- H must be stable; that is, all the eigenvalues of H should have negative real parts.
- The spectrum of H must be disjoint from that of A (to ensure that X is the unique solution of (2)).
- V must be such that (H^t, V^t) be controllable; that is, the matrix

$$\begin{bmatrix} V^t, & H^tV^t, \dots, (H^t)^{n-1}V^t \end{bmatrix}$$

has rank n.

Since we are free to choose H as long as it satisfies the above criteria, we can choose it as a block upper-Hessenberg matrix with a suitable preassigned spectrum. It can then be shown quite easily that, for this particular structure of H, and

$$V = \begin{pmatrix} 0, & 0, \dots, & 0, & I \end{pmatrix},$$

partitioned conformally, (H^t, V^t) is controllable. This choice of V then reduces (2) to the form

$$AX - XH = \begin{pmatrix} 0, & 0, & \ldots, & 0, & C \end{pmatrix}, \tag{4}$$

where A is a given an $n \times n$ matrix, C is an $n \times r$ matrix, H is a chosen $n \times n$ block upper-Hessenberg matrix with a preassigned spectrum, and X is an $n \times n$ matrix to be constructed. Because we can always choose V in this fashion, we simplified the notation in (2) by using C as shorthand for $C(:, n - r + 1 : n)$. It should be clear from the context whether the whole matrix or only its last r columns are meant.

If W is an invertible matrix, (2) is equivalent to

$$(WAW^{-1})(WX) - (WX)H = (WC)V, \tag{5}$$

and so one can reduce the complexity of the problem by applying a suitably chosen similarity transformation to A. For example, if we were to apply the well-known Hessenberg-Schur method developed by Golub, Nash, and Van Loan [10] for the usual Sylvester equation, to the Sylvester observer equation (4), A would be reduced to Hessenberg form and H to real Schur form (RSF). The RSF of a matrix is a quasi-triangular matrix in which the diagonal entries are either 1×1 or 2×2 matrices (see [11]). Because the matrix H can be chosen for the Sylvester observer equation, one can choose it in RSF with a desired set of eigenvalues on the diagonal and then easily solve for the columns of X. This approach, though numerically effective, does not offer as good a potential for parallelism as the proposed method. A more detailed discussion of this method, from the point of view of solving the Sylvester observer equation, is given in §5.

Another possible approach is the method suggested by Van Dooren [9]. It uses an observer-Hessenberg form for the pair (A, C) in which both A and C are put in certain condensed forms. This approach also requires knowledge of the eigenvalues of the matrix A and is recursive. Like the Hessenberg-Schur method, it computes the columns of X sequentially and does not offer much scope for the exploitation of parallelism.

Yet another approach, based on Arnoldi's method, has recently been proposed by Datta and Saad [3] for the case where C is a vector. It constructs an orthonormal solution to equation (4). The method is suitable for large and sparse problems but does not offer much scope for parallelism.

In this paper, we present a simple yet efficient method for solving (4) which is well suited for parallel and high-performance computers. The method is a block generalization of Datta's method [2] for the case when $r = 1$. In the case where C is $n \times r$, $r > 1$, our method entails solving a total of n independent systems of equations to compute the first r columns of X, and then obtaining the other columns of X, r at a time, essentially through matrix-matrix multiplications. Like the Hessenberg-Schur method, our approach assumes that A is a Hessenberg matrix, and we will not concern ourselves with the reduction of A to Hessenberg form, or the backtransformation of the solution. That is, unless otherwise noted, we assume in the sequel that A in (4) is a lower-Hessenberg matrix. We also note that in our approach, H will be chosen to be a block lower-bidiagonal matrix, with the blocks being diagonal themselves.

We also point out that parallel algorithms for control problems are virtually nonexistent, with only a few algorithms being proposed in recent years (for references to these algorithms, see the recent survey papers of Datta [4] and [5]). The need for expanded research in this area has been clearly outlined in a recent panel report [13].

The outline of the paper is as follows. In the next section we present the algorithm and prove its correctness. In §3 we describe how this algorithm can be implemented efficiently. We show that by initially reducing A to lower-Hessenberg form, and by employing an orthogonal reduction to solve the equation systems, we can fully exploit parallelism in the solution of the independent equation systems, while requiring little additional workspace. In §4 we report on results obtained on a CRAY C90 shared-memory multiprocessor. In §5 we show how to modify the Hessenberg-Schur method for solving the Sylvester observer equation. Results of its parallel implementation are also presented as a means of comparison with the proposed method. Last, we summarize our results and outline directions of further research.

2. The algorithm. In this section we present our algorithm for solving the Sylvester observer equation and prove its correctness. To repeat, we are trying to solve

$$AX - XH = (0, C), \tag{6}$$

where A and C are given $n \times n$ and $n \times r$ matrices, respectively; X is the sought-after $n \times n$ solution matrix; and H is an $n \times n$ matrix that we can choose as long as it satisfies the requirements of (3). In our algorithm we choose

$$H = \begin{bmatrix} \Lambda_{11} & & & & \\ \Lambda_{21} & \ddots & & & \\ & \ddots & \ddots & & \\ & & \ddots & \ddots & \\ & & & \Lambda_{k,k-1} & \Lambda_{kk} \end{bmatrix}. \tag{7}$$

Let

$$(\lambda_{11}, \lambda_{12}, \ldots, \lambda_{1r}), \ldots, (\lambda_{k1}, \lambda_{k2}, \ldots, \lambda_{kr})$$

be the eigenvalues assigned to the diagonal blocks $\Lambda_{11}, \ldots, \Lambda_{kk}$ of the block bidiagonal matrix H with off-diagonal blocks $\Lambda_{i,i-1}$. All of the blocks are of size $r \times r$, where r is the number of outputs or the number of columns of C, and k is the number of blocks such that $rk = n$. The subdiagonals $\Lambda_{i,i-1}$ containing the scaling factors of the ith block X_i will be computed as a byproduct of our solution algorithm such that (6) holds. We partition X conformally such that $X = (X_1, \ldots, X_k)$, where $X_i = (x_1^{(i)}, \ldots, x_r^{(i)})$, and let $C = (c_1, \ldots, c_r)$. In Figure 1 we give our algorithm to solve (6). We now prove the correctness of the algorithm.

THEOREM 2.1. *The algorithm in Figure* 1 *computes the solution of the Sylvester observer equation* (6).

Proof. First, we notice from the block-Hessenberg structure of H in (6) that the blocks X_i of the actual solution X are obtained from the blocks $\hat{X}_i$ of the computed solution $\hat{X}$ by the relation

$$X_{i+1}\Lambda_{i+1,i} = \hat{X}_{i+1} = AX_i - X_i\Lambda_{ii}, i = 1, \ldots, k-1,$$

where $\Lambda_{i+1,i}$ of H contain the 2-norm of the columns of the computed solution $\hat{X}_{i+1}$; that is, $\Lambda_{i+1,i} = \text{diag}(\|\hat{x}_1^{(i+1)}\|_2, \ldots, \|\hat{x}_r^{(i+1)}\|_2)$. Then the first two-block columns of (6) are related by the relation

$$\hat{X}_2 = X_2\Lambda_{2,1} = AX_1 - X_1\Lambda_{1,1}. \tag{8}$$

So if $x_j^{(2)}$ denotes the jth column of X_2, then

$$\hat{x}_j^{(2)} = \|\hat{x}_j^{(2)}\|_2 x_j^{(2)} = (A - \lambda_{1,j}I)x_j^{(1)} \tag{9}$$

```
Compute $X_1$, the first block of $X$:
    For $i = 1, \dots, r$ do
        For $j = 1, \dots, k$ do
            Solve $(A - \lambda_{j,i} I) y_j = c_i$ for $y_j$
            $\alpha_j = (\prod_{\substack{l=1 \\ l \neq j}}^{k} (\lambda_{ji} - \lambda_{li}))^{-1}$
        Enddo
        $x_i^{(1)} = \sum_{j=1}^{k} \alpha_j y_j$
    Enddo

Compute $X_2, \dots, X_k$, the remaining blocks of $X$:
    For $i = 1, 2, \dots, k - 1$ do
        $\hat{X}_{i+1} = A X_i - X_i \Lambda_{ii}$
        $\Lambda_{i+1,i} = \text{diag}(\|\hat{x}_1^{(i+1)}\|_2, \dots, \|\hat{x}_r^{(i+1)}\|_2)$
        $X_{i+1} = \hat{X}_{i+1} \Lambda_{i+1,i}^{-1}$
    End Do
```

FIG. 1. *Algorithm for the solution of the Sylvester observer equation.*

or

$$x_j^{(2)} = \frac{1}{\|\hat{x}_j^{(2)}\|_2} (A - \lambda_{1,j} I) x_j^{(1)}. \tag{10}$$

The remaining blocks $\hat{X}_3, \dots, \hat{X}_k$ then satisfy

$$\hat{X}_{i+1} = X_{i+1} \Lambda_{i+1,i} = A X_i - X_i \Lambda_{i,i}, \; i = 2, \dots, k - 1. \tag{11}$$

If we denote $\hat{x}_j^{(i)}$ to be the jth column of the ith block $\hat{X}_i$, (11) together with the diagonality of $\Lambda_{i,i}$ implies

$$\hat{x}_j^{(i)} = \|\hat{x}_j^{(i)}\|_2 x_j^{(i)} = \frac{(A - \lambda_{i-1,j} I)}{\|\hat{x}_j^{(i-1)}\|_2} \frac{(A - \lambda_{i-2,j} I)}{\|\hat{x}_j^{(i-2)}\|_2} \cdots \frac{(A - \lambda_{2,j} I)}{\|\hat{x}_j^{(2)}\|_2} (A - \lambda_{1,j} I) x_j^{(1)}. \tag{12}$$

Thus, $X_2, \dots, X_k$ are completely determined by X_1.

Then, comparing the last block column in (6), we obtain

$$A X_k - X_k \Lambda_{k,k} = C \tag{13}$$

or

$$(A - \lambda_{k,j} I) x_j^{(k)} = c_j, \; j = 1, \dots, r. \tag{14}$$

Substituting (12) into (14), we obtain

$$\frac{(A - \lambda_{k,j} I)}{\|\hat{x}_j^{(k)}\|_2} \frac{(A - \lambda_{k-1,j} I)}{\|\hat{x}_j^{(k-1)}\|_2} \cdots \frac{(A - \lambda_{2,j} I)}{\|\hat{x}_j^{(2)}\|_2} (A - \lambda_{1,j} I) x_j^{(1)} = c_j, \; j = 1, \dots, r, \tag{15}$$

or

$$(A - \lambda_{k,j} I)(A - \lambda_{k-1,j} I) \dots (A - \lambda_{1,j} I) x_j^{(1)} = \gamma_j c_j, \; j = 1, \dots, r, \tag{16}$$

where

$$\gamma_j = \prod_{i=2}^{k} (\|\hat{x}_j^{(i)}\|_2). \tag{17}$$

Thus, if we solve the polynomial system

$$x_j^{(1)} = p_j(A)^{-1}\gamma_j c_j, \text{ where } p_j(x) = (x - \lambda_{k,j})(x - \lambda_{k-1,j}) \dots (x - \lambda_{1,j}), \quad \text{for } j = 1, \dots, r, \tag{18}$$

we solve (6). □

As (18) indicates, the obvious bottleneck in a practical implementation of the algorithm is the solution of the polynomial system $p_j(A)x_j^{(1)} = \hat{c}_j$, where $\hat{c}_j = \gamma_j c_j$:

$$(A - \lambda_{k,j}I)(A - \lambda_{k-1,j}I) \dots (A - \lambda_{1,j}I)x_j^{(1)} = \hat{c}_j, \; j = 1, \dots, r. \tag{19}$$

The obvious way of solving this system is to successively solve the linear systems

$$(A - \lambda_{i,j}I)y_{i-1} = y_i, \quad i = k, k-1, \dots, 1 \tag{20}$$

with $y_k = c_j$ and $y_1 = x_j^{(1)}$ the final solution. For a very small k, this might not pose any problem. In general, however, it is not satisfactory as it is clearly too expensive. Direct methods for factorization are excluded because A is assumed to be very large. A more effective way, proposed in Datta and Saad [3], is as follows. If we define

$$q(t) = \prod_{j=1}^{k} (t - \lambda_{ji}), \tag{21}$$

the desired solution $x_j^{(1)}$ can be written as

$$x_j^{(1)} = \sum_{i=1}^{k} \frac{(A - \lambda_{i,j}I)^{-1}\hat{c}_j}{q'(\lambda_{i,j})}. \tag{22}$$

In other words, all we need is to solve k independent linear systems

$$(A - \lambda_{j,i}I)y_j = \hat{c}_i, \quad j = 1, \dots, k, \tag{23}$$

and then we obtain $x_j^{(1)}$ as the linear combination

$$x_j^{(1)} = \sum_{i=1}^{k} \alpha_i y_i, \tag{24}$$

where

$$\alpha_i = \left(\prod_{\substack{l=1 \\ l \neq i}}^{k} (\lambda_{i,j} - \lambda_{l,j}) \right)^{-1}. \tag{25}$$

In our experience, this approach for solving the matrix polynomial does not result in any stability problems for the solution of the Sylvester observer equation for different values of the output parameter. This experience is in line with the results in [3].

We note here that the algorithm in Figure 1 will break down if any of the eigenvalues of A and H are close: step 1 or (23) will be singular. By using an appropriate test matrix generator, however, we can guarantee that their spectra do not intersect. In general, we have observed experimentally that the spectra of H and A do not intersect for random matrices, although there is a small probability that they might.

3. Efficient implementation on a shared-memory multiprocessor. In this section we develop an efficient parallel algorithm for the Sylvester observer equation on a shared-memory multiprocessor.

The overall performance of the algorithm hinges critically on efficiently exploiting the apparent parallelism in the computation of X_1, where we have to solve n equation systems $(A - \lambda_{ji}I)y_j = c_i$. Omitting indices for simplicity, we can either use Gaussian elimination or an orthogonal decomposition.

Gaussian Elimination: We decompose $(A - \lambda I)P = LR$, where L is lower triangular, R upper triangular, and P a permutation, then solve the triangular systems $Lw = c$ and $Rz = w$, and, last, undo the permutation by computing $y = Pz$.

Orthogonal Decomposition: Here we have two choices:

QR Factorization: Decompose $(A - \lambda I) = QR$, and solve $Ry = Q^T c$.

LQ Factorization: Decompose $(A - \lambda I) = LQ$, solve $Lz = c$, and compute $y = Q^T z$.

Again, L and R are lower and upper triangular, respectively, and Q is orthogonal. Note that, in contrast to the Gaussian elimination approach, no pivoting is required.

Because we are not interested in the factorization of $(A - \lambda_{ji}I)$ per se, but only in the solution of the equation systems $(A - \lambda_{ji}I)y_j = c_i$, we can perform a forward solve involving a lower triangular matrix L at the same time that we compute L during the factorization. By the same token, we can apply the orthogonal matrix Q to c on the fly if we use the QR factorization.

The drawback is that in both Gaussian elimination and the QR factorization we have to store the upper triangular matrix R, because we cannot start a backsolve involving R before its last element has been computed. Because A is assumed to be dense, both Gaussian elimination and the QR factorization produce a dense upper triangular factor R, which requires a storage of $O(n^2/2)$ words per equation system.

On the other hand, if Q does require little storage, an LQ factorization is well suited. This is the case when A is lower Hessenberg, because then Q can be computed by a sequence of $n-1$ Givens rotations, requiring $O(n)$ storage and only $O(4n^2)$ flops overall. Assuming, as we have done so far, that A is of lower-Hessenberg form, the Sylvester observer equation algorithm in Figure 1 then requires the following:

1. the computation of X_1 by solving a series of systems of equations with lower-Hessenberg coefficient matrices, through an LQ factorization; and
2. the computation of $X_2, \ldots, X_k$ through a recurrence relation involving matrix-matrix products of a lower-Hessenberg and a dense matrix.

As will be seen, the choice of lower-Hessenberg form for A allows us to fully exploit parallelism while keeping extra working storage to a minimum.

3.1. Computing the first block of the solution. To compute the first block X_1 of X, we have to solve n independent systems of linear equations with a lower-Hessenberg coefficient matrix. Each of the r columns c_i of C is the right-hand side for k equation systems.

We have observed experimentally that the conditioning of the problem or the accuracy of our results is not altered appreciably by varying the value of k relative to n, and we assume the ratio $k = n/r$ to be a small constant. This is motivated by the need for obtaining an efficient loop parallelism strategy, as discussed below.

The LQ solver for solving $(A - \lambda I)y = c$ is shown in Figure 2. Here we assume that the vector y holds c on entry and that it contains the solution on exit. The vector e_i is the ith canonical unit vector. Let $P = [1 \rightarrow n, 2 \rightarrow 1, \ldots, n \rightarrow n-1]$ be a left cyclical shift. Then $(A - \lambda I)P = [L, t]$, where L is lower triangular and t is a column vector.

```
Workspace: $w_1, w_2, s$ and $c$, all $n$-vectors.
           $w_1$ and $w_2$ hold the current columns of $L$
           $s$ and $c$ store the $(\sin(\phi_i), \cos(\phi_i))$ pairs.
           We also assume that $A \leftarrow AP$, $P$ being the left cyclic shift.
(1) Initialization: $w_1 = A(:, n) - \lambda e_1, w_2 = A(:, 1) - \lambda e_2$
(2) Compute $L$ and forward solve $Ly = c$ on the fly:
    for $i = 1$ to $n - 1$
      Generate $(c(i), s(i))$ such that $\begin{pmatrix} c(i) & s(i) \\ -s(i) & c(i) \end{pmatrix} \begin{pmatrix} w_1(i) \\ w_2(i) \end{pmatrix} = \begin{pmatrix} 0 \\ \bullet \end{pmatrix}$
      $(w_1(i:n), w_2(i:n)) \leftarrow (w_1(i:n), w_2(i:n)) \begin{pmatrix} c(i) & -s(i) \\ s(i) & c(i) \end{pmatrix}$
      $y(i) \leftarrow y(i)/w_2(i)$
      $y(i+1:n) \leftarrow y(i+1:n) - y(i)w_2(i+1:n)$
      if $i < n - 1$ then
        $w_2(i+1:n) \leftarrow A(i+1:n, i+1) - \lambda e_2$
      endif
    endfor
    $y(n) \leftarrow y(n)/w_1(n)$
(3) Apply $Q^T$ to $y$:
    for $i = n - 1$ downto 1
      $\begin{pmatrix} y(i) \\ y(n) \end{pmatrix} \leftarrow \begin{pmatrix} c(i) & s(i) \\ -s(i) & c(i) \end{pmatrix}^T \begin{pmatrix} y(i) \\ y(n) \end{pmatrix}$
    endfor
(4) Undo Permutation $P$:
    $y \leftarrow Py$
```

FIG. 2. *LQ solver for $(A - \lambda I)y = c$. On entry, the vector y contains the right-hand side c; on exit, it contains the solution of the equation.*

The use of an LQ factorization for a lower-Hessenberg coefficient matrix allows us to compute the orthogonal factor Q, reducing $[L, t]$ to a lower triangular form as a sequence of $n - 1$ Givens rotations:

$$Q = G_1 \cdots G_{n-1},$$

where G_i involves columns i and n. By solving the triangular system $Lz = c$ on the fly, we need to store only two columns of L at any given time. Thus, if we solve p such systems in parallel, we require storage for

$$\begin{array}{ccc} n(n+1)/2 & + & 4pn \\ \text{(for the lower Hessenberg } A) & & \text{(workspace for equation solvers)} \end{array}$$

words. The other alternatives considered before (Gaussian elimination, QR factorization) require $O(pn^2)$ storage instead. Our LQ solver requires roughly $4n^2$ flops to solve an $n \times n$ equation system: $3n^2$ flops for the computation of L and Q, and n^2 flops for the forward solve $Lz = c$. The original solution y is then obtained from $y \leftarrow PQ^Tz$. The algorithm is shown in Figure 2.

The partial drawback of this algorithm is that it employs vector-vector operations, which in general do not perform well on high-performance processors because they require many memory accesses per floating-point operation. (For a discussion of this issue, see, for example, [1,7,8].) If we allow more workspace per processor, we can partially overcome this

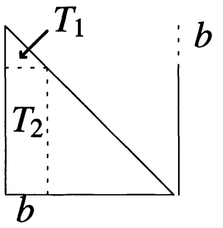

FIG. 3. *Partially completed LQ factorization.*

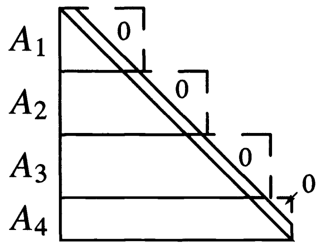

FIG. 4. *Lower-Hessenberg matrix partitioned into four block rows.*

drawback and arrive at a variant that computes the forward solve $Lz = c$ with matrix-vector operations. In particular, if we allow for b columns of workspace for L, we do not have to update the right-hand side y until b columns of L have been updated, while eliminating the first b entries of the last column of A, as shown in Figure 3. After obtaining a strictly lower triangular block, as discussed above, we can now compute the first b entries of y with a triangular solve (BLAS2 routine STRSV),

$$y(1:b) \leftarrow T_1^{-1}\, y(1:b),$$

and update the remaining entries of y with a matrix-vector multiplication (BLAS2 routine SGEMV),

$$y(b+1:n) \leftarrow y(b+1:n) - T_2\, y(1:b).$$

Therefore, instead of computing y one column at a time, the computation is carried out b columns at a time. Thus, in the overall algorithm, roughly 25% of the work is now done by using matrix-vector instead of vector-vector kernels.

3.2. Computing the remaining blocks of *X*. The computational performance of the third step depends on the performance of the matrix-matrix product AX_i. To achieve optimal performance, we should compute this matrix-matrix product in parallel, employing matrix-matrix multiplication as much as possible, while exploiting the lower-Hessenberg structure of A. To this end, we partition A in block rows A_j of width b (not necessarily the same b that is used for the equation solve) and compute AX_i in a block rowwise fashion. That is, we independently compute the first b rows of AX_i by forming A_1X_i, the second b rows by forming A_2X_i, and so on. In general, A_j will be a $b \times (j * b + 1)$ matrix, with a trailing zero upper triangle. A sample partition of A into four block rows is shown in Figure 4. Since in general $b \ll n$, the computations involving zeros will account for only a small portion of the overall computations performed. In particular, for $b = 1$ we employ a matrix-vector multiplication kernel, and no operations with zeros are performed.

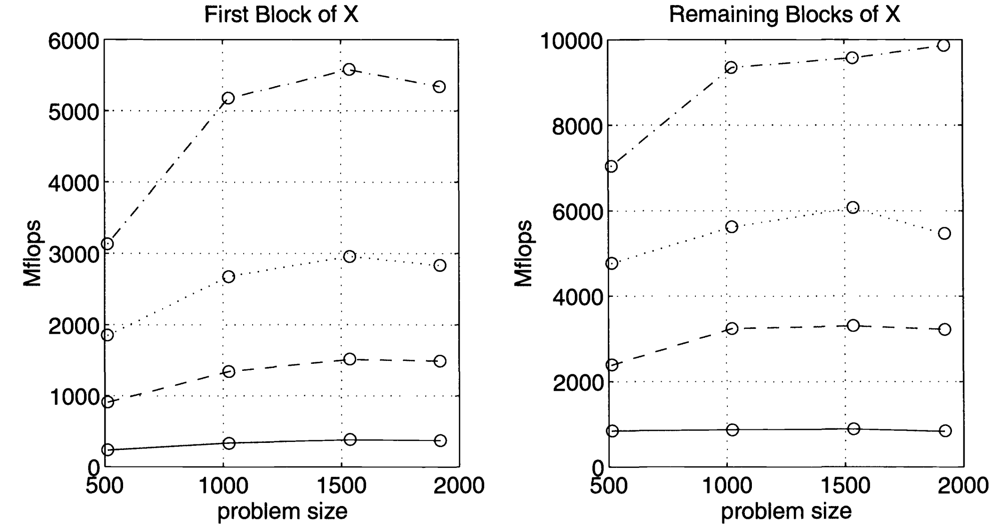

FIG. 5. *Performance of the main kernels of the parallel Sylvester observer equation algorithm on a CRAY C90 (– 1 proc., - - 4 procs., ... 8 procs., -. 16 procs.).*

4. Numerical results. We tested our parallel Sylvester observer equation algorithm on a CRAY C90/16256, a sixteen-processor vector machine with 256 Mwords of shared memory. The CRAY C90 has two sets of vector units per processor, each producing two results per clock-cycle, resulting in a peak performance of 16 Gflops.

As our test problem we generated matrices of dimensions

$$n = 512, 1024, 1536, 1920.$$

To generate lower-Hessenberg matrices with the desired spectrum, we used the LAPACK test matrix generator SLATME [6] to generate a dense nonsymmetric matrix with the desired spectrum, used the LAPACK routine SGEHRD to reduce this matrix to upper Hessenberg form, and then transposed the resulting matrix. In all cases k the number of blocks is 4, so $r = n/4$. We checked the accuracy of our results by computing $fl(C) \equiv A.fl(X_k) - fl(X_k).\Lambda_{k,k}$, which, according to (13), should equal C. In all cases, $fl(C)$ and C agreed to 12 digits. This test is not only cheaper than the usual residual check, but the last block contains the accumulation of all the recurrences and thus is a good indicator of the accuracy of the algorithm.

The BLAS on the CRAY C90 were assembler implementations provided by Cray Research, which exploit multiple CPUs in a fashion that is transparent to the user (unless they are called within a parallel loop, as is the case when we compute the first block of X). Our code obtained the performance and parallel efficiency shown in Figures 5 and 6, respectively.

The plots labeled "First Block of X" and "Remaining Blocks of X" correspond to the two main steps of the Sylvester observer equation algorithm. Figure 7 shows execution rate and efficiency of the two steps combined. In these figures, the solid, dashed, dotted, and dash-dotted lines correspond to runs with 1, 4, 8, and 16 processors, respectively. Efficiency is defined as $\frac{T_1}{T_p \times p} \times 100$, where T_p is the wall-clock time for executing any algorithm on p processors. For all of the segments (i.e., system solutions and matrix products) we get the best results, in general, for blocksize $b = 1$.

Figure 5 shows that the AX_i recursion of the parallel Sylvester observer equation algorithm performs very well. This result is not surprising, because it relies on the highly optimized assembler implementations of the BLAS.

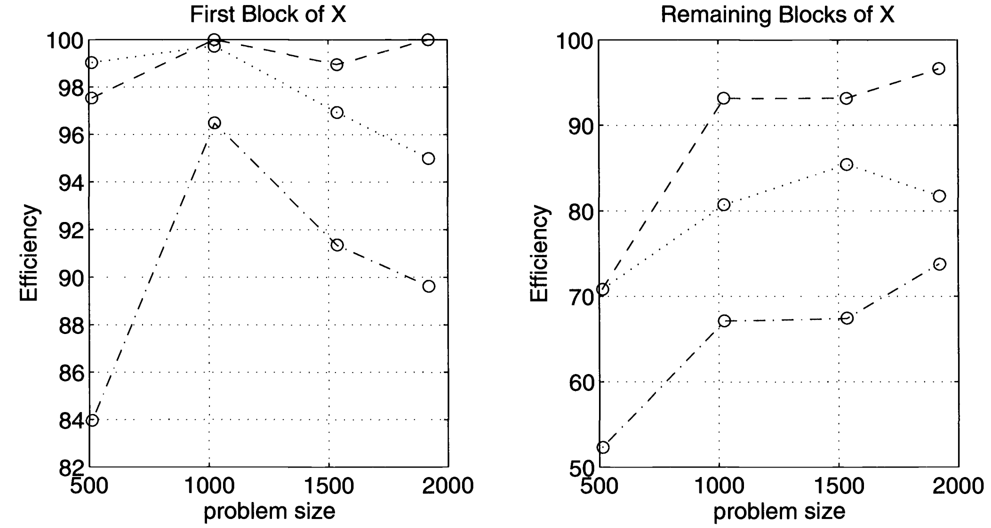

FIG. 6. *Efficiency of the main kernels of the parallel Sylvester observer equation algorithm on a CRAY C90 (- - 4 procs., ... 8 procs., -. 16 procs.).*

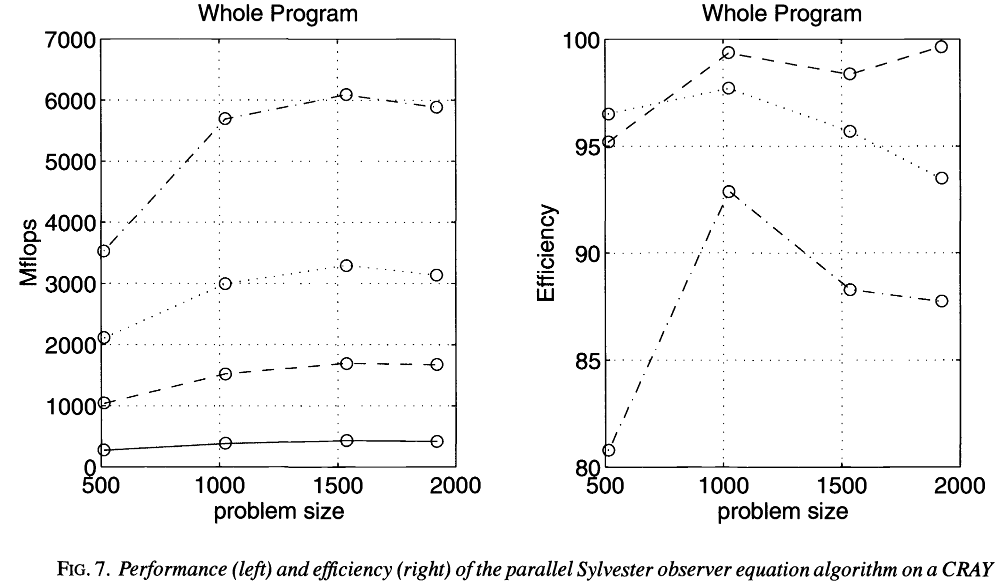

FIG. 7. *Performance (left) and efficiency (right) of the parallel Sylvester observer equation algorithm on a CRAY C90 (– 1 proc., - - 4 procs., ... 8 procs., -. 16 procs.).*

On the other hand, the computation of the first block of X runs much more slowly, at slightly more than half the speed of the other transformations. This is because our on-the-fly LQ solver relies only on BLAS 1 operations for all of its work and the number of systems being solved. The fact that we blocked the computation of y did not result in any improvement on this machine — at most, 8% principally on smaller problems. As a matter of fact, the performance advantage of the blocked version diminished for larger problems because of an increased number of copies in and out of buffers. We also noted that, due to the high internal bandwidth of the C90, the unblocked matrix-matrix multiply does much better than the blocked version, usually performing around 25% faster. However, as the computation

```
Compute $X_k$, the last block of $X$:
    For $i = 1, \ldots, r$ do
        Solve $(A - \lambda_{k,i} I)\hat{x}_i^{(k)} = c_i$
    Enddo
    $\Lambda_{k,k-1} = \mathrm{diag}(\|\hat{x}_1^{(k)}\|_2, \ldots, \|\hat{x}_r^{(k)}\|_2)$
    $X_k = \hat{X}_k \Lambda_{k,k-1}^{-1}$

Solve for $X_{k-1}, \ldots, X_1$, the remaining blocks of $X$:
    For $j = k - 1, \ldots, 1$ do
        For $i = 1, \ldots, r$ do
            Solve $(A - \lambda_{j,i} I)\hat{x}_i^{(j)} = x_i^{(j+1)}$
        Enddo
        $\Lambda_{j,j-1} = \mathrm{diag}(\|\hat{x}_1^{(j)}\|_2, \ldots, \|\hat{x}_r^{(j)}\|_2)$
        $X_j = \hat{X}_j \Lambda_{j,j-1}^{-1}$
    Enddo
```

FIG. 8. *The Hessenberg–Schur method for solution of the Sylvester observer equation.*

of X_1 and the computations of $X_2, \ldots, X_k$ account for roughly 80% and 20%, respectively, of the floating-point operations to be performed, the performance of the overall program very much reflects the performance of the LQ solver. There is little we can do about this situation, since any other solver would require $O(pn^2)$ workspace, which is clearly undesirable.

On the other hand, by exploiting the parallelism inherent in the computation of X, our algorithm scales very well with the number of processors, as the plots in Figures 6 and 7 demonstrate. Not surprisingly, the parallel solution of the equation systems scales the best: because there are many parallel jobs, all with the same computational requirements, the parallel loop is almost perfectly load-balanced. This step is responsible for about half of all floating-point operations, resulting in the high overall parallel efficiency of our code.

5. Comparison of the proposed algorithm with the Hessenberg–Schur method. In this section we make a performance comparison of our proposed parallel algorithm with that of the Hessenberg-Schur method [10] adapted for the solution of the Sylvester observer equation $AX - XH = (0, C)$. The Hessenberg-Schur method solves the usual Sylvester equation $AX - XH = C$, where the matrices A, H, and C are given and X needs to be found. We first show how the Hessenberg-Schur method can be adapted for the solution of the Sylvester observer equation (2).

In the Sylvester observer equation, the matrix H can be chosen arbitrarily as long as it has a preassigned spectrum and its spectrum is different from that of A. Again, we choose H block bidiagonal with $r \times r$ blocks as in (7). Then the Hessenberg-Schur method adapted to the Sylvester observer equation can be described as given by the algorithm in Figure 8.

As assumed in our algorithm, A is also first reduced to Hessenberg form. However, there are key differences in the two approaches. In the proposed new algorithm the first block X_1 is computed first, by solving n systems of linear equations in parallel, and the remaining blocks are then computed recursively using higher-level BLAS operations. In the Hessenberg-Schur algorithm, the last block X_k is computed first, by solving a system of r equations, while the remaining blocks, obtained from the rear, are also obtained by solving systems of r equations at a time. Hence step 2 of Figures 1 and 8 bear little resemblence. In the Hessenberg-Schur approach, it makes sense therefore to parallelize the inner loop, because, as before, r is much larger than k. So we spawn r parallel jobs k times, incurring a greater overhead than in the proposed algorithm, where we spawn n parallel jobs once. Also, there are almost no

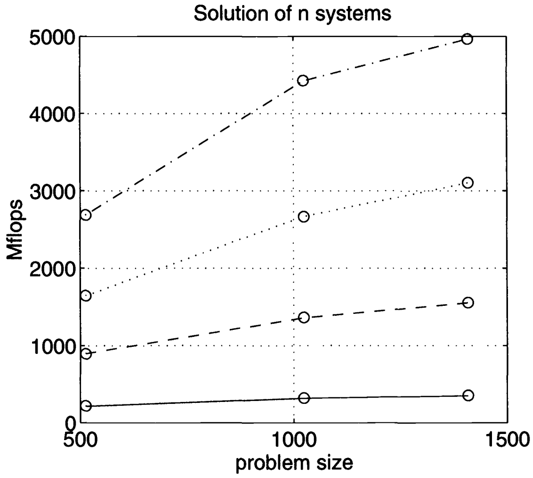

FIG. 9. *Performance of Hessenberg-Schur algorithm on a CRAY C90 (– 1 proc., - - 4 procs., ... 8 procs., -. 16 procs.).*

opportunities for using higher-level BLAS operations in the Hessenberg-Schur algorithm, except in the first step, common to both algorithms, for reducing the matrix to Hessenberg form.

The experimental results on the C90 for the Hessenberg-Schur algorithm is shown in Figure 9. A comparison of the performance graph of Figure 7 with Figure 9 shows that the Hessenberg-Schur algorithm does not perform as well as the new proposed algorithm. For example, for $n = 1536$ and $p = 16$, we obtain around six GFlops with the new algorithm and around five Gflops with the Hessenberg-Schur approach—an improvement of around 20%. Due to memory limitations (the Hessenberg-Schur method seems to require more space to execute), we could not run the case $n = 1920$.

6. Conclusions. In this paper we presented a new parallel algorithm for solving the Sylvester observer equation. The algorithm is simple and relies on standard linear algebra building blocks. The main computational steps are a reduction to Hessenberg form, the solution of a series of independent equation systems, and a recurrence relation based on matrix-matrix multiplies. These attributes, together with the parallelism in the algorithm, are key requirements for an efficient implementation on a shared-memory multiprocessor. By reducing the coefficient matrix to lower-Hessenberg form, we can implement our algorithm with little additional workspace, thereby ensuring that we can solve big problems and that our algorithm scales well with the number of processors. Experimental results on a CRAY C90 show that the algorithm is indeed well suited for a shared-memory multiprocessor. Also, a comparison is made with the well-known Hessenberg-Schur algorithm.

At the moment we are working on a version of this algorithm that is suitable for a distributed-memory multiprocessor. As in our current implementation, the key issue will be an efficient implementation of the parallel equation solves and the limitation of workspace. Research into sparse implementations is also in progress.

Acknowledgments. We are indebted to Bruce Kelly and Moe Jette of the National Energy Research Supercomputer Center at Lawrence Livermore National Laboratory for their dedicated help with the benchmarking of our code. We also thank Klaus Geers of the University of Karlsruhe and Phuong Vu of Cray Research for performing some preliminary benchmark runs for us. We are also indebted to Phuong Vu for suggesting some programming enhancements.

Last, we thank an anonymous referee for suggesting the left cyclic shift reordering in the LQ solver.

PERFORMANCE OF PANEL AND BLOCK APPROACHES TO SPARSE CHOLESKY FACTORIZATION ON THE iPSC/860 AND PARAGON MULTICOMPUTERS*

EDWARD ROTHBERG†

Abstract. Sparse Cholesky factorization has historically achieved extremely low performance on distributed-memory multiprocessors. We believe that three issues must be addressed to improve this situation: (1) parallel factorization methods must be based on more efficient sequential methods; (2) parallel machines must provide higher interprocessor communication bandwidth; and (3) the sparse matrices used to evaluate parallel sparse factorization performance should be more representative of the sizes of matrices people would factor on large parallel machines. This paper demonstrates that all three of these issues have in fact already been addressed. Specifically, (1) single node performance can be improved by moving from a column-oriented approach, where the computational kernel is level 1 BLAS, to either a panel- or block-oriented approach, where the computational kernel is level 3 BLAS; (2) communication hardware has improved dramatically, with new parallel computers (the Intel Paragon system) providing one to two orders of magnitude higher communication bandwidth than previous parallel computers (the Intel iPSC/860 system); and (3) several larger benchmark matrices are now available, and newer parallel machines offer sufficient memory per node to factor these larger matrices. The result of addressing these three issues is extremely high performance on moderately parallel machines. This paper demonstrates performance levels of 650 double-precision Mflops on 32 nodes of the Intel Paragon system, 1 Gflop on 64 nodes, and 1.7 Gflops on 128 nodes. This paper also does a direct performance comparison between the iPSC/860 and Paragon systems, as well as a comparison between panel- and block-oriented approaches to parallel factorization.

Key words. sparse Cholesky factorization, parallel machines, sparse matrices, scalability

AMS subject classifications. 65F05, 65F50

1. Introduction. Sparse Cholesky factorization is an extremely important computation. It arises in a wide variety of application domains, including finite-element analysis, linear programming, and semiconductor simulation. Sparse Cholesky factorization is extremely time consuming and, consequently, there is substantial interest in obtaining higher factorization performance. One seemingly promising approach is the use of distributed-memory multiprocessors.

Unfortunately, parallel sparse Cholesky factorization results on distributed-memory multiprocessors have been disappointing so far [2, 8, 11, 15, 21]. Such machines have not yet been shown to offer substantial advantages over alternative platforms for the computation. Specifically, their performance has not been significantly higher than that of high-end uniprocessors available at the same time, and their performance has not been at all competitive with the performance of vector supercomputers [4, 14, 20].

We believe there are three primary reasons for the disappointing performance of distributed-memory multiprocessors for this computation. The first is that parallel factorization methods have traditionally been based on inefficient sequential methods. Virtually all of these parallel methods distribute columns of the matrix among the processors, leading to a level 1 BLAS computational kernel. Many researchers [1, 4, 14, 17, 18] have demonstrated that sequential sparse factorization methods that are based on level 3 BLAS kernels [5] provide many times the performance of sequential methods that are based on level 1 kernels. This paper considers two approaches to integrating level 3 BLAS operations into the parallel computation. The first, a panel multifrontal method, distributes sets of adjacent columns among the processors. The second, a block fan-out method, distributes rectangular patches.

We demonstrate the advantages of the higher-level kernels by directly comparing performance against previously reported performance numbers for a parallel column method [21] on an iPSC/860 system. The improvements are significant on small machines but fall off for larger machines.

The second reason for the low performance observed in earlier investigations is the fact that earlier distributed-memory multiprocessors did not have sufficient communication bandwidth to support the enormous interprocessor communication demands of parallel sparse Cholesky factorization. Fortunately, multiprocessor communication hardware has improved dramatically. For example, the Intel Paragon system provides one to two orders of magnitude higher communication bandwidth than the earlier Intel iPSC/860 system. We will show that communication bandwidth is now sufficient to support extremely high parallel performance for this computation.

The third factor that limits parallel performance is the size of problems that have traditionally been used as parallel sparse factorization benchmarks. While these problems often require several hundred million floating-point operations to factor, they are still too small to make good use of even a moderate number of processors. This can best be observed by examining the task dependency graphs that result from these sparse problems [18]. The critical paths in the task graphs for these problems are too long to allow more than a small number of processors to be productively employed in the factorization. The limited size of these benchmark matrices has probably been motivated by the small amount of memory available on each node of a parallel machine. Fortunately, parallel machines are now available with substantially more memory per node. It is our belief that the matrices that have been used as benchmarks are unrealistically small, and that the larger matrices we will consider in the latter part of this paper are more representative of the sparse matrices people will want to factor on large parallel machines.

Overall, this paper demonstrates the following results. First, it demonstrates that both panel- and block-oriented methods produce higher performance than column-oriented methods on the iPSC/860 system. However, the improvement falls off with an increasing number of processors, primarily because communication costs begin to dominate. These alternative methods do not significantly reduce these costs. Second, the paper demonstrates that the Paragon system provides substantial performance advantages over the iPSC/860 system. We observe factors of three or more performance improvement on 32 or 64 processors for the traditional benchmark matrices. Third, the paper demonstrates that the block fan-out method produces significantly higher performance than the panel multifrontal method on larger parallel machines. Finally, this paper demonstrates that for large sparse problems, a distributed-memory multiprocessor is capable of producing extremely high factorization performance. We demonstrate factorization performance on the Paragon system in the range of 650 double-precision Mflops on 32 processors, 1 Gflop on 64 processors, and 1.7 Gflops on 128 processors.

We should note that the factorization methods we consider in this paper, the panel multifrontal method and the block fan-out method, have been described and investigated previously [16, 18]. The main contributions of this paper are its direct comparison of these two methods on widely available parallel machines and its direct comparison of the performance of two generations of parallel machines for this important computation.

The organization of this paper is as follows. Section 2 provides a short background on sparse Cholesky factorization and the parallel methods we use to perform the computation. Section 3 describes our experimental environment, including the sparse matrices we use as benchmarks and the machines on which we factor these matrices. Section 4 looks at parallel factorization performance, comparing the performance of the panel multifrontal and block fan-out methods on the iPSC/860 and Paragon systems. Section 5 then considers the performance improvement that comes from factoring larger problems on the Paragon system. Finally, §6 presents a brief discussion, and §7 presents conclusions.

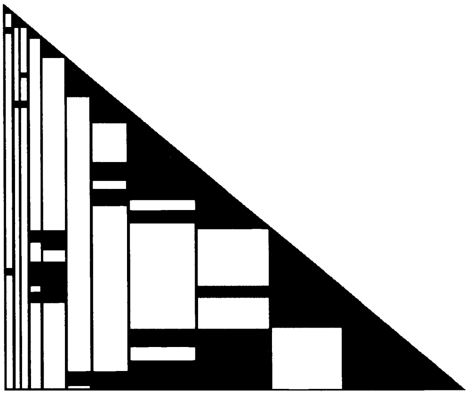

FIG. 1. *Supernodal structure of a sparse matrix.*

2. Sparse Cholesky factorization.

2.1. Computation structure. The goal of sparse Cholesky factorization is to factor a sparse-symmetric positive-definite matrix **A** into the form **A** = $\mathbf{LL}^{\mathrm{T}}$, where **L** is lower triangular with positive diagonal elements. This is typically accomplished in three steps. The first step, *heuristic reordering*, reorders the rows and columns of **A** using a heuristic such as multiple minimum degree [12] or nested dissection [9] to reduce *fill* in the factor matrix. The second step, *symbolic factorization*, performs the factorization symbolically to determine the nonzero structure of the factor matrix after all fill has occurred. This step allocates storage for the factor matrix. The third step, *numerical factorization*, computes the actual numerical values in **L**. We refer the reader to [9] for more information. We concentrate on the numerical factorization step in this paper, since it is by far the most time consuming.

The following pseudocode performs Cholesky factorization:

```
1. Set L = A
2. for k = 1 to n do
3.    for i = k to n do
4.       $L_{ik} := L_{ik}$ / sqrt($L_{kk}$)
5.    for j = k + 1 to n do
6.       for i = j to n do
7.          $L_{ij} := L_{ij} - L_{ik}\ L_{jk}$
```

For a sparse matrix, the factorization would only perform operations on nonzeros in the matrix, and it would only store these nonzeros. Thus, the loops in steps 3, 5, and 6 would iterate over a subset of all possible values (the subset is easily determined from the structure of the sparse matrix).

Sparse factorization is typically expressed in terms of columns of the sparse matrix. Within a column-oriented framework, steps 3 and 4 above can be thought of as a single column division or cdiv(k) operation. This operation divides all nonzeros in a column by the square root of its diagonal. Steps 6 and 7 form a column modification or cmod(j, k) operation. This operation adds a multiple of column k into column j.

2.2. Supernodal structure. A crucial notion for improving the performance of sparse factorization is that of the *supernode* [4]. A supernode is a set of adjacent columns in the sparse factor matrix whose structure consists of a dense triangular block on the diagonal and identical nonzero structures in each column below the diagonal. Supernodes arise in any sparse factorization, and they are typically quite large. Figure 1 gives an example of the structure of a typical factor matrix. The shaded areas represent nonzero values, and the vertical lines delineate the supernodes.

The factorization computation can easily be expressed in terms of supernodes; there are simple supernode analogues for the column-oriented operations described earlier. An sdiv(K) would multiply supernode K by the inverse of its diagonal block. Similarly, an smod(J, K) operation would modify the values in supernode J by those in supernode K. These supernode analogues are rich in level 3 BLAS operations and, as a result, they lead to substantially higher performance than the corresponding column versions.

Performance of the factorization can be further improved by performing *supernode amalgamation* [3] on the factor matrix before the factorization. Supernode amalgamation is a process of identifying zero-valued locations in the matrix that would produce larger supernodes if they were treated as nonzeros and explicitly stored in the sparse representation. All factorization methods we investigate in this paper perform supernode amalgamation before the factorization.

In the context of parallel factorization, supernodes unfortunately represent too coarse of a distribution grain. Some supernodes are so large that mapping them to a single processor would cause load balance problems. The methods investigated in this paper divide supernodes into finer-grain objects. Our panel multifrontal method divides supernodes into panels, which are contiguous sets of columns from within the same supernode. Our block fan-out method divides supernodes into rectangular blocks. We will describe the block decomposition in more detail shortly.

2.3. Parallel sparse Cholesky factorization. We now briefly describe the two parallel factorization methods we consider in this paper, the panel multifrontal method and the block fan-out method. These methods have been described in detail elsewhere [16, 18], so this discussion will omit the details and concentrate only on the aspects of these methods that are relevant for this paper.

2.3.1. Panel multifrontal method. The panel multifrontal method is a simple variant of the parallel column multifrontal method [2, 13]. The multifrontal method is quite complicated, and its details are beyond the scope of this paper. We only discuss its most important components here.

Perhaps the most important computational operation in the parallel *column* multifrontal method is the column modification, or cmod(j, k). Recall that this operation adds a multiple of column k of the matrix into column j. The multifrontal method structures the computation in such a way that, even though columns j and k may have different nonzero structures, the cmod(j, k) operation can be performed using dense matrix operations. For a column method, the appropriate dense matrix operation is a DAXPY.

Another important operation in the parallel column multifrontal method is the column multicast. In a parallel multifrontal method, modifications *from* a particular column k are typically performed by several processors. Thus, once a column k has received all modifications from other columns, it is multicast from its owner (each column has an owner processor) to all processors that perform modifications with k as their source. We use a *proportional mapping* scheme [15] to map columns and column modifications to processors. This scheme does a good job of balancing the computational load among the processors while simultaneously limiting communication volumes.

The panel version of the multifrontal method is quite similar to the column version. The main difference is that the former distributes panels among the processors while the latter distributes columns. The main computational operation becomes a panel modification, pmod(J, K). It is performed as a dense matrix-matrix multiplication (a DGEMM using BLAS

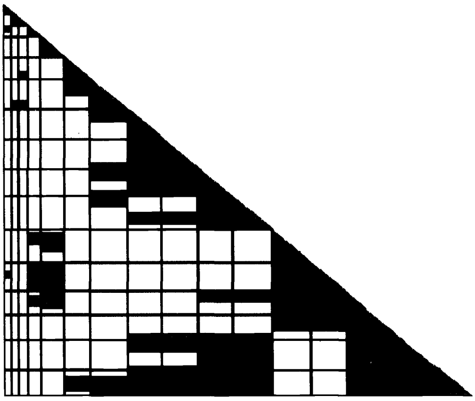

FIG. 2. *Block decomposition of a sparse matrix.*

terminology). The main communication operation is a panel multicast, which multicasts coarser-grain panels instead of columns.

One detail about the panel multifrontal method that we must mention is how supernodes are divided into panels. We do so by choosing a global panel width and dividing all supernodes in the matrix into panels of this width. Since supernode widths are not necessarily multiples of the chosen panel width, there will sometimes be leftover panels. For example, if the global panel width is 16, a supernode containing 60 columns would be divided into three panels of width 16 and one panel of width 12.

2.3.2. Block fan-out method. The details of the block fan-out approach [16] are again beyond the scope of this paper. We just describe the most important issues for this method, which are (1) the decomposition of the sparse matrix into blocks, (2) the operations processors perform on these blocks, and (3) the communication performed by the processors.

The block fan-out method partitions the columns of the matrix $(1, \ldots, n)$ into contiguous subsets $(\{1, \ldots, p_2 - 1\}, \{p_2, \ldots, p_3 - 1\}, \ldots, \{p_N, \ldots, n\})$, where N is the number of subsets. All columns in a subset must be members of the same supernode. An identical partitioning is performed on the rows. A block L_{IJ} (we refer to subsets using capital letters) consists of the set of nonzeros that fall simultaneously in rows $\{p_I, \ldots, p_{I+1} - 1\}$ and columns $\{p_J, \ldots, p_{J+1} - 1\}$. To form these subsets, we again choose a single global block size and partition all supernodes into subsets of this size. Figure 2 gives an example of such a decomposition.

Perhaps the most important operation in the block fan-out method is the block modification. A block modification, or bmod(L_{IJ}, L_{IK}, L_{JK}), modifies one destination block (L_{IJ}) using two source blocks (L_{IK} and L_{JK}). This modification is performed as a dense matrix-matrix multiplication (or DGEMM). Blocks sometimes have sparse structure, which may necessitate sparse operations in the bmod() operation. Such operations are infrequent, however.

To restrict communication volumes, blocks are mapped to processors using a *scatter decomposition* [7]. In this mapping strategy, the processors are thought of as a two-dimensional (2-D) r-by-s-grid. A block L_{IK} is mapped to processor (I mod r, K mod s) in this grid. All block modifications are performed by the processor that owns the destination block. This mapping, combined with the property that a block L_{IK} can only modify blocks in block row I or block column I, leads to the property that L_{IK} need only be sent to the row and column of processors in the processor grid that own row I and column I of blocks. This property limits communication volumes.

We should mention that we do not perform a scatter decomposition on the entire sparse matrix. It is possible to assign a large, contiguous set of columns of the matrix (typically referred to as a *domain* [2]) to each processor. The remainder of the matrix (whose size is still substantial) is then distributed among the processors using a scatter decomposition. The use of domains reduces communication, since the matrix blocks in these domains do not have to be communicated to other processors.

2.3.3. Important issues for parallel methods. We now briefly comment on some of the more important properties of these parallel methods. In particular, we comment on four issues that may affect parallel speedups and relative performance. We will refer back to these issues throughout this paper when we investigate performance of the methods.

The first issue that may affect parallel performance is load imbalance. Recall that the proportional mapping used for the panel multifrontal method does a good job of balancing the computational load. In contrast, the block fan-out method uses a relatively rigid scatter decomposition, which makes load balancing more difficult. The panel multifrontal method will have better overall load balance.

A second issue that may affect performance is communication costs. For a k-by-k 2-D grid problem, which requires $O(k^3)$ floating-point operations to factor, the panel multifrontal method asymptotically generates $O(k^2P)$ communication volume [10, 16]. The block fan-out method generates $O(sqrt(P)k^2 \log P)$ communication. Expressed as computation to communication ratios, these methods perform $O(k/P)$ and $O(k/(sqrt(P) \log P))$ floating-point operations per communicated word, respectively. Similar growth rates apply for other sparse problems. While these growth rates favor the block approach, the measured differences turn out to be small for 64 or fewer processors. For the problems we consider, the difference in communication volumes between the column multifrontal method, the panel multifrontal method, and the block fan-out method is always less than 30%. Furthermore, none of the three methods always produces either the most or the least communication. Communication volume issues therefore do not favor one method over the other in this study. Communication volumes are extremely high, however, and they will affect performance for both methods.

The other important cost associated with communication, the *fixed* cost of sending a message between processors, is not very important for either the panel multifrontal or the block fan-out method. Both methods group nonzeros into sufficiently large-grain messages that the cost of sending a message is dominated by the bandwidth component of the message send cost, not the fixed component.

A third issue that affects performance is the length of the critical path in the factorization computation task graph. This critical path places a lower bound on parallel runtime, or, equivalently, it places an upper bound on parallel performance. For a k-by-k 2-D grid problem using a partition width of B, the critical path for a panel multifrontal method contains $O(k^2B)$ floating-point operations and $O(k^2)$ words of communication. In contrast, the critical path for a block fan-out method contains $O(kB^2)$ operations and $O(kB)$ words of communication. Expressed as maximum parallel speedups, these bounds give $O(k/B)$ best-case speedup for the panel multifrontal method and $O(k^2/B^2)$ speedup for the block fan-out method. In practice, the critical path is much more constraining for the panel multifrontal method.

A fourth issue that affects parallel performance is single node performance. The panel multifrontal and block fan-out methods are both based on level 3 BLAS kernels and they both provide similar single-node performance. For larger numbers of processors, however, the panel and block widths must be decreased to reduce the computational grain and increase available concurrency. This will lead to lower per-node performance than would be obtained for a sequential code, where there is no need to limit the panel or block sizes.

TABLE 1
Benchmark matrices.

Problem name	Equations	NZ in A	NZ in L	Ops for factorization
GRID150	22,500	111,900	774,652	56,428,437
CUBE20	8,000	53,600	1,235,018	302,639,877
BCSSTK15	3,948	117,816	684,655	165,039,042
BCSSTK16	4,884	290,378	773,384	149,105,832
BCSSTK17	10,974	428,650	1,054,402	144,280,005
BCSSTK18	11,948	149,090	738,935	140,919,771
BCSSTK29	13,992	619,488	1,757,352	393,059,150

One thing to note about these four issues is that each becomes less problematic with larger problems. Load balancing becomes easier when there are more panels or blocks to distribute. Computation-to-communication ratios increase with increasing k, reducing relative communication costs. Similarly, maximum parallel speedups due to critical path limits improve with increasing k. Larger problems also allow larger panel or block sizes, which increase per-node performance. We therefore expect higher parallel performance from larger problems.

When we investigate obtained performance in this paper, we will try to explain it in terms of these four factors. Unfortunately, parallel performance cannot be perfectly explained in this way. The intricacies of the parallel machine and of the sparse Cholesky factorization computation make it impossible to account for every millisecond of parallel runtime. We therefore use these factors to provide insight into the observed parallel behavior.

3. Experimental environment.

3.1. Benchmark matrices. Table 1 describes the matrices we use as initial benchmarks. These include some of the larger matrices from the Harwell-Boeing sparse-matrix test set [6]. We also include simple 2-D and 3-D grid problems, which we refer to as GRID and CUBE problems, respectively.

We use double-precision arithmetic for all factorizations in this paper. All matrices are ordered using the multiple minimum degree ordering heuristic [12], with the exception of the GRID and CUBE problems, which are ordered using nested dissection [9]. All Mflop numbers in this paper are computed by dividing the total number of floating-point operations required to factor the problem using a sequential method by the appropriate runtime. Floating-point operation counts do not include operations introduced by the supernode amalgamation.

3.2. Parallel machines. As mentioned earlier, we perform our performance evaluation using the iPSC/860 and Paragon distributed-memory multiprocessors. Both use a message-passing programming model, wherein processors exchange data through explicit send and receive commands.

The iPSC/860 system uses a 40 MHz Intel i860 XR processor at each node. The machine we use has 64 nodes; 8 of these have 64 MBytes of memory and the other 56 have 8 MBytes of memory. The interconnection network has a hypercube topology. The peak bandwidth between two nodes is 2.8 MBytes per second.

The Paragon system uses a 50 MHz i860 XP processor at each node. The machine we use has 140 nodes, all with 32 MBytes of memory. The Paragon system interconnection network is organized as a 2-D mesh. Peak hardware communication bandwidth between two nodes is 200 MBytes per second. The machine we use is running release 1.2 of the operating system, which delivers a peak application message passing bandwidth of 80 MBytes per second. We

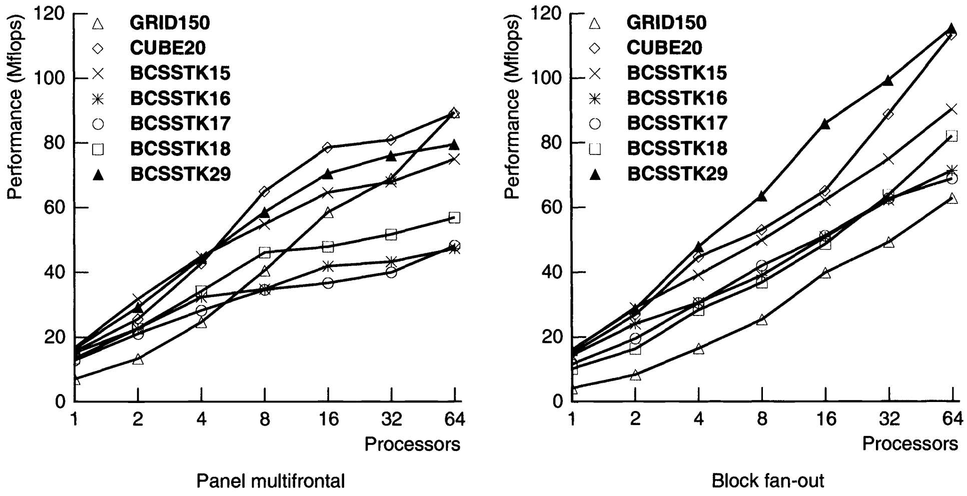

FIG. 3. *Factorization performance on the iPSC/860 system.*

measured roughly 40 MBytes per second of delivered bandwidth for the message sizes that are typical for the factorization. This represents more than a factor of 10 increase in delivered bandwidth over the iPSC/860 system.

It is often convenient to view the costs of communicating data between nodes in terms of the costs of performing floating-point operations on the nodes. If we use computation rates of 20 Mflops for the iPSC/860 system and 25 Mflops for the Paragon system (reasonable approximations, as we will show), then the incremental cost of sending one floating-point datum on the iPSC/860 system is roughly equal to the cost of performing 55 floating- point operations. The corresponding number is 5 floating-point operations on the Paragon system.

3.3. Implementation details. Our implementations of both the panel multifrontal and block fan-out methods are written in the C programming language, although we call the vendor-provided, hand-coded BLAS library routines whenever possible. Note that the BLAS routines on the machines we use cannot work with packed storage formats for triangular or trapezoidal matrices. Consequently, we store an upper-triangular block of zeros at the top of each panel in the panel multifrontal method and at the top of each diagonal block in the block fan-out method. The storage costs associated with these zeros are small.

We use dynamic memory for all important matrix data structures. Panels and blocks are stored as individually allocated objects. Similarly, temporary results (panel modifications in the panel multifrontal method and blocks received from other nodes in the block fan-out method) are stored in dynamically allocated blocks. We measured the costs of managing this dynamic memory and found them to be negligible.

We note that the iPSC/860 and Paragon systems are source-code compatible. We use the identical factorization codes on both. We also note that the Paragon system is a virtual-memory machine. To eliminate paging effects, our codes perform four factorizations in succession and report the best of the four runtimes.

4. Parallel performance.

4.1. iPSC/860. We now look at parallel performance of the panel multifrontal and block fan-out methods on the iPSC/860 system. Figure 3 shows factorization performance on 1 to 64 nodes. For the panel multifrontal method, the numbers in the figure give the best performance obtained using a panel width of 16, 24, or 32. For the block fan-out method, the numbers

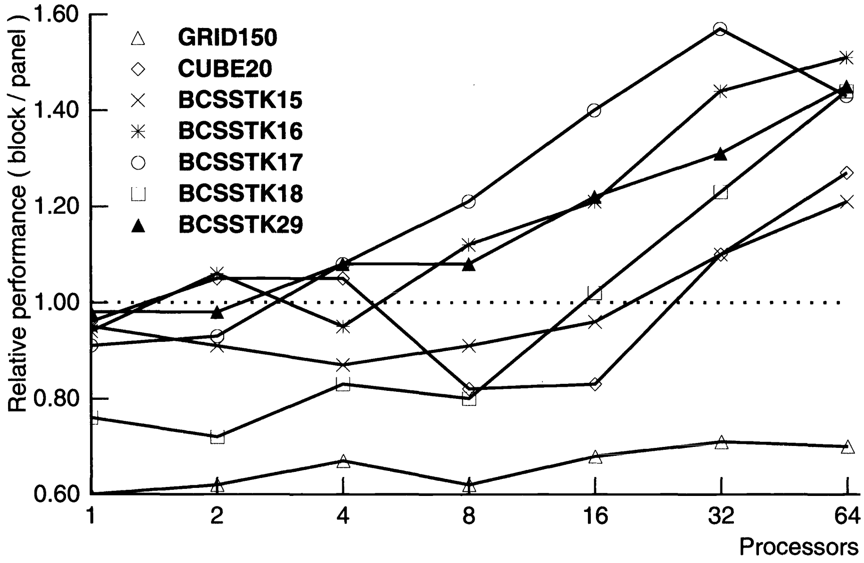

FIG. 4. *Relative performance (block fan-out versus panel multifrontal) on the iPSC/860 system.*

give the best performance obtained using a block size of 32, 48, or 64. We limit the number of cases we look at to limit the time required to gather performance data. For both methods, however, these partition size choices were observed to produce performance numbers that are within a few percent of the best that we obtained with any partition size. One exception is for large problems on a small number of nodes, where larger partition sizes that the ones we considered may give better performance.

The data in the figure indicates that performance of these methods is quite low, even on a large number of processors. Further investigation of the panel multifrontal method reveals that the main factor that limits performance is the critical path. As an example, consider problem BCSSTK15. If we assume a per-word communication cost of 55 floating-point operations (our estimate for the iPSC/860 system) and a panel width of 16 columns, then we find that the critical path for this problem limits parallel speedups to roughly 6-fold, no matter how many nodes are used. The corresponding bound for the larger BCSSTK29 is 7-fold speedup. Given these performance bounds, it is not surprising that achieved performance levels are low. If we look at the factors that contribute to this critical path, we find that communication costs account for more than half, and computation costs account for the rest. Recall that the amount of computation on the critical path can be reduced by reducing the panel width (at the cost of reduced single-node performance). Communication costs on the critical path, on the other hand, are unaffected by the panel width.

Now let us consider the performance of the block fan-out method on the iPSC/860 system. To allow a more direct comparison between panel multifrontal and block fan-out performance, Figure 4 shows the ratio of block fan-out performance to panel multifrontal performance for our benchmark problems. Note that performance is quite similar for a small number of nodes (with a few exceptions), and that performance diverges as the number of nodes increases. The block fan-out method produces significantly higher performance for 64 nodes.

Further investigation reveals that there are two primary performance bottlenecks for the block fan-out method on a large number of nodes. The first is load imbalance. As an example, for problem BCSSTK15 on 64 nodes using a block size of 48 (the block size that gives the best performance), the node with the most work assigned to it has 2.5 times more work than

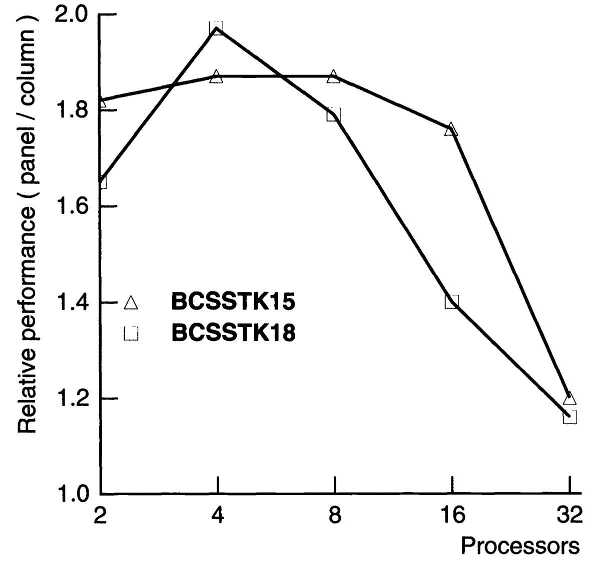

FIG. 5. *Relative performance (panel multifrontal versus column multifrontal) on the iPSC/860 system.*

it would with a perfect load balance. The second bottleneck is communication costs. The computation-to-communication ratio for our example is roughly 35 floating-point operations per communicated word. Recall that one word of communication costs roughly the same as 55 floating-point operations on the iPSC/860 system. This means that, on average, a node spends 1.6 times as much time communicating data as it spends performing computation. We find that the node that must perform 2.5 times as much work as it ideally would also must perform roughly 2.5 times as much communication as it ideally would. These two bottlenecks lead to a best-case parallel speedup for this problem of around 11-fold. The corresponding bound for BCSSTK29 is 12-fold. The critical path, which was quite constraining for the panel multifrontal method, is not very constraining for the block fan-out method. It limits parallel speedups to around 18-fold and 22-fold for BCSSTK15, and BCSSTK29, respectively. Overall, the performance upper bounds are much less constraining for the block fan-out method than they are for the panel multifrontal method. The result is higher performance on larger numbers of processors.

To evaluate the advantages of a panel or block approach to the computation over a more traditional column method, we now compare the performance numbers for our panel multifrontal method against the best performance numbers we are aware of for a column multifrontal method on the iPSC/860 system [21]. Figure 5 shows relative performance for two matrices where our studies overlap. Notice that the panel method gives roughly 80% higher performance for small numbers of nodes, but the performance difference decreases with increasing numbers of nodes. The reason is simply that the panel method improves per-node performance but increases the length of the critical path. Critical path costs are the more important determinant of performance when using more than a few nodes.

We therefore find that the block fan-out method provides higher performance than the panel multifrontal method on the iPSC/860 system, and both provide higher performance than a column approach. However, none of these methods can truly overcome the performance limitations that we observed on this machine.

4.2. Paragon. We now investigate factorization performance on the Paragon system. Figure 6 shows absolute parallel factorization performance on 1 to 64 nodes, and Figure 7 compares the performance of the Paragon system against that of the iPSC/860 system for both

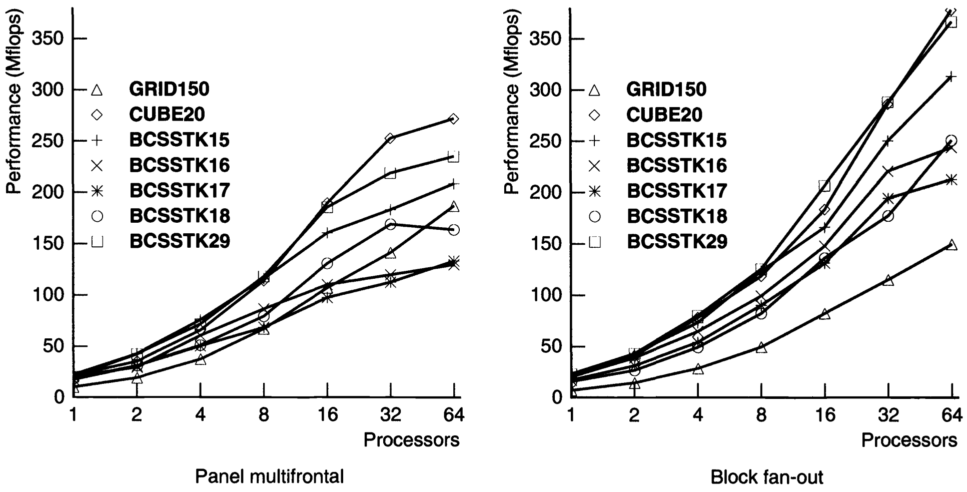

FIG. 6. *Factorization performance on the Paragon system.*

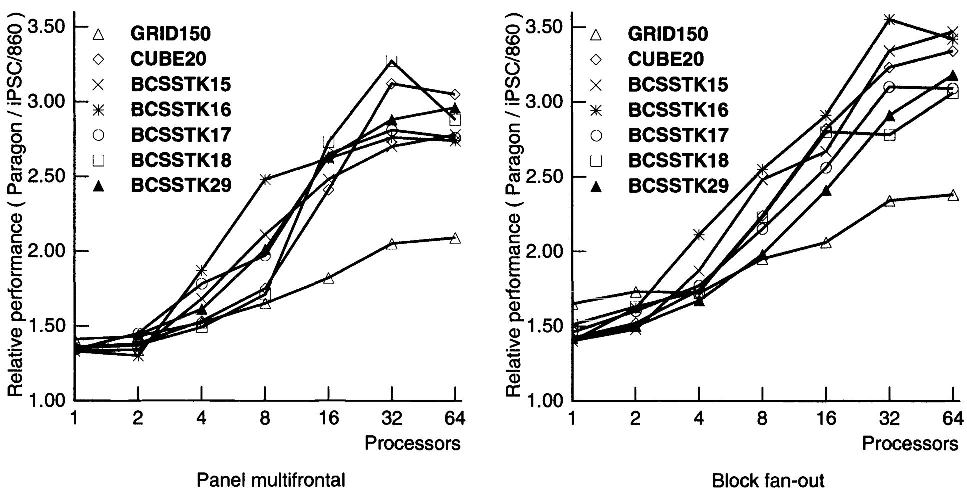

FIG. 7. *Performance improvement on the Paragon system (relative to the iPSC/860 system).*

the panel multifrontal and block fan-out methods. The figures show that the Paragon system provides substantially higher performance, and that the performance improvement grows as the number of nodes is increased. Improvements on 32 or 64 nodes are between 2.5-fold and 3.5-fold, depending on the matrix and the method.

These observed performance improvements can be better understood as follows. First, we note from the figures that the Paragon system provides higher single-node performance than the iPSC/860 system (roughly 40% higher for the panel multifrontal method and roughly 50% higher for the block fan-out method). Reasons include (1) a 25% increase in processor clock speed, (2) a factor of two increase in cache size (from 8 KBytes to 16 KBytes), and (3) the addition of a quad-word load instruction, which reduces the cost of fetching data from memory.

To better understand the performance increase for the panel multifrontal method, recall that on the iPSC/860 system the primary performance bottleneck for this method on a large number of processors was the critical path length. More than half of this critical path was

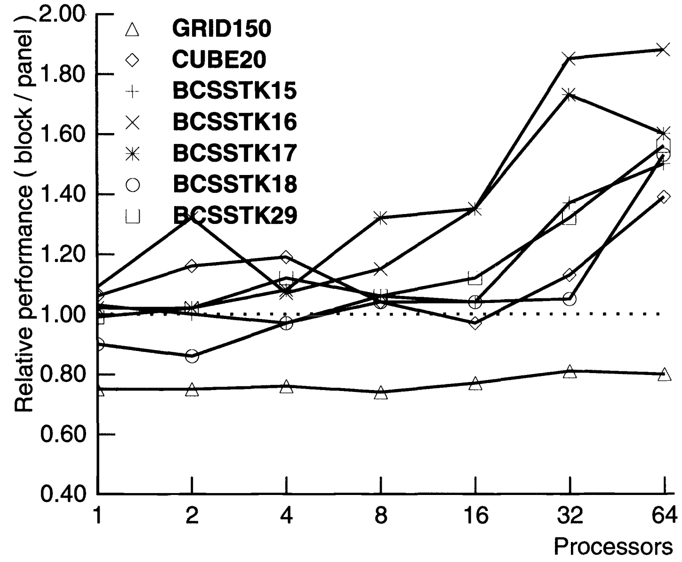

FIG. 8. *Relative performance (block fan-out method versus panel multifrontal) on the Paragon system.*

due to interprocessor communication costs. On the Paragon system, communication costs are reduced by a factor of more than 10. As a result, the overall critical path is roughly halved in length. Equivalently best-case parallel speedups are roughly doubled. When one combines this doubling in best-case speedup with a 40% improvement in single node performance, one finds that the improvement in observed performance is quite similar to the improvement in the performance bound.

For the block fan-out method, recall that the main performance bottleneck on the iPSC/860 system was the uneven distribution of work and communication among the nodes. The work distribution naturally has not changed. However, the communication costs, which magnified the performance impact of this imbalance by more than a factor of two, have been reduced by a factor of more than 10. The performance bound is therefore improved by roughly a factor of two. This factor of two improvement, combined with the 50% improvement in node performance, is consistent with the observed overall performance improvement.

Let us now compare the performance of the panel multifrontal and block fan-out methods on the Paragon system. Figure 8 shows relative performance numbers. This figure shows that the block fan-out method again produces significantly higher performance for larger numbers of nodes.

While parallel factorization performance is substantially higher on the Paragon system than it was on the iPSC/860 system, it is still not outstanding. As an example, we obtain roughly 300 Mflops for BCSSTK15 on 64 nodes, or roughly 5 Mflops per node. Considering that the sequential code produces nearly 25 Mflops on a single node, the nodes in the parallel method are clearly not being very well utilized. Our performance analysis indicates that the main performance bottleneck for the panel multifrontal method on the Paragon system is the cost of the floating-point operations on the critical path. The critical path length can be reduced by decreasing the panel width, but this leads to a drop in per-node performance. The decrease was observed to cancel the advantage of the shorter critical path. For the block fan-out method the main bottleneck is load imbalance. Again, this bottleneck can be improved by moving to a smaller block size, but the advantage was again observed to be cancelled by the resulting drop in per-node performance. The real solution in both cases is to consider larger problems.

TABLE 2
Larger benchmark matrices.

Problem name	Equations	NZ in A	NZ in L	Ops for factorization
BCSSTK31	35,588	1,181,416	5,485,320	2,550,990,053

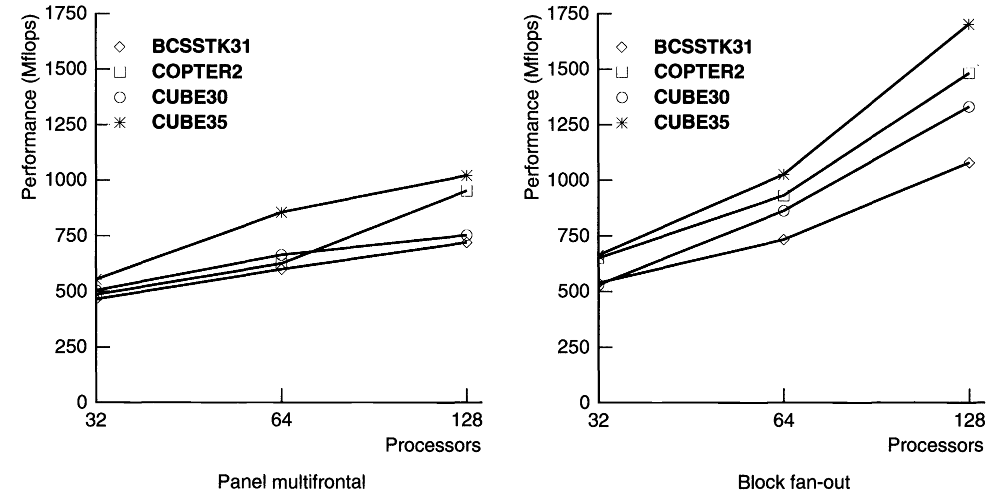

FIG. 9. *Paragon system performance for larger problems.*

5. Larger problems. It is our belief that the matrices we have considered so far, which are some of largest matrices in the Harwell-Boeing sparse-matrix test set, are not representative of the size of problems that people would want to solve on a large parallel machine. We believe that the primary reason these matrices have been used as benchmarks in the past is simply that larger matrices would not fit in the memories that were available on earlier machines. Fortunately, the larger amounts of memory available on newer parallel systems allow us to consider much larger problems. We now look at performance for matrices that are perhaps more appropriate factorization benchmark matrices for large parallel machines. Table 2 gives descriptions of these matrices. Problem BCSSTK31 is the largest problem in the Harwell-Boeing collection. Problem COPTER2 comes from a model of a helicopter rotor. It was given to us by Horst Simon at NASA Ames. The other two problems are simple 3-D grid problems. Note that these matrices are by no means unrealistically large. Even the largest one, COPTER2, requires only a few minutes to factor on a high-performance workstation (and a few seconds on a parallel machine).

Figure 9 shows factorization performance for these matrices on 32, 64, and 128 nodes of the Paragon system. Note that performance for these larger problems is extremely high. We obtain as much as 1.7 Gflops on 128 nodes. Also note that the performance of the block fan-out method diverges from the performance of the panel multifrontal method with increasing numbers of nodes. On 128 nodes, the block fan-out method provides roughly 70% higher performance than the panel multifrontal method. Further analysis reveals that the performance of the panel multifrontal method is again constrained by the critical path for these larger problems on 128 nodes. The improved scalability of the block fan-out method appears to become extremely important for these problems when more than 64 nodes are used.

6. Discussion and future work. The results of this paper demonstrate that it is possible to obtain very high performance for sparse Cholesky factorization on a distributed-memory multiprocessor. Indeed, the Paragon system is quite competitive with vector supercomputers for this computation. The 650 Mflops performance of a 32-node Paragon system is more than twice the performance of one CRAY Y-MP processor [14, 20]. Similarly, the 1.7 Gflops performance of a 128-node Paragon system is more than five times the performance of a CRAY Y-MP processor.

An obvious next step is to try to obtain even higher performance by using a larger number of nodes. We believe that the block fan-out method is the more promising of the two methods we have considered for doing this. One reason is that the block fan-out method produces asymptotically shorter critical paths than the panel multifrontal method. The critical path limited panel multifrontal performance on 128 nodes, so we would expect it to severely limit performance when using more nodes. A second reason is that the block fan-out method requires asymptotically less communication than the panel multifrontal method. The growth rate difference did not lead to a significant difference in communication volume on 128 or fewer nodes, but the communication volume difference would increase with increasing P.

We should note that one important piece missing from the scalable sparse factorization puzzle is scalable preprocessing. For this study, we performed most of the preprocessing sequentially, often on a separate workstation. The performance of the numerical factorization code is now sufficiently high that the preprocessing phases can require as much time as the parallel factorization. We are currently investigating parallel approaches to heuristic reordering and symbolic factorization.

7. Conclusions. This paper has investigated the impact of new technologies on parallel sparse Cholesky factorization performance. Specifically, we considered the impact of new algorithms (the panel multifrontal and block fan-out methods) and new hardware (the Intel Paragon system).

On the algorithm front, we found that these new algorithms improve parallel performance substantially on small iPSC/860 systems, providing nearly a factor of two improvement over a column method on eight nodes or fewer. With more nodes, however, the improvements are much smaller. The main performance bottleneck for multifrontal methods on the iPSC/860 system, the cost of communicating data on the critical path, is not addressed by the panel multifrontal method. The block fan-out method relieves this bottleneck, and it produces significantly higher performance for large numbers of nodes. However, it still suffers from several important bottlenecks. Parallel performance on the iPSC/860 system is still relatively low.

On the hardware front, we find that the Intel Paragon system, which delivers an order of magnitude higher communication bandwidth than the earlier Intel iPSC/860 system, provides 2.5 to 3.5 times the performance of the iPSC/860 system for large numbers of nodes (32 or more) using traditional benchmark matrices. Furthermore, we find that by considering larger benchmark matrices, we obtain extremely high performance. The Paragon system performs the factorization at 650 Mflops on 32 nodes, 1 Gflop on 64 nodes, and 1.7 Gflops on 128 nodes.

We conclude from this investigation that the factors that have historically limited parallel sparse factorization performance have been overcome, and that distributed-memory machines can now deliver extremely high factorization performance. We believe that these machines are now quite appealing platforms for performing this important computation, and that they will become increasingly so in the future.

A STABLE HIGH-ORDER INTERPOLATION SCHEME FOR SUPERCONVERGENT DATA*

STEVEN PRUESS† AND HONGSUNG JIN†

Abstract. A local collocation scheme is developed that yields stable high-order accurate interpolants of discrete data arising from the numerical solution of a differential equation. It should prove to be especially attractive for applications where data are superconvergent, e.g., spline collocation at Gauss points. For simplicity, the formulas are initially developed for a scalar equation, but generalizations are later given for systems. Numerical examples are shown that illustrate the stability, even for the case of highly nonuniform meshes which have proven difficult in prior studies.

Key words. stable interpolation, spline collocation, superconvergence, boundary value problems

AMS subject classifications. 65D05, 65L10, 65L60, 65L20

1. Introduction and mathematical background. Some difficulties encountered in attempting to uniformly preserve the superconvergent accuracy of meshpoint approximations to collocation solutions of two-point boundary value problems were discussed in Pruess [9]. While several of the piecewise polynomial interpolation schemes introduced there were adequate on many examples, all suffered in some particular cases, especially when highly nonuniform meshes were used. The essential difficulty is the lack of sufficient superconvergent data to produce high-order accurate uniform interpolants. To preserve the same order of accuracy, if data from neighboring intervals are used, this leads to inaccuracies when local mesh ratios are high (see [9] and [10]). In this paper we discuss and illustrate a means of overcoming this difficulty; because it appears essential to use only local data, the missing information is supplied by a local collocation of the underlying differential equation. The resulting algorithms are straightforward for linear differential equations; extensions to nonlinear problems by iteration on approximating linear problems should be self-evident.

Another alternative is to use an implicit Runge–Kutta approach. Cash [4] has developed such formulas for first-order systems; their derivation is tedious, especially for higher-order equations and for a variety of orders of accuracy. The collocation approach given here appears to be much more direct and general; the determination of which approach is more efficient will require comparison of specific implementations.

The remainder of this section presents the notation used and some mathematical background needed below. The next section contains material about Hermite-Birkhoff interpolation which is needed to understand the behavior of the algorithms to follow. Section 3 is concerned with developing the formulas for local collocation for a scalar equation; the stability of the algorithm also is established. These ideas are generalized to systems of differential equations in §4; the final section contains numerical examples.

While it is more practical to consider systems of differential equations, for simplicity we begin with a scalar linear differential equation:

$$D^m u = \sum_{j=1}^{m} c_j(x) D^{j-1} u + f(x) \tag{1.1}$$

*Received by the editors October 22, 1993; accepted for publication (in revised form) December 20, 1994. This research was partially supported by National Science Foundation grant DMS-9322615 to the Colorado School of Mines.

†Department of Mathematical and Computer Sciences, Colorado School of Mines, Golden, CO 80401-1887 (spruess@slate.mines.edu, hjin@mines.edu).

for $a < x < b$. Of course, m boundary conditions also are needed, but because they will not play a major role in this paper, their details are ignored. Here D denotes differentiation with respect to x. We assume that the coefficient functions in equation (1.1) are "sufficiently smooth" and that (1.1) and the boundary conditions are such that there is a unique solution $u(x)$ for each choice of $f(x)$.

All approximate solutions considered will be piecewise polynomials. The set of breakpoints (also called nodes or meshpoints) for the pieces is denoted by Δ. With $\Delta = \{a = x_1 < x_2 < \cdots < x_{N+1} = b\}$, set $h_n = x_{n+1} - x_n$ and $h = \max h_n$. The symbol $P_{k,\Delta}$ denotes the space of piecewise polynomials of order k (degree $< k$) with breakpoints in Δ.

If collocation at Gaussian points (e.g., see de Boor and Swartz [2]) is used to produce an approximation $\hat{u}(x)$ in $P_{m+k,\Delta} \cap C^{m-1}[a, b]$ to the exact solution $u(x)$, then for $j = 1, 2, \ldots, m$ the errors satisfy (when $k \geq m$)

$$|D^{j-1}u(x_n) - D^{j-1}\hat{u}(x_n)| \leq Ch^{2k} \tag{1.2}$$

at the breakpoints. At general points x not in Δ,

$$|D^{j-1}u(x) - D^{j-1}\hat{u}(x)| \leq Ch^{m+k-j} \tag{1.3}$$

for some generic constant C. Hence, superconvergence occurs as long as $k > m$. Superconvergent accuracy on a discrete set of points also occurs when Galerkin approximations are used; e.g., see Bramble and Schatz [3] or Zlamal [11].

In Pruess [9] several high-order interpolation schemes were derived in an attempt to preserve the superconvergent accuracy. While all were proven to have uniform $O(h^{2k})$ errors as $h \to 0$, as previously mentioned, the actual errors for typical meshes were not satisfactorily small. Mathematically, nearly all the methods presented had large constants (involving local mesh ratios) in the h^{2k} term in the error expansion. We view this as a case of "instability": the small errors in $\hat{u}$ at meshpoints were magnified by the interpolation schemes used. In §3 we present a family of methods which does not suffer from this difficulty; i.e., the uniform error in the interpolation scheme has the same $O(h^{2k})$ accuracy but the error constant does not contain mesh-dependent quantities.

2. A Hermite-Birkhoff interpolation problem. In this section we digress with a discussion of a particular Hermite-Birkhoff interpolation problem which will be used to explain the behavior of the algorithms developed in later sections. The problem is the following.

Given integers m and k with $k > m$, some sufficiently smooth function $f(x)$, and a set of points $\{\zeta_i\}$ in $[-1, 1]$, find a polynomial $p(x)$ of order $2k$ satisfying

1. $(D^{j-1}p)(-1) = (D^{j-1}f)(-1)$ for $j = 1, 2, \ldots, m$;
2. $(D^{j-1}p)(1) = (D^{j-1}f)(1)$ for $j = 1, 2, \ldots, m$;
3. $(D^m p)(\zeta_i) = (D^m f)(\zeta_i)$ for $i = 1, 2, \ldots, 2k - 2m$.

Of course, it is well known that, in general, there may be no solution or many solutions to Hermite-Birkhoff problems. Some references for theory on Hermite-Birkhoff interpolation are [5], [7], and [8]. A Hermite-Birkhoff problem is said to be *poised* if for zero data ($f \equiv 0$) the only solution is $p(x) \equiv 0$. In the thesis of Jin [6] it was shown that the stated problem (for typical k and m) is poised for most choices of points including the important ones (for the algorithms in §§3 and 4) of uniform, either open (not including ±1) or closed (including ±1). This was done by explicitly calculating the determinant of the coefficient matrix associated with the interpolation conditions using a monomial representation of $p(x)$. In contrast, it was noticed that the choice of Gauss points (zeros of Legendre polynomials) was not poised for most k and m. The latter can be easily shown without computing any determinants.

LEMMA 2.1. *Assume*

$$p \in P_{2k}; \tag{2.1}$$

$$D^{j-1}p(\pm 1) = 0 \textit{ for } j = 1, 2, \ldots, m; \tag{2.2}$$

$$D^m p(\zeta_i) = 0 \textit{ for some } \{\zeta_i\} \in [-1, 1]. \tag{2.3}$$

Then $q = D^m p$ satisfies

$$q \in P_{2k-m}, \tag{2.4}$$

$$q(\zeta_i) = 0, \tag{2.5}$$

$$\int_{-1}^{1} t^{j-1} q(t)\, dt = 0 \textit{ for } j = 1, 2, \ldots, m. \tag{2.6}$$

Moreover, if q satisfies (2.4)-(2.6) *then p, the mth antiderivative of q with $p^{(j-1)}(-1) = 0$ for $j = 1, 2, \ldots, m$, satisfies* (2.1)-(2.3).

Proof. The consequences (2.4) and (2.5) are trivial; (2.6) follows inductively using repeated integrations by parts. Conversely, if (2.4)-(2.6) hold, then (2.1), (2.3), and half of (2.2) follow trivially. To show that $p^{(j-1)}(1) = 0$ for $j = 1, 2, \ldots, m$, it is also straightforward using integration by parts inductively.

Consequently, to show the stated Hermite-Birkhoff problem is not poised we can either find a nonzero p satisfying (2.1)-(2.3) or a nonzero q satisfying (2.4)-(2.6).

THEOREM 2.2. *The stated Hermite-Birkhoff problem is not poised when the set $\{\zeta_i\}$ is the set of zeros of the $(2k - 2m)$th degree Legendre polynomial L_{2k-2m} and $3m \leq 2k$.*

Proof. Let $q = L_{2k-2m}$; then for $m \leq 2k - 2m$ the conditions (2.4)-(2.6) trivially hold.

The condition that $3m \leq 2k$ is usually satisfied for typical choices of m and k arising from two-point boundary value problems. In fact, because we are requiring $k > m$ for superconvergence, the condition always holds for first- and second-order differential equations.

3. Formulas and theory for a single equation. As in §1 we denote the superconvergent approximation to the solution of the differential equation by $\hat{u}(x)$. The final uniformly high-order accurate approximation will be written $\bar{u}(x)$. We assume that $\hat{u}$ has errors satisfying (1.2)-(1.3) with $k > m$.

The approximation $\bar{u}(x)$ is characterized by the following.

1. $\bar{u}(x)$ is a piecewise polynomial of order $2k$ with breakpoints in Δ.
2. $(D^{j-1}\bar{u})(x_n) = (D^{j-1}\hat{u})(x_n)$ for $1 \leq j \leq m$; $x_n \in \Delta$.
3. On each $[x_n, x_{n+1}]$,

$$D^m \bar{u} = \sum_{j=1}^{m} c_j D^{j-1}\bar{u} + f \tag{3.1}$$

is evaluated at some ξ_{in}.

Since $\hat{u}$ is a piecewise polynomial of order $2k$, there are a total of $2kN$ coefficients in a local representation. The interpolation conditions determine $2mN$ of these, leaving $2(k - m)$ to be determined by the collocation conditions (3.1). This says that there should be $2k - 2m$ of the ξ's for each subinterval. These points will be referred to as the set of *secondary* collocation points.

A local Hermite representation is used for $\bar{u}$; i.e., on $[x_n, x_{n+1}]$,

$$\begin{aligned} \bar{u}(x) = &\sum_{j=1}^{k} (D^{j-1}\bar{u})(x_n^+)\Phi_j\left(-1 + 2\frac{x_{n+1} - x}{h_n}\right)\left(\frac{-h_n}{2}\right)^{j-1} \\ &+ \sum_{j=1}^{k} (D^{j-1}\bar{u})(x_{n+1}^-)\Phi_j\left(-1 + 2\frac{x - x_n}{h_n}\right)\left(\frac{h_n}{2}\right)^{j-1} \end{aligned} \tag{3.2}$$

where $\Phi_j(t)$ satisfies

$$(D^{\nu-1}\Phi_j)(-1) = 0, \qquad 1 \le \nu \le k, \tag{3.3}$$

$$(D^{\nu-1}\Phi_j)(1) = \delta_{\nu j}, \qquad 1 \le \nu \le k, \tag{3.4}$$

with D here denoting differentiation with respect to t.

Because there are the same number of secondary collocation points on each interval, it is convenient to adopt the same relative spacing on each interval; i.e., write

$$\xi_{in} = x_n + (1+\zeta_i)\frac{h_n}{2} \tag{3.5}$$

for some choice of $\{\zeta_i\}$ in $[-1, 1]$ to be specified later. For simplicity, we additionally assume that the $\{\zeta_i\}$ are chosen symmetrically; i.e., for some

$$\eta_1 > \eta_2 > \cdots > \eta_{k-m} > 0,$$

we have $\zeta_i = -\eta_i$ for $i = 1, \dots, k-m$ and $\zeta_i = \eta_{2k-2m-i+1}$ for $i = k-m+1, \dots, 2k-2m$.

Then the secondary collocation equations (3.1) become

$$\begin{aligned}
&\sum_{j=1}^{k}(D^{j-1}\bar{u})(x_n^+)\Phi_j^{(m)}(-\zeta_i)\left(\frac{-h_n}{2}\right)^{j-m-1} + \sum_{j=1}^{k}(D^{j-1}\bar{u})(x_{n+1}^-)\Phi_j^{(m)}(\zeta_i)\left(\frac{h_n}{2}\right)^{j-m-1} \\
&\quad = \sum_{\nu=1}^{m} c_\nu(\xi_{in})\left\{\sum_{j=1}^{k}(D^{j-1}\bar{u})(x_n^+)\Phi_j^{(\nu-1)}(-\zeta_i)\left(\frac{-h_n}{2}\right)^{j-\nu}\right. \\
&\quad\quad \left. + \sum_{j=1}^{k}(D^{j-1}\bar{u})(x_{n+1}^-)\Phi_j^{(\nu-1)}(\zeta_i)\left(\frac{h_n}{2}\right)^{j-\nu}\right\} + f(\xi_{in})
\end{aligned}$$

for $1 \le i \le 2k-2m$. Rearranging this and using the fact that $\bar{u}$ interpolates $\hat{u}$ at the endpoints of each piece, we have

$$\begin{aligned}
&\sum_{j=m+1}^{k}(D^{j-1}\bar{u})(x_n^+)\left(-\frac{h_n}{2}\right)^{j-m-1}\left\{\Phi_j^{(m)}(-\zeta_i) - \sum_{\nu=1}^{m} c_\nu(\xi_{in})\Phi_j^{(\nu-1)}(-\zeta_i)\left(-\frac{h_n}{2}\right)^{m+1-\nu}\right\} \\
&+ \sum_{j=m+1}^{k}(D^{j-1}\bar{u})(x_{n+1}^-)\left(\frac{h_n}{2}\right)^{j-m-1}\left\{\Phi_j^{(m)}(\zeta_i) - \sum_{\nu=1}^{m} c_\nu(\xi_{in})\Phi_j^{(\nu-1)}(\zeta_i)\left(\frac{h_n}{2}\right)^{m+1-\nu}\right\} \\
&\quad = f(\xi_{in}) - \sum_{j=1}^{m}(D^{j-1}\hat{u})(x_n)\left\{\Phi_j^{(m)}(-\zeta_i)\left(\frac{-h_n}{2}\right)^{j-m-1}\right. \\
&\quad\quad \left. - \sum_{\nu=1}^{m} c_\nu(\xi_{in})\Phi_j^{(\nu-1)}(-\zeta_i)\left(\frac{-h_n}{2}\right)^{j-\nu}\right\} \\
&\quad\quad - \sum_{j=1}^{m}(D^{j-1}\hat{u})(x_{n+1})\left\{\Phi_j^{(m)}(\zeta_i)\left(\frac{h_n}{2}\right)^{j-m-1} - \sum_{\nu=1}^{m} c_\nu(\xi_{in})\Phi_j^{(\nu-1)}(\zeta_i)\left(\frac{h_n}{2}\right)^{j-\nu}\right\}.
\end{aligned} \tag{3.6}$$

For each subinterval this is a linear system of $2k-2m$ equations in the unknowns $(D^{j-1}\bar{u})(x_n^+)$ and $(D^{j-1}\bar{u})(x_{n+1}^-)$ for $m+1 \le j \le k$.

Note that the coefficient matrix on each subinterval is an $O(h)$ perturbation of the one for the corresponding (same k and m) Hermite-Birkhoff problem in the previous section. Hence, we would expect, for sufficiently fine grids, that the matrix is invertible for most choices of the η_i and typical k and m. On the other hand, we would anticipate near singularity (ill conditioning) if Gauss points are chosen for the secondary collocation points on problems where $3m \leq 2k$. It should also be pointed out that for singularly perturbed differential equations the $O(h)$ change may in fact be an $O(h/\epsilon)$ change for some small ϵ, and, consequently, the value of ϵ has a major effect on the conditioning of the linear system.

In Jin [6] it is proven that when the associated Hermite-Birkhoff problem is poised, then the projector associated with the local interpolation scheme is well defined (the above coefficient matrix is invertible) and is bounded independently of the mesh. From this it is straightforward to establish error bounds; the arguments follow those of [9] without the local change of variable (see [6] for details). Assuming the associated Hermite-Birkhoff problem is poised, the error has the expected form

$$|D^{j-1}u(x) - D^{j-1}\bar{u}(x)| \leq Ch^{2k-j+1} \tag{3.7}$$

for $j = 1, 2, \ldots, 2k$ and any x in $[a, b]$. The constant C can depend on $u(x)$ and its derivatives, k, m, and the choice of $\{\eta_i\}$, but not the mesh. Numerical experiments (some displayed in §5) confirm these rates of convergence.

4. Generalizations to mixed-order systems. As in [9] we consider the mixed-order system of linear equations

$$D^{m_l}u_l = \sum_{j=1}^{p}\sum_{i=1}^{m_j} c_{lij}D^{i-1}u_j + f_l, \quad 1 \leq l \leq p, \tag{4.1}$$

for x in $[a, b]$. Let

$$m^* = \sum_{j=1}^{p} m_j; \tag{4.2}$$

then m^* boundary conditions also are needed.

Analogous to the scalar case, we denote the lth component of the collocation approximation by $\hat{u}_l(x)$ and its interpolant by $\bar{u}_l(x)$. Then $\bar{u}_l(x)$ satisfies (for $1 \leq l \leq p$) the following:

1. $\bar{u}_l(x)$ is a piecewise polynomial of order $2k$ with breakpoints in Δ.
2. $(D^{j-1}\bar{u}_l)(x_n) = (D^{j-1}\hat{u}_l)(x_n)$ for $1 \leq j \leq m_l$; $x_n \in \Delta$.
3. On each $[x_n, x_{n+1}]$,

$$D^{m_l}\bar{u}_l = \sum_{\mu=1}^{p}\sum_{\nu=1}^{m_\mu} c_{l\nu\mu}D^{\nu-1}\bar{u}_\mu + f_l \tag{4.3}$$

is evaluated over some finite set of secondary collocation points.

Because each component is a piecewise polynomial of order $2k$, there are a total of $2kpN$ coefficients in a local representation. The interpolation conditions determine $2m^*N$ of these leaving

$$2[(k - m_1) + (k - m_2) + \cdots + (k - m_p)]N$$

to be determined by the collocation conditions (4.3). This says that there should be $2k - 2m_l$ secondary collocation points for each l and n. These points are denoted by ξ_{inl} and, analogous to (3.5), for convenience we require that there be $\{\zeta_{il}\}$ in $(-1, 1)$ such that

$$\xi_{inl} = x_n + (1 + \zeta_{il})\frac{h_n}{2}$$

for $i = 1, \dots, 2k - 2m_l$, $l = 1, \dots, p$, and $n = 1, \dots, N$.

As in §2 a local Hermite representation is used for each $\bar{u}_l$, i.e., on $[x_n, x_{n+1}]$

$$\begin{aligned} \bar{u}_l(x) = {} & \sum_{j=1}^{k} (D^{j-1}\bar{u}_l)(x_n^+)\Phi_j\left(-1 + 2\frac{x_{n+1} - x}{h_n}\right)\left(\frac{-h_n}{2}\right)^{j-1} \\ & + \sum_{j=1}^{k} (D^{j-1}\bar{u}_l)(x_{n+1}^-)\Phi_j\left(-1 + 2\frac{x - x_n}{h_n}\right)\left(\frac{h_n}{2}\right)^{j-1} \end{aligned} \tag{4.4}$$

where $\Phi_j(t)$ satisfies (3.3)-(3.4).

Then, after some rearrangement, (4.3) becomes

$$\begin{aligned} & \sum_{j=m_l+1}^{k} (D^{j-1}\bar{u}_l)(x_n^+)\left(\frac{-h_n}{2}\right)^{j-1-m_l} (D^{m_l}\Phi_j)(-\zeta_{il}) \\ & - \sum_{\mu=1}^{p} \sum_{j=m_\mu+1}^{k} (D^{j-1}\bar{u}_\mu)(x_n^+) \sum_{\nu=1}^{m_\mu} c_{l\nu\mu}(\xi_{inl})\left(\frac{-h_n}{2}\right)^{j-\nu} (D^{\nu-1}\Phi_j)(-\zeta_{il}) \\ & + \sum_{j=m_l+1}^{k} (D^{j-1}\bar{u}_l)(x_{n+1}^-)\left(\frac{h_n}{2}\right)^{j-1-m_l} (D^{m_l}\Phi_j)(\zeta_{il}) \\ & - \sum_{\mu=1}^{p} \sum_{j=m_\mu+1}^{k} (D^{j-1}\bar{u}_\mu)(x_{n+1}^-) \sum_{\nu=1}^{m_\mu} c_{l\nu\mu}(\xi_{inl})\left(\frac{h_n}{2}\right)^{j-\nu} (D^{\nu-1}\Phi_j)(\zeta_{il}) \\ & = f_l(\xi_{inl}) - \sum_{j=1}^{m_l}\left[(D^{j-1}\hat{u}_l)(x_n)\left(\frac{-h_n}{2}\right)^{j-1-m_l} (D^{m_l}\Phi_j)(-\zeta_{il})\right. \\ & \qquad \left. + (D^{j-1}\hat{u}_l)(x_{n+1})\left(\frac{h_n}{2}\right)^{j-1-m_l} (D^{m_l}\Phi_j)(\zeta_{il})\right] \\ & + \sum_{\mu=1}^{p}\sum_{\nu=1}^{m_\mu} c_{l\nu\mu}(\xi_{inl}) \sum_{j=1}^{m_\mu}\left[(D^{j-1}\hat{u}_\mu)(x_n)\left(\frac{-h_n}{2}\right)^{j-\nu} (D^{\nu-1}\Phi_j)(-\zeta_{il})\right. \\ & \qquad \left. + (D^{j-1}\hat{u}_\mu)(x_{n+1})\left(\frac{h_n}{2}\right)^{j-\nu} (D^{\nu-1}\Phi_j)(\zeta_{il})\right] \end{aligned} \tag{4.5}$$

in analogy with the scalar case (3.6). Hence, in an implementation this $2(kp - m^*)$-by-$2(kp - m^*)$ linear system must be solved for each subinterval.

5. Examples and conclusions. In this section the local collocation algorithm is tested to verify the expected behavior. Many examples were tried, but for brevity only four are presented here; the first three are those from [9]. The local interpolant $\bar{u}$ is compared with the collocation solution $\hat{u}(x)$. We do not repeat data for the other interpolants in [9] because overall, none of them was as effective as the $\bar{u}(x)$ introduced here.

Many different choices for the secondary collocation points also were explored. The ones considered follow:

1. open uniform: $\eta_i = (k - m + 1 - i)/(2k - 2m + 1)$,
2. closed uniform: $\eta_i = (2k - 2m - i)/(2k - 2m - 1)$,
3. Gauss points: $\{\eta_i\}$ is the set of roots of the Legendre polynomial of degree $2k - 2m$,
4. pseudo-Chebyshev points: $\eta_i = 1 - \sin[i\pi/(2k - 2m + 2)]$

for $1 \leq i \leq k - m$.

If we were ignorant of the material in §2, the choice of Gauss points would seem a natural one for collocation because of its importance in generating the $\hat{u}(x)$ which has superconvergent values at the breakpoints. Neither the open or closed uniform nor the pseudo-Chebyshev set should have nonpoised underlying Hermite-Birkhoff problems so their coefficient matrices should be better behaved. However, it was observed in [9] that interpolants using the differential equation at breakpoints (corresponding to $\zeta = -1$ or 1) frequently were poor on singularly perturbed problems because the errors $u^{(j-1)} - \hat{u}^{(j-1)}$ for $1 \leq j \leq m$ were magnified by the reciprocal of the perturbation parameter. Hence, we anticipate that, at least on singularly perturbed problems, the closed choice will be inferior to the open one. The motivation for the pseudo-Chebyshev set is to try a standard distribution which clusters points near the midpoint of the subintervals.

All numerical calculations in this section were done on an 80386-based PC using double precision arithmetic (approximately 16 decimal digits). In contrast to [9], we have not chosen to make operation counts in this work. Partly this is due to the difficulty of comparisons since k, m, p, and N are all parameters. There is no doubt that the interpolants using local collocation are more expensive to produce because they require additional (small) linear systems to be solved; however, their total effort is still minor compared with the time required to produce $\hat{u}(x)$.

In some of the tables below, condition numbers are displayed; in fact, these are estimates using the standard LINPACK algorithms. Because these estimates are felt to be reliable as to the order of magnitude, we have not bothered to compute exact condition numbers themselves. However, they must be interpreted with some caution; row and column scaling can have a considerable affect on the condition number estimate even though the answer to the associated linear system was usually unaffected. Also, rather than implement (4.5) as given, we have actually used an equivalent system of equations where each (x_n, x_{n+1}) was mapped into $[0, 1]$ rather than $[-1, 1]$.

The first example is the first from [9] which is a system of two ordinary differential equations.

$$u_1''' = u_1' - 4e^{2x}u_2 + 4(x^2 + 1)e^x,$$

$$u_2' = -xu_1 + xu_1'' - u_2 - 4x^2e^x + (2x - 1)e^{-x},$$

$$u_1(0) = u_2(0) = u_1(1) = u_2(1) = 0.$$

The exact answers are $u_1(x) = x(x - 1)\exp(x)$ and $u_2(x) = x(x - 1)\exp(-x)$. The errors (nodal and uniform) for the standard collocation approximation $\hat{u}(x)$, and for $\bar{u}(x)$ based on several choices of secondary collocation points are shown in Table 1. All cases used $k = 4$ and $N = 12$ equally spaced breakpoints (nodes). We have also tabulated the maximum over the mesh of a condition number estimate for the coefficient matrix of the secondary collocation

TABLE 1
Absolute errors for the first example.

	u_1	u_1'	u_1''	u_2

Chebyshev	0.614E−12	0.307E−11	0.174E−09	0.244E−11	9.6E+06

equations. Note that the choice of Gauss points does produce the most ill conditioned of the coefficient matrices, although on this example the accuracy of $\bar{u}_1$ is relatively unaffected by this. The other three choices of secondary collocation points produce interpolants of comparable accuracy, all superior to the full collocation solutions $\hat{u}_1(x)$ and $\hat{u}_2(x)$. The decline in the derivative accuracy for $\hat{u}_1$ reflects the expected error bounds (3.7).

The next example also is from [1] and was studied in [9].

$$u'' = -xu'/\epsilon - (\pi x \sin^2 \pi x)/\epsilon - \pi^2 \cos \pi x,$$

$$u(-1) = 2, \qquad u(1) = 0,$$

for which

$$u(x) = \cos \pi x + \operatorname{erf}(x/\sqrt{2\epsilon})/\operatorname{erf}(1/\sqrt{2\epsilon}).$$

This problem has an interior layer near the origin. For a given mesh the *maximum local mesh ratio* is defined by

$$\max_i\{\max[h_i/h_{i-1}, h_{i-1}/h_i]\};$$

the *global mesh ratio* is

$$\max h_i / \min h_i.$$

For the initial choice of $\epsilon = 10^{-4}$ we used 36 breakpoints chosen so that an approximation to $||u^{(6)}||^{1/6}$ was roughly equidistributed. The maximum local mesh ratio was 3.0 while the global mesh ratio was 32.8; again $k = 4$ was used. A second case $\epsilon = 10^{-6}$ was used with 64 breakpoints based on the same equidistribution principle; here the maximum local mesh ratio was 9.8 while the global mesh ratio was 295.

The uniform errors in $\bar{u}(x)$ and $\bar{u}'(x)$ were better than those for standard collocation; in fact, the superconvergent accuracy in the derivative approximation did not degrade at all. Table 2 contains the data comparing $\bar{u}(x)$ with $\hat{u}(x)$. Again, the choice of Gauss points led to ill-conditioned matrices and inferior accuracies, especially in $\bar{u}'(x)$. The choice of closed points (including the nodes) for the secondary collocation points was poor as we had anticipated for singularly perturbed differential equations in the initial discussion of this section.

The third example is a generalization of the final example cited in [9], motivated by an example in [1]. This is a set of two second-order ODEs with boundary layers.

$$u_1'' = (u_1 - u_2)/\epsilon - u_1',$$

$$u_2'' = (u_2 - u_1)/\epsilon^2 - u_2',$$

TABLE 2
Absolute errors for the second example.

	$\epsilon = 10^{-4}$			$\epsilon = 10^{-6}$		
	u	u'		u	u'	
At nodes	0.140E−7	0.786E−5		0.741E−9	0.475E−5	
Uniform						
$\hat{u}(x)$	0.110E−6	0.213E−3		0.147E−7	0.219E−3	
$\bar{u}(x)$			Max Cond			Max Cond
open	0.327E−7	0.786E−5	1.6E+4	0.521E−8	0.475E−5	2.2E+06
closed	0.872E−5	0.276E−3	2.8E+4	0.183E−3	0.110E−1	2.8E+06
Gauss	0.110E−6	0.213E−3	4.8E+9	0.880E−7	0.220E−3	1.8E+12
Chebyshev	0.331E−7	0.786E−5	5.6E+4	0.587E−8	0.475E−5	8.7E+05

$$\begin{aligned} u_1(0) + u_1'(0) &= 3 + 2(1+\epsilon)\exp(-5/\epsilon), \\ u_2(0) &= 1 - 2\exp[-5(1+1/\epsilon)], \\ u_1(5) - u_2(5) &= 2(1+\epsilon)(1 - \exp[-5(1+1/\epsilon)]), \\ u_1'(5) + u_2(5) &= 1 + 2(2+\epsilon)\exp[-5(1+1/\epsilon)]. \end{aligned}$$

The exact answers are

$$\begin{aligned} u_1(x) &= 1 - 2\exp(-x) + 2\epsilon\{\exp[(x-5)/\epsilon] - \exp[-(1+1/\epsilon)x]\}, \\ u_2(x) &= 1 - 2\exp(-x) - 2\{\exp[(x-5)/\epsilon] - \exp[-(1+1/\epsilon)x]\}. \end{aligned}$$

This was tried for $k = 4$ and two values of ϵ; in each case, meshes were chosen to equidistribute an approximation of $||u^{(6)}||^{1/6}$. For $\epsilon = 10^{-2}$ the mesh consisted of 20 breakpoints with a local mesh ratio of 13.5 and a global mesh ratio of 178.3; when $\epsilon = 10^{-4}$ and $N = 28$ the mesh ratios were 466 and 18771, respectively. Table 3 displays the errors for the interpolant based on local collocation with several choices of secondary collocation points. The superiority of $\bar{u}_1(x)$ and $\bar{u}_2(x)$ from local collocation is quite evident. The best choice for secondary collocation points was the open uniform one though the pseudo-Chebyshev choice is only slightly inferior.

The final example is a scalar third-order one whose solution is mildly oscillatory.

$$\begin{gathered} u''' = -[28^2\pi^2/(1+7x)^4]u + [28^3\pi^2/(1+7x)^5]u', \\ u(0) = 1, \qquad u(1) = 0, \qquad u''(1) = 0. \end{gathered}$$

The exact answer is $u(x) = (1+7x)\cos[4\pi/(1+7x)]$. The output for different k and N values is found in Table 4. In both cases the mesh was chosen to equidistribute an approximation of $||u^{(k+3)}||^{1/(k+3)}$. When $k = 4$ for this example, we have $3m > 2k$ so the theory in §2 says nothing about the poisedness of the Hermite-Birkhoff problem associated with the choice of Gauss points. The arguments in Jin [6] show that it is in fact poised. In contrast, when $k = 5$ the Gauss points definitely do not have a poised Hermite-Birkhoff problem since now $3m \leq 2k$. The data in Table 4 are consistent with this.

In conclusion, it is clear that an interpolant based on local collocation using an open uniform set of secondary collocation points can do a very good job of preserving the superconvergent accuracy at breakpoints of $\hat{u}(x)$ and its first $m - 1$ derivatives. Even on very irregular meshes the stability of $\bar{u}$ is quite evident: for singularly perturbed differential equations, $\bar{u}(x)$ preserves the superconvergent accuracy of $\hat{u}(x)$ at the grid points as long as a good initial mesh has been found.

The choice of the "best" or at least a "better" choice of local collocation points merits further theoretical study; this is the subject of continuing research on the part of the authors.

AN ASSESSMENT OF NONMONOTONE LINESEARCH TECHNIQUES FOR UNCONSTRAINED OPTIMIZATION*

PHILIPPE L. TOINT†

Abstract. The purpose of this paper is to discuss the potential of nonmonotone techniques for enforcing convergence of unconstrained minimization algorithms from starting points distant from the solution. Linesearch-based algorithms are considered for both small and large problems, and extensive numerical experiments show that this potential is sometimes considerable. A new variant is introduced in order to limit some of the identified drawbacks of the existing techniques. This variant is again numerically tested and appears to be competitive. Finally, the impact of preconditioning on the considered methods is examined.

Key words. nonmonotone algorithms, linesearch, unconstrained optimization

AMS subject classifications. 90C30, 90C26, 49M37

1. Introduction.

In this paper, we consider algorithms for the numerical solution to the problem

$$\underset{x \in \mathbf{R}^n}{\text{minimize}} \quad f(x), \tag{1}$$

where $f(x)$ is a real-valued smooth function, which we assume is bounded below. Most widely available algorithms for solving the *nonlinear unconstrained minimization problem* (1) are, today, *descent methods*, in that they generate a sequence of iterates $\{x_k\}$ such that the associated sequence of objective function values $\{f(x_k)\}$ is monotonically decreasing. This is the case of all methods described in [9], a now classical reference on this subject, such as that of many packages for solving unconstrained problems, as well as UNCMIN [17], TENMIN [22], LANCELOT [7], and those from the Harwell Subroutines VA15 [18], VE08 [23], and VE10 [24], to cite just a few. This monotonicity property may be considered as natural, since one wishes to find a point with the lowest possible objective function value, and has been extensively used, both in theory and practice, to ensure that convergence to a minimizer occurs, even when the minimization is started far away from such a point (see [3], [4], [6], or [25] for examples of convergence theory heavily relying on this important property).

It has been noted, however, that imposing monotonicity of the sequence of objective function values is not without drawbacks. A typical case where monotonicity can cause severe loss of efficiency is when the objective function features deep narrow curved valleys: once trapped near the bottom of such a valley, the sequence of iterates must follow the valley's floor rather closely, which can result in very short steps or even undesired zigzagging. This observation has led researchers to propose algorithms that do not always guarantee the monotonicity properties. In particular, Grippo, Lampariello, and Lucidi published a few papers (see [13], [14], and [15]) where they demonstrated on some examples that substantial efficiency gains could be achieved in the solution of (1) if one is ready to abandon, at least to some extent, the constraint of generating monotonically decreasing sequences of objective function values. They also provided the convergence analysis to support their algorithmic proposals. In all fairness, Grippo, Lampariello, and Lucidi were not the only researchers interested in nonmonotone techniques for nonlinear optimization: the watchdog technique of Chamberlain et al. [5] is also a strategy of this type, although intended for the solution of constrained problems.

*Received by the editors May 31, 1994; accepted for publication (in revised form) January 3, 1995.

†Department of Applied Mathematics, Facultes Universitaires Notre Dame de la Paix, Rue de Bruxelles, 61, B-5000 Namur, Belgium (pht@math.fundp.ac.be).

Surprisingly, and despite their obvious potential practical implications, the findings of Grippo, Lampariello, and Lucidi didn't lead to any substantial validation by other researchers, at least as far as the author is aware. These ideas have been sometimes used in the literature (see [16], for instance), but have not yet been incorporated in the mainstream research on nonlinear unconstrained minimization. It is the first purpose of this paper to re-examine their proposals and contribute to their evaluation. The second purpose is to present a variant of their original methods, also based on a succession of unidimensional (approximate) minimizations, usually known as "linesearches." The third and final aim of the paper is to examine the impact of preconditioning on the considered nonmonotone algorithms.

The paper is organized as follows. The original proposals of Grippo, Lampariello, and Lucidi are considered in §2, where a specific implementation of these proposals is compared with a more classical monotone linesearch algorithm on a large collection of both small and larger test problems from the CUTE collection [2]. A variant of these methods is introduced and tested in §3. Section 4 is devoted to the numerical investigation of the effect of preconditioning. Finally, we present some conclusions and perspectives in §5.

2. The algorithms of Grippo, Lampariello, and Lucidi.

2.1. The original proposals. The classical framework in which Grippo, Lampariello, and Lucidi discuss their proposals is that of a "gradient related" method using an Armijo linesearch. If we denote the usual Euclidean inner product and norm by $\langle \cdot, \cdot \rangle$ and $\| \cdot \|$, respectively, and define $g_k = \nabla f(x_k)$, we may describe this basic method as follows.

Basic Linesearch Algorithm (BLS)

0. Initialization. A starting point x_0 is given, as well as constants $\beta \in (0,1)$ and $\gamma \in (0,1)$. Set $k = 0$.

1. Test for convergence. Stop if the chosen convergence criteria are met.

2. Determination of a search direction. Find a direction d_k such that

$$\langle d_k, g_k \rangle \leq -\kappa_1 \|g_k\|^2 \tag{2}$$

and

$$\|d_k\| \leq \kappa_2 \|g_k\| \tag{3}$$

for some positive constants κ_1 and κ_2.

3. Linesearch. Determine the smallest integer j_k such that, if one defines

$$\alpha_k = \beta^{j_k}, \tag{4}$$

then

$$f(x_k + \alpha_k d_k) \leq f(x_k) + \gamma \alpha_k \langle g_k, d_k \rangle. \tag{5}$$

Then, set

$$x_{k+1} = x_k + \alpha_k d_k. \tag{6}$$

4. Prepare for the next iteration. Increment k by one and go to step 1.

There are several possible ways to determine the step d_k in step 2 of this prototype algorithm, in order to ensure that conditions (2) and (3) are satisfied. Grippo, Lampariello, and Lucidi propose to use the "modified Cholesky" factorization technique of Gill and Murray [10]. Other techniques will be discussed in § 2.3, in relation to our numerical experiments.

For future reference, we will refer to the linesearch calculation of step 3 as a procedure for obtaining x_{k+1} from the *base point* x_k (which determines the gradient $g_k = \nabla f(x_k)$), the *search direction* d_k, and the *reference value* $f(x_k)$ (the first term of the right-hand side of (5)). More concisely, we will express this relationship by the statement

$$x_{k+1} = LS_{\beta,\gamma}(x_k, d_k, f(x_k)), \tag{7}$$

which is therefore an alternative equivalent specification of step 3.

It is now easy to describe the original idea of Grippo, Lampariello, and Lucidi [13]: instead of using $f(x_k)$ as the reference value in step 3, they propose to use an objective function value corresponding to a previous iterate. More precisely, they propose to define

$$r_k = \max_{j=0,\dots,p} f(x_{k-j}) \tag{8}$$

for some fixed nonnegative integer p and then to replace step 3 in the basic algorithm by

$$x_{k+1} = LS_{\beta,\gamma}(x_k, d_k, r_k) \tag{9}$$

instead of (7). We will call the resulting algorithm the *GLL*1 *Algorithm*. As a consequence of (8), the strict monotonicity of the sequence $\{f(x_k)\}$ is no longer enforced, giving the algorithm more flexibility in the way in which successive iterates are obtained. Grippo, Lampariello, and Lucidi in fact describe and analyze several possible rules for the definition of the reference value r_k, but only provide numerical examples for the choice (8).

In a subsequent paper, Grippo, Lampariello, and Lucidi [15] introduce a further relaxation of the monotonicity property. Briefly speaking, they argue that some steps could be *automatically* accepted, without even checking any condition like (5), provided that these steps are sufficiently short (they require the subsequence of the norms of these steps to be geometrically converging to zero). To avoid convergence to undesirable maxima or saddle points, the value of the objective function is occasionally checked: if a suitable decrease has not been obtained since the last such verification, the algorithm is then restarted from the iterate corresponding to this last acceptable value. The precise manner in which the reference value r_k is redefined and this idea realized is a little more complex than the modification leading to Algorithm GLL1. It can be cast in the framework of Algorithm BLS as follows.

ALGORITHM GLL2

0. Initialization. A starting point x_0 is given, as well as constants $\beta \in (0,1), \gamma \in (0,1)$, $\eta \in (0,1)$, $\mu > 0$, $\xi \in (0,1)$, $\Delta_0 > 0$, $p \geq 1$, and $N \geq 1$. Set $k = \ell = 0$ and $f_0 = r_0 = f(x_0)$.

1. Test for convergence. Compute g_k and stop if $\|g_k\|$ is sufficiently small.

2. Determination of a search direction. Find d_k such that (2) and (3) hold and such that

$$\|d_k\| \geq \kappa_3 \|g_k\| \tag{10}$$

for some positive constant $\kappa_3 \leq \kappa_2$. If x_k has been obtained by step 5 or if $k = 0$, define $d_\ell = d_k$. Then, if $k = \ell + N$ go to step 3. Otherwise, go to step 4.

3. Tests after N **automatic step acceptances.** Compute $f(x_k)$ if necessary. If $f(x_k) \geq r_k$, set

$$x_k = x_\ell, \quad d_k = d_\ell, \quad \Delta_{k+1} = \Delta_k \tag{11}$$

and go to step 5. Otherwise, increment ℓ by one and define

$$x_\ell = x_k, \quad d_\ell = d_k, \quad f_\ell = f(x_k), \text{ and } r_k = \max_{j=0,\dots,p} f_{\ell-j}. \tag{12}$$

Then, if $\|d_k\| \le \Delta_k$, set

$$x_{k+1} = x_k + d_k, \quad \Delta_{k+1} = \eta\Delta_k, \quad r_{k+1} = r_k \tag{13}$$

and go to step 6. Otherwise go to step 5.

4. Tests before N automatic step acceptances. If $\|d_k\| \le \Delta_k$, perform step 4.a. Otherwise, perform step 4.b.

Step 4.a. If $\|d_k\| > \|d_{k-1}\|$, compute $f(x_k + d_k)$ and $f(x_k)$ if necessary. Then test if $f(x_k + d_k) - f(x_0) \ge \mu(f(x_0) - f(x_k))$. If this latter inequality holds, set

$$x_k = x_\ell, \quad d_k = d_\ell, \quad \Delta_{k+1} = \xi\Delta_k \tag{14}$$

and go to step 5. In all other cases, set x_{k+1}, Δ_{k+1}, and r_{k+1} according to (13) and go to step 6.

Step 4.b. Compute $f(x_k)$ if necessary. Then, if $f(x_k) \ge r_k$, set x_k, d_k and Δ_{k+1} using (11) and go to step 5. Otherwise, increment ℓ by one, recompute x_ℓ, d_ℓ, f_ℓ, and r_k using (12) and go to step 5.

5. Linesearch. Define

$$x_{k+1} = LS_{\beta,\gamma}(x_k, d_k, r_k), \tag{15}$$

increment ℓ by one and define

$$x_\ell = x_{k+1}, \quad f_\ell = f(x_{k+1}) \text{ and } r_{k+1} = \max_{j=0,\dots,p} f_{\ell-j}. \tag{16}$$

6. Prepare for the next iteration. Increment k by one and go to step 1.

We now briefly comment on this algorithm.

1. Condition (10) is introduced by Grippo, Lampariello, and Lucidi [15] and makes the length of the step an adequate measure of criticality. Section 2.3 shows that it does not constitute a strong additional requirement in a practical algorithm.

2. The step d_k is automatically accepted (see step 4) if its norm is at most equal to Δ_k and has not increased compared with that of d_{k-1}. In this case, the function value is not even computed. Observe also that the index ℓ denotes the last iterate at which the value of the objective function has been evaluated and has decreased enough. As indicated above, the algorithm "restarts" from this point if the objective function has not sufficiently diminished after N automatic acceptances.

3. The idea behind step 4.a is that it might be advisable to enforce closer control of the monotonicity of the objective function values if these become significantly larger than the initial value $f(x_0)$: this behavior combined with large steps may indeed indicate that the iterates are leaving the region of interest.

4. The mechanism for updating the reference value r_k is essentially identical to that used in GLL1, except that it only uses the last p function values that have been computed and which do not exceed their corresponding reference values. This distinction is necessary because, as indicated in the previous paragraph, some function values may not have been calculated when short steps are automatically accepted.

Grippo, Lampariello, and Lucidi [15] indicate that Algorithm GLL2 may be more efficient than GLL1 and often compare favorably with the modified Newton routine E04LBF from the NAG library.

2.2. Convergence theory. Grippo, Lampariello, and Lucidi proved that every limit point of the sequence of iterates produced by Algorithms GLL1 and GLL2 is a stationary point for problem (1). In order to obtain this result, they assume that the objective function is twice continuously differentiable on the compact level set $\{x \mid f(x) \leq f(x_0)\}$. Their argument is no longer based on the (abandoned) decreasing nature of the sequence of objective function values $f(x_k)$, but rather on the monotonicity of the references values r_k. The analysis is slightly more involved for Algorithm GLL2, since the effect of restarting the algorithm after an "unsuccessful" series of N automatically accepted steps must be taken into account; see [13] and [15] for details.

Note that the same convergence result is automatically obtained for Algorithm BLS by viewing this algorithm as a special case of Algorithm GLL1 where $p = 0$, but may also be obtained by directly exploiting (2)-(6). In particular, (2) and (3) imply that BLS produces "gradient-related" search directions (see [19, §14.3]).

2.3. An implementation. Our implementation of Algorithms BLS, GLL1, and GLL2 in Fortran 77 is rather straightforward.

- Termination occurs when $\|g_k\| \leq 10^{-5}$.
- The determination of the search direction d_k at step 2 is achieved by approximately solving the Newton system

$$(H_k + M_k)d_k = -g_k \tag{17}$$

where H_k denotes $\nabla^2 f(x_k)$, and where M_k is a symmetric positive semidefinite perturbation matrix such that the eigenvalues of $H_k + M_k$ are in the interval $[\kappa_4, \kappa_5]$ (for some positive constants κ_4 and κ_5 independent of k). The main motivation for allowing an approximate solution of (17) is the considerable reduction of computational effort (compared with a full solution) that is typically obtained for large-scale problems. The step d_k obtained as an approximate solution of (17) can thus be regarded as the exact solution of a "perturbed" Newton system of the form

$$(H_k + M_k)d_k = -g_k + h_k \tag{18}$$

where we request the "residual" h_k to satisfy the conditions

$$\langle d_k, h_k \rangle = 0 \tag{19}$$

and

$$\|h_k\| \leq \|g_k\| \min(0.1, \|g_k\|^{1/2}). \tag{20}$$

Among the many possible ways of selecting the perturbation matrix M_k, we have chosen the modified conjugate-gradients (CG) method proposed by Arioli et al. [1]. This method guarantees both (19) and the uniform positive definite and bounded character of the matrices $H_k + M_k$ by construction. Note that the modified Cholesky factorization technique used by Grippo, Lampariello, and Lucidi in their papers also guarantees the same conditions (with $h_k = 0$), as would other types of modified factorizations (see [7], [11], [21], or [20], for instance). However, since our approach allows for nonzero h_k, we have to enforce (20) explicitly: this is simply achieved in our code by stopping the modified CG method whenever this condition is satisfied. Note that condition (19) is automatically ensured by the properties of the CG algorithm.

It is now easy to verify that (2), (3), and (10) follow from (19), (20), and the requirements imposed on the matrices $H_k + M_k$. We note first that (20) and (18) imply that

$$\|(H_k + M_k)d_k\| \geq \|g_k\| - \|h_k\| \geq 0.9\|g_k\|, \tag{21}$$

which yields that

$$\|d_k\| \geq \frac{0.9}{\kappa_5}\|g_k\|, \tag{22}$$

and (10) is satisfied. Using now (19), one can prove (see [12]) that

$$\langle g_k, d_k\rangle \leq -[\mathrm{cond}(H_k + M_k)]^{-2}\|g_k\| \, \|d_k\| \tag{23}$$

where cond(X) is the ℓ_2 condition number of the matrix X. Since the eigenvalues of $H_k + M_k$ are contained in $[\kappa_4, \kappa_5]$, its condition number is bounded above by κ_5/κ_4, which, together with (10), gives (2). For the same reason, one immediately obtains that (3) holds. Indeed, using (18),

$$\|d_k\| \leq \frac{1}{\kappa_4}(\|g_k\| + \|h_k\|) \leq \frac{1.1}{\kappa_4}\|g_k\|, \tag{24}$$

where we used (20) to derive the second inequality.

- In our code, the constants $\mu = 10^6$ and $\xi = 10^{-3}$ are used in step 4.a, as recommended in [15].
- After some experimenting, a value of $p = 10$ was chosen in (12) and (16), the initial step threshold Δ_0 was set to unity, and the maximum number of successive automatic step acceptances N was fixed at 10.
- The linesearch procedures follows step 3 of Algorithm BLS nearly exactly (with $\gamma = 0.01$ and $\beta = 0.5$), except that doubling the stepsize is attempted if the unit step satisfies (5) and M_k nonzero, in an attempt to make a step as big as possible along a direction of (possibly) negative curvature.
- A maximum number of 10000 iterations and a maximum CPU time of five hours were allowed.

2.4. Numerical comparisons. We now present the results of an extensive numerical investigation of Algorithms BLS, GLL1, and GLL2. We have run these three methods on a set of 327 unconstrained problems available[1] from the CUTE collection [2]. All tests were performed on a DEC 3000/500 under OSF and using version 3.3 of the Fortran compiler with the default optimizing option. As the total number of test runs discussed in this paper exceeds 2500, it is impossible to include their detailed results in this text and we only present statistical summaries. The complete results, however, are available as a separate report [26].

In order to clarify the comparison, we divided our set of 327 problems into two subsets: the first contains all problems of dimension at most 500 (226 problems), and the second contains all larger cases (101 problems). This allows us to distinguish the effects of the nonmonotone strategies for small and large problems.

We first consider the relative reliability of our three algorithms on both problem sets and note that BLS failed on eleven small and six large problems, while GLL1 failed on nine small and five large problems and GLL2 on ten small and five large ones. Failures were caused by an excessive number of iterations, excessive CPU time, or by the occurrence of an arithmetic error during the computation of the objective function. The latter occurred often in the early iterations where a large step was attempted that lead outside the region where the problem functions are well defined on the computer.

Among the remaining 212 small and 93 large problems that could be solved by all three algorithms, six small ones and one large problem exhibited more than one local minimizer and, therefore, were rejected from our test sets, leaving 206 small and 92 large problems for further

[1] In March 1994.

analysis. Table 1 shows the cumulative statistics for the three methods on these problems. In this table, "iters" stands for the total number of iterations needed to solve all problems, "evals" for the total number of objective function evaluations, "CG-its" for the total number of iterations within the modified conjugate-gradients procedure defining the search direction and "time" for the total CPU time (rounded to the second). Note that the objective function's gradient and Hessian are evaluated once per iteration.

These cumulative measures tend to suggest that GLL1 and GLL2 provide an average improvement in CPU time on BLS for small problems. This is obtained at the expense of more CG iterations and function evaluations. The situation is similar for the larger problems.

In order to refine our conclusions, we now look at more disaggregate performance measures and report, in Table 2, how many times each of the three considered methods has been best, second, or last. In these comparisons, two CPU times are considered equal if they correspond to runs yielding identical iterates or if they differ by at most 5% of the best or by at most half a second. We immediately notice that the performance of GLL1 and GLL2 is much better than suggested by Table 1. In particular, we observe that GLL2 is most often the best method in CPU time, in CG iterations, and, even more clearly, in function evaluations.

Finally, these results indicate very few reasons why one should use GLL1 instead of GLL2. The latter method is admittedly more complex to code, but is very often preferable to GLL1, as is indicated by the more detailed comparison between these methods presented in Table 3. In this table, we restrict our attention to 215 small and 94 large problems that were coherently solved by both methods, that is for which both methods converged to critical points with identical objective function values. Columns three to five of the tables indicate how many times each method was best and how many ties occurred. Columns six to ten describe the distribution of differences in values of the relevant criterion (iterations, function evaluations, CG iterations, or time) for the two methods, *when these values are different*: we report the minimum of this distribution (min), its first quartile (q1), its median (med), its third quartile (q3), and its maximum (max).

TABLE 3

Table 3 generally favors GLL2: this method indeed wins more often for all criteria and the medians of all difference distributions are positive. However, we observe that these distributions are rather dispersed. In particular, we note the striking difference of 10676 CG iterations in Table 3 for a large problem (MSQRTBLS (n = 1024)) in favor of GLL1, which results in an advantage of 1131 seconds for GLL1 on the same problem.

We conclude this analysis of the ideas of Grippo, Lampariello, and Lucidi presenting a detailed comparison of the best nonmonotone method, GLL2, with our basic linesearch algorithm (BLS). This comparison is given in Table 4 for the 206 small and 88 large problems coherently solved by both methods. The format of this table is identical to that of Table 3.

A few conclusions can be drawn from this comparison.

• The conclusions of Grippo, Lampariello, and Lucidi are confirmed in that a nonmonotone procedure appears to be often better than the basic linesearch method, and sometimes by a quite substantial amount. However, GLL1 and GLL2 occasionally perform quite badly compared with BLS. In particular, this is the case for problem FMINSURF (n = 1024), which corresponds to the large differences at the minimum of the distributions of BLS-GLL2 in Table 4.

• The dispersed character of most reported performance difference distributions indicates that a large part of the variations between methods, as appearing in Table 1, are explained by their behavior on a relatively small number of more difficult problems. The sometimes dramatic differences between BLS, GLL1, and GLL2 are caused by the strongly nonlinear nature of these problems. However, the trend is rather clear overall, indicating that one might indeed lose in performance by using a nonmonotone method on a very nonlinear problem, but with the potential of winning substantially more.

• It also results from Tables 3 and 4 that performance differences are relatively small for at least half the test problems used, but that these small differences also often favor GLL2 over both GLL1 and BLS.

- At variance with previously reported numerical experience, the results presented here dıstinguish the relative merits of nonmonotone techniques for small and large problems separately. As expected, the potential benefits and losses in CPU time are more important for the large problems, at least on our test set where the cost of computing the objective function and its derivatives is often small or modest compared with that of the involved linear algebra.

Furthermore, a remarkable effect seems to occur when combining the nonmonotone GLL1 and GLL2 methods and the truncated modified CG technique on some large problems. Because of the nonmonotonicity, the iterates do not appear to follow the bottom of curved valleys so closely for these two algorithms, but rather "stay higher on the slope." This implies that the average size of g_k is larger for these methods than for BLS, which in turn implies, because of (20), that the modified CG can be stopped sooner, which finally results in a smaller number of CG steps on average. As a large proportion of the computational effort for large problems is concentrated in this part of the algorithms, this effect yields a noticeable reduction in the overall CPU time for such problems.

3. A new nonmonotone variant.

3.1. Motivation and specification. In order to alleviate the difficulties of GLL2 revealed, for instance, by the FMINSURF problem, a more careful analysis of the performance of GLL2 was carried out for this case and a few others. It then appeared that the quadratic model implicit in Newton's method is often not well suited to represent the objective function, and that the stepsizes determined by the linesearch procedure are very often much smaller than one. Moreover, this behavior is accentuated for GLL1 and GLL2 compared with BLS. It is therefore natural to think of controlling the amount of nonmonotonicity allowed by a measure indicating how well adapted the truncated Newton step is to the true objective function. It also appeared in the tests that it is often advantageous to enforce monotonicity in the first few iterations. The purpose of this section is to show that these simple ideas can indeed produce additional benefits.

We therefore modified Algorithm GLL2 as follows.

- The equality $r_k = f(x_k)$ is enforced for the first 10 iterates.
- For all subsequent iterations, r_k is defined by

$$r_k = f(x_k) + \left(\prod_{j=1}^{j_k} \alpha_{k(\ell-j)}\right)^{\frac{1}{j_k}} [f_{\ell-j_k} - f(x_k)] \tag{25}$$

where

$$j_k = \arg \max_{j=1,\dots,p} f_{\ell-j} \tag{26}$$

and $\alpha_{k(\ell-j)}$ is the stepsize corresponding to the $(\ell - j)$th accepted step.

In this proposal, we have chosen to measure the adequacy of the Newton step by examining how close the past stepsizes α_k are to unity. The amount of nonmonotonicity allowed in the method is then controlled by this measure: it is indeed easy to see that r_k as given by (25) is equal to the value calculated by Algorithm GLL2 whenever the last j_k accepted stepsizes are equal to one (the coefficient of the second term in the right-hand side of (25) is their geometric mean). Because most stepsizes do not exceed one, it is typically smaller in other cases. In our implementation, p is chosen to be 10, as for GLL1 and GLL2. Of course, the convergence theory developed for GLL2 still holds for this variant, which we call the NMLS (nonmonotone linesearch) Algorithm.

3.2. Numerical comparison. In order to assess this new variant, we also ran it on the set of test problems described above. This algorithm successfully solved 222 of the 226 small problems and 97 of the 101 large ones, a slightly better result than GLL2. We also computed values of the cumulative performance statistics for the 206 small and 92 large problems coherently solved by BLS, GLL1, GLL2, and NMLS. The comparison shown in Table 5 indicates a clear improvement on average for all criteria, compared with GLL1 and GLL2. In particular, the reduction in CG iterations is noticeable.

Examining the rankings presented in Table 6 confirms that NMLS is better than BLS, GLL1, or GLL2 not only on average, but also in a number of instances. This conclusion applies for both small and large problems. One interesting observation is that NMLS seems to require fewer iterations and fewer function evaluations than GLL2 on a significant number of problems.

If we now consider the detailed comparisons between NMLS, BLS, and GLL2 presented in Tables 7 and 8, the following additional comments can be made.

• Observations about the relative importance of more difficult problems in the average performance apply to NMLS as well as to the previously analyzed methods. However, one notices that the cases that are most unfavorable to NMLS compared with BLS (see Table 8) are much less so than those reported for GLL2 (see Table 4). We note, in particular, the very remarkable (although extreme) gain of 599569 CG iterations between GLL2 and NMLS on problem FMINSURF ($n = 1024$). This is not so surprising since NMLS is in fact designed

TABLE 7

to overcome the deficiency of GLL2 on that problem and similar ones. This big advantage in CG iterations results in a corresponding gain in CPU time.

- The smaller differences in performance (on the easier problems) also appear to favor NMLS over GLL2 and, more clearly, over BLS.

- As expected, the potential gain in CPU time between NMLS and GLL2 is more considerable for large problems and parallels, in this case, the potential gain in CG iterations. The same comment applies, although to a lesser extent, to the comparison between NMLS and BLS.

- We note that it is advantageous to use NMLS rather than BLS or even GLL2 when the objective function is costly to evaluate.

4. Preconditioning. We now examine the impact of preconditioning the iterative solution of the system (18) on the relative performance of BLS, GLL2, and NMLS. The preconditioner used is constructed by extracting from H_k its main 11-banded symmetric submatrix, which is then modified, if necessary, to ensure its positive definiteness. This modification is carried out according to the proposal of Schnabel and Eskow [21]. We note that this preconditioner has not been formally analyzed and, thus, that its effect is essentially unknown, although often beneficial. It is used in the default variant of trust-region-based LANCELOT package, although it is applied here in a context different from that of trust-region methods. This difference is quite significant because the typically longer steps determined by the modified CG procedure make the preconditioner's adequacy more crucial. The same preconditioner is also used by Conn et al. [8] in their study of iterated subspace minimization (ISM) methods. The preconditioned methods corresponding to BLS, GLL2, and NMLS are called PBLS, PGGL2, and PNMLS, respectively.

	Time	10	51	22	−5519	−1	6	19	7417

A first observation is that preconditioning slightly deteriorates reliability on our set of test problems: PBLS succeeds on 215 of the 226 small problems and both PGLL2 and PNMLS on 214. Of the 101 large problems, PBLS solves 89, PGLL2 solves 87, and PNMLS 86. In addition to the reasons for failure discussed above for the unpreconditioned case, we note that the search direction computed with the preconditioner sometimes causes the iterates to leave the region where the problem's functions are safely defined, causing arithmetic errors. Another effect is that the test (20) is not always adapted to the preconditioned system and may cause very early termination of the modified CG method, yielding a search direction identical or close to steepest descent. When this happens, convergence is typically very slow.

On the other hand, the preconditioner fulfills its purpose on most problems: it reduces the number of CG iterations requested for solution (although it might indeed deteriorate speed due to their increased computational cost). We illustrate this effect by comparing, in Table 9, the cumulative performances of the preconditioned algorithms and their unpreconditioned counterparts on the 188 small and 75 large problems that were coherently solved by all six methods. PNMLS appears to be the best of the two preconditioned methods on average for small problems, while PGLL2 takes the lead for the large ones, except, marginally, on CPU time.

The detailed comparisons between PBLS, PGLL2, and PNMLS are presented in Tables 10, 11, and 12.

These comparisons reinforce our previous conclusions on the relative merits of monotone versus nonmonotone methods. We note that the gap between preconditioned methods is smaller than that between unpreconditioned ones. We also see (Table 12) that PGLL2 seems to outperform PNMLS slightly. This may indicate that the additional caution introduced in NMLS may be less relevant when the computed search direction is closer to the true Newton step.

5. Conclusion and perspectives. In this paper, we have revisited Grippo, Lampariello, and Lucidi's proposals to use nonmonotone techniques in the framework of linesearch algorithms for unconstrained optimization. At variance with the original experiences reported

by these authors, we used a (preconditioned) truncated CG technique to compute the search directions and applied the resulting methods to a large collection of both small- and large-dimensional test problems, totaling more than 2500 test runs.

Using the results of these experiments, we have assessed the potential of NMLS techniques as proposed by Grippo, Lampariello, and Lucidi. The effects of problem size and preconditioning have also been specifically pointed out. We finally proposed a new variant that uses similar techniques.

The general conclusions of these tests and proposals can be summarized as follows.

- The impact of NMLS in the context of truncated CG methods is clear, and most noticeable on the more difficult and nonlinear problems.
- This impact is often favorable, in that nonmonotone methods show superior efficiency when compared with standard linesearch algorithms. This is especially true if preconditioning is not used. However, unfavorable problem-dependent effects also appear, but seem to be outweighed by the favorable ones.
- As expected, the differences in CPU time between monotone and nonmonotone methods are most important for the large problems. This distinction, however, is irrelevant when the number of problem function evaluations is considered: the gains provided by some of the analyzed nonmonotone methods are consistent, regardless of problem size.
- In the absence of preconditioning, the new proposed variant appears to yield the highest potential for substantial efficiency gains while best limiting the probability of losses, at least on the set of test problems used in this comparison. However, this advantage seems to disappear when preconditioning is applied.

As is the case for all practical comparisons between optimization algorithms, the results presented here do not pretend to be either complete or decisive. Further confirmation by continued experience is of course necessary for a true validation of NMLS techniques, but the trends outlined in this study are definitely encouraging. The application of these techniques in the context of merit function minimization for the solution of constrained problems and in the framework of ISM [8] are of particular interest. Finally, the extension of the nonmonotone approach to a trust-region algorithm is the object of ongoing research.

Acknowledgments. The author is indebted to N. Gould for kindly providing a Fortran 77 code for the modified CG technique and to S. Lucidi, M. Roma, and A. Sartenaer for many useful comments. Thanks are also due to a referee who suggested pursuing the tests with PGLL2, which resulted in a better appraisal of the methods compared in this paper.

A REGULARIZATION PARAMETER IN DISCRETE ILL-POSED PROBLEMS*

TERESA REGIŃSKA†

Abstract. The Tikhonov regularization method for discrete ill-posed problems is considered. For the practical choice of the regularization parameter α, some authors use a plot of the norm of the regularized solution versus the norm of the residual vector for all α considered. This paper contains an analysis of the shape of this plot and gives a theoretical justification for choosing the regularization parameter so it is related to the "L-corner" of the plot considered in the logarithmic scale. Moreover, a new criterion for choosing α is introduced (independent of the shape of the plot) which gives a new interpretation of the "corner criterion" mentioned above. The existence of "L-corner" is discussed.

Key words. discrete ill-posed problems, least squares solution, Tikhonov regularization, regularization parameter

AMS subject classifications. 65F20, 65J20

1. Introduction. A linear integral equation of the first kind in $L^2(I)$ with a smooth kernel is a classical example of an ill-posed problem. A solution of this equation, if it exists, does not continuously depend on the right-hand side and may not be unique. A discretization of such a problem leads to a matrix equation in $\mathbb{C}^m$,

$$Ku = f, \tag{1.1}$$

where K is an $m \times n$ matrix with a large condition number, $m \geq n$. A linear least squares solution of the system (1.1) is a solution to the problem

$$\min_{u \in \mathbb{C}^n} \|Ku - f\|^2, \tag{1.2}$$

where the Euclidian vector norm in $\mathbb{C}^m$ is used. Using the notation introduced in other papers (e.g., [3, 8]), we say that the algebraic problems (1.1) and (1.2) are discrete ill-posed problems.

There are many papers concerning numerical methods for solving ill-posed problems in function spaces (cf. [5, 10, 16, 17, 12, 13]), as well as for solving discrete ill-posed problems (cf. [2, 3, 6, 8, 11]). These methods are based on so-called regularization methods. The most well known is the Tikhonov approach, which consists of replacing the least squares problem (1.2) by the problem of a suitably chosen Tikhonov functional. The simplest version of this method has the form

$$\min_{u \in \mathbb{C}^n} \{\|Ku - f\|^2 + \alpha^2 \|u\|^2\}, \tag{1.3}$$

where $\alpha \in R$ is called the regularization parameter.

An important and still current problem is a proper choice of the regularization parameter. There are several possible strategies that depend on additional information concerning the considered problem and its solution. For instance, in order to apply the well-known discrepancy principle (cf. [5, 10, 16, 17]), which is an a posteriori strategy for choosing α as a function of error level, the input error level must be known.

Another strategy based on a priori knowledge of a structure of input error, namely, when error in f can be considered to be uncorrelated zero mean random variables with a common variance (white noise), is the generalized cross-validation method [4, 18]. Surveys of the different methods can be found in [2, 7, 8, 18].

In [7] and [8] the authors investigated another practical method for choosing α in the case when data are noisy. The method is based on a plot of the norm of the regularized

*Received by the editors July 21, 1993; accepted for publication (in revised form) December 19, 1994.

†Institute of Mathematics, Polish Academy of Sciences, 00-950 Warsaw, POB 137, Poland (reginska@impan.gov.pl).

solution versus the norm of the corresponding residual. The idea of the proposed L-curve corner criterion is to choose the regularization parameter related to a characteristic L-shaped "corner" of the graph.

Unfortunately, the location of the "corner" is dependent on the scale in which the L-curve is considered, and in some scales it may not appear. Moreover, in the aforementioned papers, some statements concerning a characterization of the L-curve have only intuitive justification and are not true in general. Nevertheless, the idea of the method is intuitively clear and numerical results (cf. [7]) confirm the utility of it when the logarithmic scale is used.

The present paper is devoted to more rigorous analysis of the method mentioned above. Moreover, an interpretation of the L-curve corner criterion in terms of minimization is given.

In §2, we give a short review of properties of the norm of regularized solution (in the Tikhonov sense (1.3)), the residual norm, and the corresponding plot in different scales. In §3, we formulate another criterion for choosing α which is independent of the shape of L. Next, we prove that this criterion is equivalent to the L-curve corner criterion related to the plot in the logarithmic scale. In §4, the problem of existence of an "L-corner" indicating the regularization parameter α is discussed.

2. L-curve. It was observed in [9] and extended in [7, 8] that a simple graphic presentation of the curve

$$x(\alpha) = \|Ku_\alpha - f\|^2, \tag{2.1}$$

$$y(\alpha) = \|u_\alpha\|^2, \tag{2.2}$$

where u_α is the solution of (1.3), can be very useful in studying the least square problem connected with it. In this section we give a short review of the properties of this curve in different scales. Some of them were formulated in other papers (cf. [7, 8, 14]). According to the notation introduced in [7], by L-curve we will mean

$$\{x(\alpha), y(\alpha)\}_{\alpha\in(0,\infty)}. \tag{2.3}$$

The L-curve in ϕ-scale will be denoted by

$$L_\phi = \{\phi(x(\alpha)), \phi(y(\alpha))\}_{\alpha\in(0,\infty)}. \tag{2.4}$$

$\phi = \sqrt{\ }$ and $\phi = \ln$ will be considered.

The following lemma for $\phi = \sqrt{\ }$ describes a standard property of the Tikhonov regularization method (cf. [9, Thm. 25.99]).

LEMMA 1. *If $\phi : R^+ \to R$ is a positive, increasing function then any point (ξ, η) on the L_ϕ is a solution of the following two inequality-constrained least squares problems:*

$$\xi = \min \phi(\|Ku - f\|^2) \textit{ subject to } \phi(\|u\|^2) \le \eta,$$

$$\eta = \min \phi(\|u\|^2) \textit{ subject to } \phi(\|Ku - f\|^2) \le \xi.$$

For the further investigation of $x(\alpha)$ and $y(\alpha)$ we shall apply the singular value decomposition for the matrix K. This is a well-known approach for least squares problems (cf. [18]).

If $K \in \mathbb{C}^{m,n}$ is a matrix of rank r, then there exist unitary matrices $U \in \mathbb{C}^{m,m}$ and $V \in \mathbb{C}^{n,n}$ such that

$$K = U\Sigma V^*, \ \Sigma = \begin{pmatrix} \Sigma_r & 0 \\ 0 & 0 \end{pmatrix},$$

where $\Sigma \in R^{m,n}$, $\Sigma_r = \operatorname{diag}(\sigma_1, \dots, \sigma_r)$, and $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > 0$. The σ_i are called the singular values of K and the ith column vectors u_i, v_i of U and V, respectively, are the left and right singular vectors corresponding to σ_i, $i = 1, \dots, r$.

The least squares solution of (1.1) of the minimal norm is the minimal norm solution of the normal equation $K^*Ku = K^*f$, and thus if

$$f = \sum_{i=1}^{m} f_i u_i, \quad \text{where } f_i = u_i^* f, \; i = 1, \dots, m \tag{2.5}$$

then

$$u = \sum_{i=1}^{r} \frac{f_i}{\sigma_i} v_i. \tag{2.6}$$

For a discrete ill-posed problem (just the case considered here) the singular values σ_i tend with i very rapidly to zero. Due to the errors in the right-hand side ($f = \bar{f} + e$), for which it cannot be assumed that $u_i^* e$, $i = 1, \dots, r$, tend to zero faster than σ_i, the solution u is perturbed mainly by contributions corresponding to the small singular values.

The regularized solution u_α of (1.3) satisfies the normal equation $K^*Ku + \alpha^2 u = K^*f$, thus

$$u_\alpha = \sum_{i=1}^{r} \frac{\sigma_i f_i}{\sigma_i^2 + \alpha^2} v_i. \tag{2.7}$$

Because of $\alpha > 0$, the problem of computing u_α becomes less ill-conditioned than that of computing u, i.e., an influence of errors corresponding to the small singular values becomes smaller.

It can easily be found that

$$y(\alpha) = \|u_\alpha\|^2 = \sum_{i=1}^{r} \frac{\sigma_i^2 |f_i|^2}{(\sigma_i^2 + \alpha^2)^2}. \tag{2.8}$$

Moreover, denoting $f_\perp = \sum_{i=r+1}^{m} f_i u_i$, we get

$$Ku_\alpha - f = -\left(\sum_{i=1}^{r} \frac{\alpha^2 f_i}{\sigma_i^2 + \alpha^2} u_i + f_\perp \right).$$

Thus

$$x(\alpha) = \sum_{i=1}^{r} \frac{\alpha^4 |f_i|^2}{(\sigma_i^2 + \alpha^2)^2} + \|f_\perp\|^2. \tag{2.9}$$

From this it follows that for $f \neq f_\perp$

$$\frac{dx}{d\alpha} = 4\alpha^3 \sum_{i=1}^{r} \frac{|f_i|^2 \sigma_i^2}{(\sigma_i^2 + \alpha^2)^3} > 0, \tag{2.10}$$

which means that the function $x(\alpha)$ is strictly increasing. Thus there exists a function $\alpha(x)$ inverse to x, and the curve $\{x(\alpha), y(\alpha)\}_{\alpha \in R^+}$ has only one branch which can be represented as the function $y(x) = y(\alpha(x))$.

LEMMA 2. *If x, y are defined by* (2.1), (2.2) *then y as a function of x is decreasing and strictly convex.*

Proof. The function $x : (0, \infty) \to (\|f_\perp\|^2, \|f\|^2)$ is increasing; thus the inverse function

$$\alpha(x) : (\|f_\perp\|^2, \|f\|^2) \to (0, \infty)$$

is also increasing. From the formula (2.8)

$$\frac{dy}{d\alpha} = -4\alpha \sum_{i=1}^{r} \frac{\sigma_i^2 |f_i|^2}{(\sigma_i^2 + \alpha^2)^3}. \tag{2.11}$$

Taking into account (2.10) we get

$$\frac{dy}{dx} = -\frac{1}{\alpha^2}. \tag{2.12}$$

Thus $y(\cdot)$ is decreasing and $\frac{dy}{dx} \to -\infty$ when $x \to \|f_\perp\|^2$; $\frac{dy}{dx} \to 0$ when $x \to \|f\|^2$. We have

$$\frac{d^2y}{dx^2} = -\frac{d}{dx}\frac{1}{\alpha^2} = \frac{2}{\alpha^3}\frac{d\alpha(x)}{dx} > 0,$$

since $\alpha(x)$ is increasing. This means that $y(x)$ is strictly convex. □

From formulas (2.8) and (2.6) it follows that $y(\alpha) \to \|u\|^2$ when $\alpha \to 0$. Moreover, $y(\alpha) \to 0$ when $\alpha \to \infty$.

REMARK 1. *The L-curve remains decreasing in any differentiable strictly monotonic scale ϕ, among others, for $\phi = \ln$ and $\phi = \sqrt{}$. Using the notation $\eta = \phi(y(\alpha))$, $\xi = \phi(x(\alpha))$,*

$$\frac{d\eta}{d\xi} = -\frac{1}{\alpha^2}\frac{\phi'(y(\alpha))}{\phi'(x(\alpha))}. \tag{2.13}$$

REMARK 2. *A change of the scale ϕ does not preserve the convexity of the L-curve. For instance, the parametric curve $L = \{\alpha^4/(1+\alpha^2)^2, 1/(1+\alpha^2)^2\}_{\alpha\in(0,\infty}$ (which is a particular case of an L-curve defined by* (2.8), (2.9) *for $r = 1$, $\sigma_1 = 1$, $f_1 = 1$, $f_i = 0$ for $i \neq 1$) in the scale $\phi = \sqrt{}$ is the straight line interval with ends $\{1, 0\}$ and $\{0, 1\}$, while in the logarithmic scale it becomes a strictly concave curve.*

Because of the fact that the shape of the L-curve in the scales $\phi = \sqrt{}$ and $\phi = \ln$ determines the practical choice of a proper α (cf. [7], [8]), we present the following lemmas to give some information about that shape.

First, let us consider the L-curve in the logarithmic scale.

LEMMA 3. *If $f_\perp = 0$, the L-curve in the logarithmic scale is strictly concave for $\alpha \in (0, \sigma_r)$ and for $\alpha \in (\sigma_1, \infty)$. If $f_\perp \neq 0$ then this curve is convex for $\alpha \in (0, \epsilon)$ where ϵ is sufficiently small, and remains concave for $\alpha \in (\sigma_1, \infty)$.*

Proof. According to (2.13)

$$\frac{d\eta}{d\xi} = -\frac{1}{\alpha^2}\frac{x}{y}.$$

Since $x = e^\xi$, $y = e^\eta$, we easily find that

$$\frac{d^2\eta}{d\xi^2} = -\frac{x}{\alpha^4 y^2}\left[\alpha^2 y + x - 2\alpha y \frac{1}{\frac{d\xi}{d\alpha}}\right],$$

and by (2.10)

$$\frac{d\xi}{d\alpha} = \frac{4\alpha^3}{x}z, \quad \text{where } z = \sum_{i=1}^{r} \frac{|f_i|^2\sigma_i^2}{(\sigma_i^2+\alpha^2)^3}.$$

Thus

$$\frac{d^2\eta}{d\xi^2} = -\frac{x^2}{\alpha^6 y}\left(\frac{\alpha^4}{x} + \frac{\alpha^2}{y} - \frac{1}{2z}\right).$$

Let us observe that for $\alpha \leq \sigma_r$

$$\frac{2\sigma_i^2}{\sigma_i^2+\alpha^2} \geq 1, \quad i = 1, \dots, r,$$

and for $\alpha \geq \sigma_1$

$$\frac{2}{\sigma_i^2+\alpha^2} \geq \frac{1}{\alpha^2}, \quad i = 1, \dots, r.$$

It follows that for $\alpha \leq \sigma_r$ and $f_\perp = 0$ we have $2z \geq \frac{x}{\alpha^4}$, while for $\alpha \geq \sigma_1$ (independently of $f_\perp$) $2z \geq \frac{y}{\alpha^2}$. This implies that in both cases

$$\frac{\alpha^4}{x} + \frac{\alpha^2}{y} - \frac{1}{2z} > 0, \quad \text{i.e.,} \quad \frac{d^2\eta}{d\xi^2} < 0,$$

which ends the proof. □

From Remark 2 it follows that in the case $f_i = 0$, $\forall i \neq 1$, the curve $\mathrm{L}_{\ln}$ is strictly concave. Due to continuity this curve remains concave for sufficiently small perturbation of coefficients. The following lemma gives a sufficient condition (in the case of two components of f) under which the $\mathrm{L}_{\ln}$-curve does not have a "corner property."

LEMMA 4. *Let $i_1 < i_2$ be such that $f_i \neq 0$ for $i \in \{i_1, i_2\}$ and $f_i = 0$ for $i \notin \{i_1, i_2\}$. If*

$$\frac{|f_{i_2}|}{\sigma_{i_2}^2} < \frac{|f_{i_1}|}{\sigma_{i_1}^2}$$

then the $L_{\ln}$-curve is strictly concave.

Proof. The proof follows from simple calculations concerning the second derivative $\frac{d^2\xi}{d\eta^2}$, where $\xi = \ln x(\alpha)$ and $\eta = \ln y(\alpha)$. The sign of $\frac{d^2\xi}{d\eta^2}$ is equal to the sign of a certain polynomial of degree 4 with respect to α^2. Under the assumption of Lemma 4, all coefficients of this polynomial are positive. □

A relation between the magnitude of quotients $\frac{|f_i|}{\sigma_i}$ and the shape of the corresponding $L_{\log}$-curve is illustrated in Figs. 1 and 2 for the case of two components of f. Figure 1 presents $L_{\log}$-curves for $\sigma_1 = 1$, $\sigma_2 = 0.01$, $f_1 = 1$, and various values of f_2: 0.001, 0.03, 0.1. Figure 2 shows the changing shape of the $L_{\log}$-curve when $\|f_\perp\|$ grows. For the case $\sigma_1 = 1$, $\sigma_2 = 0.01$, $f_1 = 1$, $f_2 = 0.05$ the values $\|f_\perp\|^2 = 0$, 0.001, 0.01 are taken. The "+" sign denotes the points of the $L_{\log}$-curves corresponding to $\alpha = \sigma_2$.

Finally, let us consider a shape of an L-curve in the square-root scale. In the particular case when the decomposition of the right-hand side in the basis $\{u_i\}$ has only two nonzero components we have the following result.

LEMMA 5. *Let $i_1 < i_2$ be such that $f_i \neq 0$ for $i \in \{i_1, i_2\}$ and $f_i = 0$ for $i \notin \{i_1, i_2\}$. Then the parametric curve*

$$L_{\sqrt{}} = \{\|Ku_\alpha - f\|, \|u_\alpha\|\}_{\alpha\in(0,\infty)}$$

is convex.

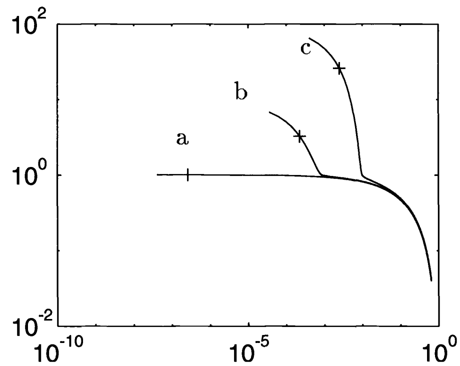

FIG 1. $L_{\log}$*-curves for* $f_\perp = 0$, $\sigma_1 = 1, \sigma_2 = 0.01$, *and*
(a) $\frac{f_1}{\sigma_1} = 1$, $\frac{f_2}{\sigma_2} = 0.1$;
(b) $\frac{f_1}{\sigma_1} = 1$, $\frac{f_2}{\sigma_2} = 3$;
(c) $\frac{f_1}{\sigma_1} = 1$, $\frac{f_2}{\sigma_2} = 10$.

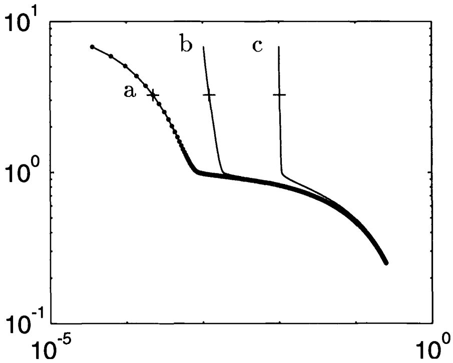

FIG 2. $L_{\log}$*-curves for different* $f_\perp$, $\sigma_1 = 1, \sigma_2 = 0.01, f_1 = 1, f_2 = 0.05$,
(a) $\|f_\perp\|^2 = 0$;
(b) $\|f_\perp\|^2 = 0.01$;
(c) $\|f_\perp\|^2 = 0.001$.

Proof. Let $\{\xi, \eta\} \in L_{\sqrt{}}$, i.e., $\xi = \sqrt{x(\alpha)}$, $\eta = \sqrt{y(\alpha)}$. According to (2.13), $\frac{d\eta}{d\xi} = -\frac{1}{\alpha^2}\sqrt{\frac{x}{y}}$. If $\sigma_{i_1} = \sigma_{i_2}$ then $\frac{d\eta}{d\xi} = -\frac{1}{\sigma_{i_1}} = const.$

Let $\sigma_{i_1} > \sigma_{i_2}$. Using the formulas (2.8) and (2.9) we get

$$\frac{d\eta}{d\xi} = -\sqrt{\frac{|f_{i_1}|^2(\sigma_{i_2}^2+\alpha^2)^2 + |f_{i_2}|^2(\sigma_{i_1}^2+\alpha^2)^2}{|f_{i_1}|^2\sigma_{i_1}^2(\sigma_{i_2}^2+\alpha^2)^2 + |f_{i_2}|^2\sigma_{i_2}^2(\sigma_{i_1}^2+\alpha^2)^2}} \tag{2.14}$$

and consequently,

$$f_{i_1}{}^2\left(\sigma_{i_2}^2+\alpha^2\right)^2\left(1-\sigma_{i_1}^2\left(\frac{d\eta}{d\xi}\right)^2\right) = |f_{i_2}|^2\left(\sigma_{i_1}^2-\alpha^2\right)^2\left(\sigma_{i_2}^2\left(\frac{d\eta}{d\xi}\right)^2-1\right). \tag{2.15}$$

Suppose that $\frac{d\eta}{d\xi}(\alpha_1) = \frac{d\eta}{d\xi}(\alpha_2)$. From (2.15)

$$\frac{f_{i_1}{}^2\left(\sigma_{i_2}^2+\alpha_1^2\right)^2}{|f_{i_2}|^2\left(\sigma_{i_1}^2-\alpha_1^2\right)^2} = \frac{f_{i_1}{}^2\left(\sigma_{i_2}^2+\alpha_2^2\right)^2}{|f_{i_2}|^2\left(\sigma_{i_1}^2-\alpha_2^2\right)^2}.$$

Thus

$$\sigma_{i_1}^2\alpha_1^2 + \sigma_{i_2}^2\alpha_2^2 = \sigma_{i_1}^2\alpha_2^2 + \sigma_{i_2}^2\alpha_1^2,$$

which is true only if $\alpha_1 = \alpha_2$.

The conclusion is that $\frac{d\eta}{d\xi}$ is a continuous one-to-one function of α, i.e., it is strictly monotonic. If $\frac{d\eta}{d\xi}$ is monotonically decreasing, the function $\eta(\xi)$ is strictly convex. On the other hand, if $\frac{d\eta}{d\xi}$ is monotonically increasing then $\eta(\xi)$ is concave.

Let us introduce an auxiliary function $f : R^+ \times R^+ \to R^+$,

$$f(t, s) := \frac{t+s}{t\sigma_{i_1}^2 + s\sigma_{i_2}^2}.$$

If we put $t_o = |f_{i_1}|^2 \frac{\sigma_{i_2}^4}{\sigma_{i_1}^4}$, $s_o = |f_{i_2}|^2$, $t_\infty = |f_{i_1}|^2$, then from (2.14)

$$\lim_{\alpha\to 0} \frac{d\eta}{d\xi} = -\sqrt{f(t_o, s_o)}; \quad \lim_{\alpha\to\infty} \frac{d\eta}{d\xi} = -\sqrt{f(t_\infty, s_o)}.$$

Since for $\sigma_{i_1} > \sigma_{i_2}$ we have $\frac{\partial f}{\partial t} < 0$, the function f is decreasing in t. This and $t_0 < t_\infty$ imply $f(t_o, s_o) > f(t_\infty, s_o)$. Thus

$$\lim_{\alpha\to 0} \frac{d\eta}{d\xi} < \lim_{\alpha\to\infty} \frac{d\eta}{d\xi},$$

which means that $\frac{d\eta}{d\xi}$ is increasing, i.e., η is strictly convex. □

Moreover, it can be proved (cf. [14, Thm. 1]) that in the case of arbitrary components f_i of f the maximum of curvature of the L-curve in square-root scale is always attained inside the interval $[\frac{1}{\sigma 1}, \infty)$. The above results suggest that the maximum of curvature of $L_{\sqrt{}}$ may not indicate a proper regularization parameter α.

3. A local minimum criterion. Let us consider a discrete ill-posed problem (1.2) and its solution u (2.6) and a regularized solution u_α (2.7) by means of Tikhonov regularization (1.3).

The right-hand side f in (1.1) is assumed to be contaminated with measurement errors. While the unperturbed right-hand side $\bar{f}$ satisfies the discrete Picard condition (i.e., the Fourier coefficients $u_i^* \bar{f}$ tend to zero faster than σ_i), the perturbation vector $f - \bar{f}$ does not need to satisfy such a condition. A consequence is a large influence of the errors $f_i - \bar{f}_i$ corresponding to small singular values on the solution norm (cf. (2.6)). Any $\alpha > 0$ reduces the norm of u. The problem is how to choose a proper α.

1. The first postulate is to choose α such that $y(\alpha)$ (cf. (2.8)) is not too large, say $y(\alpha) \le y(\alpha_o)$, i.e., $\alpha \ge \alpha_o$.

2. On the other hand, another natural postulate is to have a small norm of residuum, i.e., $x(\alpha) \le x(\alpha_1)$, which means that $\alpha \le \alpha_1$.

Because of the fact that $x(\alpha)$ is increasing while $y(\alpha)$ is a decreasing function of α, it is reasonable to consider the function $\Psi(\alpha) = x(\alpha)y(\alpha)$, or more generally,

$$\Psi_\lambda(\alpha) = x(\alpha)y^\lambda(\alpha), \quad \text{where } \lambda > 0, \tag{3.1}$$

and look for its minima over the interval $[\alpha_o, \alpha_1]$. Since $y(\alpha) \to 0$ as $\alpha \to \infty$, and if $f_\perp = 0$ then $x(0) = 0$, the global infimum is always equal to zero. It is attained at ∞ and, if $f_\perp = 0$, at 0. The question is about existence of local minima points inside the open interval $(0, \infty)$ and about their characterization.

The following theorem shows that the local minimum of Ψ_λ has a simple geometric interpretation, very similar to the so-called L-curve corner described and applied in [7] and [8], where the L-corner means the point of the L-curve with the maximum curvature.

THEOREM 1. *The function Ψ_λ has a local minimum at $\bar{\alpha}$ if and only if*

(i) *the L_{ln}-curve is tangent at the point $\{\xi(\bar{\alpha})\eta(\bar{\alpha})\}$ to a straight line $\eta + \lambda\xi = const$, and*

(ii) *the L_{ln} is convex in a neighbourhood of $\{\xi(\bar{\alpha})\eta(\bar{\alpha})\}$.*

Proof. Using the notation $\xi(\alpha) = \ln x(\alpha)$, $\eta(\alpha) = \ln y(\alpha)$, we have

$$\Psi(\alpha) = \exp(\xi(\alpha) + \lambda\eta(\alpha)).$$

Since $\frac{d\xi}{d\alpha} > 0$, the necessary condition for a local extreme of Ψ is

$$\frac{d\eta}{d\xi}(\alpha) + \frac{1}{\lambda} = 0, \tag{3.2}$$

which is equivalent to the condition of a tangent of L_{ln} to the straight line $\xi + \lambda\eta = const$.

If $\Psi(\alpha)$ attains a local minimum at $\hat{\alpha}$ then $\xi(\alpha) + \lambda\eta(\alpha)$ also attains a local minimum at $\hat{\alpha}$. It means that for a certain neighbourhood of $\hat{\alpha}$ all points $\{\xi(\alpha), \eta(\alpha)\}$ of the $L_{\ln}$-curve lay above the straight line $\xi + \lambda\eta = \xi(\hat{\alpha}) + \lambda\eta(\hat{\alpha})$. Thus condition (ii) is satisfied. The inverse implication is evident. □

REMARK 3. *When $\hat{\alpha} > 0$ is determined by the maximum of curvature of $L_{\ln}$ then there exists $\lambda > 0$ such that*

$$\hat{\alpha} = \arg loc \min_{0<\alpha<\infty} \Psi_\lambda(\alpha).$$

Inversely, if $\Psi_\lambda(\alpha)$ attains at $\hat{\alpha}$ a local minimum then the maximum curvature criterion indicates $\hat{\alpha} > 0$.

REMARK 4. *Let ϕ be an arbitrary one from the considered scales (I, $\surd$, ln). If $\hat{\alpha}$ is determined by conditions* (i) *with $\lambda = 1$, and* (ii) *(Theorem* 1*) applied to L_ϕ then*

$$\frac{d\eta}{d\xi}(\hat{\alpha}) = \frac{d\xi}{d\eta}(\hat{\alpha}), \text{ where } \eta(\alpha) = \phi(y(\alpha)),\ \xi(\alpha) = \phi(x(\alpha)).$$

For $\phi = I$, these conditions give exactly one $\hat{\alpha} = 1$ (from (2.12)*).*

In the general case the problem of uniqueness of a local minimum of Ψ_λ inside $(0, \infty)$ is open. The same question applies to the L-corner.

4. When do the L-curve criteria indicate $\alpha > 0$? By L-curve criteria we mean (i) Hansen's criterion [7, 8] taking α as the point at which the L-curve has the maximum curvature, and (ii) a choice of α according to conditions (i) and (ii) of Theorem 1 (the local minimum criterion).

The case described in Lemma 4 shows that the $L_{\ln}$-curve may have no L-corners, i.e., local minima of Ψ_λ may not exist, as well as that the maximum of curvature of $L_{\ln}$ may be attained at $\alpha = 0$. We are going to explain when the local minimum of Ψ exists (i.e., when L-corner of $L_{\ln}$ appears) and what it means when there are no local minima.

First, let us formulate the following auxiliary lemma.

LEMMA 6. *There exists a local minimum of $\Psi(\alpha)$ at $\hat{\alpha} \in (0, \infty)$ iff in the case $f_\perp = 0$*

$$(4.1) \qquad \exists\alpha_1, \alpha_2 \quad 0 \le \alpha_1 < a_2, \text{ such that } x(\alpha_1) \ge \alpha_1^2 y(\alpha_1),\ x(\alpha_2) \le \alpha_2^2 y(\alpha_2),$$

or in the case $f_\perp \neq 0$

$$(4.2) \qquad \exists\alpha_2 > 0 \text{ such that } x(\alpha_2) \le \alpha_2^2 y(\alpha_2),$$

Proof. Let $\tilde{\Psi}(x) = \Psi(\alpha(x))$. If

$$(4.3) \qquad \exists\alpha_1, \alpha_2 \quad 0 \le \alpha_1 < a_2, \text{ such that } \frac{d\tilde{\Psi}}{dx}(\alpha_1) \le 0,\ \frac{d\tilde{\Psi}}{dx}(\alpha_2) \ge 0,$$

then, by continuity of $\tilde{\Psi}'_x$ there exists $\hat{\alpha} \in [\alpha_1, \alpha_2]$ such that $\frac{d\tilde{\Psi}}{dx}(\hat{\alpha}) = 0$ and $\frac{d^2\tilde{\Psi}}{dx^2}(\hat{\alpha}) > 0$. This means also that $\frac{d\Psi}{d\alpha}(\hat{\alpha}) = 0$ and $\frac{d^2\Psi}{d\alpha^2}(\hat{\alpha}) > 0$, i.e., Ψ attains a local minimum at $\hat{\alpha}$. If $f_\perp \neq 0$ then the above condition becomes simpler, since

$$\frac{d\tilde{\Psi}}{dx} = y - \sum_{i=1}^{r} \frac{\alpha^2|f_i|^2}{(\sigma_i^2 + \alpha^2)^2} - \frac{1}{\alpha^2}\|f_\perp\|^2 \longrightarrow -\infty, \text{ as } \alpha \to 0,$$

and we can put $\alpha_1 = 0$.

Since $\frac{d\tilde{\Psi}}{dx} = y + x\frac{dy}{dx}$ and $\frac{dy}{dx} = -\frac{1}{\alpha^2}$ (cf. (2.12)), conditions (4.3) may be rewritten in the form (4.1). □

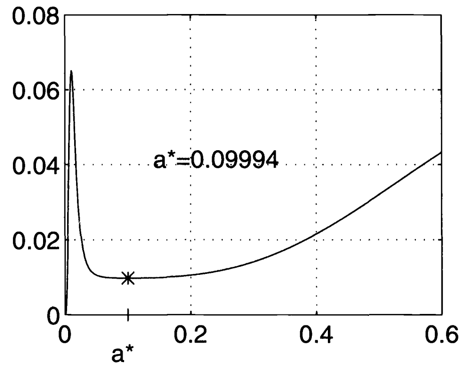

FIG 3. *The function $\psi(\alpha)$. $a* = \arg\min_{\sigma_1<\alpha<\sigma_2} \psi(\alpha)$.*

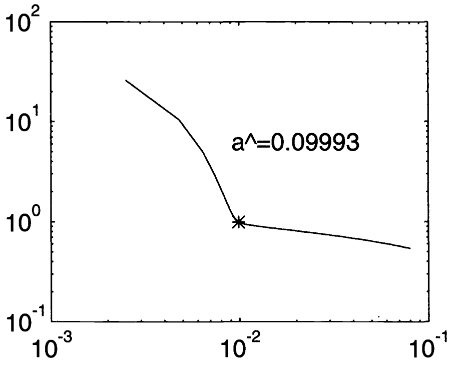

FIG 4. *The $L_{\log}$-curve. Maximum of the L-curve curvature for α =a^.*

Now let us introduce a class $\mathcal{K}$ of discrete ill-posed problems $Ku = f$. Let $\sigma_{i_1} = \sigma_1 > \sigma_{i_2} > \cdots > \sigma_{i_s} = \sigma_r$ be all different singular values of K greater than 0 with the multiplicities m_{i_j}, $j = 1, \dots, s$ ($s \geq 2$), respectively. Let u_i, $i = 1, \dots, r$, denote the corresponding left singular vectors. The right-hand side then has the representation $f = \sum_{i=1}^{r} f_i u_i + f_\perp$, where $f_i = u_i^* f$ and $f_\perp \perp u_i$ for $i = 1, \dots, r$. Let $g_{i_j}^2 := \sum_{k=0}^{m_{i_j}-1} |f_{i_j+k}|^2$.

The problem $Ku = f$ belongs to a class $\mathcal{K}$ iff $f_\perp \neq 0$ or $f_\perp = 0$ and the following conditions are satisfied:

(i) $\sigma_{i_j} \leq \frac{1}{2}\sigma_{i_{j-1}}$ for $j = 2, \dots, s$, and

(ii) $\frac{g_{i_j}^2}{\sigma_{i_j}} > 2.5\frac{g_{i_{j-1}}}{\sigma_{i_{j-1}}}$ for $j = 2, \dots, s$.

THEOREM 2. *Let the problem $Ku = f$ belong to the class $\mathcal{K}$.*

(i) *If $f_\perp = 0$ and $\sqrt{3} g_{i_s} \leq g_{i_j}$ for $j = 1, \dots, s-1$ then there exists a local minimum of $\Psi(\alpha)$ inside the open interval $(0, \infty)$.*

(ii) *If $f_\perp \neq 0$ then there exists λ such that $\Psi_\lambda(\alpha)$ has a local minimum inside the open interval $(0, \infty)$. This local minimum exists for $\lambda = 1$ if $\|f_\perp\|$ is sufficiently small.*

The proof is based on Lemma 6. The parameters α_1, α_2 are chosen a priori. A detailed proof of the first part is in [15]. The second part follows from the equivalence of the L-curve corner criterion and a local minimum of Ψ_λ described in Remark 3 and from Lemma 3 for $f_\perp \neq 0$.

CONCLUSION 1. *From Theorem 2 and Remark 3 it follows that if the problem* (1.1) *belongs to the class $\mathcal{K}$ then there exists an L-corner of the curve $L_{\ln}$.*

CONCLUSION 2. *Let $\sigma_{i-1} > 2\sigma_i > 0$ for $i = 2, \dots, r$, and let*

$$f \in \{f \in \mathbb{C}^m : |f_i| \geq \sqrt{3}|f_r| \text{ and } \|f_\perp\| \leq \gamma\}.$$

If there are no local minima of $\Psi(\alpha)$ inside $(0, \infty)$ then the $|f_i|^2$ tend to zero faster than the corresponding σ_i. In such a case it is reasonable to take $\alpha = 0$ assuming that the right-hand side is unperturbed.

Let us return to the example considered in §2, when the decomposition of the right-hand side in the basis $\{u_i\}_{i=1}^r$ has two nonzero components only: $f_1 = u_1^* f$ and $f_2 = u_2^* f$, where u_1, u_2 correspond to the singular values σ_1 and σ_2, respectively. Figures 3 and 4 present the plot of the function ψ in a neighbourhood of the smaller singular value σ_2 and the plot of the corresponding $L_{\log}$-curve for the case $\sigma_1 = 1, \sigma_2 = 0.01, f_1 = 1, f_2 = 0.1$. The regularization parameters defined by the local minimum criterion and the L-corner criterion are denoted by a* and a^, respectively. Their difference a*−a^ is of the order $0.1\sigma_2^2$ in this case.

COMPUTATION OF SHOT-NOISE PROBABILITY DISTRIBUTIONS AND DENSITIES*

JOHN A. GUBNER†

Abstract. The computation of the cumulative distribution (cdf), the complementary cdf (ccdf), and the density of certain shot-noise random variables is discussed. After subtracting off a few terms that can be computed in closed form, what remains can be approximated by a general method for approximating samples of a cdf or ccdf by summing a Fourier series whose coefficients are modulated samples of their characteristic function. To approximate the density, a spline is fit to the cdf samples and then differentiated. When the density has corners, it is important that the spline have coincident knots at these locations. For shot-noise densities, these locations are easily identified.

Key words. filtered point process, Poisson process

AMS subject classification. 62E17

1. Introduction.

The computation of the cumulative distribution (cdf) $F(y)$, the complementary cdf (ccdf) $F^c(y) := 1 - F(y)$, and the probability density function $f(y)$ of a shot-noise random variable

$$Y := \sum_{\nu} A_\nu g(T_\nu)$$

is considered; here the $\{T_\nu\}$ are points of a Poisson process in $\mathbb{R}^d$ with intensity function $\lambda: \mathbb{R}^d \to [0, \infty)$, and $\{A_\nu\}$ is an independent, identically distributed, nonnegative "gain" sequence. We assume $\{A_\nu\}$ and $\{T_\nu\}$ are statistically independent. The function $g: \mathbb{R}^d \to \mathbb{R}$ is typically determined by a system impulse response or point-spread function, depending on the application in which it arises; e.g., optical communications, imaging, etc. In these situations there has been much interest in computing shot-noise distributions and densities [6, 7, 9–15, 18]. One of the reasons that this is such a hard problem is that many shot-noise densities contain jumps and corners, in addition to an impulse at the origin. It is precisely these features that make it difficult to directly apply simple methods such as Fourier inversion of the characteristic function or summation of Beaulieu's series [2]. The purpose of this paper is to expose the structure of shot-noise distributions and densities and to exploit this structure to obtain easy-to-compute approximations with the proper jumps and corners in order to obtain better accuracy.

We point out that our results also have an immediate application to the computation of the distribution of the test statistic corresponding to the likelihood ratio for Poisson process observations. Suppose we are testing the hypothesis $H_0: \lambda(\tau) = \lambda_0(\tau)$ against $H_1: \lambda(\tau) = \lambda_1(\tau)$ based on observing the points $\{T_\nu\}$ themselves. Then the likelihood ratio test for this problem is equivalent to comparing the shot-noise random variable $\mathcal{L} := \sum_\nu \ell(T_\nu)$ against a threshold, where $\ell(T_\nu) := \ln(\lambda_1(T_\nu)/\lambda_0(T_\nu))$ [16, p. 94, eq. (2.112)].

The paper is organized as follows. In §2 we state our results concerning the structure of shot-noise characteristic functions, cdfs, ccdfs, and densities. This structure allows us to decompose shot-noise distributions into various terms that can be separately approximated. In §3 we discuss a general method for approximating a cdf and ccdf from their characteristic

function. If the distribution has a density that is piecewise smooth except for corners, and if their locations can be identified, then excellent density approximation can be obtained by fitting a spline with coincident knots to the cdf approximation and then differentiating the spline. In §4 we use this general method to approximate one of the terms in the decomposition of a shot-noise cdf, ccdf, and density. Numerical examples are given. The conclusion is in §5.

2. Statement of results and their applications. The characteristic function of Y [17, p. 221] is

$$\varphi(\omega) := \mathsf{E}[e^{j\omega Y}] = e^{\psi(\omega)},$$

where

$$\psi(\omega) := \int \lambda(\tau)[\varphi_A(\omega g(\tau)) - 1]\, d\tau, \tag{1}$$

and φ_A is the common characteristic function of the $\{A_\nu\}$. In Theorem 5 in Appendix A we show that the condition

$$B_0 := \int_{\{\tau : g(\tau)\neq 0\}} \lambda(\tau)\, d\tau \ < \infty \tag{2}$$

implies that $\psi(\omega) = \tilde{\psi}(\omega) - B$, where $B = B_0 \mathsf{P}(A_\nu > 0)$, and $\tilde{\psi}$ is the characteristic function of a finite measure Γ on $\mathbb{R}$. The reason for doing this is that we can then write $\varphi(\omega) = e^{\psi(\omega)} = e^{-B} e^{\tilde{\psi}(\omega)}$ and see that for $C \subseteq \mathbb{R}$,

$$\mathsf{P}(Y \in C) = e^{-B}\left[\mathbf{1}_C(0) + \sum_{m=1}^{\infty} \frac{\Gamma^{*m}(C)}{m!}\right], \tag{3}$$

where $\mathbf{1}$ is the indicator function of the specified set, and Γ^{*m} is the finite measure whose characteristic function is $\tilde{\psi}(\omega)^m$. If Γ has density γ, (Theorem 6 and the remark following it in Appendix A give sufficient conditions for the existence of γ), then the density of Y, denoted by f, can be written as

$$f(y) = e^{-B}\left[\delta(y) + \sum_{m=1}^{\infty} \frac{\gamma^{*m}(y)}{m!}\right], \tag{4}$$

where γ^{*m} denotes the convolution of γ with itself m times.

2.1. Standard example. In order to illustrate our results, it is useful to keep in mind a simple example to which we can refer. We take $\lambda(\tau)$ to be a positive constant, say λ_0, and let $g(\tau) = (1-\tau)\mathbf{1}_{[0,1]}(\tau)$. Take $A_\nu \equiv 1$. Then $B = B_0 = \lambda_0$, and a simple calculation shows $\psi(\omega) = \lambda_0[(e^{j\omega} - 1)/(j\omega) - 1]$ for $\omega \neq 0$, and $\psi(0) = 0$. Hence, $\tilde{\psi}(\omega) = \lambda_0(e^{j\omega} - 1)/(j\omega)$. Note that $\tilde{\psi}$ is the characteristic function of the unnormalized density $\gamma(\theta) = \lambda_0 \mathbf{1}_{[0,1]}(\theta)$.

2.2. Application of (3) and (4) to density approximation. For $M = 0, 1, \ldots,$ let

$$\mu_M(C) := \sum_{m=M+1}^{\infty} \frac{\Gamma^{*m}(C)}{m!}.$$

Then the characteristic function of μ_M is

$$R_M(\omega) := \sum_{m=M+1}^{\infty} \frac{\tilde{\psi}(\omega)^m}{m!}.$$

Suppose $\widetilde{\psi}(\omega)$ is $O(\omega^{-\alpha_0})$ for some $\alpha_0 > 0$. Then $R_M(\omega)$ is $O(\omega^{-(M+1)\alpha_0})$. Given any positive integer p, for large enough M, $(M+1)\alpha_0 > p$, and thus μ_M is absolutely continuous; in fact, $G_M(y) := \mu_M(-\infty, y]$ has p uniformly continuous derivatives [8, §§2.7 and 11.6]. If we make the additional assumption that Γ has density γ, then (4) becomes

$$f(y) = e^{-B}\left[\delta(y) + \sum_{m=1}^{M} \frac{\gamma^{*m}(y)}{m!} + \frac{d}{dy}G_M(y)\right]. \tag{5}$$

For example, if $\alpha_0 = 1$, then G_1 has one continuous derivative, and $G_1(y) = \int_{-\infty}^{y}(\gamma * \gamma)(\theta)/2\, d\theta + G_2(y)$, where G_2 has two continuous derivatives. If we know, for example, that γ is piecewise continuous, and we know the locations of its jump discontinuities, say 0 and 1 as in our standard example, then *even without explicitly computing* $\gamma * \gamma$, we see that it, and hence the density of G_1, have corners at 0, 1, and 2. Hence, it is easy to approximate G_1 by a cubic spline $\widetilde{G}_1$ with double knots at 0, 1, 2, and simple knots elsewhere [4]. We then have $f(y) \approx e^{-B}\left[\delta(y) + \gamma(y) + \frac{d}{dy}\widetilde{G}_1(y)\right]$.

To fit a spline to G_M, we require samples of the function G_M. In §3 we discuss a method to approximate samples of G_M by applying a fast Fourier transform (FFT) to modulated samples of its characteristic function. Computable error bounds are also given.

Remark. The choice of M in (5) is limited by the cost of computing the convolutions $\gamma^{*m}(y)$. For $M = 0$ or 1, no convolutions are required.

2.3. Application of (3) to the computation of tail probabilities. For $M = 1, 2, \ldots$, let

$$\eta_M(C) := \sum_{m=1}^{M} \frac{\Gamma^{*m}(C)}{m!}.$$

Take $\eta_0(C) \equiv 0$. Then (3) becomes $\mathsf{P}(Y \in C) = e^{-B}[1_C(0) + \eta_M(C) + \mu_M(C)]$. In many applications, the measure Γ has bounded support; i.e., there exist $\theta_{\min} < \theta_{\max}$ such that $\Gamma(C) = 0$ if $C \subseteq (-\infty, \theta_{\min}) \cup (\theta_{\max}, \infty)$. Since Γ^{*m} is the convolution of Γ with itself m times, each Γ^{*m}, and hence η_M, has bounded support. It follows that for C outside the support of η_M, and for $0 \notin C$, $\mathsf{P}(Y \in C) = e^{-B}\mu_M(C)$. For example, if $\theta_{\min} < 0 < \theta_{\max}$, then

$$\mathsf{P}(Y \le y) = e^{-B}G_M(y), \quad y < M\theta_{\min},$$

and setting $G_M^c(y) := \mu_M(y, \infty)$,

$$\mathsf{P}(Y > y) = e^{-B}G_M^c(y), \quad y > M\theta_{\max}.$$

In §3 we discuss a method of approximating $G_M(y)$ and $G_M^c(y)$ by summing a Fourier series whose coefficients depend on the characteristic function of G_M. Fortunately, the larger M is, the faster the characteristic function of G_M decays, reducing the number of terms to be summed from that required using the characteristic function of G_0. We give a numerical example in §4.

3. Fourier series/spline approximation for cdfs and densities. We begin with some notation. We say G is an unnormalized cdf if G is nondecreasing, right continuous, and satisfies $G(-\infty) = 0$ and $G(\infty) < \infty$. In this case we set $G^c(y) := G(\infty) - G(y)$. The characteristic function of G is

$$\Phi(\omega) := \int_{-\infty}^{\infty} e^{j\omega x}\, dG(x).$$

Set

$$(6)\quad G_{L,N}(y) := \sum_{n=-N}^{N} b_n \Phi\left(\frac{n\pi}{L}\right) e^{-jn\pi y/L} \quad \text{and} \quad G^c_{L,N}(y) := \sum_{n=-N}^{N} b_{-n} \Phi\left(\frac{n\pi}{L}\right) e^{-jn\pi y/L},$$

where

$$(7)\qquad b_n = \begin{cases} 1/2, & n = 0, \\ j/n\pi, & n \text{ odd}, \\ 0 & \text{otherwise}. \end{cases}$$

Under certain conditions, as $N \to \infty$, $G_{L,N}(y)$ and $G^c_{L,N}(y)$ converge to the infinite sums

$$(8)\qquad G_L(y) := \lim_{N\to\infty} G_{L,N}(y) \quad \text{and} \quad G^c_L(y) := \lim_{N\to\infty} G^c_{L,N}(y).$$

A sufficient condition for these limits to exist is that $\Phi(\omega)$ be $O(\omega^{-\alpha})$ for some $\alpha > 0$. In fact, the weaker condition (9) below suffices.

THEOREM 1. *Let G be an unnormalized cdf with characteristic function Φ. If*

$$(9)\qquad \lim_{L\to\infty} \frac{1}{2L} \int_{-L}^{L} |\Phi(\omega)|^2 \, d\omega = 0,$$

then the limits in (8) *exist and satisfy*

$$(10)\qquad -G(-L+y) \le G_L(y) - G(y) \le G^c(L+y),$$

and

$$(11)\qquad -G^c(L+y) \le G^c_L(y) - G^c(y) \le G(-L+y).$$

A nonrigorous derivation of (11) was first given by Beaulieu [2] under the assumption that G possessed a density. In Appendix B, our proof of Theorem 1 shows that condition (9) is sufficient. Condition (9) is important in applications where one knows only Φ and is trying to find G; i.e., one does not know a priori if G has a density.

Remarks. There are several important observations to make about (10) and (11). (Similar observations are made in [2].) Since G is an unnormalized cdf, for any fixed y, both $G(y-L)$ and $G^c(L+y)$ in (10) and (11) go to zero as $L \to \infty$; i.e.,

$$\lim_{L\to\infty} G_L(y) = G(y) \quad \text{and} \quad \lim_{L\to\infty} G^c_L(y) = G^c(y).$$

Suppose that for some $L_1 < L_2$, $G(x) = 0$ for $x \le L_1$, and $G^c(x) = 0$ for $x \ge L_2$. Then $G(y-L)$ and $G^c(L+y)$ would both be zero when $y \in [L_1, L_2]$ and $L > L_2 - L_1$; it would then follow from (10) and (11) that $G_L(y) = G(y)$ and $G^c_L(y) = G^c(y)$. This would be the situation, for example, if G were the cdf of a bounded random variable. Similarly, if one knows only that $G(x) = 0$ for $x < 0$, corresponding to a nonnegative random variable, then $G(y-L) = 0$ for $0 \le y < L$; i.e., the lower bound in (10) and the upper bound in (11) are both zero. A weaker condition than bounded support would be the existence of the moment generating function of G. In this case, numerical bounds on $G(-L+y)$ and $G^c(L+y)$ can be obtained via the Chernoff bound.

The preceding theorem and remarks address the convergence of G_L and G^c_L to G and G^c, respectively. We next address the respective convergence of $G_{L,N}$ and $G^c_{L,N}$ to G_L and G^c_L.

THEOREM 2. *Suppose that $\Phi(\omega)$ is $O(\omega^{-\alpha})$ for some $\alpha > 0$; i.e., suppose that there exist nonnegative constants K and ω_0 such that $|\Phi(\omega)| \leq K|\omega|^{-\alpha}$ for $|\omega| > \omega_0$. Then for $N > \max\{1, \omega_0 L/\pi\}$, both*

$$|G_L(y) - G_{L,N}(y)| \quad \text{and} \quad |G_L^c(y) - G_{L,N}^c(y)| \tag{12}$$

are upper bounded by

$$\frac{K}{\alpha\pi}\left[\frac{L}{(N-1)\pi}\right]^{\alpha}.$$

Proof. Observe that the differences in (12) are just the tails of the series defining $G_{L,N}$ and $G_{L,N}^c$. Since the terms of these series have the same magnitude for positive and negative n, we can upper bound either quantity in (12) by

$$2\sum_{\substack{n=N+1\\ n\text{ odd}}}^{\infty} \frac{|\Phi(n\pi/L)|}{n\pi} \leq 2\sum_{\substack{n=N+1\\ n\text{ odd}}}^{\infty} \frac{K}{n\pi}\left(\frac{L}{n\pi}\right)^{\alpha},$$

provided that $(N+1)\pi/L > \omega_0$. Now apply an integral comparison to the sum over odd $n \geq N+1$ of $1/n^{\alpha+1}$. □

Theorem 2 says that for fixed L, $G_{L,N}$ and $G_{L,N}^c$ converge uniformly in y. We now observe that (10) and (11) imply that for y restricted to a finite closed interval, say $[L_1, L_2]$, G_L and G_L^c also converge uniformly. To see this, note that for $y \in [L_1, L_2]$, $G^c(L+y) \leq G^c(L+L_1)$ and $G(y-L) \leq G(L_2-L)$. The following result is now an immediate consequence of the triangle inequality and Theorems 1 and 2.

COROLLARY 3. *If $\Phi(\omega)$ is $O(\omega^{-\alpha})$ for some $\alpha > 0$, then $G_{L,N}$ and $G_{L,N}^c$ converge uniformly to G and G^c, respectively, on any finite closed interval as L and N become large.*

3.1. Density approximation by splines.

If Φ is integrable, then G is absolutely continuous with a uniformly continuous density [3, p. 301], which we denote by G'. In particular, if $\Phi(\omega)$ is $O(\omega^{-\alpha})$ for some $\alpha > 1$, then Φ is integrable, and for fixed $L > 0$,

$$\frac{d}{dy}G_{L,N}(y) = \frac{1}{L}\sum_{\substack{n=-N\\ n\text{ odd}}}^{N} \Phi\left(\frac{n\pi}{L}\right)e^{-jn\pi y/L} \tag{13}$$

converges uniformly to $\frac{d}{dy}G_L(y)$ as $N \to \infty$. The problem is that (13) converges more slowly than (6). Hence, we propose the following approach for approximating G'.

To begin, let $c_0 := 0$ and $c_n := b_n\Phi(n\pi/L)$ for $n \neq 0$. Then c_{-n} is the complex conjugate of c_n, and $c_N = 0$ for N even. We can therefore write, for even N,

$$G_{L,N}(y) = b_0\Phi(0) + 2\,\mathrm{Re}\sum_{n=0}^{N-1} c_n e^{-jn\pi y/L}.$$

If we let $y = k\,\Delta y$, where $\Delta y = 2L/N$, then the samples $G_{L,N}(k\,\Delta y)$ for $k = 0, \ldots, N-1$ can be computed with an N-point FFT. We can then use these samples to construct a spline approximation of $G_{L,N}(y)$; to approximate G', we differentiate the spline. The advantage of approximating G' by differentiating a spline approximation of $G_{L,N}$ rather than differentiating $G_{L,N}$ itself is that the series for $G_{L,N}$ converges faster (in N) than the series for its derivative.

3.1.1. Complexity of the approximation. To estimate the complexity of the approximation, we proceed as follows. The first step, computing an FFT of N characteristic function samples to obtain N cdf samples is an order $N \log N$ operation. Next, to compute a cubic spline approximation using the N cdf samples and i interior knots is an order $2N + (i + 8)$ operation using the NAG Library routine E02BAF [19]. Hence, these two steps combined are at most an order $N \log N$ operation. To evaluate the spline or its derivative at one point is an order $\log(i + 8)$ operation using the NAG routine E02BCF [19], which is independent of the number of characteristic function samples N.

3.1.2. Other considerations. Ordinary spline fitting routines, which operate by efficiently solving a highly structured set of linear equations, do not guarantee that a spline fit to $G_{L,N}$ will be monotone or, equivalently, that the spline derivative will be nonnegative. Although we have not found this to be a serious problem in our experience, we briefly discuss three solutions. The simplest solution to the negative density problem is to replace the spline derivative by zero whenever it is negative. Since the spline derivative typically becomes negative only in regions where the true density is almost zero, zero itself is a good approximation. However, this method does yield a nonsmooth density approximation, which may not be acceptable. A second solution, which works in our examples, is simply to increase N. Finally, we note that there are algorithms for constructing monotone splines; e.g., [1] and the references therein. However, such algorithms require solving *non*linear equations.

4. Numerical examples. Motivated by (5), we consider spline approximations of the form

$$\tilde{f}_{M,L,N}(y) := e^{-B}\left[\delta(y) + \sum_{m=1}^{M} \frac{\gamma^{*m}(y)}{m!} + \frac{d}{dy}\tilde{G}_{M,L,N}(y)\right], \tag{14}$$

where $\tilde{G}_{M,L,N}$ is a spline fit to

$$G_{M,L,N}(y) := \sum_{n=-N}^{N} b_n R_M\left(\frac{n\pi}{L}\right) e^{-jn\pi y/L}. \tag{15}$$

We also consider the direct Fourier series approximation (cf. (13))

$$f_{M,L,N}(y) := e^{-B}\left[\delta(y) + \sum_{m=1}^{M} \frac{\gamma^{*m}(y)}{m!} + \frac{d}{dy}G_{M,L,N}(y)\right]. \tag{16}$$

For our standard example (§2.1), f is known in closed form, and so in Example 1 we set $M = 1$ and compare both $\tilde{f}_{M,L,N}$ and $f_{M,L,N}$ with f. In Example 2 we apply the ideas from §2.3 to compute a tail probability $\mathsf{P}(Y > y)$ for our standard example.

Example 1. For our standard example, the density of Y was obtained in closed form, modulo a typo, by Gilbert and Pollack [6, p. 344]. The correct formula is, for $y > 0$,

$$f(y) = \lambda_0 e^{-\lambda_0} \sum_{k=0}^{\lfloor y \rfloor} \frac{(-1)^k}{k!}\left(\sqrt{\lambda_0(y-k)}\right)^{k-1} I_{k-1}\left(2\sqrt{\lambda_0(y-k)}\right),$$

where $\lfloor y \rfloor$ denotes the greatest integer less than or equal to y, and I_k is the modified Bessel function of order k. Note that $I_{-1} = I_1$. A plot of $f(y)$, $y > 0$, is shown in Fig. 1 for the case $\lambda_0 = 1$. When $\lambda_0 = 1$ we approximate $f(y)$ on $[0, 7.1]$ as follows. First we must select the knots for the spline approximation of $G_{1,L,N}$ in (15). To begin, we placed 35 uniformly spaced interior knots between 0.2 and 7. The cubic spline program we used (NAG Library routine

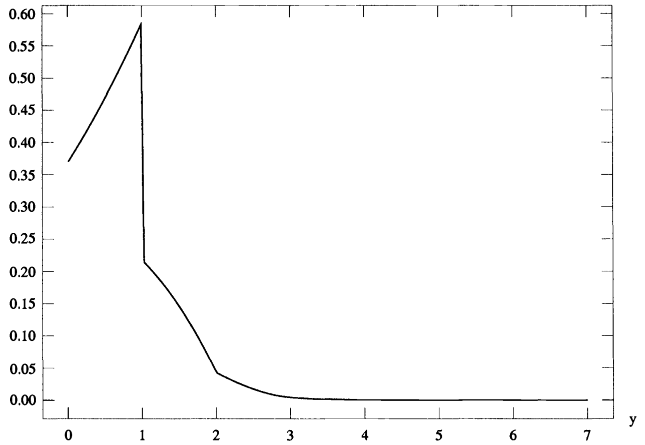

FIG. 1. *Plot of* $f(y)$ *from Example* 1.

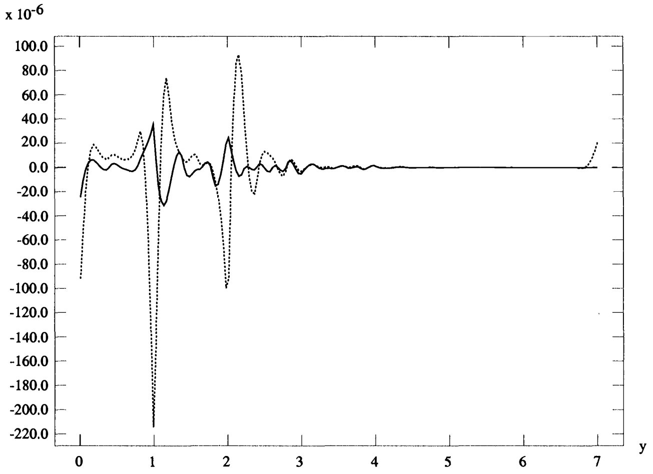

FIG. 2. *Plot of* $f(y) - \widetilde{f}_{1,L,128}(y)$ *(dotted line) and* $f(y) - \widetilde{f}_{1,L,256}(y)$ *(solid line) from Example* 1.

E02BAF) automatically put four coincident knots at each of the endpoints, 0 and 7.1. Now, as noted in §2.2, the density of G_1 has corners at 0, 1, and 2. We therefore added a coincident knot at 1 and at 2, for a total of 37 interior knots. We now take $L = 10$. If $N = 128$, a plot of $\widetilde{f}_{1,L,N}(y)$ would be graphically indistinguishable from the curve in Fig. 1. Hence, in Fig. 2 we plot the errors $f(y) - \widetilde{f}_{1,L,128}(y)$ (dotted line) and $f(y) - \widetilde{f}_{1,L,256}(y)$ (solid line) for $y \in [0.01, 7]$. Letting $\widetilde{F}_{M,L,N}(y) := e^{-B}[\mathbf{1}_{[0,\infty)}(y) + \eta_M(y) + \widetilde{G}_{M,L,N}(y)]$, we note that $\widetilde{F}_{1,L,128}(7.03125) = 1.00000$; i.e., our density approximation integrates to 1 to the number of digits shown. The spline fitting routine we used did not require that $\widetilde{f}_{1,L,N}$ be nonnegative. In fact, when $N = 128$ and y is close to 7, $\widetilde{f}_{1,L,N}(y) \approx -10^{-5}$. For $N = 256$, this problem disappears.

Finally, we note that our spline approximation (14) yields a much smaller error than the direct Fourier series approximation (16). This is demonstrated in Fig. 3 where we plot $f(y) - \widetilde{f}_{1,L,256}(y)$ (solid line) and $f(y) - f_{1,L,256}(y)$ (dotted line).

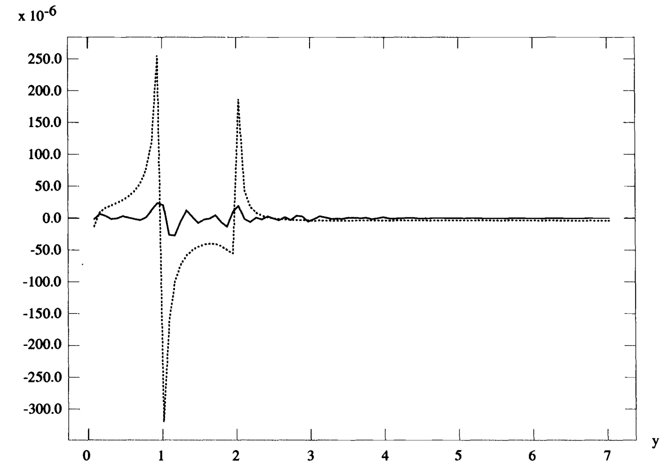

FIG. 3. *Plot of* $f(y) - \tilde{f}_{1,L,256}(y)$ *(solid line) and* $f(y) - f_{1,L,256}(y)$ *(dotted line) from Example* 1.

Example 2. As noted in §2.3, in many cases we can write $F^c(y) = e^{-B}G^c_M(y)$ for large y. Suppose $|\tilde{\psi}(\omega)| \le K_0|\omega|^{-\alpha_0}$ for large ω. Letting $\alpha = \alpha_0(M+1)$ and

$$K = \sum_{m=M+1}^{\infty} \frac{K_0^m}{m!},$$

we have $|R_M(\omega)| \le K|\omega|^{-\alpha}$. For our standard example, we have $K_0 = 2\lambda_0$ and $\alpha_0 = 1$. Hence, $R_M(\omega)$ is $O(\omega^{-(M+1)})$. Since γ lives on $[0,1]$, we see that for $y \ge M$, $\mathsf{P}(Y > y) = e^{-\lambda_0}G^c_M(y)$. By Theorem 1, the error between $\mathsf{P}(Y > y)$ and $e^{-\lambda_0}G^c_{M,L}(y)$ is less than $e^{-\lambda_0}G^c_M(L+y)$ and, by Theorem 2, the error between $e^{-\lambda_0}G^c_{M,L}(y)$ and $e^{-\lambda_0}G^c_{M,L,N}(y)$ is less than

$$(17) \qquad e^{-\lambda_0}\frac{K}{\alpha\pi}\left[\frac{L}{(N-1)\pi}\right]^{\alpha}, \quad N > 1.$$

Taking $\lambda_0 = 1$, $L = 10$, $N = 64$, and $y = M = 6$, we computed $e^{-1}G^c_{6,10,64}(6) = 1.3012036133501\times10^{-7}$. We conclude that $\mathsf{P}(Y > 6) = 1.3012\times10^{-7}$ to the number of digits shown as follows. First, using a Chernoff bound, we find numerically that $e^{-1}G^c_6(10+6) \le 8\times10^{-24}$. Second, the bound in (17) is less than 5×10^{-13}.

5. Conclusion. In §3 we discussed a general method for approximating a cdf and ccdf from their characteristic function using $G_{L,N}$ and $G^c_{L,N}$, respectively. The error due to taking L finite is given in (10) and (11); when the moment generating function exists, numerical bounds on this error can be determined with the Chernoff bound. In Theorem 2 we gave a simple bound on the error due to taking N finite. In §3.1 we proposed fitting a spline to the cdf approximation and then differentiating the spline to approximate the density. With appropriately chosen knots, excellent density approximation can be obtained.

These general results do not apply directly to shot-noise random variables because their densities contain impulses and discontinuities. Hence, Theorems 4–6 in Appendix A are the key to obtaining the decompositions (3) and (4), from which the analysis of the shot-noise density in §2.2 and the shot-noise tail probabilities in §2.3 followed. From this analysis, we see how to apply the general method of §3 to the components of the shot-noise decomposition.

In particular, the shot-noise decomposition permits the easy identification of the knot locations needed for good spline approximation.

Appendix A: Analysis of ψ. We show that $\psi(\omega) = \widetilde{\psi}(\omega) - B$, where $B = B_0\mathsf{P}(A_\nu > 0)$, and $\widetilde{\psi}$ is the characteristic function of a finite measure Γ on the Borel subsets of $\mathbb{R}$. To begin the analysis, we make the additional technical assumption that λ and g are Borel measurable. Let

$$\psi_0(\omega) := \int \lambda(\tau)[e^{j\omega g(\tau)} - 1]\,d\tau. \tag{18}$$

Then if

$$\mathsf{E}\left[\int \lambda(\tau)|e^{j\omega g(\tau)A_\nu} - 1|\,d\tau\right] < \infty, \tag{19}$$

Fubini's theorem [3, p. 200] allows (1) to be rewritten as

$$\psi(\omega) = \mathsf{E}\big[\psi_0(\omega A_\nu)\big].$$

Note that since $|e^{j\theta} - 1| \leq \min\{|\theta|, 2\}$, (2) is a sufficient condition for (19) to hold. This condition is not necessary; for example, the power-law shot-noise random variables in [9, §IV-B] satisfy (19) but not (2).

On the Borel subsets of $\mathbb{R}$, define the measure

$$\Gamma_0(C) := \int_{\{\tau : g(\tau)\in C,\, g(\tau)\neq 0\}} \lambda(\tau)\,d\tau. \tag{20}$$

Note that $\Gamma_0(\mathbb{R}) = B_0$ (cf. (2)).

Remark. The measure Γ_0 can be interpreted as an unnormalized conditional probability as follows. Recall that conditioned on the number of points $\{T_\nu\}$ occurring in a region D, the point locations in D are independent and identically distributed with common density $\lambda(\tau)/\int_D \lambda(\tau)\,d\tau$ [17, p. 90]. If $D = \{\tau \in \mathbb{R}^d : g(\tau) \neq 0\}$, then $\Gamma_0(C)/\Gamma_0(\mathbb{R})$ is the conditional probability that $g(T_\nu) \in C$ given that T_ν is one of the points in D.

THEOREM 4. *If* (2) *holds, then*

$$\psi_0(\omega) = \int_{-\infty}^{\infty} e^{j\omega\theta}\,d\Gamma_0(\theta) - \Gamma_0(\mathbb{R}).$$

Proof. Let D be a Borel subset of $\mathbb{R}^d$, and let C be a Borel subset of $\mathbb{R}$. Define two measures $\Lambda(D) := \int_D \lambda(\tau)\,d\tau$ and $H(C) := \Lambda\big(g^{-1}(C)\big)$. The change-of-variable formula for measures [3, p. 185] allows us to rewrite (18) to obtain

$$\begin{aligned}\psi_0(\omega) &= \int [e^{j\omega g(\tau)} - 1]\,d\Lambda(\tau)\\ &= \int_{-\infty}^{\infty} [e^{j\omega\theta} - 1]\,dH(\theta).\end{aligned}$$

Note that the integrand is zero for $\theta = 0$. Also note that $\Gamma_0(C) = H(C\backslash\{0\})$. Hence, we can replace $dH(\theta)$ by $d\Gamma_0(\theta)$, and the theorem follows. □

THEOREM 5. *Assume* (2) *holds, and define the finite measure*

$$\Gamma(C) := \mathsf{E}\left[\mathbf{1}_{\{A_\nu>0\}}\int_{-\infty}^{\infty} \mathbf{1}_C(A_\nu\theta)\,d\Gamma_0(\theta)\right]. \tag{21}$$

Let $B := \Gamma(\mathbb{R}) = \Gamma_0(\mathbb{R})\mathsf{P}(A_\nu > 0) = B_0\mathsf{P}(A_\nu > 0)$, *and set* $\widetilde{\psi}(\omega) := \psi(\omega) + B$. *Then*

$$\int_{-\infty}^{\infty} e^{j\omega\theta}\, d\Gamma(\theta) = \widetilde{\psi}(\omega).$$

Proof. Using the definition of Γ in (21) and proceeding in the usual way from simple functions to nonnegative functions to integrable functions, one can see that for the particular function of ζ, $e^{j\omega\zeta}$, we have

$$\int_{-\infty}^{\infty} e^{j\omega\zeta}\, d\Gamma(\zeta) = \mathsf{E}\left[\mathbf{1}_{\{A_\nu>0\}} \int_{-\infty}^{\infty} e^{j\omega(A_\nu\theta)}\, d\Gamma_0(\theta)\right],$$

which by Theorem 4 is equal to $\mathsf{E}\big[\mathbf{1}_{\{A_\nu>0\}}[\psi_0(\omega A_\nu) + \Gamma_0(\mathbb{R})]\big]$, which, since $\psi_0(0) = 0$, is equal to $\mathsf{E}\big[\psi_0(\omega A_\nu)\big] + \Gamma_0(\mathbb{R})\mathsf{P}(A_\nu > 0)$. □

THEOREM 6. *If* Γ_0 *has density* γ_0, *then* Γ *has density*

$$\gamma(\theta) = \mathsf{E}\big[\mathbf{1}_{\{A_\nu>0\}}\gamma_0(\theta/A_\nu)/A_\nu\big].$$

Proof. From the definition of Γ in (21) we can write

$$\Gamma(C) = \mathsf{E}\left[\mathbf{1}_{\{A_\nu>0\}} \int_{-\infty}^{\infty} \mathbf{1}_C(A_\nu\theta)\gamma_0(\theta)\, d\theta\right].$$

Then a change of variable followed by Tonelli's theorem [3, p. 200] yields

$$\Gamma(C) = \int_C \mathsf{E}\big[\mathbf{1}_{\{A_\nu>0\}}\gamma_0(\theta/A_\nu)/A_\nu\big]\, d\theta. \qquad \square$$

Remark. Under certain symmetry conditions, it is often quite easy to use (20) to express $\Gamma_0(\theta, \infty)$ or $\Gamma_0(-\infty, \theta]$ in a form in which γ_0 can be obtained via differentiation. A large class of such examples can be constructed as follows. Let $\|\cdot\|$ be a norm on $\mathbb{R}^d$. Let q map $[0, r)$ onto $(0, 1]$, where q is nonnegative and strictly decreasing so that q^{-1}: $(0, 1] \to [0, r)$ exists and is nonnegative and strictly decreasing. Set $g(\tau) = q(\|\tau\|)$ for $0 \le \|\tau\| < r$ and $g(\tau) = 0$ otherwise. Since $g(\tau) \ge 0$, $\Gamma_0(\theta, \infty) = B_0$ for $\theta \le 0$, and since $g(\tau) \le 1$, $\Gamma_0(\theta, \infty) = 0$ for $\theta \ge 1$. For $0 < \theta < 1$,

$$\Gamma_0(\theta, \infty) = \int_{\{\tau:\|\tau\|<q^{-1}(\theta)\}} \lambda(\tau)\, d\tau.$$

Now suppose $\lambda(\tau) = u(\|\tau\|^2)$, where u is nonnegative. If $U(\rho) = U(0) + \int_0^\rho u(x^2)x^{d-1}\, dx$, and if $\mathcal{A}_d$ denotes the area of the unit sphere $\{\tau \in \mathbb{R}^d : \|\tau\| = 1\}$, then $\Gamma_0(\theta, \infty) = \mathcal{A}_d[U\big(q^{-1}(\theta)^2\big) - U(0)]$. If q is piecewise continuously differentiable, then $\gamma_0(\theta) = -\mathcal{A}_d u\big(q^{-1}(\theta)^2\big)q^{-1}(\theta)(d/d\theta)q^{-1}(\theta)$, where the discontinuities and corners of γ_0 are easily determined from those of u and q.

Appendix B: Proof of Theorem 1. We claim that it suffices to prove the theorem for $y = 0$. To see this, suppose (10) and (11) hold with $y = 0$; note the resulting simplifications in the expressions for $G_{L,N}(0)$ and $G^c_{L,N}(0)$, in terms of which $G_L(0)$ and $G^c_L(0)$ are defined. Then replace G by G_y, where $G_y(x) := G(x + y)$, and note that the characteristic function of G_y is $\int_{-\infty}^{\infty} e^{j\omega x} dG_y(x) = \Phi(\omega)e^{-j\omega y}$. This establishes the claim.

We now prove the theorem when $y = 0$. We begin with (11). Observe that $G^c(0) = \int_{-\infty}^{\infty} \mathbf{1}_{(0,\infty)}(x)\, dG(x)$. Now, for any $L > 0$, define the periodic pulse train β_L with period $2L$ by specifying its values on $(-L, L]$ to be

$$\beta_L(x) = \begin{cases} 1, & 0 < x \le L, \\ 0, & -L < x \le 0. \end{cases}$$

Observe that for all x,

$$\beta_L(x) \leq \mathbf{1}_{(0,\infty)}(x) + \mathbf{1}_{(-\infty,-L]}(x)$$

and

$$\beta_L(x) \geq \mathbf{1}_{(0,L]}(x) = \mathbf{1}_{(0,\infty)}(x) - \mathbf{1}_{(L,\infty)}(x).$$

Hence, we have the error bounds

$$-G^c(L) \leq \int_{-\infty}^{\infty} \beta_L(x)\,dG(x) - G^c(0) \leq G(-L).$$

The next step is to approximate β_L by its Fourier series. Set

$$\beta_{L,N}(x) := \sum_{n=-N}^{N} b_{-n}e^{jn\pi x/L},$$

where the b_n are given by (7). Now, as $N \to \infty$, $\beta_{L,N}(x) \to \beta_L(x)$ for all x except at points of discontinuity of β_L. Since (9) is equivalent to the condition that the measure induced by G have no point masses [3, p. 306], $\beta_{L,N}$ converges to β_L almost everywhere with respect to this measure. Since $\beta_{L,N}(x)$ is uniformly bounded in N and x (with L fixed) [5, p. 151, eq. (10.1.5)], the dominated convergence theorem yields

$$\begin{aligned}\int_{-\infty}^{\infty} \beta_L(x)\,dG(x) &= \sum_{n=-\infty}^{\infty} b_{-n} \int_{-\infty}^{\infty} e^{jn\pi x/L}\,dG(x)\\ &= \sum_{n=-\infty}^{\infty} b_{-n}\Phi\left(\frac{n\pi}{L}\right)\\ &= G_L^c(0).\end{aligned}$$

This establishes (11). To establish (10), repeat the preceding derivation, but replace $\beta_L(x)$ by $\beta_L(-x)$. Then note that G is real and equal to its complex conjugate. □

TOEPLITZ-CIRCULANT PRECONDITIONERS FOR TOEPLITZ SYSTEMS AND THEIR APPLICATIONS TO QUEUEING NETWORKS WITH BATCH ARRIVALS*

RAYMOND H. CHAN† AND WAI-KI CHING‡

Abstract. The preconditioned conjugate gradient method is employed to solve Toeplitz systems $T_n \mathbf{x} = \mathbf{b}$ where the generating functions of the n-by-n Toeplitz matrices T_n are functions with zeros. In this case, circulant preconditioners are known to give poor convergence, whereas band-Toeplitz preconditioners offer only linear convergence and can handle only real-valued functions with zeros of even orders. We propose here preconditioners which are products of band-Toeplitz matrices and circulant matrices. The band-Toeplitz matrices are used to cope with the zeros of the given generating function and the circulant matrices are used to speed up the convergence rate of the algorithm. Our preconditioner can handle complex-valued functions with zeros of arbitrary orders. We prove that the preconditioned Toeplitz matrices have singular values clustered around 1 for large n. We apply our preconditioners to solve the stationary probability distribution vectors of Markovian queueing models with batch arrivals. We show that if the number of servers is fixed independent of the queue size n, then the preconditioners are invertible and the preconditioned matrices have singular values clustered around 1 for large n. Numerical results are given to illustrate the fast convergence of our methods.

1. Introduction. In this paper, we discuss the solutions of linear systems $T\mathbf{x} = \mathbf{b}$ where T is a Toeplitz matrix. Direct methods that are based on the Levinson recursion formula are in constant use; see for instance, Trench [25]. For an n-by-n Toeplitz matrix T_n, these methods require $O(n^2)$ operations. Faster algorithms that require $O(n \log^2 n)$ operations have been developed; see Ammar and Gragg [1] for instance. The stability properties of these direct methods for symmetric positive definite matrices are discussed in Bunch [5].

Here we will consider solving Toeplitz systems by the preconditioned conjugate gradient squared (PCGS) method. There are many circulant preconditioning strategies for Toeplitz systems; see for instance [23, 11, 16, 15, 17, 18, 4, 3]. The convergence results for these circulant preconditioners are all based on the regularity of the function $g(\theta)$ whose Fourier coefficients give the diagonals of T_n. The function $g(\theta)$ with $\theta \in [-\pi, \pi]$ is called the generating function of the sequence of Toeplitz matrices T_n. A general result is that if $g(\theta)$ is a positive function in the Wiener class, then for large enough n, the preconditioned matrix has eigenvalues clustered around 1. In particular, the PCGS method applied to the preconditioned system converges superlinearly and the n-by-n Toeplitz system can be solved in $O(n \log n)$ operations. However, we remark that if $g(\theta)$ has a zero, then the result fails to hold and the circulant preconditioned systems can converge at a very slow rate (see the numerical examples in §4 or in [9]).

To this end, Chan in [6] used trigonometric functions of the form $\sin^\ell(\theta - \theta_0)$ to approximate the function $g(\theta)$ around the zeros θ_0 of g. The power ℓ is the order of the zero θ_0 and is required to be an even number. The resulting preconditioner is a band-Toeplitz matrix which gives linear convergence. The bandwidth of the preconditioner is $(\ell + 1)$. To speed up the convergence rate, Chan and Tang [9] have considered using the Remez algorithm to find the

best trigonometric polynomial that approximates g in the supremum norm and yet matches the order of the zeros of g in a neighborhood of the zeros. The resulting band-Toeplitz preconditioner can significantly reduce the condition number of the preconditioned systems at the expense of enlarging the bandwidth. We note that both methods work only for real-valued generating functions with zeros of even orders and fail for complex-valued functions or real-valued functions with zeros of odd order. A typical example is the Toeplitz matrix tridiag$[-1, 1, 0]$. Its generating function is given by $g(\theta) = 1 - e^{-i\theta}$ and it has a zero of order 1 at $\theta = 0$. We note that if we write $z = e^{i\theta}$, then g as a function of z has a zero of order 1 at $z = 1$.

In this paper, we will design preconditioners that give superlinear convergence and work for generating functions that are complex valued and have zeros with arbitrary orders. Our idea is to approximate g, as a function of the complex variable z, around its zeros z_0 by functions of the form $(z - z_0)^\ell$, where ℓ is the order of the zero z_0. Then we approximate the quotient $g(z)/(z - z_0)^\ell$ by using the usual circulant approach. This results in a preconditioner which is a product of a band-Toeplitz matrix with bandwidth $(\ell + 1)$ and a circulant matrix. We will prove that if the quotient is a nonvanishing Wiener-class function, then the preconditioner is invertible and the iterative method converges superlinearly for large n.

We then apply our preconditioner to solve the stationary probability distribution vectors for Markovian queueing networks with batch arrivals. We note that the generator matrices A_n for these queueing networks are singular matrices with a Toeplitz-like structure. In fact, when there is only one server in the system, A_n differs from a lower Hessenberg Toeplitz matrix by a rank-one matrix. The preconditioner P_n is constructed by exploiting the near-Toeplitz structure of A_n and will also be a product of a band-Toeplitz matrix and a circulant matrix. We prove that if the number of servers is independent of the queue size n, then for all sufficiently large n, P_n are invertible and the preconditioned matrices have singular values clustered around 1.

The outline of this paper is as follows. In §2 we define our preconditioners P_n for general Toeplitz matrices with generating functions that have zeros. We then prove that the preconditioned systems have singular values clustered around 1. In §3 we consider solving Markovian queueing networks with batch arrivals by using our preconditioners. In §4 numerical results are given to illustrate the fast convergence of our methods when compared to other methods and other preconditioners used in solving Toeplitz systems and queueing networks. Finally, concluding remarks are given in §5.

2. Construction and analysis of preconditioners.

In this section, we discuss how to construct preconditioners for Toeplitz systems T_n whose generating functions are functions having zeros. Then we analyze the convergence rate of the resulting preconditioned systems.

Let us first recall the definitions of Toeplitz and circulant matrices. An n-by-n matrix $T_n = (t_{i,j})$ is said to be Toeplitz if $t_{i,j} = t_{i-j}$, i.e., if T_n is constant along its diagonals. It is said to be circulant if its diagonals t_k further satisfy $t_{n-k} = t_{-k}$ for $0 < k \leq n - 1$. The idea of using circulant matrices as preconditioners for Toeplitz matrices has been studied extensively in recent years; see for instance [23, 11, 16, 26, 15]. In this paper, we will concentrate on the T. Chan circulant preconditioners. The results for the other circulant preconditioners can be obtained similarly; see §5.

For a given Toeplitz matrix T_n with diagonals $\{t_j\}_{j=-(n-1)}^{n-1}$, the T. Chan circulant preconditioner to T_n is defined to be the circulant matrix C_n which minimizes the Frobenius norm $||T_n - C_n||_F$ among all circulant matrices. The (i, j)th entry of C_n is given by c_{i-j}, where

$$(1) \qquad c_k = \begin{cases} \dfrac{(n-k)t_k + kt_{k-n}}{n}, & 0 \leq k < n, \\ c_{n+k}, & 0 < -k < n; \end{cases}$$

see T. Chan [11]. We note that the diagonals $\{c_j\}_{j=-(n-1)}^{n-1}$ and hence the matrix C_n can be obtained in $O(n)$ operations. The eigenvalues of C_n, which are required in the inversion of C_n, can be computed in $O(n \log n)$ operations by using fast Fourier transforms; see Strang [23] for instance. Because of the good approximating properties of the T. Chan circulant preconditioners, they have been used when solving numerical elliptic partial differential equations [7] and signal processing problems [8].

We will analyze the convergence rate of the preconditioned systems $C_n^{-1}T_n$ in the limit $n \to \infty$, assuming that a fixed sequence of entries $\{t_j\}_{j=-\infty}^{\infty}$ has been prescribed. As usual in the study of Toeplitz matrices and operators (see for instance Grenander and Szegö [14]) we consider the Laurent series

$$g(z) = \sum_{j=-\infty}^{\infty} t_j z^j$$

whose coefficients $\{t_j\}$ are the entries of T_n, with $t_{j,k} = t_{j-k}$ for $0 \le j, k < n$. We will call $g(z)$ the generating function of the sequence of Toeplitz matrices T_n and for clarity, we will denote such T_n by $\mathcal{T}_n[g]$ and the corresponding T. Chan circulant preconditioner by $\mathcal{C}_n[g]$.

We note that if

$$\sum_{j=-\infty}^{\infty} |t_j| < \infty,$$

i.e., if $g(z)$ belongs to the Wiener class of functions $\mathcal{W}$ defined on the unit circle $|z| = 1$ and if $g(z)$ has no zeros on $|z| = 1$, then $\mathcal{C}_n[g]$ is a good approximation to $\mathcal{T}_n[g]$ as far as PCGS methods are concerned.

LEMMA 2.1. *Let $g \in \mathcal{W}$ and have no zeros on $|z| = 1$. Then for large n, $\mathcal{C}_n[g]$ will be invertible and the sequence of matrices $\mathcal{C}_n[g]^{-1}\mathcal{T}_n[g]$ will have singular values clustered around* 1. *More precisely, for any fixed $\epsilon > 0$, there exist integers $M, N > 0$ such that for all $n > N$, $\mathcal{C}_n[g]$ is invertible and the matrix $\mathcal{C}_n[g]^{-1}\mathcal{T}_n[g]$ has no more than M singular values lying outside the interval* $(1-\epsilon, 1+\epsilon)$.

Proof. We note that by the Weierstrass M-test, $g(z)$ is a 2π-periodic complex-valued function defined on the unit circle $|z| = 1$ with respect to the angle θ; see for instance Conway [12, p. 29]. The lemma now follows from Lemma 3 and Theorem 2 of Chan and Yeung [10]. □

In this paper, we relax the requirement that $g(z)$ has no zeros on $|z| = 1$. In particular, we consider $g(z)$ that are of the form

$$g(z) = \left\{\prod_j (z - z_j)^{\ell_j}\right\} h(z),$$

where z_j are the roots of $g(z)$ on $|z| = 1$ with order ℓ_j and $h(z)$ is a nonvanishing function in $\mathcal{W}$. Our Toeplitz-circulant preconditioner P_n is defined to be

$$P_n = \mathcal{T}_n\left[\prod_j (z - z_j)^{\ell_j}\right] \mathcal{C}_n[h].$$

By expanding the product $\prod_j (z - z_j)^{\ell_j}$ we see that the Toeplitz matrix $\mathcal{T}_n[\prod_j (z - z_j)^{\ell_j}]$ is a lower triangular matrix with bandwidth equal to $(\ell + 1)$, where

$$\ell = \sum_j \ell_j.$$

Moreover, its main diagonal entry is 1 and therefore it is invertible for all n.

In each iteration of the PCGS method, we have to solve a linear system of the form $P_n\mathbf{y} = \mathbf{r}$. We first claim that P_n is invertible for large n. As mentioned above, the Toeplitz matrix $\mathcal{T}_n[\prod_j (z - z_j)^{\ell_j}]$ is invertible for all n. Since $h \in \mathcal{W}$ and has no zeros, the invertibility of $\mathcal{C}_n[h]$ for large n is guaranteed by Lemma 2.1. Hence P_n is invertible for large n. Let us consider the cost of solving the system

$$P_n\mathbf{y} = \mathcal{T}_n\left[\prod_j (z - z_j)^{\ell_j}\right]\mathcal{C}_n[h]\mathbf{y} = \mathbf{r}.$$

Because the matrix $\mathcal{T}_n[\prod_j (z - z_j)^{\ell_j}]$ is a lower triangular matrix with bandwidth $(\ell + 1)$, the system involving $\mathcal{T}_n[\prod_j (z - z_j)^{\ell_j}]$ can be solved by forward substitution and the cost is $O(\ell n)$ operations. Given any vector $\mathbf{x}$, the matrix-vector product $\mathcal{C}_n[h]^{-1}\mathbf{x}$ can be done by using fast Fourier transforms in $O(n \log n)$ operations; see Strang [23] and O'Leary and Simmons [20]. Thus the system $P_n\mathbf{y} = \mathbf{r}$ can be solved in $O(n \log n) + O(\ell n)$ operations. In comparison, the systems involving the preconditioners proposed by Chan [6] and Chan and Tang [9] require $O(n \log n) + O(\ell^2 n)$ operations to be solved.

We now investigate the convergence rate of the preconditioned systems.

THEOREM 2.2. *The sequence of matrices $P_n^{-1}\mathcal{T}_n[g]$ has singular values clustered around 1 for all sufficiently large n.*

Proof. Since $\mathcal{T}_n[\prod_j (z - z_j)^{\ell_j}]$ is a lower triangular Toeplitz matrix of bandwidth $(\ell + 1)$, we see that the matrix

$$\left\{\mathcal{T}_n[g] - \mathcal{T}_n\left[\prod_j (z - z_j)^{\ell_j}\right]\mathcal{T}_n[h]\right\}$$

only has nonzero entries in the first $l + 1$ rows. Hence it is clear that

$$\mathcal{T}_n[g] = \mathcal{T}_n\left[\prod_j (z - z_j)^{\ell_j}\right]\mathcal{T}_n[h] + L_1,$$

where rank $L_1 \le \ell + 1$. Therefore

$$\begin{aligned}
P_n^{-1}\mathcal{T}_n[g] &= \mathcal{C}_n[h]^{-1}\mathcal{T}_n\left[\prod_j (z - z_j)^{\ell_j}\right]^{-1}\mathcal{T}_n[g] \\
&= \mathcal{C}_n[h]^{-1}\mathcal{T}_n\left[\prod_j (z - z_j)^{\ell_j}\right]^{-1}\left(\mathcal{T}_n\left[\prod_j (z - z_j)^{\ell_j}\right]\mathcal{T}_n[h] + L_1\right) \\
&= \mathcal{C}_n[h]^{-1}\mathcal{T}_n[h] + L_2, \qquad (2)
\end{aligned}$$

where rank $L_2 \le \ell$. Since h has no zeros, by Lemma 2.1, $\mathcal{C}_n[h]^{-1}\mathcal{T}_n[h]$ has clustered singular values. In particular, we can write $\mathcal{C}_n[h]^{-1}\mathcal{T}_n[h] = I + L_3 + U$, where U is a small norm matrix and rank L_3 is fixed independent of n; see [10, Cor. 1]. Hence (2) becomes

$$P_n^{-1}\mathcal{T}_n[g] = I + L_4 + U,$$

where the rank of L_4 is again fixed independent of n. By using the Cauchy interlace theorem [28, p. 103] on

$$(P_n^{-1}\mathcal{T}_n[g])^*(P_n^{-1}\mathcal{T}_n[g]) = (I + L_4 + U)^*(I + L_4 + U),$$

it is straightforward to show that $P_n^{-1}\mathcal{T}_n[g]$ has singular values clustered around 1; see [10, Thm. 2] for details. □

Accordingly, the PCGS methods will converge quickly when applied to solving the preconditioned systems; see Axelsson and Barker [2, p. 26] for instance. Numerical examples are given in §4 to illustrate this fast convergence.

3. Markovian queueing networks. In this section, we consider using the PCGS method with our Toeplitz-circulant preconditioners for solving the stationary probability distribution vectors for Markovian queueing models with batch arrivals. This kind of queueing system occurs in many applications, such as telecommunication networks [19] and loading dock models [21]. We will see that the generator matrices of these systems have a near-Toeplitz structure and our preconditioners are constructed by exploiting this fact.

Let us first introduce the following queueing parameters. Definitions of queueing theory terminologies used below can be found in Cooper [13]. The input of the queueing system will be an exogenous Poisson batch arrival process with mean batch interarrival time λ^{-1}. For $k \geq 1$, denote λ_k to be the batch arrival rate for batches with size k. We note that

$$\lambda_k = \lambda p_k, \tag{3}$$

where p_k is the probability that the arrival batch size is k. Clearly we have

$$\sum_{k=1}^{\infty} \lambda_k = \lambda. \tag{4}$$

The number of servers in the queueing system will be denoted by s. The service time of each server is independent of the others and is exponentially distributed with mean μ^{-1}. The waiting room is of size $(n-s-1)$ and the queueing discipline is blocked-customers-cleared. If the arrival batch size is larger than the number of waiting places left, then only part of the arrival batch will be accepted; the other customers will be treated as overflows and will be cleared from the system.

By ordering the state-space lexicographically, i.e., the ith variable corresponds to the state where there are $i-1$ customers in the system, the queueing model can be characterized by the infinitesimal generator matrix

$$A_n = \begin{pmatrix} \lambda & -\mu & 0 & 0 & 0 & \dots & 0 \\ -\lambda_1 & \lambda+\mu & -2\mu & 0 & 0 & \dots & 0 \\ -\lambda_2 & -\lambda_1 & \lambda+2\mu & \ddots & \ddots & & \vdots \\ \vdots & -\lambda_2 & \ddots & \ddots & -s\mu & \ddots & \\ & \vdots & \ddots & \ddots & \lambda+s\mu & \ddots & 0 \\ -\lambda_{n-2} & -\lambda_{n-3} & & & \vdots & \lambda+s\mu & -s\mu \\ -r_1 & -r_2 & -r_3 & \cdots & -r_{s+1} & \cdots & s\mu \end{pmatrix}, \tag{5}$$

where r_i are such that each column sum of A_n is zero; see Seila [21].

Clearly A_n has zero column sum, positive diagonal entries and nonpositive off-diagonal entries. Moreover the matrix A_n is irreducible. In fact, if $\lambda_i = 0$ for all $i = 1, \dots, n-2$, then $r_1 = \lambda$ and the matrix is irreducible. If the λ_i's are not all zero, say λ_j is the first nonzero λ_i, then $r_{n-j} = \lambda$, and hence A_n is also irreducible. From the theory of Perron and Frobenius [27, p. 30], A_n has a 1-dimensional null-space with a positive null vector.

The stationary probability distribution vector $\mathbf{p}$ of the queueing system is the normalized null-vector of the generator matrix A_n given in (5). Much useful information about the queueing system, such as the blocking probability and the expected waiting time of customers, can be obtained from $\mathbf{p}$. Since A_n has a 1-dimensional null-space, $\mathbf{p}$ can be found by deleting the last column and the last row of A_n and solving the $(n-1)$-by-$(n-1)$ reduced linear system $Q_{n-1}\mathbf{y} = (0, \ldots, 0, s\mu)^t$. After getting $\mathbf{y}$, the distribution vector $\mathbf{p}$ can then be obtained by normalizing the vector $(\mathbf{y}^t, 1)^t$.

Thus let us concentrate on solving nonhomogeneous systems of the form

$$Q_n\mathbf{x} = \mathbf{b}, \tag{6}$$

where

$$Q_n = \begin{pmatrix} \lambda & -\mu & 0 & 0 & 0 & \ldots & 0 \\ -\lambda_1 & \lambda+\mu & -2\mu & 0 & 0 & \ldots & 0 \\ -\lambda_2 & -\lambda_1 & \lambda+2\mu & \ddots & \ddots & & \vdots \\ \vdots & -\lambda_2 & \ddots & \ddots & -s\mu & \ddots & \\ & \vdots & \ddots & \ddots & \lambda+s\mu & \ddots & 0 \\ -\lambda_{n-2} & -\lambda_{n-3} & & \ddots & \ddots & \ddots & -s\mu \\ -\lambda_{n-1} & -\lambda_{n-2} & & \cdots & -\lambda_2 & -\lambda_1 & \lambda+s\mu \end{pmatrix}. \tag{7}$$

Notice that if all of the λ_i, $i = 1, \ldots, n-1$ are zeros, then Q_n will be a bidiagonal matrix and can easily be inverted. Therefore in the following, we assume that at least one of the λ_i is nonzero. Then clearly Q_n^t is an irreducibly diagonally dominant matrix. In particular, if the system (6) is solved by classical iterative methods such as the Jacobi or the Gauss-Seidel method, both methods will converge for arbitrary initial guesses; see for instance Varga [27, Thm. 3.4].

We will see in §3.2 that the costs per iteration of the Jacobi and the Gauss-Seidel methods are $O(n \log n)$ and $O(n^2)$, respectively. The memory requirement is $O(n)$ for both methods. We note that the system (6) can also be solved by Gaussian elimination in $O(n^2)$ operations with $O(n^2)$ memory. In the remainder of this section, we are interested in solving (6) by the PCGS method. We will see that the cost per iteration of the method is $O(n \log n)$ and memory requirement is $O(n)$, the same as those of the Jacobi method. However, we are able to show that if s is independent of n, then with our Toeplitz-circulant preconditioner, the PCGS method converges superlinearly for all sufficiently large n. In particular, the method converges in a finite number of steps independent of the queue size n. Therefore the total cost of finding the steady-state probability distribution is $O(n \log n)$ operations.

3.1. Construction of the preconditioner. We observe that in the single server case, i.e., when $s = 1$, the matrix Q_n given in (7) differs from a lower Hessenberg Toeplitz matrix by only its $(1, 1)$ entry. In general, Q_n can be written as

$$Q_n = T_n + R_n, \tag{8}$$

where T_n is the Toeplitz matrix

$$T_n = \begin{pmatrix} \lambda+s\mu & -s\mu & 0 & 0 & 0 & \ldots & 0 \\ -\lambda_1 & \lambda+s\mu & -s\mu & 0 & 0 & \ldots & 0 \\ -\lambda_2 & -\lambda_1 & \lambda+s\mu & \ddots & \ddots & & \vdots \\ \vdots & -\lambda_2 & \ddots & \ddots & -s\mu & \ddots & \\ & \vdots & \ddots & \ddots & \lambda+s\mu & \ddots & 0 \\ -\lambda_{n-2} & & & \ddots & \ddots & \ddots & -s\mu \\ -\lambda_{n-1} & -\lambda_{n-2} & & \ldots & -\lambda_2 & -\lambda_1 & \lambda+s\mu \end{pmatrix} \tag{9}$$

and R_n is a matrix of rank s. From (9), we see that $T_n = \mathcal{T}_n[g]$, where the generating function $g(z)$ of T_n is given by

$$g(z) = -s\mu\frac{1}{z} + \lambda + s\mu - \sum_{k=1}^{\infty} \lambda_k z^k. \tag{10}$$

We note that by (4), $g \in \mathcal{W}$.

Unfortunately, it is also clear from (10) and (4) that $g(z)$ has a zero at $z = 1$ and therefore Lemma 2.1 is not applicable. However, if we look at the real part of $g(z)$ on the unit circle $|z| = 1$, we see that

$$\text{Re}\{g(z)\} = -s\mu\cos\theta + \lambda + s\mu - \sum_{k=1}^{\infty} \lambda_k \cos(k\theta) \geq s\mu - s\mu\cos\theta.$$

Hence the zeros of $g(z)$ can only occur at $z = 1$. In particular, we can write

$$g(z) = (z-1)^{\ell} b(z), \tag{11}$$

where ℓ is the order of the zero of $g(z)$ at $z = 1$ and $b(z)$ will have no zeros on the unit circle. According to the discussion in §2, we define our preconditioner for Q_n as

$$P_n = \mathcal{T}_n[(z-1)^{\ell}]\mathcal{C}_n[b]. \tag{12}$$

Let us consider cases where the quotient function $b(z)$ will be in $\mathcal{W}$. We first note that if the radius of convergence ρ of the power series $\sum_{k=1}^{\infty} \lambda_k z^k$ in (10) is greater than 1, then $g(z)$ and hence $b(z)$ are analytic functions in a neighborhood of $|z| = 1$; see Conway [12, p. 31]. In particular, $h(z)$ will be in $\mathcal{W}$. A formula for computing ρ is given by

$$\frac{1}{\rho} = \limsup |\lambda_j|^{1/j}; \tag{13}$$

see Conway [12, p. 31].

Next we consider the case $\ell = 1$ in more depth. By straightforward division of $g(z)$ in (10) by $(z - 1)$, we have

$$b(z) = s\mu\frac{1}{z} - \lambda - \sum_{k=1}^{\infty}\left(\lambda - \sum_{j=1}^{k} \lambda_j\right) z^k. \tag{14}$$

Therefore, by (3) and (4),

$$b(1) = s\mu - \sum_{k=0}^{\infty}\sum_{j=k+1}^{\infty} \lambda_j = s\mu - \lambda\sum_{k=0}^{\infty} kp_k = s\mu - \lambda E(B), \tag{15}$$

where $E(B)$ is the expected value of the arrival batch size. Thus if $s\mu \neq \lambda E(B)$ then $b(1) \neq 0$ and hence $\ell = 1$. Moreover, if $E(B) < \infty$, then $b \in \mathcal{W}$. Clearly from (14), the first n Laurent coefficients of $b(z)$, i.e., $\sum_{j=1}^{k} \lambda_j - \lambda$, $k = 1, 2, \ldots, n$, can be computed recursively in $O(n)$ operations. Hence by using (1), $\mathcal{C}_n[h]$ and also P_n can be constructed in $O(n)$ operations.

3.2. Convergence analysis and computation cost. In this section, we prove the fast convergence of the PCGS method and discuss its computational cost.

THEOREM 3.1. *Let $b(z)$ defined in (11) be in $\mathcal{W}$ and the number of servers s in the queue be independent of the queue size n. Then the sequence of preconditioned matrices $P_n^{-1}Q_n$ has singular values clustered around* 1 *for large n.*

Proof. By (8) and (12),

$$P_n^{-1}Q_n = \mathcal{C}_n[b]^{-1}\mathcal{T}_n[(z-1)^\ell]^{-1}(\mathcal{T}_n[g] + R_n) = \mathcal{C}_n[b]^{-1}\mathcal{T}_n[(z-1)^\ell]^{-1}\mathcal{T}_n[g] + L_5,$$

where rank $L_5 \le s$. By Theorem 2.2 and the Cauchy interlace theorem (see [28]), we see that $P_n^{-1}Q_n$ has singular values clustered around 1 for sufficiently large n. □

It follows from standard convergence theory of the PCGS method that the method will converge superlinearly and in particular in a finite number of steps independent of n.

In each iteration of the PCGS method, the main computational cost consists of solving a linear system $P_n\mathbf{y} = \mathbf{r}$ and multiplying Q_n to some vector $\mathbf{r}$. We first recall from §2 that the cost of solving $P_n\mathbf{y} = \mathbf{r}$ is of $O(n \log n) + O(\ell n)$ operations. To compute $Q_n\mathbf{r}$, we make use of the partitioning (8). Note that R_n in (8) is a matrix containing only $2s-1$ nonzero entries; we therefore need $O(s)$ operations for computing $R_n\mathbf{r}$. Since T_n is a Toeplitz matrix, $T_n\mathbf{r}$ can be computed in $O(n \log n)$ operations by embedding T_n into a $2n$-by-$2n$ circulant matrix, see Strang [23]. Hence $Q_n\mathbf{r}$ can be obtained in $O(n \log n)$ operations. Thus the number of operations required for each iteration of the PCGS method is of order $O(n \log n)$.

Finally, we consider the memory requirement. We note that in addition to some n-vectors, we have to store only the first column (or eigenvalues) of the matrices T_n, $\mathcal{T}_n[(z-1)^\ell]$ and $\mathcal{C}_n[b]$ but not the whole matrices. Thus we need $O(n)$ memory for the PCGS method.

4. Numerical results. In this section, we test the performance of our Toeplitz-circulant preconditioners P_n for solving Toeplitz systems and the queueing problems discussed in §3. All computations were done by Matlab on an HP 715 workstation.

For the tests on Toeplitz systems, we tried the following generating functions:

$$\text{(i)}\ g_1(z) = \frac{(z^4-1)}{(z-\frac{3}{2})(z-\frac{1}{2})} = \frac{15}{8}\sum_{k=1}^{\infty}\frac{1}{(2z)^k} + \frac{13}{24} + \frac{7}{36}z - \frac{11}{54}z^2 - \frac{65}{24}\sum_{k=3}^{\infty}\left(\frac{2z}{3}\right)^k.$$

$$\text{(ii)}\ g_2(z) = \frac{(z+1)^2(z-1)^2}{(z-\frac{3}{2})(z-\frac{1}{2})} = -\frac{9}{8}\sum_{k=1}^{\infty}\frac{1}{(2z)^k} + \frac{5}{24} + \frac{47}{36}z + \frac{29}{54}z^2 - \frac{25}{24}\sum_{k=3}^{\infty}\left(\frac{2z}{3}\right)^k.$$

$$\text{(iii)}\ g_3(z) = \frac{(z+1)^2(z-1)}{(z-\frac{3}{2})(z-\frac{1}{2})} = \frac{9}{4}\sum_{k=1}^{\infty}\frac{1}{(2z)^k} + \frac{11}{12} - \frac{7}{18}z - \frac{25}{12}\sum_{k=2}^{\infty}\left(\frac{2z}{3}\right)^k.$$

Clearly the functions $g_i, i = 1, 2, 3$, all have zeros on $|z| = 1$. We note that the preconditioners proposed in Chan [6] and Chan and Tang [9] are not applicable here because g_i are complex-valued functions on $|z| = 1$.

We note that the Toeplitz matrices formed by g_i's are nonsymmetric, therefore the systems $\mathcal{T}_n[g_i]\mathbf{x} = \mathbf{b}$ are solved by the PCGS method; see Sonneveld [22]. The stopping criterion we used is

$$(16) \qquad \frac{||\mathbf{r}_k||_2}{||\mathbf{r}_0||_2} < 10^{-6},$$

where $\mathbf{r}_k$ is the residual at the kth iteration. The right-hand side vector is $(1, 1, \dots, 1)^t$ and the initial guess is the zero vector. Table 1 gives the numbers of iterations required for convergence by using preconditioners I, P_n, and $\mathcal{C}_n[g]$. The symbol ** there denotes that the method does not converge in 5000 iterations. We see that the circulant preconditioner does not work well when the generating function has zeros on $|z| = 1$ and that the number of iterations required for convergence actually grows with n. However, our preconditioner P_n gives very fast convergence in all cases and the rate is actually improving with increasing n.

Next we test our preconditioner for queueing networks mentioned in §3. Since Q_n in (7) is irreducibly diagonally dominant, both the Jacobi and Gauss-Seidel methods converge

TABLE 1

when applied to solving the system (6). However, by using the partitioning of Q_n as in (8) and taking advantage of the Toeplitz matrix-vector multiplication (see §3.2), we see that each iteration of the Jacobi method can be done in $O(n \log n)$ operations, the same count as that of the PCGS method. This special property is not shared by the Gauss-Seidel method, which will still require $O(n^2)$ operations per iteration. Thus in our comparisons, we used only the Jacobi method.

We tried two sets of queueing parameters:

(i) $\lambda_j = \frac{1}{2^j}$, $j = 1, 2, \ldots$, and

(ii) $\lambda_j = \frac{90}{(\pi j)^4}$, $j = 1, 2, \ldots$.

We note that, in both cases, $\lambda = \sum_{k=1}^{\infty} \lambda_k = 1$. The service rate μ is set to $\mu = \lambda/s$. By (15), we see that $b(1) \neq 0$ and hence $\ell = 1$. Clearly, in both cases the mean arrival batch size $E(B)$ is finite because $\sum_j j\lambda_j < \infty$. Therefore, $b(z) \in \mathcal{W}$ and is given by (14). We remark that by using (13), the radius of convergence ρ for the first set of queueing parameters is 2. Hence regardless of the values of μ, its $b(z)$ will always be in $\mathcal{W}$.

The initial guess for both methods is $(1, 1, \ldots, 1)/n$. The stopping criteria for the PCGS method is again given by (16), whereas for the Jacobi method, it is $||\mathbf{x}_k - \mathbf{x}_{k-1}||_2 < 10^{-6}$, where $\mathbf{x}_k$ is the solution obtained at the kth iteration. Tables 2-3 give the numbers of iterations required for convergence for $s = 1, 4$ and $n - 1$. The symbol J means the Jacobi method is used. Again $**$ signifies that the method does not converge in 5000 iterations. In Table 4 the symbol "kflop" means 1000 floating point operations. Note that the case $s = n - 1$ is not covered by our Theorem 3.1. However, we note that in all the cases we tested, our preconditioner P_n is clearly the best choice.

5. Concluding remarks. We note that although we concentrate on the T. Chan circulant preconditioners here, the convergence results in Theorems 2.2 and 3.1 can easily be extended to include other circulant preconditioners. For instance, results for Strang's circulant preconditioners can be obtained if we replace Lemma 2.1 by theorems in [24]. In particular, using

Theorem 6 from [24], we can show that if the quotient function $h(z)$ is a rational function of type (μ, ν), then our method converges in at most $(1 + 2\max\{\mu, \nu\} + \ell)$ steps for large n.

GREENGARD'S N-BODY ALGORITHM IS NOT ORDER N*

SRINIVAS ALURU†

Abstract. Greengard's N-body algorithm claims to compute the pairwise interactions in a system of N particles in $O(N)$ time for a fixed precision. In this paper, we show that the choice of precision is not independent of N and has a lower bound of $\log N$. We use this result to show that Greengard's algorithm is not $O(N)$.

Key words. Greengard's algorithm, N-body problem, particle simulation, tree algorithms for particle simulation

AMS subject classifications. 70-08, 70F15

1. Introduction.

The N-body problem constitutes simulating the motion of N particles under the influence of mutual gravitational interactions. Since the problem cannot be solved in closed form, a discrete approximation has to be used. The force on every particle due to the rest of the system is computed and this information is used to update the system over a small interval of time δt. This constitutes one iteration in the solution of an N-body problem. A straightforward computation of the interactions takes $O(N^2)$ time per iteration, which is prohibitive since physicists want to simulate the motion of large collections of particles over long time scales. A number of algorithms have been designed to reduce the time complexity per iteration. The main principle behind these algorithms is approximating the force between two collections of particles that are far apart, without having to compute every pairwise interaction. With the notable exception of Greengard [2], most researchers paid little attention to a rigorous worst-case analysis of the complexity of their algorithms. Greengard's algorithm remains the only algorithm so far with a proven worst-case complexity of $O(N)$.

We limit the discussion to the two-dimensional version of Greengard's algorithm for convenience and simplicity. The first step in Greengard's algorithm is creating a hierarchical subdivision of the space containing the particles constructed as follows: let D be the length of a square box enclosing all the particles. (Greengard assumes the box has length 1, which can easily be achieved by a change of units.) The box is subdivided into four boxes with a side length half of the original box. Boxes that do not contain any particles are discarded. Boxes containing a single particle (or k particles for some fixed $k > 0$) are left as they are. The rest of the boxes are recursively subdivided. This recursive subdivision is naturally represented by a tree. The tree has N leaves and at most four children per node.

Let s be the smallest interparticle distance. (The terminology used here is different from Greengard's.) Each subdivision of a box reduces the box length by half. To separate two particles that are s apart, we may need a box of length less than $\frac{s}{\sqrt{2}}$. The worst-case number of subdivisions required to separate two particles s apart in two dimensions is given by the smallest k for which $\frac{D}{2^k} < \frac{s}{\sqrt{2}}$. Consequently, the height of the tree is bounded by $O(\log \frac{D}{s})$ and the total number of nodes in the tree is bounded by $O(N \log \frac{D}{s})$. In three dimensions, the worst-case

number of subdivisions required is the smallest k for which $\frac{D}{2^k} < \frac{s}{\sqrt{3}}$. Therefore, the bounds on the height of the tree and the number of nodes is the same as in the case of two dimensions.

Greengard's arguments can be summarized as follows: for a fixed machine precision, only certain classes of particle distributions can be modeled, independent of the algorithm used. Therefore, by restricting attention to only those particle distributions that can be modeled on a given machine, D can be bound by the largest floating point number representable on the machine and s has to be no less than the smallest floating point number representable. Thus, $\log \frac{D}{s}$ is bounded by the log of the ratio of the largest to the smallest floating point number representable, a constant termed p. The size of the tree is bounded by $O(pN)$. Greengard determines the running time of his algorithm to be $N(\alpha p^2 + \beta p + \gamma)$ in two dimensions and $N(\alpha p^4 + \beta p^2 + \gamma)$ in three dimensions, where α, β, and γ are constants. Since p is taken to be a constant, the algorithm is claimed to run in $O(N)$ time in two or three dimensions.

The above arguments imply that the height of the tree is bounded by $O(p)$, a constant. Yet we know that the height of a tree with N leaves and at most a constant number of children per node is $\Omega(\log N)$. How can this disparity be explained?

To further highlight the discrepancy, consider the first step in Greengard's algorithm—the construction of the tree representing the hierarchical subdivision. At every level of the tree, the nodes containing more than one particle (or more than a fixed number of particles) are subdivided and particles in each parent box are distributed among its child boxes. Since each particle is assigned to a box at every level and there are at most p levels, the work involved is proportional to Np. Since p is taken to be a constant, the complexity is computed to be $O(N)$.

Consider running this algorithm on a distribution such that each child box contains exactly a fourth of the particles of the parent box. The resulting tree is a quadtree with $\log N$ levels and the work involved in constructing the tree is easily seen to be $O(N \log N)$, not $O(N)$.

The problem lies in the assumption that the parameters D and s are entirely dependent on the spatial distribution of the particles and not related to the number of particles N. To understand why this assumption is invalid, consider the behavior of $\frac{D}{s}$ for a fixed N. In particular, we shall investigate the upper and lower bounds for $\frac{D}{s}$ as a function of N.

For any $N \geq 3$ particles, $\frac{D}{s}$ can be made arbitrarily large by reducing the distance between the closest particles (thus reducing s) or by increasing the spread of the particles (thus increasing D). This validates the argument that for a fixed machine precision, only certain classes of particle distributions can be modeled, independent of the algorithm used.

To minimize the ratio $\frac{D}{s}$ for a fixed N, all the particles should be at a distance of s from their nearest neighbors. To see why, suppose this is not true. We can reduce D by "moving in" particles that are farther than s from each other, while keeping s the same. Or else, we can increase s by increasing the distance between particles that are s apart, while keeping D unchanged. In either case, $\frac{D}{s}$ decreases contradicting minimality. Furthermore, the particles must be packed as closely as possible. Figure 1 shows the configuration minimizing the ratio $\frac{D}{s}$ for a fixed N in two dimensions. Each particle has six nearest neighbors in the close packing, all at a distance of s from it. The particle is at the center of the hexagon formed by its nearest neighbors. The particles fit exactly in a cell of size $D \times D$ (i.e., boundaries of the cell are inhabited by particles). Adding the particles columnwise,

$$N = \left\lfloor \frac{D}{s} + 1 \right\rfloor + \left\lfloor \frac{D}{s} \right\rfloor + \left\lfloor \frac{D}{s} + 1 \right\rfloor + \cdots \quad \left(\left\lfloor \frac{2D}{\sqrt{3}s} + 1 \right\rfloor \text{terms} \right),$$

$$N \leq \frac{D}{s}\left[\frac{2D}{\sqrt{3}s} + 1\right] + \frac{D}{\sqrt{3}s} + 1,$$

$$N \leq \frac{2}{\sqrt{3}}\frac{D^2}{s^2} + \left(1 + \frac{1}{\sqrt{3}}\right)\frac{D}{s} + 1,$$

$$\frac{D}{s} \geq c_1 N^{\frac{1}{2}}$$

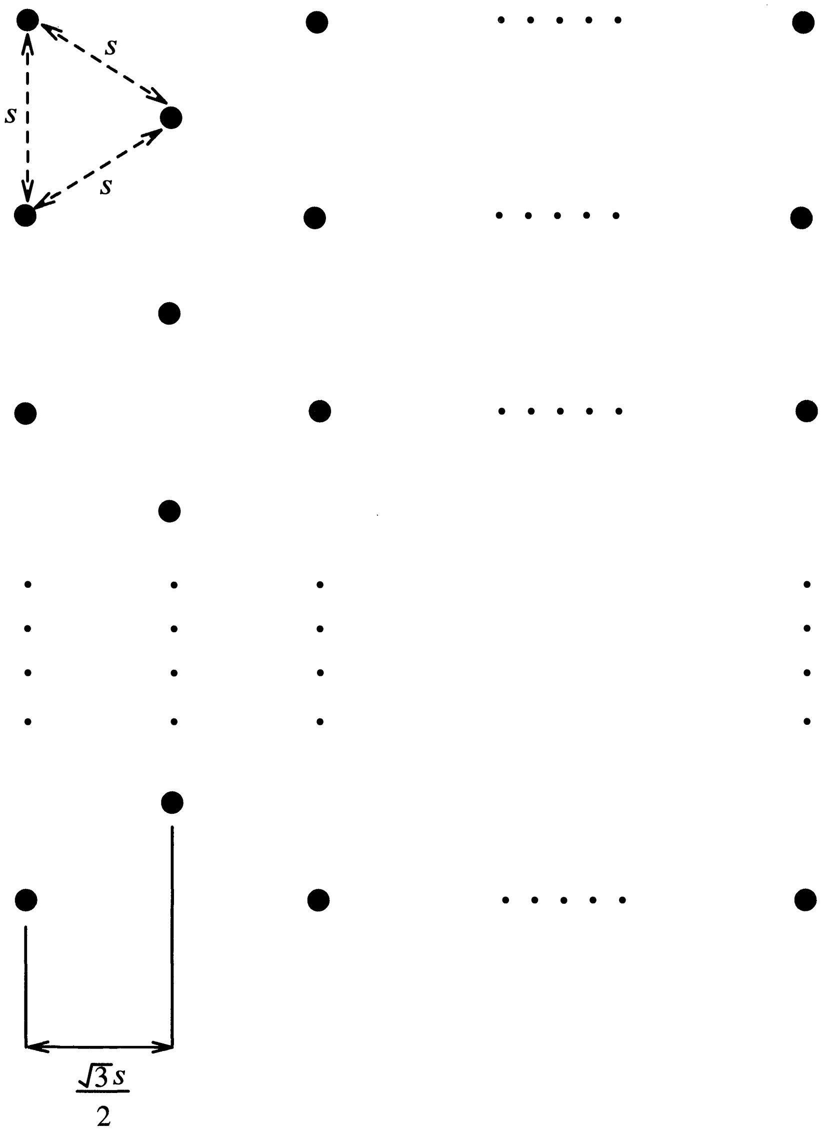

FIG. 1. *The configuration minimizing the ratio of the cell length D containing all the particles and the smallest interparticle distance s in two dimensions. The ratio $\frac{D}{s}$ is minimized when all particles are a distance s apart from their nearest neighbors and the particles are packed as closely as possible.*

for some constant c_1. Since this is computed using the configuration minimizing $\frac{D}{s}$, $\log \frac{D}{s}$ is $\Omega(\log N)$. Since $\log \frac{D}{s}$ is bounded by p, p is also $\Omega(\log N)$. In three dimensions, it can be shown that

$$\frac{D}{s} \geq c_2 N^{\frac{1}{3}}.$$

In this case also, $\log \frac{D}{s}$ is $\Omega(\log N)$ and p is $\Omega(\log N)$.

How does this translate to what classes of particle distributions can be modeled on a machine with precision parameter p? It is already noted that not all distributions can be modeled for any given $N \geq 3$ because of precision limits. However, unless $p \geq c \log N$ (c is a constant), no distribution can be modeled for that N. The very fact that we are able to run an N-body problem for a collection of N particles with precision parameter p implies that $p \geq c \log N$. Thus, p cannot be taken as a constant in the analysis of the running time of the algorithm, and Greengard's algorithm is not $O(N)$. Greengard's time complexity in two dimensions is $N(\alpha p^2 + \beta p + \gamma)$, which is $\Omega(N \log^2 N)$. In three dimensions, the complexity is $N(\alpha p^4 + \beta p^2 + \gamma)$, which is $\Omega(N \log^4 N)$. The running time matches the lower bound only for a uniform distribution. For arbitrary distributions, the running time is unbounded.

Acknowledgments. I wish to thank John Gustafson and G. M. Prabhu for discussion and helpful comments.

ON THE REMOVAL OF BOUNDARY ERRORS CAUSED BY RUNGE-KUTTA INTEGRATION OF NONLINEAR PARTIAL DIFFERENTIAL EQUATIONS*

SAUL ABARBANEL[†], DAVID GOTTLIEB[‡], AND MARK H. CARPENTER[§]

Abstract. The temporal integration of hyperbolic partial differential equations (PDEs) has been shown to lead sometimes to the deterioration of accuracy of the solution because of boundary conditions. A procedure for removal of this error in the linear case has been established previously.

In this paper we consider hyperbolic PDEs (linear and nonlinear) whose boundary treatment is accomplished via the simultaneous approximation term (SAT) procedure. A methodology is presented for recovery of the full order of accuracy and has been applied to the case of a fourth-order explicit finite-difference scheme.

Key words. Runge-Kutta scheme, temporal accuracy, time-dependent boundary conditions

AMS subject classifications. 65L06, 65M15, 65M20

1. Introduction. A growing interest is evident in long-time integration for solving problems in areas such as aeroacoustics, electromagnetics, and material science. The use of long-time integration [1] necessitates working with higher-order (fourth-order accuracy and above) schemes. Often the methodology of choice is to semidiscretize the equations by applying a high-order (fourth-order and above) spatial difference operator and then advancing temporally with single-level multistage Runge-Kutta (RK) integrators. The question arises of how to supply boundary values at the intermediate stages of the RK integrations. For hyperbolic PDEs, time-dependent conditions must be imposed at the inflow boundary.

The conventional (and intuitive) method of imposing inflow boundary conditions (BCs) at the intermediate stages is to use the "appropriate" value of the boundary data $g(t)$ at each stage. Thus, for example, at a stage that corresponds to $t + \frac{\Delta t}{2}$ one would impose $g(t + \frac{\Delta t}{2})$.

In a previous paper [2], when applied to hyperbolic PDEs with time-dependent BCs, the procedure described above was shown to reduce the accuracy near the inflow boundary to first order; thus, the overall accuracy could not exceed $O(\Delta x)^2$. This conclusion was independent of the order of accuracy of the spatial difference operator.

One way to avoid the dilemma of determining which boundary values to supply at the intermediate stages is to advance the RK integration without imposing any intermediate values and obtain the intermediate boundary values from the numerical solution operator. However, this approach reduces substantially the stability limit (e.g., the allowable time step is reduced

by a factor of 2 in the case of a fourth-order classic RK scheme with a fourth-order spatial derivative operator); hence, this method is not desirable.

In [2], a general methodology was presented in the case of linear PDEs for the correct imposition of the intermediate-stage boundary values to enable the scheme to recover its full formal accuracy. This method was expounded in detail for the case of the classic fourth-order RK integration with a hyperbolic fourth-order spatial difference operator. In [2] it was shown that in the nonlinear case (e.g., hyperbolic conservation laws) this methodology was applicable to RK integration up to third order. For RK methods of fourth order and above, we were unable to extend the theoretical approach described in [2].

In this paper, we address anew the issue of dealing with the nonlinear case. We present a methodology for retaining the full accuracy even in the nonlinear case. The application of this methodology involves numerical determination of free parameters in contradistinction to the linear procedure described in [2]. We find, for example, that for the fourth-order classic RK integrator with fourth-order explicit spatial derivative operator, the full accuracy is retained without any reduction in the allowable time step.

The new procedure is demonstrated for hyperbolic problems in which the BCs are satisfied with the SAT approach [4]. We consider the SAT procedure because it is the only one that prevents temporal growth not present in the true solution of a system of PDEs. Section 2 describes how to correctly apply the intermediate SAT BCs in the case of a linear problem. In §3 we address the nonlinear case.

2. The linear case. In this section we analyze the effect of imposing inflow boundary conditions by conventional methods for cases in which the discretization algorithm employs the SAT approach. (See [3].) The SAT is a penalty type of method that was constructed to ensure that the numerical solution does not include temporal growth that is not of a physical origin. This construction is achieved by mimicking the energy estimate of the PDE.

We consider the following hyperbolic problem [3]:

$$\frac{\partial u}{\partial t} + \frac{\partial u}{\partial x} = 0, \quad 0 \leq x \leq t, \quad t \geq 0, \tag{2.1}$$

$$u(0,t) = g(t). \tag{2.2}$$

The SAT formulation for the semidiscrete version of (2.1) and (2.2), based on a uniform grid, is

$$\frac{dv_i(t)}{dt} = \left[\frac{1}{h} D \vec{V}(t)\right]_i - \frac{1}{h}\tau \vec{\sigma}\, [v_0(t) - g(t)], \quad i = 0, 1, \ldots, N, \quad t \geq 0, \tag{2.3}$$

where $\vec{V} = [v_0, v_1, \ldots, v_N]^T$ is the semidiscrete approximation that converges to $u(x_i, t)$ at the spatial grid points x_i (for stable discretizations) and $\frac{1}{h}D$ is the differential matrix representation of the derivative operator $-\frac{\partial}{\partial x}$. The vector $\vec{\tau\sigma}$ depends on the differentiation matrix $\frac{1}{h}D$, and on the energy norm used in bounding the error. This vector is determined as described in [3]; see the discussion after (6).

The demonstration of accuracy deterioration will be shown for the four-stage "classic" RK algorithm, which is one of the most commonly used RK time-advancement schemes. So that the analysis makes sense, we assume that the spatial discretization is at least fourth-order accurate.

The above-mentioned four-stage RK integrator is implemented as follows ($\lambda = \frac{\Delta t}{\Delta x}$):

$$V^{(1)} = V^{(n)} + \frac{\lambda}{2} D V^{(n)} - \frac{\lambda}{2}\tau \vec{\sigma}\, [v_0^{(n)} - g(t)], \tag{2.4}$$

$$V^{(2)} = V^{(n)} + \frac{\lambda}{2} D V^{(1)} - \frac{\lambda}{2} \tau \vec{\sigma} \left[v_0^{(1)} - g\left(t + \frac{\Delta t}{2}\right)\right], \tag{2.5}$$

$$V^{(3)} = V^{(n)} + \lambda D V^{(2)} - \lambda \tau \vec{\sigma} \left[v_0^{(2)} - g\left(t + \frac{\Delta t}{2}\right)\right], \tag{2.6}$$

$$\begin{aligned} V^{(n+1)} &= V^{(n)} + \frac{\lambda}{6} D [V^{(n)} + 2V^{(1)} + 2V^{(2)} + V^{(3)}] \\ &\quad - \frac{\lambda}{6} \tau \vec{\sigma} \left\{ [v_0^{(n)} - g(t)] + 2\left[v_0^{(1)} - g\left(t + \frac{\Delta t}{2}\right)\right] + 2\left[v_0^{(2)} - g\left(t + \frac{\Delta t}{2}\right)\right] \right. \\ &\quad \left. + [v_0^{(3)} - g(t + \Delta t)] \right\}. \end{aligned} \tag{2.7}$$

To check for accuracy we substitute for $V^{(n)}$ the exact values $u(x_i, t)$ and, in particular, $v_0^{(n)} = g(t)$. From (2.4), one can see that on the boundary (using the differential equations (2.1) and (2.2)), we have

$$v_0^{(1)} = v_0^{(n)} - \frac{\Delta t}{2} \left(\frac{\partial}{\partial x} u \right)_0 = g(t) + \frac{\Delta t}{2} g'(t). \tag{2.8}$$

Thus, in (2.7) we have, for the term $v_0^{(1)} - g\left(t + \frac{\Delta t}{2}\right)$,

$$v_0^{(1)} - g\left(t + \frac{\Delta t}{2}\right) = \left[g(t) + \frac{\Delta t}{2} g'(t) \right] - g\left(t + \frac{\Delta t}{2}\right) = 0(\Delta t)^2. \tag{2.9}$$

Thus, $V^{(n+1)} - V^{(n)}$ is at best $O(\Delta t)^2$, rather than $O(\Delta t)^5$, which was expected from the RK scheme used.

In this linear case, the remedy proposed in the previous paper [2] works here as well. In particular, (2.4) - (2.7) take the following form:

$$V^{(1)} = V^{(n)} + \frac{\lambda}{2} D V^{(n)} - \frac{\lambda}{2} \tau \vec{\sigma} \, [v_0^{(n)}(t) - g(t)], \tag{2.10}$$

$$V^{(2)} = V^{(n)} + \frac{\lambda}{2} D V^{(1)} - \frac{\lambda}{2} \tau \vec{\sigma} \left[v_0^{(1)} - g(t) - \frac{\Delta t}{2} g'(t) \right], \tag{2.11}$$

$$V^{(3)} = V^{(n)} + \lambda D V^{(2)} - \lambda \tau \vec{\sigma} \left[v_0^{(2)} - g(t) - \frac{\Delta t}{2} g'(t) - \frac{\Delta t^2}{4} g''(t) \right], \tag{2.12}$$

$$\begin{aligned} V^{n+1} &= V^n + \frac{\lambda}{6} D \left[V^{(n)} + 2V^{(1)} + 2V^{(2)} + V^{(3)} \right] \\ &\quad - \frac{\lambda}{6} \tau \vec{\sigma} \left\{ [v_0^{(n)} - g(t)] + 2\left[v_0^{(1)} - g(t) - \frac{\Delta t}{2} g'(t) \right] \right. \\ &\quad + 2\left[v_0^{(2)} - g(t) - \frac{\Delta t}{2} g'(t) - \frac{\Delta t^2}{4} g''(t) \right] \\ &\quad \left. + \left[v_0^{(3)} - g(t) - \Delta t g' - \frac{\Delta t^2}{2} g'' - \frac{\Delta t^3}{4} g''' \right] \right\}. \end{aligned} \tag{2.13}$$

We can readily verify that $V^{(n+1)} - V^{(n)} = 0(\Delta t)^5$, as required.

3. The nonlinear case. For simplicity, first we consider the scalar conservation law PDE:

$$\frac{\partial u}{\partial t} + \frac{\partial f(u)}{\partial x} = 0, \qquad 0 \le x \le 1, \quad t \ge 0, \tag{3.1}$$

$$u(0, t) = g(t). \tag{3.2}$$

In general, for any spatial discretization (whether explicit or implicit), the semidiscrete form of (3.1) and (3.2) is

$$\frac{dV}{dt} = \frac{1}{h} Df(V) - \frac{1}{h}\tau \vec{\sigma} \, [v_0 - g(t)]. \tag{3.3}$$

Using the notation of [3],

$$D = -P^{-1}Q, \tag{3.4}$$

where $\frac{1}{h}D$ is the differentiation matrix that represents the differential operator $(-\frac{\partial}{\partial x})$; this matrix is composed of the explicit part Q and the inverse of the implicit part P. For a fully explicit spatial differentiation, $P = I + B$, where B differs from zero only at the two diagonal corners. (See examples of P and Q in [4].)

The vector $\vec{\sigma}$, again with the notation in [4], is given by

$$\vec{\sigma} = ha(u_0) g_{00} P^{-1} H^{-1} S,$$

where $a(u_0) = (\frac{\partial f}{\partial u})_{x=0}$ and g_{00} is twice the value of the left upper corner element of HQ. For the definition of the matrix H, see assumption I in [1]. The parameter τ is determined from the stability consideration to be $\tau \ge 1$. (See [3].)

Next, we demonstrate that writing the classic fourth-order RK integration for (3.3), using the linear "fix" as in (2.10) - (2.13), does not yield the required fourth-order accuracy:

$$V^{(1)} = V^{(n)} + \frac{\lambda}{2} Df(V^{(n)}) - \frac{\lambda}{2}\tau \vec{\sigma} \, [v_0^{(n)} - g(t)], \tag{3.5}$$

$$V^{(2)} = V^{(n)} + \frac{\lambda}{2} Df(V^{(1)}) - \frac{\lambda}{2}\tau \vec{\sigma} \left[v_0^{(1)} - g(t) - \frac{\Delta t}{2} g'(t) \right], \tag{3.6}$$

$$V^{(3)} = V^{(n)} + \lambda Df(V^{(2)}) - \lambda\tau \vec{\sigma} \left[v_0^{(2)} - g(t) - \frac{\Delta t}{2} g'(t) - \frac{\Delta t^2}{4} g''(t) \right], \tag{3.7}$$

$$\begin{aligned} V^{(n+1)} = {} & V^{(n)} + \frac{\lambda}{6} D[f(V^n) + 2f(V^{(1)}) + 2f(V^{(2)}) + f(V^{(3)})] \\ & -\frac{\lambda}{6}\tau \vec{\sigma} \left\{ [v_0^{(n)} - g(t)] + 2\left[v_0^{(1)} - g(t) - \frac{\Delta t}{2} g'(t) \right] \right. \\ & +2\left[v_0^{(2)} - g(t) - \frac{\Delta t}{2} g'(t) - \frac{\Delta t^2}{4} g''(t) \right] \\ & \left. + \left[v_0^{(3)} - g(t) - \Delta t g' - \frac{\Delta t^2}{2} g'' - \frac{\Delta t^3}{4} g''' \right] \right\}. \end{aligned} \tag{3.8}$$

Again, in checking the accuracy, we take $V^{(n)} = u(x_i, t)$ and, in particular, $v_0^{(n)} = g(t)$; furthermore, $\frac{1}{h}Df(V^n) = -\frac{\partial}{\partial x} f(u) + O(\Delta t)^4$. With these preliminary calculations, we immediately obtain the following from (3.5):

$$v_0^{(1)} = v_0^n - \frac{\Delta t}{2}\frac{\partial}{\partial x} f(\mu)_0 = g(t) + \frac{\Delta t}{2}\frac{\partial}{\partial t}(u)_0 = g(t) + \frac{\Delta t}{2} g'(t). \tag{3.9}$$

Note that this result is the same for the linear case. (See (2.8).) Thus, with $v_0^{(n)} = g(t)$ and (3.9), we can supply, for the purpose of checking accuracy, the correct values of $v^{(n)}$ and $v_0^{(1)}$. When we examine (3.6) using the above results, the governing nonlinear PDE, and a simple Taylors expansion, we have

$$\begin{aligned}
V^{(2)} &= V^{(n)} + \frac{\lambda}{2} Df\left[V^{(n)} + \frac{\lambda}{2} Df(V^n)\right] \\
&= V^{(n)} - \frac{\Delta t}{2}\frac{\partial}{\partial x} f\left[u - \frac{\Delta t}{2}\frac{\partial}{\partial x} f(u) + O(\Delta t)^5\right] \\
&= V^n - \frac{\Delta t}{2}\frac{\partial}{\partial x} f\left[u + \frac{\Delta t}{2}\frac{\partial u}{\partial t} + O(\Delta t)^5\right] \\
&= V^{(n)} - \frac{\Delta t}{2}\frac{\partial}{\partial x}\left\{f(u) + \frac{\Delta t}{2}\frac{\partial f}{\partial u}\frac{\partial u}{\partial t} + \frac{\Delta t^2}{8}\left(\frac{\partial^2 f}{\partial u^2}\right)\left(\frac{\partial u}{\partial t}\right)^2 + O(\Delta t)^3\right\} \\
&= V^{(n)} - \frac{\Delta t}{2}\left\{\frac{\partial f}{\partial x} + \frac{\Delta t}{2}\frac{\partial}{\partial t}\left(\frac{\partial f}{\partial x}\right)\right\} + O(\Delta t)^3 \\
&= u - \frac{\Delta t}{2}\left[-u_t - \frac{\Delta t}{2} u_{tt}\right] + O(\Delta t)^3. \qquad (3.10)
\end{aligned}$$

Finally, on the boundary we have

$$v_0^{(2)} = g(t) + \frac{\Delta t}{2} g'(t) + \frac{\Delta t^2}{4} g''(t) + 0(\Delta t)^3. \qquad (3.11)$$

From (3.11) we see that the "penalty" term in (3.8) introduces an error of $(\Delta t)^3$. Because the coefficient of $(\Delta t)^3$, $[f_{uu}(u_t)^2]_0$, cannot generally be expressed as a function of $g(t)$ and its derivatives, this situation is difficult to remedy. Thus, the "linear procedure" fails at the third RK stage.

We now propose a methodology for dealing with the RK integration of nonlinear hyperbolic conservation laws. We first present this procedure in the case of the classic fourth-order RK scheme. Our starting point is the observation that the "linear procedure" yields the required accuracy for $v_0^{(n)}$ and $v_0^{(1)}$. At each stage, the idea is to use a linear combination of the "linear" SAT or penalty terms used in (3.5) and (3.6). Thus, the fourth-order classic RK stages will be

$$V^{(1)} = V^{(n)} + \frac{\lambda}{2} Df(V^n) - \frac{\lambda}{2}\alpha\, \vec{\sigma}\, [v_0^{(n)} - g(t)], \qquad (3.12)$$

$$V^{(2)} = V^{(n)} + \frac{\lambda}{2} Df(V^{(1)}) - \frac{\lambda}{2}\beta\, \vec{\sigma}\left[v_0^{(1)} - g(t) - \frac{\Delta t}{2} g'(t)\right] - \frac{\lambda}{2}\gamma\, \vec{\sigma}\, [v_0^{(n)} - g(t)], \qquad (3.13)$$

$$V^{(3)} = V^{(n)} + \lambda Df(V^{(2)}) - \lambda\delta\, \vec{\sigma}\, [v_0^{(n)} - g(t)] - \lambda\varepsilon\, \vec{\sigma}\left[v_0^{(1)} - g(t) - \frac{\Delta t}{2} g'(t)\right], \qquad (3.14)$$

$$\begin{aligned}
V^{(n+1)} &= V^{(n)} + \frac{\lambda}{6} D[f(V^n) + 2f(V^{(1)}) + 2f(V^{(2)}) + f(V^{(3)})] \\
&\quad - \frac{\lambda}{6}\mu\, \vec{\sigma}\, [v_0^{(n)} - g(t)] - \frac{\lambda}{3}\nu\, \vec{\sigma}\left[v_0^{(1)} - g(t) - \frac{\Delta t}{2} g'(t)\right], \qquad (3.15)
\end{aligned}$$

where the free parameters α, β, γ, δ, ε, μ, and ν will be chosen to maximize the allowable time step. The previous discussion clearly shows that the system ((3.12) - (3.15)) maintains the fourth-order accuracy. The question remains of whether the CFL stability condition deteriorates in comparison with the conventional application of the RK integration. Also, optimal choice of the free parameters $\alpha, \ldots, \nu$ clearly varies with the spatial discretizations (i.e., the differentiation matrix D) and boundary closures. The absolute values of the eigenvalues of the amplification matrix that result from (3.12) - (3.15) should not exceed unity. We carried out this procedure (with Mathematica software) in the case of an explicit fourth-order algorithm with third-order boundary closure (in V). In this case, $H = I$, and the matrices P and Q can be found in §9.1 of [4]. The CFL condition becomes $\lambda \leq 2.1$ with the following values of the free parameters: $\alpha = \beta = -\varepsilon = 1, \delta = 2, \mu = 0, \nu = 3$, and $\gamma = -0.37$. This restriction on the time step Δt is the same as that for the linear problem with "conventional" (i.e., less accurate) boundary values with or without the SAT term.

4. Conclusions. In summary, we have a fourth-order RK scheme in (3.12) - (3.15) applied to a nonlinear PDE that maintains overall fourth-order accuracy without a decrease in the allowable time step. The extension to a system of hyperbolic PDEs is quite straightforward with the use of the SAT approach delineated in [3].

COMPARISONS OF LATTICE BOLTZMANN AND FINITE DIFFERENCE METHODS FOR A TWO-DIMENSIONAL VISCOUS BURGERS EQUATION*

BRACY H. ELTON[†]

Abstract. Lattice Boltzmann methods have been proposed as a computational means for solving various partial differential equations. We look at three lattice Boltzmann methods and an analogous finite difference method for solving a two-dimensional scalar, viscous Burgers equation with periodic boundary conditions. First, using monotonicity arguments we prove that in the ℓ_1 norm the lattice Boltzmann methods converge first-order temporally and second-order spatially. Then we provide some computational results which substantiate the theoretical results. Finally, we compare the lattice Boltzmann and finite difference methods. The basis of comparison includes numerical results with regard to accuracy, order of convergence, performance, and timing measurements; memory requirements; and conservations laws.

Key words. consistency, convection–diffusion, convergence, explicit, finite difference, Hilbert expansion, lattice Boltzmann, monotone, nonlinear, parallel, periodic, stability, viscous Burgers equation

1. Introduction.

Lattice gas and lattice Boltzmann methods have been proposed as computational means, efficient on parallel and vector architectures, for solving a variety of partial differential equations [3]. We will look at three lattice Boltzmann methods for solving the two-dimensional (2-D) nonlinear convection–diffusion equation

$$(1) \qquad \frac{\partial}{\partial t}\rho + \rho\frac{\partial}{\partial x}\rho = \nu\left(\frac{\partial^2}{\partial x^2}\rho + \frac{\partial^2}{\partial y^2}\rho\right),$$

which is a two-dimensional scalar, viscous Burgers equation, for $\rho = \rho(t, \mathrm{x})$, $\mathrm{x} = (x, y) \in [0, L]^2$, diffusion coefficient ν, initial condition $\rho(0, \mathrm{x}) = \rho_I(\mathrm{x})$, and periodic boundary conditions. We introduce the methods and establish theoretically their convergence, verify computationally the theoretical results, and compare the lattice Boltzmann methods and an analogous finite difference method.

The underlying purpose of this paper is to present a fairly thorough analysis of some simple lattice Boltzmann methods and some computational techniques that can be used to study more complex methods in the absence of strong theoretical results. It is hoped that those investigating more complex lattice Boltzmann and lattice gas methods, for example, ones for the Navier–Stokes equations and those with more complex boundary conditions, can and will employ some of the techniques described herein to evaluate (at least numerically) their models and methods.

The paper is outlined as follows. Section 2 introduces the lattice Boltzmann methods and establishes the theory of their convergence. Under certain conditions we show that in the ℓ_1 norm the methods are spatially second-order, temporally first-order, conservative, monotone difference methods for computing solutions to (1). The theoretical results are obtained by applying the key results of [7]. Section 3 contains detailed numerical studies and comparisons of the lattice Boltzmann methods with each other and with an analogous finite difference method. The numerical studies include such aspects as domains of monotonicity, accuracy, order of convergence, performance and timing measurements, and memory requirements; also included are conservation laws and collision rules and their effect on accuracy. The numerical studies also substantiate the theoretical results. The performance and timing measurements

were taken on Fujitsu VPX240 and VPP500 systems. Finally, concluding remarks are made in §4.

2. Theory. We will be discussing three lattice Boltzmann methods, enumerated LB1, LB2, and LB3, for computing solutions to (1) with periodic boundaries. LB1 and LB2 are introduced here; LB3 was introduced in earlier work [4, 5].

Although our lattice Boltzmann methods could be motivated by analogous lattice gas methods, we describe them directly. In our analysis, we will be applying (and borrowing) much of the notation, properties, and theorems of [7], in which key theorems and properties of convective–diffusive lattice Boltzmann methods appear. Note that for purposes of increasing readability, specific details of the sometimes rather involved analyses have been deferred to the appendices.

2.1. The lattice Boltzmann methods. The following are the essential elements of our 2-D lattice Boltzmann methods, each of which abides by an exclusion principle that restricts the number of particles per velocity per node.[1]

1. A 2-D doubly periodic (toroidal) regular lattice, $\mathbf{X} = [0, L]^2$, where L is the spatial scale length (Figure 1).
2. The set of unit velocity vectors $\mathbf{V}=\{\mathrm{v}_k \mid k \in \{0,1,2,3\}\} \subset \mathbf{R}^2$, where
$$\mathrm{v}_0 = (+1, 0)\,, \quad \mathrm{v}_1 = (0, +1)\,, \quad \mathrm{v}_2 = (-1, 0)\,, \quad \mathrm{v}_3 = (0, -1)\,.$$
3. $|\mathbf{V}| = 4$ links per node, each link having length Δx, where $|\mathbf{V}|$ is the cardinality of $\mathbf{V}$.
4. Mean occupation numbers: for each time step, lattice node, and velocity, there is an associated mean occupation number, $F \in [0, 1]^{\mathbf{V}} \equiv \mathcal{I}$.[2] The mean occupation number can be viewed as a normalized particle distribution, i.e., the likelihood of the presence of a particle, as in the Boltzmann equation, e.g., [1].
5. An advection operator, $\mathcal{A}$, that advances particle distributions to neighboring nodes and discrete time steps of duration $\Delta t > 0$, where $\Delta t = (\Delta x)^2/(4\nu)$ with ν the diffusion coefficient of (1). (The specification of Δt is an artifact of the construction of the lattice Boltzmann methods via a discrete Hilbert expansion, as explained in §2.3.)
6. A collision operator, $\mathcal{C}(F)$, that determines the nature of interactions between particle distributions at nodes of the lattice.

[1] We use bold typefaces to indicate a set, e.g., $\mathbf{R} = \{reals\}$.

[2] $[0, 1]^{\mathbf{V}}$ is the set of functions from $\mathbf{V}$ to the closed interval $[0, 1]$.

	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1+\epsilon}{4}$	$\frac{1-\epsilon}{4}$
	1			

The mean occupation number F of a lattice node denotes the expected number of particles with a particular velocity at that node. Let $F(m, \mathbf{i}, \mathrm{v}) \in [0, 1]$ denote the expected number of particles with velocity v at time step m and lattice node $\mathbf{i} \in \mathbf{X}$. Thus, $F(m, \mathbf{i}, \mathrm{v})$ is in the single particle phase space $\mathbf{X} \times \mathbf{V}$ at time step m ; it evolves according to a kinetic equation of the form, $\mathcal{A}F = F + \mathcal{C}(F)$, where $\mathcal{A}$ models the movement of particle distributions (advection operator) and $\mathcal{C}(F)$, operating only on v, models the interactions of particle distributions (collision operator).

