M2L translation, so the speedup may not be as substantial.

Figure 10 shows the results of a comparison between the FFT version of the FMA with the M2L done in Fourier space and the original version of the FMA with the M2L done in coefficient space. The two versions have identical code from a locally generated FMA program except for the routines relating to the M2L translation. The plot shows the average time spent in the M2L subroutine as reported by the UNIX *prof* utility. The simulation is a 20K uniform distribution of charged particles, with an equal distribution of -1.0 and $+1.0$ charges. The simulation region is a cube in free space. The simulations were run on a single-processor IBM RS-6000 Model 360. The FFT routines used were derived from off-the-shelf code, optimized by fully unrolling the 1-D FFT portion of the routines and eliminating the unnecessary computations arising from the known zeros and data dependencies in the multipole expansion coefficients. On the RS-6000 the results of computing the M2L translation in the Fourier domain show a speedup factor of 2 measured in milliseconds per subroutine call (msec/call) at $p = 8$, and even higher speedup for p values greater than 8.

An additional benefit of conversion to Fourier space is the vectorizability of the code. Figure 11 shows the msec/call performance comparison for single-processor runs on a CRAY YMP-8 vector supercomputer, showing a nearly 3 times speedup at $p = 8$. Other computations in the M2L subroutine were not vectorized in this implementation (accounting for the faster msec/call time of the RS-6000 over the Cray), but this figure shows the improved vectorizability of the FFT method with no other changes to the code.

The runtime performance of any implementation of the FMA is dominated by two factors, only one of which is the subroutine calls to the M2L translations. While M2L dominates the

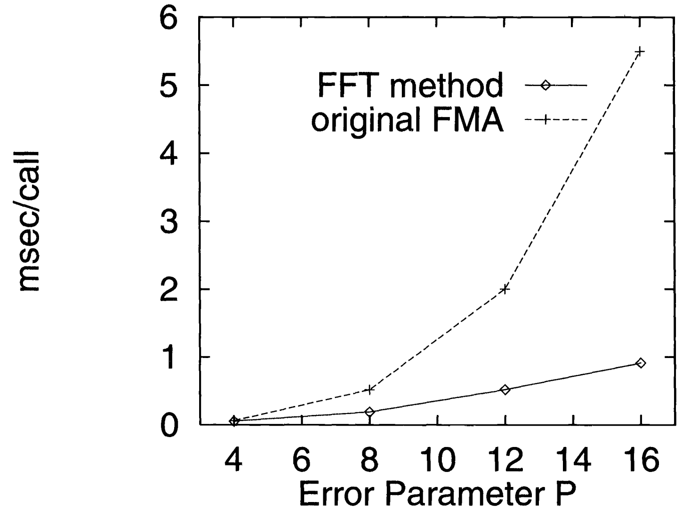

FIG. 11. M2L *subroutine performance comparison on Cray YMP-8. The simulation is the same as that used for the previous figure.*

multipole calculations, the direct, particle-to-particle interactions consume significant CPU time; these computations are necessary for regions where the multipole expansion series convergence criteria are not met. These regions are the cells at the leaf nodes of the oct-tree that are too close together to be put on the M2L interaction list. Particle-to-particle calculations in these regions are an independent task from the M2L cell-to-cell interactions, and the runtime of these calculations is dominated by the floating point square root calculation. In fact, extracting maximum performance from an FMA program for a given number of particles N and given p for desired accuracy typically results in roughly equal time spent between the particle-to-particle calculations and the M2L calculations. Thus, efforts to speed up the entire FMA algorithm by FFT conversion of the M2L are mitigated by the independent task of the particle-to-particle calculations. Figure 12 compares the speedup in peak particles per second (particles/sec) for various p values of the FFT version of the FMA code over the original version with the same particle-to-particle routines in both versions. The simulation is the same 20K system of uniformly distributed charged particles run on the single IBM RS-6000 processor described above.

6. Conclusion. In this paper we described a faster FMA, accelerated by converting the most common subroutine, the M2L translation, to the Fourier domain using an FFT. The result is an implementation that is $\mathcal{O}(p^2 \log_2(p)N)$. Conversion of the multipole expansion coefficients to the Fourier domain is satisfactory only after prewarping and zero-padding the coefficients. Block decomposition provides numerical stability to $p = 32$, and efficient block sizing reduces the overhead of the FFT enough to outperform coefficient-space convolution at low p values. Our implementation speeds up the FMA for $p > 4$, and speeds up the M2L subroutine call by a factor of 2 at $p = 8$ on an RISC processor and a factor of 3 at $p = 8$ on a vector processor.

To our knowledge, this is the first published version of the implementation details of an FFT version of the FMA, using the convolution form of the FMA computations described by Greengard and Rokhlin. The efficient block decomposition scheme described here is new. This block decomposition scheme provides numerical stability for the algorithm at double

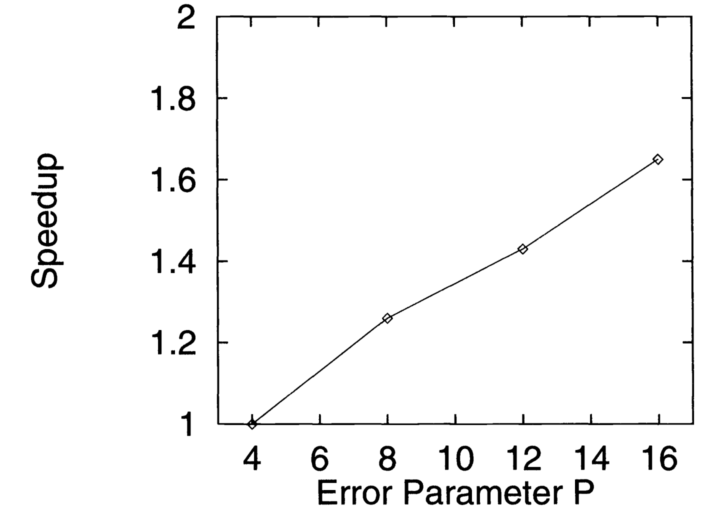

FIG. 12. *Speedup of a full FMA algorithm with FFT version of* M2L *on* RS-6000/360. *The simulation is the same as previous figures. The speedup of the multipole computations from the FFT enhancements is mitigated by the necessary particle-to-particle computations in the overall FMA algorithm.*

precision out to $p = 32$ over a wide range of geometry scales and provides an opportunity to restrict computations to the nonzero values in the multipole expansion coefficient matrix.

The speedup of the FMA described in this paper is particularly relevant to electrostatic applications. In gravitational computations, all the "charge" (mass) is positive, so the leading monopole term of the multipole expansion is large. Many astrophysical applications of multipole-based methods in fact retain only the monopole term in their expansions; i.e., they set $p = 1$. In electrostatics with approximate charge neutrality, the first moment of charge distributions will be nearly zero, so more terms must be retained in the expansions. Electrostatic applications typically felt the effect of the $\mathcal{O}(p^4)$ growth in runtime as terms were added to improve accuracy much more severely than gravitational applications. The runtime reductions achieved in this paper allow high accuracy electrostatic computations to be undertaken at moderate cost.

Appendix: FFT version of other FMA transformations. Multipole-to-multipole translation (M2M):

$$\Phi(\mathbf{r}) = \Phi'(\mathbf{r}') = \sum_{l,m}^{p-1} \mathbf{M}_l^m \frac{Y_l^m(\theta,\phi)}{r^{l+1}} = \sum_{l',m'}^{p-1} \mathbf{M}_{l'}^{m'} \frac{Y_{l'}^{m'}(\theta',\phi')}{r'^{l'+1}}, \tag{18}$$

$$\mathbf{M}_{l'}^{m'} = \sum_{l,m} \mathbf{T}^{M2M}_{l,m,l',m'} \mathbf{M}_l^m, \tag{19}$$

$$\mathbf{T}^{M2M}_{l,m,l',m'} = \frac{(-1)^{l'-l} A_l^m A_{l'-l}^{m'-m}}{A_{l'}^{m'}} Y_{l'-l}^{*m'-m}(\alpha,\beta)\rho^{l'-l}, \tag{20}$$

$$\left[(-1)^{-l'}\mathbf{M}_{l'}^{m'} A_{l'}^{m'}\right] = \sum_{l,m}\left[\mathbf{H}_{l'-l}^{m'-m}\right]\left[(-1)^{l}\mathbf{M}_l^m A_l^m\right], \tag{21}$$

$$[\mathbf{H}_l^m] = A_l^m Y_l^{*m}(\alpha, \beta)\rho^l, \tag{22}$$

$$y(l, m) = \left[(-1)^l \mathbf{M}_l^m A_l^m\right], \tag{23}$$

$$h(l, m) = [\mathbf{H}_l^m] = A_l^m Y_l^{*m}(\alpha, \beta)\rho^l, \tag{24}$$

$$x(l, m) = \left[(-1)^l \mathbf{M}_l^m A_l^m\right], \tag{25}$$

$$y(l', m') = \sum_{l,m} h(l' - l, m' - m)x(l, m) = h(l', m') \circledast x(l', m'), \tag{26}$$

$$y(l, m) = h(l, m) \circledast x(l, m) \leftrightarrow Y(\omega_l, \omega_m) = H(\omega_l, \omega_m)X(\omega_l, \omega_m). \tag{27}$$

Local-to-local translation (L2L):

$$\Phi(\mathbf{r}) = \Phi'(\mathbf{r}') = \sum_{l,m}^{p-1} \mathbf{L}_l^m Y_l^m(\theta, \phi) r^l = \sum_{l',m'}^{p-1} \mathbf{L}_{l'}^{m'} Y_{l'}^{m'}(\theta', \phi') r'^{l'}, \tag{28}$$

$$\mathbf{L}_{l'}^{m'} = \sum_{l,m} \mathbf{T}_{l,m,l',m'}^{L2L} \mathbf{L}_l^m, \tag{29}$$

$$\mathbf{T}_{l,m,l',m'}^{L2L} = \frac{A_{l'}^{m'} A_{l-l'}^{m-m'}}{A_l^m} Y_{l-l'}^{m-m'}(\alpha, \beta)\rho^{l-l'}, \tag{30}$$

$$\left[\frac{\mathbf{L}_{l'}^{m'}}{A_{l'}^{m'}}\right] = \sum_{l,m} \left[\mathbf{H}_{-(l'-l)}^{-(m'-m)}\right] \left[\frac{\mathbf{L}_l^m}{A_l^m}\right], \tag{31}$$

$$[\mathbf{H}_l^m] = A_l^m Y_l^m(\alpha, \beta)\rho^l, \tag{32}$$

$$y(l, m) = \left[\frac{\mathbf{L}_l^m}{A_l^m}\right], \tag{33}$$

$$h(l, m) = [\mathbf{H}_l^m] = A_l^m Y_l^m(\alpha, \beta)\rho^l, \tag{34}$$

$$x(l, m) = \left[\frac{\mathbf{L}_l^m}{A_l^m}\right], \tag{35}$$

$$y(l', m') = \sum_{l,m} h(-(l' - l), -(m' - m))x(l, m) = h(-l', -m') \circledast x(l', m'), \tag{36}$$

$$y(l, m) = h(-l, -m) \circledast x(l, m) \leftrightarrow Y(\omega_l, \omega_m) = H(\omega_{-l}, \omega_{-m})X(\omega_l, \omega_m). \tag{37}$$

COMPUTATION OF PSEUDO-DIFFERENTIAL OPERATORS*

GANG BAO† AND WILLIAM W. SYMES‡

Abstract. A simple algorithm is described for computing general pseudo-differential operator actions. Our approach is based on the asymptotic expansion of the symbol together with the fast Fourier transform (FFT). The idea is motivated by the characterization of the pseudo-differential operator algebra. We show that the algorithm is efficient through analyzing its complexity. Some numerical experiments are also presented.

Key words. pseudo-differential operators, fast Fourier transform, spatially varying filters, microlocal cut-off, data processing

AMS subject classifications. 35S05, 65T20, 86A22

1. Introduction. The theory of pseudo-differential operators (ΨDOs) has made many important contributions to the development of partial differential equations. It provides a natural way to decompose a differential operator, which may be difficult to study directly, into several pieces with a simple structure. A precise way to describe propagation of singularities for differential equations is in terms of ΨDOs. Pseudo-differential operators may be viewed as spatially varying filters with simple asymptotics at high frequencies. Pseudo-differential operators differentiate waves and wave-like signals according to directions of propagation. Pseudo-differential operators also arise naturally in diverse fields (often under different names!) such as wave propagation, electrical engineering, and geophysics.

Although the theory of ΨDOs, or, more generally, microlocal analysis, has been well established since the '60s, little attention appears to have been paid to the computation of ΨDOs. In this paper, we present a simple algorithm for the computation of general ΨDO actions. Our idea is based on the following characterization of ΨDOs.

Fact. The ΨDO algebra is generated by all differential operators and all powers of the Laplacian.

More precisely, ΨDOs and many functions of these (inverse, powers, ...) are included in ΨDOs in the high frequency asymptotic sense.

See Kohn and Nirenberg [3] for a detailed discussion.

2. Pseudo-differential operators. Here, we shall give a brief introduction to a class of ΨDOs. For a complete account of ΨDOs, as well as the calculus, the reader is referred to Taylor [5], Nirenberg [4], or Hörmander [2].

We begin with the introduction of the Fourier transform and the inverse Fourier transform. The Fourier transform acting on a "nice" function u defined in $\mathbf{R}^n$ is

$$\mathcal{F}(u) = \hat{u} = (2\pi)^{-n} \int u(x) e^{-ix\cdot\xi} dx,$$

and the inverse Fourier transform is defined by

$$\mathcal{F}^{-1}(u) = \int \hat{u}(\xi) e^{ix\cdot\xi} d\xi\ .$$

Remark. A number of algorithms for the numerical computation of (discrete) Fourier transforms have been made available. We shall use a version of the FFT in our numerical work. A detailed description may be found in Conte and De Boor [1]. See also Van Loan [6] for the most recent development in the field.

Pseudo-differential operators are usually defined in terms of symbols, which are smooth functions of both space and frequency variables satisfying certain estimates. More precisely, $q(x, \xi)$ is a member of the symbol class $S^m_{1,0}(\mathbf{R}^n)$ iff $q(x, \xi)$ is a smooth function and for any compact subset K of $\mathbf{R}^n$, and real α, β, there exists a constant $C_{K,\alpha,\beta}$, such that

$$|D^\alpha_x D^\beta_\xi q(x, \xi)| \le C_{K,\alpha,\beta}(1 + |\xi|)^{m-|\beta|} \tag{2.1}$$

for all $x \in K$ and $\xi \in \mathbf{R}^n$.

In this paper, we shall confine ourselves to a subclass of $S^m_{1,0}$, the class S^m, which is the most natural class and sufficient for many applications. A function $q(x, \xi)$ is in S^m if $q(x, \xi) \in S^m_{1,0}$ and there are smooth $q_{m-j}(x, \xi)$, homogeneous of degree $m - j$ in ξ for $|\xi| \ge 1$; i.e.,

$$q_{m-j}(x, r\xi) = r^{m-j} q_{m-j}(x, \xi), \quad |\xi| \ge 1\ , \quad r \ge 1 \tag{2.2}$$

such that

$$q(x, \xi) \sim \sum_{j \ge 0} q_{m-j}(x, \xi)\ , \tag{2.3}$$

in the sense that

$$q(x, \xi) - \sum_{j=0}^{N} q_{m-j}(x, \xi) \in S^{m-N-1}_{1,0}\ , \tag{2.4}$$

where $q_m(x, \xi)$ is called the principal symbol or principal part of $q(x, \xi)$ that carries the most important information about q.

Then the operator Q defined by

$$Q(x, D_x)u = \int q(x, \xi)\hat{u}(\xi)e^{ix\cdot\xi}d\xi \tag{2.5}$$

is called a ΨDO of order m or $Q \in OPS^m(\mathbf{R}^n)$.

In particular, differential operators with smooth coefficients are ΨDOs. Indeed, for such a differential operator of order m, the corresponding symbol is a polynomial in ξ of degree m, and consequently is a symbol in S^m. The asymptotic expansion of a symbol (2.3) is unique up to smoothing operators.

3. Algorithm. In this section we describe the algorithm explicitly. Its complexity will be examined in the section that follows. For the sake of simplicity, we shall only describe the idea of computing two-dimensional ΨDOs. Some obvious modifications may be made to compute ΨDOs of arbitrary dimension. Throughout, we shall always assume that the action of Q on u is meaningful. The precise conditions may be found in any one of the references [2]-[5].

Given a ΨDO $Q(x, z, D_x, D_z) \in OPS^m$ whose symbol is $q(x, z, \xi, \eta)$ and a function $u(x, z)$, our goal is to compute the action Qu efficiently. Let us assume that the asymptotic expansion of the symbol is given by

$$q(x, z, \xi, \eta) \sim \sum_{j \ge 0} q_{m-j}(x, z, \xi, \eta)\ , \tag{3.1}$$

where $q_{m-j}(x,z,r\xi,r\eta) = r^{m-j}q_{m-j}(x,z,\xi,\eta)$ for $(|\xi|, |\eta| \geq 1)$. Again, q_m denotes the principal symbol of q.

Knowing the asymptotic expansion of q we compute the ΨDO action Qu through computing $Q_{m-j}u$ for $j \geq 0$. We describe the calculation for $j = 0$, as it is representative. That is, we will describe an algorithm for computing the action of the principal part of a ΨDO. Evidently this algorithm could be applied recursively to compute general ΨDO actions. However, the principal part gives the dominant effect on high frequency inputs, which is most important for our intended applications. Thus, for us, computation of the principal part above is sufficient.

Let

$$\xi = \omega\cos\theta\ , \quad \eta = \omega\sin\theta\ , \quad \omega = \sqrt{\xi^2+\eta^2}\ . \tag{3.2}$$

The homogeneity of q_m in ξ and η yields

$$q_m(x,z,\xi,\eta) = q_m(x,z,\omega\cos\theta,\omega\sin\theta) = \omega^m\tilde{q}_m(x,z,\theta)\ , \tag{3.3}$$

where $\tilde{q}_m(x,z,\theta)$ is defined to be $q_m(x,z,\cos\theta,\sin\theta)$.

Since $\tilde{q}_m$ is periodic in θ, it has a Fourier series expansion as follows:

$$\begin{aligned}\tilde{q}_m(x,z,\theta) = \sum_{l=-\infty}^{\infty} c_l(x,z)e^{il\theta} &\simeq \sum_{l=-K/2}^{K/2} c_l(x,z)e^{il\theta}\\ &= \sum_{l=-K/2}^{K/2} c_l(x,z)(\cos\theta + i\sin\theta)^l\ ,\end{aligned} \tag{3.4}$$

where K is an indicator of the number of terms in the expansion.

It follows from the definition of ΨDO (2.5) that

$$\begin{aligned}Q_m u &\simeq \int\!\!\int d\xi d\eta e^{i(x\xi+z\eta)} \sum_{l=-K/2}^{K/2} \omega^m c_l(x,z)(\cos\theta+i\sin\theta)^l\hat{u}(\xi,\eta)\\ &= \sum_{l=-K/2}^{K/2} c_l(x,z)\int\!\!\int d\xi d\eta\omega^m e^{i(x\xi+z\eta)}(\cos\theta+i\sin\theta)^l\hat{u}(\xi,\eta)\\ &= \sum_{l=-K/2}^{K/2} c_l(x,z)\mathcal{F}^{-1}[\omega^{m-l}(\xi+i\eta)^l\hat{u}(\xi,\eta)],\end{aligned} \tag{3.5}$$

where, to obtain the last equality, we have used the relations $\cos\theta = \xi/\omega$ and $\sin\theta = \eta/\omega$ in (3.2). Observe that ω^{m-l} is the symbol of the $(m-l)/2$-power of the (negative) Laplacian, while ξ and η are symbols of differential operators $D_x = -i\partial_x$ and $D_z = -i\partial_z$, respectively.

The procedure implicit in the above formulae leads to an algorithm to evaluate $Q_m u$ approximately, as follows. Assume that u is sampled on a discrete grid,

$$\begin{aligned}U_{i,j} &= u(x_0+(i-1)\Delta x, z_0+(j-1)\Delta z)\ ,\\ &i = 1,\ldots,M,\ \ j = 1,\ldots,N\ ,\end{aligned} \tag{3.6}$$

with spacings Δx, $\Delta z > 0$. Assume similarly that a sampling of $\tilde{q}_m$ is given

$$\begin{aligned}Q_{i,j,k} &= \tilde{q}_m(x_0+(i-1)\Delta x, z_0+(j-1)\Delta z, k\Delta\theta)\ ,\\ i &= 1,\ldots,M,\ \ j = 1,\ldots,N,\ \ k = -K/2,\ldots,K/2\ .\end{aligned} \tag{3.7}$$

With $X = (M-1)\Delta x$, $Z = (N-1)\Delta z$, the sample rates in the frequency domain are $\Delta\xi = 1/X$, $\Delta\eta = 1/Z$, so the (unaliased) samples of the symbols of the Laplacian, D_x, and D_z are

$$\Omega_{p,r} = 2\pi\sqrt{(p\Delta\xi)^2 + (r\Delta\eta)^2}\ , \tag{3.8}$$

$$\Xi_{p,r} = 2\pi p\Delta\xi\ , \tag{3.9}$$

$$Z_{p,r} = 2\pi r\Delta\eta\ , \tag{3.10}$$

$$p = -M/2, \dots, M/2,\ r = -N/2, \dots, N/2\ ,$$

respectively.

PROCEDURE FOR COMPUTING $Q_m u$

```
1. Compute the discrete Fourier transform $\hat{U}$ of $U$.
2. For each $i \in \{1, \dots, M\}$ and $j \in \{1, \dots, N\}$, compute the discrete Fourier transform
   $\hat{Q}_{i,j} = \{Q_{i,j,l}\}_{l=-K/2}^{K/2}$ of $Q_{i,j} = \{Q_{i,j,k}\}_{k=-K/2}^{K/2}$.
3. Initialize $(QU)_{i,j} = 0.0$, for $i = 1, \dots, M$, $j = 1, \dots, N$.
   DO $l = -K/2,\ K/2$
     a  compute the inverse Fourier transform $\{R^l_{i,j}\}_{i=1,j=1}^{M,N}$ of
            $\Omega^{m-l}_{p,r}(\Xi_{p,r} + iZ_{p,r})^l \hat{U}_{p,r}$
        for $p = -M/2, \dots, M/2$ and $r = -N/2, \dots, N/2$.
     b  accumulate
            $(QU)_{i,j} = (QU)_{i,j} + \hat{Q}_{i,j,l}R^l_{i,j}$
   END DO
```

4. Complexity analysis. We return to the general case. The complexity will be analyzed by the number of multiplications. We also make a few remarks about the accuracy of the algorithm.

The direct method of computing the ΨDO action is by straightforward discretization of the definition

$$\begin{aligned} Q_m u &= \int\int q_m(x,\xi)\hat{u}(\xi)e^{ix\cdot\xi}d\xi \\ &= \mathcal{F}^{-1}[q_m(x,\xi)\hat{u}(\xi)]\ . \end{aligned}$$

Let us assume that the input function is discretized on a regular d-dimensional grid, as is the symbol q_m. We denote by N the number of grid points in each direction, assuming these are roughly similar. Assuming also that the discrete Fourier transforms are computed using an FFT algorithm. We then have the following result.

LEMMA 4.1. *The direct algorithm has $O(N^{2d}\log N)$ complexity.*

This is an immediate consequence of the well-known fact that the FFT exhibits $O(N\log N)$ complexity, where N is the length of the input sequence.

We next discuss the complexity of the new algorithm. For simplicity, we once again consider the two-dimensional case. The approximate complexity orders of the steps in the algorithm proposed above are

1. $N^2\log N$;
2. $N^2K\log K$; and
3. a. $KN^2\log N$, b. KN^2.

Hence the total complexity is $O(KN^2(\log N + \log K))$ in two dimensions.

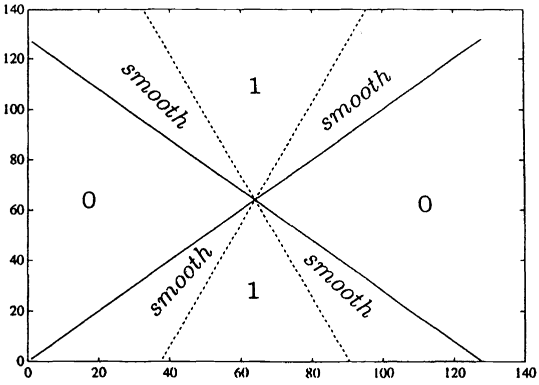

FIG. 1. *The symbol of a convolutional operator.*

In general, when the number of dimensions is d, a similar calculation will give Lemma 4.2.

LEMMA 4.2. *The new algorithm exhibits $O(K^{d-1}N^d(\log N + \log K))$ complexity.*

Remarks. The new algorithm is significantly superior to the direct method. In practice, the number of terms K in the finite θ-Fourier series approximation of q_m (3.4) ought to be chosen properly to make the sup-norm error small. If this is the case, the error in the computation of Q_m, modulo compact operators, will also be small (Taylor [5], p. 52). In particular the error will be small for oscillatory inputs u. Note that K is completely independent of N in this regard. Thus, in effect, the complexity of our algorithm is $O(N^d \log N)$!

In actual applications, N is usually big. When N and K are given, the numbers of multiplications involved in our algorithm and the direct method may be calculated easily. What makes the real difference is the number K. The theory and our numerical experiments both indicate that the number K depends only on the smoothness of the symbol, is insensitive to N, and can always be small.

5. Numerical experiments. In this section, we present the results of some numerical experiments carried out with the ΨDO algorithm. The class of ΨDO of great importance in our applications are microlocal cutoff operators, i.e., operators whose symbols are asymptotically one in some conic set and asymptotically zero in the complement of a slightly bigger conic set (essential support or aperture). These are the simplest undecomposable order zero ΨDOs. Our numerical experiments exhibit some interesting features of ΨDOs.

We begin with convolutional ΨDOs, which are ΨDOs that are independent of spatial variables. Convolutional operators are natural extensions of differential operators with constant coefficients. For this class of operators, it is easy to show that

$$\mathcal{F}(Qu) = Q(\xi)\hat{u}(\xi)\ . \tag{5.1}$$

This simple identity is useful in verifying the code. In fact, according to (5.1), one can recover the symbol from $\mathcal{F}(Qu)$ and $\hat{u}$. A symbol that characterizes a microlocal cutoff is specified by Figure 1, where the symbol is designed to be a C^2 function. Figure 2 displays the symbol function in terms of the angle θ. From this one-dimensional array, the ΨDO algorithm may be employed to compute the action, and hence the two-dimensional symbol function Q. The result, Figure 3, shows the symbol when the number of terms in Fourier series expansion of the symbol $K = 4$. It is easy to see that the symbol in Figure 3 illustrates the right direction

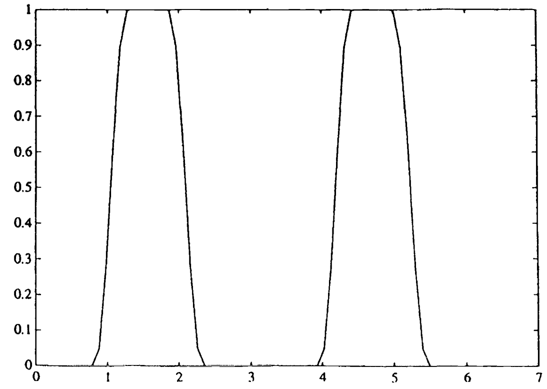

FIG. 2. *The same symbol as a function of θ: The angle with the horizontal axis.*

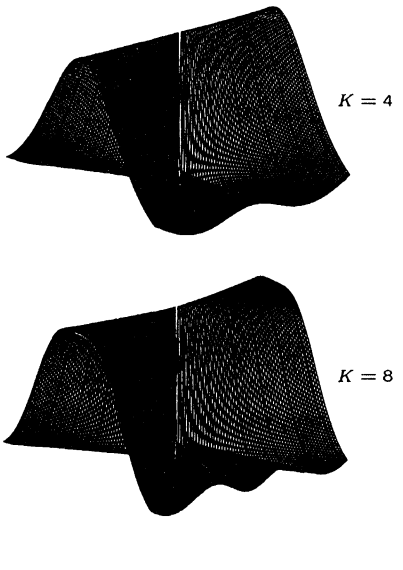

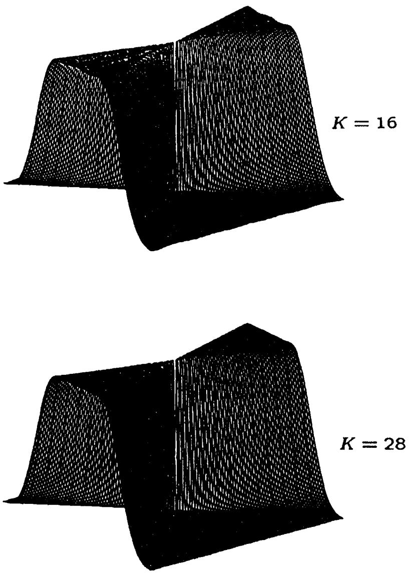

FIG. 3. *Symbol recovery*: $k = 4$.

FIG. 4. *Symbol recovery*: $k = 28$.

but wrong amplitude within the aperture. As the number of terms K increases, the recovery of the symbol becomes better and better. Figure 4 shows that the symbol is perfectly recovered after several steps. Again, we want to emphasize that the number K only depends on the smoothness of the symbol, and particularly is independent of the grid size N.

Another numerical experiment of ours concerns the rotation of apertures for convolutional operators. The function plotted in Figure 5 is a slightly smoothed characteristic function of a circle. We apply a ΨDO cutoff, whose symbol is given in Figure 6, to this function. Just as the theory predicts, the high frequency information of the resulting function (Figure 7) is well preserved within the aperture. We then rotate the symbol (Figures 8 and 10), and again the high frequency information is preserved in Figures 9 and 11, respectively. These examples are only illustrative, as the discrete Fourier transform allows a very simple and fast computation of convolution operators.

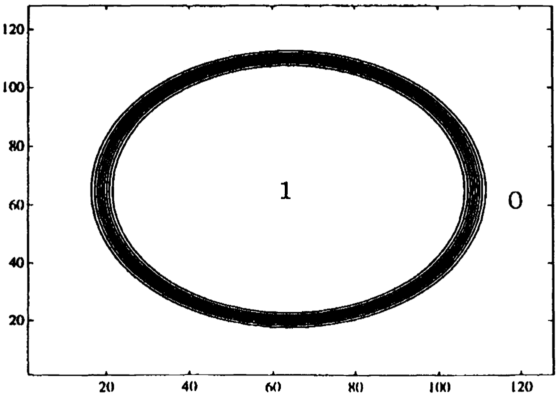

FIG. 5. *Function u.*

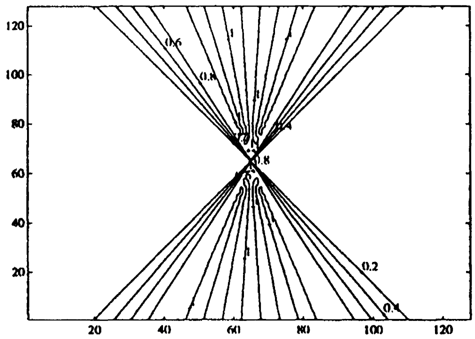

FIG. 6. *Symbol* q_0.

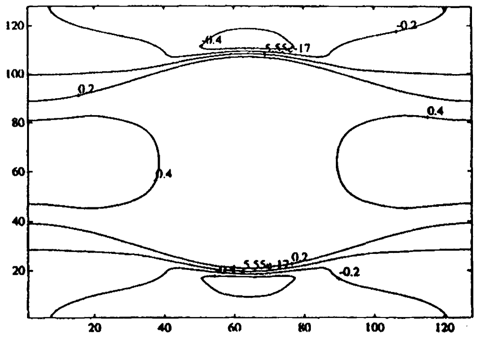

FIG. 7. *The action* $q_0 u$.

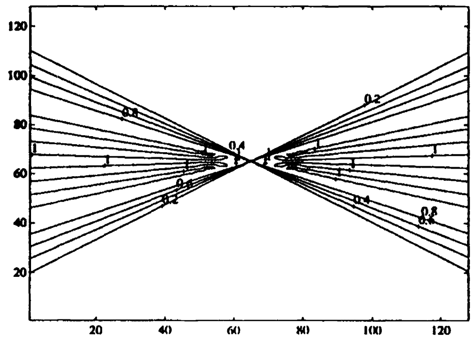

FIG. 8. *Symbol rotation* 1.

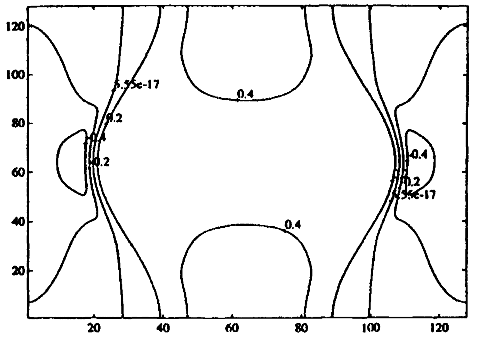

FIG. 9. *The action for rotation* 1.

Our next example is meant to illustrate the success of our algorithm with nonconvolutional ΨDOs. Figure 12 shows the symbol of a two-dimensional ΨDO, which is spatially varying (in the z-direction). The symbol can be generated from $q(z, \theta) = q_0(\theta + \delta\theta \sin(\pi z/z_{\max}))$, where q_0 is given in Figure 6, $\delta\theta$ is selected to be $\pi/2$, and $z \in [0, z_{\max}]$. Thus, as z increases, the symbol rotates smoothly; in particular the symbol will be equal to q_0 when z reaches its

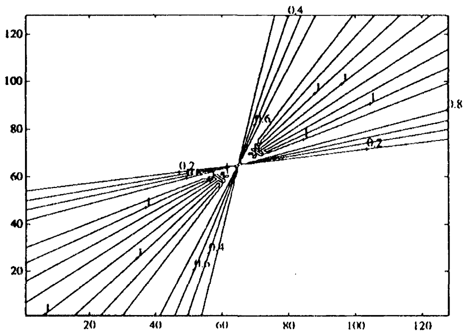

FIG. 10. *Symbol rotation* 2.

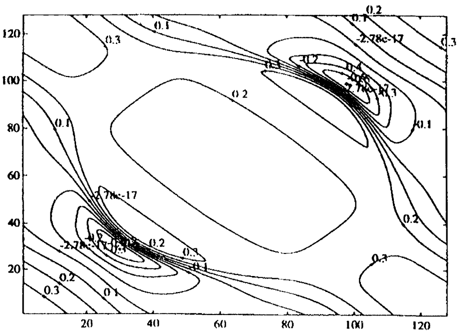

FIG. 11. *The action for rotation* 2.

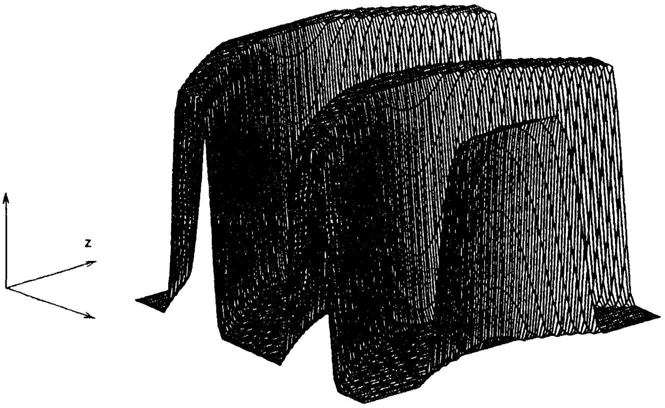

FIG. 12. *A spatially varying symbol.*

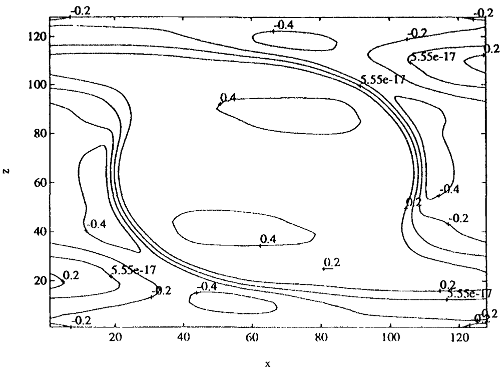

FIG. 13. *The action for the spatially varying symbol.*

maximum. Once again, the function u is the same as before in Figure 5. The result, as shown in Figure 13, agrees with the theory. Observe that the aperture is vertical for z near 0. The symbol rotates as z increases, so we start to see some high frequency horizontal components. When z is getting close to its maximum, the symbol rotates back, and the aperture becomes vertical again.

Our final example demonstrates an important application of the ΨDO algorithm to the seismic data processing in reflection seismology. The basic objective of all seismic processing is to convert the information recorded in a field into a form that most greatly facilitates geological interpretation of such a field. Evidently, real reflection data, which carry most of the information of the mechanical properties of the earth, are what geophysicists are most interested in obtaining through this process. Thus, an essential object of the processing is to eliminate or suppress all signals not associated with reflections. Figure 14 displays a seismogram, i.e., the recorded seismic data at receivers on the surface of the earth after an energy source is fired. The dark region that can be seen clearly contains very strong signals. These signals represent the early arrivals (direct and head waves). In the region below, there are other signals (reflections) which are not nearly as strong as the early arrivals. Unfortunately, the direct and head waves do not penetrate the earth; hence they contain no information about the subsurface about which we are interested. What contains useful information is the reflection energy in the lower region. This can be observed more clearly if one increases the amplitude of the seismogram as in Figure 15. The question arises: can one remove the early arrivals and yet keep the useful information of reflections? Applying the ΨDO computation algorithm, we design a microlocal cutoff (ΨDO) whose action on the seismogram is shown in Figure 16. The result appears to be very encouraging. The amplitude of the early arrivals is reduced dramatically, and meanwhile information of reflections is well preserved. We apply the same ΨDO filter to the data set once more to obtain an even better result shown in Figure 17. Now, the early arrivals are essentially gone, while again most of the reflections are preserved. We believe the noise left in the region where the early arrivals resided is caused by numerical scales; hence they can be eliminated. This processing technique is actually used in reflection seismology, where it is called "f-k dip filtering," e.g., Yilmaz [7], pp. 69–78. Our ΨDO algorithm yields an accurate and efficient means of "spatially variable dip filtering," for which we envision numerous uses. However, the enormous amount of computations of ΨDOs by the direct method makes any practical application impossible. Note that in the above examples, the grid size is taken to be 256 in each direction, which should be much bigger in real applications. However, the number K may be chosen much smaller than N due to the fact that K is independent of N.

6. Concluding remarks. A simple algorithm for the computation of a class of ΨDOs is introduced in this work. We exhibit some of the features of the algorithm. The complexity analysis indicates that the algorithm is much more efficient than the direct computation. Because of the simple structure, various massive parallel computers may be used to implement this algorithm so long as a fast FFT routine and fast array operations are available. In fact, some of our numerical experiments reported in this paper were obtained by using the Connection Machine.

We anticipate many applications of this algorithm. For example, ΨDOs are expected to play an important role in regularizing a class of ill-posed problems in multidimensional wave propagation that arise naturally in seismic inversion, oil and gas exploration, and many other related geophysical problems. Our experiment indicates the usefulness of microlocal (or ΨDO) cutoff in seismic data processing, i.e., sorting of waves according to direction in seismic data.

Mathematically, this algorithm should provide a way to compute the so-called microlocal norms of microlocal Sobolev spaces, which in turn would help us test the sharpness of various results on propagation of singularities for partial differential equations. This algorithm should also have some impact on signal processing, where ΨDOs form a class of spatially varying filters.

BOUNDARY LAYER RESOLVING PSEUDOSPECTRAL METHODS FOR SINGULAR PERTURBATION PROBLEMS*

TAO TANG[†] AND MANFRED R. TRUMMER[‡]

Abstract. Pseudospectral methods are investigated for singularly perturbed boundary value problems for ordinary differential equations (ODEs) which possess boundary layers. It is well known that if the boundary layer is very small then a very large number of spectral collocation points is required to obtain accurate solutions. We introduce here a new effective procedure based on coordinate stretching and the Chebyshev pseudospectral method to resolve the boundary layers. Stable and accurate results are obtained for very thin boundary layers with a fairly small number of spectral collocation points.

Key words. spectral methods, singular perturbation, boundary layer

AMS subject classification. 65N35

1. Introduction.

We consider the pseudospectral (PS) method for the singular perturbation boundary value problem (BVP) given by

$$(1)\quad \epsilon u''(x) + p(x)u'(x) + q(x)u(x) = f(x), \quad x \in (-1,1), \quad u(-1) = \alpha, \;\; u(1) = \beta,$$

where $\epsilon > 0$ denotes a fixed (small) constant. In many applications, (1) possesses boundary layers, i.e., regions of rapid change in the solution near the endpoints, with widths $o(1)$ as $\epsilon \to 0$. It has been found that PS methods are attractive in solving this problem (see, e.g., [4]). By clustering the gridpoints toward the boundaries, for example, as in the Chebyshev method ($x_j = \cos\frac{\pi j}{N}$, $j = 0, 1, \ldots, N$), PS methods are more efficient than finite difference methods in resolving the boundary layers. However, in performance they still lag behind collocation methods with adaptive mesh selection (e.g., COLSYS [1]).

Although PS methods are remarkably accurate in exact arithmetic, there are a number of difficulties associated with its use. Especially with very small parameter ϵ in (1), large N is required to obtain accurate solutions (see, e.g., [11]). In addition, ill conditioning of the corresponding differentiation matrices with increasing N frequently causes degradation of the observed precision. Furthermore, as clarified in recent studies by Trefethen and Trefethen and Trummer [14, 15] the time step restrictions due to this ill conditioning can be more severe than those predicted by the standard stability theory, if such methods were to be applied to a time-dependent problem. Therefore, there has been considerable interest in recent years in developing well-conditioned spectral methods (see, e.g., [5-7]).

If $\epsilon \ll 1$ (e.g., $\epsilon < 10^{-6}$) and the problem possesses a boundary layer of width $O(\epsilon)$, high accuracy cannot be expected no matter how stable the spectral method is (see, e.g., [5, 11]). In the Chebyshev PS method, the spacing between the collocation points near the boundary is $O(N^{-2})$. For good resolution of the numerical solution at least one of the collocation points ought to lie in the boundary layer, which implies that $N = O(\epsilon^{-1/2})$. If $\epsilon = 10^{-8}$ then about 10^4 collocation points should be used, which is not practical in most calculations.

The Chebyshev spectral method and the finite difference method with coordinate stretching [8, 12] are two potentially useful methods for resolving the boundary layers. However,

*Received by the editors July 13, 1992; accepted for publication (in revised form) October 19, 1994.

[‡]Department of Mathematics, Simon Fraser University, Burnaby, British Columbia V5A 1S6, Canada (trummer@sfu.ca). The research of this author was supported by Natural Science and Engineering Research Council of Canada grant OGP0036901.

neither method works well if $\epsilon \ll 1$, since in this case N has to be very large. To avoid this difficulty we combine the two methods (with a new coordinate stretching technique) to solve (1). The idea is simple: first, the problem is replaced by an equivalent one using a transformation of the computational domain; second, the transformed problem is solved with the standard Chebyshev PS method. After the transformation more collocation points lie in the boundary layer than before, and there are collocation points in the layer even for fairly small values of N.

2. Transformations. As mentioned in §1, at least one of the collocation points should lie in a small neighborhood of $x = \pm 1$ in order to resolve the boundary layers. Therefore, we introduce a sequence of variable transformations so that there are some collocation points within distance ϵ from the boundaries ± 1 even for $\epsilon \ll 1$ and $N = O(10)$. These transformations are iterated SINE functions $x = g_m(y)$, $m = 0, 1, \ldots,$ where

$$(2) \qquad g_0(y) := y, \qquad g_m(y) = \sin\left(\frac{\pi}{2} g_{m-1}(y)\right), \quad m \geq 1.$$

The theorem below characterizes these transformations based on the relative spacing of the transformed Chebyshev-Gauss-Lobatto nodes.

THEOREM 2.1. *The following two statements hold for any integer $m \geq 0$.* (a) *The map g_m is one-to-one and $g_m([-1, 1]) = [-1, 1]$.* (b) *If $y_j = \cos(\frac{j\pi}{N})$, $j = 0, \ldots, N$, then*

$$g_m(y_0) - g_m(y_1) = g_m(y_{N-1}) - g_m(y_N) = \frac{8}{\pi^2}\left(\frac{\pi^2}{4N}\right)^{2^{m+1}} \left(1 + O(N^{-2})\right).$$

Proof. For (a) We need to show that $g'_m(y) \neq 0$ for $y \in (-1, 1)$, $|g_m(y)| \leq 1$ and $g_m(\pm 1) = \pm 1$, which can be proved by induction (see also (6)). To establish (b), we note that $g_0(y_0) - g_0(y_1) = \frac{\pi^2}{2N^2}\left(1 + O(N^{-2})\right)$. Assuming that

$$g_k(y_0) - g_k(y_1) = \frac{8}{\pi^2}\left(\frac{\pi^2}{4N}\right)^{2^{k+1}} \left(1 + O(N^{-2})\right)$$

and noting that $g_k(y_0) = g_{k+1}(y_0) = 1$, we obtain

$$\begin{aligned} g_{k+1}(y_0) - g_{k+1}(y_1) &= 1 - \sin\left(\frac{\pi}{2} g_k(y_1)\right) \\ &= 1 - \sin\left(\frac{\pi}{2}\left(1 - \frac{8}{\pi^2}\left(\frac{\pi^2}{4N}\right)^{2^{k+1}} \left(1 + O(N^{-2})\right)\right)\right) \\ &= 1 - \cos\left(\frac{4}{\pi}\left(\frac{\pi^2}{4N}\right)^{2^{k+1}} \left(1 + O(N^{-2})\right)\right) = \frac{8}{\pi^2}\left(\frac{\pi^2}{4N}\right)^{2^{k+2}} \left(1 + O(N^{-2})\right). \end{aligned}$$

Since $g_m(y_N) = -g_m(y_0)$ and $g_m(y_{N-1}) = -g_m(y_1)$, the proof of (b) is hereby complete. □

From Theorem 2.1 it can be expected that the transformations (2) together with the Chebyshev PS method can deal with extremely small boundary layers with a fairly small number of collocation points. For $m = 1, 2,$ and 3 (which correspond to one, two, and three SINE transformations), the distance between each boundary point and its nearest interior point is $O(N^{-4})$, $O(N^{-8})$, and $O(N^{-16})$, respectively. Therefore, even for very small ϵ such as $\epsilon = 10^{-12}$, at least one collocation point lies in the boundary layer even for moderate values of N, if two or three SINE transformations are used.

3. The transformed equations. We transform the singularly perturbed linear BVP (1) via the variable transformation $x \mapsto y(x)$ (or $x = x(y)$) into the new BVP

$$\epsilon v''(y) + P(y)v'(y) + Q(y)v(y) = F(y), \tag{3}$$

where v is the transplant of u, $v(y) = u(x(y))$. The transformed coefficients are

$$P(y) := \frac{p(x)}{y'(x)} + \epsilon \frac{y''(x)}{y'(x)^2}, \tag{4}$$

$$Q(y) := \frac{q(x)}{y'(x)^2}, \qquad F(y) := \frac{f(x)}{y'(x)^2}, \tag{5}$$

where again $x = x(y)$. It is clear from (3) - (5) that for any variable transformation $x \mapsto y(x)$ the two quantities $1/y'(x)$ and $y''(x)/[y'(x)]^2$ are of interest and should be easy to calculate.

We now consider the transformation $x = x(y) := g_m(y)$ of §2. In this case, the computation of $1/y'(x)$ is straightforward. Differentiating the recursion (2) we obtain

$$g_0'(y) = 1, \quad g_m'(y) = \frac{\pi}{2} \cos\left(\frac{\pi}{2} g_{m-1}(y)\right) g_{m-1}'(y), \quad m \geq 1. \tag{6}$$

Since $y'(x) = 1/g_m'(y)$, we have

$$\frac{1}{y'(x)} = \prod_{k=0}^{m-1} \left(\frac{\pi}{2} \cos\left(\frac{\pi}{2} g_k(y)\right)\right), \quad m \geq 1. \tag{7}$$

Now we define the functions $h_m(x)$, mapping $[-1, 1]$ onto itself, recursively via

$$h_0(x) := x, \qquad h_m(x) := \frac{2}{\pi} \arcsin\left(h_{m-1}(x)\right), \quad m \geq 1. \tag{8}$$

LEMMA 3.1. $h_m = g_m^{-1}$ *for* $m = 0, 1, \ldots$.

Proof. The case $m = 0$ is trivial. For $m \geq 1$, we let $z = h_m(g_m(y))$. It can be shown by induction that for $k = 0, \ldots, m$,

$$g_k(z) = h_{m-k}(g_m(y)). \tag{9}$$

For $k = m$ we therefore obtain

$$g_m(z) = h_0(g_m(y)) = g_m(y),$$

and, since g_m is injective, it follows $y = z$; i.e., $y = h_m(g_m(y))$. □

We now proceed to find a recursion for the quantity $h_m''(x)/[h_m'(x)]^2$. From (8) we obtain

$$\sin\left(\frac{\pi}{2} h_m(x)\right) = h_{m-1}(x), \qquad m \geq 1. \tag{10}$$

Differentiating (10) twice with respect to x yields

$$\frac{\pi}{2} \cos\left(\frac{\pi}{2} h_m(x)\right) h_m'(x) = h_{m-1}'(x), \tag{11}$$

$$-\left(\frac{\pi}{2}\right)^2 \sin\left(\frac{\pi}{2} h_m(x)\right) \left(h_m'(x)\right)^2 + \left(\frac{\pi}{2}\right) \cos\left(\frac{\pi}{2} h_m(x)\right) h_m''(x) = h_{m-1}''(x). \tag{12}$$

Finally, using (11) and (12) we obtain the recursion

$$\frac{h_m''(x)}{\left(h_m'(x)\right)^2} = \frac{\pi}{2} \tan\left(\frac{\pi}{2} h_m(x)\right) + \frac{\pi}{2} \cos\left(\frac{\pi}{2} h_m(x)\right) \frac{h_{m-1}''(x)}{\left(h_{m-1}'(x)\right)^2}. \tag{13}$$

Note that $h_0'(x) \equiv 1$ and $h_0''(x) \equiv 0$. Since $y(x) = h_m(x)$, the quantity $y''(x)/[y'(x)]^2$ can be computed easily using (13).

TABLE 1
Maximum errors for Example 1 ("-" *indicates the error is greater than* 10).

		$N = 32$	$N = 64$	$N = 128$	$N = 256$	$N = 512$
$\epsilon = 10^{-3}$	$m = 0$	4.39(00)	3.02(−01)	1.60(−04)	6.84(−14)	2.36(−13)
	$m = 1$	1.50(−01)	4.27(−04)	2.22(−11)	9.30(−14)	2.13(−13)
	$m = 2$	2.20(−02)	3.91(−04)	1.74(−09)	5.57(−12)	9.02(−11)
$\epsilon = 10^{-6}$	$m = 1$	-	8.37(00)	2.60(00)	1.14(−01)	2.32(−05)

	$m = 3$	1.01(00)	1.73(−01)	2.50(−03)	2.59(−07)	1.08(−10)
$\epsilon = 10^{-9}$	$m = 1$	-	-	-	-	-
	$m = 2$	6.56(−01)	3.20(−01)	3.03(−01)	9.00(−02)	6.25(−5)
	$m = 3$	2.66(00)	9.11(−01)	2.33(−02)	3.06(−04)	1.08(−07)

4. Examples. We denote by Q_N the space of polynomials of degree $\leq N$. We collocate (3) at the Chebyshev-Gauss-Lobatto nodes $y_j = \cos\frac{j\pi}{N}$, $j = 1, \ldots, N-1$, leading to the PS method for (3) as follows: find $v_N \in Q_N$ such that

$$\epsilon v_N''(y_j) + P(y_j)v_N'(y_j) + Q(y_j)v_N(y_j) = F(y_j), \quad j = 1, \ldots, N-1; \tag{14}$$

$$v_N(-1) = \alpha, \quad v_N(1) = \beta. \tag{15}$$

To solve (14) and (15), we have to solve a matrix equation of the form $AV = b$, where $A \in \mathbf{R}^{(N-1)\times(N-1)}$ and $V, b \in \mathbf{R}^{N-1}$, with $V = (V_1, \ldots, V_{N-1})^T$. The $V_j = v_N(y_j)$ are approximations of $v(y_j)$. The matrix equation is solved in MATLAB, which uses the standard LINPACK routines.

Example 1. Our first example has variable coefficients and the solution develops two boundary layers of width $O(\epsilon)$ near $x = \pm 1$. The equation is

$$\epsilon u''(x) - xu'(x) - u(x) = f(x) = \left(\frac{x+1}{\epsilon} - 1\right)e^{\frac{x+1}{\epsilon}} - 2\left(\frac{x-1}{\epsilon} + 1\right)e^{\frac{x-1}{\epsilon}}, \tag{16}$$

where f is chosen such that the function

$$u(x) = e^{-\frac{(x+1)}{\epsilon}} + 2e^{\frac{x-1}{\epsilon}} \tag{17}$$

is an exact solution of the differential equation. The boundary conditions are $u(-1) = 1$ and $u(+1) = 2$. Note that function (17) will satisfy these boundary conditions to machine precision (machine epsilon equals $2.22 * 10^{-16}$ in double precision) for all values of $\epsilon \leq 0.05$.

This is a difficult problem since high resolution is needed to avoid oscillations in the middle of the interval. The Chebyshev PS method *without* transformation fails to resolve the solution satisfactorily for $\epsilon = 10^{-4}$, even with $N = 256$ (the maximum error, defined by $\max_j\{|v(y_j) - V_j|\}$, is approximately equal to 0.13 in this case, compared with errors of approximately 2×10^{-12} for $m = 1$ and $m = 2$). Table 1 contains the results of our experiments for $\epsilon = 10^{-3}$, $\epsilon = 10^{-6}$, and $\epsilon = 10^{-9}$.

Figure 1 shows the plot of the solution for $\epsilon = 10^{-9}$, $N = 256$, and $m = 3$, and Figure 2 shows the corresponding error. It may not come as a surprise to find the major portion of the error located in the middle of the interval since we have a coarser grid spacing there. However, it is interesting to note that in this case the strategy of moving points out of the region of large errors actually helps in the solution process. This indicates that a strategy for adaptive gridding will have to be rather sophisticated, as it would appear natural to move more points *into* the region exhibiting large errors.

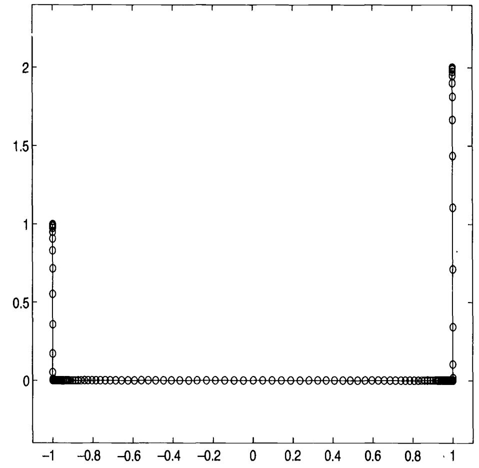

FIG. 1. *Numerical solution of Example* 1 *for* $\epsilon = 10^{-9}$, $N = 256$, *and* $m = 3$.

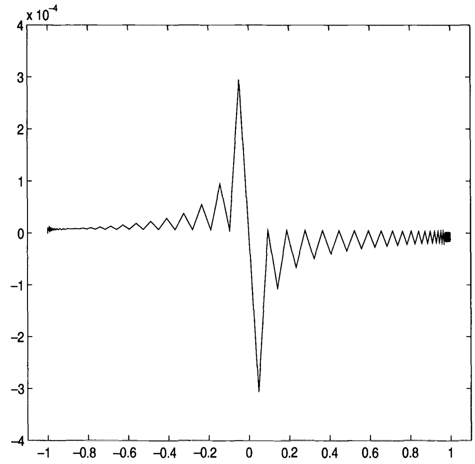

FIG. 2. *Error of Example* 1 *for* $\epsilon = 10^{-9}$, $N = 256$, *and* $m = 3$.

Example 2. Our second example is a nonlinear one; namely the stationary Burgers equation

$$\epsilon u''(x) + u(x)u'(x) = 0, \qquad x \in [-1, 1], \tag{18}$$

with boundary conditions chosen such that the function

$$u(x) = \tanh\left(\frac{x+1}{2\epsilon}\right) \tag{19}$$

is an exact solution. This function is 0 at the left boundary, and extremely close to 1 for most of the interval, with a boundary layer of width $O(\epsilon)$ at $x = -1$. The transformed equation with new variable $y = y(x)$ is simply

$$\epsilon v''(y) + \left[\frac{1}{y'(x)}v(y) + \epsilon\frac{y''(x)}{y'(x)^2}\right]v'(y) = 0, \qquad y \in [-1, 1]. \tag{20}$$

The solution is computed by Newton's method with $v \equiv 1$ as an initial guess; for small values of the parameter ϵ a continuation procedure for ϵ to obtain better initial guesses is advisable, and at times essential. Newton's method converges quickly and often in monotone (convergence problems during the first few iterations appear to indicate insufficient resolution of the discretization). Table 2 lists the results for $\epsilon = 10^{-3}$, $\epsilon = 10^{-6}$, and $\epsilon = 10^{-9}$.

A similar procedure has been applied to obtain numerical solutions for

$$\epsilon u''(x) + \frac{1}{2}u(x)u'(x) - \frac{1}{4}u(x) = 0, \qquad x \in [-1, 1], \tag{21}$$

with boundary conditions $u(-1) = u(1) = \frac{1}{2}$. This problem has the same type of nonlinearity as the stationary Burgers equation; it has been studied in detail in [9], and has been solved with COLSYS [2, pp. 382-383]. We find that for $\epsilon = 10^{-4}$ and $N = 64$ the method without transformation is developing oscillations near the boundary layer, whereas the approximation obtained with one SINE transformation ($m = 1$) easily resolves the boundary layer. Our results appear to be more accurate than the ones obtained with COLSYS for a comparable number of collocation points. In fact, with $m = 2$ we have no problem in resolving the boundary layer with $N = 128$ for ϵ as small as $\epsilon = 10^{-8}$ (see [13] for more details).

5. Conditioning. Some recent work on spectral methods for BVPs is concerned with improving the condition numbers of the matrices for which linear systems have to be solved (e.g., [3, 5, 7]). Since the second-order Chebyshev differentiation matrix has a condition number $O(N^4)$, the corresponding linear systems quickly become very ill conditioned, even for moderate values of N. Interestingly enough, these large condition numbers do not appear to affect the accuracy in the solutions nearly as badly as one would expect. This was first observed by Berrut [3], who transformed the BVP to the circle and solved it with the much better conditioned Fourier spectral method, without seeing any improvement in the accuracy of solutions. However, the large condition numbers would be important in time stepping (so in this sense the PDE case is more difficult than the ODE case), or, if one were to solve the linear systems by iterative methods.

We would like to give a heuristic argument why our solutions are surprisingly accurate (we get close to machine precision, even in cases where the condition number of the linear system is approximately 10^8). Denoting the n-by-n matrix ($n = N - 1$) of our linear system by A, we compute the singular value decomposition $A = W\Sigma V^T$. Σ is a diagonal matrix with the singular values $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n \geq 0$ on its diagonal. The singular vectors $v_1, v_2, \ldots,$ are the columns of V. Both V and. W are orthogonal n-by-n matrices. It is easy to see that the maximum magnification of roundoff errors in the right-hand side occurs when the exact solution u of the system is a multiple of the first singular vector v_1 and the perturbation δu is entirely in the direction of the last singular vector v_n. Figure 3 shows plots of four of the singular vectors[1] for the matrix A of Example 1, with $\epsilon = 10^{-2}$. Singular vectors belonging to large singular values are highly oscillatory, whereas singular vectors associated with small singular values are smooth (here, v_j has $n + 1 - j$ local extrema). This is not surprising, as A is a discretization of a differential operator, and therefore the statement above holds not only for Example 1. The exact solution has a substantial smooth component and roundoff errors cannot be expected to produce a completely smooth perturbation to the exact solution—on the contrary, a nonsmooth perturbation is much more likely to emerge. Thus, the actual amplification of the roundoff error is much smaller than the worst-case scenario of an amplification by $\text{cond}(A) = \sigma_1/\sigma_n$.

The condition numbers of the matrices generated by our repeated SINE transformations exhibit the same growth rates with N as the matrices for the original problem. The conditioning problem is largely unaffected by the transformation.

[1] The vectors are plotted against a stretched version of the interval (0, 1) to make the oscillations near the boundaries more visible.

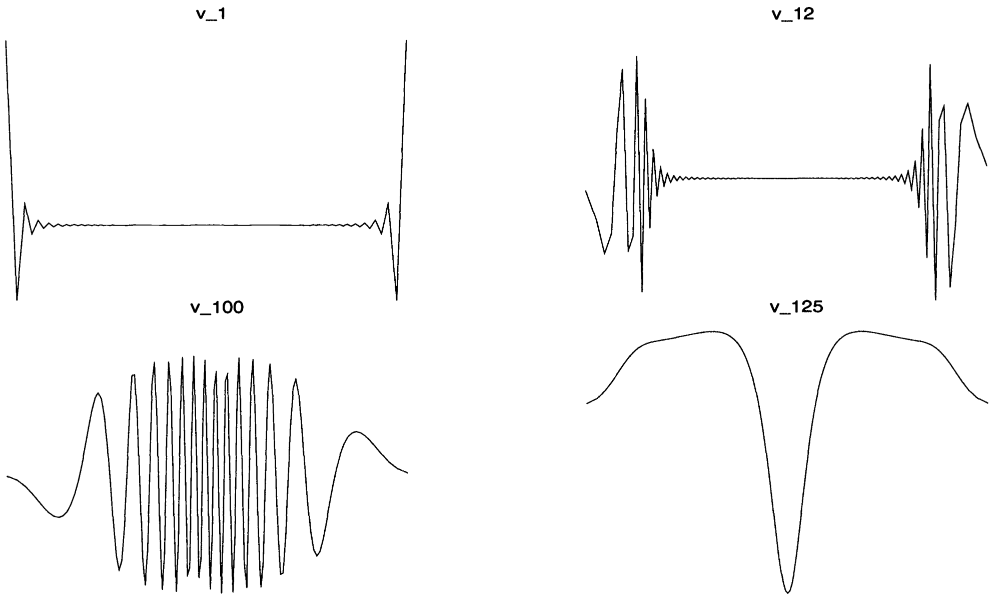

FIG. 3. *Singular vectors* v_1, v_{12}, v_{100}, *and* v_{125} *of* A *of Example* 1 *for* $\epsilon = 10^{-2}$, *plotted against a stretched interval* (0, 1).

Denoting again the Chebyshev-Gauss-Lobatto nodes by $y_j = \cos\frac{\pi j}{N}$, $j = 0, \ldots, N$, the first-order Chebyshev differentiation matrix D is given by

$$D_{kj} = \frac{c_k}{c_j}\frac{(-1)^{j+k}}{y_k - y_j}, \quad k \neq j, \tag{22}$$

$$D_{kk} = -\frac{y_k}{2(1-y_k^2)}, \quad k \neq 0, N, \tag{23}$$

$$D_{00} = -D_{NN} = \frac{2N^2+1}{6}, \tag{24}$$

where $c_k = 1$, except for $c_0 = c_N = 2$. It has been observed [4] that for large N the direct implementation of (22) - (24) suffers from cancellation, causing errors in the elements of the matrix D. Thus, it is advisable to replace (22) and (23) using trigonometric identities by the formulas

$$D_{kj} = \frac{c_k}{c_j}\frac{(-1)^{j+k}}{\sin((k+j)\pi/(2N))\sin((k-j)\pi/(2N))}, \quad k \neq j, \tag{25}$$

$$D_{kk} = -\frac{y_k}{2\sin^2(k\pi/N)}, \quad k \neq 0, N. \tag{26}$$

Finally, to avoid computing the SINE of arguments larger than $\pi/2$ in absolute value, one can take advantage of the symmetry property

$$D_{N-k,N-j} = D_{kj}. \tag{27}$$

Thus the most accurate method of computing D is using formulas (25) - (26) to find the *upper left triangle* of D (i.e., compute D_{kj} with $k + j \leq N$), and then use relation (27) for the other elements. This also appears to be more efficient (at least in our MATLAB implementation).

It should be noted that the effect of a more accurate matrix D cannot always be felt. To be noticeable, N has to be quite large, and the approximate solution must be extremely accurate. For Example 1 (see §4) with $\epsilon = 10^{-2}$, $N = 128$, and $m = 2$, the maximum error is $1.29 * 10^{-14}$, if the more accurate D is used, whereas the error with D computed by formulas (22)-(24) is $1.22 * 10^{-13}$.

6. Conclusions. Very thin boundary layers still must have one or more collocation points within the boundary layer. This results in extremely fine discretizations if the relative spacing of the gridpoints remains unchanged. Although the Chebyshev PS methods are more efficient than finite difference methods in resolving boundary layers, for $\epsilon \ll 1$ they still may need extremely large N to produce reasonable results, as discussed in §1. A much better approach for resolving the boundary layer is to use a mapping. However, a single mapping such as that of [8] is often not sufficient when $\epsilon \ll 1$.

To obtain good resolution for boundary layer problems, at least one of the grid points should lie in the boundary layer no matter how small the boundary layer is. The iterated SINE transformations introduced in §2 provide a very useful coordinate stretching technique to achieve this goal. Theoretically, as indicated in Theorem 2.1, these particular transformations together with the Chebyshev PS method can deal effectively with very small boundary layers using only a fairly small number of collocation points. Even for very small ϵ such as $\epsilon = 10^{-9}$, two or three SINE transformations with $N \approx 100$ are found to be sufficient to resolve the boundary layer, while most of the previously reported finite difference or spectral calculations cannot handle the case when ϵ is as small as 10^{-9}.

Section 3 of this paper gives a practical procedure for implementing the transformations. The transformation technique is also successful for nonlinear BVPs whose solutions have boundary layers. To date the most reliable methods for solving two-point BVPs are based on the collocation method with adaptive mesh selection (e.g., COLSYS [1, 2]). However, for boundary layer problems the present method is a serious competitor, in particular when spectral accuracy is a desirable feature.

The ill conditioning of the linear systems to be solved does not appear to be a serious problem as our experiments and the heuristic argument in §5 indicate. However, care must be taken if one uses these matrices in explicit time stepping in the time-dependent case, or, in the ODE case, if iterative methods are employed to solve the linear system.

Many practical problems possess boundary layers. For example, viscous flows have boundary layers next to solid surfaces where the tangential velocity is reduced to zero. The use of the finite difference method or the Chebyshev PS method is expensive for high Reynolds number flows. The numerical technique introduced in this work can be applied to solve more practical problems (see, e.g., [10]).

TOWARDS AUTOMATIC MULTIGRID ALGORITHMS FOR SPD, NONSYMMETRIC AND INDEFINITE PROBLEMS*

YAIR SHAPIRA†, MOSHE ISRAELI†, AND AVRAM SIDI†

Abstract. A new multigrid algorithm is constructed for the solution of linear systems of equations which arise from the discretization of elliptic PDEs. It is defined in terms of the difference scheme on the fine grid only, and no rediscretization of the PDE is required. Numerical experiments show that this algorithm gives high convergence rates for several classes of problems: symmetric, nonsymmetric and problems with discontinuous coefficients, nonuniform grids, and nonrectangular domains. When supplemented with an acceleration method, good convergence is achieved also for pure convection problems and indefinite Helmholtz equations.

Key words. convection-diffusion equation, discontinuous coefficients, elliptic PDEs, indefinite Helmholtz equation, automatic multigrid method

AMS subject classifications. 65F10, 65N22, 65N55

1. Introduction.

The multigrid method is a powerful tool for the solution of linear systems which arise from the discretization of elliptic PDEs [4], [5]. In a multigrid iteration the equation is first relaxed on a fine grid in order to smooth the error; then the residual equations are transferred to a coarser grid, to be solved subsequently and to supply correction terms. Recursion is used to solve the coarser grid problem in a similar way. In order to implement this procedure the PDE has to be discretized on all grids and restriction and prolongation operators must be defined in order to transfer information between fine and coarse grids. The basic multigrid method works well for the Poisson equation in the square, but difficulties arise with nonsymmetric and indefinite problems and problems with variable coefficients, complicated domains, or nonuniform grids. In these cases, an effective discretization of the PDE on coarse grids becomes more complicated than that provided by a naive approach. Some suggestions on handling discontinuous coefficients are given in [1], while the nonsymmetric case is analyzed in [9] and [10]. A projection method for the solution of slightly indefinite problems is developed in [7]. Another projection method for such problems is presented and analyzed in [3]. These approaches, however, involve specialized and problem-dependent treatment, and the need for a uniform approach is not yet fulfilled.

Present multigrid procedures are not able to serve as "black box" solvers. Special attention has to be given to the neighborhood of the boundary and to the presence of discontinuities. In [6], [20], and [21] the algebraic multigrid (AMG) method is developed. This method is algebraic in the sense that it depends on the discrete system of equations and not on the original PDE or the difference scheme for it. It automatically chooses the coarse level variables and constructs the coarse level equations and the restriction and prolongation operators; hence it applies to general linear systems of equations. However, the set-up time required is large (equivalent to about 10 V-cycles).

Multigrid versions whose definition depends on the difference scheme on the original grid only also exist; these methods, which are called automatic methods in the sequel, reduce the original grid to further coarse grids and automatically construct the coarse-grid coefficient matrix and the restriction and prolongation operators. The black-box multigrid method of [11] applies to problems with discontinuous coefficients and nonrectangular domains and also to nonsymmetric problems [12]. Another robust automatic method is presented in [34].

*Received by the editors November 23, 1993; accepted for publication (in revised form) October 25, 1994.

†Computer Science Department, Technion, Haifa 32000, Israel (yairs@cs.technion.ac.il, israeli@cs.technion.ac.il, sidi@uconnvm.uconn.edu).

None of these methods, however, handles highly indefinite equations; they use coarse-grid operators which are derived from a Galerkin approach, resulting in highly indefinite coarse-grid equations.

All the automatic multilevel methods mentioned above suffer from the disadvantage that for d-dimensional PDE discretizations the coarse-grid operators involve stencils with 3^d coefficients, even when the original difference equation has a $(2d + 1)$-coefficient stencil. This significantly enlarges the amount of arithmetic operations and storage required to generate and store coarse-grid operators (in comparison to algorithms which use $(2d + 1)$-coefficient stencils at all levels). Moreover, it enlarges the cost of a multigrid V-cycle (implemented, e.g., with a Gauss–Seidel smoother) by roughly 25% and 40% for 2-d and 3-d problems, respectively. When W-cycles or more expensive smoothers are used the overhead may be even larger; in particular, the red-black Gauss–Seidel relaxation is not applicable any more and 2^d-color relaxation (whose parallel and vector implementations are more complicated) must be used instead. Furthermore, since the coarse coefficienf matrices lack property A, most of the analysis of [33] for the successive over-relaxation (SOR) method does not apply (the SOR smoother in multigrid methods is considered in [32]). These difficulties are partially relaxed in the algorithm of [31], where $(2^{d+1} - 1)$-coefficient coarse-grid stencils are used; this version, however, is not satisfactory for nonsymmetric problems and problems with discontinuous coefficients.

The aim of this work is to present an automatic multigrid method which does not suffer from the above difficulties; that is, it uses $(2d + 1)$-coefficient stencils only and can be used to solve indefinite problems and several other important classes of problems, e.g., nonsymmetric problems and problems with discontinuous coefficients and nonrectangular domains. Moreover, coarse-grid, restriction, and prolongation operators are obtained from the linear system of equations by a simple and inexpensive recursive process; actually, the cost of this recursion is approximately one work unit, that is, it is equivalent to one fine-grid Gauss–Seidel sweep (compared to five work units for the method of [31]). This fact is especially important for implicit time marching in evolution problems with differential operator or boundary varying in time, where coarse-grid operators are to be reconstructed at every time level. In addition, the fact that operators on different levels are of the same stencil allows easy programming, with data structures and smoothing procedures for coarse-grid equations similar to those used for the finest-grid equation. Like the methods of [11] and [34], the algorithm is robust with respect to the number of fine-grid points, boundary condition type, and shape of the domain. Unlike these methods, however, it is not applicable to schemes which use 3^d-coefficient stencils on the finest grid. We call this algorithm AutoMUG (automatic multigrid).

Our numerical experiments show that, for some difficult problems, the basic AutoMUG iteration may be efficiently accelerated by a Lanczos-type method. It is likely that the existing automatic multigrid methods can also profit from such techniques; indeed, it is shown in [22] that even for highly indefinite, nearly singular Helmholtz equations the two-level implementation of both modified black-box multigrid and AutoMUG can be efficiently accelerated.

AutoMUG is described in §2. In §3 numerical examples are presented. In §4 the algorithm and the numerical results are discussed.

2. The AutoMUG (automatic multigrid) method.

In this section we define the AutoMUG method for the solution of finite difference equations which have $(2d + 1)$-coefficient stencils (for $d = 1, 2$) and examine the properties of its coarse-grid coefficient matrices.

2.1. Abstract definition of AutoMUG.

We begin with an abstract definition of AutoMUG for the solution of the linear system of equations

$$Ax = b.$$

The notation of this definition will be useful in the sequel. In the following, "←" means replacement, S_1 and S_2 are some smoothing procedures, and ϵ, ν_1, ν_2, and o are nonnegative integers denoting, respectively, the cycle index, the number of presmoothings, the number of postsmoothings, and the minimal order of A for which AutoMUG is called recursively. The operators R, P, and Q will be defined later.

```
AutoMUG($x_{\text{in}}, A, b, x_{\text{out}}$) :
        if order($A$) $< o$
                $x_{\text{out}} \leftarrow A^{-1}b$
            otherwise:
                $x_{\text{in}} \leftarrow S_1 x_{\text{in}}$   (repeat $\nu_1$ times)
(1)             $e \leftarrow 0$
                  AutoMUG($e, Q, R(Ax_{\text{in}} - b), e_{\text{out}}$)  }  repeat $\epsilon$ times
                  $e \leftarrow e_{\text{out}}$                           }
                $x_{\text{out}} \leftarrow x_{\text{in}} - Pe$
                $x_{\text{out}} \leftarrow S_2 x_{\text{out}}$   (repeat $\nu_2$ times).
```

For simplicity, we assume in this paper that the method is implemented with a V-cycle ($\epsilon = 1$) and a maximal number of levels ($o = 2$). An iterative application of AutoMUG is given by

```
                $x_0 = 0,\ k = 0$
                while $\|Ax_k - b\|_2 \geq$ threshold $\cdot\ \|Ax_0 - b\|_2$
(2)             AutoMUG($x_k, A, b, x_{k+1}$)
                $k \leftarrow k + 1$
                endwhile
```

Below we define the operators R, P, and Q of (1) for the case in which A is a tridiagonal matrix. Although this is of little significance in itself, it is crucial in the development of the algorithm for other more complicated cases that arise in practical applications and are treated next in this paper.

2.2. The tridiagonal case. In this subsection we define the operators R, P, and Q used in (1) for linear systems which arise, for example, from finite-difference discretization of the ODE

$$(au')' + cu' + \beta u = f \tag{3}$$

where a, c, β, u, and f are functions defined on $\Omega \subset R$ and suitable boundary conditions are imposed on $\partial\Omega$ (this illustrative example will be used in the sequel).

For any matrix B, $B = (b_{i,j})_{1 \leq i \leq K,\ 1 \leq j \leq L}$, define

$$\text{rowsum}(B) \equiv \text{diag}\left(\sum_{j=1}^{L} b_{i,j}\right)_{1 \leq i \leq K}.$$

For a diagonal matrix B, $B = \text{diag}(b_i)_{1 \leq i \leq K}$, let

$$\text{even}(B) \equiv \text{diag}(b_{2i})_{1 \leq i \leq \lfloor K/2 \rfloor} \text{ and } \text{odd}(B) \equiv \text{diag}(b_{2i-1})_{1 \leq i \leq \lceil K/2 \rceil}.$$

Let I denote an identity matrix of a suitable order. Let N be a positive integer, $n = \lfloor \log_2 N \rfloor$, $h \equiv 1/(N+1)$ be the mesh size, and A be a tridiagonal matrix of order N resulting, for example, from a difference scheme approximating (3). For any positive integer K, let $M(K)$ be the permutation matrix which reorders the variables of a K-dimensional vector such that odd-numbered variables appear in the first block and even-numbered variables appear in the second block. Define

$$A_0 = A \text{ and } M_i = M(N/2^i), \quad 0 \le i \le n, \tag{4}$$

where, here and in the sequel, $N/2^i$ means an integer division, that is, $\lfloor N/2^i \rfloor$. In the following we give some motivation for the definition of the operators R, P, and Q used in (1). Suppose A has no vanishing diagonal element and let $D = \text{diag}(A)$. Then, for some bidiagonal matrices B and C, we have

$$A = DM_0^T \begin{pmatrix} I & -B \\ -C & I \end{pmatrix} M_0 = M_0^T(M_0DM_0^T) \begin{pmatrix} I & -B \\ -C & I \end{pmatrix} M_0 = R^{-1}QP^{-1},$$

where

$$R = (M_0DM_0^T) \begin{pmatrix} I & 0 \\ C & I \end{pmatrix} (M_0DM_0^T)^{-1}M_0, \quad Q = (M_0DM_0^T) \begin{pmatrix} I & 0 \\ 0 & I - CB \end{pmatrix},$$

$$P = M_0^T \begin{pmatrix} I & B \\ 0 & I \end{pmatrix}.$$

Suppose these operators are used in (1). Since Q is tridiagonal, one may repeat the above procedure with A replaced by Q to generate suitable operators for the recursive call in (1). With $\nu_1 = \nu_2 = 0$ in (1) this yields a direct solver which is equivalent to the cyclic reduction method [2].

Suppose odd-numbered variables are red-colored. If $\nu_1 = 0$, $\nu_2 = 1$, and the smoothing procedure S_2 of (1) corresponds to the red leg of a red-black Gauss-Seidel relaxation, then an equivalent algorithm is obtained when the definition of R, Q, and P is modified to read

$$\tilde{C} = \text{even}(D)C\text{odd}(D)^{-1}, \ R = \begin{pmatrix} \tilde{C} & I \end{pmatrix} M_0, \ Q = \text{even}(D)(I - CB), \ P = M_0^T \begin{pmatrix} B \\ I \end{pmatrix}.$$

Moreover, $Q = RAP$ still holds; hence this is an appropriate choice for the operators in (1). This procedure is equivalent to that used in [26] for tridiagonal systems.

Note that Q is the Schur complement of A relative to the even-numbered variables. These variables may be viewed as abstract coarse-grid points. Then Q is a coarse-grid operator, R is a fine-to-coarse-grid restriction, and P is a coarse-to-fine-grid prolongation.

We come now to a precise definition of the operators R, P, and Q used in (1). For $0 \le i < n$, define the matrices D_i, B_i, C_i, $P_{A,i+1}$, $\tilde{C}_i$, $R_{A,i+1}$, A_{i+1}, and $S_{A,i+1}$, in this order, by

$$\begin{aligned}
D_i &= \text{diag}(A_i), \\
A_i &= D_iM_i^T \begin{pmatrix} I & -B_i \\ -C_i & I \end{pmatrix} M_i, \\
P_{A,i+1} &= M_i^T \begin{pmatrix} B_i \\ I \end{pmatrix}, \\
\tilde{C}_i &= \text{even}(D_i)C_i\text{odd}(D_i)^{-1}, \\
R_{A,i+1} &= \begin{pmatrix} \tilde{C}_i & I \end{pmatrix} M_i, \\
A_{i+1} &= I - C_iB_i, \\
S_{A,i+1} &= \text{rowsum}(2I - A_{i+1}), \\
A_{i+1} &\leftarrow \text{even}(D_i)A_{i+1}.
\end{aligned} \tag{5}$$

Note that all the A_i are tridiagonal, hence B_i and C_i are well defined (vanishing of a diagonal element of D_i, for some i, is discussed at the end of §2.3). The operator $S_{A,i+1}$ is not used in the present case, but will be helpful in §2.4, where it serves as an approximation to $R_{A,i+1}P_{A,i+1}$. Indeed, when D_0 is a multiple of the identity,

$$\begin{aligned} S_{A,1} - R_{A,1}P_{A,1} &= \text{rowsum}(I + C_0B_0) - (I + C_0B_0) \\ &= \begin{pmatrix} -C_0 & \text{rowsum}(C_0B_0) \end{pmatrix} \begin{pmatrix} B_0 \\ I \end{pmatrix} \sim \frac{h^2}{|a|}\left(\frac{d}{dx}a\frac{d}{dx} + c\frac{d}{dx}\right), \end{aligned} \tag{6}$$

which is negligible when operating on functions u for which $(au')'$ and cu' are not too large. This condition is fulfilled for the solution of the ODE (3), according to the assumptions made in [1].

Remark. The above definition of $S_{A,i+1}$ may be replaced by $S_{A,i+1} = \text{rowsum}(H_i)$, with

$$H_i = R_{A,i+1}P_{A,i+1},\ H_i = R_{A,i+1} \text{ or } H_i = \begin{pmatrix} C_i & I \end{pmatrix}.$$

This yields no essential change in either the theory or the numerical results presented in this paper. The third version is slightly better for indefinite problems, and is used in [23], [24], and [25].

The AutoMUG procedure, namely

$$\text{AutoMUG}(x_{\text{in}}, A, b, x_{\text{out}}),$$

defined in (1), is called $n+1$ times per iteration. In the $(n+1)$st time the AutoMUG procedure is a direct solver. For $1 \le i \le n$, the ith call to the AutoMUG procedure is accomplished with the operators

$$Q \leftarrow A_i,\ P \leftarrow P_{A,i},\ R \leftarrow R_{A,i}.$$

2.3. Properties of the coarse-grid operators. In this subsection we show that the coarse-grid operators A_i defined in (5) preserve some desirable properties of A. To this end, we prove the following lemmas.

For any matrix T let $T^{(i)}$ and $T^{[j]}$ denote its ith row and jth column, respectively, $|T|$ denote the matrix defined by $|T|_{i,j} = |T_{i,j}|$, and $T \ge 0$ (T is nonnegative) hold if all the elements of T are positive or zero. For any two matrices T and S of the same size let $T \ge S$ hold if $T - S \ge 0$. Let $(\cdot,\cdot)$ denote the l_2 inner product and e be the vector whose components are all equal to 1.

LEMMA 2.1. *Assume T and S are two matrices for which the number of rows of S is equal to the number of columns of T. Then*

$$\text{rowsum}(|S|) \le I \ \Rightarrow\ \text{rowsum}(|TS|) \le \text{rowsum}(|T|).$$

Furthermore, if $\text{rowsum}(|S|) \le I$ *and for some* i_0 $\text{rowsum}(|S|)_{i_0,i_0} < 1$ *and* $T^{[i_0]} \ne 0$ *then*

$$\exists\ j_0 \ \textit{s.t.}\ \ \text{rowsum}(|TS|)_{j_0,j_0} < \text{rowsum}(|T|)_{j_0,j_0}.$$

Proof. Suppose $T \ge 0$ and $S \ge 0$. Then

$$\text{rowsum}(TS)_{i,i} = \left(T^{(i)}, \sum_j S^{[j]}\right) \le (T^{(i)}, e) = \text{rowsum}(T)_{i,i}.$$

For the second part of the lemma, by assumption there exists a j_0 such that $T_{j_0,i_0} > 0$. Consequently,

$$\text{rowsum}(TS)_{j_0,j_0} = (T^{(j_0)}, \sum_j S^{[j]}) < (T^{(j_0)}, e) = \text{rowsum}(T)_{j_0,j_0}.$$

For the general case, the lemma follows from

$$\text{rowsum}(|TS|) \le \text{rowsum}(|T||S|).$$

This completes the proof of the lemma.

LEMMA 2.2. *Let I_m be the identity matrix of order m. For some positive integers k and l let W be a matrix of the form*

$$W = \begin{pmatrix} I_k & -S \\ -T & I_l \end{pmatrix},$$

where either T and S are bidiagonal matrices satisfying $T_{i,j} = 0 \Leftrightarrow S_{j,i} = 0$ and $|k - l| \le 1$ or T and S are nonnegative matrices. Then if W is irreducible, so is $I_l - TS$.

Proof. For any square matrix U of order m let $G[U]$ be the directed graph defined by

$$G[U] \equiv \{1, 2, \dots, m\},\ \{(i, j) \mid U_{j,i} \ne 0\}$$

where the first set denotes the nodes and the second one the edges of the graph. Irreducibility of U is equivalent to strong connectivity of $G[U]$, which is equivalent to strong connectivity of $G[I - U]$ (see [30]). From the assumptions of the lemma, there follows, at least for $i \ne j$,

$$((I_{k+l} - W)^2)_{j,i} \ne 0 \ \Leftrightarrow\ \{\exists\, m,\ (I_{k+l} - W)_{j,m} \ne 0,\ (I_{k+l} - W)_{m,i} \ne 0\}.$$

Consequently,

$$\{1, 2, \dots, k + l\},\ \{(i, j) \mid i \ne j \text{ and } \exists\, m \text{ s.t. } (I_{k+l} - W)_{j,m} \ne 0, (I_{k+l} - W)_{m,i} \ne 0\}$$
$$\subset G[(I_{k+l} - W)^2].$$

Let i_1 and i_2 be some integers satisfying $k + 1 \le i_1, i_2 \le k + l$. Since $G[I_{k+l} - W]$ is strongly connected, there exists a path in $G[I_{k+l} - W]$ leading from i_1 to i_2. From the structure of $I_{k+l} - W$ this path must include an even number of edges. Hence i_1 is connected to i_2 also in $G[(I_{k+l} - W)^2]$. The lemma follows from

$$(I_{k+l} - W)^2 = \begin{pmatrix} ST & 0 \\ 0 & TS \end{pmatrix}.$$

This completes the proof of the lemma.

LEMMA 2.3. *Assume T is an M-matrix and* diag$(T) = I$. *Then $(2I - T)T$ is an M-matrix.*

Proof. From the assumptions of the lemma, we have $I - T \ge 0$, and, by Theorem 3.10 of [30], $\rho(I - T) < 1$, where ρ denotes the spectral radius. Hence $(I - T)^2 \ge 0$ and $\rho((I - T)^2) < 1$. Since

$$(2I - T)T = I - (I - T)^2$$

the lemma follows from Theorem 3.8 of [30]. This completes the proof of the lemma.

THEOREM 2.4. *Assume A is tridiagonal and one of the following*: (a) *an M-matrix,* (b) *a nonsingular weakly diagonally dominant matrix, or* (c) *an irreducibly diagonally dominant matrix. Then so are all the matrices A_{i+1} defined in* (4) *and* (5); *moreover, the matrices D_i defined in* (5) *are symmetric positive definite* (*SPD*) *and, in case* (a), *so are the matrices $S_{A,i+1}$.*

Proof. The proof is by induction on i in (5). For case (a), the SPD property of D_i follows from A_i being an M-matrix, and the M-matrix property of A_{i+1} follows from Lemma 2.3 and

$$(2I - D_i^{-1}A_i)D_i^{-1}A_i = M_i^T \begin{pmatrix} I & B_i \\ C_i & I \end{pmatrix} \begin{pmatrix} I & -B_i \\ -C_i & I \end{pmatrix} M_i$$
$$= M_i^T \begin{pmatrix} I - B_iC_i & 0 \\ 0 & I - C_iB_i \end{pmatrix} M_i.$$

For case (b), the SPD property of D_i follows from the nonsingularity and weak diagonal dominance of A_i, the nonsingularity of A_{i+1} follows from

$$D_i^{-1}A_i = M_i^T \begin{pmatrix} I & -B_i \\ -C_i & I \end{pmatrix} M_i$$
$$= M_i^T \begin{pmatrix} I & 0 \\ -C_i & I \end{pmatrix} \begin{pmatrix} I & 0 \\ 0 & I - C_iB_i \end{pmatrix} \begin{pmatrix} I & -B_i \\ 0 & I \end{pmatrix} M_i,$$

and the weak diagonal dominance of A_{i+1} follows from Lemma 2.1. For case (c), the SPD property of D_i follows from irreducible diagonal dominance of A_i, and the irreducible diagonal dominance of A_{i+1} follows from Lemmas 2.1 and 2.2. The last part of the theorem follows from A_i being an M-matrix. This completes the proof of the theorem.

When its assumption holds, Theorem 2.4 ensures that the matrices B_i and C_i of (5) are well defined and that no division by zero occurs. Otherwise, a diagonal element of D_i (for some i) may vanish; this may be handled by a reasonable definition of the corresponding line of C_i and column of B_i, and, similarly, of the off-diagonal elements in the corresponding line of $R_{A,i+1}$ and column of $P_{A,i+1}$ (e.g., the templates $[0, 1, 0]$ for restriction and $[0, 1, 0]^t$ for prolongation).

2.4. The two-dimensional case. In this subsection we define the operators R, P, and Q used in (1) for linear systems which arise, for example, from finite difference discretization of the PDE

$$(au_x)_x + (bu_y)_y + cu_x + du_y + \beta u = f,$$

where a, b, c, d, β, u, and f are functions defined on $\Omega \subset R^2$ and suitable boundary conditions are imposed on $\partial\Omega$.

Let $U(K, L)$ be a permutation matrix such that for any vector v defined on a $K \times L$ grid and ordered lexicographically row by row, $U(K, L)v$ is the same vector v ordered lexicographically column by column. Let

$$U_{k,l} \equiv U(N/2^k, N/2^l), \qquad 0 \leq k, l \leq n,$$

where, here and in the sequel, $N/2^j$ means an integer division, that is, $\lfloor N/2^j \rfloor$. Suppose A is of the form

$$A = \text{blockdiag}(X^{(j)})_{1 \leq j \leq N} + U_{0,0}^T \cdot \text{blockdiag}(Y^{(j)})_{1 \leq j \leq N} U_{0,0} \tag{7}$$

where $X^{(j)}$ and $Y^{(j)}$ are tridiagonal matrices of order N. For example, if

$$X^{(j)} = Y^{(j)} = \text{tridiag}\left(\frac{1}{h^2}, \frac{-2}{h^2} + \frac{\beta}{2}, \frac{1}{h^2}\right), \quad 1 \leq j \leq N$$

for some $\beta \in C$, then A represents a central discretization of the Helmholtz equation

$$u_{xx} + u_{yy} + \beta u = f$$

in the unit square with Dirichlet boundary conditions.

In the following we give some motivation to the definition of the operators R, P, and Q used in (1). For simplicity, we treat semi-coarsening in the x-direction only; the y-direction coarsening is implemented analogously.

By replacing A in (4) with $X^{(j)}$ and applying (5) to it one may define

$$R_x = \text{blockdiag}(R_{X^{(j)},1})_{1\le j\le N}, \quad P_x = \text{blockdiag}(P_{X^{(j)},1})_{1\le j\le N}.$$

The natural definition $Q = R_x A P_x$ is undesirable because it spoils the tridiagonal structure of the second term in the right-hand side of (7). In order to avoid this, only the first term in the right-hand side of (7) is multiplied by R_x and P_x from the left and right sides, respectively; the second term is multiplied instead by $\text{rowsum}(R_x P_x)$. According to (6), the relative error inserted into $R_x A P_x$ by this approximation is negligible, at least for functions in the neighborhood of the solution.

In order to perform a y-direction coarsening, the second term in the right-hand side of (7) is treated similarly (using restriction and prolongation operators R_y and P_y), while not spoiling the structure of the first term. (1) is then implemented with the resulting coarse-grid operator Q and the restriction and prolongation operators $R = R_y R_x$ and $P = P_x P_y$.

We come now to a precise definition of the operators R, P, and Q of (1) for the 2-d case. Define

$$X_0^{(j)} \equiv X^{(j)}, \quad Y_0^{(j)} \equiv Y^{(j)}, \quad 1 \le j \le N.$$

For $i = 1, \ldots, n$, define the matrices R_i, P_i, and A_i, in this order, by

For $1 \le j \le N/2^{i-1}$, do (5) with A and i replaced by $X^{(2^{i-1}j)}$ and $i-1$, respectively,

For $1 \le j \le N/2^{i-1}$, do (5) with A and i replaced by $Y^{(2^{i-1}j)}$ and $i-1$, respectively,

$$R_i \equiv U_{i,i}^T \cdot \text{blockdiag}(R_{Y^{(2^i j)},i})_{1\le j\le N/2^i} U_{i-1,i} \cdot \text{blockdiag}(R_{X^{(2^{i-1} j)},i})_{1\le j\le N/2^{i-1}},$$

$$P_i \equiv \text{blockdiag}(P_{X^{(2^{i-1} j)},i})_{1\le j\le N/2^{i-1}} U_{i-1,i}^T \cdot \text{blockdiag}(P_{Y^{(2^i j)},i})_{1\le j\le N/2^i} U_{i,i},$$

$$\text{blockdiag}(X_i^{(2^i j)})_{1\le j\le N/2^i} \quad \leftarrow$$

$$\leftarrow U_{i,i}^T \cdot \text{blockdiag}(S_{Y^{(2^i j)},i}))_{1\le j\le N/2^i} U_{i,i} \cdot \text{blockdiag}(X_i^{(2^i j)})_{1\le j\le N/2^i}, \tag{8}$$

$$\text{blockdiag}(Y_i^{(2^i j)})_{1\le j\le N/2^i} \quad \leftarrow$$

$$\leftarrow U_{i,i} \cdot \text{blockdiag}(S_{X^{(2^i j)},i}))_{1\le j\le N/2^i} U_{i,i}^T \cdot \text{blockdiag}(Y_i^{(2^i j)})_{1\le j\le N/2^i},$$

$$A_i \equiv \text{blockdiag}(X_i^{(2^i j)})_{1\le j\le N/2^i} + U_{i,i}^T \cdot \text{blockdiag}(Y_i^{(2^i j)})_{1\le j\le N/2^i} \cdot U_{i,i}.$$

As in the tridiagonal case, the ith call to the AutoMUG procedure in (1), $1 \le i \le n$, is accomplished with the operators

$$Q \leftarrow A_i, \quad P \leftarrow P_i, \quad R \leftarrow R_i.$$

The following theorem ensures that the coarse-grid operators A_i enjoy a desirable property.

THEOREM 2.5. *Assume A is defined as in* (7) *with $X^{(j)}$ and $Y^{(j)}$ being tridiagonal irreducibly diagonally dominant M-matrices of order N. Then all the matrices A_i defined in* (8) *are irreducibly diagonally dominant M-matrices.*

Proof. Following the route of the proof of Theorem 2.4, by induction on i in (8) all the tridiagonal matrices X_i and Y_i are irreducibly diagonally dominant M-matrices and the diagonal matrices S_i are SPD. Hence the A_i are weakly diagonally dominant, with a strict diagonal dominance for at least one row. Irreducibility of A_i follows from

$$G[A_i] = \{1, 2, \dots, N/2^i\} \times \{1, 2, \dots, N/2^i\},$$

$$\{((k,l),(m,l)) \mid (X_i^{(2^i l)})_{m,k} \neq 0\} \cup \{((l,k),(l,m)) \mid (Y_i^{(2^i l)})_{m,k} \neq 0\}.$$

Hence the A_i are irreducibly diagonally dominant matrices. Since the A_i have positive diagonal elements and nonpositive off-diagonal elements, it follows from [30] that they are also M-matrices. This completes the proof of the theorem.

The definition (7) of the coefficient matrix A assumes that the grid is logically rectangular. Problems involving complicated domains may be treated by embedding the original grid into a logically rectangular grid [28] and appending trivial equations for the redundant variables. This approach was used in the numerical experiments in §3. Note that these dummy variables, as well as their corresponding equations, do not have to be stored, since they do not influence the values of the original variables.

3. Numerical experiments. Our aim in this section is to show the applicability of AutoMUG to several classes of problems, including indefinite Helmholtz equations. We compare the performance of AutoMUG to that of a standard multigrid version which has the same complexity, that is, uses $(2d + 1)$-coefficient coarse-grid stencils only (see §1). This version, denoted by MG, is implemented as follows: coarse-grid operators are generated from the PDE by the same scheme as that used on the finest grid. Full weighting and bilinear interpolation are used for restriction and prolongation, respectively. For both AutoMUG and MG the maximal number of levels (e.g., six levels for 63 × 63 grids) is used, which means setting $o = 2$ in (1); the only exceptions are examples 13 and 14, where four levels are used.

When implementing MG one must use $2^{n+1} - 1$ grid points on the finest grid and $2^q - 1$, $1 \leq q \leq n$, for coarser grids in order to preserve uniformity. Here the even points, which are taken as coarse-grid points, are always internal points of the original grid. For 2^n-point grids, on the other hand, the last fine-grid point appears as a last grid point in all grids. Hence, coarse grids are biased towards the boundary. For AutoMUG, on the other hand, grids of both 2^n points or $2^{n+1} - 1$ points may be used, and actually achieve the same convergence rates; this is because in the 2^n points case AutoMUG automatically chooses in the coarse-grid schemes the most accurate extrapolation of boundary points. An odd number of points $N = 63$ is used here for an easier comparison between AutoMUG and MG.

On all grids the smoother was either the one provided by the ILU(1,1) decomposition of [18] and [29] (namely, ILU with no fill-in) or the red-black Gauss-Seidel (RB) relaxation. ILU was considered as a smoother in multigrid in [16] and 17]. One presmoothing and one postsmoothing is performed in each level of a V-cycle ($\epsilon = \nu_1 = \nu_2 = 1$ in (1)). The initial guess is random in (0, 1). Double-precision arithmetic is used.

AutoMUG and MG are iterated according to (2) with $10^{-12} \leq$ threshold $\leq 10^{-14}$, to avoid the effect of round-off errors. It was checked that the l_∞ norm of the error is reduced during this process by more than 10 orders of magnitude. Convergence factors are computed from the last four iterations, namely

$$\text{convergence factor} = \left(\frac{\|Ax_{\text{last}} - b\|_2}{\|Ax_{\text{last}-3} - b\|_2} \right)^{1/3}$$

where *last* is the index of the last iteration. When the basic iteration (2) by itself diverges (denoted by "*") or unsatisfactorily converges, it is also implemented with an acceleration

TABLE 1

Convergence factors for MG and AutoMUG (in parentheses: averaged convergence factors when the TFQMR acceleration is used).

	MG	MG	AutoMUG	AutoMUG
example	ILU	RB	ILU	RB

method applied to it. We have used the Transpose-free quasi-minimal residual (TFQMR) method (Algorithm 5.2 in [15]) which avoids the computation of the transpose of the coefficient matrix and preconditioner (the latter is only implicitly given in (1), so its transpose is not available). As a matter of fact, the TFQMR method may be considered a modification of the conjugate gradients squared (CGS) method of [27] and [28], which is a generalization of the conjugate gradients (CG) method to nonsymmetric and indefinite problems. We have found that the performance of CGS is similar to that of TFQMR; however, we have preferred the latter because of its smooth convergence curve.

All the above acceleration techniques require an amount of storage and arithmetical operations comparable to that of CG, namely an additional 1 – 1.5 work units per iteration. For the accelerated iteration the convergence factor defined above often oscillates; hence the averaged convergence factor defined by

$$\text{averaged convergence factor} = \left(\frac{\|Ax_{\text{last}} - b\|_2}{\|Ax_0 - b\|_2}\right)^{1/\text{last}}$$

is considered instead, and displayed in parentheses in Table 1. When the accelerated iteration stagnates, the sign "$*$" alone is presented.

The problems solved are of the form

$$Lu(x, y) = f(x, y), \quad (x, y) \in \Omega \subset R^2,$$

with the exact solution $u = xy$ (except of examples 7, 9, 10b, and 12, for which the exact solution is $u = 0$). Since the initial guess is random and the problem is linear, the rates of convergence are independent of the specific choice of the solution. A second-order central finite difference scheme is used. For most examples the region Ω is the unit square, Dirichlet boundary conditions are imposed, and uniform grids are used. Exceptions to the above are noted at particular examples.

It is seen from the numerical results that for some examples AutoMUG by itself diverges or unsatisfactorily converges, while when supplemented with an acceleration scheme it converges quickly; this is apparently because the iteration matrix has some isolated eigenvalues of large magnitude, while most of its spectrum is clustered around zero.

List of examples.

1. The Poisson equation $L = -\Delta$.
2. The anisotropic equation

$$-u_{xx} - \sigma u_{yy} = 0$$

with (a) $\sigma = 10^{-2}$ and (b) $\sigma = 10^{-4}$. This example is more difficult than the Poisson equation, since error components which are smooth in the x-direction and oscillate in the y-direction are not easily smoothed by a point Gauss-Seidel smoother; this difficulty may be handled by employing an appropriate line relaxation [4].

The ILU smoother used here is lexicographically ordered; hence oscillations in the x-direction are smoothed much better than those of the y-direction. According to the above remark, it is likely that an anti-lexicographical ordering is more suitable to this example.

Case (a) is the most difficult one considered in [31]. The convergence factors derived there are similar to those obtained here.

3. The Poisson equation with a Chebyshev-type grid; it is discretized via central differences on the two-dimensional grid

$$P_N(j,k) \equiv \left(\frac{1-\cos\left(\dfrac{j\pi}{N+1}\right)}{2}, \frac{1-\cos\left(\dfrac{k\pi}{N+1}\right)}{2} \right), \quad 1 \le j,k \le N.$$

The matrix operator for this scheme may be used as a preconditioner for a Chebyshev-collocation discretization of the Poisson equation (see [19]). Coarse-grid operators for MG are obtained from the discretization of the PDE on the grids $P_{\lfloor N/2^i \rfloor}$, $1 \le i \le 5$. As in the previous example, the RB smoother is inferior to ILU; the reason for this is that the equation is locally anisotropic in most of the mesh cells.

4. The Poisson equation in a square with a slit. The actual shape is a 63 × 63 grid minus a narrow strip of width 2 points and length 32 points emerging from the center in the x-direction. This problem is considered more difficult than the Poisson equation in a square (see [5]).
5. The Poisson and definite Helmholtz equations in a domain approximating the North Atlantic, from about 10° to 53° north. A definite Helmholtz problem of the form

$$-u_{xx} - u_{yy} + \beta u = f$$

stems from explicit time-stepping in the quasi-geostrophic version of the shallow-water equations. The domain is embedded in a Cartesian grid of 45 × 93 points. The bounding points are assumed to lie on that grid. The cases under consideration are (a) $\beta = 0$ and (b) $\beta = 20$.

6. The Poisson equation with boundary conditions of the third kind

$$\frac{\partial u}{\partial n} + 1.5u = 0,$$

where $\vec{n}$ denotes the outer normal vector. This example is presented mainly for the sake of comparison with the next one.

For this example MG was implemented with restriction and prolongation operators modified near the boundaries such that their rowsums equal 1 everywhere; otherwise, much slower convergence occurs. For all other examples, however, MG with this modification was inferior to MG with the standard bilinear interpolation and full-weighting restriction.

7. The diffusion equation

$$-(a(x,y)u_x)_x - (a(x,y)u_y)_y = 0$$

with the discontinuous coefficient

$$a(x,y) = \begin{cases} \gamma & \max(|x-0.5|, |y-0.5|) \le 3h, \\ 1 & \text{otherwise,} \end{cases}$$

where h is the mesh size and $\gamma = 10^4$ and the boundary conditions of the previous example. It is known [1] that standard multigrid approaches cannot simulate the problem appropriately on coarse grids.

This problem is similar to Problem 3 in [34] and to the most difficult case of Problem 1 in [1]. The fine-grid (for MG, also the coarse-grid) discretization is done as in [1].

8. The Poisson equation on the L-shaped region

$$\Omega = ((0,1) \times (0,0.5)) \cup ((0,0.5) \times (0.5,1)).$$

Dirichlet and Neumann boundary conditions are imposed on

$$\Gamma \equiv (\{0.5\} \times [0.5,1]) \cup ([0.5,1] \times \{0.5\})$$

and $\partial\Omega \setminus \Gamma$, respectively. This example is presented mainly for the sake of comparison with the next one.

9. A diffusion equation in the spirit of Kershaw's problem (Problem 7 in [34]) is solved in the same L-shaped region as above. The equation is that of example 7 with $\gamma = 10^6$. Boundary conditions of the same type as those of example 8 are imposed.

By comparing the results of examples 7 and 9 to those of examples 6 and 8 (respectively) it may be concluded that the discontinuity inserted in examples 7 and 9 does not affect the efficiency of AutoMUG.

10. The convection-diffusion equation with fan-like streamlines

$$-u_{xx} - u_{yy} + \eta(xu_x + yu_y) = f$$

whose characteristics are rays starting at the origin so that they all intersect a boundary. This kind of equation is hard to solve with the multigrid approach, since error terms which are smooth in the convection direction and oscillate in the perpendicular direction are only half-corrected by the coarse-grid term [9].

Two cases were examined: (a) $\eta = 150$, for which diagonal dominance holds and (b) $\eta = 300$, for which it is violated for most of the equations in the linear system.

Unlike all other examples in this section, MG was implemented with coarse-grid operators derived from an upwind, rather than central, scheme; otherwise, considerably slower convergence (or even divergence) was reported.

11. The circulating flow equation

$$\sin(\pi(y-0.5))\cos(\pi(x-0.5))u_x - \sin(\pi(x-0.5))\cos(\pi(y-0.5))u_y = f.$$

The region is a square with a 1 × 1 point hole at the middle of it. For this region, an upwind scheme is inadequate [8]; following [10], we have thus inserted isotropic artificial viscosity, the amount of which is locally chosen to be the minimal amount required for weak diagonal dominance. The results for AutoMUG are far better than those of the V-cycle in [10]. The coarse-grid operators generated by AutoMUG may thus be used in conjunction with the defect correction approach of [10] to accelerate convergence.

For the MG approach divergence was reported no matter whether coarse-grid operators are derived from the central or upwind scheme.

Convection diffusion equations similar to those considered here are solved efficiently in [34]. The method of [34], however, uses the incomplete line LU (ILLU) smoother; this is a robust smoother, which also achieves high rates of convergence when used as a preconditioner in preconditioned CG (with no multigrid strategy) [28]. Since we are interested in investigating the efficiency of multigrid methods on their own, we avoid implementing AutoMUG with smoothers which are also efficient preconditioners.

The last three examples are of special difficulty, involving oscillating coefficients or indefiniteness.

12. The diffusion equation

$$-(a(x-y)u_x)_x - (a(x-y)u_y)_y = 0$$

with the oscillating coefficient

$$a(t) = 1.05 + \sin\left(\frac{t}{\sqrt{2}h}\right)$$

(see [13]). The discretization is symmetric, as in [30].

13. The indefinite Helmholtz equation

$$-u_{xx} - u_{yy} - \beta u = f$$

with $\beta = 200$. Note that for $h = 1/64$ the (k, l) eigenvalue of the Poisson equation, with $(k, l) \in \{(2, 4), (4, 2)\}$, is equal to

$$\frac{4}{h^2}\left(\sin^2\frac{kh}{2} + \sin^2\frac{lh}{2}\right) = 196.8537;$$

hence, with the above choice for β, the coefficient matrix has nearly singular eigenvalues (see [7]). Furthermore, eight distinct eigenvalues of the Helmholtz equation are negative; hence the problem is indefinite, and the iteration matrix for either AutoMUG or MG often has eigenvalues of magnitude larger than 1 (see [22]-[24]). The use of an acceleration scheme is thus crucial to ensure convergence.

For the current and the following example only four levels are used, and the fourth-level equation is approximately solved by 100 Kacmarz sweeps. The reason for this is that the coefficient matrix for the fifth-level problem is nonpositive for either AutoMUG or MG, hence cannot serve as a suitable approximation to the PDE (see [23] and [24] for a detailed explanation).

14. The indefinite Helmholtz equation (Example 6.3 in [14])

$$-u_{xx} - u_{yy} - \beta u = f$$

with $\beta = 200$, complex boundary conditions of the third kind

$$\frac{\partial u}{\partial n} + 10iu = g, \quad (x, y) \in [0, 1] \times \{0\},$$

and Dirichlet boundary conditions on the rest of $\partial\Omega$. The mixed boundary conditions are discretized via a first-order scheme as in [14]. Like the previous problem, this problem is indefinite, hence the use of acceleration is crucial.

Unlike most of the examples in this section, for the indefinite examples RB is a better smoother than ILU. We believe this is due to the instability of ILU for coarse-grid equations; this may be handled by adding some positive weights to main diagonal elements in the ILU decomposition which become too small.

4. Discussion. AutoMUG is a multilevel method for the solution of finite difference schemes of $(2d+1)$-coefficient stencils which arise, for example, from d-dimensional second-order PDEs. It is automatic in the sense that its definition depends on the scheme on the original grid only, and no rediscretization of the PDE is required. Derivation of coarse-grid, restriction, and prolongation operators for AutoMUG is inexpensive and straightforward. In addition, property A of the coefficient matrix is preserved at all levels; this simplifies the programming and enables the use of the RB and SOR smoothers.

The numerical examples show that, when implemented with a suitable smoother, AutoMUG gives high rates of convergence for several classes of problems: symmetric, nonsymmetric and problems with discontinuous coefficients, nonuniform grids, and nonrectangular domains. When supplemented with an acceleration scheme, high rates of convergence also are achieved for pure convection problems and indefinite Helmholtz equations.

For some problems AutoMUG is inferior to nonautomatic multigrid algorithms designed especially for the specific problem. In particular, it is inferior to the method of [7] for slightly indefinite problems and to that of [10] for problems with circulating flow. In these cases, it is recommended that the coarse-grid operators of AutoMUG be used in conjunction with the specific approach, that is, the projection of [7] or the overresidual weighting and defect correction of [10]. Alternatively, accelerating AutoMUG by a Lanczos-type method also yields high rates of convergence. For highly indefinite problems, the use of such acceleration is crucial, since the basic iteration often diverges. Hence for problems which involve several sources of difficulty, e.g., indefiniteness, convection, jumps, singularities, etc., AutoMUG supplemented with an acceleration scheme seems to provide an effective solver.

Acknowledgment. We wish to thank Dr. Irad Yavneh for valuable comments and for suggesting examples 4 and 5.

ALTERNATING-DIRECTION LINE-RELAXATION METHODS ON MULTICOMPUTERS*

JÖRN HOFHAUS† AND ERIC F. VAN DE VELDE‡

Abstract. We study the multicomputer performance of a three-dimensional Navier–Stokes solver based on alternating-direction line-relaxation methods. We compare several multicomputer implementations, each of which combines a particular line-relaxation method and a particular distributed block-tridiagonal solver. In our experiments, the problem size was determined by resolution requirements of the application. As a result, the granularity of the computations of our study is finer than is customary in the performance analysis of concurrent block-tridiagonal solvers. Our best results were obtained with a modified half-Gauss-Seidel line-relaxation method implemented by means of a new iterative block-tridiagonal solver that is developed here. Most computations were performed on the Intel Touchstone Delta, but we also used the Intel Paragon XP/S, the Parsytec SC-256, and the Fujitsu S-600 for comparison.

Key words. Navier–Stokes equations, concurrency, parallelism, block-tridiagonal systems, tridiagonal systems, ADI, alternating directions

AMS subject classifications. 65M20, 65N40, 65Y05, 76C05, 76M20

1. Introduction.

When using alternating-direction line-relaxation methods for systems of partial-differential equations discretized on a rectangular grid, one must solve many block-tridiagonal systems of linear equations in every relaxation step. This type of computation surfaces in many applications. In our work, we faced it when parallelizing a highly vectorized solver for the three-dimensional, unsteady, and incompressible Navier–Stokes equations [4] for use on multicomputers. In this paper, we shall discuss and analyze five line-relaxation methods and six distributed block-tridiagonal solvers used during the course of this project. We have measured the performance of several combinations of relaxation methods and block-tridiagonal solvers on three multicomputers (the Intel Touchstone Delta [5], the Intel Paragon XP/S [6], and the Parsytec SC-256 [13]) and on one conventional vector processor (the Fujitsu S-600).

Three-dimensional computations are more complex than two-dimensional ones because of additional coordinates for the geometry and the vector fields. Three-dimensional computations are also algorithmically different, because every line-relaxation step requires the solution of a larger number of smaller-sized linear systems than a comparable two-dimensional line-relaxation step. To see this, consider a two- and a three-dimensional problem of the same size, i.e., with the same number of unknowns. The two-dimensional problem on an $M \times M$ grid requires the solution of $O(M)$ block-tridiagonal systems of size $O(M)$, while the three-dimensional problem on an $N \times N \times N$ grid with $N^3 = M^2$ requires the solution of $O(N^2) = O(M^{4/3})$ systems of size $O(N) = O(M^{2/3})$.

On multicomputers, the reduced system size has a serious impact. There exist many concurrent algorithms to solve block-tridiagonal systems; see, e.g., [2], [10], [12], [14]–[16]. However, these methods have been studied mainly for very coarse-grain computations, i.e., for computations in which the ratio of the system size over the number of nodes is high. Bondeli [2] studied computations with less than 25 nodes and system sizes exceeding 16, 800. Krechel,

Plum, and Stüben [14] improved the efficiency of a modified cyclic-reduction algorithm on the 16-node iPSC/2-VX. Their computations of moderate-to-coarse granularity solved 256 tridiagonal systems of size 128 and the highest-achieved efficiency was about 50%. For the reasons mentioned above, the granularity of the block-tridiagonal solver in our three-dimensional application is much smaller when running the code for a grid of fixed size on all 512 computing nodes of the Delta. Constructing an efficient concurrent program for this problem is a challenge.

An outline of the paper follows. In §2, a brief description of the implemented relaxation methods is given. In §3, we shall study algorithm and concurrency issues of several basic concurrent alternating-direction relaxation methods. Each method is based on a different distributed solver for block-tridiagonal systems. First, the sequential block-tridiagonal solver is distributed and pipelined to obtain a concurrent line-relaxation method. Subsequently, we use concurrent tridiagonal solvers based on recursive doubling, cyclic reduction, partitioning, and divide and conquer, respectively. Finally, a new iterative tridiagonal solver is developed. In §4, we analyze the performance on the Delta of the proposed methods applied to a Navier-Stokes solver. The Navier-Stokes equations and their discretization for an interesting application are given in §4.1. We give this description for the sole purpose of defining precisely how the performance data were obtained. The fluid-dynamical results of our computations are discussed in another paper [1]. In §5, computations on the Paragon, the Parsytec, and the Fujitsu are compared with those on the Delta.

2. Relaxation methods. The discretization of partial-differential equations often leads to a large sparse system of equations

$$A\vec{u} = \vec{f}. \tag{1}$$

Classical relaxation methods to solve (1) are obtained by splitting the coefficient matrix A into

$$A = G + H$$

with G an easily inverted matrix. This defines the iteration

$$G\vec{u}^{(\nu)} = \vec{f} - H\vec{u}^{(\nu-1)}, \tag{2}$$

which converges to the exact solution $\vec{u}^*$ if the spectral radius of $G^{-1}H$ is less than one; e.g., see [11].

In the description that follows, it is convenient to think of the three-dimensional Poisson problem discretized to second-order accuracy on a three-dimensional rectangular grid of size $M \times N \times K$. Then, interior grid points are identified by means of a triple (m, n, k) with $1 \leq m \leq M$, $1 \leq n \leq N$, and $1 \leq k \leq K$. One unknown and one equation is associated with each interior grid point.

One *elementary line-relaxation step* updates all unknowns of one grid line simultaneously. For example, an x-line is a set of grid points (m, n, k) where $1 \leq m \leq M$ and n and k are fixed. An x-line is, therefore, identified by means of a couple (n, k). An elementary x-line-relaxation step reduces to the tridiagonal system

$$a_m\, u_{m-1} \;+\; b_m\, u_m \;+\; c_m\, u_{m+1} \;=\; d_m, \qquad m = 1, \ldots, M \tag{3}$$

for each x-line. One *x-line-relaxation step* updates all x-lines of the grid once, i.e., it performs an elementary x-line-relaxation step for all (n, k) with $1 \leq n \leq N$ and $1 \leq k \leq K$. For three-dimensional problems, an *alternating-direction line-relaxation step* consists of an *x-line-relaxation step*, a *y-line-relaxation step*, and a *z-line-relaxation step*. We restrict our discussion to the x-line-relaxation step. In matrix-vector notation, the system (3) has the form

$$T\,\vec{u} = \vec{d}, \tag{4}$$

with

$$T = \begin{pmatrix} b_1 & c_1 & & & & \\ a_2 & b_2 & c_2 & & \mathbf{0} & \\ & \cdot & \cdot & \cdot & & \\ & & \cdot & \cdot & \cdot & \\ & & & \cdot & \cdot & \cdot \\ & \mathbf{0} & & a_{M-1} & b_{M-1} & c_{M-1} \\ & & & & a_M & b_M \end{pmatrix}.$$

The right-hand side vector $\vec{d}$ depends on the boundary conditions, which add the terms $a_1 u_0$ and $c_M u_{M+1}$ to the right-hand side of the first and the last equation, respectively. The right-hand side vector also depends on neighboring x-lines $(n+1, k)$, $(n-1, k)$, $(n, k-1)$, and $(n, k+1)$. (This assumes a classical seven-point stencil for second-order discretization of the Poisson equation in three dimensions.) Three variants of the line-relaxation method were implemented.

When the right-hand side terms for x-line (n, k) are computed exclusively with u-values that were known before the x-line-relaxation step began, the method is called *Jacobi line relaxation.* In this case, all elementary x-line-relaxation steps and all systems (3) are independent. In principle, all tridiagonal solves may be performed concurrently provided that the coefficients of T are not distributed over several processes.

Gauss–Seidel line relaxation assigns an order to the x-lines and uses the updated u-values obtained in preceding elementary x-line-relaxation steps to compute the right-hand sides of the current elementary x-line-relaxation step. *Lexicographic ordering* approach enforces a rigid and sequential ordering on the solution of the tridiagonal systems: (n, k) follows $(n-1, k)$ and $(n, k-1)$.

For the purpose of vectorization and/or concurrent computing, it makes sense to make many tridiagonal systems independent of one another so that they can be solved simultaneously. *Red-black ordering* performs elementary line-relaxation steps first for all x-lines for which $n+k$ is even and, subsequently, for all x-lines for which $n+k$ is odd.

Lexicographic ordering may be kept provided the relaxation method is modified. For the x-line-relaxation step, e.g., the systems of grid plane $k =$ constant are made independent of those of grid plane $k-1$ by using the old u-values of x-line $(n, k-1)$ when computing the system for the u-values for x-line (n, k). In the remainder of this paper, we call this *half-Gauss-Seidel line relaxation.* In principle, grid planes may now be solved concurrently and/or the solution of all tridiagonal systems (n, k) for fixed n may be vectorized. Because the nodes of our target computers contain vector processors, all our implementations use the vectorization in the z-direction for the x-line-relaxation step.

The $M \times N \times K$ grid is distributed over a $P \times Q \times R$ process grid. The data distribution over P processes in the x-direction forces us to use a distributed tridiagonal solver for the x-line-relaxation step; see §3. For Jacobi and half-Gauss-Seidel line relaxation, the data distribution over R processes in the z-direction allows us to solve systems (n, k_0) and (n, k_1) concurrently if they are mapped to different processes. Systems (n, k) with fixed n mapped to the same process may be solved using a solver that is vectorized in the z-direction.

For Jacobi line relaxation, the data distribution over Q processes in the y-direction allows us to solve systems of a grid plane concurrently. For half-Gauss-Seidel line relaxation, however, the tridiagonal systems within one grid plane $k =$ constant still depend on one another, because system (n, k) depends on $(n-1, k)$. This prevents concurrency within one plane. A further modification allows us to obtain a concurrent program: at the process boundaries in the y-direction, we use old u-values for x-line $(n-1, k)$ in the computation of system (n, k). This *modified half-Gauss–Seidel line relaxation* allows concurrency and vectorization for all grid blocks of the $P \times Q \times R$ process grid.

We shall also consider one alternative to line relaxation. *Segment relaxation* avoids distributed tridiagonal systems by moving terms that couple the system across process boundaries to the right-hand side. For an elementary x-line-relaxation step, this leads to systems with coefficient matrices of the form:

$$T' = \left(\begin{array}{cccccccccc} b_1 & c_1 & & & & & & & & \\ a_2 & b_2 & c_2 & & & & & & & \\ & a_3 & b_3 & & & & & & & \\ \hline & & & b_4 & c_4 & & & & & \\ & & & a_5 & b_5 & c_5 & & & & \\ & & & & a_6 & b_6 & & & & \\ \hline & & & & & & \ddots & & & \\ \hline & & & & & & & b_{M-2} & c_{M-2} & \\ & & & & & & & a_{M-1} & b_{M-1} & c_{M-1} \\ & & & & & & & & b_M & c_M \end{array} \right).$$

Such systems can be solved without any communication and only require solving a tridiagonal system in each process. In §4.2.4, we shall see that, for our application, the price for simplicity is a decreased convergence rate and a lack of robustness.

A discussion of point-relaxation methods is omitted, because they diverge when used for our application. We focus the remainder of this paper on modified half-Gauss-Seidel line, Jacobi line, red-black line, and segment relaxation. Each has a certain convergence rate, which is dependent on the particular application. We postpone a discussion of convergence rates until §4, where our application is introduced.

For simplicity of exposition, the relaxation methods were described with the Poisson equation in mind. Their use in our Navier-Stokes application is more complicated, because every grid point corresponds to four unknowns. In (3), the unknowns u_m and the right-hand side coefficients d_m are vectors of dimension 4. The coefficients a_m, b_m, and c_m are 4×4 matrices. The coefficient matrix T of (4) is block-tridiagonal instead of tridiagonal, and its blocks are 4×4 matrices.

3. Distributed block-tridiagonal solvers. In this section, we shall present several methods to solve sets of block-tridiagonal systems (3) defined on an $M \times N \times K$ computational grid that is distributed over a $P \times Q \times R$ process grid. Each solver can be combined with at least one relaxation method of §2.

In process (p, q, r) of the process grid, we have available an $I \times J \times L$ subgrid of the computational grid. The solution of the discretized Navier-Stokes equations requires alternating-direction line relaxations. Hence, even if the grid is distributed in one dimension only (say $Q = R = 1$ or $P = Q = 1$), process boundaries cross the relaxation lines in at least one direction. We consider only the x-line relaxation with systems of M equations distributed over P processes; the extension to y- and z-line relaxations and to nondistributed line relaxations are obvious.

We shall introduce six different distributed tridiagonal solvers. Each can be converted into a block-tridiagonal solver that can be used to solve the systems that arise in our Navier-Stokes application. To convert, scalars of the tridiagonal solvers must be changed into 4×4 matrices or vectors of dimension 4. Divisions like

$$u_m = \frac{a_m}{b_m}$$

must be replaced by 4×4 systems of equations:

$$b_m u_m = a_m.$$

For the remainder of this section, we treat all coefficients and unknowns as scalars and all line-relaxation systems as tridiagonal. The conversion to block-tridiagonal systems considerably complicates the implementation, but it does not affect the fundamental algorithmic structure.

3.1. Pipelining. The classical sequential direct solver for tridiagonal systems, sometimes referred to as the Thomas algorithm, can be used on distributed data. Although a sequential algorithm, there is sufficient concurrency left, because we must solve many tridiagonal systems. For all practical purposes, this solver can only be used in conjunction with the Jacobi line-relaxation method, for which all tridiagonal systems are independent of one another. In the y- and z-directions, the Jacobi x-line relaxation is concurrent, and the only communication requirement is a boundary exchange.

An elementary x-line-relaxation step uses all processes (p, q, r) with $0 \leq p < P$ and q and r fixed. We now use the J systems of the y-direction to introduce concurrency in the x-direction by a *pipelining* technique (this technique is also studied by Ho and Johnsson [8]).

Assuming that the coefficient matrix T is factored once, the Thomas algorithm solves tridiagonal systems by means of two elementary sequential loops. After data distribution over P processes, these loops remain sequential. In process (p, q, r), we must run through J identical loops. As soon as process (p, q, r) hands over the loop of system j to process $(p + 1, q, r)$, process (p, q, r) may start evaluating the loop of system $j + 1$. Filling the pipeline requires P elementary x-line-relaxation steps.

This procedure is also vectorized in the z-direction: instead of evaluating the loop for one system, all L loops of the z-direction are evaluated. This also reduces communication latency, because messages of L systems are combined into one message. On the other hand, this merging of communication increases the time required for filling the pipeline.

3.2. Concurrent direct tridiagonal solvers. As an alternative to pipelining, it is possible to replace the sequential tridiagonal solver by a concurrent direct tridiagonal solver. This avoids the cost of pipelining. However, all known concurrent direct tridiagonal solvers carry a high floating-point overhead. We have used four different direct solvers. From a fundamental point of view, all four are equivalent. They solve a tridiagonal system by LU-decomposition without pivoting, and their operation counts are very similar. Performance differences are due to technical implementation details.

To identify the different solvers, we follow the nomenclature of Frommer [7] in this paper. Note, however, that there is no generally agreed-upon terminology in the literature. For example, the term "recursive doubling" is used for several methods [7], [15]. We shall use "recursive doubling" and "cyclic reduction" for two variants of the cyclic odd-even reduction algorithm, first proposed by Hockney [9].

3.2.1. Recursive doubling. By eliminating unknowns and equations, one can obtain a new tridiagonal system with half the number of unknowns of the original system. This reduction procedure is repeated until a system is obtained that can be solved immediately.

In the recursive-doubling algorithm, one reduction is computed for each of the M equations. Hence, we can determine all solution components immediately after the last reduction step.

3.2.2. Cyclic reduction. The cyclic-reduction method also performs repeated reductions of the system (3). However, it computes only one solvable equation for the whole system. Subsequently, the solution is computed through back-substitution.

In general, the number of equations per process, I, is greater than one. Therefore, we have to distinguish between a local and a global reduction. In the first $\log_2 I$ steps, we reduce the system such that the unknowns are coupled exclusively with unknowns in neighboring processes. Each tridiagonal system now consists of only one equation per process. In the

$$\left(\begin{array}{ccccccccc}
b_1 & & c_2 & & & & & & \\
& b_2 & c_2 & & & & & & \\
& & b_3 & & & c_3 & & & \\
\hline
& & a_4 & b_4 & & c_4 & & & \\
& & a_5 & & b_5 & c_5 & & & \\
& & a_6 & & & b_6 & & & c_6 \\
\hline
& & & & & a_7 & b_7 & & c_7 \\
& & & & & a_8 & & b_8 & c_8 \\
& & & & & a_9 & & & b_9
\end{array}\right)$$

FIG. 1. *Matrix T after eliminating the upper and lower diagonal entries.*

subsequent global reduction, we eliminate the remaining equations of the first, second, fourth, etc. neighbors.

3.2.3. Partition method. In §3.2.2, the local part of the odd-even reduction reduced the system to a new tridiagonal system with one equation per process. The required communication and the arithmetic overhead of solving the latter system are high. This problem is avoided in Wang's partition method [16].

After an elimination of the upper and lower diagonal entries, the coefficient matrix has the shape given in Fig. 1 for a system with $M = 9$ equations distributed over $P = 3$ processes. The fill that results from this operation can be stored in the original arrays a_m and c_m. This matrix is triangularized and, subsequently, diagonalized. For these operations, Wang transposes T from a row-distributed into a column-distributed matrix. Because this transposition of the matrix requires extensive communication, we follow an alternative procedure. We solve the following tridiagonal system with one equation per process:

$$\begin{pmatrix} b_3 & c_3 & \\ a_6 & b_6 & c_6 \\ & a_9 & b_9 \end{pmatrix} \begin{pmatrix} u_3 \\ u_6 \\ u_9 \end{pmatrix} = \begin{pmatrix} d_3 \\ d_6 \\ d_9 \end{pmatrix}, \tag{5}$$

which is obtained by collecting the equations of the last row in each process. We solved the system (5) by recursive doubling, which we found to be most efficient in the case of one equation per process.

3.2.4. Divide and conquer. In his divide-and-conquer method, Bondeli [2] obtains the solution of (3) by solving a local tridiagonal system in each process concurrently and a global tridiagonal system with one equation in the boundary processes and two equations in the inner processes.

Here, the global problem is solved by eliminating one equation in the inner processes. Again, we obtain a tridiagonal system with one equation per process which is solved with recursive doubling.

3.3. Concurrent iterative tridiagonal solver. The direct solvers of §3.2 solve the system (3) to round-off error (if the systems are well conditioned). Here, we propose a concurrent iterative solver to compute the solution to a certain tolerance.

Splitting the matrix T into a sum $G + H$, as indicated in Fig. 2, the matrix G contains globally uncoupled tridiagonal blocks, and H contains the coefficients that couple the systems across the process boundaries.

This splitting of the coefficient matrix defines the iteration

$$G\,\vec{u}^{(\mu)} = \vec{d} - H\,\vec{u}^{(\mu-1)}. \tag{6}$$

A multicomputer implementation of (6) is easily obtained and is efficient for several reasons:

$$T=\left(\begin{array}{ccc|ccc|ccc}
b_1 & c_1 & & & & & & & \\
a_2 & b_2 & c_2 & & & & & & \\
 & a_3 & b_3 & & & & & & \\ \hline
 & & & b_4 & c_4 & & & & \\
 & & & a_5 & b_5 & c_5 & & & \\
 & & & & a_6 & b_6 & & & \\ \hline
 & & & & & & b_7 & c_7 & \\
 & & & & & & a_8 & b_8 & c_8 \\
 & & & & & & & a_9 & b_9
\end{array}\right)+\left(\begin{array}{ccc|ccc|ccc}
 & & & & & & & & \\
 & & & & & & & & \\
 & & & c_3 & & & & & \\ \hline
 & & a_4 & & & & & & \\
 & & & & & & & & \\
 & & & & & & c_6 & & \\ \hline
 & & & & & a_7 & & & \\
 & & & & & & & & \\
 & & & & & & & &
\end{array}\right)$$

FIG. 2. *Splitting of T for $M = 9$ and $P = 3$.*

1. Because G contains only the uncoupled tridiagonal matrices, its inversion is trivially concurrent. The LU-decomposition of G needs to be carried out only once. We can solve (6) by computing the right-hand side terms and by evaluating two back-substitution loops in each process.

2. The matrix-vector operation $\vec{d} - H\,\vec{u}^{\,(\mu-1)}$ requires only nearest-neighbor communication.

3. Only the right-hand side terms of the first and the last row in each process change within one iteration step. Hence, the arithmetic costs of one iteration step are low.

4. A good initial guess for the iteration is found by solving the system

$$G\,\vec{u}^{\,(0)} = \vec{d}. \tag{7}$$

5. The iteration (6) is continued until some stopping criterion is satisfied. This criterion can be chosen to fit the need and, usually, depends on the specific application; see §4.2.5 for a further discussion.

4. Computational results. In this section, we compare the performance on the Intel Touchstone Delta of the relaxation methods of §2 implemented using the block-tridiagonal solvers of §3. All performance data are obtained for a solver of the Navier–Stokes equations for three-dimensional, incompressible, unsteady, and viscous flows. In §4.1, we describe the problem in sufficient detail to understand the computational complexity of the application. However, fluid-dynamical results obtained with this code are published elsewhere [1]. Additional physical and numerical details are found in [3] and [4].

Our problem sizes and convergence properties are not artificial creations. The problem size was determined by realistic resolution requirements and was NOT increased to obtain artificially high efficiency typically associated with coarse-grain computations. Similarly, our selection of numerical methods, i.e., of line-relaxation methods over point-relaxation methods, was guided by realistic needs. There is no compelling reason to use line-relaxation methods for the Poisson equation, because one can always use simple point-relaxation methods. This alternative is not available now, because point-relaxation methods do not even converge for our application. In §4.2.4, we shall also observe that segment relaxation is not sufficiently robust for our Navier–Stokes problem. It is very important that our performance measurements are obtained for a "real" problem. The grid size and the accuracy with which the discrete problems are solved are dictated by the physics of our application.

In our performance analysis of concurrent relaxation methods, we distinguish between numerical and implementation issues. Numerical issues primarily determine the number of relaxation-iteration steps necessary for convergence. This is, of course, extremely application dependent. Implementation issues primarily determine the execution time of one relaxation step through cost of communication, load balance, number of processes, etc. This depends on the application through computational parameters like grid dimensions and number of unknowns. Nevertheless, the performance results of one relaxation step are more readily transferred to other applications. For this reason, we consider these two performance issues separately.

We shall present the convergence rates for the different relaxation methods in §4.2. Multicomputer performance of one alternating-direction line-relaxation step will be discussed in §4.3. Convergence-rate and per-step-performance information are combined into global-performance results in §4.4.

4.1. Discretization of the Navier–Stokes equations. The Navier–Stokes equations are a set of coupled nonlinear partial-differential equations, which describe the conservation of mass, momentum, and energy for continuous media. For an incompressible fluid, a time-dependent flow in three dimensions is defined by the pressure $p(x, y, z, t)$ and the three velocity components $u(x, y, z, t)$, $v(x, y, z, t)$, and $w(x, y, z, t)$. In a dimensionless matrix-vector form, the conservation equations are given by

$$\bar{R}\cdot\frac{\partial Q}{\partial t}+\frac{\partial F}{\partial x}+\frac{\partial G}{\partial y}+\frac{\partial H}{\partial z}=\frac{1}{Re}\cdot\left(\frac{\partial^2 S}{\partial x^2}+\frac{\partial^2 S}{\partial y^2}+\frac{\partial^2 S}{\partial z^2}\right), \tag{8}$$

where

$$\bar{R}=\begin{pmatrix}0&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{pmatrix},\quad Q=\begin{pmatrix}p\\u\\v\\w\end{pmatrix},\quad S=\begin{pmatrix}0\\u\\v\\w\end{pmatrix},$$

$$F=\begin{pmatrix}u\\u^2+p\\uv\\uw\end{pmatrix},\quad G=\begin{pmatrix}v\\vu\\v^2+p\\vw\end{pmatrix},\quad H=\begin{pmatrix}w\\wu\\wv\\w^2+p\end{pmatrix}.$$

Breuer and Hänel [4] extended the method of artificial compressibility to unsteady flows. They define an artificial time τ and add a supplementary time derivative $\hat{R}\frac{\partial Q}{\partial \tau}$, with

$$\hat{R}=\begin{pmatrix}\frac{1}{\beta^2}&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{pmatrix},$$

to the Navier–Stokes equations. The pressure field is now coupled to the velocity distribution, and (8) can be integrated. Because a steady solution is computed at time τ, the additional terms vanish, and we obtain the unsteady solution of (8) at the physical time t.

Let ξ be an index for the physical time step and ζ an index for the artificial time step. The approximation

$$\frac{\partial Q}{\partial \tau}\approx\frac{Q^{\xi+1,\zeta+1}-Q^{\xi+1,\zeta}}{\Delta\tau}=\frac{\Delta Q^{\zeta}}{\Delta\tau}$$

leads to an implicit discretization scheme for the artificial time step. In this scheme, the Euler and viscous fluxes are defined at the new physical time step $\xi+1$ and at the new artificial time step $\zeta+1$. Consider, e.g., the Euler flux F. The implicit discretization uses its value $F^{\xi+1,\zeta+1}$ at physical time step $\xi+1$ and artificial time step $\zeta+1$. This term is expanded in a Taylor series with respect to the artificial time τ to obtain the following linearization:

$$F^{\xi+1,\zeta+1}=F^{\xi+1,\zeta}+J_F^{\xi+1,\zeta}\Delta Q^{\zeta}.$$

Here, J_F is the Jacobian matrix of the Euler flux F with respect to Q, say $J_F = \frac{\partial F}{\partial Q}$. The resulting discrete system of equations is given by

$$\text{LHS} \cdot \Delta Q^{\zeta} = \text{RHS}\,. \tag{9}$$

The right-hand side contains the expressions that arise from the discretization of the derivatives in (8) using a high-order upwind scheme for the convective terms, central differences for the diffusive terms, and a second-order discretization for the physical time t. The left-hand side contains first-order spatial derivatives of the Jacobian matrices.

Because the left-hand side terms in (9) vanish for the exact solution vector Q, the discrete solution has the order of accuracy of the right-hand side. The numerical advantage is that the spatial discretization of the Jacobian matrices has no influence on the order of accuracy of the solution. Therefore, we have gained some flexibility in choosing a discretization of LHS. This flexibility is used to improve the diagonal dominance of the coefficient matrix and to increase the size of the time step.

Although central differences would be the most straightforward choice, they do not add terms to the main diagonal of the coefficient matrix. That is why we use a first-order upwind formulation combined with a matrix-splitting technique: after splitting the Jacobian matrices into positive and negative parts, forward differences are applied to the positive parts and backward differences to the negative parts. Consider, e.g., the Jacobian matrix J_F. This 4×4 matrix is diagonalized such that

$$J_F = M \Lambda M^{-1},$$

where M is the matrix of eigenvectors of J_F, and Λ is the diagonal matrix containing the eigenvalues of J_F on its diagonal. Let

$$\Lambda = \Lambda^{+} + \Lambda^{-},$$

where Λ^{+} and Λ^{-} contain, respectively, the positive and negative eigenvalues. After transforming back to the Jacobian J_F, we obtain the splitting

$$J_F = M\Lambda^{+}M^{-1} + M\Lambda^{-}M^{-1} = J_F^{+} + J_F^{-}.$$

The spatial derivatives in J_F^{+} and J_F^{-} are discretized, respectively, with forward and backward differences. This method tends to increase the diagonal entries of the coefficient matrix, and the resulting system of equations can be solved with a line-relaxation method. For further details and for a validation of the above scheme, refer to Breuer [3] and Breuer and Hänel [4].

Every solution component consists of four elements: the pressure and the three velocity components. Hence, when applying the methods described in §3, the system (3) becomes a block-tridiagonal system, the coefficients a_m, b_m, and c_m are 4×4 matrices, and the right-hand side terms d_m are vectors consisting of four components. It follows that the discretized Navier-Stokes equations require much more arithmetic per grid point than, e.g., the discretized Poisson equation.

All computations of this paper use the above method to simulate the flow of an isolated slender vortex embedded in an axial flow. The scientific interest in this flow is the study of the phenomenon of a bursting vortex or vortex breakdown. Although the initial conditions are axially symmetric, the flow is fully three-dimensional after vortex breakdown. The boundary conditions in the outflow plane and on the lateral boundaries are extrapolated from the case of a free vortex. At the outflow plane, a nonreflecting boundary condition simulates undisturbed vortical flow through the boundary. At the lateral boundaries, the pressure is imposed such

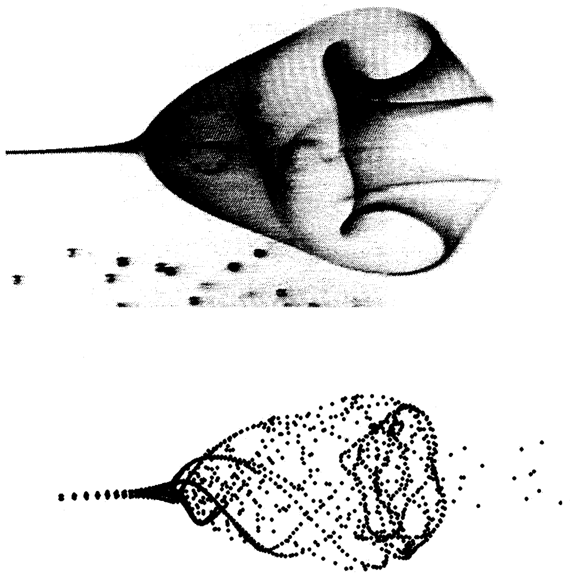

FIG. 3. *Experimental and numerical flow visualization of bubble-type vortex breakdown: top picture shows experimental streaklines and bottom picture shows numerical streaklines.*

that the bursted part of the vortex lies well within the domain of integration. Breuer [3] gives complete details on the initial and on the boundary conditions required to simulate this flow.

Figure 3 compares a numerical simulation and an experiment of Althaus et al. [1]. Using a Reynolds number based on the radius of the vortex core as length scale and the mean axial velocity as velocity scale, both cases have a Reynolds number of 500. Our simulation uses a $32 \times 32 \times 64$ rectangular grid with the z-direction being the axial coordinate. The physical time step is 0.3, and the artificial time step is 100. Althaus et al. [1] perform a detailed comparison of numerical and experimental results. It is this computation that we use to evaluate the performance of all our codes.

Depending on the orientation of the relaxation line, we have to solve $32 \times 64 = 2048$ systems of 32 blocks or $32 \times 32 = 1024$ systems of 64 blocks of size 4×4. Our challenge is to make effective use of all 512 computing nodes of the Delta to solve the block-tridiagonal systems of this moderate size. As discussed in §2, we use a $P \times Q \times R$ process grid. Preliminary tests, which we do not report, showed that three-dimensional grid distributions outperform one- and two-dimensional grid distributions with $P = 1$ and/or $Q = 1$, in spite of the fact that the latter can use efficient sequential tridiagonal solvers in at least one direction. This may seem somewhat counterintuitive. Given a certain number of nodes, choosing $P = 1$ leads to higher values for Q and/or R. The fact that x-line-relaxation steps are very efficient when $P = 1$ is offset by the increased load imbalance and the decreased efficiency in the other directions. Therefore, we always use a process grid with $P \approx Q \approx R$; see Table 1. In all our computations, each process is mapped to a separate node of the multicomputer.

The experiments of this section were performed on the Intel Touchstone Delta [5], which consists of an ensemble of 512 computing nodes connected in a two-dimensional mesh. The computational engine of each node is an Intel i860 processor with an advertised peak perfor-

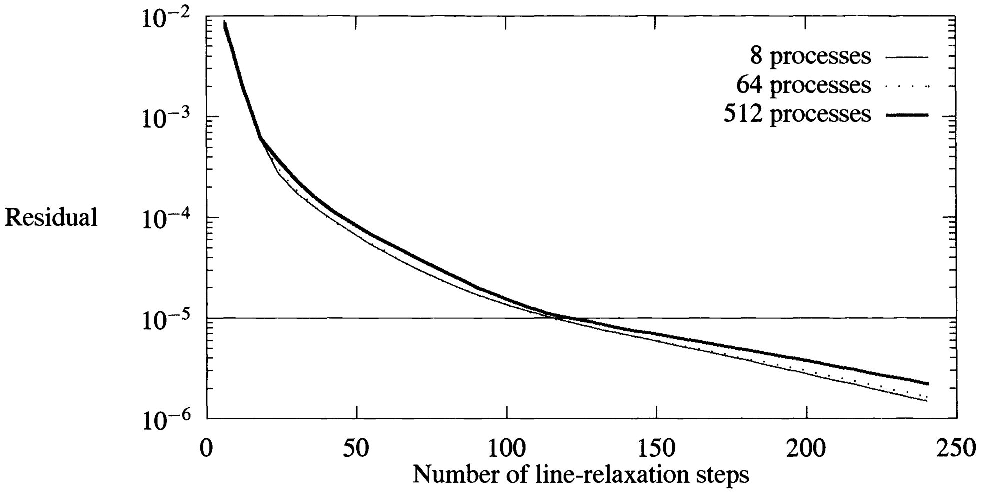

FIG. 4. *Maximal residual as a function of the number of modified half-Gauss–Seidel line-relaxation steps for three different process grids.*

TABLE 1
Process grids used in our computational tests.

Total	Number of processes in		
Number	x-direction (P)	y-direction (Q)	z-direction (R)
4	1	1	4
8	2	2	2
16	2	2	4
32	2	2	8
64	4	4	4
128	4	4	8
256	4	4	16
512	8	8	8

mance of 60 double-precision MFLOPS. Each node has a local memory of 16 MB. On the Delta, our standard problem needs a minimum of four nodes because of memory requirements.

4.2. Convergence of relaxation methods.

4.2.1. Modified half-Gauss–Seidel line relaxation. The modified half-Gauss-Seidel line relaxation uses the updated unknowns of the previously computed plane except at process boundaries; see §2. The convergence rate of the modified method is dependent on the number of processes and on the choice of process boundaries, because they determine the matrix splitting underlying the relaxation method. Figure 4 shows the residual as a function of the number of relaxations for some of the partitions of Table 1. Although the convergence depends on the partition, all computations achieve the required residual of 10^{-5} within approximately the same number of iteration steps.

4.2.2. Jacobi line relaxation. In the case of Jacobi line relaxation, all relaxation lines may be computed simultaneously. The convergence rate of the Jacobi line relaxation does not depend on the number of processes. Note that the modified half-Gauss-Seidel line relaxation turns into the Jacobi line relaxation when the number of processes is equal to the number of grid planes.

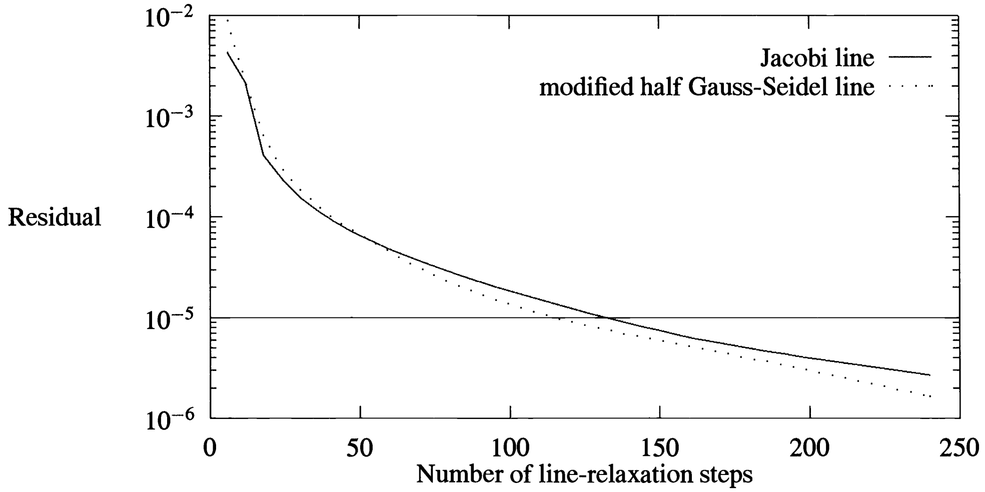

FIG. 5. *Maximal residual as a function of the number of line-relaxation steps in a computation with* 64 *processes.*

In Fig. 5, half-Gauss-Seidel and Jacobi line relaxation on the 64-node partition are compared. The Jacobi method needs about 10% more iteration steps to reach the required tolerance on the residual.

4.2.3. Red-Black line relaxation. Like the Jacobi line relaxation, the convergence rate of the Gauss-Seidel line relaxation with red-black ordering does not depend on the number of processes. We obtained a test program for the red-black line relaxation easily by splitting the Jacobi relaxation into the two steps explained in §2 and changing the step width of the inner loops to two. After the first step, the updated unknowns have to be exchanged between the processes. Besides the required additional communication, there is a loss of performance, because the inner loops can no longer be vectorized.

For our application, there is no observable difference in the convergence rate between the red-black and the Jacobi line iteration. The red-black line relaxation is, therefore, not a viable alternative to the modified half-Gauss-Seidel line method and, because of the communication and vectorization losses, its global performance is worse than the Jacobi line relaxation.

4.2.4. Segment relaxation. The segment relaxation computes relaxation lines interrupted by the process boundaries. Efficiency and applicability of this method depend on the convergence rate of the resulting iteration. Consider a segment-relaxation step in one direction with M grid points distributed over P processes, and let

$$I = \frac{M}{P}$$

be the number of local grid points. For $I = M$, we obtain a sequential line relaxation, while a Jacobi point relaxation results if $I = 1$.

We implemented an alternating-direction segment relaxation and plot the residual as a function of the number of relaxation steps for a 256- and a 512-node partition in Fig. 6. The plot shows that the relaxation fails to converge for the unbalanced $4 \times 4 \times 16$ partition. The $8 \times 8 \times 8$ partition needs about 20% more iteration steps than the modified half-Gauss-Seidel line relaxation.

We observed a nonconverging iteration even for the $2 \times 2 \times 8$ partition. We conclude that segment relaxation is not suitable, because robustness of the algorithm cannot be guaranteed.

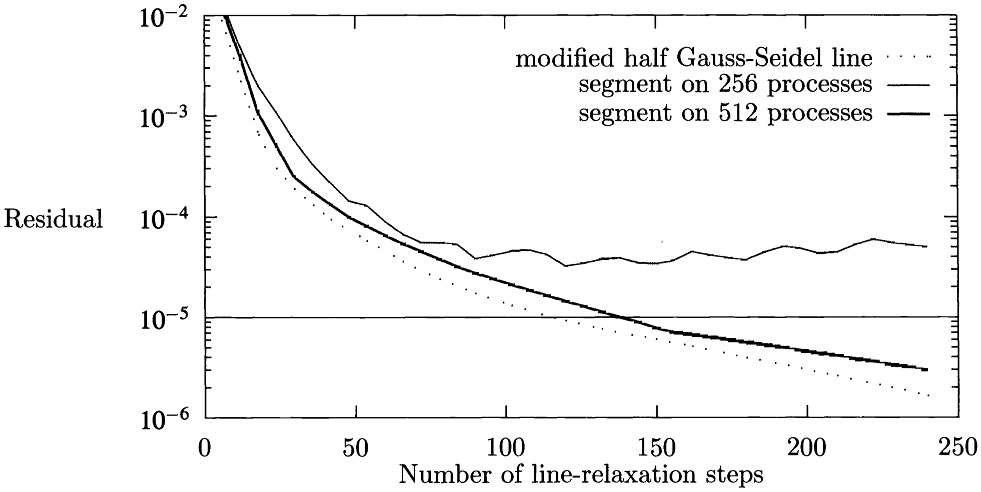

FIG. 6. *Maximal residual as a function of the number of line-relaxation steps for segment relaxation and modified half-Gauss–Seidel line relaxation.*

Although we achieve convergence when using all nodes on the Delta, it is uncertain whether the code would converge on a larger configuration of the same hardware. We consider this nonrobust behavior unacceptable.

4.2.5. Iterative block-tridiagonal solver. The modified half-Gauss–Seidel line relaxation of §4.2.1 can also be implemented using the concurrent iterative block-tridiagonal solver of §3.3. Because this method solves the system (3) only approximately, one should consider the effect of less-accurate block-tridiagonal solvers on the convergence rate of the line-relaxation method.

In Fig. 7, we examine the impact on the number of line-relaxation steps of using the iterative solver with six block-tridiagonal iteration steps. (The rationale for using six iteration steps is discussed in §4.3.6.) The curves for the exact and iterative solvers show the same progress, and the required residual of 10^{-5} is reached almost within the same relaxation step.

With an increasing number of processes, the initial guess (7) gets worse, and more coupling coefficients are set equal to zero to obtain the tridiagonal-iteration matrix. The partition, therefore, has an impact on the convergence rate. Figure 8 compares three different partitions. Up to 256 processes, the curves virtually coincide. The computation with 512 nodes requires only a few additional line-relaxation steps to converge.

4.3. Performance of one alternating-direction line-relaxation step. In this section, we shall compare the multicomputer performance of one alternating-direction line-relaxation step, i.e., one line relaxation in each spatial direction. To obtain a dimensionless efficiency for a multicomputer program, one must relate the execution time to a meaningful reference time. In principle, this reference time must be the best execution time possible on one node of the same multicomputer. In reality, one must settle for the sequential-execution time of a reasonable but not necessarily the best sequential program. For us, even the reasonable sequential time is impossible, because our problem requires too much memory to solve on one node. We defined a fictitious reference time in the following manner. To obtain a sequential time for the relaxation in the x-direction, we distribute the grid only in the y- and z-directions over the processes. Subsequently, the concurrent-execution time for this partition is then multiplied by the number of processes. We repeat this method for the y- and z-directions. Our

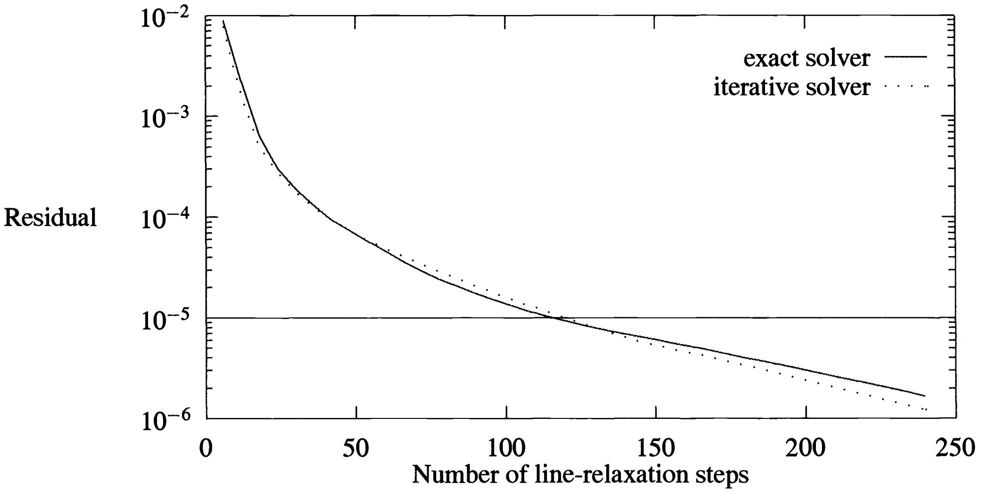

FIG. 7. *Maximal residual as a function of the number of line-relaxation steps when using the exact and the iterative block-tridiagonal solver to implement modified half-Gauss–Seidel line relaxation with* 64 *processes.*

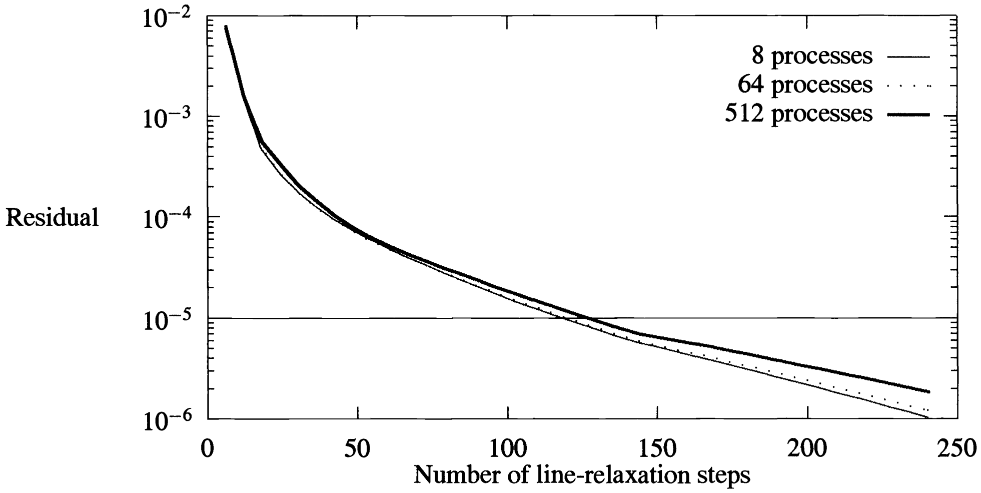

FIG. 8. *Maximal residual as a function of the number of line-relaxation steps to examine impact of process grids on the iterative block-tridiagonal solver.*

sequential-execution time for the alternating-direction line relaxation is the sum of these three terms. With process boundaries that are parallel to the relaxation lines, the block-tridiagonal systems can be solved by sequential LU-decomposition, which is the optimal procedure for sequential computations.

The same reference time is used for all methods, such that the efficiency results can be compared directly. The efficiency η_P of a P-node computation is the ratio

$$\eta_P = \frac{\text{(reference sequential time)}}{P \cdot \text{(execution time of the } P\text{-node program)}}.$$

We shall compare the multicomputer performance by means of two different kinds of plots. The first kind plots the efficiency η_P as a function of the number of nodes, and the second plots the execution time T_P in seconds as a function of the number of nodes. In both plots, a logarithmic scale is used for the number of nodes. In the execution-time plot, we also use a logarithmic scale for the second axis such that the line of linear speedup has slope -1. (The slope is distorted, however, because different scaling factors are used for the horizontal and vertical axes.)

The increased computational requirements of the discrete Navier-Stokes equations over, e.g., the discrete Poisson equation actually results in a more efficient computation, because more arithmetic occurs for the same number of messages. Although the messages are longer for the discrete Navier-Stokes equations, the latency usually dominates the communication time, and the length of the messages is less important than the number of messages.

4.3.1. Pipelining. In §3.1, we described a pipelining method for the sequential LU-decomposition. This makes sense if the number of processes is small compared with the number of unknowns per block-tridiagonal system [8]. This method, compared with all other methods we implemented, has the lowest floating-point operation count and requires the least amount of communication. However, it is less concurrent than some other methods because of load imbalance. The pipelining implements the Jacobi line relaxation.

Figure 9 shows the performance of the pipelining algorithm. As expected, the algorithm shows good efficiency for a small number of processes. However, for larger numbers of processes, the startup time required for all processes to participate in the computation causes a progressive loss of efficiency.

4.3.2. Recursive doubling. A concurrent implementation of the modified half-Gauss-Seidel line relaxation with the recursive-doubling algorithm for block-tridiagonal systems requires more arithmetic and more communication than the pipelining method, but offers higher concurrency. The recursive-doubling computations in the execution-time plot of Fig. 10 lie on a line that is almost parallel to the line of linear speedup. These lines are parallel and the efficiency is constant as a function of the number of nodes, because the communication overhead plays only a secondary role in computations with up to 512 nodes. The vertical distance between these two lines can be related to the arithmetic overhead, which is mainly responsible for the disappointing efficiency of about 15%.

4.3.3. Cyclic reduction. The cyclic-reduction algorithm is based on the same reduction procedure as recursive doubling and is also an implementation of the half-Gauss-Seidel line relaxation. This method needs less arithmetic, but additional communication for the back-substitution. Whereas the local part of the cyclic reduction shows a good load balance, the number of processes that participate during the global part halves after each reduction step. Both facts lead to a significant loss of efficiency for large numbers of processes (Fig. 10). However, cyclic reduction always beats recursive doubling. It beats the pipelining method for computations with all available nodes (see also Table 2).

For the back-substitution, the cyclic-reduction algorithm must store the entries of the coefficient matrix T and the right-hand side terms in (3), which change after each reduction step. The additional memory made a run on four nodes impossible.

The dips in the efficiency curves for 32 and 256 processes occur, because we double the partitions in the x- and y-directions (see Table 1). In these cases, the z-line-relaxation steps are inefficient compared to the next larger partition ($2 \times 2 \times 8 \rightarrow 4 \times 4 \times 4$ and $4 \times 4 \times 16 \rightarrow 8 \times 8 \times 8$, respectively).

4.3.4. Partition method. When modified half-Gauss-Seidel line relaxation is implemented by means of Wang's partition method, we realize an improved efficiency compared with the cyclic-reduction algorithm; compare Figs. 10 and 11. We examined in detail execution profiles of the z-line relaxation with a $1 \times 1 \times 8$ process grid. In this case, already

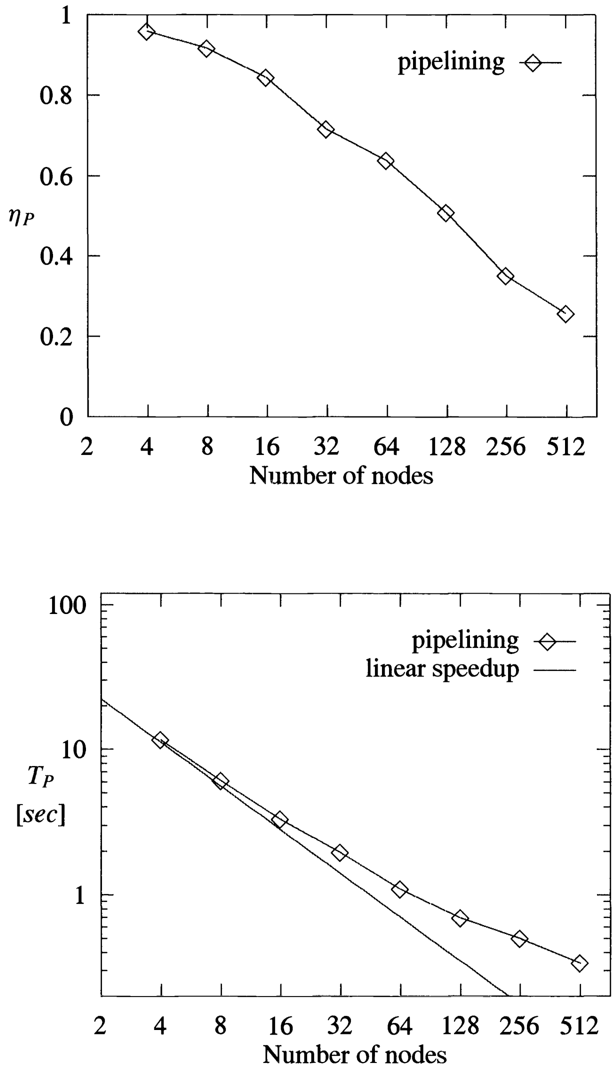

FIG. 9. *Efficiency and execution time of the pipelining algorithm.*

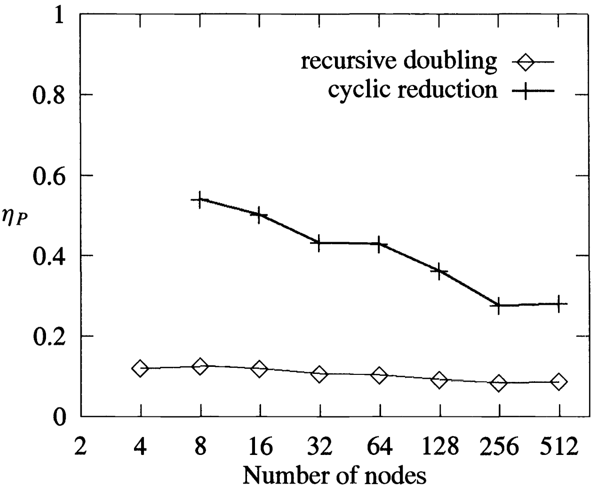
about 40% of the execution time was needed for solving the reduced system computed in the first part of Wang's partition method. This step is communication intensive and becomes even more so when the number of processes is increased further. It is this part of the computation that is responsible for the gradual loss of efficiency as the number of processes is increased.

4.3.5. Divide and conquer. The performance of the divide-and-conquer algorithm applied to the modified half-Gauss-Seidel line-relaxation method is given in Fig. 11. Like the partition method, divide and conquer reduces the size of the tridiagonal systems down to one block of equations per process.

The communication needed for the solution of the reduced system, obtained again with recursive doubling, decreases the efficiency of larger partitions in our application. The performance as a function of the number of processes is almost identical to that of the partition



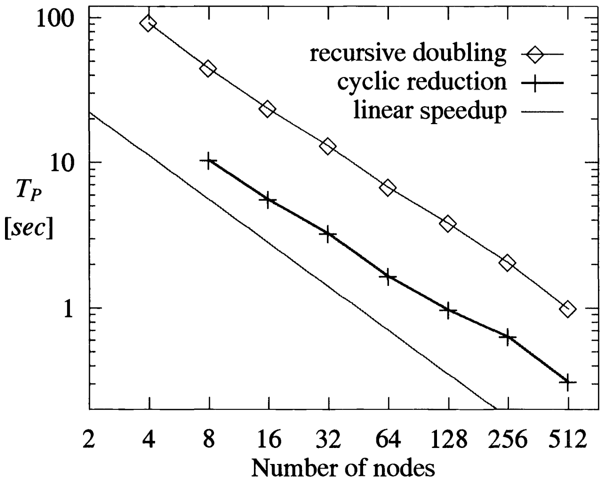


FIG. 10. *Efficiency and execution time of recursive doubling and cyclic reduction.*

TABLE 2
Execution times until convergence on 512 *nodes.*

Block-tridiagonal solver	Execution time in seconds
Iteration method	10.12

Cyclic reduction	12.44
Pipelining	14.96
Recursive doubling	39.64

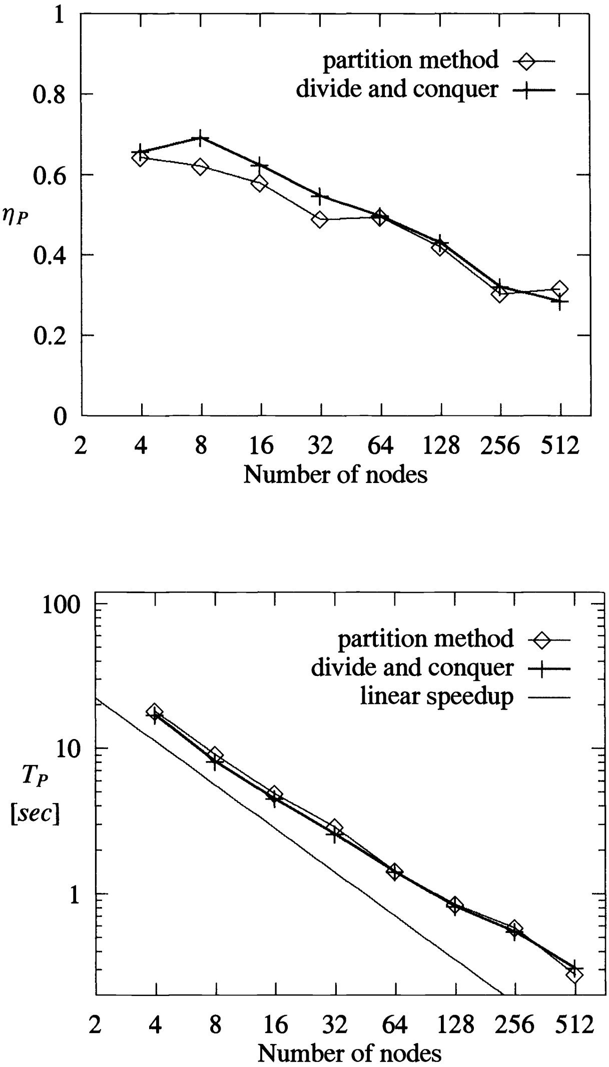

FIG. 11. *Efficiency and execution time of the partition and the divide-and-conquer method.*

method. The divide-and-conquer algorithm outperforms the partitioning method on smaller process grids.

4.3.6. Iterative block-tridiagonal solver. With the iterative block-tridiagonal solver, we implemented the modified half-Gauss-Seidel line relaxation. Because the iteration method solves the block-tridiagonal systems approximately, the accuracy requirements are a decisive determinant for the performance of the iteration method. In principle, it would be possible to iterate until a certain criterion is satisfied, e.g.,

$$|\vec{u}^{(\mu)} - \vec{u}^{(\mu-1)}| \leq \varepsilon, \tag{10}$$

where ε is a certain tolerance. If ε is small, the iterative solver is numerically equivalent to a direct solver. However, if ε is large, the error on the solution of the tridiagonal system may have an impact on the convergence rate of the line relaxation. The size of ε in (10), therefore, not only determines the number of block-tridiagonal iteration steps, but also the number of line-relaxation steps.

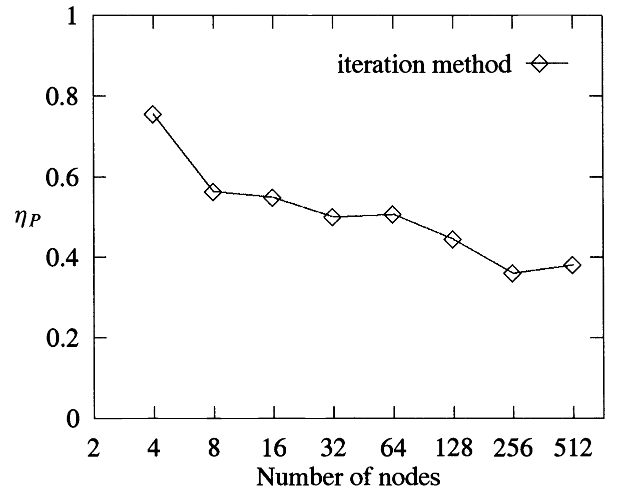
In a multicomputer computation, error-adaptive strategies like those suggested by (10) add significant costs that are difficult to recoup by the expected reduction in the number of iteration steps: computing error estimates is expensive, because they require global communication. Therefore, (10) is not used in our final computation. Instead, we are using a fixed number of block-tridiagonal iteration steps. We found that this is more efficient, while highly reliable if the number of block-tridiagonal iteration steps is sufficiently large. To determine an appropriate number, we performed a sequence of experiments on a $1 \times 1 \times 8$ process grid. In (10), we set $\varepsilon = 10^{-6}$, which is one order of magnitude below the requested residual of the global relaxation. We found that six iterations were always sufficient to reach the required accuracy if the initial guess $\vec{u}^{(0)}$ of (7) was used. The performance results shown in Fig. 12 were all measured with the number of block-tridiagonal iteration steps set equal to 6. With more than 32 processes, the algorithm is more efficient than the partition method and more efficient than the divide-and-conquer technique. With 256 processes, the performance is better than any other concurrent algorithm we implemented.

It was already shown in §4.2.5 that, with six block-tridiagonal iteration steps, there was virtually no difference in the number of line-relaxation steps between the iterative and the exact block-tridiagonal solver. Line-relaxation steps based on either solver are, therefore, practically equivalent. It is possible to reduce the number of block-tridiagonal iteration steps below six. However, the resulting line-relaxation method is no longer equivalent with the original method and may require a larger number of line-relaxation steps. On the other hand, each line-relaxation step may be considerably less expensive. We did not pursue this possibility of trading off the accuracy of the block-tridiagonal solver with the convergence rate of the line-relaxation method. However, segment relaxation is equivalent to line relaxation with one iteration step of the iterative block-tridiagonal solver. Considering the robustness problems of segment relaxation, at least two block-tridiagonal iteration steps are needed.

4.4. Global performance. The interesting performance of a program is, of course, the execution time until convergence within tolerance. In Fig. 13, we compare this time for the Jacobi line-relaxation method implemented with pipelining and for the modified half-Gauss–Seidel line relaxation implemented with the partition method and with the iterative block-tridiagonal solver. Here, we focus only on the execution time needed for the relaxation routines. To obtain the actual time to solve the Navier–Stokes equations, we must add to this the time for the computation of the right-hand side terms and the boundary conditions, which are independent of the solution procedure.

The better performance of the iterative block-tridiagonal solver for computations with more than 256 processes is partially offset by the required additional relaxation-iteration steps; see §4.2.5. The convergence losses of the Jacobi line relaxation (§4.2.2) deteriorate the performance of the pipelining algorithm. The execution times until convergence on 512 nodes for all implementations are given in Table 2. The modified half-Gauss–Seidel line relaxation implemented with the iterative block-tridiagonal solver clearly beats all competitors. As pointed out before, there are several techniques that could improve its performance even further. Most importantly, the fastest method is also, by far, the easiest to implement.

5. Computer dependence. The execution time of a program is, by its very nature, a computer-dependent characteristic. One must, therefore, always question whether or not particular performance results for a set of algorithms obtained on one computer carry over to other computers. Although not our main concern here, comparative performance studies can also be used for computer-evaluation purposes. In a preliminary comparative study, we obtained



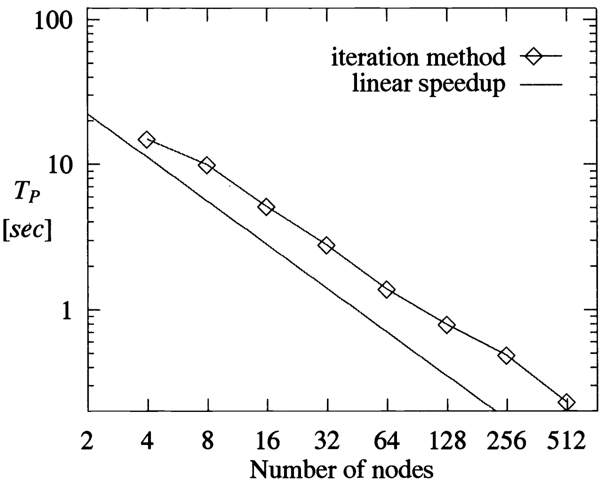


FIG. 12. *Efficiency and execution time of the iteration method.*

some performance data on the Intel Paragon XP/S [6] and the Parsytec SuperCluster [13]. We also used the Fujitsu S-600, which is a conventional vector processor with an advertised peak performance of five GFLOPS.

The Paragon design is similar to that of the Delta. The i860 processors of the Paragon have a higher clock frequency than those of the Delta: 50 MHz instead of 40 MHz. In principle, this increases the advertised peak performance by 25% to 75 MFLOPS per node. Furthermore, Paragon nodes have larger caches and contain improved communication hardware to reduce latency and increase bandwidth.

The Parsytec SuperCluster consists of 256 Transputers T-805, which are clocked at 30 MHz. Each Transputer has an advertised peak performance of 2.2 MFlops. With 4 MBytes of memory per node, our application requires at least 16 Parsytec nodes. Each node contains four bidirectional communication links, which can be used to configure the nodes into a large

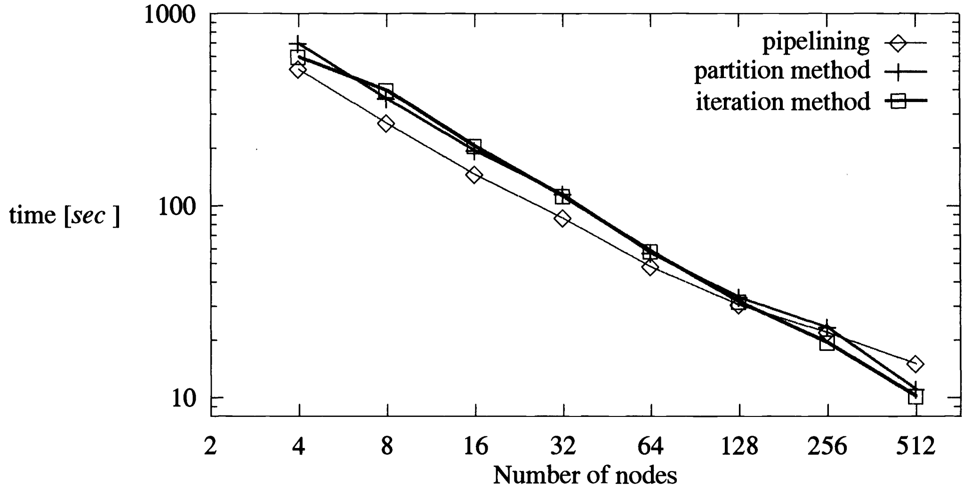

FIG. 13. *Execution time until residual* $\leq 10^{-5}$.

variety of network topologies. The floating-point performance of the Transputer is considerably less than that of a Paragon or a Delta node. However, the Parsytec has an excellent ratio of communication versus arithmetic time.

In Figs. 14, 15, and 16, the execution time of one alternating-direction line-relaxation step is displayed as a function of the number of nodes. Figure 14 considers Jacobi line relaxation implemented using the pipelined block-tridiagonal solver on the Delta, Paragon, and Parsytec. Figures 15 and 16 display execution times obtained with modified half-Gauss-Seidel line relaxation. Figure 15 is for the program based on the concurrent iterative block-tridiagonal solver, and Figure 16 for the program that uses the partition method to solve the block-tridiagonal systems concurrently. In these three figures, the lines of linear speedup are based on a sequential-execution time obtained for the Delta as explained in §4.3. The lines of linear speedup for Paragon and Parsytec are parallel to this line, but are not displayed to avoid crowding the figures; Parsytec efficiency is compared with Delta efficiency in Fig. 17.

In the execution-time plots, the Parsytec computations lie on a line that is almost parallel to the line of linear speedup. This is most pronounced for the method based on the iterative block-tridiagonal solver. This is an indication that almost all overhead on the Parsytec is due to the increased operation count of the concurrent computations and not to communication. This is confirmed in the efficiency plots of Fig. 17, which displays the efficiencies as a function of the number of nodes. (Efficiencies are computed using the sequential-execution time on the computer of the concurrent computation.) The iteration method on the Parsytec has a constant efficiency of about 40%, which indicates that communication overhead is negligible. When executed on one node, the concurrent Parsytec program is about $\frac{1}{0.4} = 2.5$ times slower than the sequential Parsytec program. However, the concurrent program speeds up linearly.

The pipelining method does not have a constant efficiency on the Parsytec. However, its decrease in efficiency is much less pronounced than on the Delta: communication and load-imbalance effects are not as important on the Parsytec as on the Delta. This is, of course, easily explained by the smaller communication-arithmetic ratio of the Parsytec.

Because of the low floating-point-operation count of the pipelining method and the high communication efficiency of the Parsytec, pipelining remains the fastest algorithm for up to the maximum available number of nodes (256). However, extrapolating Fig. 17, we expect that

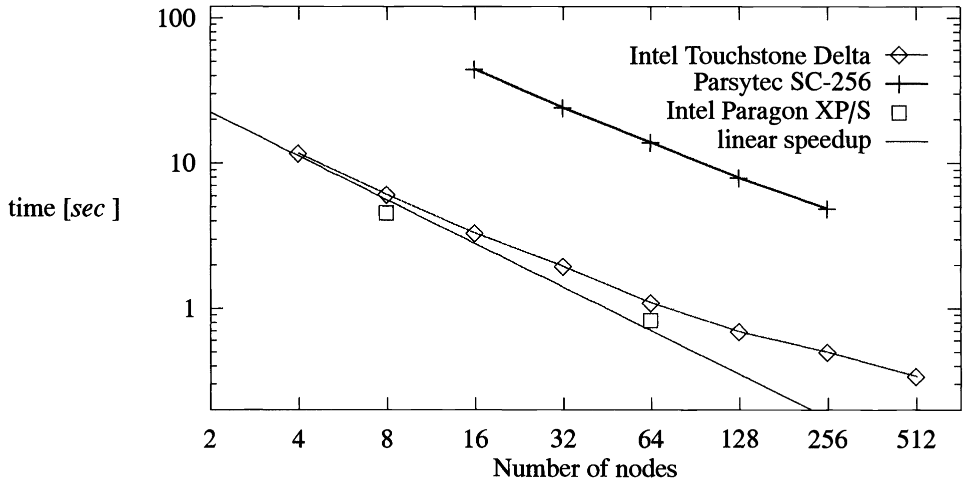

FIG. 14. *Execution time of the pipelining method.*

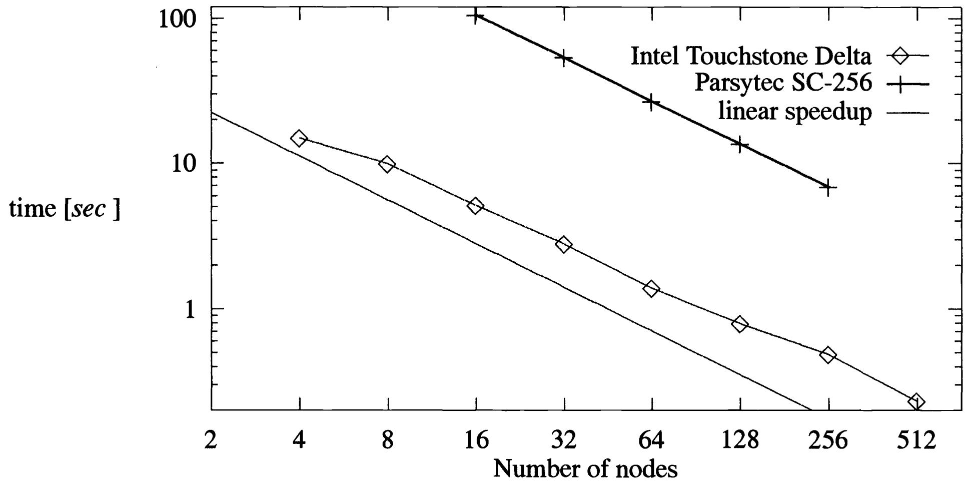

FIG. 15. *Execution time of the iteration method.*

the iteration method will perform better than the pipelining method on Parsytec-like computers with more than 512 nodes.

For our computations, the Delta is about 10–13 times faster than the Parsytec. Based on the advertised peak performance of their nodes, the Delta should be about 30 times faster than the Parsytec. The speed difference between Parsytec and Delta is smaller for fine-grain computations, because the Parsytec is a more efficient computer. The higher efficiency is not enough, however, to close the speed gap with the Delta.

As mentioned before, our code solves the Navier–Stokes equations to simulate time-dependent, incompressible, and unsteady flows. Table 3 displays typical execution times to obtain useful fluid-dynamical results. These require about 1000 physical time steps, and each time step requires many line-relaxation steps. These execution times also include all other computations that surround the actual alternating-direction line-relaxation iteration. The most

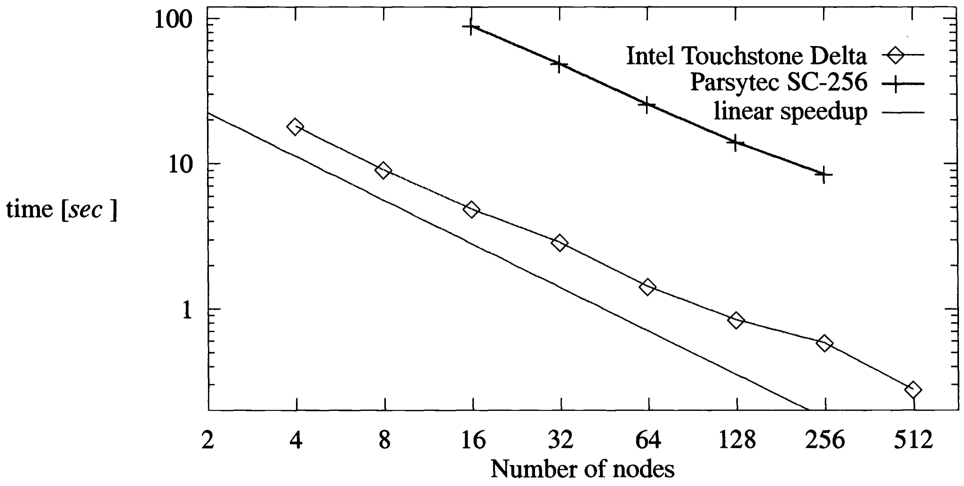

FIG. 16. *Execution time of the partition method.*

TABLE 3
Typical execution times for the production of fluid-dynamical results.

Computer	Execution time in hours on			
	8 nodes	64 nodes	256 nodes	512 nodes
Intel Paragon XP/S	70.8	14.3	-	-
Intel Touchstone Delta	97.2	18.2	9.1	8.4
Parsytec SC-256	-	235.2	84.2	-
Fujitsu S-600	13.1			

important factor in these periferal-but-necessary computations is the evaluation of the boundary conditions. For our application, the Fujitsu S-600 is equivalent to about 64 Paragon nodes. Whereas an individual line-relaxation step is almost four times faster on 256 Delta nodes than on 64 Delta nodes, only a factor of two is obtained in the global computation. This is due to the increasing influence of the evaluation of the boundary conditions, which introduces significant load imbalance in finer-grain computations.

6. Summary. We presented several concurrent methods for solving sets of block-tridiagonal systems on a rectangular grid. Previous studies concentrated on computations of very high granularity, which we found to be unrealistically high for our application. Therefore, we tested several methods to solve a larger number of smaller systems. All methods show a significant speedup on test runs up to 512 processes. On the Touchstone Delta, the best efficiency achieved was about 40%.

Although problem sizes will significantly increase beyond the size of the problem studied in this paper, we believe that granularity will remain of the same order of magnitude or might even decrease significantly. For most problems, the total amount of arithmetic increases faster than linearly with the total amount of data (which itself is proportional to the number of unknowns). To keep the total execution time reasonable, one should use a number of nodes proportional to the total amount of arithmetic. Hence, the amount of data per node (the granularity) is likely to decrease. There is also a numerical reason why fine-grain concurrency will become increasingly important. To improve the convergence rate, one could consider

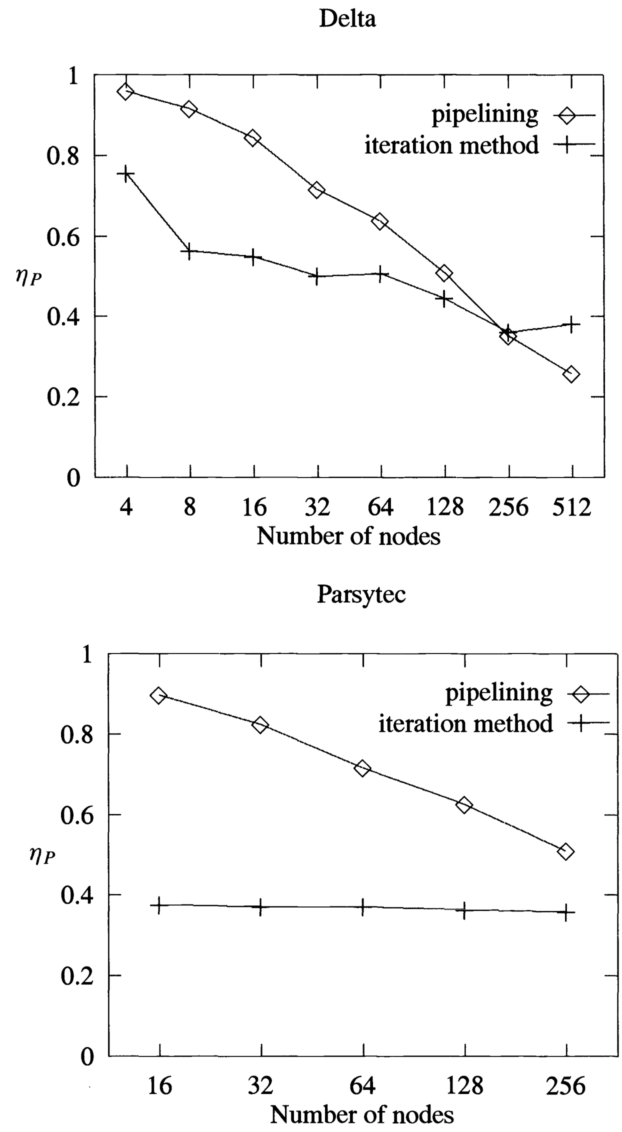

FIG. 17. *Efficiency of pipelining and iteration methods on the Delta and Parsytec multicomputers.*

using line-relaxation methods as smoothers in a nonlinear multigrid method. The coarser levels, however, quickly require computations of fine granularity.

Block-tridiagonal solvers that are efficient for fine-grain computations are difficult to implement. Nevertheless, it is possible to achieve significant execution-time improvements through the use of relatively fine-grain concurrency. A significant simplification for future endeavors is that our best results were obtained with the iterative block-tridiagonal solver, which is, from an algorithmic point of view, the simplest.

RUNGE-KUTTA SOFTWARE WITH DEFECT CONTROL FOR BOUNDARY VALUE ODES*

W. H. ENRIGHT† AND P. H. MUIR‡

Abstract. A popular approach to the numerical solution of boundary value ODE problems involves the use of collocation methods. Such methods can be naturally implemented so as to provide a continuous approximation to the solution over the entire problem interval. On the other hand, several authors have suggested as an alternative, certain subclasses of the implicit Runge-Kutta formulas, known as mono-implicit Runge-Kutta (MIRK) formulas, which can be implemented at a lower cost per step than the collocation methods. These latter formulas do not have a natural implementation that provides a continuous approximation to the solution; rather, only a discrete approximation at certain points within the problem interval is obtained. However, recent work in the area of initial value problems has demonstrated the possibility of generating inexpensive interpolants for any explicit Runge-Kutta formula. These ideas have recently been extended to develop continuous extensions of the MIRK formulas. In this paper, we describe our investigation of the use of continuous MIRK formulas in the numerical solution of boundary value ODE problems. A primary thrust of this investigation is to consider defect control, based on the continuous MIRK formulas, as an alternative to the standard use of global error control, as the basis for termination and mesh redistribution criteria.

1. Introduction.

A popular approach to the numerical solution of boundary value ODE (BVODE) problems involves the use of collocation formulas based on, for example, Gauss points. Gauss point formulas have been implemented in the widely used code, COLSYS [Ascher, Christiansen, and Russell, 1981] and its descendant, COLNEW [Bader and Ascher, 1987]. For many numerical methods for BVODE problems, one obtains an approximation to the solution at a discrete set of mesh points which partition the problem interval. An advantage of the collocation approach is that a continuous approximation to the solution over the entire problem interval is obtained as a natural consequence of the standard implementation of these methods. For a mesh with subintervals of size h and collocation based on Gauss points with s collocation points per subinterval, the continuous solution provides an approximation with global error $O(h^s)$, while the associated discrete solution at the mesh points has a global error that is (in the absence of order reduction phenomenon (see, e.g., [Prothero and Robinson, 1974]) $O(h^{2s})$, a property known as superconvergence. The continuous solution approximation can be very useful when the user requires solution information throughout the problem interval. Furthermore it can also be useful within the code, itself, for example, for error estimation, mesh refinement and redistribution, and generation of initial iterates for Newton iterations. In addition, the presence of a continuous approximate solution makes it possible to assess solution quality by examining the defect, which is the amount by which the approximate solution fails to satisfy the BVODE system.

It is well known (see, e.g., [Weiss, 1974]) that the collocation formulas, when applied to first-order systems of ODEs, can be viewed as equivalent to certain subclasses of implicit Runge-Kutta formulas. Recently several authors have suggested, as an alternative to the collocation formulas, other subclasses of implicit Runge-Kutta formulas for use in the numerical

solution of BVODE problems. These formulas are known as mono-implicit Runge-Kutta (MIRK) formulas [van Bokhoven, 1980], [Cash and Singhal, 1982a]. A recent investigation of MIRK formulas is presented in [Burrage, Chipman, and Muir, 1994], where families of orders one through six are characterized and an order barrier result is presented. An advantage of these formulas over the collocation formulas is that the calculations on each subinterval, which use MIRK formulas in the setup of the Newton systems, are explicit and therefore can be implemented more efficiently [Cash and Singhal, 1982b], [Gupta, 1985], [Enright and Muir, 1986], [Cash, 1986, 1988]. The most recent work using these formulas [Cash and Wright, 1990, 1991] makes use of three specific MIRK formulas of orders four, six, and eight within a software package for the numerical solution of BVODEs, called HAGRON. An early software effort, described in [Gupta, 1985], involved modifying the PASVA code [Lentini and Pereyra, 1977] to use MIRK formulas. Both of these codes use deferred correction to provide error estimation and return a discrete solution approximation.

Unlike the collocation formulas, the MIRK formulas do not directly provide a continuous approximation to the solution. The idea of extending the discrete solution approximation to a continuous one has received considerable attention over the last few years, primarily in the area of initial value ODE problems. In that context, a number of authors have demonstrated the possibility of generating inexpensive interpolants for general explicit Runge-Kutta formulas; see, for example, [Enright, Jackson, Nørsett, and Thomsen, 1986], [Gladwell, Shampine, Baca, and Brankin, 1987], [Owren and Zennaro, 1991, 1992], and [Verner, 1993]. These interpolants are obtained by performing extra derivative evaluations, within the current step, thus preserving the one-step nature of the formula. Recently, [Muir and Owren, 1993] have developed continuous versions of the MIRK formulas. In addition to presenting a general analysis, they establish order barriers for continuous MIRK (CMIRK) schemes of orders one through six, and provide characterizations of CMIRK families of these orders. For BVODEs, the question of extending a discrete solution to obtain a continuous one has received less attention. Most BVODE codes do not provide a continuous solution approximation. Examples of such codes are the PASVA code and the modified version mentioned above, some experimental codes based on special one-sided Runge-Kutta schemes [Kreiss, Nichols, and Brown, 1986], [Brown and Lorenz, 1987], and the HAGRON code mentioned earlier.

In this paper, we investigate the computation of continuous solution approximations for the numerical solution of BVODEs based on CMIRK schemes. A primary thrust of the investigation involves the use of defect control as an alternative to the standard global error estimate control, for use in both mesh selection and accuracy control. The size of the defect gives a different measure of the suitability of the approximate solution; it is the amount by which the computed solution fails to satisfy the system of differential equations. It is a natural choice for control since it is the defect which arises in the analysis of the mathematical conditioning of the underlying problem where appropriate condition numbers are introduced to quantify the sensitivity of the global error to perturbations of the ODEs. See [Ascher, Mattheij, and Russell, 1988, Chap. 3, §4]. It has been suggested (see, e.g., [Cash and Silva, 1993]) that monitoring the defect may be appropriate in situations where difficulties arise in estimating the global error. The use of the defect has also been studied in the context of the numerical solution of initial value ODE problems; see, e.g., [Hanson and Enright, 1983], [Enright, 1989a, 1989b], and [Higham, 1989a, 1989b, 1991].

This paper is organized as follows. In §2 we describe the use of MIRK and CMIRK schemes in an algorithm for the numerical solution of BVODEs. In §3 we briefly discuss the class of CMIRK formulas and describe the specific continuous formulas we have chosen to implement. In §4, we identify several implementation issues associated with the development of software based on the algorithm of §2. In §5, we demonstrate the effectiveness of the software we have written by applying to some systems of first-order ODEs with uniform tolerance constraints. We also provide corresponding results from the COLNEW code for the same test set in order to show that the performance of our software is reasonable. It is not our intention to conduct extensive comparisons of the two codes. The COLNEW code has well-known advantages, e.g., it can handle mixed-order BVODE systems with different tolerance constraints for each component and multipoint conditions. We close, in §6, with our conclusions and a summary of our plans for future work in this area.

2. The numerical solution of BVODEs using MIRK and CMIRK schemes. In this section we review an algorithm for solving a system of BVODEs using MIRK and CMIRK schemes. The basic approach is to use the MIRK formulas to form a discrete algebraic system which can then be solved with a Newton iteration to obtain a discrete solution. Once this solution is obtained, a CMIRK scheme is employed to provide a continuous solution approximation over the problem interval for use in the computation of defect estimates, mesh redistribution, and initial guesses for subsequent Newton iterates.

We assume that the boundary value ODEs to be solved can be expressed in the general form,

$$y'(t) = f(t, y(t)), \qquad t \in [a, b],$$

where $y \in R^n$ and $f : R \times R^n \rightarrow R^n$, and where we assume for convenience of implementation that we have separated boundary conditions,

$$g(y(a), y(b)) = \begin{pmatrix} g_0(y(a)) \\ g_1(y(b)) \end{pmatrix} = 0,$$

where $g_0 : R^n \rightarrow R^{n_0}$ and $g_1 : R^n \rightarrow R^{n_1}$ and $n_0 + n_1 = n$.

A standard approach for employing a Runge-Kutta scheme to solve such problems can be described in terms of a two-level iteration scheme:

(0) Prior to beginning the two-level iteration we determine an initial mesh, $\{t_i\}_{i=0}^{N}$, which partitions $[a, b]$ with $t_0 = a$ and $t_N = b$, and an initial discrete solution approximation, $Y^{(0)} = [y_0^{(0)}, y_1^{(0)}, \ldots, y_N^{(0)}]^T$, where $y_i^{(0)} \approx y(t_i)$, the exact solution evaluated at t_i.

(1) The first step of the upper-level iteration is the setup and solution of a discrete system, $\Phi(Y) = 0$, where the "residual function"

$$\Phi(Y) = [g_0(y_0), \phi_1, \phi_2, \ldots, \phi_{N-1}, g_1(y_N)]^T.$$

Each vector ϕ_i is of size n and is defined by a Runge-Kutta scheme. We solve this discrete system using a Newton iteration, which constitutes the lower-level iteration. For $m = 0, 1, 2, \ldots,$ the Newton system has the form

$$\begin{pmatrix} \frac{\partial g_0}{\partial y_0}^{(m)} & 0 & 0 & \ldots & 0 & 0 \\ \frac{\partial \phi_0}{\partial y_0}^{(m)} & \frac{\partial \phi_0}{\partial y_1}^{(m)} & 0 & \ldots & 0 & 0 \\ 0 & \ddots & \ddots & \ldots & 0 & 0 \\ 0 & 0 & 0 & \ldots & \frac{\partial \phi_{N-1}}{\partial y_{N-1}}^{(m)} & \frac{\partial \phi_{N-1}}{\partial y_N}^{(m)} \\ 0 & 0 & 0 & \ldots & 0 & \frac{\partial g_1}{\partial y_N}^{(m)} \end{pmatrix} \begin{pmatrix} \Delta y_0^{(m)} \\ \vdots \\ \Delta y_N^{(m)} \end{pmatrix} = - \begin{pmatrix} g_0(y_0^{(m)}) \\ \phi_0^{(m)} \\ \vdots \\ \phi_{N-1}^{(m)} \\ g_1(y_N^{(m)}) \end{pmatrix},$$

and $y_i^{(m+1)} = y_i^{(m)} + \Delta y_i^{(m)}, i = 0, \ldots, N$. Here $y_i^{(m)}$ is the mth iterate value for y_i, $\Delta y_i^{(m)}$ is the corresponding Newton correction, $\phi_i^{(m)}$, $\frac{\partial \phi_i}{\partial y_i}^{(m)}$, and $\frac{\partial \phi_i}{\partial y_{i+1}}^{(m)}$ are the ith residual function component and its derivatives evaluated at $y_i^{(m)}$ and $y_{i+1}^{(m)}$, and $g_0(y_0^{(m)})$, $g_1(y_N^{(m)})$, $\frac{\partial g_0}{\partial y_0}^{(m)}$, and $\frac{\partial g_1}{\partial y_N}^{(m)}$ are the boundary conditions and derivatives evaluated at $y_0^{(m)}$ and $y_N^{(m)}$.

When a MIRK scheme is used as the underlying discretization the ith component of the residual function takes the form

$$\phi_i = y_{i+1} - y_i - h_i \sum_{r=1}^{s} b_r K_r, \tag{2.1}$$

where the stages, K_r, are given by

$$K_r = f\left(t_i + c_r h_i, (1 - v_r) y_i + v_r y_{i+1} + h_i \sum_{j=1}^{r-1} x_{rj} K_j\right), \qquad r = 1, \ldots, s. \tag{2.2}$$

Because the stages are defined explicitly in terms of the unknowns y_i and y_{i+1}, these methods can be implemented quite efficiently (see, e.g., [Cash, 1986]). The corresponding partial derivatives are also easily computed. We get

$$\frac{\partial \phi_i}{\partial y_i} = -I - h_i \sum_{r=1}^{s} b_r \frac{\partial K_r}{\partial y_i} \quad \text{and} \quad \frac{\partial \phi_i}{\partial y_{i+1}} = I - h_i \sum_{r=1}^{s} b_r \frac{\partial K_r}{\partial y_{i+1}}, \tag{2.3}$$

where, for $r = 1, \ldots, s$,

$$\frac{\partial K_r}{\partial y_i} = \mathbf{J}_r \left((1 - v_r) I + h_i \sum_{j=1}^{r-1} x_{rj} \frac{\partial K_j}{\partial y_i}\right) \text{ and } \frac{\partial K_r}{\partial y_{i+1}} = \mathbf{J}_r \left(v_r I + h_i \sum_{j=1}^{r-1} x_{rj} \frac{\partial K_j}{\partial y_{i+1}}\right). \tag{2.4}$$

Here $\mathbf{J}_r$ is the evaluation of $\frac{\partial f(t,y(t))}{\partial y}$ at the argument of the rth stage of the MIRK scheme, as in (2.2). If the Newton iteration does not converge, we go to step (5), with a new mesh that is obtained by halving each subinterval of the current mesh, and with the same current solution approximation.

(2) The converged Newton iteration yields a discrete solution approximation, $\{y_i\}_{i=0}^{N}$, for the given mesh. We next use an associated CMIRK scheme to construct a C^1 continuous solution approximation over the entire problem interval. The CMIRK scheme will usually employ the stages (2.2) of the MIRK scheme as well as a few additional stages of the same form as those in (2.2). It is important to note that the evaluation of these additional stages involves only explicit calculations and these are only performed after the Newton iteration has converged. As a result, the cost of obtaining the required continuous approximation is relatively small. On each subinterval the CMIRK scheme provides a polynomial interpolant to the approximate solution over that subinterval. The interpolant is obtained using information that is local to the step. (This is particularly relevant for a parallel implementation where it is important that the calculations for each subinterval be based only on local information.) The continuous solution approximation, $u(t)$, has the same order of accuracy as the underlying discrete solution. The defect, $\delta(t)$, is then given by

$$\delta(t) = u'(t) - f(t, u(t)), \quad a \le t \le b.$$

We sample the defect on each subinterval to obtain an estimate of its magnitude on that subinterval and terminate if this estimate is less than a given user-defined tolerance.

(3) If the termination condition is not met, the relative sizes of the maximum defect estimates associated with each subinterval are examined in the mesh selection algorithm to determine a more appropriate mesh. The basic idea is to redistribute the mesh while possibly adding or deleting points so that the maximum defect estimates obtained on the new mesh will be approximately the same on each subinterval (equidistribution of the defect) and will be bounded by the user tolerance. The maximum defect estimates are employed within a monitor function which provides the basis for the equidistribution process. Based on these considerations a new mesh is determined by employing standard strategies such as described in [Ascher, Mattheij, and Russell, 1988, Chap. 9, §1]. The algorithm is terminated, unsuccessfully, if the predicted number of mesh points for the new mesh is too large (according to a user-defined storage restriction).

(4) When a new mesh is determined, the continuous solution approximation is used to compute an initial discrete solution approximation for the next discrete problem and associated Newton iteration.

(5) This algorithm is then repeated, beginning at step (1), using the new mesh and solution approximation.

3. CMIRK schemes.

3.1. Overview. In the paper [Muir and Owren, 1993], the class of CMIRK schemes is investigated and we refer the reader to that paper for a description of these schemes. For the ith subinterval, the basic form of a CMIRK scheme is a polynomial in θ (where $\theta = (t - t_i)/h_i$),

$$u(t) = u(t_i + \theta h_i) = y_i + h_i \sum_{r=1}^{s^*} b_r(\theta) K_r, \quad 0 \le \theta \le 1, \quad t_i \le t \le t_{i+1}, \tag{3.1}$$

with s^* stages, K_r, of the same general form as in (2.2). (Usually the first s stages are those of an associated MIRK scheme. In such a case, the MIRK scheme is said to be embedded within the CMIRK scheme.) The main difference between MIRK schemes and CMIRK schemes is that the weight coefficients, $\{b_r\}_{r=1}^{s}$, of the MIRK scheme are replaced by weight polynomials, $\{b_r(\theta)\}_{r=1}^{s^*}$, in the CMIRK scheme.

In [Muir and Owren, 1993] multiparameter families of CMIRK formulas having a minimal number of stages for each order $p = 1, \ldots, 6$ are presented. Similarly, [Burrage, Chipman and Muir, 1994] identifies multiparameter families of discrete MIRK schemes having a minimal number of stages for each order $p = 1, \ldots, 6$. We will employ in our software the standard symmetric MIRK schemes of orders four and six. These two schemes are included in the families presented in [Burrage, Chipman, and Muir, 1994] and were first mentioned in the literature in [van Bokhoven, 1980]. We choose symmetric schemes since this can be advantageous (see [Ascher, Mattheij, and Russell, 1988, p. 440]). Since it is efficient to reuse the stages from the MIRK scheme within the CMIRK scheme, we will embed the MIRK schemes within optimal CMIRK schemes from [Muir and Owren, 1993], when possible.

In the remainder of this section we will present fourth-order and sixth-order CMIRK schemes containing optimal embedded MIRK schemes. These representative schemes will give us the opportunity to assess the role that the order of the MIRK and CMIRK schemes plays in the overall performance of a BVODE code. We are currently extending the results of [Burrage, Chipman, and Muir, 1994] and [Muir and Owren, 1993] to develop eighth-order MIRK and CMIRK families. An eighth-order MIRK scheme has already appeared in the literature (see, e.g., [Gupta, 1985]).

The coefficients defining a CMIRK scheme are usually presented in the form of a tableau as in Table 3.1.

TABLE 3.1

c_1	v_1	0	0	$\dots$	0	0
c_2	v_2	x_{21}	0	$\dots$	0	0
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$

		$b_1(\theta)$	$b_2(\theta)$	$b_3(\theta)$	$b_4(\theta)$

3.2. CMIRK schemes of fourth order. The general form for the family of fourth-order CMIRK schemes is given in [Muir and Owren, 1993]. It uses four stages and has free parameters c_3, c_4, and v_4. It is possible to choose c_3 so that the unique optimal, three-stage, fourth-order discrete MIRK scheme ([van Bokhoven, 1980], Method VI) is embedded within this CMIRK family. The first three stages of the CMIRK scheme will be the same as those of this MIRK scheme and the values of the first three continuous weight polynomials at $\theta = 1$ will be the weights of the discrete scheme.

A careful analysis to determine suitable optimization criteria based, for example, on minimizing the error coefficients of the dominant error terms followed by a thorough numerical investigation would be needed to determine optimal values for the remaining free parameters, c_4 and v_4. However, experience with the selection of such parameters for explicit Runge-Kutta pairs (see, e.g., [Sharp and Smart, 1993]) has indicated that as long as one avoids "pathological choices" for these parameters, the overall performance of a code will not be particularly sensitive to the choice of these parameters. After some preliminary testing to establish that the choices lead to reasonable schemes, we chose $c_4 = \frac{3}{4}$ and $v_4 = \frac{27}{32}$. This gives the fourth-order CMIRK scheme, given in Table 3.2, where

$$b_1(\theta) = -\frac{\theta\,(2\theta-3)\left(2\theta^2-3\theta+2\right)}{6}, \quad b_2(\theta) = \frac{\theta^2\left(9-20\theta+12\theta^2\right)}{6},$$

$$b_3(\theta) = \frac{2\theta^2\left(9-14\theta+6\theta^2\right)}{3}, \quad b_4(\theta) = -\frac{16\theta^2\,(\theta-1)^2}{3}.$$

3.3. CMIRK schemes of sixth order. A particular family of eight-stage, sixth-order CMIRK schemes is given in [Muir and Owren, 1993]. Although the family has nine free parameters $c_3, c_4, c_5, c_6, c_7, v_7, c_8, v_8, x_{81}$, it is not possible to embed within it the standard five-stage, sixth-order discrete MIRK schemes ([van Bokhoven, 1980], Method VIII). In order to get a family of sixth-order CMIRK schemes within which the optimal five-stage, sixth-order discrete scheme of [van Bokhoven, 1980] can be embedded, it is necessary to look outside the sixth-order CMIRK family in [Muir and Owren, 1993] and derive a new sixth-order CMIRK family. An analysis of the continuous order conditions up to order six shows that

TABLE 3.3
A nine-stage sixth-order CMIRK scheme.

$\frac{7}{16}$	$\frac{7}{16}$	$\frac{1547}{32768}$	$\frac{-1225}{32768}$	$\frac{749}{4096}$	$\frac{-287}{2048}$	$\frac{-861}{16384}$	0	0	0	0
$\frac{1}{8}$	$\frac{1}{8}$	$\frac{83}{1536}$	$\frac{-13}{384}$	$\frac{283}{1536}$	$\frac{-167}{1536}$	$\frac{-49}{512}$	0	0	0	0
$\frac{9}{16}$	$\frac{9}{16}$	$\frac{1225}{32768}$	$\frac{-1547}{32768}$	$\frac{287}{2048}$	$\frac{-749}{4096}$	$\frac{861}{16384}$	0	0	0	0
$\frac{3}{8}$	$\frac{3}{8}$	$\frac{233}{3456}$	$\frac{-19}{1152}$	0	0	0	$\frac{-5}{72}$	$\frac{7}{72}$	$\frac{-17}{216}$	0
		$b_1(\theta)$	$b_2(\theta)$	$b_3(\theta)$	$b_4(\theta)$	$b_5(\theta)$	$b_6(\theta)$	$b_7(\theta)$	$b_8(\theta)$	$b_9(\theta)$

such a scheme may require one additional stage beyond that required by an optimal continuous CMIRK scheme of sixth-order. Hence we have derived a nine-stage, sixth-order CMIRK family with an optimal embedded five-stage, sixth-order MIRK scheme, which we present in Table 3.3. The free parameters have been chosen to avoid "pathological cases," as was done for the fourth-order case. The first five stages of the CMIRK scheme are the stages of this MIRK scheme. The first five weight polynomials evaluated at $\theta = 1$ are the weights of this MIRK scheme. Recall, from §2, that the Newton iteration will employ only the five-stage discrete MIRK scheme and only after the Newton iteration converges will the extra four stages be evaluated in order to determine the CMIRK scheme.

The weight polynomials in Table 3.3 are

$$b_1(\theta) = \frac{\theta\left(334530 - 1287315\,\theta - 1662100\,\theta^2 + 10043400\,\theta^3 - 11467776\,\theta^4 + 4065280\,\theta^5\right)}{334530},$$

$$b_2(\theta) = \frac{\theta^2\left(3083913 - 25341580\,\theta + 62657400\,\theta^2 - 62874624\,\theta^3 + 22657024\,\theta^4\right)}{2341710},$$

$$b_3(\theta) = -\frac{16\,\theta^2\left(8505 - 69430\,\theta + 168780\,\theta^2 - 164352\,\theta^3 + 56320\,\theta^4\right)}{7965},$$

$$b_4(\theta) = -\frac{16\,\theta^2\left(8505 - 69430\,\theta + 168780\,\theta^2 - 164352\,\theta^3 + 56320\,\theta^4\right)}{7965},$$

$$b_5(\theta) = -\frac{2\,\theta^2\left(8505 - 69430\,\theta + 168780\,\theta^2 - 164352\,\theta^3 + 56320\,\theta^4\right)}{2655},$$

$$b_6(\theta) = -\frac{1024\,\theta^2\left(45568\,\theta^2 - 45856\,\theta + 7533\right)(\theta - 1)^2}{33453},$$

$$b_7(\theta) = \frac{128\,\theta^2\left(128\,\theta^2 - 128\,\theta + 21\right)(\theta - 1)^2}{15},$$

$$b_8(\theta) = \frac{1024\,\theta^2\left(134144\,\theta^2 - 132128\,\theta + 21609\right)(\theta - 1)^2}{234171}, \quad b_9(\theta) = -\frac{16384\,\theta^3(\theta - 1)^3}{441}.$$

4. Implementation issues. In this section we comment on several of the algorithms and heuristics employed within the software we have written for the numerical solution of BVODEs, based on continuous MIRK schemes and defect control, for which the general algorithm was given in §2. The reader is referred to [Enright and Muir, 1993] for further details related to this discussion.