The collision operator for such lattice Boltzmann methods is written according to the formula $\mathcal{C}(F) \equiv \sum_{n,n'\in \mathbf{2}^{\mathbf{V}}} \alpha(n,n')(n'-n)F^n\bar{F}^{\bar{n}}$, where $\mathbf{2} \equiv \{0, 1\}$, and F^n and $\bar{F}^{\bar{n}}$ are defined by $F^n \equiv \prod_{\mathrm{v}\in\mathbf{V}}(F(\mathrm{v}))^{n(\mathrm{v})}$ and $\bar{F}^{\bar{n}} \equiv \prod_{\mathrm{v}\in\mathbf{V}}(1 - F(\mathrm{v}))^{(1-n(\mathrm{v}))}$, an overbarred quantity meaning one minus that quantity.[3] Requirements on $\alpha(n, n')$ are that $\alpha(n, n') \in [0, 1]$ and that it maintains conservation of probability, i.e., $\sum_{n'\in\mathbf{2}^{\mathbf{V}}} \alpha(n, n') = 1$, for all $n \in \mathbf{2}^{\mathbf{V}}$.

The advection operator $\mathcal{A}$ is defined by $\mathcal{A}F(m, \mathbf{i}, \mathrm{v}) = F(m + 1, \mathbf{i} + \mathrm{v}, \mathrm{v})$. Finally, the behavior of a lattice Boltzmann method is characterized by the microdynamical evolution equation

$$(2) \qquad \mathcal{A}F(m, \mathbf{i}, \mathrm{v}) = F(m, \mathbf{i}, \mathrm{v}) + \mathcal{C}(F(m, \mathbf{i}, \cdot)(F(m, \mathbf{i}, \mathrm{v}))\,,$$

which states that the new mean occupation numbers (on the left) at the new locations $(m+1, \mathbf{i}+\mathrm{v})$ are the same as the mean occupation numbers at the current location $(m, \mathbf{i})$ plus collisional corrections. This is analogous to a certain type of differencing of the Boltzmann equation, i.e., forward Euler (first order in time), central conservative finite difference in space (second order in space), and fixed in velocity (velocities are restricted to the directions available on the particular lattice and a fixed set of predetermined speeds, which in our case is $\{\Delta x/\Delta t\}$). Note that $F \mapsto F + \mathcal{C}(F) \in [0, 1]^{\mathbf{V}}$.

Collision rules for LB1, LB2, and LB3 appear in Tables 1, 3, and 4. Therein the rules are given pictorially. As an example, collision rules for LB1 are listed formally in Table 2.

Our lattice Boltzmann methods are then defined as the finite difference methods that, given the collision rules specified in Tables 1–4, evolve according to (2), in which $F(0, \mathbf{i}, \mathrm{v})$

[3] $\mathbf{2}^{\mathbf{V}}$ is the set of functions from $\mathbf{V}$ to $\mathbf{2}$.

$= F_I(\mathbf{i}, \mathrm{v})$, for all $\mathbf{i} \in \mathbf{X}$ and for all $\mathrm{v} \in \mathbf{V}$, where F_I is the initial condition. Approximate solutions to (1) are obtained through a special combination of the mean occupation numbers $F(m, \mathbf{i}, \mathrm{v})$, i.e., the average over the set of velocities, as is determined by the local conservation law.

2.2. Conservation, equilibria, and the H-theorem. Note that the lattice Boltzmann methods LB1, LB2, and LB3, which are governed by (2), each possess the local conservation law of conservation of mass, the locally conserved quantity being $\sum_{\mathrm{v}\in\mathbf{V}} F(m, \mathbf{i}, \mathrm{v})$. Also, because of the assumed periodic nature of the lattice, i.e., periodic boundary conditions, the presence of a local conservation law gives rise to a global conservation law. The globally conserved quantity is the sum of the mean occupation numbers over the entire lattice, i.e., $\sum_{\mathbf{i}\in\mathbf{X}} \sum_{\mathrm{v}\in\mathbf{V}} F(m, \mathbf{i}, \mathrm{v})$.

	 1			

Note that using $\epsilon = K\delta$, for constant K, a convection scaling parameter the collision operators for LB1, LB2, and LB3 can be written in the form, $\mathcal{C}(F) = \mathcal{C}^{(0)}(F) + \delta\mathcal{C}^{(1)}(F)$, where $\delta > 0$ is a dimensionless parameter and $\mathcal{C}^{(0)}(F)$ and $\mathcal{C}^{(1)}(F)$ are generalized Boltzmann operators in terms of $\mathcal{S}^{(0)}(n, n')$ and $\mathcal{S}^{(1)}(n, n')$, each not depending on δ, where $\mathcal{S}(n, n') = \mathcal{S}^{(0)}(n, n') + \delta\mathcal{S}^{(1)}(n, n')$ and $\mathcal{C}^{(0)}(F)$ is in semidetailed balance, i.e., $\sum_{n' \in 2^{\mathrm{V}}} \mathcal{S}^{(0)}(n', n) = \sum_{n' \in 2^{\mathrm{V}}} \mathcal{S}^{(0)}(n, n') = 1$, for every $n \in \mathbf{2}^{\mathrm{V}}$.

The H-theorem for diffusive lattice Boltzmann methods [7, Thm. 2.2] states in part that at an equilibrium, $\mathcal{C}^{(0)}(F) = 0$. For LB1, LB2, and LB3, we find that at equilibrium $F(\mathrm{v}_0) = F(\mathrm{v}_1) = F(\mathrm{v}_2) = F(\mathrm{v}_3) \equiv u$.

2.3. Hilbert expansion and diffusion. For the purposes of conducting our analyses, let us review some of the main points regarding the Hilbert expansion and diffusion from [7]. Let $\delta > 0$ be a small parameter and assume the lattice spacing $\Delta x = \delta L$ and the time step $\Delta t = \delta^2 T$ for some $L, T > 0$. The Taylor expansion of $\mathcal{A}H(t, \mathrm{x}, \mathrm{v})$ about $(t, \mathrm{x}, \mathrm{v})$ is $\mathcal{A}H(t, \mathrm{x}, \mathrm{v}) = H(t + \Delta t, \mathrm{x} + \mathrm{v}\Delta x, \mathrm{v}) = \sum_{j=0}^{\infty} \frac{1}{j!}\left[\delta^2 T \partial_t + \delta L \mathrm{v} \cdot \nabla\right]^j H(t, \mathrm{x}, \mathrm{v})$. Note that the terms can be grouped by order of δ.

A solution H of the lattice Boltzmann method (2) can be regarded as a function of the variables t, x, and v. We postulate that H can be expanded in the form

$$H(t, \mathrm{x}, \mathrm{v}) = \sum_{k=0}^{\infty} \delta^k h^{(k)}(t, \mathrm{x}, \mathrm{v}), \tag{3}$$

where $h^{(0)}$ is an equilibrium solution of $\mathcal{C}^{(0)}(H)$. The series (3) is called a *Hilbert expansion* of H. We examine conditions for the existence of a Hilbert expansion of H under the assumption that H is infinitely differentiable.

Define

$$a(\delta) = \mathcal{A}H - H = (\mathcal{A} - I)\sum_{k=0}^{\infty} \delta^k h^{(k)},$$

$$c(\delta) = \mathcal{C}(H) = \mathcal{C}\left(\sum_{k=0}^{\infty} \delta^k h^{(k)}\right) = \mathcal{C}^{(0)}\left(\sum_{k=0}^{\infty} \delta^k h^{(k)}\right) + \delta\mathcal{C}^{(1)}\left(\sum_{k=0}^{\infty} \delta^k h^{(k)}\right).$$

Expanding $a = a(\delta)$ and $c = c(\delta)$ about $\delta = 0$ in Taylor series gives

$$a(\delta) = a^{(0)} + \delta\, a^{(1)} + \delta^2 a^{(2)} + \delta^3 a^{(3)} + \cdots, \tag{4}$$

$$c(\delta) = c^{(0)} + \delta\, c^{(1)} + \delta^2 c^{(2)} + \delta^3 c^{(3)} + \cdots. \tag{5}$$

Matching the terms order by order yields

$$H(t+\Delta t, \mathrm{x}+\mathrm{v}\Delta x, \mathrm{v}) - H(t, \mathrm{x}, \mathrm{v}) = \mathcal{C}(H) = \mathcal{C}^{(0)}(h^{(0)}) + \sum_{j=1}^{\infty}(g^{(j)} - \mathcal{L}\cdot h^{(j)})\delta^j \equiv \sum_{j=0}^{\infty} \mathcal{T}_j \delta^j, \tag{6}$$

where $\mathcal{L} = \mathcal{D}\mathcal{C}^{(0)}(h^{(0)})$ is the so-called *linearized collision operator* and the $g^{(j)}$ are the remaining terms.

Since H is purported to be a solution of the lattice Boltzmann equation (2), it follows that $\mathcal{T}_j = 0$, or, equivalently,

$$\mathcal{C}(h^{(0)}) = 0, \tag{7}$$

$$\mathcal{L}\cdot h^{(j)} = g^{(j)}, \quad j = 1, 2, \ldots. \tag{8}$$

Thus, the asymptotic series (3) is constructed by solving each of the linear systems in (8).

For each of LB1, LB2, and LB3, the linearized collision operator $\mathcal{L}$ is the derivative, i.e., the Jacobian, of the $\mathcal{O}[1]$ portion of the collision operator, i.e., $\mathcal{C}^{(0)}(H)$, evaluated at equilibrium and to which the H-theorem is applied. In each method, $\mathcal{L}$ is singular. (Please see the appendices for the details.) Hence, the Hilbert series can be constructed if and only if $g^{(k)} \in \mathrm{Range}(\mathcal{L})$, in which case

$$h^{(j)} = \mathcal{L}^{+}\cdot g^{(j)} + s^{(j)}, \tag{9}$$

where $s^{(j)} \in \mathrm{Kernel}(\mathcal{L})$ is arbitrary and $\mathcal{L}^{+}$ is the pseudoinverse of $\mathcal{L}$. Note that each $\mathcal{L}$ is symmetric and nonpositive definite in the equilibrium solution u. Further, although the eigenvectors are the same, i.e., the eigenmatrix for each method is given by

$$\mathbf{Q} = [\mathbf{q}_0, \mathbf{q}_1, \mathbf{q}_2, \mathbf{q}_3] = \begin{bmatrix} 1 & 1 & 0 & 1 \\ 1 & 0 & 1 & -1 \\ 1 & -1 & 0 & 1 \\ 1 & 0 & -1 & -1 \end{bmatrix},$$

their respective eigenvalues differ. The eigenvalues are denoted $\boldsymbol{\lambda} = (\lambda_0, \lambda_1, \lambda_2, \lambda_3)$. It turns out for all three methods that $\lambda_0 = 0$ is the only zero eigenvalue; hence, $\mathcal{L}$ is indeed singular for each of the methods, and the pseudoinverse $\mathcal{L}^{+}$ of each method is given by $\mathcal{L}^{+} = \sum_{k=1}^{3} \frac{1}{\lambda_k} \frac{\mathbf{q}_k \mathbf{q}_k^T}{\mathbf{q}_k^T \mathbf{q}_k}$.

2.4. Consistency, stability, and convergence.

2.4.1. General definitions and theorems. For completeness, we include the definitions and statements of the theorems related to consistency, stability, and convergence. Interested readers can find the relevant proofs in [7], which also includes some theory for more general lattice Boltzmann methods.

Consider the finite sums $H^{(q)}(m, \mathbf{i}, \cdot) = \sum_{k=0}^{q} \delta^k h^{(k)}$, where $h^{(k)} = h^{(k)}(m, \mathbf{i}, \cdot)$ are grid functions.

Definition 2.1. *Let $q > 0$ be a fixed integer and $B_{\Delta t}$ a finite-dimensional Banach space with ℓ_1 norm $\|\cdot\|_{\Delta t}$.*

1. Consistency: *Let $\mathcal{A}H^{(q)} - H^{(q)} - \mathcal{C}[H^{(q)}] = \mathcal{T}^{(q)}$. If $\lim_{\Delta t \to 0} \frac{1}{\Delta t} \|\mathcal{T}^{(q)}(m, \cdot, \cdot)\|_{\Delta t} = 0$, then the lattice Boltzmann method is said to be consistent.*
2. Convergence: *If $F(m, \cdot, \cdot) \in B_{\Delta t}$ is the solution to the lattice Boltzmann method* (2) *and $\lim_{\Delta t \to 0} \|F(m, \cdot, \cdot) - H^{(q)}(m, \cdot, \cdot)\|_{\Delta t} = 0$, for all integers m such that $0 \leq m\Delta t \leq T$, then the lattice Boltzmann method is said to be convergent.*
3. Stability: *Define the block diagonal matrix $L_{\Delta t} : B_{\Delta t} \to B_{\Delta t}$ where the* **i***th diagonal block is defined by $\mathcal{L}(F, H^{(q)}) \cdot G = \int_0^1 \left[I + \mathcal{DC}\big((1-s)F + sH^{(q)}\big)\right] \cdot G\, ds$, for $G \in \mathcal{I} \equiv [0, 1]^{\mathbf{V}}$. The lattice Boltzmann method is said to be stable if for some $\tau > 0$, the family of matrices $\{\prod_{k=0}^{m} L_{\Delta t} : 0 < \Delta t < \tau$ and $0 \leq m\Delta t \leq T\}$, is uniformly bounded.*

Theorem 2.2. *Suppose a lattice Boltzmann method is consistent. Then stability is a sufficient condition for convergence.*

Using the ideas of monotone difference methods [12], sufficient conditions for stability of convective–diffusive lattice Boltzmann methods have been established [7]. The advection operator $\mathcal{A}$ can be interpreted as a vector-valued function defined on $\mathcal{I}$ having the vth coordinate function given by $\mathcal{A}[F](\mathrm{v}) = F(\mathrm{v}) + \mathcal{C}[F](\mathrm{v})$. The derivative of $\mathcal{A}$ is the $|\mathbf{V}| \times |\mathbf{V}|$ Jacobian matrix $\mathcal{J}_{\mathcal{A}}(F)$ whose v, wth element is

$$\frac{\partial}{\partial F(\mathrm{w})} \mathcal{A}[F](\mathrm{v}) . \tag{10}$$

Definition 2.3. *Let $\mathcal{E} = \prod_{k=0}^{|\mathbf{V}|} [M_-^{(k)}, M_+^{(k)}] \subseteq \mathcal{I}$ be a $|\mathbf{V}|$-dimensional interval upon which $\mathcal{J}_{\mathcal{A}}$ is nonnegative. That is, $F \in \mathcal{E}$ implies $\mathcal{J}_{\mathcal{A}}(F) \geq 0$. Then $\mathcal{E}$ is called a* domain of monotonicity *of the lattice Boltzmann method* (2)*, and the vectors $\mathbf{M}_- = \left[M_-(\mathrm{v})\right]_{\mathrm{v} \in \mathbf{V}}$ and $\mathbf{M}_+ = \left[M_+(\mathrm{v})\right]_{\mathrm{v} \in \mathbf{V}}$ are called the* extreme points *of $\mathcal{E}$.*

The following lemma demonstrates the invariance property of the advection operator on a domain of monotonicity.

Lemma 2.4. *Let $\mathcal{E}$ be a domain of monotonicity with extreme points $\mathbf{M}_-$ and $\mathbf{M}_+$ for a lattice Boltzmann method* (2)*. Suppose $\mathcal{C}[F](\mathbf{M}_-) = \mathcal{C}[F](\mathbf{M}_+) = 0$. Then $\mathcal{A}$ leaves $\mathcal{E}$ invariant. That is, $F \in \mathcal{E}$ implies $\mathcal{A}F \in \mathcal{E}$.*

The following is a stability condition.

Theorem 2.5. *Let $\mathcal{E}$ be a domain of monotonicity for a lattice Boltzmann method* (2)*. Let the extreme points $\mathbf{M}_-$ and $\mathbf{M}_+$ be such that $\mathcal{C}[F](\mathbf{M}_-) = \mathcal{C}[F](\mathbf{M}_+) = 0$. Suppose $F(0, \mathbf{i}, \cdot)$ and $H^{(q)}(0, \mathbf{i}, \cdot)$ are vectors in $\mathcal{E}$. If $\mathcal{C}(F)$ conserves mass locally, i.e., $F(\mathrm{v}) = \sum_{\mathrm{v} \in \mathbf{V}} \mathcal{C}(F)(\mathrm{v}) = 0$, then the method is stable.*

2.4.2. Convergence. From Theorems 2.2 and 2.5, we can obtain second-order (in δ) convergence of LB1 and LB2 in the ℓ_1 norm for sufficiently smooth initial conditions $F(0, \mathrm{x}, \cdot)$ that are wholly contained within each method's respective domain of monotonicity by (i) proving consistency and (ii) showing that the purported domain of monotonicity is indeed a domain of monotonicity. Similar arguments apply for LB3, except that Lemma 2.4 does not apply directly, making the arguments somewhat more involved. This case will be treated separately. The following standard notation is used: $\nabla \equiv (\partial_x, \partial_y)$ and $\overline{\nabla} \equiv (\partial_x, -\partial_y)$.

THEOREM 2.6 (Consistency of LB1). *Let* $\Delta x = L\delta$, $\nu = \frac{L^2}{4T}$, $\Delta t = T\delta^2$, $c = \frac{KL}{2T}$, $\epsilon = \frac{c\Delta x}{2\nu}$, *and* $A(u) = u(1-u)$. *Suppose*

$$\partial_t u + c\partial_x A(u) = \nu\nabla^2 u\,, \tag{11}$$

$$\partial_t \sigma^{(2)} + 6c\partial_x[A'(u)\sigma^{(2)}] = \nu\nabla^2\sigma^{(2)} - \mathcal{F}\,, \tag{12}$$

$$\sigma^{(1)} = \sigma^{(3)} = 0\,, \tag{13}$$

where $\mathcal{F} = \mathcal{F}(T, K, L, t, x, y, u, u_x, u_y, u_{xx}, u_{xy}, u_{yy}, u_{xxx}, u_{xyy}, u_{xxxx}, u_{xxyy}, u_{yyyy})$, *which is given in Appendix* A, *is a smooth function. Then* $g^{(j)} \in \mathrm{Range}(\mathcal{L})$, $j = 1, 2, 3, 4$, *and LB*1 *is consistent.*

Proof. Part (i): First we show $g^{(j)} \in \mathrm{Range}(\mathcal{L})$, for $j = 1, 2, 3, 4$. The first part of the proof follows by carrying out the expansions in (4), (5), (7), and (8) to get that $g^{(j)} = \sum_{k=1}^{3} c_k^{(j)}\mathbf{q}_k$. The specific values of $c_k^{(j)}$ are given in Appendix A. Applying (11)–(13) to the coefficients $c_k^{(j)}$ yields the desired result.

Part (ii): Now, we show consistency. Let $h^{(j)}$, $j = 0, 1, 2, 3, 4$, be defined by $h^{(0)} = (u, u, u, u)$ and $h^{(j)} = \mathcal{L}^+ \cdot g^{(j)} + \sigma^{(j)}$, $j = 1, 2, 3, 4$, as per (9). Consider the grid function $H^{(3)}(m, \mathbf{i}, \cdot) = \sum_{j=0}^{3} h^{(j)}(m, \mathbf{i}, \cdot)\,\delta^j$. Then $\mathcal{A}H^{(3)} - H^{(3)} - \mathcal{C}(H^{(3)}) = -\mathbf{T}(H^{(3)}) +$ higher-order terms, where $\mathbf{T}(H^{(3)}) = \sum_{j=0}^{4} \mathbf{T}^{(j)}\delta^j$.

Since $\mathbf{T}^{(0)} = \mathcal{L}\cdot h^{(0)}$ and $\mathbf{T}^{(j)} = \mathcal{L}\cdot h^{(j)} - g^{(j)}$, $j = 1, 2, 3$, it follows that $\mathbf{T}^{(j)} = 0$, $j = 0, 1, 2, 3$. Moreover, $\mathbf{T}^{(4)} = -\sum_{k=0}^{3} c_k^{(4)}\mathbf{q}_k = -c_3^{(4)}\mathbf{q}_3$, where $c_3^{(4)}$ is given in Appendix A. Consequently, if $u \in C^4([0,1]^2, (0,1))$ and $\sigma^{(2)} \in C^2(\mathbf{R}^2, \mathbf{R})$, then $\mathcal{T}(H^{(3)}) = \mathcal{O}[\delta^4]$ and the method will be consistent. Since u and $\sigma^{(2)}$ are solutions to the uniformly parabolic equations (11) and (12), respectively, it follows that they and their corresponding derivatives are uniformly bounded and, consequently, consistency is in fact true. □

THEOREM 2.7 (Consistency of LB2). *Let* $\Delta x = L\delta$, $\nu = \frac{L^2}{4T}$, $\Delta t = T\delta^2$, $c = \frac{KL}{2T}$, $\epsilon = \frac{c\Delta x}{2\nu}$, *and* $A(u) = u(1-u)$. *Suppose*

$$\partial_t u + c\partial_x A(u) = \nu\nabla^2 u\,, \tag{14}$$

$$\partial_t \sigma^{(2)} + 6c\partial_x(A'(u)\sigma^{(2)}) = \nu\nabla^2\sigma^{(2)} - \mathcal{F}\,, \tag{15}$$

$$\sigma^{(1)} = \sigma^{(3)} = 0\,, \tag{16}$$

where $\mathcal{F}$ *is a smooth function of* u *and its spatial derivatives, as defined in Appendix* B. *Then* $g^{(j)} \in \mathrm{Range}(\mathcal{L})$, $j = 1, 2, 3, 4$, *and LB*2 *is consistent.*

Proof. The proof is similar to that for Theorem 2.6, with the supporting details appearing in Appendix B. □

Showing consistency of LB3 is slightly different than of LB1 and LB2 due to $\sigma^{(3)} = 0$ not being a solution to the method's $\mathcal{O}[\delta^5]$ consistency condition (see (20) below and Appendix C).

THEOREM 2.8 (Consistency of LB3). *Let* $\Delta x = L\delta$, $\nu = \frac{L^2}{4T}$, $\Delta t = T\delta^2$, $c = \frac{KL}{2T}$, $\epsilon = \frac{c\Delta x}{2\nu}$, $A(u) = u(1-u)$, *and* $\lambda = -4A(u)$. *Suppose*

$$\partial_t u + c\partial_x A(u) = \nu\nabla^2 u\,, \tag{17}$$

$$\sigma^{(1)} = 0\,, \tag{18}$$

$$\partial_t \sigma^{(2)} + 6c\partial_x(A'(u)\sigma^{(2)}) = \nu\nabla^2\sigma^{(2)} - \mathcal{F}\,, \tag{19}$$

$$\partial_t \sigma^{(3)} + \tfrac{c}{2}\partial_x[A'(u)\sigma^{(3)}] = \nu\nabla^2\sigma^{(3)} - \mathcal{G}\,, \tag{20}$$

where for $u \in C^4((0,1)^2,(0,1))$, $\mathcal{F}$ *and* $\mathcal{G}$ *are smooth functions of* (a) T, K, L, *and* u *and its derivatives, and* (b) T, K, L, *and* u *and* $\sigma^{(2)}$ *and their derivatives, respectively, as defined in Appendix* C. *Then* $g^{(j)} \in \mathrm{Range}(\mathcal{L})$, $j = 1,2,3,4$, *and LB*3 *is consistent.*

Proof. Part (i): First we show $g^{(j)} \in \mathrm{Range}(\mathcal{L})$, for $j = 1,2,3,4$. The first part of the proof follows by carrying out the expansions in (4), (5), (7), and (8) to get that $g^{(j)} = \sum_{k=1}^{3} c_k^{(j)} \mathbf{q}_k$. The specific values of $c_k^{(j)}$ are given in Appendix C. Applying (17)–(20) to the coefficients $c_k^{(j)}$ yields the desired result.

Part (ii): Now, we show consistency. Let $h^{(j)}$, $j = 0,1,2,3,4$, be defined by $h^{(0)} = (u,u,u,u)$ and $h^{(j)} = \mathcal{L}^{+} \cdot g^{(j)} + \sigma^{(j)}$, $j = 1,2,3,4$, as per (9). Consider the grid function $H^{(3)}(m,\mathbf{i},\cdot) = \sum_{j=0}^{3} h^{(j)}(m,\mathbf{i},\cdot)\,\delta^j$. Then $\mathcal{A}H^{(3)} - H^{(3)} - \mathcal{C}(H^{(3)}) = -\mathbf{T}(H^{(3)}) +$ (higher-order terms), where $\mathbf{T}(H^{(3)}) = \sum_{j=0}^{4} \mathbf{T}^{(j)}\delta^j$.

Since $\mathbf{T}^{(0)} = \mathcal{L} \cdot h^{(0)}$ and $\mathbf{T}^{(j)} = \mathcal{L} \cdot h^{(j)} - g^{(j)}$, $j = 1,2,3$, it follows that $\mathbf{T}^{(j)} = 0$, $j = 0,1,2,3$. Moreover, $\mathbf{T}^{(4)} = -\sum_{k=0}^{3} c_k^{(4)} \mathbf{q}_k$, where the $c_k^{(4)}$ are given in Appendix C. Consequently, if $u \in C^4((0,1)^2,(0,1))$, $\sigma^{(2)} \in C^2(\mathbf{R}^2,\mathbf{R})$, and $\sigma^{(3)} \in C^2(\mathbf{R}^2,\mathbf{R})$, then $\mathcal{T}(H^{(3)}) = \mathcal{O}[\delta^4]$, and the method will be consistent. Since u, $\sigma^{(2)}$, and $\sigma^{(3)}$ are solutions to the uniformly parabolic equations (17), (19), and (20), they and their corresponding derivatives are uniformly bounded and consistency is in fact true. □

THEOREM 2.9 (Domain of monotonicity for LB1). *The set* $\mathcal{E} = [M_-, M_+]^{|\mathbf{V}|}$, *where* $M_- = 0$ *and* $M_+ = 1$, *is a domain of monotonicity for LB*1. *Let* $\mathbf{M}_- = M_-^{\mathbf{V}}$ *and* $\mathbf{M}_+ = M_+^{\mathbf{V}}$. *Then* $\mathcal{C}[F](\mathbf{M}_-) = \mathcal{C}[F](\mathbf{M}_+) = 0$.

Proof. Part (i): First we show that $\mathcal{E}$ is a domain of monotonicity. Let $f(x,y,z) = \frac{3+\epsilon[3-2(x+y+z)]}{12}$ and $g(x,y,z) = \frac{3-\epsilon[3+2(x+y+z)]}{12}$. Let $F_k = F(\mathrm{v}_k), k = 0,1,2,3$. We find that the Jacobian $\mathcal{J}_{\mathcal{A}}(F)$, which is defined generally by (10), in the case of LB1 is given by

$$\mathcal{J}_{\mathcal{A}}(F) = \begin{bmatrix} f(F_1,F_2,F_3) & f(F_0,F_2,F_3) & f(F_0,F_1,F_3) & f(F_0,F_1,F_2) \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \\ g(F_1,F_2,F_3) & g(F_0,F_2,F_3) & g(F_0,F_1,F_3) & g(F_0,F_1,F_2) \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \end{bmatrix}.$$

Consequently, showing that $\mathcal{J}_{\mathcal{A}}(F) \geq 0$ for $F \in \mathcal{E}$ is equivalent to showing that each of the two functions $f(x,y,z)$ and $g(x,y,z)$ is nonnegative for $M_- = 0 \leq x,y,z \leq M_+ = 1$. We now show that the local and boundary minima of f and g are nonnegative. If we examine the gradients of these functions, then we see that they are nonzero. Hence, there are no interior minima.

Standard variational arguments on the boundary easily establish that

$$\min \tfrac{1}{12}\{3(1+\epsilon), 3(1-\epsilon), 3+\epsilon, 3-\epsilon\} \leq f, g \leq \max \tfrac{1}{12}\{3(1+\epsilon), 3(1-\epsilon), 3+\epsilon, 3-\epsilon\}.$$

Since $\epsilon \in [-1,1]$, it quickly follows that $0 \leq f, g \leq \frac{1}{2}$.

Part (ii): It follows from (22) (in Appendix A) that $\mathcal{C}[F](\mathbf{M}_+) = \mathcal{C}[F](\mathbf{M}_-) = 0$. □

THEOREM 2.10 (Domain of monotonicity for LB2). *The set* $\mathcal{E} = [M_-, M_+]^{|\mathbf{V}|}$, *where* $M_- = 0$ *and* $M_+ = 1$, *is a domain of monotonicity for LB*2. *Let* $\mathbf{M}_- = M_-^{\mathbf{V}}$ *and* $\mathbf{M}_+ = M_+^{\mathbf{V}}$. *Then* $\mathcal{C}[F](\mathbf{M}_-) = \mathcal{C}[F](\mathbf{M}_+) = 0$.

Proof. Part (i): First we show $\mathcal{E}$ is a domain of monotonicity. Let $f(x) = \frac{1+\epsilon}{4} - \frac{\epsilon}{2}x$ and $g(x) = \frac{1-\epsilon}{4} + \frac{\epsilon}{2}x$. Let $F_k = F(\mathrm{v}_k), k = 0,1,2,3$. We find that the Jacobian $\mathcal{J}_{\mathcal{A}}(F)$ for LB2 is given by

$$\mathcal{J}_{\mathcal{A}}(F) = \begin{bmatrix} f(F_2) & f(F_3) & f(F_0) & f(F_1) \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \\ g(F_2) & g(F_3) & g(F_0) & g(F_1) \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \end{bmatrix}.$$

Consequently, showing that $\mathcal{J}_{\mathcal{A}}(F) \geq 0$ for $F \in \mathcal{E}$ is equivalent to showing that each of the two functions $f(x)$ and $g(x)$ is nonnegative for $M_- = 0 \leq x, y, z \leq M_+ = 1$. We now show that the local and boundary minima of f and g are nonnegative. If we examine the gradients of these functions, then we see that they are nonzero. Hence, there are no interior minima.

Standard variational arguments on the boundary easily establish that

$$\min\{\tfrac{1+\epsilon}{4}, \tfrac{1-\epsilon}{4}\} \leq f, g \leq \max\{\tfrac{1+\epsilon}{4}, \tfrac{1-\epsilon}{4}\}.$$

Since $\epsilon \in [-1, 1]$, it quickly follows that $0 \leq f, g \leq \frac{1}{2}$.

Part (ii): It follows from (23) (in Appendix B) that $\mathcal{C}[F](\mathbf{M}_+) = \mathcal{C}[F](\mathbf{M}_-) = 0$. □

THEOREM 2.11 (Domain of monotonicity for LB3). *The set* $\mathcal{E} = [M_-, M_+]^{|\mathrm{V}|}$, *where* $M_- = 0$ *and* $M_+ = \frac{1}{2}$, *is a domain of monotonicity for LB3.*

Proof. Let $f_1(x, y, z) = \frac{1+\epsilon}{2}(1 - 2y) + xy - xz + yz$, $f_2(x, y, z) = \frac{1-\epsilon}{2}(1 - 2y) + xy - xz + yz$, $g(x, y, z) = x - xy - xz + yz$ and $h(x, y, z) = \frac{1}{2} - y + xy - xz + yz$. Let $F_k = F(\mathrm{v}_k)$, $k = 0, 1, 2, 3$. The Jacobian $\mathcal{J}_{\mathcal{A}}(F)$ for LB3 is given by

$$\mathcal{J}_{\mathcal{A}}(F) = \begin{bmatrix} f_1(F_1, F_2, F_3) & g(F_3, F_0, F_2) & f_1(F_1, F_0, F_3) & g(F_1, F_0, F_2) \\ g(F_2, F_1, F_3) & h(F_0, F_3, F_2) & g(F_0, F_1, F_3) & h(F_0, F_1, F_2) \\ f_2(F_1, F_2, F_3) & g(F_3, F_0, F_2) & f_2(F_1, F_0, F_3) & g(F_1, F_0, F_2) \\ g(F_2, F_1, F_3) & h(F_0, F_3, F_2) & g(F_0, F_1, F_3) & h(F_0, F_1, F_2) \end{bmatrix}.$$

Consequently, showing that $\mathcal{J}_{\mathcal{A}}(F) \geq 0$ for $F \in \mathcal{E}$ is equivalent to showing that each of the functions $f_1(x, y, z)$, $f_2(x, y, z)$, $g(x, y, z)$, and $h(x, y, z)$ is nonnegative for $M_- = 0 \leq x, y, z \leq M_+ = \frac{1}{2}$. We now show that the local and boundary minima of f_1, f_2, g, and h are nonnegative. Examining the gradients of these functions, we find (1) $f_1(x, y, z) = 0$ at the point $x = y = z = \frac{1+\epsilon}{2}$, (2) $f_2(x, y, z) = 0$ at the point $x = y = z = \frac{1-\epsilon}{2}$, and (3) $g(x, y, z) = h(x, y, z) = 0$ at the point $x = y = z = \frac{1}{2}$. However, the Hessians $D^2 f_1$, $D^2 f_2$, $D^2 g$, and $D^2 h$ are nowhere positive or negative definite. Hence, there are no interior extrema.

Standard variational arguments on the boundary easily establish that

$$\begin{gathered} \min\{0, \tfrac{1+\epsilon}{2}, \tfrac{1+\epsilon}{2} - \tfrac{1}{4}\} \leq f_1 \leq \max\{\tfrac{1}{4}, \tfrac{1+\epsilon}{2}, \tfrac{1+\epsilon}{2} - \tfrac{1}{4}\}, \\ \min\{0, \tfrac{1-\epsilon}{2}, \tfrac{1-\epsilon}{2} - \tfrac{1}{4}\} \leq f_2 \leq \max\{\tfrac{1}{4}, \tfrac{1-\epsilon}{2}, \tfrac{1-\epsilon}{2} - \tfrac{1}{4}\}, \\ 0 \leq g, h \leq \tfrac{1}{2}. \end{gathered}$$

If $\epsilon \in [-\frac{1}{2}, \frac{1}{2}]$, it quickly follows that $0 \leq f_1, f_2 \leq \frac{1}{2}$. □

In LB3, Lemma 2.4 (invariance of the advection operator on domains of monotonicity) does not apply because the collision operator is nonzero at one of the extreme points of the domain of monotonicity $\mathcal{E}$. *Indeed,* $\mathcal{C}[F](\mathbf{M}_+) = \frac{\epsilon}{4}\mathbf{q}_1$, *which tends to zero as* ϵ *tends to zero, however.* Hence, in the limit as $\epsilon \to 0$ the invariance property is recovered. This suggests the possibility of invariance on $\mathcal{E}$ of the advection operator under conditions other than those of Lemma 2.4.

LEMMA 2.12. *Let* $\epsilon' \in (M_-, M_+)$ *be given. Let* $\mathcal{E}' = [M_-, M_+ - \epsilon']^{\mathrm{V}}$. *Then there exists* $\epsilon \in (-\epsilon', \epsilon')$ *such that if* $F(0, \mathrm{x}, \cdot) \in \mathcal{E}'$ *then* $F(m, \mathrm{x}, \cdot) \in \mathcal{E}$, *for all* m *such that* $0 < m\Delta t < T$, *where* Δt *and* ϵ *are defined in Theorem* 2.8.

Proof. We outline the proof as follows: (i) determine the extrema of $H(F)$ given that $F \in \mathcal{E}''$, where $\mathcal{E}'' = [M_-, M_+ - \zeta]$ and $\zeta \in (M_-, M_+)$; (ii) choose ϵ (depending on ϵ', M_-, M_+, T, K, and L, and the extrema determined in (i)) so that $H(F)$ applied recursively m times to $F(0, \mathbf{i}, \cdot) \in \mathcal{E}'$ yields a result in $\mathcal{E}$; and (iii) turn the recursion in step (ii) into an induction on m. □

The rather severe weaknesses of Lemma 2.12 suggest that LB3 may have difficulties in practice, as will be evident in the numerical studies in the subsequent section.

2.4.3. Summary. Given the above theorems, approximate solutions to (1) can be obtained from LB1, LB2, and LB3 according to the following prescription. Define $u_{\mathbf{i}}^m = \frac{1}{4}\sum_{\mathrm{v}\in\mathrm{V}} F(m,\mathbf{i},\mathrm{v})$ and $p_{\mathbf{i}}^m = cA'(u_{\mathbf{i}}^m)$, with $u_{\mathbf{i}}^m$ being defined as per the local conservation law. Then in the ℓ_1 norm, $p_{\mathbf{i}}^m$ is a second-order spatial, first-order temporal approximation to $\rho(m\Delta t, \mathbf{i}\Delta x)$.

We have shown that under certain conditions and transformations the lattice Boltzmann methods LB1, LB2, and LB3 converge second order in space and first order in time to the solution of (1). Note that the convergence of LB3 appears to be somewhat weaker than that of LB1 and LB2. In part this may be due to the increased number of nonzero coefficients (of the eigenvectors of the linearized collision operator) of the fourth-order term in the Hilbert expansion for LB3, as compared to the corresponding terms in the expansions for LB1 and LB2. In particular, $\sigma^{(3)} = 0$ is a solution to the fifth-order consistency condition for both LB1 and LB2, while it is not a solution to the same for LB3. Hence, $c_k^{(4)}$, $k = 0, 1, 2, 3$, are nonzero in LB3, which strengthens the influence of the fourth-order term of the Hilbert expansion on the truncation error.

3. Numerical studies. Several numerical studies, motivated by an earlier work [6], were conducted for the purposes of verifying the theory, comparing the lattice Boltzmann methods with each other, and comparing the lattice Boltzmann and finite difference methods. For each of the lattice Boltzmann and finite difference methods, the studies included acquiring (numerical) error and timing measurements in order to investigate their accuracy, order of convergence, and performance. All the methods were implemented in FORTRAN77 on a Fujitsu VPX240/10 and on one processing element of a Fujitsu VPP500, which we denote the VPP500/1. Both systems comprise high-performance vector-processing architectures, which are discussed later in more detail.

The following test problem was used: solve (1) with $(x, y) \in \Omega = [0, L] \times [0, L]$, $L = 1$, and $t \in [0, T]$, $T = 1$, for periodic boundary conditions with diffusion coefficients $\nu \in \{2^{-k} : k = 2, 3, 4, 5, 6\}$. Accuracy data in the ℓ_1 and ℓ_∞ norms were collected for the time steps corresponding to $t \in \{2^{-k} : k = 5, 4, 3, 2\}$. (Due to space limitations we present only ℓ_∞ norm results for $\nu \in \{2^{-k} : k = 2, 4, 6\}$.)

3.1. Lattice Boltzmann implementations. The lattice Boltzmann methods LB1, LB2, and LB3 compute the occupation numbers $F_{i,j}^m(\mathrm{v}_0)$, $F_{i,j}^m(\mathrm{v}_1)$, $F_{i,j}^m(\mathrm{v}_2)$, and $F_{i,j}^m(\mathrm{v}_3)$ over the prescribed lattice locations (i, j) and time steps m. In addition to this computation, there is also the calculation of the quantity $u_{i,j}^m = \frac{1}{4}\sum_{\mathrm{v}\in\mathrm{V}} F_{i,j}^m(\mathrm{v})$, which is the lattice Boltzmann methods' approximation to the solution of the second-order consistency conditions (11), (14), (17) for LB1, LB2, and LB3, respectively. The approximations $u_{i,j}^m$ must further be transformed via $p_{i,j}^m = c(1 - 2u_{i,j}^m)$ to obtain the approximation $p_{i,j}^m$ to the solution of (1). (These extra calculations were not included when collecting the performance and timing measurements of the lattice Boltzmann methods, as they are needed only when sampling a particular time step, which is generally sparse compared to the number of time steps.)

The difference formulae for the lattice Boltzmann methods are listed in Table 5, and except for the treatment of the periodic boundary conditions, their kernel implementations are found in Table 6. The methods' arithmetic operation counts are given in Table 7.

3.2. The finite difference method. The finite difference method employed for solving (1) is the following conservative, forward Euler-type, central difference scheme:

$$\begin{aligned} P_{i,j}^{m+1} = {} & P_{i,j}^m - \tfrac{\Delta t}{4\Delta x}\left[(P_{i+1,j}^m)^2 - (P_{i-1,j}^m)^2\right] \\ & + \tfrac{\nu\Delta t}{(\Delta x)^2}\left[P_{i+1,j}^m - 2P_{i,j}^m + P_{i-1,j}^m\right] + \tfrac{\nu\Delta t}{(\Delta y)^2}\left[P_{i,j+1}^m - 2P_{i,j}^m + P_{i,j-1}^m\right]. \end{aligned} \tag{21}$$

TABLE 5

Lattice Boltzmann difference equations. Note that for brevity here $F^{m}_{i,j}(\mathrm{v}_k) \equiv F(m,(i,j),\mathrm{v}_k)$.

LB1
$F^{m+1}_{i-1,j}(\mathrm{v}_0) \;=\; \frac{1+\epsilon}{4}[F^{m}_{i,j}(\mathrm{v}_0)+F^{m}_{i,j}(\mathrm{v}_1)+F^{m}_{i,j}(\mathrm{v}_2)+F^{m}_{i,j}(\mathrm{v}_3)]$
$-\frac{\epsilon}{6}[(F^{m}_{i,j}(\mathrm{v}_0)+F^{m}_{i,j}(\mathrm{v}_2))(F^{m}_{i,j}(\mathrm{v}_1)+F^{m}_{i,j}(\mathrm{v}_3))+F^{m}_{i,j}(\mathrm{v}_0)F^{m}_{i,j}(\mathrm{v}_2)+F^{m}_{i,j}(\mathrm{v}_1)F^{m}_{i,j}(\mathrm{v}_3)]$

One can show, e.g., by techniques for monotone methods (see, e.g., [12, Chap. IV]), that (21) is an $\mathcal{O}\big[(\Delta x)^2\big]+\mathcal{O}\big[(\Delta y)^2\big]+\mathcal{O}[\Delta t]$ convergent, conservative, monotone finite difference method for (1). The monotonicity criteria that ensure stability are that $\Delta t \leq \frac{(\Delta x)^2}{4\nu}$ and $\|P\|_{\ell_\infty} \leq \frac{2\nu}{\Delta x}$ (the latter is analogous to a Courant condition, e.g., [11]).

The finite difference method (21) was implemented at its limit of stability, $\Delta t = \frac{(\Delta x)^2}{4\nu}$, which is inherent in the lattice Boltzmann methods LB1, LB2, and LB3. Thus, the finite difference and lattice Boltzmann methods are approximating solutions to (1) for identical discretizations of the spatial–temporal domain ($[0, L] \times [0, L]) \times [0, T)$ and can be straightforwardly compared. Barring the treatment of the periodic boundary conditions, the implementation of the finite difference kernel is given in Table 6. Its arithmetic operation count is also given in Table 7.

3.3. Accuracy. The absolute errors in the ℓ_∞ norm for LB1, LB2, LB3, and the finite difference method are given in Table 8. We see that the absolute errors worsen progressively from LB1 to LB2 to LB3, with the errors in LB3 being significantly worse than in LB1. We also see that all the methods depict increasing accuracy with increasing diffusion coefficients. The finite difference method reflects the greatest accuracy of all the methods, however, with LB1 being a close second. The ratios of the errors observed in LB1, LB2, and LB3 to those

TABLE 8

Accuracy. Absolute errors in the ℓ_∞ norm of the lattice–Boltzmann-computed and finite–difference-computed solutions are given for various diffusion coefficients ν.

ν	LB1	LB2	LB3	Finite Difference
1/4				1/16				1/64				
in the finite difference method appear in Table 9. Overall the errors in LB1 are quite good compared to those in the finite difference method, with the maximum error observed being about twice as great. The results for LB3 are not as good, with the errors being as high as about 100 times those in the finite difference method. (Similar comments apply to the errors in the ℓ_1 norm.)

TABLE 9

ν	1/4	1/16	1/64
LB1			LB2			LB3			Finite Difference			
3.4. Order of convergence. The ratios between the absolute errors at a given problem size and twice that problem size, i.e., for $N \times N$ and $(2N) \times (2N)$ grids, respectively, can be reflective of the order of convergence of a supposed second-order convergent method. Although not necessary for second-order convergence, a ratio near four is indictive of second-order convergence. The error ratios in the ℓ_∞ norm for LB1, LB2, LB3, and the finite difference method are given in Table 10.

In the finite difference method, the error ratio is definitely near four, which supports the theoretical second-order convergence of the method. The error ratio in LB3 appears slightly less than four, which mimics its difficulties with accuracy, as pointed out in §2.4. Across the lattice Boltzmann methods LB3, LB2, and LB1, the error ratio progressively approaches four. In addition, the lattice Boltzmann methods appear generally to produce error ratios nearer to four for larger diffusion coefficients. This is expected, however, since the convergence proofs assume that $\epsilon = \frac{\Delta x}{2\nu} = \mathcal{O}[\Delta x]$. So, for a particular lattice size, i.e., a fixed Δx, the smaller the diffusion coefficient ν, the less ϵ appears to be $\mathcal{O}[\Delta x]$. Indeed, for $\nu = \mathcal{O}[\Delta x]$ the convection bias ϵ is $\mathcal{O}[1]$ and the convergence proofs for LB1, LB2, and LB3 fail altogether. As the theory predicts, this behavior is evident in the error ratios shown. Of the three lattice Boltzmann methods, LB1 appears to exhibit the most convincing error ratios for the widest variety of diffusion coefficients. (Again, the above comments apply to the ℓ_1 norm also.)

3.5. Performance and timing measurements. Because the errors in LB1 are close to those in the finite difference method (they are at most a factor of two apart), LB1 might be considered an alternative to the finite difference method in some circumstances, which among other considerations may depend on the performance of the methods on a particular architecture. To this end, we obtained performance and timing measurements for the three lattice Boltzmann methods and the finite difference method for two high-performance computer systems: a Fujitsu VPX240/10, which has a peak performance of 2.5 Gflop/s, and a Fujitsu VPP500/1, one processing element (PE) of which has a peak performance of 1.6 Gflop/s. While both systems comprise vector-pipelined architectures, they differ in several ways.

1. The VPX240/10 has two multiply–add pipelines, each of which delivers two results per clock cycle; a VPP500 PE has one multiply pipeline and one add pipeline, each of which delivers eight results per clock cycle. In both systems, the vector pipelines can operate concurrently and can also be chained.
2. The VPX240/10 has two universal load/store pipelines, each of which can operate concurrently; a VPP500 PE has one load pipeline and one store pipeline, each of which can operate concurrently. In both systems the load/store and arithmetic pipelines can operate concurrently.
3. The VPP500 PEs and the VPX240/10 possess 32-way and 256-way interleaved memory, respectively.
4. A VPP500 PE has a larger vector register size (128 kilobytes) than does the VPX240/10 (64 kilobytes). Both vector register sets are reconfigurable: from 8×2048-element to 256×64-element 64-bit vectors on the VPP500/1 and from 8×1024-element to 256×32-element 64-bit vectors on the VPX240/10.

Further characteristics of these systems can be found in [13–15]. The above identifying characteristics affect the way the various algorithms perform on the two systems. For instance, because the arithmetic vector pipelines on the VPX240/10 are multiply–add pipelines, peak performance is achieved with two vector "multiply–add" instructions operating simultaneously on the separate pipelines; concurrent "add" and "multiply" instructions achieve the peak performance on the VPP500. Which architecture performs best for a given application depends, among other considerations, on how well vectorizable loops can be mapped to the peak performance situations, as we will see.

3.5.1. Theory. By analyzing the corresponding dependency graphs of our methods, the performance of the applications on the two architectures can be predicted. Given a particular architecture and assuming a certain level of unrolling, a dependency graph can be mapped to a timing diagram, which then can be used to predict how the calculation will perform. In our case, the architectures are vector-pipelined machines. Thus, the timing diagrams will involve scheduling of the pipelines into chimes, as the arithmetic and load/store pipelines can be chained.

As examples, we will examine closely the LB1 and finite difference calculations and only summarize the results for LB2 and LB3. Figures 2 and 3 depict the dependency graphs for LB1 and the finite difference method, respectively (cf. Table 6). Mapping the dependency graphs onto the two architectures in an optimal fashion (without loop unrolling) yields the pipeline

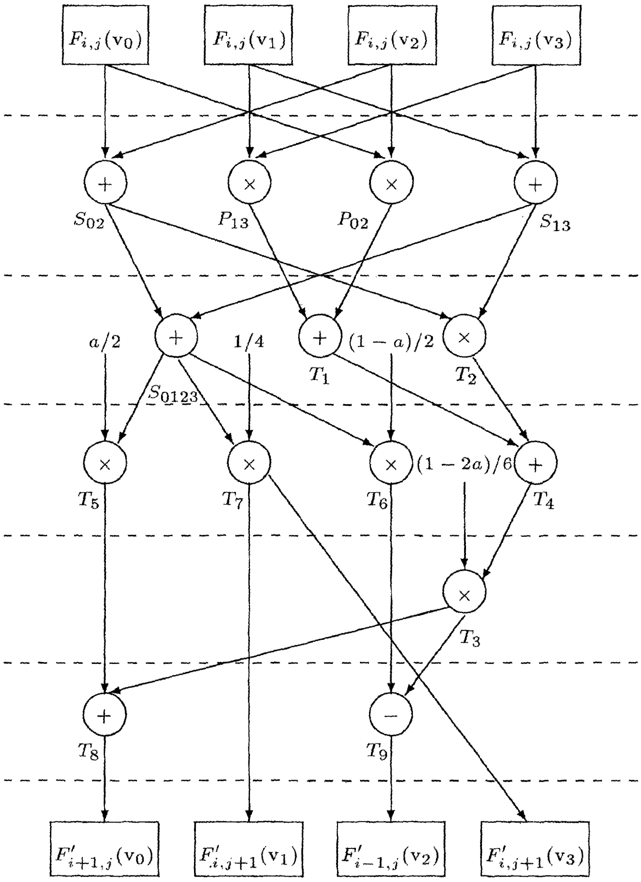

FIG. 2. *Dependency graph of LB*1 *computation.*

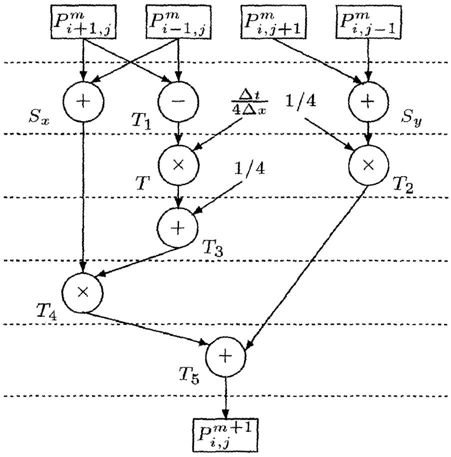

FIG. 3. *Dependency graph of finite difference computation*

scheduling timing diagrams given in Figures 4 and 5. Note that a certain amount of unrolling can offset some of the load and store operations and occupy otherwise idle arithmetic pipelines. Table 11 summarizes the chimes to compute the lattice Boltzmann and finite difference kernels for the two vector architectures in the study. With regard to timing predictions, Table 11 suggests certain relative timings for the methods. Table 12 gives the asymptotic timings of each lattice Boltzmann method relative to the finite difference method.[4] The predictions and actual results are compared below.

3.5.2. Measurements. Performance and timing measurements were obtained on the kernels for all four methods. These measurements included both interior and boundary node calculations. Measurements were taken for 512 time steps and a range of problem sizes $N \times N$ up to 1617×1617. Tables 13 and 14 list figures exhibiting the performance and timing measurements for the VPX240/10 and the VPP500/1, respectively. Timings relative to that of the finite difference method are depicted in Table 15. Asymptotically, we see that, respectively, LB1, LB2, and LB3 consume about 1.5, 1.4, and 2.0 of the time required of the finite difference computation, which is in agreement with the predictions of Table 12.

In terms of absolute performance, all four of the methods attain their highest performance levels on the VPX240/10 (Table 16). The highest maximum utilization (91.8%) is with LB1 on the VPP500/1; the lowest maximum utilization (53.8%) is with the finite difference method on the VPX240/10. Accuracy aside, a bottom-line comparison considers how much time it takes to compute a solution for a given problem size. Because of the differences observed in the utilization of the two systems, we find that the computational time for both systems is nearly the same for each of the respective methods, except for problem sizes below about 100×100. For each of the lattice Boltzmann and finite difference methods, the ratio between the VPP500/1 and VPX240/10 computational times is exhibited in the last column of Table 14. Indeed, for problems larger than about 100×100, the computational time on the VPP500/1 is less than 120% of that on the VPX240/10. This is interesting to note because the peak performance of the VPP500/1 is only 64% that of the VPX240/10, and it accents differences between the two vector-pipelined architectures.

3.6. Memory requirements. The memory requirements (in bytes) using 64-bit data for the lattice Boltzmann and finite difference methods are given by $M_{\text{lb}}(N_x, N_y) = 64N_xN_y$ and $M_{\text{fd}}(N_x, N_y) = 16N_xN_y$, respectively. However, due to the exclusion principle of the lattice Boltzmann methods, it may not be necessary to maintain full 64-bit precision arithmetic. Using single-bit precision arithmetic (with a special rounding function) would be analogous to a lattice gas method. But with regard to solving partial differential equations, lattice gas methods suffer from statistical fluctuations due to the limited precision of the occupation numbers. Certainly, there is some trade-off here between the full precision of lattice Boltzmann methods and the extremely limited precision of lattice gas methods. (See, for example, [2] for a thorough treatment of correlations in lattice gas methods.)

3.7. A remark on conservation laws and accuracy. The one conservation law in the lattice Boltzmann methods LB1, LB2, and LB3 is conservation of mass. Although they each possess (only) this local conservation law, the individual collision rules therein do not wholly adhere to it. Consider, for example, the single particle collision rules for LB3 (see Table 4). The mass along each of the two orthogonal directions is conserved separately. (A

[4] Note that in some cases, increasing the depth of unrolling can yield a *slight* gain in performance, but this is not significant with regard to our discussions.

similar observation can be made about the triple particle collisions in LB3.) However, in LB2 the single- and triple-particle collision rules do not preserve mass along the two orthogonal directions separately. (This is also the case in LB1.) The difference between LB1 and LB2 is that in LB1 two-particle collisions involve all possible configurations, i.e., both "orthogonal" and "head-on" collisions, whereas in LB2 the orthogonal and head-on configurations are treated separately. Keeping all this in mind, it is interesting to note that the accuracy of the lattice Boltzmann methods improves progressively from LB3 to LB2 to LB1. This suggests the hypothesis that lattice Boltzmann methods achieve greater accuracy when the collision rules are individually faithful to the overriding local conservation laws.

Table 15

Lattice Boltzmann to finite difference timing comparisons. Ratios of lattice Boltzmann to finite difference computational time, based on Table 14, are given on a per-time-step basis as a function of problem size N, for N × N grids.

METHOD	RATIO TO FINITE DIFFERENCE COMPUTATION TIME	
	VPX240/10 (2.5 Gflop/s peak)	VPP500/1 (1.6 Gflop/s peak)
LB1		LB2		LB3		
Table 16

Maximum sustained performances.

METHOD	VPX240/10			VPP500/1		
	Size (N×N)	Maximum Performance (Gflop/s)	Maximum Utilization (percent)	Size (N×N)	Maximum Performance (Gflop/s)	Maximum Utilization (percent)
LB1	1014	1.644	65.8	1026	1.469	91.8
LB2	1464	1.419	56.3	1026	1.363	85.2
LB3	1538	1.427	57.1	1026	1.321	82.6
FD	801	1.345	53.8	1602	1.228	76.8

4. Conclusions. We have introduced and studied three lattice Boltzmann methods for the 2-D convection–diffusion equation (1). The study included theoretical results such as conditions for convergence, the numerical verification of those results, and a detailed comparison of the methods with an analogous finite difference method. We conclude with the following observations:

1. *Domain of monotonicity.* LB1 and LB2 possess larger domains of monotonicity than does LB3. Further, the domain of monotonicity for LB3 is not preserved from one time step to another; hence, convergence for LB3 was obtained only for those initial conditions not only bounded by the domain of monotonicity but also bounded (much) more severely.
2. *Accuracy.* The accuracy improved progressively from LB3 to LB2 to LB1 over the test cases. LB1 exhibited the greatest accuracy; it was a little less than one (1) to about three (3) times worse than the accuracy exhibited by the finite difference method.
3. *Order of convergence.* Progressively from LB3 to LB2 to LB1, the lattice Boltzmann methods exhibited stronger and stronger evidence for second-order convergence. The evidence for the finite difference method was the strongest, however, with LB1 a close second.
4. *Performance measurements.* Generally, given a particular problem size the level of performance attained increased from the finite difference method to LB3 to LB2 to LB1, with LB1 achieving the highest utilization of the two systems tested.
5. *Timing measurements.* Timing measurements were compared given a particular problem size, i.e., without regard to accuracy. The computations of LB3 took twice the time of the finite difference method, and those of LB1 and LB2 each took about one and a half the time of the finite difference method.
6. *Memory requirements.* The lattice Boltzmann implementations required four times as much memory as the finite difference implementation. (At the expense of increased memory references, the lattice Boltzmann memory usage can be halved by employing "in place" calculations and a separate "advection step.") While in diffusive lattice Boltzmann methods this may be expected, it is not necessarily so in methods for systems involving multiple dependent variables, e.g., lattice Boltzmann methods for the Navier–Stokes equations. For example, the FHP model [9] for the 2-D Navier–Stokes equations requires six values per node, whereas a standard finite difference method would require three or five values per node, depending on whether a Eulerian or Lagrangian formulation is used. The 24-velocity model for the three-dimensional (3-D) Navier–Stokes equations can be reduced to 18 values per node [8]. A standard Navier–Stokes implementation would require four or seven values per node, depending on the formulation. The 2-D and 3-D Navier–Stokes lattice gas methods use at worst two and four and a half times as much memory as the finite difference methods, respectively. Additionally, it is unclear just how much precision is required in the lattice Boltzmann methods in order to obtain a certain level of accuracy. In lattice Boltzmann methods with the exclusion principle, it seems that full precision may not be necessary, depending on the objectives of the calculations. (The computations for the results presented herein were all performed in 64-bit arithmetic.) Perhaps even fixed point arithmetic can be used.
7. *Conservation laws and accuracy.* The computational results suggest that a lattice Boltzmann method attains greater accuracy the more the collision rules are individually faithful to the overriding local conservation laws.
8. *Entropy.* The lattice Boltzmann methods carefully control dissipation. Indeed, their entropy condition implies that they will dissipate physically [7, 10].

Appendices.

A. Analysis of LB1. Following are the details for the collision operator, linearized collision operator, discrete Hilbert expansion, and the consistency conditions.

Simplified, the collision operator can be written as follows:

$$
\begin{aligned}
\mathcal{C}(F)(\mathrm{v}_0) &= \tfrac{1+\epsilon}{4}[F(\mathrm{v}_0)+F(\mathrm{v}_1)+F(\mathrm{v}_2)+F(\mathrm{v}_3)]-F(\mathrm{v}_0)\\
&\quad -\tfrac{\epsilon}{6}[(F(\mathrm{v}_0)+F(\mathrm{v}_2))(F(\mathrm{v}_1)+F(\mathrm{v}_3))+F(\mathrm{v}_0)F(\mathrm{v}_2)+F(\mathrm{v}_1)F(\mathrm{v}_3)],\\
\mathcal{C}(F)(\mathrm{v}_1) &= \tfrac{1}{4}[F(\mathrm{v}_0)+F(\mathrm{v}_1)+F(\mathrm{v}_2)+F(\mathrm{v}_3)]-F(\mathrm{v}_1),\\
\mathcal{C}(F)(\mathrm{v}_2) &= \tfrac{1-\epsilon}{4}[F(\mathrm{v}_0)+F(\mathrm{v}_1)+F(\mathrm{v}_2)+F(\mathrm{v}_3)]-F(\mathrm{v}_2)\\
&\quad +\tfrac{\epsilon}{6}[(F(\mathrm{v}_0)+F(\mathrm{v}_2))(F(\mathrm{v}_1)+F(\mathrm{v}_3))+F(\mathrm{v}_0)F(\mathrm{v}_2)+F(\mathrm{v}_1)F(\mathrm{v}_3)],\\
\mathcal{C}(F)(\mathrm{v}_3) &= \tfrac{1}{4}[F(\mathrm{v}_0)+F(\mathrm{v}_1)+F(\mathrm{v}_2)+F(\mathrm{v}_3)]-F(\mathrm{v}_3)\,.
\end{aligned}
\tag{22}
$$

The linearized collision operator is given by

$$
\mathcal{L}=\tfrac{1}{4}\begin{bmatrix} -3 & 1 & 1 & 1\\ 1 & -3 & 1 & 1\\ 1 & 1 & -3 & 1\\ 1 & 1 & 1 & -3 \end{bmatrix},
$$

which is the circulant $\frac{1}{4}$ Circ$[-3, 1, 1, 1]$, and has the eigenvalues $\boldsymbol{\lambda}(\mathcal{L}) = (\lambda_0, \lambda_1, \lambda_2, \lambda_3) = (0, -1, -1, -1)$. (The corresponding eigenvectors are given in the text.)

The first few terms of the Hilbert expansion (2.3) are given as follows[5]:

1. $g^{(1)} = \sum_{k=0}^{3} c_k^{(1)}\mathbf{q}_k$, where $c_0^{(1)} = 0$, $c_1^{(1)} = -KA(u) + Lu_x$, $c_2^{(1)} = Lu_y$, and $c_3^{(1)} = 0$.
2. $g^{(2)} = \sum_{k=0}^{3} c_k^{(2)}\mathbf{q}_k$, where

$$
\begin{aligned}
c_0^{(2)} &= Tu_t + \tfrac{KL}{2}A'(u)u_x - \tfrac{L^2}{4}\nabla^2 u\,, & c_1^{(2)} &= L\sigma^{(1)}{}_x - KA'(u)\sigma^{(1)}\,,\\
c_2^{(2)} &= L\sigma^{(1)}{}_y\,, & c_3^{(2)} &= \tfrac{KL}{2}A'(u)u_x - \tfrac{L^2}{4}\nabla\cdot\overline{\overline{\nabla}}u\,.
\end{aligned}
$$

3. $g^{(3)} = \sum_{k=0}^{3} c_k^{(3)}\mathbf{q}_k$, where

$$
\begin{aligned}
c_0^{(3)} &= T\sigma^{(1)}{}_t + \tfrac{KL}{2}\partial_x[A'(u)\sigma^{(1)}] - \tfrac{L^2}{4}\nabla^2\sigma^{(1)}\,,\\
c_1^{(3)} &= L\sigma^{(2)}{}_x + K[1-6A'(u)\sigma^{(2)})] + \tfrac{KL^2}{4}A'(u)\nabla^2 u - \tfrac{K^2L}{2}(A'(u))^2u_x\\
&\quad - \tfrac{L^3}{12}(u_{xxx}+3u_{xyy})\,,\\
c_2^{(3)} &= L\sigma^{(2)}{}_y + \tfrac{KL^2}{2}[A'(u)u_{xy}+2u_xu_y] - \tfrac{L^3}{12}(3u_{xxy}+u_{yyy})\,,\\
c_3^{(3)} &= -\tfrac{L^2}{4}\nabla\cdot\overline{\overline{\nabla}}\sigma^{(1)} + \tfrac{KL}{2}\partial_x[A'(u)\sigma^{(1)}]\,.
\end{aligned}
$$

4. $g^{(4)} = \sum_{k=0}^{3} c_k^{(4)}\mathbf{q}_k$, where

$$
\begin{aligned}
c_0^{(4)} &= T\sigma^{(2)}{}_t - \tfrac{L^2}{4}\nabla^2\sigma^{(2)} + 3KL\partial_x[A'(u)\sigma^{(2)}]\\
&\quad + \tfrac{L^4}{96}(u_{xxxx}+6u_{xxyy}+u_{yyyy}) + \tfrac{K^2L^2}{8}A'(u)[A'(u)u_{xx}-4(u_x)^2]\\
&\quad + \tfrac{KL^3}{24}[6(u_xu_{yy}+u_yu_{xy}) - A'(u)(u_{xxx}+3u_{xyy})]\,,\\
c_1^{(4)} &= L\sigma^{(3)}{}_x + \tfrac{K}{2}[4-A'(u)\sigma^{(3)}]\,,\\
c_2^{(4)} &= L\sigma^{(3)}{}_y\,,\\
c_3^{(4)} &= -\tfrac{L^2}{4}\nabla\cdot\overline{\overline{\nabla}}\sigma^{(2)} + 3KL\partial_x[A'(u)\sigma^{(2)}] - \tfrac{L^4}{24}\nabla^3\cdot\overline{\overline{\nabla}}u\\
&\quad + \tfrac{KL^3}{6}[3u_xu_{xx} - A'(u)u_{xxx} - 3u_yu_{xy}] + \tfrac{K^2L^2}{4}A'(u)[A'(u)u_{xx}-4(u_x)^2]\,.
\end{aligned}
$$

[5] Note that lower-order consistency conditions have been used to simplify the coefficients of higher-order coefficients (this includes applying the choice that $\sigma^{(1)} = 0$ where appropriate).

5. $g^{(5)} = \sum_{k=0}^{3} c_k^{(5)}\mathbf{q}_k$, where $c_0^{(5)} = T\sigma^{(3)}{}_t - \frac{L^2}{4}\nabla^2\sigma^{(3)} + \frac{KL}{4}\partial_x[A'(u)\sigma^{(3)}]$, and the remaining coefficients $c_1^{(5)}$, $c_2^{(5)}$, and $c_3^{(5)}$ are not given because they are not used in the proofs.

The following are the consistency conditions for the first few orders of the Hilbert expansion:

1. $\mathcal{O}\big[\delta^2\big]$: $\partial_t u + c\partial_x A(u) = \nu\nabla^2 u$, in which $c = \frac{KL}{2T}$, $\nu = \frac{L^2}{4T}$, and $A(u) = u(1-u)$.
2. $\mathcal{O}\big[\delta^3\big]$: $\partial_t\sigma^{(1)} + c\partial_x[A'(u)\sigma^{(1)}] = \nu\nabla^2\sigma^{(1)}$.
3. $\mathcal{O}\big[\delta^4\big]$: $\partial_t\sigma^{(2)} + 6c\partial_x[A'(u)\sigma^{(2)}] = \nu\nabla^2\sigma^{(2)} - \mathcal{F}$, where $\mathcal{F} = \frac{\nu}{24}[u_{xxxx} + 6u_{xxyy} + u_{yyyy}] - \frac{KL^3}{24T}[A'(u)(u_{xxx}+3u_{xyy}) - 6(u_x u_{yy} + u_y u_{xy}) - \frac{K^2L^2}{8T}A'(u)[4(u_x)^2 - A'(u)u_{xx}]$.
4. $\mathcal{O}\big[\delta^5\big]$: $\partial_t\sigma^{(3)} + \frac{c}{2}\partial_x[A'(u)\sigma^{(3)}] = \nu\nabla^2\sigma^{(3)}$, which emits the exact solution $\sigma^{(3)} = 0$.

B. Analysis of LB2. The collision operator can be written as follows:

$$
\begin{aligned}
\mathcal{C}(F)(\mathrm{v}_0) &= \tfrac{1+\epsilon}{4}[F(\mathrm{v}_0) + F(\mathrm{v}_1) + F(\mathrm{v}_2) + F(\mathrm{v}_3)] - F(\mathrm{v}_0)\\
&\quad - \tfrac{\epsilon}{2}[F(\mathrm{v}_0)F(\mathrm{v}_2) + F(\mathrm{v}_1)F(\mathrm{v}_3)],\\
\mathcal{C}(F)(\mathrm{v}_1) &= \tfrac{1}{4}[F(\mathrm{v}_0) + F(\mathrm{v}_1) + F(\mathrm{v}_2) + F(\mathrm{v}_3)] - F(\mathrm{v}_1),\\
\mathcal{C}(F)(\mathrm{v}_2) &= \tfrac{1-\epsilon}{4}[F(\mathrm{v}_0) + F(\mathrm{v}_1) + F(\mathrm{v}_2) + F(\mathrm{v}_3)] - F(\mathrm{v}_2)\\
&\quad + \tfrac{\epsilon}{2}[F(\mathrm{v}_0)F(\mathrm{v}_2) + F(\mathrm{v}_1)F(\mathrm{v}_3)],\\
\mathcal{C}(F)(\mathrm{v}_3) &= \tfrac{1}{4}[F(\mathrm{v}_0) + F(\mathrm{v}_1) + F(\mathrm{v}_2) + F(\mathrm{v}_3)] - F(\mathrm{v}_3)\,.
\end{aligned}
\tag{23}
$$

The linearized collision operator $\mathcal{L}$ is as in LB1 and consequently so are its eigenvalues and eigenvectors.

The first few terms of the Hilbert expansion[5] are given as follows:

1. $g^{(1)} = \sum_{k=0}^{3} c_k^{(1)}\mathbf{q}_k$, where $c_0^{(1)} = c_3^{(1)} = 0$, $c_1^{(1)} = -KA(u) + Lu_x$, and $c_2^{(1)} = Lu_y$.
2. $g^{(2)} = \sum_{k=0}^{3} c_k^{(2)}\mathbf{q}_k$, where

$$
\begin{aligned}
c_0^{(2)} &= Tu_t + \tfrac{KL}{2}A'(u)u_x - \tfrac{L^2}{4}\nabla^2 u\,, & c_1^{(2)} &= L\sigma^{(1)}{}_x - KA'(u)\sigma^{(1)}\,,\\
c_2^{(2)} &= L\sigma^{(1)}{}_y\,, & c_3^{(2)} &= \tfrac{KL}{2}A'(u)u_x - \tfrac{L^2}{4}\nabla\cdot\overline{\nabla}u\,.
\end{aligned}
$$

3. $g^{(3)} = \sum_{k=0}^{3} c_k^{(3)}\mathbf{q}_k$, where

$$
\begin{aligned}
c_0^{(3)} &= T\sigma^{(1)}{}_t + \tfrac{KL}{2}\partial_x[A'(u)\sigma^{(1)}] - \tfrac{L^2}{4}\nabla^2\sigma^{(1)}\,,\\
c_1^{(3)} &= L\sigma^{(2)}{}_x + K[1 - 6A'(u)\sigma^{(2)})] + \tfrac{KL^2}{4}A'(u)\nabla^2 u - \tfrac{K^2L}{2}(A'(u))^2 u_x\\
&\quad - \tfrac{L^3}{12}(u_{xxx} + 3u_{xyy})\,,\\
c_2^{(3)} &= L\sigma^{(2)}{}_y - \tfrac{L^3}{12}(u_{xxx} + 3u_{xyy}) + \tfrac{KL^2}{2}(A'(u)u_y)\,,\\
c_3^{(3)} &= -\tfrac{L^2}{4}\nabla\cdot\overline{\nabla}\sigma^{(1)} + \tfrac{KL}{2}\partial_x[A'(u)\sigma^{(1)}]\,.
\end{aligned}
$$

4. $g^{(4)} = \sum_{k=0}^{3} c_k^{(4)}\mathbf{q}_k$, where

$$
\begin{aligned}
c_0^{(4)} &= T\sigma^{(2)}{}_t - \tfrac{L^2}{4}\nabla^2\sigma^{(2)} + 3KL\partial_x[A'(u)\sigma^{(2)}] + \tfrac{L^4}{96}(u_{xxxx} + 6u_{xxyy} + u_{yyyy})\\
&\quad + \tfrac{KL^3}{24}[6(u_x u_{yy} + u_y u_{xy}) - A'(u)(u_{xxx} + 3u_{xyy})]\\
&\quad + \tfrac{K^2L^2}{8}A'(u)[u_{xx} - 4(u_x)^2]\,,\\
c_1^{(4)} &= L\sigma^{(3)}{}_x + \tfrac{K}{2}[4 - A'(u)\sigma^{(3)}]\,,\\
c_2^{(4)} &= L\sigma^{(3)}{}_y\,,\\
c_3^{(4)} &= -\tfrac{L^2}{4}\nabla\cdot\overline{\nabla}\sigma^{(2)} + 3KL\partial_x[A'(u)\sigma^{(2)}] + \tfrac{L^4}{24}\nabla^3\cdot\overline{\nabla}u\\
&\quad + \tfrac{KL^3}{6}[3u_x u_{xx} - A'(u)u_{xxx} - 3u_y u_{xy}] + \tfrac{K^2L^2}{4}A'(u)[A'(u)u_{xx} - 4(u_x)^2]\,.
\end{aligned}
$$

5. $g^{(5)} = \sum_{k=0}^{3} c_k^{(5)} \mathbf{q}_k$, where $c_0^{(5)} = T\sigma^{(3)}{}_t - \frac{L^2}{4}\nabla^2\sigma^{(3)} + \frac{KL}{4}\partial_x[A'(u)\sigma^{(3)}]$, and the remaining coefficients $c_1^{(5)}$, $c_2^{(5)}$, and $c_3^{(5)}$ are not given because they are not used in the proofs.

The following are the consistency conditions for the first few orders of the Hilbert expansion:

1. $\mathcal{O}\big[\delta^2\big]$: $\partial_t u + c\partial_x A(u) = \nu\nabla^2 u$, in which $c = \frac{KL}{2T}$, $\nu = \frac{L^2}{4T}$, and $A(u) = u(1-u)$.
2. $\mathcal{O}\big[\delta^3\big]$: $\partial_t\sigma^{(1)} + c\partial_x[A'(u)\sigma^{(1)}] = \nu\nabla^2\sigma^{(1)}$.
3. $\mathcal{O}\big[\delta^4\big]$: $\partial_t\sigma^{(2)} + 6c\partial_x[A'(u)\sigma^{(2)}] = \nu\nabla^2\sigma^{(2)} - \mathcal{F}$, where $\mathcal{F} = \frac{\nu}{24}[u_{xxxx} + 6u_{xxyy} + u_{yyyy}] - \frac{KL^3}{24T}[A'(u)(u_{xxx} + 3u_{xyy}) - 6(u_x u_{yy} + u_y u_{xy})] - \frac{K^2L^2}{8T}A'(u)[4(u_x)^2 - A'(u)u_{xx}]$.
4. $\mathcal{O}\big[\delta^5\big]$: $\partial_t\sigma^{(3)} + \frac{c}{2}\partial_x[A'(u)\sigma^{(3)}] = \nu\nabla^2\sigma^{(3)}$, which emits the exact solution $\sigma^{(3)} = 0$.

C. Analysis of LB3. The collision operator can be written as follows:

$$
\begin{aligned}
\mathcal{C}(F)(\mathrm{v}_0) &= \tfrac{1+\epsilon}{2}[F(\mathrm{v}_0) + F(\mathrm{v}_2)] - F(\mathrm{v}_0) \\
&\quad + F(\mathrm{v}_0)F(\mathrm{v}_2)[F(\mathrm{v}_1) + F(\mathrm{v}_3) - (1+\epsilon)] - F(\mathrm{v}_1)F(\mathrm{v}_3)[F(\mathrm{v}_0) + F(\mathrm{v}_2) - 1], \\
\mathcal{C}(F)(\mathrm{v}_1) &= \tfrac{1}{2}[F(\mathrm{v}_1) + F(\mathrm{v}_3)] - F(\mathrm{v}_1) \\
&\quad - F(\mathrm{v}_0)F(\mathrm{v}_2)(F(\mathrm{v}_1) + F(\mathrm{v}_3) - 1) + F(\mathrm{v}_1)F(\mathrm{v}_3)(F(\mathrm{v}_0) + F(\mathrm{v}_2) - 1), \\
\mathcal{C}(F)(\mathrm{v}_2) &= \tfrac{1-\epsilon}{2}[F(\mathrm{v}_0) + F(\mathrm{v}_2)] - F(\mathrm{v}_2) \\
&\quad + F(\mathrm{v}_0)F(\mathrm{v}_2)[F(\mathrm{v}_1) + F(\mathrm{v}_3) - (1-\epsilon)] - F(\mathrm{v}_1)F(\mathrm{v}_3)[F(\mathrm{v}_0) + F(\mathrm{v}_2) - 1], \\
\mathcal{C}(F)(\mathrm{v}_3) &= \tfrac{1}{2}[F(\mathrm{v}_1) + F(\mathrm{v}_3)] - F(\mathrm{v}_3) \\
&\quad - F(\mathrm{v}_0)F(\mathrm{v}_2)[F(\mathrm{v}_1) + F(\mathrm{v}_3) - 1] + F(\mathrm{v}_1)F(\mathrm{v}_3)[F(\mathrm{v}_0) + F(\mathrm{v}_2) - 1].
\end{aligned}
\tag{24}
$$

The linearized collision operator is given by $\mathcal{L} = \frac{1}{2}\,\mathrm{Circ}[-1 - 2u + 2u^2, 2A(u), 1 - 2u + 2u^2, 2A(u)]$, which has the eigenvalues $\boldsymbol{\lambda}(\mathcal{L}) = (\lambda_0, \lambda_1, \lambda_2, \lambda_3) = (0, -1, -1, -4A(u))$. (The corresponding eigenvectors are given in the main text.)

The first few terms of the Hilbert expansion (2.3) for LB3 are similar to the expansions for LB1 and LB2; however, the terms are somewhat more complicated. Let $\lambda \equiv \lambda_3$. Then the first three terms of the Hilbert expansion for LB3 follow[5]:

1. $g^{(1)} = \sum_{k=0}^{3} c_k^{(1)} \mathbf{q}_k$, where $c_0^{(1)} = c_3^{(1)} = 0$, $c_1^{(1)} = -KA(u) + Lu_x$, and $c_2^{(1)} = Lu_y$.
2. $g^{(2)} = \sum_{k=0}^{3} c_k^{(2)} \mathbf{q}_k$, where

$$
\begin{aligned}
c_0^{(2)} &= Tu_t + \tfrac{KL}{2}A'(u)u_x - \tfrac{L^2}{4}\nabla^2 u, \qquad c_1^{(2)} = L\sigma^{(1)}{}_x - KA'(u)\sigma^{(1)}, \\
c_2^{(2)} &= L\sigma^{(1)}{}_y, \\
c_3^{(2)} &= \tfrac{L^2}{4}(4uu_x^2 - \overline{\nabla}u) + \tfrac{KL}{2}u_x[A'(u) - 4uA(u)] + K^2u[A(u)]^2 \\
&\quad + u[\sigma^{(1)}(\sigma^{(1)} - 2Lu_y) - 1].
\end{aligned}
$$

3. $g^{(3)} = \sum_{k=0}^{3} c_k^{(3)} \mathbf{q}_k$, where

$$
\begin{aligned}
c_0^{(3)} &= T\sigma^{(1)}{}_t + \tfrac{KL}{2}\partial_x[A'(u)\sigma^{(1)}] - \tfrac{L^2}{4}\nabla^2\sigma^{(1)}, \\
c_1^{(3)} &= K(1 - 6\sigma^{(2)} + 12u\sigma^{(2)}) + L\sigma^{(2)}{}_x - \tfrac{L^3}{12\lambda}[u_{xxx}(3 + 4\lambda) - 3u_{xyy}] \\
&+ \tfrac{L^3}{\lambda}u_x(uu_{xx} + u_x^2) + \tfrac{L^3}{4\lambda^2}\lambda_x(u_{xx} - 4uu_x^2 - u_{yy}) \\
&- \tfrac{2L^2}{\lambda}(\sigma^{(1)}uu_{xy} + uu_y\sigma^{(1)}{}_x + u_xu_y\sigma^{(1)}) + \tfrac{2L^2}{\lambda^2}\lambda_x uu_y\sigma^{(1)} \\
&+ \tfrac{L}{\lambda}[2u\sigma^{(1)}\sigma^{(1)}{}_x - u_x(1 - (\sigma^{(1)})^2)] + \tfrac{L}{\lambda^2}\lambda_x u[1 - (\sigma^{(1)})^2] - KL^2{u_x}^2
\end{aligned}
$$

$$\begin{aligned}
&+ \tfrac{KL^2}{4} A'(u)[3u_{xx} + u_{yy}] - \tfrac{KL^2}{\lambda} u_x^2 (1 + 10u - 18u^2) \\
&+ \tfrac{2KL^2}{\lambda} u_{xx}[A'(u) - uA(u)] - \tfrac{3KL^2}{2\lambda} u_{yy} A'(u) \\
&- \tfrac{KL^2}{2\lambda^2} \lambda_x u_x [A'(u) - 4uA(u)] + \tfrac{6K}{\lambda} uA'(u)[1 - (\sigma^{(1)})^2] \\
&+ \tfrac{12KL}{\lambda} uu_y \sigma^{(1)} A'(u) - \tfrac{K^2L}{2} u_x [A'(u)]^2 \\
&- \tfrac{K^2L}{\lambda} u_x (3 - 12u - 3u^2 + 44u^3 - 29u^4) \\
&- \tfrac{K^2L}{\lambda^2} u\lambda_x [A(u)]^2 - \tfrac{6K^3}{\lambda} uA'(u)[A(u)]^2 , \\
c_2^{(3)} &= L\sigma^{(2)}{}_y - \tfrac{L}{\lambda^2} u\lambda_y [1 - (\sigma^{(1)})^2] - \tfrac{L}{\lambda}[2u\sigma^{(1)}{}_y \sigma^{(1)} - u_y(1 - (\sigma^{(1)})^2)] \\
&- \tfrac{L^3}{3} u_{yyy} + \tfrac{L^3}{4\lambda}[\partial_y \overline{\overline{\nabla}} u - 4u_x(u_x u_y + 2uu_{xy})] - \tfrac{L^3}{4\lambda^2} \lambda_y [\overline{\overline{\nabla}} u - 4uu_x^2] \\
&+ \tfrac{K^2L}{\lambda^2} \lambda_y u [A(u)]^2 + \tfrac{2L^2}{\lambda^2}[\lambda(uu_y \sigma^{(1)}{}_y + u_y^2 \sigma^{(1)} + u\sigma^{(1)} u_{yy}) - u\sigma^{(1)} \lambda_y] \\
&+ \tfrac{KL^2}{2\lambda^2} \lambda_y u_x [A'(u) - 4uA(u)] + \tfrac{KL^2}{\lambda} u_x u_y (1 + 4u - 6u^2) \\
&- \tfrac{KL^2}{2\lambda} u_{xy}[A'(u) - 4uA(u)] - \tfrac{K^2L}{\lambda} u_y u A(u)(3 - 5u) , \\
c_3^{(3)} &= -2u(1 - \sigma^{(1)}\sigma^{(2)}) + \tfrac{2}{\lambda} u^2 \sigma^{(1)}[1 - (\sigma^{(1)})^2] + \tfrac{L^3}{2\lambda} uu_y [\overline{\overline{\nabla}} u - 4uu_x^2] \\
&+ \tfrac{2L}{\lambda} u^2 u_y [1 + (\sigma^{(1)})^2] - 2Lu(\sigma^{(1)}\sigma^{(1)}{}_y + u_y + \sigma^{(2)}) \\
&- \tfrac{L^2}{4}[\overline{\overline{\nabla}} u - 8uu_x \sigma^{(1)}{}_x] + \tfrac{L^2}{2\lambda} u\sigma^{(1)}[\overline{\overline{\nabla}} u - 4u(u_x^2 - 2u_y^2)] \\
&- \tfrac{KL^2}{\lambda} uu_x u_y [A'(u) - 4uA(u)] - \tfrac{2K^2L}{\lambda} u^2 u_y [A(u)]^2 \\
&+ \tfrac{KL}{2} \sigma^{(1)}{}_x [A'(u) - 4uA(u)] - KLu_x \sigma^{(1)}(1 + 2u - 4u^2) \\
&- \tfrac{KL}{\lambda} uu_x \sigma^{(1)}[A'(u) - 4uA(u)] + 2K^2 u\sigma^{(1)} A(u) A'(u) \\
&- \tfrac{2K^2}{\lambda} u^2 \sigma^{(1)} [A(u)]^2 .
\end{aligned}$$

4. $g^{(4)} = \sum_{k=0}^{3} c_k^{(4)} \mathbf{q}_k$, where all the coefficients are nonzero—even with $\sigma^{(1)} = 0$. We do not give them here since they are much too lengthy for the present text. Note, however, that $c_0^{(4)}$ can be easily determined from the $\mathcal{O}\big[\delta^4\big]$ consistency condition, which is given below.

Let $c = \frac{KL}{2T}$, $\nu = \frac{L^2}{4T}$, and $A(u) = u(1-u)$. Then the first few consistency conditions are as follows:

1. $\mathcal{O}\big[\delta^2\big]$: $\partial_t u + c\partial_x A(u) = \nu\nabla^2 u$.
2. $\mathcal{O}\big[\delta^3\big]$: $\partial_t \sigma^{(1)} + c\partial_x[A'(u)\sigma^{(1)}] = \nu\nabla^2\sigma^{(1)}$.
3. $\mathcal{O}\big[\delta^4\big]$: $\partial_t \sigma^{(2)} + 6c\partial_x[A'(u)\sigma^{(2)}] = \nu\nabla^2\sigma^{(2)} - \mathcal{F}$, where

$$\begin{aligned}
\mathcal{F} = &\tfrac{\nu}{2\lambda^3}\big[((\lambda_x)^2 - (\lambda_y)^2)(u_{xx} + 4u(u_x)^2 - u_{yy})\big] \\
&- \tfrac{\nu}{4\lambda^2}[2(\lambda_x \nabla\cdot\overline{\overline{\nabla}} u_x - \lambda_y \nabla\cdot\overline{\overline{\nabla}} u_y) + (\lambda_{xx}\nabla\cdot\overline{\overline{\nabla}} u - \lambda_{yy}\nabla\cdot\overline{\overline{\nabla}} u) \\
&\quad - 16uu_x(\lambda_x u_{xx} + \lambda_y u_{xy}) - 4u(u_x)^2 \nabla\cdot\overline{\overline{\nabla}}\lambda + 8(u_x)^2 u_y \lambda_y \\
&\quad - 16uu_x(\lambda_x u_{xx} + \lambda_y u_{xy}) - 8(u_x)^3 \lambda_x] + \tfrac{\nu}{4\lambda}[(u_{xxxx} + 2u_{xxyy} - u_{yyyy}) \\
&\quad - 8uu_x(u_{xxx} - u_{yyy}) - 8u(u_{xx})^2 - (u_x)^2(20u_{xx} - 4u_{yy}) \\
&\quad + 8(2u_x u_y + uu_{xy})u_{xy}] + \tfrac{\nu}{24}[7u_{xxxx} - 6u_{xxyy} + 7u_{yyyy}] \\
&- \tfrac{KL^3}{4T\lambda^3}(1 - 2u - 4u^2 + 4u^3)[(\lambda_x)^2 u_x - (\lambda_y)^2 u_y] \\
&+ \tfrac{KL^3}{8T\lambda^3}\big[8(1 - 2u - u^2 - u^3)\lambda_x u_{xx} - 6(1-u)\lambda_x u_{yy} \\
&\quad + (1 - 2u - 4u^2 + 4u^3)[(u_x \nabla\cdot\overline{\overline{\nabla}}\lambda) - \lambda_y u_{xy}] \\
&\quad - 4(1 + 10u - 18u^2)\lambda_x(u_x)^2 + 4(1 + 4u - 6u^2)\lambda_y u_x u_y\big] \\
&- \tfrac{KL^3}{8T\lambda}[(7 - 14u - 4u^2 - 4u^3)\nabla\cdot\overline{\overline{\nabla}} u_x - (18 + 72u - 132u^2)u_x u_{xx}
\end{aligned}$$

$$
\begin{aligned}
&- \; 8(4-14u)(u_x)^3 + 2(7+4u-6u^2)u_x u_{yy} + 2(2+41u-12u^2)u_y u_{xy} \\
&+ \; 8(1-3u)u_x(u_y)^2] - \tfrac{KL^3}{12T}[2A'(u)u_{xxx} - 9u_x u_{xx} + 3u_y u_{xy}] \\
+ \; & \tfrac{2\nu}{\lambda^3}u[(\lambda_x)^2 - (\lambda_y)^2] - \tfrac{\nu}{\lambda^2}[(u\nabla\cdot\overline{\nabla}\lambda) + 2(\lambda_x u_x - \lambda_y u_y)] + \tfrac{\nu}{\lambda}\nabla\cdot\overline{\nabla}u \\
- \; & \tfrac{K^2L^2}{2T\lambda^3}u^3(1-2u+u^2)[(\lambda_x)^2-(\lambda_y)^2] + \tfrac{K^2L^2}{4T\lambda^2}[u^3(1-2u+u^2)(\lambda_{xx}-\lambda_{yy}) \\
&- \; (7-4u-6u^2+88u^3-58u^4)\lambda_x u_x - 2u^2(3-8u+5u^2)\lambda_y u_y] \\
+ \; & \tfrac{K^2L^2}{4T\lambda}[(6-24u-3u^2+80u^3-212u^4)u_{xx} + u^2(3-8u+5u^2)u_{yy} \\
&- \; (24+6u+240u^2-212u^3)(u_x)^2 + 2u(3-4u+u^2)(u_y)^2] \\
- \; & \tfrac{K^2L^2}{8T}[4A'(u)(u_x)^2 - (A'(u))^2u_{xx}] - \tfrac{3K^3L}{T\lambda^2}u^3(1-4u+5u^2-2u^3) \\
- \; & \tfrac{3KL}{T\lambda}(1-4u)u_x + \tfrac{3KL}{T\lambda^2}uA'(u)\lambda_x + \tfrac{3K^3L}{T\lambda}u^2(3-16u+25u^2-12u^3).
\end{aligned}
$$

4. $\mathcal{O}[\delta^5]$:

$$\partial_t\sigma^{(3)} + \tfrac{c}{2}\partial_x[A'(u)\sigma^{(3)}] = \nu\nabla^2\sigma^{(3)} - \mathcal{G}\,, \tag{25}$$

where for $u \in C^4((0,1)^2,(0,1))$, $\mathcal{G}$ is a smooth function of the constants T, K, and L, and u and $\sigma^{(2)}$ and their derivatives. In general, $\mathcal{G}$ is nonzero, and hence, contrary to the cases for LB1 and LB2, $\sigma^{(3)} = 0$ is not a solution of the fifth-order consistency condition (25). The fact the $\sigma^{(3)} = 0$ is *not* a solution to (25) may attest to the unfavorable numerical results for LB3.

Acknowledgments. The author thanks Professors C. D. Levermore (University of Arizona) and G. H. Rodrigue (University of California, Davis and LLNL), Dr. S. E. Zarantonello (Silicon Graphics Computer Systems), Messrs. S. Gavali (Fujitsu America, Inc. (FAI)) and T. Sands (FAI), and Ms. L. Tingley (FAI) for their valued comments and suggestions in reviewing the manuscript; Professor H. A. van der Vorst (University of Utrecht, The Netherlands) for an insightful and enjoyable discussion at Supercomputing '92 (Minneapolis, MN); and Dr. S. Succi (IBM-ECSEC, Rome, Italy) for valuable discussions.

DIRECT NUMERICAL CALCULATIONS OF A NEUTRAL STABILITY CURVE FOR ONE-DIMENSIONAL DETONATIONS*

WEI CAI[†], WONHO OH[‡], AND YOULAN ZHU[§]

Abstract. In this paper we calculate the neutral stability curve for one-dimensional detonation waves based on direct numerical simulations of the Euler equations. We propose multidimensional spectral methods with accurate shock tracking to study the stability of steady Chapman–Jouguet detonations. The numerical methods proposed here can be easily generalized for the simulation of multidimensional detonation waves. The detonations under consideration are for an ideal gas in an irreversible, unimolecular reaction $A \rightarrow B$ with finite Arrhenius reaction rate. Critical overdrives f^* for various heat releases Q's are computed. The neutral stability curve is obtained and compared with the results of the eigenmode analysis by Erpenbeck [*Phys. Fluids*, 7 (1964), pp. 684–696].

Key words. detonation waves, neutral stability, multidomain spectral methods, shock tracking

AMS subject classifications. 76Q05, 76V05

1. Introduction.

The stability of detonation waves is a complex yet fascinating multidimensional phenomenon. There has been renewed interest in understanding the underlying physics of this phenomenon [1, 2, 4, 10, 14, 16]. Most of the observed detonation waves travelling in rectangular or circular channels demonstrate transverse wave structures along the precursor shock front in the form of mach-stems—so-called "triple points." Such structures are believed to play important roles in the stability of multidimensional detonation waves. The study of stability of one-dimensional detonation waves provides a stepping stone to the more complete multidimensional stability problem.

Basically, there have been two approaches in studying the stability of one-dimensional detonations. The first is to study the hydrodynamic stability of the linearized Euler equations with respect to a given steady solution by using eigenmode analysis; the second approach is to use direct numerical simulation of one-dimensional Euler equations. Erpenbeck started the first approach for an ideal gas in an irreversible, unimolecular reaction $A \rightarrow B$ with an Arrhenius reaction rate [8]. Later, Abouseif and Toong [1] derived an approximate wave equation for the perturbed state variables. They successfully identified the sources of longitudinal instability under the assumption of small perturbation and high activation energy.

However, as common to any linearized analysis of a strongly nonlinear problem, it could not explain all the nonlinear phenomena of reacting flows. On the other hand, direct numerical study of one-dimensional detonations includes the work of Fickett and Wood [9] and Fickett, Jacobson, and Schott [10] using a method of characteristics. In [10], they considered two reaction rates with induction zones. Recently, Bourlioux, Majda, and Roytburd [4] have studied the same problem posed by Erpenbeck [8] using both asymptotic eigenmode analysis and improved numerical simulations based on the shock capturing scheme—piecewise parabolic methods (PPM). They provide a detailed numerical convergence study and an asymptotic analysis for the case when the heat release $Q = 50$ in the one step reaction $A \rightarrow B$ and the activation energy $E^+ = 50$ for an ideal gas with gas constant $\gamma = 1.2$.

So far there has been no attempt to calculate the neutral stability curve for all heat release and activation energy parameters based on direct numerical simulations of full Euler

equations. In Erpenbeck's early work [8], a crude curve of such kind was given based on the eigenmode analysis. In this paper, we will propose a numerical method for computing reacting shock waves and calculate the neutral stability curve for one-dimensional detonations under one-dimensional longitudinal disturbances. Theoretically, similar neutral curves could be sought for the case when the disturbance is two or three dimensional. We believe that such a question of multidimensional stability problem is best answered when simulations are done for multidimensional flows. In this paper, we will concentrate on the one-dimensional stability studies only.

The purpose of this work is twofold. The first is to introduce a high-order numerical method which is designed to fit the simulations of multidimensional detonations; the second is to provide a parametric study of the neutral stability curve for one-dimensional detonations which have aided our study of multidimensional detonations [3]. The novel feature of our algorithm is the high-order scheme used in tracking the detonation front compared with the first-order scheme used in [4]; also a multidomain approach is used so different numerical discretizations can be used in various parts of the flow field, a feature which proves to be important in the calculation of two-dimensional detonation waves where triple shocks occur along the detonation front [3].

2. Stability of steady detonations. We will consider the ideal Zeldovich, von Neumann, and Doering model of a steady detonation that is assumed to have a steady solution with constant shock speed D. According to the classical Chapman–Jouguet theory, there is a minimum shock speed D_j below which no strong detonation is possible. Within a gas dynamic shock transition, there are not enough molecular collisions to cause chemical reactions. Therefore, we will assume no chemical reactions across the shock and will treat the front as a mathematical discontinuity. This will enable us to use a shock tracking algorithm for the shock front.

We adopt the simple model suggested by Erpenbeck in [8] which assumes a one-step $A \rightarrow B$, irreversible exothermic reaction with a finite Arrhenius reaction rate. Here A denotes the unreacted fuel and B the product. Gas particles upon passing across the shock front will initiate chemical reactions immediately according to the Arrhenius rate. The reacting gas for such a system will be governed by the following Euler equations, coupled with an equation for the production of species (only one such equation is needed here, as the other species is obtained from the continuity equation):

$$\frac{\partial \vec{\mathbf{u}}}{\partial t} + \frac{\partial \mathbf{F}(\vec{\mathbf{u}})}{\partial x} = \Psi(\vec{\mathbf{u}}), \tag{1}$$

$$\vec{\mathbf{u}} = \begin{pmatrix} \rho \\ \rho u \\ \rho e \\ \rho\lambda \end{pmatrix}, \qquad \mathbf{F}(\vec{\mathbf{u}}) = \begin{pmatrix} \rho u \\ \rho u + p \\ \rho u e + u p \\ \rho u \lambda \end{pmatrix}, \tag{2}$$

and

$$\Psi(\vec{\mathbf{u}}) = \begin{pmatrix} 0 \\ 0 \\ 0 \\ -\omega \end{pmatrix}, \tag{3}$$

where $p = \rho T$, $e = \frac{1}{\gamma-1}\frac{p}{\rho} + \frac{u^2}{2} + \lambda Q$, and $\omega = K\rho\lambda \exp(-\frac{E^+}{T})$. We take the ratio of specific heats $\gamma = 1.2$ in all our computations. ρ, u, p, λ, e, T, E^+, and Q are density, flow velocity, pressure, mass fraction of reactant, total specific energy, temperature, activation energy, and heat release, respectively. Equation (1) also can be rewritten in the nonconservative form

$$\frac{\partial \vec{\mathbf{u}}}{\partial t} + \mathbf{A}\frac{\partial \vec{\mathbf{u}}}{\partial x} = \Psi(\vec{\mathbf{u}}), \tag{4}$$

where $\mathbf{A} = \frac{\partial \mathbf{F}}{\partial \vec{\mathbf{u}}}$ is the Jacobian matrix of flux function $\mathbf{F}(\vec{\mathbf{u}})$.

All quantities in (1) and (4) have been nondimensionalized by their reference quantities in the unreacted region. They are given as follows ("$\longleftarrow$" indicates nondimensionalization and the subscript "0" denotes unreacted gas states):

$$\begin{aligned} p &\longleftarrow \frac{p}{p_0}, \\ \rho &\longleftarrow \frac{\rho}{\rho_0}, \\ u &\longleftarrow \frac{u}{\sqrt{RT_0}}, \\ T &\longleftarrow \frac{T}{T_0}, \\ E^+ &\longleftarrow \frac{E^+}{RT_0}, \\ Q &\longleftarrow \frac{Q}{RT_0}, \\ t &\longleftarrow \frac{t}{t^*}, \\ x &\longleftarrow \frac{x}{\sqrt{RT_0}t^*}, \end{aligned}$$

where t^* is the half reaction time.

We consider an overdriven detonation travelling in a one-dimensional tube. The flow is driven by a piston and the shock front propagating to the right of the tube into unreacted gas. Given the speed of the piston and the initial states of unreacted gas in front of the shock, the flow field can be obtained as the solution of (1) or (4). For the case of overdriven detonation considered here, a steady solution can be easily obtained by solving the Rankine–Hugoniot condition which connects the states in front of the shock to all the states after the shock [11]. The shock speed D parameterizes the family of steady solutions if we assume that the states behind the final state (where chemical reaction terminates) remain constant. The overdrive f is defined as

$$f = \left(\frac{D}{D_j}\right)^2.$$

It has been observed since the findings of Campbell and Woodhead [5] that detonation waves in the real world are almost always unstable. The work of Erpenbeck in 1964 analyzed the stability of steady detonations based on the linearized Euler equations (1)–(3). If only one-dimensional perturbation is considered, for given heat release Q the overdrive f will dictate the stability of the detonations. There is a critical overdrive value f^* such that the steady solution will be unstable if $f < f^*$ and stable otherwise. For $Q = 50$, Erpenbeck predicted $f^* = 1.76$ [8]. Later, in the work of Bourlioux, Majda, and Roytburd [4], f^* was corrected to be 1.73. Erpenbeck provided a neutral stability curve (see the dashed curve in Figure 10 of [8]) based on his eigenmode analysis. It is our objective to calculate the neutral curve by a direct numerical simulation of equations (1)–(3).

3. Numerical methods.

3.1. Multidomain spectral solutions. In this section, we will present a numerical method which could be generalized to a multidimensional simulation of detonation waves. The major difficulties in simulating reacting flow numerically result from disparities between hydrodynamic scales and chemical reaction scales and in the strong dependence of reaction rate on the flow temperature via the Arrhenius rate constant. Traditionally shock capturing schemes were designed to smooth shock. By introducing a considerable amount of numerical viscosity near the shock front, they tend to distort the chemical reaction in the form of unphysical detonations [6] and unintended reactions [7]. With this in mind, we propose to use a multidomain technique as the main framework of our numerical method and tracking technique to accurately represent the shock dynamics without unnecessary numerical viscosities. A similar approach has been used in [13] in the study of the stability of a shock wave interacting with a vortex. In the setting of multidomain approaches, we could apply different types of spatial derivative discretization techniques in different subdomains based on the local properties of the solutions and different time integration techniques. Results in this direction for two-dimensional detonations are reported in [3].

Let $I = [x_{bd}, x_s]$ be the physical domain where the solution is sought. x_{bd} is the left boundary and $x_s = x_s(t)$ is the shock front. The solution domain I will be divided into subdomains I_k,

$$I_k = [a_{k+1}(t), a_k(t)], \qquad k = 1, \dots, M, \tag{5}$$

$$x_{bd} = a_{M+1}(t) < a_M(t) < \cdots < a_2(t) < a_1(t) = x_s(t). \tag{6}$$

The speed of the shock front is $V(t) = \dot{x_s}(t) = \dot{a_1}(t)$. Interfaces $a_1(t), \dots, a_{M+1}(t)$ are generally functions of time t and their evolutions will be determined by corresponding ODEs.

The multidomain spectral solution is denoted as

$$\vec{\mathbf{u}}(x,t) = \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} = \begin{pmatrix} \rho \\ \rho u \\ \rho e \\ \rho\lambda \end{pmatrix} \tag{7}$$

and on each domain I_k we define

$$\vec{\mathbf{u}}_{n_k} = \vec{\mathbf{u}}|_{I_k} = \begin{pmatrix} u_1^{(k)} \\ u_2^{(k)} \\ u_3^{(k)} \\ u_4^{(k)} \end{pmatrix}, \tag{8}$$

where n_k is the number of mesh points used in I_k. To compute the spectral solution $\vec{\mathbf{u}}_{n_k}$ on subdomain I_k, we first map I_k into a reference domain $[-1, 1]$,

$$x \in [a_{k+1}(t), a_k(t)] \longrightarrow \xi \in [-1, 1] \tag{9}$$

with

$$\begin{cases} T &= t, \\ \xi &= \xi(x,t) = -1 + 2\frac{x - a_{k+1}(t)}{a_k(t) - a_{k+1}(t)}, \end{cases} \tag{10}$$

or

$$\begin{cases} t &= T, \\ x &= x(\xi, T) = a_{k+1}(t) + \frac{\xi+1}{2}(a_k(t) - a_{k+1}(t)). \end{cases} \tag{11}$$

Let $\{\xi_0^{(k)}, \xi_1^{(k)}, \dots, \xi_{n_k}^{(k)}\}$ be the Chebyshev–Lobatto points on $[-1, 1]$; i.e.,

$$\xi_i^{(k)} = \cos\frac{i\pi}{n_k}, \qquad i = 0, \dots, n_k. \tag{12}$$

Then $x_i^{(k)} = x(\xi_i^{(k)}, T)$ are the mesh points in I_k.

Using the method of lines, the semidiscretized Chebyshev collocation solution $\vec{\mathbf{u}}_{n_k}(x,t)$ for (4) on subdomain I_k satisfies the following set of ODEs for the unknowns $\vec{\mathbf{u}}_{n_k}(x_i^{(k)}, t)$:

$$\tag{13} \left\{ \begin{array}{rcl} \frac{\partial \vec{\mathbf{u}}_{n_k}}{\partial t} + \mathbf{A}(\vec{\mathbf{u}}_{n_k})(\mathcal{I}_{n_k}\vec{\mathbf{u}}_{n_k})_x &=& \Psi(\vec{\mathbf{u}}_{n_k})|_{x=x_i^{(k)}}, \quad 0 \le i \le n_k, \\ \dot{a}_{k+1}(t) &=& V_{k+1}, \\ \dot{a}_k(t) &=& V_k, \\ \dot{V}_{k+1} &=& h_{k+1}, \\ \dot{V}_k &=& h_k, \end{array} \right.$$

where V_k is the speed of interface a_k and $h_k = 0$ if $k \neq 1$. The acceleration of the shock front $h_1 = \dot{V}_1 = \dot{V}(t)$ will be derived in (47). The states of gas in front of x_s are assumed to be given. The states behind $x_{bd} = a_{M+1}$ are assumed to be the steady solution at the Chapman–Jouguet points [11].

The interpolation operator $\mathcal{I}_{n_k}$ is defined on the Chebyshev–Lobatto points $\{\xi_i^{(k)}\}$ on $[-1, 1]$,

$$\tag{14} \mathcal{I}_{n_k}\vec{\mathbf{u}}_{n_k} = \sum_{j=0}^{n_k} \vec{\mathbf{u}}_{n_k}(\xi_j^{(k)})\psi_j(\xi), \qquad \xi \in [-1, 1],$$

where

$$\psi_j(\xi) = \frac{(-1)^{j+1}(1-\xi^2)T'_{n_k}(\xi)}{\bar{c}_j n_k^2(\xi - \xi_j^{(k)})}, \quad \bar{c}_0 = \bar{c}_{n_k} = 2, \quad \bar{c}_j = 1 \quad \text{if } 1 \le j \le n_k - 1.$$

$T_{n_k}(\xi) = \cos(n_k \cos^{-1}(\xi))$ is the Chebyshev polynomial of first kind. Thus

$$\tag{15} \frac{d}{d\xi}\mathcal{I}_{n_k}\vec{\mathbf{u}}_{n_k}(\xi_i^{(k)}) = \sum_{j=0}^{n_k} \vec{\mathbf{u}}_{n_k}(\xi_j^{(k)})\psi'_j(\xi_i^{(k)}).$$

And, finally,

$$\tag{16} (\mathcal{I}_{n_k}\vec{\mathbf{u}}_{n_k})_x|_{x=x_i^{(k)}} = (\mathcal{I}_{n_k}\vec{\mathbf{u}}_{n_k})_\xi(\xi_i^{(k)}, T)\xi_x(x_i^{(k)}, t).$$

We convert all $\frac{\partial}{\partial x}$ and $\frac{\partial}{\partial t}$ derivatives into $\frac{\partial}{\partial \xi}$ and $\frac{\partial}{\partial T}$ derivatives; i.e.,

$$\tag{17} \left\{ \begin{array}{rcl} \frac{\partial}{\partial t} &=& \xi_t(x,t)\frac{\partial}{\partial \xi} + \frac{\partial}{\partial T}, \\ \frac{\partial}{\partial x} &=& \xi_x(x,t)\frac{\partial}{\partial \xi}. \end{array} \right.$$

It follows from (13) that $\vec{\mathbf{u}}_{n_k}(\xi, T)$ satisfies

$$\tag{18} \left\{ \begin{array}{rcl} \frac{\partial \vec{\mathbf{u}}_{n_k}}{\partial T} + [\mathbf{A}(\vec{\mathbf{u}}_{n_k})\xi_x + \xi_t](\mathcal{I}_{n_k}\vec{\mathbf{u}}_{n_k})_\xi &=& \Psi(\vec{\mathbf{u}}_{n_k})|_{\xi=\xi_i^{(k)}}, \\ \dot{a}_k &=& V_k, \\ \dot{a}_{k+1} &=& V_{k+1}, \\ \dot{V}_k &=& h_k, \\ \dot{V}_{k+1} &=& h_{k+1}. \end{array} \right.$$

The stability of multidomain spectral solutions by (18) for $k = 1, \ldots, M$ depends on the treatment of values on the interface between neighboring subdomains. We discuss the procedure for calculating those values in the following subsection.

3.2. Characteristic correction for interface treatment. Consider subdomains $I_{k+1} = [a_{k+2}, a_{k+1}]$ and $I_k = [a_{k+1}, a_k]$ with a common interface at a_{k+1}. For the simplicity of illustration, we assume that a fully discretized version of (18) has been obtained by using the Euler forward method for the time derivative; therefore, we have

$$\vec{\mathbf{u}}^{n+1}_{n_k,i} = \vec{\mathbf{u}}^{n}_{n_k,i} - \Delta T[\mathbf{A}(\vec{\mathbf{u}}_{n_k,i})\xi_x + \xi_t](\mathcal{I}_{n_k}\vec{\mathbf{u}}^{n}_{n_k})_\xi|_{\xi=\xi_i^{(k)}} + \Delta T\Phi(\vec{\mathbf{u}}^{n}_{n_k,i}), \tag{19}$$

where $\vec{\mathbf{u}}_{n_k,i} = \vec{\mathbf{u}}_{n_k}(\xi_i^{(k)}, T^n)$ and T^n is the discretized time with $\Delta T = T^{n+1} - T^n$.

Similarly, on subdomain I_{k+1} we have

$$\vec{\mathbf{u}}^{n+1}_{n_{k+1},i} = \vec{\mathbf{u}}^{n}_{n_{k+1},i} - \Delta T[\mathbf{A}(\vec{\mathbf{u}}_{n_{k+1},i})\xi_x + \xi_t](\mathcal{I}_{n_{k+1}}\vec{\mathbf{u}}^{n}_{n_{k+1}})_\xi|_{\xi=\xi_i^{(k+1)}} + \Delta T\Phi(\vec{\mathbf{u}}^{n}_{n_{k+1},i}), \tag{20}$$

where $\vec{\mathbf{u}}_{n_{k+1},i} = \vec{\mathbf{u}}_{n_{k+1}}(\xi_i^{(k+1)}, T^n)$.

Therefore, from (19) and (20), two solution vectors will be computed on interface a_{k+1}; i.e.,

$$\vec{\mathbf{u}}^L = \vec{\mathbf{u}}_{n_{k+1}}(x_0^{(k+1)}), \qquad \vec{\mathbf{u}}^R = \vec{\mathbf{u}}_{n_k}(x_{n_k}^{(k)}). \tag{21}$$

For $\vec{\mathbf{u}}$ to be continuous at interface a_{k+1}, $\vec{\mathbf{u}}_{n_k}, \vec{\mathbf{u}}_{n_{k+1}}$ should have the same value. Also, any choice of this value should be based on the characteristic information of the hyperbolic systems (4) [12].

Let $\vec{\mathbf{u}}_{\text{roe}}(a_{k+1})$ be the Roe-average state between $\vec{\mathbf{u}}^L$ and $\vec{\mathbf{u}}^R$ [15]. Using this $\vec{\mathbf{u}}_{\text{roe}}(a_{k+1})$, we compute the Jacobian of flux $\mathbf{F}(\vec{\mathbf{u}})$ in (2) as

$$\mathbf{A} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ \alpha_1 & \alpha_2 & (\gamma - 1) & \alpha_3 \\ \beta_1 & \beta_2 & \gamma u & \beta_3 \\ -\lambda u & \lambda & 0 & u \end{pmatrix}, \tag{22}$$

where

$$\begin{aligned} \alpha_1 &= \tfrac{\gamma-3}{2}u^2, \\ \alpha_2 &= (3-\gamma)u, \\ \alpha_3 &= -(\gamma - 1)Q, \\ \beta_1 &= -\gamma u e + (\gamma - 1)(u^2 + \lambda u Q), \\ \beta_2 &= \gamma e - \tfrac{3(\gamma-1)}{2}u^2 - (\gamma - 1)\lambda Q, \\ \beta_3 &= -(\gamma - 1)u, \end{aligned}$$

and e is the internal energy

$$e = \frac{1}{\gamma - 1}\frac{p}{\rho} + \frac{u^2}{2} + \lambda Q.$$

Matrix $\mathbf{A}$ has four eigenvalues

$$\mu_1 = u - c, \quad \mu_2 = \mu_3 = u, \quad \mu_4 = u + c, \tag{23}$$

where $c = \sqrt{\gamma(p/\rho)}$ is the sound speed. The four left and right eigenvectors are $\mathbf{l}^{(k)}$ and $\mathbf{r}^{(k)}$, $1 \le k \le 4$,

$$\mathbf{l}^{(1)} = \frac{1}{2}\left(b_2 + \frac{u}{c}, -ub_1 - \frac{1}{c}, b_1, -Qb_1\right), \tag{24}$$

$$\mathbf{l}^{(2)} = (-\lambda b_2, \lambda u b_1, -\lambda b_1, 1 + \lambda b_1 Q), \tag{25}$$

$$\mathbf{l}^{(3)} = (1 - \theta b_2, \theta u b_1, -\theta b_1, -1 + \theta b_1 Q), \tag{26}$$

$$\mathbf{l}^{(4)} = \frac{1}{2}\left(b_2 - \frac{u}{c}, -u b_1 + \frac{1}{c}, b_1, -Q b_1\right), \tag{27}$$

and

$$\mathbf{r}^{(1)} = (1, u - c, h - uc, \lambda)^{\mathrm{T}}, \tag{28}$$

$$\mathbf{r}^{(2)} = \left(1, u, \frac{u^2}{2} + Q, 1\right)^{\mathrm{T}}, \tag{29}$$

$$\mathbf{r}^{(3)} = \left(1, u, \frac{u^2}{2}, 0\right)^{\mathrm{T}}, \tag{30}$$

$$\mathbf{r}^{(4)} = (1, u + c, h + uc, \lambda)^{\mathrm{T}}, \tag{31}$$

where $\theta = 1 - \lambda$, $b_1 = \frac{\gamma - 1}{c^2}$, $b_2 = \frac{u^2}{2} b_1$, and $h = c^2 + \frac{u^2}{2} - \lambda Q$.

It is easy to check that

$$\mathbf{l}^{(p)} \circ \mathbf{r}^{(q)} = \delta_{p,q}, \qquad p, q = 1, \ldots, 4. \tag{32}$$

Now define the left eigenvector matrix $\mathbf{P}$:

$$\mathbf{P} = \begin{pmatrix} \mathbf{l}^{(1)} \\ \mathbf{l}^{(2)} \\ \mathbf{l}^{(3)} \\ \mathbf{l}^{(4)} \end{pmatrix}; \tag{33}$$

then

$$\mathbf{P}^{-1} = (\mathbf{r}^{(1)}, \mathbf{r}^{(2)}, \mathbf{r}^{(3)}, \mathbf{r}^{(4)}).$$

We define both characteristic decompositions for $\vec{\mathbf{u}}^L$, $\vec{\mathbf{u}}^R$ as

$$\vec{w}^L = \mathbf{P}\vec{\mathbf{u}}^L = \begin{pmatrix} w_1^L \\ w_2^L \\ w_3^L \\ w_4^L \end{pmatrix}, \qquad \vec{w}^R = \mathbf{P}\vec{\mathbf{u}}^R = \begin{pmatrix} w_1^R \\ w_2^R \\ w_3^R \\ w_4^R \end{pmatrix}. \tag{34}$$

And common characteristic values on the interface should be assigned on interface a_{k+1} based on the signs of $\mu_i - \dot{a}_{k+1}$; i.e., for $1 \le i \le 4$,

$$w_i = \begin{cases} w_i^R & \text{if } \mu_i - \dot{a}_{k+1} \le 0, \\ w_i^L & \text{otherwise.} \end{cases} \tag{35}$$

Finally, we set $\vec{w} = (w_1, w_2, w_3, w_4)^{\mathrm{T}}$ and

$$\vec{\mathbf{u}}^L = \vec{\mathbf{u}}^R = \vec{\mathbf{u}}(a_{k+1}) \equiv \mathbf{P}^{-1}\vec{w}. \tag{36}$$

3.3. The tracking algorithm for the shock front. To complete system (18), we need to give an ODE for shock speed $V(t) = V_1(t)$. Here a higher-order tracking algorithm will be used for the front shock; a previous attempt to track detonation waves can be found in [2]. We start by using the Rankine–Hugoniot condition across the shock front; i.e.,

$$\left\{\begin{array}{rcl} \rho_0(u_0 - V) &=& \rho_1(u_1 - V), \\ \rho_0(u_0 - V)^2 + p_0 &=& \rho_1(u_1 - V)^2 + p_1, \\ \frac{\gamma}{\gamma-1}\frac{p_0}{\rho_0} + \frac{1}{2}(u_0 - V)^2 &=& \frac{\gamma}{\gamma-1}\frac{p_1}{\rho_1} + \frac{1}{2}(u_1 - V)^2, \\ \lambda_0 &=& \lambda_1, \end{array}\right. \tag{37}$$

where “0” denotes the states in front of the shock and “1” the states behind the shock.

Solving the quantities behind the shock in terms of those in front of the shock, we get

$$\left\{\begin{array}{rcl} \rho_1 &=& \rho_0\frac{\frac{\gamma+1}{\gamma-1}M_0^2}{\frac{2}{\gamma-1}+M_0^2}, \\ u_1 &=& u_0 - (u_0 - V)(1 - \frac{\rho_0}{\rho_1}), \\ p_1 &=& p_0 + \rho_0(u_0 - V)^2(1 - \frac{\rho_0}{\rho_1}), \\ \lambda_1 &=& \lambda_0, \end{array}\right. \tag{38}$$

where mach number $M_0 = \frac{|u_0-V|}{c_0}$, $c_0 = \sqrt{\gamma(p_0/\rho_0)}$.

Define the derivative following the motion of the shock front $\frac{D}{Dt} = \frac{\partial}{\partial t} + V(t)\frac{\partial}{\partial x}$ and differentiate both sides of (38) to get

$$\begin{array}{rcl} \frac{D\rho_1}{Dt} &=& E_1\dot{V} + F_1, \\ \frac{Du_1}{Dt} &=& E_2\dot{V} + F_2, \\ \frac{Dp_1}{Dt} &=& E_3\dot{V} + F_3, \\ \frac{D\lambda_1}{Dt} &=& E_4\dot{V} + F_4, \end{array} \tag{39}$$

where

$$\begin{array}{ll} E_1 = -\frac{4\rho}{\gamma-1}\frac{1}{(u_0-V)(\frac{2}{\gamma-1}+M_0^2)}, & E_2 = \frac{2(1+M_0^2)}{(\gamma+1)M_0^2}, \\ E_3 = -4\rho_0\frac{(u_0-V)}{\gamma+1}, & E_4 = 0, \end{array} \tag{40}$$

and

$$\begin{array}{l} F_1 = \frac{\rho}{\rho_0}\frac{D\rho_0}{Dt} + \frac{2\rho_0\frac{\gamma+1}{(\gamma-1)^2}}{(\frac{2}{\gamma-1}+M_0^2)^2}(\frac{2(u_0-V)}{c_0^2}\frac{Du_0}{Dt} - \frac{M_0^2}{c_0^2}\frac{Dc_0^2}{Dt}), \\ F_2 = \frac{M_0^2-\frac{2}{\gamma-1}}{\frac{\gamma+1}{\gamma-1}M_0^2}\frac{Du_0}{Dt} + \frac{2}{(\gamma+1)(u_0-V)}\frac{Dc_0^2}{Dt}, \\ F_3 = (u_0 - V)^2(1 - \frac{\rho_0}{\rho})\frac{D\rho_0}{Dt} + \frac{4\rho_0(u_0-V)}{\gamma+1}\frac{Du_0}{Dt} - \frac{2\rho_0}{\gamma+1}\frac{Dc_0^2}{Dt} + \frac{Dp_0}{Dt}, \\ F_4 = \frac{D\lambda_0}{Dt}. \end{array} \tag{41}$$

Rewriting (39) for the conserved variables $\rho_1, \rho_1 u_1, \rho e_1, \rho_1\lambda_1$, we get

$$\begin{array}{rcl} \frac{D\rho_1}{Dt} &=& G_1\dot{V} + H_1, \\ \frac{D\rho_1 u_1}{Dt} &=& G_2\dot{V} + H_2, \\ \frac{D\rho_1 e_1}{Dt} &=& G_3\dot{V} + H_3, \\ \frac{D\rho_1\lambda_1}{Dt} &=& G_4\dot{V} + H_4, \end{array} \tag{42}$$

where

$$G_1 = E_1, \qquad G_2 = u_1 E_1 + \rho_1 E_2,$$
$$G_3 = (\tfrac{1}{2}u_1^2 + \lambda_1 Q)E_1 + \rho_1 u_1 E_2 + \tfrac{1}{\gamma-1}E_3, \quad G_4 = \lambda_1 E_1,$$

and

$$H_1 = F_1, \qquad H_2 = u_1 F_1 + \rho_1 F_2,$$
$$H_3 = (\tfrac{1}{2}u_1^2 + \lambda_1 Q)F_1 + \rho_1 u_1 F_2 + \rho_1 Q F_4, \quad H_4 = \lambda_1 F_1 + \rho_1 F_4.$$

To derive the ODE for the shock speed $V(t)$, we consider the characteristic form of (18) which is obtained by multiplying (18) with matrix **P** (subscript n_k omitted):

$$\mathbf{P}\frac{\partial \vec{\mathbf{u}}}{\partial T} + \mathbf{P}[\mathbf{A}\xi_x + \xi_t]\frac{\partial \mathcal{I}\vec{\mathbf{u}}}{\partial \xi} = \mathbf{P}\Psi(\vec{\mathbf{u}}). \tag{43}$$

Now using the fact that $\mathbf{P}A\mathbf{P}^{-1} = \operatorname{diag}(u-c, u, u, u+c)$, we have

$$\mathbf{P}\frac{\partial \vec{\mathbf{u}}}{\partial T} + \left[\begin{pmatrix} u-c & & & \\ & u & & \\ & & u & \\ & & & u+c \end{pmatrix}\xi_x + \xi_t\right]\mathbf{P}\frac{\partial \mathcal{I}\vec{\mathbf{u}}}{\partial \xi} = \mathbf{P}\Psi(\vec{\mathbf{u}}). \tag{44}$$

For a strong detonation, the flow is subsonic behind the shock front $x_s(t)$. Therefore, $u + c > V(t) = \dot{a}_1(t)$ at the shock front. Thus the fourth equation of (44) corresponds to an incoming characteristic toward the shock front. Meanwhile, it is easy to verify that on the shock front $x_s(t)$, $\frac{\partial}{\partial T} = \frac{D}{Dt}$. Now denoting the last row of **P** as $(P_{4,1}, P_{4,2}, P_{4,3}, P_{4,4})$, the fourth equation of (44) reads

$$P_{4,1}\frac{D\rho_1}{Dt} + P_{4,2}\frac{D\rho_1 u_1}{Dt} + P_{4,3}\frac{D\rho_1 e_1}{Dt} + P_{4,4}\frac{D\rho_1\lambda_1}{Dt} = W, \tag{45}$$

$$W = P_{4,1}R_1 + P_{4,2}R_2 + P_{4,3}R_3 + P_{4,4}R_4, \tag{46}$$

where $\mathbf{R} = (R_1, R_2, R_3, R_4) = \Psi(\vec{\mathbf{u}}) - (\mathbf{A}\xi_x + \xi_t)\frac{\partial \mathcal{I}\vec{\mathbf{u}}}{\partial \xi}$ is the residual of solution $\vec{\mathbf{u}}$ which will be computed by the Chebyshev spectral collocation method.

Finally (42) and (45) give the ODE for the shock speed

$$\dot{V}(t) = \frac{W - (P_{4,1}H_1 + P_{4,2}H_2 + P_{4,3}H_3 + P_{4,4}H_4)}{P_{4,1}G_1 + P_{4,2}G_2 + P_{4,3}G_3 + P_{4,4}G_4}. \tag{47}$$

4. Calculation of neutral stability curve. From linear analysis [4] and [8], instability of detonation waves is associated with the eigenmodes of the linearized system whose eigenvalues have positive real parts. Disturbances containing those modes will grow exponentially in time. However, when we are close to the neutral stability limit, the growth of such disturbances will be slow. It demands highly accurate numerical techniques to distinguish the unstable and stable detonations. When we identify the stability limit based on direct numerical calculations, the accuracy of critical overdrive f^* cannot be expected to be more accurate than the truncation errors of the methods. This is why it is crucial to use highly accurate methods in studying neutral stability limits.

Convergence studies of numerical methods. Pressure history at the von Neumann spikes will be recorded at equally spaced time stations and used to determine stable or unstable detonations based on its decay or growth. When the overdrive is close to the neutral stability

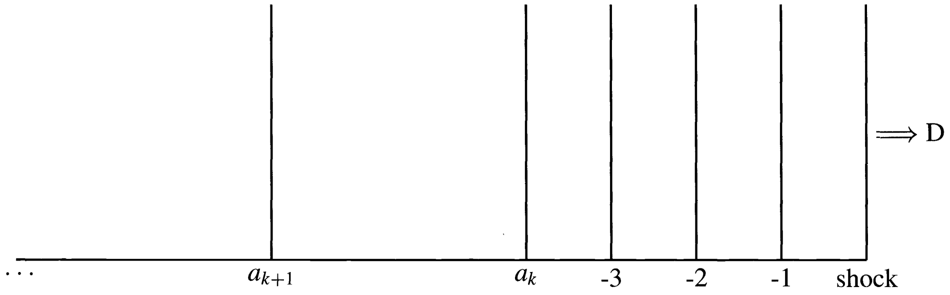

FIG. 1. *Multidomain set up. All interfaces are moving in time.*

limit f^*, it is difficult to tell visually the growth or decay of different frequencies from the pressure history. Therefore, we employ discrete Fourier transformation to analyze the growth or decay of all the frequencies. As for an unstable detonation, growth in magnitudes of initial disturbances (truncation error in our methods) will depend on the mesh size of the particular simulation. Therefore, we will not use the magnitudes of various frequencies in the pressure history as a checkup for the accuracy of mesh resolutions. Instead, we will be concerned with the unstable frequencies produced by different meshes and determine the accuracy of the numerical solution based on the convergence of the unstable frequencies.

Discrete Fourier transformation. Suppose we have N consecutive sampled values $h_k = h(t_k)$, $t_k = k\Delta_t$, $k = 0, 1, 2, \ldots, N-1$. The discrete Fourier transform is defined by

$$H(f_n) = \Delta_t \sum_{k=0}^{N-1} h_k \exp\left(\frac{2\pi ikn}{N}\right),$$

where $f_n = \frac{n}{N\Delta_t}$, $n = -\frac{N}{2}, -\frac{N}{2}+1, \ldots, \frac{N}{2}-1, \frac{N}{2}$. $H(f_n)$ gives the phase and magnitude of the wave whose frequency is f_n. When the time series data h_k are all real-valued, a symmetric property holds: $H(-f) = H(f)^*$, where * denotes the complex conjugate. Thus $2|H(f_n)|$ is the magnitude of the wave whose frequency is f_n, for $n = 1, 2, \ldots, \frac{N}{2}$.

We test the accuracy of the numerical method in §3 for the case $Q = 50$, $f = 1.6$, which has been identified as an unstable detonation [4]. The mesh setup is depicted in Figure 1.

The number of initial subdomains is nine and the interfaces will move with the average speed of the shock front except for the shock front itself whose speed is given by (47). More subdomains will be added to the rear part of the computational domain. We monitor the solutions in the last subdomains so that no waves will be interacting with the leftmost subdomain boundaries. The boundary conditions to the left of the computational domains are the steady solutions at the Chapman–Jouguet point. The initial conditions will be the Chapman–Jouguet steady detonation. Therefore, we are simulating a one-dimensional detonation wave travelling in an infinitely long tube and the driven piston is far away from the region where computations are done.

In Figure 2, results for two meshes are given; the coarse mesh has five points per half reaction length interval while the fine mesh has ten points per half reaction length interval. On the top, pressure histories are given for both runs at a time interval $\Delta_t = 0.1$. At the bottom, the Fourier transformations of the output pressure data from time $t = 140$ to $t = 200$ are given. We intentionally ignore the early time history to wait for the full development of the pressure oscillations. We can see clearly in each case that we have various frequencies. In

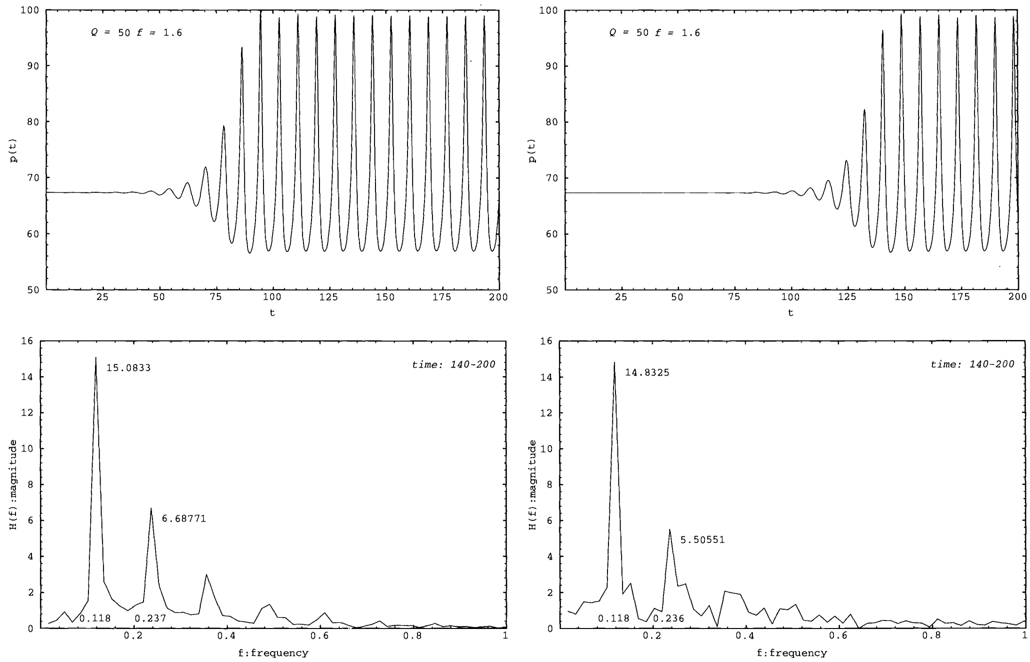

FIG. 2. $Q = 50$, $f = 1.6$. *(Left) coarse mesh—five points per half reaction length, (Right) fine mesh—10 points per half reaction length. Top plots are the pressure histories and bottom plots are their Fourier transformations for time* $t = 140$–200.

TABLE 1

Convergence tests: frequencies and magnitudes of Fourier transformations for the pressure history. Coarse mesh $5/L_{1/2}$, *fine mesh* $10/L_{1/2}$.

N	f_1		f_2	
	Location	Magnitude	Location	Magnitude
$5/L_{1/2}$	0.1184493	15.083265	0.2368986	6.6877127
$10/L_{1/2}$	0.1181893	14.832513	0.2363786	5.5055077

Table 1, we report the locations of the first two frequencies with the largest magnitudes, i.e., f_1, f_2. The accuracy for the locations of both frequencies are up to the third decimal digit.

This shows that using our methods, five points per half reaction length interval will be enough to achieve satisfactory accuracy. Still, in all our computations of critical overdrives f^*, we have used ten points per half reaction length interval for subdomains near the shock front. We use the explicit second-order Runge–Kutta method for the time discretizations. Finally, Figure 3 depicts the solution of pressure and density and mass fraction using the fine mesh (ten points per half reaction length) at time $t = 145$.

Neutral stability curve. In Table 2, we give the approximation of critical overdrive f^* for 16 heat releases Q. For each Q, we compute the largest overdrive (denoted as f^-) found to produce unstable detonation and the smallest overdrive (denoted as f^+) found to produce stable detonation. Then we conclude that an approximation for f^* can be obtained by averaging f^+ and f^-; i.e., $f^* = \frac{f^+ + f^-}{2}$.

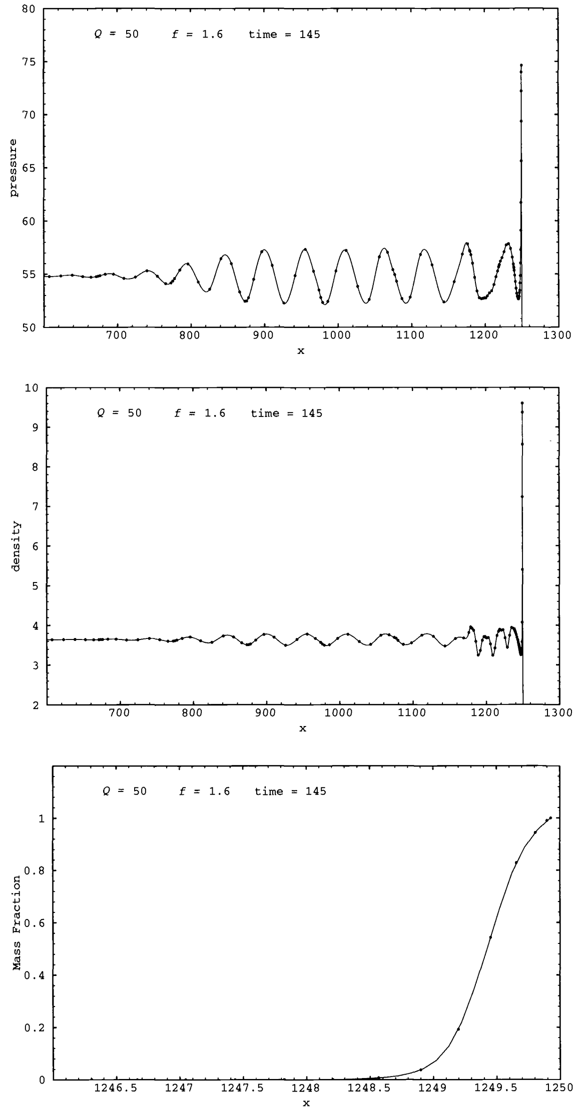

FIG. 3. $Q = 50$, $f = 1.6$. *Solutions of pressure and density and mass fraction of reactant (from top to bottom) on fine mesh (*10 *points per half reaction) at time* $t = 145$.

For a given heat release Q, in order to decide which overdrive gives stable or unstable detonation, we record the pressure $p(t)$ at the von Neumann spikes up to time $t = 150$. Then we compute two consecutive Fourier transformations of $p(t) - p_0$ (p_0 as the von Neumann pressure of the steady detonation), one for the time period [50, 100] and one for the time period [100,150]. Comparing the magnitudes of corresponding frequencies, if all frequencies are found to be decreasing, then the detonation will be considered stable. If the magnitude of any of the frequencies is found to have increased, then the detonation will be considered unstable.

TABLE 2
Critical values of overdrive for selected Q's.

Q	f^- Largest unstable overdrive	f^+ Smallest stable overdrive	$f^* = (f^- + f^+)/2$ Critical overdrive
0.5	1.120	1.125	1.1225
0.6	1.255	1.260	1.2575
0.7	1.395	1.400	1.3975
0.9	1.685	1.690	1.6875
1.0	1.825	1.830	1.8275

1.7	2.845	2.850	2.8475
2.0	3.080	3.085	3.0825
2.5	3.335	3.340	3.3375
5.0	3.615	3.620	3.6175
10.0	3.250	3.250	3.2525
15.0	2.865	2.870	2.8675
20.0	2.585	2.590	2.5875
30.0	2.200	2.205	2.2025
50.0	1.730	1.731	1.7305

In Figure 4, $Q = 1$; the left column is for the unstable case $f^- = 1.825$. The top left is the time history of the pressure perturbation $p'(t)$ in reference to the steady state pressure; i.e., $p'(t) = p(t) - p_0$. As the overdrive f^+ and f^- are close to the critical value, the pressure perturbation $p'(t)$ is very small. For display purposes, the scale for the history of pressure perturbation $p'(t)$ has been scaled up by a factor of 1000. (This scaling will be used for all pressure perturbation histories thereafter.) The left middle plot is the Fourier transformation of $p'(t)$ between time $t = 50$ and time $t = 100$. We can see there are two basic frequencies, which we denote as $f_1 = 0.12$ and $f_2 = 0.44$ in an increasing order. The magnitudes for f_1, f_2 are $H(f_1) = 0.00294285$, $H(f_2) = 0.00399988$, respectively. The left bottom plot is the Fourier transformation of $p'(t)$ from time $t = 100$ to time $t = 150$. Again we see two basic frequencies $f_1 = 0.12$, $f_2 = 0.44$. However, the magnitudes for f_1, f_2 are $H(f_1) = 0.00319032$, $H(f_2) = 0.0024562$, respectively. Comparing the magnitude of $H(f_1), H(f_2)$ in these Fourier transformations for two consecutive time windows, we find that the magnitude of the first frequency $H(f_1)$ has increased, while the magnitude for the second frequency $H(f_2)$ has decreased. Therefore, we conclude that $f^+ = 1.825$ gives unstable detonation. Meanwhile, in the right column of Figure 4, there are three plots for overdrive $f^+ = 1.830$. The top right is the time history of pressure perturbation $p'(t)$ and the middle and bottom right are the Fourier transformations of $p'(t)$ for the time periods [50, 100] and [100, 150], respectively. Again we found two basic frequencies f_1, f_2. For the time period [50, 100], $H(f_1) = 0.00267143$, $H(f_2) = 0.00317801$, while for the time period [100, 150], $H(f_1) = 0.00266544$, $H(f_2) = 0.00169358$. It is found that the magnitudes for both frequencies have decreased over the two consecutive time windows and, therefore, we conclude that $f^+ = 1.830$ gives a stable detonation. By taking the average of f^+ and f^-, we have an approximation for the critical overdrive $f^* = 1.8275$ when $Q = 1$.

In Figure 5, we present the case of $Q = 50$. On the Fourier transformation, only one basic frequency is found in this case. $f^- = 1.730$ is the largest overdrive which gives an unstable detonation, and $f^+ = 1.731$ is the smallest overdrive that gives a stable detonation. Therefore, the critical overdrive f^* can be taken approximately as $f^* = 1.7305$ when $Q = 50$.

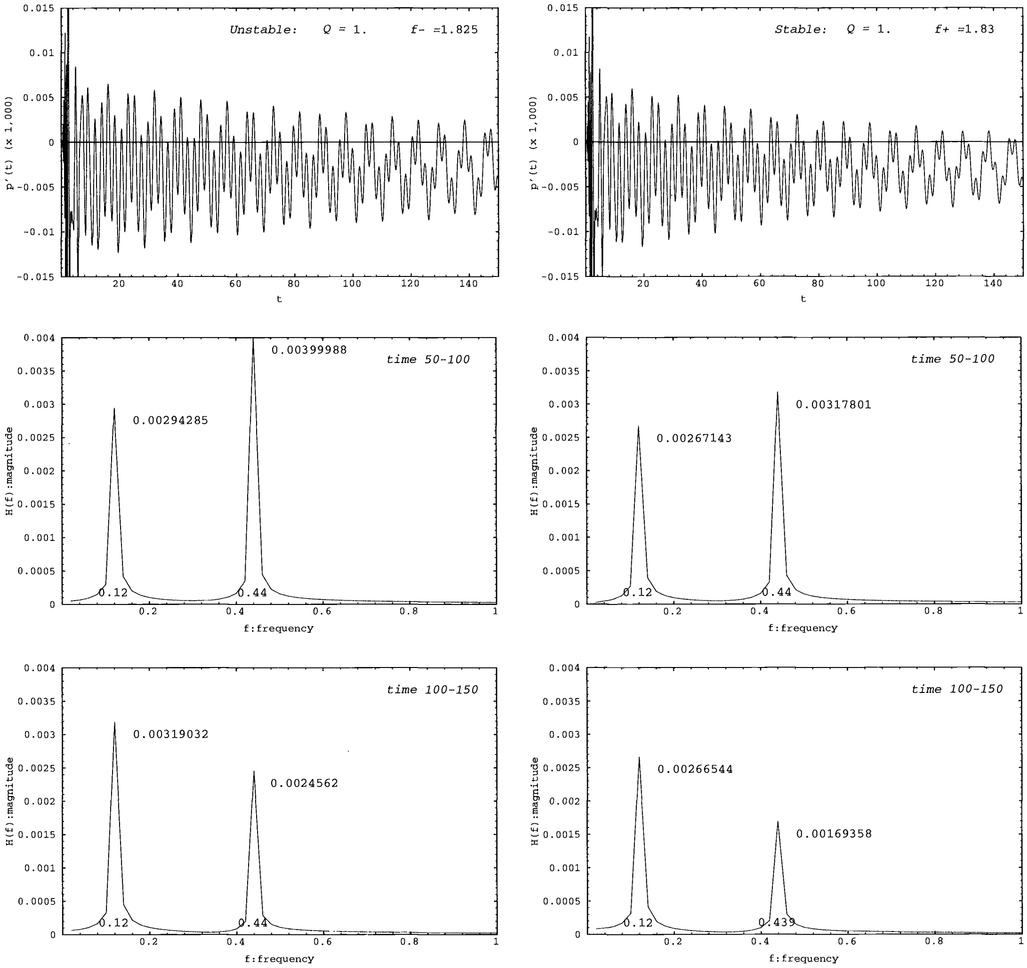

FIG. 4. $Q = 1.0$. *(Left)* $f^- = 1.825$, *unstable, pressure perturbation history (top), Fourier frequencies for* $50 \le t \le 100$ *(middle), and* $100 \le t \le 150$ *(bottom). (Right)* $f^+ = 1.830$, *stable, pressure perturbation history (top), Fourier frequencies for* $50 \le t \le 100$ *(middle), and* $100 \le t \le 150$ *(bottom).*

In Table 3, we have listed Q's for all sixteen heat releases for the first two frequencies and the magnitudes of Fourier transformations of $p'(t)$ over two time periods, i.e., one for the time [50, 100] and one for the time [100, 150]. (Again, all $p'(t)$ have been scaled up by a factor of 1000.)

Finally, in Figure 6, we plot the neutral stability curve based on the data in Table 2; the solid curve is obtained by a cubic Hermite spline interpolation. Note that the heat release Q-axis is logarithmic. The smaller dots and the dashed curve are the results of Erpenbeck using eigenmode analysis [8].

5. Conclusion. We have calculated the neutral stability curve for one-dimensional detonation waves using a highly accurate multidomain shock tracking algorithm. The study of neutral stability will provide insight into more complex studies of multidimensional stability problems. However, it should be realized that the accuracy of results based on direct numerical simulation is limited by the inherent truncation errors of the numerical methods.

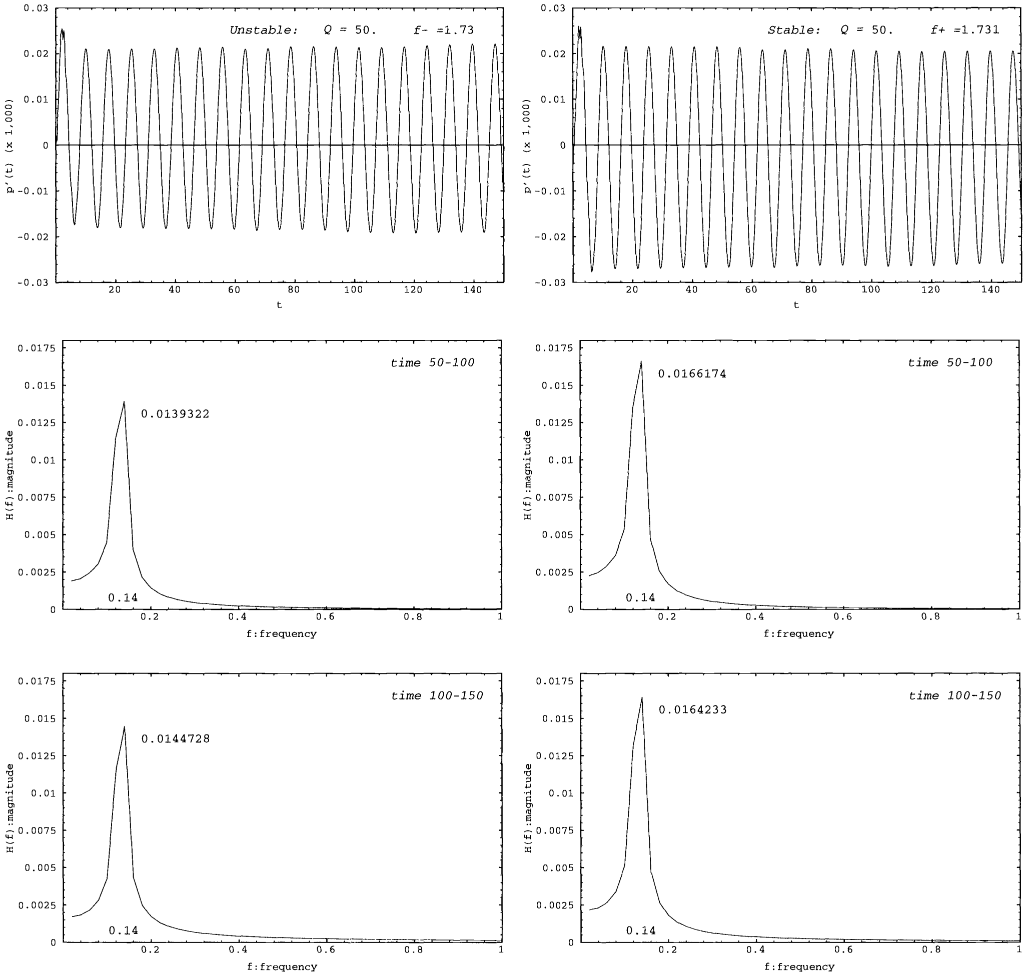

FIG. 5. $Q = 50.0$. *(Left)* $f^{-} = 1.730$, *unstable, pressure perturbation history (top), Fourier frequencies for* $50 \leq t \leq 100$ *(middle), and* $100 \leq t \leq 150$ *(bottom). ILUM: A MULTI-ELIMINATION ILU PRECONDITIONER FOR GENERAL SPARSE MATRICES*

Y. SAAD†

Abstract. Standard preconditioning techniques based on incomplete LU (ILU) factorizations offer a limited degree of parallelism, in general. A few of the alternatives advocated so far consist of either using some form of polynomial preconditioning or applying the usual ILU factorization to a matrix obtained from a multicolor ordering. In this paper we present an incomplete factorization technique based on independent set orderings and multicoloring. We note that in order to improve robustness, it is necessary to allow the preconditioner to have an arbitrarily high accuracy, as is done with ILUs based on threshold techniques. The ILUM factorization described in this paper is in this category. It can be viewed as a multifrontal version of a Gaussian elimination procedure with threshold dropping which has a high degree of potential parallelism. The emphasis is on methods that deal specifically with general unstructured sparse matrices such as those arising from finite element methods on unstructured meshes.

Key words. sparse linear systems, preconditioned Krylov subspace methods, incomplete LU factorizations, independent set orderings, multicoloring, graph coloring, threshold dropping strategies

AMS subject classification. 65F10

1. Introduction. In this paper we address the problem of developing preconditioners for solving a linear system of the form

$$Ax = b, \tag{1}$$

where A is a general sparse matrix of dimension N. The incomplete LU (ILU) factorization with no fill-in, or ILU(0) [36], is one of the most popular preconditioners currently available. Its implementation on high-performance computers can be optimized by a technique referred to as "level scheduling" or "wavefront ordering"; see, e.g., [3]. A notable disadvantage of ILU(0) is that it is a rather crude approximation, and for this reason it is unreliable when used to solve problems arising from certain applications, such as computational fluid dynamics. To improve the efficiency and robustness of ILU factorizations, many alternatives which allow higher levels of fill-in in the ILU factorizations have been developed [24, 38, 13, 12, 53, 52, 45]. Although these alternatives are more robust than the low-accuracy ILU(0) or symmetric successive overrelaxation (SSOR), they are often intrinsically sequential.

A number of different approaches have been advocated to remedy the "sequential nature" of the preconditioners developed in the 1970s and later; see, for example, the survey papers [14, 42]. The first of these approaches was motivated by vectorization and consisted mainly of replacing occurrences of matrix inverses by polynomials in these matrices. For example, the solutions of bidiagonal systems that arise in the forward and backward solutions on the ILU(0) preconditioning for model problems were replaced by low-degree polynomial expansions in the matrices [47]. The paper [27], and subsequently a few others, advocated using polynomials in A as preconditioners. A second class of methods that has been developed consists of introducing parallelism by exploiting "graph coloring," or *multicoloring*, as we will refer to it here. The unknowns are colored in such a way that no two unknowns of the same color are coupled by an equation. In the simplest case of the five-point matrix arising from the centered difference discretization of the Laplacian in two- or three-dimensional spaces, only two colors are needed, and they are commonly referred to as "red" and "black." When the unknowns of the same color are numbered consecutively, and a standard ILU factorization

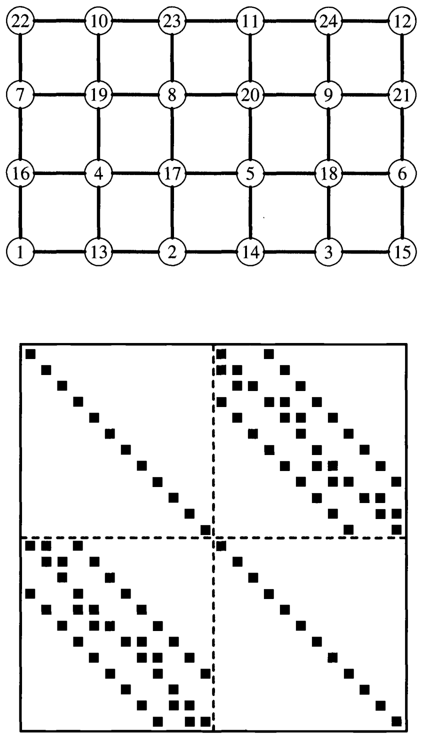
is applied to the reordered system, then a large degree of parallelism is available in both the preprocessing phase and the preconditioning operations, during the iteration phase. A well-known drawback of this approach is that the number of iterations to achieve convergence may increase substantially, when compared with that required for the original system [19, 18, 20]. More generally, preconditioners that allow a large degree of parallelism such as, in the simplest case, diagonal scaling, tend to necessitate a much larger number of iterations to converge when compared with their sequential counterparts, e.g., the standard ILU.

However, experience suggests that a good remedy for regaining an acceptable level of convergence rate is to *increase the accuracy of the underlying preconditioning*. For example, ILU preconditioners with more fill-in, or multistep SSOR or SOR preconditioners, may be used. Experiments in [44] reveal that an approach based on SOR(k) preconditioning, in which each preconditioning operation consists of k steps of SOR sweeps, is superior to the best optimized ILU preconditioning on some problems. Unfortunately, for the standard ILU factorization, the use of a higher level of fill-in destroys the structure obtained from the multicolor reordering.

In this paper we consider a technique which is based on exploiting the idea of successive independent set orderings [33], a simpler form of multicoloring. This technique is very closely related to multifrontal elimination [15, 40], a classical method that is employed in the parallel implementations of sparse direct methods. Both multifrontal elimination and ILUM (ILU with multi-elimination) rely on the fact that at a given stage of Gaussian elimination, there are many rows that can be eliminated simultanously. The set that consists of such rows is called an independent set. The idea then is to find this set, and then eliminate the unknowns associated with it, to obtain a smaller reduced system. This reduction process is applied recursively a few times to the consecutive reduced systems until the system can be solved by a direct solver (multifrontal) or by an iterative technique (ILUM). In ILUM, we perform the reductions approximately, with the help of a standard threshold strategy, in order to control the sparsity of the L and U factors.

We start by describing the ideas of multicoloring and independent set orderings. Then we briefly show how these ideas can be exploited to develop direct solution methods and, finally, we derive incomplete factorization techniques by introducing numerical dropping strategies.

2. Independent set ordering and multicoloring. Graph theory provides numerous useful tools in sparse matrix computations and can be helpful in unraveling parallelism in standard algorithms [25, 15]. We recall that the adjacency graph of a sparse matrix is a graph $G = (V, E)$, whose N vertices in V represent the N unknowns and whose edges represent the binary relations established by the equations in the following manner: there is an edge from node j to node i when $a_{ij} \neq 0$. This edge will therefore represent the binary relation *equation i involves unknown j*, or equivalently *the unknown x_i depends on unknown x_j*. Note that the graph is directed, except when the matrix has a symmetric pattern ($a_{ij} \neq 0$ iff $a_{ji} \neq 0$ for all $1 \leq i, j \leq N$). Parallelism in the Gaussian elimination process can be obtained by finding unknowns that are independent at a given stage of the elimination, i.e., unknowns that do not depend on each other according to the above binary relation. The rows corresponding to such unknowns can then be used as pivots simultaneously. Thus, in one extreme, when the matrix is diagonal, all unknowns are independent. On the other extreme, when a matrix is dense, each unknown will depend on all other unknowns. Sparse matrices lie somewhere in between these two extremes. Multicoloring techniques attempt to find sets of independent equations by coloring the vertices of a graph so that neighboring vertices have different colors. Independent set ordering can be viewed as a less restrictive form of multicoloring, in which a set of vertices in the adjacency graph is found so that no equation in the set involves unknowns



Red-Black ordering

Corresponding Matrix

FIG. 1. *Red-black labeling of a* 6×4 *rectangular mesh and associated matrix.*

from the same set. Multicoloring is best known in the partial differential equation context for a two-dimensional finite difference grid (five-point operator), which is our starting point in this discussion.

2.1. Red-black ordering for finite difference grids. For simple two-dimensional centered finite difference grids, we can easily separate the grid points into two sets, red and black, so that the nodes in one set are adjacent only to nodes from the other set. This two-color (red-black) ordering is illustrated in Figure 1 for a 6×4 grid.

If we reorder the unknowns in such a way as to list the red unknowns first together and then the black ones, as is illustrated in Figure 1, we will obtain a system of the form

$$\begin{pmatrix} D & F \\ E & C \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}, \tag{2}$$

where D and C are diagonal matrices. Matrices that can be permuted into the above form are said to have property A [51]. Several techniques have traditionally been used to exploit the above convenient structure (see, e.g., [23, 41, 21]).

Perhaps the simplest of these approaches is to use a conjugate gradient-type technique combined with the standard ILU(0) preconditioner on the block system (2). Here, the degree of parallelism, i.e., the maximum number of arithmetic operations which can be executed in parallel, is of order N. A drawback is that often the number of iterations is higher than with the natural ordering, but the approach may still be competitive for problems for which the natural ordering requires a relatively small number of steps, e.g., less than 30, to converge.

We have observed [44] that the number of iterations can be reduced back to a competitive level by using a more accurate ILU factorization on the red-black system, e.g., ILU with threshold (ILUT) [45]. In fact the situation may be improved in that for the same level of fill-in p, the red-black ordering will outperform the natural ordering preconditioner for p large enough, in terms of number of iterations required for convergence. However, the fill-in introduced in the "black" part of the system with such high-level ILUs ruin the degree of parallelism achieved from the red-black ordering. A remedy is to resort to similar *high-level SOR or SSOR preconditioners* instead of ILUT [44]. These consist of performing several SOR or SSOR steps in each preconditioning operation, instead of just one, as is traditionally done. A significant advantage of relaxation-type preconditioners is that these higher-level preconditioners do not lose their degree of parallelism as the accuracy increases.

A second method that has been used in conjunction with the red-black ordering is to eliminate the red unknowns by forming the reduced system which involves only the black unknowns, namely,

$$(C - ED^{-1}F)y = g - ED^{-1}f.$$

This linear system is again sparse and has about half as many unknowns. It has been observed that for easy problems, i.e., problems for which the natural ordering requires a relatively small number of steps to converge, this reduced system can often be efficiently solved with only diagonal preconditioning. The preprocessing to compute the reduced system is highly parallel and inexpensive. In addition, the reduced system is usually well conditioned and has some interesting properties when the original system is highly nonsymmetric [21].

A general sparse matrix rarely has property A, and as a result the application of the red-black ordering is quite limited. Fortunately, many of the above techniques can be generalized by using less restrictive forms of reorderings. For example, to exploit the reduced system approach, all we need is to reorder the original matrix into a matrix of the form

$$\begin{pmatrix} D & F \\ E & C \end{pmatrix}, \tag{3}$$

where D is diagonal but C can be arbitrary. There are three ways of generalizing the standard red-black ordering.

1. Independent set orderings, which lead to the form (3) above.
2. Multicolor orderings, which lead to block matrices in which the diagonal blocks are pointwise diagonal.
3. Full-block versions of the above techniques which allow the diagonal matrices to be block diagonal instead where each block is dense.

In the remainder of this paper we will consider the first and second generalizations. The block versions arise naturally in the solution of partial differential equations (PDEs) when each mesh point involves several unknowns. We also note that a further generalization would consist of allowing these diagonal blocks to be sparse matrices.

2.2. Independent set orderings. We now consider generalizations of the red-black ordering which consist of transforming the matrix into the block form (3), where D is diagonal. Let $G = (V, E)$ denote the adjacency graph of the matrix, and let (x, y) denote an edge from vertex x to vertex y. An *independent set* S is a subset of the vertex set V such that

$$\text{if } x \in S \quad \text{then} \quad \{\, (x, y) \in E \ \text{ or } \ (y, x) \in E \,\} \rightarrow y \notin S.$$

In words, elements of S are not allowed to be connected to other elements of S either by incoming or outgoing edges. An *independent set* is maximal if it cannot be augmented by elements in its complement to form a larger independent set. Note that a maximal independent set is by no means the largest possible independent set that can be found. In fact, finding the independent set of maximum cardinality is NP-hard [32]. Independent set orderings have been used mainly in the context of parallel direct solution techniques for sparse matrices [33, 34, 11], and multifrontal techniques [15] can be viewed as a particular case. One of the goals of this paper is to show how to exploit these ideas in the context of iterative methods.

There are a number of simple and inexpensive heuristics for finding large maximal independent sets. For our purposes simple greedy algorithms such as the ones to be described next are inexpensive and yield enough parallelism in general. In the following we will use the term *independent set* to always refer to *maximal independent set.*

A simple greedy procedure for finding an independent set S is to traverse the graph and accept each visited node as a new member of S, if it is not already marked. We then mark this new member and all of its nearest neighbors. Note that by nearest neighbors of a node x we mean the adjacent nodes, linked to x by incoming or outgoing edges.

ALGORITHM 2.1. Greedy algorithm for independent set ordering.

```
Let $S = \emptyset$.
For $j = 1, 2, \ldots, n$ Do:
        If node $j$ is not marked then
                $S = S \cup \{j\}$.
                Mark $j$ and all its nearest neighbors.
        endif
enddo
```

In the above algorithm, the nodes are visited in the natural order $1, 2, \ldots, n$ but we can also visit them in any permutation $\{i_1, \ldots, i_n\}$ of $\{1, 2, \ldots, n\}$. In what follows we denote by $|S|$ the size of S, i.e., its cardinal. Since the size of the reduced system is $n - |S|$ it is reasonable to attempt to maximize the size of S in order to obtain a small reduced system, although the size is not all that matters.

We would like to give a rough idea of the size of S. Recall that the degree of a vertex v is the total number of edges that are adjacent to v. Assume that the maximum degree of each node does not exceed ν. Whenever the above algorithm accepts a node as a new member of S it potentially puts all its nearest neighbors, i.e., at most ν nodes, in the complement of S. Therefore, the size $n - |S|$ of its complement is such that $n - |S| \leq \nu |S|$ and as a result,

$$|S| \geq \frac{n}{1+\nu}.$$

This lower bound can be improved slightly by observing that we can replace ν by the maximum degree ν_S of *all the vertices that constitute* S, resulting in the inequality

$$|S| \geq \frac{n}{1+\nu_S},$$

which suggests that it may be a good idea to visit first the nodes with smaller degrees. In fact this observation leads to a general heuristic regarding a good order of traversal. We can view the algorithm as follows. Each time a node is visited, we remove it and its nearest neighbors from the graph and then visit a node from the remaining graph and continue in the same manner until exhaustion of all nodes. Every node that is thus visited is a member of S, and its nearest neighbors are members of the complement $\bar{S}$ of the set S. As a result, if we call ν_i the degree of the node visited at step i, adjusted for all the edge deletions resulting from the previous visitation steps, then the number n_i of nodes that are left at step i satisfies the relation

$$n_i = n_{i-1} - \nu_i - 1.$$

The process adds a new element to the set S at each step and stops when $n_i = 0$. In order to maximize $|S|$ we need to maximize the number of steps in the procedure. The difficulty in the analysis comes from the fact that the degrees are updated at each step i because of the removal of the edges associated with the removed nodes. All we can say is that if we wish to lengthen the process, a rule of thumb would be to visit the nodes that have the smallest degrees first.

ALGORITHM 2.2. Independent set ordering with increasing degree traversal.

```
Let $S = \emptyset$. Find an ordering $i_1, \dots, i_n$ of the nodes by increasing degree.
For $j = 1, 2, \dots n$ Do:
    If node $i_j$ is not marked then
        $S = S \cup \{i_j\}$.
        Mark $i_j$ and all its nearest neighbors.
    endif
enddo
```

A refinement to the above algorithm would be to update the degrees of all nodes involved in a removal and dynamically select the one with smallest degree as the next node to be visited. This can be efficiently implemented using a min-heap data structure [9]. A different heuristic is to attempt to maximize the number of elements in S by a form of local optimization that determines the order of traversal dynamically. In the following the action of removing a vertex from a graph consists of deleting the vertex and all edges incident to/from this vertex.

ALGORITHM 2.3. Locally optimal algorithm for independent set ordering.

```
Set $S = \emptyset$ and $n_{left} = n$.
While $n_{left} > 0$ do
        Select the vertex with minimum degree in current graph.
        Add this vertex to $S$, then
        Remove it and all of its nearest neighbors from graph
        Update degrees of all vertices
        $n_{left} := n_{left} -$ number_of_removed_vertices.
endwhile
```

There is a striking similarity with the minimal-degree ordering algorithm used in sparse Gaussian elimination. The only difference is that the elimination of a node does not introduce what is referred to as fill-in in Gaussian elimination, i.e., the edges of the removed nodes are simply deleted.

There are other similar techniques for generating independent sets. The method described in [33] for an alternative ordering for Gaussian elimination starts with the observation that constructing a large independent set is equivalent to building a small complement $\bar{S}$ to S. One observes that all the edges of the graph are edges between vertices in $\bar{S}$, i.e., the vertices in $\bar{S}$ form a *vertex cover* of the graph. To find a small vertex cover, Leuze suggests a locally optimal technique which can be viewed as the dual of the previous algorithm. At each step of the procedure, the vertex of *maximum* degree is found, and this vertex together with all the incident edges are removed. The process is continued until exhaustion of all edges.

ALGORITHM 2.4. Vertex cover algorithm.

```
Set $\bar{S} = \emptyset$
While (there are still edges left in $G$) Do
```

        remove it and all its adjacent edges from the graph.
    EndWhile
```

One drawback with this type of "local minimization" technique illustrated by the last two algorithms is its cost. The fact that the improvements over the simpler procedures (Algorithms 2.1 and 2.2) are likely to be small suggests that it is probably preferable to use these less expensive algorithms in practice. This will be confirmed by our experiments in §4.

We now illustrate these algorithms with the help of a little comparison. We consider two test matrices. The first is a 9-point matrix obtained simply by squaring the 5-point discretization of the Laplacian on a 25×25 grid. This matrix of size $N = 625$ has 7629 nonzero elements and it pattern is symmetric. The second matrix is taken from the Harwell-Boeing collection and is called JPWH_991; see [16, 17]. It is of dimension $N = 991$ and has a total of 6,027 nonzero elements, and its pattern is nonsymmetric.

Tables 1 and 2 show the results for two reduction steps (see §3). In addition, Table 2 illustrates a simple dropping strategy by showing the effect of adding a drop tolerance, called tol in the table. When forming the reduced system, a row a_i will be modified by linear combinations of rows corresponding to adjacent nodes in the graph. If $\|a_i\|$ is the 2-norm of a_i, then every element obtained in this transformation is dropped if its magnitude is less than $tol \times \|a_i\|$. In the table N_i is the size of the reduced system obtained at the ith level reduction, and NZ_i its number of nonzero elements. As can be seen from the tables the difference in the performances is rather small. An interesting observation is that Algorithm 2.3 seems to be best at minimizing the size of the reduced system, i.e., maximizing the size of S, whereas Algorithm 2.4 seems to be better at reducing the amount of fill-in generated in the reduced system. This is somewhat expected because of the nature of the heuristics used. Overall, Algorithm 2.2 seems to perform remarkably well given the simplicity of the underlying heuristic.

2.3. Multicoloring for arbitrary sparse matrices. Multicoloring techniques have often been used in the context of PDEs as a means of introducing parallelism [39, 37, 1, 30, 31, 28]. The goal here is to color the vertices of an arbitrary adjacency graph in such a way that two adjacent nodes do not have a common color. In terms of graphs, this means that we must find a partition $S_1, S_2, \ldots, S_k$ of the vertex set V, such that

$$\text{if } (x, y) \in E \text{ with } x \in S_i \text{ and } y \in S_j \quad \text{then } i \neq j.$$

Clearly, the red-black ordering is just a particular case with $k = 2$.

As for independent set orderings, finding a multicolor ordering is inexpensive, provided we do not seek to achieve optimality. Multicoloring ideas have been employed in particular to understand the theory of relaxation techniques [51, 49] as well as for deriving efficient alternative formulations of some relaxation algorithms [49, 23]. More recently, they have emerged as useful tools for introducing parallelism in iterative methods; see, for example, [2, 1, 39, 20, 37]. Multicoloring is also commonly employed in a slightly different form (coloring elements (or edges) as opposed to nodes) in finite elements (or finite volume) techniques especially when using the element-by-element approach [6, 50, 26, 22, 46]. Note that "multicoloring" is generally based on a graph coloring of some sort, and that there are numerous other applications of these techniques which are unrelated to parallel computing. Thus, in a quite different context, a form of multicoloring has also been used in [7] to extract independent columns in a sparse matrix for the purpose of numerically evaluating Jacobians with difference formulas.

There is a rich literature on graph coloring, and we refer to [7, 28] for references and a few algorithms that attempt to achieve optimality by some heuristics similar to the ones introduced earlier for independent set orderings. In this paper we will only consider a simple greedy technique for obtaining a multicoloring of an arbitrary graph. Initially, the algorithm assigns a color of zero to each node i. Then, it traverses the graph in the natural order and assigns the smallest positive *admissible* color to each node i visited. Here, an admissible color is a color not already assigned to any of the neighbors of node i. In the following description of the greedy algorithm, we use the notation Adj(i) to represent the set of nodes that are adjacent to node i.

ALGORITHM 2.5. Greedy multicoloring algorithm.

```
Set $Color(i) = 0, i = 1, \ldots, N$.
For $i = 1, 2, \ldots, N$ Do:
    $\text{Color}(i) = \min\{k > 0 \mid k \neq \text{Color}(j), \forall\, j \in \text{Adj}(i)\}$.
EndDo
```

At the end of the algorithm, each node i will be assigned the color $Color(i)$. This procedure is illustrated in Figure 2.

In a manner similar to that for independent set orderings we can traverse the nodes in any order $\{i_1, i_2, \ldots, i_n\}$, and this initial order of traversal may be important in reducing the number of colors. However, the difference between a poor ordering and a good one is usually small. Here are a few additional properties concerning this greedy algorithm.

- If a graph is bipartite (i.e., two-colorable), the algorithm will find the optimal two-color (red-black) ordering for *breadth-first search* traversals.
- Any chain traversal, i.e., a traversal following a *path through all the nodes* in the graph, will also find the optimal two-color ordering for any bipartite graph.
- The number of colors needed does not exceed $\nu + 1$ where ν is the maximum degree of all nodes.

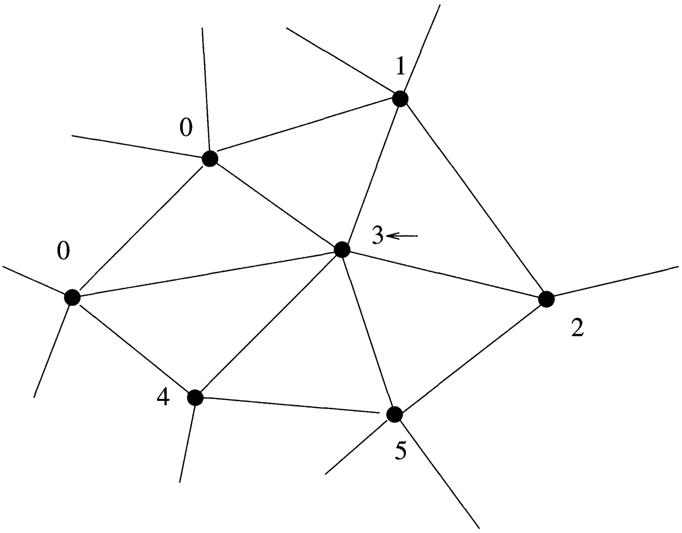

FIG. 2. *The greedy multicoloring algorithm. The node being colored is indicated by an arrow. It will be assigned color number* 3, *the smallest positive integer different from* 1, 2, 4, 5.

Here, we recall that a breadth-first search traversal starts from an arbitrary node and visits its nearest neighbors which form the first level. Then it visits the nearest neighbors of all the nodes in level 1, which have not been visited. These will constitute the second level. The algorithm continues in this fashion until all nodes have been visited. The proofs of the above properties are straightforward and are omitted. In [7] it is proved that a different ordering, referred to as the "incidence degree" ordering, also achieves optimality for bipartite graphs.

For the natural traversal ordering, we can parallelize this graph coloring algorithm in one of several ways. A simple mechanism implemented in [35] is to impose a local order in which the coloring is to be done. For example, a given node can wait until all its nearest neighbors whose processor numbers are less than its own have colored their nodes. Once this is done the processor assigns colors to each of its nodes and then sends the color information needed by the nearest neighbors with higher processor number. Several other alternative algorithms exist; see, for example, [29].

3. ILUM: a multi-elimination ILU factorization.

A parallel direct solver based on performing several successive levels of independent set orderings and reduction was suggested in [33] and in a slightly more general form in [10]. Although the ideas were presented differently, their essence is that when we eliminate the unknowns associated with an independent set we obtain another system, which is a smaller sparse linear system. We can then find an independent set for this reduced system and repeat the process of reduction. We refer to the resulting second reduced system as the second-level reduced system. The process can be repeated recursively a few times. As the level of the reduction increases, the reduced systems gradually lose their sparsity. A direct solution method would consist of continuing the reduction until the reduced system is small enough or dense enough that we can resort to a dense Gaussian elimination to solve it. A sparse direct solution method based on a similar argument was suggested in [33]. In [44] we suggested performing a small number of reduction steps and then switching to a traditional iterative solver, preferably one that has a high level of parallelism such as multicolor successive overrelaxation (SOR), accelerated with GMRES.

ILUM is a form of block preconditioning [8, 4] in which reordering is used to ensure that the diagonal blocks to be inverted during the factorization remain diagonal matrices.

After a brief review of the direct solution method based on independent set ordering, we will show how to exploit this approach to derive ILU factorization strategies based on a drop tolerance.

3.1. Multi-level reduced systems. We start by a brief discussion of an *exact* reduction step. Let A_j be the matrix obtained at the jth step of the reduction, $j = 0, \ldots, nlev$ with $A_0 = A$. Assume that an independent set ordering is applied to A_j and that the matrix is permuted accordingly as follows:

$$P_j A_j P_j^T = \begin{pmatrix} D_j & F_j \\ E_j & C_j \end{pmatrix}, \tag{4}$$

where D_j is a diagonal matrix. We can now reduce the system by eliminating the unknowns of the independent set to get the next reduced matrix via the formula

$$A_{j+1} = C_j - E_j D_j^{-1} F_j. \tag{5}$$

Note that we have implicitly performed the block LU factorization

$$P_j A_j P_j^T = \begin{pmatrix} D_j & F_j \\ E_j & C_j \end{pmatrix} = \begin{pmatrix} I & 0 \\ E_j D_j^{-1} & I \end{pmatrix} \times \begin{pmatrix} D_j & F_j \\ 0 & A_{j+1} \end{pmatrix} \tag{6}$$

with A_{j+1} defined above. As a result, in order to solve a system with the matrix A_j we need to perform a forward and backward substitution with the block matrices on the right-hand side of (6). The backward solution involves solving a system with the matrix A_{j+1} and the forward solution can be performed with a diagonal scaling and a matrix-vector product.

We can use this block factorization approach recursively until we obtain a system that is small enough to be solved with a standard method, e.g., a dense Gaussian elimination. We must save the transformations used in the elimination process, i.e., the matrices $E_j D_j^{-1}$ and the matrices F_j. The permutation matrices P_j can also be saved, or we can explicitly permute the matrices involved in the factorization at each new reordering step.

3.2. ILUM. Clearly, the successive reduced systems obtained in the way described above will become more and more expensive to form and store as the number of levels increases. This is due to the fill-in introduced by the elimination process. A common cure for this in developing preconditioners is to neglect some of the fill-in introduced by using a simple dropping strategy as we form the reduced systems. For example, we can drop any fill-in element introduced, whenever its size is less than a given tolerance τ times the 2-norm of the original row. Thus, an "approximate" version of the successive reduction steps can be used to provide an approximate solution $M^{-1}v$ to $A^{-1}v$ for any given v. This can be used to precondition the original linear system. Conceptually, the modification leading to an "incomplete" factorization consists of replacing (5) by

$$A_{j+1} = (C_j - E_j D_j^{-1} F_j) - R_j, \tag{7}$$

in which R_j is the matrix of the elements that are dropped in this reduction step. Globally, the algorithm can be viewed as a form of block incomplete LU [8, 5], with permutations.

Thus, we have a succession of incomplete block LU factorizations of the form

$$P_j A_j P_j^T = \begin{pmatrix} D_j & F_j \\ E_j & C_j \end{pmatrix} = \begin{pmatrix} I & 0 \\ E_j D_j^{-1} & I \end{pmatrix} \times \begin{pmatrix} D_j & F_j \\ 0 & A_{j+1} \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ 0 & R_j \end{pmatrix} \tag{8}$$

with A_{j+1} defined by (7). We can now recursively find an independent set ordering for the new matrix A_{j+1} and reduce it again in the same manner. Note that we need not save the successive A_j matrices, but only the last one that is generated. We must also save the sequence of sparse matrices

$$B_{j+1} = \begin{pmatrix} D_j & F_j \\ E_j D_j^{-1} & 0 \end{pmatrix}, \tag{9}$$

which contain the transformation needed at level j of the reduction. We can discard the successive permutation matrices P_j if we apply them to the previous B_i matrices as soon as these permutation matrices are known. We then need only the global permutation which is the product of all these successive permutations. The successive B_j matrices without the diagonal D_j are stored as a succession of sparse matrices in a sparse row format. The diagonals D_j are all stored in an N-dimensional array.

An illustration of the matrices obtained after three reduction steps is shown in Figure 3. The algorithm used for the independent set ordering in the illustration is Algorithm 2.3. The original matrix is a five-point matrix associated with a 15×15 grid, and is therefore of size $N = 225$. Here the matrices B_1, B_2, B_3 (with permutations applied) are shown together with the matrix A_3 occupying the location of the 0 block in (9).

We refer to this incomplete factorization as ILUM (ILU with multi-elimination). The preprocessing phase consists of a succession of $nlev$ applications of the three steps: (1) finding the independent set ordering, (2) permuting the matrix, and (3) reducing it.

ALGORITHM 3.1. ILUM: preprocessing phase.

```
Set $A_0 = A$.
For $j = 0, 1, \ldots, nlev - 1$ Do:
        Find an independent set ordering permutation $P_j$ for $A_j$;
        Apply $P_j$ to $A_j$ to permute it into the form (4);
        Apply $P_j$ to $B_1, \ldots, B_j$;
        Apply $P_j$ to $P_0, \ldots, P_{j-1}$;
        Compute the matrices $A_{j+1}$ and $B_{j+1}$ defined by (7) and (9).
Enddo
```

In the backward and forward solution phases we must solve the last reduced system but we need not solve it accurately. We can, for example, solve it according to the level of tolerance that we have allowed in the dropping strategy during the preprocessing phase. Observe that since we would like to solve the linear system inaccurately, we should only use an accelerator that allows variations in the preconditioning. Such methods have been developed in [43] and [48]. Alternatively, we can use a fixed number of multicolor SOR or SSOR steps. The implementation of the ILUM preconditioner corresponding to this strategy is rather complicated and involves several parameters.

In order to describe the forward and backward solution we need to introduce some notation. We start by applying the "global permutation," i.e., the product $P_{nlev-1}P_{nlev-2}\ldots P_0$, to the right-hand side. We overwrite the result on the current solution vector, an N-vector which we call x_0. We now partition this vector into

$$x_0 = \begin{pmatrix} y_0 \\ x_1 \end{pmatrix}$$

according to the partitioning (4). The forward step consists of transforming the second component of the right-hand side as

$$x_1 := x_1 - E_0 D_0^{-1} y_0.$$

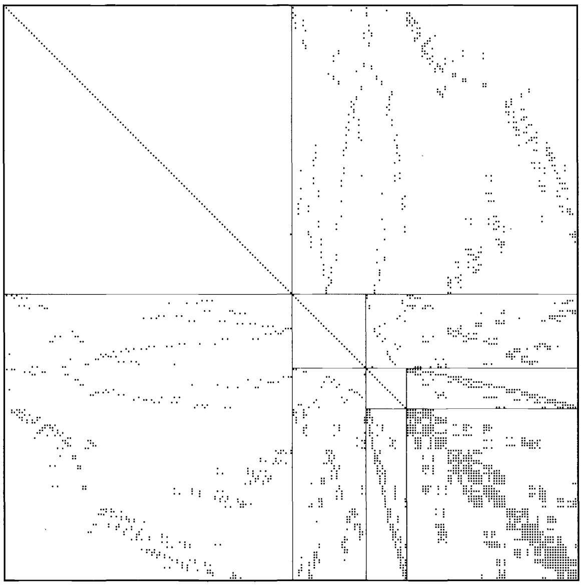

FIG. 3. *Illustration of the processed matrices obtained from three steps of independent set ordering and reductions.*

Now x_1 is partitioned in the same manner as x_0 and the forward elimination is continued the same way. Thus, at each step we partition each x_j as

$$x_j = \begin{pmatrix} y_j \\ x_{j+1} \end{pmatrix}.$$

A forward elimination step defines the new x_{j+1} using the old x_{j+1} and y_j for $j = 0, \ldots, nlev - 1$ while a backward step defines y_j using the old y_j and x_{j+1}, for $j = nlev - 1, \ldots, 0$. Algorithm 3.2 describes the general structure of the forward and backward solution sweeps. Because we apply the global permutation at the beginning, we need not apply the successive permutations. However, we need to permute the final result obtained back into the original ordering.

ALGORITHM 3.2. ILUM: Forward and backward solutions.

```
1. Apply global permutation to right-hand side $b$ and copy into $x_0$.
2. For $j = 0, 1, \ldots, nlev - 1$ do: [Forward sweep]
       $x_{j+1} := x_{j+1} - E_j D_j^{-1} y_j$
   EndDo
3. Solve with a relative tolerance $\epsilon$:
       $A_{nlev} x_{nlev} := x_{nlev}$.
4. For $j = nlev - 1, \ldots, 1, 0$ do: [Backward solution]
       $y_j := D_j^{-1}(y_j - F_j x_{j+1})$.
   EndDo
5. Permute the resulting solution vector back to the original ordering
   to obtain the solution $x$.
```

A major source of difficulty with the use of ILUM lies in its implementation. The implementation issues are similar to those that arise when implementing parallel direct solution methods for sparse linear systems. Some of the issues have been briefly discussed above. Here are some of the important questions that arise, along with some comments or solutions.

1. Should we permute the matrices A_j explicitly or is it preferable to avoid step 3 in Algorithm 3.1? There are two additional burdens if we do not permute the matrices. First, we must store the successive permutations and second, we must apply the permutations during the forward and backward solutions when passing from one level to the other. As was mentioned, in our implementation we explicitly permute the matrices.
2. How to store the successive matrices B_j? In our implementation these are stored in sequence one after the other in a single data structure. As a result the data structure used for storing the successive matrices has two levels of pointers. It is also possible to store all the B_j matrices as a single sparse matrix, the upper part in row format and the lower part in column format. We would then need two sparse data structures and an additional pointer.
3. What number of levels should we use? How do we relate the number of levels to the tolerance used in the factorization? These are difficult questions to answer in a rigorous way. The number of levels is left as a parameter in our implementation.

4. Numerical tests. In this section we provide a few experimental results to (i) help give an idea of the performance of the ILUM preconditioner when compared with similar techniques and (ii) examine how these performances vary with respect to the type of independent set ordering used. All experiments have been performed on a Cray-2 in single precision (64-bit arithmetic) and the times are in seconds. Although parallelism is not exploited our implementation of the iterative phase, which excludes the preprocessing required to compute the ILU factorization itself, takes advantage of vectorization.

In all tests, we construct the right-hand sides artificially to be of the form $b = Ae$, where the solution e is the vector whose components are all ones. The initial guess is taken to be a random vector. Although some of the test matrices used in these experiments are associated with regular grids, this was not exploited, i.e., the matrices are considered as general sparse. The iterations were stopped as soon as the 2-norm of the residual was reduced by a factor of $\epsilon = 10^{-7}$.

4.1. An elliptic problem. We consider the partial differential equation

$$-\Delta u + \gamma \left(\frac{\partial e^{xy} u}{\partial x} + \frac{\partial e^{-xy} u}{\partial y} \right) + \alpha u = f,$$

with Dirichlet boundary conditions and $\gamma = 10, \alpha = -60$, discretized with centered differences on a $27 \times 27 \times 27$ grid. This leads to a linear system with $N = 25^3 = 15,625$ unknowns. We refer to the linear system associated with this matrix as Problem 1.

The results obtained with a drop tolerance of $\tau = 0.0001$ in ILUM are shown in Table 3. The last reduced system is solved with GMRES(20) preconditioned by SOR(1) and using a tolerance of $\epsilon = 0.01$ for the stopping criterion. Note that in all the SOR preconditioning operations we use $\omega = 1$ as a relaxation parameter. The reordering algorithms tested are indicated on the left column, in which "Multicolor" refers to taking the first set (color) obtained from the greedy multicoloring Algorithm 2.5. The column "its_T" shows the time required to solve the system excluding the preprocessing phase required to compute the incomplete factorization. The total time, including preprocessing, is shown in the column "tot_T." The column "memory" shows the total memory requirement in thousands of words to store the real values (excluding integer indices) of the incomplete factorization. The numbers "its-out" refer to the number of outer iterations required, i.e., the number of ILUM preconditioned GMRES steps needed to achieve convergence. The numbers "its-tot" refer to the total number

of inner iterations required, i.e., the overall total number of matrix-vector products in the calls to GMRES(20)-SOR(1) needed to solve all the reduced systems occurring throughout the solution of the linear system under consideration.

4.2. Experiments with Harwell-Boeing matrices. We first consider a linear system made up from the matrix Sherman-3 of the Harwell-Boeing collection [16, 17]. This matrix is of dimension $N = 5,005$ and has $nz = 20,033$ nonzero elements. It arises in an IMPES (IMplicit Pressure, Explicit Saturation) simulation of a black-oil reservoir on a $35 \times 11 \times 13$ grid. We refer to the linear system associated with this matrix as Problem 2. Results similar to those of the previous example are shown in Table 4.

The number of outer iterations is roughly the same in all cases but the number of inner iterations varies rather substantially. We should point out that the preprocessing to build the incomplete factorization has not been optimized. It is possible to improve performance by exploiting parallelism in the elimination since the main operation in forming the reduced systems consists of a sparse matrix-matrix product. In addition, even if the preprocessing costs remain high, this technique may be appealing for solving linear systems with several right-hand sides on parallel or vector computers. It is worth noting that if we ignore the preprocessing times then for Problem 2, some of the best performances, in terms of execution time, are obtained with larger numbers of reductions, a situation which is opposite to that of Problem 1. This depends largely on the parameters used in the factorization.

For comparison, we show in Table 5 typical execution times using an optimized ILUT preconditioned GMRES approach. The ILUT(p, τ) preconditioner described in [45] is a dual-threshold-based incomplete LU factorization which performs numerical dropping based on a relative tolerance τ and which retains at most the p largest fill-in elements in L and in U. The optimization of ILUT on the CRAY consists of using level scheduling [3] as well as jagged diagonal data structures to optimize matrix-vector products. Note that if we ignore preprocessing times, the best times achieved with ILUT and ILUM are comparable, but the degree of parallelism in ILUM is much higher that in ILUT.

Finally, we show the performance of ILUM and an optimized ILUT preconditioned GMRES approach, both with various parameters, on eight matrices from the Harwell-Boeing collection. The two methods are not comparable for similar values of their parameters. How-

ever, the results will give an indication of how the two methods may compare for reasonable choices of the parameters and for unstructured matrices. The sizes (N) of these matrices and their number of nonzero elements (Nz) are shown in the first column of Table 6. Of these matrices, only ORSREG1, SHERMAN1, and SHERMAN5 are regularly structured.

Here, the ILUT(p, τ) preconditioner was used with $\tau = 10^{-4}$, and the level-of-fill parameter p takes the values 0, 5, 10, 15. For ILUM we took the same value for τ and retained at most 20 elements in each row of the reduced system. Since the size of the reduced matrices decreases at each level, it is difficult to compare the number of nonzero elements obtained with a given value of p for ILUM and ILUT. The reduced systems are solved with GMRES(10) with diagonal preconditioning. Only one outer GMRES(10) iteration is performed for each different system. The algorithm used for obtaining the independent sets was Algorithm 2.4. The results are shown in Table 6. In most cases the best iteration times with ILUM are achieved for larger values of the level number. In addition, these times are often better than the level-scheduling implementation of ILUT. The preprocessing times are not optimized for both algorithms, so it is difficult to give a comparison with the current implementations of

the overall process. These experiments do indicate, however, that a good implementation of ILUM may be a competitive approach to vector supercomputers.

5. Conclusion. The ideas of graph coloring and independent set ordering can be exploited to derive highly parallel incomplete LU factorizations. We have developed such incomplete factorizations and tested them on a Cray computer, exploiting only vectorization. However, the implementation of these techniques on massively parallel computers is likely to be complex. In most cases a good compromise may well be to perform a small number of ILUM reductions, perhaps one or two, and then solve the last reduced system with a multicolor multistep SOR preconditioned Krylov subspace iteration [44]. Nevertheless, the general idea of independent set orderings is powerful and can certainly be exploited in many other ways than those described in this paper.

Acknowledgments. The author would like to thank the anonymous referees for their help in improving the quality of this paper, and the Minnesota Supercomputer Institute for providing the computer facilities and an excellent research environment in which to conduct this research.

EFFICIENT ALGORITHMS FOR COMPUTING A STRONG RANK-REVEALING QR FACTORIZATION*

MING GU† AND STANLEY C. EISENSTAT‡

Abstract. Given an $m \times n$ matrix M with $m \geq n$, it is shown that there exists a permutation Π and an integer k such that the QR factorization

$$M\,\Pi = Q\begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix}$$

reveals the numerical rank of M: the $k \times k$ upper-triangular matrix A_k is well conditioned, $\|C_k\|_2$ is small, and B_k is linearly dependent on A_k with coefficients bounded by a low-degree polynomial in n. Existing rank-revealing QR (RRQR) algorithms are related to such factorizations and two algorithms are presented for computing them. The new algorithms are nearly as efficient as QR with column pivoting for most problems and take $O(mn^2)$ floating-point operations in the worst case.

Key words. orthogonal factorization, rank-revealing factorization, numerical rank

AMS subject classifications. 65F25, 15A23, 65F35

1. Introduction. Given a matrix $M \in \mathbf{R}^{m\times n}$ with $m \geq n$, we consider partial QR factorizations of the form

$$M\,\Pi = QR \equiv Q\begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix}, \tag{1}$$

where $Q \in \mathbf{R}^{m\times m}$ is orthogonal, $A_k \in \mathbf{R}^{k\times k}$ is upper triangular with nonnegative diagonal elements, $B_k \in \mathbf{R}^{k\times(n-k)}$, $C_k \in \mathbf{R}^{(m-k)\times(n-k)}$, and $\Pi \in \mathbf{R}^{n\times n}$ is a permutation matrix chosen to reveal linear dependence among the columns of M. Usually k is chosen to be the smallest integer $1 \leq k \leq n$ for which $\|C_k\|_2$ is sufficiently small [24, p. 235].

Golub [20] introduced these factorizations and, with Businger [8], developed the first algorithm (QR with column pivoting) for computing them. Applications include least-squares computations [11, 12, 17, 20, 21, 23, 36], subset selection and linear dependency analysis [12, 18, 22, 34, 44], subspace tracking [7], rank determination [10, 39], and nonsymmetric eigenproblems [2, 15, 26, 35]. Such factorizations are also related to condition estimation [4, 5, 25, 40] and the URV and ULV decompositions [14, 41, 42].

1.1. RRQR factorizations. By the interlacing property of the singular values [24, Cor. 8.3.3], for *any* permutation Π we have[1]

$$\sigma_i(A_k) \leq \sigma_i(M) \quad \text{and} \quad \sigma_j(C_k) \geq \sigma_{k+j}(M) \tag{2}$$

for $1 \leq i \leq k$ and $1 \leq j \leq n-k$. Thus,

$$\sigma_{\min}(A_k) \leq \sigma_k(M) \quad \text{and} \quad \sigma_{\max}(C_k) \geq \sigma_{k+1}(M). \tag{3}$$

Assume that $\sigma_k(M) \gg \sigma_{k+1}(M) \approx 0$, so that the numerical rank of M is k. Then we would like to find a Π for which $\sigma_{\min}(A_k)$ is sufficiently large and $\sigma_{\max}(C_k)$ is sufficiently

[1] Here $\sigma_i(X)$, $\sigma_{\max}(X)$, and $\sigma_{\min}(X)$ denote the ith largest, the largest, and the smallest singular values of the matrix X, respectively.

small. We call the factorization (1) a rank-revealing QR (RRQR) factorization if it satisfies (cf. (3))

$$\sigma_{\min}(A_k) \geq \frac{\sigma_k(M)}{p(k,n)} \quad \text{and} \quad \sigma_{\max}(C_k) \leq \sigma_{k+1}(M)\; p(k,n), \tag{4}$$

where $p(k,n)$ is a function bounded by a low-degree polynomial in k and n [13, 28]. Other, less restrictive definitions are discussed in [13] and [37]. The term "rank-revealing QR factorization" is due to Chan [10].

The Businger and Golub algorithm [8, 20] works well in practice, but there are examples where it fails to produce a factorization satisfying (4) (see Example 1 in §2). Other algorithms fail on similar examples [13]. Recently, Hong and Pan [28] showed that there exist RRQR factorizations with $p(k,n) = \sqrt{k(n-k) + \min(k, n-k)}$, and Chandrasekaran and Ipsen [13] developed an algorithm that computes one efficiently in practice,[2] given k.

1.2. Strong RRQR factorizations. In some applications it is necessary to find a basis for the approximate right null space of M, as in rank-deficient least-squares computations [23, 24] and subspace tracking [7], or to separate the linearly independent columns of M from the linearly dependent ones, as in subset selection and linear dependency analysis [12, 18, 22, 34, 44]. The RRQR factorization does not lead to a stable algorithm because the elements of $A_k^{-1}B_k$ can be very large (see Example 2 in §2).

In this paper we show that there exist QR factorizations that meet this need. We call the factorization (1) a *strong* RRQR factorization if it satisfies (cf. (2))

$$\sigma_i(A_k) \geq \frac{\sigma_i(M)}{q_1(k,n)} \quad \text{and} \quad \sigma_j(C_k) \leq \sigma_{k+j}(M)\; q_1(k,n) \tag{5}$$

and

$$\left|\left(A_k^{-1}B_k\right)_{i,j}\right| \leq q_2(k,n), \tag{6}$$

for $1 \leq i \leq k$ and $1 \leq j \leq n-k$, where $q_1(k,n)$ and $q_2(k,n)$ are functions bounded by low-degree polynomials in k and n. Clearly a strong RRQR factorization is also a RRQR factorization. In addition, condition (6) makes

$$\Pi \begin{pmatrix} -A_k^{-1}B_k \\ I_{n-k} \end{pmatrix}$$

an approximate right null space of M with a small residual independent of the condition number of A_k, provided that A_k is not too ill conditioned [38, pp. 192–198]. See [26] for another application.

We show that there exists a permutation Π for which conditions (5) and (6) hold with

$$q_1(k,n) = \sqrt{1 + k(n-k)} \quad \text{and} \quad q_2(k,n) = 1.$$

Since this permutation might take exponential time to compute, we present algorithms that, given $f \geq 1$, find a Π for which (5) and (6) hold with

$$q_1(k,n) = \sqrt{1 + f^2 k(n-k)} \quad \text{and} \quad q_2(k,n) = f.$$

Here k can be either an input parameter (Algorithm 4) or the smallest integer for which $\sigma_{\max}(C_k)$ is sufficiently small (Algorithm 5). When $f > 1$, these algorithms require $O\left((m + n\log_f n)n^2\right)$ floating-point operations. In particular, when f is a small power of n (e.g., $\sqrt{n}$ or n), they take $O(mn^2)$ time (see §4.4).

[2] In the worst case the runtime might be exponential in k or n. The algorithm proposed by Golub, Klema, and Stewart [22] also computes an RRQR factorization [30], but requires an orthogonal basis for the right null space.

Recently, Pan and Tang [37] presented an algorithm that, given $f > 1$, computes an RRQR factorization with $p(k,n) = f\sqrt{k(n-k)} + \max(k, n-k)$. This algorithm can be shown to be mathematically equivalent to Algorithm 5 and thus computes a strong RRQR factorization with $q_1(k,n) = \sqrt{1 + f^2k(n-k)}$ and $q_2(k,n) = f$. However, it is much less efficient. Pan and Tang [37] also present two practical modifications to their algorithm, but they do not always compute strong RRQR factorizations.

1.3. Overview. In §2 we review QR with column pivoting [8, 20] and the Chandrasekaran and Ipsen algorithm [13] for computing an RRQR factorization. In §3 we give a constructive existence proof for the strong RRQR factorization. In §4 we present an algorithm (Algorithm 5) that computes a strong RRQR factorization and bound the total number of operations required when $f > 1$; and in §5 we show that this algorithm is numerically stable. In §6 we report the results of some numerical experiments. In §7 we show that the concept of a strong RRQR factorization is not completely new in that the QR factorization given by the Businger and Golub algorithm [8, 20] satisfies (5) and (6) with $q_1(k,n)$ and $q_2(k,n)$ functions that grow exponentially with k. Finally, in §8 we present some extensions of this work, including a version of Algorithm 5 that is nearly as fast as QR with column pivoting for most problems and takes $O(mn^2)$ floating-point operations in the worst case.

1.4. Notation. By convention, A_k, $\bar{A}_k \in \mathbf{R}^{k\times k}$ denote upper-triangular matrices with nonnegative diagonal elements, and B_k, $\bar{B}_k \in \mathbf{R}^{k\times(n-k)}$ and C_k, $\bar{C}_k \in \mathbf{R}^{(m-k)\times(n-k)}$ denote general matrices.

In the partial QR factorization

$$X = Q\begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix}$$

of a matrix $X \in \mathbf{R}^{m\times n}$ (where the diagonal elements of A_k are nonnegative), we write

$$\mathcal{A}_k(X) = A_k, \quad \mathcal{C}_k(X) = C_k, \quad \text{and} \quad \mathcal{R}_k(X) = \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix}.$$

For A, a nonsingular $\ell \times \ell$ matrix, $1/\omega_i(A)$ denotes the 2-norm of the ith *row* of A^{-1} and $\omega_*(A) = (\omega_1(A), \ldots, \omega_\ell(A))^T$. For C, a matrix with ℓ columns, $\gamma_j(C)$ denotes the 2-norm of the jth *column* of C and $\gamma_*(C) = (\gamma_1(C), \ldots, \gamma_\ell(C))$.

$\Pi_{i,j}$ denotes the permutation that interchanges the ith and jth columns of a matrix.

A *flop* is a floating-point operation $\alpha \circ \beta$, where α and β are floating-point numbers and $\circ$ is one of $+$, $-$, $\times$, and $\div$. Taking the absolute value or comparing two floating-point numbers is also counted as a flop.

2. RRQR algorithms. QR with column pivoting [8, 20] is a modification of the ordinary QR algorithm.

ALGORITHM 1. QR with column pivoting.

```
$k := 0$; $R := M$; $\Pi := I$;
while $\max_{1\le j\le n-k} \gamma_j\,(\mathcal{C}_k(R)) \ge \delta$ do
    $j_{\max} := \operatorname{argmax}_{1\le j\le n-k}\ \gamma_j\,(\mathcal{C}_k(R))$;
    $k := k+1$;
    Compute $R := \mathcal{R}_k(R\,\Pi_{k,k+j_{\max}-1})$ and $\Pi := \Pi\,\Pi_{k,k+j_{\max}-1}$;
endfor;
```

When Algorithm 1 halts, we have

$$\sigma_{\max}\,(\mathcal{C}_k(M\,\Pi)) \le \sqrt{n-k}\ \max_{1\le j\le n-k} \gamma_j\,(\mathcal{C}_k(M\,\Pi)) \le \sqrt{n-k}\ \delta,$$

and if δ is sufficiently small, then the numerical rank of M is at most k. If the vector of column norms $\gamma_*\ (\mathcal{C}_k(R))$ is updated rather than recomputed from scratch each time, then Algorithm 1 takes about $4mnk - 2k^2(m+n) + 4k^3/3$ flops [24, p. 236].

Algorithm 1 uses a greedy strategy for finding well-conditioned columns: having determined the first k columns, it picks a column from the remaining $n-k$ columns that maximizes $\det\left[\mathcal{A}_{k+1}(R)\right]$ (see [13]). When there are only a few well-conditioned columns, this strategy is guaranteed to find a strong RRQR factorization (see §7). It also works well in general, but it fails to find an RRQR factorization for the following example.

Example 1 (Kahan [33]). Let $M = S_n K_n$, where

$$(7) \qquad S_n = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & \varsigma & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & \varsigma^{n-1} \end{pmatrix} \quad \text{and} \quad K_n = \begin{pmatrix} 1 & -\varphi & \cdots & -\varphi \\ 0 & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & -\varphi \\ 0 & \cdots & 0 & 1 \end{pmatrix},$$

with $\varphi, \varsigma > 0$ and $\varphi^2 + \varsigma^2 = 1$. Let $k = n-1$. Then Algorithm 1 does not permute the columns of M, yet it can be shown that

$$\frac{\sigma_k(M)}{\sigma_{\min}(A_k)} \geq \frac{\varphi^3(1+\varphi)^{n-4}}{2\varsigma},$$

and the right-hand side grows faster than any polynomial in k and n.

When $m = n$ and the numerical rank of M is close to n, Stewart [39] suggests applying Algorithm 1 to M^{-1}. Recently, Chandrasekaran and Ipsen [13] combined these ideas to construct an algorithm Hybrid-III(k) that is guaranteed to find an RRQR factorization, given k. We present it in a different form here to motivate our constructive proof of the existence of a strong RRQR factorization.

```
ALGORITHM 2. Hybrid-III(k).
  $R := M$; $\Pi := I$;
  repeat
    $i_{\min} := \mathrm{argmin}_{1 \leq i \leq k}\ \omega_i\ (\mathcal{A}_k(R))$;
    if there exists a $j$ such that $\det\left[\mathcal{A}_k(R\,\Pi_{i_{\min},j+k})\right] / \det\left[\mathcal{A}_k(R)\right] > 1$ then
      Find such a $j$;
      Compute $R := \mathcal{R}_k(R\,\Pi_{i_{\min},j+k})$ and $\Pi := \Pi\,\Pi_{i_{\min},j+k}$;
    endif;
    $j_{\max} := \mathrm{argmax}_{1 \leq j \leq n-k}\ \gamma_j\ (\mathcal{C}_k(R))$;
    if there exists an $i$ such that $\det\left[\mathcal{A}_k(R\,\Pi_{i,j_{\max}+k})\right] / \det\left[\mathcal{A}_k(R)\right] > 1$ then
      Find such an $i$;
      Compute $R := \mathcal{R}_k(R\,\Pi_{i,j_{\max}+k})$ and $\Pi := \Pi\,\Pi_{i,j_{\max}+k}$;
    endif;
  until no interchange occurs;
```

Since the objective is to find a permutation Π for which $\sigma_{\min}\ (\mathcal{A}_k(M\,\Pi))$ is sufficiently large and $\sigma_{\max}\ (\mathcal{C}_k(M\,\Pi))$ is sufficiently small, Algorithm 2 keeps interchanging the most "dependent" of the first k columns (column $i_{\min}$) with one of the last $n-k$ columns, and interchanging the most "independent" of the last $n-k$ columns (column $j_{\max}$) with one of the first k columns, as long as $\det\left[\mathcal{A}_k(R)\right]$ strictly increases.

Since $\det[\mathcal{A}_k(R)]$ strictly increases with every interchange, no permutation repeats; and since there are only a finite number of permutations, Algorithm 2 eventually halts. Chandrasekaran and Ipsen [13] also show that it computes an RRQR factorization, given k. Due to efficiency considerations, they suggest that it be run as a postprocessor to Algorithm 1.

But Algorithm 2 may not compute a strong RRQR factorization either.

Example 2. Let $k = n - 2$ and let

$$M \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} = \begin{pmatrix} S_{k-1}K_{k-1} & 0 & 0 & -\varphi S_{k-1}c_{k-1} \\ & \mu & 0 & 0 \\ & & \mu & 0 \\ & & & \mu \end{pmatrix},$$

where S_{k-1} and K_{k-1} are defined as in (7), $c_{k-1} = (1, \ldots, 1)^T \in \mathbf{R}^{k-1}$, and

$$\mu = \frac{1}{\sqrt{k}} \min_{1 \le i \le k-1} \omega_i(S_{k-1}K_{k-1}).$$

Then Algorithm 2 does not permute the columns of M (note that $i_{\min} = k$ and $j_{\max} = k + 1$), yet it can be shown that

$$\frac{\sigma_{k-1}(M)}{\sigma_{k-1}(A_k)} \ge \frac{\varphi^3(1+\varphi)^{k-4}}{2\varsigma} \quad \text{and} \quad \|A_k^{-1}B_k\|_\infty = \varphi(1+\varphi)^{k-2},$$

and the right-hand sides grow faster than any polynomial in k and n.

Since Algorithm 1 does not permute the columns of M, this example also shows that Algorithm 2 may not compute a strong RRQR factorization even when it is run as a postprocessor to Algorithm 1.

3. The existence of a strong RRQR factorization.

A strong RRQR factorization satisfies three conditions: *every* singular value of A_k is sufficiently large, *every* singular value of C_k is sufficiently small, and *every* element of $A_k^{-1}B_k$ is bounded. Since

$$\det(A_k) = \prod_{i=1}^{k} \sigma_i(A_k) = \sqrt{\det(M^TM)} \Bigg/ \prod_{j=1}^{n-k} \sigma_j(C_k),$$

a strong RRQR factorization also results in a large $\det(A_k)$. Given k and $f \ge 1$, Algorithm 3 below[3] constructs a strong RRQR factorization by using column interchanges to try to maximize $\det(A_k)$.

```
ALGORITHM 3. Compute a strong RRQR factorization, given $k$.
  $R := \mathcal{R}_k(M)$; $\Pi := I$;
  while there exist $i$ and $j$ such that $\det(\bar{A}_k))/\det(A_k) > f$,
     where $R = \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix}$ and $\mathcal{R}_k(R\,\Pi_{i,j+k}) = \begin{pmatrix} \bar{A}_k & \bar{B}_k \\ & \bar{C}_k \end{pmatrix}$, do
     Find such an $i$ and $j$;
     Compute $R := \mathcal{R}_k(R\,\Pi_{i,j+k})$ and $\Pi := \Pi\,\Pi_{i,j+k}$;
  endwhile;
```

While Algorithm 2 interchanges either the most "dependent" column of A_k or the most "independent" column of C_k, Algorithm 3 interchanges any pair of columns that sufficiently increases $\det(A_k)$. As before, there are only a finite number of permutations and none can repeat, so that it eventually halts.

[3] The algorithms in this section are only intended to prove the existence of a strong RRQR factorization. Efficient algorithms will be presented in §§4 and 8.

To prove that Algorithm 3 computes a strong RRQR factorization, we first express $\det(\bar{A}_k)/\det(A_k)$ in terms of $\omega_i(A_k)$, $\gamma_j(C_k)$, and $\left(A_k^{-1}B_k\right)_{i,j}$.

LEMMA 3.1. *Let*

$$R = \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} \quad \textit{and} \quad \mathcal{R}_k(R\,\Pi_{i,j+k}) = \begin{pmatrix} \bar{A}_k & \bar{B}_k \\ & \bar{C}_k \end{pmatrix},$$

where A_k *has positive diagonal elements. Then*

$$\frac{\det(\bar{A}_k)}{\det(A_k)} = \sqrt{\left(A_k^{-1}B_k\right)_{i,j}^2 + \left(\gamma_j(C_k)/\omega_i(A_k)\right)^2}.$$

Proof. First, assume that $i < k$ or that $j > 1$. Let $A_k\,\Pi_{i,k} = \tilde{Q}\tilde{A}_k$ be the QR factorization of $A_k\,\Pi_{i,k}$, let $\tilde{B}_k = \tilde{Q}^T B_k\,\Pi_{1,j}$ and $\tilde{C}_k = C_k\,\Pi_{1,j}$, and let $\tilde{\Pi} = \operatorname{diag}(\Pi_{i,k}, \Pi_{1,j})$. Then

$$R\,\tilde{\Pi} \equiv \begin{pmatrix} A_k\,\Pi_{i,k} & B_k\,\Pi_{1,j} \\ & C_k\,\Pi_{1,j} \end{pmatrix} = \begin{pmatrix} \tilde{Q} & \\ & I_{m-k} \end{pmatrix} \begin{pmatrix} \tilde{A}_k & \tilde{B}_k \\ & \tilde{C}_k \end{pmatrix}$$

is the QR factorization of $R\,\tilde{\Pi}$. Since both A_k and $\tilde{A}_k$ have positive diagonal elements, we have $\det(A_k) = \det(\tilde{A}_k)$. Since $\tilde{A}_k^{-1}\tilde{B}_k = \Pi_{i,k}^T A_k^{-1} B_k \Pi_{1,j}$, we have $(A_k^{-1}B_k)_{i,j} = (\tilde{A}_k^{-1}\tilde{B}_k)_{k,1}$. Since $\tilde{A}_k^{-1} = \Pi_{i,k}^T A_k^{-1} B_k \tilde{Q}$ and postmultiplication by an orthogonal matrix leaves the 2-norms of the rows unchanged, we have $\omega_i(A_k) = \omega_k(\tilde{A}_k)$. Finally, we have $\gamma_j(C_k) = \gamma_1(\tilde{C}_k)$. Thus it suffices to consider the special case $i = k$ and $j = 1$.

Partition

$$\mathcal{R}_{k+1}(R) = \begin{pmatrix} A_{k-1} & b_1 & b_2 & B \\ & \gamma_1 & \beta & c_1^T \\ & & \gamma_2 & c_2^T \\ & & & C_{k+1} \end{pmatrix}.$$

Then $\omega_i(A_k) = \gamma_1$, $\gamma_j(C_k) = \gamma_2$, and $\left(A_k^{-1}B_k\right)_{i,j} = \beta/\gamma_1$. But $\det(A_k) = \det(A_{k-1})\,\gamma_1$ and $\det(\bar{A}_k) = \det(A_{k-1})\sqrt{\beta^2 + \gamma_2^2}$, so that

$$\frac{\det(\bar{A}_k)}{\det(A_k)} = \sqrt{(\beta/\gamma_1)^2 + (\gamma_2/\gamma_1)^2} = \sqrt{\left(A_k^{-1}B_k\right)_{i,j}^2 + \left(\gamma_j(C_k)/\omega_i(A_k)\right)^2},$$

which is the result required. □

Let

$$\rho(R,k) = \max_{1\le i\le k,\ 1\le j\le n-k} \sqrt{\left(A_k^{-1}B_k\right)_{i,j}^2 + \left(\gamma_j(C_k)/\omega_i(A_k)\right)^2}.$$

Then by Lemma 3.1, Algorithm 3 can be rewritten as the following.

ALGORITHM 4. Compute a strong RRQR factorization, given k.

```
Compute $R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} := \mathcal{R}_k(M)$ and $\Pi = I$;
while $\rho(R,k) > f$ do
    Find $i$ and $j$ such that $\sqrt{\left(A_k^{-1}B_k\right)_{i,j}^2 + \left(\gamma_j(C_k)/\omega_i(A_k)\right)^2} > f$;
    Compute $R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} := \mathcal{R}_k(R\,\Pi_{i,j+k})$ and $\Pi := \Pi\,\Pi_{i,j+k}$;
endwhile;
```

Since Algorithm 4 is equivalent to Algorithm 3, it eventually halts and finds a permutation Π for which $\rho(\mathcal{R}_k(M\,\Pi), k) \le f$. This implies (6) with $q_2(k,n) = f$. Now we show that this also implies (5) with $q_1(k,n) = \sqrt{1 + f^2 k(n-k)}$, i.e., that Algorithms 3 and 4 compute a strong RRQR factorization, given k.

THEOREM 3.2. *Let*

$$R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} = \mathcal{R}_k(M\,\Pi)$$

satisfy $\rho(R,k) \le f$. *Then*

$$\sigma_i(A_k) \ge \frac{\sigma_i(M)}{\sqrt{1 + f^2 k(n-k)}}, \qquad 1 \le i \le k, \tag{8}$$

and

$$\sigma_j(C_k) \le \sigma_{j+k}(M)\,\sqrt{1 + f^2 k(n-k)}, \qquad 1 \le j \le n-k. \tag{9}$$

Proof. For simplicity we assume that M (and therefore R) has full column rank. Let $\alpha = \sigma_{\max}(C_k)/\sigma_{\min}(A_k)$, and write

$$R = \begin{pmatrix} A_k & \\ & C_k/\alpha \end{pmatrix} \begin{pmatrix} I_k & A_k^{-1}B_k \\ & \alpha I_{n-k} \end{pmatrix} \equiv \tilde{R}_1 W_1.$$

Then by [29, Thm. 3.3.16],

$$\sigma_i(R) \le \sigma_i(\tilde{R}_1)\; \|W_1\|_2, \qquad 1 \le i \le n. \tag{10}$$

Since $\sigma_{\min}(A_k) = \sigma_{\max}(C_k/\alpha)$, we have $\sigma_i(\tilde{R}_1) = \sigma_i(A_k)$ for $1 \le i \le k$. Moreover,

$$\begin{aligned}
\|W_1\|_2^2 &\le 1 + \|A_k^{-1}B_k\|_2^2 + \alpha^2 \\
&= 1 + \|A_k^{-1}B_k\|_2^2 + \|C_k\|_2^2 \|A_k^{-1}\|_2^2 \\
&\le 1 + \|A_k^{-1}B_k\|_F^2 + \|C_k\|_F^2 \|A_k^{-1}\|_F^2 \\
&= 1 + \sum_{i=1}^{k} \sum_{j=1}^{n-k} \left\{ \left(A_k^{-1}B_k\right)_{i,j}^2 + \gamma_j(C_k)^2/\omega_i(A_k)^2 \right\} \\
&\le 1 + f^2 k(n-k),
\end{aligned}$$

so that $\|W_1\|_2 \le \sqrt{1 + f^2 k(n-k)}$. Plugging these relations into (10), we get (8). Similarly, let

$$\tilde{R}_2 \equiv \begin{pmatrix} \alpha A_k & \\ & C_k \end{pmatrix} = \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} \begin{pmatrix} \alpha I_k & -A_k^{-1}B_k \\ & I_{n-k} \end{pmatrix} \equiv R W_2.$$

Then

$$\sigma_j(C_k) = \sigma_{j+k}(\tilde{R}_2) \le \sigma_{j+k}(R) \|W_2\|_2 \le \sigma_{j+k}(M)\,\sqrt{1 + f^2 k(n-k)},$$

which is (9). □

4. Computing a strong RRQR factorization. Given $f \ge 1$ and a tolerance $\delta > 0$, Algorithm 5 below computes both k and a strong RRQR factorization. It is a combination of the ideas in Algorithms 1 and 4 but uses

$$\hat{\rho}(R,k) = \max_{1 \le i \le k,\ 1 \le j \le n-k} \max\left\{ \left| \left(A_k^{-1}B_k\right)_{i,j} \right|,\ \gamma_j(C_k)/\omega_i(A_k) \right\}$$

instead of $\rho(R,k)$ and computes $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$ recursively for greater efficiency.

ALGORITHM 5. Compute k and a strong RRQR factorization.

```
$k := 0$; $R \equiv C_k := M$; $\Pi := I$;
Initialize $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$;
while $\max_{1\le j\le n-k} \gamma_j(C_k) \ge \delta$ do
    $j_{\max} := \operatorname{argmax}_{1\le j\le n-k}\ \gamma_j(C_k)$;
    $k := k+1$;
    Compute $R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} := \mathcal{R}_k(R\,\Pi_{k,k+j_{\max}-1})$ and $\Pi := \Pi\,\Pi_{k,k+j_{\max}-1}$;
    Update $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$;
    while $\hat{\rho}(R,k) > f$ do
        Find $i$ and $j$ such that $\left|\left(A_k^{-1}B_k\right)_{i,j}\right| > f$ or $\gamma_j(C_k)/\omega_i(A_k) > f$;
        Compute $R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} := \mathcal{R}_k(R\,\Pi_{i,j+k})$ and $\Pi := \Pi\,\Pi_{i,j+k}$;
        Modify $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$;
    endwhile;
endwhile;
```

Since its inner **while**-loop is essentially equivalent to Algorithm 4, Algorithm 5 must eventually halt, having found k and a permutation Π for which $\hat{\rho}(R,k) \le f$. This implies that $\rho(\mathcal{R}_k(M\,\Pi),k) \le \sqrt{2}\,f$, so that (5) and (6) are satisfied with[4] $q_1(k,n) = \sqrt{1+2f^2k(n-k)}$ and $q_2(k,n) = \sqrt{2}f$.

Remark 1. Note that

$$\frac{\sigma_{k+1}(M)}{\sigma_k(M)} \ge \frac{1}{q_1(k,n)^2}\,\frac{\sigma_{\max}(C_k)}{\sigma_{\min}(A_k)} \ge \frac{1}{q_1(k,n)^2} \max_{1\le i\le k,\ 1\le j\le n-k} \frac{\gamma_j(C_k)}{\omega_i(A_k)}$$

and

$$\frac{\sigma_{k+1}(M)}{\sigma_k(M)} \le \frac{\sigma_{\max}(C_k)}{\sigma_{\min}(A_k)} \le \sqrt{k(n-k)} \max_{1\le i\le k,\ 1\le j\le n-k} \frac{\gamma_j(C_k)}{\omega_i(A_k)}.$$

Thus Algorithm 5 can detect a sufficiently large gap in the singular values of M if we change the condition in the outer **while**-loop to

$$\max_{1\le j\le n-k} \gamma_j(C_k) \ge \delta \quad \textbf{or} \quad \max_{1\le i\le k,\ 1\le j\le n-k} \gamma_j(C_k)/\omega_i(A_k) \ge \zeta,$$

where ζ is some tolerance. This is useful when solving rank-deficient least-squares problems using RRQR factorizations (see [11, 12] and the references therein).

In §§4.1–4.3 we show how to update A_k, B_k, C_k, $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$ after k increases and to modify them after an interchange. In §4.4 we bound the total number of interchanges and the total number of operations. We will discuss numerical stability in §5.

4.1. Updating formulas.

Let

$$R = \begin{pmatrix} A_{k-1} & B_{k-1} \\ & C_{k-1} \end{pmatrix} \quad \text{and} \quad \mathcal{R}_k(R\,\Pi_{k,k+j_{\max}-1}) = \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix}.$$

Assume that we have already computed A_{k-1}, B_{k-1}, C_{k-1}, $\omega_*(A_{k-1})$, $\gamma_*(C_{k-1})$, and $A_{k-1}^{-1}B_{k-1}$. In this subsection we show how to compute A_k, B_k, C_k, $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$. For simplicity we assume that $j_{\max} = 1$, so that $\gamma_1(C_{k-1}) \ge \gamma_j(C_{k-1})$ for $1 \le j \le n-k+1$.

[4] To get $q_1(k,n) = \sqrt{1+f^2k(n-k)}$ and $q_2(k,n) = f$, replace $\hat{\rho}(R,k)$ by $\rho(R,k)$ or replace f by $f/\sqrt{2}$ (assuming that $f > \sqrt{2}$) in Algorithm 5.

Let $H \in \mathbf{R}^{(m-k)\times(m-k)}$ be an orthogonal matrix that zeroes out the elements below the diagonal in the first column of C_{k-1}, and let

$$B_{k-1} = (\, b \quad B\,) \quad \text{and} \quad HC_{k-1} = \begin{pmatrix} \gamma & c^T \\ & C \end{pmatrix},$$

where $\gamma = \gamma_1(C_{k-1})$. Then

$$\begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} = \begin{pmatrix} A_{k-1} & b & B \\ & \gamma & c^T \\ & & C \end{pmatrix},$$

so that

$$A_k = \begin{pmatrix} A_{k-1} & b \\ & \gamma \end{pmatrix}, \quad B_k = \begin{pmatrix} B \\ c^T \end{pmatrix}, \quad \text{and} \quad C_k = C.$$

Let $A_{k-1}^{-1}B_{k-1} = (\, u \quad U\,)$. Then

$$A_k^{-1} = \begin{pmatrix} A_{k-1}^{-1} & -u/\gamma \\ & 1/\gamma \end{pmatrix} \quad \text{and} \quad A_k^{-1}B_k = \begin{pmatrix} U - uc^T/\gamma \\ c^T/\gamma \end{pmatrix}.$$

Let $u = (\mu_1, \ldots, \mu_{k-1})^T$ and $c = (\nu_1, \ldots, \nu_{n-k})^T$. Then $\omega_*(A_k)$ and $\gamma_*(C_k)$ can be computed from

$$\omega_k(A_k) = \gamma \quad \text{and} \quad 1/\omega_i(A_k)^2 = 1/\omega_i(A_{k-1})^2 + \mu_i^2/\gamma^2, \quad 1 \le i \le k-1$$

and

$$\gamma_j(C_k)^2 = \gamma_{j+1}(C_{k-1})^2 - \nu_j^2, \quad 1 \le j \le n-k.$$

The main cost of the updating procedure is in computing HC_{k-1} and $U - uc^T/\gamma$, which take about $4(m-k)(n-k)$ and $2k(n-k)$ flops, respectively, for a total of about $2(2m-k)(n-k)$ flops.

Remark 2. Since $f \ge 1$, $\rho(R, k-1) \le \sqrt{2}\, f$, and $\gamma \ge \gamma_{j+1}(C_{k-1}) \ge \nu_j$, for $1 \le j \le n-k$, we have

$$\left|\left(A_k^{-1}B_k\right)_{i,j}\right| \le 2f \quad \text{and} \quad \gamma_j(C_k)/\omega_i(A_k) \le \sqrt{2}\, f,$$

so that

$$\rho(\mathcal{R}_k(R\,\Pi_{k,j_{\max}}), k) \le \sqrt{6}\, f.$$

This bound will be used in §5.1.

4.2. Reducing a general interchange to a special one. Assume that there is an interchange between the ith and $(j+k)$th columns of R. In this subsection we show how to reduce this to the special case $i = k$ and $j = 1$.

Let

$$R = \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix}.$$

If $j > 1$, then interchange the $(k+1)$st and $(k+j)$th columns of R. This only interchanges the corresponding columns in B_k, C_k, $\gamma_*(C_k)$, and $A_k^{-1}B_k$. Henceforth we assume that $i < k$ and $j = 1$.

Partition

$$A_k = \begin{pmatrix} A_{1,1} & a_1 & A_{1,2} \\ & \alpha & a_2^T \\ & & A_{2,2} \end{pmatrix},$$

where $A_{1,1} \in \mathbf{R}^{(i-1)\times(i-1)}$ and $A_{2,2} \in \mathbf{R}^{(k-i)\times(k-i)}$ are upper triangular. Let Π_k be the permutation that cyclically shifts the last $k - i + 1$ columns of A_k to the left, so that

$$A_k\,\Pi_k = \begin{pmatrix} A_{1,1} & A_{1,2} & a_1 \\ & a_2^T & \alpha \\ & A_{2,2} & \end{pmatrix}.$$

Note that $A_k\,\Pi_k$ is an upper-Hessenberg matrix with nonzero subdiagonal elements in columns $i, i+1, \ldots, k-1$.

To retriangularize $A_k\,\Pi_k$, we apply Givens rotations to successively zero out the nonzero subdiagonal elements in columns $i, i+1, \ldots, k-1$ (see [19, 24]). Let Q_k^T be the product of these Givens rotations, so that $Q_k^T A_k\,\Pi_k$ is upper triangular.

Let $\tilde{\Pi} = \operatorname{diag}(\Pi_k, I_{n-k})$, so that the ith column of R is the kth column of $R\,\tilde{\Pi}$. Then

$$R\,\tilde{\Pi} = \begin{pmatrix} A_k\,\Pi_k & B_k \\ & C_k \end{pmatrix} \quad \text{and} \quad \mathcal{R}_k(R\,\tilde{\Pi}) \equiv \begin{pmatrix} \bar{A}_k & \bar{B}_k \\ & \bar{C}_k \end{pmatrix} = \begin{pmatrix} Q_k^T A_k\,\Pi_k & Q_k^T B_k \\ & C_k \end{pmatrix}.$$

Since $\bar{A}_k^{-1} = \Pi_k^T A_k^{-1} Q_k$ and postmultiplication by an orthogonal matrix leaves the 2-norms of the rows unchanged, it follows that

$$\omega_*(\bar{A}_k) = \Pi_k^T\,\omega_*(A_k), \quad \gamma_*(\bar{C}_k) = \gamma_*(C_k), \quad \text{and} \quad \bar{A}_k^{-1}\bar{B}_k = \Pi_k^T\left(A_k^{-1}B_k\right).$$

The main cost of this reduction is in computing $Q_k^T A_k\,\Pi_k$ and $Q_k^T B_k$, which takes about $3\left((n-i)^2 - (n-k)^2\right) \le 3k(2n-k)$ flops.

4.3. Modifying formulas. In this subsection we show how to modify A_k, B_k, C_k, $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$ when there is an interchange between the kth and $(k+1)$st columns of R. We assume that we have already zeroed out the elements below the diagonal in the $(k+1)$st column.

Writing

$$R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} = \begin{pmatrix} A_{k-1} & b_1 & b_2 & B \\ & \gamma & \gamma\mu & c_1^T \\ & & \gamma\nu & c_2^T \\ & & & C_{k+1} \end{pmatrix},$$

we have

$$\mathcal{R}_{k+1}(R\,\Pi_{k,k+1}) \equiv \begin{pmatrix} \bar{A}_k & \bar{B}_k \\ & \bar{C}_k \end{pmatrix} = \begin{pmatrix} A_{k-1} & b_2 & b_1 & B \\ & \bar{\gamma} & \gamma\mu/\rho & \bar{c}_1^T \\ & & \gamma\nu/\rho & \bar{c}_2^T \\ & & & C_{k+1} \end{pmatrix},$$

where $\rho = \sqrt{\mu^2 + \nu^2}$, $\bar{\gamma} = \gamma\rho$, $\bar{c}_1 = (\mu c_1 + \nu c_2)/\rho$, and $\bar{c}_2 = (\nu c_1 - \mu c_2)/\rho$.

From the expression for R, we also have

$$A_k^{-1} = \begin{pmatrix} A_{k-1}^{-1} & -u/\gamma \\ & 1/\gamma \end{pmatrix},$$

where $u = A_{k-1}^{-1} b_1$. Since A_{k-1} is upper triangular, we can compute u using back-substitution. Moreover,

$$A_k^{-1} B_k \equiv \begin{pmatrix} u_1 & U \\ \mu & u_2^T \end{pmatrix} = \begin{pmatrix} A_{k-1}^{-1} & -u/\gamma \\ & 1/\gamma \end{pmatrix} \begin{pmatrix} b_2 & B \\ \gamma\mu & c_1^T \end{pmatrix},$$

so that

$$A_{k-1}^{-1} b_2 = u_1 + \mu u \quad \text{and} \quad A_{k-1}^{-1} B = U + u c_1^T/\gamma.$$

It follows that

$$\bar{A}_k^{-1} = \begin{pmatrix} A_{k-1}^{-1} & -A_{k-1}^{-1} b_2/\bar{\gamma} \\ & 1/\bar{\gamma} \end{pmatrix} = \begin{pmatrix} A_{k-1}^{-1} & -(u_1 + \mu u)/\bar{\gamma} \\ & 1/\bar{\gamma} \end{pmatrix}$$

and

$$\begin{aligned} \bar{A}_k^{-1} \bar{B}_k &= \begin{pmatrix} A_{k-1}^{-1} & -(u_1 + \mu u)/\bar{\gamma} \\ & 1/\bar{\gamma} \end{pmatrix} \begin{pmatrix} b_1 & B \\ \gamma\mu/\rho & \bar{c}_1^T \end{pmatrix} \\ &= \begin{pmatrix} \left(1 - \gamma\mu^2/(\bar{\gamma}\rho)\right) u - (\gamma\mu/(\bar{\gamma}\rho))\, u_1 & A_{k-1}^{-1} B - (u_1 + \mu u)\bar{c}_1^T/\bar{\gamma} \\ \gamma\mu/(\bar{\gamma}\rho) & \bar{c}_1^T/\bar{\gamma} \end{pmatrix}. \end{aligned} \tag{11}$$

Simplifying,

$$1 - \gamma\mu^2/(\bar{\gamma}\rho) = 1 - \mu^2/\rho^2 = \nu^2/\rho^2 \quad \text{and} \quad \gamma\mu/(\bar{\gamma}\rho) = \mu/\rho^2.$$

We also have

$$\begin{aligned} A_{k-1}^{-1} B - (u_1 + \mu u)\bar{c}_1^T/\bar{\gamma} &= U + u c_1^T/\gamma - \mu u \bar{c}_1^T/\bar{\gamma} - u_1 \bar{c}_1^T/\bar{\gamma} \\ &= U + u\,(\rho c_1 - \mu \bar{c}_1)^T/\bar{\gamma} - u_1 \bar{c}_1^T/\bar{\gamma} \\ &= U + \nu u \bar{c}_2^T/\bar{\gamma} - u_1 \bar{c}_1^T/\bar{\gamma}. \end{aligned}$$

Plugging these relations into (11), we get

$$\bar{A}_k^{-1} \bar{B}_k = \begin{pmatrix} \left(\nu^2 u - \mu u_1\right)/\rho^2 & U + \left(\nu u \bar{c}_2^T - u_1 \bar{c}_1^T\right)/\bar{\gamma} \\ \mu/\rho^2 & \bar{c}_1^T/\bar{\gamma} \end{pmatrix}.$$

Let

$$u = \begin{pmatrix} \mu_1 \\ \vdots \\ \mu_{k-1} \end{pmatrix}, \quad u_1 + \mu u = \begin{pmatrix} \bar{\mu}_1 \\ \vdots \\ \bar{\mu}_{k-1} \end{pmatrix}, \quad c_2 = \begin{pmatrix} \nu_2 \\ \vdots \\ \nu_{n-k} \end{pmatrix}, \quad \text{and} \quad \bar{c}_2 = \begin{pmatrix} \bar{\nu}_2 \\ \vdots \\ \bar{\nu}_{n-k} \end{pmatrix}.$$

Then $\omega_*(A_k)$ and $\gamma_*(C_k)$ can be computed from

$$\omega_k(\bar{A}_k) = \bar{\gamma} \quad \text{and} \quad \omega_i(\bar{A}_k)^2 = \omega_i(A_k)^2 + \bar{\mu}_i^2/\bar{\gamma}^2 - \mu_i^2/\gamma^2, \quad 1 \le i \le k-1,$$

and

$$\gamma_1(\bar{C}_k) = \gamma\nu/\rho \quad \text{and} \quad \gamma_j(\bar{C}_k)^2 = \gamma_j(C_k)^2 + \bar{\nu}_j^2 - \nu_j^2, \quad 2 \le j \le n-k.$$

The cost of zeroing out the elements below the diagonal in the $(k+1)$st column is about $4(m-k)(n-k)$ flops, the cost of computing u is about k^2 flops, and the cost of computing $\bar{A}_k^{-1}\bar{B}_k$ is about $4k(n-k)$ flops. Thus the total cost of the modification is about $4m(n-k)+k^2$ flops.

4.4. Efficiency. In this subsection we derive an upper bound on the total number of interchanges and bound the total number of flops. We only consider the case $f > 1$.

Let τ_k be the number of interchanges performed for a particular value of k (i.e., within the inner **while**-loop), and let Δ_k be the determinant of A_k after these interchanges are complete (by convention, $\Delta_0 = 1$). Since $\det(A_k) = \Delta_{k-1}\,\gamma_{j_{\max}}(C_{k-1})$ before the interchanges, and each interchange increases $\det(A_k)$ by at least a factor of f, it follows that

$$\Delta_k \geq \Delta_{k-1}\,\gamma_{j_{\max}}(C_{k-1})\,f^{\tau_k}.$$

By (3), we have

$$\sigma_{l+1}(M) \leq \sigma_{\max}\left(\mathcal{C}_l(M)\right) \leq \|\mathcal{C}_l(M)\|_F \leq \sqrt{n-l}\;\gamma_{j_{\max}}\left(\mathcal{C}_l(M)\right),$$

for $1 \leq l < n$, so that

$$\Delta_k \geq \Delta_{k-1}\,\frac{1}{\sqrt{n}}\,\sigma_k(M)\,f^{\tau_k} \geq \left(\frac{1}{\sqrt{n}}\right)^k \left\{\prod_{i=1}^{k}\sigma_i(M)\right\} f^{t_k},$$

where $t_k = \sum_{i=1}^{k}\tau_i$ is the total number of interchanges up to this point. On the other hand, from (2) we also have

$$\Delta_k = \prod_{i=1}^{k}\sigma_i(A_k) \leq \prod_{i=1}^{k}\sigma_i(M).$$

Combining these relations, we have $f^{t_k} \leq (\sqrt{n})^k$, so that $t_k \leq k\log_f\sqrt{n}$.

The cost of the updating procedure is about $2(2m-k)(n-k)$ flops (see §4.1), the cost of the reduction procedure is at most about $3k(2n-k)$ flops (see §4.2), and the cost of the modifying procedure is about $4m(n-k)+k^2$ flops (see §4.3). For each increase in k and each interchange, the cost of finding $\hat{\rho}(R,k)$ is about $2k(n-k)$ flops (taking $k(n-k)$ absolute values and making $k(n-k)$ comparisons).

Let k_f be the final value of k when Algorithm 5 halts. Then the total number of interchanges t_{k_f} is bounded by $k_f\log_f\sqrt{n}$, which is $O(k_f)$ when f is taken to be a small power of n (e.g., $\sqrt{n}$ or n). Thus the total cost is at most about

$$\begin{aligned}&\sum_{k=1}^{k_f}\left[2(2m-k)(n-k)+2k(n-k)\right]\\ &\qquad + t_{k_f}\max_{1\leq k\leq k_f}\left[3k(2n-k)+4m(n-k)+k^2+2k(n-k)\right]\\ &\leq 2mk_f(2n-k_f)+4t_{k_f}n(m+n)\end{aligned}$$

flops. When f is taken to be a small power of n (e.g., $\sqrt{n}$ or n), the total cost is $O(mnk_f)$ flops. Normally t_{k_f} is quite small (see §6), and thus the cost is about $2mk_f(2n-k_f)$ flops. When $m \gg n$, Algorithm 5 is almost as fast as Algorithm 1; when $m \approx n$, Algorithm 5 is about 50% more expensive. We will discuss efficiency further in §§6 and 8.

5. Numerical stability. Since we update and modify $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$ rather than recompute them, we might expect some loss of accuracy. But since we only use these quantities for deciding which pairs of columns to interchange, Algorithm 5 could only be unstable if they were extremely inaccurate.

In §5.1 we give an upper bound for $\rho(R,k)$ during the interchanges. Since this bound grows slowly with k, Theorem 3.2 asserts that A_k can never be extremely ill conditioned, provided that $\sigma_k(M)$ is not very much smaller than $\|M\|_2$. This implies that the elements of $A_k^{-1}B_k$ cannot be too inaccurate. In §5.2 we discuss the numerical stability of updating and modifying $\omega_*(A_k)$ and $\gamma_*(C_k)$.

5.1. An upper bound on $\rho(R,k)$ during interchanges.

We only consider the case $f > 1$.

LEMMA 5.1. *Let $A, C, U \in \mathbf{R}^{k\times k}$, where A is upper triangular with positive diagonal elements and $U = (u_{i,j})$. If*

$$\sqrt{u_{i,j}^2 + \left(\gamma_j(C)/\omega_i(A)\right)^2} \le f, \qquad 1 \le i, j \le k,$$

then

$$\sqrt{\det\left[(AU)^T AU + C^T C\right]} \le \det(A)\,\left(\sqrt{2k}\,f\right)^k.$$

Proof. First, note that

$$\sqrt{\det\left[(AU)^T AU + C^T C\right]} = \prod_{i=1}^{k} \sigma_i\left(\begin{pmatrix} AU \\ C \end{pmatrix}\right).$$

Let $\alpha = \sigma_{\min}(A)$, and write

$$W \equiv \begin{pmatrix} AU \\ C \end{pmatrix} = \begin{pmatrix} A & \\ & \alpha I_k \end{pmatrix}\begin{pmatrix} U \\ C/\alpha \end{pmatrix} \equiv \tilde{D}\,\tilde{W}.$$

By [29, Thm. 3.3.4], we have

$$\prod_{i=1}^{k} \sigma_i(W) \le \prod_{i=1}^{k} \sigma_i(\tilde{D})\,\sigma_i(\tilde{W}).$$

Since $\sigma_i(\tilde{D}) = \sigma_i(A)$, for $1 \le i \le k$, we have

$$\prod_{i=1}^{k} \sigma_i(\tilde{D}) = \prod_{i=1}^{k} \sigma_i(A) = \det(A).$$

Now, since $\tilde{W}^T\tilde{W}$ is symmetric and positive definite,

$$\prod_{i=1}^{k} \sigma_i(\tilde{W}) = \sqrt{\det(\tilde{W}^T\tilde{W})} \le \sqrt{\prod_{i=1}^{k} (\tilde{W}^T\tilde{W})_{i,i}} = \prod_{i=1}^{k} \|\tilde{W}e_i\|_2,$$

and, since

$$\frac{1}{\alpha} = \|A^{-1}\|_2 \le \sqrt{k}\max_{1\le i\le k}\frac{1}{\omega_i(A)} = \frac{\sqrt{k}}{\min\limits_{1\le i\le k}\omega_i(A)},$$

we have

$$\|\tilde{W}e_j\|_2^2 = \sum_{i=1}^{k} u_{ij}^2 + \frac{\gamma_j(C)^2}{\alpha^2} \le kf^2 + \frac{k\gamma_j(C)^2}{\min\limits_{1\le i\le k}\omega_i(A)^2} \le 2kf^2.$$

The result follows immediately. □

To derive an upper bound on $\rho(R,k)$ during the interchanges, we use techniques similar to those used by Wilkinson [43] to bound the growth factor for Gaussian elimination with complete pivoting.[5] Let

$$\mathcal{W}(\tau) = \left(\tau\prod_{s=2}^{\tau} s^{1/(s-1)}\right)^{1/2},$$

[5] See [13] for a connection between the growth factor for Gaussian elimination with *partial* pivoting and the failure of RRQR algorithms.

which is Wilkinson's upper bound on the growth factor for Gaussian elimination with complete pivoting on a $\tau \times \tau$ matrix. Although $\mathcal{W}(\tau)$ is not a polynomial in τ, it grows rather slowly [43]: $\mathcal{W}(\tau) = O\big(\tau^{1+\frac{1}{4}\log\tau}\big)$.

THEOREM 5.2. *If Algorithm 5 performs τ interchanges for some $k > 1$, then*

$$\rho(\mathcal{R}_k(M\,\Pi), k) \le 2\sqrt{6}\, f\, (\tau+1)\, \mathcal{W}(\tau+1).$$

Proof. Assume that Algorithm 5 will perform at least one interchange for this value of k; otherwise the result holds trivially.

Let $\Pi^{(l)}$ be the permutation after the first l interchanges, where $0 \le l \le \tau + 1$. Partition

$$M\,\Pi^{(l)} = \begin{pmatrix} M_k^{(l)} & M_{n-k}^{(l)} \end{pmatrix},$$

where $M_k^{(l)} \in \mathbf{R}^{m\times k}$ and $M_{n-k}^{(l)} \in \mathbf{R}^{m\times(n-k)}$. Assume that $\eta(l,\tau)$ columns of $M_k^{(\tau+1)}$ are from $M_{n-k}^{(l)}$, and that the rest are from $M_k^{(l)}$. Since there are $\tau - l + 1$ more interchanges, we have[6] $\eta(l,\tau) \le \tau - l + 1$.

Without loss of generality, we assume that the first $k - \eta(l,\tau)$ columns of $M_k^{(\tau+1)}$ are the first $k - \eta(l,\tau)$ columns of $M_k^{(l)}$, and that the last $\eta(l,\tau)$ columns of $M_k^{(\tau+1)}$ are the first $\eta(l,\tau)$ columns of $M_{n-k}^{(l)}$. Then we can write

$$R^{(l)} \equiv \mathcal{R}_k(M\,\Pi^{(l)}) \equiv \begin{pmatrix} A_k^{(l)} & B_k^{(l)} \\ & C_k^{(l)} \end{pmatrix} = \begin{pmatrix} A_{1,1} & A_{1,2} & B_{1,1} & B_{1,2} \\ & A_{2,2} & B_{2,1} & B_{2,2} \\ & & C_{1,1} & C_{1,2} \\ & & & C_{2,2} \end{pmatrix},$$

where $A_{2,2}, C_{1,1} \in \mathbf{R}^{\eta(l,\tau)\times\eta(l,\tau)}$ and the partition is such that

$$R^{(\tau+1)} \equiv \mathcal{R}_k(M\,\Pi^{(\tau+1)}) \equiv \begin{pmatrix} A_k^{(\tau+1)} & B_k^{(\tau+1)} \\ & C_k^{(\tau+1)} \end{pmatrix} = \mathcal{R}_k \begin{pmatrix} A_{1,1} & B_{1,1} & A_{1,2} & B_{1,2} \\ & B_{2,1} & A_{2,2} & B_{2,2} \\ & C_{1,1} & & C_{1,2} \\ & & & C_{2,2} \end{pmatrix}.$$

These relations imply that

$$\det(A_k^{(l)}) = \det(A_{1,1})\,\det(A_{2,2}) \tag{12}$$

and

$$\det(A_k^{(\tau+1)}) = \det(A_{1,1})\sqrt{\det\left[B_{2,1}^T B_{2,1} + C_{1,1}^T C_{1,1}\right]}. \tag{13}$$

Let $f^{(l)} = \rho(R^{(l)}, k)$. By the definition of $\rho(R,k)$, we have

$$\sqrt{\left(A_{2,2}^{-1}B_{2,1}\right)_{i,j}^2 + \left(\gamma_j(C_{1,1})/\omega_i(A_{2,2})\right)^2} \le f^{(l)}$$

for $1 \le i, j \le \eta(l,\tau)$. Applying Lemma 5.1 and recalling that $\eta(l,\tau) \le \tau - l + 1$, we have

$$\sqrt{\det\left[B_{2,1}^T B_{2,1} + C_{1,1}^T C_{1,1}\right]} \le \det(A_{2,2})\left(\sqrt{2(\tau - l + 1)}\, f^{(l)}\right)^{\tau-l+1}.$$

Combining with (12) and (13), we get

$$\det(A_k^{(\tau+1)}) \le \det(A_k^{(l)})\left(\sqrt{2(\tau - l + 1)}\, f^{(l)}\right)^{\tau-l+1}.$$

[6] It is possible that $\eta(l,\tau) < \tau - l + 1$ since a column may be interchanged more than once.

On the other hand, Algorithm 5 ensures that

$$\det(A_k^{(\tau+1)}) \geq \det(A_k^{(l)}) \left(f^{(l)}/\sqrt{2}\right) \cdots \left(f^{(\tau)}/\sqrt{2}\right).$$

Comparing these two relations, we have

$$f^{(l)} \cdots f^{(\tau)} \leq \left(2\sqrt{\tau - l + 1}\, f^{(l)}\right)^{\tau - l + 1}, \quad 0 \leq l \leq \tau. \tag{14}$$

Since

$$\sum_{l=1}^{s-1} \frac{1}{(\tau - l)(\tau - l + 1)} + \frac{1}{\tau} = \frac{1}{\tau - s},$$

taking the product of the $(\tau - l)(\tau - l + 1)$st root of (14) with $l = 1, 2, \ldots, \tau - 1$ and the τth root of (14) with $l = 0$, we have

$$\begin{aligned} \prod_{s=0}^{\tau-1} \left(f^{(s)}\right)^{1/(\tau - s)} f^{(\tau)} &\leq \left(\prod_{l=1}^{\tau-1} \left(2\sqrt{\tau - l + 1}\, f^{(l)}\right)^{1/(\tau - l)}\right) \left(2\sqrt{\tau + 1}\, f^{(0)}\right)^{(\tau+1)/\tau} \\ &\leq 2^{1 + \sum_{l=0}^{\tau-1} 1/(\tau - l)} \left((\tau + 1) \prod_{l=0}^{\tau-1} (\tau - l + 1)^{1/(\tau - l)}\right)^{1/2} \left(\prod_{l=0}^{\tau-1} \left(f^{(l)}\right)^{1/(\tau - l)}\right) f^{(0)}, \end{aligned}$$

which simplifies to

$$f^{(\tau)} \leq f^{(0)}\, 2^{1 + \sum_{s=1}^{\tau} 1/s} \left((\tau + 1) \prod_{s=2}^{\tau+1} s^{1/(s-1)}\right)^{1/2} \leq 2 f^{(0)}\, (\tau + 1) \mathcal{W}(\tau + 1).$$

Remark 2 at the end of §4.1 implies that $f^{(0)} \leq \sqrt{6}\, f$. Plugging this into the last relation proves the result. □

From §4.4 we have $\tau_k \leq k \log_f \sqrt{n}$. For example, when $\sqrt{n} \leq f \leq n$, we have $\tau_k \leq k$, so that $\rho(R, k) \leq O\left(n\, k\, \mathcal{W}(k)\right)$.

5.2. Computing the row norms of A_k^{-1} and the column norms of C_k. In this section we discuss the numerical stability of updating and modifying $\omega_*(A_k)$ and $\gamma_*(C_k)$ as a result of interchanges, assuming that f is a small power of n.

For any $\alpha > 0$, we let $\mathcal{O}_n(\alpha)$ denote a positive number that is bounded by α times a slowly increasing function of n. By Theorems 3.2 and 5.2, $\|A_k^{-1}\|_2 = \mathcal{O}_n\left(1/\sigma_k(M)\right)$ and $\|C_k\|_2 = \mathcal{O}_n\left(\sigma_{k+1}(M)\right)$ after each interchange. As Algorithm 5 progresses, $\|A_k^{-1}\|_2$ increases from $\mathcal{O}_n\left(1/\sigma_1(M)\right)$ to $\mathcal{O}_n\left(1/\sigma_k(M)\right)$, while $\|C_k\|_2$ decreases from $\mathcal{O}_n\left(\sigma_1(M)\right)$ to $\mathcal{O}_n\left(\sigma_{k+1}(M)\right)$. A straightforward error analysis shows that the errors in $1/\omega_i(A_k)^2$ and $\gamma_j(C_k)^2$ are bounded by $\mathcal{O}_n\left(\epsilon/\sigma_k^2(M)\right)$ and $\mathcal{O}_n\left(\epsilon\, \sigma_1^2(M)\right)$, respectively, where ϵ is the machine precision. Hence the error in $1/\omega_i(A_k)^2$ is less serious than the error in $\gamma_j(C_k)^2$, which can be larger than $\|C_k\|_2^2$ when $\|C_k\|_2 \leq \mathcal{O}_n\left(\sqrt{\epsilon}\, \sigma_1(M)\right)$.

Algorithm 5 uses the computed values of $\omega_*(A_k)$ and $\gamma_*(C_k)$ only to decide which columns to interchange. But although these values do not need to be very accurate, we do need to avoid the situation where they have no accuracy at all. Thus we recompute rather than update or modify $\gamma_*(C_k)$ when $\max_{1 \leq j \leq n-k} \gamma_j(C_k) = \mathcal{O}_n\left(\sqrt{\epsilon}\, \sigma_1(M)\right)$. This needs to be done at most twice if one wants to compute a strong RRQR factorization with A_k numerically nonsingular. A similar approach is taken in xgeqpf, the LAPACK [1] implementation of Algorithm 1.

6. Numerical experiments. In this section we report some numerical results for a Fortran implementation (SRRQR) of Algorithm 5 and the all-Fortran implementation (DGEQPF) of Algorithm 1 in LAPACK [1]. The computations were done on a SPARCstation/10 in double precision where the machine precision is $\epsilon = 1.1 \times 10^{-16}$.

We use the following sets of $n \times n$ test matrices:

1. *Random*: a random matrix with elements uniformly distributed in $[-1, 1]$;
2. *Scaled random*: a random matrix whose ith row is scaled by the factor $\eta^{i/n}$, where $\eta > 0$;
3. *GKS*: an upper-triangular matrix whose jth diagonal element is $1/\sqrt{j}$ and whose (i, j) element is $-1/\sqrt{j}$, for $j > i$ (see Golub, Klema, and Stewart [22]);
4. *Kahan* (see Example 1 in §2);
5. *Extended Kahan*: the matrix $M = S_{3l} R_{3l}$, where
$$S_{3l} = \mathrm{diag}(1, \varsigma, \varsigma^2, \ldots, \varsigma^{3l-1}) \quad \text{and} \quad R_{3l} = \begin{pmatrix} I_l & -\varphi H_l & 0 \\ & I_l & \varphi H_l \\ & & \mu I_l \end{pmatrix};$$
l is a power of 2; $\varsigma > 0$, $\varphi > 1\big/\sqrt[4]{4l-1}$, and $\varsigma^2 + \varphi^2 = 1$; $0 < \mu \ll 1$; and $H_l \in \mathbf{R}^{l \times l}$ is a symmetric Hadamard matrix (i.e., $H_l^2 = l\, I_l$ and every component of H_l is ± 1).

In particular, we chose $\eta = 20\epsilon$, $\varphi = 0.285$, and $\mu = 20\epsilon/\sqrt{n}$.

In exact arithmetic Algorithm 1 does not perform any interchanges for the Kahan and extended Kahan matrices. To preserve this behavior in DGEQPF we scaled the jth columns of these matrices by $1 - 100 j\sqrt{\epsilon}$ and $1 - 10 j\epsilon$, respectively, for $1 \le j \le n$. To prevent DGEQPF from taking advantage of the upper-triangular structure we replaced all of the zero entries by random numbers of the order ϵ^2.

For each test matrix, we took $n = 96$, 192, and 384, and set $f = 10\sqrt{n}$ and $\delta \approx 3 \times 10^{-13} \times \|M\|_2$ in SRRQR. For the extended Kahan matrix, we also used $f = \varphi^2 l 1$ and $\delta = 4l^2 \sigma_{2l+1}(M)$; these results are labeled *Extended Kahan**.

The results are summarized in Tables 1 and 2. Execution time is in seconds; rank is the value of k computed by SRRQR; t_{k_f} is the total number of interchanges in the inner **while**-loop of SRRQR; and
$$q_1(k, n) = \sqrt{1 + 2f^2 k(n-k)} \quad \text{and} \quad q_2(k, n) = \begin{cases} f & \text{if } k < n \\ 0 & \text{if } k = n \end{cases}$$
are the theoretical upper bounds on
$$\max_{1 \le i \le k,\ 1 \le j \le n-k} \left(\frac{\sigma_i(M)}{\sigma_i(A_k)}, \frac{\sigma_j(C_k)}{\sigma_{k+j}(M)} \right) \quad \text{and} \quad \max_{1 \le i \le k,\ 1 \le j \le n-k} \left| \left(A_k^{-1} B_k\right)_{i,j} \right|,$$
respectively, for SRRQR.

The execution times confirm that Algorithm 5 is about 50% more expensive than Algorithm 1 on matrices that require only a small number t_{k_f} of interchanges. And as predicted, Algorithm 1 failed to reveal the numerical rank of the Kahan matrix. Finally, the results suggest that the theoretical upper bounds $q_1(k, n)$ and $q_2(k, n)$ are much too large for $0 < k < n$.

For the extended Kahan matrices with $f = \varphi^2 l$ there were no interchanges until the $2l$th step, when the ith column was interchanged with the $(2l + i)$th column for $i = 1, 2, \ldots, l$. These $l = n/3$ column interchanges show that Algorithm 5 may have to perform $O(n)$ interchanges before finding a strong RRQR factorization for a given f (see §4.4) and can be more than twice as expensive as Algorithm 1. However, the extended Kahan matrix is already a strong RRQR factorization with $f = 10\sqrt{n}$ for the values of n used here, which is why no interchanges were necessary.

7. Algorithm 1 and the strong RRQR factorization.

Using the techniques developed in §3, we now show that Algorithm 1 satisfies (5) and (6) with $q_1(k, n)$ and $q_2(k, n)$ functions that grow exponentially with k. We need the following lemma.

LEMMA 7.1 (Faddeev, Kublanovskaya, and Faddeeva [16]). *Let $W = (w_{i,j}) \in \mathbf{R}^{n\times n}$ be an upper-triangular matrix with $w_{i,i} = 1$ and $|w_{i,j}| \le 1$ for $1 \le i \le j \le n$. Then*

$$|(W^{-1})_{i,j}| \le 2^{n-2}, \quad 1 \le i, j \le n, \qquad \textit{and} \qquad \|W^{-1}\|_F \le \frac{\sqrt{4^n + 6n - 1}}{3}.$$

THEOREM 7.2. *Let Π be the permutation chosen by Algorithm* 1, *and let*

$$R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} = \mathcal{R}_k(M\,\Pi).$$

Then

$$\sigma_i(A_k) \geq \frac{\sigma_i(M)}{\sqrt{n-i}\,2^i}, \tag{15}$$

$$\sigma_j(C_k) \leq \sigma_{k+j}(M)\,\sqrt{n-k}\,2^k, \tag{16}$$

and

$$\left|\left(A_k^{-1}B_k\right)_{i,j}\right| \leq 2^{k-i}, \tag{17}$$

for $1 \leq i \leq k$ *and* $1 \leq j \leq n-k$.

Proof. For simplicity we assume that M (and therefore R) has full rank.

Let

$$R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} = D \begin{pmatrix} W_{1,1} & W_{1,2} \\ & W_{2,2} \end{pmatrix} \equiv DW \quad \text{and} \quad \widetilde{W}_j = \begin{pmatrix} W_{1,1} & w_j \\ & 1 \end{pmatrix},$$

where $D = \operatorname{diag}(d_1, d_2, \ldots, d_m)$ is the diagonal of R, $W_{1,1} \in \mathbf{R}^{k\times k}$ is unit upper triangular, $W_{1,2} \in \mathbf{R}^{k\times(n-k)}$, $W_{2,2} \in \mathbf{R}^{(m-k)\times(n-k)}$, and $w_j \in \mathbf{R}^k$ is the jth column of $W_{1,2}$. Since Algorithm 1 would not cause any column interchanges if it were applied to R, it follows that $d_1 \geq d_2 \geq \cdots \geq d_k$ and that no component of $\widetilde{W}_j$ has absolute value larger than 1.

Let $u_{i,j} = \left(A_k^{-1}B_k\right)_{i,j}$. Then $-u_{i,j}$ is the $(i, k+1)$ component of $\widetilde{W}_j^{-1}$. Applying the first result in Lemma 7.1 to the lower right $(k-i+2) \times (k-i+2)$ submatrix of $\widetilde{W}_j$, we have $|u_{i,j}| \leq 2^{k-i}$, which is (17).

As in the proof of Theorem 3.2, let $\alpha = \sigma_{\max}(C_k)/\sigma_{\min}(A_k)$, and write

$$\tilde{R}_2 = \begin{pmatrix} \alpha A_k & \\ & C_k \end{pmatrix} = \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} \begin{pmatrix} \alpha I_k & -A_k^{-1}B_k \\ & I_{n-k} \end{pmatrix} \equiv RW_2.$$

Then

$$\sigma_j(C_k) = \sigma_{j+k}(\tilde{R}_2) \leq \sigma_{j+k}(R)\,\|W_2\|_2 = \sigma_{j+k}(M)\,\|W_2\|_2.$$

But

$$\begin{aligned} \|W_2\|_2^2 &\leq 1 + \|A_k^{-1}B_k\|_2^2 + \alpha^2 \\ &\leq 1 + \sum_{i=1}^{k}\sum_{j=1}^{n-k} u_{i,j}^2 + \|C_k\|_F^2 \|A_k^{-1}\|_F^2 \\ &= 1 + \sum_{i=1}^{k}\sum_{j=1}^{n-k} \{u_{i,j}^2 + \left(\gamma_j(C_k)/\omega_i(A_k)\right)^2\}. \end{aligned}$$

Since $1/\omega_i(A_k) \leq 1/(d_k\omega_i(W_{1,1}))$ and $\gamma_j(C_k) \leq d_k$, we have

$$u_{i,j}^2 + \left(\gamma_j(C_k)/\omega_i(A_k)\right)^2 \leq (\widetilde{W}_j^{-1})_{i,k+1}^2 + 1/\omega_i(W_{1,1})^2 = 1/\omega_i(\widetilde{W}_j)^2.$$

Using the second result in Lemma 7.1, it follows that

$$\sum_{i=1}^{k} \left\{u_{i,j}^2 + \left(\gamma_j(C_k)/\omega_i(A_k)\right)^2\right\} \leq \sum_{i=1}^{k} 1/\omega_i(\widetilde{W}_j)^2 = \|\widetilde{W}_j^{-1}\|_F^2 - 1 \leq 4^k - 1,$$

so that $\|W_2\|_2^2 \leq 4^k(n-k)$, which gives (16).

Similarly, writing

$$R = \begin{pmatrix} A_k & \\ & C_k/\alpha \end{pmatrix} \begin{pmatrix} I_k & A_k^{-1}B_k \\ & \alpha I_{n-k} \end{pmatrix} \equiv \tilde{R}_1 W_1,$$

we have

$$\sigma_k(M) = \sigma_k(R) \le \sigma_k(\tilde{R}_1) \, \|W_1\|_2 \le \sigma_k(A_k) \, \sqrt{n-k} \, 2^k.$$

Taking $k = i$ and noting that $\sigma_i(A_i) \le \sigma_i(A_k)$ by the interlacing property of the singular values [24, Cor. 8.3.3], we get (15). □

If R has very few linearly independent columns, then we can stop Algorithm 1 with a small value of k and are guaranteed to have a strong RRQR factorization. Results similar to Theorem 7.2 can be obtained for the RRQR algorithms in [10, 18, 25], and [39].

8. Some extensions. We have proved the existence of a strong RRQR factorization for a matrix $M \in \mathbf{R}^{m\times n}$ with $m \ge n$ and presented an efficient algorithm for computing it. In this section, we describe some further improvements and extensions of these results.

Since Algorithm 1 seems to work well in practice [5, 10, 11, 13], Algorithm 5 tends to perform very few (and quite often no) interchanges in its inner **while**-loop. This suggests using Algorithm 1 as an initial phase (cf. [13] and [37]), and then using Algorithm 4 to remove any dependent columns from A_k, reducing k as needed (cf. [10] and [18]). In many respects the resulting algorithm is equivalent to applying Algorithm 5 to M^{-1} (cf. Stewart [39]).

ALGORITHM 6. Compute k and a strong RRQR factorization.

```
$k := 0$;  $R \equiv C_k := M$;  $\Pi := I$;
Compute $\gamma_*(C_k)$;
while $\max_{1\le j\le n-k} \gamma_j(C_k) \ge \delta$ do
  $j_{\max} := \operatorname{argmax}_{1\le j\le n-k} \gamma_j(C_k)$;
  $k := k+1$;
  Compute $R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} := \mathcal{R}_k(R\,\Pi_{k,k+j_{\max}-1})$ and $\Pi := \Pi\,\Pi_{k,k+j_{\max}-1}$;
  Update $\gamma_*(C_k)$;
endwhile;
Compute $\omega_*(A_k)$ and $A_k^{-1}B_k$;
repeat
  while $\hat{\rho}(R,k) > f$ do
    Find $i$ and $j$ such that $\left|(A_k^{-1}B_k)_{i,j}\right| > f$ or $\gamma_j(C_k)/\omega_i(A_k) > f$;
    Compute $R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} := \mathcal{R}_k(R\,\Pi_{i,j+k})$ and $\Pi := \Pi\,\Pi_{i,j+k}$;
    Modify $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$;
  endwhile;
  if $\min_{1\le i\le k} \omega_i(A_k) \le \delta$ then
    $i_{\min} := \operatorname{argmin}_{1\le i\le k} \omega_i(A_k)$;
    $k := k-1$;
    Compute $R \equiv \begin{pmatrix} A_k & B_k \\ & C_k \end{pmatrix} := \mathcal{R}_k(R\,\Pi_{i_{\max},k+1})$ and $\Pi := \Pi\,\Pi_{i_{\max},k+1}$;
    Downdate $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$;
  endif;
until $k$ is unchanged;
```

As before, Algorithm 6 eventually halts and finds k and a strong RRQR factorization. The total number of interchanges t_k is bounded by $(n-k)\log_f \sqrt{n}$, which is $O(n-k)$ when f is taken to be a small power of n (see §4.4). The formulas for downdating $\omega_*(A_k)$, $\gamma_*(C_k)$, and $A_k^{-1}B_k$ are analogous to those in §4.1.

Algorithm 6 initializes $\omega_*(A_k)$ and $A_k^{-1}B_k$ after the first **while**-loop, at a cost of $O(k^2n)$ flops. However, since they are only used to decide which (if any) columns to interchange and whether to decrease k, they do not need to be computed very accurately. To make the algorithm more efficient, we could instead use the condition estimation techniques in [4, 5, 10, 27], and [40] to generate unit vectors u and v such that

$$\|A_k^{-1}u\|_2 \approx \|A_k^{-1}\|_2 \quad \text{and} \quad \|B_k^T A_k^{-T} v\|_2 \approx \|B_k^T A_k^{-T}\|_2 \,.$$

Let the $i_{\max}$th component of $A_k^{-1}u$ be the largest in absolute value. To find the smallest entry in $\omega_*(A_k)$, we note that

$$1/\omega_{i_{\max}}(A_k) \approx \max_{1\le i\le k} 1/\omega_i(A_k) \approx \left|(A_k^{-1}u)_{i_{\max}}\right| \,.$$

Similarly, let the $j_{\max}$th component of $B_k^T A_k^{-T} v$ be the largest in absolute value. To find the largest entry of $A_k^{-1}B_k$ in absolute value, we compute the $j_{\max}$th column of $A_k^{-1}B_k$ and look for the largest component in absolute value. Since the condition estimates cost $O(n^2)$ flops, the resulting algorithm will take nearly the same number of flops as QR with column pivoting when at most a few interchanges are needed. As Algorithm 6 could take $O(n)$ interchanges and all condition estimation techniques can fail, Algorithm 6 could be very inefficient and can fail as well, although we believe that this is quite unlikely in practical applications.

Most of the floating-point operations in Algorithms 5 and 6 can be expressed as Level-2 BLAS. Using ideas similar to those in [3] and [6], it should be straightforward to develop block versions of these algorithms so that most of the floating-point operations are performed as Level-3 BLAS.

The restriction $m \ge n$ is not essential and can be removed with minor modifications to Algorithms 5 and 6. Thus these algorithms can also be used to compute a strong RRQR factorization for M^T, which may be preferable when one wants to compute an orthogonal basis for the right approximate null space.

Finally, the techniques developed in this paper can easily be adopted to compute *rank-revealing* LU factorizations [9, 13, 31, 32]. This result will be reported at a later date.

Acknowledgments. The authors thank Shivkumar Chandrasekaran and Ilse Ipsen for many helpful discussions and suggestions, and Gene Golub, Per Christian Hansen, W. Kahan, and Pete Stewart for suggestions that improved the presentation.

PARALLELIZING THE QR ALGORITHM FOR THE UNSYMMETRIC ALGEBRAIC EIGENVALUE PROBLEM: MYTHS AND REALITY*

GREG HENRY† AND ROBERT VAN DE GEIJN‡

Abstract. Over the last few years, it has been suggested that the popular QR algorithm for the unsymmetric Schur decomposition does not parallelize. In this paper, we present both positive and negative results on this subject. In theory, asymptotically perfect speedup can be obtained. In practice, reasonable speedup can be obtained on an MIMD distributed memory computer for a relatively small number of processors. However, we also show theoretically that it is impossible for the standard QR algorithm to be scalable. Performance of a parallel implementation of the LAPACK DLAHQR routine on the Intel Paragon™ system is reported.

Key words. parallel computing, eigenvalue, Schur decomposition, QR algorithm

AMS subject classifications. 65F15, 15A18

1. Introduction.

Distributed memory parallel algorithms for the unsymmetric eigenvalue problem have been elusive. There are several matrix multiply-based methods currently being studied. Auslander and Tsao [2] and Lederman, Tsao, and Turnbull [27] have a matrix multiply-based parallel algorithm, which uses a polynomial mapping of the eigenvalues. Bai and Demmel [4] have another parallel algorithm based on bisection with the matrix sign function. Matrix tearing methods for finding the eigensystem of an unsymmetric Hessenberg matrix have been proposed by Dongarra and Sidani [11]. These involve making a rank-one change to the Hessenberg matrix to create two separate submatrices and then finding the eigenpairs of each submatrix, followed by performing Newton's method on these values to find the solution to the original problem. None of the above algorithms are particularly competitive in the serial case. They suffer from requiring more floating point operations (flops) and/or yield a loss of accuracy when compared with efficient implementations of the QR algorithm.

Efficient sequential (and shared memory parallel) implementations of the QR algorithm use a blocked version of the Francis double implicit shifted algorithm [15] or a variant thereof [23]. There have also been attempts at improving data reuse by increasing the number of shifts either by using a multi-implicit shifted QR algorithm [3] or pipelining several double shifts simultaneously [34, 35].

A number of attempts at parallelizing the QR algorithm have been made. (See Boley and Maier [9], Geist et al. [17], Geist and Davis [16], and Stewart [30].) Distributing the work evenly amongst the processors has proven difficult for conventional storage schemes, especially when compared with the parallel solution of dense linear systems [25, 26]. Communication also becomes a more significant bottleneck for the parallel QR algorithm. As noted by van de Geijn [32] and van de Geijn and Hudson [33], the use of a block Hankel-wrapped storage scheme can alleviate some of the problems involved in parallelizing the QR algorithm.

In this paper, we present a number of results of theoretical significance on the subject. We reexamine the results on the Hankel-wrapped storage schemes in the setting of a parallel implementation of a state-of-the-art sequential implementation. Theoretically we can show that under certain conditions the described approach is asymptotically 100% efficient: if the number of processors is fixed and the problem size grows arbitrarily large, perfect speedup can be approached. However, we also show that our approach is not scalable in the following sense: to maintain a given level of efficiency, the dimension of the matrix must grow

*Received by the editors March 1, 1995; accepted for publication September 12, 1995.

linearly with the number of processors. As a result, it will be impossible to maintain performance as processors are added, since memory requirements grow with the square of the dimension, and physical memory grows only with the number of processors. While this could be a deficiency attributable to our implementation, we also show that for the standard implementations of the sequential QR algorithm, it is impossible to find an implementation with better scalability properties. Finally, we show that these techniques can indeed be incorporated into a real code by giving details of a prototype distributed memory implementation of the serial algorithm DLAHQR [1], the LAPACK version of the double implicit shifted QR algorithm. Full functionality of the LAPACK code can be supported. That is, the techniques can be extended to allow for the cases of computing the Schur vectors, computing the Schur decomposition of H, or just computing the eigenvalues alone. We have implemented a subset of this functionality for which the code is described and performance results are given.

Thus this paper makes four contributions: it describes a data decomposition that allows, at least conceptually, straightforward implementation of the QR algorithm; it gives theoretical limitations for parallelizing the standard QR algorithm; it describes a parallel implementation based on the proposed techniques; it reports performance results of this proof-of-concept implementation obtained on the Intel Paragon™ system.

2. Sequential QR algorithm.

While we assume the reader of this paper to be fully versed in the intricate details of the QR algorithm, we briefly review the basics in this section.

The Francis double implicit shifted QR algorithm has been a successful serial method for computing the Schur decomposition $H = QTQ^T$. Here T is an upper pseudotriangular matrix, with 1×1 or 2×2 blocks along the diagonal, and Q is orthogonal. We assume for simplicity that our initial matrix H is Hessenberg. The parallelization of the reduction to Hessenberg form is a well-understood problem, and, unlike the eigenvalue problem, the Hessenberg reduction has been shown to parallelize well [6, 12].

One step of the Francis double shift Schur decomposition is in Figure 1. Here, the Householder matrices are symmetric orthogonal transforms of the form

$$P_i = I - 2\frac{vv^T}{v^T v},$$

where $v \in \Re^n$ and

$$v_j = \begin{cases} 0 & \text{if } j < i+1 \text{ or } j > i+3, \\ 1 & \text{if } j = i+1. \end{cases}$$

We assume the Hessenberg matrix is unreduced and, if not, we find the largest unreduced submatrix of H. Suppose this submatrix is $H(k : l, k : l)$. We then apply the Francis Hessenberg QR (HQR) step to the rows and columns of H corresponding to the submatrix; that is,

$$\begin{aligned} H(k:l,:) &\leftarrow P_i H(k:l,:), \\ H(:,k:l) &\leftarrow H(:,k:l)P_i. \end{aligned}$$

The double implicit shifts in this case are chosen to be the eigenvalues of

$$e = \text{eig}(H(l-1:l, l-1:l)).$$

In practice, after every couple of iterations, some of the subdiagonals of H will become numerically zero, and at this point the problem deflates into smaller problems.

```
Francis HQR Step
$e = \mathrm{eig}(H(n-1:n, n-1:n))$
Let $x = (H - e(1)I_n) * (H - e(2)I_n)e_1$
Let $P_0 \in \Re^{n \times n}$ be a Householder matrix s.t.
    $P_0 x$ is a multiple of $e_1$.
$H \leftarrow P_0 H P_0$
for $i = 1, \ldots, n-2$
        Compute $P_i$ so that
            $P_i H$ has zero $(i+2, i)$ and
                $(i+3, i)$ entries.
        Update $H \leftarrow P_i H P_i$
        Update $Q \leftarrow Q P_i$
endfor
```

FIG. 1. *Sequential Francis HQR step.*

3. Parallel QR algorithms.

3.1. Data decomposition. We briefly describe the storage scheme presented in [33]. Suppose $A \in \Re^{n \times n}$ where $n = mhp$ for some integers h and m, and p is the number of processors. Suppose A is partitioned as follows:

$$A = \begin{bmatrix} A_{1,1} & A_{1,2} & \cdots & A_{1,mp-1} & A_{1,mp} \\ A_{2,1} & A_{2,2} & \cdots & A_{2,mp-1} & A_{2,mp} \\ A_{3,1} & A_{3,2} & \cdots & A_{3,mp-1} & A_{3,mp} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ A_{mp,1} & A_{mp,2} & \cdots & A_{mp,mp-1} & A_{mp,mp} \end{bmatrix},$$

where $A_{i,j} \in \Re^{h \times h}$. We denote processor k owning block $A_{i,j}$ with a superscript $A_{ij}^{(k)}$. The one-dimensional block Hankel-wrapped storage for $m = 1$ assigns submatrix $A_{i,j}$ to processor

$$(i + j - 2) \ \mathbf{mod}\ p.$$

That is, the distribution amongst the processors is as follows [33]:

$$\begin{bmatrix} A_{1,1}^{(0)} & A_{1,2}^{(1)} & A_{1,3}^{(2)} & \cdots & A_{1,mp-1}^{(p-2)} & A_{1,mp}^{(p-1)} \\ A_{2,1}^{(1)} & A_{2,2}^{(2)} & A_{2,3}^{(3)} & \cdots & A_{2,mp-1}^{(p-1)} & A_{2,mp}^{(0)} \\ & A_{3,2}^{(3)} & A_{3,3}^{(4)} & \cdots & A_{3,mp-1}^{(0)} & A_{3,mp}^{(1)} \\ & & \ddots & & \vdots & \vdots \\ & & & & A_{mp,mp-1}^{(p-3)} & A_{mp,mp}^{(p-2)} \end{bmatrix},$$

where the superscript indicates the processor assignment.

3.2. Basic parallel algorithm. We start describing the basic parallel QR algorithm by considering the Francis HQR step and finish this subsection with a brief look at the overall algorithm. The basic loop in Figure 1, indexed by i, is generally referred to as "chasing the bulge." Figure 2 gives an arbitrary example of $i = 7$, in a 20×20 matrix, where the integers indicate nonzero elements of the upper Hessenberg matrix, and the B's indicate the fill-in at that stage of the loop. In the next step of the Francis HQR step, a Householder transformation P_i is computed and applied from the left and the right. The affected elements are within the dashed lines. After this application of the Householder transformation, the bulge moves down the diagonal one position, and the next iteration starts.

```

FIG. 2. *Data decomposition and chasing of the bulge.*

Figure 2 also demonstrates the possible parallelism in the Francis HQR step: the application of P_i to the appropriate elements of H, referred to as a reflection, is perfectly distributed among the processors, except for the processor that owns the bulge and the fill-in elements. This processor must do slightly more work (associated with the intersection of the two boxes). *It is the parallelism within the application of each Householder transformation that is the key to the success of the approach.*

The entire Francis HQR step now parallelizes as follows:

1. The processor(s) that holds $\operatorname{eig}(H(n-1:n, n-1:n))$ computes the shifts and sends them to the first processor. Alternatively, all processors could compute the shifts, since it is a lower-order operation.
2. The processor that owns the data required to compute P_0 computes it and then broadcasts it to all other processors.
3. All processors update their portions of the matrix according to P_0.
4. **for** $i = 1, \ldots, n-2$,
   (a) the processor that owns the data required to compute P_i computes it and then broadcasts it to all other processors;
   (b) all processors update their portions of the matrix according to P_i.

Naturally, every time the computation hits data that lies on the boundaries between processors, a limited amount of communication is required to bring appropriate rows and columns together.

The overall Schur decomposition involves more than just the application of Francis HQR steps. Deflation decreases the problem size as subdiagonals converge to zero. Since a Francis HQR step requires an unreduced Hessenberg matrix, at some point in the Schur decomposition we have the following matrix [18]:

$$H = \begin{bmatrix} H_{11} & H_{12} & H_{13} \\ & H_{22} & H_{23} \\ & & H_{33} \end{bmatrix},$$

where H_{33} has already converged and H_{22} is the largest unreduced Hessenberg matrix above H_{33} in the current iteration. One might worry that the property of each row and column being

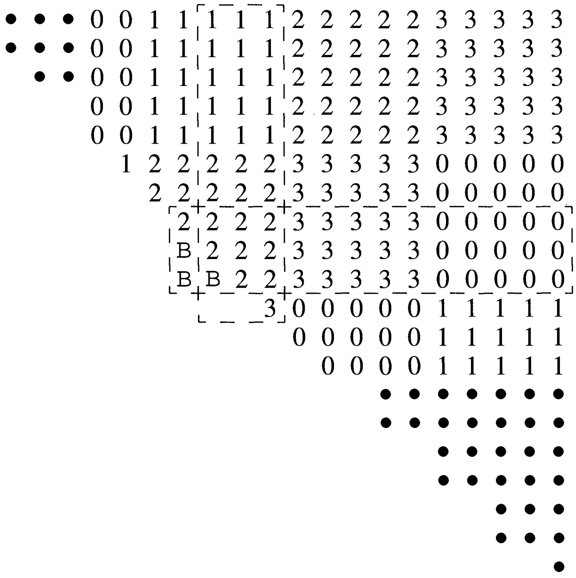

FIG. 3. *Chasing of the bulge after deflation.*

distributed amongst all the processors no longer applies to H_{22}. In the Schur decomposition, however, H_{12} and H_{23} are also involved in the computation (see Figure 3) as well as the Schur vectors, so that the overall work distribution remains equal even after deflation has reduced the problem size. Again, we point out that it is the parallelism within the application of each Householder transformation that is the key to the success of this approach. In §4, experimental results confirm that the overall performance of the code is fairly accurately modeled by the first few iterations.

3.3. Analysis of the simple parallel algorithm. Before discussing the finer details of the parallel code, let us analyze the simple algorithm given above. This will give us an idea of how well the basic approach works. For simplicity, we restrict our timing analysis to a single Francis step. We justified this restriction in the previous subsection and will further justify it with discussion of experimental results in §4. We also ignore shift derivation, convergence, or decoupling set-up costs. We show later how this extra work can be done without incurring excessive overhead.

3.3.1. Cost analysis. For our analysis, we will use the following model: performing a floating point computation requires time γ. Sending a message of length n between two nodes requires time $\alpha + n\beta$, where α represents the latency, and β the penalty per double precision number transferred. For convenience, we shall assume all communication is to the nearest neighbor (processor in a network), and hence no network conflicts occur. Processors can send and receive simultaneously.

We start by computing the sequential expense of the algorithm: computing a Householder transformation from a vector of length three requires C, which are some small constant flops. Applying such a Householder transformation of size three to three rows or columns of length n requires $10n$ flops. Within the loop indexed by i, each transformation is applied to $n - i + 1$ triplets of rows and $i + 3$ triplets of columns. Applying the transformations to the Hessenberg matrix therefore requires $10(n + 4)$ flops and applying the transformations to the Schur matrix requires $10n$ flops. The total cost of executing a single Francis step thus becomes approximately

$$\sum_{i=1}^{n-1}(C + 10(n+4) + 10n)\,\gamma = 20n^2\gamma + O(n).$$

Now turning to the parallel implementation, contributions to the critical path are given roughly as follows: computing a transformation still contributes C flops. Broadcasting this transformation requires time $\alpha + 3\beta$, since the parallel computation can be arranged to pipeline around the logical ring of processors.[1] After this, the processor that computed the transformation must update its part of the rows and columns. The row and column vectors are of length approximately n/p, with a few extra introduced by the bulge. This contributes the equivalent of about $20(n/p+4)$ flops. Now, the processor that computed the current transformation can start computing the next transformation, and the process repeats itself $n-1$ times. The total contribution becomes

$$\sum_{i=1}^{n-1}\left(C\gamma + 10\left(\frac{n}{p}+4\right) + 10\frac{n}{p}\gamma + \alpha + 3\beta\right) = Cn\gamma + 20\frac{n^2}{p}\gamma + 40n\gamma + n\alpha + 3n\beta + O(1). \tag{1}$$

Here we cannot ignore $O(n)$ terms, since if p is comparable to n, these terms matter.

Equation (1) ignores the communication required when a boundary of processors is reached, which happens every h iterations. Each "border" row contains roughly $(n-i)/p$ elements per processor, and each "border" column contains roughly i/p elements per processor. Using transformations of size three implies that when the boundary of processors is reached, the next transformation will also cross the boundary. Hence $2n/p$ items must be communicated to the right and returned. This means that the total communication volume for "border" or boundary data is

$$\frac{n}{h}\left(4\frac{n}{p}\right). \tag{2}$$

The communication volume in (2) can be done in anywhere from one to eight messages depending on the implementation. Eight messages are required when both rows and both columns for the two iterations are sent separately and returned again. One message is possible if data are only sent rightward around the ring, and the results accumulated into a buffer and sent back in $O(1)$ communications at the end of the Francis step. For the purpose of our model, we assume two communications, requiring time

$$2\frac{n}{h}\left(\alpha + 2\frac{n}{p}\beta\right) \tag{3}$$

for a total estimated parallel time of

$$T_{\text{est}}(n,p,h) = Cn\gamma + 20\frac{n^2}{p}\gamma + 40n\gamma + n\alpha + 3n\beta + 2\frac{n}{h}\alpha + 4\frac{n^2}{hp}\beta + O(1). \tag{4}$$

We conclude with a few additional comments.

[1] That is, because of the pipeline between computation and communication, the effective overhead is the cost for the first message transfer to the nearest neighbor. While the second transfer of the same message starts on the next node, the first node has already started the computation.

- Equation (4) ignores a slight disruption in the pipeline of communication and computation, because it is no longer the processor that computed the current transformation that also computes the next transformation. This disruption is minor and we will ignore it.
- It may appear that at the end of a single Francis step, the processors must synchronize. However, if P_{p-2} is the last processor to compute a transformation, P_0 will complete its computation early in the pipeline and will have enough information to start the next Francis step before the pipeline is flushed.[2] If P_{p-2} is not the last processor to compute a transformation, a slight bubble in the pipeline can be expected. This could occur depending on the exact mapping of data used or after deflation.

However, (4) does reflect the expected cost per iteration during the first few iterations. Since experimental results show that the first few iterations quite accurately predict the overall performance of an implementation that includes deflation, we will use (4) for subsequent analysis, ignoring the stated deficiencies in our model.

3.3.2. Scalability. On current generation architectures, the above model shows that the bulk of inefficiency comes from the *number* of messages generated, since α is typically several orders of magnitude greater than either β or γ. To investigate the scalability of the approach, we start by computing the estimated speedup, based on the estimated cost of a single Francis step:

$$\text{(5)} \quad \text{speedup}_{\text{est}}(n, p, h) = \frac{T_{\text{seq}}(h)}{T_{\text{est}}(n, p, h)} = \frac{20n^2}{20\frac{n^2}{p}\gamma + 4\frac{n^2}{hp} + O(n)} = \frac{p}{1 + \frac{4}{h} + O(\frac{p}{n})}.$$

If h is chosen big enough, e.g., $h \approx n/p$, the second term in the denominator also becomes $O(p/n)$, and we can make the following observations: if p is fixed, and n is allowed to grow, eventually perfect speedup will be approached. Furthermore, the estimated efficiency attained is given by

$$\text{(6)} \quad \text{efficiency}_{\text{est}}(n, p, h) = \text{speedup}_{\text{est}}(n, p, h) = \frac{1}{1 + O(\frac{p}{n})}.$$

From this last equation, we can say something about the scalability of the implementation: in order to maintain efficiency, we must grow n linearly with p. This poses a serious problem: memory grows linearly with p, but memory requirements grow with n^2. We conclude that this approach to parallelization will not scale, since memory constraints dictate that eventually efficiency cannot be maintained, even if the problem is allowed to grow to fill the combined memories.

The previous modeling extends to the overall algorithm in a simple manner. On average, to find the eigenvalues of a matrix of size n requires $2n$ HQR iterations. In every other iteration, there is typically a deflation of size one or two. Since deflation occurs less frequently in the beginning than the end, our overall model satisfies

$$\text{overall flops } = \sum_{k=1}^{n} 3 * 20k^2 = 20n^3,$$

where 3 is a heuristic fudge factor. Compare, for example, [18] which uses a similar heuristic, but different fudge factor, to suggest overall flops at $25n^3$.

Similarly, we can extend all of the formulas in the previous subsection. In (4), the number of communication start-ups is $n + 2n/h$. For the overall algorithm, before the bundling

[2] Recall that every other processor owns diagonal blocks in an antidiagonal mapping.

described in §3.4.4, we can estimate

$$\text{communication start-ups } = \sum_{k=1}^{n} 3 * \left(k + \frac{2k}{h}\right) = \left(\frac{3}{2} + \frac{3}{h}\right) n^2.$$

3.3.3. Theoretical limitations. For many dense linear algebra algorithms, better scalability can be obtained by using a so-called two-dimensional data decomposition. Examples include the standard decomposition algorithms, like LU, QR, and Cholesky factorization [13, 19], as well as the reduction to condensed form required for reducing a general matrix to upper Hessenberg form [6, 12]. It is therefore natural to try to reformulate the parallel QR algorithm in an attempt to extract an algorithm that has better scalability properties. In this section we show *theoretically* that there is an *inherent* limitation to the scalability of the QR algorithm that indicates that a more complicated data and work decomposition alone *cannot* improve the scalability of the parallel implementation.

We present a simple analysis of the theoretical limitations of the QR algorithm. There is a clear dependence in the chasing of the bulge that requires at least $O(n)$ steps to complete one Francis HQR step. The associated computation can be thought of as running down the diagonal of the matrix. Moreover, the last element of the matrix must be computed before the next Francis step can start, since it is needed to compute the shift. Since there are $O(n^2)$ computations performed in one such step, the speedup is limited to $O(n)$, which indicates that the maximal number of processors that can be usefully employed is $O(n)$. Hence, $p \leq Cn$ for some constant C.

Let us now analyze the implications of this: if efficient use of the processors is to be attained, the equation $p \leq Cn$ must hold for some constant C. The total memory requirements for a problem of size n is Kn^2 for some constant K. Hence,

$$\text{memory requirements} = Kn^2 \geq \frac{K}{C^2}p^2 = O(p^2).$$

Notice, however, that memory only grows linearly with the number of processors. We conclude that due to memory restrictions, it is impossible to solve a problem large enough to maintain efficiency as processors are added. In the conclusion, we indicate how it may be possible to overcome this apparent negative result.

3.4. Refinements of the parallel algorithm. The above analysis shows that there is reason to believe that trying to generalize the Hankel-wrapped mapping to yield the equivalent of a two-dimensional wrapping will not result in the same kinds of benefits as it would for a factorization algorithm. However, there are a number of refinements that can be made that will improve the performance of the parallel QR algorithm. Moreover, the algorithm as it was described in §3.2 is far from a complete implementation.

3.4.1. Accumulating Q. The algorithm in §3.2 ignores the accumulation of the orthogonal matrix Q. There is a perfect parallelism in this operation, requiring no more communication than must already be performed as part of the updating of H.

Each stage of the Francis HQR step in Figure 1 requires the computation $Q \leftarrow QP_i$. Since P_i is broadcast during the update of the Hessenberg matrix, all processors already have this information. The computation $Q \leftarrow QP_i$ reflects three columns of Q. Which three get reflected depends on i. Since Q is not accessed elsewhere within the HQR kernel, we can assume Q has the best data storage possible for reflecting three columns. This data storage is a one-dimensional row mapping. With a one-dimensional row mapping, the data in any row is always contained on a single processor. Each row in a column transform can be computed independently. So there is no extra communication required to complete the column transform, and this extra work is embarrassingly parallel.

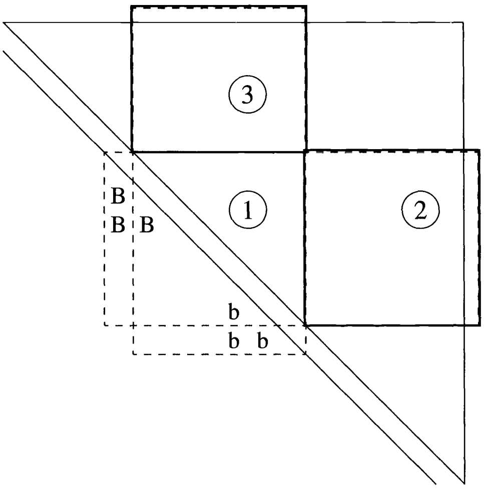

FIG. 4. *Bundling Householder transformations and order of updates.*

3.4.2. Deflation. We previously mentioned that as subdiagonal elements become numerically zero, the process proceeds with unreduced submatrices on the diagonal. This process is known as deflation. One convenient way to determine the points where such a block start and end is to broadcast enough diagonal information during the bulge chase so that at the end of a complete HQR step, all processors hold all information required to determine when breakpoints occur. After rotating columns i, $i+1$, and $i+2$, column i remains fixed for the remainder of that Francis HQR step. Therefore, the three elements of the tridiagonal portion of H in column i ($H(i-1:i+1, i)$) can also be broadcast with the three elements defining the Householder reflection at step i. This requires sending six elements instead of three per transformation. While this creates a certain redundancy, the overhead is $O(n)$, and hence lower order.

3.4.3. Determining shifts. Related to the refinement mentioned above concerning deflation, it is convenient to broadcast all entries of the tridiagonal of the newly formed Hessenberg matrix, as we describe in §3.4.2, since this allows all processors access to the data required to compute the next shifts.

3.4.4. Bundling transformations. As is argued in §3.3, the bulk of the communication overhead is due to communication start-up cost. This cost can be amortized over several computations and applications of Householder transformations by bundling several Householder transformations before broadcasting.

We direct the reader's attention to Figure 4.

This picture represents the data in the block that currently holds the bulge. This block is assumed to be completely assigned to one processor. In chasing the bulge a few positions, to where it moves from the position indicated by "B"s to the position indicated by "b"s, a number of Householder transformations are computed. To do so, only the computation associated with the region marked by "1" needs to be performed.[3] Thus these transformations can be bundled by performing this minimal computation, followed by the broadcast, after which the other regions, marked by "2" and "3" can be updated. The net effect is that the number of start-ups

[3] As is noted in Henry [20, 23], the minimal information needed to determine the upcoming transforms is roughly eighty percent of the total flops required to actually complete the entire update in region "1" of Figure 4. This "partial" step is referred to as a lookahead step and can also be used to determine better shifts (cf. Henry [22]).

is reduced by the number of transformations that are bundled. Naturally, bundling across processor boundaries becomes complicated and has only marginal benefit.

Repeating the analysis in §3.3 above, we get the following estimates: computing r transformations, updating only region "1" in Figure 4 requires approximately

$$r(C + 10(r + 4))\gamma$$

time. Broadcasting the transformations requires time

$$\alpha + 3r\beta.$$

Next, updating regions "2" and "3" on the processor that computes the transformations requires time

$$10r\left(\frac{n}{p} - r\right)\gamma$$

to update matrix A, and

$$10r\frac{n}{p}\gamma$$

to update matrix Q. This is repeated n/r times, and border information must be communicated every h transformations, giving a (very rough) total estimated time of

$$20\frac{n^2}{p}\gamma + Cn\gamma + 40n\gamma + \frac{n}{r}\alpha + 3n\beta + 2\frac{n}{h}\alpha + 4\frac{n^2}{hp}\beta + O(1).$$

Clearly the above estimate is only a rough estimate: it suggests that increasing bundling factor r arbitrarily will continue to improve total time. Notice that this estimate is only reasonable when the pipe is undisturbed. However, every time a boundary is encountered, the boundary will be disturbed and therefore larger bundling factors will increase load imbalance. Nonetheless, our model gives us insight.

4. Performance results. In this section, we report the performance of a prototype working implementation of the described parallel implementation. Our implementation is a parallelization of the LAPACK [1] routine DLAHQR, and is mathematically exact except that the sequential routine applies one final rotation per converged eigenpair so that the resulting "Schur" form has some regularity. Hence, there is no need to report in detail on the numerical accuracy of the implementation: all numerical properties of the LAPACK code apply to this parallel implementation.

We report performance obtained on an Intel Paragon™ XP/S Model 140 Supercomputer, running SUNMOS version S1.4.8. The following is crucial to our analysis:

> Since finding all eigenvalues of a very large matrix takes a considerable amount of time (measured in days) we report the performance of the algorithm during the first five iterations. For problems of size 2750 or less, and for 64 processors or less, we saw extrapolating total time from measuring five iterations always yielded a predicted performance that was within three percent measured performance when the code was executed to completion.[4]

In addition, it is hard to measure speedup with respect to a single processor, due to insufficient memory to hold a large matrix. As a result, we measured the performance of the best-known sequential QR algorithm and report the parallel performance with respect to that: the single

[4] This is possible because we restricted our timings to a Schur decomposition.

TABLE 1
Parallel HQR.

p	n	Scaled speedup	Efficiency
4	2000	2.5	.63
8	2800	5.2	.65
16	4000	10.0	.63
32	4800	17.1	.53
48	6000	23.0	.48
64	8000	30.1	.47
96	9600	37.4	.39

node performance of the fastest QR algorithm (not necessarily a standard double shift algorithm from LAPACK) peaks at 10 Mflops for the five iterations. We report scaled speedup as being the speedup obtained with respect to the calculated time required to run a given problem on a single node performing at 10 Mflops. In this case, actual flops within the algorithm were calculated and used for results, and not heuristics.