4.1. The modified Newton iteration. To solve the system, $\Phi(Y) = 0$, described in §2, we use a combination of a damped Newton iteration and a fixed Jacobian iteration, with a scheme for switching between the two. The switching scheme involves monitoring the rate of decrease of a function known as the "natural criterion function," $||J(Y^{(m)})^{-1}\Phi(Y^{(m+1)})||$, (see, e.g., [Ascher, Mattheij, and Russell, 1988, Chap. 8]), where $Y^{(m)}$ is the mth iterate, $\Phi(Y)$ is the residual function defined in §2, and $J(Y)$ is the Jacobian of $\Phi(Y)$.

A point of some concern here is the evaluation of the blocks of the Newton matrix, as given in (2.3). The literature for initial value ODEs (see, e.g., [Butcher 1987, p. 214]) indicates that the usual practice is to evaluate $\frac{\partial f}{\partial y}$ at only one point on each subinterval, with this one value being used in place of each instance of J_r arising in (2.4). For boundary value ODEs, [Cash, 1986, p. 1037] describes an approach which involves evaluating $\frac{\partial f}{\partial y}$ once for each subinterval. This same idea is mentioned in [Ascher, Mattheij, and Russell, 1988, p. 217]. On the other hand, the COLNEW code performs evaluations of $\frac{\partial f}{\partial y}$ at each of the s collocation points of each subinterval. We implemented both approaches, i.e., a scheme with one evaluation per subinterval and a scheme with s evaluations per subinterval, as in (2.4). We found major differences in performance between the two approaches, especially when applied to difficult nonlinear problems. When using the single Jacobian evaluation per subinterval approach, we found some savings in the cost of computing the Jacobian blocks, but the resulting degradation in the performance of the Newton iteration more than offset these savings. Not only was the rate of convergence for the single Jacobian evaluation approach much slower, but also the likelihood of achieving convergence was much lower. This suggests that on some problems it is better to incur the extra cost of using multiple Jacobian values on each subinterval in order to achieve a lower overall cost, and we have adopted this approach.

4.2. Defect estimation. Both the termination criterion and the mesh selection algorithms we employ require an estimate of the maximum value of the defect on each subinterval, as discussed in §2. To avoid excessive computational costs, it is important to obtain an estimate of these maximums by sampling the defect at as few points as possible. In an analogous setting, COLNEW samples the global error at two points per subinterval but it is indicated in [Ascher and Jacobs, 1989] that sampling at the s collocation points of each subinterval can be advantageous. In the initial value ODE setting, defect estimation based on one sample point per step has been found to be quite reliable (see, e.g., [Enright, 1989b]). Employing a standard analysis for continuous Runge-Kutta schemes, we determined suitable candidates for the defect sample points, $0 \leq \theta^* \leq 1$, within each subinterval, for the two CMIRK schemes of §3. For the fourth-order CMIRK scheme we choose $\theta^* \approx 0.226$, while for the sixth-order CMIRK scheme we choose $\theta^* \approx 0.716$.

We performed numerical experiments to determine the reliability of one-point sampling and also two-point sampling, with the second sample point chosen to be $1 - \theta^*$ (due to the presence of certain symmetries in the form of the defect). We compared the estimates for each subinterval with a "true" maximum defect obtained by sampling the defect at many points on the subinterval, and monitored the number of times that the estimation schemes were deceived, i.e., reported a maximum defect that was less than 20% of the "true" maximum defect. We found that sampling at two points provided substantially more reliability; the maximum percentage of deceptions reported by the two-point sampling scheme was usually an order of magnitude smaller than that of the one-point sampling scheme, and was generally 1% or lower. Furthermore, although the execution time specifically associated with the defect estimation module was approximately doubled when two-point sampling was used, the overall execution cost was approximately the same. This occurs because the availability of a sharper estimate of the defect profile over the mesh subintervals allows the mesh redistribution algorithm to determine meshes that are better suited to the underlying solution behavior, thus leading to a final acceptable solution more quickly.

4.3. Mesh selection. We refer the reader to [Ascher, Mattheij, and Russell, 1988, Chap. 9] for an overview of a generic mesh selection algorithm for BVODE codes. The mesh selection algorithm we have implemented is based on this model algorithm but uses defect estimates rather than global error estimates as the basis for the equidistribution process. There are several parameters that control various aspects of the performance of a mesh selection algorithm, such as the frequency of application of the refinement and redistribution process and the estimation of the number of points needed for the new mesh. We conducted a number of experiments to examine several of these parameters and have reported the results in [Enright and Muir, 1993]. One result concerns the parameter which determines when the redistribution is applied. In COLNEW, the value of this parameter is chosen so that mesh redistribution is used only when the maximum error estimate over all subintervals is much larger than the average value, and as a result, mesh redistributions within COLNEW are infrequent. We have profiled our software and have noted that the execution costs associated with the mesh selection algorithm are relatively small, so efficiency concerns over execution costs directly associated with the mesh selection module are not an issue. Further testing has indicated that substantial savings in overall execution costs are usually obtained when mesh redistribution is employed, and thus our software invokes its mesh redistribution algorithm for every converged solution. This makes it possible to adapt the mesh to the approximate solution more quickly than when mesh doubling is used.

It should be noted that the defect estimate can be computed and the termination criterion applied whenever a converged solution is obtained on a given mesh. This can be contrasted with the scheme used in COLNEW where termination occurs only when the current solution can be compared with the previously computed solution obtained on a mesh which is exactly half the current one. (That is, the current mesh is obtained by halving each subinterval of the previous mesh.) This appears to have influenced the choice within COLNEW to favor mesh doubling over mesh redistribution.

5. Performance analysis.

5.1. Overview. In this section we present some results on the performance of our BVODE software, called MIRKDC, which uses MIRK and CMIRK schemes and defect control, as described in the previous sections. We will present results for 18 test problems selected from three problem families. In order to demonstrate that the performance of MIRKDC on this test set is reasonable, we will also present the results of applying COLNEW to this same test set. It is not the purpose of this paper to conduct a comparison of these codes. See [Pereyra and Russell, 1982] for a discussion of the difficulties involved in such comparisons. The purpose of presenting these results is to show that the performance of MIRKDC is reasonable, compared to that of a well-known, widely used package, for a particular test set. It is essential to have both codes treat the same problem class and to apply the tolerance request in the same way. Thus we consider the solution of first-order systems with the same tolerance applied to all solution and derivative components since this is the problem class that MIRKDC can currently handle. COLNEW has more flexibility; e.g., it can handle mixed-order multipoint ODE systems directly and can apply different tolerances to each solution and derivative component.

We shall quantify the performance according to several criteria. For each test problem, we will first present a "performance profile." This traces the sequence of discrete problems that a code attempts during its efforts to compute a final solution. The performance profile consists of a list of ordered pairs, (n, q), one pair for each discrete system, where n is the number of subintervals in the mesh from which the discrete system was derived, and q is the number of Newton iterations performed on that discrete problem. The profile gives an indication of the costs incurred by the code in attempting to solve the given problem. In addition to the profile, our assessment of the performance of each code on a given problem will include the CPU time (in seconds, on a DEC Micro-Vax 3800), the global error of the computed solution, and the defect of the solution. The global error is computed by comparing the computed solution with a high accuracy numerical solution at one hundred points uniformly distributed over the problem interval.

An additional difficulty here is that COLNEW controls the global error while MIRKDC controls the defect. These two measures of solution quality are not equivalent (although they are related as mentioned earlier and as given in [Ascher, Mattheij, and Russell, 1988, Chap. 3, §4]). COLNEW is not designed to control the defect and would require modification in order to allow it to compute a continuous solution approximation appropriate for use in a defect control setting. On the other hand, the global error of the continuous solution produced by MIRKDC can be measured, even though this quantity is not controlled by the code. Thus we arrange for each code to return a solution for which the global error on each solution and derivative component is within a given tolerance. Since COLNEW is designed to control the global error, it is straightforward to make this specification to COLNEW. MIRKDC controls the defect so, for each test problem, we experimentally determine a tolerance for the defect that will yield a solution whose global error is within the desired tolerance.

COLNEW can handle mixed-order BVODE systems directly and this is often an advantage over all codes that can treat only first-order systems. Since MIRKDC can only handle first-order systems, our set of test problems will be presented as first-order systems. However there are possibilities for improving the flexibility of MIRK-based BVODE solvers. When we consider a BVODE system obtained from the conversion of a mixed-order system to a first-order system, we note that the matrices that arise during the setup of the almost block diagonal system do exhibit some structure which could be exploited by a special purpose algorithm. We are currently investigating matrix setup algorithms which will take advantage of this special structure. Another approach we are also investigating involves developing extensions of the MIRK and CMIRK formulas for the direct treatment of higher-order ODE systems (analogous to the situation for initial value ODE problems where Runge-Kutta-Nystrom formulas are available).

For each test problem, we require each code to compute two solutions, one with a global error of less than 10^{-6} and one with a global error of less than 10^{-8}. For MIRKDC, for each test problem, we give the tolerance value that was imposed on the defect in order to obtain a solution with the desired global error. We provide results for both fourth- and sixth-order methods. A "*" indicates that the Newton iteration for a discrete problem did not converge. A failure is indicated (by the entry $FAIL$) if a code required more than 2000 subintervals to solve the problem. In all cases where failure occurred, the performance profile was always $(10, *)$, $(20, *)$, $(40, *)$, $(80, *)$, $(160, *)$, $(320, *)$, $(640, *)$, $(1280, *)$, so we do not list it in the tables.

We make the observation that all the test problems we consider here are single problem instances, although they are chosen from problem families. In particular, no use is made of "parameter continuation," in which the solution and mesh from one problem are used as the initial solution guess and initial mesh for a more difficult problem from the same family.

This causes the performance of the Newton iteration to play a larger role in determining the execution time required by the code to solve a given problem. If the performance of a code is examined in a parameter continuation setting, one expects the initial guesses and meshes will be sufficiently good that the Newton iterations usually will converge more readily, and thus the costs of other parts of the codes will play a larger role in determining overall performance. Of course, the success of a parameter continuation scheme depends heavily on the strategy used to select the parameter steps; thus in our current study we avoid the use of parameter continuation, preferring to study code performance in the simpler setting where each problem is solved independently.

5.2. Numerical results. For each problem family, the initial guesses for the solution are chosen to be straight lines through the boundary conditions, where applicable, and zero otherwise.

The first family of test problems is the Swirling Flow III family given in [Ascher, Mattheij, and Russell, 1988, p. 23]. The problem statement given there, however, has a slight error. The corrected form of the problem, which can be found in, for example, [Batchelor, 1951], is

$$\epsilon f'''' + ff''' + gg' = 0, \qquad \epsilon g'' + fg' - f'g = 0,$$

with

$$f(0) = f(1) = f'(0) = f'(1) = 0, \quad g(0) = \Omega_0, \quad g(1) = \Omega_1.$$

For our testing, we chose $\Omega_0 = 1$ and $\Omega_1 = -1$ (which specifies a counter-rotating disk problem) and consider values of the viscosity parameter $\epsilon = 1.0, 0.1, 0.05, 0.01, 0.005, 0.001, 0.0005$. The results are given in Tables 5.1-5.8.

estimate (after a convergent solution on $N/2$ subintervals has been determined), can result in a solution that is more accurate than requested at a cost that is higher than necessary. This behavior leads to costs being very sensitive to small changes in the accuracy request (or to any other problem parameter) and therefore makes direct comparison of results very difficult. This must be kept in mind when interpreting our numerical results. The error control strategy and mesh selection strategy of MIRKDC are more flexible than that of COLNEW (allowing a more finely adapted selection of an appropriate mesh) and leads to a generally smoother relationship between the cost and requested accuracy.

From the results presented here one can observe that MIRKDC can be as efficient and can exhibit smoother and more predictable behavior as we consider more difficult problems in the same problem family. There are some instances (for both methods) where the cost is unexpectedly large or no results are available. By studying the corresponding performance profiles we see that the former behavior is usually the result of a large number of Newton iterations associated with a coarse-mesh approximate solution, while the latter behavior is the result of a Newton iteration failure at all attempted meshes. In practical applications these two related difficulties are not uncommon, and special method-independent techniques are often used to overcome them. For example, when the Newton iteration fails to converge for any mesh one can obtain more accurate initial guesses by employing continuation with respect to the problem parameter that quantifies the level of difficulty.

Note that the rather large defects observed in the performance profiles associated with COLNEW should not be interpreted as a deficiency. This code was not designed to control this quantity, and a different interpolating strategy would lead to a much improved relationship between the size of the defect and the requested accuracy. This statistic is only reported to confirm that MIRKDC is controlling the defect in the way that is intended.

6. Conclusions and future work. In this paper we have discussed an alternative approach for the numerical solution of BVODE problems. The major new aspects are the use of continuous MIRK formulas and the use of defect estimation rather than global error estimation for accuracy control and mesh selection. The algorithms for this alternate approach have been implemented in a code called MIRKDC which, in some preliminary testing, has demonstrated performance comparable to that of the widely used software package, COLNEW. The results are sufficiently encouraging to indicate that further work in the development of MIRKDC is worthwhile. Further testing on a larger set of test problems is now proceeding.

There are several aspects of the new approach and software that require further investigation. Foremost among these is the need to explore the space of available MIRK formulas to select specific optimal formulas of each order. A related question involves a theoretical analysis of CMIRK schemes containing optimal embedded MIRK schemes. It is clear that the order barriers in such a case may be different than those of [Muir and Owren, 1993], where the restriction of an embedded optimal discrete formula is not included. The new nine-stage, sixth-order CMIRK scheme presented in §3 is an example of this kind of scheme. Subsequent to the characterization of optimal CMIRK formulas with optimal embedded discrete MIRK formulas, a study to explore the parameter space of the CMIRK families to discover appropriate specific formulas is needed.

Additional areas for future work include further investigation of the parameters which control the Newton iteration since the overall efficiency and robustness of a BVODE code is very much dependent on the performance of this algorithm. Further investigation of controlling parameters within the mesh redistribution algorithm and in the algorithm controlling continuation of solutions and meshes over the discrete problem sequences may also lead to significant performance improvements. A number of questions remain to be answered concerning the use of defect control in the numerical solution of BVODE problems. A variety of defect estimation schemes are available and the most appropriate choice for the BVODE context remains to be established. Also, the use of defect control allows more freedom in mesh selection, which in turn appears to lead to some performance advantages which must be further explored.

THE DIFFERENTIATION MATRIX FOR DAUBECHIES-BASED WAVELETS ON AN INTERVAL*

LELAND JAMESON†

Abstract. The differentiation matrix for a Daubechies-based wavelet basis defined on an interval is constructed. It is shown that the differentiation matrix based on the currently available boundary constructions does not maintain the superconvergence encountered under periodic boundary conditions.

Key words. wavelet approximation, differentiation matrix, superconvergence

AMS subject classifications. 65N30, 65D25

1. Introduction. Superconvergence is a property of wavelet methods, which is Daubechies- (see [4]), and spline-based (see [10]), when periodic boundary conditions are assumed and a Galerkin projection is used. That is, for Daubechies-based methods under the assumption of periodicity, it was proven in [6] that the differentiation matrix is accurate of order $2M$, even though the highest degree polynomial that can be reconstructed exactly in the wavelet subspace is of degree $M - 1$, where M is the number of vanishing moments of the wavelet. For spline-based methods, again assuming periodicity, it was proven in [7] that the differentiation matrix is accurate of order $2n + 2$, even though one can only construct splines of order n exactly in the underlying subspace. For Daubechies- and spline-based wavelet systems this approximate doubling of the differentiation accuracy is known as superconvergence, a name borrowed from the finite element literature.

When periodicity is no longer assumed and one defines wavelets on an interval, one of the goals when building boundary functions should be to maintain the superconvergence of the differentiation matrix across the entire interval. It has been proven by Gottlieb et al. [5] that the superconvergence encountered in finite element methods under the assumption of periodicity cannot be maintained on the interval if there are characteristics leaving the domain. Furthermore, it was shown in [7] that for spline-based wavelet systems superconvergence is lost at the boundaries when the boundary functions are truncated B-splines. The goal of this paper is to explore the accuracy of the differentiation matrix for Daubechies-based wavelet systems defined on an interval. In particular, I will explore the differentiation accuracy of the differentiation matrices constructed from the currently available boundary constructions for Daubechies wavelets defined on an interval. The differentiation matrix for the Daubechies-4 (D_4)wavelet basis using the boundary functions defined in [3] will be calculated explicitly and the accuracy will be found. From this explicit example one can see a necessary condition for superconvergence to be maintained with other boundary constructions.

We begin by defining the differentiation matrix $\mathcal{D}$ as the product of three matrices: $\mathcal{D} = \hat{C}DC$. The three matrices are defined as follows:

- The first matrix C is a quadrature matrix mapping from samples in the physical space to approximate scaling function coefficients at the finest scale: $\vec{s} = C\vec{f}$. C can be derived from the moments of the scaling function. C, also, can be simply the inverse of the third matrix: $C = (\hat{C})^{-1}$.

- The second matrix D maps from the scaling function coefficients of a function to the scaling function coefficients of the derivative of the same function. For convenience I will, henceforth, refer to this matrix as the "derivative projection" matrix.
- The third matrix $\hat{C}$ is a quadrature matrix mapping from approximate scaling function coefficients to approximate point values in the physical space: $\vec{f} = \hat{C}\vec{s}$. $\hat{C}$ can be derived from samples of the scaling function or can simply be the inverse of the first matrix: $\hat{C} = C^{-1}$.

This paper contains the following sections.

1. **Introduction**
2. **Boundary functions.** An outline of the boundary functions constructed in [3] is given.
3. **Derivative projection matrix D.** The entries of D are defined and calculated. D has a banded structure due to the local support of the basis functions, but D is not antisymmetric. The number of nonzero entries in each row of D bounds the maximum differentiation accuracy for the corresponding row in the differentiation matrix. Furthermore, the number of nonzero entries in the first few and last few rows of D are related to the overlap of the boundary functions.
4. **Approximating scaling function coefficients.** An outline of scaling function coefficient approximation is given.
5. **Quadrature matrix C using moments.** C performs the mapping $C : \vec{f} \rightarrow \vec{s}$. The D_4 wavelet has two vanishing moments which yield well-conditioned two-point quadrature matrices and ill-conditioned three-point quadrature matrices.
6. **Quadrature matrix $\hat{C}$ using samples.** $\hat{C}$ performs the mapping, $\hat{C} : \vec{s} \rightarrow \vec{f}$. For the D_4 wavelet the matrix $\hat{C}$ has three entries in each row and is banded. $\hat{C}$, however, is ill conditioned.
7. **Examples and order of accuracy.** The matrix D is fixed. However, there are many choices for the quadrature matrix producing many versions of $\mathcal{D}$. In all cases superconvergence is lost at the boundaries. Furthermore, choosing among the quadrature matrices which are not ill conditioned, one gets a differentiation matrix which is essentially full. A banded $\mathcal{D}$ can be constructed from a combination of the two types of quadrature matrices C and $\hat{C}$. The bandwidth from such a construction is large, 9, for a D_4 wavelet and, again, the superconvergence is lost at the boundaries. In addition, all of these matrices display directional dependency. This directional dependency can be "fixed" by reversing the coordinate system and averaging the appropriate differentiation matrices.
8. **Conclusion.** The differentiation matrices for wavelets on an interval using the boundary functions defined in [3] do not maintain the superconvergence encountered when periodic boundary conditions are assumed. By simply counting the overlap of boundary functions in other boundary constructions it can be seen that all currently available boundary constructions fail to maintain the superconvergence encountered under periodic boundary conditions.

2. Construction of boundary functions. This section is a brief outline of the boundary function construction proposed by Cohen, Daubechies, and Vial; see [3].

The goal is to build a wavelet basis on an interval where the scaling functions and wavelets away from the boundaries are the usual Daubechies scaling functions and wavelets. At the boundaries, boundary scaling functions are constructed such that polynomials of order up to the number of vanishing moments of the wavelet can be reproduced exactly across the entire interval.

The boundary function construction begins by building independent, but not orthogonal, functions as follows:

$$\hat{\phi}^k(x) = \sum_{n=k}^{2N-2} \binom{n}{k} \phi(x+n-N+1), \tag{1}$$

where $\phi(x)$ is the usual Daubechies scaling function and N is the number of vanishing moments of the associated wavelet. Note that these functions are compactly supported, and their supports are staggered, i.e.,

$$\operatorname{supp}(\hat{\phi}^k) = [0, 2N-1-k]. \tag{2}$$

The staggered support yields independence, and the boundary functions are then defined by simply orthonormalizing these functions by a Gram-Schmidt method.

Coefficients h^L and h^R can be found, see [3], such that the boundary functions are defined recursively as follows beginning with the left-hand side boundary functions:

$$\phi_k^L(x) = \sqrt{2}\sum_{l=0}^{N-1} h_{k,l}^L \phi_l^L(2x) + \sqrt{2}\sum_{m=N}^{N+2k} h_{k,m}^L \phi(2x-m), \tag{3}$$

and the equation defining the right-hand side boundary functions is

$$\phi_k^R(x) = \sqrt{2}\sum_{l=0}^{N-1} h_{k,l}^R \phi_l^R(2x) + \sqrt{2}\sum_{m=N}^{N+2k} h_{k,m}^R \phi(2x+m+1). \tag{4}$$

Figure 1 is a plot of the four boundary scaling functions for the D_4 wavelet.

3. The derivative projection matrix D. Let us recall the origin of the matrix D. First, we begin with a function $f(x) \in L^2(R)$. Next, we want to approximate, or discretize, this function in a scaling function subspace $V_0 \subset L^2(R)$,

$$P_{V_0} f(x) = \sum_{k=0}^{d-1} s_k b_k(x), \tag{5}$$

where $\{b_k(x)\}$ denotes the basis functions of this finest scale discretization, and d is the dimension or number of degrees of freedom of the subspace. In the case of wavelets with periodic boundary conditions $b_k(x) = \phi_k(x)$, the usual Daubechies scaling functions, for all $k \in \{0, \dots, d-1\}$. However, in the current scenario of wavelets on an interval, $b_k(x)$ are different at the boundaries:

$$b_k(x) = \phi_k^L(x)$$

for $k = 0, \dots, N-1$,

$$b_k(x) = \phi_k(x)$$

for $N \le k \le d-2N+1$, and

$$b_k(x) = \phi_k^R(x)$$

for $k = d-2N+2, \dots, d-1$, where N is the number of vanishing moments of the wavelet. Under the orthonormality of the current basis set $\langle b_k, b_l\rangle = \delta_{k,l}$, where

$$\langle g, h\rangle \equiv \int_I g(x)h(x)dx, \tag{6}$$

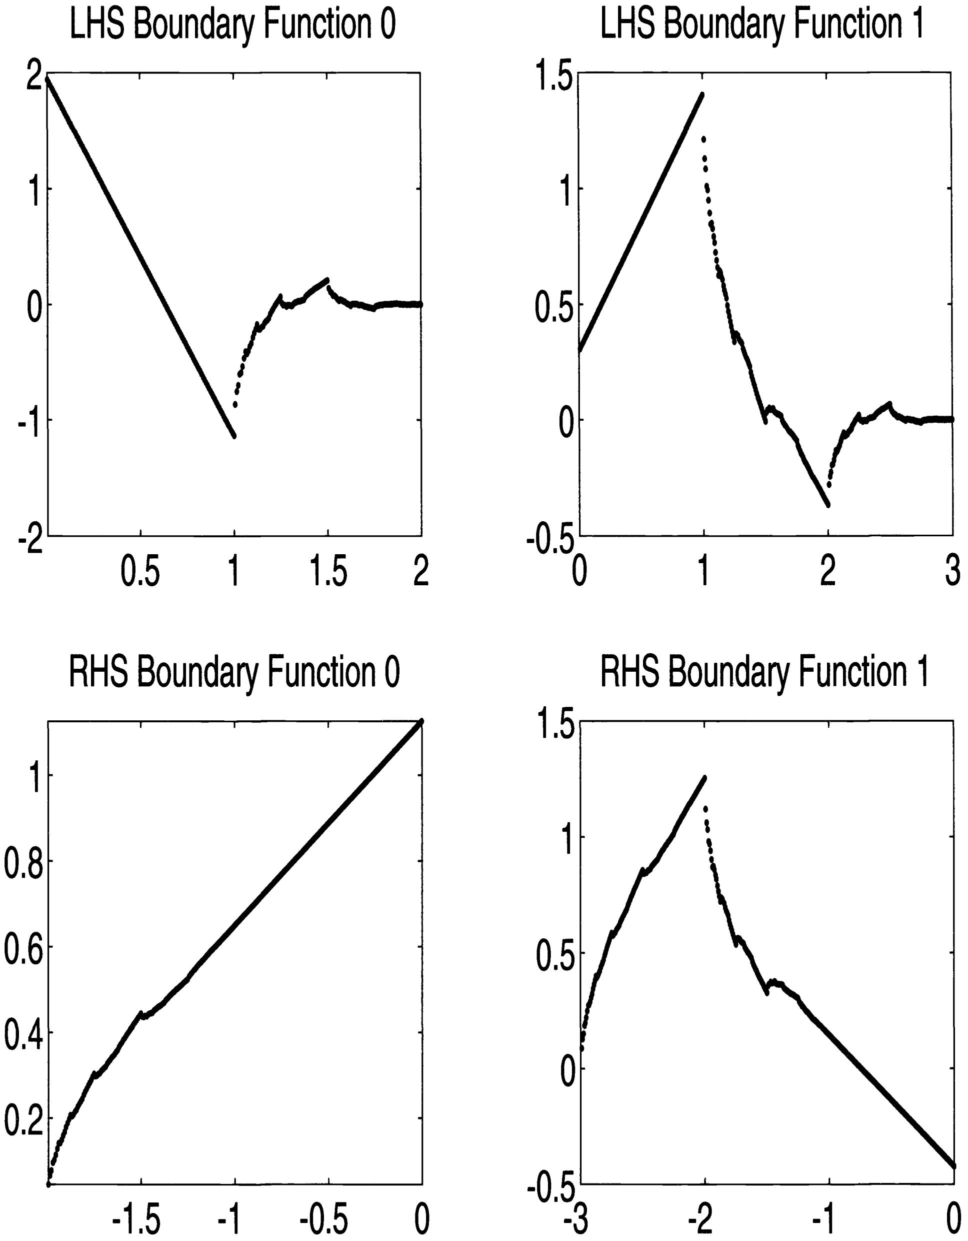

FIG. 1. *The boundary functions for the D_4 scaling function.*

and $\int_I$ denotes integration over the interval, we get

$$s_k = \langle b_k, f \rangle . \tag{7}$$

Now we differentiate the approximation $P_{V_0} f(x)$ to get

$$\frac{d}{dx} P_{V_0} f(x) = \sum_{k=0}^{d-1} s_k \acute{b}_k(x), \tag{8}$$

where $\acute{b}(x) = \frac{d}{dx}b(x)$. The derivative takes $P_{V_0}f(x)$ out of V_0. Projecting back into V_0 we get,

$$P_{V_0}\frac{d}{dx}P_{V_0}f(x) = \sum_{l=0}^{d-1}\left\langle \frac{d}{dx}P_{V_0}f, b_l \right\rangle b_l(x) \tag{9}$$

or

$$P_{V_0}\frac{d}{dx}P_{V_0}f(x) = \sum_{l=0}^{d-1}\sum_{k=0}^{d-1} s_k \left\langle \acute{b}_k, b_l \right\rangle b_l(x). \tag{10}$$

The elements $\langle \acute{b}_k, b_l\rangle$ comprise the derivative projection matrix D. If we let $\vec{s}$ denote the vector of the scaling function coefficients s_k, for $k = 0, \dots, d-1$, then D maps from the scaling function coefficients of a function at the finest scale to the scaling function coefficients of the derivative of the same function:

$$D : \vec{s} \to \vec{\acute{s}}.$$

D, in effect, contains all the derivative information in a wavelet expansion. The elements of D contain the numerical values of the derivative of each scaling function projected onto all scaling functions in the basis. Due to the compact support of the basis functions, the matrix D has a band diagonal form. The following matrix illustrates the form of D for the D_4 wavelet basis with boundary functions defined as in the previous section:

$$D = \begin{bmatrix}
\rho^L_{0,0} & \rho^L_{1,0} & \alpha^L_{2,0} & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
\rho^L_{0,1} & \rho^L_{1,1} & \alpha^L_{2,1} & \alpha^L_{3,1} & 0 & 0 & 0 & 0 & 0 & 0 \\
\beta^L_{0,2} & \beta^L_{1,2} & r_0 & r_1 & r_2 & 0 & 0 & 0 & 0 & 0 \\
0 & \beta^L_{1,3} & r_{-1} & r_0 & r_1 & r_2 & 0 & 0 & 0 & 0 \\
0 & 0 & r_{-2} & r_{-1} & r_0 & r_1 & r_2 & 0 & 0 & 0 \\
0 & 0 & 0 & r_{-2} & r_{-1} & r_0 & r_1 & r_2 & 0 & 0 \\
0 & 0 & 0 & 0 & r_{-2} & r_{-1} & r_0 & r_1 & \beta^R_{1,4} & 0 \\
0 & 0 & 0 & 0 & 0 & r_{-2} & r_{-1} & r_0 & \beta^R_{1,5} & \beta^R_{0,5} \\
0 & 0 & 0 & 0 & 0 & 0 & \alpha^R_{4,1} & \alpha^R_{5,1} & \rho^R_{1,1} & \rho^R_{0,1} \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & \alpha^R_{5,0} & \rho^R_{1,0} & \rho^R_{0,0}
\end{bmatrix},$$

where the coefficients r are the derivative projections due to scaling function interaction, the coefficients ρ are the projections of the derivatives of boundary functions projected onto boundary functions, and the coefficients α and β contain the interactions between derivatives of boundary functions and scaling functions.

In the following subsections the entries of D will be found.

3.1. The equations for the derivative projections. To find the elements of D one needs to find the interaction of the derivative of each basis function with every other basis function. Due to the local support of the basis functions, the left-hand side (LHS) boundary functions and the right-hand boundary functions do not interact. (Assuming, of course, that one does not choose an unreasonably small domain relative to the support of the scaling functions.)

Each entry in the matrix D must be found separately, but the calculations are straightforward. A sampling of the relevant derivations will be given below.

3.1.1. Derivation of the LHS equations. Recall that the LHS boundary functions $\phi_k^L(x)$ are generated by

$$\phi_k^L(x) = \sqrt{2}\sum_{l=0}^{N-1} h_{k,l}^L \phi_l^L(2x) + \sqrt{2}\sum_{m=N}^{N+2k} h_{k,m}^L \phi(2x-m). \tag{11}$$

Differentiate the above equation to get

$$\frac{d}{dx}\phi_k^L(x) = 2\sqrt{2}\sum_{l=0}^{N-1} h_{k,l}^L \acute{\phi}_l^L(2x) + 2\sqrt{2}\sum_{m=N}^{N+2k} h_{k,m}^L \acute{\phi}(2x-m). \tag{12}$$

Multiply $\acute{\phi}_k^L(x)$ by $\phi_p^L(x)$ and integrate to get

$$\begin{aligned} \int_I \acute{\phi}_k^L(x)\phi_p^L(x)dx &= 4\sum_{l=0}^{N-1}\sum_{i=0}^{N-1} h_{k,l}^L h_{p,i}^L \int_I \acute{\phi}_l^L(2x)\phi_i^L(2x)dx \\ &+ 4\sum_{m=N}^{N+2k}\sum_{i=0}^{N-1} h_{p,i}^L h_{k,m}^L \int_I \phi_i^L(2x)\acute{\phi}(2x-m)dx \\ &+ 4\sum_{l=0}^{N-1}\sum_{q=N}^{N+2p} h_{k,l}^L h_{p,q}^L \int_I \acute{\phi}_l^L(2x)\phi(2x-q)dx \\ &+ 4\sum_{m=N}^{N+2k}\sum_{q=N}^{N+2p} h_{k,m}^L h_{p,q}^L \int_I \acute{\phi}(2x-m)\phi(2x-q)dx. \end{aligned} \tag{13}$$

Rename the integrals as

$$\rho_{k,p}^L = \int_I \acute{\phi}_k^L(x)\phi_p^L(x)dx, \tag{14}$$

$$\alpha_{m,i}^L = \int_I \acute{\phi}(x-m)\phi_i^L(x)dx, \tag{15}$$

$$\beta_{l,q}^L = \int_I \acute{\phi}_l^L(x)\phi(x-q)dx, \tag{16}$$

$$r_{m,q} = \int_I \acute{\phi}(x-m)\phi(x-q)dx, \tag{17}$$

to get the following system of equations:

$$\begin{aligned} \frac{1}{2}\rho_{k,p}^L &= \sum_{l}^{N-1}\sum_{i}^{N-1} h_{k,l}^L h_{p,i}^L \rho_{l,i}^L + \sum_{i=0}^{N-1}\sum_{m=N}^{N+2k} h_{p,i}^L h_{k,m}^L \alpha_{m,i}^L \\ &+ \sum_{l=0}^{N-1}\sum_{q=N}^{N+2p} h_{k,l}^L h_{p,q}^L \beta_{l,q}^L + \sum_{m=N}^{N+2k}\sum_{q=N}^{N+2p} h_{k,m}^L h_{p,q}^L r_{m,q}. \end{aligned} \tag{18}$$

The numerical values of the coefficients $\{r\}$ were found in [2], and the numerical values of the coefficients ρ^L, α^L, and β^L will be found in the following subsections.

3.2. The coefficients $\rho_{i,i}^L$ for $i = 0, 1$. In this subsection we will find the corner diagonal elements of D. These elements represent the projection of the derivative of each boundary function onto itself.

3.2.1. The coefficients $\rho^L_{0,0}$ and $\rho^L_{1,1}$. For simplicity, allow the lower limit to be 0 and the upper limit be ∞ in the definition of $\rho^L_{k,k}$:

$$\rho^L_{k,k} = \int_0^\infty \phi'^L_k(x)\phi^L_k(x)dx.$$

Apply integration by parts to this equation to get

$$\rho^L_{k,k} = (\phi^L_k(x))^2|_0^\infty - \int_0^\infty \phi^L_k(x)\phi'^L_k(x)dx \tag{19}$$

or

$$2\rho^L_{k,k} = (\phi^L_k(x))^2|_0^\infty. \tag{20}$$

$\phi^L_k(x)$ is 0 at $x = \infty$ leaving only the value at the lower limit

$$\rho^L_{k,k} = -\frac{(\phi^L_k(0))^2}{2}. \tag{21}$$

That is, $\rho^L_{k,k}$ is determined by the value of the boundary function at the boundary. Before evaluating the boundary functions at the boundary it will be shown that $\rho^L_{0,0}$ and $\rho^L_{1,1}$ are related by a constant multiple.

3.2.2. The relationship between $\rho^L_{0,0}$ and $\rho^L_{1,1}$. In (11) set $x = 0$ to get

$$\phi^L_k(0) = \sqrt{2}\sum_{l=0}^{1} h^L_{k,l}\phi^L_l(0) + \sqrt{2}\sum_{m=2}^{2+2k} h^L_{k,m}\phi(-m). \tag{22}$$

For $k = 0$ we get

$$\phi^L_0(0) = \sqrt{2}(h^L_{0,0}\phi^L_0(0) + h^L_{0,1}\phi^L_1(0)), \tag{23}$$

which yields

$$\phi^L_1(0) = c^L\phi^L_0(0), \tag{24}$$

where

$$c^L = \frac{1-\sqrt{2}h^L_{0,0}}{\sqrt{2}h^L_{0,1}}. \tag{25}$$

Recall from above that the $\rho^L_{k,k}$'s can be found from the boundary functions evaluated at the boundary. Combine this information with (24) to get

$$\rho^L_{1,1} = (c^L)^2\rho^L_{0,0}. \tag{26}$$

That is, we only need to evaluate one of the boundary functions at the boundary in order to know $\rho^L_{0,0}$ and $\rho^L_{1,1}$. The following subsection will evaluate the boundary function $\phi^L_0(x)$ at $x = 0$.

3.2.3. Evaluation of the boundary function $\phi_0^L(x)$ at $x = 0$. In this subsection the straightforward evaluation of the boundary function $\phi_0^L(x)$ at $x = 0$ will be given.

In (11) let $k = 1$ and $x = 2$ to get

$$\phi_1^L(2) = \sqrt{2}(h_{1,3}^L\phi(1) + h_{1,4}^L\phi(0)). \tag{27}$$

The values of the scaling function $\phi(x)$ in the above integers are $\phi(0) = 1/2(1 + \sqrt{3})$ and $\phi(1) = 1/2(1 - \sqrt{3})$; see [9]. Using these numbers and the coefficients provided in [3] we get $\phi_1^L(2) = -.3654971039$. Similar to above, let $k = 0$ and $x = 1$ in (11) to get

$$\phi_0^L(1) = \sqrt{2}h_{0,1}^L\phi_1^L(2) + \sqrt{2}h_{0,2}^L\phi(0), \tag{28}$$

and evaluate to get $\phi_0^L(1) = -1.1265992786$. In this way, one can get the following values for the boundary functions: $\phi_1^L(1) = 1.4058555636$, $\phi_0^L(1/2) = .4123639530$. Now we have two values for $\phi_0^L(x)$ at $x = 1/2$ and $x = 1$. Furthermore, the two boundary functions are lines between $x = 0$ and $x = 1$. We can, therefore, find the value of $\phi_0^L(x)$ at $x = 0$: $\phi_0^L(0) = 1.9513271847$. As outlined in the previous subsection we now have sufficient information to find $\rho_{0,0}^L$ and $\rho_{1,1}^L$:

$$\rho_{0,0}^L = -1.9038388908$$

and

$$\rho_{1,1}^L = -.04295212263.$$

The calculation of the remaining elements of the derivative projection matrix is straightforward and will not be given. The next subsection provides the complete matrix D.

3.3. The complete matrix *D*. This section of the paper will be concluded by giving a 10-by-10 version of the matrix D. Only four-digit accuracy will be given for the corner entries ρ, α, and β. The entries r are known exactly.

$$D = \begin{bmatrix}
-1.9038 & .9444 & -.2565 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
-1.5163 & -.0430 & .6752 & -.0832 & 0 & 0 & 0 & 0 & 0 & 0 \\
.2565 & -.6752 & 0 & \frac{2}{3} & -\frac{1}{12} & 0 & 0 & 0 & 0 & 0 \\
0 & .0832 & -\frac{2}{3} & 0 & \frac{2}{3} & -\frac{1}{12} & 0 & 0 & 0 & 0 \\
0 & 0 & \frac{1}{12} & -\frac{2}{3} & 0 & \frac{2}{3} & -\frac{1}{12} & 0 & 0 & 0 \\
0 & 0 & 0 & \frac{1}{12} & -\frac{2}{3} & 0 & \frac{2}{3} & -\frac{1}{12} & 0 & 0 \\
0 & 0 & 0 & 0 & \frac{1}{12} & -\frac{2}{3} & 0 & \frac{2}{3} & -.0765 & 0 \\
0 & 0 & 0 & 0 & 0 & \frac{1}{12} & -\frac{2}{3} & 0 & .5825 & -.0397 \\
0 & 0 & 0 & 0 & 0 & 0 & .0765 & -.5825 & .0899 & .3150 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & .0397 & -.7936 & .6369
\end{bmatrix}.$$

Note that, as expected, away from the boundaries D is the same as the derivative projection matrix which was found for periodic boundary conditions; see [6]. Also, note D is not antisymmetric, but is banded. D is not in itself the differentiation matrix, but D is the component of the differentiation matrix, $\mathcal{D} = C^{-1}DC$, which does the differencing. Later in this paper it will become obvious how one can simply "look" at D in order to tell the maximum differentiation accuracy at the boundaries. The next section begins the discussion of choosing a quadrature matrix C.

4. Approximating scaling function coefficients. Once again, let us work with only the D_4 wavelet. Recall, as constructed in [3], that there are two boundary functions at each end of the interval, as well as the usual D_4 scaling functions away from the boundaries. Let N denote the number of degrees of freedom of the approximation space V_0. Our function $f(x) \in L^2(R)$ is then discretized as follows. (In order to simplify the presentation I will let the "interval" be $[0, N]$, and there will be no overlap between left-hand boundary functions and right-hand boundary functions.)

First, the LHS,

$$s_i^L = \int_0^N \phi_i^L(x) f(x) dx, \tag{29}$$

then the right-hand side (RHS),

$$s_i^R = \int_0^N \phi_i^R(x) f(x) dx, \tag{30}$$

where $i = 0, 1$. Next, discretize in the middle with the usual scaling functions

$$s_k = \int_0^N \phi(x - k) f(x) dx \tag{31}$$

for $k = 2, \dots, N - 4$.

Now we will assume that $f(x)$ is defined on a discrete evenly spaced grid $f(x_i)$ for $i = 1, \dots, N$. Therefore, we must approximate the above three integrals by an appropriate quadrature matrix.

In the following two sections two types of quadrature matrices will be considered. The first type is constructed using the moments of the scaling function and is represented by

$$\vec{s} = C\vec{f}. \tag{32}$$

It will be seen that two-point quadrature matrices for this method are well conditioned, whereas three-point quadrature matrices are ill conditioned.

The second type of quadrature matrix is constructed from samples of the scaling function and boundary functions and is represented by

$$\vec{f} = \hat{C}\vec{s}. \tag{33}$$

It will be seen that this type of quadrature matrix is always ill conditioned.

5. Quadrature matrix C using moments. The quadrature matrix C maps from evenly spaced point values $f(x_i)$ of a function to the approximate scaling function coefficients at the finest scale $\vec{s}$. The quadrature matrix depends on three quantities: the number of vanishing moments of the wavelet, the grid that the function $f(x)$ is defined on, and which grid points are used to approximate each scaling function coefficient.

5.1. Moments of scaling and boundary functions. The moments of the D_4 scaling functions were calculated in Appendix A of [6]. The first three moments are $M_0 = 1$, $M_1 = .6339745962$, and $M_2 = .4019237886$.

We will concentrate here on calculating the moments of the boundary functions.

5.1.1. Moment 0 of LHS boundary functions. The 0th moment of the boundary function k is

$$\int_0^\infty \phi_k^L(x)dx = \sqrt{2}\sum_{l=0}^{1} h_{k,l}^L \int_0^\infty \phi_l^L(2x) + \sqrt{2}\sum_{m=2}^{2+2k} h_{k,m}^L \int_0^\infty \phi(2x-m). \tag{34}$$

Now, adopt the notation $m_k^0 = \int \phi_k^L(x)dx$ and let $y = 2x$ where appropriate in the above integrals to get

$$\sqrt{2}m_k^0 = \sum_{l=0}^{1} h_{k,l}^L m_l^0 + \sum_{m=2}^{2+2k} h_{k,m}^L \int_{-m}^\infty \phi(x)dx. \tag{35}$$

The integral $\int_{-m}^\infty \phi(x)dx$ is 1 since $m \geq 2$, and the scaling function, as defined here, is supported on $[-1, 2]$. Equation (35) defines the following 2-by-2 system:

$$\begin{bmatrix} h_{0,0}^L - \sqrt{2} & h_{0,1}^L \\ h_{1,0}^L & h_{1,1}^L - \sqrt{2} \end{bmatrix} \begin{bmatrix} m_0^0 \\ m_1^0 \end{bmatrix} = \begin{bmatrix} -h_{0,2}^L \\ -h_{1,2}^L - h_{1,3}^L - h_{1,4}^L \end{bmatrix}. \tag{36}$$

The solution to the above system is

$$m_0^0 = .3620520589,$$

$$m_1^0 = 1.001445402.$$

In a similar fashion all moments can be found for the LHS and RHS boundary functions.

5.2. The choice of grid points. In this subsection the affect of the choice of different grid points on the quadrature matrix will be illustrated. For simplicity, in this subsection we will work with only eight basis functions and eight grid points. The interval will be $[0, 8]$. When choosing our grid points to approximate the scaling function coefficient s_i we must use only the grid points that lie within the support of the basis function $b_i(x)$. That is, the inner product that is being approximated is

$$s_i = \int_0^8 b_i(x)f(x)dx,$$

and the data that is available to approximate s_i must be limited to function values defined within the support of $b_i(x)$. The support of each of the eight basis functions is

$$\begin{aligned} \text{supp}\{\phi_1^{bd}\} &= [0, 2], \\ \text{supp}\{\phi_2^{bd}\} &= [0, 3], \\ \text{supp}\{\phi_3\} &= [1, 4], \\ \text{supp}\{\phi_4\} &= [2, 5], \\ \text{supp}\{\phi_5\} &= [3, 6], \\ \text{supp}\{\phi_6\} &= [4, 7], \\ \text{supp}\{\phi_7^{bd}\} &= [5, 8], \\ \text{supp}\{\phi_8^{bd}\} &= [6, 8], \end{aligned}$$

where the superscript "*bd*" denotes a boundary function.

The following subsections will consider a few of the possible quadrature matrices corresponding to the following two grids:

$$\vec{x} = \begin{bmatrix} .5 \\ 1.5 \\ 2.5 \\ 3.5 \\ 4.5 \\ 5.5 \\ 6.5 \\ 7.5 \end{bmatrix} \tag{37}$$

and

$$\vec{y} = \begin{bmatrix} 0 \\ 8/7 \\ 2*8/7 \\ 3*8/7 \\ 4*8/7 \\ 5*8/7 \\ 6*8/7 \\ 8 \end{bmatrix}. \tag{38}$$

5.2.1. The entries of the quadrature matrices. Now, one must use the scaling function and boundary function moments and at least two grid points contained within the support of each basis function in order to build the quadrature matrix. The first row of the quadrature matrix will estimate the basis function coefficient for the boundary function with the smallest support ϕ_1^{bd}. Suppose we have chosen grid $\vec{x}$. We know that for the D_4 wavelet that constants and lines can be represented exactly in the wavelet subspace V_0. There are only two grid points within the support of ϕ_1^{bd}. Therefore, the solution to the following linear system will yield the two coefficients $c_{1,1}$ and $c_{1,2}$ in the first row of the quadrature matrix. The linear system is

$$\begin{bmatrix} \int_I \phi_1^{bd}(x)dx \\ \int_I \phi_1^{bd}(x)xdx \end{bmatrix} = \begin{bmatrix} 1 & 1 \\ .5 & 1.5 \end{bmatrix} \begin{bmatrix} c_{1,1} \\ c_{1,2} \end{bmatrix}. \tag{39}$$

In a similar manner all the entries of a quadrature matrix can be found once one has calculated the moments of the basis functions and chosen the grid points. The following subsection will illustrate a few of the quadrature matrices associated with various grid choices.

5.2.2. All grid points contained in scaling function support. As a first possible choice of grid points, let us use every grid point that is contained within the support of the respective basis functions. Such a quadrature matrix will the following structure:

$$C_1^{3pt} = \begin{bmatrix} c_{1,1} & c_{1,2} & 0 & 0 & 0 & 0 & 0 & 0 \\ c_{2,1} & c_{2,2} & c_{2,3} & 0 & 0 & 0 & 0 & 0 \\ 0 & c_{3,2} & c_{3,3} & c_{3,4} & 0 & 0 & 0 & 0 \\ 0 & 0 & c_{4,3} & c_{4,4} & c_{4,5} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{5,4} & c_{5,5} & c_{5,6} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{6,5} & c_{6,6} & c_{6,7} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{7,6} & c_{7,7} & c_{7,8} \\ 0 & 0 & 0 & 0 & 0 & 0 & c_{8,7} & c_{8,8} \end{bmatrix}. \tag{40}$$

For both of the grids $\vec{x}$ and $\vec{y}$ the matrix C_1^{3pt} is ill conditioned. The condition number is proportional to N^2, where N is the number of grid points, and inversion of C_1^{3pt} unacceptably corrupts the differentiation matrix.

5.2.3. Two-point quadrature at boundary and three-point otherwise. The quadrature matrix has the following structure:

$$(41)\qquad C_2^{3pt} = \begin{bmatrix} c_{1,1} & c_{1,2} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & c_{2,2} & c_{2,3} & 0 & 0 & 0 & 0 & 0 \\ 0 & c_{3,2} & c_{3,3} & c_{3,4} & 0 & 0 & 0 & 0 \\ 0 & 0 & c_{4,3} & c_{4,4} & c_{4,5} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{5,4} & c_{5,5} & c_{5,6} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{6,5} & c_{6,6} & c_{6,7} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{7,6} & c_{7,7} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & c_{8,7} & c_{8,8} \end{bmatrix}.$$

This matrix is also ill conditioned for both grids $\vec{x}$ and $\vec{y}$. Again, the condition number is proportional to N^2.

5.2.4. A first option using a two-point quadrature. We have

$$(42)\qquad C_1^{2pt} = \begin{bmatrix} c_{1,1} & c_{1,2} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & c_{2,2} & c_{2,3} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & c_{3,3} & c_{3,4} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{4,4} & c_{4,5} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{5,5} & c_{5,6} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{6,6} & c_{6,7} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{7,6} & c_{7,7} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & c_{8,7} & c_{8,8} \end{bmatrix}.$$

This quadrature matrix is well conditioned for both grids $\vec{x}$ and $\vec{y}$.

5.2.5. Second option for two-point quadrature. We have

$$(43)\qquad C_2^{2pt} = \begin{bmatrix} c_{1,1} & c_{1,2} & 0 & 0 & 0 & 0 & 0 & 0 \\ c_{2,1} & c_{2,2} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & c_{3,3} & c_{3,4} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{4,4} & c_{4,5} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{5,5} & c_{5,6} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{6,6} & c_{6,7} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & c_{7,7} & c_{7,8} \\ 0 & 0 & 0 & 0 & 0 & 0 & c_{8,7} & c_{8,8} \end{bmatrix}.$$

This quadrature matrix is also well conditioned for grids $\vec{x}$ and $\vec{y}$.

5.3. Conclusion. In this section a variety of structures for quadrature matrices have been shown where the matrices are found by using the moments of the scaling function. In general, the pattern is that three-point quadrature matrices are ill conditioned and two-point quadrature matrices are well conditioned.

The next section will explore quadrature matrices constructed from the samples of the scaling functions.

6. Quadrature matrix $\hat{C}$ using samples. Let $g(x)$ denote the projection of $f(x) \in L^2(R)$ in V_0:

$$(44)\qquad g(x) = P_{V_0} f(x) = \sum_{k=1}^{N} s_k b_k(x).$$

The quadrature formula based on samples of the basis functions can be found from

$$g(x_i) = P_{V_0} f(x_i) = \sum_{k=1}^{N} s_k b_k(x_i). \tag{45}$$

In matrix form the quadrature formula is

$$\vec{g} = \hat{C}\vec{s}, \tag{46}$$

or let $\vec{\sigma}$ be the approximation of $\vec{s}$ to get

$$\vec{f} = \hat{C}\vec{\sigma}, \tag{47}$$

where for an 8-by-8 case the quadrature matrix is

$$\hat{C} = \begin{bmatrix} \phi_0^L(x_1) & \phi_1^L(x_1) & 0 & 0 & 0 & 0 & 0 & 0 \\ \phi_0^L(x_2) & \phi_1^L(x_2) & \phi_2(x_2) & 0 & 0 & 0 & 0 & 0 \\ 0 & \phi_1^L(x_3) & \phi_2(x_3) & \phi_3(x_3) & 0 & 0 & 0 & 0 \\ 0 & 0 & \phi_2(x_4) & \phi_3(x_4) & \phi_4(x_4) & 0 & 0 & 0 \\ 0 & 0 & 0 & \phi_3(x_5) & \phi_4(x_5) & \phi_5(x_5) & 0 & 0 \\ 0 & 0 & 0 & 0 & \phi_4(x_6) & \phi_5(x_6) & \phi_1^R(x_6) & 0 \\ 0 & 0 & 0 & 0 & 0 & \phi_5(x_7) & \phi_1^R(x_7) & \phi_0^R(x_7) \\ 0 & 0 & 0 & 0 & 0 & 0 & \phi_1^R(x_8) & \phi_0^R(x_8) \end{bmatrix}. \tag{48}$$

Now $\hat{C}$ will be found for the two previously defined grids $\vec{x}$ and $\vec{y}$.

6.1. A quadrature matrix based on grid $\vec{x}$. Finding the explicit form of the above-defined $\hat{C}$ for the grid $\vec{x}$ is relatively simple since we only need the numerical values of the scaling functions and boundary functions halfway between the integers.

6.1.1. The numerical values of the scaling function. Using the definition of the scaling function supported on [0, 3],

$$\phi(x) = \sqrt{2}\sum_{k=0}^{3} h_k \phi(2x - k),$$

we get

$$\phi(5/2) = \sqrt{2}h_3\phi(2) = .06698729811, \tag{49}$$

$$\phi(3/2) = \sqrt{2}(h_1\phi(2) + h_2\phi(1)), \tag{50}$$

and

$$\phi(1/2) = \sqrt{2}h_0\phi(1) = .9330127019. \tag{51}$$

The numerical values of ϕ at the integers are provided in [9]:

$$\phi(1) = 1/2(1 + \sqrt{3})$$

and

$$\phi(2) = 1/2(1 - \sqrt{3}).$$

6.1.2. The numerical values of the LHS boundary functions. Given the numerical values of the scaling function $\phi(x)$ on grid $\vec{x}$ one can now find the numerical values of the boundary functions on grid $\vec{x}$ from the expression

$$\phi_k^L(x) = \sqrt{2}\sum_{l=0}^{1} h_{k,l}^L \phi_l^L(2x) + \sqrt{2}\sum_{m=2}^{2+2k} h_{k,m}^L \phi(2x-m). \tag{52}$$

In a similar manner one can find the numerical values for the RHS boundary functions to get the quadrature matrix of the next subsection.

6.1.3. The complete quadrature matrix for grid $\vec{x}$. An 8-by-8 example of the quadrature matrix for grid $\vec{x}$ is

$$\hat{C}_{\vec{x}} = \begin{bmatrix} .4124 & .8495 & 0 & 0 & 0 & 0 & 0 & 0 \\ .2062 & -.0077 & .9330 & 0 & 0 & 0 & 0 & 0 \\ 0 & .0669 & 0 & .9330 & 0 & 0 & 0 & 0 \\ 0 & 0 & .0670 & 0 & .9330 & 0 & 0 & 0 \\ 0 & 0 & 0 & .0670 & 0 & .9330 & 0 & 0 \\ 0 & 0 & 0 & 0 & .0670 & 0 & .8561 & 0 \\ 0 & 0 & 0 & 0 & 0 & .0670 & .3270 & .4451 \\ 0 & 0 & 0 & 0 & 0 & 0 & -.1406 & .8902 \end{bmatrix}. \tag{53}$$

This matrix is ill conditioned just as the three-point quadrature formulas were for the quadrature matrix derived using moments.

6.2. A quadrature matrix based on grid $\vec{y}$. Using the definition of the scaling function

$$\phi(x) = \sqrt{2}\sum_{k=0}^{3} h_k \phi(2x-k),$$

one can set up a matrix such that the eigenvector for the eigenvalue $\lambda = 1$ gives a scalar multiple of the scaling function $\phi(x)$ at $x = i/7$ for $i = 1, \ldots, 20$. The eigenspace for the eigenvalue $\lambda = 1$, however, is two dimensional. To avoid this complication one can approximate the numerical values of $\phi(x)$ at $x = i/7$ for $i = 1, \ldots, 20$ by generating $\phi(x)$ at a large number of diadic points; in this case 2^{14} points were chosen. This approximation is sufficient to understand the character of the quadrature matrix, specifically if it is well conditioned or not. Once the numerical values of the scaling function are known then we can find the numerical values of the boundary functions.

6.2.1. The numerical values of the LHS boundary functions. As before, the numerical values of the LHS boundary functions on grid $\vec{y}$ can be found from

$$\phi_k^L(x) = \sqrt{2}\sum_{l=0}^{1} h_{k,l}^L \phi_l^L(2x) + \sqrt{2}\sum_{m=2}^{2+2k} h_{k,m}^L \phi(2x-m).$$

The numerical values in terms of the scaling function values on grid $\vec{y}$ are

$$\begin{aligned} &\phi_0^L(8/7) = \sqrt{2}(h_{0,1}^L \phi_1^L(16/7) + h_{0,2}^L \phi(2/7)), \\ &\phi_1^L(8/7) = \sqrt{2}(h_{1,1}^L \phi_1^L(16/7) + h_{1,2}^L \phi(2/7) + h_{1,3}^L \phi(-5/7)), \\ &\phi_1^L(16/7) = \sqrt{2}(h_{1,3}^L \phi(11/7) + h_{1,4}^L \phi(4/7)). \end{aligned} \tag{54}$$

As with grid $\vec{x}$ the quadrature matrix produced using grid $\vec{y}$ is ill conditioned. Recall from the previous section that all three-point quadrature matrices were ill conditioned. Therefore, I conclude this section with the observation, not a proof, that quadrature matrices for wavelet bases on an interval using the construction in [3] should be constructed using moments and that the number of grid points used to approximate each scaling function coefficient should be equal to the number of vanishing moments of the corresponding wavelet.

7. Order of accuracy. In this section the order of accuracy for a few of the differentiation matrices that can be constructed from the derivative projection matrix D and the quadrature matrices constructed in the previous three sections will be found. We begin with the differentiation matrices constructed using grid $\vec{x}$ followed by the differentiation matrices constructed using grid $\vec{y}$.

7.1. Accuracy using grid $\vec{x}$. Recall that grid $\vec{x}$ is comprised of the points halfway between the integers and, consequently, the spacing between the grid points is the same as the translation distance for the scaling functions on the finest scale. Furthermore, this grid does not provide a grid point at the boundary itself. This lack of a grid point at the boundary makes this grid an unlikely choice, but I have chosen to study the accuracy as an experiment. Let us begin by giving a few explicit examples of differentiation matrices.

7.1.1. Differentiation matrix $(C_1^{2pt})^{-1}DC_1^{2pt}$, grid $\vec{x}$. Note the unusual form of the following matrix. It is essentially upper triangular in form. This form is due to the inversion of C_1^{2pt}. From Table 1 it can be seen that this differentiation matrix does not maintain the superconvergence at the boundaries. That is, the differentiation is first-order accurate at the boundaries, whereas it is fourth-order accurate at the middle 50% of the grid points. The total differentiation accuracy across the entire domain, therefore, is second-order accurate. We have

$$\mathcal{D} =$$

$$\begin{bmatrix}
-25.33 & 42.38 & -20.77 & 3.73 & -6e^{-4} & 0 & 0 & -7e^{-4} & 7e^{-3} & -9e^{-3} & 2e^{-5} & 3e^{-3} \\
-5.71 & -1.59 & 8.35 & -1.04 & -1e^{-3} & 0 & 0 & -2e^{-3} & .02 & -.02 & 3e^{-5} & 6e^{-3} \\
1.05 & -8.11 & .05 & 8 & -1 & 0 & 0 & -3e^{-3} & .03 & -.04 & 7e^{-5} & .01 \\
0 & 1 & -8 & 0 & 8 & -1 & 0 & -7e^{-3} & .07 & -.09 & 2e^{-4} & .03 \\
0 & 0 & 1 & -8 & 0 & 8 & -1 & -.02 & .16 & -.20 & 3e^{-4} & .06 \\
0 & 0 & 0 & 1 & -8 & 0 & 8 & -1.03 & -.34 & -.43 & 7e^{-4} & .13 \\
0 & 0 & 0 & 0 & 1 & -8 & 0 & 7.93 & -.28 & -.94 & 2e^{-3} & .29 \\
0 & 0 & 0 & 0 & 0 & 1 & -8 & -.16 & 9.56 & -3.02 & 3e^{-3} & .62 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & -8.35 & 3.36 & 3.65 & -.99 & 1.33 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & .25 & -.76 & -8.37 & 6.02 & 2.86 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & -1.62 & 16.61 & -33.66 & 11.96 & 6.71 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & .53 & -5.47 & 2.78 & -3.27 & 5.43
\end{bmatrix}.$$

7.1.2. Differentiation matrix $(C_2^{2pt})^{-1}DC_2^{2pt}$, grid $\vec{x}$. Now we use the quadrature matrix C_2^{2pt}. But the results are similar to the previous matrix. The structure is unacceptable and the superconvergence is lost at the boundaries as can be seen from Table 1. We have

$$\mathcal{D} =$$

$$\begin{bmatrix}
-12.21 & 7.44 & 10.48 & -6.44 & .74 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
-10.99 & -11.15 & 44.98 & -24.53 & 1.70 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
-2.50 & -1.01 & -3.50 & 8 & -1 & 0 & 0 & 0 & 0 & .01 & -.01 & 0 \\
.46 & .07 & -7.54 & 0 & 8 & -1 & 0 & 0 & 0 & .01 & -.02 & .01 \\
0 & 0 & 1 & -8 & 0 & 8 & -1 & 0 & -.03 & .02 & -.04 & .02 \\
0 & 0 & 0 & 1 & -8 & 0 & 8 & -1 & -.01 & .05 & -.09 & .04 \\
0 & 0 & 0 & 0 & 1 & -8 & 0 & 8 & -1.01 & .11 & -.19 & .09 \\
0 & 0 & 0 & 0 & 0 & 1 & -8 & 0 & 7.97 & -.75 & -.41 & .19 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & -8 & -.06 & 8.53 & -1.89 & .04 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & -8.13 & 1.14 & 6.09 & -.11 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & .73 & -5.53 & -3.12 & 7.93 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -.24 & 2.74 & -16.75 & 14.26
\end{bmatrix}.$$

TABLE 1

Differentiation accuracy for Daubechies wavelets defined on an interval using grid points halfway between the integers.

Differentiation matrix	Grid size	Boundary l_1 error	Error ratio	Inner l_1 error	Error ratio	Total l_1 error	Error ratio
$(C_1^{2pt})^{-1}DC_1^{2pt}$	16	.0066		$2.86e^{-4}$		.0024	
Grid $\vec{x}$	32	.0032	2.06	$3.20e^{-6}$	89	$5.73e^{-4}$	4.19
	64	.0016	2.00	$2.10e^{-9}$	1524	$1.41e^{-4}$	4.06
	128	$7.85e^{-4}$	2.04	$2.80e^{-11}$	75	$3.50e^{-5}$	4.03
	256	$3.81e^{-4}$	2.06	$1.75e^{-12}$	16.0	$8.53e^{-6}$	4.10
	512	$1.69e^{-4}$	2.25	$1.07e^{-13}$	16.4	$1.94e^{-6}$	4.40

7.1.3. Conclusion for grid $\vec{x}$. Recall that in the construction of the differentiation matrix that the middle matrix D is fixed. Table 1 contains the accuracy for two well-conditioned quadrature matrices C_1^{2pt} and C_2^{2pt}. In addition, as an experiment I have combined two ill-conditioned matrices: one mapping from $\vec{f}$ to $\vec{s}$ and the other mapping from $\vec{s}$ to $\vec{f}$.

First the noteworthy points are that in all three cases the accuracy at the boundary is first order. Recall that when periodic boundary conditions are imposed that the differentiation accuracy is fourth order for the D_4 wavelet. This loss of superconvergence is a serious problem. Furthermore, note from the table that the two well-conditioned quadrature matrices maintain the superconvergence away from the boundary. But in all three cases the total error of the differentiation matrix across the entire domain is one higher than the boundary accuracy; i.e., we get second-order differentiation accuracy.

Note: Inner accuracy is calculated at the middle 50% of the grid points, and boundary accuracy is calculated at the two outermost grid points at each end of the interval.

7.2. Accuracy using grid $\vec{y}$. We now study the differentiation accuracy where we have included a boundary point at each end of the interval in the grid and the remainder of the grid points are required to be evenly spaced across the interval. This choice of grid is a much more likely choice than grid $\vec{x}$. However, superconvergence again is lost at the boundary. This reduces the total accuracy of the differentiation to second order as with grid $\vec{x}$. Again, let us note a few explicit examples of differentiation matrices.

7.2.1. Differentiation matrix $(C_1^{2pt})^{-1}DC_1^{2pt}$, grid $\vec{y}$. Again note the unusual, and undesirable, form of the following matrix. As can be seen from Table 2, again, the superconvergence is lost at the boundary. We have

$$\mathcal{D} =$$

$$\begin{bmatrix}
-1.99 & 3.33 & -1.60 & .26 & -2e^{-4} & -1e^{-4} & -6e^{-5} & -4e^{-5} & 1e^{-4} & -2e^{-4} & 6e^{-5} & 2e^{-5} \\
-.46 & -.14 & .72 & -.13 & -1e^{-3} & -6e^{-4} & -3e^{-4} & -2e^{-4} & 7e^{-4} & -1e^{-3} & 3e^{-4} & 1e^{-4} \\
.08 & -.63 & -.02 & .70 & -.12 & -2e^{-3} & -1e^{-3} & -7e^{-4} & 2e^{-3} & -4e^{-3} & 1e^{-3} & 3e^{-4} \\
0 & .07 & -.63 & -.02 & .69 & -.12 & -3e^{-3} & -2e^{-3} & 7e^{-3} & -.01 & 3e^{-3} & 1e^{-3} \\
0 & 0 & .08 & -.63 & -.02 & .69 & -.11 & -5e^{-3} & .02 & -.03 & 9e^{-3} & 3e^{-3} \\
0 & 0 & 0 & .08 & -.63 & -.02 & .69 & -.12 & .05 & -.08 & .02 & 7e^{-3} \\
0 & 0 & 0 & 0 & .08 & -.63 & -.02 & .68 & 5e^{-3} & -.18 & .05 & .02 \\
0 & 0 & 0 & 0 & 0 & .08 & -.63 & -.04 & .94 & -.50 & .12 & .03 \\
0 & 0 & 0 & 0 & 0 & 0 & .08 & -.69 & .52 & -.12 & .15 & .07 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & -.03 & .43 & -1.54 & 1.00 & .14 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & -.20 & 2.12 & -4.25 & 2.05 & .29 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & .44 & -4.62 & 7.00 & -2.83 & 8e^{-3}
\end{bmatrix}.$$

It has been mentioned many times that the structure is undesirable. This is due to the lack of directional independence of the matrix. One "fix" for this problem is given in the next subsection.

7.2.2. The no-preferred-direction (NPD) differentiation matrix $(C_1^{2pt})^{-1}DC_1^{2pt}$, grid $\vec{y}$. It is possible to fix one of the problems with the above matrices: the problem of directional dependence. That is, a general differentiation matrix should never treat data coming from the right differently than data coming from the left. This problem can be "fixed" if one simply turns the basis around and builds another differentiation matrix. That is, turn all the inner scaling functions around and interchange the role of the RHS and LHS boundary functions. The new differentiation matrix $\tilde{\mathcal{D}}$ can be found from the unreversed differentiation matrix $\mathcal{D}$ by first flipping the matrix by a middle horizontal axis and then by a middle vertical axis and then negating. That is,

$$\tilde{\mathcal{D}} = -flipud(fliplr(\mathcal{D})), \tag{55}$$

and we build a new NPD differentiation matrix by averaging these two matrices:

$$\mathcal{D}_{NPD} = \frac{1}{2}(\mathcal{D} + \tilde{\mathcal{D}}). \tag{56}$$

TABLE 2

Differentiation accuracy for Daubechies wavelets defined on an interval using grid points at the boundaries and all other grid points evenly spaced across the interval.

Differentiation matrix	Grid size	Boundary l_1 error	Error ratio	Inner l_1 error	Error ratio	Total l_1 error	Error ratio
$(C_1^{2pt})^{-1}DC_1^{2pt}$	16	.0181		$8.70e^{-4}$		.00598	
grid $\vec{y}$	32	.00933	1.94	$2.31e^{-4}$	3.77	.00162	3.69

-1e^{-4} & -4e^{-4} & 1e^{-3} & -8e^{-4} & 2e^{-4} & 3e^{-4} & 7e^{-4} & 2.67 & -29.29 & 51.58 & -36.96 & 12.00
\end{bmatrix}.$$

Table 2 gives the accuracy results for two differentiation matrices constructed from the well-conditioned quadrature matrix C_1^{2pt}.

Again, Table 2 shows the loss of superconvergence at the boundaries regardless of the differentiation matrix. Also, note that for grid $\vec{y}$ the superconvergence is not even achieved away from the boundary as it is for grid $\vec{x}$. Inner error and boundary error are defined in the same manner as for the previous table.

In conclusion, in this section I have presented a number of differentiation matrices along with the orders of accuracy of the differentiation. In all cases the superconvergence that is encountered under periodic boundary conditions is lost.

8. Other constructions and conclusion. In this paper I have explored the differentiation matrix for Daubechies-type wavelets defined on an interval using the boundary construction defined in [3]. The exploration has been limited to the wavelet with two vanishing moments usually referred to as the D_4 wavelet. It was seen that the superconvergence encountered with periodic boundary conditions which was proven in [6] is lost with this boundary construction.

There are other boundary constructions available for Daubechies wavelets, see [1], [8], but none of the constructions can maintain the superconvergence. There is a very straightforward way to find the maximum accuracy at the boundary for a given boundary construction. That is, when the basis functions are orthogonal under translation, as they are for Daubechies wavelets, one can simply count the number of basis functions which have support overlapping the support of the outermost boundary functions. This defines the number of nonzero entries in the first and last rows of the middle matrix D referred to here as the derivative projection matrix. All differencing in wavelet differentiation is done by D, and, therefore, the differentiation accuracy at the boundaries cannot exceed one less than the number of nonzero entries in the first and last rows of D. Of course, this argument holds for every row of D, but I am particularly concerned with the boundaries here.

Perhaps it is not possible to construct boundary functions for wavelets which give everything. That is, boundary functions which maintain the wavelet structure, which maintain the approximation properties across the entire interval, and which maintain superconvergence. This conjecture is based first on the fact that to date there is no boundary construction which satisfies these criteria for either Daubechies wavelets or spline-based wavelets; see [7]. In further support of this conjecture, in a paper by Gottlieb et al. [5], it is proven that it is not possible to construct boundary functions for a finite element subspace which maintain the superconvergence encountered with periodic boundary conditions if there are characteristics leaving the domain. Note that the finite element subspace is the same as the first-order spline wavelet subspace; see [7].

In conclusion, under the currently available boundary constructions the superconvergence, which is encountered under periodic boundary conditions, is not maintained at the boundaries. In the case of the D_4 wavelet under the boundary construction examined here one gets fourth-order differentiation away from the boundaries and only first-order differentiation at the boundaries producing a scheme with only second-order accurate spatial differentiation. It remains to be seen if it is possible to construct boundary functions for a wavelet subspace which can maintain superconvergence at the boundaries.

A DATA SMOOTHING TECHNIQUE FOR PIECEWISE CONVEX/CONCAVE CURVES*

W. LI†, D. NAIK†, AND J. SWETITS†

Abstract. A data smoothing technique for piecewise convex/concave curves is developed and its computational aspects are discussed. Some of its statistical properties are determined and the difficulty in computing the general expression for bias and the mean squared error are illustrated through an example. A variety of examples are considered to demonstrate the potential of the proposed smoothing technique, and the behavior of the piecewise convex/concave smoother is shown by Monte-Carlo simulations. We also give a detailed comparison between the proposed smoothing technique and spline smoothing.

Key words. nonparametric regression, divided difference, monotone regression, convex regression, quadratic program, piecewise convex/concave curve, spline smoothing, Monte-Carlo simulation, mean squared error, bias

1. Introduction.

Given a set of sample data $\{(x_i, y_i) : 1 \leq i \leq n\}$, where $y_i = f(x_i)+\eta_i$ with some piecewise monotone or convex/concave function $f(x)$ on a closed interval $[a, b]$ and η_i is the random noise induced by the sampling process, we want to estimate the original function $f(x)$. Classical examples of regression by piecewise monotone or convex/concave functions are monotone regression and convex regression, which are two important cases in regression under order restriction. In certain applications, the number of extreme points or inflection points of the underlying function is very important for any useful estimator of $f(x)$. For example, in the processing of a digitized image of a profile curve of a mechanical part, one can have an a priori estimate of how many inflection points the curve has. As a consequence, one expects to have a curve with the same number of inflection points as an approximation of the profile curve. Levels of certain hormones in a woman are to go up and down during a one month period. Therefore, it is a practical need to model the hormone level by a function that has one inflection point in a month. For the problem of estimating the hazard rate of change, one wants to find the location of the extrema of the derivative $f'(x)$ (or the maximum jump of $f'(x)$). Müller and Wang [30], [31] proposed the following nonparametric approach for solving the change-point problem: (1) find a nonparametric estimator $\hat{f}(x)$ of $f(x)$ from the given sample; (2) use the change-point of $\hat{f}(x)$ as an estimator of the change-point for $f(x)$. They used this model to analyze life expectancy of 65 patients with acute lymphocytic leukemia after bone marrow transplantation. Note that if one knows that $f'(x)$ has one extreme point, then it is wise to use an $\hat{f}(x)$ that has only one inflection point as an estimator of $f(x)$. In fact, a recent study by Cuevas and Gonzalez-Manteiga [4] revealed that the weak convergence of a sequence of density functions $\{f_n(x)\}$ is equivalent to the strong convergence of $\{f_n(x)\}$ if all density functions have the same number of inflection points. Moreover, under certain conditions, the inflection points of $f_n(x)$ converge to the inflection points of $f(x)$. Roughly speaking, forcing constraint on the number of inflection points yields more reliable estimators. As pointed out by Cuevas and Gonzalez-Manteiga [4], an interesting consequence is that the bumps and the dips (i.e., the intervals of concavity and convexity) of $f(x)$ can be estimated consistently from those of $f_j(t)$; therefore, an inflection-point-preserving regression method is well suited for the so-called bump-hunting problem [16], [39], [32]. There are both practical and theoretical reasons for finding an estimator of $f(x)$ that resembles $f(x)$ geometrically. In this paper, we propose an efficient algorithm for fitting $f(x)$ by an estimator $\hat{f}(x)$ that has an a priori given number of inflection points.

†Department of Mathematics and Statistics, Old Dominion University, Norfolk, VA 23529.

The geometric shape parameters for a piecewise monotone or convex/concave function $f(x)$ are given by

$$I(g) := \inf \{m : \text{there exists a partition of } [a,b] \text{ into } m \text{ intervals } T_1, \dots, T_m \text{ such that } g(x) \text{ is convex or concave on every } T_i \text{ for } i = 1, \dots, m\}$$

and

$$M(g) := \inf \{m : \text{there exists a partition of } [a,b] \text{ into } m \text{ intervals } T_1, \dots, T_m \text{ such that } g(x) \text{ is monotone on every } T_i \text{ for } i = 1, \dots, m\}.$$

The integer $I(g)$ behaves like the number of inflection points of $g(x)$, and $M(g)$ like the number of relative extrema of $g(x)$. Let $\mathcal{I}_m := \{g(x) : g(x) \in \mathcal{W} \text{ and } I(g) = m\}$ and $\mathcal{M}_m := \{g(x) : g(x) \in \mathcal{W} \text{ and } M(g) = m\}$, where $\mathcal{W}$ is a given set of functions. Then, consider least squares fitting with constraints on $I(g)$ or $M(g)$:

$$\min_{g \in \mathcal{M}_m} \sum_{i=1}^{n} (g(x_i) - y_i)^2 \tag{1}$$

or

$$\min_{g \in \mathcal{I}_m} \sum_{i=1}^{n} (g(x_i) - y_i)^2, \tag{2}$$

where m is a given positive integer which controls the fitting scheme and $\mathcal{W}$ represents either a parametric or a nonparametric model. Let

$$S_n := \{g(x) : g(x) \text{ is a linear spline with knots } x_1 < x_2 < \cdots < x_n\},$$

i.e., $g(x) \in S_n$ if and only if $g(x)$ is a continuous function on $[x_1, x_n]$ and is a linear polynomial on each subinterval $[x_{i-1}, x_i]$. For $\mathcal{W} = S_n$, (1) and (2) are the piecewise monotone and convex/concave data smoothing methods, respectively, proposed by Demetriou and Powell [9], [7]. Here we consider $S_n \equiv \mathbf{R}^n$, the n-dimensional vector space, since every $g(x)$ in S_n is uniquely determined by its values at $x_1, \dots, x_n$. In particular, for $\mathcal{W} = S_n$ and $m = 1$, (1) is the classical monotone regression problem and is considered an important case of statistical inference under ordered restrictions. The monotone regression problem has been thoroughly investigated and documented [1], [35]. For $\mathcal{W} = S_n$ and $m = 1$, (2) is the classical convex/concave regression problem which was first introduced by Hildreth [21] for the estimation of production functions. Twenty two years after that, Hanson and Pledger [17] established the consistency of concave regression estimators while Demetriou and Powell [10] provided an algorithm suited specifically to this problem. Some more applications of convex/concave regression can be found in [28], [27], and [8]. Even though the convex/concave regression problem is a standard strictly convex quadratic programming problem, the ill-conditioned nature of the second divided difference matrix could cause some difficulty for efficient computation of the solution [25], [10], [5], [28], [24]. Moreover, even if $\mathcal{W} = S_n$, neither $\mathcal{M}_m$ nor $\mathcal{I}_m$ with $m \geq 2$ is a polyhedral set. In fact, they are not convex sets. Hence it becomes extremely difficult to find a numerical solution to (1) or (2). In a recent paper, Demetriou and Powell [9] developed a dynamic programming procedure with complexity $\mathcal{O}(n^2 + mn \ln n)$ for solving (1) with $\mathcal{W} = S_n$. However, for $m > 2$, (2) presents a challenging computational problem (cf. [22], [6] and Chap. 6 of [7]).

While (1) or (2) provides a practical means to compute a regression estimator with certain geometric shape from the sample data $\{(x_i, y_i)\}$, it is important to ensure the consistency of piecewise monotone (or convex/concave) regression estimators. Motivated by Holm and Frisén's work, Mammen [26] considered the following regression problem:

$$(3) \qquad \min_{g \in \mathcal{H}_{k,m,D}} \sum_{i=1}^{n} (g(x_i) - y_i)^2,$$

where, for $k \geq 1$,

$$\mathcal{H}_{k,m,D} := \left\{ g(x) : I\left(g^{(k-1)}\right) \leq m \text{ and there exists a scalar } \gamma \right.$$
$$\left. \text{such that } \sup_{x_1 \neq x_2} \left| \frac{g^{(k-1)}(x_1) - g^{(k-1)}(x_2)}{x_1 - x_2} - \gamma \right| \leq D \right\}$$

and

$$\mathcal{H}_{0,m,D} := \left\{ g(x) : M(g) \leq m \text{ and } \sup_x g(x) - \inf_x g(x) \leq D \right\}.$$

Mammen [26] proved that, for every function $g(x) \in \mathcal{H}_{k,m,D}$, there exists a spline function $\hat{g}(x)$ of order k such that $g(x_i) = \hat{g}(x_i)$ for $1 \leq i \leq n$ and $\hat{g}^k(x)$ is a piecewise constant function. Mammen [26] also established an asymptotic stochastic bound for the distance between the regression function $f(x)$ and the $\mathcal{H}_{k,m,D}$ least squares estimator. However, computationally, (3) seems to be more difficult than (2). In fact, Mammen [26] suggested considering $g(x)$ as a function defined on the design points $\{x_1, \ldots, x_n\}$ and replace the $(k-1)$th derivative by divided difference of order $(k-1)$. With such a discretization for $k = 1$ and $m = 2$, Mammen [26] uses a successive projection method introduced by Dykstra [13] (cf. also [11] and [12]) ($(n-2)$ times!) to find the corresponding regression estimator and compares it with a kernel estimator by simulations for two regression functions on [0,1].

Our research interest on piecewise convex/concave regression was motivated by the k-convex regression problem [5], [24]:

$$(4) \qquad \min \sum_{i=1}^{n} (\theta_i - y_i)^2$$

subject to the following constraints on the kth divided difference of $\{\theta_i\}_1^n$:

$$(5) \qquad \Delta_k \theta \geq 0,$$

where Δ_k is the kth divided difference matrix defined as follows:

$$(\Delta_k \theta)_j = \sum_{i=j}^{k+j} \left(\theta_i \prod_{\substack{s=j \\ s \neq i}}^{k+j} (x_i - x_s)^{-1} \right), \quad j = 1, \ldots, n-k.$$

However, due to the stringent constraints (5), the mean least squared error $\frac{1}{n} \sum_{i=1}^{n} (\theta_i - f(x_i))^2$ is usually too large in comparison with the noise level. Therefore, we want to relax the constraints and find a method which can produce a curve with a given number of convex/concave pieces. For convenience, we will identify a vector $\theta := (\theta_1, \ldots, \theta_n)$ with its unique spline interpolator $\theta(x)$ in S_n so that $I(\theta)$ and $M(\theta)$ can be defined for vectors $(\theta_1, \ldots, \theta_n)$. With such a convention, we propose the following nonparametric data smoothing method:

$$\min_{-\epsilon \le \Delta_k \theta \le \epsilon, I(\theta)=m} \sum_{i=1}^{n} (\theta_i - y_i)^2, \tag{6}$$

where ϵ is a nonnegative scalar. One could consider (6) as a discretized version of least squares fitting by functions whose kth derivative is bounded by ϵ:

$$\min_{\theta \in \mathcal{B}_\epsilon, I(\theta)=m} \sum_{i=1}^{n} (\theta(x_i) - y_i)^2, \tag{7}$$

where $\mathcal{B}_\epsilon := \{g(x) : |g^{(k)}(x)| \le \epsilon\}$. Note that (7) is actually (2) with $\mathcal{W} \equiv \mathcal{B}_\epsilon$. When $k = 1$, $\{g(x) : |g^{(k)}(x)| \le \epsilon, I(g) = m\}$ is more or less the same set as $\mathcal{H}_{1,m,\epsilon}$. In a sense, (6) is a variation of (3). However, as we mentioned before, (6) is a computationally difficult problem even without the constraints on the kth divided difference of θ. Therefore, we replace (6) by the following least squares problem:

$$\min_{-\epsilon \le \Delta_k \theta \le \epsilon} \sum_{i=1}^{n} (\theta_i - y_i)^2, \tag{8}$$

where ϵ controls the smoothing process. However, we still want to produce an estimator with m convex/concave pieces by an appropriate choice of ϵ. Note that (8) is actually a regression by polynomials of degree at most $(k-1)$ when $\epsilon = 0$. In general, the estimator is smoother if ϵ is smaller. On the other hand, the least squared error will be reduced if ϵ is increased and is zero if ϵ is large enough. Therefore, in order to make a good fit to the sample data, we want to make ϵ as large as possible; meanwhile, we want to control the magnitude of ϵ to produce a smooth estimator. Hence, it seems a good idea to choose the largest ϵ such that $I(\hat{\theta}(\epsilon)) = m$ for the solution $\hat{\theta}(\epsilon)$ to (8). Such a strategy for the selection of ϵ reflects the following concern about the selection of a smoothing parameter. Theoretically, under certain assumptions, one can establish some kinds of asymptotic results to justify a particular strategy for selection of the smoothing parameter (or the bandwidth) for a nonparametric regression method. However, for practical applications, the choice of the smoothing parameter is mainly a delicate balance between the fidelity to the sample data and the visual smoothness of the fitting curve. Based on the consistency results established by Cuevas and Gonzalez-Manteiga and by Mammen, it is a statistically sound decision to choose the largest ϵ such that $I(\hat{\theta}(\epsilon)) = m$. Our strategy for selection of the smoothing parameter is very similar to Silverman's bandwidth selection for a kernel smoothing method [37], [38]. See §2 for more details.

For a given ϵ, one can find $\hat{\theta}(\epsilon)$ by any algorithm designed for strictly convex quadratic programming problems. However, the difficulty is how to find the largest ϵ such that $I(\hat{\theta}(\epsilon)) = m$. In §2, a continuation approach is used to implement the strategy for the selection of ϵ based on control of $I(\theta)$. Further discussions of (8) as a nonparametric smoothing method are also given in §2.

Section 3 is devoted to the related statistical properties of the piecewise convex/concave smoother.

Most nonparametric smoothing techniques studied in the literature are linear for any fixed smoothing parameter (cf. [19]), whereas the proposed smoother is nonlinear with respect to the raw data. However, some similarity with spline smoothing is discussed in §4. Some discrepancy in using the classical "leave-one-out" cross-validation scheme to determine the smoothing parameter for spline smoothing is pointed out. It is noted that for a spline version of the proposed smoother the classical cross-validation technique can be correctly adopted. The detailed analysis of this observation will be done later and reported elsewhere.

In §5 we consider eleven simulation models studied by previous authors and apply our smoothing procedure on them. These models are included to study the effect of the variance of noise, the location of x_i's, the sample size, the shape of the underlying smooth curves, and outliers on the smoother. Several performance parameters, which are important and essential in any simulation analysis of a model, are included in the study. Also, we repeat the numerical simulations done by Mammen [26] to show that (8) with the proposed strategy for the selection of ϵ is very similar to (3) with $k = 1$.

Some final conclusions and future research problems are presented in §6.

2. A piecewise convex/concave smoother. We first give a detailed description of the proposed data smoothing algorithm controlled by $I(\theta)$. Then a continuation approach is given to implement the computation of the piecewise convex/concave smoother.

In the introduction, for convenience, we identified a vector θ with its linear spline interpolator so that $I(\theta)$ and $M(\theta)$ can also be defined for vectors. However, for piecewise linear functions, $I(\theta)$ and $M(\theta)$ can be computed easily. Given a vector $z \in \mathbf{R}^n$, we say that z has m sign changes, if there exist indices $0 =: i_0 < i_1 < \cdots < i_m < i_{m+1} := n$ such that the following hold:

1. for any given s, z_j's are not all zeros for $i_s < j \leq i_{s+1}$;
2. $z_i \cdot z_j \leq 0$ for $i_{s-1} < i \leq i_s, i_s < j \leq i_{s+1}$, and $1 \leq s \leq m$.

Then one can verify that $I(\theta) = m$ if and only if $\Delta_2\theta$ has $(m - 1)$ sign changes and $M(\theta) = m$ if and only if $\Delta_1\theta$ has $(m - 1)$ sign changes. Therefore, for a given vector θ, it is very easy to compute $I(\theta)$ and $M(\theta)$, and our regression scheme based on control of $I(\theta)$ can be stated as follows.

A piecewise convex/concave smoothing scheme. Let $\hat{\theta}(\epsilon)$ denote the solution to the following least squares problem:

$$\min_{-\epsilon \leq \Delta_3\hat{\theta} \leq \epsilon} \sum_{i=1}^{n} (\theta_i - y_i)^2. \tag{9}$$

Given a positive integer m and a positive integer r,

1. set $\delta := \frac{x_n - x_1}{n}$, $j := 0$, and $\epsilon_0 := 0$;
2. compute $\hat{\theta}(\epsilon_0)$ and s_0, the number of sign changes of $\Delta_2\hat{\theta}(\epsilon_0)$;
3. reset $j := j + 1$;
4. set $\epsilon_j := \epsilon_{j-1} + \delta$, if $\epsilon < r\delta$; or $\epsilon_j := \epsilon_{j-1}\left(1 + \frac{1}{r}\right)$, if $\epsilon \geq r\delta$;
5. compute $\hat{\theta}(\epsilon_j)$ and s_j, the number of sign changes of $\Delta_2\hat{\theta}(\epsilon_j)$;
6. if $s_j \geq m$, then output the smoother $\bar{\theta} := \hat{\theta}(\epsilon_{j-1})$ and stop; otherwise, go back to step 3.

Remarks. 1. Note that the scalar δ is the average length of the subintervals $[x_i, x_{i+1}]$. Let $\theta_i = g(x_i)$ for $1 \leq i \leq n$. Then $(\Delta_3\theta)_i = \frac{g^{(3)}(\xi_i)}{6}$ for some ξ_i between x_i and x_{i+3}. The uncertainty of ξ_i produces a possible error of magnitude δ. Therefore, $\hat{\theta}(\epsilon)$ and $\hat{\theta}(\epsilon')$ are regarded as "indistinguishable", if $\|\epsilon - \epsilon'\| \leq \delta$. However, if we only use $\epsilon_j := \epsilon_{j-1} + \delta$ to increase the bound on the third divided difference, then it might take thousands of iterations in the above regression scheme to find the right value of ϵ. This is not practical. Therefore, we allow a relative error tolerance in ϵ of $\frac{100}{r}\%$; i.e., if $\frac{\|\epsilon-\epsilon'\|}{\|\epsilon\|} < \frac{100}{r}\%$, then $\hat{\theta}(\epsilon)$ and $\hat{\theta}(\epsilon')$ are considered as "indistinguishable." With $\epsilon_j := \epsilon_{j-1}\left(1 + \frac{1}{r}\right)$, ϵ_j grows exponentially as j increases. This enables the scheme to handle problems with a large optimal smoothing parameter $\hat{\epsilon}$ defined by

$$\hat{\epsilon} := \sup \left\{ \epsilon : \Delta_2 \hat{\theta}(\epsilon) \text{ has at most } (m-1) \text{ sign changes or } I(\hat{\theta}(\epsilon)) \leq m \right\}.$$

Notice that a larger r produces a more accurate choice of ϵ; while smaller r means less computational cost.

2. If possible, we want to compute $\hat{\theta}(\hat{\epsilon})$. If $I(\hat{\theta}(\epsilon))$ is a nondecreasing function of ϵ, then the above regression scheme does produce $\hat{\theta}(\hat{\epsilon})$ with reasonable error tolerance as explained in remark 1. To prevent the case in which we might miss a larger ϵ with $I(\hat{\theta}(\epsilon)) \leq m$, we actually computed a few more (up to 25) $\hat{\theta}(\epsilon_j)$'s after we found $\bar{\theta}$ in our preliminary numerical tests. However, all of those $I(\hat{\theta}(\epsilon_j))$'s are larger than $I(\bar{\theta})$. Therefore, we are confident about the above regression scheme even without the proof that $I(\hat{\theta}(\epsilon))$ is a nondecreasing function of ϵ.

3. Note that, if $\epsilon \geq \|\Delta_3 y\|_\infty =: \epsilon_\infty$, then $\hat{\theta}(\epsilon_\infty) \equiv y$. It seems a good idea to use bisection of the interval $[0, \epsilon_\infty]$ to find the optimal smoothing parameter $\hat{\epsilon}$, under the assumption that, in general, the number of sign changes of $\Delta_2 \hat{\theta}(\epsilon)$ is a nondecreasing function of ϵ. However, we can use the Lagrange multiplier of $\hat{\theta}(\epsilon_{j-1})$ as an initial guess of the Lagrange multiplier of $\hat{\theta}(\epsilon_j)$ to achieve a very efficient implementation of the above regression scheme. This is in essence a continuation method. In order to compute $\hat{\theta}(\epsilon_j)$, we start with the polynomial fitting $\hat{\theta}(0)$ which is extremely easy to compute, then gradually move to the solution $\hat{\theta}(\epsilon_j)$ as ϵ changes from 0 to ϵ_j.

4. When $\Delta_2 \hat{\theta}(\epsilon_j)$ has at least m sign changes and $\Delta_2 \hat{\theta}(\epsilon_{j-1})$ has at most $(m-2)$ sign changes, we know that neither $\hat{\theta}(\epsilon_{j-1})$ nor $\hat{\theta}(\epsilon_j)$ has the required structure and the smoothing process has failed. In this circumstance, under-smoothing seems to be more desirable than over-smoothing. Therefore, one might select $\hat{\theta}(\epsilon_j)$ as the smoother instead of $\hat{\theta}(\epsilon_{j-1})$.

5. In our preliminary numerical tests, we also tested (8) with different k's. For $k \geq 3$, the solutions are more or less the same, while the solutions are a little bit rougher if $k \leq 2$. Since a larger k increases the ill-conditioning of (8) [24], [5], we choose $k = 3$.

6. One might also use $M(\theta)$ to control the smoothing process. However, $I(\theta)$ provides an implicit control on $M(\theta)$, since $M(\theta) \leq I(\theta) + 1$. But one can construct θ such that $I(\theta)$ is large and $M(\theta) = 0$. Hence it is more effective to use $I(\theta)$ as a geometric shape parameter.

7. Let $K_h(x)$ be a kernel smoother of y with the standard normal density as the kernel function, and $\nu_k(g)$ denote the number of sign changes of the kth derivative of $g(x)$. Then Silverman [37] proved that $\nu_k(K_h)$ is a right continuous decreasing function of h and used the modes to control the kernel smoothing process in the same way as we use $I(\theta)$: for a given set of sample data $\{(x_i, y_i)\}$, find K_{h_n} where h_n is defined as

$$h_n := \inf \{h : K_h \text{ has at most } m \text{ modes}\}.$$

Silverman [37], [38] used h_n to test the null hypothesis that $f(x)$ has m modes against the alternative in which $f(x)$ has more than m modes. For density function estimation, Cuevas and Gonzalez-Manteiga [4] also proposed to use the minimum h such that K_h has m inflection points.

The algorithm for computing $\hat{\theta}(\epsilon_j)$ is essentially the same algorithm proposed in [24] for solving the k-convex approximation problem. In order to understand why the continuation method works here, we need a dual reformulation of (8) as an unconstrained minimization of a strictly convex quadratic spline function. First, one could verify that the Karush-Kuhn-Tucker condition of (8) is equivalent to the following system of piecewise linear equations:

$$\text{(10)} \qquad \theta = y + \Delta_k^T w, \; w = (Bw + c)_+ - (d - Bw)_+,$$

where $B := I - \alpha\Delta_k\Delta_k^T$, I is the $(n-k)\times(n-k)$ identity matrix, α is any positive scalar, $c, d \in \mathbf{R}^{n-k}$, with $c_i := \alpha(-\epsilon - (\Delta_k y)_i)$ and $d_i := \alpha((\Delta_k y)_i - \epsilon)$, w in $\mathbf{R}^{n-k}$ is the Lagrange multiplier, Δ_k^T denotes the transpose of the matrix Δ_k, and z_+ is the vector whose ith component is $\max\{z_i, 0\}$. Let $\varphi(w) := w - (Bw + c)_+ + (d - Bw)_+$. Then φ is a linear transformation of the gradient of the following quadratic spline function:

$$\Phi(w) := \frac{1}{2}w^T Bw - \frac{1}{2}\|(Bw + c)_+\|^2 - \frac{1}{2}\|(d - Bw)_+\|^2, \tag{11}$$

where $\|z\|^2 = \sum_{i=1}^{n-k}|z_i|^2$. The explicit relation is the following:

$$\Phi'(w) = B\varphi(w). \tag{12}$$

If $0 < \alpha < \|\Delta_k\Delta_k^T\|^{-1}$, where $\|\Delta_k\Delta_k^T\|$ is the spectral radius of $\Delta_k\Delta_k^T$, then B is nonsingular and Φ is a strictly convex spline function. Therefore, (8) is equivalent to the following unconstrained minimization problem:

$$\min_{w\in\mathbf{R}^{n-k}} \Phi(w). \tag{13}$$

Hence, if $\hat{w}$ is a solution of (13), then $\hat{\theta} := y + \Delta_k^T\hat{w}$ is the solution of (8). See [24] for the implementation of a Newton method for solving (13), which uses only finitely many flops (in exact arithmetic) to find the solution.

Now, if $|\epsilon_j - \epsilon_{j-1}|$ is very small, one can actually prove that the difference between the corresponding Lagrange multipliers (w's) is also small. Therefore, the Lagrange multiplier of $\hat{\theta}(\epsilon_{j-1})$ is an excellent initial guess of the Lagrange multiplier of $\hat{\theta}(\epsilon_j)$. This makes the above regression scheme computationally much easier than it appears to be.

3. Some statistical properties. It is not an uncommon practice in statistics to first reduce the noise in data using some smoothing techniques and then fit a model on smoothed data for further analysis (cf. [29]). Suppose the function $g(x)$ is a polynomial in x, of degree $(k-1)$, and it is contaminated by a very noisy error variable. Suppose we observe the data $y_i = f(x_i) + \eta_i$, $i = 1, \dots, n$. If we fit a polynomial model of degree $(k-1)$ in x for these data $y_1, \dots, y_n$, the solution is given by Py, where the matrix $P = X(X'X)^{-1}X'$, X being the matrix of polynomial terms of $x_1, \dots, x_n$; i.e.,

$$X = \begin{pmatrix} 1 & x_1 & x_1^2 & \cdots & x_1^{k-1} \\ 1 & x_2 & x_2^2 & \cdots & x_2^{k-1} \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ 1 & x_n & x_n^2 & \cdots & x_n^{k-1} \end{pmatrix}.$$

Instead of this, noting the noisy appearance of the data, suppose we first smooth the data using a piecewise convex/concave smoother and then fit the polynomial model. It can be easily shown that the result is again Py. At least in this special case we see that no useful information is lost in the smoothing process.

Two important measures for the precision of an estimator are bias and mean squared error (MSE) of the estimator. In the present case, the bias (or the squared bias) of $\hat{f}$ is measured by

$$\|E(\hat{f}) - f\|^2 = \frac{1}{n}\sum_{i=1}^{n}[E(\hat{f}(x_i)) - f(x_i)]^2 \tag{14}$$

and the MSE is measured by

$$E\|\hat{f} - f\|^2 = E\left\{\frac{1}{n}\sum_{i=1}^{n}[\hat{f}(x_i) - f(x_i)]^2\right\}. \tag{15}$$

Again assume that $f(x)$ is a polynomial of degree $(k-1)$ in x. Then it can be shown that the bias (14) is zero. In order to prove this, we reformulate (8) to get a better understanding of the relationship between y and $\hat{f}$.

From the Karush-Kuhn-Tucker conditions we know that (8) is equivalent to the following problem:

$$\min \|\Delta_k^T w\|^2 \text{ subject to } -\epsilon \le \Delta_k y + \Delta_k \Delta_k^T w \le \epsilon, \tag{16}$$

in the sense that $\hat{f} = y + \Delta_k^T \hat{w}$ if and only if $\hat{w}$ is the solution of (16). Note $\Delta_k X = 0$, which implies $\Delta_k y = \Delta_k \eta$. Therefore, (16) can be rewritten as

$$\min \|\Delta_k^T w\|^2 \text{ subject to } -\epsilon \le \Delta_k \eta + \Delta_k \Delta_k^T w \le \epsilon. \tag{17}$$

Since (17) is invariant if we replace η by $-\eta$ and w by $-w$, the solution $\hat{w}(\equiv \hat{w}(\epsilon, \eta))$ of (16) is an odd mapping of η; i.e., $\hat{w}(\epsilon, -\eta) = -\hat{w}(\epsilon, \eta)$. Therefore, if the density function of η is an even function, then $E(\hat{w}) = 0$, which implies $E(\hat{f}) = E(y + \Delta_k \hat{w}) = E(y) + \Delta_k E(\hat{w}) = E(y)$.

Now let us assume that $y = f(x) + \eta$ as before and the kth derivative $f^{(k)}(x)$ of $f(x)$ exists. Then using Taylor's expansion we can write

$$\begin{aligned} f(x) &= f(\bar{x}) + f'(\bar{x})(x-\bar{x}) + \frac{f''(\bar{x})}{2!}(x-\bar{x})^2 \\ &\quad + \cdots + \frac{f^{(k-1)}(\bar{x})}{(k-1)!}(x-\bar{x})^{k-1} + \frac{f^{(k)}(t)}{k!}(x-\bar{x})^k, \end{aligned}$$

where $\bar{x} = \frac{1}{n}\sum_{i=1}^n x_i$ and t is some point between x and $\bar{x}$. This can be rewritten as

$$f(x_i) = \beta_0 + \beta_1 x_i + \beta_2 x_i^2 + \cdots + \beta_{k-1} x_i^{k-1} + \beta_{ki} x_i^k,$$

where $\beta_{ki} = \frac{f^{(k)}(t_i)}{k!}$ and t_i is between x_i and $\bar{x}$ for $i = 1, \dots, n$.

Thus we have $y_i = f(x_i) + \eta_i$ or $y = X\beta + d + \eta$, where $\beta' = (\beta_0, \dots, \beta_{k-1})$, $d' = (d_1, \dots, d_n)$, and $d_i = \beta_{ki} x_i^k$.

If we set $u = y - d$, then we have $u = X\beta + \eta$, which is the polynomial model considered as before, and for this we know $E(u) = E(\hat{f})$. Thus, bias (14) is $\frac{1}{n}\sum_{i=1}^n \beta_{ki}^2 x_i^{2k}$ which is in terms of the kth derivative of the function $f(x)$.

Computation of bias in general is not easy. It involves the expected value of a certain truncated distribution. Even in the simplest of cases, computation of MSE would be difficult. We consider the following simple example which indicates how the bias and the variance (MSE-Bias^2) of the estimator depend on a certain truncated distribution.

Let $y_1 := c_1 + \eta_1$ and $y_2 := c_2 + \eta_2$, where c_1 and c_2 are real numbers and η_1 and η_2 are two independent $N(0, 1)$ random variables. Then (8) reduces to the following simple problem:

$$\min \frac{1}{2}(y_1 - \theta_1)^2 + \frac{1}{2}(y_2 - \theta_2)^2 \text{ subject to } -\epsilon \le \theta_2 - \theta_1 \le \epsilon. \tag{18}$$

It is easy to verify that the solution $\hat{\theta}$ should satisfy the following conditions: if $\epsilon = 0$, then $\hat{\theta}_1 = \hat{\theta}_2 = \frac{y_1+y_2}{2}$; if $|y_2 - y_1| \le \epsilon$, then $\hat{\theta}_1 = y_1$ and $\hat{\theta}_2 = y_2$; if $y_2 - y_1 > \epsilon$, then $\hat{\theta}_1 = \frac{y_1+y_2}{2} - \frac{\epsilon}{2}$ and $\hat{\theta}_2 = \frac{y_1+y_2}{2} + \frac{\epsilon}{2}$; if $y_2 - y_1 < -\epsilon$, then $\hat{\theta}_1 = \frac{y_1+y_2}{2} + \frac{\epsilon}{2}$ and $\hat{\theta}_2 = \frac{y_1+y_2}{2} - \frac{\epsilon}{2}$. If we denote the solution of (18) by $(\hat{\theta}_1(\epsilon), \hat{\theta}_2(\epsilon))$, then

$$\hat{\theta}_1(\epsilon) = \begin{cases} \frac{y_1+y_2}{2} + \frac{\epsilon}{2}, & \text{if } y_2 - y_1 < -\epsilon, \\ \frac{y_1+y_2}{2} + \frac{y_1-y_2}{2}, & \text{if } |y_2 - y_1| \le \epsilon, \\ \frac{y_1+y_2}{2} - \frac{\epsilon}{2}, & \text{if } y_2 - y_1 > \epsilon, \end{cases}$$

and

$$\hat{\theta}_2(\epsilon) = \begin{cases} \frac{y_1+y_2}{2} - \frac{\epsilon}{2}, & \text{if } y_2 - y_1 < -\epsilon, \\ \frac{y_1+y_2}{2} + \frac{y_2-y_1}{2}, & \text{if } |y_2 - y_1| \leq \epsilon, \\ \frac{y_1+y_2}{2} + \frac{\epsilon}{2}, & \text{if } y_2 - y_1 > \epsilon. \end{cases}$$

Now we want to compute the mean and the variance of $\hat{\theta}_i(\epsilon)$, $i = 1, 2$, and also the covariance between $\hat{\theta}_1(\epsilon)$ and $\hat{\theta}_2(\epsilon)$. For this, write $\hat{\theta}_1(\epsilon) = u + v$ and $\hat{\theta}_2(\epsilon) = u - v$, where $u := \frac{y_1+y_2}{2}$ and

$$v = \begin{cases} \frac{\epsilon}{2}, & \text{if } y_2 - y_1 < \epsilon, \\ \frac{y_1-y_2}{2}, & \text{if } -\epsilon \leq y_2 - y_1 \leq \epsilon, \\ -\frac{\epsilon}{2}, & \text{if } y_2 - y_1 > \epsilon. \end{cases}$$

We observe that $E(\hat{\theta}_1(\epsilon)) = E(u) + E(v)$, $E(\hat{\theta}_2(\epsilon)) = E(u) - E(v)$, $\text{var}(\hat{\theta}_1(\epsilon)) = \text{var}(\hat{\theta}_2(\epsilon)) = \text{var}(u) + \text{var}(v)$, and $\text{cov}(\hat{\theta}_1(\epsilon), \hat{\theta}_2(\epsilon)) = \text{var}(u) - \text{var}(v)$. Furthermore, $E(u) = \frac{c_1+c_2}{2}$, $\text{var}(u) = \frac{1}{2}$, and

$$\begin{aligned} E(v) &= E[vI_{\{y_2-y_1<-\epsilon\}}] + E[vI_{\{-\epsilon\leq y_2-y_1\leq\epsilon\}}] + E[vI_{\{y_2-y_1>\epsilon\}}] \\ &= \tfrac{\epsilon}{2}\Pr[y_2 - y_1 < -\epsilon] - \tfrac{1}{2}E[(y_2 - y_1)I_{\{-\epsilon\leq y_2-y_1\leq\epsilon\}}] - \tfrac{\epsilon}{2}\Pr[y_2 - y_1 > \epsilon], \end{aligned}$$

where I_A is the indicator of the event A; i.e., $I_A = 1$ if A is true and 0 otherwise. Notice that the middle term is the expected value of the truncated normal distribution with mean $c_2 - c_1$, variance two, and truncated at $-\epsilon$ and ϵ. (For a discussion of the truncated normal distribution, see [23].) Therefore, we can write

$$E(v) = \frac{\epsilon}{2}\Phi(t_1) - \frac{c_2 - c_1}{2} - \frac{\sqrt{2}}{2} \cdot \frac{\phi(t_1) - \phi(t_2)}{\Phi(t_2) - \Phi(t_1)} - \frac{\epsilon}{2}(1 - \Phi(t_2)),$$

where

$$\phi(t) := \frac{1}{\sqrt{2\pi}}e^{-t^2/2}, \quad \Phi(t) := \int_{-\infty}^{t} \phi(s)ds,$$

$$t_1 := \frac{-\epsilon - (c_2 - c_1)}{\sqrt{2}} \quad \text{and} \quad t_2 := \frac{\epsilon - (c_2 - c_1)}{\sqrt{2}}.$$

Similar calculations show that

$$\begin{aligned} \text{var}(v) = \tfrac{1}{2}&\left\{1 + \tfrac{t_1\phi(t_1)-t_2\phi(t_2)}{\Phi(t_2)-\Phi(t_1)} - \left(\tfrac{\phi(t_1)-\phi(t_2)}{\Phi(t_2)-\Phi(t_1)}\right)^2\right\} \\ &+\tfrac{\epsilon^2}{4}\Phi(t_1) + \tfrac{\epsilon^2}{4}[1 - \Phi(t_2)]. \end{aligned}$$

In the special case when $c_1 = c_2$, we see that $E(v) = 0$ and

$$\text{var}(v) = \frac{\epsilon^2}{2}\Phi(-\epsilon/\sqrt{2}) + \frac{1}{2} \cdot \left(1 - \frac{\epsilon\phi(\epsilon)}{\Phi(\epsilon) - 0.5}\right).$$

Since the first term in $\text{var}(v)$ tends to zero as $\epsilon \to 0$ as well as $\epsilon \to \infty$,

$$\lim_{\epsilon\to 0+} \frac{\epsilon\phi(\epsilon)}{\Phi(\epsilon) - 0.5} = 1, \quad \text{and} \quad \lim_{\epsilon\to\infty} \frac{\epsilon\phi(\epsilon)}{\Phi(\epsilon) - 0.5} = 0,$$

we obtain

$$\lim_{\epsilon \to 0} \operatorname{var}(v) = 0 \quad \text{and} \quad \lim_{\epsilon \to \infty} \operatorname{var}(v) = \frac{1}{2}.$$

The above calculations show that $\hat{\theta}_i(\epsilon)$'s are unbiased estimators of θ_i's only when

$$\frac{\epsilon}{2}\Phi(t_1) - \frac{\sqrt{2}}{2} \cdot \frac{\phi(t_1) - \phi(t_2)}{\Phi(t_2) - \Phi(t_1)} - \frac{\epsilon}{2}(1 - \Phi(t_2)) = 0,$$

i.e., when $c_1 = c_2$.

This simple example indicates how difficult it is, in general, to compute the bias and the variance of the estimator. Therefore, in the numerical examples that we consider later in §5, we use Monte-Carlo simulation to compute the bias and the MSE. That is, we compute $\mathbf{B}_S := \frac{1}{n}\sum_{i=1}^n |E\hat{f}(x_i) - f(x_i)|^2$ and $\mathbf{E}_S := \frac{1}{n}E\left(\sum_{i=1}^n |\hat{f}(x_i) - f(x_i)|^2\right)$, where the expected value, $E(\cdot)$, is the average over 1,000 simulations.

4. Comparison with spline smoothing. Although we treat our piecewise convex/concave smoother as a shape preserving estimator of the underlying function $f(x)$, (8) can also be viewed as a nonparametric regression method with ϵ as the smoothing parameter. Nonparametric smoothing is very useful and flexible for exploring a general relationship between two variables or a general pattern in data. Every nonparametric model is tuned by some smoothing parameter (such as ϵ in (8)) which balances the degree of fidelity to the data against the smoothness of the estimated curve (cf. [19]). Most nonparametric smoothing techniques, such as moving averaging, k-nearest neighbor estimates, kernel smoothing, orthogonal series estimates, spline smoothing, etc., are linear in the sense that the estimator is a linear mapping of the raw data for any fixed smoothing parameter (cf. [19]) except median smoothing and M-smoothing. As we mentioned before, the proposed data smoother is nonlinear with respect to the raw data. However, despite its nonlinearity, it is very similar to spline smoothing models. In this section, we try to analyze the similarity and the difference between (8) and spline smoothing.

Let $S_{n,k}$ be the space of all splines of order $(k+1)$ and with knot sequence $x_1 < \cdots < x_n$ on $[a, b]$; i.e., $g \in S_{n,k}$ if and only if $g(x)$ is a polynomial of degree at most k on each subinterval $[x_{i-1}, x_i]$ for $2 \le i \le n$, and the $(k-1)$th derivative $g^{(k-1)}(x)$ of $g(x)$ is continuous. The spline smoothing model can be formulated as follows:

$$\min_{g \in S_{n,k}} \sum_{i=1}^{n} (y_i - g(x_i))^2 + \lambda \int_a^b |g^{(k)}(x)|^2 dx, \tag{19}$$

where λ is the smoothing parameter. The solution of (19) is called the smoothing spline of Schoenberg and Reinsch by de Boor (cf. pp. 235-237 in [2]), due to the fact that Schoenberg [36] and Reinsch [33] were the first to study such a smoothing technique. However, the idea goes back to Whittaker [42], who proposed the following data smoothing scheme:

$$\min \sum_{i=1}^{n} (y_i - \theta_i)^2 + \lambda \sum_{i=1}^{n-k} (\Delta_k \theta_i)^2. \tag{20}$$

First, note that the kth divided difference in (20) is replaced by the kth derivative in (19) and that the summation in (20) is replaced by the integration in (19). Therefore, (19) can be considered as the spline version of (20).

It is well known that, for each $\lambda \geq 0$, there is a unique $\epsilon \geq 0$ such that (19) is equivalent to the following constrained optimization problem:

$$\begin{array}{l} \min \sum_{i=1}^{n}(y_i - g(x_i))^2 \\ \text{subject to } g \in S_{n,k} \text{ and } \int_a^b |g^{(k)}(x)|^2 dx \leq \epsilon. \end{array} \tag{21}$$

Note that a smaller ϵ in (21) (corresponding to a larger λ in spline) yields a smoother spline fitting of y. While ϵ provides explicit control on the magnitude of the 2-norm of $g^{(k)}(x)$, (19) is much easier to solve than (21).

Similarly, if we define $\|y\|_\infty := \max_{1 \leq i \leq n} |y_i|$, then the penalty function formulation of (8) yields the following unconstrained minimization problem:

$$\min \sum_{i=1}^{n}(y_i - \theta_i)^2 + \lambda \|\Delta_k \theta\|_\infty, \tag{22}$$

where λ is some nonnegative number. Notice the similarity between (22) and (20). In essence, (22) is (20) with the l_∞-norm replacing the l_2-norm. Hence, (8) can be viewed as the discretized version of (19) with the l_2-norm being replaced by the l_∞-norm. As a consequence of this observation, the spline version of (8) should be the following:

$$\begin{array}{l} \min \sum_{i=1}^{n}(y_i - g(x_i))^2 \\ \text{subject to } g \in S_{n,k} \text{ and } -\epsilon \leq g^{(k)}(x) \leq \epsilon \text{ for } x \neq x_i,\ 1 \leq i \leq n. \end{array} \tag{23}$$

Recall that $g(x)$ is a polynomial of degree at most k on each subinterval $[x_{i-1}, x_i]$. Thus, $g^{(k)}(x)$ is constant for $x \in [x_{i-1}, x_i]$ for a fixed i. Therefore, (23) is actually a convex quadratic programming problem with $(n-1)$ linear constraints. Similarly, (23) can be reformulated as

$$\min_{g \in S_{n,k}} \sum_{i=1}^{n}(y_i - g(x_i))^2 + \lambda \max_{a \leq x \leq b} |g^{(k)}(x)|. \tag{24}$$

Since the constraint in (21) is a differentiable mapping of g, the penalty function approach yields a simple smooth unconstrained minimization problem which is very easy to solve. However, the penalty function approach applied to (8) or (23) transforms a linearly constrained quadratic programming problem into a nonsmooth unconstrained minimization problem (22) or (24), which seems more difficult to solve than (8) or (23).

Our numerical experiments indicate that it takes about $\mathcal{O}(n^2)$ flops to solve (8) (cf. [24] and Table 1), which is comparable with the computational cost of solving (19). We believe that the computational cost of solving (23) is more or less $\mathcal{O}(n^3)$ flops, due to a full constraint matrix. One difference between (8) and (19) is that ϵ directly controls the magnitude of the kth difference of the fitting curve in (8), while λ indirectly controls the magnitude of the kth derivative of the fitting curve in (19). Practically, they both achieve the purpose of controlling the smoothness of fitting curves. For example, the shape control strategy in the previous section can be modified to determine the smoothing parameter λ in (19). However, there is some fundamental difference in statistical analysis of a constrained data fitting model and its penalty function reformulation.

Suppose we want to fit data by a model $F(\alpha)$ involving the parameter α; i.e., for a fixed α, $F(\alpha)$ is a set of fitting curves. Then the classical "leave-one-out" cross-validation scheme is a means to determine which α provides the best model for the given data.

Consider the "leave-one-out" cross-validation scheme for the determination of λ in (19) and ϵ in (21):

$$\min_{g \in S_{n,k}} \sum_{i=1, i \neq j}^{n} (y_i - g(x_i))^2 + \lambda \int_a^b |g^{(k)}(x)|^2 dx \tag{25}$$

and

$$(26)\qquad \begin{array}{l} \min \sum_{i=1, i\neq j}^{n} (y_i - g(x_i))^2 \\ \text{subject to } g \in S_{n,k} \text{ and } \int_a^b |g^{(k)}(x)|^2 dx \leq \epsilon. \end{array}$$

Notice that, for the same ϵ, the equivalent penalty function reformulation of (26) has different λ values for different missing indices j. Therefore, the "leave-one-out" scheme has different meanings depending on whether it is applied to (19) or (21). From the data smoothing point of view, it seems easier to explain the statistical meaning of applying the "leave-one-out" scheme to (21). Since the fitting curve belongs to a class of spline functions whose 2-norms are bounded by $\sqrt{\epsilon}$, the scheme is to determine the ability of this class to predict a missing value. However, when applying the "leave-one-out" scheme to (19), the 2-norms of the fitting curves produced by (25) depend on the missing index j; i.e., for different indices, the fitting curves produced by (25) have different "degrees of smoothness." If one tries to explain the "leave-one-out" scheme to spline from the classical point of view, it will be difficult to figure out which parametric family of models is involved. Therefore, there is a fundamental difference between applying the "leave-one-out" scheme to (19) and to (21). However, the generalized cross-validation derived from applying the "leave-one-out" scheme to (19) is an effective way of selecting the smoothing parameter in (19) (cf. [40] and the references therein). Also, it is very interesting to see that, for a fixed λ, the smoother defined by (19) is a linear mapping of y, while the solution of (21) is a nonlinear mapping of y for a fixed ϵ.

5. Numerical examples. In this section, we discuss the numerical performance of the proposed regression scheme. In order to understand how the smoother is affected by different aspects of the contaminated data y, such as the variance of noise, the location of x_i's, the sample size n, the shape of the underlying smooth curve, and outliers, we select the following eleven simulation models considered earlier in the literature to test the proposed regression scheme. For each simulation model, we have performed 1000 simulations.

Numerical simulation models. Assume that η_i's are independent normal random variables with mean 0 and variance 1. We use $x \sim U(0, 1)$ to denote that x is a random variable which has the uniform distribution in the interval (0,1).

1. Wahba and Wold's simulation model (cf. [40] or [41]): $n = 100, \sigma = 0.2$,

$$f(x) := 4.26(e^{-x} - 4e^{-2x} + 3e^{-3x}),$$
$$x_i = \tfrac{3.25i}{n-1} \text{ and } y_i = f(x_i) + \sigma\eta_i, \; 1 \leq i \leq n.$$

2. Cleveland's simulation model [3]: $n = 50, \sigma = 1$,

$$f(x) := x,$$
$$x_i = \tfrac{i}{n} \text{ and } y_i = f(x_i) + \sigma\eta_i, \; 1 \leq i \leq n.$$

3. Rice's simulation model [34]: $n = 75, \sigma = 0.0015$,

$$f(x) := x^3(1-x)^3,$$
$$x_i = \tfrac{i-1}{n} \text{ and } y_i = f(x_i) + \sigma\eta_i, \; 1 \leq i \leq n.$$

4. Friedman's simulation model (cf. [15] or [19]): $n = 100, \sigma = 1$,

$$f(x) := \sin\left(2\pi(1-x)^2\right),$$
$$x_i \sim U(0,1) \text{ and } y_i = f(x_i) + \sigma x_i\eta_i, \; 1 \leq i \leq n.$$

5. Härdle and Bowman's simulation model [20]: $n = 100, \sigma = 0.1$,

$$f(x) := \sin(4\pi x),$$
$$x_i = \tfrac{i-\frac{1}{2}}{n} \text{ and } y_i = f(x_i) + \sigma\eta_i, \; 1 \leq i \leq n.$$

6. Härdle's simulation model I (cf. p. 77 of [19]): $n = 200, \sigma = 1$,

$$f(x) := 1 - x + e^{-200(x-\frac{1}{2})^2},$$
$$x_i \sim U(0,1) \text{ and } y_i = f(x_i) + \sigma\eta_i, \; 1 \leq i \leq n.$$

7. Härdle's simulation model II [18]: $n = 100, \sigma = 1$,

$$f(x) := \sin(\pi x),$$
$$x_i \sim U(0,1) \text{ and } t_i \sim U(0,1),$$
$$y_i = \begin{cases} f(x_i) + \sigma\eta_i, & \text{if } t_i > 0.1 \\ f(x_i) + 9\sigma\eta_i, & \text{if } t_i \leq 0.1, \end{cases} \quad 1 \leq i \leq n.$$

8. Mammen's simulation model I-1 [26]: $n = 200$, $\sigma = 0.1$, $f(x)$ is the broken line joining the points (0,0),(0.3,−1),(0.7,1), and (1,0),

$$x_i = \frac{i}{n} \text{ and } y_i = f(x_i) + \sigma\eta_i, \; 1 \leq i \leq n.$$

9. Mammen's simulation model I-2 [26]: the same as Mammen's simulation model I-1, except $\sigma = 0.5$.
10. Mammen's simulation model II-1 [26]: $n = 200, \sigma = 0.1$,

$$f(x) = 15x(x-0.5)(1-x),$$
$$x_i = \tfrac{i}{n} \text{ and } y_i = f(x_i) + \sigma\eta_i, \; 1 \leq i \leq n.$$

11. Mammen's simulation model II-2 [26]: the same as Mammen's simulation model II-1, except $\sigma = 0.5$.

Figures 1-7 correspond to the simulation models 1-7. The contaminated data $\{(x_i, y_i)\}_1^n$ are plotted as little circles, the smoother $\{(x_i, \hat{\theta}(\epsilon_1)_i)\}_1^n$ is plotted as the solid line, and the original curve $\{(x_i, f(x_i))\}_1^n$ is plotted as the dashed line.

Wahba and Wold's simulation model 1 is for comparison between our data smoothing model and the spline smoothing model. It is interesting to note that our smoother is almost identical to the smoother produced by Wahba and Wold (cf. Fig. 1).

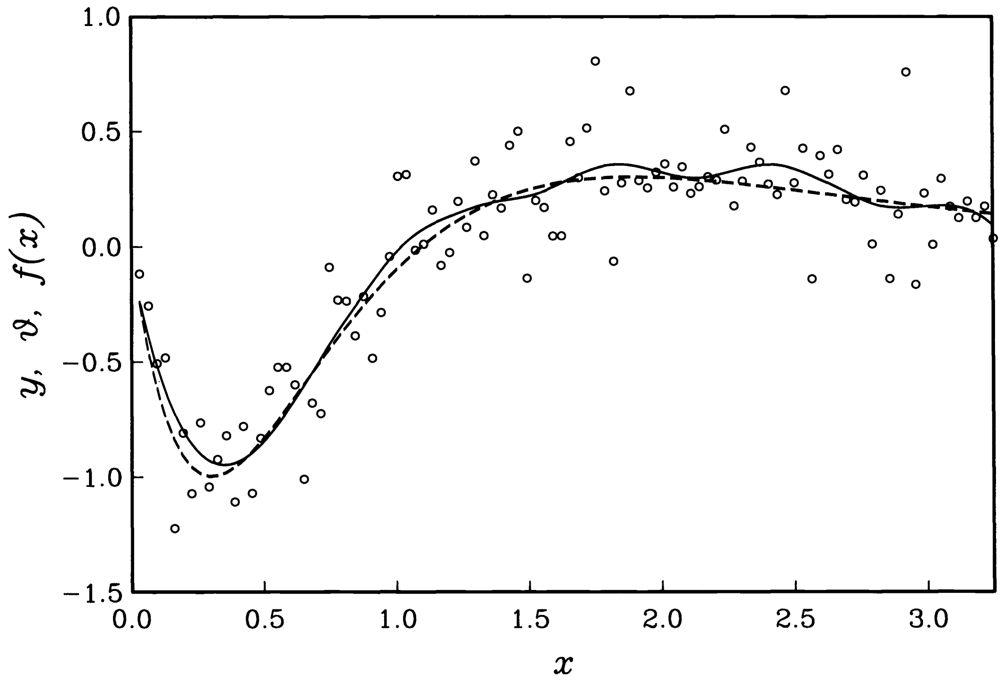

FIG. 1. *Simulation for* $f(x) = 4.26(e^{-x} - 4e^{-2x} + 3e^{-3x})$.

Simulation models 3 and 5 are for recovery of smooth regression functions without a "fairly flat" segment and we see that our procedure produces curves almost identical to the original curves (cf. Figs. 3 and 5).

Simulation models 2 and 7 are considered to study the effect of outliers or very noisy data (large variance relative to the signal) on the procedure. Simulation model 2 was used by Cleveland to illustrate locally weighted scatter plot smoothing (LOWESS) proposed by him. Our procedure identifies the underlying function fairly closely (cf. Fig. 2). Simulation model 7 was considered by Härdle to study the behavior of a kernel M-smoother on the data with outliers. Application of our procedure to this data indicates that the procedure is quite resistant to the presence of outliers. We want to point out that about 10% of the observations in this data set are extremely large in absolute magnitude as compared to the rest of the observations. However, our procedure is able to identify the true function hidden in this highly scattered cloud of data (cf. Fig. 7).

Simulation model 6 represents a somewhat extreme case where most of the signal is buried in the noise. Härdle contends that these types of data are not uncommon in practice. Even in this case our method is able to pick up the signal which is fairly close to the original curve (cf. Fig. 6).

Simulation model 4 was considered by Friedman to illustrate the behavior of a smoother introduced by him called supersmoother. Figure 4 indicates that our smoother picks up the original function well and is not sensitive to the location of x_i's.

Simulation models 8-11 are used to compare our piecewise convex/concave smoothing method with Mammen's piecewise convex/concave smoothing method. The mean squared errors, produced by our piecewise convex/concave estimator and by Mammen's piecewise convex/concave estimator, are comparable; this indicates that the proposed regression scheme is very similar to (3) with $k = 1$ and $D = \infty$.

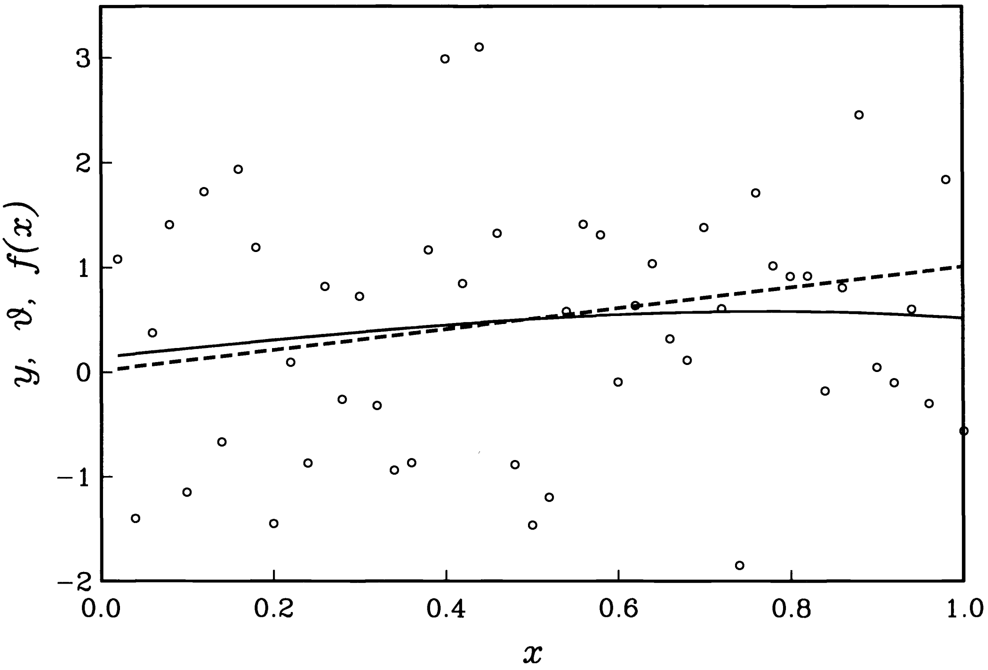

FIG. 2. *Simulation for* $f(x) = x$.

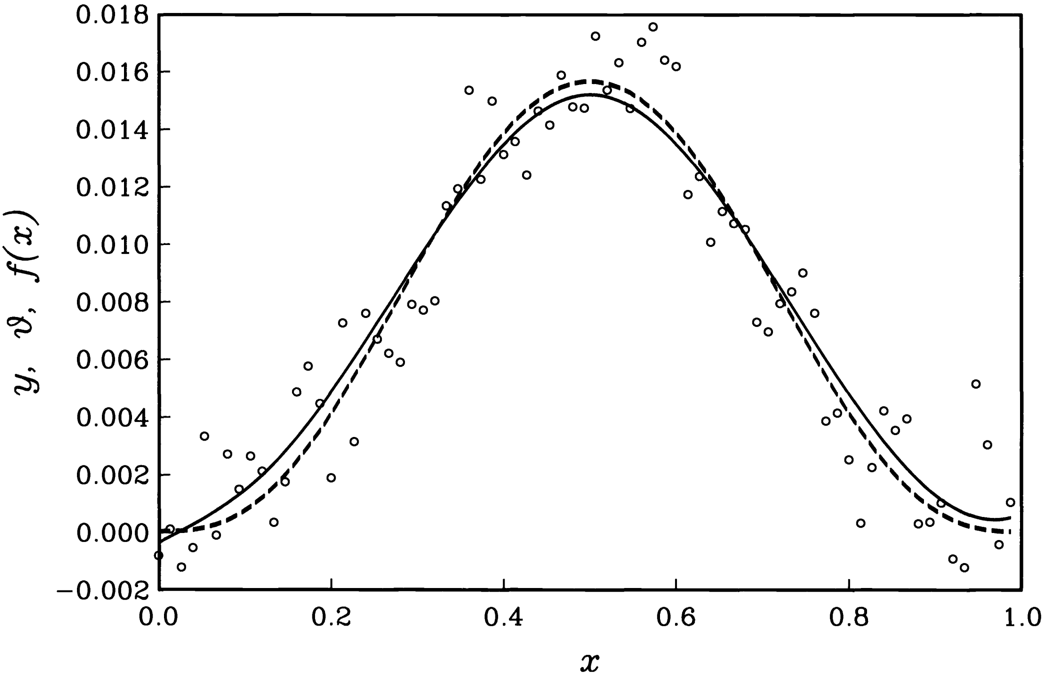

FIG. 3. *Simulation for* $f(x) = x^3(1-x)^3$.

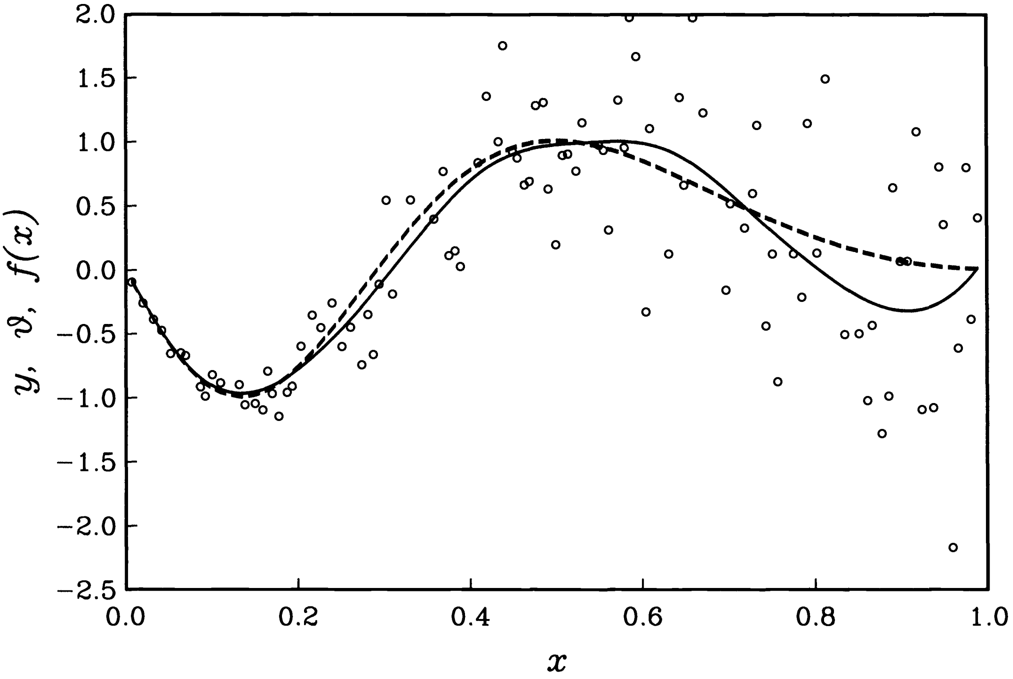

FIG. 4. *Simulation for* $f(x) = \sin(2\pi(1-x)^2)$.

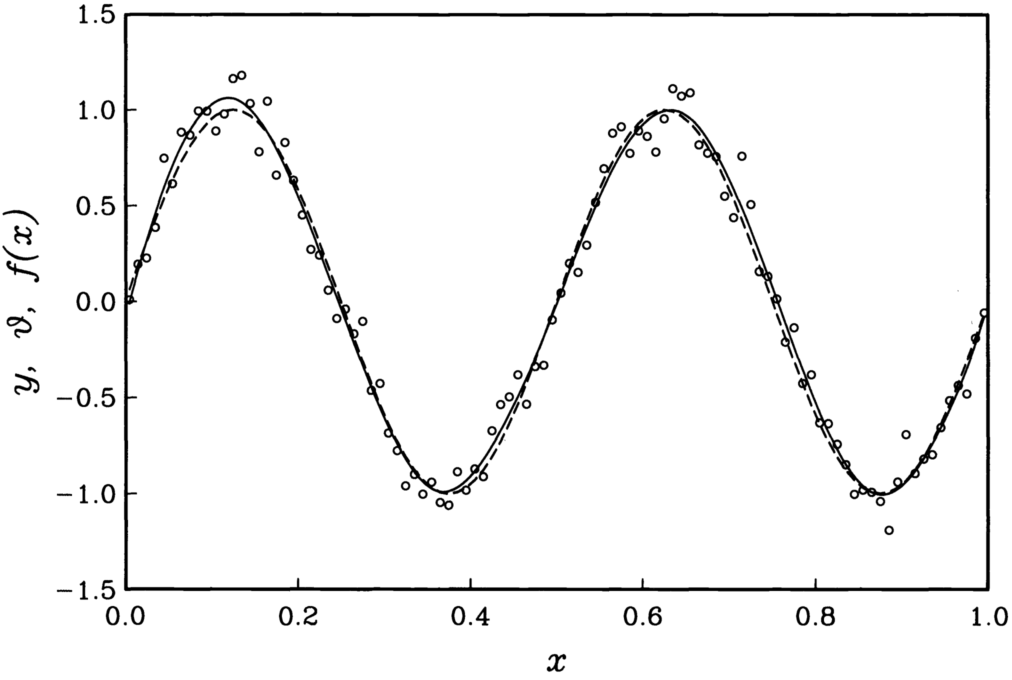

FIG. 5. *Simulation for* $f(x) = \sin(4\pi x)$.

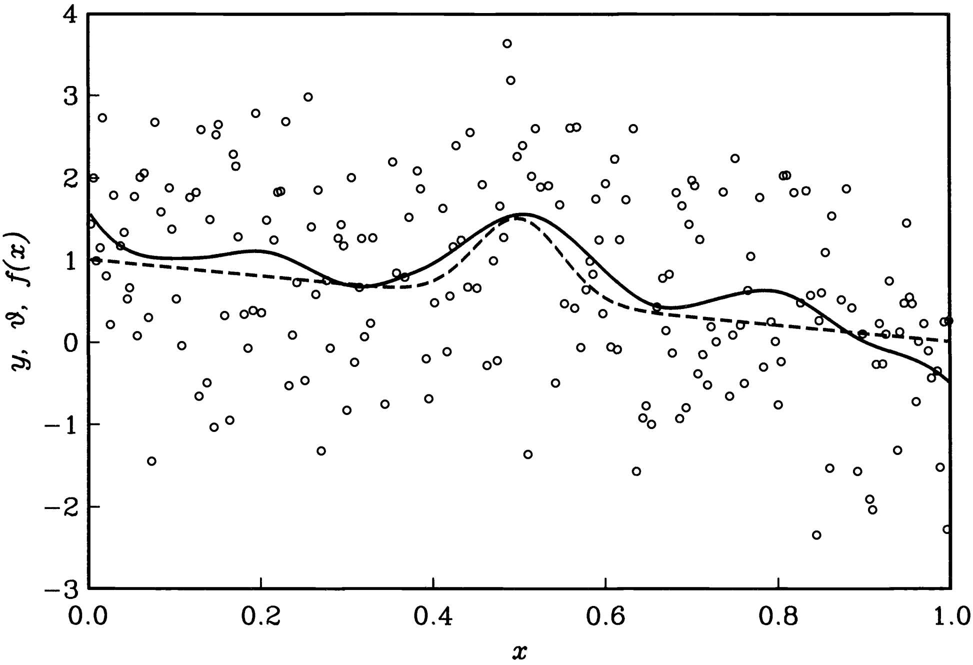

FIG. 6. *Simulation for* $f(x) = 1 - x + e^{-200(x-0.5)^2}$.

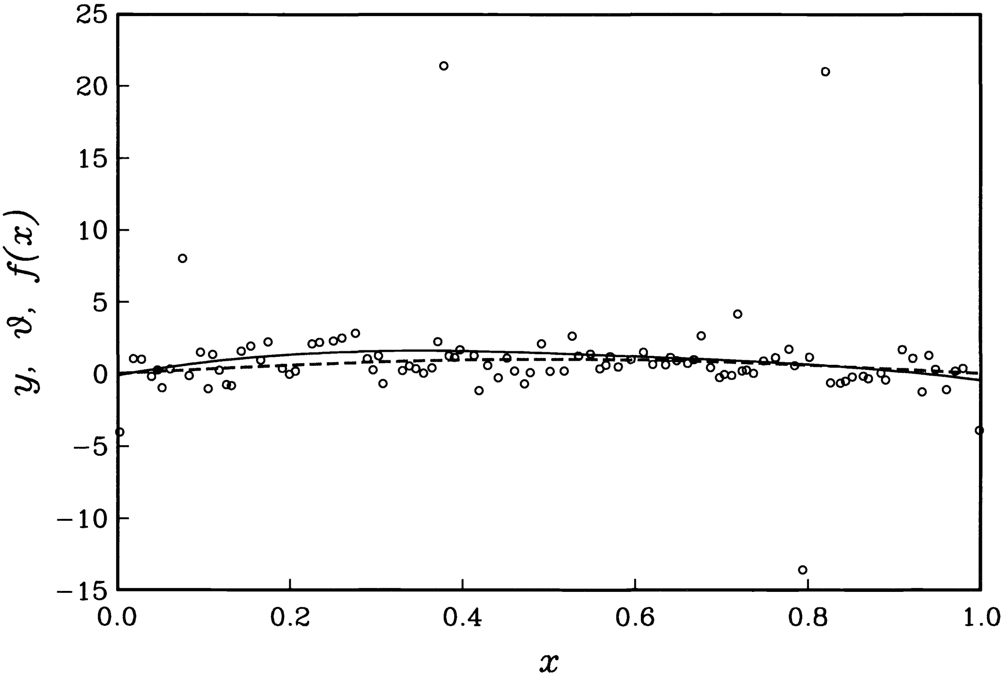

FIG. 7. *Simulation for* $f(x) = \sin(\pi x)$.

The only parameter needed for the regression scheme is the number of sign changes. When the structure of $f(x)$ is visible in $\{(x_i, y_i)\}_1^n$ (such as Rice's simulation model 3 and the Härdle-Bowman model 5), it is not difficult to find the right choice of m. However, in general, the parameter m is a means for exploring the structure of the underlying curve $f(x)$. In each of the above simulation models, we select the integer m such that the regression scheme produces $\hat{\theta}(\epsilon_{j-1})$, which is closest to $\{f(x_i)\}_1^n$. Our purpose is to show that the regression scheme does have some kind of ability to recover the original curve with an appropriate choice of the number of sign changes of the second divided difference of the fitting vector. For each model, we determine the best choice of m by experimenting on a set of simulation data and then use the same m for all 1000 simulations. The simulations indicate that, for a particular function $f(x)$, there is a corresponding optimal choice of m which will produce a curve closest to $f(x)$. The most interesting part is that, with appropriate choice of m, the corresponding smoother $\hat{\theta}(\epsilon_S)$ is more or less the same as the ideal smoother $\hat{\theta}(\epsilon_I)$, which is the solution closest to $f(x)$ among all $\theta(\epsilon)$'s. As a consequence, we can conclude that one can find the best fitting of $f(x)$ among all $\theta(\epsilon)$'s by selecting an appropriate m instead of ϵ. This is a very important property of our smoothing process, since the range of m is discrete and the range of ϵ is continuous. In a practical situation, it is easy to experiment with a few different values of m to decide which m produces the most desirable estimator.

There are several key performance parameters we want to measure when the regression scheme is applied to produce a smoother:

1. $\mathbf{E}_0 := \frac{1}{n}E\left(\sum_{i=1}^n |y_i - f(x_i)|^2\right)$, the mean squared error between f and the contaminated data y;
2. ϵ_S : the smoothing parameter determined by the regression scheme;
3. $\mathbf{E}_S := \frac{1}{n}E\left(\sum_{i=1}^n |\hat{\theta}(\epsilon_S)_i - f(x_i)|^2\right)$, the mean squared error between $f(x)$ and the smoother $\hat{\theta}(\epsilon_S)$;
4. $\mathbf{B}_S := \frac{1}{n}\sum_{i=1}^n |E\hat{\theta}(\epsilon_S)_i - f(x_i)|^2$, the squared bias of the smoother $\hat{\theta}(\epsilon_S)$;
5. $\mathbf{R}_S := (\mathbf{E}_S - \mathbf{E}_0)/\mathbf{E}_0$, the rate of noise reduction by the smoother $\hat{\theta}(\epsilon_S)$;
6. ϵ_I : the ideal smoothing parameter;
7. $\mathbf{E}_I := \frac{1}{n}E\left(\sum_{i=1}^n |\hat{\theta}(\epsilon_I)_i - f(x_i)|^2\right)$, the mean squared error between f and the ideal smoother $\hat{\theta}(\epsilon_I)$;
8. $\mathbf{B}_I := \frac{1}{n}E\sum_{i=1}^n |E\hat{\theta}(\epsilon_I)_i - f(x_i)|^2$, the squared bias of the ideal smoother $\hat{\theta}(\epsilon_I)$;
9. $\mathbf{R}_I := (\mathbf{E}_I - \mathbf{E}_0)/\mathbf{E}_0$, the rate of noise reduction by the ideal smoother $\hat{\theta}(\epsilon_I)$;
10. **N** : the number of Newton iterations involved in the algorithm (for solving (13)) which is used in step 5 of the piecewise convex/concave smoothing scheme;
11. $\mathbf{N}_0$: the average number of iterations involved in a line search for each Newton iteration;
12. **CPU**: the average CPU time (in seconds) for solving a simulation problem;

where the expected value, $E(\cdot)$, is the average over 1000 Monte-Carlo simulations, and ϵ_I is the so-called ideal smoothing parameter in the sense that

$$\sum_{i=1}^n |\hat{\theta}(\epsilon)_i - f(x_i)|^2$$

is minimum when $\epsilon = \epsilon_I$. The parameter $\mathbf{R}_I$ is a measurement of the capability of (9) as a data smoothing model, while the comparison of $\mathbf{R}_S$ and $\mathbf{R}_I$ provides a sense of intelligence of the regression scheme in determining the optimal smoothing parameter. The computational cost is about $\mathcal{O}(n\mathbf{N}_0\mathbf{N})$ flops [24], while **CPU** provides a sense of the amount of computer time for the computation of the smoother $\hat{\theta}(\epsilon_S)$. The computation is done on an IRIS Workstation and the random noise is generated by **DRNOR**$(\cdot)$, which is a subroutine in the SLATEC library and generates random numbers with the normal distribution of mean 0 and variance 1. The random design points $x_i \sim U(0, 1)$ are generated in the following way:

1. for $i = 1, \ldots, n$, generate $x_i :=$ **DRAND**(0) until $|x_i - x_j| \geq \frac{1}{2n}$ for all $1 \leq j < i$;
2. rearrange x_i's such that $x_i < x_{i+1}$ for $1 \leq i \leq n-1$.

Here **DRAND**$(\cdot)$ is the standard FORTRAN 77 function which generates uniformly distributed random numbers between 0 and 1. Note that we reject randomly generated x_i if it is too close to previously generated x_j's, since the smoothing result would not be very satisfactory if

$$\min_{2 \leq i \leq n} |x_i - x_{i-1}| / \max_{2 \leq i \leq n} |x_i - x_{i-1}|$$

were too small. We consider $\frac{1}{2n}$ as a reasonable lower bound for the minimum distance between two consecutive x_i's, since $\max_{2 \leq i \leq n} |x_i - x_{i-1}|$ could be $\frac{1}{2}$ in the worst case. Here we are not particularly interested in how the estimator will be affected by the design points. The purpose of including $x_i \sim U(0, 1)$ is to see whether unequally spaced design points will affect the smoothing process or not.

In summary, we can conclude from our numerical simulations that

1. $\mathbf{E_S} \cong \mathbf{E_I}$ and $\mathbf{R_S} \cong \mathbf{R_I}$ in all cases;
2. $\mathbf{R_I}$ is more or less in a neighborhood of 90%;
3. the smoother $\hat{\theta}(\epsilon_S)$ is not very sensitive to the variance of the noise or outliers;
4. the smoothing process is not affected by the location of x_i's as long as the ratio $\min_{2 \leq i \leq n} |x_i - x_{i-1}| / \max_{2 \leq i \leq n} |x_i - x_{i-1}|$ is not too small;
5. in all testing cases, $\frac{\mathbf{N}}{n} \leq 8$ and $\mathbf{N_0} \leq 5$; in general, $\frac{\mathbf{N}}{n}$ is very small and it only took a few seconds to find $\hat{\theta}(\epsilon_S)$;
6. the smoothing process can not effectively produce a satisfactory estimator with desirable shapes, if the underlying regression function $f(x)$ has a "fairly flat" segment.

The numerical results indicate that the computational cost of the regression scheme is about $\mathcal{O}(n^2)$ flops (cf. [24] and Table 1), which is far less expensive than we expected. More importantly, it seems very easy and effective to use $(m-1)$ (the number of sign changes of the second divided difference) to tune the smoothing process. First of all, one can always have a reasonable estimate of the number of inflection points that the original curve has. Even if the estimate does not produce a smoother with the desirable shape, it is easy to adjust m accordingly and recalculate the new smoother.

6. Conclusions and comments.

We have proposed a smoothing technique controlled by the number of convex/concave pieces of the fitting curve. The smoother is fairly easy to calculate, it has many good properties a smoother should have, and it has statistical properties similar to that of polynomial regression in some situations.

Extensive numerical simulations indicate that our piecewise convex/concave smoothing scheme does produce a fairly good piecewise convex/concave fitting in many different circumstances. However, the smoothing process might not be able to produce a satisfactory estimator with a desirable shape if the original regression function $f(x)$ has a "fairly flat" segment. A remedy to this deficiency might be an adaptive smoothing process as follows:

$$\begin{aligned} &\min \ \Sigma_{i=1}^{n}(y_i - \theta_i)^2 \\ &\text{subject to } l \leq \Delta_k\theta \leq u, \end{aligned}$$

where l and u are column vectors with $(n-k)$ components. Then, if necessary, one can make $l_i = u_i = 0$ for those x_i's in the x-range where $f(x)$ is supposed to be flat. From our simulation experiments, we notice that, in most cases, the smoother is not sensitive to an overestimation of m by 1. That is, if we increase m by 1 in our simulations, the mean squared errors will be more or less the same and, visually, one can hardly see the difference between the old and new smoothers.

It may be pointed out that the emphasis of this paper is on the computation of a piecewise convex/concave estimator. Much more is to be done about the smoothing procedure proposed here. For example, the monotonicity of $I(\hat{\theta}(\epsilon))$ as a function of ϵ, construction of a confidence band for the curve, perhaps using bootstrap techniques, and use of the method for prediction, etc., are yet to be explored. Note that Mammen [26] proved that, under some mild conditions on η_i which guarantee that the distribution of η_i does not have heavier tails than a Gaussian distribution,

$$\frac{1}{n}\sum_{i=1}^{n}(\hat{g}_n(x_i) - f(x_i))^2 \leq \mathcal{O}_p\left((mD)^{\frac{1}{2(k+1)}} n^{-\frac{k+1}{k+2}}\right),$$

where $\hat{g}_n$ is the solution to (3) and $A_n = \mathcal{O}_p(B_n)$ means that there exists a positive constant C such that, for any $\delta > 0$,

$$\Pr\left(\left|\frac{A_n}{B_n}\right| \leq C\right) \geq 1 - \delta$$

for sufficiently large n. It would be interesting to see whether similar results hold for (7) or (6).

The objective function considered in this article is the negative log likelihood function of normal errors. Hence the problem (9) can be viewed as a constrained maximum likelihood problem, that is, maximizing the likelihood function subject to certain constraints. One can take any one-dimensional exponential family of distributions instead of the normal distribution and maximize the likelihood function subject to the restrictions we have considered. Adoption of the algorithm to this case can be done, for example, by using sequential programming techniques (cf. [14]).

AN ANALYSIS OF APPROXIMATE NONLINEAR ELIMINATION*

PAUL J. LANZKRON†, DONALD J. ROSE‡, AND JAMES T. WILKES§

Abstract. We present a method for solving systems of nonlinear equations suitable for problems where convergence of an approximate Newton method is initially slow. The method, nonlinear elimination (NlEm), eliminates the nonlinear equations and appropriate variables deemed to be causing the problem. An analysis of the method is given and leads to a detailed algorithm that reduces automatically to an approximate Newton method near the root of the system of nonlinear equations. Several examples are given that demonstrate the efficacy of the method.

Key words. nonlinear equations, global methods, approximate Newton method

AMS subject classifications. 65H10, 65H20

1. Introduction.

We consider the numerical solution of a system of nonlinear equations

$$g(w) = 0, \tag{1.1}$$

where $g = (g_1, g_2, \ldots, g_n)^T$ and $w = (w_1, w_2, \ldots, w_n)^T$. Generically we consider the methodology of [1] and the analytic framework presented there. This setting ensures that for any w_0 in some set S, a sequence of iterates w_k will converge to $w^* \in S$ and $g(w^*) = 0$. The iterates are defined as

$$w_{k+1} = w_k + t_k x_k, \tag{1.2}$$

where x_k *approximates* z_k in

$$g'_k z_k = -g_k, \tag{1.3}$$

$g'_k \equiv g'(w_k)$, and $g_k \equiv g(w_k)$, and $t_k \in (0, 1]$ is chosen to force

$$\|g_{k+1}\| < \theta \|g_k\| \tag{1.4}$$

for some $0 < \theta < 1$. The sense in which x_k approximates z_k of (1.3) is measured by

$$\alpha_k = \|g'_k x_k + g_k\| / \|g_k\| \tag{1.5}$$

and all $\alpha_k \leq \alpha_0 < 1$ suffices for convergence (for some sequence of t_k). We call this algorithmic approach GAN, for global approximate Newton, "global" referring to the set S which can be $\mathbb{R}^n$ under appropriate conditions.

Such variations of Newton's method have been used successfully in significant technology areas including circuit and device simulation [2, 5]. The trick in any of these applications is in picking an "inner" solver for (1.3) to make $\alpha_k \to 0$ and $t_k \to 1$ to ensure (1.4) and superlinear convergence. This can be particularly challenging in practice since we often cannot be sure a priori that the sufficient convergence conditions are satisfied, nor can we wait for $k \to \infty$.

The use of nonlinear elimination (NlEm, en-lem) is motivated by problems in which convergence seems to be interminably tedious and yet there is no evidence of ill conditioning (or singularity). This leads us to believe that the nonlinearities in g are unbalanced, by which

§Department of Mathematical Sciences, Appalachian State University, Boone, NC 28608 (jtw@cs.appstate.edu).

we mean some "subfunction" $g_1(u, v)$ regarded as a function of u given v causes t_k to be small. We propose to eliminate g_1 as an inner iteration.

Consider $g(w)$ to be partitioned as

$$\begin{aligned} &g(w) = (g_1(u, v), g_2(u, v))^T, \\ &w = (u, v)^T. \end{aligned} \tag{1.6}$$

This leads to a block Jacobian

$$g'(u, v) = \begin{bmatrix} g_{11}(u, v) & g_{12}(u, v) \\ g_{21}(u, v) & g_{22}(u, v) \end{bmatrix}, \tag{1.7}$$

where $g_{ij}(u, v) = \frac{\partial g_i}{\partial g_j}(u, v)$. For conciseness we write $g_{ij} \equiv g_{ij}(u, v)$.

For smooth $g_1(u, v)$ the solvability of $g_1(u, v) = 0$ for v in an appropriate set leads to an implicit function $h(v)$ such that

$$g_1(h(v), v) = 0. \tag{1.8}$$

Differentiating (1.8) as a function of v leads to

$$g_{11}h'(v) + g_{12} = 0, \tag{1.9}$$

and if $g_{11}(h(v), v)$ is nonsingular, then

$$h'(v) = -g_{11}^{-1}g_{12}. \tag{1.10}$$

Indeed the operational equation (1.10) and the existence of the unique mapping $h(v)$ constitute the essence of the implicit function theorem, see [12, Thm. 5.2.4], which requires the nonsingularity of g_{11}.

Assuming that $u = h(v)$ exists on an appropriate set, we attempt to solve equation (1.1), which can be rewritten as

$$f(v) = 0, \tag{1.11}$$

where $f(v) \equiv g_2(h(v), v)$ for v using GAN. To use GAN we must compute the Jacobian $f'(v)$; differentiating (1.11) yields

$$f'(v) = g_{21}h'(v) + g_{22}, \tag{1.12}$$

where g_{21}, g_{22} are evaluated at $(h(v), v)$. Making the substitution (1.10), we obtain

$$f'(v) = g_{22} - g_{21}g_{11}^{-1}g_{12} \tag{1.13}$$

and we recognize the right-hand side of (1.13) as a Schur complement. More precisely we see that the Newton direction equation associated with (1.11), namely,

$$f'(v)\Delta v = -f(v), \tag{1.14}$$

can be embedded into the larger matrix equation

$$\begin{bmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{bmatrix} \begin{bmatrix} \Delta u \\ \Delta v \end{bmatrix} = \begin{bmatrix} -g_1 \\ -g_2 \end{bmatrix}, \tag{1.15}$$

where all functions are evaluated at $(h(v), v)$ and $g_1(h(v), v) = 0$. Equation (1.14) arises from block Gaussian elimination on (1.15) as indicated by (1.13). This is computationally attractive since nonlinear elimination leads to the same algebra as GAN on the whole system, but now applied at the point $(h(v), v)$. To summarize there are two nonlinear solve processes: an "inner" equation solve to evaluate $h(v)$ from (1.8) and an "outer" Newton iteration to solve (1.11) via (1.15). When $h(v)$ is evaluated "exactly," i.e., $g_1(h(v), v) = 0$, then we show (Theorem 4.2) that the outer GAN (1.15) converges quadratically to the solution $g_2(h(v), v) = 0$ as expected.

Note that when a sparse matrix package can be used for GAN, it is also applicable for NlEm. That is, starting at the point $(h(v), v)$, both NlEm and GAN would need to solve the system (1.15). It is unimportant that the variables be ordered so that the Δu variables are first. In fact it is easy to imagine cases where such an ordering would lead to significant fill. After the linear system is solved the Δv variables can be gathered easily.

Many investigators have studied nonlinear elimination for particular applications. We discuss two of these applications here. The first is macromodeling circuits. A circuit can be thought of as a k-terminal device. In modeling the circuit the user wishes to know how changing the voltage at some of the input terminals affects the voltage at other terminals. The number of unknowns for the system is then k plus the number of internal unknowns in the device. In [6] the authors show how to eliminate the internal unknowns from the system of nonlinear equations that must be solved at each time step. More recent work on applying NlEm to circuit simulation is reported in [13].

A second widely used, although only tangentially connected, application of nonlinear elimination is in nonlinear least squares. Consider the problem of finding (u, v) such that

$$\|y - g(u, v)\|_2 \tag{1.16}$$

is minimized, where $y \in \mathbb{R}^{n\times 1}$ is a set of observations and $g : \mathbb{R}^p \to \mathbb{R}^n$ is nonlinear. Consider the case where

$$g(u, v) \equiv l(v)u = \begin{bmatrix} g_{11}(v) \\ g_{21}(v) \end{bmatrix} u. \tag{1.17}$$

When v is fixed in equation (1.17), equation (1.16) turns into a linear least squares problem. The problem given in (1.16) may then be rewritten as

$$\min_v \|y - g(h(v), v)\|_2, \tag{1.18}$$

where

$$h(v) = \left(l(v)^T l(v)\right)^{-1} l(v)^T y. \tag{1.19}$$

We have assumed, as in [10], that $l(v)$ has full column rank. The case when $l(v)$ does not have full column rank is handled in [7, 8]. The difference between this approach and our approach is that we eliminate variables *and* equations so that $f(v)$ is still a system of p nonlinear equations in p unknowns.

Nonlinear elimination arises naturally in constrained optimization and can be viewed in the context of Lagrange multipliers. Most authors do not choose such an exposition; see [3, p. 141] for a related discussion. We remark also that Brown's method [4] can be regarded as a specialization of nonlinear elimination as discussed in [12, NR 7.14-15, pp. 227-229].

This paper is organized as follows. In §2 the NlEm algorithm is presented along with a simple example. Sections 3-5 contain an analysis of the whole procedure, presented as constructively as possible. Since we suggest that NlEm can be part of a general algorithmic strategy for solving nonlinear systems, this analysis presents conditions that ensure convergence in a way that is compatible with the theory presented in [1]. Section 4 discusses the

```
Input: $w_0 = (u_0, v_0)$ and $g$.
1.  Choose $g_1$ equations splitting $g(w)$ into $g_1(u, v)$ and $g_2(u, v)$.
    By $g_1(u, v)$ we mean that if $g_1 : \mathbb{R}^n \rightarrow \mathbb{R}^j$, then $u \in \mathbb{R}^j$.
2.  Given the initial $v_0$, solve $g_1(h(v_0), v_0) = 0$ for $h(v_0)$.
3.  $k \leftarrow 0$
4.  repeat until convergence
5.      Solve
        $\begin{bmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{bmatrix} \begin{bmatrix} \Delta u_k \\ \Delta v_k \end{bmatrix} = \begin{bmatrix} -g_1 \\ -g_2 \end{bmatrix}$,
        with $g_{11}, g_{12}, g_{21}, g_{22}$, and $g_2$ evaluated at $(h(v_k), v_k)$.

6.      Find $t_k \in (0, 1]$ such that
        $\|g(h(v_k + t_k\Delta v_k), v_k + t_k\Delta v_k)\| < \theta\|g(h(v_k), v_k)\|$
        Note: a solve for $u = h(v_k + t_k\Delta v_k)$ of
        $g_1(u, v_k + t_k\Delta v_k) = 0$
        is required for every $t_k$.

7.      $v_{k+1} = v_k + t_k\Delta v_k$
        Note: $h(v_{k+1})$ is implicitly determined in step 6.
```

FIG. 1. *Outline of the NlEm algorithm.*

case when (1.8) is solved exactly and §5 discusses how accurately (1.8) must be solved to retain the higher-order convergence of Newton's method. The analysis in §5 leads to a refined algorithm in §6 that unifies NlEm and GAN into a single methodology. Section 7 contains several computed examples.

2. Implementation overview. In this section we give a brief overview of how to implement the NlEm algorithm along with an illustrative example. In §6, a detailed algorithm is presented that unifies GAN and NlEm.

2.1. NlEm algorithm. The outline of the algorithm is given in Figure 1.

Often the hardest part of the implementation is in step 1, since determining the set of equations that belong in g_1 is usually problem dependent. Once the set is chosen the solve in step 2 moves the initial point (u_0, v_0) to a new point in the domain $(h(v_0), v_0)$. There may be an increase in the overall norm of g at this new point; i.e.,

$$\|g(h(v_0), v_0)\| > \|g(u_0, v_0)\|. \tag{2.1}$$

However, the norm of g decreases monotonically thereafter under appropriate conditions. There are times when the set of g_1 equations may be changed dynamically after the algorithm has been started. However, arbitrarily changing the set of equations represented by g_1 could lead to thrashing (i.e., the norm of g goes down for a while, but the g_1 equations are changed causing $\|g\|$ to be as large or larger than previously).

The computation in step 6 implicitly requires a solve of the g_1 equation. That is, to compute $h(v_k + t_k\Delta v_k)$ the g_1 equation must be solved. Step 6 is potentially expensive, since every new choice of t_k requires a solve of the g_1 equations. Note that in step 6 we are trying to make the overall norm of g go down. This is necessary since $g_1 \neq 0$ in practice. When $g_1 \neq 0$ we only have an approximation to $h(v)$, say $\tilde{h}(v)$. Thus, $g_2(h(v), v)$ is approximated

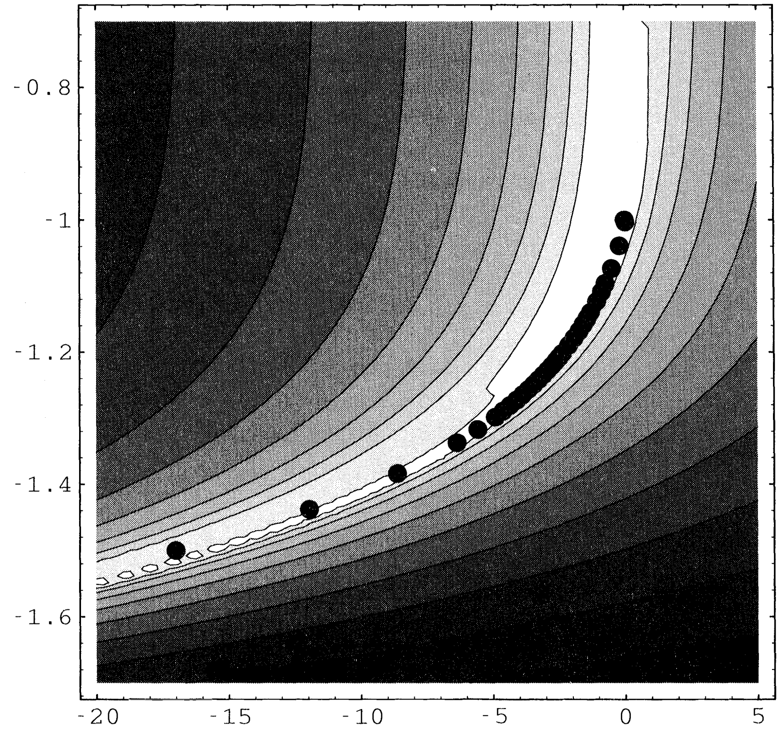

FIG. 2. *Convergence of GAN overlaid on* $\log(\|f\| + 1)$.

by $g_2(\tilde{h}(v), v)$. A decrease in $\|g_2(\tilde{h}(v), v)\|$ does not imply that $\|g_2(h(v), v)\|$ has decreased; see §5. Therefore, we enforce norm reduction on all of g.

2.2. A simple illustrative example. We believe NlEm will be helpful when the system of equations has some badly scaled components. The poor scaling is not in terms of normal linear misscaling, rather it is due to the nonlinearity of the problem. In this section, we present a simple example demonstrating how NlEm helps.

Consider the system f of two equations given by

$$\begin{aligned} f_1(u, v) &= (u - v^7)^3 + v^3, \\ f_2(u, v) &= (u + v)^{\frac{1}{5}} + 1. \end{aligned} \tag{2.2}$$

When viewed in terms of norms the curve $u = v^7 - v$ is close to the bottom of a very steep valley. A GAN iterate in the valley causes the Newton direction to point tangent to the valley. Since the valley curves and the Newton direction points in a direction nearly tangent to the bottom of the valley, only small values of the damping parameter can be chosen; larger values give an increase in $\|g\|$. In Figure 2 the starting point $(-17.085938, -1.5)$ leads the GAN iterates into the steep curved valley. GAN takes 32 steps to converge to the solution $(0, -1)$.

To use NlEm we must first decide on the equation to eliminate. For this problem it is clear that the first equation is causing the difficulties; that is, movement away from the curve $u = v^7$ causes a large increase in the norm of the system. This is not true for the second equation. Having decided on the equation to eliminate, we must then decide on the variable to be eliminated with it; in this case we choose to eliminate the u variable. In realistic problems the variable eliminated will be more obvious. For a given v we will solve for a u such that

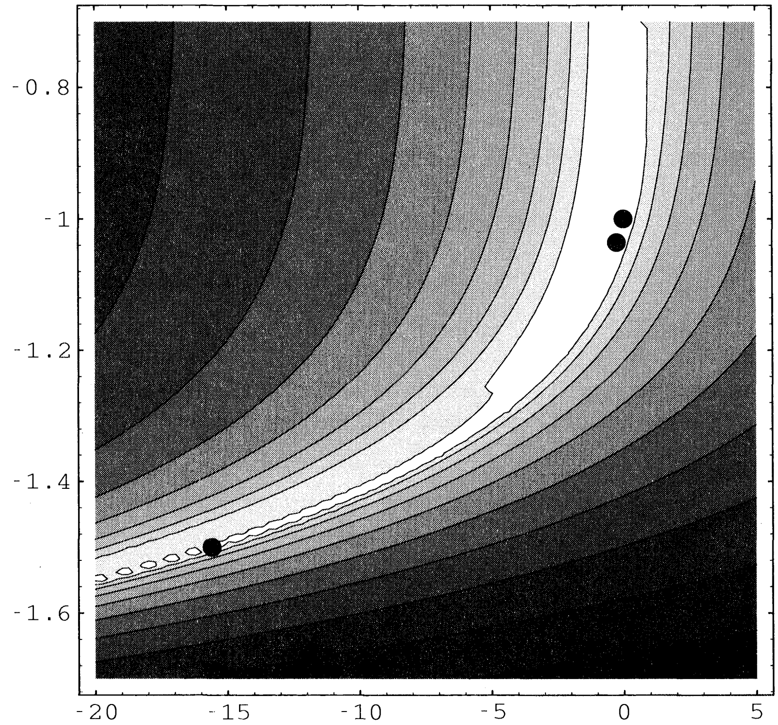

FIG. 3. *Convergence of NlEm overlaid on* $\log(\|f\|+1)$.

$g_1(u, v) = 0$. Solving for u in the first equation means that $u = h(v) = v^7 - v$. The eliminated system, $g_2(h(v), v) = v^{7/5} + 1$, is a much simpler problem to solve. In Figure 3 we see that the number of NlEm iterations from the same starting point drops to three.

3. Preliminaries. Recall that our objective is to solve (1.11) using Newton's method. This section gives a review of the GAN convergence theory and provides results used in later sections.

3.1. Analysis of GAN. The following analysis of GAN is derived from [1]. Let $g_k \equiv g(w_k)$ with w_0 some initial guess for the solution. There are three basic assumptions used to prove convergence of GAN.

Assumption A1. The closed level set

$$S_0 = \{w \mid \|g(w)\| \leq \|g_0\|\} \tag{3.1}$$

is bounded.

The following assumption is equivalent to Assumption A2 presented in [1].

Assumption A2. g is differentiable, the Jacobian $g'(w)$ is continuous and nonsingular on S_0, and the sequence $\|x_k\|$ is uniformly bounded, i.e.,

$$\|x_k\| \leq k_1\|g_k\| \tag{3.2}$$

for $k_1 \geq 0$ and $w_k \in S_0$.

Assumption A3. The Jacobian g' is Lipschitz; i.e.,

$$\|g'(y) - g'(z)\| \leq k_2\|y - z\| \tag{3.3}$$

for

$$y, z \in S_1 = \{y \mid \|y\| \leq \sup_{z \in S_0} \|z\| + k_1\|g_0\|\}. \tag{3.4}$$

To continue the analysis of GAN we define the quantities

$$\begin{aligned} A_k &= (g_k + g_k' x_k)/\|g_k\|, \\ B_k &= \left\{ \int_0^1 \left[g'(w_k + st_k x_k) - g_k' \right] t_k x_k ds \right\} / \, (t_k\|g_k\|)^2, \\ \alpha_k &= \|A_k\|, \qquad \beta_k = \|B_k\|, \end{aligned} \tag{3.5}$$

where we have assumed $g_k \neq 0$. The quantity α_k defines the relative size of the linear residual.

Following the analysis of [1], the mean value theorem yields

$$g_{k+1} = g_k + \int_0^1 g'(w_k + st_k x_k)(w_{k+1} - w_k) ds. \tag{3.6}$$

Adding and subtracting $g_k'(w_{k+1} - w_k)$ on the right-hand side yields

$$g_{k+1} = g_k + g_k'(w_{k+1} - w_k) + \int_0^1 \left[g'(w_k + st_k x_k) - g_k' \right] (w_{k+1} - w_k) ds. \tag{3.7}$$

Recalling that $w_{k+1} = w_k + t_k x_k$ we have

$$g_{k+1} = (1 - t_k) g_k + t_k A_k \|g_k\| + t_k^2 B_k \|g_k\|^2. \tag{3.8}$$

And finally taking norms we are left with

$$\|g_{k+1}\| \leq \|g_k\| \left((1 - t_k) + t_k \alpha_k + t_k^2 \beta_k \|g_k\| \right). \tag{3.9}$$

Under Assumptions A1-A3, β_k can be shown to be bounded, $\beta_k \leq k_1^2 k_2/2$. It is usually possible to control the size of α_k by computing x_k more accurately. This is the case when an iterative method is being used to solve the Newton equations. It is clear from (3.9) that if $\alpha_k < 1$ then there exists a t_k such that $\|g_{k+1}\| < \|g_k\|$.

Convergence of GAN is given by the following proposition and theorem.

PROPOSITION 3.1 (see [1]). *Assume that* A1-A3 *hold and that all* $\alpha_k \leq \alpha_0$. *If* t_k *is chosen appropriately, then*

1. *all* $w_k \in S_0$, *the sequence* $\|g_k\|$ *is strictly decreasing, and* $\|g_k\| \to 0$; *furthermore,*
2. $\|g_{k+1}\|/\|g_k\| \to 0$ *iff* $\alpha_k \to 0$ *and for any fixed* $p \in (0, 1]$,

$$\|g_{k+1}\| \leq c_1 \|g_k\|^{1+p}, \tag{3.10}$$

iff

$$\alpha_k \leq c_2 \|g_k\|^p \tag{3.11}$$

for positive constants c_1 *and* c_2.

THEOREM 3.2 (see [1]). *Under the conditions of Proposition* 3.1,

1. *there exists a* $w^* \in S_0$ *with* $w^* = \lim w_k$ *and* $g(w^*) = 0$;
2. *on* S_0 *the convergence of* $\{w_k\}$ *to* w^* *is superlinear or Q-order* $(p + 1)$ *if* $\alpha_k \to 0$ *or* $\alpha_k \leq c_2 \|g_k\|^p$, *respectively.*

3.2. Additional results. We conclude this section with results that will be used in subsequent sections.

PROPOSITION 3.3. *Assume that GAN starting from w_0 is convergent to w^* with $g(w^*) = 0$. Let $\|g'^{-1}(w)\| \leq M$, for $u \in S_0$, and $\|g_{i+1}\| \leq \theta \|g_i\|$ for every i, where $g_i \equiv g(w_i)$ and $\theta < 1$. Then*

$$\|w_0 - w^*\| \leq \frac{1}{1-\theta} M \|g(w_0)\|. \tag{3.12}$$

Proof. Since GAN is assumed to be convergent, we know that $w_i \in S_0$ for all i. Thus.

$$\begin{aligned}\|w_0 - w^*\| &= \left\| w_0 - \left(w_0 + \sum_0^\infty t_i \Delta w_i \right) \right\| = \left\| \sum_0^\infty t_i \Delta w_i \right\| \\ &\leq \sum_0^\infty \|\Delta w_i\| = \sum_0^\infty \| - g_i'^{-1} g_i \| \\ &\leq M \sum_0^\infty \|g_i\| \leq M \|g_0\| \sum_0^\infty \theta^i = \frac{1}{1-\theta} M \|g(w_0)\|. \qquad \square\end{aligned}$$

The proofs in this paper are complicated somewhat by the changes in sizes of norms. We will address this problem by restricting the matrix norms we consider to p-norms. These norms have the following properties.

Property P1. Let $u \in \mathbb{R}^m$, and $v = [0, 0, \ldots, 0, u]^T \in \mathbb{R}^n$; then

$$\|u\|_p = \|v\|_p. \tag{3.13}$$

For example,

$$\|u\|_p = \left(\sum_{i=1}^m w_i^p \right)^{\frac{1}{p}} = \left(\sum_{i=1}^m w_i^p + \sum_{i=m+1}^n 0^p \right)^{\frac{1}{p}} = \|v\|_p. \tag{3.14}$$

Note that (3.13) holds however the elements of u are distributed in v.

Property P2. Let $u \in \mathbb{R}^m$, $v = [u, 0, 0, \ldots, 0]^T \in \mathbb{R}^n$ and $w = [u, y]^T \in \mathbb{R}^n$; then

$$\|v\|_p \leq \|w\|_p. \tag{3.15}$$

The following lemma can easily be verified to show that Properties P1 and P2 carry through to matrices.

LEMMA 3.4. *Let $A \in \mathbb{R}^{j \times k}$, $j, k \leq n$; then*

$$\|A\|_p = \left\| \begin{bmatrix} 0 & 0 \\ 0 & A \end{bmatrix} \right\|_p \leq \left\| \begin{bmatrix} B & C \\ D & A \end{bmatrix} \right\|,$$

where $\left[\begin{smallmatrix} B & C \\ D & A \end{smallmatrix}\right] \in \mathbb{R}^{n \times n}$.

We will refer to (3.13) as Property P1, and (3.15) as Property P2 without distinguishing between matrices and vectors.

LEMMA 3.5. *Let the nonsingular $A \in \mathbb{R}^{n \times n}$ be partitioned as*

$$\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}$$

with $A_{11} \in \mathbb{R}^{j\times j}$ *and nonsingular. If* $\|A^{-1}\| < k$ *and properties* P1 *and* P2 *hold for* $\|\cdot\|$, *then*

$$\|(A_{22} - A_{21}A_{11}^{-1}A_{12})^{-1}\| < k. \tag{3.16}$$

Proof.

$$\begin{aligned} \|(A_{22} - A_{21}A_{11}^{-1}A_{12})^{-1}\| &= \left\| \begin{bmatrix} 0 & 0 \\ 0 & (A_{22} - A_{21}A_{11}^{-1}A_{12})^{-1} \end{bmatrix} \right\| \\ &\le \|A^{-1}\| \\ &< k. \quad \square \end{aligned} \tag{3.17}$$

PROPOSITION 3.6. *If* g *is Lipschitz on a bounded set* S, *then* $\|g\|$ *is bounded.*

Proof. Since S is bounded, there exists $k \in \mathbb{R}^+$ such that $\|w - y\| \le k$ for all $w, y \in S$. Let w_0 be a particular member of S with $\|g(w_0)\| = C$. Then, for any $w \in S$, we have

$$\|g(w)\| \le \|g(w) - g(w_0)\| + \|g(w_0)\| = L\|w - w_0\| + C = Lk + C, \tag{3.18}$$

where L is the Lipschitz constant. □

PROPOSITION 3.7. *Let* $M(w) \in \mathbb{R}^{n\times n}$ *with* $M(w)$ *Lipschitz on some convex set with Lipschitz constant* k_0. *If* $M(w)$ *is partitioned as*

$$\begin{bmatrix} M_{11}(w) & M_{12}(w) \\ M_{21}(w) & M_{22}(w) \end{bmatrix} \tag{3.19}$$

with $M_{11}(w) \in \mathbb{R}^{j\times j}$ *and* $\|M_{11}^{-1}(w)\| \le k_1$, *then the Schur complement of* $M(w)$ *is also Lipschitz with Lipschitz constant*

$$k_0(1 + k_1k_2)^2, \tag{3.20}$$

where $\|M(w)\| \le k_2$.

Proof. Applying Proposition 3.6 gives us $\|M(w)\| \le k_2$. Using Properties P1 and P2, we know that $\|M_{ij}\| \le k_2$ for $i, j = 1, 2$. Let $A \equiv M(w_1)$ and $B \equiv M(w_2)$.

$$\begin{aligned} &\|\left(A_{22} - A_{21}A_{11}^{-1}A_{12}\right) - \left(B_{22} - B_{21}B_{11}^{-1}B_{12}\right)\| \\ &\le \|A_{22} - B_{22}\| \\ &\quad + \|B_{21}B_{11}^{-1}B_{12} - B_{21}B_{11}^{-1}A_{12} + B_{21}B_{11}^{-1}A_{12} - A_{21}A_{11}^{-1}A_{12}\| \\ &\le k_0\|x - y\| + \|B_{21}B_{11}^{-1}\left(B_{12} - A_{12}\right)\| + \|\left(B_{21}B_{11}^{-1} - A_{21}A_{11}^{-1}\right)A_{12}\| \\ &\le k_0\|x - y\| + k_2k_1k_0\|x - y\| \\ &\quad + \|\left(B_{21}B_{11}^{-1} - A_{21}B_{11}^{-1} + A_{21}B_{11}^{-1} - A_{21}A_{11}^{-1}\right)A_{12}\| \\ &\le k_0\|x - y\| + k_2k_1k_0\|x - y\| \\ &\quad + k_2\|\left(B_{21} - A_{21}\right)B_{11}^{-1}\| + k_2\|A_{21}\left(B_{11}^{-1} - A_{11}^{-1}\right)\| \\ &\le k_0\|x - y\| + k_2k_1k_0\|x - y\| + k_2k_1k_0\|x - y\| \\ &\quad + k_2^2\|B_{11}^{-1}\|\|A_{11}^{-1}\|\|\left(B_{11} - A_{11}\right)\| \\ &\le k_0\|x - y\| + 2k_2k_1k_0\|x - y\| + k_2^2k_1^2k_0\|x - y\| \\ &= k_0(1 + k_1k_2)^2\|x - y\|. \quad \square \end{aligned} \tag{3.21}$$

4. Exact NlEm. The exact NlEm algorithm is Newton's method applied to the equation

$$f(v) \equiv g_2(h(v), v) = 0. \tag{4.1}$$

To show that the algorithm converges, we need to show that, under appropriate conditions, $h(v)$ exists and that the basic Assumptions A1–A3 hold on the function $f(v)$. These assumptions and making $\alpha_k \to 0$ ensure that Proposition 3.1 and Theorem 3.2 hold.

First, assume that GAN is convergent on g and that from any point (u, v) in a given set, GAN converges on g_1 giving $g_1(\hat{u}, v) = 0$ where $\hat{u} = h(v)$. For clarity sake, let $S_0(g)$ be the set S_0 given in (3.1) and let $S_1(g)$ be the set S_1 given in (3.4). Because of the partitioning of g, projections of sets are needed. In particular, let

$$S_1^2(g) = \{v \mid (u, v) \in S_1(g) \quad v \in \mathbb{R}^{n-j}\}. \tag{4.2}$$

The following assumptions are required for proof of the convergence of GAN applied to (4.1).

Assumption A1 remains unchanged and for Assumption A2 we make the stronger restriction that $\|g'^{-1}\| \le k_1$ over $S_0(g)$. Assumption A3 is modified below.

Assumption A4. Let

$$\|\hat{g}_1\| = \max_{w \in S_1(g)} \|g_1(w)\|; \tag{4.3}$$

then the set

$$S_0(g_1) = \{(u, v) \mid v \in S_1^2(g) \text{ and } \|g_1(u, v)\| \le \|\hat{g}_1\|\} \tag{4.4}$$

is bounded.

Assumption A5. The function g_1 is differentiable and g_{11} is continuous and nonsingular on $S_0(g_1)$, and

$$\|g_{11}^{-1}(w)\| \le k_5, \qquad w \in S_0(g_1). \tag{4.5}$$

Since convergence of the g_1 system is required only on the projection of $S_0(g_1)$, i.e., $g_1(u, v) = 0$ is solved with v fixed; the projection sets of $S_0(g_1)$ are defined as

$$S_0^1(g_1) = \{u \mid (u, v) \in S_0(g_1), \qquad u \in \mathbb{R}^j\}, \tag{4.6}$$

$$S_0^2(g_1) = \{v \mid (u, v) \in S_0(g_1), \qquad v \in \mathbb{R}^{n-j}\}. \tag{4.7}$$

This leads to a modification of Assumption A3 given previously.

Assumption A3. The Jacobian g' is Lipschitz with Lipschitz constant k_2 on

$$S_1(g_1) = \{(u, v) \mid v \in S_0^2(g_1) \text{ and } \|u\| \le \max_{w \in S_0^1(g_1)} \|w\| + k_5\|\hat{g}_1\|\}, \tag{4.8}$$

where $\|\hat{g}_1\|$ is defined as before.

The sets $S_0(g)$, $S_1(g)$, $S_0(g_1)$, and $S_1(g_1)$ are illustrated in two dimensions in Figure 4; the u-axis is horizontal and the v-axis is vertical. Note that $S_0(g)$ need not be connected. Under Assumptions A1–A5, there is a root of g in both of the disconnected regions. The sets $S_1(g)$ and $S_1(g_1)$ are both convex, but the set $S_1(g_1)$ has a capsule shape because it is stretched in the direction of the eliminated variable.

These sets come into play during various phases of the solution algorithm. Initially w_k is in $S_0(g)$. The approximate Newton direction is computed and a potential w_{k+1} produced. The potential $w_{k+1} = w_k + t_k x_k$ may be outside $S_0(g)$, but is within $S_1(g)$ (of course, when the final w_{k+1} is determined it must be in $S_0(g)$). At this point in the algorithm, a root u is sought for $g_1(u, v)$ from a starting point in $S_1(g)$. This root will be somewhere in $S_0(g_1)$. The Newton method used to find that root may generate points in $S_1(g_1)$ (in the same way as $w_k + t_k x_k$ may be outside of $S_0(g)$).

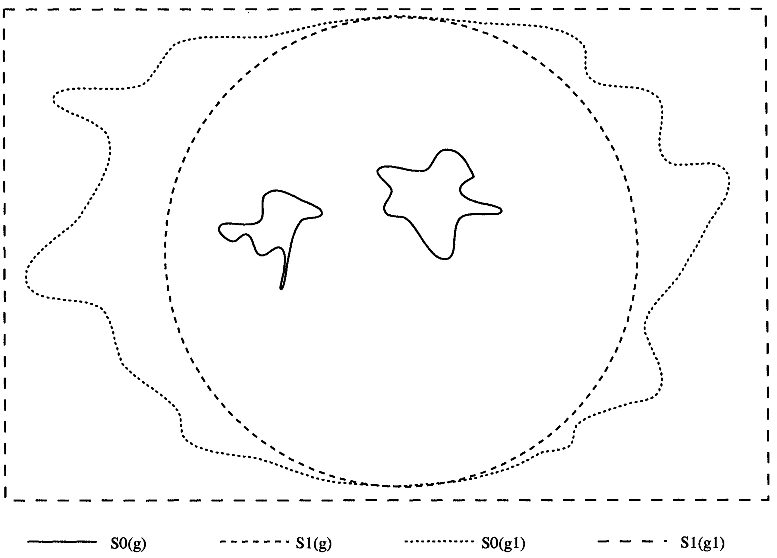

FIG. 4. *Illustration of the sets $S_0(g)$, $S_1(g)$, $S_0(g_1)$, and $S_1(g_1)$ in two dimensions.*

LEMMA 4.1. *Consider Assumptions* A3–A5. *For $v \in S_1^2(g)$, there is a $u \in S_0^1(g_1)$ such that*

$$g_1(u, v) = 0. \tag{4.9}$$

Thus, $h(v)$ exists for $v \in S_1^2(g)$ and

$$h'(v) = -g_{11}^{-1}(h(v), v)g_{12}(h(v), v). \tag{4.10}$$

Proof. Let

$$\|g'(w_1) - g'(w_2)\| \le k_2\|w_1 - w_2\| \tag{4.11}$$

hold for $\|\cdot\|$ satisfying Properties P1 and P2. Let $w_1 = (u_1, v)$ and $w_2 = (u_2, v)$. It follows that

$$\|g_{11}(w_1) - g_{11}(w_2)\| \le k_2\|u_1 - u_2\|. \tag{4.12}$$

Assumptions A4 and A5 and (4.12) represent the conditions for Proposition 3.1 and Theorem 3.2 to hold. Thus $g_1(u, v)$ has a root for fixed $v \in S_0^1(g_1)$. The remainder of the lemma follows from the implicit function theorem. □

THEOREM 4.2. *Consider Assumptions* A1–A5. *If $(u_0, v_0) \in S_0(g)$ with $g_1(u_0, v_0) = 0$, and at every iteration* (1.15) *is solved exactly, then GAN converges to the solution of $f(v) = 0$ and, furthermore, convergence is quadratic* (*Q-order* 2).

Proof. The proof will show that Assumptions A1–A3 hold for $f(v)$ and that $\alpha_k = 0$ (α_k as defined in (3.5)).

(A1) Let $z \in S_0(f) = \{v \| \|f(v)\| \le \|f(v_0)\|\}$, then by Property P1,

$$\|g(h(z), z)\| = \|f(z)\| \le \|f(v_0)\| = \|g(h(v_0), v_0)\|. \tag{4.13}$$

Thus, $(h(z), z) \in S_0(g)$ and by Property P2, $S_0(f)$ is bounded.

(A2) Since $(h(z), z) \in S_0(g)$ for $z \in S_0(f)$, we know that

$$\|\Delta v_k\| \leq \left\|\begin{bmatrix} \Delta u_k \\ \Delta v_k \end{bmatrix}\right\| = \|x_k\| \leq k_1\|g(h(v_k), v_k)\| = k_1\|f(v_k)\|, \tag{4.14}$$

using Properties P1 and P2 where appropriate.

Define

$$S_1(f) \equiv \{v \mid \|v\| \leq \sup_{w \in S_0(f)} \|w\| + k_1\|f(v_0)\|\}. \tag{4.15}$$

(A3) From Assumption A5 $g_{11}^{-1}(h(v), v)$ exists and is bounded. Note that $S_1(f) \subset S_0^2(g_1)$ and $g_1(h(v), v) = 0$ for $v \in S_0^2(g_1)$; thus

$$(h(v), v) \in S_0(g_1) \subset S_1(g_1). \tag{4.16}$$

These observations and Proposition 3.7 gives

$$\|f'(v_1) - f'(v_2)\| \leq k_2(1 + k_5k_3)^2\|(h(v_1), v_1)^T - (h(v_2), v_2)^T\| \tag{4.17}$$

for $v_1, v_2 \in S_1(f)$.

By the triangle inequality and Property P1 it follows that

$$\left\|\begin{bmatrix} h(v_1) - h(v_2) \\ v_1 - v_2 \end{bmatrix}\right\| \leq \|v_1 - v_2\| + \|h(v_1) - h(v_2)\|. \tag{4.18}$$

Since bounded derivative implies Lipschitz continuous (see Theorem 3.2.4 [12]) and

$$\|h'(v)\| = \| - g_{11}^{-1}(h(v), v)g_{12}(h(v), v)\| \leq k_5k_3, \tag{4.19}$$

we know that

$$\|h(v_1) - h(v_2)\| \leq k_7\|v_1 - v_2\|. \tag{4.20}$$

for some k_7.

Putting these results together gives

$$\|f'(v_1) - f'(v_2)\| \leq \left(k_2(1 + k_5k_3)^2(1 + k_7)\right) \|v_1 - v_2\| = k_8\|v_1 - v_2\|. \tag{4.21}$$

Finally, since in the exact case $\Delta v_k = -f_k'^{-1} f_k$, it follows that $\alpha_k = 0$. Therefore, Proposition 3.1 and Theorem 3.2 hold for $f(v)$. □

5. Approximate NlEm. In an approximate Newton method, the Newton correction is computed by

$$M_k x_k = -g_k, \tag{5.1}$$

where M_k is an approximation of g_k'. Convergence of this method is given by showing that $\alpha_k < 1$ in (3.5).

Recall that NlEm can be viewed as GAN applied to (1.11). The α_k for this nonlinear system is

$$\alpha_k = \frac{\|f(v_k) + f'(v_k)\Delta v_k\|}{\|f(v_k)\|}. \tag{5.2}$$

In approximate NlEm, (1.15) and $g_1(u, v_k) = 0$ are not solved exactly. Since the g_1 system is not solved exactly, the actual $h(v_k)$ is not computed at iteration k. Thus, verifying $\alpha_k < 1$ is impossible because the actual f and f' are not computed. Denote by $\tilde{h}(v)$ the computed approximation to $h(v)$. Although $h(v)$ was continuous and differentiable, $\tilde{h}(v)$ may be neither. In the remainder of this section we will use $\tilde{g}_k, \tilde{g}'_k, \tilde{g}_{1k}, \tilde{g}_{2k}, \tilde{g}_{11k}, \tilde{g}_{12k}, \tilde{g}_{21k}, \tilde{g}_{22k}$ to denote $g, g', g_1, g_2, g_{11}, g_{12}, g_{21}, g_{22}$, respectively, evaluated at $(\tilde{h}(v_k), v_k)$. Recall that at each step of NlEm, a linear system is solved. Define the residual of this solve in the approximate case to be

$$r_k \equiv \tilde{g}'_k \begin{bmatrix} \Delta u_k \\ \Delta v_k \end{bmatrix} + \tilde{g}_k. \tag{5.3}$$

In this section, a bound is given for the α_k in (5.2). This bound will allow us to show that in the limit quadratic convergence is attainable if the g_1 system and (1.15) are solved accurately enough. The analysis of the convergence of approximate NlEm proceeds in two stages. In the first stage, an expression is derived that bounds the α_k in (5.2) in terms of the accuracy of solving the g_1 system of equations, i.e., $\|g_{1k}\|$. In the second stage, the terms of that expression are bounded in two ways with two theorems. The first theorem is existential, giving the conditions under which approximate NlEm attains higher-order convergence. These conditions are not verifiable. The second theorem gives computable conditions for approximately determining α_k.

5.1. Bounding α_k.

LEMMA 5.1. *Under the assumptions of Theorem* 4.2, *the* α_k *of* (5.2) *can be bounded by*

$$\begin{aligned} \alpha_k \|f_k\| = \alpha_k \|g_{2k}\| \le & \left\| \tilde{g}_{21k} \tilde{g}_{11k}^{-1} \int_0^1 \left[g_{11}(\tilde{h} + s(h - \tilde{h}), v_k) - \tilde{g}_{11k} \right] (h - \tilde{h}) ds \right\| \\ & + \left\| \int_0^1 \left[g_{21}(\tilde{h} + s(h - \tilde{h}), v_k) - \tilde{g}_{21k} \right] (h - \tilde{h}) ds \right\| \\ & + \|(g_{22k} - g_{21k} g_{11k}^{-1} g_{12k}) - (\tilde{g}_{22k} - \tilde{g}_{21k} \tilde{g}_{11k}^{-1} \tilde{g}_{12k})\| \; \|\Delta v_k\| \\ & + \|r_{2k} - \tilde{g}_{21k} \tilde{g}_{11k}^{-1} r_{1k}\|, \end{aligned} \tag{5.4}$$

where we have partitioned r_k *into* r_{1k}, r_{2k} *corresponding to the blocking of* g.

Proof. Recall that

$$\begin{aligned} \alpha_k \|f_k\| = \alpha_k \|g_{2k}\| & = \|(g_{21k} h' + g_{22k}) \Delta v_k + g_{2k}\| \\ & = \|(g_{22k} - g_{21k} g_{11k}^{-1} g_{12k}) \Delta v_k + g_{2k}\| \end{aligned} \tag{5.5}$$

where, from (5.3), Δv_k satisfies

$$\begin{bmatrix} \tilde{g}_{11k} & \tilde{g}_{12k} \\ \tilde{g}_{21k} & \tilde{g}_{22k} \end{bmatrix} \begin{bmatrix} \Delta u_k \\ \Delta v_k \end{bmatrix} + \begin{bmatrix} \tilde{g}_{1k} \\ \tilde{g}_{2k} \end{bmatrix} = \begin{bmatrix} r_{1k} \\ r_{2k} \end{bmatrix}. \tag{5.6}$$

That the $\tilde{g}_{ijk}$ exist, for $i, j = 1, 2$, and $\tilde{g}_{11k}$ nonsingular follows from

$$(\tilde{h}(v_k), v_k) \in S_0(g) \subset S_0(g_1). \tag{5.7}$$

From (5.6) it follows that

$$\begin{aligned} \Delta v_k = & (\tilde{g}_{22k} - \tilde{g}_{21k} \tilde{g}_{11k}^{-1} \tilde{g}_{12k})^{-1} (\tilde{g}_{2k} - \tilde{g}_{21k} \tilde{g}_{11k}^{-1} \tilde{g}_{1k}) \\ & + (\tilde{g}_{22k} - \tilde{g}_{21k} \tilde{g}_{11k}^{-1} \tilde{g}_{12k})^{-1} (r_{2k} - \tilde{g}_{21k} \tilde{g}_{11k}^{-1} r_{1k}). \end{aligned} \tag{5.8}$$

We begin by deriving an inequality relating g_{2k} in terms of $\tilde{g}_{2k}$. Applying the mean value theorem gives

$$\begin{aligned} g_{2k} &= \tilde{g}_{2k} + \int_0^1 g_2'(\tilde{h} + s(h-\tilde{h}), v_k)\begin{bmatrix} h-\tilde{h} \\ 0 \end{bmatrix} ds \\ &= \tilde{g}_{2k} + \tilde{g}_{21k}(h-\tilde{h}) + \int_0^1 \left[g_{21}(\tilde{h}+s(h-\tilde{h}), v_k) - \tilde{g}_{21k}\right](h-\tilde{h})ds. \end{aligned} \tag{5.9}$$

Similarly, for g_1,

$$\begin{aligned} 0 = g_{1k} &= \tilde{g}_{1k} + \tilde{g}_{11k}(h-\tilde{h}) \\ &\quad + \int_0^1 \left[g_{11}(\tilde{h}+s(h-\tilde{h}), v_k) - \tilde{g}_{11k}\right](h-\tilde{h})ds. \end{aligned} \tag{5.10}$$

We derive an expression for g_{2k} by solving for $h-\tilde{h}$ in the second term of (5.10) and substituting into (5.9). The expression is given by

$$\begin{aligned} g_{2k} &= \tilde{g}_{2k} - \tilde{g}_{21k}\tilde{g}_{11k}^{-1}\tilde{g}_{1k} \\ &\quad - \tilde{g}_{21k}\tilde{g}_{11k}^{-1}\int_0^1 \left[g_{11}(\tilde{h}+s(h-\tilde{h}), v_k) - \tilde{g}_{11k}\right](h-\tilde{h})ds \\ &\quad + \int_0^1 \left[g_{21}(\tilde{h}+s(h-\tilde{h}), v_k) - \tilde{g}_{21k}\right](h-\tilde{h})ds. \end{aligned} \tag{5.11}$$

Inequality (5.4) is determined by substituting (5.8) and (5.11) into (5.5) and applying the triangle inequality. □

PROPOSITION 5.2. *Under the assumptions of Theorem* 4.2, *the* α_k *of Lemma* 5.1 *satisfies*

$$\begin{aligned} \alpha_k\|g_{2k}\| &\le k_2(1+k_5k_3)^2c\|\tilde{g}_{1k}\|\|\Delta v_k\| \\ &\quad + \frac{k_3+k_5k_3^2}{2}c^2\|\tilde{g}_{1k}\|^2 + (1+k_3k_5)\|r_k\|, \end{aligned} \tag{5.12}$$

where $c = \frac{M}{1-\theta}$.

We preface the proof with a few remarks. Previously we noted the existence of $\tilde{g}_{ijk}$ and the nonsingularity of $\tilde{g}_{11k}$. The assumptions allow us to actually bound these quantities. That is, $\|\tilde{g}_{ijk}\| \le k_3, i, j = 1, 2$, and $\|\tilde{g}_{11k}^{-1}\| \le k_5$. Note also that

$$(\tilde{h}(v_k) + t_k\Delta u_k, v_k + t_k\Delta v_k) \in S_1(g) \subset S_0(g_1). \tag{5.13}$$

Thus we may use Δu_k to generate a starting guess for the solution of $g_1(u, v_k + t_k\Delta v_k)$. The algorithmic implication of this point is that in the regime of quadratic convergence of (the whole) g, NlEm need not do a solve of the g_1 equations; they will already be small enough. Finally, note that

$$(h(v_k), v_k), (\tilde{h}(v_k), v_k) \in S_0(g_1); \tag{5.14}$$

thus

$$(\tilde{h}(v_k) + s(h(v_k) - \tilde{h}(v_k)), v_k) \in S_1(g_1) \tag{5.15}$$

for $0 \le s \le 1$ and therefore the Lipschitz condition holds along the line segment.

Proof. The proof proceeds by bounding each of the terms of (5.4). Expanding norms and applying the Lipschitz condition to the first term in (5.4) yields

$$\|\tilde g_{21k}\tilde g_{11k}^{-1}\int_0^1\Big[g_{11}(\tilde h+s(h-\tilde h),v_k)-\tilde g_{11k}\Big](h-\tilde h)ds\| \le k_5\frac{k_3^2}{2}\|h-\tilde h\|^2. \tag{5.16}$$

Similarly, the second term can also be bounded yielding

$$\left\|\int_0^1\Big[g_{21}(\tilde h+s(h-\tilde h),v_k)-\tilde g_{21k}\Big](h-\tilde h)ds\right\| \le \frac{k_3}{2}\|h-\tilde h\|^2. \tag{5.17}$$

Applying Proposition 3.7 and Property P1 to the third term of (5.4), we get

$$\|(g_{22k}-g_{21k}g_{11k}^{-1}g_{12k})-(\tilde g_{22k}-\tilde g_{21k}\tilde g_{11k}^{-1}\tilde g_{12k})\| \le k_2(1+k_5k_3)^2\|h-\tilde h\|. \tag{5.18}$$

The fourth term is bounded by applying Properties P1 and P2 to note that

$$\|r_{2k}-\tilde g_{21k}\tilde g_{11k}^{-1}r_{1k}\| \le \|L^{-1}\|\|r_k\|, \tag{5.19}$$

where

$$L=\begin{bmatrix} I & 0\\ \tilde g_{21k}\tilde g_{11k}^{-1} & I\end{bmatrix}. \tag{5.20}$$

Thus

$$\|r_{2k}-\tilde g_{21k}\tilde g_{11k}^{-1}r_{1k}\| \le (1+k_3k_5)\|r_k\|. \tag{5.21}$$

Collecting (5.16) - (5.21) gives

$$\begin{aligned}\alpha_k\|g_{2k}\| &\le k_2(1+k_5k_3)^2\|h-\tilde h\|\|\Delta v_k\|\\ &\quad+\frac{k_3+k_5k_3^2}{2}\|h-\tilde h\|^2+(1+k_3k_5)\|r_k\|.\end{aligned} \tag{5.22}$$

Since $h(v_k)$ is the root of the equation $g_1(u,v_k)$ with v_k fixed and the assumptions assure that GAN converges from $\tilde h(v_k)$, we may apply Proposition 3.3 to conclude that

$$\|h-\tilde h\| \le c\|\tilde g_{1k}\|. \tag{5.23}$$

Substituting (5.23) into (5.22) gives the desired result. □

5.2. Convergence theorems. We continue by giving conditions for bounding the terms of α_k in (5.12). Two theorems are presented. The first theorem gives the conditions under which higher-order convergence can be expected; however, the result is existential. It is not possible to verify the conditions computationally. The second theorem gives a method for testing the size of α_k computationally.

THEOREM 5.3. *Under the assumptions of Proposition* 5.2, *if conditions*
C1: $\|g_1(\tilde h(v_k),v_k)\| \le \|g_2(h(v_k),v_k)\|$, *and*
C2: $\|r_k\| \le \|g_2(h(v_k),v_k)\|^{(1+p)}$
hold, then

$$\begin{aligned}\alpha_k\|g_{2k}\| &\le (1+k_3k_5)\|g_{2k}\|^{1+p}\\ &\quad+\left(2k_1k_2(1+k_5k_3)^2c_1+\frac{k_3+k_5k_3^2}{2}c_1\right)\|\tilde g_{2k}\|^2,\end{aligned} \tag{5.24}$$

where

$$\|\tilde{g}_{2k}\| \le (1 + k_5 c_1)\|g_{2k}\| + \frac{k_3}{2} c_1^2 \|g_{2k}\|^2. \tag{5.25}$$

Proof. The theorem follows from Proposition 5.2 by bounding the quantities $\|\tilde{g}_{1k}\|$, $\|\Delta v_k\|$, and $\|\tilde{g}_{2k}\|$. The bound for $\|\tilde{g}_{1k}\|$ is given by condition C1.

By Assumption A2 we know that

$$\left\| \begin{bmatrix} \Delta u_k \\ \Delta v_k \end{bmatrix} \right\| \le k_1 \|\tilde{g}_k\|. \tag{5.26}$$

Applying Properties P1 and P2 and condition C1 it follows that

$$\|\Delta v_k\| \le k_1(\|\tilde{g}_{1k}\| + \|\tilde{g}_{2k}\|) \le 2k_1 \|\tilde{g}_{2k}\|. \tag{5.27}$$

All that remains is to bound $\|\tilde{g}_{2k}\|$. We apply the mean value theorem to give

$$\tilde{g}_{2k} = g_{2k} + \int_0^1 g_2'(h + s(\tilde{h} - h), v_k) \begin{bmatrix} \tilde{h} - h \\ 0 \end{bmatrix} ds. \tag{5.28}$$

Following the methodology that led to inequality (5.17) and applying the triangle inequality and (5.23) gives

$$\|\tilde{g}_{2k}\| \le \|g_{2k}\| + k_5 c_1 \|\tilde{g}_{1k}\| + \frac{k_3}{2} c_1^2 \|\tilde{g}_{1k}\|. \tag{5.29}$$

Finally, applying condition C1 yields the inequality (5.25). □

Neither condition C1 nor C2 are verifiable. The following theorem gives conditions that are verifiable.

THEOREM 5.4. *Under the assumptions of Proposition* 5.2, *if conditions*

C1a: *the g_1 equation is solved for $\tilde{h}(v_k)$ so that $\|g_1(\tilde{h}(v_k), v_k)\| \le \|g_2(\tilde{h}(v_k), v_k)\|$, and*

C2a: $\|r_k\| \le \|g_2(\tilde{h}(v_k), v_k)\|^{(1+p)}$

hold, then

$$\begin{aligned} \alpha_k \|g_{2k}\| &\le (1 + k_3 k_5)\|\tilde{g}_{2k}\|^{1+p} \\ &\quad + \left(2k_1 k_2 (1 + k_5 k_3)^2 c_1 + \frac{k_3 + k_5 k_3^2}{2} c_1\right) \|\tilde{g}_{2k}\|^2. \end{aligned} \tag{5.30}$$

The proof of Theorem 5.4 follows directly from the proof of Theorem 5.3. The intention of Theorem 5.4 is twofold. First, if $\|\tilde{g}_{2k}\|$ is small enough, then at the very least $\alpha_k < 1$ and, therefore, the method is converging (cf. Proposition 3.1). Second, in the limit when $\|r_k\| \le \|\tilde{g}_{2k}\|^2$, quadratic convergence is attained.

Note that in the statement of Theorem 5.4 we write that g_1 should be solved so that $\|g_1(\tilde{h}(v_k), v_k)\| < \|g_2(\tilde{h}(v_k), v_k)\|$. Unfortunately, this inequality can only be checked after a function evaluation is done to determine $g_2(\tilde{h}(v_k), v_k)$. To avoid having to recompute g_2 every time a new $\tilde{h}(v_k)$ is generated, i.e., after every iteration of GAN on the g_1 system, we suggest that g_1 be solved so that $\|g_1(\tilde{h}(v_k), v_k)\| < \|g_2(\tilde{h}(v_{k-1}), v_{k-1})\|^2$.

COROLLARY 5.5. *Under the conditions of Theorem* 5.4, *with $p = 1$, if* C1a *is replaced with*

$$\|g_1(\tilde{h}(v_k), v_k)\| = O(\|g_2(\tilde{h}(v_{k-1}), v_{k-1})\|^2), \tag{5.31}$$

then when $\|g_2(\tilde{h}(v_{k-1}), v_{k-1})\|$ *is sufficiently small, i.e., close enough to the root, the convergence of the method is quadratic.*

Proof. The proof follows from Theorem 3.2 with the observation that sufficiently close to the root

$$\|g_2(\tilde{h}(v_k), v_k)\| = O(\|g_2(\tilde{h}(v_{k-1}), v_{k-1})\|^2), \tag{5.32}$$

and therefore condition C1 holds. □

5.3. Accuracy requirement for g_1 system. As pointed out in §2, inaccuracies in computing f_k cause a practical problem in the solution process. Even if the seemingly fortuitous inequality

$$\|g_2(\tilde{h}(v_k), v_k)\| < \|f(v_k)\| \tag{5.33}$$

holds, there might not be any t_k such that

$$\|g_2(\tilde{h}(v_{k+1}), v_{k+1})\| < \|g_2(\tilde{h}(v_k), v_k)\|. \tag{5.34}$$

Algorithmically, failure to satisfy equation (5.34) for a given choice of t_k leads to two options. The first is to keep trying smaller t_k's. The second is to go back to the previous iteration because the g_1 system was not solved accurately at that point. This section gives an approximate formula for determining whether $\|\tilde{g}_{1k}\|$ is close enough to zero to make $\|\tilde{g}_{2k+1}\| < \|\tilde{g}_{2k}\|$ a possibility. Satisfying this formula will give the user confidence that a norm reduction will eventually occur for t_k small enough.

PROPOSITION 5.6. *Recall* $f_k \equiv g_2(h(v_k), v_k)$. *Define* $\tilde{f}_k$ *to be an approximation of* f_k. *Let*

$$\|\tilde{f}_k - f_k\| \le \delta_k \|f_k\|. \tag{5.35}$$

If $0 < \delta_k,\ \delta_{k+1} < 1$, *and* $\|\tilde{f}_{k+1}\| \le \mu_1 \|\tilde{f}_k\|$, $\mu_1 < 1$, *then*

$$\|f_{k+1}\| \le \mu_2 \|f_k\|, \tag{5.36}$$

where

$$\mu_2 \|f_k\| \equiv \mu_1 \frac{(1+\delta_k)}{1-\delta_{k+1}} \|f_k\|. \tag{5.37}$$

Proof. We have

$$\begin{aligned} \|\tilde{f}_{k+1}\| &\le \mu_1 \|\tilde{f}_k\| \\ &\le \mu_1 \|\tilde{f}_k - f_k\| + \mu_1 \|f_k\| \\ &\le \mu_1 \delta_k \|f_k\| + \mu_1 \|f_k\| = (1+\delta_k)\mu_1 \|f_k\|; \end{aligned} \tag{5.38}$$

adding $\|\tilde{f}_{k+1} - f_{k+1}\|$ to both sides gives

$$\begin{aligned} \|\tilde{f}_{k+1} - f_{k+1}\| + \|\tilde{f}_{k+1}\| &\le (1+\delta_k)\mu_1 \|f_k\| + \|\tilde{f}_{k+1} - f_{k+1}\| \\ \|f_{k+1}\| &\le (1+\delta_k)\mu_1 \|f_k\| + \delta_{k+1} \|f_{k+1}\|; \end{aligned} \tag{5.39}$$

solving for $\|f_{k+1}\|$ gives

$$\|f_{k+1}\| \le \mu_1 \frac{(1+\delta_k)}{1-\delta_{k+1}} \|f_k\|. \quad \square \tag{5.40}$$

FIG. 5. *A detailed view of the NlEm algorithm.*

For our purposes we will assume that there is some μ_2 we wish to achieve. We compute a candidate $\tilde{f}_{k+1}$, yielding a μ_1. We are then able to determine if μ_2 is achievable. Recall from (5.11) and subsequent analysis that

$$\|\tilde{g}_{2k} - g_{2k}\| \le C\|h - \tilde{h}\|^2 + \|\tilde{g}_{21k}\tilde{g}_{11k}^{-1}\tilde{g}_{1k}\|. \tag{5.41}$$

An estimate for δ_k can be obtained by dropping the $C\|h - \tilde{h}\|^2$ term. Hence

$$\delta_k \cong \frac{\|\tilde{g}_{21k}\tilde{g}_{11k}^{-1}\tilde{g}_{1k}\|}{\|\tilde{g}_{2k} - \tilde{g}_{21k}\tilde{g}_{11k}^{-1}\tilde{g}_{1k}\|}, \tag{5.42}$$

where the denominator is an $O(\|h - \tilde{h}\|^2)$ approximation for $g_2(h(v_k), v_k)$.

6. Implementation details. While the outline of NlEm given in §2 is sufficient for a programmer to generate a piece of code, we have noticed certain improvements that make the transition from NlEm back to GAN transparent. Thus, in this section we present a more detailed algorithm and address certain issues raised in §5.

The algorithm in Figure 5 is a recursive algorithm that allows NlEm to be performed on more than two levels; i.e., NlEm is used to solve the g_1 equations. One place we view this as a possibility is on a system of nonlinear PDEs. The g_1 equation at one level might be one or more of the PDEs, while the g_1 equation at the next level might be the equations associated with some of the grid points. While we believe this to be a case where nested NlEM might be useful, we have not actually implemented NlEm for this problem.

Define by g^l the set of equations associated with level l. g^1 is the full set of equations. Define P^{l+1} to be a projector function that, when applied to the variables w^l (the variables associated with level l), returns w^{l+1}.

There are several interesting points about this routine.

1. If g^2 consists of no equations then the code above is GAN.
2. Notice that after computing x_k^l, all of $\hat{u}_{k+1}^l$ is updated. When the answer is close enough to the root that GAN is in the regime of quadratic convergence, the call

to NlEm at the next step will (if the tol_k is chosen reasonably) return doing no computation. Thus, the transition from NlEm back to GAN is achieved with just the cost of an extra function call.