Many parameters are used to describe the parallel implementation, including the number of nodes used p, the matrix size n, the blocking factor h, and the bundling factor r. All the runs in Table 1 were for problems of size approximately 10 to 14 Mbytes per processor, all with blocking factors h given by n/p, with a bundling factor of $r = 2$. Our models predict that varying h and r impacts communication overhead incurred. However, in practice , the major source of inefficiency appears to come from the fact that row and column updates do not have the same memory access patterns and therefore execute at different rates. Our experiments indicate row transforms are 13 percent faster than column transforms. At each step there is a roughly even amount of work for all the nodes, but there is not the same amount of row or column work. This means that at *each* step there is a delay for a few of the nodes to complete the ring broadcast. Hence, although our model predicts the load balance to be quite good, the different rates of execution make it much less well balanced. This shows up in the timings given in Table 1. Notice that, at best, about 65 percent efficiency is attained.

5. Conclusion. The research described in this paper was meant as a response to claims that no parallelism exists in the QR algorithm. The theoretical results in this paper show there are approaches to implementing the QR algorithm that allow parallelism to be extracted in a natural way. The actual implementation of this method on a high performance parallel computer shows that, in practice, parallelism can be extracted as well.

We caution the reader against misinterpreting the results in this paper as largely supporting the notion that new methods like those developed by Bai and Demmel [4] and Dongarra and Sidani [11] must be pursued if nonsymmetric eigenvalue problems are to be solved on massively parallel computers. Let us address some of the arguments that can be made to support such an interpretation and how these arguments are somewhat unsatisfactory.

No parallelism exists in the nonsymmetric QR algorithm. We believe the major results in this paper are a counterexample to this statement, both in theory and practice.

The performance of even the sequential algorithm leaves something to be desired. One argument for matrix–matrix multiplication-based methods is that matrix multiplication can achieve much higher performance rates than a kernel that applies a Householder transformation. This more than offsets the added floating point operations required for such novel solutions. This argument is true only because the matrix–matrix multiplication is recognized as an important kernel that warrants highly optimized implementation. It is the data reuse available in the matrix–matrix multiplication that allows near-peak performance to be achieved on a large number of platforms. However, a careful analysis of reuse of data when *multiple*

Householder transformations are applied, which could be exploited with bundling, shows that the performance of the sequential QR algorithm could be greatly improved if such a kernel were assembly coded. Clearly a user who can afford a massively parallel computer would be able to afford to assembly code such a kernel.

One could argue that assembly coding this kernel would only improve the 40 percent of total time spent in useful computation and hence would actually *decrease* efficiency. However, we argue that since most overhead is due to load imbalance, the total time should benefit, not just the time spent in useful computation.

Parallel QR algorithms cannot be scalable. One could draw this conclusion from §3.3.3. However, notice that the analysis holds for the algorithm when only a single double-shift is used during each iteration. If a method is parallelized that uses s shifts, the total computation per iteration is increased to $O(sn^2)$, while the dependence during the bulge chase only increases to $O(n+s)$ if multiple bulges are chased in a pipelined fashion. We conclude that the limit on speedup is now given by $O(sn^2)/O(n+s) \approx O(sn)$. $O(sn)$ processors can be usefully employed, leading to memory requirements

$$\text{memory requirements} = Kn^2 >= O\left(\frac{p^2}{s^2}\right).$$

As long as $p/s^2 = O(1)$, i.e., $s = O(\sqrt{p})$, it may be possible to achieve scalability while meeting the fixed memory per processor criteria.

Scalable implementations of the QR algorithm may be achievable for parallel implementations that use s shifts simultaneously, provided the number of shifts grows with the square-root of the number of processors.

We must note that our data decomposition inherently requires n to grow with p and therefore it will not provide for the required parallel implementation. Therefore, generalizations to two-dimensional data decompositions will be necessary.

Notice that some of the above comments indicate that many of the observations made from the earlier sections were merely due to the fact that in this paper we restricted ourselves to discussing the parallel implementation of widely used QR algorithms.

In contrast, we mention the advantages of using the QR algorithm:

- Fewer flops, fast convergence. In many cases (cf. [5]), other algorithms can require several times the number of floating point calculations (although they can be in matrix multiplication).
- High accuracy. The QR algorithm has always remained one of the most accurate algorithms for the unsymmetric Schur decomposition.
- Parallelism. This paper demonstrates that for a moderate-sized system, parallelism is possible.

We conclude by saying that the reason parallel QR algorithm implementations may not be competitive is because insufficient resources have been allocated to study their implementation. Those resources are currently being used instead to explore novel algorithms. If someone has the required resources, our research points clearly to what properties a parallel implementation must have to be successful.

Acknowledgments. Our final runs were made on Sandia's Paragon™ XP/S Model 140 Supercomputer running SUNMOS S1.4.8, and we are grateful for this resource and operating system. AN OVERDETERMINED SCHWARZ ALTERNATING METHOD*

HUOSHENG SUN† AND WEI-PAI TANG†

Abstract. Developing modern extensions of the Schwarz alternating method (SAM) has been a primary focus in the research of domain decomposition during the past 10 years. Among the various research efforts, the generalized Schwarz alternating method (GSAM) was an attempt to use the Robin condition

$$\omega u + (1 - \omega)\frac{\partial u}{\partial n}$$

on those artificial boundaries to improve the performance of the SAM. Its convergence rate is much faster than the classical SAM (with a large overlap), yet only a minimum overlap is required. Unfortunately, sensitivity of the convergence of the GSAM to the parameter ω has limited its practical applications. In this paper, a new kind of coupling is proposed which possesses the same benefits as the GSAM. The advantage of our new algorithm over the GSAM is that the optimal convergence rate is achieved on a wider range of the parameter. That is, selection of the optimal parameter is not crucial to the new algorithm's performance. Numerical tests have been carried out for a variety of difficult problems including nonsymmetric and indefinite problems.

Key words. Schwarz alternating method, generalized Schwarz splitting, generalized Schwarz alternating method, overdetermined Schwarz alternating method, domain decomposition, parallel computation, overlap

1. Introduction.

Schwarz-type alternating methods have become some of the most important approaches in domain decomposition techniques during the past few years [2, 3, 5, 7, 9–11, 13, 15–18, 20]. The theoretical foundations for the classical Schwarz alternating method (SAM) and its modern extension are maturing [11, 19, 21]. Our list of references can only reflect a small portion of the studies done in this direction. Current popular approaches are seeking superior preconditioners to improve performance. A multilevel preconditioner, for example, is a typical technique used by many [3, 17, 19, 21]. However, one of the most interesting aspects of the SAM, namely, the coupling on those artificial boundaries, has not received enough attention. Our studies show that further investigation in this direction can be promising as well.

It is well known that the amount of overlap affects the rate of convergence, yet large overlap is not desirable. Tang proposed *generalized Schwarz splitting* a few years ago [18]. One special element of his approach to the solution of an elliptic PDE is to use the Robin boundary condition

$$\omega u + (1 - \omega)\frac{\partial u}{\partial n}$$

on the artificial boundaries. P. Lions [11] presented a very similar idea, "a variant for nonoverlapping subdomains," in using the Robin condition on the interfaces between subregions.

It was shown that a fast convergence can be achieved with minimum overlap if an optimal ω is chosen [18]. The convergence is even faster than with the classical SAM with a large overlap. The minimum overlap requirement is, of course, an attractive feature of the generalized Schwarz alternating method (GSAM). Unfortunately, the analysis also indicates that the convergence can be sensitive to this parameter. In particular, to identify a robust algorithm for estimating the optimal parameter in real applications is an extremely difficult task. An

†Department of Computer Science, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1.

attempt to use a similar idea in a symmetric successive overrelaxation (SSOR) for removing the sensitivity is not successful.

Therefore, retaining the good features of the GSAM, namely fast convergence and the minimum overlap requirement, and eliminating the sensitivity of any parameter to the convergence, are the two most important characteristics we need for the new approaches.

It is easy to see that the motivation behind the GSAM is to use the information of both the unknown and its derivative in the coupling of the neighboring subdomains. A weighted combination of the unknown and its derivative forces a contribution of both. If the combination is proper, a fast convergence with a minimum overlap can be achieved. This combination, therefore, poses a "*stronger*" constraint, or consistency of the neighboring solutions, on those artificial boundaries. On the other hand, the most forceful combination of this constraint can only be reached in a very narrow range of the parameter ω. Though the GSAM suffers from its practical implications, it demonstrates a successful attempt to use a stronger coupling. If a more vigorous coupling between the solutions of those neighboring subdomains can be introduced, the ideal goal may become reality.

Based on the above observation, we are looking for alternative couplings which can be introduced between the neighboring subdomains. In fact, the enforcement of the solutions between the two neighboring subdomains may not necessarily be just on the artificial boundaries. On the whole overlapping part of the two neighboring subdomains, the two solutions also have the same values for both the unknown and its derivative. Therefore, we can introduce an artificial boundary layer for the corresponding artificial boundary. The Robin condition is imposed on the entire layer. The primary motive of the new approach is to impose the constraints on the boundary layer rather than on a single boundary as the GSAM did. We hope that this stronger enforcement will be beneficial to the convergence behavior of the new approach.

In the next section, the new method, the overdetermined Schwarz alternating method (OSAM), is introduced. Section 3 describes the technique for the discretization of the artificial boundary layer. The analysis of the convergence for the model problem is shown in §4. Numerical testing results are shown in §5. The last section concludes.

2. Overdetermined SAM. Let L be an elliptic operator

$$L = -\frac{\partial}{\partial x}\left(w_1\frac{\partial}{\partial x}\right) - \frac{\partial}{\partial y}\left(w_2\frac{\partial}{\partial y}\right) + s\frac{\partial}{\partial x} + t\frac{\partial}{\partial y} + c, \tag{1}$$

where w_1, w_2, s, t, and c are functions of x and y which satisfy[1]

$$w_1(x,y),\quad w_2(x,y) \geq C > 0, \qquad c(x,y) \geq 0.$$

Consider the following boundary value problem:

$$\left\{\begin{array}{rcll} L(u) & = & f, & \Omega, \\ u & = & g, & \partial\Omega, \end{array}\right. \tag{2}$$

where Ω is a bounded region in R^2. For simplicity, we consider only the two-overlapping-subdomain case (see Figure 1). The generalization to an irregular solution domain or multisubdomain is straightforward. The rectangular solution region Ω is partitioned into two overlapping subdomains Ω_1 and Ω_2. Let

$$\begin{array}{ll} \Gamma_{21} = \partial\Omega_2 \cap \Omega_1, & \Gamma_{12} = \partial\Omega_1 \cap \Omega_2, \\ \Gamma_1 = \partial\Omega \cap \partial\Omega_1, & \Gamma_2 = \partial\Omega \cap \partial\Omega_2. \end{array}$$

[1] Our methods can also be applied to nonself-adjoint and indefinite cases (see §5).

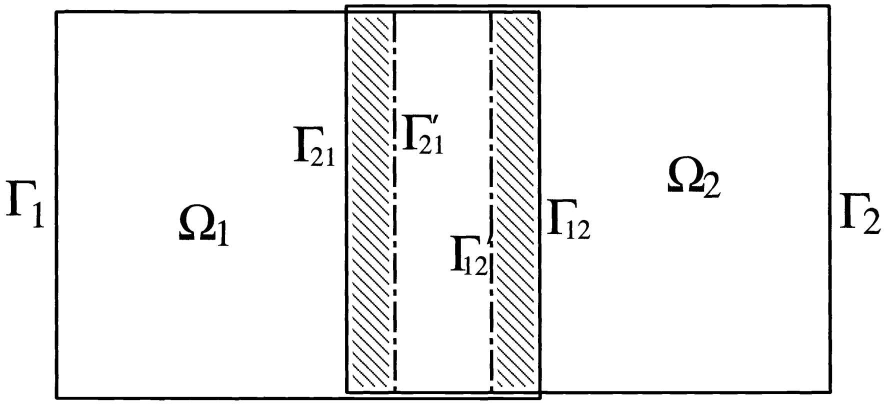

FIG. 1. *Artificial boundary layers of two overlapping subdomains.*

Here, Γ_{12} and Γ_{21} are the artificial boundaries for subdomains Ω_1 and Ω_2, respectively. To make the picture more readable, the Ω_2 has been shifted upwards slightly. We introduce two artificial boundary layers $\mathcal{L}_1$ and $\mathcal{L}_2$ (shaded parts in Figure 1), which are next to the corresponding artificial boundaries Γ_{12} and Γ_{21} (they will be called boundary layers, for simplicity, later). The thickness of these layers depends on the grid. When a uniform grid is employed, the corresponding thickness of the boundary layer will be the grid size h. For a general triangular mesh, the boundary layer will be the union of all triangles for which at least one of its edges or nodes is on the artificial boundary. The motivation for this choice is to allow the minimum overlap needed in the new algorithm. Denote Γ'_{12} and Γ'_{21} as the inner boundaries of the boundary layers $\mathcal{L}_1$ and $\mathcal{L}_2$, respectively.

The Robin condition is imposed on the entire boundary layer. Then, a new problem can be stated as follows:

$$(3)\qquad \begin{cases} L(u_1) = f, & x \in \Omega_1, \\ u_1|_{\Gamma_1} = g, & \\ b(u_1)|_{\mathcal{L}_1} = b(u_2)|_{\mathcal{L}_1}, & \end{cases}$$

$$(4)\qquad \begin{cases} L(u_2) = f, & x \in \Omega_2, \\ u_2|_{\Gamma_2} = g, & \\ b(u_2)|_{\mathcal{L}_2} = b(u_1)|_{\mathcal{L}_2}, & \end{cases}$$

where $b(u) = \omega u + (1-\omega)\frac{\partial u}{\partial n}$. There are infinitely many choices for the function ω. To focus our discussion, we only investigate a very special case in this paper:

$$(5)\qquad \omega = \omega(x, y) = \begin{cases} 1, & (x, y) \text{ is on the artificial boundary,} \\ 0, & \text{otherwise.} \end{cases}$$

Therefore, the constraint on the artificial boundaries is Dirichlet type and Neumann type in the rest part of the boundary layer. Compared to the original SAM, the new form has a stronger coupling between the two solutions of the neighboring subdomains. Problem (3)–(4) is obviously overdetermined. In general, the solution for an overdetermined problem may not exist, and a least square type of solution should be sought. In this case, the solution of (2) is a solution of (3)–(4).

An iterative algorithm for solving this problem can be easily extended from the classical SAM:

```
Choose  $u_2^0|_{\Gamma_{12}}$,  $\frac{\partial u_2^0}{\partial n}\Big|_{\Gamma'_{12}}$
for     $k = 1, 2, \ldots,$
    solve
        $L(u_1^k) = f,$                              $(x, y) \in \Omega_1,$
        $u_1^k|_{\Gamma_1} = g|_{\Gamma_1},$
        $b(u_1^k)|_{\mathcal{L}_1} = b(u_2^{k-1})|_{\mathcal{L}_1},$
    solve
        $L(u_2^k) = f,$                              $(x, y) \in \Omega_2,$
        $u_2^k|_{\Gamma_2} = g|_{\Gamma_2},$
        $b(u_2^k)|_{\mathcal{L}_2} = b(u_1^k)|_{\mathcal{L}_2},$
end  for
```

The implementation and analysis of this algorithm will be shown next.

3. Discretization of the boundary layers. Each of the problems (3)–(4) is overdetermined. To design a deterministic algorithm, reconstruction of the coupling on the boundary layer is necessary. When the problem is discretized, the constraint on the artificial boundary layer affects only the grid nodes on the boundary of the layer (assume the boundary layer is one grid thick), for example, the grid nodes on Γ_{12} and Γ'_{12} of the subdomain Ω_1. The grid nodes of the boundary layer are called inner boundary layer nodes if they are inside the subdomain and outer boundary layer nodes otherwise.

We observe that the solution on Γ'_{12} and Γ'_{21} satisfies both the difference equation[2] and the derivative coupling between two solutions on the neighboring subdomain. Therefore, a natural approach is to apply a weighted combination of these two conditions. It is enough to demonstrate how the two constraints on Γ'_{12} are combined into a single equation. The following part of this section gives the procedure.

Let u^1 and u^2 be the solutions on subdomains Ω_1 and Ω_2, respectively. For each interior node (i, j) in Ω_1, a difference equation

$$Du^1_{i,j} = a^{i,j}_{0,-1}u^1_{i,j-1} + a^{i,j}_{-1,0}u^1_{i-1,j} + a^{i,j}_{0,0}u^1_{i,j} + a^{i,j}_{1,0}u^1_{i+1,j} + a^{i,j}_{0,1}u^1_{i,j+1} = b^{i,j} \tag{6}$$

can be derived using any common discretization strategy.[3] We use $u^1_{i,j}$ to denote the solution u^1 at node (i, j). Let (i, j) be a node next to Γ'_{12} in the subdomain Ω_1. Both this node and its neighboring nodes are indicated by "○". Then, the neighbor node $(i, j+1)$ is located on Γ'_{12}. Both the node $(i, j+1)$ and its neighboring nodes are indicated by "▽" (see Figure 2). By the construction of our boundary layer, it is clear that node $(i, j+2)$ is located on the artificial boundary Γ_{12}. The difference equation at node $(i, j+1)$ is then

$$\begin{aligned} Du^1_{i,j+1} &= a^{i,j+1}_{0,-1}u^1_{i,j} + a^{i,j+1}_{-1,0}u^1_{i-1,j+1} + a^{i,j+1}_{0,0}u^1_{i,j+1} + a^{i,j+1}_{1,0}u^1_{i+1,j+1} + a^{i,j+1}_{0,1}u^1_{i,j+2} \\ &= b^{i,j+1}. \end{aligned} \tag{7}$$

By the Dirichlet condition on Γ_{12}, we have

$$u^1_{i,j+2} = u^2_{i,j+2}. \tag{8}$$

[2] We assume that this boundary value problem has been discretized by finite difference or finite element methods.

[3] Both central and upwind schemes are tested for our new algorithms. Their convergence characteristics are rather similar.

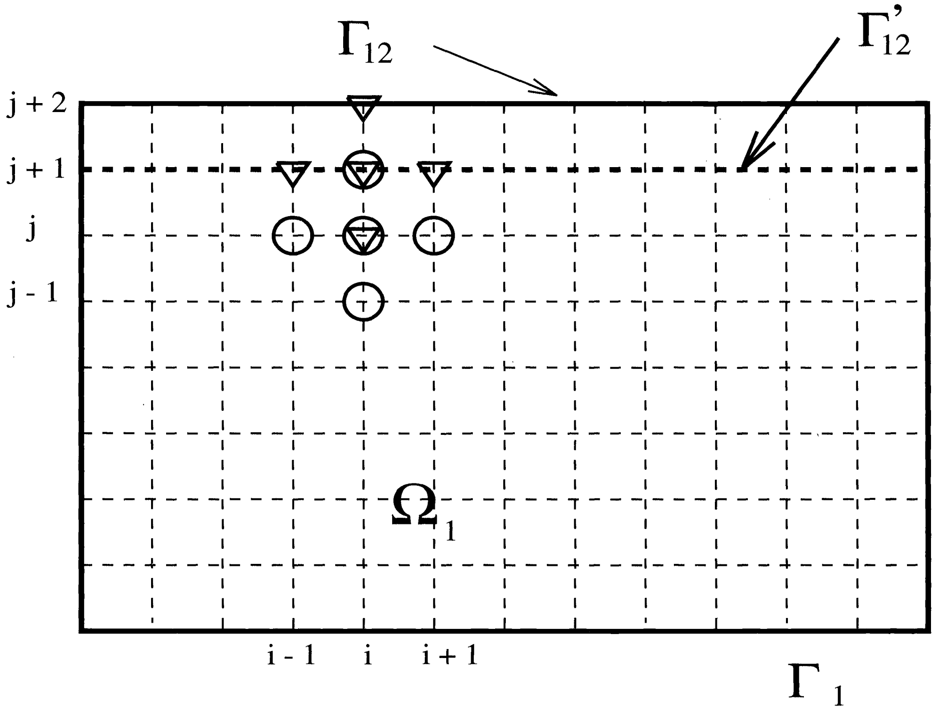

FIG. 2.

Substituting (8) into (7) and solving for $u^1_{i,j+1}$, we get

$$(9)\quad a^{i,j+1}_{0,0}u^1_{i,j+1} = b^{i,j+1} - a^{i,j+1}_{0,-1}u^1_{i,j} - a^{i,j+1}_{-1,0}u^1_{i-1,j+1} - a^{i,j+1}_{1,0}u^1_{i+1,j+1} - a^{i,j+1}_{0,1}u^2_{i,j+2}.$$

If $a^{i,j+1}_{0,0} \neq 0$ (in general, this is true for an elliptic equation), we solve for $u^1_{i,j+1}$ from (9) to get

$$(10)\quad u^1_{i,j+1} = (b^{i,j+1} - a^{i,j+1}_{0,-1}u^1_{i,j} - a^{i,j+1}_{-1,0}u^1_{i-1,j+1} - a^{i,j+1}_{1,0}u^1_{i+1,j+1} - a^{i+1,j}_{0,1}u^2_{i,j+2})/a^{i,j+1}_{0,0}.$$

From the Neumann condition on Γ'_{12}, we have

$$\left.\frac{\partial u^1}{\partial x}\right|_{\Gamma'_{12}} = \left.\frac{\partial u^2}{\partial x}\right|_{\Gamma'_{12}}.$$

In discrete form, at node $(i, j+1)$, this reads

$$(11)\qquad u^1_{i,j+1} = u^1_{i,j} + u^2_{i,j+1} - u^2_{i,j}.$$

Similarly we have, at nodes $(i \pm 1, j+1)$,

$$(12)\qquad u^1_{i\pm1,j+1} = u^1_{i\pm1,j} + u^2_{i\pm1,j+1} - u^2_{i\pm1,j}.$$

Substituting (12) into (10), $u^1_{i,j+1}$ can then be expressed as

$$\begin{aligned} u^1_{i,j+1} = \Big\{ & b^{i,j+1} - a^{i,j+1}_{0,-1}u^1_{i,j} - a^{i,j+1}_{-1,0}(u^1_{i-1,j} + u^2_{i-1,j+1} - u^2_{i-1,j}) \\ (13)\qquad & -a^{i,j+1}_{1,0}(u^1_{i+1,j} + u^2_{i+1,j+1} - u^2_{i+1,j}) - a^{i+1,j}_{0,1}u^2_{i,j+2}\Big\} / a^{i,j+1}_{0,0}. \end{aligned}$$

There are two conditions (13) and (11) for the unknown $u_1^{i,j+1}$ in (6). Let $0 < \theta \leq 1$ be the weight parameter. Then a weighted combination of (13) and (11) gives

$$\begin{aligned} u^1_{i,j+1} = \theta \Big\{ & b^{i,j+1} - a^{i,j+1}_{0,-1} u^1_{i,j} - a^{i,j+1}_{-1,0} (u^1_{i-1,j} + u^2_{i-1,j+1} - u^2_{i-1,j}) \\ & -a^{i,j+1}_{1,0} (u^1_{i+1,j} + u^2_{i+1,j+1} - u^2_{i+1,j}) - a^{i+1,j}_{0,1} u^2_{i,j+2} \Big\} / a^{i,j+1}_{0,0} \\ & +(1-\theta)(u^1_{i,j} + u^2_{i,j+1} - u^2_{i,j}). \end{aligned} \tag{14}$$

Substituting (14) into (6) for any interior nodes next to Γ'_{12}, we can essentially eliminate all the nodes on Γ'_{12} in the final matrix equation for Ω_1.

It should also be pointed out that our new algorithm may appear to require more overlap for the boundary layer. However, after a combination of the two conditions on the boundary layer, only the minimum overlap is really needed for this new approach. In other words, the unknowns on the boundary layer can be eliminated totally from the matrix equation of the subdomain before the iteration starts.

4. Convergence analysis. As shown in [18], Schwarz splitting is a useful tool for analyzing the convergence behavior of the Schwarz-type algorithms. Here, a three-subdomain case is presented. The generalization to more subdomains in the strip case is straightforward.

Consider problem (2), and assume its solution domain is decomposed in the y-direction into three overlapped subdomains. The discretized matrix form can be written as

$$Ax = \begin{pmatrix} A_{11} & A_{12} & 0 & 0 & 0 \\ A_{21} & A_{22} & A_{23} & 0 & 0 \\ 0 & A_{32} & A_{33} & A_{34} & 0 \\ 0 & 0 & A_{43} & A_{44} & A_{45} \\ 0 & 0 & 0 & A_{54} & A_{55} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \end{pmatrix} = \begin{pmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \\ b_5 \end{pmatrix} = b. \tag{15}$$

The order of the unknowns is arranged so that $\{x_1, x_2\}$ are located in Ω_1, $\{x_2, x_3, x_4\}$ are located in Ω_2, and $\{x_4, x_5\}$ are located in Ω_3. $\{x_2\}$, $\{x_4\}$ correspond to the unknowns in the overlapping parts Ω_{12} and Ω_{23}, respectively.

The GSAM procedure for (2) is equivalent to a 3 by 3 block Gauss–Seidel iteration for the enhanced matrix problem of (15)[18],

$$\tilde{A}\tilde{x} = \begin{pmatrix} A_{11} & A_{12} & 0 & 0 & 0 & 0 & 0 \\ A_{21} & B_2 & C_2 & A_{23} & 0 & 0 & 0 \\ A_{21} & C'_2 & B'_2 & A_{23} & 0 & 0 & 0 \\ 0 & 0 & A_{32} & A_{33} & A_{34} & 0 & 0 \\ 0 & 0 & 0 & A_{43} & B_4 & C_4 & A_{45} \\ 0 & 0 & 0 & A_{43} & C'_4 & B'_4 & A_{45} \\ 0 & 0 & 0 & 0 & 0 & A_{54} & A_{55} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x'_2 \\ x_3 \\ x_4 \\ x'_4 \\ x_5 \end{pmatrix} = \begin{pmatrix} b_1 \\ b_2 \\ b_2 \\ b_3 \\ b_4 \\ b_4 \\ b_5 \end{pmatrix} = \tilde{b}, \tag{16}$$

where

$$A_{22} = B_2 + C_2 = C'_2 + B'_2, \quad A_{44} = B_4 + C_4 = C'_4 + B'_4. \tag{17}$$

The splitting in (17) corresponds to the coupling on the artificial boundaries of the GSAM. The corresponding matrix splitting is called a generalized Schwarz splitting (GSS). The analysis of the convergence is, therefore, to study the spectral radius of the iteration matrix $M^{-1}N$, where

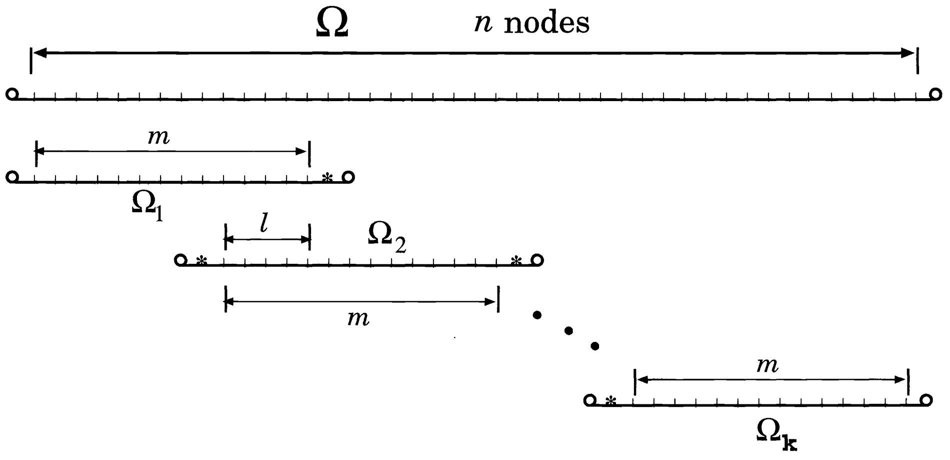

FIG. 3. *1-D overlapping grid.*

$$M = \begin{pmatrix} A_{11} & A_{12} & 0 & 0 & 0 & 0 & 0 \\ A_{21} & B_2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & B_2' & A_{23} & 0 & 0 & 0 \\ 0 & 0 & A_{32} & A_{33} & A_{34} & 0 & 0 \\ 0 & 0 & 0 & A_{43} & B_4 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & B_4' & A_{45} \\ 0 & 0 & 0 & 0 & 0 & A_{54} & A_{55} \end{pmatrix}, \tag{18}$$

$$N = -\begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & C_2 & A_{23} & 0 & 0 & 0 \\ A_{21} & C_2' & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & C_4 & A_{45} \\ 0 & 0 & 0 & A_{43} & C_4' & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}. \tag{19}$$

The OSAM procedure for (2) can also be expressed in the Schwarz splitting form. First, the derivation for a one-dimensional (1-D) model problem is presented. Although the one-dimensional case has no practical importance, it will, however, be used for a higher-dimensional case. Consider

$$-y'' + qy = f, \qquad x \in (0,1), \tag{20}$$

where $q(x) \geq 0$. Denote the number of total nodes as n and the number of overlapping subdomains as k. For convenience, we assume the overlap pattern is uniform. Each subdomain and overlapping part contains m and l nodes, respectively, excluding the boundary layer, which is one grid in width. We also assume that the artificial boundary for each subdomain corresponds to one grid and that no three subdomains have a common overlap (see Figure 3). The open circles represent the artificial boundaries, and the asterisks represent the other grids of the boundary layer for each subdomain.

After discretization using the central finite difference scheme, the resulting linear algebraic equation from (20) is

$$Ax = b, \tag{21}$$

where A is a tridiagonal matrix with p $(p \geq 2)$ on the diagonal and -1 on the off-diagonals. For readability, only the three-subdomain case is displayed.

The partitioned form of A is, then,

$$(22)\quad A = \left(\begin{array}{ccccccccccccccc}
p & -1 & & & & & & & & & & & & & \\
 & \ddots & & & & & & & & & & & & & \\
 & -1 & p & -1 & & & \leftarrow & & & & & & & & \\
 & & -1 & p & -1 & & & & & & & & & & \\
 & & & & \ddots & & & & & & & & & & \\
 & & & & -1 & p & -1 & & & & & & & & \\
 & & & \rightarrow & & -1 & p & -1 & & & & & & & \\
 & & & & & & & \ddots & & & & & & & \\
 & & & & & & & -1 & p & -1 & & \leftarrow & & & \\
 & & & & & & & & -1 & p & -1 & & & & \\
 & & & & & & & & & & \ddots & & & & \\
 & & & & & & & & & & -1 & p & -1 & & \\
 & & & & & & & & & \rightarrow & & -1 & p & -1 & \\
 & & & & & & & & & & & & & \ddots & \\
 & & & & & & & & & & & & & -1 & p
\end{array}\right).$$

The rows which correspond to the inner boundary layer nodes are indicated by "←" or "→". The reconstruction of the boundary layer procedure can be described as follows. First, we multiply the rows $(m-l)$, $(m+1)$, $2(m-l)$, and $(2m-l+1)$ (i.e., those rows corresponding to the inner boundary layer nodes) by $\eta = \theta/p$ and add to rows $m-l+1$, m, $2(m-l)+1$, and $2m-l$, respectively. If the same operations are carried out for the right-hand side, the solution of the new matrix equation $A'x' = b'$ will be the same as that of $Ax = b$, since A' is row equivalent to A. A' is as follows:

$$A' = \left(\begin{array}{ccccccccccccccc}
p & -1 & & & & & & & & & & & & & \\
 & \ddots & & & & & & & & & & & & & \\
 & -1 & p & -1 & & & & & & & & & & & \\
 & -\eta & \theta\text{-}1 & p' & -1 & & & & & & & & & & \\
 & & & & \ddots & & & & & & & & & & \\
 & & & & -1 & p' & \theta\text{-}1 & -\eta & & & & & & & \\
 & & & & & -1 & p & -1 & & & & & & & \\
 & & & & & & & \ddots & & & & & & & \\
 & & & & & & & -1 & p & -1 & & & & & \\
 & & & & & & & -\eta & \theta\text{-}1 & p' & -1 & & & & \\
 & & & & & & & & & & \ddots & & & & \\
 & & & & & & & & & & -1 & p' & \theta\text{-}1 & -\eta & \\
 & & & & & & & & & & & -1 & p & -1 & \\
 & & & & & & & & & & & & & \ddots & \\
 & & & & & & & & & & & & & -1 & p
\end{array}\right),$$

(23)

where $p' = p - \eta$. This step is equivalent to a half-step of the elimination of the boundary layer, namely the weighted combination for the boundary layer nodes. The overlapping block matrices A_{22} and A_{44} in (22) are now modified to

$$A_{22} = A_{44} = \begin{pmatrix} \mathrm{p} & \text{-1} & 0 & \cdots & 0 \\ \text{-1} & \mathrm{p} & \text{-1} & \cdots & 0 \\ & & \ddots & & \\ 0 & \cdots & \text{-1} & \mathrm{p} & \text{-1} \\ 0 & \cdots & 0 & \text{-1} & \mathrm{p} \end{pmatrix} \longrightarrow \begin{pmatrix} p' & \text{-1} & 0 & \cdots & 0 \\ \text{-1} & \mathrm{p} & \text{-1} & \cdots & 0 \\ & & \ddots & & \\ 0 & \cdots & \text{-1} & \mathrm{p} & \text{-1} \\ 0 & \cdots & 0 & \text{-1} & p' \end{pmatrix} = A'_{22} = A'_{44}.$$

To implement the Neumann boundary condition on the inner boundary layers, the GSS is applied. The above overlapping block matrices are split into

$$(24) \qquad \begin{cases} A'_{22} = B_2 + C_2 = C'_2 + B'_2, \\ A'_{44} = B_4 + C_4 = C'_4 + B'_4, \end{cases}$$

where

$$B_2 = B_4 = \begin{pmatrix} p' & \text{-1} & 0 & \cdots & 0 \\ & & \ddots & & \\ 0 & \cdots & \text{-1} & \mathrm{p} & \text{-1} \\ 0 & \cdots & 0 & \text{-1} & p'\text{-1-}\theta \end{pmatrix}, \quad C_2 = C_4 = \begin{pmatrix} 0 & 0 & 0 & \cdots & 0 \\ & & \ddots & & \\ 0 & \cdots & 0 & 0 & 0 \\ 0 & \cdots & 0 & 0 & 1\text{+}\theta \end{pmatrix},$$

$$B'_2 = B'_4 = \begin{pmatrix} p'\text{-1-}\theta & \text{-1} & 0 & \cdots & 0 \\ \text{-1} & \mathrm{p} & \text{-1} & \cdots & 0 \\ & & \ddots & & \\ 0 & \cdots & 0 & \text{-1} & p' \end{pmatrix}, \quad C'_2 = C'_4 = \begin{pmatrix} 1\text{+}\theta & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ & & \ddots & & \\ 0 & \cdots & 0 & 0 & 0 \end{pmatrix}.$$

The diagonal entry p' of the overlapping block matrices A'_{22} and A'_{44} is split into

$$p' = (p' - 1 + \theta) + (1 - \theta) = \tilde{p} + (1 - \theta),$$

where

$$(25) \qquad \tilde{p} = p' - 1 + \theta = p - (\theta/p + (1 - \theta)).$$

Note the right-most side in (25). The two terms, θ/p and $(1 - \theta)$, have been subtracted from the diagonal entry p of the original matrix. These two terms reflect the contributions of two conditions on the inner boundary layer, namely the difference operator on the inner boundary layer and the Neumann boundary condition. This is different from the GSAM, where the splitting only contains the Robin condition.

Then the enhanced form of A', denoted by $\tilde{A}$, is

$$\tilde{A} = \left(\begin{array}{ccccccccccccccccc}
\ddots &&&&&&&&&&&&&&&& \\
-1 & \mathrm{p} & -1 &&&&&&&&&&&&&& \\
-\eta & \theta\text{-}1 & p' & -1 &&&&&&&&&&&&& \\
&&& \ddots &&&&&&&&&&&&& \\
&&& -1 & \tilde{p} &&& 1\text{-}\theta & \theta\text{-}1 & -\eta &&&&&&& \\
-\eta & \theta\text{-}1 & 1\text{-}\theta &&& \tilde{p} & -1 &&&&&&&&&& \\
&&&&&& \ddots &&&&&&&&&& \\
&&&&&& -1 & p' & \theta\text{-}1 & -\eta &&&&&&& \\
&&&&&&&& \ddots &&&&&&&& \\
&&&&&&& -\eta & \theta\text{-}1 & p' & -1 &&&&&& \\
&&&&&&&&&& \ddots &&&&&& \\
&&&&&&&&&& -1 & \tilde{p} &&& 1\text{-}\theta & \theta\text{-}1 & -\eta \\
&&&&&&& -\eta & \theta\text{-}1 & 1\text{-}\theta &&& \tilde{p} & -1 &&& \\
&&&&&&&&&&&&& \ddots &&& \\
&&&&&&&&&&&&& -1 & p' & \theta\text{-}1 & -\eta \\
&&&&&&&&&&&&&& -1 & \mathrm{p} & -1 \\
&&&&&&&&&&&&&&&& \ddots
\end{array}\right).$$

Using the same convention as in [18], matrix A' is equivalent to its enhanced form $\tilde{A}$ under splitting (24) if and only if matrices $B_2 - C'_2$ and $B_4 - C'_4$ are nonsingular according to Theorem 3 in [18]. It will be shown later that this is true if $0 \leq \theta \leq 1$. The diagonal blocks in the above matrix $\tilde{A}$ are not the regular tridiagonal form after the splitting, and are not convenient for the convergence analysis. However, the regular tridiagonal form on the diagonal can be easily recovered. We multiply rows $m - l$, $m + l + 1$, $2m - l$, and $2m + l + 1$ by $(-\eta)$ and add to rows $m - l + 1$, $m + l$, $2m - l + 1$, and $2m + l$, respectively. This results in a new matrix, denoted by $\tilde{A}'$:

$$\tilde{A}' = \left(\begin{array}{ccccccccccccccccc}
\ddots &&&&&&&&&&&&&&&& \\
-1 & \mathrm{p} & -1 &&&&&&&&&&&&&& \\
& -1 & \mathrm{p} & -1 &&&&&&&&&&&&& \\
&&& \ddots &&&&&&&&&&&&& \\
&&& -1 & \tilde{p} &&& 1\text{-}\theta & \theta\text{-}1 & -\eta &&&&&&& \\
-\eta & \theta\text{-}1 & 1\text{-}\theta &&& \tilde{p} & -1 &&&&&&&&&& \\
&&&&&& \ddots &&&&&&&&&& \\
&&&&&& -1 & \mathrm{p} & -1 &&&&&&&& \\
&&&&&&&& \ddots &&&&&&&& \\
&&&&&&&& -1 & \mathrm{p} & -1 &&&&&& \\
&&&&&&&&&& \ddots &&&&&& \\
&&&&&&&&&& -1 & \tilde{p} &&& 1\text{-}\theta & \theta\text{-}1 & -\eta \\
&&&&&&& -\eta & \theta\text{-}1 & 1\text{-}\theta &&& \tilde{p} & -1 &&& \\
&&&&&&&&&&&&& \ddots &&& \\
&&&&&&&&&&&&& -1 & \mathrm{p} & -1 & \\
&&&&&&&&&&&&&& -1 & \mathrm{p} & -1 \\
&&&&&&&&&&&&&&&& \ddots
\end{array}\right),$$

which is now equivalent to matrix $\tilde{A}$. We call $\tilde{A}'$ an *enhanced* OSAM matrix of A.

Let $T_m(p)$ be the m-dimensional tridiagonal matrix with p on the diagonal and -1 on the off-diagonals. Denote by $T_m^l(p, \beta)$ and $T_m^f(p, \beta)$ the two matrices which are identical to $T_m(p)$, except for the last diagonal entry of $T_m^l(p, \beta)$ and the first diagonal entry of $T_m^f(p, \beta)$, which are $p - \beta$. Similarly, $T_m^b(p, \beta)$ denotes a matrix which is identical to $T_m(p)$, except that both the first and last diagonal entries are $p - \beta$. Then the OSAM enhanced matrix $\tilde{A}'$ can be represented as

$$\tilde{A}' = \begin{pmatrix} T_m^l(p, \beta) & -U & 0 \\ -L & T_m^b(p, \beta) & -U \\ 0 & -L & T_m^f(p, \beta) \end{pmatrix},$$

where

$$U = \begin{pmatrix} 0 & \cdots & 0 & 0 & 0 & \cdots & 0 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & 0 & 0 & \cdots & 0 \\ 0 & \cdots & \theta\text{-}1 & 1\text{-}\theta & \eta & \cdots & 0 \end{pmatrix}$$

is an m by m matrix with only three possible nonzero entries located on the lth, $(l+1)$th, and $(l+2)$th columns of the last row. Matrix L can be obtained by rotating U 180°. The convergence behavior of the OSAM depends on the spectral radius of the Jacobi matrix $J = M^{-1}N$, where

$$M = \begin{pmatrix} T_m^l(p, \beta) & 0 & 0 \\ 0 & T_m^b(p, \beta) & 0 \\ 0 & 0 & T_m^f(p, \beta) \end{pmatrix}, \qquad N = \begin{pmatrix} 0 & U & 0 \\ L & 0 & U \\ 0 & L & 0 \end{pmatrix}.$$

For $T_n(p)$, we have [8]

$$\det(T_n(p)) = \begin{cases} \sinh(n+1)\omega/\sinh\omega, & p > 2, \quad 2\cosh\omega = p, \\ n+1, & p = 2, \\ \sin(n+1)\omega/\sin\omega, & p < 2, \quad 2\cos\omega = p. \end{cases}$$

Thus, the following result can be obtained by using the expansion of the determinant of the last (or first) row.

LEMMA 4.1. *Let $T_m^l(p, \beta)$, $T_m^b(p, \beta)$, and $T_m^f(p, \beta)$ be defined as above; then*

$$\det(T_m^l(p, \beta)) = \det(T_m^f(p, \beta)) = \begin{cases} (m+1) - \beta m, & p = 2, \\ (\sinh(m+1)\omega - \beta\sinh m\omega)/\sinh\omega, & p > 2, \end{cases}$$

$$\det(T_m^b(p, \beta)) = \begin{cases} (m+1) - 2\beta m + \beta^2(m-1), & p = 2, \\ (\sinh(m+1)\omega - 2\beta\sinh m\omega + \beta^2\sinh(m-1)\omega)/\sinh\omega, & p > 2. \end{cases}$$

Let

$$t^{(l)} = (t_1^{(l)}, t_2^{(l)}, \cdots, t_m^{(l)})^T, \qquad t^{(b)} = (t_1^{(b)}, t_2^{(b)}, \cdots, t_m^{(b)})^T$$

be the *last* columns of the matrices $(T_m^l(p,\beta))^{-1}$, $(T_m^b(p,\beta))^{-1}$, respectively, and

$$\tilde{t}^{(b)} = (\tilde{t}_1^{(b)}, \tilde{t}_2^{(b)}, \cdots, \tilde{t}_m^{(b)})^T, \qquad \tilde{t}^{(f)} = (\tilde{t}_1^{(f)}, \tilde{t}_2^{(f)}, \cdots, \tilde{t}_m^{(f)})^T$$

be the *first* columns of the matrices $(T_m^b(p,\beta))^{-1}$, $(T_m^f(p,\beta))^{-1}$, respectively. It is not difficult to see that

$$t_j^{(b)} = \tilde{t}_{m-j+1}^{(b)}, \qquad t_j^{(l)} = \tilde{t}_{m-j+1}^{(f)},$$

and

$$(26) \quad t_i^{(l)} = \det(T_{i-1}(p))/\det(T_m^l(p,\beta)) = \begin{cases} i/\Delta_m^l(2,\beta), & p = 2, \\ \sinh i\omega/\Delta_m^l(p,\beta), & p > 2, \end{cases}$$

$$(27) \quad t_i^{(b)} = \det(T_{i-1}^l(p,\beta))/\det(T_m^b(p,\beta)) = \begin{cases} \Delta_{i-1}^l(2,\beta)/\Delta_m^b(2,\beta), & p = 2, \\ \Delta_{i-1}^l(p,\beta)/\Delta_m^b(p,\beta), & p > 2, \end{cases}$$

where

$$\Delta_m^l(p,\beta) = \begin{cases} \det(T_m^l(2,\beta)), & p = 2, \\ \det(T_m^l(p,\beta))\sinh\omega, & p > 2, \end{cases}$$

$$\Delta_m^b(p,\beta) = \begin{cases} \det(T_m^b(2,\beta)), & p = 2, \\ \det(T_m^b(p,\beta))\sinh\omega, & p > 2, \end{cases}$$

and $\det(T_0(p)) = \det(T_0^l(p,\beta)) = 1$.

Applying a transformation similar to that used in [18], the Jacobi matrix J has the same nonzero eigenvalues as the following matrix G:

$$G = \begin{pmatrix} 0 & g_1 & 0 & \\ g_2 & 0 & 0 & g_3 \\ g_3 & 0 & 0 & g_2 \\ 0 & 0 & g_1 & 0 \end{pmatrix},$$

where

$$(28) \quad \begin{aligned} g_1 &= \theta/pt_{m-l-1}^{(l)} + (1-\theta)t_{m-l}^{(l)} - (1-\theta)t_{m-l+1}^{(l)}, \\ g_2 &= \theta/pt_{m-l-1}^{(b)} + (1-\theta)t_{m-l}^{(b)} - (1-\theta)t_{m-l+1}^{(b)}, \\ g_3 &= \theta/pt_{l+2}^{(b)} + (1-\theta)t_{l+l}^{(b)} - -\theta)t_l^{(b)}. \end{aligned}$$

Matrix G has four eigenvalue values, which are:

$$\lambda_{1,2} = \pm\sqrt{g_1(g_2 - g_3)}, \qquad \lambda_{3,4} = \pm\sqrt{g_1(g_2 + g_3)}.$$

Substituting (26) into (28), we have

$$g_1 = \begin{cases} (m-l-\beta(m-l+1))/\Delta^l_m(2,\beta), & p=2, \\ (\sinh(m-l)\omega - \beta\sinh(m-l+1)\omega)/\Delta^l_m(p,\beta), & p>2, \end{cases}$$

$$g_2 = \begin{cases} (1-\beta)^2(m-l)/\Delta^b_m(2,\beta), & p=2, \\ (1-p\beta+\beta^2)\sinh(m-l)\omega/\Delta^b_m(p,\beta), & p>2, \end{cases}$$

$$g_3 = \begin{cases} ((l+1)-2\beta l+\beta^2(l-1))/\Delta^b_m(2,\beta), & p=2, \\ (\sinh(l+1)\omega - 2\beta\sinh l\omega + \beta^2\sinh(l-1)\omega)/\Delta^b_m(p,\beta), & p>2. \end{cases}$$

In particular, when

$$\beta = \begin{cases} (m-l)/(m-l+1), & p=2, \\ \sinh(m-l)\omega/\sinh(m-l+1)\omega, & p>2, \end{cases}$$

we have $g_1 = 0$. Only one iteration is needed for the three-subdomain case. Generally, for any k subdomains, the Jacobi matrix J has the same nonzero eigenvalues as the following $2(k-1)$ by $2(k-1)$ matrix G_k,

$$G_k = \left(\begin{array}{ccccccccccc} 0 & g_1 & 0 & & & & & & & & \\ g_2 & 0 & 0 & g_3 & & & & & & & \\ g_3 & 0 & 0 & g_2 & & & & & & & \\ & & g_2 & 0 & 0 & g_3 & & & & & \\ & & g_3 & 0 & 0 & g_2 & & & & & \\ & & & & \ddots & 0 & 0 & \ddots & & & \\ & & & & & & & g_2 & 0 & 0 & g_3 \\ & & & & & & & g_3 & 0 & 0 & g_2 \\ & & & & & & & & 0 & g_1 & 0 \end{array} \right).$$

In order to obtain a consistent solution from the OSAM with the original problem (22), it is necessary to show that the *enhanced* OSAM matrix $\tilde{A}'$ is equivalent to matrix A.

THEOREM 4.2. *For the model problem, the matrix A is equivalent to its enhanced* OSAM *matrix $\tilde{A}'$, for* $0 \le \theta \le 1$.

Proof. Since A and A', $\tilde{A}$ and $\tilde{A}'$ are row equivalent, we only need to prove A' is equivalent to $\tilde{A}$. From the GSS corresponding to (24), we have

$$B_2 - C_2' = B_4 - C_4' = T^b_l(p,\beta),$$

where $0 < \beta = \theta/p + 1 - \theta \le 1$ for $0 \le \theta \le 1$. From Lemma 4.1, $\det(B_2 - C_2') \ne 0$. So $\tilde{A}$ is equivalent to A' by Theorem 3 in [18]. This completes the proof. □

In a two-dimensional case, the resulting linear algebraic equation is a block version of the corresponding one-dimensional case. Suppose the solution domain has an n^2 grid and is decomposed in the y-direction into three strips. Each subdomain has n by m grids, excluding the artificial boundaries and boundary layers, and all the other assumptions are the same as in the one-dimensional case.

The partitioned coefficient matrix is

$$A=\left(\begin{array}{ccccccccccccccc}
P & -I & & & & & & & & & & & & & \\
 & \ddots & & & & & & & & & & & & & \\
 & -I & P & -I & & & \leftarrow & & & & & & & & \\
 & & -I & P & -I & & & & & & & & & & \\
 & & & & \ddots & & & & & & & & & & \\
 & & & & -I & P & -I & & & & & & & & \\
 & & \rightarrow & & & -I & P & -I & & & & & & & \\
 & & & & & & & \ddots & & & & & & & \\
 & & & & & & & -I & P & -I & & & \leftarrow & & \\
 & & & & & & & & -I & P & -I & & & & \\
 & & & & & & & & & & \ddots & & & & \\
 & & & & & & & & & & -I & P & -I & & \\
 & & & & & & & & \rightarrow & & & -I & P & -I & \\
 & & & & & & & & & & & & & \ddots & \\
 & & & & & & & & & & & & & -I & P
\end{array}\right)$$

(29)

where I is an n by n identity matrix and $P = T_n(p)$ with $p = 4$ for the model problem. Similarly, the rows which correspond to the inner boundary layer nodes are indicated by " $\leftarrow$ " or "$\rightarrow$". After the splitting of the overlapping blocks, the final *enhanced* OSAM matrix is

$$\tilde{A}'=\left(\begin{array}{ccccccccccccccccccc}
P & -I & & & & & & & & & & & & & & & & & \\
 & \ddots & & & & & & & & & & & & & & & & & \\
 & -I & P & -I & & & & & & & & & & & & & & & \\
 & & -I & p & -I & & & & & & & & & & & & & & \\
 & & & & \ddots & & & & & & & & & & & & & & \\
 & & & & -I & \tilde{P} & & & \Gamma & -\Gamma & -\Theta & & & & & & & & \\
 & -\Theta & -\Gamma & \Gamma & & & \tilde{P} & -1 & & & & & & & & & & & \\
 & & & & & & & \ddots & & & & & & & & & & & \\
 & & & & & & & -I & P & -I & & & & & & & & & \\
 & & & & & & & & & \ddots & & & & & & & & & \\
 & & & & & & & & & -I & P & -I & & & & & & & \\
 & & & & & & & & & & & \ddots & & & & & & & \\
 & & & & & & & & & & & -I & \tilde{P} & & & \Gamma & -\Gamma & -\Theta & \\
 & & & & & & & & -\Theta & -\Gamma & \Gamma & & & \tilde{P} & -I & & & & \\
 & & & & & & & & & & & & & & \ddots & & & & \\
 & & & & & & & & & & & & & & -I & P & -I & & \\
 & & & & & & & & & & & & & & & -I & P & -I & \\
 & & & & & & & & & & & & & & & & & \ddots & \\
 & & & & & & & & & & & & & & & & & -I & P
\end{array}\right),$$

where $\Theta = \eta I$ with $\eta = \theta/p$,

$$(30) \qquad \tilde{P} = P - (\Theta + \Gamma), \qquad \Gamma = \begin{pmatrix} 1-\theta & \eta & & & \\ \eta & 1-\theta & \eta & & \\ & & \ddots & & \\ & & \eta & 1-\theta & \eta \\ & & & \eta & 1-\theta \end{pmatrix}.$$

As in the one-dimensional case, Θ and Γ are subtracted from P to reflect the contributions of both the differential operator and the Neumann boundary condition on the boundary layer. The difference between the OSAM and the GSAM is now clear. Notice that the matrix Γ in (30) is a tridiagonal matrix. For GSAM the corresponding splitting is $P = (P - \Gamma') + \Gamma'$, and Γ' is a diagonal matrix. $\Gamma' = \text{diag}(\alpha)$, where $\alpha = (1-\omega)/(1-\omega+\omega h)$, and h represents the mesh size. The difference in a three-dimensional case is also not difficult to see.

The splitting matrices M and N of $\tilde{A}'$ have the same block sparsity pattern as in a one-dimensional case. They are the block version of the corresponding matrices in the one-dimensional case. Each block is either an identity or a tridiagonal matrix. The Jacobi iterative matrix of the OSAM $J = M^{-1}N$ is also similar. Let E_n be a matrix in which each column corresponds to a normalized eigenvector of matrix $T_n(p)$. Then E_n is an orthogonal matrix such that $E_n^T\, T_n(p)\, E_n = \text{diag}\{p_i\},\ p_i = p - 2\cos(i\pi/(n+1)),\ i = 1, 2, \ldots, n$.

Let

$$U = \begin{pmatrix} I_m \otimes E_n & 0 & 0 \\ 0 & I_m \otimes E_n & 0 \\ 0 & 0 & I_m \otimes E_n \end{pmatrix};$$

then J and $J' = U^T J U$ are similar:

$$\begin{aligned} J' &= U^T J U = U^T(M^{-1}N)U = (U^T M^{-1} U)(U^T N U) \\ &= (U^T M U)^{-1}(U^T N U) = \widetilde{M}^{-1}\,\widetilde{N}. \end{aligned}$$

Matrices $\widetilde{M}$ and $\widetilde{N}$ are exactly the same as M and N, except that those tridiagonal matrices are changed to diagonal matrices as follows:

$$\begin{aligned} &\Gamma \to \text{diag}\{\gamma_i\}, \quad \gamma_i = (1-\theta) + 2\eta\cos\omega_i, \\ &P \to \text{diag}\{p_i\}, \quad p_i = p - 2\cos\omega_i, \\ &\widetilde{P} \to \text{diag}\{\tilde{p_i}\}, \quad \tilde{p_i} = (p - \eta - 1 + \theta) - 2(1+\eta)\cos\omega_i, \end{aligned}$$

where $\omega_i = i\pi/(n+1)$.

The above matrix J' can be spectrally decomposed into n one-dimensional Jacobi iterative matrices. Let Q be the permutation matrix which permutes row $(k-1)n + i$ to $(i-1)3m + k$, $k = 1, \ldots, 3m$, $i = 1, \ldots, n$. Then we have

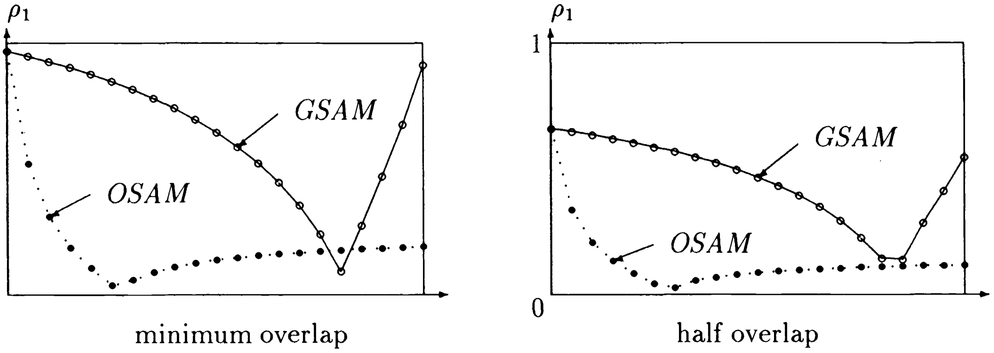

FIG. 4. *2-D three-subdomain case.*

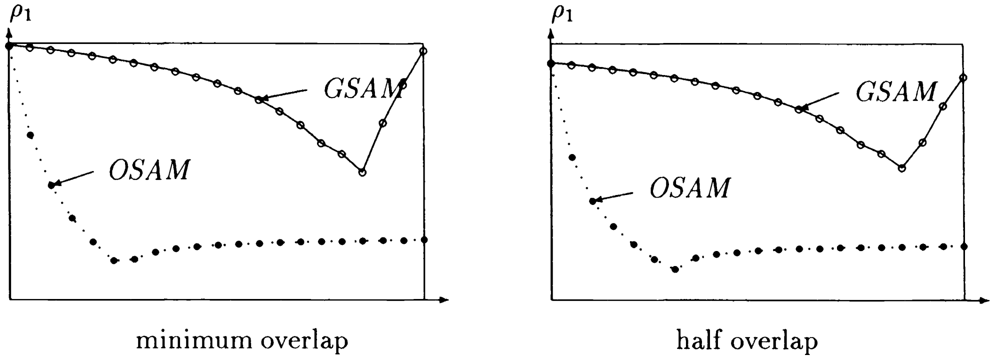

FIG. 5. *2-D seven-subdomain case.*

$$Q^T J' Q = Q^T(\widetilde{M}^{-1}\widetilde{N})Q = (Q^T\widetilde{M}Q)^{-1}(Q^T\widetilde{N}Q)$$

$$= \begin{pmatrix} M_1^{-1} & & & \\ & M_2^{-1} & & \\ & & \ddots & \\ & & & M_n^{-1} \end{pmatrix} \begin{pmatrix} N_1 & & & \\ & N_2 & & \\ & & \ddots & \\ & & & N_n \end{pmatrix}.$$

Each diagonal block $M_i^{-1}N_i$ is a $3m$ by $3m$ matrix, which is a Jacobi iterative matrix for the corresponding one-dimensional case. As in the analysis in GSAM [18], the largest eigenvalue of J' is decided by the maximum eigenvalue of $M_1^{-1}N_1$.

For the model problem in the two-dimensional (2-D) case, the maximum eigenvalues ρ_1 versus the parameter θ for the OSAM are calculated and shown in Figures 4 and 5. For comparison, the maximum eigenvalues, still denoted by ρ_1, versus the parameter ω for the GSAM are also shown there. Both parameters range from 0 to 1. The maximum eigenvalues are between 0 and 1. For a minimum overlapping case, the total number of grids n in each direction is 58 for 3 subdomains or 136 for 7 subdomains. For the corresponding half-overlapping case, the total number of grids varies slightly to fit the decomposition.

It can be seen from Figures 4 and 5 that the OSAM gives better convergence behavior. For a wide range of the parameter θ, the OSAM is better than the GSAM and the SAM, which is the special case of the GSAM with $\omega = 1$. Sensitivity of convergence of the OSAM to its parameter is almost insignificant. Moreover, the OSAM with a minimum overlap is still much better than the SAM with a half-overlap. As the number of subdomains increases, the improvement is even more significant.

5. Numerical tests. Results for several testing problems in a 2-D case are presented in this section. All the tests are carried out on a Sun 4/670 server, which is normally rated at four MFLOPS. The arithmetic is performed in Fortran 77 double precision. The differential equations are discretized by the standard central difference scheme. The upwind scheme has also been tested. The convergence characteristics are similar to those of the central scheme. To save space, these results will not be listed. Except for the first problem, all the rest are nonself-adjoint asymmetric problems. There is one discontinuous coefficient problem and one indefinite problem.

For each test problem, the solution domain is decomposed into a different number of subdomains, such as 4 by 4, 10 by 10, etc. In all the cases, each subdomain contains a 20 by 20 grid of unknowns and the minimum overlap is considered. Thus, the total number of unknowns will be increased as the number of subdomains increases. We are mainly concerned with the improvement of the OSAM over the SAM and the reduction of the sensitivity of the convergence behavior to the parameter.

The domain decomposition method is used as a preconditioner, and Bi-CGSTAB is employed for the acceleration scheme. The convergence behavior for other acceleration schemes is similar. The iteration is stopped if the l_2 norm of the residual is less than 10^{-5} times the initial residual norm.

There are several notations in the tables of results. The SAM represents the result for using the traditional Schwarz alternating method as the preconditioner. The "$*$" and "$**$" mean that the OSAM does not converge within 100 and 200 iterations, respectively, and the iteration is stopped. "Iter" and "SubD" represent the number of linear iterations needed to reach the precision and the total number of subdomains, respectively. We also define the improvement factor to be $\tau = \frac{\text{SAM}-\text{OSAM}}{\text{SAM}}$. The notation τ_b represents the best improvement factor of the results.

5.1. Helmholz equation. In this test, the following problem is considered:

$$\begin{cases} -\Delta u + u &= f, \quad x \in \Omega, \\ u &= g, \quad x \in \partial\Omega, \end{cases}$$

with $\Omega = (0,1) \times (0,1)$ and true solution $u = e^{x+y} \sin(2x) \cos y$.

To verify our convergence analysis, the problem is solved using pure domain decomposition first. The solution domain is decomposed into three strips. The number of iterations versus parameter is shown in Figure 6. The two curves indicated by "osam.comp" and "gsam.comp" represent the number of iterations (from numerical testing) versus the parameter ω for the GSAM, and θ for the OSAM, respectively. The other two curves, "osam.anal" and "gsam.anal," are the number of iterations needed, which are calculated analytically from our spectral results. The numerical tests match our analysis very closely.

For the rest of the tests, the domain decomposition technique is applied as a preconditioner. The number of iterations is much decreased. Furthermore, the sensitivity to the parameter is also reduced. The corresponding results with the same decomposition pattern as for the above test are shown in Figure 7. The advantages of using the domain decomposition method as a preconditioner are obvious.

The more general case is that in which the solution domain is decomposed in both directions. Table 1(a) gives the result of the Helmholz equation in this case. From Table 1(a), it can be seen that a small parameter value θ is not good for the OSAM. In this case, the Neumann

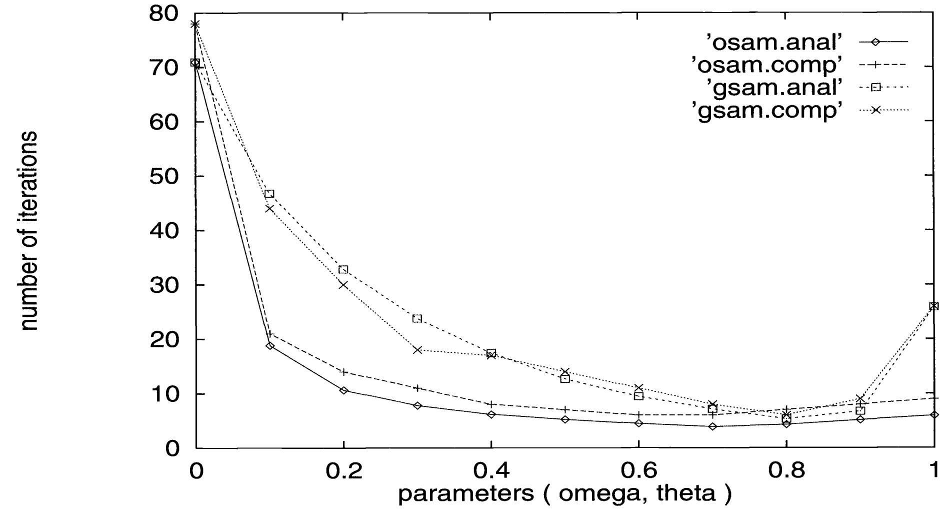

FIG. 6. *Number of iterations (analytical and computational).*

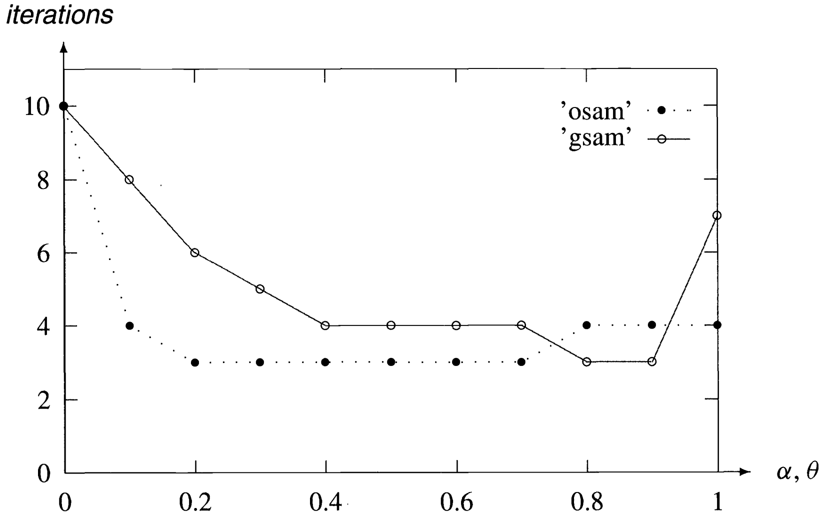

FIG. 7. *Number of iterations: three strips with domain decomposition as preconditioner.*

condition is more dominant than the differential operator on the boundary layer, which means the Neumann condition shares more "weight" in the weighted combination. The Neumann condition is bad, as we have already shown in the previous analysis. But for $0.2 < \theta \leq 1$, the OSAM is an obvious improvement over the SAM. There is little sensitivity shown for $\theta > 0.2$. Note that the improvement in performance and the reduction of the sensitivity to the parameter θ exist not only for the model problem, but also for the rest of our tests. Moreover, the OSAM improves more with difficult problems.

5.2. Stress in helical spring. If a single turn of a helical spring of small angle α and radius R is deformed into a plane ring under the influence of an axial load, the stress-function Φ can be shown to satisfy the differential equation [6]

$$\Phi_{xx} + \Phi_{yy} + \frac{3}{R - y}\Phi_x - 2G\lambda = 0,$$

and it vanishes on the boundary Γ, where Γ is the boundary of the cross-section in the (x, y)-plane which contains the axis of the spring. G is the modulus of rigidity and $\lambda = \sin\alpha\cos\alpha/R$.

The special case we considered is that in which the problem has rectangular cross-section $\Omega = (-.5, .5) \times (-1, 1)$ and $R = 5$. The problem has an exact solution [14],

$$\Phi = (1 - y^2)(1 - 4x^2)(5 - y^3)(0.0004838y + 0.0010185).$$

The angle α is specified for a fixed modulus of rigidity G. In this case, the solution domain is no longer a square. We test the OSAM for the case of different mesh lengths in the two directions. The solution domain is decomposed into 3 by 4, 6 by 8, and 8 by 12 subdomains, respectively.

Unlike the previous one, the results of this problem show that the OSAM performs better than the SAM with only one exception: $\theta = 0.1$. For the optimal case, $\theta = 0.3$, the OSAM takes only half as many iterations as the SAM. The general convergence behavior of the OSAM with respect to the parameter θ follows the same rule as in the last test. Table 1(b) represents the detailed results of this test.

5.3. Variable coefficients of second order derivative terms. In the previous two cases, the second order operator is the Laplacian. This problem has continuous variable coefficients for second order derivative terms. The unknown is defined on a unit square with homogeneous Dirichlet boundary condition. It satisfies the following equation:

$$((1 + x^2)u_x)_x + u_{yy} + (\tan y)^3 u_y = -100x^2.$$

The numerical results were given in Table 2(a). In general, the improvement factor is still a little more than one-third on average, and the best case of the OSAM saves almost half the work of the SAM.

5.4. Discontinuous coefficient problem. In this test, the following equation was considered:

$$(K_x u_x)_x + (K_y u_y)_y + u_x + u_y = \sin(\pi xy).$$

The unknown vanishes on the boundary of the solution domain $\Omega = (0, 1) \times (0, 1)$, where

$$K_x = K_y = \begin{cases} 1, & [0, .5] \times [0, .5], \\ 10^{+3}, & [.5, 1] \times [0, .5], \\ 10^{-3}, & [0, .5] \times [.5, 1], \\ 1, & [.5, 1] \times [.5, 1]. \end{cases}$$

Generally, discontinuous coefficient problems are relatively difficult to solve. The harmonic scheme [1, 12] is applied to discretizing the second order derivative terms in this test. The numerical linear approaches are the same as for the last several tests, which aim to compare the OSAM and the SAM. The results are shown in Table 2(b). It can be seen that the improvement factor in this test is larger than those in the last several ones. From this test, the OSAM shows great potential for difficult problems. This will be further demonstrated by the following test.

5.5. Variable-coefficient, indefinite problem. The problem tested is

$$\begin{aligned} Lu = {} & -[(1+\tfrac{1}{2}\sin(50\pi x))u_x]_x - [(1+\tfrac{1}{2}\sin(50\pi x)\sin(50\pi y))u_y]_y \\ & + 20\sin(10\pi x)\cos(10\pi y)u_x - 20\cos(10\pi x)\sin(10\pi y)u_y + cu, \end{aligned} \tag{31}$$

where $u = \exp(xy)\sin(\pi x)\sin(\pi y)$ is defined on a unit square. This testing problem is taken from the paper of Cai, Gropp, and Keyes [4]. The sign of the coefficient c in (31) has a keen effect on this problem. The difficulty of the linear system depends on both the mesh widths $\triangle x$, $\triangle y$ and the magnitude of c. For a fixed number of grids, the larger the magnitude of the negative value c, the more difficult the problem will be. In this work, the cases for $c = -20$, -70 were tested. We will see that the second case requires much more work than the first one.

The numerical results are reported in Table 3. From these results, the difficulty of this problem is obvious as compared with the corresponding count of iterations of the previous tests. The difficulty is also reflected in the performance of the OSAM with respect to the parameter θ. As $\theta = 0.3$, the OSAM failed to compete with the SAM in the count of iterations for this problem, but the OSAM was better than the SAM in all the previous tests.

When $c = -20$, the problem is more weakly indefinite than for $c = -70$ with the same number of grids. The results show that the work done for $c = -20$ is only a little more than in corresponding situations in the last several tests. The improvement factor varies from one third to one half. However, when $c = -70$, the OSAM demonstrates its superiority over the SAM. The improvement factors for all three decomposition cases are greater than one half. For the 10 by 10 subdomain case, the SAM took 144 iterations, while the OSAM only needed 43 iterations for the optimal parameter. It is more than three times faster than the SAM. Even in the worst case, $\theta = 1$, which is known to not be good from the analysis and tests, the number

of iterations is 82 for the OSAM, and the improvement factor in this case is still larger than one third. For an 8 by 8 subdomain case, the SAM took 85 iterations, but the OSAM requires less than half of that with only one exception, $\theta = 0.9$. When $\theta = 0.5$, the OSAM took only 31 iterations. This test further demonstrates that the OSAM performs better for difficult problems.

6. Conclusion. In this paper, a new extension of the classical Schwarz alternating method, the overdetermined Schwarz alternating method, is proposed. In this new approach, a stronger coupling is imposed on the artificial boundary layers. The superior convergence behavior is demonstrated for a wide range of test problems. In particular, the weighted parameter θ does not cause the sensitivity problem from which the GSAM suffers. So far, our testing has been restricted to the single level approach. A multilevel preconditioner approach is a natural future extension of this work.

RANDOM RELAXATION OF FIXED-POINT ITERATION*

MARKKU VERKAMA†

Abstract. This paper considers a stochastic fixed-point iteration where each coordinate is updated with a certain probability and otherwise left unchanged. The iteration is interesting from the viewpoint of parallel distributed computation because the realized sequences belong to the class of asynchronous fixed-point iterations. It is demonstrated with a linear system that the convergence conditions for randomly relaxed iterations are less stringent than their asynchronous counterparts, and that they can illuminate the tightness of the convergence conditions for asynchronous iterations, which are typically worst-case conditions.

Key words. asynchronous algorithm, fixed points, stochastic stability, linear systems

AMS subject classifications. 65Y10, 60G35, 65F10, 93E15

1. Introduction.

In this paper we examine the following stochastic iteration in the n-dimensional Euclidean space $\mathbf{R}^n$. For a given function $f : \mathbf{R}^n \mapsto \mathbf{R}^n$, let $x_i(k+1) = f_i(x(k))$ with probability p and let $x_i(k+1) = x_i(k)$ with probability $1-p$. All randomizations across the coordinates and across the iterates are independent in the process. In other words, the coordinates are updated independently at each iteration step and the iterations are independent as well. An iteration of this type will be called a *randomly relaxed* iteration. When the coordinates of x are updated randomly, a sequence of random vectors in $\mathbf{R}^n$ is realized. We are interested in the convergence of the random vector sequences to a fixed point of f.

Randomly relaxed iterations are closely related to so-called asynchronous fixed-point iterations. In the (zero-delay) *asynchronous* execution of the iteration

$$x_i \leftarrow f_i(x_1, \dots, x_n), \quad i = 1, \dots, n, \tag{1.1}$$

the coordinates of x are updated in arbitrary order, each infinitely many times. In so-called *totally* asynchronous iterations the values of the coordinates used on the right side of (1.1) may also be arbitrarily out-of-date, so that $x(k)$ does not sufficiently describe the state of the system [2], [6]. Such iterations also go under the name chaotic relaxation. It is clear that randomly relaxed iterations belong to the class of asynchronous iterations—an arbitrary set of coordinates is updated at a time. Hence the analysis of randomly relaxed iterations can give new insight into the convergence of asynchronous iterations, especially zero-delay iterations. A difference to iterations with delays is that coordinate values older than $x(k)$ cannot appear in the computation of $x(k+1)$ in randomly relaxed iterations.

Tsitsiklis [11] has shown, in a rather general sense, that zero-delay asynchronous iterations converge if and only if there exists a Lyapunov function that testifies to this. Related results were obtained in [3] and [4] for linear systems in $\mathbf{R}^n$. These studies, like most of the studies on asynchronous iterations, are, however, concerned with the notion of convergence that requires all possible sequences $\{x(k)\}$ to converge to a fixed point of f. It is therefore interesting to note that a randomly relaxed iteration can converge, for example, almost surely (that is, with probability 1) even if the necessary conditions of [11] are violated. This can happen if the probability measure over the events that produce diverging sequences is zero. This kind of analysis can give an idea of the rarity of worst-case events. One can thus think that results of the convergence of randomly relaxed iterations shed light on the tightness of the convergence conditions derived for asynchronous iterations.

*Received by the editors January 12, 1994; accepted for publication (in revised form) March 6, 1995. This research has been supported by the Väinö Tanner Foundation, the Finnish Cultural Foundation, and the Swedish Foundation of Culture in Finland.

†Systems Analysis Laboratory, Helsinki University of Technology, Otakaari 1, FIN-02150 Espoo, Finland (markku.verkama@ntc.nokia.com).

To illustrate this we shall consider iterations with affine functions. For these, both necessary and sufficient conditions for convergence under total asynchronism are known [6]. Necessary and sufficient conditions for the quadratic mean (q.m.) convergence of randomly relaxed iterations will be derived here. These conditions turn out to be less stringent than the conditions in [6]. It is also shown that a randomly relaxed iteration can converge in a stochastic sense for some $p < 1$ even if the Jacobi iteration $x(k+1) = f(x(k))$, which corresponds to $p = 1$, is unstable. It thus appears that a certain type of asynchronicity can induce stability into otherwise unstable iterations.

This study is not the first one that uses stochastic models to analyze asynchronous iterations. The effects of random communication delays and processor failures have been considered in [1] and [10], and a Poisson transition model has been used to analyze the effects of different processing times in [8].

We shall use standard vector notation throughout the paper. Subscripts refer to vector and matrix elements. The transpose is denoted by the prime; the unit matrix is I. $\|\cdot\|$ denotes the Euclidean norm, and $\|\cdot\|_w$ denotes weighted maximum norm; that is, $\|x\| = (x'x)^{1/2}$ and $\|x\|_w = \max_i |x_i|/w_i$ $(w_i > 0)$. $\rho(A)$ denotes the spectral radius of a matrix A. $A \otimes B$ denotes the Kronecker product of matrices A and B and it is given by

$$A \otimes B = \begin{bmatrix} a_{11}B & \cdots & a_{1m}B \\ \vdots & \ddots & \vdots \\ a_{n1}B & \cdots & a_{nm}B \end{bmatrix},$$

where $A = (a_{ij})$. The matrix $|A|$ is obtained from A by taking absolute value of all elements of A; hence, $|A| = (|a_{ij}|)$. δ_{ij} denotes the Kronecker delta. Finally, $E[\cdot]$ denotes expected value.

2. Random relaxation. Next we define random relaxation and a convergence concept suitable for the analysis of randomly relaxed iterations.

DEFINITION 2.1. *Let* $\{\xi_i(k); k = 0, 1, \ldots\}$ $(i = 1, \ldots, n)$ *be random sequences such that* $\Pr[\xi_i(k) = 1] = p$ *and* $\Pr[\xi_i(k) = 0] = 1 - p$, *where* $p \in (0, 1]$ *is a constant. Randomly relaxed fixed-point iteration of a function* $f : \mathbf{R}^n \mapsto \mathbf{R}^n$ *is defined by*

$$(2.1) \qquad x_i(k+1) = x_i(k) + \xi_i(k)(f_i(x(k)) - x_i(k)), \quad i = 1, \ldots, n, \quad k = 0, 1, \ldots.$$

Iteration (2.1) defines a sequence of random vectors for a given initial vector $x(0)$. Note that for any k_0, the probability of the event "$\xi_i(k) = 0$ for all $k \geq k_0$" (i.e., of the event that x_i is not updated after k_0) is zero, and that by Borel's zero-one criterion [9, p. 228] all coordinates are updated infinitely many times with probability 1. It is, thus, intuitive that if the iteration (2.1) converges in some sense, it must converge to a fixed point of f. In particular, if $x^* = f(x^*)$ and if $x(k_0) = x^*$ for some k_0, then $x(k) = x^*$ for all $k \geq k_0$.

There is another way of looking at random relaxation. Define the operators $T_j : \mathbf{R}^n \mapsto \mathbf{R}^n$, $j = 1, \ldots, 2^n$, by taking all the possible coordinate combinations of f and the identity operator; that is, either $T_{j,i}(x) := f_i(x)$ or $T_{j,i}(x) := x_i$. Then at each step of the iteration, one of the operators is applied with a certain probability $p^{n_j}(1-p)^{n-n_j}$, where $n_j \in \{0, \ldots, n\}$. This makes explicit the relationship to the zero-delay asynchronous iterations in [11]. When $p = 1$ only the operator f is applied, and iteration (2.1) becomes the Jacobi-type fixed-point iteration. Otherwise, the Jacobi iteration as well as the Gauss–Seidel-type iterations are possible realizations among others.

When we define the diagonal random matrices $\Xi(k) = (\xi_i(k)\delta_{ij})$, (2.1) can be written equivalently as

$$(2.2) \qquad x(k+1) = x(k) + \Xi(k)(f(x(k)) - x(k)).$$

Since $\xi_i(k)$ are identically distributed across k, we will refer to the generic random variables as ξ_i and Ξ; the same convention will be used with other random variables and matrices as well.

In this paper we consider the following concept of convergence.

DEFINITION 2.2. *Let $x(k)$, $k = 1, 2, \dots$, be generated by the iteration* (2.1) *starting from an initial vector $x(0)$. We say that the iteration* (2.1) *converges in q.m. to a fixed point x^* of f if*

$$\lim_{k \to \infty} E[\|x(k) - x^*\|^2] = 0 \tag{2.3}$$

for any $x(0)$.

This definition is adapted from the standard definitions used in probability theory; see, e.g., [7], [9].

3. Some convergence results. Let us now consider iterations with affine functions of the form

$$f(x) = Ax + b, \tag{3.1}$$

where A is an $n \times n$ matrix and b is an n vector. Assume that $I - A$ is nonsingular. Then f has a unique fixed point $x^* = (I - A)^{-1}b$.

It was shown in [6] that totally asynchronous fixed-point iterations of f converge to x^* if and only if

$$\rho(|A|) < 1. \tag{3.2}$$

This is also a sufficient condition for the convergence of zero-delay asynchronous iterations. It is, however, not generally known if and how (3.2) can be relaxed for these iterations. Clearly, a necessary condition is always $\rho(A) < 1$, because otherwise the Jacobi iteration $x(k + 1) = Ax(k) + b$ is unstable.

Next we derive results concerning randomly relaxed iterations with the same function. Using (2.2) we can write the randomly relaxed iteration as

$$x(k + 1) = x(k) + \Xi(k)(A - I)x(k) + \Xi(k)b. \tag{3.3}$$

Inserting $y = x - x^*$ into (3.3) shows that, without loss of generality, we can always consider the iteration $x(k + 1) = \Psi(k)x(k)$ where $\Psi(k) = I + \Xi(k)(A - I)$.

It will be useful to define $\zeta_i(k) = \xi_i(k) - E[\xi_i(k)] = \xi_i(k) - p$ and denote $Z(k) = (\zeta_i(k)\delta_{ij}) = \Xi(k) - pI$. Hence, $E[\zeta_i(k)\zeta_j(l)] = p(1 - p)\delta_{ij}\delta_{kl}$ and $E[Z(k)] = 0$. One can then write

$$\Psi(k) = I + p(A - I) + Z(k)(A - I). \tag{3.4}$$

This shows that the randomly relaxed iteration contains a deterministic part and a stochastic part with a zero expected value (even though zero is not a possible realization). The deterministic part corresponds precisely to the underrelaxed Jacobi iteration $x(k+1) = x(k) + p(f(x(k)) - x(k))$.

A necessary and sufficient condition for the convergence of (3.3) in q.m. is given in the following.

THEOREM 3.1. *Denote $J = \{1 + j(n + 1)\}_{j=0}^{n-1} = \{1, n + 2, 2n + 3, \dots, n^2\}$ and let R be an $n^2 \times n^2$ diagonal matrix such that $r_{ii} = 1$ if $i \in J$ and $r_{ii} = 0$ if $i \notin J$. The randomly relaxed iteration* (3.3) *converges in q.m. if and only if*

$$\rho((I + p(A - I)) \otimes (I + p(A - I)) + p(1 - p)R((A - I) \otimes (A - I))) < 1. \tag{3.5}$$

Proof. The stochastic dynamic system $x(k+1) = \Psi(k)x(k)$ is asymptotically stable in q.m. if and only if $\rho(E[\Psi \otimes \Psi]) < 1$ (e.g., [7, p. 214]). Straightforward calculation gives

$$\begin{aligned} E[\Psi \otimes \Psi] &= E[(I + p(A-I) + Z(A-I)) \otimes (I + p(A-I) + Z(A-I)) \\ &= (I + p(A-I)) \otimes (I + p(A-I)) + E[(Z(A-I)) \otimes (Z(A-I))] \\ &= (I + p(A-I)) \otimes (I + p(A-I)) + E[Z \otimes Z]((A-I) \otimes (A-I)). \end{aligned}$$

Condition (3.5) follows when we note that $Z \otimes Z$ is a diagonal matrix with the diagonal blocks $\zeta_i Z$, so that $E[Z \otimes Z] = p(1-p)R$. □

The condition of Theorem 3.1 can also be expressed in terms of a matrix equation.

THEOREM 3.2. *Consider the matrix equation*

$$(3.6)\quad (I + p(A-I))'K(I + p(A-I)) - K + p(1-p)(A-I)'\bar{K}(A-I) = -G$$

where $\bar{K} = (k_{ii}\delta_{ij})$ (i.e., $\bar{K}$ is a diagonal matrix with its diagonal equal to the diagonal of K).

(i) *If the randomly relaxed iteration* (3.3) *converges in q.m., then equation* (3.6) *has a positive definite solution K for every positive definite matrix G.*

(ii) *If equation* (3.6) *has a positive definite solution K for some positive definite matrix G, then the randomly relaxed iteration* (3.3) *converges in q.m.*

Proof. We only need to show that $E[\Psi' K \Psi] - K$ equals the left side of (3.6), and the result will follow directly from Theorems 6.1 and 6.2 in [7, pp. 214–215]. Inserting $\Psi = I + p(A-I) + Z(A-I)$ we get

$$E[\Psi' K \Psi] = (I + p(A-I))'K(I + p(A-I)) + (A-I)'E[ZKZ](A-I).$$

Noting that $ZKZ = (\zeta_i \zeta_j k_{ij})$ so that $E[ZKZ] = p(1-p)\bar{K}$, we arrive at (3.6). □

It is interesting to note that with $p = 1$, Theorems 3.1 and 3.2 together reduce to the following well-known result. The Lyapunov matrix equation $A'KA - K = -G$ has a positive definite solution K for a positive definite G if and only if $\rho(A) < 1$.

Theorem 3.2 has an important consequence pertaining to almost sure convergence. Namely, if $E[\Psi' K \Psi] - K$ is negative definite for some positive definite K, then $V(x) = x'Kx$ is a suitable Lyapunov function and $V(x(k))$ is a positive supermartingale, showing the convergence of (3.3) in almost sure sense [5].

COROLLARY 3.3. *If the randomly relaxed iteration* (3.3) *converges in q.m., then it also converges almost surely; that is*

$$\Pr[\lim_{k \to \infty} \|x(k) - x^*\| = 0] = 1.$$

Because randomly relaxed iterations belong to the class of asynchronous iterations, one expects that the convergence condition (3.2) derived for asynchronous iterations is also sufficient for the convergence of (3.3) in q.m. This is indeed the case as is shown in the next theorem.

THEOREM 3.4. *Assume that $\rho(|A|) < 1$. Then the randomly relaxed iteration* (3.3) *converges in q.m. for all $p \in (0, 1]$.*

Proof. By a corollary to the Perron–Frobenius theorem [2, p. 150], $\rho(|A|) < 1$ implies that $\|A\|_w < 1$ for some w. From the equivalence of norms, $\|x\| \le c\|x\|_w$ for any x and for some constant c (precisely, $c = \sqrt{n}\cdot\max_i w_i$), so that

$$\begin{aligned} E\|x(k)\|^2 &\le c^2 E\|x(k)\|_w^2 = c^2 E\|\Psi(k-1)\cdots\Psi(0)x(0)\|_w^2 \\ &\le c^2 E[\|\Psi(k-1)\|_w^2 \cdots \|\Psi(0)\|_w^2 \|x(0)\|_w^2] = c^2\|x(0)\|_w^2 (E\|\Psi\|_w^2)^k, \end{aligned}$$

where the fact that $\Psi(k)$ are independent and identically distributed was used. Hence, $E\|x(k)\|^2 \to 0$ if $E\|\Psi\|_w^2 < 1$. Now the realizations of Ψ are matrices with the ith row equal to the ith row of A (denoted by a_i') or to the ith row of I. Hence, for any realization of Ψ and for any vector x we have

$$\begin{aligned} \|\Psi x\|_w &\le \max\{|x_1|/w_1, |a_1'x|/w_1, \ldots, |x_n|/w_n, |a_n'x|/w_n\} \\ &= \max\{\|x\|_w, \|Ax\|_w\} = \|x\|_w \end{aligned}$$

so that $\|\Psi\|_w \le 1$, and in particular, $\|\Psi\|_w < 1$ when $\Psi = A$. Likewise $\|\Psi\|_w^2 \le 1$ for all realizations and $\|\Psi\|_w^2 < 1$ for at least one realization of Ψ. Thus $E\|\Psi\|_w^2 < 1$ for all $p \in (0, 1]$. □

If $E\|x(k) - x^*\|^2 \to 0$, then also $E[x(k)] \to x^*$. Conversely, if the sequence $E[x(k)]$ diverges, then the randomly relaxed iteration cannot converge in q.m. We have the following result on the behavior of $E[x(k)]$.

THEOREM 3.5. *Let $x(k)$ be generated by the randomly relaxed iteration* (3.3). *Then $E[x(k)] \to x^*$ for all $x(0)$ if and only if*

$$\rho(I + p(A - I)) < 1. \tag{3.7}$$

Proof. $E[x(k)] = E[\Psi(k-1)\cdots\Psi(0)x(0)] = E[\Psi(k-1)]\cdots E[\Psi(0)]x(0) = E[\Psi]^k x(0) = (I + p(A - I))^k x(0)$, from which the result follows. □

The expected value convergence of (3.3) is thus equivalent to the convergence of an underrelaxed Jacobi iteration. It follows immediately from (3.7) that if A has real eigenvalues greater than unity, then the randomly relaxed iteration (3.3) is unstable. By the Perron–Frobenius theorem, $\rho(A)$ is an eigenvalue of A if A is nonnegative. Hence we have the following corollary to Theorems 3.4 and 3.5.

COROLLARY 3.6. *Let A be a nonnegative matrix. Then for any $p \in (0, 1]$, the randomly relaxed iteration* (3.3) *converges to x^* in q.m. if and only if $\rho(A) < 1$.*

This means that the convergence condition derived for totally asynchronous iterations, $\rho(|A|) < 1$, is tight for nonnegative matrices.

4. Remarks. Let us then consider some implications of the results presented. It follows from Theorem 3.1 that if the Jacobi iteration converges (i.e., $\rho(A) < 1$), then also the randomly relaxed iteration converges in q.m. for some $p < 1$. To see this, set $p = 1$ in (3.5) to arrive at $\rho(A \otimes A) < 1$. This is equivalent to $\rho(A) < 1$ so that, by the continuity of spectral radius, (3.5) must hold for some p close to 1. However, this does not guarantee that (3.5) is satisfied for all $p \in (0, 1)$. One can also find examples where condition (3.5) holds for some $p \in (0, 1)$ even though $\rho(A) > 1$ (cf. the numerical example in §5 below). This indicates that asynchronicity, as described by random relaxation, can in fact improve the stability of schemes such as the Jacobi iteration. An interesting research problem is whether a corresponding deterministic updating scheme could be uncovered that would have the same effect.

Theorem 3.2 can be used to derive other sufficient conditions for the convergence of randomly relaxed iterations. For example, inserting $K = I$ into (3.6) we get that $\rho(A'A) < 1$ guarantees q.m. convergence for all $p \in (0, 1]$. If A is normal ($AA' = A'A$), this is equivalent to $\rho(A) < 1$. This presents a considerable relaxation to condition (3.2).

5. Numerical example. Let us consider iterations with the matrix

$$A = \begin{bmatrix} -0.61 & -0.11 & -0.20 & 0.81 & 0.43 \\ 0.28 & 0.06 & 0.09 & -0.47 & -1.04 \\ -0.36 & -0.14 & 0.08 & 0.30 & -0.12 \\ 0.27 & 0.04 & -0.01 & -0.80 & -0.33 \\ 0.20 & -0.08 & 0.11 & -0.51 & -0.73 \end{bmatrix}.$$

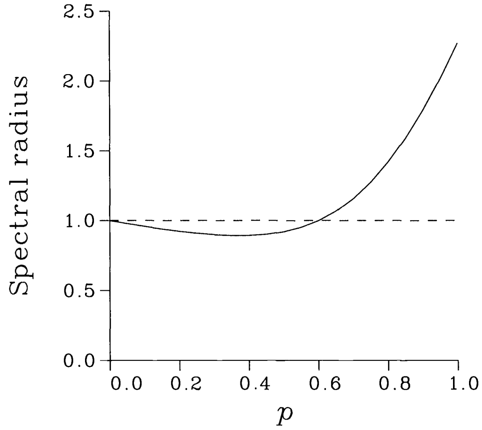

FIG. 5.1. *The spectral radius condition* (3.5) *of q.m. convergence as a function of p in the numerical example.*

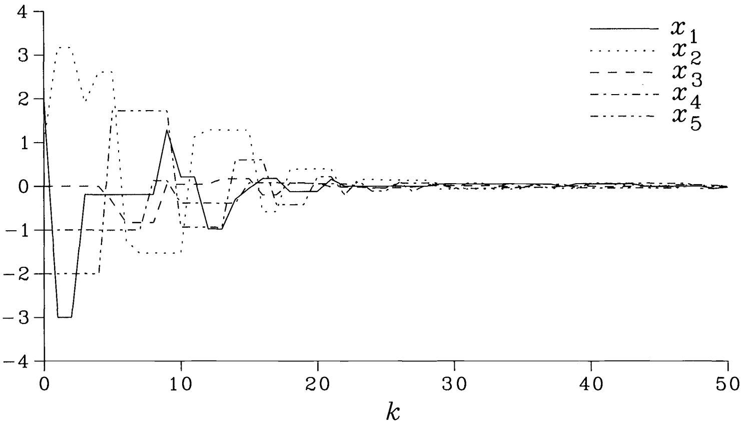

FIG. 5.2. *A simulation of the iteration* $x(k+1) = x(k) + \Xi(k)(A - I)x(k)$ *with* $p = 0.35$ *and* $x(0) = (2, 1, 0, -1, -2)$.

This provides an example where suitable asynchronism can be stabilizing. We have $\rho(|A|) \approx 1.6407$ and $\rho(A) \approx 1.5067$; in other words, the necessary condition for the convergence of asynchronous iterations is not satisfied and even the Jacobi iteration is unstable. Nevertheless, it turns out that condition (3.5) holds for all $p \in (0, \bar{p})$ where $\bar{p} \approx 0.60$, see Figure 5.1. When p decreases, the time intervals between coordinate updates become longer on the average. Hence, the interpretation is that randomly relaxed iterations converge in q.m. as well as almost surely if there is enough asynchronism. This phenomenon was first observed in numerical simulations of asynchronous Cournot processes in [12]. Figure 5.2 illustrates a simulation of the randomly relaxed iteration $x(k+1) = x(k) + \Xi(k)(A - I)x(k)$ with $p = 0.35$.

6. Conclusion. A stochastic model of zero-delay asynchronous iterations has been analyzed. Necessary and sufficient conditions for convergence in q.m. have been derived for linear systems. The results show that the convergence condition $\rho(|A|) < 1$ is tight for nonnegative matrices. It is also shown that asynchronous iterations, produced by random relaxation, can be stable even if the corresponding Jacobi iteration is unstable.

Acknowledgment. The author would like to thank Timo Eirola for helpful comments on the paper.

RAPID COMPUTATION OF THE DISCRETE FOURIER TRANSFORM*

CHRIS ANDERSON† AND MARIE DILLON DAHLEH‡

Abstract. Algorithms for the rapid computation of the forward and inverse discrete Fourier transform for points which are nonequispaced or whose number is unrestricted are presented. The computational procedure is based on approximation using a local Taylor series expansion and the fast Fourier transform (FFT). The forward transform for nonequispaced points is computed as the solution of a linear system involving the inverse Fourier transform. This latter system is solved using the iterative method GMRES with preconditioning. Numerical results are given to confirm the efficiency of the algorithms.

Key words. iterative methods, nonuniform fast Fourier transform

AMS subject classification. 65T20

1. Introduction.

The fast Fourier transform (FFT) [1] is a powerful tool used in numerous applications ranging from signal processing to rock mechanics [4]. In order to use the FFT one must have uniformly spaced data and numbers of points which are restricted to have certain values (e.g., a power of 2 or a product of primes). The goal of this paper is to describe a method for computing rapidly a forward and inverse discrete Fourier transform on sets of data points which are either nonequispaced and/or are unrestricted in number. Our method is similar in spirit to the papers of Dutt and Rokhlin [2], [3], in that the method relies on approximation of results obtained with the standard FFT. The major differences between the two approaches is that Dutt and Rokhlin utilize a fast multipole method to perform the approximation whereas we use a local Taylor series expansions. Our method also differs in the construction of the forward transform in that we employ a preconditioner and use an iterative method which does not require the transpose of the inverse transform matrix. We found our approach easier to implement because it is based on conventional computational techniques which are easy to program, namely the standard FFT and Taylor series expansions whose coefficients are computed spectrally.

In the next section we describe the specific computational problem associated with the discrete forward and inverse Fourier transform. In §3 we give a detailed description of our numerical algorithm. The key idea behind the inverse transform is to compute transformed values at a set of equispaced points using a standard FFT and then approximate the required values at the nonequispaced points (or arbitrary number) using local Taylor series expansions. The derivatives necessary for these expansions are computed spectrally. The use of local Taylor series expansions to represent the trigonometric sum is entirely appropriate since the sum is an analytic function. The computational procedure for the forward transform of a set of equispaced points of arbitrary number is the same as for the inverse transform (one just interchanges the notion of coefficients and function values). For nonequispaced points the forward transform is computed as the solution of a linear system of equations defined via the inverse transform. This system is solved iteratively using the generalized minimum residual method (GMRES) with preconditioning [5]. For each iteration an inverse Fourier transform must be computed, but, because the number of iterations is quite small, the method is efficient.

2. The problem.

In this paper we consider the forward Fourier transform as solving the trigonometric interpolation problem: Given the N distinct data points $\{x_j\}$ (not necessarily

uniformly spaced) on the interval $[0, 2\pi]$ and associated function values $\{y_j\}$, find the N coefficients $\{\alpha_k\}$ so that the trigonometric sum formed with these coefficients interpolates the given data; i.e.,

$$y_j = \frac{1}{N}\sum_{k=0}^{N-1} \alpha_k e^{i\,k\,x_j} \tag{1}$$

for $j = 0, \dots, N-1$.

The set of values $\{\alpha_k\}$ are thus the coefficients of the data $\{y_j\}$ when expressed in the discrete basis obtained by evaluating the Fourier basis elements at the nodes $\{x_j\}$, i.e., the discrete forward Fourier transform of $\{y_j\}$.

If the points are equispaced, then the orthogonality of the discrete Fourier basis functions implies that

$$\alpha_k = \sum_{j=0}^{N-1} y_j e^{-i\,k\,x_j}. \tag{2}$$

Alternately, the inverse discrete Fourier transform consists of evaluating the trigonometric interpolant; i.e., given a set of Fourier coefficients $\{\beta_k\}$ and a set of points $\{x_j\}$ determine the values $\{y_j\}$ by evaluating the sums

$$y_j = \frac{1}{N}\sum_{k=0}^{N-1} \beta_k e^{i\,k\,x_j} \tag{3}$$

for $j = 0, \dots, N-1$.

3. The numerical method.

3.1. Inverse transform. Our procedure for the forward discrete Fourier transform uses our construction of the inverse discrete Fourier transform, and so we describe the inverse transform first. The procedure for the inverse transform consists of using the standard fast inverse transform on a set of $M = 2^q$ equispaced points to determine a set of local Taylor series expansions centered at these points. The Taylor series expansions are then evaluated at the desired set of nonequispaced points or equispaced points of arbitrary number.

Assume we have the N distinct points $\{x_j\}$ in an interval $[0, 2\pi]$ and we are given a set of N Fourier coefficients $\{\beta_k\}$. We first choose a value of M which is a power of 2, and for which $2\pi(N-1) \le M$. Let $\{\tilde{x}_m\}$ be the set of M equispaced points in the interval $[0, 2\pi]$. Then

- Construct a new set of coefficients $\{\tilde{\beta}_k\}$ by padding and scaling the coefficients $\{\beta_k\}$,

$$\tilde{\beta}_k = \begin{cases} \left(\frac{M}{N}\right)\beta_k, & k \le N, \\ 0, & N < k \le M. \end{cases}$$

  The scaling factor $\frac{M}{N}$ is introduced so that the inverse transform of the padded coefficients $\{\tilde{\beta}_k\}$ yields a function which is equivalent to that of the original coefficients at the points $\{x_j\}$.
- Using the discrete inverse FFT, compute the values and the first p derivatives of the function

$$\tilde{y}(x) = \frac{1}{M}\sum_{k=0}^{M-1} \tilde{\beta}_k e^{i\,k\,\tilde{x}} \tag{4}$$

at the points $\{\tilde{x}_m\}$. The derivatives are evaluated spectrally; i.e., the pth derivative is obtained by computing the inverse transform of a set of coefficients of the form $(i\,k)^p\,\tilde{\beta}_k$.

- For a given point x_j, determine the closest of the equispaced points, say $\tilde{x}^*$, to it. Using the values and derivatives of (4) at $\tilde{x}^*$ one approximates the value at the point x_j by using a pth order Taylor series expansion about $\tilde{x}^*$.

The order p of the Taylor series expansion used is determined by the desired precision required in the function values. If these values are required to a precision ϵ (which may be unit round-off) then the maximal order of the approximation required to do this is the value of p so that

$$\frac{\gamma}{(p+1)!} \leq \epsilon \tag{5}$$

where $\gamma = \max_{0\leq k\leq N-1} \mid \beta_k \mid$. This follows from the fact that the error in an order p Taylor expansion of an individual term in (4) with wavenumber k is bounded by

$$\frac{1}{M}\frac{\mid \tilde{\beta}_k \mid h^{p+1}k^{p+1}}{(p+1)!} = \frac{1}{N}\frac{\mid \beta_k \mid h^{p+1}k^{p+1}}{(p+1)!}.$$

Since $k \leq N-1$ and $h = \frac{2\pi}{M}$ we have

$$\frac{1}{N}\frac{\mid \beta_k \mid h^{p+1}k^{p+1}}{(p+1)!} \leq \frac{1}{N}\left(\frac{\mid \beta_k \mid}{(p+1)!}\right)\left(\frac{2\pi(N-1)}{M}\right)^{p+1} \leq \frac{1}{N}\frac{\mid \beta_k \mid}{(p+1)!}.$$

The error in approximating the sum of N Fourier components is thus bounded by N times the maximum of this value, i.e., (5). The estimate (5) is only a bound, and in the implementation of the approximation procedure one adaptively determines the size of p that one should use; i.e., one accumulates the Taylor series approximation term-by-term and stops when the error is within the desired precision. Our computational experiments indicate that far fewer terms than the number suggested by the error bound need be used.

3.2. Forward transform.

3.2.1. Equispaced points. If the points $\{x_j\}$ are equispaced then the forward transform of values $\{y_j\}$ is given by

$$\alpha_k = \sum_{j=0}^{N-1} y_j e^{-i\,k\,x_j}. \tag{6}$$

Since $x_j = j\left(\frac{2\pi}{N}\right)$, then we can rewrite the sum as

$$\alpha_k = \sum_{j=0}^{N-1} y_j e^{-i\,k\,x_j} = \sum_{j=0}^{N-1} y_j e^{-i\,jk\left(\frac{2\pi}{N}\right)} = \sum_{j=0}^{N-1} y_j e^{-i\,j\,z_k}.$$

Thus, the α_k's are the values of the function $\sum_{j=0}^{N-1} y_j e^{-i\,j\,z_k}$ evaluated at the N equispaced points $z_k = k\left(\frac{2\pi}{N}\right)$ in the interval $[0, 2\pi]$. The task of evaluating the forward transform for equispaced points thus has the same form as the evaluation of the inverse transform, so one can use the technique for the inverse transform described previously with only slight modifications. In particular, since the factor $\frac{1}{N}$ does not appear in the forward transform sum, one does not scale $\{y_j\}$ by $\left(\frac{M}{N}\right)$ when padding these values to create the M values $\{\tilde{y}_j\}$. Also, the error bound for the Taylor series approximation becomes

$$\frac{N\nu}{(p+1)!} \leq \epsilon \tag{7}$$

where $\nu = \max_{0 \leq j \leq N-1} \mid y_j \mid$. While this error bound does depend on N, the dependence is rather weak, and our computational experiments indicate that it is of no great concern.

The problem of the forward transform for nonequispaced points is more challenging because the the coefficients $\{\alpha_k\}$ are not given by the sum (6). Thus, a different procedure must be employed. In our procedure we build upon the fact that we can compute the inverse transform for nonequispaced points rapidly. In particular, the goal of the forward transform is to find coefficients $\{\alpha_k\}$ so that the inverse transform of these coefficients interpolates a given set of function values $\{y_j\}$. Expressed in matrix/vector notation, the forward transform consists of finding the vector of coefficients $\vec{\alpha}$ so that the linear system

$$A\vec{\alpha} = \vec{y} \tag{8}$$

is satisfied. A is the representation in matrix form of the inverse Fourier transform.

Our procedure for the forward transform is just to solve the linear system (8) for the coefficients $\vec{\alpha}$. We choose to solve this system iteratively, because this will involve operations of the form $A\vec{z}$ for vectors $\vec{z}$, i.e., applications of the inverse transform which can be computed efficiently using the technique described above.

The iterative method we choose to use was the GMRES method with preconditioning [5]. The GMRES method is a Krylov subspace iterative method for solving nonsymmetric linear systems. There are several advantages to this method. First, each iteration can be performed quickly because the bulk of the work is contained in the matrix multiplication step $A\vec{\alpha}^{(i)}$ which is just the evaluation of the inverse transform for each iterate. Second, it is optimal in the sense that it minimizes the residual in a given Krylov subspace. Third, it does not require the knowledge of A^T. The major disadvantage of this method is that it may require several iterations to converge. At each iteration, one computes the next basis element for the Krylov subspace. All previous basis elements are needed. If one needs a large number of iterations to converge, then one may need significant storage for this procedure. However, with the preconditioner described below, the method converges in a few iterations, and the storage requirements of GMRES does not pose a problem.

A preconditioner for the system (8) consists of an operator which takes a set of values $\vec{y}$ and returns another set of values $\vec{\alpha}$. After some experimentation we found that a satisfactory preconditioner was simply the forward Fourier transform of the values $\{y_j\}$ assuming that they are associated with equispaced points. (Thus the preconditioner is the exact inverse of the matrix A in the case of equispaced points.)

4. Numerical experiments. We have implemented our method in Fortran using double precision arithmetic. All the calculations were run on a Sparc 10. For the inverse transform we report two types of errors. The first is the relative ∞-norm which is defined to be

$$E_\infty = \frac{\max_{1 \leq i \leq N} |y_i^a - y_i|}{\max_{1 \leq i \leq N} |y_i|},$$

and the second is the relative 2-norm error defined by

$$E_2 = \left(\frac{\sum_{i=1}^{N} |y_i^a - y_i|^2}{\sum_{i=1}^{N} |y_i|^2} \right)^{\frac{1}{2}}$$

where y_i^a represents the approximation of the y_i. For the forward transform we report the final residual error.

4.1. Inverse transform experiments. The first set of experiments are concerned with the inverse transform. We consider two cases. In Tables 1–3, we present results for points which are not equispaced but whose number is a power of 2. We examine how the degree of nonuniformity of the points affects the number of terms in the Taylor series, p, needed to obtain a desired accuracy. We define the nonuniform grid as follows:

$$x_j = x_j^{\text{unif}} + h * \eta * factor$$

where x_j^{unif} represents the jth grid point on a uniform grid, h is the grid spacing, η a uniformly distributed random number between 0 and 1, and *factor* is either .01 (Table 1) or .1 (Table 2). As one can see from Tables 1 and 2, for both perturbation factors, our method is slower than the direct evaluation of (3) for $n < 64$ and faster for $n > 64$. One would expect as the perturbation factor increases from .01 to .1, the number of Taylor series terms required to

obtain a given accuracy increases. This is in fact what happens. We use an error tolerance of 10^{-10}. The number of points for which our method is faster than the direct method is lower than the break-even point reported for a similar problem in either [2] or [3]. In [2], the break-even point occurs for $n \geq 256$ and in [3] the break-even point occurs for $n \geq 2048$.

For Tables 1 and 2, we use smooth Fourier coefficients generated by $\beta_k = \sin(x_k)$. In Table 3 we use randomly generated coefficients. The coefficients are contained in the interval $[0, 1]$. As one can see, for a given perturbation factor, the required number of Taylor series terms does not depend on the smoothness of the coefficients. Again, the order of the Taylor series required is substantially lower than the order predicted by our error estimates.

In Table 4 we present the results for a calculation with uniformly spaced points which are not a power of 2. One sees that our method is faster than the direct evaluation of (3) for calculations of more than 371 points.

4.2. Forward transform experiments. As we have mentioned previously, the computational task for the forward transform for equally spaced points has the same form as that for the inverse transform; therefore, there is no need to discuss it independently. Thus, in this section we only consider the case of the forward transform for data which is nonequispaced and whose number is a power of 2. In Tables 5 and 6, we consider a .01 perturbation and a .1 perturbation, respectively. For a given perturbation the number of GMRES iterations needed to converge remains almost constant. This is an indication that the preconditioner is doing a good job. Without the preconditioner the number of iterations increases dramatically with increasing N.

As the size of the perturbation increases, the number of iterations also increases. One should expect this behavior because the larger the perturbation the further the preconditioner is from the true matrix inverse. Even so, a ten-fold increase in the perturbation produces less than a three-fold increase in the CPU seconds needed for the calculation. In comparison with directly evaluating (1), the break-even point for the forward transform is about N = 4096. As better preconditioners are developed this number should drop.

In [2], Dutt and Rohklin present an iterative method for the solution of the algebraic problem. Our approach differs from theirs in that they use a conjugate gradient method whereas we use GMRES. Since the matrix A in (8) is not symmetric, one cannot use the conjugate gradient method directly for this system. Dutt and Rohklin therefore work with a reformulation of the matrix problem. By using GMRES we avoid using this reformulation. We also employ a preconditioner—a component we found to be critical for success.

5. Conclusions. In this paper we present a method for computing the forward and inverse discrete Fourier transform. The method for the inverse transform (and the forward transform of equispaced data with arbitrary numbers of points) is a combination of the standard FFT and approximation using local Taylor series expansions. Both the forward and inverse transforms are easy to implement and faster than directly evaluating (1) and (3) for a reasonably small number of points. The procedures reduce significantly the penalty of using the discrete Fourier transform on numbers of points which are not power of 2 or the product of primes.

The forward transform for nonequispaced data relies on the inverse transform and the iterative method GMRES with a preconditioner. The choice of the preconditioner was essential for the iterative method to converge rapidly. In our implementation we found that the procedure for the forward transform on nonequispaced points is less efficient than the direct method for numbers of points less than 4096. However, with improved coding and development of more appropriate preconditioners, this value should decrease. The methods presented here clearly extend to higher-dimensional discrete Fourier transforms.

FAST RECURSIVE LEAST SQUARES ADAPTIVE FILTERING BY FAST FOURIER TRANSFORM-BASED CONJUGATE GRADIENT ITERATIONS*

MICHAEL K. NG† AND ROBERT J. PLEMMONS‡

Abstract. Recursive least squares (RLS) estimations are used extensively in many signal processing and control applications. In this paper we consider RLS with sliding data windows involving multiple (rank k) updating and downdating computations. The least squares estimator can be found by solving a near-Toeplitz matrix system at each step. Our approach is to employ the preconditioned conjugate gradient method with circulant preconditioners to solve such systems. Here we iterate in the time domain (using Toeplitz matrix-vector multiplications) and precondition in the Fourier domain, so that the fast Fourier transform (FFT) is used throughout the computations. The circulant preconditioners are derived from the spectral properties of the given input stochastic process. When the input stochastic process is stationary, we prove that with probability 1, the spectrum of the preconditioned system is clustered around 1 and the method converges superlinearly provided that a sufficient number of data samples are taken, i.e., the length of the sliding window is sufficiently long. In the case of point-processing ($k = 1$), our method requires $O(n \log n)$ operations per adaptive filter input where n is the number of least squares estimators. In the case of block-processing ($k \geq n$), our method requires only $O(\log n)$ operations per adaptive filter input. A simple method is given for tracking the spectral condition number of the data matrix at each step, and numerical experiments are reported in order to illustrate the effectiveness of our FFT-based method for fast RLS filtering.

1. Introduction.

1.1. Background.

Adaptive filters are used extensively in many signal processing and control applications: for instance, in system identification, equalization of telephone channels, spectrum analysis, noise cancellation, echo cancellation, and linear predictive coding. A large number of books and papers have been written on various aspects of these applications, notably [13, pp. 17–75], [2, pp. 1–5], and [24]. In these applications the *recursive least squares* (RLS) algorithm is a well-known and extremely powerful tool.

The standard *linear least squares problem* can be posed as follows: given a complex M-by-n data matrix X with full column rank n (so that X^*X is Hermitian positive definite) and an M-vector $\mathbf{d}$ (desired signal vector), find the n-vector $\mathbf{w}$ (filter coefficient vector) that solves

$$\min \|\mathbf{d} - X\mathbf{w}\|_2, \tag{1.1}$$

where $\|\cdot\|_2$ denotes the usual Euclidean norm. Here X^* denotes the conjugate transpose. The solution to (1.1) is given by

$$\mathbf{w} = (X^*X)^{-1}X^*\mathbf{d}. \tag{1.2}$$

Here X^*X is often called the normal equations matrix [11, p. 142], and is known as the information matrix for (1.1) in the signal processing literature [13, p. 383]. It measures the information content in the experiment leading to (1.1).

In RLS computations arising in adaptive control and signal processing, it is required that one recalculate $\mathbf{w}$ when observations (i.e., equations) are successively added to, or deleted from, the problem (1.1); i.e., the least squares estimator at step t is found by solving for the n-vector $\mathbf{w}(t)$ in

$$\min ||\mathbf{d}(t) - X(t)\mathbf{w}(t)||_2. \tag{1.3}$$

Here $\mathbf{d}(t)$ is a desired signal M-vector at step t, and $X(t)$ is a corresponding M-by-n data matrix at step t. In the area of signal processing, RLS algorithms are often used to process signals that result from time-varying environments. RLS estimations for a time-varying finite impulse response or a transversal filter are often obtained by limiting the filter memory. The most common technique uses an exponential data weighting infinite memory method controlled by a forgetting factor γ, with $0 < \gamma \leq 1$ [13, p. 478]. This facilitates simplified computations in contrast to finite memory sliding data window methods, but at the cost of diminished tracking and stability characteristics [15, 23]. In many applications it is desirable to use a true finite memory algorithm, i.e., a sliding window algorithm, in order to avoid undesired effects from data in the distant past. A typical situation is where the parameters of the underlying model that generates the signal are subject to jump-type variations of random amplitudes [26, 27]. For a sliding window M-by-n data matrix, the least squares estimators can be computed by modifying the Cholesky factor of the normal equations with $O(n^2)$ operations per adaptive filter input where n is number of filter coefficients; see, for instance, [21].

Recently, fast recursive least squares (FRLS) algorithms have been a topic of considerable interest because of their low computational cost [13, pp. 583–584]. In most applications in signal processing, for instance linear predictive coding and system identification, the Toeplitz (displacement) structure of the data matrix allows one to develop computationally efficient algorithms, which are fast in the sense that they require only $O(n)$ operations per adaptive filter input. But the numerical stability of these FRLS algorithms has always been in question [14, 15, 23]. In particular, Luo and Qiao and Qiao [15, 23] have recently shown that *all known infinite memory FRLS algorithms are unstable* when the forgetting factor, used to diminish the effects of the old data, is less than 1.

The purpose of this paper is to propose a new FFT-based iterative RLS algorithm with reasonable complexity for computing least squares estimators recursively, that may also avoid some of the instability problems associated with direct FRLS methods.

1.2. FFT-based preconditioned iterative method. The use of conjugate gradient methods with circulant preconditioners for solving n-by-n Toeplitz systems $A_n\mathbf{u} = \mathbf{v}$ has been studied extensively in recent years. The key idea is to use n-by-n circulant matrices S_n to precondition the Toeplitz systems so as to speed up the convergence rate of the method (see, e.g., Chan and Strang [4]). That means, instead of solving the original Toeplitz system, one solves the preconditioned system

$$S_n^{-1}A_n\mathbf{u} = S_n^{-1}\mathbf{v}$$

by the conjugate gradient method.

Circulant matrices can always be diagonalized by the discrete Fourier matrix F_n with entries given by $[F_n]_{j,k} = (1/\sqrt{n})e^{-2\pi ijk/n}$. Thus linear systems with circulants can be solved in $O(n \log n)$ operations using the fast Fourier transform (FFT). Also, matrix-vector multiplications $A_n\mathbf{v}$ can be computed using the FFT in $O(n \log n)$ operations, by first embedding A_n into a $2n$-by-$2n$ circulant matrix; see [4]. It follows that the number of operations per iteration of the preconditioned conjugate gradient (PCG) method is of order $O(n \log n)$, using the FFT.

The convergence rate of this FFT-based PCG method has been analyzed by Chan and Strang [4]. They proved that if the diagonals of the Toeplitz matrix A_n are Fourier coefficients of a positive function in the Wiener class, then the spectrum of the preconditioned system $S_n^{-1}A_n$ will be clustered around 1 for large n, and thus the method will converge superlinearly. More precisely, for all $\epsilon > 0$, there exists a constant $c(\epsilon) > 0$ such that the error vector $\mathbf{b}_j$ of the preconditioned conjugate gradient method at the jth iteration satisfies

$$||\mathbf{b}_j||_{S_n^{-1/2}A_nS_n^{-1/2}} \leq c(\epsilon)\epsilon^j||\mathbf{b}_0||_{S_n^{-1/2}A_nS_n^{-1/2}}$$

when n is sufficiently large. Here

$$||\mathbf{v}||^2_{S_n^{-1/2}A_nS_n^{-1/2}} = \mathbf{v}^*S_n^{-1/2}A_nS_n^{-1/2}\mathbf{v}.$$

Hence the complexity of solving a large class of Toeplitz systems can be reduced to $O(n \log n)$ operations in such situations.

We remark that circulant approximations to Toeplitz matrices have been considered and used for some time in image processing, signal processing and time series analysis; see [8, 18] for references. Besides Strang's circulant preconditioner S_n, several other successful circulant preconditioners have been proposed and analyzed; see [6, 9, 25]. Recently, the use of circulant preconditioners for Toeplitz least squares problems was considered by Chan, Nagy and Plemmons [7, 8] and Ng and Chan [18]. In these papers, formal convergence results are established for the least squares problems, and some applications to signal and image processing are derived.

1.3. Outline. In this paper, we consider the recursive least squares computations where the data matrices are assumed to have a Toeplitz (displacement) structure. We propose a new algorithm for computing least squares estimators recursively. Our approach uses sliding data windows involving multiple updating and downdating computations, for superior tracking capabilities. When $X(t)$ is an M-by-n rectangular data matrix (M is the length of the sliding window) with full column rank, then the least squares estimator $\mathbf{w}(t)$ at step t can be obtained by solving the normal equations

$$X(t)^*X(t)\mathbf{w}(t) = X(t)^*\mathbf{d}(t). \tag{1.4}$$

We note that $X(t)^*X(t)$, although generally not Toeplitz, is an n-by-n "near-Toeplitz" matrix, as it can be written in the form $T(t) - L(t)^*L(t) - U(t)^*U(t)$, where $T(t)$ is Toeplitz, and $L(t)$ and $U(t)$ are lower triangular and upper triangular Toeplitz matrices, respectively (see §2).

Our approach is to apply the preconditioned conjugate gradient algorithm with circulant preconditioners to solve the system (1.4) at each step t. In our algorithm, the proposed n-by-n circulant preconditioner $C(t)$ is taken to be an approximation to $T(t)$. We prove that if the input stochastic process is stationary and its underlying spectral density function is positive and in the Wiener class, then our circulant preconditioner $C(t)$ will be positive definite, and its smallest eigenvalue will be uniformly bounded away from zero with probability 1, provided that sufficiently large numbers of data samples are taken, i.e., M is sufficiently large. Under the same assumptions, we also prove that the spectrum of the preconditioned matrix $C(t)^{-1}X(t)^*X(t)$ is clustered around 1 with probability 1. Thus, when we apply the conjugate gradient method to the preconditioned system, the method converges superlinearly with probability 1.

We also derive a convergence analysis of the sliding window RLS involving multiple updating and downdating computations. We prove that with probability 1, if the desired response and the input stationary stochastic process are related by a *multiple linear regression model*, then the ℓ_2 norm of the difference between the least squares estimator computed by the sliding window RLS algorithm and the constant regression parameter is bounded by a constant, provided that a large number of data samples is taken, i.e., M is sufficiently large. Under the same assumptions, we prove that with probability 1, the average least squares error of the sliding window RLS is also bounded by a constant.

The outline of the paper is as follows. In §2, we first formulate the sliding window RLS method for a Toeplitz data matrix and analyze the convergence rate of the preconditioned conjugate gradient method probabilistically. In §3, we present our FFT-based RLS algorithms and study the convergence of the sliding window RLS algorithm. In §4, numerical experiments are reported for the sliding window RLS scheme in order to illustrate the effectiveness of the method. A simple method is also given for tracking the spectral condition number of the data matrix at each step. Some concluding remarks are given in §5.

2. Sliding window RLS with Toeplitz data matrix. To present the sliding window RLS method, we first introduce some notation from adaptive filter theory [13, p. 18].

- discrete time index or step: t,
- order of filter: n,
- input sample scalar at time t: $x(t)$,
- input sample row vector at time t: $\mathbf{x}(t)^* = [\overline{x(t)}, \overline{x(t-1)}, \ldots, \overline{x(t-n+1)}]$,
- optimal filter coefficient column vector (the least squares estimator) at time t: $\mathbf{w}(t) = [w_1(t), w_2(t), \ldots, w_n(t)]^T$,
- desired signal scalar at time t: $d(t)$,
- filter output scalar at time t: $o(t) = \mathbf{x}(t)^*\mathbf{w}(t)$,
- difference (estimation error) between the desired response $d(n)$ and the output $o(t)$ produced by the filter at time t: $e(t) = d(t) - o(t)$,
- length of sliding window: M (we assume that $M \geq n$),
- rank number for updating and downdating computations: k ($k \leq M$).

In the sliding window RLS method, the corresponding data matrix at step t ($t \geq M$) is an M-by-n rectangular Toeplitz matrix of the form

$$X(t) = \begin{bmatrix} \overline{x(t-M+1)} & \cdots & \cdots & \overline{x(t-M-n+2)} \\ \vdots & \ddots & & \vdots \\ \vdots & & \ddots & \vdots \\ \vdots & \ddots & & \overline{x(t-M+1)} \\ \vdots & & \ddots & \vdots \\ \overline{x(t)} & \cdots & \cdots & \overline{x(t-n+1)} \end{bmatrix}. \tag{2.1}$$

We assume that $t - M - n + 2 \geq 1$ in $X(t)$. Thus all data samples are available at step t except when $t = M$. In this case, we let $x(j) = 0$ for $j \leq 0$. Moreover, we always assume that the data matrix $X(t)$ is of full column rank n at each updating and downdating step $t = M, M+k, M+2k, \ldots$. By minimizing the estimation error over the steps from $t - M + 1$ to t,

$$\sum_{j=t-M+1}^{t} |e(j)|^2, \tag{2.2}$$

the least squares estimator $\mathbf{w}(t)$ can be found by solving the least squares problem

$$\min ||\mathbf{d}(t) - X(t)\mathbf{w}(t)||_2.$$

Here $\mathbf{d}(t)$ is a known M-vector given by

$$\mathbf{d}(t) = [d(t-M+1), d(t-M+2), \ldots, d(t)]^T. \tag{2.3}$$

It follows that the solution $\mathbf{w}(t)$ can be obtained by solving normal equations

$$X(t)^*X(t)\mathbf{w}(t) = X(t)^*\mathbf{d}(t).$$

Since the data matrix $X(t)$ is assumed to have full column rank n, the normal equations matrix is nonsingular. We remark that the data matrix has a special structure. Each row of $X(t)$ is a right-shifted version of the previous row. By utilizing this special rectangular Toeplitz (displacement) structure of the data matrix, the normal equations matrix $X^*(t)X(t)$ can be written in the form

$$X(t)^*X(t) = T(t) - L(t)^*L(t) - U(t)^*U(t), \tag{2.4}$$

where $T(t)$ is Hermitian and Toeplitz, and $L(t)$ and $U(t)$ are lower triangular and upper triangular Toeplitz matrices, respectively (see, e.g., [18]). As the product of a lower triangular Toeplitz matrix and an upper triangular Toeplitz matrix is not Toeplitz, in general, the normal equations matrix $X(t)^*X(t)$ is not Toeplitz. We call $X(t)^*X(t)$ *near-Toeplitz.*

Here, the first column of the Hermitian Toeplitz matrix $T(t)$ in (2.4) is given by

$$[\gamma_0(t), \gamma_1(t), \ldots, \gamma_{n-1}(t)],$$

where

$$\gamma_j(t) = \sum_{s=t-M-n+2}^{t-|j|} x(s)\overline{x(s+|j|)}, \quad j = 0, 1, \ldots, n-1.$$

Moreover, in the statistics literature, if the input stochastic process is stationary, the parameters

$$\hat{r}_j(t) \equiv \frac{\gamma_j(t)}{M+n-1}, \quad j = 0, 1, \ldots, n-1, \tag{2.5}$$

are called estimators of the autocovariances r_j of the stationary process; see, for instance, Priestley [22, p. 322]. We also note that the first column of the lower triangular Toeplitz matrix $L(t)$ and the first row of the upper triangular Toeplitz matrix $U(t)$ are given by

$$[0, \overline{x(t-M-n+2)}, \ldots, \overline{x(t-M)}]^T \quad \text{and} \quad [0, \overline{x(t)}, \ldots, \overline{x(t-n+2)}],$$

respectively (see, e.g., [18]).

2.1. Updating and downdating computations. Figure 2.1 displays the sliding data window RLS method. Here, k rows, denoted by the k-by-n updating matrix $Y(t)$, are added, and k rows, denoted by the k-by-n downdating matrix $Z(t)$, are removed, forming the M-by-n data matrix $X(t+k)$ at step $t+k$. We note that the k-by-n updating matrix $Y(t)$ and downdating matrix $Z(t)$ are given by

$$Y(t) = \begin{bmatrix} \overline{x(t+1)} & \cdots & \cdots & \cdots & \overline{x(t-n+2)} \\ \vdots & \ddots & \ddots & & \vdots \\ \vdots & & \ddots & \ddots & \vdots \\ \overline{x(t+k)} & \cdots & \cdots & \cdots & \overline{x(t+k-n+1)} \end{bmatrix}$$

and

$$Z(t) = \begin{bmatrix} \overline{x(t-M+1)} & \cdots & \cdots & \cdots & \overline{x(t-M-n+2)} \\ \vdots & \ddots & \ddots & & \vdots \\ \vdots & & \ddots & \ddots & \vdots \\ \overline{x(t-M+k)} & \cdots & \cdots & \cdots & \overline{x(t-M+k-n+1)} \end{bmatrix}.$$

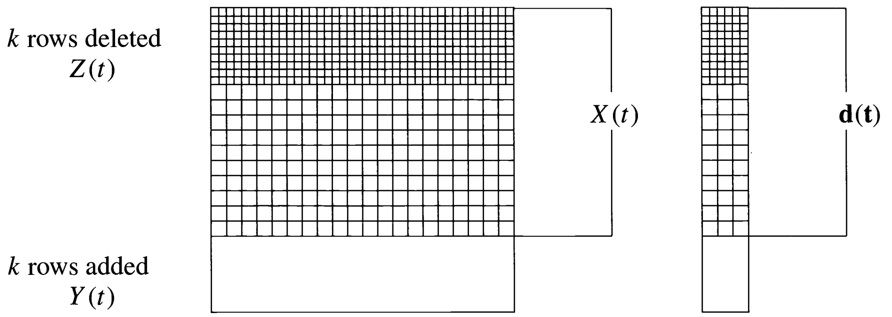

FIG. 2.1. *Sliding window RLS method: Updating with $Y(t)$ and downdating with $Z(t)$.*

The right-hand side data vector $\mathbf{d}(t+k)$ is modified in a corresponding fashion. In practice, the sliding window length M can be modified adaptively in the recursive computations. This is accomplished easily. For instance, to increase (decrease) M one can downdate with fewer (more) rows than used for updating. For simplicity of notation, however, we describe only the case where the window length M is fixed, i.e., we describe the FFT-based sliding window RLS algorithm only for combined rank k updates and downdates. Next we show how to generate the normal equations matrix $X(t+k)^*X(t+k)$ and the right-hand side vector of the normal equations $X(t+k)^*\mathbf{d}(t+k)$ at the next step.

We use the fact that at the step $t+k$, the normal equations matrix can be written as the following form which corresponds to (2.4),

$$X(t+k)^*X(t+k) = T(t+k) - L(t+k)^*L(t+k) - U(t+k)^*U(t+k),$$

where the first column of $T(t+k)$ is given by

$$[\gamma_0(t+k), \gamma_1(t+k), \dots, \gamma_{n-1}(t+k)]$$

and

$$\gamma_j(t+k) = \sum_{s=t-M+k-n+2}^{t+k-|j|} x(s)\overline{x(s+|j|)}.$$

Here the first column of the lower triangular and the first row of the upper triangular Toeplitz matrices $L(t+k)$ and $U(t+k)$ are given by

$$[0, \overline{x(t-M+k-n+2)}, \dots, \overline{x(t-M+k)}]^T \quad \text{and} \quad [0, \overline{x(t+k)}, \dots, \overline{x(t+k-n+2)}]$$

respectively. Both the matrices $L(t+k)$ and $U(t+k)$ can be easily generated from the updating matrix $Y(t)$ and downdating matrix $Z(t)$. Moreover, the first column of the Toeplitz matrix $T(t+k)$ can be generated by

$$T(t+k)\mathbf{e_1} = T(t)\mathbf{e_1} + Y(t)^*Y(t)\mathbf{e_1} - HZ(t)^T(Z(t)^T)^*\mathbf{e_n},$$

where H is the n-by-n antidiagonal identity matrix, and $\mathbf{e_1}$ and $\mathbf{e_n}$ are the first unit and last unit vectors. By utilizing the special Toeplitz (displacement) structure of the data matrices $Y(t)$ and $Z(t)$, the first column of $T(t+k)$ can be obtained by the FFT in $O(\max\{n,k\}\log n)$

operations. We note that the right-hand side vector $X(t+k)^*\mathbf{d}(t+k)$ of the normal equations at the step $t+k$ can be obtained in $O(\max\{k,n\}\log n)$ operations by using similar updating and downdating computations, i.e.,

$$X(t+k)^*\mathbf{d}(t+k) = X(t)^*\mathbf{d}(t) - Z^*(t)\mathbf{d}_d(t) + Y^*(t)\mathbf{d}_u(t),$$

where the vectors $\mathbf{d}_d(t)$ and $\mathbf{d}_u(t)$ are given by

$$\mathbf{d}_d(t) = [d(t-M+1), d(t-M+2), \ldots, d(t-M+k)]^T$$

and

$$\mathbf{d}_u(t) = [d(t+1), d(t+2), \ldots, d(t+k)]^T,$$

respectively.

We remark that in the case of point-processing, i.e., when $k = 1$, the updating and downdating computations for the sliding window RLS process is much simpler than the case of block-processing ($k > 1$). More precisely, we do not need to use the FFT to compute the first column of the Toeplitz matrix $T(t+1)$ and the right-hand side vector at the step $t+1$. The first column of $T(t+1)$ can be generated by

$$T(t+1)\mathbf{e}_1 = T(t)\mathbf{e}_1 + \overline{x(t+1)}\mathbf{x}(t) - x(t-M-n+2)H\mathbf{x}(t-M+1).$$

Similarly, the right-hand side vector $X^*(t+1)\mathbf{d}(t+1)$ is computed by the following formula:

$$X^*(t+1)\mathbf{d}(t+1) = X(t)^*\mathbf{d}(t) - d(t-M+1)\mathbf{x}(t-M+1) + d(t+1)\mathbf{x}(t+1).$$

Here, the complexity of these rank 1 updating and downdating computations is $O(n)$.

Recall that our propose is to use the circulant preconditioned conjugate gradient method to compute the filter coefficient vectors at each adaptive time step. In the next section, we introduce our circulant preconditioner and show that the circulant preconditioned system converges very quickly at each adaptive time step.

2.2. FFT-based preconditioned conjugate gradient iterations. In this paper, we only focus on the optimal circulant preconditioner $C(t)$ at the step t, which is defined to be the minimizer of $||Q_n - T(t)||_F$ over all n-by-n circulant matrices Q_n [9]. Here $||\cdot||_F$ denotes the Frobenius norm. The following lemma gives the spectral properties of the optimal circulant preconditioner. Its proof can be found in Tyrtyshnikov [25].

LEMMA 2.1 (of Tyrtyshnikov). *Let A_n be an arbitrary n-by-n Hermitian matrix and C_n be the optimal preconditioner, which is defined to be the minimizer of $||Q_n - A_n||_F$ over all n-by-n circulant matrices Q_n. Then C_n is Hermitian and*

$$\lambda_{\min}(A_n) \le \lambda_{\min}(C_n) \le \lambda_{\max}(C_n) \le \lambda_{\max}(A_n), \tag{2.6}$$

where $\lambda_{\max}(\cdot)$ and $\lambda_{\min}(\cdot)$ denote the largest and the smallest eigenvalues, respectively. In particular, if A_n is positive definite, then C_n is also positive definite.

We remark that most of the other circulant preconditioners do not satisfy (2.6); see Chan and Yeung [6]. Since $T(t)$ is a Toeplitz matrix, the first column of $C(t)$ can be obtained in $O(n\log n)$ operations by the FFT; i.e., the circulant matrix $C(t)$ can be generated in $O(n\log n)$ operations [9].

Next we analyze the convergence rate of the conjugate gradient method when applied to solving the preconditioned system, which can be expressed as

$$C(t)^{-1}[X(t)^*X(t)]\mathbf{w}(t) = C(t)^{-1}X(t)^*\mathbf{d}(t),$$

at each step t. As we deal with data samples from random input processes, the convergence rate will be considered in a probabilistic way, which is different from the deterministic case discussed in §1.2. For simplified notation in the following discussions, we define an integer

$$J = M + n - 1,$$

which refers to *number of data samples* given in the data matrix $X(t)$ (cf. (2.1)).

We first make the following practical assumption (A) on the input signal process, so that results of the convergence rate can be derived.

(A1) The input discrete-time stochastic process is stationary.

(A2) The underlying spectral density function $f(\theta)$ (see Haykin [13, pp. 116–117] for definition) of the input process is real-valued, positive, and in the Wiener class; i.e., the autocovariances $\{r_k\}$ of the process are absolutely summable:

$$\sum_{k=-\infty}^{\infty} |r_k| \leq \alpha < \infty. \tag{2.7}$$

(A3) The variances of the estimators $\hat{r}_k(t)$ given in (2.5) are bounded by

$$\mathrm{Var}(\hat{r}_k(t)) \equiv \mathrm{Var}\left(\frac{\gamma_k(t)}{J}\right) \leq \frac{\beta}{J}, \quad k = 0, \pm 1, \pm 2, \dots, \tag{2.8}$$

where β is a constant.

(A4) The stationary process has zero-mean, i.e., $\mathcal{E}(x(t)) = \mu = 0$ for all t where $\mathcal{E}$ is the expectation operator.

Here are some remarks on the assumptions.

1. The assumption (A1) is often true in signal-processing applications. For instance (A1) holds for *autoregressive* (AR) *processes*, *moving-average* (MA) *processes* and *autoregressive and moving-average* (ARMA) *processes*, which are commonly used as input stochastic stationary processes, see Haykin [13, pp. 90–94].
2. In time-series analysis, assumption (A2) is often valid. For example, the spectral density functions of ARMA processes are rational functions [3, p. 121]. The positiveness of the spectral density function can be guaranteed by the causality of the process [3, p. 85], whereas the absolute summability of the autocovariances can be assured by the invertibility of the process [3, p. 86]. In the time-series literature, the Hermitian Toeplitz matrix R_n with its first column given by

$$[r_0, r_1, \dots, r_{n-2}, r_{n-1}]^T$$

is called the covariance matrix of the input stochastic stationary process [13, p. 82]. Moreover, we have the following lemma about the spectrum $\sigma(R_n)$ of R_n given in Haykin [13, p. 139].

LEMMA 2.2. *Let the input process satisfy assumptions* (A1) *and* (A2). *Then the spectrum $\sigma(R_n)$ of R_n satisfies*

$$\sigma(R_n) \subseteq [f_{\min}, f_{\max}], \quad \forall n \geq 1, \tag{2.9}$$

where $f_{\min}$ and $f_{\max}$ are the minimum and maximum values of $f(\theta)$, respectively. In particular, if $f(\theta)$ is positive, then R_n is positive definite.

We note that further remarks on the assumptions can also be found in [18]. We first establish the result that the smallest eigenvalue and the largest eigenvalue of $X(t)^*X(t)$ are uniformly bounded away from zero with probability 1. Basically, the lemma states that the normal equations matrix is a good approximation to the covariance matrix R_n in the stochastic sense. In time-series analysis and signal processing, the normal equations matrix is sometimes called a sample covariance matrix [22, pp. 321–322], [13, pp. 378–379].

LEMMA 2.3 (Ng and Chan [18, Thm. 2 and Lem. 4]). *Let the input process satisfy assumption* (A). *Then for any given* $\epsilon > 0$ *and* $0 < \delta < 1$, *there exists a positive integer* N *such that for* $n > N$,

$$\Pr\left\{\lambda_{\min}\left(\frac{1}{J}[X(t)^*X(t)]\right) \geq \lambda_{\min}(R_n) - \epsilon \geq f_{\min} - \epsilon\right\} > 1 - \delta$$

and

$$\Pr\left\{\lambda_{\max}\left(\frac{1}{J}[X(t)^*X(t)]\right) \leq \lambda_{\max}(R_n) + \epsilon \leq f_{\max} + \epsilon\right\} > 1 - \delta,$$

provided that the number of data samples $J (= M + n - 1)$ *is sufficiently large* $(J \gg n)$.

Next we prove that the circulant preconditioned matrices have clustered spectra. The result is stated as the following theorem.

THEOREM 2.4. *Let the input process satisfy assumption* (A). *Then, for any given* $\epsilon > 0$ *and* $0 < \delta < 1$, *there exist positive integers* K *and* N *such that for* $n > N$,

$$\Pr\{\textit{at most } K \textit{ eigenvalues of } I_n - C(t)^{-1}X(t)^*X(t) \textit{ have absolute value} > \epsilon\} > 1 - \delta,$$

provided that the number of data samples J *is sufficiently large* $(J \gg n)$.

Proof. We define the following events:

$E_1 = \{$at most K eigenvalues of $\frac{1}{J}[C(t) - X(t)^*X(t)]$ have absolute value $> \epsilon\}$,
$E_2 = \{\lambda_{\min}(C(t))$ is uniformly bounded away from zero$\}$, and
$E_3 = \{$at most K eigenvalues of $I_n - C(t)^{-1}X(t)^*X(t)$ have absolute value $> \epsilon\}$.

By the results proved in Ng and Chan [18, Thm. 3 and Lem. 4], we have, for any given $\epsilon > 0$ and $0 < \delta < 1$, that there exist positive integers K and N such that for $n > N$, Pr $\{E_1\} > 1 - \delta$. Using Lemmas 2.2 and 2.3, we have Pr $\{E_2\} > 1 - \delta$. Then we note that

$$\Pr\{E_1 \text{ and } E_2\} = \Pr\{E_1\} + \Pr\{E_2\} - \Pr\{E_1 \text{ or } E_2\} \geq 1 - 2\delta.$$

Since events E_1 and E_2 together imply E_3, the theorem follows. □

Using Theorem 2.4, we can easily show that the conjugate gradient method, when applied to the preconditioned matrix $C(t)^{-1}X(t)^*X(t)$, converges superlinearly with probability 1 provided that the number of data samples $J(= M + n - 1)$ is sufficiently large, i.e., M is sufficiently large. For details of the proof of the superlinearly convergence rate, see Chan and Strang [4]. Thus the number of iterations required to achieve a fixed accuracy remains bounded as the filter order n is increased (see the numerical examples in [18]). Recall that for each iteration, the work is of order $O(n \log n)$ operations. Therefore, the work of obtaining the least squares estimator $\mathbf{w}(t)$ at each step t to a given accuracy is also of order $O(n \log n)$.

3. FFT-based sliding window RLS algorithm. As the FFT-based preconditioned conjugate gradient method is efficient in solving the normal equations (1.2), we employ the method in the sliding window RLS computations. In the following, we describe our FFT-based sliding window RLS algorithm. We assume that the sliding window RLS process is initialized, i.e., at time $t = M$, the Toeplitz matrices $T(M)$, $L(M)$, and $U(M)$ are given and the least squares estimator $\mathbf{w}(M)$ is also computed. Otherwise, the first step can be done by applying the conjugate gradient method to solving the preconditioned system

$$C(M)^{-1}[X(M)^*X(M)]\mathbf{w}(M) = C(M)^{-1}X^*(M)\mathbf{d}(M),$$

in factored form [7, 18], with the zero-vector as our initial approximation to the filter coefficient vector. The general step of our algorithm is described as follows.

ALGORITHM: FFT-BASED SLIDING WINDOW RLS ALGORITHM. Let M denote the length of the sliding data window, and let k denote the block length of the update and downdate blocks. The n-by-n Toeplitz matrix $T(t)$, the k-by-n downdating matrix $Z(t)$, the k-by-n updating matrix $Y(t)$, and the associated right-hand side M-vector $X(t)^*\mathbf{d}(t)$ at step t in the RLS process are given. Let $\mathbf{w}(t)$ denote the least squares estimator at step t. This algorithm computes the least squares estimator $\mathbf{w}(t+k)$ at step $t+k$.

- Generate information for the three n-by-n Toeplitz matrices $T(t+k)$, $L(t+k)$, and $U(t+k)$ and the associated right-hand side n-vector $X(t+k)^*\mathbf{d}(t+k)$, using the method proposed in §2.1.
- Find the first column of the optimal circulant preconditioner $C(t+k)$ for $T(t+k)$ using the method described in §2.2.
- Apply the conjugate gradient algorithm, as in §2.2, to solving the preconditioned system represented as

$$C(t+k)^{-1}[X(t+k)^*X(t+k)]\mathbf{w}(t+k) = C(t+k)^{-1}X(t+k)^*\mathbf{d}(t+k),$$

with starting initial guess $\mathbf{w}(t)$.

Next we provide some remarks about the algorithm:

1. The FFT-based sliding window RLS algorithm consists of three basic parts. The FFT can be used to generate normal equations and circulant preconditioners in the first and second parts. The number of operations required is $O(\max\{k, n\}\log n)$. In the third part, by using FFT, the cost of matrix-vector multiplications involving the matrices $C(t+k)^{-1}$, $T(t+k)$, $L(t+k)$, $L(t+k)^*$, $U(t+k)$, and $U(t+k)^*$ can be done efficiently in $O(n\log n)$ operations. It follows that the number of operations per iteration in the preconditioned conjugate gradient method is $O(n\log n)$. The total work of obtaining the least squares estimators at each step t to a given accuracy is of order $O(n\log n)$ operations for point-processing and $O(\max\{k, n\}\log n + n\log n)$ for block-processing. In the case of block-processing when $k \geq n$, the method on average will require only $O(\log n)$ operations per adaptive filter input. A corresponding scheme for averaging the computations over n steps has been considered for the LMS algorithm by Marshall and Jenkins [16].
2. The basic tool of our fast sliding window RLS algorithm is the FFT. Since the FFT is highly parallelizable and has been implemented on multiprocessors efficiently [1, p. 238], our algorithm can be expected to perform efficiently in a parallel environment for large-scale or for near real-time applications. One could, for example, assign each step of the algorithm to a different group of processors. A group of processors would be responsible for generation of the right-hand side vector $X(t)^*d(t)$ of the normal equations, and the first columns of the Toeplitz matrices $T(t)$, $L(t)$, and $U(t)$ at step t, respectively. Then a group of processors can be used to generate the first column of circulant preconditioner $C(t)$. The conjugate gradient method can be implemented on an another group of processors.
3. When the input stochastic process is stationary and the adaptive filter system is subjected to the effect of white noise, both the expected value of the least squares estimators $\mathbf{w}(t+k)$ and $\mathbf{w}(t)$ are equal to the solution of the discrete Wiener–Hopf equation, see [13, pp. 165–167]. Thus if k is not large, $\mathbf{w}(t)$ will be a good initial approximation (instead of a randomly chosen one) to the least squares estimator $\mathbf{w}(t+k)$ when the input process of the adaptive system is time varying in practical

applications. It follows that the number of iterations of the preconditioned conjugate gradient method can possibly be reduced with this choice of starting vector; see the numerical results in §4.

Next we demonstrate the convergence of the sliding window RLS algorithm involving multiple updating and downdating computations. We consider two aspects of the problem in the analysis: (1) the estimate $\mathbf{w}(t)$, and (2) the average least squares error of the RLS process. We use a probabilistic approach to consider these aspects of the problem. For the analysis, we first assume that the desired response $d(t)$ and the input sample column vector $\mathbf{x}(t)$ are related by a *multiple linear regression model.* In particular, we write

$$d(t) = e_0(t) + \mathbf{x}(t)^* \hat{\mathbf{w}}, \tag{3.1}$$

where $\hat{\mathbf{w}}$ is an n-by-1 constant regression parameter vector of the model and $e_0(t)$ is the measurement error. We also assume that the measurement error process $\{e_0(t)\}$ is white noise with zero mean and variance τ^2. In addition, we assume that the input process satisfies assumption (A). This assumption is equivalent to saying that the adaptive system operates in a stationary environment.

We first give the following lemma which is useful later in the analysis of the convergence of the sliding window RLS algorithm.

LEMMA 3.1. *Let $\{e_0(t)\}$ be a discrete-time white noise process where the mean of the process is equal to* 0 *and the variance of the process is equal to τ^2. If* $\mathrm{Var}(e_0(t)^2) = \nu \quad \forall t = 1, 2, \ldots,$ *then for any given $\epsilon > 0$,*

$$\Pr\left\{ \left\| \frac{1}{\sqrt{M}} \mathbf{e}_0(t) \right\|_2 \le \sqrt{\tau^2 + \epsilon^2} \right\} > 1 - \frac{\nu}{M\epsilon^4},$$

where $\mathbf{e}_0(t)$ is an M-vector given by

$$\mathbf{e}_0(t) = [e_0(t - M + 1), e_0(t - M + 2), \ldots, e_0(t)]^T \tag{3.2}$$

and $t = M, M + 1, \ldots.$

Proof. Since $\{e_0(t)\}$ is a white noise process, i.e., it is a sequence of uncorrelated random variables, the mean and the variance of the random variable $\frac{1}{M} \sum_{j=1}^{M} e_0(t - M + j)^2$ is equal to τ^2 and ν/M, respectively. By Chebyshev's inequality (see Fuller [10]), we get the following result:

$$\Pr\left\{ \left| \frac{1}{M} \sum_{j=1}^{M} e_0(t - M + j)^2 - \tau^2 \right| \le \epsilon^2 \right\} > 1 - \frac{\nu}{M\epsilon^4}.$$

The remaining results can be derived in a straightforward way by considering simple probability arguments. □

We let $\mathbf{a}(t)$ denote the weight-error vector at step t, defined as the difference between the least squares estimator $\mathbf{w}(t)$ produced by the sliding window RLS algorithm and the regression parameter vector $\hat{\mathbf{w}}$ of the multiple linear regression model, i.e.,

$$\mathbf{a}(t) \equiv \mathbf{w}(t) - \hat{\mathbf{w}}. \tag{3.3}$$

We first prove that with probability 1, $||\mathbf{a}(t)||_2$ is bounded by a constant depending on the variance of the process of the measurement error and minimum values of the spectral density function $f(\theta)$ of the input process.

THEOREM 3.2. *Let the input process satisfy assumption* (A). *Let the desired response* $d(t)$ *be given by* (3.1). *If the variance of* $e_0(t)^2$ *is bounded* $\forall t = 1, 2, \ldots$, *then for any given* $\epsilon > 0$ *and* $0 < \delta < 1$,

$$\Pr\left\{ \|\mathbf{a}(t)\|_2 \le \sqrt{\frac{\epsilon^2 + \tau^2}{f_{\min} - \epsilon}} \right\} > 1 - \epsilon, \tag{3.4}$$

provided that the number of data samples J *is sufficiently large* ($J \gg n$), *where* τ^2 *is the variance of the measurement error* $\{e_0(t)\}$.

Proof. We assume in §2.1 that the normal equations matrix $X(t)^*X(t)$ is non-singular. Thus the least squares estimator $\mathbf{w}(t)$ at step t is given by

$$\mathbf{w}(t) = [X(t)^*X(t)]^{-1}X(t)^*\mathbf{d}(t),$$

where $\mathbf{d}(t)$ is an M-vector given by (2.3). Therefore, by (3.1) and (3.3), we have

$$\mathbf{a}(t) = [X(t)^*X(t)]^{-1}X(t)^*\mathbf{e}_0(t),$$

where the vector $\mathbf{e}_0(t)$ is given by (3.2). It follows that

$$\begin{aligned} ||\mathbf{a}(t)||_2 &= \left(\frac{1}{J}X(t)^*X(t)\right)^{-1}\frac{1}{J}X(t)^*\mathbf{e}_0(t) \\ &\le \left\| \left(\frac{1}{J}X(t)^*X(t)\right)^{-1}\frac{1}{\sqrt{J}}X(t)^*\right\|_2 \left\|\frac{1}{\sqrt{J}}\mathbf{e}_0(t)\right\|_2 \\ &\le \sqrt{\lambda_{\min}\left(\frac{1}{J}X(t)^*X(t)\right)}\left\|\frac{1}{\sqrt{J}}\mathbf{e}_0(t)\right\|_2 . \end{aligned} \tag{3.5}$$

Then we note by Lemma 2.3 that

$$\Pr\left\{\lambda_{\min}\left(\frac{1}{J}X(t)^*X(t)\right) \ge f_{\min} - \epsilon\right\} > 1 - \delta,$$

where $f_{\min}$ are the maximum and the minimum values of the positive spectral density function $f(\theta)$ of the input stationary process. Combining the above result with Lemma 3.1, we have

$$\Pr\left\{ ||\mathbf{a}(t)||_2^2 \le \sqrt{\frac{\epsilon^2 + \tau^2}{f_{\min} - \epsilon}} \right\} > 1 - \frac{\nu}{J\epsilon^4} - 2\delta, \tag{3.6}$$

where ν is the variance of $e_0(t)$. The theorem follows by using simple probability arguments in (3.6), provided that J is sufficiently large. □

We see from the bound (3.4) that the ℓ_2 norm of the weight-error vector is magnified by the smallest eigenvalue of $X(t)^*X(t)$. Thus the sensitivity of the sliding window RLS algorithm is determined initially by the conditioning of the normal equations matrix $X(t)^*X(t)$.

Next, we consider the average least squares error of the sliding window RLS algorithm. For the sliding window RLS method, we solve the least squares problem (2.4), and thus the average least squares error is given by (2.2). In the following analysis, we let $\zeta(t)$ denote the average least squares error of the sliding window RLS estimate at each step t, i.e.,

$$\zeta(t) = \frac{1}{J}\sum_{j=t-M+1}^{t} |e(j)|^2.$$

Recall that J is the number of data samples taken in the sliding window RLS method at step t. We will show that with probability 1, the average least squares error $\zeta(t)$ is bounded by a constant depending on the variance of the process of the measurement error and the maximum and minimum values of spectral density function $f(\theta)$ of the input process, provided that J is sufficiently large.

THEOREM 3.3. *Let the input process satisfy assumption (A). If the desired response $d(t)$ is given by* (3.1), *then for any given $\epsilon > 0$ and $0 < \delta < 1$,*

$$\Pr\left\{ |\zeta(t)| \le (\tau^2+\epsilon^2)\left(1+\sqrt{\frac{f_{\max}+\epsilon}{f_{\min}-\epsilon}}\right)^2 \right\} > 1-\delta,$$

provided that the number of data samples J is sufficiently large $(J \gg n)$.

Proof. By (3.1) and (3.3), we can write

$$\begin{aligned}
|\zeta(t)| &= \frac{1}{J}\,\|\mathbf{d}(t) - X(t)\mathbf{w}(t)\|_2^2 \\
&= \frac{1}{J}[\mathbf{d}(t) - X(t)\mathbf{w}(t)]^*[\mathbf{d}(t) - X(t)\mathbf{w}(t)] \\
&= \frac{1}{J}\mathbf{e}_0^*(t)\mathbf{e}_0(t) + \frac{1}{J}\mathbf{a}^*(t)X(t)^*X(t)\mathbf{a}(t) + \frac{1}{J}\mathbf{e}_0^*(t)X(t)\mathbf{a}(t) + \frac{1}{J}\mathbf{a}^*(t)X(t)^*\mathbf{e}_0(t) \\
&\le \left\|\frac{1}{\sqrt{J}}\mathbf{e}_0(t)\right\|_2^2 + \left\|\frac{1}{J}X(t)^*X(t)\right\|_2 \|\mathbf{a}(t)\|_2^2 \\
&\quad +2\left\|\frac{1}{\sqrt{J}}\mathbf{e}_0(t)\right\|_2 \left\|\frac{1}{J}X(t)^*X(t)\right\|_2^{\frac{1}{2}} \|\mathbf{a}(t)\|_2 . \qquad (3.7)
\end{aligned}$$

Combining Theorem 3.2, Lemma 2.3, and Lemma 3.1, the theorem follows by considering probability arguments and using (3.7). □

Based on Theorems 3.2 and 3.3, it follows that the sliding window RLS algorithm always converges when the adaptive system is operated in a stationary environment.

4. Numerical experiments. In this section, numerical experiments are reported to illustrate the convergence performance of the FFT-based sliding window RLS algorithm. All the computations are done using Matlab on an HP-715 workstation. We first illustrate the convergence rate of the preconditioned conjugate gradient method by using adaptive finite impulse response (FIR) system identification computations. FIR system identification has wide applications in engineering [13]. Figure 4.1 is a block diagram for the implementation of our algorithm in an adaptive FIR system identification model. The input signal $x(t)$ drives the unknown system to produce the output sequence $d(t)$. We model the unknown system as an FIR filter. If the unknown system is actually an FIR system, then the model is exact.

We apply our method to first and second order autoregressive models as input stochastic processes. The first order autoregressive AR(1) and second order autoregressive AR(2) processes are given by

$$x(t) + \rho x(t-1) = v(t) \quad \text{and} \quad x(t) + \chi_1 x_{t-1} + \chi_2 x_{t-2} = v(t)$$

[22, pp. 238, 241], respectively, where $\{v(t)\}$ is a white noise process with variance η^2. In our tests, we choose the parameters in each input process so that the corresponding spectral density functions $f(\theta)$ are positive and in the Wiener class. The variance η^2 of $\{v(t)\}$ is chosen as 1. The reference (unknown) system is an nth order linear phase FIR filter with

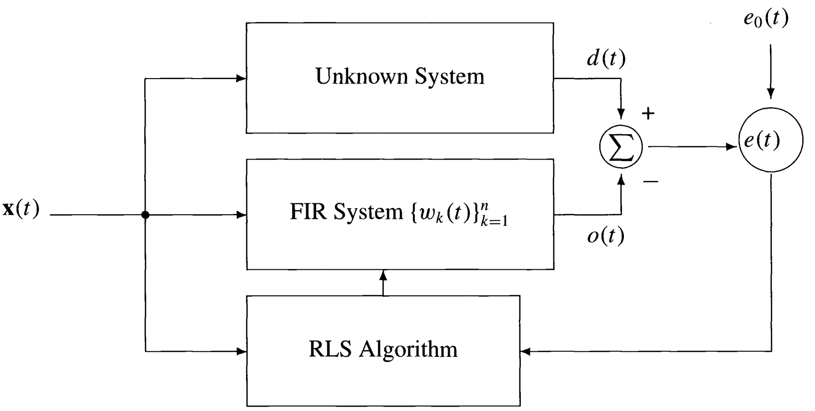

FIG. 4.1. *Adaptive FIR system identification model.*

uncorrelated Gaussian white noise added. The finite impulse response $\{\hat{w}_k\}_{k=1}^n$ used for the unknown system is given by

$$\hat{w}_k = 1.1 - \frac{|2k-n-1|}{n-1}, \quad k = 1, 2, \ldots, n.$$

We note that the shape of the FIR filter is triangular. The Gaussian white noise measurement error $\{e_0(t)\}$ with variance τ^2 is added into the FIR system identification model to test the performance of the RLS algorithm. In the figures below, $N = M/n$ is the number of blocks of the data samples used in data matrix $X(t)$, where the size of each block is equal to n. Recall that M is the length of the sliding window RLS. In the numerical tests, the stopping criterion of the preconditioned conjugate gradient method is that the ℓ_2 norm of the residual vector after j iterations is less than 10^{-7}.

We first consider the number of iterations at each recursive updating and downdating step of the FFT-based sliding window RLS algorithm. We use $k = 1$ as rank numbers for the updating and downdating computations to test our method. Figures 4.2 and 4.3 show the average numbers of iterations of the normal systems and of the preconditioned systems at each adaptive time step, averaged over 20 runs of the algorithm. In the tests, we use zero vector and current filter coefficient vectors as our initial guesses at time step $t = M$ and at time step $t = M + k, M + 2k, \ldots$, respectively. From the numerical results, we see that the conjugate gradient algorithm for our preconditioned systems converges very quickly, and the number of iterations required for convergence is always less than that of nonpreconditioned systems. Figure 4.4 shows how the choice of the initial vectors in the preconditioned conjugate gradient method improves the convergence. In these tests, the current solution vectors and randomly chosen vectors are used as initial guesses at each adaptive time step to test the performance of the algorithm. From the numerical results, we see that when $k = 1$, the reduction in the number of iterations required for convergence in preconditioned systems at each updating and downdating step is significant. However, when $k = n$, the reduction is not as significant as $k = 1$. This trend is not surprising, since $\mathbf{w}(t)$ is expected to be a less effective starting vector at time $t + k$, for larger k.

Next, we consider the ℓ_2 norm of the weight-error vector $\mathbf{a}(t)$ and the average least square error $\zeta(t)$ at each recursive step to test the convergence behavior of our algorithm. Figure 4.5 shows the ℓ_2 norm of the weight-error vector and the average least square error for AR(1) with $\rho = -0.9999$ as input stationary processes at each recursive updating and downdating step. In these cases, the variances of the Gaussian white noise measurement error $\{e_0(t)\}$ are equal

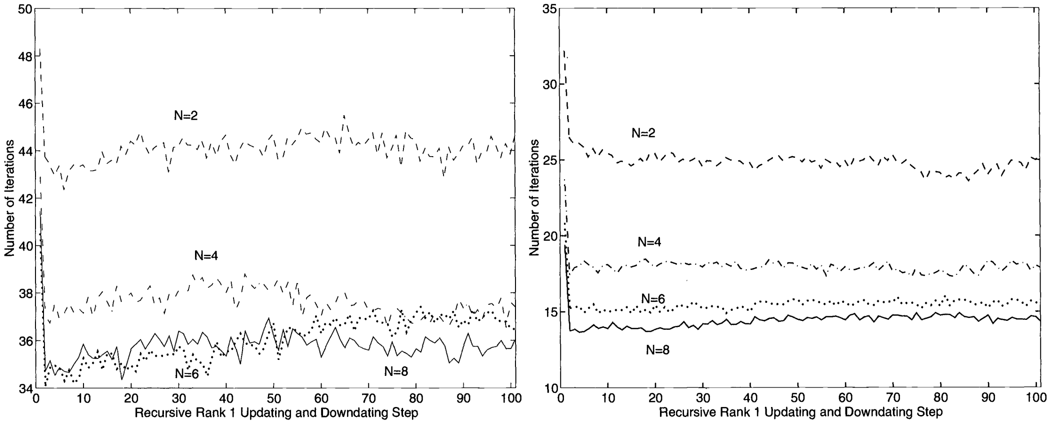

FIG. 4.2. (*Left*) AR(1) *input process when* $n = 32$, $\rho = -0.9999$, *variance of noise* = 0.025, *and no preconditioner is used.* (*Right*) AR(1) *input process when* $n = 32$, $\rho = -0.9999$, *variance of noise* = 0.025, *and FFT-based preconditioner is used.*

to 0.025. We remark that the numerical results are average values based on 20 runs of our algorithm. From the figures, we note that both $||\mathbf{a}(t)||_2$ and $\zeta(t)$ are bounded by a constant depending on the variances of the background white noise. We also see that as $M = N * n$ increases, the average least squares error $|\zeta(t)|$ increases; however, $||\mathbf{a}(t)||_2$ decreases.

The latter phenomenon can be explained by considering the expected value of the weight-error correlation matrix $K(t)$ defined by

$$K(t) \equiv \mathcal{E}(\mathbf{a}(t)\mathbf{a}(t)^*)$$

at step t. Haykin [13, pp. 487–489] proved that the least squares estimator $\mathbf{w}(t)$ is unbiased, i.e.,

$$\mathcal{E}(\mathbf{w}(t)) = \hat{\mathbf{w}},$$

and the expected value of $K(t)$ is given by

$$K(t) = \tau^2[X(t)^*X(t)]^{-1}, \tag{4.1}$$

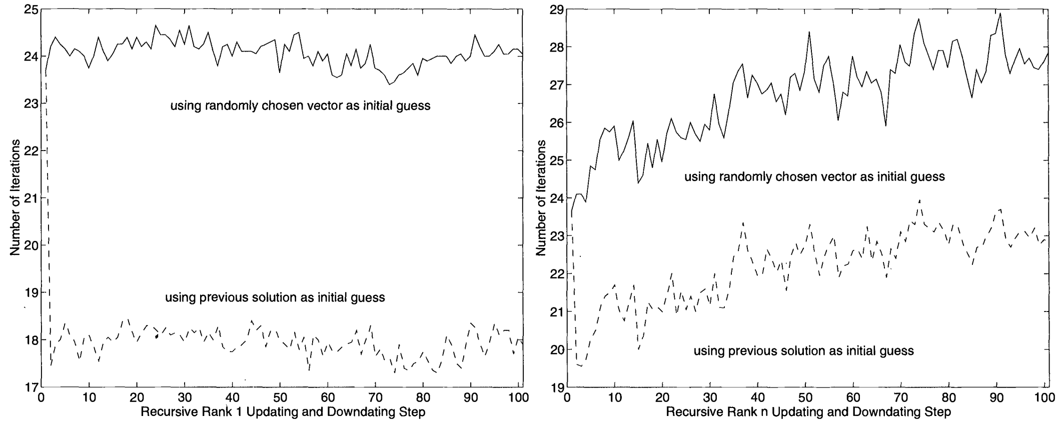

FIG. 4.4. *(Left)* AR(1) *input process when* $n = 32$, $\rho = -0.9999$, *variance of noise* $= 0.025$, *and FFT-based preconditioner is used. (Right)* AR(1) *input process when* $n = 32$, $\rho = -0.9999$, *variance of noise* $= 0.025$, *and FFT-based preconditioner is used.*

where τ^2 is the variance of the measurement error $\{e_0(t)\}$. We can rewrite (4.1) as follows:

$$K(t) = \frac{\tau^2}{J}\left[\frac{X(t)^*X(t)}{J}\right]^{-1}.$$

From Lemma 2.3 we observe that with probability 1, $||K(t)||_2$ is bounded by

$$||K(t)||_2 \le \frac{\tau^2}{J(f_{\min} - \epsilon)},$$

provided that J is sufficiently large. Based on the result about the correlation matrix of the weight-error vector, we will expect $||\mathbf{a}(t)||_2$ to decrease as J increases. Moreover, Figure 4.6 shows the effect of background white noise on $||\mathbf{a}(t)||_2$ and $|\zeta(t)|$. Different levels of variances τ^2 of the Gaussian white noise are used. We see that both $||\mathbf{a}(t)||_2$ and $|\zeta(t)|$ increase as τ^2 increases.

In the following tests we compare our FFT-based sliding window RLS algorithm with standard recursive least squares $O(n^2)$ operations [13, p. 485] and fast transversal filter $O(n)$

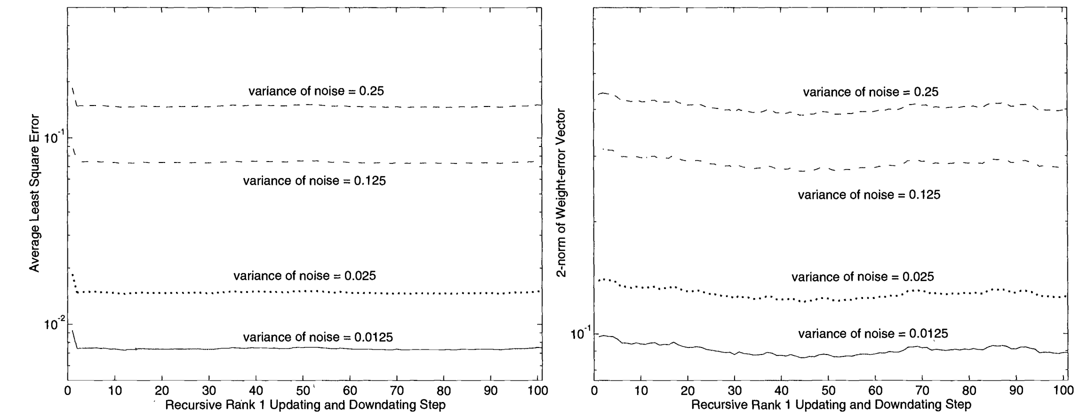

FIG. 4.6. (*Left*) AR(1) *input process when* $n = 32$, $\rho = -0.9999$, *and* $N = 4$. (*Right*) AR(1) *input process when* $n = 32$, $\rho = -0.9999$, *and* $N = 4$.

operations algorithms [13, pp. 586–599]. An exponential weighting factor γ is generally used in the standard recursive least squares and fast transversal filter algorithms. The inverse of $1-\gamma$ is approximately related to a "measure" of the memory of the algorithm. Here, the length of the sliding window M used in our FFT-based sliding window RLS algorithm is related to γ by the approximation formula,

$$M \approx \frac{1}{1-\gamma}.$$

Figures 4.7 and 4.8 show the prior average least squares error $(d(t) - \mathbf{w}^*(t-1)\mathbf{x}(t))^2$ and the ℓ_2 norm of weight-error vector of different adaptive filter algorithms when an AR(1) input process with $\rho = -0.9999$ is used. Different levels of variances of the Gaussian white noise are used to test the performances of different adaptive filter algorithms. We see from Figures 4.7(b) and 4.8(b) that the fast transversal filter algorithm given in [13, pp. 586–599] does not converge when noise is added to the adaptive FIR system. However, both the standard recursive least squares (Figures 4.7(a) and 4.8(a)) and our FFT-based sliding window (Figures 4.7(c) and 4.8(c)) algorithms converge very quickly.

Next, we compare the complexity of our algorithm with the standard recursive least squares algorithm. Figures 4.9 and 4.10 show the number of kilo-flops used by the standard recursive least squares algorithm and the FFT-based preconditioned conjugate gradient method for rank 1, rank 4, rank 10, and rank n recursive updating. We see that when the order of the filter is small, the complexity of our algorithm is greater than that of the standard recursive least squares algorithm. However, when the order of the filter is large, the complexity of our algorithm is quite competitive with the standard least squares algorithm. From Figures 4.9 and 4.10, we note that the reduction in the complexity of our algorithm is significant for rank n recursive updating. Thus our algorithm is particularly useful in signal processing applications where the sizes of the filters are very large. (For example, in the case of acoustic echo or active noise cancellation problems, n is between 250 and 2000, depending on the precise application [17], [20].) In addition, more effective parallel implementations of our FFT-based scheme are possible [21].

Finally, we remark that our FFT-based sliding window RLS scheme also facilitates tracking the smallest and largest eigenvalues of the normal equations matrix $X(t)^*X(t)$ at each time step. The procedure is to determine the optimal circulant approximation to the normal

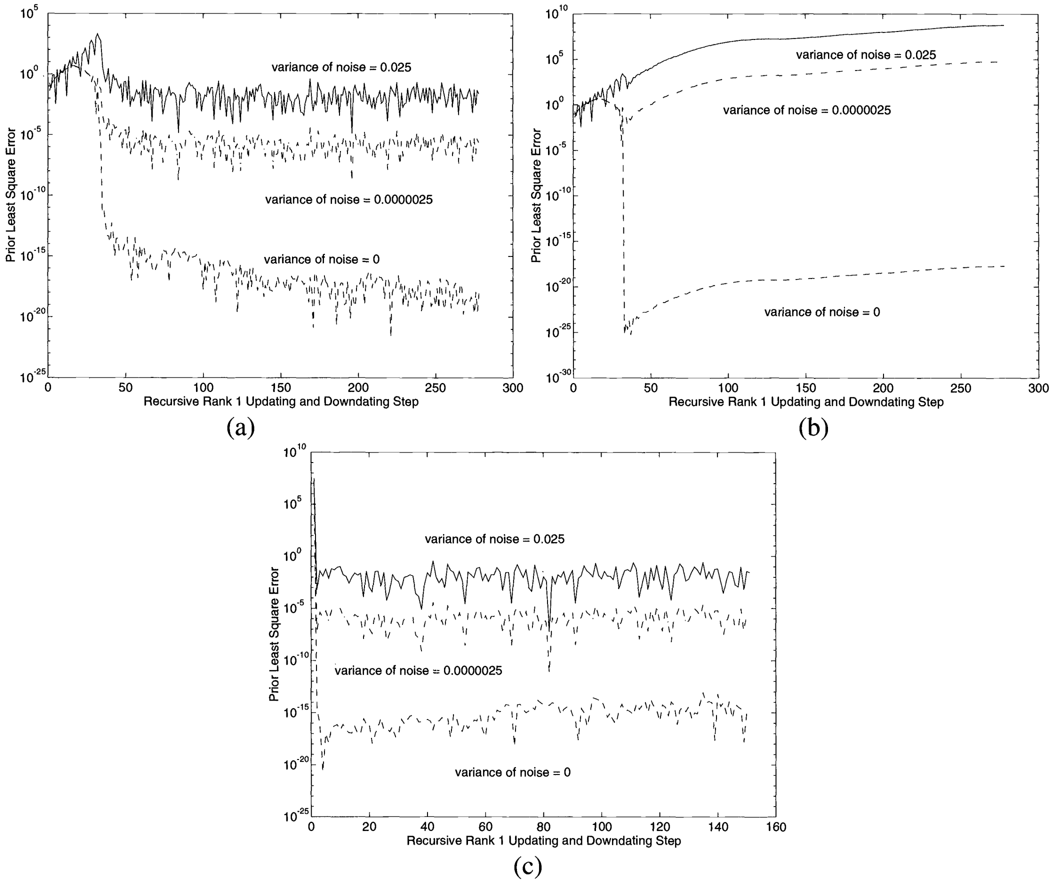

FIG. 4.7. (a) *Standard recursive least squares algorithm with* $\gamma = 0.9922$. (b) *Fast transversal filter algorithm with* $\gamma = 0.9922$. (c) *FFT-based sliding window RLS algorithm with* $N = 4$.

equations matrix. We note that by (2.4) and linearity of the optimal circulant approximation, we have

$$||C - X(t)^*X(t)||_F \leq ||C(t) - T(t)||_F + ||C_L(t) - L(t)^*L(t)||_F + ||C_U(t) - U(t)^*U(t)||_F,$$

where we define

$$C = C(t) - C_L(t) - C_U(t). \tag{4.2}$$

Here circulant matrices $C(t)$, $C_L(t)$, and $C_U(t)$ are the optimal circulant preconditioners of the matrices $T(t)$, $L(t)^*L(t)$, and $U(t)^*U(t)$ respectively. By Lemma 2.1, we have

$$\lambda_{\min}(X(t)^*X(t)) \leq \lambda_{\min}(C) \leq \lambda_{\max}(C) \leq \lambda_{\max}(X(t)^*X(t)). \tag{4.3}$$

By considering the spectral condition number $\kappa(C(t))$, it follows from (4.3) that

$$\kappa(C(t)) = \frac{\lambda_{\max}(C(t))}{\lambda_{\min}(C(t))} \leq \kappa(X(t)^*X(t)), \quad \text{or} \quad \sqrt{\kappa(C(t))} \leq \kappa(X(t)). \tag{4.4}$$

Here $\kappa(\cdot)$ denotes the spectral condition number of a matrix. Thus (4.4) provides a lower bound on the spectral condition number of $X(t)^*X(t)$. For the generation of the circulant matrices

$C_L(t)$ and $C_U(t)$, Chan, Jin, and Yeung [5] have proved that the circulant matrices $C_L(t)$ and $C_U(t)$ can be generated in $O(n \log n)$ operations. It follows that the eigenvalues of C can be obtained in $O(n \log n)$ operations. Consequently, if (4.4) is large, then the data matrix $X(t)$ is ill-conditioned. Regularization schemes can then be used to stabilize the computations in the FFT-based sliding window RLS algorithm if $X(t)$ is ill-conditioned. In particular, Hanke, Nagy, and Plemmons [12] have devised a regularization scheme based on modifying the eigenvalues of $C(t)$ that can be applied to overcome the effects of ill-conditioning in $X(t)$. In addition, other regularization techniques for Toeplitz least squares problems have also been studied by Chan, Nagy, and Plemmons [7, 8]. These approaches using regularization can lead to stable and robust implementations of our FFT-based sliding window RLS algorithm. Figure 4.11 lists the corresponding average spectral condition number of the circulant matrix C and the data matrix $X(t)$ (symbol X) at each recursive updating and downdating step. We note that the condition number for C provides a reasonable lower bound as it adaptively tracks the changes in the condition number of the data matrix at each time step.

5. Concluding remarks. In this paper we have proposed a new FFT-based sliding window recursive least squares algorithm. Preliminary results show that, for many important problems, FFT-based iterative methods can compete with direct methods in an adaptive signal processing environment. A summary of some of these results is also included in [19].

Also, we remark that our iterative FFT-based sliding window algorithm can be adapted to handle two-dimensional (2-D) signal processing applications. Here direct methods are well known to experience numerous difficulties (see, e.g., [13]). Chan, Nagy, and Plemmons [8] have studied block least squares computations, min $\|b - Tx\|_2$, where T is a rectangular Toeplitz-block matrix. They consider there the solution of block least squares problems by the preconditioned conjugate gradient algorithm using square nonsingular circulant-block and related preconditioners, constructed from the blocks of the rectangular matrix T. Preconditioning with such matrices allows efficient implementation using the 2-D FFT. This extends the earlier work on preconditioners for Toeplitz least squares iterations for 1-D problems outlined in §2. Our iterative FFT-based sliding window RLS algorithm described in §3 can thus be applied to 2-D signal processing applications, where the data matrix $X(t)$ generally has a Toeplitz-block structure.

Acknowledgment. We would like to thank the referees for their valuable comments.

A CONVOLUTION ALGORITHM WITH APPLICATION TO DATA ASSIMILATION*

RANJIT M. PASSI†, R. KENT GOODRICH‡, MARK LIMBER‡, AND JOHN C. DERBER§

Abstract. A computationally efficient algorithm to approximate a convolution $w * f$ is derived when the real-valued weighting functions w are dimensionally separable, i.e., $w(x_1, x_2) = w_1(x_1)w_2(x_2)$ and $w(x_k) = w(-x_k)$, and the function $f(i, j)$ is defined on a discrete integer lattice in $\mathcal{R}^2$. The algorithm consists of a product of operator polynomials $P_k(D_k)$, $k = 1, 2$, which are composed of simple averaging operators D_k operating on f. It generalizes the smoothing algorithm of Goodrich, Passi, and Limber [*Proc. 24th Symposium on the Interface: Computing Science and Statistics*, 1992] for data constrained to a uniformly spaced, large-dimensioned orthogonal grid lying in a two-dimensional space, using a Gaussian weighting function $w(r) = \exp(-r^2/b^2)$.

The new algorithm has a direct application to data assimilation problems in meteorology and oceanography. Data assimilation optimally combines output of a numerical model with observational data to derive more accurate initial conditions needed for numerical integration of the model equations. Computer simulations with the algorithm were found to be about ten times faster than a comparable algorithm of Derber and Rosati [*J. Phys. Ocean*, (1989), pp. 1333–1347].

1. Introduction.

Nowcasting and forecasting are important activities in meteorology. Nowcasting combines the output of a numerical forecast model with observations to provide dynamically balanced initial conditions used by the model to calculate the forecast. Now that the numerical models of the general circulation of the ocean have matured, these two activities are playing an important role in oceanography also to provide a realistic description of the various oceanic regions.

To describe adequately the general circulation of the ocean requires a fine spatial resolution and extremely small time steps for model integration. This combination leads to large in-core computer memory and computer processing time for the model integration. In addition, the numerical models have to be coupled with data assimilation schemes to derive accurate initial conditions for computing model forecasts. To make the nowcasting and forecasting practical, it is necessary that numerical modeling and data assimilation schemes be computationally efficient and not require inordinately large computer in-core memories.

The nowcasting step involves two separate operations of (i) optimally melding model output with observations (data assimilation), which is followed by (ii) dynamically balancing the melded output so that transients are not introduced in subsequent model integration. In this paper, we are mainly concerned with data assimilation where one combines the model output with the observations using a linear least squares method. Because of the large dimensions involved, the minimization in the least squares procedure is performed by the method of steepest descent, as it avoids inversion of the covariance matrix Σ_m of the model output (Derber and Rosati [5], hereafter, referred to as DR). The minimization procedure requires several matrix multiplications of the type $\Sigma_m \mathbf{g}$, where Σ_m stays fixed but vector $\mathbf{g}$ is varying. Because the dimensions of Σ_m are large and in-core memory parsimony is a necessity, Σ_m is

not stored in-core. For a Gaussian covariance function, DR developed an algorithm to evaluate $\Sigma_m \mathbf{g}$ that was computationally efficient and avoided a direct evaluation and storage of Σ_m. This was achieved by repeated applications of a Laplacian operator.

In this paper, we develop a new algorithm (the product-polynomial operator (PPO) algorithm) that, while maintaining the accuracy, approximates $\Sigma_m \mathbf{g}$ more efficiently than the Laplacian algorithm; the approximation is affected by applying a product of operators that are polynomials in simple averaging operators. In addition, it is shown to admit, with equal ease and efficiency, a wider class of covariance functions which can be expressed as a product of factors that are even functions in a single dimension. The theory is developed in $\mathcal{R}^2$, but is easily generalized to higher dimensions. Finally, using computer simulations, our approximation is compared with the actual matrix multiplication, $\Sigma_m \mathbf{g}$, and with the DR algorithm.

In §2 we first develop the statistical framework needed to arrive at a common formulation of the optimum interpolation problem, leading to the least squares minimization solution by the steepest descent, iterative process, and the step where the matrix multiplication $\Sigma_m \mathbf{g}$ has to be evaluated. This is followed, in §3, by the development and description of the PPO algorithm for approximating $\Sigma_m \mathbf{g}$, along with a discussion on the determination of the operator-polynomial degrees, approximation accuracy, and implementation procedures. Although our emphasis is on the data assimilation aspect, in §4 we describe some steps that maintain dynamical balance in the different fields and minimize the effects of transients in our ocean data assimilation experiments. Finally, in §5, we present the results of numerical simulations that compare the performance of the PPO and the DR algorithms.

2. Statistical formulation of the data assimilation problem. The purpose of data assimilation is to estimate the true state of the ocean $\boldsymbol{\Theta}$ by combining the model output $\mathbf{T}_m$ and observations $\mathbf{T}_o$. The combined estimator (after dynamic initialization, in some cases; see [4]) is then used as the initial condition for the model integration. The vectors $\boldsymbol{\Theta}$ and $\mathbf{T}_m$ are N-vectors defined on the model grid $\mathcal{G}_m$; the observation vector $\mathbf{T}_o$ is an M-vector defined on the observation grid $\mathcal{G}_o$.

Usually, $M \ll N$, and $\mathbf{T}_o$ alone cannot provide an adequate representation of $\boldsymbol{\Theta}$. Thus, assimilation is performed resulting in initial conditions on $\mathcal{G}_m$, which are used for the numerical integration of the model equations. We assume there exists a mapping such that $\mathbf{D}(\mathcal{G}_m) = \mathcal{G}_o$. Then $\boldsymbol{\Theta}_o$, the true state of the ocean at the observation grid, can be written as $\boldsymbol{\Theta}_o = \mathbf{D}(\boldsymbol{\Theta})$. Often $\mathbf{D}$ is assumed to be a linear mapping so that

$$\boldsymbol{\Theta}_o = \mathbf{D}\boldsymbol{\Theta}. \tag{2.1}$$

The motivation to perform such data assimilation is the assumption that both the model values and the observational data are unbiased estimators of the true state of the ocean, so that the optimal combination of the two will lead to an estimator of $\boldsymbol{\Theta}$, which has a smaller error variance than either of the two. Under the unbiasedness assumption, we can write the following linear model:

$$\begin{pmatrix} \mathbf{T}_m \\ \mathbf{T}_0 \end{pmatrix} = \begin{pmatrix} \boldsymbol{\Theta} \\ \mathbf{D}\boldsymbol{\Theta} \end{pmatrix} + \begin{pmatrix} \mathbf{e}_m \\ \mathbf{e}_0 \end{pmatrix}, \tag{2.2}$$

where $\mathbf{e}_m$ and $\mathbf{e}_o$ are vectors of zero mean, random errors in the model output, and observations, with Σ_m and Σ_o as their respective covariance matrices. It is reasonable to assume that the errors in $\mathbf{T}_o$ and $\mathbf{T}_m$ are statistically independent. Then the least squares solution to the true state $\boldsymbol{\Theta}$ is obtained by minimizing the quadratic functional

$$\mathcal{Q} = (\mathbf{T}_m - \boldsymbol{\Theta})'\Sigma_m^{-1}(\mathbf{T}_m - \boldsymbol{\Theta}) + (\mathbf{T}_o - \mathbf{D}\boldsymbol{\Theta})'\Sigma_o^{-1}(\mathbf{T}_o - \mathbf{D}\boldsymbol{\Theta}), \tag{2.3}$$

where the prime indicates matrix transposition. It is customary to write Q in terms of corrections to the model values

$$Q = \mathbf{T}_c'\Sigma_m^{-1}\mathbf{T}_c + (\mathbf{D}\mathbf{T}_c - \mathbf{T}_{co})'\Sigma_o^{-1}(\mathbf{D}\mathbf{T}_c - \mathbf{T}_{co}), \tag{2.4}$$

where $\mathbf{T}_c = \mathbf{T}_m - \mathbf{\Theta}$ and $\mathbf{T}_{co} = \mathbf{D}\mathbf{T}_m - \mathbf{T}_o$. Ordinarily, this minimization should be quite simple except for the large dimensions of the model grid and hence that of the covariance matrix Σ_m; thus, the routinely used optimization procedures are rendered inadequate, and more efficient minimization algorithms must be devised.

With a given Σ_m, DR gave an efficient, preconditioned conjugate gradient algorithm for minimizing Q, which avoids computing Σ_m^{-1} (also, see [10]). It iteratively reduces the gradient vector $\mathbf{g}$ to zero; i.e.,

$$\Sigma_m^{-1}\mathbf{T}_c + \mathbf{D}'\Sigma_o^{-1}(\mathbf{D}(\mathbf{T}_c) - \mathbf{T}_{co}) \to 0. \tag{2.5}$$

Preconditioning is supplied by the matrix Σ_m. The iteration steps of the conjugate gradient method are as follows. Let $\mathbf{T}_j$ be the iterative solution to $\mathbf{T}_c$ at iteration j. We start with initialization:

$$\mathbf{T}_1 = \mathbf{0}, \tag{2.6a}$$

$$\mathbf{g}_1 = -\mathbf{D}'\Sigma_o^{-1}\mathbf{T}_0, \tag{2.6b}$$

$$\mathbf{h}_1 = \Sigma_m\mathbf{g}_1, \tag{2.6c}$$

$$\mathbf{d}_0 = \mathbf{e}_0 = \mathbf{0}. \tag{2.6d}$$

Then, the iterations are carried out via equations (2.7a)–(2.7h) given below:

$$\mathbf{d}_n = \mathbf{h}_n + \beta_{n-1}\mathbf{d}_{n-1}, \tag{2.7a}$$

$$\mathbf{e}_n = -\mathbf{g}_n + \beta_{n-1}\mathbf{e}_{n-1}, \tag{2.7b}$$

$$\mathbf{f}_n = \mathbf{e}_n + \mathbf{D}'\Sigma_o^{-1}\mathbf{D}\mathbf{d}_n, \tag{2.7c}$$

$$\alpha_n = \frac{\langle \mathbf{g}_n \mathbf{h}_n \rangle}{\langle \mathbf{d}_n, \mathbf{f}_n \rangle}, \tag{2.7d}$$

$$\mathbf{g}_{n+1} = \mathbf{g}_n + \alpha_n\mathbf{f}_n, \tag{2.7e}$$

$$\mathbf{T}_{n+1} = \mathbf{T}_n + \alpha_n\mathbf{d}_n, \tag{2.7f}$$

$$\mathbf{h}_{n+1} = \Sigma_m\mathbf{g}_{n+1}, \tag{2.7g}$$

$$\beta_{n+1} = \frac{\langle \mathbf{g}_{n+1}, \mathbf{h}_{n+1} \rangle}{\langle \mathbf{g}_n, \mathbf{h}_n \rangle}, \tag{2.7h}$$

where n is the iteration index. These steps are repeated until convergence is achieved. The terms involving Σ_o^{-1} in (2.6b) and (2.7c) are easily computed, since the assumption of statistically independent observation errors yields Σ_o and Σ_o^{-1} as diagonal matrices. The major computation is involved in (2.6c) and (2.7g), where the multiplication $\mathbf{h}_{n+1} = \Sigma_m\mathbf{g}_{n+1}$ is carried out.

For most implemented covariance structures, this operation is quite expensive, more so for repeated applications of the operation. In fact, there is a two-fold problem at this step: one is the multiplication operation that we just mentioned; the second is the practical problem of actual storage of the large-dimensioned computed covariance matrix. Although the computed matrix can be stored on a file and read when needed, the input/output operations can result in excessive demand on computer time, especially in repeated applications. Thus, a fast and accurate algorithm must be developed to handle this matrix multiplication operation.

3. Product-polynomial operator algorithm. The DR algorithm alleviates the above difficulties, to some extent, when the covariance structure of Σ_m is based on a Gaussian function

$$e(r) = a\exp(-r^2/b^2). \tag{3.1}$$

$e(r)$ represents the covariance between two model grid values, r is the distance between the two grid points, and b is the correlation length scale. The parameter a represents the error variance of the model values. With (3.1), the matrix multiplication $\Sigma_m \mathbf{g}$ can be expressed as

$$h(m,n) = \sum_s \sum_t g(s,t) a \exp\left[-\frac{(m-s)^2\delta_1^2 + (n-t)^2\delta_2^2}{b^2} \right]. \tag{3.2}$$

The DR algorithm approximates the $h(m,n)$ array via K applications of the operator $\mathcal{L} = (1 + \frac{\nabla^2}{N})$, where ∇^2 is the discrete Laplacian operator and K is an empirically determined, large integer [11].

A close examination of the DR algorithm reveals two possible improvements. The first is to replace the operator $\mathcal{L}^K$ by some other polynomial in ∇^2, $p(\nabla^2)$ that is a better approximation to (3.2) than $\mathcal{L}^K$. If a more accurate approximation is achieved, then it would be possible to pick the degree of p much lower than K, thus saving many computations when computing $p(\nabla^2)$. As we analyze this possibility, we notice the second improvement: since the quantity we are trying to estimate is a convolution product over a discrete space, it should be possible to give an analysis that exploits this fact directly without using continuous approximations that lead to the application of the operator $\mathcal{L}^K$ [11]. We found that, in this new domain analysis, the Laplacian operator could be replaced by a product of polynomials in simple averaging operators. In fact, the implementation of our observations showed that our algorithm is readily adapted to a much more general covariance structure that is (termed as) separable.

DEFINITION. *A real function of several variables $f(x_1, \dots, x_n)$ is* separable *if it can be expressed as a product of factors that are even functions of a single variable*; *i.e., $f(x_1, \dots, x_n) = \prod f_i(x_i)$ such that $f_i(-s) = f_i(s)$ for all s, and f_i are absolutely integrable.*

A referee has provided us with an intriguing insight into looking at the behavior of the Laplacian operator $\mathcal{L}^K$. Using the analogy of the classical differential equation

$$y' = Ay \quad \text{with} \quad y(0) = y_0,$$

the operator $\mathcal{L}^K$ can be seen as a forward Euler approximation to the associated diffusion equation

$$y' = \nabla^2 y.$$

This suggests that the DR algorithm can be made computationally faster by using better integration methods, e.g., the Adams–Bashforth second-order method, and we fully subscribe to the referee's suggestion. In fact, this suggestion opens up the possibility of any number of modifications to the DR algorithm, depending on the order of the Adams–Bashforth method employed. Although we will improve the computing efficiency, we still would not have the enhancements that the PPO algorithm offers, viz, ease of implementation, generalization to a wider class of covariance functions, parallel computing, and better accuracy in the boundary regions.

We shall derive the PPO algorithm in the general framework of computing convolutions using separable smoothing functions. The Gaussian structure in (3.1) forms a special case.

3.1. Preliminaries and notation. For notational convenience, the details of our development are provided in two-dimensional Cartesian coordinates; the results are easily generalized to higher dimensions. The Fourier transform of g will be denoted by $\hat{g}$, and the convolution operation will be denoted by $*$. We will require the covariance functions to be separable, i.e., in two dimensions, $e(s,t) = f_1(s)f_2(t)$ with $f_k(x) = f_k(-x)$.

Let $\mathcal{Z}^2$ be the group of all ordered pairs (m,n), where m and n are integers. Let $L_1(\mathcal{Z}^2)$ be the set of all sequences $\{a_{mn}\}$ such that $\sum\sum |a_{mn}| < \infty$. We define the matrix operator E on $L_1(\mathcal{Z}^2)$ by $E(g)(m,n) = g * e(m,n)$, where e is a fixed element of $L_1(\mathcal{Z}^2)$. It is easily seen that $g * e \in L_1(\mathcal{Z}^2)$. Since $\widehat{g * e} = \hat{g} \cdot \hat{e}$, this suggests using a typical Fourier analysis on the group. With this setup, we can now derive our algorithm.

The matrix multiplication, analogous to (3.2), is written as

$$h(m,n) = \sum_{s,t} g(s,t)e(m-s,n-t) \tag{3.3a}$$

$$= (g * e)(m,n), \tag{3.3b}$$

where $g * e$ is the convolution of the two, two-dimensional arrays [13]. We will exploit to our advantage the following facts that (1) the covariance functions are separable, which leads to their Fourier transform to be functionally separable and real, and that (2) the matrix multiplication operation $E(g)$ is equivalent to a convolution of two, two-dimensional arrays, so that the Fourier transform of $E(g)$ is a product of the Fourier transforms.

3.2. Derivation of canonical forms. The development of the PPO algorithm is aided by deriving two canonical forms that are functionally similar. One canonical form expresses the two-dimensional convolution $h(m,n)$ in the Fourier domain, and the other represents the resultant of when $g(m,n)$ is operated on by the PPO. A comparison of the two expressions leads to the selection of the polynomials that constitute the PPO.

We would like to show that $h(m,n)$ in (3.3a) can be approximated by successively applying yet-to-be-determined polynomial operators $P_1(D_1)$ and $P_2(D_2)$ where D_k, $k = 1, 2$ are the simple averaging operators given by

$$D_1 g(m,n) = [g(m+1,n) + g(m-1,n)]/2, \tag{3.4a}$$

$$D_2 g(m,n) = [g(m,n+1) + g(m,n-1)]/2. \tag{3.4b}$$

The canonical expressions are given in the following theorems.

THEOREM 1. *Let $\hat{g}(\theta,\phi)$ be the two-dimensional Fourier transform of $g(m,n)$. Then*

$$h(m,n) = \int_0^1 \int_0^1 \hat{g}(\theta,\phi) q_1(\theta) q_2(\phi) e^{2\pi i(m\theta+n\phi)} d\theta d\phi, \tag{3.5}$$

where

$$q_k(\theta) = \sum_s f_k(s) \exp[(-2\pi i s\theta)]. \tag{3.6}$$

THEOREM 2. *Let D_k, $k = 1, 2$ be the averaging operators from* (3.4). *Then*

$$P_2(D_2)P_1(D_1)g(m,n) = \int_0^1 \int_0^1 \hat{g}(\theta,\phi) P_2(\cos 2\pi\phi) P_1(\cos 2\pi\theta) e^{2\pi i(m\theta+n\phi)} d\theta d\phi. \tag{3.7}$$

Note that the right-hand sides of (3.5) and (3.7) are similar functional forms. An examination of the two indicates that we could approximate $h(m,n)$ as

$$h(m,n) \simeq P_2(D_2)P_1(D_1)g(m,n), \tag{3.8}$$

provided $P_1(\cos 2\pi\theta) \simeq q_1(\theta)$ and $P_2(\cos 2\pi\phi) \simeq q_2(\phi)$. How good an approximation (3.8) is depends on how well we can approximate q_k by polynomials P_k over the domain of q_k. First, we prove the two results in (3.5) and (3.7).

Proof of Theorem 1. We start by computing the Fourier transform $\hat{e}$ of the covariance function

$$\hat{e}(\theta, \phi) = \sum\sum e(s, t) \exp(-2\pi is\theta - 2\pi it\phi), \tag{3.9}$$

where θ and ϕ are in the interval [0, 1]. Because $e(s, t)$ is separable, we can write

$$\begin{aligned}\hat{e}(\theta, \phi) &= \left(\sum f_1(s) \exp[(-2\pi is\theta)]\right)\left(\sum f_2(t) \exp[(-2\pi it\phi)]\right)\\ &= q_1(\theta)q_2(\phi),\end{aligned}$$

where $q_k, k = 1, 2$ are defined in (3.6). Thus, $\hat{e}(\theta, \phi)$ "separates" as a product of functions in θ and ϕ. So, from (3.3b), we know $\widehat{E(g)}$ is in the transform space. That is,

$$\widehat{E(g)} = \hat{g} \cdot \hat{e} = \hat{g}q_1q_2. \tag{3.10}$$

But, by the Fourier inversion theorem [7],

$$E(g)(m, n) = \int_0^1 \int_0^1 \widehat{E(g)} e^{+2\pi im\theta} e^{+2\pi in\phi} d\theta d\phi. \tag{3.11}$$

Finally, Theorem 1 is proved when $\widehat{E(g)}$ in (3.11) is replaced by the right-hand side of (3.10). □

Proof of Theorem 2. With $\hat{g}$ as the Fourier transform of g, we can write

$$g(m, n) = \int_0^1 \int_0^1 \hat{g}(\theta, \phi) e^{2\pi i(m\theta+n\phi)} d\theta d\phi. \tag{3.12}$$

Applying operator D_1 from (3.4a) to (3.12), we get

$$\begin{aligned}D_1 g(m, n) &= \int_0^1 \int_0^1 \hat{g}(\theta, \phi) \frac{(e^{2\pi i\theta} + e^{-2\pi i\theta})a}{2} e^{2\pi i(m\theta+n\phi)} d\theta d\phi\\ &= \int_0^1 \int_0^1 \hat{g}(\theta, \phi) \cos(2\pi\theta) e^{2\pi i(m\theta+n\phi)} d\theta d\phi.\end{aligned}$$

We note that every time D_1 operates on g, we get an extra factor of $\cos(2\pi\theta)$ inside the integral. Thus, computing $D_1, D_1^2, \ldots$, it is easy to see that an application of the polynomial operator $P_1(D_1)$ yields

$$P_1(D_1)g(m, n) = \int_0^1 \int_0^1 \hat{g}(\theta, \phi) P_1(\cos 2\pi\theta) e^{2\pi i(m\theta+n\phi)} d\theta d\phi.$$

A similar application of operator polynomial $P_2(D_2)$ yields

$$P_2(D_2)g(m, n) = \int_0^1 \int_0^1 \hat{g}(\theta, \phi) P_2(\cos 2\pi\phi) e^{2\pi i(m\theta+n\phi)} d\theta d\phi.$$

Successive application of the two polynomial operators P_1 and P_2 gives the desired expression (3.7), thus, proving Theorem 2. □

If we approximate $E(g)(m,n)$ by $P_2(D_2)P_1(D_1)(g)(m,n)$, then the error is bounded by

$$\begin{aligned}|(E - P_2(D_2)P_1(D_1))g(m,n)| \le \int_0^1 \int_0^1 |\hat{g}(\theta,\phi)| d\theta d\phi \\ \times \sup |q_1(\theta)q_2(\phi) - P_1(\cos 2\pi\theta)P_2(\cos 2\pi\phi)|,\end{aligned} \tag{3.13}$$

where q_k are given by (3.6). Thus, our goal should be to estimate $q_k(\theta)$ by $P_k(\cos 2\pi\theta)$, $k = 1, 2$.

3.3. Polynomial-operator approximations. By (3.6) we have

$$q_1(\theta) = \sum_s f_1(s) \exp[(-2\pi i s\theta)].$$

Using the assumption that f_1 is an even and real function, then

$$q_1(\theta) = \sum_{s\ge1} f_1(s) 2\cos(2\pi s\theta) + f_1(0).$$

Now, we want to pick a polynomial P_1 so that $P_1(\cos 2\pi\theta)$ is a good approximation to $q_1(\theta)$. To more easily compute this polynomial, we make the change of variables $t = \cos 2\pi\theta$, such that t ranges over $[-1,1]$. Thus, we need to compute $T_k = \cos(2\pi k\theta)$ in terms of t. This is easily achieved using the Chebyshev polynomial recursion formula [1, p. 239]. This result implies there exists a kth degree polynomial T_k such that $T_k(t) = T_k(\cos 2\pi\theta) = \cos(2\pi k\theta)$, and

$$T_{k+1} = 2tT_k(t) - T_{k-1}(t), \quad k = 1, 2, \ldots,$$

where $T_0(t) = 1$ and $T_1(t) = t$. We can compute $q_1(\theta)$ for any value of $t = \cos(2\pi\theta)$ using the recursion to compute $\cos(2\pi s\theta)$ in terms of t and adding up enough terms so that the remainder of the terms will be small. This is possible since $f_i(s)$ is absolutely integrable, which implies $\sum_{s\ge0} |f_i(s)| < \infty$.

Now we want to construct P_1 as an approximation to $q_1(\theta)$ considered as a function of t. The idea here is to compute P_1 as an interpolating polynomial on $[-1,1]$ in t. The question is at which points do we interpolate? We use the expanded Chebyshev points [1, p. 244]. These points are

$$x_i = \left[a + b + (a-b)\cos\left(\frac{2i+1}{2n+2}\pi\right) \Big/ \cos\left(\frac{\pi}{2n+2}\right)\right] \Big/ 2, \quad i = 0, \ldots, n,$$

where $a = -1$, $b = 1$. This choice of points gives a nearly optimal polynomial P_1 such that $\max_{-1\le t\le1} |P_1(t) - q_1(t)|$ is nearly minimized [1, p. 243]. At worst, the error is only about four times as great using these points as it would be if we actually found the optimal polynomial. There are algorithms for computing these optimal polynomials, for example, the second algorithm of Remes and the differential correction algorithm [12, pp. 315–320]. We use the expanded Chebyshev points instead because of their simplicity, and because we have not decided what degree polynomial to use. It will be less of a computational effort to determine the degree using the expanded Chebyshev points than if we were to use these more-complicated algorithms to determine the actual best approximation.

Thus, we let $P_1(t)$ be the interpolating polynomial to $q_1(t) = q_1(\theta)$ at the expanded Chebyshev points. The function $q_1(\theta) = q_1(t)$ is computed to ϵ-tolerance by using the Chebyshev recursion formula, and

$$q_1(\theta) \approx \tilde{q}_1(\theta) = f_1(0) + \sum_{s=1}^{s_0} f_1(s) 2\cos(2\pi s\theta), \tag{3.14}$$

where we pick s_0 such that $2\sum_{s=s_0+1}^{\infty} |f_1(s)| \le Tol_1$, where Tol_1 will be determined below.

3.4. Determination of the degree of P_1. To determine the degree of P_1 requires some computational effort. We first determine an error tolerance Tol_2 (given below). We pick n and find the polynomial of degree n that interpolates $\tilde{q}_1(\theta)$ at the expanded Chebyshev points $x_i, i = 0, \dots, n$. We approximate $\|q_1 - P_1\|$ by $\max_{1\leq i\leq 100} |\tilde{q}_1(\theta_i) - P_1(t_i)|$ where t_i are one hundred equally spaced points on [−1,1]. If $\|\tilde{q}_1 - P_1\| \leq Tol_2$, we stop. Otherwise, we increase the degree. We stop if the tolerance is satisfied or if the degree exceeds some predetermined degree. In our simulations with the Gaussian weighting function, this degree stayed below 10. If the degree becomes too large, the computations become numerically unstable, and the algorithm loses its computational advantage. One should also stop if $||\tilde{q}_1 - P_1||$ starts to increase. If the error goal $||\tilde{q}_1 - P_1|| \leq Tol_2$ is not satisfied then an error message is given, and the degree that minimized $||\tilde{q}_1 - P_1||$ is used. Assuming the error goal is achieved, we have $||q_1 - P_1|| \leq ||q_1 - \tilde{q}_1|| + ||\tilde{q}_1 - P_1|| \leq Tol_1 + Tol_2 = Tol_3$. A similar analysis holds for q_2 and P_2 with $||q_2 - P_2|| \leq Tol_3$.

3.5. Determination of error tolerances. To determine the error tolerances above, we need to keep in mind the goal of making

$$|E(g) - P_2(D_2)P_1(D_1)g(m,n)| \leq \epsilon \quad \forall\ (m,n) \in \mathcal{Z}^2,$$

where ϵ is given. Note ϵ should not be chosen much smaller than the expected error in one's measurements. To determine Tol_1, Tol_2, we need an approximate error estimate

$$\begin{aligned}|E(g) - P_2(D_2)P_1(D_1)g(m,n)| &\leq \int_0^1 \int_0^1 |\hat{g}(\theta,\phi)| d\theta d\phi \|q_1 q_2 - P_1 P_2\| \\ &\leq (M_1 Tol_3 + M_2 Tol_3)||\hat{g}||_1,\end{aligned}$$

where $||\hat{g}||_1 = \int_0^1 \int_0^1 |\hat{g}(\theta,\phi)| d\theta d\phi$, and $M_k = ||q_k||$ (sup-norm). We have also approximated $||P_2|| \approx M_2$. We can estimate $||q_k|| \leq |f_k(0)| + \sum_{s\geq 1} 2|f_k(s)|$, $k = 1, 2$. One can also show that $||\hat{g}||_1 \leq ||g||_1$. Now, if $||g||_1$ is large, the above error estimate is too conservative to be of any use. Instead of an arbitrary g, we choose the special case of $g = \delta_{s,t}$, which is one at (s,t) and zero at all other points. Then $||g||_1 = 1$, and we need to make $Tol_3 \leq \frac{\epsilon}{M_1+M_2}$ and pick $Tol_1 = Tol_2 = \frac{Tol_3}{2}$. This is justified since

$$g(m,n) = \sum_s \sum_t g(s,t)\delta_{s,t}(m,n); \tag{3.15}$$

i.e., $g = \sum_s \sum_t g(s,t)\delta_{s,t}$ and

$$E(g) = \sum_s \sum_t g(s,t)E(\delta_{s,t}). \tag{3.16}$$

So, if we approximate $E(\delta_{s,t})$, we have a good approximation to $E(g)$. In our simulations, the above strategy has worked well. Other error estimates are too pessimistic and, hence, require much more computational effort.

3.6. What to do at the boundary. In practice, data are missing from some finite set. We set this missing data to zero. This is justified since the convolution product contains only nonzero data. The algorithm is applied in one dimension at a time. Each row can be done independently. This means many of these computations can be done in parallel. The nonzero values in the data propagate into the missing data, one unit on each end of a fixed data line, each time we apply D_k. Thus, we need to add temporary memory of size $2n_k$, where n_k = degree of polynomial P_k, $k = 1, 2$. We only need to start the computations at a point once there is a nonzero value on either side of the point.

3.7. Computational effort. When we interpolate q_k at the expanded Chebyshev points $x_0, \dots, x_n$, we obtain a polynomial P_k in Newton form [1, pp. 40–44]

$$P_k(x) = a_0 + a_1(x - x_0) + a_2(x - x_0)(x - x_1) + \cdots + a_n(x - x_0)\dots(x - x_{n-1}).$$

Replacing x by D_k, we need to compute

$$P_k(D_k) = a_0 + a_1(D_k - x_0) + a_2(D_i - x_0)(D_k - x_1) + \cdots + a_n(D_k - x_0)\dots(D_k - x_{n-1}).$$

We evaluate this in Newton nested form, just as we do for a polynomial. Thus, a typical step in this evaluation is to compute $k_1 I + k_2(D - k_3 I)$ where I is the identity operator. One application of such an operator at a grid point requires three multiplications and two additions. Evaluating D requires one more addition and a division by 2 (a shift register, so we will not count this operation). Thus, one step in the nested evaluation is six arithmetic operations—three multiplications and three additions. We do this at each point of the grid. We do this operation n_i times (degree of P_i). Let N be the total number of points on the grid. We can either add $2n_i$ points to the data points or ignore the calculations at the boundary if the degree is small compared with the length of the line. So, we have $6n_i N$ operations so far. After we have computed $P_1(D_1)$, we compute $P_2(D_2)$. So, we have a total of $6N(n_1 + n_2)$ arithmetic operations $(O(N))$. Thus, if the degrees of n_1 and n_2 are fairly small, we have an efficient algorithm. If n_1 and n_2 are large, then there are too many computations, and the numerical stability is a problem. The key question is how large are these degrees? It is thus important not to make unreasonable error requirements.

Additional remarks. This technique fits into the general philosophy found in [14] and references therein. One estimates in an optimal way the response function q_k by selecting coefficients of a filter to best estimate q_k in the infinity (sup-norm) norm. Our algorithm exploits this idea by using a polynomial in the simple averaging operators (filters).

4. Steps for dynamical balance.

In ocean modeling, it is possible to assimilate observational data on any of the fields of temperature, salinity, current velocities, and sea surface elevation. The problem of dynamical imbalance occurs when available observations for assimilation do not include every field. In addition, if the observations provide only a partial spatial coverage and/or if they are too different from the model output, it is possible develop an imbalance. As a counterbalance, "transients" or "gravity waves" are generated, which could lead to model instability.

To avoid generation of the transients, as an additional step, a dynamic initialization is often performed in atmospheric data assimilation [2, 3]. However, using the following conservative steps, such initialization has not been necessary in our ocean data assimilation experiments.

4.1. Assign more weight to model output versus observations. If initially the observations are significantly different from the model output, it is advisable that data be injected into the system without any undue shock. This is achieved by assigning to the model output relatively more weight than the observations. For this, instead of (2.3), we minimize the quadratic functional

$$(4.1) \qquad \mathcal{Q}_\alpha = \alpha(\mathbf{T}_m - \boldsymbol{\Theta})'\Sigma_m^{-1}(\mathbf{T}_m - \boldsymbol{\Theta}) + (\mathbf{T}_o - \mathbf{D}\boldsymbol{\Theta})'\Sigma_o^{-1}(\mathbf{T}_o - \mathbf{D}\boldsymbol{\Theta}).$$

Thus, if we assign 10-to-1 weighting in favor of model output then $\alpha = 10$. Such a weighting will gently nudge the model integration toward the observations. Once the model has adjusted to the observations, the weighting factor α can be modified to an appropriate level.

4.2. Incorporate temporal data window. The effect of data shock can be mitigated by letting the data gradually affect the model dynamics. This is done by implementing a temporal weight factor that gradually allows the data to phase in and out of the window. For instance, DR used a thirty-day triangular window where the weight changes from 0 to 1 and from 1 to 0 as the difference in time between the model and the observation goes from -15 to 0 to $+15$. This temporal window acts as a temporal filter reducing the effect of high frequency data. In fact, due to ocean dynamics such implementation is actually advantageous when comparing the large spatial and time scales with the atmosphere. The length of the temporal window depends on the temporal scales that need to be resolved.

4.3. Increase frequency of assimilation. Imbalance between different fields can be avoided by also increasing the frequency of assimilation. By inserting the temperature data continuously, DR allowed the velocity field to adjust to the density field and noted no adverse effect due to transients except perhaps in the data-sparse equatorial regions. In their assimilation of satellite sea surface elevation data, Ezer and Mellor [6] also found no velocity imbalance with continuous data insertion. However, in their earlier experiments with a larger time between assimilation of sea surface elevation data, Mellor and Ezer [9] had to perform a geostrophic adjustment to the velocity field.

5. Efficiency comparisons. In order to assess accuracy and efficiency of our approximation, we ran three test cases to compute the convolution $E(g)$ given by

$$E(g)(m,n) = \sum_s \sum_t g(s,t) \exp[(-(m-s)^2\delta_1^2 - (n-t)^2\delta_2^2)/b^2], \tag{5.1}$$

with an elliptical Gaussian smoothing function. We implemented two pieces of code in portable FORTRAN and tested the algorithm performance on the CRAY YMP: the first routine, called matrix-mult, performs the actual calculations of the convolution in (5.1) and the second approximates $E(g)$ with the PPO algorithm. We used the first as a basis from which to judge the accuracy of the second, and to compare it with the accuracy of the DR algorithm, which is our de facto standard.

For the first test case, we recall our basis representation (3.15) of the $g(m,n)$ array in terms of the Kronecker delta function. It is clear from (3.16) that to approximate $E(g)$ we must be successful in approximating $E(\delta_{s,t})$ at all (s,t). We choose a uniform grid with a rectangular boundary and approximate $E(\delta_{s,t})$ at three representative locations: the center of the grid, a corner, at the middle point of a side. The three sub-cases will demonstrate the capability of our algorithm at selected, isolated points. In the next test case, we want to test the PPO algorithm performance over a region enclosed by an irregular boundary. Because of our data assimilation interest, the Gulf of Mexico (GOM) boundary was selected for this case, and for an overall picture, we set $g = \sum_s \sum_t \delta_{s,t}$, i.e., $g(s,t) = 1$, at all points of a uniform grid over the region enclosed by the GOM boundary. Finally, as the third case, we test the PPO algorithm performance in an actual data assimilation experiment over the GOM region.

Because the evaluation of the Laplacian ∇^2 at the grid point (i,j) requires information at both $(i \pm 1, j)$ and $(i, j \pm 1)$, the DR algorithm cannot be applied at any point on the boundary. Thus, in choosing the three points for simulations with the Kronecker delta function, we moved three grid spacings inward from the boundary. Also, in order to make a comparison with the DR algorithm, the results from DR had to be normalized to bring its maximum amplitude to the level of the matrix-mult algorithm. In all cases, the grid used was an 86×62 grid, which conformed to the grid dimensions used in the actual data assimilation experiment.

While implementing the PPO algorithm, the number of terms s_0 retained in $\tilde{q}_1$ and $\tilde{q}_2$ in (3.14) are calculated as functions of the grid spacing, a preset tolerance ($Tol = 0.001$),

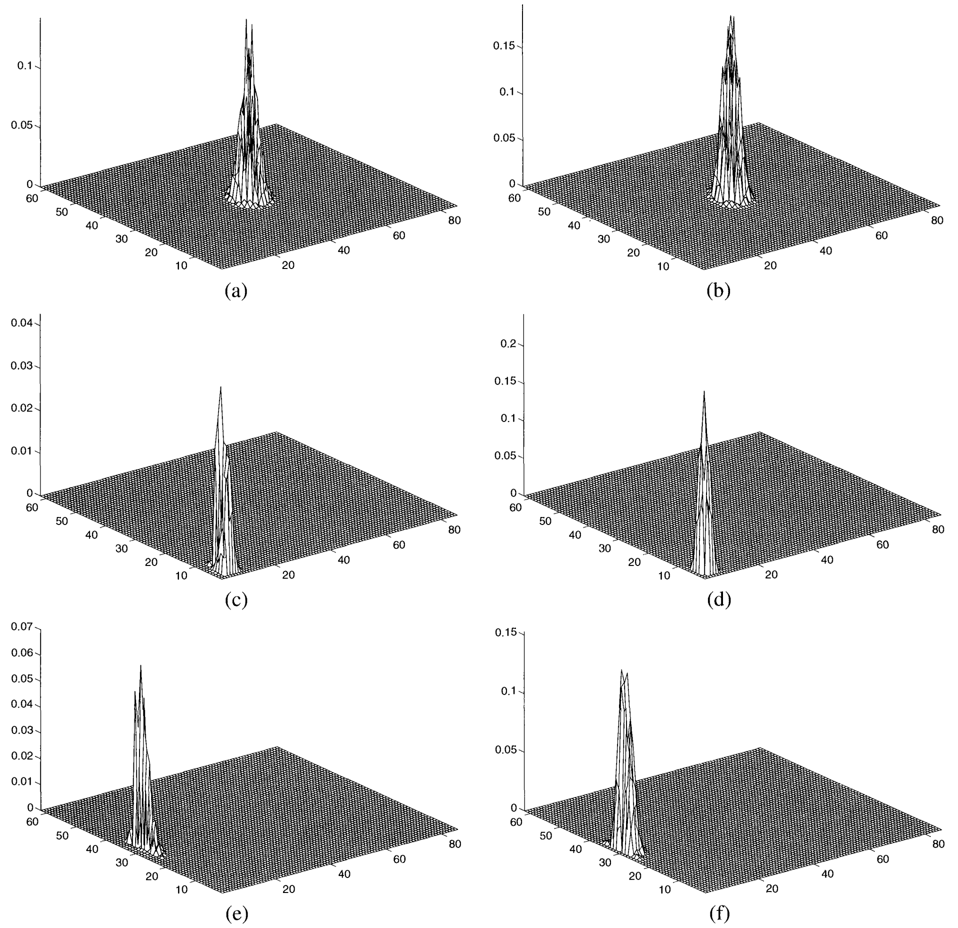

FIG. 1. *Test case* 1. *Gaussian convolution of delta functions at three strategic points—the middle, a corner, and the middle of a side—of a rectangular domain. The results are presented as differences of the PPO and DR algorithms from the matrix-mult algorithm.*

and the scale parameter b as specified for matrix-mult. Explicitly, we set the s_0 such that $|\exp(-s_0^2\delta_k^2/b^2)| \leq Tol$; i.e.,

$$s_0 = \text{int}\,[\sqrt{-\ln(Tol)}/(\delta_i/b)] + 1, \tag{5.2}$$

where int(*) is the greatest integer function. For both $\tilde{q}_k$, (5.2) gave $s_0 = 7$. This led to the Chebyshev polynomials P_k of degree 8 that uniformly approximated the $\tilde{q}_k$'s with an error of 0.000186.

For the first two test cases, the results due to the three algorithms are so similar that it was difficult to tell the differences. Thus, as suggested by a referee, we present the results as differences from the matrix-mult algorithm. Figure 1 shows the results of approximating convolution with the delta function. At the center $(s, t) = (43, 31)$, both the PPO and the DR algorithms exhibit the maximum error around 0.15 (Fig. 1a). However, the PPO algorithm improves at the corner $(s, t) = (3, 3)$ with a maximum error of ~ 0.03, which compares with ~ 0.2 in the DR algorithm (Fig. 1b). The PPO algorithm shows a similar gain in accuracy at the middle of a side of the boundary $(s, t) = (3, 31)$ where PPO versus DR algorithm maximum errors are 0.07 to 0.15 (Fig. 1c).

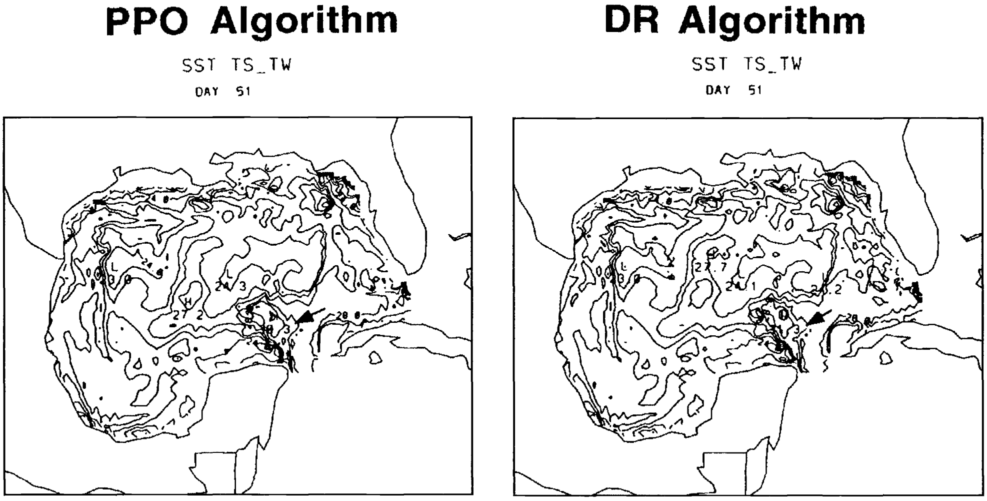
FIG. 2. *Test case 2. Gaussian convolution of $g(s,t) = 1 \; \forall \; s,t$ on an irregular domain provided defined by the Gulf of Mexico topography. The results are presented as differences of the PPO and DR algorithms from the matrix-mult algorithm.*



PPO Algorithm

DR Algorithm

FIG. 3. *Test case 3. Sea-surface temperature from a data assimilation experiment using the PPO and DR algorithms. To the accuracy of the map, the matrix-mult algorithm results (not shown) matched the PPO algorithm. The arrow indicates notable differences between the two algorithms.*

The results from the Kronecker delta simulations indicate that the PPO algorithm should perform well over all points (as was expected from our theoretical analysis), while the DR algorithm may perform poorly over the boundary regions. This fact is borne out in the second test case (Fig. 2). The PPO and DR algorithms perform equally well in the interior of the grid. However, around the boundaries the average PPO errors are around 0.1, while the average errors due to the DR algorithm is around 0.5; the maximum errors are 0.3 for PPO and 0.8 for the DR algorithm.

Finally, to test the performance of the PPO algorithm in a full data assimilation mode, a primitive equation numerical model of the GOM was integrated for forty days without data assimilation, followed by a ten-day integration with assimilation of vertical temperature profile data. The DR algorithm was also tested for comparison using $K = 320$ repeated applications of the Laplacian operator on the same set of data. The model employed a 86×62 grid. The resultant sea-surface temperatures are shown in Fig. 3. To the accuracy of the map, the PPO and matrix-mult algorithms provided identical results; only the PPO algorithm results are shown. While there is a remarkable similarity between the PPO and DR algorithm results, there is noticeable deviation at the location indicated by arrows. The DR algorithm produces a high of 31.3 degrees instead of 30.3 degrees by the PPO (and matrix-mult) algorithm.

In addition, the PPO is quite fast. For a single convolution approximation (matrix multiplication) on a single CRAY YMP processor with "real" data on a 86 × 62 grid, the PPO algorithm takes approximately 0.09 seconds and the DR algorithm takes 2.2 seconds, as compared with 15.4 seconds with matrix-mult. For a comparison of computation times in the full data assimilation mode, the DR algorithm took 6.87 seconds per assimilation step using a single CRAY YMP processor versus .68 seconds with the PPO algorithm. We hasten to add here that the DR algorithm when modified with the Adams–Bashforth second-order method would probably be quite competitive with the PPO algorithm. In the present form, the DR algorithm could be made faster by using values of K somewhat smaller than 320 used in the simulations. However, in our test runs with smaller values, the model integration was unstable.

6. Concluding remarks. We have formulated the problem of data assimilation in terms of a statistical linear model, where the true state of the ocean/atmosphere is estimated by minimizing a quadratic functional. Matrix multiplication $\Sigma_m \mathbf{g}$ is identified to be the major computational bottleneck, where Σ_m is a fixed covariance matrix based on some covariance formulation and $\mathbf{g}$ is a multidimensional, varying vector defined on a specified uniform rectangular grid.

Although, our initial thrust was to improve the efficiency of the DR algorithm based on Gaussian covariance functions, we have made several generalizations:

1. Identify that $\Sigma_m \mathbf{g}$ is a convolution and, thus, express it in the spectral domain (3.5).
2. Identify simple averaging operators (3.4) and show their ability to smooth with a wider class of covariance functions characterized by the separability property; Gaussian covariance functions are an obvious case of separable functions.

The overall effect is that, for computing convolutions, we have come up with a simple, elegant, and efficient algorithm that supports a wider class of covariance structures that may be encountered in the physical sciences. However, the utility of the enhancement to a wider class of covariance functions is yet to be explored. Whereas the Gaussian functions fall into this class quite naturally, the other covariance structures do not appear to be amenable to factorability.

Although, the derivation is carried out in two dimensions, its extension to higher dimensions is obvious. Our Fourier transform pair in one dimension is the integers and the circle group. In higher dimensions, we take the corresponding product of these groups as our Fourier pair.

The algorithm is efficient if one of the functions remains fixed and the convolution is computed many times. This is because we must construct a polynomial fit to a Fourier transform of the fixed factor. If we are able to find a fit within our error tolerance with a low-degree polynomial, then we are able to efficiently and accurately estimate the convolution with our polynomial fit applied to a simple averaging operator.

Acknowledgments. The authors thank the reviewers for their constructive comments. The advice on looking at the DR algorithm in terms of a solution to the diffusion equation was greatly appreciated.

A GENERAL HEURISTIC FOR CHOOSING THE REGULARIZATION PARAMETER IN ILL-POSED PROBLEMS[*]

MARTIN HANKE[†] AND TOOMAS RAUS[‡]

Abstract. For a variety of regularization methods, including Tikhonov regularization, Landweber iteration, ν-method iteration, and the method of conjugate gradients, we develop and illustrate a heuristic for choosing an appropriate regularization parameter. Our choice requires no particular a priori knowledge, since the parameter is determined from computable information only. However, if an estimation for the noise level in the data is at hand, then this can be used as a justification. In contrast to known parameter choice heuristics, a posteriori error estimates for the computed approximations can be given. Numerical examples show that the new parameter choice rules are promising alternatives to known parameter choice rules.

Key words. ill-posed problems, Tikhonov regularization, iterative regularization, conjugate gradients, a posteriori parameter choice

AMS subject classification. 65J10

1. Introduction.

We consider regularization methods for the solution of the ill-posed linear equation

$$Tx = y, \tag{1.1}$$

where T is a bounded operator between Hilbert spaces $\mathcal{X}$ and $\mathcal{Y}$, and y belongs to the range $\mathcal{R}(T)$. We are interested in the solution $x = T^\dagger y$ of (1.1) of minimal norm; here, $T^\dagger$ is the Moore–Penrose generalized inverse of T. Recall that this problem is called ill posed when there lacks a continuous dependency $y \mapsto x$. This is known to be the case if and only if the range of T is nonclosed in $\mathcal{Y}$. As a matter of fact, if only approximate data $\tilde{y} \in \mathcal{Y}$ are given, any straightforward numerical computation of x is unstable (for finite-dimensional discretizations, this will be reflected by large condition numbers of the corresponding matrices).

Ill-posed equations (1.1) arise frequently in the context of *inverse problems*, where it is the aim to recover unknown parameters of a physical system from measurable data. A typical example (although nonlinear) is the determination of the interior conductivity of a medium from measured flux at its boundary; see Engl [3] for several other examples arising in industrial applications.

For a stable numerical approximation of the solution x of (1.1) some regularization technique has to be applied. We refer to the survey [11] for a discussion of different possibilities for incorporating regularization and their algorithmic implementation. Roughly speaking, a regularization method provides a sequence of approximations $\{x_r\}_{r \geq 0}$, with x_0 being some initial guess and $x_r \to T^\dagger y$ as $r \to \infty$, provided exact data $y \in \mathcal{R}(T)$ are available. In general, however, approximate data $\tilde{y}$ do not belong to the domain of $T^\dagger$, in which case $\|x_r\|$ diverges to infinity as $r \to \infty$. Thus, we are left with the important problem of choosing an appropriate regularization parameter r. When r is too big, the numerical implementation will be unstable and x_r will be useless; when r is too small, the approximation x_r is dominated by the initial guess.

Essentially, two types of methods for choosing the regularization parameter r can be distinguished: rules which use information about the noise level $\delta = \|y - \tilde{y}\|$, and rules which do not use such information. The former ones associate each approximation x_r with some positive number η_r (think of the residual norm $\|\tilde{y} - Tx_r\|$, for example), and the regularization

[‡] Department of Mathematics, Tartu University, EE–2400 Tartu, Estonia (yrmitrØ@raud.ut.ee).

parameter $r = r(\delta)$ is chosen such that $\eta_{r(\delta)}$ has about the order of the noise level. Given that the sequence $\{\eta_r\}$ satisfies certain assumptions, convergence of the approximations follows, i.e., $x_{r(\delta)} \to T^\dagger y$ as $\delta \to 0$. Moreover, convergence rates may be derived for the case when the solution $T^\dagger y$ has additional properties. It is clear, however, that the accuracy of these rules depends on precise knowledge of $\|y - \tilde{y}\|$.

The second type of parameter choice rules, on the other hand, seeks to avoid any a priori information, including the noise level. In other words, the chosen regularization parameter $r = r(\tilde{y})$ depends solely on the given data $\tilde{y}$. Typically, these methods are based on a heuristic estimation of the unknown error $\|T^\dagger y - x_r\|$, in one way or the other. Thus we shall speak of *heuristic parameter choice rules* for this type of method below. In practice, such heuristic rules are often the only possibility, because at most only a rough guess of the noise level is usually known. Although these methods often work as well as, or even better than, the rules using information about the noise level (cf. [11] for computational results and comparisons), it was shown by Bakushinskii [1] that no convergence theory as above (i.e., as $\delta \to 0$) can exist for heuristic parameter choice rules. In other words, there always exist "bad" right-hand data $\tilde{y}$ converging to y, for which the corresponding approximations $x_{r(\tilde{y})}$ *fail to converge* to $T^\dagger y$. Because of Bakushinskii's negative result, mathematicians sometimes hesitate to trust heuristic parameter choice rules.

To overcome these concerns we suggest in the following a new methodology for deriving heuristic parameter choice rules for the most important regularization methods. To our knowledge, for each regularization method the resulting algorithm is new, although some similarities to known algorithms may exist. Our approach is based on a very general observation in connection with our experience with so-called order-optimal parameter choice rules (cf. Definition 2.1 below), which preassume knowledge of $\|y - \tilde{y}\|$. In fact, the suggested heuristic rules are always deduced from known and established order-optimal ones. In this way, we are able to derive error bounds for the resulting approximations $x_{r(\tilde{y})}$. A by-product of each new rule is an estimate for $\|y - \tilde{y}\|$. This allows a simple a posteriori check of our parameter choice: if the estimate of the noise level is presumably too small, the regularization parameter should be discarded, and some other parameter choice rule should be used instead.

We emphasize, however, that *no* rule for choosing the regularization parameter in ill-posed problems, and in particular no heuristic rule, should be considered a "black box routine." One can always construct examples where the chosen regularization parameter is far from optimal.

The outline of this paper is as follows. In §2 we motivate our basic idea and present the resulting parameter choice rules for some of the most important regularization methods, namely for Tikhonov regularization, Landweber iteration, and ν-method iteration. In §3, we choose a common framework for the analysis of these regularization methods and derive the theoretical estimates. One of the most important regularization methods is the method of conjugate gradients (CG), because it can be very efficient for large-scale problems. Our algorithm and the theoretical results carry over to this method; see §4. This is probably the most important practical consequence of our general approach, because so far there exist only very few reliable parameter choice rules (i.e., stopping rules) for CG. After a brief comment on some modifications for the discrete setting, we provide some numerical results in §6.

2. Examples. Let us start with a few preliminary remarks. First, we restrict ourselves to problems with $\|T\| \leq 1$. This can be done without loss of generality, since otherwise we simply rescale (1.1). Given perturbed data $\tilde{y}$ with

$$\|y - \tilde{y}\| \leq \delta,$$

the exact solution $T^\dagger y$ can only be approximated within limited accuracy. It is thus a natural approach to ask for approximations that converge to $T^\dagger y$ as quickly as possible as $\delta \to 0$. In this context, we review some results from the literature; cf., e.g., Vainikko and Veretennikov [20] or Louis [14].

DEFINITION 2.1. *Given $\mu > 0$, a parameter choice rule for a regularization method is said to be* order-optimal *(for μ), if the regularization parameter $r = r(y, \tilde{y})$ is chosen in such a way that for some $c > 0$ the error bound*

$$\|T^\dagger y - x_{r(\delta)}\| \leq c\,\delta^{2\mu/(2\mu+1)}\omega^{1/(2\mu+1)} \tag{2.1}$$

holds, whenever $\|y - \tilde{y}\| \leq \delta$ and

$$T^\dagger y - x_0 = (T^*T)^\mu w, \qquad \|w\| = \omega. \tag{2.2}$$

In ill-posed problems T is usually a smoothing operator, hence condition (2.2) corresponds to a certain degree of smoothness of $T^\dagger y - x_0$. It can be shown (cf. [20, 14]) that the exponents on the right-hand side of (2.1) are the best possible under these conditions. Note the loss of information: $T^\dagger y$ can only be approximated within an accuracy of some fractional power of δ. The larger μ is, i.e., the better x_0 approximates the nonsmooth parts of $T^\dagger y$, the better $T^\dagger y$ can be approximated.

The maximum, μ_0 say, of all admissible μ in (2.1) depends on the particular regularization method. We call μ_0 the *qualification* of the method (cf. [20]), and we are only interested in parameter choice rules which are order-optimal for μ_0.

We emphasize that the order-optimal parameter choice rules that we present below are all a posteriori in nature. Besides δ, no further information is required. In particular, we do not need to know whether some condition like (2.2) holds. The point is that *if* such a condition is satisfied *then* we obtain an approximation with order-optimal accuracy, without modifying the algorithm. Let us give some examples.

2.1. Tikhonov regularization. The most well-known regularization technique is Tikhonov regularization; cf. Groetsch [6]. Here, x_r is determined as the minimizer of

$$\|\tilde{y} - Tx\|^2 + \frac{1}{r}\,\|x - x_0\|^2$$

over $x \in \mathcal{X}$. This yields

$$x_r = x_0 + (T^*T + r^{-1}I)^{-1}T^*(\tilde{y} - Tx_0).$$

The qualification of Tikhonov regularization is $\mu_0 = 1$. The *discrepancy principle* is a parameter choice rule, which is order-optimal for $0 < \mu \leq 1/2$; cf. [6]. A parameter choice rule which is order-optimal for all $0 < \mu \leq 1$ has been developed independently by Raus, Engl, and Gfrerer; cf. [17, 5, 4]. It requires that we apply one step of iterative refinement to x_r (cf. [11, Alg. 5.2]),

$$z_r = (T^*T + r^{-1}I)^{-1}T^*(\tilde{y} - Tx_r), \qquad x_r^{\mathrm{II}} = x_r + z_r\,,$$

and that we subsequently determine

$$\eta_r := \langle \tilde{y} - Tx_r^{\mathrm{II}}, \tilde{y} - Tx_r\rangle^{1/2}.$$

Note that x_r^{II} is sometimes called iterated Tikhonov approximation. Given fixed $\tau > 1$, the regularization parameter $r = r(\delta)$ is defined to be the smallest number for which $\eta_r \leq \tau\delta$ holds.

If (2.2) is fulfilled for some $\mu \leq \mu_0$, then the error analysis in [17, 5, 4] shows that for $r > 0$¶

$$\begin{aligned} \|T^\dagger y - x_r\| &\leq c\big((r+1)^{-\mu}\omega + r^{1/2}\delta\big), \\ \eta_r &\leq c\big((r+1)^{-\mu-1/2}\omega + \delta\big). \end{aligned} \tag{2.3}$$

Note that this gives a sequence of bounds corresponding to the continuous range of parameters μ in (2.2). It can further be shown that the upper bounds in (2.3) are the best possible in the sense that there are converse results which specify a sort of one-to-one relation between the exponent μ in (2.2) and the powers $-\mu$ and $-\mu - 1/2$ in (2.3); cf. [6, §3.2] and [16]. In other words, we can expect the sequences $\|T^\dagger - x_r\|$ and η_r to behave asymptotically *like* the right-hand sides of (2.3), where the parameter μ in (2.3) is the supremum of all μ for which (2.2) holds.

Note that the above bound for the error $T^\dagger y - x_r$ attains its minimum for

$$r \sim (\omega/\delta)^{1/(2\mu+1)},$$

which is precisely the same range of r for which the bound for η_r decreases to the order of δ. Further, note that the right-hand side bound for η_r in (2.3) is (up to multiplicative constants) by a factor of $(r+1)^{-1/2}$ smaller than the bound for the error. Because of our discussion on the validity of (2.3) in the previous paragraph, this suggests the following heuristic parameter choice rule.

HEURISTIC PARAMETER CHOICE RULE. *Compute the numbers* $\varphi_r := (r+1)^{1/2}\eta_r, r \geq 0$, *and consider them as approximations of* $\|T^\dagger y - x_r\|$. *Accordingly, determine the (heuristic) regularization parameter* r_* *as a location of the global minimum of* $\{\varphi_r\}$.

We mention that in the special case when $x_0 = 0$, we have

$$\varphi_r = \langle \tilde{y}, r^{-2}(TT^* + r^{-1}I)^{-3}\tilde{y}\rangle^{1/2}.$$

Another heuristic parameter choice rule, namely the *quasi-optimality criterion*, was suggested by Tikhonov and Glasko [18]. They choose the regularization parameter r for which

$$\phi_r = \langle \tilde{y}, r^{-2}(TT^* + r^{-1}I)^{-4}TT^*\tilde{y}\rangle^{1/2} \tag{2.4}$$

attains its minimum. Our theory, however, does not apply to this method. Instead, we refer to Leonov [13].

Other quite successful parameter choice rules for Tikhonov regularization which do not use any information about the noise level are Wahba's generalized cross-validation (cf. [22]) and Hansen's L-curve criterion (cf. [12]).

2.2. Landweber iteration. In the context of ill-posed problems, the method of successive approximations is often called Landweber iteration (cf. [20, 14]). Starting with initial guess x_0, x_{r+1} is obtained from x_r via

$$x_{r+1} = x_r + T^*(\tilde{y} - Tx_r), \qquad r \in \mathbb{N}_0. \tag{2.5}$$

It is known that the iteration (2.5) has an inherent regularizing property. This means that the regularization parameter $r \in \mathbb{N}_0$ is simply the iteration index, and any stopping rule of the iteration renders a parameter choice rule.

¶Here, as below, c denotes a generic constant.

The qualification of Landweber iteration is $\mu_0 = \infty$, and it is known that the discrepancy principle is an order-optimal stopping rule, cf. Vainikko [19]. With this method the iteration is terminated when for the first time

$$\eta_r := \|\tilde{y} - Tx_r\| \leq \tau\delta.$$

Again, $\tau > 1$ is a fixed number.

It is known that the same estimates hold as in (2.3), i.e.,

$$\begin{aligned} \|T^\dagger y - x_r\| &\leq c\big((r+1)^{-\mu}\omega + r^{1/2}\delta\big), \\ \eta_r &\leq c\big((r+1)^{-\mu-1/2}\omega + \delta\big), \end{aligned} \tag{2.6}$$

provided $r \in \mathbb{N}$ and the solution $T^\dagger y$ satisfies (2.2) for some $\mu > 0$. Converse results connecting the validity of the bounds in (2.6) with (2.2) have been established in [7]. With the same argument as above, we therefore suggest the following rule.

HEURISTIC PARAMETER CHOICE RULE. *Compute the numbers*

$$\varphi_r := (r+1)^{1/2}\eta_r = (r+1)^{1/2}\|\tilde{y} - Tx_r\|, \qquad r \in \mathbb{N}_0,$$

and consider them as approximations of $\|T^\dagger y - x_r\|$. *Accordingly, determine the (heuristic) regularization parameter* r_* *as a location of the global minimum of* $\{\varphi_r\}$.

Another order-optimal stopping rule for Landweber iteration has been suggested by Engl and Gfrerer [4]. Instead of the residual they monitor differences between consecutive iterates (see [4] for details). For their method, estimates like (2.6) hold, hence our approach immediately yields another heuristic rule. We are not aware of any further heuristic stopping rules for Landweber iteration.

2.3. ν-methods. A more sophisticated iterative procedure was developed by Brakhage [2]; see also [8, 10]. As opposed to (2.5), the ν-methods are two-step iterative procedures, i.e., x_{r+1} is determined from x_r and x_{r-1} via

$$x_{r+1} = \mu_r x_r + (1-\mu_r)x_{r-1} + \omega_r T^*(\tilde{y} - Tx_r), \qquad r \in \mathbb{N}_0.$$

Here, x_0 is the initial guess and $x_{-1} = 0$. The coefficients μ_r and ω_r can be given explicitly; we refer the reader to the aforementioned papers. The definition of these coefficients depends on a parameter $\nu > 0$ (hence the name ν-method). This parameter also determines the qualification of the method, i.e., we have $\mu_0 = \nu$. Although μ_0 is finite, the ν-methods are much more efficient than Landweber iteration. Roughly speaking, they require only about the square root of iterations compared with Landweber iteration (cf. (2.7) below).

The analysis of the ν-methods is based on their alternative (nonrecursive) definition via Jacobi polynomials. Using this connection, an order-optimal stopping rule (for all $0 < \mu \leq \mu_0$) has been developed only recently; cf. [10]. As for Tikhonov regularization, the discrepancy principle is not order-optimal for the full range $0 < \mu \leq \mu_0$. The order-optimal stopping rule determined in [10] recursively computes a sequence $\{\eta_r\}$ in the course of the iteration and terminates as soon as, for the first time, $\eta_r \leq \tau\delta$ ($\tau > 1$, fixed).

For $r \in \mathbb{N}$ the following bounds are the best possible under the information (2.2) with $0 < \mu \leq \mu_0$:

$$\begin{aligned} \|T^\dagger y - x_r\| &\leq c\big((r+1)^{-2\mu}\omega + r\delta\big), \\ \eta_r &\leq c\big((r+1)^{-2\mu-1}\omega + \delta\big). \end{aligned} \tag{2.7}$$

Note that $r+1$ has taken the role of $(r+1)^{1/2}$ in (2.3) and (2.6). Thus, for the ν-methods, we propose the following modification of the previous stopping rules.

HEURISTIC PARAMETER CHOICE RULE. *Compute the numbers* $\varphi_r := (r+1)\eta_r$, $r \in \mathbb{N}_0$ *and consider them as approximations of* $\|T^\dagger y - x_r\|$. *The computation of* η_r *can be implemented as in* [10, Alg. 4.2]. *Determine the (heuristic) regularization parameter* r_* *as a location of the global minimum of* $\{\varphi_r\}$.

It can be shown that this heuristic stopping rule is asymptotically equivalent to the so-called *update criterion*, which has been suggested previously in [8]. By asymptotically equivalent, we mean that the ratio of φ_r^ϵ as defined in [8, Alg. 3.1] (substituting r for k) and the present φ_r is bounded by positive numbers from above and from below, independent of r, T, and $\tilde{y}$. This means that the theoretical analysis from the following section holds for the update criterion as well (but see also the complementary theoretical results in [8]). We remark that the update criterion results from a completely different motivation.

3. Error bounds. The examples from the foregoing section can be viewed within a well-known spectral theoretical framework; cf., e.g., [6, 20, 14]. We briefly review this general setting, where, for notational convenience, we restrict our attention to the case $x_0 = 0$; the more general case can be handled analogously.

In each of the above examples, $\{x_r\}$ can be expressed via a sequence of functions $\{g_r\}$ as

$$x_r = g_r(T^*T)T^*\tilde{y}. \tag{3.1}$$

Accordingly, we have for the residual $\tilde{y} - Tx_r$ the expression

$$\tilde{y} - Tx_r = h_r(TT^*)\tilde{y} \qquad \text{with} \qquad h_r(\lambda) = 1 - \lambda g_r(\lambda). \tag{3.2}$$

Note that $h_r(0) = 1$.

For example, in Tikhonov regularization we have

$$g_r(\lambda) = \frac{r}{1+r\lambda}, \qquad h_r(\lambda) = \frac{1}{1+r\lambda};$$

Landweber iteration can be defined via (3.1) with

$$g_r(\lambda) = \sum_{k=0}^{r-1}(1-\lambda)^k, \qquad h_r(\lambda) = (1-\lambda)^r;$$

for the ν-method, g_r is such that h_r is a translated and rescaled Jacobi polynomial (see [2, 8] for more details).

We assume throughout that there exists an increasing sequence $\{\rho_r\}$,

$$\begin{aligned} &\rho_0 = 1, \qquad \rho_r \to \infty \quad \text{as } r \to \infty, \\ &\frac{\rho_{r+1}}{\rho_r} \le c \quad \text{for } r \ge 0, \end{aligned} \tag{3.3}$$

such that, uniformly for $\lambda \in [0, 1]$,

$$\begin{aligned} \lambda^{1/2}|g_r(\lambda)| &\le c\rho_r^{1/2}, \\ \lambda^{\mu}|h_r(\lambda)| &\le c\rho_r^{-\mu}, \qquad 0 \le \mu \le \mu_0. \end{aligned} \tag{3.4}$$

Recall that μ_0 is the qualification of the regularization method (3.1). In the examples above, (3.4) is fulfilled with $\rho_r = r + 1$ (Tikhonov, Landweber) and $\rho_r = (r+1)^2$ (ν-methods), respectively.

Since the total error for x_r can be expressed as

$$T^\dagger y - x_r = h_r(T^*T)T^\dagger y + g_r(T^*T)T^*(y - \tilde{y}),$$

one immediately obtains from (3.4) and the spectral theorem the estimates for the error as given in the previous section. Consequently, $1/\rho_r$ can be viewed as *modulus of convergence* of the regularization method.

For the parameter choice rules we also assume that there are functions s_r fulfilling the inequalities

$$\lambda^{\mu} s_r(\lambda) \leq c\rho_r^{-\mu} \qquad \text{for} \quad 0 \leq \mu \leq 2\mu_0 + 1, \ 0 \leq \lambda \leq 1, \tag{3.5}$$

and

$$|h_r(\lambda)|^{2+1/\mu_0} \leq c s_r(\lambda), \qquad 0 \leq \lambda \leq 1. \tag{3.6}$$

If $\mu_0 = \infty$ then we consider $1/\mu_0$ to be zero in (3.6). In many cases, e.g., in Tikhonov regularization and for the Landweber iteration, we will *define* s_r via equality in (3.6). Equality in (3.6) is also the basic assumption for the general theory in [17]. We only know of the ν-methods as a relevant example where the appropriate functions s_r do not satisfy (3.6) with equality.

With the functions s_r we can define an order-optimal parameter choice rule for the regularization method (3.1) via numbers

$$\eta_r = \langle \tilde{y}, s_r(TT^*)\tilde{y}\rangle^{1/2}, \qquad r \geq 0, \tag{3.7}$$

by choosing the smallest regularization parameter $r = r(\|y - \tilde{y}\|)$ for which

$$\eta_r \leq \tau\|y - \tilde{y}\|.$$

Here, τ has to be a fixed number, greater than the supremum over [0, 1] of all functions s_r, $r \geq 0$.

If (2.2) is satisfied for some $0 < \mu \leq \mu_0$, then one easily concludes that

$$\eta_r = \|\big(s_r(TT^*)\big)^{1/2}\tilde{y}\| \leq \|\big(s_r(T^*T)\big)^{1/2}T(T^*T)^{\mu}w\| + \|\big(s_r(TT^*)\big)^{1/2}(\tilde{y} - y)\|;$$

hence (3.5) yields the bound

$$\eta_r \leq c\big(\rho_r^{-\mu-1/2}\omega + \|\tilde{y} - y\|\big). \tag{3.8}$$

Now we state our main result concerning the corresponding heuristic parameter choice rule.

THEOREM 3.1. *Let assumptions* (3.1) *through* (3.6) *be satisfied and assume that* $\|y\| \geq \|y - \tilde{y}\|$, $T^{\dagger}y = (T^*T)^{\mu}w$ *with* $0 < \mu \leq \mu_0$, *and* $\|w\| = \omega$. *Furthermore, let* $r = r_* < \infty$ *be a global minimum of the sequence*

$$\varphi_r := \rho_r^{1/2}\eta_r.$$

Then we have the error bound

$$\|T^{\dagger}y - x_{r_*}\| \leq c\left(1 + \frac{\|\tilde{y} - y\|}{\eta_{r_*}}\right)\delta_*^{2\mu/(2\mu+1)}\omega^{1/(2\mu+1)}, \tag{3.9}$$

where c is a uniform constant and

$$\delta_* = \max\{\eta_{r_*}, \|\tilde{y} - y\|\}. \tag{3.10}$$

Proof. We estimate the two terms in the error decomposition

$$T^{\dagger}y - x_r = h_r(T^*T)T^{\dagger}y + g_r(T^*T)T^*(y - \tilde{y}). \tag{3.11}$$

Consider first the case when $\mu_0 = \infty$. We estimate the first term in (3.11) by means of the moment inequality and assumption (3.4) with $\mu = 0$:

$$\begin{aligned} \|h_r(T^*T)T^\dagger y\| &= \|(T^*T)^\mu h_r(T^*T)w\| \\ &\le \|h_r(T^*T)w\|^{1/(2\mu+1)} \|Th_r(T^*T)(T^*T)^\mu w\|^{2\mu/(2\mu+1)} \\ &\le c\,\omega^{1/(2\mu+1)} \|h_r(TT^*)y\|^{2\mu/(2\mu+1)}. \end{aligned}$$

Using (3.6), this yields

$$\|h_r(T^*T)T^\dagger y\| \le c\,\omega^{1/(2\mu+1)} \langle y, s_r(TT^*)y\rangle^{\mu/(2\mu+1)}. \tag{3.12}$$

Consider next the case when $\mu_0 < \infty$. We define the operator

$$B_r = \big(h_r(T^*T)\big)^{1/\mu_0},$$

and observe from (3.4) that $\{B_r\}$ is uniformly bounded. Applying the moment inequality to $B_r T^*T$, and using the fact that $\mu \le \mu_0$ yields

$$\begin{aligned} \|h_r(T^*T)T^\dagger y\| &= \|(B_r T^*T)^\mu B_r^{\mu_0-\mu} w\| \\ &\le \|B_r^{\mu_0-\mu} w\|^{1/(2\mu+1)} \|T B_r^{\mu_0+1/2} (T^*T)^\mu w\|^{2\mu/(2\mu+1)} \\ &\le c\,\omega^{1/(2\mu+1)} \|\big(h_r(TT^*)\big)^{(2\mu_0+1)/2\mu_0} y\|^{2\mu/(2\mu+1)}. \end{aligned}$$

Thus, from (3.6) it follows that (3.12) holds for $\mu_0 < \infty$ as well. Since

$$\begin{aligned} \|\big(s_r(TT^*)\big)^{1/2} y\| &\le \|\big(s_r(TT^*)\big)^{1/2} \tilde y\| + \|s_r(TT^*)\|^{1/2} \|y - \tilde y\| \\ &\le \eta_r + c\|y - \tilde y\|, \end{aligned}$$

(3.12) with $r = r_*$ implies

$$\|h_{r_*}(T^*T)T^\dagger y\| \le c\,\omega^{1/(2\mu+1)} \big(\eta_{r_*} + c\|y - \tilde y\|\big)^{2\mu/(2\mu+1)}.$$

In other words, using the definition (3.10) of δ_* we have shown:

$$\|h_{r_*}(T^*T)T^\dagger y\| \le c\,\omega^{1/(2\mu+1)} \delta_*^{2\mu/(2\mu+1)}. \tag{3.13}$$

To estimate the second term in (3.11), we first note that

$$\frac{\omega}{\|y - \tilde y\|} \ge \frac{\|y\|}{\|y - \tilde y\|} \ge 1$$

by assumption. Thus, it follows from (3.3) that we can find some number r_0 such that

$$(\omega / \|y - \tilde y\|)^{2/(2\mu+1)} \le \rho_{r_0} \le c\,(\omega / \|y - \tilde y\|)^{2/(2\mu+1)}.$$

Hence, the minimal value φ_{r_*} can be estimated from (3.8) as follows:

$$\varphi_{r_*} \le \varphi_{r_0} \le c\, \|y - \tilde y\|^{2\mu/(2\mu+1)} \omega^{1/(2\mu+1)}. \tag{3.14}$$

Using the first inequality in (3.4) we obtain

$$g_{r_*}(T^*T)T^*(y - \tilde y) \le c\,\rho_{r_*}^{1/2} \|y - \tilde y\| = c\,\varphi_{r_*} \frac{\|y - \tilde y\|}{\eta_{r_*}},$$

where we have used the definition of φ_r for the last equality. Inserting (3.14) and keeping (3.10) in mind, this yields

$$\|g_{r_*}(T^*T)T^*(y-\tilde{y})\| \le c\,\frac{\|y-\tilde{y}\|}{\eta_{r_*}}\,\delta_*^{2\mu/(2\mu+1)}\omega^{1/(2\mu+1)}. \tag{3.15}$$

Finally, (3.11), together with (3.13) and (3.15), verifies the assertion. □

The assumption $\|y\| \ge \|y-\tilde{y}\|$ in the statement of Theorem 3.1 is quite natural. It means that the exact right-hand side is not completely dominated by noise; otherwise, no reasonable reconstruction is possible. Order-optimal parameter choice rules usually return $x_r = 0$ in such a case; since we do not know the magnitude of the perturbation, we cannot do anything alike.

We mention that there is no guarantee that the sequences $\{\varphi_r\}$ as determined above will actually attain a global minimum. It is easy to see that the numbers φ_r are all nonnegative and finite. However, it may happen that $\varphi_r \to 0$ as $r \to \infty$. In this case no global minimum exists. Such an event should be handled with care, and we recommend considering it as a failure of the parameter choice rule; note that one cannot conclude in this case that $\tilde{y}$ belongs to the domain of $T^\dagger$ (cf. [8, Ex. 6.1]).

The situation in which the global minimum is attained for several values of r is not a critical one. Our theory is not affected by this and applies for *all* respective parameters. Nevertheless, we suggest taking r_* as the smallest parameter for which the minimum is attained.

Let us now turn to an interpretation of the bound (3.9). To this end, consider the smallest parameter r_* for which the global minimum of $\{\varphi_r\}$ is attained. Furthermore, let $\delta_* = \eta_{r_*}$ be the resulting estimate for $\|y-\tilde{y}\|$. Note that if we use the order-optimal parameter choice rule with δ_*/τ as an a priori guess for $\|y-\tilde{y}\|$, this method would precisely yield x_{r_*} as a regularized approximation. As long as δ_* is of the order of $\|y-\tilde{y}\|$, it can be seen from Theorem 3.1 that the computed approximations converge to $T^\dagger y$ with order-optimal accuracy. On the other hand, if δ_* does not decrease as quickly as $\tilde{y} \to y$, then the convergence will be suboptimal. More dangerous is the case when δ_* decreases more quickly. In this case, the additional factor $\|y-\tilde{y}\|/\delta_*$ in (3.9) blows up, and the approximations x_{r_*} may diverge. Therefore, the value of δ_* should always be monitored, and the computed approximation should be discarded if δ_* is significantly smaller than the expected noise level.

Stipulating additional conditions, however, we can get rid of the factor $\|y-\tilde{y}\|/\delta_*$ in (3.9). To show this, we denote by Q the orthoprojector in $\mathcal{Y}$ onto the orthogonal complement of the closure of $\mathcal{R}(T)$. To facilitate the argumentation we assume in the sequel for noniterative methods (with regularization parameter $r \in \mathbb{R}_0^+$) that $g_r(\lambda)$ and $s_r(\lambda)$ are continuous with respect to r for every fixed $\lambda \in [0,1]$.

COROLLARY 3.2. *If, in addition to the assumptions of Theorem* 3.1,

$$\|Q(y-\tilde{y})\| \ge \varepsilon\,\|y-\tilde{y}\|$$

for some $\varepsilon > 0$, *then* φ_r *attains a global minimum for some finite* $r_* \ge 0$, *and*

$$\|T^\dagger y - x_{r_*}\| \le \frac{c}{\varepsilon}\,\delta_*^{2\mu/(2\mu+1)}\omega^{1/(2\mu+1)}, \tag{3.16}$$

where δ_* *is as in* (3.10).

Proof. By virtue of (3.6), $s_r(0) \ge c\,h_r(0) = c$, which implies

$$\eta_r = \|\big(s_r(TT^*)\big)^{1/2}\tilde{y}\| \ge \|Q\big(s_r(TT^*)\big)^{1/2}\tilde{y}\| = s_r^{1/2}(0)\,\|Q\tilde{y}\|.$$

Since $Q\tilde{y} = Q(\tilde{y}-y)$ it follows from the additional assumption that

$$\eta_r \ge \varepsilon\sqrt{c}\,\|y-\tilde{y}\|, \tag{3.17}$$

and hence $\varphi_r \to \infty$ as $r \to \infty$. Consequently, there exists a finite r_* for which φ_{r_*} becomes minimal, and the assertion follows from (3.9) and (3.17). □

As will be shown next, if condition (3.18) holds uniformly as $\tilde{y} \to y$, then this is strong enough to prove convergence of $x_{r_*} \to T^\dagger y$.

THEOREM 3.3. *Let $y \in \mathcal{R}(T)$ and $\{y^\delta\}_{\delta>0}$ be a sequence of perturbations of y with $y^\delta \to y$ as $\delta \to 0$. Assume that there exists $\varepsilon > 0$ such that*

$$\|Q(y - y^\delta)\| \geq \varepsilon \|y - y^\delta\| \quad \textit{for all } \delta > 0. \tag{3.18}$$

For each $\delta > 0$, denote by $\{x_r^\delta\}$ the regularized approximation and by $r_*(\delta)$ the regularization parameter defined in Corollary 3.2. Then $x^\delta_{r_*(\delta)}$ converges to $T^\dagger y$ as $\delta \to 0$.

Proof. Let $x = T^\dagger y$ and fix $\delta > 0$. Since $\mu_0 > 0$, it follows from (3.5) that $\rho_r \lambda s_r(\lambda)$ converges to zero as $r \to \infty$, pointwise on $[0, 1]$. Hence, by the Banach–Steinhaus theorem,

$$\|s_r(TT^*)Tx\| = o(\rho_r^{-1/2}), \qquad r \to \infty.$$

Consequently,

$$\begin{aligned} \eta_r &= \|\big(s_r(TT^*)\big)^{1/2} y^\delta\| \leq \|\big(s_r(TT^*)\big)^{1/2} Tx\| + \|\big(s_r(TT^*)\big)^{1/2}(y^\delta - y)\| \\ &\leq o(\rho_r^{-1/2}) + c\,\|y - y^\delta\|, \end{aligned}$$

and

$$\varphi_r = \rho_r^{1/2}\eta_r \leq o(1) + c\rho_r^{1/2}\|y - y^\delta\|, \qquad r \to \infty.$$

Choose $r = r(\delta)$ such that $r(\delta) \to \infty$ and $\rho_{r(\delta)}^{1/2}\|y - y^\delta\| \to 0$ as $\delta \to 0$: this implies

$$\varphi_{r_*(\delta)} \leq \varphi_{r(\delta)} \longrightarrow 0, \qquad \delta \to 0.$$

Because of (3.18), inequality (3.17) with $\tilde{y} = y^\delta$ follows as in the proof of Corollary 3.2, hence,

$$\rho_{r_*(\delta)}^{1/2}\|y - y^\delta\| \leq \frac{1}{\varepsilon\sqrt{c}}\rho_{r_*(\delta)}^{1/2}\eta_{r_*(\delta)} = \frac{1}{\varepsilon\sqrt{c}}\varphi_{r_*(\delta)} = o(1), \qquad \delta \to 0. \tag{3.19}$$

Since $\rho_r \geq 1$, $\varphi_{r_*(\delta)}$ can go to zero only if $\eta_{r_*(\delta)}$ goes to zero as well. This leads to two cases which have to be distinguished. Assume first that a subsequence of $\{r_*(\delta)\}$ converges to some $r_\infty < \infty$ as $\delta \to 0$: then $\eta_{r_\infty} = 0$ and (3.6) implies $Tx_{r_\infty} = y$; by continuity, the corresponding approximations $x_{r_*(\delta)}$ converge to $x_{r_\infty} = T^\dagger y$. Assume next that a subsequence of $\{r_*(\delta)\}$ goes to infinity as $\delta \to 0$: this, together with (3.19) implies that both terms in the error decomposition (3.11) go to zero; hence, $x_{r_*(\delta)} \to T^\dagger y$ as $\delta \to 0$. □

To prove stronger results, for instance convergence rates for $x_{r_*} \to T^\dagger y$, we need to find better bounds than (3.13) for the approximation error. Such bounds may be obtained, for example, if r_* can be estimated from below. This, however, is an extremely difficult problem, very much related to the aforementioned converse results.

4. The conjugate gradient method. One of the most efficient regularization methods is the conjugate gradient method (CG) applied to the normal equation $T^*Tx = T^*y$ (cf. [14, 9]). Like the other iterative methods from §2 it has an inherent regularizing property; that is, the iteration count $r \in \mathbb{N}_0$ can be seen as the regularization parameter. Although the CG-iterates can be expressed as in (3.1), they cannot be analyzed with the techniques from the previous section, since the functions g_r to be used in (3.1) depend on $\tilde{y}$.

Nemirovskii [15] has shown that the qualification of CG is $\mu_0 = \infty$, and that the discrepancy principle is an order-optimal stopping rule. Furthermore, for $r > 0$, Nemirovskii obtained (more or less explicitly) the following bounds, provided (2.2) is fulfilled and $\|y - \tilde{y}\| \le \delta$:

$$\begin{aligned} \|T^\dagger y - x_r\| &\le c(\rho_r^{-\mu}\omega + \rho_r^{1/2}\delta), \\ \eta_r &\le c(\rho_r^{-\mu-1/2}\omega + \delta). \end{aligned} \tag{4.1}$$

Here, as in Landweber's method, $\eta_r = \|\tilde{y} - Tx_r\|$; ρ_r in (4.1) is defined as

$$\rho_0 = 1, \qquad \rho_r = g_r(0), \quad r \in \mathbb{N}.$$

Note that in all examples from §2 we have $\rho_r \approx g_r(0)$ for $r \in \mathbb{N}$, the ratio of the two numbers going to 1 as $r \to \infty$.

Our considerations motivate the following stopping rule for CG.

HEURISTIC PARAMETER CHOICE RULE. *Compute the numbers*

$$\varphi_r := \rho_r^{1/2}\eta_r = \max\{1, g_r(0)\}^{1/2}\|\tilde{y} - Tx_r\|, \qquad r \in \mathbb{N}_0,$$

and consider them as approximations of $\|T^\dagger y - x_r\|$. *Accordingly, determine the (heuristic) regularization parameter* r_* *as a location of the global minimum of* $\{\varphi_r\}$.

We emphasize that $g_r(0)$ is easily computed recursively in the course of the iteration (cf. display (2.11) in [9]), and hence the above stopping rule is efficiently implementable. Theorems 3.1 and 3.3 and Corollary 3.2 hold accordingly. For the proofs we refer to [9]. They are considerably more complicated and rely on techniques developed by Nemirovskii in [15]. We finally mention that the idea of computing $g_r(0)$ for diagnostic purposes has previously been suggested in [14][1]. So far, there is no other heuristic stopping rule for CG with a theoretical foundation; cf. [11].

5. The discrete setting. For a numerical implementation, (1.1) has to be discretized to obtain a finite-dimensional matrix equation

$$Ax = b. \tag{5.1}$$

For this discrete problem, however, we encounter an additional difficulty. For example, if the null space of A is trivial then the normal equations system for (5.1) always has a solution, whatever data $\tilde{b}$ are used. Denote this solution by $\tilde{x}$. Then, the computed numbers φ_r^{comp} defined via

$$\eta_r^{\text{comp}} := \big(\tilde{b}^* s_r(AA^*)\tilde{b}\big)^{1/2}, \qquad \varphi_r^{\text{comp}} := \rho_r^{1/2}\eta_r^{\text{comp}},$$

satisfy

$$\varphi_r^{\text{comp}} = \rho_r^{1/2}\big((A\tilde{x})^* s_r(AA^*)A\tilde{x}\big)^{1/2} = \|\big(\rho_r s_r(A^*A)A^*A\big)^{1/2}\tilde{x}\|.$$

It is an immediate consequence of (3.5) and the Banach–Steinhaus theorem that

$$\big(\rho_r s_r(A^*A)A^*A\big)^{1/2}\tilde{x} \to 0 \qquad \text{as } r \to \infty.$$

Therefore, the computed quantities φ_r^{comp} always converge to zero as $r \to \infty$, i.e., the global infimum of $\{\varphi_r^{\text{comp}}\}$ equals zero.

[1] Be aware of the misprint for $g_r(0)$ on p. 127 of [14].

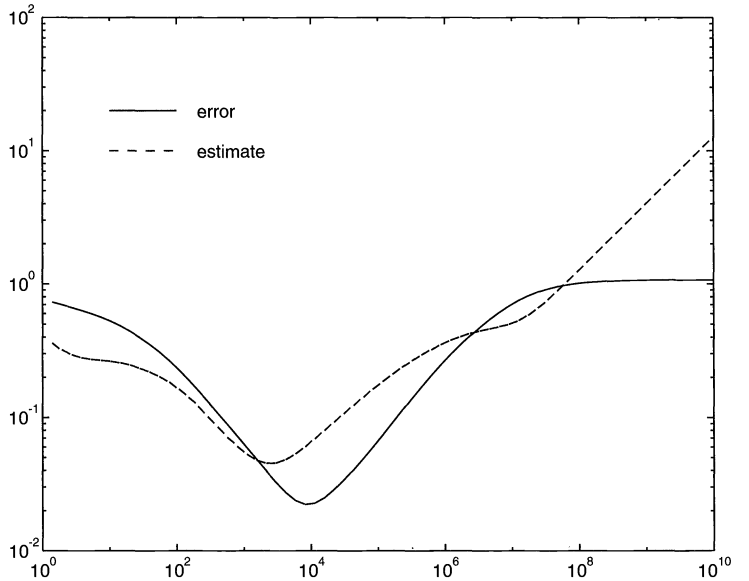

FIG. 5.1. *Error history and estimates $\{\varphi_r\}$ versus r for Tikhonov regularization.*

We emphasize that this phenomenon is only due to the discretization process: the computed numbers φ_r^{comp} and the numbers φ_r for the continuous problem (1.1) are no longer related for $r > r_\infty$, say. In fact, in our computations we have typically observed a significant increase of φ_r^{comp} as r becomes large, before φ_r^{comp} eventually starts to decay towards zero. To satisfy formal needs, we might nevertheless modify our parameter choice rule by first defining r_∞ as the parameter r where φ_r^{comp} eventually starts to decrease, and by choosing r_* as the location of the global minimum of $\{\varphi_r^{\text{comp}}\}$ in $[0, r_\infty]$. However, in practical computations, the parameter r is rarely made so large that one would encounter this phenomenon; instead, the location of the "global minimum" of φ_r^{comp} is usually obvious. To illustrate this claim we show a typical plot of the error history $\|T^\dagger y - x_r\|$ and its approximations φ_r in Figure 5.1. This plot shows the results for a sample run of Tikhonov regularization corresponding to the problem described in §6.2 below with 0.1% noise. The plot exhibits a distinct minimum of the comparison sequence $\{\varphi_r\}$, and a "hump" as r goes to infinity. The magnitude of the regularization parameter r_* is the same as for the optimal regularization parameter; the error $\|T^\dagger y - x_{r_*}\|$ is by about a factor of 1.8 worse than the best possible error.

Another point that we would like to mention is the behavior of our method when we increase the level of discretization. Since the theory developed in §3 is independent of the dimension n of the chosen Hilbert space, we expect similar outputs when the discrete problems approach the continuous problem, i.e., when $n \to \infty$. In fact, in our numerical experiments the sequences $\{\varphi_r\}$ did not change much when we increased n, but kept the relative data error at a constant level. As a consequence, the chosen regularization parameter r_* stagnated at a certain level. Moreover, the estimates η_{r_*} for $\|y - \tilde{y}\|$ in Theorem 3.1 approached a constant value as $n \to \infty$, comparable to the true data error. In view of this, the error bound (3.9) of Theorem 3.1 asserts order-optimal accuracy, which is what we want to get.

We mention, however, that with increasing n the best possible regularization parameter typically goes to infinity, and the error of the corresponding approximation goes to zero. This is a phenomenon which cannot be explained by the "deterministic" continuous setting that we have used for our paper, but is in agreement with the statistical approach to regularization methods advocated by Wahba [22] and others. The method of generalized cross-validation for estimating the regularization parameter is based on this theory, and captures the expected behavior of the optimal regularization parameter as $n \to \infty$. There is no hint, however, that generalized cross-validation can realize error bounds like (3.9) or even order-optimal accuracy.

Just recently, Vogel [21] has shown that the regularization parameter chosen by the L-curve criterion also stagnates when $n \to \infty$. It would be interesting to find a method for which deterministic error bounds like (3.9) hold, and which give the "correct" (i.e., expected) behavior of the regularization parameter as $n \to \infty$. We plan to come back to this problem in some future work.

6. Numerical results. We now summarize some of our numerical experiments with two model problems. For each problem, perturbed data are generated by adding 1% and 0.1% noise, respectively (i.e., if b and $\tilde{b}$ denote the exact and the perturbed right-hand sides then $\|b - \tilde{b}\| / \|b\| = 0.01$ or 0.001). As usual, the noise is a random vector, normally distributed with zero mean. For each of the two noise levels we have applied Tikhonov regularization, the ν-method with $\nu = 1$, and CG to (the same) 20 noisy copies of the right-hand side, respectively. In all the examples, $x_0 = 0$ is the initial guess.

6.1. Model problem 1: A compact operator equation. Our first problem is taken from [8]. It is a first-kind integral equation

$$(Tx)(s) = \int_0^1 k(s,t)x(t)\,dt = y(s), \qquad 0 \le s \le 1,$$

where

$$k(s,t) = \begin{cases} \pi^2 s(1-t), & 0 \le s \le t \le 1, \\ \pi^2 t(1-s), & 0 \le t < s \le 1 \end{cases}$$

is the Green's function for the differential operator $Lx = -x''/\pi^2$ with boundary conditions $x(0) = x(1) = 0$. The integral equation is discretized by collocation with piecewise linear splines and 51 equidistant collocation points $s_j = j/50$, $j = 0, \dots, 50$. As in [8] two different right-hand sides are considered, namely

$$\begin{aligned} y_1(s) &= (7s^6 - 18s^5 + 15s^4 - 5s^3 + s)\pi^2/3, \\ y_2(s) &= \left(-7s^8 + 24s^7 - 28s^6 + 14s^5 - \frac{28}{3}s^3 + \frac{19}{3}s\right)\pi^2/14. \end{aligned}$$

The two right-hand sides differ in the admissible range for the parameter μ in (2.2): for y_1, (2.2) is satisfied for $0 < \mu < 5/8$; for y_2 the range is $0 < \mu < 9/8$.

6.2. Results for y_1. In the sequel, we describe the results with $y = y_1$. We restrict our attention to a comparison of the order-optimal and heuristic parameter choice rules, and to their accuracy as compared to the best possible regularization parameter. For the order-optimal rules we have to fix a parameter τ, which in all cases must be greater than 1; cf. §2. We took $\tau = 1.1$, since our experience indicates that this is a reasonable choice for many applications. In Figure 6.1 the relative errors of the regularization methods are shown. The two plots correspond to the two different noise levels. Each plot contains three columns: the left-hand column presents the results for Tikhonov regularization, the middle column corresponds to the ν-method, and the right-hand side column contains the results for CG. In every column, for each of the 20 experiments (corresponding to the 20 different perturbations of the right-hand side) the relative errors are drawn for the optimal regularization parameter (solid line), the order-optimal parameter choice rule (dotted line), and the corresponding heuristic parameter

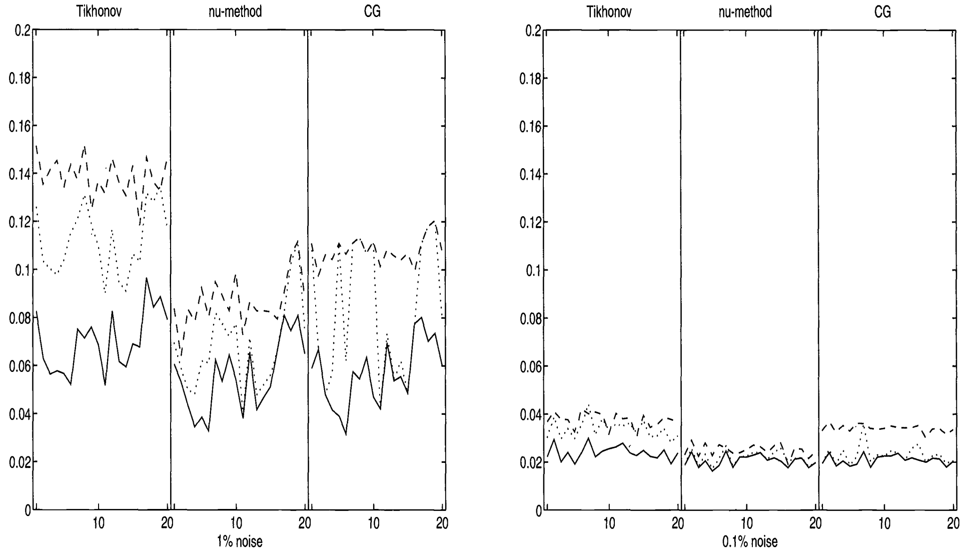

FIG. 6.1. *Model problem* 1, $y = y_1$*: relative errors for* 1% *noise* (*left*) *and* 0.1% *noise* (*right*).

TABLE 6.1
Model problem 1, $y = y_1$*: average iteration counts.*

	ν-method			Conjugate gradients		
Noise level	Opt.	Ord.	Heu.	Opt.	Ord.	Heu.
1%	48.0	33.9	27.0	4.5	3.6	3.0
0.1%	111.9	98.9	82.0	7.5	6.0	5.0

choice rule (dashed line). The actual accuracy is not so important; what matters is the relative accuracy of the competing rules.

Table 6.1 complements the figure by providing the average iteration count of the two iterative schemes corresponding to the optimal iteration index (Opt.), to the order-optimal stopping rule (Ord.), and to the heuristic stopping rule (Heu.).

As can be seen from Figure 6.1, the order-optimal stopping rules provide better approximations than the heuristic rules. The stability of the reconstructions is comparatively robust, i.e., the accuracy is quite independent of the actual noise sample. Although less information is used, the heuristic parameter choice rules perform not much worse than the deterministic rules. In fact, the error of the heuristic rules is never more than twice the error of the corresponding order-optimal rule, except for the case of CG with 1% noise, where differences up to a factor of 2.5 occur. However, it should be remarked that CG requires only about four to five iterations to reach optimal accuracy in the 1% noise case, and the stopping indices of the two stopping rules under consideration never differ by more than 1 (cf. Table 6.1); it seems unrealistic to expect a better coincidence of the stopping indices.

In view of Theorem 3.1 it is also instructive to consider the ratio $\eta_{r_*} / \|y - y^\delta\|$; cf. (3.9). In all experiments this ratio is between 0.89 and 1.41. With 0.1% noise, the ratio never drops below 0.96. In other words, the heuristic rules provide very reliable approximations.

6.3. Results for y_2. Figure 6.2 and Table 6.2 illustrate the numerical results for the first model problem with right-hand side $y = y_2$. Since y_2 satisfies (2.2) for larger values of μ as compared to y_1, the iterative methods require less iterations to reach optimal accuracy.

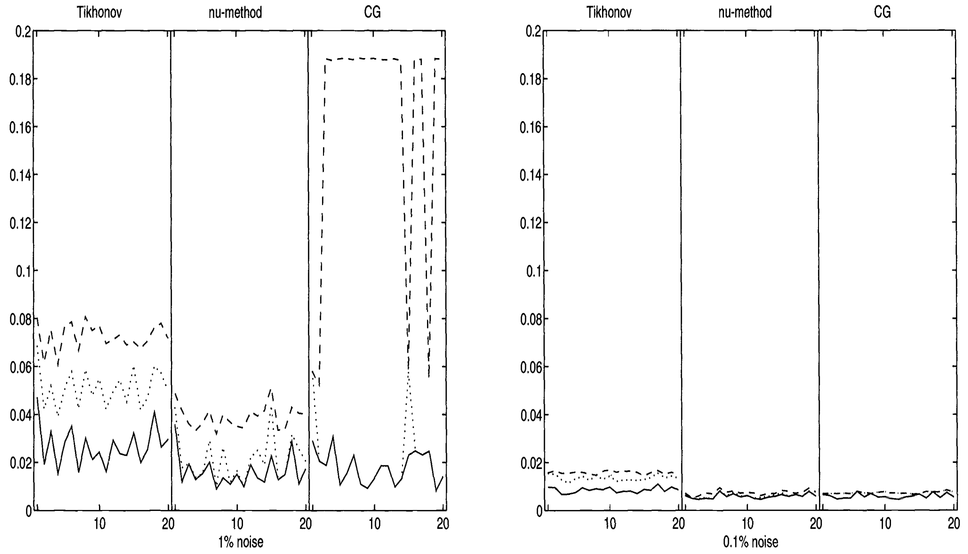

FIG. 6.2. *Model problem* 1, $y = y_2$: *relative errors for* 1% *noise* (*left*) *and* 0.1% *noise* (*right*).

TABLE 6.2
Model problem 1, $y = y_2$: *average iteration counts.*

	ν-method			Conjugate gradients		
Noise level	Opt.	Ord.	Heu.	Opt.	Ord.	Heu.
1%	16.8	13.9	10.0	3.0	2.9	1.2
0.1%	31.8	33.8	29.1	3.9	3.0	3.0

This is evident from Table 6.1, and it particularly applies to CG. In fact, $r = 3$ is throughout the optimal stopping index for CG in the 1% noise case. While this is essentially matched by the order-optimal rule (except for two experiments where stopping index is $r = 2$), the heuristic rule returns $r_* = 2$ in four and $r_* = 1$ in sixteen experiments, respectively. This is the reason for the comparatively large gap in the accuracy between the two stopping rules in the left-hand figure. For 0.1% noise, both stopping rules terminate CG after three iterations whatever perturbation is used, whereas the optimal stopping index is almost always $r = 4$.

As above, the a posteriori estimates η_{r_*} for the perturbation error in the data turn out to be very good approximations, except for the outlying CG approximations in the 1% noise case where $r_* = 1$. For these latter approximations η_{r_*} goes up to almost five times the actual noise magnitude. Nevertheless, as has been mentioned earlier, it would be more dramatic if the ratio dropped significantly *below* 1.

6.4. Model problem 2: A convolution over $\mathbb{R}^2$. The second model problem is a two-dimensional deconvolution taken from [11, §8.2]. The corresponding integral operator T has continuous spectrum instead of a sequence of isolated singular values as in the previous problem. We include this problem to see whether these spectral properties affect the performance of the parameter choice rules. For details on the problem and the (simple collocation) discretization we refer to [11]. Figure 6.3 and Table 6.3 provide the results of the numerical experiments (the properties of the additive noise are the same as before).

Note that the iterative methods require many more iterations; this is due to the fact that the solution has very sharp contours; the actual values of μ for which (2.2) holds are not known.

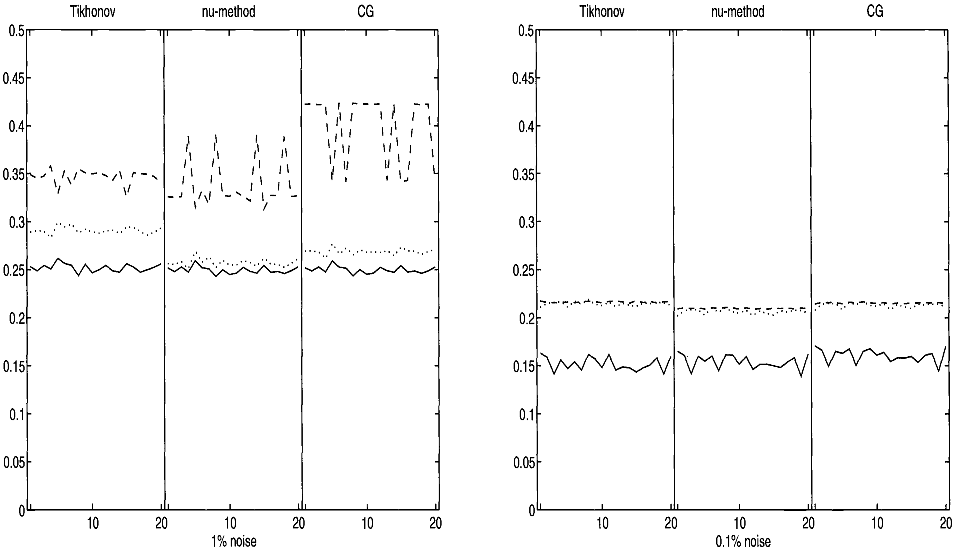

FIG. 6.3. *Model problem* 2*: relative errors for* 1% *noise* (*left*) *and* 0.1% *noise* (*right*).

TABLE 6.3
Model problem 2*: average iteration counts.*

	ν-method			Conjugate gradients		
Noise level	Opt.	Ord.	Heu.	Opt.	Ord.	Heu.
1%	68.0	45.4	17.6	30.8	18.2	6.5
0.1%	871.1	177.2	151.2	209.8	52.2	47.4

Furthermore, CG needs more iterations because the spectrum of T is a continuum; see the discussion in [11].

From a qualitative point of view, the robustness of the parameter choice rules does not change at all. As before, the errors of the regularized approximations obtained with the heuristic parameter choice rules are at most by a factor of 1.6 worse than those of the order-optimal rules; for the reduced noise level, the ratio between the corresponding errors decreases even down to at most 1.04.

On the other hand, the a posteriori estimates for the 1% noise level are larger, up to 4.5 times the actual value. For 0.1% noise, however, all estimates are between 1 and 1.5 times the actual magnitude.

7. Concluding remarks. Heuristic parameter choice rules have found renewed interest in recent works on the regularization of ill-posed problems. The major drawback of many of the suggested rules is the lack of a thorough theoretical analysis. With this in mind, the parameter choice rules presented in this paper are especially attractive, since they are based on the established theoretical framework developed for order-optimal parameter choice rules. As a consequence, we obtain a posteriori bounds for the actual error of the regularized approximation; cf. Theorem 3.1.

We conclude from the numerical experiments that the actual performance of the new parameter choice rules is quite promising, except for the conjugate gradient method, where the results are somewhat worse in the case of 1% noise. With even more noise the heuristic parameter choice rules tend to a too-conservative choice of the parameter; however, it was always possible to detect this from the computed estimate for $\|y - \tilde{y}\|$. Note that with significantly more noise than 1%, sound reconstructions are almost impossible, anyway.

It must again be emphasized that the proposed rules should not be understood as black box routines, and the presented numerical results can only indicate the limitations of these rules. Other examples naturally will meet other limitations. It is our philosophy and our intention to suggest these rules primarily for diagnostic purposes; the use of a variety of different parameter choice rules should always be the ultimate goal.

Acknowledgments. We are grateful to Robert Plato for pointing out a simplified proof of Corollary 3.2, and to Curtis Vogel and an anonymous referee for useful remarks concerning the presentation. The second author greatly appreciates travel support by the Christian-Doppler-Society, Austria.

BAYESIAN-VALIDATED SURROGATES FOR NOISY COMPUTER SIMULATIONS; APPLICATION TO RANDOM MEDIA*

SERHAT YEŞİLYURT†, CHAHID K. GHADDAR‡, MANUEL E. CRUZ‡, AND ANTHONY T. PATERA‡

Abstract. Many numerical simulations remain too resource-intensive to be directly incorporated into engineering design and optimization efforts. An attractive alternative to direct insertion considers models for computational systems: the expensive simulation is evoked only to construct and validate a simplified input–output model; this simplified input–output model then serves as a simulation *surrogate* in ensuing design and optimization studies. We present here a nonparametric statistical procedure for the validation and optimization-purposive application of simplified (static) input–output models for *noisy* computer simulations.

For the case of unbounded symmetric measurement noise, we show that, with probability greater than $1 - \varepsilon_2$, the difference between the *noise-free* simulation output and the proposed surrogate is bounded over more than $1 - \varepsilon_1$ of the specified input domain by U, the largest discrepancy observed between the *noisy* simulation output and the proposed surrogate in a validation sample of size $N = \ln\varepsilon_2 / \ln(1 - \varepsilon_1/2)$. Several a priori and a posteriori density-independent and density-dependent bounds are presented for the expected noise contribution to the model prediction error estimator, U; for the important case of a normal parent, bias-variance balance requires that the standard deviation of the noise decrease no more slowly than $(2\ln N)^{-1/2}$ as $N \to \infty$.

As an example, we consider the selection of the inclusion concentration of a random fibrous composite to obtain a desired effective thermal conductivity: a parallel Monte-Carlo finite-element simulation is polled to validate a microstructure-independent effective-conductivity upper bound; this upper bound then serves as a simulation surrogate in subsequent discrimination exercises. A validation-based nonparametric a posteriori error framework is evoked to quantify the effects of surrogate-for-simulation substitution on system predictability and optimality.

1. Introduction.

Computer simulation plays an increasingly important role in engineering design and optimization. Two alternative approaches to the incorporation of simulation into engineering synthesis are *direct insertion* and *simulation surrogates*.

In *direct insertion*, the simulation is directly evoked by the parent mathematical programming procedure. Direct insertion permits accurate system-performance prediction and great flexibility in design-space definition and dimension. However, direct insertion is often not viable for resource-intensive, large-scale simulations: optimization procedures may exhaust resources before interesting, or even feasible, results are obtained; inevitable variations in design specifications and optimization criteria cannot be efficiently accomodated; only limited prior information can be incorporated. Lastly, direct insertion requires a degree of automation that many large-scale simulations do not readily admit.

In the *simulation surrogate* approach, the large-scale numerical simulation is evoked only to construct and validate a simplified model which relates selected design-variable inputs to system-performance outputs; this simplified input–output model then serves as a simulation *surrogate* in ensuing optimization studies. Surrogate techniques enjoy several advantages: optimization procedures will not terminate prematurely; midprocess modifications to design objectives can be efficiently accomodated; simulation results can be effectively recycled; prior information can be gainfully exploited; design interactivity is enhanced; and simulation

automation, though desirable, is not necessary. However, the surrogate approach also suffers from several significant disadvantages: simplified input–output models introduce additional prediction errors; the input space definition and dimension must be prescribed "a priori"; design localization deteriorates as the dimension of the input space increases.

Clearly, the direct insertion and surrogate approaches must be treated as complementary and potentially collateral, with inexpensive simulations or final analyses preferring the former, and expensive simulations or exploratory studies selecting the latter. Although continuing advances in parallel computing (Gustafson, Montry, and Benner (1988); Fox et al. (1988); Fischer and Patera (1994)) will certainly render *current* calculations less expensive, increased computational capability will also enable *new* simulations that offer increased physical and engineering relevance. As formerly expensive calculations migrate to the direct insertion class of simulations, formerly "impossible" problems will replenish the surrogate category. There is, therefore, a continuing need for both direct insertion and surrogate approaches; our concern here is with the latter.

The work to date on surrogate procedures for noise-free simulations ranges from early efforts to characterize *average* properties of simulation outputs (McKay, Beckman, and Conover (1979)), to more recent activities focussed on the replication of *detailed* input–output relationships for subsequent application in optimization studies (Sacks, Welch, Mitchell, and Wynn (1989); Sacks, Schiller, and Welch (1989); Cox and John (1992); Morris, Mitchell, and Ylvisaker (1993); Yeşilyurt and Patera (1995)). These surrogate procedures do not, however, explicitly treat the situation in which the simulation output is subject to significant "measurement" noise, and the methods cannot, therefore, address the important issue of bias-variance balance.

Simulation measurement noise—broadly defined as the difference between the (assumed) *deterministic* output of a "continuous" mathematical system and the corresponding (perhaps random) output of an associated approximate solution procedure—arises in many different computational techniques: in finite-difference, finite-element, and finite-volume procedures for partial differential equations, measurement error comprises discretization error, incomplete-iteration error, and arithmetic rounding; in Monte-Carlo techniques for the evaluation of deterministic integrals or the statistics of chaotic or stochastic processes, measurement error takes the more familiar form of estimator variance. In this paper, we propose a nonparametric statistical procedure for the validation and optimization-purposive application of (static) noisy-simulation surrogates; the Bayesian-validated surrogate procedure for noise-free simulations developed in Yeşilyurt and Patera (1995) is, in fact, a special case of the more general framework developed in the current work.

We briefly remark on the relationship between the current work and the much broader field of statistical prediction. The preference for a statistical approach—ostensibly similar to physical-experiment design—to the *noise-free* simulation-surrogate approximation problem reflects, first, the perforce limited samples associated with expensive simulations (this is particularly acute in the absence of computational economies of scale), and second, the lack of regularity information for complex simulation input–output relationships. However, surrogate procedures for noise-free computer experiments differ significantly from statistical prediction techniques for physical experiments in that, for the former, noise mitigation is *not* a factor in efficient "design" (Sacks et al. (1989), Yeşilyurt and Patera (1995)). It may appear that in developing surrogates for noisy simulations we might now appeal more directly to corresponding statistical prediction techniques for physical experiments (Box, Hunter, and Hunter (1978); Seber and Wild (1989); Härdle (1990)).

We believe this is not (or need not be) the case: noisy simulations and noisy physical experiments remain essentially different. In particular, in a typical numerical simulation, first, we need not be concerned with unknown or confounding variables since, by construction, all independent variables are explicit in the formulation of the originating simulation, and second, we can directly control the magnitude of the measurement noise through, for example, mesh refinement or precise replication. Because numerical simulations correspond to a "naive" physical experiment, surrogate procedures for noisy numerical simulations permit both simpler formulation and more explicit error estimation than corresponding methods for physical experiments. For example, nonlinear nonparametric kernel-smoothing regression techniques for physical experiments (Wahba (1975), Silverman (1985), Härdle (1990)) balance predictor bias and measurement variance by an asymptotic relationship between validation sample size and kernel scale; in contrast, the simulation surrogate procedures we propose here balance surrogate bias and measurement error by direct requirements on validation sample size and the (presumed controllable) noise level.

The paper is organized as follows. In §2 we review the optimization-purposiveness structure introduced in Yeşilyurt and Patera (1995), motivate the desired form for the surrogate-validation statement, and introduce our random simulation hypotheses. In §3 we present the validation result and derive the validation error estimate. In §4 we examine the noise contribution to the model prediction error estimator. Lastly, in §5 we present several examples, including a random-media effective-conductivity nested Monte-Carlo finite-element calculation which constitutes a "real," as opposed to contrived, application. We note that in the current paper we take the proposed surrogates as given, "graybox" models; regression procedures by which to generate either blackbox models or corrections to graybox models are discussed in Yeşilyurt and Patera (1995), Yeşilyurt (1995), Otto et al. (1995), and Paraschivoiu (in progress).

2. Optimization purposiveness. We take as given a design-variable M-vector $\mathbf{p}$ in an admissible (closed) design space $\Omega \subset \mathbb{R}^M$, and a (here single) output s which is described by the input–output function $\mathcal{S}(\mathbf{p}) : \Omega \to \mathbb{R}$; we require only that $\mathcal{S}(\mathbf{p}) \in L^\infty(\Omega)$. We assume that there is no *systematic* simulation error: $\mathcal{S}(\mathbf{p})$ is the deterministic input–output function for both the underlying "continuous" mathematical system (e.g., an integral) *and* the numerical simulation in the limit of no measurement noise (e.g., the Monte-Carlo sample mean as the sample size tends to infinity). We next presume that the target value of the output s is prescribed as λ, and that the "best" design point $\mathbf{p}^*$ is defined by

$$(1) \qquad \mathbf{p}^* = \arg \min_{\mathbf{p}\in\Omega} \Phi(\mathbf{p}, \lambda) \,,$$

where

$$(2) \qquad \Phi(\mathbf{p}, \lambda) = |\mathcal{S}(\mathbf{p}) - \lambda| \,.$$

A much more general optimization framework, in which the objective function, $\Phi(\mathbf{p}, \lambda)$, is an arbitrary function of the simulation input–output relationship $\mathcal{S}(\mathbf{p})$, is developed in Yeşilyurt and Patera (1995); the specific case given here, related to the problem of "discrimination" (Seber and Wild (1989)), leads to a simpler exposition which is adequate for our current purposes.

We next introduce the simulation surrogate, $\widetilde{\mathcal{S}}(\mathbf{p})$, which should, first, admit considerably simpler evaluation than the original input–output function, $\mathcal{S}(\mathbf{p})$, and, second, provide a reasonable approximation to $\mathcal{S}(\mathbf{p})$ over the design space Ω. We then replace $\mathcal{S}(\mathbf{p})$ in (2) with $\widetilde{\mathcal{S}}(\mathbf{p})$ to construct the approximate design problem

$$(3) \qquad \widetilde{\mathbf{p}}^* = \arg \min_{\mathbf{p}\in\Omega} |\widetilde{\mathcal{S}}(\mathbf{p}) - \lambda| \,;$$

the discussion that follows is perhaps clearest when $\widetilde{\mathcal{S}}(\widetilde{\mathbf{p}}^*) = \lambda$. The advantage of (3) over (1) is, of course, more ready and certain solution; perhaps more importantly, midprocess modifications in design specifications, here represented by λ, can be treated without re-appeal to $\mathcal{S}(\mathbf{p})$. We must, however, understand how errors in the surrogate will be reflected in predicted system configuration and performance.

We describe a particular surrogate-validation error estimate which leads to practically relevant purposive statements. We first assume, given small positive real parameters $0 < \varepsilon_1 < 1$ and $0 < \varepsilon_2 < 1$, and an importance function $\rho(\mathbf{p})$ which is strictly positive and integrates to unity over Ω, that we can find a model prediction error estimator B such that

$$\Pr\left\{\int_{\{\mathbf{p}\in\Omega\,|\,|\mathcal{S}(\mathbf{p})-\widetilde{\mathcal{S}}(\mathbf{p})|\leq B\}} \rho(\mathbf{p})\mathbf{dp} \geq 1-\varepsilon_1\right\} \geq 1-\varepsilon_2\,, \tag{4}$$

where Pr{*event*} refers to the probability of *event*, and **dp** is a differential element of Ω. The result (4) can be viewed as a probably approximately correct statement (Valiant (1984), Gallant (1990)), and is also related to the probabilistic framework of information-based complexity theory (Traub, Wasilkowski, and Wozniakowski (1988)). In words, this validation error statement indicates that, over some volumetrically important subdomain of Ω, the surrogate L^∞-prediction error is less than B with high probability.

It can then readily be shown (Yeşilyurt and Patera (1995), Yeşilyurt (1995)) that, with probability greater than $1-\varepsilon_2$, for any region $\mathcal{R} \subset \Omega$ for which $\int_{\mathcal{R}} \rho(\mathbf{p})\mathbf{dp} > \varepsilon_1$, there exists a (in fact, many) $\hat{\mathbf{p}}^* \in \mathcal{R}$ for which

$$|\mathcal{S}(\hat{\mathbf{p}}^*) - \lambda| \leq |\widetilde{\mathcal{S}}(\widetilde{\mathbf{p}}^*) - \lambda| + B + \delta_{\mathcal{R}}\,, \tag{5}$$

where

$$\delta_{\mathcal{R}} = \max_{\mathbf{p}\in\mathcal{R}} |\,\widetilde{\mathcal{S}}(\mathbf{p}) - \widetilde{\mathcal{S}}(\widetilde{\mathbf{p}}^*)\,|\,. \tag{6}$$

The choice of $\mathcal{R}$ may be optimized with respect to various metrics (Otto et al. (1995)); for example, in Yeşilyurt and Patera (1995), $\mathcal{R}$ is chosen as the region $\mathcal{R}'$ of "size" $\nu\varepsilon_1$ ($1 < \nu \leq 1/\varepsilon_1$ given) that minimizes $\delta_{\mathcal{R}'}$. From (5) we deduce, assuming minimal continuity requirements on $\mathcal{S}(\mathbf{p})$ and $\widetilde{\mathcal{S}}(\mathbf{p})$, that for sufficiently accurate $\widetilde{\mathcal{S}}(\mathbf{p})$ (small B) and sufficiently small ε_1 (small $\delta_{\mathcal{R}}$), there exist many design points $\hat{\mathbf{p}}^*$ arbitrarily near $\widetilde{\mathbf{p}}^*$ at which *actual* system performance, as measured by $|\mathcal{S}(\hat{\mathbf{p}}^*) - \lambda|$, is arbitrarily close to the optimal system performance predicted by the surrogate. If we further presume that $|\mathcal{S}(\mathbf{p}) - \lambda|$ and $|\widetilde{\mathcal{S}}(\mathbf{p}) - \lambda|$ are quasi-convex, we can construct, based solely on the surrogate $\widetilde{\mathcal{S}}(\mathbf{p})$, a random region $\mathcal{K}$ that shrinks to $\widetilde{\mathbf{p}}^*$ as $B \to 0$, $\varepsilon_1 \to 0$, and that, with probability greater than $1-\varepsilon_2$, contains the *actual* design point, $\mathbf{p}^*$ (Yeşilyurt and Patera (1995), Yeşilyurt (1995)).

The many practical ramifications of these purposiveness estimates are described in §5 of this paper and, more extensively, in Yeşilyurt and Patera (1995) and Otto et al. (1995); other approaches to optimization purposiveness in the context of nonlinear nonparametric regression can be found in Silverman (1985) and Härdle (1990, Chap. 8). Note that, although our estimates in volume are independent of input dimension M, the variations in individual components of $\mathbf{p}$ will increase with increasing M. As a consequence, our methods are viable for large M only if the inputs are strongly correlated through $\rho(\mathbf{p})$, as in shape optimization (Otto et al. (1995), Otto (in progress)), or if screening techniques are applied prior to surrogate construction-validation (Welch et al. (1992)).

It remains to find a validation algorithm which yields the error estimate (4). For the case in which there is no measurement error in the simulation (that is, given a $\mathbf{p} \in \Omega$, $s = \mathcal{S}(\mathbf{p})$ can be determined with infinite precision), the algorithm and associated proof are very simple

(Yeşilyurt and Patera (1995)). We consider here the slightly more complicated case in which the simulation result is subject to measurement noise. More precisely, we shall assume that our simulation output is now a random variable, R, characterized by mean $\mathcal{S}(\mathbf{p})$, the deterministic input–output function of the underlying exact (unapproximated) mathematical model; finite variance $\sigma_W(\mathbf{p})$; and scale-parametrized (smooth) conditional probability density

$$f_{R|\mathbf{P}}(r|\mathbf{p}) = \frac{1}{\sigma_W(\mathbf{p})} g\left(\frac{r - \mathcal{S}(\mathbf{p})}{\sigma_W(\mathbf{p})}\right) . \tag{7}$$

Equivalently, we can express the simulation output as

$$R = \mathcal{S}(\mathbf{p}) + W , \tag{8}$$

where W is a (possibly unbounded) absolutely continuous measurement noise random variable with probability density

$$f_{W|\mathbf{P}}(w|\mathbf{p}) = \frac{1}{\sigma_W(\mathbf{p})} g\left(\frac{w}{\sigma_W(\mathbf{p})}\right) . \tag{9}$$

As the expectation of R given $\mathbf{p}$ is $\mathcal{S}(\mathbf{p})$, or, equivalently, the expectation of W is zero, we implicitly preclude biased simulation estimators; we shall further assume that the noise is symmetric, $g(w) = g(-w)$. These assumptions, though not essential, greatly facilitate the subsequent analysis, in particular in the case of unbounded noise. Note that we aim to predict the exact mathematical-model output, $\mathcal{S}(\mathbf{p})$, not the simulation result, R, since the simulation measurement error is presumed not relevant to the mathematical system which the numerical calculation purportedly represents.

3. Validation procedure. In this section we present (in §3.1) and prove (in §3.2) our central validation result for noisy simulations.

3.1. Validation statement. We take as given $0 < \varepsilon_1 < 1, 0 < \varepsilon_2 < 1$, and $0 \leq \alpha \leq 1$, and define $\gamma_\alpha(\mathbf{p})$ and N as

$$\int_{-\infty}^{-\gamma_\alpha(\mathbf{p})} f_{W|\mathbf{P}}(w|\mathbf{p}) dw = \alpha \tag{10}$$

and

$$N = \frac{\ln \varepsilon_2}{\ln[1 - \varepsilon_1(1 - \alpha)]} , \tag{11}$$

respectively. We next construct the sample of independent identically distributed ordered pairs

$$\{(\mathbf{P}_1, R_1), \ldots, (\mathbf{P}_N, R_N)\} , \tag{12}$$

where each $(\mathbf{P}_j, R_j)$ has joint probability density function

$$f_{\mathbf{P},R}(\mathbf{p}, r) = \rho(\mathbf{p}) f_{R|\mathbf{P}}(r|\mathbf{p}) ; \tag{13}$$

the importance function-cum-marginal density $\rho(\mathbf{p})$ can thus be viewed as a Bayesian prior on the simulation input vector (Yeşilyurt and Patera (1995)). Then,

$$\Pr\left\{\int_{\{\mathbf{p}\in\Omega \,|\, |\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})| \leq U\}} \rho(\mathbf{p}) \mathbf{dp} \geq 1 - \varepsilon_1\right\} \geq 1 - \varepsilon_2 , \tag{14}$$

where

$$U = \max_{j\in\{1,\dots,N\}} \{|R_j - \widetilde{\mathcal{S}}(\mathbf{P}_j)| + \gamma_\alpha(\mathbf{P}_j)\} \tag{15}$$

is the noisy *model prediction error estimator* (that is, the surrogate "bias"). Identifying $U = B$, we recognize the probably approximately correct error statement, (4), motivated in §2.

The Monte-Carlo algorithm associated with (14) and (15) is transparent: we sample N values of the design random vector over Ω, $\mathbf{P}_j$, $j = 1, \dots, N$, according to the specified density $\rho(\mathbf{p})$; we compute a (noisy) simulation result, R_j, at each design point $\mathbf{P}_j$; finally, we calculate the model prediction error estimator, U, from (10) and (15). The result can be interpreted from two perspectives: as a tolerance limit, U, for $|\mathcal{S}(\mathbf{P}) - \widetilde{\mathcal{S}}(\mathbf{P})|$; and as a nonparametric joint confidence interval over $1-\varepsilon_1$ of the design domain, Ω, for the surrogate-simulation misfit, $-U \le \mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p}) \le U$, or, equivalently, for the noise-free simulation result, $\widetilde{\mathcal{S}}(\mathbf{p}) - U \le \mathcal{S}(\mathbf{p}) \le \widetilde{\mathcal{S}}(\mathbf{p}) + U$. We now turn to a proof of (14).

3.2. Proof of validation error estimate. To begin, we define ξ_q as the q "quantile" of $|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})|$,

$$\xi_q = \min \zeta \text{ such that } \mathcal{F}(\zeta) \ge q \ , \tag{16}$$

where

$$\mathcal{F}(\zeta) = \int_{\{\mathbf{p}\in\Omega \,|\, |\mathcal{S}(\mathbf{p})-\widetilde{\mathcal{S}}(\mathbf{p})|\le\zeta\}} \rho(\mathbf{p})\mathbf{dp} \ . \tag{17}$$

We then introduce the domain

$$\mathcal{Q} = \{\mathbf{p} \in \Omega \,|\, |\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})| \ge \xi_{1-\varepsilon_1}\} \tag{18}$$

and associated partition

$$\mathcal{Q} = \mathcal{Q}^+ \cup \mathcal{Q}^- \ , \tag{19}$$

where

$$\begin{aligned} \mathcal{Q}^+ &= \{\mathbf{p} \in \mathcal{Q} \,|\, \mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p}) \ge 0\} \ , \\ \mathcal{Q}^- &= \{\mathbf{p} \in \mathcal{Q} \,|\, \mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p}) < 0\} \ . \end{aligned} \tag{20}$$

It then follows from (16), (18), and the right-continuity of $\mathcal{F}(\zeta)$, that

$$\int_{\mathcal{Q}} \rho(\mathbf{p})\mathbf{dp} = \beta\varepsilon_1 \tag{21}$$

for some β, $1 \le \beta \le 1/\varepsilon_1$. Note that, if $\mathcal{F}(\zeta)$ is continuous (that is, no contours of $|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})|$ are of finite measure), then β will be unity.

We now define $(\mathbf{p}, w) \in \mathcal{D} \equiv \Omega \times \mathbb{R}$, and introduce $\mathcal{T} \subset \mathcal{D}$,

$$\begin{aligned} \mathcal{T}^+ &= \{(\mathbf{p}, w) \in \mathcal{D} \,|\, \mathbf{p} \in \mathcal{Q}^+, w \ge -\gamma_\alpha(\mathbf{p})\}, \\ \mathcal{T}^- &= \{(\mathbf{p}, w) \in \mathcal{D} \,|\, \mathbf{p} \in \mathcal{Q}^-, w \le \gamma_\alpha(\mathbf{p})\}, \\ \mathcal{T} &= \mathcal{T}^+ \cup \mathcal{T}^-. \end{aligned} \tag{22}$$

It then follows from (21) and (22) that

$$\begin{aligned}
&\int_{\mathcal{T}} \rho(\mathbf{p}) f_{W|\mathbf{P}}(w|\mathbf{p}) dw\, \mathbf{dp} \\
&= \int_{\mathcal{Q}^+} \rho(\mathbf{p}) \left(\int_{-\gamma_\alpha(\mathbf{p})}^{\infty} f_{W|\mathbf{P}}(w|\mathbf{p}) dw \right) \mathbf{dp} + \int_{\mathcal{Q}^-} \rho(\mathbf{p}) \left(\int_{-\infty}^{\gamma_\alpha(\mathbf{p})} f_{W|\mathbf{P}}(w|\mathbf{p}) dw \right) \mathbf{dp} \\
&= \int_{\mathcal{Q}} \rho(\mathbf{p}) \mathbf{dp}\, (1-\alpha) = \beta\varepsilon_1(1-\alpha) \ . \qquad (23)
\end{aligned}$$

We now introduce $W_j = R_j - \mathcal{S}(\mathbf{P}_j)$, the noise contribution associated with the $\mathbf{P}_j$ sample point; from (7)–(9) and (13) we know that $(\mathbf{P}_j, W_j)$ has joint probability density function

$$f_{\mathbf{P},W}(\mathbf{p}, w) = \rho(\mathbf{p}) f_{W|\mathbf{P}}(w|\mathbf{p}) \ . \qquad (24)$$

We therefore infer from (23) and (24) that

$$\begin{aligned}
&\Pr\{\exists\, j^* \in \{1, \dots, N\} \text{ such that } (\mathbf{P}_{j^*}, W_{j^*}) \in \mathcal{T}\} \\
&= 1 - (1 - \beta\varepsilon_1(1-\alpha))^N \geq 1 - (1 - \varepsilon_1(1-\alpha))^N \ , \qquad (25)
\end{aligned}$$

and thus

$$\Pr\{\exists\, j^* \in \{1, \dots, N\} \text{ such that } (\mathbf{P}_{j^*}, W_{j^*}) \in \mathcal{T}\} \geq 1 - \varepsilon_2 \qquad (26)$$

for N satisfying the sample-size requirement (11).

To complete the demonstration we note from (18) and (22) that, for $(\mathbf{P}_{j^*}, W_{j^*}) \in \mathcal{T}$,

$$\begin{aligned}
|R_{j^*} - \widetilde{\mathcal{S}}(\mathbf{P}_{j^*})| + \gamma_\alpha(\mathbf{P}_{j^*}) &= |\mathcal{S}(\mathbf{P}_{j^*}) - \widetilde{\mathcal{S}}(\mathbf{P}_{j^*}) + W_{j^*}| + \gamma_\alpha(\mathbf{P}_{j^*}) \\
&\geq |\mathcal{S}(\mathbf{P}_{j^*}) - \widetilde{\mathcal{S}}(\mathbf{P}_{j^*})| \geq \xi_{1-\varepsilon_1} \ . \qquad (27)
\end{aligned}$$

Therefore, from (16) and (27)

$$\begin{aligned}
&\int_{\{\mathbf{p}\in\Omega \,|\, |\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})| \leq |R_{j^*} - \widetilde{\mathcal{S}}(\mathbf{P}_{j^*})| + \gamma_\alpha(\mathbf{P}_{j^*})\}} \rho(\mathbf{p}) \mathbf{dp} \\
&\geq \int_{\{\mathbf{p}\in\Omega \,|\, |\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})| \leq \xi_{1-\varepsilon_1}\}} \rho(\mathbf{p}) \mathbf{dp} \geq 1 - \varepsilon_1 \ . \qquad (28)
\end{aligned}$$

Finally, (14) follows from

$$\begin{aligned}
&\int_{\{\mathbf{p}\in\Omega \,|\, |\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})| \leq |R_{j^*} - \widetilde{\mathcal{S}}(\mathbf{P}_{j^*})| + \gamma_\alpha(\mathbf{P}_{j^*})\}} \rho(\mathbf{p}) \mathbf{dp} \geq 1 - \varepsilon_1 \\
&\Rightarrow \int_{\{\mathbf{p}\in\Omega \,|\, |\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})| \leq U\}} \rho(\mathbf{p}) \mathbf{dp} \geq 1 - \varepsilon_1 \ , \qquad (29)
\end{aligned}$$

and the probability statement (26). This result can be extended to multiple outputs by application of Boole's inequality (Yeşilyurt (1995)). In summary, the proof is simply a binomial argument in a product space comprising both the input and the noise contributions to the simulation result.

4. Model prediction error estimator. In this section we aim to understand the effect of the simulation noise on the model prediction error estimator, U. In particular, improved validation (smaller ε_1 and ε_2) implies, from (11), larger N, and hence greater likelihood that U, the $|R_j - \tilde{\mathcal{S}}(\mathbf{P}_j)|$ sample *maximum*, will reflect—in fact, select—larger noise contributions. We remark that the rigorous application of the validation statement (14) to the purposive structure described in §2 is not dependent on estimation of the noise; our noise estimates serve only to minimize the computational effort or to sharpen the bounds. In this sense, we can proceed somewhat less stringently, looking at expectation rather than confidence intervals.

4.1. Bounded noise. We consider here the case in which the noise is bounded: $f_{W|\mathbf{P}}(w|\mathbf{p}) = 0$ for $|w| > (c_W/2)\sigma_W(\mathbf{p})$, where $c_W > 0$ is independent of $\mathbf{p}$; equivalently, $g(v) = 0$ for $|v| > c_W/2$. Bounded noise is a reasonable model (or bound) for the measurement noise associated with finite-element methods for partial differential equations. For bounded noise it is interesting to consider $\alpha = 0$, which implies from (10) and (11) that

$$\gamma_\alpha(\mathbf{p}) = (c_W/2)\sigma_W(\mathbf{p}) \tag{30}$$

and

$$N = \frac{\ln \varepsilon_2}{\ln(1-\varepsilon_1)} , \tag{31}$$

respectively. Finally, from (8) and (15) we derive that

$$U \le \max_{j\in\{1,\dots,N\}} |\mathcal{S}(\mathbf{P}_j) - \tilde{\mathcal{S}}(\mathbf{P}_j)| + c_W \sigma_W^{\max} , \tag{32}$$

where $\sigma_W^{\max} = \max_{\mathbf{p}\in\Omega} \sigma_W(\mathbf{p})$. In the limit that $\sigma_W^{\max} \to 0$, both the sample size requirement, (31), and the model prediction error estimator, (32), approach the corresponding limits for a *noise-free* simulation (Yeşilyurt and Patera (1995)); at least in this particular limit, our noisy result is, in some sense, sharp. Biased bounded noise is considered in Yeşilyurt (1995).

4.2. Unbounded noise. We consider here the case of unbounded noise, in which the probability density for the noise is potentially nonzero for all values of $w \in \mathbb{R}$. To make our ideas more concrete, we shall assume that $\alpha = 1/2$, so that $\gamma_\alpha(\mathbf{p}) = 0$ (independent of both $\mathbf{p}$ and the form of the assumed-symmetric $g(w)$), and

$$N = \frac{\ln \varepsilon_2}{\ln(1-\frac{\varepsilon_1}{2})} . \tag{33}$$

Unbounded noise is relevant to Monte-Carlo simulations (Rubinstein (1981)). We will occasionally appeal to a canonical "Monte-Carlo subproblem," by which we shall refer to a specific simulation procedure in which the simulation random output is the result of a standard sample mean calculation,

$$R = \frac{1}{\mathcal{N}} \sum_{k=1}^{\mathcal{N}} Q_k , \tag{34}$$

where the Q_k are (for any particular $\mathbf{p} \in \Omega$) independent identically distributed random variables with mean $\mathcal{S}(\mathbf{p})$, finite variance $\sigma_Q^2(\mathbf{p})$, and probability density function $f_Q(q)$. It follows that $\sigma_W(\mathbf{p}) = \sigma_Q(\mathbf{p})/\sqrt{\mathcal{N}}$, and that R is asymptotically normal as $\mathcal{N} \to \infty$. We refer to $\mathcal{N}$ as the subproblem sample size to avoid confusion with the validation sample size, N.

We measure the effect of the noise by the random variable $Y = \mathcal{Y}(\underline{\mathbf{P}}, \underline{W})$,

$$\mathcal{Y}(\underline{\mathbf{P}}, \underline{W}) = \max_{j\in\{1,\ldots,N\}} |\mathcal{S}(\mathbf{P}_j) + W_j - \widetilde{\mathcal{S}}(\mathbf{P}_j)| - \max_{j'\in\{1,\ldots,N\}} |\mathcal{S}(\mathbf{P}_{j'}) - \widetilde{\mathcal{S}}(\mathbf{P}_{j'})| \,, \tag{35}$$

where $\underline{\mathbf{P}} = (\mathbf{P}_1, \ldots, \mathbf{P}_N)$ and $\underline{W} = (W_1, \ldots, W_N)$. Note that, even in the absence of noise, our validation statement does not permit a priori estimation of $|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})|$ without further assumptions on $\mathcal{S}(\mathbf{p})$ and $\widetilde{\mathcal{S}}(\mathbf{p})$; our focus here is on understanding the incremental effect of noise on the model prediction error estimator. (The presence of unbounded noise also increases N, (33), with respect to the bounded-noise and noise-free cases, (31); this "secondary" effect is not reflected in Y.) Ultimately, we will require a relationship which specifies the allowable simulation noise, as a function of ε_1 and ε_2, such that "variance" does not dominate surrogate "bias." We implicitly assume that the simulation noise can be controlled through precise random sampling and subproblem replication, as in our model Monte-Carlo subproblem (34); if this were not the case, we would need to pursue a kernel smoothing approach (Wahba (1975), Silverman (1985), Härdle (1990)), in which local-in-$\mathbf{p}$ validation averages (or, equivalently, smoothness requirements) replace subproblem replication.

4.2.1. Bound for expected noise contribution. We consider here estimates for the expectation of Y with respect to $\underline{\mathbf{P}}$ and $\underline{W}$ *conditioned* on the event that $A = 1$, where A is the indicator random variable,

$$A = \begin{cases} 0 & \text{if} \quad \int_{\{\mathbf{p}\in\Omega\,|\,|\mathcal{S}(\mathbf{p})-\widetilde{\mathcal{S}}(\mathbf{p})|\le U\}} \rho(\mathbf{p})\mathbf{dp} < 1-\varepsilon_1 \\ 1 & \text{if} \quad \int_{\{\mathbf{p}\in\Omega\,|\,|\mathcal{S}(\mathbf{p})-\widetilde{\mathcal{S}}(\mathbf{p})|\le U\}} \rho(\mathbf{p})\mathbf{dp} \ge 1-\varepsilon_1, \end{cases} \tag{36}$$

that signals successful validation. Denoting the sample space as $\Xi = \Omega^N \times \mathbb{R}^N$, we can express the required conditional expectation as

$$E_{\underline{\mathbf{P}},\underline{W}|A=1}(Y) = \frac{\int_{\{(\underline{\mathbf{p}},\underline{w})\in\,\Xi\,|\,A=1\}} \mathcal{Y}(\underline{\mathbf{p}},\underline{w}) \prod_{i=1}^N f_{\mathbf{P},W}(\mathbf{p}_i, w_i)\mathbf{dp}_i dw_i}{\int_{\{(\underline{\mathbf{p}},\underline{w})\in\,\Xi\,|\,A=1\}} \prod_{i=1}^N f_{\mathbf{P},W}(\mathbf{p}_i, w_i)\mathbf{dp}_i dw_i} \,. \tag{37}$$

Denoting

$$\hat{j} = \arg \max_{j\in\{1,\ldots,N\}} |\mathcal{S}(\mathbf{P}_j) + W_j - \widetilde{\mathcal{S}}(\mathbf{P}_j)|, \tag{38}$$

we deduce that

$$\begin{aligned} Y &\le |\mathcal{S}(\mathbf{P}_{\hat{j}}) + W_{\hat{j}} - \widetilde{\mathcal{S}}(\mathbf{P}_{\hat{j}})| - |\mathcal{S}(\mathbf{P}_{\hat{j}}) - \widetilde{\mathcal{S}}(\mathbf{P}_{\hat{j}})| \\ &\le |W_{\hat{j}}| \le Z \,, \end{aligned} \tag{39}$$

where $Z = \mathcal{Z}(\underline{\mathbf{P}}, \underline{W})$ is the random variable

$$Z = \max_{j\in\{1,\ldots,N\}} (|W_j|) \,. \tag{40}$$

Since Z is nonnegative, and since the denominator of (37) is, by (14), greater than or equal to $1 - \varepsilon_2$, we conclude that

$$\begin{aligned} E_{\underline{\mathbf{P}},\underline{W}|A=1}(Y) &\le \int_{\{(\underline{\mathbf{p}},\underline{w})\in\,\Xi\,|\,A=1\}} \mathcal{Z}(\underline{\mathbf{p}},\underline{w}) \prod_{i=1}^N f_{\mathbf{P},W}(\mathbf{p}_i, w_i)\mathbf{dp}_i dw_i/(1-\varepsilon_2) \\ &\le \int_{\{(\underline{\mathbf{p}},\underline{w})\in\,\Xi\}} \mathcal{Z}(\underline{\mathbf{p}},\underline{w}) \prod_{i=1}^N f_{\mathbf{P},W}(\mathbf{p}_i, w_i)\mathbf{dp}_i dw_i/(1-\varepsilon_2) \\ &= E_{\underline{\mathbf{P}},\underline{W}}(Z)/(1-\varepsilon_2) \,. \end{aligned} \tag{41}$$

Finally, applying standard conditional-expectation and order-statistic manipulations (Mood, Graybill, and Boes (1974); David (1981); Arnold and Balakrishnan (1989)), we arrive at the explicit expression

$$E_{\underline{\mathbf{P}},\underline{W}}(Z) = \int_{\Omega^N} \prod_{k=1}^{N} \rho(\mathbf{p}_k) \times \left(\int_0^\infty \sum_{i=1}^{N} \prod_{j \neq i} (1 - 2F_{W|\mathbf{P}}(-v|\mathbf{p}_j)) 2 f_{W|\mathbf{P}}(v|\mathbf{p}_i) v \, dv \right) \mathbf{dp}_k \,, \tag{42}$$

where $F_{W|\mathbf{P}}(w|\mathbf{p})$ is the cumulative distribution function associated with $f_{W|\mathbf{P}}(w|\mathbf{p})$. Expression (42) now admits a priori treatment since all dependence on the uncharacterized functions $\mathcal{S}(\mathbf{p})$ and $\widetilde{\mathcal{S}}(\mathbf{p})$ has been eliminated.

Estimation for unknown density. We consider here a further bound which requires knowledge only of the (assumed-finite) variance, $\sigma_W^2(\mathbf{p})$, of the noise conditional density $f_{W|\mathbf{P}}$. Applying the Cauchy–Schwarz inequality to the integral over v in (42), we find

$$E_{\underline{\mathbf{P}},\underline{W}}(Z) \leq \int_{\Omega^N} \prod_{k=1}^{N} \rho(\mathbf{p}_k) \times \sum_{i=1}^{N} \left(\int_0^\infty \prod_{j \neq i} (1 - 2F_{W|\mathbf{P}}(-v|\mathbf{p}_j))^2 \, 2 f_{W|\mathbf{P}}(v|\mathbf{p}_i) dv \right)^{1/2} \sigma_W(\mathbf{p}_i) \mathbf{dp}_k . \tag{43}$$

Next we apply the Cauchy–Schwarz inequality to the sum over i to obtain

$$E_{\underline{\mathbf{P}},\underline{W}}(Z) \leq \int_{\Omega^N} \prod_{k=1}^{N} \rho(\mathbf{p}_k) \times \left(\int_0^\infty \sum_{i=1}^{N} \prod_{j \neq i} (1 - 2F_{W|\mathbf{P}}(-v|\mathbf{p}_j))^2 \, 2 f_{W|\mathbf{P}}(v|\mathbf{p}_i) dv \right)^{1/2} \times \left(\sum_{\ell=1}^{N} \sigma_W^2(\mathbf{p}_\ell) \right)^{1/2} \mathbf{dp}_k . \tag{44}$$

Noting that we can conservatively (albeit crudely) replace the exponent of the $(1 - 2F_{W|\mathbf{P}}(-v|\mathbf{p}_j))$ term in the integral over v by unity (this is not required if $\sigma_W(\mathbf{p})$ is constant), we find

$$E_{\underline{\mathbf{P}},\underline{W}}(Z) \leq \int_{\Omega^N} \prod_{k=1}^{N} \rho(\mathbf{p}_k) \left(\sum_{\ell=1}^{N} \sigma_W^2(\mathbf{p}_\ell) \right)^{1/2} \mathbf{dp}_k \,. \tag{45}$$

A final application of the Cauchy–Schwarz inequality then yields

$$E_{\underline{\mathbf{P}},\underline{W}}(Z) \leq \sqrt{N} \sigma_W^\rho \tag{46}$$

where

$$\sigma_W^\rho = \left(\int_\Omega \rho(\mathbf{p}) \sigma_W^2(\mathbf{p}) \mathbf{dp} \right)^{1/2} . \tag{47}$$

In cases where $\sigma_W(\mathbf{p})$ is known only at the validation sample points, the integral (47) is approximated by an N-point Monte-Carlo quadrature,

$$\sigma_W^\rho \approx \left(\frac{1}{N} \sum_{j=1}^{N} \sigma_W^2(\mathbf{p}_j) \right)^{1/2} , \tag{48}$$

where $\{\mathbf{p}_1, \ldots, \mathbf{p}_N\}$ is the validation input sample realization. In the case where $\sigma_W(\mathbf{p})$ is, in fact, constant, the prefactor in (46) is easily improved to

$$\sqrt{N/2}\sqrt{2N/(2N-1)}.$$

In effect, (46), (47) extends certain standard results for extreme values (David (1981), Arnold and Balakrishnan (1989)) to the case of "marginal," or noisy (Ho, Sreenivas, and Vakili (1992)), order statistics. The bound (46), (47) indicates that, as expected, isolated noisy regions of the input space Ω will not unduly contaminate the model prediction error estimator. This result also suggests heuristics for designing computationally efficient "coupled" subproblem-validation evaluation procedures. For example, if we generalize (34) to permit $\mathbf{p}$-variable subproblem sample size, $\mathcal{N}(\mathbf{p})$, a simple constrained optimization exercise demonstrates that σ_W^ρ is minimized at fixed computational cost—defined as $\sum_{j=1}^N \mathcal{N}(\mathbf{p}_j)$—for $\mathcal{N}(\mathbf{p}_j) \propto \sigma_Q(\mathbf{p}_j)$. This particular coupled strategy is of limited computational relevance, as (46), (47) is not sharp for the noise densities typically encountered in practice.

Our fully assembled bound, (41), (46), and (47) (or (48)), states that σ_W^ρ must decrease no more slowly than $1/\sqrt{N}$ if the noise contribution to the model prediction error is not to dominate. For example, for our Monte-Carlo subproblem, (34), we need to increase the subproblem sample size, $\mathcal{N}$, roughly in proportion to the validation sample size, N, to bound the noise contribution as $N \to \infty$. Rephrasing our condition in terms of ε_1 and ε_2 from (33), we require that

$$\frac{\sigma_W^\rho\sqrt{-\ln\varepsilon_2}}{(1-\varepsilon_2)\sqrt{\varepsilon_1/2}} \tag{49}$$

remain bounded as $\varepsilon_1 \to 0$, $\varepsilon_2 \to 0$ (note we approximate $\ln(1-\varepsilon_1/2)$ by $(-\varepsilon_1/2)$). Although the dependence on ε_1 and certainly ε_2 is relatively weak, (49) is pessimistic for most noise densities that will obtain in practice. □

Estimation for known density. In the event that we know (or can approximate) the noise conditional density, $f_{W|\mathbf{P}}$, we can directly evaluate (42) as

$$E_{\underline{\mathbf{P}},\underline{W}}(Z) = N\int_0^\infty \mathcal{I}_1(v)^{N-1}\mathcal{I}_2(v)v\,dv\ , \tag{50}$$

where

$$\mathcal{I}_1(v) = \int_\Omega \rho(\mathbf{p})(1-2F_{W|\mathbf{P}}(-v|\mathbf{p}))\mathbf{dp}\ , \tag{51}$$

$$\mathcal{I}_2(v) = \int_\Omega \rho(\mathbf{p})2f_{W|\mathbf{P}}(v|\mathbf{p})\mathbf{dp}\ . \tag{52}$$

In cases where $f_{W|\mathbf{P}}$ is known only at the validation sample points, the integrals (51) and (52) are effected by an N-point Monte-Carlo quadrature,

$$\mathcal{I}_1(v) \approx \frac{1}{N}\sum_{j=1}^N (1-2F_{W|\mathbf{P}}(-v|\mathbf{p}_j))\ , \tag{53}$$

$$\mathcal{I}_2(v) \approx \frac{1}{N}\sum_{j=1}^N 2f_{W|\mathbf{P}}(v|\mathbf{p}_j)\ , \tag{54}$$

where $\{\mathbf{p}_1, \ldots, \mathbf{p}_N\}$ is the validation input sample realization. Our fully assembled bound is, thus, (41), (50), and (51)–(52) or (53)–(54), in which (50) is evaluated by numerical or symbolic integration. □

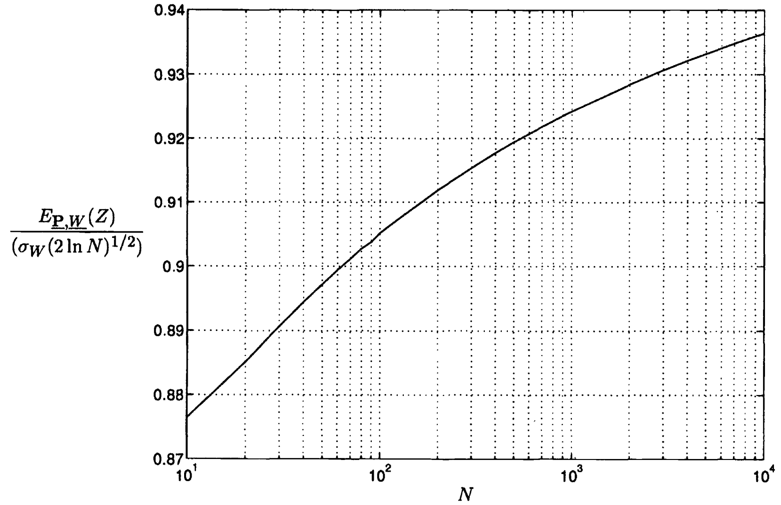

FIG. 1. *Plot of $E_{\underline{\mathbf{P}},\underline{W}}(Z)/(\sigma_W(2\ln N)^{1/2})$ as a function of sample size N for the normal parent.*

Estimation for normal parent. We briefly discuss the application of the bound (41), (50), (51)–(52) to the particular case in which the noise density is normal, first, because of the central importance of the normal density in many Monte-Carlo calculations, and second, to demonstrate that, in practice, (49) is unduly pessimistic. We consider a particularly simple situation, $\sigma_W(\mathbf{p}) = \sigma_W$ constant, for which (50) admits ready numerical evaluation. In Figure 1 we plot $E_{\underline{\mathbf{P}},\underline{W}}(Z)/(\sigma_W(2\ln N)^{1/2})$ as a function of sample size for $10 \leq N \leq 10^4$. As expected from asymptotic theory (David (1981)), this normalized expectation slowly approaches unity as N increases. We thus conclude that, if the noise contribution is not to dominate the model prediction error estimator, σ_W must decrease no more slowly than $(2\ln N)^{-1/2}$. More precisely, from (33), (41), (50), and Figure 1, we require that

$$\text{(55)} \qquad \frac{\sqrt{2}\sigma_W}{1-\varepsilon_2}\left(\ln(-\ln\varepsilon_2) + \ln\frac{2}{\varepsilon_1}\right)^{1/2}$$

remain bounded as $\varepsilon_1 \to 0$, $\varepsilon_2 \to 0$. This condition is clearly much less stringent than (49). (It is certainly of interest to develop an asymptotic theory for the normal parent $E_{\underline{\mathbf{P}},\underline{W}}(Z)$ which includes variance-variability ($\sigma_W(\mathbf{p}) \neq$ constant), as this would permit the design of practically relevant optimally coupled subproblem-validation evaluation procedures; to date, however, we have been unable to obtain a useful expression.) □

We conclude by remarking that our estimates of this section and §3 are similar to—but simpler than—corresponding $L^\infty(\Omega)$ estimates for the kernel smoothing approach (Härdle (1990)). Our results are simpler because we are less ambitious: first, we obtain estimates only for a "holey" (or "quantile") L^∞-seminorm which admits the possibility of an uncharacterized region of relative volume as large as ε_1 (Traub, Wasilkowski, and Wozniakowski (1988)); and second, we rely on precise sampling and replication for noise control. An advantage of the "holey" seminorm is that we require only minimal regularity hypotheses on $\mathcal{S}(\mathbf{p})$ and $\widetilde{\mathcal{S}}(\mathbf{p})$; however, if we do assume further smoothness, the "holey" L^∞-seminorm and true L^∞-norm can, of course, be related. For example, if we presume that $|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})|$ has sufficiently many derivatives in the neighborhood of a unique maximizer $\overline{\mathbf{p}}$ in the interior of $\Omega \subset \mathbb{R}^M$, then (Yeşilyurt (1995))

$$\text{(56)} \qquad \xi_{1-\varepsilon_1} \sim \|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})\|_{L^\infty(\Omega)} - \frac{1}{2}\left\{\frac{\varepsilon_1|H|^{1/2}}{\rho(\overline{\mathbf{p}})\,\omega_M}\right\}^{2/M} \qquad \text{as } \varepsilon_1 \to 0\,.$$

Here $|H|$ refers to the absolute value of the determinant of the Hessian matrix of $|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})|$ evaluated at $\mathbf{p} = \bar{\mathbf{p}}$, and ω_M is the volume of a hypersphere in $\mathbb{R}^M$ of unit radius ($\omega_\ell = 2\pi(\frac{\ell-2}{\ell})\omega_{\ell-2}$; $\omega_2 = \pi, \omega_1 = 2$). The expression (56) again illustrates the adverse effect of increased input-space dimension, M, on predictability and localization.

4.2.2. A posteriori guide. The distribution of Y of (35) is clearly sensitive not only to $f_{W|\mathbf{P}}$, but also to the relative magnitude and*form* of $|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})|$. The bounds of the previous section assume the worst–case scenario, in which the noise—not the variation in $|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})|$—selects $\hat{j}$ of (38). There are, however, instances in which the form of $|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})|$ will preclude many validation input points from contending for the $|R_j - \widetilde{\mathcal{S}}(\mathbf{P}_j)|$ sample maximizer, thereby reducing $E_{\underline{\mathbf{P}},\underline{W}|A=1}(|W_{\hat{j}}|)$, and hence $E_{\underline{\mathbf{P}},\underline{W}|A=1}(Y)$, relative to $E_{\underline{\mathbf{P}},\underline{W}|A=1}(Z)$.

In order to better reflect the form of $|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})|$ in our estimate of the noise contribution, we propose the simple a posteriori noise guideline,

$$\hat{\mathcal{Y}}(\underline{\mathbf{P}}, \underline{W}) = |\mathcal{S}(\mathbf{P}_{\hat{j}}) + W_{\hat{j}} - \widetilde{\mathcal{S}}(\mathbf{P}_{\hat{j}})| - |\mathcal{S}(\mathbf{P}_{\hat{j}}) - \widetilde{\mathcal{S}}(\mathbf{P}_{\hat{j}})| \,. \tag{57}$$

Although neither $\mathcal{S}(\mathbf{P}_j)$ nor W_j are known individually, calculation of $\hat{j}$ from (38) requires only the sum $\mathcal{S}(\mathbf{P}_j) + W_j$, which is simply the noisy simulation result, R_j. It is true that the second term in (57) requires $\mathcal{S}(\mathbf{P}_{\hat{j}})$, however the relative additional computational effort required to recompute the noise for this *single* input point will, in general, be small. The desirable properties of the random variable $\hat{Y} = \hat{\mathcal{Y}}(\underline{\mathbf{P}}, \underline{W})$ follow directly from (39):

$$Y \leq \hat{Y} \,, \tag{58}$$

$$E_{\underline{\mathbf{P}},\underline{W}|A=1}(\hat{Y}) \leq E_{\underline{\mathbf{P}},\underline{W}|A=1}(|W_{\hat{j}}|) \leq E_{\underline{\mathbf{P}},\underline{W}|A=1}(Z) \,. \tag{59}$$

The random variable $\hat{Y}$ is thus an upper bound for the noise effect for any particular realization which, in expectation, will be sharper than our previous estimates based on the maximum sample noise. In particular, $\hat{Y}$ will only reflect the noise from the validation subsample containing input points which are viable candidates for the $|R_j - \widetilde{\mathcal{S}}(\mathbf{P}_j)|$ sample maximizer. In actual practice (see §5.2), we will construct confidence intervals for $\hat{y}$, a particular realization of our noise bound.

5. Examples.

In this section we apply our surrogate-validation algorithm and associated error analysis to several test (§5.1) and actual (§5.2) noisy simulations in order to illustrate the performance and capability of the approach. We consider only unbounded noise, and set $\alpha = 1/2$ in all examples.

5.1. Test cases. In test case I we specify $M = 1 (\mathbf{p} = p)$, $\Omega = [0, 1]$, $\rho(\mathbf{p}) = 1$, and

$$(\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p}))_{\mathrm{I}} = \begin{cases} 0, & 0. \leq p < .9 \\ 1, & .9 \leq p \leq 1. \end{cases} \tag{60}$$

We take $f_{W|\mathbf{P}}$ to be normal with constant standard deviation, $\sigma_W(\mathbf{p}) = \sigma_W$. As our first set of parameters (test case I_1), we choose $\sigma_W = .1$, and $\varepsilon_1 = .1, \varepsilon_2 = .1$ (thus $N = 45$ from (33)). We then perform the validation algorithm described in §3.1 $L = 10,000$ times, and denote the validation success indicator variable, model prediction error estimate, actual noise contribution, and a posteriori noise guideline for the ℓth trial as a_ℓ, u_ℓ, y_ℓ, and $\hat{y}_\ell$, respectively. We define the number of successful validations as $L_A = \sum_{\ell=1}^{L} a_\ell$. For this test case we find $L_A/L = .902$; as expected, L_A/L is quite close to the success rate predicted from (14), $1 - \varepsilon_2 = .9$. Turning now to the noise contribution to the model prediction error estimate, we obtain $\frac{1}{L_A}\sum_{\ell=1}^{L} y_\ell a_\ell = .118$ for the empirical average of Y conditioned on $A = 1$. Our two bound procedures, (41), (46), (47) and (41), (50), (51)–(52) yield .745 and .275, respectively.

Given the form of $|\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p})|$ and the relatively low noise level, both bounds are, not surprisingly, quite conservative. Conversely, $\hat{Y}$ should be extremely sharp: indeed, we find $\frac{1}{L_A}\sum_{\ell=1}^{L} \hat{y}_\ell a_\ell = .118$ for the empirical average of $\hat{Y}$ conditioned on $A = 1$.

For our second set of parameters (test case I$_2$), we select $\sigma_W = .1$ and $\varepsilon_1 = .02$, $\varepsilon_2 = .1$ (thus $N = 230$ from (33)). We now find that $L_A/L = 1.000$, significantly greater than $1 - \varepsilon_2$; since $\beta > 1$ (see (21)), our probability statement (26) is conservative. We obtain $\frac{1}{L_A}\sum_{\ell=1}^{L} y_\ell a_\ell = .192$ for the empirical average of Y conditioned on $A = 1$; the noise is larger for $\varepsilon_1 = .02$ than for $\varepsilon_1 = .1$ as N (and the validation subsample of candidate maximizers) is larger in the former case. Our two bound procedures, (41), (46), (47) and (41), (50), (51)–(52) yield 1.69 and .334, respectively. The (41), (46), (47) bound is relatively worse for $\varepsilon_1 = .02$ than for $\varepsilon_1 = .1$ because of the increased validation sample size, N, required in the $\varepsilon_1 = .02$ case; the (41), (50), (51)–(52) bound is relatively *sharper* for $\varepsilon_1 = .02$ than for $\varepsilon_1 = .1$ because the $\varepsilon_1 = .02$ case is closer to the assumed-worst-case scenario. Finally, our a posteriori noise bound, $\hat{Y}$, remains the best estimate for the noise effect, as $\hat{Y}$ correctly disregards those input sample points ($\mathbf{P}_j < .9$) which, for $\sigma_W = .1$, are not candidates for the $|R_j - \widetilde{\mathcal{S}}(\mathbf{P}_j)|$ sample maximizer: we find $\frac{1}{L_A}\sum_{\ell=1}^{L} \hat{y}_\ell a_\ell = .192$ for the empirical average of $\hat{Y}$ conditioned on $A = 1$.

For our third set of parameters (test case I$_3$) we choose $\sigma_W = 10$ and $\varepsilon_1 = .1$, $\varepsilon_2 = .1$ (thus $N = 45$ from (33)). We find $L_A/L = 1.000$, again significantly greater than $1 - \varepsilon_2$; in this case, the increased validation success rate can be traced to the bounds (27)–(29). We obtain $\frac{1}{L_A}\sum_{\ell=1}^{L} y_\ell a_\ell = 23.8$ for the empirical average of Y conditioned on $A = 1$. Our two bound procedures (41), (46), (47) and (41), (50), (51)–(52) yield 74.5 and 27.5, respectively; as expected, the latter bound is now quite sharp, since for $\sigma_W = 10$ the maximum is entirely variance-dominated. The a posteriori noise guideline can provide relatively little improvement in this case: we find $\frac{1}{L_A}\sum_{\ell=1}^{L} \hat{y}_\ell a_\ell = 24.7$ for the empirical average of $\hat{Y}$ conditioned on $A = 1$.

In test case II we specify $M = 2(\mathbf{p} = (p_{(1)}, p_{(2)}))$, $\Omega = [0, 1]^2$, $\rho(\mathbf{p}) = 1$, and

$$(\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p}))_{\mathrm{II}} = \sin(\pi p_{(1)}) \sin(\pi p_{(2)}) \;. \tag{61}$$

We take $f_{W|\mathbf{P}}$ to be normal with constant standard deviation, $\sigma_W(\mathbf{p}) = \sigma_W = .1$, and choose $\varepsilon_1 = .1$, $\varepsilon_2 = .1$ (thus $N = 45$ from (33)). Performing $L = 10,000$ trials of the validation algorithm, we obtain $L_A/L = .994$; here again, the increased validation success rate originates in the bounds (27)–(29). Note that successful validation ($a_\ell = 1$) implies that $|(\mathcal{S}(\mathbf{p}) - \widetilde{\mathcal{S}}(\mathbf{p}))_{\mathrm{II}}| > u_\ell$ over an "uncharacterized" region of relative volume, μ, no greater than ε_1; for this two-dimensional input space, however, the "uncharacterized" region will, perforce, include excursions of greater than $\sqrt{\mu}$ in at least one input variable. We find $\frac{1}{L_A}\sum_{\ell=1}^{L} y_\ell a_\ell = .0736$ for the empirical average of Y conditioned on $A = 1$. Our two bound procedures (41), (46), (47) and (41), (50), (51)–(52) yield .745 and .275, respectively; as for test case I$_1$, these bounds are rather pessimistic. The a posteriori noise guideline remains relatively sharp, $\frac{1}{L_A}\sum_{\ell=1}^{L} \hat{y}_\ell a_\ell = .114$, however there is some deterioration relative to the ideal performance obtained in test case I$_1$.

5.2. Multicomponent media.

5.2.1. Formulation. We consider here the calculation of the transverse effective thermal conductivity of a random fibrous composite comprising a continuous phase of thermal conductivity unity and a dispersed phase of volumetric concentration ϕ consisting of co-oriented insulating cylindrical rods of unity diameter (Sangani and Yao (1988); Cruz and Patera (1995); Cruz, Ghaddar, and Patera (1995); Ghaddar (1995)). The calculation proceeds in a periodically replicated supercell, $\mathbf{x} \in [0, \theta] \times [0, \theta]$, containing $N_c = 4\phi\theta^2/\pi$ cylinders, as shown

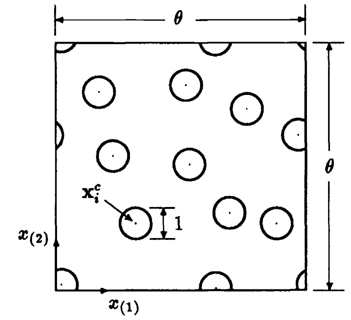

FIG. 2. *Fibrous-composite supercell* $[0,\theta]\times[0,\theta]$ *containing* N_c *cylindrical insulating inclusions.*

in Figure 2; the placement of the cylinder centers within the supercell, $\underline{\mathbf{x}}^c = (\mathbf{x}_1^c,\ldots,\mathbf{x}_{N_c}^c)$, is prescribed in terms of an assumed isotropic and homogeneous joint probability density function, $f_{\underline{\mathbf{X}}^c}(\underline{\mathbf{x}}^c;\phi,\theta)$. The (by isotropy, scalar) transverse *supercell effective conductivity*, normalized by the continuous phase conductivity, is then defined as

$$k_e(\phi,\theta) = \int_{([0,\theta]\times[0,\theta])^{N_c}} k(\underline{\mathbf{x}}^c,\phi,\theta) f_{\underline{\mathbf{X}}^c}(\underline{\mathbf{x}}^c;\phi,\theta)\underline{\mathbf{d}}\,\underline{\mathbf{x}}^c \ . \tag{62}$$

Here $k(\underline{\mathbf{x}}^c,\phi,\theta)$ is the transverse *configuration effective conductivity* for a particular θ-supercell cylinder placement, defined as the actual heat transfer across any (say) $x_{(1)}$ plane, normalized by the product of the imposed $x_{(1)}$ temperature gradient and the superficial area/depth, θ; $k(\underline{\mathbf{x}}^c,\phi,\theta)$ is a functional of the solution to the microstructure conduction problem on $\mathbf{x} = (x_{(1)}, x_{(2)}) \in [0,\theta]\times[0,\theta]$. Note that the longitudinal effective conductivity is trivial (in fact, structure-independent) for a co-oriented fibrous composite.

The effective property analysis is completed by (Cruz and Patera (1995)): defining *the* effective conductivity, $k_e^\infty(\phi)$, as $k_e(\phi,\theta\to\infty)$; determining a correlation-length function, $\Theta(\phi)$, such that, for $\theta \geq \Theta(\phi)$, (i) $k_e(\phi,\theta)$ no longer changes appreciably, and (ii) the standard deviation of the random variable K,

$$K = k(\underline{\mathbf{X}}^c,\phi,\theta) \ , \tag{63}$$

is sufficiently small. It then follows that $k_e^\infty(\phi)$ (or, equivalently, $k_e(\phi,\Theta(\phi))$ serves as an accurate effective conductivity for any macroscale problem for which the domain is large compared to $\Theta(\phi)$. (More generally, we may consider any macroscale problem for which the concentration and inclusion distribution vary only over a lengthscale large compared to $\Theta(\phi)$; within the purposiveness framework described in §2, however, we are restricted to uniform-concentration macroscale problems.) For the purposes of the current paper we will not consider the limiting process in θ; rather, we shall compute the supercell effective conductivity-concentration relationship for a particular θ, $\theta_0 = 6$, which is sufficiently large that size effects are reasonably small (Cruz and Patera (1995)). Note that, in practice, for each concentration ϕ we choose that θ closest to θ_0 for which N_c is an integer.

Finally, in order to proceed further, we must know the inclusion joint probability density function. Unfortunately, in most physical systems, details of the inclusion distribution are, at best, costly to obtain, and, more typically, simply unavailable. Furthermore, although it is possible to develop effective property *bounds* which are either independent of the inclusion joint probability density or dependent only on certain low-order correlation functions (Hashin (1983); Torquato (1991)), these bounds are often not sufficiently tight for a priori application.

For example, for our insulating fibrous medium, the best possible structure-independent *upper* bound for $k_e(\phi, \theta)$ is $\widetilde{k}_e(\phi) = (1 - \phi)/(1 + \phi)$ (Hashin (1970)), however the corresponding *lower* bound is, perforce, zero. We propose to exploit the complementary attributes of structure-dependent and structure-independent approaches by adopting the latter as surrogates for the former; if the structure-independent upper bound, $\widetilde{k}_e(\phi)$, proves an accurate estimate for $k_e(\phi, \theta_0)$ for a physically relevant inclusion density function, then (i) we will have expanded the prognostic range of the upper bound, and (ii) we will have obtained a simple, robust expression for the effective conductivity for the particular random medium of interest.

As our (arguably) physically relevant inclusion joint probability density function we assume

$$f_{\underline{\mathbf{X}}^c} = \left(\prod_{i=2}^{N_c} f_{\mathbf{x}_i^c | \mathbf{x}_{i-1}^c, \ldots, \mathbf{x}_1^c} \right) f_{\mathbf{x}_1^c} \,, \tag{64}$$

where

$$f_{\mathbf{x}_1^c}(\mathbf{x}_1^c) = 1/\theta_0^2 \,, \quad \mathbf{x}_1^c \in [0, \theta_0] \times [0, \theta_0] \,, \tag{65}$$

and

$$f_{\mathbf{x}_j^c | \mathbf{x}_{j-1}^c, \ldots, \mathbf{x}_1^c}(\mathbf{x}_j^c | \mathbf{x}_{j-1}^c, \ldots, \mathbf{x}_1^c) = \begin{cases} 0, & \mathbf{x}_j^c \notin \mathcal{P}_j \\ 1/\int_{\mathcal{P}_j} \mathbf{dx}^c, & \mathbf{x}_j^c \in \mathcal{P}_j, \end{cases} \tag{66}$$

$$\mathcal{P}_j = [0, \theta_0] \times [0, \theta_0] \setminus \bigcup_{n=1}^{j-1} D_{\mathbf{x}_n^c} \,, \tag{67}$$

for $j = 2, \ldots, N_c$. Here $D_{\mathbf{x}_n^c}$ is the (periodically extended) disk with center $\mathbf{x}_n^c$ and diameter 2. The density (64)–(67) describes a "random sequential addition" process (Widom (1966), Torquato (1991)), and is closely related to several other commonly used microstructure distributions (Torquato (1991), Cruz and Patera (1995)).

5.2.2. Simulation subproblem. Our numerical procedure consists of Monte-Carlo and finite-element treatment of the integral and integrand, respectively, of the supercell effective conductivity relationship, (62). In particular, the calculation of the configuration conductivity for a particular cylinder placement $\underline{\mathbf{X}}^c$, $K = k(\underline{\mathbf{X}}^c, \phi, \theta_0)$, is effected by (Cruz and Patera (1995); Cruz, Ghaddar, and Patera (1995); Ghaddar (1995)): automatic domain decomposition and parallel partition; automatic parallel mesh generation; second-order isoparametric finite-element discretization of the supercell conduction partial differential equation (Laplacian) over $[0, \theta_0] \times [0, \theta_0]$; parallel conjugate gradient iterative solution of the symmetric positive-definite system of finite-element equations; computation of the effective property as an energy norm on the finite-element solution; implementation on the Intel iPSC/860 hypercube multiprocessor. We occasionally encounter configurations in which extremely close inclusions either prohibit successful mesh generation, or produce discretizations characterized by excessive degrees of freedom, extreme ill-conditioning, or poor parallel load balancing. For these problematic realizations we evoke variational "nip-element" procedures which mitigate the numerical difficulties associated with geometric stiffness while simultaneously providing rigorous, *sharp* upper and lower bounds for the configuration effective conductivity (Cruz, Ghaddar, and Patera (1995)). In what follows, we shall assume that the nip-element, discretization, and incomplete-iteration errors are sufficiently small that the configuration conductivity simulation solution is effectively exact. The particular ("representative") realization shown in Figure 3 comprises 26,000 finite-element degrees of freedom and requires 2 minutes of computation on 16 nodes of the Intel iPSC/860 hypercube.

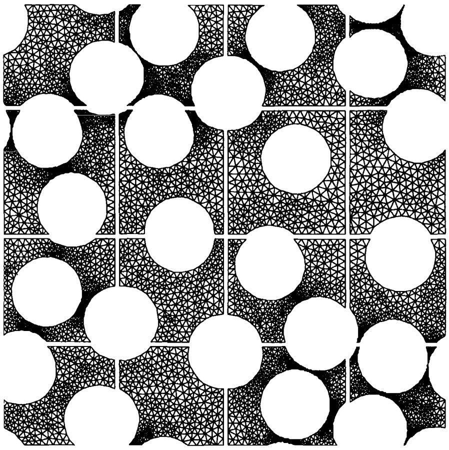

FIG. 3. *Typical geometry, parallel partition (for* 16 *processors), and finite-element mesh for inclusion concentration* $\phi = .492$.

We now turn to the Monte-Carlo component of the algorithm. For any particular concentration ϕ, we approximate the integral (62) as the sample mean

$$\overline{K} = \frac{1}{N_r} \sum_{i=1}^{N_r} K_i \,, \tag{68}$$

where $K_i = k(\underline{\mathbf{X}}_i^c, \phi, \theta_0), i = 1, \dots, N_r$. The N_r microstructure realizations, $\{\underline{\mathbf{X}}_1^c, \dots, \underline{\mathbf{X}}_{N_r}^c\}$, are generated by an acceptance–rejection Monte-Carlo sampling procedure (Rubinstein (1981)) for the joint probability density function (64)–(67). We approximate the variance of K, $\sigma_K^2(\phi, \theta_0)$, by the sample variance,

$$\sigma_K^2(\phi, \theta_0) \approx \widetilde{\sigma}_K^2(\phi, \theta_0) = \frac{1}{N_r - 1} \sum_{i=1}^{N_r} (K_i - \overline{K})^2 \,. \tag{69}$$

Finally, we assume that N_r is sufficiently large that the density of the random variable

$$V = \frac{\sqrt{N_r}[\overline{K} - k_e(\phi, \theta_0)]}{\widetilde{\sigma}_K} \tag{70}$$

is approximately normal with zero mean and unity variance.

Before turning to the validation results, we make several final remarks. First, our assumptions on V in (70) in no way affect our validation statement (14), nor, in fact, our density-independent noise bound, (41), (46), (47) (or (48)). Second, although the measurement noise is, in fact, bounded ($0 \leq K \leq \widetilde{k}_e(\phi)$), the range of $\overline{K}$ is large compared to the standard deviation of $\overline{K}$, and thus the unbounded assumption is more profitable. Third, $\sigma_K(\phi, \theta)$ will decrease with increasing θ due to spatial averaging effects. It is, however, more economical to effect variance reduction by increasing N_r than by increasing θ, as the former, first, requires less memory, and, second, leads to better conditioned problems. Nevertheless, even for $\theta \approx \Theta(\phi)$, $\sigma_K(\phi, \theta)$ will be relatively small. Fourth, for computational efficiency, N_r should be chosen so as to control—but not unnecessarily eliminate—the noise contribution to the model prediction error. We select, based on earlier "pilot" calculations (Cruz and Patera (1995)), $N_r = 20$; this modest sample size reflects the relatively small variance of K. Although for $N_r = 20$ the t-distribution is already approximately normal (Mood, Graybill, and Boes (1974)), we have no such assurances for the sample mean. Fifth, and finally, we note that, for $N_r = 20$, the effective conductivity calculation, (68), for a particular (relatively time-consuming) concentration, $\phi = .492$, requires approximately 47 minutes of computation and costs roughly \$10 on (16 processors of) the Intel iPSC/860 hypercube. If the same computation were performed on a workstation (respectively, serial/vector supercomputer), the time-to-compute (respectively, cost-to-compute) would increase significantly; the relative advantage of the parallel approach increases with increasing problem size (Fischer and Patera (1994)).

5.2.3. Surrogate validation results. We now formally identify our multicomponent surrogate problem in terms of the general variables introduced in earlier sections of the paper:

$$\begin{aligned}
M &\mapsto 1,\\
\mathbf{p} &\mapsto \phi,\\
\Omega &\mapsto [.05, .5],\\
\rho(\mathbf{p}) &\mapsto 1/.45 \text{ (uniform)},\\
\mathcal{S}(\mathbf{p}) &\mapsto k_e(\phi, \theta_0),\\
\widetilde{\mathcal{S}}(\mathbf{p}) &\mapsto \widetilde{k}_e(\phi) = (1-\phi)/(1+\phi),\\
Q &\mapsto K,\\
\sigma_Q(\mathbf{p}) &\mapsto \approx \widetilde{\sigma}_K(\phi, \theta_0),\\
\mathcal{N} &\mapsto N_r (= 20),\\
R &\mapsto \overline{K},\\
\sigma_W(\mathbf{p}) &\mapsto \approx \widetilde{\sigma}_K(\phi, \theta_0)/\sqrt{N_r},\\
g(v) &\mapsto \approx (1/2\pi)^{1/2} e^{-v^2/2}\ .
\end{aligned}$$

(The most "interesting" behavior of the effective conductivity occurs near maximum packing, $\phi \approx .82$ (Berryman (1983)). However, we do not consider this case here, as the random sequential addition Monte-Carlo sampling procedure becomes prohibitively inefficient for concentrations greater than a "jamming" threshold of roughly .55 (Sangani and Yao (1988), Torquato (1991), Cruz and Patera (1995)).) Finally, we specify $\varepsilon_1 = .1, \varepsilon_2 = .1$, and thus, from (33), $N = 45$.

Performing the validation procedure of §3.1, we find for the model prediction error estimate $u = .0574$: with confidence level greater than 90%, $|k_e(\phi, \theta_0) - \widetilde{k}_e(\phi)|$ is less than .0574 over more than 90% of the concentration range [.05, .5]. In Figure 4 we plot the surrogate-simulation discrepancy, $|\overline{K}_j - \widetilde{k}_e(\phi_j)|$, and the estimated noise standard deviation, $\widetilde{\sigma}_K(\phi_j, \theta_0)/\sqrt{N_r}$, at the validation input points, ϕ_j, $j = 1, \ldots, N$. Our bound procedures for the noise contribution to the model prediction error, (41), (46), (48) and (41), (50), (53)–(54), then yield .0273 and .0110, respectively; the latter suggests that the noise contribution to the prediction error is, relatively, not too large. Lastly, with 160 additional evaluations of K we can construct 90% confidence intervals for $k_e(\phi_{\hat{j}}, \theta_0)$, $|k_e(\phi_{\hat{j}}, \theta_0) - \widetilde{k}_e(\phi_{\hat{j}})|$, and hence $\hat{y}$ of [.290, .294], [.0462, .0507], and [.00663, .0111], respectively. This a posteriori result is ostensibly disappointing; note, however, that from (41), (50), and (53)–(54) we can only infer that $E_{\underline{\mathbf{P}},\underline{W}|A=1}(Y) \leq .0110$, whereas from (58) we can conclude (with confidence level .9) that $y \leq .0111$ for our *particular* validation realization. The a posteriori noise estimate is "sharper" than the corresponding a priori bounds because $|k_e(\phi, \theta_0) - \widetilde{k}_e(\phi)|$ is nonuniform, with significantly larger discrepancies at larger concentrations.

Finally, we briefly reconsider the optimization-purposive a posteriori analysis summarized in §2 (Yeşilyurt and Patera (1995), Yeşilyurt (1995)). We take the target value for the nondimensional effective conductivity to be $\lambda = .5$, for which our surrogate, $\widetilde{k}_e(\phi) = (1-\phi)/(1+\phi)$,

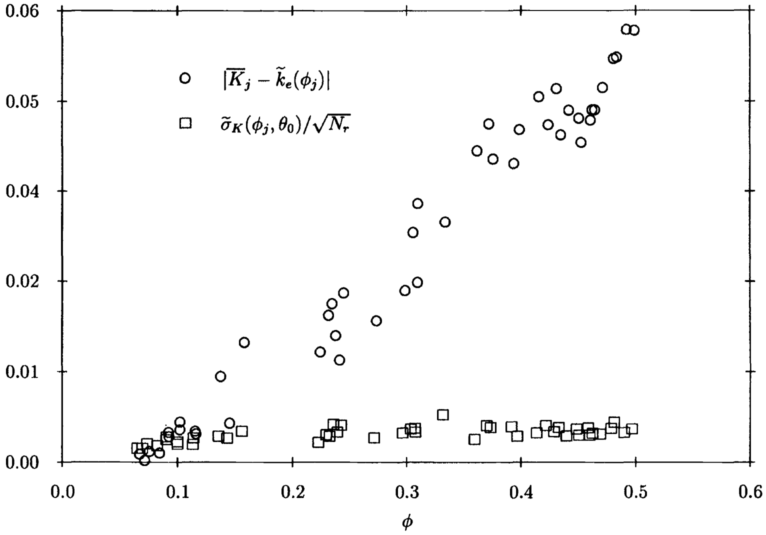

FIG. 4. *Surrogate-simulation discrepancy,* $(|\overline{K}_j - \widetilde{k}_e(\phi_j)| - \circ)$, *and estimated noise standard deviation,* $(\widetilde{\sigma}_K(\phi_j, \theta_0)/\sqrt{N_r} - \square)$, *at validation input points,* ϕ_j, $j = 1, \ldots, N$.

predicts the design point $\widetilde{\phi}^* = .333$, that is, $\widetilde{k}_e(\widetilde{\phi}^*) = .5$. Then, from (5) and (6), we can construct design intervals, $\mathcal{R}$, which contain concentration values, ϕ, for which the *actual* effective conductivity, $k_e(\phi, \theta_0)$, is within a known tolerance of λ; for example, with confidence level greater than $1-\varepsilon_2 = .9$, on over half the interval $\phi \in \mathcal{R} = [.333-.45\varepsilon_1, .333+.45\varepsilon_1] = [.288, .378]$, the actual effective conductivity, $k_e(\phi, \theta_0)$, is within $u+\delta_{\mathcal{R}} = .110\,(\delta_{\mathcal{R}} = .0528)$ of the target value $\lambda = .5$. In the context of a preliminary design exercise, this result may be sufficient without any further analysis. If we make the additional assumption that $|k_e(\phi, \theta_0) - \lambda|$ and $|\widetilde{k}_e(\phi) - \lambda|$ are quasi-convex (probably true for this apparently monotone input–output function), we can show that, with confidence level greater than $1 - \varepsilon_2 = .9$, the interval $[.155, .5]$ contains ϕ^*, the value of the concentration at which the *actual* (noise-free simulation) effective conductivity, $k_e(\phi, \theta_0)$, is closest to the target value, $\lambda = .5$ (Yeşilyurt (1995)). This (admittedly not so) restricted region can now serve, for example, as a reduced search domain in a subsequent, more refined, design exercise. Perhaps most importantly, we can now repeat our optimization analysis for different λ *without* re-appeal to the originating Monte-Carlo finite-element simulation; our probability estimates are joint over multiple studies (Yeşilyurt and Patera (1995), Yeşilyurt (1995), Otto et al. (1995)).

For the particular example presented, in which the input space is only one-dimensional, and the input–output function is rather simple, the complete surrogate framework is, arguably, an algorithmic indulgence. We contend, however, that this example is representative of more complex problems (e.g., prediction of the sedimentation rate of dense suspensions from Monte-Carlo finite-element simulations, prediction of the properties of new materials from atomistic calculations) for which the surrogate procedure is no longer a luxury, but a necessity. These problems, in turn, require improvements in, and enhancements to, the simple (train) test surrogate framework presented in this paper. Several of these new developments, including elemental approaches, sequential techniques, elemental-sequential (adaptive) procedures, proximal-candidate a posteriori analyses, and cross-validation schemes, are described in Otto et al. (1995).

Acknowledgments. We thank Professor Ben Fitzpatrick of North Carolina State University for helpful comments.

PRIMAL-DUAL COMBINATORIAL RELAXATION ALGORITHMS FOR THE MAXIMUM DEGREE OF SUBDETERMINANTS*

SATORU IWATA[†], KAZUO MUROTA[†], AND IZUMI SAKUTA[‡]

Abstract. A primal-dual framework of combinatorial relaxation algorithms is proposed for computing the highest degree of a minor of order k of a rational function matrix. The algorithm can be used for computing the index of nilpotency of a matrix pencil (or the index of the associated differential algebraic equation). It is a linear algebraic version of the Hungarian method for the assignment problem. The proposed framework stands in contrast to the previous combinatorial relaxation algorithm based on weighted matchings, and may also be regarded as an extension of the Wolovich algorithm for row/column properness. Several algorithms are evaluated through computer experiments.

Key words. combinatorial relaxation, degree of subdeterminant, index of DAE, Kronecker form, Smith–McMillan form at infinity

1. Introduction.

Let $A(x) = (A_{ij}(x))$ be an $m \times n$ rational function matrix with $A_{ij}(x)$ being a rational function in x with coefficients from the real number field $\mathbf{R}$. This paper deals with algorithms for computing the highest degree of a minor of order k ($\leq \min(m, n)$) of $A(x)$:

$$\delta_k(A) = \max_{I,J}\{\deg \det A[I, J] \mid |I| = |J| = k\}, \tag{1.1}$$

where $A[I, J]$ denotes the submatrix of A with row-set I and column-set J and the degree of a rational function $f(x) = p(x)/q(x)$ is defined by $\deg f(x) = \deg p(x) - \deg q(x)$. By convention we put $\deg f(x) = -\infty$ if $f(x) = 0$. This is one of the fundamental problems in combinatorial matrix theory [3] and has various applications in practice.

By computing $\delta_k(A)$ ($k = 1, 2, \ldots$) we can obtain the Smith–McMillan form at infinity (described in §2), which is also known as the structure at infinity in the literature of control theory (Commault–Dion [5], Hautus [12], Verghese–Kailath [23]). When $A(x)$ is a regular pencil of order n, on the other hand, $\delta_k(A)$ ($k = 1, 2, \ldots$) determines the structural indices of its Kronecker form (see Murota [15, §2.2]), and hence the index ν as well as the dynamical degree of freedom of the associated differential algebraic equations (DAEs) (Brenan–Campbell–Petzold [2], Gear [9, 10], Hairer–Wanner [11]). To be specific, the index is given by $\nu = \delta_{n-1}(A) - \delta_n(A) + 1$, whereas the dynamical degree of freedom is equal to $\delta_n(A)$. Thus the problem of computing $\delta_k(A)$ ($k = 1, 2, \ldots$) is of fundamental engineering significance.

It is not a coincidence but a necessity that the structural approach has been made recently both in the control theory and in the literature of DAEs. Taking advantage of the combinatorial nature inherent in the computation of $\delta_k(A)$ ($k = 1, 2, \ldots$) the structural approach derives combinatorial characterizations under certain genericity assumptions on the numerical values involved. In the literature of control theory a graph-theoretic method for computing the Smith–McMillan form at infinity has been developed independently by Commault, Dion, and Perez [6], Suda, Wan, and Ueno [21], and van der Woude [25] based on the primitive structural model that considers all the nonzeros independent parameters. Using the more sophisticated framework of Murota [13, Chap. 4], which distinguishes between independent parameters and

nonzero fixed constants, Murota and van der Woude [17] have derived another combinatorial characterization in terms of matroid-theoretic concepts and algorithms. For the numerical analysis of DAEs, on the other hand, extensive study has been done on the index problem of DAEs and a number of practical methods for the structural analysis have been developed (Bujakiewicz [4], Duff–Gear [7], Pantelides [19], Ungar–Kröner–Marquardt [22]).

It has been recognized through these studies that structural considerations should be useful and effective in practice and that the generic values computed by structural algorithms will have practical significance. At the same time, however, the limitation of the structural approach has also been demonstrated. A structural algorithm may fail to render the correct answer if numerical cancellations do occur for some reason or other. In emphasizing the need for an appropriate genericity assumption, Murota and van der Woude [17] demonstrated this for the Smith–McMillan form at infinity. Pantelides [19] had already recognized this phenomenon in the structural analysis of DAEs, and very recently Ungar, Kröner, and Marquardt [22] expounded upon this point, referring to the following example (significant in chemical engineering) due to Gani and Cameron [8].

The problem arises from an analysis of distillation columns and amounts to finding the index of the following matrix pencil $A(x)$ of order 13:

$$A(x) = \begin{array}{c} \\ (34) \\ (35.1) \\ (35.2) \\ (36) \\ (39) \\ (40) \\ (41) \\ (42) \\ (44.1) \\ (44.2) \\ (45.1) \\ (45.2) \\ (46) \end{array}
\begin{array}{c}
\begin{array}{ccccccccccccc} M & T & p & H^L & H^V & L & x_1 & x_2 & y_1 & y_2 & V & v_1 & v_2 \end{array} \\
\left(\begin{array}{ccccccccccccc}
x & & & & & \ast & & & & & \ast & & \\
 & & & & & \ast & x & & \ast & & \ast & & \\
 & & & & & \ast & & x & & \ast & \ast & & \\
x & & & x & \ast & \ast & & & & & \ast & & \\
\ast & & & & & \ast & & & & & & & \\
 & \ast & & \ast & & & \ast & \ast & & & & & \\
 & \ast & \ast & & \ast & & & & \ast & \ast & & & \\
\ast & & \ast & & & & & & & & & & \\
 & & & & & & & & \ast & & \ast & \ast & \\
 & & & & & & & & & \ast & \ast & & \ast \\
 & \ast & \ast & & & & \ast & \ast & & & -a_1 & 1-b_{11} & -b_{12} \\
 & \ast & \ast & & & & \ast & \ast & & & -a_2 & -b_{21} & 1-b_{22} \\
 & & & & & & & & & & 1 & -1 & -1
\end{array}\right)
\end{array},$$

where we assume $NC = 2$ in the notation of [22], and attach the equation numbers and the variable names taken from [22]. The symbol $\ast$, designating an occurrence of a variable in an equation, is to be considered an independent (or generic) parameter. In contrast, the six parameters $a_1, a_2, b_{11}, b_{21}, b_{12}, b_{22}$ appearing in the lower-right corner cannot be regarded as independent parameters, since they satisfy the relations

$$a_1 + a_2 = 1, \quad b_{11} + b_{21} = 0, \quad b_{12} + b_{22} = 0.$$

Structural algorithms, ignoring these relations among the parameters, yield an erroneous answer $\widehat{\nu} = 1$ in contradiction to the true index $\nu = 2$.

In this paper we are interested in algorithms which yield correct values even in the nongeneric case, namely those algorithms which return $\nu = 2$ for the above example. In particular, we are interested in such algorithms that rely primarily on structural information and ask for numerical information only when it is needed to ensure correct answers. The recent algorithm of Murota [15] is of this kind. It is a combinatorial relaxation-type algorithm that employs the weighted matching problem as a relaxed problem. In contrast, the elimination-type algorithm (described in §2) does not fall into this category, though it will be considered for comparison in our evaluation of the algorithms.

An algorithm of combinatorial relaxation type generally consists of the following three phases.

Phase 1: Consider a relaxed (or an easier) combinatorial problem of the original algebraic problem and find a solution to the relaxed one.

Phase 2: Test for the validity of this solution with respect to the original problem. If valid, output the solution and stop.

Phase 3 (in case of invalid solution): Modify the relaxation so that the invalid solution is eliminated.

This type of algorithm has been found for the Newton polygon for Puiseux-series solutions to determinantal equations [14] and for the degree of determinant of a skew-symmetric matrix [16].

It may be said that such an approach was already implicit in the algorithm described in Wolovich [24] for transforming a polynomial matrix into the row-proper form and for computing δ_m as a byproduct, where m denotes the number of rows. This algorithm takes the sum of row degrees (the maximum degrees of the entries in a row) as an estimate of δ_m and tests for row properness. In case the estimate turns out to be nonproper it modifies the matrix so as to improve the estimate without changing δ_m. From this, we might regard it as a combinatorial relaxation-type algorithm. We extend this algorithm for computing $\delta_k(A)$ for $k = 1, \dots, r$, where r denotes the rank of A.

The present paper aims to propose a primal-dual framework of combinatorial relaxation algorithms for computing the maximum degree of subdeterminants. Like the Hungarian method for the assignment problem [1, 20], the algorithms keep a set of admissible potentials (feasible dual variables), which determines the estimate (dual objective value), and check its tightness (dual optimality) by solving a simpler (restricted primal) problem. If it turns out to be nontight, we obtain information useful for modifying the potentials as well as the matrix. Thus the proposed framework can be interpreted as a linear algebraic version of the Hungarian method. It stands in contrast to the previous combinatorial relaxation algorithm based on weighted matchings (see Remarks 3.1 and 3.2) and may also be regarded as an extension of the Wolovich algorithm for row/column properness. Several algorithms are evaluated through computer experiments.

This paper is organized as follows. In §2, we describe the Smith–McMillan form at infinity and its relationship to the maximum degree of subdeterminants. Section 3 provides the framework, the details, and the time complexity of the proposed algorithm. Experimental results are described in §4, followed by discussions in §5.

2. Smith–McMillan form at infinity.

In this section, we describe the Smith–McMillan form at infinity, which is a canonical form of a rational function matrix. A rational function $f(x)$ is called proper if $\deg f(x) \leq 0$, and a rational function matrix $A(x)$ is also called proper if all of its entries are proper. A nonsingular proper matrix $U(x)$ is said to be biproper if its inverse is also proper, or equivalently, if $\deg \det U(x) = 0$. The Smith–McMillan form at infinity is the canonical form of a rational function matrix under biproper equivalency as stated below (Hautus [12], Verghese–Kailath [23]).

THEOREM 2.1 (Smith–McMillan form at infinity). *For any rational function matrix $A(x)$ of rank r, there exist biproper matrices $U(x)$ and $V(x)$ such that*

$$U(x)A(x)V(x) = \begin{pmatrix} \Gamma(x) & O \\ O & O \end{pmatrix}, \tag{2.1}$$

where

$$\Gamma(x) = \operatorname{diag}(x^{t_1}, x^{t_2}, \dots, x^{t_r}), \quad t_1 \geq t_2 \geq \cdots \geq t_r.$$

Since the maximum degrees of subdeterminants δ_k $(k = 1, \ldots, r)$ defined in (1.1) are invariant under biproper transformations, we have

$$t_k = \delta_k(A) - \delta_{k-1}(A) \quad (k = 1, \ldots, r),$$

where $\delta_0(A) = 0$ by convention. Therefore we can compute the set of δ_k $(k = 1, \ldots, r)$ from the Smith–McMillan form at infinity, and conversely, the latter from the former.

We note that the set of proper rational functions forms a Euclidean ring with a rather trivial division rule. By specializing the standard elimination procedure in a general Euclidean ring [18], we can obtain a procedure for the Smith form in the proper rational function ring, and furthermore a procedure for the Smith–McMillan form at infinity as a minor variant thereof.

Elimination Algorithm for Smith–McMillan Form at Infinity.

Step 1: If $A(x) = 0$, then go to Step 6.

Step 2: Permute rows and columns independently so that $\deg A_{11}(x)$ is larger than or equal to that of any other entry.

Step 3: For each entry in the first row or in the first column, calculate its quotient:

$$q_{i1}(x) = \frac{A_{i1}(x)}{A_{11}(x)} \quad \text{for } i = 2, 3, \ldots, m,$$

$$q_{1j}(x) = \frac{A_{1j}(x)}{A_{11}(x)} \quad \text{for } j = 2, 3, \ldots, n.$$

Step 4: Subtract (the first row)×$q_{i1}(x)$ from the ith row $(i = 2, \ldots, m)$, and then subtract (the first column)×$q_{1j}(x)$ from the jth column $(j = 2, \ldots, n)$. Then we obtain a matrix as follows:

$$\left(\begin{array}{c|ccc} A_{11}(x) & 0 & \cdots & 0 \\ \hline 0 & A_{22}(x) & \cdots & A_{2n}(x) \\ \vdots & \vdots & \ddots & \vdots \\ 0 & A_{m2}(x) & \cdots & A_{mn}(x) \end{array}\right).$$

Note that $\deg A_{11}(x) \geq \deg A_{ij}(x)$ $(i = 2, \ldots, m; j = 2, \ldots, n)$.

Step 5: Execute Step 1 to Step 4 on the lower-right submatrix recursively.

Step 6: At this point, $A(x)$ has been transformed to

$$\left(\begin{array}{cccc|c} A_{11}(x) & 0 & \cdots & 0 & \\ 0 & A_{22}(x) & \ddots & \vdots & O \\ \vdots & \ddots & \ddots & 0 & \\ 0 & \cdots & 0 & A_{rr}(x) & \\ \hline & & O & & O \end{array}\right),$$

where $\deg A_{11}(x) \geq \deg A_{22}(x) \geq \cdots \geq \deg A_{rr}(x)$. We can further transform it to the form (2.1) with $t_k = \deg A_{kk}(x)$ for $k = 1, \ldots, r$ by multiplying the kth row with $x^{t_k}/A_{kk}(x)$ for $k = 1, \ldots, r$.

The elimination procedure above requires $O(\min(m, n)mn)$ additions and multiplications of rational functions. After several iterations, however, the number of terms in each entry will increase. Therefore, the whole procedure takes more than $O(\min(m, n)mn)$ time. This phenomenon is shown in §4.

3. Combinatorial relaxation algorithms.

In this section, we present a new framework of combinatorial relaxation-type algorithms for computing δ_k. This shares the approach of "combinatorial relaxation" with the previous algorithm of Murota [15], while featuring potentials (dual variables) rather than matchings in constructing the combinatorial estimate. The proposed framework may be thought of as a linear algebraic version of the primal-dual approach to the assignment problem that is well known in the context of combinatorial optimization [1, 20].

3.1. Outline of the proposed framework.

For a rational function matrix $A(x)$, let R and C denote the row-set and the column-set, respectively. By potentials we mean integer numbers associated with rows or columns. With appropriately chosen potentials, say, $\rho = (\rho_i \mid i \in R)$ and $\gamma = (\gamma_j \mid j \in C)$, we compute an estimate $\widehat{\delta_k}(A; \rho, \gamma)$ of $\delta_k(A)$ such that $\delta_k(A) \leq \widehat{\delta_k}(A; \rho, \gamma)$. We then test for tightness (equality) in this inequality without computing $\delta_k(A)$. If the estimate turns out to be nontight, we modify the matrix $A(x)$ as well as the potentials.

The outline of the combinatorial relaxation algorithm to compute δ_k for a fixed k is summarized as follows (see §3.5 for a concrete example).

Phase 0: Choose appropriate (ρ, γ).

Phase 1: Compute the combinatorial upper estimate $\widehat{\delta_k}(A; \rho, \gamma)$.

Phase 2: Test whether $\widehat{\delta_k}(A; \rho, \gamma) = \delta_k(A)$ or not. If the equality holds, output $\widehat{\delta_k}(A; \rho, \gamma)$ and stop.

Phase 3: Modify A to another matrix A' and (ρ, γ) to (ρ', γ') such that $\delta_k(A') = \delta_k(A)$ and $\widehat{\delta_k}(A'; \rho', \gamma') < \widehat{\delta_k}(A; \rho, \gamma)$, namely A' has the same true value as A and an improved estimate. Put $A := A'$, $\rho := \rho'$, $\gamma := \gamma'$ and go to Phase 1.

3.2. Phase 1—combinatorial estimation.

The combinatorial estimate, denoted as $\widehat{\delta_k}(A; \rho, \gamma)$ in §3.1, is specified in this section. Define c_{ij} by

$$c_{ij} = \deg A_{ij}(x), \tag{3.1}$$

where by convention we put $c_{ij} = -\infty$ if $A_{ij}(x) = 0$. We choose a set of potentials $\rho = (\rho_i \mid i \in R)$ and $\gamma = (\gamma_j \mid j \in C)$ which satisfies the condition

$$\rho_i + \gamma_j \geq c_{ij} \quad \text{for } i \in R \text{ and } j \in C. \tag{3.2}$$

Such potentials are said to be admissible. Then for $I \subseteq R$ and $J \subseteq C$ with $|I| = |J|$ it holds that

$$\deg\det A[I, J] \leq \rho(I) + \gamma(J), \tag{3.3}$$

where $\rho(I) = \sum_{i\in I} \rho_i$ and $\gamma(J) = \sum_{j\in J} \gamma_j$.

By considering the maximum possible value of the right-hand side, i.e., by introducing

$$\widehat{\delta_k}(A; \rho, \gamma) = \max_{|I|=k} \rho(I) + \max_{|J|=k} \gamma(J),$$

we obviously have

$$\rho(I) + \gamma(J) \leq \widehat{\delta_k}(A; \rho, \gamma) \tag{3.4}$$

for $I \subseteq R$ and $J \subseteq C$ with $|I| = |J| = k$. The inequalities (3.3) and (3.4) imply

$$\delta_k(A) \leq \widehat{\delta_k}(A; \rho, \gamma), \tag{3.5}$$

which shows that $\widehat{\delta_k}(A;\rho,\gamma)$ serves as an upper bound on the true value. Remember that (ρ,γ) must be admissible in the sense of (3.2) before (3.5) can be true.

The estimate $\widehat{\delta_k}(A;\rho,\gamma)$ admits an alternative expression suitable for its efficient computation. Consider the following permutations for the row-set R and the column-set C of A:

$$\tau:\{1,\dots,m\}\to R \qquad \text{such that } \rho_{\tau(1)}\ge\rho_{\tau(2)}\ge\cdots\ge\rho_{\tau(m)}; \tag{3.6}$$

$$\sigma:\{1,\dots,n\}\to C \qquad \text{such that } \gamma_{\sigma(1)}\ge\gamma_{\sigma(2)}\ge\cdots\ge\gamma_{\sigma(n)}. \tag{3.7}$$

Then it is easy to see that

$$\widehat{\delta_k}(A;\rho,\gamma)=\sum_{i=1}^{k}\rho_{\tau(i)}+\sum_{j=1}^{k}\gamma_{\sigma(j)}.$$

REMARK 3.1. We could optimize the choice of potentials (ρ,γ) to minimize the estimate $\widehat{\delta_k}(A;\rho,\gamma)$. Then the estimate $\widehat{\delta_k}(A;\rho,\gamma)$ would coincide in value with the maximum weight of a matching (transversal) of size k, which has been employed in [15] as another combinatorial estimate for $\delta_k(A)$, and would satisfy (3.5) with equality in the generic case (see [15, Thm. 3]). In this paper, however, we consider algorithms that do not rely on the optimal choice of (ρ,γ).

3.3. Phase 2—test for tightness. This section provides a way to test whether $\delta_k(A)=\widehat{\delta_k}(A;\rho,\gamma)$ or not without computing $\delta_k(A)$ directly.

Define $I^\sharp$, $J^\sharp$, $\tilde I$, and $\tilde J$ as follows:

$$I^\sharp=\{i\in R\mid \rho_i>\rho_{\tau(k+1)}\},\qquad \tilde I=\{i\in R\mid \rho_i\ge\rho_{\tau(k)}\}; \tag{3.8}$$

$$J^\sharp=\{j\in C\mid \gamma_j>\gamma_{\sigma(k+1)}\},\qquad \tilde J=\{j\in C\mid \gamma_j\ge\gamma_{\sigma(k)}\}. \tag{3.9}$$

Exceptionally, in case $k=m$, we put $I^\sharp=\tilde I=R$, and in case $k=n$, we put $J^\sharp=\tilde J=C$. Then $\rho(I)$ attains the maximum subject to $|I|=k$ if and only if $I^\sharp\subseteq I\subseteq\tilde I$. Similarly, $\gamma(J)$ is maximized subject to $|J|=k$ if and only if $J^\sharp\subseteq J\subseteq\tilde J$. Therefore (3.4) holds with equality if and only if $I^\sharp\subseteq I\subseteq\tilde I$ and $J^\sharp\subseteq J\subseteq\tilde J$. Define a constant matrix $A^\sharp$ by

$$A^\sharp=(A^\sharp_{ij}),\qquad A^\sharp_{ij}=\begin{cases}\lim\limits_{x\to\infty}x^{-\rho_i-\gamma_j}A_{ij}(x) & \text{if } i\in\tilde I \text{ and } j\in\tilde J;\\ 0 & \text{otherwise.}\end{cases}$$

PROPOSITION 3.1 (tightness). *The following three conditions* (a)–(c) *are equivalent.*

(a) $\delta_k(A)=\widehat{\delta_k}(A;\rho,\gamma)$.

(b) *There exist* $I\supseteq I^\sharp$ *and* $J\supseteq J^\sharp$ *such that* $\operatorname{rank}A^\sharp[I,J]=|I|=|J|=k$.

(c) *The following four conditions* (r1)–(r4) *are satisfied:*

(r1) $\operatorname{rank}A^\sharp[R,C]\ge k$;

(r2) $\operatorname{rank}A^\sharp[I^\sharp,C]=|I^\sharp|$;

(r3) $\operatorname{rank}A^\sharp[R,J^\sharp]=|J^\sharp|$;

(r4) $\operatorname{rank}A^\sharp[I^\sharp,J^\sharp]\ge|I^\sharp|+|J^\sharp|-k$.

Proof. See Lemma 6 of [15] for (b)$\Leftrightarrow$(c). Let us prove (a)$\Leftrightarrow$(b). From the definition of $A^\sharp$, we have

$$A_{ij}(x)=x^{\rho_i+\gamma_j}(A^\sharp_{ij}+o(1))\quad \text{for } i\in\tilde I \text{ and } j\in\tilde J,$$

which implies

$$\det A[I,J]=x^{\rho(I)+\gamma(J)}(\det A^\sharp[I,J]+o(1)) \tag{3.10}$$

if $I\subseteq\tilde I$, $J\subseteq\tilde J$, and $|I|=|J|$.

Suppose $\delta_k = \widehat{\delta_k}$, and then there exist I and J with $|I| = |J| = k$ that satisfy both (3.3) and (3.4) with equalities. Hence $I \subseteq \tilde{I}$ and $J \subseteq \tilde{J}$, and it follows from (3.10) that $A^\sharp[I, J]$ is nonsingular. Thus (a)⇒(b) has been shown. Conversely, suppose $I \supseteq I^\sharp$, $J \supseteq J^\sharp$, and $\operatorname{rank} A^\sharp[I, J] = |I| = |J| = k$. Then we must have $I \subseteq \tilde{I}$ and $J \subseteq \tilde{J}$, and consequently (3.4) holds with equality. Furthermore, from (3.10), we obtain an equality in (3.3). Therefore, $\deg \det A[I, J] = \widehat{\delta_k}$, which together with (3.5) shows $\delta_k = \widehat{\delta_k}$. □

According to Proposition 3.1 above, the test for $\widehat{\delta_k} = \delta_k$ in Phase 2 can be reduced to computing the ranks of the four constant matrices. Actually, for (r1), (r2), and (r4), we use the Gaussian elimination by elementary row transformations, and for (r3), we use the Gaussian elimination by elementary column transformations.

3.4. Phase 3—modification. When the estimate $\widehat{\delta_k}(A; \rho, \gamma)$ turns out to be nontight, we modify the matrix as well as the potentials. Recall that the maximum degree of subdeterminants of a fixed order is invariant under biproper equivalence transformations. That is,

$$A'(x) = U(x)A(x)V(x) \tag{3.11}$$

satisfies $\delta_k(A') = \delta_k(A)$ if both $U(x)$ and $V(x)$ are biproper. We use this type of transformation in the modification of the matrix $A(x)$.

Let U be a nonsingular constant matrix of order m such that

$$U_{hi} = 0 \quad \text{if } \rho_h > \rho_i,$$

and define a transformation matrix $U(x)$ by

$$U(x) = \operatorname{diag}(x; \rho) \cdot U \cdot \operatorname{diag}(x; -\rho), \tag{3.12}$$

where $\operatorname{diag}(x; \rho)$ designates the diagonal matrix $\operatorname{diag}(x^{\rho_1}, x^{\rho_2}, \ldots, x^{\rho_m})$. Then $U(x)$ is a biproper matrix. Similarly, using a nonsingular constant matrix V that satisfies the condition

$$V_{jh} = 0 \quad \text{if } \gamma_h > \gamma_j,$$

we define a transformation matrix $V(x)$ by

$$V(x) = \operatorname{diag}(x; -\gamma) \cdot V \cdot \operatorname{diag}(x; \gamma), \tag{3.13}$$

which is also a biproper matrix.

We now explain how to construct such a pair of constant matrices U and V efficiently according to which of the four conditions (r1)–(r4) is violated by the constant matrix $A^\sharp$ (see Proposition 3.1 (c)).

When (r1) is violated: In checking the condition (r1) by means of the Gaussian row elimination with column pivoting, applied to the matrix $A^\sharp$ with rows rearranged by τ according to the magnitude of ρ_i, we obtain a nonsingular matrix S of order m such that $S_{\tau(l)\tau(i)} = 0$ if $l < i$ and such that $SA^\sharp$ has $(m - \operatorname{rank} A^\sharp)$ zero vectors among its row vectors. Let H be a subset of $\tilde{I}$ such that $|H| = |\tilde{I}| - k + 1$ and $(SA^\sharp)[H, C] = O$. Construct the constant matrix U as follows:

$$U[H, R] = S[H, R], \ U[R - H, H] = O, \ U[R - H, R - H] = I_{|R-H|}, \tag{3.14}$$

where $I_{|R-H|}$ denotes the unit matrix. Let V be the unit matrix of order n.

When (r2) is violated: In checking the condition (r2) by the Gaussian row elimination with column pivoting, applied to the matrix $A^\sharp[I^\sharp, C]$ with rows rearranged by τ according to the magnitude of ρ_i, we obtain a nonsingular matrix S of order $|I^\sharp|$ such that $S_{\tau(l)\tau(i)} = 0$ if $l < i$ and such that $S \cdot A^\sharp[I^\sharp, C]$ has $(|I^\sharp| - \operatorname{rank} A^\sharp[I^\sharp, C])$ zero row vectors. Let $H \subseteq I^\sharp$ be the singleton set corresponding to a zero row vector in $S \cdot A^\sharp[I^\sharp, C]$. Then construct U as in (3.14). Let V be the unit matrix of order n.

When (r3) is violated: In checking the condition (r3) by the Gaussian column elimination with row pivoting, applied to the matrix $A^{\sharp}[R, J^{\sharp}]$ with columns rearranged by σ according to the magnitude of γ_j, we obtain a nonsingular matrix S of order $|J^{\sharp}|$ such that $S_{\sigma(j)\sigma(l)} = 0$ if $l < j$ and such that $A^{\sharp}[R, J^{\sharp}] \cdot S$ has $(|J^{\sharp}| - \mathrm{rank}\, A^{\sharp}[R, J^{\sharp}])$ zero column vectors. Construct the constant matrix V of order n in a (transposed) way similar to that in which we constructed U in the case of (r2), namely

$$(3.15)\quad V[C, H] = S[C, H],\ V[H, C - H] = O,\ V[C - H, C - H] = I_{|C-H|}.$$

Let U be the unit matrix of order m.

When (r4) is violated: In checking the condition (r4) by means of the Gaussian row elimination with column pivoting, applied to the matrix $A^{\sharp}[I^{\sharp}, J^{\sharp}]$ with rows rearranged by τ according to the magnitude of ρ_i, we obtain a nonsingular matrix S of order $|I^{\sharp}|$ such that $S_{\tau(l)\tau(i)} = 0$ if $l < i$ and such that $S \cdot A^{\sharp}[I^{\sharp}, J^{\sharp}]$ has $(|I^{\sharp}| - \mathrm{rank}\, A^{\sharp}[I^{\sharp}, J^{\sharp}])$ zero row vectors. Let H be a subset of $I^{\sharp}$ corresponding to $(k - |J^{\sharp}| + 1)$ zero row vectors in $S \cdot A^{\sharp}[I^{\sharp}, J^{\sharp}]$. Then construct the constant matrix U in the same way as in (3.14). Let V be the unit matrix of order n.

After modifying the matrix $A(x)$ to $A'(x)$ by (3.11) with $U(x)$ and $V(x)$ thus constructed, the set of potentials is updated as follows. Put $c'_{ij} = \deg A'_{ij}(x)$ as in (3.1). It follows from (3.11), (3.12), and (3.13) that

$$\mathrm{diag}\,(x; -\rho) \cdot A'(x) \cdot \mathrm{diag}\,(x; -\gamma) = U \cdot \mathrm{diag}\,(x; -\rho) \cdot A(x) \cdot \mathrm{diag}\,(x; -\gamma) \cdot V,$$

which, together with (3.2), implies

$$(3.16)\qquad \rho_i + \gamma_j \geq c'_{ij} \quad \text{for } i \in R \quad \text{and } j \in C.$$

We update the set of potentials to improve the estimate, exploiting the fact that (3.16) holds with strict inequality for some $i \in R$ and $j \in C$. Roughly speaking, we reduce the potentials of such rows or columns without violating the admissibility. A more specific description, according to which condition of the four is violated, is given below.

When (r1) is violated:

$$(3.17)\ \rho'_i = \begin{cases} \max\left\{ \max\limits_{j \in \tilde{J}}(c'_{ij} - \gamma_j),\ \max\limits_{j \in (C - \tilde{J})} c'_{ij} - \gamma_{\sigma(k)} \right\} & \text{if } i \in \tilde{I}, \\ \rho_i & \text{otherwise;} \end{cases}$$

$$(3.18)\ \gamma'_j = \max_{i \in R}(c'_{ij} - \rho'_i).$$

When (r2) is violated:

$$(3.19)\ \rho'_i = \begin{cases} \max\left\{ \max\limits_{j \in \tilde{J}}(c'_{ij} - \gamma_j),\ \max\limits_{j \in (C - \tilde{J})} c'_{ij} - \gamma_{\sigma(k)} \right\} & \text{if } i \in I^{\sharp}, \\ \rho_i & \text{otherwise;} \end{cases}$$

$$(3.20)\ \gamma'_j = \max_{i \in R}(c'_{ij} - \rho'_i).$$

When (r3) is violated:

$$(3.21)\ \gamma'_j = \begin{cases} \max\left\{ \max\limits_{i \in \tilde{I}}(c'_{ij} - \rho_i),\ \max\limits_{i \in (R - \tilde{I})} c'_{ij} - \rho_{\tau(k)} \right\} & \text{if } j \in J^{\sharp}, \\ \gamma_j & \text{otherwise;} \end{cases}$$

$$(3.22)\ \rho'_i = \max_{j \in C}(c'_{ij} - \gamma'_j).$$

When (r4) is violated:

$$(3.23)\quad \rho_i' = \begin{cases} \rho_i - \beta & \text{if } i \in H; \\ \rho_i & \text{otherwise,} \end{cases} \qquad \gamma_j' = \begin{cases} \gamma_j & \text{if } j \in J^\sharp, \\ \gamma_j + \beta & \text{otherwise,} \end{cases}$$

where

$$(3.24)\quad \beta = \min \left\{ \rho_{\tau(|I^\sharp|)} - \rho_{\tau(|I^\sharp|+1)}, \quad \gamma_{\sigma(|J^\sharp|)} - \gamma_{\sigma(|J^\sharp|+1)}, \quad \min_{h \in H, j \in J^\sharp} (\rho_h + \gamma_j - c_{hj}') \right\}.$$

Exceptionally, the first term is excluded from the minimization when $I^\sharp = R$, and the second is excluded when $J^\sharp = C$.

As to the admissibility of the updated set of potentials, the following lemma holds.

LEMMA 3.2. *The updated set of potentials (ρ', γ') is admissible with respect to the modified matrix A'. That is, $\rho_i' + \gamma_j' \geq c_{ij}'$ for $i \in R$ and $j \in C$.*

Proof. The proof is immediate when (r1), (r2), or (r3) is violated. When (r4) is violated, however, this lemma follows from (3.16). □

The following theorem shows that the estimate is improved by the modification described above.

THEOREM 3.3. *The following inequality holds:*

$$(3.25)\qquad \widehat{\delta}_k(A'; \rho', \gamma') < \widehat{\delta}_k(A; \rho, \gamma).$$

Proof. With respect to ρ' and γ', we define permutations τ' of R and σ' of C, in a similar way to τ, σ (see (3.6) and (3.7)). We now prove (3.25) according to which condition of the four is violated.

When (r1) or (r2) is violated: It follows from the definition of ρ' and (3.16) that $\rho_i' \leq \rho_i$ for $i \in R$. Furthermore, since $\rho_h + \gamma_j > c_{hj}'$ for $h \in H$ and $j \in \tilde{J}$, we have $\rho_h' < \rho_h$ for $h \in H$. Similarly, we have $\gamma_j' \leq \gamma_j$ for $j \in \tilde{J}$ and $\gamma_j' \leq \gamma_{\sigma(k)}$ for $j \in (C - \tilde{J})$. As a result,

$$\sum_{i=1}^{k} \rho_{\tau'(i)}' < \sum_{i=1}^{k} \rho_{\tau(i)}, \qquad \sum_{j=1}^{k} \gamma_{\sigma'(j)}' \leq \sum_{j=1}^{k} \gamma_{\sigma(j)}.$$

Hence, $\widehat{\delta}_k(A'; \rho', \gamma') < \widehat{\delta}_k(A; \rho, \gamma)$.

When (r3) is violated: It can be shown in a way similar to that in which the case (r2) is violated.

When (r4) is violated: Since $\rho_h + \gamma_j > c_{hj}'$ for $h \in H$ and $j \in J^\sharp$, we have $\beta > 0$. It follows from the definition of ρ' that

$$\sum_{i=1}^{k} \rho_{\tau'(i)}' \leq \sum_{i=1}^{k} \rho_{\tau(i)} - \beta |H|.$$

On the other hand, the definition of γ' implies

$$\sum_{j=1}^{k} \gamma_{\sigma'(j)}' \leq \sum_{j=1}^{k} \gamma_{\sigma(j)} + \beta(k - |J^\sharp|).$$

Since $|H| = k - |J^\sharp| - 1$ and $\beta > 0$, we obtain $\widehat{\delta}_k(A'; \rho', \gamma') < \widehat{\delta}_k(A; \rho, \gamma)$. □

REMARK 3.2. The previous algorithm [15] of combinatorial relaxation type mentioned in Remark 3.1, which will be called the matching method in this paper, also makes use of the potentials (dual variables). The test for tightness is reduced to the rank conditions on a constant matrix defined with the aid of the optimal dual variables. If the combinatorial estimate (maximum weight of matchings) turns out to be nontight, the matrix is modified by a biproper transformation determined with reference to the optimal dual variables. The set of potentials, however, is not updated from the current one, but recomputed by solving the weighted matching problem from scratch. Thus the matchings, which are the combinatorial counterpart of determinants, play the primary role in the matching method. In this sense, the matching method might be regarded as a primal approach rather than a primal-dual.

3.5. Example. Let us consider $\delta_3(A)$ for a polynomial matrix

$$A(x) = \begin{array}{c} \\ \mathrm{R1} \\ \mathrm{R2} \\ \mathrm{R3} \\ \mathrm{R4} \end{array} \!\!\begin{array}{c} \begin{array}{cccc} \mathrm{C1} & \mathrm{C2} & \mathrm{C3} & \mathrm{C4} \end{array} \\ \begin{pmatrix} x^4 & x^5 & 0 & 2x^3 \\ x^5 & x^6+1 & x^4 & x^2 \\ x^4+x & x^5 & -x^3 & 0 \\ 2x^2 & x & 0 & x+2 \end{pmatrix} \end{array},$$

following Example 1 of [15]. As an initial set of admissible potentials, we take

$$\rho = (0,0,0,0), \quad \gamma = (5,6,4,3).$$

Then we have $\widehat{\delta_3}(A;\rho,\gamma) = (0+0+0)+(6+5+4) = 15$ and

$$I^\sharp = \emptyset, \quad \tilde{I} = \{\mathrm{R1},\mathrm{R2},\mathrm{R3},\mathrm{R4}\},$$
$$J^\sharp = \{\mathrm{C1},\mathrm{C2},\mathrm{C3}\}, \quad \tilde{J} = \{\mathrm{C1},\mathrm{C2},\mathrm{C3}\}.$$

Hence

$$A^\sharp = \begin{array}{c} \begin{array}{ccc} \longleftarrow & J^\sharp & \longrightarrow \end{array} \\ \begin{pmatrix} 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \end{array}.$$

In this case, (r1) and (r3) are violated. Let us change $A(x)$ according to the modification rule for the case when (r1) is violated (see §3.4). The modification matrix $U(x)$ is the unit matrix, and hence $A'(x) = A(x)$ (not changed). The set of potentials, however, is updated to

$$\rho' = (-1,0,-1,-3), \quad \gamma' = (5,6,4,4).$$

Then we have $\widehat{\delta_3}(A';\rho',\gamma') = (0+(-1)+(-1))+(6+5+4) = 13$ and

$$I^\sharp = \{\mathrm{R1},\mathrm{R2},\mathrm{R3}\}, \quad \tilde{I} = \{\mathrm{R1},\mathrm{R2},\mathrm{R3}\},$$
$$J^\sharp = \{\mathrm{C1},\mathrm{C2}\}, \quad \tilde{J} = \{\mathrm{C1},\mathrm{C2},\mathrm{C3},\mathrm{C4}\}.$$

Hence

$$(A')^\sharp = \begin{array}{c} \\ \uparrow \\ I^\sharp \\ \downarrow \\ \end{array} \!\!\begin{array}{c} \begin{array}{ccc} \leftarrow J^\sharp & & \longrightarrow \end{array} \\ \begin{pmatrix} 1 & 1 & 0 & 2 \\ 1 & 1 & 1 & 0 \\ 1 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \end{array}.$$

In this case, (r3) and (r4) are violated. First suppose we change $A'(x)$ according to the modification rule for the case of (r3), whereas the other possibility is considered later. We detect the violation of (r3) through the Gaussian column elimination

$$(A')^\sharp[R, J^\sharp] \cdot S = \begin{pmatrix} 1 & 1 \\ 1 & 1 \\ 1 & 1 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 0 & 1 \\ 0 & 1 \\ 0 & 0 \end{pmatrix},$$

in which we note $\gamma'_{\mathrm{C2}} > \gamma'_{\mathrm{C1}}$. Hence we have $H = \{\mathrm{C1}\}$ and

$$V = \begin{pmatrix} 1 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

According to (3.13) we have

$$\begin{aligned} V(x) \quad &= \mathrm{diag}\,(x^{-5}, x^{-6}, x^{-4}, x^{-4}) \cdot V \cdot \mathrm{diag}\,(x^5, x^6, x^4, x^4) \\ &= \begin{pmatrix} 1 & 0 & 0 & 0 \\ -x^{-1} & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \end{aligned}$$

which modifies $A'(x)$ to

$$A''(x) = A'(x)V(x) = \begin{pmatrix} 0 & x^5 & 0 & 2x^3 \\ -x^{-1} & x^6+1 & x^4 & x^2 \\ x & x^5 & -x^3 & 0 \\ 2x^2-1 & x & 0 & x+2 \end{pmatrix}. \tag{3.26}$$

The updated potentials, defined by (3.21) and (3.22), are

$$\rho'' = (-1, 0, -1, -1), \qquad \gamma'' = (3, 6, 4, 4). \tag{3.27}$$

Now, $\widehat{\delta_3}(A''; \rho'', \gamma'') = (0 + (-1) + (-1)) + (6 + 4 + 4) = 12$ and

$$\begin{aligned} I^\sharp &= \{\mathrm{R2}\}, & \tilde{I} &= \{\mathrm{R1}, \mathrm{R2}, \mathrm{R3}, \mathrm{R4}\}, \\ J^\sharp &= \{\mathrm{C2}, \mathrm{C3}, \mathrm{C4}\}, & \tilde{J} &= \{\mathrm{C2}, \mathrm{C3}, \mathrm{C4}\}. \end{aligned}$$

Hence

$$(A'')^\sharp = \begin{array}{cc} & \begin{array}{cccc} & \longleftarrow & J^\sharp & \longrightarrow \end{array} \\ I^\sharp \updownarrow & \begin{pmatrix} 0 & 1 & 0 & 2 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \end{array}.$$

In this case, all of (r1)–(r4) are satisfied. Consequently, we conclude that $\delta_3(A) = \delta_3(A'') = \widehat{\delta_3}(A''; \rho'', \gamma'') = 12$.

Let us explore the other possibility of modifying $A'(x)$. Namely, we change $A'(x)$ according to the modification rule for the case of (r4). Then we have a different modified matrix and a different set of potentials, as follows. We detect the violation of (r4) through the Gaussian row elimination

$$S \cdot (A')^\sharp[I^\sharp, J^\sharp] = \begin{pmatrix} 1 & -1 & 0 \\ 0 & 1 & 0 \\ 0 & -1 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 1 \\ 1 & 1 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 1 & 1 \\ 0 & 0 \end{pmatrix},$$

in which we note $\rho'_{\mathrm{R2}} > \rho'_{\mathrm{R1}} = \rho'_{\mathrm{R3}}$. Hence we have $H = \{\mathrm{R1}, \mathrm{R3}\}$ and

$$U = \begin{pmatrix} 1 & -1 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

According to (3.12) we have

$$\begin{aligned} U(x) &= \mathrm{diag}\,(x^{-(-1)}, x^{-0}, x^{-(-1)}, x^{-(-3)}) \cdot U \cdot \mathrm{diag}\,(x^{-1}, x^{0}, x^{-1}, x^{-3}) \\ &= \begin{pmatrix} 1 & -x^{-1} & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & -x^{-1} & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \end{aligned}$$

which modifies $A'(x)$ to

$$A''(x) = U(x)A'(x) = \begin{pmatrix} 0 & -x^{-1} & -x^3 & 2x^3 - x \\ x^5 & x^6 + 1 & x^4 & x^2 \\ x & -x^{-1} & -2x^3 & x \\ 2x^2 & x & 0 & x + 2 \end{pmatrix}.$$

In updating potentials, we have $\beta = 1$ from (3.24) and

$$\rho'' = (-2, 0, -2, -3), \qquad \gamma'' = (5, 6, 5, 5).$$

Note that $A''(x)$ and (ρ'', γ'') defined here are different from those in (3.26) and (3.27). Now, $\widehat{\delta}_3(A''; \rho'', \gamma'') = (0 + (-2) + (-2)) + (6 + 5 + 5) = 12$ and

$$\begin{aligned} I^\sharp &= \{\mathrm{R1}, \mathrm{R2}, \mathrm{R3}\}, \quad \tilde{I} = \{\mathrm{R1}, \mathrm{R2}, \mathrm{R3}\}, \\ J^\sharp &= \{\mathrm{C2}\}, \quad \tilde{J} = \{\mathrm{C1}, \mathrm{C2}, \mathrm{C3}, \mathrm{C4}\}. \end{aligned}$$

Hence

$$(A'')^\sharp = \begin{array}{c|cccc|} & & J^\sharp & & \\ & & \leftrightarrow & & \\ \uparrow & 0 & 0 & -1 & 2 \\ I^\sharp & 1 & 1 & 0 & 0 \\ \downarrow & 0 & 0 & -2 & 0 \\ & 0 & 0 & 0 & 0 \end{array}.$$

In this case, all of (r1)–(r4) are satisfied. Consequently, we conclude again, but using a different $A''(x)$, that $\delta_3(A) = \delta_3(A'') = \widehat{\delta}_3(A''; \rho'', \gamma'') = 12$.

3.6. Algorithm description. We have so far fixed the size k of a submatrix. It is necessary to compute δ_k for $k = 1, 2, \ldots, r$ for obtaining the Smith–McMillan form at infinity.

Before describing the whole algorithm, we should remark how we can detect $\delta_k = -\infty$. For a rational function

$$f(x) = \frac{a_1 x^{d_1} + a_2 x^{d_2} + \cdots + a_\ell x^{d_\ell}}{q(x)} \qquad (d_1 > d_2 > \cdots > d_\ell),$$

we define $\text{min-deg}\, f(x) \equiv d_\ell - \deg q(x)$ with respect to its expression. Put $d_{\min} = \min_{i,j} \text{min-deg}\, A_{ij}(x)$ while $d_{\max} = \max_{i,j} \deg A_{ij}(x)$. If δ_k is finite, it must satisfy $\delta_k \geq k \cdot d_{\min}$. Hence we can conclude that $\delta_k = -\infty$ when $\widehat{\delta}_k(A; \rho, \gamma) < k \cdot d_{\min}$ for some admissible (ρ, γ).

We now summarize the algorithm for computing δ_k for $k = 1, 2, \ldots, r (= \mathrm{rank}\, A)$ as follows. It is not necessary to input r, since it is computed in the procedure.

ALGORITHM FOR COMPUTING $\delta_k(A)$ $(k = 1, 2, \ldots)$.

Step 0: Compute $d_{\min}$. Set $k := 1$. Find a set of initial potentials (ρ, γ) which satisfies $\rho_i + \gamma_j \geq c_{ij}$ for $i \in R$ and $j \in C$.

Step 1: Compute

$$\widehat{\delta_k} := \sum_{i=1}^{k} \rho_{\tau(i)} + \sum_{j=1}^{k} \gamma_{\sigma(j)},$$

where τ and σ are permutations such that $\rho_{\tau(1)} \geq \rho_{\tau(2)} \geq \cdots \geq \rho_{\tau(m)}$ and $\gamma_{\sigma(1)} \geq \gamma_{\sigma(2)} \geq \cdots \geq \gamma_{\sigma(n)}$. If $\widehat{\delta_k} < k \cdot d_{\min}$, then halt (at this point $(k-1)$ equals the rank r).

Step 2: Put

$$I^\sharp := \{i \in R \mid \rho_i > \rho_{\tau(k+1)}\}, \qquad \tilde{I} := \{i \in R \mid \rho_i \geq \rho_{\tau(k)}\},$$
$$J^\sharp := \{j \in C \mid \gamma_j > \gamma_{\sigma(k+1)}\}, \qquad \tilde{J} := \{j \in C \mid \gamma_j \geq \gamma_{\sigma(k)}\};$$

where exceptionally $I^\sharp = R$ and $J^\sharp = C$ in case $k = m$ and $k = n$, respectively. Put

$$A^\sharp_{ij} := \begin{cases} \lim_{x\to\infty} x^{-\rho_i-\gamma_j} A_{ij}(x) & \text{if } i \in \tilde{I} \text{ and } j \in \tilde{J}, \\ 0 & \text{otherwise.} \end{cases}$$

If the four conditions (r1)–(r4) in Proposition 3.1 are satisfied, then output $\widehat{\delta_k}$. If at least one condition of the four is violated, go to Step 3. If $k = \min(m, n)$, then halt. Otherwise $k := k + 1$ and go to Step 1.

Step 3: Modify the matrix $A(x)$ and the potentials as described in (3.17)–(3.23), according to which of (r1)–(r4) is violated. Go to Step 1.

In the algorithm described above, we may start with an arbitrary set of admissible potentials. It is desirable, however, to adopt reasonably small integers as the initial potentials.

One of the natural choices is to put

$$\rho_i = \max_{j\in C} c_{ij} \quad \text{for } i \in R, \qquad \gamma_j = 0 \quad \text{for } j \in C. \tag{3.28}$$

In this case, $\gamma_j = 0$ for $j \in C$ throughout the computation. Hence ρ_i for $i \in R$ always coincide with the row degrees. Since $J^\sharp = \emptyset$ and $\tilde{J} = C$, the four rank conditions in the test for tightness (see Proposition 3.1) are reduced to a couple of conditions, (r1) and (r2). This algorithm will be called the row-degree method, and is an extension of the well-known algorithm for $\delta_m(A)$ of an $m \times n$ row-full rank matrix $A(x)$ based on the concept of row properness (Wolovich [24]).

Another natural choice is, of course, the symmetric (transposed) version of the above, i.e.,

$$\rho_i = 0 \quad \text{for } i \in R, \qquad \gamma_j = \max_{i\in R} c_{ij} \quad \text{for } j \in C. \tag{3.29}$$

This algorithm, however, does not behave in a manner symmetric to the row-degree method. This is because the symmetry between rows and columns is broken in the process of modification. In fact, any condition of the four may possibly be violated. Thus this algorithm is not the "column-degree method," and the primal-dual framework is not a simple extension of the Wolovich algorithm.

3.7. Complexity. In this section, we analyze the time complexity of our algorithm. First we consider the number of possible modifications when k ranges from 2 to r.

LEMMA 3.4. *The total number of modifications for $k = 2, \ldots, r$ is bounded by $r(d_{\max} - d_{\min})$.*

Proof. Let $A^{(\ell)}$ denote the matrix constructed for $k = \ell$ such that $\delta_\ell(A) = \delta_\ell(A^{(\ell)}) = \widehat{\delta}_\ell(A^{(\ell)})$, where the potentials are omitted for notational simplicity. First note $\delta_{\ell\pm1}(A^{(\ell)}) \leq \widehat{\delta}_{\ell\pm1}(A^{(\ell)})$ and $\widehat{\delta}_{\ell+1}(A^{(\ell)}) \leq 2\widehat{\delta}_\ell(A^{(\ell)}) - \widehat{\delta}_{\ell-1}(A^{(\ell)})$ (concavity). Then (the number of modifications for $k = \ell + 1$) $\leq \widehat{\delta}_{\ell+1}(A^{(\ell)}) - \delta_{\ell+1}(A^{(\ell)}) \leq 2\delta_\ell(A) - \delta_{\ell-1}(A) - \delta_{\ell+1}(A)$. Therefore, the total number of modifications in the course of computation for $k = 2, \ldots, r$ is bounded as follows:

$$\begin{aligned}\sum_{\ell=1}^{r-1}(\widehat{\delta}_{\ell+1}(A^{(\ell)}) - \delta_{\ell+1}(A^{(\ell)})) &\leq \delta_1(A) + \delta_{r-1}(A) - \delta_r(A)\\ &\leq d_{\max} + (r-1)\cdot d_{\max} - r\cdot d_{\min}\\ &= r\cdot(d_{\max} - d_{\min}). \qquad \square\end{aligned}$$

Consequently, from Lemma 3.4, the number of modifications is $O(r)$ provided that $(d_{\max} - d_{\min})$ is a constant, which is the case with matrix pencils.

Next, we consider the time complexity with respect to m and n (the size of the matrix) and r (the rank of A).

THEOREM 3.5. *The time complexity of the proposed algorithm for computing all the δ_k is $O(rmn\max(m, n))$, provided that $(d_{\max} - d_{\min})$ is a constant.*

Proof. The time complexity for computing δ_k for $k = 1, 2, \ldots, r$ can be estimated by (r+the number of modifications)$\times O(mn\max(m, n))$. According to Lemma 3.4, the number of modifications is $O(r)$, and therefore the whole time complexity is $O(rmn\max(m, n))$. $\square$

3.8. Extension. We will extend the proposed algorithm so as to compute

$$\delta_k(A; I_0, J_0) = \max_{I,J}\{\deg\det A[I, J] \mid I \supseteq I_0, J \supseteq J_0, |I| = |J| = k\},$$

the maximum degree of a minor of order k, which covers the specified row-set I_0 and column-set J_0.

For (ρ, γ) admissible in the sense of (3.2) we define

$$\widehat{\delta}_k(A; I_0, J_0; \rho, \gamma) = \max_{I \supseteq I_0, |I|=k} \rho(I) + \max_{J \supseteq J_0, |J|=k} \gamma(J),$$

and then we have

$$\delta_k(A; I_0, J_0) \leq \widehat{\delta}_k(A; I_0, J_0; \rho, \gamma). \tag{3.30}$$

With permutations τ and σ such that

$$\tau : \begin{cases} \{1, \ldots, |I_0|\} \to I_0, & \\ \{|I_0| + 1, \ldots, m\} \to R - I_0 & \text{such that } \rho_{\tau(|I_0|+1)} \geq \rho_{\tau(|I_0|+2)} \geq \cdots \geq \rho_{\tau(m)}; \end{cases}$$

$$\sigma : \begin{cases} \{1, \ldots, |J_0|\} \to J_0, & \\ \{|J_0| + 1, \ldots, n\} \to C - J_0 & \text{such that } \gamma_{\sigma(|J_0|+1)} \geq \gamma_{\sigma(|J_0|+2)} \geq \cdots \geq \gamma_{\sigma(n)}, \end{cases}$$

it holds that

$$\widehat{\delta}_k(A; I_0, J_0; \rho, \gamma) = \sum_{i=1}^{k} \rho_{\tau(i)} + \sum_{j=1}^{k} \gamma_{\sigma(j)}.$$

We redefine $I^\sharp$, $J^\sharp$, $\tilde{I}$, and $\tilde{J}$ as follows:

$$I^\sharp = \{i \in (R - I_0) \mid \rho_i > \rho_{\tau(k+1)}\}, \qquad \tilde{I} = \{i \in (R - I_0) \mid \rho_i \geq \rho_{\tau(k)}\},$$
$$J^\sharp = \{j \in (C - J_0) \mid \gamma_j > \gamma_{\sigma(k+1)}\}, \qquad \tilde{J} = \{j \in (C - J_0) \mid \gamma_j \geq \gamma_{\sigma(k)}\}.$$

Exceptionally, in case $k = m$, we set $I^\sharp = \tilde{I} = R - I_0$, and in case $k = n$, $J^\sharp = \tilde{J} = C - J_0$.

The definition of the constant matrix $A^\sharp$ is also modified:

$$A^\sharp_{ij} = \begin{cases} \lim\limits_{x\to\infty} x^{-\rho_i-\gamma_j} A_{ij}(x) & \text{if } i \in (I_0 \cup \tilde{I}) \text{ and } j \in (J_0 \cup \tilde{J}), \\ 0 & \text{otherwise.} \end{cases}$$

Proposition 3.1 for tightness is rewritten as follows.

PROPOSITION 3.6 (tightness). *The following three conditions are equivalent.*

(a) $\widehat{\delta}_k(A; I_0, J_0) = \delta_k(A; I_0, J_0)$.

(b) *There exist* $I \supseteq I_0 \cup I^\sharp$ *and* $J \supseteq J_0 \cup J^\sharp$ *such that* $\operatorname{rank} A^\sharp[I, J] = |I| = |J| = k$.

(c) *The following four conditions are satisfied:*

(r1) $\operatorname{rank} A^\sharp[R, C] \geq k$;

(r2) $\operatorname{rank} A^\sharp[I_0 \cup I^\sharp, C] = |I_0 \cup I^\sharp|$;

(r3) $\operatorname{rank} A^\sharp[R, J_0 \cup J^\sharp] = |J_0 \cup J^\sharp|$;

(r4) $\operatorname{rank} A^\sharp[I_0 \cup I^\sharp, J_0 \cup J^\sharp] \geq |I_0 \cup I^\sharp| + |J_0 \cup J^\sharp| - k$.

The matrix $A(x)$ is modified on the basis of the following fact. For simplicity, I_0 and J_0 are assumed to be the first $|I_0|$ rows and the first $|J_0|$ columns. Then $A'(x) = U(x)A(x)V(x)$ satisfies $\delta_k(A') = \delta_k(A)$ if

$$U(x) = \begin{array}{c|c|c} & I_0 & R - I_0 \\ \hline I_0 & U_0(x) & O \\ R - I_0 & U_2(x) & U_1(x) \end{array}, \qquad V(x) = \begin{array}{c|c|c} & J_0 & C - J_0 \\ \hline J_0 & V_0(x) & V_2(x) \\ C - J_0 & O & V_1(x) \end{array},$$

where $U_0(x)$ is an $|I_0| \times |I_0|$ matrix with $\deg\det U_0(x) = 0$, $U_1(x)$ is a biproper matrix, and $U_2(x)$ is an arbitrary rational matrix; and $V_0(x)$ is a $|J_0| \times |J_0|$ matrix with $\deg\det V_0(x) = 0$, $V_1(x)$ is a biproper matrix, and $V_2(x)$ is an arbitrary rational matrix.

4. Experimental evaluation.

4.1. Method. We perform experiments on Sun SPARC Station 10 to evaluate the three combinatorial relaxation-type algorithms, the primal-dual method (PD) with initial potentials given by (3.29), the row-degree method (RD), and the matching method (M). All of these are implemented in C language. For comparison, we also realize in Maple (a computer algebraic system) the elimination method (E) described in §2.

Our program restricts input matrices to Laurent polynomial matrices of which each entry is a polynomial in x and $1/x$.

We provide two types of sample problems, regular pencils (P) and band matrices (B). A regular pencil $xE - F$ used here is generated randomly in the following way:

$$E_{ij} = \begin{cases} g & \text{with probability } \frac{1-p}{2K} \quad \text{for } g = \pm1, \pm2, \ldots, \pm K, \\ 0 & \text{with probability } p; \end{cases}$$

$$F_{ij} = \begin{cases} h & \text{with probability } \frac{1-q}{2K} \quad \text{for } h = \pm1, \pm2, \ldots, \pm K, \\ 0 & \text{with probability } q. \end{cases}$$

We put $K = 1$, $p = 0.0625$, and $q = 0.5$.

On the other hand, we provide band matrices in the following way. First we put

$$X = \operatorname{diag}(x; \mathbf{d}), \quad \mathbf{d} = (d_1, d_2, \ldots d_n),$$

where d_i is generated randomly as follows:

$$d_i = \ell \quad \text{with probability } \frac{1}{2L+1} \quad \text{for } \ell = 0, \pm 1, \pm 2, \ldots, \pm L.$$

With a lower bidiagonal matrix

$$P = \begin{pmatrix} 1 & & & \\ \frac{1}{x} & 1 & & \\ & \ddots & \ddots & \\ & & \frac{1}{x} & 1 \end{pmatrix}$$

and an upper bidiagonal matrix

$$Q = \begin{pmatrix} 1 & \frac{1}{x} & & \\ & \ddots & \ddots & \\ & & 1 & \frac{1}{x} \\ & & & 1 \end{pmatrix}$$

we construct a pentadiagonal (band) matrix $A(x) = P^2XQ^2$. We put $L = 10$. Obviously, both P and Q are biproper, and hence the Smith–McMillan form at infinity of $A(x)$ is the same as that of X, which is easily obtained by sorting $(d_1, \ldots, d_n)$. Therefore, we know $\delta_k(A)$ in advance, and we use this type of matrix as sample data to ensure that our program returns correct answers.

We measure CPU time and the number of modifications (for PD, RD, and M) to evaluate each algorithm.

4.2. Results. Before we report experimental results, we should recall that the time complexity is $O(rmn \max(m, n))$ if $(d_{\max} - d_{\min})$ is bounded by a constant (see Theorem 3.5). In fact, we have $(d_{\max} - d_{\min}) \leq 1$ with the pencils and $(d_{\max} - d_{\min}) \leq 2L + 2$ with the band matrices. Therefore, the time complexity is $O(rmn \max(m, n))$.

Table 1 and Figure 1 show the results for the pencils, and Table 2 and Figure 2 show the results for the band matrices. In Figures 1 and 2, the abscissa is $\log_2 n$, where n is the size of a matrix, while the ordinate is $\log_{10} T$, where T is the CPU time. Algorithm PD failed for $n = 128$ because of a memory shortage. The experiments with algorithm E for large n were given up because it would have taken many days.

It is observed in our experiment that for an $n \times n$ matrix A, approximately $O(n^{3.4})$ time is needed by each combinatorial relaxation algorithm, while time complexity given by Theorem 3.5 is $O(n^4)$ since rank $A = n$ in both problem types P and B. On the other hand, the elimination method takes approximately $O(n^4)$ time in our experiment, whereas the number of operations on rational functions is $O(n^3)$, as mentioned in §2.

In the above experiment, no distinction in computing time is recognized among algorithms PD, RD, and M. Since algorithm RD lacks symmetry, it is natural that this algorithm takes longer than the other algorithms for a matrix with a special structure. For example, let us consider

$$A(x) = \begin{pmatrix} 1 & 1 & 1 & \cdots & 1 \\ 1 & x & x^2 & \cdots & x^{n-1} \\ 1 & x^2 & x^4 & \cdots & x^{2(n-1)} \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ 1 & x^{n-1} & x^{2(n-1)} & \cdots & x^{(n-1)^2} \end{pmatrix}. \tag{4.1}$$

The results for the matrix with $n = 16$ are shown in Table 3.

5. Discussion. First we compare various aspects of the three combinatorial relaxation algorithms: accuracy, running time, and facility in implementation.

Numerical difficulty is inherent in the problem of computing the maximum degree of subdeterminants, and hence inevitable with any kind of algorithm. We intend, however, to exert the greatest possible effort to circumvent this numerical difficulty by making use of combinatorial (or structural) information. The total amount of numerical computation, which causes the accumulation of rounding errors, increases in proportion to the number of modifications in combinatorial relaxation algorithms. In this regard we recommend method M among the combinatorial relaxation algorithms, because it usually requires fewer modifications.

TABLE 3
CPU time in seconds and the number of modifications for the matrix $A(x)$ *of* (4.1) *with* $n = 16$.

Algorithms	CPU time (s)	# Modifications
PD	1.67	139
RD	2.03	156
M	8.33×10^{-2}	0

When $r = \text{rank}\, A(x) < \min(m, n)$, however, even the recommended method, M, requires a large number of modifications and hence suffers from numerical difficulty in detecting $\delta_k(A) = -\infty$ for $k = r + 1$. In fact, we often encountered this numerical difficulty in experiments with some singular pencils. If we know the rank r in advance, we should therefore stop the computation at $k = r$.

As to running time, the experimental results show that although we take more time to compute the estimate in method M than in method PD or RD, the whole running time of these three are almost equal. This is due to the fact that M involves a smaller number of modifications.

Let us focus on facility in implementation. In this respect, method PD, as well as method RD, is advantageous, because it does not rely on any sophisticated algorithms in combinatorial optimization, whereas method M depends on a refined algorithm for the weighted matching problem.

Next we discuss the applicability of our programs of combinatorial relaxation algorithms. Recall that our implementation is restricted to Laurent polynomial matrices. In order to make our program capable of dealing with rational function matrices, we have to use simplification procedures for rational functions, which are realized in computer algebraic systems. Taking this into consideration, the combinatorial relaxation-type algorithm for the maximum degree of subdeterminants is expected to be implemented in computer algebraic systems.

6. Conclusion. In this paper, we have proposed a primal-dual framework of combinatorial relaxation algorithms for computing the maximum degree of subdeterminants. Furthermore, we have realized combinatorial relaxation algorithms in computer programs and made experiments. It turns out that combinatorial relaxation algorithms are effective for computing the maximum degree of subdeterminants and the index of nilpotency.

The numerical difficulty is inherent in the problem. In particular, the index of nilpotency is very sensitive to perturbations unless it coincides with that obtained under a genericity assumption. Hence the structural approach has been taken extensively. When we model practical engineering systems such as electric networks or chemical plants, however, we often encounter numerical cancellations (or degeneracy) arising from fixed constants or an algebraic relationship among system parameters. In this case the naive genericity assumption is not valid, and the answer of a naive structural approach loses its physical significance. Hence it is necessary to use more than the naive structural approaches. We may employ a more sophisticated framework in the structural approach, as in [13, Chap. 4] and [17], on the basis of the observation that this kind of cancellation phenomena is robust against perturbations to physical parameters, because such constants or relations are determined by the combinatorial or geometric structure of the system rather than by physical characteristics. Alternatively, we may resort to algorithms of the kind treated in the present paper. We conclude this paper by mentioning that our algorithms gave the correct answer $\nu = 2$ to the example problem from [22] described in the Introduction.

Acknowledgments. The authors are grateful to Dr. Pawel Bujakiewicz for providing a number of relevant references, to Professor Kokichi Sugihara for his support, and to Dr. Keiichi Kaneko for advice on implementation. They also appreciate essential comments by anonymous referees that improved the presentation.

TIMELY COMMUNICATION

Under the "timely communications" policy for the SIAM Journal on Scientific Computing, papers that have significant timely content and do not exceed five pages automatically will be considered for a separate section of the journal with an accelerated reviewing process. It will be possible for the note to appear approximately six months after the date of acceptance.

VERIFICATION MAY BE BETTER THAN ESTIMATION*

C. FALCÓ KORN[†], B. HÖRMANN[‡], AND C. P. ULLRICH[§]

Abstract. Error bounds for an approximate solution of a linear system of equations are usually derived from backward error analysis. It is known that such error bounds do not guarantee a certain accuracy in the approximation. On the other hand, verification provides componentwise guaranteed bounds. A series of examples gives evidence that for H-matrices error verification may be better than traditional error estimation with respect to both the quality of the delivered bounds and computational performance.

Key words. error analysis, error estimation, verification, linear systems, numerical libraries, LAPACK, ITPACK

AMS subject classifications. 65G05, 65G10

1. Introduction.

Wilkinson showed that a computer solution is the exact solution of a nearby problem thus initiating backward error analysis. Subsequently, main results from this theory were incorporated into all major numerical packages like ITPACK, LINPACK, or LAPACK. But backward error analysis is not able to guarantee lower bounds on the number of correct digits in the approximation. In this paper we outline the basic idea behind error verification and demonstrate its effectiveness by a series of examples.

2. Backward error estimation.

Let $\widehat{x}$ be an approximation of the solution to the linear system $Ax = b$. The (normwise) backward error is defined by

$$\min_{E,f}\left(\max\left(\frac{\|E\|}{\|A\|},\frac{\|f\|}{\|b\|}\right)\right)$$

such that $\widehat{x}$ satisfies $(A+E)\widehat{x} = b+f$. The (normwise) forward error $\|x-\widehat{x}\|/\|x\|$ is related to the backward error by the condition number $\kappa(A) = \|A\| \cdot \|A^{-1}\|$. Indeed, if $\|E\| \leq \delta\|A\|$ and $\|f\| \leq \delta\|b\|$, Theorem 2.7.2 in [7] gives the bound

$$\frac{\|x-\widehat{x}\|}{\|x\|} \leq \frac{2\delta}{1-r}\kappa(A),$$

where $r = \delta\kappa(A)$ must be less then 1.

Although all packages compute the error (and thus the accuracy) in terms of the underlying backward error, definitions for the backward error and the condition number vary. (See, for example, [1], where a condition number is proposed which depends not only on the data matrix but on the approximation $\widehat{x}$ and the right-hand side b as well.) In practice, however, the exact condition number is not known. Moreover, the normwise forward error cannot be translated into a statement about the number of correct digits if the components in $\widehat{x}$ are not of the same order of magnitude. (See [7, Ex. 2.2.1, p. 54].)

3. Verified error bounds. In contrast to an error estimating routine, an error verifying routine determines upper bounds for the vector of relative errors which is defined as

$$t_i = \frac{|x_i - \widehat{x}_i|}{|x_i|} \quad (x_i \neq 0),$$

where again $\widehat{x}$ is an approximation and x is the exact solution of the linear system. Thus, a vector w from a verifying routine satisfies $w_i \geq t_i$. It tells us that at least $\lfloor -\log(w_i) \rfloor$ digits are correct in the ith component of the approximation. Furthermore, all components in the approximation are correct to at least $\min_i(\lfloor -\log(w_i)\rfloor)$ digits. We say that $\widehat{x}$ has a *true accuracy* of $\min_i(\lfloor -\log(t_i)\rfloor)$ digits. We call $\min_i(\lfloor -\log(w_i)\rfloor)$ the *lowest verified accuracy* and $\max_i(\lfloor -\log(w_i)\rfloor)$ the *highest verified accuracy*.

Error verifying routines were implemented by Falcó Korn [2]. His thesis provides the whole theoretical background. A concise English description can be found in [3, 4].

4. Examples. We preset the solution x and compute the right-hand side $b = Ax$ by a matrix–vector product. The right-hand sides will be $b1 = Ax1$ where all components of $x1$ are equal to 1, $b2 = Ax2$ with the ith component of $x2$ set to $1/i$, and $b3 = Ax3$ with $x3$ like $x1$ but with the last component set to 2^{50}. Examples 1 and 2 are computed on a NeXT workstation (NeXTstation II) and Example 3 is computed on a Macintosh IIci. Floating-point numbers conform to the IEEE double format which corresponds to at least 16 decimal digits.

4.1. Example 1. LAPACK [1] provides two different error estimation methods, both derived from backward error analysis. The first one (*Estimation* 1) is based on the DxxCON routine (where xx denotes one of LAPACK's storage schemes) which estimates the normwise condition number (see §2). The second one (*Estimation* 2) is computed with the DxxRFS routine. It calculates a componentwise backward error and an estimation of a componentwise condition number depending on A, b, and the approximation $\widehat{x}$.

For large narrow banded systems, Estimation 1 is feasible only for symmetric, positive definite, tridiagonal matrices [9]. To compare results over a wide range of dimensions, we consider the one-dimensional discrete Laplacian

$$(1) \qquad A = \underbrace{\begin{bmatrix} 2 & -1 & & \\ -1 & \ddots & \ddots & \\ & \ddots & \ddots & -1 \\ & & -1 & 2 \end{bmatrix}}_{n}.$$

First we compute approximations of $Ax = bi$ $(i = 1, 2, 3)$ using LAPACK's DPTTRF and DPTTRS routines [1]. Then we estimate the error using Estimations 1 and 2 for xx = PT and compare their results to the output of a verifying routine; see Table 1. Note that figures in the rows labeled with *Estimation* 1 and *Estimation* 2 denote $\lfloor -\log(\epsilon)\rfloor$, where ϵ denotes the normwise forward error as given by the corresponding LAPACK routines.

To summarize, accuracy statements from either estimation or verification are comparable to each other as long as all components of the solution vector are of the same order of magnitude. If this is not the case, overestimations may occur (see the last five rows). This is a consequence of the remarks at the end of §2.

For this example, verification is significantly slower than both estimations. Since no PT verifying routine is available yet, such a case is mapped onto a verifying routine which operates on PB-matrices.

Now consider the two-dimensional discrete Laplacian:

$$(2) \qquad A = \underbrace{\begin{bmatrix} B & C & & \\ C & \ddots & \ddots & \\ & \ddots & \ddots & C \\ & & C & B \end{bmatrix}}_{n}, B = \underbrace{\begin{bmatrix} 4 & -1 & & \\ -1 & \ddots & \ddots & \\ & \ddots & \ddots & -1 \\ & & -1 & 4 \end{bmatrix}}_{\sqrt{n}}, C = \underbrace{\begin{bmatrix} -1 & & \\ & \ddots & \\ & & -1 \end{bmatrix}}_{\sqrt{n}}.$$

Since this matrix is not tridiagonal, we use LAPACK's PB routines. Table 2 summarizes the results. The verifying routine is now significantly faster than both estimations. For the case where the right-hand side is $b3$, it gives the only realistic answer.

4.2. Example 2. For dense matrices the dominant time factor is the factorization of the matrix. In cases where L and U are computed once to solve several linear systems, we compare the time for the computation of an approximation $\widetilde{x}$ with the time needed to obtain a statement about its accuracy.

The following strictly diagonally dominant matrix is used in [8], a statistical study on condition numbers and estimation methods:

$$(3) \qquad A = (a_{ij}) = \begin{cases} \frac{i-j}{i+j-1}, & i \neq j, \\ n, & i = j. \end{cases}$$

We proceed as in Example 1. Since the matrix is dense we use LAPACK's GE routines. Table 3 lists execution times normalized by the time needed to compute $\widetilde{x}$. It shows a typical situation for dense systems: Estimation 1 is faster than Estimation 2, while the verifying routine offers the fastest way to obtain an error bound.

The accuracy results for this example are listed in Table 4. LAPACK's Estimation 1 overestimates the true accuracy.

4.3. Example 3. Iterative solvers stop when the backward error reaches some prescribed threshold. (See Chapter 4.2 of [10].) Since ITPACK [6] does not provide condition estimators,

it is not possible to check the forward error. Nevertheless, it can be determined with a verifying routine as long as the iterative solver relies on a splitting of the data matrix [2].

Table 5 summarizes the results for different prescribed backward errors. (As before, we express errors in terms of accuracies.) The computing times normalized by the time needed to compute the approximation $\hat{x}$ are listed in Table 6. For low dimensions, verifying the error is twice as fast as the solving process, but for very high dimensions determining the error with a verifying routine can be as expensive as the computation of the approximation itself.

5. Further remarks. The quality of the delivered error bounds depends on the quality of the bound

$$|(LU)^{-1}| \leq \langle U\rangle^{-1}\langle L\rangle^{-1}, \tag{4}$$

where $\langle\cdot\rangle$ denotes Ostrowski's comparison matrix[1] [2]. If $A = LU$ is an M-matrix[2] then equality holds in (4) and good results can be expected. For most H-matrices[3] (4) is still a good bound. Although many positive definite matrices (in particular symmetric M-matrices) are H-matrices, further research is needed to generalize the concept of verification to a wider class of matrices. Furthermore, an implementation of a verifying routine relies on the ability to manipulate the rounding direction and to check for floating-point exceptions.

Experiences with porting a library of verifying routines to another platform are reported in [5].

The C-programming code of the verifying routines can be obtained on the World Wide Web. At the time of this writing, the address is `http://www.ifi.unibas.ch/gruul/gruul.html`.

HYBRID MULTIFLUID ALGORITHMS*

SMADAR KARNI†

Abstract. Extensions of many successful single-component schemes to compute multicomponent gas dynamics suffer from oscillations and other computational inaccuracies near material interfaces that are caused by the failure of the schemes to maintain pressure equilibrium between the fluid components. A new algorithm based on the compressible Euler equations for multicomponent fluids augmented by the pressure evolution equation is presented. The extended set of equations offers two alternative ways to update the pressure field: (i) using the equation of state or (ii) using the pressure evolution equation. In a numerical implementation, these two procedures generally yield different answers. The former is a standard conservative update, but may produce oscillations near material interfaces; the latter is nonconservative, but becomes exact near interfaces and automatically maintains pressure equilibrium. A hybrid scheme which selects from the two pressure update procedures is presented. The scheme perfectly conserves total mass and momentum and conserves total energy everywhere except at a finite (very small) number of grid cells. Computed solutions exhibit oscillation-free interfaces and have *negligible* relative conservation errors in total energy even for very strong shocks. The proposed hybrid approach and switching strategies are independent of the numerical implementation and may provide a simple framework within which to extend one's favourite scheme to solve multifluid dynamics.

Key words. Euler equations, compressible interfaces, shock-capturing

AMS subject classifications. 65M0G, 65M12, 65N15, 76T05

1. Introduction.

Within the shock-capturing numerical approach to solve the gas dynamics equations, flow discontinuities are not perfectly represented on a discrete grid. They take on diffused viscous-like profiles, typically occupying two to three grid cells for shock fronts and five to seven grid cells for contact surfaces. Problems posed by nonzero shock width have received attention in the literature in various computational contexts [7, 15, 16, 22]. In multifluid dynamics, the problem is not diffused shock layers but rather diffused material interfaces across which the fluid composition changes. From a computational aspect, this is a harder problem since shocks possess compressive mechanisms which tend to absorb any induced error back into the shock front. Interfaces do not possess such mechanisms, and it is easier for errors generated near or within the diffused front to escape and contaminate the solution. The transition across the interface is governed by numerical viscosity mechanisms and intermediate states are not necessarily physically consistent. Indeed, when extended to multicomponent fluids, many successful single-species schemes [9, 19, 23, 28] encounter difficulties maintaining pressure equilibrium among the fluid components across diffused interfaces [1, 12, 13, 14]. Consequently, updating the pressure field via the equation of state (EOS) often generates erroneous pressure fluctuations at material interfaces, which subsequently contaminate the solution of other flow variables. These oscillations are not the ones commonly associated with high-order schemes. They are present already in first-order schemes and are persistent. They not only render the solutions (at times fatally) oscillatory, but also set off dispersive acoustic mechanisms which tend to further thicken the interfaces. While exceptions may apply [2, 6], it is generally true that extending one's favourite single-species scheme to multispecies is likely to produce solutions that are plagued by oscillations and other computational inaccuracies [1, 12, 13, 14]. A phenomenon of similar flavour, which has received some appreciation within the aerodynamic community, is the occurrence of erroneous pressure fluctuations across numerically diffused shear interfaces.

One possible cure is to employ algorithms which reconstruct the material front as a sharp discontinuity [3, 4, 17, 20], thus circumventing the problems arising due to interface smearing. This, however, comes at the expense of simplicity as such front-fitting/front-tracking algorithms raise nontrivial computational issues (e.g., keeping track of subgrid geometries for front reconstruction, net flux distribution on oddly shaped cells, stability restrictions due to the occurrence of small cells, etc.) and become quite involved to implement in multispace dimensions. A multifluid front-tracking algorithm has been developed in [6], based on the notion of volume-of-fluid (see for example [20] and references cited therein). The equations are written for the individual species, the jumps in the thermodynamic variables across the interface are tracked (the jump in tangential velocity is captured), and the interface geometry is reconstructed from the partial volumes of the fluid components and then evolved using the underlying single-fluid velocity field. Assuming isentropic compression effective, thermodynamic quantities are obtained for the fluid mixture which keep the fluid components in pressure equilibrium and also account for their possibly different compressibilities. This last property, while less critical for gas mixtures, could prove indispensable in gas/liquid interfaces where compressibilities of the individual components are widely different. This algorithm was used in [10] to study oblique shock refraction at a planar gas interface and has been applied to a more general EOS in [30].

In this paper we wish to remain within the front-capturing framework, particularly because of its attractive simplicity. We take a different approach, based on the instrumental observation that if the pressure field is evolved by using the pressure evolution equation, then pressure equilibrium among fluid components is automatically maintained and the generation of spurious pressure fluctuations is avoided. This observation has led the author to develop a scheme based on formulating the gas dynamics equations in terms of the so-called primitive variables [11, 12, 21]. Near material interfaces, the primitive formulation completely decouples into a set of linear advection equations for the density and the fluid marker variable (also the cross velocity components in higher space dimensions). Although generally nonconservative, near material fronts the model becomes *exact* and does not introduce conservation errors. Applications of interest, however, invariably involve shock waves near which conservation errors are introduced, manifested in incorrect shock speed and strength. By using a viscous perturbation approach, these conservation errors can be controlled and kept acceptably small for shocks of weak to moderate strengths (up to $M_s \approx 2.0$) [11, 12, 29]. Solutions thus produced have clean oscillation-free interfaces, and relative conservation errors are within 1%–2%.

It may be argued that sacrificing conservation completely for the sake of a primitive formulation is a drastic measure which discards the baby together with the bathwater. Indeed, the failure of schemes which are based on conservative flow models is local, predictable, and limited to the immediate vicinity of material fronts. Everywhere else, these schemes are perfectly adequate. In this paper, we present an elegant hybrid scheme, which switches between conservative and primitive updates of the pressure/energy fields. For simplicity, we focus on a two-component ideal gas model. Ideas certainly extend to more than two components in multispace dimension, and we believe also to nonideal cases. The latter may require some extra care in treating the multifluid thermodynamics. Work is already in progress for gas/liquid interfaces. We augment the standard two-component Euler system by the pressure evolution equation. The extended (degenerate) system offers two alternative ways to update the pressure field: (i) using the conserved variables via the EOS or (ii) using the pressure evolution equations. Numerically, the two procedures are equivalent to within numerical truncation error. Near flow discontinuities, however, they will give different answers. The former is a standard conservative solution update, which is good everywhere except possibly at material fronts where it might generate oscillations. The latter is nonstandard and nonconservative but, provided it is averaged in a thermodynamically consistent manner, becomes *exact* at interfaces and automatically maintains pressure equilibrium between the fluid components. We present a hybrid scheme that switches between the two pressure update procedures. Broadly speaking, the EOS is used either to update the pressure field from the total energy equation (conservative) or to update the total energy field from the pressure equation (nonconservative), depending on whether the grid cell is away from/near the material front. The resulting scheme conserves perfectly the total mass and momentum. The total energy is conserved everywhere except across a very small number of grid interfaces, namely those that lie within the material interface layer. In miscible multifluid models this may amount to as few as four to five cell interfaces. In immiscible models it may amount to only *one* (!), but is enough to prevent the pressure fluctuations from arising, thus preventing the oscillations in the rest of the flow variables which follow. Relative conservation errors in total energy are *negligible* (at less than 0.1% for reasonably fine grids) and decrease under mesh refinement. Furthermore, the errors seem not to be sensitive to the strengths of the shocks that are involved. The numerical results clearly demonstrate that the hybrid method is suitable for computing gas dynamics involving *very* strong shocks ($M_s \geq 100$) and in that respect constitutes a major improvement over the scheme in [11, 12]. Using the pressure evolution equation in this manner may be interpreted as imposing a thermodynamically consistent boundary condition on the moving material interface.

2. The equations. Consider the Euler system for two-component fluids, where ρ, u, p, and E are the density, velocity, pressure, and total energy of the fluid mixture:

$$\rho_t + (\rho u)_x = 0, \tag{1a}$$

$$(\rho u)_t + (\rho u^2 + p)_x = 0, \tag{1b}$$

$$E_t + (u(E + p))_x = 0, \tag{1c}$$

$$(\rho\psi)_t + (\rho\psi u)_x = 0, \tag{1d}$$

with the EOS for ideal gases

$$p = (\gamma(\psi) - 1)\left(E - \frac{1}{2}\rho u^2\right). \tag{2}$$

In the above equation, ψ represents a marker variable whose role is to identify the fluid composition. Various quantities can serve that purpose: ψ can represent the mass fraction of one of the species [13, 14, 12], in which case equation (1d) expresses species conservation. The resulting system conserves not only the total mass of the mixture but also the mass of the individual components. Alternatively, fluid state variables propagate with the fluid flow and obey an evolutionary equation of the form (1d). Such variables may also serve as marker variables (e.g., the specific heat ratio γ [25] or any function of it [2], or the heat release constant Q in chemically reactive flows [5]), in which case equation (1d) expresses passive advection of the state variable with the fluid velocity. These formulations conserve the total mass but may not strictly conserve the mass of the individual components. Another possibility is to take ψ to be a level-set function which, for example, measures the distance of a fluid particle from the material interface. The evolution of ψ in this case also obeys (1d) [18]. Note that although this choice has a front-tracking flavour, the overall algorithm remains a front-capturing algorithm and thus avoids the complexities associated with front tracking.

$\gamma = \gamma(\psi)$ is the effective specific heat ratio of the fluid mixture and depends naturally on the fluid composition. The specific functional form of $\gamma(\psi)$ depends on the assumptions of the model. If ψ denotes the mass fraction of one fluid component, then assuming pressure and thermal equilibrium yields an average γ based on specific heat constants [1, 13, 14]

$$\gamma(\psi) = \frac{\psi C_{v_1}\gamma_1 + (1-\psi)C_{v_2}\gamma_2}{\psi C_{v_1} + (1-\psi)C_{v_2}}. \tag{2a}$$

Assuming isentropic compression, the effective γ for a mixture of two fluid components in pressure equilibrium is an average based on specific volumes [6]:

$$\frac{1}{\gamma} = \frac{V}{\gamma_1} + \frac{1-V}{\gamma_2}, \tag{2b}$$

where V bears a simple relation to the level-set function $V = 1/(|\psi_l/\psi_r| + 1)$.

Note that the Euler model (1) does not account for mixing processes. Unless the fluid components are premixed, the only mixing that may occur is numerical mixing due to numerical diffusion induced by front-capturing schemes. The formulas for effective thermodynamics should thus be interpreted in that context. These formulas are more meaningful (probably also more critical) in the viscous case where genuine mixing takes place. Note further that exact solutions to (1) do not depend on the specific heat constants, hence neither should the numerical solution. The extent to which this happens in practice may serve to indicate the appropriateness of the formula for the effective thermodynamics.

We now augment system (1) by the pressure evolution equation. This equation is obtained by differentiating the EOS, which for ideal gases gives

$$p_t + up_x + \gamma p u_x = 0. \tag{1e}$$

We observe that if the fluid components are in pressure equilibrium, both p and u are constant (continuous) across the interface. If p is evolved using (1e), pressure remains constant (continuous) and equilibrium between fluid components is automatically preserved.

The augmented system (1a)–(1e) is, of course, degenerate and will be analyzed below. Here, we first note that the system offers two alternative ways to compute the pressure: (a) using the conserved variables (1a)–(1d) and the EOS (2) or (b) using the pressure evolution equation (1e). Numerically, the two procedures are equivalent to within numerical truncation error. Near flow discontinuities, however, they will generally give different answers and we can choose which answer we care to believe. The former is a standard conservative update which is suitable everywhere except possibly near material interfaces where pressure fluctuations may occur due to smearing of the interface. The latter is a nonconservative update, but it becomes *exact* near material fronts and automatically maintains pressure equilibrium. The algorithm we propose involves switching between the two update schemes for the pressure field, depending on whether the grid cell is near/away from a material interface. The switching strategy depends on the precise definition of the fluid marker variable ψ. Two simple switching strategies are discussed below which have proved effective.

The augmented system in matrix quasilinear form is

$$\begin{pmatrix} \rho \\ \rho u \\ E \\ \rho\psi \\ p \end{pmatrix}_t + \begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ -u^2 & 2u & 0 & 0 & 1 \\ -uH & H & u & 0 & u \\ -u\psi & \psi & 0 & u & 0 \\ -ua^2 & a^2 & 0 & 0 & u \end{pmatrix} \begin{pmatrix} \rho \\ \rho u \\ E \\ \rho\psi \\ p \end{pmatrix}_x = 0, \tag{3}$$

where we use $a^2 = \sqrt{\gamma p/\rho}$ to denote the speed of sound and $H = \frac{a^2}{\gamma-1} + \frac{1}{2}u^2$ to denote the specific enthalpy. The characteristic polynomial of the matrix is

$$(\lambda - u)^3((\lambda - u)^2 - a^2) = 0,$$

revealing that the augmented system is hyperbolic, with a *triple* degeneracy in the particle field. The matrix of eigenvalues is

$$\Lambda = \operatorname{diag}(u - a,\ u,\ u,\ u,\ u + a) \tag{4}$$

and the corresponding complete set of eigenvectors is

$$\mathbf{r}_1 = \begin{pmatrix} 1 \\ u - a \\ H - ua \\ \psi \\ a^2 \end{pmatrix},\ \mathbf{r}_2 = \begin{pmatrix} 1 \\ u \\ \frac{1}{2}u^2 \\ \psi \\ 0 \end{pmatrix},\ \mathbf{r}_3 = \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{pmatrix},\ \mathbf{r}_4 = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 0 \end{pmatrix},\ \mathbf{r}_5 = \begin{pmatrix} 1 \\ u + a \\ H + ua \\ \psi \\ a^2 \end{pmatrix}. \tag{5}$$

Eigenvectors are defined to within a constant, and for consistency of physical dimensions the nonzero entry in $\mathbf{r}_3$ should have the dimensions of (velocity)^2. We leave this point for a moment and will return to it later. The eigenvectors $\{\mathbf{r}_k\}_{k=1}^5$ are linearly independent, and so a small change to the solution vector $\mathbf{W} = (\rho,\ \rho u,\ E,\ \rho\psi,\ p)^T$ has a unique representation as

$$\delta\mathbf{W} = \sum_{k=1}^{5} \alpha_k \mathbf{r}_k \tag{6}$$

for some wave strengths $\{\alpha_k\}_{k=1}^5$. The first, second, and fifth components of (6) involve only α_1, α_2, and α_5,

$$\alpha_1 + \alpha_2 + \alpha_5 = \delta\rho,$$

$$(\alpha_1 + \alpha_2 + \alpha_5)u + (-\alpha_1 + \alpha_5)a = \delta(\rho u),$$

$$(\alpha_1 + \alpha_5)a^2 = \delta p,$$

which, after using standard differential relations, have the recognizable solution

$$\begin{aligned} \alpha_1 &= \frac{\delta p - \rho a \delta u}{2a^2}, \\ \alpha_2 &= \frac{a^2 \delta\rho - \delta p}{a^2}, \\ \alpha_5 &= \frac{\delta p + \rho a \delta u}{2a^2}. \end{aligned} \tag{7a}$$

The fourth component in (6) can now be solved for α_4:

$$\alpha_4 = \rho\delta\psi. \tag{7b}$$

The fifth component in (6) gives

$$\alpha_3 = \delta E - \left(\frac{\delta p}{\gamma - 1} + \rho u \delta u + \frac{1}{2}u^2 \delta\rho\right).$$

Since pressure and energy changes are related through the EOS, we use (2) to simplify further, i.e.,

$$\tag{7c}\begin{aligned}\alpha_3 &= p\delta\left(\frac{1}{\gamma-1}\right)\\ &= -\frac{p}{(\gamma-1)^2}\gamma'(\psi)\delta\psi\\ &= -\frac{X}{\gamma-1}\rho\delta\psi\\ &= -\frac{X}{\gamma-1}\alpha_4,\end{aligned}$$

where we borrowed the notation $X = \frac{p}{(\gamma-1)\rho}\gamma'(\psi)$ from [14, 18, 12]. The degeneracy of the system is thus reflected in the fact that the third and fourth eigenfields can be combined into a single eigenfield

$$\mathbf{r}_{3,4} = \begin{pmatrix} 0 \\ 0 \\ -\dfrac{X}{\gamma-1} \\ 1 \\ 0 \end{pmatrix}, \qquad \alpha_{3,4} = \rho\delta\psi.$$

3. Switching strategy. Adopting a strategy to switch between the two procedures of updating the pressure field depends on the precise definition of the marker variable ψ. We have experimented with two flow models: (i) an immiscible level-set model [18] and (ii) a miscible mass-fraction model [13, 14, 27]. The models in [1, 25] are closely related. Both models take the form (1a)–(1d), with different definitions for the variable ψ. They have been thoroughly analyzed in [12] with respect to their properties for computing propagating interfaces and are briefly discussed below. The reader is referred to [13, 14, 18] for more details. We have extended these models by (1e) in the fashion described in the previous section and have found the following very simple switching strategies to be effective.

3.1. Level-set model. This is essentially the two-component immiscible Euler model proposed in [18]. In this model, the marker variable ψ is a level-set function. It is initialized so that at time $t = 0$ it is positive on one side of the interface (component 1) and negative on the other side (component 2) and is zero at the material interface separating the two components (as, for example, would be a function measuring the distance of a fluid particle from the interface). Since material interfaces propagate with the fluid velocity, it follows from equation (1d) that at any later time $t > 0$, the level set $\psi(x,t) = 0$ (which is a single point in this one-dimensional case) locates the material interface, and the condition $\psi < 0$ or $\psi > 0$ identifies which fluid component is being solved for. The ratio of specific heats, $\gamma(\psi)$, is then determined according to

$$\tag{8}\gamma(\psi) = \begin{cases}\gamma_1, & \psi > 0,\\ \gamma_2, & \psi < 0,\end{cases}$$

and the EOS (2) switches discontinuously across the interface. On a discrete mesh, one seeks the cell interface $(j + \frac{1}{2})$ satisfying

$$\psi_j \cdot \psi_{j+1} < 0 \,, \tag{9}$$

which indicates that the material interface is located somewhere between the grid point j and the grid point $j + 1$. Across this one cell interface, the pressure field is evolved by using the pressure evolution equation (1e). Everywhere else, (1e) is ignored and the pressure field is updated using the EOS (2) with the appropriate value of γ, depending on whether $\psi < 0$ or $\psi > 0$.

A slight variation of the above procedure gives a model which is consistent with the specific volume averaging for the effective γ (2b), where ψ is used to obtain the effective γ in the *one* cell occupied by both fluid components:

$$\frac{1}{\gamma(\psi)} = \frac{V}{\gamma_1} + \frac{1-V}{\gamma_2}, \quad V = \frac{1}{|\psi_j/\psi_{j+1}| + 1}.$$

3.2. Mass-fraction model. This model was used in [12, 13, 14, 27] (also [1, 2, 25]). The function ψ is the mass fraction of one gas component, and equation (1d) expresses species conservation. $\psi = 1$ or $\psi = 0$ indicate the presence of only one fluid component while intermediate values $0 < \psi < 1$ indicate a mixture. The gas components are assumed to be in thermal equilibrium. Using Dalton's law of partial pressures, the effective $\gamma(\psi)$ of the fluid mixture is

$$\gamma(\psi) = \frac{\psi C_{v_1}\gamma_1 + (1-\psi)C_{v_2}\gamma_2}{\psi C_{v_1} + (1-\psi)C_{v_2}}, \tag{10}$$

where C_{v_1} and C_{v_2} are the specific heat coefficients at constant volume for the respective fluid components. In this model, the interface layer is defined by the condition $0 < \psi < 1$ or, alternatively, by the condition $|\psi'| > 0$. On a discrete mesh, one identifies the cell interfaces where

$$|\psi_{j+1} - \psi_j| > 0. \tag{11}$$

Across the cell interfaces where the above condition is satisfied, the pressure field is evolved using the pressure evolution equation (1e). Everywhere else, the EOS (2)+(10) is used. Note that in the latter situations ψ is very close to either 0 or 1, and $\gamma(\psi)$ automatically takes the appropriate value of either γ_1 or γ_2. In practice, one uses the condition $|\psi_{j+1} - \psi_j| > \epsilon$, where $\epsilon > 0$ is a small number (typically between 0.01 and 0.05), to ensure that only genuine interface layers are identified.

4. Numerical results. The hybrid approach described above is independent of the details of the numerical implementation. Thus, it may provide a general framework within which to extend one's favourite scheme to multicomponent flow computations and yield a scheme which is capable of producing clean oscillation-free interfaces as well as handling complicated interactions involving *very* strong shocks.

4.1. The scheme. We have implemented a Roe-type second-order upwind scheme [23, 14, 18]. Using the *fluctuation-and-signal* approach [24], the scheme lends itself to a convenient and uniform treatment of both the conservative (1a)–(1d) and nonconservative (1e) parts of the system. When restricted to only the conservative part, the scheme has an equivalent flux formulation. There is, of course, no flux formulation for the solution of the pressure evolution equation (1e), since pressure is not a conserved quantity. As with the standard Roe method, the system is locally linearized about an average state. Flow gradients are projected onto the linearized eigenvectors

$$\mathbf{r}_1 = \begin{pmatrix} 1 \\ \tilde{u} - \tilde{a} \\ \tilde{H} - \tilde{u}\tilde{a} \\ \tilde{\psi} \\ \tilde{a}^2 \end{pmatrix}, \quad \mathbf{r}_2 = \begin{pmatrix} 1 \\ \tilde{u} \\ \frac{1}{2}\tilde{u}^2 \\ \tilde{\psi} \\ 0 \end{pmatrix}, \quad \mathbf{r}_3 = \begin{pmatrix} 0 \\ 0 \\ -\dfrac{\tilde{X}}{\tilde{\gamma} - 1} \\ 1 \\ 0 \end{pmatrix}, \quad \mathbf{r}_4 = \begin{pmatrix} 1 \\ \tilde{u} + \tilde{a} \\ \tilde{H} + \tilde{u}\tilde{a} \\ \tilde{\psi} \\ \tilde{a}^2 \end{pmatrix} \tag{12}$$

with wave strengths

$$\begin{aligned} \alpha_1 &= \frac{\Delta p - \tilde{\rho}\tilde{a}\Delta u}{2\tilde{a}^2}, \\ \alpha_2 &= \frac{\tilde{a}^2\Delta\rho - \Delta p}{\tilde{a}^2}, \\ \alpha_3 &= \tilde{\rho}\Delta\psi, \\ \alpha_4 &= \frac{\Delta p + \tilde{\rho}\tilde{a}\Delta u}{2\tilde{a}^2} \end{aligned} \tag{13}$$

and are propagated by a limited Lax–Wendroff marching step [26] with linearized wave speeds

$$\begin{aligned} \lambda_1 &= \tilde{u} - \tilde{a}, \\ \lambda_2 &= \tilde{u}, \\ \lambda_3 &= \tilde{u}, \\ \lambda_4 &= \tilde{u} + \tilde{a}. \end{aligned} \tag{14}$$

Note that due to the degeneracy of the system, we have in this case *four* eigenfields, each of which is a *five*-component vector.

The Roe averages satisfy the property $\tilde{A}(\mathbf{W}_L - \mathbf{W}_R) = \mathbf{F}_L - \mathbf{F}_R$ for any two states $\mathbf{W}_L$ and $\mathbf{W}_R$ and the corresponding flux functions $\mathbf{F}_L$ and $\mathbf{F}_R$. For the two models described above, the average values are calculated from the conservative part of the governing equations (1a)–(1d). This guarantees that away from the material interface the method reduces to the standard conservative Roe scheme [23, 24]. The averages are given by

$$\begin{aligned} \tilde{\rho} &= \sqrt{\rho_L \rho_R}, \\ \tilde{u} &= \frac{\sqrt{\rho_L}u_L + \sqrt{\rho_R}u_R}{\sqrt{\rho_L} + \sqrt{\rho_R}}, \\ \tilde{H} &= \frac{\sqrt{\rho_L}H_L + \sqrt{\rho_R}H_R}{\sqrt{\rho_L} + \sqrt{\rho_R}}, \\ \tilde{\psi} &= \frac{\sqrt{\rho_L}\psi_L + \sqrt{\rho_R}\psi_R}{\sqrt{\rho_L} + \sqrt{\rho_R}}, \\ \tilde{a}^2 &= (\gamma(\tilde{\psi}) - 1)\left(\tilde{H} - \frac{1}{2}\tilde{u}^2\right). \end{aligned} \tag{15a}$$

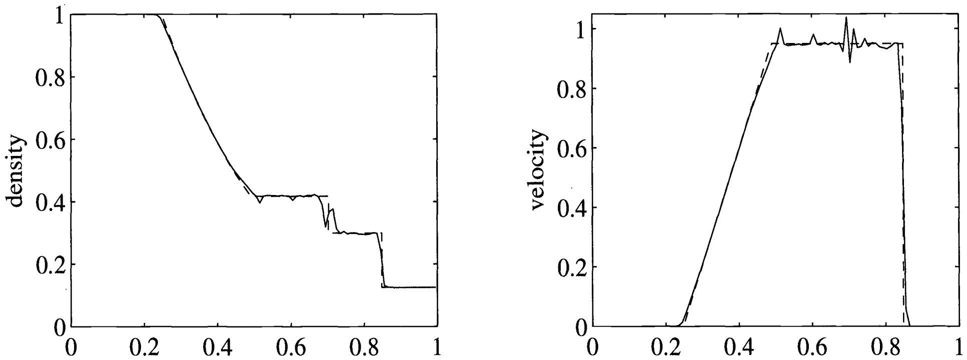

FIG. 1a. *Two-component shock-tube problem computed by the level-set model in* [18]. *Computed* (*solid*) *and exact* (*dash*) *solutions.*

For the level-set model (see [18] for details),

$$\tilde{X} = \frac{\Delta p - (\gamma(\tilde{\psi}) - 1)\Delta \frac{p}{\gamma - 1}}{\tilde{\rho}\Delta\psi}. \tag{15b}$$

For the mass-fraction model (see [13, 14] for details),

$$\begin{aligned} \tilde{X} &= \frac{C_{v_1}C_{v_2}}{\tilde{C}_v}\tilde{e}(\gamma_1 - \gamma_2), \\ \tilde{e} &= \frac{\sqrt{\rho_L}e_L + \sqrt{\rho_R}e_R}{\sqrt{\rho_L} + \sqrt{\rho_R}}, \\ \tilde{C}_v &= C_{v_1}\tilde{\psi} + C_{v_2}(1 - \tilde{\psi}), \end{aligned} \tag{15c}$$

where $e = \frac{p}{\rho(\gamma-1)}$ is the internal energy and $\gamma(\tilde{\psi})$ is given by equation (10). The pressure field is updated using the EOS (2), while ignoring the fifth component of the solution vector $\mathbf{W}$ everywhere in the flow field except across cell interfaces where either condition (9) or (11) holds. Across those cell interfaces, the pressure field is evolved via the fifth component of the solution algorithm by using the same limited Lax–Wendroff marching scheme with the same conservative linearization (15). The amount of extra work required for the nonstandard update of the pressure field is *negligible* since all the information needed (sound speed, wave strengths, etc.) is already available. Once the new pressure field is calculated, the new energy field E is computed using (2). This step is not strictly conservative (work is currently in progress to modify this step so that it is conservative).

4.2. The experiments.

Test A. The initial data correspond to a two-component shock-tube problem, also used in [12, 13, 27]:

$$\mathbf{W}_L = (\rho_L,\ u_L,\ p_L,\ \gamma_L) = (1.0,\quad 0.0,\ 1.0,\ 1.4),$$

$$\mathbf{W}_R = (\rho_R,\ u_R,\ p_R,\ \gamma_R) = (0.125,\ 0.0,\ 0.1,\ 1.2).$$

Figure 1 shows solutions based on the conservative flow models in [13, 14, 18] and by the present hybrid scheme. In these computations we used 200 grid points and a Courant–Friedrichs–Lewy (CFL) number of 0.9. For the second-order calculations we used the superbee flux limiter [26]. Strong oscillations plague the solution obtained by the level-set algorithm of [18] near the material interface (Figure 1a). These oscillations are visible in all

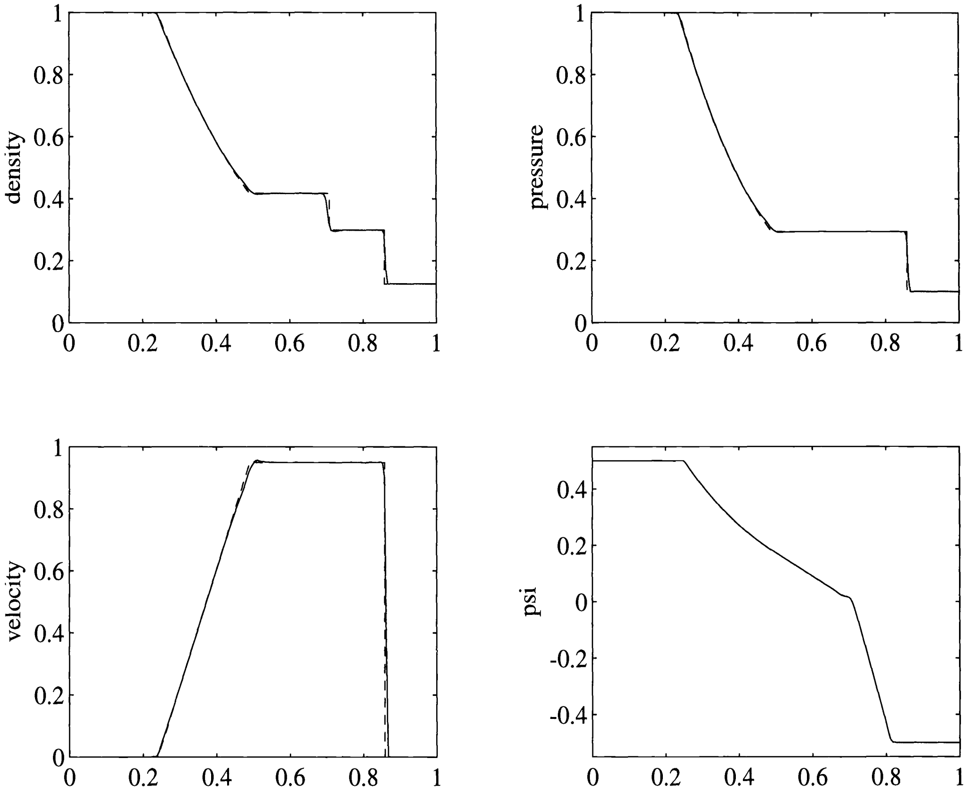

FIG. 1b. *Same as Figure* 1a, *computed by the hybrid level-set scheme* (12)–(14), (15a), (15b). *Nonconservative solution update across one cell interface. Computed* (*solid*) *and exact* (*dash*) *solutions.*

flow variables. (Interestingly, the only nonoscillatory variable is the fluid marker function ψ which is obtained by computing at each grid point $(\rho\psi)_j/(\rho)_j$, both of which are apparently oscillating in phase, see [12].)

The oscillations are completely eliminated from the solution by switching to a nonconservative pressure update at the material interface using the pressure evolution equation (1e) (Figure 1b). This pressure update is used across only *one* (!) cell interface, but is sufficient to prevent the generation of pressure fluctuations at the interface, thereby preventing the subsequent oscillations in the other flow variables. Comparison between the computed and the exact solution (also included in the figure) shows excellent agreement, although the scheme is not strictly conservative. With this hybrid algorithm, the total mass and momentum are perfectly conserved but the total energy is not. For the calculation shown in Figure 1b, the relative error in total energy is 0.242% on a 200-point mesh. Repeating the same test with 800 mesh points yields relative conservation error of 0.066% in the total energy.

The solution obtained by the mass-fraction model of [13, 14] exhibits a nonphysical velocity step across the material front and a density undershoot (hence, a temperature overshoot). Both are present already in a first-order computation (velocity profile, Figure 1c), with the density undershoot becoming more pronounced in a second-order computation (density profile, Figure 1c); see also [1, 13, 12]. Interestingly, the computed pressure field itself (not shown) appears to be well behaved. The computational inaccuracies are most apparent in the velocity and density profiles. Nonetheless, the cause for this false behaviour is the initial erroneous pressure fluctuations that disturb the pressure equilibrium. Indeed, taking measures

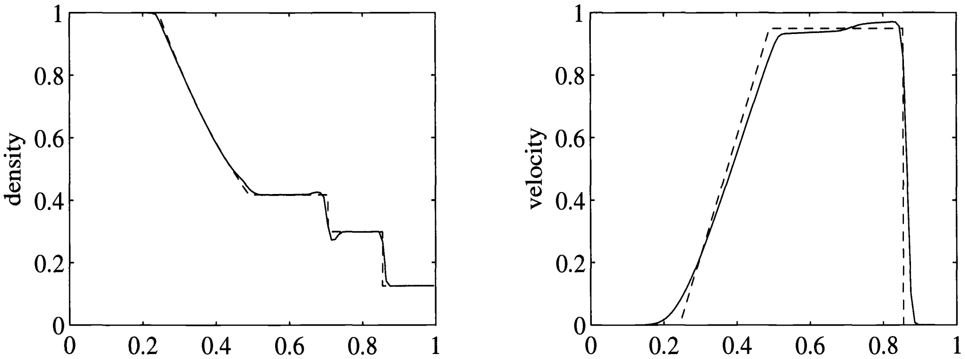

FIG. 1c. *Two-component shock-tube problem computed by the mass-fraction model in* [13, 14]. *Computed* (*solid*) *and exact* (*dash*) *solutions.*

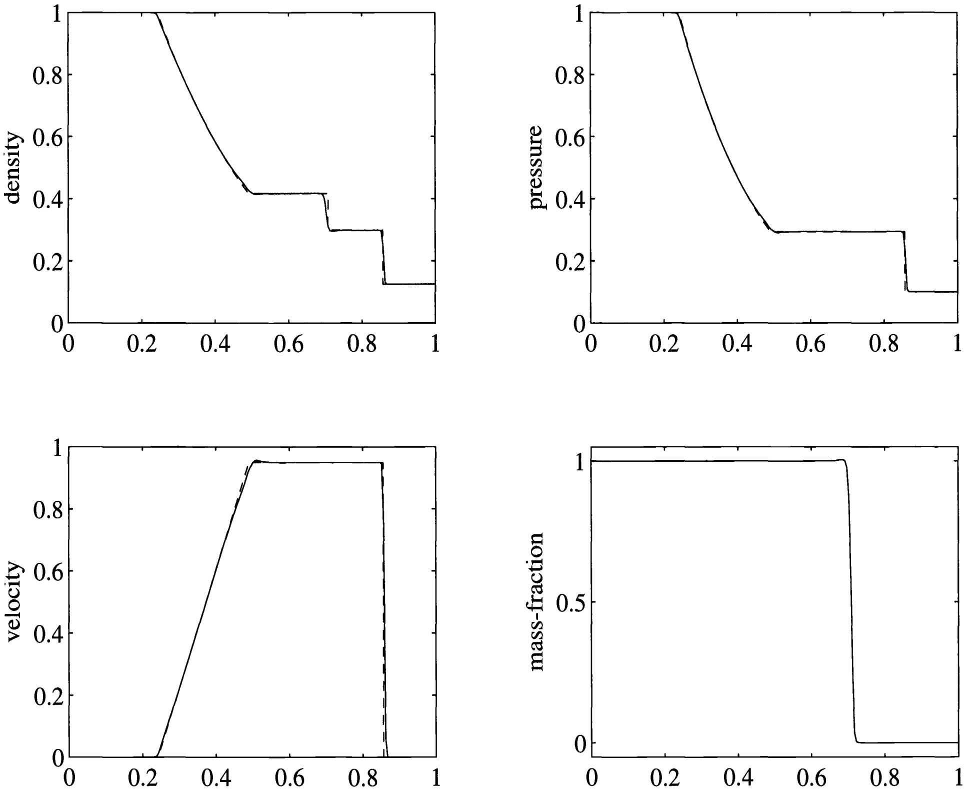

FIG. 1d. *Same as Figure* 1c, *computed by the hybrid mass-fraction scheme* (12)–(14), (15a), (15c). *Nonconservative solution update across four to five cell interfaces. Computed* (*solid*) *and exact* (*dash*) *solutions.*

to prevent the pressure fluctuations from arising completely removes the false behaviour from the density and velocity fields (Figure 1d). Using (1e) only at cell interfaces where condition (11) is satisfied (approximately four to five cell interfaces with $\epsilon = 0.05$) is sufficient to prevent the generation of pressure fluctuations and the computational inaccuracies in the other flow variables which follow (Figure 1d). The computed solution shows excellent agreement with the exact solution (also included in the figures) although the computation is not strictly

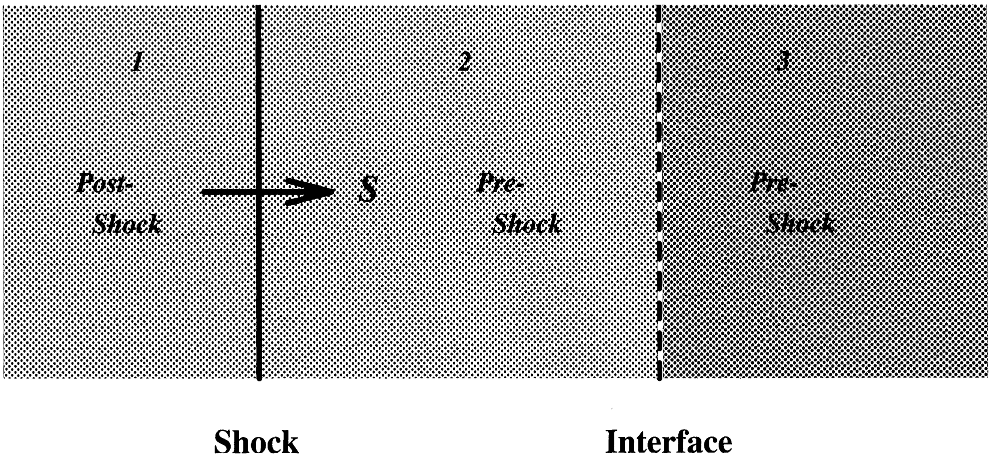

FIG. 2. *Shock wave impinging on a material interface.*

conservative. Here again, the total mass (also the mass of the individual species) and momentum are perfectly conserved, and relative conservation error in the total energy is negligible at 0.054% for the calculation shown in Figure 1d. If the same calculation is repeated with 800 grid points, the relative conservation error decreases further to 0.026%.

Test B. The initial data correspond to a weak shock wave in air ($M_s = 1.1952$), refracting at a helium material interface (see Figure 2):

$$\mathbf{W}_1 = (\rho_1,\ u_1,\ p_1,\ \gamma_1) = (1.3333,\ 0.3535,\ 1.5,\ 1.4), \quad \text{air, postshock;}$$

$$\mathbf{W}_2 = (\rho_2,\ u_2,\ p_2,\ \gamma_2) = (1.0,\quad 0.0,\ 1.0,\ 1.4), \quad \text{air, preshock;}$$

$$\mathbf{W}_3 = (\rho_3,\ u_3,\ p_3,\ \gamma_3) = (0.1379,\ 0.0,\ 1.0,\ 1.67), \quad \text{helium, preshock.}$$

In shock refraction problems like this, upon being hit by the incident shock wave, the interface is set into motion. A shock wave is transmitted across the interface into the receiving gas, which travels at a higher or lower speed than that of the incident shock depending on the respective speed of sound. In geometrical acoustics, the ratio of incident/transmitted shock speeds is often called the *index of refraction.* Depending on the so-called acoustic impedance of the receiving gas, the reflected wave is either a shock wave or an expansion [8, 10]. While playing a less apparent role in one-dimensional shock refraction problems, both the index of refraction and the acoustic impedance are crucial parameters in two-dimensional shock refraction at oblique/curved interfaces, dictating the sign and amount of vorticity generation at the interface, hence the characteristics of global dynamics [21] and the appearance of regular and irregular shock refraction patterns (see [10, 21] and references cited therein). In such problems, the material interface is also a physically unstable shear interface, and any erroneous numerical behaviour may trigger completely false dynamics. In this air/helium case, the reflected wave is a very narrow rarefaction. The transmitted shock wave is very weak. As the sound speed in helium is higher than that in air, the weak transmitted shock wave travels faster than the incident shock.

Figure 3a shows the computed solution by the level-set model. As soon as the incident shock wave hits the interface and sets it into motion, strong oscillations appear in the solution. Once generated, the oscillations disperse and appear to follow behind the transmitted shock front. As in the previous shock-tube test, switching to a pressure update based on the pressure evolution equation (1e) across only one cell interface prevents the generation of the initial

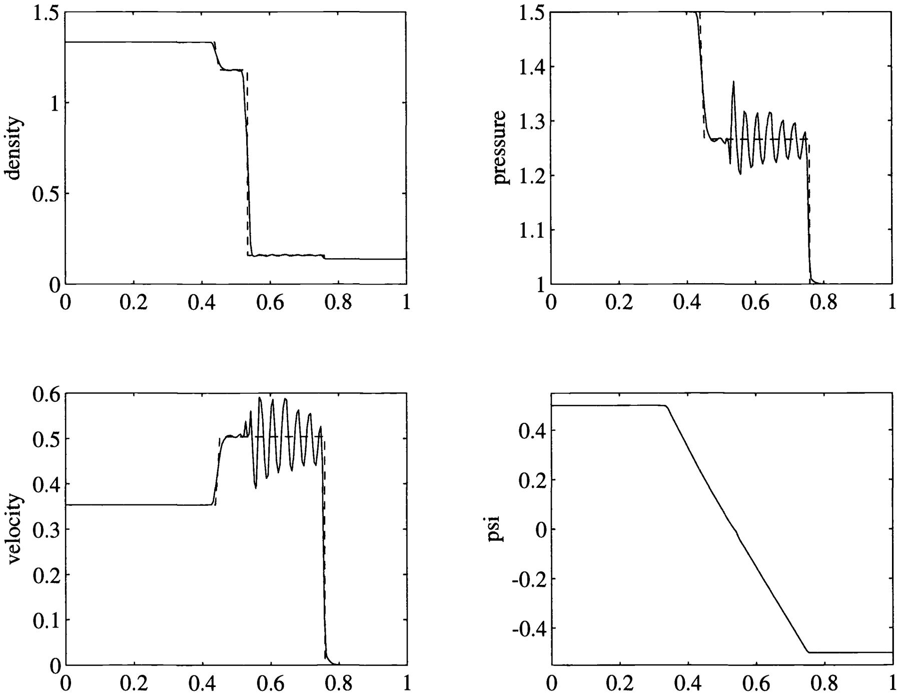

FIG. 3a. *Shock wave in air, $M_s = 1.1952$, refracting at a helium interface computed by the level-set model in* [18]. *Computed* (*solid*) *and exact* (*dash*) *solutions.*

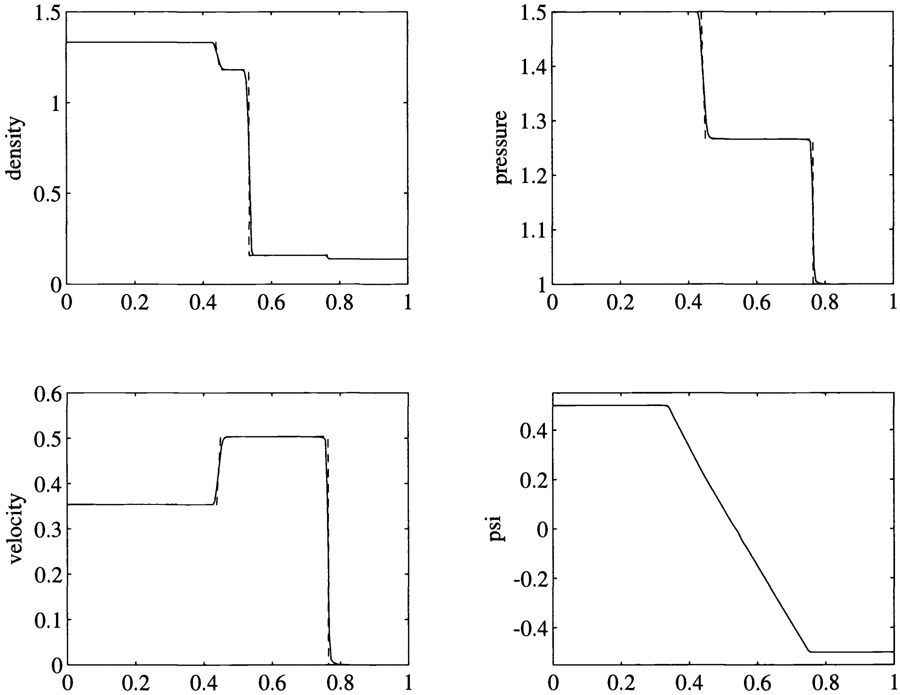

FIG. 3b. *Same as Figure* 3a, *computed by the hybrid level-set scheme* (12)–(14), (15a), (15b). *Nonconservative solution update across one cell interface. Computed* (*solid*) *and exact* (*dash*) *solutions.*

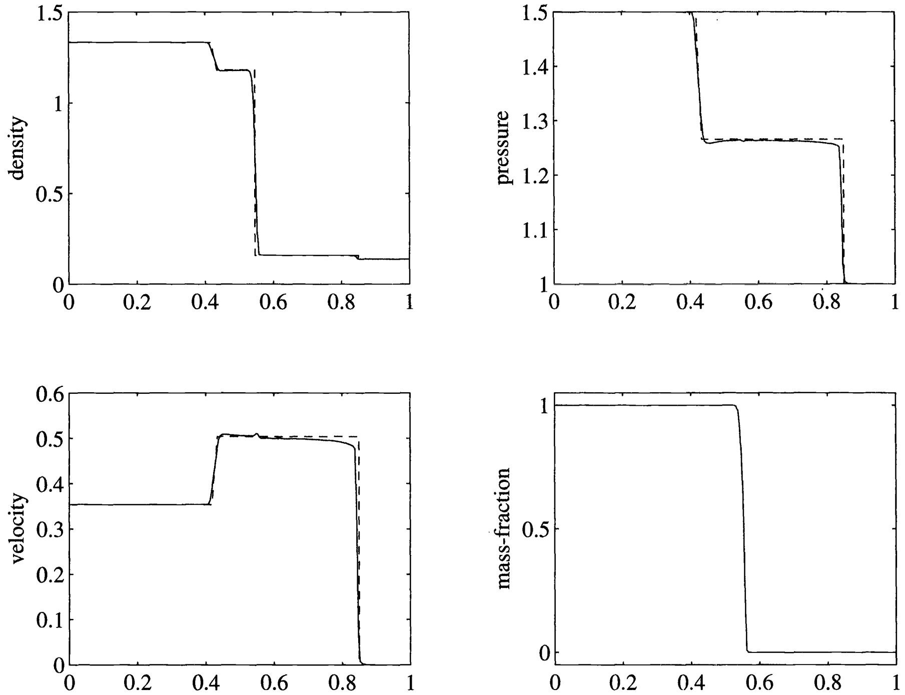

FIG. 3c. *Shock wave in air, $M_s = 1.1952$, refracting at a helium interface computed by the mass-fraction model in* [13, 14]. *Computed (solid) and exact (dash) solutions.*

pressure fluctuation and is sufficient to completely eliminate the oscillations from the solution (Figure 3b). The agreement between the computed and exact solutions is excellent.

The computed solution obtained by the mass-fraction model (Figure 3c) also exhibits a nonphysical behaviour. The velocity profile fails to maintain uniform velocity in the region between the transmitted shock and the tail of the reflected fan. The pressure profiles are also visibly nonuniform. Updating the pressure field via equation (1e) across as few as four to five cell interfaces is sufficient to eliminate these problems (Figure 3d). The agreement between the computed and exact solutions is again excellent.

Test C. We present another example of a weak shock wave in air ($M_s = 1.1952$) refracting at a material interface, with in this case a heavy gas refrigerant R22 (commercially known as freon). The initial data are

$$\mathbf{W}_1 = (\rho_1,\ u_1,\ p_1,\ \gamma_1) = (1.3333,\ 0.3535,\ 1.5,\ 1.4), \quad \text{air, postshock;}$$

$$\mathbf{W}_2 = (\rho_2,\ u_2,\ p_2,\ \gamma_2) = (1.0,\ \ 0.0,\ 1.0,\ 1.4), \quad \text{air, preshock;}$$

$$\mathbf{W}_3 = (\rho_3,\ u_3,\ p_3,\ \gamma_3) = (3.1538,\ 0.0,\ 1.0,\ 1.249), \quad \text{R22, preshock.}$$

The transmitted shock speed in R22 is lower than that of the incident shock wave in air, and the reflected wave is a weak shock. Results are shown for the level-set model (Figure 4a) and the hybrid level-set version (Figure 4b). The former solution is contaminated by strong oscillations. As in the previous tests, switching to a pressure update via (1e) across only one cell interface is sufficient to remove completely the oscillations from the computed level-set solution. The agreement between the computed and the exact solutions is excellent.

Test D. The data in this test correspond to a stronger shock in air ($M_s = 3.6055$) refracting on helium (Figure 5a) and R22 (Figure 5b) material interfaces, respectively. In both cases,

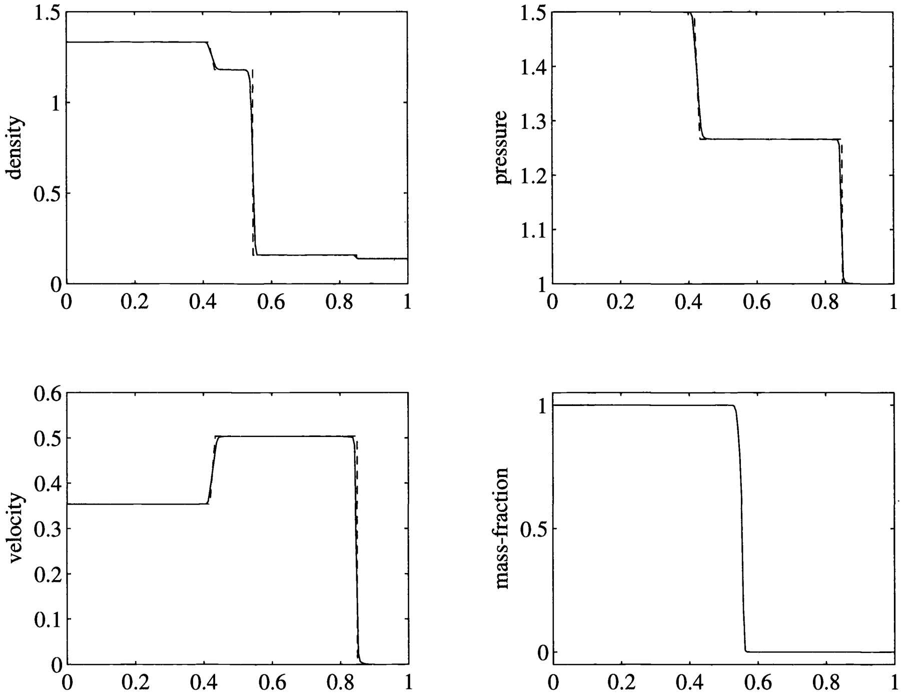

FIG. 3d. *Same as Figure* 3c, *computed by the hybrid mass-fraction scheme* (12)–(14), (15a), (15c). *Nonconservative solution update across four to five cell interfaces. Computed* (*solid*) *and exact* (*dash*) *solutions.*

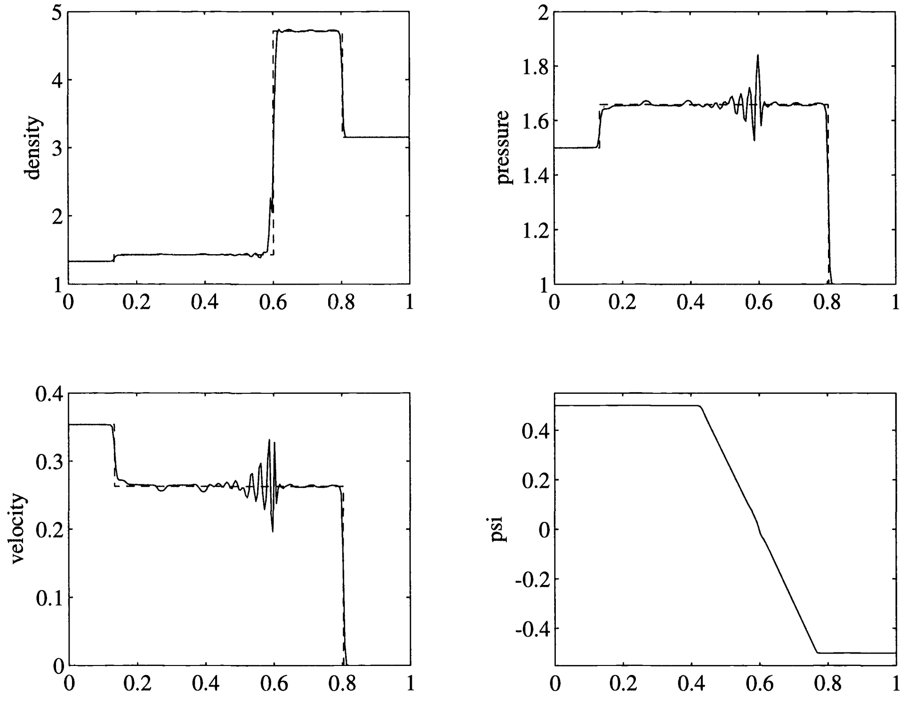

FIG. 4a. *Shock wave in air, M_s = 1.1952, refracting at an* R22 *interface computed by the level-set model in* [18]. *Computed* (*solid*) *and exact* (*dash*) *solutions.*

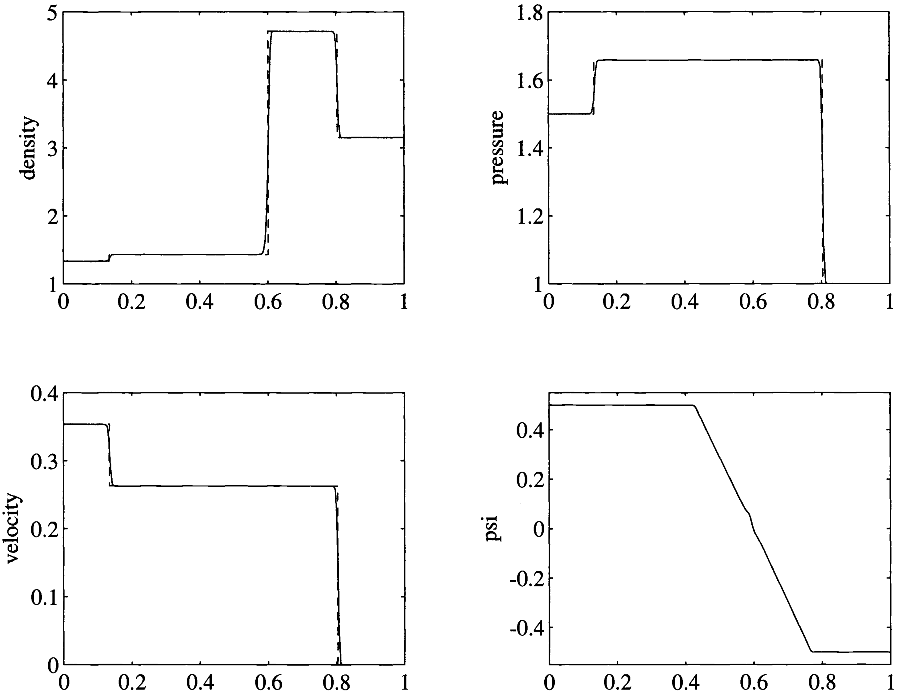

FIG. 4b. *Same as Figure* 4a, *computed by the hybrid level-set scheme* (12)–(14), (15a), (15b). *Nonconservative solution update across one cell interface. Computed* (*solid*) *and exact* (*dash*) *solutions.*

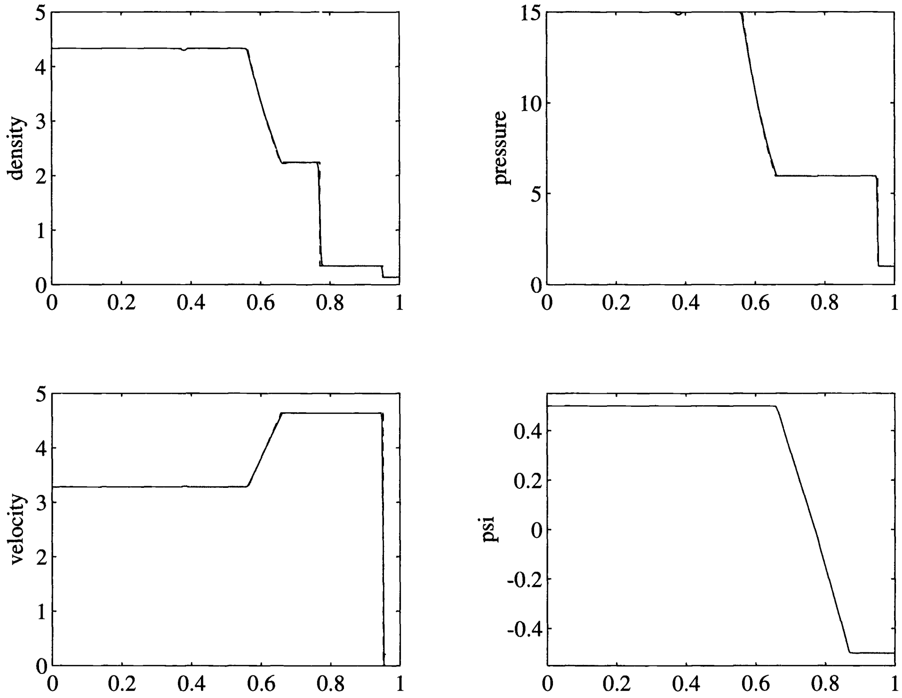

FIG. 5a. *Stronger shock wave in air,* $M_s = 3.6055$, *refracting at a helium interface computed by the hybrid level-set scheme* (12)–(14), (15a), (15b). *Computed* (*solid*) *and exact* (*dash*) *solutions.*

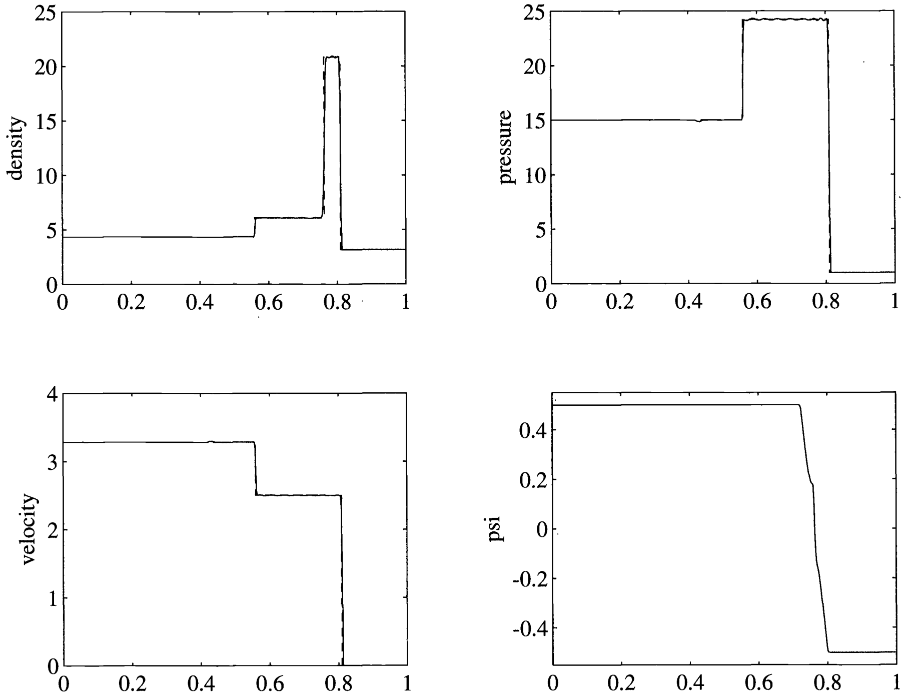

FIG. 5b. *Stronger shock wave in air, M_s = 3.6055, refracting at an* R22 *interface computed by the hybrid level-set scheme* (12)–(14), (15a), (15b). *Computed* (*solid*) *and exact* (*dash*) *solutions.*

due to the high velocity driving the incident shock, the entire flow field is supersonic and all the waves (including the reflected waves) are rightgoing. The incident shock as well as the transmitted and reflected waves are now stronger (compare with Figures 3 and 4). The aim in this test is to demonstrate the capability of the hybrid scheme to handle well interactions involving strong shocks.

Results with the hybrid level-set scheme are shown in Figure 5 for both a helium interface in which the refracted wave is a rarefaction, and for an R22 interface, in which the reflected wave is a shock. The preshock states for the air/helium case (Figure 5a) are the same as in Test B. The postshock state is

$$\mathbf{W}_1 = (\rho_1,\ u_1,\ p_1,\ \gamma_1) = (4.3333,\ 3.2817,\ 15.0,\ 1.4), \quad \text{air, postshock.}$$

The preshock states for the air/R22 case (Figure 5b) are the same as in Test C. The postshock state is the same as $\mathbf{W}_1$ above. The agreement between the computed and the exact solutions is excellent in both cases, and the relative conservation errors in total energy are negligible. For example, for the air/helium case the relative conservation error in total energy at time $T = 0.1169$ is 0.1301% with 400 grid points (0.0621% with 800 grid points). For the air/R22 case, the relative conservation error at time $T = 0.1637$ is 0.2249% with 400 grid points (0.1729% with 800 grid points). Table 1 summarizes a convergence study of the relative energy conservation errors for an $M_s = 9.2659$ shock wave in air impinging on a helium and an R22 interface, respectively (errors are measured against exact solutions). The errors are extremely small and decrease under mesh refinement at what appears to be a linear rate. These results clearly demonstrate that the present hybrid method is capable of handling well wave interactions involving strong shocks.

1600	0.021
air/R22	(final time $T = 6.41 \times 10^{-2}$)
400	0.084
800	0.048
1600	0.030

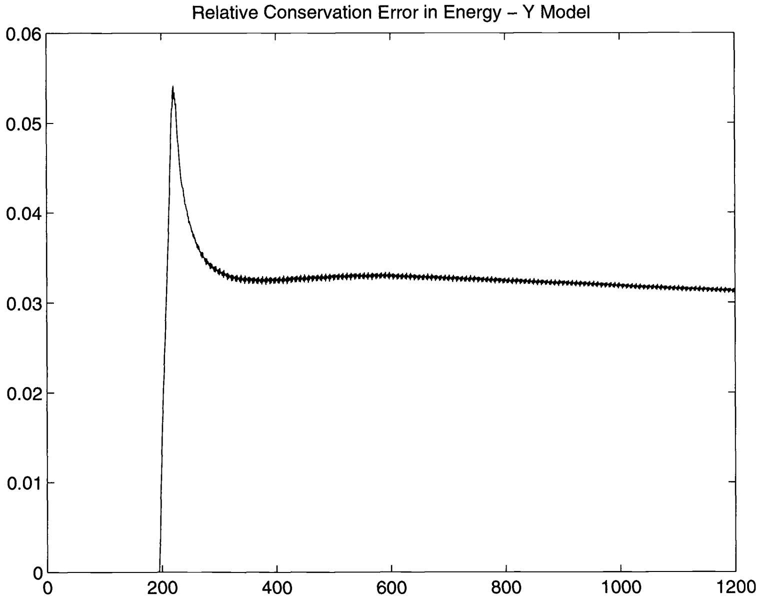

FIG. 6. *Relative conservation error in total energy as a function of number of time steps for a very strong shock wave in air, $M_s = 113.4$, refracting at a helium interface. Computed solution by the hybrid mass-fraction scheme* (12)–(14), (15a), (15c).

Test E. It is interesting to see where conservation error is generated and how it manifests itself. The data for the present test correspond to a very strong shock, $M_s = 113.4$, hitting an air/helium interface. Figure 6 shows relative conservation error in total energy as a function of the number of time steps. The error is obtained by comparing the results from a conservative and a hybrid computation:

$$100 * \frac{|(\sum E_j)_{\text{hybrid}} - (\sum E_j)_{\text{conservative}}|}{(\sum E_j)_{\text{conservative}}}.$$

From Figure 6 we observe that conservation error is generated only during wave interaction, namely, when the shock wave hits the interface. During the first couple hundred time steps, there is no conservation error. Error is then generated and reaches a peak value during the interaction, which then relaxes toward a constant value. No additional error is generated after the interaction is complete, which seems to indicate that waves propagate at the correct

TABLE 2

Relative conservation error in total energy as a function of number of time steps for a strong shock wave in air ($M_s = 113.4$) *impinging on a helium interface.*

No. of points	Relative error in %

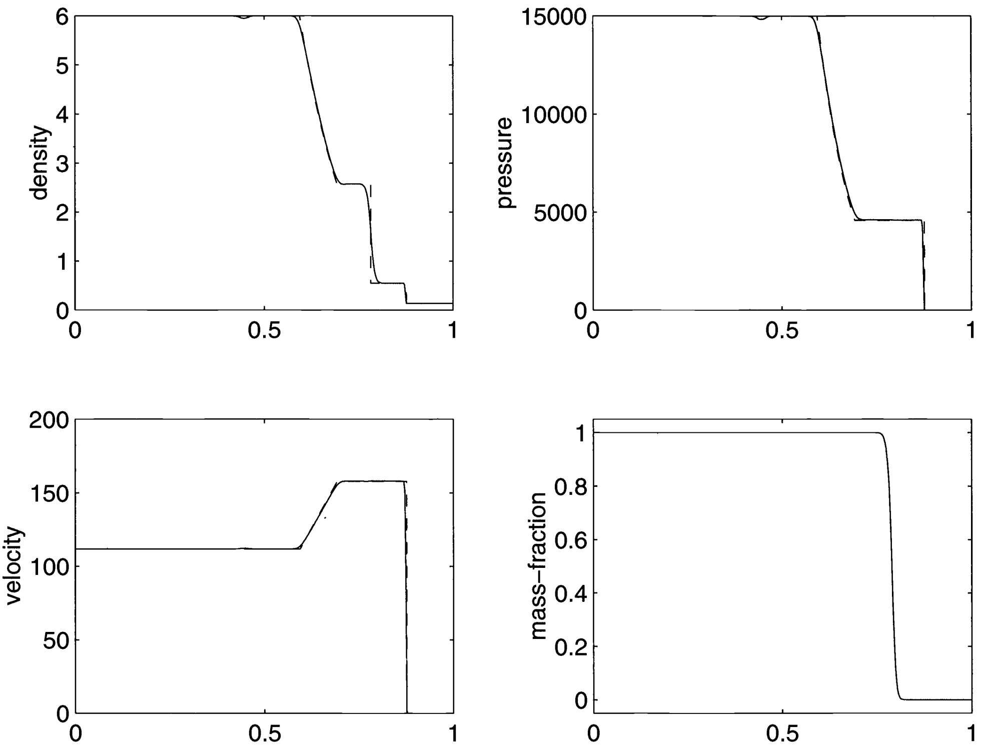

FIG. 7. *A very strong shock wave in air,* $M_s = 113.4$, *refracting at a helium interface computed by the hybrid mass-fraction scheme* (12)–(14), (15a), (15c). *Computed* (*solid*) *and exact* (*dash*) *solutions.*

speed. In one-dimensional setups, the generation of errors is a one-off event. In higher dimensions, for example, in shock-bubble interactions, errors may be provoked more commonly. In view of the smallness of the relative error, this issue does not seem to be a concern.

Table 2 gives relative errors in a sequence of runs with increasingly fine grids from which it is clear that (i) the solution seems to converge to the right place, (ii) convergence appears to be linear, and (iii) conservation error is *very* small and seems not to be sensitive to the strength of the shock involved. Actual results for this test are shown in Figure 7.

5. Conclusions. A hybrid approach has been presented for computing the dynamics of compressible multicomponent fluids based on augmenting the standard multicomponent gas dynamics equations by the pressure evolution equation. The extended system offers two choices for updating the pressure field: (i) a conservative update using the EOS (2) used throughout the flow field except near material interfaces where it may produce oscillations and (ii) a nonconservative update using the pressure evolution equation (1e) used near interfaces to ensure monotone solutions. A simple switching strategy between the two pressure update procedures has been presented (i) for an immiscible flow model based on a level-set formulation [18] and (ii) for a miscible flow model based on a mass-fraction formulation [1, 13, 14, 25, 27]. The resulting hybrid algorithm conserves the total mass and momentum of the system. The total energy is not perfectly conserved but relative conservation errors are *negligible* (of the order of a fraction of a percent). The hybrid strategy has proved to be very effective in computing shock-interface interactions involving shocks ranging from $M_s \approx 1.1$ to $M_s \approx 100$. Both the hybrid approach and the switching strategies are independent of the numerical implementation and may provide a convenient framework within which to extend one's favourite single-component scheme to multicomponents.

Acknowledgments. I would like to thank Mike Minion who read an earlier version of this manuscript and was more than happy to do to me what Alex Chorin had done to him. His comments were invaluable and are gratefully acknowledged. I would also like to thank Marsha Berger and Vinh Ton for their observant and constructive comments.

A PARALLEL IMPLEMENTATION OF THE *P*-VERSION OF THE FINITE ELEMENT METHOD*

YIMIN ZHU† AND I. NORMAN KATZ†

Abstract. An iterative method based on the textured decomposition (TD) is developed in order to solve the systems of linear equations arising in the p-version of the finite element method. The iteration is used to implement the p-version in parallel on an MIMD computer NCUBE/six. The objectives are twofold: to achieve high computational efficiency (that is, computational load should be balanced among the processors) and simultaneously to achieve rapid convergence.

A superelement, consisting of four adjacent rectangular finite elements, is constructed for two-dimensional problems. Based on the structural property of the shape functions, each superelement is partitioned into three blocks in two different ways, and a two-leaf TD is used. Computations for a superelement associated with each leaf are assigned to two processors and are performed in parallel. A new preconditioner is introduced to accelerate convergence in a preconditioned textured decomposition (PTD). A special local communication strategy is used to avoid global assembly and global communication.

Two model problems including a Laplace equation on a rectangular domain with a near singular solution and a Poisson equation on an L-shaped domain, are solved. The conjugate gradient (CG) method, the TD method, the recursive textured decomposition (RTD) method, both with and without preconditioning, and the classical iterative methods (Jacobi, Gauss–Seidel (GS), successive overrelaxation (SOR)), are used to solve both model problems. Load balance, speedup ratio, and spectral radii of the various iterations are studied. The test results indicate that recursive PTD with a local communication strategy gives at least a 30% improvement in computational time over the other methods.

Key words. p-version of the finite element method, parallel implementation

AMS subject classifications. 65N22, 65N30, 65F10

1. Introduction.

The finite element method is currently one of the most popular numerical methods used in the solution of engineering problems governed by partial differential equations. However, large problems, especially in three dimensions, are often not solvable on serial computers because of prohibitive computation time. Improvements in computing technology, based on large-scale parallel computers, offer the possibility of expanding the set of problems that can be solved efficiently. Such parallel computers appear attractive to finite element methods in which the local element provides a natural decomposition of the problem into (partially) computationally independent sets.

Variants of the finite element methods include the standard h-version, which uses low-order basis functions and achieves accuracy by refining meshes; the p-version, which uses a fixed mesh and achieves accuracy by increasing the order of the basis functions; and the h-p version, which combines these two approaches. For the first and last of these techniques, which divide the domain into local elements and compute associated local stiffness matrices, a large component of the required computations can be implemented very naturally on parallel computers [3]. In particular, for the h-version, domain decomposition methods [8], [9] group collections of elements into superelements. Construction of all local stiffness matrices associated with a superelement is independent of another superelement, so that they can be performed in parallel on separate processors. For the p- and h-p versions, we can think of the space of high-order basis functions in a single element as analogous to h-version grouping into superelements in the sense that construction of local operators can be done partially in parallel. The majority of elemental computations are performed on local data in a fully parallel manner.

Direct methods are fully satisfactory for the solution of the resulting assembled system of linear equations for small-size problems or large sparse systems. But large-size problems (with more than 30,000 degrees of freedom [13]), which are common in the p-version of the finite element analysis, are inefficient both in terms of CPU time and storage. Iterative methods are a preferable choice for problems with a large number of elements and do not suffer from fill-in. Iterative methods can be implemented on parallel computers and achieve computational load balance; that is, the computational load can be balanced among processors. Classical iterative methods including Jacobi, Gauss–Seidel (GS), successive overrelaxation (SOR), symmetric successive overrelaxation (SSOR), and Chebyshev methods [7] have been studied thoroughly and solve well-conditioned systems efficiently. But these methods converge very slowly for the ill-conditioned systems. Multigrid methods have proved to be efficient solvers for problems arising by discretization of partial differential equations by the h-version finite element method [14], [15]. A straightforward application of multigridlike ideas to the p-version was studied by Brussino et al. [5], Foresti et al. [6], Mandel [13], [14], and Hu and Katz [10], [11]. The conjugate gradient (CG) method has been applied to solve discretized systems by the p-version in Babuska et al. [3], [4] in a parallel manner, and they have achieved impressive results. In this paper, a class of new parallel iterative algorithms based on a textured model decomposition is introduced to solve problems arising from discretization of elliptic partial differential equations by the p-version. Numerical results show that the textured decomposition (TD) methods converge faster than the CG method on sample problems. The recursive textured decomposition (RTD) method is also used in our scheme to achieve still better results. The model problems are intended only to compare the efficiency of iterative methods. For the relatively small number of unknowns in these problems (at most 2,500) direct methods could be more efficient. The comparisons given here for the various iterative methods are meant to provide a guide for their use in problems with large (more than 30,000) unknowns.

In recent years, preconditioners have been developed for the CG methods to accelerate the convergence. A preconditioner which uses the hierachic property of the p-version has been proposed by Babuska et al. [4]. It is shown in [4] that the condition number grows at most as $(\log p)^2$ for large p. We use a closely related preconditioner for the TD and RTD methods. The preconditioning successfully reduces the spectral radius of their iteration matrices.

This paper is organized as follows: in §2, we introduce the p-version of the finite element method [1]. We use the concepts from Szabo and Babuska's book [2] to give a brief introduction to one-dimensional and two-dimensional cases. The finite element space and the corresponding hierachic basis functions are introduced. Computations of elemental stiffness matrices and load vectors are discussed. Our finite element computations were made by using MSC/PROBE [17] and PEGASYS. We discuss assembly of the stiffness matrices and load vectors. Finally, we use the Schur complement to condense the internal variables and corresponding load vectors.

In §3, we construct the TD method. In order to apply the TD method to parallel computation, we introduce a superelement. A PTD method, based on structural properties of the superelement, is introduced. We study a three-level recursive TD with and without preconditioning.

In §4, we study parallel implementations of the TD method. First, we discuss how to map a superelement onto two processors. Then we propose a local communication strategy to minimize communication costs. Performance analysis focused on speedup ratios is studied.

In §5, we present the numerical results of using the TD method, the PTD method, and the RTD method to solve two model problems: a Laplace equation on a rectangular domain with near singular solution and an L-shaped domain problem. Both model problems are typical problems in elasticity for which finite element analysis is generally used. We compare these results with the results from using the classical iterative methods: Jacobi, GS, SOR, and the CG and preconditioned conjugate gradient (PCG) methods. Convergence rate and performance analysis is given.

2. The p-version of the finite element method. We consider the representative problem:

$$-\Delta u = f \quad \text{on } \Omega, \tag{2.1a}$$

$$u = f_1 \quad \text{on } \partial^1\Omega, \tag{2.1b}$$

$$\frac{\partial u}{\partial n} = f_2 \quad \text{on } \partial^2\Omega, \tag{2.1c}$$

where Ω is the bounded domain, $\partial^1\Omega \cup \partial^2\Omega = \partial\Omega$ is the piecewise smooth boundary, and f, f_1, f_2 are functions that satisfy the conditions guaranteeing existence and uniqueness of the solution.

Let

$$H(\Omega) \equiv \{u \in H^1(\Omega) | u = f_1 \text{ on } \partial^1\Omega\}, \tag{2.2}$$

where $H^1(\Omega)$ is a *Hilbert space.*

Let

$$B(u, v) = \int_\Omega (\nabla u \cdot \nabla v)\, dx_1 dx_2 \tag{2.3}$$

be the bilinear form defined on $H(\Omega) \times H(\Omega)$, and let

$$F(v) = \int_\Omega f v\, dx_1\, dx_2 + \int_{\partial^2\Omega} f_2 v\, ds \tag{2.4}$$

be a linear functional on $H(\Omega)$. Then we change problem (2.1) to the standard variational formulation: find

$$u_{EX} \in H(\Omega),$$

such that

$$B(u_{EX}, v) = F(v) \quad \forall v \in H(\Omega). \tag{2.5}$$

The p-version approximation consists of restricting the subspace $H(\Omega)$ and finding a solution in this restricted subspace. First, we choose a polynomial subspace $S^p \subseteq H(\Omega)$; then we find an approximate solution $u_{FE}(S^p) \in S^p$, such that

$$B(u_{FE}(S^p), v) = F(v) \quad \forall v \in S^p. \tag{2.6}$$

The goal is

$$\|u_{FE}(S^p) - u_{EX}\|_{E(\Omega)} \leq \tau, \tag{2.7}$$

where

$$\|u\|_{E(\Omega)} \equiv B(u, u)^{\frac{1}{2}} \tag{2.8}$$

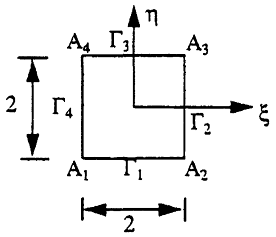

FIG. 2.1. *The standard quadrilateral element* $\Omega_{st}^{(q)}$.

is the *energy norm*, $E(\Omega)$ is the energy space defined as $E(\Omega) \equiv \{u|B(u,u) < \infty\}$, and τ is a given tolerance.

The finite element space in two dimensions is defined as follows:

$$S^p \equiv S^p(\Omega, \Delta, Q) \equiv \{\{u\}|\{u\} \in E(\Omega), u(Q_x^{(k)}(\xi,\eta), Q_y^{(k)}(\xi,\eta)) \in S_{st}^{p_k}, \quad k = 1, 2, \dots, M(\Delta)\}, \tag{2.9}$$

where Ω is the domain, Δ is the finite element mesh, and $x = Q_x^{(k)}(\xi,\eta)$, $y = Q_y^{(k)}(\xi,\eta)$, are mapping functions defined for the kth finite element which map a standard quadrilateral element onto the kth finite element. S_{st}^p is the space of polynomials defined on the standard elements [2].

In the finite element method, S^p is typically constructed by partitioning Ω into subdomains, called finite elements. Then the standard element $\Omega_{st}^{(q)}$ is selected. A standard square is shown in Fig. 2.1 which is mapped onto each finite element.

The space S_{st}^p is spanned by the following basis functions (for further details, see [2]):

1. *Nodal shape functions.* A nodal shape function is associated with a vertex A_i of the element $\Omega_{st}^{(q)}$. It is zero on the opposite sides of the vertex with which it is associated. There are four nodal shape functions:

$$N_1(\xi,\eta) = \frac{1}{4}(1-\xi)(1-\eta), \tag{2.10a}$$

$$N_2(\xi,\eta) = \frac{1}{4}(1+\xi)(1-\eta), \tag{2.10b}$$

$$N_3(\xi,\eta) = \frac{1}{4}(1+\xi)(1+\eta), \tag{2.10c}$$

$$N_4(\xi,\eta) = \frac{1}{4}(1-\xi)(1+\eta). \tag{2.10d}$$

2. *Side shape functions.* The side shape function is associated with a side Γ_i and is zero on all three other sides of the element. There are $4(p-1)$, $(p \geq 2)$ shape functions. These shape functions are defined as

$$N_i^{(1)} = \frac{1}{2}(1-\eta)\phi_i(\xi), \qquad i = 2, \dots, p, \tag{2.11a}$$

$$N_i^{(2)} = \frac{1}{2}(1+\xi)\phi_i(\eta), \qquad i = 2, \dots, p, \tag{2.11b}$$

$$N_i^{(3)} = \frac{(-1)^i}{2}(1+\eta)\phi_i(\xi), \qquad i = 2, \dots, p, \tag{2.11c}$$

$$N_i^{(4)} = \frac{(-1)^i}{2}(1-\xi)\phi_i(\eta), \qquad i = 2, \dots, p, \tag{2.11d}$$

where ϕ_j is defined in terms of the Legendre polynomial P_{j-1}:

$$\phi_j(\xi) \equiv \sqrt{\frac{2j-1}{2}} \int_{-1}^{\xi} P_{j-1}(t)\, dt, \qquad j = 2, 3, \ldots. \tag{2.12}$$

The term $(-1)^i$ is needed in $N_i^{(3)}$ and $N_i^{(4)}$ to obtain invariance with respect to the rotation of coordinates.

3. *Internal shape functions.* Internal shape functions are zero on all four sides. For $p < 4$ there are no internal shape functions. For $p \geq 4$ there are $(p-2)(p-3)/2$ internal shape functions defined as

$$N_{i,j}^{(0)}(\xi, \eta) = (1-\xi^2)(1-\eta^2)P_i(\xi)P_j(\eta), \qquad 0 \leq i + j \leq p - 4. \tag{2.13}$$

These basis functions are mapped onto each element. Let Ψ_i denote the mapped basis functions on an element; then we have

$$u_{FE}(S^p) = \sum_{i=1}^{N} x_i \Psi_i, \qquad F(\Psi_i) = y_i; \tag{2.14}$$

then problem (2.6) becomes the solution of a system of linear equations

$$Ax = y, \tag{2.15}$$

where

$A = [a_{ij}]$ is called the elemental *stiffness matrix* with $a_{ij} = B(\Psi_i, \Psi_j)$,
x is the vector of coefficients of basis functions,
y is called the elemental *load vector*.

After the elemental stiffness matrices are generated, we eliminate the internal unknowns by computing the Schur complement. The elemental stiffness matrices and load vectors can be written in block form:

$$A = \begin{bmatrix} A_{11} & A_{12} \\ A_{12}^T & A_{22} \end{bmatrix}, \qquad b = \begin{bmatrix} b_1 \\ b_2 \end{bmatrix}, \tag{2.16}$$

where

A_{11} corresponds to the interior unknowns,
A_{22} corresponds to the boundary unknowns,
A_{12} corresponds to the connections between interior and boundary unknowns.

After computing the Schur complement, the stiffness matrices can be written in the following form:

$$\hat{A} = BAB^T = \begin{bmatrix} A_{11} & 0 \\ 0 & \hat{A}_{22} \end{bmatrix}, \tag{2.17}$$

where

$$\hat{A}_{22} = A_{22} - A_{12}^T A_{11}^{-1} A_{12}$$

is the Schur complement of A with respect to A_{11} and

$$B = \begin{bmatrix} I_1 & 0 \\ -A_{12}^T A_{11}^{-1} & I_2 \end{bmatrix}. \tag{2.18}$$

The elemental load vector will be modified similarly by

$$\hat{b} = [b_1, \hat{b}_2]^T, \tag{2.19a}$$

where

$$\hat{b}_2 = b_2 - A_{12}^T A_{11}^{-1} b_1. \tag{2.19b}$$

Remark. The condensation of internal unknowns is processed element by element, so these computations are fully parallizable.

DEFINITION 2.1. *Let* $A = (a_{ij})$ *be an* $n \times n$ *matrix with eigenvalues* λ_1, $1 \le i \le n$. *Then*

$$\rho(A) \equiv \max_{1 \le i \le n} |\lambda_i| \tag{2.20}$$

is the spectral radius *of the matrix* A.

3. Textured decomposition method.

3.1. The TD method. The TD method [12] for the p-version of the finite element method is a new class of linear iterative algorithms, using a class of parallel algorithms developed in different contexts at Washington University [18], [19], [20]. Unlike the standard iterative methods, the TD method uses multiple splittings of A called *leaves*, say (D_1, E_1), $(D_2, E_2), \ldots$, (D_m, E_m), and

$$A = D_1 - E_1 = D_2 - E_2 = \cdots = D_m - E_m. \tag{3.1}$$

The algorithm for the m-leaf TD method is defined as

$$\begin{aligned} &(3.2a) & D_1 x(k+1) &= E_1 x(k) + b, \\ &(3.2b) & D_2 x(k+2) &= E_2 x(k+1) + b, \\ && &\vdots \\ &(3.2c) & D_m x(k+m) &= E_m x(k+m-1) + b, \qquad k = 1, 2, \ldots. \end{aligned}$$

In each splitting (D_i, E_i), D_i is an approximation of A and $-E_i$ contains the remaining nonzeros of A. In the TD method, we use multiple approximations of A in round-robin fashion which yields a textured group of decompositions of the system matrix A. In this way, the approximation error incurred in one splitting is compensated by the other splittings in the overall TD. The central feature of our investigation is to find a choice of $D_1, E_1, \ldots, D_m, E_m$ for the p-version of the finite element method to assure rapid convergence and minimal idle time.

In our investigation, we focus on two-leaf TD. First we discuss how to choose the splittings. The system matrix A can be written in block form

$$A = \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ A_{31} & A_{32} & A_{33} \end{bmatrix}; \tag{3.3}$$

then we choose the two splittings:

$$D_1 = \begin{bmatrix} A_{11} & 0 & 0 \\ 0 & A_{22} & A_{23} \\ 0 & A_{32} & A_{33} \end{bmatrix}, \qquad -E_1 = \begin{bmatrix} 0 & A_{12} & A_{13} \\ A_{21} & 0 & 0 \\ A_{31} & 0 & 0 \end{bmatrix}, \tag{3.4a}$$

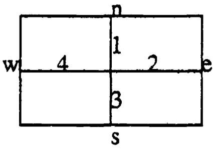

FIG. 3.1. *Superelement.*

$$D_2 = \begin{bmatrix} A_{11} & A_{12} & 0 \\ A_{21} & A_{22} & 0 \\ 0 & 0 & A_{33} \end{bmatrix}, \qquad -E_2 = \begin{bmatrix} 0 & 0 & A_{13} \\ 0 & 0 & A_{23} \\ A_{31} & A_{32} & 0 \end{bmatrix}. \tag{3.4b}$$

In the above decomposition, the dimensions of A_{11} and A_{33} are identical, say $m \times m$. Then the overlap between two leaves is of dimension $(n - 2m) \times (n - 2m)$. The two-leaf TD takes the form

$$D_1 x^{(k+1)} = E_1 x^{(k)} + b, \tag{3.5a}$$

$$D_2 x^{(k+2)} = E_2 x^{(k+1)} + b. \tag{3.5b}$$

Equations (3.5a,b) can be solved either by a direct solver or by an iterative solver. We discuss this later.

3.2. The TD method applied to the finite element method. In this paper, we consider the parallel implementations of the TD methods for solving the system of linear equations (3.1) derived from the discretization of a two-dimensional elliptic problem by the p-version of the finite element method on rectangular meshes. In order to be applicable to a parallel computer, first, we group the elements into clusters. We call each cluster a *superelement.* A superelement can be one element, two adjacent elements, or several adjacent elements. In our investigation, we use four adjacent quadrilateral elements as a superelement. (See Fig. 3.1.) Let A be the assembled stiffness matrix corresponding to a superelement. Our objectives are to partition A so as to achieve two goals: (1) rapid convergence and (2) maximum load balance in parallel computation.

Now we discuss how to partition the matrix A. Suppose matrix A is an assembled stiffness matrix for a superelement with all internal variables eliminated by computing the Schur complement. The matrix A can be reorganized as the block form

$$A = \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ A_{31} & A_{32} & A_{33} \end{bmatrix}. \tag{3.6}$$

We consider two ways to partition these blocks, which we denote as BLOCK1 and BLOCK2. In BLOCK1, each block is chosen as follows:

A_{11} corresponds to all side variables of sides 1,2,n,e;

A_{22} corresponds to all vertex variables;

A_{33} corresponds to all side variables of sides 3,4,s,w.

In BLOCK2, each block is chosen as follows:

A_{11} corresponds to side variables of sides 1,2,n,e of order $\leq p - 1$;

A_{22} corresponds to all vertex variables and pth-order side variables;

A_{33} corresponds to side variables of sides 3,4,s,w of order $\leq p - 1$.

Remark. Block A_{22} is the overlap of the two leaves. It is a key part of our partitioning, which will help to accelerate the convergence. In our numerical investigations, we found

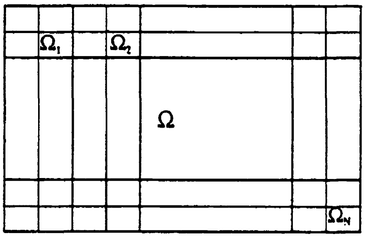

FIG. 3.2. *General case.*

that the error in the variables corresponding to vertices always decreased slower than other variables. If we put these vertex variables in the overlap, they will be computed twice (once in each leaf) per iteration. This will help to decrease the error. In BLOCK2, we use the hierachic property of the p-version of the finite element method and put the pth order of side variables in A_{22} as perturbation to the variables of order $\leq p-1$ to accelerate the convergence.

Generally, we use N superelements, each superelement contains four adjacent elements, and there are a total of $4N$ elements. (See Fig. 3.2.) The assembled stiffness matrix is in the form

$$A=\left[\begin{array}{c|c|c|c}
\begin{matrix}A_{11}&A_{12}&A_{13}\\A_{21}&A_{22}&A_{23}\\A_{31}&A_{32}&A_{33}\end{matrix} & X & X & X \\ \hline
X & \begin{matrix}A_{44}&A_{45}&A_{46}\\A_{54}&A_{55}&A_{56}\\A_{64}&A_{65}&A_{66}\end{matrix} & X & X \\ \hline
X & X & \ddots & X \\ \hline
X & X & X & \begin{matrix}A_{n-2,n-2}&A_{n-2,n-1}&A_{n-2,n}\\A_{n-1,n-2}&A_{n-1,n-1}&A_{n-1,n}\\A_{n,n-2}&A_{n,n-1}&A_{n,n}\end{matrix}
\end{array}\right]
\begin{array}{c}\Omega_1\\ \\ \Omega_2\\ \\ \\ \\ \Omega_N\end{array}.$$

The matrices indicated with X's correspond to coupling between different superelements. The diagonal blocks whose submatrices are denoted by A_{ij} have been emphasized because they are used in the textured decomposition.

Using the two-leaf TD method, D_i is chosen as

$$D_1=\left[\begin{array}{c|c|c|c}
\begin{array}{c|cc}A_{11}&0&0\\\hline 0&A_{22}&A_{23}\\0&A_{32}&A_{33}\end{array} & Y & Y & Y \\ \hline
Y & \begin{array}{c|cc}A_{44}&0&0\\\hline 0&A_{55}&A_{56}\\0&A_{65}&A_{66}\end{array} & Y & Y \\ \hline
Y & Y & \ddots & Y \\ \hline
Y & Y & Y & \begin{array}{c|cc}A_{n-2,n-2}&0&0\\\hline 0&A_{n-1,n-1}&A_{n-1,n}\\0&A_{n,n-1}&A_{n,n}\end{array}
\end{array}\right]
\begin{array}{c}\Omega_1\\ \\ \Omega_2\\ \\ \\ \\ \Omega_N\end{array}.$$

$$D_2=\left[\begin{array}{c|c|c|c}
\begin{array}{cc|c} A_{11} & A_{12} & 0 \\ A_{21} & A_{22} & 0 \\ \hline 0 & 0 & A_{33} \end{array} & Z & Z & Z \\
\hline
Z & \begin{array}{cc|c} A_{44} & A_{45} & 0 \\ A_{54} & A_{55} & 0 \\ \hline 0 & 0 & A_{66} \end{array} & Z & Z \\
\hline
Z & Z & \ddots & Z \\
\hline
Z & Z & Z & \begin{array}{cc|c} A_{n-2,n-2} & A_{n-2,n-1} & 0 \\ A_{n-1,n-2} & A_{n-1,n-1} & 0 \\ \hline 0 & 0 & A_{n,n} \end{array}
\end{array}\right]\begin{array}{c} \Omega_1 \\ \\ \Omega_2 \\ \\ \\ \Omega_N \end{array},$$

where $n = 3N$.

In the above splitting, each diagonal block corresponds to a superelement, so for N superelements, there are N diagonal blocks. Each block is defined as before. To solve equation (3.5a), we need to solve

$$A_{11}x_1^{(k+1)} = -\sum_{i\neq 1}^{n} A_{1i}x_i^{(k)} + b_1, \tag{3.7a}$$

$$\begin{bmatrix} A_{22} & A_{23} \\ A_{32} & A_{33} \end{bmatrix}\begin{bmatrix} x_2 \\ x_3 \end{bmatrix}^{(k+1)} = -\sum_{i\neq 2,3}^{n}\begin{bmatrix} A_{2i}x_i^{(k)} \\ A_{3i}x_i^{(k)} \end{bmatrix} + \begin{bmatrix} b_2 \\ b_3 \end{bmatrix}. \tag{3.7b}$$

For (3.5b), we need to solve

$$\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}\begin{bmatrix} x_1 \\ x_2 \end{bmatrix}^{(k+2)} = -\sum_{j\neq 1,2}^{n}\begin{bmatrix} A_{1j}x_j^{(k+1)} \\ A_{2j}x_j^{(k+1)} \end{bmatrix} + \begin{bmatrix} b_1 \\ b_2 \end{bmatrix}, \tag{3.8a}$$

$$A_{33}x_3^{(k+2)} = -\sum_{j\neq 3}^{n} A_{3j}x_j^{(k+1)} + b_3. \tag{3.8b}$$

In (3.7a,b) and (3.8a,b), the system matrices, i.e., A_{11},

$$\begin{bmatrix} A_{22} & A_{23} \\ A_{32} & A_{33} \end{bmatrix}, \quad \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix},$$

and A_{33}, are all symmetric positive definite by the property of the p-version of the finite element discretization. These equations are solved using Cholesky factorization and a block forward solver.

From (3.6),

$$\begin{aligned} x^{(k+2)} &= D_2^{-1}E_2x^{(k+1)} + D_2^{-1}b \\ &= D_2^{-1}E_2D_1^{-1}E_1x^{(k)} + R, \end{aligned} \tag{3.9}$$

where

$$R = D_2^{-1}E_2D_1^{-1}b + D_2^{-1}b. \tag{3.10}$$

So the iteration matrix for the two-leaf TD method is

$$G_1 = D_2^{-1}E_2D_1^{-1}E_1, \tag{3.11}$$

and the convergence rate of this algorithm depends on the spectral radius of the iteration matrix G_1.

3.3. Preconditioning. We note that, for the iterative method, the system $M^{-1}Ax = M^{-1}b$ is called the *preconditioned system* of system (3.1). The matrix M is called the "preconditioner." In this section, we discuss the PCG method [7], the PTD method, and how to choose a proper preconditioner to accelerate the convergence.

3.3.1. The PTD method. In order to reduce the spectral radius of the iteration matrix G_1, we introduce a PTD method with preconditioner M^{-1}. The idea of a PTD method is to modify the residual in each iteration, then update x. The algorithm is as follows.

ALGORITHM 3.1 (PRECONDITIONED TEXTURED DECOMPOSITION METHOD).
Given a symmetric positive definite matrix $A \in \Re^{n\times n}$ and $b \in \Re^{n}$ we use a two-leaf TD method with preconditioner M and splittings D_1, D_2, E_1, and E_2 to solve the system of the linear equation $Ax = b$.

```
         Set $k = 0, x^0 = 0, r^0 = b$
(3.12a)  while $(\|x^{k+2} - x^k\| < \varepsilon)$
(3.12b)  Solve: $M^{-1}\tilde{r}^k = r^k$
(3.12c)  Update: $\tilde{x}^k = x^k + \tilde{r}^k$
(3.12d)  $D_1x^{k+1} = E_1\tilde{x}^k + b$
(3.12e)  $D_2x^{k+2} = E_2x^{k+1} + b$
         Update $k$
(3.12f)  $r^k = b - Ax^k$
End
```

Since the auxiliary system $M^{-1}\tilde{r} = r$ must be solved at each iteration in each preconditioned method, it is critical that this system be "easy" to solve. On the other hand, in order that the preconditioning be effective, we want preconditioner M to be a "good" approximation of A. Clearly, the two requirements are in conflict since the more closely M approximates A, the more likely that the system $M^{-1}\tilde{r} = r$ will be nearly as difficult to solve as the system $Ax = b$. We next discuss how to choose an efficient preconditioner so that the convergence is very fast and the equation $M^{-1}\tilde{r} = r$ is easy to solve.

3.3.2. Preconditioner. In the PTD method, from Algorithm 3.1,

$$\begin{aligned}
x^{k+2} &= G_1\tilde{x}^k + R && \text{(3.13a)}\\
&= G_1(x^k + \tilde{r}^k) + R && \text{(3.13b)}\\
&= G_1(x^k + Mr^k) + R && \text{(3.13c)}\\
&= G_1(x^k + M(b - Ax^k)) + R && \text{(3.13d)}\\
&= G_1(I - MA)x^k + G_1Mb + R, && \text{(3.13e)}
\end{aligned}$$

where G_1 and R are defined in (3.11) and (3.10), respectively.

The convergence rate of the PTD matrix depends on the spectral radius of the matrix

$$\tilde{G}_1 \equiv G_1(I - MA). \tag{3.14}$$

If $M^{-1} = A$, then $I - MA = 0$, and $\tilde{G}_1 = 0$; the iteration will terminate immediately.

In our investigation, we focus on choosing a proper preconditioner M^{-1} for the p-version approximation system equation, so that the spectral radius of iteration matrix $\tilde{G}_1$ is as small as possible.

More specifically consider a system of linear equations

$$Ax = b, \tag{3.15}$$

where A is the assembled stiffness matrix corresponding to a superelement with internal variables eliminated. We reform matrix A into block forms BLOCK1 and BLOCK2 as in §3.2. The preconditioner M will be chosen as

$$M = \begin{bmatrix} I & 0 & 0 \\ 0 & A_{22} & 0 \\ 0 & 0 & I \end{bmatrix}. \tag{3.16}$$

In §5, we show numerically that M^{-1} accelerates the convergence of the TD method. There are other preconditioners that have been used for the PCG method, such as the incomplete Cholesky factorization, polynomial preconditioners (SSOR, SOR, GS, etc.) [7], and the multigrid method as a preconditioner [15]. In §5, we study the use of the preconditioner M^{-1} defined in (3.16) for the PCG and the PTD methods.

3.4. The RTD method. In the p-version of the finite element method, we use polynomials of high degree for approximation. For larger p, each block of the matrix A is relatively big and load imbalance is considerable. So we divide each block of matrices into smaller blocks recursively and use the TD on the smaller blocks.

Consider the system of the linear equation

$$Ax = b, \tag{3.17}$$

where A is defined in §3.2 as BLOCK1.

We use a two-leaf TD to solve (3.17).

(i) *Level one.*

$$A = D_1 - E_1 = D_2 - E_2, \tag{3.18}$$

where

$$D_1 = \left[\begin{array}{c|cc} A_{11} & 0 & 0 \\ \hline 0 & A_{22} & A_{23} \\ 0 & A_{32} & A_{33} \end{array}\right], \qquad D_2 = \left[\begin{array}{cc|c} A_{11} & A_{12} & 0 \\ A_{21} & A_{22} & 0 \\ \hline 0 & 0 & A_{33} \end{array}\right], \tag{3.19}$$

are *leaves*. Let

$$D_1^1 \equiv [A_{11}], \qquad D_1^2 \equiv \begin{bmatrix} A_{22} & A_{23} \\ A_{32} & A_{33} \end{bmatrix}, \tag{3.20a}$$

$$D_2^1 \equiv \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}, \qquad D_2^2 \equiv [A_{33}], \tag{3.20b}$$

which we call *partition of leaves*

$$D_1 = \left[\begin{array}{c|c} D_1^1 & 0 \\ \hline 0 & D_1^2 \end{array}\right], \qquad D_2 = \left[\begin{array}{c|c} D_2^1 & 0 \\ \hline 0 & D_2^2 \end{array}\right]. \tag{3.21}$$

Similarly, we define E_1^1, E_1^2, E_2^1, and E_2^2.

At the first level, we solve

$$D_1 x^{k+1} = E_1 x^k + b, \tag{3.22a}$$

$$D_2 x^{k+2} = E_2 x^{k+1} + b, \tag{3.22b}$$

where

$$\begin{bmatrix} D_1^1 & 0 \\ 0 & D_1^2 \end{bmatrix} \begin{bmatrix} x_{1,1} \\ x_{1,2} \end{bmatrix}^{k+1} = \begin{bmatrix} 0 & E_1^1 \\ E_1^2 & 0 \end{bmatrix} \begin{bmatrix} x_{1,1} \\ x_{1,2} \end{bmatrix}^{k} + \begin{bmatrix} b_1^1 \\ b_1^2 \end{bmatrix}, \tag{3.23a}$$

$$\begin{bmatrix} D_2^1 & 0 \\ 0 & D_2^2 \end{bmatrix} \begin{bmatrix} x_{2,1} \\ x_{2,2} \end{bmatrix}^{k+2} = \begin{bmatrix} 0 & E_2^1 \\ E_2^2 & 0 \end{bmatrix} \begin{bmatrix} x_{2,1} \\ x_{2,2} \end{bmatrix}^{k+1} + \begin{bmatrix} b_2^1 \\ b_2^2 \end{bmatrix}; \tag{3.23b}$$

i.e., we solve

$$D_1^1 x_{1,1}^{k+1} = E_1^1 x_{1,2}^k + b_1^1, \tag{3.24a}$$

$$D_1^2 x_{1,2}^{k+1} = E_1^2 x_{1,1}^k + b_1^2, \tag{3.24b}$$

$$D_2^1 x_{2,1}^{k+2} = E_2^1 x_{2,2}^{k+1} + b_2^1, \tag{3.24c}$$

$$D_2^2 x_{2,2}^{k+2} = E_2^2 x_{2,1}^{k+1} + b_2^2. \tag{3.24d}$$

Note. Equations (3.24a) and (3.24b) can be solved simultaneously, (3.24c) and (3.24d) can be solved simultaneously, but (3.24c) and (3.24d) need results from (3.24a) and (3.24b). That is, the partitions of leaves can be solved in parallel, but leaves have to be solved sequentially.

(ii) *Level two.* To solve equations (3.24a–d), we use the two-leaf TD method again. First, we discuss how to solve (3.23a). We reorganize D_1^1 as follows:

$$D_1^1 = \begin{bmatrix} A_{11}^1 & A_{12}^1 & A_{13}^1 \\ A_{21}^1 & A_{22}^1 & A_{23}^1 \\ A_{31}^1 & A_{32}^1 & A_{33}^1 \end{bmatrix}, \tag{3.25}$$

where

A_{11}^1 corresponds to all side variables of side 1 and n,
A_{22}^1 corresponds to all vertex variables,
A_{33}^1 corresponds to all side variables of side 2 and e.

Let

$$D_1^1 = D_1^{1,1} - E_1^{1,1} = D_1^{1,2} - E_1^{1,2}, \tag{3.26}$$

where

$$D_1^{1,1} \equiv \left[\begin{array}{c|c} D_1^{1,1,1} & 0 \\ \hline 0 & D_1^{1,1,2} \end{array}\right] = \left[\begin{array}{c|cc} A_{11}^1 & 0 & 0 \\ \hline 0 & A_{22}^1 & A_{23}^1 \\ 0 & A_{32}^1 & A_{33}^1 \end{array}\right], \tag{3.27a}$$

$$D_1^{1,2} \equiv \left[\begin{array}{c|c} D_1^{1,2,1} & 0 \\ \hline 0 & D_1^{1,2,2} \end{array}\right] = \left[\begin{array}{cc|c} A_{11}^1 & A_{12}^1 & 0 \\ A_{21}^1 & A_{22}^1 & 0 \\ \hline 0 & 0 & A_{33}^1 \end{array}\right]. \tag{3.27b}$$

Now we need to solve

$$D_1^{1,1}x_{1,1}^{k_1+1} = E_1^{1,1}x_{1,2}^{k_1}+b_1^1, \tag{3.28a}$$

$$D_1^{1,2}x_{1,1}^{k_1+2} = E_1^{1,2}x_{1,2}^{k_1+1}+b_1^1, \tag{3.28b}$$

where k_1 is the iteration index in this level. We have

$$\begin{bmatrix} D_1^{1,1,1} & 0 \\ 0 & D_1^{1,1,2} \end{bmatrix}\begin{bmatrix} x_{1,1,1,1} \\ x_{1,1,1,2} \end{bmatrix}^{k_1+1} = \begin{bmatrix} 0 & E_1^{1,1,1} \\ E_1^{1,1,2} & 0 \end{bmatrix}\begin{bmatrix} x_{1,1,1,1} \\ x_{1,1,1,2} \end{bmatrix}^{k_1} + \begin{bmatrix} b_{1,1}^{1,1} \\ b_{1,1}^{1,2} \end{bmatrix}, \tag{3.29a}$$

$$\begin{bmatrix} D_1^{1,2,1} & 0 \\ 0 & D_1^{1,2,2} \end{bmatrix}\begin{bmatrix} x_{1,1,2,1} \\ x_{1,1,2,2} \end{bmatrix}^{k_1+2} = \begin{bmatrix} 0 & E_1^{1,2,1} \\ E_1^{1,2,2} & 0 \end{bmatrix}\begin{bmatrix} x_{1,1,2,1} \\ x_{1,1,2,2} \end{bmatrix}^{k_1+1} + \begin{bmatrix} b_{1,2}^{1,1} \\ b_{1,2}^{1,2} \end{bmatrix}; \tag{3.29b}$$

i.e., we solve

$$D_1^{1,1,1}x_{1,1,1,1}^{k_1+1} = E_1^{1,1,1}x_{1,1,1,2}^{k_1}+b_{1,1}^{1,1}, \tag{3.30a}$$

$$D_1^{1,1,2}x_{1,1,1,2}^{k_1+1} = E_1^{1,1,2}x_{1,1,1,1}^{k_1}+b_{1,1}^{1,2}, \tag{3.30b}$$

$$D_1^{1,2,1}x_{1,1,2,1}^{k_1+2} = E_1^{1,2,1}x_{1,1,2,2}^{k_1+1}+b_{1,2}^{1,1}, \tag{3.30c}$$

$$D_1^{1,2,2}x_{1,1,2,2}^{k_1+1} = E_1^{1,2,2}x_{1,1,2,1}^{k_1+1}+b_{1,2}^{1,2}. \tag{3.30d}$$

Similarly, we can use a two-leaf TD method to solve (3.24 b,c,d).

(iii) *Level three.* To solve equations (3.30a–d) in level two, we use two-leaf textured decomposition again. For equation (3.30a), we reorganize the block of matrix $D_1^{1,1,1}$ into the following form:

$$D_1^{1,1,1} = \begin{bmatrix} A_{11}^{1,1} & A_{12}^{1,1} & A_{13}^{1,1} \\ A_{21}^{1,1} & A_{22}^{1,1} & A_{23}^{1,1} \\ A_{31}^{1,1} & A_{32}^{1,1} & A_{33}^{1,1} \end{bmatrix}, \tag{3.31}$$

where

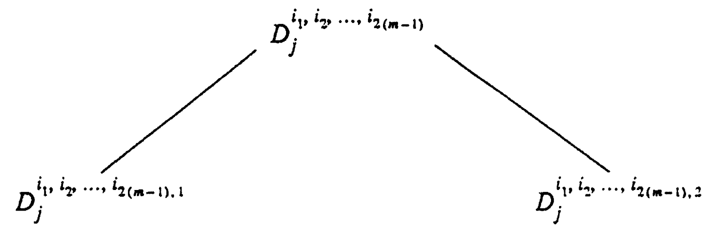
$A_{11}^{1,1}$ corresponds to side variables of side 1,
$A_{22}^{1,1}$ corresponds to all vertex variables,
$A_{33}^{1,1}$ corresponds to side variables of side n.

We then proceed as in BLOCK1 and BLOCK2.

A binary tree can be used to represent the RTD method. A *binary tree* is a tree where each node in the tree has 0, 1, or 2 children. Children are often referred to as "left child" or the "right child." The connection between children and their root parents are called *links*. We define the left link and the right link with respect to the connections between a parent with a left child and a right child. Figure 3.3 shows the mth-leaf binary tree. Figure 3.4 shows the three levels of the RTD. When we use preconditioning for the RTD method, we modify residuals in the final level by the preconditioner

$$M_j^{i_1,i_2,\ldots,i_{2(m-1)}} \equiv \begin{bmatrix} I & 0 & 0 \\ 0 & A_{22}^{l,k} & 0 \\ 0 & 0 & I \end{bmatrix}, \tag{3.32}$$

where $l, k = 1, 2$.



$D_j^{i_1, i_2, \ldots, i_{2(m-1)}}$
$D_j^{i_1, i_2, \ldots, i_{2(m-1)}, 1}$
$D_j^{i_1, i_2, \ldots, i_{2(m-1)}, 2}$

where $i_k, j = 1, 2$ and $k = 1, 2, \ldots, 2(m-1)$

FIG. 3.3. *mth-leaf binary tree.*

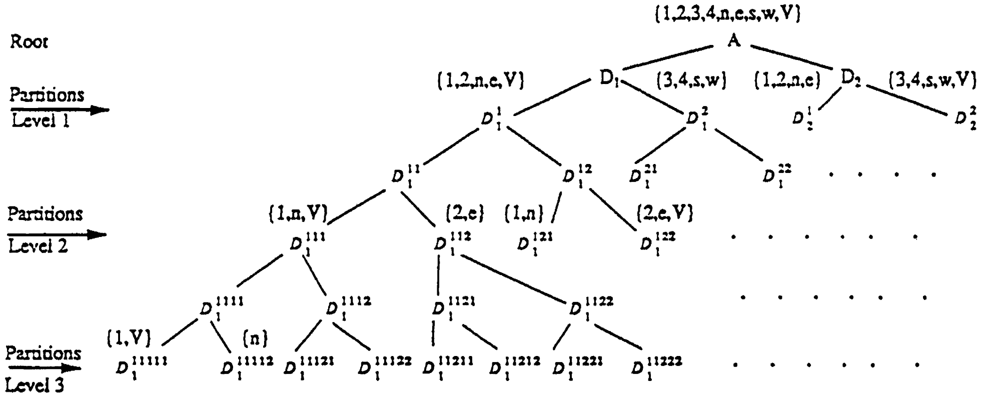


FIG. 3.4. *Three-level RTD.*

4. Parallel implementations. In this chapter, we discuss how to apply our iterative methods to a distributed parallel computer. We will discuss the mapping of a superelement onto parallel processors, communication strategy, and performance analysis. Our computations were performed on an NCUBE/6, a 64-processor MIMD parallel computer with hypercube architecture.

4.1. Superelements mapping. The hypercube interconnection system was chosen for three main reasons:

(i) It is an inductive structure; i.e., each node has its own memory, so it is usually easy to write programs that are independent of the hypercube.

(ii) It maps directly onto the most important common interconnection patterns.

(iii) It is so extensively interconnected that it gives a good approximation of maximal interconnection (every processor connected to all others). Thus, if a problem does not have an obvious interconnection structure, it will normally be acceptable to assign subproblems arbitrarily to hypercube nodes and let the communication software take care of routine messages [16].

In §3.2, we discussed how to construct a superelement. Now we map superelements onto a parallel computer. In our investigation, we use four adjacent elements as a superelement. We use a two-leaf TD method for each superelement and map each superelement onto two processors. Now we show how to map a superelement onto two processors. Suppose A is the global stiffness matrix defined in §3.2 for the general case

$$A=\left[\begin{array}{c|c|c|c}
\begin{matrix}A_{11}&A_{12}&A_{13}\\A_{21}&A_{22}&A_{23}\\A_{31}&A_{32}&A_{33}\end{matrix} & \mathrm{X} & \mathrm{X} & \mathrm{X} \\ \hline
\mathrm{X} & \begin{matrix}A_{44}&A_{45}&A_{46}\\A_{54}&A_{55}&A_{56}\\A_{64}&A_{65}&A_{66}\end{matrix} & \mathrm{X} & \mathrm{X} \\ \hline
\mathrm{X} & \mathrm{X} & \ddots & \mathrm{X} \\ \hline
\mathrm{X} & \mathrm{X} & \mathrm{X} & \begin{matrix}A_{n-2,n-2}&A_{n-2,n-1}&A_{n-2,n}\\A_{n-1,n-2}&A_{n-1,n-1}&A_{n-1,n}\\A_{n,n-2}&A_{n,n-1}&A_{n,n}\end{matrix}
\end{array}\right]
\begin{array}{c}\Omega_1\\ \\ \Omega_2\\ \\ \\ \\ \Omega_N\end{array}.$$

When using the two-leaf TD method, we solve the following equations in each superelement. In the first-leaf method we solve

$$A_{11}x_1^{(k+1)} = -\sum_{i\neq 1}^{n} A_{1i}x_i^{(k)} + b_1, \tag{4.1a}$$

$$\begin{bmatrix} A_{22} & A_{23} \\ A_{32} & A_{33} \end{bmatrix}\begin{bmatrix} x_2 \\ x_3 \end{bmatrix}^{(k+1)} = -\sum_{i\neq 2,3}^{n}\begin{bmatrix} A_{2i}x_i^{(k)} \\ A_{3i}x_i^{(k)} \end{bmatrix} + \begin{bmatrix} b_2 \\ b_3 \end{bmatrix}, \tag{4.1b}$$

and in the second-leaf method we solve

$$\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}\begin{bmatrix} x_1 \\ x_2 \end{bmatrix}^{(k+2)} = -\sum_{j\neq 1,2}^{n}\begin{bmatrix} A_{1j}x_j^{(k+1)} \\ A_{2j}x_j^{(k+1)} \end{bmatrix} + \begin{bmatrix} b_1 \\ b_2 \end{bmatrix}, \tag{4.2a}$$

$$A_{33}x_3^{(k+2)} = -\sum_{j\neq 3}^{n} A_{3j}x_j^{(k+1)} + b_3. \tag{4.2b}$$

Equation (4.1a) will be solved in one processor and (4.1b) will be solved simultaneously in another processor. Similarly, we solve (4.2a) in the same processor where we solve (4.1a), and solve (4.2b) in the processor where we solve (4.1b). In this way, we map one superelement onto two processors.

4.2. Special communication strategy. In §3, we discussed how to construct and assemble the stiffness matrix and how to partition the assembled stiffness matrix into two kinds of blocks. Now we reconstruct and assemble the stiffness matrix so that we only need to assemble stiffness matrices locally (superelementwise) and communicate between neighbors. This is important on an N cube because communication between neighboring processors is much faster than between distant processors.

Let A be the assembled stiffness matrix for a superelement Ω_e with internal variables eliminated. See Fig. 4.1. A can be written as

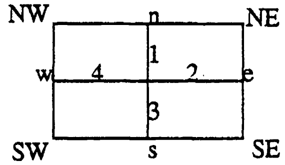

FIG. 4.1. *Superelement* Ω_e.

$$A = \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ A_{31} & A_{32} & A_{33} \end{bmatrix}. \tag{4.3}$$

In §3.2, we have discussed two ways of partitioning A.

For BLOCK1, each block of matrix A is chosen such that

A_{11} corresponds to all side variables of sides 1,2,n,e;

A_{22} corresponds to all vertex variables;

A_{33} corresponds to all side variables of sides 3,4,s,w.

For BLOCK2, each block of matrix A is chosen such that

A_{11} corresponds to side variables of sides 1,2,n,e of order $\leq p-1$;

A_{22} corresponds to all vertex variables and pth order side variables;

A_{33} corresponds to side variables of sides 3,4,s,w of order $\leq p-1$.

$$A = \left[\begin{array}{c|c|c} A_{11} & A_{12} & A_{13} \\ \hline A_{21} & A_{22} & A_{23} \\ \hline A_{31} & A_{32} & A_{33} \end{array}\right] = \left[\begin{array}{c|cc|ccc} A'_{11} & A'_{12} & A'_{13} & A'_{14} & A'_{15} & A'_{16} \\ \hline A'_{21} & A'_{22} & A'_{23} & A'_{24} & A'_{25} & A'_{26} \\ A'_{31} & A'_{32} & A'_{33} & A'_{34} & A'_{35} & A'_{36} \\ \hline A'_{41} & A'_{42} & A'_{43} & A'_{44} & A'_{45} & A'_{46} \\ A'_{51} & A'_{52} & A'_{53} & A'_{54} & A'_{55} & A'_{56} \\ A'_{61} & A'_{62} & A'_{63} & A'_{64} & A'_{65} & A'_{66} \end{array}\right]. \tag{4.4}$$

Now we reconstruct A in the following way. Instead of assembling the global stiffness matrix, we assemble the stiffness matrix of each superelement. So, for each superelement, the assembled stiffness matrix takes the form BLOCK1, where

A'_{11} corresponds to all side variables of sides 1,2 and boundary n,e;

A'_{22} corresponds to all vertex variables excluding SW;

A'_{33} corresponds to vertex variables on SW;

A'_{44} corresponds to all side variables of sides 3 and 4;

A'_{55} corresponds to side variables of boundary w;

A'_{66} corresponds to side variables of boundary s.

From (4.4) we see that A'_{11} is the same as A_{11}, A_{22} is broken into two parts with diagonals A'_{22} and A'_{33}, and A_{33} is broken into three parts with diagonals A'_{44}, A'_{55}, and A'_{66}. Let $A'_{33}=0$, $A'_{55}=0$, and $A'_{66}=0$. We have the new stiffness matrix for the superelement

$$A' = \left[\begin{array}{c|cc|ccc} A'_{11} & A'_{12} & A'_{13} & A'_{14} & A'_{15} & A'_{16} \\ \hline A'_{21} & A'_{22} & A'_{23} & A'_{24} & A'_{25} & A'_{26} \\ A'_{31} & A'_{32} & 0 & A'_{34} & A'_{35} & A'_{36} \\ \hline A'_{41} & A'_{42} & A'_{43} & A'_{44} & A'_{45} & A'_{46} \\ A'_{51} & A'_{52} & A'_{53} & A'_{54} & 0 & A'_{56} \\ A'_{61} & A'_{62} & A'_{63} & A'_{64} & A'_{65} & 0 \end{array}\right]. \tag{4.5}$$

Let

$$A' = D_1 - E_1 = D_2 - E_2, \tag{4.6}$$

where

$$D_1 = \left[\begin{array}{ccc|ccc} A'_{11} & A'_{12} & A'_{13} & 0 & 0 & 0 \\ A'_{21} & A'_{22} & A'_{23} & 0 & 0 & 0 \\ A'_{31} & A'_{32} & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & A'_{44} & A'_{45} & A'_{46} \\ 0 & 0 & 0 & A'_{54} & 0 & A'_{56} \\ 0 & 0 & 0 & A'_{64} & A'_{65} & 0 \end{array}\right], \tag{4.7}$$

$$D_2 = \left[\begin{array}{c|ccccc} A'_{11} & 0 & 0 & 0 & 0 & 0 \\ \hline 0 & A'_{22} & A'_{23} & A'_{24} & A'_{25} & A'_{26} \\ 0 & A'_{32} & 0 & A'_{34} & A'_{35} & A'_{36} \\ 0 & A'_{42} & A'_{43} & A'_{44} & A'_{45} & A'_{46} \\ 0 & A'_{52} & A'_{53} & A'_{54} & 0 & A'_{56} \\ 0 & A'_{62} & A'_{63} & A'_{64} & A'_{65} & 0 \end{array}\right]. \tag{4.8}$$

Similarly, we define E_1 and E_2.

Using the two-leaf TD method we have

$$D_1 x^{k+1} = E_1 x^k + b, \tag{4.9}$$

$$D_2 x^{k+2} = E_2 x^{k+1} + b, \tag{4.10}$$

where

$$x^k = [x_1^k, x_2^k, x_3^k, x_4^k, x_5^k, x_6^k]^T;$$

i.e.,

$$\left[\begin{array}{ccc|ccc} A'_{11} & A'_{12} & A'_{13} & 0 & 0 & 0 \\ A'_{21} & A'_{22} & A'_{23} & 0 & 0 & 0 \\ A'_{31} & A'_{32} & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & A'_{44} & A'_{45} & A'_{46} \\ 0 & 0 & 0 & A'_{54} & 0 & A'_{56} \\ 0 & 0 & 0 & A'_{64} & A'_{65} & 0 \end{array}\right] \left[\begin{array}{c} x_1 \\ x_2 \\ x_3 \\ \hline x_4 \\ x_5 \\ x_6 \end{array}\right]^{(k+1)}$$

$$= \left[\begin{array}{ccc|ccc} 0 & 0 & 0 & A'_{14} & A'_{15} & A'_{16} \\ 0 & 0 & 0 & A'_{24} & A'_{25} & A'_{26} \\ 0 & 0 & 0 & A'_{34} & A'_{35} & A'_{36} \\ \hline A'_{41} & A'_{42} & A'_{43} & 0 & 0 & 0 \\ A'_{51} & A'_{52} & A'_{53} & 0 & 0 & 0 \\ A'_{61} & A'_{62} & A'_{63} & 0 & 0 & 0 \end{array}\right] \left[\begin{array}{c} x_1 \\ x_2 \\ x_3 \\ \hline x_4 \\ x_5 \\ x_6 \end{array}\right]^{(k)} + b, \tag{4.11a}$$

$$\left[\begin{array}{c|ccccc} A'_{11} & 0 & 0 & 0 & 0 & 0 \\ \hline 0 & A'_{22} & A'_{23} & A'_{24} & A'_{25} & A'_{26} \\ 0 & A'_{32} & 0 & A'_{34} & A'_{35} & A'_{36} \\ 0 & A'_{42} & A'_{43} & A'_{44} & A'_{45} & A'_{46} \\ 0 & A'_{52} & A'_{53} & A'_{54} & 0 & A'_{56} \\ 0 & A'_{62} & A'_{63} & A'_{64} & A'_{65} & 0 \end{array}\right] \left[\begin{array}{c} x_1 \\ \hline x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{array}\right]^{(k+2)}$$

$$\text{(4.11b)} \qquad = \left[\begin{array}{c|ccccc} 0 & A'_{12} & A'_{13} & A'_{14} & A'_{15} & A'_{16} \\ \hline A'_{21} & 0 & 0 & 0 & 0 & 0 \\ A'_{31} & 0 & 0 & 0 & 0 & 0 \\ A'_{41} & 0 & 0 & 0 & 0 & 0 \\ A'_{51} & 0 & 0 & 0 & 0 & 0 \\ A'_{61} & 0 & 0 & 0 & 0 & 0 \end{array}\right] \left[\begin{array}{c} x_1 \\ \hline x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{array}\right]^{(k+1)} + b.$$

In (4.11a,b), each matrix block is mapped onto a processor. After one iteration, we send x_5, which is associated with boundary w, to the neighbor processors on the west; send x_6, which is associated with boundary s, to the neighbors on the south; send x_3, which is associated with vertex SW, to the neighbors on the south, west, and southwest. Meanwhile, Ω_e receives values from the neighbors on the north, east, and northeast. (See Fig. 4.2.) Then we communicate values between the two processors associated with the same superelement, then update. In this way, we avoid assembly of the global stiffness matrix and global communication. Intuitively speaking, the west boundary w is a common boundary of superelement Ω_e and its superelement to the west. So the variables x_5, which are the variables associated with boundary w, depend on both superelement Ω_e and its western superelement. After each iteration, superelement Ω_e sends x_5 to its western superelement. The western superelement will add the received x_5 to its x_1 which is associated with the western node of Ω_e, i.e., w.

For BLOCK2, we reconstruct the local stiffness for a superelement as follows:

$$\text{(4.12)} \quad A = \left[\begin{array}{c|c|c} A_{11} & A_{12} & A_{13} \\ \hline A_{21} & A_{22} & A_{23} \\ \hline A_{31} & A_{32} & A_{33} \end{array}\right] = \left[\begin{array}{c|cccc|ccc} A'_{11} & A'_{12} & A'_{13} & A'_{14} & A'_{15} & A'_{16} & A'_{17} & A'_{18} \\ \hline A'_{21} & A'_{22} & A'_{23} & A'_{24} & A'_{25} & A'_{26} & A'_{27} & A'_{28} \\ A'_{31} & A'_{32} & A'_{33} & A'_{34} & A'_{35} & A'_{36} & A'_{37} & A'_{38} \\ A'_{41} & A'_{42} & A'_{43} & A'_{44} & A'_{45} & A'_{46} & A'_{47} & A'_{48} \\ A'_{51} & A'_{52} & A'_{53} & A'_{54} & A'_{55} & A'_{56} & A'_{57} & A'_{58} \\ \hline A'_{61} & A'_{62} & A'_{63} & A'_{64} & A'_{65} & A'_{66} & A'_{67} & A'_{68} \\ A'_{71} & A'_{72} & A'_{73} & A'_{74} & A'_{75} & A'_{76} & A'_{77} & A'_{78} \\ A'_{81} & A'_{82} & A'_{83} & A'_{84} & A'_{85} & A'_{86} & A'_{87} & A'_{88} \end{array}\right],$$

where

A'_{11} corresponds to all side variables of sides 1,2, n,e of order $\leq p - 1$;

A'_{22} corresponds to all vertex variables excluding SW, and the pth-order side variables of sides 1, 2, 3, 4, n, and e;

A'_{33} corresponds to vertex variables on SW;

A'_{44} corresponds to pth-order side variables on side w;

A'_{55} corresponds to pth-order side variables on side s;

A'_{66} corresponds to all side variables on 3,4 of order $\leq p - 1$;

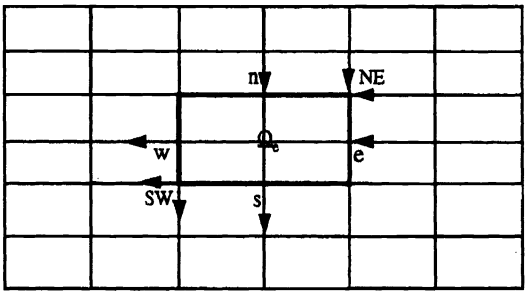

FIG. 4.2. *Local communication.*

A'_{77} corresponds to all side variables on w of order $\leq p-1$;
A'_{88} corresponds to all side variables on s of order $\leq p-1$.
Now we let $A'_{33}=0$, $A'_{44}=A'_{55}=0$, $A'_{77}=A'_{88}=0$; stiffness matrix A is changed to

$$A' = \left[\begin{array}{c|cccc|ccc} A'_{11} & A'_{12} & A'_{13} & A'_{14} & A'_{15} & A'_{16} & A'_{17} & A'_{18} \\ \hline A'_{21} & A'_{22} & A'_{23} & A'_{24} & A'_{25} & A'_{26} & A'_{27} & A'_{28} \\ A'_{31} & A'_{32} & 0 & A'_{34} & A'_{35} & A'_{36} & A'_{37} & A'_{38} \\ A'_{41} & A'_{42} & A'_{43} & 0 & A'_{45} & A'_{46} & A'_{47} & A'_{48} \\ A'_{51} & A'_{52} & A'_{53} & A'_{54} & 0 & A'_{56} & A'_{57} & A'_{58} \\ \hline A'_{61} & A'_{62} & A'_{63} & A'_{64} & A'_{65} & A'_{66} & A'_{67} & A'_{68} \\ A'_{71} & A'_{72} & A'_{73} & A'_{74} & A'_{75} & A'_{76} & 0 & A'_{78} \\ A'_{81} & A'_{82} & A'_{83} & A'_{84} & A'_{85} & A'_{86} & A'_{87} & 0 \end{array}\right]. \tag{4.13}$$

Similarly, we define D_1, D_2, E_1, E_2; then using two-leaf TD method we have

$$D_1 x^{k+1} = E_1 x^k + b, \tag{4.14}$$

$$D_2 x^{k+2} = E_2 x^{k+1} + b, \tag{4.15}$$

where

$$x^k = [x_1^k, x_2^k, x_3^k, x_4^k, x_5^k, x_6^k, x_7^k, x_8^k]^T.$$

4.3. Performance analysis. Our performance metric for a parallel computer is the *speedup* factor S associated with a particular calculation. The way *speedup* is defined varies widely. The following are two common formulations for speedup:

$$S_N(p) = \frac{T_{seq}(p)}{T_N(p)}, \tag{4.16}$$

$$S_N(p) = \frac{T_1(p)}{T_N(p)}, \tag{4.17}$$

where $T_N(p)$ is the time required to solve a problem in parallel on N processors, $T_1(p)$ is the time required to execute a parallel program on one processor, while T_{seq} is the time required to execute an equivalent sequential program on one processor.

It is unrealistic to use equation (4.17), since $T_1(p)$ includes all the overhead of parallel computing. We choose equation (4.16) to calculate the speedup.

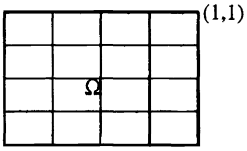

FIG. 5.1. *Model problem* 1.

Note. (1) Speedup is dependent on both the number of processors used and the size of the problem to be solved on the parallel computer. The polynomial degree p determines the size of the problem.

(2) The sequential computing time T_{seq} is measured by running the program (no parallel constructs at all) on a single processor. If T_{seq} cannot be measured directly, then it can usually be found by running a small problem on one processor and then extrapolating to the real problem by using a predicted or measured dependence on problem size.

5. Numerical results and comparisons. In previous sections, we discussed the p-version of the finite element method and how to use this method to discretize elliptic partial differential equations; we then introduced a new type of iterative method, the TD method, to solve the system of linear equations generated by the p-version of the finite element method on a parallel computer. To determine whether the TD method converges faster than the classical iterative methods and CG method, we use numerical experiments for solving two model problems. These experiments demonstrate how efficient the TD method is, compared with other classical iterative methods.

5.1. Model problem 1: Rectangular domain, near singular solution. Now we discuss a model problem, a Laplace equation on a rectangular domain with a near singular solution. Consider the equation

$$\Delta u = 0 \quad \text{on} \quad \Omega = [0,1] \times [0,1], \tag{5.1}$$

with

$$\frac{\partial u}{\partial n}(x,0) = \frac{\partial u}{\partial n}(0,y) = 0, \tag{5.2}$$

$$\frac{\partial u}{\partial n}(X,1) = g_1(x), \tag{5.3}$$

$$\frac{\partial u}{\partial n}(1,y) = g_2(y), \tag{5.4}$$

where $g_1(x)$ and $g_2(y)$ are determined so that the solution is

$$u(x,y) = \operatorname{Re}[(a^2+z^2)^{-1} + (a^2-z^2)^{-1}] - 2a, \tag{5.5}$$

with constant $a > 1$ and $z = x + iy$. This example is taken from Babuska et al. [4]. See Fig. 5.1.

Note that the solution u is a harmonic function with a singularity at $z = \pm a, \pm ia$. The solution becomes less smooth as $a \to 1$. This is a typical model problem in structural mechanics, where the solution has a singularity in a known location. The parameter a characterizes the regularity of the solution. We solve this problem for $a = 1.05$.

We divide the domain into four superelements (see Fig. 5.2); then we solve it with eight processors. Using the p-version approximation (the finite element computations were made

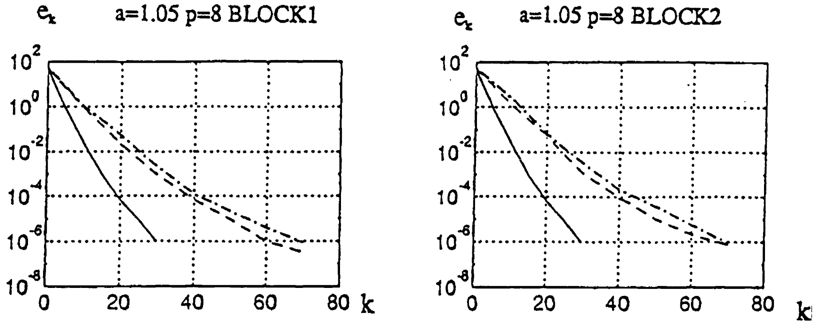

FIG. 5.2. *Convergence of iterative methods.*

with the commercial code MSC/PROBE), we generate the elemental stiffness matrix and load vector. We eliminate the internal variables elementwise; then we assemble the stiffness matrix and the load vector. We solve the following system of the linear equation

$$Ax = b, \tag{5.6}$$

where A and b are the assembled stiffness matrix and load vector, respectively.

We choose initial value randomly between 0 and 1, and the iteration is stopped when $\|x^k - x\| \leq 10^{-6}$. The true solution x is achieved when the iteration satisfies $\|x^{k+2} - x^k\| \leq 10^{-12}$. First we compare the number of iterations of the RTD, two-leaf TD, CG, Jacobi (J), GS, and SOR methods for $p = 8$. Table 5.1 shows the results of the number of iterations for $p = 8$ using partition BLOCK1 and BLOCK2.

Remark 5.1. From Table 5.1 we see that both the RTD and the TD methods converge much faster than the classical iterative method and about 30% to 60% faster than the CG method. The RTD method converges 30% to 40% faster than the nonrecursive TD method.

Table 5.2 shows he results of the number of iterations of the PCG, PTD, and PRTD methods for different partitions. Compared with the results in Table 5.1, we see that the preconditioned methods converge faster than unpreconditioned methods. The PRTD method has the fastest convergence rate among these iterative methods. It seems that when we use more superelements, BLOCK2 will accelerate the convergence slightly compared with BLOCK1 but at the high cost of the communication and programming complexity. We suggest that for a small number of superelements, BLOCK2 should be used to achieve best performance; for a large number of superelements, BLOCK1 should be used.

Figure 5.2 presents the convergence of the iterative methods: the RTD method (solid line), the TD method (dashed line), and the CG method (dashed-dotted line) for different partitions.

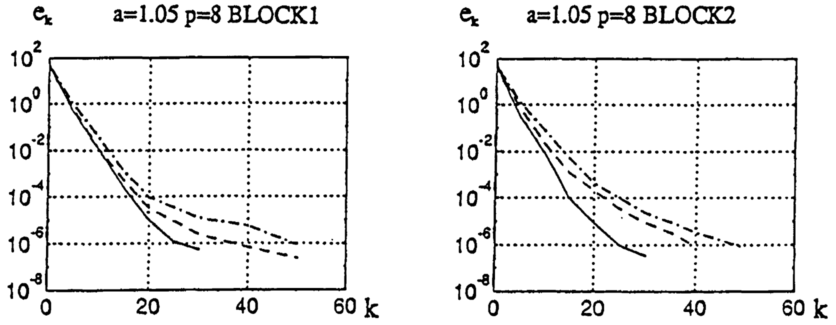

FIG. 5.3. *Convergence of iterative methods (preconditioned).*

TABLE 5.3
Comparison of spectral radius.

a	TD(B1)	PTD(B1)	RTD(B1)	PRTD(B1)	TD(B2)	PTD(B2)	RTD(B2)	PRTD(B2)
1.05	0.741	0.708	0.641	0.580	0.741	0.699	0.631	0.551

Figure 5.3 shows the convergence of the PRTD method (solid line), the PTD method (dashed line), and the PCG method (dashed-dotted line) for different partitions. The left figures of both Figs. 5.2 and 5.3 are BLOCK1 case, and right figures are BLOCK2 case. e_k is the error; k is the number of iterations. Comparing Fig. 5.3 with Fig. 5.2, it is clear that the preconditioning accelerates the convergence. RTD converges faster than TD and CG; PRTD converges faster than PTD and PCG. BLOCK2 improves the convergence, but communication is expensive. This will be shown in performance analysis.

Table 5.3 shows the spectral radius of the iteration matrices for TD, PTD, RTD, and PRTD for different partitions. For TD, the iteration matrix is $G_1 = D_2^{-1}E_2D_1^{-1}E_1$ (see equation (3.22)); for PTD, the iteration matrix is $\tilde{G}_1 \equiv G_1(I - M^{-1}A)$. (See equation (3.22).) When we use RTD and PRTD, we use equation $\rho(A) \approx \frac{e_{k+1}}{e_k}$ to compute the spectral radius.

Remark 5.2. Table 5.3 shows that the PRTD method has the smallest spectral radius among those iterative methods in the table. BLOCK2 improves the spectral radius a little but not significantly, but requires more time to communicate among each processors. The initial error e^0 increases because x^0 is chosen between 0 and 1, whereas the exact x is of larger magnitude. Therefore more iterations are needed to achieve the given accuracy.

In the performance analysis, first we present the execution time required for each iterative method for both BLOCK1 and BLOCK2. Both global communication and local communication strategies are used in our numerical experiment. The local communication strategy, as introduced in 4.3, is also used in the CG method. Then we implement the various algorithms on 2, 4, 8, 16, and 32 processors and compute the speedup ratios of these applications. In the following table, L refers to the local communication strategy, and G refers to the global communication strategy.

Tables 5.4 and 5.5 show the execution times of the TD, PTD, RTD, and PRTD methods running on 16 processors for different partitions for both global communication strategy and local communication strategy. The data shows that it takes more time to use BLOCK2 than to use BLOCK1. Local communication strategy has greatly reduced the communication time (more than 50%).

Figure 5.4 shows the speedup of the RTD method (solid line), the TD method (dashed-dotted line), and the CG method (dashed line) achievable for different choices of parameters and communication strategy. The left-hand side of the figure shows the speedup ratio using

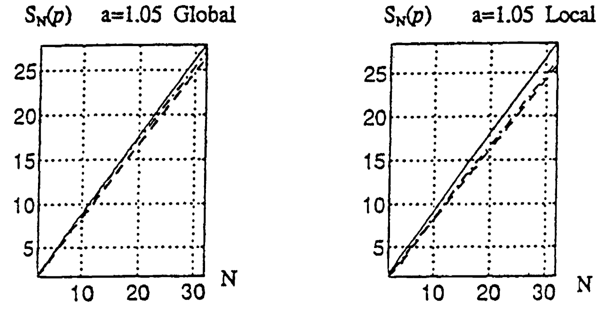

FIG. 5.4. *Speedup ratio.*

the global communication strategy, and the local communication strategy is shown on the right-hand side. It shows that the local communication strategy increases the speedup ratios. In most cases, the RTD method has the best performance.

From the results of model problem 1, it is clear that the PRTD method is the winner among the various iterative methods we discussed both on convergence rate and communication time. The preconditioner we used accelerates the convergence of the CG, TD, and RTD methods. The local communication strategy saves almost 50% of the communication time required for the global communication. BLOCK2 requires more communication than BLOCK1 for the multiple superelements case.

Similar results have been obtained for $p = 6$, $a = 1.5, 1.1, 1.05$, and for $p = 8$, $a = 1.5, 1.1$.

5.2. Model problem 2: L-shaped domain problem. The second model problem is a Poisson equation on an L-shaped domain. Consider the model problem, a two-dimensional Poisson equation

$$-\Delta u = f \quad \text{in } \Omega \tag{5.7}$$

with boundary conditions

$$\begin{aligned} &u = 0 \quad \text{on } \Gamma^2, \Gamma^3,\\ &\frac{\partial u}{\partial n} = 0 \quad \text{on } \Gamma^1, \Gamma^4,\\ &\frac{\partial u}{\partial n} = 1 \quad \text{on } \Gamma^5, \Gamma^6. \end{aligned}$$

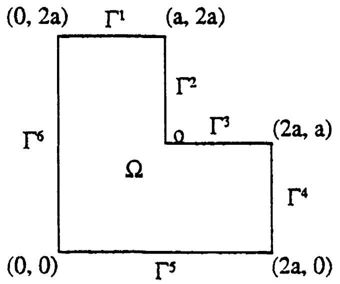

FIG. 5.5. *Model problem* 2.

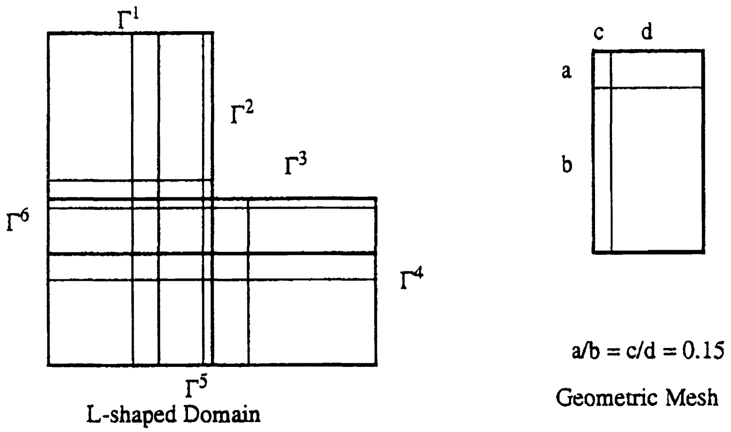

FIG. 5.6. *Mesh refinement.*

Assume $f = 0$; the exact solution is

$$u_0(r, \theta) = \sum_{k=1}^{\infty} a_k r^{(\frac{2}{3})k} \sin\left(\frac{2}{3}\right) k\theta. \tag{5.8}$$

From the exact solution we know that there is a singularity at point O. (See Fig. 5.5.) So we use a geometric mesh (see [2]) to divide the L-shaped domain into eight superelements which consist of 32 elements. (See Fig. 5.6.) We use the p-version finite element method discretization of the partial differential equation. The finite element computations were made with a test code called PEGASYS, which is under development by Engineering Software Research and Development, Inc. After we generate the elemental stiffness matrices and load vectors, we eliminate the internal unknowns, then assemble the elemental stiffness matrices into one global stiffness. We are now solving the system of linear equations

$$Ax = b, \tag{5.9}$$

where A is the assembled stiffness matrix, and b is the assembled load vector. To solve equation (5.9), we again use two kinds of communications: global communication, which communicates among all the processors, and local communication, which assembles stiffness matrices only in each superelement and communicates through its neighbors. Since the classical iterative methods, Jacobi, GS, and SOR, take more than 500 iterations (the limit we set)

to solve the systems of linear equation (5.9), we only use the TD, RTD, CG, PTD, PRTD, and the PCG methods to solve (5.9). We focus on BLOCK1 which is efficient for multiple superelements as seen in problem 2.

First we compare the number of iterations of the following methods: the CG, TD, RTD, PCG, PTD, and PRTD methods. The eight superelements are mapped onto 16 processors. The initial values are chosen randomly between 0 and 1; the stopping condition is $\|x^k - x\| \leq 10^{-6}$.

Table 5.6 shows the number of iterations in the RTD, PTD, TD, PTD, CG, and PCG methods for different values of p. From Table 5.6 we see that, for the L-shaped domain problem, TD methods converge faster than CG methods; PTD methods converge faster than PCG methods with the same preconditioner. Among the above methods we used, the PRTD method is the fastest convergence iterative method.

Table 5.7 shows the spectral radius of iteration matrices of the RTD, PRTD, TD, and PTD methods. From Table 5.7, the PRTD method has the smallest spectral radius among the above-mentioned four iterative methods. Our preconditioner accelerates the convergence of TD and RTD.

Tables 5.8 and 5.9 show the results of comparison of the execution time of TD, PTD, RTD, and PRTD for different values of p, using both local communication strategy and global communication strategy. It shows that PRTD has the best performance. Compared with the

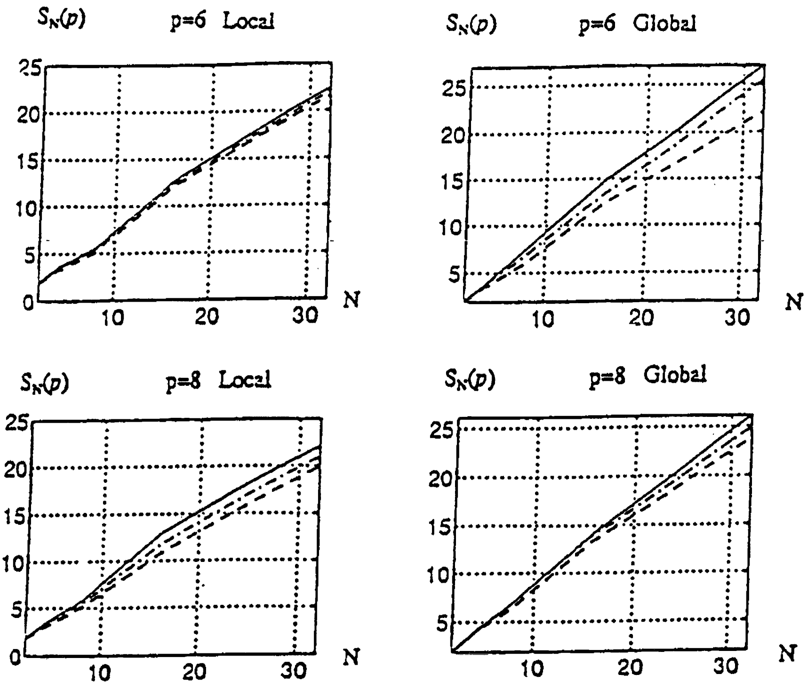

FIG. 5.7. *Speedup ratios.*

global communication strategy, local communication strategy saves more than 50% of communication time. L refers to local communication strategy; G refers to global communication strategy.

Now we apply the above iterative methods on 2^i, $i = 1, 2, 3, 4, 5$ processors and see the speedup ratio for each iterative method. Both global communication strategy and local communication strategy will be discussed. Figure 5.7 shows the speedups achievable for the RTD method (solid line), the TD method (dashed-dotted line), and the CG method (dashed line). Figure 5.8 shows the speedups achievable for the PRTD method, the PTD method (dashed-dotted line), and the PCG method (dashed line). $S_N(p)$ is the speedup ratio we defined in equation (4.16), and N is the number of processors.

From the numerical results of model problem 2 it is clear that the PRTD method with local communication strategy has the best performance in both computation and communication. The preconditioner accelerates the convergence for the CG, TD, and RTD methods. The PTD method converges faster than the PCG method with the same preconditioner. Local communication strategy saves almost two-thirds of the communication time required for the global communication.

6. Conclusions. Based on the numerical results from the two sample problems it is clear that the PRTD method using local communication strategy has the fastest convergence rate and best performance among the various iterative methods we discussed. The TD method converges faster than the CG method both with and without preconditioning. Local communication strategy saves not only the communication time but also the time required to assemble the global stiffness matrix and load vector. Superelement structure makes the TD method easy to map onto parallel computers (as shown here) and achieve high efficiency, i.e., computational load balance.