3. We make tol_k smaller and MAX_k bigger as t_k decreases. As pointed out in §5 there is a problem with determining whether norm reduction fails because t_k has not been made small enough, or if the g_1 equations were not solved accurately enough at the previous level. While solving the g_1 equations more accurately at this level does not help the problem of failure at the moment, we have more confidence that it will not be a problem on the next iteration.
4. The maximum number of NlEm iterations needs to be set carefully. MAX_{-1} should be set very high so that NlEm does not give up too early trying to solve them. On the other hand MAX_k should be set to a small level (increasing as t_k decreases). Long periods of time should not be spent trying to get solutions for t_k's when some smaller t_k will get an answer faster. We know that the answer can be found for some smaller t_k since the u from the previous iteration can be used if t_k is sufficiently close to 0.
5. It is sometimes the case that g^2 is not known before beginning. In that case g^2 would be calculated before the initial call to **NlEm**. It is important that g^2 not be changed after this. If for some reason the user does wish to dynamically change g^2, it is important to check that after the initial call to **NlEm** there has been a norm reduction. If this is not done, thrashing can occur and the code will not terminate.

7. Examples. In this section we give examples showing the performance of NlEm. The first two examples demonstrate how NlEm is used for a system of nonlinear equations arising from the discretization of an ODE. The first example shows that NlEm can improve performance on a problem where grid refinement might otherwise have been used. That is, the user would recognize that most of the action is taking place at some set of points and the rest of the domain is quiescent. Instead of gridding the domain differently, a fine uniform grid is used, and more computation is done on the points of interest. The cost of the algorithm is improved by five times. The second example shows how NlEm can be used to solve problems where too few grid points are used. When too few grid points are used, the steep valleys as seen in §2 sometimes occur. NlEm can be used on the "bad" grid points giving results where GAN fails. The third example is a simple 2-D semiconductor device. By eliminating two of the PDEs, we get convergence with an example that would not converge using GAN.

7.1. Elimination by grid 1. Consider the nonlinear boundary value problem given by

$$\begin{aligned} &-u'' + u^3 + \left(4\frac{(x-0.5)^2}{10^8} - 2\times 10^{-4}\right)u - 10^9 e^{-3(\frac{x-0.5}{0.01})^2} = 0, \\ &u(0) = 0, \quad u(1) = 0. \end{aligned} \tag{7.1}$$

This has the solution

$$u(x) = 10^3 e^{-(\frac{x-0.5}{0.01})^2}. \tag{7.2}$$

The action in this problem is around $x = 0.5$, where a large spike occurs.

We give a few details about this example using 100 discretized equations. An initial guess for $u_1 \ldots u_{100}$ is made. The g_1 system is the discretized equations 49-52. Using the initial guess for u_{48} and u_{53} as fixed values, the nonlinear subsystem g_1 is solved to a very high accuracy (e.g., 10^{-12} for the norm of the residual). Following this initial solve of the g_1 system, the main loop begins. The entire system g is evaluated at the new point; that is, $u_1 - u_{48}$ and $u_{53} - u_{100}$ are unchanged and $u_{49} - u_{52}$ have the values just computed. The

TABLE 1

Comparison of NlEm to GAN for example given in §7.1. *"Points" refers to the number of grid points in the domain. "its" refers to the number of iterations required. The grid points between LEFT and RIGHT are in* g_1.

Points	GAN time	GAN its	NlEm time	NlEm its	LEFT	RIGHT
100	0.15	10	0.03	5	48	53
500	1.47	10	0.17	5	240	261
1000	2.81	10	0.32	5	480	521
5000	10.7	10	1.66	5	2400	2601

Jacobian is computed and the Newton equations are solved, giving the update vector Δu. Then a damping parameter t is chosen, and $u_{48} + t\Delta u_{48}$ and $u_{53} + t\Delta u_{53}$ are computed. These are used as fixed values in the g_1 solve, as above, except that the accuracy of the solution is relaxed, to say $t * (\|g\|/\|g_i\|)^2$, where g_i is the residual at the initial guess. Although we used the damping parameter to control the accuracy, any function of t can be used that shows similar behavior; i.e., the accuracy requirement is increased for smaller t and is relaxed when t approaches 1. This ensures that as the regime of quadratic convergence is approached, few (if any) iterations of Newton's method on equations 49-52 are required. The main loop repeats when a damping parameter is chosen so that a norm reduction for the whole g has occurred following the g_1 solve.

In Table 1 we see that NlEm runs about five times faster than GAN. It is so much faster because in the first few iterations of GAN, very small values of the damping parameter are required. The very small damping parameters mean that the function must be evaluated many times. NlEm also has to use small values for the damping parameter for the g_1 equations, but performing a large number of function evaluations on four percent of the points is not very costly.

7.2. Elimination by grid 2. Consider the nonlinear boundary value problem given by

$$\begin{gathered} -u'' + \alpha(x)u' + u^3e^u + k(x) = 0, \\ u(0) = 0, \quad u(1) = 0, \\ \alpha(x) = 10^9 e^{-(\frac{x-0.5}{0.01})^2}\sqrt{|x-0.5|}, \quad k(x) = \begin{cases} -10^6 & x < 0.5, \\ 10^6 & x \geq 0.5, \end{cases} \end{gathered} \tag{7.3}$$

where u' is discretized using central differences. Fifty grid points were used on this problem; but because central differences were used, this was not enough grid points. Using the same code as in the previous example, the computed solution under these circumstances shows ringing around 0.5. GAN is unable to solve this problem. NlEm solves the problem in 17 iterations. Both methods solve the problem when more grid points are used.

7.3. Example from semiconductor device simulation. One of the areas in which we have been directing the application of this method is semiconductor device simulation [9]. NlEm was implemented in the semiconductor device simulator SIMUL [11]. In the example presented here, the equations take the form

$$-\nabla \cdot (\epsilon \nabla u) + n - p + N = 0, \tag{7.4}$$

$$-\nabla \cdot \mathbf{J}_n + R_n(n, p) = 0, \tag{7.5}$$

$$-\nabla \cdot \mathbf{J}_p + R_p(n, p) = 0, \tag{7.6}$$

where u, n, and p are functions in space (for the example we present here, $(x, y) \in \mathbb{R}^2$), ϵ and N are spatially related constants, J_n and J_p are electron and hole current densities, and R_n and R_p are recombination terms.

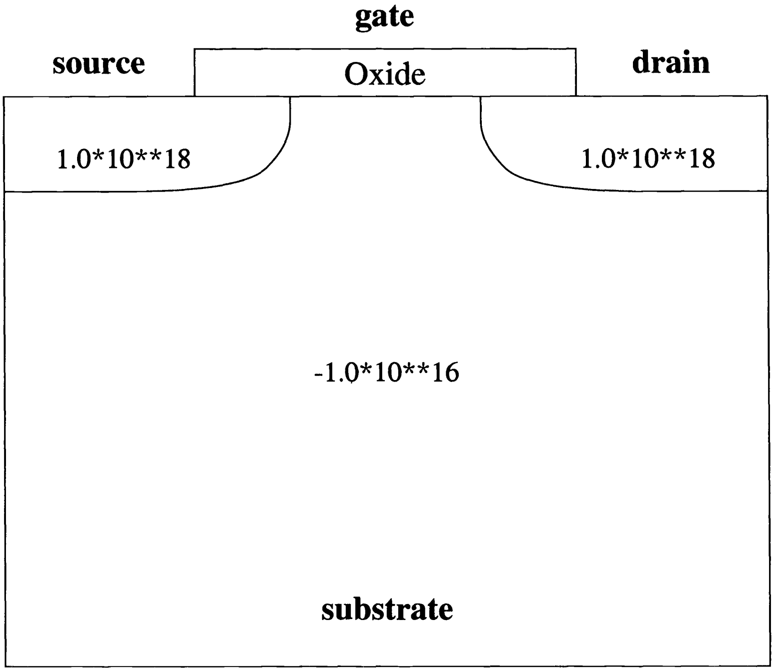

FIG. 6. *NMOS transistor. The numbers represent the background dopings of the N and P regions.*

These steady state equations are usually solved using GAN. Under certain circumstances GAN fails to converge or converges too slowly. In these cases, other methods are employed to generate a good initial guess so that GAN converges well. These methods include nonlinear Gauss-Seidel and continuation in the boundary conditions. In nonlinear Gauss-Seidel each equation is solved in turn using the most recent values for the other variables as constants. Sometimes nonlinear Gauss-Seidel also fails in which case continuation in the voltage at the contacts is employed.

The example given in Figure 6 is an NMOS transistor. The voltages at the various contacts are source=0, gate=1, substrate=0, and drain=1 volts. The problem was originally solved using a combination of nonlinear Gauss-Seidel and continuation in 235 seconds. When the system is solved with NlEm, with the g_1 equations being the electron and hole continuity equations, the solution time is 36 seconds. Other choices for the g_1 equations did not perform as well. In the experience of the author of SIMUL, choosing electron and hole continuity equations to be g_1 works in many cases. We also point out that when the problem is easy, e.g., for drain voltage of 0.1 volts, NlEm takes longer than GAN. We reiterate that NlEm should be used in cases where GAN is having difficulties.

Acknowledgment. We are indebted to Stephan Müller for implementing NlEm in the semiconductor device simulation package SIMUL and for patiently helping the authors find an interesting example. We also thank Wolfgang Fichtner for allowing us to spend time with his student.

THREE-DIMENSIONAL STEADY FLOW IN A DIVIDING CHANNEL USING FINITE AND PSEUDOSPECTRAL DIFFERENCES*

ROLAND HUNT†

Abstract. A numerical solution for the flow of a steady incompressible fluid in a general symmetric three-dimensional bifurcation having uniform thickness is presented for Reynolds numbers up to 100. The physical region is divided into three subdomains, each of which is transformed onto a rectangular parallelepiped upon which the calculations are made. The Navier–Stokes equations are differenced using standard second-order differences in the direction of each tube and pseudospectral differences in the two transverse directions. The use of such differences in the transverse plane greatly reduces the number of nodes required for a given accuracy, and this particular mix of differences minimizes the CPU time requirement when Newton's method is used to solve the resulting algebraic system. Two bifurcations have been considered with daughter tubes angled to the main tube at 60° and 90°, respectively. By comparing results on different sized grids the estimated relative accuracy is typically of order 10^{-3}. The resulting flows display novel three-dimensional features not present in two-dimensional flows. In particular, as fluid passes from main to daughter tubes it twists in a fairly complex vortex-like fashion.

Key words. pseudospectral methods, three-dimensional flow

AMS subject classification. 65N35

1. Introduction.

In a previous paper [11] we presented the numerical solution of the steady incompressible flow in a three-dimensional tube having general specifiable boundaries using a judicious combination of finite and pseudospectral differences. The ensuing nonlinear system was solved using Newton's iteration. This blend of finite and pseudospectral differences meant that it was possible to obtain results of reasonable accuracy on a workstation.

The aim of that paper was first to examine the possibility of using such a mix of finite and pseudospectral differences. Along the tube second-order central finite differences are employed but in the two transverse directions pseudospectral differences are used (see [7] for an overview). For a given tolerance this particular mix of differences is optimal in the sense that it gives a minimum CPU requirement when Newton's method is employed to solve the resulting algebraic system which was the method adopted. The use of pseudospectral differences across the tube, rather than finite differences, greatly reduces the number of nodes required for a given accuracy which, in turn, greatly reduces the CPU requirement. Typically for an accuracy of 10^{-3}, the number of nodes required across the tube is 10 compared with 50 for finite differences which leads to an enormous saving of storage (typically 500) and CPU time (typically 10000). However, replacing finite differences by pseudospectral differences along the tube can considerably increase the CPU requirement. It was shown that using pseudospectral discretizations in all three directions can result in the CPU time being increased by as much as a factor of 60. This is because the Jacobian matrix employed in Newton's method, which is banded when pseudospectral differences are only used across the tube, now becomes full.

A second aim was the use and suitability of Newton's method for solving the algebraic system resulting from a three-dimensional flow problem. The use of Newton's iteration to provide a numerical solution for fluid flow problems was pioneered by Fornberg [3]-[6] and studied by the author [9], [10]. The advantage of using Newton's method is that it is second-order convergent. This means that provided a suitable starting iterate is available, which is not a difficulty for flow problems of this type, the iteration always converges and, furthermore, only requires three or four iterations for a tolerance of $\sim 10^{-6}$. This contrasts with traditional SOR methods in which, for large Reynolds number, some kind of additional artificial viscosity

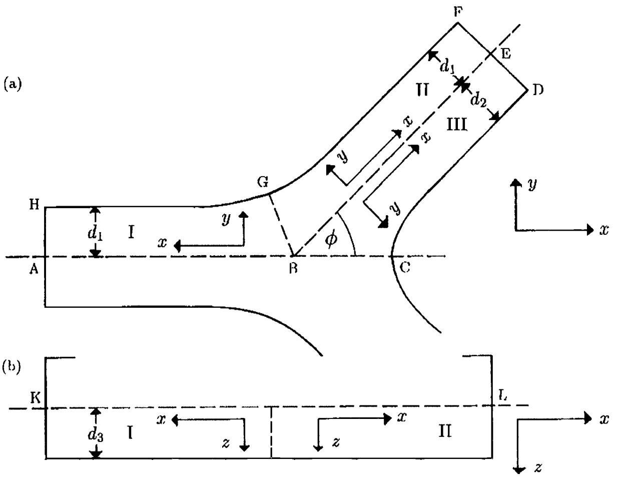

FIG. 1. *The geometry of the bifurcation showing* (a) *side view and* (b) *plan. The bifurcation is symmetric about AC and KL. The coordinates used for the three domains ABGH, BEFG, and BCDE are shown inside each domain. The physical coordinates are shown outside the domain.*

or upwinding is necessary, the introduction of which can seriously degrade the accuracy of the solution [4], [9]. The cost of each iteration in terms of CPU time is high but, because of the few iterations required, the total time is comparable with that needed by an SOR method for a two-dimensional flow and somewhat higher for three dimensions. A disadvantage of the method is that the Jacobian is so huge that it needs to be stored outside the memory of the computer; for example, on a hard disk. However, by transferring data in large batches the program can be made very efficient.

This study of the flow in a tube was a precursor to the study of the flow in a three-dimensional bifurcation in which three tubes are patched together. This is the subject of this paper. The motivation for such a study is the simulation of blood flow through an arterial bifurcation which is known to be a preferred site for atherosclerosis (see [12] for a review). The vast majority of numerical fluid flow calculations have two space dimensions and little has been done in three dimensions. A physical arterial bifurcation is three dimensional and it is known that the flow contains significant secondary circulations not present in a two-dimensional representation and hence the need for a full three-dimensional numerical study of the problem.

In this paper we present the numerical calculation of the three-dimensional, steady, incompressible flow in a symmetric bifurcation having constant thickness (Fig. 1). The bifurcation is divided into three domains labeled I, II, and III, and the flow in each domain is solved numerically in a similar manner as for the generalized tube. First each domain is mapped onto a rectangular parallelepiped having a rectilinear grid on which the governing equations are solved. Because the mapping is quite general the boundaries CD and FH can be specified arbitrarily. Second, as for the generalized tube, the derivatives of the governing equations are approximated by second-order central differences along the tube and by pseudospectral differences in the two transverse directions. And, finally, the resulting nonlinear system of equations is solved using Newton's method.

2. The governing equations, their transformation and differencing. The equations governing the flow of an incompressible fluid are given by the Navier–Stokes equations. In a steady state these are

(2.1a) $$\nabla.\mathbf{u} = 0,$$

(2.1b) $$(\mathbf{u}.\nabla)\mathbf{u} + \frac{1}{\rho}\nabla p = \nu\nabla^2\mathbf{u},$$

where (2.1a) is the continuity constraint and (2.1b) the momentum balance. The symbols ρ, $\mathbf{u}$, p, and ν are the density, velocity, pressure, and kinematic velocity, respectively. If U and L are representative of the central velocity and typical "width" of a tube then we nondimensionalize the equations using

(2.2) $$\mathbf{u} = U\mathbf{u}' \qquad p = \frac{\rho U^2}{R}p'$$

to give

(2.3a) $$\nabla.\mathbf{u} = 0,$$

(2.3b) $$R(\mathbf{u}.\nabla)\mathbf{u} + \nabla p = \nabla^2\mathbf{u},$$

where the dashes have been dropped for clarity and $R = UL/\nu$ is the Reynolds number. The pressure has been nondimensionalized in this manner so that setting $R = 0$ in (2.3b) gives the Stokes equation.

To solve equations (2.3), each domain (I, II, or III) is first transformed onto a rectangular parallelepiped such that the original boundary is transformed onto a boundary of the parallelepiped. We will use (x, y, z) or (x^1, x^2, x^3), as shown in Fig. 1, to denote the original coordinates and (ξ, η, ζ) or (ξ^1, ξ^2, ξ^3) as the coordinates in transform space. Similarly the velocity components in the (x, y, z) directions will be denoted by (u, v, w) or (u^1, u^2, u^3). Then equations (2.3) are

(2.4a) $$\frac{\partial u^J}{\partial x^J} = 0,$$

(2.4b) $$Ru^J\frac{\partial u^I}{\partial x^J} + \frac{\partial p}{\partial x^I} = \frac{\partial^2 u^I}{\partial x^J \partial x^J},$$

where $I = 1, 2, 3$ and repeated superscripts are summed from 1 to 3. The transformed equations then are

(2.5a) $$\frac{\partial \xi^K}{\partial x^J}\frac{\partial u^J}{\partial \xi^K} = 0,$$

(2.5b) $$Ru^J\frac{\partial \xi^K}{\partial x^J}\frac{\partial u^I}{\partial \xi^K} + \frac{\partial \xi^K}{\partial x^I}\frac{\partial p}{\partial \xi^K} = \frac{\partial \xi^K}{\partial x^J}\frac{\partial \xi^L}{\partial x^J}\frac{\partial^2 u^I}{\partial \xi^K \partial \xi^L} + \frac{\partial^2 \xi^K}{\partial x^J \partial x^J}\frac{\partial u^I}{\partial \xi^K}.$$

The transformations used in this paper are expressed algebraically and the terms $\partial\xi^K/\partial x^J$ and $\partial^2\xi^K/\partial x^J\partial x^J$ were determined using the symbolic algebraic package Maple [2]. The terms $\partial u^I/\partial x^K$ and $\partial^2 u^I/\partial x^K \partial x^K$ are approximated using difference formulae.

The grid employed in transform space is shown in Fig. 2. In the ξ direction the spacing $\Delta\xi$ is uniform and the transformation is chosen such that $\Delta\xi = 1$. We will assume, without loss of generality, that η has domain $0 \le \eta \le 1$ and choose the Gauss-Lobatto collocation points as nodal values; that is

(2.6) $$\eta_j = \frac{1}{2}\left(1 - \cos\frac{\pi j}{n}\right), \qquad j = 0, 1, \ldots, n$$

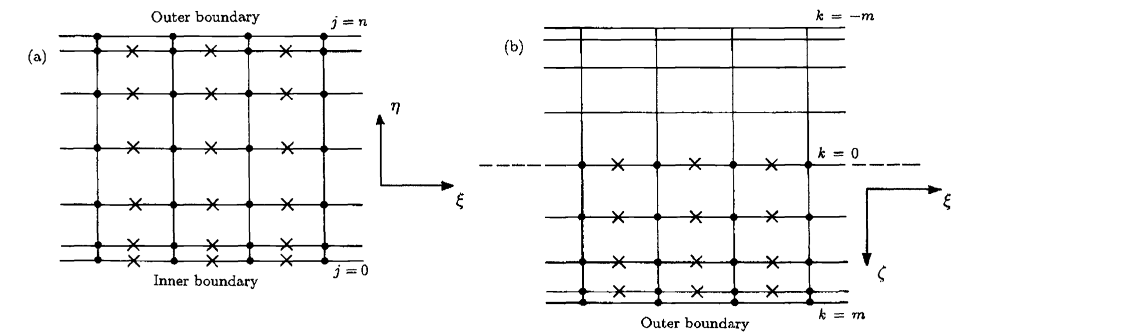

FIG. 2. *Sections of the grid in* (a) *the ξ-η planes and* (b) *the ξ-ζ planes showing the position of the velocity nodes (filled circles) and pressure nodes (crosses). In* (b) *the dashed line shows the axis of symmetry.*

for a specified integer n. Similarly the domain for ζ is $0 \le \zeta \le 1$ but, in order to take full advantage of the symmetry about $\zeta = 0$, we will use the Gauss-Lobatto points on $-1 \le \zeta \le 1$; namely,

$$\zeta_k = \sin\frac{\pi k}{m}, \qquad k = 0, 1, \ldots, m \tag{2.7}$$

for which we regard $k = -m, -m+1, \ldots, -1$ as auxiliary fictitious nodes. These will enable us to have difference formulae of optimum accuracy in the ζ direction.

On the grid the velocity components u^I are associated with integer points (i, j, k), $0 \le i \le l + 1$, $0 \le j \le n$, $0 \le k \le m$, and the pressure p with points $(i + \frac{1}{2}, j, k)$, $0 \le i \le l$, $1 \le j \le n - 1$, $1 \le k \le m - 1$ where i denotes the integer collocation points in the ξ direction. For fluid flows there is no physical boundary condition for the pressure similar to the no-slip condition for the velocity, although one can be derived from the Navier–Stokes equations. This poses considerable numerical difficulties, first, in setting up a complete set of algebraic equations and, second, in obtaining a stable solution due to the presence of several spurious pressure modes [1]. Both of these problems can be overcome by simply not using the pressure collocation points on the boundary ($j = n$ or $k = m$) and using an interpolant of one degree less in the η and ζ directions. This avoids the need to supply a pressure boundary condition and there will be no spurious pressure modes since there no longer exists a nonconstant pressure solution which vanishes at all interior collocation points. In fact an attempt to include boundary pressure points resulted in a highly oscillatory saw-tooth solution which clearly shows the presence of unstable modes. Another possibility which would have a similar effect would be to use a staggered grid for the pressure similar to that originally proposed by Harlow and Welch in their "marker and cell" method [8]. This would be more difficult to program without any obvious advantage. However, we use half-integer points for the pressure in the i-direction since this gives a more accurate difference formula for the first derivative in ξ direction.

The derivatives of u^I in the ξ direction are approximated by second-order central differences which about the point (i, j, k) are

$$\frac{\partial u^I}{\partial \xi} \simeq G_1^I \equiv \frac{1}{2}\left(u^I_{i+1,j,k} - u^I_{i-1,j,k}\right), \quad \frac{\partial^2 u^I}{\partial \xi^2} \simeq H^I_{1,1} \equiv u^I_{i+1,j,k} - 2u^I_{i,j,k} + u^I_{i-1,j,k}, \tag{2.8}$$

and in the η direction by pseudospectral differences given by

$$\frac{\partial u^I}{\partial \eta} \simeq G_2^I \equiv \sum_{jj=0}^{n} D^n_{j,jj} u^I_{i,jj,k}, \qquad \frac{\partial^2 u^I}{\partial \eta^2} \simeq H^I_{2,2} \equiv \sum_{jj=0}^{n} E^n_{j,jj} u^I_{i,jj,k} \tag{2.9}$$

where $D^n_{j,jj}$ and $E^n_{j,jj}$ are the first- and second-derivative pseudospectral collocation matrices using the points (2.6). In the ζ direction using all the fictitious nodes we have

$$\frac{\partial u^I}{\partial \zeta} \simeq \sum_{kk=-m}^{m} D^{2m}_{k,kk} u^I_{i,j,kk}. \tag{2.10}$$

Noting that $u^I_{i,j,k}$ is symmetric for $I = 1, 2$ and antisymmetric for $I = 3$ we have

$$\frac{\partial u^I}{\partial \zeta} \simeq G^I_3 \equiv \sum_{kk=-0}^{m}{}' \left(D^{2m}_{k,kk} \pm D^{2m}_{k,2m-kk}\right) u^I_{i,j,kk} \tag{2.11}$$

where "+" is used for $I = 1, 2$ and "−" for $I = 3$ and $\sum'$ denotes a summation whose first term is halved. Similarly,

$$\frac{\partial^2 u^I}{\partial \zeta^2} \simeq H^I_{3,3} \equiv \sum_{kk=-0}^{m}{}' \left(E^{2m}_{k,kk} \pm E^{2m}_{k,2m-kk}\right) u^I_{i,j,kk}. \tag{2.12}$$

The second-order mixed derivatives are obtained by applying the appropriate first derivatives twice and are

$$\frac{\partial^2 u^I}{\partial \xi \partial \eta} \simeq H^I_{1,2} \equiv \frac{1}{2} \sum_{jj=0}^{n} D^n_{j,jj} \left(u^I_{i+1,jj,k} - u^I_{i-1,jj,k}\right), \tag{2.13a}$$

$$\frac{\partial^2 u^I}{\partial \xi \partial \zeta} \simeq H^I_{1,3} \equiv \frac{1}{2} \sum_{kk=-0}^{m}{}' \left(D^{2m}_{k,kk} \pm D^{2m}_{k,2m-kk}\right) \left(u^I_{i+1,jj,k} - u^I_{i-1,jj,k}\right), \tag{2.13b}$$

$$\frac{\partial^2 u^I}{\partial \eta \partial \zeta} \simeq H^I_{2,3} \equiv \frac{1}{2} \sum_{jj=0}^{n} \sum_{kk=-0}^{m}{}' D^n_{j,jj} \left(D^{2m}_{k,kk} \pm D^{2m}_{k,2m-kk}\right) u^I_{i+1,jj,kk}. \tag{2.13c}$$

For the pressure we have

$$\frac{\partial p}{\partial \xi} \simeq P_1 \equiv p_{i+\frac{1}{2},j,k} - p_{i-\frac{1}{2},j,k}, \tag{2.14a}$$

$$\frac{\partial p}{\partial \eta} \simeq P_2 \equiv \frac{1}{2} \sum_{jj=0}^{n-1} F^{n-1}_{j,jj} \left(p_{i+\frac{1}{2},jj,k} + p_{i-\frac{1}{2},jj,k}\right), \tag{2.14b}$$

$$\frac{\partial p}{\partial \zeta} \simeq P_3 \equiv \frac{1}{2} \sum_{kk=0}^{m-1}{}' \left(F^{2m-2}_{k,kk} + F^{2m-2}_{k,2m-kk}\right) \left(p_{i+\frac{1}{2},j,kk} + p_{i-\frac{1}{2},j,kk}\right), \tag{2.14c}$$

where $F^{n-1}_{j,jj}$ is the first-derivative collocation matrix using the points (2.6) excluding $j = n$ since there is no pressure collocation point on the boundary. Because p is not defined at integer points in the ξ direction, it has been represented by the average of its two nearest neighbors. Substituting equations (2.7)-(2.14) into (2.5b) we obtain the difference equations for the momentum balance at each interior node as

$$\left(Ru^J - \frac{\partial^2 \xi^K}{\partial x^J x^J}\right) G^I_K + P_K \frac{\partial \xi^K}{\partial x^I} - H^I_{K,L} \frac{\partial \xi^K}{\partial x^J} \frac{\partial \xi^L}{\partial x^J} = 0 \tag{2.15}$$

where u^I and the derivatives of ξ^K are evaluated at i, j, k and the repeated suffices J and K are summed from 1 to 3.

The continuity equation (2.5a) is to be satisfied at the pressure collocation points. Hence the derivatives at $(i+\frac{1}{2}, j, k)$ are approximated by

$$\frac{\partial u^I}{\partial \xi} \simeq u^I_{i+1,j,k} - u^I_{i,j,k}, \tag{2.16a}$$

$$\frac{\partial u^I}{\partial \eta} \simeq \frac{1}{2}\sum_{jj=0}^{n} D^n_{j,jj}\left(u^I_{i+1,jj,k} + u^I_{i,jj,k}\right), \tag{2.16b}$$

$$\frac{\partial u^I}{\partial \zeta} \simeq \frac{1}{2}\sum_{kk=0}^{m}{}' \left(D^{2m}_{k,kk} + D^{2m}_{k,2m-kk}\right)\left(u^I_{i+1,j,kk} + u^I_{i,j,kk}\right). \tag{2.16c}$$

Substituting into (2.5a) gives

$$\begin{aligned}&\left(u^J_{i+1,j,k} - u^J_{i,j,k}\right)\frac{\partial \xi}{\partial x^J} + \frac{1}{2}\sum_{jj=0}^{n} D^n_{j,jj}\left(u^J_{i+1,jj,k} + u^J_{i,jj,k}\right)\frac{\partial \eta}{\partial x^J}\\ &+\frac{1}{2}\sum_{kk=0}^{m}{}' \left(D^{2m}_{k,kk} + D^{2m}_{k,2m-kk}\right)\left(u^J_{i+1,j,kk} + u^J_{i,j,kk}\right)\frac{\partial \zeta}{\partial x^J} = 0\end{aligned} \tag{2.17}$$

where the repeated superscript J is summed from 1 to 3. The discretized equations (2.15) and (2.17) are applied to the interior points of each grid. In order to complete the system of equations we now consider the boundary conditions.

3. Boundary conditions. Referring to Fig. 1 the boundary conditions are as follows.

(i) CD and FGH. On these boundaries we have the no-slip condition $u^I = 0$; that is

$$u^I_{i,j,k} = 0. \tag{3.1}$$

(ii) AH and DEF. At the ends of the tubes we will suppose that the inlet and outlet pressures are prescribed; that is $p = P_s$ and $p = P_f$ on AH and DEF, respectively. For the numerical difference scheme to be closed we need to supply additional velocity boundary conditions. Assuming that far upstream and downstream the tube, and consequently the flow, is uniform we will impose velocity boundary conditions $\partial u/\partial x = 0$ and $v = w = 0$. Numerically these give

$$u^1_{0,j,k} - u^1_{1,j,k} = 0, \qquad u^1_{l+1,j,k} - u^1_{l,j,k} = 0, \tag{3.2a}$$

$$u^2_{0,j,k} = u^3_{0,j,k} = 0, \qquad u^2_{l+1,j,k} = u^3_{l+1,j,k} = 0, \tag{3.2b}$$

$$p_{l+\frac{1}{2},j,k} - P_s = 0, \qquad p_{l+\frac{1}{2},j,k} - P_f = 0. \tag{3.2c}$$

(iii) AB and BE. These are interior boundaries and hence require that the dependent variables should be continuous and have continuous normal derivatives. For BE this is

$$\left.\begin{aligned} g_2 &= g_3\\ \frac{\partial g_2}{\partial y_2} &= -\frac{\partial g_3}{\partial y_3}\end{aligned}\right\} g = u, w, p \qquad \begin{aligned} v_2 &= v_3\\ \frac{\partial v_2}{\partial y_2} &= -\frac{\partial v_3}{\partial y_3}\end{aligned} \tag{3.3}$$

where the suffixes 1, 2, and 3 refer to grids I, II, and III in Fig. 1. The y derivatives are calculated numerically at $j = 0$ using

$$\frac{\partial g}{\partial y} = \frac{\partial \xi}{\partial y}\frac{\partial g}{\partial \xi} + \frac{\partial \eta}{\partial y}\frac{\partial g}{\partial \eta} + \frac{\partial \zeta}{\partial y}\frac{\partial g}{\partial \zeta} \tag{3.4}$$

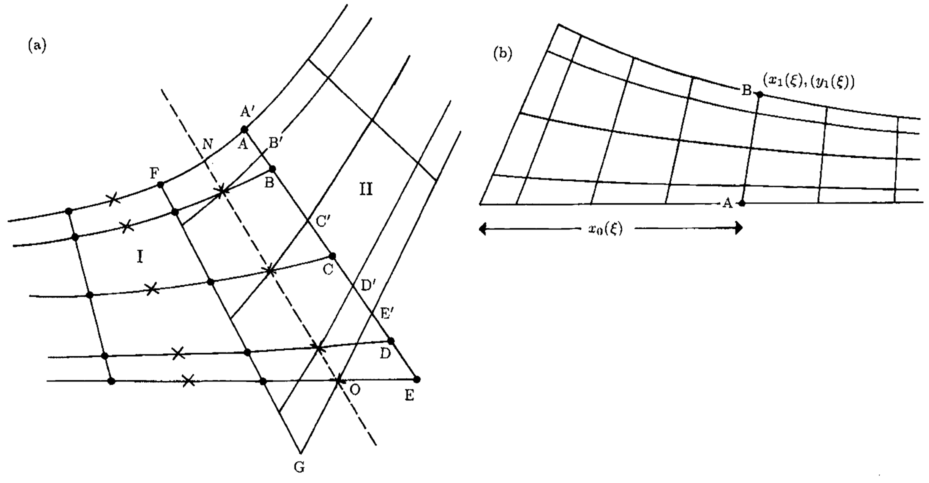

FIG. 3. (a): *The geometry of the overlap region between domains* I *and* II. (b): *The definition of* $x_0(\xi)$, $x_1(\xi)$, *and* $y_1(\xi)$ *illustrated.*

where $\partial\xi/\partial y$, $\partial\eta/\partial y$, and $\partial\zeta/\partial y$ are known algebraically and $\partial g/\partial\xi$, $\partial g/\partial\eta$, and $\partial g/\partial\zeta$ are approximated using formulae similar to (2.8), (2.9), and (2.11) except that the pressure p is centered at $i+\frac{1}{2}$ rather than i (i.e., replace i by $i+\frac{1}{2}$ in these equations).

The boundary conditions on AB are similar and, taking into account the symmetry about this line, give

$$\frac{\partial g_1}{\partial y_1}=0, \quad g=u,w,p, \qquad v_1=0. \tag{3.5}$$

(iv) BC and BG. The interior boundary BG is chosen to occur at the end pressure collocation points. In order to apply the discretized momentum balance equation near this boundary it is necessary to extend the grids by half a grid spacing so that grids I and II overlap as shown in Fig. 3(a) in which BG is now labeled ON. The values of u^I at A, B, C, D, and E (illustrated as $n=4$ in Fig. 3(a)) for grid I are obtained from the values of u^I at A′, B′, C′, D′, and E′ using interpolation. In order to preserve pseudospectral accuracy in the η direction, the interpolating polynomial is of degree m using all the nodal points $(1,j,k)$, $j=0,1,\dots,m$ for fixed k. The x and y coordinates for grids I and II do not coincide and hence the velocities on grid II calculated at positions A, B, C, D, and E need to be resolved in the directions of the velocities on grid I, using the formulae

$$\begin{aligned} u_1 &= -u_2\cos\phi + v_2\sin\phi,\\ v_1 &= u_2\sin\phi + v_2\cos\phi,\\ w_1 &= w_2. \end{aligned} \tag{3.6}$$

Similarly, boundary values along FG for grid II in Fig. 3(a) are obtained from grid I using interpolation. Finally, the boundary BG in Fig. 1 is treated in a similar way to that described for BC. The two grids involved, corresponding to grids I and II for BC, will be grid III and its reflection about BG.

4. Geometry of the bifurcation. The shape of the boundaries CD and FGH in Fig. 1, together with the parameters d_1, d_2, d_3, and ϕ, are arbitrary and, hence, user specifiable. To illustrate the numerical solution we suppose that the boundaries GH, FG, and CD for the three grids are given by

$$\sinh[b(y-d)]\sinh[b(y\cos\epsilon - x\cos\epsilon - d)] = \sinh^2(bh) \tag{4.1}$$

where $d = d_1$, $h = h_2$, and $\epsilon = \phi$ for grids I and II and $d = d_2$, $h = h_2$, and $\epsilon = \pi - 2\phi$ for grid III. This produces a curve which asymptotes exponentially quickly to the lines $y = d$ and $y\cos\epsilon - x\cos\epsilon = d$; that is, the inlet and output tubes are essentially uniform away from the bifurcation. The parameter b controls the rate at which the curve approaches the asymptote, and h controls the sharpness of the "corner" at the bifurcation.

The grid employed is specified by three functions $x_0(\xi)$, the distance from the origin along the center line, and $x_1(\xi)$ and $y_1(\xi)$ representing a point on the curve (Fig. 3(b)). Because the main changes in the flow occur near $x = 0$ we require a transformation in ξ which gives close grid spacings at small x and wider spacings at large x where the flow is essentially uniform. Hence a suitable choice of function for $x_0(\xi)$ is

$$x_0(\xi) = A\sinh[k(\xi - \tfrac{1}{2})] \tag{4.2}$$

where $\xi = 0, 1, \dots, l+1$ give the velocity collocation points and $\xi = \frac{1}{2}, \frac{3}{2}, \dots, l+\frac{1}{2}$ the pressure points. If x_s is the length of grid I, Δx_0 is the width of the spacing at $x = 0$, and l_0 is the number of grid spacings in grid I, then the parameters A and k are obtained iteratively from the equations

$$Ak = \Delta x_0, \qquad A\sinh(l_0 k) = -x_s. \tag{4.3}$$

If x_f is the minimum length of grids II and III then the number of grid spacings l in these grids is the smallest integer such that the lengths of the grids is at least x_f. The functions $x_1(\xi)$ and $y_1(\xi)$ are chosen such that AB in Fig. 3(b) meets the boundary curve at right angles, these being found numerically using Newton iteration. Hence, the transformation is

$$\begin{aligned} x &= \eta x_1(\xi) + (1-\eta)x_0(\xi), \\ y &= \eta y_1(\xi), \\ z &= d_3\zeta, \end{aligned} \tag{4.4}$$

from which the transformation functions $\partial\xi^K/\partial x^J$ and $\partial^2\xi^K/\partial x^J\partial x^J$ can be found. The algebra is formidable and consequently they were obtained using Maple. In this paper we consider two grids with (i) $\phi = 60°$ and (ii) $\phi = 90°$ having parameters

$$\begin{aligned} &x_s = 3 \quad x_f = 3 + \tfrac{1}{5}R, \quad \Delta x_0 = 0.5/l_0, \quad d_1 = d_2 = d_3 = 0.5, \quad b = 4, \\ &P_s = 15(x_s + x_f), \quad h_1 = 0.2, \quad \text{(i)} \quad h_2 = 0.2, \quad \text{or} \quad \text{(ii)} \quad h_2 = 0. \end{aligned} \tag{4.5}$$

The resulting grids for $l_0 = 20$ and $m = 8$ are shown in Fig. 4.

5. Newton's method and its implementation. Equations (2.9), (2.11), and (2.12) form a closed set for the unknowns $u^I_{i,j,k}$ and $p_{i+\frac{1}{2},j,k}$ which can be written as

$$\mathbf{f}(\mathbf{u}) = 0 \tag{5.1}$$

where $\mathbf{f}$ contains the right-hand sides of the equations and $\mathbf{u}$ the unknowns $u^I_{i,j,k}$ and $p_{i+\frac{1}{2},j,k}$. Equation (2.17) has been solved using Newton's method, which is

$$\mathbf{u}^{(s+1)} = \mathbf{u}^{(s)} + \Delta\mathbf{u}^{(s)}, \qquad s = 0, 1, \dots, \tag{5.2a}$$

$$J\Delta\mathbf{u}^{(s)} = -\mathbf{f}(\mathbf{u}^{(s)}) \tag{5.2b}$$

where J is the Jacobian $\partial\mathbf{f}/\partial\mathbf{u}$ evaluated with $\mathbf{u} = \mathbf{u}^{(s)}$.

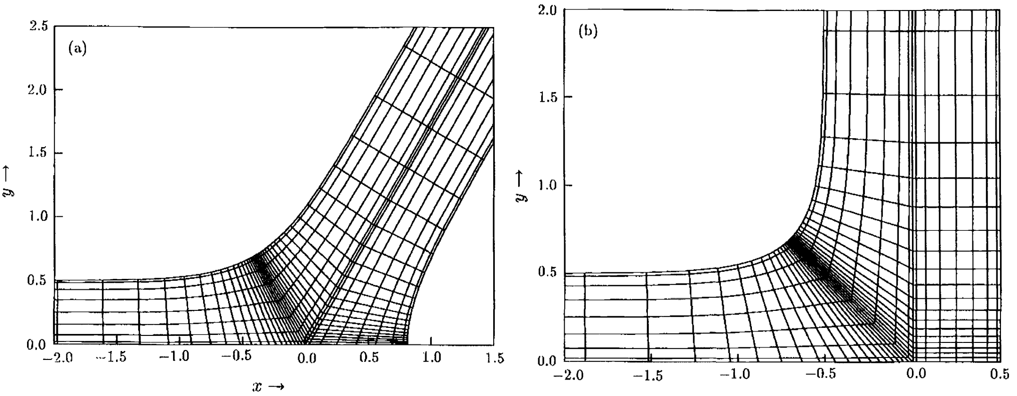

FIG. 4. *Section of the grid used in the x-y plane with* $l_0 = 20$ *and* $m = 8$ *for* (a) $\phi = 60°$ *and* (b) $\phi = 90°$.

The variables $u^l_{i,j,k}$ and $p_{i+\frac{1}{2},j,k}$ are ordered such that i is the "outermost loop" which varies the least. The order commences with the collocation points of grid I for $i = l_0 + 1, l_0 + \frac{1}{2}, l_0, \ldots, \frac{1}{2}, 0$ and the points of grids II and III are ordered together, that is, in parallel for $i = 0, \frac{1}{2}, 1, \ldots, l + \frac{1}{2}, l + 1$. This ordering causes the Jacobian J whose size $N \sim 4nm(l_0 + 2l)$ to be banded. The semibandwidth $W \sim 5nm$ for the elements resulting from the equations from grid I and $W \sim 9nm$ for grids II and III with a significant increase in width near the boundary of the two grids. Equation (5.2b) is solved using Gaussian elimination. The number of multiplications in reducing the Jacobian to triangular form $\sim W^2N$ and the storage requirement for the reduced matrix is $\sim 4WN$ bytes assuming four bytes per word. (The calculation is performed entirely in double precision, but it is sufficient to store the Jacobian on the hard disk in single precision.) For one of the cases depicted in the computer log (shown later), $l_0 = 60$, $l = 74$, $m = 14$, and $n = 7$ giving N as 83594, the maximum value for W as 1267 requiring 225.6 Mbytes for the reduced Jacobian. The reduction of the Jacobian to triangular form has been performed efficiently taking into account the "jaggedness" of the banding. The following were adopted:

(i) After each row of J is calculated, that row is immediately reduced using forward elimination and then transferred to the hard disk. This minimizes the number of disk transfers required and only the reduced Jacobian needs to be stored.

(ii) Transfers to the hard disk are done in large batches which take up less than 1 percent of the total CPU time.

(iii) The elimination process consists of three nested DO loops, with the inner loop being the most expensive. This inner loop is only performed when it makes nonzero changes, that is only for nonzero multipliers and then only up to the last nonzero element of the pivotal row.

(iv) Pivoting was not used except in the case of a zero pivot. It was found to be unnecessary (although it could be switched on if required) since pivoted and unpivoted reductions were essentially the same.

The implementation of the above resulted in a considerable reduction in the CPU time compared with the case when the "jaggedness" is not taken into account.

In order to test the validity of the code, a comparison with an analytical solution of equations (2.5) given by

$$\begin{aligned} u &= e^x \cosh y \cos \sqrt{2}z, \\ v &= e^x \sinh y \cos \sqrt{2}z, \\ w &= -\sqrt{2}e^x \cosh y \sin \sqrt{2}z, \\ p &= \tfrac{1}{2}Re^{2x}(\cos^2 \sqrt{2}z - \cosh^2 y) \end{aligned} \tag{5.3}$$

has been performed. The boundary conditions (3.1) and (3.2) are replaced by Dirichlet boundary conditions whose dependent variables are given by (5.3) and the interior discretizations (2.15) and (2.17) remain unchanged. The exact solution for the interior is then given by (5.3) and a comparison with numerical results can be made. Setting $R = 2$ gave results which demonstrated that the differenced equations (2.15) and (2.17), which form the most complex part of the program, are indeed correct.

In order to estimate the error in a particular set of results with, say, array parameters (l, m, n), three further sets of results were obtained to see the effect of altering l, m, and n in turn. To assess the effect of the choice of l on accuracy we compare the results with those obtained with half the number of grid points in the ξ direction, that is with parameters $(\frac{1}{2}l, m, n)$. Because central finite differences are used in the ξ direction, which are second order, we can estimate the error using the formula

$$\tfrac{1}{3}\left|q(l,n,m) - q(\tfrac{1}{2}l, n, m)\right| \tag{5.4}$$

where $q(l,n,m)$ and $q(\frac{1}{2}l, n, m)$ are two estimates for any variable q at a common location. For the pressure each grid location on the coarser grid coincides with a grid location on the fine grid. For the velocity, however, the points do not coincide and we use cubic interpolation to compare these values.

We can assess the effect of the choice of n and m on accuracy by obtaining results by varying these two parameters over a range of values. Numerical experimentation indicated that it is sufficient to alter these parameters by one in order to obtain a reasonable estimate of the accuracy. Hence, by obtaining results with parameters $(l, m-1, n)$ and $(l, m, n-1)$, the error due to changing each of these parameters in turn can be estimated by simple differences, that is

$$|q(l,n,m) - q(l,n-1,m)| \qquad \text{and} \qquad |q(l,n,m) - q(l,n-1,m)| \tag{5.5}$$

at a common location. Because the collocation points in the η and ζ directions do not coincide, we evaluate these differences by comparing the results at the collocation points on one grid with the interpolated solution from the other grid. Formula (5.4) estimates the error on the finer grid, but (5.5) estimates the error on the coarser and, hence, it is anticipated that the actual errors in the η and ζ directions will be significantly smaller than those given by (5.5).

To apply Newton's iteration we need a starting iterate $\mathbf{u}^{(0)}$ in (5.2). For this we choose the velocity $u^l_{i,j,k} = 0$ everywhere and $p_{i+\frac{1}{2},j,k}$ to vary linearly with x from P_s to P_f. For convergence to a specified tolerance (see later), typically four to six iterations are usually required depending on the value of R. However, for each case considered, four sets of results are obtained in order to estimate the accuracy. Hence once a set of results has been obtained an accurate starting value $\mathbf{u}^{(0)}$ is available by interpolating these results. Thus the number of iterations required in the last three runs is considerably reduced and typically two or three iterations is sufficient. Below are shown some elements of the computer log for the case $R = 20$ when $l_0 = 60$, $m = 14$, and $n = 7$.

$l_0 = 60, \quad l = 74, \quad m = 14, \quad n = 6.$
Jacobian: Size $= 71652$, semibandwidth $= 1086$, storage $= 165.8$ Mbytes.

Iteration	CPU	Error
1	4208	2.40 (+1)
2	4232	1.86 (+1)
3	4209	8.92 (−1)
4	4210	7.49 (−3)

Newton accuracy = 5.27 (−7)

$$l_0 = 60, \quad l = 74, \quad m = 14, \quad n = 7.$$

Jacobian: Size = 83594, semibandwidth = 1267, storage = 225.6 Mbytes.

Iteration	CPU	Error
1	6699	3.25 (−3)
2	6699	4.81(−6)

Newton accuracy = 1.05 (−11)

$$l_0 = 60, \quad l = 74, \quad m = 13, \quad n = 7.$$

Jacobian: Size = 77623, semibandwidth = 1176, storage = 194.2 Mbytes.

Iteration	CPU	Error
1	5354	1.40 (−3)
2	5345	4.16 (−6)

Newton accuracy = 3.69 (−11)

$$l_0 = 30, \quad l = 37, \quad m = 14, \quad n = 7.$$

Jacobian: Size = 42826, semibandwidth = 1267, storage = 114.8 Mbytes.

Iteration	CPU	Error
1	3339	1.02 (+0)
2	3338	7.24 (−3)

Newton accuracy = 3.62 (−7)

The order in which the runs have been made is chosen to reduce the CPU time as much as possible and the results (l, m, n), which take the most time per iteration, are performed second. The error recorded at each iteration is $E^{(s)} = \|\Delta\mathbf{u}^{(s)}\|_\infty$ which estimates the maximum absolute error in $\mathbf{u}^{(s)}$, that is, the previous iteration (see (5.2a)). Newton's iteration is theoretically second order and we have observed that as $E^{(s)} \to 0$ this is indeed the case to a reasonable degree of accuracy. Hence assuming that the iteration does perform as second order we can estimate the error in $\mathbf{u}^{(s+1)}$ using the formula $E_{\text{est}} = [E^{(s)}]^3/[E^{(s-1)}]^2$. The runs were terminated when either $E^{(s)} < 10^{-4}$ or $E_{\text{est}} < 10^{-6}$. In the log the item "Newton accuracy" is the value of E_{est} for the final iteration and shows that all the runs are accurate to at most 10^{-8}. Also in the log are details of the Jacobian, its size, bandwidth, and storage requirement.

It is possible to speed up the program using a quasi-Newton iteration technique in which Newton's method is applied for two or three iterations and subsequent iterations use the L and U factors from the last full iteration. This approach avoids the costly inversion of the matrix J at each iteration, and, although the iteration is now first order, the convergence is usually

rapid. As discussed in a previous paper [11] this technique was found to save significant CPU time after the initial few full iterations had been performed. Because, for each case, the last three runs only take two or three iterations to converge, the technique could only be applied to the first run which typically requires four to six iterations. For ease of programming, quasi-Newton was not used in these calculations.

The calculations were performed on a DEC Alpha. The 0.5 factor used in the formula for Δx_0 in (4.5) was chosen because numerical experimentation indicated that this gave the most accurate results. Also the values of l, m, and n employed (see next section) are the maximum values allowed by the limits of the machine. A typical run required 16–20 hours of CPU time and up to 300 Megabytes of disk space.

6. Results and discussion. Results have been obtained for $R = 0, 10, \ldots, 100$ using $l_0 = 60$, $m = 14$, and $n = 7$ for the case $\phi = 60°$ and $l_0 = 60$, $m = 12$ and $n = 8$ for the case $\phi = 90°$. Table 1 shows the central inlet velocity of the main tube and the central outlet velocity of the daughter tubes as obtained from the results for selected values of R. Also shown are the lengths of the daughter tubes used and the pressure P_s applied at the end of the main tube. The length of the main tube x_s is set at three and the pressure at the end of the daughter tubes is zero. Tables 2 and 3 list the maximum and average errors resulting from changing the values of l, m, and n in turn as given by equations (5.4) and (5.5) for the two cases of ϕ considered. The velocity error recorded is the absolute error (since the velocity is order unity throughout the flow), but the pressure error is relative to the average drop in pressure per unit distance, i.e., $(P_s - P_f)/(x_f + x_s)$. Average errors for the velocity are at most a few times 10^{-4} and for pressure a few times 10^{-3}, with maximum errors about a magnitude higher. As expected the errors increase as the Reynolds number increases.

The results for $\phi = 60°$ with $R = 50$ are shown in Fig. 5. The diagram traces the paths of streamlines showing them from four viewpoints, namely, side elevation, end elevation, plan, and in the direction of the axis of the daughter tube. The magnitude of the velocities is indicated by the distance between arrowheads shown in the side elevation. More precisely the arc length between arrowheads is proportional to the velocity magnitude in the x-y plane, i.e., $\sqrt{u^2 + v^2}$, evaluated at the tail-end of the arrow. The arrow shown between side elevation and plan has unit velocity. As the flow passes through the bifurcation it twists in a fairly complex fashion. The nature of this twist can be shown by placing a uniform grid in the flow far upstream (Fig. 6(a)) and comparing it with the resulting distorted grid far downstream (Fig. 6(b)). The corners ABCD become mapped into A′B′C′D′. A careful examination of the diagrams shows that it is very unlikely that, at this Reynolds number, there are any

recirculation regions in the flow. The pressure contours on the plane of symmetry ($z = 0$) and on the plane passing through the edge $z = \frac{1}{2}$ are shown in Fig. 7. These are typically as one would expect, that is, decreasing pressure from upstream to downstream, with a local maximum at the apex ($y = z = 0$ with x on the boundary) since the flow is slow within this neighborhood.

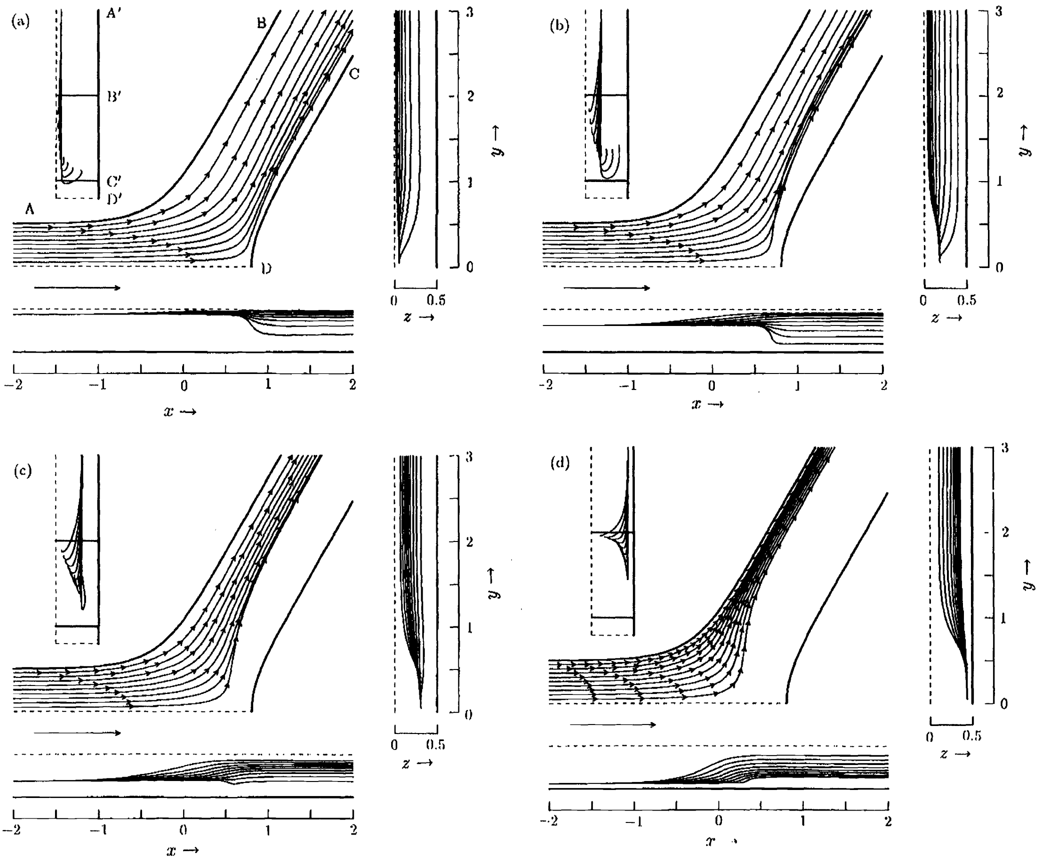

FIG. 5. *Streamlines for $\phi = 60°$ at $R = 50$. The diagram shows side elevation, end elevation, and plan. The insert at the top left shows the view along the daughter tube for which the points $A'B'C'D'$ correspond to the points ABCD in side elevation. Dashed lines are lines of symmetry. The component of the velocity magnitude in the x-y plane is shown by the distance between arrowheads in side elevation. Unit velocity is shown by the arrow between side elevation and plan. The streamlines shown commence downstream at $y = 0.1, 0.2, \ldots, 0.9$ and* (a) *at $z = 0.125$,* (b) *at $z = 0.375$,* (c) *at $z = 0.625$, and* (d) *at $z = 0.875$.*

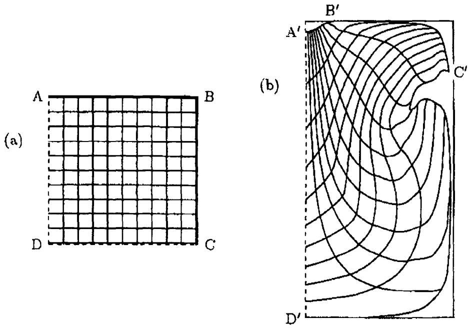

FIG. 6. *The distortion of a uniform grid far upstream:* (b) *which was originally placed perpendicularly in the flow far downstream* (a) *for $\phi = 60°$ at $R = 50$. The points ABCD are transformed into $A'B'C'D'$.*

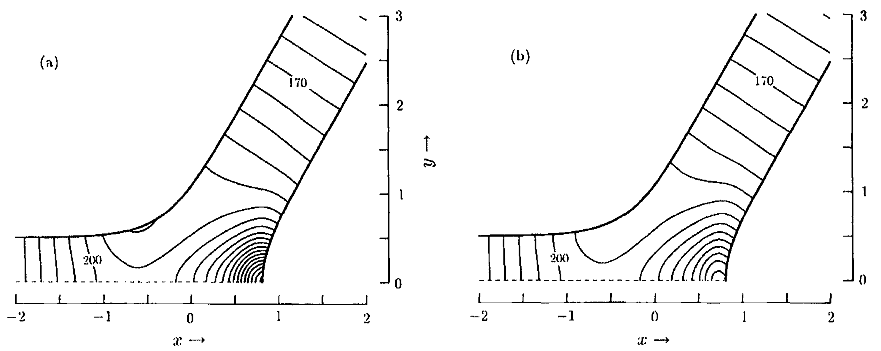

FIG. 7. *Pressure contours for* $\phi = 60°$ *at* $R = 50$ *in the plane:* (a) $z = 0$ *and* (b) $z = 0.5$. *The contour levels are equally spaced with* $\Delta p = 5$. *Two values of the contour levels are given from which the others can be determined.*

Figures 8 and 9 show the velocity streamlines and pressure contours for $\phi = 90°$ with $R = 50$. The characteristics of the flow are similar to those described for $\phi = 60°$ with the similar twisting of the flow as it passes through the bifurcation. As the Reynolds number increases, the twisting of the flow becomes much more pronounced and is illustrated in Fig. 10, which shows the streamlines of the flow for $R = 100$ and $\phi = 60°$.

7. Conclusions and future work.

(i) Numerical results have been obtained for the steady incompressible flow in a symmetric three-dimensional bifurcation having uniform thickness and specifiable boundaries in the x-y plane. This is accomplished by dividing the physical region into three domains each of which is transformed onto a rectangular parallelepiped upon which the calculations are made. The results have acceptable relative accuracy of $\sim 10^{-3}$ for Reynolds number up to 100 with daughter tubes orientated at 60° and 90° to the main tube.

(ii) The results show that there are significant flow features which do not appear in a corresponding two-dimensional flow model. In particular as the flow moves from the main tube to the daughter tubes it twists in a vortex-like fashion.

(iii) We have only considered a steady solution leaving the unsteady pulsatile case, which is a characteristic of blood flow, to a future study. However, the steady case does represent the "time averaged" situation and should be capable of predicting the areas of high/low wall shear stress where atherosclerotic lesions can occur.

(iv) Instead of using second-order differences along the tube, it would be feasible to use fourth-order central differences in order to increase the accuracy in this direction. Equations (2.8) would then encompass five nodal points rather than three with the result that the width of the Jacobian would double. This would lead to a fourfold increase in the CPU time and a doubling of the storage requirement. To be competitive with second-order differences it would be necessary to decrease the number of nodes along the tube to be at least a factor four while maintaining the same level of accuracy. It is unclear whether this is the case and would require further investigation.

(v) Although only two tubes of constant thickness have been considered, the strategy can deal with any bifurcation that is symmetric in the y and z planes. The boundaries can be specified quite generally and then the coefficients $\partial\xi^K/\partial x^J$ and $\partial^2\xi^K/\partial x^J\partial x^J$ of equation (2.5) can be found using a Maple program designed for the purpose. Such a program produces Fortran coding which is then used directly in the main fluid flow calculation.

(vi) In two-dimensional flow the CPU time requirement is proportional to N^2 for both a Newton- and a Gauss–Seidel-type method where N is the total number of nodal points. In

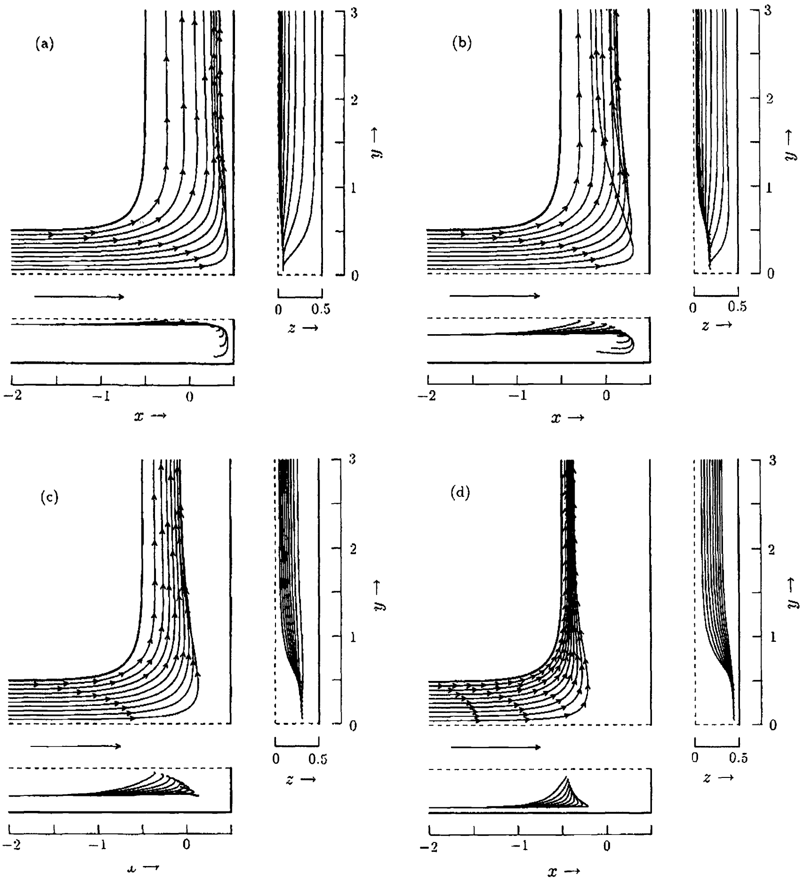

FIG. 8. *Streamlines for $\phi = 90°$ at $R = 50$. The diagram is similar to Fig. 5 except the insert is no longer necessary:* (a) *at* $z = 0.125$ *and* (b) *at* $z = 0.375$. *Streamlines for $\phi = 90°$ at $R = 50$:* (c) *at* $z = 0.625$ *and* (d) *at* $z = 0.875$.

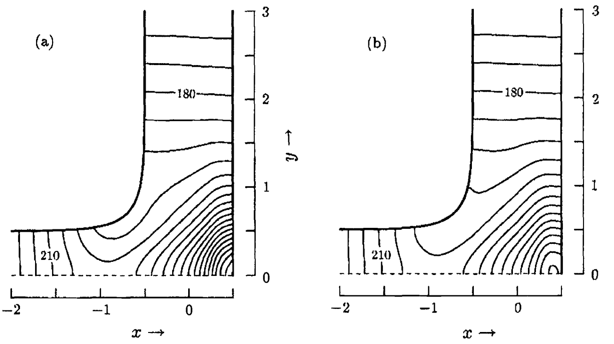

FIG. 9. *Pressure contours for $\phi = 90°$ at $R = 50$ in the plane:* (a) $z = 0$ *and* (b) $z = 0.5$. *The contour levels are equally spaced with $\Delta p = 5$.*

three dimensions the time requirement is proportional to $N^{7/3}$ and $N^{5/3}$, respectively, making Newton's method the more expensive. It is hoped that we can investigate the possibility that

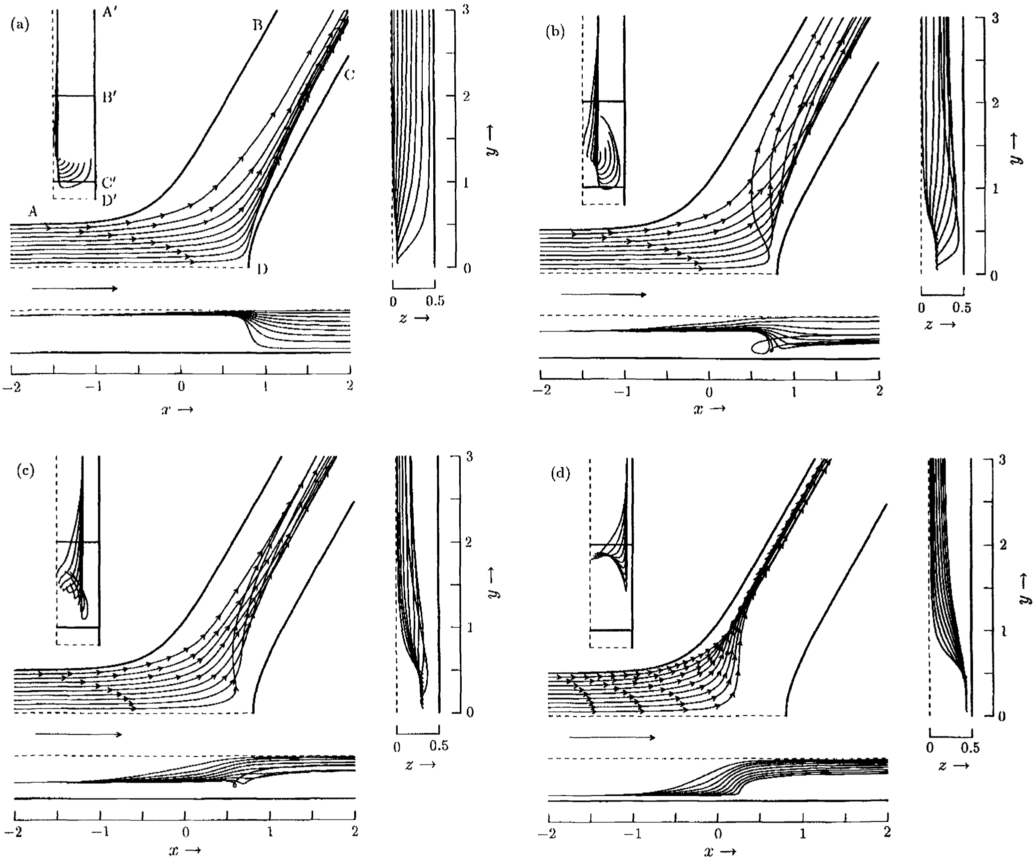

FIG. 10. *Streamlines for* $\phi = 60°$ *at* $R = 50$: (a) *at* $z = 0.125$ *and* (b) *at* $z = 0.375$. *Streamlines for* $\phi = 60°$ *at* $R = 50$: (c) *at* $z = 0.125$ *and* (d) *at* $z = 0.875$.

a combination of a Newton- and a Gauss-Seidel-type method would pick out the best of both methods in terms of speed and stability.

(vii) In the future we hope to extend the method to include cylindrical-like tubes and nonsymmetric bifurcations from which we should be able to obtain results for a realistic arterial bifurcation. Also the code needs adapting to cope with slender bifurcations (e.g., $\phi = 30°$) which gave disappointing results.

A STABLE PENALTY METHOD FOR THE COMPRESSIBLE NAVIER-STOKES EQUATIONS: I. OPEN BOUNDARY CONDITIONS*

J. S. HESTHAVEN†‡ AND D. GOTTLIEB†§

Abstract. The purpose of this paper is to present asymptotically stable open boundary conditions for the numerical approximation of the compressible Navier-Stokes equations in three spatial dimensions. The treatment uses the conservation form of the Navier-Stokes equations and utilizes linearization and localization at the boundaries based on these variables.

The proposed boundary conditions are applied through a penalty procedure, thus ensuring correct behavior of the scheme as the Reynolds number tends to infinity. The versatility of this method is demonstrated for the problem of a compressible flow past a circular cylinder.

Key words. open boundary conditions, stable penalty methods, Navier-Stokes equations

1. Introduction.

In the present paper, we discuss boundary conditions for dissipative, wave-dominated problems, exemplified by the Burgers equation and the three-dimensional, compressible Navier-Stokes equations given in conservation form. The emphasis is on deriving open boundary conditions that ensure the continuous problems are well posed and on devising asymptotically stable semi-discrete schemes for imposing these conditions. The boundary conditions and the semi-discrete schemes are valid even in the limit of vanishing viscosity.

When addressing exterior wave-dominated, dissipative problems, one is often forced to introduce an artificial boundary for computational reasons. This introduces the well-known problem of specifying appropriate boundary conditions at the artificial open boundary. For purely hyperbolic problems, it is well known that enforcing these boundary conditions through the characteristic variables leads to a stable approximation. However, for dissipative wave problems the procedure is considerably more complicated.

Naturally, we require that the boundary conditions lead to a well-posed, continuous problem. For wave problems of dissipative type, the problem must, in order to be compatible with weak boundary layers, remain well posed even in the limit where the dissipation vanishes and the problem becomes purely hyperbolic. In addition to this, we want the discrete approximation of the problem to be asymptotically stable and the boundary conditions to be easily implemented.

For general nonlinear problems the issues of well-posedness and asymptotic stability are very complicated and for most problems only very little is known. However, as discussed by Kreiss and Lorenz [1], we may, for a large class of operators, simplify the problem significantly if the solutions are smooth. It was shown that in this case it is sufficient to consider the questions of well-posedness and asymptotic stability for the locally linearized, constant coefficient version of the full problem.

The energy method is applied to the linearized, constant coefficient version of the continuous problem in order to obtain energy inequalities which bound the temporal growth of the solutions to the initial-boundary value problem. This technique allows the handling of such

complex problems as the Navier-Stokes equations and is in general applicable to symmetrizable systems of conservation laws for which an entropy function can be defined [2].

The usual way to enforce the boundary conditions in the numerical scheme, once their proper form for the continuous problem is known, is to solve the equation in the interior of the computational domain and then enforce the boundary conditions at the boundary points. However, this approach does not take into account the fact that the equation should be obeyed arbitrarily close to the open boundary. To circumvent this problem, Funaro and Gottlieb [3, 4] and Carpenter, Gottlieb, and Abarbanel [5] developed the penalty method, which enforces the boundary conditions as well as considers the equation at the boundary. They showed asymptotic stability for the scheme applied to scalar hyperbolic equations and systems of hyperbolic equations. Don and Gottlieb [6] showed how this idea can help in applying the Legendre collocation method on the Chebyshev grids.

The proofs presented in this paper are all done for semi-discrete schemes. The relation between the stability of the semi-discrete and the fully discrete scheme was recently discussed by Kreiss and Wu [7].

The issue of well-posed boundary conditions for the compressible Navier-Stokes equations was previously considered by Gustafsson and Sundström [8], Oliger and Sundström [9], and Nordström [10, 11]. They all used the energy method to derive boundary conditions for the linearized, constant coefficient Navier-Stokes equations in the primitive variable formulation. Dutt [12] introduced an entropy function, which allowed him to derive boundary conditions for the nonlinear problem, ensuring that the solution remains bounded in an entropy norm. Halpern [13] has devised well-posed artificial boundary conditions that remain valid in the limit of vanishing viscosity. He approached the problem by viewing the linearized Navier-Stokes equations as a hyperbolic system subjected to an incomplete elliptic perturbation and obtained nonlocal as well as local open boundary conditions by considering the Fourier-Laplace transformed problem in the semi-infinite half-plane. However, for most of the previous work only few suggestions are given on how to enforce the derived boundary conditions in a natural and consistent way.

The remaining part of this paper is organized as follows. In §2 we review some well-known results on Legendre polynomials and collocation methods. Section 3 discusses the Burgers equation and boundary conditions that ensure well-posedness of the problem are derived. We continue by proposing an asymptotically stable penalty method through which the boundary conditions are enforced. This scheme ensures the correct behavior even in the limit, where the problem becomes hyperbolic, and may in general be applied to any nonlinear scalar equation. The penalty method for linear scalar hyperbolic, parabolic, and advection-diffusion equations is briefly discussed and the proposed scheme is evaluated by numerical tests. The importance of properly choosing the penalty parameter is addressed in §4, where we discuss the effect of the penalty method on the Courant-Friedrichs-Levy (CFL) condition when using explicit Runge-Kutta methods for time-stepping linear problems. We show that the results from the linear analysis carry over to the nonlinear case by performing simulations of the Burgers equation. We briefly discuss the equivalent penalty method for Chebyshev collocation methods. In §5 we derive open boundary conditions for the compressible Navier-Stokes equations given in conservation form and propose a penalty method for enforcing these boundary conditions. We derive the symmetrized form of the Navier-Stokes equation in conservation form and prove well-posedness for the continuous case and asymptotic stability of the proposed semi-discrete scheme using a Legendre collocation method. The boundary conditions and the semi-discrete approximation remain valid in the limit where the Reynolds number approaches infinity. The performance of the scheme in direct simulations of the Navier-Stokes equations is illustrated by simulating compressible flow around a circular cylinder using a Fourier-

Chebyshev collocation method. Section 6 concludes the paper and discusses the application of the scheme in finite difference/finite element simulations.

2. Legendre polynomials and collocation methods. The schemes, which we analyze in the present paper, are all based on Legendre collocation methods. This choice is dictated merely by a wish to obtain analytical results, and the methods extend trivially to other collocation methods and even to finite difference/finite element methods.

The Legendre polynomial of order N, $P_N(x)$, is defined as

$$P_N(x) = \frac{1}{2^N N!} \frac{d^N}{dx^N}(x^2-1)^N \ ,$$

where $|x| \leq 1$. In what follows, we will only consider collocation methods where the collocation points are given as the Legendre-Gauss-Lobatto points, defined as the roots of the polynomial $(1-x^2)P_N'(x)$. There is no known explicit formula for these roots.

Associated with the Gauss-Lobatto points is the quadrature formula, stating that if $f(x)$ is a polynomial of degree $2N-1$, then

$$\sum_{k=0}^{N} f(x_k)\omega_k = \int_{-1}^{1} f(\xi)\,d\xi \ , \tag{1}$$

where x_k are the Legendre-Gauss-Lobatto collocation points, and the Gauss-Lobatto weights, ω_k, are given as

$$\begin{aligned} \omega_k &= -\frac{2}{N+1}\frac{1}{P_N(x_k)\,P_{N-1}'(x_k)} \ , \quad 1 \leq k \leq N-1 \ , \\ \omega_0 = \omega_N &= \frac{2}{N(N+1)} \ . \end{aligned} \tag{2}$$

For further details on the properties of the Legendre polynomials, we refer to [14].

In a Legendre collocation method, the function, $f(x)$, is approximated by a grid function, $f_k = f(x_k)$, where the grid points are the Gauss-Lobatto collocation points. Thus, we construct a global Legendre interpolant, I_N, to obtain an approximation to the function as

$$(I_N f)(x) = \sum_{k=0}^{N} f_k\, h_k(x) \ ,$$

where the interpolating Legendre-Lagrange polynomials are given as

$$h_k(x) = -\frac{(1-x^2)P_N'(x)}{N(N+1)\,(x-x_k)P_N(x_k)} \ .$$

We note that by construction,

$$(I_N f)(x_k) = f_k \ .$$

To seek equations for an approximate solution, $(I_N f)(x)$, to a partial differential equation, we need to obtain values for the spatial derivatives at the collocation points. This is done by approximating the differential operator by a matrix operator, with the matrix entries given as

$$\mathcal{D}_{kl} = h_l'(x_k) \ .$$

For the explicit expression of the entries, we refer to [15, 16].

3. The Burgers equation. In this section, we consider the Burgers equation

$$\frac{\partial U}{\partial t} + U\frac{\partial U}{\partial x} = \varepsilon\frac{\partial^2 U}{\partial x^2} \quad |x| \leq 1 \quad t > 0 \ , \tag{3}$$

where $\varepsilon \geq 0$. The initial condition is given as

$$U(x, 0) = f(x) \ ,$$

with boundary conditions of the form

$$\alpha U(-1, t) - \beta\varepsilon \left.\frac{\partial U}{\partial x}\right|_{x=-1} = 0 \ , \tag{4}$$

$$\gamma U(1, t) + \delta\varepsilon \left.\frac{\partial U}{\partial x}\right|_{x=1} = 0 \ . \tag{5}$$

When addressing the issue of well-posedness it is sufficient to consider the linearized, constant coefficient version of the Burgers equation

$$\frac{\partial U}{\partial t} + \lambda\frac{\partial U}{\partial x} = \varepsilon\frac{\partial^2 U}{\partial x^2} \quad |x| \leq 1 \ t > 0 \ . \tag{6}$$

Here $\lambda = U_0$ is the uniform solution around which we have linearized. Equation (6) is also known as the linear advection-diffusion equation.

The four real constants, α, β, γ, and δ, in the boundary conditions, (4) and (5), may not be chosen arbitrarily, since the resulting problem should be well posed. Bounds yielding a sufficient condition for well-posedness are given in the following lemma.

LEMMA 3.1. *Equation* (6), *with boundary conditions given by* (4) *and* (5), *is well posed if one of the following conditions holds:*

(i) $\beta = 0$, $\delta = 0$.

(ii) $\beta \neq 0$, $\delta = 0$ *and* $(\varepsilon - \lambda) + 2\alpha/\beta \geq 0$.

(iii) $\beta = 0$, $\delta \neq 0$ *and* $(\varepsilon + \lambda) + 2\gamma/\delta \geq 0$.

(iv) $\beta \neq 0$, $\delta \neq 0$ *and* $2(\varepsilon - \lambda)\gamma/\delta + 2(\varepsilon + \lambda)\alpha/\beta + 4(\alpha\gamma)/(\beta\delta) \geq \lambda^2$.

Proof. Construct the energy integral as

$$\frac{1}{2}\frac{d}{dt}\|U\|^2 = -\lambda\,(U, U_x) + \varepsilon\,(U, U_{xx}) = \frac{1}{2}\left[-\lambda U^2 + 2\varepsilon U\,U_x\right]_{-1}^{1} - \varepsilon\|U_x\|^2 \ .$$

Here we have introduced

$$(U, V) = \int_{-1}^{1} U\,V\,dx \ , \quad (U, U) = \|U\|^2 \ .$$

Following an analysis similar to that in [17], we apply the following

$$-\varepsilon\|U_x\|^2 \leq -\frac{\varepsilon}{2}[U(1) - U(-1)]^2 \ .$$

Following this, the condition for well-posedness becomes

$$\frac{1}{2}\frac{d}{dt}\|U\|^2 \leq \frac{1}{2}\left[-\lambda U^2 + 2\varepsilon U\,U_x\right]_{-1}^{1} - \frac{\varepsilon}{2}[U(1) - U(-1)]^2 \leq 0 \ .$$

Condition (i) implies that $U(-1) = U(1) = 0$ such that

$$\frac{1}{2}\frac{d}{dt}\|U\|^2 \leq 0 \ .$$

For condition (ii) we obtain $U(1) = 0$ and thus

$$\frac{1}{2}\frac{d}{dt}\|U\|^2 \leq -\frac{1}{2}\left(\varepsilon - \lambda + 2\frac{\alpha}{\beta}\right)U^2(-1) \leq 0 \ ,$$

yielding the condition

$$\varepsilon - \lambda + 2\frac{\alpha}{\beta} \geq 0 \ .$$

Likewise, for condition (iii) we obtain

$$\frac{1}{2}\frac{d}{dt}\|U\|^2 \leq -\frac{1}{2}\left(\varepsilon + \lambda + 2\frac{\gamma}{\delta}\right)U^2(1) \leq 0 \ ,$$

showing that this choice yields well-posedness. For condition (iv) we obtain the constraint

$$\frac{1}{2}\frac{d}{dt}\|U\|^2 \leq -\frac{1}{2}\left(\varepsilon - \lambda + 2\frac{\alpha}{\beta}\right)U^2(-1) + \varepsilon U(-1)U(1) - \frac{1}{2}\left(\varepsilon + \lambda + 2\frac{\gamma}{\delta}\right)U^2(1) \leq 0.$$

This is obeyed if

$$\varepsilon^2 - \left(\varepsilon - \lambda + 2\frac{\alpha}{\beta}\right)\left(\varepsilon + \lambda + 2\frac{\gamma}{\delta}\right) \leq 0 \ ,$$

implying

$$2(\varepsilon - \lambda)\gamma/\delta + 2(\varepsilon + \lambda)\alpha/\beta + 4(\alpha\gamma)/(\beta\delta) \geq \lambda^2 \ . \qquad \square$$

3.1. The semi-discrete scheme. Equation (3) will be solved using a Legendre collocation method where the collocation points are the Legendre-Gauss-Lobatto points. This involves finding an Nth degree polynomial, $u(x, t)$, satisfying

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} = \varepsilon\frac{\partial^2 u}{\partial x^2} \quad \text{at } x = x_k \ , \quad k \in [1 \ldots N-1] \ , \tag{7}$$

in the interior. The boundary points are given by boundary conditions of Robin type

$$\alpha u(x_0, t) - \beta\varepsilon\left.\frac{\partial u}{\partial x}\right|_{x_0} = g_1(t) \ ,$$

$$\gamma u(x_N, t) + \delta\varepsilon\left.\frac{\partial u}{\partial x}\right|_{x_N} = g_2(t) \ ,$$

where $g_1(t)$ and $g_2(t)$ are prescribed boundary conditions. The traditional method of imposing the boundary conditions is to solve (7) in the interior and enforce the boundary conditions at the boundary points only. However, this approach does not take into account the fact that the equation must be obeyed arbitrarily close to the boundary. In addition to this, it has proven difficult to implement Robin boundary conditions consistently when using spectral approximations of nonlinear problems. To overcome these problems, we follow the line of thought initiated by Funaro and Gottlieb [3, 4] and propose a penalty method for approximating the Burgers equation at the Legendre-Gauss-Lobatto collocation points, $x = x_k$, $k \in [0, \ldots, N]$, as

$$\begin{aligned}\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} = \ & \varepsilon\frac{\partial^2 u}{\partial x^2} \\ & - \tau_1 Q^-(x)\left[\alpha u(x_0, t) - \beta\varepsilon\left.\frac{\partial u}{\partial x}\right|_{x_0} - g_1(t)\right] \\ & - \tau_2 Q^+(x)\left[\gamma u(x_N, t) + \delta\varepsilon\left.\frac{\partial u}{\partial x}\right|_{x_N} - g_2(t)\right] \ ,\end{aligned} \tag{8}$$

where

$$(9) \qquad Q^-(x) = \frac{(1-x)P_N'(x)}{2P_N'(-1)} \ , \quad Q^+(x) = \frac{(1+x)P_N'(x)}{2P_N'(1)} \ .$$

These two functions have the property of being zero at all the Legendre-Gauss-Lobatto collocation points except at the two endpoints of the domain. Although Q^- and Q^+ here are defined as delta-functions at the boundary, we may also choose other definitions. As shown by Don and Gottlieb [6], this approach may also be applied for implementing Legendre methods at Chebyshev grids.

We note here that the penalty method as given by (8) combines the boundary conditions and the governing equation into one equation. When using the penalty method, the boundary conditions are only enforced weakly at the boundary. However, the method remains spectrally accurate, as we will soon illustrate. One may also observe that the scheme is equivalent to the traditional way of imposing boundary conditions as τ_1, τ_2 approach infinity.

The parameters, τ_1 and τ_2, are then to be determined such that the semi-discrete approximation to the initial-boundary value problem is asymptotically stable.

In order to obtain the energy inequality, we consider only homogeneous boundary conditions. As discussed in [1], this is not a restriction, since we may always introduce a variable transform such the boundary conditions become homogeneous. In the following lemma we state the bounds on τ_1 and τ_2 which ensure that the linearized, constant coefficient version of (8) is asymptotically stable.

LEMMA 3.2. *Assume $u(x,t)$ exists and let $\tau^-_{a,b}$ and $\tau^+_{a,b}$ be defined as*

$$\tau^-_{a,b} = \frac{1}{\omega\varepsilon b}[\varepsilon + 2\kappa - 2\sqrt{\kappa^2 + \varepsilon\kappa - 1/2\varepsilon\omega|\lambda|}] \ ,$$

$$\tau^+_{a,b} = \frac{1}{\omega\varepsilon b}[\varepsilon + 2\kappa + 2\sqrt{\kappa^2 + \varepsilon\kappa - 1/2\varepsilon\omega|\lambda|}] \ ,$$

where $\kappa = \omega a/b$ and

$$\omega = \frac{2}{N(N+1)}$$

is the Legendre weight at the endpoints.

If

$$\tau^-_{\alpha,\beta} \le \tau_1 \le \tau^+_{\alpha,\beta} \ ,$$

$$\tau^-_{\gamma,\delta} \le \tau_2 \le \tau^+_{\gamma,\delta} \ ,$$

then the linearized, constant coefficient version of (8) *is asymptotically stable and the solution is bounded as*

$$\frac{1}{2}\frac{d}{dt}\|u\|_N^2 \le -\varepsilon \sum_{k=1}^{N-1} \left(\frac{\partial u}{\partial x}(x_k)\right)^2 \omega_k \ .$$

Proof. We start by defining the discrete, weighted inner product as

$$(u,\ v)_N = \sum_{k=0}^{N} u(x_k)\, v(x_k)\, \omega_k \ \ , (u,u)_N = \|u\|_N^2$$

and note that since we are using a Legendre collocation method, we have, through (1), the identity

$$(u, v_x)_N = (U, V_x) \ .$$

This makes it straightforward to apply partial differentiation. Following the results stated previously, it is sufficient to obtain the energy estimate for the linearized, constant coefficient version of (8) with homogeneous boundary conditions:

$$\begin{aligned}\frac{1}{2}\frac{d}{dt}\|u\|_N^2 =& -\frac{\lambda}{2}[u^2]_{-1}^{1} + \varepsilon[u\,u_x]_{-1}^{1} - \varepsilon\|u_x\|_N^2 \\ & -\tau_1\omega u(-1)[\alpha u(-1) - \beta\varepsilon u_x(-1)] - \tau_2\omega u(1)[\gamma u(1) + \delta\varepsilon u_x(1)] \ .\end{aligned}$$

Here the subscripts designate differentiation and ω is the Legendre weight at the endpoints (2). Using the quadrature rule allows for rewriting as

$$\|u_x\|_N^2 = u_x^2(-1)\omega + u_x^2(1)\omega + \sum_{k=1}^{N-1} u_x^2(x_k)\omega_k \ .$$

Contrary to the approach followed by Funaro and Gottlieb [3, 4], we recast the problem of stability into an algebraic eigenvalue problem. For the present problem, this may seem an additional complication. However, we find that for more complicated problems this approach greatly simplifies the proofs.

Isolating the terms contributing to stability at each boundary, we obtain two conditions for asymptotic stability:

$$\mathbf{u}_-^T\mathcal{H}^-\mathbf{u}_- \le 0 \ , \quad \mathbf{u}_+^T\mathcal{H}^+\mathbf{u}_+ \le 0 \ ,$$

where $\mathbf{u}_- = [u(-1), u_x(-1)]^T$, $\mathbf{u}_+ = [u(1), u_x(1)]^T$, and

$$\mathcal{H}^- = \frac{1}{2}\begin{bmatrix} \lambda - 2\alpha\omega\tau_1 & -\varepsilon(1-\beta\omega\tau_1) \\ -\varepsilon(1-\beta\omega\tau_1) & -2\varepsilon\omega \end{bmatrix} ,$$

$$\mathcal{H}^+ = \frac{1}{2}\begin{bmatrix} -\lambda - 2\gamma\omega\tau_2 & \varepsilon(1-\delta\omega\tau_2) \\ \varepsilon(1-\delta\omega\tau_2) & -2\varepsilon\omega \end{bmatrix} .$$

Since both matrices are symmetric, the problem is reduced to ensuring that $\mathcal{H}^-$ and $\mathcal{H}^+$ are negative, semi-definite. The eigenvalues of the two matrices are found to be

$$\rho_{1,2}(\mathcal{H}^-) = \frac{1}{8}\left(-\zeta^- \pm \sqrt{(\zeta^-)^2 + 16\varepsilon(\beta^2\omega^2\varepsilon\tau_1^2 - 2\omega(\beta\varepsilon + 2\alpha\omega)\tau_1 + 2\omega\lambda + \varepsilon)}\right) ,$$

$$\rho_{1,2}(\mathcal{H}^+) = \frac{1}{8}\left(-\zeta^+ \pm \sqrt{(\zeta^+)^2 + 16\varepsilon(\delta^2\omega^2\varepsilon\tau_2^2 - 2\omega(\delta\varepsilon + 2\gamma\omega)\tau_2 - 2\omega\lambda + \varepsilon)}\right) ,$$

where $\zeta^- = -2\lambda + 4\omega\varepsilon + 4\alpha\omega\tau_1$ and $\zeta^+ = 2\lambda + 4\omega\varepsilon + 4\gamma\omega\tau_2$. It is evident that negative semi-definiteness is ensured, provided $\zeta^- > 0$ and $\zeta^+ > 0$, if

$$\begin{aligned}\beta^2\omega^2\varepsilon\tau_1^2 - 2\omega(\beta\varepsilon + 2\alpha\omega)\tau_1 + 2\omega\lambda + \varepsilon \le 0 \ , \\ \delta^2\omega^2\varepsilon\tau_2^2 - 2\omega(\delta\varepsilon + 2\gamma\omega)\tau_2 - 2\omega\lambda + \varepsilon \le 0 \ .\end{aligned}$$

The roots of the two polynomials are

$$\tau_1^{\pm} = \frac{1}{\omega\varepsilon\beta}\left(\varepsilon + 2\kappa_- \pm 2\sqrt{\kappa_-^2 + \varepsilon\kappa_- - 1/2\varepsilon\omega\lambda}\right) ,$$

$$\tau_2^{\pm} = \frac{1}{\omega\varepsilon\delta}\left(\varepsilon + 2\kappa_+ \pm 2\sqrt{\kappa_+^2 + \varepsilon\kappa_+ + 1/2\varepsilon\omega\lambda}\right) ,$$

where $\kappa_- = \omega\alpha/\beta$ and $\kappa_+ = \omega\gamma/\delta$. We introduce

$$\tau^-_{a,b} = \frac{1}{\omega\varepsilon b}[\varepsilon + 2\kappa - 2\sqrt{\kappa^2 + \varepsilon\kappa - 1/2\varepsilon\omega|\lambda|}] \ ,$$
$$\tau^+_{a,b} = \frac{1}{\omega\varepsilon b}[\varepsilon + 2\kappa + 2\sqrt{\kappa^2 + \varepsilon\kappa - 1/2\varepsilon\omega|\lambda|}] \ ,$$

where $\kappa = \omega a/b$. Since

$$\tau^-_{a,b} \geq \frac{|\lambda|}{2a\omega} + \frac{1}{4}\varepsilon\frac{1}{\omega^2} \ ,$$

for $\varepsilon \ll 1$, this ensures $\zeta^- > 0$ and $\zeta^+ > 0$.

Hence, stability is ensured for

$$\tau^-_{\alpha,\beta} \leq \tau_1 \leq \tau^+_{\alpha,\beta} \ ,$$
$$\tau^-_{\gamma,\delta} \leq \tau_2 \leq \tau^+_{\gamma,\delta} \ ,$$

with the solution being bounded as

$$\frac{1}{2}\frac{d}{dt}\|u\|^2_N \leq -\varepsilon\sum_{k=1}^{N-1} u^2_x(x_k)\omega_k \ . \qquad \square$$

3.1.1. Remarks on the penalty method for linear equations. The results stated in Lemma 3.2 allows us to derive the appropriate penalty parameter for a large class of linear equations. We consider the general linear advection-diffusion equation, (6), with the Robin boundary conditions given in (4) and (5). Solving this problem by a penalty method, equivalent to that given by (8), requires bounds on the penalty parameters in order to ensure stability of the scheme.

In what follows we will give these bounds for reference and will return to the numerical validation of these results in §4. Some of these results may be found in [3, 4, 6], but are given here in a more general framework. Remember that $\omega^{-1} \sim \mathcal{O}(N^2)$.

Hyperbolic equations. ($\varepsilon = 0.$)

1. $\lambda > 0$. Well-posedness is ensured by choosing $\alpha > 0$ and $\beta = \gamma = \delta = 0$. Thus, for this case we will only need bounds on τ_1:

$$\tau^-_{\alpha,0} = \frac{\lambda}{2\omega\alpha} \ , \quad \tau^+_{\alpha,0} = \infty \ .$$

The scheme for the hyperbolic case is stable for

$$\infty \geq \tau_1 \geq \frac{\lambda}{2\omega\alpha} \ .$$

2. $\lambda < 0$. Well-posedness is ensured by choosing $\gamma > 0$ and $\alpha = \beta = \delta = 0$. Thus, for this case we will only need bounds on τ_2:

$$\tau^-_{\gamma,0} = \frac{|\lambda|}{2\omega\gamma} \ , \quad \tau^+_{\gamma,0} = \infty \ .$$

The scheme for the hyperbolic case is stable for

$$\infty \geq \tau_2 \geq \frac{|\lambda|}{2\omega\gamma} \ .$$

Parabolic equations. ($\lambda = 0,\ \varepsilon > 0$.) Necessary and sufficient conditions for well-posedness may be obtained by choosing the four parameters, $\alpha,\ \beta,\ \gamma$, and δ, properly as stated in Lemma 3.1 [17]. We only state the results for the bounds of τ_1, since the results for τ_2 are equivalent.

1. Dirichlet boundary condition ($\alpha > 0,\ \beta = 0$).

$$\tau^-_{\alpha,0} = \frac{\varepsilon}{4\alpha}\frac{1}{\omega^2}\ ,\quad \tau^+_{\alpha,0} = \infty\ .$$

Stability is ensured for

$$\infty \geq \tau_1 \geq \frac{\varepsilon}{4\alpha}\frac{1}{\omega^2}\ .$$

2. Neumann boundary condition ($\alpha = 0,\ \beta > 0$).

$$\tau^-_{0,\beta} = \frac{1}{\beta\omega}\ ,\quad \tau^+_{0,\beta} = \frac{1}{\beta\omega}\ .$$

Stability is ensured for

$$\tau_1 = \frac{1}{\beta\omega}\ .$$

3. Robin boundary condition ($\alpha > 0,\ \beta > 0$).

$$\tau^-_{\alpha,\beta} = \frac{1}{\omega\varepsilon\beta}[\varepsilon + 2\kappa - 2\sqrt{\kappa^2 + \varepsilon\kappa}]\ ,$$
$$\tau^+_{\alpha,\beta} = \frac{1}{\omega\varepsilon\beta}[\varepsilon + 2\kappa + 2\sqrt{\kappa^2 + \varepsilon\kappa}]\ ,$$

where $\kappa = \omega\alpha/\beta$. Stability is ensured for

$$\tau^+_{\alpha,\beta} \geq \tau_1 \geq \tau^-_{\alpha,\beta}\ .$$

Advection-diffusion equations. ($\lambda \neq 0,\ \varepsilon \geq 0$). Again we must ensure well-posedness by proper choice of the four parameters as given by Lemma 3.1. We only state the results for the bounds of τ_1 since the results for τ_2 are equivalent.

1. Dirichlet boundary condition ($\alpha > 0,\ \beta = 0$).

$$\tau^-_{\alpha,0} = \frac{|\lambda|}{2\alpha}\frac{1}{\omega} + \frac{\varepsilon}{4\alpha}\frac{1}{\omega^2}\ ,\quad \tau^+_{\alpha,0} = \infty\ .$$

Stability is ensured for

$$\infty \geq \tau_1 \geq \frac{|\lambda|}{2\alpha}\frac{1}{\omega} + \frac{\varepsilon}{4\alpha}\frac{1}{\omega^2}\ .$$

2. Neumann boundary condition ($\alpha = 0,\ \beta > 0$).

$$\tau^-_{0,\beta} = \frac{1}{\beta\omega} - \sqrt{\frac{2|\lambda|\omega}{\epsilon\beta^2}}\ ,\quad \tau^+_{0,\beta} = \frac{1}{\beta\omega} + \sqrt{\frac{2|\lambda|\omega}{\epsilon\beta^2}}\ .$$

Stability is ensured for

$$\frac{1}{\beta\omega} + \sqrt{\frac{2|\lambda|\omega}{\epsilon\beta^2}} \geq \tau_1 \geq \frac{1}{\beta\omega} - \sqrt{\frac{2|\lambda|\omega}{\epsilon\beta^2}}\ .$$

3. Robin boundary conditions, $\alpha > 0,\ \beta > 0$. Results are given in Lemma 3.2.

3.2. Numerical tests. Because we aim to solve the full nonlinear Burgers equation, and not the linearized, constant coefficient version, we need to validate the results obtained from the linear analysis. We have solved the Burgers equation using the scheme given by (8) and employ a standard Legendre collocation method as described in §2 [15, 18].

The Burgers equation, (3), has a rightward traveling wave solution (see, e.g., [1]) of the form

$$U(x,t) = -a \tanh\left(a\frac{x-ct}{2\varepsilon}\right) + c \quad , x \in [-\infty, \infty] \quad , t \geq 0 \quad , \tag{10}$$

where the free-stream values

$$\lim_{x\to-\infty} U(x,t) = b_{-\infty} \quad , \quad \lim_{x\to\infty} U(x,t) = b_{\infty} \quad ,$$

are associated with the wave-speed, c, and the constant, $a \geq 0$, as

$$c = \frac{b_{-\infty} + b_{\infty}}{2} \quad , \quad a = \frac{b_{-\infty} - b_{\infty}}{2} \quad .$$

Following the results in Lemma 3.1 (condition (iv): $\alpha = \lambda,\ \beta = 1,\ \gamma = 0,\ \delta = 1$), we expect the nonlinear problem to be well posed for boundary conditions of the type

$$\lambda U(-1,t) - \varepsilon\frac{\partial U(-1,t)}{\partial x} = g_1(t) \quad , \quad \varepsilon\frac{\partial U(1,t)}{\partial x} = g_2(t) \quad ,$$

where $\lambda \geq 0$ is the value around which we have linearized locally. In the present study we have used the free-stream value at the inflow, i.e., $\lambda = b_{-\infty}$. Since we know an exact solution, the boundary conditions may be given exactly at all times using (10). As the initial condition we use

$$U(x,0) = -a \tanh\left(a\frac{x}{2\varepsilon}\right) + c \quad .$$

The solution is time-stepped using a classical fourth-order Runge-Kutta method, where the boundary conditions are imposed at the intermediate time levels.

Using the values of the penalty parameters given in Lemma 3.2 results in a stable scheme. However, the CFL number, relating the maximum allowable time-step to the spatial resolution as

$$\Delta t_{\max} \leq \text{CFL} \times \min_k \left[\frac{|u(x_k)|}{\Delta_k x} + \frac{\varepsilon}{(\Delta_k x)^2}\right]^{-1} \quad ,$$

will have to be very small in order to ensure stability. Here $|u(x_k)|$ signifies the local absolute value of u and $\Delta_k x$ represents the local grid spacing. Thus, with the theoretical value of the penalty parameter, the proposed method compares unfavorably with the traditional method because of severe time-step restrictions. Fortunately, the limits of the penalty parameters, in between which asymptotic stability is ensured, are obtained as a result of a conservative energy estimate and, hence, are not strict bounds.

We have used the values of the penalty parameter (see Lemma 3.2) as

$$\tau_1 = \frac{\tau_{\lambda,1}^-}{4} \quad , \quad \tau_2 = \frac{\tau_{0,1}^-}{4} \quad .$$

These values are found to lead to a stable scheme, provided the cell Reynolds number $\text{Re}_N = \lambda/(\varepsilon N^2) \ll 1$. The constraint simply states that increasing the Reynolds number

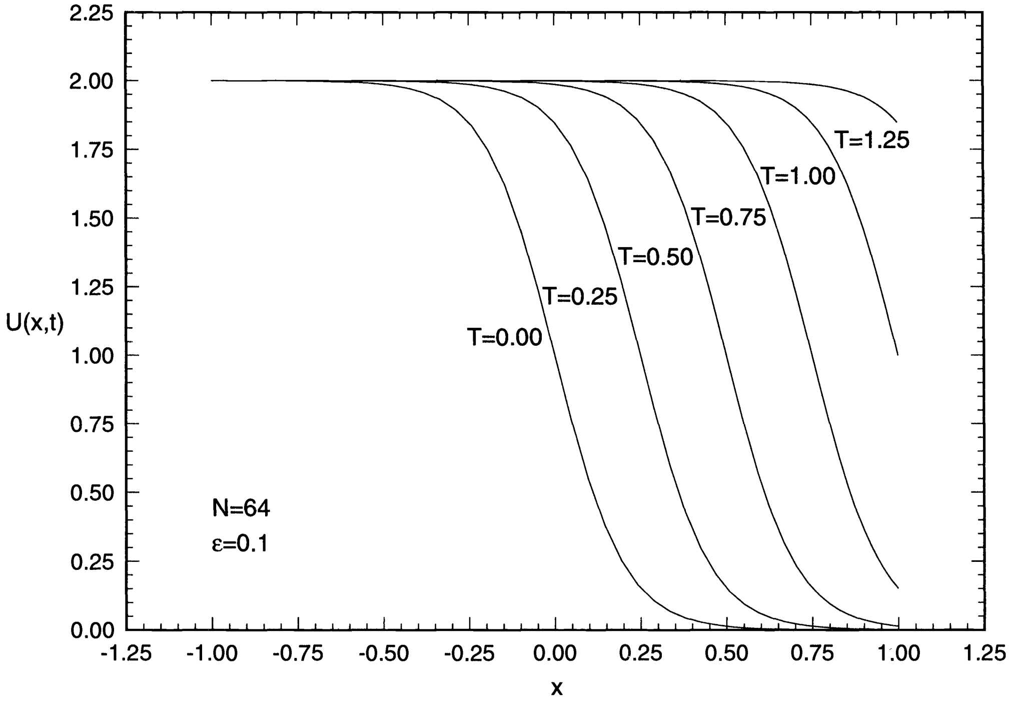

FIG. 1. *Traveling wave solution of the Burgers equation.*

TABLE 1

Error in the spectral simulation of the Burgers equation using the penalty method. The maximum error (L_∞) occurs at the boundary.

N	L_2	L_∞
16	3.41E-03	3.26E-02
32	2.43E-05	3.50E-04
64	1.09E-09	2.21E-08
128	4.98E-12	7.62E-11

requires increased spatial resolution, which is a natural restriction. For advection-dominated problems, stability is obtained by increasing the penalty parameters toward the values stated in Lemma 3.2.

With these values of the penalty parameters, we have been able to perform the simulations with a CFL number of 4, which is equivalent to what is usually allowed when using a traditional method. Thus, by fine-tuning the penalty parameters we were able to avoid any effect of the penalty method on the CFL condition. The following section contains a study of the effect of the penalty method on the CFL condition and guidelines for fine-tuning the penalty parameter for practical applications.

In Fig. 1 we show the temporal evolution of the traveling wave solution when using the scheme given by (8). The simulation is done with $N = 64$ and $\varepsilon = 0.1$. We observe no spurious reflections from the open boundary and the kink is seen to travel undisturbed out of the domain. Table 1 shows the error at $T = 1.00$, where the kink has propagated halfway through the boundary. It is evident that the proposed scheme maintains the spectral accuracy. The time-step is small enough to neglect time-stepping errors.

4. CFL restrictions for the penalty method. As discussed briefly in the previous section, choosing too large a penalty parameter results in severe CFL restrictions. For this reason, it is vital to understand how the penalty method alters the eigenvalue spectrum of the operators and consequently changes the CFL restriction.

In the present section we will study these effects for the linear advection and diffusion operators for Legendre collocation methods. For completeness, we will also give the results for Chebyshev collocation methods, which are widely used for solving nonlinear partial differential equations. The analysis will include both third- and fourth-order Runge-Kutta methods, which are often employed when addressing problems of the type considered here. At the end of the section we will compare the results from our linear analysis with simulations of the nonlinear Burgers equation.

Consider now the semi-discrete linear, constant coefficient problem

$$\begin{array}{llll} (\mathbf{q})_t = \mathcal{L}_N\mathbf{q} & x_k \in \Omega & , & t \geq 0 \ , \\ \mathbf{q} = 0 & x_k \in \Omega & , & t = 0 \ , \\ \mathcal{B}_N\mathbf{q} = 0 & x_k \in \Gamma & , & t \geq 0 \ , \end{array} \tag{11}$$

where $\mathbf{q} = (\mathbf{q}(x_0), \ldots, \mathbf{q}(x_N))^T$, $\mathcal{L}_N$ is the discrete approximation of the continuous operator for the interior, $\mathcal{L}$, and $\mathcal{B}_N$ determines the appropriate discrete boundary conditions by approximating the boundary operator, $\mathcal{B}$. We assume that the semi-discrete approximation is a consistent approximation of the continuous problem. A time-differencing scheme, where the boundary conditions are enforced exactly at the boundary points, may then be expressed as

$$\begin{array}{l} \mathbf{q}^{n+1} = K_N(\Delta t,\ \mathcal{L}_N)\mathbf{q}^n \ , \\ \mathcal{B}_N\mathbf{q}^{n+1} = 0 \ . \end{array}$$

Here $\mathbf{q}^n$ signifies the solution vector at time-step n. Thus, for strong stability we must require

$$|K_N(\Delta t,\ \mathcal{L}_N)| < 1 \ .$$

However, employing the penalty method changes the time-stepping scheme to be

$$\mathbf{q}^{n+1} = K_N(\Delta t\ , \mathcal{L}_N - \tau\mathcal{B}_N)\mathbf{q}^n,$$

and strong stability is ensured if

$$|K_N(\Delta t\ , \mathcal{L}_N - \tau\mathcal{B}_N)| < 1 \ ,$$

explaining why the CFL condition depends strongly on the correct choice of the penalty parameter.