MULTIGRID METHODS FOR SYMMETRIC POSITIVE DEFINITE BLOCK TOEPLITZ MATRICES WITH NONNEGATIVE GENERATING FUNCTIONS[*]

GIUSEPPE FIORENTINO[†] AND STEFANO SERRA[‡]

Abstract. In this paper we introduce a generalized multigrid method for solving linear systems $\mathbf{T}_{N,M}\mathbf{x} = \mathbf{b}$ where $\mathbf{T}_{N,M} \in \Re^{NM \times NM}$ is a symmetric block Toeplitz matrix with symmetric Toeplitz blocks. We use a special choice of the projection operator whose coefficients simply depend on the generating functions associated with the proposed class of matrices. This choice leads to iterative methods with convergence rates independent of the Euclidean condition number $\kappa_2(\mathbf{T}_{N,M})$ and of the dimension of the involved matrices. The total arithmetic cost is $O(NM\log(NM))$ for dense matrices and $O(NM)$ for band matrices with band blocks; in the PRAM model only $O(\log(NM))$ parallel steps are required. This algorithm is therefore competitive with the preconditioned conjugate gradient methods proposed by Chan and Jin [*SIAM J. Sci. Statist. Comput.*, 13 (1992), pp. 1218–1235], Ku and Kuo [*SIAM J. Sci. Statist. Comput.*, 13 (1992), pp. 948–966], Di Benedetto [*SIAM J. Sci. Comput.*, 17 (1996)], and Serra [*BIT*, 34 (1994), pp. 579–594] for dense matrices and improves those results for band block Toeplitz matrices with band Toeplitz blocks.

Key words. Toeplitz matrices, multigrid, iterative methods

AMS subject classification. 65F10

1. Introduction.

In this paper we introduce and discuss a generalized multigrid method [H1, H2] for the solution of linear systems associated with positive definite symmetric block Toeplitz matrices with symmetric Toeplitz blocks.

We consider the solution of the linear system of the form

$$\mathbf{T}_{N,M}\mathbf{x} = \mathbf{b}, \tag{1}$$

where

$$\mathbf{T}_{N,M} = \begin{bmatrix} \mathbf{T}_0 & \mathbf{T}_1 & \cdots & \mathbf{T}_{N-1} \\ \mathbf{T}_1 & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \mathbf{T}_1 \\ \mathbf{T}_{N-1} & \cdots & \mathbf{T}_1 & \mathbf{T}_0 \end{bmatrix} \quad \text{and} \quad \mathbf{T}_i = \begin{bmatrix} a_{i,0} & a_{i,1} & \cdots & a_{i,M-1} \\ a_{i,1} & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & a_{i,1} \\ a_{i,M-1} & \cdots & a_{i,1} & a_{i,0} \end{bmatrix}, \tag{2}$$

with coefficients $a_{j,k}$ related to a continuous nonnegative function $a(x, y)$ as follows:

$$a_{j,k} = \frac{1}{\pi^2}\iint_Q a(x, y)e^{-i(jx+ky)}dxdy, \qquad Q = [0, \pi] \times [0, \pi].$$

The function $a(x, y)$ is called the generating function of $\mathbf{T}_{N,M}$. All the eigenvalues of $\mathbf{T}_{N,M}$ belong to the range of $a(x, y)$ and, moreover (see [S2]), we have

$$\lim_{N,M\to\infty} \lambda_{\max}(\mathbf{T}_{N,M}) = \max_Q a(x, y) \quad \text{and} \quad \lim_{N,M\to\infty} \lambda_{\min}(\mathbf{T}_{N,M}) = \min_Q a(x, y).$$

Consequently, when the function $a(x, y)$ is nonnegative and vanishes at some point of Q, we find that $\mathbf{T}_{N,M}$ is ill conditioned for any value of N and M. More precisely, the Euclidean condition number of $\mathbf{T}_{N,M}$, as a function of the dimensions, is unbounded:

$$\lim_{N,M\to\infty} \kappa_2(\mathbf{T}_{N,M}) = +\infty.$$

Thus, unless some preconditioning is used, all classic iterative methods are very slow.

The state of the art in the most recent literature is the following.

(a) *Direct methods*:

(1) *Fast methods* with arithmetic cost of $O(N^2M^3)$ [Tr],

(2) *Superfast methods* with arithmetic cost of $O(NM^3\log^2(N))$ [Mu, Ri].

These methods are not suitable for implementation in a parallel model of computation since they are intrinsically sequential; this problem is not encountered using iterative methods.

(b) *Preconditioned conjugate gradient methods*:

(1) Using a preconditioner in the two-level circulant algebra, [Da, KK], and [CJ] obtain an iterative method with an overall arithmetic cost of $O(NM(N+M)\log(NM))$, but in actual computations the cost is generally $O(NM\log(NM))$, i.e., the cost of a bivariate fast Fourier transform [BP].

(2) The same result is reported in [DB] where preconditioners have been chosen in the two-level τ algebra [BC].

(3) A cost of $O(NM\log(NM))$ is proved in [S2] by means of block band Toeplitz preconditioners with band blocks.

In these cases, a parallel cost of $O(\log(NM))$ is found in practice; for b.3 it is also proved.

In this paper, at first we devise a multigrid algorithm for block-τ systems; then we extended it to the Toeplitz case. The main features are the following:

- The overall arithmetic cost is $O(NM\log(NM))$ in the sequential model and $O(\log(NM))$ in the parallel case. Moreover, when $\mathbf{T}_{N,M}$ is a band block Toeplitz matrix with band blocks, our algorithm achieves a linear cost of $O(NM)$ arithmetic operations, while methods b.1, b.2, and b.3 lead to the same arithmetic cost of $O(NM\log(NM))$. This feature makes our method also profitable as an efficient preconditioner solver for methods like b.3.
- The choice of a projector, the most delicate step in a multigrid scheme, is straightforward in our method since, in this case, the projector simply depends on some properties of the generating function $a(x,y)$.

The main idea is to define a projector operator in terms of the bivariate function associated with the matrix; in fact, we only require the knowledge of the zeros of $a(x,y)$ and their multiplicity to devise a rapidly convergent method.

The paper is organized as follows: in §2 we introduce the two-grid method; in §3 we describe the τ algebra [BC], its connections with Toeplitz matrices, and a special kind of two-grid method (TGM) for these matrices.

In §4 we perform a structural analysis of the two-grid iteration matrix that, in §5, allows us to devise a class of projector operators which guarantee a convergence rate independent of the size of the related linear system.

In §6 we exploit the close spectral similarity of τ and Toeplitz matrices applying our multigrid technique to Toeplitz systems. All numerical results reported in §6 confirm the effectiveness of the method.

2. Overview of a TGM. Given an $n\times n$ linear system $\mathbf{Ax}=\mathbf{b}$, an iterative method for its solution

$$\mathbf{z}^{(i+1)}=\mathbf{Sz}^{(i)}+\mathbf{c}=\mathcal{S}_{\mathbf{c}}(\mathbf{z}^{(i)}), \tag{3}$$

and a $k\times n$ $(k<n)$ matrix $\mathbf{p}$, a general TGM is defined by the following steps [H1, Gr]:

Step 1. $\mathbf{x}^{(i,\sigma)}=\mathcal{S}_{\mathbf{c}}^{\sigma}(\mathbf{x}^{(i)})$,

Step 2. $\mathbf{d}_n=\mathbf{Ax}^{(i,\nu)}-\mathbf{b}$,

Step 3. $\mathbf{d}_k=\mathbf{pd}_n$,

Step 4. $\mathbf{A}_k = \mathbf{pAp}^T$,
Step 5. Solve $\mathbf{A}_k\mathbf{y} = \mathbf{d}_k$,
Step 6. $\mathbf{x}^{(i+1)} = \mathbf{x}^{(i,\sigma)} - \mathbf{p}^T\mathbf{y}$.

Step 1, the "smoothing iteration" in the literature, consists of σ sweeps of the iterative method (3). For a broad class of methods like (3), after a few iterations the error $\mathbf{d}_n = \mathbf{Ax}^{(i,\sigma)} - \mathbf{b}$ is typically confined in a subspace where the method converges slowly. When this subspace is known, it is possible to accelerate the convergence by means of a "coarse grid correction" that computes and subtracts from $\mathbf{x}^{(i,\sigma)}$ an approximation of the error $\mathbf{d}_n$.

Steps 2–6 define this coarse grid correction: the error is first multiplied by the rectangular $k \times n$ matrix $\mathbf{p}$ to obtain the projected error $\mathbf{d}_k = \mathbf{pd}_n$; then a "correction" is calculated on a k-dimensional subspace strongly related to the subspace where (3) is slowly contractive.

The global iteration matrix of a TGM is therefore given by

$$TGM(\mathbf{S}, \mathbf{p}) = \left[\mathbf{I}_n - \mathbf{p}^T(\mathbf{pAp}^T)^{-1}\mathbf{pA}\right]\mathbf{S}^\sigma, \tag{4}$$

where the expression within brackets is related to the coarse grid correction while the rightmost matrix comes from the σ sweeps of (3).

In order to define a fast generalized TGM for block Toeplitz problems, we need to find a matrix $\mathbf{p}$ that better exploits the spectral features of $\mathbf{A}$ and $\mathbf{S}$. The objective is to arrive at a spectral radius of the matrix TGM(**S**,**p**) smaller than 1 and independent of the dimension n.

3. The TGM for τ matrices. In this section we introduce a generalized TGM for block τ matrices, but first we recall some important facts about τ matrices and their strong relations with the Toeplitz class.

The two-level algebra $\tau_{N,M}$ is generated by the matrices $\mathbf{H}_n \otimes \mathbf{I}_M$ and $\mathbf{I}_N \otimes \mathbf{H}_M$, where

$$\mathbf{H}_k = \begin{bmatrix} 0 & 1 & & O \\ 1 & \ddots & \ddots & \\ & \ddots & \ddots & 1 \\ O & & 1 & 0 \end{bmatrix} \in \Re^{k\times k}$$

and $\otimes$ denotes the Kronecker product defined by $[a_{ij}]_{ij} \otimes \mathbf{B} = [a_{ij}\mathbf{B}]_{ij}$.

Since $\mathbf{H}_k$ is diagonalized by

$$\mathbf{H}_k = 2\mathbf{F}_k \begin{bmatrix} \cos(x_1^{(k)}) & & O \\ & \ddots & \\ O & & \cos(x_k^{(k)}) \end{bmatrix} \mathbf{F}_k, \quad \text{where } x_i^{(k)} = \frac{i\pi}{k+1},$$

and $\mathbf{F}_k = [\mathbf{f}_1 | \dots | \mathbf{f}_k]$ with $\mathbf{f}_i = \sqrt{\frac{2}{k+1}}\,[\sin\frac{ij\pi}{k+1}]_{j=1}^k$, it follows that the eigenvectors of any $\tau_{N,M}$ matrix are given by the columns of $\mathbf{F}_N \otimes \mathbf{F}_M$.

There is a strong link between $\tau_{N,M}$ and the Toeplitz class; namely, given the Toeplitz matrix

$$\mathbf{T} = \begin{bmatrix} a_0 & a_1 & \cdots & a_{k-1} \\ a_1 & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & a_1 \\ a_{k-1} & \cdots & a_1 & a_0 \end{bmatrix}$$

and the Hankel operator

$$H(\mathbf{T}) = \begin{bmatrix} a_2 & \cdots & a_{k-1} & 0 & 0 \\ \vdots & \cdot^{\cdot^{\cdot}} & \cdot^{\cdot^{\cdot}} & \cdot^{\cdot^{\cdot}} & 0 \\ a_{k-1} & \cdot^{\cdot^{\cdot}} & \cdot^{\cdot^{\cdot}} & \cdot^{\cdot^{\cdot}} & a_{k-1} \\ 0 & \cdot^{\cdot^{\cdot}} & \cdot^{\cdot^{\cdot}} & \cdot^{\cdot^{\cdot}} & \vdots \\ 0 & 0 & a_{k-1} & \cdots & a_2 \end{bmatrix},$$

a $\tau_{N,M}$ approximation $\mathbf{A}_{N,M}$ of $\mathbf{T}$ is obtained by the following two steps [DB]:

(1) for each block $\mathbf{T}_i$ in (2), define $\mathbf{A}_i = \mathbf{T}_i - H(\mathbf{T}_i)$ and

$$\tilde{\mathbf{T}} = \begin{bmatrix} \mathbf{A}_0 & \mathbf{A}_1 & \cdots & \mathbf{A}_{N-1} \\ \mathbf{A}_1 & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \mathbf{A}_1 \\ \mathbf{A}_{N-1} & \cdots & \mathbf{A}_1 & \mathbf{A}_0 \end{bmatrix};$$

(2) define $\mathbf{A}_{N,M} = \tilde{\mathbf{T}} - H(\tilde{\mathbf{T}})$ in terms of blocks.

The matrix $\mathbf{A}_{N,M} \in \tau_{N,M}$ is closely related to $\mathbf{T}_{N,M}$; in fact its eigenvalues $\alpha_{\mu,\nu}$ are obtained by sampling an approximation of the generating function of $\mathbf{T}_{N,M}$:

$$(5) \qquad \alpha_{\mu,\nu} = \mathrm{Trunc}(a, N-1, M-1)\big|_{(x_\mu^{(N)}, x_\nu^{(M)})},$$

where $\mathrm{Trunc}(a, p, q)$ is the bivariate trigonometric polynomial of degree p and q given by the first terms of the Fourier expansion of $a(x, y)$.

For the solution of the linear system $\mathbf{A}_{N,M}\mathbf{x} = \mathbf{b}$ we use the iterative method of the form

$$(6) \qquad \mathbf{x}^{(i+1)} = (\mathbf{I} - \mathbf{A}_{N,M}/\alpha)\mathbf{x}^{(i)} + \mathbf{b}/\alpha, \quad \text{where } \alpha = \max_{Q} a(x, y).$$

Since the Fourier transform is a linear operator and the iteration matrix $\mathbf{S}_{N,M} = \mathbf{I} - \mathbf{A}_{N,M}/\alpha$ of (6) is an affine transformation of $\mathbf{A}_{N,M}$, it follows that the generating function of $\mathbf{S}_{N,M}$ is given by $s(x, y) = 1 - a(x, y)/\alpha$. The value of $s(x, y)$ is therefore close to one when $a(x, y)$ is close to zero; consequently (6) is slowly convergent on the subspaces generated by the eigenvectors of $\mathbf{A}_{N,M}$ corresponding to eigenvalues close to zero.

We obtain an efficient algorithm introducing a TGM for which a suitable coarse grid correction takes care of the slowly convergent subspaces. The search for a fitting projector $\mathbf{p}$ will be solved in functional terms.

First we show how to obtain a projector from a $\tau_{N,M}$ matrix $\mathbf{P}_{N,M}$ generated by a generic function $p(x, y) \geq 0$. In the next sections we explain how to get a profitable function $p(x, y)$ to achieve a convergence rate independent of the dimension of the matrices.

Given $\mathbf{P}_{N,M}$, assuming $N = 2n + 1$ and $M = 2m + 1$, we set

$$(7) \qquad \mathbf{p} = \mathbf{K}_{N,M}\mathbf{P}_{N,M},$$

where $\mathbf{K}_{N,M}$ is the cutting matrix [FS] in two dimensions defined by

$$\mathbf{K}_{N,M} = \mathbf{K}_N \otimes \mathbf{K}_M = \begin{bmatrix} 0 & \mathbf{K}_M & 0 & \cdots & & & O \\ 0 & 0 & 0 & \mathbf{K}_M & 0 & \cdots & \\ & & & & \ddots & \ddots & \ddots \\ O & & & \cdots & 0 & \mathbf{K}_M & 0 \end{bmatrix} = [\Re^{m\times M}]^{n\times N}$$

with

$$\mathbf{K}_M = \begin{bmatrix} 0 & 1 & 0 & \cdots & & & & O \\ 0 & 0 & 0 & 1 & 0 & \cdots & & \\ & & & & \ddots & \ddots & \ddots & \\ O & & & & \cdots & 0 & 1 & 0 \end{bmatrix} \in \Re^{m\times M}.$$

In this way we easily obtain a two-grid iteration matrix like (4):

$$TGM(\mathbf{S},\mathbf{p}) \equiv [\mathbf{I} - \mathbf{p}^T(\mathbf{A}_{n,m})^{-1}\mathbf{p}\mathbf{A}_{N,M}]\mathbf{S}^{\sigma}_{N,M}, \tag{8}$$

where $\mathbf{A}_{n,m} \equiv \mathbf{p}\mathbf{A}_{N,M}\mathbf{p}^T$ is the reduced problem matrix related to the course grid correction operator

$$CGC(\mathbf{p}) \equiv [\mathbf{I} - \mathbf{p}^T(\mathbf{A}_{n,m})^{-1}\mathbf{p}\mathbf{A}_{N,M}].$$

4. Spectral properties. Now we introduce some tools that will be useful for analyzing the convergence of our TGM. A full spectral analysis of the matrices involved in the algorithm will be given along with a complete block decomposition. For the sake of simplicity, and without loss of generality, we assume $\sigma = 1$.

Rearranging the columns of $\mathbf{F}_N$ we define

$$\hat{\mathbf{F}}_N = [\mathbf{f}_1|\mathbf{f}_N|\ldots|\mathbf{f}_i|\mathbf{f}_{N-i+1}|\ldots|\mathbf{f}_n]$$

and $\hat{\mathbf{F}}_M$ analogously. The matrix

$$\mathbf{V}_N = \left[\begin{array}{cc|cc|cc|cc|c} 1 & -1 & & & & & & & \\ \hline & & 1 & -1 & & & & & \\ \hline & & & & \ddots & \ddots & & & \\ \hline & & & & & & 1 & -1 & \\ \hline & & & & & & & & 0 \end{array}\right]$$

allows us to relate the cutting matrix and the projector as follows:

$$\mathbf{K}_N\hat{\mathbf{F}}_N = \sqrt{2}\,\mathbf{F}_n\mathbf{V}_N. \tag{9}$$

The reduced problem matrix $\mathbf{A}_{n,m} = \mathbf{p}\mathbf{A}_{N,M}\mathbf{p}^T$, in view of (7) and (9), can be therefore written as

$$\begin{aligned} \mathbf{p}\mathbf{A}_{N,M}\mathbf{p}^T &= (\mathbf{K}_N \otimes \mathbf{K}_M)\mathbf{P}_{N,M}\mathbf{A}_{N,M}\mathbf{P}_{N,M}(\mathbf{K}_N \otimes \mathbf{K}_M)^T \\ &= (\mathbf{K}_N \otimes \mathbf{K}_M)(\hat{\mathbf{F}}_N \otimes \hat{\mathbf{F}}_M)\hat{\Lambda}_{\mathbf{p}}\hat{\Lambda}_{\mathbf{A}}\hat{\Lambda}_{\mathbf{p}}(\hat{\mathbf{F}}_N \otimes \hat{\mathbf{F}}_M)(\mathbf{K}_N \otimes \mathbf{K}_M)^T \\ &= 4(\mathbf{F}_n \otimes \mathbf{F}_m)(\mathbf{V}_N \otimes \mathbf{V}_M)\hat{\Lambda}_{\mathbf{p}}\hat{\Lambda}_{\mathbf{A}}\hat{\Lambda}_{\mathbf{p}}(\mathbf{V}_N \otimes \mathbf{V}_M)^T(\mathbf{F}_n \otimes \mathbf{F}_m) \\ &\equiv 4(\mathbf{F}_n \otimes \mathbf{F}_m)\hat{\mathbf{A}}_{n,m}(\mathbf{F}_n \otimes \mathbf{F}_m), \end{aligned} \tag{10}$$

where

$$\hat{\Lambda}_{\mathbf{A}} = \left[\begin{array}{c|c} \operatorname*{diag}_{1\le\mu\le n}\begin{bmatrix} \hat{\Lambda}_{\mathbf{A},\mu} & O \\ O & \hat{\Lambda}_{\mathbf{A},\mu'} \end{bmatrix} & 0 \\ \hline O & \hat{\Lambda}_{A,n} \end{array}\right],$$

$$\hat{\Lambda}_{\mathbf{A},\mu} = \left[\begin{array}{c|c} \operatorname*{diag}_{1\le\nu\le m}\begin{bmatrix} \alpha_{\mu,m} & 0 \\ 0 & \alpha_{\mu,\nu'} \end{bmatrix} & O \\ \hline O & \alpha_{\mu,m} \end{array}\right]$$

with $\mu' = N - \mu + 1$ and $\nu' = M - \nu + 1$. $\hat{\Lambda}_{\mathbf{p}}$ is defined in the same way.

A generic block of $\hat{\mathbf{A}}_{n,m} = (\mathbf{V}_N \otimes \mathbf{V}_M)\hat{\Lambda}_{\mathbf{p}}\hat{\Lambda}_{\mathbf{A}}\hat{\Lambda}_{\mathbf{p}}(\mathbf{V}_N \otimes \mathbf{V}_M)^T$ in (10) is consequently given by

$$[\mathbf{V}_M \quad -\mathbf{V}_M]\begin{bmatrix} \hat{\Lambda}_{\mathbf{A},\mu}\hat{\Lambda}^2_{\mathbf{p},\mu} & 0 \\ 0 & \hat{\Lambda}_{\mathbf{A},\mu'}\hat{\Lambda}^2_{\mathbf{p},\mu'} \end{bmatrix}\begin{bmatrix} \mathbf{V}^T_M \\ -\mathbf{V}^T_M \end{bmatrix}.$$

It follows that $\hat{\mathbf{A}}_{n,m} = \operatorname{diag}_{1\le\mu\le n}[\operatorname{diag}_{1\le\nu\le m}[\hat{\alpha}_{\mu,\nu}]]$, where

$$\hat{\alpha}_{\mu,\nu} = \alpha_{\mu,\nu}p^2_{\mu,\nu} + \alpha_{\mu,\nu'}p^2_{\mu,\nu'} + \alpha_{\mu'\nu}p^2_{\mu',\nu} + \alpha_{\mu',\nu'}p^2_{\mu',\nu'}$$

and $p_{\mu,\nu} = \operatorname{Trunc}(p, N-1, M-1)|_{(x^{(N)}_\mu, x^{(M)}_\nu)}$ (compare (5)).

The spectral block decomposition of the coarse grid correction operator is obtained in a similar way:

$$CGC(\mathbf{p}) = \mathbf{F}_N \otimes \mathbf{F}_M \cdot \operatorname*{diag}_{1\le\mu\le n}\left[\operatorname*{diag}_{1\le\nu\le m}[C_{\mu,\nu}]\right] \cdot \mathbf{F}_n \otimes \mathbf{F}_M,$$

where

$$C_{\mu,\nu} = \mathbf{I}_4 - \underbrace{\begin{bmatrix} p_{\mu,\nu} \\ -p_{\mu,\nu'} \\ p_{\mu'\nu} \\ -p_{\mu',\nu'} \end{bmatrix}\frac{1}{\hat{\alpha}_{\mu,\nu}}[p_{\mu,\nu} \quad -p_{\mu,\nu'} \quad p_{\mu',\nu} \quad -p_{\mu',\nu'}]}_{(*)}$$

$$\times \underbrace{\begin{bmatrix} \alpha_{\mu,\nu} & & & O \\ & \alpha_{\mu,\nu'} & & \\ & & \alpha_{\mu',\nu} & \\ O & & & \alpha_{\mu',\nu'} \end{bmatrix}}_{(**)}.$$

Thus, the matrix $\hat{\mathbf{F}}_N \otimes \hat{\mathbf{F}}_M \cdot TGM(\mathbf{p}) \cdot \hat{\mathbf{F}}_N \otimes \hat{\mathbf{F}}_M$ is diagonalized into nm 4×4 blocks and $N+M-1$ scalar zeros; the spectral radius of $TGM(\mathbf{S}, \mathbf{p})$ is therefore given by $\sup_{\mu,\nu}\{\rho(M_{\mu,\nu})\}$ where

$$M_{\mu,\nu} = C_{\mu,\nu}\begin{bmatrix} s_{\mu,\nu} & & & O \\ & s_{\mu,\nu'} & & \\ & & s_{\mu',\nu} & \\ O & & & s_{\mu',\nu'} \end{bmatrix}$$

and $s_{\mu,\nu} = \operatorname{Trunc}(N-1, M-1, s)|_{(x^{(N)}_\mu, x^{(M)}_\nu)}$ (compare (5)).

From [Gr], we know that (*) is the inverse of (**) in the linear subspace generated by $\hat{p} = [p_{\mu,\nu} \quad -p_{\mu,\nu'} \quad p_{\mu',\nu} \quad -p_{\mu',\nu'}]^T$ and represents the null matrix in the three-dimensional orthogonal subspace. The product of (*) and (**) is therefore the identity operator in $\mathbf{span}(\hat{p})$ and the null operator in $\mathbf{span}(\hat{p})^\perp$.

It follows that the eigenvalues of $C_{\mu,\nu}$ are zero with multiplicity one and one with multiplicity three; as a result, one eigenvalue of $M_{\mu,\nu}$, say $\lambda_1^{\mu,\nu}$, is equal to zero, but further considerations are needed to evaluate the other three: $\lambda_2^{\mu,\nu}$, $\lambda_3^{\mu,\nu}$, and $\lambda_4^{\mu,\nu}$.

Recalling that both $\mathbf{A}$ and $\mathbf{S} \equiv \mathbf{I} - \mathbf{A}/\alpha$ are positive definite and that they commute (because $\mathbf{S}$ is a polynomial of $\mathbf{A}$), we find that $TGM(\mathbf{S}, \mathbf{p})$ is similar to

$$\begin{aligned} TGM^*(\mathbf{S}, \mathbf{p}) &= \mathbf{S}^{1/2}\mathbf{A}^{1/2} TGM(\mathbf{p})\mathbf{A}^{-1/2}\mathbf{S}^{-1/2} \\ &= \mathbf{S} - \mathbf{S}^{1/2}\mathbf{A}^{1/2}\mathbf{p}^T(\mathbf{p}\mathbf{A}\mathbf{p}^T)^{-1}\mathbf{p}\mathbf{A}\mathbf{S}\mathbf{A}^{-1/2}\mathbf{S}^{-1/2} \\ &= \mathbf{S} - \mathbf{S}^{1/2}\mathbf{A}^{1/2}\mathbf{p}^T(\mathbf{p}\mathbf{A}\mathbf{p}^T)^{-1}\mathbf{p}\mathbf{A}^{1/2}\mathbf{S}^{1/2}, \end{aligned}$$

which is clearly symmetric; hence, $\lambda_i^{\mu,\nu} \in \Re$ for $i = 1, \dots, 4$.

From the previous equation it also follows that

$$TGM^*(\mathbf{p}) = \mathbf{S}^{1/2}(\mathbf{I} - \mathbf{A}^{1/2}\mathbf{p}^T(\mathbf{p}\mathbf{A}\mathbf{p}^T)^{-1}\mathbf{p}\mathbf{A}^{1/2})\mathbf{S}^{1/2}$$

and, since $\mathbf{I} - \mathbf{A}^{1/2}\mathbf{p}^T(\mathbf{p}\mathbf{A}\mathbf{p}^T)^{-1}\mathbf{p}\mathbf{A}^{1/2}$ is an orthogonal projector operator, its eigenvalues belong to the set $\{0, 1\}$; see [Gr]. Therefore, for any $\mathbf{x} \in \Re^{NM}$ setting $\mathbf{y} = \mathbf{S}^{1/2}\mathbf{x}$, by means of the Rayleigh quotient, we obtain

$$(11) \qquad 0 \le \frac{\mathbf{x}^T TGM^*(\mathbf{p})\mathbf{x}}{\mathbf{x}^T\mathbf{x}} = \frac{\mathbf{y}^T(\mathbf{I} - \mathbf{A}^{1/2}\mathbf{p}^T(\mathbf{p}\mathbf{A}\mathbf{p}^T)^{-1}\mathbf{p}\mathbf{A}^{1/2})\mathbf{y}}{\mathbf{x}^T\mathbf{x}} \le \frac{\mathbf{y}^T\mathbf{y}}{\mathbf{x}^T\mathbf{x}} = \frac{\mathbf{x}^T\mathbf{S}\mathbf{x}}{\mathbf{x}^T\mathbf{x}}.$$

Finally, from (11), we have

$$0 \le \lambda_i^{\mu,\nu} \le \rho(\mathbf{S}) < 1 \quad \text{for } i = 1, \dots, 4.$$

5. The choice of p. Inequality (11) shows that, for any choice of $\mathbf{p}$, the multigrid method outlined in the previous section is never slower than the relaxation method (6) alone.

We recall that the spectral decomposition (10) holds for τ matrices; for Toeplitz matrices it can be proved that (10) is true only in an approximate sense. On the other hand, inequality (11) is completely general.

In the following, without loss of generality, we assume that $0 \le a(x, y) \le 1$ and the existence of a point $z_0 = (x_0, y_0) \in [0, \pi]^2$ such that $a(x, y)$ vanishes in z_0 and is positive elsewhere. This zero leads to numerical difficulties in the resolution of (1) for any N and M since, for any N and M, we may find indexes μ_N and ν_n such that

$$\lim_{N,M \to +\infty} (x_{\mu_N}^{(N)}, x_{\nu_M}^{(M)}) = z_0, \quad \text{where } x_i^{(k)} = \frac{i\pi}{k+1}.$$

To analyze the convergence of $TGM(\mathbf{S}, \mathbf{p})$ as given in (8), we assume for brevity $\mu = \mu_n$, $\nu = \nu_m$ and analyzé the behavior in the worst subspace.

From

$$\mathbf{y}_{N,M} = M_{\mu,\nu} \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix},$$

if we set $\mathbf{S} = \mathbf{I} - \mathbf{A}$ in (8), we find that

$$\mathbf{y}_{N,M} = CGC(\mathbf{p})(1-\alpha_{\mu,\nu})\begin{bmatrix}1\\0\\0\\0\end{bmatrix} = (1-\alpha_{\mu,\nu})\left[\begin{bmatrix}1\\0\\0\\0\end{bmatrix} - \frac{\hat{\mathbf{p}}\cdot\hat{\mathbf{p}}^T}{\hat{\alpha}_{\mu,\nu}}\begin{bmatrix}\alpha_{\mu,\nu}\\0\\0\\0\end{bmatrix}\right]$$

$$= \frac{1-\alpha_{\mu,\nu}}{\hat{\alpha}_{\mu,\nu}}\begin{bmatrix}\alpha_{\mu,\nu'}p^2_{\mu,\nu'} + \alpha_{\mu',\nu}p^2_{\mu',\nu} + \alpha_{\mu',\nu'}p^2_{\mu',\nu'}\\ \alpha_{\mu,\nu}p_{\mu,\nu}p_{\mu,\nu'}\\ -\alpha_{\mu,\nu}p_{\mu,\nu}p_{\mu',\nu}\\ \alpha_{\mu,\nu}p_{\mu,\nu}p_{\mu',\nu'}\end{bmatrix}.$$

Recalling that $\hat{a}_{\mu,\nu} = a_{\mu,\nu}p^2_{\mu,\nu} + a_{\mu,\nu'}p^2_{\mu,\nu'} + a_{\mu',\nu'}p^2_{\mu',\nu'} + a_{\mu',\nu'}p^2_{\mu',\nu'}$, if we choose an arbitrary function $p(x, y) > 0$, from $\lim_{N,M\to+\infty}\alpha_{\mu,\nu} = a(z_0) = 0$, we obtain

$$\lim_{N,M\to+\infty} M_{\mu,\nu}\begin{bmatrix}1\\0\\0\\0\end{bmatrix}^T = \begin{bmatrix}1\\0\\0\\0\end{bmatrix},$$

that is, a $TGM(\mathbf{S}, \mathbf{p})$ with a spectral radius close to one.

To improve the contractivity we need a function $p(x, y)$ such that

$$\limsup_{N,M\to+\infty}\left\{\frac{p^2_{\mu,\nu'}}{\alpha_{\mu,\nu}}, \frac{p^2_{\mu',\nu}}{\alpha_{\mu,\nu}}, \frac{p^2_{\mu',\nu'}}{\alpha_{\mu,\nu}}\right\} < +\infty;$$

this implies that

$$\limsup_{N,M\to+\infty}\frac{\alpha_{\mu,\nu'}p^2_{\mu,\nu'} + \alpha_{\mu',\nu}p^2_{\mu',\nu} + \alpha_{\mu',\nu'}p^2_{\mu',\nu'}}{\hat{\alpha}_{\mu,\nu}} = \rho < 1. \tag{12}$$

In this case we have $\|\mathbf{y}_{N,M}\|_2^2 = (1-\alpha_{\mu,\nu})^2(\chi_{N,M} + \gamma_{N,M})$, where

$$\chi_{N,M} = \left(\frac{\alpha_{\mu,\nu'}p^2_{\mu,\nu'} + \alpha_{\mu',\nu}p^2_{\mu',\nu} + \alpha_{\mu',\nu'}p^2_{\mu',\nu'}}{\hat{\alpha}_{\mu,\nu}}\right)^2 \quad \text{and}$$

$$\gamma_{N,M} = \frac{\alpha^2_{\mu,\nu}p^2_{\mu,\nu}(p^2_{\mu,\nu'} + p^2_{\mu',\nu} + p^2_{\mu',\nu'})}{\hat{\alpha}^2_{\mu,\nu}}.$$

Then, for $N, M \to +\infty$, we find $\chi_{N,M} \to \rho^2 < 1$, $(1-\alpha_{\mu,\nu})^2 \to 1$, and $\gamma_{N,M} \to 0$. Consequently we obtain $\|y_{N,M}\|_2^2 \to \rho^2 < 1$ and a $TGM(\mathbf{S}, \mathbf{p})$ strongly contractive in the subspace where $\mathbf{S}$ is a slowly convergent iteration matrix.

Condition (12) gives enough information to construct a projector operator that guarantees a convergence speed independent of the dimensions N and M; it states that whenever $a(x, y)$ has a minimum in (x_0, y_0), we have to choose a projector among those vanishing at the "mirror" points $(\pi - x_0, y_0)$, $(x_0, \pi - y_0)$, and $(\pi - x_0, \pi - y_0)$. See Fig. 1.

The trigonometric polynomial

$$\begin{aligned}p(x, y) &= [\cos(2x) - \cos(2x_0) + \cos(y) - \cos(\pi - y_0)]\\ &\quad\times [\cos(x) - \cos(\pi - x_0) + \cos(2y) - \cos(2y_0)]\end{aligned}$$

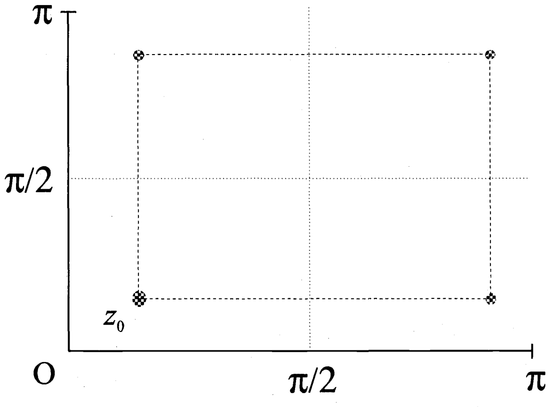

FIG. 1. *"Mirror" points for* z_0.

is a convenient choice for the function $p(x, y)$ because, ignoring any constant factor, we may easily find an associated matrix $\mathbf{P}$ in the Toeplitz class; in fact, setting

$$\mathbf{C}_1^{(\theta)} = \begin{bmatrix} -2\cos(\theta) & 1 & & & O \\ 1 & \ddots & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & 1 \\ O & & & 1 & -2\cos(\theta) \end{bmatrix} \quad \text{and}$$

$$\mathbf{C}_2^{(\theta)} = \begin{bmatrix} -2\cos(2\theta) & 0 & 1 & & & O \\ 0 & \ddots & \ddots & \ddots & & \\ 1 & \ddots & \ddots & \ddots & & 1 \\ & \ddots & \ddots & \ddots & & 0 \\ O & & & 1 & 0 & -2\cos(2\theta) \end{bmatrix},$$

the matrix $\mathbf{P}$ can be written as

$$\mathbf{P} = \mathbf{P}(x_0, y_0) \equiv (\mathbf{C}_2^{(x_0)} \otimes \mathbf{I}_M + \mathbf{I}_N \otimes \mathbf{C}_1^{(\pi - y_0)}) \cdot (\mathbf{C}_1^{(\pi - x_0)} \otimes \mathbf{I}_M + \mathbf{I}_N \otimes \mathbf{C}_2^{(y_0)}).$$

Moreover, when we find $a(z_0) = 0$ with multiplicity $d > 1$, i.e.,

$$0 < \limsup_{z \to z_0} \frac{a(z)}{\|z - z_0\|_2^d} < +\infty,$$

we have to choose $p(x, y)$ such that its zeros at the mirror points have multiplicity at least $d/2$ to obtain a rapidly convergent method. In this case, we may use $\mathbf{P} \equiv \mathbf{P}(z_0)^{\lceil d/2 \rceil}$.

6. Numerical results. We now present some numerical results obtained by applying our generalized multigrid method to ill-conditioned block symmetric Toeplitz matrices of increasing difficulty. All the generating functions associated with these problems are equal to zero at some point z_0. In all cases the knowledge of z_0 and its multiplicity has been enough to devise a convergent algorithm.

We have to recall that the projector operators are constructed by considering $\mathbf{A}_{N,M}$; therefore, much of the convergence analysis performed in the previous sections only concerns τ matrices. In this section, by using the strong spectral similarity between τ and Toeplitz matrices, we apply our algorithm to Toeplitz systems like (1). Also in this case we obtain fast multigrid methods as shown by the numerical tests in the following sections.

6.1. The framework. In the following, we consider linear systems $\mathbf{Tx} = \mathbf{b}$, where $\mathbf{T}$ is a square 400×400 matrix, i.e.; $N = M = 20$. (We have performed numerical experiments with different values of N and M, but we report only this case since, when the dimension changes, the number of required iterations remains almost the same.) For all tests, starting from a randomly chosen vector, we report the 2-norm of the error at each iteration. All numerical computations have been carried out with double precision arithmetic.

We choose the projectors according to the theoretic considerations of the preceding sections obtaining spectral radii bounded by constants less than one and independent of the dimension of the matrices. As validated by the numerical experiments in this section, at each step the error is reduced by a constant factor that is independent of N and M.

We will use smoothers taken from amongst the relaxed methods of the form

$$\mathbf{x}^{(i+1)} = \mathbf{x}^{(i)} - (\mathbf{Ax} - \mathbf{b})/\alpha.$$

Our numerical experiments have been performed using two smoothers (called pre- and postsmoother) as proposed in [FS]. More precisely, setting $\alpha = \|a\|_\infty$ that is asymptotically close to $\|\mathbf{A}\|_2$, we define the presmoother iteration matrix as

$$\mathbf{S}_1 = \mathbf{I} - \mathbf{A}/\alpha, \tag{13}$$

while the postsmoother is

$$\mathbf{S}_2 = \mathbf{I} - 2\mathbf{A}/\alpha, \tag{14}$$

The method is therefore a multi-iterative one [S1], where the presmoother approaches the exact solution in a fixed subspace then the coarse grid correction approaches it in the complementary one. The postsmoother $\mathbf{S}_2$ accelerates the overall convergence rate reducing the error in a third intermediate subspace where neither $\mathbf{S}_1$ nor the coarse grid correction is highly contractive. In Tables 1–4 the parameters `Pre` and `Post` denote the number of the pre- and postsmoothing sweeps made at each global iteration.

6.2. The Poisson problem on the unit square. The first example is a classical one, the Poisson problem on the unit square $\Omega = [0, 1] \times [0, 1]$:

$$\begin{cases} \Delta f(x, y) = g(x, y), & (x, y) \in \Omega, \\ f(x, y) = 0, & (x, y) \in \partial\Omega; \end{cases}$$

it is discretized by means of the well-known 5-point finite difference formula to obtain the matrix $\mathbf{A} = \mathbf{I}_N \otimes \mathbf{H}_N + \mathbf{H}_N \otimes \mathbf{I}_N$. The associated function, given by $a(x, y) = 4 - 2\cos(x) - 2\cos(y)$, is nonnegative with a zero of multiplicity two in (0, 0); because of the zero, the condition number of $\mathbf{A}$ grows as N^2.

An adequate projector is therefore given by

$$\mathbf{p} = (\mathbf{C}_2^{(0)} \otimes \mathbf{I}_M + \mathbf{I}_N \otimes \mathbf{C}_1^{(\pi)}) \times (\mathbf{C}_1^{(\pi)} \otimes \mathbf{I}_M + \mathbf{I}_N \otimes \mathbf{C}_2^{(0)}), \tag{15}$$

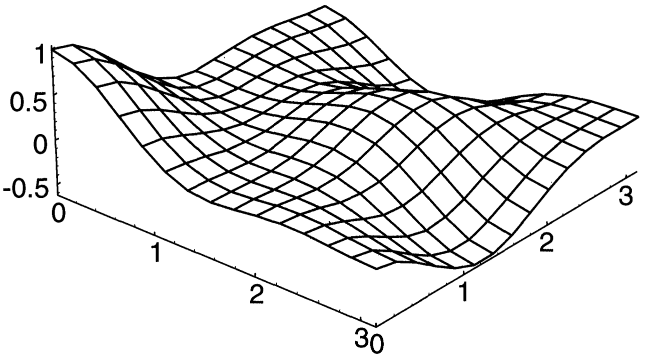

FIG. 2. *Scaled $p(x, y)$ as defined in* (15).

TABLE 1
Two-dimensional Laplacian operator.

18	5.275 e−05	5.277 e−08
20	1.609 e−05	7.188 e−09

where

$$\mathbf{C}_1^{(\pi)} = \begin{bmatrix} 2 & 1 & & & O \\ 1 & \ddots & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & 1 \\ O & & & 1 & 2 \end{bmatrix} \quad \text{and} \quad \mathbf{C}_2^{(0)} = \begin{bmatrix} -2 & 0 & 1 & & O \\ 0 & \ddots & \ddots & \ddots & \\ 1 & \ddots & \ddots & \ddots & 1 \\ & \ddots & \ddots & \ddots & 0 \\ O & & 1 & 0 & -2 \end{bmatrix}.$$

As required, $\mathbf{p}$ is such that its generating function $p(x, y)$ vanishes at the mirror points $(0, \pi)$, $(\pi, 0)$, and (π, π) as shown in Fig. 2.

The smoothers have been constructed as in (13) and (14) using $\alpha = 8$, i.e., the maximum of $a(x, y)$ on $Q = [0, \pi]^2$.

The results of the first 20 iterations reported in Table 1 show that in both cases the convergence rate is linear.

Note that, keeping the same computational cost, we achieve a considerable improvement using both the pre- and postsmoother to reduce the error on complementary subspaces.

6.3. The square function. In order to test the method under the same conditions of ill conditioning but in a full matrix case, we consider the matrix $\mathbf{A}$ generated by the function

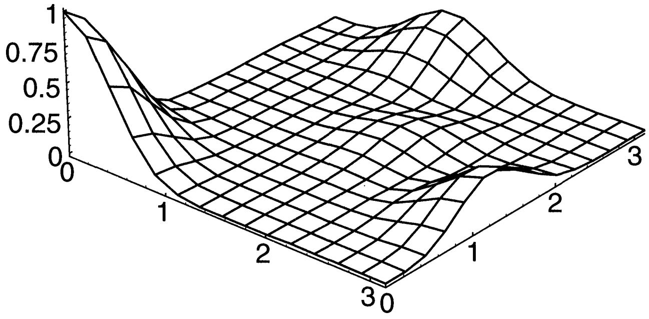

FIG. 3. *Scaled $p(x, y)$ as defined in* (16).

TABLE 2
The square function.

Iter.	Pre=2 Post=0	Pre=1 Post=1
2	2.903 e+00	2.108 e+00
4	1.016 e+00	4.586 e−01
6	4.314 e−01	1.387 e−01
8	2.007 e−01	4.635 e−02
10	9.807 e−02	1.626 e−02
12	4.933 e−02	5.869 e−03
14	2.531 e−02	2.155 e−03
16	1.317 e−02	7.998 e−04
18	6.926 e−03	2.989 e−04
20	3.668 e−03	1.123 e−04

$a(x, y) = x^2+y^2$. The condition number of this matrix grows quadratically because $a(0, 0) = 0$ with multiplicity two.

The matrix $\mathbf{A}$ can be written as $\mathbf{Q}_N \otimes \mathbf{I}_N + \mathbf{I}_N \otimes \mathbf{Q}_N$, where $\mathbf{Q}_N$ is generated by the trigonometric series for $f(x) = x^2$:

$$x^2 = \frac{\pi^2}{3} + 4\sum_{i=1}^{+\infty} \frac{(-1)^i \cos(ix)}{i^2}.$$

This time we use a projector better suited to correct the flat zero in (0, 0):

$$\mathbf{p} = [(\mathbf{C}_2^{(0)} \otimes \mathbf{I}_M + \mathbf{I}_N \otimes \mathbf{C}_1^{(\pi)}) \times (\mathbf{C}_1^{(\pi)} \otimes \mathbf{I}_M + \mathbf{I}_N \otimes \mathbf{C}_2^{(0)})]^2. \tag{16}$$

See Fig. 3.

The smoothers have been constructed from (13) and (14) using $a = 18$, an approximation of $\max_Q a(x, y)$.

The result of 20 iterations, reported Table 2, shows the effectiveness of the method also in the case of full matrices.

6.4. The absolute value. A more critical case comes from the matrix associated with the function $a(x, y) = |x| + |y|$. The matrix $\mathbf{A}_{N,M}$ can be constructed as in the previous case from the series expansion

$$|x| = \frac{\pi}{2} - \frac{4}{\pi}\sum_{i=0}^{+\infty} \frac{\cos((2i + 1)x)}{(2i + 1)^2}.$$

TABLE 3
The absolute value.

Iter.	Pre=2 Post=0	Pre=1 Post=1

TABLE 4
Comparison of the methods.

	Preconditioned	Multigrid	
Iter.	conj. grad.	Pre=2 Post=0	Pre=1 Post=1
2	5.304 e−01	1.933 e+00	1.127 e+00
4	5.162 e−02	2.900 e−01	1.015 e−02
6	7.175 e−03	5.069 e−02	1.189 e−04
8	8.065 e−04	9.212 e−03	1.468 e−06
10	9.608 e−05	1.699 e−03	1.859 e−08
12	9.731 e−06	3.159 e−04	2.399 e−10
14	9.384 e−07	5.897 e−05	3.151 e−12
16	9.152 e−08	1.103 e−05	4.212 e−14
18	1.191 e−08	2.069 e−06	5.731 e−16
20	1.337 e−09	3.883 e−07	7.929 e−18

Observe that, for any fixed value of N and M, the corresponding matrix $\mathbf{A}_{N,M}$ is generated by the truncated bivariate trigonometric series of $a(x, y)$. Actually, this polynomial is regular in its domain, whereas the limit function $a(x, y)$ is not differentiable at (0, 0). Using the full function as a guideline to construct a projector may seem to be a poor approximation; on the contrary, using projector (15) again and smoothers obtained with $\alpha = 2\pi$, we find again a convergence rate independent of the dimension. See Table 3.

6.5. Comparison of the methods. As a final example we report a comparison between the preconditioned conjugated gradient as proposed [S2] and our method on a case treated in [KK]; the matrix arises from the discretisation of a partial differential equation [CC] by means of a finite difference scheme and is constructed as follows.

Denoting with $\mathbf{BST}_N[a_1, \ldots, a_k]$ the $N \times N$ band symmetric Toeplitz matrix with $a_1, \ldots, a_k$ as the first entries in the first row, we may write the matrix of the problem as

$$\mathbf{A} = \mathbf{I} \otimes \mathbf{B} + \mathbf{H} \otimes \mathbf{C} + \mathbf{K} \otimes \mathbf{D},$$

where

$$\mathbf{B} = \mathbf{BST}_N[1, -0.12, -0.04], \qquad \mathbf{C} = \mathbf{BST}_N[-0.12, -0.04, -0.02],$$
$$\mathbf{D} = \mathbf{BST}_N[-0.04, -0.02, -0.01], \quad \mathbf{H} = \mathbf{BST}_N[0 \quad 1], \quad \text{and} \quad \mathbf{K} = \mathbf{BST}_N[0 \quad 0 \quad 1].$$

Since $a(0, 0) = 0$ with multiplicity two, we calibrate our multigrid method using projector (15) and smoothers (13) and (14) with $\alpha = 1.25$, i.e., an approximation for $\max_Q a(x, y)$.

In Table 4 we compare the error reductions of the preconditioned conjugate gradients of [S2] and our multigrid scheme.

Note that the preconditioners proposed in [CC, KK] do not apply to this case because the resulting condition number is $O(N)$. The convergence rate of these methods is sublinear requiring $O(N)$ steps to reduce the error by a constant factor.

DEFECT CORRECTION FOR CONVECTION-DOMINATED FLOW*

WILHELM HEINRICHS†

Abstract. A defect correction scheme with the first-order upwind preconditioner is considered. By Fourier analysis the preconditioning properties for the second-order upwind scheme, the central scheme, and spectral methods are examined. Since the eigenvalues of the preconditioned operator are complex the generalized minimal residual iteration is used for the iterative solution. This procedure is applied to the Boussinesq flow problem in vorticity–streamfunction formulation. Numerical results are presented for increasing Rayleigh numbers.

Key words. convection–diffusion, defect correction, finite differences, spectral, multigrid, Boussinesq flow

AMS subject classification. 65N35

1. Introduction.

Here we consider convection–diffusion problems which can in their most general form be written as

$$-\epsilon \Delta u + c u_x + d u_y = f \ \text{ in } \Omega = (-1, 1)^2, \tag{1.1}$$

$$u = g \ \text{ on } \partial\Omega, \tag{1.2}$$

where $\epsilon > 0$ denotes a constant, c, d, f are functions defined in Ω, and g is defined on $\partial\Omega$. Such problems arise after a linearization of the Navier–Stokes equations (or Boussinesq flow problem). Here ϵ corresponds to $\frac{1}{Re}$. The part $-\epsilon\Delta u$ denotes the diffusive part and $cu_x + du_y$ denotes the convective part of the above equation. Here we are mainly interested in convection-dominated flows where $\epsilon << h$. Here h denotes the step size of the finite difference (FD) scheme. For the FD approximation of convection–diffusion problems one observes certain phenomena of instability. For small ϵ standard discretizations can lead to a solution of the discrete problem which has nothing to do with the solution of the original problem. For instance, the discretization of

$$-\epsilon u'' - 2u' = 0 \ \text{ in } [0, \infty),$$
$$u(0) = 1, \ u(\infty) = 0$$

with central differences yields as the discrete solution

$$u_{\epsilon,h}(ih) = \left(\frac{\epsilon - h}{\epsilon + h}\right)^i .$$

This is an $O(h^2)$ discretization. For ih fixed and $\frac{h}{\epsilon} \to 0$ we obtain

$$|(u_{\epsilon,h} - u)(ih)| = \left| \left(\frac{\epsilon - h}{\epsilon + h}\right)^i - \left(e^{-\frac{2h}{\epsilon}}\right)^i \right| \leq C \left(\frac{h}{\epsilon}\right)^2$$

with C independent of i, h, and ϵ. But the solution of the reduced equation is

$$u_{0,h}(ih) = \lim_{\epsilon \to 0} u_{\epsilon,h}(ih) = (-1)^i,$$

which means that for $\epsilon << h$, the solution of the FD problem has nothing to do with the exact solution

$$u(x) = e^{-\frac{2x}{\epsilon}}.$$

*Received by the editors February 1, 1993; accepted for publication (in revised form) May 2, 1995.

†Mathematisches Institut der Heinrich-Heine-Universität Düsseldorf, Universitätsstraße 1, D-4000 Düsseldorf 1, Germany (wheinric@numerik.uni-duesseldorf.de).

For this special problem we further observe a boundary layer in which the first derivative behaves as $O(\epsilon^{-1})$ for $\epsilon \to 0$. One possibility to avoid the phenomenon of instability is to use upstream discretization for u'. Clearly, an obvious disadvantage of this scheme lies in the fact that the method now becomes only first-order accurate. Hence it makes sense to use the first-order upstream scheme only as a preconditioner for a higher-order scheme. We analyze the preconditioning properties of this method for the following higher-order schemes:

- second-order upstream scheme,
- central finite difference scheme,
- Chebyshev pseudospectral scheme.

In the spectral scheme (see [4]) the solution is approximated by Chebyshev polynomials of degree $\leq N$. This space is denoted by $\mathbf{P}_N$. By a Fourier analysis it can be shown that the eigenvalues of the preconditioned operator are bounded but complex. Hence one has to employ a nonsymmetric matrix iteration for the solution. Here we recommend the generalized minimal residual (GMRES) iteration which belongs to the residual minimization methods.

Clearly, for the general convection–diffusion problem (1.1), (1.2) the first derivatives u_x and u_y have to be approximated according to the sign of the coefficients c and d, respectively. Therefore for the iterative solution we recommend flow directed schemes. Since the Chebyshev nodes are dense near the boundary, it is necessary to use line Gauss–Seidel relaxation (in an alternating manner). Finally this iterative solver is applied to the Boussinesq flow problem in vorticity–streamfunction formulation. We obtained numerical results for increasing Rayleigh numbers up to $Ra = 10^5$.

2. Preconditioning by the upstream scheme. From the one-dimensional model problem it can be seen that for $\epsilon \to 0$ we first have to find a good preconditioner for the derivative operator

$$\frac{du}{dx}.$$

Here we employ the first-order upstream scheme (L^1_{up}) for preconditioning, i.e.,

$$\frac{du}{dx}(x_i) \cong \frac{u(x_{i+1}) - u(x_i)}{x_{i+1} - x_i} \quad \text{if } x_{i+1} < x_i$$

or

$$\frac{du}{dx}(x_i) \cong \frac{u(x_i) - u(x_{i-1})}{x_i - x_{i-1}} \quad \text{if } x_{i-1} < x_i.$$

In the spectral discretization we have collocation points $x_i = \cos\theta_i$, $\theta_i = \frac{i\pi}{N}$, so that $x_{i+1} < x_i$, whereas in the finite difference case we have grid points $x_i = ih$, $h = \frac{1}{N}$, so that $x_{i-1} < x_i$ for $i = 1, \dots, N-1$. Now we were interested in the preconditioning properties of L^1_{up} for the following three higher-order methods:

- second-order upstream scheme: $L^2_{up}u := \frac{1}{h}\left(\frac{1}{2}u(x_{i-2}) - 2u(x_{i-1}) + \frac{3}{2}u(x_i)\right)$,
- second-order central scheme: $L_{ce}u := \frac{1}{2h}\left(u(x_{i+1}) - u(x_{i-1})\right)$,
- Chebyshev pseudospectral scheme: L_{sp} (see [3], [4], [12], [13]).

Hence we are interested in the eigenvalues of the discrete operators

$$\left(L^1_{up}\right)^{-1} L^2_{up}, \ \left(L^1_{up}\right)^{-1} L_{ce}, \ \left(L^1_{up}\right)^{-1} L_{sp}.$$

Eigenvalue bounds are obtained by a Fourier analysis. It is well known (see [4]) that the Fourier analysis also yields a good prediction for the eigenvalues in the Chebyshev case. For

TABLE 1
ρ_k *for* $k = 1, \ldots, 4$.

k	ρ_k
1	0.3333
2	0.2425
3	0.2162
4	0.2040

$\left(L^1_{up}\right)^{-1} L^2_{up}$ the absolute values of the eigenvalues are given by

$$|\lambda^{up}_p| = \sqrt{4 - 3\cos^2 \frac{p\pi}{2N}}, \quad p = 1, \ldots, N-1.$$

For $\left(L^1_{up}\right)^{-1} L_{ce}$ they are given by

$$|\lambda^{ce}_p| = \cos \frac{p\pi}{2N}, \quad p = 1, \ldots, N-1.$$

Since $\cos \frac{p\pi}{2N} \in [0, 1]$ we obtain

$$|\lambda^{up}_p| \in [1, 2] \text{ and } |\lambda^{ce}_p| \in [0, 1].$$

Because zero is the lower bound for the eigenvalues of the preconditioned central scheme, it is already clear that this method is not good. For the second-order upstream scheme we observed that the imaginary parts are small compared to the real parts. Hence a simple Richardson iteration can be applied. By choosing one relaxation parameter we obtain a convergence factor of $\frac{1}{3}$. Clearly, the convergence speed can be accelerated by using more parameters (nonstationary Richardson relaxation [11]). As shown in [11] the convergence factor ρ_k for k relaxations is here given by

$$\rho_k := |T_k(3)|^{-\frac{1}{k}},$$

where T_k denotes the kth Chebyshev polynomial. In Table 1 we present ρ_k for $k = 1, \ldots, 4$. We recommend using $k = 3$ since the improvement for increasing k is no more significant.

For the spectral Fourier operator (see [4, §5.2.2]) the eigenvalues of the preconditioned spectral operator are

$$\lambda^{sp}_p = \frac{p\pi/N}{\sin(p\pi/N)} e^{-i\frac{p\pi}{N}}, \quad p = -\frac{N}{2}, \ldots, \frac{N}{2},$$

and hence

$$|\lambda^{sp}_p| = \frac{p\pi/N}{\sin(p\pi/N)}, \quad p = -\frac{N}{2}, \ldots, \frac{N}{2}.$$

This implies that

$$|\lambda^{sp}_p| \in \left[1, \frac{\pi}{2}\right] \cong [1, 1.57].$$

Therefore in all three cases the eigenvalues are bounded but complex. The iterative solver must be able to handle complex eigenvalues. Here we recommend the GMRES iteration (see [19]–[21]) which belongs to the residual minimization methods. Consider the general linear system

$$Bv = g,$$

where B is a large nonsymmetric matrix. If v_0 is an initial approximation to the solution and $r_0 = g - Bv_0$, we define the mth Krylov subspace

$$K_m := \text{span}\{r_0, Br_0, B^2r_0, \ldots, B^{m-1}r_0\}.$$

Then the GMRES approximation v_m with

$$v_m \in v_0 + K_m \tag{2.1}$$

is determined such that the mth residual r_m fulfills

$$||r_m||_2 = \text{minimum}. \tag{2.2}$$

An equivalent statement is the orthogonality condition

$$r_m \perp BK_m. \tag{2.3}$$

The GMRES iteration is a robust implementation of (2.1)–(2.3) by means of an Arnoldi construction of an orthonormal basis for the Krylov space, which leads to an $(m+1) \times m$ Hessenberg least-squares solution [21].

3. Stabilization techniques and iterative solvers. Here we consider convection–diffusion problems which are in their most general form given by (1.1), (1.2). It is well known that these problems lead to instabilities for $\epsilon << h$ in the FD case (see [7], [8], [10]) and for $\epsilon << N^{-2}$ in the spectral case (see [2], [15]). Canuto [2] has shown that the spectral approximations are affected by spurious oscillations which deteriorate the spectral accuracy. For instance, for the one-dimensional model problem

$$-\epsilon u'' + u' = 0 \ \text{ in } (-1, 1), \tag{3.1}$$

$$u(-1) = 0, \ u(1) = 1, \tag{3.2}$$

the exact solution is given by

$$u_\epsilon(x) = \frac{e^{\frac{x+1}{\epsilon}} - 1}{e^{\frac{2}{\epsilon}} - 1}. \tag{3.3}$$

Hence the boundary layer exhibited near $x = 1$ when $\epsilon \to 0$ has a width of order $O(\epsilon)$.

The pseudospectral approximation $u_N \in \mathbf{P}_N$ of (3.1), (3.2) is now defined by

$$-\epsilon u_N''(x_i) + u_N'(x_i) = 0 \ \text{ for } i = 1, \ldots, N-1, \tag{3.4}$$

$$u_N(-1) = 0, \ u_N(1) = 1, \tag{3.5}$$

where $x_i = \cos\frac{i\pi}{N}$ denotes the Chebyshev collocation points. In [2] the spectral approximation is explicitly calculated and finally one obtains

$$\begin{aligned} u_N &\cong \tfrac{1}{2} + \tfrac{1}{2}T_N \quad \text{for odd } N, \\ u_N &\cong \hat{u}_0 + \hat{u}_N T_N, |\hat{u}_0| \cong \hat{u}_N \cong O(\epsilon N^2)^{-1} \quad \text{for even } N \end{aligned}$$

as $\epsilon \to 0$, $\epsilon << N^{-2}$. Here T_N denotes the Nth Chebyshev polynomial.

Therefore in both cases u_N is strongly oscillating but for a given ϵ the oscillations created by the boundary layer are less pronounced if N is chosen to be odd. This shows that attention should be paid to the parity of the degree of polynomials to be used in a spectral approximation of boundary layer problems. This example further demonstrates the instability of the convection-dominated problem. In particular, for even N we can read from the coefficients $\hat{u}_0$ and $\hat{u}_N$ that the approximation error is perturbed by an instability rate of $O(\epsilon N^2)^{-1}$.

The problem of instability is also well known for finite difference (or finite element) discretizations if central finite differences are used (see, e.g., [9]). Here also spurious oscillations are introduced by the discretization scheme. This problem is avoided by applying an upstream scheme where the first derivative is approximated by a one-sided finite difference star. Another possibility is to add an artificial diffusion (or viscosity) term of the form $-N^{-1}\Delta u$ to the convection–diffusion equation. Now these methods are stable and produce nonoscillating solutions but are only first-order accurate being based on solving a modified problem. Clearly such techniques are of no interest for spectral approximations since the high spectral accuracy is completely lost.

Therefore we thought of other techniques of stabilization which maintain the high accuracy of spectral methods. Together with Eisen [8] we obtained a stable scheme by adding one additional equation of collocation to the original system. Hence we obtain an overdetermined system of equations and the instability caused by the highest mode is avoided. This is a certain kind of penalty method. We prove stability independent of ϵ and present the numerically calculated condition numbers for several types of collocation points (Chebyshev Gauss or Gauss–Lobatto nodes). A drawback of this approach is that the method is not flow directed and therefore in our model problem for $\epsilon \to 0$, $\epsilon << N^{-2}$, the spectral solution approximates the straight line $u_s(x) = 0.5(x+1)$ (see [8, Fig. 2]) instead of the boundary layer solution (3.3). Another drawback is that for overdetermined systems no efficient iterative solvers like multigrid methods are available. For these reasons this method is probably not the best way to go.

A flow directed method is the *streamline diffusion method* which was introduced by Hughes and Brooks [17], [18] for a finite element discretization. This method is stable and no accuracy is lost. It is a Petrov–Galerkin modification of the standard Galerkin method where artificial diffusion in the streamline direction is introduced by modifying the test functions from v to

$$v + \delta_x c v_x + \delta_y d v_y,$$

where $\delta_x = \delta_y = O(h)$ and h denotes the step size of the finite element scheme. Clearly, for the spectral method with Chebyshev Gauss–Lobatto points one has to choose a point-dependent viscosity given by $\delta_x = \delta_x(x)$, $\delta_y = \delta_y(y)$, where

$$\delta_x(x_i) = C_x \sin\left(\frac{\pi}{N}\right) \sin\left(i\frac{\pi}{N}\right), \quad i = 1, \ldots, N-1,$$
$$\delta_y(y_j) = C_y \sin\left(\frac{\pi}{N}\right) \sin\left(j\frac{\pi}{N}\right), \quad j = 1, \ldots, N-1$$

with suitable constants C_x, C_y. These formulas result from the finite difference discretization with central differences (see [11]). The constants C_x, C_y can be chosen such that the resulting finite difference matrix yields an M-matrix (see [9]), i.e., its inverse has only nonnegative entries. For the practically more efficient pseudospectral method, the stabilization is achieved by adding the viscosity term to the right-hand side f. Here f is replaced by

$$f + \delta_x c f_x + \delta_y d f_y,$$

and the corresponding differential operator is modified such that the new problem is equivalent to the original system (1.1), (1.2). In [15] we investigated this method in connection with a multidomain approach for the above boundary layer problem. Stability is shown and suitable multigrid components for the efficient solution of the stabilized problem are presented. Clearly, a drawback of this approach is that high-order derivatives have to be computed, which makes it quite expensive.

For preconditioning of the original spectral system we recommend an upwind FD method, for which each of the first derivatives u_x and u_y is differenced according to the sign of the coefficients c and d, respectively. The Laplace operator is discretized by standard central finite differences and the first derivatives u_x and u_y in (x_i, y_j), $i, j = 1, \dots, N-1$ are approximated as follows:

$$\begin{aligned}
c(x_i, y_j) \geq 0 : \quad & u_x(x_i, y_j) \cong \frac{u(x_{i+1}, y_j) - u(x_i, y_j)}{x_{i+1} - x_i}, \\
c(x_i, y_j) < 0 : \quad & u_x(x_i, y_j) \cong \frac{u(x_i, y_j) - u(x_{i-1}, y_j)}{x_i - x_{i-1}}, \\
d(x_i, y_j) \geq 0 : \quad & u_y(x_i, y_j) \cong \frac{u(x_i, y_{j+1}) - u(x_i, y_j)}{y_{j+1} - y_j}, \\
d(x_i, y_j) < 0 : \quad & u_y(x_i, y_j) \cong \frac{u(x_i, y_j) - u(x_i, y_{j-1})}{y_j - y_{j-1}}.
\end{aligned}$$

For the iterative solution we recommend flow directed schemes. Since the Chebyshev nodes are dense near the boundary it is necessary to use line Gauss–Seidel relaxation. For smoothing it is recommended to use alternate iterations of flow directed horizontal iterations (FDHI) and flow directed vertical iterations (FDVI). In the literature this combination is called FDHVI (see [7], [10]). The iterative scheme FDHI is a variant of line Gauss–Seidel relaxation. Let P_i denote the mesh points on the vertical line $x = x_i$. We divide P_i into two subsets:

$$\begin{aligned}
P_{i,E} &:= \{(i, j) : c(x_i, y_j) \geq 0\}, \\
P_{i,W} &:= \{(i, j) : c(x_i, y_j) < 0\}.
\end{aligned}$$

The FDHI partitioning and ordering of the unknowns consists of the subsets $P_{i,E}$ arranged in order of increasing i, followed by the subsets $P_{i,W}$, arranged in order of decreasing i. The difference equations on each of the subsets $P_{i,E}$ or $P_{i,W}$ are a collection of tridiagonal systems. By considering the mesh points P_j on a horizontal line $y = y_j$ and dividing P_j into subsets $P_{j,N}$, $P_{j,S}$, we may construct the iterative scheme FDVI. Finally one alternates between FDHI and FDVI, resulting in FDHVI. For a more detailed description including numerical results, we refer the reader to [7] and [10]. Han et al. [10] describe a procedure based on directed graphs to partition and order the unknowns of the Gauss–Seidel process. This is performed by inspection of the coefficient matrix. Nevertheless, this algorithm is expensive for nonlinear problems, like those coming from the Navier–Stokes or Boussinesq equations, when the coefficients are solution dependent and require the reconstruction of the directed graph several times. The penalty for such a choice is proportional to the number of mesh points. In §4 the FDHVI scheme is applied to the Boussinesq flow problem.

4. Application to the Boussinesq flow problem. The problem specifically considered here is that of the two-dimensional flow of a Boussinesq fluid of Prandtl number $Pr = 0.71$ (i.e., air) in an upright square cavity (see [1], [6]). The walls are nonslip and impermeable. The horizontal walls are adiabatic and the vertical sides are at fixed temperatures. In addition to the Navier–Stokes equations we have one further equation for the temperature T. By Ra we denote the Rayleigh number. The Boussinesq flow problem in vorticity–streamfunction formulation reads as follows:

$$4\Delta\psi + \omega = 0 \text{ in } \Omega = (-1,1)^2, \tag{4.1}$$

$$-2Pr\Delta\omega + \frac{\partial}{\partial x}(v_1\omega) + \frac{\partial}{\partial y}(v_2\omega) = RaPr\frac{\partial T}{\partial x} \text{ in } \Omega, \tag{4.2}$$

$$-2\Delta T + \frac{\partial}{\partial x}(v_1 T) + \frac{\partial}{\partial y}(v_2 T) = 0 \text{ in } \Omega. \tag{4.3}$$

As usual $(v_1, v_2)^t$ denotes the velocity. The scalar factors 2 in equations (4.2) and (4.3) and 4 in equation (4.1) are due to the fact that we here define the problem in $(-1,1)^2$ instead of the original square cavity $(0,1)^2$. ψ fulfills homogeneous Dirichlet boundary conditions, i.e.,

$$\psi = \frac{\partial\psi}{\partial\nu} = 0 \text{ on } \partial\Omega$$

and T fulfills mixed Dirichlet–Neumann boundary conditions, i.e.,

$$T(-1,y) = 1,\ T(1,y) = 0 \text{ for } y \in (-1,1),$$
$$\frac{\partial T}{\partial y}(x,-1) = \frac{\partial T}{\partial y}(x,1) = 0 \text{ for } x \in [-1,1].$$

The homogeneous Neumann boundary conditions correspond to the fact that the horizontal walls are adiabatic.

Now the equations (4.1)–(4.3) are linearized by a quasi-Newton method (see [16]), where the velocity from the previous iteration is employed. Hence we have to solve the linear problem:

$$4\Delta\psi^{n+1} + \omega^{n+1} = 0 \text{ in } \Omega, \tag{4.4}$$

$$-2Pr\Delta\omega^{n+1} + \frac{\partial}{\partial x}(v_1^n\omega^{n+1}) + \frac{\partial}{\partial y}(v_2^n\omega^{n+1}) = RaPr\frac{\partial T^{n+1}}{\partial x} \text{ in } \Omega, \tag{4.5}$$

$$-2\Delta T^{n+1} + \frac{\partial}{\partial x}(v_1^n T^{n+1}) + \frac{\partial}{\partial y}(v_2^n T^{n+1}) = 0 \text{ in } \Omega, \tag{4.6}$$

where the index n denotes the nth iterate.

Clearly, the velocity is related to the streamfunction by

$$v_1^n = \frac{\partial\psi^n}{\partial y},\quad v_2^n = -\frac{\partial\psi^n}{\partial x}.$$

The linear system (4.4)–(4.6) is now approximately solved by a spectral multigrid (SMG) method (see [12], [13]). We first describe the pseudospectral discretization of the system (4.4)–(4.6). The functions ψ^{n+1} and ω^{n+1} are spectrally approximated by polynomials $u_{N+2} \in \mathbf{P}_{N+2}$, $v_N \in \mathbf{P}_N$. T^{n+1} is approximated by a polynomial $w_N \in \mathbf{P}_N$. Here the index $n+1$ is omitted. Hence v_1^n, v_2^n are approximated by the polynomials $v_{1,N}$, $v_{2,N} \in \mathbf{P}_{N+2}$, where

$$v_{1,N} = \frac{\partial\bar{u}_{N+2}}{\partial y},\quad v_{2,N} = -\frac{\partial\bar{u}_{N+2}}{\partial x},$$

and $\bar{u}_{N+2} \in \mathbf{P}_{N+2}$ corresponds to the polynomial u_{N+2} from the previous iteration. Now the pseudospectral problem related to (4.4)–(4.6) reads as follows: Find $u_{N+2} \in \mathbf{P}_{N+2}$, $v_N \in \mathbf{P}_N$, $w_N \in \mathbf{P}_N$ such that

$$[4\Delta u_{N+2} + v_N](x_i, y_j) = 0 \tag{4.7}$$

for $i, j = 0, \ldots, N$ and

$$\left[-2Pr\Delta v_N + \frac{\partial}{\partial x}(v_{1,N}v_N) + \frac{\partial}{\partial y}(v_{2,N}v_N)\right](x_i, y_j) = RaPr\frac{\partial w_N}{\partial x}(x_i, y_j), \tag{4.8}$$

$$\left[-2\Delta w_N + \frac{\partial}{\partial x}(v_{1,N}w_N) + \frac{\partial}{\partial y}(v_{2,N}w_N)\right](x_i, y_j) = 0 \tag{4.9}$$

for $i, j = 1, \ldots, N-1$. Since u has to fulfill two types of boundary conditions we choose $u_{N+2} \in \mathbf{P}_{N+2}$, fulfilling the homogeneous Dirichlet boundary conditions. For v_N there are no boundary conditions. The pseudospectral boundary conditions for $w_N \in \mathbf{P}_N$ are given by

$$w_N(-1, y_j) = 1, \; w_N(1, y_j) = 0 \;\text{ for } j = 1, \ldots, N-1, \tag{4.10}$$

$$\frac{\partial w_N}{\partial y}(x_i, -1) = \frac{\partial w_N}{\partial y}(x_i, 1) = 0 \;\text{ for } i = 0, \ldots, N. \tag{4.11}$$

The system (4.7)–(4.11) completely determines the spectral approximations u_{N+2}, v_N, w_N. It is clear that the polynomials u_{N+2}, v_N are uniquely determined by the equations (4.7), (4.8). Furthermore the equation (4.9) together with the boundary conditions (4.10), (4.11) uniquely determine the polynomial w_N. Hence in the linearized version the systems (4.7), (4.8) for determining u_{N+2}, v_N and (4.9)–(4.11) for determining w_N can be handled separately. First, one solves the system (4.9)–(4.11) for w_N by an SMG method, then one calculates $\frac{\partial w_N}{\partial x}(x_i, y_j)$, $i, j = 1, \ldots, N-1$, and finally one solves the system (4.7), (4.8) by the SMG method introduced in [14]. Here we employed six V-cycles of SMG to get a nearly exact solution of the linear systems.

Now we turn to a more precise description of the SMG method. We use the same components as already introduced in §3. A somewhat different treatment results from the fact that the diffusive part is now perturbed by the first-order derivatives $\frac{\partial}{\partial x}$, $\frac{\partial}{\partial y}$. For an increasing Rayleigh number the convective part becomes dominant. Hence in the defect correction step one has to use an FD approximation which remains stable also for an increasing Rayleigh number. Furthermore the FD problem has to be solved approximately by a suitable iterative method which also works for convection-dominated flows. Here we employed the FDHVI iteration for preconditioning of the spectral system resulting from the equations (4.8), (4.9). To handle the complex eigenvalues of the preconditioned spectral operator we employ nonsymmetric matrix iterations. Here we choose the GMRES iteration. For a more detailed description of these components, we refer to §3.

By using these components we numerically calculated for various Rayleigh numbers and mesh sizes the following quantities:

$|\psi|_{\text{mid}}$: absolute value of the streamfunction at the midpoint of the cavity,
$|\psi|_{\max}$: maximum absolute value of the streamfunction,
$v_{1,\max}$: maximum horizontal velocity on the vertical midplane of the cavity,
$v_{2,\max}$: maximum horizontal velocity on the horizontal midplane of the cavity.

The local heat flux in a horizontal direction at any point in the cavity is given by

$$Q := v_1 T - 2\frac{\partial T}{\partial x}.$$

Let us further introduce the following Nusselt numbers:

$\overline{Nu} := \frac{1}{4}\int_{-1}^{1}\int_{-1}^{1} Q(x, y)dxdy$: average Nusselt number throughout the cavity,
$Nu_{\frac{1}{2}} := \frac{1}{2}\int_{-1}^{1} Q(0, y)dy$: average Nusselt number on the vertical midplane,

$Nu_0 := \frac{1}{2}\int_{-1}^{1} Q(-1, y)dy$: average Nusselt number on the vertical boundary,
$Nu_{\max} := \max\{|Q(-1, y)| : y \in [-1, 1]\}$: maximum value of the Nusselt number,
$Nu_{\min} := \min\{|Q(-1, y)| : y \in [-1, 1]\}$: minimum value of the Nusselt number.

The above integrals in the definition of $\overline{Nu}$, $Nu_{\frac{1}{2}}$, and Nu_0 are evaluated by the Clenshaw–Curtis quadrature (see [5, p. 68]). In Tables 2–4 we present the numerical results for different Rayleigh numbers and $N = 8, 16, 24$. The numerical results are in good accordance with the results obtained in [6]. However, for a larger Rayleigh number or increasing N the above SMG method is no more convergent. The reason is that upstream preconditioning is not good enough. Here one has to find some better ways of preconditioning. We are currently trying to find improved preconditioners where the finite difference discretization is performed on staggered grids.

A MODEL NUMERICAL SCHEME FOR THE PROPAGATION OF PHASE TRANSITIONS IN SOLIDS*

BERNARDO COCKBURN† AND HUIING GAU‡

Abstract. In this paper, we devise a simple finite difference scheme that produces approximations to the viscosity-capillarity solutions of the equations that govern the propagation of phase transitions in solids (or to the equations of van der Waals fluids) for all positive values of the dimensionless parameter that characterizes the viscosity-capillarity solution. Numerical experiments showing the convergence properties of the method are presented.

Key words. viscosity-capillarity, phase transitions, mixed-type conservation laws

1. Introduction. In this paper, we devise and validate a method for numerically solving the initial value problem associated with the equations that govern the propagation of phase transitions in solids, namely,

$$
\begin{aligned}
\gamma_t &= v_x, \\
v_t &= (\sigma(\gamma))_x, \\
\gamma(0) &= \gamma_0, \\
v(0) &= v_0,
\end{aligned}
\tag{1.1}
$$

where v is the velocity, γ the strain, and σ the stress. We consider Lipschitz stresses that are increasing on phase 1 ($-1 < \gamma < \gamma_{1,2}$) and phase 3 ($\gamma_{2,3} < \gamma$) of the material and are decreasing on phase 2 ($\gamma_{1,2} < \gamma < \gamma_{2,3}$); see Fig. 1.

This renders (1.1) a system of mixed type, since it is well known that when $\sigma' > 0$ the system (1.1) is hyperbolic and that when $\sigma' < 0$ the system is elliptic. As pointed out by James in [6], this fact enriches the problem of finding a solution for (1.1) because now the standard entropy condition for hyperbolic systems is not enough to single out a physically relevant solution. A way to do so is through the so-called viscosity-capillarity (VC) approach which consists of obtaining solutions of (1.1) as limits of the solutions of the system

$$
\begin{aligned}
\tilde{\gamma}_t &= \tilde{v}_x, \\
\tilde{v}_t &= (\sigma(\tilde{\gamma}))_x + \nu\, \tilde{v}_{xx} - \lambda\, \tilde{\gamma}_{xxx}, \\
\tilde{\gamma}(0) &= \gamma_0, \\
\tilde{v}(0) &= v_0,
\end{aligned}
\tag{1.2}
$$

when the parameters ν and λ go to zero while the number $\omega = 2\sqrt{\lambda}/\nu$ is maintained fixed. The solutions of (1.1) obtained in this way will thus be called the VC solutions of (1.1). In this paper, we restrict ourselves to the problem of devising a numerical scheme capable of converging to those solutions.

Truskinovsky [14] and Slemrod [10] proposed independently the notion of VC solutions for the equations of van der Waals fluids, which are of the form (1.1). In this context, $\gamma < \gamma_{1,2}$ represents the liquid phase and $\gamma > \gamma_{2,3}$ the vapor phase; the phase $\gamma_{1,2} < \gamma < \gamma_{2,3}$ is the

region in which the system is elliptic. The VC criterion re-incorporates in equations (1.1) the physics lost in neglecting the second-order and third-order terms of (1.2). In [5], a review of recent results about the VC solutions of the Riemann problem for (1.1) can be found.

There are very few papers in the available literature concerning numerical methods for mixed-type systems like (1.1). In [9], Slemrod proposed the idea of using the Lax–Friedrichs scheme to numerically approximate the VC solution of (1.1) for $\omega = 1$. This idea was later successfully numerically tested in the pioneering work of Slemrod and Flaherty [11] who considered a Lax–Friedrichs-type scheme with which they could handle the case $\omega \in [0, 1]$. In [12], Shu developed a technique that allows the use of the essentially nonoscillatory schemes for numerically solving mixed-type problems. In [7], Jin considered formally second-order accurate relaxation Lax–Friedrichs-type schemes for VC solutions with $\omega \in [0, 1]$. Our simple finite difference scheme is the first scheme to work for all nonnegative values of ω. Affouf and Caflish [4] used a second-order finite difference scheme to study the stability of the solutions of Riemann problems for (1.2); they took the parameters ν and λ to be order-one parameters. Pitman and Ni [8] have also studied mixed systems like (1.1) with a so-called visco-elastic relaxation law.

To give an idea of the performance of our model scheme, we display in Fig. 2 the exact VC solution of (1.1) for $\omega = 3$ and the strain–stress curve of Fig. 1 with the following parameter values:

$$\gamma_{1,2} = .1, \ \gamma_{2,3} = .2, \ \sigma'(\gamma) = \begin{cases} 20, & \gamma \in [-1, \gamma_{1,2}), \\ -10, & \gamma \in (\gamma_{1,2}, \gamma_{2,3}), \\ 5, & \gamma \in (\gamma_{2,3}, \infty). \end{cases}$$

Thus, in this case the elliptic region (phase 2) is the region $\gamma \in [.1, .2]$. The initial data is

$$\gamma_0(x) = \begin{cases} .3, & x < 0, \\ .4, & x > 0, \end{cases} \qquad v_0(x) = \begin{cases} 0, & x < 0, \\ -.8, & x > 0. \end{cases}$$

The exact VC strain displays two 1–3 phase transitions (or boundaries) near the origin and two shocks both of which occur within phase 3. Note that the phase boundaries are very well approximated and that no spurious oscillations or spikes are present.

We stress the fact that in this paper we are mainly concerned with the problem of how to deal with the presence of the elliptic region. The quality of the approximation outside the elliptic region can be improved by using several well-known techniques for hyperbolic conservation laws. This will be done in a forthcoming paper.

There are several other criteria to select a solution for systems like (1.1); see, for example, the papers by Truskinovsky [15] and Abeyaratne and Knowles [1], and the survey by Truskinovsky [16]. We consider this paper to be the first step in our effort of devising a numerical scheme capable of converging to the solutions singled out by general criteria.

The paper is organized as follows. In §2, we present the heuristics that will guide us in devising our numerical scheme which we construct in §3. In §4, we study the stability of its semidiscrete version and obtain information about the effect of the discretization parameters on the stability of the scheme. In §5, we display our numerical results which indicate that the scheme converges to the VC solutions of (1.1) for a wide range of values of the dimensionless parameter ω. We end in §6 with some concluding remarks.

2. Heuristics. As in [11], the idea that guides us in devising our numerical scheme is very simple: the numerical scheme must have a model equation whose solutions behave like the solutions of (1.2).

We look for numerical schemes whose model equation is of the following form:

$$\begin{aligned} \hat{\gamma}_t &= \hat{v}_x + r_0 \nu_0 \hat{\gamma}_{xx}, \\ \hat{v}_t &= (\sigma(\hat{\gamma}))_x + \nu_0 \hat{v}_{xx} - \lambda_0 \hat{\gamma}_{xxx}. \end{aligned} \tag{2.1a}$$

This form of the model equation is very convenient because by changing variables as follows:

$$\bar{\gamma} = \hat{\gamma}, \tag{2.2a}$$

$$\bar{v} = \hat{v} + r_0 \nu_0 \hat{\gamma}_x, \tag{2.2b}$$

we can rewrite system (2.1) as

$$\bar{\gamma}_t = \bar{v}_x, \tag{2.3a}$$

$$\bar{v}_t = (\sigma(\bar{\gamma}))_x + \nu_0 (1 + r_0) \bar{v}_{xx} - (\lambda_0 + r_0 \nu_0^2) \bar{\gamma}_{xxx}, \tag{2.3b}$$

and if we set

$$\omega = 2 \frac{\sqrt{\lambda_0 + r_0 \nu_0^2}}{(1 + r_0) \nu_0}, \tag{2.4}$$

we see that the functions $(\bar{v}, \bar{\gamma})$ given by (2.2), (2.1a) and satisfying the initial conditions

$$\bar{\gamma}(0) = \gamma_0, \qquad \bar{v}(0) = v_0, \tag{2.1b}$$

are exactly equal to $(\tilde{v}, \tilde{\gamma})$ for $\nu = (1 + r_0)\nu_0$. Thus, to obtain the scheme we are looking for, we simply have to discretize (2.1) and (2.2) in a suitable way.

In [11], Slemrod and Flaherty took the viscosity coefficient ν_0 proportional to $(\Delta x)^{2/3}$ and $\lambda_0 = 0$. The relation (2.4) becomes then

$$\omega = 2\frac{\sqrt{r_0}}{(1 + r_0)},$$

which implies that ω must lie in the interval $[0, 1]$. By (2.4), to allow the parameter ω to be bigger than one, λ_0 must be strictly bigger than zero. In this paper, we explore the following choices of the discretization parameters:

$$r_0 = 1, \tag{2.5a}$$

$$\nu_0 = \left\{ \sup_{\gamma \geq -1} \max\{0, \sigma'(\gamma)\}\right\}^{1/2} (\Delta x)^\beta, \tag{2.5b}$$

$$\lambda_0 = (\omega^2 - 1)\,\nu_0^2, \tag{2.5c}$$

for several values of β in $(0, 1]$. Note that (2.5c) follows from (2.5a) and (2.4).

If we pick the very convenient choice $\beta = 1$, in order to obtain a numerical scheme with (2.1a) as a model equation, we simply have to discretize (2.1a) with

(1) a third-order accurate approximation of the first-order space derivatives,
(2) a second-order accurate approximation of the second-order space derivatives,
(3) a consistent approximation of the third-order derivative,
(4) a third-order accurate time discretization.

In what follows, we construct such a scheme.

Note that only the parameters $\nu = (1 + r_0)\nu_0$ and $\lambda = \lambda_0 + r_0\,\nu_0^2$ have an effect on the properties of the solution $(\bar{\gamma}, \bar{v})$ of (2.1) and (2.2). However, the particular value of the parameter r_0, for example, may have an influence on the properties of the approximate solution due to the properties of the discretization procedure. In §4, we show that this is indeed the case for the scheme we devise next. We have found, experimentally, that the choice (2.5a) works well.

3. A finite difference scheme. For the sake of simplicity, we consider uniform partitions in both space and time and set, as usual, $x_j = j\,\Delta x$, $x_{j+1/2} = (j + 1/2)\Delta x$, $t^n = n\Delta t$. We denote by u_j^n an approximation of $u(t^n, x_j)$ and by $u_{j+1/2}^n$ an approximation of $u(t^n, x_{j+1/2})$. We assume that $n \in \mathbb{N}$ and that $j \in \mathbb{Z}$.

3.1. Discretizing equations (2.1a). The following space discretizations satisfy the above requirements:

$$(u_x)_j \sim (u_{j-2} - 8\,u_{j-1} + 8\,u_{j+1} - u_{j+2})/12\Delta x,$$
$$(u_{xx})_j \sim (u_{j-1} - 2\,u_j + u_{j+1})/(\Delta x)^2,$$
$$(u_{xxx})_j \sim (-u_{j-2} + 2\,u_{j-1} - 2\,u_{j+1} + u_{j+2})/2(\Delta x)^3.$$

We can rewrite the resulting space discretization of (2.1) in conservation form as follows:

$$\frac{d}{dt}U_j = \frac{1}{\Delta x}(F_{j+1/2} - F_{j-1/2}), \tag{3.1a}$$

where

$$U_j = \begin{pmatrix} \hat{\gamma}_j \\ \hat{v}_j \end{pmatrix}, \quad F_{j+1/2}(U) = \begin{pmatrix} (f_v)_{j+1/2} \\ (f_\sigma)_{j+1/2} \end{pmatrix}, \tag{3.1b}$$

and

$$\begin{aligned} (f_v)_{j+1/2} &= (-\hat{v}_{j-1} + 7\hat{v}_j + 7\hat{v}_{j+1} - \hat{v}_{j+2})/12 \\ &\quad + r_0\, \nu_0\, (-\hat{\gamma}_j + \hat{\gamma}_{j+1})/\Delta x, \end{aligned} \tag{3.1c}$$

$$\begin{aligned} (f_\sigma)_{j+1/2} &= \sigma((-\hat{\gamma}_{j-1} + 7\hat{\gamma}_j + 7\hat{\gamma}_{j+1} - \hat{\gamma}_{j+2})/12) \\ &\quad + \nu_0\, (-\hat{v}_j + \hat{v}_{j+1})/\Delta x \\ &\quad - \lambda_0\, (\hat{\gamma}_{j-1} - \hat{\gamma}_j - \hat{\gamma}_{j+1} + \hat{\gamma}_{j+2})/2(\Delta x)^2. \end{aligned} \tag{3.1d}$$

Finally, we discretize in time by the following third-order accurate TVD-Runge–Kutta time stepping [13]:

$$\begin{aligned} V_j &= U_j^n + \frac{\Delta t}{\Delta x}(F_{j+1/2}(U^n) - F_{j-1/2}(U^n)), \\ W_j &= \frac{3}{4}\, U_j^n + \frac{1}{4}\left\{ V_j^n + \frac{\Delta t}{\Delta x}(F_{j+1/2}(V) - F_{j-1/2}(V))\right\}, \\ U_j^{n+1} &= \frac{1}{3}\, U_j^n + \frac{2}{3}\left\{ W_j^n + \frac{\Delta t}{\Delta x}(F_{j+1/2}(W) - F_{j-1/2}(W))\right\}. \end{aligned} \tag{3.2}$$

3.2. The initial condition and the definition of the approximate solution. Note that a discrete version of (2.2) which is consistent with our space discretization (3.1a), (3.1c) is the following:

$$\begin{aligned} \bar{\gamma}_j &= \hat{\gamma}_j, \\ \bar{v}_{j+1/2} &= (f_v)_{j+1/2}. \end{aligned} \tag{3.3}$$

With this way of defining the approximate strain and velocity, the spike that appears in the approximate velocity at the phase boundaries reported by [11] is totally eliminated; see §5.

To obtain the initial values $(\hat{\gamma}_j^0, \hat{v}_j^0)$, we must take into account (3.3). To do so, we proceed as follow. First, we discretize the initial condition (2.1b) as usual; namely,

$$\begin{aligned} \bar{\gamma}_j^0 &= \frac{1}{\Delta x}\int_{x_{j-1/2}}^{x_{j+1/2}} \gamma_0(x)\, dx, \\ \bar{v}_{j+1/2}^0 &= \frac{1}{\Delta x}\int_{x_j}^{x_{j+1}} v_0(x)\, dx. \end{aligned} \tag{3.4}$$

Then, we solve the linear system set

$$\begin{aligned} &\hat{\gamma}_j^0 = \bar{\gamma}_j^0, \\ &(-\hat{v}_{j-1}^0 + 7\hat{v}_j^0 + 7\hat{v}_{j+1}^0 - \hat{v}_{j+2}^0)/12 = s_{j+1/2}, \end{aligned} \tag{3.5}$$

where

$$s_{j+1/2} = \bar{v}_{j+1/2}^0 - r_0\, \nu_0(-\bar{\gamma}_j^0 + \bar{\gamma}_{j+1}^0)/\Delta x. \tag{3.6a}$$

However, to avoid having to invert the matrix equation $My = b$ given by (3.5) (which could render the initial value $\hat{v}^0$ a highly oscillating function), we consider the matrix equation $M^t Mx = M^t b$ and we *lump the masses* of the matrix $M^t M$. We thus obtain the following simple approximate evaluation of the initial condition:

$$\hat{\gamma}_j^0 = \bar{\gamma}_j^0, \tag{3.6b}$$

$$\hat{v}_j^0 = (-s_{j-3/2}^0 + 7s_{j-1/2}^0 + 7s_{j+1/2}^0 - s_{j+3/2}^0)/12. \tag{3.6c}$$

3.3. Definition of the scheme. We are now ready to define the numerical scheme. Given any $\omega \geq 0$, we compute an approximation of the corresponding VC solution of (1.1) at time T as follows:

(1) compute the initial data $(\bar{v}^0, \bar{\gamma}^0)$ by using (3.4);
(2) compute $(\hat{v}^0, \hat{\gamma}^0)$ by using (3.6);
(3) set $\Delta t = T/N$ for some N suitably chosen (see §5.1);
(4) for $n = 1$ to $N-1$, compute $(\hat{v}^{n+1}, \hat{\gamma}^{n+1})$ by using the scheme (3.2), (3.1);
(5) compute the wanted approximation $(\bar{v}^N, \bar{\gamma}^N)$ by using (3.3).

4. Stability analysis of the semidiscrete scheme. We now turn to the question of the stability of our numerical scheme. Our goal is to prove that the semidiscrete version of the scheme is stable. To do so, we mimic the procedure for obtaining stability for the solutions of our model equation which we show next for the sake of completeness.

Multiplying equation (2.3b) by $\bar{v}$ and integrating over x, we get, after integrating by parts,

$$\frac{1}{2}\frac{d}{dt}\int_{\mathbb{R}} \bar{v}^2 = -\int_{\mathbb{R}} \sigma(\bar{\gamma})\,\bar{v}_x - \nu_0(1+r_0)\int_{\mathbb{R}}(\bar{v}_x)^2 + (\lambda_0 + r_0\nu_0^2)\int_{\mathbb{R}} \bar{\gamma}_{xx}\,\bar{v}_x.$$

By (2.3a), $\bar{v}_x = \bar{\gamma}_t$, and so we get

$$\begin{aligned}\frac{1}{2}\frac{d}{dt}\int_{\mathbb{R}} \bar{v}^2 &= -\int_{\mathbb{R}} \sigma(\bar{\gamma})\,\bar{\gamma}_t - \nu_0(1+r_0)\int_{\mathbb{R}}(\bar{\gamma}_t)^2 + (\lambda_0 + r_0\nu_0^2)\int_{\mathbb{R}} \bar{\gamma}_{xx}\,\bar{\gamma}_t \\ &= -\frac{d}{dt}\int_{\mathbb{R}} W(\bar{\gamma}) - \nu_0(1+r_0)\int_{\mathbb{R}}(\bar{\gamma}_t)^2 - \frac{1}{2}(\lambda_0 + r_0\nu_0^2)\frac{d}{dt}\int_{\mathbb{R}}(\bar{\gamma}_x)^2,\end{aligned}$$

where $W' = \sigma$. Thus,

$$\frac{d}{dt}E(\bar{v}, \bar{\gamma}) = -\nu_0(1+r_0)\int_{\mathbb{R}}(\bar{\gamma}_t)^2, \tag{4.1a}$$

where the energy $E(\bar{v}, \bar{\gamma})$ is defined as follows:

$$E(\bar{v}, \bar{\gamma}) = \frac{1}{2}\int_{\mathbb{R}} \bar{v}^2 + \int_{\mathbb{R}} W(\bar{\gamma}) + \frac{1}{2}(\lambda_0 + r_0\nu_0^2)\int_{\mathbb{R}}(\bar{\gamma}_x)^2 \tag{4.1b}$$

or, if the choice (2.4) for λ_0 is taken,

$$E(\bar{v}, \bar{\gamma}) = \frac{1}{2}\int_{\mathbb{R}} \bar{v}^2 + \int_{\mathbb{R}} W(\bar{\gamma}) + \frac{1}{2}\left(\frac{1+r_0}{2}\right)^2 \nu_0^2\,\omega^2\int_{\mathbb{R}}(\bar{\gamma}_x)^2. \tag{4.1c}$$

We now follow the above process to try to obtain a similar stability result for the semidiscrete scheme (3.1). We proceed in several steps.

4.1. Rewriting the scheme. We start by rewriting the semidiscrete scheme in terms of $\bar{v}$ and $\bar{\gamma}$. To facilitate such a rewriting, we introduce the shifting operators S_i defined by $S_i u_k = u_{k+i}$. Setting $M = (-S_{-1} + 7S_0 + 7S_1 - S_2)/12$ and $D = (S_{-1} - S_0 - S_1 + S_2)/2$, we can now rewrite the semidiscrete scheme (3.1) as follows:

$$\frac{d}{dt}\hat{\gamma}_j = (-S_{-1} + S_0)(M\hat{v}_j + r_0\nu_0(-S_0 + S_1)\hat{\gamma}_j/\Delta x)/\Delta x,$$
$$\frac{d}{dt}\hat{v}_j = (-S_{-1} + S_0)(\sigma(M\hat{\gamma}_j) + \nu_0(-S_0 + S_1)\hat{v}_j/\Delta x - \lambda_0 D\hat{\gamma}_j/(\Delta x)^2)/\Delta x.$$

Since, by (3.3), we have

$$\begin{aligned}\bar{\gamma}_j &= \hat{\gamma}_j,\\ \bar{v}_{j+1/2} &= M\hat{v}_j + r_0\nu_0(-S_0 + S_1)\bar{\gamma}_j/\Delta x,\end{aligned} \tag{4.2}$$

we can write the first equation of the above scheme as follows:

$$\frac{d}{dt}\bar{\gamma}_j = (-S_{-1} + S_0)\bar{v}_{j+1/2}/\Delta x. \tag{4.3a}$$

To express the second equation in terms of $\bar{\gamma}$ and $\bar{v}$, we proceed as follows. By (4.2), we have

$$\begin{aligned}\frac{d}{dt}\bar{v}_{j+1/2} &= M\frac{d}{dt}\hat{v}_j + r_0\nu_0(-S_0 + S_1)\frac{d}{dt}\bar{\gamma}_j\\ &= M\frac{d}{dt}\hat{v}_j + r_0\nu_0(-S_0 + S_1)(-S_{-1} + S_0)\bar{v}_{j+1/2}/\Delta x,\end{aligned}$$

by (4.3a). Inserting the expression for $\frac{d}{dt}\hat{v}_j$ and rearranging terms, we obtain

$$\begin{aligned}\frac{d}{dt}\bar{v}_{j+1/2} = {}& M(-S_{-1} + S_0)\sigma(M\hat{\gamma}_j)/\Delta x\\ &+ \nu_0(-S_{-1} + S_0)(-S_0 + S_1)(M\hat{v}_j + r_0\bar{v}_{j+1/2})/(\Delta x)^2\\ &- \lambda_0(-S_{-1} + S_0)\, M\, D\hat{\gamma}_j/(\Delta x)^3.\end{aligned}$$

Finally, since, by (4.2), $M\hat{v}_j = \bar{v}_{j+1/2} - r_0\nu_0(-S_0 + S_1)\bar{\gamma}_j/\Delta x$, we have

$$\begin{aligned}\frac{d}{dt}\bar{v}_{j+1/2} = {}& M(-S_{-1} + S_0)\sigma(M\hat{\gamma}_j)/\Delta x\\ &+ (1 + r_0)\nu_0(-S_0 + S_1)(-S_{-1} + S_0)\bar{v}_{j+1/2}/(\Delta x)^2\\ &- r_0\nu_0^2(-S_{-1} + S_0)(-S_0 + S_1)^2\bar{\gamma}_j/(\Delta x)^3\\ &- \lambda_0(-S_{-1} + S_0)\, M\, D\hat{\gamma}_j/(\Delta x)^3\\ \equiv {}& \Theta^1_{j+1/2} + \Theta^2_{j+1/2} + \Theta^3_{j+1/2} + \Theta^4_{j+1/2}.\end{aligned} \tag{4.3b}$$

4.2. Multiplying by $\bar{v}_{j+1/2}$. Following the procedure for the model equation, we multiply (4.3b) by $\bar{v}_{j+1/2}\,\Delta x$ and sum over j. We get

$$\frac{1}{2}\frac{d}{dt}\sum_{j\in\mathbb{Z}}(\bar{v}_{j+1/2})^2\,\Delta x = \sum_{j\in\mathbb{Z}}(\Theta^1_{j+1/2} + \Theta^2_{j+1/2} + \Theta^3_{j+1/2} + \Theta^4_{j+1/2})\bar{v}_{j+1/2}\,\Delta x.$$

Summing by parts, we obtain

$$\begin{aligned}\sum_{j\in\mathbb{Z}} \Theta^1_{j+1/2}\bar{v}_{j+1/2}\,\Delta x &= \sum_{j\in\mathbb{Z}}[M(-S_{-1}+S_0)\sigma(M\hat{\gamma}_j)]\,\bar{v}_{j+1/2}\\ &= \sum_{j\in\mathbb{Z}}[M\sigma(M\hat{\gamma}_j)]\,[(-S_1+S_0)\bar{v}_{j+1/2}]\\ &= -\sum_{j\in\mathbb{Z}}[M\sigma(M\hat{\gamma}_j)]\,\frac{d}{dt}\bar{\gamma}_{j+1}\Delta x\end{aligned}$$

by (4.3a). Summing by parts once more, we get

$$\sum_{j\in\mathbb{Z}} \Theta^1_{j+1/2}\bar{v}_{j+1/2}\,\Delta x = -\sum_{j\in\mathbb{Z}}\sigma(M\hat{\gamma}_j)\,\frac{d}{dt}[M\bar{\gamma}_j]\Delta x = -\frac{d}{dt}\sum_{j\in\mathbb{Z}}W(M\hat{\gamma}_j)\,\Delta x,$$

since $W' = \sigma$. For the second term, we have

$$\begin{aligned}\sum_{j\in\mathbb{Z}} \Theta^2_{j+1/2}\bar{v}_{j+1/2}\,\Delta x &= (1+r_0)\nu_0\sum_{j\in\mathbb{Z}}[(-S_0+S_1)(-S_{-1}+S_0)\bar{v}_{j+1/2}]\,\bar{v}_{j+1/2}/(\Delta x)\\ &= (1+r_0)\nu_0\sum_{j\in\mathbb{Z}}[(-S_{-1}+S_0)\bar{v}_{j+1/2}]\,[(-S_0+S_{-1})\bar{v}_{j+1/2}]/(\Delta x)\\ &= -(1+r_0)\nu_0\sum_{j\in\mathbb{Z}}\left(\frac{d}{dt}\bar{\gamma}_j\right)^2\,(\Delta x)\end{aligned}$$

by (4.3a). For the third term, after a summation by parts, we get

$$\begin{aligned}\sum_{j\in\mathbb{Z}} \Theta^3_{j+1/2}\bar{v}_{j+1/2}\,\Delta x &= -r_0\nu_0^2\sum_{j\in\mathbb{Z}}[(-S_{-1}+S_0)(-S_0+S_1)^2\bar{\gamma}_j]\,[\bar{v}_{j+1/2}]/(\Delta x)^2\\ &= -r_0\nu_0^2\sum_{j\in\mathbb{Z}}[(-S_{-1}+S_0)(-S_0+S_1)\bar{\gamma}_j]\\ &\qquad\times[(-S_0+S_{-1})\bar{v}_{j+1/2}]/(\Delta x)^2\\ &= r_0\nu_0^2\sum_{j\in\mathbb{Z}}[(-S_{-1}+S_0)(-S_0+S_1)\bar{\gamma}_j]\,\frac{d}{dt}\bar{\gamma}_j/\Delta x\end{aligned}$$

by (4.3a). Hence, summing by parts once more, we obtain

$$\begin{aligned}\sum_{j\in\mathbb{Z}} \Theta^3_{j+1/2}\bar{v}_{j+1/2}\,\Delta x &= r_0\nu_0^2\sum_{j\in\mathbb{Z}}[(-S_0+S_1)\bar{\gamma}_j]\,\frac{d}{dt}[(-S_1+S_0)\bar{\gamma}_j]/\Delta x\\ &= -\frac{1}{2}r_0\nu_0^2\frac{d}{dt}\sum_{j\in\mathbb{Z}}(-\bar{\gamma}_j+\bar{\gamma}_{j+1})^2/\Delta x.\end{aligned}$$

Finally, for the fourth term, we have

$$\begin{aligned}\sum_{j\in\mathbb{Z}} \Theta^4_{j+1/2}\bar{v}_{j+1/2}\,\Delta x &= -\lambda_0\sum_{j\in\mathbb{Z}}[(-S_{-1}+S_0)\,M\,D\hat{\gamma}_j]\,\hat{v}_{j+1/2}/(\Delta x)^2\\ &= -\lambda_0\sum_{j\in\mathbb{Z}}[M\,D\hat{\gamma}_j]\,[(-S_1+S_0)\,\hat{v}_{j+1/2}]/(\Delta x)^2\end{aligned}$$

$$= \lambda_0 \sum_{j\in\mathbb{Z}} [M\, D\hat{\gamma}_j] \left[\frac{d}{dt}\bar{\gamma}_{j+1}\right] /(\Delta x)$$

$$= \lambda_0 \sum_{j\in\mathbb{Z}} [D\hat{\gamma}_j] \left[M\frac{d}{dt}\bar{\gamma}_j\right] /(\Delta x).$$

Since

$$\begin{aligned} M\hat{\gamma}_j &= (-\hat{\gamma}_{j-1} + 7\hat{\gamma}_j + 7\hat{\gamma}_{j+1} - \hat{\gamma}_{j+2})/12 \\ &= (-\hat{\gamma}_{j-1} + \hat{\gamma}_j + \hat{\gamma}_{j+1} - \hat{\gamma}_{j+2})/12 + (\hat{\gamma}_j + \hat{\gamma}_{j+1})/2 \\ &= -D\hat{\gamma}_j/6 + (S_0 + S_1)\hat{\gamma}_j/2, \end{aligned}$$

we can write

$$\sum_{j\in\mathbb{Z}} \Theta^4_{j+1/2}\bar{v}_{j+1/2}\,\Delta x = -\frac{1}{48}\lambda_0\frac{d}{dt}\sum_{j\in\mathbb{Z}}(\bar{\gamma}_{j-1} - \bar{\gamma}_j - \bar{\gamma}_{j+1} + \bar{\gamma}_{j+2})^2/(\Delta x) + \Psi,$$

where

$$\Psi = \lambda_0\frac{1}{2}\sum_{j\in\mathbb{Z}}[D\hat{\gamma}_j]\left[(S_0 + S_1)\frac{d}{dt}\hat{\gamma}_j\right]/\Delta x.$$

Since $D = (S_0 - S_2)(S_{-1} - S_0)/2$, we have

$$\begin{aligned} \Psi &= \frac{1}{4}\lambda_0\sum_{j\in\mathbb{Z}}[(S_0 - S_2)\hat{\gamma}_j]\,\frac{d}{dt}[(S_1 - S_0)(S_0 + S_1)\hat{\gamma}_j]/\Delta x \\ &= \frac{1}{4}\lambda_0\sum_{j\in\mathbb{Z}}[(S_0 - S_2)\hat{\gamma}_j]\,\frac{d}{dt}[(-S_0 + S_2)\hat{\gamma}_j]/\Delta x \\ &= -\frac{1}{8}\lambda_0\frac{d}{dt}\sum_{j\in\mathbb{Z}}(-\hat{\gamma}_{j-1} + \hat{\gamma}_{j+1})^2/\Delta x. \end{aligned}$$

Putting together the above equalities, we find that we have the following discrete version of (4.1):

$$\frac{d}{dt}E_h = -\nu_0(1 + r_0)\sum_{j\in\mathbb{Z}}\left(\frac{d}{dt}\bar{\gamma}_j\right)^2\Delta x, \tag{4.4a}$$

where the approximate energy E_h is defined by

$$\begin{aligned} E_h = {} & \frac{1}{2}\sum_{j\in\mathbb{Z}}(\bar{v}_{j+1/2})^2\,\Delta x + \sum_{j\in\mathbb{Z}} W((-\bar{\gamma}_{j-1} + 7\bar{\gamma}_j + 7\bar{\gamma}_{j+1} - \bar{\gamma}_{j+2})/12)\,\Delta x \\ & + \frac{1}{2}r_0\nu_0^2\sum_{j\in\mathbb{Z}}(-\bar{\gamma}_j + \bar{\gamma}_{j+1})^2/\Delta x + \frac{1}{2}\lambda_0\sum_{j\in\mathbb{Z}}\frac{1}{4}(-\bar{\gamma}_{j-1} + \bar{\gamma}_{j+1})^2/\Delta x \\ & + \frac{1}{48}\lambda_0\sum_{j\in\mathbb{Z}}(\bar{\gamma}_{j-1} - \bar{\gamma}_j - \bar{\gamma}_{j+1} + \bar{\gamma}_{j+2})^2/\Delta x. \end{aligned} \tag{4.4b}$$

4.3. The energy E_h for the choice (2.4) of λ_0. Next, we find the expression of E_h for the choice (2.4) λ_0; namely,

$$\lambda_0 = \left(\frac{1+r_0}{2}\right)^2 \nu_0^2\,\omega^2 - r_0\,\nu_0^2.$$

Inserting this form of λ_0 in the expression of E_h (4.4b), we obtain

$$\begin{aligned} E_h &= \frac{1}{2}\sum_{j\in\mathbb{Z}}(\bar{v}_{j+1/2})^2\,\Delta x + \sum_{j\in\mathbb{Z}} W((-\bar{\gamma}_{j-1} + 7\bar{\gamma}_j + 7\bar{\gamma}_{j+1} - \bar{\gamma}_{j+2})/12)\,\Delta x \\ &+ \frac{1}{2}\left(\frac{1+r_0}{2}\right)^2 \nu_0^2\,\omega^2 \sum_{j\in\mathbb{Z}} \frac{1}{4}(-\bar{\gamma}_{j-1} + \bar{\gamma}_{j+1})^2/\Delta x \\ &+ \frac{1}{48}\left(\frac{1+r_0}{2}\right)^2 \nu_0^2\,\omega^2 \sum_{j\in\mathbb{Z}}(\bar{\gamma}_{j-1} - \bar{\gamma}_j - \bar{\gamma}_{j+1} + \bar{\gamma}_{j+2})^2/\Delta x + r_0\,\nu_0^2\,R_{0h}/\Delta x, \end{aligned}$$

where

$$R_{0h} = \sum_{j\in\mathbb{Z}}\left\{\frac{1}{2}(-\bar{\gamma}_j + \bar{\gamma}_{j+1})^2 - \frac{1}{48}(\bar{\gamma}_{j-1} - \bar{\gamma}_j - \bar{\gamma}_{j+1} + \bar{\gamma}_{j+2})^2 - \frac{1}{8}\,(-\bar{\gamma}_{j-1} + \bar{\gamma}_{j+1})^2\right\}.$$

Setting $z_{j+1/2} = -\bar{\gamma}_j + \bar{\gamma}_{j+1}$ and $\rho_j = -z_{j-1/2} + z_{j+1/2}$, we rewrite R_{0h} as follows:

$$\begin{aligned} R_{0h} &= \sum_{j\in\mathbb{Z}}\left\{\frac{1}{2}\,(z_{j+1/2})^2 - \frac{1}{48}(-z_{j-1/2} + z_{j+3/2})^2 - \frac{1}{8}\,(z_{j-1/2} + z_{j+1/2})^2\right\} \\ &= \frac{1}{48}\sum_{j\in\mathbb{Z}}\left\{24\,(z_{j+1/2})^2 - (-z_{j-1/2} + z_{j+3/2})^2 - 6\,(z_{j-1/2} + z_{j+1/2})^2\right\} \\ &= \frac{1}{48}\sum_{j\in\mathbb{Z}}\left\{6\,(-z_{j-1/2} + z_{j+1/2})^2 - (-z_{j-1/2} + z_{j+3/2})^2\right\} \\ &= \frac{1}{48}\sum_{j\in\mathbb{Z}}\left\{6\,(\rho_j)^2 - (\rho_j + \rho_{j+1})^2\right\} \\ &= \frac{1}{48}\sum_{j\in\mathbb{Z}}\left\{2(\rho_j)^2 + (-\rho_j + \rho_{j+1})^2\right\} \end{aligned}$$

or

$$R_{0h} = \frac{1}{48}\sum_{j\in\mathbb{Z}}\left\{2(\bar{\gamma}_{j-1} - 2\bar{\gamma}_j + \bar{\gamma}_{j+1})^2 + (-\bar{\gamma}_{j-1} + 3\bar{\gamma}_j - 3\bar{\gamma}_{j+1} + \bar{\gamma}_{j+2})^2\right\}.$$

As a consequence, we can write that with the choice (2.4) the energy E_h is indeed a nonnegative quantity given by

$$
\begin{aligned}
E_h = {} & \frac{1}{2}\sum_{j\in\mathbb{Z}} (\bar{v}_{j+1/2})^2\,\Delta x + \sum_{j\in\mathbb{Z}} W((-\bar{\gamma}_{j-1} + 7\bar{\gamma}_j + 7\bar{\gamma}_{j+1} - \bar{\gamma}_{j+2})/12)\,\Delta x \\
& + \frac{1}{2}\left(\frac{1+r_0}{2}\right)^2 \nu_0^2\,\omega^2 \sum_{j\in\mathbb{Z}} \frac{1}{4}(-\bar{\gamma}_{j-1} + \bar{\gamma}_{j+1})^2/\Delta x \\
& + \frac{1}{48}\left(\frac{1+r_0}{2}\right)^2 \nu_0^2\,\omega^2 \sum_{j\in\mathbb{Z}} (\bar{\gamma}_{j-1} - \bar{\gamma}_j - \bar{\gamma}_{j+1} + \bar{\gamma}_{j+2})^2/\Delta x \\
& + \frac{1}{48} r_0\,\nu_0^2 \sum_{j\in\mathbb{Z}} \left\{ 2(\bar{\gamma}_{j-1} - 2\bar{\gamma}_j + \bar{\gamma}_{j+1})^2 + (-\bar{\gamma}_{j-1} + 3\bar{\gamma}_j - 3\bar{\gamma}_{j+1} + \bar{\gamma}_{j+2})^2 \right\}/\Delta x.
\end{aligned} \tag{4.4c}
$$

We summarize the results obtained thus far in this section in the following result.

PROPOSITION 4.1 (stability of the semidiscrete scheme (3.1)). *Let the energy E_h be the quantity defined by* (4.4b) *(or* (4.4c) *when λ_0 satisfies* (2.4)*). Then, the equality* (4.4a) *holds and so, for all $t \geq 0$, we have*

$$
E_h(t) + \nu_0(1 + r_0) \int_0^t \sum_{j\in\mathbb{Z}} \left(\frac{d}{dt}\bar{\gamma}_j\right)^2 \Delta x = E_h(0).
$$

In what follows, we argue that (i) the case $\omega \ll 1$ is more difficult to treat than the case $\omega \gg 1$, (ii) it is crucial to maintain the "stability enhancer" parameter r_0 strictly positive, and (iii) the artificial viscosity ν_0 must be reasonably large.

4.4. On the parameters ω, r_0, and ν_0. Notice that it is very important to ensure that the numerical scheme damps away spurious oscillations in the approximate strains. The presence of these oscillations might prevent the convergence to the correct VC solution of (1.1) because, since the stored energy W is nonlinear, even if the approximate strain converges weakly to γ, the approximate stored energy might not converge (weakly) to $W(\gamma)$. From the above stability result, it is clear that the role of the last three terms of the energy E_h is to control those oscillations.

The effect of the size of ω. From the expression (4.4c) of the energy and from the stability result of Proposition 4.1, it is clear that when $\omega \ll 1$ the control on the oscillations of the approximate strain is relaxed and that if $\omega \gg 1$ such control is enhanced.

The effect of the size of r_0. When $\omega = 0$, control on the possible spurious oscillations in the approximate strain can be exerted only if $r_0 > 0$. Moreover, even when $\omega > 0$ it is still crucial to take r_0 strictly positive. Notice that the third and fourth terms of the energy E_h are equal to zero for (and only for) the highly oscillatory wave

$$
\bar{\gamma}_j = \begin{cases} \bar{\gamma}_1 & \text{for } j \text{ even}, \\ \bar{\gamma}_2 & \text{for } j \text{ odd}, \end{cases}
$$

where $\bar{\gamma}_1$ and $\bar{\gamma}_2$ are arbitrary constants. This unfortunate fact is a direct consequence of the presence of the dispersive term in the second model equation (2.1a). However, if $r_0 > 0$, the dissipative term introduced in the first model equation (2.1a) enhances the stability of the scheme by controlling those unwanted oscillations. Indeed, if $r_0 > 0$, the last term of the energy is equal to zero if and only if the approximate strain is an affine function. Moreover, if $r_0 > 0$, the last term of the energy is infinity not only for the above approximate oscillating strain but also for approximate strains with highly oscillatory first derivatives

$$-\bar{\gamma}_{j-1} + \bar{\gamma}_j = \begin{cases} \bar{\gamma}_{x1} & \text{for } j \text{ even,} \\ \bar{\gamma}_{x2} & \text{for } j \text{ odd,} \end{cases}$$

and with highly oscillatory second derivatives

$$\bar{\gamma}_{j-1} - 2\bar{\gamma}_j + \bar{\gamma}_{j+1} = \begin{cases} \bar{\gamma}_{xx1} & \text{for } j \text{ even,} \\ \bar{\gamma}_{xx2} & \text{for } j \text{ odd.} \end{cases}$$

Since the energy must remain bounded, by Proposition 4.1, all three types of highly oscillatory waves in the approximate strain will be controlled, at least partially, even when $\omega = 0$. It is thus crucial to take $r_0 > 0$.

The effect of the size of ν_0. The stability result of Proposition 4.1 and the expression of the energy (4.4c) suggest that a good control on the variation of the strain and on the variation of its first and second derivatives can be achieved if we take $\beta = 1/2$ in the expression (2.5b) defining ν_0; namely, $\nu_0 = c_0\,(\Delta x)^{\beta}$. Taking β bigger than $1/2$ does not seem to be a reasonable strategy, because this would penalize too much the terms of the energy which control the oscillations of the strain. Taking β smaller than $1/2$ is certainly desirable, because then the computational cost, which is proportional to $(\Delta x)^{-3+\beta}$, decreases. However, in doing so, the control on the variation of the strain and on the variation of its first and second derivatives is relaxed, and mildly oscillatory waves might appear which can destroy the convergence to the exact solution.

5. Numerical experiments.

In this section we carry out several numerical experiments devised (i) to verify that the parameter r_0 must be taken to be strictly positive and (ii) to see for what values of the parameter β (recall we are taking $\nu_0 = c_0\,(\Delta x)^{\beta}$) the scheme converges. These experiments are done for the strain–stress relation of Fig. 1. We also report a convergence study for a piecewise-cubic strain–stress curve. Before presenting those numerical experiments, we perform a simple stability analysis that will guide us in the choice of the Courant–Friedrichs–Lewy (CFL) condition.

5.1. Linear stability analysis.

To have an idea of the stability condition for the above scheme, we study its linear stability. We thus consider linear stresses $\sigma(\gamma) = \sigma'\,\gamma$, and we assume that $\sigma' \geq 0$, since otherwise the resulting scheme is unconditionably unstable.

A simple computation gives the following form for the amplification matrix for the numerical scheme (3.1):

$$A = Id + \Lambda + \frac{1}{2}\Lambda^2 + \frac{1}{6}\Lambda^3,$$

where

$$\Lambda = \frac{\Delta t}{\Delta x}\begin{pmatrix} r_0\,\frac{\nu_0}{\Delta x}\,b & i\,a \\ i\sigma'\,a - i\,\frac{\lambda_0}{(\Delta x)^2}\,c & \frac{\nu_0}{\Delta x}\,b \end{pmatrix}$$

and

$$\begin{aligned} a &= \frac{2}{3}\sin(\theta/2)\cos(\theta/2)\,(3 + 2\sin^2(\theta/2)), \\ b &= -4\sin^2(\theta/2), \\ c &= -8\sin^3(\theta/2)\cos(\theta/2) \end{aligned}$$

for $\theta \in (-\pi, \pi]$. The eigenvalues of Λ are, taking into account (2.4),

$$\xi_\pm = \frac{\Delta t}{\Delta x}\left(\frac{\nu_0}{\Delta x}\right)\left\{\left(\frac{1+r_0}{2}\right)b \pm \left[\left(\frac{1+r_0}{2}\right)^2 b^2 - \Theta\right]^{1/2}\right\},$$

where

$$\Theta = r_0\,(b^2 + ac) + \left(\frac{\sigma'}{(\nu_0/\Delta x)^2}\right)a^2 - \left(\frac{1+r_0}{2}\right)^2 \omega^2\, ac.$$

Since $b \leq 0$, $b^2 + ac = \frac{16}{3}\big(\sin(\theta/2)\big)^6\big(1 + 2(\sin(\theta/2))^2\big) \geq 0$, and $ac \leq 0$, we have that $\Theta \geq 0$. Thus, the real part of the eigenvalues $\xi_\pm$ is always nonpositive, provided that $r_0 \geq 0$. Thus, the scheme is always linearly stable under a condition of the form

$$\frac{\Delta t}{\Delta x}\left(\frac{\nu_0}{\Delta x}\right) \leq \varphi\left(\omega, r_0, \frac{\sigma'}{(\nu_0/\Delta x)^2}\right).$$

We have numerically verified that the function

$$\varphi\left(\omega, r_0 = 1, \frac{\sigma'}{(\nu_0/\Delta x)^2}\right) \leq \phi(\omega) = \begin{cases} .44, & \omega \in [0, 1], \\ 1.848/(2.5 + \omega^{1.2}), & \omega \in (1, 50], \\ .8712/\omega, & \omega \in (50, 1000], \end{cases}$$

can be used when $\frac{\sigma'}{(\nu_0/\Delta x)} \leq 1$. In all our computations, we have chosen Δt as follows:

$$\Delta t = \Big\{ \sup_{\gamma \geq -1} \max\{0, \sigma'(\gamma)\}\Big\}^{-1/2} (\Delta x)^{2-\beta}\, \phi(\omega).$$

Note that $\Theta = 0$ if and only if $\theta = 0$ or $\theta = \pi$, and $r_0 = 0$. In this case, we have

$$\Lambda = \frac{\Delta t}{\Delta x}\begin{pmatrix} 0 & 0 \\ 0 & -4\frac{\nu_0}{\Delta x} \end{pmatrix},$$

and so, highly oscillatory waves of the form $\bar{\gamma}_j = \bar{\gamma}_0\,(-1)^j$ will never be damped away, regardless of the values of Δt, Δx, and ν_0. This fact agrees strongly with the analysis of the energy of the semidiscrete scheme.

5.2. Experiments for a piecewise linear stress–strain curve. Next, we present a study of the convergence properties of the scheme under consideration to the VC solution of (1.1) for the strain–stress curve and the initial data used at the introduction and the values $\omega = .15$, $\omega = 1$, and $\omega = 3$. Abeyaratne and Knowles [2] solved this Riemann problem. A classification of all the possible solutions of Riemann problems for the strain–stress relation of Fig. 1 (and general kinetic and nucleation criteria) was carried out by Abeyaratne and Knowles in [3]. The Riemann problem we have chosen is the most challenging among all the possible types of solutions since it has both phase boundaries and shocks.

The effect of the size of r_0. In Fig. 3, we compare the exact VC solution for $\omega = .15$ and the different approximate solutions given by the scheme, with $r_0 = 0$ and $\beta = 1/2$, for $\Delta x = 1/800, 1/1600, 1/3200, 1/6400$, and $1/12800$. In Fig. 4, we take $r_0 = 1$. We clearly see that the highly oscillatory waves that appear in the approximate strain for $r_0 = 0$ disappear

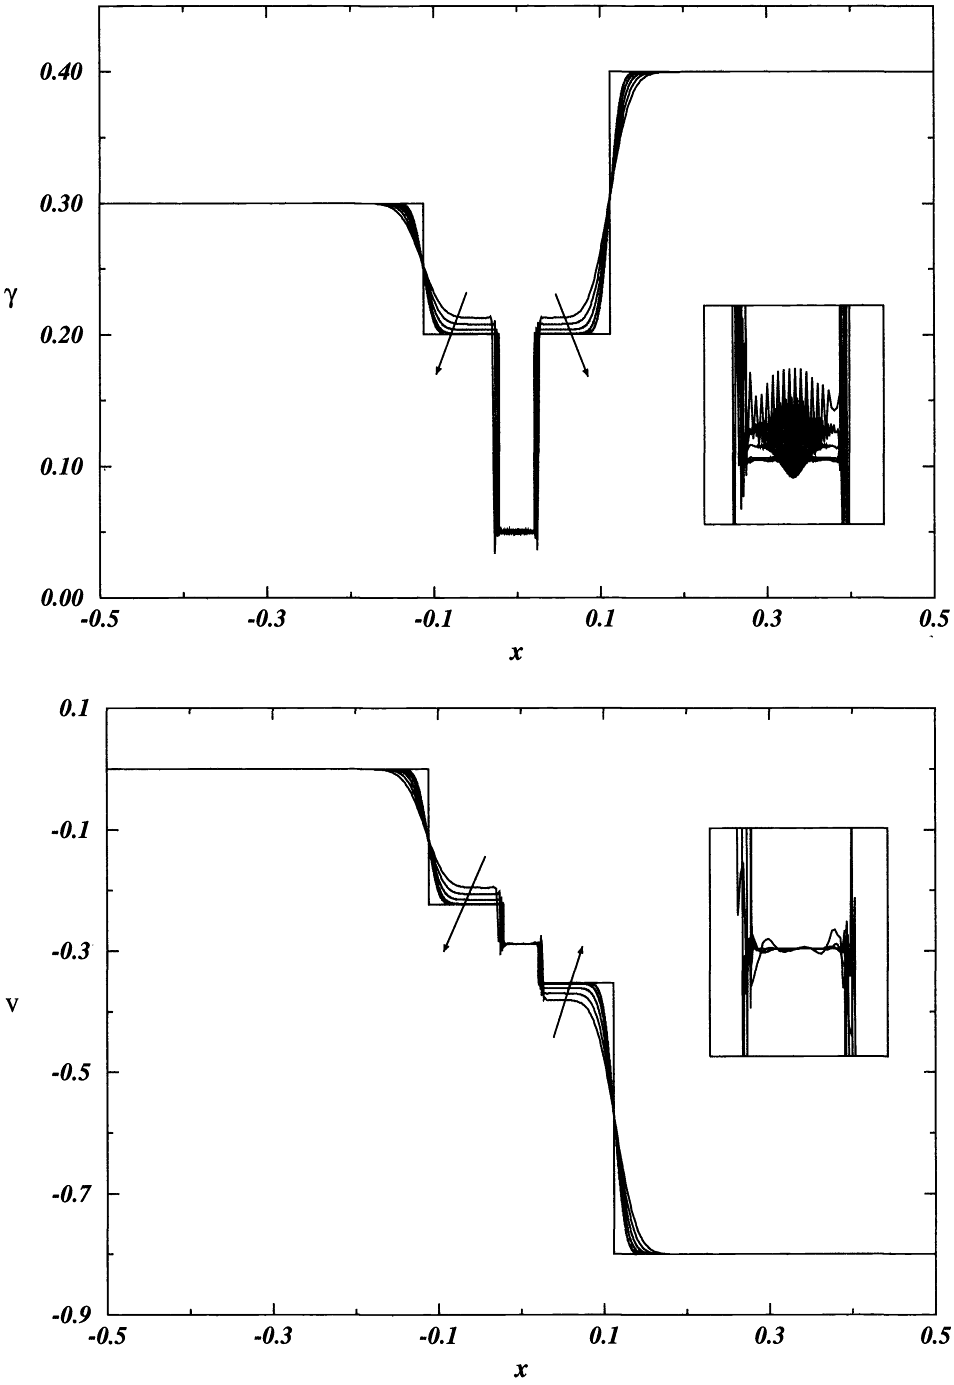

FIG. 3. *The choice $r_0 = 0$ (and $\beta = 1/2$) for $\omega = .15$.*

completely when $r_0 = 1$, as expected. The same phenomenon occurs for $\omega = 1$, as can be seen in Figs. 5 and 6, and for $\omega = 3$, as can be seen in Figs. 7 and 8. These results confirm that we must take $r_0 > 0$ and that choice (2.5a), $r_0 = 1$, is a reasonable one.

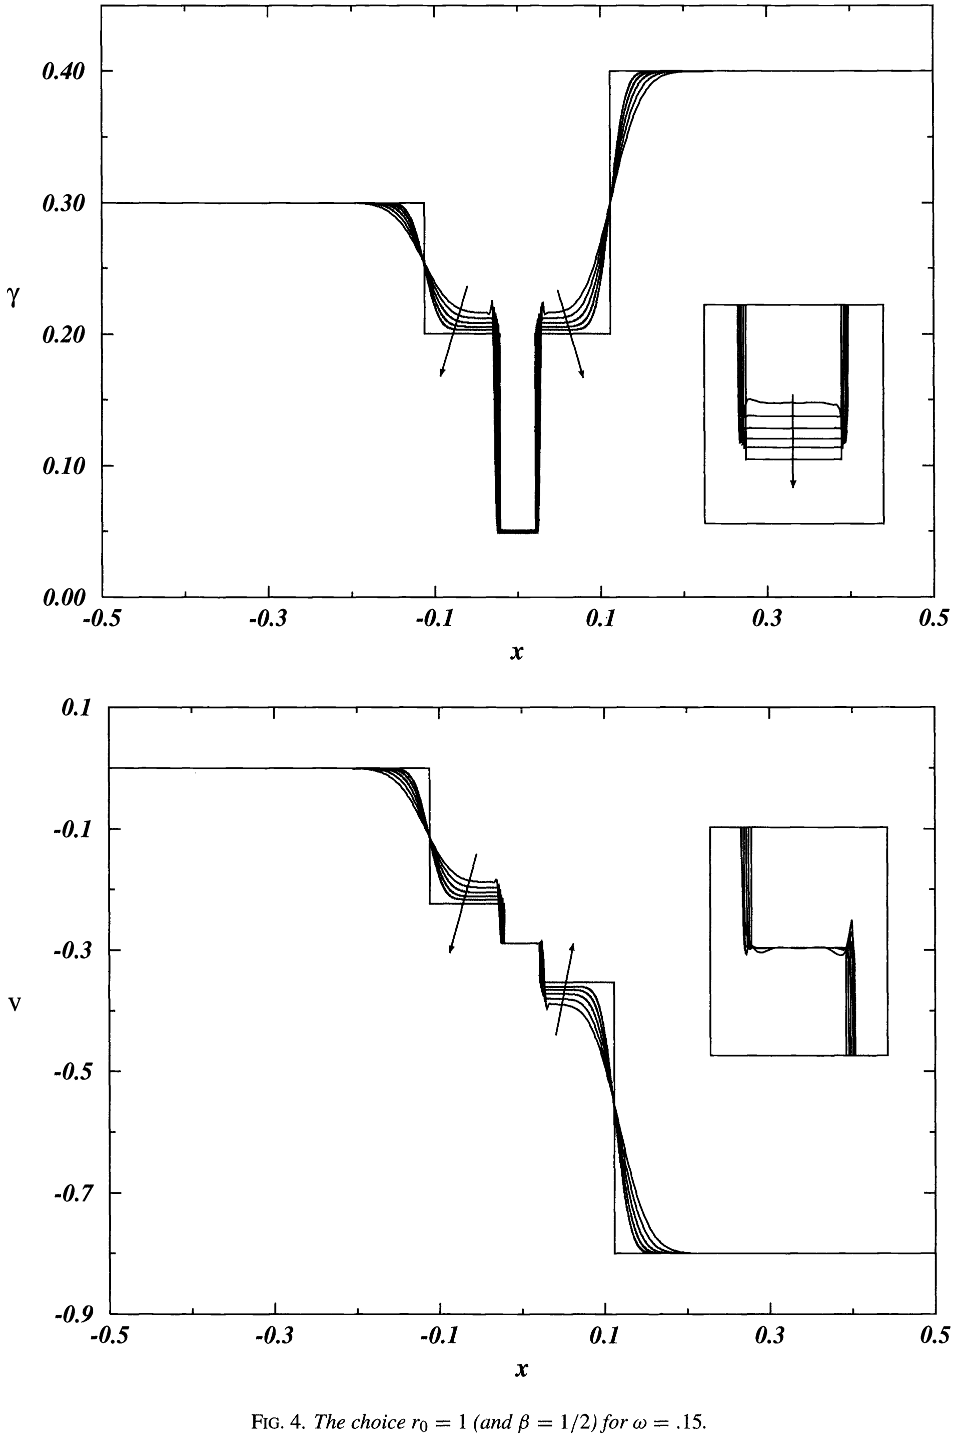

FIG. 4. *The choice $r_0 = 1$ (and $\beta = 1/2$) for $\omega = .15$.*

The effect of the size of β. In Figs. 9 and 10, we compare the exact VC solution for $\omega = .15$ and the different approximate solutions given by the scheme, with $r_0 = 1$ for $\Delta x = 1/800, 1/1600, 1/3200, 1/6400$, and $1/12800$. This is done for several values of β

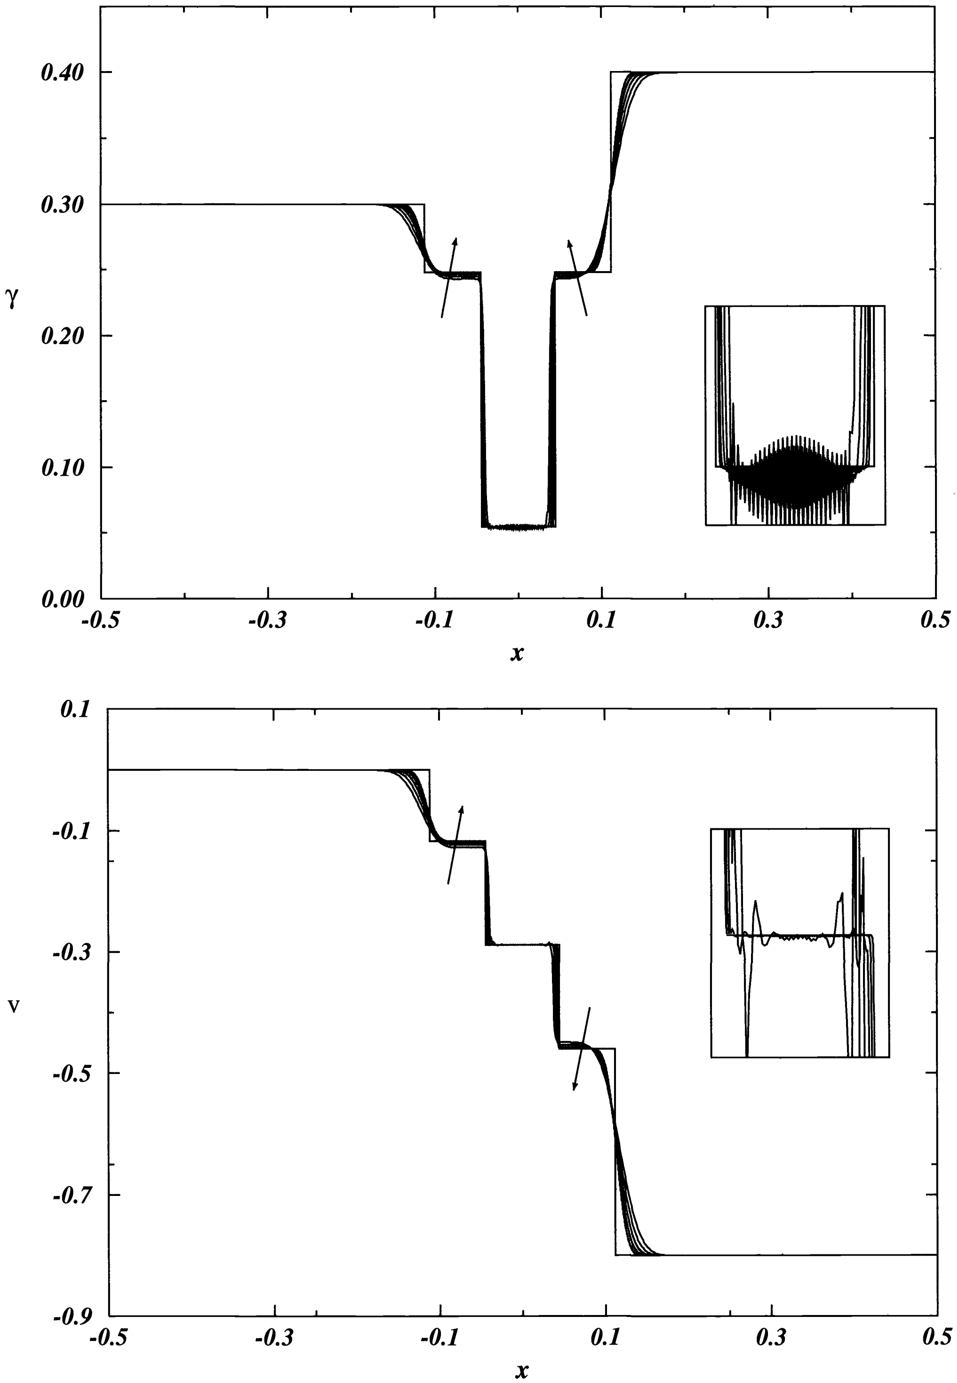

FIG. 5. *The choice* $r_0 = 0$ *(and* $\beta = 1/2$*) for* $\omega = 1$.

to see the effect of the parameter β on the convergence properties of the scheme. We clearly see that the scheme does not converge to the proper VC solution. We also see that as β decreases, the approximation properties of the scheme improve around the elliptic region.

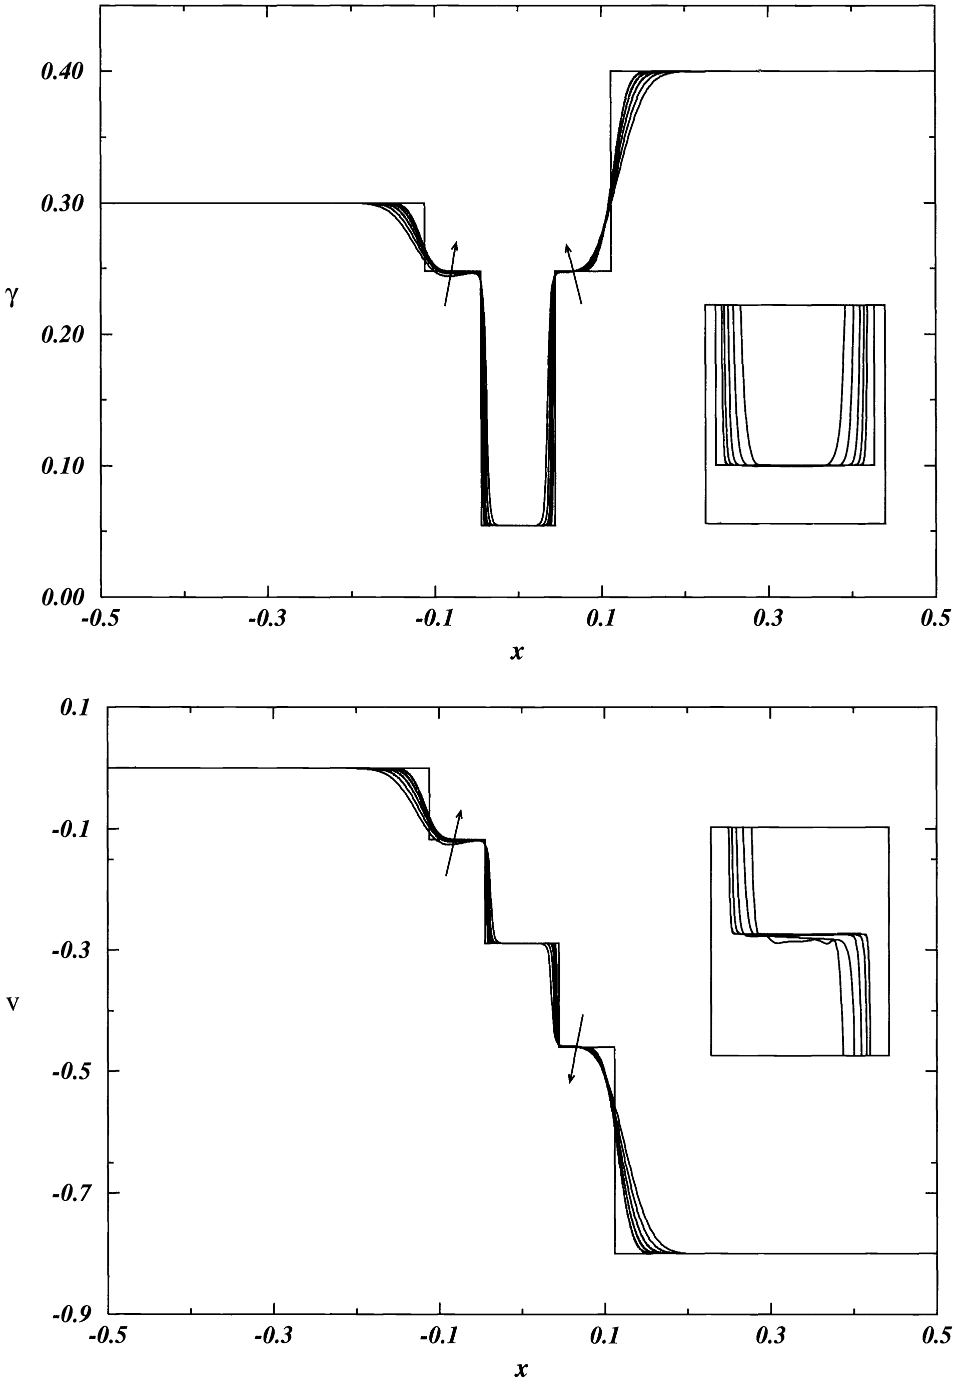

FIG. 6. *The choice* $r_0 = 1$ *(and* $\beta = 1/2$*) for* $\omega = 1$.

(Although they deteriorate around the hyperbolic region, as is expected, our main concern in this paper is to assess the quality of the approximation around the elliptic region, since it is very well known how to improve the quality of the approximation on the hyperbolic region.)

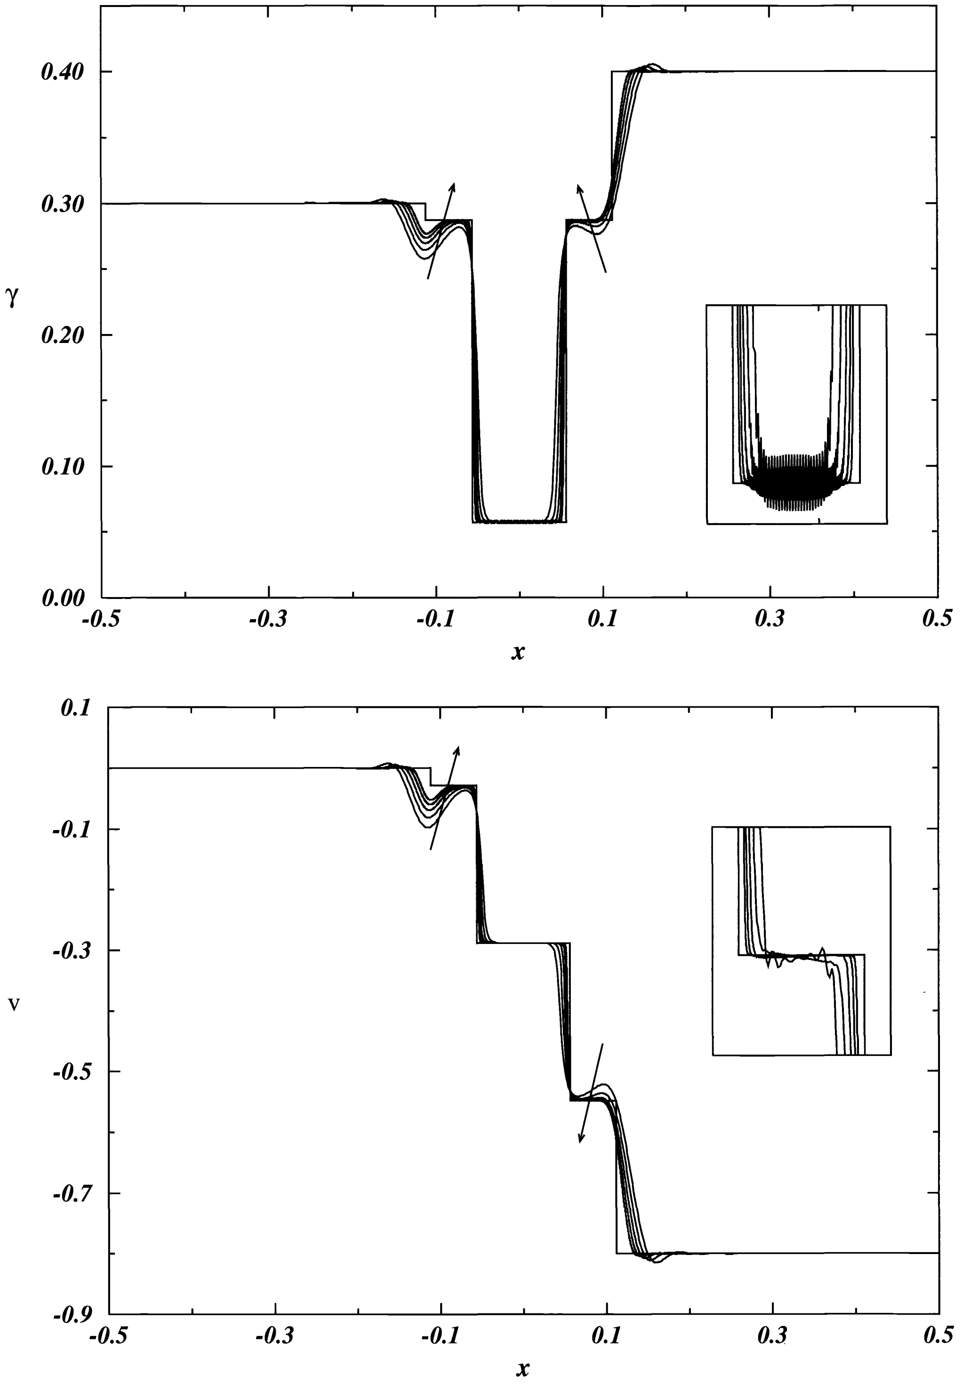

FIG. 7. *The choice* $r_0 = 0$ *(and* $\beta = 1/2$*) for* $\omega = 3$.

We have verified that the same phenomenon takes place for $\omega = 1$ and $\omega = 3$, but we are only displaying the results for $\omega = .15$ because for small ω this phenomenon is accentuated. A

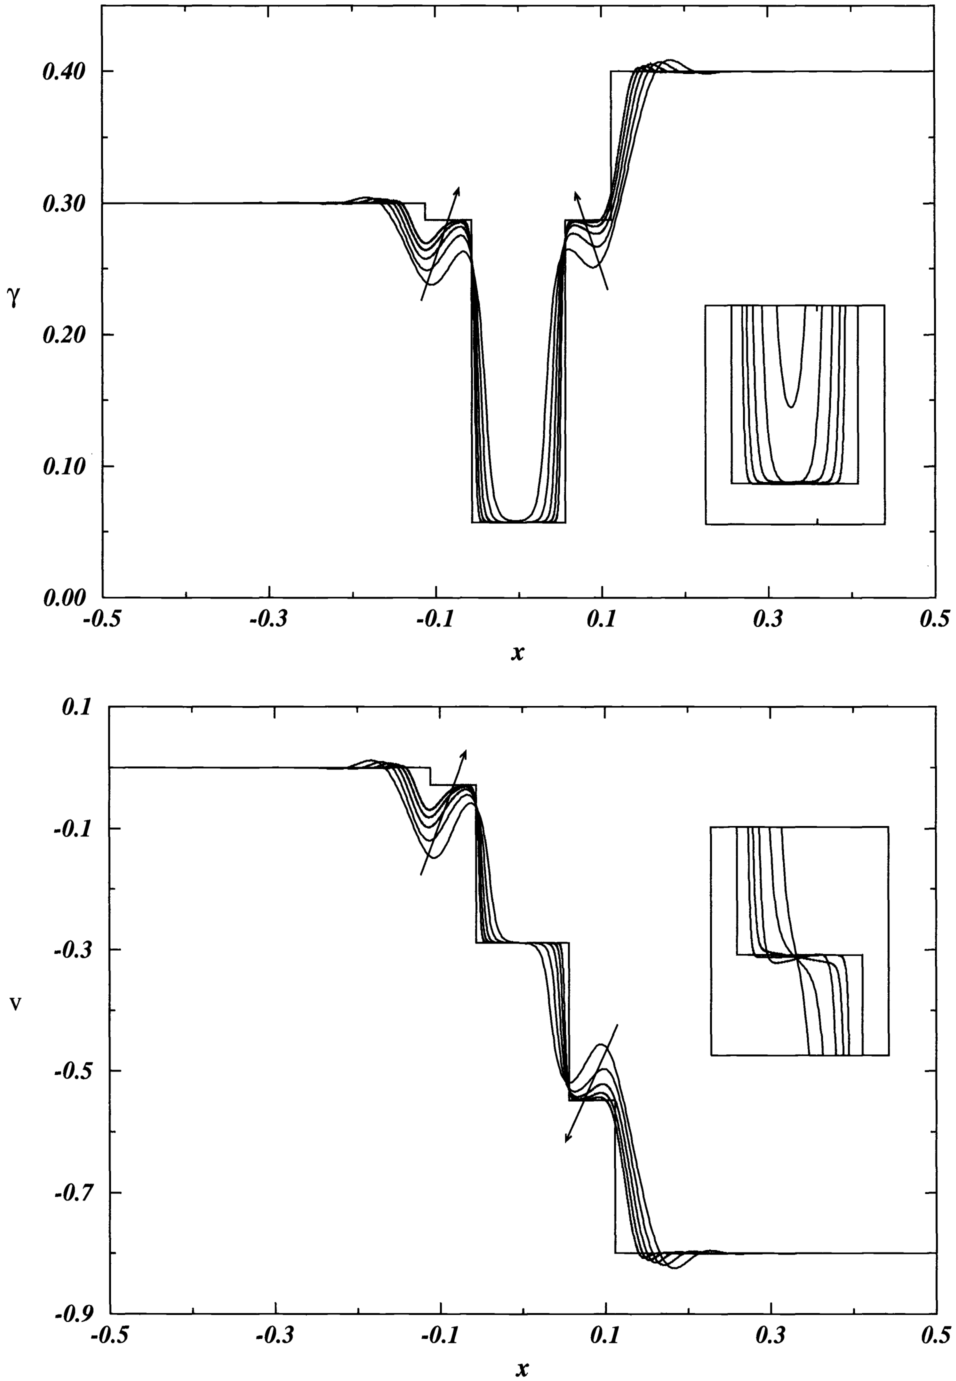

FIG. 8. *The choice* $r_0 = 1$ *(and* $\beta = 1/2$*) for* $\omega = 3$.

more precise assessment of this phenomenon is shown in Figs. 11, 12, and 13, where the case $\Delta x = 1/25600$ has been included.

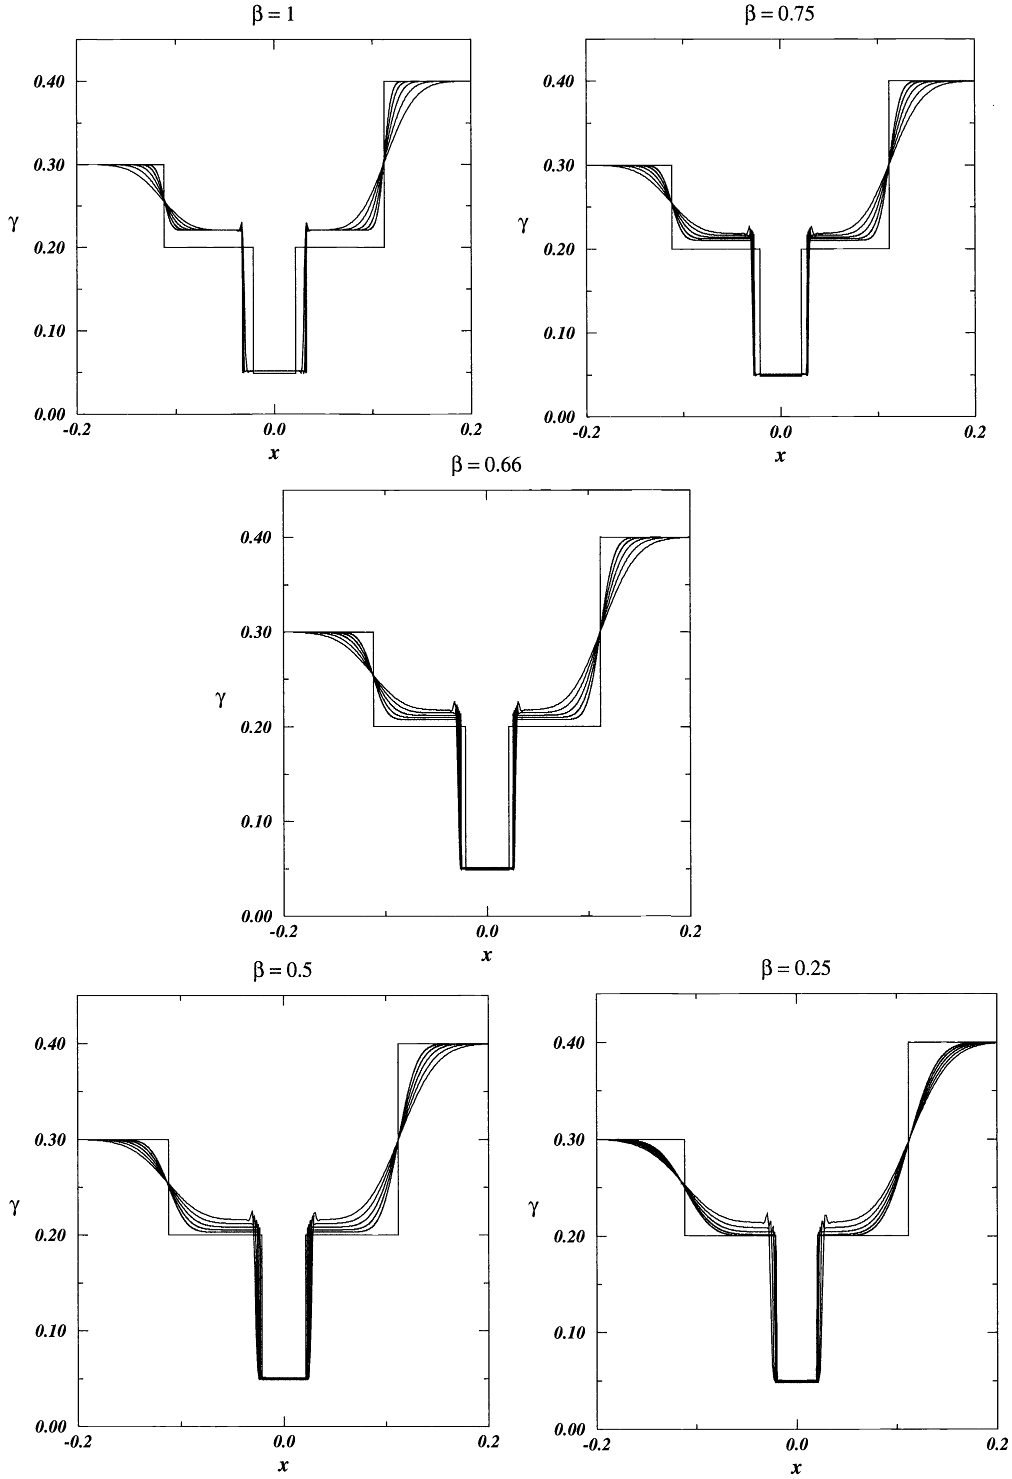

FIG. 9. *The effect of β: exact and approximate strains for $\omega = .15$.*

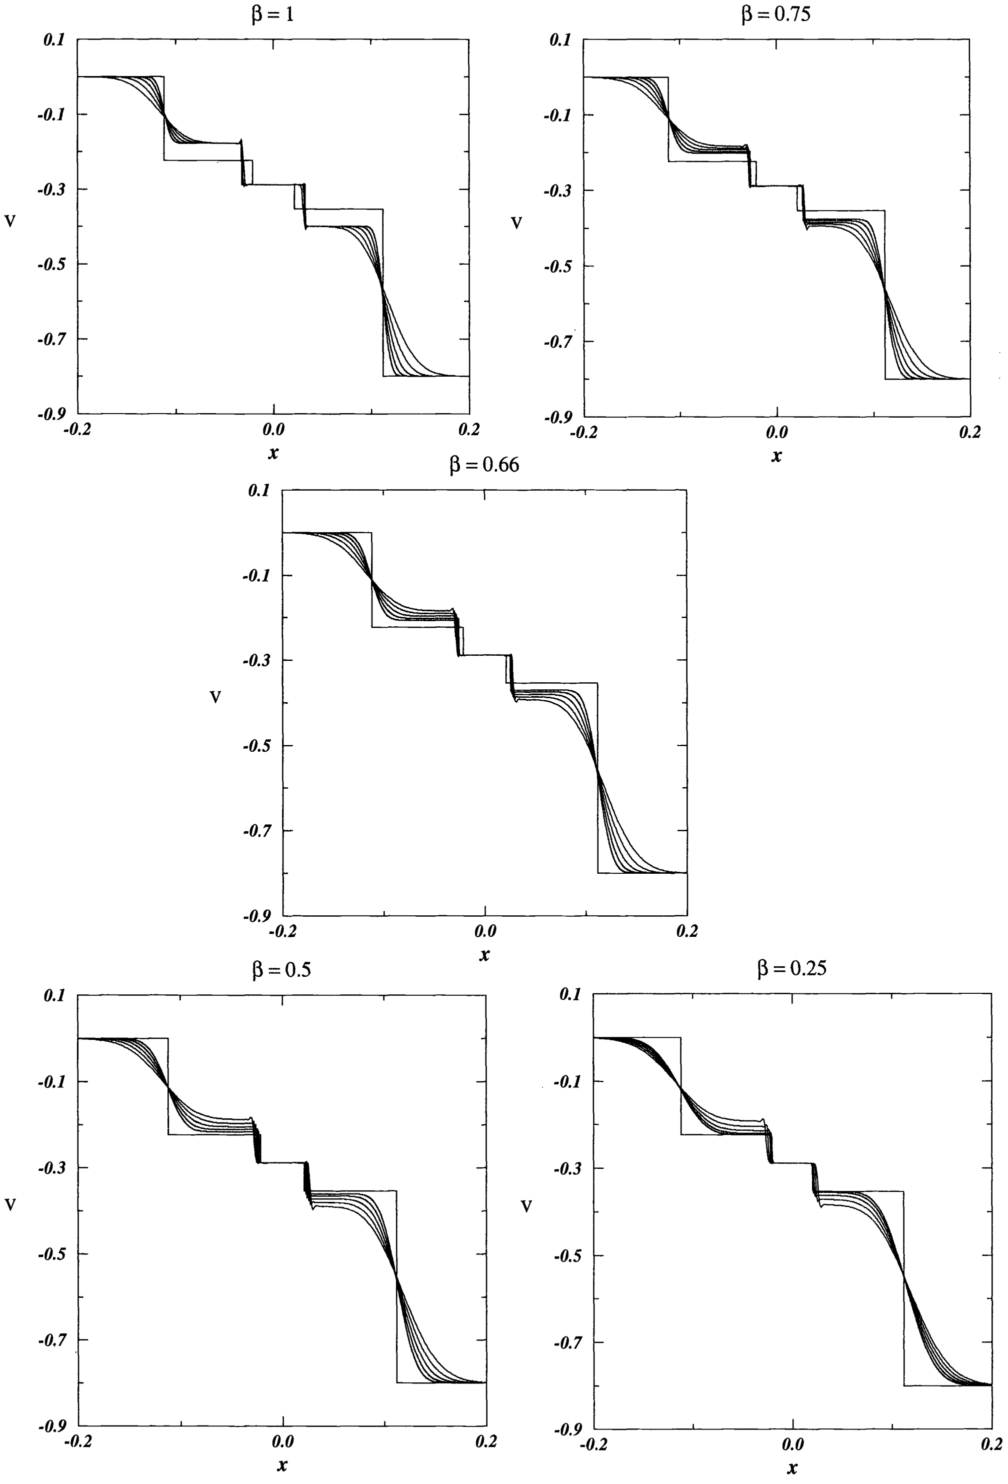

FIG. 10. *The effect of β: exact and approximate velocities for $\omega = .15$.*

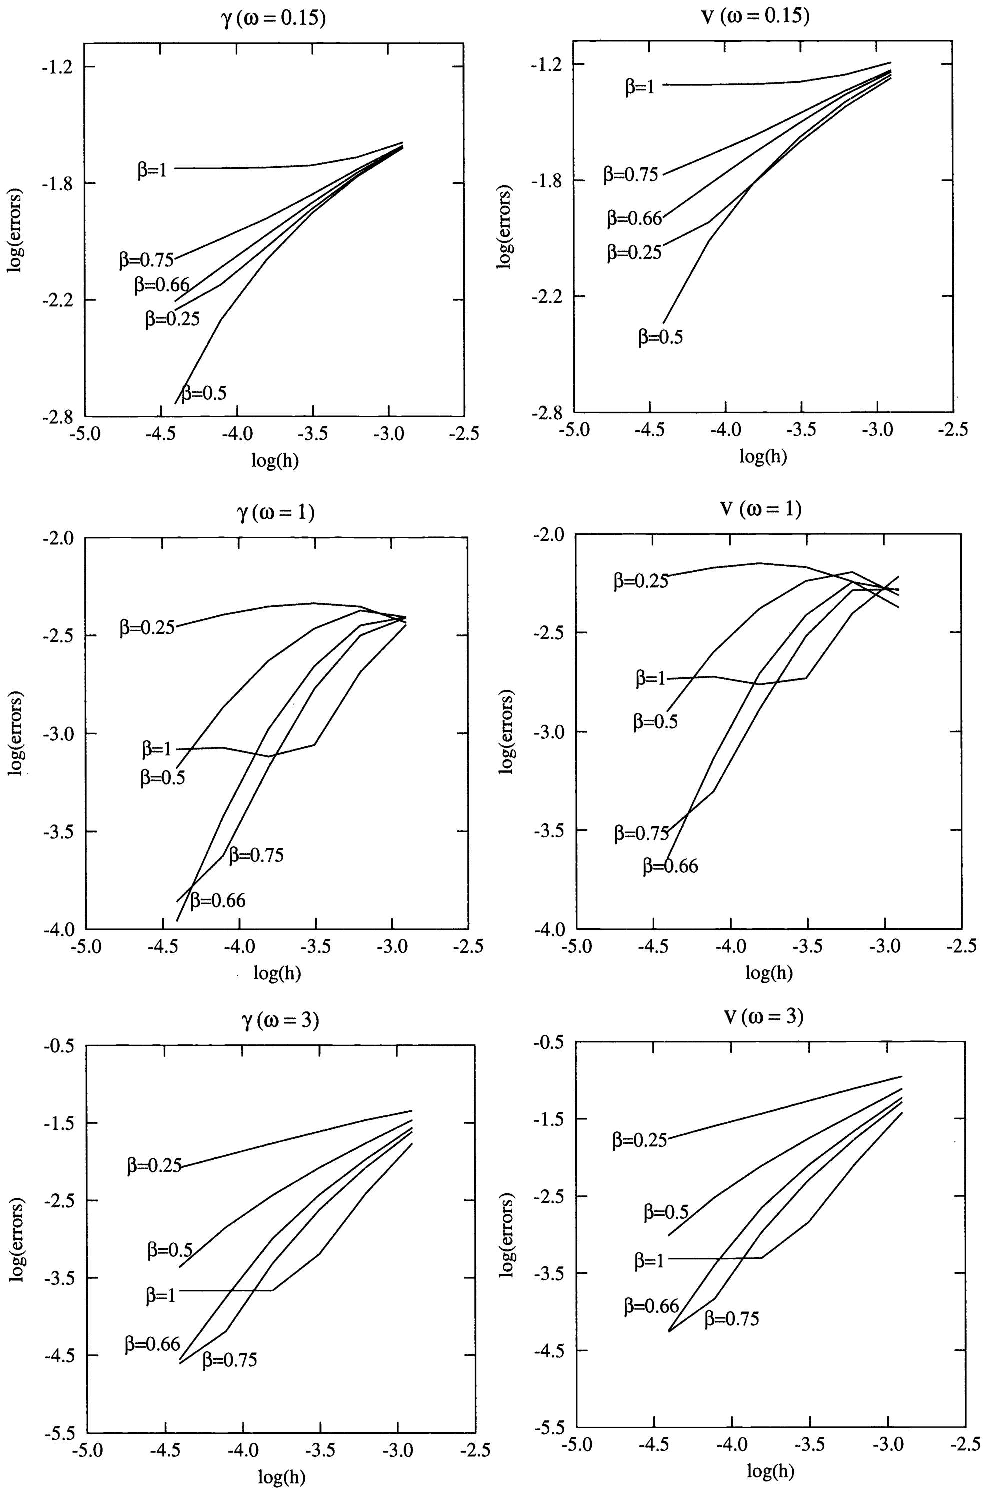

FIG. 11. *History of convergence of the average of the error on the region $R_{r.\ ph.\ b.}$ to the right of a phase boundary.*

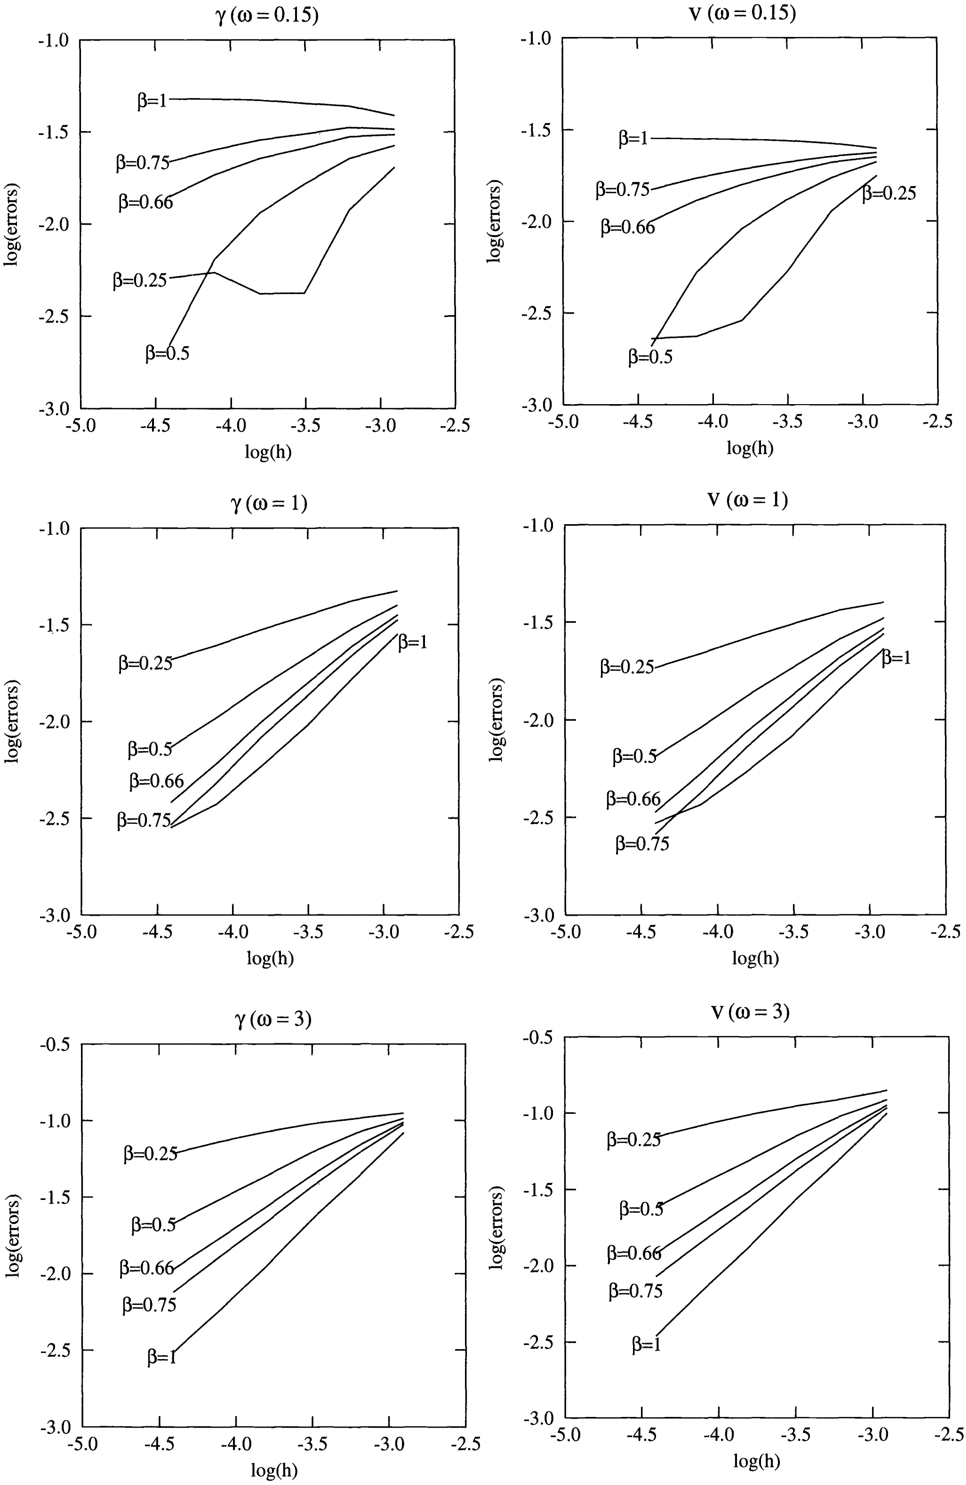

FIG. 12. *History of convergence of the average of the error on the region $R_{ph.\,b.}$ around a phase boundary.*

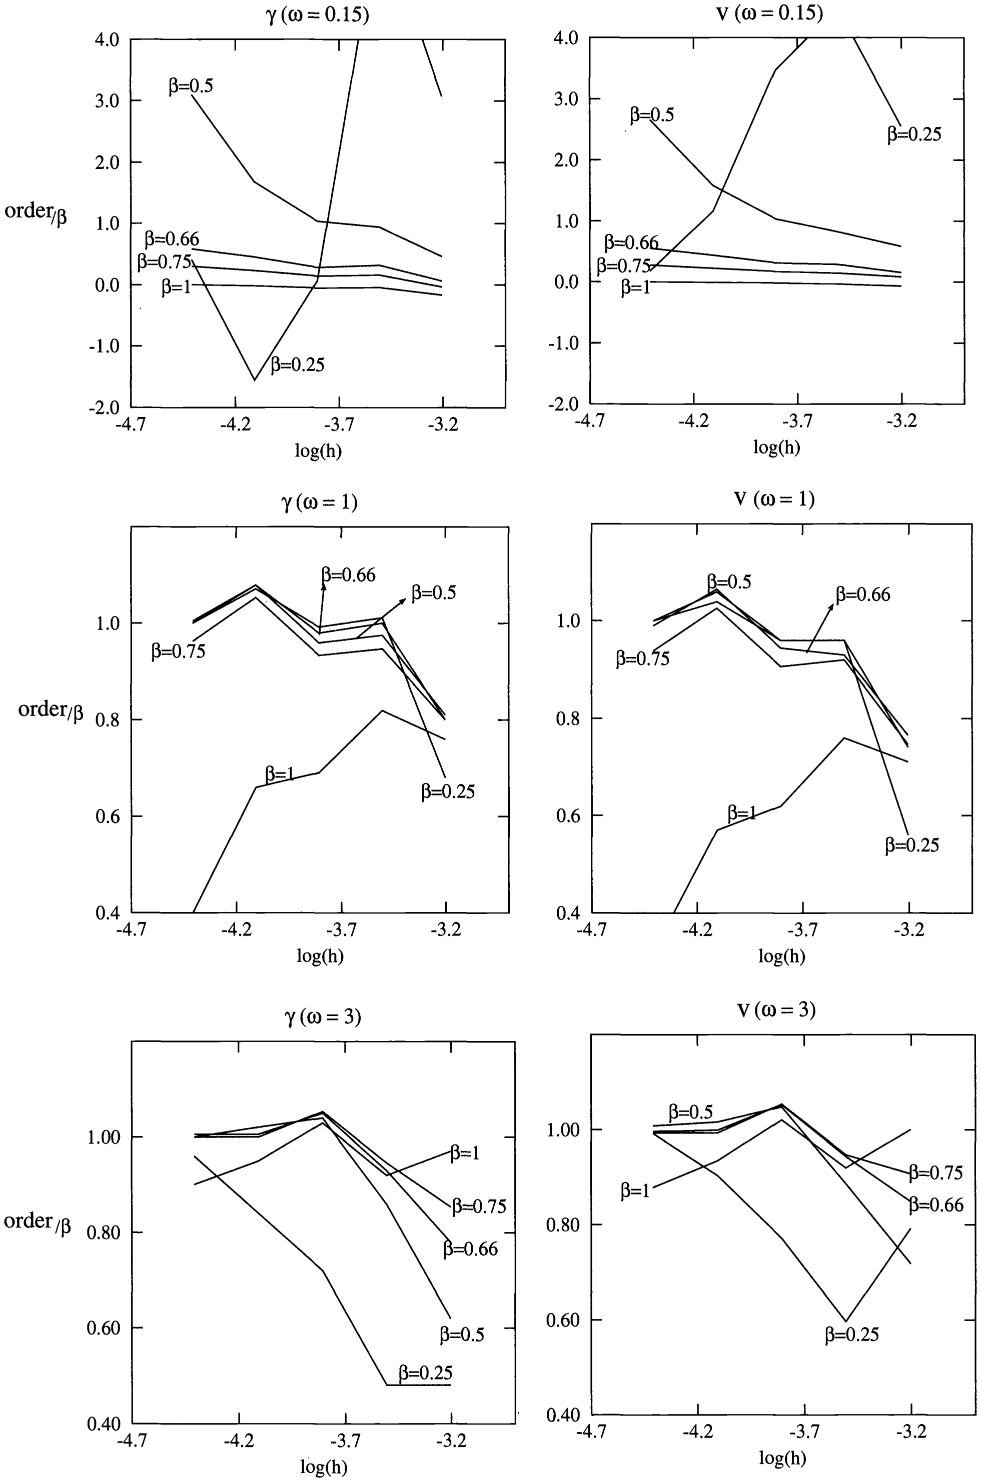

FIG. 13. *History of the ratio (numerical order of convergence)/β.*

In Fig. 11, we show the history of convergence of the scheme on the region $R_{r.\ ph.\ b.}$ which is a region located at the right of the rightmost phase boundary. The region $R_{r.\ ph.\ b.}$ is defined as follows:

$$R_{r.\ ph.\ b.} = \begin{cases} (.041, .092), & \omega = .15, \\ (.064, .092), & \omega = 1, \\ (.076, .092), & \omega = 3. \end{cases}$$

The average of the error on the region $R_{r.\ ph.\ b.}$ is plotted as a function of Δx for different values of β and ω. Again, we see that the scheme converges well for $\beta = 1/2$ but does not converge for $\beta = 1$. Notice how this feature becomes more acute as ω decreases. Also note that the scheme begins to be noticeably nonconvergent when the error is of the order of 10^{-2} for $\omega = .15$, 10^{-3} for $\omega = 1$, and 10^{-4} for $\omega = 3$. Thus, this phenomenon may not be appreciated on standard pictures.

In Fig. 12, we show the history of convergence of the scheme on the region $R_{ph.\ b.}$ which is a small region around one of the rightmost phase boundaries. The region $R_{ph.\ b.}$ is defined as follows:

$$R_{ph.\ b.} = \begin{cases} (.001, .041), & \omega = .15, \\ (.024, .064), & \omega = 1, \\ (.036, .076), & \omega = 3. \end{cases}$$

Theoretically, the width of the boundary layer around a phase boundary of the solution of (1.2) is of the order of the viscosity coefficient ν; see [9], [2], and [4]. Since we have constructed our approximate solution as a good approximation of the solutions (1.2), the width of the boundary layer around a phase boundary of our approximate solutions should be of order $(1 + r_0)\,\nu_0$, which by assumption (2.5b) is of order $(\Delta x)^{\beta}$ as Δx goes to zero. Thus, if the scheme is converging well around the phase boundary, the estimated rate of convergence of the average of the error on $R_{ph.\ b.}$ should be very similar to the parameter β. We display the ratios of these numbers in Fig. 13.

We can see very good agreement with the theoretical order of convergence for $\beta = .5$ and $\omega = 1$ and $\omega = 3$; for $\beta = .5$ and $\omega = .15$, the width of the boundary layer around the phase boundary is much smaller than expected. (We conjecture that this is so because one of the values of the exact strain at the phase boundary is .20017..., which is extremely close to the value $\gamma_{2,3} = .2$ that separates phases 2 and 3.) For $\beta = 1$ and $\omega = 3$, we see that for Δx the ratio of the orders of convergence decreases as Δx decreases. This unfortunate situation is accentuated as the value of ω decreases. As β varies from 1/2 to 1, the behavior of the ratios of orders of convergence seems to vary almost monotonically with β. In the case $\beta = .25$ the asymptotic regime does not seem to have been achieved most probably because there is an enormous amount of artificial viscosity.

5.3. A piecewise-cubic stress–strain curve. Finally, we present a short study of the convergence properties of the scheme under consideration to the VC solution of (1.1) for the strain–stress curve

$$\sigma(\gamma) = \gamma\,(\gamma - .5)\,(\gamma - 1);$$

see Fig. 14, $\omega = .15$, $\omega = 1$, and $\omega = 3$. The initial data is the following:

$$\gamma_0(x) = \begin{cases} 1.072649343, & x < 0 \\ .15, & x > 0 \end{cases}, \qquad v_0(x) \equiv 0.$$

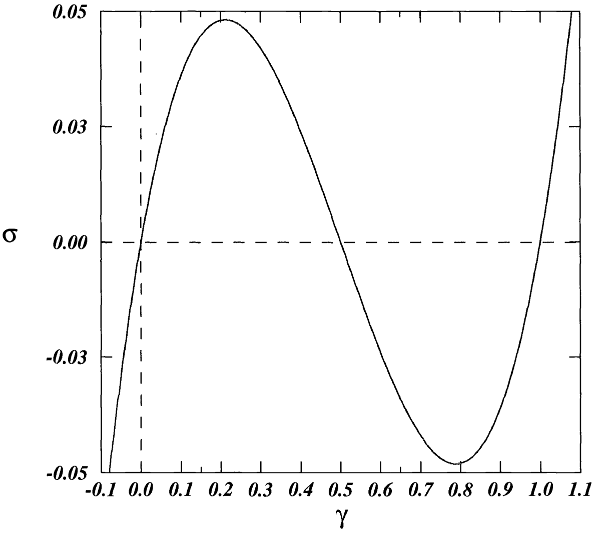

FIG. 14. *The piecewise-cubic strain–stress relation.*

The results are very similar to those of the piecewise linear stress–strain curve; see Figs. 15–17. Moreover, as Δx goes to zero, the numerical order of convergence gets closer and closer to the value $\beta = .5$ for all the values of ω. We do not observe the unusually thin boundary layer around the phase transition for $\omega = .15$ observed in the case of the piecewise-linear stress–strain curve. (This strengthens our conviction that the thinning of the numerical boundary layer is due to the closeness of one of the values of the strain to the elliptic region.)

6. Conclusion. In this paper, we continue the work initiated by Slemrod and Flaherty [11] and devise and numerically test a simple finite-difference method for approximating the VC solutions of the Cauchy problem for the mixed-type system governing the propagation of phase transitions in solids (or in van der Waals fluids). The numerical experiments show that (i) the scheme produces approximate velocities that do not display the spike at the phase transitions reported in [11] and (ii) it converges for all positive values of the VC parameter ω when the artificial viscosity is taken to be proportional to $(\Delta x)^{1/2}$ but fails to converge if it is taken proportional to Δx. This shows that an incorrect discretization procedure can significantly alter the nature of the solutions to which the scheme is converging.

The next step in the development of numerical methods for (1.1) is to find out how to use the heuristics introduced in this paper to devise formally high-order accurate (finite difference, finite volume, or relaxation) methods that incorporate the various techniques (characteristicwise evaluation of the fluxes, slope limiting, etc.) that work well for purely hyperbolic systems.

Acknowledgments. The authors thank Rohan Abeyaratne, who sparked the interest of the authors in this topic, Richard James for fruitful discussions about the spikes on the approximate velocity, Lev Truskinovsky for stimulating input and for providing the exact solution of the numerical experiment in §5, and Shi Jin for his incisive and constructive remarks. They also thank John Lowengrub for fruitful conversations.

A TWO-DIMENSIONAL COMPOSITE GRID NUMERICAL MODEL BASED ON THE REDUCED SYSTEM FOR OCEANOGRAPHY*

Y. F. XIE[†], G. L. BROWNING[†], AND G. CHESSHIRE[‡]

Abstract. The proper mathematical limit of a hyperbolic system with multiple time scales, the reduced system, is a system that contains no high-frequency motions and is well posed if suitable boundary conditions are chosen for the initial-boundary value problem. The composite grid method, a robust and efficient grid-generation technique that smoothly and accurately treats general irregular boundaries, is used to approximate the two-dimensional version of the reduced system for oceanography on irregular ocean basins. A change-of-variable technique that substantially increases the accuracy of the model and a method for efficiently solving the elliptic equation for the geopotential are discussed. Numerical results are presented for circular and kidney-shaped basins by using a set of analytic solutions constructed in this paper.

Key words. composite mesh, shallow-water equations, reduced systems, stability, ocean basins

1. Introduction.

Kreiss [11] introduced the concept of a smooth solution of a hyperbolic system with multiple time scales. The smooth motions are of interest to meteorologists and oceanographers because they carry the majority of the energy. In the original theory, the existence of a well-posed limit system, the reduced system, which could be used to accurately describe the smooth solutions, was also proved. The limit procedure removes the high-frequency motions from the original hyperbolic system. A reduced system for three-dimensional oceanic flows has recently been introduced (Browning, Holland, and Kreiss [2]) and numerical solutions of this system in a channel for a single scale of motion, i.e., a mesoscale eddy, have been obtained (Browning et al. [3]). In the latter study a uniform mesh was appropriate; however, in a full ocean basin where the spatial scales vary widely, a uniform mesh is inappropriate. The composite grid method described in detail by Chesshire and Henshaw [9] treats an irregular boundary smoothly and accurately, places fine resolution only where it is needed, and is flexible for a multiple mesh configuration because interpolation is used on the overlapping regions. Therefore, the composite grid method is an ideal candidate for solving the multiscale oceanic problem in an accurate and efficient manner.

To implement the reduced system by using the composite grid method for ocean circulation studies, we introduce a change-of-variable technique to overcome the truncation error imbalance in the system and a method to efficiently and accurately solve the elliptic equation of the system. The efficiency and accuracy of the reduced system when using the composite grid method are demonstrated by constructing a set of analytic solutions of the shallow-water equations with different scales and boundary configurations. In §2 the reduced system for the shallow-water equations is introduced, and the absence of high-frequency motions is proved. We construct analytic solutions of the full shallow-water equations on circular and kidney-shaped domains in §3. On the basis of a truncation error analysis, a change-of-variable technique is introduced. In §4, we generate overlapping grids for circular and kidney-shaped domains by using the composite grid method. An efficient method for the direct solution of the elliptic equation with Neumann boundary conditions for the geopotential is proposed for

the reduced system. In §5, we present numerical results and discuss a numerical technique to control the numerical divergence. Finally, our conclusions are presented in §6.

2. The reduced system. The shallow-water equations are frequently used to describe atmospheric and oceanic motions. In Cartesian coordinates x and y, directed eastward and northward, respectively, the shallow-water equations are (e.g., [4])

$$\frac{du}{dt} + \phi_x - fv = 0, \tag{2.1a}$$

$$\frac{dv}{dt} + \phi_y + fu = 0, \tag{2.1b}$$

$$\frac{d\phi}{dt} + (\phi_0 + \phi)(u_x + v_y) = 0, \tag{2.1c}$$

where t is time, u and v are the velocity components in the x- and y-directions, ϕ_0 is the mean geopotential, ϕ is the deviation of the geopotential from the mean, and f is the Coriolis parameter that is assumed to have the constant value $f = 10^{-4}$. The total differential operator d/dt is defined as

$$\frac{d}{dt} = \frac{\partial}{\partial t} + u\frac{\partial}{\partial x} + v\frac{\partial}{\partial y}.$$

The shallow-water equations contain two classes of motions, i.e., the low-frequency (or Rossby) motions and the high-frequency (or inertial-gravity) motions (see, e.g., Browning, Kasahara, and Kreiss [4]). The majority of the energy of atmospheric and oceanographic flows is contained in the low-frequency motions but the high-frequency motions in the system adversely affect the Courant–Freidrichs–Lewy (CFL) stability criterion and physical parameterizations. Therefore it is desirable to use a system where the high-frequency motions are not present.

Kreiss [11] showed that the low-frequency motions (the smooth solutions) can be approximated by using the proper mathematical limit called the reduced system, which is automatically well posed. The proper limit of the full system (2.1) in the external mode case is

$$\frac{du}{dt} + \phi_x - fv = 0, \tag{2.2a}$$

$$\frac{dv}{dt} + \phi_y + fu = 0, \tag{2.2b}$$

$$u_x + v_y = 0, \tag{2.2c}$$

which to first approximation accurately determines the smooth solution of the original system. To simplify the discussion, we define the Jacobian for any functions (x', y') of (x, y) as

$$J(x, y; x', y') = \begin{pmatrix} \frac{\partial x'}{\partial x} & \frac{\partial x'}{\partial y} \\ \frac{\partial y'}{\partial x} & \frac{\partial y'}{\partial y} \end{pmatrix}.$$

If (2.2a) and (2.2b) are appropriately differentiated, an elliptic equation can be derived from (2.2c) to determine ϕ:

$$\nabla^2\phi = f\zeta + 2\ \det[J(x, y; u, v)], \tag{2.3}$$

where $\zeta = -u_y + v_x$ is the vertical component of the vorticity.

In addition to being well posed, the reduced system has another important feature, namely, no high-frequency waves. To see this, assume the solution of the reduced system (2.2) to be

2π-periodic in the x- and y-directions and consider the linear constant coefficient system

$$u_t + \bar{u}u_x + \bar{v}u_y + \phi_x - fv = 0, \tag{2.4a}$$

$$v_t + \bar{u}v_x + \bar{v}v_y + \phi_y + fu = 0, \tag{2.4b}$$

$$u_x + v_y = 0, \tag{2.4c}$$

where $\bar{u}$ and $\bar{v}$ are given constants. Cross differentiating (2.4a) and (2.4b), one determines ϕ by

$$\nabla^2\phi - f\zeta = 0; \tag{2.5}$$

i.e., for this linear system, the Jacobian term disappears in the elliptic equation. Fourier transforming in space yields the system of ordinary differential equations

$$\hat{u}_t + i\bar{u}k\hat{u} + i\bar{v}l\hat{u} + ik\hat{\phi} - f\hat{v} = 0,$$

$$\hat{v}_t + i\bar{u}k\hat{v} + i\bar{v}l\hat{v} + il\hat{\phi} + f\hat{u} = 0,$$

$$-(k^2 + l^2)\hat{\phi} - f(-il\hat{u} + ik\hat{v}) = 0,$$

where k and l are the wave numbers corresponding to x and y, respectively. If the last equation is solved for $\hat{\phi}$ and substituted into the first two equations, the system can be written in the vector form

$$\hat{V}_t = \left[i(\bar{u}k + \bar{v}l)I + \frac{f}{k^2 + l^2}A \right] \hat{V},$$

where $\hat{V} = (\hat{u}, \hat{v})^T$, I is the identity matrix, and

$$A = \begin{pmatrix} -kl & -l^2 \\ k^2 & kl \end{pmatrix}.$$

Because both of the eigenvalues of A are zero, both of the eigenvalues of the coefficient matrix of $\hat{V}$ are $i(\bar{u}k + \bar{v}l)$; i.e., only the slow time scale is contained in this system (compare with the analysis of the full shallow-water equations in [4]).

For the reduced system, an elliptic solver is needed to determine ϕ, but a much larger time step can be used because the high-frequency waves are absent. For example, if a second-order in space and in time finite difference scheme is used, the stability of the linearized reduced and full systems requires the time steps to be

$$\Delta t \le \frac{\Delta x}{2 + f\Delta x},$$

$$\Delta t \le \frac{\Delta x}{2 + \sqrt{\Delta x^2 f^2 + 2\phi_0}},$$

respectively (assuming $\Delta y = \Delta x$). Because $\phi_0 = gh_0$, where $g \simeq 10ms^{-1}$ is the gravity acceleration and h_0 is the mean depth, $\phi_0 \simeq 10^3$ if $h_0 = 100$ m or $\phi_0 \simeq 10^4$ if $h_0 = 1$ km for the ocean problem. Thus the time step for the full system must be much smaller than the one for the reduced system. For example, when $\Delta x = 10^4$ m and $\phi_0 = 10^4$, the time step for the full system must be 100 times smaller. The longer time step for the reduced system can compensate for the additional expense of the solution of the elliptic equation for the geopotential if an elliptic equation solver is efficient (the elliptic solver takes only about two times longer than the hyperbolic part for the test problems presented in §5). Therefore, the reduced system is chosen for solving the oceanographic problem because it can be solved very efficiently compared to the full system.

3. Analytic solutions and change-of-variable technique. To construct an analytic solution on a relatively realistic basin, an analytic solution of the shallow-water equations on a kidney-shaped region (the East Coast of the United States looks like the west boundary of the kidney-shaped basin) is constructed to demonstrate the efficiency and accuracy of the reduced system when using the composite grid method. An analytic steady-state solution on a circular basin is mapped to a kidney-shaped region. This invertible mapping is used to map the solution (u, v, ϕ) and the shallow-water equations on the circle onto the kidney-shaped region; i.e., the transformed variables are an analytic solution of the transformed shallow-water equations. Although the transformed streamfunction Ψ looks realistic, the transformed solution is not a solution of the untransformed shallow-water equations on the kidney-shaped region. By mapping only the streamfunction Ψ of the circular region onto the kidney-shaped region, one can form a solution of the untransformed forced shallow-water equations on the kidney-shaped domain. A similar technique of constructing an analytic solution of a forced system is used in [1].

By using polar coordinates (i.e., $x = r\cos\theta$ and $y = r\sin\theta$), one can obtain a set of analytic solutions of the full shallow-water equations (1) on the circular domain. Let us choose one particular solution from this set of solutions for the circular basin with radius $R = 2500$ km:

$$u = -\left[\left(\frac{x}{R}\right)^2 + \left(\frac{y}{R}\right)^2\right]\frac{y}{R}, \tag{3.6a}$$

$$v = \left[\left(\frac{x}{R}\right)^2 + \left(\frac{y}{R}\right)^2\right]\frac{x}{R}, \tag{3.6b}$$

$$\phi = \frac{1}{6}\left[\left(\frac{x}{R}\right)^2 + \left(\frac{y}{R}\right)^2\right]^3 + \frac{fR}{4}\left[\left(\frac{x}{R}\right)^2 + \left(\frac{y}{R}\right)^2\right]^2. \tag{3.6c}$$

Using the solutions, we can derive an analytic solution for the shallow-water equations in a more realistic ocean basin by constructing an invertible mapping between a circle and a kidney-shaped region. A modified cardioid mapping

$$x' = (0.8 + 0.5x)^2 - (0.75y)^2,$$
$$y' = 2(0.8 + 0.5x)(0.75y)$$

is used to map any function from a circular region to a kidney-shaped region shown in Fig. 1. The Jacobian of this mapping is bounded away from zero $(\det[J(x, y; x', y')] \geq 0.135)$ so the analytic solution (u, v, ϕ) on the circle can be mapped to the kidney-shaped region without a singularity problem. The streamfunction is shown in Fig. 1 and u and v obtained by differentiating the streamfunction are shown in Fig. 2.

To construct a more realistic solution with small spatial scale and that evolves in time, we tested a streamfunction $\Psi(x, y, t) = \Psi_B + \Psi_E$ with Ψ_B the steady-state background flow constructed above and Ψ_E a 350-km eddy. The eddy is constructed on the circle first and then mapped onto the kidney-shaped region by using the modified cardioid mapping. On the unit circle the eddy has the form

$$\Psi_E = 0.05\exp\left(-\frac{(x - x_0)^2 + (y - y_0)^2}{0.003(1 + \cos^2(0.2\pi t))}\right), \tag{3.7}$$

where

$$x_0 = -0.1 + 0.7\cos(0.4\pi t),$$
$$y_0 = 0.7\cos(0.4\pi t).$$

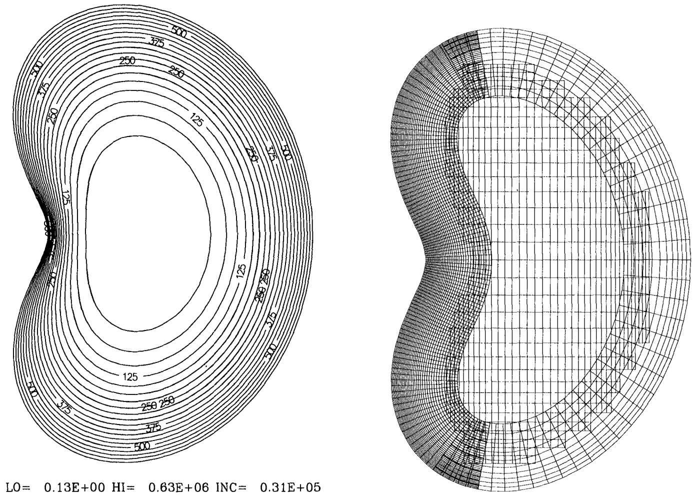

FIG. 1. *The streamfunction and the mesh on the kidney-shaped region.*

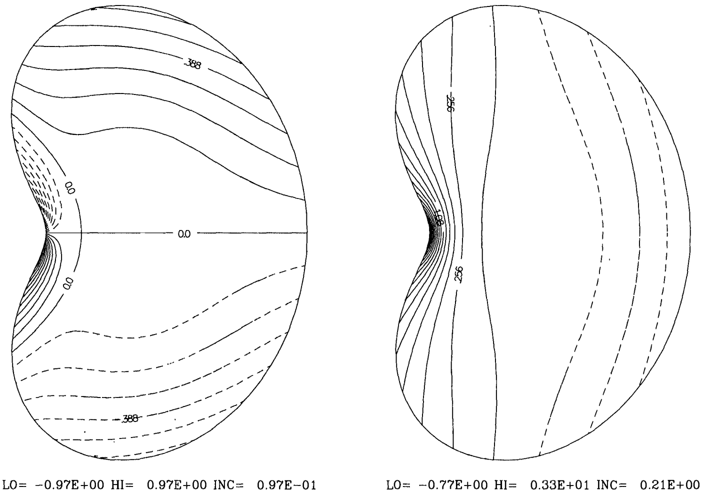

FIG. 2. *The contour plot of u and v on the kidney-shaped region.*

This eddy's radius is increased as it moves away from the west boundary. The streamfunction $\Psi_B + \Psi_E$ at $t = 0$ is shown in Fig. 3.

From the solution for the circle, it can be seen that the amplitudes of u and v are approximately 1 m/s near the boundary and ϕ is about 64 m^2/s^2 for $f = 10^{-4}$. This is also true for the transformed solution on the kidney-shaped domain. Thus, in the u and v equations of the reduced or full system, the truncation errors are not balanced. For example, in the u equation (2.1a), the truncation error of ϕ_x is approximately 64 times larger than the errors in the advection terms. This phenomenon is not particular to the special solution used here. Through scale analysis [2], it is known that the pressure gradient term is generally 10–100 times larger than the advection terms. This imbalance can be overcome in a number of ways. A straightforward solution is to use a higher-order finite difference scheme for ϕ_x. It is interesting to note that applying higher-order finite differences to all the terms in the shallow-water equations is not efficient because the truncation error in ϕ_x is dominant. So an efficient technique would use, for

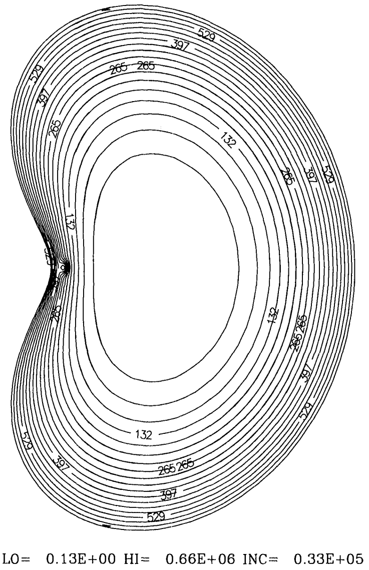

FIG. 3. *The streamfunction with the* 350-*km eddy.*

example, a fourth-order scheme for ϕ_x and a second-order scheme for the other terms. Treating fourth-order boundary conditions is another interesting issue in developing a well-posed system (see Henshaw [10]). In this paper, a change-of-variable approach is proposed for the two-dimensional reduced system and a similar idea can be applied to the three-dimensional reduced system. This approach can dramatically increase the accuracy without increasing either the resolution or the order of the finite difference scheme.

Suppose there is a function ϕ' satisfying

$$\phi = f\Psi + \phi'.$$

The amplitude of ϕ' is of the same order as u and v because the large part of ϕ is contained in the geostrophic portion $f\Psi$. Because the solution of the reduced system is nondivergent,

$$u = -\Psi_y, \quad v = \Psi_x,$$

the reduced system becomes

$$\begin{aligned} u_t + uu_x + vu_y + \phi'_x &= 0, \\ v_t + uv_x + vv_y + \phi'_y &= 0, \\ \nabla^2\phi' - 2\det[J(x, y; u, v)] &= 0. \end{aligned}$$

For this system, the truncation errors of the gradient of ϕ' and advective terms are the same size. This technique is called a change-of-variable method. Even for the two-dimensional flow, the original system requires a 3–10 times finer resolution for a second-order method in each direction to reach the same accuracy as the reduced system with a change-of-variable. In other words, the change-of-variable method is at least nine times more efficient than the system without the change-of-variable for two-dimensional flows and even more for three-dimensional ones. The original deviation of the geopotential ϕ can be recovered by solving the elliptic equation

$$\nabla^2\phi = f\zeta + \nabla^2\phi'$$

whenever it is needed. In the next section we discuss how to determine a unique solution from the boundary condition.

4. Composite grid method and the boundary treatment. The composite grid method was introduced over a decade ago [12], [13]. Chesshire and Henshaw [9] describe in considerable detail the implementation of this method for solving partial differential equations. This method allows multiple overlapping grids to cover an irregular domain of interest. Each grid is mapped onto a rectangular grid, for example, by a Coons [6] mapping. Then all numerical schemes can be applied as if on a rectangular grid. On the overlapping regions between grids, interpolation is used. Like other nested-grid and refinement methods (Ciment [5]), the stability of the composite grid method has been analyzed by Starius [12], [13]. Although Starius [13] considered only the Lax–Wendroff difference scheme, the same analysis can also be applied to other finite difference schemes. The nested-grid and refinement method have some difficulty dealing with an irregular boundary because it is complicated to make the separate components of the grid join precisely and smoothly. Usually, a stairwise nested grid is used to approximate an irregular basin, which reduces the accuracy near the boundary. The flexibility of the composite grid method for this problem can be seen in the grid construction for the kidney-shaped region in Fig. 1. For the kidney-shaped region, there are three overlapping grids: a western boundary, an eastern boundary, and an interior grid. The three overlapping grids cover the kidney-shaped domain to resolve the solution derived from the streamfunction shown in Fig. 1. Note that without the interior grid, there is a singularity problem when two grid lines intersect. Splines are used to fit irregular boundaries in general, and then the composite grid method handles the boundary smoothly and accurately. The boundary grids are tangential and orthogonal to the physical boundaries, and this makes the boundary conditions easy to implement. Note that much finer resolution is placed on the western boundary to help resolve the western boundary current.

To demonstrate the accuracy and efficiency of the composite grid method, the reduced shallow-water system is tested in the 4000-km wide by 6000-km high, kidney-shaped basin shown in Fig. 1 using the analytic solutions constructed in the previous section. Because the composite mesh has a fine resolution where Ψ changes quickly and where the eddy has a diameter of approximately 350 km before becoming large, and coarse resolution where Ψ changes slowly and the eddy is larger, it requires very few grid points to obtain a very accurate solution. This makes it possible to resolve this kind of solution on a workstation.

Solving the reduced system on a solid boundary basin requires explicit specification of the finite difference scheme and boundary conditions. In this paper, a simple finite different scheme, i.e., central finite differences in space and time, is used to discretize the reduced system, and biquadratic interpolation is used on the overlapped region of the composite grid. Near the boundary, the composite grid method provides a mapping from (x, y) to (r, s) such that the direction along r is the normal direction and the one along s is the tangential direction; i.e., (r, s) are orthogonal coordinates. This simplifies the implementation of the boundary conditions. Because

$$x = x(r, s), \qquad y = y(r, s), \tag{4.8}$$

the transformation between the velocity components is

$$\begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} \frac{\partial x}{\partial r}\frac{dr}{dt} + \frac{\partial x}{\partial s}\frac{ds}{dt} \\ \frac{\partial y}{\partial r}\frac{dr}{dt} + \frac{\partial y}{\partial s}\frac{ds}{dt} \end{pmatrix} = J(r, s; x, y)\begin{pmatrix} n \\ \tau \end{pmatrix} = J^{-1}(x, y; r, s)\begin{pmatrix} n \\ \tau \end{pmatrix}.$$

The mapping (4.8) or its inverse form,

$$r = r(x, y), \qquad s = s(x, y),$$

is chosen to be orthogonal; i.e.,

$$(r_x \; r_y)(s_x \; s_y)^T = 0.$$

The Jacobian matrix $J(x, y; r, s)$ is essentially orthogonal; i.e.,

$$J(x, y; r, s)J^T(x, y; r, s) = \Lambda(x, y),$$

where $\Lambda(x, y)$ is a diagonal matrix determined by the mapping

$$\Lambda(x, y) = \begin{pmatrix} r_x^2 + r_y^2 & 0 \\ 0 & s_x^2 + s_y^2 \end{pmatrix}.$$

Therefore, the time derivatives of (u, v) can be written as

$$(u_t \; v_t) = J^{-1}(x, y; r, s)(n_t \; \tau_t)^T$$

and for any function P the spatial derivatives can be written as

$$(P_x \; P_y)^T = J^T(x, y; r, s)(P_r \; P_s)^T = J^{-1}(x, y; r, s)\Lambda(x, y)(P_r \; P_s)^T.$$

The advective equations in the reduced system can be written as

$$\begin{aligned} &\begin{pmatrix} n_t \\ \tau_t \end{pmatrix} + J(x, y; r, s) \begin{pmatrix} nu_r + \tau u_s \\ nv_r + \tau v_s \end{pmatrix} \\ &+ \Lambda \begin{pmatrix} \phi_r \\ \phi_s \end{pmatrix} + fJ(x, y; r, s) \begin{pmatrix} -v \\ u \end{pmatrix} = 0 \end{aligned} \tag{4.9}$$

because

$$uu_x + vu_y = (u \quad v)(u_x \; u_y)^T = (n \quad \tau)J^{-T}(x, y; r, s)J^T(x, y; r, s)(u_r \; u_s)^T = nu_r + \tau u_s$$

and, similarly,

$$uv_x + vv_y = nv_r + \tau v_s.$$

For a solid-wall boundary condition, the normal velocity is zero, and τ can be updated by the second component of equation (4.9) by using only the function values of (u, v, ϕ) in the s-direction, i.e., along the boundary.

The first component of equation (4.9) gives a Neumann boundary condition for ϕ, i.e., the value of ϕ_r. Thus an elliptic equation with a Neumann boundary condition needs to be solved at every time step for the reduced shallow-water equations and the three-dimensional reduced system. That is, in general

$$\begin{aligned} \nabla^2\phi &= g_1(x, y, t), \\ \phi_r &= g_2(x, y, t) \quad \text{on the boundary,} \end{aligned}$$

where ϕ_r is the derivative in normal direction and $g_{1,2}$ are given functions of (x, y, t). In the following the direct solver of this Neumann boundary problem is discussed. How to implement the direct method for solving the elliptic equation with a Neumann boundary condition has a significant impact on applying the composite grid method to reduced systems. In addition to the fact that the direct method is faster than the multigrid method for low resolutions, all other techniques for solving the elliptic system rely on a proper implementation of the direct method. For example, the multigrid method needs a proper direct solver for its coarsest resolution and a conjugate gradient solver requires a proper projection of the Neumann boundary problem to obtain a nonsingular coefficient matrix. Therefore, it is crucial to implement the Neumann boundary problem accurately and efficiently for a direct solver.

The finite difference approximation of the continuous equations and the boundary condition gives a linear system

$$A\tilde{\phi} = b,$$

where $\tilde{\phi}$ is some enumeration of the grid function describing ϕ and b is the discrete right-hand side. For the Neumann boundary condition problem, it is known that A is rank-one deficient with a right-hand side null vector $r = (1, 1, \dots, 1)^T$, i.e., $Ar = 0$. Because $Null(A^T) \oplus \text{Range}(A) = R^n$, suppose $b = b_1 + b_2$, where $b_1 \in Null(A^T)$ and $b_2 \in \text{Range}(A)$, where $Null(A^T) = \{x | A^T x = 0\}$, the null space of A^T, and $\text{Range}(A) = \{x | \exists y \text{ s.t. } Ay = x\}$, the range space of A. The component b_1 may not be zero in general but of the order of the truncation error of the finite difference scheme and for second-order finite differences, $b_1 = O(\Delta x^2)$. An ideal solution to this problem is to find a minimal norm solution of

$$\min_{\tilde{\phi}} \|A\tilde{\phi} - b\|_2. \tag{4.10}$$

The problem is equivalent to solving

$$\begin{pmatrix} A & l \\ r^T & 0 \end{pmatrix} \begin{pmatrix} \tilde{\phi} \\ \tilde{x} \end{pmatrix} = \begin{pmatrix} b \\ 0 \end{pmatrix}, \tag{4.11}$$

where l and r are the left and right null vectors of A; i.e., $l^T A = Ar = 0$ and usually the coefficient matrix is called the augmented matrix of A, which is nonsingular. One additional computation is that of the left null vector because the right one is known. If the direct solver is used, an LU decomposition is usually computed, for example, by the Yale sparse matrix solver (YSMP) [8] or the Harwell package (MA28) [7]. (Symmetric sparse decomposers are not suitable because the matrix is not symmetric if interpolation is used in the composite grid method.) The null vector l can be computed inexpensively. Suppose

$$A = P_l L U P_r, \tag{4.12}$$

where P_l and P_r are the pivot matrices (if only the row pivot is considered in the decomposition, $P_r = I$), and

$$U = \begin{pmatrix} U_1 & U_2 \\ 0 & u_{nn} \end{pmatrix},$$

where u_{nn} is zero theoretically and of round-off error size numerically because of the singularity of A. There are two ways to compute l. One is to solve $l = P_l^{-T} L^{-T} e_n$, where $e_n = (0, 0, \dots, 0, 1)^T$, and the computation of l requires only one backsubstitution. In this paper, another way, the inverse iteration method, is used to compute l because one does not need to have any knowledge about the data structure of MA28 or YSMP storing the L and P matrices. The method is very efficient because one iteration is sufficiently accurate for the numerical approximation.

Clearly (4.11) contains dense row and column vectors, namely, l and r. If an LU decomposer is applied directly to the augmented matrix, the fill-ins may be significant. The decomposition of the augmented matrix and the decomposition of A are tested on the circular basin with the mesh shown in Fig. 4. The former decomposition takes eight times longer than the latter. One can modify the pivoting such that the last row and column of the augmented matrices will not be pivoted until the last row and column of matrix A are reached. This requires some knowledge of the data structure of a matrix solver. In this paper, the LU decomposition

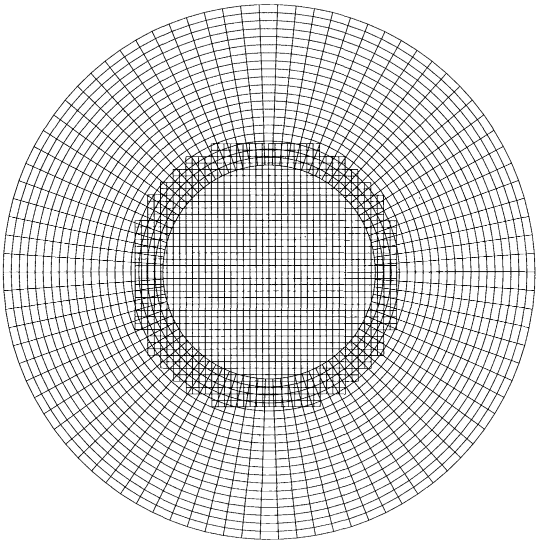

FIG. 4. *The composite grid on the circle.*

is applied to A. By using the computed l, one can obtain the minimal norm solution of (4.10) by solving

$$P_l L U P_r \tilde{\phi} = b - \frac{l^T b}{l^T l} l \tag{4.13}$$

and setting the last component of $P_r \tilde{\phi}$ to zero, which projects $\tilde{\phi}$ in the range space of A and ensures that $\tilde{\phi}$ has a minimal norm. For simplicity, let $P_l = P_r = I$. Because $l = L^{-T} e_n$, the last component of

$$L^{-1}\left(b - \frac{l^T b}{l^T l} l\right)$$

is

$$e_n^T L^{-1} b - \frac{e_n^T L^{-1} b}{\|L^{-T} e_n\|^2} e_n^T L^{-1} L^{-T} e_n = 0.$$

Thus (4.13) exactly holds. For the solution of (4.10), $\|A\tilde{\phi} - b\| = |l^T b| / \|l\|$, i.e., $\|A\tilde{\phi} - b\| = \min \|A\phi - b\|$. This method is implemented in this paper to test the numerical approximation of the reduced system.

5. Numerical results.

In this section, numerical results are presented. On the circular domain, results with and without the change-of-variable technique are compared. Following the numerical tests for the steady-state solution on the circular region, the numerical results for the untransformed, forced, reduced shallow-water equations on the kidney-shaped region are presented. Finally, the mesoscale eddy is considered.

The numerical results presented use the l_2-norm to calculate the relative errors and all the numerical errors are plotted in time for two weeks for all resolutions for both the circular and kidney-shaped regions.

5.1. Steady-state solution on the circular region and divergence damping technique.

In this subsection, numerical results are presented for the circular region because the analytic solution for the circular region does not require forcing terms.

TABLE 1

The relative errors in u on the circular region on day 14 *for low* (357 *km*), *medium* (178 *km*), *and high* (89 *km*) *resolutions* (%).

Different systems	Low	Medium	High
Original system	inf	128.3	44.5
System with damping	9.25	6.76	3.53
System with change-of-variable	0.98	0.25	0.06

Consider the analytic solution given by (3.6). The initial values are obtained using (3.6). Three resolutions are tested in this subsection and they have 357-km (low), 178-km (medium), and 89-km (high) minimum grid sizes, respectively. (Figure 4 shows the medium resolution grid.) Because a second-order finite difference is used in this paper, the relative errors should be reduced by a factor of four when the resolution is doubled (i.e., the grid size is halved). On the first time step, the relative errors of the three resolutions in u are 0.75×10^{-2}, 0.21×10^{-2}, and 0.49×10^{-3} (sizes are similar in v and ϕ). Although the errors do not reduce exactly by a factor of four from the low to the medium resolution because the low resolution may not be in the asymptotic range, the errors reduce properly from the medium to the high resolution.

Table 1 shows the increases with time of the relative errors for the three resolutions. It is found that the residual of (2.2c) grows quickly; i.e., the divergence $\delta = u_x + v_y$ grows too fast. To control the divergence, consider the divergence equation derived from (2.2a) and (2.2b):

$$\delta_t + \delta^2 + \nabla^2\phi - f\zeta - 2\det[J(x, y; u, v)] = 0.$$

The reduced shallow-water equations solve the elliptic equation (2.3) to obtain ϕ with the assumption $\delta = 0$. However, δ is not zero numerically but can be forced to be zero at the next time step in the following manner:

$$\frac{0 - \delta^{n-1}}{2\Delta t} + \nabla^2\phi - f\zeta - 2\det[J(x, y; u, v)] = 0,$$

where the low-order term δ^2 has been ignored. The first term is usually called a damping mechanism. This mechanism is used to test the numerical approximation of the reduced shallow-water equations, and the relative errors of u are shown in Table 1 using the same time step for all three resolutions. When the change-of-variable technique discussed in §3 is used, the accuracy can be increased dramatically and the damping mechanism is unnecessary for the circular case. Table 1 shows the increases of the relative errors in time for the three resolutions with the change-of-variable technique. In a two-month integration, even using the low resolution, the relative error in u is 4.8%.

The numerical approximation for the reduced system is very efficient. The Sun SS-2 central processing unit time used for a two-week integration for the three resolutions was as follows: low, 1.4 minutes; medium, 3.2 minutes; and high, 11.8 minutes. Note the time indicated does not include the preprocessing time (e.g., the time for constructing the grids and decomposition of the matrices).

5.2. Steady-state solution on the kidney-shaped region. In this subsection we test the solution for the untransformed, forced, reduced shallow-water system. Two resolutions are tested. Figure 1 shows the high resolution and the low resolution is obtained by halving the grid size of the high one. For the test purpose, ϕ is chosen as $\phi = f\Psi$. With the change-of-variable technique, the relative errors of the low and high resolutions in u are 0.65×10^{-3} and 0.19×10^{-3} without the damping mechanism. Table 2 shows the increase of the relative errors in time. After two months, the low resolution can achieve relative errors under 10%.

TABLE 2
Relative errors in u on the Kedney domain on day 14 *for the low and high resolutions (%).*

Different solutions	Low	High
Steady flow	3.67	0.90
With eddy	inf	57.4
Eddy passing overlap	127.5	20.6

5.3. A mesoscale eddy on the kidney-shaped region. It is difficult to resolve the eddy constructed in §3. Even with the change-of-variable technique, the relative errors are large. More resolution could be placed on the western boundary to resolve the eddy when no change-of-variable is made, but then the memory required would exceed the capacity of the SS-2 workstation. Therefore, we present only the numerical results from the change-of-variable technique and the damping mechanism. The eddy takes five months to travel a circle. Table 2 shows the relative errors in u without the background flow. The eddy starts at the position shown in Fig. 3 and stops two weeks later. From Table 2, it can be seen that the relative error can be around 10% if the resolution on the western boundary shown in Fig. 1 is doubled. Several tests have been made to allow the eddy to pass through the interpolation regions (i.e., the test starts near the overlapping areas and the eddy passes the areas in two weeks), and the relative errors are smaller than the errors shown in Table 2 because the eddy becomes larger in the overlapping areas than in the center of the western boundary. For example, Table 2 shows the relative errors of u for the two resolutions in two weeks when the eddy passes the overlapping area between the western and eastern boundaries.

6. Conclusions. The composite grid method has been applied to the reduced system for the shallow-water equations. From the analyses and numerical experiments in this paper, this combination of the reduced system with the composite grid method has been shown to be efficient and accurate, particularly for irregular boundary basins.

Acknowledgments. The authors would like to thank Dezso Devenyi for his careful and constructive comments during the internal review and Christy Sweet for her editorial review.

A SPARSE APPROXIMATE INVERSE PRECONDITIONER FOR THE CONJUGATE GRADIENT METHOD[*]

MICHELE BENZI[†], CARL D. MEYER[‡], AND MIROSLAV TŮMA[§]

Abstract. A method for computing a sparse incomplete factorization of the inverse of a symmetric positive definite matrix A is developed, and the resulting factorized sparse approximate inverse is used as an explicit preconditioner for conjugate gradient calculations. It is proved that in exact arithmetic the preconditioner is well defined if A is an H-matrix. The results of numerical experiments are presented.

Key words. sparse approximate inverses, preconditioned conjugate gradient method, H-matrices, incomplete factorizations

1. Introduction.

In this paper we develop a method for computing an incomplete factorization of the inverse of a symmetric positive definite (SPD) matrix A. The resulting factorized sparse approximate inverse is used as an explicit preconditioner for the solution of $Ax = b$ by the preconditioned conjugate gradient (PCG) method. Due to the fact that an explicit preconditioning step only requires matrix–vector products, explicit preconditioners are of considerable interest for use on parallel computers [7, 9, 17, 19–21]. This is in contrast with more traditional preconditioners based on incomplete factorizations of the coefficient matrix A which necessitate triangular solves (a serial bottleneck) in the preconditioning steps. Sparse incomplete inverses are also useful in the construction of sparse approximate Schur complements for use in incomplete block factorization preconditioners [2, 8]. Furthermore, our preconditioner does not require that A be explicitly stored, a feature which is useful for some problems where A is only implicitly given as an operator.

The paper is organized as follows. In §2 we describe the main idea upon which the preconditioner is based. Section 3 is devoted to a proof of the existence of the incomplete inverse factorization for H-matrices, while in §§4 and 5 implementation details and the results of numerical experiments are discussed. Our experiments indicate that this preconditioning strategy can insure rapid convergence of the PCG iteration with convergence rates comparable with those of the best serial preconditioners. In §6 we draw some conclusions and we indicate some future research directions.

This paper can be viewed as a natural outgrowth of work on a direct sparse linear solver based on oblique projections [3, 4, 28].

2. Computing an incomplete inverse factorization. If $A_{n\times n}$ is an SPD matrix, then a factorization of A^{-1} can readily be obtained from a set of conjugate directions $z_1, z_2, \ldots, z_n$ for A. If

$$Z = [z_1, z_2, \ldots, z_n]$$

is the matrix whose i th column is z_i, we have

$$Z^TAZ = D = \begin{pmatrix} p_1 & 0 & \cdots & 0 \\ 0 & p_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & p_n \end{pmatrix} \quad \text{where} \quad p_i = z_i^T A z_i.$$

It follows that

$$A^{-1} = ZD^{-1}Z^T,$$

and a factorization of A^{-1} is obtained. A set of conjugate directions z_i may be constructed by means of a "conjugate Gram–Schmidt" (or A-orthogonalization) process applied to any set of linearly independent vectors $v_1, v_2, \ldots, v_n$. The choice $v_i = e_i$ (the i th unit vector) is computationally convenient. The resulting Z matrix is unit upper triangular; indeed,

$$Z = L^{-T} \quad \text{where} \quad A = LDL^T$$

is the root-free Cholesky factorization of A. Denoting the i th row of A by a_i^T , the inverse factorization algorithm can be written as follows.

THE INVERSE FACTORIZATION ALGORITHM

```
(1) Let $z_i^{(0)} := e_i \quad (1 \le i \le n)$
(2) for $i = 1, 2, \ldots, n$
        for $j = i, i+1, \ldots, n$
            $p_j^{(i-1)} := a_i^T z_j^{(i-1)}$
        end
        if $i = n$ go to (3)
        for $j = i+1, \ldots, n$
            $z_j^{(i)} := z_j^{(i-1)} - \left(\frac{p_j^{(i-1)}}{p_i^{(i-1)}}\right) z_i^{(i-1)}$
        end
    end
(3) Let $z_i := z_i^{(i-1)}$ and $p_i := p_i^{(i-1)}$ , for $1 \le i \le n$ .
    Return $Z = [z_1, z_2, \ldots, z_n]$ and $D = \begin{pmatrix} p_1 & 0 & \cdots & 0 \\ 0 & p_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & p_n \end{pmatrix}$ .
```

Notice that the matrix A need not be explicitly stored—only the capability of forming inner products involving the rows of A is required. This is an attractive feature for cases where the matrix is only implicitly given as an operator. Once Z and D are available, the solution of $Ax = b$ can be computed as

$$x^* = A^{-1}b = ZD^{-1}Z^Tb = \sum_{i=1}^{n} \left(\frac{z_i^T b}{p_i} \right) z_i.$$

A similar algorithm was first proposed in [14]; see also [13, 18]. Further references and a few historical notes can be found in [3, 4]. For a dense matrix this method requires roughly twice as much work as Cholesky. For a sparse matrix the cost can be substantially reduced, but the method is still impractical because the resulting Z tends to be dense. The idea of computing a sparse approximation of Z to construct a preconditioner for the conjugate gradient method was first proposed in [3] (see also [4, 5]). This paper is devoted to developing and testing this idea.

Sparsity is preserved by reducing the amount of fill-in occurring in the computation of the z-vectors (that is, above the main diagonal in the unit upper triangular matrix Z). This can be achieved either by ignoring all fill outside selected positions in Z or by discarding fill whose magnitude falls below a preset drop tolerance (see §4 for details). The motivation for this approach is based upon theoretical results and computer experiments which show that many of the entries in the inverse (or in the inverse Cholesky factor) of a sparse SPD matrix are small in absolute value [2, 10, 25]. Several authors have exploited this fact to construct explicit preconditioners based on sparse approximate inverses [2, 20, 21]. However, the approach taken in this paper is quite different from the previous ones.

If the incomplete inverse factorization process is successfully completed, one obtains a unit upper triangular matrix $\bar{Z}$ and a diagonal matrix $\bar{D}$ with positive diagonal entries such that

$$M^{-1} := \bar{Z}\bar{D}^{-1}\bar{Z}^T \approx A^{-1}$$

is a factorized sparse approximate inverse of A. It is shown in the next section that such an incomplete inverse factorization of A exists (in exact arithmetic) for arbitrary values of the drop tolerance and for any choice of the sparsity pattern in $\bar{Z}$ when A is an H-matrix. For general SPD matrices the process may break down due to the occurrence of negative or zero pivots $\bar{p}_i$. Although numerical experiments show that this breakdown is not very likely to occur for reasonably well-conditioned problems, it is necessary to safeguard the computation of the approximate pivots against breakdown in order to obtain a robust procedure (see §4).

In this paper we limit ourselves to SPD matrices, but it is possible to apply the inverse factorization algorithm to arbitrary matrices. In exact arithmetic, the procedure can be carried out provided that all leading principal minors of A are nonzero [3]. The resulting Z and D matrices satisfy

$$AZ = LD$$

where L, a unit lower triangular matrix, is not explicitly computed. Hence, Z is the inverse of U in the LDU factorization of A. The application of such an implicit Gaussian elimination method to the solution of sparse linear systems has been investigated in [3, 4, 28].

3. Existence of the incomplete inverse factorization. The preconditioner based on the incomplete inverse factorization of A exhibits many analogies with the classical incomplete LDU factorization of Meijerink and van der Vorst [24]. These authors proved that such an incomplete factorization is well defined for arbitrary zero structures of the incomplete factors if A is an M-matrix. In other words, if A is a nonsingular M-matrix, then the incomplete factorization can be carried out (in exact arithmetic) and the computed pivots are strictly positive. Furthermore, the pivots in the incomplete factorization are no smaller than the pivots in the exact factorization. In [23], Manteuffel extended the existence of incomplete LDU factorizations to the class of H-matrices. Recall that $A = [a_{ij}]$ is an H-matrix if $\hat{A} = [\hat{a}_{ij}]$ is an M-matrix where

$$\hat{a}_{ij} = \begin{cases} -|a_{ij}| & \text{when } i \neq j, \\ a_{ii} & \text{when } i = j. \end{cases}$$

Note that a diagonally dominant matrix is an H-matrix.

This result means that if A is a symmetric H-matrix, then the incomplete Cholesky factorization always exists and it can be used to construct an SPD preconditioner for the conjugate gradient method. If A is a general (non-H) SPD matrix, the incomplete factorization may break down due to the occurrence of zero pivots, or the corresponding preconditioner may fail to be positive definite due to the presence of negative pivots.

The same turns out to be true for the incomplete inverse factorization described in the previous section. Here we prove that in exact arithmetic the inverse factorization algorithm given in §2 will never break down provided that A is an H-matrix. In the symmetric case this implies that the approximate inverse $\bar{Z}\bar{D}^{-1}\bar{Z}^T$ is positive definite, so it may be used as preconditioner for the conjugate gradient method. This fact was first proved for M-matrices in [3].

The proof runs as follows. First we show that the incomplete process will never break down if A is an M-matrix. This is a consequence of the fact that dropping a nonzero fill-in in the computation of a vector z_j at step i is equivalent to setting the corresponding entry of the ith row of A to zero. Because the off-diagonal entries of an M-matrix are nonpositive and the entries of $\bar{Z}$ are nonnegative, this shows that the pivots $\bar{p}_i$ produced by the inexact scheme are greater than or equal to the exact pivots p_i. Since these are strictly positive for an M-matrix, no breakdown can occur during the inexact inverse factorization scheme.

Subsequently we show that when A is an H-matrix, the pivots p_i computed by the inverse factorization scheme are no smaller than the pivots $\hat{p}_i$ corresponding to the associated M-matrix.

When combined, these two results will insure the stability of the incomplete procedure for H-matrices. For symmetric matrices this will mean that the factorized approximate inverse is positive definite and can be used as a preconditioner for the conjugate gradient method. However, symmetry is not required in our proof.

PROPOSITION 3.1. *Let A be an M-matrix and let p_i be the pivots produced by the inverse factorization algorithm. If $\bar{p}_i$ are the pivots computed by the incomplete inverse factorization algorithm with any preset zero pattern in the strictly upper triangular part of Z or any value of the drop tolerance, then*

$$\bar{p}_i \geq p_i > 0.$$

Proof. From the identity $AZ = LD$ and the fact that Z and L are unit triangular matrices it follows that the pivots p_i can be expressed in terms of the leading principal minors Δ_i of A as

$$p_i = \frac{\Delta_i}{\Delta_{i-1}} \quad (1 \leq i \leq n; \;\; \Delta_0 = 1).$$

Because A is an M-matrix, all its leading principal minors are positive and therefore $p_i > 0$ for all i. After $i-1$ steps of the inverse factorization scheme, the column vectors $z_j^{(i-1)}$ $(i \le j \le n)$ are available. Let $z_{kj}^{(i-1)}$ denote the kth entry of $z_j^{(i-1)}$. At step i of the inverse factorization scheme, the following are computed:

$$p_j^{(i-1)} = \sum_{l=1}^{i-1} a_{il} z_{lj}^{(i-1)} + a_{ij} \quad (i \le j \le n). \tag{3.1}$$

Suppose now that a sparsity pattern is imposed on the z-vectors, or that all fill-in in the z-vectors whose magnitude falls below a given drop tolerance is to be dropped. The modified z-vectors will be denoted by $\bar{z}_j^{(i-1)}$, and the pivots are now given by

$$\bar{p}_i^{(i-1)} = \sum_{l=1}^{i-1} a_{il} \bar{z}_{li}^{(i-1)} + a_{ii}. \tag{3.2}$$

We show by induction that $\bar{p}_i^{(i-1)} > 0$ for $1 \le i \le n$. We also show that $\bar{p}_j^{(i-1)} \le 0$ for $i+1 \le j \le n$ and that $\bar{z}_j^{(i-1)} \ge 0$ (componentwise) for $i \le j \le n$ for all i. For $i = 1$ the inequalities are obviously true. Now fix $i \ge 2$ and assume that $\bar{p}_{i-1}^{(i-2)} > 0$, $\bar{p}_j^{(i-2)} \le 0$ for $i \le j \le n$, and $\bar{z}_j^{(i-2)} \ge 0$ for $i-1 \le j \le n$. It follows that in the updates

$$\bar{z}_j^{(i-1)} := \bar{z}_j^{(i-2)} - \left(\frac{\bar{p}_j^{(i-2)}}{\bar{p}_{i-1}^{(i-2)}} \right) \bar{z}_{i-1}^{(i-2)}$$

nonpositive quantities are subtracted from nonnegative quantities. Therefore, even after dropping, no component of $\bar{z}_j^{(i-1)}$ can become negative. That is, $\bar{z}_j^{(i-1)} \ge 0$ for $i \le j \le n$. Using this inequalities and the fact that the off-diagonal entries of an M-matrix are nonpositive, we see from (3.1) that $\bar{p}_j^{(i-1)} \le 0$ for $i+1 \le j \le n$. Finally, it is clear from (3.2) that $\bar{p}_i^{(i-1)} \ge p_i^{(i-1)}$. Thus, the pivots cannot become smaller because of dropping. Since the exact pivots are positive, this proves that the incomplete inverse factorization process will not break down. □

We explicitly observe that when A is an M-matrix, our method is guaranteed to produce a nonnegative approximate inverse.

Now let A be an H-matrix, and apply the inverse factorization scheme to A as well as to the associated M-matrix $\hat{A}$. In the sequel, quantities with hats correspond to the associated process on $\hat{A}$. We need to compare pivots and z-vectors for the original process (on A) and for the associated process (on $\hat{A}$). To do this we also need to introduce intermediate quantities—denoted with tildes—which are constructed with entries from $\hat{A}$ and with pivots from A.

PROPOSITION 3.2. *Let A be an H-matrix and let $\hat{A}$ be the associated M-matrix. If p_i and $\hat{p}_i$ denote the pivots computed by the inverse factorization scheme applied to A and to $\hat{A}$, respectively, then $p_i \ge \hat{p}_i$. Furthermore, if $\bar{p}_i$ denote the pivots computed by the incomplete inverse factorization algorithm applied to A, then $\bar{p}_i \ge \hat{p}_i$.*

Proof. Consider the elements $z_{lj}^{(k)}$ of $z_j^{(k)}$ as rational functions

$$z_{lj}^{(k)} = F_{lj}^{(k)}(a_{11}, \ldots, a_{kn}, p_1, \ldots, p_k)$$

dependent on the elements of A and on the pivots $p_1, \ldots, p_k$. Likewise, we can consider the entries $\hat{z}_{lj}^{(k)}$ as rational functions depending on the entries in the first k rows of $\hat{A}$ and on the corresponding pivots $\hat{p}_1, \ldots, \hat{p}_k$. Let

$$\tilde{z}_{lj}^{(k)} = F_{lj}^{(k)}(\hat{a}_{11}, \ldots, \hat{a}_{kn}, p_1, \ldots, p_k)$$

be computed in the same way as $\hat{z}_{lj}^{(k)}$ using $p_1, \ldots, p_k$ instead of $\hat{p}_1, \ldots, \hat{p}_k$. In the following, it helps to think of the pivots p_i, $\hat{p}_i$ as parameters, ignoring their dependency on the entries of A and $\hat{A}$, respectively. In this way, the entries of $z_j^{(k)}$, $\hat{z}_j^{(k)}$, and $\tilde{z}_j^{(k)}$ can be regarded as polynomials in the entries of A and $\hat{A}$, respectively. We will prove that $p_i \geq \hat{p}_i$ using induction on i. We make the following inductive assumptions for all $k \leq i-1$.

$$p_k \geq \hat{p}_k, \tag{3.3}$$

$$\hat{z}_{lj}^{(k)} \geq \tilde{z}_{lj}^{(k)} \text{ for } l \leq j, j \geq i, \tag{3.4}$$

$$\tilde{z}_{lj}^{(k)} \text{ has all its terms nonnegative (as a polynomial).} \tag{3.5}$$

I. For $i = 1$ we have $p_1 = a_{11} = \hat{a}_{11} = \hat{p}_1 > 0$ and $\hat{z}_{lk}^{(1)} \geq \tilde{z}_{lk}^{(1)} \geq 0$.
II. Using (3.1) for $\hat{p}_i$ we get

$$\hat{p}_i = \sum_{l=1}^{i-1} \hat{a}_{il} \hat{z}_{li}^{(i-1)} + \hat{a}_{ii} \leq \sum_{l=1}^{i-1} \hat{a}_{il} \tilde{z}_{li}^{(i-1)} + \hat{a}_{ii}.$$

This inequality follows from the inductive assumption $\hat{z}_{li}^{(i-1)} \geq \tilde{z}_{li}^{(i-1)}$ and from the fact that the $\hat{a}_{il}$'s are nonpositive (being off-diagonal elements of the associated M-matrix).

Notice that corresponding terms in the expressions of $\tilde{z}_{li}^{(i-1)}$ and $z_{li}^{(i-1)}$ as polynomials have the same absolute value, so they can differ only by the sign. Using the defining identities for the H-matrix, i.e., $\hat{a}_{ii} = a_{ii}$ and $\hat{a}_{ik} = -|a_{ik}|$ for $i \neq k$, we get

$$\sum_{l=1}^{i-1} \hat{a}_{il} \tilde{z}_{li}^{(i-1)} + \hat{a}_{ii} \leq \sum_{l=1}^{i-1} a_{il} z_{li}^{(i-1)} + a_{ii} = p_i.$$

All terms in $\hat{a}_{il} \tilde{z}_{li}^{(i-1)}$ on the left-hand side, when considered as a polynomial in elements of $\hat{A}$, are nonpositive. On the right-hand side, some of the terms in the expression for $z_{li}^{(i-1)}$ can be positive. But corresponding terms of these polynomials have the same absolute value, so they differ only by the sign. Hence the inequality.

Using the updating formula—given in the inverse factorization algorithm—for $\hat{z}_j^{(i)}$ we have

$$\hat{z}_j^{(i)} = \hat{z}_j^{(i-1)} - \frac{\sum_{l=1}^{i-1} \hat{a}_{il} \hat{z}_{lj}^{(i-1)} + \hat{a}_{ij}}{\hat{p}_i} \hat{z}_i^{(i-1)}.$$

Since the off-diagonal elements of the M-matrix are nonpositive, and since $p_i \geq \hat{p}_i > 0$, we obtain

$$\hat{z}_j^{(i)} \geq \tilde{z}_j^{(i-1)} - \frac{\sum_{l=1}^{i-1} \hat{a}_{il} \tilde{z}_{lj}^{(i-1)} + \hat{a}_{ij}}{p_i} \tilde{z}_i^{(i-1)} \equiv \tilde{z}_j^{(i)}.$$

This follows from the set of inequalities

$$-\hat{a}_{il}\hat{z}_{lj}^{(i-1)} \geq -\hat{a}_{il}\tilde{z}_{lj}^{(i-1)},$$

$$\hat{z}_i^{(i-1)} \geq \tilde{z}_i^{(i-1)},$$

$$\hat{p}_i^{-1} \geq p_i^{-1}.$$

Assembling everything together we have

$$-\frac{\sum_{l=1}^{i-1}\hat{a}_{il}\hat{z}_{lj}^{(i-1)} + \hat{a}_{ij}}{\hat{p}_i}\hat{z}_i^{(i-1)} \geq -\frac{\sum_{l=1}^{i-1}\hat{a}_{il}\tilde{z}_{lj}^{(i-1)} + \hat{a}_{ij}}{p_i}\tilde{z}_i^{(i-1)}.$$

This inequality is added to the inequality from the assumption

$$\hat{z}_j^{(i-1)} \geq \tilde{z}_j^{(i-1)}$$

to arrive at

$$\hat{z}_j^{(i)} \geq \tilde{z}_j^{(i)}.$$

In addition, all the terms of $\tilde{z}_j^{(i)}$ are nonnegative.

Using the inductive assumption and defining identities for the H-matrix it can also be seen that (3.5) is true for $k = i$.

Concerning the second statement, it is easily seen that the same inequality for the pivots holds when the inverse factorization algorithm is applied to A incompletely, as the same argument for the polynomial terms can be applied even when some elements of $\hat{z}_j^{(i)}$ are set to zero. □

It follows from Propositions 3.1 and 3.2 that the incomplete inverse factorization process will never break down (in exact arithmetic) when A is an H-matrix. This is true for arbitrary zero patterns in the strictly upper triangular part of $\bar{Z}$ and for arbitrary choices of the drop tolerance.

The pivots produced by the incomplete inverse factorization of an H-matrix are no smaller than the pivots produced by the incomplete inverse factorization of the associated M-matrix. However, they are not necessarily larger than the pivots produced by the exact inverse factorization of A, contrary to what happens in the M-matrix case. For example, consider the H-matrix

$$\begin{pmatrix} 4 & -1 & -\epsilon \\ -1 & 4 & 1 \\ -\epsilon & 1 & 4 \end{pmatrix}.$$

If $0 < \epsilon < 1/4$, the incomplete inverse factorization algorithm with drop tolerance $Tol = 1/16$ returns a pivot $\bar{p}_3$ which is smaller than the pivot p_3 produced by the exact inverse factorization scheme. This is in perfect analogy with incomplete Cholesky factorizations (see [23, p. 479]).

If A is not an H-matrix, the incomplete inverse factorization algorithm may break down. For instance, applying the algorithm with a drop tolerance $Tol = 0.06$ to the SPD matrix

$$\begin{pmatrix} 2.00 & 0.40 & 0.10 \\ 0.40 & 1.08 & 2.00 \\ 0.10 & 2.00 & 3.96 \end{pmatrix}$$

results in $\bar{p}_3 = 0$ (a breakdown).

In finite precision computations, zero or negative pivots may occur even for H-matrices, due to round-off errors. Also, trouble can be expected in the presence of extremely small pivots. Indeed, this is one way for severe ill conditioning to manifest itself. Furthermore, there are many applications leading to SPD matrices which are not H-matrices—typically, finite element analysis. It is therefore desirable to incorporate some safeguard mechanism in the incomplete algorithm which guarantees that the computation of the preconditioner will run to completion and that it will always produce a symmetric positive definite approximate inverse factorization. Similar techniques have been implemented in connection with incomplete Cholesky factorization preconditioning and with approximate Hessian modifications [23, 16, 27].

4. Notes on implementation. We have implemented the PCG algorithm with our approximate inverse preconditioner—hereafter referred to as AINV—based on the inverse factorization algorithm of §2 as well as with a standard incomplete Cholesky (IC) preconditioner. The purpose of this comparison is to explore some characteristic algorithmic properties of the explicit preconditioner and to get a feeling for the convergence rate for the explicit PCG method as compared with one of the best implicit preconditioners.

We first describe the IC preconditioner used in our comparison. It was computed by a standard column algorithm with symbolic and numeric phases (see [15, 22]). During the decomposition we removed all the elements of the factor less than a prescribed drop tolerance Tol. Necessary working space was thus dominated by the size (number of nonzero entries) of the lower triangular factor of the IC preconditioner.

This decomposition, which could break down for general (non-H) matrices, was modified by a standard stabilization; see [16]. The algorithm insures that all diagonal elements of D in the LDL^T decomposition are strictly positive and the absolute values of the elements of L satisfy a uniform upper bound in order to preserve numerical stability and to prevent excessively large elements in the factors. We refer to [16] for details.

Computing the AINV preconditioner is a slightly more complicated process. In the Cholesky case we can use an elimination tree structure to minimize symbolic integer overhead and working storage. Due to the complicated rules governing fill-in in the AINV case, it is not clear how to realize an analogous symbolic process. Therefore, we used a submatrix type of algorithm which updates at each step all the remaining z-vectors by a rank-one modification. We adopted dynamic data structures similar to those used in submatrix formulations of sparse unsymmetric Gaussian elimination (see [11,28,29]). This requires the user to provide an estimate for the number of nonzeros allowed in the preconditioner. Additionally, some elbow space is needed for the data structures. In our implementation the elbow space was four times the estimated space for storing the nonzeros in the preconditioner—similar to the implementation of sparse Gaussian elimination in the widely used packages MA28 [11] and Y12M [29].

However, there are some differences in the use of such data structures in Gaussian elimination and in the AINV procedure. For instance, these data structures are used in AINV for the matrix Z but not for A, now stored in static data structures. During the AINV process, A is delivered into the cache by rows since we need at each step only one row of A. Recall that in some cases it may even be possible to avoid storage of A altogether—e.g., when a routine is available to compute the action of A on a vector (we did not take advantage of this option in our implementation).

The amount of fill-in created during the computation of the AINV preconditioner in most of the first steps is very small and thus the integer overhead and CPU time spent in these initial stages is very small. This is in contrast with sparse Gaussian elimination (as represented, for instance, by MA28), where the proportion of integer overhead and CPU time is distributed more uniformly over the algorithmic steps.

The sizes of the data structures in the AINV case which are necessary in the top level of the memory hierarchy (cache and registers) were found to be small, often much smaller than the size of the preconditioner. This fact can strongly influence performance, especially on workstation equipment. Nevertheless, working storage for the implementation of AINV is larger than for the implementation of IC.

Sparsity was preserved on the basis of value rather than on the positions of fill-in. For capturing the relevant entries in the inverse Cholesky factor of A, this is a better strategy than imposing a preset sparsity pattern on Z. Consistency suggested that drop tolerances be used with IC as well.

Skipping some z-vector updates in step (2) of the inverse factorization algorithm when the coefficients $p_j^{(i-1)}/p_i^{(i-1)}$ were in some sense "small" produced bad numerical results, so no skipping was done.

In the AINV case we also implemented an algorithmic modification to avoid breakdown for general SPD (non-H) matrices. When some computed diagonal element $\bar{p}_i$ was too small—in our case, less than $\sqrt{\epsilon_M}$ where ϵ_M is the machine precision—we replaced it by

$$\bar{p}_i \longleftarrow \max\{\sqrt{\epsilon_M},\ \mu\sigma\theta\} \tag{4.1}$$

where

$$\mu = 0.1 \text{ (a relaxation parameter)},$$
$$\sigma = \max_{i\le k\le n-1}\left\{p_k^{(i-1)}\right\},$$
$$\theta = \|z_i^{(i-1)}\|_\infty \neq 0.$$

The rule (4.1) was chosen to avoid breakdowns due to very small or negative diagonal elements $\bar{p}_i$. It also has the effect of constraining the growth of elements in the z-vectors. This avoids break downs, but, just as in the IC case, there is no guarantee that we will get a good preconditioner after this regularization.

5. Numerical experiments. The following experiments illustrate some properties of the two preconditioners when applied within the PCG algorithm to SPD matrices. Nine test matrices were taken from the Harwell–Boeing collection [12] and the remaining two were kindly provided by G. Zilli (Padua University).

All experiments were run on a SGI Crimson computer with RISC processor R4000. Codes were written in Fortran 77 and compiled with the optimization level –O4. CPU time was measured using the standard function *dtime*. We also experimented with the compiling option $-MIPS2$ which enables double word loads and stores. It is known that this can substantially enhance the performance of floating point arithmetic of some codes. This option led to slightly improved timings in only a few cases, mostly for ICCG. The timings reported in the tables are the best between those obtained with the two compiling options.

All matrices were rescaled by dividing their elements by their largest nonzero entry, but no preordering of their elements was used. The right-hand side of each system was computed using the solution vector composed of ones. The PCG iteration was terminated when the 2-norm of the unpreconditioned residual had been reduced to less than 10^{-9}. The matrices used in the experiments correspond to finite element approximations to problems in structural engineering (NOS3, NOS5, PADUA1, PADUA2), finite difference approximations to elliptic PDEs (NOS6, NOS7, GR3030) and to modelling of power system networks (BUS matrices).

TABLE 1
Behavior of the unpreconditioned CG algorithm.

test matrix	n	density	time	iterations
NOS3	960	8,402	1.76	266
NOS5	468	2,820	0.88	468*
NOS6	675	1,965	1.66	675*
NOS7	729	2,673	1.89	729*
494BUS	494	1,080	0.91	494*
662BUS	662	1,568	1.30	614
685BUS	685	1,967	1.44	556
1138BUS	1,138	2,596	3.83	1,138*
GR3030	900	4,322	0.28	45
PADUA1	812	3,135	3.06	812*
PADUA2	1,802	13,135	24.11	1,802*

The listings in Table 1 are for the unpreconditioned CG algorithm. Column 1 is the name of the test matrix; column 2 lists the size (n) of the matrix; column 3 (density) gives the number of nonzeros in the lower triangular part including the diagonal of the test matrix; column 4 (time) reports the execution time in seconds; and column 5 (iterations) gives the number of iterations. An asterisk (*) in column 5 indicates that the algorithm failed to converge after n steps using the above mentioned stopping criterion, and computations were terminated.

From the description of our implementation it can be expected that the CPU times for computing the two preconditioners IC and AINV will be different because the IC computation has very small integer overhead. Of course, this difference may become negligible if a sequence of linear systems with the same coefficient matrix (or a slightly modified one) and different right-hand sides has to be solved, since the time for computing the preconditioners is then only a small fraction of the time required for the overall computation.

Drop tolerances parameterize IC and AINV in different ways. That is, using the same Tol value will produce very different results in the two cases. It is preferable to compare the two preconditioners in terms of amount of fill-in rather than to compare two preconditioners obtained using the same value of Tol. The key role in the experiments is played by the fill-in allowed in the preconditioners. Allowing more fill-in results in less PCG iterations, though not always in less overall CPU time. The relation between preconditioner size (measured by fill-in) and number of PCG iterations for AINV and IC is one of the objectives of our comparison.

Table 2 lists the results of applying PCG with different sizes (measured by fill-in) of IC and AINV on the 675×675 Harwell–Boeing test matrix NOS6 which is derived from Poisson's equation in an L-shaped region with mixed boundary conditions. The timings in this table do not include the time required to compute the preconditioner.

TABLE 2
Behavior of PCG using IC versus AINV on H–B test matrix NOS6.

IC			AINV		
fill-in	**iterations**	**time**	**fill-in**	**iterations**	**time**
675	87	0.33	743	76	0.32
897	53	0.18	780	74	0.32
912	51	0.18	1,135	54	0.26
1,204	38	0.14	1,208	47	0.18
1,439	32	0.14	1,300	40	0.21
1,520	28	0.10	1,502	37	0.16
1,565	24	0.10	3,654	22	0.14
1,918	8	0.03	17,387	6	0.09

The results in Table 2 indicate that by using preconditioners of restricted size (obtained by adjusting the drop tolerances), the iteration counts as well as the timings for IC and AINV preconditioning are comparable, even in scalar mode allowing slightly more fill-in for the AINV preconditioner. For preconditioners of comparable size, slightly more iterations are needed by AINV preconditioning.

If we keep the size of the preconditioners "moderate," we usually decrease overall CPU time. What moderate means here is strongly problem and architecture (CPU, memory hierarchy) dependent.

The AINV method tends to generate more fill-in than IC, and for small drop tolerances the fill-in for AINV can be so high on some structured problems that we can no longer talk of sparse approximate inverse preconditioning thus making the comparison with IC not very meaningful (a preconditioner can be considered sparse if it contains about the same number of nonzeros as the original matrix or less). However, as discussed in [3, 4], problems having irregular sparsity patterns seem to be well suited for the AINV preconditioner because fill-in is often reasonably low.

TABLE 3
Iteration counts and timings for the IC preconditioner in PCG.

Test Matrix	**Fill-in**	**PCG steps**	**IC time**	**PCG time**	**Fill-in**	**PCG steps**	**IC time**	**PCG time**
NOS3	2,290	150	0.08	1.45	10,875	32	0.08	0.38

PADUA2	5,305	143	0.23	2.71	7,777	84	0.20	1.65

Table 3 shows iteration counts and timings for PCG using the IC preconditioner, and Table 4 gives the same information for PCG using the AINV preconditioner. These tables also report the time required to compute each preconditioner. Again, the timings for PCG refer to the iterative part only. The IC and AINV preconditioners were computed with similar restricted sizes up to about the original number of nonzeros. Drop tolerances for IC were taken between 0.0001 and 0.01, and drop tolerances for AINV were in the range 0.1 to 0.6. For each test matrix two sparse preconditioners were computed—the first being very sparse while the second contains roughly the same number of nonzeros as the test matrix being used.

TABLE 4
Iteration counts and timings for the AINV preconditioner in PCG.

Test Matrix	Fill-in	PCG steps	AINV time	PCG time	Fill-in	PCG steps	AINV time	PCG time
NOS3	1,946	139	0.27	1.53	6,213	89	0.27	1.14

GR3030	900	45	0.12	0.29	13,541	26	0.35	0.37
PADUA1	1,274	63	0.14	0.38	1,459	48	0.14	0.31
PADUA2	5,269	159	0.25	3.14	11,095	80	0.42	1.92

Our results indicate that implicit and explicit sparse preconditioners can have similar behavior—even in the scalar case. The fact that a somewhat higher fill-in is required by the AINV preconditioner in order to achieve the same reduction in the number of PCG iterations as with IC is only natural, since in AINV we are approximating the inverse Cholesky factor (usually a dense matrix), whereas IC is a sparse approximation to the Cholesky factor L itself. If $\bar{L}$ is an incomplete Cholesky factor of A and $\bar{Z}$ is an incomplete inverse Cholesky factor, and if the amount of nonzeros in these two matrices is about the same, then one can expect that $\bar{L}^{-1}$ will be substantially denser than $\bar{Z}$.

In other words, for the same amount of fill-in in the preconditioners, IC yields a better approximation to A^{-1} than AINV. But this comes at a price—namely that two triangular solves are needed at each PCG iteration. On the other hand, the price to pay for the explicitness afforded by the AINV preconditioner is the increased size of the preconditioner, so, on a scalar computer, IC has a slight edge over AINV. However, the situation could be reversed in a parallel computing environment thanks to the explicit nature of AINV. This is a point which warrants further research, and no firm conclusion can be drawn until a parallel version of AINV-PCG has been actually implemented and compared with recent work on parallel solution of sparse triangular systems (see, for instance, [1]). In any event, we observe that even in scalar mode there are problems for which AINV is superior to IC—e.g., PADUA1.

It should be observed that all test matrices used are M-matrices except for NOS3, NOS5, PADUA1, and PADUA2, and these are not even H-matrices. In no case was safeguarding necessary during the computation of the AINV preconditioners, whereas in a few cases IC shifted positive pivots away from zero by a very small amount. This did not adversely affect the convergence of PCG.

6. Conclusions and future work. Our study involved a novel approach to approximate inverse preconditioning for conjugate gradient calculations. One interesting feature of this technique is the fact that the entries of the coefficient matrix A are not explicitly needed, which may be useful for problems where A is only implicitly given as an operator. It was proven that the computation of the preconditioner has the same robustness as standard IC factorization, and numerical evidence was given to make the point that the new preconditioner is competitive with IC—even in scalar mode. The results presented in this paper suggest that our approximate inverse preconditioner can be a useful tool for the solution of large sparse SPD linear systems on modern high-performance architectures.

Future research will focus on efficient parallel implementations and on the extension to unsymmetric problems. A sparse approximate inverse preconditioner for a nonsymmetric matrix A may be obtained by constructing a set of approximate A-biconjugate directions. This can be achieved by applying the inverse factorization algorithm to both A and A^T together with suitable sparsity-preserving strategies. The resulting factorized sparse approximate inverse, which is guaranteed to exist when A is an H-matrix, is an explicit preconditioner which can be used to enhance the convergence of conjugate gradient-like methods for the solution of $Ax = b$.

A different approach, applicable to general sparse matrices, is based on the normal equations $A^TAx = A^Tb$. The solution of this system by the preconditioned conjugate gradient method (PCGNR) is an effective strategy for problems which are unsymmetric and strongly indefinite; see [26, 29]. Also, the PCGNR method is attractive for solving large sparse linear least squares problems. Some of the most effective preconditioners for PCGNR are based on incomplete orthogonal factorizations of A and do not require explicitly forming the matrix A^TA. These procedures compute a sparse approximation to the upper triangular factor R in the QR decomposition of A. It is known that this approach is more robust than computing an incomplete Cholesky factorization of A^TA (notice that R is the transpose of the Cholesky factor of A^TA).

A natural idea is to compute an approximate inverse preconditioner for A^TA based on the inverse factorization scheme of §2. At step i of the algorithm the ith row of A^TA is computed and used and then discarded. The resulting $\bar{Z}$ is a sparse approximation to R^{-1}. The PCGNR scheme can be carried out free of triangular solves in the preconditioning steps. This approach was found to be effective for problems in which A^TA enjoys some form of diagonal dominance but in general was not competitive with more traditional schemes based on variants of the Gram–Schmidt orthogonalization process. More important, there exist other methods which can be used to compute R^{-1} directly from A. A description of some incomplete orthogonalization methods for approximating R and R^{-1}, together with the results of numerical experiments on a variety of general sparse matrices (including rectangular ones), can be found in [6].

ACCURACY OF THE DISCRETE FOURIER TRANSFORM AND THE FAST FOURIER TRANSFORM*

JAMES C. SCHATZMAN†

Abstract. Fast Fourier transform (FFT)-based computations can be far more accurate than the slow transforms suggest. Discrete Fourier transforms computed through the FFT are far more accurate than slow transforms, and convolutions computed via FFT are far more accurate than the direct results. However, these results depend critically on the accuracy of the FFT software employed, which should generally be considered suspect. Popular recursions for fast computation of the sine/cosine table (or twiddle factors) are inaccurate due to inherent instability. Some analyses of these recursions that have appeared heretofore in print, suggesting stability, are incorrect. Even in higher dimensions, the FFT is remarkably stable.

Key words. fast Fourier transform (FFT), discrete Fourier transform (DFT)

AMS subject classifications. 65T20, 65Y25, 68Q25, 42A65, 42C10

1. Introduction.

The Fourier transform is one of the most important fundamental mathematical tools in existence today. While the discrete Fourier transform (DFT) and fast Fourier transform (FFT) are generally considered to be stable algorithms, reported quantifications of the stability have been inconsistent and confusing. Some analyses neglect the effect of errors in the coefficients (also called the sine/cosine table or twiddle factors), which turns out to be potentially the largest source of error.

Gentleman and Sande [4] report an analysis of FFT errors (for the Cooley–Tukey algorithm) in which the root mean square (RMS) relative error is

$$E_{RMS} = 1.06 \sum_{j=1}^{K} (2p_j)^{\frac{3}{2}} \epsilon, \tag{1}$$

where ϵ is the machine epsilon and $N = p_1 p_2 ... p_K$. For $N = 2^K$, and using the radix-2 algorithm, this becomes

$$E_{RMS} = 8.48 \log_2 N\epsilon. \tag{2}$$

Their corresponding formula for the slow DFT is

$$E_{RMS} = 1.06(2N)^{\frac{3}{2}}\epsilon. \tag{3}$$

The results of Gentleman and Sande are upper bounds. Our own *typical* results are quite different, being asymptotically of far better (smaller) order when the twiddle factors are accurate.

Kaneko and Liu [7] give an analysis for the Cooley–Tukey FFT with several types of input data sequences. Their results are rather complex, but their conclusion that errors in the twiddle factors have virtually no effect on the results (compare their Figures 4 and 7) is misleading.

Calvetti [2] gives an involved analysis for the Cooley–Tukey algorithm and the slow transform. She separates the effects of roundoff errors in addition and multiplication. The results are

$$
\begin{aligned}
&E_{RMS} = \sqrt{\log_2 N}\,\sigma_a, && \text{addition errors, FFT;}\\
&E_{RMS} = \frac{1}{2}\sqrt{\log_2 N}\,\sigma_a, && \text{multiplication errors, FFT;}\\
&E_{RMS} = \frac{\sqrt{n-1}}{n}\,\sigma_m, && \text{addition errors, slow DFT;}\\
&E_{RMS} = \frac{1}{n}\,\sigma_m, && \text{multiplication errors, slow DFT;}
\end{aligned}
\tag{4}
$$

where σ_a, σ_m are the standard deviations of the assumed independent random errors in addition and multiplication. These errors are relative to the maximum norm of the input data. Calvetti claims, "For very small expected value of the relative error for addition and multiplication, the traditional [slow] algorithm will produce more accurate results." She further suggests, "The FFT can be considered more accurate than the TFT [slow DFT] only if the expected value of the relative error for addition is of the same size or larger than the expected value of the relative error for multiplication." I do not believe that the analysis for the slow algorithm is correct, nor is the general sense of Calvetti's conclusion (that the slow DFT is accurate compared to the FFT) correct. I do agree with Calvetti's formulas for FFT errors, in the case where the twiddle factors are accurate. Calvetti's paper gives a useful bibliography of earlier work.

According to Gottlieb and Orszag [5], "Transform methods normally give no appreciable amplification of roundoff errors. In fact, the evaluation of convolution-like sums using FFTs often gives results with much smaller roundoff error than would be obtained if the convolution sums were evaluated directly." See Van Loan [12] for a more recent publication on this topic.

Our own conclusions concerning accuracy are that the FFT is *remarkably* stable, when implemented properly. The FFT is vastly more accurate than the slow DFT. However, the FFT is very sensitive to accuracy of the internal sine/cosine table (twiddle factors). A popular technique for calculating the sine/cosine table by recursion is ill-advised for this reason.

2. The DFT.

2.1. Properties of the standard DFT. The square DFT might be written $\vec{c} = G\vec{x}$ or

$$c_k = \sum_{n=0}^{N-1} e^{-\imath\omega_k t_n} x_n, \tag{5}$$

where most commonly

$$\omega_k = k\Delta\omega, \qquad 0 \le k \le N\text{–}1, \tag{6}$$

$$t_n = n\Delta t, \qquad 0 \le n \le N\text{–}1, \tag{7}$$

$$\Delta\omega\Delta t = \frac{2\pi}{N}. \tag{8}$$

2.1.1. Numerical errors. Errors in the computation of the DFT are limited to errors in the approximations of the sine/cosine phase factors and roundoff errors in multiplication and addition. To aid in characterizing these errors, we define the machine ϵ in the usual way as the smallest positive number such that $1 + \epsilon$ is distinguishable from unity in the floating point representation employed. For tests with 32- and 64-bit IEEE floating point, we use the corresponding $\epsilon_{32} = 6 \cdot 10^{-8}$ and $\epsilon_{64} = 1.1 \cdot 10^{-16}$.

A useful exact characterization of expected error with floating point calculations is difficult or impossible, particularly in the case of addition, because of the nature of the floating point

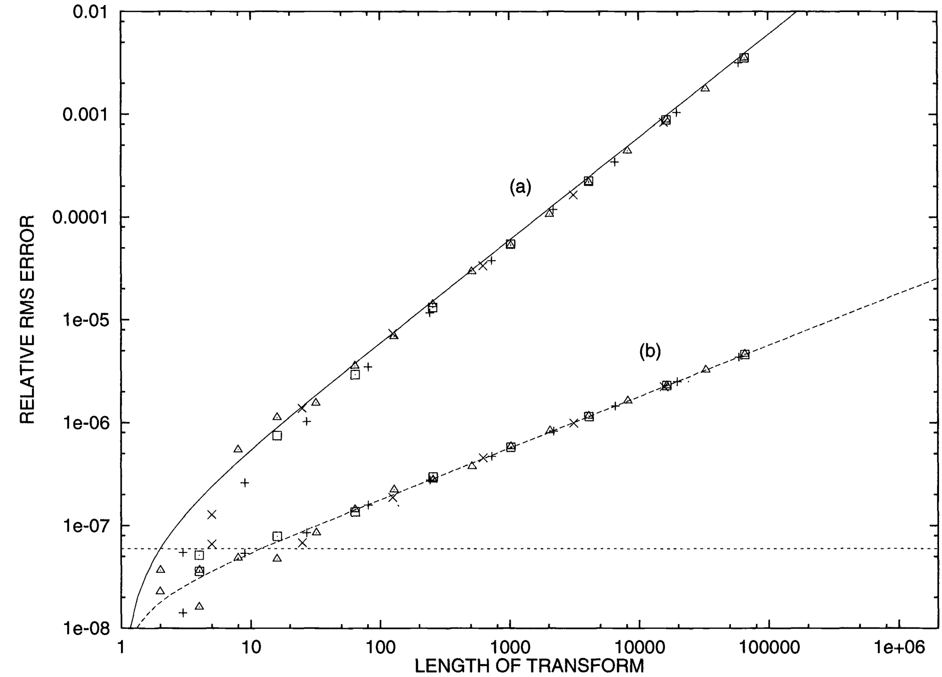

FIG. 1. *Relative RMS errors in the computed DFT for the* 32*-bit IEEE floating point slow Fourier transform using* (a) *the IBM* RS6000 *library* 32*-bit sine and cosine functions and the NCAR FFTPAK table calculation code, and* (b) *an accurate sine/cosine table.* △, □, +, *and* × *denote lengths that are powers of* 2, 3, 4, *and* 5, *respectively. The interpolating error functions (smooth curves) are* $e_1(N) = \epsilon_{32}(N{-}1)$ *and* $e_2(N) = 0.3\epsilon_{32}\sqrt{N{-}1}$. *The horizontal dashed line represents the constant* $\epsilon_{32} = 5.96 \cdot 10^{-8}$.

representation. Error bounds tend to lead to excessively pessimistic error estimates. Roughly, for data vectors exhibiting a reasonable degree of stationarity, if the errors associated with each coefficient, multiplication, and addition are uncorrelated (not a very reasonable assumption) the RMS error of the DFT would be expected to be approximately $\sqrt{N-1}$ times the error standard deviation associated with each term. If the errors are correlated, an RMS error proportional to $N - 1$ would be expected. Assuming that relative multiplication errors are uniformly distributed on $[-\epsilon/2, \epsilon/2]$ (a reasonable approximation if full rounding is used), the corresponding error standard deviation is $\epsilon/\sqrt{12}$. Assuming that relative addition errors are uniformly distributed on $[-\epsilon, \epsilon]$ (a poor approximation), the corresponding error standard deviation is $\epsilon/\sqrt{3}$.

Putting these ideas together, we obtain a rough estimate of the overall RMS error in the case of uncorrelated individual errors:

$$E_{RMS} = \sqrt{(N{-}1)\left(\frac{1}{12} + \frac{1}{3}\right)\epsilon^2 + (N{-}1)\sigma_C{}^2}, \tag{9}$$

where σ_C is the error standard deviation of the coefficients. If σ_C is $\epsilon/\sqrt{12}$, (9) reduces to $E_{RMS} = (\epsilon/\sqrt{2})\sqrt{N{-}1}$.

Figures 1 and 2 show a comparison of 128-bit floating point DFT results (taken to be truth) with

(1a) IEEE 32-bit DFT computations using the manufacturer's 32-bit sine/cosine functions,
(1b) IEEE 32-bit DFT computations modified to use an accurate table of phase factors,

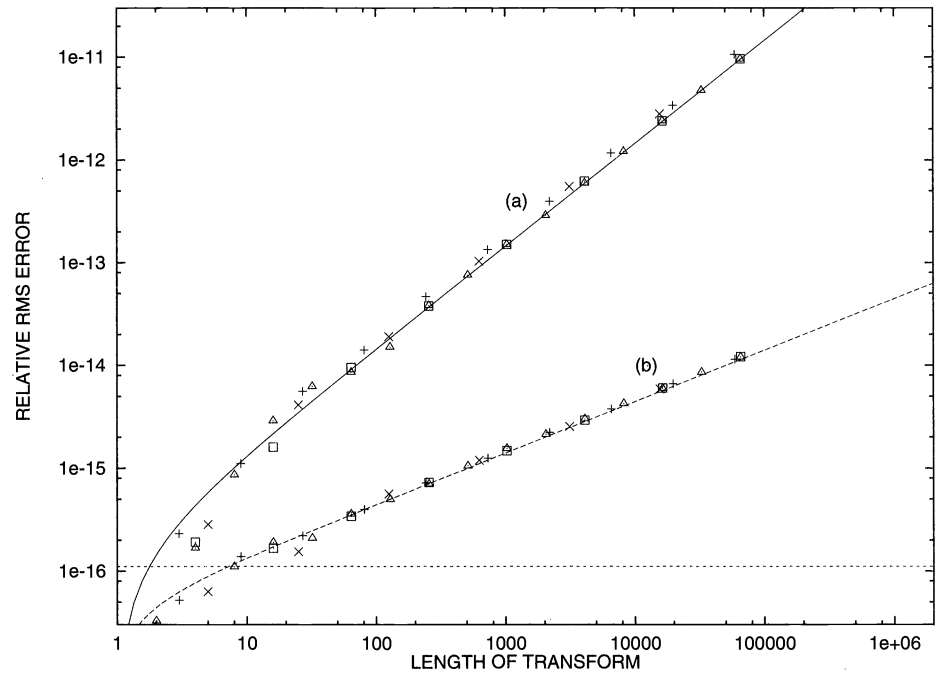

FIG. 2. *Relative RMS errors in the computed DFT for the* 64-*bit IEEE floating point slow Fourier transform using* (a) *the IBM RS6000 library* 64-*bit sine and cosine functions and the NCAR FFTPAK table calculation code, and* (b) *an accurate sine/cosine table.* △, +, □, *and* × *denote lengths that are powers of* 2, 3, 4, *and* 5, *respectively. The interpolating error functions (smooth curves) are* $e_1(N) = 1.3\epsilon_{64}(N{-}1)$ *and* $e_2(N) = 0.4\epsilon_{64}\sqrt{N{-}1}$. *The horizontal dashed line represents the constant* $\epsilon_{64} = 1.11 \cdot 10^{-16}$.

(2a) IEEE 64-bit DFT computations using the manufacturer's 64-bit sine/cosine functions,

(2b) IEEE 64-bit DFT computations modified to use an accurate table of phase factors. The tests were performed on an IBM RS/6000 computer. The input data was a series of independent, identically distributed Gaussian random sequences (for the real and imaginary components). The RMS difference between the two computations, scaled by the RMS value of the "true" result, is displayed as a function of transform length.

As shown in the figures, fits to the measured RMS errors were obtained for the following error functions:

(1a) 32-bit: $\epsilon_{32}(N{-}1)$,

(1b) improved 32-bit: $0.3\epsilon_{32}\sqrt{N{-}1}$,

(2a) 64-bit: $1.3\epsilon_{64}(N{-}1)$,

(2b) improved 64-bit: $0.4\epsilon_{64}\sqrt{N{-}1}$.

When accurate phase factors are used (Figures 1b and 2b) square root error growth is observed; results are obtained that are more accurate than predicted by (9) by about a factor of two. When inaccurate phase factors are used (Figures 1a and 2a), linear growth is observed, suggesting that individual errors are correlated.

From these results we conclude the following:

(1) Accuracy of the sine/cosine table is critical to overall performance of the numerical DFT. When the sine/cosine table of the FFT is inaccurate, errors in the DFT may be correlated and the overall RMS DFT errors are then roughly proportional to the length of the transform.

(2) The IBM RS/6000 library sine/cosine functions are not very accurate; we do not recommend their use except for noncritical applications. A similar observation has been made for the Cray CFT77 library routines. The computation of long slow DFTs with IEEE 32-bit floating point may be expected to be of questionable accuracy unless more accurate sine/cosine approximations are used. Using the RS/6000 library routines, only about five significant figures should be expected for about 100 points ranging down to two significant figures for about 100k points.

(3) When the sine/cosine table is accurate, performance is dramatically superior for both 32- and 64-bit computations, and the RMS DFT errors grow proportionally to the square root of the length of the transform. In this case, the DFT may be regarded as a stable process. However, there still may be significant error for very long transforms; five to six significant figures of accuracy may be expected for transforms in the 100k+ point range using 32-bit floating point.

There is obviously some sensitivity of the errors to the data. An extreme example is the case of data consisting of mostly zeros. The above results should be interpreted as typical rather than definitive.

3. The FFT.

3.1. Sources of error. It is helpful to list the theoretical sources of error:

(1) instability of the FFT computations associated with the factorization,

(2) instability of the underlying DFT blocks,

(3) errors in the sine/cosine table (twiddle factors),

(4) roundoff error in all of the computations, compounded randomly.

While all errors could be considered roundoff errors, the above breakdown is reasonable. In particular, the idea of approximating roundoff by an instability effect and a random effect is a powerful tool. The validity of this model for general numerical computations remains to be demonstrated; there is good agreement between theoretical and empirical results in this analysis.

We will show that sources (1) and (2) may be discounted (the associated computations are extremely stable). Sources (3) and (4) are the principal sources of error; in a properly designed code, source (4) will dominate.

3.2. FFT formulation. We formulate the conventional version of the FFT to concretize the differences between it and the slow DFT. Suppose N is even. We observe

$$c_k = \sum_{j=0}^{N-1} w^{kn} x_j = \sum_{j=0}^{\frac{N}{2}-1} w^{2kj} x_{2j} + w^k \sum_{j=0}^{\frac{N}{2}-1} w^{2kj} x_{2j+1}$$

$$(10) \qquad = \begin{cases} c_k^{(0)} + w^k c_k^{(1)}, & 0 \leq k \leq \frac{N}{2} - 1, \\ c_{k'}^{(0)} - w^{k'} c_{k'}^{(1)}, & \frac{N}{2} \leq k \leq N-1, \end{cases}$$

where $k' = k - \frac{N}{2}$, $w = e^{-\imath \frac{2\pi}{N}}$, $\vec{c}^{(0)}$ is the length $\frac{N}{2}$ DFT of the even terms $x_0, x_2, \ldots$, and $\vec{c}^{(1)}$ is the length $\frac{N}{2}$ DFT of the odd terms $x_1, x_3, \ldots$. This is the well-known result that a DFT of even length N can be computed as the combination of two DFTs of length $\frac{N}{2}$. The coefficients w^i and $w^{i'}$ are called the twiddle factors. In matrix notation (10) may be written

$$(11) \qquad \vec{c} = \begin{pmatrix} I_{\frac{N}{2}} & \Omega^{\frac{1}{2}}_{\frac{N}{2}} \\ I_{\frac{N}{2}} & -\Omega^{\frac{1}{2}}_{\frac{N}{2}} \end{pmatrix} \begin{pmatrix} \vec{c}^{(0)} \\ \vec{c}^{(1)} \end{pmatrix},$$

where

$$\Omega_q = \mathrm{diag}(z^0, z^1, z^2, \ldots, z^{q-1}), \qquad z = e^{-i\frac{2\pi}{q}}, \tag{12}$$

and $I_{\frac{N}{2}}$ is the $\frac{N}{2}$-by-$\frac{N}{2}$ identity matrix. Repeating this process for N a power of 2, we obtain

$$F_N = S_N^{(2)} \begin{pmatrix} S_{\frac{N}{2}}^{(2)} & \bigcirc \\ \bigcirc & S_{\frac{N}{2}}^{(2)} \end{pmatrix} \begin{pmatrix} S_{\frac{N}{4}}^{(2)} & \bigcirc & \bigcirc & \bigcirc \\ \bigcirc & S_{\frac{N}{4}}^{(2)} & \bigcirc & \bigcirc \\ \bigcirc & \bigcirc & S_{\frac{N}{4}}^{(2)} & \bigcirc \\ \bigcirc & \bigcirc & \bigcirc & S_{\frac{N}{4}}^{(2)} \end{pmatrix}$$

$$\cdots \begin{pmatrix} S_2^{(2)} & \cdots & \bigcirc \\ \vdots & \ddots & \vdots \\ \bigcirc & \cdots & S_2^{(2)} \end{pmatrix} P_N^{(2,2,2,\ldots,2)}, \tag{13}$$

where

$$\begin{cases} S_m^{(2)} = \begin{pmatrix} I_{\frac{m}{2}} & \Omega_{\frac{m}{2}}^{\frac{1}{2}} \\ I_{\frac{m}{2}} & -\Omega_{\frac{m}{2}}^{\frac{1}{2}} \end{pmatrix}, \\ P_N^{(2,2,2,\ldots,2)} = \text{bit-reversal ordering permutation matrix.} \end{cases} \tag{14}$$

For more general N, if $N = p_1 p_2 \cdots p_K$, where p_j are natural numbers, the FFT formula may be written

$$F_N = S_N^{(p_1)} \begin{pmatrix} S_{\frac{N}{p_1}}^{(p_2)} & & \bigcirc \\ & \ddots & \\ \bigcirc & & S_{\frac{N}{p_1}}^{(p_2)} \end{pmatrix} \begin{pmatrix} S_{\frac{N}{(p_1 p_2)}}^{(p_3)} & & \bigcirc \\ & \ddots & \\ \bigcirc & & S_{\frac{N}{(p_1 p_2)}}^{(p_3)} \end{pmatrix}$$

$$\cdots \begin{pmatrix} S_{p_K}^{(p_K)} & & \bigcirc \\ & \ddots & \\ \bigcirc & & S_{p_K}^{(p_K)} \end{pmatrix} P_N^{(p_1, p_2, \ldots, p_K)}, \tag{15}$$

where

$$S_m^{(p)} = \begin{pmatrix} (F_p)_{1,1} I_{\frac{m}{p}} & (F_p)_{1,2} \Omega_{\frac{m}{p}}^{\frac{1}{p}} & \cdots & (F_p)_{1,p} \Omega_{\frac{m}{p}}^{\frac{p-1}{p}} \\ (F_p)_{2,1} I_{\frac{m}{p}} & (F_p)_{2,2} \Omega_{\frac{m}{p}}^{\frac{1}{p}} & \cdots & (F_p)_{2,p} \Omega_{\frac{m}{p}}^{\frac{p-1}{p}} \\ \vdots & \vdots & & \vdots \\ (F_p)_{p,1} I_{\frac{m}{p}} & (F_p)_{p,2} \Omega_{\frac{m}{p}}^{\frac{1}{p}} & \cdots & (F_p)_{p,p} \Omega_{\frac{m}{p}}^{\frac{p-1}{p}} \end{pmatrix} \tag{16}$$

$$= F_m^{(p)} \, Q_m^{(p)}.$$

Here $F_m^{(p)}$ is the m-by-m matrix constructed from the p-by-p DFT matrix F_p by replacing each element of F_p by the product of the element and the m/p-by-m/p identity matrix. Also,

$$Q_m^{(p)} = \operatorname{diag}\left(I_{\frac{m}{p}}, \Omega_{\frac{m}{p}}^{\frac{1}{p}}, \Omega_{\frac{m}{p}}^{\frac{2}{p}}, \dots, \Omega_{\frac{m}{p}}^{\frac{p-1}{p}}\right) \tag{17}$$

is the diagonal matrix of twiddle factors, and $P_N^{(p_1,p_2,\dots,p_K)}$ is the mixed-radix digit-reversal ordering permutation matrix, defined as

$$\left\{\begin{aligned} P_N^{(p_1,p_2,\dots,p_K)}{}_{j,k} &= \delta_{j,k'}, \qquad 0 \le j,k \le N{-}1,\\ k' &= k'(k)\\ &= d_K + p_K(d_{K-1} + p_{K-1}(d_{K-2} + \cdots + p_2 d_1)),\\ k &= d_1 + p_1(d_2 + p_2(d_3 + p_3(d_4 + \cdots + p_{K-1}d_K))), \end{aligned}\right. \tag{18}$$

where the mixed-radix digits d_l satisfy $0 \le d_l \le p_l - 1$. The formula (15) represents the so-called mixed-radix time-decimation FFT algorithm.

A mathematically equivalent formula that leads to the frequency-decimation algorithm follows from the observation that

$$\begin{aligned} F_N &= \left(\tfrac{1}{N} F_N^*\right)^{-1}\\ &= N\left(P_N^{(p_1,p_2,\dots,p_K)}\right)^{-1} \begin{pmatrix} S_{p_K}^{(p_K)*} & & \bigcirc\\ & \ddots & \\ \bigcirc & & S_{p_K}^{(p_K)*} \end{pmatrix}^{-1}\\ &\qquad \cdots \begin{pmatrix} S^{(p_3)\ *}_{\frac{N}{(p_1p_2)}} & & \bigcirc\\ & \ddots & \\ \bigcirc & & S^{(p_3)\ *}_{\frac{N}{(p_1p_2)}} \end{pmatrix}^{-1}\\ &\qquad \begin{pmatrix} S^{(p_2)*}_{\frac{N}{p_1}} & & \bigcirc\\ & \ddots & \\ \bigcirc & & S^{(p_2)*}_{\frac{N}{p_1}} \end{pmatrix}^{-1} \left(S_N^{(p_1)*}\right)^{-1}. \end{aligned} \tag{19}$$

Then

$$\left(P_N^{(p_1,p_2,\dots,p_K)}\right)^{-1} = P_N^{(p_K,p_{K-1},\dots,p_1)} \tag{20}$$

and

$$\left(S_m^{(p)*}\right)^{-1} = \frac{1}{p} R_m^{(p)}, \tag{21}$$

where

$$R_m^{(p)} = \begin{pmatrix} (F_p)_{1,1} I_{\frac{m}{p}} & (F_p)_{1,2} I_{\frac{m}{p}} & \cdots & (F_p)_{1,p} I_{\frac{m}{p}} \\ (F_p)_{2,1} \Omega_{\frac{m}{p}}^{\frac{1}{p}} & (F_p)_{2,2} \Omega_{\frac{m}{p}}^{\frac{1}{p}} & \cdots & (F_p)_{2,p} \Omega_{\frac{m}{p}}^{\frac{1}{p}} \\ \vdots & \vdots & \vdots & \vdots \\ (F_p)_{p,1} \Omega_{\frac{m}{p}}^{\frac{p-1}{p}} & (F_p)_{p,2} \Omega_{\frac{m}{p}}^{\frac{p-1}{p}} & \cdots & (F_p)_{p,p} \Omega_{\frac{m}{p}}^{\frac{p-1}{p}} \end{pmatrix} \tag{22}$$

$$= Q_m^{(p)}\ F_m^{(p)}$$

so that

$$F_N = P_N^{(p_K, p_{K-1}, \dots, p_1)} \begin{pmatrix} R_{p_K}^{(p_K)} & & \bigcirc \\ & \ddots & \\ \bigcirc & & R_{p_K}^{(p_K)} \end{pmatrix} \tag{23}$$

$$\cdots \begin{pmatrix} R_{\frac{N}{(p_1 p_2)}}^{(p_3)} & & \bigcirc \\ & \ddots & \\ \bigcirc & & R_{\frac{N}{(p_1 p_2)}}^{(p_3)} \end{pmatrix} \begin{pmatrix} R_{\frac{N}{p_1}}^{(p_2)} & & \bigcirc \\ & \ddots & \\ \bigcirc & & R_{\frac{N}{p_1}}^{(p_2)} \end{pmatrix} R_N^{(p_1)}.$$

These formulas may be simplified by use of the Kronecker matrix product $\otimes$ which is defined so that $A \otimes B$ is the LI-by-MJ matrix

$$A \otimes B = \begin{pmatrix} A_{1,1}B & A_{1,2}B & \cdots & A_{1,M}B \\ A_{2,1}B & A_{2,2}B & \cdots & A_{2,M}B \\ \vdots & \vdots & & \vdots \\ A_{L,1}B & A_{L,2}B & \cdots & A_{L,M}B \end{pmatrix} \tag{24}$$

for an L-by-M matrix A and an I-by-J matrix B. Then

$$\begin{aligned} F_m^{(p)} &= F_p \otimes I_{\frac{m}{p}}, \\ S_m^{(p)} &= F_m^{(p)}\ Q_m^{(p)} \\ &= \left(F_p \otimes I_{\frac{m}{p}}\right)\ Q_m^{(p)}, \\ R_m^{(p)} &= Q_m^{(p)}\ F_m^{(p)} \\ &= Q_m^{(p)}\ \left(F_p \otimes I_{\frac{m}{p}}\right), \end{aligned} \tag{25}$$

and

$$\begin{aligned}
F_N &= S_N^{(p_1)} \left(I_{p_1} \otimes S^{(p_2)}_{\frac{N}{p_1}} \right) \left(I_{p_1 p_2} \otimes S^{(p_3)}_{\frac{N}{(p_1 p_2)}} \right) \\
&\quad \cdots \left(I_{p_1 p_2 \ldots p_{K-1}} \otimes S^{(p_K)}_{p_K} \right) P_N^{(p_1, p_2, \ldots, p_K)} \\
&= \left(F_{p_1} \otimes I_{\frac{N}{p_1}} \right) Q_N^{(p_1)} \left\{ I_{p_1} \otimes \left[\left(F_{p_2} \otimes I_{\frac{N}{p_1 p_2}} \right) Q^{(p_2)}_{\frac{N}{p_1}} \right] \right\} \\
&\quad \left\{ I_{p_1 p_2} \otimes \left[\left(F_{p_3} \otimes I_{\frac{N}{p_1 p_2 p_3}} \right) Q^{(p_3)}_{\frac{N}{(p_1 p_2)}} \right] \right\} \\
&\quad \cdots \left\{ I_{p_1 p_2 \ldots p_{K-1}} \otimes \left[F_{p_K} \; Q^{(p_K)}_{p_K} \right] \right\} \; P_N^{(p_1, p_2, \ldots, p_K)} \\
&= \left\{ I_{q_1} \otimes \left[\left(F_{p_1} \otimes I_{m_2} \right) Q^{(p_1)}_{m_1} \right] \right\} \\
&\quad \left\{ I_{q_2} \otimes \left[\left(F_{p_2} \otimes I_{m_3} \right) Q^{(p_2)}_{m_2} \right] \right\} \\
&\quad \left\{ I_{q_3} \otimes \left[\left(F_{p_3} \otimes I_{m_4} \right) Q^{(p_3)}_{m_3} \right] \right\} \\
&\quad \cdots \left\{ I_{q_{K-1}} \otimes \left[\left(F_{p_{K-1}} \otimes I_{m_K} \right) Q^{(p_{K-1})}_{m_{K-1}} \right] \right\} \\
&\quad \left\{ I_{q_K} \otimes \left[\left(F_{p_K} \otimes I_{m_{K+1}} \right) Q^{(p_K)}_{m_K} \right] \right\} \; P_N^{(p_1, p_2, \ldots, p_K)} \\
&= \prod_{j=1}^{K} \left\{ I_{q_j} \otimes \left[\left(F_{p_j} \otimes I_{m_{j+1}} \right) Q^{(p_j)}_{m_j} \right] \right\} \; P_N^{(p_1, p_2, \ldots, p_K)} \qquad (26)
\end{aligned}$$

for the time-decimation algorithm, and

$$F_N = P_N^{(p_K, p_{K-1}, \ldots, p_1)} \prod_{j=K}^{1} \left\{ I_{q_j} \otimes \left[Q^{(p_j)}_{m_j} \left(F_{p_j} \otimes I_{m_{j+1}} \right) \right] \right\} \qquad (27)$$

for the frequency-decimation algorithm, where $m_j \equiv N/(p_1 p_2 p_3 \ldots p_{j-1})$ and $q_j \equiv p_1 p_2 \cdots p_{j-1}$.

A modification of (26) and (27) is possible where the mixed-radix permutation is distributed through the calculation as a series of two-factor permutations. The result is

$$F_N = \prod_{j=1}^{K} A_j \left(P^{(q_j, p_j)}_{q_{j+1}} \otimes I_{m_{j+1}} \right) = \prod_{j=K}^{1} \left(P^{(p_j, q_j)}_{q_{j+1}} \otimes I_{m_{j+1}} \right) B_j, \qquad (28)$$

where

$$A_j = \left\{ I_{q_j} \otimes \left[\left(F_{p_j} \otimes I_{m_{j+1}} \right) Q^{(p_j)}_{m_j} \right] \right\}, \qquad (29)$$

$$B_j = \left\{ I_{q_j} \otimes \left[Q^{(p_j)}_{m_j} \left(F_{p_j} \otimes I_{m_{j+1}} \right) \right] \right\}. \qquad (30)$$

More details are given in Schatzman [9]. We note that the permutations in (28) can be accomplished without an explicit permutation, but by appropriate indexing in each block diagonal matrix-vector multiplication step

$$\sum_{l,m=0}^{N-1} (A_j)_{k,l} \left(P_{q_{j+1}}^{(q_j,p_j)} \otimes I_{m_{j+1}}\right)_{l,m} z_m = \sum_{m=0}^{N-1} (A_j)_{k,m'} z_m, \tag{31}$$

where the index mapping $m'(m)$ is computed according to

$$\begin{aligned} m' &= d_0 + d_2 m_{j+1} + d_1 m_{j+1} p_j, \\ m &= d_0 + d_1 m_{j+1} + d_2 m_{j+1} q_j, \end{aligned} \tag{32}$$

where the three-radix digits d_0, d_1, and d_2 satisfy $0 \le d_0 \le m_{j+1} - 1$, $0 \le d_1 \le q_j - 1$, and $0 \le d_2 \le p_j - 1$. This constitutes a block two radix reversed-digit mapping with a block size of m_{j+1}. These results are similar to those of Temperton [11].

Finally, the prime factor algorithm version of the FFT is nearly identical to the above, except that inputs and outputs are reordered, generally to effect the elimination of the twiddle factors (Burrus [1]; Schatzman [10]). Although the computations are reordered, and in some versions the underlying FFT blocks are modified by raising each element to a fixed integer power, the arguments above about stability of the stages of the algorithm still apply. The absence of twiddle factors could result in some improvement in accuracy; to this author's knowledge no results on this question have been published.

3.3. Stability of the FFT decomposition. If we examine (26)–(28) we see that the DFT is accomplished through a series of matrix-vector products. The permutation matrices have eigenvalues on the unit circle, with phases equal to multiples of $\frac{2\pi}{L}$, where L is the length of a permutation cycle associated with the matrix.

The matrices A_j and B_j are more complex. The matrix $F_{p_j} \otimes I_{m_{j+1}}$ has the same spectrum as F_{p_j}, namely eigenvalues $\pm\sqrt{p_j}$ and $\pm\imath\sqrt{p_j}$, but multiplied in multiplicity by the factor m_{j+1}. Likewise, the premultiplication $I_{q_j} \otimes C$ only multiplies the multiplicity of the eigenvalues of an arbitrary matrix C. Thus, the eigenvalues of A_j and B_j are modified only by the effect of postmultiplying and premultiplying $F_{p_j} \otimes I_{m_{j+1}}$ by $Q_{m_j}^{(p_j)}$, respectively. Because the matrices are unitary or scaled unitary, the eigenvalues of A_j and B_j all have magnitude $\sqrt{p_j}$; however, the phases of the eigenvalues are not the same as F_{p_j}. For example, the eigenvalues of $S_m^{(2)} = \left(F_2 \otimes I_{m/2}\right) Q_m^{(2)}$ are

$$\lambda_j = \frac{1}{2}\left(1 - w^j \pm \sqrt{(w^j - 1)^2 + 8w^j}\right), \qquad 0 \le j \le \frac{m}{2} - 1, \tag{33}$$

where $w = e^{-\imath 2\pi/m}$, which are irregularly distributed around the circle of radius $\sqrt{2}$ in the complex plane. From this elementary analysis, we see that no complications, such as increased sensitivity to numerical error due to increased condition number of the coefficient matrices, are to be expected from the FFT in any form. In fact, as we will see below, the FFT is very stable in most respects.

3.4. Numerical errors. Like the slow DFT, errors in the computation of the FFT consist of errors in the approximations of the sine/cosine phase factors and roundoff errors in multiplication and addition.

To test these predictions, slow DFTs were computed with single and double precision IEEE floating point. Figures 3 and 4 show a comparison of 128-bit floating point FFT results (taken to be truth) with

(3a) IEEE 32-bit FFT computations using the manufacturer's 32-bit sine/cosine functions and the FFTPAK recursion (see comments below),

(3b) IEEE 32-bit FFT computations modified to use accurate sine/cosine phase factors,

(4a) IEEE 64-bit FFT computations using the manufacturer's 32-bit sine/cosine functions and the FFTPAK recursion (see comments below),

(4b) IEEE 64-bit FFT computations modified to use accurate sine/cosine phase factors.

The NCAR FFTPAK (Version 2, February 1978) FFT code was used as the basis for these results. However, the package was modified in several ways:

(1) Minor modifications to the code were made to bring it into conformance with the ANSI Fortran 77 standard.

(2) Power-of-two transforms were evaluated using $p = 2$, not a mix of $p = 2$ and $p = 4$ as in the original code. This change was made so that the performance of the $p = 2$ code could be measured independently of the $p = 4$ code.

(3) For the accurate table tests, the 32- and 64-bit sine/cosine table computations were replaced with 64- or 128-bit precision computations, respectively.

Input data and analysis of the results were as above for the slow DFT.

Fits to the measured RMS errors were obtained for the following error functions:

(3a) $\frac{1}{10}\epsilon_{32}(N-1)$,

(3b) $0.6\epsilon_{32}\sqrt{\log_2 N}$,

(4a) $\frac{1}{20}\epsilon_{64}(N-1)$,

(4b) $0.6\epsilon_{64}\sqrt{\log_2 N}$.

Also shown as Figures 3c, 3d, 4c, and 4d are results for the new algorithm of Schatzman [9] for prime lengths. Conclusions from these results follow:

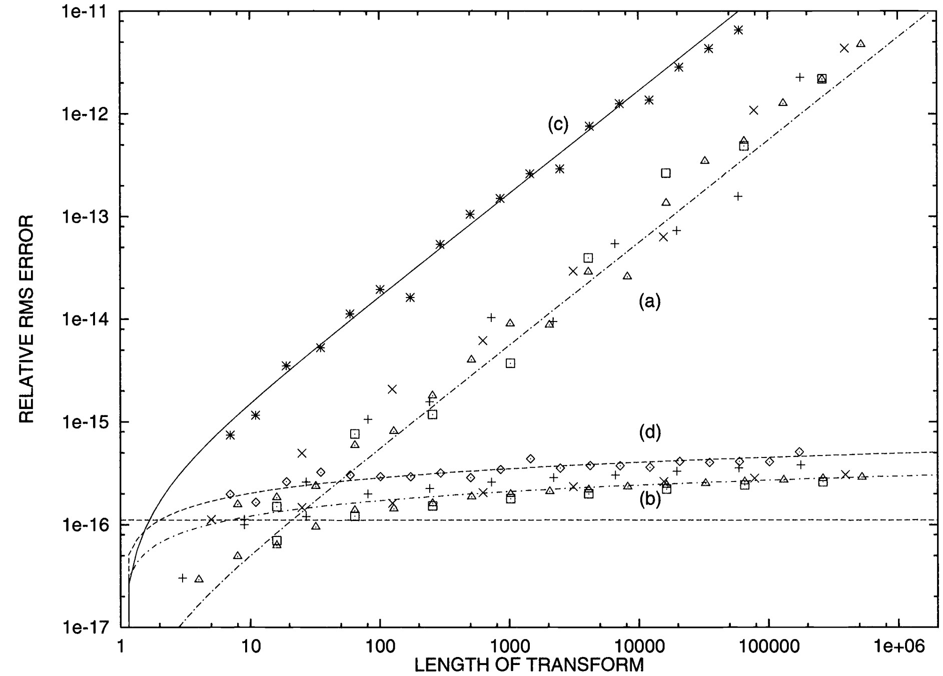

FIG. 4. *Relative RMS errors in the computed DFT for the* 64*-bit IEEE floating point FFT using* (a) *the IBM RS6000 library* 64*-bit sine and cosine functions and the NCAR FFTPAK table calculation code,* (b) *an accurate sine/cosine table,* (c) *the Schatzman algorithm* [9] *with inaccurate tables, and* (d) *the Schatzman algorithm* [9] *with accurate tables.* △, +, □, *and* × *denote lengths that are powers of* 2, 3, 4, *and* 5, *respectively;* $*$ *and* ◇ *denote the results for the Schatzman algorithm* [9] *with inaccurate and accurate tables, respectively. The horizontal dashed line represents the constant* $\epsilon_{64} = 1.11 \cdot 10^{-16}$.

(1) Comparing Figures 1a and 3a, 1b and 2b, etc., we conclude that *FFTs typically produce approximate DFTs that are more accurate than the slow algorithm by a factor of at least* 10.

(2) Accuracy of the sine/cosine phase factors are crucial to the overall accuracy of the DFT. However, in the NCAR FFTPAK code, only part of the table is computed by explicit sine and cosine evaluations. The remainder of the table is generated recursively. Replacing the explicit sine/cosine evaluations with extremely accurate calculations (128-bit) made very little difference. The resulting plots are nearly indistinguishable from Figures 3a and 4a. *The recursive evaluation of entries of the sine/cosine table, as implemented in the NCAR FFTPAK code, is by far the largest single source of error.* The particular recursion used in the NCAR FFTPAK accentuates the errors of the initial sine/cosine approximations.

(3) When the sine/cosine table of the FFT is inaccurate (as in Figures 3a and 4a) the RMS DFT errors are roughly proportional to the length of the transform.

(4) When the sine/cosine table is accurate (Figures 3b and 4b) the RMS DFT errors grow slowly, apparently more slowly than the logarithm of the length of the transform.

(5) The computation of long DFTs with IEEE 32-bit floating point is a process about which one should be cautious. If accuracy of better than 0.1% is required (three digits) for transforms in the 10,000+ point range, 64-bit floating point or a very carefully implemented 32-bit FFT should be used.

(6) The Schatzman [9] algorithm is less accurate than the conventional FFT, but only modestly so.

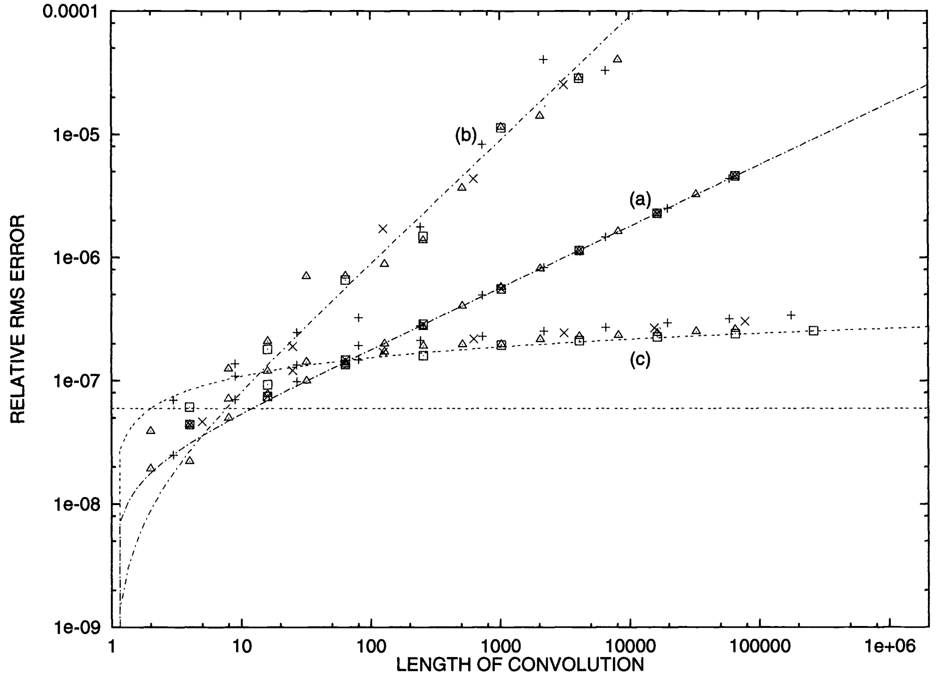

FIG. 5. *Relative RMS errors in the computed convolution for* (a) *the* 32-*bit IEEE floating point direct computation,* (b) *the FFT computation with inaccurate sine/cosine tables, and* (c) *with accurate tables.* △, +, □, *and* × *denote lengths that are powers of* 2, 3, 4, *and* 5, *respectively. The interpolating error functions (smooth curves) are* (a) $e_1(N) = 0.3\epsilon_{32}\sqrt{N{-}1}$, (b) $e_2(N) = 0.15\epsilon_{32}(N{-}1)$, *and* (c) $e_3(N) = \epsilon_{32}\sqrt{\log_2 N}$. *The horizontal dashed line represents the constant* $\epsilon_{32} = 5.96 \cdot 10^{-8}$.

4. Numerical errors for convolutions. We now study the computation of a circular convolution or cross-correlation via Fourier transform. Figures 5 and 6 show results for cross-correlation of white Gaussian complex sequences using direct computation and the comparable results using FFTs. We obtain fits to the data with the following functions:

(5a) Direct computation, 32-bit: $0.3\epsilon_{32}\sqrt{N{-}1}$;

(5b) FFT computation, 32-bit: $0.15\epsilon_{32}(N{-}1)$;

(5c) FFT computation, 32-bit with accurate sine/cosine table: $\epsilon_{32}\sqrt{\log_2 N}$;

(6a) Direct computation, 64-bit: $0.3\epsilon_{64}\sqrt{N{-}1}$;

(6b) FFT computation, 64-bit: $0.2\epsilon_{64}(N{-}1)$;

(6c) FFT computation, 64-bit with accurate sine/cosine table: $\epsilon_{64}\sqrt{\log_2 N}$.

These errors are very similar to the errors for the slow and fast DFT themselves, as reported above.

We recall the claim of Gottlieb and Orszag [5]: "Transform methods normally give no appreciable amplification of roundoff errors. In fact, the evaluation of convolution-like sums using FFTs often gives results with much smaller roundoff error than would be obtained if the convolution sums were evaluated directly." We have quantitatively confirmed these observations; the FFT method gives more accurate results for vector lengths of approximately 100 and greater with IEEE 32- and 64-bit floating point. However, this conclusion depends on having accurate FFT software. For example, the stock NCAR FFTPAK software gives less accurate results for the convolution than direct computation by arithmetic of the same precision. Asymptotically for large vector lengths, the RMS error is proportional to the square root of the logarithm of the vector length for the (accurate) FFT method and proportional to

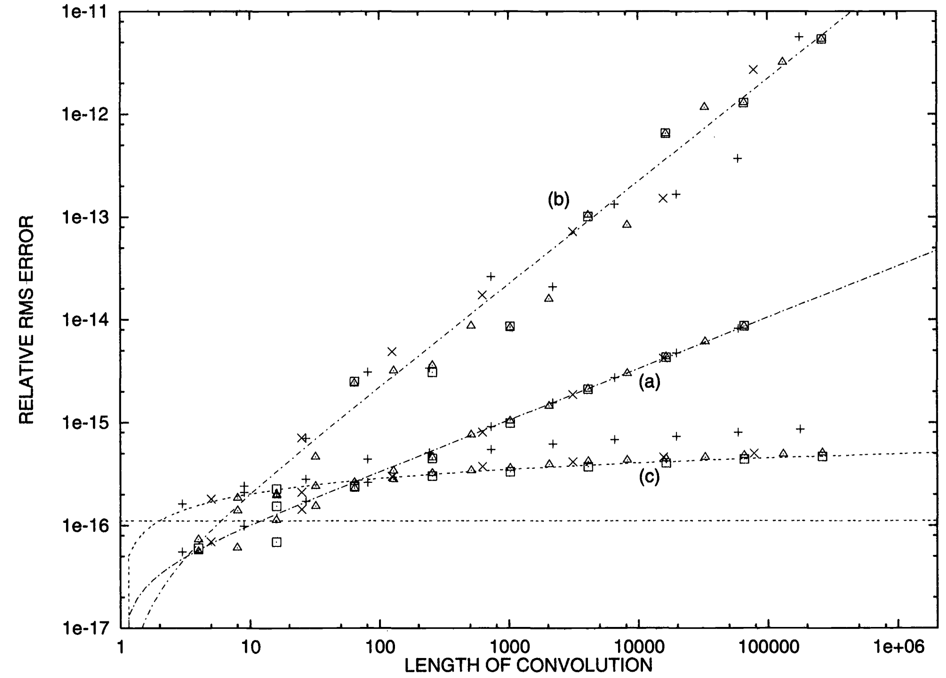

FIG. 6. *Relative RMS errors in the computed convolution for* (a) *the* 64-*bit IEEE floating point direct computation,* (b) *the FFT computation with inaccurate sine/cosine tables, and* (c) *with accurate tables. The interpolating error functions (smooth curves) are* (a) $e_1(N) = 0.3\epsilon_{64}\sqrt{N-1}$, (b) $e_2(N) = 0.2\epsilon_{64}(N-1)$, *and* (c) $e_3(N) = \epsilon_{64}\sqrt{\log_2 N}$. *The horizontal dashed line represents the constant* $\epsilon_{64} = 1.11 \cdot 10^{-16}$.

the square root of the vector length for the direct method. The explanation is that the FFT involves $\log(N)$ additions of uncorrelated errors for each component of the result, whereas the direct computation involves N–1 additions of uncorrelated errors.

5. Error in the twiddle factors. As observed above, the twiddle factors can be the dominant source of error. In some cases the library software for the sine/cosine is inaccurate. For example, on the Cray Y/MP, it appears that the decision was made to provide speed instead of accuracy. Accuracy of standard library routines should be tested; high-accuracy routines should be substituted if the library routines are inaccurate, keeping in mind that speed is generally irrelevant for this application (initiation of the FFT).

How to design algorithms that produce high-accuracy (one-half machine epsilon) sine/consine functions given floating point arithmetic of only machine epsilon accuracy is beyond the scope of this paper. I have found that it is difficult to obtain highly accurate sine and cosine functions using standard Taylor series or continued fraction expansions with floating hardware that does not provide double precision intermediary products. For example, the IBM RS/6000 processors provide high-accuracy (rounded) products whereas popular Intel and MIPS processors do not. After considerable experimentation, I offer the following conclusions and advice:

(1) Empirically, the error in accurate rounded 32- and 64-bit IEEE twiddle factor values as required by the FFT is essentially uniformly distributed on $[-\epsilon/2, \epsilon/2]$ for all n between 16 and 131,072. In other words, there is nothing peculiar about the twiddle factors that would upset this standard assumption. Therefore, the standard deviation of error in optimal twiddle factors is $\epsilon/\sqrt{12}$.

(2) The error obtained by direct library call to sine/cosine functions with the best libraries I tested is somewhat greater than the optimum—nearly 1.3–1.5 times the optimum. With other libraries the error can be much greater. Direct implementation of Taylor series leads to errors (with full-rounding floating point) of nearly 0.7ϵ. Kahan's summation method (Higham [6]) added to the Taylor series computation reduces the error to the theoretically optimal $\epsilon/\sqrt{12}$ or below.

(3) Errors resulting from the use of the recursion (34) are typically all of one sign (more about this below). The point is that the errors in the sine/consine table when computed this way are definitely not random (that is, not uniformly distributed over $[-\epsilon/2, \epsilon/2]$). A consequence is that overall FFT errors can be much larger than anticipated.

(4) If higher-precision arithmetic is available, by all means I recommend using that higher precision to compute the twiddle factors, which should then be rounded to the desired precision. Of course, arbitrary precision software is available (public domain) but the slowness may be objectionable.

(5) The sine/cosine tables could be pretabulated to high accuracy and recorded in binary form. Once this is done for a given floating point format, the code is portable to machines using that format. If implemented intelligently, the amount of disk space required for a complete tabulation for modestly large N is quite reasonable.

Some standard FFT packages use the following recursion for the sine and cosine functions:

$$(34)\qquad \begin{cases} C_n = \cos\theta\ C_{n-1} - \sin\theta\ S_{n-1}, \\ S_n = \cos\theta\ S_{n-1} + \sin\theta\ C_{n-1} \end{cases}$$

for $n = 1, 2, \ldots, C_0 = \cos\theta_0$, and $S_0 = \sin\theta_0$. Replacing $\cos\theta$ by the approximate value c and $\sin\theta$ by the approximate value s, we obtain

$$(35)\qquad \begin{pmatrix} C \\ S \end{pmatrix}_n = \begin{pmatrix} c & -s \\ s & c \end{pmatrix} \begin{pmatrix} C \\ S \end{pmatrix}_{n-1}.$$

The eigenvalues of the coefficient matrix are $\lambda = c \pm \imath s$, and

$$(36)\qquad \lambda^N = (c^2 + s^2)^{\frac{N}{2}} e^{\imath N \tan^{-1} \frac{s}{c}}.$$

Applying asymptotic analysis to (36), we see that errors in C_n and S_n grow at first linearly and later exponentially with the length of the recursion. This is highly undesirable; what is needed is a self-correcting recursion in which errors do not grow. While this analysis ignores roundoff error, actual calculations verify this exponential growth.

Chu [3] analyses the recursion (34), including the effects of roundoff, and concludes that errors grow linearly. This analysis is erroneous, resulting from ignoring errors in sines in the analysis of the cosines and vice versa. Oliver [8] gives an excellent review of recursions known at that time, but does not include (34). Chu [3] describes (34) and many other algorithms; some of the results of this paper are in error, however. Also, (34) can easily be improved as follows:

$$(37)\qquad \begin{cases} A_n = \cos\theta\ C_{n-1} - \sin\theta\ S_{n-1} + \sin\theta\ \alpha, \\ B_n = \cos\theta\ S_{n-1} + \sin\theta\ C_{n-1}, \\ C_n = \frac{A_n}{\sqrt{A_n^2 + B_n^2}}, \\ S_n = \frac{B_n}{\sqrt{A_n^2 + B_n^2}}, \end{cases}$$

where α depends on N and the type of floating point hardware. Thus, we correct both the phase and amplitude of the sine/cosine pair at each step. This improved method is based on the empirical observations that the errors in (34) are patterned. However, the results of the best recursions are still significantly worse than accurate direct calculations.

My recommendation is that the twiddle factors be computed to high accuracy, either with high-precision arithmetic or Kahan's summation method (if Kahan's method works effectively on the given hardware). Truncated Taylor's series work very well for this purpose. If speed in initialization is required, depending on the machine architecture, either twiddle factors should be precomputed and stored on disk or faster converging approximations such as rational or continued fraction approximations should be used. Finally, if a recursive computation must be used for some reason, (34) should never be used but a more stable recursion (Oliver [8] and Chu [3]) should be employed.

6. Two and higher dimensions. I have not undertaken a thorough examination of the two- and higher-dimensional problem to verify that the one-dimensional results extend in a natural way. However, cursory examination of the problem suggests that higher-dimensional FFTs are even more remarkably stable, at least if the size of the dimensions is large and the number of dimensions is small.

For example, 1024-by-1024 transforms were executed with white random data using IEEE 64-bit floating point arithmetic. Using the manufacturer's sine/cosine functions and the usual recursions, RMS relative errors of $200\epsilon_{64}$ were observed. Using accurate sine/cosine tables, RMS relative errors of less than $3\epsilon_{64}$ were observed. These two-dimensional transforms were done in the usual way through repeated application of one-dimensional transforms along the rows and columns. Interestingly, the differences between the rows first/columns last and columns first/rows last results were observed to be approximately $4\epsilon_{64}$ regardless of the accuracy of the sine/cosine table. Finally, averaging the row/column and column/row results for the accurate sine/cosine table gave RMS relative errors of approximately $2\epsilon_{64}$. This is very little larger than the error for a one-dimensional transform of length 1024 $(1.9\epsilon_{64})$. It is remarkable that the transforms along the second dimension do not increase the error more than this. To lose only one bit of accuracy after thousands of floating point operations dramatizes the great stability of the FFT, when implemented carefully!

7. Conclusions. When an accurate sine/cosine table is used, the FFT is remarkably stable. However, the accuracy is greatly impaired by inaccurate sine/cosine tables. Inaccuracy in the sine/cosine table is common and results from inaccurate underlying software library functions and ill-advised recursions for table construction.

Acknowledgments. The anonymous reviewers were very helpful in drawing the author's attention to relevant literature.

COMPUTING THE EXTREMAL POSITIVE DEFINITE SOLUTIONS OF A MATRIX EQUATION*

XINGZHI ZHAN†

Abstract. An efficient and numerically stable implementation of a known algorithm is suggested for finding the extremal positive definite solutions of the matrix equation $X+A^*X^{-1}A=I$, if such solutions exist. The convergence rate is analyzed. A new algorithm that avoids matrix inversion is presented. Numerical examples are given to illustrate the effectiveness of the algorithms.

Key words. matrix equation, positive definite solution, iteration

AMS subject classifications. 65F10, 65F30

1. Introduction.

The problem of positive definite solutions of the matrix equation $X+A^*X^{-1}A=Q$, with Q positive definite, arises in many applications. These areas include control theory [7, 10, 16, 17], ladder networks [1, 4, 18], dynamic programming [14], stochastic filtering [2, 6], and statistics [6, 13]. Recently this equation has been studied by some authors [3, 7, 8, 19] and they mainly concentrated on the theoretical properties such as necessary and sufficient conditions for the existence of a positive definite solution. Obviously the equation can be reduced to

$$X+A^*X^{-1}A=I, \tag{1.1}$$

where I is the identity matrix. Note that the equation may have non-Hermitian or indefinite solutions. For example, if $A=I_2$, then

$$X=\begin{pmatrix} 1 & -\alpha \\ \alpha^{-1} & 0 \end{pmatrix},$$

with any real number $\alpha \neq 0$, is always a solution. We will not consider this kind of solution in our applications. Throughout this paper, a solution means a Hermitian positive definite one. Since the equation is highly nonlinear, designing an efficient algorithm does not seem easy. We will take one step in this direction.

Let matrices B and C be Hermitian. If $B-C$ is positive definite (semidefinite), we write $B>C(B\geq C)$. It was proved in [8] that if (1.1) has a solution, then it has a maximal solution X_L and a minimal solution X_S in the sense that for any solution X, $X_S\leq X\leq X_L$. If A is invertible, then it is easy to verify (see [8, Thm. 3.3]) that X_S is the minimal solution of (1.1) if and only if $Y_L=I-X_S$ is the maximal solution of $Y+AY^{-1}A^*=I$. Thus any algorithm for computing X_L is also one for computing X_S, and in the paper we only discuss how to compute X_L.

If A is a normal matrix, we have formulae for both X_L and X_S, which are conjectured in [7] and proved in [19]. From the computational point of view, in the case where A is singular the problem of obtaining the minimal solution X_S is not solved here and remains a topic of future research. If A is singular, theoretically we can always reduce (1.1) to the nonsingular case of the same form in lower dimensions [8, §3], but this is not practical. Perhaps there are some direct methods for computing X_S without this reduction.

In §2 we analyze the convergence rate of a known algorithm and the implementation of it. A new algorithm that avoids matrix inversion is presented in §3. Numerical examples are given in §4.

2. Implementation of a known algorithm and analysis of its convergence rate. To solve (1.1) we can use the following natural iterative procedure.

ALGORITHM 2.1.

$$X_0 = I, \qquad X_{n+1} = I - A^* X_n^{-1} A. \tag{2.1}$$

It was proved in [7] that (1.1) has a solution if and only if $X_n > AA^*$ for all n. If (1.1) has a solution, then X_n is a monotone decreasing sequence and converges to the maximal solution X_L [8]. It is said in [8, §4] that whether both solutions X_L and X_S are obtained from this algorithm in a numerically reliable way remains an open question. We will show that it is indeed so with the implementation here. What we should consider about the implementation of this algorithm is how to compute $A^* X_n^{-1} A$. In most cases A is real and now we make this assumption. Suppose that (1.1) has a solution. The computations may be done as follows.

Step 1. Computing the Cholesky factorization of X_n, $X_n = LL^T$.

Very effective methods for this factorization are available and they are numerically stable. See [9, §4.2].

Step 2. Solving the triangular systems

$$Lb_i = a_i, \quad i = 1, 2, \ldots, m,$$

where a_i are the columns of A, $A = (a_1, \ldots, a_m)$. Set $B = (b_1, \ldots, b_m)$.

We may use any algorithms described in [9, §3.1] and it is pointed out that the accuracy of a computed solution to a triangular system is often surprisingly good. If the order of the matrices is large enough, we use the block forward substitution algorithm [9, §3.1.4] to $LB = A$, which is rich in matrix multiplication.

Step 3. Computing $B^T B$ and forming $X_{n+1} = I - B^T B$.

Note that using the symmetry we need only to compute half of the entries of $B^T B$, say, the upper triangular part. As to the storage, we should also use the symmetry.

If $A \in \mathbb{R}^{m \times m}$, then the algorithm costs $\frac{m^3}{3} + m^3 + m^3 = \frac{7}{3}m^3$ flops per iteration. Now we examine the convergence rate. In what follows we denote by $\|\cdot\|$ the spectral norm. Since X_n is monotone decreasing and converges to X_L, $0 \leq X_{n+1} - X_L \leq X_n - X_L$, and thus $\|X_{n+1} - X_L\| \leq \|X_n - X_L\|$.

THEOREM 2.2. *Suppose that* (1.1) *has a solution. If* $\|X_L^{-1} A\| < 1$, *then* X_n *converges to* X_L *with at least the linear convergence rate.*

Proof. The convergence of X_n has been proved in [8]. From (2.1) and

$$X_L = I - A^* X_L^{-1} A,$$

we have

$$\begin{aligned} X_{n+1} - X_L &= A^*(X_L^{-1} - X_n^{-1})A \\ &= A^* X_n^{-1}(X_n - X_L) X_L^{-1} A. \end{aligned}$$

Thus

$$\begin{aligned} \|X_{n+1} - X_L\| &\leq \|A^* X_n^{-1}\| \cdot \|X_L^{-1} A\| \cdot \|X_n - X_L\| \\ &= \|X_n^{-1} A\| \cdot \|X_L^{-1} A\| \cdot \|X_n - X_L\|. \end{aligned}$$

Choose a real number θ satisfying $\|X_L^{-1} A\| < \theta < 1$. Since $X_n \to X_L$, there exists a k such that for any $n \geq k$, $\|X_n^{-1} A\| \leq \theta$. Hence

$$\|X_{n+1} - X_L\| \leq \theta^2 \|X_n - X_L\|. \qquad \square$$

COROLLARY 2.3. *Let X_n be the sequence in Algorithm* 2.1. *If* $\|A\| < 1/2$, *then* X_n *converges to* X_L *with at least the linear convergence rate.*

Proof. It is proved in [7, Thm. 13] that if $\|A\| < 1/2$, then (1.1) has a solution and thus the maximal solution X_L exists. By Theorem 2.2 we need only to show $\|X_L^{-1}A\| < 1$. Choose a number δ satisfying $\|A\| < \delta < 1/2$. We prove $\|X_n^{-1}A\| \leq \delta$ for all n by induction. First, $\|X_0^{-1}A\| = \|A\| < \delta$. Assume that $\|X_k^{-1}A\| \leq \delta$. From (2.1) we have

$$X_{k+1}^{-1}A = (I - A^*X_k^{-1}A)^{-1}A.$$

Using the expansion

$$(I - A^*X_k^{-1}A)^{-1} = \sum_{p=0}^{\infty}(A^*X_k^{-1}A)^p$$

and the assumption, we get

$$\begin{aligned}\|(I - A^*X_k^{-1}A)^{-1}\| &\leq 1/(1 - \|A^*X_k^{-1}A\|)\\ &\leq 1/(1 - \|A^*\| \cdot \|X_k^{-1}A\|)\\ &\leq 1/(1 - \|A\|\delta).\end{aligned}$$

Thus

$$\|X_{k+1}^{-1}A\| \leq \|A\|/(1 - \|A\|\delta) \leq \delta.$$

The last inequality can be easily verified. Notice that $(1-\sqrt{1 - 4\|A\|^2})/2 \leq \|A\| < \delta < 1/2$. Therefore $\|X_n^{-1}A\| \leq \delta$ for all n. Letting $n \to \infty$ yields $\|X_L^{-1}A\| \leq \delta < 1$. □

Remark 2.4. From [8, Thm. 3.4] we have that X_L is the unique solution for which $X + \lambda A$ is invertible for all $|\lambda| < 1$. Now, $X_L + \lambda A = X_L(I + \lambda X_L^{-1}A)$. So $I + \lambda X_L^{-1}A$ is invertible for all $|\lambda| < 1$. From this it follows that the spectral radius $\rho(X_L^{-1}A) \leq 1$. So, in view of Theorem 2.2, whether this property also implies that $\|X_L^{-1}A\| \leq 1$ whenever (1.1) has a solution remains an open question. Note that using [19, Thm. 2.1] this last question can be reformulated as follows: Given square matrices W and Z satisfying $W^*W + Z^*Z = I$, with the additional properties that W is invertible and $\rho(W^{-1}Z) \leq 1$, does this imply that $\|W^{-1}Z\| \leq 1$?

Remark 2.5. Linear convergence means possibly very slow convergence. It would be of great interest to get a quadratically convergent iteration.

3. A new algorithm. Golub and Van Loan [9, p. 9] said that the design of matrix algorithms that are rich in high-level linear algebra operations is an area of intensive research. To pursue a computational simplicity we develop an algorithm for (1.1) that is of level 3. See [9, p. 9] for the notion of "level." It involves only matrix–matrix multiplication. The basic idea is to replace computing the inverse X_n^{-1} in Algorithm 2.1 by another simultaneous iteration. This is reasonable since Algorithm 2.1 is itself an iterative procedure. The Schulz iteration [15] for A^{-1} has been used to compute the Moore–Penrose generalized inverse [5]. Let $0 < \alpha < 2\|A\|^{-2}$,

$$\begin{cases} X_0 = \alpha A^*,\\ X_{k+1} = X_k(2I - AX_k).\end{cases}$$

Then $\lim_{k\to\infty} X_k = A^+$. It is easy to check that X_k is quadratically convergent. Recently this iteration was also used in [12]. Incorporating the Schulz iteration into Algorithm 2.1 yields our next algorithm.

ALGORITHM 3.1.

$$X_0 = Y_0 = I,$$

$$\begin{cases} X_{n+1} = I - A^*Y_nA, \\ Y_{n+1} = Y_n(2I - X_nY_n). \end{cases} \tag{3.1}$$

If (1.1) has a solution, then X_n is monotone decreasing and converges to X_L. In the case where A is nonsingular, this procedure can also be used to decide whether (1.1) has a solution.

For real numbers p and c with $p > 0$, we have $c^2p + p^{-1} \geq 2c$. The matrix analogue of this fact is also true. The following result will play a crucial role in the analysis of the convergence.

LEMMA 3.2. *Let C and P be Hermitian matrices of the same order and let $P > 0$. Then*

$$CPC + P^{-1} \geq 2C. \tag{3.2}$$

Proof. Let $P = Q^*Q$ for some nonsingular Q. Rewrite (3.2) as

$$CQ^*QC + Q^{-1}Q^{-*} \geq 2C$$

or, equivalently, as

$$QCQ^*QCQ^* + I \geq 2QCQ^*.$$

Since C is Hermitian, the above inequality is equivalent to

$$(QCQ^* - I)^*(QCQ^* - I) \geq 0,$$

which is obviously true. □

Now we investigate the properties of Algorithm 3.1. The fact that $A \geq B > 0$ implies that $0 < A^{-1} \leq B^{-1}$ will be used.

THEOREM 3.3. *Let X_n be the iterates in Algorithm* 3.1. *If* (1.1) *has a positive definite solution, then the sequence X_n is monotone decreasing and converges to the maximal solution X_L. Moreover, if the matrix A is nonsingular and all $X_n > 0$, then* (1.1) *has a positive definite solution.*

Proof. Suppose that (1.1) has a solution. We first prove by induction that each $X_n \geq X_L$ and the sequence of Y_n is monotone increasing. From

$$X_L = I - A^*X_L^{-1}A, \tag{3.3}$$

we have $X_0 = I \geq X_L$, $X_1 = X_2 = I - A^*A \geq X_L$, and $Y_0 = Y_1 = I \leq I + A^*A = Y_2$.

Suppose $X_k \geq X_L$ and $Y_k \geq Y_{k-1}$ for all $k \leq n, n \geq 2$. Note that every X_i and Y_i is Hermitian and $Y_n \geq I$. Using Lemma 3.2 with $C = Y_{n-1}$ and $P = X_n$, we have

$$X_n^{-1} \geq 2Y_{n-1} - Y_{n-1}X_nY_{n-1}. \tag{3.4}$$

From (3.1) we get

$$X_{n-1} - X_n = A^*(Y_{n-1} - Y_{n-2})A. \tag{3.5}$$

But $Y_{n-1} \geq Y_{n-2}$, so $X_{n-1} \geq X_n$ and, therefore,

$$2Y_{n-1} - Y_{n-1}X_nY_{n-1} \geq 2Y_{n-1} - Y_{n-1}X_{n-1}Y_{n-1} = Y_n. \tag{3.6}$$

Combining (3.4) with (3.6) yields

$$X_n^{-1} \geq Y_n \quad \text{or} \quad Y_n^{-1} \geq X_n. \tag{3.7}$$

The assumption $X_n \geq X_L$ implies $X_n^{-1} \leq X_L^{-1}$. From (3.7) we get

$$Y_n \leq X_L^{-1}. \tag{3.8}$$

Thus $X_{n+1} = I - A^*Y_nA \geq I - A^*X_L^{-1}A = X_L$. Rewrite the second formula of (3.1) as

$$Y_{n+1} - Y_n = Y_n(Y_n^{-1} - X_n)Y_n.$$

From (3.7) and the above expression we obtain $Y_{n+1} \geq Y_n$. This completes the induction. As Y_n is monotone increasing, by (3.5) we know that X_n is monotone decreasing. Since Y_n is monotone increasing and bounded from above by X_L^{-1} because of (3.8), $\lim_{n\to\infty} Y_n = Y$ exists and thus from (3.1) $\lim_{n\to\infty} X_n = X$ exists. Taking limits in (3.1) gives $Y = X^{-1}$ and $X = I - A^*X^{-1}A$. As each $X_n \geq X_L$, $X = X_L$.

Now suppose that A is nonsingular and all $X_n > 0$. Then the above proof of the monotonicity of Y_n remains valid. It follows that X_n is monotone decreasing and bounded from below by 0, so $\lim_{n\to\infty} X_n = X \geq 0$ exists. Since A is nonsingular, (3.1) implies that $Y_n = A^{-*}(I - X_{n+1})A^{-1}$. Therefore $\lim_{n\to\infty} Y_n = Y$ also exists. As $Y_0 = I$ and Y_n is monotone increasing, $Y \geq I$. Taking limits in (3.1) yields

$$X = I - A^*YA,$$
$$Y = YXY.$$

Since $Y \geq I$, $X = Y^{-1} > 0$, and thus $X = I - A^*X^{-1}A$. So (1.1) has a solution. □

The implementation of this algorithm is very simple. The symmetry should be exploited. If the order of A is m, then $6m^3$ flops are needed per iteration. The number of flops is larger than that of Algorithm 2.1 per iteration. By the monotonicity of X_n, $0 \leq X_{n+1} - X_L \leq X_n - X_L$, and thus $\|X_{n+1} - X_L\| \leq \|X_n - X_L\|$. For computational simplicity, we use the row sum norm $\|\cdot\|_\infty$. Note that from (3.1) $I - X_nY_n = Y_n^{-1}(Y_{n+1} - Y_n) \to 0$, as $n \to \infty$. Given a small number $\epsilon > 0$, one stopping criterion may be

$$\|I - X_nY_n\|_\infty < \epsilon. \tag{3.9}$$

Checking this criterion adds very little amount of work, since in view of (3.1) the product X_nY_n must be computed in the iteration itself. The effect of the criterion can be seen from the following result.

THEOREM 3.4. *Suppose* (1.1) *has a solution. If after n iterative steps of Algorithm* 3.1 *we have* $\|I - X_{n-1}Y_{n-1}\| < \epsilon$ *and* $\|I - X_nY_n\| < \epsilon$, *then*

$$\|X_n + A^*X_n^{-1}A - I\| \leq 2\|A\|^2\|X_L^{-1}\|\epsilon.$$

Proof.

$$\begin{aligned} X_n + A^*X_n^{-1}A - I &= X_n - X_{n+1} + A^*(X_n^{-1} - Y_n)A \\ &= A^*(Y_n - Y_{n-1})A + A^*(X_n^{-1} - Y_n)A \\ &= A^*[Y_{n-1}(I - X_{n-1}Y_{n-1}) + X_n^{-1}(I - X_nY_n)]A. \end{aligned}$$

Since $0 < Y_{n-1} \leq X_{n-1}^{-1} \leq X_L^{-1}$ and $0 < X_n^{-1} \leq X_L^{-1}$, we have

$$\|Y_{n-1}\| \leq \|X_L^{-1}\|, \quad \|X_n^{-1}\| \leq \|X_L^{-1}\|.$$

Thus

$$\begin{aligned}\|X_n + A^*X_n^{-1}A - I\| &\le \|A\|^2(\|Y_{n-1}\|\|I - X_{n-1}Y_{n-1}\| + \|X_n^{-1}\|\|I - X_nY_n\|)\\ &\le 2\|A\|^2\|X_L^{-1}\|\epsilon. \qquad \square\end{aligned}$$

Note that if (1.1) has a solution, then $\|A\| < 1$. If $A \in \mathbb{C}^{m\times m}$ and we have $\|I - X_{n-1}Y_{n-1}\|_\infty < \epsilon$ and $\|I - X_nY_n\|_\infty < \epsilon$, then $\|X_n + A^*X_n^{-1}A - I\| \le 2\|A\|^2\|X_L^{-1}\|\sqrt{m}\epsilon$. Usually this is an overestimation since we have used the relation $\|G\| \le \sqrt{m}\|G\|_\infty$ for $G \in \mathbb{C}^{m\times m}$.

According to Theorem 3.3, if we do not know whether (1.1) has a solution and A is nonsingular, then Algorithm 3.1 can also be used, and after some number of iterative steps, we begin to check the positive definiteness of X_n. If $X_n > 0$ we go up to some step n large enough and we claim numerically that (1.1) has a solution. Otherwise we stop and affirm that (1.1) has no positive definite solution. The Cholesky factorization is a good approach to test the positive definiteness. See the discussion in [11, §5].

Analysis of the convergence rate of Algorithm 3.1 seems hard. In particular, the author does not know whether this algorithm also has a linear convergence rate and he conjectures that this is the case.

4. Numerical examples. We carry out the following numerical experiments on an IBM-PC 286 computer with single precision. The machine precision is approximately 5.96×10^{-8}.

Example 1.

$$A = \begin{pmatrix} .1000000 & -.1500000 & -.2598076 \\ .1500000 & .2125000 & -.0649519 \\ .2598076 & -.0649519 & .1375000 \end{pmatrix}.$$

A is a normal matrix chosen at random so that (1.1) has a solution. In the case where A is normal and (1.1) has a solution (iff $\|A\| \le 1/2$, see [7]), it is conjectured in [7] and proved in [19, Thm. 4.1] that $X_L = \frac{1}{2}[I + (I - 4A^*A)^{1/2}]$. According to this formula the accurate maximal solution is

$$X_L = \begin{pmatrix} .88729835 & .00000000 & .00000000 \\ & .92158407 & -.01979489 \\ \mathit{symm.} & & .89872694 \end{pmatrix}.$$

After seven iterations of Algorithm 2.1 we get

$$\widetilde{X}_L = \begin{pmatrix} .88729840 & .00000000 & .00000001 \\ & .92158410 & -.01979488 \\ \mathit{symm.} & & .89872700 \end{pmatrix}.$$

Note that each entry of $\widetilde{X}_L$ has at least six correct digits. Ten iterations and 13 iterations of this algorithm give the same result:

$$\widetilde{X}_L = \begin{pmatrix} .88729830 & .00000000 & .00000001 \\ & .92158410 & -.01979491 \\ \mathit{symm.} & & .89872690 \end{pmatrix}.$$

Each entry of $\widetilde{X}_L$ has at least seven correct digits. After seven iterations of Algorithm 3.1, we get

$$\widetilde{X}_L = \begin{pmatrix} .88730160 & .00000000 & .00000000 \\ & .92158500 & -.01979354 \\ \mathit{symm.} & & .89872940 \end{pmatrix}.$$

The entry $\widetilde{X}_L(1,1)$ has four correct digits and other entries have at least six correct digits. Ten iterations of Algorithm 3.1 give

$$\widetilde{X}_L = \begin{pmatrix} .88729850 & .00000000 & .00000000 \\ & .92158410 & -.01979486 \\ \mathit{symm.} & & .89872700 \end{pmatrix}.$$

The entry $\widetilde{X}_L(3,3)$ has six correct digits and other entries have at least seven correct digits.

Example 2.

$$A = \frac{1}{40}\begin{pmatrix} 2 & -1 & 3 & 4 \\ 7 & 6 & -5 & 9 \\ 4 & 8 & 10 & 6 \\ -3 & 5 & 2 & 8 \end{pmatrix}.$$

A is nonnormal. We use the criterion $\|X_n - X_{n+1}\|_\infty = \|X_n + A^*X_n^{-1}A - I\|_\infty < tol$ for Algorithm 2.1. If $tol = 10^{-4}$, eight iterations are required. If $tol = 10^{-6}$, 11 iterations are required. If $tol = 10^{-8}$, 13 iterations are required. Use the criterion $\|I - X_nY_n\|_\infty < tol$ for Algorithm 3.1. If $tol = 10^{-4}$, 12 iterations are required. If $tol = 10^{-6}$, 18 iterations are required. Therefore we affirm numerically that for this A, (1.1) has a solution. One of the computed results is

$$\widetilde{X}_L = \begin{pmatrix} .94687310 & -.04486766 & -.00670385 & -.05718690 \\ & .89817360 & -.04311119 & -.11904720 \\ & & .90854990 & -.03544480 \\ \mathit{symm.} & & & .82728140 \end{pmatrix}.$$

Example 3. Modifying a scalar multiple of the matrix in Example 2 we get

$$A = \frac{1}{32}\begin{pmatrix} 2 & -1 & 3 & 4 \\ 7 & 6 & -5 & 9 \\ 4 & 8 & 10 & 6 \\ -3 & 5 & 2 & 8 \end{pmatrix}.$$

When using Algorithm 2.1, at the sixth implementation of the iteration a square root of negative argument appears, which occurs in the Cholesky factorization. This means that X_5 is not positive definite. Therefore we conclude that for this A, (1.1) has no positive definite solution.

The above examples show that both Algorithms 2.1 and 3.1 are numerically reliable methods either for judging the existence of positive definite solutions of (1.1) or for computing the extremal solutions X_L and X_S. Algorithm 2.1 converges slightly faster than Algorithm 3.1 in the sequential computations.

Acknowledgments. The author wishes to thank Erxiong Jiang for his continuous advice and encouragement and two anonymous referees for their helpful comments which improved the paper.

A SCHWARZ ALTERNATING PROCEDURE FOR SINGULAR PERTURBATION PROBLEMS*

MARC GARBEY†

Abstract. We show that the Schwarz alternating procedure offers a good algorithm for the numerical solution of singular perturbation problems, provided the domain decomposition is properly designed to resolve the boundary and transition layers. We give sharp estimates for the optimal position of the domain boundaries and study the convergence rates of the algorithm for various linear second-order singular perturbation problems. We report on implementation results for a turning-point problem and a combustion problem.

Key words. singular perturbations, boundary layers, domain decomposition

AMS subject classifications. Primary, 35B25, 65N05; Secondary, 35J25, 35J40

1. Introduction. The goal of this paper is to show that a properly designed Schwarz alternating procedure [5] offers an effective algorithm to solve singular perturbation problems. In particular, we show that a multiple-domain method can be *more accurate* and *more efficient* than a single-domain method—at least in the context of singular perturbation problems where the domain decomposition can be justified on the basis of physical arguments.

Since the First International Symposium on Domain Decomposition [16], much work has been done on domain decomposition methods, especially from the perspective of numerical linear algebra. However, few studies have been concerned with domain decomposition methods that are motivated by the physics of the phenomenon under investigation or by the properties of the underlying partial differential equations (PDEs); see [29, 7, 17, 31] and the references cited there.

In multiple-scale problems [24, 21], one can clearly take advantage of the special structure of a solution in the design of a domain decomposition method, as was first shown in the work of Chin [6]. In [19, 20], we began a systematic investigation of how to apply results of asymptotic analysis in the numerical computation of multiple-scale problems. As discussed in [11, 12], there are basically two approaches: one can start from a known asymptotic expansion and devise a numerical algorithm to compute the expansion, or one can start from a robust domain decomposition method and adjust the decomposition on the basis of asymptotic criteria. The former approach is very interesting but has several drawbacks: the algorithm cannot be a direct implementation of the method of matched asymptotic expansion [9, 4, 14] and, furthermore, the implementation in two or three space dimensions is not easy and can be compared to the difficulties encountered implementing a sophisticated method of front tracking.

In this paper we are concerned with the latter approach. We have chosen to start from the well-known Schwarz iterative procedure [18, 23, 26, 27, 30, 32] with *Dirichlet boundary conditions* for the sake of simplicity. We suppose that we have some knowledge of the position and thickness of boundary and transition layers [1] and derive accurate representations of the interface positions, which give the optimal numerical accuracy of the domain decomposition. We also propose a practical way to implement an adaptive domain decomposition method. With adaptivity it is not necessary to know accurately in advance the representation of the layers and the algorithm converges to the optimal interface(s) position(s).

For specific singular perturbation problems, we compute the convergence rate of the Schwarz alternating procedure *as a function of the small perturbation parameter*. We show

*Received by the editors October 15, 1993; accepted for publication (in revised form) February 25, 1995. This research was supported by Region Rhone Alpes-France.

†LAN, Université Claude Bernard Lyon 1, 69622 Villeurbanne cedex, France (garbey@lan1.univ-lyon1.fr).

that the Schwarz alternating procedure converges in a few iterations, particularly when the problem is convection-dominated. This last result is related, for example, to the work of Kuznetsov [22], who showed that the time step for a parabolic problem can be considered as a small perturbation parameter. However, Kuznetsov did not consider the singular perturbation problem.

An advantage of the approach under discussion is that the computation of more realistic problems is relatively easy to implement, as it is based on the improvement of an already existing technique. Also, one may want to solve irregular structures, such as layers, and keep the discretization grid regular in each subdomain (as opposed to taking an adaptive mesh without domain decomposition). This advantage is important for parallel computing; one can still use different numerical schemes in different subdomains.

For problems in two space dimensions, we show that a combination of the alternating direction iteration (ADI) and the Schwarz alternating procedure offers a good option for the accurate resolution of an inner layer; ADI is used as a massively parallel algorithm [10] to solve a problem that is smooth in the outer as well as the inner domain because of the stretching of the layer. Also, the coupling between the subdomain computations can be weak because ADI is implicit only in one space direction. We have implemented the Schwarz alternating procedure for a combustion problem to illustrate the potential of the method.

In this paper, we have not yet taken full advantage of the asymptotic results since the numerical scheme is basically the same on each subdomain. Most often, the asymptotic results suggest a heterogeneous domain decomposition [29]. We have recently focused our work in this direction [13]. Our choice of *Dirichlet boundary conditions* for the Schwarz alternating procedure is then useful to efficiently implement the so-called (numerical) matching between different approximations in the overlapping regions.

The plan of this paper is as follows. In §2 we compute the optimal interface position for the solution of an ordinary layer and compute the convergence rate of the Schwarz alternating procedure for different linear elliptic singular perturbation problems in one dimension. In §3 we implement an adaptive Schwarz domain decomposition to solve the inner layer of a turning-point problem. In §4 we test our technique on a two-dimensional turning-point problem; we solve the inner layer with a combination of Schwarz domain decomposition and ADI and illustrate the efficiency of the method. In §5 we solve a combustion problem describing a cellular flame; this problem is highly nonlinear and difficult to solve [2].

2. Boundary layers in one dimension. In this section we consider linear second-order singular perturbation problems of the following type:

$$L_\varepsilon \Phi \equiv \varepsilon L_1 \Phi + L_0 \Phi = F \text{ on } \Omega = (0, 1); \quad \Phi(0) = \alpha_0, \;\; \Phi(1) = \alpha_1. \tag{2.1}$$

Here, $L_1 \equiv \left(d^2/dx^2\right)$, $L_0 \equiv \beta(x, \varepsilon)(d/dx) + \gamma(x, \varepsilon)$, and $F \equiv F(x, \varepsilon)$; ε is a small positive parameter, $\varepsilon \in (0, \varepsilon_0]$ for some $\varepsilon_0 > 0$. The coefficients β, γ, and the function F are infinitely differentiable on $[0, 1]$.

Problems of this type exhibit boundary layers and transition layers; cf. [24]. We restrict ourselves to the case of a single boundary layer in the neighborhood of 0.

The Schwarz alternating procedure for problems of the type (2.1) is described in [5]. First, the domain Ω is split into two overlapping subdomains, $\Omega_{\text{inner}} = [0, a]$ and $\Omega_{\text{outer}} = [b, 1]$, with $a > b$; Ω_{inner} covers the boundary layer at 0, Ω_{outer} represents the domain of validity of the outer approximation. On each subdomain, the differential expressions are discretized by means of a finite difference scheme.

We assume that the mesh on each subdomain is regular; h_1 is the mesh size on Ω_{outer}, h_2 the mesh size on Ω_{inner}. If L^{h1} and L^{h2} are the corresponding discretized operators, then the iterative scheme is

$$L^{h1}\Phi^{p}_{\text{outer}} = F \text{ on } \Omega_{\text{outer}}, \quad \Phi^{p}_{\text{outer}}(b) = \Phi^{p}_{\text{inner}}(b), \ \Phi^{p}_{\text{outer}}(1) = \alpha_1, \tag{2.2}$$

$$L^{h2}\Phi^{p+1}_{\text{inner}} = F \text{ on } \Omega_{\text{inner}}, \quad \Phi^{p+1}_{\text{inner}}(0) = \alpha_0, \ \Phi^{p+1}_{\text{inner}}(a) = \Phi^{p}_{\text{outer}}(a), \tag{2.3}$$

for $p = 0, 1, \dots$. To start the scheme, one imposes an artificial boundary condition at point b.

The method is readily generalized to an arbitrary number of subdomains $\Omega_i = [b_i, a_i]$, where $0 = b_N < b_{N-1} < a_N < b_{N-2} < a_{N-1} < \cdots < b_0 < a_1 < a_0 = 1$. For example, the case of three subdomains leads to an iterative scheme with two possibly decoupled subproblems:

$$L^{h_0}\Phi^{p}_{0} = F \text{ on } \Omega_0, \quad \Phi^{p}_{0}(b_0) = \Phi^{p}_{1}(b_0), \ \Phi^{p}_{0}(1) = \alpha_1,$$

$$L^{h_2}\Phi^{p}_{2} = F \text{ on } \Omega_2, \quad \Phi^{p}_{2}(0) = \alpha_0, \ \Phi^{p}_{2}(a_2) = \Phi^{p}_{1}(a_2),$$

followed by

$$L^{h_1}\Phi^{p+1}_{1} = F \text{ on } \Omega_1, \quad \Phi^{p+1}_{1}(b_1) = \Phi^{p}_{0}(b_1), \ \Phi^{p+1}_{1}(a_1) = \Phi^{p}_{0}(a_1).$$

Artificial boundary conditions at the pair (a_2, b_0) are imposed to start the scheme. To solve a problem with a boundary layer at 0, one uses Ω_2 as an inner domain and Ω_0 as an outer domain; the intermediate domain Ω_1 links the inner and outer domains. A priori, we have $h_0(\varepsilon) \succ\succ h_1(\varepsilon) \succ\succ h_2(\varepsilon)$.

We restrict ourselves to use the same finite difference scheme in each subdomain with *Dirichlet boundary conditions*. For an arbitrary domain D with a mesh size parametrized by h, we suppose that the scheme must be such that the estimate

$$\max |\psi - \psi^h| \sim C\delta^q h^n \max \left| \frac{d^{n+p}\psi}{dx^{n+p}} \right| \tag{2.4}$$

is satisfied for some set of integers p, q, and n. Here, ψ is the exact solution of the Dirichlet problem in domain D and ψ^h its discrete approximation; the constant δ is a measure of the size of the domain D and C a generic positive constant or possibly an order function of ϵ, which does not depend on h. The symbol $\sim$ ($\approx$) denotes strong (weak) asymptotic equivalence; see [3]. By way of example, a centered second-order finite difference scheme applied to $-u'' = f$ gives $p = q = n = 2$.

2.1. Interface positions. First, we wish to determine the optimal interface positions, a_i and b_i, which minimize the error. We assume that the number of mesh points is the same, N, in each subdomain and consider only the case where the subgrids coincide at their endpoints, so no interpolation is needed in the iterative Schwarz procedure.

Let us start with a two-subdomains decomposition; we consider in this section the following decoupled subproblems:

$$L^{h1}\Phi^{h_1}_{\text{outer}} = F \text{ on } \Omega_{\text{outer}}, \quad \Phi^{h_1}_{\text{outer}}(b) = \Phi(b), \ \Phi^{h_1}_{\text{outer}}(1) = \alpha_1, \tag{2.5}$$

$$L^{h2}\Phi^{h_2}_{\text{inner}} = F \text{ on } \Omega_{\text{inner}}, \quad \Phi^{h_2}_{\text{inner}}(0) = \alpha_0; \ \Phi^{h_2}_{\text{inner}}(a) = \Phi(a), \tag{2.6}$$

where Φ is the exact solution of (2.1). Let Φ_{outer} (resp., Φ_{inner}) the restriction of Φ to Ω_{outer} (resp., Ω_{inner}). We define the following errors:

$$e_{\text{outer}} = \max_{\Omega_{\text{outer}}} |\Phi - \Phi^{h1}_{\text{outer}}| \tag{2.7}$$

and

$$e_{\text{inner}} = \max_{\Omega_{\text{inner}}} |\Phi - \Phi^{h2}_{\text{inner}}|. \tag{2.8}$$

According to the hypothesis on the finite difference discretization, we have

$$e_{\text{outer}} \sim C h_1^n \max \left| \frac{d^{n+p}\Phi_{\text{outer}}}{dx^{n+p}} \right| \tag{2.9}$$

and

$$e_{\text{inner}} \sim C a^q h_2^n \max \left| \frac{d^{n+p}\Phi_{\text{inner}}}{dx^{n+p}} \right| . \tag{2.10}$$

Our criteria to define the best interface positions (a, b) is that $\max(e_{\text{outer}}, e_{\text{inner}})$ should be asymptotically minimum.

Theorems 1 and 2 in §2.2 will show for some specific operators that this criterion is correct; i.e., we do not need to consider the artificial error introduced at the boundaries in the Schwarz alternating procedure to properly choose the interface positions.

The optimal position of the interface defined above now depends only on the property of the solution that we want to approximate. We restrict our analysis to functions that exhibit boundary layer phenomena as it can be the case for solutions of (2.1). But the following estimates on the interface position are independent of the operator. Let Φ_0 be the outer expansion of Φ. The main hypothesis is that we have some a priori knowledge of the *qualitative behavior* of the corrector $\Theta(x, \varepsilon) = \Phi(x, \varepsilon) - \Phi_0(x, \varepsilon)$ in the boundary layer. In the case of two subdomains, we have the following result.

LEMMA 1. *Suppose that*

(i) *the corrector function Θ is strictly of order one,*

(ii) *the inner variable is $\xi = x/\varepsilon$ and all derivatives of $\tilde{\Theta}(\xi, \varepsilon) = \Theta(x, \varepsilon)$ with respect to ξ are of order one,*

(iii) *the corrector function Θ is exponentially decreasing, $\tilde{\Theta}(\xi, \varepsilon) \sim C \exp(-C_0\xi)$ as $\xi \to \infty$.*

Then the error in each subdomain is minimum when the overlap is minimum. For any fixed overlap $(a - b = k_0 h_1)$, the accuracy is optimal in both subdomains if

$$a^{n+q} \sim C \exp\left(-(C_0/\varepsilon)(a - k_0/N)\right).$$

Proof. The error in the outer domain is

$$E^1 = \max_{\Omega_{\text{outer}}} |\Phi - \Phi^{h1}_{\text{outer}}| \sim C h_1^n \max_{\Omega_{\text{outer}}} \left| \frac{d^{n+p}\Phi}{dx^{n+p}} \right| \sim C \exp(-C_0 b/\varepsilon) h_1^n \varepsilon^{-(n+p)}.$$

Similarly, the error in the inner domain is

$$E^2 = \max_{\Omega_{\text{inner}}} |\Phi - \Phi^{h2}_{\text{inner}}| \sim C a^q h_2^n \max_{\Omega_{\text{inner}}} \left| \frac{d^{n+p}\Phi}{dx^{n+p}} \right| \sim C h_2^n a^q \varepsilon^{-(n+p)}.$$

If we impose a fixed overlap, $a - b = k_0 h_1$, where k_0 is an integer of order one (possibly equal to one), then

$$E^1 \sim C \exp\left(-(C_0/\varepsilon)(a - k_0/N)\right) N^{-n} \varepsilon^{-(n+p)}$$

and

$$E^2 \sim C a^{n+q} N^{-n} \varepsilon^{-(n+p)}.$$

Hence, if ε is sufficiently small, then E^2 is an increasing function and E^1 a decreasing function of a. The accuracy is optimal in both subdomains if $E^2 \sim E^1$, which is the case if $a^{n+q} \sim C \exp(-(C_0/\varepsilon)(a - k_0/N))$.

The asymptotic relation above shows that the optimal position of the interface a is an increasing function of k_0. Therefore, the optimal error E^2 is an increasing function of k_0 as well as E^1 and the error in both domains is minimum when the overlap is minimum that is $k_0 = 1$. □

LEMMA 2. *Suppose that the conditions of Lemma* 1 *are satisfied and that, in addition,* $b \sim Ca$. *Then, for any fixed overlap, the maximum of the error in each subdomain is minimum if*

$$b = (n + q + o(1))(\varepsilon/C_0)\log(C_0/\varepsilon)$$

and, consequently,

$$a \approx \varepsilon \log(\varepsilon^{-1}).$$

Proof. The maximum of the error in both subdomains is minimum when $e_{\text{inner}} \sim e_{\text{outer}}$, which is the case if $a^{n+q} \sim C \exp(-C_0 b/\varepsilon)$. If $b \sim Ca$, we obtain $b^k \sim C \exp(-b/\varepsilon_1)$, where $k = n + q$ and $\varepsilon_1 \sim \varepsilon/C_0$.

We look for b of the form $b = \eta(\varepsilon_1)\varepsilon_1 \log \varepsilon_1^{-1}$, where η is a positive function of order one. Then $b^k \sim C\varepsilon_1^k \log^k \varepsilon_1^{-1}$ and $\exp(-b/\varepsilon_1) \sim \varepsilon_1^\eta$. Therefore, the quantity $b^k/\exp(-b/\varepsilon_1)$ is very sensitive to the choice of the function $\eta(\varepsilon_1)$. We obtain

$$(k - \nu)\varepsilon_1 \log\left(\varepsilon_1^{-1}\right) < b < k\varepsilon_1 \log\left(\varepsilon_1^{-1}\right)$$

for all $\nu > 0$. More precisely, we look for b of the form $b = (k - \delta(\varepsilon_1))\varepsilon_1 \log\left(\varepsilon_1^{-1}\right)$, where $\delta \prec\prec 1$. The condition $b^{n+q} \sim \exp(-C_0 b/\varepsilon)$ is satisfied if and only if $\delta(\varepsilon_1) \sim (n+q)\log\left(\log\left(\varepsilon_1^{-1}\right)\right)/\log\left(\varepsilon_1^{-1}\right)$. As $a \approx b$, we conclude that $a \approx \varepsilon \log\left(\varepsilon_1^{-1}\right)$. □

Note that the hypothesis $b \sim Ca$ is satisfied when $N \geq 1/(C\varepsilon \log(\varepsilon/C_0)^{-1})$.

Remark 1. The estimate of Lemma 2 shows that the size of the inner subdomain Ω_{inner} increases with the order of the scheme and with the size of the overlap. It is interesting to note that the thickness of the layer obtained on the basis of the previous criterion is not simply ε but involves logarithmic terms, as in [1].

Remark 2. The estimate on b in Lemma 2 is numerically accurate only for very small values of ε. For moderate values of ε, one should use the next higher-order approximation of b, including the order function $\delta(\varepsilon)$.

Lemma 2 can be generalized to an arbitrary number of subdomains; the numerical error in each subdomain $\Omega_j = [b_j, a_j]$ is

$$E_j \sim C \exp(-C_0 b_j/\varepsilon) a_j^q h_j^n \varepsilon^{-(n+p)}.$$

We will show that the quantity $\max_{j=0,\ldots,N}(E_j)$ is minimum when the sequence of interfaces (b_j) satisfies the set of asymptotic relations $E_j \sim E_{j+1}$ for $j = 0, \ldots, N - 1$, that is, when the numerical error in each subdomain is of the same order.

The computation of the sequence of interfaces that satisfies the nonlinear problem $E_j = E_{j+1}$ for $j = 0, \ldots, N - 1$ can be done numerically for a given ε. However, we can obtain an asymptotic approximation of the b_j.

LEMMA 3. *Suppose we have* $N + 1$ *overlapping subdomains,* $\Omega_j = [b_j, a_j]$, *where* $0 = b_N < b_{N-1} < a_N < b_{N-2} < a_{N-1} < \cdots < b_0 < a_1 < a_0 = 1$, *and that* $a_j \sim b_{j-1}$ *for* $j = 1, \ldots, N$. *The maximum of the error in each subdomain will be minimum when*

$$b_j = (n + q + o(1))\varepsilon \log_{j+1}(C_0/\varepsilon).$$

Here, $\log_j$ *stands for* $\log(\log(\log\ldots))$, *j times.*

Proof. Let $k = n + q$ and $\varepsilon_1 \sim \varepsilon/C_0$. Since $a_j \sim b_{j-1}$, the error in each subdomain is $E_j \sim C\exp\left(-b_j/\varepsilon_1\right) b_{j-1}^k \varepsilon^{-(n+p)}$. For any j, E_j is a decreasing function of b_j and E_{j+1} is an increasing function of b_j. Therefore, by induction, $\max_{j=1,\dots,N}(E_j)$ is minimum when $E_j = E_{j+1}$ for $j = 0, \dots, N-1$.

For any function b_{N-1}, one explicitly gets a set of functions $(b_j)_{j=0,\dots,N-2}$ which satisfy the relation $E_j \sim E_{j+1}$ for $j = 1, \dots, N-1$. The corresponding b_j, and in particular b_0, are increasing functions of b_{N-1}. Therefore, E_0 is a decreasing function of b_{N-1} under the constraint $E_j = E_{j+1}$ for $j = 0, \dots, N-1$ and E_N is an increasing function of b_{N-1}. The existence and uniqueness of b_{N-1} such that $E_0 = E_N$ then follow from the intermediate variable theorem.

Next, we will derive an asymptotic estimate for the interface position in the case of three subdomains. The error in each subdomain balances when

$$\exp(-b_0/\varepsilon_1) \sim C b_0^k \exp(-b_1/\varepsilon_1) \sim C b_1^k.$$

We look for b_0 in the form $b_0 = (k - \delta(\varepsilon))\varepsilon_1 \log(\varepsilon_1^{-1})$, where $\delta \prec\prec 1$. As $\exp(-b_0/\varepsilon_1) \sim \varepsilon_1^{k-\delta}$, we have $b_1 \sim C\varepsilon_1^{1-\delta/k}$. Therefore, δ must satisfy the asymptotic relation $\varepsilon_1^{k-\delta} \sim C\varepsilon_1^k \log^k(\varepsilon_1^{-1}) \exp(-\varepsilon_1^{-\delta/k})$. Using the fact that

$$\frac{\log(\log^k(\log^k \varepsilon_1^{-1}))}{\log \varepsilon_1^{-1}} > \delta > \frac{\log(\log^k(\log^{k-\nu} \varepsilon_1^{-1}))}{\log \varepsilon_1^{-1}},$$

for all $\nu > 0$, we conclude that $b_1 \sim k\varepsilon_1 \log(\log(\varepsilon_1^{-1}))$. Thus, in the case of three subdomains,

$$b_0 = (k + o(1))\varepsilon_1 \log(\varepsilon_1^{-1}), \quad b_1 = (k + o(1))\varepsilon_1 \log(\log(\varepsilon_1^{-1})).$$

The proof for an arbitrary number of subdomains proceeds along the same lines. □

Remark 3. All previous results are still valid for nonoverlapping subdomains. When one solves a boundary layer at 0, the numerical accuracy in each subdomain is dominated by the error in the neighborhood of its left boundary.

2.2. Damping of artificial boundary errors and convergence. Let $[A, B] \subset [0, 1]$ be a given subdomain of Ω used in a Schwarz iterative procedure. The convergence and accuracy of the Schwarz method essentially depend on the way an error introduced at one of the artificial boundary points propagates inside the subdomain.

Following Cai and McCormick [5], we consider the linear problem

$$-u'' = F, \quad u(0) = \alpha_0, \quad u(1) = \alpha_1, \tag{2.11}$$

with the usual three-point discretization applied to each subdomain $[A, B]$. Let $e_i = u_i - u(x_i)$ be the error on the regular grid $\{x_i = A + i(B - A)/N : i = 0, \dots, N\}$. Suppose that $e_0 = 0$, and let e_N be the error at the artificial boundary B. We have $e_i = (i/N)e_N$ for $i = 0, \dots, N$. In other words, any error at the artificial boundary B decreases linearly inside the subdomain $[A, B]$. The situation is analogous for the damping of an error introduced at the artificial boundary A. This linear convergence is the key reason for the poor efficiency of the *straightforward Schwarz alternating procedure with Dirichlet boundary conditions* for the elliptic operator $L[u] = -\Delta u$ demonstrated in [5]. Of course, the situation is different for the positive operator $L[u] = -\Delta u + \gamma u$ with $\gamma > 0$. Also, for regular problems (as opposed to singular perturbation problems), it is well known that more sophisticated boundary conditions can lead to a very efficient Schwarz method; see [32], for example. We will show that the situation is considerably different for a singular perturbation problem of elliptic-type and that we may, in fact, have fast convergence with relatively small overlap even if we restrict ourselves to *Dirichlet boundary conditions.*

Let $[b_0, a_0]$ and $[b_1, a_1]$ be the two overlapping subdomains of a domain decomposition, with $b_1 < b_0 < a_1 < a_0$. We consider the homogeneous discretized problems

$$L^{h_1}[e_1] = 0, e_1(b_0) = \alpha_1,\ e_1(a_0) = 0, \tag{2.12}$$

$$L^{h_2}[e_2] = 0, e_2(b_1) = 0,\ e_2(a_1) = \alpha_2. \tag{2.13}$$

We will say that the real numbers $\zeta_{\rightarrow}$ and $\zeta_{\leftarrow}$ are *damping factors* if $e_2(a_1) \leq \zeta_{\rightarrow} e_2(b_0)$ and $e_1(b_0) \leq \zeta_{\leftarrow} e_1(a_1)$.

An iteration of the Schwarz method on a domain decomposition that includes the previous two particular overlapping subdomains results in $e_1^{p+1}(b_0) \leq \zeta_{\rightarrow}\zeta_{\leftarrow} e_1^p(b_0)$ and $e_2^{p+1}(a_1) \leq \zeta_{\rightarrow}\zeta_{\leftarrow} e_2^p(a_1)$. The convergence of the scheme follows when the discretized operator satisfies a maximum principle and the product of the damping factors is less than one.

The damping factors can be computed for various singular perturbation problems and finite difference schemes.

2.2.1. The case $L[u] = -\varepsilon u'' + \gamma(x)\, u = F$, $\gamma > 0$. First, we solve a boundary layer at 0 with a two-subdomain Schwarz procedure and the usual three-point discretization. For the singular perturbation problem $-\varepsilon u'' + \gamma u = F$ on $[0, 1]$, the thickness of the boundary layer at 0 is $\varepsilon^{1/2}$. The inner variable is $\xi = x/\varepsilon^{1/2}$, and the layer can be resolved with a corrector function $\tilde{\Theta}$ which satisfies the asymptotic relation $\tilde{\Theta}(\xi, \varepsilon) \sim C \exp(-C_0\xi)$ as $\xi \rightarrow \infty$. Furthermore, $C_0 = \gamma^{1/2}(0)$. It follows from Lemma 2 that $\max(e_{\text{outer}}, e_{\text{inner}})$ defined by (2.7) and (2.8) is minimum if

$$a \approx \varepsilon^{1/2} \log \varepsilon^{-1}, \quad N \geq C/\left(\varepsilon^{1/2} \log \varepsilon^{-1}\right).$$

LEMMA 4. *Let $[0, a]$ and $[b, 1]$ be two overlapping subdomains, with $a - b = k_0 h_1$ and $a \sim b \approx \varepsilon^{1/2} \log \varepsilon^{-1}$.*

If $N \sim 1/\left(\varepsilon^{1/2} \log \varepsilon^{-1}\right)$, then

$$\zeta_{\rightarrow} \sim \log^{-2k_0} \varepsilon^{-1}, \quad \zeta_{\leftarrow} \sim \varepsilon^{k_0}.$$

If $N \sim C^{-1}(\gamma(0))/\varepsilon)^{1/2}$, then

$$\zeta_{\rightarrow} \sim R^{-k_0}, \quad \zeta_{\leftarrow} \sim \exp(-k_0 C),$$

where $R = 1 + \frac{1}{2}C^2 + C(1 + \frac{1}{4}C^2)^{1/2}$.

Proof. We compute the damping factor by applying the three-point discretization in each subdomain to the homogeneous problem

$$-\varepsilon(e_{i+1} - 2e_i + e_{i-1}) + h^2 \gamma_i e_i = 0.$$

The finite difference equation can be written as

$$e_{i+1} - (2 + \gamma_i h^2/\varepsilon) e_i + e_{i-1} = 0.$$

Then

$$\zeta_{\leftarrow} \sim (R(h_2, \varepsilon))^{-k_0 h_1/h_2}, \quad \zeta_{\rightarrow} \sim (R(h_1, \varepsilon))^{-k_0},$$

where $R(h, \varepsilon)$ is the larger root of the quadratic polynomial $R^2 - (2 + \gamma(0)h^2/\varepsilon)R + 1$,

$$R(h, \varepsilon) = 1 + 1/2(h^2\gamma(0)/\varepsilon) + (h\gamma(0)^{1/2}/\varepsilon^{1/2})\left(1 + h^2\gamma(0)/(4\varepsilon)\right)^{1/2}.$$

The lemma follows upon substitution of the expression of R. □

We now prove the convergence of the method using the result of Lemma 3 and show that the criterion to locate the best interface position defined in §2.1 is correct.

THEOREM 1. *Let* $\zeta = \zeta_{\leftarrow} \times \zeta_{\rightarrow}$, *and let* Φ *be the solution of the Dirichlet problem*

$$L[u] = -\varepsilon u'' + \gamma(x)u = F, \quad u(0) = \alpha_0, \; u(1) = \alpha_1. \tag{2.14}$$

Let Φ^p_{outer} *and* Φ^p_{inner} *be the solutions of the iterative scheme*

$$L^{h1}\Phi^p_{\text{outer}} = F \text{ on } \Omega_{\text{outer}}, \quad \Phi^p_{\text{outer}}(b) = \Phi^p_{\text{inner}}(b), \quad \Phi^p_{\text{outer}}(1) = \alpha_1, \tag{2.15}$$

$$L^{h2}\Phi^{p+1}_{\text{inner}} = F \text{ on } \Omega_{\text{inner}}, \quad \Phi^{p+1}_{\text{inner}}(0) = \alpha_0, \quad \Phi^{p+1}_{\text{inner}}(a) = \Phi^p_{\text{outer}}(a), \tag{2.16}$$

where

$$L^{h_i}[u] = -\varepsilon\frac{u_{i+1} - 2u_i + u_{i-1}}{h_i^2} + \gamma(x_i)u^i.$$

Let

$$\Phi^p = \begin{cases} \Phi^p_{\text{inner}} & \text{on } M_{\text{inner}} = \{x_i = i(a/N), i = 0, \dots, N\}, \\ \Phi^p_{\text{outer}} & \text{on } M_{\text{outer}} = \{y_i = b + i\frac{1-b}{N}, i = 0, \dots, N, \; y_i \in \Omega_{\text{outer}}\backslash\Omega_{\text{inner}}\}. \end{cases}$$

Let e_{outer} *and* e_{inner} *be the numerical errors in the solution of the Dirichlet subproblems defined by* (2.5), (2.7), (2.6), *and* (2.8). *Let* $\|\cdot\|_\infty$ *be the maximum norm on the composite grid* $M_{\text{outer}} \bigcup M_{\text{inner}}$. *Then*

$$\|\Phi - \Phi_p\|_\infty \leq C(\zeta^p + \max(e_{\text{outer}}, e_{\text{inner}})).$$

Proof. Let $\tilde{\Phi} = (\tilde{\Phi}_{i,j})_{i=0..N, j=1,2}$ be the solution to the following linear system:

$$-\varepsilon\frac{\tilde{\Phi}_{i+1,1} - 2\tilde{\Phi}_{i,1} + \tilde{\Phi}_{i-1,1}}{h_1^2} + \gamma(y_i)\tilde{\Phi}_{i,1} = F(y_i), \quad i = 1, \dots, N-1, \tag{2.17}$$

$$-\varepsilon\frac{\tilde{\Phi}_{i+1,2} - 2\tilde{\Phi}_{i,2} + \tilde{\Phi}_{i-1,2}}{h_2^2} + \gamma(x_i)\tilde{\Phi}_{i,2} = F(x_i), \quad i = 1, \dots, N-1, \tag{2.18}$$

$$\tilde{\Phi}_{N,1} = \alpha_1, \; \tilde{\Phi}_{0,2} = \alpha_0, \tag{2.19}$$

$$\tilde{\Phi}_{0,1} = \tilde{\Phi}_{k,2}, \; \tilde{\Phi}_{N,2} = \tilde{\Phi}_{1,1}, \tag{2.20}$$

with $h_1 = \frac{1-b}{N}$, $h_2 = \frac{a}{N}$, $x_k = b$. Let Φ be the exact solution of the Dirichlet problem: $-\varepsilon u'' + \gamma(x)u = F$, $u(0) = \alpha_0, u(1) = \alpha_1$. Using a discrete maximum principle on the composite grid $M_{\text{inner}} \bigcap M_{\text{outer}}$, we have the existence and uniqueness of $\tilde{\Phi}$.

Let $e_{i,j} = \Phi_{i,j} - \tilde{\Phi}_{i,j}, i = 0, \dots, N, j = 1, 2$, where $\Phi_{i,j}$ is the trace of Φ on the composite grid $M_{\text{outer}} \bigcup M_{\text{inner}}$. We have

$$-\varepsilon\frac{e_{i+1,1} - 2e_{i,1} + e_{i-1,1}}{h_1^2} + \gamma(y_i)e_{i,1} = \epsilon\frac{h_1^2}{12}\Phi^{(4)}_{i,1}, \quad i = 1, \dots, N-1, \tag{2.21}$$

$$-\varepsilon\frac{e_{i+1,2} - 2e_{i,2} + e_{i-1,2}}{h_2^2} + \gamma(x_i)e_{i,2} = \epsilon\frac{h_2^2}{12}\Phi^{(4)}_{i,2}, \quad i = 1, \dots, N-1, \tag{2.22}$$

$$e_{N,1} = 0, \; e_{0,2} = O, \tag{2.23}$$

$$e_{0,1} = e_{k,2}, \; e_{N,2} = e_{1,1}, \tag{2.24}$$

where $\Phi^{(4)}_{i,j}$ denotes the fourth-order derivative of Φ obtained in the Taylor expansion. If $|e_{i,1}|$ is not maximal at the boundary $i = 0$, we have

$$\max_{i=0,\dots,N} |e_{i,1}| \leq C\epsilon h_1^2 \max(\Phi^{(4)}) \approx e_{\text{outer}},$$

otherwise, we have

$$|e_{N,2}| = |e_{1,1}| < |e_{k,2}| = |e_{0,1}|;$$

that is, $|e_{i,2}|$ cannot be maximal at the boundary $i = N$ and

$$\max_{i=0,\dots,N} |e_{i,2}| \leq C\epsilon a^2 h_2^2 \max_{\Phi^{(4)}} \approx e_{\text{inner}}.$$

Consequently, we have

$$\|\Phi - \tilde{\Phi}\|_\infty \leq C \max(e_{\text{outer}}, e_{\text{inner}}).$$

Let $\tilde{\Phi}_{\text{outer}} = (\tilde{\Phi}_{i,1})_{i=0,\dots,N}$ (resp., $\tilde{\Phi}_{\text{inner}} = (\tilde{\Phi}_{i,2})_{i=0,\dots,N}$) and $v^p_{\text{outer}} = \Phi^p_{\text{outer}} - \tilde{\Phi}_{\text{outer}}$ (resp., $v^p_{\text{inner}} = \Phi^p_{\text{inner}} - \tilde{\Phi}_{\text{inner}}$).

We have

$$L^{h1} v^p_{\text{outer}} = 0 \text{ on } \Omega_{\text{outer}}, \; v^p_{\text{outer}}(b) = v^p_{\text{inner}}(b), \; v^p_{\text{outer}}(1) = 0,$$

$$L^{h2} v^{p+1}_{\text{inner}} = 0 \text{ on } \Omega_{\text{inner}}, \; v^{p+1}_{\text{inner}}(a) = v^p_{\text{outer}}(a), \; v^{p+1}_{inner}(0) = 0.$$

We conclude from Lemma 4 that

$$\|v^p_{\text{outer}}\|_\infty \leq C\zeta^p \text{ on } M_{\text{outer}}$$

and

$$\|v^p_{\text{inner}}\|_\infty \leq C\zeta^p \text{ on } M_{\text{inner}}$$

and, therefore,

$$\|\Phi - \Phi^p\| \leq C\zeta^p + \max(e_{\text{outer}}, e_{\text{inner}}).$$

According to this estimation p must be chosen such that

$$\zeta^p \approx \max(e_{\text{outer}}, e_{\text{inner}})$$

and the interfaces a and b such that $\max(e_{\text{outer}}, e_{\text{inner}})$ is asymptotically minimum. □

It is interesting to see how the damping factors behave when the number of subdomains increases. First, consider the three-subdomain case with $a_1 \sim b_0$ and $a_2 \sim b_1$. We consider the optimal situation described in Lemma 3, for which $a_1 \approx \varepsilon^{1/2}\log(\varepsilon^{-1})$ and $a_2 \approx \varepsilon^{1/2}\log(\log(\varepsilon^{-1}))$. To minimize the damping factor, we choose the smallest order for N that is still compatible with our hypothesis on the overlapping

$$N \sim 1/\left(\varepsilon^{1/2}\log(\varepsilon^{-1})\right).$$

The damping factors $\zeta_{\rightarrow}^{0,1}$ and $\zeta_{\leftarrow}^{0,1}$ corresponding to the two overlapping subdomains $\Omega_0 = [b_0, a_0 = 1]$ and $\Omega_1 = [b_1, a_1]$ are as good as in Lemma 4: $\zeta_{\rightarrow}^{0,1} \approx \log^{-2k_0} \varepsilon^{-1}$, and $\zeta_{\leftarrow}^{0,1} \approx \varepsilon^{k_0}$. On the other hand, for the subsequent damping factors corresponding to the overlapping domains Ω_1 and Ω_2, we obtain $\zeta_{\rightarrow}^{1,2} \approx \zeta_{\leftarrow}^{1,2} \approx 1 - k_1 \varepsilon^{1/2} \log^2(\varepsilon^{-1})$. Hence, the three-subdomain Schwarz method may converge very slowly under the previous hypothesis. We observe that $\varepsilon^{1/2} \log^2(\varepsilon^{-1})$ is less than $1/2$ if and only if $\varepsilon < 0.000017$. In other words, the damping factors $\zeta_{\rightarrow}^{1,2}$ and $\zeta_{\leftarrow}^{1,2}$ can be practically small for ε larger than 10^{-4}.

Under the hypothesis of Lemma 3, one can show that the situation deteriorates when the number of subdomains increases. For $i > 0$, $1 - \zeta_{\rightarrow}^{i,i+1} \gg 1 - \zeta_{\rightarrow}^{i+1,i+2}$ and $1 - \zeta_{\leftarrow}^{i,i+1} \gg 1 - \zeta_{\leftarrow}^{i+1,i+2}$. In practice, N may be much smaller than $\varepsilon^{-1/2} \log^{-1}(\varepsilon^{-1})$. However, we have observed in our numerical experiments that the convergence deteriorates when the number of subdomains increases and the relative size of the overlap $(a_i - b_{i-1})/h_i$ stays fixed.

2.2.2. The case $L[u] = \varepsilon u'' + \beta(x)u' + \gamma(x)u = F$, $\beta > 0$. We suppose for simplicity that the real function β is strictly positive on Ω, so we do not consider turning-point problems in this section. Let us first consider a first-order finite difference scheme with the appropriate one-sided difference approximation of the convective term

$$\varepsilon \frac{u_{i+1} - 2u_i + u_{i-1}}{h^2} + \beta(x_i) \frac{u_{i+1} - u_i}{h} + \gamma(x_i) u_i = F_i.$$

This scheme is monotone when γ is a negative function. We know that for the Dirichlet singular perturbation problem $\varepsilon u'' + \beta u' + \gamma u = F$ on $[0, 1]$, the thickness of the boundary layer at 0 is ε. The inner variable is $\xi = x/\varepsilon$, and the layer can be resolved with a corrector function $\tilde{\Theta}$ that satisfies the estimate $\tilde{\Theta}(\xi, \varepsilon) \sim C \exp(-C_0 \xi)$ as $\xi \to \infty$. Furthermore, $C_0 = \beta^{1/2}(0)$. Let N be such that

$$N \geq (C/\varepsilon) \log \varepsilon^{-1}.$$

According to Lemma 2, $\max(e_{\text{outer}}, e_{\text{inner}})$ is minimum when

$$a \approx \varepsilon \log \varepsilon^{-1}.$$

LEMMA 5. *Let* $[0, a]$ *and* $[b, 1]$ *be two overlapping subdomains, with* $a - b = k_0 h_1$ *and* $a \sim b \approx \varepsilon \log \varepsilon^{-1}$.

If $N \sim 1/\left(\varepsilon \log \varepsilon^{-1}\right)$, *then*

$$\zeta_{\rightarrow} \sim \beta(0)^{-k_0} \log^{-k_0} \varepsilon^{-1}, \quad \zeta_{\leftarrow} \sim 1 + k_0 \frac{\gamma(0)}{\beta(0)} \varepsilon \log \varepsilon^{-1}.$$

If $N \sim C\varepsilon^{-1}$, *then*

$$\zeta_{\rightarrow} \sim \frac{1}{(1 + \beta(0)C)^{k_0}}, \quad \zeta_{\leftarrow} \sim 1 + Ck_0 \frac{\gamma(0)}{\beta(0)} \varepsilon.$$

Proof. The proof is analogous to the proof of the previous lemma. The three-point discretization in any subdomain applied to the homogeneous problem satisfies

$$\varepsilon(e_{i+1} - 2e_i + e_{i-1}) + \beta_i h(e_{i+1} - e_i) + h^2 \gamma_i e_i = 0.$$

The asymptotic behavior of the damping factors follows from a straightforward computation. □

When the previous first-order scheme satisfies a maximum principle, we have Theorem 2.

THEOREM 2. *With the same notational convention as in Theorem* 1, *we have*

$$\|\Phi - \Phi_p\|_\infty \leq C\zeta^p + \max(e_{\text{outer}}, e_{\text{inner}}).$$

Remark 4. Even if $\gamma(0)$ is positive, the product $\zeta_\rightarrow\zeta_\leftarrow$ is less than one for ε sufficiently small. However, for singular perturbation problems with convection, where $\beta(0) \neq 0$, the rate of damping is less advantageous than in the case where $\beta = 0$.

The result of Lemma 5 can be extended to the three-subdomain case as before. The conclusion is the same; namely, the efficiency of the method deteriorates as the number of subdomains increases. With the notation of the previous section we have in the three-subdomain case

$$\zeta_\rightarrow^{1,2} \sim \zeta_\leftarrow^{1,2} \sim 1 - k_1\beta(0)\varepsilon\log^2(\varepsilon^{-1}).$$

Now, let us consider the central finite difference scheme

$$\varepsilon\frac{u_{i+1} - 2u_i + u_{i-1}}{h^2} + \beta_i\frac{u_{i+1} - u_{i-1}}{2h} + \gamma_i u_i = 0.$$

In general, the scheme is not monotone. However, one can still do the asymptotic analysis of the damping factor.

LEMMA 6. *Let* $[0, a]$ *and* $[b, 1]$ *be two overlapping subdomains with* $a - b = k_0 h_1$ *and* $a \sim b \approx \varepsilon\log\varepsilon^{-1}$. *If* $N \sim 1/\left(\varepsilon\log\varepsilon^{-1}\right)$, *then*

$$\zeta_\rightarrow \sim 1 - \frac{4k_0}{\beta(0)\log\varepsilon^{-1}}, \quad \zeta_\leftarrow \sim 1 + k_0\frac{\gamma(0)}{\beta(0)}\varepsilon\log\varepsilon^{-1}.$$

If $N \sim C\varepsilon^{-1}$, *where* $C \neq \frac{1}{2}\beta(0)$, *then*

$$\zeta_\rightarrow \sim \left(\frac{1 - 2C/\beta(0)}{1 + 2C/\beta(0)}\right)^{k_0}, \quad \zeta_\leftarrow \sim 1 + Ck_0\frac{\gamma(0)}{\beta(0)}\varepsilon.$$

We notice that the Schwarz alternating procedure converges faster with the appropriate one-sided finite difference scheme than with the centered finite difference scheme.

2.2.3. Time-dependent case, $u_t = \varepsilon u_{xx} + \beta(x)u_x + \gamma(x)u$. Next, we consider an initial boundary value problem on $\Omega \times [0, T]$ with Dirichlet conditions

$$\frac{\partial u}{\partial t} = \varepsilon\frac{\partial^2 u}{\partial x^2} + \beta(x, t)\frac{\partial u}{\partial x} + \gamma(x, t)u.$$

If we use an implicit Euler scheme for the time marching

$$\frac{u^{n+1} - u^n}{\Delta t} = \varepsilon u_{xx}^{n+1} + \beta^{n+1}u_x^{n+1} + \gamma^{n+1}u^{n+1};$$

then

$$-\varepsilon\Delta T u_{xx}^{n+1} - \beta^{n+1}\Delta T u_x^{n+1} + (1 - \gamma^{n+1}\Delta T)u^{n+1} = u^n.$$

In other words, the time-marching scheme leads to the solution of a singular perturbation problem at each time step. The small parameter of this singular perturbation problem is even smaller than ε, as the time step is a priori a small number, but the structure of the boundary layers is independent of the time step. Also, the implicit scheme is appropriate if the time-dependent singular perturbation problem exhibits an initial layer.

Again, we distinguish the case where we have convection ($\beta \neq 0$) from the case where convection is absent ($\beta = 0$).

For steady problems without convection, we have seen in Lemma 4 that the efficiency of the alternating Schwarz procedure improves as the perturbation parameter decreases. As ε is multiplied by ΔT, where $\Delta T \ll 1$, we can expect the method to be especially efficient for the solution of time-dependent singular perturbation problems without convection.

The case $\beta = 0$ is trivial, so from now on we consider only nonzero convection.

Consider a Schwarz alternating procedure with two overlapping subdomains to solve the equation

$$-\varepsilon \Delta T u_{xx} - \beta \Delta T u_x + (1 - \gamma \Delta T) u = F.$$

For the one-sided difference scheme we obtain the following result.

LEMMA 7. *Let* $[0, a]$ *and* $[b, 1]$ *be two overlapping subdomains, with* $a - b = k_0 h_1$ *and* $a \sim b \approx \varepsilon \log \varepsilon^{-1}$. *Let* δ *be an order function such that* $\delta \succ\succ 1$. *Let* N *be such that* $N \sim \varepsilon^{-1}\delta^{-1}$.

If $\Delta T \succ\succ \varepsilon\delta^2$, *then*

$$\zeta_{\rightarrow}\zeta_{\leftarrow} \sim (\beta\delta)^{-k_0}.$$

Proof. The proof of this lemma is a straightforward computation. □

From the asymptotic approximation of the damping factors given above we observe that the efficiency of the method improves compared with the steady case. Also, very few iterations of the Schwarz alternating procedure are required since the initial artificial boundary condition can be the trace of the solution at the previous time step. The constraint on the time step is reasonable, as the accuracy of the spatial Schwarz alternating procedure must be of at least the same order as the accuracy of the temporal Euler scheme. However, one can use higher-order time differencing schemes and, therefore, a larger time step. For larger time steps, we are progressively back to the situation of the steady problems described by Lemmas 5 and 6.

2.3. Numerical experiments. We consider, first, a linear second-order singular perturbation problem

$$\varepsilon u'' + \beta u' + \gamma u = f$$

on the interval $\Omega = [0, 1]$, with a boundary layer located at the right end of the interval. To obtain a good numerical experiment, we choose f such that the outer expansion is nontrivial, so the reduced problem $\beta u' + \gamma u = f$ has a solution that is not constant. Furthermore, to simplify the numerics, we impose the condition that the grids of the subdomains coincide at the boundary points. For each experiment we use a known explicit solution, and any numerical error will be given in the discrete maximum norm on the composite grid, which is the union of the grids of the subdomains.

To balance the amount of work for each subproblem, we use the same number of points N for each subgrid. Then there is a finite number of possible sets of n subgrids that coincide at their end points. For example, in the two-subdomains case, the regular grids $\{x_i = ih_1 : i = 0, \dots, N\}$ of $\Omega_1 = [0, a]$ and $\{y_i = ih_2 + b : i = 0, \dots, N\}$ of $\Omega_2 = [b, 1]$, where $h_1 = a/N$ and $h_2 = (1 - b)/N$, $0 < b < a < 1$, coincide in a and b if and only if there exist $k_1, k_2 \in \{1, \dots, N - 1\}$, such that $a = k_1 h_2 + b$ and $b = k_2 h_1$. Hence, we have exactly $(N - 2)^2$ possible choices. A similar analysis for three subdomains gives $(N - 1)^4$ possible sets of interface positions.

 ••• best interface position
```

For each of the following cases, we numerically tested all possible interface positions and obtained the position that minimizes the error and the number of iterations to reach this accuracy. Following are the conclusions of our tests.

1. In the two-subdomain case without convection ($\beta = 0$), we obtain the best accuracy with a minimum overlap, $a - b = h_1$ and the ratio h_2/h_1 as well as $1 - b$ in agreement with the asymptotic estimates of Lemmas 1 and 2. The numerical error of the Schwarz alternating procedure reaches its minimum in a few (two or three) steps; see Table 1. Also, the numerical error is very sensitive to the position of the interface; Figure 1 shows the dependence of the error on the interface position when we assume a minimum overlap; the data are extracted from Table 1.

   The efficiency of the Schwarz procedure is impressive, and the method is certainly more efficient in terms of elapsed time for a given accuracy than a classical computation with one domain and a regular mesh.

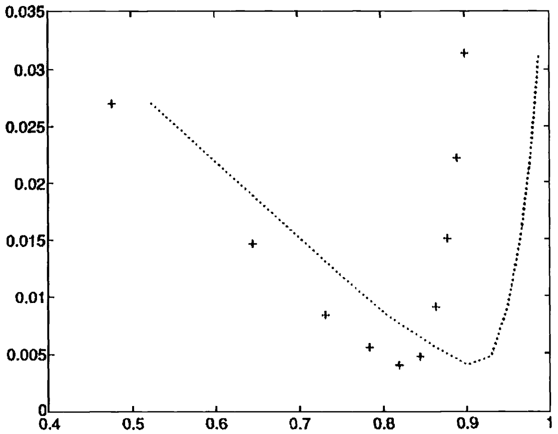

FIG. 1. *Dependence of the error on the interface position.* + *left interface of the boundary layer subdomain.* ··· *right interface of the outer subdomain.*

2. In the three-subdomain case without convection, one obtains the best accuracy when the intermediate subdomain almost completely overlaps the inner and outer subdomains. Therefore, the convergence rate of the method is still good; two or three iterations suffice, but the efficiency of the algorithm is less clear. We did not obtain an advantage over the previous two-subdomain strategy except that the inner and outer subdomain computations are decoupled. Numerically, the best position for the interfaces occurs when the accuracy in each subdomain is of the same order as it should be.

   We observed that one can get very good accuracy in the maximum norm on the composite grid when there is no representation of the solution in the layer—that is, when no discretization points are present in the layer. Hence, it is valuable to use any a priori knowledge of the existing layers given by the asymptotic analysis, and not only an adaptive scheme.
3. For the convective case ($\beta \neq 0$), we tested the Schwarz alternating procedure with a one-sided first-order difference scheme, as well as a centered second-order finite difference scheme. The adaptive domain decomposition renders the centered finite difference scheme very effective. The interface position is in agreement with the asymptotic analysis; see Tables 2 and 3.

   Again, because of the singular perturbation nature of the problem, the Schwarz alternating procedure converges in a few iterations, even with a minimum overlap ($b - a = h_1$) in the two-subdomain case, so the Schwarz method is still more efficient than a straightforward method with one domain and a regular mesh for the solution of a layer.

   Again, we observed numerically that the addition of more subdomains does not result in an improvement of the method.

3. Adaptive domain decomposition. One can have an accurate representation of the solution in the inner layer with three overlapping subdomains, two outer subdomains on each side of the inner layer, and one inner subdomain to solve the layer. For example, let $\Omega = [-1, 1]$ be the computational domain and S the location of an inner layer. By applying the previous asymptotic analysis for boundary layers on each of the subdomains $\Omega_l = [-1, S]$ and $\Omega_r = [S, 1]$, one obtains the best interface positions to solve the inner layer. In this section, we consider the following turning-point problem:

TABLE 2

Error in the maximum norm and number of iterations with two subdomains for the operator $-\varepsilon u'' + \beta u' + \gamma u$ and a decentered scheme (backward). $-\varepsilon u'' + \beta u' + \gamma u = f$ with $\beta = 1$, $\gamma = -0.5$, two subdomains with $N = 12$ and $\varepsilon = 0.02$ (one-sided scheme).

$$\varepsilon \frac{d^2}{dx^2} u + x^{\gamma} \frac{d}{dx} u = f, \quad u(-1) = 1, \quad u(1) = -1,$$

where γ is an odd integer. This turning-point problem has an inner layer at $S = 0$, and we alternate the computation on the outer domains $\Omega_1 = [-1, -b]$ and $\Omega_3 = [b, 1]$ with the computation on the overlapping subdomain $\Omega_2 = [-a, a]$. The thickness of the transition layer is $\varepsilon^{1/(\gamma+1)}$, and there exists a corrector that vanishes exponentially outside the layer. Therefore, we must choose $b \approx \varepsilon^{1/(\gamma+1)} \log(\varepsilon^{-1})$. Since the coefficient of the convection term is small in the overlap area,

$$\beta(x) = x^{\gamma} \approx \varepsilon^{\gamma/(\gamma+1)} \log(\varepsilon) \text{ on } (b, a) \text{ and } (-a, -b),$$

the convergence rate of the Schwarz alternating procedure defined below is better than stated in Lemmas 5 and 6.

We use a one-sided first-order finite difference approximation of $x^{\gamma} du/dx$, oriented depending on the sign of x. For the interval [0, 1] we obtain the following result. Let $\delta \succ\succ 1$ and $N \sim \varepsilon^{-1/(\gamma+1)}/\delta$. Then

$$\zeta_{\leftarrow} \sim 1, \quad \zeta_{\rightarrow} \sim (C\delta \log(\varepsilon^{-1}))^{-k_0}.$$

A similar result holds for the interval $[-1, 0]$.

Our numerical experiments confirm that we get the best numerical accuracy with a minimum overlap, $b - a = h_1 = h_3$, a ratio h_1/h_2 in agreement with the asymptotic analysis, and few iterations. In our experiments, we used various values of γ to vary the thickness of the layer.

The main problem with inner layers is that the asymptotic analysis gives only a rough estimate of their location. We propose an adaptive Schwarz procedure to refine the location of the layers based on the following procedure.

We start with a given domain decomposition based on a rough localization of the layer. During the iteration process of the Schwarz procedure, we let the interfaces of the subdomains evolve according to the equilibrium principle of the numerical error in each subdomain. This criterion has been shown in Lemmas 1–3 to give the best interface position. We measure the error in each subdomain based on a numerical approximation of

$$E_1 = Ch_1^n \max\left(\frac{d^{n_1+p_1}}{dx^{n_1+p_1}}u\right) \text{ for } \Omega_1 = [-1, b_-],$$

$$E_3 = Ch_3^n \max\left(\frac{d^{n_3+p_3}}{dx^{n_3+p_3}}u\right) \text{ for } \Omega_3 = [b_+, 0],$$

$$E_2 = C(a_+ - a_-)^{q_2} h_2^n \max\left(\frac{d^{n_2+p_2}}{dx^{n_2+p_2}}u\right) \text{ for } \Omega_2 = [a_-, a_+],$$

where p_i, n_i, and q_i depend on the discretization of the operator in the corresponding subdomain. It is convenient to use the fact that the numerical error in the outer domains is dominated by the error at the endpoint $b_\pm$.

We have implemented this adaptive procedure on this turning-point problem with $\gamma = 1$. We still restrict ourselves to letting the subgrids coincide at their endpoints and need to interpolate the solution on the new subgrids for each displacement of the interfaces. We use a decentered first-order finite difference scheme in the outer domains and a second-order centered difference scheme in the inner subdomain. Figure 2e shows the evolution of the interfaces during the adaptivity process. The initial position of the interfaces gives the solution plotted in Figure 2a; then our adaptivity criterion gives the sequence of the solutions plotted in Figure 2b, 2c, 2d, and, finally, 2c. For the solution plotted in Figure 2c, the numerical error in each subdomain balances. We observe that the limit of the interface position is in agreement with the asymptotic analysis.

Our measure of the error in each subdomain is relatively rough and a further step in this research is to use a posteriori local estimates to drive the adaptivity of the interface positions.

Remark 5. Suppose that we use a finite difference scheme that satisfies a maximum principle inside each subdomain. We observe that the evolution of the interfaces does not necessarily slow down the speed of convergence of the Schwarz procedure when, for example, a subdomain Ω_i shrinks *and* when the measure of its overlap with the subdomains Ω_{i-1} and Ω_{i+1} stays the same.

4. ADI and domain decomposition for the two-dimensional problem. We consider the following two-dimensional turning-point problem, P_ε:

$$L[u] = \varepsilon^2 \Delta u + a(x, y)\frac{\partial u}{\partial x} = 0 \text{ in } \Omega = (-2, 2) \times (-1, 1),$$

$$u(-2, y) = 1, u(2, y) = -1, \ y \in [-1, 1], \tag{4.25}$$

$$\frac{\partial u}{\partial y}(x, \pm 1) = 0, \ x \in [-2, 2],$$

(e)

FIG. 2. *Turning-point problem in one space dimension.*

where

$$a(x, y) = \begin{cases} x & \text{for } y < 0\,, \\ x - y & \text{for } y > 0\,. \end{cases}$$

Let $S(y)$ be the curve parameterized by y, such that

$$x = S(y) \Leftrightarrow a(x, y) = 0.$$

An asymptotic analysis shows that $u = 1 + o(1)$ $(u = -1 + o(1))$ to the left (right) of a transition layer centered at S. Also, the thickness of this layer is of the order of ε.

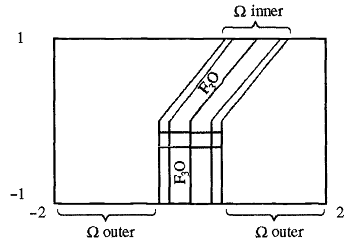

FIG. 3. *Turning-point problem in two space dimensions.*

We have tested the Schwarz alternating procedure on this turning-point problem in two space dimensions. The numerical challenge is to solve an inner layer centered on a curve that is not smooth. Inner layers are characteristic of so-called frontal processes; examples are combustion fronts, polymerization fronts, and reactive shock layers. These problems are truly nonlinear, and it is well known that even a linear turning-point problem is numerically difficult to solve [31].

Let Ω^h be a regular two-dimensional grid of mesh size h. We first solve P_{ε_0} approximately on the grid Ω^h with $\varepsilon = \varepsilon_0$, such that $1 \succ\succ \varepsilon_0 \succ\succ h$. Our goal is to solve P_ε with $\varepsilon \prec\prec h$. We then use this solution as an initial guess for the Schwarz alternating procedure.

To discretize the operator, we use a second-order centered finite difference approximation of the second-order derivatives and a one-sided finite difference approximation of $a(x, y)\partial u/\partial x$ that depends on the sign of $a(x, y)$ as usual. We choose a very simple discretization, as we only want to test the Schwarz alternating procedure. To have an accurate representation of the transition layer, we introduce the following domain decomposition:

$$\Omega^{\text{outer}}_{\text{west}} = \{M(x, y) \in \Omega,\ |x - S(y)| \geq (d-1)h, x - S(y) < 0\},$$

$$\Omega^{\text{outer}}_{\text{east}} = \{M(x, y) \in \Omega,\ |x - S(y)| \geq (d-1)h, x - S(y) > 0\},$$

$$\Omega^{\text{inner}}_{\text{north}} = \{M(x, y) \in \Omega,\ |x - S(y)| \leq dh, y > -dh\},$$

$$\Omega^{\text{inner}}_{\text{south}} = \{M(x, y) \in \Omega,\ |x - S(y)| \leq dh, y < -(d-1)h\},$$

where d is a fixed positive integer. To demonstrate the efficiency of the Schwarz alternating procedure in the worst possible case, we assume a minimum overlap between the subdomains; see Figure 3.

A standard asymptotic argument shows that we have a two-dimensional layer in a neighborhood Ω^* of the corner point (0, 0) of S. One needs to stretch *both* variables x and y to solve this internal layer; $\hat{x} = x/\varepsilon$ and $\hat{y} = y/\varepsilon$ are the inner variables. Outside Ω^*, the transition layer is really a one-dimensional phenomenon, and one needs to stretch only the layer in the direction normal to the front. For example, in $\Omega^{\text{inner}}_{\text{south}}$, the inner variables are $(\hat{x}, y)$.

Globally, the transition layer is of thickness ε in the x-direction for $y \in (-1, 1)$, and there exists a corrector to the transition layer that vanishes exponentially outside the layer, so we take $dh = O(\varepsilon \log \varepsilon^{-1})$.

To simplify the implementation, we extended the subdomain that solves the inner layer in the neighborhood of (0, 0) to $\Omega^{\text{inner}}_{\text{north}}$ with the same stretching for both variables.

The discretization grid for the inner problems are refinements of the global rough grid. In $\Omega^{\text{inner}}_{\text{south}}$, we use a regular grid of step $\hat{h} = h\varepsilon$ in the x-direction and h in the y-direction. In $\Omega^{\text{inner}}_{\text{north}}$, we use a regular grid of step $\hat{h} = h\varepsilon$ in both directions x and y.

We are going to use a strip domain decomposition at each stage of the algorithm in order to keep the same convergence properties as in the one-dimensional case. The numerical algorithm is the following (we do not repeat the boundary conditions on $\partial\Omega$):

While $\|u^{p+1} - u^p\|_\Omega \prec \text{tol}$,

- solve the outer problems (eventually in parallel),

$$L[u_{\text{outer}}^{\text{west},p+1}] = 0 \text{ in } \Omega_{\text{outer}}^{\text{west}},$$

$$u_{\text{outer}}^{\text{west},p+1} = u_{\text{inner}}^{p} \text{ on } \Gamma_{\text{west}} = \{(S(y) - (d-1)h, y), y \in [-1,1]\},$$

$$L[u_{\text{outer}}^{\text{east},p+1}] = 0 \text{ in } \Omega_{\text{outer}}^{\text{east}},$$

$$u_{\text{outer}}^{\text{east},p+1} = u_{\text{inner}}^{p} \text{ on } \Gamma_{\text{east}} = \{(S(y) - (d-1)h, y), y \in [-1,1]\};$$

- solve the inner problem (P_{inner}),

$$L[u_{\text{inner}}^{p+1}] = 0 \text{ in } \Omega_{\text{inner}} = \Omega_{\text{south}}^{\text{inner}} \cup \Omega_{\text{north}}^{\text{inner}},$$

$$u_{\text{inner}}^{p+1} = u_{\text{outer}}^{\text{west},p+1} \text{ on } \Gamma_{\text{west}}^{*} = \{(S(y) - dh, y), y \in [-1,1]\},$$

$$u_{\text{inner}}^{p+1} = u_{\text{outer}}^{\text{est},p+1} \text{ on } \Gamma_{\text{est}}^{*} = \{(S(y) + dh, y), y \in [-1,1]\};$$

- define u^{p+1} by

$$u^{p+1} = \begin{cases} u_{\text{outer}}^{p+1} & \text{in } \Omega_{\text{outer}} \backslash \Omega_{\text{inner}}, \\ u_{\text{inner}}^{p+1} & \text{in } \Omega_{\text{inner}}. \end{cases}$$

end while.

To solve the inner problem (P_{inner}), we use a second Schwarz alternating procedure inside the previous loop.

While $\|u_{\text{inner}}^{p,q+1} - u_{\text{inner}}^{p,q}\| \leq \text{tol}$,

- solve the south inner problem,

$$L[u_{\text{inner}}^{\text{south},p,q+1}] = 0 \text{ in } \Omega_{\text{south}}^{\text{inner}},$$

$$u_{\text{inner}}^{\text{south},p,q+1} = u_{\text{inner}}^{\text{north},p,q} \text{ on } \Gamma = \{(x, -(d-1)h), x \in [-dh, dh]\};$$

- solve the north inner problem,

$$L[u_{\text{inner}}^{\text{north},p,q+1}] = 0 \text{ in } \Omega_{\text{north}}^{\text{inner}},$$

$$u_{\text{inner}}^{\text{north},p,q+1} = u_{\text{inner}}^{\text{south},p,q+1} \text{ on } \Gamma = \{(x, -dh), x \in [-dh, dh]\};$$

- define $u_{\text{inner}}^{p,q+1}$ by

$$u_{\text{inner}}^{p,q+1} = \begin{cases} u_{\text{inner}}^{\text{south},p,q+1} & \text{in } \Omega_{\text{south}}^{\text{inner}} \backslash \Omega_{\text{north}}^{\text{inner}}, \\ u_{\text{inner}}^{\text{north},p,q+1} & \text{in } \Omega_{\text{north}}^{\text{inner}}. \end{cases}$$

end while.

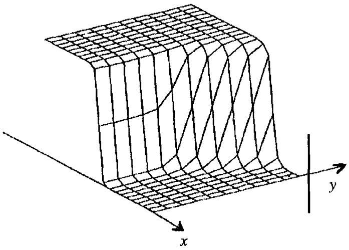

FIG. 4. *Domain decomposition.* $\varepsilon^2 \Delta u + F(x, y) u_x = 0$. *Solution projected on the rough grid.*

Let u^p_{inner} be the result of the last computation of this second Schwarz alternating procedure. The initial guess for $u^{p,0}_{\text{inner}}$ is obviously u^{p-1}_{inner}. Therefore, as the first Schwarz alternating procedure proceeds, the inner loop of the second Schwarz alternating procedure takes fewer and fewer iterations to converge.

To complete the description of this algorithm, we give the following details. We solved each subproblem with an ADI method [10]. This method has at least four advantages:

- It is a nice way to get an efficient massively parallel algorithm. We really need a powerful computer, as frontal processes are computationally very intensive.
- It induces a weak coupling between the computations in each subdomain because it is an explicit scheme with respect to one of the space directions.
- It is an easy way to solve each subproblem with a nontrivial geometry. This is important because we need to adapt the shape of the inner domain according to the location of the layer.
- It is an iterative procedure. One can start the ADI iteration with the last-known subdomain solution. As the Schwarz iteration progresses, the number of ADI iterations required decreases. Also, we do not need to solve each subproblem very accurately at the beginning of the Schwarz iterations.

We observe that our domain decomposition and stretching in the inner subdomains make each subproblem nonstiff and suitable for an ADI solver.

Our numerical experiments were obtained with $\varepsilon = 10^{-1}$, $d = 2$, and $h = 5 \times 10^{-2}$. Thus, the refinement of the grid is $\hat{h} = h/10$; see Figures 4 and 5. The number of iterations for the loop that alternates the computation in the north and south inner domains was held fixed at two. The evolution of $\|u^{p+1} - u^p\|_\Omega$ as p increases shows that, above $p = 4$, $\|u^{p+1} - u^p\|_\Omega$ is dominated by the discretization error; see Figure 6. Therefore, this experiment confirms that the Schwarz alternating procedure converges in a few iterations, as in the one-dimensional case.

We intend to implement these ideas for arbitrarily shaped curves S and local coordinate systems that stretch only the *normal component* of S.

5. Nonlinear combustion problem. So far, we have shown the efficiency of the Schwarz alternating procedure for linear second-order singular perturbation problems whose formal limit as $\varepsilon \rightarrow 0$ is a zero- or first-order operator. Now, we illustrate the domain decomposition method for a nonlinear singular perturbation problem arising in combustion [2]. The problem involves two variables— θ, a scaled temperature, and C, a concentration of reactant, both functions of the polar coordinates r and ψ— and corresponds to a thermodiffusive model for a one-step Arrhenius reaction [25]. The equations satisfied by θ and C are

$$\theta_t = \theta_{rr} + \frac{1}{r^2}\theta_{\psi\psi} + (1 - K)\frac{\theta_r}{r} + A_r(\theta, C),$$

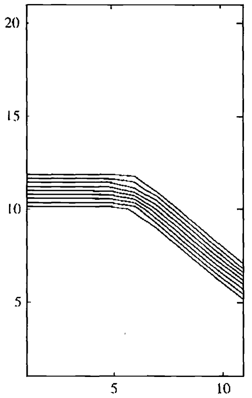

FIG. 5 *Solution in the inner layer.*

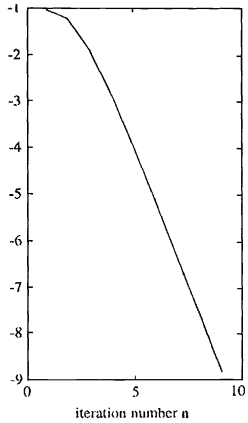

FIG. 6 *Convergence history.* $\log(u(n+1)-u(n))$.

$$C_t = \frac{1}{L}\left(C_{rr} + \frac{1}{r^2}C_{\psi\psi}\right) + \left(\frac{1}{L} - K\right)\frac{Cr}{r} - A_r(\theta, C),$$

where A_r is a nonlinear source term

$$A_r(\theta, C) = \beta C \exp\frac{N(1-\sigma)(\theta-1)}{\sigma+(1-\sigma)\theta}.$$

The parameters are L, the Lewis number; N, the (scaled) activation energy; and K, a measure for the strength of the fuel injection; furthermore, $\beta = M^2/2L$ and $M = N(1-\sigma)$. The parameters K and N are both supposed to be large.

Both θ and C are periodic functions of ψ. The boundary conditions satisfied by θ and C are

$$\theta \to 0,\ C \to 1 \text{ as } r \to 0; \quad \theta \to 1,\ C \to 0 \text{ as } r \to \infty.$$

For the computational domain we take $(r, \psi) \in (r_0, r_1) \times (0, 2\pi)$, where $0 < r_0 < r_1 < \infty$; r_0 is sufficiently small and r_1 is sufficiently large so that the boundary conditions can be replaced by the Dirichlet conditions

$$\theta(r_0, \psi) = 0,\ C(r_0, \psi) = 1; \quad \theta(r_1, \psi) = 1,\ C(r_1, \psi) = 0.$$

When $N \gg 1$, the flame is a thin layer, and the combustion problem is of singular perturbation type. The asymptotic analysis can be found in [25]. When $N \to \infty$ (infinite activation energy) and $L = 1$ (equal coefficients for mass and heat diffusion), the basic solution is given by

$$(5.26)\quad \theta(r,\psi) = (r/K)^K \text{ for } r \le K,\ \theta(r,\psi) = 1 \text{ for } r \ge K, \quad C(r,\psi) = 1 - \theta(r,\psi).$$

This solution represents a cylindrical combustion front.

For finite activation energies, θ and C are smooth functions which exhibit a transition layer of thickness $0(1/N)$. The transition layer is centered at $r = K$. The nonlinear source term $A_r(\theta, C)$ vanishes exponentially outside the layer. When $L < 1$, the cylindrical combustion front becomes unstable, and a cellular flame appears [25]. Moreover, the location of the front is a perturbation of K.

To compute the combustion front accurately, we use a three-subdomain strategy. We assume that the combustion front corresponds to the curve $r = S(\psi)$, $\psi \in (0, 2\pi)$, such that $A_r(S(\psi), \psi) = \max_{r\in(r_0,r_1)} A_r(r, \psi)$.

A Hopf bifurcation occurs when the Lewis number L reaches a critical value $L_0 < 1$. When L is not too far from L_0, the amplitude of the cells of the combustion front is small compared with the size of the domain, so we assume

$$\max_{\psi} S - \min_{\psi} S \ll r_1 - r_0$$

and use a strip domain decomposition technique. Let Ω_l^{outer}, Ω^{inner}, and Ω_r^{outer} be the subdomains. We impose a minimum overlap between the outer and inner domains. We notice that the Schwarz alternating procedure applied to the time-dependent problem converges rather well for small time steps, but we want to illustrate two other possible advantages of the domain decomposition to solve the combustion front.

5.1. Large activation energy. Because $N \gg 1$, the source term A_r vanishes exponentially outside the neighborhood of the combustion front. In fact, the location of the transition layer corresponds to the zone where the source term is strictly of order one. Therefore, the right boundary P of Ω_l^{outer} and the left boundary G of Ω_r^{outer} can be chosen *adaptively*, based on the asymptotic criterion

$$\max_{\Omega_l, \Omega_r} A_r < \text{tol}, \tag{5.27}$$

where tol is a very small tolerance number fixed in advance.

We use the following semi-implicit scheme in the left outer domain:

$$L[\theta^{n+1}] = \theta^n + \Delta t \ A_r(\theta^n, C^n) \text{ in } \Omega_{\text{left}}^{\text{outer}}, \tag{5.28}$$

$$L[C^{n+1}] = C^n - \Delta t \ A_r(\theta^n, C^n) \text{ in } \Omega_{\text{left}}^{\text{outer}}, \tag{5.29}$$

$$\theta^{n+1}(r_0, \psi) = 0, \quad C^{n+1}(r_0, \psi) = 1, \qquad \psi \in (0, 2\pi),$$

$$\theta^{n+1}(P, \psi) = \theta^{\text{inner}}(P, \psi), \qquad C^{n+1}(P, \psi) = C^{\text{inner}}(P, \psi).$$

Here, L is the operator

$$L[\theta] = \theta - \Delta t \left(\theta_{rr} + \frac{1}{r^2}\theta_{\psi,\psi} + (1 - K)\frac{\theta r}{r} \right),$$

and θ^{n+1} and C^{n+1} are periodic in ψ. The values θ^{inner} and C^{inner} are given artificial boundary conditions.

Since L satisfies a maximum principle, we can estimate the influence of the source term A_r,

$$\|\theta^{n+1} - \theta_0\|_\infty \le C\Delta t \|A_r\|_\infty, \qquad \|C^{n+1} - C_0\|_\infty \le C\Delta t \|A_r\|_\infty,$$

where (θ_0, C_0) is the solution when $A_r = 0$. Hence, if tol in (5.27) is small enough, the explicit treatment of the nonlinear source terms in the outer domains is justified [15]. In fact, we may choose not to compute these source terms at every time step, or simply neglect them altogether in the outer domains. In any case, the equations for the temperature (5.28) and for the concentration (5.29) can be solved in parallel.

It is well known that the computation of the flame front is very sensitive to the accuracy of the scheme. Since we have a strong interaction between the diffusion process and the nonlinear reaction term A_r *only* in the neighborhood of the combustion front, we need to use a highly accurate scheme in the transition layer; on the contrary, a less accurate scheme may be good enough in the outer domains where $\max_{\Omega_l,\Omega_r} A_r < \text{tol}$.

5.2. Strong fuel injection. As $K \gg 1$, r is large in the neighborhood of the combustion front. When the combustion front $r = S(\psi)$ is a smooth curve, we have

$$\frac{1}{r^2}\theta_{\psi\psi} \prec\prec \theta_{rr} \text{ on } \Omega^{\text{inner}}. \tag{5.30}$$

This asymptotic behavior makes the use of an explicit scheme with respect to the angle dependence very attractive. We therefore consider the following scheme:

$$\hat{L}[\theta^{n+1}] = \theta^n + \Delta t\left(\frac{1}{r^2}\theta^n_{\psi\psi} + A_r(\theta^n, C^n)\right) \text{ on } \Omega^{\text{inner}}, \tag{5.31}$$

$$\hat{L}[C^{n+1}] = C^n + \Delta t\left(\frac{1}{r^2}C^n_{\psi\psi} - A_r(\theta^n, C^n)\right) \text{ on } \Omega^{\text{inner}}. \tag{5.32}$$

The penalty on the time step is moderated by the relation (5.30). Also, equations (5.31) and (5.32) represent a parallel scheme for the most intensive part of the computation, that is, in the transition layer. One can map a ring of processors to the set of equations (5.31) and (5.32) for $\psi \in \{\psi_i = 2\pi i/n : i = 0, \dots, n\}$ [8].

We have implemented the Schwarz alternating procedure with moving interfaces to solve a steady flame with the parameter values $N = 20$, $\sigma = 0.615$, $K = 14.8$. The domain of computation was $(1, 41) \times (0, 2\pi)$. The ratio of the space step for the radial direction in the outer and inner domain was N, equal to the asymptotic thickness of the layer.

Figure 7 shows the solution $(\theta, C, A_r(\theta, C))$ and the convergence history for decreasing values of the Lewis number L in the one-dimensional case. The combustion front moves slowly on the left as the Lewis number goes from $L = 1$ to $L = 0.7$. We used an iteration analogous to (5.31) and (5.32) to solve each subproblem of the Schwarz alternating procedure but with a domain-dependent relaxation factor. The nonlinear terms were solved explicitly in the scheme, but since most of the convergence process occurs in the transition layer, it might be valuable to use a Newton-like scheme in the inner subdomain to take a larger time step.

The convergence of the Schwarz iteration is very sensitive to the position of the left boundary of the inner domain and is improving as the left boundary moves on the left; see Figure 8. This can be explained in the following way: as the left boundary of the inner domain moves on the left, the convection factor $(K - 1)/r$ is getting larger in the overlap zone with the left outer domain and the operator becomes convection dominant. This is in agreement with the result of §2.2.1 and can be proved, for example, with the linearized operator for this domain decomposition. We recall that we keep the overlap to be only one cell of the rough grid.

Finally, when we cut off the source term $A_r(\theta, C)$ in the outer domains, this numerical experiment shows that the error is less than the numerical accuracy of the discretization with this domain decomposition.

In the two-dimensional case, we simply incorporated the explicit dependence of the second-order derivative with respect to the angle ψ in the scheme and used a fourth-order finite difference scheme for $\theta_{\psi\psi}$ and $C_{\psi\psi}$ in the transition layer. For convenience and in order to compute a more interesting case, we have computed a cellular flame for a *two step chemistry*. We consider the model of Pelaez and Linan [28]. We have compared our result to the numerical result using adaptive pseudospectral method for the case where the first Lewis number is $L_1 = 0.37$ and the second Lewis number is $L_2 = 0.9$. The heat release of the first reaction is 0.85. So the second chemical reaction gives a rather weak front, and the stiff front is mainly due to the first chemical reaction. For both reactions the activation energy is equal to 20. Figure 9 shows a representation of this cellular flame. Since the front is stiff mainly in the radial direction, we used the same number of discretization points, $\{\psi_i : i = 1, \dots, n\}$,

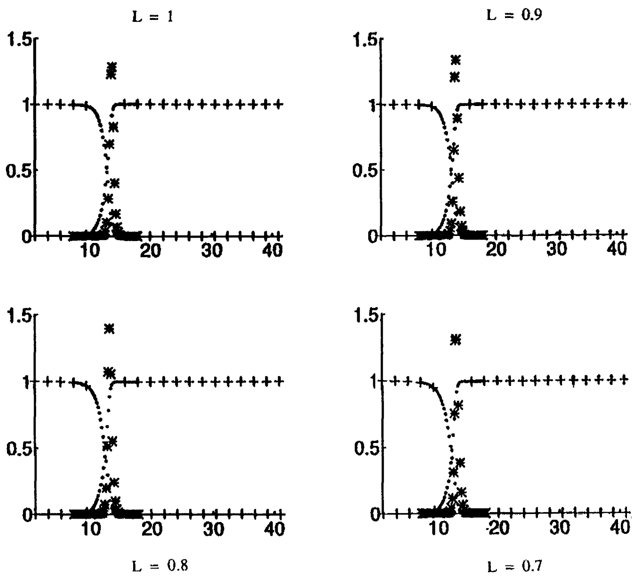

FIG. 7. *Combustion problem in one space dimension for different values of the Lewis number. * temperature, concentration, and Arrhenius term.*

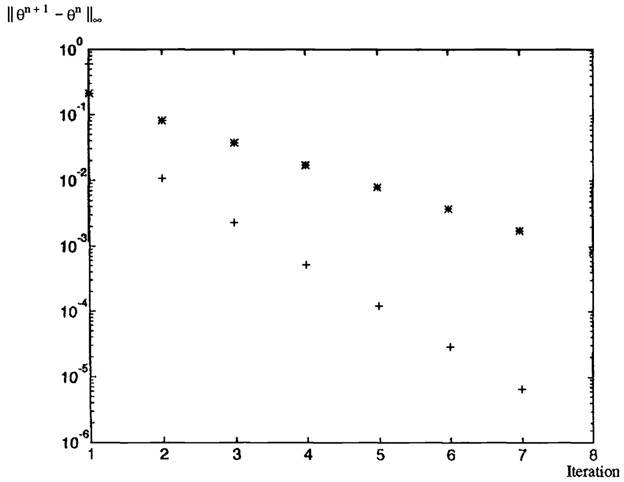

FIG. 8. *Combustion problem in one space dimension for different values of the Lewis number. * left interface of Ω inner at $x = 7.3$. + left interface of Ω inner at $x = 5.2$.*

for each subdomain with $n = 64$. We have used 20 discretization points in the radial direction for the rough grid, and the ratio of the space step for the radial direction in the outer and inner domain is equal to the activation energy.

We found good global agreement between the Schwarz procedure and the pseudospectral method of [2] but did not compute a very difficult case with $L_1 < 0.37$. More precisely, we have compared an adaptive domain decomposition with the pseudospectral method using 80 Chebyshev collocation points in the radial directions and 64 Fourier discretization points in the angular direction with the Schwarz procedure described above. We believe that the pseudospectral method is more accurate and we observe that the difference between the two solutions is of order 10^{-2} on the rough grid in the maximum norm.

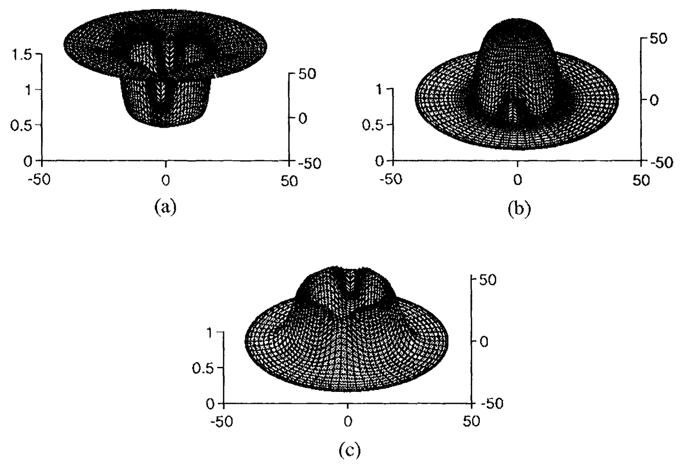

FIG. 9. *A cellular flame with two-step Arrhenius kinetics.* (*a*) *Temperature* ($L1 = 0.37$; $L2 = 0.90$). (*b*) *Concentration of the first species* ($L1 = 0.37$; $L2 = 0.90$). (*c*) *Concentration of the second species* ($L1 = 0.37$; $L2 = 0.90$).

Since the cost of the computation with the Schwarz alternating procedure is very cheap compared with the cost of computation of the adaptive pseudospectral domain decomposition, we expect that this new technique may be helpful to compute stationary cellular flame in three space dimensions. Also, an efficient implementation of this algorithm on a massively parallel computer is easy.

Acknowledgments. The author is very grateful to H. G. Kaper for many interesting discussions and the referee for some valuable comments on this paper.

AN INVESTIGATION OF INTERIOR-POINT ALGORITHMS FOR THE LINEAR TRANSPORTATION PROBLEM*

L. PORTUGAL†, F. BASTOS‡, J. JÚDICE§, J. PAIXÃO¶, AND T. TERLAKY‖

Abstract. Recently, Resende and Veiga [*SIAM J. Optim.*, 3 (1993), pp. 516–537] proposed an efficient implementation of the dual affine (DA) interior-point algorithm for the solution of linear transportation models with integer costs and right-hand-side coefficients. This procedure incorporates a preconditioned conjugate gradient (PCG) method for solving the linear system that is required in each iteration of the DA algorithm. In this paper, we introduce an incomplete QR decomposition (IQRD) preconditioning for the PCG algorithm. Computational experience shows that the IQRD preconditioning is appropriate in this instance and is more efficient than the preconditioning introduced by Resende and Veiga. We also show that the primal dual (PD) and the predictor corrector (PC) interior-point algorithms can also be implemented by using the same type of technique. A comparison among these three algorithms is included and indicates that the PD and PC algorithms are more appropriate for the solution of transportation problems with well-scaled cost and right-hand-side coefficients and assignment problems with poorly scaled cost coefficients. On the other hand, the DA algorithm seems to be more efficient for assignment problems with well-scaled cost coefficients and transportation problems whose cost coefficients are badly scaled.

Key words. linear transportation models, interior-point algorithms, preconditioned conjugate gradient methods, large-scale problems

1. Introduction. Let $O = \{1, \dots, n\}$ and $D = \{1, \dots, m\}$ be the sets of origins and destinations of a product to be shipped. The transportation problem (TP) consists of finding the quantities x_{ij} that should be shipped from each origin $i \in O$ to each destination $j \in D$ in such a way that the total transportation cost is minimized. The TP problem is usually stated as the following linear program:

$$(1)\qquad \begin{aligned} &\min \sum_{i\in O}\sum_{j\in D} c_{ij}x_{ij} \\ &\text{subject to } \sum_{j\in D} x_{ij} = a_i, \qquad i \in O, \\ &\qquad\qquad \sum_{i\in O} x_{ij} = b_j, \qquad j \in D, \\ &\qquad\qquad x_{ij} \ge 0, \quad i \in O, \quad j \in D, \end{aligned}$$

where c_{ij} is the unitary transportation cost from the origin i to the destination j and a_i, b_j represent the quantities available in origin i and required at destination j, respectively. Transportation models have become quite popular during the past several years [32]. Many extensions of the TP problem have been mentioned in the literature. The assignment problem (AP) should be distinguished in this context, as it can be stated in the form (1) with $m = n$ and $a_i = b_j = 1$ for all i and j.

If we assume without loss of generality that $\sum_{i\in O} a_i = \sum_{j\in D} b_j$, the formulation (1) of the dense TP problem contains exactly one redundant constraint. By dropping this constraint (for instance, the last), we can write the TP problem in the form

$$\begin{aligned} &\min\ c^T x \\ &\text{subject to}\ \ Ax = d, \\ &\qquad\qquad\quad x \geq 0, \end{aligned} \tag{2}$$

where $d \in \mathbb{R}^{m+n-1}$, $x, c \in \mathbb{R}^{mn}$, and $A \in \mathbb{R}^{(m+n-1)\times(mn)}$ has full row rank.

After the introduction of slack variables, the dual of the TP problem (2) can be stated as

$$\begin{aligned} &\max\ d^T y \\ &\text{subject to}\ \ A^T y + s = c, \\ &\qquad\qquad\quad s \geq 0, \end{aligned} \tag{3}$$

where $y \in \mathbb{R}^{n+m-1}$ and $s \in \mathbb{R}^{mn}$.

We note for completeness that a primal feasible solution x is called an *interior point* of the primal problem if $x > 0$, and a dual feasible solution (y, s) is called an *interior point* of the dual problem if $s > 0$.

It is well known that the TP problem can be seen as a minimum-cost network flow problem on a bipartite connected graph [32]. Furthermore, there exists a one-to-one correspondence between basic solutions of the TP problem (2) and spanning trees of this graph. Based on these facts, Resende and Veiga [35, 34] developed an efficient implementation of the dual affine (DA) interior-point algorithm [8] for the solution of large-scale TP problems where the vectors c and d have integer components. This procedure incorporates a preconditioned conjugate gradient (PCG) algorithm [9] to find the ascent direction that is required in each iteration of the DA algorithm.

Resende and Veiga [35, 34] proposed and tested a diagonal and a maximum spanning tree (MST) preconditioning to the PCG algorithm. Extensive computational experience has shown that the diagonal preconditioning is recommended in the very first iterations of the DA algorithm. Then, the MST preconditioning should be used until the end. Because of this observation, they proposed a switch from one preconditioning to the other in the first iterations of the DA algorithm. This type of implementation has worked in practice and seems to be competitive with more traditional techniques that have been designed for the solution of large-scale TP problems [35].

Despite these benefits, the implementation suffers from two drawbacks. First, both preconditionings lose effectiveness during the intermediate iterations of the DA algorithm. Furthermore, the switching point is not known in advance, hence this change can be made earlier or later than desirable.

In this paper we propose an incomplete QR decomposition (IQRD) preconditioning with the objective of overcoming these two drawbacks. Computational experience presented in this paper shows that this technique is, in general, superior to the procedure introduced by Resende and Veiga. Furthermore, we also develop an implementation of the same type for the primal dual (PD) [29, 30, 26] and predictor corrector (PC) [23, 27, 7] interior-point algorithms. A comparative study of these three methods on large-scale TP and AP problems is also presented. This study indicates that the PD and PC algorithms are more appropriate for the solution of TP problems with well-scaled cost and right-hand-side coefficients and assignment problems with poorly scaled cost coefficients. On the other hand, the DA algorithm seems to be more efficient for AP problems with well-scaled cost coefficients and transportation problems whose cost coefficients are badly scaled. The PC algorithm usually takes a smaller number of iterations than the remaining techniques. However, the need of solving two linear systems in each iteration and the use of an iterative method for this purpose renders the PC algorithm, in many cases, less appropriate than the PD method for TP and AP problems.

The paper is organized as follows. Section 2 contains a short description of the DA, PD, and PC interior-point algorithms. Implementation issues are discussed in §3. Finally, the computational experience is described in the last section of the paper.

2. Interior-point algorithms. Since Karmarkar [15] in 1984 presented his polynomial time algorithm for linear programming, hundreds of papers have been published in the field of interior-point methods (see [20] for references). Now, it is, in general, accepted that interior-point methods are strong competitors of the simplex method in solving practical problems and are, in many cases, more efficient for large-scale problems [6, 21, 22, 24]. It is beyond the scope of this paper to discuss and classify the literature of interior-point methods. In this section we restrict ourselves to briefly describing the three interior-point algorithms (the DA scaling, the PD, and the PC) considered in this paper. We include some additional references for the interested reader.

2.1. DA-scaling algorithm. The affine-scaling algorithm [8, 5, 36, 37] was the first interior-point algorithm shown to be competitive [1, 3] with the simplex method for the solution of large-scale linear programs. The dual form of this method was first introduced by Adler et al. [3], and is the more computationally suitable form of the affine-scaling algorithm. The DA method finds an optimal solution by solving the linear program in the standard dual form (3). Having a dual interior starting point, the DA method can be formally presented as follows.

```
DA ALGORITHM.
Given $y^0 \in \{y : A^T y < c\}$, $\delta \in ]0, 1[$,
set $k = 0$.
Repeat
    $s^k = c - A^T y^k.$
    $S_k = \mathrm{diag}(s_1^k, \ldots, s_{mn}^k).$
    $\Delta y = (A S_k^{-2} A^T)^{-1} d.$
    $\Delta s = -A^T \Delta y.$
    $\lambda = \min_{i=1,\ldots,mn}\{-s_i^k/\Delta s_i : \Delta s_i < 0\}.$
    $y^{k+1} = y^k + \delta\lambda\Delta y.$
    $x^{k+1} = -S_k^{-2}\Delta s.$
    $k = k + 1.$
until stopping criterion is verified.
```

The parameter δ is used to guarantee that, in each iteration, y^{k+1} is in the interior of the dual feasible region. The DA algorithm is believed not to be polynomial [2] and its convergence (and the convergence of the primal estimates) depends on the parameter δ. Although it has been shown that δ should be chosen smaller than .66 for good theoretical properties [31, 11], we follow the suggestion of many authors [1, 3, 25, 28] to use $\delta = 0.95$ at every iteration.

2.2. PD algorithm. The so-called PD interior-point methods currently enjoy the most popularity [24]. They were first introduced as path-following methods [18, 29], but they have been extended to potential reduction and logarithmic barrier approaches [19] that are more practical. However, depending on the step size, they still have a bound of $O(\sqrt{n}L)$ and $O(nL)$ iterations (see, also, [12, 30, 26]).

As their name indicates, the PD algorithms operate simultaneously on the primal (2) and the dual (3) problems. Having an initial PD interior-point pair, the search direction in these methods is given as the Newton direction associated with the following asymmetric system of equations that defines the so-called central path:

$$\begin{aligned} Ax &= d, & x &\geq 0, \\ A^T y + s &= c, & s &\geq 0, \\ x_i s_i &= \mu & &\text{for all } i. \end{aligned}$$

The search direction can also be derived as a descent direction for the PD logarithmic barrier function.

As usual, the practical implementation of the PD algorithm slightly differs from the theoretical polynomial variant. The main differences between these two versions rely on the updating of the parameter μ and on the selection of the step sizes (α_p, α_d). If a primal and dual interior starting point is at hand, the practical version of the PD method may be stated in the following form.

```
PD ALGORITHM.
Given $(x^0, y^0, s^0) \in \{(x, y, s) : A^T x = d,\ A^T y + s = c,\ x > 0,\ s > 0\}$, $\delta \in ]0, 1[$,
set $k = 0$.
**Repeat**
    $\mu = (c^T x^k - d^T y^k)/10mn = (x^k)^T s^k/10mn.$
    $X_k = \text{diag}(x_1^k, \dots, x_{mn}^k)$ and $S_k = \text{diag}(s_1^k, \dots, s_{mn}^k).$
    $\Delta y = -(A S_k^{-1} X_k A^T)^{-1} A S_k^{-1}(X_k S_k e - \mu e).$
    $\Delta s = -A^T \Delta y$ and $\Delta x = S_k^{-1}(X_k S_k e - \mu e) - S_k^{-1} X_k \Delta s.$
    $(\alpha_p, \alpha_d) = (\min_{\alpha_i > 0}(x_i - \alpha_i \Delta x_i \geq 0), \min_{\alpha_i > 0}(s_i - \alpha_i \Delta s_i \geq 0)).$
    $x^{k+1} = x^k - \delta\alpha_p \Delta x$, $y^{k+1} = y^k - \delta\alpha_d \Delta y$ and $s^{k+1} = s^k - \delta\alpha_d \Delta s.$
    $k = k + 1.$
**until** stopping criterion is verified.
```

As before, the parameter δ is introduced to assure that $(x^{k+1}, y^{k+1}, s^{k+1}) \in \{(x, y, s) : A^T x = d,\ A^T y + s = c,\ x > 0,\ s > 0\}$. The value $\delta = 0.99995$ has been suggested in the literature [23] and we have followed this recommendation in our experiments. In our implementation we use different step sizes (α_p, α_d) in the primal and dual space, although the use of such parameters is, theoretically, not fully justified yet.

2.3. PC algorithm. The PC algorithm [23, 27] is a technique that has been designed to improve the numerical efficiency of the PD algorithm. In each iteration a descent direction is found by a two-step procedure. In the first step the direction $(\Delta x, \Delta y, \Delta s)$ is computed as in the PD algorithm with $\mu = 0$ (this direction is the so-called PD affine-scaling direction [30]). This direction is used to obtain the value of the so-called barrier parameter μ. The corrector direction $(\Delta x^c, \Delta y^c, \Delta s^c)$ is then computed as a function of this parameter μ. The steps of the PC algorithm are stated below.

```
PC ALGORITHM.
Given $(x^0, y^0, s^0) \in \{(x, y, s) : A^T x = d,\ A^T y + s = c,\ x > 0,\ s > 0\}$, $\delta \in ]0, 1[$,
set $k = 0$.
Repeat
    $X_k = \mathrm{diag}(x_1^k, \ldots, x_{mn}^k)$ and $S_k = \mathrm{diag}(s_1^k, \ldots, s_{mn}^k)$.
    $\Delta y = -(A S_k^{-1} X_k A^T)^{-1} d$.
    $\Delta s = -A^T \Delta y$ and $\Delta x = X_k e - S_k^{-1} X_k \Delta s$.
    $(\alpha_p, \alpha_d) = (\min_{\alpha_i > 0}(x_i - \alpha_i \Delta x_i \geq 0), \min_{\alpha_i > 0}(s_i - \alpha_i \Delta s_i \geq 0))$.
    $\hat{g} = (x - \delta \alpha_p \Delta x)^T (s - \delta \alpha_d \Delta s)$.
    compute $\mu$.
    $\Delta y^c = -(A S_k^{-1} X_k A^T)^{-1} A S_k^{-1} (X_k S_k e - \mu e + \Delta x \Delta s)$.
    $\Delta s^c = -A^T \Delta y^c$ and $\Delta x^c = S_k^{-1}(X_k S_k e - \mu e + \Delta x \Delta s) - S_k^{-1} X_k \Delta s^c$.
    $(\alpha_p, \alpha_d) = (\min_{\alpha_i > 0}(x_i - \alpha_i \Delta x_i{}^c \geq 0), \min_{\alpha_i > 0}(s_i - \alpha_i \Delta s_i{}^c \geq 0))$.
    $x^{k+1} = x^k - \delta \alpha_p \Delta x^c$, $y^{k+1} = y^k - \delta \alpha_d \Delta y^c$ and $s^{k+1} = s^k - \delta \alpha_d \Delta s^c$.
    $k = k + 1$.
until stopping criterion is verified.
```

As in the PD algorithm we use $\delta = 0.99995$ in the implementation of the PC algorithm. According to the recommendations stated in [7], the parameter μ is chosen in the following adaptive way:

$$\mu = \begin{cases} \frac{\hat{g}^3}{mn((x^k)^T s^k)^2} & \text{if } (x^k)^T s^k \geq 1 \\ \frac{(x^k)^T s^k}{\psi(mn)} & \text{if } (x^k)^T (s^k) < 1 \end{cases} \text{, where } \psi(mn) = \begin{cases} (mn)^2 & \text{if } mn \geq 5000 \\ (mn)^{\frac{3}{2}} & \text{if } mn < 5000. \end{cases}$$

The choice of the initial point and the stopping criterion are two important issues in interior-point techniques that have not been discussed yet. The second topic is addressed in the next section. By exploiting the special structure of the TP problem, it is easy to see that if $\alpha = \min\{c_{ij},\ i \in O,\ j \in D\}$, then

$$x_{ij} = \frac{a_i b_j}{\sum_{i \in O} a_i} \quad i \in O,\ j \in D \quad \text{and} \quad y_i = \frac{\alpha}{2} - 1,\ \ i = 1, \ldots, n + m - 1$$

lead to a primal feasible $x > 0$ interior solution and a dual feasible $s > 0$ interior solution. These solutions have been used as starting points in our implementations of the algorithms.

3. Implementation issues. In this section we discuss the implementation of the three algorithms introduced in the previous section for the solution of large-scale transportation problems. It follows from their descriptions that the main computational effort in each iteration relies on the solution of the linear system

$$AGA^T u = t, \tag{4}$$

where $G \in \mathbb{R}^{(mn) \times (mn)}$ and $t \in \mathbb{R}^{n+m-1}$ are defined below.

- $G = S_k^{-2}$ and $t = d$ in the algorithm DA.
- $G = S_k^{-1} X_k$ and $t = A S_k^{-1}(X_k S_k e - \mu e)$ in the algorithm PD.

- $G = S_k^{-1}X_k$ and $t = d$ in the algorithm PC (predictor phase).
- $G = S_k^{-1}X_k$ and $t = AS_k^{-1}(X_kS_ke - \mu e + \Delta x \Delta s)$ in the algorithm PC (corrector phase).

It is easy to see that the explicit computation of AGA^T leads to an almost dense matrix. So the use of a direct method for the solution of the system (4) is not appropriate when m and n are reasonably large. Since AGA^T is a symmetric positive definite matrix, A is sparse and G is diagonal, the PCG algorithm seems to be a good alternative for the solution of the system. In fact, this algorithm only requires sums and scalar products of vectors and matrix-by-vector products. Furthermore, this latter type of operation can be performed without the explicit computation of the matrix AGA^T. The choice of the preconditioning matrix M is the most important issue in the design of such an algorithm. A PCG algorithm for the solution of the system AGA^T is first discussed in this section. Then, we introduce an IQRD preconditioning technique that improves the iterative linear system solver.

3.1. The PCG method. This method attains to find the solution of the linear system $M^{-1}(AGA^T)u = M^{-1}t$, where M is the so-called preconditioning matrix. This matrix should be chosen in such a way that the condition number of $M^{-1}(AGA^T)$ is smaller than that of AGA^T. We discuss later how this matrix can be chosen for the particular instance of the system (4). The steps of the PCG algorithm are presented below.

PCG ALGORITHM.

```
$u^0 = M^{-1}t.$
$r^0 = t - (AGA^T)u^0.$
$z^0 = M^{-1}r^0.$
$p^0 = z^0.$
**Repeat**
    $q^i = (AGA^T)p^i.$
    $\alpha_i = (z^i)^T r^i / (p^i)^T q^i.$
    $u^{i+1} = u^i + \alpha_i p^i.$
    $r^{i+1} = r^i - \alpha_i q^i.$
    $z^{i+1} = M^{-1}r^{i+1}.$
    $\beta_i = (z^{i+1})^T r^{i+1} / (z^i)^T r^i.$
    $p^{i+1} = z^{i+1} + \beta_i p^i.$
    $i = i + 1.$
**until** stopping criterion is verified.
```

It follows from the description of the PCG algorithm that the main issues of this procedure are the stopping criterion, the computation of the product $(AGA^T)\alpha$ for a given vector α, and the choice of the preconditioning matrix M. Next, we discuss these three points.

Stopping criterion. The stopping criterion (*crit* 1) $(z^i)^T r^i < \varepsilon$, where ε is a small tolerance, has been commonly recommended in the PCG algorithm [10]. Its dependence on scaling has suggested more elaborate forms that do not share this drawback. Resende and Veiga [35] proposed the following criterion:

$$\left| 1 - \frac{|t^T(AGA^T)u^i|}{\|t\|_2 \|(AGA^T)u^i\|_2} \right| < \varepsilon. \tag{5}$$

This criterion might be expensive since the quantity $(AGA^T)u^i$ has to be computed. However, it follows from the steps of the PCG algorithm that $AGA^Tu^i = t - r^i$, where r^i is the residual given by the PCG algorithm. So (5) can be replaced by

$$\left| 1 - \frac{|t^T(t-r^i)|}{||t||_2||t-r^i||_2} \right| < \varepsilon. \tag{6}$$

Furthermore, as r^i tends to lose precision as the algorithm progresses, it is advisable to use the criterion (5) after (6) is satisfied.

Hence, we propose the following stopping criterion (*crit* 2):

```
if condition (6) is verified then
    if condition (5) is verified then stop.
    else continue.
else continue.
```

In [4] the following criterion has been proposed:

$$\frac{||r||_\infty}{||AGA^T||_\infty ||u^i||_1 + ||t||_\infty} < \varepsilon, \tag{7}$$

where $r = t-(AGA^T)u^i$. As before, we substitute r by r^i in order to reduce the computational effort of this procedure and use the exact residual when the criterion (7) is satisfied with $r = r^i$.

Hence, we propose the following stopping criterion (*crit* 3):

```
if condition (7) is verified for $r = r^i$ then
    if condition (7) is verified for $r = t - (AGA^T)u^i$ then stop.
    else continue.
else continue.
```

In the last section we discuss the effectiveness of these criteria in the implementation of the interior-point algorithms that have been introduced in the previous section. In particular, special attention will be devoted to the value of the tolerance ε.

The product $\gamma = AGA^T\alpha$. As suggested in [35], the product $\gamma = AGA^T\alpha$ is computed by

$$\begin{aligned} &\text{(i)} \quad \bar{\alpha} = A^T\alpha, \\ &\text{(ii)} \quad \hat{\alpha} = G\bar{\alpha}, \text{ and} \\ &\text{(iii)} \quad \gamma = A\hat{\alpha}. \end{aligned}$$

By doing this, there is no need for computing explicitly the matrix AGA^T, and the sparsities of the matrices A and G are fully exploited in this operation.

Preconditioning. The diagonal preconditioning $M = \text{diag}(AGA^T)$ is simple to construct and has been recommended by many authors [10, 38, 35, 34]. In the context of interior-point algorithms for network flows (as well as for general linear programming), the diagonal preconditioning was first used by Yeh [38]. Computational experience described in [35, 34] has shown that this type of preconditioning may be useful in the first iterations of the DA algorithm but tends to lose effectiveness as the DA algorithm progresses.

This numerical evidence has motivated the search for other forms of preconditionings [35, 34, 13]. It is well known that at least an optimal solution of a linear program is attained at an extreme point of its feasible set, that is, it is a basic feasible solution. For the TP problem each basic solution corresponds to a spanning tree of the graph associated with the model (1). Therefore, we can associate each solution used by the DA algorithm to a partition of the form $A = \begin{bmatrix} B & N \end{bmatrix}$, where B is a basis matrix corresponding to a MST of the graph. In our experiments we define this MST using the diagonal elements of the current matrix G as edge weights.

Let B be the basis matrix associated with such a tree. Then, the MST preconditioning takes the form $M = BG_BB^T$, where G_B is the diagonal matrix of order $n + m - 1$ whose diagonal elements are the edge weights of the tree.

It is important to notice that at the last stages of the DA algorithm the matrix M is quite close to AGA^T, since the values of the diagonal elements of G that are not in G_B are, in general, quite small. Furthermore, B differs from a triangular matrix by a permutation matrix, hence the solution of a system with M simply amounts to solving two triangular systems and performing $n+m-1$ divisions. These two properties explain why the MST preconditioning is quite suitable for this PCG algorithm.

The matrix M may be quite different from AGA^T when all the diagonal entries of G are sufficiently positive. This actually occurs in the first iterations of the DA algorithm. To overcome this fact, Resende and Veiga [35, 34] have advocated a *hybrid scheme* in which diagonal preconditioning is employed in the first iterations of the DA algorithm and MST preconditioning is used from then on. This procedure has been shown to work well in practice but has two drawbacks that are presented below.

(i) The switching point is not known in advance.

(ii) The computational effort of the PCG algorithm is usually large in the intermediate iterations of the DA algorithm, namely, in the last iterations where the diagonal preconditioning is used and in the first iterations in which the MST preconditioning is employed.

In the next subsection we propose a preconditioning technique that overcomes these disadvantages.

3.2. An IQRD technique. Suppose that we are at iteration k of the DA algorithm and let

$$G = \begin{bmatrix} G_B & \\ & G_N \end{bmatrix},$$

where $G_B \in \mathbb{R}^{(n+m-1)\times(n+m-1)}$ is the submatrix of G containing the edge weights of a MST of the graph that represents the TP problem. Furthermore, assume that B is the basis matrix associated with such a tree. If N represents the remaining columns of A, we can write

$$AGA^T = \begin{bmatrix} B & N \end{bmatrix} \begin{bmatrix} G_B & \\ & G_N \end{bmatrix} \begin{bmatrix} B^T \\ N^T \end{bmatrix} = \begin{bmatrix} BG_B^{\frac{1}{2}} & NG_N^{\frac{1}{2}} \end{bmatrix} \begin{bmatrix} G_B^{\frac{1}{2}}B^T \\ G_N^{\frac{1}{2}}N^T \end{bmatrix}.$$

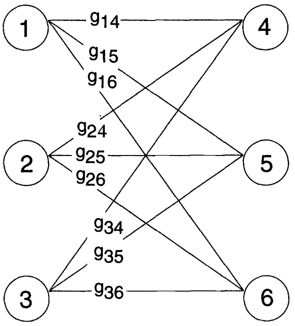
Now, there exist permutation matrices P_c and P_r such that $P_r G_B^{\frac{1}{2}} B^T P_c$ is a triangular matrix. Suppose that $P_c = P_r = I_{(n+m-1)}$ without loss of generality. Then, the Cholesky factorization of the matrix AGA^T can be found by simply computing the QR factorization of the matrix

$$\bar{A} = \begin{bmatrix} G_B^{\frac{1}{2}}B^T \\ G_N^{\frac{1}{2}}N^T \end{bmatrix}. \tag{8}$$

In fact, if $Q\bar{A} = R$, then $AGA^T = \bar{A}^T\bar{A} = R^TQ^TQR = R^TR$.

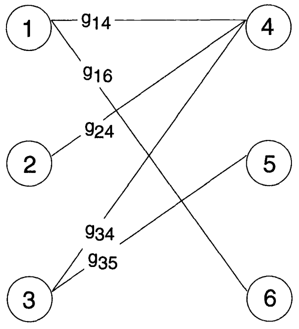
The computation of the QR factorization is not recommended in this instance, since it is not cheaper to compute and destroys the sparsity of the matrix $\bar{A}$. Instead, we propose the computation of an incomplete QR decomposition of the matrix $\bar{A}$ given by (8). In this procedure all the elements of $G_N^{\frac{1}{2}}N^T$ become null by using the diagonal elements of the matrix $G_B^{\frac{1}{2}}B^T$. Furthermore, no fill-in is considered during the entire factorization. It is easy to see that Givens rotations are particularly attractive in this instance. After the factorization, we have $M = FDF^T$, where F is a lower triangular matrix with a diagonal of ones and D is a diagonal matrix with positive diagonal elements. The following example illustrates how this incomplete QR factorization works. Consider the following matrix $G^{\frac{1}{2}}A^T$ and its associated graph obtained from a TP problem after dropping the flow conservation constraint corresponding to node 6:

$$G^{\frac{1}{2}}A^T = \begin{bmatrix}
\sqrt{g_{14}} & & & \sqrt{g_{14}} & \\
\sqrt{g_{15}} & & & & \sqrt{g_{15}} \\
\sqrt{g_{16}} & & & & \\
& \sqrt{g_{24}} & & \sqrt{g_{24}} & \\
& \sqrt{g_{25}} & & & \sqrt{g_{25}} \\
& \sqrt{g_{26}} & & & \\
& & \sqrt{g_{34}} & \sqrt{g_{34}} & \\
& & \sqrt{g_{35}} & & \sqrt{g_{35}} \\
& & \sqrt{g_{36}} & &
\end{bmatrix}$$



Furthermore, consider the following maximum spanning tree and its related matrix $\bar{A}$:

$$\bar{A} = \left[\begin{array}{ccccc|l}
\sqrt{g_{35}} & \sqrt{g_{35}} & & & & \\
& \sqrt{g_{34}} & & \sqrt{g_{34}} & & \\
& & \sqrt{g_{24}} & \sqrt{g_{24}} & & G_B^{\frac{1}{2}}B^T \\
& & & \sqrt{g_{14}} & \sqrt{g_{14}} & \\
& & & & \sqrt{g_{16}} & \\
\cdots & \cdots & \cdots & \cdots & \cdots & \\
\sqrt{g_{15}} & & & & \sqrt{g_{15}} & \\
\sqrt{g_{25}} & & \sqrt{g_{25}} & & & \\
& & \sqrt{g_{26}} & & & G_N^{\frac{1}{2}}N^T \\
& \sqrt{g_{36}} & & & &
\end{array}\right]$$



We start by eliminating the element (6, 1) of the matrix $\bar{A}$ by using the first diagonal element of $G_B^{\frac{1}{2}}B^T$. We note that the element (6, 5) is not transformed and we do not incur fill-in in the places (1, 5) and (6, 2) in the following matrix 1:

$$\begin{bmatrix}
\sqrt{g_{35}+g_{15}} & \frac{g_{35}}{\sqrt{g_{35}+g_{15}}} & & & \\
& \sqrt{g_{34}} & & \sqrt{g_{34}} & \\
& & \sqrt{g_{24}} & \sqrt{g_{24}} & \\
& & & \sqrt{g_{14}} & \sqrt{g_{14}} \\
& & & & \sqrt{g_{16}} \\
\cdots & \cdots & \cdots & \cdots & \cdots \\
0 & & & & \sqrt{g_{15}} \\
\sqrt{g_{25}} & & \sqrt{g_{25}} & & \\
& & \sqrt{g_{26}} & & \\
& \sqrt{g_{36}} & & &
\end{bmatrix}.$$

Now, by using the last diagonal element of the upper block matrix we turn to zero the element (6, 5) in the following matrix 2:

$$\begin{bmatrix}
\sqrt{g_{35}+g_{15}} & \frac{g_{35}}{\sqrt{g_{35}+g_{15}}} & & & \\
 & \sqrt{g_{34}} & & \sqrt{g_{34}} & \\
 & & \sqrt{g_{24}} & \sqrt{g_{24}} & \\
 & & & \sqrt{g_{14}} & \sqrt{g_{14}} \\
 & & & & \sqrt{g_{16}+g_{15}} \\
\cdots & \cdots & \cdots & \cdots & \cdots \\
0 & & & & 0 \\
\sqrt{g_{25}} & & \sqrt{g_{25}} & & \\
 & & \sqrt{g_{26}} & & \\
 & \sqrt{g_{36}} & & &
\end{bmatrix}.$$

The procedure can be repeated to annihilate the second row of the lower block matrix in the following matrix 3:

$$\begin{bmatrix}
\sqrt{g_{35}+g_{15}+g_{25}} & \frac{g_{35}}{\sqrt{g_{35}+g_{15}+g_{25}}} & & & \\
 & \sqrt{g_{34}} & & \sqrt{g_{34}} & \\
 & & \sqrt{g_{24}+g_{25}} & \frac{g_{24}}{\sqrt{g_{24}+g_{25}}} & \\
 & & & \sqrt{g_{14}} & \sqrt{g_{14}} \\
 & & & & \sqrt{g_{16}+g_{15}} \\
\cdots & \cdots & \cdots & \cdots & \cdots \\
0 & & & & 0 \\
0 & & 0 & & \\
 & & \sqrt{g_{26}} & & \\
 & \sqrt{g_{36}} & & &
\end{bmatrix}.$$

After all the rows of $G_N^{\frac{1}{2}}N^T$ are eliminated we have

$$P_r D^{\frac{1}{2}} F^T P_c$$

$$= \begin{bmatrix}
\sqrt{g_{35}+g_{15}+g_{25}} & \frac{g_{35}}{\sqrt{g_{35}+g_{15}+g_{25}}} & & & \\
 & \sqrt{g_{34}+g_{36}} & & \frac{g_{34}}{\sqrt{g_{34}+g_{36}}} & \\
 & & \sqrt{g_{24}+g_{25}+g_{26}} & \frac{g_{24}}{\sqrt{g_{24}+g_{25}+g_{26}}} & \\
 & & & \sqrt{g_{14}} & \sqrt{g_{14}} \\
 & & & & \sqrt{g_{16}+g_{15}}
\end{bmatrix}.$$

Now, if we repermute the rows and columns of this last matrix to the original ordering, we obtain

$$D^{\frac{1}{2}}F^T = \begin{bmatrix} \sqrt{g_{16}+g_{15}} & & & & \\ & \sqrt{g_{24}+g_{25}+g_{26}} & & \frac{g_{24}}{\sqrt{g_{24}+g_{25}+g_{26}}} & \\ & & \sqrt{g_{34}+g_{36}} & \frac{g_{34}}{\sqrt{g_{34}+g_{36}}} & \\ \sqrt{g_{14}} & & & \sqrt{g_{14}} & \\ & & \frac{g_{35}}{\sqrt{g_{35}+g_{15}+g_{25}}} & & \sqrt{g_{35}+g_{15}+g_{25}} \end{bmatrix}.$$

For this example,

$$D = \begin{bmatrix} g_{16}+g_{15} & & & & \\ & g_{24}+g_{25}+g_{26} & & & \\ & & g_{34}+g_{36} & & \\ & & & g_{14} & \\ & & & & g_{35}+g_{15}+g_{25} \end{bmatrix}$$

and

$$F^T = \begin{bmatrix} 1 & & & & \\ & 1 & & \frac{g_{24}}{g_{24}+g_{25}+g_{26}} & \\ & & 1 & \frac{g_{34}}{g_{34}+g_{36}} & \\ \frac{g_{14}}{g_{14}} & & & 1 & \\ & & \frac{g_{35}}{g_{35}+g_{15}+g_{25}} & & 1 \end{bmatrix}.$$

We notice that matrices D and F are actually obtained without computing $D^{\frac{1}{2}}F^T$ in order to avoid square root operations. Suppose that the MST is rooted at node r, which is the node corresponding to the flow conservation equation that has been removed from the formulation. Furthermore, let $\mathcal{A}$ denote the subset of arcs belonging to the tree and let $pred(i)$ represent the predecessor node of node i in the tree. Then, the procedure used to compute the nonzero elements of matrix D and the off-diagonal elements of matrix F can be presented as follows:

```
for all nodes $i : i \neq r$ do
    $j = pred(i)$.
    if arc $(i, j) \in \mathcal{A}$ then $d_{ii} = g_{ij}$ else $d_{ii} = g_{ji}$.
for all arcs $(i, j) : (i, j) \notin \mathcal{A}$ do
    if node $i \neq r$ then $d_{ii} = d_{ii} + g_{ij}$.
    if node $j \neq r$ then $d_{jj} = d_{jj} + g_{ij}$.
for all nodes $i : i \neq r$ do
    $j = pred(i)$.
    if node $j \neq r$ then
        if arc $(i, j) \in \mathcal{A}$ then $f_{ij} = g_{ij}/d_{ii}$ else $f_{ji} = g_{ji}/d_{ii}$.
```

It is important to notice that the PCG algorithm discussed in this section can be incorporated in all three interior-point algorithms introduced in the previous section.

In the first iterations of the interior-point algorithms, $D \approx \text{diag}(AGA^T)$ and $F \approx I_{m+n-1}$. In the last iterations of the interior-point algorithms, $G_N \approx 0$ and, consequently, $D \approx G_B$ and $F \approx B$. Thus, we can conclude that the IQRD preconditioning is quite similar to the diagonal and MST preconditionings in the initial and terminal phases of the interior-point methods, respectively. Since the IQRD preconditioning also takes into account the elements of $G_N^{\frac{1}{2}}N$, then it should require fewer conjugate gradient iterations in the intermediate phase of the interior-point algorithms.

The solution of the system with FDF^T requires $O(n+m)$ divisions, $O(n+m)$ multiplications, and $O(m+n)$ subtractions, since D is a diagonal matrix and F can be permuted into a triangular matrix with diagonal elements equal to one. Furthermore, solving a system with the matrix BG_BB^T requires $O(n+m)$ divisions and $O(n+m)$ subtractions. So there is an increase of $O(n+m)$ multiplications in each iteration of the PCG algorithm if the IQRD preconditioning is used instead of the MST procedure. Furthermore, the IQRD preconditioning amounts to an increase of $O(n+m)$ multiplications and $O(n+m)$ subtractions over the diagonal preconditioning. These gaps are not too meaningful, since each computation of a product $AGA^T\alpha$ that is required in each iteration of the PCG algorithm involves $O(nm)$ multiplications and $O(nm)$ sums. It is also important to add that the construction of the preconditioning matrices F and D is done once in each iteration of the interior-point methods and requires $O(nm)$ sums and $O(n+m)$ divisions. This is smaller than the computation of a product $AGA^T\alpha$. All these considerations lead to the conclusion that the IQRD preconditioning is recommended provided it reduces the number of PCG iterations by even a small fraction. This is exactly what occurs in practice in instances from the class considered in our experiments and is well displayed in the computational results presented in the last section of this paper.

3.3. Stopping criteria for the interior-point algorithms. Given a basic solution for the TP problem with a basis matrix B, it is well known that this solution is optimal if it satisfies the following conditions:

$$x_B = B^{-1}d \geq 0, \tag{9}$$

$$c_N - N^T(B^T)^{-1}c_B \geq 0, \tag{10}$$

where N is the matrix corresponding to the columns of A associated with the nonbasic variables. We note that the first criterion is quite cheap to verify, but the second inequality may lead into a large computational effort. As suggested in [35], a further criterion can be useful when the data of the transportation problem is integer. This criterion follows from the duality theory of linear programming and simply states that if x_B satisfies the condition (9), and a dual feasible solution y^k given by any of the interior-point methods satisfies

$$c_B^T x_B - d^T y^k < 1, \tag{11}$$

then $x = (x_B, 0)$ is an optimal solution of the TP problem. This criterion is obviously quite cheap to compute, since y^k is available from the interior-point methods. However, in some instances the criterion (10) is verified without the satisfaction of the inequality (11). These observations lead to the following stopping criterion that is used in the three interior-point methods discussed in the previous section:

Let B be the basis matrix associated with the current MST and y^k be the approximation to y at the iteration k of the interior-point algorithm.

```
**if** $x_B = B^{-1}d \geq 0$ **then**
    **if** $c_B^T x_B - d^T y^k < 1$ **then** stop.
    **else**
        **if** $c_N - N^T(B^T)^{-1}c_B \geq 0$ **then** stop.
        **else** continue.
**else** continue.
```

It is important to notice that this stopping criterion fails to hold if the condition $B^{-1}d \geq 0$ is never satisfied. This situation has never occurred in our computational experiments. However, when the problem is degenerate and the perturbation schemes fail, it is possible that the algorithms may never achieve a MST corresponding to a primal optimal feasible solution. We refer to [33, 34] for a procedure to overcome this difficulty.

4. Computational experience. In this section we first compare the efficiency of the IQRD preconditioning with the hybrid preconditioning (diagonal and MST) introduced by Resende and Veiga [35, 34]. These two techniques are incorporated in the PCG algorithm that is employed in the solution of the linear systems required by the three interior-point methods. In our second experiment we investigate the three stopping criteria for this method discussed in the previous section. We come to some conclusions about the value of the tolerance ε used in these criteria. Our third experiment is devoted to investigating the effect of the scaling in the cost coefficients and right-hand-side elements on the performance of the interior-point algorithms. Finally, we report a computational comparison between the interior-point methods and the network simplex code NETFLO of Kennington and Helgason [16] on problems generated by the standard problem generator NETGEN [17]. In these last two experiments we use the stopping criterion and the tolerance value that are indicated by our second experiment as the most recommended to be incorporated in the interior-point methods.

All the experiments were performed on a SUN SPARCstation 10-52 with 64 Mbytes of RAM. The codes are written in FORTRAN and were compiled with the Sun Fortran Compiler (f77) using flags **-O4 -cg89 -libmil -native**. All the CPU times reported are excluded from input and output time and were measured with the internal function **etime**.

All the test problems described in this paper are dense with a number of arcs equal to mn. In the first three experiments, the test problems are generated by a technique that first considers a spanning tree related with a basic optimal solution. Then, the components of the dual (primal) solution associated with the edges that belong (do not belong) to the tree are fixed to zero. The remaining primal and dual variables are randomly generated in such a way that the elements of the right-hand-side and cost vectors are integers belonging to the intervals $[1, d_{max}]$ (1 for the assignment problem) and $[1, c_{max}]$, respectively. If we wish the solution to be degenerate (as in the assignment problem), then some of these latter variables are also set equal to zero.

As stated before, we considered test problems with nondegenerate and degenerate optimal solutions. Our experience has shown that the stopping criterion loses effectiveness in the second case. In fact, if the dual optimal solution is degenerate, the current maximum spanning tree may be related with an infeasible primal basic solution when the interior-point algorithms converge to the optimal primal face. Furthermore, if the optimal primal solution is degenerate it is also possible to be correctly identified by the current MST without the verification of the stopping criterion. As suggested in [35], we can use an ε-perturbation technique to help to overcome such difficulties. In this procedure we solve a perturbed TP problem where the cost coefficient $\bar{c}$ and right-hand-side $\bar{d}$ vectors are defined by $\bar{c}_j = c_j + \delta_{c_i}\varepsilon$ and $\bar{d}_j = d_j + \delta_{d_j}\varepsilon$, where δ_{c_i} and δ_{d_j} are uniform random values in the interval $[-1, 1]$, and ε is a small perturbation. This technique is far from being perfect despite being, as far as we know, the most effective device in preventing degeneracy effects in practice. If ε is too small, then usually the perturbed problem is still degenerate. If ε is too big, then two cases may be possible. If we use the perturbed data in the termination criterion, the interior-point algorithms may reach a suboptimal solution. On the other hand, if we use the termination criterion with the original vectors c and d, the interior-point algorithms may never stop. In order to avoid obtaining suboptimal solutions, we have set $\varepsilon = \min(10^{-3}, 10^{-6}(m + n - 1))$ and we have used the original data in the stopping criterion, as suggested in Kaliski and Ye [14]. The implementations of this

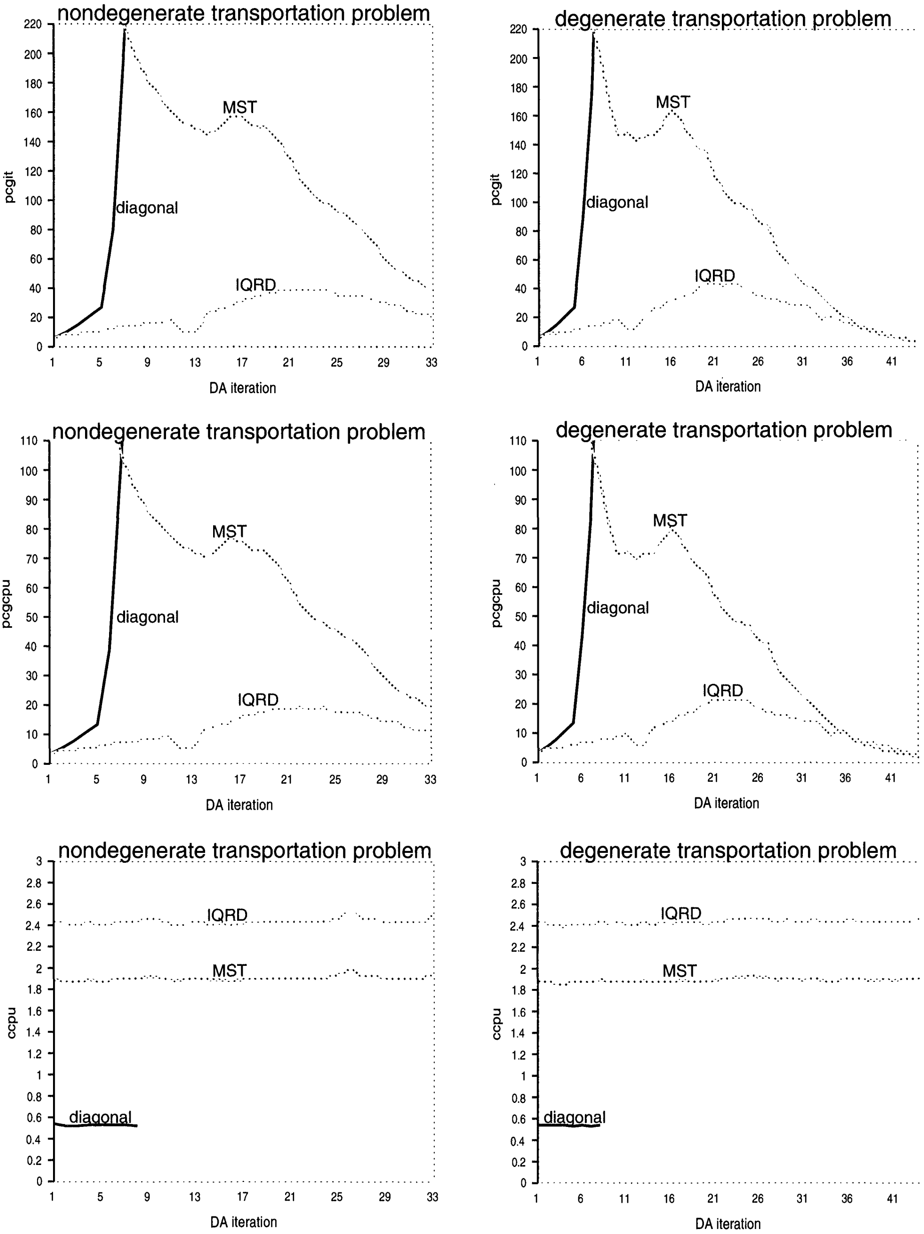


FIG. 1. *Performance of the preconditionings for transportation problems with* $n = m = 1000$.

procedure in our codes have provided an optimal solution for all the test problems described in this paper.

As stated before, we study in our first experiment the efficiency of the IQRD, diagonal, and MST preconditionings for the PCG algorithm that is implemented in the DA method. We have used stopping criterion crit 1 with $\varepsilon = 10^{-6}$. The results of this experiment are illustrated in Figures 1 and 2 and Table 1 for the solution of assignment and general transportation problems with $m = n = 1000$, $c_{max} = 10$, and $d_{max} = 10$. Figures 1 and 2 report each iteration of the DA algorithm and Table 1 reports a comparison between the IQRD preconditioning and the hybrid scheme of Resende and Veiga. In this last experiment we suppose that the optimal

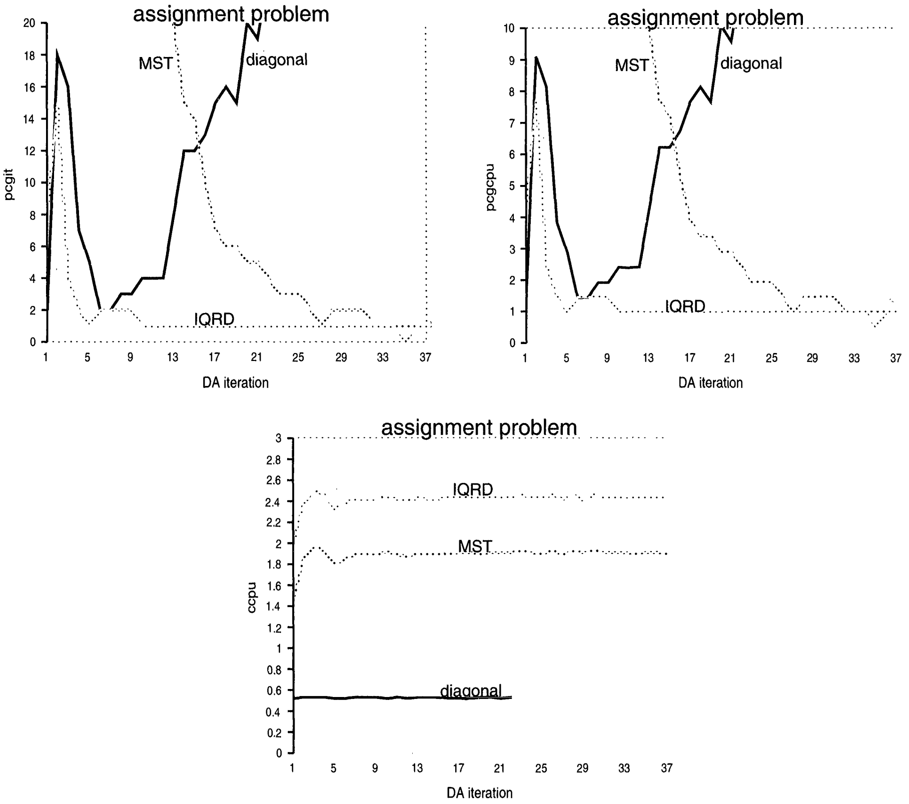

FIG. 2. *Performance of the preconditionings for an assignment problem with $n = m = 1000$.*

switching iteration for each problem is known in advance, that is, that we know previously the best iteration in which the hybrid scheme should switch from one preconditioning to the other. The symbols **ccpu**, **pcgit**, **pcgcpu**, and **optiter** represent the CPU time in seconds to construct the preconditioners plus the time to compute the MST (this last item is not included if the diagonal preconditioning is used), the number of PCG iterations, the CPU time in seconds required by the PCG method, and the optimal switching iteration for each problem, respectively.

We make the following conclusions:

- The diagonal preconditioning is effective during the initial iterations of the DA algorithm, but its efficiency is lost after this stage. On the other hand the opposite situation occurs with the MST preconditioning. Actually, this confirms the claims presented in [35] that have led to the hybrid scheme proposed by Resende and Veiga.

- The IQRD preconditioning usually requires a smaller number of PCG iterations than the diagonal and the MST preconditionings at any stage of the DA algorithm. The gap is bigger in the intermediate iterations of that algorithm.
- The IQRD preconditioning requires a bit more CPU time to construct than the other two preconditionings. However, the IQRD preconditioning is able to reduce sufficiently the number of PCG iterations that compensate for such an additional computational effort. In fact, except in the very first and in the very last DA iterations, the CPU time ccpu+pcgcpu is smaller if the IQRD preconditioning is used than if the diagonal or MST preconditionings are employed.
- For dense TP and AP problems the IQRD preconditioning is preferable to the hybrid scheme of Resende and Veiga to be incorporated in the interior-point methods, even if we suppose that it is possible to know previously the optimal switching iteration. In fact, if we use the IQRD preconditioning instead of the hybrid scheme, we reduce by 77.0%, 71.5%, and 62.0% the number of PCG iterations required to solve the nondegenerate TP problem, the degenerate TP problem, and the AP problem, respectively. The corresponding decrease in the CPU time ccpu+pcgcpu when those test problems are solved is 72.8%, 65.8%, and 7.35%.

Based on the results of the first experiment, we decided to use the IQRD preconditioning in the implementation of the DA, PD, and PC interior-point algorithms. In our second experiment we study the performance of these methods under stopping criteria crit 1, crit 2, and crit 3 discussed in the previous section and a set of different values for the tolerance ε. The results of this experiment are illustrated in Tables 2 and 3, which report the performance of interior-point methods DA, PD, and PC on TP and AP problems with $m = n = 1000$. It is important to add that we chose the test problems for which the interior-point algorithms have the most difficulty in finding their optimal solutions. The data in Tables 2 and 3 represent the number of iterations

of the PCG algorithm for different values of the tolerance ε when the three stopping criteria are incorporated in this procedure. If for a certain criterion there is no number for a value of $\varepsilon = 10^{-p}$, then either this tolerance value is too big for the interior-point method to reach an appropriate direction and, consequently, the method cannot converge to the optimal solution, or it is too small for the PCG algorithm to converge in some iteration of this latter technique.

The results shown in Tables 2 and 3 lead to the following conclusions:

- crit 1 allows a large choice for the value of tolerance ε. As expected, the total number of PCG iterations increases with a decrease of the tolerance value. On the other hand, the incorporation of the other two criteria requires much care in the choice of the value of ε. For instance, the DA algorithm can only work with a value of the tolerance smaller than or equal to 10^{-14} if crit 3 is used. Hence, we can conclude that crit 1 is the most robust among the three criteria discussed in the previous section. This does not mean that crit 1 takes a smaller number of iterations than the other criteria. On the contrary, crit 2 usually leads to the smallest iteration count; crit 3 is also better than crit 1 in this respect.
- When a TP problem is solved, then a value of ε in the interval $[10^{-6}, 10^{-3}]$ is quite safe if crit 1 is used in the implementation of the three interior-point algorithms. The same kind of conclusions can be stated for the solution of AP problems by the DA algorithm. However, a slightly smaller value for ε should be considered ($\varepsilon \in [10^{-8}, 10^{-6}]$) when AP problems are solved by any of the remaining interior-point PD and PC algorithms.

Based on these results, we have decided to use in our third experiment criterion crit 1 for all the interior-point methods. In the DA algorithm we set the value of the tolerance to be equal to 10^{-6}. The same value of ε is employed in the PD and PC algorithms when TP problems are solved. Furthermore, $\varepsilon = 10^{-8}$ is used in these last procedures for the solution of AP problems. As stated before, in the next study we investigate the importance of scaling of the vectors c and d. We considered assignment and general nondegenerate and degenerate transportation problems with integer data, $m = n = 200, 400, 600, 800, 1000$ and different scalings of the vectors d and c. The results of this study are illustrated in Tables 4–9. The symbols **iter**, **pcgit**, and **cpu** represent the number of interior-point iterations, the number of

PCG iterations, and the CPU time in seconds, respectively. We only report the results with nondegenerate TP problems, since we have observed that the relative performance of the three interior-point algorithms is similar for degenerate and nondegenerate transportation problems.

We have achieved the following conclusions about the scaling of the vectors c and d:

- All three interior-point algorithms seem to be sensitive to bad scaling in the right-hand-side vector d of the transportation problem. However, the PD techniques are usually more effected than the DA algorithm by an increase in d_{max}. In fact, when d_{max} changes from $1.1e1$ to $2.5e3$, the CPU time increases, on average, 327.0% and

196.8% for both PD and PC algorithms, respectively, and only 153.4% for the DA algorithm.

- The PD and PC algorithms seem to be less effected by bad scaling in c than by bad scaling in d. In fact, the computational effort of the PD method grows, on average, 26.4% for TP problems and 102.5% for AP problems when c_{max} changes from $1.8e1$ to $1.0e6$. Furthermore, the average CPU time increasing for the PC algorithm is 44.7% for the transportation problem and 181.4% for the assignment problem. It is interesting to note that the variation of the performance of the DA algorithm with the scaling in c depends on the class of problem. In the transportation problem we obtain an average decrease of 67.27% in CPU time when the value of c_{max} changes from $1.8e1$ to $1.0e6$. On the other hand, for the same change in the scaling of c, that value increases 233.13% when we solve the assignment problem.

In this last experiment we compare the three interior-point methods with the network simplex code NETFLO of Kennington and Helgason [16] on problems generated by the standard problem generator NETGEN [17]. We have considered assignment and transportation problems with integer data, $m = n =$ 200, 400, 600, 800, 1000, number of arcs equal to mn, cost for the arcs in the interval $[1, c_{max}]$ with $c_{max} = 1.0e1, 1.0e6$, and total supply equal to $1.0e2n$ and $1.0e6n$ (equal to n in the assignment problems). The results of this study are illustrated in Tables 10–13. The symbols iter and cpu represent the number of iterations and the CPU time in seconds required by the different algorithms to achieve an optimal solution for the test problems, respectively.

The results displayed in Tables 10–13 show that the network simplex code NETFLO is faster than the interior-point methods in all the test problems. However, one should not draw any final conclusions from these results. First, we have used in the interior-point methods a tighten robust stopping criterion that is not the best for all the problems. Second, we have not worried about the initial point, since the main purpose of the paper was to investigate the efficiency of a new preconditioning and to compare the PD interior-point techniques with the DA method used by Resende and Veiga [35]. Most importantly, instances are dense and too small. As in Resende and Veiga [35], competitiveness is achieved in sparse problems only in instances that are much larger than those considered in this paper. We believe that a more appropriate initial point and a different stopping criterion in which the values of the tolerance in the PCG method change during the progress of the interior-point methods may turn these methods more competitive with the classical algorithms for transportation and assignment problems.

Despite it being difficult to draw final claims about the most efficient interior-point method, the results indicate that the PD and the PC algorithms seem to be the most appropriate techniques for the solution of TP problems when the cost coefficients and right-hand-side vectors c and d are not badly scaled. If c and d are both badly scaled, then the DA algorithm usually performs better than the PD methods. The efficiencies of the three algorithms seem to be similar for the TP problems in which only the vector d is badly scaled. Finally, if only vector c is badly scaled, then, generally, the DA algorithm outperforms the algorithms PD and PC. In the solution of AP problems, bad scaling in the vector c seems to have an opposite effect on the performance of the interior-point methods. In fact, the DA algorithm seems to be more efficient than the PD algorithm when c is well scaled, while the opposite situation occurs in the presence of badly scaled AP problems. The PC method performs worse than the DA and PD algorithms in the solution of AP problems.

Currently the use of the PC algorithm for the solution of large-scale linear programs is well accepted [7]. In fact, this technique usually reduces the overall amount of iterations of the PD algorithm. Furthermore, as a direct solver is used to process the Newton equations, then there is an increase of only two triangular systems per iteration of the PD method. The

results shown in Tables 4–13 seem to confirm the ability of the PC strategy to reduce the total amount of the interior-point iterations. However, the use of an iterative solver almost doubles the computational effort of each iteration of the PD algorithm. This explains why the CPU time is in many cases smaller for the simple PD algorithm. So the PD algorithm may be more appropriate than the PC method for the solution of TP and AP problems when these procedures are implemented in the way described in this paper.

Our final remark is concerned with the competitiveness of the interior-point methods with the classical techniques (which NETFLO represents in this paper) in solving linear minimum-cost network flow problems. Resende and Veiga [35] have already shown that if the parallelism of the PCG algorithm is exploited, the DA method is expected to outperform NETFLO and the relaxation code RELAX in the solution of sufficiently large assignment problems. Later, the same authors also demonstrated that the DA algorithm is more efficient than the classical methods in several classes of linear network flow problems, even when implemented in sequential architectures [34]. In this paper, despite having introduced a new preconditioning that greatly reduces the computational effort required by the PCG algorithm, the results show that NETFLO is still more efficient than the interior-point methods in the solution of dense assignment and transportation problems in sequential architectures. As we stated before, there is much work to be done for the interior-point algorithms to be competitive with the classical techniques. We have already mentioned some possible modifications in the algorithms that may help in this instance. This is certainly one of the major topics of our current research.

COMPUTATION OF THE NONCENTRAL GAMMA DISTRIBUTION*

L. KNÜSEL† AND B. BABLOK†

Abstract. This paper deals with the computation of upper and lower tail probabilities of the noncentral gamma distribution and with the computation of the noncentrality parameter given the upper or lower tail probability. The tail probabilities are computed in an efficient and numerically stable manner with a given relative accuracy even for small probabilities and for a wide range of parameters where other algorithms found in the statistical literature fail. The basic ideas in this paper can also be applied to the noncentral chisquare, beta, F, and t distributions.

Key words. noncentral distributions, noncentrality parameter

AMS subject classification. 65U05

1. Overview.

Noncentral distributions play an important role in statistics, e.g., when we are interested in the power function of the chisquare, F, or t test. In §2 we give the definition of the central and noncentral gamma and beta distributions and indicate how the (central and noncentral) chisquare, F, and t distributions can be derived from these distributions which are mathematically and numerically simpler to handle. In §3 we give the basic ideas of the computation of the central gamma distribution. The algorithms are based upon open forward and backward recursions as described in Knüsel [5]. Section 4 deals with the computation of the noncentral gamma distribution and §5 shows how we can compute the noncentrality parameter given the other parameters and the upper or lower tail probability of the distribution by using the Newton algorithms for finding zeros of a real function.[1] The essential point is the fact that the derivative with respect to λ of the noncentral gamma distribution can also be computed in a numerically stable and fast way with a given relative precision using ideas similar to those in §§3 and 4. We want to point out that for many applications the computation of the noncentrality parameter is of higher practical relevance than the computation of quantiles (e.g., for the computation of the effect size or the necessary sample size at a given power).

We can compute the noncentral beta distribution in a manner analogous to that of the gamma distribution. So, all three commonly used noncentral distributions (chisquare, F, and t) can be computed by the methods described in this paper as these distributions can be derived from the gamma and beta distributions.

2. Relationship between the different distributions.

In this section we want to give in short the definition of the gamma and beta distributions considered and to show the relationship between these distributions and the classical central and noncentral chisquare, F, and t distributions.

Central gamma distribution. Let X denote a random variable with a (central) gamma distribution with parameter $a > 0$. The distribution function of X is defined as

$$F(x|a) = Pr\{X < x\} = \frac{1}{\Gamma(a)} \int_0^x t^{a-1} e^{-t} dt \quad \text{for} \quad x > 0,$$

where

$$\Gamma(a) = \int_0^\infty t^{a-1} e^{-t} dt.$$

*Received by the editors February 23, 1994; accepted for publication (in revised form) May 22, 1995.

†Department of Statistics, University of Munich, 80539 Munich, Germany (leo.knuesel@lrz.uni-muenchen.de; deccpfl9@ibmmail.com).

[1] The ideas in these two sections are mainly due to Bablok (cf. Bablok [1]).

The function $\Gamma(a)$ is the (complete) gamma function while the integral in the definition of $F(x|a)$ is called the incomplete gamma function.

Central beta distribution. Let X_1 and X_2 be independent random variables having gamma distributions with parameters a and b, respectively, and let $X = X_1/(X_1 + X_2)$. Then X has a beta distribution with parameters a and b and the distribution function of X is given by

$$F(x|a,b) = Pr\{X < x\} = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \int_0^x t^{a-1}(1-t)^{b-1}dt \quad \text{for} \quad 0 < x < 1.$$

The function $\Gamma(a)\Gamma(b)/\Gamma(a+b)$ is called the (complete) beta function while the integral in the definition of $F(x|a,b)$ is called the incomplete beta function.

Noncentral gamma distribution. Let X denote a random variable with a noncentral gamma distribution with parameter $a > 0$ and with noncentrality parameter $\lambda > 0$. The distribution function of X is defined as

$$F(x|a,\lambda) = Pr\{X < x\} = \sum_{i=0}^{\infty} p_\lambda(i)F(x|a+i), \qquad \text{where} \qquad p_\lambda(i) = \frac{e^{-\lambda}\lambda^i}{i!}$$

(see Patnaik [7]). So, the noncentral gamma distribution is a mixture of central gamma distributions $F(x|a+i)$ with Poisson weights $p_\lambda(i)$.

Noncentral beta distribution. Let X_1 and X_2 be independent random variables: X_1 with a noncentral gamma distribution with parameter $a > 0$ and noncentrality parameter $\lambda > 0$, and X_2 with a central gamma distribution with parameter $b > 0$. Then the random variable $X = X_1/(X_1 + X_2)$ has a noncentral beta distribution with parameters a and b and with noncentrality parameter λ, and the distribution function of X is given by

$$F(x|a,b,\lambda) = Pr\{X < x\} = \sum_{i=0}^{\infty} p_\lambda(i)F(x|a+i,b), \qquad \text{where} \qquad p_\lambda(i) = \frac{e^{-\lambda}\lambda^i}{i!}$$

(see Patnaik [7]). So, the noncentral beta distribution is a mixture of central beta distributions $F(x|a+i,b)$ with Poisson weights $p_\lambda(i)$.

The following results concerning the chisquare, F, and t distributions can also be derived from Patnaik [7] or they can be found in Johnson–Kotz–Balakrishnan [4]. If X has a noncentral chisquare distribution with noncentrality parameter λ, then the random variable $Y = X/2$ has a noncentral gamma distribution with parameter $a = n/2$ and with noncentrality parameter $\lambda' = \lambda/2$. If X has a noncentral F distribution with (n_1, n_2) degrees of freedom and with noncentrality parameter λ, then the random variable $Y = n_1X/(n_2+n_1X)$ has a noncentral beta distribution with parameters $a = n_1/2, b = n_2/2$ and with noncentrality parameter $\lambda' = \lambda/2$. If X has a noncentral t distribution with n degrees of freedom and with noncentrality parameter δ, then the random variable $Y = X^2$ has a noncentral F distribution with $(1, n)$ degrees of freedom and with noncentrality parameter $\lambda = \delta^2$. As the noncentral t distribution is no longer symmetric, only probabilities of the form $Pr\{|X| < t\}$ or $Pr\{|X| > t\}$ can be computed by means of the F or beta distribution. Probabilities of the form $Pr\{X < t\}$ or $Pr\{X > t\}$ cannot be found in this way.

So, all three commonly used central and noncentral distributions (chisquare, F, and t) can be derived from the central and noncentral gamma and beta distributions.

3. Computation of the (central) gamma distribution. This section is a short summary of the methods used to compute the upper and lower tail probability of the central gamma distribution as described in more detail in Knüsel [5]. Let X denote a random variable having a (central) gamma distribution with parameter $a > 0$:

$$(1) \qquad Pr\{X < x\} = \frac{1}{\Gamma(a)} \int_0^x t^{a-1}e^{-t}dt \quad \text{for} \quad x > 0,$$

where $\Gamma(a)$ denotes the gamma function

$$\Gamma(a) = \int_0^\infty t^{a-1}e^{-t}dt. \tag{2}$$

We define the following three basic quantities for $a > 0, x > 0$:

$$\begin{aligned} p(a,x) &= \frac{e^{-x}x^{a-1}}{\Gamma(a)}, \\ I(a,x) &= xe^{-x}\int_0^1 t^{a-1}e^{-xt}dt, \\ J(a,x) &= xe^{-x}\int_1^\infty t^{a-1}e^{-xt}dt. \end{aligned} \tag{3}$$

Denoting by $F(x|a)$ and $F^c(x|a)$ the distribution function and the complementary distribution function of X, respectively, we have

$$\begin{aligned} F(x|a) &= Pr\{X < x\} = p(a,x)I(a,x), \\ F^c(x|a) &= Pr\{X > x\} = p(a,x)J(a,x). \end{aligned} \tag{4}$$

The two probabilities add up to one, and therefore it is sufficient to compute the smaller of the two terms. As the median of the gamma distribution is about a if a is not too small, we therefore have, as a rough rule, to compute $I(a,x)$ when $x \le a$ and $J(a,x)$ when $x > a$. From the definition of $I_a = I(a,x)$ and $J_a = J(a,x)$, we derive the following properties for any given $x > 0$:

$$\begin{aligned} &I_a \downarrow 0 \quad \text{for} \quad a \uparrow \infty, \\ &I_a = \frac{x}{a}(1 + I_{a+1}) \quad \text{for} \quad a > 0 \end{aligned} \tag{5}$$

and

$$\begin{aligned} &J_a \downarrow 0 \quad \text{for} \quad a \downarrow -\infty \quad (J_1 = 1), \\ &J_{a+1} = \left(1 + \frac{a}{x}J_a\right) \quad \text{for} \quad a \in R. \end{aligned} \tag{6}$$

Using these properties, we can compute the quantities I_a and J_a with open recursions without knowing an exact starting value but with the approximate starting value zero. In the case of I_a, the following open backward recursion can be used:

Set $\tilde{I}_{a+n} = 0$ for some positive integer n.
For $b = a + n - 1, a + n - 2, \dots, a$ compute

$$\tilde{I}_b = \frac{x}{b}(1 + \tilde{I}_{b+1}). \tag{7}$$

Then $\tilde{I}_a$ is an approximation to $I_a = I(a,x)$ with the relative error

$$0 \le \frac{I_a - \tilde{I}_a}{I_a} \le fac, \quad \text{where} \quad fac = \frac{x^n}{a(a+1)\cdots(a+n-1)}.$$

Therefore, we can guarantee a relative error of less than a given $\varepsilon > 0$ if we choose n as the smallest positive integer such that$fac < \varepsilon$. In regard to the computation of J_a, we can use the following forward recursion:

Set $\tilde{J}_{a-n} = 0$ for some positive integer $n \leq a$.
For $b = a - n, a - n + 1, \dots, a - 1$ compute

$$\tilde{J}_{b+1} = 1 + \frac{b}{x}\tilde{J}_b. \tag{8}$$

Then $\tilde{J}_a$ is an approximation to $J_a = J(a, x)$ with the relative error

$$0 \leq \frac{J_a - \tilde{J}_a}{J_a} \leq fac, \quad \text{where} \quad fac = \frac{(a-1)(a-2)\cdots(a-n)}{x^n}.$$

Note that $\tilde{J}_{a-n} = 0$ implies $\tilde{J}_{a-n+1} = 1$ and so the first step in the recursion could be saved. Thus, we can guarantee a relative error of less than a given $\varepsilon > 0$ if we choose n as the smallest positive integer such that $fac < \varepsilon$. If such an integer does not exist, we have to compute the exact starting value J_b for $0 < b < 1$ for our recursion.

4. Computation of the noncentral gamma distribution. Now, let X denote a random variable having a noncentral gamma distribution with parameter a and noncentrality parameter λ. The distribution function of X can be written as a mixture of central gamma distributions with Poisson weights:

$$\begin{aligned} F(x|a,\lambda) &= Pr\{X < x\} = \sum_{i=0}^{\infty} p_\lambda(i) F(x|a+i), \\ F^c(x|a,\lambda) &= Pr\{X > x\} = \sum_{i=0}^{\infty} p_\lambda(i) F^c(x|a+i) \end{aligned} \tag{9}$$

with

$$p_\lambda(i) = \frac{e^{-\lambda}\lambda^i}{i!} = Pr\{Po(\lambda) = i\},$$

where $Po(\lambda)$ denotes a random variable with a Poisson distribution with parameter λ (cf. Patnaik [7]). Note, that $p_\lambda(i)$ is related to the function $p(a, x)$ defined in (3) by $p_\lambda(i) = p(i + 1, \lambda)$. We want to show how both probabilities in (9) can be computed with a given relative error by using techniques similar to those used for the central distributions. First, we deal with the computation of the lower tail probability $F(x|a, \lambda)$ for given x, a, and λ. For the central gamma distribution we have the relations (4) and (5). Furthermore, not only the component $I_a = I(a, x)$ but also the distribution function $F(x|a) = p(a, x)I(a, x)$ itself is monotonous in a:

$$F(x|a) \downarrow 0 \quad \text{for} \quad a \uparrow \infty. \tag{10}$$

This follows from the addition theorem of the gamma distribution; the sum of two gamma variables has again a gamma distribution, the parameter being the sum of the individual parameters. Now, we decompose the lower tail probability $F(x|a, \lambda)$ in three terms:

$$F(x|a,\lambda) = \sum_{i=0}^{k_1} \cdots + \sum_{i=k_1+1}^{k_2-1} \cdots + \sum_{i=k_2}^{\infty} \cdots = S_1 + S_2 + S_3. \tag{11}$$

The number k_2 is chosen as the smallest integer such that

$$Pr\{Po(\lambda) \geq k_2\} \leq \varepsilon, \tag{12}$$

i.e., k_2 is the upper ε-quantile of a Poisson distribution with parameter λ. Because of the monotonicity relation (10) we have

$$\begin{aligned} S_3 &\le F(x|a+k_2)Pr\{Po(\lambda) \ge k_2\} \le F(x|a+k_2)\varepsilon, \\ S_1 + S_2 &\ge F(x|a+k_2)Pr\{Po(\lambda) < k_2\} \ge F(x|a+k_2)(1-\varepsilon), \end{aligned} \tag{13}$$

and so

$$\frac{S_3}{S_1+S_2} \le \frac{\varepsilon}{1-\varepsilon} \approx \varepsilon, \quad \text{i.e.,} \quad S_3 \le \varepsilon(S_1+S_2) \quad \text{(approximately).} \tag{14}$$

The sum S_2 can be written as

$$S_2 = \sum_{i=k_1+1}^{k_2-1} T_i, \tag{15}$$

where $T_i = T_i(x,a,\lambda) = p_\lambda(i)F(x|a+i) = p(i+1,\lambda)p(a+i,x)I(a+i,x)$. Using the obvious relation

$$p(a+1,x) = \frac{x}{a}p(a,x), \tag{16}$$

we find

$$T_i = q_i T_{i+1}, \quad \text{where} \quad q_i = \frac{i+1}{\lambda}\frac{a+i}{x}\left(\frac{I(a+i,x)}{I(a+i+1,x)}\right). \tag{17}$$

Starting the summation of S_2 at the end $i = k_2 - 1$ and using the backward recursion (5) for $I_{a+i} = I(a+i,x)$, we can compute each term T_i of this sum with a relative error smaller than ε and thus, all terms being positive, the overall relative error of $\tilde{S}_2$, the computed value of S_2, is also smaller than ε. We must now determine the value k_1 such that $S_1 \le \varepsilon S_2$. Using the backward recursion (5) for $I_{a+i} = I(a+i,x)$ in (17), we obtain

$$q_i = \frac{i+1}{\lambda}\left(\frac{1}{I(a+i+1,x)} + 1\right), \tag{18}$$

and due to the monotonicity property (5) of $I_a = I(a,x)$ it follows that

$$q_i = T_i/T_{i+1} \quad \text{is decreasing for} \quad i \downarrow 0. \tag{19}$$

This means that the terms $T_i (i = k_2 - 1, k_2 - 2, \dots, 0)$ in the sum $S_1 + S_2$ are increasing as long as $q_i > 1$ and decreasing as soon as $q_i < 1$ and that the partial sum S_1 can be estimated by the geometric series

$$S_1 = \sum_{i=0}^{k_1} T_i \le \frac{T_{k_1}}{1-q_{k_1}}, \quad \text{where} \quad q_{k_1} = \frac{T_{k_1}}{T_{k_1+1}} \quad (\text{if } q_{k_1} < 1). \tag{20}$$

Now, if we stop the summation of S_2 as soon as

$$\frac{T_{k_1}}{1-q_{k_1}} \le \varepsilon \tilde{S}_2, \tag{21}$$

then the approximation $F(x|a,\lambda) \approx \tilde{S}_2$ has a relative error smaller than 3ε (approximately) as $S_1 \le \varepsilon\tilde{S}_2$ due to (20) and (21), $S_3 \le \varepsilon S_2$ due to (14), and because the relative error of $\tilde{S}_2$, the computed value of S_2, is also smaller than ε.

We want to point out that it is crucial for the computation of S_2 to start off the summation at the upper end k_2. Many algorithms found in the literature (see, e.g., Frick [3], Lenth [6], Farebrother [2]) start the summation at the lower ε-quantile or even at zero and proceed toward the upper end using a recursion similar to (7) but in the forward instead of the backward direction. This summation is instable due to numerical cancellation and the relative error cannot be kept under control. The paper of Wang and Gray [8] uses approximation methods without known approximation bounds.

The computation of the upper tail probability $F^c(x|a,\lambda)$ can be performed in quite an analogous way. The series (9) is decomposed in three terms:

$$F^c(x|a,\lambda) = \sum_{i=0}^{k_1} \cdots + \sum_{i=k_1+1}^{k_2-1} \cdots + \sum_{i=k_2}^{\infty} \cdots = S_1 + S_2 + S_3. \tag{22}$$

This time we have to use the recurrence relation (6) for $J(a,x)$ that works in the forward direction. The number k_1 is chosen as the largest integer such that

$$Pr\{Po(\lambda) \le k_1\} \le \varepsilon. \tag{23}$$

Because of the monotonicity relation

$$F^c(x|a) \downarrow 0 \quad \text{for} \quad a \downarrow 0 \quad \text{and} \quad x > 0, \tag{24}$$

we have estimations completely analogous to those of the lower tail probability and further computations offer no new problems.

5. Computation of the noncentrality parameter. In this section we want to compute the noncentrality parameter λ of a noncentral gamma distribution given the parameters a and x and given the lower tail probability p:

(25) For given x, a, and p determine λ such that $F(x|a,\lambda) = p$ with $p \le \frac{1}{2}$.

If the upper tail probability were given we would use the complementary distribution function $F^c(x|a,\lambda)$ instead of $F(x|a,\lambda)$ to avoid cancellation. We want to point out that for noncentral distributions the inversion with respect to the noncentrality parameter is of higher practical relevance than the computation of classical quantiles in many applications (e.g., for the computation of the effect size or the necessary sample size at a given power). Now we want to show how to solve the problem (25). For given x and a we have $F(x|a,\lambda) \downarrow 0$ for $\lambda \uparrow \infty$ as we shall see in a moment, and therefore the probability p must be smaller than $F(x|a,0) = F(x|a)$ or there exists no solution to (25). We propose using the Newton algorithm for finding zeros of a function $f(\lambda)$:

$$\lambda_{i+1} = \lambda_i - \frac{f(\lambda_i)}{f'(\lambda_i)}. \tag{26}$$

In our case we have $f(\lambda) = F(x|a,\lambda) - p$ with $x > 0, a > 0, 0 < p \le F(x|a)$, and $\lambda \ge 0$. The computation of $f(\lambda)$ can be performed using the methods in the previous sections and all we need is a numerically stable algorithm for the computation of $f'(\lambda)$ that can guarantee a given relative precision. Relative precision is crucial as otherwise the recursion becomes useless if $f'(\lambda)$ becomes small, although a moderate relative precision of 10^{-3} or so would be sufficient. From the representation (9) we derive

$$f'(\lambda) = \frac{d}{d\lambda}F(x|a,\lambda) = \sum_{i=0}^{\infty} \frac{d}{d\lambda}p(i+1,\lambda)F(x,a+i), \tag{27}$$

and as

$$\frac{d}{d\lambda}p(i+1,\lambda) = \begin{cases} -p(i+1,\lambda) + p(i,\lambda) & \text{for} \quad i > 0, \\ -p(i+1,\lambda) & \text{for} \quad i = 0, \end{cases} \tag{28}$$

we find

$$f'(\lambda) = -F(x|a,\lambda) + F(x|a+1,\lambda). \tag{29}$$

As $f'(\lambda)$ is the first derivative of $F(x|a,\lambda)$ with respect to λ, we could also compute derivatives of higher order by iterative application of (29). Now, the monotonicity property (10) for the central gamma distribution is also valid for noncentral distributions:

$$F(x|a,\lambda) \downarrow 0 \quad \text{for} \quad a \uparrow \infty. \tag{30}$$

This is obvious from the representation (9) of the noncentral distribution. So, we see from (29) that $f'(\lambda) < 0$ and this proves the above-mentioned monotonicity property in λ. Now, using the factorization $F(x|a) = p(a,x)I(a,x)$ given by (4) and the recurrence relations (5) and (16) for the factors $I(a,x)$ and $p(a,x)$, equation (29) simplifies to

$$f'(\lambda) = -\sum_{i=0}^{\infty} t_i, \quad \text{where} \quad t_i = t_i(x,a,\lambda) = p(i+1,\lambda)p(a+i+1,x). \tag{31}$$

Again using the recurrence relation (16) for $p(a,x)$, we find

$$t_i = c_i t_{i-1} \quad \text{with} \quad c_i = \frac{\lambda x}{i(a+i)} \quad \text{for} \quad i > 0. \tag{32}$$

We see that $c_i \downarrow 0$ for $i \uparrow \infty$ which means that for increasing i the terms t_i are increasing as long as $c_i > 1$ and decreasing as soon as $c_i < 1$. Let k be the smallest integer i with $c_i < 1$, i.e.,

$$k = \lceil \sqrt{a^2/4 + \lambda x} - a/2 \rceil. \tag{33}$$

Then the term t_k is the largest term in the series $\sum t_i$. Now, we decompose this series as follows:

$$f'(\lambda) = -\sum_{i=0}^{\infty} t_i = -\left(\sum_{i=0}^{k-1} t_i + t_k + \sum_{i=k+1}^{\infty} t_i \right) = -(L_k + t_k + U_k). \tag{34}$$

We have

$$\begin{aligned} U_k &= t_{k+1} + t_{k+2} + \cdots \\ &= t_k(c_{k+1} + c_{k+1}c_{k+2} + \cdots) \\ &= t_k I_k, \end{aligned} \tag{35}$$

and from this we see that

$$\begin{aligned} &I_k \downarrow 0 \quad \text{for} \quad k \uparrow \infty, \\ &I_{k-1} = c_k(1 + I_k). \end{aligned} \tag{36}$$

As (36) is equivalent to (5), we can compute the factor I_k with a given relative error ε in exactly the same way as in (7). For the term L_k we use the recurrence relation (32) in the other direction:

$$t_i = d_i t_{i+1} \quad \text{with} \quad d_i = \frac{(i+1)(a+i+1)}{\lambda x} = \frac{1}{c_{i+1}} \quad \text{for} \quad i \geq 0 \tag{37}$$

and now we can write

$$\begin{aligned} L_k &= t_{k-1} + t_{k-2} + \cdots \\ &= t_k(d_{k-1} + d_{k-1}d_{k-2} + \cdots) \qquad (38) \\ &= t_k J_k. \end{aligned}$$

From this we see that

$$\begin{aligned} J_k \downarrow 0 \quad &\text{for} \quad k \downarrow 0, \\ J_{k+1} &= d_k(1 + J_k). \end{aligned} \qquad (39)$$

Note that this is completely symmetric to (36) up to the direction of the recursion, and J_k can be computed in exactly the same way as the quantity I_k up to the direction of the recursion. Also notice that $J_0 = 0$ and so the open recursion with the approximate starting value $\tilde{J}_{k-n} = 0$ becomes exact if $n = k$; the problem with the exact starting value J_b for $0 < b < 1$ in the recursion (8) does not exist here as k is an integer. If we set $\bar{L}_k = L_k + t_k$ and $\bar{J}_k = J_k + 1$ then we have the recurrence relation $\bar{J}_{k+1} = 1 + d_k \bar{J}_k$ which is equivalent to (6). But as the number of steps to compute the quantities J_k and $\bar{J}_k$ is exactly the same (up to the first trivial step when computing $\bar{J}_k$), we prefer here the quantity J_k that is completely symmetric to I_k. So, all terms t_k, I_k, and J_k can be computed with a given relative precision and this means that

$$f'(\lambda) = -\sum_{i=0}^{\infty} t_i = -(L_k + t_k + U_k) = -t_k(J_k + 1 + I_k) \qquad (40)$$

can also be computed with a given relative precision.

So, the numerator $f(\lambda_i)$ and the denominator $f'(\lambda_i)$ in the Newton algorithm (26) can be computed with the methods described in this paper. Further, a useful starting value can be derived from the facts that the distribution of a standardized noncentral gamma variable is approximately normal if a is not too small and the expectation and the variance of a noncentral gamma variable are $a + \lambda$ and $a + 2\lambda$, respectively.

LOCATING AND COMPUTING ALL THE SIMPLE ROOTS AND EXTREMA OF A FUNCTION*

DIMITRIS J. KAVVADIAS†‡ AND MICHAEL N. VRAHATIS†

Abstract. This paper describes and analyzes two algorithms for locating and computing with certainty all the simple roots of a twice continuously differentiable function $f: (a, b) \subset \mathbb{R} \to \mathbb{R}$ and all the extrema of a three times continuously differentiable function in (a, b). The first algorithm locates and computes all the simple roots or all the extrema, while the second one is more efficient in the case where both simple roots and extrema are required.

This paper also gives analytical estimation of the expected complexity of the algorithms based on the distribution of the roots in (a, b). Here only the case of uniform distribution is examined, which is also the approach to be followed when no statistical data are available for the function at hand.

The algorithms have been implemented and tested. Performance information for a well-known Bessel function is reported.

Key words. zeros isolation, Kronecker–Picard theory, topological degree, locating simple roots and extrema, computing simple roots and extrema, combinatorial optimization, zeros identifications, distribution of the roots and extrema, expected algorithms complexity, Bessel functions

AMS subject classifications. 65H05, 68C25

1. Introduction.

It is well known that information concerning all the roots and/or all the extrema of a function

$$f: (a, b) \subset \mathbb{R} \to \mathbb{R} \tag{1.1}$$

is of major importance in many different fields of science and technology.

An immediate method to accomplish this task suggests scanning the interval (a, b) and applying some rootfinding method for each consecutive root. The method that is employed here is heavily based on the knowledge of the total number of roots within (a, b). In order to obtain this information we use results from topological degree theory and especially from the theory of the Kronecker–Picard integral [24, 25]. This theory gives a formula for the computation of the total number of roots of a system of equations within a given region. With this tool in hand one can construct a procedure for the localization and isolation of all the roots by dividing the given region successively and applying the above formula to these subregions until the final domains contain at most one root. To our knowledge, the first method to this end was introduced by Hoenders and Slump [10, 11, 28], who recently reconsidered and applied Kronecker–Picard theory to calculate the total number of simple roots of a system of nonlinear equations as well as to calculate the total number of multiple roots of a single equation of any multiplicity.

Other approaches that have been used successfully to find all solutions of systems of equations as well as the global optimum of a function are based on interval analysis (see, for example, [1, 7, 8, 9, 15, 16, 17]). The corresponding existence tool of these methods is the availability of the range of the function in a given interval, which can be implemented very efficiently using interval arithmetic, though accuracy problems must be resolved. This tool, however, reports with certainty only the negative case, i.e., when no roots are in the interval. The positive case proceeds by subdividing the interval into two halves and employing additional criteria. This case is common when the function has many extrema but few roots in the interval of interest. In addition, this tool provides the existence of a root and not their exact number, which means that more sophisticated decisions (than merely subdividing) cannot be made.

In this paper we implement Kronecker–Picard theory and give a method for locating and computing all the simple roots of a twice continuously differentiable function and all the extrema of a three times continuously differentiable function in an interval (a, b). In addition, we give analytical expressions of the total *expected* work needed in achieving the isolation and computation of all the roots of (1.1) under certain assumptions that we present in the sequel. This may prove to be very useful in real life applications since very early estimations of the total running time of the algorithm are available, contrary to other methods which are totally unpredictable. Nevertheless, it is important to notice that our analytical results and techniques also apply to any method that proceeds by repeated subdivisions, giving the expected depth of the subdivision under the same assumptions. Moreover, the main computational burden of our method comes from the need of an integration, a problem that has been studied extensively and for which numerous methods exist.

The rootfinding portion of our method employs a modification of the well-known bisection method. Alternatively, any one of the one-dimensional rootfinding methods (see [23, 20, 21, 26, 2]) can be used. We use the bisection method for several reasons which we explain in §2.2, among which is its known behavior concerning the number of iterations required when we seek the root with a predetermined accuracy.

Here we study the one-dimensional case only. The reason for this restriction is that the corresponding analysis of our method to n dimensions seems to be quite different.

2. Theoretical aspects. Our algorithms are separated in two phases: (1) the phase of the localization and the isolation of all the roots, and (2) the rootfinding phase for the computation of all the roots within a predetermined accuracy.

For the localization phase we use a method of determining the total number of simple roots of a single equation within a given interval. To this end we briefly exploit degree theory for determining the exact number of roots of a single equation by computing the value of topological degree using Kronecker's integral [19, 3, 29, 22, 13] on Picard's extension [24, 25, 10, 28, 11].

For the rootfinding phase we have chosen the bisection method for reasons to be explained later.

2.1. The topological degree for the computation of the total number of roots and extrema. Let us first define the notion of the topological degree. Suppose that the function $F_n = (f_1, \dots, f_n): \mathcal{D}_n \subset \mathbb{R}^n \to \mathbb{R}^n$ is defined and two times continuously differentiable in a bounded domain $\mathcal{D}_n$ of $\mathbb{R}^n$ with boundary $b(\mathcal{D}_n)$. Suppose further that the roots of the equation $F_n(x) = \Theta_n$ ($\Theta_n = (0, \dots, 0)$ denotes the origin of $\mathbb{R}^n$) are not located on $b(\mathcal{D}_n)$ and they are simple; i.e., the Jacobian determinant of F_n at these roots is nonzero. Then the *topological degree of F_n at Θ_n relative to $\mathcal{D}_n$* is denoted by $\deg[F_n, \mathcal{D}_n, \Theta_n]$ and can be defined by the following sum:

$$\deg[F_n, \mathcal{D}_n, \Theta_n] = \sum_{x \in F_n^{-1}(\Theta_n)} \operatorname{sgn} J_{F_n}(x), \tag{2.1}$$

where J_{F_n} denotes the determinant of the Jacobian matrix and sgn defines the sign function.

The above definition can be generalized when F_n is only continuous [23]. In this case, Kronecker's theorem [3, 23] states that $F_n(x) = \Theta_n$ has at least one root in $\mathcal{D}_n$ if $\deg[F_n, \mathcal{D}_n, \Theta_n] \neq 0$. Furthermore, if $\mathcal{D}_n = \mathcal{D}_n^1 \cup \mathcal{D}_n^2$ where $\mathcal{D}_n^1$ and $\mathcal{D}_n^2$ have disjoint interiors and $F_n(x) \neq \Theta_n$ for all $x \in b(\mathcal{D}_n^1) \cup b(\mathcal{D}_n^2)$, then the topological degree is additive.

Several methods for the computation of the topological degree have been proposed in the past few years [29, 22, 13, 14, 30, 31, 4]. Also, $\deg[F_n, \mathcal{D}_n, \Theta_n]$ can be represented by the

Kronecker integral, which is closely tied with facts used later and is defined as follows:

$$(2.2)\quad \deg[F_n, \mathcal{D}_n, \Theta_n] = \frac{\Gamma(n/2)}{2\pi^{n/2}} \int\int_{b(\mathcal{D}_n)} \cdots \int \frac{\sum_{i=1}^{n} A_i dx_1 \ldots dx_{i-1} dx_{i+1} \ldots dx_n}{({f_1}^2 + {f_2}^2 + \ldots + {f_n}^2)^{n/2}},$$

where A_i is defined by the following determinant:

$$(2.3)\qquad A_i = (-1)^{n(i-1)} \begin{vmatrix} F_n & \dfrac{\partial F_n}{\partial x_1} & \cdots & \dfrac{\partial F_n}{\partial x_{i-1}} & \dfrac{\partial F_n}{\partial x_{i+1}} & \cdots & \dfrac{\partial F_n}{\partial x_n} \end{vmatrix}.$$

Now, since $\deg[F_n, \mathcal{D}_n, \Theta_n]$ is equal to the number of simple roots of $F_n(x) = \Theta_n$ which give positive Jacobian minus the number of simple roots which give negative Jacobian, then of course the total number $\mathcal{N}^r$ of simple roots of $F_n(x) = \Theta_n$ can be obtained by the value of $\deg[F_n, \mathcal{D}_n, \Theta_n]$ if all these roots give the same Jacobian sign. To this end Picard considered the following extensions of the function F_n and the domain $\mathcal{D}_n$:

$$(2.4)\qquad F_{n+1} = (f_1, \ldots, f_n, f_{n+1}) \colon \mathcal{D}_{n+1} \subset \mathbb{R}^{n+1} \to \mathbb{R}^{n+1},$$

where $f_{n+1} = y\, J_{F_n}$, $\mathbb{R}^{n+1} : x_1, x_2, \ldots, x_n, y$, and $\mathcal{D}_{n+1}$ is the direct product of the domain $\mathcal{D}_n$ with an arbitrary interval of the real y–axis containing the point $y = 0$. Then the roots of the system of equations

$$(2.5)\qquad \begin{aligned} &f_i(x_1, x_2, \ldots, x_n) = 0, \quad i = 1, \ldots, n, \\ &y\, J_{F_n}(x_1, x_2, \ldots, x_n) = 0 \end{aligned}$$

are the same simple roots of $F_n(x) = \Theta_n$ provided $y = 0$. On the other hand, it is easily seen that the Jacobian of (2.5) is equal to $\left(J_{F_n}(x)\right)^2$, which is always positive. Thus, we conclude that the total number $\mathcal{N}^r$ of roots of $F_n(x) = \Theta_n$ can be given by the following relation:

$$(2.6)\qquad \mathcal{N}^r = \deg[F_{n+1}, \mathcal{D}_{n+1}, \Theta_{n+1}].$$

We consider now the problem of calculating the total number of simple roots of $f(x) = 0$, where $f \colon (a, b) \subset \mathbb{R} \to \mathbb{R}$ is twice continuously differentiable in a predetermined interval (a, b), where a and b are arbitrarily chosen such that $f(a)\, f(b) \neq 0$. According to Picard's extension we define the function $F_2 = (f_1, f_2) \colon \mathcal{P} \subset \mathbb{R}^2 \to \mathbb{R}^2$ and the corresponding system

$$(2.7)\qquad \begin{aligned} f_1(x, y) &= f(x) = 0, \\ f_2(x, y) &= yf'(x) = 0, \end{aligned}$$

where the prime denotes differentiation and where $\mathcal{P}$ is an arbitrarily chosen rectangular parallelepiped in the (x, y)–plane given by $a \leq x \leq b$ and $-\gamma \leq y \leq \gamma$ with γ a small positive constant.

Now, since the roots are simple, which means $f'(x) \neq 0$ for $x \in f^{-1}(0)$, it is easily seen that the roots of (2.7) in the above-defined region are the same roots as (1.1). Also, since $J_{F_2} = {f'}^2$, the total number of simple zeros $\mathcal{N}^r$ of the function (1.1) in (a, b) can be given by

$$(2.8)\qquad \mathcal{N}^r = \deg[F_2, \mathcal{P}, \Theta_2].$$

Now, for $n = 2$, by applying (2.1) and using the relations $df_j = \frac{\partial f_j}{\partial x_1} dx_1 + \frac{\partial f_j}{\partial x_2} dx_2$, where $j = 1, 2$, we can easily obtain

$$(2.9)\qquad \mathcal{N}^r = \frac{1}{2\pi} \oint_{b(\mathcal{P})} \frac{f_1 df_2 - f_2 df_1}{{f_1}^2 + {f_2}^2} = \frac{1}{2\pi} \oint_{b(\mathcal{P})} d \arctan\left(\frac{f_2}{f_1}\right).$$

Replacing f_1 and f_2 by virtue of (2.7) and performing the integration in (2.9) we finally get

$$\mathcal{N}^r = -\frac{1}{\pi}\left[\gamma \int_a^b \frac{f(x)f''(x) - f'^2(x)}{f^2(x) + \gamma^2 f'^2(x)}\, dx + \arctan\left(\frac{\gamma f'(b)}{f(b)}\right) - \arctan\left(\frac{\gamma f'(a)}{f(a)}\right)\right]. \tag{2.10}$$

It has been shown by Picard [24, 25] that the relation (2.10) is independent of the value of γ.

Of course the total number $\mathcal{N}^e$ of the extrema of $f \in C^3$, i.e., $x \in (a, b)$ such that $f'(x) = 0$, can be obtained by setting in (2.9) $f_1 = f'$ and $f_2 = yf''$.

Remark 2.1. Using (2.10) it is possible that in many applications $\mathcal{N}^r$ can be computed analytically. If not, one can use numerical integration [26].

The Kronecker–Picard integral can also be applied for the determination of the total number of multiple roots [5, 32]. Along these lines, Hoenders and Slump gave in [11] a method for the determination of the total number of multiple roots of a single function. According to their method, if $f\colon (a, b) \subset \mathbb{R} \to \mathbb{R}$ is a k times continuously differentiable function, then the total number of zeros $\mathcal{N}_m^r$ of $f(x) = 0$ with multiplicity m or higher where $m \leq k$ can be obtained by the value of the topological degree calculated in a parallelepiped $\mathcal{P}$ by using in (2.7) as f_1 and f_2

$$\begin{aligned} f_1 &= f^2 + \sum_{l=1}^{m} \left(\frac{d^l f}{dx^l}\right)^2, \\ f_2 &= yf_1'. \end{aligned} \tag{2.11}$$

2.2. A modified bisection method. *Notation* 2.1. Throughout this paper the notation $\lceil\cdot\rceil$ refers to the smallest integer not less than the real number quoted; $\ell(I)$ indicates the length of the interval I.

It is well known that a solution of $f(x) = 0$ where the function f is continuous is guaranteed to exist in some interval $[a, b]$ if the following criterion is fulfilled:

$$f(a)\, f(b) \leq 0. \tag{2.12}$$

This criterion is known as Bolzano's existence criterion. Instead of Bolzano's criterion one may also use the value of the topological degree of f at origin relative to (a, b), which in this case can be defined as follows:

$$\deg[f, (a, b), 0] = \frac{1}{2}\left(\operatorname{sgn} f(b) - \operatorname{sgn} f(a)\right). \tag{2.13}$$

Now, if $\deg[f, (a, b), 0]$ is not zero, we know with certainty that there is at least one root in (a, b). Note that if $\deg[f, (a, b), 0]$ is not zero, then Bolzano's criterion is fulfilled. The value of $\deg[f, (a, b), 0]$ gives additional information concerning the behavior of the solutions of $f(x) = 0$ in (a, b) relative to the slopes of f [35]. For example, if $\deg[f, (a, b), 0] = 1$, which means that $f(b) > 0$ and $f(a) < 0$, then the number of solutions at points where $f(x)$ has a positive slope exceeds by one the number of solutions at points at which $f(x)$ has a negative slope.

Using the value of the topological degree (or, alternatively, Bolzano's criterion) we are able to calculate a solution of $f(x) = 0$ by bisecting the interval $I_0 = (a, b)$. So we subdivide I_0 into two intervals $(a, c], [c, b)$ where $c = (a + b)/2$ is the midpoint of (a, b) and we keep the subinterval for which the value of the topological degree is not zero relative to itself by checking the information on the boundaries. In this way we always keep at least one solution within a smaller interval. We can continue this procedure in order to approximate a solution until the endpoints of the final subinterval differ from each other by less than a fixed amount. This method is called the *bisection method* and can be generalized to higher dimensions [33, 34].

The main idea in order to locate all the solutions r_j, where $j = 1, \ldots, \mathcal{N}^r$ of $f(x) = 0$ in (a, b), is to subdivide the interval (a, b) and find $\mathcal{N}^r$ subintervals (a_j, b_j) for which the relation (2.12) is fulfilled. Now, for each one subinterval (a_j, b_j) we can apply any method to compute the root which is included in (a_j, b_j). Here we shall use the above-mentioned bisection method which has been modified to the following simplified version described in [33, 34]:

$$x_{i+1} = x_i + \operatorname{sgn} f(x_0) \operatorname{sgn} f(x_i)\, \ell(I_0)/2^{i+1}, \qquad x_0 = a, \qquad i = 0, 1, \ldots . \tag{2.14}$$

The sequence (2.14) converges to a root $r \in (a, b)$ if, for some x_i, $\operatorname{sgn} f(x_0) \operatorname{sgn} f(x_i) = -1$. Also, the number of iterations ν, which are required in obtaining an approximate root r^* such that $|r - r^*| \leq \varepsilon$ for some $\varepsilon \in (0, 1)$, is given by

$$\nu = \lceil \log_2(\ell(I_0)\, \varepsilon^{-1}) \rceil. \tag{2.15}$$

Instead of the iterative formula (2.14) we can also use

$$x_{i+1} = x_i - \operatorname{sgn} f(x_0) \operatorname{sgn} f(x_i)\, \ell(I_0)/2^{i+1}, \qquad x_0 = b, \qquad i = 0, 1, \ldots . \tag{2.16}$$

The bisection method always converges within the given interval (a, b) and it is a global convergence method. Moreover, it has a great advantage since it is optimal; i.e., it possesses asymptotically the best possible rate of convergence [27]. Also, using the relation (2.15) it is easy to have beforehand the number of iterations that are required for the attainment of an approximate root to a predetermined accuracy. Finally, it requires only the algebraic signs of the functions values to be computed, as is evident from (2.14) or (2.16); thus, it can be applied to problems with imprecise function values.

3. The algorithms. The algorithms are a sort of "guided" form of the bisection method. They use the outcome of relation (2.10) in order to isolate the roots or extrema by dividing the initial interval (a, b) into smaller intervals. Algorithm *find_roots*, described below in "pseudo Pascal," first determines the number of roots in the interval by applying (2.10) (step 8) and, if there are more than one, it divides the interval into m_n equal-size subintervals (steps 6 and 7) and proceeds recursively to each of the subintervals. We propose m_n to be equal to the number of roots though there are several issues to be considered here. We discuss this subject later on.

```
ALGORITHM find_roots($a$, $b$, $S$);
{comment: This algorithm locates and computes all the roots or all the extrema of $f(x) = 0$
  in $(a, b)$. It exploits (2.10) and (2.14). For (2.10) it requires $f$, $f'$, $f''$, and $\gamma$ while for (2.14)
  it requires $f$ and $\varepsilon$}
01. procedure roots($a, b, \mathcal{N}^r$); {comment: adds to set $S$ the $\mathcal{N}^r$ roots of the interval $(a, b)$}
      begin
02.     if $\mathcal{N}^r = 1$ then find the single root $r$ using the bisection (2.14), set $S \longleftarrow S \cup \{r\}$
        else
          begin
03.         $j \longleftarrow 1$; {comment: this counts the subintervals $I_j = (a_j, b_j)$}
04.         $k \longleftarrow 0$; {comment: this counts the computed roots}
05.         while $k < \mathcal{N}^r$ do
              begin
06.             $a_j \longleftarrow a + (j-1)\frac{b-a}{m_n}$; {comment: $m_n$ is the number of subintervals
                                                  in which we choose to divide $(a, b)$}
07.             $b_j \longleftarrow a + j\frac{b-a}{m_n}$;
08.             Find $\mathcal{N}_j^r$, the number of roots in $I_j$ using (2.10);
09.             if $\mathcal{N}_j^r > 0$ then roots($a_j, b_j, \mathcal{N}_j^r$);
```

```
            $k \longleftarrow k + \mathcal{N}_j^r$;
            $j \longleftarrow j + 1$
        **end** {while}
    **end**
  **end** {roots}
**begin** {find_roots}
  input $a, b$; {**comment**: $f(a)\, f(b)$ must be nonzero}
  $S \longleftarrow \emptyset$; {**comment**: $S$ is the set of roots in $(a, b)$}
  Find $\mathcal{N}_0^r$, the number of roots in $(a, b)$ using (2.10);
  roots($a, b, \mathcal{N}_0^r$);
  output $S$
**end.** {find_roots}
```

Remark 3.1. The case where only the extrema are required can be handled by the same algorithm by replacing the function f by its first derivative f'.

In the case where both roots and extrema are required, we can certainly apply the above method twice for f and f', respectively. But since the extrema lie between consecutive simple roots which are discovered by the first run of *find_roots* (for f), we now choose to divide initially at exactly the points of the roots. We next apply *find_roots* for f' for each subinterval between two consecutive roots. A high-level description of this algorithm follows.