In the following analysis we consider explicit Runge-Kutta time-stepping methods, which, for time independent operators, may be expressed as

$$K_N^p(\Delta t, \mathcal{L}_N) = \sum_{i=0}^{p} \frac{1}{i!}(\Delta t\mathcal{L}_N)^i \ ,$$

where p is the order of the scheme. We have for simplicity assumed that the boundary conditions are included in the operators. Assuming $\mathcal{L}_N = \mathcal{S}_N\Lambda_N\mathcal{S}_N^{-1}$, where $|\mathcal{S}_N|$ and $|\mathcal{S}_N^{-1}|$ are bounded independently of N, strong stability of the Runge-Kutta schemes is obtained if

$$|K_N^p(\Delta t,\ \mathcal{L}_N)| = \mathcal{S}_N\left|\sum_{i=0}^{p}\frac{1}{i!}(\Delta t\Lambda_N)^i\right|\mathcal{S}_N^{-1} = \left|\sum_{i=0}^{p}\frac{1}{i!}(\Delta t\Lambda_N)^i\right| < 1 \ .$$

TABLE 2

Scaling constants for the advection operator. The proper boundary conditions are of Dirichlet type (D).

N-R	Exact BC	99	109	53	58
	Penalty BC	130	135	91	96
R-R	Exact BC	99	109	53	58
	Penalty BC	130	141	93	97

Hence, the problem is reduced to finding the eigenvalue spectrum of the operator $\mathcal{L}_N$ and choosing Δt accordingly.

In the present study we consider the linear advection-diffusion operator

$$\mathcal{L} = \lambda \frac{\partial}{\partial x} + \varepsilon \frac{\partial^2}{\partial x^2} ,$$

with the Robin boundary condition operators

$$\mathcal{B}^- = \alpha - \varepsilon\beta \frac{\partial}{\partial x} \quad , \quad \mathcal{B}^+ = \gamma + \varepsilon\delta \frac{\partial}{\partial x} \quad .$$

The boundary conditions for the exact method are enforced through the operator as described in [18].

In order to compare time-step restrictions found for the two different approaches, we now define the two CFL-like constants, C_L and C_C, as

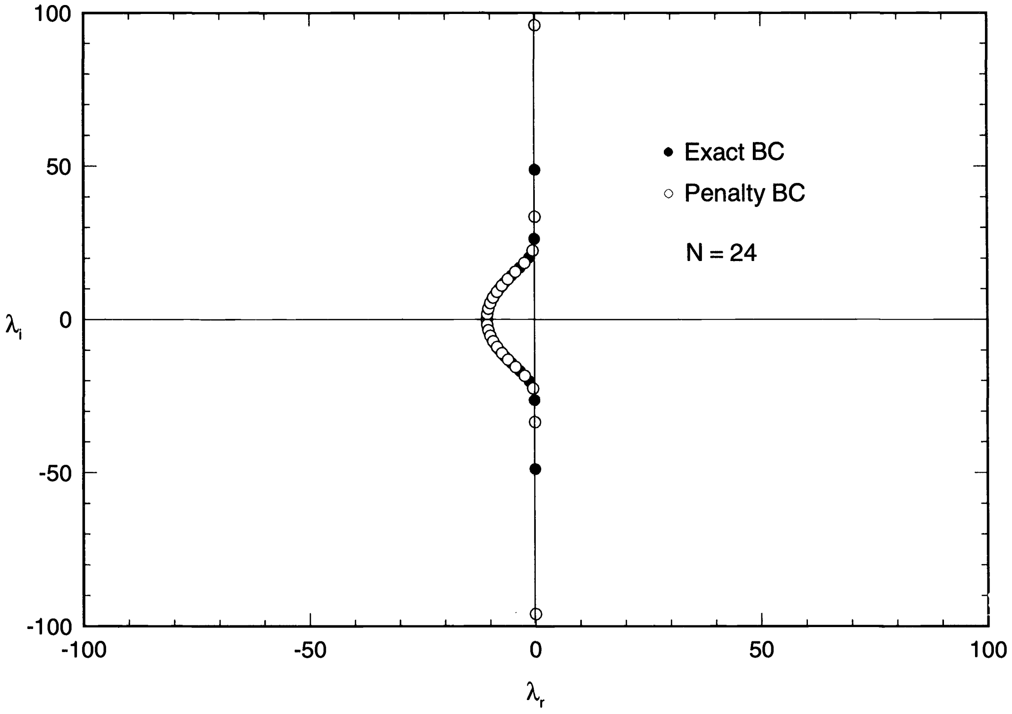
$$\Delta t_L \leq \frac{C_L}{\lambda N(N+1) + \varepsilon N^2(N+1)^2} \quad , \quad \Delta t_C \leq \frac{C_C}{\lambda N^2 + \varepsilon N^4} \quad ,$$

where the subscripts refer to Legendre (L) and Chebyshev (C) operators, respectively. These constants are determined by solving the eigenvalue problem and calculating the maximum Δt which ensures stability and, hence, supplies an upper bound on the time-step.

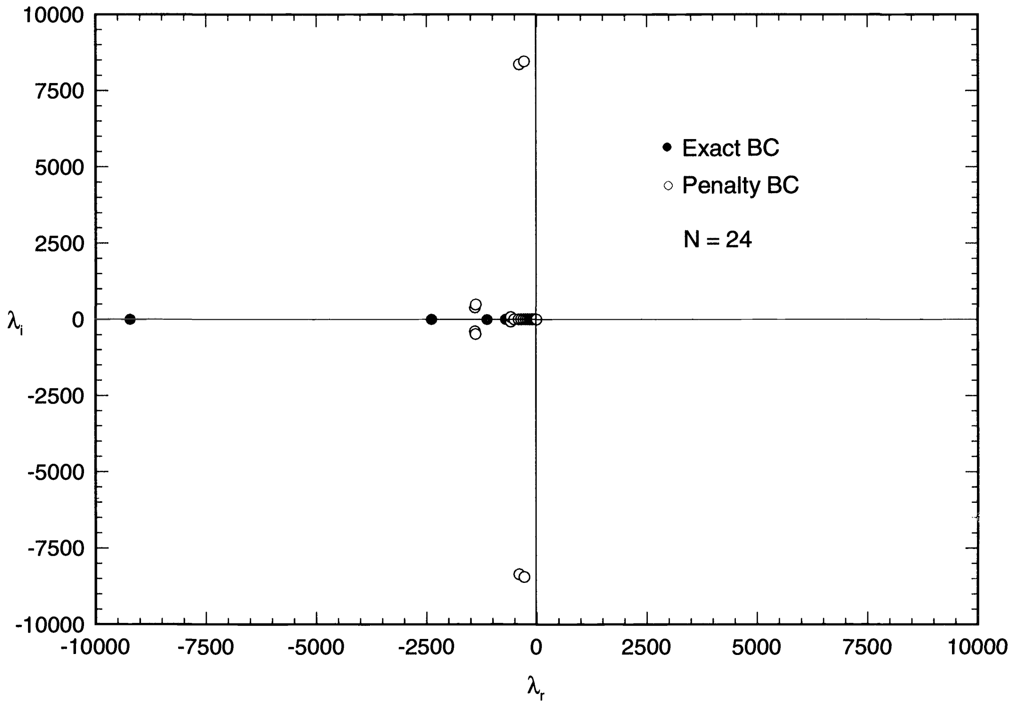
Tables 2 and 3 show the calculated values of C_L and C_C for the advection and the diffusion operator. The results are the same for the full advection-diffusion operator as for the diffusion operator, provided $\mathrm{Re}_N \ll 1$, and are therefore omitted.

It is clear from Table 2 that using the penalty method to enforce boundary conditions on purely advective problems results in a significant reduction of the maximum allowable time-step. However, more importantly, Table 3 shows that for problems where the diffusion operator dominates the eigenvalue spectrum, the penalty method may allow for increasing the time-step as much as 50%. The effect is most pronounced when using a fourth-order Runge-Kutta method for time-stepping a Chebyshev collocation scheme.

In order to explain the results in Tables 2 and 3, we compare in Fig. 2 the spectrum of the Legendre collocation advection (Fig. 2a) and diffusion (Fig. 2b) operators when enforcing Dirichlet boundary conditions through the exact method and the penalty method.



(a)



(b)

FIG. 2. *Eigenvalue spectrum ($\lambda = \lambda_r + i\,\lambda_i$) for the Legendre advection operator* (a) *and the Legendre diffusion operator* (b) *as obtained by using exact boundary conditions* (●) *and the penalty method* (○).

For the advection operator (Fig. 2a) we observe that the effect of the penalty method is to introduce an extreme, purely imaginary, complex conjugate eigenvalue-pair, which dominates the spectrum and consequently determines the maximum allowable time-step. This results in the decreased CFL number observed in Table 2.

The effect on the diffusion operator is more complicated and depends strongly on the value of the penalty parameter. As proved by Gottlieb and Lustman [17], the diffusion operator with exact Robin boundary conditions has a real, negative, and distinct eigenvalue spectrum. This property is preserved if a sufficiently large value of τ is used in the penalty method. However, by decreasing the penalty parameter the two dominating eigenvalues split into two pairs of complex conjugate eigenvalues, which move toward the imaginary axis as τ is decreased. In Fig. 2b we show the eigenvalue spectrum for the optimal choice of τ. The important observation to make is that moduli of these new eigenvalues are smaller than the original extreme negative real eigenvalue. Additionally, since the dominating eigenvalue now is complex, it clearly becomes advantageous to use the fourth-order Runge-Kutta method because of the increased extension of the stability region along the imaginary axis as compared to the third-order Runge-Kutta method. Thus, we conclude that for diffusion-dominated problems, the penalty method may allow for a significant increase in the maximum CFL number when applied in conjunction with the fourth-order Runge-Kutta method. This is true for Legendre as well as Chebyshev collocation methods.

The validity of this conclusion is, however, strongly dependent on the proper choice of the penalty parameter. The values derived in the previous section do indeed ensure asymptotic stability, but result in a significant reduction in the maximum allowable CFL number. Fortunately the limits of the penalty parameters are based on a conservative energy estimate and, consequently, are not very strict. In what follows we give the penalty parameters used to obtain the results given in Tables 2 and 3. These values result in a stable scheme as long as the problem is purely advective or $\mathrm{Re}_N \ll 1$, and allow in most cases for a significant increase in the time-step.

Legendre collocation methods.

1. Dirichlet boundary conditions.

$$\tau = \frac{|\lambda|}{4}N(N+1) + \frac{\varepsilon}{64}N^2(N+1)^2 \ .$$

2. Neumann boundary conditions.

$$\tau = \frac{N(N+1)}{8} \ .$$

3. Robin boundary conditions.

$$\tau = \frac{\tau^-_{\alpha,\beta}}{4} \ .$$

Chebyshev collocation methods.

1. Dirichlet boundary conditions.

$$\tau = \frac{|\lambda|}{2}N^2 + \frac{\varepsilon}{50}N^4 \ .$$

2. Neumann boundary conditions.

$$\tau = \frac{N^2}{8} \ .$$

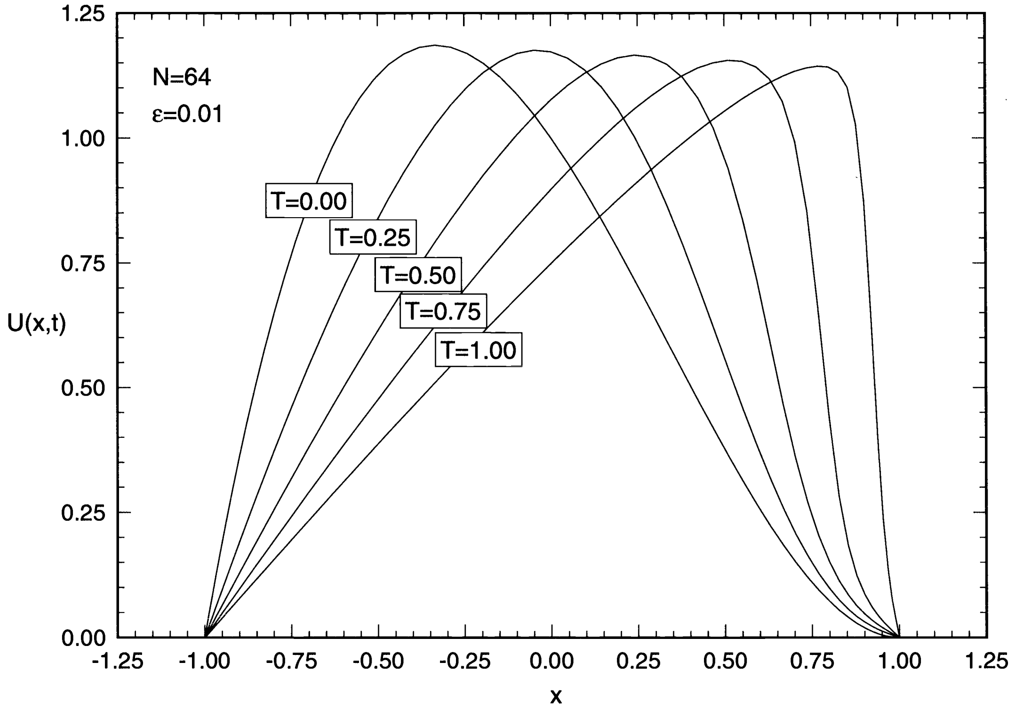


FIG. 3. *Temporal evolution of the Burgers equation with initial conditions given by* (12).

3. Robin boundary conditions.

$$\tau = \frac{\tau^{-}_{\alpha,\beta}}{4} \text{ with } \kappa = \frac{\alpha N^2}{\beta} .$$

Note that the only difference between the parameter values quoted here and those found in Lemma 3.2 is a factor of 1/4 on those terms related to the diffusion operator. This reduction is found to lead to optimal time-step restrictions.

We would like to stress the importance of choosing the appropriate value of the penalty parameter. It is our experience, that this is best done by deriving the theoretical value of this parameter through an analysis similar to that done in §3.1. This leads to a parameter which scales correctly with the resolution and other significant parameters. If the time-step restriction is dominated by a viscous time-scale, it is very likely that the theoretical estimate leads to severe time-step restrictions. However, the theoretical value may often be decreased considerably, and good results may be obtained after only a few tests. As we have seen for the Burgers equation, decreasing the penalty parameter four times leads to acceptable CFL restrictions. We are not aware of any systematic way to determine the optimal factor by which the theoretical value can be decreased, but it may usually be determined by trial and error through a few tests.

To conclude our study we have solved the Burgers equation, (3), with initial condition

$$U(x,0) = (1-x)(1-x^2) \tag{12}$$

and homogeneous Dirichlet boundary conditions. A typical temporal evolution is shown in Fig. 3. In Table 4 we show the maximum CFL number resulting in a stable scheme. This result confirms that the results from the linear analysis carry over to the scalar nonlinear problem.

TABLE 4

Penalty BC	3.00	4.50	4.75	6.75

5. The compressible Navier–Stokes equations. In the present section, we obtain energy estimates for the solution of the three-dimensional compressible Navier-Stokes equations given in conservation form. Additionally, we derive open boundary conditions taking into account the full stress-tensor, and prove well-posedness for the continuous problem. The derivations follow the approach introduced in [8, 9]. The main differences are that we develop the theory for the conservation form of the Navier-Stokes equations and that we include the off-diagonal terms of the stress-tensor in the full derivations. In the second part of this section we continue by showing how to apply the boundary conditions and prove asymptotic stability of the semi-discrete scheme.

Consider now the nondimensionalized, compressible Navier-Stokes equations given in conservation form

$$\frac{\partial \mathbf{q}}{\partial t}+\frac{\partial \mathbf{F}}{\partial x}+\frac{\partial \mathbf{G}}{\partial y}+\frac{\partial \mathbf{H}}{\partial z}=\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\left(\frac{\partial \mathbf{F}_\nu}{\partial x}+\frac{\partial \mathbf{G}_\nu}{\partial y}+\frac{\partial \mathbf{H}_\nu}{\partial z}\right) , \tag{13}$$

with $\mathbf{x} \in \Omega = [-1, 1]^3$. The state vector, $\mathbf{q}$, and the inviscid flux vectors are given as

$$\mathbf{q}=\begin{bmatrix}\rho\\ \rho u\\ \rho v\\ \rho w\\ E\end{bmatrix} , \quad \mathbf{F}=\begin{bmatrix}\rho u\\ \rho u^2+p\\ \rho uv\\ \rho uw\\ (E+p)u\end{bmatrix} , \quad \mathbf{G}=\begin{bmatrix}\rho v\\ \rho uv\\ \rho v^2+p\\ \rho vw\\ (E+p)v\end{bmatrix} , \quad \mathbf{H}=\begin{bmatrix}\rho w\\ \rho uw\\ \rho vw\\ \rho w^2+p\\ (E+p)w\end{bmatrix} .$$

Here ρ is the density, u, v, w are the three Cartesian velocity components, E is the total energy, and p is the pressure. In the remaining part of this paper we will use (x, y, z) and (x_1, x_2, x_3) interchangeably to denote the spatial coordinates. The total energy

$$E=\rho\left(T+\frac{1}{2}\left(u^2+v^2+w^2\right)\right) ,$$

and the pressure are related through the ideal gas law

$$p=(\gamma-1)\rho T ,$$

where T is the temperature field and $\gamma = c_p/c_v$ is the ratio between the heat capacities at constant pressure (c_p) and volume (c_v), respectively, and is assumed constant.

The viscous flux vectors are given as

$$\mathbf{F}_\nu=\begin{bmatrix}0\\ \tau_{xx}\\ \tau_{yx}\\ \tau_{zx}\\ \tau_{xx}u+\tau_{yx}v+\tau_{zx}w+\frac{\gamma k}{\mathrm{Pr}}\frac{\partial T}{\partial x}\end{bmatrix} , \quad \mathbf{G}_\nu=\begin{bmatrix}0\\ \tau_{xy}\\ \tau_{yy}\\ \tau_{zy}\\ \tau_{xy}u+\tau_{yy}v+\tau_{zy}w+\frac{\gamma k}{\mathrm{Pr}}\frac{\partial T}{\partial y}\end{bmatrix} ,$$

$$\mathbf{H}_\nu=\begin{bmatrix}0\\ \tau_{xz}\\ \tau_{yz}\\ \tau_{zz}\\ \tau_{xz}u+\tau_{yz}v+\tau_{zz}w+\frac{\gamma k}{\mathrm{Pr}}\frac{\partial T}{\partial z}\end{bmatrix} .$$

Considering only Newtonian fluids, the stress-tensor elements are given as

$$\begin{aligned}
\tau_{xx} &= 2\mu\frac{\partial u}{\partial x} + \lambda\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right), &\quad \tau_{xy} = \tau_{yx} &= \mu\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right),\\
\tau_{yy} &= 2\mu\frac{\partial v}{\partial y} + \lambda\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right), &\quad \tau_{yz} = \tau_{zy} &= \mu\left(\frac{\partial w}{\partial y} + \frac{\partial v}{\partial z}\right),\\
\tau_{zz} &= 2\mu\frac{\partial w}{\partial z} + \lambda\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right), &\quad \tau_{xz} = \tau_{zx} &= \mu\left(\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z}\right),
\end{aligned}$$

where μ is the dynamic viscosity, λ is the bulk viscosity, and k is the coefficient of thermal conductivity.

The equations are normalized using the reference values, $u_{\text{ref}} = u_0$, $\rho_{\text{ref}} = \rho_0$, $p_{\text{ref}} = \rho_0 u_0^2$, $T_{\text{ref}} = u_0^2/c_v$, and a reference length L, where (ρ_0, u_0) is some uniform state, e.g., the ambient free-stream conditions of the flow. This gives a Reynolds number as $\text{Re} = \rho_0 u_0 L/\mu_0$ and a Prandtl number as $\text{Pr} = c_p\mu_0/k_0$. Note that the Reynolds number in (13), Re_{ref}, based on the reference values, in general is different from Re. In the remaining part of the paper we shall refer to the latter as the Reynolds number unless clarification is deemed necessary. With this normalization we need to specify the Mach number, M, the Reynolds number, Re, the length scale, L, and a dimensional temperature, T_0.

5.1. Well-posedness and open boundary conditions for the continuous problem. Consider the linearized, constant coefficient form of (13). The viscous fluxes are split as

$$\mathbf{F}_v = \mathbf{F}_P + \mathbf{F}_M^y + \mathbf{F}_M^z = \begin{bmatrix} 0 \\ (\lambda + 2\mu)\frac{\partial u}{\partial x} \\ \mu\frac{\partial v}{\partial x} \\ \mu\frac{\partial w}{\partial x} \\ (\lambda + 2\mu)u\frac{\partial u}{\partial x} + \mu v\frac{\partial v}{\partial x} + \mu w\frac{\partial w}{\partial x} + \frac{\gamma k}{\text{Pr}}\frac{\partial T}{\partial x} \end{bmatrix}$$

$$+ \begin{bmatrix} 0 \\ \lambda\frac{\partial v}{\partial y} \\ \mu\frac{\partial u}{\partial y} \\ 0 \\ \lambda u\frac{\partial v}{\partial y} + \mu v\frac{\partial u}{\partial y} \end{bmatrix} + \begin{bmatrix} 0 \\ \lambda\frac{\partial w}{\partial z} \\ 0 \\ \mu\frac{\partial u}{\partial z} \\ \lambda u\frac{\partial w}{\partial z} + \mu w\frac{\partial u}{\partial z} \end{bmatrix},$$

$$\mathbf{G}_v = \mathbf{G}_P + \mathbf{G}_M^x + \mathbf{G}_M^z = \begin{bmatrix} 0 \\ \mu\frac{\partial u}{\partial y} \\ (\lambda + 2\mu)\frac{\partial v}{\partial y} \\ \mu\frac{\partial w}{\partial y} \\ \mu u\frac{\partial u}{\partial y} + (\lambda + 2\mu)v\frac{\partial v}{\partial y} + \mu w\frac{\partial w}{\partial y} + \frac{\gamma k}{\text{Pr}}\frac{\partial T}{\partial y} \end{bmatrix}$$

$$+ \begin{bmatrix} 0 \\ \mu\frac{\partial v}{\partial x} \\ \lambda\frac{\partial u}{\partial x} \\ 0 \\ \lambda v\frac{\partial u}{\partial x} + \mu u\frac{\partial v}{\partial x} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \lambda\frac{\partial w}{\partial z} \\ \mu\frac{\partial v}{\partial z} \\ \lambda v\frac{\partial w}{\partial z} + \mu w\frac{\partial v}{\partial z} \end{bmatrix},$$

$$\mathbf{H}_v = \mathbf{H}_P + \mathbf{H}_M^x + \mathbf{H}_M^y = \begin{bmatrix} 0 \\ \mu\frac{\partial u}{\partial z} \\ \mu\frac{\partial v}{\partial z} \\ (\lambda + 2\mu)\frac{\partial w}{\partial z} \\ \mu u\frac{\partial u}{\partial z} + \mu v\frac{\partial v}{\partial z} + (\lambda + 2\mu) w\frac{\partial w}{\partial z} + \frac{\gamma k}{\mathrm{Pr}}\frac{\partial T}{\partial z} \end{bmatrix}$$

$$+ \begin{bmatrix} 0 \\ \mu\frac{\partial w}{\partial x} \\ 0 \\ \lambda\frac{\partial u}{\partial x} \\ \lambda w\frac{\partial u}{\partial x} + \mu u\frac{\partial w}{\partial x} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \mu\frac{\partial w}{\partial y} \\ \lambda\frac{\partial v}{\partial y} \\ \lambda w\frac{\partial v}{\partial y} + \mu v\frac{\partial w}{\partial y} \end{bmatrix} .$$

Introducing the transformation Jacobians

$$\mathcal{A}_1 = \frac{\partial \mathbf{F}}{\partial \mathbf{q}} \ , \ \mathcal{A}_2 = \frac{\partial \mathbf{G}}{\partial \mathbf{q}} \ , \ \mathcal{A}_3 = \frac{\partial \mathbf{H}}{\partial \mathbf{q}} \ ,$$

$$\mathcal{B}_{11} = \frac{\partial \mathbf{F}_P}{\partial \mathbf{q}_x} \ , \ \mathcal{B}_{22} = \frac{\partial \mathbf{G}_P}{\partial \mathbf{q}_y} \ , \ \mathcal{B}_{33} = \frac{\partial \mathbf{H}_P}{\partial \mathbf{q}_z} \ ,$$

$$\mathcal{B}_{12} = \left(\frac{\partial \mathbf{F}_M^y}{\partial \mathbf{q}_y} + \frac{\partial \mathbf{G}_M^x}{\partial \mathbf{q}_x}\right) \ , \ \mathcal{B}_{23} = \left(\frac{\partial \mathbf{G}_M^z}{\partial \mathbf{q}_z} + \frac{\partial \mathbf{H}_M^y}{\partial \mathbf{q}_y}\right) \ , \ \mathcal{B}_{13} = \left(\frac{\partial \mathbf{F}_M^z}{\partial \mathbf{q}_z} + \frac{\partial \mathbf{H}_M^x}{\partial \mathbf{q}_x}\right) \ ,$$

allows us to write Navier-Stokes equations as

$$\frac{\partial \mathbf{q}}{\partial t} + \sum_{i=1}^{3} \mathcal{A}_i \frac{\partial \mathbf{q}}{\partial x_i} = \frac{1}{\mathrm{Re}_{\mathrm{ref}}} \sum_{i=1}^{3}\sum_{j=i}^{3} \mathcal{B}_{ij} \frac{\partial^2 \mathbf{q}}{\partial x_i\, \partial x_j} \ .$$

It is well known that the Navier-Stokes equations, although not of hyperbolic nature, support waves very similar to those encountered in the hyperbolic Euler equations. For hyperbolic systems, Gottlieb, Gunzburger, and Turkel [19] have shown that enforcing the boundary conditions through the characteristic variables of the system results in a stable approximation.

For Navier-Stokes equations, we linearize around a uniform state, $\mathbf{q}_0$, by fixing all the matrices. We transform into characteristic variables by diagonalizing $\mathcal{A}_1$ through a similarity transform $\Lambda = \mathcal{S}^{-1}\mathcal{A}_1\mathcal{S}$, where Λ is the eigenvalue matrix and $\mathcal{S}$ and $\mathcal{S}^{-1}$ are the matrices of right and left eigenvectors, respectively. These matrices are given in the Appendix. Applying this, the symmetrized, linearized set of equations transforms into

$$\mathcal{Q}^T\mathcal{Q}\frac{\partial \mathbf{R}}{\partial t} + \sum_{i=1}^{3} \mathcal{A}_i^s \frac{\partial \mathbf{R}}{\partial x_i} = \frac{1}{\mathrm{Re}_{\mathrm{ref}}} \sum_{i=1}^{3}\sum_{j=i}^{3} \mathcal{B}_{ij}^s \frac{\partial^2 \mathbf{R}}{\partial x_i\, \partial x_j} \ , \tag{14}$$

where $\mathbf{R} = \mathcal{S}^{-1}\mathbf{q}$ are the characteristic variables. We have introduced a positive definite, symmetrizing diagonal matrix, $\mathcal{Q}^T\mathcal{Q}$, given as

$$\mathcal{Q}^T\mathcal{Q} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 \\ 0 & 0 & \frac{2c_0^2}{\gamma-1} & 0 & 0 \\ 0 & 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} ,$$

where $c_0 = \sqrt{\gamma p_0/\rho_0}$ is the uniform state sound speed. Additionally we define the symmetrized matrices

$$\mathcal{A}_i^s = \mathcal{Q}^T\mathcal{Q}\mathcal{S}^{-1}\mathcal{A}_i\mathcal{S} \ , \quad \mathcal{B}_{ij}^s = \mathcal{Q}^T\mathcal{Q}\mathcal{S}^{-1}\mathcal{B}_{ij}\mathcal{S} \ .$$

The explicit forms of the symmetric matrices are given in the Appendix. The characteristic variables, $\mathbf{R} = [R_1,\ R_2,\ R_3,\ R_4,\ R_5]^T$, are given as

$$\mathbf{R} = \begin{bmatrix} \rho u - u_0\rho + \frac{\gamma-1}{c_0}\left(E + \frac{1}{2}(u_0^2+v_0^2+w_0^2)\rho - u_0\rho u - v_0\rho v - w_0\rho w\right) \\ \rho v - v_0\rho \\ \rho - \frac{\gamma-1}{c_0^2}\left(E + \frac{1}{2}\rho(u_0^2+v_0^2+w_0^2) - u_0\rho u - v_0\rho v - w_0\rho w\right) \\ \rho w - w_0\rho \\ -(\rho u - u_0\rho) + \frac{\gamma-1}{c_0}\left(E + \frac{1}{2}\rho(u_0^2+v_0^2+w_0^2) - u_0\rho u - v_0\rho v - w_0\rho w\right) \end{bmatrix} .$$

We are now ready to state the following lemma.

LEMMA 5.1. *Assume there exists a solution, $\mathbf{q}$, which is periodic or held at a constant value at the y- and z-boundary. If the boundary conditions in the x-direction are given such that*

$$\forall (y,z) \in \Omega_y \times \Omega_z \ : \ -\frac{1}{2}\left[\mathbf{R}^T\mathcal{A}_1^s\mathbf{R} - \frac{2}{\mathrm{Re}_{\mathrm{ref}}}\sum_{j=1}^{3}\mathbf{R}^T\mathcal{B}_{1j}^s\frac{\partial\mathbf{R}}{\partial x_j}\right]_{x=-1}^{1} \le 0 \ ,$$

and the fluid properties are constrained by

$$\mu_0 \ge 0 \ , \quad \lambda_0 \le 0 \ , \quad \lambda_0 + \mu_0 \ge 0 \ , \quad \frac{\gamma k_0}{\mathrm{Pr}} \ge 0 \ , \quad \gamma \ge 1 \ ,$$

then (14) *constitutes a well-posed problem and the solution is bounded as*

$$\frac{1}{2}\frac{d}{dt}\|\mathcal{Q}\mathbf{R}\|^2 \le -\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\int_\Omega\left(\sum_{i=1}^{3}\sum_{j=i}^{3}\frac{\partial\mathbf{R}^T}{\partial x_i}\mathcal{B}_{ij}^s\frac{\partial\mathbf{R}}{\partial x_j}\right)d\Omega \le 0 \ .$$

Proof. Construct the energy integral as

$$\begin{aligned}\frac{1}{2}\frac{d}{dt}\|\mathcal{Q}\mathbf{R}\|^2 &= \int_\Omega\left(-\sum_{i=1}^{3}\mathbf{R}^T\mathcal{A}_i^s\frac{\partial\mathbf{R}}{\partial x_i} + \frac{1}{\mathrm{Re}_{\mathrm{ref}}}\sum_{i=1}^{3}\sum_{j=i}^{3}\mathbf{R}^T\mathcal{B}_{ij}^s\frac{\partial^2\mathbf{R}}{\partial x_i\partial x_j}\right)d\Omega \\ &= \int_{\Omega_y}\int_{\Omega_z} -\frac{1}{2}\left[\mathbf{R}^T\mathcal{A}_1^s\mathbf{R} - \frac{2}{\mathrm{Re}_{\mathrm{ref}}}\sum_{j=1}^{3}\mathbf{R}^T\mathcal{B}_{1j}^s\frac{\partial\mathbf{R}}{\partial x_j}\right]_{x=-1}^{1} dydz \\ &\quad - \frac{1}{\mathrm{Re}_{\mathrm{ref}}}\int_\Omega\left(\sum_{i=1}^{3}\sum_{j=i}^{3}\frac{\partial\mathbf{R}^T}{\partial x_i}\mathcal{B}_{ij}^s\frac{\partial\mathbf{R}}{\partial x_j}\right)d\Omega \ ,\end{aligned}$$

where $\Omega = \Omega_x \times \Omega_y \times \Omega_z$. In deriving this expression, we use partial integration and assume the solution to be periodic or held at a constant value along the y- and z-boundaries, i.e., contributions from these boundaries cancel. This is not a severe restriction, as this assumption is valid for a large variety of situations where open boundary conditions are applied.

It is evident that if we can prove

$$\text{(15)} \qquad \frac{1}{\mathrm{Re}_{\mathrm{ref}}}\int_\Omega\left(\sum_{i=1}^{3}\sum_{j=i}^{3}\frac{\partial\mathbf{R}^T}{\partial x_i}\mathcal{B}_{ij}^s\frac{\partial\mathbf{R}}{\partial x_j}\right)d\Omega \ge 0 \ ,$$

then well-posedness may be ensured by properly constructing the boundary operator at the x-boundary.

Since the matrices, $\mathcal{B}^s_{ij}$, are all symmetric, (15) may be rewritten in a block-quadratic form as

$$\frac{1}{2\mathrm{Re}_{\mathrm{ref}}}\int_\Omega \tilde{\mathbf{R}}^T \mathcal{H}^s \tilde{\mathbf{R}}\, d\Omega \geq 0 \ ,$$

where we have introduced

$$\tilde{\mathbf{R}} = \left[\frac{\partial \mathbf{R}}{\partial x}, \frac{\partial \mathbf{R}}{\partial y}, \frac{\partial \mathbf{R}}{\partial z}\right]^T \ , \ \mathcal{H}^s = \begin{bmatrix} 2\mathcal{B}^s_{11} & \mathcal{B}^s_{12} & \mathcal{B}^s_{13} \\ \mathcal{B}^s_{12} & 2\mathcal{B}^s_{22} & \mathcal{B}^s_{23} \\ \mathcal{B}^s_{13} & \mathcal{B}^s_{23} & 2\mathcal{B}^s_{33} \end{bmatrix} \ .$$

We observe that $\mathcal{H}^s$ is a 15×15 symmetric block matrix, ensuring that the eigenvalue spectrum, $\rho(\mathcal{H}^s)$, is real. Hence, if $\mathcal{H}^s$ is positive semi-definite, (15) is obeyed. The eigenvalue spectrum, $\rho(\mathcal{H}^s)$, may be found to be

$$\begin{aligned}
\rho_1 &= \rho_2 = \rho_3 = 0 \ , \\
\rho_4 &= 2(\mu_0 - \lambda_0) \ , \\
\rho_5 &= \rho_6 = 2(\lambda_0 + 3\mu_0) \ , \\
\rho_7 &= \rho_8 = 3\mu_0 - \sqrt{\mu_0^2 + 2(\mu_0 + \lambda_0)^2} \ , \\
\rho_9 &= \rho_{10} = 3\mu_0 + \sqrt{\mu_0^2 + 2(\mu_0 + \lambda_0)^2} \ , \\
\rho_{11} &= 7\mu_0 + 4\lambda_0 - \sqrt{\mu_0^2 + 4(\mu_0 + \lambda_0)(3\mu_0 + 2\lambda_0)} \ , \\
\rho_{12} &= 7\mu_0 + 4\lambda_0 + \sqrt{\mu_0^2 + 4(\mu_0 + \lambda_0)(3\mu_0 + 2\lambda_0)} \ , \\
\rho_{13} &= \rho_{14} = \rho_{15} = \left(\frac{2c_0^2}{(\gamma - 1)^2} + 1\right)\frac{2(\gamma - 1)k_0}{\mathrm{Pr}} \ .
\end{aligned}$$

Here subscript "0" signifies the parameter values in the uniform state around which we have linearized. For most real fluids under nonextreme conditions, it is true that μ_0 is positive, λ_0 is negative, and the following relationship is obeyed [20]:

$$\frac{\gamma\mu_0}{\mathrm{Pr}} \geq \lambda_0 + 2\mu_0 \geq \mu_0 \ . \tag{16}$$

A simple investigation of the eigenvalues reveals that $\mathcal{H}^s$ is positive semi-definite under these conditions. Thus, (15) is true provided

$$\mu_0 \geq 0 \ , \quad \lambda_0 \leq 0 \ , \quad \lambda_0 + \mu_0 \geq 0 \ , \quad \frac{\gamma k_0}{\mathrm{Pr}} \geq 0 \ , \quad \gamma \geq 1 \ .$$

These conditions are only natural as discussed in [21]. In fact, if they are not obeyed, Navier-Stokes equations violate the second law of thermodynamics.

We now obtain that well-posedness is ensured under the additional condition

$$\forall (y,z) \in \Omega_y \times \Omega_z \quad -\frac{1}{2}\left[\mathbf{R}^T \mathcal{A}^s_1 \mathbf{R} - \frac{2}{\mathrm{Re}_{\mathrm{ref}}}\sum_{j=1}^{3} \mathbf{R}^T \mathcal{B}^s_{1j}\frac{\partial \mathbf{R}}{\partial x_j}\right]_{x=-1}^{1} \leq 0 \ ,$$

with the solution being bounded as

$$\frac{1}{2}\frac{d}{dt}\|\mathcal{Q}\mathbf{R}\|^2 \leq -\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\int_\Omega \left(\sum_{i=1}^{3}\sum_{j=i}^{3}\frac{\partial \mathbf{R}^T}{\partial x_i}\mathcal{B}^s_{ij}\frac{\partial \mathbf{R}}{\partial x_j}\right) d\Omega \leq 0 \ ,$$

where $\mathcal{Q}\mathbf{R} = \mathcal{Q}\mathcal{S}^{-1}\mathbf{q}$. □

As stated in Lemma 5.1, appropriate boundary conditions at the x-boundary have to obey

$$-\frac{1}{2}\left[\mathbf{R}^T\mathcal{A}^s_1\mathbf{R} - \frac{2}{\mathrm{Re}_{\mathrm{ref}}}\sum_{j=1}^{3}\mathbf{R}^T\mathcal{B}^s_{1j}\frac{\partial \mathbf{R}}{\partial x_j}\right]_{-1}^{1} \leq 0 \ .$$

We now define

$$\mathcal{Q}^T\mathcal{Q}\mathbf{G} = \sum_{j=1}^{3}\mathcal{B}^s_{1j}\frac{\partial \mathbf{R}}{\partial x_j} \ ,$$

where

$$\begin{aligned}
G_1 &= \frac{k_0(\gamma-1)}{2\rho_0\mathrm{Pr}}\frac{\partial\zeta_1}{\partial x} + \frac{\lambda_0+2\mu_0}{2\rho_0}\frac{\partial\zeta_2}{\partial x} + \frac{\lambda_0+\mu_0}{\rho_0}\left(\frac{\partial R_2}{\partial y}+\frac{\partial R_4}{\partial z}\right) \ , \\
G_2 &= \frac{\mu_0}{\rho_0}\frac{\partial R_2}{\partial x} + \frac{\lambda_0+\mu_0}{2\rho_0}\frac{\partial\zeta_2}{\partial y} \ , \\
G_3 &= -\frac{k_0(\gamma-1)}{2\rho_0 c_0\mathrm{Pr}}\frac{\partial\zeta_1}{\partial x} \ , \\
G_4 &= \frac{\mu_0}{\rho_0}\frac{\partial R_4}{\partial x} + \frac{\lambda_0+\mu_0}{2\rho_0}\frac{\partial\zeta_2}{\partial z} \ , \\
G_5 &= \frac{k_0(\gamma-1)}{2\rho_0\mathrm{Pr}}\frac{\partial\zeta_1}{\partial x} - \frac{\lambda_0+2\mu_0}{2\rho_0}\frac{\partial\zeta_2}{\partial x} - \frac{\lambda_0+\mu_0}{\rho_0}\left(\frac{\partial R_2}{\partial y}+\frac{\partial R_4}{\partial z}\right) \ ,
\end{aligned} \tag{17}$$

where we, for simplicity, have introduced

$$\zeta_1 = R_1 + R_5 - \frac{2c_0}{\gamma-1}R_3 \ , \ \zeta_2 = R_1 - R_5 \ .$$

Some physical meaning can be given to the components of $\mathbf{G}$. The three components G_1, G_3, and G_5 account for effects caused by the normal heat flux and stress, whereas the remaining two, G_2 and G_4, are a consequence of tangential stress at the boundary.

This formulation allows for rewriting the constraint on the boundary contribution as

$$-\frac{1}{2}\mathcal{Q}^T\left[\mathbf{R}^T\Lambda\mathbf{R} - \frac{2}{\mathrm{Re}_{\mathrm{ref}}}\mathbf{R}^T\mathbf{G}\right]_{-1}^{1}\mathcal{Q} \leq 0 \ ,$$

where Λ is the diagonal eigenvalue matrix obtained from the similarity transform. Because $\mathcal{Q}^T\mathcal{Q}$ is positive definite, this inequality may be reformulated as

$$-\frac{1}{2}\left[\sum_{i=1}^{5}\lambda_i^{-1}\left(\left(|\lambda_i|R_i - \varepsilon\frac{|\lambda_i|}{\lambda_i}G_i\right)^2 - (\varepsilon G_i)^2\right)\right]_{-1}^{1} \leq 0 \ , \tag{18}$$

where λ_i are the wave speeds by which the characteristic variables are advected, as given by the diagonal elements of Λ, and we have introduced $\varepsilon = \mathrm{Re}_{\mathrm{ref}}{}^{-1}$. This formulation makes it straightforward to devise inflow-outflow boundary conditions, which are maximal dissipative and ensure well-posedness of the complete problem.

We note in particular that this formulation takes into account the off-diagonal terms of the stress-tensor, which are neglected in most previous work [8-10]. These terms may be of importance if the artificial boundary is introduced into a strongly vortical region of the flow, e.g., a wake flow behind a blunt body.

Inflow boundary conditions. At $x = -1$, (18) becomes

$$\frac{1}{2}\sum_{i=1}^{5}\lambda_i^{-1}\left(\left(|\lambda_i|R_i - \varepsilon\frac{|\lambda_i|}{\lambda_i}G_i\right)^2 - (\varepsilon G_i)^2\right) \le 0 \ .$$

Subsonic inflow: $\lambda_1 > 0$, $\lambda_2 > 0$, $\lambda_3 > 0$, $\lambda_4 > 0$, $\lambda_5 < 0$.

$$\begin{aligned} \lambda_1 R_1 - \varepsilon G_1 &= 0 \ , \\ \lambda_2 R_2 - \varepsilon G_2 &= 0 \ , \\ \lambda_3 R_3 - \varepsilon G_3 &= 0 \ , \\ \lambda_4 R_4 - \varepsilon G_4 &= 0 \ , \\ \varepsilon G_5 &= 0 \ . \end{aligned} \tag{19}$$

Supersonic inflow: $\lambda_1 > 0$, $\lambda_2 > 0$, $\lambda_3 > 0$, $\lambda_4 > 0$, $\lambda_5 > 0$.

$$\begin{aligned} \lambda_1 R_1 - \varepsilon G_1 &= 0 \ , \\ \lambda_2 R_2 - \varepsilon G_2 &= 0 \ , \\ \lambda_3 R_3 - \varepsilon G_3 &= 0 \ , \\ \lambda_4 R_4 - \varepsilon G_4 &= 0 \ , \\ \lambda_5 R_5 - \varepsilon G_5 &= 0 \ . \end{aligned} \tag{20}$$

Outflow boundary conditions. At $x = 1$, (18) becomes

$$\frac{1}{2}\sum_{i=1}^{5}-\lambda_i^{-1}\left(\left(|\lambda_i|R_i - \varepsilon\frac{|\lambda_i|}{\lambda_i}G_i\right)^2 - (\varepsilon G_i)^2\right) \le 0 \ .$$

Subsonic outflow: $\lambda_1 > 0$, $\lambda_2 > 0$, $\lambda_3 > 0$, $\lambda_4 > 0$, $\lambda_5 < 0$.

$$\begin{aligned} \varepsilon G_2 &= 0 \ , \\ \varepsilon G_3 &= 0 \ , \\ \varepsilon G_4 &= 0 \ , \\ |\lambda_5|R_5 + \varepsilon G_5 &= 0 \ . \end{aligned} \tag{21}$$

Supersonic outflow: $\lambda_1 > 0$, $\lambda_2 > 0$, $\lambda_3 > 0$, $\lambda_4 > 0$, $\lambda_5 > 0$.

$$\begin{aligned} \varepsilon G_1 &= 0 \ , \\ \varepsilon G_2 &= 0 \ , \\ \varepsilon G_3 &= 0 \ , \\ \varepsilon G_4 &= 0 \ . \end{aligned} \quad \text{or} \quad \begin{aligned} \varepsilon G_2 &= 0 \ , \\ \varepsilon G_3 &= 0 \ , \\ \varepsilon G_4 &= 0 \ , \\ \varepsilon G_5 &= 0 \ . \end{aligned} \tag{22}$$

We note that for both types of outflow boundary conditions, it is only necessary to specify four conditions, since $\varepsilon G_3 = 0 \Rightarrow \varepsilon G_1 = -\varepsilon G_5$. Due to the special structure of **G** we also observe that adding an extra condition on εG_1 at the outflow does not place extra conditions on the solution, since such a condition is redundant. This observation will be used later.

It was shown by Strikwerda [22] that the proper number of boundary conditions for an incomplete, parabolic system as the compressible Navier-Stokes equations is 5 in the inflow region and 4 in the outflow region. Our result clearly conforms with that.

We also note that in the limit of infinite Reynolds number, these boundary conditions converge uniformly toward the well-known characteristic boundary conditions for the compressible Euler equations [23]. This property is important in order to avoid weak boundary layers of the order $\exp(-x/\varepsilon)$ (see [8]).

5.2. The semi-discrete scheme. Following the line of thought that led to the asymptotically stable scheme for Burgers equation, we now propose a penalty method for enforcing open boundary conditions to a Legendre collocation approximation of the compressible Navier-Stokes equations

$$\frac{\partial \mathbf{q}}{\partial t}+\frac{\partial \mathbf{F}}{\partial x}+\frac{\partial \mathbf{G}}{\partial y}+\frac{\partial \mathbf{H}}{\partial z}=\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\left(\frac{\partial \mathbf{F}_v}{\partial x}+\frac{\partial \mathbf{G}_v}{\partial y}+\frac{\partial \mathbf{H}_v}{\partial z}\right) \\ -\tau_1 \mathcal{Q}^-(x)\mathcal{S}\left(\mathcal{R}^-\left(\mathbf{R}-\mathcal{S}^{-1}\mathbf{g}_1(t)\right)-\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\mathcal{G}^-\mathbf{G}\right) \\ -\tau_2 \mathcal{Q}^+(x)\mathcal{S}\left(\mathcal{R}^+\left(\mathbf{R}-\mathcal{S}^{-1}\mathbf{g}_2(t)\right)+\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\mathcal{G}^+\mathbf{G}\right) . \tag{23}$$

Here $\mathcal{Q}^-(x)$ and $\mathcal{Q}^+(x)$ are given by (9) and $\mathcal{S}$ is the right eigenvector matrix as given in the Appendix. The boundary conditions for the state vector are given through the two vectors, $\mathbf{g}_1(t)$ and $\mathbf{g}_2(t)$, which we for convenience assume to represent a uniform state outside of the computational domain. The four matrices $\mathcal{R}^-$, $\mathcal{R}^+$, $\mathcal{G}^-$, and $\mathcal{G}^+$ are chosen to construct the appropriate boundary operator as derived in the previous section. Hence, we have for the inflow region

$$\mathcal{R}^-=\begin{bmatrix}\lambda_1&0&0&0&0\\0&\lambda_2&0&0&0\\0&0&\lambda_3&0&0\\0&0&0&\lambda_4&0\\0&0&0&0&\alpha\lambda_5\end{bmatrix}, \quad \mathcal{G}^-=\begin{bmatrix}1&0&0&0&0\\0&1&0&0&0\\0&0&1&0&0\\0&0&0&1&0\\0&0&0&0&1\end{bmatrix},$$

where $\alpha=0$ for subsonic conditions and $\alpha=1$ for supersonic conditions. Likewise we define

$$\mathcal{R}^+=\begin{bmatrix}0&0&0&0&0\\0&0&0&0&0\\0&0&0&0&0\\0&0&0&0&0\\0&0&0&0&\beta|\lambda_5|\end{bmatrix}, \quad \mathcal{G}^+=\begin{bmatrix}0&0&0&0&0\\0&1&0&0&0\\0&0&1&0&0\\0&0&0&1&0\\0&0&0&0&1\end{bmatrix},$$

where $\beta=1$ for subsonic conditions and $\beta=0$ for supersonic outflow conditions.

We have to choose τ_1 and τ_2 such that the semi-discrete scheme is asymptotically stable. The proper choice is stated in the following lemma.

LEMMA 5.2. *Assume there exists a solution,* $\mathbf{q}$, *which is periodic or held at a constant value at the* y*- and* z*-boundary, and that the fluid properties of the uniform state,* $\mathbf{q}_0$, *are constrained by*

$$\mu_0 \geq 0 \ , \quad \lambda_0 \leq 0 \ , \quad \lambda_0+\mu_0 \geq 0 \ , \quad \frac{\gamma k_0}{\mathrm{Pr}} \geq 0 \ , \quad \gamma \geq 1 \ ,$$

and related as

$$\frac{\gamma\mu_0}{\mathrm{Pr}} \geq \lambda_0+2\mu_0 \geq \mu_0 \ .$$

The linearized, constant coefficient version of the scheme given by (23) *is asymptotically stable at the* inflow *if*

$$\frac{1}{\omega\kappa}\left(1+\kappa+\sqrt{1+\kappa}\right) \geq \tau_1 \geq \frac{1}{\omega\kappa}\left(1+\kappa-\sqrt{1+\kappa}\right) .$$

Here

$$\kappa = \frac{\varepsilon}{2\omega}\frac{\gamma k_0}{\mathrm{Pr}\rho_0 u_0} .$$

This result is independent of whether the inflow is subsonic or supersonic.

For supersonic outflow

$$\frac{1}{\omega}\left(1+\sqrt{\frac{1}{\kappa}}\right) \geq \tau_2 \geq \frac{1}{\omega}\left(1-\sqrt{\frac{1}{\kappa}}\right) .$$

For subsonic outflow

$$\frac{1}{\omega\kappa}\left(1+\kappa+\sqrt{1+\kappa}\right) \geq \tau_2 \geq \frac{1}{\omega\kappa}\left(1+\kappa-\sqrt{1+\kappa}\right) .$$

The solution to (23) *is bounded in the form*

$$\frac{1}{2}\frac{d}{dt}\|\mathcal{Q}\mathbf{R}\|_N^2 \leq -\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\sum_{k=1}^{N-1}\omega_k\int_{\Omega_y}\int_{\Omega_z}\left[\sum_{i=1}^{3}\sum_{j=i}^{3}\frac{\partial\mathbf{R}^T}{\partial x_i}\mathcal{B}^s_{ij}\frac{\partial\mathbf{R}}{\partial x_j}\right]_{x=x_k} dy\,dz \leq 0 .$$

Proof. Write (23) in its symmetrized, linearized, constant coefficient version

$$\begin{aligned}\mathcal{Q}^T\mathcal{Q}\frac{\partial\mathbf{R}}{\partial t}+\sum_{i=1}^{3}\mathcal{A}^s_i\frac{\partial\mathbf{R}}{\partial x_i} =&\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\sum_{i=1}^{3}\sum_{j=i}^{3}\mathcal{B}^s_{ij}\frac{\partial^2\mathbf{R}}{\partial x_i\,\partial x_j}\\ &-\tau_1 Q^-(x)\left(\mathcal{Q}^T\mathcal{Q}\mathcal{R}^-\mathbf{R}-\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\mathcal{Q}^T\mathcal{Q}\mathcal{G}^-\mathbf{G}\right)\\ &-\tau_2 Q^+(x)\left(\mathcal{Q}^T\mathcal{Q}\mathcal{R}^+\mathbf{R}+\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\mathcal{Q}^T\mathcal{Q}\mathcal{G}^+\mathbf{G}\right) ,\end{aligned}$$

where, without loss of generality, we have assumed homogeneous boundary conditions. We construct the energy integral, apply the Gauss-Lobatto quadrature rule, and use partial integration to obtain

$$\begin{aligned}(24)\quad \frac{1}{2}\frac{d}{dt}\|\mathcal{Q}\mathbf{R}\|_N^2=&\int_{\Omega_y}\int_{\Omega_z}-\frac{1}{2}\left[\mathbf{R}^T\mathcal{A}^s_1\mathbf{R}-2\varepsilon\sum_{j=1}^{3}\mathbf{R}^T\mathcal{B}^s_{1j}\frac{\partial\mathbf{R}}{\partial x_j}\right]_{x=-1}^{1} dy\,dz\\ &-\varepsilon\int_{\Omega}\left(\sum_{i=1}^{3}\sum_{j=i}^{3}\frac{\partial\mathbf{R}^T}{\partial x_i}\mathcal{B}^s_{ij}\frac{\partial\mathbf{R}}{\partial x_j}\right)d\Omega\\ &-\tau_1\omega\int_{\Omega_y}\int_{\Omega_z}\left[\mathbf{R}^T\mathcal{Q}^T\mathcal{Q}\mathcal{R}^-\mathbf{R}-\varepsilon\mathbf{R}^T\mathcal{G}^-\sum_{j=1}^{3}\mathcal{B}^s_{1j}\frac{\partial\mathbf{R}}{\partial x_j}\right]_{x=-1} dy\,dz\\ &-\tau_2\omega\int_{\Omega_y}\int_{\Omega_z}\left[\mathbf{R}^T\mathcal{Q}^T\mathcal{Q}\mathcal{R}^+\mathbf{R}+\varepsilon\mathbf{R}^T\mathcal{G}^+\sum_{j=1}^{3}\mathcal{B}^s_{1j}\frac{\partial\mathbf{R}}{\partial x_j}\right]_{x=1} dy\,dz ,\end{aligned}$$

where we have used the assumption about periodicity or constant value at the y- and z-boundary. Additionally, we have introduced $\varepsilon = \mathrm{Re_{ref}}^{-1}$ and ω, which is the Legendre weight at the endpoints and applied the definition

$$\mathcal{Q}^T \mathcal{Q} \mathbf{G} = \sum_{j=1}^{3} \mathcal{B}^s_{1j} \frac{\partial \mathbf{R}}{\partial x_j} \ .$$

Using the Gauss-Lobatto quadrature rule allows us to write

$$\text{(25)} \quad \int_\Omega \left(\sum_{i=1}^{3} \sum_{j=i}^{3} \frac{\partial \mathbf{R}^T}{\partial x_i} \mathcal{B}^s_{ij} \frac{\partial \mathbf{R}}{\partial x_j} \right) d\Omega = \int_{\Omega_y} \int_{\Omega_z} \left(\sum_{k=1}^{N-1} \omega_k \left[\sum_{i=1}^{3} \sum_{j=i}^{3} \frac{\partial \mathbf{R}^T}{\partial x_i} \mathcal{B}^s_{ij} \frac{\partial \mathbf{R}}{\partial x_j} \right]_{x=x_k} \right. \\ + \omega \left[\sum_{i=1}^{3} \sum_{j=i}^{3} \frac{\partial \mathbf{R}^T}{\partial x_i} \mathcal{B}^s_{ij} \frac{\partial \mathbf{R}}{\partial x_j} \right]_{x=-1} \\ \left. + \ \omega \left[\sum_{i=1}^{3} \sum_{j=i}^{3} \frac{\partial \mathbf{R}^T}{\partial x_i} \mathcal{B}^s_{ij} \frac{\partial \mathbf{R}}{\partial x_j} \right]_{x=1} \right) dy\, dz \geq 0 \ .$$

Here x_k signifies the Legendre-Gauss-Lobatto collocation points. The inequality follows from the analysis done in the proof of Lemma 5.1 and is ensured provided the fluid properties are constrained by

$$\mu_0 \geq 0 \ , \quad \lambda_0 \leq 0 \ , \quad \lambda_0 + \mu_0 \geq 0 \ , \quad \frac{\gamma k_0}{\mathrm{Pr}} \geq 0 \ , \quad \gamma \geq 1 \ .$$

It was shown by Abarbanel and Gottlieb [20] that if a scheme is stable without the contributions from the off-diagonal stress-tensor terms, then it will remain so even if the these terms are included. This is a consequence of the general relation

$$\frac{\gamma \mu_0}{\mathrm{Pr}} \geq \lambda_0 + 2\mu_0 \geq \mu_0 \ ,$$

which roughly gives the relation between the eigenvalues of the normal stress-tensor elements and the off-diagonal elements. Thus, it is sufficient to prove stability in the absence of the off-diagonal contributions.

The penalty parameters, τ_1 and τ_2, must be chosen such that the boundary term of the energy integral does not destroy the stability of the Cauchy problem. We treat the two boundary contributions separately.

Inflow condition. The contribution of the boundary term at the inflow ($x = -1$) follows from combining (24) and (25) and neglecting the off-diagonal contributions to obtain

$$\mathbf{R}^T \left(\frac{1}{2} \mathcal{A}^s_1 - \tau_1 \omega \mathcal{Q}^T \mathcal{Q} \mathcal{R}^- \right) \mathbf{R} - \varepsilon \mathbf{R}^T \left(\mathcal{I} - \tau_1 \omega \mathcal{G}^- \right) \mathcal{B}^s_{11} \frac{\partial \mathbf{R}}{\partial x_1} - \varepsilon \omega \sum_{i=1}^{3} \frac{\partial \mathbf{R}^T}{\partial x_i} \mathcal{B}^s_{ii} \frac{\partial \mathbf{R}}{\partial x_i} \leq 0 \ ,$$

where $\mathcal{I}$ is the identity matrix.

First we note that

$$-\varepsilon \omega \frac{\partial \mathbf{R}^T}{\partial x_2} \mathcal{B}^s_{22} \frac{\partial \mathbf{R}}{\partial x_2} - \varepsilon \omega \frac{\partial \mathbf{R}^T}{\partial x_3} \mathcal{B}^s_{33} \frac{\partial \mathbf{R}}{\partial x_3} \leq 0 \ ,$$

since $\mathcal{B}^s_{22}$ and $\mathcal{B}^s_{33}$ are positive semi-definite with an eigenvalue spectrum given as

$$\rho_1(\mathcal{B}^s_{22}) = \rho_1(\mathcal{B}^s_{33}) = 0 \ , \qquad \rho_2(\mathcal{B}^s_{22}) = \rho_2(\mathcal{B}^s_{33}) = \frac{\mu_0}{\rho_0} \ ,$$

$$\rho_3(\mathcal{B}^s_{22}) = \rho_3(\mathcal{B}^s_{33}) = 2\frac{\mu_0}{\rho_0} \ , \qquad \rho_4(\mathcal{B}^s_{22}) = \rho_4(\mathcal{B}^s_{33}) = 2\frac{\lambda_0 + 2\mu_0}{\rho_0} \ ,$$

$$\rho_5(\mathcal{B}^s_{22}) = \left(\frac{2c_0^2}{(\gamma-1)^2} + 1 \right) \frac{(\gamma-1)k_0}{\rho_0 \mathrm{Pr}} \ , \quad \rho_5(\mathcal{B}^s_{33}) = \left(\frac{2c_0^2}{(\gamma-1)^2} + 1 \right) \frac{(\gamma-1)k_0}{\rho_0 \mathrm{Pr}} \ .$$

Since all matrices are symmetric, the remaining part of the constraint may be expressed in block-quadratic form as

$$\tilde{\mathbf{R}}^T \mathcal{H}^- \tilde{\mathbf{R}} \le 0 \ ,$$

where

$$\tilde{\mathbf{R}} = \left[\mathbf{R}, \frac{\partial \mathbf{R}}{\partial x} \right]^T \ , \quad \mathcal{H}^- = \frac{1}{2} \begin{bmatrix} \mathcal{A}_1^s - 2\tau_1 \omega \mathcal{Q}^T \mathcal{Q} \mathcal{R}^- & -\varepsilon(1-\tau_1\omega)\mathcal{B}_{11}^s \\ -\varepsilon(1-\tau_1\omega)\mathcal{B}_{11}^s & -2\varepsilon\omega\mathcal{B}_{11}^s \end{bmatrix} \ ,$$

where we have used $\mathcal{G}^- = \mathcal{I}$. $\mathcal{H}^-$ is a 10 × 10 symmetric block-matrix. Similar to the approach applied in §3.2, we have transformed the problem of stability into proving that $\mathcal{H}^-$, for a suitable value of τ_1, is negative semi-definite. The eigenvalue-spectrum, $\rho(\mathcal{H}^-)$, can be found by doing an LU-decomposition. Since $\mathcal{H}^-$ is symmetric, the eigenvalues appear as $\rho_i(\mathcal{H}^-) = U_{ii}$, i.e., the diagonal elements of the upper triangular matrix.

We will not give the general form of the eigenvalues here, since they are rather complicated. However, straightforward but very lengthy algebra shows that all eigenvalues are negative if τ_1 is chosen such that

$$\frac{1}{\omega\kappa}\left(1+\kappa+\sqrt{1+\kappa}\right) \ge \tau_1 \ge \frac{1}{\omega\kappa}\left(1+\kappa-\sqrt{1+\kappa}\right) \ ,$$

where

$$\kappa = \frac{\varepsilon}{2\omega} \frac{\gamma k_0}{\mathrm{Pr}\rho_0 u_0} \ .$$

This result is independent of whether the inflow is subsonic or supersonic.

Outflow condition. Neglecting the contribution from the off-diagonal terms yields a criteria for stability at the outflow ($x = 1$)

$$-\mathbf{R}^T \left(\frac{1}{2}\mathcal{A}_1^s + \tau_2\omega\mathcal{Q}^T\mathcal{Q}\mathcal{R}^+ \right) \mathbf{R} + \varepsilon \mathbf{R}^T \left(\mathcal{I} - \tau_2\omega\mathcal{G}^+ \right) \mathcal{B}_{11}^s \frac{\partial \mathbf{R}}{\partial x_1} - \varepsilon\omega \sum_{i=1}^{3} \frac{\partial \mathbf{R}^T}{\partial x_i} \mathcal{B}_{ii}^s \frac{\partial \mathbf{R}}{\partial x_i} \le 0 \ .$$

Similar to the approach followed in the previous part of the proof, we see that the contributions from $\mathcal{B}_{22}^s$ and $\mathcal{B}_{33}^s$ are always negative and independently ensure stability.

We now rewrite the remaining part of the condition at the outflow in block-quadratic form:

$$\tilde{\mathbf{R}}^T \mathcal{H}^+ \tilde{\mathbf{R}} \le 0 \ ,$$

where

$$\mathcal{H}^+ = \frac{1}{2} \begin{bmatrix} -\mathcal{A}_1^s - 2\tau_2 \omega \mathcal{Q}^T \mathcal{Q} \mathcal{R}^+ & \varepsilon(1-\tau_2\omega)\mathcal{B}_{11}^s \\ \varepsilon(1-\tau_1\omega)\mathcal{B}_{11}^s & -2\varepsilon\omega\mathcal{B}_{11}^s \end{bmatrix} \ .$$

To form $\mathcal{H}^+$ we have assumed $\mathcal{G}^+ = \mathcal{I}$. The additional boundary condition introduced by this replacement is redundant, as discussed in §5.1, and, hence, no extra restrictions are put on the system by this approach. The eigenvalue spectrum, $\rho(\mathcal{H}^+)$, may again be found through an LU-decomposition. We state here only the bounds on τ_2 that ensure negative semi-definiteness of $\mathcal{H}^+$ for supersonic outflow

$$\frac{1}{\omega}\left(1+\sqrt{\frac{1}{\kappa}}\right) \ge \tau_2 \ge \frac{1}{\omega}\left(1-\sqrt{\frac{1}{\kappa}}\right) \ .$$

For subsonic outflow the bounds become

$$\frac{1}{\omega\kappa}\left(1+\kappa+\sqrt{1+\kappa}\right) \ge \tau_2 \ge \frac{1}{\omega\kappa}\left(1+\kappa-\sqrt{1+\kappa}\right) \; .$$

Combining (24) and (25), we obtain a bound for the growth of the solution

$$\frac{1}{2}\frac{d}{dt}\|\mathcal{Q}\mathbf{R}\|_N^2 \le -\frac{1}{\mathrm{Re}_{\mathrm{ref}}}\sum_{k=1}^{N-1}\omega_k\int_{\Omega_y}\int_{\Omega_z}\left[\sum_{i=1}^{3}\sum_{j=i}^{3}\frac{\partial \mathbf{R}^T}{\partial x_i}\mathcal{B}^s_{ij}\frac{\partial \mathbf{R}}{\partial x_j}\right]_{x=x_k} dy\,dz \le 0 \; . \qquad \square$$

We wish to emphasize that the bounds on τ_1 and τ_2 given in Lemma 5.2 remain valid in the limit when the Reynolds number approaches infinity. This is easily realized by expanding the bounds for $\varepsilon \ll 1$ to obtain

$$\infty > \tau_1 \ge \frac{1}{2\omega} + \varepsilon\frac{1}{8\omega}\kappa$$

in the inflow region and

$$\infty > \tau_2 > -\infty \quad , \quad \infty > \tau_2 \ge \frac{1}{2\omega} + \varepsilon\frac{1}{8\omega}\kappa$$

for supersonic and subsonic outflow, respectively. The linearized, constant coefficient version of the Euler equations may be transformed into 5 independent hyperbolic equations for which we should expect the bounds on the penalty parameters to be given by the results in §3.1.1. We observe that the bounds given above converge uniformly to the expected values in the limit of vanishing viscosity and, thus, the scheme remains stable. The observation that no bounds are necessary on τ_2 for supersonic outflow simply reflects the fact that no boundary conditions are required for the Euler equations at such a boundary.

5.3. Numerical tests. The proof given in the previous section is only strictly valid for the linearized, constant coefficient version of Navier-Stokes equations. To validate the results and show that it carries over to full nonlinear Navier-Stokes equations, we have implemented the scheme in an existing spectral code (see [24] for details), originally developed for studying two-dimensional compressible flow around an infinitely long circular cylinder.

For the spatial approximation scheme we used a standard Chebyshev-Fourier collocation scheme in polar coordinates, (r, θ), with a third-order Runge-Kutta method for time-stepping.

The new scheme is simple to implement in existing codes, because we only need to apply a correction of the flux of the state vector at the boundary. Following the scheme, given by (23), we need to derive the two vectors **R** and **G**. The characteristic variables are given as

$$\begin{aligned} R_1 &= (m_r - \rho u_r) + \frac{p}{c_0} \; , \\ R_2 &= m_\theta - \rho u_\theta \; , \\ R_3 &= \rho - \frac{p}{c_0^2} \; , \\ R_4 &= -(m_r - \rho u_r) + \frac{p}{c_0} \; , \end{aligned}$$

where c_0 is the uniform state sound speed.

We have for convenience introduced

$$u_r = u_0\hat{k}_1 + v_0\hat{k}_2 \; , \quad u_\theta = u_0\hat{k}_2 - v_0\hat{k}_1 \; ,$$

which are the radial and azimuthal velocity components, respectively, of the uniform state, and

$$m_r = m_u \hat{k}_1 + m_v \hat{k}_2 \ , \quad m_\theta = m_u \hat{k}_2 - m_v \hat{k}_1 \ ,$$

which are the radial and azimuthal components of the momentum of the flow field. Here $\mathbf{k} = (\hat{k}_1, \hat{k}_2)$ signifies an outward pointing normal-vector at the boundary. The linearized pressure, p, is given as

$$p = (\gamma - 1)\left[E + \frac{1}{2}\rho(u_0^2 + v_0^2) - u_0 m_u - v_0 m_v\right] \ .$$

The eigenvalues corresponding to the characteristic functions and determining the direction and propagation velocity of the characteristic waves are

$$\lambda_1 = u_r + c_0 \ , \ \lambda_2 = \lambda_3 = u_r \ , \ \ \lambda_4 = u_r - c_0 \ .$$

Following the approach outlined in the previous section, we have likewise derived the viscous correction vector, $\mathbf{G}$, at the outer boundary as

$$G_1 = \frac{1}{\rho_0 r}\left[\frac{(\gamma-1)k_0}{2\mathrm{Pr}}\frac{\partial(r\zeta_1)}{\partial r} + \frac{2}{3}\mu_0\frac{\partial(r\zeta_2)}{\partial r} - \frac{1}{3}\mu_0\frac{\partial R_2}{\partial\theta}\right] \ ,$$
$$G_2 = \frac{\mu_0}{\rho_0 r}\left[\frac{\partial(rR_2)}{\partial r} - \frac{1}{6}\frac{\partial\zeta_2}{\partial\theta}\right] \ ,$$
$$G_3 = -\frac{(\gamma-1)k_0}{\mathrm{Pr}}\frac{1}{2c_0\rho_0}\frac{1}{r}\frac{\partial(r\zeta_1)}{\partial r} \ ,$$
$$G_4 = \frac{1}{\rho_0 r}\left[\frac{(\gamma-1)k_0}{2\mathrm{Pr}}\frac{\partial(r\zeta_1)}{\partial r} - \frac{2}{3}\mu_0\frac{\partial(r\zeta_2)}{\partial r} + \frac{1}{3}\mu_0\frac{\partial R_2}{\partial\theta}\right] \ ,$$

where again we have defined

$$\zeta_1 = R_1 + R_4 - \frac{2c_0}{\gamma - 1}R_2 \ , \ \ \zeta_2 = R_1 - R_4 \ ,$$

and applied Stokes hypothesis to obtain $\lambda = -\frac{2}{3}\mu$. We note that only two extra calculations of derivatives, $(\partial\rho/\partial r, \ \partial\rho/\partial\theta)$, are needed in order to form the two vectors, since the radial and azimuthal derivatives at the boundary of the remaining variables are calculated during evaluation of the interior dynamics when employing a global scheme. Thus, compared with evaluation of the flux, the computational requirement for enforcing the boundary conditions through this new method is negligible.

The boundary conditions are enforced at each intermediate time-step of the Runge-Kutta method. Simulations were done with a Reynolds number of 100, a Mach number of 0.4, a diameter (L) of the cylinder of 6.10 mm, and a reference temperature of 300°K. These parameters ensure that the flow field remains subsonic. The resolution was 96 Fourier modes, 72 Chebyshev modes and the radius (L_D) of the computational domain was 20 cylinder diameters.

As penalty parameters we used

$$\tau_1 = \tau_2 = \frac{N^2}{4\kappa}\frac{2}{L_D}(1 + \kappa - \sqrt{1+\kappa}) \ ,$$

where N is the number of Chebyshev modes, $2/L_D$ is a result of the radial mapping of L_D into $[-1, 1]$, and

$$\kappa = \frac{\varepsilon N^2}{2}\frac{\gamma k_0}{\mathrm{Pr}\rho_0|u_r|} \ ,$$

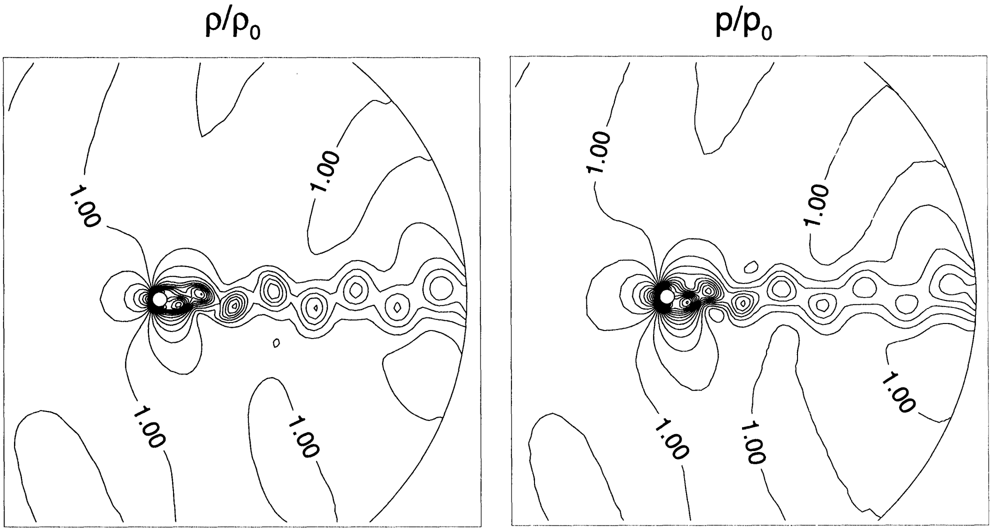

FIG. 4. *Contour plots of the normalized density,* ρ/ρ_0, *and the normalized pressure,* p/p_0, *at the nondimensional time* $T = 143.5$ *for a flow at* Re = 100, M = 0.4, $D = 6.10$ mm, *and* $T_0 = 300$°K.

This choice appears natural from the results stated in Lemma 5.2 and the experience gained in §4, indicating that for dissipative problems we may reduce the penalty parameter by a factor of 4 to obtain the optimal value of τ. With this choice of penalty parameters we were able to perform the simulations without any reduction in time-step as compared with the exact method of enforcing the boundary conditions. It should be mentioned that in the original code only characteristic boundary conditions for the Euler equations were enforced. Comparing with results discussed in §4, we observe that for third-order Runge-Kutta methods we should expect the two methods to impose almost equivalent time-step restrictions. This is confirmed by the simulations and shows that the results from the simple linear analysis carries over to the full nonlinear Navier-Stokes equations in this case.

In Fig. 4 we show contour plots of the normalized density and the pressure at $T = 143.5$, corresponding to approximately 23 shedding cycles. The von Karman vortex street is clearly demonstrated, and we observe that the boundary conditions at the outflow boundary affect the flow only slightly. The Strouhal number for the shredding frequency is found to be $St = 0.163$, which is in full accordance with experimental findings [25] and we observe no spurious frequencies or reflections from the artificial boundary back into the flow field (see [24] for a further discussion of this).

6. Concluding remarks. The purpose of the present paper has been twofold. The first goal has been to develop boundary conditions for wave-dominated problems, leading to well-posed total problems. It was argued that for smooth solutions and the class of operators we have considered here, it is sufficient to consider the problem of well-posedness for the locally linearized, constant coefficient version of the nonlinear initial-boundary value problem. Using this allowed the derivation of proper boundary conditions to the Burgers equation and to the three-dimensional, compressible Navier-Stokes equations, and these boundary conditions were shown to ensure well-posedness of the total problem. It should be stressed that the boundary conditions derived for the Navier-Stokes equations take into account all elements of the stress-tensor, and only very light assumptions were made to derive these. Additionally, they remain valid even in the limit of vanishing viscosity.

Having derived appropriate boundary conditions naturally leads to the question of how to enforce these in a discrete approximation of the problem. This has been the second, and main, contribution of the paper. Results [7] on the connection between stability of discrete and semi-discrete approximations suggest that it is sufficient to consider asymptotic stability for the semi-discrete approximation. We have only considered Legendre collocation methods here. This choice is dictated merely by a wish to obtain analytical results and we have indicated, by numerical tests, that all results carry over to Chebyshev collocation methods. The stability proofs for the semi-discrete approximations to the linearized, constant coefficient versions of the Burgers equation and the compressible Navier-Stokes equations are all completed by using the classical energy method. We emphasized that the proposed schemes remain stable even in the limit where the problems become purely hyperbolic.

The proposed penalty method changes the eigenvalue spectra of the discrete approximations of the operators considerably. In order to understand this, we performed a detailed investigation of the effect of the penalty method on the eigenvalue spectra of linear operators. It has been shown that the value of the penalty parameter, which is obtained from the theoretical analysis, often implies that the maximum allowable time-step compares unfavorably with that allowed for more traditional methods. However, we discussed in detail how to remedy this and showed that choosing the penalty parameter properly may in some cases allow for increasing the maximum time-step by as much as 50%. Although we are not aware of a systematic way of determining the optimal value of the penalty parameter, we do not see that as a significant disadvantage. Our experience tells that once the theoretical values of the penalty parameters are obtained, only a few tests are needed to obtain the optimal value. Additionally, this has to be done only once, and since only a few hundred time-steps are required to test whether the scheme is stable, we consider this an insignificant problem.

Most of the theoretical results, obtained for linearized, constant coefficient versions of the equations, are confirmed by numerical simulations of the full nonlinear equations. It is stressed that the proposed penalty method is very easy to implement in existing codes, which is an attractive feature.

Although all results and numerical simulations in this paper are obtained using spectral collocation methods, the main conclusions carry over to finite difference/finite element methods. The derivation of the proper boundary operators, for either the Burgers equation or for the compressible, Navier-Stokes equations, is obviously unaffected by the choice of the spatial approximation method. The proposed penalty method for enforcing the boundary conditions may be applied in exactly the same manner as discussed here when using alternative spatial discretization methods. The only difference is the value of the penalty parameter, which will depend strongly on the order of the method. Thus, applying another method requires one to derive this penalty parameter. This may be done by an approach equivalent to the one utilized here.

In a future paper [26], we will extend the penalty method developed here to include multidomain solutions of the compressible Navier-Stokes equations in general curvilinear coordinates.

Appendix: Symmetric matrices for the Navier-Stokes equations. Consider the linearized, constant coefficient compressible Navier-Stokes equations in conservation form given as

$$\frac{\partial \mathbf{q}}{\partial t} + \sum_{i=1}^{3} \mathcal{A}_i \frac{\partial \mathbf{q}}{\partial x_i} = \frac{1}{\mathrm{Re}_{\mathrm{ref}}} \sum_{i=1}^{3} \sum_{j=i}^{3} \mathcal{B}_{ij} \frac{\partial^2 \mathbf{q}}{\partial x_i \, \partial x_j} \quad .$$

The matrix, $\mathcal{A}_1$, diagonalizes under the similarity transform, $\Lambda = \mathcal{S}^{-1}\mathcal{A}_1\mathcal{S}$, where the right eigenvector matrix, $\mathcal{S}$, and the left eigenvector matrix, $\mathcal{S}^{-1}$, are given as

$$\mathcal{S} = \begin{bmatrix} \alpha & 0 & 1 & 0 & \alpha \\ \alpha(u+c) & 0 & u & 0 & \alpha(u-c) \\ \alpha v & 1 & v & 0 & \alpha v \\ \alpha w & 0 & w & 1 & \alpha w \\ \alpha(H+cu) & v & \frac{1}{2}c^2M^2 & w & \alpha(H-cu) \end{bmatrix},$$

$$\mathcal{S}^{-1} = \begin{bmatrix} \beta\left(\frac{1}{2}(\gamma-1)c^2M^2 - cu\right) & -\beta((\gamma-1)u-c) & -\beta(\gamma-1)v & -\beta(\gamma-1)w & \beta(\gamma-1) \\ -v & 0 & 1 & 0 & 0 \\ 1-\frac{1}{2}(\gamma-1)M^2 & \frac{\gamma-1}{c^2}u & \frac{\gamma-1}{c^2}v & \frac{\gamma-1}{c^2}w & -\frac{\gamma-1}{c^2} \\ -w & 0 & 0 & 1 & 0 \\ \beta\left(\frac{1}{2}(\gamma-1)c^2M^2 + cu\right) & -\beta((\gamma-1)u+c) & -\beta(\gamma-1)v & -\beta(\gamma-1)w & \beta(\gamma-1) \end{bmatrix}.$$

Here

$$\alpha = \frac{1}{2c}, \quad \beta = \frac{1}{c}.$$

Introducing this transformation into the Navier–Stokes equations yields

$$\mathcal{Q}^T\mathcal{Q}\frac{\partial \mathbf{R}}{\partial t} + \sum_{i=1}^{3} \mathcal{A}_i^s \frac{\partial \mathbf{R}}{\partial x_i} = \frac{1}{\mathrm{Re}_{\mathrm{ref}}} \sum_{i=1}^{3}\sum_{j=i}^{3} \mathcal{B}_{ij}^s \frac{\partial^2 \mathbf{R}}{\partial x_i\, \partial x_j},$$

where $\mathbf{R}$ are the characteristic variables and $\mathcal{Q}^T\mathcal{Q}$ is a positive definite, symmetrizing diagonal matrix.

The symmetrized matrices

$$\mathcal{A}_i^s = \mathcal{Q}^T\mathcal{Q}\mathcal{S}^{-1}\mathcal{A}_i\mathcal{S}, \quad \mathcal{B}_{ij}^s = \mathcal{Q}^T\mathcal{Q}\mathcal{S}^{-1}\mathcal{B}_{ij}\mathcal{S}$$

are given as

$$\mathcal{A}_1^s = \begin{bmatrix} u+c & 0 & 0 & 0 & 0 \\ 0 & 2u & 0 & 0 & 0 \\ 0 & 0 & \frac{2c^2}{\gamma-1}u & 0 & 0 \\ 0 & 0 & 0 & 2u & 0 \\ 0 & 0 & 0 & 0 & u-c \end{bmatrix}, \quad \mathcal{A}_2^s = \begin{bmatrix} v & c & 0 & 0 & 0 \\ c & 2v & 0 & 0 & c \\ 0 & 0 & \frac{2c^2}{\gamma-1}v & 0 & 0 \\ 0 & 0 & 0 & 2v & 0 \\ 0 & c & 0 & 0 & v \end{bmatrix},$$

$$\mathcal{A}_3^s = \begin{bmatrix} w & 0 & 0 & c & 0 \\ 0 & 2w & 0 & 0 & 0 \\ 0 & 0 & \frac{2c^2}{\gamma-1}w & 0 & 0 \\ c & 0 & 0 & 2w & c \\ 0 & 0 & 0 & c & w \end{bmatrix},$$

$$\mathcal{B}_{11}^s = \frac{1}{2\rho}\begin{bmatrix} (\lambda+2\mu)+\theta & 0 & -\frac{2c}{\gamma-1}\theta & 0 & -(\lambda+2\mu)+\theta \\ 0 & 4\mu & 0 & 0 & 0 \\ -\frac{2c}{\gamma-1}\theta & 0 & \frac{4c^2}{(\gamma-1)^2}\theta & 0 & -\frac{2c}{\gamma-1}\theta \\ 0 & 0 & 0 & 4\mu & 0 \\ -(\lambda+2\mu)+\theta & 0 & -\frac{2c}{\gamma-1}\theta & 0 & (\lambda+2\mu)+\theta \end{bmatrix},$$

$$\mathcal{B}_{22}^{s} = \frac{1}{2\rho}\begin{bmatrix} \mu+\theta & 0 & -\frac{2c}{\gamma-1}\theta & 0 & -\mu+\theta \\ 0 & 4(\lambda+2\mu) & 0 & 0 & 0 \\ -\frac{2c}{\gamma-1}\theta & 0 & \frac{4c^2}{(\gamma-1)^2}\theta & 0 & -\frac{2c}{\gamma-1}\theta \\ 0 & 0 & 0 & 4\mu & 0 \\ -\mu+\theta & 0 & -\frac{2c}{\gamma-1}\theta & 0 & \mu+\theta \end{bmatrix},$$

$$\mathcal{B}_{33}^{s} = \frac{1}{2\rho}\begin{bmatrix} \mu+\theta & 0 & -\frac{2c}{\gamma-1}\theta & 0 & -\mu+\theta \\ 0 & 4\mu & 0 & 0 & 0 \\ -\frac{2c}{\gamma-1}\theta & 0 & \frac{4c^2}{(\gamma-1)^2}\theta & 0 & -\frac{2c}{\gamma-1}\theta \\ 0 & 0 & 0 & 4(\lambda+2\mu) & 0 \\ -\mu+\theta & 0 & -\frac{2c}{\gamma-1}\theta & 0 & \mu+\theta \end{bmatrix}.$$

We have for convenience introduced

$$\theta = \frac{\gamma-1}{\gamma}\frac{\gamma k}{\mathrm{Pr}},$$

$$\mathcal{B}_{12}^{s} = \frac{\lambda+\mu}{\rho}\begin{bmatrix} 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 \end{bmatrix}, \quad \mathcal{B}_{13}^{s} = \frac{\lambda+\mu}{\rho}\begin{bmatrix} 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & -1 \\ 0 & 0 & 0 & -1 & 0 \end{bmatrix},$$

$$\mathcal{B}_{23}^{s} = \frac{\lambda+\mu}{\rho}\begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}.$$

SEMICIRCULANT SOLVERS AND BOUNDARY CORRECTIONS FOR FIRST-ORDER PARTIAL DIFFERENTIAL EQUATIONS*

SVERKER HOLMGREN† AND KURT OTTO†

Abstract. Fast solvers for systems of partial differential equations (PDEs) in two space dimensions are considered. The solvers are used as direct solution methods or as preconditioners for a conjugate gradient (CG)-like iteration. Mainly first-order PDEs are considered, but second-order terms may be included. Employing a semicirculant framework, PDEs with constant coefficients in one space direction and arbitrary boundary conditions are considered. A factorization of the inverse of the difference approximation matrix is described. This factorization is exploited to derive a direct solver, where the complexity for the first right-hand side is $\mathcal{O}(n^{3/2}\log_2 n)$, but only $\mathcal{O}(n\log_2 n)$ for subsequent right-hand sides. From the factorization an iteration resembling the Schur complement matrix method known from domain decomposition is also constructed. The eigendecomposition of the iteration matrix is investigated. The new solution methods are compared with iterations with semicirculant preconditioners and to Gaussian elimination. An application solving the time-dependent, almost incompressible Navier–Stokes equations is also studied.

Key words. first-order PDE, finite-difference discretizations, fast solvers, low-rank corrections

AMS subject classifications. 65N22, 65F10

1. Introduction.

We study the solution of time-dependent and time-independent PDEs on the unit square:

$$\tag{1}\begin{cases} \left(\dfrac{\partial \mathbf{u}}{\partial t}+\right) \mathcal{A}_1\dfrac{\partial \mathbf{u}}{\partial x_1}+\mathcal{B}_1\dfrac{\partial^2 \mathbf{u}}{\partial x_1^2}+\mathcal{A}_2\dfrac{\partial \mathbf{u}}{\partial x_2}+\mathcal{B}_2\dfrac{\partial^2 \mathbf{u}}{\partial x_2^2}=\mathbf{g}\\ +\text{(boundary condition)}_1\\ +\text{(boundary condition)}_2. \end{cases}$$

Here $\mathcal{A}_d=\mathcal{A}_d(x_1,x_2)$ and $\mathcal{B}_d=\mathcal{B}_d(x_1,x_2)$ are $n_c\times n_c$ matrices. $\mathbf{u}$ is an n_c-vector containing the solution functions, and (boundary condition)$_d$ denotes a set of boundary conditions in the x_d-direction. Our main interest is to develop efficient solution methods for first-order systems of PDEs, exploiting centered finite-difference approximations. Then artificial viscosity must usually be added to damp high-frequency oscillations. Hence, it is important to take second-order terms into account. The methods presented are applicable both to problems with viscosity in the PDE and to first-order PDEs where artificial viscosity is added only in the difference approximation.

The PDE (1) is discretized using a five-point stencil on a uniform $m_1\times m_2$ grid. Note that nonuniform grids may be accounted for by solving a transformed PDE on a grid with constant stepsize. The methods presented here can be generalized to a $(2q_1+1)\times(2q_2+1)$ rectangular stencil. Thus, it is possible to treat higher-order approximations and mixed second-order terms. Furthermore, nonrectangular grids may be handled by using a domain decomposition technique. These generalizations will be described and analyzed in future work.

We use the notation

$$\operatorname{diag}_{j,m}(\beta_j)=\begin{pmatrix}\beta_1&&\\&\ddots&\\&&\beta_m\end{pmatrix},\quad \operatorname{ptrid}_{j,m}(\alpha_j,\beta_j,\gamma_j)=\begin{pmatrix}\beta_1&\gamma_1&&\alpha_1\\ \alpha_2&\ddots&\ddots&\\ &\ddots&\ddots&\gamma_{m-1}\\ \gamma_m&&\alpha_m&\beta_m\end{pmatrix}.$$

At the boundaries we impose the restriction that the difference stencil may not be wider than the five-point stencil used in the interior. Hence, e.g., periodic, Dirichlet, and Neumann boundary conditions are allowed. Also numerical outflow boundary conditions may be used in the difference approximation. Note that for hyperbolic PDEs, outflow boundary conditions are always required for the characteristic variables corresponding to outgoing characteristics. Outflow boundary conditions may also be needed for incompletely parabolic problems, e.g., the Navier–Stokes equations.

An approximate solution u of (1) is obtained by solving

$$M^{-1}Bu = M^{-1}g. \tag{2}$$

Here B is the coefficient matrix arising from the discretization of (1), and M is a preconditioner matrix. If we order the $n = n_c m_1 m_2$ unknowns in u first by equation in the system of PDEs and then lexicographically in the domain, B has the following structure:

$$B = \operatorname{ptrid}_{k,m_2}(B_{k,-1}, B_{k,0}, B_{k,1}),$$

where $B_{k,-1} = \operatorname{diag}_{j,m_1}(\nu_{j,k,-2})$ and $B_{k,1} = \operatorname{diag}_{j,m_1}(\nu_{j,k,2})$. The matrix $B_{k,0}$ is given by $B_{k,0} = \operatorname{ptrid}_{j,m_1}(\nu_{j,k,-1}, \nu_{j,k,0}, \nu_{j,k,1})$. Here $\nu_{j,k,r}$, $r = -2, \dots, 2$, are $n_c \times n_c$ matrices. The matrices B or $B_{k,0}$ are periodic tridiagonal only if the PDE is subject to periodic boundary conditions in the x_2- or x_1-direction.

The matrix B is very sparse and highly structured. The number of nonzero elements is only $\sim 5n_c n$. For the PDEs we are interested in, B may be highly nondiagonally dominant. If we impose the restriction that B is nonperiodic tridiagonal, then B is a band matrix with semibandwidth $n_c m_1$. Using band Gaussian elimination with pivoting, the storage and arithmetic requirements grow rapidly with increasing problem size. Instead it is natural to study iterative methods, since multiplying a vector by B requires only $\sim 10n_c n$ arithmetic operations (a.o.). However, iterating on the matrix B, the number of iterations required will generally grow when the problem size is increased. A preconditioner M must be employed to attain acceptable convergence rates for large problems. The preconditioner solve has to be performed by an efficient algorithm. The preconditioner is introduced to obtain acceptable execution time and not to minimize the number of iterations. The preconditioner must also exploit the sparsity of B, so that the storage requirement does not become prohibitive. Many approaches for constructing preconditioners have been considered, e.g., incomplete LU factorization [VdVo82] and polynomial preconditioners [Ashby87]. We use a PDE approach; i.e., M is defined by the system of equations

$$Mu = g, \tag{3}$$

arising from a PDE closely related to (1). The objective is to find simplified PDEs such that it is possible to solve (3) efficiently, and that the number of iterations required to solve (2) is independent of problem size. Apart from yielding preconditioners, efficient solution methods for (3) may also be directly applicable to some PDEs of practical interest.

For constant coefficient elliptic PDEs subject to periodic or Dirichlet boundary conditions, M has a circulant or Toeplitz structure. Then (3) can be solved in $\mathcal{O}(n \log_2 n)$ complexity using a fast Poisson solver based on fast trigonometric transforms [VLoan92]. For constant coefficient hyperbolic or incompletely parabolic PDEs subject to periodic boundary conditions, M again has a circulant structure allowing a solver based on fast Fourier transforms. However, for PDE problems subject to Dirichlet boundary conditions, this is not the case. As previously mentioned, numerical outflow boundary conditions must be supplied in the difference approximation. Thus, the Toeplitz structure of M will be disturbed at the entries corresponding to the boundaries. The purpose of this paper is to study solvers for problems of this type. We use the fast transform framework but extend it to allow the disturbances arising from the outflow boundary conditions.

In previous papers we have described *semicirculant* (SC) solvers. Here, we use a specific SC solver described by $M_{(SC)}$ corresponding to a discretization of a PDE related to (1) but where two approximations are introduced. The coefficients are approximated by constants in the x_1-direction, and the boundary conditions in the same space direction are changed to periodic. In [HoOtto92], [Otto97], and [HoOtto94], SC solvers are used as preconditioners for problems of type (2), where B corresponds to first-order time-dependent and time-independent PDEs subject to Dirichlet boundary conditions. Empirically, the number of iterations required is found to be independent of problem size for both problem types. In [Otto97] and [HoOtto94], it is also proved that both the eigenvalues and the eigenvectors of $M_{(SC)}^{-1}B$ are "improved" compared with those of B. The SC solver is the basis for the new solution methods presented in this paper, and it is briefly described in §2.

In §3 we present the boundary corrected semicirculant (BCSC) framework. Also the matrix $M_{(BCSC)}$ corresponds to a PDE closely related to (1). We approximate the coefficients in the x_1-direction by constants, whereas the original boundary conditions are retained. The basis for the BCSC framework is a factorization for $M_{(BCSC)}^{-1}$, given by the Sherman-Morrison-Woodbury formula. This factorization could be used in different ways. We first derive an efficient direct solver for (3). We also use the factorization to construct an iteration for (3), which resembles the Schur complement matrix method used in domain decomposition [KeyGr87]. In §6 we prove that the eigendecomposition of the iteration matrix is closely related to that of $M_{(SC)}^{-1}M_{(BCSC)}$. This makes it possible to exploit theoretical results for model problems derived in [Otto97] and [HoOtto94].

In §4 we summarize the arithmetic complexities and storage requirements for the solvers, and in §5 two model problems are presented. Sections 7 and 8 contain numerical results for these PDEs. Finally, in §9 the BCSC solver is employed to solve the Navier-Stokes equations.

2. The SC solver. In this section a brief review of the SC framework is given. For a more complete discussion on SC preconditioners and some numerical results, see [HoOtto90], [HoOtto92], [Otto97], and [HoOtto94].

Define the circulant tridiagonal matrix $\mathrm{ctrid}_m(\alpha, \beta, \gamma)$ by

$$\mathrm{ctrid}_m(\alpha,\beta,\gamma) = \begin{pmatrix} \beta & \gamma & & \alpha \\ \alpha & \ddots & \ddots & \\ & \ddots & \ddots & \gamma \\ \gamma & & \alpha & \beta \end{pmatrix}.$$

The matrix $M_{(SC)}$ is defined by

$$M_{(SC)} = \mathrm{ptrid}_{k,m_2}(M_{k,-1}, M_{k,0}^{(SC)}, M_{k,1}), \tag{4}$$

where

$$M_{k,-1} = I_{m_1} \otimes \rho_{k,-2}, \quad M_{k,0}^{(SC)} = \mathrm{ctrid}_{m_1}(\rho_{k,-1}, \rho_{k,0}, \rho_{k,1}), \quad M_{k,1} = I_{m_1} \otimes \rho_{k,2}.$$

The matrix $M_{(SC)}$ is as sparse as B and completely described by the $5m_2$ $n_c \times n_c$ matrices $\rho_{k,r}$. Several choices for these parameters are possible [HoOtto92], but when using the PDE approach a natural choice is

$$\rho_{k,r} = \frac{1}{m_1}\sum_{j=1}^{m_1} \tilde{v}_{j,k,r}, \qquad k = 1, \ldots, m_2, \qquad r = -2, \ldots, 2,$$

where $\tilde{v}_{j,k,r}$ is a set of matrix entries forming the matrix $\tilde{B}$, corresponding to the difference approximation of (1), but subject to periodic boundary conditions in the x_1-direction. Thus, $M_{(SC)}$ is a discretization of the PDE

$$(5)\qquad \begin{cases} \left(\dfrac{\partial \mathbf{u}}{\partial t}+\right) \tilde{\mathcal{A}}_1 \dfrac{\partial \mathbf{u}}{\partial x_1} + \tilde{\mathcal{B}}_1 \dfrac{\partial^2 \mathbf{u}}{\partial x_1^2} + \tilde{\mathcal{A}}_2 \dfrac{\partial \mathbf{u}}{\partial x_2} + \tilde{\mathcal{B}}_2 \dfrac{\partial^2 \mathbf{u}}{\partial x_2^2} = \mathbf{g} \\ + \text{periodic boundary conditions in the } x_1\text{-direction} \\ + (\text{boundary condition})_2. \end{cases}$$

Here $\tilde{\mathcal{A}}_d = \tilde{\mathcal{A}}_d(x_2)$ and $\tilde{\mathcal{B}}_d = \tilde{\mathcal{B}}_d(x_2)$ are defined as averages over x_1 of $\mathcal{A}_d(x_1, x_2)$ and $\mathcal{B}_d(x_1, x_2)$.

The reason for introducing circulant matrices in $M_{(SC)}$ is that such matrices are diagonalized by using discrete Fourier transforms, which are performed by the fast Fourier transform (FFT) algorithm. For each new SC preconditioner, i.e., each new set of parameters $\rho_{k,r}$, $k = 1, \ldots, m_2$, $r = -2, \ldots, 2$, a factorization phase requiring $\mathcal{O}(n)$ a.o. is performed once. The arithmetic complexity for each SC solve is $\mathcal{O}(n \log_2 m_1)$, and the memory requirement is $\mathcal{O}(n)$.

3. The BCSC solver. We now study solution methods for (3), arising from the discretization of the PDE

$$(6)\qquad \begin{cases} \left(\dfrac{\partial \mathbf{u}}{\partial t}+\right) \tilde{\mathcal{A}}_1 \dfrac{\partial \mathbf{u}}{\partial x_1} + \tilde{\mathcal{B}}_1 \dfrac{\partial^2 \mathbf{u}}{\partial x_1^2} + \tilde{\mathcal{A}}_2 \dfrac{\partial \mathbf{u}}{\partial x_2} + \tilde{\mathcal{B}}_2 \dfrac{\partial^2 \mathbf{u}}{\partial x_2^2} = \mathbf{g} \\ + (\text{boundary condition})_1 \\ + (\text{boundary condition})_2. \end{cases}$$

The direct BCSC solver is derived, but also an iterative solver is described. The matrix $M_{(BCSC)}$ is defined by

$$(7)\qquad M_{(BCSC)} = \operatorname{ptrid}_{k,m_2}(M_{k,-1}, M_{k,0}^{(BCSC)}, M_{k,1}),$$

where $M_{k,-1}$ and $M_{k,1}$ are defined in (4), and $M_{k,0}^{(BCSC)}$ is given by

$$M_{k,0}^{(BCSC)} = \begin{pmatrix} \rho_{k,0}+\xi_{k,0} & \rho_{k,1}+\xi_{k,1} & & & \\ \rho_{k,-1} & \rho_{k,0} & \rho_{k,1} & & \\ & \ddots & \ddots & \ddots & \\ & & \rho_{k,-1} & \rho_{k,0} & \rho_{k,1} \\ & & & \rho_{k,-1}+\zeta_{k,-1} & \rho_{k,0}+\zeta_{k,0} \end{pmatrix}.$$

The disturbances of the Toeplitz structure arising from (boundary condition)$_1$ are now accounted for.

The solution methods for (3) described below are based on SC solves. We first note that $M_{(BCSC)} - M_{(SC)}$ is very sparse, and

$$(8)\qquad E \equiv M_{(BCSC)} - M_{(SC)} = SV^T,$$

where $S = I_{m_2} \otimes s$ and $V = \operatorname{diag}_{k,m_2}(v_k)$. Here s and v_k are $n_c m_1 \times 2n_c$ matrices given by

$$s^T = \begin{pmatrix} I_{n_c} & 0 & \cdots & 0 & 0 \\ 0 & 0 & \cdots & 0 & I_{n_c} \end{pmatrix}$$

and

$$v_k^T = \begin{pmatrix} \xi_{k,0} & \xi_{k,1} & 0 & \cdots & 0 & 0 & -\rho_{k,-1} \\ -\rho_{k,1} & 0 & 0 & \cdots & 0 & \zeta_{k,-1} & \zeta_{k,0} \end{pmatrix}.$$

Exploiting the Sherman-Morrison-Woodbury formula, a factorization for $M_{(BCSC)}^{-1}$ is obtained:

$$M_{(BCSC)}^{-1} = (M_{(SC)} + SV^T)^{-1} = (I - M_{(SC)}^{-1} SP^{-1}V^T)M_{(SC)}^{-1}, \tag{9}$$

where

$$P = I + V^T M_{(SC)}^{-1} S. \tag{10}$$

This factorization can be used in several ways. We first describe the BCSC solver. The two multiplications by $M_{(SC)}^{-1}$ in (9) can be performed as SC solves. Exploiting the sparsity of V, it is relatively cheap to form the $2n_c m_2 \times 2n_c m_2$ matrix P. For simplicity, we only show the computation of P for the case $n_c = 1$, but the generalization to blocks is straightforward. The algorithm is given in a MATLAB style.

```
ALGORITHM FOR COMPUTING $P$
for $\ell = 1$ to $2m_2$ do
    $z = M_{(SC)}^{-1} S(:, \ell)$
    for $k = 1$ to $m_2$ do
        $k_1 = (k-1)m_1$
        $P(2k-1, \ell) = \xi_{k,0} z(k_1+1) + \xi_{k,1} z(k_1+2) - \rho_{k,-1} z(k_1+m_1)$
        $P(2k, \ell) = -\rho_{k,1} z(k_1+1) + \zeta_{k,-1} z(k_1+m_1-1) + \zeta_{k,0} z(k_1+m_1)$
    endfor
endfor
$P = I + P$
```

Using SC solves, $\mathcal{O}(m_2 n \log_2 m_1)$ a.o. are required to form P. The factorization $P = LU$ can be computed in $\mathcal{O}(m_2^3)$ complexity. In §6 we prove that P^{-1} exists for some first-order model problems. Now $u = M_{(BCSC)}^{-1} g$ is computed according to the following method.

```
BCSC SOLVE
        $u \leftarrow M_{(SC)}^{-1} g$
        $z \leftarrow SU^{-1}L^{-1}V^T u$
        $z \leftarrow M_{(SC)}^{-1} z$
        $u \leftarrow u - z$
```

Here $\mathcal{O}(n \log_2 m_1)$ a.o. are required. Note that, excluding storage required for the SC solver, only storage for the factorization of P and an auxiliary vector of length n is required. Hence, the storage requirement for the BCSC solver is $\mathcal{O}(n)$.

If it is considered too expensive to form P, P^{-1} may be approximated by some matrix H which is cheaper to form. Then the matrix $M_H^{-1} \equiv (I - M_{(SC)}^{-1} SHV^T)M_{(SC)}^{-1}$ could be used as a preconditioner in an iteration for (3). It is a trivial matter to show that $\operatorname{rank}(M_H^{-1} - M_{(BCSC)}^{-1}) \leq 2n_c m_2$, implying that $M_H^{-1} M_{(BCSC)}$ has at most $2n_c m_2$ eigenvalues separated from 1. Note that the choice $H = 0$ yields $M_H = M_{(SC)}$.

It is also possible to utilize the factorization (9) to derive another iteration for (3), which is in some sense related to the Schur complement matrix method used in domain decomposition. When computing $u = M_{(BCSC)}^{-1} g$, operations of the type $x = P^{-1} y$ must be performed. If we solve $Px = y$ using a CG-like iterative method, P need not be formed, since only

multiplications by $P = I + V^T M_{(SC)}^{-1} S$ are required. Due to the sparsity of S and V, $y = Px$ can be performed using basically one SC solve. Multiplying a vector by S requires no arithmetic, and the complexity for a multiplication by V^T is only $\mathcal{O}(m_2)$. Note that x and y are $2n_c m_2$-vectors. We iterate on the boundaries in the x_1-direction, whereas an exact solver is used in the interior of the domain. This iteration could be used for solving (3) or as an inner iteration for the preconditioner when solving (2).

4. Summary of arithmetic and storage requirements. In [Holm92] the implementation of the SC solver is considered, and savings in arithmetic complexity, generalizations, and parallelization are discussed. In Tables 1 and 2, we summarize the arithmetic complexities for the Gaussian elimination (bandGE), SC, and BCSC solvers. In Table 3 we give the corresponding storage requirements for the implementation used here.

In §§7 and 8, we use the restarted GMRES method denoted by GMRES(ℓ) [SaadSch86]. The average number of arithmetic operations required for one iteration is $(2\ell + 10)n$, excluding the work required for the matrix-vector multiplication and preconditioner solve. The storage requirement is $(\ell + 2)n$. We use the initial guess $u_0 = 0$ and the following stopping criterion:

$$\frac{\|M^{-1}(g - Bu_i)\|_2}{\|M^{-1}g\|_2} \le 10^{-6}.$$

5. Model problems. As representative model problems, we use a scalar hyperbolic PDE subject to Dirichlet boundary conditions in a time-dependent and a time-independent setting. The time-dependent problem is given by

$$\frac{\partial \mathbf{u}}{\partial t} + \sigma_1(x_1)\frac{\partial \mathbf{u}}{\partial x_1} + \sigma_2(x_2)\frac{\partial \mathbf{u}}{\partial x_2} = \mathbf{g}, \tag{11}$$

on the unit square for $t > 0$. We assume that $\sigma_d(x_d) > 0$. The PDE (11) is well posed if $\mathbf{u}(0, x_2, t)$, $\mathbf{u}(x_1, 0, t)$, and $\mathbf{u}(x_1, x_2, 0)$ are supplied. Note that the solution must not be prescribed at the outflow boundaries.