```
ALGORITHM *roots_extrema*($a$, $b$, $S'$);
{**comment**: This algorithm locates and computes all the roots and all the extrema of $f(x)$
in $(a, b)$. It uses (2.10) and (2.14). For (2.10) it requires $f$, $f'$, $f''$, $f'''$, and $\gamma$ while for
(2.14) it requires $f$, $f'$, and $\varepsilon$}
**begin** {roots_extrema}
Find $\mathcal{N}^e$, the number of extrema in $(a, b)$ using (2.10);
Apply algorithm find_roots; Let $S = \{r_1, \dots, r_{\mathcal{N}^r}\}$ be its sorted output.
Construct the subintervals $I_j = (a_j, b_j) = (r_{j-1}, r_j)$, $j = 1, \dots, \mathcal{N}^r + 1$, $r_0 = a$,
  $r_{\mathcal{N}^r+1} = b$.
$E \longleftarrow \mathcal{N}^r - 1$; {**comment**: $E$ counts the number of verified extrema}
**if** $f'(a)\, f'(r_1) < 0$ **then** $E \longleftarrow E + 1$;
**if** $f'(r_{\mathcal{N}^r})\, f'(b) < 0$ **then** $E \longleftarrow E + 1$;
**if** $E = \mathcal{N}^e$ **then** apply bisection (2.14) (using $f'$) in all $I_j$. Let $S'$ the set of the extrema.
**else**
  **begin**
    $S' \longleftarrow \emptyset$;
    $j \longleftarrow 1$; {**comment**: this counts the subintervals $I_j = (a_j, b_j)$}
    $k \longleftarrow 0$; {**comment**: this counts the computed extrema}
    **while** $k < \mathcal{N}^e - E + j - 1$ **do**
      {**comment**: when $k + E - j + 1 = \mathcal{N}^e$, it is assured that
       only one extremum exists in each remaining interval}
      **begin**
        Apply algorithm *find_roots* in $I_j$ using $f'$; Let $S_j'$ be its output;
        Set $S' \longleftarrow S' \cup S_j'$; {**comment**: $S_j'$ will be the set of the extrema in $(a_j, b_j)$}
        $k \longleftarrow k + |S_j'|$;
        $j \longleftarrow j + 1$
      **end** {while}
    Apply bisection (2.14) (using $f'$) in all $I_l$ for $l = j + 1, \dots, \mathcal{N}^r$; set $S' \longleftarrow S' \cup S_l'$
  **end**
output $S'$
**end.** {roots_extrema}
```

Returning to algorithm *find_roots* and assuming that the number of roots in a subinterval is always available (say it is given by an "oracle"), it is clear that the computational complexity of the algorithm is determined by (1) the total number of calls to the oracle and (2) the iterations required by the $\mathcal{N}^r$ bisection calls which will compute the isolated roots.

4. The expected complexity of the algorithm. In this section we study the expected complexity of algorithm *find_roots*. First, we focus our attention on the number of times the number of roots has to be found in a given interval, i.e., the *average number of oracle calls* as this is the most demanding step of the localization phase. The rootfinding phase is dominated by the *average number of iterations* of the bisection method.

4.1. Preliminaries, definitions, and notations. The study presented here follows certain assumptions:

(i) The size of the problem is the total number of roots of $f(x)$ in (a, b).

(ii) We view each root of $f(x)$ as a random variable having a given distribution in (a, b). All roots are considered as pairwise independent variables having the same distribution. In this paper we assume that the distribution is *uniform*; i.e., it is equally likely for any point in the interval to be a root.

(iii) The study of the expected complexity of the algorithm is *over all possible inputs to the algorithm*, that is, over all possible sets of n points in the interval (a, b) and, consequently, independent of the given function.

Assumption (iii) implies only partial knowledge of the properties of the specific function (the distribution of its roots), which may vary from complete ignorance as to whether the roots lie (our case) to full knowledge of the roots if the properties of the function are known. Hence, the analysis is independent of the specific function which merely serves (through Picard's integral) as an "oracle" that reveals the number of roots in a specific interval. This models real life applications where some physical quantity is of interest whose zeros are statistically independent with known (or suspected) distribution. It is indeed intermediate cases of the form "the roots are expected around the center of the interval" that are really the most interesting since this type of knowledge may "tune up" appropriate algorithms that take into account the additional information and perform better. It is also worthwhile mentioning that the same analysis applies to any method that isolates the roots by repeated subdivisions of the intervals, independently of how the oracle is implemented (a good example is interval analysis techniques for which the main result of §4.2 is a lower bound). In this paper we completely ignore possible properties of $f(x)$ and solve the following combinatorial problem, leaving the more complete study for future research:

Find the expected number of oracle calls that algorithm find_roots *will require in order to isolate all n points which are randomly and independently chosen with uniform distribution.*

In other words, we want to find the expected value $\big($over all possible patterns of appearances of n roots in the interval $I_0 = (a, b)\big)$ of a function H which, given a specific pattern of roots in the interval, returns the number of oracle calls required to isolate each root in a subinterval (a formal definition follows). Since, however, this function is noncontinuous and we want to avoid integrating in subintervals, we adopt a simpler approach *discretizing* the interval $I_0 = (a, b)$ and summing instead of integrating.

We begin by giving a list of symbols and definitions that we shall need later.

Notation 4.1. Let $|S|$ denote the cardinality of the set S. Let $[\cdot]$ denote the integer part of the number quoted. Notice that $[x, y]$ refers to the closed interval with endpoints x and y.

DEFINITION 4.1. *We call resolution δ of the algorithm a small positive real such that if x is a root in (a, b), any point in the interval $\left[x - \frac{\delta}{2}, x + \frac{\delta}{2}\right]$ is considered to be the root x.*

This definition means that as far as the algorithm is concerned, any two roots less that δ apart are considered to be one and, as one, are reported by the oracle in (2.10). We next consider I_0 to be divided into a large number of consecutive subintervals of length δ which we call *elementary*. Any subdivision of I_0 into small intervals (as stated in steps 6 and 7 of the algorithm, as well as any subdivision thereof) is considered to take place at points that are *integer* multiples of δ. Going one step beyond, we consider (for simplicity reasons) I_0 to be rounded to the smallest integer multiple of δ, say μ, such that $a + \mu\delta \geq b$. Clearly, $\mu = \lceil \frac{b-a}{\delta} \rceil$. Consequently, if m roots are reported by the oracle at step 14 of the algorithm, steps 6 and 7 will divide I_0 with length $\ell(I_0)$ into m intervals $I_i, i = 1, \ldots, m$ such that

$$I_i = \left(a + \delta \left[(i-1)\frac{\ell(I_0)}{m\delta} \right], a + \delta \left[i \frac{\ell(I_0)}{m\delta} \right] \right], \quad i = 1, 2, \ldots, m.$$

In the above we adopt the convention that all subintervals be open from the left and closed from the right, thus avoiding a point belonging in more than one subinterval at each level of subdivision. Unifying these conventions, we consider the initial interval I_0 to be $I_0 = (a, a + \mu\delta]$.

The above discretization suggests a more convenient way of representing intervals, namely, as sets of the elementary consecutive subintervals which are included in them. More specifically, consider assigning to each elementary subinterval of I_0 an integer from 1 to μ in increasing order from left to right. This suggests representing I_0 by the set of consecutive integers $T_0 = \{l \in \mathbb{N} \colon 1 \leq l \leq \mu\}$. The representation of a subinterval I_i is

$$T_i = \left\{ l \in T_0 \colon \left[(i-1)\frac{\ell(I_0)}{m\delta} \right] + 1 \leq l \leq \left[i \frac{\ell(I_0)}{m\delta} \right] \right\}.$$

Analogous relations hold for any subinterval of I_0. For our study, T_0 is the sample space with each of its points a candidate of being a root. In the sequel we shall use the term "interval" both for a standard interval I and its corresponding T set when no confusion arises. Similarly, extending Notation 2.1, we denote by $\ell(T)$ the length of the corresponding standard interval I.

In the analysis that follows we shall denote by X a variable representing a set of integers (or, for our purposes, a set of roots). If $X \subset T_l$, X is any set of elementary subintervals, i.e., a set of integers in T_l. In the context described above, the probability of a set X of cardinality k, denoted by Prob$\{X\}$, is the probability of choosing the k elementary subintervals that correspond to the k roots. For example, if the distribution of the roots is uniform, then the probability of a specific X set is $\binom{\mu}{|X|}^{-1}$. Using the above, we are now ready to formally define the function H.

DEFINITION 4.2. *Let S be the set of all subsets of T_0. The function $H \colon X \in S \to \mathbb{N}$ maps X to the number of oracle calls that the algorithm will do in order to isolate the roots represented by the set X. Similarly, we define the H function relative to an interval T denoted by $H_T(X)$ and which gives the number of oracle calls that the algorithm will do in the specific interval T*; *that is, in the latter case we only count oracle calls required for roots inside T.*

Remark 4.1. If the interval T_0 is divided in m_n subintervals, T_i, $i = 1, \ldots, m_n$, the number of oracle calls in T_0 is clearly $H_{T_0} = 1 + \sum_{i=1}^{m_n} H_{T_i} - 1 = \sum_{i=1}^{m_n} H_{T_i}$. The "1" comes from the initial oracle call which returns the number of roots in T_0 and the "-1" from the fact that no oracle call is required to obtain the number of roots of the last interval since this can be obtained by subtracting from the total number the sum of the roots in the rest of the $m_n - 1$ subintervals. The same relation holds for the value of the H function of any interval. Note that here we assume that all $m_n - 1$ oracle calls will be required in the while loop of step 5.

4.2. Theoretical results. We now study the expected behavior of our algorithm beginning from the first stage, where the roots are isolated each in an interval by its own. Specifically, we study the *expected number of oracle calls* required for this task as a function of the number of roots n. Observe that the number of intervals into which we choose to divide can be either constant or a function of n. By n we denote the total number of roots in the given interval (n is the $\mathcal{N}_0^r$ of step 14 of the algorithm *find_roots*.) In any case, deciding the value of m_n is based only on n, and this is the reason why we denoted the number of subdivisions subscribed by n. As stated in Remark 4.1, the approach that follows assumes that all $m_n - 1$ calls are required in an interval which is divided into m_n subintervals. This is equivalent to replacing the while statement of step 5 by the statement **while** $j < m_n$ **do**. This is done for simplicity reasons and it is removed after the next theorem is proved.

THEOREM 4.1. *Suppose that the algorithm find_roots divides any interval T_0 with n roots into m_n subintervals $T_i, i = 1, \ldots, m_n$. Then the expected number of oracle calls required by the algorithm to isolate all n roots is given by the formula*

$$E_H(n) = {m_n}^{1-n} \sum_{k=0}^{n} \binom{n}{k} (m_n - 1)^{n-k} E_H(k) \tag{4.1}$$

or, equivalently,

$$E_H(n) = \sum_{k_1+\cdots+k_{m_n}=n} \frac{n!}{k_1!\cdots k_{m_n}!} {m_n}^{-n} \left(E_H(k_1) + \cdots + E_H(k_{m_n})\right), \tag{4.2}$$

where $E_H(0) = E_H(1) = 1$.

Proof. We shall show first (4.2). Clearly, $E_H(0) = E_H(1) = 1$ since, when no root or a single root is in T_0, then only one oracle call is required. For $n \geq 2$ let $X_i, i = 1, \ldots, m_n$ be the set of roots that lay in interval T_i. Clearly, $|X_1| + \cdots + |X_{m_n}| = n$. The distribution of the corresponding vector of the cardinalities of the X_i's $(|X_1|, \ldots, |X_{m_n}|)$ is polynomial; that is,

$$\text{Prob}\{|X_1| = k_1, \ldots, |X_{m_n}| = k_{m_n}\} = \frac{n!}{k_1!\cdots k_{m_n}!} {m_n}^{-n}. \tag{4.3}$$

This is immediate since Prob{some specific root lies in T_i} $= {m_n}^{-1}$ because of the uniform distribution of the roots in (a, b).

Let $\tilde{X} = X_1 \cup X_2 \cup \cdots \cup X_{m_n}$. By Remark 4.1 we have

$$H(\tilde{X}) = H_{T_1}(X_1) + H_{T_2}(X_2) + \cdots + H_{T_{m_n}}(X_{m_n}).$$

Taking the expectation [6] of both sides of the above we have

$$\begin{aligned} E\{H(\tilde{X})\} &= E\{H_{T_1}(X_1) + H_{T_2}(X_2) + \cdots + H_{T_{m_n}}(X_{m_n})\} \\ &= E\left\{E\{H_{T_1}(X_1) + H_{T_2}(X_2) + \cdots + H_{T_{m_n}}(X_{m_n}) \,\Big|\, |X_1| = k_1, \ldots, |X_{m_n}| = k_{m_n}\}\right\}, \end{aligned} \tag{4.4}$$

where the outer expectation is over all sets $\tilde{X} = X_1 \cup \cdots \cup X_{m_n}$ such that $|X_1| = k_1, \ldots, |X_{m_n}| = k_{m_n}$ with $k_1 + \cdots + k_{m_n} = n$. Now, the expectation of $H_{T_i}(X_i)$ where X_i runs over all possible choices of sets in T_i with $|X_i| = k_i$ depends only on the cardinality k_i of X_i. We may, therefore, simplify our notation and denote by $E_H(k_i)$ the expectation $E\{H_{T_i}(X_i)\}$. Note that we have also dropped the subscript T_i since the expectation does not depend on the specific interval either, as the distribution is uniform. Using linearity in the inner conditional expectation and the above observation we get

$$E_H(n) = E\left\{E_H(k_1) + \cdots + E_H(k_{m_n}) \,\Big|\, |X_1| = k_1, \ldots, |X_{m_n}| = k_{m_n}\right\}.$$

Using (4.3) we finally obtain

$$E_H(n) = \sum_{k_1+\cdots+k_{m_n}=n} \frac{n!}{k_1!\cdots k_{m_n}!} {m_n}^{-n} \left(E_H(k_1) + \cdots + E_H(k_{m_n})\right).$$

In order to show (4.1), observe that the above equation may be written as

$$\begin{aligned} E_H(n) &= \sum_{k=0}^{n} \binom{n}{k} {m_n}^{-k} \sum_{\substack{k_1+\cdots+k_{i-1}\\ +k_{i+1}+\cdots+k_{m_n}=n-k}} \binom{n-k}{k_1,\ldots,k_{i-1},k_{i+1},\ldots,k_m} {m_n}^{k-n} E_H(k) \\ &= \sum_{k=0}^{n} {m_n}^{-k} \binom{n}{k} \left(\frac{1}{m_n} + \cdots + \frac{1}{m_n}\right)^{n-k} E_H(k), \end{aligned}$$

where $m_n - 1$ fractions are added. Equation (4.1) now follows easily. □

Remark 4.2. Solving (4.1) with respect to $E_H(n)$ results in the following formula which can be used to obtain numerical values for $E_H(n)$:

$$E_H(n) = \left({m_n}^{n-1} - 1\right)^{-1} \sum_{k=0}^{n-1} \binom{n}{k} (m_n - 1)^{n-k} E_H(k). \tag{4.5}$$

An interesting question is raised as to whether we can remove recursion from (4.1). It turns out that recurrences of the above form are very difficult to handle. We were unable to do so in the general case, that is, when m is a function of n, or even in the case $m = n$, which is particularly interesting. However, when m is constant, we reduced (4.1) to a known recurrence solved in [18] by the use of *binomial transformations*. This is done by finding a recurrence for the sequence $E'_H(k) = E_H(k) - 1$, $k = 0, 1, \ldots$. By employing the techniques described in [18, p. 501] we can show that for $n \geq 2$

$$E'_H(n) = (m-1) \sum_{k=2}^{n} \binom{n}{k} \frac{(-1)^k (k-1) m^{k-1}}{m^{k-1} - 1}. \tag{4.6}$$

Observe that m is referred to without a subscript since the above hold when m is a constant.

We conclude the study of the first phase by examining the complexity of the algorithm *find_roots* as stated originally, that is, when step 5 includes the condition $k < \mathcal{N}^r$. Then we may be able to save several oracle calls if all the roots fall into the first few intervals and, consequently, it is unnecessary to call the oracle for the rest of the intervals. In order to calculate how much we overestimated the expected complexity in Theorem 4.1, observe that in (4.4) the expectation is over every possible $\tilde{X}$ with cardinality n. But if $\tilde{X}$ totally falls in intervals T_1 to T_i, algorithm *find_roots* will not require oracle calls for the last $m_n - i$ intervals. So the expectation was overestimated by $(m_n - i) \times \text{Prob}\{\tilde{X}$ totally falls in intervals T_1 to $T_i\}$. For example, when $\tilde{X}$ is totally included in the first interval, then a term $(\frac{1}{m_n})^n (m_n - 1)$ must be subtracted. Similarly, an additional $(m_n - 2)\left((\frac{2}{m_n})^n - (\frac{1}{m_n})^n\right)$ must be subtracted when $\tilde{X}$ is totally included in the first two intervals. The subtracted $(\frac{1}{m_n})^n$ is the probability of $\tilde{X}$ to fall totally in the first interval and was already counted in the term $(\frac{1}{m_n})^n (m_n - 1)$. Hence, we must decrease (4.1) by

$$\sum_{i=1}^{m_n} \left[\left(\frac{i}{m_n}\right)^n - \left(\frac{i-1}{m_n}\right)^n \right] (m_n - i) = \sum_{i=1}^{m_n - 1} \left(\frac{i}{m_n}\right)^n .$$

We, therefore, have the following theorem.

THEOREM 4.2. *The expected number of oracle calls of algorithm find_roots is given by*

$$E_H(n) = m_n^{1-n} \sum_{k=0}^{n} \binom{n}{k} (m_n - 1)^{n-k} E_H(k) - \sum_{i=1}^{m_n - 1} \left(\frac{i}{m_n} \right)^n . \tag{4.7}$$

Proof. The proof follows immediately from Theorem 4.1 and the above discussion. □

We next proceed to the study of the second phase of the algorithm when all the roots have been isolated, each in its own interval. This second phase consists of a number of bisections that are applied in those intervals. Our task, therefore, requires the definition of a complexity function that will capture the actual work of the second phase, like the H function defined above. A promising approach might be to use the *average length* of the n intervals that are searched by bisection. (Note here that we are talking about the average length of the intervals of a *specific* run of the algorithm and not over every possible run. Should we accept this approach, we must next calculate the *expected average length* of the intervals.) But there is a subtle point here. The actual average case work of the bisection is logarithmically related to the length of the interval in which it is applied (see §2). This means that if we want to estimate the work of the second phase, the average (the arithmetic mean, to be precise) length of the intervals is not the best measure. In fact, it is not difficult to see that the *geometric mean* is a quantity proportional to the total number of iterations required. Seeking for an appropriate complexity measure we give the following definition.

DEFINITION 4.3. *Let $\tilde{X}$ be the set of roots and T any subinterval of T_0. We denote by $SP[T;\tilde{X}]$ the set of subsets of T into which the algorithm will divide T and that include one element of $\tilde{X}$.*

In other words, $\mathrm{SP}[T;\tilde{X}]$ is the set of subintervals of T produced by the algorithm each containing a single root and to which bisection must be applied. Observe now that the total number of iterations IT, involved in phase two, is given by

$$\mathrm{IT} = \sum_{T \in \mathrm{SP}[T_0;\tilde{X}]} \log_2 \left(\ell(T)\, \varepsilon^{-1} \right).$$

The above formula has the disadvantage that it involves the absolute length of the intervals that remains after phase one, which makes it inappropriate for a recursive relation. By a slight modification we get the following relation which, contrary to the above, involves the relative (with respect to the initial interval T_0) lengths of the intervals:

$$\mathrm{IT} = \sum_{T \in \mathrm{SP}[T_0;\tilde{X}]} \log_2 \frac{|T|}{|T_0|} + n \log_2 \left(\ell(T_0)\, \varepsilon^{-1} \right). \tag{4.8}$$

Observe that if we manage to estimate the average value of the sum, then finding the expected number of iterations is a trivial task. Therefore, we focus our attention to this sum which we call the "characteristic complexity function of phase two" and define it as follows.

DEFINITION 4.4. *Let $\tilde{X}$ be a set of roots in a specific instance of the problem. The "characteristic complexity function" of phase two is defined by*

$$B(\tilde{X}) = \sum_{T \in \mathrm{SP}[T_0;\tilde{X}]} \log_2 \frac{|T|}{|T_0|}.$$

Similarly, we define the function B relative to an interval T' and denote it by $B_{T'}$ to be

$$B_{T'}(\tilde{X}) = \sum_{T \in \mathrm{SP}[T';\tilde{X}]} \log_2 \frac{|T|}{|T'|}.$$

Our next task will be to calculate the expected value of B.

THEOREM 4.3. *Suppose that the algorithm divides an interval T_0 with n roots into m_n subintervals. Then the expected value of the characteristic complexity function is given by the formula*

$$E_B(n) = {m_n}^{1-n} \sum_{k=0}^{n} \binom{n}{k} (m_n - 1)^{n-k} E_B(k) - n\log_2 m_n \tag{4.9}$$

or, equivalently,

$$E_B(n) = \sum_{k_1+\cdots+k_{m_n}=n} \frac{n!}{k_1!\cdots k_{m_n}!} {m_n}^{-n} \left(E_B(k_1) + \cdots + E_B(k_{m_n})\right) - n\log_2 m_n, \tag{4.10}$$

where $E_B(0) = E_B(1) = 0$.

Proof. First observe that $E_B(0) = 0$ since $\mathrm{SP}[T;\emptyset] = \emptyset$. Also, $E_B(1) = 0$ since when only one root is in an interval, the whole interval must be searched by the bisection. For any $n \geq 2$ let, as in Theorem 4.1, $X_i, i = 1, \ldots, m_n$ be the set of roots in intervals $T_i, i = 1, \ldots, m_n$, respectively. Also, let $\tilde{X}$ be the total set of roots in T_0. Then

$$\begin{aligned} B(\tilde{X}) &= \sum_{T\in \mathrm{SP}[T_0;\tilde{X}]} \log_2 \frac{|T|}{|T_0|} = \sum_{T\in \mathrm{SP}[T_1;X_1]} \log_2 \frac{|T|}{|T_0|} + \cdots + \sum_{T\in \mathrm{SP}[T_{m_n};X_{m_n}]} \log_2 \frac{|T|}{|T_0|} \\ &= \sum_{T\in \mathrm{SP}[T_1;X_1]} \log_2 \frac{|T|}{|T_1|} - k_1\log_2 m_n + \cdots + \sum_{T\in \mathrm{SP}[T_{m_n};X_{m_n}]} \log_2 \frac{|T|}{|T_{m_n}|} - k_{m_n}\log_2 m_n, \end{aligned}$$

where $k_1, \ldots, k_{m_n}$ are the numbers of roots in intervals $T_1, \ldots, T_{m_n}$, respectively. Consequently, under the above assumptions

$$B(\tilde{X}) = B_{T_1}(X_1) + B_{T_2}(X_2) + \cdots + B_{T_{m_n}}(X_{m_n}) - n\log_2 m_n. \tag{4.11}$$

The key observation in (4.11) is, once again, that the expectations of the B functions are independent of the intervals in which they are applied and depend only on the cardinalities of the corresponding X set. Moreover, the subtracted term $n\log_2 m_n$ is independent of the X sets. Hence, by taking the expectations of both sides of (4.11) we may apply the same line of thought as in Theorem 4.1 and obtain (4.10). Proving (4.9) is then completely analogous to proving relation (4.1). □

Remark 4.3. Solving (4.9) with respect to $E_B(n)$ we get the following formula which may be used to obtain numerical values for $E_B(n)$:

$$E_B(n) = \frac{1}{{m_n}^{n-1} - 1} \sum_{k=0}^{n-1} \binom{n}{k} (m_n - 1)^{n-k} E_B(k) - n{m_n}^{n-1}\log_2 m_n. \tag{4.12}$$

COROLLARY 4.4. *The expected number of iterations required by the algorithm in order to compute all n roots is given by the formula*

$$\mathrm{IT} = E_B(n) + n\log_2\left(\ell(T_0)\,\varepsilon^{-1}\right). \tag{4.13}$$

Proof. The proof follows from (4.8) and Theorem 4.3. $E_B(n)$ must be computed from (4.12). □

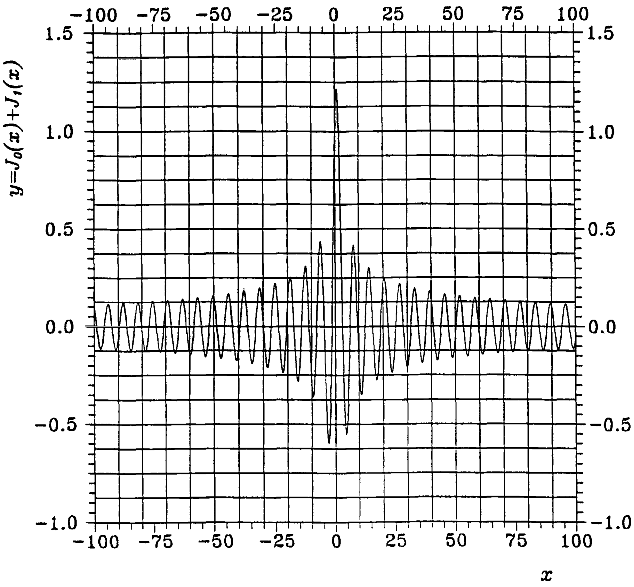

FIG. 1. *The function* (5.1) *for* $c = 0$, $a = -100$, *and* $b = 100$.

5. An example and numerical applications. We illustrate our method and analysis on a parametric problem based on a well-known function also studied in [10]:

$$f(x) = J_0(x) + J_1(x) + c, \tag{5.1}$$

where J_0 and J_1 indicate the zero-order and first-order Bessel functions [26], respectively, and c a constant, where

$$J_n(x) = \sum_{k=0}^{\infty}(-1)^k \frac{(x/2)^{2k+n}}{k!(n+k)!}, \quad n = 0, 1, \dots . \tag{5.2}$$

Function (5.1) was selected as this and related functions attract the attention of several researchers. Moreover, it possesses some nice properties which make it especially suitable for our purposes. It has a large number of roots which means that arbitrarily large rootfinding problems may be generated, restricted only by the boundaries of the interval. Also, the roots of the function are within a small neighborhood almost equally spaced, which, in turn, results in a performance of the algorithm close to that predicted by the analytical estimations. Finally, as it is obvious from Figure 1, by varying the constant c we can, in effect, raise or lower the function relative to the x–axis and, consequently, "move" the roots toward one end of the interval and study the results in the performance of the algorithm. We applied the algorithm *find_roots* for various intervals in order to compute the corresponding roots. The behavior of the algorithm for the extrema is analogous.

Using the relations

$$\begin{aligned} J_0'(x) &= -J_1(x), \\ J_1'(x) &= J_0(x) - \frac{1}{x}J_1(x), \end{aligned} \tag{5.3}$$

we are able to find the derivatives used in (2.10) as functions of $J_0(x)$ and $J_1(x)$ which, in turn, may be computed using, for example, the routines of [26].

TABLE 1
Computer runs and behavior of the algorithm find_roots for various instances of the problem.

Function	a	b	$\mathcal{N}^r$	OC	IT	EOC	EIT
$J_0(x) + J_1(x)$	-1000	1000	636	636	26712	1027.9	25438.4
$J_0(x) + J_1(x)$	-100	100	63	63	2646	101.1	2521.5
$J_0(x) + J_1(x)$	0	100	31	31	1302	49.3	1241.9
$J_0(x) + J_1(x) - 0.125$	-100	100	50	67	2194	80.0	2018.0
$J_0(x) + J_1(x) - 0.125$	0	100	25	32	1205	39.6	1009.4
$J_0(x) + J_1(x) - 0.125$	0	200	25	40	1611	39.6	1034.4
$J_0(x) + J_1(x) - 0.125$	0	300	25	43	1760	39.6	1049.1
$J_0(x) + J_1(x) - 0.15$	-100	100	34	50	1522	54.2	1392.4
$J_0(x) + J_1(x) - 0.15$	0	100	17	25	933	26.7	696.2
$J_0(x) + J_1(x) - 0.15$	0	200	17	29	1202	26.7	713.2
$J_0(x) + J_1(x) - 0.15$	0	300	17	31	1302	26.7	723.1

Using bisection for this kind of problem has the advantage that only signs need to be computed, which can be achieved by considering relatively few terms of (5.2).

The results for locating and computing all the zeros are summarized in Table 1. The columns labeled a and b indicate the endpoints of the searched interval; the columns labeled $\mathcal{N}^r$, OC, and IT show the number of computed roots within (a, b), the number of oracle calls, and the number of iterations required by the algorithm *find_roots*, respectively. The two final columns EOC and EIT indicate the values of (4.7) and (4.13) for the same parameters.

As it is evident from Table 1, the predictions from (4.7) and (4.13) are closer to the actual performance in the cases where the pattern of the roots has a certain degree of "asymmetry" that captures the possible variations from uniformity.

6. Discussion and open problems. Let us now focus our attention on the results of §4 and discuss the expected behavior of the algorithm as described by (4.7) and (4.12). The first equation describes the behavior of phase one of the algorithm as a function of n, the number of roots. In Figure 2 we plot (4.7) for various values of m_n, the number of subintervals in which we divide. It is clear that the expected number of calls decreases when we decrease the number of subintervals with a minimum reached for $m_n = 2$. An interesting choice seems to be $m_n = n$ since the curve for this case remains close to the curve of $m_n = 2$.

The reverse holds for the number of iterations of phase two which is plotted in Figure 3. There we plot (4.12) since this is actually the expected number of iterations "saved" by this method (this is represented by the negative sign of the E_B values) compared with n bisections on the interval T_0. When the actual number of iterations is desired, then the term $n \log_2 \left(\ell(T_0)\, \varepsilon^{-1}\right)$ must be added. It is clear, therefore, that what we save must be compared with this last term. Figure 3 shows that the saved iterations grow roughly like $-10n$ (for $m_n = 2$). The added term depends on the quantity $\ell(T_0)\, \varepsilon^{-1}$. Assuming a value of 10^{12} reasonable for this term, i.e., 12 significant digits (this corresponds to 12 decimal digits for the normalized case $\ell(T_0) = 1$), we see that the added term grows like $40n$. Hence, we save about 25% of the iterations. Less demanding accuracy, for example, for $\ell(T_0)\, \varepsilon^{-1} = 10^6$, results in a savings of about 50%. (At this point one may wonder whether the negative part of (4.13) exceeds, in absolute value, the positive part for suitable $\ell(T_0)$ and ε. This is not the case since the analysis above presumes that each subinterval is greater than ε, the desired accuracy. Hence, (4.13) holds for sufficiently small ε.)

It is clear, therefore, that the total complexity of the algorithm is a combination of the complexities of phases one and two. A central issue is the choice of m_n:. phase one requires small m_n, if possible two, but phase two requires large m_n. A reasonable choice (which is also the one proposed in the algorithms) seems to be $m_n = n$.

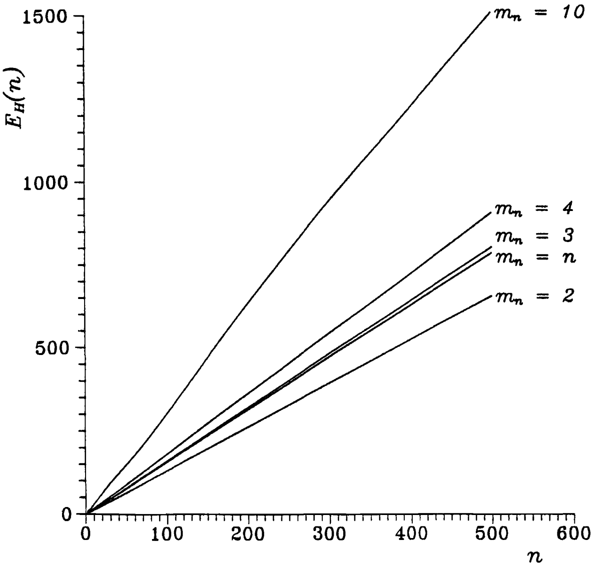

FIG. 2. *Expected number of oracle calls by virtue of* (4.7) *for various values of* m_n.

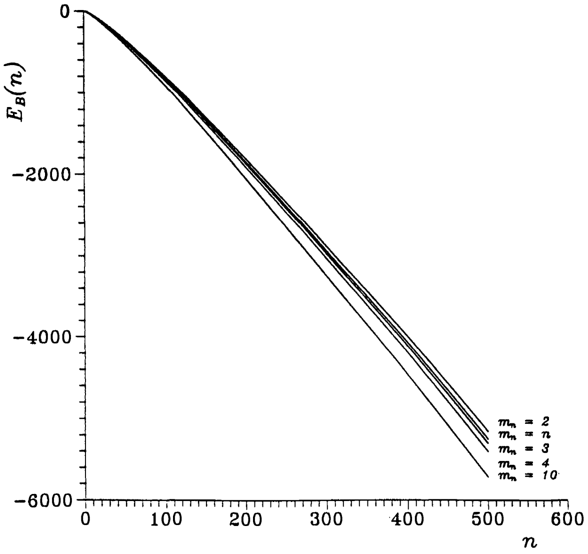

FIG. 3. *Expected number of iterations saved by virtue of* (4.12) *for various values of* m_n.

Every “real life” estimation, however, heavily depends on the way the “oracle” is implemented. The central part of (2.10) is clearly the integral. If the integral can be implemented in a nontime-consuming way (for example, when the analytical form can be found or an efficient numerical method can be applied), then phase one will be less demanding and we must concentrate on phase two by increasing the m_n value. If, however, this is not the case, then probably small values of m_n would be preferred. In any case, the integral must be computed with an error of, at most, 0.5 since it is known that (2.10) returns an integer. This suggests that relatively few function evaluations will be necessary. And, most importantly, the implementation of the oracles for the subintervals can take into account the function evaluations that have already been computed for the oracle of the divided interval. This last observation suggests that numerical values should be stored and reused for the oracles of higher levels of subdivision. Such an approach could dramatically reduce the total number of function evaluations for the oracles implementation. The full exploitation of this idea and the trade-off between phases one and two will be presented in a future publication.

Several other open problems remain to be examined in different directions. A first direction is to apply the method for more general distributions of the roots. This will, first of all, broaden the class of problems for which the analytical estimations apply. Next, one may apply the same techniques and derive complexity bounds for other methods on the same problem along the lines of Theorems 4.1 and 4.3. But we also feel that there are several things to be examined here in the algorithm itself. For example, if we expect the roots to be concentrated around the middle of the interval, then clearly more refined subdivisions must take place there, while close to the boundaries the subdivision can be sparser. That is, we believe that the algorithm itself can be guided if the distribution of the roots is known, in order to improve its performance. Results on this direction will be reported in [12].

Furthermore, preliminary investigations suggest that the algorithms can be generalized to higher dimensions to locate and compute with certainty all the simple roots of equations $F(x) = (0, 0, \dots, 0)$ where $F = (f_1, f_2, \dots, f_n)\colon (a, b)^n \subset \mathbb{R}^n \to \mathbb{R}^n$, as well as all the extrema of functions $f\colon (a, b)^n \subset \mathbb{R}^n \to \mathbb{R}$.

Finally, we would like to point out the possibilities of efficient parallelization of the algorithm, thus exploiting the tremendous capabilities of modern parallel computers. This opens a totally new subject where all the discussed problems should be reexamined in the light of massive parallelism.

Acknowledgments. The authors wish to thank Stavros Kourouklis for useful discussions that led to an alternative proof of Theorem 4.1 and Dimitris Sotiropoulos for programming assistance.

ON WEAK RESIDUAL ERROR ESTIMATION*

JINN-LIANG LIU†

Abstract. A general framework for weak residual error estimators applying to various types of boundary value problems in connection with finite element and finite volume approximations is developed. Basic ideas commonly shared by various applications in error estimation and adaptive computation are presented and illustrated. Some numerical results are given to show the effectiveness and efficiency of the estimators.

Key words. adaptivity, a posteriori error estimates, finite element, finite volume, variational problems

AMS subject classifications. 65N30, 65N50, 35J20, 35J60

1. Introduction.

Adaptivity is a trend in contemporary computational science. The remarkable advances in adaptive methodology for finite element applications since the pioneer work by Babuška and Rheinboldt [7] have had a profound impact on practical, large-scale computations.

There are four types of adaptivity which can be identified by the letters r (relocating nodes), h (mesh size h refinement), p (spectral order p increment), and hp (both h refinement and p increment). All adaptive methods require more or less a posteriori information about the computed solution for optimizing overall computational efforts in the sense that the methods deliver a given level of accuracy with a minimum of degrees of freedom. In essence, the *a posteriori error estimation* can be regarded as the heart of the adaptive mechanism. In the development of a posteriori error estimators, three main approaches may be distinguished [22], [29], namely, those based on residual, postprocessing, or interpolation techniques. Our estimators here follow the first approach.

In the first approach it has become practically standard to specify the interior residuals in terms of the governing differential equation and to measure the boundary residuals by the jumps in the normal derivatives on the interfaces between elements; see [3], [4], [6], [7], [8], [11], [19]. The various error estimators then differ essentially in the way the jumps are handled. In contrast, we consider here error equations (or inequalities) in which the right side is a residual of the computed solution in weak form. It appears to be natural to call the resulting error estimates *weak residual* estimators. A special case of the estimators seems to be first proposed by Adjerid and Flaherty in [1]. The weak residual error estimators tend to be more widely applicable since, in many applications, the governing equation may not be available in differential form. In recent years, there has been growing evidence, in theory as well as in application, showing the promise of the use of weak residual estimators; see [1], [2], [9], [21], [25].

This paper attempts to give an overall view of the weak residual error estimation in connection with the adaptive process, different numerical methods, and various types of boundary value problems. The numerical schemes of particular interest belong to two families of widely used methods—the finite element method (FEM) and the finite volume method (FVM). All estimators presented here can be extracted to two basic components which are *weak residuals* and *complementary finite element (FE) spaces*. Two types of complementary spaces can be classified. One is the conforming type which together with the original FE space preserves the continuity across adjacent FEs. This in turn corresponds to an elementwise error estimation using error residuals only interior to elements. The estimators used in [1], [2], [9],

[25] are of this type. The other is the nonconforming type which instead uses both interior and boundary residuals for each element. It is shown in [21] that the nonconforming type is independent of the FE order used for the computed solution, whereas the conforming type considers more closely the effect of the order of the FEs [1], [8]. While this study is not comprehensive, we do illustrate the two components in error estimation and the adaptive process by four model problems; namely, we consider elliptic boundary value problems, parametrized nonlinear equations, symmetric hyperbolic equations, and variational inequalities.

In §2, the error estimators are derived in a general framework by means of abstract variational formulations. Definitions, notation, and basic ideas are then introduced along the course of the derivation. Although the estimators are not restricted to any particular type of adaptivity, we also discuss briefly a standard h-refinement strategy in two space dimensions. In §3, the four model problems and the two numerical methods are specifically used to demonstrate how they can be cast into the general framework. Finally, in §4, numerical results are given with respect to each subsection in §3 to show the effectiveness and efficiency of the estimators.

2. Background and basic ideas. The aim of this paper is to offer, to the extent possible, a global view of the use of weak residual error estimators. It is instructive to summarize some fundamental features which constitute various adaptive methods for various model problems considered herein.

2.1. Abstract variational problems. Let Ω be a bounded region in the plane with a Lipschitz boundary $\partial\Omega = \partial\Omega_D \cup \partial\Omega_N$ and $H^k(\Omega)$ and $H^r(\Gamma)$, $\Gamma \subset \partial\Omega$, be the usual Sobolev spaces equipped with the norms $\|\cdot\|_k$ and $|\cdot|_{r,\Gamma}$, respectively. Let $H(\Omega) \subset L^2(\Omega)$ be a Sobolev space equipped with the norm $\|\cdot\|$. For simplicity, we assume that all functions in $H(\Omega)$ satisfy a homogeneous Dirichlet boundary condition on $\partial\Omega_D$, if any. Let K be a closed convex subset of $H(\Omega)$. Let $F : H(\Omega) \to R$ be a continuous linear form. Let $B(\cdot,\cdot) : H(\Omega) \times H(\Omega) \to R$ be a bilinear form such that there exist two positive constants β, δ and a nonnegative constant α for which

$$B(u,v) \le \beta\|u\|\,\|v\|, \quad u, v \in H(\Omega), \tag{2.1}$$

$$B(u,u) \ge \delta\|u\|^2 - \alpha\|u\|_0^2, \quad u \in H(\Omega). \tag{2.2}$$

We shall consider a class of very general problems in an abstract variational setting: Find $u \in K$ such that

$$B(u,v) - F(v) \ge B(u,u) - F(u) \quad \forall v \in K. \tag{2.3}$$

Depending on the definition of the closed convex set K and the properties of the bilinear form B, the abstract variational problem (2.3) can give various equivalent formulations of problems which will be exemplified in §3. Discussions of well-posedness of the problem (2.3), in some selective settings, can be found, e.g., in [13], [18].

2.2. FE spaces. To discretize (2.3), we introduce S a finite-dimensional subspace of $H(\Omega)$ characterized by a mesh size h and associated with a regular, but not necessarily quasi-uniform, triangulation $\mathcal{T}$ on Ω. To approximate K, we construct a closed convex subset K_s of S. The approximate problem of (2.3) is then to find $u_s \in K_s$ such that

$$B(u_s, v_s) - F(v_s) \ge B(u_s, u_s) - F(u_s) \quad \forall v_s \in K_s. \tag{2.4}$$

Our objective is to present various error formulations on which various a posteriori error estimators assessing the exact error between the solutions u and u_s of (2.3) and (2.4), respectively, are based. All estimators can be extracted to two basic components—weak residuals and complementary FE spaces. We first discuss the complementary spaces.

For the sake of efficiency, the estimators will be based on local computations. We introduce some local function spaces that we will require. Associated with $\mathcal{T}$, let $\bar{S}$ be another larger FE subspace of $H(\Omega)$, i.e., $S \subset \bar{S}$. Let $H(\tau)$ denote the restriction of $H(\Omega)$ to $\tau \in \mathcal{T}$ and $H_{\mathcal{T}}(\Omega) = \prod_{\tau \in \mathcal{T}} H(\tau)$ denote the space of piecewise $H(\Omega)$ functions. For instance, if $H(\Omega) \equiv H^1(\Omega)$, then $H_{\mathcal{T}}(\Omega)$ will be the space of piecewise H^1 functions. For v, w in $H_{\mathcal{T}}(\Omega)$, we define the broken L^2 inner product and norm by $(v, w) = \sum_{\tau \in \mathcal{T}} (v, w)_\tau$, $\|v\|_0^2 = (v, v)$, analogously, the broken $H(\Omega)$ norm, $\|v\|^2 = \sum_{\tau \in \mathcal{T}} \|v\|_{H(\tau)}^2$. Note that $H(\Omega) \subset H_{\mathcal{T}}(\Omega) \subset L^2(\Omega)$ and the above definitions reduce to the usual ones whenever v, w are in $H(\Omega)$. Let $\bar{S}$ be split into two subspaces $\bar{S} = S \oplus S^c$, $S \cap S^c = \{0\}$. Let S_τ^c denote the restriction of S^c to $\tau \in \mathcal{T}$ and let $S_{\mathcal{T}}^c = \prod_{\tau \in \mathcal{T}} S_\tau^c$. We shall consider in particular the splitting

$$\bar{S}_{\mathcal{T}} = S \oplus S_{\mathcal{T}}^c, \quad S \cap S_{\mathcal{T}}^c = \{0\}, \quad S_{\mathcal{T}}^c \neq \emptyset. \tag{2.5}$$

The spaces $S_{\mathcal{T}}^c$ and $\bar{S}_{\mathcal{T}}$ are spaces of piecewise polynomials locally defined in each element τ in $\mathcal{T}$. Note the inclusions $\bar{S} \subset \bar{S}_{\mathcal{T}} \subset H_{\mathcal{T}}(\Omega)$ and $S^c \subset S_{\mathcal{T}}^c$. The error estimators given in §3 will be calculated in the complementary space $S_{\mathcal{T}}^c$. We assume that the bilinear form B can define an inner product $B(\cdot, \cdot)$ on $\bar{S}_{\mathcal{T}}$ and with it the energy norm $|||w|||^2 = B(w, w)$. All error estimators below are measured in this norm, although, in theory, they are not strictly restricted to this norm.

2.3. Abstract variational error formulation. Let $e = u - u_s$ denote the exact error of the approximate solution u_s. We now derive a general formulation for the exact error in terms of the approximate solution. Substituting $u = e + u_s$ into problem (2.3), we have

$$\begin{aligned} &B(e, v) - F(v) + B(u_s, v) \\ &\geq B(e, e) + B(e, u_s) + B(u_s, e) + B(u_s, u_s) - F(e) - F(u_s) \quad \forall v \in K. \end{aligned}$$

Note that the bilinear form B can be nonsymmetric. By rearranging terms in the above inequality, we can rewrite this as

$$\begin{aligned} &B(e, v - u_s) - [F(v - u_s) - B(u_s, v - u_s)] \\ &\geq B(e, e) - [F(e) - B(u_s, e)] \quad \forall v \in K. \end{aligned}$$

The left-hand side of the inequality clearly suggests that we can define the following new closed convex subset by translating the original convex set K with respect to the computed solution u_s:

$$K' = K - u_s \subset H(\Omega).$$

Moreover, by virtue of the boundedness of the bilinear form B and the linear functional F on $H(\Omega)$, the Riesz representation theorem shows that there exists a unique linear functional G on $H(\Omega)$ defined by

$$G(w) = F(w) - B(u_s, w) \ \forall w \in H(\Omega). \tag{2.6}$$

We call G a *weak residual* in contrast to the usual formulation in which the residual is in terms of the governing differential equation used by many authors [8], [11], [19].

The error estimation is then based on the following new variational (error) problem: Determine $e \in K'$ such that

$$B(e, w) - G(w) \geq B(e, e) - G(e) \quad \forall w \in K'. \tag{2.7}$$

The reason we use the weak residual form G instead of the governing equation is twofold. First, since u_s is itself an approximate solution, its second derivative, for second-order partial

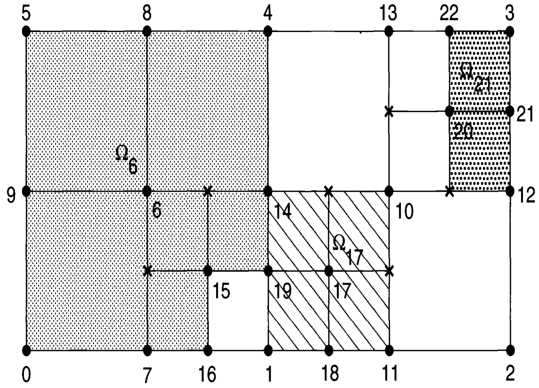

FIG. 2.1. *1-irregular mesh refinement.*

differential equations (PDEs), in the sense of distribution will further incur error. Second, for many applications, the governing differential equation may not be available, i.e., only the integral form is available. For such cases, the formulation of error problems like (2.7) is certainly more general.

2.4. A mesh refinement strategy. There are many refinement strategies proposed in the literature. The error estimators presented here are not restricted to any particular adaptive refinement. In fact, it has been shown in [21] that there is no order restriction for the FE spaces used in the approximate solution or in the error estimation; that is, the error estimators can be used in connection with any one of the h-, p-, or hp-versions of the FEM. In the numerical experiments, to test our error estimators (see §4), we use in particular the so-called 1-irregular mesh refinement strategy first proposed in [7] and later detailed in [14]. Since the refinement scheme has been extended to include adaptive finite volume computations, we briefly discuss its basic features.

Recall that a node is called *regular* if it constitutes a vertex for each of the neighboring elements; otherwise it is *irregular*. Figure 2.1 shows a particular 1-irregular mesh where irregular nodes marked by $\times$ are all of index-1 irregularity, that is, the maximum number of irregular nodes on an element side is one. In implementation, no degrees of freedom will be associated with these irregular nodes. Hence, supports of the shape functions defining a basis for an FE space change adaptively with mesh refinements; for example, the shaded subdomains Ω_6, Ω_{17}, and Ω_{21} are the supports of the shape functions corresponding, respectively, to the regular nodes 6, 17, and 21 in Fig. 2.1. The FE spaces so constructed preserve the conformality required by the standard FE approximation provided that some special element constraint methods are used to invoke continuity across interelement boundaries of elements of different size and with shape functions of differing polynomial degree [14].

For finite volume approximation, control volumes have to adapt accordingly to their dual elements. Let $\mathcal{B}$ denote the dual mesh for $\mathcal{T}$. Note that the FVM requires a control volume for each regular node where degrees of freedom are defined. Thus, in particular, 23 control volumes in the dual mesh of Fig. 2.1 are constructed and shown, by dotted lines, in Fig. 2.2. Notice that the pattern of the boundaries of control volumes appearing in elements may differ element by element. This plays an essential role in the implementation since most computations, approximations, as well as error estimations, are to be performed elementwise before the assembling process.

3. Model problems and numerical methods. We now apply the general formulations and the basic ideas discussed above to four model problems in connection with FEM and FVM.

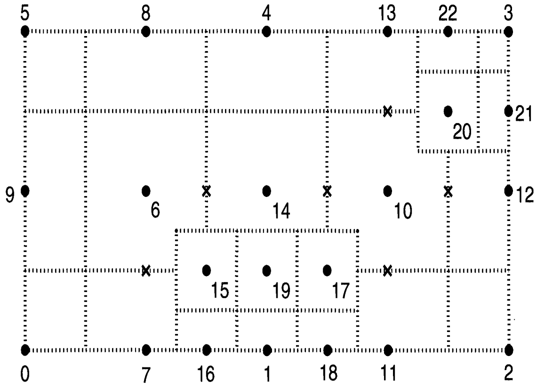

FIG. 2.2. *Adaptive control volumes.*

Since the a posteriori error estimation is the heart of a complete selfadaptive mechanism, we stress particularly various error equations or inequalities on which the error estimators are based. Some rigorous theories of the estimators can be found in [2], [21].

We first note that if the closed convex set K in (2.3) is itself the Sobolev space $H(\Omega)$, then the inequality (2.3) reduces to a *variational equation.* In §§3.1–3.3, 3.5 we will address this equality form.

3.1. Elliptic boundary value problems. Consider the boundary value problem

$$\begin{aligned} &Lu := -\nabla\cdot(a(x)\nabla u(x)) + b(x)u(x) = f(x) \quad \text{in } \Omega, \\ &u = 0 \quad \text{on } \partial\Omega_D, \qquad a(x)\frac{\partial u}{\partial n} = g(x) \text{ on } \partial\Omega_N. \end{aligned} \tag{3.1}$$

The associated variational problem is to find $u \in H(\Omega)$ such that

$$B(u, v) = (f, v) + \langle g, v\rangle_{\partial\Omega_N} \quad \forall v \in H(\Omega), \tag{3.2}$$

where

$$\begin{aligned} H(\Omega) &:= \{u \in H^1(\Omega) : u = 0 \text{ on } \partial\Omega_D\}, \qquad \|\cdot\| := \|\cdot\|_1, \\ B(u, v) &:= \int_\Omega (a\nabla u\nabla v + buv)\,dx, \\ (f, v) &:= \int_\Omega fv\,dx, \qquad \langle g, v\rangle_{\partial\Omega_N} := \int_{\partial\Omega_N} gv\,ds. \end{aligned}$$

To begin with and to avoid technical details, we always assume the unique solvability of the variational problems considered here and below. Note that we do not assume the coefficient function $b(x)$ in (3.1) to be strictly positive in Ω, hence the error estimators to be given apply to indefinite problems as well [21].

Corresponding to (2.4) and (2.7), the approximation and error problems for (3.2) are to determine $u_s \in S$ and $e \in H(\Omega)$ such that

$$B(u_s, v) = (f, v) + \langle g, v\rangle_{\partial\Omega_N} \quad \forall v \in S \tag{3.3}$$

and

$$B(e, v) = -B(u_s, v) + (f, v) + \langle g, v\rangle_{\partial\Omega_N} \quad \forall v \in H(\Omega), \tag{3.4}$$

respectively, where the computed FE solution u_s can only be assessed a posteriori, i.e., after its availability.

Since the space $H(\Omega)$ is still infinite dimensional and the discretization of (3.4) in the original FE space S only produces trivial estimated errors, (3.4) has to be solved in a larger space $\bar{S}$. However, this would cause the error calculation to be impractically expensive since (3.4) will result in a larger system of equations than that of (3.3). Hence, the use of the complementary subspaces appears to be natural. Nevertheless, if the subspace is chosen to be S^c, the error calculation may involve a global solution to a system of equations. We are therefore led to consider the complementary subspaces $S^c_{\mathcal{T}} \subset H_{\mathcal{T}}(\Omega)$ and, consequently, to solve the following reduced problem: Determine $\tilde{e} \in S^c_{\mathcal{T}}(\tau_i)$, in each element $\tau_i \in \mathcal{T}$, such that

$$B(\tilde{e}, v) = -B(u_s, v) + (f, v) + \langle g, v\rangle_{\partial\Omega_N} \quad \forall v \in S^c_{\mathcal{T}}(\tau_i). \tag{3.5}$$

Note that if $S^c_{\mathcal{T}} \subset H(\Omega)$, a conforming subspace, the unique solvability of (3.5) can be ensured as that of (3.3) and only the interior residual in each element will be used. On the other hand, if $S^c_{\mathcal{T}} \subset H_{\mathcal{T}}(\Omega)$ but not in $H(\Omega)$, a nonconforming subspace, then (3.5) results in a nonconforming solution scheme [13] and the estimation will include both interior and boundary residuals for each element. With some moderate assumptions on the bilinear form and the complementary spaces (sufficiently large), it is shown in [21] that the unique solvability for such problems still holds.

As noted already, the error residuals can be expressed in either differential or weak form. We briefly describe the differences between these two approaches. For more detailed theoretical investigation we refer the reader to [11], [21].

Let E be the collection of curves which forms an edge of an element τ in T. The set of edges may be decomposed as the union of two disjoint sets $E = E_B \cup E_I$, where E_B is the set of edges on $\partial\Omega$ and E_I is the set of edges in the interior of Ω. For each edge ε in E, we define a normal direction $n = n_\varepsilon$. More specifically, n_ε is the usual outward normal when $\varepsilon \in E_B$ while, for $\varepsilon \in E_I$, its choice is arbitrary. Let τ_{in}, τ_{out} be two elements sharing an edge ε in E_I and suppose that the normal n is outward from τ_{in}. Then, for x on ε, the jump and the average of v on ε are defined, respectively, by

$$[v]_J(x) = v(x)|_{\tau_{\text{out}}} - v(x)|_{\tau_{\text{in}}} \quad \text{and} \quad [v]_A(x) = \frac{1}{2}\{v(x)|_{\tau_{\text{out}}} + v(x)|_{\tau_{\text{in}}}\}.$$

Substitute $u = e + u_s$ into (3.1) and multiply by a test function v; then we obtain, in each element τ,

$$(Le, v)_\tau = -(Lu_s, v)_\tau + (f, v)_\tau, \tag{3.6}$$

where Lu_s is defined in the sense of distributions. Now integration by parts of the left term in (3.6) yields

$$(Le, v)_\tau = B(e, v)_\tau - \left\langle a\frac{\partial u}{\partial n}, v\right\rangle_{E_\tau} + \left\langle a\frac{\partial u_s}{\partial n}, v\right\rangle_{E_\tau}, \tag{3.7}$$

and after summing (3.6) over all elements, we find that

$$B(e, v) = (f - Lu_s, v) + \left\langle g - a\frac{\partial u_s}{\partial n}, v\right\rangle_{\partial\Omega_N} + \left\langle \left[a\frac{\partial u_s}{\partial n}\right]_J, v\right\rangle_{E_I}. \tag{3.8}$$

This is the standard formulation for estimating errors used by many authors [7], [8], [11], [19]. On the other hand, if the term $(Lu_s, v)_\tau$ in (3.6) is rewritten as in (3.7), then in each element

τ, we obtain

$$B(e, v)_\tau - \left\langle a\frac{\partial u}{\partial n}, v\right\rangle_{E_\tau} = -B(u_s, v)_\tau + (f, v)_\tau.$$

Hence a summation over all elements leads to

$$B(e, v) - \left\langle a\frac{\partial u}{\partial n}, v\right\rangle_{E_B} - \left\langle \left[a\frac{\partial u}{\partial n}\right]_J, [v]_A\right\rangle_{E_I} = -B(u_s, v) + (f, v),$$

which gives (3.4) with more general test functions $v \in H_{\mathcal{T}}(\Omega)$ if the exact solution u is in $H^2(\Omega)$.

It is necessary to reuse the differential operator L when the estimators are calculated based on (3.8). In contrast, in terms of (3.4), the same bilinear formulation (3.2) can be used in both approximation and error estimation. This is certainly preferable, from the user's viewpoint, in adaptive implementation. Moreover, the formal approach can only utilize the complementary spaces $S^c_{\mathcal{T}}$ in a nonconforming setting while the weak residual approach may be used in either a conforming or a nonconforming setting. Finally, in [11], the following saturation condition is introduced for the spaces $\bar{S}$ used in the error analysis:

$$\|u - u_{\bar{s}}\|_1^2 + \left| h_\varepsilon^{1/2}\left[a\frac{\partial(u - u_{\bar{s}})}{\partial n}\right]_J\right|^2_{0,E_I} \le \rho(h)^2\|u - u_s\|_1^2, \tag{3.9}$$

where $u_{\bar{s}}$ is the approximated solution (for analytical purposes only) sought in the larger spaces $\bar{S}$. It is assumed that $\lim_{h\to 0}\rho = 0$; that is, $\bar{S}$ has higher order than S. On the other hand, in weak form, the saturation condition is as follows:

$$\|u - u_{\bar{s}}\|_1 \le \rho\|u - u_s\|_1, \quad 0 \le \rho < 1. \tag{3.10}$$

Thus the condition (3.10) is somewhat weaker than (3.9) since it allows the FE orders of S and $\bar{S}$ to be equal (see, e.g., [21] and Example 4.2 below). The introduction of the jumps in the normal derivative of the computed solutions at interelement boundaries actually forces ρ to become larger and hence deteriorates the quality of the error estimator [21]. Almost all differential-type residual error estimators [3], [4], [7], [8], [11], [19] require some compatibility conditions or auxiliary local problems to overcome this intrinsic difficulty simply because the distribution and jump terms are included in the residual, i.e., the right-hand side of (3.8). These conditions or problems are somewhat ad hoc depending strongly on the model problem under consideration; see the above references. The complementary spaces are essential for both differential and weak residual approaches. With the weak residual form, one can concentrate primarily on the construction of the shape functions of $S^c_{\mathcal{T}}$, which can still handle jumps across element boundaries (with a nonconforming setting), if they are dominant errors.

The norm $|||\tilde{e}|||_{\tau_i} =: \eta_i$, for each element $\tau_i \in \mathcal{T}$, is called the *error indicator* of the element which assesses the quality of the approximate solution u_s in this element and indicates whether the element needs to be refined, derefined, or unchanged. Summing over all elements, the *error estimator* for u_s can be defined by

$$|||\tilde{e}||| = \left[\sum_i \eta_i^2\right]^{1/2}.$$

The error estimator can serve as one of the major stopping criteria for an entire adaptive process. The quality of a proposed error estimator is usually tested by various model problems to which the exact solutions are explicitly known. A computable *effectivity index*

$$\theta = \frac{|||\tilde{e}|||}{|||e|||}$$

is usually introduced to quantify the quality of the estimator and, consequently, the quality of the approximate solution.

3.2. Parametrized nonlinear equations. Stationary problems for many scientific and engineering problems are modeled by a parameter-dependent equation

$$F(u, \lambda) = 0, \tag{3.11}$$

where u is a state variable, λ is a d-dimensional parameter vector, and F denotes some differential operator on a suitable state space. Typically, the solution set $M = F^{-1}(0)$ turns out to be a differentiable submanifold M of dimension d of the product X of the state space and the parameter space. This can be ensured, for instance, when F is a Fredholm map of index d on X [23].

All standard discretizations of a parametrized boundary value problem (3.11) leave the parameter vector untouched and hence approximate the equations by some finite-dimensional system $F_s(u_s, \lambda) = 0$. Hence, under suitable conditions, we may expect the solution set $M_s = F_s^{-1}(0)$ to be a d-dimensional submanifold of some discretization space X_s. Frequently, X_s can be embedded in X and then the discretization error represents some measure of the distance between M and M_s in X.

Our goal now is to estimate the discretization error. There are two major issues for the error estimation of M_s. The first issue is efficiency. It is intrinsically more expensive for nonlinear parametrized problems than it is for linear problems. The second issue is consistency. It is well known [23] that the parameter dependence causes the discretization error to become a local concept which depends on the choice of the local coordinate system on the manifold. For instance, in the continuation method, we must often fix a local coordinate system for calculating several points on the manifold and then change the coordinate system as needed, and so on. However, for error estimation, the coordinate system is usually fixed, [23], throughout the entire manifold and hence is not applicable near any foldpoint with respect to the parameter space. The main way to resolve these difficulties is to use linearization and a local coordinate system.

At any $x_0 = (u_0, \lambda_0) \in M$, we define a local coordinate system that satisfies the following conditions:

$$X = W \oplus T, \quad \dim T = d, \quad W \cap \ker DF(x_0) = \{0\}. \tag{3.12}$$

It is shown in [25] that the constrained linearized (infinite-dimensional) problem

$$F(x_s) + DF(x_s)\omega = 0, \quad \pi(\omega) = 0, \tag{3.13}$$

for (3.11) has a unique solution $\omega = x_0 - x_s \in W$ which is the exact error of the approximate solution $x_s = (u_s, \lambda_s)$. Here $\pi \in L(X)$ is a natural projection of X onto T along W. The FE approximation of (3.11) is of interest here. We consider, in particular, the following mildly nonlinear problem: Find $(u, \lambda) \in H_0^1(\Omega) \times \Lambda$ such that

$$\langle F(u, \lambda), v\rangle := \int_\Omega [a(\lambda, \xi)\nabla u \cdot \nabla v + g(u, \lambda, \xi)v]\, d\xi = 0 \quad \forall v \in H_0^1(\Omega), \tag{3.14}$$

where $F : X = H_0^1(\Omega) \times \Lambda \to Y = H^{-1}(\Omega)$ and the coefficient functions a and g are given so that the problem is well posed.

Apparently, the nonlinear problem (3.14) does not fit into the general variational formulation given in the previous section. However, its weak residual form can be cast in the framework of the variational error setting.

In weak form (3.13) requires the determination of $(w, \mu) \in H_0^1 \times \Lambda$ such that

$$B(w, v) + C(\mu, v) = -\langle F(u_s, \lambda_s), v\rangle \;\; \forall v \in H_0^1(\Omega), \tag{3.15}$$

$$\pi(w, \mu) = 0, \tag{3.16}$$

where

$$B(w, v) := \int_\Omega (a(\lambda_s, \xi)\nabla w \cdot \nabla v + g_u(u_s, \lambda_s, \xi)wv)\, d\xi,$$

$$C(\mu, v) := \int_\Omega ((a_\lambda(\lambda_s, \xi) \cdot \mu)\nabla u_s \cdot \nabla v + (g_\lambda(u_s, \lambda_s, \xi) \cdot \mu)v)\, d\xi.$$

At any computed point $(u_s, \lambda_s) \in M_s$, our a posteriori error estimates thus require the determination of $(\tilde{w}, \tilde{\mu}) \in S_{\mathcal{T}}^c(\tau_i) \times \Lambda$ such that

$$B(\tilde{w}, v) + C(\tilde{\mu}, v) = -\langle F(u_s, \lambda_s), v\rangle \;\; \forall v \in S_{\mathcal{T}}^c(\tau_i), \tag{3.17}$$

$$\pi(\tilde{w}, \tilde{\mu}) = 0. \tag{3.18}$$

The choice of the local coordinate system at any point x_0 on M is arbitrary as long as it satisfies the conditions in (3.12). By definition, the local coordinate system (3.12) and hence the constraint $\pi(\omega, \mu) = 0$ can change from point to point on the solution manifold. We choose $T = \ker DF(x_0)$ in particular. The constraint (3.18) is then equivalent to $(\tilde{w}, \tilde{\mu}) \in W_s = X_s \cap W$ which is orthogonal to the d-dimensional subspace $T = \ker DF_s(x_s)$ of X_s corresponding to the tangent space of M_s at the computed point x_s. If Λ is one dimensional and a standard continuation process is used, then a normalized tangent vector is usually available at each computed point. Analogously, in the multiparameter case, if a triangulation of M_s is computed by the method of [24], then again orthonormal bases of the tangent space are available at the computed points on the manifold. This uniform treatment of the a posteriori error estimation along the computed manifold M_s avoids aforementioned difficulties. Moreover, the introduction of the linear, local, solution scheme ensures that the method is computationally relatively inexpensive.

An a posteriori error estimation has been developed for strongly nonlinear equations with a scalar parameter in [27]. There the asymptotic exactness of a residual estimator was proved under suitable hypotheses. Tsuchiya's approach requires one to fix the local coordinate system in two stages. In the first stage before the turning point, the system is defined by the natural parameter. In the second stage when the continuation process is near and after the turning point, the system is then rotated by 90 degrees thus allowing a more elaborate error estimate near the turning point. In the sense of the definition of the local coordinate system, this is a special case of our approach. Moreover, Tsuchiya's approach requires a global solution to the linearized residual equations for error estimation.

3.3. Symmetric hyperbolic equations. In the theory of PDEs there is a fundamental distinction between those of elliptic, hyperbolic, and parabolic types. The theory of symmetric positive differential equations developed by Friedrichs [17] is known for its unified treatment, analytically as well as numerically, for PDEs that change type within the domain of interest such as the Tricomi problem and forward–backward heat equations. In the development of the error estimator for the Friedrichs system, we use in particular the FEM proposed by Lesaint [20].

An unknown p-dimensional vector-valued function defined on Ω is given by $\mathbf{u} = (u_1, u_2, \dots, u_p)^T$. Let $\mathbf{f} = (f_1, f_2, \dots, f_p)^T$ be a given p-dimensional vector-valued function defined on Ω. Let the operators $\mathbf{L}$ and $\mathbf{M}$ be defined by and consider the following systems:

$$\mathbf{Lu}(x) := \sum_{i=1}^{2} A_i(x)\frac{\partial \mathbf{u}}{\partial x_i} + A_0(x)\mathbf{u} = \mathbf{f}(x) \quad \text{for } x \in \Omega, \tag{3.19}$$

$$\mathbf{Mu}(x) := (\mu(x) - \beta(x))\mathbf{u}(\mathbf{x}) = 0 \quad \text{for } x \in \partial\Omega, \tag{3.20}$$

where $\beta = \sum_{i=1}^{2} n_i A_i$, the n_i's being the components of the outer normal on $\partial\Omega$. The matrices A_i, $i = 1, 2$, are symmetric, Lipschitz continuous in $x = (x_1, x_2)$ for $x \in \bar{\Omega}$. The coefficients of the matrix $A_0(x)$ of $L(R^p)$ are bounded in Ω. The matrix $\mu(x)$ of $L(R^p)$ is defined for $x \in \partial\Omega$ so that the boundary condition (3.20) is *admissible* and the operator $\mathbf{L}$ is *positive* in the sense of Friedrichs [17]; i.e.,

$$\begin{cases} \text{(i)} \;\; \mu(x) + \mu^*(x) \text{ is positive semidefinite on } \partial\Omega, \\ \text{(ii)} \;\; \operatorname{Ker}(\mu - \beta) \oplus \operatorname{Ker}(\mu + \beta) = R^p \text{ on } \partial\Omega, \text{ and} \\ \text{(iii)} \;\; A_0 + A_0^* - \sum_{i=1}^{2} \frac{\partial A_i}{\partial x_i} \geq c_0 I \quad \forall x \in \Omega, \end{cases}$$

where μ^* and A_0^* are adjoint matrices of μ and A_0, respectively, c_0 is a positive constant, and I is the identity matrix.

The adjoint operators $\mathbf{L}^*$ and $\mathbf{M}^*$ of $\mathbf{L}$ and $\mathbf{M}$ are defined, respectively, by

$$\mathbf{L}^*\mathbf{v}(x) := -\sum_{i=1}^{2} \frac{\partial}{\partial x_i}(A_i(x)\mathbf{v}(x)) + A_0^*(x)\mathbf{v}(x) \;\; \forall x \in \Omega, \tag{3.21}$$

$$\mathbf{M}^*\mathbf{v}(x) := (\mu^*(x) + \beta(x))\mathbf{v}(x) \;\; \forall x \in \partial\Omega. \tag{3.22}$$

Let $(\mathbf{q}, \mathbf{g}) := \int_\Omega \mathbf{q}(x) \cdot \mathbf{g}(x)\, dx$ and $\langle \mathbf{q}, \mathbf{g} \rangle := \int_{\partial\Omega} \mathbf{q} \cdot \mathbf{g}\, ds$, where $\mathbf{q} \cdot \mathbf{g} = \sum_{i=1}^{p} q_i g_i$. One variational formulation of (3.19) and (3.20) is to find $\mathbf{u} \in (H^1(\Omega))^p$ such that

$$B(\mathbf{u}, \mathbf{v}) := \frac{1}{2}(\mathbf{Lu}, \mathbf{v}) + \frac{1}{2}(\mathbf{u}, \mathbf{L}^*\mathbf{v}) + \frac{1}{2}\langle \mu\mathbf{u}, \mathbf{v} \rangle = (\mathbf{f}, \mathbf{v}) \;\forall \mathbf{v} \in (H^1(\Omega))^p. \tag{3.23}$$

For any given approximate solution $\mathbf{u}_s \in (S)^p \subset (H^1(\Omega))^p$ of (3.23), again analogous to (2.7), the error estimator (3.23) can then be calculated by solving the reduced error problem: Determine $\tilde{\mathbf{e}} \in (S_T^c)^p$ such that

$$B(\tilde{\mathbf{e}}, \mathbf{v}) = (\mathbf{f}, \mathbf{v}) - B(\mathbf{u}_s, \mathbf{v}) \;\; \forall \mathbf{v} \in (S_T^c)^p. \tag{3.24}$$

Since the boundary conditions (3.20) and (3.22) for test and trial functions $\mathbf{u}$ and $\mathbf{v}$, respectively, are different, this would make it impossible to show the coercivity in a simple manner if the adjoint operator $\mathbf{L}^*$ were not included in (3.23). With the formulation of (3.23) and Friedrichs's identities [17], the coercivity is guaranteed in [20] but only in the lower-order norm, i.e., $\|\cdot\|_0$, instead of the general Gårding-type inequality (2.2).

3.4. Variational inequalities. In the previous subsections, in terms of abstract settings, the closed convex set K is the Sobolev $H(\Omega)$ itself. This in turn leads to variational equations for the preceding model problems. In this subsection, we deal with variational inequalities formulated in the general form (2.3) where now the K is indeed a closed convex subset of $H(\Omega)$. As we would in a typical problem, we shall now also consider the abstract minimization problem: Find $u \in K$ such that

$$J(u) = \inf_{v \in K} J(v), \tag{3.25}$$

where the functional $J : H(\Omega) \to R$ is defined by

$$J(v) = \frac{1}{2}B(v, v) - F(v),$$

provided that the bilinear form $B(\cdot, \cdot)$ is symmetric and $H(\Omega)$-elliptic, i.e., $\alpha = 0$ in (2.2).

Corresponding to (2.4), (3.25) reduces to the finite-dimensional approximate problem

$$J(u_s) = \inf_{v_s \in K_s} J(v_s), \tag{3.26}$$

which, under suitable conditions on the approximate convex set K_s [16], [18] can be solved by mathematical programming subject to a finite number of constraints induced by K_s.

Clearly, the variational error problem (2.7) suggests the needed formulation for error estimation; that is, determine $\tilde{e} \in K_c'$ such that

$$B(\tilde{e}, w) - G(w) \geq B(\tilde{e}, \tilde{e}) - G(\tilde{e}) \quad \forall w \in K_c', \tag{3.27}$$

where K_c' is a complementary closed convex set of $S_{\mathcal{T}}^c$ under similar conditions as those of K_s. Inequality (2.7) also suggests that a new functional can be defined in terms of the weak residual G, namely,

$$E(w) = \frac{1}{2}B(w, w) - G(w).$$

Consequently, we have the following reduced minimization problem: Determine $\tilde{e} \in K_c'$ such that

$$E(\tilde{e}) = \inf_{w \in K_c'} E(w). \tag{3.28}$$

3.5. The finite volume element method. There are many variants of FVMs. We consider specifically the finite volume element method (FVEM). As noted in [12], the FVEM was developed as an attempt to use FE ideas to create a more systematic finite volume (FV) methodology. The basic idea is to approximate the discrete fluxes needed in FV by replacing the unknown PDE solution by an FE approximation. It turns out that the approximate solution by FVEM is in fact sought in a standard FE trial function space whereas the corresponding test function space consists of volumewise constant step functions (zero-order polynomials). In [10], Bank and Rose termed the FVEM the *box method* and showed that, under reasonable hypotheses, the solution u_b generated by the FVEM is of comparable accuracy to the solution u_s generated by the standard Galerkin procedure using piecewise linear FEs. More precisely, the a priori errors of u_b and u_s are of the same order in the energy norm.

As far as a posteriori error estimation is concerned, there are surprisingly fewer results available for the FVMs than for their FE counterparts. From the above observations and by the actual implementation features of the FVEM, we can see that FEMs and FVMs do have many important similarities in error estimation and the adaptive process.

First of all, the FVEM solution u_b is itself an element of the standard FE space S associated with the regular mesh $\mathcal{T}$. Therefore, it is perfectly all right to replace u_s by u_b in (2.6) so that the weak residual G is now in terms of the FV solution u_b. Second, since the solution u_b was computed with degrees of freedom defined at the nodal points of elements instead of volumes, it is quite reasonable to do the error estimation on an element-by-element basis. Third, most computations in practice are customarily carried out elementwise, including control volumes which are constructed according to their dual elements; see, e.g., [10], [12]. Finally, it is interesting to explore how the well-established adaptive features of FE technology can be utilized in FV computations. In short, it is plausible to develop error estimators for the FVEM elementwise instead of volumewise.

We consider again the selfadjoint elliptic boundary value problem (3.1). For the FV element approximation of (3.1), we follow the formulation proposed in [10] which is in a more general setting than that in [12]. The FVEM (or the box method) for (3.1) is defined as follows: Find $u_b \in S$ such that

$$\bar{B}(u_b, \bar{v}) + (b\bar{u}_b, \bar{v}) = (f, \bar{v}) \;\; \forall \bar{v} \in P_0^0(\mathcal{B}), \tag{3.29}$$

where

$$\bar{B}(u_b, \bar{v}) = -\sum_{b_i \in \mathcal{B}} \int_{\partial b_i} a \frac{\partial u_b}{\partial n} \bar{v}\, ds,$$

and $P_0^0(\mathcal{B})$ denotes the space of discontinuous piecewise constants with respect to the control volumes (or boxes), whose elements are zero on $\partial\Omega_D$. Note that to avoid a nondiagonal (and generally nonsymmetric) matrix, $\bar{u}_b$ is used instead of u_b in the second term on the left-hand side of (3.29); see [10]. Here, the $\bar{u}_b$ is defined as a volumewise constant and has the same values as u_b at vertices of $\mathcal{T}$.

From the above observation, we see that the error estimator of the FV solution u_b is proposed by determining $\tilde{e} \in S_{\mathcal{T}}^c(\tau_i)$ such that

$$B(\tilde{e}, v) = -B(u_b, v) + (f, v) + \langle g, v\rangle_{\partial\Omega_N} \quad \forall v \in S_{\mathcal{T}}^c(\tau_i), \tag{3.30}$$

where the bilinear form B is defined exactly as in (3.5).

The FV solution u_b is obtained quite differently in the sense of the abstract setting (2.4). Nevertheless, the error estimation based on (3.30) is still in the unifying theme presented so far. Note also that there is no direct link between (3.29) and (3.30). It is precisely our intention to use the weak residual error estimation. Otherwise, if the boundary integrals $\bar{B}$ were used in (3.30), we would then be forced to perform the estimation volumewise. However, the theoretical investigation of the estimators would certainly involve the a priori results concerning u_b and yet remains open. Equation (3.30) is in exactly the same form as (3.5). As a result, the error indicators and estimators can be calculated in exactly the same way as those of the FEM. Further, the remarks made in §3.1 apply here.

4. Numerical examples. The numerical examples presented in this section correspond with those of the previous subsections. Some examples were also considered in the places cited. Although we intend to stress the performance (the effectivity index) of the respective error estimators, some adaptive computational results are also presented.

There are two different types of the complementary spaces. The conforming shape functions of $S_{\mathcal{T}}^c$ vanish on boundaries of elements; consequently, the error indicators ignore interelement jumps in fluxes. The shape functions for the nonconforming case are discontinuous across element boundaries and hence the error indicators will include both the interior errors and the jumps in, of course, weak form.

Although most applications require only the use of conforming shape functions [1], [9], [25], there are some cases in which this approach would fail (see Example 4.1) if the FE order of S were not properly considered [1], [8]. We shall illustrate both conforming (Examples 4.2, 4.3) and nonconforming (Examples 4.1, 4.4, 4.5) error calculations. General algorithms in implementing these error estimators, for equality-type problems, are detailed in [21], [25]. We shall present an algorithm for the variational inequalities in Example 4.4.

Example 4.1. Following [15] we consider Laplace's equation on an L-shaped domain:

$$\begin{aligned} \Delta u &= 0 \quad \text{in } \Omega = (-1,1) \times (-1,1) \backslash (0,1) \times (-1,0), \\ u &= 0 \quad \text{on } \partial\Omega_D, \qquad \frac{\partial u}{\partial n} = g \quad \text{on } \partial\Omega_N, \end{aligned} \tag{4.1}$$

where $\partial\Omega_D = \{(x, y) : x \in [0, 1],\ y = 0\} \cup \{(x, y) : x = 0,\ y \in [-1, 0]\}$, $\partial\Omega_N = \partial\Omega\backslash\partial\Omega_D$ and g is defined so that, in polar coordinates, the exact solution u becomes $u = r^{2/3} \sin \frac{2\theta}{3}$ and hence has a point singularity at the origin.

For our computations, bilinear elements are used to define S. Hence, by the nature of the problem, the computed solution u_s is a harmonic function in each element and therefore satisfies (4.1) on each element. This means that the errors occur purely on the edges of elements; that is, the complementary space $S^c_{\mathcal{T}}$ has to be nonconforming. For this, we construct four edge midpoint basis functions defined, on the reference element $\hat{\tau} = \{(\xi, \eta) : |\xi| \leq 1,\ |\eta| \leq 1\}$, by

$$(4.2)\qquad \begin{cases} \psi_1(\xi, \eta) = (1 - \xi^2)(1 - \eta)/2, & \psi_2(\xi, \eta) = (1 + \xi)(1 - \eta^2)/2, \\ \psi_3(\xi, \eta) = (1 - \xi^2)(1 + \eta)/2, & \psi_4(\xi, \eta) = (1 - \xi)(1 - \eta^2)/2. \end{cases}$$

For the p-version FEM, this type of construction for the complementary spaces can be readily extended to high-order shape functions. For instance, given basis functions defining S on each element, one can simply add one or more shape functions to the element by higher-order side mode or internal mode or both (see [26]) for $S^c_{\mathcal{T}}$. In essence, this corresponds to a hierarchical basis method [2].

Of course, the conforming-type shape functions can still be used for this kind of problem provided that the original space S is chosen so that the effects of the boundary residuals are negligible. In [8] it was shown that for linear elliptic problems the discretization error of odd-order FE solutions is mainly due to the jumps, while that of even-order approximations occurs principally in the interior of the elements, allowing the jumps across element boundaries to be neglected. In line with this, eight-node biquadratic FEs were used in [1] for the approximation while two fifth-degree polynomials were introduced for the error estimation in weak residual form.

Figure 4.1 is a given initial mesh on the domain. The adaptive computation shown in Fig. 4.2 is very similar to those using the code FEARS (finite element adaptive research solver); see, e.g., [6]. Our approach however is much simpler in terms of implementing the error indicators. Depending on the model problem, the location of singularity, the quantity of interest (displacement, stress, etc.), and the spectral order of the FE, different extraction expressions for an auxiliary problem associated with the model problem should be chosen accordingly for Babuška–Miller indicators; see [6] for more details. Our error indicators are not confined by the above effects; namely, ours do not depend on singularity and spectral order and there are no auxiliary problems. In fact, based on the ideas in the present paper, we are able to develop a very general and robust code which we call **AdaptC++**. So far, we have successfully tested our code for linear elasticity problems, mixed-type problems, flows in porous media, obstacle problems, Navier–Stokes equations, and semiconductor device simulation with FE, FV, and least-squares FE methods. Among other things, one of its advantageous features is the simplicity in implementing the error indicators which disregard input model problems and see only a very general setting of linear and bilinear forms and boundary conditions. From the user's viewpoint, use of the code is even simpler partly due to the refinement scheme and the object-oriented programming language. All numerical data presented in this section except that in Example 4.2 were produced by **AdaptC++**.

Tables 4.1 and 4.2 show that adaptive computations are clearly superior to uniform mesh reductions. For instance, if a tolerance is set to 3% of the relative error (r.e. $= \frac{|||e|||}{|||u|||}$), the uniform approach requires over 10 times the degrees of freedom (DOF) of the adaptive approach. Also, the effectivity indices θ show reliable error estimators for both uniform and adaptive approximations.

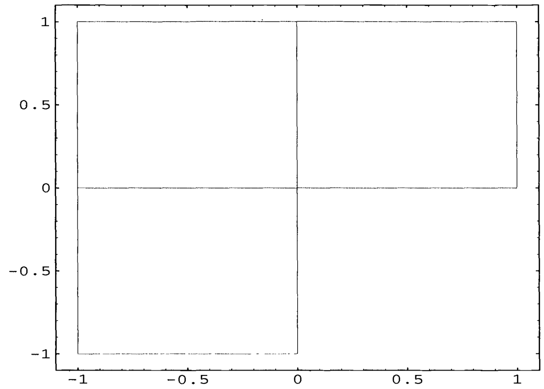

FIG. 4.1. *Initial mesh for Example* 4.1.

Example 4.2. The discussions in §3.2 are illustrated by the nonlinear boundary value problem

$$\begin{aligned} &-\Delta u = \lambda e^u, \quad u = u(x,y) \quad \forall (x,y) \in \Omega = (0,1) \times (0,1), \\ &\quad u = 0 \quad \text{on } \partial\Omega. \end{aligned} \tag{4.3}$$

The weak formulation of (4.3) is given as

$$\langle F(u,\lambda), v\rangle := \int_\Omega (u_x v_x + u_y v_y - \lambda e^u v)\, dx\, dy = 0 \;\; \forall v \in H_0^1(\Omega) \tag{4.4}$$

and we assume that $\lambda \in R^1$, which means that the solutions of (4.4) form a one-dimensional manifold M.

We use a uniform mesh, $\mathcal{T}$, of 16 biquadratic elements on Ω. For the computation of the one-dimensional solution manifold M_s of the discretized problem, a continuation process (PITCON [23]) is applied starting from $(u_s^0, \lambda_s^0) = (0, 0)$, and our aim is to determine a posteriori estimates of the error between M and M_s at all computed solutions $(u_s, \lambda_s) \in M_s$.

In line with (3.15) and (3.16), the linearized problem at $(u_s, \lambda_s) \in M_s$ is to determine $(w, \mu) \in H_0^1(\Omega) \times \Lambda$ such that

$$\int_\Omega \left[w_x v_x + w_y v_y - \lambda_s e^{u_s} wv + e^{u_s}\mu v\right] dx\,dy \tag{4.5}$$

$$= -\int_\Omega (u_{h_x} v_x + u_{h_y} v_y - \lambda_s e^{u_s} v)\,dx\,dy \quad \forall v \in H_0^1(\Omega),$$

$$\langle (w, \mu), t_s\rangle = 0. \tag{4.6}$$

As noted, the t_s are chosen as normalized tangent vectors on M_s at (u_s, λ_s). Such tangent vectors are available at each step of the continuation process and hence the equation (4.6) involves little additional computational cost.

For local solutions each one, $\tau_i \in \mathcal{T}$, of the 16 elements of Ω is divided into $m = (k+1)^2$ biquadratic subelements with $k = 1, 4$. That means that on each subelement, $\tau_{ij}, i = 1, \dots, 16,\ j = 1, \dots, m$, a bubble-shaped function $\psi_{ij}(x, y)$ is constructed via the mapping of the shape function

$$\psi(\xi, \eta) = (1 - \xi^2)(1 - \eta^2)$$

defined on the reference element. We thus have $S_\mathcal{T}^c(\tau_i) = span\{\psi_{ij}\}_{j=1}^m \subset H_0^1(\tau_i)$ for each element $\tau_i \in \mathcal{T}$ and hence $S_\mathcal{T}^c \subset H_0^1(\Omega)$ is a conforming FE subspace. The more subelements are used, the more accurate auxiliary condition (4.6) becomes and a better quality estimator can be obtained.

The resulting error estimates are shown in Table 4.3, where $|||w_{\bar{s}_k}|||$ denotes the computed error norms for the two cases of k. The computations are very cost-effective, since each local problem involves only a fixed number of degrees of freedom depending on the value of k. The table also shows that, as expected, the estimated errors vary smoothly along the solution path M_s and show no sudden increases near the limit point $\lambda = 6.804524$. As mentioned earlier, if the natural coordinate system induced by the parameter space Λ is chosen, then we expect the resulting error estimates $|||\hat{w}|||$ to become unduly large near the limit point. This is indeed the case as the last column of Table 4.3 shows. At the same time, it should be noted that the computational cost of the two approaches is practically identical.

Example 4.3. For mixed-type PDEs, we consider the forward–backward heat equation

$$x\phi_t(x,t) - \phi_{xx}(x,t) = f(x,t) \quad \forall (x,t) \in \Omega = (-1,1) \times (0,1), \tag{4.7}$$

$$\begin{cases} \phi(\pm 1, t) = 0 & \forall t \in [0,1], \\ \phi(x,0) = 0 & \forall x \in [0,1], \\ \phi(x,1) = 0 & \forall x \in [-1,0]. \end{cases} \tag{4.8}$$

Note that the equation changes type as x changes sign in Ω. There have been a number of papers addressing this kind of mixed-type heat equation; for further references see [5], [28].

For our computations, the exact solution ϕ is chosen as

$$\phi(x,t) = (x^2-1)t^2[(t-1)^2 - 4x^2] \;\; \forall x \geq 0, \;\; t \in [0,1],$$
$$\phi(x,t) = (x^2-1)(t^2-4x^2)(t-1)^2 \;\; \forall x \leq 0, \;\; t \in [0,1].$$

Denote the boundary $\partial\Omega$ by $\Gamma_1 \cup \cdots \cup \Gamma_6$,

$$\begin{aligned} \Gamma_1 &= \{(x,t) : x \in [-1,0], \;\; t = 0\}, \\ \Gamma_2 &= \{(x,t) : x = -1, \;\; t \in [0,1]\}, \\ \Gamma_3 &= \{(x,t) : x \in [-1,0], \;\; t = 1\}, \\ \Gamma_4 &= \{(x,t) : x \in [0,1], \;\; t = 1\}, \\ \Gamma_5 &= \{(x,t) : x = 1, \;\; t \in [0,1]\}, \\ \Gamma_6 &= \{(x,t) : x \in [0,1], \;\; t = 0\}. \end{aligned}$$

By a change of dependent variables,

$$\mathbf{u} = \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} = \begin{pmatrix} e^{-0.1t}\phi \\ e^{-0.1t}\phi_x \end{pmatrix},$$

(4.7) can then be expressed in symmetric positive form

$$L\mathbf{u} := A_1\mathbf{u}_x + A_2\mathbf{u}_t + A_0\mathbf{u} = \mathbf{f}, \tag{4.9}$$

with boundary condition

$$M\mathbf{u} := (\mu - \beta)\mathbf{u} = 0 \quad \forall (x,t) \in \partial\Omega, \tag{4.10}$$

where

$$A_1 = \begin{pmatrix} -x & -1 \\ -1 & 0 \end{pmatrix}, \quad A_2 = \begin{pmatrix} x & 0 \\ 0 & 0 \end{pmatrix}, \quad A_0 = \begin{pmatrix} 0.1x & x \\ 0 & 1 \end{pmatrix}, \quad \mathbf{f} = \begin{pmatrix} e^{-0.1t} f \\ 0 \end{pmatrix},$$

μ, β, and M are given in Table 4.4. It can be readily shown that the system (4.9), (4.10) is symmetric positive.

The adjoint operator $\mathbf{L}^*$ of $\mathbf{L}$ is defined by

$$\mathbf{L}^*\mathbf{v} := \begin{pmatrix} x & 1 \\ 1 & 0 \end{pmatrix} \mathbf{v}_x - \begin{pmatrix} x & 0 \\ 0 & 0 \end{pmatrix} \mathbf{v}_t + \begin{pmatrix} 0.1x + 1 & 0 \\ x & 1 \end{pmatrix} \mathbf{v}.$$

Now, the weak formulation corresponding to (3.23) for (4.7), (4.8) is complete.

For FE approximation of (3.23), a uniform mesh is introduced on Ω and bilinear elements are used. On the other hand, the bubble-shaped functions

$$\psi(\xi, \eta) = \xi(1 - \xi^2)(1/4 - \xi^2)\eta(1 - \eta^2)(1/4 - \eta^2) \tag{4.11}$$

are used to define $(S_{\mathcal{T}}^c)^2$. The effectivity of error estimates using (3.24) is shown in Table 4.5.

In view of error equations (3.5) and (3.24), the calculation of error indicators for the present example proceeds in a similar way as that of Example 4.1 except that we now have, in each element, a 2 × 2 system induced by (3.24) and by the complementary functions (4.11) for the vector-valued functions. However, by the nature of symmetric positive linear differential equations, the bilinear form associated with the system is coercive only in the L^2 norm instead of in the usual H^1 norm for elliptic problems. Hence, there is no equivalence of the energy

TABLE 4.6
Example 4.4 *using adaptive meshes.*

DOF	$\|\|\|e\|\|\|$	r.e.	θ
32	0.0223	0.1930	0.890
92	0.0117	0.1015	0.956
345	0.0053	0.0462	0.958

5156	0.0012	0.0108	0.986
6833	0.0011	0.0096	0.987

norm found in elliptic problems. Our numerical experience has shown that the quadratic order of the complementary basis functions used as in Example 4.1 gives rather pessimistic error estimates. The only remedy to this difficulty seems to be to use higher order $(S^2_{\mathcal{T}})^2$, e.g., (4.11). Note that this will not cause more computational cost, in fact, the cost is almost the same as when lower orders are used. Apparently, the a posteriori error analysis for mixed-type PDEs remains largely to be further investigated.

Example 4.4. Our error estimators for variational inequalities (2.3) are tested by the model problem given in [4] with the convex set $K = \{v(x, y) \in H^1(\Omega) : v(x, y) \geq 0$ and $v(x, y) = g(x, y)$ on $\partial\Omega\}$, where $\Omega = (0, \frac{1}{2}) \times (0, 1)$ and g is chosen so that we have the exact solution

$$u = \begin{cases} 0, & \text{if } (x+1)^2 + y^2 \geq 2, \\ \dfrac{1}{4}[(x+1)^2 + y^2] - \dfrac{1}{2} - \dfrac{1}{2}\ln\{[(x+1)^2 + y^2]\}, & \text{otherwise.} \end{cases}$$

The bilinear and linear forms are defined by

$$B(u, v) := \int_\Omega \nabla u \cdot \nabla v \, dxdy, \qquad F(v) := \int_\Omega v \, dxdy.$$

ALGORITHM.

1. Given an initial mesh Ω_h on Ω.
2. Construct a convex set K_s with linear shape functions on Ω_h.
3. Use the Gauss–Seidel–SOR method [18] with the relaxation parameter and the relative error chosen to be 1.2 and 10^{-6}, respectively, to obtain an approximate solution $u_s \in K_s$ of the minimization problem (3.26).
4. Construct the complementary convex set $K'_c := \{w \in S^c_{\mathcal{T}} \subset H_{\mathcal{T}}(\Omega)$ and $w \geq -u_s\}$, where $S^c_{\mathcal{T}}$ is defined via (4.2).
5. In each element τ_i, use the method in Step 3 to solve the reduced problem (3.28) for $\tilde{e} \in K'_c$, which involves only four equations with four unknowns, and then calculate the error indicator η_i for that element. Calculate the error estimator for u_s. If r.e. > 0.01 then refine all elements with $\eta_i \geq 0.1\eta_{\max}$, $\eta_{\max} = \max_i \eta_i$, and go back to Step 2, otherwise stop.

The numerical results are shown in Table 4.6.

Example 4.5. To compare FV and FE computations, we consider again the L-shaped problem (4.1).

For any particular (1-irregular) mesh, e.g., Fig. 4.3, on Ω, the FV element approximation of (4.1) is to find $u_b \in S$ such that

$$-\sum_{b_i \in \mathcal{B}} \int_{\partial b_i} \frac{\partial u_b}{\partial n} ds = 0,$$

where the FE space S is defined as in Example 4.1. Note that the test functions defined on the volumes $b_i \in \mathcal{B}$ are equal to one.

TIMELY COMMUNICATION

Under the "timely communications" policy for the SIAM Journal on Scientific Computing, papers that have significant timely content and do not exceed five pages automatically will be considered for a separate section of the journal with an accelerated reviewing process. It will be possible for the note to appear approximately six months after the date of acceptance.

PRECONDITIONING COMPLICATED FINITE ELEMENTS BY SIMPLE FINITE ELEMENTS[*]

SUSANNE C. BRENNER[†]

Abstract. We discuss a method of preconditioning finite elements with a large number of degrees of freedom by simpler finite elements.

Key words. finite elements, preconditioning, additive Schwarz methods

AMS subject classification. 65N30

1. Introduction.

In recent years the additive Schwarz theory (cf. [12], [17]) has been successfully used in the construction of multilevel preconditioners. In this paper we show that it also provides a useful conceptual framework for the preconditioning of complicated finite elements by simple finite elements on the same level.

It has long been folklore in the finite element community (cf. [2], [8]) that for second-order problems one can use the conforming $\mathcal{P}_1$ element to construct optimal preconditioners for higher-order elements. We give a transparent explanation of this folklore within the additive Schwarz framework in our first example. For fourth-order problems, conforming elements are C^1 elements which are, in general, quite complicated. In our second example we construct optimal preconditioners for such elements using simple nonconforming finite elements. Consequently, multigrid and domain decomposition results for nonconforming finite elements obtained in recent years become relevant even for those who prefer C^1 elements.

For the convenience of the reader, we first give a self-contained treatment of some results (Lemmas 1–3) from the theory of additive Schwarz preconditioners.

Let $\big(V, (\cdot,\cdot)_V\big)$ and $\big(W_j, (\cdot,\cdot)_{W_j}\big)$, $1 \le j \le 2$, be three finite-dimensional inner product spaces. Let $A : V \longrightarrow V$ and $A_j : W_j \longrightarrow W_j$ $(j = 1, 2)$ be linear symmetric positive definite operators. Assume that there exist linear maps $I_1 : W_1 \longrightarrow V$ and $I_2 : W_2 \longrightarrow V$ such that

$$V = I_1(W_1) + I_2(W_2). \tag{1}$$

We shall denote the transpose of I_j by I_j^t; i.e., $(I_j w, v)_V = (w, I_j^t v)_{W_j}$ for all $w \in W_j$ and $v \in V$. Let $B : V \longrightarrow V$ be the preconditioner of A defined by

$$B := I_1 A_1^{-1} I_1^t + I_2 A_2^{-1} I_2^t. \tag{2}$$

LEMMA 1. *The operator B is positive definite with respect to $(\cdot,\cdot)_V$.*

Proof. That B is symmetric positive semidefinite follows immediately from (2). If $(Bv, v)_V = 0$ for some $v \in V$, then $(A_1^{-1} I_1^t v, I_1^t v)_{W_1} + (A_2^{-1} I_2^t v, I_2^t v)_{W_2} = 0$. It follows that

$$I_1^t v = I_2^t v = 0. \tag{3}$$

[*] Received by the editors November 14, 1994; accepted for publication (in revised form) April 1, 1996.

Let $\tilde{v} \in V$ be arbitrary. By (1) we can write $\tilde{v} = I_1 w_1 + I_2 w_2$ for some $w_1 \in W_1$, $w_2 \in W_2$. Then (3) implies that $(v, \tilde{v})_V = (v, I_1 w_1 + I_2 w_2)_V = (I_1^t v, w_1)_{W_1} + (I_2^t v, w_2)_{W_2} = 0$. Therefore we have $v = 0$, and B is positive definite. □

It follows from Lemma 1 that the operator BA is symmetric positive definite with respect to $(A\cdot, \cdot)_V$ (or $(B^{-1}\cdot, \cdot)_V$), and the eigenvalues of BA are all positive.

LEMMA 2. *The following identity holds:*

$$(4) \qquad (B^{-1}v, v)_V = \inf_{\substack{v = I_1 w_1 + I_2 w_2 \\ w_1 \in W_1, w_2 \in W_2}} \left[(A_1 w_1, w_1)_{W_1} + (A_2 w_2, w_2)_{W_2}\right] \quad \forall v \in V.$$

Proof. Let $v \in V$. Then $v = I_1 w_1 + I_2 w_2$ for some $w_1 \in W_1$ and $w_2 \in W_2$. It follows from the Cauchy–Schwarz inequality and (2) that

$$\begin{aligned}
(B^{-1}v, v)_V &= (B^{-1}v, I_1 w_1)_V + (B^{-1}v, I_2 w_2)_V \\
&= (I_1^t B^{-1} v, w_1)_{W_1} + (I_2^t B^{-1} v, w_2)_{W_2} \\
&= (A_1^{-1/2} I_1^t B^{-1} v, A_1^{1/2} w_1)_{W_1} + (A_2^{-1/2} I_2^t B^{-1} v, A_2^{1/2} w_2)_{W_2} \\
&\le \sqrt{(I_1 A_1^{-1} I_1^t B^{-1} v, B^{-1} v)_V \, (A_1 w_1, w_1)_{W_1}} \\
&\quad + \sqrt{(I_2 A_2^{-1} I_1^t B^{-1} v, B^{-1} v)_V \, (A_2 w_2, w_2)_{W_2}} \\
&\le \sqrt{(v, B^{-1} v)_V} \sqrt{(A_1 w_1, w_1)_{W_1} + (A_2 w_2, w_2)_{W_2}}.
\end{aligned}$$

Therefore we have $(B^{-1}v, v)_V \le \inf\left[(A_1 w_1, w_1)_{W_1} + (A_2 w_2, w_2)_{W_2}\right]$. The opposite inequality follows from the special decomposition where $w_1 = A_1^{-1} I_1^t B^{-1} v$ and $w_2 = A_2^{-1} I_2^t B^{-1} v$. □

Note that Lemma 2 also follows from the so-called fictitious domain lemma (cf. [18], [13]). The following lemma can be traced back to Lions ([15]; cf. also [17] and [12]).

LEMMA 3. *Let C_1 and C_2 be two positive constants such that*

$$(5) \qquad C_1 (Av, v)_V \le \inf_{\substack{v = I_1 w_1 + I_2 w_2 \\ w_1 \in W_1, w_2 \in W_2}} \left[(A_1 w_1, w_1)_{W_1} + (A_2 w_2, w_2)_{W_2}\right] \le C_2 (Av, v)_V$$

for all $v \in V$. Then we have

$$\lambda_{\max}(BA) \le C_1^{-1} \quad \textit{and} \quad \lambda_{\min}(BA) \ge C_2^{-1}.$$

Proof. We have the following identities:

$$(6) \qquad \lambda_{\max}(BA) = \max_{v \ne 0} \frac{(Av, v)_V}{(B^{-1}v, v)_V} \quad \text{and} \quad \lambda_{\min}(BA) = \min_{v \ne 0} \frac{(Av, v)_V}{(B^{-1}v, v)_V}.$$

The lemma follows immediately from (4), (5), and (6). □

In applications we look for W_j, I_j, and A_j such that (i) condition (1) holds, (ii) the constants C_1 and C_2 in (5) are independent of the mesh size, and (iii) the operators I_1, I_2, A_1^{-1}, and A_2^{-1} can be constructed efficiently.

Example 1. Let Ω be a polygonal domain in $\mathbb{R}^2$. We consider the Dirichlet problem for the Laplace equation

$$(7) \qquad -\Delta u = f \quad \text{in } \Omega, \qquad u = 0 \quad \text{on } \partial\Omega.$$

Let $\mathcal{T}_h$ be a quasi-uniform triangulation (cf. [8]) of Ω and V_h be the quadratic finite element space $\{v \in H_0^1(\Omega) : v\big|_T \in \mathcal{P}_2(T)\,\forall\, T \in \mathcal{T}_h\}$. The inner product $(\cdot,\cdot)_{V_h}$ is defined by $(v_1, v_2)_{V_h} := h^2(\sum_p v_1(p)v_2(p) + \sum_m v_1(m)v_2(m))$, where the summation is over all the vertices p and midpoints m. The operator $A : V_h \longrightarrow V_h$ is defined by

$$(8)\qquad (Av_1, v_2)_{V_h} := \int_\Omega \nabla v_1 \cdot \nabla v_2\, dx \quad \forall v_1, v_2 \in V_h.$$

Let W_h be the linear finite element space $\{w \in H_0^1(\Omega) : w\big|_T \in \mathcal{P}_1(T) \text{ for all } T \in \mathcal{T}_h\}$ with the following inner product: $(w_1, w_2)_{W_h} := \sum_p h^2 w_1(p)w_2(p)$. The operator $\tilde{A} : W_h \longrightarrow W_h$ is the analogue of A:

$$(9)\qquad (\tilde{A}w_1, w_2)_{W_h} := \int_\Omega \nabla w_1 \cdot \nabla w_2\, dx \quad \forall w_1, w_2 \in W_h.$$

For $v \in V_h$, let $v^I \in W_h$ be the nodal interpolant of v. We define the subspace $\tilde{V}_h$ of V_h to be $\{v \in V_h : v^I = 0\}$. Let $I_1 : \tilde{V}_h \longrightarrow V_h$ and $I_2 : W_h \longrightarrow V_h$ be natural injections. Clearly we have $V_h = I_1(\tilde{V}_h) \oplus I_2(W_h)$. The preconditioner B of A is defined to be $B := h^2 I_1 I_1^t + I_2 \tilde{A}^{-1} I_2^t$.

LEMMA 4. *There exist positive constants C_1 and C_2, independent of h, such that*

$$(10)\qquad C_1(Av, v)_{V_h} \le h^{-2}(v - v^I, v - v^I)_{V_h} + (\tilde{A}v^I, v^I)_{W_h} \le C_2(Av, v)_{V_h}.$$

Proof. From here on we shall adopt the notation $\lesssim$ and $\approx$. The statement $F \lesssim G$ means that F is bounded by G multiplied by a constant which is independent of h and the functions involved. The statement $F \approx G$ means $F \lesssim G$ and $G \lesssim F$.

It is clear from (8) and (9) that

$$(11)\qquad (Av, v)_{V_h} = |v|^2_{H^1(\Omega)} \quad \forall\, v \in V_h \quad \text{and} \quad (\tilde{A}w, w)_{W_h} = |w|^2_{H^1(\Omega)} \quad \forall\, w \in W_h.$$

By the quasi uniformity of $\mathcal{T}_h$ and a standard homogeneity (scaling) argument we have

$$(12)\qquad (v, v)_{V_h} \approx \|v\|^2_{L^2(\Omega)} \quad \forall\, v \in V_h.$$

We also have the following standard inverse estimate (cf. [8], [10]):

$$(13)\qquad |v|_{H^1(\Omega)} \lesssim h^{-1}\|v\|_{L^2(\Omega)} \quad \forall\, v \in V_h.$$

Then (11)–(13) imply that $(Av, v)_{V_h} = |v|^2_{H^1(\Omega)} \lesssim |v - v^I|^2_{H^1(\Omega)} + |v^I|^2_{H^1(\Omega)} \lesssim h^{-2}\|v - v^I\|^2_{L^2(\Omega)} + |v^I|^2_{H^1(\Omega)} \lesssim h^{-2}(v - v^I, v - v^I)_{V_h} + (\tilde{A}v^I, v^I)_{W_h}$. Therefore the first inequality in (10) holds.

By a standard homogeneity argument we find

$$(14)\qquad \|v - v^I\|_{L^2(\Omega)} + h|v^I|_{H^1(\Omega)} \lesssim h|v|_{H^1(\Omega)} \quad \forall\, v \in V_h.$$

We deduce from (11), (12), and (14) that $h^{-2}(v - v^I, v - v^I)_{V_h} + (\tilde{A}v^I, v^I)_{W_h} \lesssim |v|^2_{H^1(\Omega)} = (Av, v)_{V_h}$. Therefore the second inequality in (10) holds. □

We conclude from Lemmas 3 and 4 (where $V = V_h$, $W_1 = \tilde{V}_h$, $W_2 = W_h$, $A_1 = h^{-2}I$, and $A_2 = \tilde{A}$) that the condition number of BA is bounded by a constant independent of h. We can also define a preconditioner $\tilde{B}$ by $\tilde{B} := h^{-2} I_1 I_1^t + I_2 R I_2^t$, where R is a positive definite operator on $(W_h, (\cdot,\cdot)_{W_h})$ such that $(R^{-1}w, w)_{W_h} \approx (\tilde{A}w, w)_{W_h}\, \forall\, w \in W_h$. For example, R can be a symmetric multigrid approximation of $\tilde{A}^{-1}$ (cf. [3]) or a preconditioner of $\tilde{A}$ based on domain decomposition (cf. [9]). It is clear that (10) holds with different constants (independent of h) if we replace $\tilde{A}$ by R^{-1}. It follows from Lemma 3 that the condition number of $\tilde{B}A$ is also bounded by a constant independent of h. Of course, other higher-order C^0 Lagrange finite element methods for (7) can likewise be preconditioned by the C^0 $\mathcal{P}_1$ element.

Example 2. Let Ω be a polygonal domain in $\mathbb{R}^2$. We consider the Dirichlet problem for the biharmonic equation

$$\Delta^2 u = f \quad \text{in } \Omega, \quad u = \frac{\partial u}{\partial n} = 0 \quad \text{on } \partial\Omega. \tag{15}$$

Let $\mathcal{T}_h$ be a quasi-uniform triangulation of Ω and $V_h = \{v \in H_0^2(\Omega) : v\big|_T \in \mathcal{P}_5(T)\ \forall T \in \mathcal{T}_h$ and the second derivatives of v are continuous at the vertices$\}$ be the quintic Argyris C^1 element (cf. [1]). The inner product on V_h is defined by

$$(v_1, v_2)_{V_h} := h^2 \sum_p \sum_{j=0}^{2} h^{2j} \sum_{|\alpha|=j} \partial^\alpha v_1(p) \partial^\alpha v_2(p) + h^4 \sum_m \frac{\partial v_1}{\partial n}(m) \frac{\partial v_2}{\partial n}(m)$$

for all $v_1, v_2 \in V_h$, where the summation is taken over all the vertices p and midpoints m. The operator $A : V_h \longrightarrow V_h$ is defined by

$$(Av_1, v_2)_{V_h} := \sum_{i,j=1}^{2} \int_\Omega \frac{\partial^2 v_1}{\partial x_i \partial x_j} \frac{\partial^2 v_2}{\partial x_i \partial x_j} dx \quad \forall\, v_1, v_2 \in V_h. \tag{16}$$

Let $W_h = \{w \in L^2(\Omega) : w\big|_T \in \mathcal{P}_2(T)\ \forall\, T \in \mathcal{T}_h$, w is continuous at the vertices and vanishes at the vertices along $\partial\Omega$, $\partial w/\partial n$ is continuous at the midpoints, and $\partial w/\partial n$ vanishes at the midpoints along $\partial\Omega\}$ be the Morley finite element space (c.f. [16]). The inner product on W_h is defined by

$$(w_1, w_2)_{W_h} := h^2 \sum_p w_1(p) w_2(p) + h^4 \sum_m \frac{\partial w_1}{\partial n}(m) \frac{\partial w_2}{\partial n}(m) \quad \forall\, w_1, w_2 \in W_h.$$

The operator $\tilde{A} : W_h \longrightarrow W_h$ is the following nonconforming analogue of A:

$$(\tilde{A} w_1, w_2)_{W_h} := \sum_{T \in \mathcal{T}_h} \left(\int_T \sum_{i,j=1}^{2} \frac{\partial^2 w_1}{\partial x_i \partial x_j} \frac{\partial^2 w_2}{\partial x_i \partial x_j} dx \right) \quad \forall\, w_1, w_2 \in W_h. \tag{17}$$

For each $v \in V_h$, let $v^I \in W_h$ be the nodal interpolant of v. We define the subspace $\tilde{V}_h$ of V_h to be $\{v \in V_h : v^I = 0\}$. Let $J : \tilde{V}_h \longrightarrow V_h$ be the natural injection. We define the map $E : W_h \longrightarrow V_h$ as follows: (i) $(Ew)(p) = w(p)$, (ii) $[\partial(Ew)/\partial n](m) = (\partial w/\partial n)(m)$, (iii) $[\partial^\alpha(Ew)](p) = 0$ for $|\alpha| = 2$, and (iv) $[\partial^\alpha(Ew)](p) =$ average of the values of $(\partial^\alpha w\big|_T)(p)$ over all $T \in \mathcal{T}_h$ which is a subset of the supporting set of the basis functions at p for $|\alpha| = 1$. (Here p and m are the vertices and midpoints of $\mathcal{T}_h$.)

This map E has the following properties (cf. [7]):

$$(Ew)^I = w \quad \forall\, w \in W_h, \tag{18}$$

$$\|w - Ew\|_{L^2(\Omega)} + h^2 |Ew|_{H^2(\Omega)} \lesssim h^2 |w|_{H^2(\mathcal{T}_h)} \quad \forall w \in W_h, \tag{19}$$

where the nonconforming energy norm $|\cdot|_{H^2(\mathcal{T}_h)}$ on the Morley finite element space is defined by $|w|_{H^2(\mathcal{T}_h)} = (\sum_{T \in \mathcal{T}_h} |w|^2_{H^2(T)})^{1/2}$.

It follows from (18) that $V_h = J(\tilde{V}_h) \oplus E(W_h)$. The preconditioner B of A is defined to be $B := h^4 J J^t + E\tilde{A}^{-1}E^t$.

LEMMA 5. *There exist positive constants C_1 and C_2, independent of h, such that*

$$C_1(Av, v)_{V_h} \le h^{-4}(v - Ev^I, v - Ev^I)_{V_h} + (\tilde{A}v^I, v^I)_{W_h} \le C_2(Av, v)_{V_h} \tag{20}$$

for all $v \in V_h$.

Proof. It is clear from (16) and (17) that

$$(Av, v)_{V_h} = |v|^2_{H^2(\Omega)} \quad \forall\, v \in V_h \quad \text{and} \quad (\tilde{A}w, w)_{W_h} = |w|^2_{H^2(\mathcal{T}_h)} \quad \forall\, w \in W_h. \tag{21}$$

By the quasi uniformity of $\mathcal{T}_h$ and a standard homogeneity argument for almost-affine finite elements (cf. [10]) we have

$$(v, v)_{V_h} \approx \|v\|^2_{L^2(\Omega)} \quad \forall\, v \in V_h. \tag{22}$$

The following inequality is a standard inverse estimate (cf. [8], [10]):

$$|v|_{H^2(\Omega)} \lesssim h^{-2}\|v\|_{L^2(\Omega)} \quad \forall\, v \in V_h. \tag{23}$$

The proof of the first inequality in (20) proceeds as in the corresponding proof of Lemma 4 using (19) and (21)–(23).

By the standard homogeneity argument for an almost-affine family of finite elements (cf. [10], [7]) we have

$$\|v - v^I\|_{L^2(\Omega)} + h^2|v^I|_{H^2(\mathcal{T}_h)} \lesssim h^2|v|_{H^2(\Omega)} \quad \forall v \in V_h. \tag{24}$$

We deduce from (19), (21), (22), and (24) that

$$\begin{aligned}
&h^{-4}(v - Ev^I, v - Ev^I)_{V_h} + (\tilde{A}v^I, v^I)_{W_h} \\
&\lesssim h^{-4}\|v - Ev^I\|^2_{L^2(\Omega)} + |v^I|^2_{H^2(\mathcal{T}_h)} \\
&\lesssim h^{-4}\big(\|v - v^I\|^2_{L^2(\Omega)} + \|v^I - Ev^I\|^2_{L^2(\Omega)}\big) + |v|^2_{H^2(\Omega)} \\
&\lesssim |v|^2_{H^2(\Omega)} = (Av, v)_{V_h}.
\end{aligned}$$

Therefore the second inequality in (20) holds. □

It follows from Lemmas 3 and 5 (where $V = V_h$, $W_1 = \tilde{V}_h$, $W_2 = W_h$, $I_1 = J$, $I_2 = E$, $A_1 = h^{-4}I$, and $A_2 = \tilde{A}$) that the condition number of BA is bounded by a constant independent of h. We can also replace $\tilde{A}^{-1}$ by any symmetric positive definite operator $R : W_h \longrightarrow W_h$ such that $(R^{-1}w, w)_{W_h} \approx (\tilde{A}w, w)_{W_h}\, \forall\, w \in W_h$. For example, R can be a symmetric multigrid approximation of $\tilde{A}^{-1}$ (cf. [5], [14]) or a two-level additive Schwarz preconditioner for $\tilde{A}$ (cf. [6], [7]).

Other C^1 elements can also be preconditioned by simpler nonconforming finite elements; for example, the Hsieh–Clough–Tocher macro element (cf. [11]) can be preconditioned by the Morley finite element and the Fraeijs de Veubeke–Sander element (cf. [20]) can be preconditioned by the incomplete biquadratic element (cf. [21]).

Remark. We assume $\mathcal{T}_h$ to be quasi uniform in the two examples only for simplicity. If the mesh size h in the definitions of the inner products and B is replaced by the diameters of the local triangles, our results would hold under the weaker assumption that $\mathcal{T}_h$ is regular.

Remark. We note that results similar to ours have also been obtained independently in the forthcoming papers [4] and [22] and that the opposite approach of preconditioning nonconforming finite elements by conforming ones was investigated in [19].

COMPUTING HOPF BIFURCATIONS II: THREE EXAMPLES FROM NEUROPHYSIOLOGY*

JOHN GUCKENHEIMER† AND MARK MYERS‡

Abstract. In [Guckenheimer, Myers, and Sturmfels, *SIAM J. Numer. Anal.*, 34 (1997)] we present algorithms for detecting Hopf bifurcations in two-parameter families of vector fields based on classical algebraic constructions. In addition to their utility as augmented systems for use with standard Newton-type continuation methods, they are shown to be particularly well adapted for solution by computer algebra techniques for vector fields of small or moderate dimension. The present study examines the performance of these methods on test problems selected from models of current research interest in neurophysiology. Implementation issues are examined and the numerical properties of the proposed methods are compared with several alternative algorithms for Hopf pathfollowing that appear in the literature.

Key words. Hopf bifurcation, resultant, bialternate product, neuron model

AMS subject classifications. 58F14, 65H17, 92-08, 92C20

1. Introduction.

The onset of small amplitude oscillations in dynamical systems occurs at Hopf bifurcations. The simplest version of the Hopf theorem is the following.

THEOREM 1.1. *Let*

$$\dot{x} = f(x, \mu), \qquad f : \mathbb{R}^n \times \mathbb{R}^k \to \mathbb{R}^n \tag{1}$$

be a smooth n-dimensional vector field depending upon k parameters with the property that (x_0, μ_0) is an equilibrium point at which the Jacobian matrix $D_x f$ has no zero eigenvalues and a single, simple pair of pure imaginary eigenvalues $\lambda, \bar{\lambda}$. Assume further that $\lambda, \bar{\lambda}$ cross the imaginary axis transversely as the parameters μ are varied. Then there is a smooth submanifold P of dimension $k+1$ containing (x_0, μ_0) that is a union of periodic orbits and equilibrium points of f.

We are concerned with the numerical *detection* of Hopf bifurcation points. This constitutes location of values (x, μ) at which $f(x, \mu) = 0$ and $Df(x, \mu)$ has a pair of pure imaginary eigenvalues. Several methods for computing such points have been proposed and implemented by various authors (for recent reviews, see [18, 24]).

To motivate the discussion that follows, we begin by considering the following planar vector field:

$$\begin{aligned} \dot{x} &= \gamma\left(x + y - x^3/3 + \xi\right), \\ \dot{y} &= -(x - \alpha + \beta y)/\gamma. \end{aligned} \tag{2}$$

This model for the propagation of electrical impulses along a nerve axon was proposed by Fitzhugh [6] as a tractable simplification of the more complicated Hodgkin–Huxley equations discussed as the first example in §2. Equilibrium points for (2) are points which satisfy $\dot{x} = \dot{y} = 0$. Hopf bifurcation points are determined by the Jacobian at the equilibrium. They occur where the trace $\beta/\gamma - \gamma(1 - x^2)$ is zero and the determinant $1 - \beta(1 - x^2)$ is positive. Thus, the determination of Hopf bifurcation points for (2) described above can be written as the following problem:

*Received by the editors August 6, 1993; accepted for publication (in revised form) May 10, 1995. This research was partially supported by grants from the National Science Foundation and the Department of Energy.

‡Center for Applied Mathematics, Cornell University, Ithaca, NY 14853 (mrm@utrc.utc.com).

Problem (P1):

Find: $(\hat{x}, \hat{y})$ and $(\alpha, \beta, \gamma, \xi)$

Satisfying:

$$\begin{pmatrix} \gamma\left(x + y - x^3/3 + \xi\right) \\ -(x - \alpha + \beta y) \\ \beta/\gamma - \gamma(1 - x^2) \end{pmatrix} = 0$$

Subject To:

$$1 - \beta(1 - x^2) > 0.$$

We seek to extend the approach to detecting Hopf bifurcations in this example to vector fields of higher dimension. We need a nonlinear system of equations comprised of the equilibrium condition of (1) and the algebraic criteria that determine when the Jacobian matrix has a single pair of pure imaginary, conjugate eigenvalues in its spectrum. In [11] we discuss classical algebraic constructions for determining matrices of arbitrary dimension with pure imaginary eigenvalues. A single equality condition and an inequality in the coefficients of the characteristic polynomial are formulated in terms of *resultants*, determinants of special matrices whose elements are functions of the characteristic polynomial coefficients. The equality condition is also derived directly from the Jacobian as the determinant of a *bialternate product* (biproduct) matrix constructed from the Jacobian entries. The biproduct matrix is generally sparse and block structured. Thus, in arbitrary dimensions the nonlinear rootfinding problem corresponding to that of (P1) can be expressed in terms of the defining equations for the vector field and the Jacobian elements alone. We note that there is some overlap in our approach with work of previous authors. In particular, the program *LINLBF* by Khibnik and his coworkers [15] incorporates a method for following curves of Hopf bifurcations based on the resultant of two polynomials which is similar to that used here. In [11] we extend their work by examining several variations of the resultant methods which have differing numerical properties and derive the inequality condition that makes identification of the Hopf points possible. The biproduct formulation is new as is the formulation of conditions under which regularity holds.

Here we discuss the implementation of our new methods, describe their application to three examples from neurophysiology, and make comparisons with other approaches to computing Hopf bifurcations. Each of the examples that we describe comes from a neurophysiological model for the electrical activity of a neuron and each illustrates a different aspect of the methods. In some other problems of modest size or special structure, computer algebra programs produce curves of Hopf bifurcations analytically. However, given an arbitrary nonlinear vector field, solving for the roots of the required system of equations is generally infeasible in closed form. One can attempt to solve (P1) numerically and to follow curves of Hopf bifurcation points in two-parameter families of vector fields. In [11] we show that these augmented systems do, indeed, satisfy the properties required for use in Newton-type numerical continuation.

Our goal in examining these algorithms has been to develop computational methods that facilitate the comparison of biologically based neural models with experimental data. In the first example of §2, we illustrate the application of symbolic methods to the detection of Hopf bifurcations in the classical Hodgkin–Huxley model for action potentials of a squid giant axon. We also use the Hodgkin–Huxley example to compare the accuracy of numerical calculations of derivatives using "automatic differentiation" with finite difference techniques and analytic evaluation. The second example shows the performance of the resultant approach on a more complex model for the electrical activity of a bursting neuron. This model contains a pointof double Hopf bifurcation in its parameter space. We make a detailed comparison of our algorithms with other strategies for detecting Hopf bifurcations for this model. The third example is a still larger and stiffer system of differential equations formulated as a model for electrical activity of a stomatogastric neuron of the crab *Cancer borealis*. We examine the problems caused in the detection of Hopf bifurcations by large eigenvalues in the linearization of this model.

The paper is organized into two sections. The first section is a review of methods for detecting Hopf bifurcations, including those discussed in [11]. The second section presents results obtained for the three examples, beginning with a brief description of the biological origins of each model. We conclude with a summary of our experiments and discuss directions for future work.

2. Review of Hopf bifurcation algorithms.

2.1. Minimally augmented systems. In this section we review strategies for detecting curves of Hopf bifurcation points in two-parameter families of vector fields. We consider first methods based on the algebra of polynomial resultants in families of autonomous vector fields of the form

$$\dot{x} = f(x, \alpha; \beta) \tag{3}$$

where $f : D \subset \mathbb{R}^n \times \mathbb{R} \times I \to \mathbb{R}^n$ and $\beta \in I \subset \mathbb{R}$. For simplicity, we distinguish the second parameter by considering both $x(\beta)$ and $\alpha(\beta)$ to be functions of β. The Jacobian matrix of the vector field is given by

$$\mathbf{J} \equiv \mathbf{J}(x, \alpha; \beta) = \frac{\partial f}{\partial x}(x, \alpha; \beta).$$

$\mathbf{J}$ defines a map from the product space of phase and parameter variables to the space of n-square matrices, denoted by $\mathcal{M}$.

Direct methods for computing curves of Hopf bifurcation for (3) involve appending a determining equation that vanishes when $\mathbf{J}$ has pure imaginary eigenvalues to the equilibrium equations $f(x, \alpha; \beta) = 0$. Thus, we seek a C^2-smooth function $g : \mathbb{R}^n \times \mathbb{R} \times \mathbb{R} \to \mathbb{R}^{n+1}$ so that the *augmented* system

$$F(x, \alpha; \beta) = \begin{pmatrix} f(x, \alpha; \beta) \\ g(x, \alpha; \beta) \end{pmatrix} \tag{4}$$

vanishes at a point of Hopf bifurcation. Furthermore, we require that a point of Hopf bifurcation $(x^*, \alpha^*; \beta^*)$ be a regular solution of (4).

If the characteristic polynomial of $\mathbf{J}$ is given by

$$p(\lambda) = c_0 + c_1\lambda + \cdots + c_{n-1}\lambda^{n-1} + \lambda^n,$$

then p has the nonzero root pair $\{\lambda, -\lambda\}$ if and only if λ is a common root of the two equations $p(\lambda) + p(-\lambda)$ and $p(\lambda) - p(-\lambda)$. Making the substitution $z = \lambda^2$ and rearranging, we construct two new polynomials. If n is even, let

$$\begin{aligned} r_e(z) &= c_0 + c_2 z + c_4 z^2 + \cdots + c_{n-2} z^{\frac{n-2}{2}} + z^{\frac{n}{2}}, \\ r_o(z) &= c_1 + c_3 z + c_5 z^2 + \cdots + c_{n-1} z^{\frac{n-2}{2}}, \end{aligned} \tag{5a}$$

while if n is odd, set

$$\begin{aligned} r_e(z) &= c_0 + c_2 z + c_4 z^2 + \cdots + c_{n-3} z^{\frac{n-3}{2}} + c_{n-1} z^{\frac{n-1}{2}}, \\ r_o(z) &= c_1 + c_3 z + c_5 z^2 + \cdots + c_{n-2} z^{\frac{n-3}{2}} + z^{\frac{n-1}{2}}. \end{aligned} \tag{5b}$$

Then p has a nonzero root pair $\{\lambda, -\lambda\}$ if there exists a z that satisfies

$$\begin{pmatrix} r_e(z) \\ r_o(z) \end{pmatrix} = 0.$$

Two polynomials have a common root if and only if they share a common factor. There are several equivalent ways of determining whether two univariate polynomials have a common root. First, the Euclidean algorithm yields a sequence of polynomials of decreasing degree that are ideally generated by $r_e(z)$ and $r_o(z)$. The last term in this sequence can be expressed as a determinant constructed from the coefficients of two polynomials. We describe one way to do so.

The *Bezout* resultant is a determinant that indicates whether r_e and r_o have a common root. For n even, consider the two polynomials specified by (5a). We define the brackets

$$[i, j] = \det \begin{bmatrix} c_{2i} & c_{2j} \\ c_{2i+1} & c_{2j+1} \end{bmatrix}$$

where $0 \le i, j \le \frac{n}{2}$ and we take $c_n = 1,\ c_{n+1} = 0$. The *Bezout* matrix $\mathcal{B}$ corresponding to the polynomial pair (r_e, r_o) is an $\frac{n}{2}$-dimensional square, symmetric matrix with entries constructed as sums of brackets in the coefficients c_i as follows: for $1 \le i \le j \le \frac{n}{2}$ set

$$\begin{aligned} k_{min} &= \max(0, i + j - n/2 - 1), \\ k_{max} &= i - 1, \end{aligned} \tag{6}$$

$$(\mathcal{B})_{ij} = \sum_{k=k_{min}}^{k_{max}} [i + j - k - 1, k] = (\mathcal{B})_{ji}. \tag{7}$$

The only modification required in this definition for the case of n odd is that c_n has the value prescribed by the characteristic polynomial p and c_{n+1} is taken to be unity. We also define the *Bezout subresultants* $\mathcal{B}_0$ and $\mathcal{B}_1$ as the determinants of the matrices obtained from $\mathcal{B}$ by deleting the first column and the ith row of $\mathcal{B}$. The following theorem is proved in [11].

THEOREM 2.1. *Let B be the Bezout matrix for the polynomials r_e and r_o in* (2). *Then* **J** *has precisely one pair of pure imaginary eigenvalues if*

$$\det(\mathcal{B}) = 0 \quad \textit{and} \quad \det(\mathcal{B}_0) \cdot \det(\mathcal{B}_1) > 0.$$

If $\det(\mathcal{B}) \neq 0$ *or* $\det(\mathcal{B}_0) \cdot \det(\mathcal{B}_1) < 0$, *then* $p(\lambda)$ *has no pure imaginary roots.*

Table 1 provides a list of the resultant equality and subresultant inequality conditions, as functions of the polynomial coefficients, for vector fields of dimensions two to six.

To circumvent possible difficulties in explicitly determining the characteristic polynomial coefficients of **J**, we described a method for determining whether a square matrix has a pair of eigenvalues with zero sum directly from the entries in the Jacobian matrix.

DEFINITION. *Let* **A** *and* **B** *be $n \times n$ matrices with entries (a_{ij}) and (b_{ij}), respectively,* $1 \le i, j \le n$. *Set $m = \frac{n}{2}(n-1)$. Then the* bialternate product *(or biproduct) of* **A** *and* **B**, *denoted*

TABLE 1
Resultant equality and subresultant inequality conditions required for Hopf bifurcation for vector fields of dimensions two through six.

n	$\det(\mathcal{B})$ $\det(\mathcal{S}_0)\cdot\det(\mathcal{S}_1)$
2	c_1
	c_0
3	$c_0 - c_1c_2$
	c_1
4	$c_0c_3^2 - c_1c_2c_3 + c_1^2$
	c_1c_3
5	$(c_2 - c_3c_4)(c_1c_2 - c_0c_3) + c_1c_4(c_1c_4 - 2c_0) + c_0^2$
	$(c_2 - c_3c_4)\cdot(c_0 - c_1c_4)$
6	$c_0c_5^2(c_0c_5 - c_2c_3) + c_1c_5^2(c_2^2 - c_0c_4) + c_1(c_1^2 + c_0c_3c_5)$ $+c_1c_5(c_0c_3 - 2c_1c_2) + (c_4c_5 - c_3)(c_0c_3^2 - c_0c_1c_5 + c_1^2c_4 - c_1c_2c_3)$
	$(c_1c_3 + c_0c_5^2 - c_1c_4c_5)\ \cdot(c_3^2 - c_1c_5 + c_2c_5^2 - c_3c_4c_5)$

$\mathbf{A}\odot\mathbf{B}$, *is an* $m\times m$ *matrix whose rows are labeled* pq ($p = 2, 3, \dots, n$; $q = 1, 2, \dots, p-1$) *and columns labeled* rs ($r = 2, 3, \dots, n$; $s = 1, 2, \dots, r-1$) *with entries*

$$(\mathbf{A}\odot\mathbf{B})_{\{pq,rs\}} = \frac{1}{2}\left\{\begin{vmatrix} a_{pr} & a_{ps} \\ b_{qr} & b_{qs}\end{vmatrix} + \begin{vmatrix} b_{pr} & b_{ps} \\ a_{qr} & a_{qs}\end{vmatrix}\right\}.$$

THEOREM 2.2. *Let* $\mathbf{A}$ *be an* $(n\times n)$ *matrix with eigenvalues* $(\lambda_1, \dots, \lambda_n)$. *Then*

(i) $\mathbf{A}\odot\mathbf{A}$ *has eigenvalues* $\lambda_i\cdot\lambda_j$ *and*

(ii) $2\mathbf{A}\odot\mathbf{I}_n$ *has eigenvalues* $\lambda_i+\lambda_j$

where $\mathbf{I}_n$ *is the n-square identity matrix and* $1\le j<i\le n$.

Substituting $\mathbf{I}_n$ into the definition of the bialternate product and solving for the elements yields a simple formula for the entries. For the $\frac{n}{2}(n-1)$-square matrix $2\mathbf{A}\odot\mathbf{I}_n$ with rows pq and columns rs the entries are given by the formula

$$(8)\qquad (2\mathbf{A}\odot\mathbf{I}_n)_{\{pq,rs\}} = \begin{cases} -(A)_{ps} & \text{if } r = q, \\ (A)_{pr} & \text{if } r \neq p \text{ and } s = q, \\ (A)_{pp} + (A)_{qq} & \text{if } r = p \text{ and } s = q, \\ (A)_{qs} & \text{if } r = p \text{ and } s \neq q, \\ -(A)_{qr} & \text{if } s = p, \\ 0 & \text{otherwise.}\end{cases}$$

From the algebraic theory of symmetric matrix products described above we have a simple *necessary* condition for a Hopf point: if the point (x^*, λ^*) is a Hopf bifurcation point for $\dot{x} = f(x, \alpha)$, then the $(n + 1)$-dimensional system

$$F(x^*, \alpha^*) = \begin{pmatrix} f(x^*, \alpha^*) \\ \det\left(D_x f \odot \mathbf{I}_n\Big|_{(x^*,\alpha^*)}\right) \end{pmatrix} \tag{9}$$

vanishes. However, we have not found a condition that distinguishes pure imaginary eigenvalues from real pairs with zero sum directly from the Jacobian and its bialternate products in analogy to the subresultant criteria described earlier.

Both the determinant of the biproduct and the resultant provide augmentation functions g that can be used in detecting Hopf bifurcations in one-parameter families of vector fields or in applying continuation methods for the computation of curves of Hopf bifurcations in two-parameter families. The regularity theorem of [11] guarantees that the matrix of partial derivatives of the augmented system $F = 0$ has maximum rank $n + 1$ at points of simple Hopf bifurcation. In §2, we discuss several aspects of standard rootfinding and continuation methods that can be improved by taking into account the nature of the augmenting function g.

2.2. Other methods based on the characteristic polynomial. Kubiček has previously described two direct methods for computing Hopf bifurcation points which explicitly require the coefficients of a matrix characteristic polynomial [16, 17]. Both methods result in $(n+2)$-dimensional systems of algebraic equations which may be solved by conventional continuation techniques. Performance of these algorithms has been evaluated on a variety of testcases, including panel flutter and nonadiabatic tubular reactions [24], continuous-stirred tank reactions [13], and parabolic reaction-diffusion equations [23] with favorable results.

The two methods of Kubiček are based on the direct determination of the pure imaginary eigenvalues, say $\lambda^*_{1,2} = \pm\sqrt{\omega} i$, of the Jacobian characteristic polynomial p. Suppose such an eigenvalue pair exists. Then there is a polynomial q of degree $(n-2)$ such that

$$\begin{aligned} p(\lambda) &= (\lambda^2 + \omega) q(\lambda) \\ &= (\lambda^2 + \omega) \sum_{k=0}^{n-2} b_k \lambda^{n-k-2} + A\lambda + B \end{aligned}$$

where the b_i are given recursively by the formula $b_i = c_i - \omega b_{i-2}$ for $1 \leq i \leq n-2$ with $b_{-1} = 0$. We require the constant and linear coefficients A and B to be zero; that is,

$$\begin{pmatrix} A(x, \alpha) \\ B(x, \alpha) \end{pmatrix} = \begin{pmatrix} c_{n-1} - \omega b_{n-3} \\ c_n - \omega b_{n-2} \end{pmatrix} = 0 \tag{10}$$

where the dependence of A and B on (x, α) has been emphasized. Thus, (10) yields a two-dimensional augmented system which must vanish at a Hopf bifurcation point

$$F(x, \alpha, \omega) = \begin{pmatrix} f(x, \alpha) \\ c_{n-1} - \omega b_{n-3} \\ c_n - \omega b_{n-2} \end{pmatrix}. \tag{K1}$$

Kubiček's second method depends on the observation that if (x^*, α^*) is a point of Hopf bifurcation with imaginary eigenvalues $\pm\sqrt{\omega} i$, then the matrix $\mathbf{J}^2$ has a real eigenvalue $-\omega$ with multiplicity equal to two. Suppose the characteristic polynomial of $\mathbf{J}^2$ has r eigenvalues distinct from $-\omega$; that is, we take the spectrum of $\mathbf{J}^2$ to be $\{-\omega, \lambda_1, \ldots, \lambda_r\}$ with respective multiplicities $\{m_\omega, m_1, \ldots, m_r\}$ where $(m_\omega + m_1 + \ldots m_r) = n$. Then q may be written

$$q(\lambda) = (\lambda + \omega)^{m_\omega} \prod_{k=0}^{r} (\lambda - \lambda_k)^{m_k}. \tag{11}$$

Differentiating with respect to λ we obtain

$$\frac{dq}{d\lambda} = m_\omega (\lambda + \omega)^{m_\omega - 1} \prod_{k=0}^{r} (\lambda - \lambda_k)^{m_k} + (\lambda + \omega)^{m_\omega} \frac{d}{d\lambda} \prod_{k=0}^{r} (\lambda - \lambda_k)^{m_k}.$$

For $-\omega$ to be a double real root,

$$q(-\omega) = 0 = \frac{dq}{d\omega}(-\omega),$$

which leads to the augmented system

$$F(x, \alpha, \omega) = \begin{pmatrix} f(x, \alpha) \\ q(-\omega) \\ \frac{dq}{d\omega}(-\omega) \end{pmatrix}. \tag{K2}$$

2.3. Other methods not based on the characteristic polynomial. Here we review methods for computing Hopf bifurcations, which do not require the coefficients of the Jacobian characteristic polynomial. Most of the methods in this category use variants of two distinct defining equations. Our discussion summarizes the main features of these methods; for more details see Roose and Hlavacek [22].

Suppose (x^*, α^*) is a Hopf bifurcation point for (2) with pure imaginary eigenvalues $\pm\omega i$ and associated eigenvector $u + vi$. Denote $E = span(u, v)$, which is two-dimensional if $\mathbf{J}$ is nonsingular. The defining relation

$$(D_x f - \omega \mathbf{I})\,(u + vi) = 0$$

leads to the augmented system

$$F_1(x, \alpha, u, v, \omega) = \begin{pmatrix} f(x, \alpha) \\ [D_x f]\, u - \omega v \\ [D_x f]\, v + \omega u \\ \mathcal{N}(u, v) \end{pmatrix}.$$

If the same construction is applied to the matrix $\mathbf{J}^2 = [D_x f]^2$, we obtain the inflation

$$F_2(x, \alpha, u, \omega) = \begin{pmatrix} f(x, \alpha) \\ [D_x f]^2\, u + \omega^2 u \\ \mathcal{N}(u) \end{pmatrix}.$$

The operator $\mathcal{N} : X \to \mathbb{R}^2$, where X is either $\mathbb{R}^n \times \mathbb{R}^n$ or $\mathbb{R}^n$, is used to normalize the vectors u and v and typically requires a fixed vector l. Precisely how l is selected is a matter of implementation, but it must be chosen so that $l \notin E$. Two choices for $\mathcal{N}$ have been discussed extensively in the literature. Griewank and Reddien [9] suggested the use of

$$\mathcal{N}_1 = \begin{pmatrix} \langle l, u \rangle \\ \langle l, v \rangle - 1 \end{pmatrix}$$

in conjunction with F_1 and showed that both Hopf and simple quadratic turning points are regular, isolated solutions to the system of equations. An alternative proposed by Roose and Hlavacek [22] is to take

$$\mathcal{N}_2 = \begin{pmatrix} \langle l, u \rangle \\ \langle v, v \rangle - 1 \end{pmatrix},$$

which, for l chosen as prescribed above, does not admit turning points as isolated solutions.

Each of the four possible choices available by this construction can be used with standard continuation techniques to track curves of Hopf bifurcation in two-parameter families. For example, if we set $y = (x, \alpha, u, v, \omega)$, then the kth Newton step taken to find a local root $F_1(y) = 0$ will require the solution of the linearized system

$$y_{k+1} = y_k - \left[D_y F_1(y_k)\right]^{-1} F_1(y_k).$$

While it is possible to ignore the special structure of $D_y F(y_k)$ and solve for the updated step with LU decomposition, much faster algorithms may be obtained by exploiting the block structure of the Jacobian for the augmented system. Computer software designed to implement general-purpose numerical bifurcation techniques must be specially modified to accommodate these special Newton-step solution methods. Table 2 summarizes the defining equations for the direct methods described above.

3. Three examples.

3.1. Hodgkin–Huxley equations.

The space-clamped Hodgkin–Huxley equations are a system of four nonlinear ordinary differential equations that describe the electrical response of the giant nerve axon from the squid *Loligo* to an externally applied current [14]. The typical response of the axon to a step in the stimulus current I is characterized by an abrupt spike in the electrical potential difference v between the intracellular fluid and the extracellular medium called an *action potential.* In the Hodgkin–Huxley model this depolarization is induced primarily by an inward flux of sodium (Na^+) followed by an outward flow of potassium (K^+) ions. Other ions contribute to a "leak" current across the axon membrane. The sodium and potassium currents are controlled by three *gating* variables denoted m, n, and h, together with parameters $\bar{g}_{Na}$, $\bar{g}_K$, and $\bar{g}_l$ that measure the maximum conductances of the channels. The resulting vector field is given by

$$\begin{aligned} \dot{v} &= -G(v, m, n, h) - I, \\ \dot{m} &= \Phi(T)\left[(1 - m)\alpha_m(v) - m\beta_m(v)\right], \\ \dot{n} &= \Phi(T)\left[(1 - n)\alpha_n(v) - n\beta_n(v)\right], \\ \dot{h} &= \Phi(T)\left[(1 - h)\alpha_h(v) - h\beta_h(v)\right] \end{aligned} \tag{12}$$

where $\dot{x}$ stands for dx/dt and Φ is given by $\Phi(T) = 3^{(T-6.3)/10}$. The other functions involved are

$$G(v, m, n, h) = \bar{g}_{\mathrm{na}} m^3 h(v - \bar{v}_{\mathrm{na}}) + \bar{g}_{\mathrm{k}} n^4 (v - \bar{v}_{\mathrm{k}}) + \bar{g}_{\mathrm{l}}(v - \bar{v}_{\mathrm{l}})$$

TABLE 2

Summary of the defining equations for the direct methods discussed in the paper for use with pathfollowing numerical codes. Labels are used in the sequel to distinguish the various algorithms.

Label	$g : \mathbb{R}^n \times \mathbb{R}^m \times \mathbb{R} \times \mathbb{R} \to \mathbb{R}^l$	m	l
RS,RB	$g(x, \alpha; \beta) = \det(\mathcal{B})(x, \alpha; \beta)$	0	1
BP	$g(x, \alpha; \beta) = \det([D_x f] \odot I_n)$	0	1
JGR	$g(x, v, w, \omega, \alpha; \beta) = \begin{pmatrix} [D_x f]\, v - \omega w \\ [D_x f]\, w + \omega v \\ < v, w > -1 \\ < l, v > \end{pmatrix}$	$2n+1$	$2n+2$
RH	$g(x, w, \omega, \alpha; \beta) = \begin{pmatrix} [D_x f]^2\, w - \omega^2 w \\ < w, w > -1 \\ < l, w > \end{pmatrix}$	$n+1$	$n+2$
K1	$g(x, \omega, \alpha; \beta) = \begin{pmatrix} c_{n-1} - \omega b_{n-3} \\ c_n - \omega b_{n-2} \end{pmatrix}$	1	2
K2	$g(x, \omega, \alpha; \beta) = \begin{pmatrix} q(-\omega) \\ \frac{dq}{d\omega}(-\omega) \end{pmatrix}$	1	2

and the following equations modeling the variation of membrane permeability:

$$\begin{aligned} \alpha_m(v) &= \Psi((v+25)/10), & \beta_m(v) &= 4e^{v/18}, \\ \alpha_n(v) &= \tfrac{1}{10}\Psi((v+10)/10), & \beta_n(v) &= 0.125e^{v/80}, \\ \alpha_h(v) &= 0.07e^{v/20}, & \beta_h(v) &= \left(1 + e^{(v+30)/10}\right)^{-1}, \\ \Psi(x) &= x/(e^x - 1). \end{aligned}$$

In the following, we use the temperature $T = 6.3$°C and parameter values for $\bar{g}_{\text{ion}}$ and $\bar{v}_{\text{ion}}$ used by Hodgkin and Huxley [14]:

$$\begin{aligned} \bar{g}_{\text{na}} &= 120\text{mS/cm}^2, & \bar{g}_{\text{k}} &= 36\text{mS/cm}^2, & \bar{g}_{\text{l}} &= 0.3\text{mS/cm}^2, \\ \bar{v}_{\text{na}} &= -115\text{mV}, & \bar{v}_{\text{k}} &= 12\text{mV}, & \bar{v}_{\text{l}} &= 10.599\text{mV}. \end{aligned}$$

The space-clamped Hodgkin–Huxley equations exhibit periodic solutions that arise through Hopf bifurcation with varying (v_k, I) [21]. In general, one does not expect to be able to find explicit analytic expressions for the solutions to multi-dimensional systems of equations, but the special structure of the Hopf bifurcation points allows us to do so. All the Hopf data reported in the discussion which follows was computed using the Maple© symbolic algebra package, reproduced using the same approach in Mathematica© and verified by standard numerical continuation using the augmented systems denoted by (JGR) and (RH) in Table 2 and described in §3.2.

The Jacobian matrix corresponding to (12), tedious to derive by hand, is found easily in Maple©. The corresponding characteristic polynomial

$$p(\lambda) = \lambda^4 + \sum_{i=0}^{3} c_i(v, m, n, h;\, v_k, I) \cdot \lambda^i$$

may be formed and the expressions required by Theorem 2.1 follow by inspection:

$$\det(\mathcal{B}) = c_0 c_3^2 - c_1 c_2 c_3 + c_1^2, \tag{13a}$$

$$\det(\mathcal{B}_0) \cdot \det(\mathcal{B}_1) = c_1 \cdot c_3. \tag{13b}$$

The locus of Hopf bifurcation points in the (v_k, I) plane will be computed as a curve parameterized by v^*, the equilibrium values of v. Suppose that, for a prescribed v_k and I, the point (v^*, m^*, n^*, h^*) is an equilibrium for (12). Since the equations for $\dot{m}$, $\dot{n}$, and $\dot{h}$ depend linearly on m, n, and h,

$$\begin{aligned} m^* &= \frac{\alpha_m(v^*)}{\alpha_m(v^*) + \beta_m(v^*)}, \\ n^* &= \frac{\alpha_n(v^*)}{\alpha_n(v^*) + \beta_n(v^*)}, \\ h^* &= \frac{\alpha_h(v^*)}{\alpha_h(v^*) + \beta_h(v^*)}. \end{aligned} \tag{14}$$

Observe that (14) is independent of I and v_k and have nonzero denominators. Therefore, we obtain equilibrium values of m^*, n^*, and h^* to be used in calculating I and v_k. The Jacobian of (12) is independent of I and (13a) depends quadratically on v_k. Therefore, we can solve (13a) for values $v_k^{\pm}(v^*)$ yielding Hopf bifurcation at the equilibrium (v^*, m^*, n^*, h^*). Finally, substitution of the equilibrium coordinates and the values $v_k^{\pm}(v^*)$ into (12) gives the value of $I = -G$ at the point of Hopf bifurcation. Algorithm 1 summarizes the steps required to compute Hopf bifurcation points in the (v_k, I) parameter plane.

ALGORITHM 1. *Procedure for computing Hopf bifurcation points in Maple© given a value for the external current I.*

```
procedure hh_hopf
    3.0  Choose $v^*$.
    3.1  Evaluate $m^*$, $n^*$, and $h^*$ symbolically.
    3.2  Substitute $m^*$, $n^*$, and $h^*$ expressions into Hopf
         determining conditions and simplify to form $v_k^{\pm}(v^*)$.
    3.3  Check the sign of the subresultant condition.
    3.4  Evaluate $G^{\pm}(v^*)$ and solve for $I = -G(v^*, m^*, n^*, h^*)$.
return $\{v_i^*, m_i^*, n_i^*, h_i^*\}$
```

For nominal values of the other system parameters, there is a single, connected curve of Hopf bifurcation points in the rectangular region [−45, 130] mV × [−150, 400] mA of the (v_k, I) plane. Table 3 lists the phase and parameter space coordinates of 19 selected points used for comparison in the discussion that follows. In particular, points 1 and 19 are chosen near Takens–Bogdanov bifurcations which lie at either terminus of the Hopf

TABLE 3

Phase- and parameter-space coordinates for the selected points in the Hopf curve. Points 1 *through* 10 *lie near a Takens–Bogdanov point at one end of the Hopf curve. The last column shows the computed magnitude of the pure imaginary eigenvalue.*

curve. The curve of Hopf points exhibits a narrow turning point with respect to the stimulus current I near one end. Points 1 through 10 resolve the turning point of the Hopf curve.

We give a brief comparison of methods for computing the partial derivatives of augmenting functions using this example. For what follows, let $y = (v, m, n, h, v_k)$ denote the vector of phase space variables augmented with the parameter v_k and $g(\cdot)$ the function for Hopf detection. We consider here the augmenting function labeled (BP) in Table 2, given by $g(y; I) = det\,(2\mathbf{J} \odot \mathbf{I}_n)$. Recall that the standard Newton-type corrector step requires the solution of a linear system, the matrix of which contains partial derivatives of the form $\frac{\partial}{\partial y_i} g(y)$. As in most examples, we cannot determine exactly the values of the relevant partial derivatives at arbitrary points along the Hopf branch. Our objective here is to compare the common techniques for computing derivatives as applied to the Hodgkin–Huxley equation and comment on their distinguishing characteristics. The Hodgkin–Huxley equations are well suited to this comparison because expressions for the higher-order derivatives of the defining equations, although lengthy, may be easily formed. For example, values for the partial derivatives $\frac{\partial}{\partial v}\,(2\mathbf{J} \odot \mathbf{I}_4)$ may be computed using the adjoint formula given in [11]. Table 4 shows a compilation of these partial derivatives, computed for point 14 of Table 3. In our experiments, the adjoint matrix was formed in a general fashion, using determinants computed using LU factorization of appropriate submatrices.

Automatic differentiation provides an alternative to difference formulas for the calculation of derivative data. Neither symbolic algebra nor numerical differencing derivatives are computed essentially by algorithmic application of the chain rule to a reduced (optimized) representation of the operation sequence. Several implementations are available and the approach has been successfully tested on a variety of problems in engineering and operations research. Data presented in Table 4 was produced with the package ADOL-C [10] using double precision (53 significand bits, 15–17 decimal digits). The partial derivative values computed by automatic differentiation agree with those calculated using the adjoint formula to 14 decimal digits, as indicated by the underscore beneath the first differing digit. These results are especially interesting because no formula for second derivative data is required, merely a slightly modified version of the routine which evaluates the expression for $g(\cdot)$. In our tests, a 16.4 Kbyte temporary storage buffer was required by the ADOL-C package for the partial derivative calculation. This appears to be the primary disadvantage to automatic differentiation: the storage requirements for the derivative calculations can be quite substantial, even for relatively simple functions.

A general-purpose package for numerical pathfollowing of equilibria typically contains a facility for computing the augmented Jacobian using finite differencing. Here the usual caveats concerning numerical differentiation apply. Finite difference approximation is unreliable, especially applied to functions where accumulated roundoff error is large. High-order formulae require multiple function evaluations. The difference in stepsize must be chosen to properly balance the effects of roundoff and truncation error. Table 4 shows a compilation of the partial derivatives, $\frac{\partial}{\partial v}\det(2\mathbf{J} \odot \mathbf{I}_n)$ and $\frac{\partial}{\partial m}\det(2\mathbf{J} \odot \mathbf{I}_n)$, computed using both forward (FD) and central (CD) difference formulae for the selected Hopf point. Next to each entry (in parenthesis) is the exponent of the stepsize h which produces the numerical derivative closest to that computed by automatic differentiation. The computed error from stepsize choices substantially larger than h are due to truncation error; stepsizes significantly smaller exhibit roundoff error and, finally, catastrophic cancellation.

3.2. A model of a bursting neuron. The second example we study is a dynamical system used to describe the electrical activity of the anterior burster (AB) neuron in the stomatogastric ganglion of the lobster *Panulirus interruptus*. Based on work of Plant [19] and Rinzel and Lee [20], the model is similar in structure to the Hodgkin–Huxley equations but more complex. Under certain physiological conditions the AB cell produces complicated, rhythmic patterns of action potentials. Guckenheimer, Gueron, and Harris-Warrick [12] have shown that some of this behavior is well described by a six-dimensional system of ordinary differential equations, referred to in what follows as the Rinzel–Lee/A-current (RLA) model for the AB neuron. The model is obtained from that of Rinzel and Lee [20] by a change of time scale and the incorporation of an additional potassium ion current called the A-current.

Let $x = (x_1, \ldots, x_6) \in \mathbb{R}^6$ denote the vector of independent variables. Components of this vector correspond to the physical model as follows: x_1 is the voltage difference across the cell membrane; x_2 is a dimensionless quantity describing the activity of intracellular free calcium; x_3 controls the activation of the delayed-rectifier potassium channel; and x_4 controls the inactivation of the sodium channel; x_5 controls the activation of the calcium channel; and x_6 controls the inactivation of the A-current channel. It is convenient to define the model in terms of exponential functions that we denote by

$$\phi_{\pm}(x_1; \alpha, \beta) \overset{\text{def}}{=} \left(1 \pm e^{\alpha+\beta x_1}\right)^{-1}.$$

TABLE 5
Experimentally derived constants used in the AB cell model equations.

The vector field describing the electrical state of the semipermeable membrane is then given by

$$\begin{aligned}
\dot{x}_1 &= -g_{Na}\varphi_2^3(x_1)\,x_4\,(x_1 - v_{na}) - 2g_{Ca}x_5\frac{(x_1 - v_{ca})}{(1+2x_2)} - g_K x_3^4\,(x_1 - v_k) \\
&\quad -2g_{KCa}x_2\frac{(x_1 - v_k)}{(1+2x_2)} - g_A\psi_2^3(x_1)\,x_6\,(x_1 - v_k) - g_l\,(x_1 - v_l)\,, \\
\dot{x}_2 &= -0.003\left[x_2 - k_{ca}x_5\frac{(x_1 - v_{ca})}{(1+2x_2)}\right], \\
\dot{x}_3 &= 0.8\left[(1 - x_3)\,\varphi_3(x_1) - x_3\psi_3(x_1)\right], \\
\dot{x}_4 &= 0.8\left[(1 - x_4)\,\varphi_4(x_1) - x_4\psi_4(x_1)\right], \\
\dot{x}_5 &= -.042553\left[x_1 - \phi_+(x_1;\alpha_5,\beta_5)\right], \\
\dot{x}_6 &= \phi_+(x_1;\gamma_5,\delta_5) - x_6
\end{aligned}$$

where

$$\begin{aligned}
\varphi_1(x_1) &= -(\alpha_1 + \beta_1 x_1)\,\phi_-(x_1;\alpha_1,\beta_1)\,, & \psi_1(x_1) &= 4e^{\gamma_1+\delta_1 x_1}, \\
\varphi_2(x_1) &= \frac{\varphi_1(x_1)}{(\varphi_1(x_1) + \psi_1(x_1))}, & \psi_2(x_1) &= \phi_+(x_1;\gamma_2,\delta_2)\,, \\
\varphi_3(x_1) &= -0.1\,(\alpha_3 + \beta_3 x_1)\,\phi_-(x_1;\alpha_3,\beta_3)\,, & \psi_3(x_1) &= 0.125e^{\gamma_3+\delta_3 x_1}, \\
\varphi_4(x_1) &= 0.07e^{\alpha_4+\beta_4 x_1}, & \psi_4(x_1) &= \phi_+(x_1;\gamma_4,\delta_4)\,.
\end{aligned}$$

The constants which enter these expressions through the functions $\phi_\pm$ were matched with the observed rates of activation and inactivation of ion channels in voltage-clamp experiments from other biological systems. Table 5 displays the values used in the numerical tests presented here. In addition, the model contains 11 physiological parameters which describe the various channel conductances and ion-reversal potentials. For our purposes, all parameters but (g_{KCa}, g_A) remain fixed at the nominal values shown in Table 5.

Numerical experiments for the RLA example were performed using a simple predictor-corrector algorithm implemented in the MATLAB© computation environment. Given an initial point at (or near) a solution, a sequence of points is advanced along the Hopf curve in a two-phase process: first, an Euler predictor step is taken using tangent data computed at

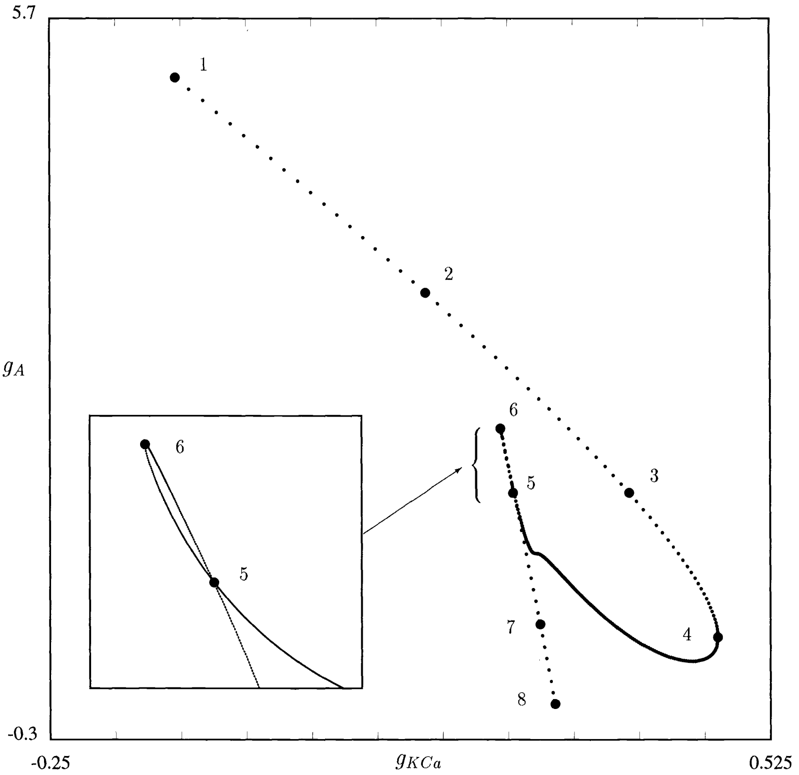

FIG. 1. *Curve of Hopf bifurcation points in the two-parameter plane (g_{KCa}, g_A) for the RLA neuron model computed using the Bezout resultant augmenting function (RB). Eight selected points corresponding to the entries in Table* 6 *are distinguished along the curve. The segment of the solution curve shown in the insert has been transformed by a simple rotation to make the closed loop visible at these scales.*

a previous solution. Then a series of Newton corrector steps is used to return the computed point on the bifurcation set. The length of the step taken between two successive solutions is determined by an algorithm of Georg [7], which seeks to maintain the initial rate of progress (contraction of the objective function values) exhibited by the sequence of corrector steps at a prescribed constant. The program design is very similar to that described by Allgower and Georg [1], suitably adapted for the current problem and MATLAB© implementation. To avoid the problems inherent in following Hopf curves which have turning points, we use pseudo-arclength continuation throughout. Using the notation introduced in (4), if $y = (x, g_{KCa}, g_A)$ is the vector of independent variables parameterized by τ, $y(\tau_i)$ is the ith Hopf solution point, $h = \tau_{i+1} - \tau_i$ is the desired steplength, and g is one of the defining equations shown in Table 2, then numerical continuation was performed using the augmented system

$$F(x, g_{KCa}, g_A; \tau) = \begin{pmatrix} f(x, g_{KCa}, g_A) \\ g(x, g_{KCa}, g_A) \\ v^t(\tau_i)\cdot[y(\tau)-y(\tau_i)]-h \end{pmatrix}$$

where $v(\tau_i)$ is the (fixed) unit tangent vector computed at the ith solution.

Figure 1 shows the Hopf bifurcation curve computed using the Bezout resultant $g = \det(\mathcal{B})$ as the augmenting equation. Eight points have been selected and enumerated for comparative purposes. The first labeled point is the initial condition used to start the continuation

algorithm, chosen very near the Takens–Bogdanov point which terminates the branch. Points 4 and 6 are turning points in the Hopf solution curve with respect to the parameter g_{KCa}, and point 5 marks a self-crossing of the Hopf branch that gives rise to a double Hopf bifurcation point. The insert provides a more detailed plot of the region near this degenerate point. Table 6 displays the phase-space coordinates of the selected points while Table 7 shows the parameter space coordinates of each selected point together with the magnitudes of the real and imaginary components of the critical eigenvalues.

The loop associated with the double point labeled 5 in the computed Hopf curve is a bit paradoxical. At the double point, there are two pairs of pure imaginary eigenvalues, and continuation around the loop must transform one of these pairs into the other. The mechanism for this transformation involves the geometry of how eigenvalues and eigenvectors depend upon matrices. The set of real $n \times n$ matrices with simple eigenvalues is not simply connected. When following a homotopically nontrivial loop in this set, eigenvalues of a matrix may be permuted. Such an interchange happens in this example. There is a point in the (g_{KCa}, g_A) plane inside the loop of the Hopf curve at which the system has a complex pair of double eigenvalues.

Our numerical experiments using the Bezout augmenting equation with the RLA model indicate that the numerical computation of the coefficients for the Jacobian characteristic polynomial $p(\lambda) = \sum_{k=0}^{5} c_k\lambda^k$, using reduction from the Hessenberg to Frobenius form by simple elimination [26], is reliable and accurate. To explore this observation further, we make the following ansatz: since the form of the RLA equations permits the explicit symbolic computation of the coefficients $\{c_k\}_0^5$ as functions of the Jacobian entries, we presume that these expressions, evaluated in extended floating point arithmetic at an equilibrium point,

TABLE 8

Condition numbers (κ_2) for the Jacobian ($\mathbf{J} = D_x f$), the corresponding companion matrix, and the spectral condition number s_λ associated with the pure imaginary eigenvalues.

Pt	s_λ	$\kappa_2(D_x f)$	$\kappa_2(C)$
1	1.0×10^{-2}	2.8×10^{6}	5.8×10^{8}
2	1.7×10^{-2}	2.5×10^{5}	1.7×10^{7}
3	1.5×10^{-2}	2.1×10^{5}	8.6×10^{6}
4	1.4×10^{-2}	1.9×10^{5}	6.8×10^{6}
5	2.0×10^{-3} 4.1×10^{-3}	6.4×10^{6}	2.4×10^{7}
6	9.0×10^{-4}	2.9×10^{7}	2.9×10^{7}
7	9.0×10^{-3}	1.6×10^{6}	9.7×10^{6}
8	1.2×10^{-2}	4.8×10^{5}	6.2×10^{6}

are exact. Moreover, we assume that the eigenvalues and eigenvectors computed using the unsymmetric QR algorithm are exact as well. Using these data we may evaluate how well conditioned the Hopf continuation task is both as an eigenvalue problem and, separately, as a polynomial rootfinding problem. The condition of the eigenproblem is equivalent to the sensitivity of the spectrum of the Jacobian to small perturbations of its elements ($\mathbf{J} + \epsilon\mathbf{E}$) reflected in the spectral condition number

$$s(\lambda) = \frac{y^H \cdot x}{||y||_2||x||_2}$$

where y and x are left and right eigenvectors of $\mathbf{J}$, respectively, of the eigenvalue λ. We expect that, for ϵ small, the perturbation of the eigenvalues will be less than $\delta\lambda = \epsilon||\mathbf{B}||_2/s(\lambda)$, and we consider the eigenproblem well conditioned if $s(\lambda)$ is near one. The first column of Table 8 presents the spectral condition number for the critical eigenvalues of the Jacobian at each selected point solution. Clearly, the data show that methods based on explicit determination of the spectrum or their sums directly from the Jacobian entries should be relatively insensitive to small perturbations to the elements of $\mathbf{J}$.

Table 8 also shows 2-norm condition estimates for the Jacobian matrix and its associated companion matrix as computed by Algorithm 1 at the selected points; in each case the reduction results in an inflation of the condition number, but the increase is mild (at most three orders of magnitude). Thus, the main source of instability in the computation of the characteristic polynomial coefficients—the use of nonunitary similarity transformations in the reduction of the Hessenberg form—is well behaved along the branch of Hopf points. We further examine the classical error estimates of the eigenvalues to the perturbation problem ($\mathcal{C} + \epsilon\mathbf{E}$) where $\mathcal{C}$ is the companion matrix associated with $\mathbf{J}$ and $\mathbf{E}$ is the matrix that contains a single nonzero entry in its nth column (which we take to be one). Now suppose λ_i is a simple root of the characteristic polynomial $charpoly(\mathcal{C}) = p(\lambda) = charpoly(\mathbf{J})$ for $1 \leq i \leq n$. A small perturbation in the kth coefficient of p

$$p(\lambda) + \epsilon\lambda^k = \lambda^6 + (c_k + \epsilon)\,\lambda^k + \sum_{i \neq k} c_i \lambda^i$$

may be related to the resulting perturbed root by the linear estimate

$$\lambda_i + \delta \approx \lambda_i - \epsilon \frac{\lambda_i^k}{\prod_{j \neq i} (\lambda_i - \lambda_j)}.$$

TABLE 9

Characteristic polynomial coefficients of maximal sensitivity for each selected point shown in Figure 1. Data is shown for each of three problems: $p(\lambda) = 0$, $r_e(z) = 0$, and $r_o(z) = 0$ where $z = \lambda^2$.

	$p(\lambda)$			$r_e(z)$			$r_o(z)$		
Pt	k	c_k	$s_k(\lambda)$	k	c_k	$s_k(\lambda)$	k	c_k	$s_k(\lambda)$
1	2	7.0e−3	8.9e−2	2	7.0e−3	2.2e−4	3	1.4e−1	2.5e−5
2	2	6.8e−3	5.1e−1	2	6.8e−3	7.1e−3	3	1.3e−1	7.3e−4
3	2	6.5e−3	7.2e−1	2	6.5e−3	1.4e−2	3	1.2e−1	1.3e−3
4	2	5.9e−3	9.0e−1	2	5.9e−3	1.9e−2	3	1.1e−1	1.6e−3
5	2	7.4e−4	8.9 43.7	2	7.4e−4	2.2e−1 6.8	3	6.0e−3	3.5e−2 1.0
6	2	2.2e−4	53.6	2	2.2e−4	4.2	1	−3.5e−6	163.6
7	1	3.8e−5	676.5	4	1.9e−1	6.9e−2	3	1.7e−2	1.3
8	4	1.9e−1	3.3e−1	4	1.9e−1	1.1e−1	3	1.2	2.1e−2

Thus, the relative sensitivity of each *simple* eigenvalue of **J** (equivalently, each simple root of p) to small perturbations in the coefficients of the characteristic polynomial are estimated by the magnitudes of the n factors s_k given by

$$s_k(\lambda_i) \triangleq \left| \frac{\lambda_i^k}{\prod\limits_{j \neq i} (\lambda_i - \lambda_j)} \right| .$$

The first three columns of Table 9 show, for each selected point, the subscript (k), value (c_k), and factor (s_k) for the coefficient of p upon which the critical eigenvalue is most sensitively dependent. For example, in the case of the last point (8), a perturbation of 1% in the value of c_4 will produce a change of approximately 0.5% in the computed critical eigenvalue. These data support the conclusion that relatively small errors in the numerically computed values of the characteristic polynomial coefficients produce only mild perturbations in the roots of p or, equivalently, the computed eigenvalues of **J**. Thus, construction of the residual polynomials in the first method of Kubiček (K1) may be expected to be well behaved.

From §2.1, the resultant methods are based on a specific rootfinding problem, that is, to find $z = \lambda^2$ which simultaneously satisfies

$$\left\{ \begin{array}{c} r_e(z) \\ r_o(z) \end{array} \right\} = \left\{ \begin{array}{c} z^3 + c_4 z^2 + c_2 z + c_0 \\ c_5 z^2 + c_3 z + c_1 \end{array} \right\} = 0.$$

Thus, sensitivity of the shared root to perturbations in the coefficients of the two separate polynomials is of interest, and the sensitivity estimates computed above for p may be extended as well to the polynomial pair (r_e, r_o) associated with p. The last six columns of Table 9 display, for each selected point, the values of s_k for the shared root corresponding to the coefficient of maximal sensitivity.

It is usual, in the discussion of Hopf pathfollowing using direct methods, to assume that a solution $(x^*, \alpha^*; \beta^*)$ on a branch is known and then to proceed to describe how subsequent solutions may be computed beginning with data from this point. However, practical experience suggests that frequently the task of finding one (or more) initial points is *by far* the most time-consuming part of a numerical bifurcation study, especially as the dimension of the phase and parameter spaces increases. We present a comparison of the rootfinding convergence regions for the augmented systems based on the Bezout resultant (labeled RB in Table 2) and the iterative eigensubspace method (JGR) for the RLA model.

The Bezout resultant is well defined at any point in the product space $\mathbb{R}^6 \times \mathbb{R}^2$, and all the information required to begin a corrector sequence at (x_0, g^0_{KCa}, g^0_A) may be derived from the linearization of the vector field at that point. This is not the case for the (JGR) system, which requires estimates for a basis $\{v, w\}$ of the eigenspace associated with the pure imaginary eigenvalue $\pm\omega i$ and a vector l not in $span\,\{v, w\}$. The intuitive choice is to use seed values v_0, w_0, ω_0, and l based on the complex elements of $spec(\mathbf{J})$ with the smallest real part. However, this eigenpair may not become critical for nearby values of (g_{KCa}, g_A) and an incorrect choice can bias the starting conditions away from the solution manifold, requiring many Newton steps to compute a solution, if convergence is achieved at all.

We explore this possibility in a small region of the (g_{KCa}, g_A) parameter space to the right of the double Hopf point in Figure 1. Two segments of Hopf bifurcation (referred to as the upper and lower branches in what follows) intersect at the double Hopf point. The RLA vector field has a single equilibrium for each choice of (g_{KCa}, g_A) in this region; moreover, the spectrum of the Jacobian for each such choice contains at least one complex eigenvalue pair. Since the rate at which the two pairs of complex eigenvalues cross the imaginary axis is very different, the intuitive choice is "correct" only in a thin band above the lower Hopf branch. If a Newton corrector is applied to choices for (g_{KCa}, g_A) in this parameter region, the results reflect the underlying structure in the spectrum of the equilibria, as shown in Figure 2. The lower plot shows data collected using the augmented system (JGR). A 75×75 point grid was established over the two-parameter regime. For each point in the grid, the unique equilibrium was found and the complete spectrum was computed. The complex eigenpair closest to the imaginary axis was used to compute starting values for the augmented variables and Newton's method was used to solve the nonlinear systems with $g(\cdot)$ chosen as in the (JGR) system of Table 2. The convergence criterion used was $||\mathbf{D}F||_\infty < TOL$, where $\mathbf{D}$ was a *constant* diagonal-scaling matrix chosen to equilibrate the disparate magnitudes of the various components in the objective function. If convergence was not achieved within 30 Newton steps, the trial was considered a failure. Successful trials are labeled with a triangle if they converged to the upper branch, a circle if to the lower branch. Thus, the plot shows the ultimate fate of a choice (g_{KCa}, g_A) given perfect information for the Jacobian at the starting conditions.

As expected, the set of converged initial conditions divides the parameter grid into roughly two parts: those which converge to the upper branch and those to the lower branch. Below the lower branch, the Jacobian has one complex eigenpair and computing the initial augmented variables based on the spectrum at the gridpoint is usually successful. In between, the dividing line occurs along the locus of intersection for the real parts of the two eigenpairs. Since this locus occurs very close to the lower branch, a disproportionate fraction of successful trials starting near the lower branch leave the neighborhood of the nearest Hopf bifurcations U. Instead of correcting the errant starting conditions for v_0, w_0, ω_0, the Newton sequence "corrects" the phase and parameter coordinates. In this example, computing v_0, w_0, ω_0 for starting conditions very near the lower branch using the "wrong" eigenpair still frequently results in a converged solution. In the general case, there is no reason why the delusive eigenpair need cross the imaginary axis at all; indeed, such a situation would typically be expected to result in convergence failure.

The analogous experiment was performed using the Bezout resultant $g = \det(\mathcal{B})$; the results are displayed in the upper plot of Figure 2. Again, the parameter region is divided by points which converge to the upper and lower Hopf branches. In this case, however, the distribution is more even. In particular, the lower branch exhibits a robust convergence neighborhood. A band of initial conditions which do not result in successful Newton sequences

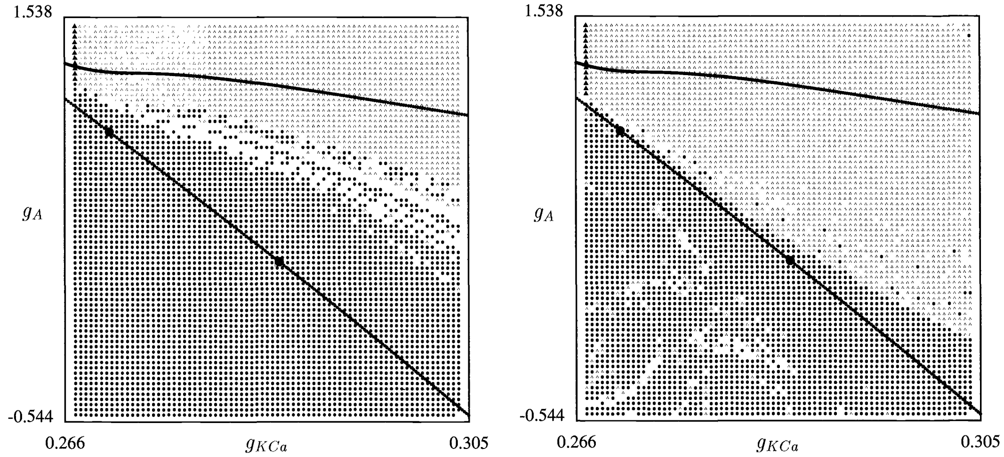

FIG. 2. *Convergence data for Newton's method in a neighborhood of Hopf branches in the* (g_{KCa}, g_A) *parameter plane. The left plot shows data for the Bezout resultant (RB) as the augmented function; the right plot shows data for the method of Jepson–Griewank–Reddien (JGR). Triangle symbols show initial conditions which ultimately converge to the upper Hopf branch while circles indicate convergence to a lower branch point.*

appears between the two Hopf branches, a zone outside the region of local convergence for Newton's method for any point in Γ. Such a failure zone is expected for any choice of augmenting functions and occurs where the quadratic model for the objective function F ceases to be sufficient to ensure adequate descent. A natural algorithmic improvement is to employ globally convergent variants of Newton's method to improve the behavior far from the solution set. In this context, a properly constructed quasi-Newton method must involve two steps: first, the full Newton step must be computed, and appropriate criteria for sufficient decrease in F evaluated. If the Newton step results in satisfactory progress, the full step is taken; otherwise, a modified step is computed. A common criterion is to guarantee that the result of the candidate step be a (sizable) fraction of the predicted improvement based on the gradient of F at the current point. More precisely, if y_k is the kth step of a corrector sequence and δy is the Newton step, then the algorithm accepts the full step if

$$F(y_k + \delta y) < F(y_k) + \epsilon[\nabla F(y_k)]^t \delta y \tag{15}$$

for some $0 < \epsilon < 1$. Typically, ϵ is chosen quite small, but it is significant that the obvious selection $\epsilon = 0$ is insufficient to ensure global convergence; some positive improvement in the objective function is required.

Figure 3 shows the result of applying the criterion (15) to the convergence experiment described above. At each step in the corrector sequence, the acceptance criterion was evaluated with $\epsilon = 0$; the point was deemed a failure if the inequality was not satisfied. Points which survive as successful trials not only converged to a Hopf bifurcation point but also made monotonic progress toward the solution at each corrector step. Thus, if a steplength adjustment (e.g., line search or dogleg) algorithm were used to improve global convergence behavior based on the acceptance criteria above (for $\alpha = 0$), the full Newton step would be accepted at each step. The results for the augmented function $g = \det(\mathcal{B})$ indicate that points near the border of the nonconvergence zone of Figure 2 are characterized by Newton steps which, early in the corrector sequence, do not strictly improve the objective function. However, apart from this band, most initial conditions are within the local convergence neighborhood. For the

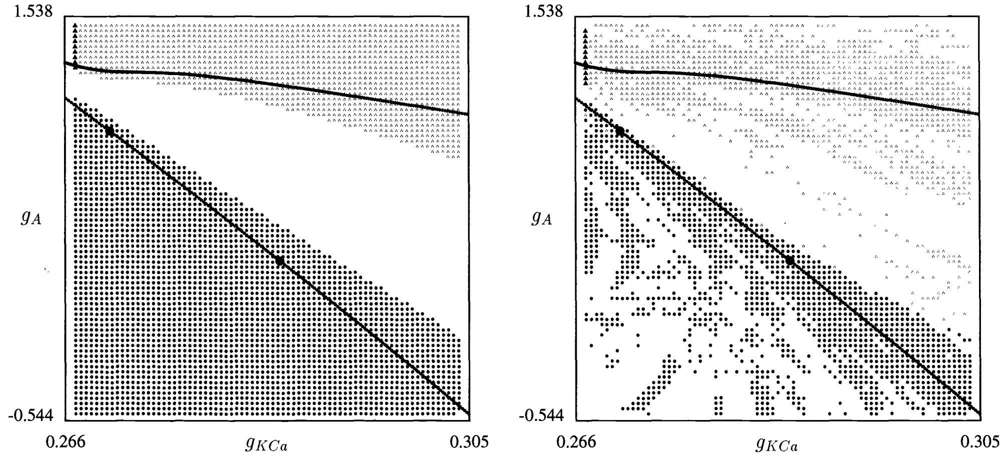

FIG. 3. *Convergence data for Newton's method in a neighborhood of Hopf branches in the* (g_{KCa}, g_A) *parameter plane including a monotonicity condition on the sequence of corrector steps. The left plot shows data for the Bezout resultant (RB) as the augmented function; the right plot shows data for the method of Jepson–Griewank–Reddien (JGR). Triangle symbols show initial conditions which ultimately converge to the left Hopf branch while circles indicate convergence to a right branch point.*

(JGR) augmenting function, nearly 50% of the trials which converge to a Hopf point without the monotonicity condition are *rejected* according to step acceptance criteria. This may be compared with a 23% reduction for the resultant method.

We regard the questions of accuracy and convergence considered above as more important than the speed of algorithms that detect Hopf detection in examples of moderate size. Nonetheless, we present some brief comparative data for our implementations of three algorithms within MATLAB©. For each of the Bezout resultant, biproduct matrix, and JGR methods from Table 2 we computed 20 points along a Hopf bifurcation curve shown in Figure 1 starting at a point along the curve and proceeding with an identical continuation algorithm. The floating point operation counts were comparable for the Bezout (664777 flops) and JGR methods (701244 flops) while the biproduct calculation was substantially slower (2786163 flops). Note, however, that the biproduct calculations did not exploit the sparsity of the biproduct matrix in computing its determinant. The biproduct method seems to offer the best opportunity to exploit the calculation of low-dimensional invariant subspaces in high-dimensional problems.

3.3. A larger neural model. Based on extensive experimental results, Golowasch [8] proposed a 14-dimensional system of ordinary differential equations as a model for the LP neuron in the stomatogastric ganglion of the crab *Cancer borealis* that incorporates the effects of eight separate ionic currents. The parameters which govern the activation kinetics for the associated conductance channels were derived from space-clamped experimental data. Buchholtz et al. [4] later amended this model; our third example is a 12-dimensional variation of these equations.

Despite the complexity of this system, analytic Jacobian derivatives were derived using Maple©. Using

$$\psi(u, v, \alpha) = e^{\frac{(u-v)}{\alpha}},$$
$$\phi(u, v, \alpha) = (1 + \psi(u, v, \alpha))^{-1}$$

the model equations for the LP neuron are given by

$$\begin{aligned}
\dot{x}_1 &= -c_{10}(g_{ca1}x_9x_{11} + g_{ca2}x_{10})(x_2 - \varphi_4(x_1)) + c_{20}(c_8 - x_1),\\
\dot{x}_2 &= (c_1 - ((g_{ca1}x_9x_{11} + g_{ca2}x_{10})(x_2 - \varphi_4(x_1)) + g_l(x_2 - e_l)\\
&\quad + g_d x_4^4(x_2 - e_k) + g_{KCa}x_5x_6(x_2 - e_k) + g_a x_8 x_7^3(x_2 - e_k)\\
&\quad + g_h x_{12}(x_2 - e_h) - c_{11}(\tfrac{1}{2}c_2(\varphi_5(x_2, x_3) - \varphi_6(x_2, x_3))))))/c_{11},\\
\dot{x}_3 &= k_h\left[c_6(1 - x_3)\psi(x_2, c_{44}, c_{27}) - x_3\phi(x_2, c_{50}, c_{33})\right],\\
\dot{x}_4 &= c_{12}\phi(x_2, c_{52}, c_{35})\,((\phi(x_2, c_{54}, c_{37}) - x_4),\\
\dot{x}_5 &= k_{oa}(\varphi_7(x_1, x_2) - x_5),\\
\dot{x}_6 &= c_{21}\left(\frac{c_4}{(c_5 + x_1)} - x_6\right),\\
\dot{x}_7 &= c_{16}(\phi(x_2, c_{41}, c_{24}) - x_7),\\
\dot{x}_8 &= c_{15}(\phi(x_2, c_{48}, c_{31}) - x_8),\\
\dot{x}_9 &= c_{17}(\phi(x_2, c_{42}, c_{25}) - x_9),\\
\dot{x}_{10} &= c_{18}(\phi(x_2, c_{43}, c_{26}) - x_{10}),\\
\dot{x}_{11} &= c_{19}(\phi(x_2, c_{49}, c_{32}) - x_{11}),\\
\dot{x}_{12} &= \frac{c_{13}(\phi(x_2, v_r, c_{38}) - x_{12})}{\phi(x_2, c_{53}, c_{36})},\\
\varphi_1(x_2) &= \frac{c_7(x_2 - c_{45})}{1 - \psi(x_2, c_{45}, c_{28})},\\
\varphi_2(x_2) &= \frac{\varphi_1(x_2)}{\varphi_1(x_1) + c_8\psi(x_1, c_{50}, c_{33})},\\
\varphi_3(x_1) &= \log\left[\psi(x_1, \tfrac{1}{100}, \tfrac{3}{100}) + \psi(x_1, -\tfrac{1}{100}, -\tfrac{3}{100})\right],\\
\varphi_4(x_1) &= c_{56} - c_{57}\ \log\left[\tfrac{2}{300}\varphi_4(x_1) + \tfrac{1}{3}(100x_1 - 1) + \tfrac{1}{100}\right],\\
\varphi_5(x_2, x_3) &= \frac{1}{c_2}\left(\frac{g_{Na}x_3\varphi_2^3(x_2)(e_{na} - x_2)}{c_{11}} - c_1\right),\\
\varphi_6(x_2, x_3) &= \log\left(e^{\varphi_5(x_2, x_3)} + e^{-\varphi_5(x_2, x_3)}\right),\\
\varphi_7(x_1, x_2) &= \frac{x_1}{(c_3 + x_1)}\phi(x_2, c_{46} - c_{14}x_1, c_{29})\phi(x_2, c_{47} - c_{14}x_1, c_{30}).
\end{aligned}$$

Table 10 lists the nominal values and units of the parameters.

The LP equations illustrate a difficulty that arises in using the determinant as an indicator of matrix singularity for methods based on polynomial resultants or biproducts. Extreme variations in the magnitude of det($\mathcal{B}$) on det($2\mathbf{I} \odot \mathbf{J}$) can adversely affect the behavior of numerical continuation methods, especially in large application problems. Moreover, since det($\cdot$) is not a true matrix condition indicator, poor scaling behavior in its (implicit) use as such can result in convergence failures. These remarks pertain not only to the use of det($\mathcal{B}$) or $2\mathbf{J} \odot \mathbf{I}$ in Hopf pathfollowing but also other applications which use the determinant as an objective function in rootfinding or optimization (detection of saddle-node bifurcations, for example). Thus, progress in addressing these issues in the context of Hopf continuation has implications to other applications, and vice versa.

The bifurcation diagram of the LP equations in the (I_{ext}, g_{Na}) plane has a fold in the surface of equilibrium points that produces a curve of saddle-node bifurcations. A cusp

occurs along the fold, dividing the saddle-node bifurcation set into upper- and lower-branch segments. Along the upper branch, one of the fixed points annihilated in the saddle-node interaction undergoes a change of stability, producing a curve of Hopf points proximal to the saddle-node curve. The Hopf branch arises at a Takens–Bogdanov point and leaves the parameter regime of physiological interest.

Table 11 shows parameter coordinates for four selected points along the Hopf branch described above. Also listed are values for the phase-space variables and the complete spectrum. Notice that the critical eigenvalues begin with zero magnitude but become the eigenvalues of largest magnitude at point 4 along the branch of Hopf bifurcations and that there are several additional eigenvalues of large magnitude.

One difficulty is immediately apparent from these data: if $\lambda_i = \bar{\lambda}_{i+1}$ is the critical eigenpair and the remaining real eigenvalues are arranged in descending order, $\lambda_j \geq \lambda_{j+1}$ for $j \neq i, i+1$, then to achieve a prescribed solution tolerance $||F(x^*, I^*_{ext}, g^*_{Na})||_\infty < \epsilon$ requires

$$Re(\lambda_i) < \frac{\epsilon}{2}\left[\prod_{\substack{k=3\\k\neq i,i+1}}^{12} \lambda_k^{k-3}\left(\lambda_k^2 + |\lambda_i|\right)\right]^{-1}$$

using the rough estimate that $(\lambda_i + \lambda_j) \approx \max(\lambda_i, \lambda_j)$ for eigenvalue pairs that do not approach zero in a neighborhood of a solution. For large systems, or even small systems with a few large eigenvalues, this explosion in the magnitude of the biproduct determinant or resultant severely restricts the size of the neighborhood about the solution manifold where the computed value contains any significant digits. In the LP equations, the effect is prohibitive.

To apply the algebraic Hopf methods previously described to problems of this type requires a strategy for eliminating the disabling effects of the unwanted large eigenvalues, so long as they do not participate in the bifurcation. One possible approach involves substituting an alternative method for determining when $2\mathbf{J} \odot \mathbf{I}_n$ or $\det(\mathcal{B})$ is singular. For example, if a true condition estimate was substituted for $\det(\cdot)$, such as

$$g(x, I_{ext}, g_{Na}) = ||\,(2\mathbf{J} \odot \mathbf{I}_n)^{-1}\,||_F^{-1} \tag{16}$$

where $||\cdot||_F$ is the Frobenius norm, the required differentiability properties are retained. Another alternative, suggested by Allgower, Georg, and Miranda [2] in the context of using multidimensional resultants to compute real polynomial roots, is the function

$$g(x, I_{ext}, g_{Na}) = \min_{||u||=1} ||\,[2\mathbf{J} \odot \mathbf{I}_n]\,u||_2^2. \tag{17}$$

Notice that this is equivalent to iteratively driving the smallest singular value σ_n to zero and, thus, uses the square of the 2-norm condition number as the augmenting equation. This choice is especially attractive since σ_n is widely considered the most reliable estimate of matrix condition, and several different methods for its computation might be adapted to the problem of Hopf pathfollowing. In the continuation framework it may also be possible to make use of spectral information computed at wide intervals and updated cheaply at intermediate solution points. For example, suppose that at (or near) a solution $(x^0, I^0_{ext}, g^0_{Na})$, the full set of eigenvalues $\lambda_1, \ldots, \lambda_n$ and corresponding eigenvectors $v_1, \ldots, v_n$ are computed. Then, by the elementary properties of the biproduct matrix, a vector in the nullspace of $\mathbf{J} \odot \mathbf{I}_n$ can be formed: using the lexicographic ordering scheme introduced in §2.3, if v^i_p is used to denote the ith component of the pth eigenvector, we can construct an eigenvector V corresponding to the eigenvalue $\lambda_i + \lambda_j$ of $2\mathbf{J} \odot I_n$ according to the formula

$$V^{\{pq\}}_{\{ij\}} = \det\begin{bmatrix} v^p_i & v^p_j \\ v^q_i & v^q_j \end{bmatrix} \tag{18}$$

where $1 \leq j, p \leq n-1$ and $2 \leq i, q \leq n$. This vector may be stored and used to start a conjugate gradient algorithm (for example), constrained to the unit sphere, as an estimate for

u in (17) to compute subsequent corrector steps. (See [2] for a discussion of the conjugate gradient method applicable to this situation.)

An important special case arises when some of the large eigenvalues are associated with an invariant subspace which evolves slowly as the parameters are varied [25]. More precisely, suppose at a point $(x^0, I^0_{ext}, g^0_{Na})$ near a Hopf bifurcation the range of the (nonsingular) Jacobian matrix $\mathbf{J}_0$ may be split into a direct sum of eigenspaces $W_c \oplus W_h$ with $\dim(W_c) = m$ and $\dim(W_h) = n - m$ such that the following hold:

1. locally, W_h contains the two-dimensional subspace corresponding to the Hopf bifurcation;
2. W_c contains some of the large eigenvalues in the spectrum of $\mathbf{J}_0$; and
3. W_c remains nearly invariant as $\mathbf{J}$ is perturbed away from $\mathbf{J}_0$.

Then we may eliminate the unwanted effects of W_c altogether by deflating the Jacobian to form a new matrix that has only the eigenvalues associated with W_h. The literature on matrix deflation in the context of eigenvalue determination is vast; explicit techniques are central to iterative methods and implicit use of deflation is integral to various Lanczos schemes. In our preliminary experiments we used a simple algorithm based on similarity transformations. Suppose an $n \times m$ rectangular matrix $\mathbf{U}$ can be obtained with linearly independent columns so that $range(\mathbf{U}) = W_c$. Then applying Gaussian elimination we form the product $\mathbf{\Sigma}$ of elementary matrices that triangularize $\mathbf{U}$:

$$\mathbf{\Sigma U} \equiv \mathbf{QPU} = \left[\begin{array}{c} \mathbf{T} \\ --- \\ \mathbf{0} \end{array} \right]$$

where $\mathbf{T}$ is upper triangular and reference to the permutation matrix $\mathbf{P}$ is made explicit to emphasize the use of partial pivoting to stabilize the transformation. Applying $\mathbf{QP}$ to $\mathbf{J}$ produces a block-structured equation involving the Jacobian:

$$\mathbf{\Sigma J} = \left[\begin{array}{cc} \mathbf{J}_{11} & \mathbf{J}_{12} \\ \mathbf{E} & \mathbf{J}_{22} \end{array} \right] \mathbf{\Sigma}$$

where $\mathbf{J}_{11}$ is an $m \times m$ matrix. It follows easily that if $\mathbf{U}$ is chosen as above, $\mathbf{U}$ commutes with $\mathbf{J}$ if and only if $\mathbf{E} = \mathbf{0}$ and, if so, $spec\ (\mathbf{J}_{22})$ displays the same set of eigenvalues as does $\mathbf{J}$ on W_h (see Wilkinson [27, Chap. 9, §§21–24] for a discussion).

Given a candidate splitting $W_c \oplus W_h$, the sensitivity of the deflating subspace $range(\mathbf{U})$ to perturbations in the Jacobian matrix is properly expressed in terms of the *separation* of the matrices $\mathbf{J}_{11}$ and $\mathbf{J}_{22}$, measured by

$$sep\ (\mathbf{J}_{11}, \mathbf{J}_{22}) = \min_{\mathbf{X} \neq \mathbf{0}} \frac{||\mathbf{J}_{11}\mathbf{X} - \mathbf{X}\mathbf{J}_{22}||}{||\mathbf{X}||}$$

where $\mathbf{X}$ ranges over the subspace of $p \times (n - p)$ matrices. The $sep(\cdot, \cdot)$ function is difficult to compute, in general, but bounds exist based on the spectra of the matrix arguments (when $\mathbf{J}$ is diagonalizable):

$$\begin{aligned} s_l\ (\mathbf{J}_{11}, \mathbf{J}_{22}) &= \frac{\min |spec(\mathbf{J}_{11}) - spec(\mathbf{J}_{22})|}{\kappa_2\ (\mathbf{Q}_1)\, \kappa_2\ (\mathbf{Q}_2)}, \\ &\leq sep\ (\mathbf{J}_{11}, \mathbf{J}_{22}), \\ &\leq \min |spec(\mathbf{J}_{11}) - spec(\mathbf{J}_{22})| = s_u\ (\mathbf{J}_{11}, \mathbf{J}_{22}) \end{aligned}$$

TABLE 12
Separation function values and bounds for deflations of dimension two to seven for the LP model equations. Each p-dimensional deflating subspace contains the p-largest real eigenvalues of the Jacobian matrix at the initial branch point.

p	$s_u()$	$sep()$	$s_l()$
2	174	36	2
3	62	3	$6 \cdot 10^{-2}$
4	81	7.0	$8 \cdot 10^{-2}$
5	26	2.5	$2 \cdot 10^{-2}$
6	15	$4 \cdot 10^{-1}$	$2 \cdot 10^{-3}$
7	4	$3 \cdot 10^{-1}$	$4 \cdot 10^{-4}$

where $\mathbf{Q}_1$ and $\mathbf{Q}_2$ are chosen to diagonalize $\mathbf{J}_{11}$ and $\mathbf{J}_{22}$, respectively. Equality holds on the right when $\mathbf{J}$ is normal, but, in general, the separation of $\mathbf{J}_{11}$ and $\mathbf{J}_{22}$ may be much less than the minimum distance between the respective spectra. Procedures for the numerical estimation of $sep(\cdot, \cdot)$ have been proposed [5], similar in form to well-known methods of matrix condition estimation. Table 12 shows values for $s_l(\cdot, \cdot)$, $sep(\cdot, \cdot)$, and $s_u(\cdot, \cdot)$ for six choices of W_c of increasing dimension m for the LP model Jacobian. Each case corresponds to a choice for W_c that contains the m-largest real eigenvalues of $\mathbf{J}$ evaluated at the second point of Table 11.

A simple strategy for incorporating deflation of the Jacobian into numerical Hopf pathfollowing is the following: suppose the complete eigenstructure for $\mathbf{J}$ is computed at the initial solution point on the Hopf branch (by any method), m is determined by $sep()$ estimates, and the columns of $\mathbf{U}$ are chosen to be the appropriate eigenvectors of $\mathbf{J}$. At each subsequent corrector step $||\mathbf{E}||_F$ is computed and, if sufficiently large, the columns of $\mathbf{U}$ are updated using a small number of inverse iteration steps. Notice that each column may be adjusted independently, so if $m >> (n - m)$ and n is of moderate size, this step can be performed in parallel. Numerical continuation was begun at selected point 2 of Table 11 using g_{Na} as the continuation parameter and proceeded toward the Takens–Bogdanov point at the beginning of the branch (near point 1). The seven-dimensional deflating subspace of Table 12 was used and updated at each corrector step. The residual real part of the critical eigenpair is below 10^{-12} near the beginning of the curve and remains below 10^{-9} as the solutions approach the Takens–Bogdanov bifurcation.

4. Concluding remarks. We have examined the application of minimal augmentation methods for computing Hopf bifurcations to three examples of vector fields that describe the electrical activity of axons and neurons. There are several conclusions we draw from this work.

1. The derivation of symbolic expressions for the detection of Hopf bifurcations in families of vector fields of moderate complexity is feasible. The usefulness of these symbolic expressions is dependent upon the complexity of expressions for the Jacobian of a vector field and upon the effectiveness of rootfinding algorithms.

2. Automatic differentiation algorithms work. They give far more accurate values for derivatives than are obtainable with the simplest finite difference methods of computing derivatives.

3. Continuation applied to minimal augmentation methods for finding Hopf bifurcations appears to work at the singularities associated with double Hopf bifurcations in two-parameter families of vector fields. The rootfinding problem has a singularity of corank 1 at these points, but the method appears to follow the smooth branches of solutions passing through this point with little difficulty. This success calls for further theoretical justification.

4. In at least some circumstances, the minimal augmentation methods are preferable to direct methods that require the computation of eigenvectors. In the example we present, iterative rootfinding algorithms that start with natural choices for their initial seeds converge more reliably and have larger regions of convergence for the minimal augmentation methods than for the direct methods that solve for eigenvectors.

5. In problems that are large or stiff, straightforward implementation of the minimal augmentation methods lead to rootfinding problems that are poorly conditioned. The difficulty lies in the determination of when a large matrix with eigenvalues of large magnitude is singular. By using the extensive numerical linear algebra theories for calculating the condition number of a matrix, the algorithms for detecting Hopf bifurcations can be significantly improved. Implementations based on calculations of the smallest singular value of a matrix appear to be an attractive target for further work in this area.

6. Despite the growth in the size of the linear algebra problems that are associated with the definition of the biproduct matrix as a strategy for computing Hopf bifurcations, the impact of this growth can be ameliorated by the intelligent use of standard algorithms for linear algebra problems. These increase the sparsity of the biproducts whose condition number must be calculated or localize these calculations to smaller matrices calculated from the biproduct.

Acknowledgments. Many of the calculations were performed with the software package DsTool [3] developed at Cornell University.

EVOLUTION OF CONVEX PLANE CURVES DESCRIBING ANISOTROPIC MOTIONS OF PHASE INTERFACES*

KAROL MIKULA† AND JOZEF KAČUR‡

Abstract. The numerical approximation schemes for solving the nonlinear initial value problem

$$\partial_t b(v) = (Av_x)_x + (Bv)_x + Dv + G$$

with periodic boundary conditions are presented. We assume that the function b is increasing, and asymptotically $b'(s) = 0$ and $b'(s) = +\infty$, so that the model describes in a sense both slow and fast diffusions. The solution also may blow up in a finite time. This problem arises from the evolving curves theory, which was used in the construction of models of motion of phase interface in multiphase thermomechanics by Angenent and Gurtin [*Arch. Rational Mech. Anal.*, 108 (1989), pp. 323–391]. The so-called "curve shortening equation" is included in the model. Our approximating solutions converge strongly in $L_2(I, V)$ space to the weak solution. We also derive an "error estimate" for semidiscretization, which implies uniqueness. The numerical experiments in various situations of the "anisotropic curve shortening" are discussed.

Key words. curve shortening flow, phase interface, nonlinear degenerate parabolic equations, blow up, numerical solution, L_∞-estimate, error estimate

AMS subject classifications. 35K65, 65N40, 53C80

1. Introduction and the background of the problem.

The aim of this paper is to study from a numerical point of view the following problem. Let v be a smooth function which satisfies

$$\begin{aligned} \partial_t b(v) &= (Av_x)_x + (Bv)_x + Dv + G, \\ v(x,t) &= v(x + 2\pi\nu, t), \qquad (1.1) \\ v(x,0) &= v_0(x) \end{aligned}$$

for $x \in \mathbb{R}$ and $t \in [0, T)$, where $\nu \in \mathbb{N}$, v_0 is a smooth function, and

(H1) $A \geq q > 0$, B, B_x, D, G are bounded measurable functions of independent variable x, periodic in interval $[0, 2\pi\nu]$;

(H2) $b(s)$ is a C^2-function, defined in interval $(-\infty, a)$, $a < \infty$, satisfying $b'(s) > 0$,

$$\begin{aligned} &b(s) \to a_1 \text{ and } b'(s) \to 0 \text{ for } s \to -\infty, \\ &b(s) \to \infty \text{ and } b'(s) \to \infty \text{ for } s \to a^-, \end{aligned} \qquad \text{(H3)}$$

$$b(0) = 0. \qquad \text{(H4)}$$

So, the nonlinearity in this model is represented by the increasing function $b(s)$ admitting asymptotical *degeneracy of two types* expressed by hypothesis (H3). In this sense our model covers locally both slow and fast diffusions. Due to the special form of the problem, the solution also may *blow up* in a finite time. From a numerical point of view, complications also arise because of the strong *convection term* in the governed equation.

We suggest two approximation schemes for solving degenerate parabolic problems of the type (1.1). We numerically solve certain regularization of (1.1), which is identical with the original problem in a local time interval. Although our results are theoretically guaranteed only locally, numerical calculations show the agreement with known exact results in time intervals

with right endpoints very near to the blow-up time. The first of the schemes is simpler; we use it, besides other things, to establish the relation between original and regularized problems. The second scheme is more sophisticated; it is based on semidiscretization which reduces (1.1) to a succession of linear elliptic equations coupled with algebraic corrections due to nonlinearity. It originates in the works of Magenes, Nochetto, and Verdi [MNV] and Jäger and Kačur [JK1], [JK2] concerning the porous medium-type equations and elliptic–parabolic problems. For this scheme we not only prove the convergence but also derive an error estimate, which implies the uniqueness of the solution. In numerical computation these schemes yield results of comparable degrees of accuracy while the second one is more precise near the degeneracy $b'(s) = +\infty$. After time semidiscretization, both schemes need to solve a convection–diffusion equation in each time step. For this purpose we use the so called "power-law scheme" described in [P], which respects the "up-wind" principle.

Problem (1.1) arises from the curve evolution model describing anisotropic motion of phase interfaces in multiphase thermomechanics given by Angenent and Gurtin in [AG1]. Assume that at time t a solid occupies a region $D(t) \subset \mathbb{R}^2$ whose boundary is a smooth curve $\mathbf{r}$. Let θ be variable representing the angle of the tangent to the curve with x-axis. By Ω we denote the range of θ. Let β, g, F be functions on Ω coming from the constitutive description of interface and representing the following physical quantities. $\beta(\theta)$ is the kinetic coefficient; from thermodynamical considerations it follows that $\beta(\theta) > 0$. The function $g(\theta)$ is given by $g(\theta) = f(\theta) + f''(\theta)$, where $f(\theta)$ is the interfacial free energy. $F \equiv$ const is the energy of the solid phase minus that of the other phase (see [AG1], [AG2], [G1], [G2], [G3]). By [AG1], the first equation of the interface motion may be written as

$$\beta(\theta)\mathcal{V} = g(\theta)k - F, \tag{1.2}$$

where $\mathcal{V} \equiv \mathcal{V}(Q, t)$ is the normal velocity and $k(Q, t)$ the curvature at a point Q of the curve $\mathbf{r}$ at a time t. The interface motion given by (1.2) is called *anisotropic*. In the case $g, \beta \equiv$ const and $F \equiv 0$ the motion is called *isotropic*. Then we have (after normalizing constants) the simple relation

$$\mathcal{V} = k, \tag{1.3}$$

which means that the velocity of the curve in the inside normal direction is proportional to its curvature. The curve evolution governed by (1.3) is also called the "curve shortening flow." Gage and Hamilton show in [GH] that this problem, which starts from a *closed* and *convex* initial curve, is equivalent to the following initial value problem for a special partial differential equation (PDE).

Let the initial convex curve $\mathbf{r}_0$ be parametrized by θ, $k_0(\theta)$ be its curvature, and $\Omega = [0, 2\pi\nu]$, $\nu \in \mathbb{N}$. Assume that the function $k(\theta, t)\, \forall t \in [0, T), \theta \in \mathbb{R}$ satisfies the *curve shortening equation*, i.e.,

$$\partial_t k = k^2(k_{\theta\theta} + k), \tag{1.4}$$

the periodicity, and initial conditions

$$k(\theta, t) = k(\theta + 2\pi\nu, t), \tag{1.5}$$

$$k(\theta, 0) = k_0(\theta). \tag{1.6}$$

Then the flow $\mathbf{r}(\theta, t)$ of the curves that solves the problem (1.3) with the initial curve $\mathbf{r}_0$ is given uniquely up to translation by the formula

$$\mathbf{r}(\theta_0, t) = \mathbf{r}(0, t) - \int_0^{\theta_0} \frac{e^{i\theta}}{k(\theta, t)} d\theta. \tag{1.7}$$

The condition of closedness $\int_0^{2\pi\nu} \frac{e^{i\theta}}{k(\theta,t)} d\theta = 0$ is an invariant of the flow. By conservation of convexity $k(\theta, t) < 0 \, \forall t \in [0, T)$. Note that, by the convention introduced in [AG1], the curvature of strictly convex curves is negative. Papers [GH], [Gr], [ALa], [A1], [A2] describe many interesting properties of isotropic curve shortening; we will illustrate them in the section containing numerical computations (§7).

Equation (1.4) also serves as the model of a magnetic field in plasma physics. (There are Dirichlet instead of periodic boundary conditions.) The blow up of the solution in this case was studied from theoretical point of view by Friedman and McLeod in [FM]; numerics were done in [W], [Z].

Angenent and Gurtin [AG1] found the equation

$$\partial_t k = k^2 \left(\frac{gk - F}{\beta}\right)_{\theta\theta} + k^2 \left(\frac{gk - F}{\beta}\right) \tag{1.8}$$

for the dynamics of the curvature in the anisotropic case. This equation together with conditions (1.5), (1.6), and with $g(\theta) > 0$ describes the *anisotropic motion of the strictly convex interface*. That flow conserves convexity; the closedness condition is also an invariant (see [AG2]). Up to condition (H4), problem (1.8) may be transformed into the form (1.1) provided one puts

$$b(v) = -\frac{1}{v}, \quad A = D = \frac{g}{\beta}, \quad B = \left(\frac{g}{\beta}\right)_x, \quad G = -\frac{F}{\beta} - \left(\frac{F}{\beta}\right)_{xx}. \tag{1.9}$$

Using the transformation $\overline{b}(s) = b(s + c_1) - c_2$, where c_1, c_2 are constants, one of which is determined by the other, we can always satisfy (H4). The solutions of (1.1) with transform functions $\overline{b}$ and b, respectively, then correspond to each other uniquely. In this sense (1.1) is a model of the anisotropic motion of strictly convex phase interfaces.

The paper is organized as follows. In §2 we introduce two approximation schemes to solve (1.1). The convergence of the first approximation scheme is proved in §3. In §4 we discuss the regularization of the original problem (1.1). The convergence of the second approximation scheme is proved in §5. The error estimate analysis is presented in §6. In §7 we discuss the numerical results. It is well known that the isoperimetric ratio decreases to 1 in the isotropic time evolution of curves. We define an isoperimetric ratio generalization for the anisotropic time evolution. Our numerical experiments confirm decreasing to 1 of that *anisotropic isoperimetric ratio.*

2. Approximation schemes—the main theoretical results. Our main goal is to solve numerically the problem (1.1), especially in the case of anisotropic curve shortening (1.9). For this purpose we regularize the original problem in the following way. Let us consider the function $b_R(s)$ instead of $b(s)$, defined by

$$b_R(s) = \begin{cases} b(-R-\sigma) + b'(-R-\sigma)(s+R+\sigma), & s \le -R-\sigma, \\ r_1(s), & s \in (-R-\sigma, -R), \\ b(s), & s \in [-R, a - \frac{1}{R}], \\ r_2(s), & s \in (a - \frac{1}{R}, a - \frac{1}{R} + \sigma), \\ b(a - \frac{1}{R} + \sigma) + b'(a - \frac{1}{R} + \sigma)(s - a + \frac{1}{R} - \sigma), & s \ge a - \frac{1}{R} + \sigma, \end{cases} \tag{2.1}$$

where R, σ are real constants, $\sigma < \frac{1}{R}$. r_1 and r_2 are functions from $C^2(\mathbb{R})$ such that the whole function $b_R \in C^2(\mathbb{R})$ and inequalities $b'_R(-R-\sigma) \le b'_R(s) \le b'_R(a - \frac{1}{R} + \sigma)$ hold $\forall s \in \mathbb{R}$.

Now we define the *regularized problem*

$$\begin{aligned}\partial_t b_R(v) &= (Av_x)_x + (Bv)_x + Dv + G,\\ v(x,t) &= v(x+2\pi\nu, t),\\ v(x,0) &= v_0(x)\end{aligned} \tag{2.2}$$

for $x \in \mathbb{R}, t \in [0,T)$, $v_0(x)$ smooth function, under assumption (H1) and definition (2.1). Thus $b_R(s)$ is a C^2-increasing globally Lipschitz continuous function in $\mathbb{R}$ such that

$$\Gamma \geq b_R'(s) \geq \gamma > 0, \quad b_R(0) = 0. \tag{2.3}$$

Denote $I = (0,T)$, $\Omega = (0, 2\pi\nu)$, $Q_T = \Omega \times I$. Let $V = \{w \in W_2^1(0, 2\pi\nu) : w(0) = w(2\pi\nu)\}$ and assume that $v_0(x) \in V$.

DEFINITION 2.1. *The function $v \in L_2(I,V)$ with $\partial_t b_R(v) \in L_2(I,V^*)$ is called a weak solution of* (2.2) *iff $v(x,0) = v_0(x)$ and the identity*

$$\langle \partial_t b_R(v), \varphi\rangle + (Av_x, \varphi_x) + (Bv, \varphi_x) - (Dv, \varphi) = (G, \varphi) \tag{2.4}$$

holds $\forall\varphi \in V$ and for almost every (a.e.) $t \in I$. Replacing b_R by b we obtain the definition of a weak solution of the original problem (1.1).

A weak solution of problem (2.2) will be found using Rothe's method.

Let $n \in \mathbb{N}$, $\tau = \frac{T}{n}$, $t_i = i\tau$ for $i = 0, \dots, n$, $u_0 = v_0(x)$. For every $i = 1, \dots, n$, let $u_i \in V$ be the function such that $\forall\varphi \in V$

$$\left(b_R'(u_{i-1})\left(\frac{u_i - u_{i-1}}{\tau}\right), \varphi\right) + (Au_{ix}, \varphi_x) + (Bu_i, \varphi_x) - (Du_i, \varphi) = (G, \varphi). \tag{2.5}$$

From these functions we construct Rothe's functions

$$\begin{aligned} &u^{(n)}(t) = u_{i-1} + (t - t_{i-1})\frac{u_i - u_{i-1}}{\tau} \quad \text{for } t_{i-1} \leq t \leq t_i, i = 1, \dots, n,\\ &\overline{u}^{(n)}(t) = u_i \quad \text{for } t_{i-1} < t \leq t_i, i = 1, \dots, n, \quad \overline{u}^{(n)}(0) = u_0. \end{aligned} \tag{2.6}$$

THEOREM 2.1. *There exists a unique weak solution u of* (2.2) *such that $u^{(n)} \to u$ in $C(I, L_2)$; $\overline{u}^{(n)}(t) \rightharpoonup u(t)$, $u^{(n)}(t) \rightharpoonup u(t)$ in $V\, \forall t \in I$; $\partial_t u^{(n)} \rightharpoonup \partial_t u$ in $L_2(I, L_2)$ for the Rothe functions defined by* (2.6). *Moreover $u \in C(I, L_2) \cap L_\infty(I, V)$ and $\partial_t u \in L_2(I, L_2)$.*

The next theorem expresses the relation between the solutions of the regularized and the original problems with the bounded initial condition.

THEOREM 2.2. *Let u be a weak solution of* (2.2) *whose existence is guaranteed by the previous theorem. Let $u(x,0) \in L_\infty(\Omega) \cap V$ and*

$$-R + \delta < u(x,0) < a - \frac{1}{R} - \delta. \tag{2.7}$$

Then there exists $0 < T_1 < \infty$ so that

(i) *$u \in L_\infty(I, V) \cap L_\infty(Q_{T_1})$, and $Q_{T_1} = (0, T_1) \times \Omega$,*

(ii) *at the same time, u is a weak solution of* (1.1) *with initial condition $v_0(x) = u(x,0)$ in the time interval $(0, T_1)$.*

Remark 2.1. In Theorem 2.2 results concerning problem (2.2) obtained in Theorem 2.1 are transferred so as to obtain local results concerning the original problem (1.1). In this sense, the process (2.5) defines the *first approximation scheme* for solving problem (1.1).

The *second approximation scheme* is based on works [MNV] and [JK1] concerning numerical solution of the slow diffusion and Stefan-like problems and mainly on [JK2] describing the solution of elliptic–parabolic problems. This scheme is based on a nonstandard time discretization using the relaxation function by means of which we reduce the nonlinear original problem to an iterative solution of linear elliptic problems.

Let $n \in \mathbb{N}$, $\tau = \frac{T}{n}$, $t_i = i\tau$ for $i = 0, \dots, n$, $v_0 = v_0(x)$, $u_0 = v_0$. For $i = 1, \dots, n$ we look for functions $u_i \in V$ and $\mu_i \in L_\infty(\Omega)$ such that $\forall \varphi \in V$

$$(\mu_i(u_i - v_{i-1}), \varphi) + \tau(Au_{ix}, \varphi_x) + \tau(Bu_i, \varphi_x) - \tau(Du_i, \varphi) = \tau(G, \varphi), \tag{2.8}$$

satisfying the "convergence condition"

$$\alpha\frac{\gamma}{2} \le \mu_i \le \frac{b_R(v_{i-1} + \alpha(u_i - v_{i-1})) - b_R(v_{i-1})}{u_i - v_{i-1}}, \tag{2.9}$$

where $0 < \alpha < 1$. If $u_i = v_{i-1}$ then we replace the difference quotient by $\alpha b'_R(v_{i-1})$. The function v_i is obtained by the algebraic correction

$$b_R(v_i) := b_R(v_{i-1}) + \mu_i(u_i - v_{i-1}). \tag{2.10}$$

There are many possibilities to determine u_i, μ_i satisfying (2.8) and (2.9). If we choose $\alpha\frac{\gamma}{2} \le \mu_i \le \alpha\gamma$ then (2.8) and (2.9) are fulfilled. However, it is more interesting (from the numerical point of view) to choose μ_i very close to the difference quotient in (2.9). This can be done iteratively; see Remark 2.2.

From u_i, v_i, obtained in each time step of (2.8)–(2.10), the Rothe functions

$$u^{(n)}, v^{(n)}, \overline{u}^{(n)}, \overline{v}^{(n)} \tag{2.11}$$

are constructed (see (2.6)). Then we can prove the following theorem.

THEOREM 2.3. *Let* $\{u^{(n)}\}$, $\{v^{(n)}\}$, $\{\overline{u}^{(n)}\}$, $\{\overline{v}^{(n)}\}$ *be the sequences from* (2.11). *Then* $u^{(n)} \to u, v^{(n)} \to u, \overline{u}^{(n)} \to u, \overline{v}^{(n)} \to u$ *in* $L_2(Q_T)$, $\overline{u}^{(n)} \rightharpoonup u$ *in* $L_2(I, V)$, *where* u *is a weak solution of* (2.2).

Using techniques developed in [ALu] and [KHK], stronger convergence results can be proved.

THEOREM 2.4. *Let* $\{\overline{u}^{(n)}\}$ *be the sequence defined in* (2.11). *Then* $\overline{u}^{(n)} \to u$ *in* $L_2(I, V)$, *where* u *is a weak solution of* (2.2).

Remark 2.2. The question is how to find in a constructive way the couple u_i, μ_i simultaneously satisfying (2.8) and (2.9). We use iterations similar to the ones from [JK1], [JK2]:

(2.8')

$$(\mu_{i,k-1}(u_{i,k} - v_{i-1}), \varphi) + \tau(Au_{i,kx}, \varphi_x) + \tau(Bu_{i,k}, \varphi_x) - \tau(Du_{i,k}, \varphi) = \tau(G, \varphi),$$

$$\overline{\mu}_{i,k} = \frac{b_R(v_{i-1} + \alpha(u_{i,k} - v_{i-1})) - b_R(v_{i-1})}{u_{i,k} - v_{i-1}},$$

$$\mu_{i,k} := \overline{\mu}_{i,k} \text{ for } 1 \le k \le k_0, \quad \mu_{i,k} := \min\{\overline{\mu}_{i,k}, \mu_{i,k-1}\} \text{ for } k = k_0 + 1, \dots, \tag{2.9'}$$

starting with

$$\mu_{i,0} = b'_R(v_{i-1}). \tag{2.9''}$$

Note that if $u_{i,k} = v_{i-1}$ then we put $\overline{\mu}_{i,k} = \alpha b'_R(v_{i-1})$.

Generally ($b(s)$ is monotone) we are not able to prove the convergence of the sequence $\{\mu_{i,k}\}$ for $\mu_{i,k} \equiv \overline{\mu}_{i,k}$. By construction (2.9') with $k_0 \geq 1$, $\{\mu_{i,k}\}$ is forced to be monotone and hence convergent. In practical implementations k_0 can be chosen in accordance with the shape of $b(s)$. In our numerical realization (in case (1.9)) we have observed that $\mu_{i,k} \equiv \overline{\mu}_{i,k}$ are convergent and hence we have used k_0 sufficiently large. In practice the iterations very quickly converge to functions satisfying (2.8) and (2.9), and from theoretical point of view we have the following

THEOREM 2.5. *Let $1 \leq i \leq n$ be fixed, $\tau \leq \tau_0$, and $v_{i-1} \in L_\infty(\Omega)$. If $\{\mu_{i,k}\}$, $\{u_{i,k}\}$ are sequences from* (2.8') *and* (2.9') *then there exist $\mu \in L_\infty(\Omega)$, $w \in V$ such that*

$$\mu_{i,k} \to \mu =: \mu_i \text{ in } L_p(\Omega) \ (\forall p > 1), \quad u_{i,k} \to w =: u_i \text{ in } C^{0,\delta}(\overline{\Omega}) \ \left(\delta < \frac{1}{2}\right)$$

for $k \to \infty$, where μ_i, u_i satisfy (2.8) *and* (2.9).

The next theorem concerns the "error estimate" for approximation scheme (2.8)–(2.10).

THEOREM 2.6. *Let u be a weak solution of* (2.2) *and $\overline{u}^{(n)}$ the sequence of Rothe's functions obtained by the approximation scheme* (2.8)–(2.10). *Then the following estimate holds:*

$$\int_I |\overline{u}^{(n)}(s) - u(s)|_2^2 ds + \left| \int_I (\overline{u}^{(n)}(s) - u(s))_x ds \right|_2^2 \leq C\tau. \tag{2.12}$$

The function u in the previous theorem is an arbitrary weak solution of the regularized problem (2.2). Its uniqueness is proved using (2.12). By standard arguments, the original sequences given in (2.11) and (2.6), respectively, converge to this solution. Combining these results with Theorem 2.2 we can formulate the next theorem concerning the solution of the original problem (1.1).

THEOREM 2.7. *Let $v_0 \in L_\infty(\Omega) \cap V$ satisfy* (2.7). *Then there exist $T_1 < \infty$ and function $u \in C(I, L_2) \cap L_\infty(I, V) \cap L_\infty(Q_{T_1})$ with $\partial_t u \in L_2(I, L_2)$, $I = (0, T_1)$, which is the unique bounded solution of the problem* (1.1). *For $\overline{u}^{(n)}$, given by approximation scheme* (2.8)–(2.10), *we have $\overline{u}^{(n)} \to u$, $b(\overline{u}^{(n)}) \to b(u)$ in $L_2(I, V)$ and* (2.12).

3. Convergence of the approximation scheme (2.5).

Remark 3.1. We denote the scalar product in $L_2(\Omega)$ by $(\cdot, \cdot)$ and duality between V and V^* by $\langle \cdot, \cdot \rangle$. We use symbols $|\cdot|_2$, $\|\cdot\|$, $\|\cdot\|_*$, $|\cdot|_\infty$, $|\cdot|_p$ for norms in $L_2(\Omega)$, V, V^*, $L_\infty(\Omega)$, and $L_p(\Omega)$, respectively. By $\to$, $\rightharpoonup$, we mean strong and weak convergence; the Landau symbol $o(1)$ represents a term c_n satisfying $c_n \to 0$ for $n \to \infty$. C denotes the generic positive constant, ε small positive number, and $C(\varepsilon)$ term dependent on ε^{-1}. Let us denote $\delta u_i = \frac{u_i - u_{i-1}}{\tau}$ and $\delta \overline{u}^{(n)}(t) = \frac{\overline{u}^{(n)}(t) - \overline{u}^{(n)}(t-\tau)}{\tau}$.

LEMMA 3.1. *There exists $\tau_0 > 0$ such that $\forall n \in \mathbb{N}$ satisfying $\tau = \frac{T}{n} < \tau_0$ we have the following: for every $i = 1, \dots, n$ there exists unique $u_i \in V$ satisfying* (2.5) *and the following a priori estimates hold:*

$$\sum_{i=1}^n |\delta u_i|_2^2 \tau \leq C, \quad \max_{1 \leq i \leq n} \|u_i\| \leq C, \quad \sum_{i=1}^n |u_{ix} - u_{i-1x}|_2^2 \leq C. \tag{3.1}$$

Proof. We put $\varphi = u_i$ into (2.5) and use the estimates

$$\begin{aligned} &(Au_{ix}, u_{ix}) \geq q|u_{ix}|_2^2, \quad |(Bu_i, u_{ix})| \leq \varepsilon |u_{ix}|_2^2 + C(\varepsilon)|u_i|_2^2, \\ &|(Du_i, u_i)| \leq C|u_i|_2^2, \quad |(G, u_i)| \leq \varepsilon |G|_2^2 + C(\varepsilon)|u_i|_2^2. \end{aligned} \tag{3.2}$$

The Lax–Milgram theorem guarantees the existence of the unique $u_i \in V$ satisfying (2.5).

Let us put $\varphi = u_i - u_{i-1}$ into (2.5) and sum the equations for $i = 1, \dots, j, j \le n$. Using (2.3), we obtain the following inequality:

$$\begin{aligned}\gamma \sum_{i=1}^{j} |\delta u_i|_2^2 \tau + \sum_{i=1}^{j} (Au_{ix}, u_{ix} - u_{i-1x}) + \sum_{i=1}^{j} (Bu_i, u_{ix} - u_{i-1x})\\ - \sum_{i=1}^{j} (Du_i, u_i - u_{i-1}) \le \sum_{i=1}^{j} (G, u_i - u_{i-1}).\end{aligned} \tag{3.3}$$

Using Abel's summation, Young's inequality, (H1), and (2.3) we estimate

$$\sum_{i=1}^{j} (Au_{ix}, u_{ix} - u_{i-1x}) \ge \frac{q}{2} \sum_{i=1}^{j} |u_{ix} - u_{i-1x}|_2^2 + \frac{q}{2} |u_{jx}|_2^2 - C,$$

$$\begin{aligned}\sum_{i=1}^{j} (Bu_i, u_{ix} - u_{i-1x}) &= - \sum_{i=1}^{j} (B(u_i - u_{i-1}), u_{i-1\,x}) + (Bu_j, u_{jx}) - (Bu_0, u_{0x})\\ &\le \varepsilon |u_{jx}|_2^2 + C(\varepsilon)|u_j|_2^2 + C(\varepsilon) \sum_{i=1}^{j} |u_{ix}|_2^2 \tau + \varepsilon \sum_{i=1}^{j} |\delta u_i|_2^2 \tau + C,\end{aligned}$$

$$\left| \tau \sum_{i=1}^{j} \left(Du_i, \frac{u_i - u_{i-1}}{\tau} \right) \right| \le \varepsilon \sum_{i=1}^{j} |\delta u_i|_2^2 \tau + C(\varepsilon) \sum_{i=1}^{j} |u_i|_2^2 \tau,$$

$$\left| \tau \sum_{i=1}^{j} \left(G, \frac{u_i - u_{i-1}}{\tau} \right) \right| \le \varepsilon \sum_{i=1}^{j} |\delta u_i|_2^2 \tau + C(\varepsilon).$$

In the previous inequalities we used an estimate for $|u_j|_2^2$. The parabolic term gives us

$$\begin{aligned}&\frac{\gamma}{2} |u_j|_2^2 - C + \frac{1}{2} \sum_{i=1}^{j} \int_\Omega (b_R'(u_{i-1}) - b_R'(u_i)) u_i^2 dx\\ &\le \frac{1}{2} \sum_{i=1}^{j} (b_R'(u_{i-1})(u_i - u_{i-1}), u_i - u_{i-1}) + \frac{1}{2} \sum_{i=1}^{j} (b_R'(u_{i-1}) u_i, u_i)\\ &- \frac{1}{2} \sum_{i=1}^{j} (b_R'(u_{i-1}) u_{i-1}, u_{i-1}) = \sum_{i=1}^{j} (b_R'(u_{i-1})(u_i - u_{i-1}), u_i)\\ &\le \delta \sum_{i=1}^{j} |\delta u_i|_2^2 \tau + C(\delta) \sum_{i=1}^{j} |u_i|_2^2 \tau.\end{aligned}$$

The regularized function b_R satisfies the condition $|b_R''(z)| \le \frac{C_1}{1+|z|^s}$, with $C_1 > 0$ and $s > 1$. Then there exists $K > 0$ such that (see [K3, Lem. 3])

$$\begin{aligned}&\left| \int_\Omega (b_R'(u_{i-1}) - b_R'(u_i)) u_i^2 dx \right| = \left| \int_\Omega (u_{i-1} - u_i) \int_0^1 b_R''(u_i + \omega(u_{i-1} - u_i)) d\omega u_i^2 dx \right|\\ &\le C_1 \int_\Omega |u_i - u_{i-1}| \int_0^1 \frac{|u_i|}{1 + |u_i + \omega(u_{i-1} - u_i)|^s} d\omega |u_i| dx \le C_1 K \int_\Omega |u_i - u_{i-1}||u_i| dx.\end{aligned}$$

Estimating the last term $\int_\Omega |u_i - u_{i-1}||u_i| \le \delta |\delta u_i|_2^2 \tau + C(\delta)|u_i|_2^2 \tau$ we obtain

$$|u_j|_2^2 \le C + C(\delta) \sum_{i=1}^{j} |u_i|_2^2 \tau + \delta \sum_{i=1}^{j} |\delta u_i|_2^2 \tau.$$

Applying all the previous estimates in (3.3) we deduce (for C sufficiently large)

$$\sum_{i=1}^{j} |\delta u_i|_2^2 \tau + |u_{jx}|_2^2 + \sum_{i=1}^{j} |u_{ix} - u_{i-1x}|_2^2 \le C + C \sum_{i=1}^{j} |u_{ix}|_2^2 \tau + C \sum_{i=1}^{j} \left(\sum_{l=1}^{i} |\delta u_l|_2^2 \tau \right) \tau.$$

Here, we apply Gronwall's argument and obtain desired a priori estimates. □

Proof of Theorem 2.1. For the Rothe functions defined in (2.6), we can rewrite a priori estimates (3.1) in the following form:

$$\int_I |\partial_t u^{(n)}(t)|_2^2 dt \le C, \quad \max_{t \in [0,T]} \|\overline{u}^{(n)}(t)\| \le C \; \forall n \ge n_0.$$

Then by standard arguments (see [K1, Lem. 1.3.13]) we obtain $u \in C(I, L_2) \cap L_\infty(I, V)$ with $\partial_t u \in L_2(I, L_2)$ such that in a sense of subsequences (a subsequence of $\{n\}$ we denote again by $\{n\}$) $u^{(n)} \to u$ in $C(I, L_2)$; $\overline{u}^{(n)}(t) \rightharpoonup u(t)$, $u^{(n)}(t) \rightharpoonup u(t)$ in V $\forall t \in I$; $\partial_t u^{(n)} \rightharpoonup \partial_t u$ in $L_2(I, L_2)$. Lemma 3.1 implies

$$\int_I |\overline{u}^{(n)}(t) - \overline{u}^{(n)}(t-\tau)|_2^2 dt \le \frac{C}{n^2}, \quad \int_I |\overline{u}^{(n)}(t) - u^{(n)}(t)|_2^2 dt \le \frac{C}{n^2}.$$

Now taking the limit for $n \to \infty$ in

$$\begin{aligned} &\int_J (\partial_t u^{(n)}(t), b'_R(\overline{u}^{(n)}(t-\tau))\varphi) dt + \int_J (A\overline{u}_x^{(n)}(t), \varphi_x) dt \\ &+ \int_J (B\overline{u}^{(n)}(t), \varphi_x) dt - \int_J (D\overline{u}^{(n)}(t), \varphi) dt = \int_J (G, \varphi) dt, \end{aligned}$$

where J is a subinterval of I, we obtain that u satisfies (2.4). The uniqueness of a weak solution will be guaranteed by Theorem 2.6. The convergence of the original sequences $\{u^{(n)}\}$, $\{\overline{u}^{(n)}\}$ then follows from the uniqueness argument. □

4. Relation between regularized and original problems.

Proof of Theorem 2.2. Let us denote

$$\gamma(R) =: b'(-R - \sigma), \quad \Gamma(R) =: b'\left(a - \frac{1}{R} + \sigma\right) \quad \text{for } R \ge R_0.$$

First we shall prove part (i). We obtained the solution u from the theorem by solving identity (2.5) for $i = 1, \dots, n$. Due to (2.3) and $u_0 \in L_\infty(\Omega)$, we have that $u_i \in L_\infty(\Omega)$ for $i = 1, \dots, n$ (see [L], [LSU]). Now we shall derive the L_∞-estimate for u_i. In what follows we use similar ideas to those in [K2]. Let us consider u_i^p, where p is odd, as a test function in the identity (2.5). (Since $u_i \in L_\infty(\Omega)$ we have $u_i^p \in V$.) Using Young's inequality we obtain

$$\begin{aligned} &\int_\Omega b'_R(u_{i-1}) u_i^{p+1} + p\tau \int_\Omega A u_{ix}^2 u_i^{p-1} \le \int_\Omega b'_R(u_{i-1}) u_{i-1} u_i^p \\ &+ \tau \left| \int_\Omega B u_i (u_i^p)_x \right| + \tau \int_\Omega |D| u_i^{p+1} + \tau \frac{\varepsilon^{p+1}}{p+1} \int_\Omega G^{p+1} + \tau \frac{p}{\varepsilon^{\frac{p+1}{p}} (p+1)} \int_\Omega u_i^{p+1}. \end{aligned} \tag{4.1}$$

Using periodicity, Young's inequality, and (H1) we estimate

$$\begin{aligned} \left| \int_\Omega B u_i (u_i^p)_x \right| &= \left| [B u_i^{p+1}]_0^{2\pi\nu} - \int_\Omega (B u_i)_x u_i^p \right| \le \int_\Omega |B_x| u_i^{p+1} + \int_\Omega |B||u_i|^p |u_{ix}| \\ &\le \int_\Omega |B_x| u_i^{p+1} + \frac{1}{2} \int_\Omega A u_i^{p-1} u_{ix}^2 + C \int_\Omega u_i^{p+1}. \end{aligned}$$

Applying it in (4.1) together with $b'_R(u_{i-1}) \geq \gamma(R) > 0$ and (H1) we obtain

$$\int_\Omega b'_R(u_{i-1})u_i^{p+1} + \left(p - \frac{1}{2}\right)\tau \int_\Omega Au_{ix}^2 u_i^{p-1} \leq \int_\Omega b'_R(u_{i-1})u_{i-1}u_i^p$$
$$+\tau K \int_\Omega b'_R(u_{i-1})u_i^{p+1} + \tau \frac{\varepsilon^{p+1}}{p+1}\int_\Omega G^{p+1},$$

where the constant K depends on $|B_x|_\infty, |D|_\infty, |B|_\infty, |A|_\infty, R, \varepsilon$. Hence we have

$$(1 - K\tau)\int_\Omega b'_R(u_{i-1})u_i^{p+1} \leq \int_\Omega b'_R(u_{i-1})u_{i-1}u_i^p + \tau\frac{\varepsilon^{p+1}}{p+1}\int_\Omega G^{p+1}.$$

Then for τ sufficiently small ($\frac{T}{n} = \tau \leq \frac{1}{K}$) we obtain (for $\varepsilon_n = \frac{2K^2T}{n}$)

$$\int_\Omega b'_R(u_{i-1})u_i^{p+1} \leq (1 + (K + \varepsilon_n)\tau)\left[\int_\Omega b'_R(u_{i-1})u_{i-1}u_i^p + \tau\frac{\varepsilon^{p+1}}{p+1}\int_\Omega G^{p+1}\right].$$

Using Young's inequality for the first term on the right-hand side we deduce

$$\int_\Omega b'_R(u_{i-1})u_i^{p+1} \leq \frac{(1 + (K+\varepsilon_n)\tau)^{p+1}}{p+1}\int_\Omega b'_R(u_{i-1})u_{i-1}^{p+1}$$
$$+\frac{p}{p+1}\int_\Omega b'_R(u_{i-1})u_i^{p+1} + (1 + (K+\varepsilon_n)\tau)\tau\frac{\varepsilon^{p+1}}{p+1}\int_\Omega G^{p+1}.$$

Now, using the estimates $\frac{\gamma(R)}{\Gamma(R)} \leq b'_R(u_{i-1}) \leq \frac{\Gamma(R)}{\gamma(R)}$ we obtain the recurrent inequality

$$\int_\Omega u_i^{p+1} \leq (1 + (K+\varepsilon_n)\tau)^{p+1}\left(\frac{\Gamma(R)}{\gamma(R)}\right)^2\left[\int_\Omega u_{i-1}^{p+1} + \tau\varepsilon^{p+1}\int_\Omega G^{p+1}\right]$$

and hence

$$\int_\Omega u_i^{p+1} \leq (1 + (K+\varepsilon_n)\tau)^{(p+1)i}\left(\frac{\Gamma(R)}{\gamma(R)}\right)^{2i}\left[\int_\Omega u_0^{p+1} + i\tau\varepsilon^{p+1}\int_\Omega G^{p+1}\right].$$

Here, we take the $(p+1)$th root and let $p \to \infty$. Then (because $(1+x)^i \leq e^{ix}$)

$$|u_i|_\infty \leq (1 + (K+\varepsilon_n)\tau)^i(|u_0|_\infty + \varepsilon|G|_\infty) \leq e^{(K+\varepsilon_n)t_i}(|u_0|_\infty + \varepsilon|G|_\infty). \tag{4.2}$$

Due to Theorem 2.1, the functions $u^{(n)}$ from (2.6) converge to the solution u in $C(I, L_2)$. Taking limit for $n \to \infty$ we derive from (4.2)

$$|u(t)|_\infty \leq e^{Kt}(|u_0|_\infty + \varepsilon|G|_\infty) \ \forall t \in I, \tag{4.3}$$

where constant K depends on $|B_x|_\infty, |D|_\infty, |B|_\infty, |A|_\infty, R, \varepsilon$. Assertion (i) of the theorem follows from (4.3). At the same time we proved that if $u(x, 0)$ satisfies the left inequality in (2.7) then for ε sufficiently small, there exists $0 < T_2 < \infty$ such that

$$-R \leq u(x,t) \quad \text{for a.e. } x \in \Omega, t \in (0, T_2). \tag{4.4}$$

Now, we shall look for the L_∞-estimate for the function $b_R(u)$ to obtain the similar result concerning the right inequality in (2.7). Due to (2.3) a weak solution u satisfies

$$\langle b_R'(u)\partial_t u, \varphi\rangle + (Au_x, \varphi_x) + (Bu, \varphi_x) - (Du, \varphi) = (G, \varphi) \quad \forall \varphi \in V. \tag{4.5}$$

From the previous part of the proof (where we derived that $u \in L_\infty(Q_{T_2})$), it follows that $b_R^p(u) \in V$ for $t \in (0, T_2)$. Thus we can put $\varphi = b_R^p(u)$, where p is odd, into (4.5) and integrate the identity over $(0, t), t \le T_2$. Using integration *per partes* in the convection term and considering the periodicity we obtain

$$\begin{aligned}
&\frac{1}{p+1}\left[\int_\Omega |b_R(u(t))|^{p+1} - \int_\Omega |b_R(u(0))|^{p+1}\right] + p\int_0^t\int_\Omega Au_x^2 b_R^{p-1}(u)b_R'(u) \\
&\le \int_0^t\int_\Omega |B_x||u||b_R(u)|^p + \int_0^t\int_\Omega |B||u_x||b_R(u)|^p + \int_0^t\int_\Omega |D||u||b_R(u)|^p \\
&+\frac{1}{p+1}\int_0^t\int_\Omega \varepsilon^{p+1}|G|^{p+1} + C(\varepsilon)\frac{p}{p+1}\int_0^t\int_\Omega |b_R(u)|^{p+1}.
\end{aligned} \tag{4.6}$$

The second term on the right-hand side can be estimated (for ε sufficiently small)

$$\begin{aligned}
\int_0^t\int_\Omega |B||u_x||b_R(u)|^p &\le \varepsilon\int_0^t\int_\Omega |B|^2u_x^2b_R^{p-1}(u) + C(\varepsilon)\int_0^t\int_\Omega b_R^{p+1}(u) \\
&\le \frac{1}{\gamma(R)}\int_0^t\int_\Omega Au_x^2b_R^{p-1}(u)b_R'(u) + C\int_0^t\int_\Omega b_R^{p+1}(u).
\end{aligned} \tag{4.7}$$

Because $|u| \le \frac{|b_R(u)|}{\gamma(R)}$ we have

$$\int_0^t\int_\Omega (|B_x| + |D|)|u||b_R(u)|^p \le \frac{(|B_x|_\infty + |D|_\infty)}{\gamma(R)}\int_0^t\int_\Omega b_R^{p+1}(u). \tag{4.8}$$

Applying (4.7) and (4.8) in (4.6) for $p > \frac{1}{\gamma(R)}$ we obtain

$$\int_\Omega |b_R(u(t))|^{p+1} \le L(p+1)\int_0^t\int_\Omega |b_R(u)|^{p+1} + T\int_\Omega \varepsilon^{p+1}|G|^{p+1} + \int_\Omega |b_R(u(0))|^{p+1},$$

where the constant L depends on $|B_x|_\infty, |D|_\infty, |B|_\infty, |A|_\infty, R, \varepsilon$. Using Gronwall's lemma and taking the $(p+1)$th root with $p \to \infty$ we obtain

$$|b_R(u(t))|_\infty \le e^{Lt}(|b_R(u(0))|_\infty + \varepsilon|G|_\infty) \quad \forall t \in (0, T_2). \tag{4.9}$$

Let $u(x, 0)$ satisfy the right inequality in (2.7). Then $|b_R(u(0))|_\infty < b_R(a - \frac{1}{R}) - \delta_1$ for some $\delta_1 > 0$. For ε sufficiently small, it follows from (4.9) that there exists $0 < T_3 < \infty$ such that $b_R(u(x,t)) \le b_R(a - \frac{1}{R})$ for a.e. $x \in \Omega, t \in (0, T_3)$. Because b_R is strictly increasing, we have

$$u(x,t) \le a - \frac{1}{R} \quad \text{for a.e. } x \in \Omega, t \in (0, T_3). \tag{4.10}$$

Let us set $T_1 = \min\{T_2, T_3\}$. Owing to the fact that the functions b and b_R are the same for arguments satisfying (4.4) and (4.10) simultaneously, we have that solution u of problem (2.2) is at the same time a solution of the original problem (1.1) in the interval $[0, T_1)$. □

5. Convergence of the approximation scheme (2.8)–(2.10).

Proof of Theorem 2.3. First we shall derive a priori estimates for the functions u_i, v_i. For this purpose we use the techniques from [JK2]. Let us put $\varphi = u_i$ into (2.8) for $i = 1, \dots, j$ and sum these identities. Using estimates (3.2) we obtain (for C sufficiently large)

$$\sum_{i=1}^{j}(\mu_i(u_i - v_{i-1}), u_i) + \sum_{i=1}^{j} |u_{ix}|_2^2\tau \le C + C\sum_{i=1}^{j} |u_i|_2^2\tau. \tag{5.1}$$

Using (2.10) we can rewrite the first term in (5.1) in the following way:

$$\begin{aligned} J_1 &= \sum_{i=1}^{j}\left(b_R(v_i) - b_R(v_{i-1}), (b_R(v_i) - b_R(v_{i-1}))\frac{1}{\mu_i} + v_{i-1}\right) \\ &= \sum_{i=1}^{j}\int_\Omega \frac{1}{\mu_i}(b_R(v_i) - b_R(v_{i-1}))^2 + \sum_{i=1}^{j}(b_R(v_i) - b_R(v_{i-1}), v_i) \\ &\quad - \sum_{i=1}^{j}(b_R(v_i) - b_R(v_{i-1}), v_i - v_{i-1}). \end{aligned} \tag{5.2}$$

Let us define $\Phi_R(s) = \int_0^s b_R(z)dz$, $\mathcal{B}_R(s) = b_R(s)s - \Phi_R(s)$. Because b_R is a continuous increasing function, the following inequality holds: $\Phi_R(v_i) - \Phi_R(v_{i-1}) \ge b_R(v_{i-1})(v_i - v_{i-1})$. It can be used to estimate the second summand in (5.2). We obtain

$$\begin{aligned} &\sum_{i=1}^{j}(b_R(v_i) - b_R(v_{i-1}), v_i) = (b_R(v_j), v_j) - (b_R(v_0), v_0) - \sum_{i=1}^{j}(b_R(v_{i-1}), v_i - v_{i-1}) \\ &\ge (b_R(v_j), v_j) - (b_R(v_0), v_0) - \sum_{i=1}^{j}\int_\Omega \Phi_R(v_i) - \Phi_R(v_{i-1}) = \int_\Omega \mathcal{B}_R(v_j) - \int_\Omega \mathcal{B}_R(v_0). \end{aligned}$$

The algebraic correction (2.10) and the convergence condition (2.9) imply

$$|b_R(v_i) - b_R(v_{i-1})| = |\mu_i(u_i - v_{i-1})| \le |b_R(v_{i-1} + \alpha(u_i - v_{i-1})) - b_R(v_{i-1})|.$$

Hence and from strict monotonicity of b_R we have

$$|v_i - v_{i-1}| \le |\alpha(u_i - v_{i-1})| = \frac{\alpha}{\mu_i}|b_R(v_i) - b_R(v_{i-1})|,$$

which implies

$$\left|\sum_{i=1}^{j}(b_R(v_i) - b_R(v_{i-1}), v_i - v_{i-1})\right| \le \alpha\sum_{i=1}^{j}\int_\Omega \frac{1}{\mu_i}(b_R(v_i) - b_R(v_{i-1}))^2.$$

Using it and the estimate $\mathcal{B}_R(s) = b_R(s)s - \int_0^s b_R(z)dz \ge \gamma s^2 - C$ in (5.2) we obtain

$$\begin{aligned} J_1 &\ge (1-\alpha)\sum_{i=1}^{j}\int_\Omega \frac{1}{\mu_i}(b_R(v_i) - b_R(v_{i-1}))^2 + \int_\Omega \mathcal{B}_R(v_j) - \int_\Omega \mathcal{B}_R(v_0) \\ &\ge \frac{1}{\Gamma}(1-\alpha)\sum_{i=1}^{j}|b_R(v_i) - b_R(v_{i-1})|_2^2 + \gamma|v_j|_2^2 - C. \end{aligned} \tag{5.3}$$

From (2.9) and (2.10) we have

$$\sum_{i=1}^{j} |u_i|_2^2 \tau \le 2\tau \frac{C}{\gamma^2} \sum_{i=1}^{j} |b_R(v_i) - b_R(v_{i-1})|_2^2 + 2\tau \sum_{i=1}^{j} |v_i|_2^2 + C. \tag{5.4}$$

Using (5.3) and (5.4) in (5.1) and applying Gronwall's argument we obtain a priori estimates

$$\max_{1\le i\le n} |v_i|_2^2 + \sum_{i=1}^{j} |u_{ix}|_2^2 \tau + \sum_{i=1}^{j} |b_R(v_i) - b_R(v_{i-1})|_2^2 \le C. \tag{5.5}$$

As a consequence of (5.5), (2.3), and (2.10) we have

$$\begin{gathered} \sum_{i=1}^{n} |u_i - v_{i-1}|_2^2 \le C, \quad \sum_{i=1}^{n} |v_i - v_{i-1}|_2^2 \le C, \\ \sum_{i=1}^{n} |u_i - v_i|_2^2 \le C, \quad \sum_{i=1}^{n} |u_i - u_{i-1}|_2^2 \le C, \quad |u_i|_2^2 \le C. \end{gathered} \tag{5.6}$$

The estimates (5.5) and (5.6) imply for the Rothe functions defined in (2.11) the following properties (holding uniformly for $n \ge n_0$):

$$\begin{gathered} \int_0^{T-\tau} |\overline{u}^{(n)}(t+\tau) - \overline{u}^{(n)}(t)|_2^2 dt \le \frac{C}{n}, \quad \int_I |\overline{u}_x^{(n)}(t)|_2^2 dt \le C, \\ |\overline{u}^{(n)}(t)|_2^2 \le C, \quad |\overline{v}^{(n)}(t)|_2^2 \le C \ \forall t \in I. \end{gathered} \tag{5.7}$$

Let $y_0 > 0$ be a sufficiently small real number. Let $\Omega^* \subset \Omega$ be an open subinterval of Ω, such that $\overline{\Omega^*} \subset \Omega$ and $x + y \in \Omega \, \forall x \in \Omega^* \ \forall y, |y| \le y_0$. Easily we obtain

$$\int_{\Omega^*} (\overline{u}^{(n)}(t, x+y) - \overline{u}^{(n)}(t,x))^2 dx \le |y| \int_{\Omega} (\overline{u}_x^{(n)}(t,z))^2 dz,$$

which together with the second inequality in (5.7) implies (for $|y| < y_0$)

$$\int_I \int_{\Omega^*} (\overline{u}^{(n)}(t, x+y) - \overline{u}^{(n)}(t,x))^2 dx dt \le |y| \int_I |\overline{u}_x^{(n)}(t)|_2^2 \le C|y|. \tag{5.8}$$

Then from the first inequality in (5.7) and (5.8) we have

$$\int_0^{T-z} \int_{\Omega^*} (\overline{u}^{(n)}(t+z, x+y) - \overline{u}^{(n)}(t,x))^2 dx dt \le C(z + |y|), \tag{5.9}$$

which holds uniformly due to n and $\forall\, 0 < z < z_0$, $|y| < y_0$. It follows from the third inequality in (5.7) and (5.9) that the sequence $\{\overline{u}^{(n)}(x,t)\}_{n=1}^{\infty}$ is compact in $L_2(Q_T)$. Thus there exists a subsequence of $\{\overline{u}^n\}_{n=1}^{\infty}$ which converges in $L_2(Q_T)$ to a function u. (We denote this subsequence again by $\overline{u}^{(n)}$.) Using (5.5) and (5.6) we obtain the following convergence results (in the sense of subsequences):

$$u^{(n)} \to u, v^{(n)} \to u, \overline{u}^{(n)} \to u, \overline{v}^{(n)} \to u \text{ in } L_2(Q_T), \quad \overline{u}^{(n)} \rightharpoonup u \text{ in } L_2(I, V),$$

$$b_R(u^{(n)}) \to b_R(u), b_R(v^{(n)}) \to b_R(u), b_R(\overline{u}^{(n)}) \to b_R(u), b_R(\overline{v}^{(n)}) \to b_R(u) \text{ in } L_2(Q_T). \tag{5.10}$$

Due to (2.8), (2.10), and (H1) we have

$$\sup_{\substack{\|\varphi\|\le 1\\ \varphi\in V}} \left| \left(\frac{b_R(v_i) - b_R(v_{i-1})}{\tau}, \varphi \right) \right| \le C\|u_i\|,$$

which implies $\|\delta b_R(v_i)\|_* \le C\|u_i\|$. Owing to a priori estimates (5.5) and (5.6) we obtain

$$\|\delta b_R(\overline{v}^{(n)})\|^2_{L_2(I,V^*)} = \int_I \|\delta b_R(\overline{v}^{(n)})\|^2_* dt = \sum_{i=1}^n \|\delta b_R(v_i)\|^2_* \tau \le C \sum_{i=1}^n \|u_i\|^2 \tau \le C,$$

and reflexivity of $L_2(I, V^*)$ implies $\delta b_R(\overline{v}^{(n)}) \rightharpoonup \chi$ in $L_2(I, V^*)$. Hence and from the ninth convergence result stated in (5.10) we obtain $\chi \equiv \partial_t b_R(u)$. Integrating the identity (2.8) over a subinterval $J \subset I$ we have $\forall \varphi \in V$

$$\begin{aligned} \int_J (\delta b_R(\overline{v}^{(n)}(t)), \varphi) dt + \int_J (A\overline{u}_x^{(n)}(t), \varphi_x) dt + \int_J (B\overline{u}^{(n)}(t), \varphi_x) dt \\ - \int_J (D\overline{u}^{(n)}(t), \varphi) dt = \int_J (G, \varphi) dt. \end{aligned} \tag{5.11}$$

Here taking limit for $n \to \infty$ we conclude

$$\langle \partial_t b_R(u), \varphi \rangle + (Au_x, \varphi_x) + (Bu, \varphi_x) - (Du, \varphi) = (G, \varphi) \ \forall \varphi \in V \text{ a.e. } t \in I,$$

so u is a weak solution of problem (2.2) in the sense of Definition 2.1. The convergence of the original sequences $\{u^{(n)}\}$, $\{v^{(n)}\}$, $\{\overline{u}^{(n)}\}$, $\{\overline{v}^{(n)}\}$ follows from the uniqueness argument. □

Proof of Theorem 2.4. Let us put $\varphi = \overline{u}^{(n)} - u$ and estimate the terms in (5.11) for $J \equiv (0, t)$. Due to (5.3), (5.10), and Fatou's lemma we obtain

$$\underline{\lim} \int_0^t (\delta b_R(\overline{v}^{(n)}), \overline{u}^{(n)}) ds \ge \int_\Omega \mathcal{B}_R(u(t)) dx - \int_\Omega \mathcal{B}_R(u(0)) dx$$

for a.e. $t \in I$. We have

$$\int_0^t (\delta b_R(\overline{v}^{(n)}), u) ds \to \int_0^t \langle \partial_t b_R(u), u \rangle = \int_\Omega \mathcal{B}_R(u(t)) dx - \int_\Omega \mathcal{B}_R(u(0)) dx,$$

where the last equality holds due to [ALu, Lem. 1.5]. Using the previous two estimates we have

$$\underline{\lim} \int_0^t (\delta b_R(\overline{v}^{(n)}), \overline{u}^{(n)} - u) ds \ge 0.$$

We estimate the second term in (5.11) in the following way:

$$\begin{aligned} \int_0^t (A\overline{u}_x^{(n)}, (\overline{u}^{(n)} - u)_x) ds = \int_0^t (A(\overline{u}^{(n)} - u)_x, (\overline{u}^{(n)} - u)_x) ds \\ + \textstyle\int_0^t (Au_x, (\overline{u}^{(n)} - u)_x) ds \ge q \int_0^t |(\overline{u}^{(n)} - u)_x|_2^2 - o(1), \end{aligned}$$

since $\overline{u}^{(n)} \rightharpoonup u$ in $L_2(I, V)$. In the third term we use integration *per partes* and obtain

$$\left| \int_0^t (B\overline{u}^{(n)}, (\overline{u}^{(n)} - u)_x) ds \right| = \left| \int_0^t ((B\overline{u}^{(n)})_x, \overline{u}^{(n)} - u) ds \right| = o(1)$$

because $\overline{u}^{(n)} \to u$ in $L_2(Q_T)$. It is for the same reason that the other terms in (5.11) are also of type $o(1)$. Thus we have the required result. □

Proof of Theorem 2.5. The monotonicity of the sequence $\{\mu_{i,k}\}$ from (2.9') for $k \geq k_0$ implies $\mu_{i,k} \to \mu$ pointwise in Ω. Since $\alpha\frac{\gamma}{2} \leq \mu_{i,k} \leq \Gamma$ we have $\mu_{i,k} \to \mu$ in $L_p(\Omega)\,\forall p > 1$. On the other hand, if $v_{i-1} \in L_\infty(\Omega)$, then the sequence $\{u_{i,k}\}$ is bounded in the norm of V and hence bounded in $C^{0,\overline{\delta}}(\Omega)$ with $\overline{\delta} = \frac{1}{2}$; see [KJF].

If we subtract (2.8') for $k = r, s$ and use the test function $\varphi = u_{i,r} - u_{i,s}$ we obtain

$$\alpha\frac{\gamma}{2}|u_{i,r} - u_{i,s}|_2^2 + \tau q|(u_{i,r} - u_{i,s})_x|_2^2 \leq \int_\Omega |\mu_{i,r-1} - \mu_{i,s-1}||u_{i,r} - u_{i,s}||u_{i,s} - v_{i-1}|dx$$
$$+ \tau\varepsilon C|(u_{i,r} - u_{i,s})_x|_2^2 + \tau C(\varepsilon)|u_{i,r} - u_{i,s}|_2^2.$$

Then for ε sufficiently small and $\tau \leq \tau_0$, from generalized Hölder inequality and from the imbedding of V to $L_q(\Omega)(\forall q > 1)$, we have

$$|u_{i,r} - u_{i,s}|_2^2 \leq C|u_{i,r} - u_{i,s}|_2|\mu_{i,r-1} - \mu_{i,s-1}|_4(|u_{i,s}|_4 + |v_{i-1}|_4).$$

Since the imbedding of V to $L_4(\Omega)$ is continuous, $\{u_{i,s}\}$ is bounded in $L_4(\Omega)$. Thus

$$|u_{i,r} - u_{i,s}|_2 \leq C|\mu_{i,r-1} - \mu_{i,s-1}|_4.$$

Boundedness of $\{u_{i,k}\}$ in $V \subset C^{0,\overline{\delta}}(\Omega)$ implies $u_{i,k} \to w$ in $C^{0,\delta}(\overline{\Omega})$ where $0 < \delta < \overline{\delta}$ and $w \in V \cap C^{0,\delta}(\overline{\Omega})$. Hence $u_{i,k} \rightharpoonup w$ in V, and we conclude $\mu_i \equiv \mu, u_i \equiv w$ satisfy (2.8). Moreover taking the limit $k \to \infty$ in (2.9') we have

$$\mu_i \equiv \mu \leq \frac{b_R(v_{i-1} + \alpha(u_i - v_{i-1})) - b_R(v_{i-1})}{u_i - v_{i-1}}$$

which implies (2.9). Thus the proof is complete. □

Remark 5.1. The smoothness $b \in C^2$ has been used in the convergence of the scheme (2.5). For the convergence of the approximation scheme (2.8)–(2.10) it is sufficient to assume $b \in C^1$.

6. Error estimate of the approximation scheme (2.8)–(2.10).

Proof of Theorem 2.6. Let u be a weak solution of problem (2.2) and $\overline{u}^{(n)}$ be a sequence defined in (2.11). We use the ideas from [MNV] to obtain the estimate of the rate of the convergence of $\overline{u}^{(n)}$ to u. Let us integrate the identities (2.4) and (2.8) over $(0, t)$, $t_j \leq t < t_{j+1}$ where j is fixed and subtract them. We obtain

$$\left(b_R(\overline{v}^{(n)}(t))\left(\frac{t - t_j}{\tau}\right) + b_R(\overline{v}^{(n)}(t - \tau))\left(1 - \frac{t - t_j}{\tau}\right) - b_R(u(t)), \varphi\right)$$
$$+ \left(A\int_0^t (\overline{u}^{(n)}(s) - u(s))_x ds, \varphi_x\right) + \left(B\int_0^t \overline{u}^{(n)}(s) - u(s)ds, \varphi_x\right)$$
$$- \left(D\int_0^t \overline{u}^{(n)}(s) - u(s)ds, \varphi\right) = 0.$$

Let us consider $\varphi = \overline{u}^{(n)}(t) - u(t)$ and integrate it over $(0, t)$. We obtain

$$\int_0^t \left(b_R(\overline{v}^{(n)}(s)) \left(\frac{s - t_j}{\tau} \right) + b_R(\overline{v}^{(n)}(s - \tau)) \left(1 - \frac{s - t_j}{\tau} \right) - b_R(u(s)), \overline{u}^{(n)}(s) - u(s) \right) ds$$
$$+ \int_0^t \left(A \int_0^s (\overline{u}^{(n)}(z) - u(z))_x dz, (\overline{u}^{(n)}(s) - u(s))_x \right) ds + \int_0^t \left(B \int_0^s \overline{u}^{(n)}(z) - u(z) dz, \right.$$
$$\left. (\overline{u}^{(n)}(s) - u(s))_x \right) ds - \int_0^t \left(D \int_0^s \overline{u}^{(n)}(z) - u(z) dz, \overline{u}^{(n)}(s) - u(s) \right) ds = 0. \tag{6.1}$$

Let us write it in the form $I_1 + I_2 + I_3 - I_4 = 0$ and estimate the terms. Using Young's inequality, (2.3), (5.5), and (5.6) we have

$$I_1 \geq \frac{\gamma}{2} \int_0^t |\overline{u}^{(n)}(s) - u(s)|_2^2 ds - C\tau. \tag{6.2}$$

We use the relation $\int_0^t (A \int_0^s H(z) dz, H(s)) ds = \frac{1}{2}(A \int_0^t H(s) ds, \int_0^t H(s) ds)$ with $H(s) = (\overline{u}^{(n)}(s) - u(s))_x$ to estimate the second term

$$I_2 \geq \frac{q}{2} \left| \int_0^t (\overline{u}^{(n)}(s) - u(s))_x ds \right|_2^2 . \tag{6.3}$$

Using integration *per partes* in the x variable together with periodicity we obtain

$$I_3 \leq \varepsilon \int_0^t |\overline{u}^{(n)}(s) - u(s)|_2^2 ds + C(\varepsilon) \int_0^t \left| \int_0^s \overline{u}^{(n)}(z) - u(z) dz \right|_2^2 ds$$
$$+ C(\varepsilon) \int_0^t \left| \int_0^s (\overline{u}^{(n)}(z) - u(z))_x dz \right|_2^2 ds. \tag{6.4}$$

$$I_4 \leq \varepsilon \int_0^t |\overline{u}^{(n)}(s) - u(s)|_2^2 ds + C(\varepsilon) \int_0^t \left| \int_0^s \overline{u}^{(n)}(z) - u(z) dz \right|_2^2 ds. \tag{6.5}$$

Using (6.2)–(6.5) in (6.1) we obtain

$$\int_0^t |\overline{u}^{(n)}(s) - u(s)|_2^2 ds + \left| \int_0^t (\overline{u}^{(n)}(s) - u(s))_x ds \right|_2^2 \leq C(\tau + \tau^{2d})$$
$$+ C \int_0^t \left| \int_0^s \overline{u}^{(n)}(z) - u(z) dz \right|_2^2 ds + C \int_0^t \left| \int_0^s (\overline{u}^{(n)}(z) - u(z))_x dz \right|_2^2 ds.$$

Now using Gronwall's lemma we conclude the proof. □

Remark 6.1. Similar convergence results and error estimates (as in §§5 and 6) can be obtained also for the full discretization scheme corresponding to (2.8)–(2.10). In the full discretization, the corresponding elliptic equation is projected on a finite-dimensional subspace $V_\lambda \subset V$; i.e., we look for $u_i^\lambda \in V_\lambda$ such that (2.8) is satisfied $\forall \varphi \in V_\lambda$. We have u^α in the place of $u^{(n)}$ now, with $\alpha = (\tau, \lambda)$ and $V_\lambda \to V$ for $\lambda \to 0$ (in canonical sense). We can proceed in the same way as in [JK1], [JK2], [Ha], and the error estimate

$$|u^\alpha - u|_{L_2(I, L_2)} \leq C \left(\tau + |u_0^\lambda - u_0|_2^2 + \left(\int_I |u - w^\alpha|^2 \right)^{\frac{1}{2}} + \int_I \|u - w^\alpha\|^2 \right) \forall w^\alpha \in L_2(I, V_\lambda)$$

can be obtained, provided $u_0^\lambda \in V_\lambda$, $u_0^\lambda \to u_0$ in $L_2(\Omega)$.

7. Discussion on numerical computations. This section is devoted to the presentation of numerical results obtained by approximation schemes (2.5) and (2.8)–(2.10) solving problem (1.1) in the case of anisotropic curve shortening (1.9). All results (graphically documented below) were computed by the semidiscretization (2.8)–(2.10). In each time step we used a few iterations (2.8')–(2.9') to find a couple u_i, μ_i satisfying the convergence condition (2.9). The linear convection–diffusion equation in (2.8') is solved numerically using the so-called "power-law scheme" given in [P]. Then the results were checked using the approximation scheme (2.5); in both procedures we obtained approximately the same degree of accuracy. Some first numerical results computed by approximation scheme (2.8)–(2.10) were presented in [KMi]. We refer to [D] for some other successful numerical method solving (isotropic) curve shortening flow.

First we give a comparison between the known exact results and those obtained numerically; their agreement indicates the usefulness of the method also in cases in which not even qualitative behavior is known.

Simple closed curves. In the isotropic case (1.3) of the curve shortening, a special solution is the circle shrinking in selfsimilar form to the center. Its radius $R(t)$ is then given by $R(t) = \sqrt{2(T-t)}$, where T is the duration of the shrinking. T is also the blow-up time of the corresponding curvature function $k(\theta, t) = 1/\sqrt{2(T-t)}$, which solves the curve shortening equation (1.4) and blows up in the whole interval $\Omega = [0, 2\pi]$. Figure 1 shows the evolution of the circle with $R(0) = 2$ computed by our approximation scheme. The precise blow-up time is 2.0 while the numerically calculated one (i.e., the time when the numerical curvature function is of order 10^6) is 2.02 for $\tau = 0.01$ and 2.007 time units for $\tau = 0.001$. The numerical solution is plotted each 0.2 time units up to time 1.8. In this scale, the exact and numerical solutions are precisely the same. The point in the center represents the solution in time 2.007 and it is a circle with radius about 10^{-6}.

Gage and Hamilton [GH] proved that in the isotropic case, any initial plane convex curve asymptotically behaves as a shrinking circle. Figure 2 illustrates this phenomenon. The initial ellipse gradually reaches a circular shape and finally shrinks to its center. Initially it has axes $a = 2, b = 1$ so the initial area $S(0) = 2\pi$. Because of the relation $S_t = -2\pi$ (see [GH]) we have $T = \frac{S(0)}{2\pi}$. So in our experiment $T = 1$. Numerical blow up is obtained at 1.06 for $\tau = 0.01$ and at 1.005 for $\tau = 0.001$, respectively.

The conservation of closedness of the evolving curves is another important criterion for the approximation scheme precision. In plotting time instants, the curves have been constructed from the computed curvature function $k(\theta, t)$ by (1.7); the integral in (1.7) is evaluated numerically. Because the curves are only given by (1.7) uniquely up to a translation, for determining the real evolution we need to know the motion of at least one point of the curve. For this purpose we use (1.2). Our numerical function $k(\theta, t)$ satisfies the closedness condition very precisely. Thus, on no figure the curve is split. The closedness conservation

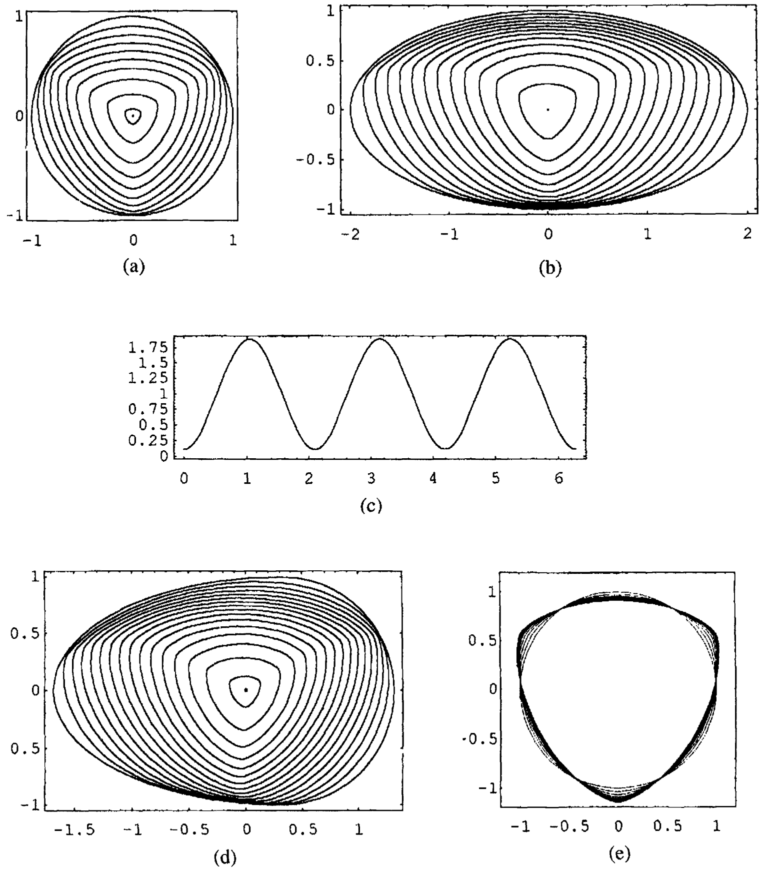

FIG. 3. (a) *Shrinking circle.* (b) *Convergence to the "oval triangle."* (c) *Coefficient* $A(x)$. (d) *Convergence to the "oval triangle."* (e) *Rescaled dynamics.*

is an intrinsic property of the schemes, so we don't have to use any supplementary means to achieve it.

Now, let us consider the anisotropic case. Owing to the data f, β, g, F describing conditions on the free boundary, evolution is more variable. Figure 3a shows the anisotropic shrinking of the circle. In this case $f(\theta) = 1 + \frac{1}{9}\cos 3\theta$, $g(\theta) = 1 - \frac{8}{9}\cos 3\theta$, $\beta(\theta) = 1$, and $F \equiv 0$. The coefficients of the general model (1.1) A, B, D, G are obtained from (1.9). Our numerical solution indicates that a certain "oval triangle" takes over the role of the shrinking circle as the asymptotical shape. In Figure 3c the function $A(x)$ in the interval $[0, 2\pi]$ is plotted. In the model, $A(x)$ represents the diffusion and shrinking terms. The evolution equation (1.2) indicates why the moving of the curve is much slower in the points with θ equal to $0, \frac{2\pi}{3}, \frac{4\pi}{3}$, where A is small, in contrast to the situation in points with θ equal to $\frac{\pi}{3}, \pi, \frac{5\pi}{3}$. Figures 3b and 3d show other initial curves's convergence to the "oval triangle" under the same data f, β, g, F. The asymptotic behavior of the shrinking curves in the anisotropic curve shortening problem has been investigated theoretically now [M]. If $F \equiv 0$ in the anisotropic case, we have for the blow-up time the relation $T = S(0)/\int_0^{2\pi} \frac{g(\theta)}{\beta(\theta)} d\theta$ (see [AG2]). For experiments from Figures 3a, 3b, and 3d the exact T is equal to 0.5, 1.0, 0.75, respectively. By approximation scheme with $\tau = 0.001$ we obtained numerical solutions

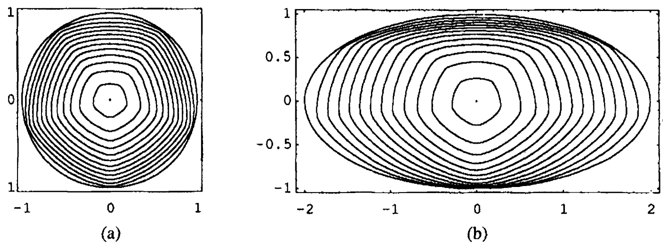

FIG. 4. (a) *Shrinking circle.* (b) *Convergence to the "oval pentagon."*

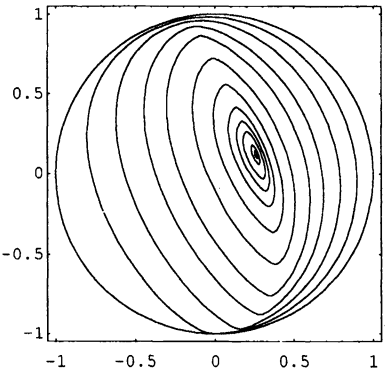

FIG. 5. *General situation of the anisotropic c.s.f.*

with numerical blow-up times 0.508, 1.007, 0.7485, respectively. For another set of data f, β, g, F, when $A(x) = 1 - \frac{5}{6}\cos 5x$, $B(x) = A'(x)$, $D(x) = A(x)$, $G \equiv 0$ the numerical evolution of the initial circle and ellipse is plotted in Figures 4a and 4b, respectively. The numerical calculations indicate that "oval pentagon" is the asymptotical shape for these coefficients. In Figure 5, the coefficients are chosen so as to illustrate the general situation of the anisotropic curve shortening flow; $f(\theta) = 1 + 0.32\cos 2\theta$, $g(\theta) = 1 - 0.96\cos 2\theta$, $\beta(\theta) = 1 + 0.5\cos(\theta - \frac{\pi}{2}) + 0.45\cos(2\theta - \frac{\pi}{2})$, $F \equiv -0.1$. This evolution seems to be a very realistic approximation of the motion of the phase interface.

Let us return to the question of the existence of the asymptotical shape for anisotropically evolving curves. Consider the special case ($F \equiv 0$), when the reference phase cannot increase in time. (For the outer evolution the asymptotical behavior is known; see [AG1], [AG2].) A circle, which is the asymptotical shape for the inner isotropic evolution, minimizes the so-called *isoperimetric ratio* $\mathrm{Iso} = L^2/4\pi S$, where L is the length of the closed curve and S is the enclosed area. For all closed plain curves we have $\mathrm{Iso} \geq 1$ and equality holds only for a circle. For a function $z = z(\theta)$, periodic in $[0, 2\pi]$, we define

$$L(z) = \int_0^{2\pi} \frac{1}{z(\theta)k(\theta)} d\theta, \tag{7.1}$$

$$S(z) = \frac{1}{2}\int_0^{2\pi} \left(\frac{\sin(\theta)}{z(\theta)k(\theta)} \int_0^{\theta} \frac{\cos(\xi)}{z(\xi)k(\xi)} d\xi - \frac{\cos(\theta)}{z(\theta)k(\theta)} \int_0^{\theta} \frac{\sin(\xi)}{z(\xi)k(\xi)} d\xi \right) d\theta \tag{7.2}$$

and call these numbers the *length* of the curve and the *area* it encompasses *with respect to the function* z, respectively. All of our numerical experiments indicate that the *isoperimetric ratio* *with respect to the function* z or the *"anisotropic isoperimetric ratio"*

$$\text{Iso}(z) = \frac{L^2(z)}{4\pi S(z)}, \tag{7.3}$$

where $z(\theta) = \frac{g(\theta)}{\beta(\theta)}$, decreases during curve evolution and converges to 1 (due to numerics approximately). The following numbers concern the same numerical experiment as plotted in Figure 3a. In this case the blow-up time $T = 0.5$. Here we give numerical values of Iso(z) for $z(\theta) = 1 - \frac{8}{9}\cos 3\theta$ in several time moments t given as subscript:

$\text{Iso}_0(z) = 1.114$, $\text{Iso}_{0.02}(z) = 1.093$, $\text{Iso}_{0.04}(z) = 1.070$, $\text{Iso}_{0.06}(z) = 1.047$, $\text{Iso}_{0.08}(z) = 1.028$, $\text{Iso}_{0.10}(z) = 1.014$, $\text{Iso}_{0.12}(z) = 1.0071$, $\text{Iso}_{0.14}(z) = 1.0031$, $\text{Iso}_{0.16}(z) = 1.0011$, $\text{Iso}_{0.36}(z) = 1.0009$, $\text{Iso}_{0.40}(z) = 1.0009$, $\text{Iso}_{0.44}(z) = 1.0009$, $\text{Iso}_{0.48}(z) = 1.0009$.

The ratio Iso(z) decreases and, from a certain time on, there is practically no change. This indicates that the shape is shrinking to a point in a selfsimilar fashion. The question arises as to whether the "oval triangle" minimizes the functional Iso(z) the way the circle minimizes Iso(1).

Let us look at the problem of the asymptotical behavior from another point of view. We consider the special case of g, β, in which $\int_0^{2\pi} \frac{g(\theta)}{\beta(\theta)} d\theta$ is equal to 2π and $F \equiv 0$. Comparing the relations for blow-up time we see that the asymptotics of the shape are different from those in the isotropic case but the growth of the maximal curvature $k_{\max}(t) = |k(\cdot, t)|_\infty$ has to be the same. So, $k_{\max}$ may not grow faster than $1/\sqrt{2(T-t)}$. Let the function $k(\theta, t)$ be the solution of (1.8). Transform the time axis by $\tau = -\frac{1}{2}\log\left(\frac{T-t}{T}\right)$ and define the *rescaled curvature* $K(\theta, \tau) = k(\theta, t)\sqrt{2(T-t)}$. Denote $z(\theta) = \frac{g(\theta)}{\beta(\theta)}$. Since

$$\begin{aligned} K_\tau = \frac{\partial K}{\partial t}\frac{\partial t}{\partial \tau} &= 2(T-t)\left(-\frac{1}{\sqrt{2T-2t}}k + \sqrt{2T-2t}\,k_t\right) \\ &= 2(T-t)\left(-\frac{1}{2T-2t}K + \sqrt{2T-2t}(k^2(zk)_{\theta\theta} + k^2(zk))\right) \\ &= 2(T-t)\left(-\frac{1}{2T-2t}K + \frac{1}{2T-2t}(K^2(zK)_{\theta\theta} + K^2(zK))\right), \end{aligned}$$

the function $K(\theta, \tau)$ is the solution of the *transformed equation*

$$\partial_\tau\left(-\frac{1}{K}\right) = (zK)_{\theta\theta} + zK - \frac{1}{K}. \tag{7.4}$$

If there exists an asymptotical shape of inner evolution with the speed $1/\sqrt{2(T-t)}$ for the given z, then the rescaled curvature of this shape is an equilibrium of equation (7.4). The following numerical experiment illustrates the previous considerations. The initial unit circle from Figure 3a remains the same after rescaling its curvature; now starting the numerical solution of the transformed equation with the same $z(\theta) = 1 - \frac{8}{9}\cos 3\theta$ we obtain the results plotted in Figure 3e. The initial circle changes to "oval triangle" form, where the changes are slower and slower so that we have finally an accentuated steady-state shape whose curvature is the equilibrium of (7.4). The agreement of this steady-state "oval triangle" and the asymptotical shape from Figure 3a may be seen from the evolution of numerical Iso(z) in the rescaled dynamics:

$\text{Iso}_0(z) = 1.114$, $\text{Iso}_{0.04}(z) = 1.072$, $\text{Iso}_{0.08}(z) = 1.033$, $\text{Iso}_{0.12}(z) = 1.011$, $\text{Iso}_{0.16}(z) = 1.003$, $\text{Iso}_{0.20}(z) = 1.0008$, $\text{Iso}_{0.50}(z) = 1.0008$, $\text{Iso}_{0.60}(z) = 1.0009$, $\text{Iso}_{0.70}(z) = 1.0009$, $\text{Iso}_{0.80}(z) = 1.0010$, $\text{Iso}_{0.90}(z) = 1.0010$, $\text{Iso}_{1.0}(z) = 1.0010$.

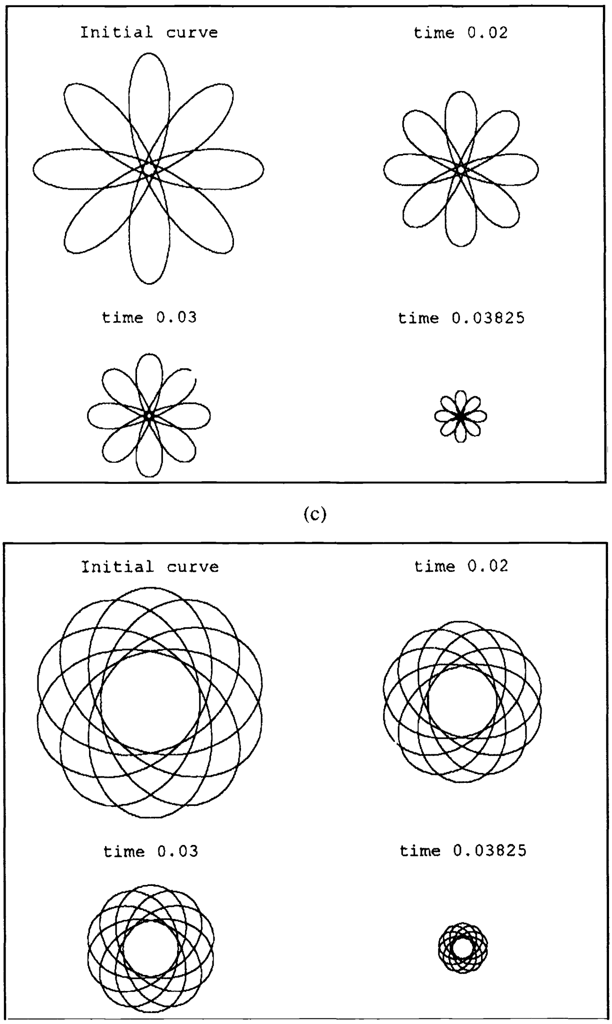
FIG. 8.

Closed plain immersed curves. If the index ν of the initial curve is greater than 1 then qualitatively new types of behavior are possible. First we consider the isotropic case. If the initial curve has self-intersections, then the corresponding solution can become singular without shrinking to a point. Figure 6a illustrates the case in which the initial "loops" contract faster than the whole curve and become a so-called *formation of the singularities* in the curve shortening flow. This behavior was studied mainly by Angenent in [A1]. Figure 6b represents this process for another immersed curve with greater inside curvature until the time when the singular curve is formed. The singularities in the form of "hairs" correspond to a blow up of the curvature function $k(\theta, t)$ in several subintervals of Ω. (Every one of these intervals has measure greater than π.) In Figures 6a and b and also in Figures 7–9, we have plotted the initial curve, three states of evolution reconstructed from the numerical solution, the last of which is very near to a blow-up time. As may be seen from previous figures, the ratio of the maximal and minimal curvatures is large and growing quickly in time. In spite of this, our approximation schemes lead to precise results, as can be checked by conservation of curve closedness also very near to the blow up.



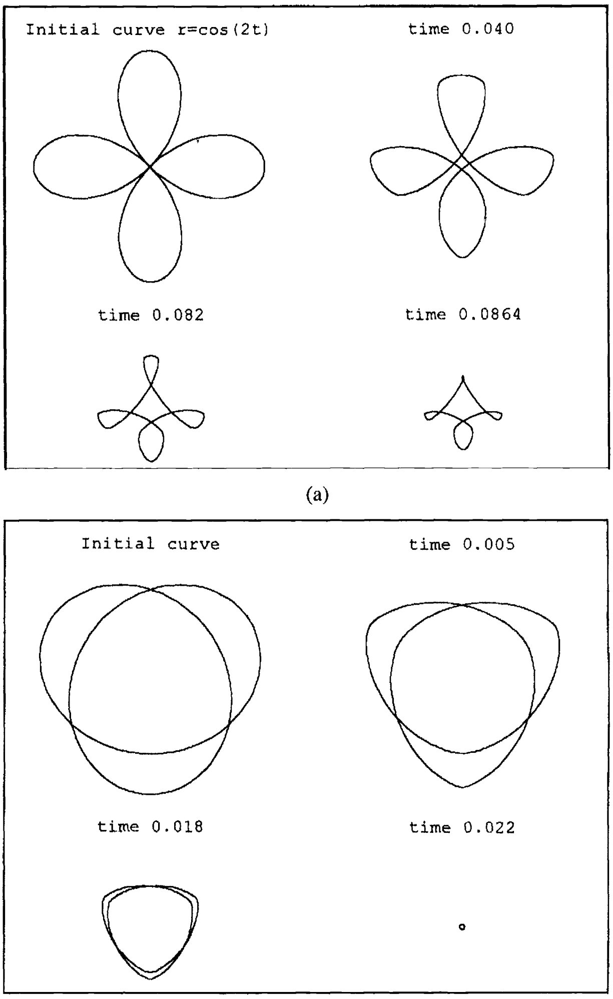
(c)

(d)

FIG. 8. *(cont.)*

Also, in the case in which $\nu > 1$, behavior similar to a shrinking of the simple closed curves into a point is possible. It can happen only in cases in which the maximal curvature does not grow faster than $1/\sqrt{2(T-t)}$. The special initial curve with $\nu = 2$ from Figure 7 gradually winds itself about the circle with index 2 before shrinking to a point. The corresponding curvature function has the blow up in the whole of Ω.

A part of the boundary between the previous two dynamics is formed by the curves which shrink to a point in a selfsimilar manner. This behavior was studied in [ALa] and [EW]. For initial curve $\mathbf{r}$, denote by $n \in \mathbb{N}$ the number of periods of its curvature function $k(\theta)$ in Ω. For curves from Figures 6a–8d it means number of loops. Abresch and Langer [ALa] have shown that, for every integer couple ν, n satisfying $1/2 < \nu/n < \sqrt{2}/2$, there exists one curve which is the homothetic solution of the isotropic curve shortening flow problem. If we add to them the circles with all indexes $\nu \in \mathbb{N}$ we obtain all the so-called *Abresch–Langer functions*. They are steady states of the rescaled equation (7.4) with $z \equiv 1$. Dynamics of



(a)

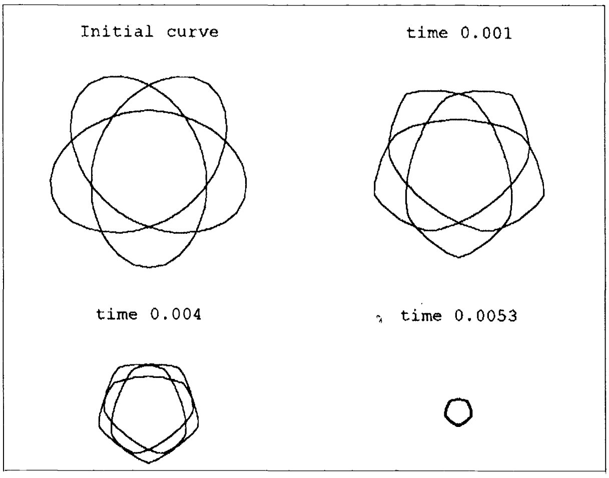
(b)

FIG. 9.

several "almost homothetic solutions" computed by our approximation scheme are plotted in Figures 8a–d.

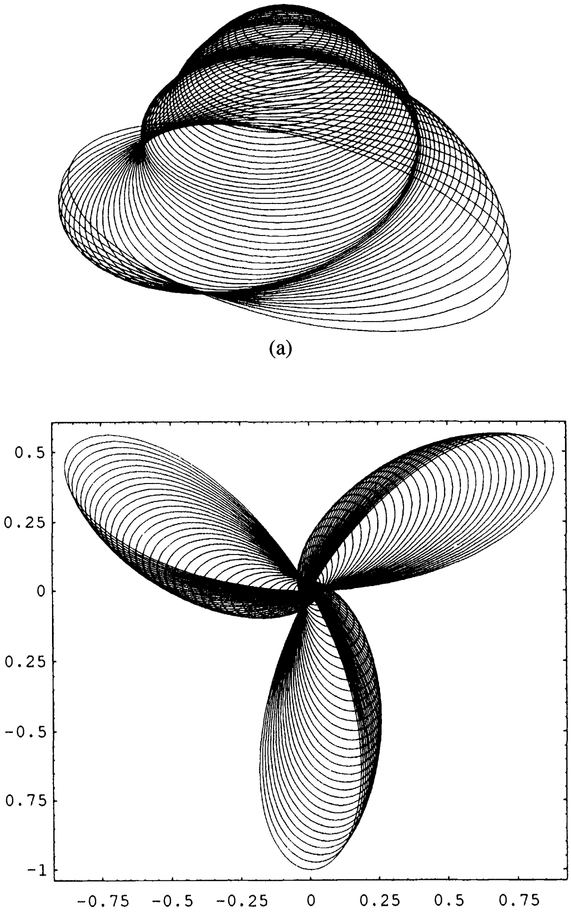
Figures 9a–c concern the anisotropic curve shortening of immersed curves. In Figures 9a–b the evolution is governed by the set of data known from Figures 3a–e, when the asymptotical behavior was the "oval triangle." The curves of Figures 9a–b exhibit a similar tendency. In the first experiment from Figure 9a, the curve becomes singular and one "hair" singularity is eventually formed. The second initial curve from Figure 9b gradually winds itself about this "oval triangle" with index 2 and then shrinks to a point. Winding about the "oval pentagon" with index 3 is shown in Figure 9c. (The coefficients of the model are the same as in experiments documented in Figures 4a and b.) Equilibriums of equation (7.4) with $z \neq 1$ constitute certain generalizations of the Abresch–Langer functions.

Shrinking with supplementary convection term. Let us consider problem (1.1) in the case of (1.9) with one exception, namely $B(x) = (g/\beta)_x + B_1(x)$ for $B_1(x)$ bounded



(c)

FIG. 9. *(cont.)*



(a)

(b)

FIG. 10. *Shrinking circle.*

measurable function periodic in interval $[0, 2\pi\nu]$. Then equation (1.1) can be written in the form (writing k instead of v)

$$\partial_t\left(-\frac{1}{k}\right) = \left(\frac{gk-F}{\beta}\right)_{xx} + \left(\frac{gk-F}{\beta}\right) + (B_1k)_x. \tag{7.5}$$

Equation (7.5) is a certain generalization of the anisotropic curve shortening where we have a supplementary convection term. Our theoretical results guarantee the local existence of a solution and also convergence of approximations. So, such problems can be handled numerically. A question arises whether the found solution satisfies the closedness condition and hence whether it could represent in a sense the evolving phase interface. Several curves which do not split during such "shrinking and whirling around the curve" are presented in Figures 10a and b. As seen in these last figures, if $B_1(x)$ is a positive constant then the curve rotates counterclockwise.

OSCILLATION ABSORPTION FINITE ELEMENT METHODS FOR CONVECTION–DIFFUSION PROBLEMS*

W. LAYTON[†] AND B. POLMAN[‡]

Abstract. This paper proposes a new approach to eliminating overshoots and undershoots when using finite element methods (FEM) for convection-dominated convection–diffusion problems. The first scheme involves an additional nonlinear "absorption" term which frequently improves the solution quality of both the usual Galerkin FEM and the streamline diffusion FEM. Mathematical support for the method is given in the form of global estimates for the overshoot, undershoot, and the basic error in the approximate solution. Although nonlinear, the additional term is in fact *monotone*. Another approach is to strongly impose zero overshoot and undershoot via a variational inequality formulation. Finally we consider the possibility of variational inequality postprocessing to remove overshoots and undershoots.

Key words. convection–diffusion, nonlinear absorption, monotone operators

AMS subject classifications. 65N12, 65N30

1. Introduction.

This paper considers the finite element approximation of convection–diffusion problems, such as

$$\text{(1.1)} \qquad \begin{cases} -\epsilon\Delta u + a_1u_x + a_2u_y + gu = f(x,y) & \text{for } (x,y)\in\Omega\subset\mathbb{R}^2, \\ u(x,y)=\alpha(x,y) & \text{for } (x,y)\in\partial\Omega. \end{cases}$$

In (1.1) $\vec{a} = (a_1, a_2)$ represents a known convection field transporting a substance whose concentration is given by $u(x, y)$, ϵ is a (small) diffusion coefficient, and $g(x, y)$ is a linear absorption term. The method studied involves adding to a standard Galerkin finite element method (FEM) or streamline diffusion FEM an additional nonlinear absorption term $(A(u^h), v)$. This term has the effect of eliminating overshoots and undershoots in the concentration $u(x, y)$. These overshoots and undershoots are well known to cause difficulties when (1.1) is coupled with, for example, chemical reaction terms.

There exist well-known flux-splitting finite difference methods for 1-dimensional conservation laws which do not introduce nonphysical maxima. These are typically extended to 2-dimensions via operator splitting along coordinate directions and applying the 1-dimensional methods in each coordinate direction; see, e.g., [4, 17] for representative examples. Finite element research has taken a slightly different tack, focusing on arbitrary order methods applicable to complex geometries and unstructured meshes. This approach has given rise to the streamline diffusion method of [8]. The success of both approaches for problems closely related has inspired attempts at obtaining a synthesis of the best features of both, e.g., [9, 15]. One possible synthesis of the two methods is to solve the linear system iteratively (or, equivalently, by imbedding it in an evolutionary problem) and, at each step, eliminating out-of-range answers as they occur. This is exactly equivalent to solving a variational inequality approximation by a projective iterative method; see §3.

To present the new method, and a first example, let $\Pi^h(\Omega)$ be an edge-to-edge triangulation of Ω with maximum triangle diameter h. $X^h(\Omega)$ will denote a typical Lagrange-type finite element space associated with $\Pi^h(\Omega)$. In our examples we shall take conforming C^0-piecewise linears for $\Pi^h(\Omega)$, any degree being possible in principle. The combinations of nonlinear

absorption plus both the usual Galerkin and the streamline diffusion FEMs are studied herein, as well as two related ideas. For example, the usual Galerkin FEM plus artificial absorption computes $u^h \in X^h(\Omega)$ via the following: for all $v \in X^h(\Omega) \cap H^1(\Omega)$,

$$(1.2) \qquad \begin{cases} (\epsilon \nabla u^h, \nabla v) + (\vec{a} \cdot \nabla u^h + g u^h, v) + (A(u^h), v) = (f, v), \\ u^h(N_j) = \alpha(N_j) \quad \text{for all nodes } N_j \text{ on } \partial\Omega. \end{cases}$$

The term $(A(u^h), v)$, given by (1.5) below, incorporates into (1.2) the fact that global bounds of the form $u_{\min} \le u(x, y) \le u_{\max}$ are known for the true solution, and the approximate solution should satisfy these bounds as well. Consider the following first (favorable) example.

Example 1.1. The following problem was solved on a uniform rectilinear mesh, each square divided into two triangles, using conforming linears with (a) standard Galerkin FEM and (b) standard Galerkin FEM with the oscillation absorption term added, method (1.2). The parameter values were $h = \frac{1}{25}$, $\epsilon = 10^{-3}$, $\Omega = (0, 1) \times (0, 1)$, $a_1(x, y) = c(1 - cx)$, $a_2(x, y) = s(1 - sy)$, where $c = \cos\theta$, $s = \sin\theta$, and $\theta = 210°$ (this is the test problem in [2]). Consider

$$(1.3) \qquad \begin{cases} -\epsilon \Delta u + a_1(x, y) u_x + a_2(x, y) u_y = 0 & \text{for } (x, y) \in \Omega, \\ u(x, y) = \alpha(x, y) & \text{for } (x, y) \in \partial\Omega, \end{cases}$$

where $\alpha(x, y) = 1$, if $12y - 5x \ge .3$, $\alpha(x, y) = 0$ otherwise. The maximum principle immediately gives $0 \le u(x, y) \le 1$ for the true solution to (1.3). This information is incorporated into the absorption term via

$$A(u)(x, y) := \rho^{-1} \left[\min\{u(x, y), 0\} + \max\{u(x, y) - 1, 0\}\right],$$

where ρ was chosen (see §§2 and 4) to be $\rho = h^2$.

The difference between Figures 1a and 1b is enormous. In §4 a comparison is also given with the streamline diffusion FEM and the streamline diffusion FEM with the $(A(u^h), v)$ term added.

The basic principle of (1.2) is that L^∞-information from the continuous problem can be incorporated in a *consistent*, *highly accurate* manner into (1.2) via the additional $(A(u^h), v)$ term. Suppose, for example, that the maximum principle for (1.1) gives the bounds

$$(1.4) \qquad u_{\min} \le u(x, y) \le u_{\max}, \qquad (x, y) \in \bar{\Omega}$$

for the true solution to (1.1). Then $A(u)$ is given by

$$(1.5) \qquad A(u)(x, y) := \rho^{-1} \left[\min\{u(x, y) - u_{\min}, 0\} + \max\{u(x, y) - u_{\max}, 0\}\right],$$

where ρ is a "small" parameter. There are many applications where bounds of the form (1.4) are immediate, for example natural convection, see [3], possibly including convection–diffusion of a pollutant as well.

Note that $A(u)$ is a penalty-type term. In §2 mathematical support for the addition of the $(A(u), v)$ term to both the usual Galerkin and the streamline diffusion formulations of (1.1) is given. Note that (1.5) is the usual penalty term employed in approximating *variational inequality* problems. Thus, associated with (1.2) is another method based upon imposing the constraint (1.4) strongly via a variational inequality formulation. Based upon the fact that the true solution lies in the relevant constraint set, optimal order estimates are given for the variational inequality approach in §3.

Additionally, there are at least two attractive generalizations of (1.2), (1.4), (1.5) involving further subdivisions of, respectively, the range of u and the domain Ω. These two will now be briefly described. A more detailed treatment is beyond the scope of this report.

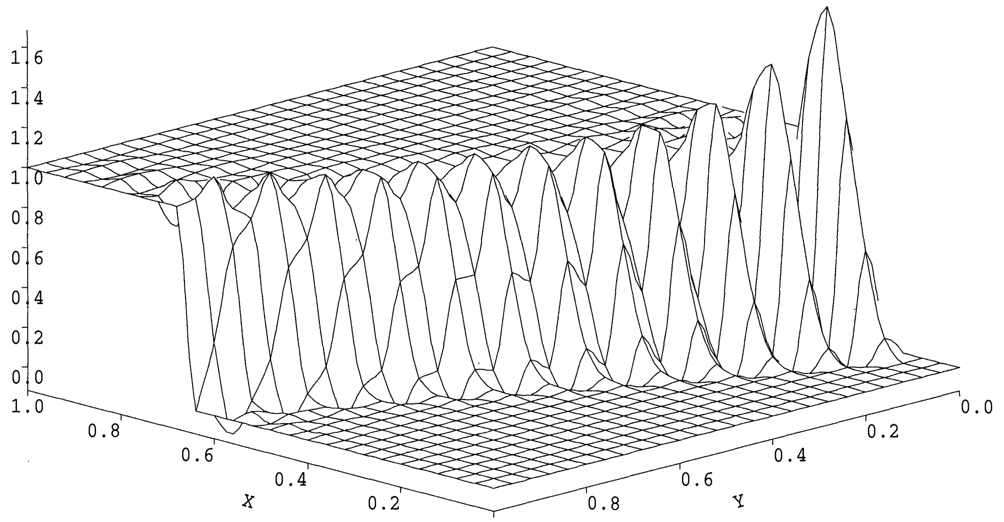

FIG. 1a. *Usual Galerkin FEM approximation to problem* (1.3).

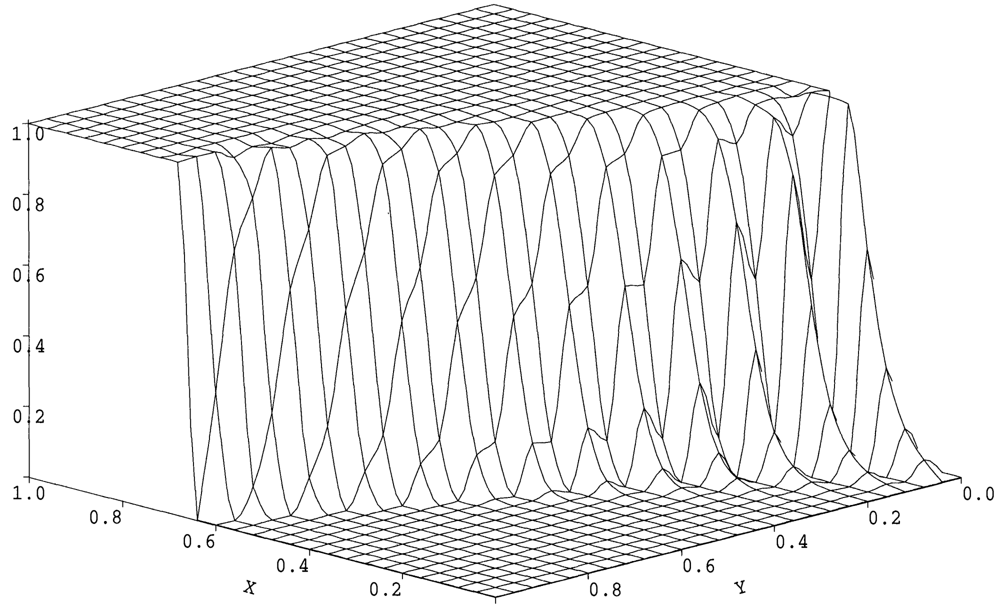

FIG. 1b. *Oscillation absorption FEM approximation* (1.2) *to problem* (1.3).

Generalization 1: Range decompositions. Consider the problem with no internal sources: seek $u(x, y)$ satisfying

$$-\epsilon\Delta u + au_x + bu_y = 0 \quad \text{in } \Omega, \qquad u = g \quad \text{on } \partial\Omega,$$

where, for compactness, $0 \leq g(x, y) \leq 1$ (and hence $0 \leq u(x, y) \leq 1$) in $\bar{\Omega}$. For a positive integer J decompose the range of u by $0 = U_0 < U_1 < \cdots < U_J = 1$. This induces an additive decomposition of the boundary data

$$g(x, y) = \sum_{j=1}^{J} g_j(x, y) \quad \text{with } g_j \in C^0(\partial\Omega)$$

and $U_0 \leq g_j(x, y) \leq (U_j - U_{j-1})$ by

$$U_{j-1} + g_j(x, y) = \begin{cases} U_{j-1} & \text{if } g(x, y) \leq U_{j-1}, \\ g(x, y) & \text{if } U_{j-1} \leq g(x, y) \leq U_j, \\ U_j & \text{if } g(x, y) \geq U_j. \end{cases}$$

A corresponding additive decomposition of the solution is induced, $u(x, y) = \sum_{j=1}^{J} u_j(x, y)$, where $u_j(x, y)$ satisfies

$$(1.6) \qquad -\epsilon\Delta u_j + a u_{j,x} + b u_{j,y} = 0 \quad \text{in } \Omega, \quad u_j = g_j \quad \text{on } \partial\Omega,$$

so that

$$(1.7) \qquad 0 \leq u_j(x, y) \leq (U_j - U_{j-1}).$$

The J uncoupled problems (1.6) can now be solved subject to the constraint (1.7), either strongly or weakly imposed as in §§2 and 3 to give u_j^h. Thereupon the global approximate solution is reassembled as $u^h = \sum_{j=1}^{J} u_j^h$. In this way, oscillations around certain critical solution values (the U_j's) can be eliminated.

Generalization 2: Further division of Ω. If Ω_j denotes possibly overlapping subdomains of Ω, $\Omega = \bigcup_{j=1,J} \Omega_j$, the term $A(u)$ could be modified to read

$$\begin{aligned} A(u)(x, y) := \rho^{-1}[&\min\{u(x, y) - \min\{u(x, y) \mid (x, y) \in \partial\Omega_j\}, 0\} \\ &+ \max\{u(x, y) - \max\{u(x, y) \mid (x, y) \in \partial\Omega_j\}, 0\}] \quad \text{for } (x, y) \in \Omega_j. \end{aligned} \tag{1.8}$$

In the limiting case where for each node N_j, $\Omega_j = \Omega(N_j)$ is the union of the triangles containing N_j, (1.8) resembles a "flux limiter," well known in finite difference theory.

The analysis herein is, however, restricted to the problems $\Omega_j \equiv \Omega$ (§2) and $\Omega_j \equiv \Omega$ and $\rho \to 0$ (§3).

Numerical experiments are given in §4. Provided one has estimates of $u_{\max}$ and $u_{\min}$, improvement in solution quality is consistently seen. Sometimes the improvement is quite dramatic and sometimes it is only moderate. In all cases, overshoots and undershoots are eliminated. In some cases, however, oscillations between the correct maximum and minimum values persist when using the usual (centered) Galerkin FEM. In these first experiments, damped Newton methods were used to solve the nonlinear penalized problem (without spectacular efficiency for the Galerkin FEM). Since the nonlinear term makes the system "more" monotone, there are other attractive and highly parallel solution procedures which are to be recommended; see [12, 13].

2. Mathematical support for the nonlinear absorption term. For brevity in the presentation, consider the problem with homogeneous, boundary conditions:

$$(2.1) \qquad \begin{cases} L_\epsilon u \equiv -\epsilon\Delta u + \vec{a} \cdot \nabla u + gu = f & \text{in } \Omega \text{ (polygonal domain in } \mathbb{R}^d), \\ u = 0 & \text{on } \partial\Omega, \\ g - \frac{1}{2}\text{div}(\vec{a})^t \geq g_{\min} \geq 0 & \text{in } \Omega. \end{cases}$$

We suppose á priori bounds on the true solution to (2.1) are known and given by (1.4):

$$(2.2) \qquad (-\infty \leq) u_{\min} \leq u(x, y) \leq u_{\max} (\leq +\infty), \qquad (x, y) \in \bar{\Omega}.$$

Let $X = \mathrm{H}_0^1(\Omega)$ and X^h denote a conforming finite element space, then $X^h \subset X$, where h represents a typical maximum element diameter. The method is now given as follows. Suppose that the true solution of (2.1) satisfies, for all $v \in X$,

$$B(u, v) = F(v), \tag{2.3}$$

where $B(u, \cdot)$ is linear on X and $F(\cdot)$ is a bounded linear functional on X.

Choose a small parameter $\rho > 0$ and define, for $w \in X$,

$$A(w)(\underline{x}) := \rho^{-1}\left[(w(\underline{x}) - u_{\min})_- + (w(\underline{x}) - u_{\max})_+\right], \tag{2.4}$$

where we use the notation $v_- = \min\{v, 0\}$ and $v_+ = \max\{v, 0\}$. We consider an approximation of the following form. For $B^h(\cdot, \cdot) : X \times X \mapsto \mathbb{R}$ and $F^h(\cdot) : X \mapsto \mathbb{R}$ continuous bilinear and linear, respectively,

$$\left\{\begin{array}{l} \text{seek } u^h \in X^h \text{ satisfying} \\ B^h(u^h, v) + (A(u^h), v) = F^h(v) \quad \forall v \in X^h. \end{array}\right. \tag{2.5}$$

We shall suppose that there are norms $\|\cdot\|_a, \|\cdot\|_b$ on X equivalent to the H^1-norm, such that

$$\left\{\begin{array}{ll} B^h(w, w) \geq C_1\|w\|_a^2 & \forall w \in X, \\ B^h(w, v) \leq C_2\|w\|_a\|v\|_b & \forall v, w \in X, \end{array}\right. \tag{2.6}$$

where C_1, C_2 are constants which as we shall see later can be chosen independent of h and ϵ in our applications. The question of existence of a solution to the nonlinear problem (2.5) is resolved in the following proposition.

PROPOSITION 2.1. *Assume* (2.6) *holds. Let $T^h : X^h \mapsto X^h$ be defined by*

$$(T^h(w), v) := B^h(w, v) + (A(w), v) \quad \forall v \in X^h. \tag{2.7}$$

Then T^h is well defined and strictly monotone for all $v, w \in X^h$,

$$(T^h(v) - T^h(w), v - w) \geq C_1\|v - w\|_a^2 + \frac{1}{\rho}\|v - w\|_{L^2(\Omega_1)}^2,$$

where $\Omega_1 := \{\underline{x} \in \Omega \mid [v(\underline{x}) < u_{\min}$ and $w(\underline{x}) < u_{\min}]$ or $[v(\underline{x}) > u_{\max}$ and $w(\underline{x}) > u_{\max}]\}$. Similarly, we can let $T : X \mapsto X$ be defined by

$$(T(w), v) := B^h(w, v) + (A(w), v) \quad \forall v \in X.$$

If (2.2) *holds, then for all $v \in X$,*

$$(T(v) - T(u), v - u) \geq C_1\|v - u\|_a^2 + \frac{1}{\rho}\left\{\|\min\{v - u_{\min}, 0\}\|^2 + \|\max\{v - u_{\max}, 0\}\|^2\right\}.$$

Proof. First note that as (2.7) is linear and continuous in v, T^h is well defined by the Riesz representation theorem. Further the $A(\cdot)$ term in (2.7) satisfies

$$(A(v) - A(w), v - w) \geq \frac{1}{\rho}\|v - w\|_{L^2(\Omega_1)}^2 \quad \forall v, w \in X$$

(note that a simple calculation shows that we only get the L^2-norm over Ω_1) and for all $v \in X$ (note that $A(u) = 0$),

$$(A(v) - A(u), v - u) \geq \frac{1}{\rho}\left\{\|\min\{v - u_{\min}, 0\}\|^2 + \|\max\{v - u_{\max}, 0\}\|^2\right\}.$$

Combining these two inequalities with coercivity of $B^h(\cdot,\cdot)$ demonstrates the claimed monotonicity. □

COROLLARY 2.1. *Supposing* (2.6) *holds,* $u^h \in X^h$*, the solution of* (2.5)*, exists uniquely.*

Proof. This proof follows immediately from monotonicity of T^h and classical results of Minty [14]. □

Since the operator T is monotone, standard techniques can be used to obtain an error bound. Adapting these appropriately yields the next theorem.

THEOREM 2.1. *Suppose* (2.6) *and* (2.2) *hold. Then there exists a constant C independent of* ρ *and h such that*

$$\begin{aligned}\|u-u^h\|_a^2 + \frac{1}{\rho}\|(u^h-u_{\min})_-\|^2 + \frac{1}{\rho}\|(u^h-u_{\max})_+\|^2 \\ \le C \inf_{\chi\in X^h}\left\{\|u-\chi\|_a^2 + \|u-\chi\|_b^2 + \frac{1}{\rho}\|u-\chi\|_{L^2(\Omega)}^2\right\} \\ + C\left\{\sup_{w^h\in X^h}\frac{|[B^h-B](u,w^h)|}{\|w^h\|_a}\right\}^2 \\ + C\left\{\sup_{w^h\in X^h}\frac{|[F^h-F](w^h)|}{\|w^h\|_a}\right\}^2.\end{aligned} \tag{2.8}$$

Proof. Let $e = u^h - u$ and for $\chi \in X^h$, $\eta = \chi - u$ and $\phi = u^h - \chi$. Then from Proposition 2.1,

$$\begin{aligned}C_1\|e\|_a^2 + \frac{1}{\rho}\|(u^h-u_{\min})_-\|^2 + \frac{1}{\rho}\|(u^h-u_{\max})_+\|^2 \\ \le (T(u^h)-T(u), u^h-u) \\ = (T(u^h)-T(u), u^h-\chi) + (T(u^h)-T(u), \chi-u).\end{aligned} \tag{2.9}$$

Consider the first term of the right-hand side (RHS) as $A(u)\equiv 0$ and u^h satisfies (2.5):

$$\begin{aligned}(T(u^h)-T(u),\phi) &= B^h(e,\phi) + (A(u^h),\phi) \\ &= B^h(u^h,\phi) - B^h(u,\phi) + F^h(\phi) - B^h(u^h,\phi) + [B(u,\phi)-F(u)] \\ &= [B-B^h](u,\phi) + [F^h-F](\phi) \\ &\le \left(\sup_{w^h\in X^h}\frac{[B^h-B](u,w^h)}{\|w^h\|_a}\right)\|\phi\|_a + \left(\sup_{w^h\in X^h}\frac{[F^h-F](w^h)}{\|w^h\|_a}\right)\|\phi\|_a \\ &\le [C_B + C_F]\,(\|u-\chi\|_a + \|e\|_a),\end{aligned} \tag{2.10}$$

where $C_B := \sup_{w^h\in X^h}\frac{[B^h-B](u,w^h)}{\|w^h\|_a}$ and $C_F := \sup_{w^h\in X^h}\frac{[F^h-F](w^h)}{\|w^h\|_a}$.

Now consider the second term on the RHS of (2.9):

$$\begin{aligned}(T(u^h)-T(u),\chi-u) &= B^h(e,\eta) + (A(u^h),\eta) \\ &\le C_2\|e\|_a\|\eta\|_b + \|A(u^h)\|\|\eta\| \\ &\le C_2\|e\|_a\|\eta\|_b + \frac{1}{\rho}\Big(\|(u^h-u_{\min})_-\| + \|(u^h-u_{\max})_+\|\Big)\|\eta\|\end{aligned}$$

$$\le C_2\|e\|_a\|\eta\|_b + \frac{1}{4\rho}\Big(\|(u^h - u_{\min})_-\| + \|(u^h - u_{\max})_+\|\Big)^2 + \frac{1}{\rho}\|\eta\|^2$$

$$\le C_2\|e\|_a\|\eta\|_b + \frac{1}{2\rho}\Big(\|(u^h - u_{\min})_-\|^2 + \|(u^h - u_{\max})_+\|^2\Big) + \frac{1}{\rho}\|\eta\|^2. \tag{2.11}$$

Inserting (2.10) and (2.11) into (2.9) yields

$$C_1\|e\|_a^2 + \frac{1}{2\rho}\Big(\|(u^h - u_{\min})_-\|^2 + \|(u^h - u_{\max})_+\|^2\Big)$$
$$\le C_2\|e\|_a\|\eta\|_b + [C_B + C_F](\|\eta\|_a + \|e\|_a) + \frac{1}{\rho}\|\eta\|^2.$$

Hiding the $\|e\|_a$ terms in the left-hand side (LHS) and taking the infimum over $\chi \in X^h$ yields (2.8). □

As an application of Theorem 2.1, we give the error estimates which (2.8) yields when applied to the usual Galerkin method and the streamline diffusion method by using C^0 conforming linear elements.

COROLLARY 2.2. *Suppose* $B^h(v, w) = B(v, w) = \int_\Omega \epsilon\nabla v\nabla w + (\vec{a}\nabla v + gv)w dx\, g_{\min} > 0$, *and* $F^h(w) = F(w) = \int_\Omega f w dx$. *Then* $u - u^h$ *satisfies*

$$\epsilon\|\nabla(u - u^h)\|^2 + \|u - u^h\|^2 + \frac{1}{\rho}\|(u^h - u_{\min})_-\|^2 + \frac{1}{\rho}\|(u^h - u_{\max})_+\|^2$$
$$\le C \inf_{\chi\in X^h}\left\{2\epsilon\|\nabla(u - \chi)\|^2 + (2 + \epsilon^{-1} + \rho^{-1})\|u - \chi\|^2\right\}. \tag{2.12}$$

Proof. Set $\|w\|_a^2 := \epsilon\|\nabla w\|^2 + \|w\|^2$ and $\|w\|_b^2 := \epsilon\|\nabla w\|^2 + (1 + \epsilon^{-1})\|w\|^2$. Then (2.6) is fulfilled with C_1 and C_2 independent of ϵ and h and the result follows directly from Theorem 2.1. □

For the streamline diffusion method a weighting parameter $\delta = O(h)$ is selected. For a detailed discussion of streamline diffusion methods, see [2, 8, 10]. The presentation of this method is a bit simpler when using for X^h the space of C^0 conforming piecewise linears. The main idea is to embed (2.1) into

$$-\delta\nabla\cdot(\vec{a}L_\epsilon u) + L_\epsilon u = -\delta\nabla\cdot(\vec{a}f) + f \tag{2.13}$$

which is consistent with the original problem if u is sufficiently smooth ($u \in H^2(\Omega)\cap \mathrm{H}_0^1(\Omega)$). This leads to the following variational formulation:

$$B_\delta(u, v) = F_\delta(v) \qquad \forall v \in \mathrm{H}_0^1(\Omega), \text{ for } u \in H^2 \cap \mathrm{H}_0^1(\Omega),$$

where

$$B_\delta(u, v) := \int_\Omega \epsilon\nabla u\nabla v - \epsilon\delta(\Delta u)\vec{a}\cdot\nabla v + (\vec{a}\cdot\nabla u + gu)(v + \delta\vec{a}\cdot\nabla v)dx, \tag{2.14a}$$

$$F_\delta(v) := \int_\Omega f(v + \delta\vec{a}\cdot\nabla v)dx. \tag{2.14b}$$

Using linear basisfunctions this results in

$$B_\delta^h(u, v) = F_\delta^h(v) \qquad \forall v \in X^h,$$

where

$$B_\delta^h(w^h, v^h) := \int_\Omega \epsilon \nabla w^h \nabla v^h + (\vec{a} \cdot \nabla w^h + g w^h)(v^h + \delta \vec{a} \cdot \nabla v^h) dx, \tag{2.15a}$$

and

$$F_\delta^h(v^h) := F_\delta(v^h). \tag{2.15b}$$

Note that in B_δ^h we have dropped the term $\epsilon\delta(\Delta u)\vec{a} \cdot \nabla v$. This is due to the fact that if we write the integral over Ω as a sum of integrals over the elements, then in each element $\Delta v \equiv 0$, where v is a linear basisfunction.

COROLLARY 2.3. *Let X^h be the space of C^0 conforming piecewise linear basisfunctions and $\delta = O(h)$, where h is the maximum triangle diameter. Let B_δ, B_δ^h, F_δ, and F_δ^h as in* (2.14), (2.15). *Then*

$$B_\delta(u, v) = B_\delta^h(u, v) - \epsilon\delta \int_\Omega (\Delta u)\vec{a} \cdot \nabla v dx$$

and the error in method (2.5) *satisfies*

$$\begin{aligned} &\epsilon \|\nabla(u - u^h)\|^2 + \delta \|\vec{a} \cdot \nabla(u - u^h)\|^2 + \|u - u^h\|^2 + \frac{1}{\rho}\|(u^h - u_{\min})_-\|^2 + \frac{1}{\rho}\|(u^h - u_{\max})_+\|^2 \\ &\leq C \inf_{\chi \in X^h} \left\{2\epsilon \|\nabla(u - \chi)\|^2 + 2\delta \|\vec{a} \cdot \nabla(u - \chi)\|^2 + (2 + \delta^{-1} + \rho^{-1})\|u - \chi\|^2\right\}. \end{aligned} \tag{2.16}$$

Proof. Set

$$\|w\|_a^2 := \epsilon \|\nabla w\|^2 + \delta \|\vec{a} \cdot \nabla w\|^2 + \|w\|^2,$$
$$\|w\|_b^2 := \epsilon \|\nabla w\|^2 + \delta \|\vec{a} \cdot \nabla w\|^2 + (1 + \delta^{-1})\|w\|^2.$$

Again (2.6) is fulfilled and the result follows by Theorem 2.1. □

Formally balancing terms on the RHS of (2.12) and (2.16) suggests the following scaling for the penalty parameter ρ.

Usual Galerkin FEM + penalty term.

$\epsilon = O(1) \Rightarrow \rho = O(h^2)$,

$\epsilon = O(h) \Rightarrow \rho = O(h)$,

$\epsilon \leq O(h^2) \Rightarrow \rho = O(\epsilon)$.

Streamline diffusion FEM + penalty term.

$\rho = O(\delta) = O(h)$.

In our first experiments, however, solution quality did not seem very sensitive to the actual choice of ρ, unlike the convergence of the damped Newton solution procedure employed (only in the case of the usual Galerkin method).

3. The variational inequality approach. For compactness of exposition, assume that the boundary conditions are homogeneous and that one knows á priori a closed, convex set $\mathbb{K}$ in $\mathrm{H}_0^1(\Omega)$ in which the true solution lies. Therefore, consider

$$\begin{cases} -\epsilon\Delta u + \vec{a} \cdot \nabla u + g u = f(x, y) & \text{in } \Omega \subset \mathbb{R}^d, \\ u = 0 & \text{on } \partial\Omega. \end{cases} \tag{3.1}$$

Assume $g - \frac{1}{2}\mathrm{div}(\vec{a})^t \geq g_{\min} \geq 0$ in $\bar{\Omega}$ and that, á priori, the true solution of (3.1) satisfies

$$u \in \mathbb{K}, \quad \mathbb{K} \subset \mathrm{H}_0^1(\Omega) \text{ a closed, convex set.} \tag{3.2}$$

LEMMA 3.1. *Suppose the true solution u of* (3.1), (3.2) *satisfies the following variational equality: for X a Hilbert space, $u \in X$,*

$$B(u, v) - F(v) = 0 \quad \forall v \in X, \tag{3.3}$$

where $B(u, v)$ is a continuous and coercive bilinear form,

$$|B(u, v)| \leq C_2(\epsilon)\|u\|_X\|v\|_X, \quad |B(w, w)| \geq C_1(\epsilon)\|w\|_X^2 \qquad \forall v, w \in X, \tag{3.4}$$

and $F(v)$ is a bounded linear functional on X. If $\mathbb{K} \subset X$ is a closed convex set in X, then the variational inequality

$$\begin{cases} \text{seek } \tilde{u} \in \mathbb{K} \text{ satisfying} \\ B(\tilde{u}, v - \tilde{u}) - F(v - \tilde{u}) \geq 0 \quad \forall v \in \mathbb{K} \end{cases} \tag{3.5}$$

has a unique solution $\tilde{u}$. If $u \in \mathbb{K}$, then $\tilde{u} \equiv u$.

Proof. Existence and uniqueness of $\tilde{u}$ in (3.5) follows from (3.4) and standard results in variational inequalities; see Kinderlehrer and Stampacchia [11, Chap. 2, Thm. 2.1]. Likewise, existence and uniqueness for (3.3) follows by the Lax–Milgram lemma. As (3.3) and $u \in \mathbb{K}$ imply that u satisfies (3.5), necessarily $u = \tilde{u}$. □

Next, consider the error in approximating the solution of the variational inequality (3.5). Since we wish to include both streamline diffusion and usual Galerkin FEMs, the classic error analysis of Falk [6] and Mosco and Strang [16] must be enlarged a bit to include perturbations of the bilinear forms, nonsymmetric problems, and the dependence upon ϵ in the final estimates. To this end, suppose the true solution $u \in X$ to the problem satisfies the following *variational equality*:

$$B(u, v) = F(v) \quad \forall v \in X, \tag{3.6}$$

where $B(u, \cdot) : X \mapsto \mathbb{R}$ is linear and $F : X \mapsto \mathbb{R}$ is a linear functional. Likewise, let $X^h \subset X$ be a closed subspace and define

$$\mathbb{K}^h := X^h \cap \mathbb{K}, \qquad \mathbb{K} \text{ a closed, convex set in } X. \tag{3.7}$$

We assume $\mathbb{K}^h \neq \emptyset$ and $u \in \mathbb{K}$. The approximate solution we consider is calculated via the following variational *inequality*:

$$\begin{cases} \text{find } u^h \in \mathbb{K}^h \text{ satisfying} \\ B^h(u^h, v^h - u^h) - F^h(v^h - u^h) \geq 0 \quad \forall v^h \in \mathbb{K}^h, \end{cases} \tag{3.8}$$

where $B^h : X^h \times X^h \mapsto \mathbb{R}$, $F^h : X^h \mapsto \mathbb{R}$ are, respectively, bilinear and linear functionals approximating $B(\cdot, \cdot)$ and $F(\cdot)$. $B^h(\cdot.\cdot)$ is assumed to satisfy the following.

Assumption 3.1. There are norms $\|\cdot\|_a$, $\|\cdot\|_b$ on X such that for positive constants $C_{1,2}$, independent of h and ϵ,

$$B^h(w, w) \geq C_1\|w\|_a^2 \qquad \forall w \in X,$$
$$B^h(v, w) \leq C_2\|v\|_a\|w\|_b \qquad \forall v, w \in X.$$

THEOREM 3.1. *Suppose Assumption* 3.1 *holds. Then, $u^h \in \mathbb{K}^h$ satisfying* (3.8) *exists and is unique. Further, if $u \in \mathbb{K}$, then the error $u - u^h$ satisfies*

$$\|u - u^h\|_a \leq C_2C_1^{-1} \inf_{\chi \in \mathbb{K}^h} \|u - \chi\|_b + 2C_1^{-1} \sup_{w^h \in X^h} \frac{[F - F^h](w^h)}{\|w_h\|_a}$$
$$+ 2C_1^{-1} \sup_{w^h \in X^h} \frac{[B^h - B](u, w^h)}{\|w_h\|_a}.$$

Proof. Letting $\chi \in \mathbb{K}^h$ be arbitrary, expand the error inequality as follows:

$$\begin{aligned} C_1\|u-u^h\|_a^2 &\le B^h(u-u^h, u-u^h) \\ &= B^h(u-u^h, u-\chi) - B^h(u^h, \chi-u^h) + B^h(u, \chi-u^h) \\ &\le B^h(u-u^h, u-\chi) + F(\chi - u^h) - F^h(\chi - u^h) + [B^h - B](u, \chi-u^h) \end{aligned}$$

using (3.8), (3.6)

$$\le C_2\|u-u^h\|_a\|u-\chi\|_b + \sup_{w^h\in X^h}\frac{[F-F^h](w^h)}{\|w_h\|_a}\|\chi-u^h\|_a + \sup_{w^h\in X^h}\frac{[B^h-B](u,w^h)}{\|w_h\|_a}\|\chi-u^h\|_a.$$

Now insert $\|\chi-u^h\|_a \le \|u-u^h\|_a + \|u-\chi\|_a$ and divide by $\|u-u^h\|_a$ in the resulting inequality. Taking the infimum over χ yields

$$C_1\|u-u^h\|_a \le C_2\inf_{\chi\in\mathbb{K}^h}\|u-\chi\|_b + 2\sup_{w^h\in X^h}\frac{[F-F^h](w^h)}{\|w_h\|_a} + 2\sup_{w^h\in X^h}\frac{[B^h-B](u,w^h)}{\|w_h\|_a},$$

which is the claimed error estimate. □

Remark 3.1. The conditions in Assumption 3.1 can be relaxed somewhat. For example, essentially the same result holds if X is replaced by X^h in Assumption 3.1. On the other hand, if coercivity is weakened to the inf-sup condition, a similar error estimate can be given but *existence* of the approximate solution (to (3.8)) is then an open question.

As applications of Theorem 3.1, consider the bilinear forms $B^h(\cdot,\cdot)$ based upon (1) the usual Galerkin FEM and (2) the streamline diffusion FEM by using linear elements.

Example 3.1. *The usual Galerkin FEM.* In the usual Galerkin FEM with exact integration $B^h(\cdot,\cdot) = B(\cdot,\cdot)$, $F^h(\cdot) = F(\cdot)$, $\|w\|_a^2 := \epsilon\|\nabla w\|^2 + \|w\|^2$, and $\|w\|_b^2 := \epsilon\|\nabla w\|^2 + (1+\epsilon^{-1})\|w\|^2$. The constants $C_{1,2}$ are $O(1)$ constants provided $g_{\min} > 0$.

COROLLARY 3.1. *Suppose* $g_{\min} > 0$, *then the error in* (3.8) *when using the usual Galerkin formulation satisfies*

$$\left[\epsilon\|\nabla(u-u^h)\|^2 + \|u-u^h\|^2\right]^{\frac{1}{2}} \le C\inf_{\chi\in\mathbb{K}^h}\left[\epsilon\|\nabla(u-\chi)\|^2 + (1+\epsilon^{-1})\|u-\chi\|^2\right]^{\frac{1}{2}}.$$

Example 3.2. *The streamline diffusion FEM.* For $u \in H^2(\Omega)\cap \mathrm{H}_0^1(\Omega)$, the solution of the continuous problem satisfies the following: for $\delta > 0$, a parameter

$$B_\delta(u,v) = F_\delta(v) \qquad \forall v \in \mathrm{H}_0^1(\Omega), \text{ for } u \in H^2\cap\mathrm{H}_0^1(\Omega),$$

with B_δ and F_δ as defined in (2.14). The streamline diffusion formulation of (3.8) with *linear* elements is defined as follows: seek $u^h \in \mathbb{K}^h$ satisfying

$$B_\delta^h(u^h, v^h-u^h) \ge F_\delta^h(v^h-u^h) \qquad \forall v^h \in \mathbb{K}^h, \tag{3.9}$$

with B_δ^h and F_δ^h as defined in (2.15). With

$$\begin{aligned} \|w\|_a^2 &:= \epsilon\|\nabla w\|^2 + \delta\|\vec{a}\cdot\nabla w\|^2 + \|w\|^2, \\ \|w\|_b^2 &:= \epsilon\|\nabla w\|^2 + \delta\|\vec{a}\cdot\nabla w\|^2 + (1+\delta^{-1})\|w\|^2 \end{aligned}$$

as the choice of norms, B_δ^h satisfies Assumption 3.1 provided $g_{\min} > 0$. Note that $[F - F^h] \equiv 0$ and $[B_\delta - B_\delta^h](u, w^h) = -\epsilon\delta \int_\Omega \Delta u(\vec{a} \cdot \nabla w^h)dx$ which we can bound by the following:

$$\left|[B_\delta - B_\delta^h](u, w^h)\right| \leq \epsilon\delta \|\Delta u\| \|\vec{a} \cdot \nabla w^h\| \leq \epsilon\delta^{\frac{1}{2}} \|\Delta u\| \|w^h\|_a.$$

Using these estimates in Theorem 3.1, we state our next corollary.

COROLLARY 3.2. *Suppose* $g_{\min} > 0$. *Then, method* (3.9) *satisfies*

$$\begin{aligned}\left[\epsilon\|\nabla(u - u^h)\|^2 + \delta\|\vec{a} \cdot \nabla(u - u^h)\|^2 + \|u - u^h\|^2\right]^{\frac{1}{2}} \\ \leq C \inf_{\chi \in \mathbb{K}^h} \left[\epsilon\|\nabla(u - \chi)\|^2 + \delta\|\vec{a} \cdot \nabla(u - \chi)\|^2 \right. \\ \left. + (1 + \delta^{-1})\|u - \chi\|^2\right]^{\frac{1}{2}} + C\epsilon\delta^{\frac{1}{2}}\|\Delta u\|.\end{aligned}$$

Remark 3.2. *Concerning the interpolation error in* $\mathbb{K}^h$. The above global estimates involve terms of the form $\inf_{v^h \in \mathbb{K}^h} \|u - v^h\|_b$. It seems to be an open question to give an asymptotic estimate of this for elements where the usual nodal basisfunctions are not nonnegative. For conforming linears, for example, if $u \in \mathbb{K}$ then $I^h(u)$, the usual nodal interpolant of u, lies in $\mathbb{K}^h$ so the infimum over K^h will yield the same asymptotic error estimates as the infimum over X^h. For more general elements, the estimates that are known, see, e.g., Wong [18], can be summarized in the following lemma.

LEMMA 3.2. *Suppose* X *is a separable Hilbert space,* $\mathbb{K} \subset X$ *is a closed, nonempty, convex subset of* X. *Let* X^h, $0 \leq h \leq 1$, *be a nested* 1*-parameter family of finite-dimensional subspaces which become dense in* X *as* $h \to 0$. *If the interior of* $\mathbb{K}$ *is nonempty, then for* $h \leq h_0$, $K^h := \mathbb{K} \cap X^h$ *is nonempty. If additionally,* $u \in \operatorname{Int}(\mathbb{K})$, *then there is an* h_1, *such that for* $h \leq h_1 (\leq h_0)$,

$$\inf_{V^h \in \mathbb{K}^h} \|u - v^h\|_X \leq C(1 + \|u\|_X) \inf_{w^h \in X^h} \|u - w^h\|_X.$$

Proof. This is proven in Wong [18]. □

Unfortunately, the application of this lemma is highly restricted due to the assumption that Int($\mathbb{K}$) is nonempty. We state the following well-known fact for completeness.

LEMMA 3.3. *Let* Ω *be a domain with smooth boundary and* $\mathbb{K} = \{v \in H^1(\Omega) \mid 0 \leq v \leq 1\}$. *Then, if* $\Omega \subset \mathbb{R}^1$, Int($\mathbb{K}$) *is nonempty. If* $\Omega \subset \mathbb{R}^d$, $d > 1$, Int($\mathbb{K}$) *is empty.*

Proof. The first claim follows from the Sobolev embedding theorem. The second follows since there are functions in $H^1(\Omega)$ for $d > 1$ with $\|\phi\|_1 = 1$ yet ϕ is unbounded. Thus, if $u \in \mathbb{K}$, $(u + \epsilon\phi) \notin \mathbb{K}$ for any $\epsilon > 0$ and Int($\mathbb{K}$) is empty. □

4. Numerical experiments. We present a few numerical examples which illustrate the approaches of the previous sections. The elimination of the overshoots and undershoots is illustrated as well as improvement in the approximate solution between its maximum and minimum values. The test problem considered is the problem in Example 1.1:

$$\begin{cases} -\epsilon\Delta u + a_1(x, y)u_x + a_2(x, y)u_y = 0 & \text{for } (x, y) \in \Omega = [0, 1]^2, \\ u(x, y) = \alpha(x, y) & \text{for } (x, y) \in \partial\Omega, \end{cases} \tag{4.1}$$

where $a_1(x, y) = c(1 - cx)$, $a_2(x, y) = s(1 - sy)$, where $c = \cos\theta$, $s = \sin\theta$ (note that $\underline{\nabla} \cdot \vec{a} = -1$ so that the associated bilinear form is coercive). On the boundary we have $\alpha(x, y) = 1$ if $12y - 5x \geq .3$, $\alpha(x, y) = 0$ otherwise.

The problem is discretized using the standard Galerkin FEM and the streamline diffusion FEM by using the standard linear nodal basisfunctions $\{\phi_i^h\}_{i=1}^N$ on a uniform mesh of isosceles right-angled triangles. This leads to a nonsymmetric linear system of equations (for more details on the actual implementation, see [2])

$$K_h \underline{x}^h = \underline{f}^h \tag{4.2}$$

which we solve by a generalized conjugate gradient method with either a point incomplete (for the Galerkin method) or a block incomplete (for the streamline diffusion method) factorization as preconditioner (see [1] and [2]). To implement our new method, we only have to add the nonlinear absorption term to the system (4.2). To simplify the practical implementation, we replace the terms

$$\int\!\!\int_{\Omega} \left(A\left(\sum_{i=1}^{N} x_i^h \phi_i^h \right), \phi_j^h \right) d\Omega \tag{4.3}$$

which are close to $M_h \tilde{A}(\underline{x}^h)$, where M_h is the finite element mass matrix, $(M_h)_{i,j} = (\phi_i^h, \phi_j^h)$, and $\tilde{A} : \mathbb{R}^N \mapsto \mathbb{R}^N$ is defined by

$$\tilde{A}(\underline{x}^h)_i = \frac{1}{\rho}[\min\{x_i^h, 0\} + \max\{x_i^h - 1, 0\}], \qquad i = 1, 2, \ldots, N, \tag{4.4}$$

by just $h^2 \tilde{A}(\underline{x}^h)$ (the h^2 term stems from the scaling of M_h).

It is easy to verify that this corresponds with a monotone operator so the theory of §2 remains applicable. Adding the term $h^2 \tilde{A}(\underline{x}^h)$ to (4.2) yields the following *nonlinear* nonsymmetric system of equations to be solved:

$$K_h \underline{x}^h + h^2 \tilde{A}(\underline{x}^h) = \underline{f}^h. \tag{4.5}$$

Equivalently, seek a zero of the functional $\mathcal{F} : \mathbb{R}^N \mapsto \mathbb{R}^N$ defined by

$$\mathcal{F}(\underline{x}^h) = K_h \underline{x}^h + h^2 \tilde{A}(\underline{x}^h) - \underline{f}^h. \tag{4.6}$$

In these preliminary tests we solved this by a damped Newton method. For a detailed analysis of this type of method see, for instance, [5]. We like to remark here that we have not tried to find an optimal solution method for this system since our main interest here lies in the actual solution; on the other hand, in most cases the solution procedure was in fact very efficient. The damped Newton method employed takes the following form:

```
Choose $\underline{x}^{(0)}$, $k = 0$
DO
    Solve for $\underline{d}^{(k)}$ : $\left[ K_h + \frac{h^2}{\rho} D_h(\underline{x}^{(k)}) \right] \underline{d}^{(k)} = -\mathcal{F}(\underline{x}^{(k)})$
    $\underline{x}^{(k+1)} = \underline{x}^{(k)} + \tau_k \underline{d}^{(k)}$
    $k = k + 1$
WHILE ( $\|\mathcal{F}(\underline{x}^{(k)})\|_2 > 10^{-4}$ ),
```

where $D_h(\underline{x})$ is a diagonal matrix defined by

$$(D_h(\underline{x}))_{i,i} = \begin{cases} 1 & \text{if } x_i < 0 \text{ or } x_i > 1, \\ 0 & \text{otherwise.} \end{cases}$$

The damping parameter τ_k is determined by a line search with the objective of decreasing $\|\mathcal{F}(\underline{x})\|_2$. One can easily verify that the computed Newton direction is a descent direction for $\|\mathcal{F}(\underline{x})\|_2$ at $\underline{x}^{(k)}$ so that there exist $\tau_k > 0$ for which $\|\mathcal{F}(\underline{x}^{(k+1)})\|_2 < \|\mathcal{F}(\underline{x}^{(k)})\|_2$. In all cases $\tau_k = 1$ (i.e., a full Newton step) is tried first. If this gives a decrease in $\|\mathcal{F}(\underline{x})\|_2$, it is accepted; otherwise, a backtrack algorithm is used based on quadratic and, if necessary, cubic interpolation.

In the following tables we display the infinity norm and the discrete L_2-norm of the undershoots and overshoots of the solutions of (4.1) and (4.5). Furthermore we give the number of Newton iterations (it_N) and the average number of conjugate gradient iterations per Newton step (it_{CG}). Tables 1 and 2 correspond to the Galerkin FEM formulation with $\theta = 60°$ and $\theta = 210°$ and Tables 3 and 4 correspond to the streamline diffusion formulation. In these tables we have chosen the parameter ρ in accordance with the remark at the end of §2. That is, $\rho = O(h)$ for the streamline diffusion formulation, and $\rho = O(h^2)$ if $\epsilon > h$, $\rho = O(\epsilon)$ otherwise for the Galerkin formulation.

In each of these tables, we display

$$\begin{array}{c|c} \|(\underline{x}^h)_-\|_\infty & \|(\underline{x}^h)_+\|_\infty \\ \hline \|(\underline{x}^h)_-\|_{L_2} & \|(\underline{x}^h)_+\|_{L_2} \end{array}$$

first for the solution of (4.1) and below we give the number of iterations for the solution of (4.5).

Note that when $it_N = 0$, it_{CG} is precisely the number of iterations needed to solve problem (4.1). In those cases the diffusion is large enough to avoid overshoots and undershoots. In Tables 1 and 2 we have not included the results for $\epsilon = 10^{-5}$ since in that case the solution of problem (4.1), that is, the standard Galerkin formulation, is extremely oscillatory and the Newton process for the solution of problem (4.5) starting with this initial guess converges very slowly. Furthermore, the preconditioner used for this problem behaves very poorly so every

iteration in the Newton process becomes very costly. Further investigations for this specific case are needed; here our main interest is in showing the feasibility of our approach.

Finally, in Table 5 we show the norms of overshoots and undershoots for varying ρ for the streamline diffusion FEM for the same model problem with $\theta = 210°$, $n = 64$, and $\epsilon = 1E{-}3$. From this table we clearly see the linear dependence on ρ.

To conclude this section we show in Figures 2a and 2b the typical qualitative improvement when adding the nonlinear absorption term to problem (4.1) in the case of a streamline diffusion approximation. In §2 we already saw an example for the Galerkin FEM approximation.

To show the local nature of the absorption term added, we show in Figure 2c the overshoot and undershoot and in Figure 2d we show the final nonlinear absorption term in the Newton process.

5. Overshoot and undershoot elimination by postprocessing. At this stage it is difficult to attribute the large number of iterations in the case of the Galerkin FEM formulation to anything except the lack of computational experience with highly nonsymmetric variational inequalities. It is possible that the solution of highly nonsymmetric variational inequalities can be circumvented if the basic, linear method produces a moderately accurate approximate solution. In this case the overshoots and undershoots can likely be eliminated by postprocessing via a symmetric variational inequality. Suppose that an approximation $u^h \in X^h(\Omega) \subset X$ is calculated by

$$B(u^h, v) = F(v), \qquad v \in X^h. \tag{5.1}$$

Here (5.1) is a nonsymmetric *linear* system. Now consider postprocessing u^h to produce an approximate solution $\Pi u^h \in \mathbb{K}^h$. The simplest method to program is simply to cut u^h off at $u_{\max}$ and $u_{\min}$ when $u^h > u_{\max}$ and $u^h < u_{\min}$, respectively. Perhaps this is acceptable; however, we study a different postprocessor for which mathematical support can be given and which does not require significantly more programmer time and computational effort than the simple clipping procedure.

Let $a(\cdot,\cdot)$ denote a *symmetric* coercive and continuous bilinear form on X. Then Π^h will denote the projection of X^h onto $\mathbb{K}^h$.

DEFINITION 5.1. *Given* $w^h \in X^h$, $\Pi^h w^h \in \mathbb{K}^h$ *is the unique element of* $\mathbb{K}^h$ *satisfying*

$$\|w^h - \Pi^h w^h\|_A = \inf_{\chi \in \mathbb{K}^h} \|w^h - \chi\|_A,$$

where $\|v\|_A = a(v, v)^{1/2}$ *is the induced norm.*

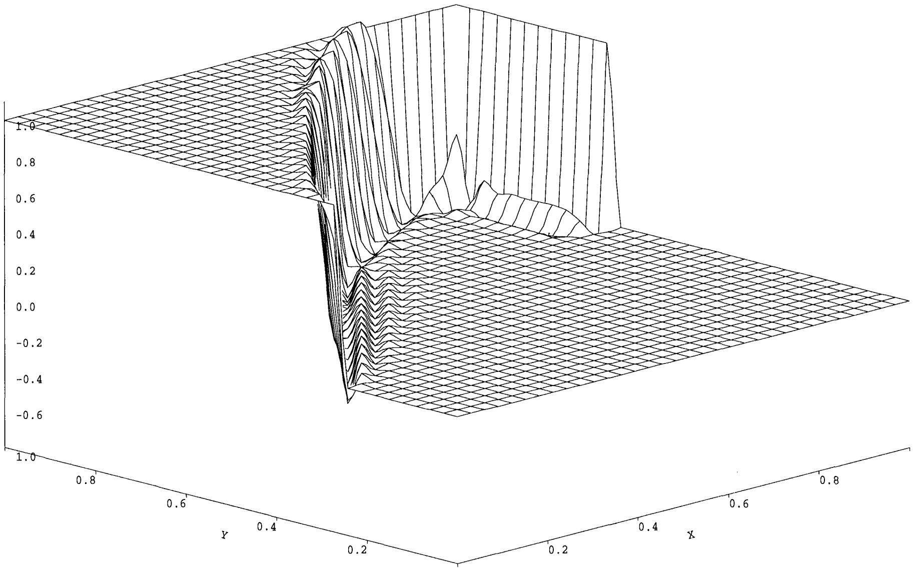

FIG. 2a. *Streamline diffusion FEM approximation to problem* (4.1).

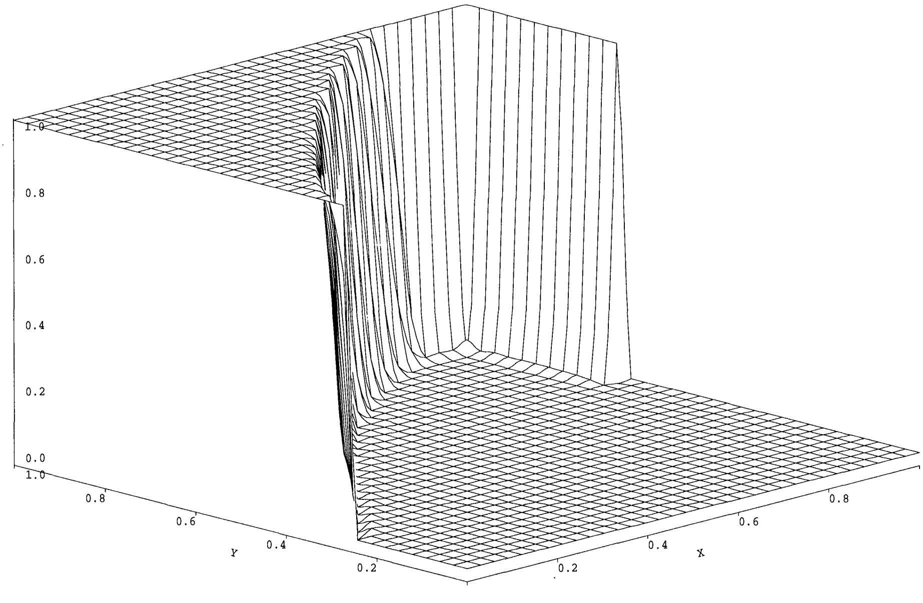

FIG. 2b. *Oscillation absorption FEM approximation to problem* (4.5).

A typical choice of $a(\cdot, \cdot)$ will be the symmetric part of $B^h(\cdot, \cdot)$,

$$a(u, v) = \frac{1}{2}(B^h(u, v) + B^h(v, u)),$$

or the $L^2(\Omega)$-inner product.

LEMMA 5.1. *Let $\mathbb{K}^h$ be closed and convex in X^h. Then $\Pi^h w^h$ exists and is unique.*

Proof. This follows immediately from the fact that a closed convex set in a Hilbert space has a unique element of minimal norm. □

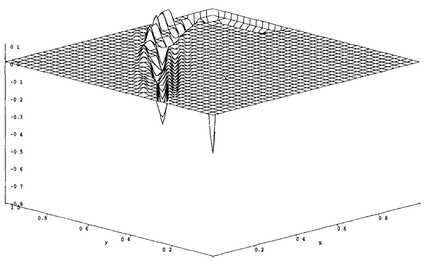

FIG. 2c. *Overshoot and undershoot in* 2a.

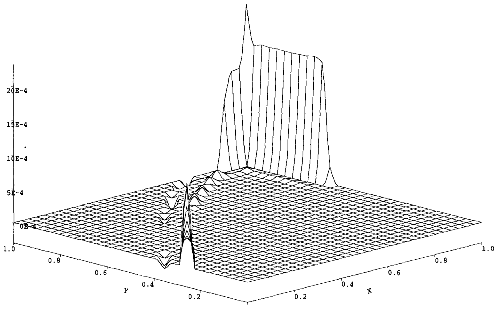

FIG. 2d. *Final nonlinear absorption term.*

$\Pi^h w^h$ is characterized by the following variational inequality: given $w^h \in X^h$, seek $\Pi^h w^h \in \mathbb{K}^h$ satisfying

$$a(w^h - \Pi^h w^h, \Pi^h w^h - v) \geq 0 \qquad \forall\, v \in \mathbb{K}^h. \tag{5.2}$$

Since $a(\cdot,\cdot)$ is symmetric, this variational inequality can be solved quite efficiently by a projected iterative method; see, e.g., Glowinski, Lions, Trémolières [7]. We propose computing the projection of u^h on $\mathbb{K}^h$ by means of a truncated projective iterative method. First note that $\Pi^h u^h$, defined by (5.2), has an error optimality property.

PROPOSITION 5.1. *Let $u^h \in X^h \subset X$ be an approximation to $u \in \mathbb{K} \subset X$. Suppose $\mathbb{K}$ is a closed, convex set and $\mathbb{K}^h := X^h \cap \mathbb{K}$ is nonempty. Then,*

$$\|u - \Pi^h u^h\|_A \leq 2\|u - u^h\|_A + \inf_{\chi \in \mathbb{K}^h} \|u - \chi\|_A.$$

Proof.

$$\begin{aligned} \|u - \Pi^h u^h\|_A &\leq \|u - u^h\|_A + \|u^h - \Pi^h u^h\|_A \\ &\leq \|u - u^h\|_A + \|u^h - \chi\|_A \end{aligned}$$

for any $\chi \in \mathbb{K}_h$

$$\leq \|u - u^h\|_A + \|u^h - u\|_A + \|u - \chi\|_A. \qquad \square$$

Remark 5.1. In the generality of the previous proposition, neither $\|u - u^h\|_A$ nor $\inf_{\chi \in \mathbb{K}^h} \|u - \chi\|_A$ may be omitted from the RHS of the inequality. This can be seen quite easily in planar examples where X^h is a line and K^h is an ellipse.

However, there are quite a few special situations in which the infimum over K^h may be replaced by an infimum over X^h. This is clear, e.g., for conforming linear finite element spaces; see Mosco and Strang [16]. For more general finite element spaces X^h, we refer to Lemma 3.2.

Concerning the calculation of $\Pi^h u^h$, note that since $a(\cdot,\cdot)$ is symmetric and positive definite, $\Pi^h u^h$ can be calculated using a projected iterative method. Letting $\{\phi_i\}$ be a basis for X^h and $A_{i,j} = a(\phi_i, \phi_j)$, suppose the constraint for $w^h = \sum_{j=1}^N c_j \phi_j(x)$ to be in $\mathbb{K}^h$ is equivalent to the coefficient bounds

$$\alpha_j \leq c_j \beta_j.$$

This holds for the standard nodal basis for conforming linears with $\alpha_j = u_{\min}$ and $\beta_j = u_{\max}$, since in that case $\phi_j(x)$ satisfies $0 \leq \phi_j(x) \leq 1$. With the pointwise projection $P_N : \mathbb{R}^N \mapsto$

($\prod_{j=1}^{N}[\alpha_j, \beta_j]$) defined by

$$(P_N x)_j = \begin{cases} x_j & \text{if } \alpha_j . \leq x_j \leq \beta_j, \\ \alpha_j & \text{if } x_j \leq \alpha_j, \\ \beta_j & \text{if } x_j \geq \beta_j, \end{cases}$$

the iterative method (projected successive overrelaxation) where $u^h = \sum d_j \phi_j$ and $\vec{f} = A\vec{d}$ now reads as follows: Given $\omega \in (0, 2)$, $\vec{c}^0 = (c_1^0, c_2^0, \ldots, c_N^0)^t$ satisfying $\alpha_j \leq c_j^0 \leq \beta_j$ define $\vec{c}^{n+1}$, $n = 0, 1, \ldots$, by

$$\text{(5.3)} \qquad \begin{cases} c_i^{n+\frac{1}{2}} = -\frac{1}{a_{i,i}} \left[\sum_{j=1}^{i-1} a_{i,j} c_j^{n+\frac{1}{2}} + \sum_{j=i+1}^{N} a_{i,j} c_j^n - f_i \right], \\ c_j^{n+1} = P_N \left[(1-\omega) c_i^n + \omega c_i^{n+\frac{1}{2}} \right]. \end{cases}$$

This is very cheap and produces an approximation in $\mathbb{K}^h$ which is close to u^h even when a few (O(1)) iterations are performed. Therefore we propose postprocessing u^h to get an approximate $\Pi^h u^h$ by applying O(1) iterations of (5.3) to (5.2). We will report on this later.

6. Conclusions. We have considered a special purpose numerical technique which is adapted to convective transport problems. Adding a nonlinear absorption term to the variational formulation of a convective transport problem effectively eliminates overshoots and undershoots in the approximate solution. With the streamline diffusion method as a basic discretization, the introduced nonlinearity causes very little increase in computational complexity. With the usual (centered) Galerkin discretization, the greatest computational challenge is simply finding a good preconditioner for the linearized problem. The usefulness of the variational inequality approach is currently limited by the lack of good iterative methods for highly nonsymmetric variational inequalities. One possible way around this difficulty is to postprocess the approximate solution using by symmetric variational inequalities. The latter are easily solvable using projective iterative methods.

QUASI-LAGUERRE ITERATION IN SOLVING SYMMETRIC TRIDIAGONAL EIGENVALUE PROBLEMS*

QIANG DU†, MING JIN‡, T. Y. LI†, AND Z. ZENG§

Abstract. In this article, the quasi-Laguerre iteration is established in the spirit of Laguerre's iteration for solving polynomial f with all real zeros. The new algorithm, which maintains the monotonicity and global convergence of the Laguerre iteration, no longer needs to evaluate f''. The ultimate convergence rate is $\sqrt{2}+1$. When applied to approximate the eigenvalues of a symmetric tridiagonal matrix, the algorithm substantially improves the speed of Laguerre's iteration.

Key words. eigenvalue, quasi-Laguerre iteration, symmetric tridiagonal matrix

AMS subject classification. 65F15

1. Introduction.

The globally and monotonically convergent Laguerre iteration

$$L_{\pm}(x) = x + \frac{n}{\left(-\frac{f'(x)}{f(x)}\right) \pm \sqrt{(n-1)\left[(n-1)\left(-\frac{f'(x)}{f(x)}\right)^2 - n\left(\frac{f''(x)}{f(x)}\right)\right]}} \tag{1}$$

has been successfully used to find the eigenvalues of an $n \times n$ symmetric tridiagonal matrix T with nonzero subdiagonal entries by approximating the zeros, always real and simple, of its characteristic polynomial

$$f(\lambda) = \det[T - \lambda I]. \tag{2}$$

Remarkable numerical results, in terms of both speed and accuracy, on a substantial variety of matrices have been obtained [10]. The algorithm employs the *split–merge* process, similar to Cuppen's divide-and-conquer strategy, which provides an excellent set of starting values that make the algorithm naturally parallel. Impressive speedups of the parallel version of the algorithm were reported in [15]. For $2,000 \times 2,000$ random matrices, the algorithm can reach a speedup of 52 on an N-cube with 64 nodes.

Laguerre's iteration, or modified Laguerre's iteration when clusters occur, converges ultimately with a very fast cubic convergence rate. Nonetheless, the most important advantage of Laguerre's iteration in solving (2), in contrast to Newton's iteration, is its monotone convergence. However, compared with Newton's iteration, a major disadvantage of Laguerre's iteration is the evaluation of f'', which is relatively time consuming. The purpose of this paper is to design a new algorithm in the spirit of Laguerre's iteration for finding zeros of (2). The algorithm, without the requirement of evaluating f'', maintains the monotonicity of Laguerre's iteration and converges globally with ultimate convergence rate $\sqrt{2}+1$ in finding zeros of any polynomial with all real zeros.

The formula (1) of Laguerre's iteration can be derived in diverse ways. The best one seems to be to answer the following question [9].

Question 1. Among all polynomials $p(x)$ of degree n with n real zeros and with $p(x_0) = f(x_0) \neq 0$, $p'(x_0) = f'(x_0)$, and $p''(x_0) = f''(x_0)$ at a specified real x_0, which one has a zero closest to x_0 and where?

§Department of Mathematics, Northeastern Illinois University, Chicago, IL 60625 (uzzeng@uxa.ecn.bgu.edu).

In general, $L_+(x_0)$ in (1) gives the closest zero from the right of all those polynomials and $L_-(x_0)$ gives the closest one from the left.

To avoid the evaluation of f'', we revise the above optimization problem as follows.

Question 2. Given two specified reals $a < b$, among all polynomials $p(x)$ of degree n with n real zeros, none of which lie in $[a, b]$, and with

$$\frac{p'(a)}{p(a)} = \frac{f'(a)}{f(a)} \quad \text{and} \quad \frac{p'(b)}{p(b)} = \frac{f'(b)}{f(b)}, \tag{3}$$

which one has a zero closest to a from the right or from the left and where?

The optimization problem for this class of polynomials can be easily solved and the solution has a closed form. To convert the solution of this optimization problem to an iterative scheme, which we call the *quasi-Laguerre iteration*, with the assumption that $x^{(k-1)}$ and $x^{(k)}$ are available, we may

(i) let $a = x^{(k-1)}$, $b = x^{(k)}$, and $x^{(k+1)}$ be the closest zero to $x^{(k)}$ from the right when $x^{(k-1)} < x^{(k)}$ and a zero of f is bigger than $x^{(k)}$,

(ii) let $a = x^{(k)}$, $b = x^{(k-1)}$, and $x^{(k+1)}$ be the closest zero to $x^{(k)}$ from the left when $x^{(k-1)} > x^{(k)}$ and a zero of f is less than $x^{(k)}$.

It is clear that the sequence so generated will converge to a zero of f monotonically.

The optimization problem in Question 2 is formulated in a more general form in §2 to account for multiple zeros. The ultimate rate of convergence of our algorithm so obtained is $\sqrt{2}+1$.

Our main goal here is to use the newly derived quasi-Laguerre iteration to approximate eigenvalues of symmetric tridiagonal matrices. To shorten our presentation, we only outline the derivation of our algorithm in this article and skip most of the theoretical details, including the tedious proof of its convergence properties. They are regrouped in [3] for interested readers.

The implementation details of our algorithm are described in §§4 and 5, and comprehensive numerical results on diverse types of matrices will be shown in §6. In general, our algorithm considerably improves the speed of Laguerre's iteration. Like Laguerre's iteration, our algorithm is inherently parallel and has a great capacity for vectorization. An intensive experiment in this regard will be reported in a future article.

During the writing of this paper, we became aware of an earlier unpublished work of Foster [5] in which a class of globally convergent iterations, including our quasi-Laguerre iteration for the case of simple roots, was studied. Our work here is based on a different approach and achieves much more general results.

2. Derivation of the quasi-Laguerre iteration. Let f be a polynomial of degree n with all of its zeros being real. For $a < b$ with $f(a)f(b) \neq 0$, let $\mathcal{F}$ be the class of polynomials $p(x)$ of degree n that satisfy the following conditions:

(i) all zeros of $p(x)$ are real,

(ii) none of the zeros of $p(x)$ are in $[a, b]$,

(iii) $p(a)p(b) \neq 0$ and

$$\frac{p'(a)}{p(a)} = \frac{f'(a)}{f(a)} \equiv q(a), \quad \frac{p'(b)}{p(b)} = \frac{f'(b)}{f(b)} \equiv q(b). \tag{4}$$

We pose here a more general optimization problem.

Question 3. For $p \in \mathcal{F}$, consider its mth $(m < n)$ zero to the right (or to the left) of a. Which polynomial in $\mathcal{F}$ has the closest one to a from the right (or from the left) and where?

To answer this question, let $z_1, z_2, \ldots, z_n$ be all the real zeros of a given polynomial $p(x)$ in $\mathcal{F}$ such that

$$z_1 \leq z_2 \leq \cdots \leq z_k < a < b < z_{k+1} \leq \cdots \leq z_n. \tag{5}$$

It follows from (4) that

$$\frac{p'(a)}{p(a)} = \sum_{i=1}^{n} \frac{1}{a - z_i} = q(a) \quad \text{and} \quad \frac{p'(b)}{p(b)} = \sum_{i=1}^{n} \frac{1}{b - z_i} = q(b). \tag{6}$$

For $1 \le i \le n$, let

$$X_i \equiv \frac{b - z_i}{a - z_i} = 1 + \frac{b - a}{a - z_i}.$$

Then, $X_i > 0$ for all i since no z_i falls between a and b. Moreover,

$$\begin{aligned} \sum_{i=1}^{n} X_i &= \sum_{i=1}^{n} \left(1 + \tfrac{b-a}{a-z_i}\right) = n + (b-a)q(a) \equiv r(a,b), \\ \sum_{i=1}^{n} \frac{1}{X_i} &= \sum_{i=1}^{n} \left(1 + \tfrac{a-b}{b-z_i}\right) = n + (a-b)q(b) = r(b,a), \end{aligned} \tag{7}$$

and from (5),

$$X_k \ge X_{k-1} \ge \cdots \ge X_1 > 1 > X_n \ge X_{n-1} \ge \cdots \ge X_{k+1} > 0. \tag{8}$$

For convenience, we rewrite (8) as

$$W_1 \ge W_2 \ge \cdots \ge W_k > 1 > W_{k+1} \ge \cdots \ge W_n \tag{9}$$

with

$$W_l = \begin{cases} X_{k+1-l} & \text{for } l \le k, \\ X_{n+k+1-l} & \text{for } l > k. \end{cases} \tag{10}$$

From (5), the mth zero of $p(x)$ to the left of a is z_{k-m+1} which, from (10), corresponds to W_m in (9), and minimizing $(a - z_{k-m+1})$ becomes maximizing W_m. Similarly, the mth zero of $p(x)$ to the right of a is z_{k+m} and minimizing $(z_{k+m} - a)$ becomes minimizing W_{n-m+1}. As a convention, if $m > k$ then the mth zero of p to the left of a will be taken as the $(n-m+1)$st zero to the right of a and if $m > n-k$ then the mth zero of p to the right of a is the $(n-m+1)$st zero to the left of a.

The optimization problem in Question 3 can now be converted to the following optimizations:

(P1) $$\text{Max } W_m$$

subject to

(11)
$$\sum_{i=1}^{n} W_i = r(a,b),$$
$$\sum_{i=1}^{n} \frac{1}{W_i} = r(b,a),$$
$$W_1 \ge W_2 \ge \cdots \ge W_n > 0,$$

(P2) $$\text{Min } W_{n-m+1}$$

subject to

$$\sum_{i=1}^{n} W_i = r(a,b),$$
$$\sum_{i=1}^{n} \frac{1}{W_i} = r(b,a),$$
$$W_1 \ge W_2 \ge \cdots \ge W_n > 0.$$

The solution of (P1) gives the mth closest zero to a from the left while the solution of (P2) gives the mth closest zero to a from the right.

For any $W = (W_1, \ldots, W_n)$ satisfying (11), it can be shown [3] that W_m satisfies

$$mr(b,a)W_m^2 - \left[r(a,b)r(b,a) - n^2 + 2mn\right] W_m + mr(a,b) \leq 0, \tag{12}$$

and the equality holds iff $W_j = W_m$ for all $j < m$ and $W_l = W_n$ for all $l > m$.

Similarly, W_{n-m+1} satisfies the same inequality, that is,

$$mr(b,a)W_{n-m+1}^2 - \left[r(a,b)r(b,a) - n^2 + 2mn\right] W_{n-m+1} + mr(a,b) \leq 0, \tag{13}$$

and the equality holds iff $W_j = W_{n-m+1}$ for all $j > n-m+1$ and $W_l = W_1$ for all $l < n-m+1$ [3].

Now, taking equalities in (12) and (13) yields the quadratic equation

$$mr(b,a)Y^2 - \left[r(a,b)r(b,a) - n^2 + 2mn\right] Y + mr(a,b) = 0.$$

Its solutions

$$Y_{m\pm} = \frac{r(a,b)r(b,a) - n^2 + 2mn \pm \sqrt{\left[r(a,b)r(b,a) - n^2\right]\left[r(a,b)r(b,a) - (n-2m)^2\right]}}{2mr(b,a)}$$

are both positive [3]. On the other hand, it follows from (12) and (13) that

$$Y_{m-} \leq W_m \leq Y_{m+} \tag{14}$$

and

$$Y_{m-} \leq W_{n-m+1} \leq Y_{m+}. \tag{15}$$

Accordingly, $\overline{W} = (\overline{W}_1, \ldots, \overline{W}_n)$ with $\overline{W}_1 = \cdots = \overline{W}_m = Y_{m+}$ and $\overline{W}_{m+1} = \cdots = \overline{W}_n$ is the solution of the maximization problem (P1) and, from (11),

$$mY_{m+} + (n-m)\overline{W}_n = r(a,b),$$

$$\frac{m}{Y_{m+}} + \frac{n-m}{\overline{W}_n} = r(b,a).$$

Solving for $\overline{W}_n$, one can easily see that $\overline{W}_n$ is actually $Y_{(n-m)-}$. So,

$$\overline{W}_j = \begin{cases} Y_{m+}, & j \leq m, \\ Y_{(n-m)-}, & j > m. \end{cases} \tag{16}$$

Similarly, the solution of the minimization problem (P2) is $\underline{W} = (\underline{W}_1, \ldots, \underline{W}_n)$ with

$$\underline{W}_j = \begin{cases} Y_{(n-m)+}, & j < n-m+1, \\ Y_{m-}, & j \geq n-m+1. \end{cases} \tag{17}$$

Recall that W_j's are defined by

$$W_j = 1 + \frac{b-a}{a-u_j}, \qquad j = 1, \ldots, n,$$

where u_j's are zeros of a certain polynomial in $\mathcal{F}$. Thus any polynomial whose zeros satisfy (16) must be in the form

$$p_1(x) = C(x - u_{m-})^m (x - v_1)^{n-m}, \tag{18}$$

where C is a constant and

$$1 + \frac{b-a}{a - u_{m-}} = Y_{m+} \quad \text{or, equivalently,} \quad u_{m-} = a - \frac{b-a}{Y_{m+} - 1} \tag{19}$$

and

$$1 + \frac{b-a}{a - v_1} = Y_{(n-m)-} \quad \text{or, equivalently,} \quad v_1 = a - \frac{b-a}{Y_{(n-m)-} - 1}.$$

Further, any polynomial whose zeros satisfy (17) must be in the form

$$p_2(x) = C(x - u_{m+})^m (x - v_2)^{n-m}, \tag{20}$$

where C is a constant and

$$1 + \frac{b-a}{a - u_{m+}} = Y_{m-} \quad \text{or, equivalently,} \quad u_{m+} = a - \frac{b-a}{Y_{m-} - 1} \tag{21}$$

and

$$1 + \frac{b-a}{a - v_2} = Y_{(n-m)+} \quad \text{or, equivalently,} \quad v_2 = a - \frac{b-a}{Y_{(n-m)+} - 1}.$$

From (19) and (21),

$$\frac{b - u_{m-}}{a - u_{m-}} = Y_{m+} > 0 \quad \text{and} \quad \frac{b - u_{m+}}{a - u_{m+}} = Y_{m-} > 0,$$

so both u_{m+} and u_{m-} are outside the interval (a, b). Similarly, both v_1 and v_2 are outside the interval (a, b) since $Y_{(n-m)\pm} > 0$. Consequently, both $p_1(x)$ and $p_2(x)$ are in $\mathcal{F}$.

Moreover, from (19) and (21)

$$\begin{aligned}
u_{m\pm} &= a - \frac{b-a}{Y_{m\mp} - 1} \\
&= a - \frac{2mr(b,a)(b-a)}{r(a,b)r(b,a) - n^2 + 2mn - 2mr(b,a) \mp \sqrt{[r(a,b)r(b,a) - n^2][r(a,b)r(b,a) - (n-2m)^2]}} \\
&= a + \frac{2m[n - (b-a)q(b)]}{-(b-a)R - 2mq(b) \pm \sqrt{R[(b-a)^2 R + 4m(n-m)]}},
\end{aligned} \tag{22}$$

where

$$q(a) = \frac{f'(a)}{f(a)}, \quad q(b) = \frac{f'(b)}{f(b)}, \quad \text{and} \quad R = n\left(\frac{q(a) - q(b)}{b-a}\right) - q(a)q(b).$$

The solutions of the optimization problems in Question 3 can now be described as follows:

(i) If f has at least m (counting multiplicities) zeros to the left of a, then the zero u_{m-} in (22) of the polynomial

$$p_1(x) = C(x - u_{m-})^m (x - v_1)^{n-m}$$

in (18) is the closest mth zero to the left of a among all polynomials in $\mathcal{F}$. It is also clear that

$$z_{m-} \leq u_{m-} \leq \cdots \leq u_{2-} \leq u_{1-} < a < b, \tag{23}$$

where z_{m-} is the mth zero of f to the left of a.

(ii) If f has at least m (counting multiplicities) zeros to the right of b, then the zero u_{m+} in (22) of the polynomial

$$p_2(x) = C(x - u_{m+})^m (x - v_2)^{n-m}$$

in (20) is the closest mth zero to the right of b among all polynomials in $\mathcal{F}$. It is also clear that

$$a < b < u_{1+} \leq u_{2+} \leq \cdots \leq u_{m+} \leq z_{m+}, \tag{24}$$

where z_{m+} is the mth zero of f to the right of b.

3. The quasi-Laguerre iteration and its rate of convergence. Let f be a polynomial of degree n with all its zeros being real. Let z_M be a zero of f with multiplicity $M \geq 1$. To approximate z_M from its left, we shall use u_{m+} in (22) with $m \leq M$ to generate a monotonically increasing sequence $\{x_{m+}^{(k)}\}$ which converges to z_M as $k \to \infty$. Similarly, to approximate z_M from its right, a monotonically decreasing sequence $\{x_{m-}^{(k)}\}$ converging to z_M, as $k \to \infty$, can be generated by using u_{m-} in (22).

To be more precise, suppose z_M is on the right-hand side of two starting points $x_{m+}^{(0)} < x_{m+}^{(1)}$ and none of the zeros of f lie between $x_{m+}^{(0)}$ and z_M. Then, for $k \geq 1$, we may let

$$\begin{aligned} x_{m+}^{(k+1)} &= x_{m+}^{(k-1)} + \\ &\frac{2m\left[n - (x_{m+}^{(k)} - x_{m+}^{(k-1)})q(x_{m+}^{(k)})\right]}{-(x_{m+}^{(k)} - x_{m+}^{(k-1)})R - 2mq(x_{m+}^{(k)}) + \sqrt{R\left[(x_{m+}^{(k)} - x_{m+}^{(k-1)})^2 R + 4m(n-m)\right]}}, \end{aligned} \tag{25}$$

where

$$q(x_{m+}^{(k-1)}) = \frac{f'(x_{m+}^{(k-1)})}{f(x_{m+}^{(k-1)})}, \quad q(x_{m+}^{(k)}) = \frac{f'(x_{m+}^{(k)})}{f(x_{m+}^{(k)})},$$

and

$$R = n\left(\frac{q(x_{m+}^{(k-1)}) - q(x_{m+}^{(k)})}{x_{m+}^{(k)} - x_{m+}^{(k-1)}}\right) - q(x_{m+}^{(k-1)})q(x_{m+}^{(k)}).$$

In other words, we replace a, b, and u_{m+} in (22) by $x_{m+}^{(k-1)}$, $x_{m+}^{(k)}$, and $x_{m+}^{(k+1)}$, respectively.

Remark. Interchanging $x_{m+}^{(k-1)}$ and $x_{m+}^{(k)}$, (25) can also be written as

$$\begin{aligned} x_{m+}^{(k+1)} &= x_{m+}^{(k)} + \\ &\frac{2m\left[n - (x_{m+}^{(k-1)} - x_{m+}^{(k)})q(x_{m+}^{(k-1)})\right]}{-(x_{m+}^{(k-1)} - x_{m+}^{(k)})R - 2mq(x_{m+}^{(k-1)}) + \sqrt{R\left[(x_{m+}^{(k-1)} - x_{m+}^{(k)})^2 R + 4m(n-m)\right]}}. \end{aligned} \tag{26}$$

From what has been derived in the last section, it is easy to see that

$$x_{m+}^{(k)} < x_{m+}^{(k+1)} \leq z_M$$

and no zeros of f fall between $x_{m+}^{(k+1)}$ and z_M. So the sequence $\{x_{m+}^{(k)}\}$ satisfies

$$x_{m+}^{(0)} < x_{m+}^{(1)} < \cdots < x_{m+}^{(k)} < \cdots \leq z_M.$$

Similarly, when two starting points $x_{m-}^{(1)} < x_{m-}^{(0)}$ are available on the right-hand side of z_M with no zeros of f lying in $(z_M, x_{m-}^{(0)})$, then for $k \geq 1$, let $a = x_{m-}^{(k)}$, $b = x_{m-}^{(k-1)}$, and $u_{m-} = x_{m-}^{(k+1)}$ in (22). Namely, let

$$x_{m-}^{(k+1)} = x_{m-}^{(k)} + \tag{27}$$
$$\frac{2m\left[n - (x_{m-}^{(k-1)} - x_{m-}^{(k)})q(x_{m-}^{(k-1)})\right]}{-(x_{m-}^{(k-1)} - x_{m-}^{(k)})R - 2mq(x_{m-}^{(k-1)}) - \sqrt{R\left[(x_{m-}^{(k-1)} - x_{m-}^{(k)})^2R + 4m(n-m)\right]}},$$

where

$$q(x_{m-}^{(k)}) = \frac{f'(x_{m-}^{(k)})}{f(x_{m-}^{(k)})}, \quad q(x_{m-}^{(k-1)}) = \frac{f'(x_{m-}^{(k-1)})}{f(x_{m-}^{(k-1)})},$$

and

$$R = n\left(\frac{q(x_{m-}^{(k)}) - q(x_{m-}^{(k-1)})}{x_{m-}^{(k-1)} - x_{m-}^{(k)}}\right) - q(x_{m-}^{(k)})q(x_{m-}^{(k-1)}).$$

Again it is clear that

$$z_M \leq x_{m-}^{(k+1)} < x_{m-}^{(k)}$$

and none of the zeros of f lie between z_M and $x_{m-}^{(k+1)}$. Moreover, the sequence $\{x_{m-}^{(k)}\}$ satisfies

$$z_M \leq \cdots < x_{m-}^{(k)} < \cdots < x_{m-}^{(1)} < x_{m-}^{(0)}.$$

We shall call the sequences $\{x_{m\pm}^{(k)}\}$ defined by (25) (or (26)) and (27) the *quasi-Laguerre iterations*. The convergence property of both sequences $\{x_{m\pm}^{(k)}\}$ is given in the following theorem.

THEOREM 3.1. *Both sequences $\{x_{m\pm}^{(k)}\}$ converge to z_M monotonically. Furthermore,*

(i) when $m < M$, the convergence is linear and the convergence ratio

$$\omega \equiv \lim_{k\to\infty} \frac{x_{m\pm}^{(k+1)} - z_M}{x_{m\pm}^{(k)} - z_M}$$

is the only real solution of

$$\frac{n-M-m}{n-M}x^3 - x^2 - x + \frac{M-m}{M} = 0$$

in $(0, 1)$.

(ii) when $m = M$, the convergence is superlinear with convergence rate $\sqrt{2}+1$.

Proof. See [3] for a complete proof of Theorem 3.1. □

4. Solving symmetric tridiagonal eigenvalue problems. In this section, we shall use the quasi-Laguerre iteration derived in previous sections to approximate all eigenvalues of symmetric tridiagonal matrices.

4.1. Evaluation of the logarithmic derivative f'/f of the determinant. Let T be a symmetric tridiagonal matrix of the form

$$T = [\beta_{i-1}, \alpha_i, \beta_i] = \begin{pmatrix} \alpha_1 & \beta_1 & & & & \\ \beta_1 & \alpha_2 & \beta_2 & & 0 & \\ & \ddots & \ddots & \ddots & & \\ & & \ddots & \ddots & \ddots & \\ & 0 & & \beta_{n-2} & \alpha_{n-1} & \beta_{n-1} \\ & & & & \beta_{n-1} & \alpha_n \end{pmatrix}. \tag{28}$$

We may assume, without loss of generality, that T is unreduced; that is, $\beta_j \neq 0$, $j = 1, \ldots, n-1$. For an unreduced T, the characteristic polynomial

$$f(\lambda) \equiv \det(T - \lambda I) \tag{29}$$

has only *real* and *simple* zeros [16, p. 300]. To use our quasi-Laguerre iteration developed in previous sections for finding zeros of $f(\lambda)$, or the eigenvalues of T, it is necessary to evaluate f and f' efficiently with satisfactory accuracy in the first place.

It is well known that the characteristic polynomial $f(\lambda)$ and its derivative with respect to λ can be evaluated by three-term recurrences [16, p. 423]:

$$\begin{cases} \rho_0 = 1, \quad \rho_1 = \alpha_1 - \lambda, \\ \rho_i = (\alpha_i - \lambda)\rho_{i-1} - \beta_{i-1}^2 \rho_{i-2}, \qquad i = 2, 3, \ldots, n, \end{cases} \tag{30}$$

$$\begin{cases} \rho_0' = 0, \quad \rho_1' = -1, \\ \rho_i' = (\alpha_i - \lambda)\rho_{i-1}' - \rho_{i-1} - \beta_{i-1}^2 \rho_{i-2}', \qquad i = 2, 3, \ldots, n, \end{cases} \tag{31}$$

and

$$f(\lambda) = \rho_n, \quad f'(\lambda) = \rho_n'.$$

However, these recurrences may suffer from a severe underflow–overflow problem and require constant testing and scaling. The following modified recurrence equation [10] is the result of careful investigation of the problem and is more stable than the code presented in [12]. It computes the logarithmic derivative $q(\lambda) = f'(\lambda)/f(\lambda)$, required in the formulae (25)–(27). Let

$$\xi_i = \frac{\rho_i}{\rho_{i-1}}, \qquad \eta_i = -\frac{\rho_i'}{\rho_i},$$

$$\begin{cases} \xi_1 = \alpha_1 - \lambda, \\ \xi_i = \alpha_i - \lambda - \dfrac{\beta_{i-1}^2}{\xi_{i-1}}, \quad i = 2, 3, \ldots, n, \end{cases} \tag{32}$$

$$\begin{cases} \eta_0 = 0, \quad \eta_1 = \dfrac{1}{\xi_1}, \\ \eta_i = \dfrac{1}{\xi_i}\left[(\alpha_i - \lambda)\eta_{i-1} + 1 - \left(\dfrac{\beta_{i-1}^2}{\xi_{i-1}}\right)\eta_{i-2}\right], \quad i = 2, 3, \ldots, n, \end{cases} \tag{33}$$

and

$$-\frac{f'(\lambda)}{f(\lambda)} = \eta_n.$$

To prevent the algorithm from breaking down when $\xi_i = 0$ for some $1 \le i \le n$, an extra check is provided:

- If $\xi_1 = 0$ (i.e., $\alpha_1 = \lambda$), set $\xi_1 = \beta_1^2 \varepsilon^2$;
- If $\xi_i = 0, i > 1$, set $\xi_i = \frac{\beta_{i-1}^2 \varepsilon^2}{\xi_{i-1}}$;

where ε is the machine precision. A determinant evaluation subroutine DETEVL has been implemented [10] according to the recurrences (32) and (33). When ξ_i, $i = 1, \ldots, n$ are known, the Sturm sequence is available [13, p. 47]. Thus, as a by-product, DETEVL also evaluates the number of eigenvalues of T which are less than λ.

Let $\lambda_1 < \lambda_2 < \cdots < \lambda_n$ be the zeros of $f(\lambda)$ and $\hat{\lambda}_1 < \hat{\lambda}_2 < \cdots < \hat{\lambda}_n$ be the zeros of the numerical approximation $\hat{f}(\lambda)$. It was shown in [10] that

$$|fl(\hat{\lambda}_i) - \lambda_i| \le \frac{5\varepsilon}{2} \max_j\{|\beta_j| + |\beta_{j+1}|\} + |\lambda_i|\varepsilon. \tag{34}$$

4.2. The split–merge process. Let

$$\lambda_1 < \lambda_2 < \cdots < \lambda_n$$

be the zeros of f in (29). To use the quasi-Laguerre iteration to approximate any λ_i, $i = 1, 2, \ldots, n$, it is essential to provide a pair of starting points $x^{(0)}$ and $x^{(1)}$, being either $x^{(0)} < x^{(1)} < \lambda_i$ or $\lambda_i < x^{(1)} < x^{(0)}$, with no other λ_j's lying between $x^{(0)}$, $x^{(1)}$, and λ_i. For this purpose, we *split* the matrix T into

$$\hat{T} = \begin{pmatrix} T_0 & 0 \\ 0 & T_1 \end{pmatrix}, \tag{35}$$

where

$$T_0 = \begin{pmatrix} \alpha_1 & \beta_1 & & \\ \beta_1 & \ddots & \ddots & \\ & \ddots & \ddots & \beta_{k-1} \\ & & \beta_{k-1} & \alpha_k - \beta_k \end{pmatrix}, \quad T_1 = \begin{pmatrix} \alpha_{k+1} - \beta_k & \beta_{k+1} & & \\ \beta_{k+1} & \ddots & \ddots & \\ & \ddots & \ddots & \beta_{n-1} \\ & & \beta_{n-1} & \alpha_n \end{pmatrix}. \tag{36}$$

Obviously, the eigenvalues of $\hat{T}$ consist of eigenvalues of T_0 and T_1. Without loss of generality, we may assume $\beta_i > 0$ for all $i = 1, 2, \ldots, n-1$, since in (30)–(33), β_i's always appear in their square form. The following interlacing property for this rank-one tearing is important to our algorithm.

THEOREM 4.1. *Let $\lambda_1 < \lambda_2 < \cdots < \lambda_n$ and $\hat{\lambda}_1 \le \hat{\lambda}_2 \le \cdots \le \hat{\lambda}_n$ be eigenvalues of T and $\hat{T}$, respectively. Then*

$$\hat{\lambda}_1 \le \lambda_1 \le \hat{\lambda}_2 \le \lambda_2 \le \cdots \le \hat{\lambda}_n \le \lambda_n < \hat{\lambda}_{n+1}$$

with the convention $\hat{\lambda}_{n+1} = \hat{\lambda}_n + 2\beta_k$.

Proof. See [6, Thm. 8.6.2, p. 462] for a complete proof of Theorem 4.1. □

The eigenvalues of $\hat{T}$ will be used critically to approximate the eigenvalues of T by our quasi-Laguerre iteration. We shall call this procedure, splitting T into T_0 and T_1 of $\hat{T}$ and

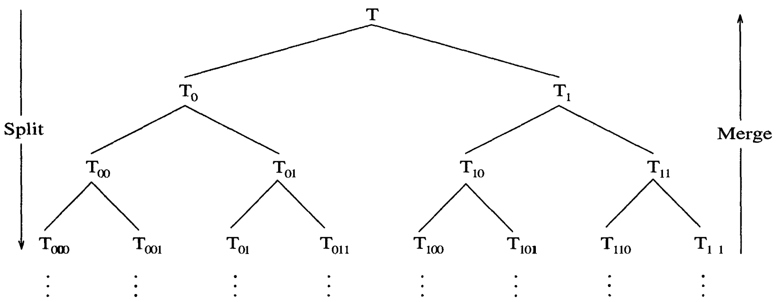

FIG. 1. *Split–merge processes.*

using eigenvalues of $\hat{T}$, consisting of eigenvalues of T_0 and T_1, to approximate eigenvalues of T, the *split–merge* process, similar to Cuppen's divide-and-conquer strategy [2, 4, 8].

To evaluate certain eigenvalues λ_i, $i = 1, 2, \ldots, n$, of T, both $\hat{\lambda}_i$ and $\hat{\lambda}_{i+1}$ are suitable candidates for the first starting point of our algorithm, since by Theorem 4.1,

$$\hat{\lambda}_i \leq \lambda_i \leq \hat{\lambda}_{i+1}.$$

For the second starting point, let

$$c = \frac{\hat{\lambda}_i + \hat{\lambda}_{i+1}}{2}$$

and evaluate $\frac{f'(c)}{f(c)}$ by the subroutine DETEVL [10]. As mentioned before, the Sturm sequence at c, which decides the position of c relative to λ_i, is a by-product of this evaluation. When $c > \lambda_i$, we let $x_-^{(0)} = \hat{\lambda}_{i+1}$, $x_-^{(1)} = c$ and when $c < \lambda_i$, we let $x_+^{(0)} = \hat{\lambda}_i$ and $x_+^{(1)} = c$. Then $\lambda_i < x_-^{(1)} < x_-^{(0)}$ or $x_+^{(0)} < x_+^{(1)} < \lambda_i$. Respectively, equations (26) and (27) with $m = 1$ are used to generate $x_\pm^{(k+1)}$ for $k \geq 1$, namely,

$$x_\pm^{(k+1)} = x_\pm^{(k)} + \frac{2\left[n - (x_\pm^{(k-1)} - x_\pm^{(k)})q(x_\pm^{(k-1)})\right]}{-(x_\pm^{(k-1)} - x_\pm^{(k)})R - 2q(x_\pm^{(k-1)}) \pm \sqrt{R\left[(x_\pm^{(k-1)} - x_\pm^{(k)})^2 R + 4(n-1)\right]}}.$$

Moreover sequences $\{x_\pm^{(k)}\}_{k=1}^{\infty}$ are obtained which converge monotonically to λ_i with ultimate convergence rate $\sqrt{2} + 1$ by Theorem 3.1.

The eigenvalues of $\hat{T}$ in (35) consist of eigenvalues of T_0 and T_1 in (36). To find eigenvalues of T_0 and T_1, the split–merge process described above may be applied again. Indeed, the splitting process can be applied to T recursively (See Figure 1) until 2×2 and 1×1 matrices are reached.

After T is well split into a tree structure as shown in Figure 1, the merging process in the reverse direction from 2×2 and 1×1 matrices can be started. More specifically, let T_σ be split into $T_{\sigma 0}$ and $T_{\sigma 1}$. Let $\hat{\lambda}_1^\sigma, \ldots, \hat{\lambda}_m^\sigma$ be eigenvalues of $\hat{T}_\sigma = \begin{pmatrix} T_{\sigma 0} & 0 \\ 0 & T_{\sigma 1} \end{pmatrix}$ in ascending order. Then the quasi-Laguerre iteration is applied to the polynomial equation

$$f_\sigma(\lambda) \equiv \det[T_\sigma - \lambda I] = 0$$

from either $\hat{\lambda}_i^{(\sigma)}$ or $\hat{\lambda}_{i+1}^{(\sigma)}$ to obtain the corresponding eigenvalue λ_i^σ, $i = 1, 2, \ldots, m$, by the merging process described above. This process continues until T_0 and T_1 are merged into T. That is, in the final step all the eigenvalues of T are obtained by applying the quasi-Laguerre iteration to $f(\lambda) = \det(T - \lambda I)$ from eigenvalues of T_0 and T_1.

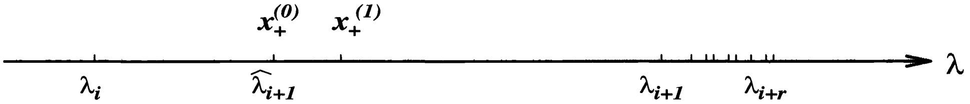

FIG. 2. *Converging to relatively closer eigenvalues.*

4.3. Cluster and deflation. By Theorem 4.1, $\lambda_i \in (\hat{\lambda}_i, \hat{\lambda}_{i+1})$ for each $i = 1, \dots, n$ with the convention $\hat{\lambda}_{n+1} = \hat{\lambda}_n + 2\beta_k$. If $\hat{\lambda}_{i+1} - \hat{\lambda}_i$ is less than the error tolerance, then either $\hat{\lambda}_i$ or $\hat{\lambda}_{i+1}$ can be accepted as λ_i. In general, if $\hat{T}$ has a cluster of $r + 1$ very close eigenvalues, for instance, $\hat{\lambda}_{j+r} - \hat{\lambda}_j$ is less than the error tolerance for certain $1 \le j \le n - r$, then r eigenvalues $\lambda_j, \lambda_{j+1}, \dots, \lambda_{j+r-1}$ of T can be obtained free of computations. They can be set to any one of $\hat{\lambda}_j, \dots, \hat{\lambda}_{j+r}$.

Since the matrix T in (28) is unreduced, its eigenvalues are all simple. Therefore using $m = 1$ in the quasi-Laguerre iterations given in (26) or (27) seems appropriate in all cases to obtain ultimate superlinear convergence with convergence rate $\sqrt{2} + 1$. However, in some cases, there may exist a group of $r > 1$ eigenvalues of T, say,

$$\lambda_{i+1} < \lambda_{i+2} < \cdots < \lambda_{i+r}$$

which are relatively close to each other, compared to the distance from the two starting points, say $x_+^{(0)} < x_+^{(1)} < \lambda_{i+1}$, as shown in Figure 2. Some of them may even be numerically indistinguishable.

Numerical evidence shows that to reach λ_{i+1} from $x_+^{(0)} (= \hat{\lambda}_{i+1})$ and $x_+^{(1)}$, it may take many steps of the quasi-Laguerre iteration with $m = 1$ before showing super-linear convergence. In this situation, the quasi-Laguerre iteration with $m = r$ in (26) may be used to speed up the convergence. Exhibited in (24), the sequences $\{x_{m+}^{(k)}\}$ in (26) with different m's satisfy

$$x_+^{(k-1)} < x_{1+}^{(k)} < x_{2+}^{(k)} < \cdots < x_{r+}^{(k)} < \lambda_{i+r}.$$

Accordingly, $x_{r+}^{(k)}$ is relatively closer to λ_{i+1}. Therefore if the number r of those relatively closer zeros can be estimated, then instead of using $m = 1$ as usual, we may let $x_+^{(k)} = x_{r+}^{(k)}$. To estimate r in our algorithm, we put λ_j in the same group with λ_{i+1} if

$$|\hat{\lambda}_j - \hat{\lambda}_{i+2}| < 0.01|\hat{\lambda}_{i+2} - \hat{\lambda}_{i+1}|.$$

It might happen that $\lambda_{i+1} < x_+^{(k)}$, which can be revealed by the information of the Sturm sequence given at $x_+^{(k)}$; in this case, the number r may be reduced. Therefore an overestimate of the number r causes essentially no harm because our algorithm can dynamically reduce r, while an underestimate may result in slow convergence.

4.4. Partial spectrum. From the strong interlacing property given in Theorem 4.1 one can easily obtain the following.

PROPOSITION 4.2. *If $[a, b]$ contains k eigenvalues of $\hat{T}$, then $[a, b]$ contains at least $k - 1$ and at most $k + 1$ eigenvalues of T. More precisely, let $\kappa(x)$ be the number of eigenvalues of T which are less than $x \in \mathbb{R}$ and $\hat{\lambda}_{s+1}, \dots, \hat{\lambda}_{s+k}$ be all the eigenvalues of $\hat{T}$ in $[a, b]$. Then $s - 1 \le \kappa(a) \le s$ and $s + k - 1 \le \kappa(b) \le s + k$.*

In our algorithm, either $\hat{\lambda}_i$ or $\hat{\lambda}_{i+1}$ of $\hat{T}$ is used as the first starting point of our quasi-Laguerre iteration to approximate λ_i of T. To find eigenvalues of T in a given interval $[a, b]$, the eigenvalues of $\hat{T}$ in $[a, b]$ are known, say $\hat{\lambda}_{s+1}, \dots, \hat{\lambda}_{s+k}$. By evaluating $\kappa(a)$ and $\kappa(b)$, the actual number of eigenvalues of T in $[a, b]$ is $\sigma = \kappa(b) - \kappa(a)$. Hence

$\lambda_{\kappa(a)+1}, \ldots, \lambda_{\kappa(a)+\sigma}$ are the eigenvalues of T in $[a, b]$. By Proposition 4.2, $s-1 \le \kappa(a) \le s$ and $s+k-1 \le \kappa(b) \le s+k$, so σ can either be $k-1$, k, or $k+1$. Thus, at most $k+2$ values are needed to be considered as the first starting points to evaluate these σ eigenvalues of T. Let

$$\hat{\hat{\lambda}}_s = a, \quad \hat{\hat{\lambda}}_{s+1} = \hat{\lambda}_{s+1}, \quad \hat{\hat{\lambda}}_{s+2} = \hat{\lambda}_{s+2}, \quad \ldots, \quad \hat{\hat{\lambda}}_{s+k} = \hat{\lambda}_{s+k}, \quad \hat{\hat{\lambda}}_{s+k+1} = b.$$

Then σ values among them can serve as the first starting points which will lead to all σ eigenvalues of T in $[a, b]$.

In some instances, the eigenvalues of T of interest are identified in magnitude, say the largest 20%, then they can be evaluated by using the largest 20% eigenvalues of $\hat{T}$ as starting points without computing the other 80% eigenvalues of $\hat{T}$ and T.

4.5. Stopping criteria. The following stopping criterion was suggested by Kahan [9]:

$$|x^{(k+1)} - x^{(k)}|^2 \le (|x^{(k)} - x^{(k-1)}| - |x^{(k+1)} - x^{(k)}|) = \tau, \tag{37}$$

where τ is the error tolerance. This criterion is based on the following observation. Let

$$q_k = \left| \frac{x^{(k+1)} - x^{(k)}}{x^{(k)} - x^{(k-1)}} \right|.$$

Then as $\{x^{(k)}\}_{k=1}^{\infty}$ converges to λ when $k \to \infty$, q_k is normally decreasing. Thus

$$\begin{aligned}|\lambda - x^{(k+1)}| &= \left| \sum_{i=0}^{\infty} (x^{(k+2+i)} - x^{(k+1+i)}) \right| \le \sum_{i=0}^{\infty} |x^{(k+2+i)} - x^{(k+1+i)}| \\ &\le |x^{(k+1)} - x^{(k)}| \sum_{i=1}^{\infty} q_k^i = \frac{q_k |x^{(k+1)} - x^{(k)}|}{1 - q_k} \\ &= \frac{|x^{(k+1)} - x^{(k)}|^2}{|x^{(k)} - x^{(k-1)}| - |x^{(k+1)} - x^{(k)}|}.\end{aligned}$$

From (34), an obvious error tolerance at λ_i can be chosen as

$$\tau = \frac{5\varepsilon}{2} \max_j \{|\beta_j| + |\beta_{j+1}|\} + |x^{(k+1)}|\varepsilon.$$

5. Practical considerations in implementation.

5.1. Initial points for the quasi-Laguerre iteration. At every stage of the merging process, we evaluate the eigenvalues $\lambda_1 < \cdots < \lambda_m$ of an $m \times m$ submatrix, given m initial values $\hat{\lambda}_1 \le \cdots \le \hat{\lambda}_m$ and an upper bound $\hat{\lambda}_{m+1}$ that interlace those m eigenvalues:

$$\hat{\lambda}_1 \le \lambda_1 \le \hat{\lambda}_2 \le \lambda_2 \le \ldots \le \hat{\lambda}_m \le \lambda_m \le \hat{\lambda}_{m+1}$$

(see Theorem 4.1). To evaluate an eigenvalue λ_i by the quasi-Laguerre iteration, two initial points, say $x^{(0)}$ and $x^{(1)}$, are required on the same side of λ_i without any other eigenvalues between them and $x^{(1)}$ is chosen to be closer to λ_i than $x^{(0)}$. As we described in §4.2, either $\hat{\lambda}_i$ or $\hat{\lambda}_{i+1}$ can be used as the first initial point $x^{(0)}$ because of the interlacing property:

$$\hat{\lambda}_i \le \lambda_i \le \hat{\lambda}_{i+1} \quad \text{for } i = 1, \ldots, m,$$

and bisection point $c = \frac{\hat{\lambda}_i + \hat{\lambda}_{i+1}}{2}$ is chosen as the second initial point $x^{(1)}$.

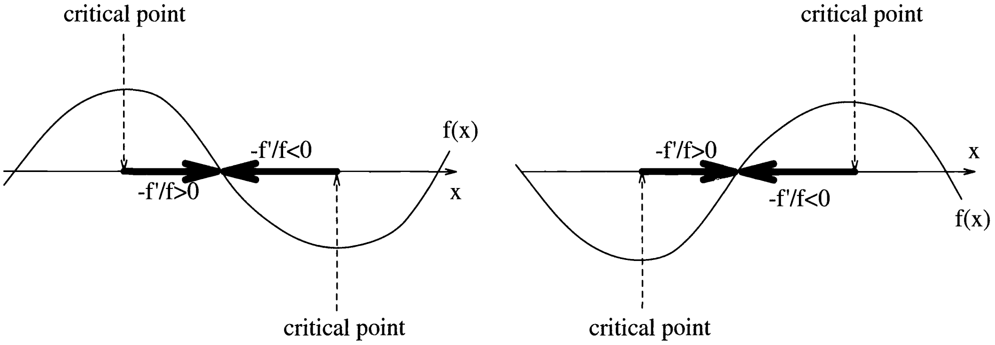

FIG. 3. *The two initial points should be between one of the nearby critical points of f and the zero. This can be identified by the sign pattern of $-f'/f$.*

While this approach of obtaining initial points is the simplest one, it may not be the most efficient. Several improvements are made in our practical implementation. First, since f'/f is evaluated at every initial value $\hat{\lambda}_j$ $(j = 1, \dots, m)$, one step of Newton's iteration can be performed without extra cost and the result can be considered as a candidate, besides c, for $x^{(1)}$. Second and more importantly, from our computing experience, the high-order convergence of the quasi-Laguerre iteration occurs only when there is no critical point of f (i.e., zero of f') between $x^{(0)}$ and λ_i (see Figure 3). In other words, if $x^{(0)}$ is to the left (resp., right) of λ_i, then it is desirable for $-f'(x^{(0)})/f(x^{(0)})$ to be positive (resp., negative). If there is at least one critical point in $[\hat{\lambda}_i, \hat{\lambda}_{i+1}]$, then bisection or one-step Newton iteration is used repeatedly until the above requirement at $x^{(0)}$ is satisfied. Based on these observations, our procedure for determining a pair of initial points among different choices to achieve the best possible efficiency is summarized in the algorithm INIPTS in Figure 4.

5.2. An alternative approach for clusters of eigenvalues. The multiplicity estimation and the quasi-Laguerre iterations (26) and (27) with $m > 1$ can successfully overcome the slow convergence when a cluster of eigenvalues occurs. An alternative approach without multiplicity estimation as well as dynamical adjustments of the multiplicities can also work very efficiently in practice.

By Theorem 3.1, when the quasi-Laguerre iteration for simple zero $(m = 1)$ is used to approximate an M-fold zero x^*, or a cluster of M simple zeros, of a polynomial $f(\lambda)$ of degree n, it converges linearly with a ratio $q_{n,M}$ which is the only solution of

$$\frac{n-M-1}{n-M}x^3 - x^2 - x + \frac{M-1}{M} = 0$$

in $(0, 1)$. Let $x^{(1)}, x^{(2)}, \dots, x^{(k)}, \dots$ be the monotone sequence of the quasi-Laguerre iterates. It can be shown [3] that $q_* \equiv q_{3,2}$, the zero of $x^2 + x - 0.5 = 0$ in $(0, 1)$, is the smallest linear ratio for multiple zeros. That is, $q_{n,M} \geq q_{3,2}$ when $n \geq 3$ and $M \geq 2$. When $\{x^{(k)}\}$ converges superlinearly, then

$$q_k \equiv \frac{|x^{(k+1)} - x^{(k)}|}{|x^{(k)} - x^{(k-1)}|} \longrightarrow 0 \quad \text{as } k \to \infty,$$

so q_k should be smaller than q_* when k is sufficiently large. Therefore, when $q_k > q_*$, linear convergence seems apparent. In this case, for sufficiently large k,

$$\frac{|x^{(k+1)} - x^*|}{|x^{(k)} - x^*|} \approx q_{n,M} \quad \text{or} \quad |x^{(k+1)} - x^*| \approx q|x^{(k)} - x^*|, \qquad \text{where } q \equiv q_{n,M},$$

```
     Input:  subscript $i$, initial end points $\hat{\lambda}_i, \hat{\lambda}_{i+1}$.