The time discretization is performed using the second-order accurate trapezoidal rule with time-step Δt. The spatial discretization is performed on a uniform grid with $(m_1 + 1) \times (m_2 + 1)$ gridpoints. Hence, the space-step in the x_d-direction is given by $h_d \equiv 1/m_d$. The spatial derivatives in (11) are approximated using second-order accurate centered differences in the interior of the domain. For the numerical boundary conditions required at the outflow boundaries, we use one-sided differences. Let $\kappa_{j,d} \equiv \sigma_d(jh_d)\Delta t/h_d$, $j = 1, \ldots, m_d$. If $\sigma_d(x_d) = \sigma_d$, then $\kappa_{j,d} = \kappa_d \equiv \sigma_d \Delta t/h_d$. Introducing the discretizations in (11) yields the following system of equations for the solution at time level $N + 1$:

$$Bu^{N+1} \equiv (I_{m_2} \otimes B_1 + B_2 \otimes I_{m_1})u^{N+1} = g. \tag{12}$$

Here g contains known quantities and

$$B_1 = \begin{pmatrix} 4 & \kappa_{1,1} & & & \\ -\kappa_{2,1} & 4 & \kappa_{2,1} & & \\ & \ddots & \ddots & \ddots & \\ & & -\kappa_{m_1-1,1} & 4 & \kappa_{m_1-1,1} \\ & & & -2\kappa_{m_1,1} & 4 + 2\kappa_{m_1,1} \end{pmatrix},$$

$$B_2 = \begin{pmatrix} 0 & \kappa_{1,2} & & & \\ -\kappa_{2,2} & 0 & \kappa_{2,2} & & \\ & \ddots & \ddots & \ddots & \\ & & -\kappa_{m_2-1,2} & 0 & \kappa_{m_2-1,2} \\ & & & -2\kappa_{m_2,2} & 2\kappa_{m_2,2} \end{pmatrix}.$$

A more detailed description is given in [HoOtto90]. We also consider the time-independent version of (11):

$$\sigma_1(x_1)\frac{\partial \mathbf{u}}{\partial x_1} + \sigma_2(x_2)\frac{\partial \mathbf{u}}{\partial x_2} = \mathbf{g}. \tag{13}$$

The boundary conditions are of the same form as for the time-dependent problem. Also the discretization in space is performed on the same type of grid, and the derivatives in the PDE are approximated using centered differences in the interior of the domain. However, we add a weak artificial viscosity in the x_1-direction. The difference operator in the interior is given by

$$\sigma_1(x_1)\left(D_{0,x_1} - \frac{\gamma}{2}h_1^{2-\alpha}D_{+,x_1}D_{-,x_1}\right) + \sigma_2(x_2)D_{0,x_2},$$

where $D_{+,x_1}u_{j,k} \equiv h_1^{-1}(u_{j+1,k} - u_{j,k})$, $D_{-,x_1}u_{j,k} \equiv D_{+,x_1}u_{j-1,k}$, and finally $D_{0,x_1} \equiv \frac{1}{2}(D_{+,x_1} + D_{-,x_1})$. Here $u_{j,k}$ is the approximation of $\mathbf{u}$ at the gridpoint (jh_1, kh_2). The constants α and γ are chosen so that $\alpha \in (0, 1)$ and $\gamma \in (0, 1)$. The order of accuracy is $2 - \alpha$ in the x_1-direction and 2 in the x_2-direction. For the numerical boundary conditions we again use one-sided differences. A more detailed description of a model problem of this type and a discussion on the choice of artificial viscosity is given in [HoOtto94]. Define $\delta_j \equiv \sigma_1(jh_1)\gamma h_1^{-\alpha}$ and $\hat{\kappa}_{j,d} \equiv \sigma_d(jh_d)h_d^{-1}$. Also define $\tau_{j,-1} \equiv -\hat{\kappa}_{j,1} - \delta_j$ and $\tau_{j,1} \equiv \hat{\kappa}_{j,1} - \delta_j$. If $\sigma_d(x_d) = \sigma_d$, then

$$\begin{aligned} \delta_j &= \delta \equiv \sigma_1\gamma h_1^{-\alpha}, \\ \hat{\kappa}_{j,d} &= \hat{\kappa}_d \equiv \sigma_d h_d^{-1}, \\ \tau_{j,-1} &= \tau_{-1} \equiv -\hat{\kappa}_1 - \delta, \\ \tau_{j,1} &= \tau_1 \equiv \hat{\kappa}_1 - \delta. \end{aligned}$$

By introducing the discretization in (13), the following system of equations is derived:

$$Bu \equiv (I_{m_2} \otimes \hat{B}_1 + \hat{B}_2 \otimes I_{m_1})u = g. \tag{14}$$

Again g contains known quantities and

$$\hat{B}_1 = \begin{pmatrix} 2\delta_1 & \tau_{1,1} & & & \\ \tau_{2,-1} & 2\delta_2 & \tau_{2,1} & & \\ & \ddots & \ddots & \ddots & \\ & & \tau_{m_1-1,-1} & 2\delta_{m_1-1} & \tau_{m_1-1,1} \\ & & & -2\hat{\kappa}_{m_1,1} & 2\hat{\kappa}_{m_1,1} \end{pmatrix},$$

$$\hat{B}_2 = \begin{pmatrix} 0 & \hat{\kappa}_{1,2} & & & \\ -\hat{\kappa}_{2,2} & 0 & \hat{\kappa}_{2,2} & & \\ & \ddots & \ddots & \ddots & \\ & & -\hat{\kappa}_{m_2-1,2} & 0 & \hat{\kappa}_{m_2-1,2} \\ & & & -2\hat{\kappa}_{m_2,2} & 2\hat{\kappa}_{m_2,2} \end{pmatrix}.$$

Note that the coefficient matrices are denoted by B for both model problems.

6. Analysis of the BCSC framework. In this section we derive formulas for the eigenvalues and eigenvectors of the matrix P defined in (10). The eigendecomposition of P is given in terms of the eigenvalues and eigenvectors of $M_{(SC)}^{-1}E$, where E is defined in (8). For first-order model problems, the eigendecomposition of $M_{(SC)}^{-1}E$ has been studied in [Otto97] and [HoOtto94]. In Theorem 2 we use this information to prove that P^{-1} exists.

THEOREM 1. *Let the eigendecomposition of $M_{(SC)}^{-1}E$ be given by*

$$(M_{(SC)}^{-1}E)W_{(SC)} = W_{(SC)}\Lambda_{(SC)},$$

where

$$\Lambda_{(SC)} = \mathrm{diag}_{k,m_2}(\Lambda_k^{(SC)}), \quad \Lambda_k^{(SC)} = \mathrm{diag}_{j,m_1}(\lambda_{j,k}^{(SC)}).$$

Then the eigenvectors of P are given by $W_P = V^T W_{(SC)} S$. Also, the $2m_2$ eigenvalues $\lambda_{(1,2),k}^{(P)}$ are $1 + \lambda_{1,k}^{(SC)}$ and $1 + \lambda_{m_1,k}^{(SC)}$, $k = 1, \dots, m_2$.

Proof. Recall that $P = I + V^T M_{(SC)}^{-1} S$. We have

$$\begin{aligned} P(V^T W_{(SC)} S) &= V^T W_{(SC)} S + V^T M_{(SC)}^{-1} S V^T W_{(SC)} S \\ &= V^T W_{(SC)} S + V^T (M_{(SC)}^{-1}E) W_{(SC)} S = V^T W_{(SC)} (I + \Lambda_{(SC)}) S. \end{aligned}$$

Also, exploiting the structure of S we obtain

$$\begin{aligned} (I + \Lambda_{(SC)})S &= S + \mathrm{diag}_{k,m_2}(\Lambda_k^{(SC)})(I_{m_2} \otimes s) = S + \mathrm{diag}_{k,m_2}(\Lambda_k^{(SC)} s) \\ &= \mathrm{diag}_{k,m_2}(s\Lambda_k^{(P)}) = (I_{m_2} \otimes s)\mathrm{diag}_{k,m_2}(\Lambda_k^{(P)}) = S\Lambda_P, \end{aligned}$$

where

$$\Lambda_P = \mathrm{diag}_{k,m_2}(\Lambda_k^{(P)}),$$

$$\Lambda_k^{(P)} = \begin{pmatrix} \lambda_{1,k}^{(P)} & \\ & \lambda_{2,k}^{(P)} \end{pmatrix} = \begin{pmatrix} 1 + \lambda_{1,k}^{(SC)} & \\ & 1 + \lambda_{m_1,k.}^{(SC)} \end{pmatrix}.$$

Thus,

$$P(V^T W_{(SC)} S) = (V^T W_{(SC)} S)\Lambda_P.$$

Hence, $W_P = V^T W_{(SC)} S$ is the eigenvector matrix to P, and $\lambda_{1,k}^{(P)} = 1+\lambda_{1,k}^{(SC)}, \lambda_{2,k}^{(P)} = 1+\lambda_{m_1,k}^{(SC)}$ are eigenvalues of P. □

If $\sigma_1(x_1) = \sigma_1$, the model problems in §5 satisfy $B = M_{(BCSC)}$. According to (8) this implies

$$M_{(SC)}^{-1} B = M_{(SC)}^{-1}(M_{(SC)} + E) = I + M_{(SC)}^{-1} E,$$

and the eigenvalues of P are trivially extracted. For the time-dependent model problem, v_k is given by

$$v_k^T = \begin{pmatrix} 0 & 0 & \cdots & 0 & 0 & \kappa_1 \\ -\kappa_1 & 0 & \cdots & 0 & -\kappa_1 & 2\kappa_1 \end{pmatrix},$$

whereas for the time-independent problem

$$v_k^T = \begin{pmatrix} 0 & 0 & \cdots & 0 & 0 & -\tau_{-1} \\ -\tau_1 & 0 & \cdots & 0 & -\tau_1 & 2\tau_1. \end{pmatrix}$$

Now assume that $\sigma_d(x_d) = \sigma_d = 1$. In [HoOtto94] formulas relating the eigendecomposition of $M_{(SC)}^{-1} E$ to the eigendecomposition of $\hat{\kappa}_2^{-1}\hat{B}_2$ are given. In [Otto97] the corresponding formulas for the time-dependent model problem are given. The two problem settings are closely related. In the discussion below, we use the time-independent problem and the notation in [HoOtto94]. By performing the relevant substitutions, the corresponding results for the time-dependent problem follow.

In [HoOtto94] it is proved that $M_{(SC)}^{-1} E$ has at most $2m_2$ nonzero eigenvalues, denoted by $\lambda_{1,k}^{(SC)}$ and $\lambda_{m_1,k}^{(SC)}$, $k = 1, \ldots, m_2$. Furthermore, it is proved that $M_{(SC)}^{-1} E$ is diagonalizable, and asymptotic formulas for the eigenvalues of $M_{(SC)}^{-1} E$ are derived. Under certain conditions it is established that, for large values of m_1 and m_2, $\lambda_{1,k}^{(SC)}$ and $\lambda_{m_1,k}^{(SC)}$ approach two finite curve segments $\lambda_{1,\infty}^{(SC)}(\theta)$, where $|\theta| \le \varphi < 1$. The curve segments are identical for the time-dependent and time-independent model problems. For the time-independent problem we have Theorem 2.

THEOREM 2. *If $\sigma_d(x_d) = \sigma_d = 1$, m_1 and m_2 are sufficiently large, and*

$$\frac{m_2(1 + 2m_2^{-3/2})}{m_1(1 - \gamma m_1^{\alpha-1})} \le \varphi, \quad \textit{for some constant } \varphi < 1,$$

then P^{-1} exists.

Proof. Under the given assumptions, Corollary 1 in [HoOtto94] yields

$$\frac{15}{28} < |1 + \lambda_{1,\infty}^{(SC)}(\theta)| < 1 + \frac{\sqrt{5}+\sqrt{7}}{4\sqrt{1-\varphi^2}}, \quad -\varphi \le \theta \le \varphi.$$

Hence, for sufficiently large values of m_1 and m_2, we have $|\lambda_{1,k}^{(P)}| = |1 + \lambda_{1,k}^{(SC)}| > 0$ and $|\lambda_{2,k}^{(P)}| = |1 + \lambda_{m_1,k}^{(SC)}| > 0, k = 1, \ldots, m_2$. □

When $m_1, m_2 \to \infty$, the condition on the grid in Theorem 2 can be reduced to $m_2/m_1 = \varphi < 1$. Normally, this is also the condition used for practical computations. Note that Theorem 2 only gives sufficient conditions for the existence of P^{-1}.

TABLE 4
The condition number of the eigenvector matrices.

	$m = 8$	$m = 12$	$m = 16$	$m = 24$	$m = 32$
$\mathrm{cond}_2(W_P)$	12.8	21.5	32.4	58.3	90.3
$\mathrm{cond}_2(W_{(SC)})$	$1.29 \cdot 10^3$	$1.05 \cdot 10^4$	$8.78 \cdot 10^4$	$3.64 \cdot 10^8$	not computable

Assume that a system of n equations

$$Ax = b$$

is solved using a *minimal residual* iteration [FrGoNa92], e.g., the GMRES method. Then we have

$$\|r_i\|_2 = \min_{p_i \in \mathcal{P}_i,\, p_i(0)=1} \|p_i(A) r_0\|_2,$$

where $r_i = Ax_i - b$ and x_i is the approximation of x computed in iteration i. If A is diagonalizable, we obtain [FrGoNa92]

$$\frac{\|r_i\|_2}{\|r_0\|_2} \le \mathrm{cond}_2(W_A) \cdot \min_{p_i \in \mathcal{P}_i,\, p_i(0)=1} \max_{1 \le \ell \le n} |p_i(\lambda_\ell)| \equiv \mathrm{cond}_2(W_A) \cdot \varepsilon_i(A). \tag{15}$$

Here W_A is the eigenvector matrix and λ_ℓ the eigenvalues of A. $\mathcal{P}_i$ is the set of all polynomials of maximal degree i. The *asymptotic convergence factor* ϱ_A is defined by

$$\varrho_A \equiv \lim_{i \to \infty} \varepsilon_i(A)^{1/i}.$$

If we can prove that $\varrho_A \le \eta_1 < 1$ and $\mathrm{cond}_2(W_A) \le \eta_2$, where $\eta_1, \eta_2 > 0$ are independent of m_1 and m_2, then asymptotically the number of iterations required does not depend on problem size. Note that (15) may yield a very pessimistic estimate of the convergence rate. It is trivial to construct a problem of arbitrary size where $\mathrm{cond}_2(W_A) = \infty$, and for which a CG-like method converges in two iterations. For non-normal matrices the spectral decomposition framework is not satisfactory, but unfortunately there is no practical theory available that yields a sharp bound on the convergence rate for polynomial iterations.

If the assumptions in Theorem 2 are fulfilled, it is proved [HoOtto94] that, in the limit $m_1, m_2 \to \infty$,

$$\varrho_{M_{(SC)}^{-1}B} < \left(\frac{1 + \frac{40}{225}\sqrt{1-\varphi^2}}{1 + \frac{616}{225}\sqrt{1-\varphi^2}} \right)^{1/2} < 1.$$

Since the eigenvalues of P constitute a subset of the eigenvalues of $M_{(SC)}^{-1}B$, ϱ_P is asymptotically bounded by the same quantity. The eigenvector matrix W_P is more difficult to analyze theoretically. Using the formulas given in [HoOtto94] and a theorem in [HoOtto93] relating W_P to these formulas, such an analysis might be possible. However, we have so far not completed this approach. For the time-independent model problem, W_P turns out to be much better conditioned than $W_{(SC)}$. In Table 4 we show $\mathrm{cond}_2(W_{(SC)})$ and $\mathrm{cond}_2(W_P)$, computed by MATLAB. The parameters for the artificial viscosity are chosen as $\alpha = 0.1$, $\gamma = 0.5$, and $m = m_1 = 2m_2$.

We see that $\mathrm{cond}_2(W_{(SC)})$ is large and grows rapidly when the problem size is increased. The results in Table 4 also show that $\mathrm{cond}_2(W_P)$ grows with increasing problem size, but it is not clear whether this quantity is bounded or not. In Table 5 we show the number of SC

TABLE 5

solves required when the same type of problems as in Table 4 are solved using the GMRES(6) iteration for P or $M_{(SC)}^{-1}B$.

It is clear that there is no significant difference between iterating on P or $M_{(SC)}^{-1}B$. The large values of $\text{cond}_2(W_{(SC)})$ do not affect the number of iterations. As previously remarked, this does not contradict the estimate (15).

7. Results for constant coefficient problems. In this and the next section, we study the model problems described in §5. Assume that $\sigma_d(x_d) = \sigma_d = 1$. Then $M_{(BCSC)}^{-1}B = I$ whereas $M_{(SC)}^{-1}B \neq I$. Hence, the bandGE and BCSC algorithms are used as direct solvers, and the SC solver is used as a preconditioner in the GMRES(6) iteration.

For time-dependent problems, the factorization is performed once prior to the time-marching. If a large number of time-steps are performed, the work required for factorization could be neglected. When the BCSC solver or the SC-preconditioned GMRES(6) iteration is used, the work required to perform one time-step is dominated by SC solves. Therefore, if more than two iterations are required for the GMRES method, the BCSC solver is presumably more efficient. This is verified in Fig. 1, where the number of a.o. per unknown required for one time-step is shown. Problems where $m_1 = 2^p$, $m_2 = \frac{15}{16}2^p$, and $\Delta t = 10 \cdot 2^{-p}$ are studied. Hence, $\kappa_1 = 10$ and $\kappa_2 = 150/16$.

From Fig. 1 it is clear that the BCSC solver is the best choice for all problem sizes studied. However, note that the work required per unknown for the SC-preconditioned GMRES(6) method actually decreases when the problem size is increased. The number of iterations required decreases so fast that the increase in the work required for the SC solve is more than canceled. The number of a.o. required for the bandGE solver becomes unrealistically large when the problem size increases.

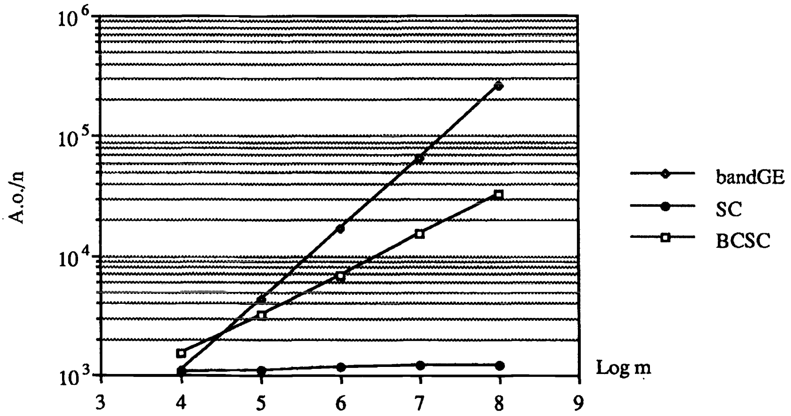

FIG. 2. *Work required for the time-independent problem.*

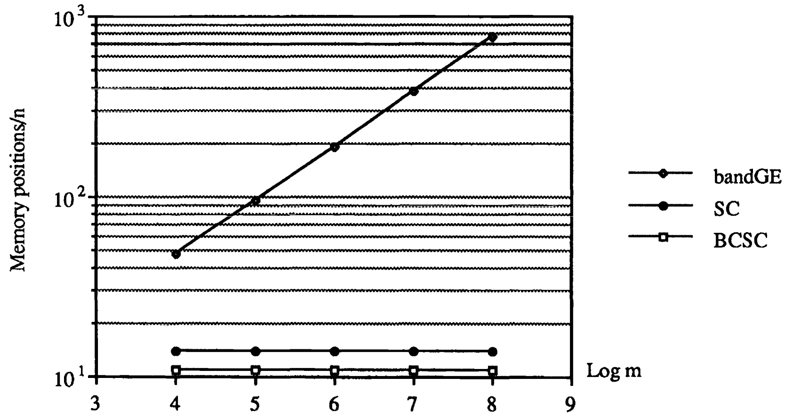

FIG. 3. *Storage requirement.*

When solving time-independent problems, normally only one system of equations has to be solved. Hence, the work required for the factorization must be accounted for. In [HoOtto94] it is found that the number of iterations required for the SC-preconditioned GMRES method is independent of problem size. The factorization for the BCSC solver requires $2n_c m_2$ SC solves. Thus, for large problems the iterative method is presumably better than the BCSC solver. In Fig. 2 the number of a.o. per unknown required for the solution of the time-independent model problem is shown.

Figure 2 clearly demonstrates that the SC-preconditioned GMRES method is the fastest solution method for large problems. Again, the work required does not grow with increasing problem size, and the bandGE solver is not a realistic alternative.

Finally, in Fig. 3 we show the number of memory positions per unknown required for the model problems. Note that the storage requirement is the same for the time-dependent and time-independent problem.

From Fig. 3 we see that, for large problems, the storage requirement for the bandGE solver is not acceptable.

8. Results for variable coefficient problems. In this section we only study the time-dependent model problem. Hence, the work required for factorization is neglected. We assume

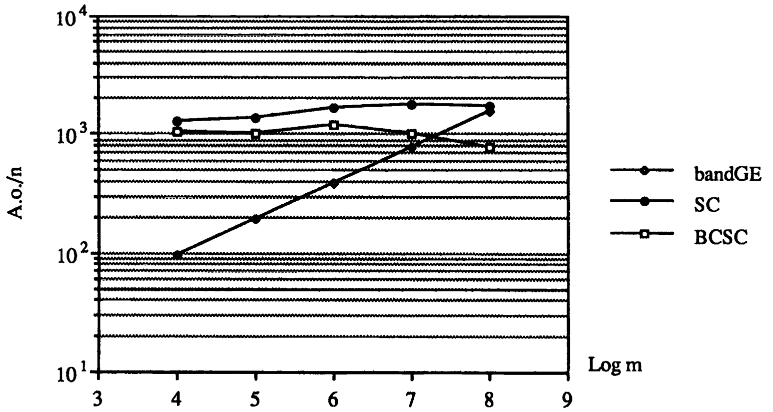

FIG. 4. *Work required for one time-step*, $s = \ln(2)$.

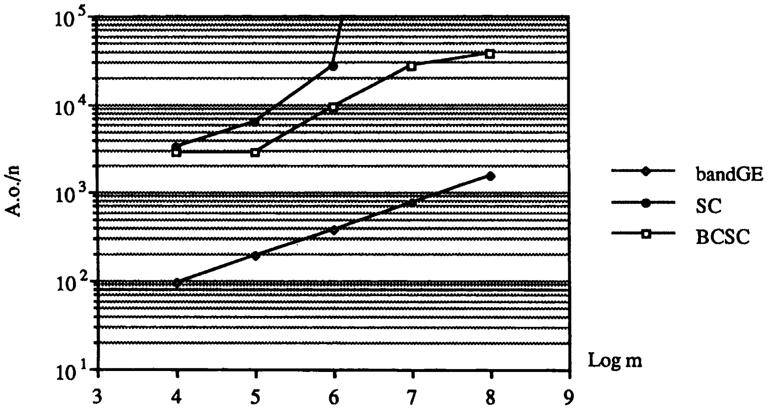

FIG. 5. *Work required for one time-step*, $s = \ln(3)$.

that

$$\sigma_d(x_d) = \sigma(x_d) = \cosh^2\left(s(2x_d - 1)\right)\frac{\tanh(s)}{s}.$$

Here $s > 0$ determines the variation of σ. In the limit $s \to 0$, $\sigma(x_d) = 1$. Coefficients of this form arise from a spatial discretization exploiting a grid adapted to boundary layers; see [HoOtto90]. The variation of $\sigma(x)$ increases rapidly with increasing s. For PDEs with variable coefficients, only the bandGE solver can be used as a direct solution method. Both the SC and BCSC solvers are used as preconditioners in the GMRES(6) iteration.

The BCSC solver takes the boundary conditions in the x_1-direction into account, which is not the case for the SC solver. Hence, $M^{-1}_{(BCSC)}$ is presumably a better approximation of B^{-1} than $M^{-1}_{(SC)}$. In Figs. 4 and 5, the number of a.o. per unknown required for the different solution methods is compared. Problems where $m_1 = 2^p$, $m_2 = \frac{15}{16}2^p$, $\kappa_1 = 10$, and $\kappa_2 = 150/16$ are studied. In Fig. 4 results are shown for $s = \ln(2) \approx 0.69$, whereas in Fig. 5 problems with $s = \ln(3) \approx 1.10$ are examined.

From Fig. 4 it is clear that the BCSC-preconditioned GMRES(6) method requires the smallest number of a.o. for large problems. As anticipated, the BCSC preconditioner performs better than the SC preconditioner. This conclusion is further corroborated by a comparison of numerically computed spectra of $M^{-1}_{(BCSC)}B$ and $M^{-1}_{(SC)}B$ [HoOtto93]. Also note that for this value of s, both the SC and BCSC preconditioners retain the property that the work per unknown does not grow with increasing problem size. For the larger value of s used in Fig. 5, this is no longer true. For both the SC and the BCSC preconditioner, the number of iterations grows when the problem size is increased. The Gaussian elimination algorithm requires the smallest number of a.o. for all problem sizes studied. However, the storage requirement for this algorithm is $\mathcal{O}(m_1)$ times larger than for the iterative methods.

9. An application. We consider the solution of the isentropic Navier-Stokes equations using a semi-implicit time-marching scheme of a type described in [GuSt91]. The specific problem studied here is the calculation of the flow in a driven cavity. The PDE is symmetrized [GuSt91] yielding

$$\frac{\partial \mathbf{u}}{\partial t} + \left(\varepsilon^{-1}\mathcal{P}_0 + \mathcal{P}_1(\mathbf{u})\right)\mathbf{u} = \mathcal{P}_2(\mathbf{u})\mathbf{u}. \tag{16}$$

Here ε is the Mach number and $\mathbf{u}$ is a vector with three components. The first component is a transformed pressure, and the second and third components are the velocities $\mathbf{u}_1$ and $\mathbf{u}_2$ in the x_1- and x_2-directions. For the driven cavity flow both velocity components vanish at all walls, except at the driving boundary $x_2 = 1$, where $\mathbf{u}_1(x_1, 1, t) = 1$ for $t > 0$. The differential operator $\mathcal{P}_2$ contains the nonlinear second-order terms in the Navier-Stokes equations corresponding to viscosity. $\mathcal{P}_1$ is a nonlinear first-order operator, and $\varepsilon^{-1}\mathcal{P}_0$ is a linear first-order operator with constant coefficients. To avoid a strict stability criterion of the form $\Delta t < \mathcal{O}(h\varepsilon)$, an implicit method is preferred for this part of the differential operator. The time-marching method exploits the implicit Euler scheme for $\varepsilon^{-1}\mathcal{P}_0$ and the explicit leap-frog scheme for $\mathcal{P}_1$ and $\mathcal{P}_2$. The discretization of spatial derivatives is performed on a uniform grid with $m \times m$ internal gridpoints and space-step h using centered differences. For smooth solutions and almost incompressible flows, this scheme is second-order time-accurate. Introducing the discretizations, the analytical boundary conditions, and numerical boundary conditions for the transformed pressure, we arrive at a system of equations with $3m^2$ unknowns:

$$Bu = g. \tag{17}$$

Here B is given by

$$B = \begin{pmatrix} B_0 - 2B_1Z & B_1 + B_1Z & & & \\ -B_1 & B_0 & B_1 & & \\ & \ddots & \ddots & \ddots & \\ & & -B_1 & B_0 & B_1 \\ & & & -B_1 - B_1Z & B_0 + 2B_1Z \end{pmatrix},$$

where

$$B_0 = \begin{pmatrix} I_3 - 2\nu_1\zeta & \nu_1 + \nu_1\zeta & & & \\ -\nu_1 & I_3 & \nu_1 & & \\ & \ddots & \ddots & \ddots & \\ & & -\nu_1 & I_3 & \nu_1 \\ & & & -\nu_1 - \nu_1\zeta & I_3 + 2\nu_1\zeta \end{pmatrix},$$

$$B_1 = I_m \otimes \nu_2, \quad Z = I_m \otimes \zeta,$$

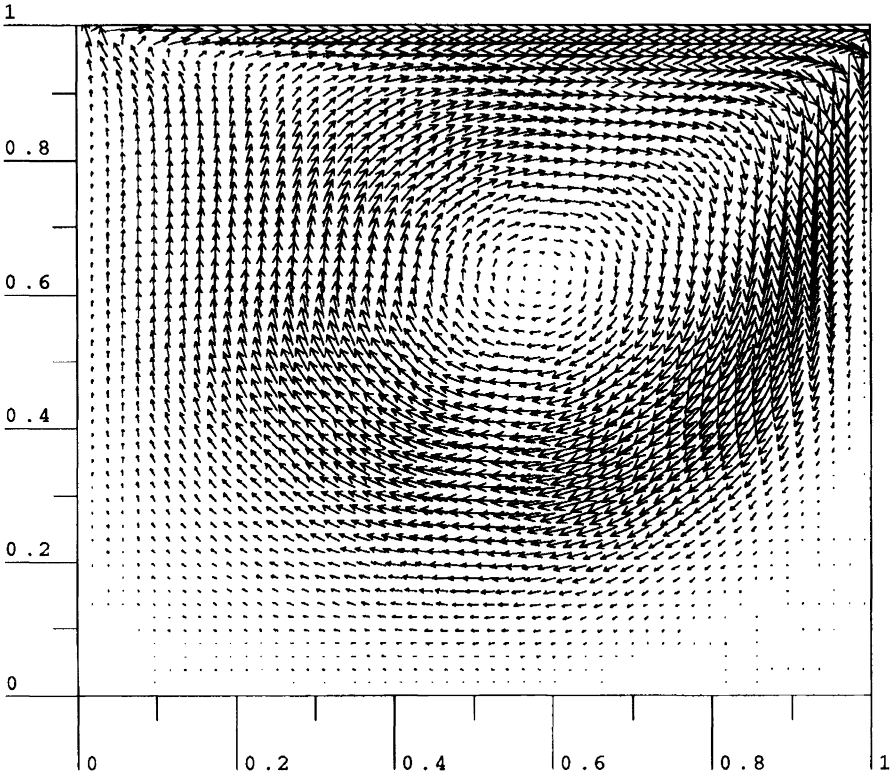

FIG. 6. *The velocity field at* $t = 5$.

and

$$\nu_1 = \begin{pmatrix} 0 & \kappa & 0 \\ \kappa & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad \nu_2 = \begin{pmatrix} 0 & 0 & \kappa \\ 0 & 0 & 0 \\ \kappa & 0 & 0 \end{pmatrix}, \quad \zeta = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad \kappa = \frac{\Delta t}{\varepsilon h}.$$

In [Stoor90] NAG routines are employed to solve (17). A general sparse matrix factorization routine (F01BRF), exploiting threshold pivoting, is called once prior to the time-marching. In each time-step, F04AXF is invoked to perform the substitutions. Because of the large storage requirement, the largest problem solved in [Stoor90] has only 4800 unknowns.

Below, we show results computed using the BCSC solver, which yields a direct solution method for (17). In Fig. 6 the velocity field at $t = 5$ is shown for a problem with Reynolds number 500. At $t = 0$, the medium was at rest. The Mach number ε is 0.01, which means that the upper boundary of the cavity moves with 1% of the speed of sound. The problem is solved using $m = 256$ and $\Delta t = 0.0005$, yielding $\kappa = 12.85$. Note that the problem studied has 196608 unknowns. The solution is computed using a Sun 670MP. The computer is configured so that $\sim$ 150 Mbyte of virtual memory may be used. Below, problems where $m = 2^p$, $\Delta t = 2^{-(p+2)}$, and $\varepsilon = 0.01$ are studied. In Fig. 7 the number of memory positions per unknown required for the BCSC, NAG, and bandGE solvers is shown. The 150 Mbyte limit is marked as a dashed line.

Figure 7 shows that the BCSC solver allows us to solve a 16 times larger problem than if the NAG solver is used. Note that the quotient between the storage requirement for the bandGE and NAG solvers is $\sim$ 3, independent of problem size. Also note that it is possible to determine

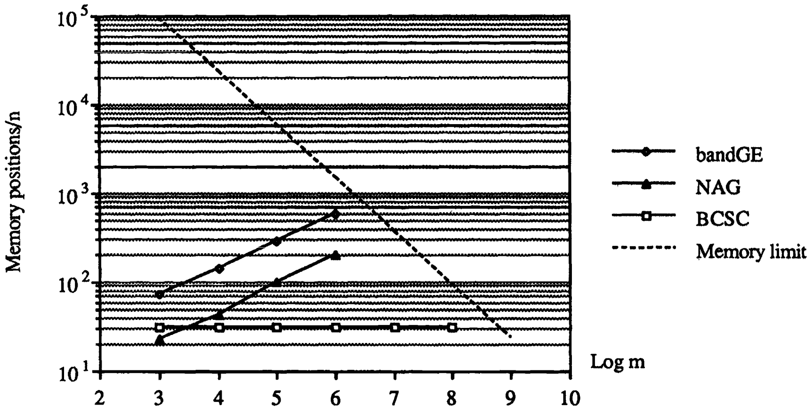

FIG. 7. *Storage requirement.*

BCSC	0.054	0.058	0.063	0.071	0.081

the storage requirement for the BCSC and bandGE solvers at the time of compilation, which is not the case for the NAG solver. When we attempted to use the NAG solver for a problem with $m = 128$, F01BRF spent 38 hours of CPU-time to determine that 396 memory positions per unknown would be required to store the factorization, which is more than the available virtual memory allows!

Tables 6 and 7 show the CPU-time required when the NAG and BCSC solvers are used for the solution of the driven cavity problem. In Table 6 the CPU-time per unknown required for the factorization is shown, and in Table 7 the CPU-time per unknown required for one time-step is displayed. Note that in Table 7 the CPU-time for performing the explicit part of the time-marching is included. The entries "too large" indicate that the corresponding problem is larger than the memory available.

Table 6 clearly shows that the NAG factorization requires much more CPU-time than the BCSC factorization. In Table 7 we see that, for small problems, the NAG substitutions are faster than the BCSC substitutions. However, if it were possible to use the NAG solver for realistic problem sizes, it is clear that the BCSC method would be much faster.

10. Conclusions. Previously, we have described the SC solver characterized by the matrix $M_{(SC)}$. This is a direct solver for systems of PDEs with constant coefficients and periodic boundary conditions in one space direction. For simplicity we now consider $m \times m$ grids, in which case the arithmetic complexity is $\mathcal{O}(m^2 \log_2 m)$. In this paper we have generalized the

SC framework to construct the BCSC solver defined by $M_{(BCSC)}$. Here, the system of PDEs may be subject to boundary conditions from a wide selection, including numerical outflow, Dirichlet, Neumann, and periodic. For quite a large class of PDEs, the SC or BCSC solver is applicable as a direct solution method. Outside the class we have shown how to construct a simplified PDE, for which the solution can be computed using the SC or BCSC solver. The solution of the original problem is then computed with a CG-like iterative method, where the simplified problem acts as a preconditioner.

The basis for the BCSC solver is a factorization of $M_{(BCSC)}^{-1}$, derived by exploiting the Sherman-Morrison-Woodbury formula. To compute the solution, a system of $\mathcal{O}(m)$ equations with coefficient matrix P must be formed and solved. P is a dense matrix containing the boundary corrections. In the BCSC solver, P is formed and LU factorized. The complexity for the first right-hand side is $\mathcal{O}(m^3 \log_2 m)$, whereas only $\mathcal{O}(m^2 \log_2 m)$ a.o. are required for subsequent right-hand sides. The storage requirement is $\mathcal{O}(m^2)$. Also, an iterative solver is considered, where $Px = y$ is solved using a CG-like iterative method. Here P is never explicitly formed. We have proved that the eigenvalues and eigenvectors of P are closely related to the eigendecomposition of $M_{(SC)}^{-1} M_{(BCSC)}$. For a time-dependent and a time-independent model problem, we have established that the spectrum of P is uniformly nonzero.

For constant coefficient PDEs, the SC solver is used as a preconditioner for the restarted GMRES iteration, whereas the BCSC solver yields a direct solution method. For the time-dependent problem, the BCSC solver is a better choice than the SC-preconditioned GMRES method, since the cost for the factorization may be amortized over a large number of time-steps. For the time-independent problem, only one system of equations has to be solved. Hence, the SC-preconditioned GMRES method is the best solution method, since the complexity per unknown is independent of the size of the problem. Comparisons with band Gaussian elimination show that, for large problems, the complexity is higher than those for both the BCSC solver and the SC-preconditioned GMRES method. Also, the storage requirement for band Gaussian elimination becomes prohibitive for large problems.

For the variable coefficient time-dependent problem, both the SC and BCSC solvers are used as preconditioners for the restarted GMRES iteration. For weakly variable coefficients, the solution methods exploiting the SC and BCSC solvers retain a complexity (per unknown) which is independent of problem size. Hence, both methods are faster than Gaussian elimination for large problems. The BCSC solver yields a better approximation of B^{-1} than the SC solver, and it requires less total work. For problems with strongly variable coefficients, the favorable convergence properties are no longer preserved, and the Gaussian elimination solver has the lowest complexity for all problem sizes studied.

Finally, we have used the BCSC solver combined with a semi-implicit time-marching scheme in the solution of the isentropic, almost incompressible Navier-Stokes equations for a driven cavity problem. In [Stoor90] the arising system of equations is solved by a general sparse solver. The two solution methods are compared, and we find that employing the BCSC solver makes it possible to solve a 16 times larger problem than by using the general sparse solver. Also, the CPU-time required is less for the BCSC solver, both in the factorization and the time-marching.

THE SOLUTION OF MULTIDIMENSIONAL REAL HELMHOLTZ EQUATIONS ON SPARSE GRIDS*

ROBERT BALDER† AND CHRISTOPH ZENGER†

Abstract. Sparse grids provide a very efficient method for the multilinear approximation of functions, especially in higher-dimensional spaces. In the d-dimensional space, the nodal multilinear basis on a grid with mesh size $h = 2^{-n}$ consists of $O(2^{nd})$ basis functions and leads to an L_2-error of order $O(4^{-n})$ and an H_1-error of order $O(2^{-n})$. With sparse grids we get an L_2-error of order $O(4^{-n}n^{d-1})$ and an H_1-error of order $O(2^{-n})$ with only $O(2^n n^{d-1})$ basis functions, if the function u fulfills the condition $\frac{\partial^{2d}}{\partial x_1^2 \partial x_2^2 ... \partial x_d^2} u < \infty$. Therefore, we can achieve much more accurate approximations with the same amount of storage.

A data structure for the sparse grid representation of functions defined on cubes of arbitrary dimension and a finite element approach for the Helmholtz equation with sparse grid functions are introduced. Special emphasis is taken in the development of an efficient algorithm for the multiplication with the stiffness matrix. With an appropriate preconditioned conjugate gradient method (cg-method), the linear systems can be solved efficiently. Numerical experiments are presented for Helmholtz equations and eigenvalue problems for the Laplacian in two and three dimensions, and for a six-dimensional Poisson problem. The results support the assertion that the L_2-error bounds for the sparse-grid approximation are also valid for sparse grid finite element solutions of elliptic differential equations. Problems with nonsmooth solutions are treated with adaptive sparse grids.

1. Introduction.

The hierarchical basis, first introduced by Faber [5] in 1909, has been used by Yserentant [12] in 1986 as a preconditioner for the solution of large linear systems arising from elliptic differential equations. Four years later, Zenger [13] showed that a multilinear approximation of a smooth multivariate function u is represented much more efficiently if we directly use a suitably chosen hierarchical basis instead of a nodal basis. This approach leads to the idea of *sparse grids*. Considering a nodal multilinear basis on a grid with uniform mesh size $h = 2^{-n}$ on a d-dimensional cube, which consists of $O(2^{nd})$ functions, then the approximation error in the L_2-norm is of order $O(4^{-n})$, in the H_1-norm of order $O(2^{-n})$. By performing a basis transformation to the hierarchical basis, an L_2-error of order $O(4^{-n}n^{d-1})$ can be obtained with a subset consisting of only $O(2^n n^{d-1})$ transformed basis functions if the function u fulfills the condition $\frac{\partial^{2d}}{\partial x_1^2 \partial x_2^2 ... \partial x_d^2} u < \infty$. If the error in the H_1-norm remains $O(2^{-n})$, we have no decrease in the order here. The application of this concept to the solution of partial differential equations on sparse grids is outlined in the papers by Zenger [13, 14, 15], Bungartz [2, 3], and Griebel [7, 8]. Data structures and algorithms for the solution of Poisson's equation on a square and a cube are presented in [3].

In this paper, we introduce a modified data structure and a sparse grid algorithm that solves Dirichlet problems for the real Helmholtz equation $-\Delta u + cu = f$ on cubes of arbitrary dimension.[1] In §2 we explain the basic characteristics of sparse grids. For a brief theoretical description, we refer to the paper of Bungartz [3]. In §3 a tree structure for the representation of sparse grid functions is introduced. Section 4 deals with a finite element approach for the Helmholtz equation with hierarchical basis functions. It turns out that the number of nonzero entries in the corresponding stiffness matrix is of order $O(4^n n^{d-2})$ for $d \geq 2$. Nevertheless, it is possible to perform a matrix-vector multiplication with $O(2^n n^{d-1})$ operations. The

[1] We remind the reader that the description of an n-electron system in quantum mechanics leads to a $3n$-dimensional Schrödinger equation.

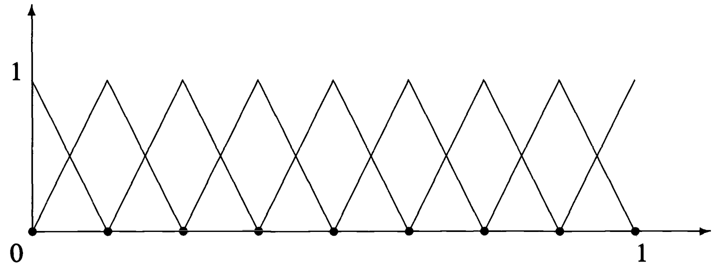

FIG. 1. *Standard basis B_3.*

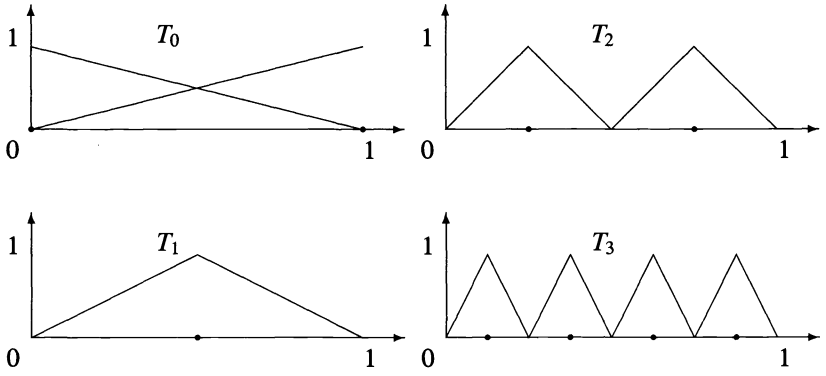

FIG. 2. *Hierarchical basis H_3.*

number of operations is proportional to the size of the vector of unknowns. We prove this constructively in §5 by developing a corresponding algorithm. With the preconditioned cg-method described in Griebel and Oswald [9], we can solve the linear systems efficiently. In §6, we present numerical examples for the solution of the Helmholtz equation with Helmholtz numbers $c \in [-1000, 1000]$ in the unit square and the unit cube. For $c \ll 0$ the corresponding stiffness matrices are indefinite. Nevertheless, we obtain good approximations of the solution of the linear system with the cg-method. Eigenvalue problems with reentrant corners in two and three dimensions are solved with adaptive sparse grids. Finally we look into a six-dimensional Poisson problem. Concluding remarks are made in §7.

2. Sparse grids. Beginning with the one-dimensional case, let S_n be the $(2^n + 1)$-dimensional finite element space of piecewise linear functions on the unit interval on an equidistant grid with mesh size $h = 2^{-n}$. For an arbitrary but fixed n, we consider two different basis representations of this space.

1. The standard basis B_n (see Fig. 1) is the set of piecewise linear functions with the value 1 on one grid point and the value zero on all others.

2. Following Yserentant [12], the hierarchical basis H_n may be defined inductively by

$$H_0 := T_0 := B_0,$$

$$H_i := H_{i-1} \cup T_i = \bigcup_{j=0}^{i} T_j,$$

where T_i, $i \geq 1$, is the set of basis functions of B_i vanishing on the grid belonging to S_{i-1}. This is illustrated in Fig. 2.

The grid point, where a basis function v has the value 1, will be called basis point $bp(v)$. The set of basis points for a given n will be called grid G_n.

Now let $u : [0, 1] \to \mathbb{R}$ be a function with existing and bounded seminorm

$$\mid u \mid_\infty := \left\| \frac{\partial^2}{\partial x^2} u \right\|_\infty \leq C < \infty,$$

and let $u_n \in S_n$ be the linear interpolant of u in the grid G_n. In the standard basis $\{v_i\}$, we define the weights g_i by

$$u_n = \sum_{v_i \in B_n} g_i v_i.$$

Obviously, g_i is just the value of u at the corresponding grid point.

In the hierarchical basis $\{\tilde{v}_i\}$, we define the weights $\tilde{g}_i$ by

$$u_n = \sum_{\tilde{v}_i \in H_n} \tilde{g}_i \tilde{v}_i.$$

The weight $\tilde{g}_i$ for the basis function $\tilde{v}_i \in T_k$ is the difference between the value of the function and the value of the interpolant of H_{k-1} at $bp(\tilde{v}_i)$. Therefore, we call $\tilde{g}_i$ a *hierarchical surplus*. It is easy to show (see [3]) that

$$(1) \qquad \mid \tilde{g}_i \mid \leq \frac{1}{2} 4^{-k} \mid u \mid_\infty \quad \text{for } \tilde{v}_i \in T_k,$$

which means that the weights of the basis functions in T_n decrease geometrically with $n \to \infty$ when $\mid u \mid_\infty$ is bounded. This is precisely the main advantage of the hierarchical over the standard basis and leads to essential savings of storage in the multivariate case. In §5.1 we will show how the hierarchical surpluses can be computed.

The generalization of the standard and the hierarchical bases to higher-dimensional multilinear functions $u_n^{(d)}$ on the unit cube $[0, 1]^d$ is derived from a tensor product decomposition as follows.

For the d-dimensional space we define

$$B_n^{(d)} := \left\{ v_I := v_{i_1,\ldots,i_d}(x_1, x_2, \ldots, x_d) = \prod_{j=1}^{d} v_{i_j}(x_j) : v_{i_j} \in B_n \right\},$$

$$H_n^{(d)} := \left\{ \tilde{v}_I := \tilde{v}_{i_1,\ldots,i_d}(x_1, x_2, \ldots, x_d) = \prod_{j=1}^{d} \tilde{v}_{i_j}(x_j) : \tilde{v}_{i_j} \in H_n \right\}.$$

An upper case index I denotes a multiindex $i_1, \ldots, i_d$. An analogous relation to (1) holds in the multivariate case. Generally, we can state this observation as the following: *The weight of a basis function decreases asymptotically with the square of the volume of its support.*

To be more specific, let $u_n^{(d)}$ be the multilinear interpolant of a function u defined on $[0, 1]^d$ with the seminorm

$$(2) \qquad \mid u \mid_\infty := \left\| \frac{\partial^{2d}}{\partial x_1^2 \partial x_2^2 \ldots \partial x_d^2} u \right\|_\infty < \infty.$$

We define the $\tilde{g}_I$ implicitly by $u_n^{(d)} = \sum_{\tilde{v}_I \in H_n^{(d)}} \tilde{g}_I \tilde{v}_I$. As defined above, we have $\tilde{v}_I = \prod_{j=1}^{d} \tilde{v}_{i_j}(x_j)$, where $\tilde{v}_{i_j} \in T_{k_j}$. Recall that 2^{-k_j} is the length of the support of $\tilde{v}_{i_j} \in T_{k_j}$. With

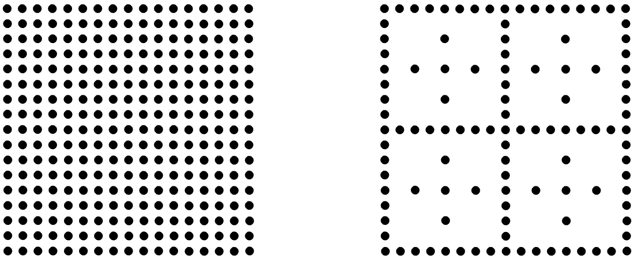

FIG. 3. *Full grid $G_4^{(2)}$ and regular sparse grid $\tilde{G}_4^{(2)}$.*

$k := \sum_{j=1}^{d} k_j$, the bound

$$| \tilde{g}_I | \leq \frac{1}{2^d} 4^{-k} | u |_\infty \tag{3}$$

holds (see [3]).

The basic idea of a sparse grid is as follows: We approximate a function with those functions $\tilde{v}_I$ from the set $H_\infty^{(d)} := \bigcup_{n \in \mathbb{N}} H_n^{(d)}$ where $\tilde{g}_I$ satisfies

$$| \tilde{g}_I | > \varepsilon \tag{4}$$

for a given $\varepsilon > 0$ (see [13]).

For an a priori estimation of $| \tilde{g}_I |$, we assume that $| \frac{\partial^{2d}}{\partial x_1^2 \partial x_2^2 \ldots \partial x_d^2} u |$ is bounded above uniformly in $[0, 1]^d$. Then (3) leads us to consider all basis functions whose support has a volume larger than a given minimal volume. This reduced *sparse* basis is called $\tilde{H}_n^{(d)}$. Note that $\tilde{H}_n^{(d)} \subset H_n^{(d)}$ and $\tilde{H}_{n+1}^{(d)} \not\subset H_n^{(d)}$. The set of the basis points of $\tilde{H}_n^{(d)}$ is exactly our *regular sparse grid* $\tilde{G}_n^{(d)}$ (see Fig. 3), in contrast to an *adaptive sparse grid* which will be defined later in this section.

The space spanned by $\tilde{H}_n^{(d)}$ is called $\tilde{S}_n^{(d)}$.

Bungartz showed in [3] that the number of basis functions in the d-dimensional case is reduced dramatically from $O(2^{nd})$ to $O(2^n n^{d-1})$, while the accuracy of the approximation degrades only from $O(4^{-n})$ to $O(4^{-n} n^{d-1})$ in the L_2-norm. We see that with a slight loss in accuracy we can drastically reduce the dimension of the approximation space and therefore the amount of required storage.

The numerical examples in §6 support our assumption that the previous error bounds are also valid for the solutions of linear elliptic boundary value problems. Multilevel preconditioners [9] assure fast convergence for iterative solvers.

For functions u where $\frac{\partial^{2d}}{\partial x_1^2 \partial x_2^2 \ldots \partial x_d^2} u$ is not bounded, we may not get satisfying results with regular sparse grids. We have to replace our a priori estimation for $| \tilde{g}_I |$ by an a posteriori estimation, say by computed values of $| \tilde{g}_I |$. This approach leads to adaptive sparse grids. Our goal is to approximate the function u by all g_I that fulfill (4). Therefore, it seems natural to refine the grid in every grid point where (4) holds. Refinement means that the basis functions corresponding to one half of the support of v_I should also belong to our grid. Asymptotically, this fulfills the basic idea of a sparse grid. Some numerical experiments with this strategy are presented in §6.2.

3. A data structure for sparse grids. In this section, we describe a data structure well suited for the representation of sparse grid functions in spaces of general dimension and for the algorithms working on it. The data structure consists of a set of trees called *grid trees*.

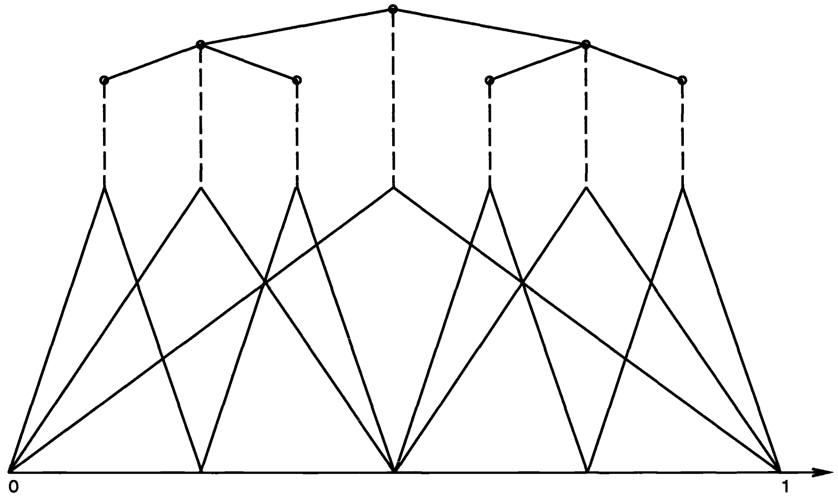

FIG. 4. *Assignment of the basis functions of $\tilde{H}_{n,0}$ to the nodes of a grid tree.*

Every basis function is assigned to a node in a grid tree. We define the subset $\tilde{H}^{(d)}_{n,0} \subset \tilde{H}^{(d)}_n$ as follows:

A basis function $\tilde{v}_I = \prod_{j=1}^d \tilde{v}_{i_j} \in \tilde{H}^{(d)}_n$ belongs to $\tilde{H}^{(d)}_{n,0}$ if and only if $\tilde{v}_{i_j} \notin T_0$ for $j = 1, \ldots, d$.

The basis points of the basis functions from $\tilde{H}^{(d)}_{n,0}$ are exactly those located in $\Omega =]0, 1[^d$ and not those on the boundary $\partial\Omega$ of the domain.

In the one-dimensional case, the grid tree is a binary tree. The basis functions of $\tilde{H}_{n,0} := \tilde{H}^{(1)}_{n,0}$ are assigned to the nodes of the grid tree as shown in Fig. 4. We may now define the grid tree for the basis functions of $\tilde{H}^{(d)}_{n,0}$ recursively. We get the d-dimensional grid tree by combining every node of a one-dimensional grid tree with the root of a $(d-1)$-dimensional grid tree. The location of the node belonging to $\prod_{j=1}^d \tilde{v}_{i_j}$ is recursively defined by the location of $\prod_{j=1}^{d-1} \tilde{v}_{i_j}$ in the $(d-1)$-dimensional grid tree that is connected with the node belonging to $\tilde{v}_{i_d}$ in the one-dimensional grid tree.

The remaining basis functions belong to the boundary of the d-dimensional cube that consists of lower-dimensional cubes. Therefore, they are assigned to nodes of lower-dimensional grid trees. A null-dimensional grid tree is a single node. See Fig. 5 for a two-dimensional example of our data structure for a regular sparse grid. New basis functions can be included by adding new nodes in the tree. Hence, the tree structure is also well suited for adaptive grids.

4. The Helmholtz equation. Let us define the sets

$$\{I\} := \{I : v_I \in H^{(d)}_n\}, \qquad \{I_0\} := \{I : v_I \in H^{(d)}_{n,0}\},$$
$$\{i\} := \{i : v_i \in H_n\}, \qquad \{i_0\} := \{i : v_i \in H_{n,0}\}.$$

We consider the Dirichlet boundary value problem

$$-\Delta u + c \cdot u = f \tag{5}$$

in $\Omega = [0, 1]^d$ with $u(x) = u_0(x)$ on $\partial\Omega$. With the finite-element method, we want an approximation $\tilde{u} \in \tilde{S}^{(d)}_n$ of u, which we obtain by solving the weak form of (5) given by

$$\int_\Omega \nabla\tilde{u} \cdot \nabla\tilde{v}_K + c \cdot \tilde{u} \cdot \tilde{v}_K \, dx = \int_\Omega \tilde{f} \cdot \tilde{v}_K \, dx, \qquad K \in \{I_0\}, \tag{6}$$

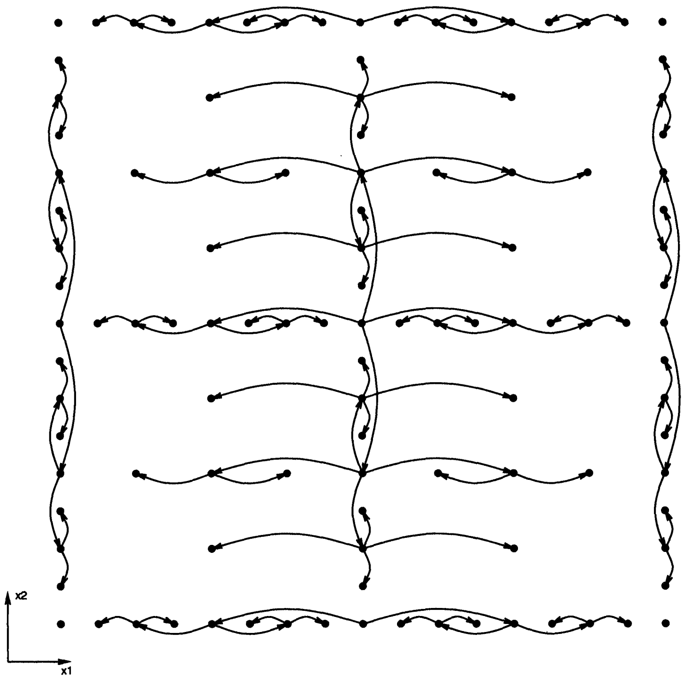

FIG. 5. *Data structure for* $\tilde{H}_4^{(2)}$.

where $\tilde{u} = \sum_{\{I\}} \tilde{g}_I \cdot \tilde{v}_I$ interpolates the function u_0 on $\partial\Omega \cap \tilde{G}_n^{(d)}$ and $\tilde{f} = \sum_{\{I\}} \tilde{f}_I \cdot \tilde{v}_I$ interpolates f in $\tilde{G}_n^{(d)}$.

We define the stiffness matrix

$$(A_{IK}) := \left(\int_\Omega \nabla\tilde{v}_I \cdot \nabla\tilde{v}_K + c \cdot \tilde{v}_I \cdot \tilde{v}_K \, dx \right), \qquad I, K \in \{I_0\},$$

the mass matrix

$$(M_{IK}) := \left(\int_\Omega \tilde{v}_I \cdot \tilde{v}_K \, dx \right), \qquad I, K \in \{I_0\},$$

and the corresponding extended rectangular matrices $(\bar{A}_{IK})$ and $(\bar{M}_{IK})$ resulting from the definitions above if $I \in \{I\}$. With the coefficient vectors $(\tilde{g}_I)$ and $(\tilde{f}_I)$, we may write (6) as

$$(\bar{A}_{IK})(\tilde{g}_I) = (\bar{M}_{IK})(\tilde{f}_I).$$

With $\tilde{v}_I = \prod_{l=1}^d \tilde{v}_{i_l}(x_l)$, the entries of the mass matrix are

$$M_{IK} = \int_\Omega \prod_{l=1}^d \tilde{v}_{i_l}(x_l) \cdot \prod_{l=1}^d \tilde{v}_{k_l}(x_l) \, dx = \prod_{l=1}^d \int_0^1 \tilde{v}_{i_l}(x_l) \cdot \tilde{v}_{k_l}(x_l) \, dx. \tag{7}$$

For the Laplacian part of the stiffness matrix, we have

$$\begin{aligned} \int_\Omega \nabla\tilde{v}_I \cdot \nabla\tilde{v}_K \, dx &= \int_\Omega \left(\nabla \prod_{l=1}^d \tilde{v}_{i_l}(x_l) \right) \cdot \left(\nabla \prod_{l=1}^d \tilde{v}_{k_l}(x_l) \right) dx \\ &= \sum_{j=1}^d \int_\Omega \frac{\partial}{\partial x_j} \prod_{l=1}^d \tilde{v}_{i_l}(x_l) \cdot \frac{\partial}{\partial x_j} \prod_{l=1}^d \tilde{v}_{k_l}(x_l) \, dx. \end{aligned} \tag{8}$$

Let us consider the first summand ($j = 1$) of this term. Due to the hierarchical structure of the basis functions, all parts of the sum are zero when $\tilde{v}_{i_1}$ is not equal to $\tilde{v}_{k_1}$. For $\tilde{v}_{i_1} = \tilde{v}_{k_1}$ we get

$$\int_0^1 \frac{\partial}{\partial x_1}\tilde{v}_{i_1}(x_1) \cdot \frac{\partial}{\partial x_1}\tilde{v}_{k_1}(x_1)\,dx_1 = \frac{2}{h_{k_1}}, \tag{9}$$

where h_{k_1} is half of the mesh size of the support of $\tilde{v}_{k_1}$. Hence, we have

$$\int_\Omega \frac{\partial}{\partial x_1}\tilde{v}_I \cdot \frac{\partial}{\partial x_1}\tilde{v}_K\,dx = \delta_{i_1k_1}\frac{2}{h_{k_1}}\prod_{l=2}^{d}\int_0^1 \tilde{v}_{i_l}(x_l) \cdot \tilde{v}_{k_l}(x_l)\,dx_l, \tag{10}$$

where $\delta_{i_1k_1}$ denotes the well-known Kronecker symbol. Apart from the number of multiplicands and the factor $\delta_{i_1k_1}\frac{2}{h_{k_1}}$, this term is analogous to the right-hand side of (7). For the other summands in (8), we get similar formulas.

We will now estimate the number of entries in the stiffness matrix. From (7) and (10), we see that

$$\int_\Omega \nabla\tilde{v}_I\nabla\tilde{v}_K\,dx \neq 0 \Rightarrow \int_\Omega \tilde{v}_I\tilde{v}_K \neq 0.$$

Therefore, if the Helmholtz coefficient c is nonzero, then the number of nonzero entries in the stiffness matrix is equal to the number of nonzero entries in the mass matrix (M_{IK}).

Let $\tilde{w}$ be the basis function from T_1, $d \geq 2$ and the sets $\mathcal{S}_1$ and $\mathcal{S}_2$ be defined as

$$\mathcal{S}_1 := \{\tilde{v}_I \in H_{n,0}^{(d)} : \tilde{v}_{i_d} = \tilde{w}\}, \qquad \mathcal{S}_2 := \{\tilde{v}_K \in H_{n,0}^{(d)} : \tilde{v}_{k_1} = \tilde{v}_{k_2} = \cdots = \tilde{v}_{k_{d-1}} = \tilde{w}\}.$$

We have card$(\mathcal{S}_1) = O(2^n \cdot n^{d-2})$ and card$(\mathcal{S}_2) = O(2^n)$, where card(.) denotes the cardinality of a set. The support of a function v is defined as the open set $\{x : v(x) \neq 0\}$. Then support$(\tilde{w}) =]0, 1[$ and from support$(\tilde{v}_i) \cap$ support$(\tilde{w}) \neq \emptyset\, \forall i \in \{i\}$, we obtain

$$v_I \in \mathcal{S}_1, v_K \in \mathcal{S}_2 \Rightarrow \text{support}(\tilde{v}_I) \cap \text{support}(\tilde{v}_K) \neq \emptyset.$$

The corresponding M_{IK} is positive because the basis functions are positive on their support. This means that we have at least card$(\mathcal{S}_1)\cdot$card$(\mathcal{S}_2) = O(4^n \cdot n^{d-2})$ nonzero entries in the mass matrix and the stiffness matrix, respectively. Nevertheless, as we will see in the next section, it is possible to perform a matrix-vector multiplication with $O(2^n \cdot n^{d-1})$ operations.

5. Algorithm. In this section we develop an algorithm that performs a matrix-vector multiplication with the stiffness matrix with a constant amount of operations per vector component. We first introduce the basis transformations between hierarchical and standard basis, called the *hierarchical transformations*. Then, we show how to perform a multiplication with the mass matrices in the one-dimensional case. Finally, we reduce the d-dimensional matrix multiplication recursively to the one-dimensional case.

5.1. The hierarchical transformations. To describe these transformations, we make the following definition.

The hierarchical neighbors of an index $i \in \{i_0\}$ are the two indices $l(i)$ and $r(i)$, $l, r : \{i_0\} \to \{i\}$, where the basis points $bp(\tilde{v}_{l(i)})$ and $bp(\tilde{v}_{r(i)})$ are located at the two ends of the support of $\tilde{v}_i$ (see Fig. 6).

Let us study the basis transformations in S_n between the hierarchical basis H_n and the standard basis B_n. If and only if their basis points are identical shall $\tilde{v}_i \in H_n$ and $v_i \in B_n$

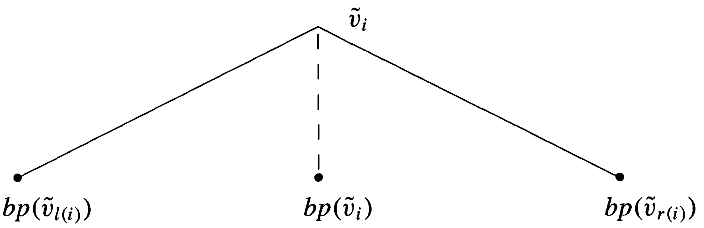

FIG. 6. *Hierarchical neighbors.*

have the same index i. Furthermore, the set $\{1, 2, \ldots, \text{card}(H_n)\}$ of indices should fulfill the conditions $i > l(i)$ and $i > r(i)$ for $i \in \{i_0\}$. Obviously the basis functions from T_0 have the indices 1 and 2, and the basis function $\tilde{w}$ from T_1 has the index 3. From the definition of the hierarchical basis, we have the relations

$$\tag{11} \begin{array}{ll} \tilde{g}_i = g_i - \frac{1}{2}(g_{l(i)} + g_{r(i)}), & i \in \{i_0\}, \\ \tilde{g}_i = g_i, & \{i : v_i \in T_0\}. \end{array}$$

Consequently, the matrix $\bar{Y} = (\bar{Y}_{ij})$ that performs the transformation from the standard to the hierarchical basis is given by

$$\bar{Y}_{ij} = \begin{cases} -\frac{1}{2} : j \in \{l(i), r(i)\}, \\ \delta_{ij} : \text{ otherwise.} \end{cases}$$

We define the matrix Y to be the submatrix of $\bar{Y}$, whose first two rows and columns corresponding to the basis functions from T_0 are missing. Because of the conditions above and (11), $\bar{Y}$ and Y are lower triangular matrices with at most three entries per line. We call these transformations *hierarchical transformations*. The inverse hierarchical transformations $\bar{Y}^{-1}$ and Y^{-1}, called *inverse transformations*, are obviously computable by backward substitution. The corresponding relations for $\bar{Y}^{-1}$ are

$$\tag{12} \begin{array}{ll} g_i = \tilde{g}_i + \frac{1}{2}(g_{l(i)} + g_{r(i)}), & i \in \{i_0\}, \\ g_i = \tilde{g}_i, & \{i : v_i \in T_0\}. \end{array}$$

Note that all these transformations can be performed with a constant amount of work per vector component.

5.2. The one-dimensional case. Here we derive a special decomposition of the mass matrices $(M_{i,k})$ and $(\bar{M}_{i,k})$. Define the matrix D by

$$D := (D_{i,k}) := (h_i \cdot \delta_{ik}), \qquad i, k \in \{i_0\}$$

and the corresponding rectangular matrix $\bar{D}$ with $i \in \{i\}$. The identity matrix is denoted by E. We distinguish the following three cases:

1. $i = k$, $\qquad \int_0^1 \tilde{v}_i(x) \cdot \tilde{v}_i(x)\, dx = \frac{2}{3} \cdot h_i$.

The "diagonal part" of the mass matrices may be written as $\frac{2}{3}D$ and $\frac{2}{3}\bar{D}$, respectively.

2. support$(\tilde{v}_i) \supset$ support$(\tilde{v}_k)$ denoted by $\{i \supset k\}$.

This corresponds to the "lower triangular part" of the mass matrices because it follows from this condition that $i < k$. We consider $(\bar{M}_{i,k})$ first. Obviously, $\sum_{\{i \supset k\}} \tilde{g}_i\, \tilde{v}_i(x)$ is linear on the support of $\tilde{v}_k$, and therefore is determined there by the absolute values $g_{l(k)}$ and $g_{r(k)}$. With that, we obtain

$$\int_0^1 \sum_{\{i\supset k\}} \tilde{g}_i\, \tilde{v}_i\, \tilde{v}_k\, dx = h_k \frac{g_{l(k)} + g_{r(k)}}{2} = h_k \left(\tilde{g}_k + \frac{g_{l(k)} + g_{r(k)}}{2} - \tilde{g}_k \right). \tag{13}$$

With (12), we easily verify that this corresponds exactly to the matrix $D(\bar{Y}^{-1} - E)$. For the lower triangular part of $(M_{i,k})$, we just have to leave out the first and second columns and get $D(Y^{-1} - E)$.

3. support$(\tilde{v}_i) \subset$ support$(\tilde{v}_k)$ denoted by $\{i \subset k\}$.

For $(M_{i,k})$ our approach is symmetric in $\tilde{v}_i$ and $\tilde{v}_k$. Here, we get the transpose of the matrix from case 2, namely $(Y^{-T} - E)D$. Because $i > k$, this is the upper triangular part of $(M_{i,k})$ and the entries are identical to the upper triangular part of $(\bar{M}_{i,k})$. For the latter, we may write $(Y^{-T} - E)\bar{D}$.

With that, the mass matrices in the one-dimensional case are

$$(M_{ik}) = D(Y^{-1} - E) + (Y^{-T} - E)D + \frac{2}{3}D,$$

$$(\bar{M}_{ik}) = D(\bar{Y}^{-1} - E) + (Y^{-T} - E)\bar{D} + \frac{2}{3}\bar{D}.$$

Note that Y^T is an upper triangular matrix and that the costs for backward substitution for computing a matrix multiplication with Y^{-T} are equal to the costs for the inverse transformation. Therefore, the costs are proportional to the number of coefficients.

5.3. Reduction to the one-dimensional case. Our goal is an algorithm for the computation of a mass matrix multiplication

$$(M_{IK})(\tilde{g}_I) = \left(\int_\Omega \sum_{\{I_0\}} \tilde{g}_I\, \tilde{v}_I\, \tilde{v}_K\, dx \right). \tag{14}$$

The problem in general dimensions is reduced to a sequence of multiplications with one-dimensional mass matrices. We explain the method only for the mass matrix (M_{IK}), because the construction of the method for the extended mass matrix is identical. We will see that we have to take special care of the storage of interim results.

Define the four sets

$$\begin{aligned}
\{J\} &:= \{J := (j_1, \dots, j_{d-1}) : \exists j_d : (j_1, \dots, j_{d-1}, j_d) \in \{I_0\}\},\\
\{I_J\} &:= \{I \in \{I_0\} : i_1 = j_1, \dots, i_{d-1} = j_{d-1}\},\\
\{j_d\} &:= \{j_d : \exists J : (j_1, \dots, j_{d-1}, j_d) \in \{I_0\}\},\\
\{I_{j_d}\} &:= \{I \in \{I_0\} : i_d = j_d\}.
\end{aligned}$$

With that, we can write

$$\int_\Omega \sum_{\{I_0\}} \tilde{g}_I\, \tilde{v}_I\, \tilde{v}_K\, dx = \begin{cases} \displaystyle\sum_{\{J\}} \left(\sum_{\{I_J\}} \tilde{g}_I \int_0^1 \tilde{v}_{i_d}\, \tilde{v}_{k_d}\, dx_d \right) \prod_{l=1}^{d-1} \int_0^1 \tilde{v}_{j_l}\, \tilde{v}_{k_l}\, dx_l, \\ \displaystyle\sum_{\{j_d\}} \left(\sum_{\{I_{j_d}\}} \tilde{g}_I \prod_{l=1}^{d-1} \int_0^1 \tilde{v}_{i_l}\, \tilde{v}_{k_l}\, dx_l \right) \int_0^1 \tilde{v}_{j_d}\, \tilde{v}_{k_d}\, dx_d. \end{cases} \tag{15}$$

We will now examine the computation of the two-dimensional integral

$$\int_{[0,1]^2} \sum_{\{I_0\}} \tilde{g}_I\, \tilde{v}_I\, \tilde{v}_K\, dx \tag{16}$$

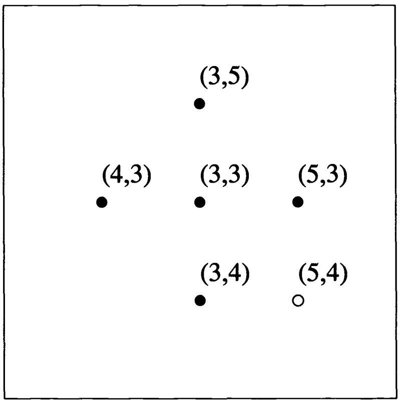

FIG. 7. *The basis points of $\tilde{H}^{(2)}_{2,0}$ in the unit square are marked with a $\bullet$, there is for example no basis function in $\tilde{H}^{(2)}_{2,0}$ that corresponds to the basis point marked with a $\circ$.*

with the upper formula of the right-hand side of (15). We can compute the terms $\sum_{\{I_J\}} \tilde{g}_I \int_0^1 \tilde{v}_{i_2}\, \tilde{v}_{k_2}\, dx_2$ from (15) with the techniques from §5.2. The interim results would be stored in the nodes with multiindex (i_1, k_2). With these coefficients, we could compute $\sum_{\{J\}}(\ldots) \int_0^1 \tilde{v}_{i_1}\, \tilde{v}_{k_1}\, dx_1$. But, if support$(\tilde{v}_{i_2}) \supset$ support$(\tilde{v}_{k_2})$, a node with multiindex (i_1, k_2) might not exist in our sparse grid (see Fig. 7).

We get an analogous effect if we compute (16) by the alternate formula of (15). On the other hand, if support$(\tilde{v}_{i_2}) \subseteq$ support$(\tilde{v}_{k_2})$, a node with multiindex (i_1, k_2) exists by construction of the sparse grid. This leads us to redefine the sets $\{I_J\}$ and $\{I_{j_d}\}$ by

$$\{I_J\} := \{I \in \{I_0\} : i_1 = j_1, \ldots, i_{d-1} = j_{d-1}, \text{support}(\tilde{v}_{i_d}) \subseteq \text{support}(\tilde{v}_{k_d})\},$$
$$\{I_{j_d}\} := \{I \in \{I_0\} : i_d = j_d, \text{support}(\tilde{v}_{i_d}) \supset \text{support}(\tilde{v}_{k_d})\}.$$

Now, we may write

$$\begin{aligned}\int_\Omega \sum_{\{I_0\}} \tilde{g}_I\, \tilde{v}_I\, \tilde{v}_K\, dx &= \sum_{\{J\}} \left[\sum_{\{I_J\}} \tilde{g}_I \int_0^1 \tilde{v}_{i_d}\, \tilde{v}_{k_d}\, dx_d\right] \prod_{l=1}^{d-1} \int_0^1 \tilde{v}_{i_l}\, \tilde{v}_{k_l}\, dx_l \\ &\quad + \sum_{\{j_d\}} \left[\sum_{\{I_{j_d}\}} \tilde{g}_I \prod_{l=1}^{d-1} \int_0^1 \tilde{v}_{i_l}\, \tilde{v}_{k_l}\, dx_l\right] \int_0^1 \tilde{v}_{i_d}\, \tilde{v}_{k_d}\, dx_d.\end{aligned} \tag{17}$$

In the first summand, the term in brackets is a one-dimensional integral; the nodes, where the interim results are stored, exist because of our new definition of $\{I_J\}$. The computed coefficients are the coefficients for $(d-1)$-dimensional problems. In the second summand, the term in brackets is a $(d-1)$-dimensional problem. Solving these problems leads to the coefficients of one-dimensional integrals. We now may apply these splittings recursively to the $(d-1)$-dimensional problems, and thus get directly solvable one-dimensional problems. Due to the splittings, all interim results are stored in existing nodes.

We now have described how to compute a term $\int_\Omega \sum_{\{I_0\}} \tilde{g}_I\, \tilde{v}_I\, \tilde{v}_K\, dx$ for a fixed K. For the computation of the vector $(\int_\Omega \sum_{\{I_0\}} \tilde{g}_I\, \tilde{v}_I\, \tilde{v}_K\, dx)$, note that the splitting in (17) corresponds to a splitting of the one-dimensional mass matrices into the two parts $(Y^{-T} - E)D + \frac{2}{3}D$ and $D(Y^{-1} - E)$. Therefore, the one-dimensional integrals can be computed by multiplication with one of the partial matrices. Considering the operations that have to be made for a matrix multiplication (e.g., relation (12) or (13)) we find that they can be computed separately for each node, similar to the computation of finite difference stars. Therefore we do not compute these matrices explicitly but replace them by procedures that traverse our data structure and perform the operations in every node. In particular, the treatment of adaptive grids is then transferred to the problem of traversing an adaptive data structure which is very simple in our case (tree structure). We find descriptions of such procedures in Balder [1].

The amount of work for the computation of the set of one-dimensional integrals is proportional to the overall number of coefficients. If we denote the number of those computations for a d-dimensional problem by $C(d)$, we get from (17) that $C(1) = 2$ and $C(l+1) = 2+2\,C(l)$. It is easy to prove by induction that $C(d) = 2^{d+1} - 2$. From (10), we see that we can use a similar algorithm for the computation of the components of the Laplacian, and, therefore, can also compute a multiplication with the stiffness matrix. Note that the amount of work for this multiplication is proportional to the number of coefficients $O(n \log(n)^{d-1})$ and has a better complexity than the number of nonzero entries in the stiffness matrix $O(n^2 \log(n)^{d-2})$. With an implementation that is optimized, with respect to storage we need for the matrix multiplication

$$OP(d) = 17\left(\left(2^d - 1\right) + (d-1)\left(2^{d-1} - 1\right)\right)$$

operations (*add* or *mult*) for every coefficient; for example, $OP(2) = 68$ and $OP(3) = 221$.

6. Numerical results. The following numerical experiments have been computed on workstations with up to 128 megabytes of main storage. The programs are written in the C++ programming language. The linear equations are solved with a BPX-like multilevel preconditioned cg-method which is described in Griebel and Oswald [9]. It uses additional residuals corresponding to functions $v_S \in \tilde{S}_n^{(d)}$ that can easily be computed by linear combination of residuals corresponding to $v_K \in \tilde{H}_n^{(d)}$. The amount of work is about $PCOP(d) = 8\left(2^d - 1\right)$ operations for every coefficient ($PCOP(2) = 24, PCOP(3) = 56$) for the computation of the additional residuals. The extended vector of residuals is about 2^d times larger than the original vector. This causes a corresponding additional amount of work for the computation of the scalar products needed for the cg-method. The preconditioner is designed for the two-dimensional Poisson equation and proved to be optimal in this case. The generalization for higher dimensions is straightforward. It also works well for the Helmholtz equation. In this paper we will not discuss this preconditioner but present convergence factors that demonstrate that the equations can be solved efficiently.

6.1. Helmholtz equation. Our first test problem is given by the equation

$$-\Delta u + c \cdot u = c \cdot w, \qquad u = 0 \text{ on } \partial\Omega,\ \Omega = [0,1]^d, \tag{18}$$

where $w = \prod_{l=1}^{d} \tilde{w}(x_l)$ and $\tilde{w}$ is the basis function from T_1.

Let u_I be the value of the function u at the node with multiindex I and $\{I_n^{(d)}\} := \{I : v_I \in H_n^{(d)}\}$. Note that $\{I_n^{(d)}\}$ corresponds to a full grid $G_n^{(d)}$. Define a discrete L_2-norm of a continuous function u by

$$\mathcal{L}(u) := \sum_{\{I_n^{(d)}\}} (u_I)^2. \tag{19}$$

We will examine here the error $\mathcal{E}$ of the numerical solution defined by

$$\mathcal{E} := \mathcal{L}(u - \tilde{u})/\mathcal{L}(u), \tag{20}$$

where $\tilde{u}$ is the numerical approximation and u the *exact* solution of (18). $\mathcal{E}$ is the discrete L_2-norm of the error scaled by the discrete L_2-norm of the solution. For this problem,

we approximate the exact solution by a solution we obtain from a finer grid. In Table 1, we examine a two- and a three-dimensional example. We have chosen $\{I_7^{(2)}\}$ ($\{I_4^{(3)}\}$) in (20) and approximate the exact solution by the numerical solution in the space $\tilde{S}_{14}^{(2)}$ ($\tilde{S}_{10}^{(3)}$) for the two- and three-dimensional case. We have listed the errors $\mathcal{E}$ depending on the approximation space $\tilde{S}_n^{(d)}$ and the corresponding number of unknowns for different Helmholtz numbers. In the last row, we have given the convergence factors cf of the preconditioned cg-method defined by

$$cf := \left(\|r^{5+m} \|_2 \, / \, \| r^5 \|_2\right)^{\frac{1}{m}} . \tag{21}$$

Here r^i is the preconditioned residual after the ith cg-iteration. We choose m so that $\| r^{5+m} \|_2 < 10^{-10} \cdot \| r^5 \|_2$. The value cf is an average decrease factor of the 2-norm of the preconditioned residual, and corresponds to the grids $\tilde{G}_{14}^{(2)}$ and $\tilde{G}_{10}^{(3)}$ respectively. We use an averaged factor because the norm of the residual is not in every case monotonely decreasing during the cg-iteration. Note that the stiffness matrix is indefinite if $c < ev \approx -d \cdot \pi^2$. We give no convergence factors for these problems because the cg-method is not convergent. On the other hand we observe a significant reduction of the 2-norm of the residual at the beginning of the cg-iteration. This leads to an error in the solution of the linear system which is small compared with the approximation error. The solution is therefore good enough for our investigations. One may use, for example, the method of conjugate residuals (e.g., Hackbusch [10]) to obtain the exact solution for these indefinite problems.

The errors behave as we could expect from the theoretical results. Asymptotically, the factor of error reduction with respect to n reaches the value 4. This confirms the $O(4^{-n}n^{-d})$ accuracy in the L_2-norm mentioned in §2. In Fig. 8, we compare how the error $\mathcal{E}$ depends on the number of unknowns for sparse and for full grids. We see that the solutions corresponding to sparse grids with about 10000 unknowns are about two orders of magnitude better than the solutions we obtained on full grids.

6.2. Eigenvalues of the Laplacian on adaptive sparse grids. By combining cubes, we may construct more complex domains. We have computed some eigenvalues and eigenfunctions of the Laplacian in the two-dimensional L-domain and its three-dimensional counterpart,

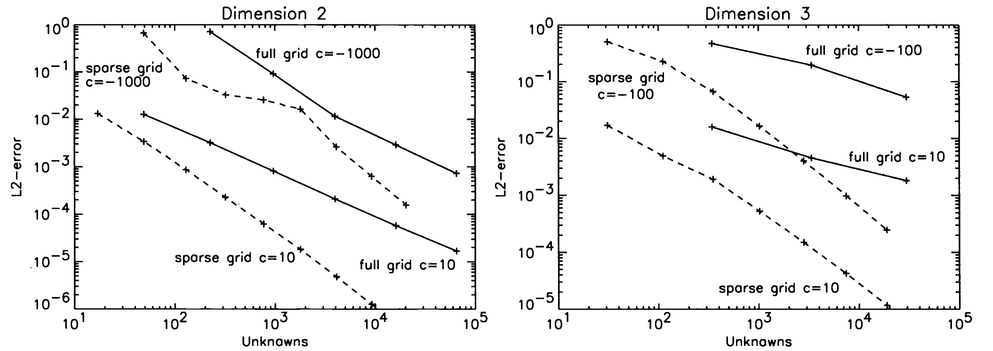

FIG. 8. *Comparison of full and sparse grids.*

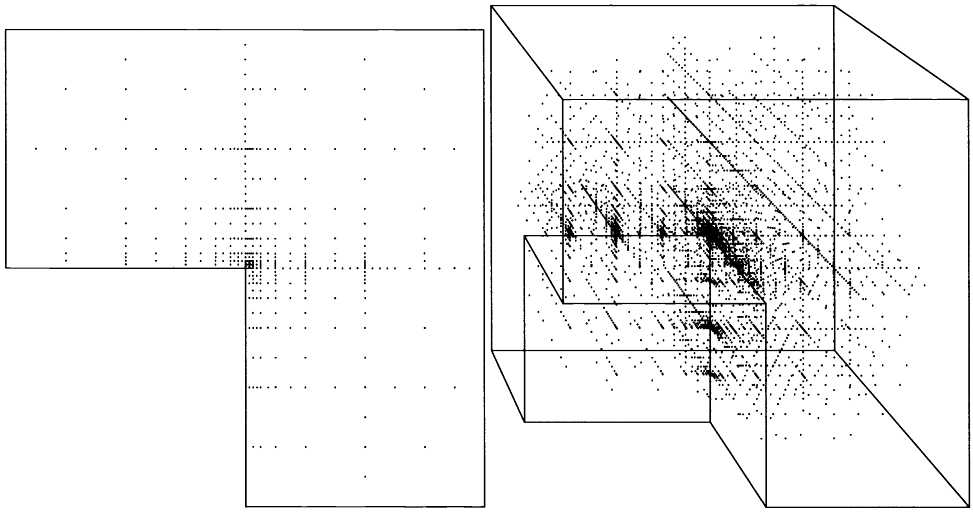

FIG. 9. *Adaptive sparse grids.*

a cube where one octant is removed. The reentrant corners in these domains lead to singularities in the solutions. It is typical for such singularities that the hierarchical surpluses at the singularity decrease asymptotically with a factor less than 4. Therefore, adaptive grids are necessary to obtain cost effective approximations. For our numerical experiments, we use the following strategy. If the hierarchical surplus satisfies $| \tilde{g}_l | > \varepsilon$ for a given $\varepsilon > 0$, then the $2d$ basis functions corresponding to one half of the support of v_l should also belong to our grid. Examples for adaptive sparse grids are given in Fig. 9. Note that the solution is singular along the reentrant edges in the three-dimensional domain. On the other hand, the solution is almost linear along those edges. Therefore, due to the basis functions that have a large support in the direction parallel to the edge and a small support in the other directions, we do not need to have a fine grid along the whole singularity.

To solve the eigenvalue problem we have to find Helmholtz numbers λ, where the Helmholtz equation

$$-\Delta u = \lambda \cdot u \tag{22}$$

with homogeneous boundary conditions has nontrivial solutions. Exact solutions for this problem are not known for the L-shaped domain, but approximate eigenvalues are given in

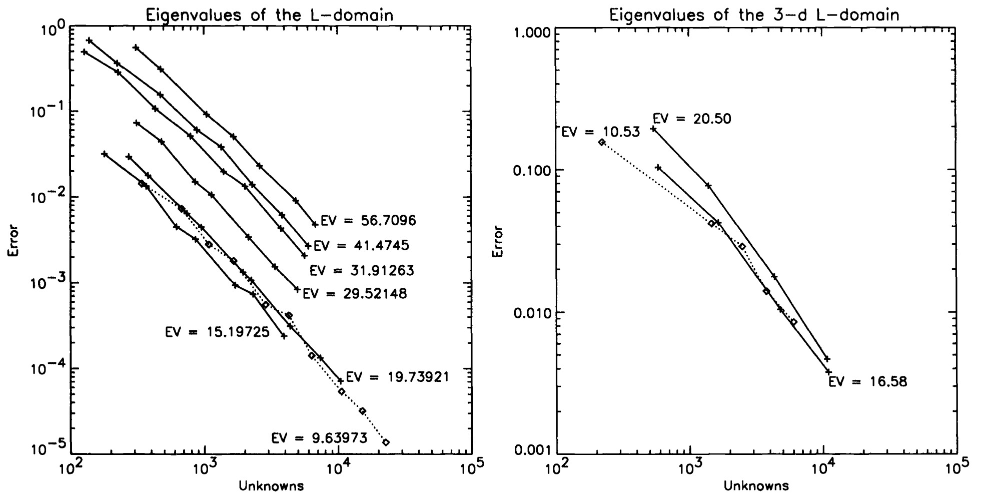

FIG. 10. *Eigenvalue errors.*

Fox, Henrici, and Moler [6]. Discretization of (22) leads to a generalized eigenvalue problem

$$-A(\tilde{g}_l) = \lambda M(\tilde{g}_l), \tag{23}$$

where A is the stiffness matrix for the Laplacian and M the mass matrix. We compute the eigenvalues and eigenvectors with a Wielandt iteration for the generalized problem. With an approximate eigenvector $(g_l)^j$ one gets an improved approximation $(g_l)^{j+1}$ by solving

$$(A - \bar{\lambda} M)(g_l)^{j+1} = \alpha_j M(g_l)^j,$$

where $\bar{\lambda}$ is an approximation of the eigenvalue and α_j a damping factor. We obtain approximations for the eigenvalue λ from the Raleigh-quotient

$$\lambda \approx \frac{(g_l)^{j^T} A(g_l)^j}{(g_l)^{j^T} M(g_l)^j}.$$

This method is described in Peters and Wilkinson [11]. In Fig. 10, we see the absolute errors err of the eigenvalues dependent on the number of unknowns N. The *exact* solutions for the two-dimensional case are taken from [6]. In the three-dimensional case we estimate the exact eigenvalue by the solution on a finer grid. The value $\log(err)$ seems to be a linear function of $\log(N)$ where the gradient of this function does not depend on the eigenvalue. This leads to the following relation between the error err and the number of unknowns N:

$$err \approx c \cdot N^{-k},$$

where $k = 1.6 \pm 0.1$ for $d = 2$ and $k = 1.35 \pm 0.1$ for $d = 3$ for the results presented here.

6.3. A six-dimensional Poisson problem. We solve the problem

$$-\Delta u = 1, \qquad u = 0 \text{ on } \partial\Omega, \ \Omega =]0, 1[^6, \tag{24}$$

with homogeneous boundary conditions. We assume the right-hand side f to be $f = 1$ on Ω and $f = 0$ on $\partial\Omega$ and expand it into a Fourier series. We may solve the differential equation

TABLE 2
A six-dimensional Poisson problem.

Dimension 6		
n	unknowns	$\mathcal{E}$
4	545	$1.03E-01$
5	2561	$5.55E-02$
6	10625	$3.07E-02$

8	141569	$1.39E-02$
fd	117649	$7.31E-02$
fe	117649	$7.58E-02$

exactly for each summand of the series. By superposition we obtain the solution u of (24)

$$u = \sum_{i_1,\dots,i_6=0}^{\infty} \alpha_I \prod_{k=1}^{6} \sin((2i_k+1)\pi x_k) \tag{25}$$

with the coefficients

$$\alpha_I := \alpha_{i_1,\dots,i_6} = \frac{4^6}{\pi^8 \prod_{k=1}^{6}(2i_k+1)\sum_{k=1}^{6}(2i_k+1)^2}. \tag{26}$$

With that formula we can compute the exact solution u of (24) with potentially arbitrary accuracy. In Table 2, we have listed the index n corresponding to the approximation space $\tilde{S}_n^{(6)}$, the number of unknowns, and the error $\mathcal{E}$ corresponding to $\{I_3^{(6)}\}$ in (20). In the last two rows we see the number of unknowns and the error we obtain by solving (24) on the full grid $\{G_3^{(6)}\}$ with mesh size $h = \frac{1}{8}$. In the first case we have used a finite difference (fd) scheme (13-point star) and in the second case the usual finite element (fe) approach with multilinear basis functions. There are two reasons why the results for the sparse grid solutions are not as good as in the previous examples. First, the error is of order $O(4^{-n}\, n^5)$ for six-dimensional problems; the term n^5 is not small compared with 4^n for $n = 8$. On the other hand we cannot even expect an error of this order because the solution does not fulfill the condition (2) as one can easily derive from (25) and (26). Nevertheless, the sparse-grid solutions are clearly better than the solution we obtained on a full grid. The error of the sparse-grid solution using 2561 unknowns is smaller than the error of the full-grid solutions using 117649 unknowns. Note that on full grids, if we assume an error of order $O(h^2)$, we need b^3 times more unknowns if we want to reduce the error by a factor b.

The time-independent Schrödinger equation for two electron atoms or molecules leads to an eigenvalue problem of the form $-\Delta\Psi + V(x)\,\Psi = E\,\Psi,\ x \in \mathbb{R}^6$ (see Conroy [4]). The treatment of such equations with sparse grids is a topic of current research.

7. Concluding remarks. Sparse grids are a technique for the efficient representation of multivariate functions. Compared with full grids, the saving in storage is dramatic, especially for higher dimensions [3]. On the other hand we are able to get much better accuracies if the amount of storage is limited. In our opinion, this is the main advantage of sparse grids. This paper has described the discretization and the solution of the Helmholtz equation on domains of general dimension with regular and adaptive sparse grids. It has been proved that one can perform a matrix-vector multiplication with the corresponding stiffness matrix with a constant amount of work per vector coefficient, although the complexity of the number of nonzero entries in the stiffness matrix is worse than the complexity of the number of unknowns. Together with the preconditioner described in [9], this allows us to solve the Helmholtz problem in optimal time. This means in the first case that we can obtain solutions with a reasonable effort. We have not made comparisons with other programs in respect to computing time. One reason for this is that we have designed our code to be as simple and as flexible as possible because we think it is more important to extend the area of applicability of sparse-grid techniques than to gain speed. Another advantage of the sparse-grid approach is adaptivity. Refinement, understood as enlargement of the approximation space, is, due to the hierarchical basis, done by inclusion of additional basis functions and not by replacement.

What remains is to investigate to what extent the sparse-grid approach can be generalized. Topics of current research directly based on this work are the treatment of more general equations, i.e., the Schrödinger equation and time-dependent problems. Other sparse-grid research in Munich is done on higher-order basis functions, general second-order equations on general domains, and higher-order equations like the biharmonic.

AN EFFICIENT ITERATIVE SOLUTION METHOD FOR THE CHEBYSHEV COLLOCATION OF ADVECTION-DOMINATED TRANSPORT PROBLEMS*

A. PINELLI†, W. COUZY‡, M.O. DEVILLE‡, AND C. BENOCCI†

Abstract. A new Chebyshev collocation algorithm is proposed for the iterative solution of advection-diffusion problems. The main features of the method lie in the original way in which a finite-difference preconditioner is built and in the fact that the solution is collocated on a set of nodes matching the standard Gauss–Lobatto–Chebyshev set only in the case of pure diffusion problems. The key point of the algorithm is the capability of the preconditioner to represent the high-frequency modes when dealing with advection-dominated problems. The basic idea is developed for a one-dimensional case and is extended to two-dimensional problems. A series of numerical experiments is carried out to demonstrate the efficiency of the algorithm. The proposed algorithm can also be used in the context of the incompressible Navier–Stokes equations.

Key words. advection-diffusion, collocation, Chebyshev, preconditioning, finite difference, staggered grid

AMS subject classifications. 65N35, 76D99

1. Introduction. The need to solve implicit equations is a basic requirement for spectral algorithms. For both steady problems, whose solution is sought through a time marching computation, and for unsteady calculations, spectral methods are often feasible only if an implicit or a semi-implicit procedure is introduced. A typical example is the solution of the unsteady Navier–Stokes equations. Many numerical solution algorithms for this problem consist of an implicit treatment of the diffusive terms in combination with an explicit scheme for the convective terms [1]. This approach results in a severe restriction to the admissible time step when the flow dynamics are dominated by convection. Alternatively, the (linearized) convective terms can be treated implicitly as well, yielding a large admissible time step. As an example of the latter family of methods for the Navier–Stokes equations on a domain Ω, we consider the following semidiscretized version of the projection method proposed by Shen [2].

$$\frac{1}{\kappa}\left(\hat{u}^{n+1}-u^{n}\right)-\nu\,\triangle\,\hat{u}^{n+1}+\left(u^{n}\cdot\nabla\right)\hat{u}^{n+1}=b^{n+1}, \tag{1}$$

$$\hat{u}^{n+1}_{\partial\Omega}=0, \tag{2}$$

$$\frac{1}{\kappa}\left(u^{n+1}-\hat{u}^{n+1}\right)+\nabla\phi^{n+1}=0, \tag{3}$$

$$\nabla\cdot u^{n+1}=0, \tag{4}$$

$$u^{n+1}\cdot\vec{n}=0, \tag{5}$$

where u is the velocity, ϕ is an approximation of the pressure, κ is the time step, $\vec{n}$ is the normal vector to the boundary $\partial\Omega$, b is a force vector, and the superscript n represents the time iteration index. Equation (1) is a series of scalar advection-diffusion equations, each one having as unknown a velocity component.

Here, we will focus on a particular algorithmical aspect related to equation (1), when the spatial operators are discretized by the Chebyshev collocation technique [1]. To this end we

‡Université Catholique de Louvain, CESAME, Av. G. Lemaître 4-6, 1348 Louvain-la-Neuve, Belgium. Present address: Ecole Polytechnique Fédérale de Lausanne, DGM-IMHEF, 1015 Ecublens, Switzerland (deville@imhfhp28.epfl.ch).

will consider the following one-dimensional equation, meant to model the linearized equation (1):

$$-\epsilon \frac{d^2u}{dx^2} + p(x)\frac{du}{dx} = b(x) \qquad \text{on } \Omega = (-1,1), \tag{6}$$

$$u = 0 \qquad \text{on } \partial\Omega. \tag{7}$$

The two-dimensional formulation of (6–7) reads

$$-\epsilon \,\Delta\, u + p(x,y)\frac{\partial u}{\partial x} + q(x,y)\frac{\partial u}{\partial y} = b(x,y) \qquad \text{on } \Omega = (-1,1)^2, \tag{8}$$

$$u = 0 \qquad \text{on } \partial\Omega, \tag{9}$$

where the given functions $p(x)$, $p(x, y)$, and $q(x, y)$ can be considered as representatives of the velocity field at the previous time step.

The collocation procedure applied to (6)-(7) or (8)-(9) yields the linear system

$$\mathbf{L}U = F. \tag{10}$$

Our goal is the design of an efficient iterative procedure to solve problem (10), such that the convergence does not depend on the ratio between local advection and the positive diffusion coefficient ϵ. An effective solution technique does not only depend on the choice of the iterative scheme but also on the efficiency of the preconditioner. We propose a particular preconditioned collocation scheme that relies on the scheme introduced by Funaro [3] for the Legendre collocation method. This method is based on the collocation of the equations on a particular set of points (termed as "staggered grid") which is determined as a deviation from the original Gauss-Lobatto-Chebyshev (GLC) quadrature nodes in function of the local ratio between advection and diffusion. In this paper, we will extend the Funaro scheme to the Chebyshev collocation method, by introducing an original definition of the staggered grid that does not rely on the Sturm-Liouville problem associated with Legendre polynomials. We will show that such a grid exists and is unique. Moreover, the numerical procedure to compute the staggered grid is simplified, yielding important savings of CPU time.

2. One-dimensional model. In this paragraph we will give some heuristic considerations to highlight the difficulties that arise when one tries to precondition discrete advection-diffusion systems dominated by the advective terms. The same reasoning will introduce the basic ideas the proposed scheme relies on.

We start considering the one-dimensional case (6)-(7), with the given function $p(x)$ strictly positive on all the domain $\Omega = (-1, +1)$. The Chebyshev polynomial of order N is denoted by $T_N(x)$. The GLC points $\{x_i\}$ are defined as the zeros of $(x^2 - 1)T'_N(x)$ and are therefore given by

$$x_i = \cos\left(\frac{\pi i}{N}\right), \qquad i = 0, \ldots, N. \tag{11}$$

For future use, we introduce as well the set of corresponding midpoints $\{\xi_i\}$, defined as the zeros of $T_N(x)$:

$$\xi_i = \cos\left(\pi\frac{2i+1}{2N}\right), \qquad i = 0, \ldots, N-1. \tag{12}$$

Next we consider a polynomial $z(x) = T'_N(x)$ (sketched in Figure 1) vanishing in all internal GLC points, according to (11). Such a polynomial represents a high-frequency mode, typical of a spectral approximation, that standard finite-difference operators fail to represent for advection-dominated problems. To explain this, we remark that the centered finite-

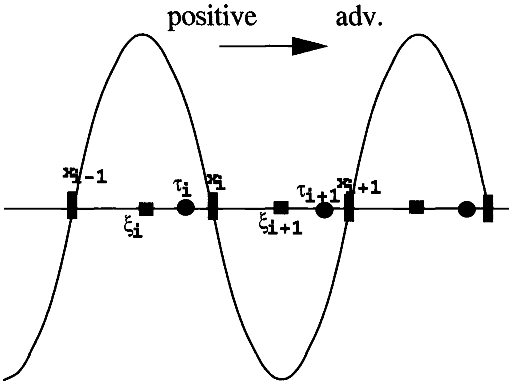

FIG. 1. *The polynomial* $z(x)$.

difference approximation of the second-order derivative in x_i (which is close to zero) is given by $\frac{h_{i+1}z(x_{i-1})-(h_i+h_{i+1})z(x_i)+h_iz(x_{i+1})}{0.5\,h_ih_{i+1}(h_i+h_{i+1})} = 0$, with $h_i = x_i - x_{i-1}$. An approximation of the first-order derivative (which attains its maximum value in x_i) will also yield zero, since $\frac{z(x_{i+1})-z(x_{i-1})}{h_i+h_{i+1}} = 0$. This observation explains the degrading behavior of classical finite-difference schemes constructed on the original GLC nodes for advection-dominated problems. In such a case, it is essential to provide a better approximation for the first-order derivative. To this end, we notice that the first-order derivative in the midpoint ξ_i is much more accurately approximated ($z'(\xi_i) \approx 0$) using the values of $z(x_i)$ and $z(x_{i-1})$. Such a heuristic approach is somehow confirmed by the theorem of Funaro [4] for first-order operators. For advection-diffusion problems, we are therefore induced to believe that the finite-difference preconditioner has to be evaluated on a special "staggered grid," although constructed using data at the GLC nodes. To set up this staggered grid, first we apply the operator (6) to the polynomial $z(x)$ that mimics the behavior of a high-frequency eigenfunction, and then we compute the zeros $\{\tau_i\}$ of the residual polynomial $f(x)$:

$$f(x) = -\epsilon z''(x) + p(x)z'(x). \tag{13}$$

For a purely second-order operator ($p(x) = 0$), the points $\{\tau_i\}$ coincide with the original set of GLC nodes, while for a first-order operator ($\epsilon = 0$) they drop on the GLC midpoints $\{\xi_i\}$. For a general advection-diffusion operator the following estimates hold:

$$\begin{aligned} \xi_i < \tau_i < x_i \text{ if } p(x) > 0, \\ x_i < \tau_i < \xi_{i+1} \text{ if } p(x) < 0. \end{aligned} \tag{14}$$

To implement the above theory, a polynomial $z(x)$ has to be found that mimics a high-frequency mode (i.e., $z(x_i) = 0$ and $z'(x_i)$ close to a local maximum or minimum at the interior collocation nodes x_i [3]). Because our target is the determination of a "staggered grid," which has the same number of nodes as the original Gauss-Lobatto grid, we require that the corresponding function $f(x)$ (see (13)) vanishes once and only once in each interval defined by $[\xi_i, x_i]$ when $p > 0$ and $[x_i, \xi_{i+1}]$ when $p < 0$. For the Legendre case, the procedure of determining a function $z(x)$ that respects all the aforementioned requirements is simplified by the possibility of reducing the complexity of the formulation by using the associated Sturm-Liouville problem [3]. In the Chebyshev case on the contrary, no simplification can be taken on the same side. Moreover, in analogy with the Legendre case, if we let the first-order derivative of the Nth Chebyshev mode play the role of the function $z(x)$, it can be shown that function $f(x)$ does not necessarily present a zero in the required interval $[\xi_i, x_i]$. For these reasons we prefer to weaken the condition of $z(x)$ vanishing in the set $\{x_i\}$. Therefore, like Funaro [3] for the Legendre case, instead of requiring that

$$z(x_i) = 0, \qquad z''(x_i) \approx 0, \qquad \text{and} \qquad \exists! \tau_i \in [\xi_i, x_i] : f(\tau_i) = 0, \tag{15}$$

we introduce a new strategy to determine the staggered grid by asking that

$$z(x_i) \approx 0, \qquad z''(x_i) = 0, \qquad \text{and} \qquad \exists! \tau_i \in [\xi_i, x_i] : f(\tau_i) = 0. \tag{16}$$

In this respect, a good candidate for $z(x)$ is

$$z(x) = \int T_N(x)dx. \tag{17}$$

It is clear that $z''(x_i) = 0$. Although $z(x)$ is not exactly zero in the set of $\{x_i\}$, we will prove that it differs from zero only by terms of order $1/N^2$ and we will also show the existence and uniqueness of a zero for the function $f(x)$ in the required interval $[\xi_i, x_i]$.

First we prove that $z(x)$ is "almost" zero in the set of $\{x_i\}$.

THEOREM 2.1. *For all* $x_i (i = 1, ..., N-1)$ *the polynomial* $z(x)$ *defined in* (17) *satisfies*

$$|z(x_i)| < \frac{1}{N^2-1}.$$

Proof. Because $T_N(x) = \frac{1}{2}\frac{1}{N+1}T'_{N+1}(x) - \frac{1}{2}\frac{1}{N-1}T'_{N-1}(x)$, one has

$$\begin{aligned} z(x_i) &= \int T_N(x)dx|_{x_i} \\ &= \frac{1}{2}\frac{1}{N+1}T_{N+1}(x_i) - \frac{1}{2}\frac{1}{N-1}T_{N-1}(x_i) \\ &= \frac{1}{2}\frac{1}{N+1}\cos\left(\frac{(N+1)\pi i}{N}\right) - \frac{1}{2}\frac{1}{N-1}\cos\left(\frac{(N-1)\pi i}{N}\right) \\ &= \frac{1}{2}\frac{1}{N+1}\left\{\cos(\pi i)\cos\left(\frac{\pi i}{N}\right) - \sin(\pi i)\sin\left(\frac{\pi i}{N}\right)\right\} \\ &\quad -\frac{1}{2}\frac{1}{N-1}\left\{\cos(\pi i)\cos\left(-\frac{\pi i}{N}\right) - \sin(\pi i)\sin\left(-\frac{\pi i}{N}\right)\right\} \\ &= \frac{1}{2}\frac{(-1)^i x_i}{N+1} - \frac{1}{2}\frac{(-1)^i x_i}{N-1} = \frac{(-1)^{i+1}x_i}{N^2-1}. \qquad \square \end{aligned} \tag{18}$$

Next, we show that the zeros of $f(x)$ can be used to build the finite-difference grid. More precisely, we have the following theorem.

THEOREM 2.2. *For all* $x_i (i = 1, \ldots, N), \epsilon > 0, p(x)$ *piecewise constant on* $[\xi_i, \xi_{i+1}]$, *the following properties hold.*

If $p(x) > 0$ *then there exists a unique* $\tau_i \in [\xi_i, x_i]$ *such that* $f(\tau_i) = 0$.

If $p(x) < 0$ *then there exists a unique* $\tau_i \in [x_i, \xi_{i+1}]$ *such that* $f(\tau_i) = 0$.

Proof. First, we assume that $p(x)$ is a positive constant in $[\xi_i, \xi_{i+1}]$. In this case, $f(x)$ is a polynomial of degree N. If we prove that there is at least one zero in each interval $[\xi_i, x_i]$, the total number of zeros is N and hence every zero is unique since N corresponds to the degree of the polynomial $f(x)$. This leaves us to show that $f(\xi_i) \cdot f(x_i) < 0$. We have

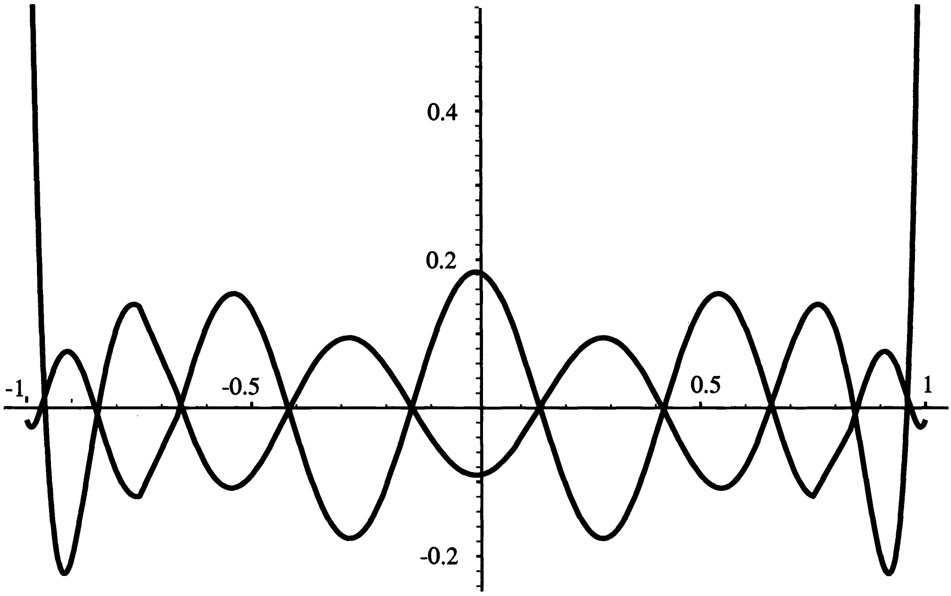

FIG. 2. $z(x)$ *and* $T_N'(x)/N^2$, *for* $N = 11$. $z(0) < 0$.

$f(\xi_i) = -\epsilon T_N'(\xi_i)$ and $f(x_i) = p(x_i)T_N(x_i)$. Because $p(x_i) > 0, \epsilon > 0$, it is enough to show that $T_N'(\xi_i) \cdot T_N(x_i) > 0$. This follows easily by noticing that

$$T_N'(\xi_i) = \frac{N}{\sqrt{1-\xi_i^2}} \sin(N \arccos(\xi_i)) = \begin{cases} < 0 & i \text{ odd}, \\ > 0 & i \text{ even}, \end{cases}$$

$$T_N(x_i) = \cos(N \arccos(x_i)) = \begin{cases} < 0 & i \text{ odd}, \\ > 0 & i \text{ even}. \end{cases} \tag{19}$$

In the same way, we demonstrate that $f(x)$ has exactly one zero in each interval $[x_i, \xi_{i+1}]$ if $p < 0$. To prove the theorem for $p(x)$ piecewise constant, we construct the family of polynomials $f_i(x) = -\epsilon z''(x) + p(x_i)z'(x)$. Each polynomial f_i has exactly one zero in the interval $[\xi_i, x_i]$ (if $p(x_i) > 0$) or in the interval $[x_i, \xi_{i+1}]$ (if $p(x_i) < 0$). Because $f(x)$ has the property that its restriction on $[\xi_i, \xi_{i+1}]$ coincides with the one of $f_i(x)$, it has exactly one zero in each desired interval. □

If $p(x)$ has a zero in an interval $[\xi_i, \xi_{i+1}]$, we map the finite-difference point on the Chebyshev node x_i.

In Figure 2, we display the function $z(x)$ and $T_N'(x)$. The latter function has $\{x_1, \dots, x_{N-1}\}$ as zeros and represents a high-frequency mode. We see that the zeros of the two polynomials practically coincide.

Based on the arguments presented in this section, we propose to use as a preconditioner the matrix associated with the centered finite-difference approximation to the problem (6)-(7) at the gridpoints $\{\tau_i\}$.

3. Two-dimensional formulation. Here, we consider the extension of the preconditioner to the two-dimensional problem (8)-(9). The GLC nodes are denoted by (x_i, y_j) and the midpoints by (ξ_i, η_j); cf. Figure 3. We propose to use the following function $z(x, y)$ that

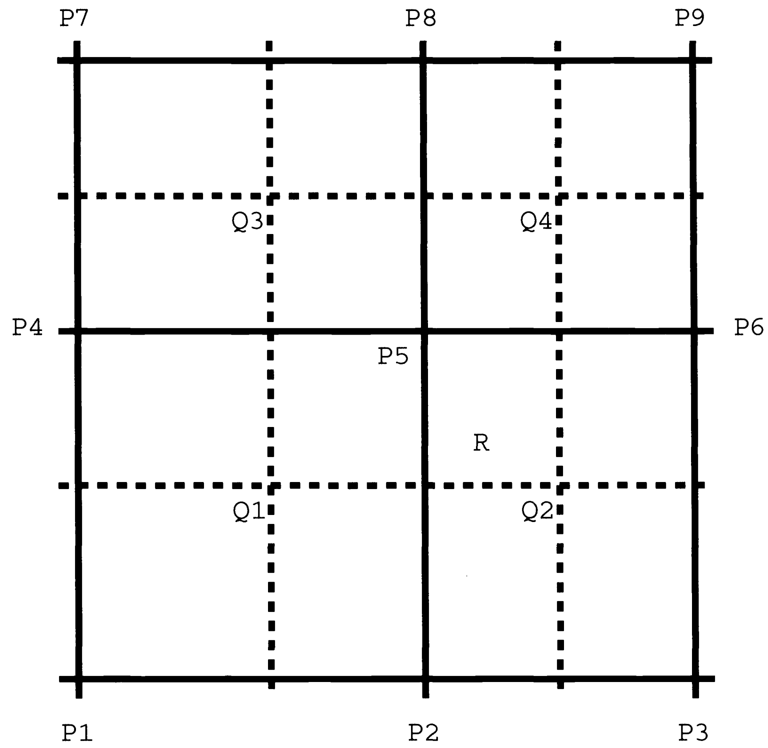

FIG. 3. *The position of the staggered point* $R = (\tau_{ij}, \upsilon_{ij})$ *in the GLC grid (straight lines) and the Gauss–Chebyshev grid (also called midpoints; dashed lines).* $P1 = (x_{i-1}, y_{j-1})$, $P5 = (x_i, y_j)$, $Q1 = (\xi_i, \eta_j)$, $Q4 = (\xi_{i+1}, \eta_{j+1})$, *etc.*

simulates a high-frequency mode in two dimensions:

$$z(x, y) = \int\int T_N(x) T_N(y) dx dy. \tag{20}$$

This function can be regarded as the tensor product of two one-dimensional functions $z(x)$ and $z(y)$. We find for all $x, y \in \Omega$ and for all $i, j = 0, \ldots, N$ that

$$z(x_i, y) \approx 0, \qquad z_{xx}(x_i, y) = 0, \qquad z(x, y_j) \approx 0, \quad \text{and} \quad z_{yy}(x, y_j) = 0. \tag{21}$$

Substitution of $z(x, y)$ in the two-dimensional analogue of (13) gives

$$f(x, y) = -\epsilon \Delta z(x, y) + p(x, y) z_x(x, y) + q(x, y) z_y(x, y). \tag{22}$$

The zeros $\{(\tau_{ij}, \upsilon_{ij})\}$ of the function $f(x, y)$ build the finite-difference grid for the preconditioner. In the following, we will assume p and q to be piecewise constant functions. Furthermore, we will focus on a rectangular domain Ω_{ij},

$$\Omega_{ij} = [\xi_i, \xi_{i+1}] \times [\eta_j, \eta_{j+1}], \tag{23}$$

on which $p(x, y) = p_{ij} > 0$ and $q(x, y) = q_{ij} > 0$. The zeros of $f(x, y)$ are given by the following relation:

$$\begin{aligned} & f(x, y) = 0 \qquad \Longleftrightarrow \\ & \{-\epsilon T_N'(x) + p_{ij} T_N(x)\} \int T_N(y) dy + \{-\epsilon T_N'(y) + q_{ij} T_N(y)\} \int T_N(x) dx = 0. \end{aligned} \tag{24}$$

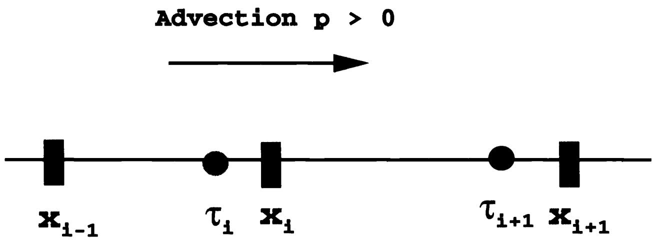

FIG. 4. *The position of three consecutive GLC nodes x_{i-1}, x_i, x_{i+1} on which the second-order Lagrange polynomial is constructed. This polynomial is evaluated in τ_i.*

From Theorem 2.1, we find

$$\exists!\tau_{ij} \in [\xi_i, x_i] : -\epsilon T_N'(\tau_{ij}) + p_{ij} T_N(\tau_{ij}) = 0, \tag{25}$$

$$\exists!\upsilon_{ij} \in [\eta_i, y_i] : -\epsilon T_N'(\upsilon_{ij}) + q_{ij} T_N(\upsilon_{ij}) = 0. \tag{26}$$

Hence, $\{(\tau_{ij}, \upsilon_{ij})\}$ are zeros of $f(x, y)$. Note that $f(x, y)$ is a polynomial of order $(N + 1)^2$, which implies that not all the zeros are found by solving (25)-(26). However, this is not a serious problem, since these additional zeros are not used to build up the finite-difference grid. If $p(x, y)$ assumes the value zero at one point at least in the rectangle Ω_{ij}, we will take x_i as the x-coordinate of the finite-difference node (analogously for $q(x, y)$).

4. Algorithmic aspects. We start focusing upon the one-dimensional model equation (6)-(7). The first step consists of determining the zeros of polynomial $f(x)$ (13). The computational cost to solve such a problem should be kept as low as possible. This issue is especially important when the preconditioner is used for nonlinear problems, like the Burgers or Navier-Stokes equations, in which the finite-difference grid has to be computed at each iteration. Therefore, we propose not to solve (13) by an expensive Newton method, as has been proposed by Funaro in [3]. Instead, we replace $f(x)$ by a piecewise parabolic function $d_i(x)$ on each $[\xi_i, x_i]$ (when $p > 0$) or on each $[x_i, \xi_{i+1}]$ (when $p < 0$). The zeros of these parabolas can be found by a simple and cheap formula. In the case of $p > 0$, we define the parabola $d_i(x)$ on the interval $[\xi_i, x_i]$ by the following three conditions.

$$d_i(\xi_i) = f(\xi_i), \qquad d_i(x_i) = f(x_i), \qquad \text{and} \qquad (d_i)_x(\xi_i) = f_x(\xi_i). \tag{27}$$

In this way, the second-order polynomial d_i has exactly one zero in $[\xi_i, x_i]$. Because our preconditioner is designed for advection-dominated problems, the first-order derivative is matched in ξ_i and not in x_i (27), yielding a better approximation for the zero which is, in this case, close to ξ_i.

Once the zeros $\{\tau_i\}$ (i.e., the "staggered grid") are found, for any i we approximate equation (6) with second-order Lagrange polynomials based on the data from three successive Chebyshev nodes x_{i-1}, x_i, x_{i+1} and collocated on the corresponding staggered point τ_i (see Figure 4). The general algorithm for the one-dimensional equation (6) with homogeneous Dirichlet boundary conditions (7) reads as follows.

- Select a guess solution U^0.
- Compute the zeros $\{\tau_i\}$ of the polynomial $f(x)$ defined in (13).
- Construct the finite-difference preconditioner $\mathbf{H}$ as

$$\mathbf{H} = \begin{bmatrix} b & c & 0 & & & & & \\ a & \ddots & \ddots & \ddots & & & & \\ & \ddots & \ddots & \ddots & \ddots & & & \\ & 0 & a_i & b_i & c_i & 0 & & \\ & & & \ddots & \ddots & \ddots & & \\ & & & & \ddots & \ddots & \ddots & \\ & & & & & \ddots & \ddots & \ddots \\ & & & & & & \ddots & \ddots \end{bmatrix} \tag{28}$$

with the following entries:

$$\begin{aligned} a_i &= p(\tau_i)l'_{i-1}(\tau_i) - \epsilon l''_{i-1}(\tau_i), \\ b_i &= p(\tau_i)l'_i(\tau_i) - \epsilon l''_i(\tau_i), \\ c_i &= p(\tau_i)l'_{i+1}(\tau_i) - \epsilon l''_{i+1}(\tau_i), \end{aligned} \tag{29}$$

as

$$l_i(x) = \frac{(x - x_{i-1})}{(x_i - x_{i-1})} \cdot \frac{(x - x_{i+1})}{(x_i - x_{i+1})}. \tag{30}$$

- Instead of $\mathbf{L}U = F$ solve

$$\mathbf{H}^{-1}\mathbf{L}U = \mathbf{H}^{-1}F \tag{31}$$

by an iterative algorithm. We remind that the system $\mathbf{L}U = F$ (see (10)) is the algebraic formulation of the spectral collocation method at the Chebyshev nodes $\{x_i\}$. Let us consider a simple preconditioned Richardson algorithm [1].

$$\begin{cases} \mathbf{H}\delta U = \quad R\tilde{H}S, \\ U^{n+1} = U^n + \delta U, \end{cases} \tag{32}$$

with

$$RHS = \omega\left(F - \mathbf{L}U^n\right) = \mathbf{W}^{-1}R\tilde{H}S, \tag{33}$$

$\mathbf{W}$ is a mapping operator that interpolates the residual computed on the collocation grid $\{x_i\}$ to the staggered grid $\{\xi_i\}$ and ω a relaxation factor. At each step a finite-difference problem is solved by inverting a tridiagonal matrix with a right-hand side that is the "spectral" residual at the previous step interpolated on the staggered grid.

- Iterate until convergence.

The previously described procedure has been extended to the two-dimensional advection-diffusion equation (8)–(9). Here, the staggered grid is given by the set of points $\{(\tau_{ij}, \eta_{ij})\}$ that are always determined as a deviation from the original Gauss-Lobatto grid in terms of the ratio between local advection $(p(x, y), q(x, y))$, and the diffusion coefficient ϵ. In particular, according to relationships (23) and (24), we approximate $f_1(x) := -\epsilon T'_N(x) + p_{ij}T_N(x)$ and $f_2(y) := -\epsilon T'_N(y) + q_{ij}T_N(y)$ locally by two one-dimensional parabolas. The zeros of these parabolas can be found following the procedure previously described for the one-dimensional case.

TABLE 1

Eigenvalues of the matrix $\mathbf{H}^{-1}\mathbf{L}$ *for different values of* ϵ.

Testcase	max $\Re(\lambda)$	min $\Re(\lambda)$	max $\Im(\lambda)$
$\epsilon = 10^{-2}$ 21 nodes	1.09	0.65	0.56
$\epsilon = 10^{-4}$ 21 nodes	2.31	0.65	0.15
$\epsilon = 10^{-5}$ 21 nodes	2.31	0.32	0.09
$\epsilon = 10^{-5}$ 41 nodes	2.31	0.32	0.10

The mapping operator for the two-dimensional case **W** is now chosen to be the local Taylor series expansion of the residual $r(x, y)$ of the current iteration:

$$r(\tau_{ij}, \eta_{ij}) \approx r(x_i, y_j) + (\tau_{ij} - x_i)\frac{\partial r}{\partial x} + (\eta_{ij} - y_j)\frac{\partial r}{\partial y} + \frac{1}{2}(\tau_{ij} - x_i)^2\frac{\partial^2 r}{\partial x^2}$$

$$(34) \qquad + \frac{1}{2}(\eta_{ij} - y_j)^2\frac{\partial^2 r}{\partial y^2} + (\tau_{ij} - x_i)(\eta_{ij} - y_j)\left(\frac{\partial^2 r}{\partial x \partial y}\right),$$

where the derivatives of the residual $r(x_i, y_j)$ are "spectrally" computed at the GLC nodes.

The finite-difference preconditioner **H** is now based on a nine-points stencil and is always constructed using second-order Lagrange polynomials. The nine entries of the stencil corresponding to the point (x_i, y_j) are denoted by $h_{i,j}^{(1)}, \ldots, h_{i,j}^{(9)}$ and are determined by imposing

$$(35) \qquad \begin{aligned} & h_{i,j}^{(1)}u_{i-1,j-1} + h_{i,j}^{(2)}u_{i,j-1} + h_{i,j}^{(3)}u_{i+1,j-1} \\ & + h_{i,j}^{(4)}u_{i-1,j} + h_{i,j}^{(5)}u_{i,j} + h_{i,j}^{(6)}u_{i+1,j} \\ & + h_{i,j}^{(7)}u_{i-1,j+1} + h_{i,j}^{(8)}u_{i,j+1}h_{i,j}^{(9)}u_{i+1,j+1} \\ = & -\epsilon \,\Delta\, u + p(x, y)\frac{\partial u}{\partial x} + q(x, y)\frac{\partial u}{\partial y} \text{ at } (\tau_{ij}, \eta_{ij}), \end{aligned}$$

meaning that equation (8) should be exactly satisfied for each Lagrange polynomial $u(x, y)$ of degree two in each variable. Such a procedure leads to a preconditioner with a bandwidth of $2N + 5$.

The iterative algorithm that we used for the two-dimensional case is an $orthomin\{5\}$ (meaning that the maximum dimension of the Krylov space kept in memory is 5; in other words the algorithm is restarted every 5 iterations) [5] preconditioned with the above-described matrix **H**.

5. Numerical experiments. To test the effectiveness of the developed preconditioner, we computed the eigenvalues of matrix $\mathbf{H}^{-1}\mathbf{L}$ for the one-dimensional case. The results are reported in Table 1 and refer to different values of the diffusion coefficient ϵ with the advection function $p(x)$ frozen at unity ($p(x) = 1$). The features of the preconditioned eigenvalues spectrum are summarized by giving the maximum and the minimum real parts together with the imaginary part. For the most severe test case at $\epsilon = 10^{-5}$ we also give the spectrum with two different sets of nodes (i.e., respectively, $N = 21$ and $N = 41$). This last result is intended to show the independence of the eigenvalues spectrum of the number of nodes. We recall here that in the nonpreconditioned case the conditioning number scales like $\sim N^2$ for the advective part and like $\sim N^4$ for the diffusive one [6]. In Figure 5, the eigenvalues spectrum is also shown for the cases $\epsilon = 10^{-2}$ and $\epsilon = 10^{-5}$.

To check the robustness of the method for the two-dimensional case, several tests were performed using different advective functions $p(x, y)$ and $q(x, y)$. In Table 2, the efficiency of the preconditioner in terms of number of iterations required to achieve machine precision (i.e.,

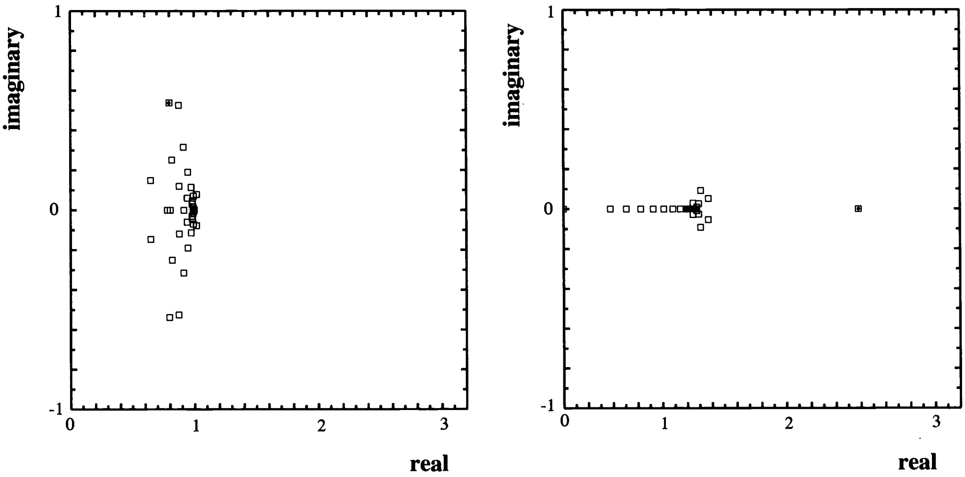

FIG. 5. *Preconditioned eigenvalues spectrum, $\epsilon = 10^{-2}$ and $\epsilon = 10^{-5}$, respectively.*

TABLE 2
Number of iterations to reduce the norm of the residual to 10^{-15}.

Testcase	Test 1	Test 2	Test 3	Test 4
Number of its.	65	45	56	82

L_∞ norm of the residuals at 10^{-15} for a double precision computation) is given at $\epsilon = 10^{-3}$ for, respectively,

$$\begin{array}{llll} & \textit{Test } 1. & p(x,y) = 1, & q(x,y) = 1, \\ & \textit{Test } 2. & p(x,y) = \sin(\pi x), & q(x,y) = 3x - y - 1, \\ (36) & \textit{Test } 3. & p(x,y) = 3x - y - 1, & q(x,y) = 3x^2 - y, \\ & \textit{Test } 4. & p(x,y) = \sin(\pi x)\sin(\pi y), & q(x,y) = \sin(\pi x)\sin(\pi y). \end{array}$$

As shown, the behavior is always satisfactory and the required number of iterations never exceeds by more than 30% the ones required for the constant advection case.

To test the developed preconditioner in a definite way, we considered equation (1) to be solved for the x-component of the velocity. The role of the advective functions $p(x, y)$ and $q(x, y)$ was played this time by an intermediate solution $u(x, y)$, $v(x, y)$ of a two-dimensional regularized driven cavity at a Reynolds number of 10000 (see Figure 6). The whole procedure converged to machine accuracy (10^{-14}) in less than 100 iterations, against the 27 iterations that are required when only the diffusive terms are treated implicitly (i.e., with a classical treatment of the diffusive terms with Crank-Nicolson and of the advective ones with Adams-Bashforth). Of course, a huge increase of the maximum allowed time step is expected from the fully implicit treatment and represents the payoff of the present method.

6. Conclusions. The basic target of the present work was the design of an efficient algorithm for the iterative solution of the advection-diffusion equations. To this end, a finite-difference preconditioner has been introduced on a "staggered" grid. The staggered points are given as the zeros of a polynomial that depends on the ratio between the local advection and the diffusion. Existence and uniqueness of these zeros is assured and the capacity of the preconditioner to represent high-frequency modes is shown. A cheap procedure to compute the staggered points has also been introduced. This is especially important when dealing with linearized problems, where the grid has to be constructed for every time step.

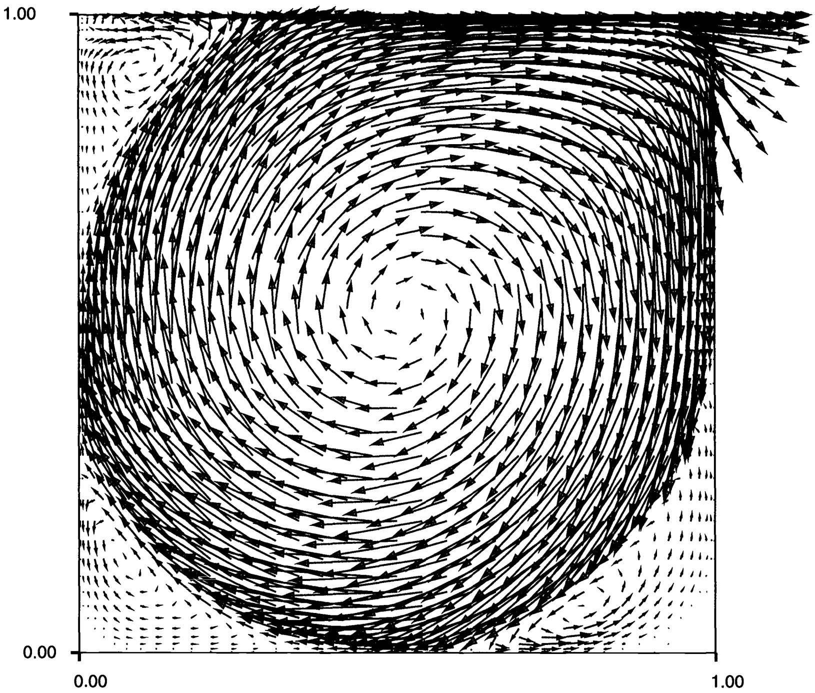

FIG. 6. *The chosen flow field.*

The efficiency of the implicit method is confirmed by numerical results for advection-dominated problems. Moreover, the distribution of the eigenvalues of the preconditioned operator seems almost independent of the value of the diffusion coefficient. The algorithm has also been applied to the projection method for the two-dimensional unsteady Navier–Stokes equations. Even for large Reynolds numbers, a very moderate number of iterations is needed to converge to machine accuracy.

Finally, we remark that we have been concerned with the development of an efficient preconditioning scheme and that no attempt has been made to cure problems related to numerical instabilities due to large Peclet numbers. Hence, we do not pretend that the presented method produces accurate results for the well-known boundary-layer problems for the values of ϵ and N that have been used to solve the analytical problem (36). Nevertheless, the present technique produces a condition number for the preconditioned operator that is almost independent of the number of nodes N. One way to take advantage of this feature is to increase N to be able to accurately capture boundary layers, without achieving prohibitive operation counts.

ON THE ORDER OF CONVERGENCE OF PRECONDITIONED NONLINEAR CONJUGATE GRADIENT METHODS*

M. AL-BAALI† AND R. FLETCHER‡

Abstract. An analysis is given of preconditioned nonlinear conjugate gradient methods in which the preconditioning matrix is the exact Hessian matrix at each iteration (or a nearby matrix). It is shown that the order of convergence of certain preconditioned methods is less than that of Newton's method when exact line searches are used, and an example is given.

Key words. unconstrained optimization, Newton's method, conjugate gradient methods, preconditioning

AMS subject classifications. 90C30, 65K05

1. Introduction.

Consider line search descent methods for solving the unconstrained optimization problem

$$\min_{x \in R^n} f(x), \tag{1}$$

where f is twice continuously differentiable. Each method generates a sequence of points $\{x^{(k)}\}$ for $k = 1, 2, \ldots$ until termination. The initial point $x^{(1)}$ is given. If $g^{(k)}[= \nabla f(x^{(k)})] = 0$, for some k, then the method terminates with $x^{(k)} = x^*$ (a stationary point). Otherwise, a search direction $s^{(k)}$ is defined for which

$$g^{(k)T} s^{(k)} < 0 \tag{2}$$

(the descent property). Then a new iterate is defined by the line search

$$x^{(k+1)} = x^{(k)} + \alpha^{(k)} s^{(k)}, \tag{3}$$

where $\alpha^{(k)}$ is a steplength chosen to minimize f along $s^{(k)}$ for which

$$g^{(k+1)T} s^{(k)} = 0. \tag{4}$$

In this case the line search is exact (e.g., Fletcher [2]).

The search direction in Newton's method is defined by

$$s^{(k)} = -G^{(k)-1} g^{(k)}, \tag{5}$$

where $G^{(k)}[= \nabla^2 f(x^{(k)})]$ is the Hessian matrix which, for $x^{(k)}$ sufficiently close to x^*, is usually positive definite.

We consider the case when a preconditioned version of a nonlinear conjugate gradient method is used to minimize f; the matrix W will denote the preconditioning matrix. At the first iteration, the search direction is defined by

$$s^{(1)} = -W^{(1)-1} g^{(1)}. \tag{6}$$

For $k > 1$,

$$s^{(k)} = -W^{(k)-1} g^{(k)} + \beta^{(k-1)} s^{(k-1)}, \tag{7}$$

where

$$\beta^{(k-1)} = \frac{\gamma^{(k-1)T} W^{(k)-1} g^{(k)}}{\gamma^{(k-1)T} s^{(k-1)}}, \tag{8}$$

and where

$$\gamma^{(k-1)} = g^{(k)} - g^{(k-1)}. \tag{9}$$

(This method is referred to as preconditioned conjugate gradient (PCG).) Resetting corresponds to defining $s^{(k)}$ as

$$s^{(k)} = -W^{(k)-1} g^{(k)}, \tag{10}$$

which in effect starts a new sequence of iterations. We note from (6) and (7), using (4), that the descent property (2) is satisfied for all k, since $W^{(k)}$ is chosen positive definite. (For further details, see Fletcher [2], for instance.)

The preconditioned Polak-Ribière (PPR) method is similar to the PCG method, except that $\beta^{(k-1)}$ is defined by

$$\beta^{(k-1)} = \frac{\gamma^{(k-1)T} W^{(k)-1} g^{(k)}}{g^{(k-1)T} W^{(k-1)-1} g^{(k-1)}} \tag{11}$$

rather than (8). But using (4), we observe from (6), (7), and (9) that

$$g^{(k-1)T} W^{(k-1)-1} g^{(k-1)} = -g^{(k-1)T} s^{(k-1)} = \gamma^{(k-1)T} s^{(k-1)},$$

for $k > 1$, which shows that the PCG and PPR methods are equivalent (i.e., (8) and (11) are identical) if exact line searches are performed. Thus the results in this paper are valid not only for the PCG method but also for the PPR method.

The preconditioned Fletcher-Reeves (PFR) method is also similar to the PCG method, except that formula (8) is replaced by

$$\beta^{(k-1)} = \frac{g^{(k)T} W^{(k)-1} g^{(k)}}{g^{(k-1)T} W^{(k-1)-1} g^{(k-1)}}. \tag{12}$$

For convenience, we also consider Newton-type methods which define $s^{(k)}$ by

$$s^{(k)} = -B^{(k)-1} g^{(k)}, \tag{13}$$

where $B^{(k)}$ is a symmetric positive definite matrix. This type of method is like Newton's method with line search, except that $G^{(k)}$ is approximated by $B^{(k)}$.

The focus of this paper is on the situation when a preconditioner is a close approximation of the exact Hessian. We show that in this case the above preconditioned methods are inferior in convergence rate to Newton's method (5). Since under certain conditions on f this method (with steps of unity) converges to x^* with R-order at least $p = \frac{1}{2}(1+\sqrt{5})$ and sometimes with Q-order at least 2 (e.g., Ortega and Rheinboldt [3], and Fletcher [2]), we approach our result as follows. In §2, we show, under those conditions on f and a strong one on $W^{(k)}$, that a PCG method with exact line searches converges to x^* with R-order at least p, and that bounds on the errors converge to zero with Q-order p. In §3, we illustrate the possibility that a PCG method and a PFR method converge with Q-order p and 1, respectively, by applying these methods to a simple quartic function. Because this result assumes that exact line searches are performed and that the exact Hessian matrix is used as the preconditioner, §3 also discusses certain numerical results which were obtained by using inexact line searches and $W^{(k)}$ is a close approximation of $G^{(k)}$. It is concluded, as for exact line searches, that the above preconditioned methods are less efficient than a Newton-type method defined by (13) and $B^{(k)} = W^{(k)}$.

This result has some theoretical significance, because even when a highly accurate Hessian approximation is used as the preconditioner and exact line searches are performed, the preconditioned methods converge slower than Newton's method or, for that matter, a Newton-type method having $B^{(k)} = W^{(k)}$.

2. Order of convergence. In order to obtain the results below, we begin by introducing some notation and by stating the assumptions we make about the objective function f and the preconditioning matrices.

Let $\|\cdot\|$ denote the usual Euclidean norm. We will use the notation $F(z) = O(z^r)$ as $z \to 0$, where r and z are scalars and F may be either a scalar, a vector, or a matrix. It means that there exists a positive constant c such that $\|F(z)\| \leq cz^r$ for z sufficiently close to zero (we do not bother to add the phrase "as $z \to 0$"). The error vector is defined by

$$h^{(k)} = x^{(k)} - x^* \tag{14}$$

and the difference between the current and new points is given by

$$\delta^{(k)} = \alpha^{(k)} s^{(k)} = x^{(k+1)} - x^{(k)}. \tag{15}$$

Assumptions 2.1. 1. The sequence of points $\{x^{(k)}\}$ remains in a closed, bounded, and convex level set $N = \{x : f(x) \leq f^{(1)}\}$, where $f^{(k)}$ denotes $f(x^{(k)})$, in which f is twice continuously differentiable.

2. The Hessian matrix G satisfies the Lipschitz condition

$$\|G(x) - G(x^*)\| \leq c_1 \|x - x^*\|, \tag{16}$$

where c_1 is a positive constant for all x in a neighborhood of x^*.

3. There exist positive constants c_2 and c_3 such that

$$c_2 \|z\|^2 \leq z^T G(x) z \leq c_3 \|z\|^2 \tag{17}$$

for all $z \in R^n$ and all $x \in N$.

4. The preconditioning matrices $W^{(k)}$ satisfy the equation

$$W^{(k)} = G^* + O(\|h^{(k)}\|) \tag{18}$$

for all $x^{(k)}$ sufficiently close to x^*.

Note that Assumption 2.1.3 and the convexity of N imply that f has a unique minimizer x^* in N. Note also that assumption (18) means that $W^{(k)}$ is a strongly consistent approximation of G^* (see Ortega and Rheinboldt [3] for instance). (For choice (18), the PCG and PFR methods are referred to as PCG1 and PFR1, respectively.)

Under the above assumptions, the Newton-type method (13) with steps of unity and $B^{(k)}$ defined by the right-hand side of (18) converges to x^* with Q-order at least 2 (e.g., Ortega and Rheinboldt [3]). However, this is not the case when the PCG1 and PFR1 methods are considered, even though both methods can be defined by (13) for some $B^{(k)-1}$. To illustrate this point, we state the following. It follows from (4), (7), (8), (9), (12), and (15) that the PCG and PFR methods define the search direction $s^{(k)}$ by (13) with $B^{(k)-1}$ replaced by

$$H_{PCG}^{(k)} = \left(I - \frac{\delta^{(k-1)}\gamma^{(k-1)T}}{\delta^{(k-1)T}\gamma^{(k-1)}}\right) W^{(k)-1}, \tag{19}$$

where I is the identity matrix, and

$$H^{(k)}_{PFR} = \left(I + \frac{\delta^{(k-1)}g^{(k)T}}{\delta^{(k-1)T}g^{(k-1)}}\right) W^{(k)-1}, \tag{20}$$

respectively. Since the matrix $H^{(k)}_{PCG}$ is singular, for all k, and, by (4), $H^{(k)-1}_{PFR} = W^{(k)}(I - \frac{\delta^{(k-1)}g^{(k)T}}{\delta^{(k-1)T}g^{(k-1)}})$ is not continuous at x^*, the inverse of both (19) and (20) cannot be defined by the right-hand side of (18). Thus we are not able to use a certain result of Ortega and Rheinboldt [3] and of Voigt [6] to obtain the rate of convergence for the PCG1 and PFR1 methods. Because the numerical results in §3 show that a PFR1 method converges linearly, we do not provide further details concerning this method. However, the following theorems are concerned with the PCG1 method. To obtain these results, we first present the following lemma.

LEMMA 2.1. *Let f satisfy Assumptions 2.1.1 and 2.1.3. Then for any minimization method that ensures that the value of f is reduced at every iteration, we have*

$$\delta^{(k)} = O(\|h^{(k)}\|) = O(\|g^{(k)}\|). \tag{21}$$

Proof. Using the mean value theorem and the fact that $g(x^*) = 0$, we obtain

$$f^{(k)} = f^* + \frac{1}{2}h^{(k)T}G(\xi)h^{(k)}, \tag{22}$$

where ξ lies on the line segment between x^* and $x^{(k)}$. Since N is a convex set and $x^{(k)} \in N$ (see Assumption 2.1.1), we have $\xi \in N$. Thus (22) and the uniform convexity assumption (17) imply

$$\frac{2}{c_3}(f^{(k)} - f^*) \le \|h^{(k)}\|^2 \le \frac{2}{c_2}(f^{(k)} - f^*). \tag{23}$$

Since $x^{(k+1)} \in N$, (23) is also satisfied with k replaced by $k+1$, which implies, using $f^{(k+1)} \le f^{(k)}$, that $\|h^{(k+1)}\|^2 \le 2(f^{(k)} - f^*)/c_2$. This inequality and the first one in (23) give

$$\|h^{(k+1)}\| \le c_4\|h^{(k)}\|, \tag{24}$$

where $c_4 = (c_3/c_2)^{1/2}$. From (14), (15), and (24) it follows that

$$\|\delta^{(k)}\| = \|h^{(k+1)} - h^{(k)}\| \le (c_4 + 1)\|h^{(k)}\|, \tag{25}$$

which shows that the first equality in (21) is correct. To prove the second equality in (21), use (25) and observe that the Taylor expansion theorem gives

$$g^{(k)} = G^*h^{(k)} + O(\|h^{(k)}\|^2), \tag{26}$$

which implies, using assumption (17), that

$$g^{(k)} = O(\|h^{(k)}\|) \tag{27}$$

and

$$h^{(k)} = O(\|g^{(k)}\|). \quad \square \tag{28}$$

THEOREM 2.2. *Let f satisfy assumptions 2.1.1-2.2.4 and assume that exact line searches are performed. Then the PCG1 method has the following properties:*

$$s^{(k)} = O(\|h^{(k)}\|), \tag{29}$$

$$\alpha^{(k)} = 1 + O(\|h^{(k-1)}\|). \tag{30}$$

Proof. In the following, we suppress the superscript "$^{(k)}$" on W, g, s, and α and replace the superscript "$^{(k-1)}$" by "$^{-}$". For convenience, we rearrange (7) with (8), using (19), as

$$s = -\left(I - \frac{\delta^- \gamma^{-T}}{\delta^{-T}\gamma^-}\right) W^{-1} g. \tag{31}$$

The Taylor expansion theorem shows that $g = g^- + G^\# \delta^-$, where $G^\# = \int_0^1 G(x^- + \delta^- t)dt$. Using the Lipschitz condition (16) and Lemma 2.1, it can be shown that $G^\# = G^* + O(\|h^-\|)$. Thus

$$g = g^- + G^*\delta^- + O(\|h^-\| \|\delta^-\|). \tag{32}$$

Substituting (18) and (32) in (31), we obtain, using assumption (17),

$$s = -\left(I - \frac{\delta^-\delta^{-T}G^*}{\delta^{-T}G^*\delta^-} + O(\|h^-\|)\right)\left(G^{*^{-1}} + O(\|h\|)\right) g.$$

Using (4), (24) (with k replaced by $k-1$ in both expressions), and (27), it follows that

$$s = -G^{*^{-1}} g + O(\|h\| \, \|h^-\|), \tag{33}$$

which, by (27), implies (29).

We now proceed to prove (30). From (4) and (32) with k replaced by $k+1$, we have

$$g^T s + \alpha s^T G^* s + O(\|h\| \|\delta\| \|s\|) = 0. \tag{34}$$

But from (33) it follows that $s^T G^* s = -g^T s + O(\|h\| \, \|h^-\| \, \|s\|)$. Substituting this expression in (34) and using the first equality in (21), (24), (28), and (29) it follows that

$$(1-\alpha) g^T s + O(\|g\|^2 \|h^-\|) = 0.$$

This result with (17), (28), and (33) imply that

$$\alpha = 1 + \frac{O(\|g\|^2\|h^-\|)}{g^T G^{*^{-1}} g + O(\|g\|^2\|h^-\|)} = 1 + O(\|h^-\|). \qquad \square$$

THEOREM 2.3. *Under the same assumptions of Theorem* 2.2, *the PCG*1 *method converges to x^* and has R-order at least $p = \frac{1}{2}(1+\sqrt{5})$. Moreover, the bounds on the errors exist and converge with exact Q and R order p.*

Proof. From (24), (26), and (33) we obtain

$$s^{(k)} = -h^{(k)} + O(\|h^{(k)}\| \, \|h^{(k-1)}\|).$$

Thus using (14), (15), (29), and (30) it follows that

$$h^{(k+1)} = O(\|h^{(k)}\| \, \|h^{(k-1)}\|)$$

or, equivalently,

$$\|h^{(k+1)}\| \leq c_5 \|h^{(k)}\| \, \|h^{(k-1)}\| \tag{35}$$

for some positive constant c_5. If we let $d_k = c_5\|h^{(k)}\|$, it follows from (35) that

$$d_{k+1} \leq d_k d_{k-1}. \tag{36}$$

If $x^{(k-1)}$ and $x^{(k)}$ are in a smaller neighborhood of x^* for which

$$d = \max(d_k, d_{k-1}) < 1, \tag{37}$$

then clearly $d_{k+1} \le d^2 < 1$. Thus $x^{(k+1)}$ is in the neighborhood and, by induction, the iterations are well defined for all k and $d_k \to 0$ (i.e., $h^{(k)} \to 0$). Thus the PCG1 method converges to x^*. Therefore, (36) implies that $\{d_k\}$ converges with R-order at least p, the positive root of the quadratic equation

$$t^2 - t - 1 = 0 \tag{38}$$

(e.g., Potra [4] and Voigt [6]).

To complete the proof, we proceed in the following way. We assume, without loss of generality, that $x^{(1)}$ is sufficiently close to x^* so that (36) holds, for all $k \ge 2$, and that (37) is true for $k = 2$. We let $\{b_k\}$, for $k \ge 1$, be a sequence of positive numbers defined by

$$b_k = \frac{1}{c_5} d^{a_k}, \tag{39}$$

where

$$a_k = \frac{1}{\sqrt{5}}(p^k - q^k), \tag{40}$$

and where $q = \frac{1}{2}(1 - \sqrt{5})$ is the negative root of (38). (Note that $b_k \to 0$, since $0 < d < 1$ and $p > 1$.) Since from (40) we obtain after a little manipulation that $a_1 = 1$, $a_2 = 1$, and $a_{k+1} = a_k + a_{k-1}$, for $k \ge 2$, it follows from (36) and (37) (by induction) that $c_5 b_k$ is an upper bound on d_k. Thus the sequence $\{b_k\}$ defines upper bounds on the errors $\|h^{(k)}\|$. To find its rate of convergence, we use (39) and (40) to obtain

$$\frac{b_{k+1}}{b_k^p} = c_5^{p-1} d^{a_{k+1} - p a_k} = c_5^{p-1} d^{q^k}. \tag{41}$$

Because $0 < d < 1$ and $-\frac{1}{2} < q^k < 1$, it follows from (41) that

$$c_6 b_k^p \le b_{k+1} \le c_7 b_k^p, \tag{42}$$

where $c_6 = c_5^{p-1} d$ and $c_7 = c_5^{p-1} d^{-1/2}$, which imply that $\{b_k\}$ converges with exact Q-order p, hence, with R-order p (e.g., Potra [4]). □

Although this result does not imply, in general, that the sequence $\{\|h^{(k)}\|\}$ converges with Q-order greater than one (e.g., Potra [4]), this sequence may have Q-order p in the following sense. If we assume that there exist constants for which the above bounds are attained, then we can expect that the sequence itself has this order. To illustrate this possibility, we present numerical results in the next section.

3. Numerical discussion. To illustrate the result in §2 that the PCG1 method (i.e., the PCG method with $W^{(k)}$ satisfying (18)) may converge with Q-order $p \approx 1.618$ and to show that the PFR1 method (i.e., PFR with (18) holds) may converge linearly, we consider the following experiments.

For the choice $W^{(k)} = G^{(k)}$, assuming an exact line search is performed at each iteration, we applied the PCG and PFR methods (referred to as PCG2 and PFR2, respectively) to the quartic function

$$f(x) = x_1^4 + x_1 x_2 + (1 + x_2)^2. \tag{43}$$

TABLE 1
Applications to problem (43).

	The PFR2 method		The PCG2 method		The Newton method	
k	$\|h^{(k)}\|$	$R1^{(k)}$	$\|h^{(k)}\|$	$R1.618^{(k)}$	$\|h^{(k)}\|$	$R2^{(k)}$
1	0.1119		0.1119		0.1119	
2	0.5362D-2	0.0479	0.5362D-2	0.1855	0.5362D-2	0.4282
3	0.1452D-3	0.0271	0.1592D-3	0.7513	0.8699D-5	0.3026
4	0.5924D-5	0.0408	0.4517D-6	0.6314	0.3151D-10	0.4164
5	0.1715D-6	0.0290	0.1958D-10	0.3615		
6	0.6496D-8	0.0379				
7	0.1983D-9	0.0305				

The starting point is given by $x^{(1)} = (0.75, -1.25)^T$ which is sufficiently close to the solution

$$x^* = (0.6958843861177639, -1.347942193058882)^T,$$

so that $G^{(k)}$, for all k, is positive definite (Fletcher [2]). (Note that the largest and smallest eigenvalues of G^* are approximately 6.06 and 1.75, respectively, and that Assumptions 2.1 hold.) The numerical results are given in columns 2, 3, 4 and 5 of Table 1. They were obtained in double precision with accuracy $2^{-56} \approx 0.14 \times 10^{-16}$. The run was stopped when $\|g^{(k)}\|^2 \leq 10^{-16}$. An examination of the ratios $R1.618^{(k)} = \|h^{(k)}\|/\|h^{(k-1)}\|^{1.618}$, given in column 5, shows that these ratios are approximately equal to a constant that illustrates that the PCG2 method has Q-order 1.618. Similarly an examination of the ratios $R1^{(k)} = \|h^{(k)}\|/\|h^{(k-1)}\|$, given in column 3, illustrates that the PFR2 method converges linearly. For convenience, we also applied Newton's method with exact line searches (defined by (3)-(5)) to the above problem. The results, given in columns 6 and 7 of Table 1, show, as expected, that the ratios $R2^{(k)} = \|h^{(k)}\|/\|h^{(k-1)}\|^2$ are nearly equal to a constant. It is clear that the PCG2 and PFR2 methods are inferior (the latter far worse) to the Newton method. (For the application of Newton's method with steps of unity, see Fletcher [2], who reported that the corresponding ratios $R2^{(k)}$ are close to 1.4.)

The above results show that even under the very strong condition (18) on the preconditioning matrix, the preconditioned methods, with exact line searches, converge slower than Newton's method. To see if these results generalize to inexact line searches and preconditioners that are only an approximation of the exact Hessian, these are conditions that are likely to hold in practice; it is worth mentioning an experiment of Al-Baali [1]. The author applied a PCG, PFR, and Newton-type method with inexact line searches to a set of standard nonlinear least squares problems. For this type of problem, the objective function is of the form $f(x) = r(x)^T r(x)$, where $r \in R^m$ and $m \geq n$. The choice

$$B^{(k)} = W^{(k)} = 2AA^T, \tag{44}$$

where $A = \nabla r(x^{(k)})^T$, the Gauss-Newton-Hessian of f, is a useful approximation of $G^{(k)}$ if $\|r(x^*)\|$ is sufficiently small (e.g., Fletcher [2]). Using (44), the three methods are referred to as PCG3, PFR3, and GN, respectively. (Note that the GN method is the so-called Gauss-Newton method and that the PFR3 method is essentially proposed by Ruhe [5].) The inexact line search algorithm used by Al-Baali [1] calculates a steplength $\alpha^{(k)}$ for which

$$|g^{(k+1)T}s^{(k)}| \leq -\sigma g^{(k)T}s^{(k)} \tag{45}$$

and

$$f^{(k+1)} \leq f^{(k)} + \rho\alpha^{(k)}g^{(k)T}s^{(k)}, \tag{46}$$

where $\rho \in (0, 0.5)$ and $\sigma \in (\rho, 1)$, the two-sided Wolfe–Powell conditions (e.g., Fletcher [2]). Note that in the limit $\sigma \rightarrow 0$, condition (45) reduces to (4). Using $\rho = 0.05$ and $\sigma = 0.1$ (which produces a fairly accurate line search), the latter three methods were implemented in single precision and terminated when

$$f^{(k)} - f^{(k+1)} \leq \epsilon \max(1, |f^{(k)}|), \tag{47}$$

where $\epsilon = 10^{-8}$. The reported numerical results (see [1] for details) show that for zero residual problems (in which $r(x^*) = 0$ and $G^* = 2A^*A^{*T}$), the performance of the GN method is better than that of both the PCG3 and PFR3 methods. Thus, in practice, the preconditioned methods converge slower than a Newton-type method having $W^{(k)}$ as a close approximation of $G^{(k)}$.

Therefore, if the preconditioning matrix $W^{(k)}$ is taken as a sufficiently close approximation of $G^{(k)}$, the Newton-type method with $B^{(k)} = W^{(k)}$ is preferable to the PCG and PFR methods.

Acknowledgments. The authors are indebted to Margaret Wright, Associate Editor, and to the two anonymous referees for many valuable comments and suggestions.

PARALLEL SPARSE ORTHOGONAL FACTORIZATION ON DISTRIBUTED-MEMORY MULTIPROCESSORS*

CHUNGUANG SUN†

Abstract. In this paper, we propose a new parallel multifrontal algorithm for the orthogonal factorization of large sparse matrices on distributed-memory multiprocessors. We explore the use of block partitioning schemes in parallel sparse orthogonal factorization. Our block-oriented parallel algorithm for sparse orthogonal factorization achieves high performance by incurring strictly less communication overhead than the conventional nonblock algorithm, maintaining relatively balanced load distribution among processors, and accelerating the parallel numerical kernel via increased cache utilization. We analyze the performance of our parallel algorithm and present its arithmetic and communication complexities for regular grid problems. We report the experimental results of an implementation of our parallel algorithm on an Intel iPSC/860 machine. Through our theoretical analysis and experimental results, we demonstrate that our new block-oriented algorithm outperforms the conventional nonblock algorithm impressively.

1. Introduction.

Let A be a sparse $m \times n$ matrix with full column rank. The QR factorization of A is expressed as

$$A = Q \begin{bmatrix} R \\ 0 \end{bmatrix},$$

where Q is an $m \times m$ orthogonal matrix and R is an $n \times n$ upper triangular matrix. Usually Q is not formed explicitly.

A row merging scheme and a general row merging scheme for sparse QR factorization are proposed in [8] and [19], respectively. Sequential algorithms for sparse QR factorization are also considered in [11, 17, 22, 23]. Parallel algorithms are described in [5, 24, 27] for implementing the numeric phase of the general row merging scheme [19] on (multiple instruction multiple data) MIMD distributed-memory multiprocessors. A parallel algorithm is discussed in [16] for implementing the numeric phase of the row merging scheme [8] on (single instruction multiple data) SIMD architecture. Previously proposed parallel sparse QR factorization algorithms [5, 16, 24, 27] are based on the nonblock or single-row partition of the dense matrices involved in the numerical computation. The block-oriented approach to parallel sparse QR factorization has not been explored before.

In this paper we consider a block-oriented approach to parallel sparse QR factorization and describe a new parallel multifrontal algorithm for sparse QR factorization on distributed-memory multiprocessors. We propose block schemes for partitioning the upper trapezoidal matrices involved in the numerical computation. We explore a spectrum of block partitioning schemes ranging from the conventional single-row partition to the block partition with maximal block size. Our block-oriented approach results in an efficient parallel multifrontal algorithm for sparse QR factorization with low communication costs, relatively balanced load distribution among processors, and a high performance parallel numerical kernel due to the increased cache utilization.

1. Find a column ordering P_1 for A such that $(AP_1)^T(AP_1)$ has a sparse Cholesky factor.
2. Compute the elimination tree of $(AP_1)^T(AP_1)$ from $G(A^TA)$ and P_1. Number the nodes of the elimination tree in postorder. Let the postorder be P_2 and set $P = P_1P_2$.
3. Determine the symbolic structure of R from $G(A^TA)$ and P, where $(AP)^T(AP) = R^TR$.
4. Compute the supernodal elimination tree of R from the elimination tree and the symbolic structure of R.
5. Perform numerical factorization by processing the supernodes in a topological ordering.

FIG. 1. *Sparse QR factorization.*

Both A and R are distributed to processors by rows. The supernodal structure of R is fully exploited. The performance of our parallel algorithm with a special block partition applied to regular grid problems is analyzed, and the arithmetic and communication complexity results of our analysis are presented. Experimental results of an implementation of our parallel algorithm on a 32-node Intel iPSC/860 machine are obtained for a collection of sparse matrix problems including regular grid problems and a general sparse problem with irregular sparsity structure. Our block-oriented approach to parallel sparse QR factorization achieves significant improvement in performance over the conventional nonblock approach described in [5].

In §2, a multifrontal sparse QR factorization scheme is reviewed. A new parallel multifrontal algorithm for sparse QR factorization is proposed in §3. The complexity analysis of our algorithm for regular grid problems is presented in §4. Experimental results are discussed in §5. Finally, concluding remarks are contained in §6.

2. A multifrontal sparse QR factorization algorithm. We briefly review a multifrontal approach to sparse QR factorization in this section. We refer the reader to [11, 17, 19] for further details. Let $A^TA = LL^T$, where L is the Cholesky factor of A^TA. It is well known that R^T is equal to L, apart from possible sign differences in the rows. Therefore, the elimination tree of A^TA can be defined in terms of the sparsity structure of R. Specifically, j is the parent of i if $r_{ij} (i < j)$ is the leading off-diagonal nonzero in the ith row of R. For simplicity, it is assumed that A^TA is irreducible and the corresponding elimination tree is indeed a tree. A node in the elimination tree corresponds to a row in R. Let $G(A^TA)$ denote the adjacency graph of A^TA. The steps involved in sparse QR factorization are described in Fig. 1.

Step 1 is done by applying a symmetric ordering such as the nested dissection ordering [7] or the minimum degree ordering [12] to $G(A^TA)$. Step 2 can be accomplished by using an algorithm described in [18]. The symbolic factorization step is discussed in [9]. There are several slightly different definitions of supernode [1, 2, 3, 10, 20]. Any of those definitions can be used in our approach. In an implementation of our algorithm, the fundamental supernode [2] is used. Let $\mathcal{R}_j$ denote the structure of row j of R, i.e., the set of nonzero column indices in row j of R. A fundamental supernode is a maximal set of contiguous rows $\{i, i+1, \dots, k\}$ in R such that $\mathcal{R}_j = \{j\} \cup \mathcal{R}_{j+1}$ for $i \le j < k$ and j is the only child of $j+1$ in the elimination tree which has been postordered. The first four steps are referred to as the *symbolic phase* of the sparse QR factorization and step 5 is referred to as the *numeric phase* of the sparse QR factorization.

A supernode K is associated with an upper trapezoidal matrix F_K called the *frontal matrix* of K. The sparsity structure of F_K is given by $\mathcal{R}_i$, where i is the least-numbered row in K. The number of columns in F_K is $|\mathcal{R}_i|$ and the number of rows in F_K is at most $|\mathcal{R}_i|$. Liu [19]

```
1  for each supernode $K$ in a topological ordering do
2      allocate space for $U_K$ and initialize $F_K$ to zero;
3      assemble $U_C$ into $F_K$ and discard $U_C$, where $C \in children(K)$;
4      for each $D \in children(K) \setminus \{C\}$ do

10 end for
```

FIG. 2. *The numeric phase of a sequential multifrontal sparse QR factorization algorithm.*

has shown that F_K can be considered as a dense matrix for all practical purposes. Our parallel algorithm described in §3 works correctly regardless of whether F_K is upper trapezoidal or upper triangular. For simplicity, we assume that F_K is a dense upper triangular matrix. The first $|K|$ rows of F_K are rows $i, i+1, \ldots, i+|K|-1$ in R and they are called the *factor rows* of F_K. The upper triangular matrix obtained by removing the factor rows of F_K is called the *update matrix* of K and is denoted by U_K.

Let A_j denote the submatrix consisting of all rows of A whose first nonzeros are in column j of A. The number of nonzero columns in A_j is at most $|\mathcal{R}_j|$. Let *children*(K) be the set of children of K in the supernodal elimination tree. The numeric phase of a sequential multifrontal sparse QR factorization algorithm is described in Fig. 2. The storage for R is allocated before the numeric phase starts. The assembly of an update matrix U_C into F_K in line 3 can be done by a matrix *extend-add* operation introduced in [20], where C is any child of K. Merging U_D into F_K in line 5, reducing A_j to an upper trapezoidal matrix T_j in line 7, and merging T_j into F_K in line 8 can be accomplished by either Householder transformations or Givens rotations. In our implementation, U_D or T_j is merged into F_K by Givens rotations and A_j is reduced to T_j by Householder transformations. It is clear that this multifrontal approach mainly involves dense matrix computations. Furthermore, the update matrices can be handled by a stack data structure, so data locality is achieved. These desirable features are also present in our parallel algorithm.

3. A parallel multifrontal sparse QR factorization algorithm.

Several parallel algorithms have been described in [5, 24, 27] for implementing the numeric phase of sparse QR factorization on distributed-memory multiprocessors.

- In the algorithm discussed in [5], a frontal matrix F is mapped to a ring of processors by assigning the rows of F to the processors in a wrap-around manner. An update matrix U which needs to be merged into F is shifted among the ring of processors in a circular fashion. Before each shift the diagonal elements of U are annihilated against the frontal matrix F by Givens rotations and U becomes a smaller upper triangular matrix. This shift is continued until U is completely merged into F. This approach is referred to as the *row-oriented approach.*
- In the approach described in [24], a global row reduction algorithm is introduced to compute a frontal matrix. Parallel computation of the tree structure required for the multifrontal method is also discussed. In this approach, the amount of arithmetic work may increase as the number of processors increases.
- A parallel algorithm is discussed in [27] for implementing the sparse QR factorization scheme proposed in [11] in parallel. In this scheme, a frontal matrix is computed by row-oriented Householder transformations. Before the parallel computation of a frontal matrix is started, the relevant update matrices are redistributed among processors to ensure rela-

tively balanced load distribution. As expected, this redistribution improves load balancing by incurring additional communication overhead.

A drawback common to all of these algorithms is that frontal matrices are computed by communicating *single* rows; i.e., a message contains only one row or one transformed row of some frontal matrix. This can result in an excessive number of small messages communicated among processors. Because of the message start-up time, the overhead associated with a short message is proportionally higher than that associated with a long message.

To reduce communication costs, a block approach is suggested as a future research topic in [5]. A frontal matrix is partitioned into blocks with the same number of rows. If F is an $h \times h$ upper triangular matrix and is mapped to p processors, block size equal to h/p^2 is recommended in [5]. As shown in §5, the communication volume of this block approach is still relatively high. To the best of our knowledge, experimental results of the row-oriented approach and the block-oriented approach described in [5] have not been reported in the literature. In §5, performance results of these two approaches will be discussed.

3.1. An overall framework for parallel sparse QR factorization. We propose a new parallel algorithm for the numeric phase of the multifrontal sparse QR factorization described in §2. The symbolic phase of the sparse QR factorization is done sequentially. After the symbolic structure of R and the corresponding supernodal elimination tree are determined, the arithmetic work associated with each subtree is estimated. The supernodal elimination tree is mapped onto processors by a proportional mapping scheme described in [26]. The root of the supernodal elimination tree is partitioned among all processors. For a supernode that has already been mapped to a set of processors, each subtree rooted at a child of that supernode is allocated a subset of processors whose size is proportional to the workload associated with that subtree.

We consider the formation of a frontal matrix as a computational task. The supernodal elimination tree is the precedence graph among the computational tasks. Computation proceeds from leaves to root. Initially each processor is working on its own subtrees. Later on, processors cooperate to compute the frontal matrix of a partitioned supernode. When independent subtrees are being processed, no communication among processors is needed.

The overall parallel algorithm for the multifrontal sparse QR factorization is described in Fig. 3. The key operation in this algorithm is to merge an upper triangular matrix into another one in parallel as will be discussed in detail in the next subsection.

3.2. A parallel numerical kernel. Let V and W be two $h \times h$ upper triangular matrices. Consider merging V into W by Givens rotations on a set of p processors $\{\mu_0, \mu_1, \dots, \mu_{p-1}\}$, i.e., transforming the matrix $[\,{W \atop V}\,]$ into an upper triangular form by Givens rotations. Let V and W be identically partitioned into $k (k \le h)$ blocks by rows as

$$V = \begin{bmatrix} V_0 \\ V_1 \\ \vdots \\ V_{k-1} \end{bmatrix} \quad \text{and} \quad W = \begin{bmatrix} W_0 \\ W_1 \\ \vdots \\ W_{k-1} \end{bmatrix}.$$

Blocks V_i and W_i are assigned to processor μ_j, where $j = i \bmod p$. The block V_i is merged into blocks $W_i, W_{i+1}, \dots, W_{k-1}$, successively.

For a given number of processors, how the upper triangular matrices are partitioned determines the performance of merging V into W. Since there are p processors, the number of blocks should be at least p. Clearly, a block must contain at least one row. Therefore, $p \le k \le h$. The total number of possible block partitions for an $h \times h$ upper triangular matrix

```

FIG. 3. *A parallel multifrontal sparse orthogonal factorization algorithm on a processor μ.*

on p processors is

$$\sum_{k=p}^{h} \binom{h-1}{k-1} = \sum_{k=p}^{h} \frac{(h-1)!}{(k-1)!(h-k)!}.$$

For reasonable h and p, it is impractical to determine an optimal block partition by examining all possible block partitions. We consider two strategies for partitioning upper triangular matrices into blocks.

Equal-row partitioning scheme. First, we consider partitioning upper triangular matrices V and W into blocks with an equal number of rows. This scheme partitions an $h \times h$ matrix into $k = h/s$ blocks, where $s(1 \le s \le h/p)$ is the block size or the number of rows in a block. This scheme is referred to as the *equal-row partitioning scheme*. The special cases $s = 1$ and $s = h/p^2$ are considered in [5].

The number of blocks k determines the arithmetic work distribution of merging V into W. The larger the number of blocks, the more balanced the arithmetic work distribution. The worst and the best arithmetic work distributions are achieved for $k = 1$ and $k = h$, respectively. To maintain load balance, the number of blocks should be large; i.e., the block size should be small.

Let α be the start-up time for a message and β the transfer time per floating-point number. The total communication cost on all processors is

$$\sum_{i=1}^{k-1} i(\alpha + \beta(s(h - is) - (s-1)s/2)) \approx \frac{\alpha}{2}k^2 + \frac{\beta h^2}{6}k - \frac{\beta h^2}{4}.$$

Clearly, the communication cost is proportional to the number of blocks k. To keep the communication cost low, the number of blocks should be small; i.e., the block size should be large.

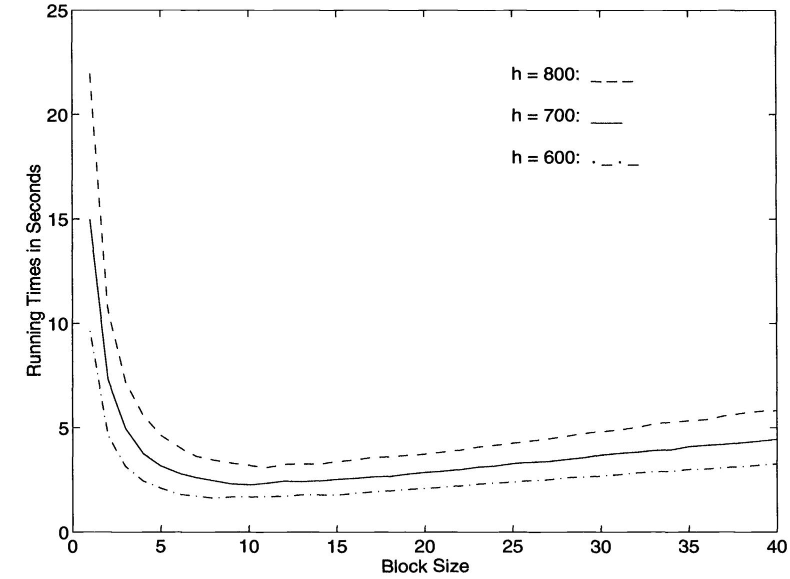

FIG. 4. *Equal-row partitioning scheme with $p = 32$ and $h = 600, 700, 800$ on an iPSC/860.*

An optimal block size minimizes the combined effect of the arithmetic work distribution and the communication cost; i.e., the overall execution time. To obtain an optimal block size or a block size that is close to optimal, it is necessary to examine how the algorithmic performance of merging V into W is dependent upon the block size.

Experiments are performed on an Intel iPSC/860 machine to investigate the relationship between the algorithmic performance and the block size used. Our results show that the special case $s = 1$ gives the worst performance. For fixed p and h, the running time initially decreases rapidly as the block size increases. Once the best performance is achieved, the running time increases slowly as the block size increases. The running times are virtually indistinguishable at the neighborhood of the optimal block size for given h and p. Therefore, it is not necessary to determine the optimal block size exactly. As an illustration, experimental results for $p = 32$ and $h = 600, 700, 800$ are shown in Fig. 4. Block sizes equal to $1, 2, \ldots, 40$ are used. The same kind of relationship is observed for other values of p and h.

The optimal block sizes for $p = 8$, 16, and 32 are shown in Table 1 under column "s." The columns under "time" and "mflops" show the corresponding running times and floating-point execution rates in megaflops per second, respectively. Floating-point operations are performed in double-precision arithmetic. Since the dense submatrices involved in the numerical kernel of our parallel sparse QR factorization algorithm are of order 100 to 900, the range of h shown in Table 1 is between 100 and 900. Let $s(h, p)$ denote an optimal block size for merging two $h \times h$ upper triangular matrices on p processors. Table 1 shows that optimal block sizes for $p = 8, 16, 32$ can be expressed as

$$(1) \qquad s(h, p) = \lceil 2h/(5p) \rceil.$$

Experimental results for $p = 2, 4$ have also been obtained. Optimal block sizes for $p = 2, 4$ can be expressed as

$$(2) \qquad s(h, p) = \lceil h/(3p) \rceil.$$

TABLE 1

Optimal block sizes and corresponding performance results on an Intel iPSC/860 machine.

h	$p=8$			$p=16$			$p=32$		
	s	time	mflops	s	time	mflops	s	time	mflops

Revised equal-volume partitioning scheme. Because of the triangular shape of the matrices, the equal-row partitioning scheme may result in load imbalance since the blocks become smaller and smaller toward the end. To correct this, we propose schemes that partition the upper triangular matrices V and W into blocks with nondecreasing number of rows. The *equal-volume partitioning scheme* introduced in [30] is one of such schemes. This scheme partitions V and W identically into k blocks by rows. Each block consists of a set of contiguous rows and contains about $h(h+1)/(2k)$ elements. Assume that the number of rows and the number of columns in the ith block are denoted by r_i and c_i, respectively. Then

$$\frac{c_i(c_i+1)}{2} \approx \frac{h(h+1)}{2}\left(\frac{k-i}{k}\right), \tag{3}$$

$$c_i \approx \sqrt{\frac{k-i}{k}}\,h, \quad \text{and} \quad r_i \approx \frac{\sqrt{k-i}-\sqrt{k-i-1}}{\sqrt{k}}\,h. \tag{4}$$

Notice that $\sum_{i=0}^{k-1} r_i = h$. It is easy to show $r_i \leq r_{i+1}$ for $0 \leq i < k-1$.

Now we propose a revised equal-volume partitioning scheme. Let k be the expected number of blocks to be partitioned. The revised equal-volume partitioning scheme actually partitions V and W into $l(l \leq k)$ blocks such that the ith block has $r_i + d$ $(d \geq 0)$ rows, where r_i is defined as in (4) and $d \geq 0$. This revised scheme is precisely the equal-volume partitioning scheme when $d = 0$. Clearly, $r_i + d \leq r_{i+1} + d$ for $0 \leq i < l-1$. The number of blocks l can be determined from $\sum_{i=0}^{l-1}(r_i + d) = h$. Our empirical results indicate that the optimal value for d is 3. Experimental results on 32 processors for $h = 800$ and $d = 0, 3, 6$ are shown in Fig. 5. In the remainder of this paper, $d = 3$ is assumed for the revised equal-volume partitioning scheme.

Depending on the number of processors used, the equal-row partitioning scheme with block size specified by expression (1) or (2) is referred to as the equal-row partitioning scheme with optimal block partition. Similarly, the revised equal-volume partitioning scheme with the expected number of blocks to be partitioned given by $h/s(h, p)$ is referred to as the revised equal-volume partitioning scheme with optimal block partition. The performance results of these two schemes with optimal block partition are compared in Fig. 6. The revised equal-volume partitioning scheme is, in general, more efficient than the equal-row partitioning scheme.

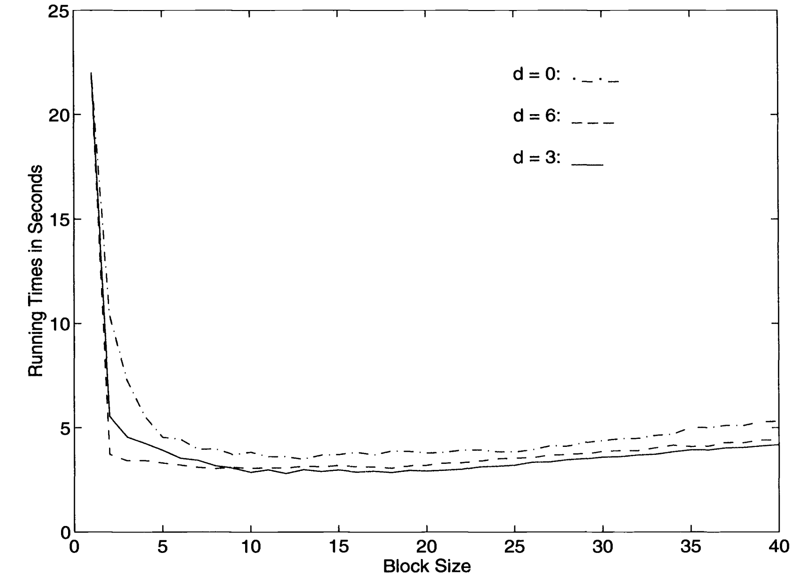

FIG. 5. *Revised equal-volume partitioning scheme with $p = 32$, $h = 800$, and $d = 0, 3, 6$ on an iPSC/860.*

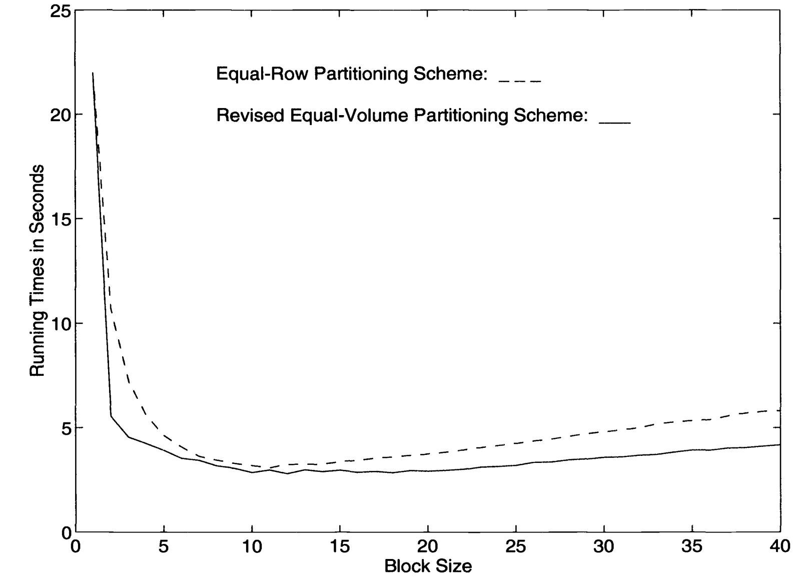

FIG. 6. *Comparison of the two partitioning schemes with $p = 32$ and $h = 800$ on an iPSC/860.*

Row-oriented kernel versus column-oriented kernel. Assume that V_i and W_j are 4×5 upper trapezoidal blocks. Two ways of merging V_i into W_j are shown below:

$$\begin{bmatrix} W_j \\ V_i \end{bmatrix} \Rightarrow \begin{bmatrix} x & x & x & x & x \\ & x & x & x & x \\ & & x & x & x \\ & & & x & x \\ 1 & 2 & 3 & 4 & x \\ & 5 & 6 & 7 & 8 \\ & & 9 & 10 & 11 \\ & & & 12 & 13 \end{bmatrix} \quad \text{or} \quad \begin{bmatrix} x & x & x & x & x \\ & x & x & x & x \\ & & x & x & x \\ & & & x & x \\ 1 & 2 & 4 & 7 & x \\ & 3 & 5 & 8 & 11 \\ & & 6 & 9 & 12 \\ & & & 10 & 13 \end{bmatrix}.$$

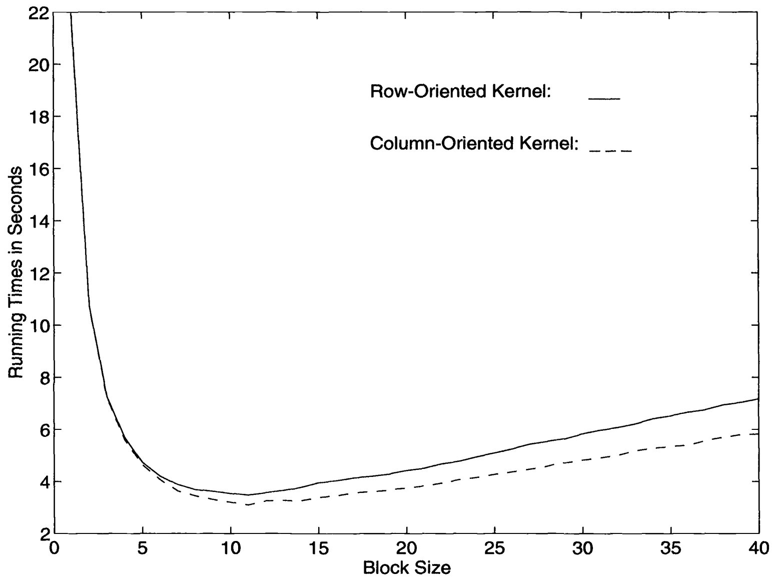

FIG. 7. *Comparison of the row-oriented and the column-oriented kernels with* $p = 32$ *and* $h = 800$ *on an iPSC/860.*

The numbers show the order in which the elements of V_i are annihilated. These two approaches correspond to merging V_i into W_j by rows and by columns, respectively. If the block size—i.e., the number of rows in V_i—is reasonably large, the column-oriented kernel is more efficient than the row-oriented kernel. The reason is that in the column-oriented kernel a rectangular submatrix of V_i is rotated into a row in W_j so this row in W_j is repetitively accessed. Therefore, the cache is better utilized and, consequently, the performance of the numerical kernel is improved. This is confirmed by the empirical results shown in Fig. 7. As the block size increases, a row in W_j is repetitively accessed more frequently in the column-oriented kernel. Therefore, the cache utilization of the column-oriented kernel gets better and it becomes increasingly more efficient than the row-oriented kernel as the block size increases.

3.3. Parallel computation of a frontal matrix. In order to compute a frontal matrix F_K in parallel, we have designed parallel algorithms for assembling the update matrix of a child of K into F_K, merging the update matrix of a child of K into F_K, and merging relevant rows from A into F_K. These algorithms correspond to lines 13, 16, and 19 in Fig. 3, respectively.

To simplify our discussion, we take the 7 x 7 nine-point grid with nested dissection ordering as an example. A portion of its supernodal elimination tree consists of supernodes $K = \{19, 20, 21\}$, $C = \{7, 8, 9\}$, and $D = \{16, 17, 18\}$. Supernodes C and D are the only children of supernode K. The frontal matrices F_K, F_C, and F_D are illustrated in Fig. 8, where the row numbers displayed with a frontal matrix show its sparsity structure.

We assume that F_K is partitioned among four processors $\{\mu_0, \mu_1, \mu_2, \mu_3\}$, F_C is partitioned among μ_0 and μ_1, and F_D is partitioned among μ_2 and μ_3, respectively. The solid lines inside the triangles in Fig. 8 show one way of partitioning F_K, F_C, and F_D into blocks.

Suppose that the frontal matrices F_C and F_D have already been computed. The update matrix U_C is the second block of F_C and is assigned to μ_1. Similarly, the update matrix U_D is the second block of F_D and is assigned to μ_3. Based on the sparsity structure of U_C, U_D, and F_K, the update matrices U_C and U_D are further partitioned into subblocks shown by the dash lines in Fig. 8.

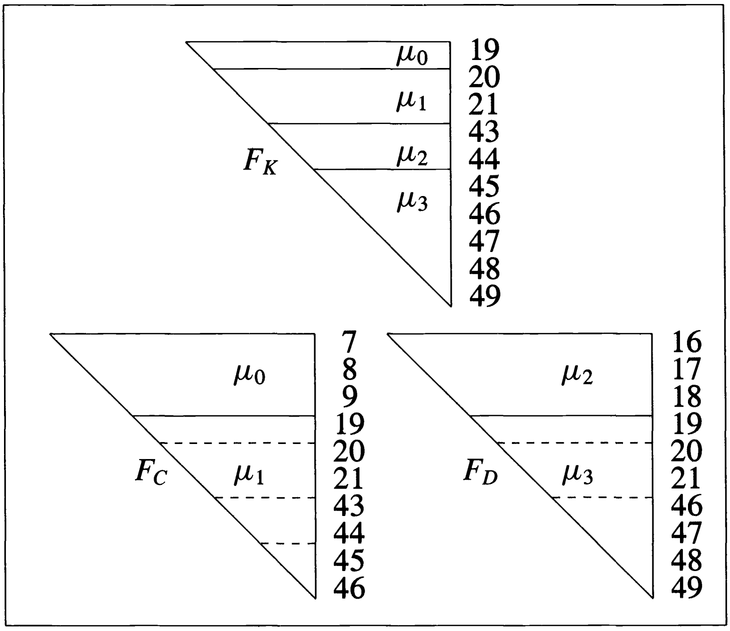

FIG. 8. *Parallel computation of a frontal matrix.*

Suppose U_C has already been assembled into F_K. Now we consider merging U_D into F_K. A subblock B of U_D is sent to a processor involved for computing F_K if the processor owns a block B_K of F_K such that the row numbers of B are contained in the row numbers of B_K. For instance, the second subblock of U_D owned by μ_3 is sent to μ_1 which owns the second block of F_K.

Once a subblock B is received by a processor, it is conceptually extended to a temporary block by the matrix *extend-add* operation introduced in [20] and this temporary block is then rotated into a block B_K owned by the processor. The result of rotating B into B_K is another upper trapezoidal block $\hat{B}$. If $\hat{B}$ is not empty, it is sent to the processor which owns the block just below the block B_K in F_K. Notice that the number of rows in $\hat{B}$ is less than or equal to the number of rows in B since block B_K may contain zero rows. Eventually, the newly created block $\hat{B}$ is merged into the remaining blocks of F_K, successively.

In order to complete the computation of F_K, a row from A whose first nonzero is in column j of A such that $i \leq j < i + |K|$ must be rotated into F_K, where i is the first row in K. The rows in the submatrix A_j, defined in §2, form a rectangular block with at most $|\mathcal{R}_j|$ nonzero columns. This block is rotated into F_K starting with a block B_K of F_K such that row $j - i$ of F_K is in block B_K. The resulting block is rotated into the remaining blocks of F_K, successively.

4. Analysis of regular grid problems. In this section, we present the complexity analysis of our parallel sparse QR factorization algorithm based on a special equal-volume partitioning scheme for regular grid problems. We compare our results with those provided in [5]. To be consistent with the results in [5], we count only the number of multiplications in our analysis.

We focus on the equal-volume partitioning scheme in which an $h \times h$ frontal matrix distributed among p processors is partitioned into p blocks. It seems to be very difficult or impossible to obtain the complexity results of an arbitrary equal-row or equal-volume partitioning scheme. The analytical results obtained for a special case of the equal-volume partitioning scheme would shed light on the performance of an arbitrary equal-row or equal-volume partitioning scheme from a theoretical angle.

Our goal is to obtain an upper bound on the overall execution time of our parallel sparse QR factorization algorithm. There are two levels of analysis. In the outer level, the supernodal elimination tree is mapped onto node processors by the subtree-to-subcube mapping scheme [13]. We identify a heaviest path of the supernodal elimination tree. The heaviest path consists of a sequence of computational tasks each of which is the computation of a frontal matrix. Careful exploration of the heaviest path leads to an upper bound on the execution time of our algorithm. In the inner level, we investigate the cost of computing a frontal matrix in parallel. The processors assigned for the task start execution at the same time. We identify a processor μ that has the most work to do and finishes its share of the task last. We characterize the sequence of subtasks executed by the processor μ. We show that there is no or very little gap between the subtasks executed by μ. Therefore, the time complexity of computing a frontal matrix in parallel is simply the sum of the time complexities of subtasks executed by μ.

The communication model assumed in our analysis is briefly described here. Consider the transmission of a message from one processor μ to another processor $\hat{\mu}$. The completion of the *send* operation on μ does not imply that the message has been received by $\hat{\mu}$, only that the message has been sent and the buffer space for the message on μ can be reused. Once the corresponding *receive* is issued by $\hat{\mu}$, processor $\hat{\mu}$ waits until the message arrives in the specified buffer. An example of this model is the communication model used on an Intel iPSC/2 or Intel iPSC/860 machine [15]. In this model, the cost of transmitting a message is charged to the receiver. Let τ denote the ratio of the time for transmitting one floating-point number from one processor to another processor to the time for one floating-point multiplication.

4.1. Analysis of the parallel numerical kernel. Consider two $h \times h$ upper triangular matrices V and W which are identically partitioned by our equal-volume partitioning scheme into p blocks as

$$V = \begin{bmatrix} V_0 \\ V_1 \\ \vdots \\ V_{p-1} \end{bmatrix} \quad \text{and} \quad W = \begin{bmatrix} W_0 \\ W_1 \\ \vdots \\ W_{p-1} \end{bmatrix}.$$

Blocks V_i and W_i are assigned to processor μ_i, $0 \le i < p$. The number of rows and the number of columns in the ith block are defined as in (4) in §3.2 except that k is replaced by p.

The total number of multiplications for merging V into W is $2h(h+1)(h+2)/3$. The tasks involved in merging V into W are illustrated in Fig. 9, where $M(V_i, W_i)(0 \le i < p)$ is the task for merging V_i into W_i, $M(V_i, V_j)(i < j)$ is the task for merging the transformed block V_i into the transformed block W_j, and $C(V_i, \mu_j, \mu_k)$ is the task for receiving the transformed block V_i from processor μ_j by processor μ_k, where $k = j + 1 \bmod p$. For simplicity, p is assumed to be 4 in Fig. 9. Clearly, the last processor has the most work to do and finishes its execution last.

Now we examine the tasks assigned to μ_{p-1} in detail. Since $|V_i| \approx |V_{i-1}|$, the arithmetic work for $M(V_i, W_i)$ is about the same as the arithmetic work for $M(V_{i-1}, W_{i-1})$. Processors μ_2 and μ_3 start execution at the same time and they finish $M(V_2, W_2)$ and $M(V_3, W_3)$ at about the same time. Then μ_3 waits for the transmission of the transformed block V_2 from μ_2 to μ_3. Therefore, there is no gap or little gap between $M(V_3, W_3)$ and $C(V_2, \mu_2, \mu_3)$. Obviously, there is no gap between $C(V_2, \mu_2, \mu_3)$ and $M(V_2, W_3)$.

$$\begin{tikzcd}
\mu_0 & \mu_1 & \mu_2 & \mu_3 \\
M(V_0, W_0) & M(V_1, W_1) \arrow[d] & M(V_2, W_2) \arrow[d] & M(V_3, W_3) \arrow[d] \\
 & C(V_0, \mu_0, \mu_1) \arrow[d] & C(V_1, \mu_1, \mu_2) \arrow[d] & C(V_2, \mu_2, \mu_3) \arrow[d] \\
 & M(V_0, W_1) & M(V_1, W_2) \arrow[d] & M(V_2, W_3) \arrow[d] \\
 & & C(V_0, \mu_1, \mu_2) \arrow[d] & C(V_1, \mu_2, \mu_3) \arrow[d] \\
 & & M(V_0, W_2) & M(V_1, W_3) \arrow[d] \\
 & & & C(V_0, \mu_2, \mu_3) \arrow[d] \\
 & & & M(V_0, W_3)
\end{tikzcd}$$

FIG. 9. *Tasks for merging V into W on four processors.*

It can be easily shown that the arithmetic work in $M(V_i, W_j)$ is slightly greater than the arithmetic work in $M(V_{i-1}, W_{j-1})$. Once $M(V_2, W_3)$ is finished, the desired message is ready to be received. Hence, there is no gap between $M(V_2, W_3)$ and $C(V_1, \mu_2, \mu_3)$. Similar arguments can be extended to the rest of the tasks executed by μ_3. Therefore, there is no gap or little gap among the tasks executed by μ_3. The discussion for this example is equally valid for a general p.

Since the total number of messages communicated by μ_{p-1} is only $p-1$, the start-up costs for the $p-1$ messages are ignored and the cost for the task $C(V_i, \mu_{p-2}, \mu_{p-1})$ is estimated by the communication volume, i.e., the number of floating-point numbers communicated by the task $C(V_i, \mu_{p-2}, \mu_{p-1})$.

The above analysis shows that the arithmetic and communication complexities for merging V into W on p processors can be obtained by considering the communication volume and the arithmetic work on the last processor μ_{p-1}. Let ℓ be the number of rows in V_{p-1} or W_{p-1}. Then $\ell \approx h/\sqrt{p}$.

Since the total number of rows received by the last processor is $h - \ell$ and each row is of length at most ℓ, the total number of numerical values received by the last processor is bounded above by $(h - \ell)\ell$. Therefore, an upper bound on the communication cost for merging two $h \times h$ upper triangular matrices on p processors is

$$\text{comm}(h, p) = \frac{h^2\tau}{\sqrt{p}} - \frac{h^2\tau}{p}.$$

The work performed by the last processor is bounded above by the arithmetic work required for merging an $(h - \ell) \times \ell$ matrix into an $\ell \times \ell$ upper triangular matrix plus the arithmetic work for merging two $\ell \times \ell$ upper triangular matrices. Therefore, an upper bound on the arithmetic work for merging two $h \times h$ upper triangular matrices on p processors is

$$\text{work}(h, p) = 2\frac{h^3}{p} - \frac{4}{3}\frac{h^3}{p\sqrt{p}} + 2\frac{h^2}{\sqrt{p}} + \frac{4}{3}\frac{h}{\sqrt{p}}.$$

4.2. Analysis of the parallel sparse QR factorization algorithm. Now we analyze the performance of our parallel sparse QR factorization algorithm applied to regular grid problems with nested dissection ordering [7]. Consider a $k \times k$ grid with $(k-1)^2$ small squares. Associated with each square is a set of four equations involving the four variables at the corners of the square. The assembly of these equations results in a sparse overdetermined system of equations $Ax = b$, where A is a $4(k-1)^2 \times k^2$ sparse matrix.

The supernodal elimination tree of a grid problem is a complete binary tree and is mapped onto node processors by the subtree-to-subcube mapping scheme [13]. The frontal matrices are partitioned by our special equal-volume partitioning scheme. A frontal matrix F_K is computed by merging the two update matrices U_1 and U_2 of the children of K. The size of the update matrix of a supernode is at most the size of the frontal matrix of its parent. Assume that the frontal matrix F_K is of order h and it is mapped to p processors. One update matrix U_1 is assembled into F_K and the other update matrix U_2 is merged into F_K. Before U_2 can be merged into F_K, it needs to be appropriately distributed among the p processors. This is equivalent to a parallel assembly of U_2 into F_K. After U_2 is properly distributed among the p processors, U_2 is merged into F_K as in the dense case.

The arithmetic work for merging U_2 into F_K is bounded above by the arithmetic work for merging two $h \times h$ upper triangular matrices in parallel since the size of U_2 is at most the size of F_K. Therefore, an upper bound on the arithmetic work for computing a frontal matrix F_K of order h on p processors is given by work(h, p).

The worst scenario in an assembly operation is that a processor receives $h(h+1)/2p$ numerical values. The communication cost for computing a frontal matrix F_K of order h on p processors is bounded above by the communication cost for assembling U_1 and U_2 into F_K on p processors and the communication cost for merging two $h \times h$ upper triangular matrices on p processors. Therefore, an upper bound on the communication cost for computing a frontal matrix F_K of order h on p processors is

$$\frac{2h(h+1)\tau}{2p} + \text{comm}(h, p) = \frac{h^2\tau}{\sqrt{p}} + \frac{h\tau}{p}.$$

Consider the supernodal elimination tree corresponding to a $k \times k$ grid with nested dissection ordering, where $k = 2^t - 1$ and t is a positive integer. Let $m_j = 2^{t-j} - 1$. The characterization of a heaviest path in the supernodal elimination tree is given in Table 2, where n_i is the size of the frontal matrix on the heaviest path at level i. The root is considered to be at level 1. The reader is referred to [28] for details on the characterization of the supernodal elimination tree associated with a regular grid.

Assume that p is a power of 4. The upper bounds for the arithmetic and communication costs of our algorithm with the special block partition and the conventional row-oriented algorithm are presented in Table 3, where $c_1 = (343 + 250\sqrt{2})/3\sqrt{2}$, $c_2 = (8801\sqrt{2} - 6202)/21\sqrt{2}$, $c_3 = (103 + 72\sqrt{2})/4\sqrt{2}$, and $c_4 = (49 + 50\sqrt{2})/\sqrt{2}$. The results of the row-oriented algorithm are taken from [5]. Under a reasonable assumption that p is less than the number of columns k^2, the communication complexity of our algorithm with the special block partition is much better. The overall time complexity of our algorithm with the special block partition is $1229k^3/4p + O(k^3 \log p/p^{3/2})$ and that of the row-oriented algorithm is $146k^3/3p + 146k^3\tau/12p + O(k^3\tau/p^{3/2})$. If $\tau \geq 22$, the overall complexity of our algorithm with the special block partition is better. Dunigan [6] has shown that the values of τ for

special block partition	$\frac{1229}{4}\frac{k^3}{p} - c_1\frac{k^3 \log p}{p^{3/2}} - c_2\frac{k^3}{p^{3/2}} + O(\frac{k^2}{\sqrt{p}})$	$c_3\frac{k^2\tau}{\sqrt{p}} - c_4\frac{k^2\tau}{p} + O(\frac{k\tau \log p}{\sqrt{p}})$
row-oriented partition	$\frac{146}{3}\frac{k^3}{p} + 31\frac{k^2 \log k}{p} + O(\frac{k^2}{p})$	$\frac{146}{12}\frac{k^3\tau}{p} - \frac{371}{12}\frac{k^3\tau}{p^{3/2}} + O(k^2\tau \log p)$

iPSC/2 and iPSC/860 are roughly 59 and 1000, respectively. Note that the communication cost dominates the arithmetic cost in the row-oriented approach.

The results shown in Table 3 are the complexity results of the algorithms which are based on two extreme partitioning schemes in which an $h \times h$ frontal matrix distributed among p processors is partitioned into h and p blocks, respectively. Therefore, it can be expected that the arithmetic complexity of our algorithm based on an arbitrary equal-row or equal-volume partitioning scheme is between the complexity bounds of the row-oriented algorithm and our algorithm with the special block partition. Similarly, the communication complexity of our algorithm based on an arbitrary equal-row or equal-volume partitioning scheme is between the complexity bounds of our algorithm with the special block partition and the row-oriented algorithm.

5. Experimental results. Our parallel multifrontal sparse QR factorization algorithm has been tested on a 32-node iPSC/860 machine for a set of problems including regular grid problems and practical problems with irregular sparsity structure. The practical problems include large and sparse linear least squares problems arising from particle methods for modelling turbulent combustion [25] and a large-problem NIMBUS from the Bramley test set used in [21]. The sparse linear least squares problems for modelling turbulent combustion correspond to three-dimensional $k \times k \times k$ 27-point grids. There are a number of particles associated with each cubic element. A particle corresponds to an equation involving the eight variables at the corners of the cubic element. Assume that a cubic element contains eight particles. The assembly of the equations corresponding to all particles results in a sparse overdetermined system of equations $Ax = b$, where A is an $8(k-1)^3$ by k^3 sparse matrix. The regular grid problems and the problems for modelling turbulent combustion are ordered by the nested dissection ordering [7]. The general sparse problem is ordered by the minimum degree ordering [12].

The characteristics of the test problems are shown in Table 4, where m is the number of rows, n the number of columns, $|A|$ the number of nonzeros in matrix A, and $|R|$ the number of nonzeros in factor R. "GRIDk" represents a $k \times k$ nine-point grid. "TCk" represents a problem for modelling turbulent combustion and corresponds to a three-dimensional $k \times k \times k$ 27-point grid. The QR factorization method described in [14] is used to solve these sparse linear least squares problems on an Intel iPSC/860 machine. The sparse QR factorization is computed by our parallel multifrontal approach described in §3. Both the equal-row partitioning scheme

TABLE 4

NIMBUS	23871	1325	181972	136356

and the revised equal-volume partitioning scheme are used. The orthogonal transformations are applied to the right-hand-side vector b and then discarded. The required parallel-sparse back-substitution algorithm is described in [29, 31]. The column-oriented kernel is used in our implementation.

Let h be the order of a frontal matrix that is assigned to p processors. We explore four instances of the equal-row partitioning scheme with block sizes equal to 1, h/p^2, $s(h, p)$ as defined in §3.2, and h/p, respectively. For convenience, the versions of our parallel sparse QR factorization algorithm, which use these four instances of the equal-row partitioning scheme in their kernels, are referred to as algorithms ERP1, ERP2, ERP, and ERPP, respectively. We explore two instances of the revised equal-volume partitioning scheme with block sizes corresponding to $s(h, p)$ as defined in §3.2 and h/p, respectively. The versions of our parallel sparse QR factorization algorithm, which use these two instances of the revised equal-volume partitioning scheme in their kernels, are referred to as algorithm EVP and EVPP, respectively. Note that ERP1 is the row-oriented approach proposed in [5] and ERP2 is only suggested as a future research topic in [5]. ERP and EVP are algorithms with optimal block partition.

We evaluate the practical performance of these six parallel sparse QR factorization algorithms on a 32-node Intel iPSC/860 machine. All algorithms are implemented in C and double-precision floating-point arithmetic is used. A dense Givens rotation is implemented as a call to the subroutine `drot` in the highly optimized Basic Math Library provided by Intel. No assembler code other than calls to `drot` is used. The compilation optimization level used is −O4.

We have obtained the running times, communication statistics, and load balance results of the six algorithms for all of our test problems. To save space, the communication statistics and load balance results are presented only for regular grid problems GRID200 and GRID255 on 32 processors. The relative performance of the six algorithms for regular grid problems on a smaller number of processors is the same as that on 32 processors. The relative performance of the six algorithms for other problems is similar to that for these two regular grid problems.

In Table 5, messages communicated per processor are tabulated. The column under "Fact Alg" shows the algorithm used in the numerical factorization. The "max," "min," and "avg" under the "Total # Msgs" are the maximum number, minimum number, and average number of messages communicated by a processor including both messages sent and messages received, respectively. The "max" and "min" under the "# Msgs Sent" are the maximum number and minimum number of messages sent by a processor, respectively. The "max" and "min" under the "# Msgs Recv" are the number of messages received by a processor. The average number of messages sent by a processor is the same as the average number of messages received by a processor and is equal to half of the average number of messages communicated by a processor. For both the equal-row partitioning scheme and the revised equal-volume partitioning scheme, the number of messages required decreases as the block size increases. The number of messages required by EVP is less than that required by ERP since EVP

partitions a frontal matrix into fewer blocks than ERP does. Similarly, EVPP communicates fewer messages than ERPP.

In Table 6, the volume of messages communicated per processor is shown. The total volume communicated by a processor is defined as the total number of floating-point double-precision numbers communicated by that processor. The volume sent by a processor is defined as the total number of floating-point double-precision numbers sent by the processor. The volume received is similarly defined. The last column in Table 6 is the average length of all messages obtained by dividing the total communication volume by total number of messages. For both the equal-row partitioning scheme and the revised equal-volume partitioning scheme, the required communication volume decreases as the block size increases.

Consider Tables 5 and 6 together. Clearly, ERP1 and ERP2 require excessive messages and excessive communication volume. For an $h \times h$ frontal matrix partitioned among p processors, the block size for ERP2 is $s = h/p^2$. For reasonable large problem, s is too small. For instance, the root frontal matrix of TC27 is 729 × 729 and is partitioned among 32 processors. Therefore, s is less than one and is set to one in our experiment. The order of the six algorithms in decreasing communication requirements is ERP1, ERP2, ERP, EVP, ERPP, and EVPP. EVPP and EVP are better than ERPP and ERP in terms of communication costs, respectively. The four algorithms ERP, ERPP, EVP, and EVPP communicate relatively long messages. This feature is desirable for distributed-memory multiprocessors

TABLE 7
Load distribution among processors ($p = 32$).

Problem	Fact alg	Max/Avg	Min/Avg
GRID200	ERP1	1.219	0.717
	ERP2	1.290	0.726
	ERP	1.260	0.707
	ERPP	1.514	0.428
	EVP	1.245	0.731
	EVPP	1.313	0.540
GRID255	ERP1	1.230	0.720
	ERP2	1.310	0.705
	ERP	1.273	0.690
	ERPP	1.538	0.412
	EVP	1.254	0.700
	EVPP	1.323	0.531

since the overhead associated with short messages is relatively higher than that associated with long messages.

Load balance results are shown in Table 7. "Max/Avg" is the ratio of the maximum number of floating-point operations performed by a processor to the average number of floating-point operations performed by a processor during the numerical factorization. "Min/Avg" is the ratio of the minimum number of floating-point operations performed by a processor to the average number of floating-point operations performed by a processor during the numerical factorization. A floating-point operation or flop is either a multiplicative or an additive operation. The number of flops performed by a processor is obtained by counting the actual number of flops performed by that processor during the numerical factorization. Roughly, the order of the six algorithms from the least balanced workload distribution to the most balanced workload distribution is ERPP, EVPP, ERP2, ERP, EVP, and ERP1. The difference in workload distribution among ERP2, ERP, EVP, and ERP1 is relatively small. However, the difference between these four algorithms and ERPP or EVPP is fairly pronounced. EVPP and EVP produce better load distribution than ERPP and ERP, respectively.

The running times of the three algorithms ERP2, ERP, and EVP for all test problems on a 32-node Intel iPSC/860 are shown in Table 8. To save space, the running times of the three algorithms ERP1, ERPP, and EVPP are shown in Table 9 for the regular grid problems only. The column under "time" is the running time for the numerical factorization in seconds, which is obtained by measuring the time spent on each processor and taking the maximum time spent on a processor. All processors start at the same time. The "mflops" is the execution rate defined as the number of megaflops performed per second during the numerical factorization. The "time" in Tables 8 and 9 includes the time for applying the Givens rotations to the right-hand-side vector b for all six algorithms; i.e., the time for $Q^T b$ is included in the numerical factorization time.

Due to insufficient storage space on node processors, some test problems cannot be run on a small number of processors. If a test problem can be run on $p = 2^i (0 \leq i \leq 5)$ processors, its timing results on p processors are reported. The running time for a problem on one processor is the time spent by the best serial sparse QR factorization algorithm we have for that problem on one processor.

From Tables 8 and 9 we observe that the order of the six algorithms in increasing efficiency is ERP1, ERP2, ERPP, EVPP, ERP, and EVP. These timing results are in agreement with the communication and workload distribution statistics shown in Tables 5, 6, and 7. Because of the excessive communication requirements, ERP1 and ERP2 are significantly worse than the other four algorithms in performance. ERPP and EVPP are inferior to ERP and EVP. Since

EVP requires fewer messages and less communication volume than ERP, and EVP produces a more balanced workload distribution than ERP, EVP is more efficient than ERP. Similarly, EVPP is more efficient than ERPP. It is worth noting that EVPP looks promising. One of the advantages of EVPP or ERPP is that it is not necessary to determine the optimal block partitions for a new machine. The performance of all six algorithms for the general sparse problem NIMBUS is worse than that for regular grid problems because of the unbalanced supernodal elimination tree associated with NIMBUS. Speedups for problem GRID100 are shown in Table 10.

6. Concluding remarks. We have described an efficient block-oriented approach to parallel multifrontal sparse QR factorization on distributed-memory multiprocessors. We have proposed novel block schemes for partitioning frontal matrices and explored a spectrum of

block partitioning schemes ranging from the conventional single-row partition to the block partition with maximal block size. Our block-oriented approach results in an efficient parallel sparse QR factorization algorithm with low communication costs, relatively balanced arithmetic work distribution among processors, and a fast parallel-numerical kernel due to the enhanced cache utilization. We have presented both complexity results of our parallel algorithm for regular grid problems and experimental results of an implementation of our parallel algorithm on an Intel iPSC/860 machine. We have demonstrated that our new block-oriented algorithm achieves significant improvement in performance over the conventional nonblock algorithm [5].

Our approach is especially suitable for machines that communicate long messages much more efficiently than they communicate short messages, such as the IBM SP1 system, since relatively long messages are used in our algorithm. An implementation of our parallel sparse QR factorization algorithm on an IBM SP1 system is currently being pursued. We are also extending our algorithm to compute the QR factorization of a sparse matrix with rank deficiency in parallel.

In the implementation of our parallel sparse QR factorization algorithm, the orthogonal matrix Q is not computed since it is often too expensive to store Q in the main memory when A is large. A sparse linear least squares problem $\min_x \|Ax - b\|$ is solved by applying the orthogonal transformations to the right-hand-side vector b during the sparse QR factorization. This approach is numerically backward stable. However, the right-hand-side vector must be available before A is factorized. The method of corrected seminormal equations (CSNE) proposed by Björck [4] can be used to handle new right sides without storing Q. Björck [4] has shown that the CSNE method is, in general, as accurate as the QR factorization method. However, it is not always backward stable and may not be accurate for "stiff" problems. A parallel multifrontal algorithm for solving sparse linear least squares problems on distributed-memory multiprocessors based on the CSNE method is described in [31].

Acknowledgments. I would like to thank Thomas F. Coleman for many discussions relating to this work and for his helpful comments and suggestions on the manuscript. I would also like to thank the referees for their constructive comments and suggestions. Numerical experiments were performed on a 32-node Intel iPSC/860 machine in the Computer Science Department, Cornell University.

A PARALLEL ALGORITHM FOR THE SYLVESTER OBSERVER EQUATION*

CHRISTIAN H. BISCHOF[†], BISWA NATH DATTA[‡], AND AVIJIT PURKAYASTHA[§]

Abstract. We present a new algorithm for solving the Sylvester observer equation arising in the context of the Luenberger observer. The algorithm embodies two main computational phases: the solution of several independent equation systems and a series of matrix-matrix multiplications. The algorithm is, thus, well suited for parallel and high-performance computing. By reducing the coefficient matrix A to lower-Hessenberg form, one can implement the algorithm efficiently, with few floating-point operations and little workspace. The algorithm has been successfully implemented on a CRAY C90. A comparison, both theoretical and experimental, has been made with the well-known Hessenberg-Schur algorithm which solves an arbitrary Sylvester equation. Our theoretical analysis and experimental results confirm the superiority of the proposed algorithm, both in efficiency and speed, over the Hessenberg-Schur algorithm.

Key words. Sylvester observer equation, parallel algorithm, orthogonal factorization, shared-memory parallelism, Hessenberg-Schur algorithm

1. Introduction. The Luenberger observer problem (see [12]) for the control system

$$\begin{aligned} \dot{x} &= Ax + Bu, \\ y &= Cx \end{aligned} \tag{1}$$

arises frequently in control theory. Its solution leads to a Sylvester-type matrix equation:

$$AX - XH = CV. \tag{2}$$

In contrast with the usual Sylvester equation, here only A and C are given, while X, H, and V are to be chosen to satisfy certain requirements. We call (2) the *Sylvester observer equation.* The requirements for choosing H and V are as follows:

(3)