         End if ;
(#)  End IniPts
```

FIG. 4. *Algorithm* IniPts.

and

$$q_k = \frac{|x^{(k+1)} - x^{(k)}|}{|x^{(k)} - x^{(k-1)}|} = \frac{|x^{(k)} - x^*| - |x^{(k+1)} - x^*|}{|x^{(k-1)} - x^*| - |x^{(k)} - x^*|} \approx \frac{(1-q)|x^{(k)} - x^*|}{(1-q)|x^{(k-1)} - x^*|} \approx q.$$

In practice, q_k's can be very close to q after several iterations. If $q_j = q$ for $j \geq k$, then

$$|x^{(j+1)} - x^*| = q|x^{(j)} - x^*| \quad \text{for } j \geq k$$

and

$$x^* = x^{(k)} + \frac{1}{1-q}(x^{(k+1)} - x^{(k)}).$$

So, at the kth iterate $x^{(k)}$, if linear convergence is revealed, namely $q_k > q_*$, then instead of performing the regular quasi-Laguerre iteration

$$x^{(k+1)} = x^{(k)} + \delta_k,$$

where δ_k is the correction $x^{(k+1)} - x^{(k)}$ from $x^{(k)}$ calculated by the quasi-Laguerre iteration with $m = 1$, one can accelerate the iteration by setting

$$x^{(k+1)} = x^{(k)} + \frac{\delta_k}{1 - q_k}.$$

```

FIG. 5. *Algorithm* ACCQ-LAG.

The fundamental features of the acceleration process described in this section are summarized in the algorithm ACCQ-LAG (Figure 5). Table 1 gives the comparison between the original quasi-Laguerre iteration and the accelerated quasi-Laguerre iteration. The Wilkinson matrix W_{99}^+ is used here with the starting points $x^{(0)} = 11.5$ and $x^{(1)} = L_-(x^{(0)}) = 11.27$ targeting $\lambda_{23} = 11.0 + 5 \times 10^{-15}$ of W_{99}^+, while $\lambda_{22} = 11.0 - 5 \times 10^{-15}$. Also note in the third column of Table 1 that the q_k's are identical up to six digits with $q = q_{99,2} \approx 0.402522$.

6. Numerical tests. Our algorithm was implemented and tested on SPARC stations with IEEE floating point standard. The machine precision was $\varepsilon \approx 2.2 \times 10^{-16}$.

6.1. Testing matrices. There are 12 types of matrices used in testing our algorithm. In the following description of these matrix types, $\alpha_i, i = 1, \ldots, n$, denote the diagonal entries and $\beta_i, i = 1, \ldots, n-1$, are the subdiagonal entries.

6.1.1. Matrices with known eigenvalues.

Type 1. Toeplitz matrices $[b, a, b]$. Exact eigenvalues: $\{a + 2b\cos\frac{k\pi}{n+1}\}_{1\le k\le n}$ [7, Ex. 7.4, p. 137].

Type 2. $\alpha_1 = a - b, \alpha_i = a$ for $i = 2, \ldots, n-1, \alpha_n = a + b$. $\beta_j = b, j = 1, \ldots, n-1$. Exact eigenvalues: $\{a + 2b\cos\frac{(2k-1)\pi}{2n}\}_{1\le k\le n}$ [7, Ex. 7.6, p. 138].

Type 3. $\alpha_i = \begin{cases} a & \text{for odd } i, \\ b & \text{for even } i, \end{cases}$ $\beta_i = 1$. Exact eigenvalues :

$$\left\{ \frac{a + b \pm \sqrt{(a-b)^2 + 16\cos^2 \frac{k\pi}{n+1}}}{2} \right\}_{1 \le k \le n/2} \qquad \text{(add } \{a\} \text{ when } n \text{ is odd)}$$

[7, Ex. 7.8 and 7.9, p. 139].

Type 4. $\alpha_i = 0$, $\beta_i = \sqrt{i(n-i)}$. Exact eigenvalues: $\{-n + 2k - 1\}_{1 \le k \le n}$ [7, Ex. 7.10, p. 140].

Type 5. $\alpha_i = -[(2i-1)(n-1) - 2(i-1)^2]$, $\beta_i = i(n-i)$. Exact eigenvalues: $\{-k(k-1)\}_{1 \le k \le n}$ [7, Ex. 7.11, p. 141].

6.1.2. Wilkinson and random matrices.

Type 6. Wilkinson matrices W_n^{+}. $\beta_i = 1$,

$$\alpha_i = \begin{cases} n/2 - i + 1 & \text{for even } n \text{ and } 1 \le i \le n/2, \\ i - n/2 & \text{for even } n \text{ and } n/2 < i \le n, \\ (n-1)/2 - i + 1 & \text{for odd } n \text{ and } 1 \le i \le (n+1)/2, \\ i - (n+1)/2 & \text{for odd } n \text{ and } (n+1)/2 < i \le n, \end{cases}$$

[16, pp. 308–309]. Most of the eigenvalues are in pairs, consisting of two numerically indistinguishable eigenvalues.

Type 7. Random matrices. The α_i's and β_i's are random numbers in [0, 1].

6.1.3. LAPACK testing matrices. (These are generated by the LAPACK test matrix generator [1].)

Type 8. Matrices with eigenvalues evenly distributed between their smallest and largest eigenvalues.

Type 9. Matrices with geometrically distributed eigenvalues. Namely, eigenvalues can be written as $\{q^k\}_{1\le k\le n}$ for some $q \in (0, 1)$.

Type 10. Matrices with an eigenvalue 1 and the remaining eigenvalues in $(-\varepsilon, \varepsilon)$.

Type 11. Matrices with eigenvalues evenly distributed in the interval (0, 1] except one eigenvalue with very small magnitude.

Type 12. Matrices with an eigenvalue 1 and the rest of the eigenvalues are evenly distributed in a small interval $[10^{-12} - \varepsilon, 10^{-12} + \varepsilon]$.

6.2. Speed test in evaluating eigenvalues without computing eigenvectors. We compare the performance of the following codes for evaluating eigenvalues of an $n \times n$ matrix:

(1) Q-LAG, our split–merge algorithm using the quasi-Laguerre iteration. Storage requirement, $9n$;

(2) LAG, split–merge algorithm using Laguerre's iteration developed by Li and Zeng [10]. Storage requirement, $9n$;

(3) B/M, bisection/multisection subroutine DSTEBZ in LAPACK. Storage requirement, $12n$;

(4) RFQR, root-free QR routine DSTERF in LAPACK, as recommended in LAPACK for evaluating eigenvalues only. Storage requirement, $2n$.

The results of this test are given in Figure 6. Matrices of Types 9–12 involve tiny eigenvalues or clusters and are used more in stability tests (See §6.4). The speed comparison in this category may not be relevant. In particular, matrices of Types 10 and 12 have big dense clusters, and intensive deflations make Q-LAG as well as LAG outscore RFQR in speed by a wide margin.

For all other matrices (Types 1–8), Q-LAG is much faster than LAG (especially for Types 1, 4, and 5) and LAG is much faster than B/M. RFQR is apparently the fastest code in almost all cases, except for matrices of Types 6 and 7 where Q-LAG is about 70% and 40% ($n = 500$) faster, respectively. Overall, Q-LAG performs very similarly to RFQR and is much more competitive than B/M. Taking into account Q-LAG's flexibility in evaluating the partial spectrum and the potential in parallel computing, Q-LAG is by far the most efficient algorithm among all the algorithms being tested here.

6.3. Speed test in evaluating eigenpairs. We compare the performance of the following codes for evaluating the eigenpairs of an $n \times n$ matrix:

(1) Q-LAG, our split–merge algorithm using the quasi-Laguerre iteration plus the inverse iteration subroutine DSTEIN in LAPACK. Storage requirement, $n^2 + O(n)$;

(2) B/M, DSTEBZ plus DSTEIN. Storage requirement, $n^2 + O(n)$;

(3) INV, DSTEIN with eigenvalues computed by Q-LAG (for analysis purposes);

(4) D&C, divide-and-conquer subroutine DSTEDC in LAPACK. Storage requirement, $3n^2 + O(n)$;

(5) QR, QR routine DSTEQR in LAPACK, as recommended in LAPACK for evaluating eigenpairs only. Storage requirement, $n^2 + O(n)$.

The storage requirement for D&C is relatively higher than those which use the inverse iteration code. The results of evaluations of all eigenpairs and one-third of the largest eigenvalues with corresponding eigenvectors are listed in columns A and B, respectively, in Table 2.

In comparing the execution time in evaluating all eigenpairs, our algorithm leads QR substantially. For matrices of Types 6, 9, and 10, where a number of clusters exist, our algorithm is slower than D&C due to drastic deflations of clusters. But this sort of matrix scarcely occurs in practice; it is often used for testing the robustness of an algorithm. For all other types of matrices, our algorithm leads D&C for large matrices ($n \geq 300$), while for small matrices, D&C is faster since it takes much longer for INV to compute eigenvectors in our algorithm.

Only Q-LAG, LAG, and B/M can be applied efficiently to evaluate one-third of the largest eigenvalues and their corresponding eigenvectors. D&C and QR must evaluate all the eigenpairs to obtain the largest one-third. This makes our algorithm more flexible and efficient. Compared with B/M in this category, our algorithm leads clearly for all types of matrices.

6.4. Accuracy test. For those matrices with known eigenvalues (Types 1–5), the accuracy of a method can be determined by

$$\text{direct error: } \mathcal{D} = \max_i \frac{|\tilde{\lambda}_i - \lambda_i|}{\|T\|_1},$$

where $\tilde{\lambda}_i$ is the approximation of the exact eigenvalue λ_i of T and $\|\cdot\|_1$ is the l_1-norm. For matrices of other types, the exact eigenvalues are unavailable; the accuracy of a method is thus determined by the residual error and the orthogonality error in the computed solution. For $T = QDQ^T$ with computed solution $\tilde{Q}\tilde{D}\tilde{Q}^T$, these errors are computed by

$$\text{residual error: } \mathcal{R} = \max_i \frac{\|(T\tilde{Q} - \tilde{Q}\tilde{D})e_i\|_2}{|\tilde{\lambda}|_{\max}},$$

$$\text{orthogonality error: } \mathcal{O} = \max_i \|(\tilde{Q}^T\tilde{Q} - I)e_i\|_2.$$

If the residual and orthogonality error are small, then the error matrix $T - \tilde{Q}\tilde{D}\tilde{Q}^T$ is small [11].

The results are listed in Table 3. It appears that our algorithm Q-LAG achieves the smallest direct error on all matrices of the first five types. The direct error of our algorithm as well as B/M is independent of the matrix size, whereas RFQR and QR seem to have larger direct error when the matrix size becomes larger. For nearly all matrices, the eigenvectors generated by D&C suffer the least loss of orthogonality, whereas our algorithm and B/M enjoy the smallest residual errors, except on those occasions where clusters of eigenvalues exist and the inverse iteration fails to compute orthogonal vectors.

PRECONDITIONED ITERATIVE METHODS FOR UNSTEADY NON-NEWTONIAN FLOW BETWEEN ECCENTRICALLY ROTATING CYLINDERS*

D. RH. GWYNLLYW† AND T. N. PHILLIPS‡

Abstract. The flow of a non-Newtonian lubricant between eccentrically rotating cylinders is considered. The fluid model includes a viscosity law which is shear thinning and pressure thickening. The governing equations are discretized in space using spectral elements and in time by a time-splitting scheme. The system of linear equations generated at each time step is solved using the conjugate gradient method. Particular emphasis is given to the choice of efficient preconditioners for both constant and variable viscosity problems. Eigenvalue spectra are presented for the preconditioned systems for a range of realistic choices of the material and geometrical parameters.

Key words. non-Newtonian fluid, spectral element method, preconditioned conjugate gradient method, eccentrically rotating cylinders

1. Introduction. The journal bearing is an essential part of all internal combustion engines as a means of transferring energy from the piston connecting rods to the rotating crankshaft (Figure 1). The *big-end* journal bearing consists essentially of an inner cylinder (the journal), which is part of the crankshaft, and an outer cylinder (the bearing), which is at the end of the connecting rod. A lubricating film of oil separates the three-dimensional region between the cylinders which are, in general, eccentrically positioned. The *big-end* bearing is driven by a time-dependent load, whilst the journal's motion is approximately circular about O, the centre of the *main* bearing. The *main* journal bearing again consists of a journal being part of the crankshaft, whilst the outer cylinder is fixed to the engine casing. If O was fixed in time then the journal within the *main* bearing would rotate about its own axis. Both the main and the big-end bearings are subject to elastic deformation.

The modelling of the behaviour of the lubricant has many important and complicated features. These include incompressibility; viscoelasticity; changes in viscosity with shear rate, strain rate, pressure, and temperature; oil feed; boundary lubrication to incorporate extreme effects when the cylinders are almost touching; and cavitation. In addition the imposition of a time-dependent load means that the centre of the journal traces out a nontrivial locus in space.

In the present study we restrict ourselves to the two-dimensional flow of a non-Newtonian fluid under static loading conditions (fixed eccentricity). This model is important in its own right and presents a genuine and challenging test for numerical solution techniques. Significant boundary layers can develop in the flow at high eccentricity, even at modest rotational speeds of the journal. The accurate resolution of such boundary layers presents a major challenge to numerical methods. The extremely high number of degrees of freedom required by traditional finite element methods to resolve these layers has led to high-order methods such as spectral or spectral element methods being tried. The present study concentrates on the feasibility of solving the static loading problem for different eccentricities with particular attention given to the speed of computation. The motivation for studying this problem is that the dynamic loading problem will involve tens of thousands of such calculations.

In previous work on the statically loaded model [18], [19], [20] a single domain spectral method was used which employed a bipolar coordinate transformation to map the region be-

tween the journal and the bearing onto a rectangle. The flow variables were then approximated on this rectangle using Fourier–Chebyshev expansions. However, to allow for future possible deformation of the journal and bearing surfaces due to increased loads for the dynamically loaded problem we have decided to use a more versatile spectral element formulation.

In the spectral element method a variational formulation of the governing equations is used. This results in a symmetric positive definite system of linear equations to be solved at each time step. This system may be solved using a conjugate gradient iterative method. Improved efficiency is gained by constructing suitable preconditioners, thus reducing the number of iterations and the computational time to reach a converged solution. These are the issues that will be addressed in this paper.

2. Formulation of the problem. We consider the flow of a pressure-thickening generalized Newtonian fluid between eccentrically rotating cylinders. The inner (journal) and outer (bearing) cylinders are of radius R_J and R_B, respectively, with the distance between the centres of the cylinders given by e. The outer cylinder is kept at rest, while the inner cylinder is rotated at an angular velocity ω. The eccentricity is defined by $\epsilon = e/c$, where $c = R_B - R_J$ is known as the average gap. Let the region between the journal and the bearing be denoted by Ω, and let Γ_J and Γ_B denote the boundaries of the journal and bearing, respectively.

The governing equations for a generalized Newtonian fluid compose the conservation of momentum

$$\rho\left(\frac{\partial \mathbf{v}}{\partial t} + \mathbf{v}.\nabla\mathbf{v}\right) = -\nabla p + \nabla.\mathbf{T}, \tag{1}$$

the conservation of mass

$$\nabla.\mathbf{v} = 0, \tag{2}$$

and the constitutive equation

$$\mathbf{T} = 2\eta(\dot\gamma, p)\mathbf{d}, \tag{3}$$

where ρ is the density, η is the variable viscosity, $\dot\gamma = \sqrt{2}\ \mathrm{tr}(\mathbf{d})^2$, $\mathbf{T}$ is the extra-stress tensor, and $\mathbf{d} = \frac{1}{2}(\nabla\mathbf{v} + (\nabla\mathbf{v})^T)$ is the rate of deformation tensor. Here tr$(\mathbf{A})$ denotes the trace of a tensor **A**. The constitutive equation written in this form can easily be modified to incorporate viscoelasticity [18]. The constitutive equation (3) is a modification of the usual generalized Newtonian model to include pressure dependence of the viscosity.

The viscosity law that we have used was proposed by Li and Davies [13]. It is shear thinning and pressure thickening. The various parameters in the model are determined empirically. The dependence of viscosity on $\dot{\gamma}$ and pressure is given by

$$\eta = \left\{ \eta_\infty + \frac{(\eta_0 - \eta_\infty)}{[1 + (K\dot{\gamma})^m]} \right\} \times \exp(-\alpha \mathrm{tr}(\sigma)/3 + F), \tag{4}$$

where K is a function of pressure

$$K = K(p) = \exp(-\bar{\alpha}\mathrm{tr}(\sigma)/3 + E),$$

$\sigma = -p\mathbf{I} + \mathbf{T}$ is the Cauchy stress tensor, and $\eta_0, \eta_\infty, m, n, \alpha, \bar{\alpha}$, E, and F are material parameters. This model describes the shear-thinning behaviour of the viscosity by a Cross-type formula [8]. Pressure thickening is modelled by a simple exponential law [1]. It is important to note that the viscosity law (4) is consistent with experiments [2] which span only limited ranges of the pressures which the lubricants experience under general operating conditions.

The governing equations (1)–(3) are solved subject to specified boundary and initial conditions. These are, respectively,

$$\mathbf{v} = \mathbf{v}_J \text{ on } \Gamma_J, \quad \mathbf{v} = \mathbf{0} \text{ on } \Gamma_B, \tag{5}$$

$$\mathbf{v}(\mathbf{x}, t = 0) = \mathbf{v}_0(\mathbf{x}). \tag{6}$$

3. Analysis of the steady Stokes problem. In this section we review previous work on the spectral discretization of the steady Stokes problem in order to motivate our choice of discrete velocity and pressure approximation spaces. For simplicity we consider the domain $D = [-1, 1] \times [-1, 1]$. The problem is to find a velocity $\mathbf{v} = (u, v)$ and a pressure p such that

$$-\eta\nabla^2\mathbf{v} + \nabla p = \mathbf{f}, \tag{7}$$

$$-\nabla.\mathbf{v} = 0, \tag{8}$$

with $\mathbf{v} = \mathbf{0}$ on the boundary of D.

To set up the variational formulation of this problem we need to introduce some function spaces. The velocity is chosen to belong to the space $X = H_0^1(D) \times H_0^1(D)$ and the pressure to the space $M = L_0^2(D)$ where

$$L_0^2(D) = \left\{ \phi \in L^2(D) : \int\!\!\int_D \phi = 0 \right\}.$$

The variational formulation is then given by the following: find $(\mathbf{v}, p) \in X \times M$ such that

$$\eta(\nabla\mathbf{v}, \nabla\mathbf{w}) - (p, \nabla.\mathbf{w}) = (\mathbf{f}, \mathbf{w}) \quad \forall\, \mathbf{w} \in X, \tag{9}$$

$$-(q, \nabla.\mathbf{v}) = 0 \quad \forall\, q \in M. \tag{10}$$

We define two bilinear forms a and b over $X \times X$ and $X \times M$, respectively, by

$$a(\mathbf{v}, \mathbf{w}) = \eta(\nabla\mathbf{v}, \nabla\mathbf{w}), \tag{11}$$

$$b(\mathbf{v}, q) = -(q, \nabla.\mathbf{v}). \tag{12}$$

The Stokes problem can then be written as follows: find $(\mathbf{v}, p) \in X \times M$ such that

$$a(\mathbf{v}, \mathbf{w}) + b(\mathbf{w}, p) = (\mathbf{f}, \mathbf{w}) \quad \forall\, \mathbf{w} \in X, \tag{13}$$

$$b(\mathbf{v}, q) = 0 \quad \forall\, q \in M. \tag{14}$$

In order to set up the corresponding variational formulation it is necessary to choose suitable polynomial subspaces X_N and M_N of X and M, respectively. Let N be an integer which will be used as a discretization parameter for the pseudospectral approximation. Let $P_N(D)$ denote the space of all polynomials of degree less than or equal to N in each spatial direction. The velocity approximation space is chosen to be the subspace of X comprising polynomials of degree at most N in each coordinate direction which vanish on the boundary of D, i.e.,

$$X_N = X \cap P_N(D)^2.$$

If the discrete pressure space is chosen to comprise polynomials of the same degree as for the discrete velocity space then spurious modes in the pressure representation might arise. If there are spurious modes in the pressure representation then the problem does not possess a unique solution [5]. For example, if Chebyshev or Legendre polynomials are used as the basis functions, then for the discrete version of (13) and (14) it can be shown that there are eight spurious modes. In practice these modes pollute the pressure approximation and need to be removed in order to recover an accurate pressure field. Phillips and Roberts [18] filter out the spurious pressure modes using a singular value decomposition of the pressure coefficient matrix. In the case of domain decomposition, however, it is not immediately self-evident how to identify and then remove the spurious modes. The spurious modes have been characterised for a rectangular domain decomposition problem [21]. However, in the general case it is preferable to define a discrete problem which is free from spurious modes in the pressure representation.

One means of circumventing this difficulty is to deplete the pressure space in an appropriate way to remove the spurious modes. Bernardi and Maday [3] propose a method based on a staggered mesh, similar to that used in some finite difference methods, in which the dependent variables are defined on a different collocation grid. Although this removes the spurious modes it does not result in optimal error estimates for either the velocity or the pressure. This method is also cumbersome to use since it is necessary to interpolate the variables between the different grids.

Another method which is free from spurious pressure modes and which does not require an inordinate amount of interpolation is the $P_N - P_{N-2}$ method of Maday, Patera, and Rønquist [17]. In this method the pressure approximation is of degree $N-2$ compared with a velocity approximation of degree N. The unknowns associated with the pressure approximation are located at the interior Gauss–Lobatto points.

Let a_N and b_N be discrete bilinear forms which are, for the moment, unprescribed analogues of the continuous ones defined by (11) and (12), respectively. The discrete variational problem is as follows: find $(\mathbf{v}_N, p_N) \in X_N \times M_N$ such that

$$a_N(\mathbf{v}_N, \mathbf{w}_N) + b_N(\mathbf{w}_N, p_N) = (\mathbf{f}, \mathbf{w}_N)_N \quad \forall\, \mathbf{w}_N \in X_N, \tag{15}$$

$$b_N(\mathbf{v}_N, q_N) = 0 \quad \forall\, q_N \in M_N. \tag{16}$$

Suppose that the discrete bilinear forms a_N and b_N satisfy the following properties:

$$|a_N(\mathbf{u}_N, \mathbf{v}_N)| \le \gamma \parallel \mathbf{u}_N \parallel_{H^1(D)} \parallel \mathbf{v}_N \parallel_{H^1(D)}, \tag{17}$$

$$|b_N(\mathbf{u}_N, q_N)| \le \delta \parallel \mathbf{u}_N \parallel_{H^1(D)} \parallel q_N \parallel_{L^2(D)}, \tag{18}$$

$$a_N(\mathbf{u}_N, \mathbf{u}_N) \ge \alpha N^{-s} \parallel \mathbf{u}_N \parallel^2_{H^1(D)}, \tag{19}$$

$$\inf_{q_N \in M_N} \sup_{\mathbf{v}_N \in X_N} \frac{b_N(\mathbf{v}_N, q_N)}{\parallel \mathbf{v}_N \parallel_{H^1(D)} \parallel q_N \parallel_{L^2(D)}} \ge \beta N^{-t} \tag{20}$$

for all $\mathbf{u}_N, \mathbf{v}_N \in X_N$, and $q_N \in M_N$ and where α, β, γ, and δ are constants independent of N and s and t are nonnegative real numbers. Conditions (17) and (18) state that the bilinear forms a_N and b_N are continuous over $X_N \times X_N$ while (19) is a statement of the ellipticity of a_N over $X_N \times X_N$. Condition (20) is known as the inf-sup or compatibility condition, and if it is satisfied then the discretization spaces X_N and M_N are said to be compatible. If these four conditions are satisfied then the problem (15)–(16) is well posed and yields a unique solution $(\mathbf{v}_N, p_N) \in X_N \times M_N$.

Suppose that the solution $(\mathbf{v}, p)$ belongs to $H^{\sigma}(D)^2 \times H^{\sigma-1}(D)$ for a real number $\sigma \geq 1$ and that $\mathbf{f}$ belongs to $H^{\rho}(D)^2$ for a real number $\rho > 1$; then the following error estimates hold for the velocity and pressure approximations:

$$\| \mathbf{v} - \mathbf{v}_N \|_{H^1(D)} \leq cN^s[N^{1-\sigma}(\| \mathbf{u} \|_{H^{\sigma}(D)^2} + \| p \|_{H^{\sigma-1}(D)}) + N^{r-\rho} \| \mathbf{f} \|_{H^{\rho}(D)}],$$

$$\| p - p_N \|_{L^2(D)} \leq cN^{s+t}[N^{1-\sigma}(\| \mathbf{u} \|_{H^{\sigma}(D)^2} + \| p \|_{H^{\sigma-1}(D)}) + N^{r-\rho} \| \mathbf{f} \|_{H^{\rho}(D)}].$$

The parameter r arises in the estimate of the interpolation error with respect to the given set of collocation points. This error is determined by measuring how closely the inner product $(\mathbf{f}, \mathbf{w}_N)$ is approximated by the discrete inner product $(\mathbf{f}, \mathbf{w}_N)_N$.

In the case of the fully staggered grid approach of Bernardi and Maday [3] we have $r = 1$, $s = 1$, and $t = \frac{5}{2}$. For the method based on the use of a pressure approximation of the same degree as the velocity but with the spurious modes removed [4] we have $r = 1$, $s = 0$, and $t = 1$. Finally, for the method based on a pressure approximation of degree $N - 2$ where N is the corresponding degree of the velocity approximation [17] we have $r = 0$, $s = 0$, and $t = \frac{1}{2}$. This method thus yields an optimal error estimate for the velocity and the best estimate for the pressure amongst the three methods. Therefore, this method has the advantages of being free from spurious pressure modes and yielding the best error estimates for the model problem (7)–(8). The lack of optimality in the pressure approximation is a direct consequence of having a nonzero value of t in the inf-sup condition. This property not only affects the accuracy of the pressure but also results in a bad condition number for the Uzawa operator used to solve the discrete set of equations. This operator results from a decoupling of the pressure and velocity computations. Therefore, from a computational as well as a theoretical point of view the lower the value of t the better. These considerations have motivated our use of the so-called $P_N - P_{N-2}$ method of Maday, Patera, and Rønquist [17] in our work.

We now define the discrete bilinear forms for the $P_N - P_{N-2}$ method. Let ξ_i, $0 \leq i \leq N$ be the set of Gauss–Lobatto–Legendre points in the interval $[-1, 1]$. There exists a unique set of positive real numbers w_i, $0 \leq i \leq N$, such that the integration rule

$$\int_{-1}^{1} \psi(x)\, dx = \sum_{i=0}^{N} w_i \psi(x_i)$$

is exact for all $\psi \in P_{2N-1}[-1, 1]$. The discrete bilinear forms a_N and b_N and the discrete inner product for this formulation are defined by

$$a_N(\mathbf{u}, \mathbf{v}) = \sum_{GL} \nabla\mathbf{u}\, \nabla\mathbf{v} \quad \forall\, \mathbf{u}, \mathbf{v} \in (C^1(D))^2,$$

$$b_N(\mathbf{u}, p) = \sum_{GL} \nabla.\mathbf{u}\, p \quad \forall\, \mathbf{u} \in (C^1(D))^2,\ p \in C^0(D),$$

$$(\mathbf{f}, \mathbf{v})_N = \sum_{GL} \mathbf{f}\, \mathbf{v},$$

where

$$\sum_{GL} \psi = \sum_{i=0}^{N} \sum_{j=0}^{N} w_i w_j\ \psi(\xi_i, \xi_j).$$

4. Time-splitting schemes. Time-splitting schemes have the advantage of enabling the different operators in a system of partial differential equations to be treated by appropriate methods of solution. In the present context time-splitting methods are used as a means of determining the solution of the corresponding steady problem. In this respect they may be viewed as iterative techniques. However, for the dynamic loading problem these schemes will be used in true time-dependent mode to track the transient solution of the journal bearing problem, i.e., to determine the locus of the journal in time. In general, nonlinear operators such as the convection operator are treated explicitly while linear operators such as the diffusion, gradient, and divergence operators are treated implicitly.

4.1. Backward Euler. In this scheme the diffusion and pressure computations are coupled. After the spatial discretization has been performed, the velocity and pressure are decoupled by means of an Uzawa method which essentially involves a block Gaussian elimination method to obtain a pressure system. The solution of this system requires the use of a nested iterative solution technique. An efficient preconditioner for this system can only be constructed easily in the case of constant viscosity since otherwise the coefficient matrix of the inner system needs to be updated for each iteration.

STAGE A

$$\frac{\rho}{\Delta t}(\mathbf{v}^* - \mathbf{v}^n) = -\frac{\rho}{\Delta t}\mathbf{v}^n.\nabla\mathbf{v}^n, \tag{21}$$

STAGE B

$$\frac{\rho}{\Delta t}(\mathbf{v}^{n+1} - \mathbf{v}^*) = -\nabla p^{n+1} + 2\nabla.\eta^n\mathbf{d}^{n+1}, \tag{22}$$

$$\nabla.\mathbf{v}^{n+1} = 0. \tag{23}$$

The solution of Stage B requires the inversion of an unsteady Stokes operator at each time step subject to the given velocity boundary conditions on the bearing and the journal. This is the computationally intensive part of the algorithm which we will be investigating in this paper. There is also an alternative backward Euler time splitting method in which the diffusion term is evaluated in Stage A at the starred time level. This scheme has the advantage of decoupling the diffusion and pressure terms completely, so that the corresponding discrete problem does not require a nested iterative solver. However, this scheme suffers from a splitting error of $O(\Delta t)$ which does not vanish as the steady state is reached. This drawback is overcome by use of the Crank–Nicolson scheme, which we describe next [16].

4.2. Crank–Nicolson scheme. In this scheme the treatment of the diffusion and the pressure terms are decoupled. This means that when the scheme is discretized in space there is no requirement for a nested solver. This method is therefore more suitable for variable viscosity problems. The splitting error in this Crank–Nicolson scheme is $O(\Delta t^2)$, and at steady state this error vanishes in contrast to the corresponding backward Euler scheme. Although the discrete pressure operator derived in this case may appear to be nested, the spectral element mass matrix is, in fact, diagonal, and therefore the calculation of its inverse requires no iteration.

5. The spectral element method. In this section we describe the spectral element method applied to Stage B of the backward Euler scheme. The spectral element method is based on a weak formulation of the problem. The variational formulation of (22) and (23) is therefore as follows: find $(\mathbf{v}, p) \in X \times M$ such that

$$\int\!\!\int_\Omega (\eta\nabla\mathbf{v}\nabla\mathbf{w})d\mathbf{x} + \frac{\rho}{\Delta t}\int\!\!\int_\Omega(\mathbf{wv})d\mathbf{x} - \int\!\!\int_\Omega(p\nabla.\mathbf{w})d\mathbf{x} = \frac{\rho}{\Delta t}\int\!\!\int_\Omega(\mathbf{wv}^*)d\mathbf{x}\ \forall\ \mathbf{v} \in X, \tag{24}$$

$$\iint_{\Omega} (\nabla.\mathbf{v}q)d\mathbf{x} = 0 \; \forall \; q \in L^2(\Omega), \tag{25}$$

where we have dropped the time level $n+1$ from the superscript on $\mathbf{v}$ and p.

The spectral element method is a technique for solving problems defined in complex geometries [11], [12]. The idea is to divide the flow into several spectral elements, Ω_k, $1 \leq k \leq K$, such that $\cup_{k=1}^{K} \bar{\Omega}_k = \bar{\Omega}$ and $\Omega_k \cap \Omega_l = \emptyset$ for all $k \neq l$. We also assume that the decomposition is geometrically conforming in the sense that the intersection of two adjacent elements is either a common vertex or an entire edge. Each of the spectral elements is mapped onto the parent element $D = [-1,1] \times [-1,1]$ using the transfinite mapping technique of Gordon and Hall [10].

Since each element Ω_k is mapped onto the parent element $[-1,1] \times [-1,1]$ we may associate with each point $(\xi, \zeta) \in D$ a point $(x(\xi,\zeta), y(\xi,\zeta)) \in \Omega_k$. Under this mapping we have, for example,

$$a^k(\mathbf{v},\mathbf{w}) = \iint_{\Omega_k} \eta \; \nabla\mathbf{v} \; \nabla\mathbf{w} d\mathbf{x} \tag{26}$$

$$= \iint_D \frac{\eta}{J^k} \left\{ G_1^k \frac{\partial \mathbf{v}}{\partial \xi}\frac{\partial \mathbf{w}}{\partial \xi} + G_2^k \frac{\partial \mathbf{v}}{\partial \zeta}\frac{\partial \mathbf{w}}{\partial \zeta} + G_3^k \left(\frac{\partial \mathbf{v}}{\partial \xi}\frac{\partial \mathbf{w}}{\partial \zeta} + \frac{\partial \mathbf{v}}{\partial \zeta}\frac{\partial \mathbf{w}}{\partial \xi} \right) \right\} d\xi \, d\zeta, \tag{27}$$

where the Jacobian J^k of the mapping is defined by

$$J^k = \frac{\partial x}{\partial \xi}\frac{\partial y}{\partial \zeta} - \frac{\partial x}{\partial \zeta}\frac{\partial y}{\partial \xi}, \tag{28}$$

$$G_1 = \left(\frac{\partial x}{\partial \zeta}\right)^2 + \left(\frac{\partial y}{\partial \zeta}\right)^2, \tag{29}$$

$$G_2 = \left(\frac{\partial x}{\partial \xi}\right)^2 + \left(\frac{\partial y}{\partial \xi}\right)^2, \tag{30}$$

$$G_3 = -\left(\frac{\partial x}{\partial \xi}\frac{\partial x}{\partial \zeta} + \frac{\partial y}{\partial \xi}\frac{\partial y}{\partial \zeta} \right). \tag{31}$$

We approximate the primitive variables using Legendre–Lagrangian interpolants of degree N in both spatial directions. Let $P_{N,K}$ denote the space of polynomials of degree N or less, defined over the K elements. We choose the velocity field in $P_{N,K}$ and construct a Gauss–Lobatto–Legendre grid in each of the elements Ω_k, $1 \leq k \leq K$. The velocity representation is then given by

$$\mathbf{v}_N^k(\xi,\zeta) = \sum_{i=0}^{N}\sum_{j=0}^{N} \mathbf{v}_{i,j}^k h_i(\xi) h_j(\zeta), \tag{32}$$

where the Lagrangian interpolants $h_i(\xi)$, $0 \leq i \leq N$, are defined on the parent interval with $\xi \in [-1,1]$ by the relationship

$$h_i(\xi) = -\frac{(1-\xi^2)L_N'(\xi)}{N(N+1)L_N(\xi_i)(\xi - \xi_i)}, \tag{33}$$

where the points ξ_i are the collocation points on the Gauss–Lobatto–Legendre grid.

As for the finite element method, the velocity and pressure approximations must satisfy the Babuška–Brezzi condition to avoid the presence of spurious modes. In the framework of

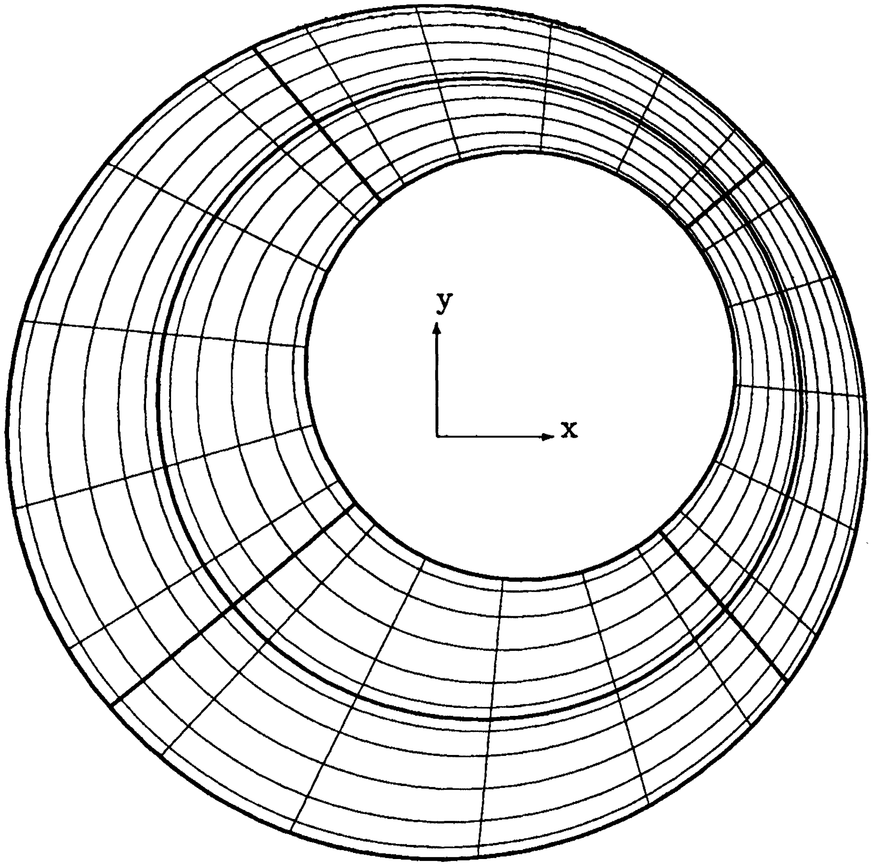

FIG. 2. *The discretization of the physical fluid domain for four elements in the azimuthal direction* ($N_a = 4$) *and two elements in the radial direction* ($N_r = 2$). *Each element is split into seven nodes in each direction* ($N = 7$).

the spectral element method Maday and Patera [15] have shown that a suitable choice for the pressure approximation space is

$$M_N = L^2(\Omega) \cap P_{N-2,K} \ . \tag{34}$$

Thus the pressure approximation is given by

$$p_N^k(\xi, \zeta) = \sum_{i=1}^{N-1} \sum_{j=1}^{N-1} p_{i,j}^k \hat{h}_i(\xi) \hat{h}_j(\zeta), \tag{35}$$

where $\hat{h}_i(\xi)$, $1 \leq i \leq N - 1$, are the Lagrangian interpolants based on the interior Gauss–Lobatto–Legendre points.

The spectral element discretization of the geometry is shown in Figure 2 together with the Gauss–Lobatto collocation grid. A typical collocation grid on the parent element is shown in Figure 3. The number of spectral elements in the radial and azimuthal directions is denoted by E_r and E_a, respectively. A full description and algorithm of the grid generation is given in Appendix A.

The integrals over each element Ω_k in (26) are approximated by a Gauss–Legendre quadrature rule.

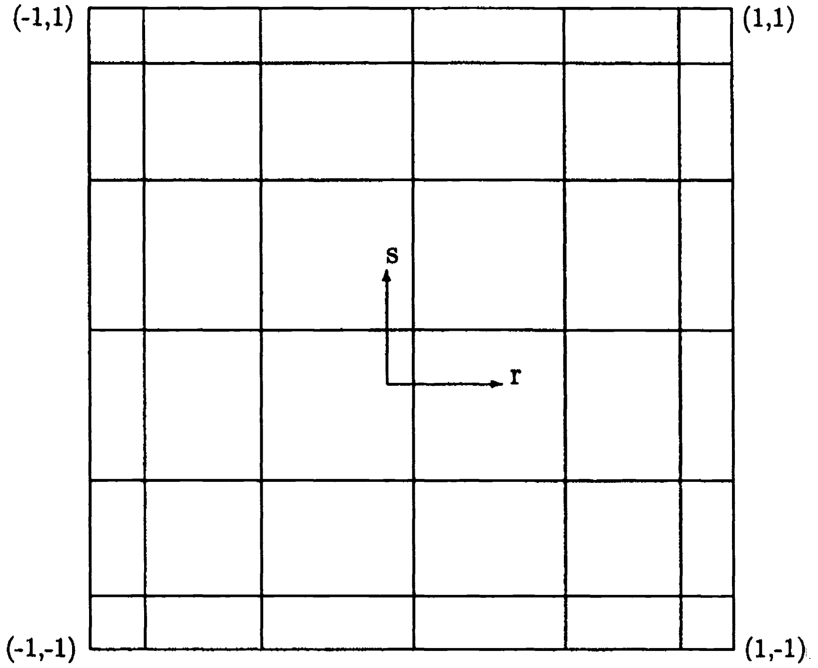

FIG. 3. *The discretization of the parent element into the N^2 nodes ($N = 7$) according to a Legendre–Gauss–Lobatto distribution.*

The velocity and pressure expansions are now inserted into the discrete form of (24)–(25), and the discrete equations are generated by choosing appropriate test functions $\mathbf{w} \in P_{N,K} \cap H_0^1(\Omega)$ which are unity at a single point (ξ_k, ζ_l) and zero at all other Gauss–Lobatto–Legendre points and test functions $q \in P_{N-2,K}$ which are unity at a single point (ξ_k, ζ_l) and zero at all other interior Gauss–Lobatto–Legendre points. Once the discrete bilinear forms have been computed for all elements, the contributions from neighbouring elements are summed along element interfaces. This procedure takes into account the situations in which the test function extends into more than one element. In this way we obtain the system of algebraic equations

$$A\mathbf{v} + \sigma B\mathbf{v} - D^T\mathbf{p} = \mathbf{f}, \tag{36}$$

$$D\mathbf{v} = \mathbf{g}, \tag{37}$$

where D is the discrete divergence operator, its transpose is the discrete gradient operator, B is the mass matrix, and $\sigma = \rho/\Delta t$. The vectors of unknowns now refer to their values at the discretization points (the Gauss–Lobatto nodes). Note that in order to evaluate the discrete gradient and divergence operators we need to map the pressure p_N and the test function q_N within each spectral element from the interior Gauss–Lobatto–Legendre nodes onto the Gauss–Lobatto–Legendre nodes on the boundary of the element.

Block Gaussian elimination yields a symmetric semipositive definite system for the pressure unknowns

$$S\mathbf{p} = \mathbf{c}, \tag{38}$$

where $S = D(A + \sigma B)^{-1}D^T$ and $\mathbf{c} = -D(A + \sigma B)^{-1}\mathbf{f} + \mathbf{g}$. The matrix S is made positive definite by imposing a zero volume condition on the pressure field. The velocity is computed using

$$(A+\sigma B)\mathbf{v} = D^T p+\mathbf{f}. \tag{39}$$

Due to the properties of S and its considerable size an iterative solver to solve (38) is sought. For the model problem on the square grid it can be shown that the maximum eigenvalue of S is fixed and is of order unity while the minimum eigenvalue scales like β_N^{-2}. Hence there is a necessity from the solution point of view to have a good inf-sup condition. Using the preconditioned conjugate gradient (PCG) method to solve this system is well documented [14], and, using a suitable preconditioner, the PCG method is found to be very efficient. For a wide range of problems [14]–[17] this preconditioner works very well within the spectral element context, and we would not advocate the use of anything else. However, for the solution of realistic journal bearing problems the system of equations is extremely ill conditioned due to the nature of the geometry. To illustrate this more clearly we will discuss our problem applied to the constant viscosity steady Stokes solver. The iterative scheme is nested since each matrix–vector multiplication $S\mathbf{p}$ requires the solution of the system

$$(A+\sigma B)\mathbf{r} = \mathbf{s}. \tag{40}$$

This inner system is also solved by the conjugate gradient method since it is a symmetric positive definite system.

6. Preconditioners. The convergence rate of iterative methods for solving a system of linear algebraic equations depends on the spectrum of the coefficient matrix. The idea underlying the preconditioning philosophy is to transform the original system into one that is equivalent in the sense that it has the same solution but that has a more favourable spectrum. We are interested in finding a matrix P, known as the preconditioner, which approximates the coefficient matrix S in some sense so that the transformed system

$$P^{-1}S\mathbf{p} = P^{-1}\mathbf{b} \tag{41}$$

has the same solution as (38) has but the eigenvalues of $P^{-1}S$ are more clustered than those of S. The trade-off between the cost of constructing and applying the preconditioner and the expected gain in convergence speed of the iterative method must be borne in mind. The transformation of the linear system (41) is not what is actually used in the computations. Instead, the preconditioner is decomposed in the form $P = QQ^T$ and the transformed system written as

$$Q^{-1}SQ^{-T}(Q^T\mathbf{p}) = Q^{-1}\mathbf{b}. \tag{42}$$

The condition number, κ, of the preconditioned system is defined by

$$\kappa = \frac{\lambda_{\max}}{\lambda_{\min}} \tag{43}$$

where $\lambda_{\max}$ and $\lambda_{\min}$ are the largest and smallest eigenvalues of the preconditioned matrix L where

$$L = Q^{-1}SQ^{-T}, \quad P = QQ^T. \tag{44}$$

A given iterative method is then preconditioned following this procedure:

1. The right-hand side vector is transformed according to

$$\tilde{\mathbf{b}} = Q^{-1}\mathbf{b}.$$

2. Apply the iterative method to the system

$$L\tilde{\mathbf{p}} = \tilde{\mathbf{b}}.$$

3. Compute

$$\mathbf{p} = Q^{-T}\tilde{\mathbf{b}}.$$

The preconditioner is chosen to be an approximation to S, in some sense, which is easier and cheaper to invert than S. Ideally the preconditioner should have similar properties to the original matrix and also be sparse so that it is efficient to construct and to store.

The decomposition of P given in (44) is not needed in practice. The steps of the conjugate gradient method can be rewritten so that the preconditioner is applied in its entirety [9].

6.1. Constant viscosity problem.

6.1.1. Steady Stokes solver. As mentioned previously, direct methods for solving (38) are undesirable due to the considerable time required in preprocessing S. Furthermore, due to the bad conditioning of S for small α we find that Choleski decomposition gives inaccurate results. In the present context accuracy is measured by comparing our results with those given in [18] and also knowledge that steady Stokes flow is symmetric with respect to the line joining the centres of the journal and the bearing. We find that preconditioning is absolutely necessary for the efficient and accurate solution of this problem.

Here we are interested in finding effective preconditioners for the matrix $S = \eta DA^{-1}D^T$. This matrix has rank equal to the number of pressure degrees of freedom, i.e., $M = K(N-1)^2$, and will be completely full due to the presence of A^{-1}. Maday and Patera [15] demonstrate that for some test problems the matrix S is extremely well conditioned. They use a heuristic argument to explain this phenomenon. They argue that the spectrum of S behaves like the variational equivalent of the identity operator since it involves the product of gradients "divided" by the Laplacian. This leads them to suggest that the pressure mass matrix would make an ideal preconditioner. For a wide range of problems [14]–[17] this preconditioner works very well within the spectral element context, and we would not advocate the use of anything else. However, we present results which show that the condition number of S is geometry dependent; i.e., for the distorted spectral elements in the physical journal bearing problem the spectrum of S is not so universally well behaved as Maday and Patera [15] perhaps suggest.

The way the spectral element grid is constructed means that as far as the geometrical parameters of the problem are concerned the entries of the pressure matrix S are dependent on the eccentricity ϵ but not on the orientation of the journal. We denote this dependence by S_ϵ. The following preconditioners were considered for the constant viscosity steady Stokes problem:

1. $P = B$ where B is the pressure mass matrix. This matrix is not sparse at the elemental level.
2. $P = \hat{B}$ where $\hat{B}$ is the diagonal of B.
3. $P = S_{\epsilon^*}$ where S_{ϵ^*} is the matrix S_ϵ evaluated at $\epsilon = \epsilon^*$.

The geometry of a typical car engine journal bearing is such that the physical aspect ratios, which are proportional to $\alpha \equiv c/2\pi R_J$, are very small where $c \equiv R_B - R_J$ is the average gap of the fluid region. Typical values are much less than $\frac{1}{100}$. Therefore, not even a significant redefinition of the spectral element discretization would overcome this problem.

We show that the eigenvalue spectrum is very much dependent on the physical aspect ratio. In Figures 4 and 5 we choose $\epsilon = 0.5$ and keep (N, E_r, E_a) fixed at $(7, 2, 2)$, which gives $M = 196$, and show the eigenvalue spectra of the preconditioned system when the

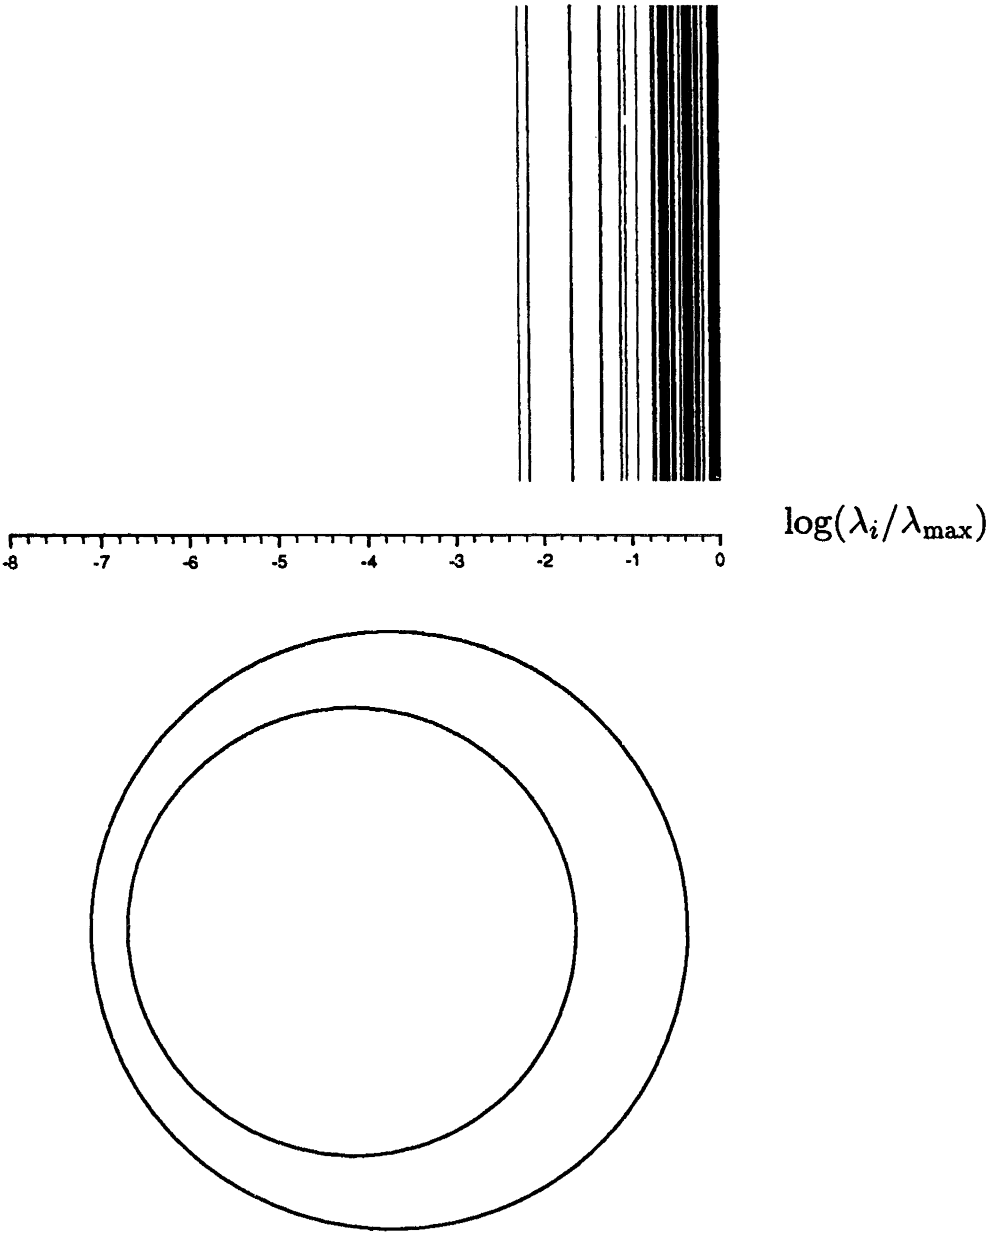

FIG. 4. *Eigenvalue spectrum of a preconditioned system with* $P = B$ *with* $(N, E_r, E_a) = (7, 2, 2)$ *and an illustration of the model for the case of* $\alpha = 5.3 \times 10^{-2}$, $\epsilon = 0.5$. *The result is a condition number* $\kappa = 188.3$ *and the number of PCG iterations* = 28.

preconditioner is the pressure mass matrix, i.e., $P = B$. The outer radius in both figures is the same ($R_B = 0.03129$) and the inner radius is varied so as to vary α.

In Figure 4, $\alpha = 0.053$ whilst in Figure 5, $\alpha = 2.04 \times 10^{-4}$. One can see from Figure 5 that the value of α is so small that the two cylinders are indistinguishable from each other. The result is that the condition number increases as α decreases with a cluster of very small eigenvalues appearing in the latter figure. In terms of conjugate gradient iterations the model with $\alpha = 0.053$ takes 28 iterations to converge whilst with $\alpha = 2.04 \times 10^{-4}$, 40 iterations

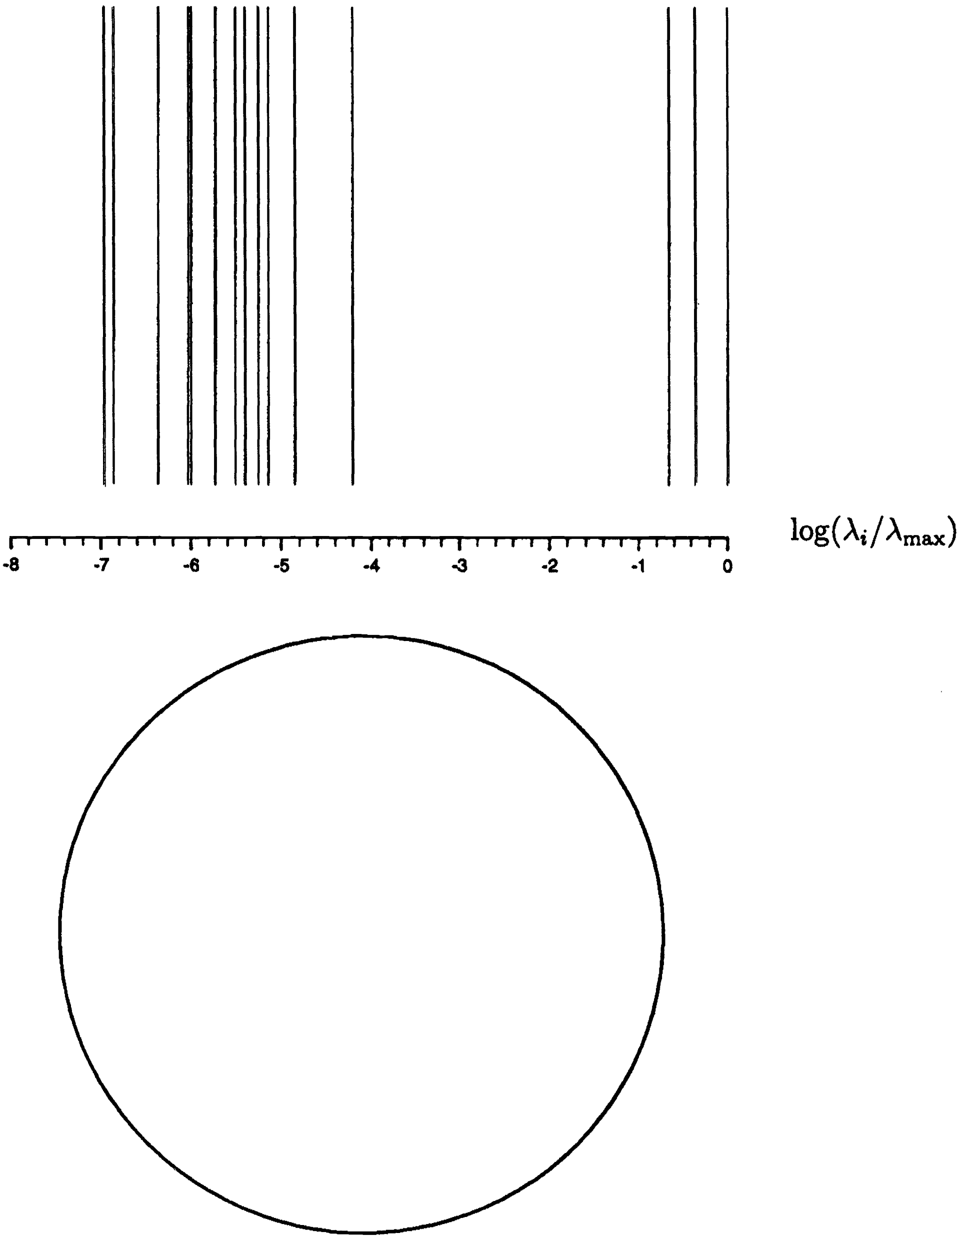

FIG. 5. *Eigenvalue spectrum of a preconditioned system with* $P = B$ *and* $(N, E_r, E_a) = (7, 2, 2)$ *together with an illustration of the model for the case of* $\alpha = 2.04 \times 10^{-4}$, $\epsilon = 0.5$. *The result is a condition number* $\kappa = 9.35 \times 10^6$ *and the number of PCG iterations* = 40.

are required. The position was much worse for the preconditioner $P = \hat{B}$ for which the PCG method failed to converge within the theoretical maximum number of M iterations for $\alpha = 2.04 \times 10^{-4}$, indicating that round-off errors dominate.

Changing the number of elements or the number of nodes whilst keeping the elemental aspect ratio fixed does not alter the condition number of the preconditioned system with $P = B$. This is illustrated in Figures 6 and 7 where the eigenvalue spectra are given for the same model as illustrated in Figure 5 except that $(N, E_r, E_a) = (7, 4, 4)$ and $(12, 2, 2)$,

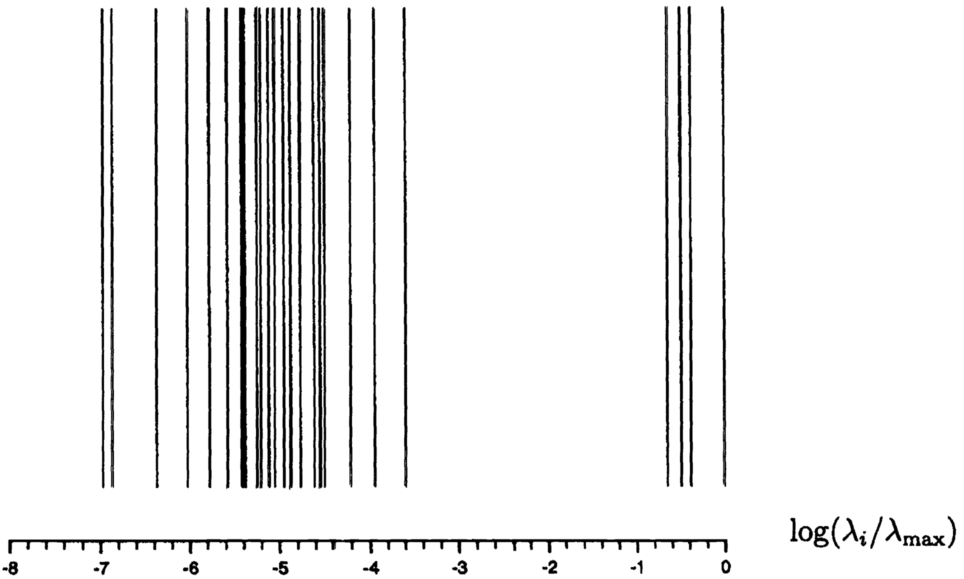

FIG. 6. *Eigenvalue spectrum of a preconditioned system with $P = B$ and $(N, E_r, E_a) = (7, 4, 4)$ for the case of $\alpha = 2.04 \times 10^{-4}$, $\epsilon = 0.5$. The result is a condition number $\kappa = 9.36 \times 10^6$.*

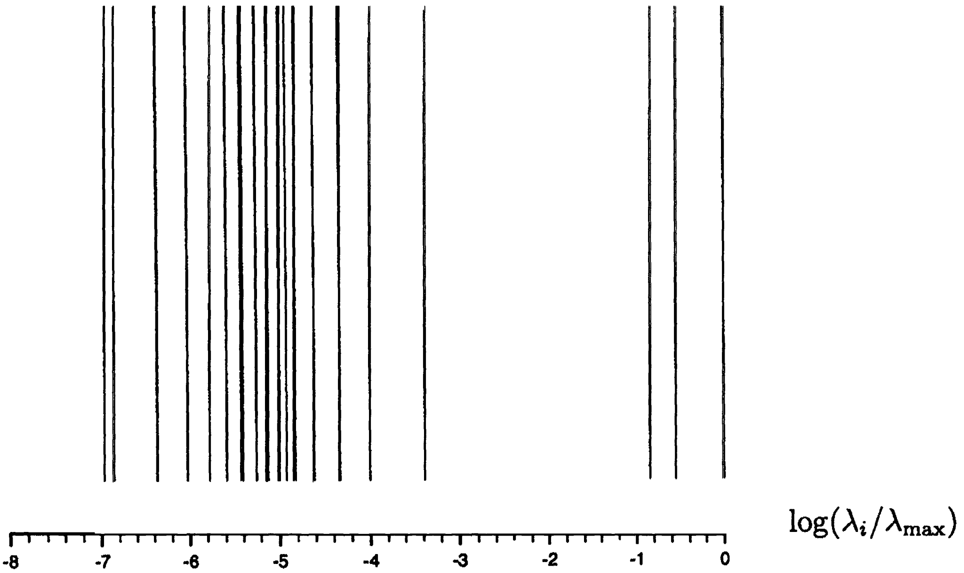

FIG. 7. *Eigenvalue spectrum of a preconditioned system with $P = B$ and $(N, E_r, E_a) = (12, 2, 2)$ for the case of $\alpha = 2.04 \times 10^{-4}$, $\epsilon = 0.5$. The result is a condition number $\kappa = 9.36 \times 10^6$.*

respectively, as opposed to (7,2,2). The resulting condition number for both these examples is $\kappa = 9.36 \times 10^6$.

Thus we have shown conclusively that the condition number of the preconditioned system is dependent on the preconditioner and the physical aspect ratio, α, but not on the elemental aspect ratio. Figures 8 and 9 give the eigenvalue spectra for two different elemental aspect ratios corresponding to (7, 2, 4) and (7, 4, 2), respectively, whilst α is kept fixed at 2.04×10^{-4}. The condition number remains unaltered with a value of $\kappa = 9.36 \times 10^6$.

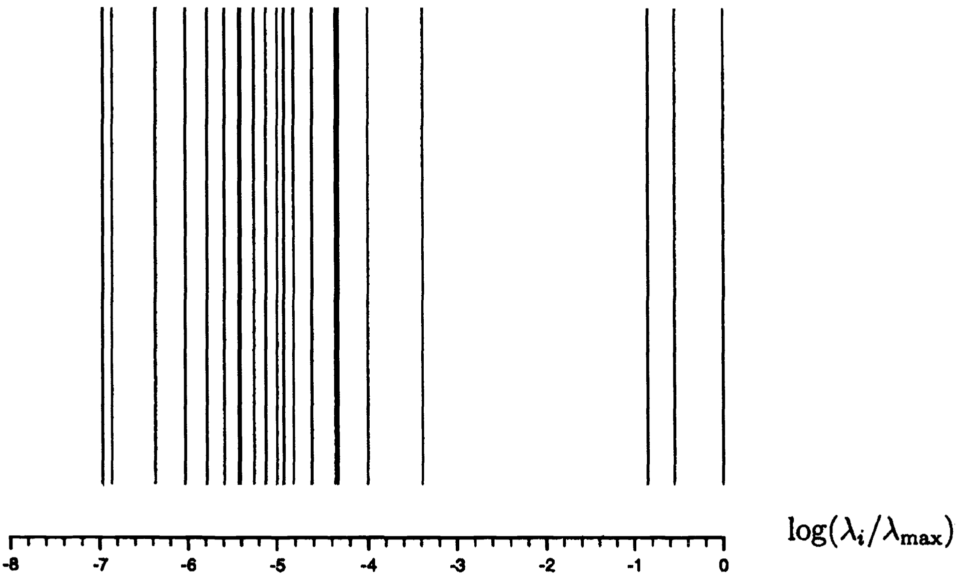

FIG. 8. *Eigenvalue spectrum of preconditioned system with* $P = B$ *and* $(N, E_r, E_a) = (7, 2, 4)$ *for the case of* $\alpha = 2.04 \times 10^{-4}$, $\epsilon = 0.5$. *The result is a condition number* $\kappa = 9.36 \times 10^6$.

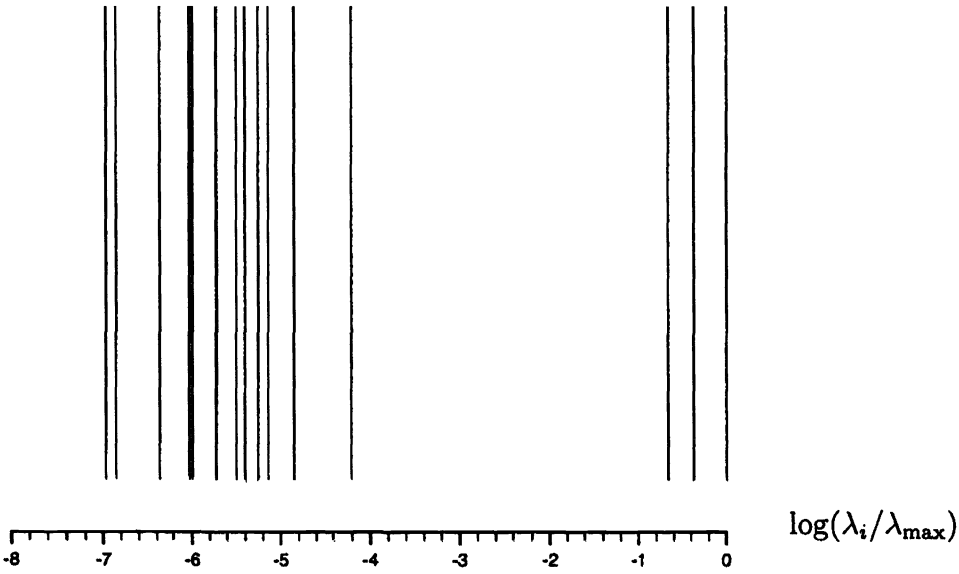

FIG. 9. *Eigenvalue spectrum of a preconditioned system with* $P = B$ *and* $(N, E_r, E_a) = (7, 4, 2)$ *for the case of* $\alpha = 2.04 \times 10^{-4}$, $\epsilon = 0.5$. *The result is a condition number* $\kappa = 9.36 \times 10^6$.

The number of eigenvalues in the cluster of small eigenvalues is the same as the number of pressure nodes N_a in the azimuthal direction, where $N_a = N \times E_a$. This is also the case for the eigenvalue spectrum of the unpreconditioned matrix S. For the unpreconditioned system the eigenvectors corresponding to these small eigenvalues display a pattern. Irrespective of the eccentricity of the system, these "zero eigenvectors" can be associated with a set of nodal points P_k which lie on the same radial line as the kth nodal point. As the average gap c decreases, the values of the "zero eigenvalues" become smaller and the corresponding "zero

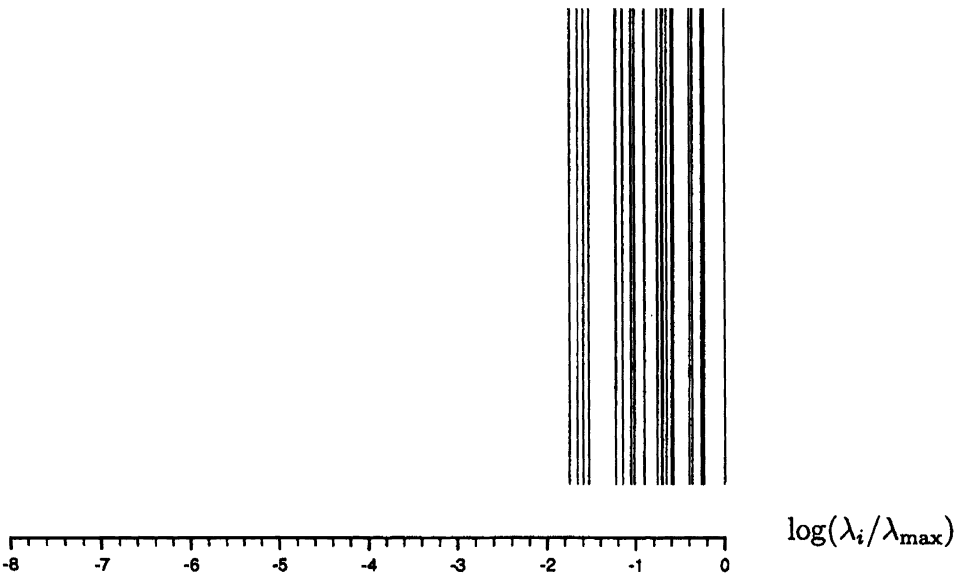

FIG. 10. *Eigenvalue spectrum of a preconditioned system with* $P = S_{0.0}$ *and* $(N, E_r, E_a) = (7, 2, 2)$, $\alpha = 2.04 \times 10^{-4}$, *and* $\epsilon = 0.5$. *The result is a condition number* $\kappa = 55.8$ *and the number of PCG iterations* $= 27$.

eigenvectors" tend toward the vectors $\mathbf{e}_k$, $k = 1, \ldots, N_a$, whose entries are given by

$$\mathbf{e}_k(i) = 0 \text{ if } i \notin P_k,$$
$$\mathbf{e}_k(i) = 1 \text{ if } i \in P_k.$$

This behaviour is independent of the eccentricity of the system. This leads us to choose as preconditioner the pressure matrix $S_{0.0}$ that is generated from the concentric model ($\epsilon = 0.0$). If the gap c is small then the structure of the "zero eigenvalues" for the two models (S, $S_{0.0}$) are similar. The resulting eigenvalue spectrum with $P = S_{0.0}$ is illustrated in Figure 10, and this can be compared directly with the spectrum given in Figure 5 where $P = B$.

The following tables compare the condition number, the number of PCG iterations, and CPU time per PCG iteration for different preconditioners for S in the case when $\epsilon = 0.5$. It is clear that the most successful preconditioner in terms of number of PCG iterations required for convergence is $S_{0.0}$. There are also advantages with respect to accuracy for using this preconditioner since its condition number is considerably lower than that of its competitors. Even with respect to CPU time, preconditioners based on nondiagonal matrices are only slightly more expensive to use than those based on diagonal matrices. The reason for this somewhat surprising statement is that the CPU times are dominated by the inner iteration process. The number of inner iterations is independent of the choice of preconditioner in the outer iteration. The only significant difference in times occurs for larger values of M when the cost of using a dense preconditioner is about 25% more than the cost of using a diagonal preconditioner. However, given the considerably fewer number of iterations required for convergence in the former case, the difference in CPU times is not enough to justify a diagonal preconditioner. The preconditioner based on $S_{0.0}$ needs to be calculated only once and can be applied to systems with different eccentricities. The inversion of the pressure mass matrix also requires a nontrivial amount of work. In addition it needs to be recomputed for different eccentricities. The other two preconditioners (I and $\hat{B}$), although trivial to calculate and invert, are very poor preconditioners in terms of the number of PCG iterations required

TABLE 1a

for convergence. In practice we are not limited to using the preconditioner based on the concentric coefficient matrix $S_{0.0}$. It is possible to construct and store a set of preconditioners S_{ϵ_i}, $1 \le i \le I$, for different eccentricities ϵ_i and to use the preconditioner S_{ϵ_j} for which ϵ_j is closest to ϵ.

Note that the condition number of the preconditioned system is independent of N for the two cases $P = B$ and $P = S_{0.0}$. In this sense we say that both preconditioners are optimal and that we can expect the number of PCG iterations to be proportional to M. However, it can be seen from Table 1 that the number of iterations using both these preconditioners increases less than in proportion with N. This effect is more pronounced in the case $P = S_{0.0}$, where the number of iterations required for $N = 10$ and $N = 13$ is almost the same.

6.1.2. Unsteady Stokes solver. For the unsteady Stokes problem with a constant viscosity η the resulting pressure matrix S_t is given by

$$S_t = D(\eta A + \sigma B)^{-1} D^T, \tag{45}$$

where $\sigma = \rho/\Delta t$. The "natural well conditioning" that exists in the steady pressure matrix S does not exist in S_t. The matrix S_t is again symmetric positive definite, and, as in the steady case, the solution to the linear system

$$S_t \mathbf{p} = \mathbf{r} \tag{46}$$

can be found using a nested PCG iteration.

A preconditioner considered in [7] is a linear combination of the inverses of the identity and the Laplacian operators. This choice is motivated in [14] by considering the two limits of S_t as $\Delta t \to 0$ and $\Delta t \to \infty$; that is,

$$S_t \to \eta^{-1} S \text{ as } \Delta t \to \infty, \tag{47}$$

$$S_t \to \sigma^{-1} E \text{ as } \Delta t \to 0, \tag{48}$$

where $E = DB^{-1}D^T$ is the discrete Poisson operator. The resulting preconditioner is written as

$$P^{-1} = \eta B^{-1} + \sigma E^{-1}. \tag{49}$$

TABLE 2

The number of PCG iterations and the condition number of the preconditioned system for the two different preconditioners corresponding to equations (50) *and* (51), *respectively. The parameters of the problem are* $(N, E_r, E_a) = (7, 2, 2)$*; that is,* $M = 196$ *for the case of* $\epsilon = 0.5$, $\alpha = 2.04 \times 10^{-4}$, $\eta = 5$ *(mPa s),* $\rho = 820 kg/\mathrm{m}^3$.

	$\epsilon^* = 0.0$	$\epsilon^* = 0.25$	$\epsilon^* = 0.5$
$\Delta t = 0$	100(2.28 × 10^7)	81(1.47×10^7)	40(9.35 × 10^6)
$\Delta t = 10^{-3}$	79(540.4)	55(324.2)	36(180.7)
$\Delta t = 10^{-4}$	48(57.3)	36(34.4)	25(19.2)
$\Delta t = 10^{-5}$	35(9.09)	28(6.04)	18(4.47)
$\Delta t = 10^{-7}$	25(6.29)	20(4.52)	11(2.65)

	$\epsilon^* = 0.0$	$\epsilon^* = 0.25$	$\epsilon^* = 0.5$
$\Delta t = 0$	29(55.8)	17(9.94)	1(1.00)
$\Delta t = 10^{-3}$	28(25.6)	17(5.65)	4(1.03)
$\Delta t = 10^{-4}$	27(18.1)	17(4.68)	7(1.11)
$\Delta t = 10^{-5}$	23(6.75)	16(2.97)	7(1.23)
$\Delta t = 10^{-7}$	22(4.26)	16(2.38)	7(1.13)

This preconditioner clearly has the advantage that in adaptive time-stepping schemes the recalculation of P^{-1} for different time steps is trivial. As in the steady solver this preconditioner would need to be recalculated if the eccentricity of the model changed. We generalize preconditioners of the form (49) as follows:

$$P^{-1} = \eta B_{\epsilon^*}^{-1} + \sigma E_{\epsilon^*}^{-1}, \tag{50}$$

where the subscript ϵ^* means that the relevant matrices are evaluated at that particular eccentricity ratio. The preconditioner defined in (50) is identical to that defined in (49) when $\epsilon^* = \epsilon$. We compare the use of (50) with

$$P^{-1} = \eta S_{\epsilon^*}^{-1} + \sigma E_{\epsilon^*}^{-1}, \tag{51}$$

which is the unsteady problem preconditioner analogous to $P = S_{\epsilon^*}$ for the steady problem.

Table 2 displays the number of PCG iterations required for the preconditioners given by (50) and (51). Also shown in this table, in brackets, is the condition number of the preconditioned system.

It is clear that the preconditioner involving the full steady pressure matrix S_{ϵ^*}, i.e., (51), is superior to that using the pressure mass matrix B_{ϵ^*}, i.e., (50). The extent to which (51) is a better preconditioner than (50) depends upon the time step. For a small Δt the two preconditioners are at their most comparable with the system matrix being closer to σE; when $\Delta t = 10^{-7}$, the preconditioner in (50) for $\epsilon^* = 0.5, 0.25$ is still better than that in (51) at $\epsilon^* = 0.25, 0.0$, respectively. However, for larger time steps, when the steady Stokes operator becomes more influential, the performance of the preconditioner in (51) becomes increasingly better when compared with (50). For example, for time steps of greater than approximately 10^{-4} the performance of (51) for the concentric geometry ($\epsilon^* = 0.0$) outperforms (50) for $\epsilon^* = \epsilon = 0.5$.

For solving (46) at a number of different eccentricities we would choose a limited number of eccentricities and for each one calculate the preconditioner from (51). The number of preconditioners that need to be calculated and for which eccentricities is dependent on the number of solutions to the pressure system (46) that is required and the range of eccentricity ratios. In a typical dynamic model as many as $O(10^5)$ solutions are performed with eccentricities

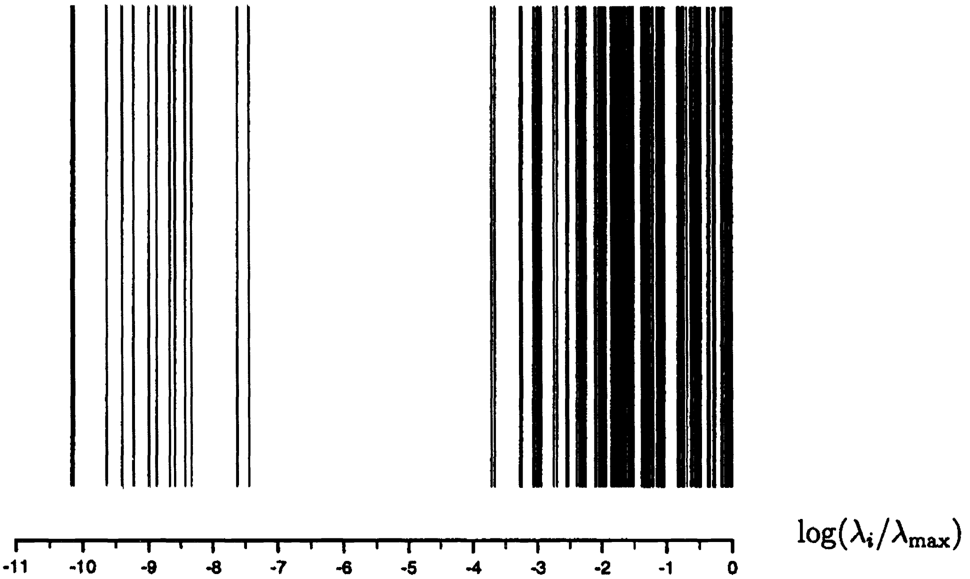

FIG. 11. *Eigenvalue spectrum of DD^T and $(N, E_r, E_a) = (7, 2, 2)$ for the case of $\alpha = 2.04 \times 10^{-4}$, $\epsilon = 0.5$. The result is a condition number $\kappa = 1.49 \times 10^{10}$.*

varying almost throughout the whole domain, i.e., $\epsilon \in [0, 1)$. For such a model the calculation of 10 preconditioners at intervals of equal eccentricity is found to be both effective and cheap in comparison with the total run time. Clearly, the number of iterations listed in Table 2 and in the rest of the paper is only for the comparison of different methods and preconditioners; the actual number of iterations can be reduced dramatically, for example, by a choice of the initial guess based upon knowledge of the solution at other eccentricities.

6.2. Variable viscosity problem. For the unsteady non-Newtonian problem difficulties arise with finding preconditioners for the resulting Schur complement matrix S^η which is now defined as

$$S^\eta = D(A_\eta + \sigma B_v)^{-1} D^T, \tag{52}$$

where A_η represents the discrete weak formulation of the diffusion operator $\eta\Delta$. For the constant viscosity case this operator was represented simply by ηA. For the corresponding variable viscosity problem this is no longer the case. If there are only slight variations in the viscosity then the preconditioner associated with the constant viscosity problem may be reasonable with effective viscosity $\hat{\eta}$ which is an average, in some sense, of the variable viscosity throughout Ω. However, in a typical high-speed journal bearing problem the viscosity can vary by as many as two orders of magnitude due to, primarily, the variation in pressure. Difficulties arise in the numerical solution process because the viscosity is now embedded in the operator A_η, and this, in turn, is nested between the multiplication of the gradient and divergence operators. For problems in which there is a large variation in viscosity there is no obvious reason why the *average viscosity* preconditioner should work well.

The poor conditioning of S, S^t, and S^η derives from the poor conditioning of DD^T, whose eigenvalue spectrum is shown in Figure 11. The Crank–Nicolson scheme described in §4.2 provides a mechanism for removing the variable viscosity from the nested solution of systems with coefficient matrices of the form (52). The resulting linear algebraic problem involves

TABLE 3

Information on the viscosity of the steady-state fluid for geometry of $\epsilon = 0.5$ and $\alpha = 2.04 \times 10^{-4}$ for angular velocity $\omega = 250$, numerical parameters $(8, 2, 2)$, and viscosity parameters given in Appendix B (η_A & η_B). All units are in (mPa s).

	η_A	η_B
$\langle\hat{\eta}\rangle$	4.9996	4.9993
$\eta_{\max}$	8.3061	9.5120
$\eta_{\min}$	4.7350	2.9996

two solutions of a system of equations of the form

$$H\mathbf{r} = \mathbf{s}, \tag{53}$$

where H is the discrete Helmholtz operator defined by

$$H = A_\eta + \sigma B_v \tag{54}$$

and one solution of a system of the form

$$S^o\mathbf{r} = \mathbf{t}, \tag{55}$$

where

$$S^o = DB_v^{-1}D^T \tag{56}$$

is a Schur complement matrix and B_v is the velocity mass matrix.

Equation (55) can be solved using a PCG method. This is not a nested iteration since the matrix B_v is diagonal and hence the calculation of its inverse is trivial. The preconditioner used is simply $S^o_{\epsilon*}$ since S^o is independent of both the variable viscosity and the time step. For the PCG method applied to (53) we use as preconditioner $\hat{H}$ the diagonal of H which can be readily calculated and inverted.

We compare the Crank–Nicolson scheme with preconditioners defined above with the scheme described in the previous section, in which the Schur complement matrix (52) is preconditioned by

$$P = \hat{\eta}S_{\epsilon*}^{-1} + \sigma E_{\epsilon*}^{-1}, \tag{57}$$

where $\hat{\eta}$ is the average viscosity of the fluid.

At a first glance it would seem that the Crank–Nicolson method involves more work, requiring three matrix solutions as compared with the one solution in the case of solving (52). However, the inversion of the system with coefficient matrix given by (52) requires a nested iteration, the inner one of which may require a large number of iterations on systems of the form (53) to converge.

We refer to the two different approaches as method-S (Schur) and method-CN (Crank–Nicolson), respectively. In comparing the performance of method-S with method-CN we require different viscosity fields. We use the standard geometry used previously defined by $\epsilon = 0.5$ and $\alpha = 2.04 \times 10^{-4}$. In addition, we use the viscosity generated for the steady flow between the cylinders with the inner cylinder rotating at an angular velocity of 250 rad/s about its own axis.

Table 3 illustrates the range of the viscosities for the two viscosity fields we have chosen, η_A and η_B. The parameters which define these viscosity functions are given in Appendix B. The viscosity parameters are chosen so that the average viscosities are similar in order to make as fair a comparison as possible.

Clearly the viscosity relating to η_B has much more variation than that relating to η_A. For this reason, a preconditioner based upon a constant viscosity is expected to be more successful

TABLE 4

The number of PCG iterations, with the condition number in parentheses, of the preconditioned system using method-S for inverting (52). *The data for the model corresponds to that in Table* 3, *and we have taken* $\epsilon^* = \epsilon$. *In addition to the two variable viscosity fields the result for the constant viscosity case of* $\eta_O = 5$ *mPa s is listed. $\Delta t = 10^{-5}$	11(1.53)	17(2.84)	7(1.23)
$\Delta t = 10^{-7}$	9(1.30)	14(2.47)	7(1.13)

for the η_A model than for the η_B model, and this is shown to be the case. The performance of method-S, in terms of number of outer PCG iterations, is illustrated in Table 4 together with the associated condition numbers. In this table we have taken $\epsilon^* = \epsilon = 0.5$.

Although neither of the two viscosities has a range covering the two orders of magnitude reported earlier in this paper, the variation is enough to illustrate the problem that can arise with variable viscosity, with a large variation increasing the number of iterations for the method-S. A variation of viscosity covering two orders of magnitude can be obtained if the eccentricity of the journal is very large or if the journal has a large squeeze (translational) velocity.

The conclusion here is that variation in viscosity causes an increase in the number of PCG iterations required for convergence, and this is most evident when σ is small and hence the contribution of A_η in (54) is large. For the variable viscosity problem it is therefore not surprising that as Δt decreases the number of iterations decreases. The opposite behaviour is observed for the constant viscosity case since for the extreme values of Δt with $\epsilon = \epsilon^*$ the preconditioner tends toward the system matrix (47), (48) and the range $\Delta t \in (10^{-5}, 10^{-7})$ corresponds roughly to a peak in the number of such iterations.

In this paper we have not mentioned the number of inner iterations required for these nested schemes. The inner problem in the nested solver associated with method-S is the same as the first two solvers required for the method-CN, that is, (53). For both these cases we compare the performance of two preconditioners, namely the diagonal of the matrix, that is, $P = \hat{H}$ and $P = \hat{\eta} A_{\epsilon^*}$, with $\epsilon^* = \epsilon = 0.5$. Clearly we could have chosen a less optimal ϵ^* for the latter preconditioner but Tables 5a and 5b should only be taken as a guide since more work needs to be done on the preconditioning of this system. The number of velocity degrees of freedom is denoted by M_v. There are surprising results in these tables, notably in Table 5a where the number of iterations does not follow the decrease in condition number. As Δt decreases, σ increases, and hence we would expect H to tend toward σB, thus making $\hat{H}$ a more powerful preconditioner. This is supported by the condition number of the system. The reason the number of iterations does not decrease with the condition number is due to the eigenvalue distribution of A. For a very small aspect ratio the eigenvalues of the preconditioned system of A with $P = \hat{A}$ are clustered into well-defined distinct groups. The band width of each cluster is dependent on α, and each of the $(N+1) \times E_r - 1$ clusters contains $(N+1) \times E_a$ eigenvalues. To illustrate this we present the eigenvalue spectrum of this system in Figure 12 in which, to the naked eye, the system has only $(N + 1) \times E_r - 1$ distinct eigenvalues. In comparison, we have in Figure 13 the eigenvalue spectrum of the preconditioned system of H with $P = \hat{H}$ now with $\Delta t = 10^{-5}$. The PCG theory [6] states that, in exact arithmetic, the number of PCG iterations required to converge to the correct solution is equal to at most the number of distinct eigenvalues. This is almost the case when $\Delta t = 0$ and explains why so few iterations are required for a system which has a large condition number.

For the $\Delta t = 10^{-5}$ case each local cluster of eigenvalues has spread out and hence, despite the lower condition number, the number of distinct eigenvalues has increased dramatically, thus increasing the maximum number of iterations required for convergence.

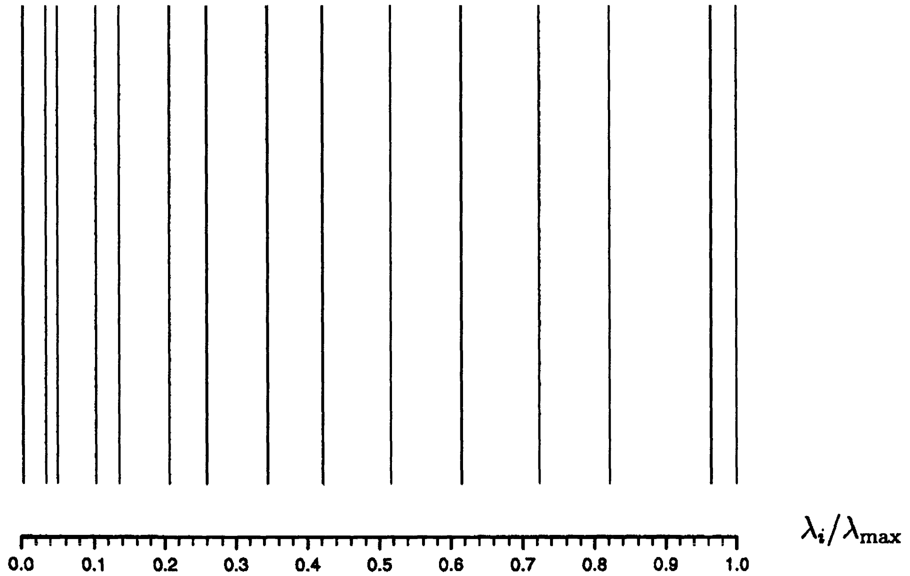

FIG. 12. *Eigenvalue spectrum of a preconditioned system of H with* $P = \hat{H}$, *constant viscosity* $\eta = 5$ *mPa s*, $\Delta t = 0$, $\alpha = 2.04 \times 10^{-4}$, $(N, E_r, E_a) = (7, 2, 2)$, *and* $\epsilon = 0.5$. *The result is a condition number* $\kappa = 243.59$ *and the number of PCG iterations* $= 30$.

The same argument can be applied to the case of variable viscosity, although the band width of each local eigenvalue cluster is greater than in the constant viscosity case. For $\Delta t = 10^{-7}$ the Helmholtz operator is sufficiently near to the diagonal mass matrix for the diagonal preconditioner to be effective.

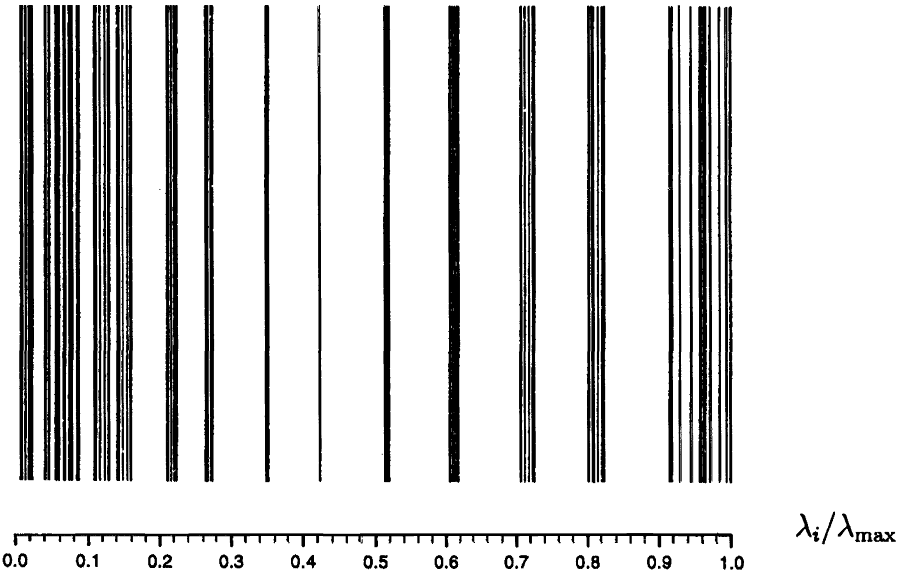

FIG. 13. *Eigenvalue spectrum of a preconditioned system of H with $P = \hat{H}$, constant viscosity $\eta = 5$ mPa s, $\rho = 820 kg/m^3$, $\Delta t = 10^{-5}$, $\alpha = 2.04 \times 10^{-4}$, $(N, E_r, E_a) = (7, 2, 2)$, and $\epsilon = 0.5$. The result is a condition number $\kappa = 150.76$ and the number PCG iterations $= 75$.*

TABLE 6

The number of PCG iterations and the condition number of the preconditioned system for the preconditioner $P = S^o_{\epsilon^*}$ applied to the problem of (56) for various ϵ^* and $\epsilon = 0.5$. The parameters of the problem are $(N, E_r, E_a) = (7, 2, 2)$; that is, $M = 196$, $\alpha = 2.04 \times 10^{-4}$.

$\epsilon^*= 0.25$	$\epsilon^*= 0.4$	$\epsilon^*= 0.45$	$\epsilon^*= 0.5$	$\epsilon^*= 0.55$	$\epsilon^*= 0.6$
21(2.26)	15(1.44)	12(1.21)	3(1.00)	12(1.24)	16(1.57)

The results of Table 5b are much as expected with the number of iterations and the condition number increasing with decreasing Δt as the Helmholtz operator departs from the Laplacian operator. We have shown that the choice of preconditioner is dependent on the time step. For practical applications we must also consider the efficiency of using $P = \hat{\eta} A_{\epsilon^*}$ for $\epsilon^* \neq \epsilon$.

Table 6 shows the performance of various preconditioners for the third stage of the Crank–Nicolson scheme, i.e., equation (55). This equation is independent of the variable viscosity and of the time step and hence all there is to vary is ϵ^*.

To make a fair comparison between method-CN and method-S we should first of all compare the results of Table 4 with those of Table 6 under the column $\epsilon^* = 0.5$, that is, $\epsilon^* = \epsilon$. The rest of the entries in Table 6 are a guide to how many preconditioners need be calculated to be within a given tolerance in the number of iterations.

Purely in terms of the number of iterations required it is clear that using method-CN is more effective than using method-S. This is because for method-S, if we use $\epsilon^* = \epsilon$ then the preconditioner is, in fact, S^o. The reason why as many as three iterations are required to solve for (56) in this case is that S^o is so badly conditioned that the resulting Choleski decomposition is inexact.

At each outer iteration of method-S nested solutions need to be performed which are of the same form as the first two time stages of the Crank–Nicolson scheme. Therefore, if the number of outer iterations in solving the system with the coefficient matrix given by (52) exceeds two then the Crank–Nicolson scheme is the quickest in this context. Further, the number of iterations required to invert (56) is less than the number of outer iterations to invert

(52). We make no comment here on the accuracy of the two approaches, which also needs to be taken into account in making a final comparison between the two methods.

7. Conclusions. In this paper we have developed efficient iterative methods for solving the two-dimensional flow of a non-Newtonian lubricant between eccentrically rotating cylinders. The constitutive model employed is a generalized Newtonian fluid with a viscosity which is shear thinning and pressure thickening. A spectral element method is used for the spatial discretization of the governing equations and first- and second-order time-splitting schemes for the time integration.

For the constant viscosity problem we have considered a first-order backward Euler scheme for the time integration. This couples the velocity and pressure computations. They are decoupled algebraically using an Uzawa-type method. The iterative solution of the resulting pressure system requires a nested iteration. Both inner and outer systems are solved using the PCG method.

When the spectral elements are not highly distorted we would advocate the use of the pressure mass matrix as preconditioner. However, we have shown that even for the steady constant viscosity problem the conditioning of the linear systems generated by the spectral element discretization is poor in the extreme case when the radii of the journal and the bearing are close. This is the situation which occurs in practice. A robust preconditioner for this problem is the pressure matrix for the corresponding concentric cylinder problem. The advantage of this preconditioner over the one based on the pressure mass matrix is that it is only necessary to calculate it once since it can be applied to systems with different eccentricities.

For the unsteady Stokes problem a preconditioner is constructed so that the calculation of its inverse is trivial if the time step is changed. This approach commends itself for adaptive time-stepping schemes. Again preconditioners based on the pressure matrix evaluated at a specific eccentricity are used to precondition systems defined for a range of eccentricities.

Finally, for the variable viscosity problem the velocity and pressure are completely decoupled using a Crank–Nicolson scheme in order to extricate the viscosity function from the inner iterative process. It is important to do this since the viscosity may vary greatly and thus an updated preconditioner may be required after a certain number of time steps. This is, of course, an expensive process. The Crank–Nicolson time-splitting scheme alleviates the need for this extra computation. Preconditioners are given for each of the velocity and pressure systems based on ideas explored for the constant viscosity problem.

Future work will concentrate on the extension of these ideas to the dynamically loaded journal bearing. In this problem we will seek to determine the minimum oil film thickness in the journal bearing due to a prescribed applied load on the journal.

Appendix A: Grid generation. This appendix explains how the grid in Figure 2 is generated. The number of elements in the azimuthal and radial direction (E_a,E_r) are known and this determines the elemental boundaries.

All the radial lines are congruent on the centre of the journal, and this includes the interelemental radial lines. We insist upon E_r being even, and this allows us to set the line joining the centre of the journal C_J and the centre of the bearing C_B as two of the interelemental radial lines. The rest of such lines are drawn so that they are equidistributed in an angle about the centre of the journal. The other radial lines are drawn so that they are distributed in between the interelemental radial lines in such a way that they are distributed in an angle about the centre of the journal in a Gauss–Lobatto distribution.

The distribution of the azimuthal lines is similar in idea to the distribution of radial lines. Every azimuthal line constitutes a circle, and these circles are defined by their centres and corresponding radii. All the centres lie on the line joining C_J and C_B and lie in between them. The interelemental circles have their centres equidistributed between C_J and C_B; the other circles have their centres distributed between the centres of the interelemental circles in a Gauss–Lobatto distribution. The radius of the interelemental circles are equidistributed between the radius of the journal and the radius of the bearing. The rest of the circles have their radii distributed between the radii of the interelemental circles in a Gauss–Lobatto distribution.

The discretization nodes constitute the intersection of all these lines with the journal and bearing's surface also constituting such lines.

The above description can be written in algorithmic form. Let N, E_a, and E_r be as defined in the main part of the paper. We label the azimuthal lines from 0 to N_a, where $N_a = N \times E_a$, and this includes the journal and bearing's boundary. The radial lines are labelled from 0 to N_r, where $N_t = (N \times E_a)$, with the zeroth and N_rth lines representing the same line. If we define the zeroth line as the line joining the centres, extended to the region of smallest gap, then the following uniquely determines the point distribution.

Let the Gauss–Lobatto point distribution be denoted by the vector

$$\mathbf{g}(i) \in [-1, 1], \quad i \in [0, N],$$

the centres and radii of the circles denoted by the respective vectors

$$\mathbf{c}(i) \in [C_J, C_B], \quad i \in [0, N_a],$$

$$\mathbf{r}(i) \in [R_J, R_B], \quad i \in [0, N_a],$$

and the angle distribution about C_j of the radial lines denoted by the vector

$$\mathbf{a}(i) \in [0, 2\pi], \quad i \in [0, N_r].$$

Then the following algorithm holds

```
begin
for $e = 1, E_a$
    step=$2 \times (E_a - 1)$
    for $i = 0, N$
        $v = \mathbf{g}(i)$+step
        $j = i + (e - 1) \times N$
        $r = (v + 1)/(2 \times E_a)$
        $\mathbf{c}(j) = r \times e$
        $\mathbf{r}(j) = R_J + r \times (R_B - R_J)$
    continue
continue

for $e = 1, E_r$
    step=$2 \times (E_r - 1)$
    for $i = 0, N$
        $v = \mathbf{g}(i)$+step
        $j = i + (e - 1) \times N$
        $r = (v + 1)/(2 \times E_r)$
        $\mathbf{a}(j) = r \times 2\pi$
    continue
continue
end
```

where e is the eccentricity.

Appendix B: Viscosity parameters. The parameter values taken for the two variable viscosity fields η_A and η_B when applied to (4) are shown in Table B1.

TABLE B1

A HIERARCHICAL DOMAIN DECOMPOSITION PRECONDITIONER FOR *h-p* FINITE ELEMENT APPROXIMATION ON LOCALLY REFINED MESHES*

MARK AINSWORTH†

Abstract. A domain decomposition preconditioner suitable for h-p finite element approximation on locally refined meshes with nonuniform polynomial degree is proposed and analysed. The preconditioner is highly suited for parallel computation. The algorithm generalizes methods proposed by Smith [*Domain Decomposition Algorithms for the Partial Differential Equations of Linear Elasticity*, Ph.D. thesis, Mathematics Department, New York University, New York, 1991] (for the h-version finite element method with piecewise linear basis functions) and by Mandel [*Comput. Methods Appl. Mech. Engrg.*, 80 (1990), pp. 117–128] (for the p-version finite element method). The analysis shows that the condition number of the preconditioned system grows at most as $\min(H/h, 1+\log^2 p)(1+\log^2(Hp/h))$. This result generalizes the known estimates in each of the special cases mentioned above. Numerical examples are given confirming the theoretical analysis.

AMS subject classifications. 65N30, 65F10

1. Introduction.

Let Ω be a bounded domain in $\mathbb{R}^2$ with piecewise smooth boundary $\partial\Omega$. Consider the second-order elliptic problem

$$-\sum_{j,k=1}^{2} \frac{\partial}{\partial x_j}\left(a_{jk}\frac{\partial U}{\partial x_k}\right) = f \text{ in } \Omega \tag{1}$$

subject to $U = 0$ on the boundary $\partial\Omega$. The data a_{jk} is assumed to be uniformly positive definite, bounded, and piecewise smooth on Ω. The bilinear form $B : H^1(\Omega) \times H^1(\Omega) \mapsto \mathbb{R}$ is given by

$$B(U,V) = \sum_{j,k=1}^{2} \int_\Omega a_{jk}\frac{\partial U}{\partial x_j}\frac{\partial V}{\partial x_k}\,\mathbf{dx} \tag{2}$$

where $H^1(\Omega)$ is the usual Sobolev space of distributions with square integrable derivatives. The subspace $H_0^1(\Omega) \subset H^1(\Omega)$ is the completion of smooth functions with support in Ω, with respect to the $H^1(\Omega)$-norm. The variational formulation of the problem defined by (1) is

$$\text{Find } U \in H_0^1(\Omega) \text{ such that } B(U,V) = (f,V) \text{ for all } V \in H_0^1(\Omega). \tag{3}$$

1.1. Coarse grid.

The finite element approximation of problem (3) will be developed by first subdividing the domain Ω into an initial "coarse" partitioning $\mathcal{P}_H$ consisting of nonoverlapping quadrilateral elements $\{\Omega_H^K\}$ such that

$$\overline{\Omega} = \bigcup_{\Omega_H^K \in \mathcal{P}_H} \overline{\Omega}_H^K \tag{4}$$

and for $K \neq J$, $\overline{\Omega}_H^K \cap \overline{\Omega}_H^J$ is either empty or an entire side or a common vertex of the domains. Let

$$H_K = \operatorname{diam} \Omega_K, \quad H = \max_K H_K \tag{5}$$

*Received by the editors September 13, 1994; accepted for publication (in revised form) June 10, 1995.

†Mathematics Department, Leicester University, Leicester LE1 7RH, U.K. (ain@mcs.le.ac.uk).

and

$$\rho_K = \sup\{\operatorname{diam} \mathcal{B} : \mathcal{B} \text{ is a ball in } \Omega_K\}. \tag{6}$$

It is supposed that there exist positive constants σ, τ independent of h such that

$$\frac{H}{H_K} \leq \tau, \quad \frac{H_K}{\rho_K} \leq \sigma. \tag{7}$$

The partitioning $\mathcal{P}_H$ is therefore quasiuniform of size $O(H)$. The space X_H consists of piecewise bilinear functions defined on the partitioning $\mathcal{P}_H$. An approximation of problem (1) can then be obtained by solving the discrete problem

$$\text{Find } u_H \in X_H \text{ such that } B(u_H, v_H) = (f, v_H) \text{ for all } v_H \in X_H. \tag{8}$$

If the data a_{jk} is discontinuous then the initial coarse partitioning $\mathcal{P}_H$ is constructed so that the element edges coincide with the interfaces along which the data is discontinuous. Such a choice has a beneficial effect on the accuracy of the approximation u_H and will have a significant impact on the preconditioning algorithm to be developed. Typically, owing to the geometry of the domain (e.g., re-entrant corners) and discontinuities in the data a_{jk}, the true solution U of problem (1) will be nonsmooth in certain regions. It is often necessary to enhance the approximation space X_H in the neighbourhood of those areas where the true solution is less regular.

1.2. Types of refinements. Various strategies have been proposed as to how to improve the accuracy. The simplest techniques are to either subdivide the mesh uniformly throughout the domain (the h-version finite element method) or to enrich the polynomial degree of the functions on each of subdomains (the p-version finite element method [4]). Alternatively, one can use a posteriori error estimates to identify specific regions in which the approximation is poor and perform a selective enrichment by locally subdividing the elements and increasing the polynomial degree nonuniformly. The latter approach is in the spirit of the h-p version of the finite element method [3, 5]. A concrete strategy for producing meshes with selective h and p refinement is given in [12] and a general data structure supporting such refinements is given in [8].

The chief advantage of the uniform refinement strategies is that the data structure is kept simple, meaning that the algorithms can often be coded extremely efficiently. However, the disadvantages are that degrees of freedom are introduced in regions where the solution can be adequately represented using the initial coarse approximation. Conversely, the h-p version can lead to approximations in which the required accuracy is obtained using a minimal number of degrees of freedom. Unfortunately, a price is paid in supporting a much more elaborate data structure both in terms of coding effort and the efficiency of the implementation.

1.3. Locally uniform refinements. One can contemplate retaining some advantages of both approaches by adopting a refinement strategy based on refining the approximation space in a *locally uniform* manner. Such a scheme allows the use of local refinements to resolve local features of the solution and at the same time retain a relatively simple data structure. Specifically, we shall consider classes of mesh obtained by subdividing specific elements in the coarse mesh into a uniform mesh of subelements of size $O(h)$. Global continuity is preserved by constraining the new basis functions obtained by the refinement on the boundaries between the parent elements. Naturally, should a pair of neighbouring coarse elements be refined, then the degrees of freedom on the common interface can be left unconstrained. This type of refinement scheme has been employed, for example, in the work of Ewing et al. [6]. Equally

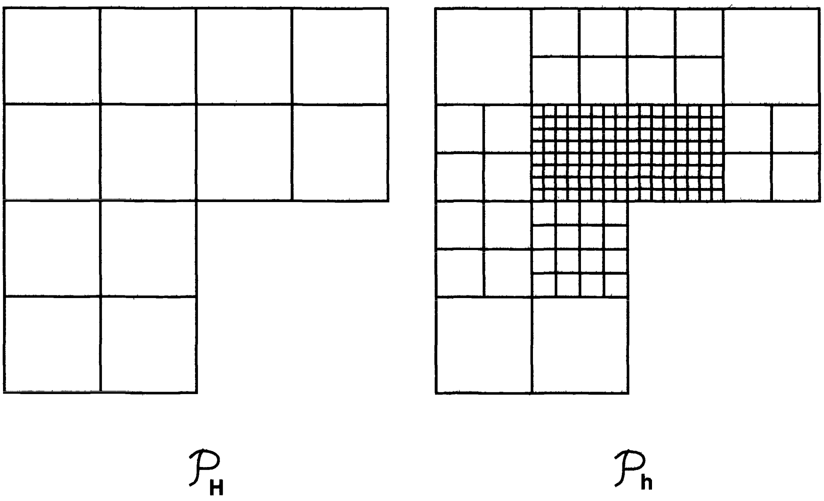

FIG. 1. *Example of a coarse mesh and locally refined mesh.*

TABLE 1
Condition number of diagonally scaled stiffness matrix for Laplacian.

	Elements in each direction (h^{-1})			
Degree (p)	1	2	4	8
1	4.73	23.88	122.07	598.63
2	22.08	49.78	227.79	1056.04
4	69.56	90.85	377.07	1755.91

well, the polynomial degree may be increased selectively. The details needed to implement selective polynomial enrichment are not trivial but are similar to the techniques described in Demkowicz et al. [8].

We shall suppose that by following some adaptive strategy, a refined partition $\mathcal{P}_h$ has been generated satisfying the above rules. The partition consists of elements from the original coarse partitioning $\mathcal{P}_H$ along with elements obtained by a locally uniform subdivision of an element from the coarse partitioning (see Figure 1).

1.4. Preconditioning. Suppose that mesh refinements and polynomial enrichments have been performed and let the associated finite element subspace be denoted by X. The finite element approximation on the refined subspace X is defined by

$$\text{Find } u \in X \text{ such that } B(u, v) = (f, v) \text{ for all } v \in X. \tag{9}$$

The discrete form of this problem is then

$$B\mathbf{x} = \mathbf{f} \tag{10}$$

where B is a symmetric positive definite matrix. The basic approach for solving the matrix equation (10) will be the conjugate gradient method. The condition number κ governs the performance of the conjugate gradient solution routine with each iteration reducing the error by at least a factor $(\sqrt{\kappa} - 1)/(\sqrt{\kappa} + 1)$. Unfortunately, it is generally found that the condition number grows rapidly as the mesh is refined or the polynomial degree increased (see Table 1). One possibility is to apply a preconditioner to the linear system. A preconditioning form

$C(\cdot,\cdot)$ is constructed for which there exist μ, Υ such that

$$\mu C(v,v) \leq B(v,v) \leq \Upsilon C(v,v) \quad \text{for all } v \in X \tag{11}$$

where μ and Υ depend on the mesh and the polynomial degree but are independent of the function v. The preconditioning form should be chosen with two properties in mind. First, the problem

$$\text{Find } w \in X \text{ such that } C(w,v) = g(v) \text{ for all } v \in X \tag{12}$$

where $g(\cdot)$ is an appropriate linear functional on X must be capable of being solved efficiently. In particular, the work required in applying the preconditioner should be modest in comparison with simply solving the problem (9) directly. Second, since the rate of convergence for the preconditioned algorithm is controlled by Υ/μ, this ratio must be controlled as the mesh is refined and the polynomial degree increased.

2. Numerical algorithm.

2.1. The basic procedure. The elements Ω_K constructed during the initial coarse partitioning $\mathcal{P}_H$ will be referred to as *subdomains*. As remarked earlier, the unrefined subdomains exist as elements in the final partitioning $\mathcal{P}_h$. The refined subdomains serve to group the elements in the final partitioning into uniform sets of elements linked by a simple topology. The preconditioner will be based on this natural domain decomposition. The overall data structure can also exploit this situation.

Step 1. Coarse Grid
- Construct the initial coarse partitioning $\mathcal{P}_H$.
- Assemble and solve the finite element problem (8) on the coarse mesh.
- Use the coarse grid solution to design the partitioning $\mathcal{P}_h$ and the space X.

Step 2. Assembly of Schur Complement
- Assemble the contributions to the global stiffness matrix and global load vector from the subdomain Ω_K.
- Apply static condensation to the subdomain stiffness matrix and subdomain load vector to eliminate the internal degrees of freedom on the subdomain.
- Assemble the reduced matrix and vector into a global matrix and vector thereby obtaining a system of the form $S\mathbf{x} = \mathbf{b}$. The Schur complement is assembled by the standard finite element subassembly (of the local Schur complements).

Step 3. Solve Schur complement $S\mathbf{x} = \mathbf{b}$
- Apply preconditioned conjugate gradient with preconditioner described below.

Step 4. Internal Degrees of Freedom
- Apply back substitution to obtain the values of the interiors of the subdomains.

One advantage of this approach is that the internal unknowns are eliminated at a local level thereby simplifying the data structure. A second advantage is that the problems associated with the interiors are constructed on a grid with regular topology.

2.2. The preconditioner. The preconditioner is based on a decomposition of the degrees of freedom (DOFs) on the edges of the subdomains into three sets:

$$\mathcal{J}_H = \{\text{DOFs associated with the vertices of the coarse grid } \mathcal{P}_H\}, \tag{13}$$

$$\mathcal{J}_h = \{\text{DOFs associated with linear functions introduced by refinement of } \mathcal{P}_H\}, \tag{14}$$

$$\mathcal{J}_p = \{\text{DOFs associated with higher-order functions}\}. \tag{15}$$

For ease of exposition, suppose that the DOFs have been ordered so that the set $\mathcal{J}_H$ is numbered first, followed by $\mathcal{J}_h$, and finally $\mathcal{J}_p$. The Schur complement and reduced load vector may be partitioned into blocks corresponding to this ordering:

$$(16) \qquad S = \begin{bmatrix} S_{HH} & S_{Hh} & S_{Hp} \\ S^t_{Hh} & S_{hh} & S_{hp} \\ S^t_{Hp} & S^t_{hp} & S_{pp} \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} \mathbf{b}_H \\ \mathbf{b}_h \\ \mathbf{b}_p \end{bmatrix}.$$

The solution of the preconditioning problem

$$(17) \qquad C\mathbf{x} = \mathbf{b}$$

consists of three main steps.

Linear DOFs. The DOFs within the set $\mathcal{J}_h$ are partitioned further into subsets corresponding to the separate edges $E_1, \dots, E_n$ of the coarse mesh $\mathcal{P}_H$. The submatrix S_{hh} then has the block structure

$$(18) \qquad S_{hh} = \begin{bmatrix} S^{(1,1)}_{hh} & \cdots & S^{(1,n)}_{hh} \\ \vdots & \ddots & \vdots \\ S^{(1,n)^t}_{hh} & \cdots & S^{(n,n)}_{hh} \end{bmatrix}.$$

Let

$$(19) \qquad D_{hh} = \operatorname{diag}(S^{(1,1)}_{hh}, \dots, S^{(n,n)}_{hh}).$$

Then inverting D_{hh} to obtain

$$(20) \qquad \mathbf{x}_h = D^{-1}_{hh}\mathbf{b}_h$$

corresponds to solving independent problems over each edge of the coarse mesh $\mathcal{P}_H$.

Higher-order DOFs. Similarly, dividing the higher-order DOFs in the set $\mathcal{J}_p$ into sets corresponding to each of the separate edges in the fine mesh $\mathcal{P}_h$ gives the matrix S_{pp} a block structure. Inverting the block diagonal D_{pp} of the matrix S_{pp} corresponds to solving independent problems over each edge of the fine mesh to compute

$$(21) \qquad \mathbf{x}_p = D^{-1}_{pp}\mathbf{b}_p.$$

Coarse grid. The problem associated with the coarse grid involves inverting the same stiffness matrix B_{HH} arising from the original bilinear discretization on the coarse grid $\mathcal{P}_H$. First, it is necessary to construct a *restriction* of the data $\mathbf{b}_H$ and $\mathbf{b}_h$ to the space X_H. This transformation is affected by writing the bilinear functions on the original coarse mesh as linear combinations of the linear functions on the edges of the refined mesh. That is, on the edges of $\mathcal{P}_H$ one has for a suitable constant matrix R

$$(22) \qquad \psi_H = \phi_H + R\phi_h$$

where ψ_H are the bilinear functions on the coarse grid $\mathcal{P}_H$, and ϕ_H and ϕ_h are the functions corresponding to the DOFs in the sets $\mathcal{J}_H$ and $\mathcal{J}_h$, respectively. The matrix R can be given explicitly if we let $\mathbf{x}_j$ denote the node on the edge of $\mathcal{P}_h$ at which the jth linear DOF $\phi_{h,j} \in \mathcal{J}_h$ is based; then

$$(23) \qquad R = [\,\psi_H(\mathbf{x}_j)]_{j\in\mathcal{J}_h}.$$

In practice, it is unnecessary to assemble the matrix explicitly. The relation (23) does not generally hold on the subdomain interiors. The matrix R is unchanged even if higher-order approximation is used provided that the functions $\phi_{h,j}$ are bilinear (as is the case when using hierarchical element basis functions).

The steps to construct the coarse grid correction may be summarized as follows:

- Form the *restriction* of the data
$$\hat{\mathbf{b}}_H = \mathbf{b}_H + R\mathbf{b}_h.$$
- Solve the coarse grid problem
$$B_{HH}\hat{\mathbf{x}}_H = \hat{\mathbf{b}}_H$$
where B_{HH} is the stiffness matrix for the discretization (8).
- *Prolongate* the solution $\hat{\mathbf{x}}_H$ to the space spanned by elements of $\mathcal{J}_H$ and $\mathcal{J}_h$ according to
$$\mathbf{x}_H^c = \hat{\mathbf{x}}_H, \quad \mathbf{x}_h^c = R^t\hat{\mathbf{x}}_H.$$

The solution of the preconditioning problem (17) is then given by

$$\mathbf{x} = \begin{bmatrix} \mathbf{x}_H^c \\ \mathbf{x}_h + \mathbf{x}_h^c \\ \mathbf{x}_p \end{bmatrix}. \tag{24}$$

The action of the inverse of the preconditioner C therefore corresponds to solving independent problems for the linear DOFs over each of the edges of $\mathcal{P}_H$ separately, independent solves for the higher-order DOFs over each of the edges of $\mathcal{P}_h$ separately, and a global solve over the DOFs in the coarse grid discretization. Moreover, each of these overall steps may be performed concurrently. In particular, the computations are ideally suited to a parallel programming environment.

As remarked earlier, the performance of the preconditioner is governed by the quantities μ and Υ in the equivalence

$$\mu C(v, v) \le B(v, v) \le \Upsilon C(v, v) \text{ for all } v \in X. \tag{25}$$

The algorithm presented above generalizes both an algorithm proposed by Smith [13] for the h-version finite element method and an algorithm proposed by Mandel [11] for the p-version. For the case of first-order ($p = 1$) approximation, Smith [13] has shown that the ratio grows at most as

$$\frac{\Upsilon}{\mu} \le C\left(1 + \log^2\left(\frac{H}{h}\right)\right) \tag{26}$$

where the constant C is independent of H and h. Conversely, for the p-version finite element method ($H/h = 1$), it has been shown [2] that the algorithm given by Mandel [11] yields

$$\frac{\Upsilon}{\mu} \le C(1 + \log^2 p) \tag{27}$$

where the constant C is independent of p and the number of elements. It is important to note that, in both cases, the constant C is independent of the variation of the coefficients a_{jk} between subdomains. The purpose of the present work is to obtain estimates of this form for the combined h-p version of the finite element method.

3. Analysis of preconditioner.

3.1. Algebraic formulation. Suppose that the standard basis functions are partitioned into the set consisting of functions $\{\phi_i\}$, $i \in \mathcal{I}$ supported on the interiors of the subdomains and the set of functions $\{\phi_i\}$, $i \in \tilde{\mathcal{I}}$ having nonzero values on at least one of the subdomain interfaces $\partial\mathcal{P}_H$. Steps 1 and 2 of the algorithm involved the static condensation of the internal DOFs on each of the subdomains. This process may be interpreted as a change of basis. Specifically, the edge basis functions $\{\phi_i\}$, $i \in \tilde{\mathcal{I}}$ are replaced by new functions $\{\tilde{\phi}_i\}$, $i \in \tilde{\mathcal{I}}$ satisfying

$$\tilde{\phi}_i = \phi_i \quad \text{on } \partial\mathcal{P}_H \tag{28}$$

and

$$B(\tilde{\phi}_i, \phi_j) = 0 \quad \text{for all } j \in \mathcal{I}. \tag{29}$$

The modified edge functions $\tilde{\phi}_i$, $i \in \tilde{\mathcal{I}}$ are obtained from the original edge functions by subtracting linear combinations of the internal functions. Introducing vectors defined by

$$\phi_{\mathcal{I}} = [\phi_i]_{i\in\mathcal{I}}, \quad \phi_{\tilde{\mathcal{I}}} = [\phi_i]_{i\in\tilde{\mathcal{I}}}, \quad \tilde{\phi}_{\tilde{\mathcal{I}}} = [\tilde{\phi}_i]_{i\in\tilde{\mathcal{I}}}, \tag{30}$$

then, for a suitable matrix T, we may write the change of basis as

$$\begin{bmatrix} \tilde{\phi}_{\tilde{\mathcal{I}}} \\ \phi_{\mathcal{I}} \end{bmatrix} = \begin{bmatrix} I & -T \\ 0 & I \end{bmatrix} \begin{bmatrix} \phi_{\tilde{\mathcal{I}}} \\ \phi_{\mathcal{I}} \end{bmatrix}. \tag{31}$$

The matrix T can be obtained by writing the stiffness matrix for the problem (10) in a block form corresponding to the ordering of the basis functions into the sets $\mathcal{I}$ and $\tilde{\mathcal{I}}$:

$$B = \begin{bmatrix} B_{\mathcal{I}\mathcal{I}} & B_{\mathcal{I}\tilde{\mathcal{I}}} \\ B_{\tilde{\mathcal{I}}\mathcal{I}} & B_{\tilde{\mathcal{I}}\tilde{\mathcal{I}}} \end{bmatrix}; \tag{32}$$

then condition (29) yields

$$T = B_{\tilde{\mathcal{I}}\mathcal{I}} B_{\mathcal{I}\mathcal{I}}^{-1}. \tag{33}$$

The stiffness matrix for the problem relative to the transformed basis would then be

$$\tilde{B} = \begin{bmatrix} I & -T \\ 0 & I \end{bmatrix} \begin{bmatrix} B_{\mathcal{I}\mathcal{I}} & B_{\mathcal{I}\tilde{\mathcal{I}}} \\ B_{\tilde{\mathcal{I}}\mathcal{I}} & B_{\tilde{\mathcal{I}}\tilde{\mathcal{I}}} \end{bmatrix} \begin{bmatrix} I & -T \\ 0 & I \end{bmatrix}^t = \begin{bmatrix} S & 0 \\ 0 & B_{\mathcal{I}\mathcal{I}} \end{bmatrix} \tag{34}$$

where the matrix S is the Schur complement (16)

$$S = B_{\tilde{\mathcal{I}}\tilde{\mathcal{I}}} - B_{\tilde{\mathcal{I}}\mathcal{I}} B_{\mathcal{I}\mathcal{I}}^{-1} B_{\mathcal{I}\tilde{\mathcal{I}}}. \tag{35}$$

The original problem (10) written in block form is

$$B \begin{bmatrix} \mathbf{x}_{\tilde{\mathcal{I}}} \\ \mathbf{x}_{\mathcal{I}} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_{\tilde{\mathcal{I}}} \\ \mathbf{f}_{\mathcal{I}} \end{bmatrix}. \tag{36}$$

Applying the transformation (31) gives

$$\begin{bmatrix} S & 0 \\ B_{\mathcal{I}\tilde{\mathcal{I}}} & B_{\mathcal{I}\mathcal{I}} \end{bmatrix} \begin{bmatrix} \mathbf{x}_{\tilde{\mathcal{I}}} \\ \mathbf{x}_{\mathcal{I}} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_{\tilde{\mathcal{I}}} - B_{\tilde{\mathcal{I}}\mathcal{I}} B_{\mathcal{I}\mathcal{I}}^{-1} \mathbf{f}_{\mathcal{I}} \\ \mathbf{f}_{\mathcal{I}} \end{bmatrix}. \tag{37}$$

This problem is solved in two stages (cf. Steps 3 and 4):

$$S\mathbf{x}_{\tilde{\mathcal{I}}} = \mathbf{f}_{\tilde{\mathcal{I}}} - B_{\tilde{\mathcal{I}}\mathcal{I}}B_{\mathcal{I}\mathcal{I}}^{-1}\mathbf{f}_{\mathcal{I}} \tag{38}$$

and

$$B_{\mathcal{I}\mathcal{I}}\mathbf{x}_{\mathcal{I}} = \mathbf{f}_{\mathcal{I}} - B_{\mathcal{I}\tilde{\mathcal{I}}}\mathbf{x}_{\tilde{\mathcal{I}}}. \tag{39}$$

The preconditioner is then applied to the reduced Schur complement system (38). Let $X_0 \in X$ be the space

$$X_0 = \operatorname{span}\left\{\tilde{\phi}_i : \quad i \in \tilde{\mathcal{I}}\right\}. \tag{40}$$

In view of condition (29), elements of the space X_0 are referred to as *discrete harmonic* functions. The Schur complement matrix S induces a bilinear form $S(\cdot,\cdot)$ on the space X_0 which agrees with the original bilinear form $B(\cdot,\cdot)$.

LEMMA 3.1. *Let u, v be discrete harmonic. Then*

$$S(u,v) = B(u,v). \tag{41}$$

Proof. Let $w \in X_0$. Then w may be written as

$$w = \alpha^t_{\tilde{\mathcal{I}}}\tilde{\phi}_{\tilde{\mathcal{I}}}.$$

Applying (34) gives

$$B(w,w) = \begin{bmatrix} \alpha_{\tilde{\mathcal{I}}} \\ 0 \end{bmatrix}^t \begin{bmatrix} S & 0 \\ 0 & B_{\mathcal{I}\mathcal{I}} \end{bmatrix} \begin{bmatrix} \alpha_{\tilde{\mathcal{I}}} \\ 0 \end{bmatrix} = \alpha^t_{\tilde{\mathcal{I}}} S\, \alpha_{\tilde{\mathcal{I}}} = S(w,w).$$

Applying this result to $w = u + v$ and simplifying completes the proof. □

The preconditioner was constructed by decomposing the degrees of freedom on the edges of the subdomains into three sets: $\mathcal{J}_H$, $\mathcal{J}_h$, and $\mathcal{J}_p$. The space X_0 is decomposed into subspaces X_0^H, X_0^h, and X_0^p using this partitioning where

$$X_0^H = \operatorname{span}\{\tilde{\phi}_i, i \in \mathcal{J}_H\} \tag{42}$$

and X_0^h and X_0^p are defined similarly. The matrix R defined in (23) maps X_0^h into X_0^H. An alternative viewpoint is to regard R as another change of basis from $\tilde{\phi}_{\tilde{\mathcal{I}}}$ to $\tilde{\psi}$ given by

$$\begin{bmatrix} \tilde{\psi}^H \\ \tilde{\psi}^h \\ \tilde{\psi}^p \end{bmatrix} = Q \begin{bmatrix} \phi^H_{\tilde{\mathcal{I}}} \\ \phi^h_{\tilde{\mathcal{I}}} \\ \phi^p_{\tilde{\mathcal{I}}} \end{bmatrix} \tag{43}$$

where

$$Q = \begin{bmatrix} I & R & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix}. \tag{44}$$

It is easily seen that the inverse of the matrix Q is given by

$$Q^{-1} = \begin{bmatrix} I & -R & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix}. \tag{45}$$

The Schur complement matrix S relative to the new basis has the form $\widehat{S}$:

$$\widehat{S} = QSQ^t = \begin{bmatrix} \widehat{S}_{HH} & X & X \\ X & S_{hh} & X \\ X & X & S_{pp} \end{bmatrix} \tag{46}$$

where X denotes appropriate matrices,

$$\widehat{S}_{HH} = \begin{bmatrix} I & R \end{bmatrix} \begin{bmatrix} S_{HH} & S_{Hh} \\ S_{hH} & S_{hh} \end{bmatrix} \begin{bmatrix} I \\ R^t \end{bmatrix}, \tag{47}$$

and $S_{HH}, \ldots, S_{pp}$ are given in (16). The submatrices appearing on the main diagonal of this matrix are approximated by (see §2.2)

$$\widehat{S}_{HH} \approx B_{HH}, \quad S_{hh} \approx D_{hh}, \quad S_{pp} \approx D_{pp}, \tag{48}$$

and, equally well,

$$\widehat{S} \approx \widehat{C} = \begin{bmatrix} B_{HH} & 0 & 0 \\ 0 & D_{hh} & 0 \\ 0 & 0 & D_{pp} \end{bmatrix}. \tag{49}$$

Transforming back to the basis $\tilde{\phi}_{\mathcal{I}}$ then gives an approximation C to the original Schur complement S:

$$S \approx C = Q^{-1}\widehat{C}Q^{-t}. \tag{50}$$

Equation (50) shows that

$$C^{-1} = Q^t\widehat{C}^{-1}Q \tag{51}$$

which, on expanding, gives

$$C^{-1} = \begin{bmatrix} I \\ R^t \\ 0 \end{bmatrix} B_{HH}^{-1} \begin{bmatrix} I & R & 0 \end{bmatrix} + \begin{bmatrix} 0 \\ I \\ 0 \end{bmatrix} D_{hh}^{-1} \begin{bmatrix} 0 & I & 0 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ I \end{bmatrix} D_{pp}^{-1} \begin{bmatrix} 0 & 0 & I \end{bmatrix}. \tag{52}$$

The decomposition (52) shows that the action of the inverse of C consists of the same three steps described in §2.2 for the action of the inverse of the preconditioner. The matrix C in (50) is the matrix representation of the preconditioner.

3.2. Formulation as an additive Schwarz method. Introduce inner products A^H, A^h, and A^p on the spaces X_0^H, X_0^h, and X_0^p, respectively, as follows:

- For given $u \in X_0^H$, noting that u is linear on the edges of the partition $\mathcal{P}_H$, let $\Pi_H u \in X_H$ be the bilinear function which interpolates to u at the nodes of the coarse grid. Evidently, $\Pi_H u$ and u agree on the boundaries $\partial\mathcal{P}^H$. The inner product A^H is then defined by

$$A^H(u, v) = B(\Pi_H u, \Pi_H v). \tag{53}$$

- For any edge e in the coarse partition $\mathcal{P}_H$, let $E_e^h : X_0^h \mapsto X_0^h$ be defined on the edges of the coarse partition by

$$E_e^h u = \begin{cases} u & \text{on } e, \\ 0 & \text{on remaining edges in } \partial\mathcal{P}_H \end{cases} \tag{54}$$

and discrete harmonic on the interiors. Note that this operator is well defined since functions belonging to the space X_0^h vanish at the nodes of the coarse grid. For given $u \in X_0^h$, we may decompose u as

$$u = \sum_{e\in\partial\mathcal{P}^H} E_e^h u. \tag{55}$$

The inner product A^h is then defined by

$$A^h(u, v) = \sum_{e\in\partial\mathcal{P}^H} S(E_e^h u, E_e^h v). \tag{56}$$

- Similarly, for any edge $e \in \partial\mathcal{P}_h$, let $E_e^p : X_0^p \mapsto X_0^p$ be defined on $\partial\mathcal{P}_h$ by

$$E_e^p u = \begin{cases} u & \text{on } e, \\ 0 & \text{on remaining edges in } \partial\mathcal{P}_h \end{cases} \tag{57}$$

and discrete harmonic on the interiors. For $u \in X_0^p$ write

$$u = \sum_{e\in\partial\mathcal{P}^h} E_e^p u \tag{58}$$

and let the inner product A^p be given by

$$A^p(u, v) = \sum_{e\in\partial\mathcal{P}^h} S(E_e^p u, E_e^p v). \tag{59}$$

Let $P^H : X_0 \mapsto X_0^H$ denote the projection defined by

$$A^H(P^H u, v) = S(u, v) \quad \text{for all } v \in X_0^H. \tag{60}$$

Define $P^h : X_0 \mapsto X_0^h$ and $P^p : X_0 \mapsto X_0^p$ similarly.

LEMMA 3.2. *Relative to the basis $\tilde{\phi}_{\mathcal{I}}$, the projection operators P^H, P^h, and P^p have the matrix representations*

$$P^H = \begin{bmatrix} I \\ R^t \\ 0 \end{bmatrix} B_{HH}^{-1} \begin{bmatrix} I & R & 0 \end{bmatrix} S, \tag{61}$$

$$P^h = \begin{bmatrix} 0 \\ I \\ 0 \end{bmatrix} D_{hh}^{-1} \begin{bmatrix} 0 & I & 0 \end{bmatrix} S, \tag{62}$$

and

$$P^p = \begin{bmatrix} 0 \\ 0 \\ I \end{bmatrix} D_{pp}^{-1} \begin{bmatrix} 0 & 0 & I \end{bmatrix} S. \tag{63}$$

Proof. Let $u \in X_0$ be represented relative to the basis $\tilde{\psi}$ by $[\mathbf{x}^H, \mathbf{x}^h, \mathbf{x}^p]$ and let $P^H u$ be represented by $[\mathbf{z}^H, 0, 0]$. Condition (60) implies that $\mathbf{z}^H$ satisfies

$$(\mathbf{y}^H)^t B_{HH} \mathbf{z}^H = \begin{bmatrix} \mathbf{y}^H \\ 0 \\ 0 \end{bmatrix}^t \widehat{S} \begin{bmatrix} \mathbf{x}^H \\ \mathbf{x}^h \\ \mathbf{x}^p \end{bmatrix}$$

for all $\mathbf{y}^H$. Hence,

$$\mathbf{z}^H = B_{HH}^{-1} \begin{bmatrix} I & R & 0 \end{bmatrix} S Q^t \begin{bmatrix} \mathbf{x}^H \\ \mathbf{x}^h \\ \mathbf{x}^p \end{bmatrix}.$$

Transforming to the basis $\tilde{\phi}_{\tilde{\mathcal{I}}}$ gives

$$P^H u = \begin{bmatrix} I \\ R^t \\ 0 \end{bmatrix} B_{HH}^{-1} \begin{bmatrix} I & R & 0 \end{bmatrix} S u$$

from which (61) follows. The remaining results are obtained in a similar manner. □

Examining the foregoing developments, one observes that

$$C^{-1} S = P^H + P^h + P^p. \tag{64}$$

The significance of (64) is that the preconditioner developed in §2.2 can be viewed as an additive Schwarz method [7, 9, 14]. The condition number of the additive Schwarz method $\kappa(C^{-1}S)$ can be bounded using the following result (see [9, 14]).

THEOREM 3.3. *Suppose that there exist positive quantities λ and Λ such that the following conditions are valid:*

1. *For any $u \in X_0$ there exists a decomposition*

$$u = u^H + u^h + u^p \tag{65}$$

such that $u^H \in X_0^H$, $u^h \in X_0^h$, $u^p \in X_0^p$, and

$$A^H(u^H, u^H) + A^h(u^h, u^h) + A^p(u^p, u^p) \le \Lambda S(u, u). \tag{66}$$

2. *For $s \in \{H, h, p\}$ there holds*

$$S(u, u) \le \lambda^{-1} A^s(u, u) \textit{ for all } u \in X_0^s. \tag{67}$$

Then

$$\frac{1}{\Lambda} S(u, u) \le S(Pu, u) \le 3\lambda S(u, u) \tag{68}$$

where $P = P^H + P^h + P^p$. Consequently,

$$\kappa(C^{-1}S) = \kappa(P) \le 3\Lambda\lambda. \tag{69}$$

3.3. Estimation of condition number. To begin with, we assume that the fine partitioning $\mathcal{P}_h$ is obtained by uniform refinement of all the elements in the coarse partition $\mathcal{P}_H$. Moreover, it is assumed that the polynomial degree is uniform throughout the domain. Later, we shall consider the case of local h and local p refinements.

Let Ω_K be a subdomain from the coarse partition $\mathcal{P}_H$. The space $X_{0,K}$ consists of the restrictions to the subdomain Ω_K of functions belonging to X_0. The spaces $X_{0,K}^H$, $X_{0,K}^h$, and $X_{0,K}^p$ are defined analogously. Let $B_K(\cdot,\cdot)$ denote the local contribution to bilinear form $B(\cdot,\cdot)$ from the subdomain Ω_K.

Let e be any edge lying on the boundary $\partial\Omega_K$ The space $H_{00}^{1/2}(e)$ consists of functions defined on the edge $e \subset \partial\Omega_K$ which have continuous extensions by zero to the rest of the boundary $\partial\Omega_K$ [10]. A norm may be defined on this space by

$$(70)\qquad |v|^2_{H_{00}^{1/2}(e)} = \int_e\int_e \frac{|v(\mathbf{x})-v(\mathbf{y})|^2}{|\mathbf{x}-\mathbf{y}|^2}\,\mathrm{d}s_x\,\mathrm{d}s_y + \int_e \left\{ \frac{|v(\mathbf{x})|^2}{|\mathbf{x}-\mathbf{x}_{e_1}|} + \frac{|v(\mathbf{x})|^2}{|\mathbf{x}-\mathbf{x}_{e_2}|} \right\} \mathrm{d}s_x$$

where $\mathbf{x}_{e_1}$ and $\mathbf{x}_{e_2}$ are the endpoints of the edge e. Finally, Π_h denotes the piecewise linear interpolation operator at the nodes of the fine grid $\mathcal{P}_h$. It will be useful to recall the following results proved in [1].

LEMMA 3.4. *Let $u \in X_{0,K}$. Then there exists a constant C independent of H, h, p, and u such that the following hold:*

1.

$$(71)\qquad \sum_{e\in\partial K\cap\partial\mathcal{P}_H} \left(u(\mathbf{x}_{e_1}) - u(\mathbf{x}_{e_2})\right)^2 \le C\left(1+\log\left(\frac{Hp}{h}\right)\right) B_K(u,u).$$

2.

$$(72)\qquad \sum_{e\in\partial K\cap\partial\mathcal{P}_H} |\Pi_h u - \Pi_H u|^2_{H_{00}^{1/2}(e)} \le C\left(1+\log\left(\frac{Hp}{h}\right)\right)^2 B_K(u,u).$$

3.

$$(73)\qquad \sum_{e\in\partial K\cap\partial\mathcal{P}_h} |u - \Pi_h u|^2_{H_{00}^{1/2}(e)} \le C\,(1+\log p)^2\, B_K(u,u).$$

4. *If $u \in X_{0,K}^p$ then*

$$(74)\qquad B_K(u,u) \le C \sum_{e\in\partial K\cap\partial\mathcal{P}_h} |u|^2_{H_{00}^{1/2}(e)}\,.$$

Proof. See Ainsworth [1]. □

LEMMA 3.5. *There exist constants C independent of H, h, p, and u such that the following hold:*

1. *If $u \in X_{0,K}^H$ then*

$$(75)\qquad B_K(u,u) \le B_K(\Pi_H u, \Pi_H u).$$

2. *If $u \in X_{0,K}^h$ then*

$$(76)\qquad B_K(u,u) \le C \sum_{e\in\partial K\cap\partial\mathcal{P}_H} B_K(E_e^h u, E_e^h u).$$

3. *If* $u \in X^p_{0,K}$ *then*

$$B_K(u,u) \le C \min\left(\frac{H}{h}, 1+\log^2 p\right) \sum_{e\in\partial K\cap\partial\mathcal{P}_h} B_K(E^p_e u, E^p_e u). \tag{77}$$

Proof.

1. Let $\Pi_H u \in X_H$. Then on the subdomain Ω_K

$$\Pi_H u = u + u_{\mathcal{I}}$$

where $u_{\mathcal{I}}$ is supported on Ω_K. Then, by condition (29),

$$\begin{aligned} B_K(\Pi_H u, \Pi_H u) &= B_K(u,u) + 2B(u,u_{\mathcal{I}}) + B_K(u_{\mathcal{I}}, u_{\mathcal{I}}) \\ &= B_K(u,u) + B_K(u_{\mathcal{I}}, u_{\mathcal{I}}) \\ &\ge B_K(u,u). \end{aligned}$$

2. Let $u \in X^h_{0,K}$ be written on the subdomain in the form

$$u = \sum_{e\in\partial K\cap\partial\mathcal{P}_H} E^h_e u.$$

Substituting for u and using the Cauchy–Schwarz inequality, we have

$$B_K(u,u) \le \sum_{e\in\partial K\cap\partial\mathcal{P}_H} 1 \cdot \sum_{e\in\partial K\cap\partial\mathcal{P}_H} B_K(E^h_e u, E^h_e u) \le C \sum_{e\in\partial K\cap\partial\mathcal{P}_H} B_K(E^h_e u, E^h_e u).$$

3. Let $u \in X^p_{0,K}$. Decompose u on the subdomain in the form

$$u = \sum_{e\in\partial K\cap\partial\mathcal{P}_h} E^p_e u.$$

Then, applying Lemma 3.4(4),

$$\begin{aligned} B_K(u,u) &\le C \sum_{e\in\partial K\cap\partial\mathcal{P}_h} |u|^2_{H^{1/2}_{00}(e)} \\ &= C \sum_{e\in\partial K\cap\partial\mathcal{P}_h} \left|E^p_e u\right|^2_{H^{1/2}_{00}(e)} \\ &\le C\,(1+\log p)^2 \sum_{e\in\partial K\cap\partial\mathcal{P}_h} B_K(E^p_e u, E^p_e u) \end{aligned}$$

where Lemma 3.4(3) has been applied to each of the functions $E^p_e u$ separately. Alternatively, observing that there are H/h elements on each subdomain edge, the Cauchy–Schwarz inequality implies

$$\begin{aligned} B_K(u,u) &\le C \sum_{e\in\partial K\cap\partial\mathcal{P}_h} 1 \cdot \sum_{e\in\partial K\cap\partial\mathcal{P}_h} B_K(E^p_e u, E^p_e) \\ &\le C\left(\frac{H}{h}\right) \sum_{e\in\partial K\cap\partial\mathcal{P}_h} B_K(E^p_e u, E^p_e). \end{aligned}$$

This completes the proof. □

LEMMA 3.6. *Let* $u \in X_{0,K}$. *Then there exists a decomposition of the form*

$$u = u^H + u^h + u^p \tag{78}$$

where $u^H \in X^H_{0,K}$, $u^h \in X^h_{0,K}$, *and* $u^p \in X^p_{0,K}$ *are such that*

$$B_K(\Pi_H u^H, \Pi_H u^H) + \sum_{e \in \partial K \cap \partial \mathcal{P}_H} B_K(E^h_e u^h, E^h_e u^h) + \sum_{e \in \partial K \cap \partial \mathcal{P}_h} B_K(E^p_e u^p, E^p_e u^p)$$
$$\le C\left(1 + \log\left(\frac{Hp}{h}\right)\right)^2 B_K(u,u) \tag{79}$$

where C is independent of H, h, p, and u.

Proof. Let $u \in X_{0,K}$. Choose $u^H \in X^H_{0,K}$, $u^h \in X^h_{0,K}$, and $u^p \in X^p_{0,K}$ such that on the subdomain boundary $\partial\Omega_K$ there holds

$$u^H = \Pi_H u, \quad u^h = \Pi_h u - \Pi_H u, \quad u^p = u - \Pi_h u.$$

Then, thanks to the quasiuniformity of the coarse grid $\mathcal{P}_H$ and Lemma 3.4(1),

$$\begin{aligned} B_K(\Pi_H u^H, \Pi_H u^H) &= B_K(\Pi_H u, \Pi_H u) \\ &\le C \sum_{e \in \partial K \cap \partial \mathcal{P}_H} \left(u(\mathbf{x}_{e_1}) - u(\mathbf{x}_{e_2})\right)^2 \\ &\le \left(1 + \log\left(\frac{Hp}{h}\right)\right) B_K(u,u) \end{aligned} \tag{80}$$

where $\mathbf{x}_{e_1}$ and $\mathbf{x}_{e_2}$ are the endpoints of the edge $e \in \partial\mathcal{P}_H$. Using Lemma 3.4(2)

$$\begin{aligned} \sum_{e \in \partial K \cap \partial \mathcal{P}_H} B_K(E^h_e u^h, E^h_e u^h) &\le C \sum_{e \in \partial K \cap \partial \mathcal{P}_H} |E^h_e u^h|^2_{H^{1/2}_{00}(e)} \\ &= C \sum_{e \in \partial K \cap \partial \mathcal{P}_H} |\Pi_H u - \Pi_h u|^2_{H^{1/2}_{00}(e)} \\ &\le C\left(1 + \log\left(\frac{Hp}{h}\right)\right)^2 B_K(u,u). \end{aligned} \tag{81}$$

Using Lemma 3.4(4)

$$\begin{aligned} \sum_{e \in \partial K \cap \partial \mathcal{P}_h} B_K(E^p_e u^p, E^p_e u^p) &\le C \sum_{e \in \partial K \cap \partial \mathcal{P}_h} |E^p_e u^p|^2_{H^{1/2}_{00}(e)} \\ &= C \sum_{e \in \partial K \cap \partial \mathcal{P}_h} |u - \Pi_h u|^2_{H^{1/2}_{00}(e)} \\ &\le C\left(1 + \log\left(\frac{Hp}{h}\right)\right)^2 B_K(u,u). \end{aligned} \tag{82}$$

The proof is completed by summing (80)–(82). □

THEOREM 3.7. *The condition number of the preconditioned system* $\kappa(C^{-1}S)$ *is bounded by*

$$\kappa(C^{-1}S) \le \frac{3K_1}{K_2}\left(1 + \log\left(\frac{Hp}{h}\right)\right)^2 \min\left(\frac{H}{h}, 1 + \log^2 p\right). \tag{83}$$

The constants K_1 *and* K_2 *are independent of H, h, and p. Moreover, the constants depend only on the variation of the coefficients* a_{jk} *within each of the subdomains. Consequently, the ratio* K_1/K_2 *is independent of the magnitude of the jump discontinuities of the coefficients between neighbouring subdomains.*

Proof. The result follows after checking the conditions of Theorem 3.3. First, let $u \in X_0$ be decomposed as

$$u = \sum_{K \in \mathcal{P}_H} u_K$$

where $u_K \in X_0^K$. Each of the functions u_K is then decomposed using the splitting of Lemma 3.6:

$$u_K = u_K^H + u_K^h + u_K^p.$$

Thanks to the definition of the functions u_K^H, u_K^h, and u_K^p on the boundaries $\partial\Omega_K$ we may construct a decomposition of u as follows:

$$u = u^H + u^h + u^p$$

with $u^H \in X_0^H$, $u^h \in X_0^h$, and $u^p \in X_0^p$ defined as

$$u^H = \sum_{K \in \mathcal{P}_H} u_K^H, \quad u^h = \sum_{K \in \mathcal{P}_H} u_K^h, \quad u^p = \sum_{K \in \mathcal{P}_H} u_K^p.$$

It then follows that

$$\begin{aligned}
&A^H(u^H, u^H) + A^h(u^h, u^h) + A^p(u^p, u^p) \\
&= B(\Pi_H u^H, \Pi_H u^H) + \sum_{e \in \partial\mathcal{P}_H} S(E_e^h u^h, E_e^h u^h) + \sum_{e \in \partial\mathcal{P}_h} S(E_e^p u^p, E_e^p u^p) \\
&= B(\Pi_H u^H, \Pi_H u^H) + \sum_{e \in \partial\mathcal{P}_H} B(E_e^h u^h, E_e^h u^h) + \sum_{e \in \partial\mathcal{P}_h} B(E_e^p u^p, E_e^p u^p) \quad \text{(Lemma 3.1)} \\
&= \sum_{K \in \mathcal{P}_H} \left\{ B_K(\Pi_H u^H, \Pi_H u^H) + \sum_{e \in \partial\mathcal{P}_H \cap \partial K} B_K(E_e^h u^h, E_e^h u^h) + \sum_{e \in \partial\mathcal{P}_h \cap \partial K} B_K(E_e^p u^p, E_e^p u^p) \right\} \\
&\le \sum_{K \in \mathcal{P}_H} C_K \left(1 + \log\left(\frac{Hp}{h}\right)\right)^2 B_K(u, u) \quad \text{(Lemma 3.6)} \\
&\le \left(\max_{K \in \mathcal{P}_H} C_K\right) \left(1 + \log\left(\frac{Hp}{h}\right)\right)^2 B(u, u) \\
&\le \left(\max_{K \in \mathcal{P}_H} C_K\right) \left(1 + \log\left(\frac{Hp}{h}\right)\right)^2 S(u, u) \quad \text{(Lemma 3.1)}
\end{aligned}$$

so that the first condition is verified with $\Lambda = \left(\max_{K \in \mathcal{P}_H} C_K\right)(1 + \log(Hp/h))^2$. Turning now to the second set of conditions, suppose $u \in X_0^H$. By Lemmas 3.1 and 3.5(1)

$$S(u, u) = \sum_{K \in \mathcal{P}_H} B_K(u, u) \le \sum_{K \in \mathcal{P}_H} B_K(\Pi_H u, \Pi_H u) = B(\Pi_H u, \Pi_H u) = A^H(u, u). \tag{84}$$

Let $u \in X_0^h$. Then, using Lemmas 3.1 and 3.5(2),

$$\begin{aligned}
S(u, u) &= \sum_{K \in \mathcal{P}_H} B_K(u, u) \\
&\le c_K \sum_{K \in \mathcal{P}_H} \sum_{e \in \partial\mathcal{P}_H \cap \partial K} B_K(E_e^h u, E_e^h u) \\
&\le c_K \sum_{e \in \partial\mathcal{P}_H} B(E_e^h u, E_e^h u) = c_K \sum_{e \in \partial\mathcal{P}_H} S(E_e^h u, E_e^h u) = c_K A^h(u, u). \qquad (85)
\end{aligned}$$

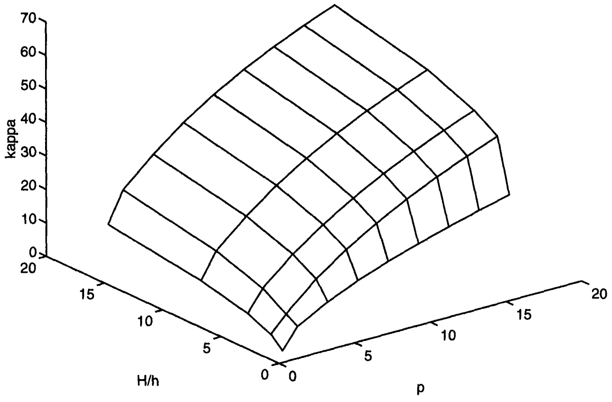

FIG. 2. *Computed bounds on condition number for preconditioner based on $\widehat{B}_{HH}$.*

Similarly, applying Lemmas 3.1 and 3.5(3) gives, for $u \in X_0^p$,

$$S(u,u) \le c_K \min\left(\frac{H}{h}, 1+\log^2 p\right) A^p(u,u). \tag{86}$$

Collecting inequalities (84)–(86) shows that the second condition of Theorem 3.3 is valid with λ given by $\left(\min_{K\in\mathcal{P}_H} c_K\right)\min\left(H/h, 1+\log^2 p\right)$. □

3.4. Numerically computed condition numbers. Let K be a square subdomain and $B_K(\cdot,\cdot)$ be the bilinear form corresponding to the Laplace operator over the subdomain K:

$$B_K(u,v) = \int_K \nabla u \cdot \nabla v \,\mathbf{dx}. \tag{87}$$

In order to assess the performance of the preconditioner in practice we compute estimates of the condition number. The numerical computations will be based on the following result.

LEMMA 3.8. *Let $S_K(\cdot,\cdot)$ and $C_K(\cdot,\cdot)$ denote the Schur complement and preconditioner restricted to the subspace X_0^K. Suppose that there exist quantities μ_K and Υ_K such that for all $u \in X_0^K$*

$$\mu_K \le \frac{S_K(u,u)}{C_K(u,u)} \le \Upsilon_K. \tag{88}$$

Then

$$\kappa(C^{-1}S) \le \frac{\Upsilon}{\mu} \tag{89}$$

where $\Upsilon = \max_K \Upsilon_K$ and $\mu = \min_K \mu_K$.

Proof. Sum (88) over all subdomains $K \in \mathcal{P}_H$. □

This result shows that one may obtain estimates for the performance of the preconditioner when applied to a partition $\mathcal{P}_H$ consisting of uniform subdomains Ω_K. Figure 2 and Table 2 show the computed condition numbers for the preconditioner described in §2. Table 2 also shows that for large values of p and H/h, the condition number can be approximated by

$$\tilde{\kappa} = 13.3493\left(1 - 0.0050\log\left(\frac{Hp}{h}\right) + 0.0280\log^2\left(\frac{Hp}{h}\right)\right) \cdot \left(1 + 0.2803\log p + 0.0980\log^2 p\right) \tag{90}$$

in agreement with the main conclusion of Theorem 3.7.

16	29.11	41.23	45.99	48.50	51.45

The discussion in §3.1 suggests that a better condition number will be obtained by using the matrix $\widehat{S}_{HH}$ defined in (47) instead of the coarse grid discretization matrix B_{HH}. The results in Table 3 confirm that the condition number is reduced slightly.

3.5. Local refinements. Suppose now that the fine grid $\mathcal{P}_h$ is obtained by selectively refining elements from the coarse grid (see Figure 1). The set $\partial\mathcal{P}_H$ of edges in the coarse partition is defined as before. However, the definition of the set $\partial\mathcal{P}_h$ must be generalized to encompass constrained DOFs between the subdomains. Therefore, the set $\partial\mathcal{P}_h$ consists of the edges joining unconstrained vertices lying on the edges of the subdomains. These edges need not coincide with the actual interelement edges as, for instance, is the case in the example shown in Figure 3.

Suppose that the elements contained in the subdomain Ω_K are quasiuniform of size h_K. Associated with each element in the subdomain are five parameters describing the polynomial degree of the approximation on the interior and the four sides of the element. The maximum polynomial degree used on the subdomain Ω_K is denoted by p_K. For technical reasons, we shall demand that the polynomial degree on the boundary of the subdomain does not exceed the polynomial degree anywhere on the interior.

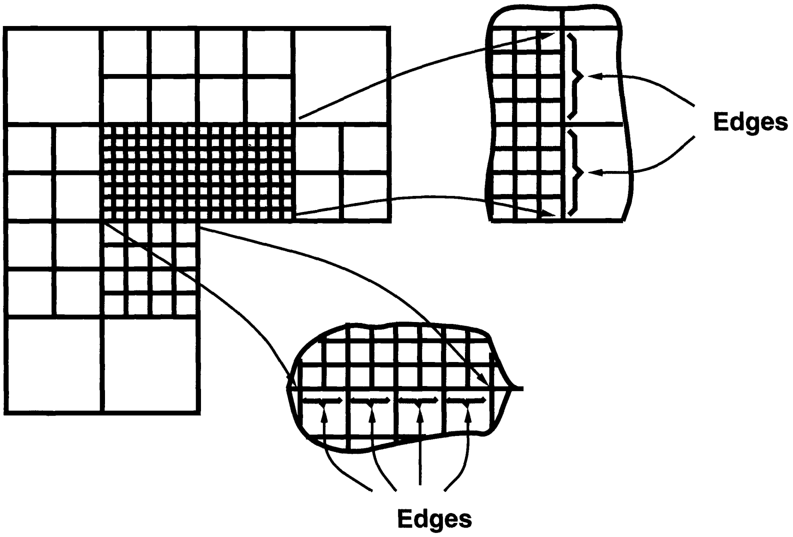

FIG. 3. *Illustration of the edges contained in the set $\partial\mathcal{P}_h$ for a locally refined mesh.*

The analysis of the preconditioner now follows from the previous results obtained for the uniform case as follows. First, the results in Lemma 3.4 are valid for each subdomain separately. However, these results have been proved only under the assumption that the polynomial degree on the boundary does not exceed the polynomial degree on the interior. Hence, Lemmas 3.5 and 3.6 also hold with p replaced by p_K and h replaced by h_K. Arguing as in the proof of Theorem 3.7 then yields the following.

THEOREM 3.9. *Suppose that on each of the refined subdomains Ω_K the mesh is quasi uniform of size h_K and the maximum polynomial degree is p_K. Suppose that the polynomial degree on the subdomain is such that the degree on the boundary does not exceed the polynomial degree on the interior. Then the condition number of the preconditioned system $\kappa(C^{-1}S)$ is bounded by*

$$\kappa(C^{-1}S) \leq K \min\left(\frac{H}{\underline{h}}, 1 + \log^2 \overline{p}\right) \cdot (1 + \log(H\overline{r}))^2 \tag{91}$$

where $\overline{p} = \max_K p_K$, $\underline{h} = \min_K h_K$, and $\overline{r} = \max_K p_K / h_K$. The constant K is independent of the parameters H, $\underline{h}$, and $\overline{p}$ and is independent of the magnitude of the jump discontinuities of the coefficients between neighbouring subdomains.

STATISTICAL EQUILIBRIUM COMPUTATIONS OF COHERENT STRUCTURES IN TURBULENT SHEAR LAYERS*

BRUCE TURKINGTON† AND NATHANIEL WHITAKER‡

Abstract. A numerical method is developed to treat the statistical equilibrium model of coherent structures in two-dimensional turbulence. In this model the vorticity, which fluctuates on a microscopic scale, is described macroscopically by a local probability distribution. A coherent vortex is identified with a most probable macrostate, which maximizes entropy subject to the constraints dictated by the complete family of conserved quantities for incompressible, inviscid flow. Attention is focused on the special case corresponding to vortex patches, and a simple, robust, and efficient algorithm is proposed in this case. The form of the iterative algorithm and its convergence properties are derived from the variational structure of the statistical equilibrium problem. Solution branches are computed for the shear layer configuration, and the results are interpreted in terms of the dynamical phenomena of rollup and coalescence.

Key words. vorticity dynamics, maximum entropy states, optimization method

1. Introduction.

The emergence of organized or coherent structures in a two-dimensional fluid flow at a high Reynolds number is observed in both physical and computational experiments. In these turbulent fields a macroscopic (coarse-grained) order is discerned in the presence of a microscopic (fine-grained) disorder. Such a coherent structure generally takes the form of a long-lived, large-scale vortical mean flow consisting of either a single, isolated vortex or a regular system of vortices. The vorticity field itself, however, typically exhibits rapid, local fluctuations of the same order of magnitude as the mean vorticity. The extensively studied free shear layer can be chosen as a representative of this general phenomenon. After a complex transient process, a perturbed free shear layer tends to roll up into a sequence of vortices whose structure depends upon the large-scale features of the initial layer but not on the precise nature of the small-scale vorticity fluctuations that result from the intervening dynamical evolution. The final vortex structure then persists as a nearly steady mean flow, changing slowly due to the dissipation dictated by a finite Reynolds number.

In constructing a theoretical explanation of this phenomenon, it is natural to invoke the methods of statistical mechanics. Under the simplifying assumption that the fluid flow is ideal, which is reasonable provided that the Reynolds number is sufficiently high, the governing dynamics are conservative. Consequently, it is possible to adopt a statistical equilibrium model [5, 14]. In such a framework a coherent structure is identified with a macroscopic equilibrium state corresponding to the complete family of conserved quantities associated with the microscopic evolution. This kind of formulation is proposed in the fundamental work of Miller [18] and Miller, Weichman, and Cross [19] and Robert [23] and Robert and Sommeria [24]. These two investigations derive the same statistical equilibrium theory for the two-dimensional flow of an incompressible and inviscid fluid, although their presentations and emphases differ in some respects. The two key ingredients of this theory are (1) a macroscopic description of the vorticity field as a local probability distribution, and (2) a weak form of the conservation of all generalized enstrophies and a mean-field form of the conservation of kinetic

energy. The equilibrium state furnished by the theory is the most probable macrostate, which has the largest number of microscopic realizations.

The formulation of the Miller–Robert theory rests on a separation of scales for the macroscopic and microscopic descriptions of the vorticity field. In contrast to the theory of homogeneous turbulence of a driven and dissipative fluid, in which energy and enstrophy cascades over a range of intermediate scales are postulated, this theory considers macroscopic variations on the scale of the domain size and microscopic fluctuations on an infinitesimal scale at each point in that domain. This idealization of the turbulent fluctuations, in which correlations are ignored at every finite scale, amounts to a simple, random model of the complex local distortions suffered by the vorticity on increasingly small scales as time increases. Thus, the theory is designed to capture the large-scale features of the vorticity field, and hence the flow, in a relaxed state after a very long evolution at a very high Reynolds number. Analytical and numerical evidence suggests that this model of the local microscopic evolution is in good qualitative agreement with the actual vorticity dynamics. In order to appraise its quantitative validity, however, its predictions must be computed and then compared with direct simulations or experimental observations. Some initial comparisons of this kind are provided by Sommeria, Staquet, and Robert [27] and Robert and Sommeria [25].

Our purpose in this paper is to develop an effective numerical method of solving these statistical equilibrium problems. We base our computations on the constrained maximum entropy formulation of Robert [23] and Robert and Sommeria [24], which seems, to us, to be the natural one from the standpoint of computation. The objective functional is the entropy of an admissible macrostate, which quantifies the multiplicity of the microscopic realizations of that macrostate. The constraint functionals are the (mean-field) energy, the (weak) generalized enstrophies, and whatever other functionals arise from special spatial symmetries. In the present paper we concentrate on the special case in which the initial microstate is assumed to be a vortex patch, meaning that the vorticity takes on the given constant values 0 and λ only.

A relaxation method of producing the maximum entropy state is given by Robert and Sommeria [25]. Their method is based on a macroscopic evolution equation that is designed to conserve all the dynamical constraints and to increase the entropy. A numerical integration over a sufficiently long time interval then provides an approximation to the statistical equilibrium state. Moreover, the evolution equation itself is of interest as a model of subgrid-scale mixing driven by the ideal dynamics.

Our numerical method of solution is an iterative algorithm derived from the optimization structure of the problem at hand. The iterative step is defined by solving a variational subproblem in which the nonlinear equality constraint on energy, which presents the principal difficulty, is replaced by an inequality constraint on its linearization about the previous iterate. We prove that our algorithm converges to a solution from any admissible initialization and that this solution satisfies all the constraints exactly. We obtain an efficient implementation of our algorithm by appealing to the dual form of the iterative subproblem.

In our implemented computations, we display branches of solutions to the statistical equilibrium problem for a periodic free shear layer of constant vorticity. We show how these branches connect the completely disordered state, which is spatially homogeneous, to the deterministic state, which is an exact steady flow. By so doing, we embed the deterministic theory of coherent structures into the statistical theory as a limiting case. Moreover, in the process of computing these branches, we exhibit a symmetry-breaking bifurcation in the statistical equilibrium problem for the free shear layer, which we interpret as an explanation of the rollup phenomenon. In the same context, we apply our method to the coalescence phenomenon for like-signed vortices in a (singly) periodic array.

2. Statistical equilibrium model.

2.1. Vorticity dynamics. The two-dimensional flow of an incompressible, inviscid fluid is described by the Euler equations

$$\frac{\partial v}{\partial t} + v \cdot \nabla v + \nabla p = 0, \quad \nabla \cdot v = 0, \tag{2.1}$$

where $v = (v_1(x,t), v_2(x,t), 0)$ and $p = p(x,t)$ are the velocity and pressure fields, and $\nabla = (\partial/\partial x_1, \partial/\partial x_2, 0)$ with $x = (x_1, x_2)$. In the presence of solid boundaries, these equations hold within a domain $D \subseteq \mathbf{R}^2$, with the boundary condition $n \cdot v = 0$ imposed on ∂D, where n denotes the outward unit normal field. (If, instead, periodic boundary conditions are imposed on either x_1 or x_2 or both, then the domain D is determined by the fundamental period for those conditions.) It is widely recognized that the salient features of these fluid dynamics are more neatly described by the vorticity field $\omega = (0, 0, \omega(x,t))$ than by the primitive fields v and p. Indeed, the governing dynamics reduce to the single equation

$$\frac{\partial \omega}{\partial t} + v \cdot \nabla \omega = 0, \tag{2.2}$$

which expresses the transport of vorticity by the flow. The velocity field is determined from the vorticity field by the elliptic system

$$\nabla \times v = \omega, \quad \nabla \cdot v = 0 \quad \text{in } D. \tag{2.3}$$

This system is easily solved by means of the streamfunction $\psi = \psi(x,t)$, which is defined according to $v = \nabla \times (0, 0, \psi)$. By virtue of the fact that $\omega = -\Delta\psi$, where Δ is the Laplacian operator in $\mathbf{R}^2$, the streamfunction is determined from the vorticity by

$$\psi(x) = G\omega(x) = \int_D g(x, x')\omega(x')dx', \tag{2.4}$$

where G is the Green operator for $-\Delta$ in D with boundary conditions $\psi = 0$ on ∂D (or suitable periodic boundary conditions), and $g(x, x')$ is the corresponding Green function.

The initial value problem for (2.2)–(2.3) is known to be well posed in the classical sense [12]. Nevertheless, the dynamics of vorticity transport tend to produce a very rapid growth in the vorticity gradient $|\nabla\omega(x,t)|$ in active regions of the flow, even though it preserves $\max_{x \in D} \omega(x,t)$ and $\min_{x \in D} \omega(x,t)$ exactly. Such a growth is consistent with the sharpest estimates provided by the existence and uniqueness theory for Euler flow [29]. It is natural, therefore, to consider weak solutions $\omega \in L^\infty(D \times [0,T])$ which are permitted to fluctuate on arbitrarily small scales. While these weak solutions $\omega(x,t)$ induce velocity fields $v(x,t)$ whose regularity properties are sufficient to determine smooth particle trajectories, they are very complex in the sense that their flow maps tend to become increasingly distorted over time at a very rapid rate. This body of qualitative theory, therefore, suggests that rearrangement of vorticity under ideal dynamics generates spatial fluctuations of ω on increasingly small scales.

This qualitative behavior of vortex dynamics, besides being indicated by analytical considerations, is strongly supported by numerical evidence. The many simulations of turbulent flows in two dimensions (Navier–Stokes flows at high Reynolds numbers) display the effects of distortion on the small scales of the vorticity, at least to the extent of the numerical resolution [17, 3, 10]. Similarly, the computations of those weak solutions for which the vorticity takes constant values 0 and λ only, which are referred to as *vortex patches*, show the same effects

[30, 6]. In particular, the free boundary of the vortex patch evolves in a very intricate way, exhibiting the characteristic phenomenon of filamentation on small scales [7].

This theoretical and computational evidence suggests that the deterministic dynamics be viewed as governing the *microscopic state* of the flow. The microstate $\omega(x, t)$ then constitutes the*fine-grained* description of the flow field. Since the information content of this deterministic evolution grows very rapidly over time, due to the complexity of the vorticity fluctuations on increasingly small scales, it does not provide a convenient description of the longtime behavior of the flow. Instead, a *coarse-grained* description of the vorticity is needed whenever an understanding of the long-lived, large-scale vortex structures inherent in the dynamics is desired. Such a description is furnished by a *macroscopic state* that only partially represents the small-scale behavior of the vorticity field. In the formulation of the statistical equilibrium theories proposed in [18, 19] and [23, 24], a macrostate is taken to be a local probability distribution on the values of the vorticity. A coherent structure is then identified with a macrostate that varies on the large scale.

2.2. Microscopic and macroscopic descriptions. We now proceed to define these concepts precisely and to formulate the statistical equilibrium theory in terms of them. For a complete motivation and justification of this theory we refer the reader to the papers cited above. In order to make our presentation accessible, we first explain the theory in the general case of arbitrary microstates and then derive the special case in which the microstates are vortex patches.

Let $I \subseteq \mathbf{R}$ be a finite interval (say the minimal interval) containing the range of the initial vorticity $\omega_0(x)$. Then, $\omega(x, t) \in I$ for all times $t > 0$, by virtue of (2.2). This invariance property allows us to define a *microstate* to be any measurable function $\omega(x)$ taking values in I and a *macrostate* to be any probability measure $p(x, dy)$ on I for almost all $x \in D$. We make a correspondence between these two levels of description by interpreting $p(x, dy)$ as the probability that the fluctuating function ω takes values in dy when sampled at points that are near x. This correspondence is determined by the identity

$$m\{x \in A : \omega(x) \in B\} = \int_A dx \int_B p(x, dy), \tag{2.5}$$

which holds for all measurable subsets $A \subseteq D$ and $B \subseteq I$. It follows that

$$p(x, B) = \lim_{\epsilon \to 0} \frac{m\{x' \in A_\epsilon(x) : \omega(x') \in B\}}{m(A_\epsilon(x))},$$

choosing $A_\epsilon(x)$ to be a neighborhood of x for which $\operatorname{diam} A_\epsilon(x) \leq \epsilon$. The interpretation of p as a volume fraction is clear from the latter expression. The expectation of the distribution p defines the mean vorticity

$$\bar{\omega}(x) = \int_I y \, p(x, dy). \tag{2.6}$$

The above correspondence between macrostates and microstates can be elucidated by considering the longtime evolution of vorticity. Over any finite interval $0 \leq t \leq T$, we can identify the unit point measure $p(x, dy, t) = \delta_{\omega(x,t)}(dy)$ concentrated at $y = \omega(x, t)$ with the evolving microstate $\omega(x, t)$. But we cannot maintain this identification in the limit as $t \to +\infty$ because of the hypothesis that the vorticity develops finite oscillations on arbitrarily small scales. If a coherent structure emerges in this evolution, then we identify it with the *weak limit* $\omega^*(x)$ of the microstate, and we describe it macroscopically by the corresponding *weak limit* $p^*(x, dy)$. Under weak convergence, the limit $p^*(x, dy)$ is not expected to be concentrated at a single point ($y = \omega^*(x)$) but rather is treated as a general probability distribution with mean $\omega^*(x)$. In other words, the x-parametrized measure $p^*(x, dy)$ encodes the local oscillations of the limiting vorticity field in a way that is compatible with weak convergence. As such, it is a Young measure [8].

2.3. Maximum entropy principle. In the theory of statistical equilibrium, we seek the most probable (most random) macrostate. Such a macrostate is characterized by maximizing an entropy functional, which quantifies the loss of information incurred by going from a microscopic to a macroscopic description. In the absence of any information that constrains the spatial variations of the admissible macrostates, the assumed ergodicity of the vorticity dynamics implies that the most probable macrostate is spatially homogeneous. This x-independent macrostate, which can be viewed as a complete mixing of the initial microstate ω_0, is simply given by

$$p_0(B) = \frac{m\{x \in D : \omega_0(x) \in B\}}{m(D)} \tag{2.7}$$

for measurable sets $B \subseteq I$. However, p_0 is not admissible, in general, because it violates the constraint dictated by the conservation of energy. Therefore, we define the (Kullback–Leibler) *entropy* of any macrostate $p(x, dy)$ relative to $p_0(dy)$ by

$$S(p) = -\int_D dx \int_I \log \frac{dp}{dp_0}(x, y)\, p(x, dy), \tag{2.8}$$

where dp/dp_0 is the density (or Radon–Nikodým derivative) of p with respect to p_0. The information functional $-S(p)$ can be interpreted as a statistical distance between p and p_0. Consequently, we formulate the statistical equilibrium theory by taking the most probable macrostate p to be the maximizer of S subject to *all* of the constraints implied by the vorticity transport equation. This equilibrium macrostate, unlike p_0, exhibits the spatial variations characteristic of a coherent structure.

The constraints imposed in the maximum entropy principle are dictated by the conserved quantities for ideal fluid dynamics. Expressed in terms of the microstate, these are the *energy* and the *generalized enstrophies*, respectively,

$$E(\omega) = \frac{1}{2}\int_D \omega G \omega\, dx, \tag{2.9}$$

$$F(\omega; f) = \int_D f(\omega)\, dx, \tag{2.10}$$

where f is any continuous function on I. Apart from those additional conserved quantities which are associated with special symmetries of the domain (and the boundary conditions), these are the only conserved quantities for ideal fluid flow in two dimensions. In order to impose these constraints in the statistical equilibrium problem, which is formulated in terms of the macrostate, it is necessary to express them as functionals of p. In these expressions the continuity with respect to weak convergence (in either ω or p) must be ensured, since this mode of convergence is expected as $t \to +\infty$. For this reason, the correct forms for these expressions are given by

$$E(p) = \frac{1}{2}\int_D \bar{\omega} G \bar{\omega}\, dx, \tag{2.11}$$

$$F(p; f) = \int_D dx \int_I f(y)\, p(x, dy). \tag{2.12}$$

The energy expression (2.11) is justified by the the compactness of the operator $G : L^2(D) \to L^2(D)$, which implies that the functional E is weakly continuous. Thus, the energy of a macrostate p is determined by the mean streamfunction $\bar{\psi} = G\bar{\omega}$. This fact gives the model the character of a mean-field theory [18, 19]. On the other hand, the generalized enstrophy functionals, even in the classical case for which $f = \frac{1}{2}\omega^2$, are not continuous with respect to weak convergence of ω, except when f is linear, which gives the circulation functional

$$(2.13) \qquad C(p) = \int_D \bar{\omega}\, dx\,.$$

In general, the appropriate relaxed form (2.12) must be taken as the definition of generalized enstrophy of the macrostate p [23, 24]. It is a central fact in the theory of Young measures that the functional (2.12) furnishes the limit of the functionals (2.10) under weak convergence [8].

With the objective functional S and the constraint functionals E and F in hand, we can state the variational principle for statistical equilibrium macrostates p:

$$(2.14) \qquad S(p) \to \max \quad \text{subject to} \quad E(p) = E_0\,, \quad F(p; f) = F_0(f)\,,$$

where the constraint values E_0 and $F_0(f)$ are derived from a given initial vorticity field ω_0. The f-parametrized family of constraints on generalized enstrophy can be expressed equivalently as the condition

$$(2.15) \qquad m(D)^{-1} \int_D p(x, dy)\, dx \;=\; p_0(dy)\,,$$

meaning that the x-average of p over D is the given distribution p_0. Of course, the constraint that $p(x, dy)$ be a probability measure for almost every $x \in D$ is also enforced. By standard arguments in functional analysis, the existence of a maximizing macrostate can be established. The equilibrium equations satisfied by such a solution are

$$(2.16) \qquad p(x, dy) = \frac{\exp(-\alpha(y) - \beta y G\bar{\omega}(x)) p_0(dy)}{\int_I \exp(-\alpha(y) - \beta y G\bar{\omega}(x)) p_0(dy)}$$

for some multipliers $\alpha(y)$ and β, which are determined by p. This result can be derived formally by a standard calculation, which is omitted. The mean flow for this equilibrium satisfies the semilinear elliptic equation

$$(2.17) \qquad -\Delta\bar{\psi} = \Phi'(\bar{\psi}) \quad \text{with} \quad \Phi(s) = -\beta^{-1} \log \int_I \exp(-\alpha(y) - \beta y s) p_0(dy).$$

These equations are supplemented by the constraints on E and F, which determine the multipliers β and $\alpha(y)$.

2.4. Statistical equilibria for vortex patches. Rather than further pursue the general formulation described above, we now specialize our development to the simplest case when ω_0 takes the values 0 and λ only, where λ is a given positive constant. For such vortex patches the microscopic evolution is described by a weak solution $\omega \in L^\infty(D \times [0, T])$ that also takes the values 0 and λ only. We therefore write $\omega(x, t) = \lambda 1_{\Omega(t)}$ where $\Omega(t)$ is an open subset of D, and $1_\Omega = 1$ in Ω, $1_\Omega = 0$ in $D\backslash\Omega$; so, $\omega_0 = \lambda 1_{\Omega(0)}$. The conservation of (total) circulation C alone replaces the family of generalized enstrophy integrals, which is degenerate in this case. Thus, the patches $\Omega(t)$ evolve in such way as to conserve their area $C_0/\lambda = m(\Omega(0))$. The macroscopic description simplifies in this case to $p(x, dy) = (1 - \rho(x))\delta_0(dy) + \rho(x)\delta_\lambda(dy)$, in which $\rho(x)$ is the probability that $\omega(x') = \lambda$ for x' near x, or, equivalently, the volume fraction occupied by Ω near x. The mean vorticity is simply $\bar{\omega}(x) = \lambda\rho(x)$.

The statistical equilibrium problem for vortex patches, which is a reduction of the general problem (2.14), can be stated in the form

$$S(\rho) := -\int_D [(1-\rho)\log(1-\rho) + \rho\log\rho]dx \quad \to \quad \max \tag{2.18}$$
$$\text{subject to} \quad C(\rho) = C_0, \quad E(\rho) = E_0.$$

This entropy functional differs from that defined in (2.8) by a constant depending only on C_0 and ρ_0, as can be checked by noting that the density dp/dp_0 equals $(1-\rho)/(1-\rho_0)$ at $y = 0$, and ρ/ρ_0 at $y = \lambda$, if $p_0(dy) = (1-\rho_0)\delta_0(dy) + \rho_0\delta_\lambda(dy)$. For the sake of simplicity, therefore, we choose the classical (Shannon) entropy as the objective functional. The constraint functionals E and C depend upon $\bar{\omega}$ as in their definitions (2.11) and (2.13), respectively.

An equilibrium solution to (2.18) satisfies the equation

$$\rho(x) = \frac{\exp(-\alpha\lambda - \beta\lambda^2(G\rho)(x))}{1 + \exp(-\alpha\lambda - \beta\lambda^2(G\rho)(x))} \tag{2.19}$$

for some real multipliers α and β. From this equation it follows that the mean flow in equilibrium satisfies

$$-\Delta\bar{\psi} = \Phi'(\bar{\psi}) \quad \text{with} \quad \Phi(s) = -\beta^{-1}\log(1 + \exp(-\alpha\lambda - \beta\lambda s)). \tag{2.20}$$

This semilinear elliptic equation is of eigenvalue type in which the multipliers α and β act as the eigenvalue parameters. In the typical situation of interest the coherent structure is a coalesced vortex and, necessarily, the inverse temperature β is negative. The statistical equilibrium problem can then have multiple solutions and bifurcating solution branches. This makes the direct solution of the mean-field equation (2.20) difficult.

The maximum entropy principle as stated above admits various extensions in the presence of additional constraints. These constraints correspond to special symmetries in the domain geometry and flow configuration. In this paper we are concerned with the shear layer problem for which the coherent structure consists of an infinite system of vortices repeated periodically in the x_1 direction and wall bounded in the x_2 direction. Consequently, we take $D = \{x \in \mathbf{R}^2 : a_1 < x_1 < b_1,\ a_2 < x_2 < b_2\}$, and for boundary conditions we impose periodicity on the sides $x_1 = a_1$ and $x_1 = b_1$ and $\bar{\psi} = 0$ on the sides $x_2 = a_2$ and $x_2 = b_2$. The x_1-translational symmetry of this configuration yields the conserved quantity

$$M = \int_D x_2\omega\, dx, \tag{2.21}$$

which is the x_1 component of linear impulse [1]. In the variational principle for statistical equilibrium, this conserved quantity introduces the additional constraint $M(\rho) = M_0$, where $M(\rho)$ is defined as in (2.21) with $\bar{\omega}$ replacing ω. In the equilibrium equations (2.19) and (2.20), the streamfunction $\bar{\psi}$ is then replaced by $\bar{\psi} + (\gamma/\beta)x_2$, which includes an x_1-translational flow with velocity $-\gamma/\beta$, where γ is the multiplier for the linear impulse constraint.

3. Deterministic equilibrium theory.

3.1. Feasible constraint values. The admissible class for the maximum entropy principle is void for constraint values outside a certain feasible range. The limits of this range are defined by the deterministic equilibrium theory of coherent structures, which itself has a variational formulation. As the constraint values approach the limits of the feasible range, the statistical equilibrium solutions tend to their deterministic analogues. In the case of vortex patches, the constraint values C_0 and E_0 in the maximum entropy principle (2.18) cannot be prescribed arbitrarily. Rather, for given values of C_0 and λ, there is a finite interval $[E_{\min}, E_{\max}]$ of feasible values of E_0. The upper and lower bounds of this range of feasible energy values are defined by deterministic coherent structures which have the property that $\rho(x)$ is either 0 or 1 for almost all $x \in D$. In order to explain this useful connection between the statistical and deterministic theories of coherent structures, we summarize below the variational theory of steady vortex flows which characterizes these limits exactly.

The upper bound for E_0 in the statistical equilibrium problem (2.18) is given by the variational principle developed in [28]. In this principle, a steady vortex patch $\omega \in L^\infty(D)$ is a solution of the constrained maximization problem

$$E(\omega) \to \max \quad \text{subject to } C(\omega) = C_0, \; 0 \leq \omega \leq \lambda. \tag{3.1}$$

As is shown in [28], a maximizer $\omega = \omega_{\max}$ exists and has the form

$$\omega = \lambda 1_\Omega, \quad \text{where} \quad \Omega = \{x \in D : G\omega(x) > \mu\} \tag{3.2}$$

for a multiplier μ determined by the circulation constraint. (The admissible class of vorticities in (3.1) admits those ω which take values in the interval $[0, \lambda]$, while the maximizer $\omega_{\max}$ equals either 0 or λ almost everywhere in D.) We, therefore, see that the energy constraint in the maximum entropy principle must be prescribed with the restriction that $E_0 \leq E_{\max} := E(\omega_{\max})$.

The limiting behavior of the statistical equilibrium solutions $\bar{\omega}$ as $E_0 \to E_{\max}$ can be determined under the condition that $\omega_{\max}$ is an isolated and nondegenerate maximizer in (3.1), meaning that $\int_D |\omega_{\max} - \omega| \, dx$ tends to zero as $E(\omega)$ approaches $E_{\max}$. Under such a condition the deterministic steady vortex patch is dynamically stable with the Lyapunov functional $E_{\max} - E(\omega)$. Since $\omega_{\max}$ and $\bar{\omega}$ are uniformly bounded in D, this stability condition expressed in the (circulation) L^1-norm implies that $\bar{\omega} \to \omega_{\max}$ in the (enstrophy) L^2-norm as $E_0 \to E_{\max}$. The limiting behavior of the multipliers α and β is inferred from the following expression for the pointwise difference:

$$\omega_{\max} - \bar{\omega} = \begin{cases} \lambda[1 + \exp(-\alpha\lambda - \beta\lambda\bar{\psi})]^{-1} & \text{in } \{\psi_{\max} > \mu\}, \\ \lambda[1 + \exp(\alpha\lambda + \beta\lambda\bar{\psi})]^{-1} & \text{in } \{\psi_{\max} < \mu\}, \end{cases}$$

which results from combining the equilibrium equations (2.19) and (3.2). In the limit, therefore, $-\alpha - \beta\bar{\psi} \to \infty$ in $\{\psi_{\max} > \mu\}$, while $\alpha + \beta\bar{\psi} \to \infty$ in $\{\psi_{\max} < \mu\}$. This, together with the fact that $\bar{\psi} \to \psi_{\max}$ uniformly on $\bar{D}$, which holds by virtue of the regularity properties of the operator G, shows that $\beta \to -\infty$ and $-\alpha/\beta \to \mu$ as $E_0 \to E_{\max}$. This behavior of the the multipliers is consistent with the fact that the admissible class in (2.18) shrinks to the singleton $\{1_{\{\psi_{\max} > \mu\}}\}$. Thus, the statistical equilibrium problem (2.18) degenerates into the deterministic equilibrium problem (3.1) in the limit of maximum feasible energy. This behavior is clearly displayed by the numerical results given in §5.

The asymptotic behavior of the $E_{\max}$ and $\omega_{\max}$ as $\lambda \to \infty$ for fixed C_0 is also known [28]. In this limit, the statistical equilibrium solutions tend to the solutions of the classical theory of a dilute point-vortex gas [21, 20, 16, 13, 4]. The equilibrium equation then reduces to the mean-field equation

$$\omega = \exp(-\tilde{\alpha} - \tilde{\beta} G\omega) \tag{3.3}$$

for the vortex density ω. The deterministic solution $\omega_{\max}$, on the other hand, tends to a point vortex with circulation C_0 located at an equilibrium point of the Kirchhoff–Routh Hamiltonian for the domain D. The corresponding energy $E_{\max}$ diverges to infinity logarithmically, and hence arbitrarily large values of E_0 are feasible in the classical theory. As E_0 increases to infinity these classical statistical equilibria condense to a point vortex, which constitutes their deterministic limit.

The lower bound for E_0 in (2.18) is given by the deterministic equilibrium problem of minimum energy analogous to (3.1). Unlike the coalesced vortices obtained at maximum energy, these minimum energy solutions are steady flows for which the vorticity is dispersed to the domain boundary. The energy of such a solution $\omega_{\min}$ provides the complementary restriction that $E_0 \geq E_{\min} := E(\omega_{\min})$. In the limit of minimum feasible energy, the statistical theory again degenerates into the deterministic theory.

Intermediate between $E_{\min}$ and $E_{\max}$ lies the energy value $E_{\text{hom}} = E(\rho_{\text{hom}})$ of the most probable macrostate ρ_{hom} over all possible energy values. This homogeneous macrostate is simply the constant $\rho_{\text{hom}} = C_0/\lambda m(D)$, which corresponds to $\beta = 0$. In simple geometries, like those of our shear layer computations, the statistical equilibria with $E_{\text{hom}} < E_0 < E_{\max}$ have negative temperatures ($\beta < 0$), while those with $E_{\min} < E_0 < E_{\text{hom}}$ have positive temperatures ($\beta > 0$). In complex geometries, however, this may not always hold.

3.2. Iterative algorithm. The deterministic equilibrium problem (3.1) can be solved numerically using the method given in [9]. Since that method can be viewed as a prototype for the iterative algorithm that we propose in the present paper to solve the statistical equilibrium problem (2.18), we briefly restate it here.

The algorithm generates the iterate ω^{k+1} ($k = 0, 1, \ldots$) by solving the optimization problem that results from linearizing the energy functional about the previous iterate ω^k. Thus, $\omega = \omega^{k+1}$ is taken to be the solution of the convex subproblem

$$\int_D \omega G\omega^k dx \;\to\; \max \quad \text{over } C(\omega) = C_0, \quad 0 \leq \omega \leq \lambda. \tag{3.4}$$

The variational equations for this subproblem are simply

$$\omega^{k+1} = \lambda 1_{\Omega^{k+1}} \quad \text{where} \quad \Omega^{k+1} = \{x \in D : G\omega^k(x) > \mu^{k+1}\} \tag{3.5}$$

for some multiplier μ^{k+1}. This multiplier is found by imposing the circulation constraint on the expression (3.5), which yields a single real equation that is easily solved. Formally, the dual subproblem to the primal subproblem (3.4),

$$C_0\mu + \int_D \lambda(G\omega^k - \mu)_+ dx \;\to\; \min \quad \text{over} \quad \mu \in \mathbf{R},$$

defines the iterative multiplier μ^{k+1}.

This iterative algorithm is designed to be globally convergent, meaning that it converges from *any* admissible initialization ω^0. This property can be inferred from the inequality

$$E(\omega^{k+1}) - E(\omega^k) \geq E(\omega^{k+1} - \omega^k),$$

which holds for all k. A general convergence theory is presented in [9]. The algorithm has a linear rate of convergence, which is observed to be quite rapid in implemented computations.

4. Numerical method.

4.1. Primal form of the algorithm. We now proceed to give a method of computing solutions of the maximum entropy problem posed in §2. This method is an iterative algorithm based on the special structure of the constrained optimization problem that it solves. In this sense, it fits into the same conceptual framework as the algorithm described in §3 which solves the related maximum energy problem.

The iterative step that generates ρ^{k+1} from ρ^k $(k = 0, 1, \ldots)$ is defined by solving the optimization subproblem

$$S(\rho) \to \max \quad \text{subject to} \quad C(\rho) = C_0, \quad E(\rho^k) + \langle E'(\rho^k), \rho - \rho^k \rangle \geq E_0. \tag{4.1}$$

Given ρ^k, the solution $\rho = \rho^{k+1}$ to this subproblem exists and is unique, since the objective functional is strictly concave and the admissible class is convex. Consequently, we obtain a well-defined iterative sequence ρ^k $(k = 0, 1, \ldots)$ for every admissible initialization ρ^0 we choose. We require only that ρ^0 satisfy a relaxation of the constraints for (2.18): $C(\rho^0) = C_0$ and $E(\rho^0) \geq E_0$. In this abstract formulation, the functional derivative (denoted by a prime) of any differentiable functional $F(\rho)$ is defined by the condition that

$$F(\rho + \delta\rho) = F(\rho) + \langle F'(\rho), \delta\rho \rangle + o(\| \delta\rho \|)$$

as $\| \delta\rho \| \to 0$, where the symbols $\langle \cdot, \cdot \rangle$ and $\| \cdot \|$ denote the $L^2(D)$ pairing and norm, respectively.

The solution ρ^{k+1} satisfies

$$S'(\rho^{k+1}) = \alpha^{k+1} C'(\rho^k) + \beta^{k+1} E'(\rho^k), \tag{4.2}$$

$$\beta^{k+1} \leq 0, \tag{4.3}$$

$$\beta^{k+1}[E(\rho^k) + \langle E'(\rho^k), \rho^{k+1} - \rho^k \rangle - E_0] = 0 \tag{4.4}$$

for some multipliers $\alpha^{k+1}, \beta^{k+1} \in \mathbf{R}$. These are the Kuhn–Tucker conditions for (4.1), which provide the natural extension of the Lagrange multiplier rule to an inequality constrained problem [26, 11]. The complementarity conditions (4.4) imply that the linearized energy constraint holds as an equality whenever $\beta^{k+1} \neq 0$. The solution triple $(\rho^{k+1}, \alpha^{k+1}, \beta^{k+1})$ is completely determined by these conditions combined with the constraints.

4.2. Convergence properties. Before expressing the iterative algorithm in the concrete form needed for numerical implementation, we first show how its convergence properties are derived from its abstract structure. These special properties justify the algorithm and explain how it makes use of the concavity/convexity properties of the objective/constraint functionals in the variational problem it solves. For this purpose we need the the following second-order expansions of S and E:

$$S(\rho + \delta\rho) \leq S(\rho) + \langle S'(\rho), \delta\rho \rangle - 2 \| \delta\rho \|^2,$$
$$E(\rho + \delta\rho) = E(\rho) + \langle E'(\rho), \delta\rho \rangle + E(\delta\rho).$$

By applying these facts along with the defining equation (4.2), we make the calculation

$$\begin{aligned} S(\rho^{k+1}) - S(\rho^k) - 2 \| \rho^{k+1} - \rho^k \|^2 &\geq \langle S'(\rho^{k+1}), \rho^{k+1} - \rho^k \rangle \\ &= \beta^{k+1} \langle E'(\rho^k), \rho^{k+1} - \rho^k \rangle \\ &= \beta^{k+1} [E_0 - E(\rho^k)] \end{aligned}$$

in which we note that the term involving α^{k+1} vanishes because C is a linear functional. By virtue of the convexity of E, we have

$$E(\rho^k) \geq E(\rho^{k-1}) + \langle E'(\rho^{k-1}), \rho^k - \rho^{k-1} \rangle \geq E_0.$$

Thus, we obtain the basic inequality of the convergence theory:

$$S(\rho^{k+1}) - S(\rho^k) \geq 2 \parallel \rho^{k+1} - \rho^k \parallel^2 + |\beta^{k+1}|[E(\rho^k) - E_0] \tag{4.5}$$

which holds for all k and for arbitrary admissible ρ^0.

We infer immediately that the entropy $S(\rho^k)$ increases along the iterative sequence, and hence that it converges to a finite limit S^* as $k \to \infty$. From this monotonicity property we conclude that $\rho^{k+1} - \rho^k \to 0$ in L^2. This conclusion shows that if the iterative sequence ρ^k converges to a limit ρ^* and the multiplier sequence β^k converges to a limit $\beta^* < 0$, then ρ^* is a solution of the maximum entropy problem with equality constraints on both circulation and energy. Indeed, if we assume that $\rho^k \to \rho^*$ in L^2 as $k \to \infty$, then it is straightforward to demonstrate that the corresponding multipliers converge: $\alpha^k \to \alpha^*$ and $\beta^k \to \beta^*$. We then deduce that the limit $(\rho^*, \alpha^*, \beta^*)$ solves the equation for statistical equilibrium

$$S'(\rho^*) = \alpha^* C'(\rho^*) + \beta^* E'(\rho^*),$$

using the fact that ρ^k and ρ^{k+1} both converge to ρ^*. Given that $\beta^* < 0$, we retrieve the equality constraints on ρ^*, since $C(\rho^k) = C_0$ and $E(\rho^k) \to E_0$.

From the inequality (4.5) alone, however, we cannot conclude that the iterative sequence ρ^k converges since we lack a rate of convergence on the difference between successive iterates. Moreover, the possible nonuniqueness of solutions ρ^* to the statistical equilibrium problem suggests that this convergence may not always hold. (The equality constraint on energy in the maximum entropy problem makes it a nonconvex optimization problem.) For these reasons, we generalize the notion of convergence to one that holds even when the statistical equilibrium problem does not have a unique (or isolated) solution. Simply put, the generalized convergence theorem states that the minimum distance from ρ^k to the *set* of solutions (critical points) ρ^* of (2.18) tends to zero as $k \to \infty$. We now give an outline of the proof of this theorem based on the analysis developed in [9] for the deterministic problem.

The core of this proof is to show that any subsequence of the iteratives has a further subsequence that converges in the energy norm to a solution of a certain relaxed version of the maximum entropy problem. Let the G-norm, which is equivalent to the energy norm, be defined by $\parallel \rho \parallel_G^2 = \int_D \rho \, G\rho \, dx$. Since the sequence ρ^k is bounded in L^2, any sequence ρ^{k_j} of iterates has a subsequence $\rho^{k'_j}$ that converges weakly to some $\rho^* \in L^2$. By virtue of the compactness of the operator G, this subsequence also converges in the G-norm. Moreover, $\rho^{k'_j+1}$ converges to the same limit ρ^* weakly in L^2 and in the G-norm. To prove that ρ^* is a solution to the statistical equilibrium equation (a critical point of the maximum entropy problem), it suffices to show that ρ^* solves the variational problem

$$S(\rho) \to \max \quad \text{subject to} \quad C(\rho) = C_0, \quad E(\rho^*) + \langle E'(\rho^*), \rho - \rho^* \rangle \geq E_0. \tag{4.6}$$

In other words, it is required to show that $S(\rho^*) \geq S(\rho)$ for any ρ that is admissible in (4.6) in which the energy constraint is linearized about ρ^* itself. For any such ρ, let $\eta \in L^\infty(D)$ be chosen such that its support is contained in $\{x \in D : \delta \leq \rho(x) \leq 1 - \delta\}$ for some positive δ, and it satisfies $C(\eta) = 0$, $\langle E'(\rho^*), \eta \rangle = 1$. (This construction is possible unless $S(\rho) = 0$, which is a trivial case.) We claim that the perturbation $\rho + \epsilon\eta$, for any small positive ϵ, is admissible in the iterative subproblem (4.1) whenever $k = k'_j$ is large enough depending on

ϵ. To verify this claim we evaluate the constraints in (4.1) on $\rho + \epsilon\eta$, using the constraints in (4.6) on ρ; thus, we find that

$$\begin{aligned} C(\rho + \epsilon\eta) &= C_0, \\ E(\rho^k) + \langle E'(\rho^k), \rho + \epsilon\eta - \rho^k\rangle &\geq E(\rho^*) + \langle E'(\rho^*), \rho - \rho^*\rangle - \epsilon_k + \epsilon \\ &\geq E_0 - \epsilon_k + \epsilon \end{aligned}$$

for a sequence of positive constants ϵ_k which, by the continuity of the energy functional, tend to zero along the subsequence. Therefore, $S(\rho+\epsilon\eta) \leq S(\rho^{k+1})$ for large $k = k'_j$, and hence in the limit, $S(\rho + \epsilon\eta) \leq S(\rho^*)$, by the weak upper semicontinuity of the entropy functional. Upon taking ϵ to zero, we obtain the desired result that ρ^* solves (4.6), which means that ρ^* satisfies the statistical equilibrium equation and the relaxed constraints: $C(\rho^*) = C_0, \quad E(\rho^*) \geq E_0$.

Let Σ^* be the *set of critical points* ρ^* of the maximum entropy problem (2.18) with the energy constraint relaxed to an inequality. From the above analysis, we obtain the generalized convergence result in terms of the G-norm distance from the iterate ρ^k to the set Σ^*:

$$\text{dist}_G(\rho^k, \Sigma^*) \ := \ \inf_{\rho^* \in \Sigma^*} \parallel \rho^k - \rho^* \parallel_G \ \rightarrow \ 0 \qquad \text{as } k \rightarrow \infty\,.$$

This convergence statement holds without any restrictions on the constraint values C_0 and E_0 or on the initialization ρ^0. In this sense, the iterative algorithm defined by (4.1) is globally convergent. The proof of the statement is immediate, since otherwise $\text{dist}_G(\rho^k, \Sigma^*) \geq \delta > 0$ for a sequence $k = k_j$, which contradicts the convergence of a subsequence $\rho^{k'_j}$ to a critical point $\rho^* \in \Sigma^*$.

It is possible to strengthen this convergence result in several ways. First, by applying a standard bootstrap argument to the statistical equilibrium equation, the G-norm can be replaced by the L^2-norm. Second, for any given initialization ρ^0, the set of limit points of ρ^k can be shown to consist of either a single solution (the sequence limit) or infinitely many solutions, none of which is isolated. Third, the convergence of the (entire) iterative sequence can be ensured by requiring that the initialization be close enough to an isolated local maximizer ρ^* for (2.18). We omit the details of these further results.

The energy constraint, which is relaxed to the inequality $E(\rho^*) \geq E_0$ in the convergence theory, is necessarily an equality whenever $\beta^* < 0$, by virtue of the complementarity conditions. Thus, it is evident that our algorithm is designed to compute solutions having negative temperature. This restriction is completely natural, however, since these solutions are the statistical equilibria of physical interest as coherent structures. Indeed, as in the theory of a point-vortex gas, the coalescence of vorticity occurs only in the negative temperature regime.

In implemented computations, our algorithm exhibits a linear rate of convergence to an isolated solution. This behavior is expected on analytical grounds whenever ρ^* is a nondegenerate local maximizer, which is the generic case. The generalized convergence behavior stated in the global convergence theorem is, therefore, rarely observed. Moreover, we find that the algorithm converges even in the regime where $\beta^* \geq 0$, which is beyond the scope of the convergence theory. As a consequence, actual implementations of the algorithm can dispense with the inequality constraint on linearized energy in favor of the simpler equality constraint.

4.3. Dual form of the algorithm.

We now give the concrete form of the iterative algorithm, which yields its numerical implementation. Equation (4.2), which defines the iterate ρ^{k+1} in terms of the multipliers α^{k+1} and β^{k+1}, can be written in the form

$$\rho^{k+1} \ = \ (s^*)'(\alpha^{k+1}\lambda \ + \ \beta^{k+1}\lambda\bar{\psi}^k) \tag{4.7}$$

where $\bar{\psi}^k = G\bar{\omega}^k, \ \bar{\omega}^k = \lambda\rho^k$. This expression employs the Legendre–Fenchel transform

$$s^*(\sigma) \ := \ \sup_{\rho}\{\rho\sigma - s(\rho)\} \ = \ -\log(1 + \exp(-\sigma))$$

of the entropy density $s(\rho) := -[\rho \log \rho + (1-\rho)\log(1-\rho)]$ in (2.18). The derivation of (4.7) follows directly from the standard properties of conjugate functions:

$$\sigma = s'(\rho) \quad \text{and} \quad \rho = (s^*)'(\sigma),$$
$$(s^*)''(\sigma) = 1/s''(\rho) = -\rho(1-\rho) < 0.$$

In view of the explicit formula (4.7), the iterative step is reduced to finding the iterative multipliers α^{k+1} and β^{k+1}. These multipliers, in turn, solve the dual to the primal subproblem (4.1), which is

$$\alpha C_0 + \beta(E_0 + E^k) - \int_D s^*(\alpha\lambda + \beta\lambda\bar{\psi}^k)dx \to \min \qquad \text{over } \alpha \in \mathbf{R},\ \beta \leq 0, \tag{4.8}$$

where $E^k := \langle E'(\rho^k), \rho^k\rangle - E(\rho^k)$ is identical with $E(\rho^k)$. This dual subproblem is easily solved numerically, at least in principle, since it involves a convex objective function on $\mathbf{R}^2$ with one simple bound constraint (which can be ignored in practice). The unique solution $(\alpha^{k+1}, \beta^{k+1})$ to (4.8) determines the unique solution ρ^{k+1} to (4.1) by means of the formula (4.7).

The equivalence of the dual subproblem (4.8) to the primal subproblem (4.1) is a standard fact from optimization theory [26, 11]. The dual subproblem is derived by substituting the expression (4.7) for ρ^{k+1} into the constraints for the primal subproblem. The variational conditions satisfied by a minimizer $(\alpha^{k+1}, \beta^{k+1})$ for (4.8) are then shown to coincide with the Kuhn–Tucker conditions for (4.1).

In the case of the free shear layer the maximum entropy principle is supplemented by an additional constraint associated with the conservation of the x_1-component of linear impulse. The above algorithm is easily adapted to this case by augmenting the circulation constraint into a pair of linear constraints on C and M and the corresponding multiplier into a multiplier vector (α, γ). The abstract construction of the iterative algorithm then generalizes in an obvious manner, and the general convergence results also continue to hold. The explicit form of the iterative step is then given by

$$\rho^{k+1} = (s^*)'(\alpha^{k+1}\lambda + \beta^{k+1}\lambda\bar{\psi}^k + \gamma^{k+1}\lambda x_2),$$

where the multipliers are determined by solving the dual subproblem

$$\alpha C_0 + \beta(E_0 + E^k) + \gamma M_0 - \int_D s^*(\alpha\lambda + \beta\lambda\bar{\psi}^k + \gamma\lambda x_2)dx \to \min$$
$$\text{over } \alpha, \gamma \in \mathbf{R},\ \beta \leq 0.$$

4.4. Numerical implementation. In the shear layer computations discussed in what follows, the numerical problem is discretized on a regular grid on the rectangular domain D. The streamfunction $\bar{\psi} = \lambda G \rho$ is found by utilizing a Poisson solver with boundary conditions that are periodic in x_1 and homogeneous Dirichlet in x_2. The dual subproblem, which presents the main computational burden, is treated by simply ignoring the inequality constraint on β so that it becomes the system of nonlinear equations

$$\left(\frac{\partial}{\partial\alpha}, \frac{\partial}{\partial\beta}, \frac{\partial}{\partial\gamma}\right) \int_D s^*(\alpha\lambda + \beta\lambda\bar{\psi}^k(x) + \gamma\lambda x_2)\,dx = (C_0, E_0 + E^k, M_0).$$

This system in $(\alpha, \beta, \gamma) \in \mathbf{R}^3$ is solved by a damped Newton method with a damping factor 2^{-m}, where m is taken to be the smallest nonnegative integer for which the residual is decreased in the Euclidean norm. (Without the damping, the Newton method can produce overshoots in the arguments of the exponential functions participating in the dual subproblem, and this can lead to divergence.) The damped Newton iterations are terminated when a residual of less than 10^{-9} is obtained. The double integrals over D that define the component equations of the system are evaluated by a standard numerical integration. This direct approach to solving the dual subproblem is fast and accurate. Moreover, if the multiplier $\beta^* = \lim \beta^k$ is strictly negative, and the initialization ρ^0 is close enough to the solution ρ^*, then it is justified theoretically since necessarily the iterative multipliers β^k are strictly negative and the linearized constraints on energy hold as equalities. In general, however, the relaxation of the constraint $\beta \leq 0$ violates the requirements of our convergence theory. Thus, the justification for this approach rests mainly on experience, which shows that over a wide range of conditions, including those in which β^* itself is positive, the iterative algorithm in this relaxed form is convergent.

The rate of convergence of the iterative algorithm is observed to be quite rapid. The stopping criterion adopted for the iterations in k is of the form

$$\frac{\| \rho^{k+1} - \rho^k \|}{\| \rho^k \|}, \frac{|S^{k+1} - S^k|}{|S^k|}, \frac{|E^{k+1} - E^0|}{|E^0|} \leq 5 \times 10^{-3}.$$

While the number of iterations required to satisfy this criterion varies with the conditions of the problem, typically about 10 iterations suffice. No significant changes are observed as a result of decreasing these or the other tolerances set on the algorithm. Similarly, the spatial resolution achieved by taking 50×50 grid nodes in D is typically adequate, since the macrostate ρ varies on the large scale. In order to accommodate some extreme cases in which ρ varies more rapidly, more refined grids are used as necessary in the implemented computations discussed below. Even with this finer resolution, the method produces a solution in the order of 100 seconds on a SPARC2 workstation.

5. Computed results.

5.1. Branches of equilibria parametrized by energy. The energy of a given vorticity distribution is the principal factor that determines how it organizes into a coherent structure [22]. Indeed, the coalescence of vorticity into a coherent vortex, which is a negative temperature macrostate, is expected to occur when the energy is sufficiently large [21]. Moreover, the spatial structure of such a vortex and the variation of the mean vorticity within its core depend upon the value of the energy. Consequently, we devote our first set of results to the computation of maximum entropy solutions parametrized by the value of the energy constraint.

We solve the statistical equilibrium problem (2.18) in the shear layer configuration on the fundamental domain $D = \{0 < x_1 < 1, -0.5 < x_2 < 0.5\}$, discretized with 61 grid nodes in both the x_1 and x_2 directions. We normalize the circulation to $C_0 = 1$ and we set $\lambda = 10$ with the consequence that $\rho_{\text{hom}} = 0.1$. We restrict our attention to solutions that are symmetric with respect to x_2 in the sense that $\rho(x_1, x_2) = \rho(x_1, -x_2)$. This restriction allows us to ignore the linear impulse constraint M and its multiplier γ since both are necessarily zero. We enforce this symmetry in our computations by choosing a symmetric initialization for the iterative algorithm, which preserves the symmetry at each iteration.

In Figure 1, the branch of macrostates with E_0 greater than E_{hom} is displayed. This figure shows the level curves of the local probability ρ at increments of 0.1; the figures that follow use the same convention. The first member of the branch, which has an energy value of $E_0 = 0.1350$, is computed by initializing the algorithm with a centered, circular patch whose radius is chosen to satisfy the circulation constraint. Since its energy is very close to $E_{\max}$, it corresponds to a large negative value of $\beta = -15.2$ and exhibits a steep transition between the vortex core ($\rho \approx 1$) and the surrounding irrotational region ($\rho \approx 0$). Larger feasible values of E_0 give equilibria that are very close to steady vortex patches, the deterministic limiting solutions. The subsequent members of the branch displayed in Figure 1 have smaller values of E_0, with correspondingly smaller values of $|\beta|$. These solutions are computed by using a continuation

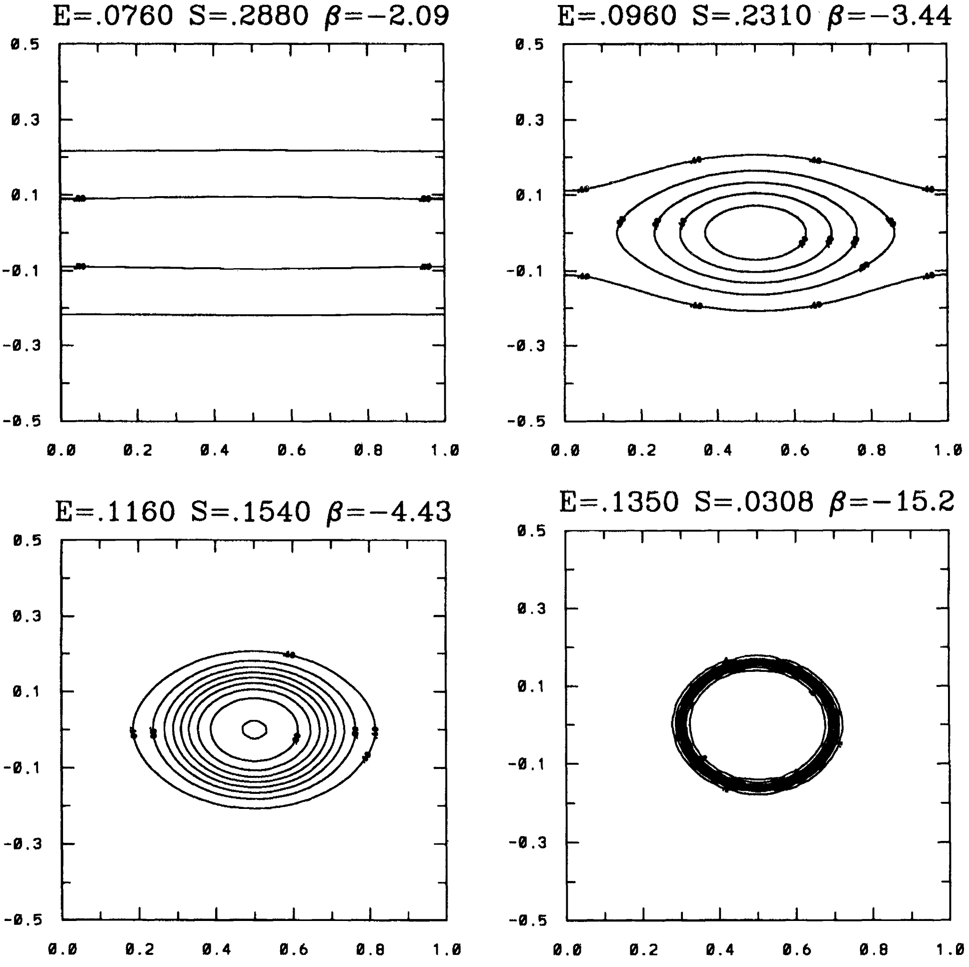

FIG. 1. *Mean streamlines for a branch of maximum entropy solutions with circulation* $C = 1$, *vorticity strength* $\lambda = 10$, *and displayed energy values in the range* $E_{\text{hom}} < E_0 < E_{\max}$ *and computed values of entropy* S *and inverse temperature* β.

strategy in which the algorithm is initialized by a previous solution along the branch having greater energy. As E_0 decreases, the maximum of ρ decreases, indicating greater mixing of entrained irrotational fluid into the vortex core. At the nearly critical value of $E_0 = 0.0760$ the mean vorticity is almost x_1-independent, which evidences almost complete homogeneity in the x_1 direction. Below a critical value of E_0 slightly less than 0.0760, the branch becomes exactly x_1-independent. With decreasing E_0, the x_2 dependence of these solutions decays until the completely homogenous (x-independent) macrostate is reached at E_{hom}.

If the x_1-independence of solutions is imposed, then the above branch of equilibrium shear layers can be continued to a maximum energy limit. This is easily accomplished by initializing the algorithm with an x_1-independent ρ^0 since the x_1 symmetry is preserved at each iteration. Such a branch is displayed in Figure 2. The x_2-dependence of these solutions grows until the parallel vortex patch is reached at a maximum energy slightly greater than $E_0 = 0.1160$. It is interesting to compare the entropies of the solutions in Figure 1 with those in Figure 2 having the same values of the constraints E_0 and C_0. For instance, for $E_0 = 0.0960$ the coherent vortex in Figure 1 has the entropy value $S = 0.2310$ while the parallel shear layer in Figure 2 has the smaller value $S = 0.2290$. This may be interpreted as indicating that the vortex is the most probable state into which the shear layer will evolve if its x_1-translational symmetry

is broken. These computations therefore provide a confirmation of the rollup phenomenon exhibited in dynamical evolution of unstable shear layers.

The continuation of these coincident branches to energy values less than E_{hom} is given in Figure 3. For these values of E_0, β is positive and the solutions are x_1-independent. As E_0 decreases along this branch of solutions, β increases and the vorticity accumulates toward the walls. This behavior is anticipated on heuristic grounds. Rather curiously, our algorithm converges to solutions on this branch even though our convergence proofs depend on the strict negativity of β.

In Figure 4, we plot the dependence of the equilibrium value of S upon the given value of E_0 for the full feasible range of the energy and for both the x_1-dependent and x_1-independent branches. This graph demonstrates how maximum entropy coherent vortex structures bifurcate from parallel shear layers as their energy is increased. Since the computation of these branches is accomplished by our iterative algorithm which is entropy increasing, we find only those branches whose members are entropy maximizing, possibly subject to a symmetry restriction. We believe that the x_1-dependent branch displayed here is the absolute maximum entropy branch.

5.2. Rollup of shear layers. In the context of x_1-periodic, x_2-bounded flows, the most basic prediction of the statistical equilibrium theory resides in the correspondence between an initial perturbed shear layer and a final array of coherent vortices. In particular, the computational solution of the maximum entropy principle (2.18) establishes a definite, quantitative relationship between the thickness of the given shear layer and the form of the coherent structure into which it evolves. We examine this relationship in our second set of computations.

We now take a domain $D = \{0 < x_1 < 1\,, -1 < x_2 < 1\}$, which we discretize with 81 grid nodes in each direction. With $C = 1$ as before, we determine the vorticity strength λ and the energy E_0 from a shear layer that is in the form of a parallel vortex patch: $\omega_0 = \lambda$ in $\{|x_2| < \delta/2\}$, $\omega_0 = 0$ elsewhere. The normalization of circulation obviously implies that $\lambda = \delta^{-1}$. Consequently, the thickness δ of the shear layer completely determines the constraints in (2.18). The energy value E_0 is a decreasing function of δ and takes its largest value in the limit as $\delta \to 0$, which corresponds to a (unit strength) vortex sheet. For $\delta \ll 1$, this configuration is a good approximation to a free shear layer with a linear velocity profile, the bounding walls at $x_2 = \pm 1$ being sufficiently far from the layer centered at $x_2 = 0$ to have only a small influence.

We compute a branch of equilibria parametrized by δ, using an initialization that breaks the x_1-independence of the defining shear layer. The iterative algorithm then mimics the

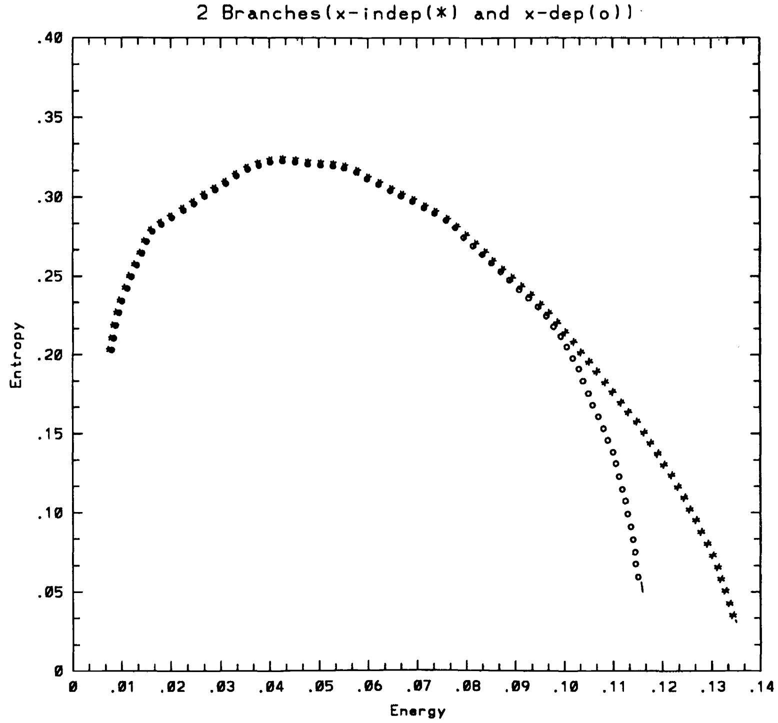

FIG. 4. *The dependence of the equilibrium value of S on the constraint value E_0 over the full feasible range. The branch of x_1-dependent solutions (coherent vortices) bifurcates from the branch of x_1-independent solutions (shear layers).*

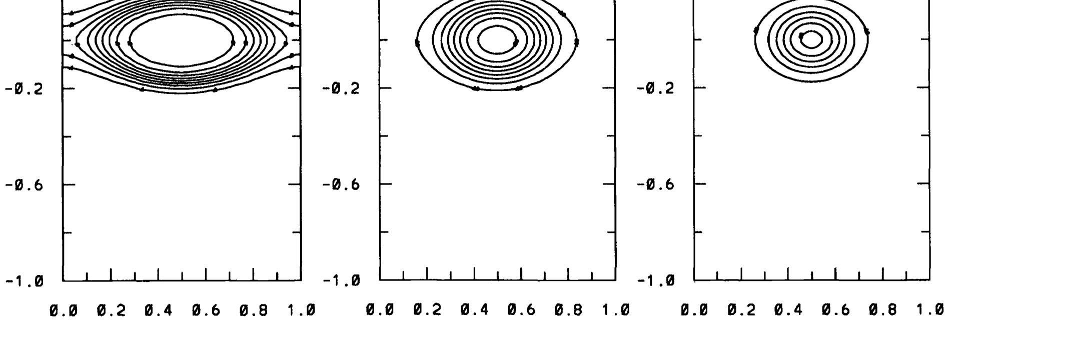

FIG. 5. *Rollup of shear layers with thicknesses δ into coherent vortices.*

temporal evolution of the perturbed shear layer as it rolls up into a coherent vortex, which the statistical equilibrium model takes to be the maximum entropy solution. In Figure 5, we show these solutions for layer thicknesses of $\delta = 0.2, 0.1, 0.05$. As δ is decreased, the vortex structure develops a more pronounced core and the mean vorticity becomes more concentrated

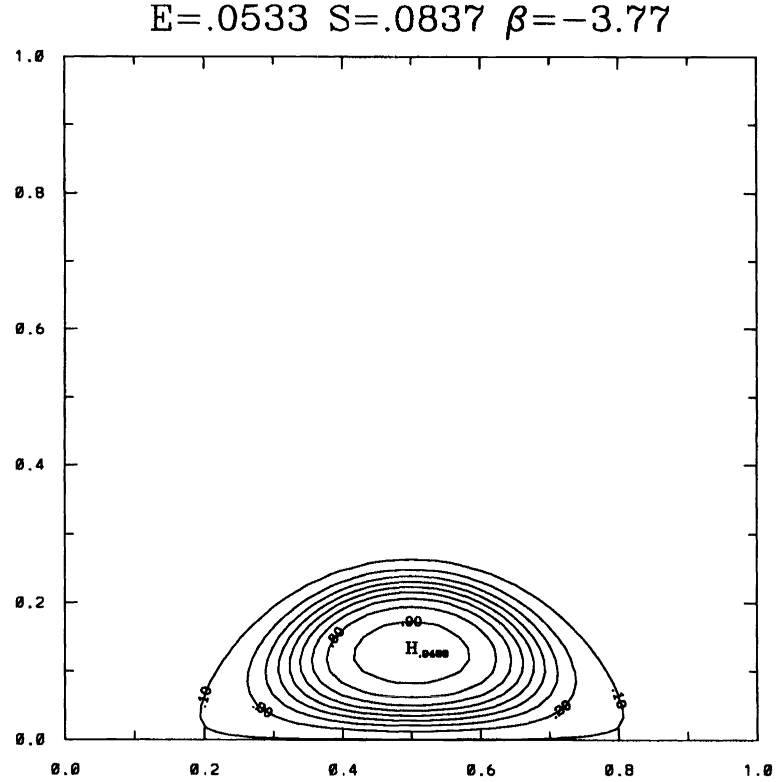

FIG. 6. *Coalescence of two circular vortex patches into a coherent vortex.*

in that core. Nevertheless, the maximum of the volume fraction ρ (which occurs at the center of the vortex) decreases along with δ, indicating that the thinner shear layers result in coherent vortices with greater mixing in their cores. This behavior is in good qualitative agreement with the results of direct simulation of rollup in thin shear layers [10] and (desingularized) vortex sheets [2, 15]. A further quantitative comparison with such results would certainly be very interesting but will not be included here.

5.3. Coalescence of vortices. A common feature of shear layer turbulence is the pairing or merging of like-signed regions of vorticity. As a simple example of this general phenomenon, we consider the leap-frogging behavior of two identical vortex patches, a combination of translational and corotational motion. The statistical equilibrium theory predicts that the longtime average of this evolution leads to a steadily translating, coalesced vortex structure. We take this example as the third application of our numerical method. In contrast to the two preceding cases in which the multiplier γ (translational speed) can be ignored, the impulse constraint is active in this case.

We are interested in the behavior of two vortex patches of unit circulation in the fundamental domain $D = \{0 < x_1 < 1,\ 0 < x_2 < 1\}$. Initially the patches are circular with centers at (0.35, 0.125) and (0.65, 0.125), and both radii are equal to 0.1. This distribution ω_0 determines the constraint values C_0, E_0, M_0 in the maximum entropy principle. Since the vortices are close to the wall at $x_2 = 0$ and are closer to each other in x_1 separation than to their periodic images, they are expected to translate in the positive x_1 direction and to corotate mutually. The distortion caused by the boundary wall and the mutual straining then promotes the coalescence of the vortex patches. The resulting coherent structure is modeled by the maximum entropy solution displayed in Figure 6. It has a translational speed of $-\gamma/\beta$, with computed values of $\beta = -3.77$ and $\gamma = 1.92$. In addition to the form of this macroscopic vortex structure, the statistical equilibrium theory thus predicts its speed of translation, using the conservation of linear impulse associated with the underlying dynamics.

Acknowledgment. The authors express their sincere thanks to Richard Jordan for his many valuable comments and illuminating conversations.

SPACE–TIME FINITE ELEMENT METHODS FOR SURFACE DIFFUSION WITH APPLICATIONS TO THE THEORY OF THE STABILITY OF CYLINDERS*

BERNARD D. COLEMAN†, RICHARD S. FALK†, AND MAHER MOAKHER†

Abstract. A family of space–time finite element approximation schemes is presented for the nonlinear partial differential equations governing diffusion in the surface of a body of revolution. The schemes share with the partial differential equations properties of conservation of volume and decrease of area. Numerical experiments are described showing that the result of the linear theory of small amplitude longitudinal perturbations of a cylinder to the effect that a long cylinder is stable against all perturbations with spatial Fourier spectra containing only wavelengths less than the circumference of the cylinder does not hold in the full nonlinear theory. Examples are given of cases in which longitudinal perturbations with high wave-number spectra grow in amplitude, after an initial rapid decay followed by a long "incubation period," and result in break-up of the body into a necklace of beads. The results of finite element calculations are compared with the predictions of a perturbation analysis.

Key words. axially symmetric motion by Laplacian of mean curvature, stability against surface diffusion

1. Introduction.

We are concerned here with the numerical computation of morphological changes induced in an isotropic and homogeneous solid body by mass diffusion within the body's bounding surface $\mathcal{S}$. We employ a constitutive equation, due to Herring [6], expressing the mass flux $\boldsymbol{q}$ in $\mathcal{S}$ as a linear function of the gradient in $\mathcal{S}$ of the sum H of the principal curvatures:

$$\boldsymbol{q} = -K\nabla_s H. \tag{1.1}$$

Here $K > 0$ is a material constant proportional to the surface self-diffusion coefficient of the isotropic material of which the body is composed, and we are using a sign convention for curvature such that H is positive for a sphere. As was observed and exploited by Mullins [9], when the only motion is the flux $\boldsymbol{q}$ in $\mathcal{S}$, the mass balance yields the following relation between the rate v of advance of $\mathcal{S}$ along its exterior normal and the surface divergence of $\boldsymbol{q}$:

$$\rho v + \mathrm{div}_s\boldsymbol{q} = 0; \tag{1.2}$$

here ρ is the mass density, per unit volume, of the material in the body.

For a given characteristic length L, the theory of (1.1), (1.2) is rendered dimensionless by replacing quantities x, r, etc., with dimension of length by xL, rL, etc., the time t by $\rho L^4 t/K$, and hence $\boldsymbol{q}$ by $K\boldsymbol{q}/L^2$ and H by H/L. When this is done, (1.1), (1.2) yield

$$v = \Delta_s H, \tag{1.3}$$

and thus are said to govern the theory of *motion by Laplacian of mean curvature*. That theory has a less-developed literature than the theory of *motion by mean curvature*, which is based on the equation

$$v = -H. \tag{1.4}$$

In a recent survey [1], Cahn and Taylor discuss the difficulties encountered when one attempts to extend techniques employed to develop the theory of motion by mean curvature to the theory of motion by Laplacian of mean curvature. Whereas H in (1.4) is given by second-order spatial derivatives of surface coordinates, $\Delta_s H$ in (1.3) depends on fourth-order derivatives of the coordinates, and this elementary fact has the important consequence that a maximum principle employed in the theory of (1.4) does not hold for (1.3).

Among the papers presenting computational methods for motion by mean curvature are that of Dziuk [3], giving a semidiscretization scheme based on tangential gradients, and that of Sethian [11], based on a level set formulation of equation (1.4).

Among recent analytical developments in the analysis of the motion of surfaces by mean curvature are Huisken's short-time existence and regularity results [8], Soner and Songanidis's analysis of the nature of singularities in axially symmetric surfaces [12], and Evans and Spruck's theory of viscosity solutions [5] for a level set formulation of (1.4).

Interesting and very recent results in the theory of motion by Laplacian of mean curvature in a plane are proofs by Elliott and Garcke [4] of the asymptotic stability of circles and of global existence of planar solutions with initial data in a neighborhood of a circle.

The numerical methods and results presented here are for initial-value problems arising in the theory of motion by Laplacian of mean curvature for axially symmetric surfaces subject to periodic boundary conditions. In §2 we give various forms taken by the system (1.1), (1.2) for such surfaces and discuss relevant laws of conservation of volume and decrease of area [2]. A variational formulation presented in §3 is discretized in §4 with space–time finite element schemes that yield analogues of the laws of conservation of volume and decrease of area that hold for (1.1), (1.2). Results of numerical experiments are presented in §5.

For an axially symmetric surface, in a natural cylindrical coordinate system with radial coordinate r and axial coordinate x, the equation (1.3) of motion by Laplacian of mean curvature becomes

$$r_t = \frac{1}{r}\left[\frac{r}{(1+r_x^2)^{1/2}}\left(\frac{1}{r(1+r_x^2)^{1/2}} - \frac{r_{xx}}{(1+r_x^2)^{3/2}}\right)_x\right]_x . \tag{1.5}$$

The emphasis here is on cases in which this equation is subject to initial data of the form

$$r(x,0) = r_0(x) = 1 + \epsilon u(x) \tag{1.6}$$

with $\epsilon > 0$ and u an almost periodic function. For simplicity we often take u to have a finite Fourier spectrum, i.e., to be of the form

$$u(x) = \sum_{i=1}^{M} c_i \sin(k_i x + \varphi_i) \tag{1.7}$$

with $c_i,\ k_i > 0$. (In the numerical calculations of this paper u is assumed periodic and hence the wave numbers k_i in (1.7) are commensurate.) For longitudinal perturbations of a cylinder of radius a, (1.5) is obtained from (1.1), (1.2) by putting $L = a$ and making the change of units discussed above. For a given u, the perturbation is small if ϵ is small compared with 1, and, in (1.7), $k_i < 1$, $= 1$, or > 1, in accord with whether the corresponding period $P_i = 2\pi/k_i$ exceeds, equals, or is less than the circumference of the unperturbed cylinder.

Since the work of Nichols and Mullins [10], in the study of small amplitude longitudinal perturbations of a cylinder it has been customary to restrict attention to the linearization of (1.5) about $r = 1$, i.e., to the equation

$$r_t + r_{xxxx} + r_{xx} = 0, \tag{1.8}$$

whose solution with the initial condition (1.6), (1.7) is

$$r(x,t) = 1 + \epsilon \sum_{i=1}^{M} c_i e^{\alpha(k_i)t} \sin(k_i x + \varphi_i) \tag{1.9}$$

where α obeys the dispersion relation

$$\alpha(k) = k^2(1-k^2). \tag{1.10}$$

The maximum value of $\alpha(k)$ is $\frac{1}{4}$ and occurs at $k = 1/\sqrt{2}$. As the right side of (1.10) is negative for $k > 1$, the linear equation (1.8) implies that whenever, in (1.7), $k_i > 1$ for all i, the perturbation decays to zero as $t \to \infty$. We recently presented arguments [2] to the effect that such is not the case in the theory of the nonlinear equation (1.5).

The arguments given in [2] are based on formal perturbation analyses employing an expansion of the solution of (1.5), (1.6) in ϵ. A perturbation argument taking into account terms $O(\epsilon^2)$ yields the conclusion that if

$$k_i > 1 \qquad \text{for} \qquad i = 1, \dots, M \tag{1.11a}$$

and, in addition, two distinct wave numbers, k_i, k_j, have $|k_i - k_j| < 1$, then, although the solution of (1.5) will exhibit an initial decay of the perturbation, after a time whose duration can be estimated, a new sinusoidal term with wave number equal to $|k_i - k_j|$, i.e., to that of the envelope of the ith and jth terms in (1.7), will appear in the solution and grow in amplitude, taking the surface far from cylindrical shape. When terms $O(\epsilon^n)$ are taken into account the following generalization of this conclusion is obtained: if (1.11a) holds, and, in addition, there is an integer $n \geq 2$ and there are M integers m_i (positive, negative, or zero) that obey the relations

$$\sum_{i=1}^{M} |m_i| = n \qquad \text{and} \qquad 0 < \left| \sum_{i=1}^{M} m_i k_i \right| < 1, \tag{1.11b}$$

then, again after an initial decay, the perturbation will grow.

The perturbation analysis given in [2] and discussed here in §5 leads one to expect, but cannot be employed to prove, that in the cases in which (1.11a) and (1.11b) hold the growth in perturbations proceeds until there is a time t^* and values x^* of x for which $\lim_{t \to t^*} r(x^*, t) = 0$. The numerical methods we present here were developed to see if such is the case and, if so, to permit precise calculation of the break-up time t^* as well as the "incubation time" required for occurrence of appreciable growth of a perturbation after its initial (and generally rapid) decay. Numerical experiments confirming expectations based on the perturbation analysis are described in §5. We also give there an example of a case in which our numerical methods can be applied to study the evolution of the body for $t > t^*$. In general, a topological change occurs at $t = t^*$, resulting in the break-up of the original body into separated subbodies. Thus we refer to t^* as the "time of break-up." (In the theory of motion by mean curvature, in which the volume is not conserved but decreases in time, similar phenomena can occur, and their times of occurrence are often referred to as times of "pinch-off.")

2. Basic equations.

To describe the evolution of the surface of an infinite body of revolution, we continue to use the cylindrical coordinates x and r of equation (1.5). We write $\boldsymbol{t}$ for the unit tangent to the time-dependent curve $r = r(x,t)$ in the (x,r)-plane, and we define the signed magnitude q of $\boldsymbol{q}$ so that $\boldsymbol{q} = q\boldsymbol{t}$. For axially symmetric surfaces, when the dimensionless units are used, (1.2) and (1.1) become, respectively,

$$rr_t = -(rq)_x, \tag{2.1}$$

$$q = -(\nabla_s H) \cdot \boldsymbol{t} = -\frac{H_x}{\sqrt{1+r_x^2}} \tag{2.2}$$

where

$$H = \frac{1}{r}\left[\sqrt{1+r_x^2} - \left(\frac{rr_x}{\sqrt{1+r_x^2}}\right)_x\right]. \tag{2.3}$$

For numerical calculations we treat the body as one with finite length subject to space-periodic boundary conditions with, say, period P. The resulting problems have properties of volume conservation and area decay which we now discuss.

It follows from (2.1) that the volume of material lying between cross-sectional planes $x = a$ and $x = b$ with $b - a = P$, i.e.,

$$V(t) = \pi \int_a^b r^2\, dx, \tag{2.4}$$

is constant in time if r and $q = -H_x/\sqrt{1+r_x^2}$ are P-periodic. Equations (2.1) and (2.2) together imply that the surface area (or the free energy) of the portion of the body lying between these two planes, i.e.,

$$\Psi(t) = 2\pi \int_a^b r\sqrt{1+r_x^2}\, dx, \tag{2.5}$$

is a monotone-decreasing function of time, provided that not only r and $H_x/\sqrt{1+r_x^2}$ but also H and $r_x/\sqrt{1+r_x^2}$ are P-periodic. The periodicity of r, H, $r_x/\sqrt{1+r_x^2}$, and $H_x/\sqrt{1+r_x^2}$ are equivalent to the periodicity of r, H, r_x, and H_x. Thus, under boundary conditions implying such periodicity, V is preserved and Ψ represents a Lyapunov function for the evolution of r.

We put $\Omega = (a, b)$ and write $\mathcal{I} = (0, T)$ for an interval with $T > 0$ on which solutions of (2.1)–(2.3) with $r > 0$ are defined. Under the conditions of periodicity just described

$$\dot{\Psi} = -2\pi \int_\Omega \frac{rH_x^2}{\sqrt{1+r_x^2}} dx = -2\pi \int_\Omega q^2 r\sqrt{1+r_x^2} dx \leq 0, \tag{2.6}$$

and hence under the same conditions

$$\Phi(t) = \Psi(t) + 2\pi \int_0^t \int_\Omega q^2(x,\tau) r(x,\tau)\sqrt{1+r_x^2(x,\tau)}\, dx\, d\tau \tag{2.7}$$

is constant:

$$\Phi(t) = \Phi(0) = \Psi(0). \tag{2.8}$$

For each initial configuration r_0 we seek $r(\cdot, t)$ satisfying (2.1), (2.2), and the periodicity conditions. The equation of evolution for r, (1.5), which is fourth order in the space variable x, can be formulated in terms of r and H to yield a coupled system of second order in x. The resulting fully nonlinear initial-value problem with periodic boundary conditions has a variational formulation that can be slightly simplified by introducing a function R defined by

$$R(x,t) = \frac{1}{2} r^2(x,t). \tag{2.9}$$

In this way we are led to the following problem.

Problem RH. Find (R, H) with $R > 0$ satisfying

$$R_t = \left(\frac{2RH_x}{\sqrt{2R + R_x^2}}\right)_x \qquad \forall (x, t) \in \Omega \times \mathcal{I}, \tag{2.10}$$

$$H = \frac{1}{\sqrt{2R + R_x^2}} - \left(\frac{R_x}{\sqrt{2R + R_x^2}}\right)_x \qquad \forall (x, t) \in \Omega \times \mathcal{I}, \tag{2.11}$$

with the periodic boundary conditions

$$\begin{aligned} R(a, t) &= R(b, t), \qquad R_x(a, t) = R_x(b, t) \qquad \forall t \in \mathcal{I}, \\ H(a, t) &= H(b, t), \qquad H_x(a, t) = H_x(b, t) \qquad \forall t \in \mathcal{I}, \end{aligned} \tag{2.12}$$

and the initial condition

$$R(x, 0) = R_0(x) = \frac{1}{2} r_0^2(x) \qquad \forall x \in \Omega. \tag{2.13}$$

3. Variational formulation. We use standard notation: $L^2(\Omega)$ is the space of square integrable functions on Ω, $L^\infty(\Omega)$ is the space of essentially bounded functions on Ω, $H^1(\Omega)$ is the Sobolev space of functions in $L^2(\Omega)$ with distributional derivative in $L^2(\Omega)$, and $W^{1,\infty}(\Omega)$ is the Sobolev space of functions in $L^\infty(\Omega)$ with distributional derivative in $L^\infty(\Omega)$. Of importance here are subspaces H_{P}^1 and $W_{\mathrm{P}}^{1,\infty}$ of $H^1(\Omega)$ and $W^{1,\infty}(\Omega)$, with $\Omega = (a, b)$, that arise from our concern with periodic boundary conditions

$$\begin{aligned} H_{\mathrm{P}}^1 &= \left\{ v \in H^1(\Omega) : v(a) = v(b) \right\}, \\ W_{\mathrm{P}}^{1,\infty} &= \left\{ v \in W^{1,\infty}(\Omega) : v(a) = v(b) \right\}. \end{aligned}$$

We also define H_{P}^{-1} as the dual space of H_{P}^1. Let X be a Banach space on Ω with norm $|| \cdot ||_X$. We denote by $L^2(0, T; X)$ the space of functions f from $(0, T)$ into X such that $(\int_0^T ||f||_X^2 dt)^{1/2} < \infty$ and by $L^\infty(0, T; X)$ the space of functions f from $(0, T)$ into X such that $||f||_X$ is essentially bounded on $(0, T)$.

For brevity we write

$$(f, g) = \int_\Omega f g \, dx.$$

Variational form of Problem RH. Find $R \in L^\infty(0, T; W_{\mathrm{P}}^{1,\infty})$ with $R > 0$ and $R_t \in L^2(0, T; H_{\mathrm{P}}^{-1})$ and $H \in L^2(0, T; H_{\mathrm{P}}^1)$ satisfying

$$\int_0^T (R_t, u) \, dt + \int_0^T \left(\frac{2RH_x}{\sqrt{2R + R_x^2}}, u_x \right) dt = 0 \quad \forall u \in L^2(0, T; H_{\mathrm{P}}^1), \tag{3.1}$$

$$\int_0^T (H, v) \, dt = \int_0^T \left(\frac{1}{\sqrt{2R + R_x^2}}, v \right) dt + \int_0^T \left(\frac{R_x}{\sqrt{2R + R_x^2}}, v_x \right) dt \quad \forall v \in L^2(0, T; H_{\mathrm{P}}^1), \tag{3.2}$$

$$(R(\cdot, 0), w) = (R_0, w) \quad \forall w \in L^2(\Omega). \tag{3.3}$$

We note that there are not yet available proofs of existence and uniqueness for solutions for either Problem RH or (3.1)–(3.3). However, if we are granted existence and uniqueness, the stated variational form of Problem RH is a useful formulation for the construction of the conforming finite element approximation schemes presented in §4.

Straightforward arguments show that solutions of (2.10)–(2.13) obey (3.1)–(3.3) and that solutions of the variational equations (3.1)–(3.3) with sufficient regularity obey (2.10)–(2.13).

Constancy of volume and monotone decrease of surface area hold for each solution (R, H) of (3.1)–(3.3). To show this, we observe that in our present notation

$$\dot{V} = 2\pi(R_t, 1), \tag{3.4}$$

and hence by putting $u \equiv 1$ in the time interval $(0, t)$ and $u \equiv 0$ in the time interval (t, T) in equation (3.1), we obtain

$$V(t) = V(0). \tag{3.5}$$

In (3.1) and (3.2) by putting $u = H$ and $v = R_t$ in the time interval $(0, t)$ and $u \equiv 0$, $v \equiv 0$ in the time interval (t, T), both of which are admissible test functions, we obtain

$$\int_0^t (R_t, H)\, dt + \int_0^t \left(\frac{2R}{\sqrt{2R + R_x^2}}, H_x^2 \right) dt = 0, \tag{3.6}$$

$$\int_0^t (H, R_t)\, dt = \int_0^t \left(\frac{1}{\sqrt{2R + R_x^2}}, R_t \right) dt + \int_0^t \left(\frac{R_x}{\sqrt{2R + R_x^2}}, R_{tx} \right) dt. \tag{3.7}$$

As $\Psi = 2\pi(\sqrt{2R + R_x^2}, 1)$ and hence

$$\dot{\Psi} = 2\pi \left(\frac{1}{\sqrt{2R + R_x^2}}, R_t \right) + 2\pi \left(\frac{R_x}{\sqrt{2R + R_x^2}}, R_{tx} \right), \tag{3.8}$$

(3.7) yields $\int_0^t \dot{\Psi}\, dt = 2\pi \int_0^t (H, R_t)\, dt$, and, by (3.6),

$$\Psi(t) - \Psi(0) = -2\pi \int_0^t \left(\frac{2R}{\sqrt{2R + R_x^2}}, H_x^2 \right) dt. \tag{3.9}$$

Hence

$$\Psi(t) - \Psi(0) = -2\pi \int_0^t \left(\frac{2R}{\sqrt{2R + R_x^2}}, H_x^2 \right) dt \leq 0.$$

4. Finite element method. To approximate the variational form of Problem RH, we here construct a family of mixed finite element methods for which piecewise polynomial approximations in space and time are used for both R and H. Let $a = x_0 < x_1 < \cdots < x_N = b$ and $0 = t^0 < t^1 < \cdots < t^K = T$ be partitions of Ω and $\mathcal{I}$, and let $h_i = x_{i+1} - x_i$, $i = 0, \ldots, N-1$ and $k^j = t^{j+1} - t^j$, $j = 0, \ldots, K-1$, be mesh spacings and time steps. Let $S_h^p(\Omega)$ be the finite element space of continuous functions Q that are piecewise polynomials of degree $p \geq 1$ on each interval of the partition of Ω and obey the periodicity condition $Q(a) = Q(b)$. We write $S_k^q(\mathcal{I})$ and $\bar{S}_k^q(\mathcal{I})$, respectively, for the finite element spaces of continuous and discontinuous functions that are piecewise polynomials of degree $q \geq 0$ on each interval of the partition of $\mathcal{I}$. The members of the tensor product spaces

$$S_{hk}^{p,q} = S_h^p(\Omega) \otimes S_k^q(\mathcal{I}), \qquad \bar{S}_{hk}^{p,q} = S_h^p(\Omega) \otimes \bar{S}_k^q(\mathcal{I})$$

are functions on $\Omega \times \mathcal{I}$. We consider, for given integers $p \geq 1, q \geq 0$, the following.

Finite element approximation of type (p,q) to Problem RH. Find $R_{hk} \in S_{hk}^{p,q+1}$ and $H_{hk} \in \bar{S}_{hk}^{p,q}$ satisfying

$$\int_0^T ((R_{hk})_t, u_{hk})dt + \int_0^T \left(\frac{2R_{hk}(H_{hk})_x}{\sqrt{2R_{hk} + (R_{hk})_x^2}}, (u_{hk})_x\right) dt = 0 \qquad \forall u_{hk} \in \bar{S}_{hk}^{p,q},$$

$$\int_0^T (H_{hk}, v_{hk})dt = \int_0^T \left(\frac{(R_{hk})_x}{\sqrt{2R_{hk} + (R_{hk})_x^2}}, (v_{hk})_x\right) dt$$

$$+ \int_0^T \left(\frac{1}{\sqrt{2R_{hk} + (R_{hk})_x^2}}, v_{hk}\right) dt \qquad \forall v_{hk} \in \bar{S}_{hk}^{p,q},$$

$$(R_{hk}(\cdot, 0), w_{hk}) = (R_0, w_{hk}) \qquad \forall w_{hk} \in S_h^p(\Omega).$$

We note that R_{hk} is a polynomial of one degree higher in time than H_{hk} and the test functions u_{hk} and v_{hk}. The simplest finite element approximation in this family is that of type (p,q) with $p = 1$ and $q = 0$, i.e., that for which R_{hk} is a continuous piecewise linear polynomial in both space and time and H_{hk} and the test functions u_{hk} and v_{hk} are continuous piecewise linear polynomials in space and piecewise constant in time.

Because the test functions u_{hk} and v_{hk} are discontinuous in time, finite element solutions (R_{hk}, H_{hk}) can be computed by marching through successive time intervals. Let $P^q(\mathcal{I}^n)$ be the set of polynomials on $\mathcal{I}^n = [t^n, t^{n+1}]$ of degree q. On the time-strip $\mathcal{I}^n$ the appropriate restrictions of R_{hk} and H_{hk} belong to $S_h^p(\Omega) \otimes P^{q+1}(\mathcal{I}^n)$ and $S_h^p(\Omega) \otimes P^q(\mathcal{I}^n)$, respectively, and obey, for each u_{hk} and v_{hk} in $S_h^p(\Omega) \otimes P^q(\mathcal{I}^n)$,

$$(4.1) \qquad \int_{t^n}^{t^{n+1}} ((R_{hk})_t, u_{hk})dt + \int_{t^n}^{t^{n+1}} \left(\frac{2R_{hk}(H_{hk})_x}{\sqrt{2R_{hk} + (R_{hk})_x^2}}, (u_{hk})_x\right) dt = 0,$$

$$(4.2) \qquad \begin{aligned} \int_{t^n}^{t^{n+1}} (H_{hk}, v_{hk})dt &= \int_{t^n}^{t^{n+1}} \left(\frac{(R_{hk})_x}{\sqrt{2R_{hk} + (R_{hk})_x^2}}, (v_{hk})_x\right) dt \\ &\quad + \int_{t^n}^{t^{n+1}} \left(\frac{1}{\sqrt{2R_{hk} + (R_{hk})_x^2}}, v_{hk}\right) dt \end{aligned}$$

where R_{hk} at $t = t^n$ is fixed by continuity (or by the initial condition if $n = 0$).

The arguments which gave us (3.4) and (3.8) hold for the spaces to which R_{hk}, H_{hk}, u_{hk}, and v_{hk} belong for each finite element approximation, and each approximate solution (R_{hk}, H_{hk}) will show constancy of V and Φ and monotone decrease of Ψ.

In the simplest case, $p = 1$ and $q = 0$, we write $R_{hk}(x,t)$ on the time-strip $\mathcal{I}^n$ as

$$R_{hk}(x,t) = \frac{t - t^n}{k^n}[R_{hk}(x, t^{n+1}) - R_{hk}(x, t^n)] + R_{hk}(x, t^n),$$

and $H_{hk}(x,t)$ reduces to the constant-in-time function $H_{hk}(x,t) = H_{hk}(x, (t^n + t^{n+1})/2)$. Upon use of the usual expansion in piecewise linear basis functions, (4.1) and (4.2) yield a system of nonlinear algebraic equations for the coefficients of the basis functions. In our numerical work that algebraic system was solved by an iteration procedure which was initialized with the choice $R_{hk}^0(x, t^1) = R_{hk}(x, t^0)$ for the time-strip $\mathcal{I}^0 = [t^0, t^1]$ and carried forward with the extrapolation

$$R^0_{hk}(x,t^{n+1}) = \left(1+\frac{k^n}{k^{n-1}}\right)R_{hk}(x,t^n) - \frac{k^n}{k^{n-1}}R_{hk}(x,t^{n-1})$$

for the strip $\mathcal{I}^n$, $n \geq 1$; here R^l_{hk} denotes the lth iterate of R_{hk}. At the lth iteration on $\mathcal{I}^n$, $n \geq 0$, R^l_{hk}, and H^l_{hk} are determined by solving the linear system

$$\int_{t^n}^{t^{n+1}} ((R^l_{hk})_t, u_{hk})dt + \int_{t^n}^{t^{n+1}} \left(\frac{2R^{l-1}_{hk}(H^l_{hk})_x}{\sqrt{2R^{l-1}_{hk} + (R^{l-1}_{hk})^2_x}}, (u_{hk})_x\right)dt = 0,$$

$$\int_{t^n}^{t^{n+1}} (H^l_{hk}, v_{hk})dt = \int_{t^n}^{t^{n+1}} \left(\frac{(R^l_{hk})_x}{\sqrt{2R^{l-1}_{hk} + (R^{l-1}_{hk})^2_x}}, (v_{hk})_x\right)dt$$

$$+\int_{t^n}^{t^{n+1}} \left(\frac{1}{\sqrt{2R^{l-1}_{hk} + (R^{l-1}_{hk})^2_x}}, v_{hk}\right)dt$$

with u_{hk} and v_{hk} as in (4.1), (4.2) and

$$R^l_{hk}(x,t) = \frac{t-t^n}{k^n}[R^l_{hk}(x,t^{n+1}) - R_{hk}(x,t^n)] + R_{hk}(x,t^n).$$

5. Numerical experiments. For the two numerical experiments described below, we employed a finite element approximation of type (1, 0). The initial data had the form (1.6), (1.7) with each phase angle, φ_i, zero and, more importantly, each wave-number k_i greater than 1, so that (1.10) yields

$$\alpha(k_i) < 0, \qquad i = 1, \ldots, M, \tag{5.1}$$

and hence each exponential term in the solution (1.9) of the linear equation (1.8) decays to zero. The wave-numbers k_i were taken to be commensurate, which makes the periodic boundary conditions (2.12) exact relations.

Let $\bar{r}$ be given by

$$\pi(b-a)\bar{r}^2 = V(0) = \pi\int_a^b r_0^2 dx \tag{5.2}$$

and put

$$g(t) = \sup_x |r(x,t) - \bar{r}|. \tag{5.3}$$

A cylindrical body can be said to be *asymptotically stable against a class $\mathcal{P}$ of perturbations*, ϵu, if for each function $r_0 = 1 + \epsilon u$ with ϵu in $\mathcal{P}$ the solution of Problem RH obeys the two conditions

$$r(x,t) > 0 \qquad \forall(x,t) \in \Omega \times (0,\infty) \tag{I}$$

and

$$g(t) \to 0 \qquad \text{as} \qquad t \to \infty. \tag{II}$$

(I) asserts that "break-up" does not occur; (II) asserts that in the limit as $t \to \infty$ the body returns to cylindrical shape with a radius $\bar{r}$ determined by the mean volume $V(0)/(b-a)$ of the perturbed cylinder. (To generalize the condition (II) to initial data that are not periodic, but instead, say, almost periodic, one may replace $V(0)/(b-a)$ in the definition of $\bar{r}$ by the quantity

$$\langle \pi r^2 \rangle = 2\langle \pi R \rangle = \lim_{X\to\infty} \frac{\pi}{2X} \int_{-X+x_0}^{X+x_0} r^2 dx \tag{5.4}$$

which is constant in time and, for almost periodic functions, independent of x_0.)

When the function u in (1.6) is specified, the solution r of the nonlinear equation (1.5) depends on ϵ. For the perturbation analysis given in [2] we made the usual assumption that the dependence of $r(x, t; \epsilon)$ on ϵ is sufficiently smooth that for each integer n one can write

$$r(x, t; \epsilon) = 1 + \sum_{l=1}^{n} \epsilon^l w^{(l)}(x, t) + O(\epsilon^{n+1}). \tag{5.5}$$

By placing (5.5) in (1.5) and using (1.6) with u as in (1.7) we found, using a perturbation analysis of order 2, i.e., setting $n = 2$ in (5.5), that the term $1 + \epsilon w^{(1)}(x, t)$ is given by the right-hand side of (1.9), and

$$\begin{aligned} w^{(2)}(x, t) = {}& \frac{1}{4}\sum_{i=1}^{M} c_i^2 - \frac{1}{4}\sum_{i=1}^{M} c_i^2 e^{2\alpha(k_i)t} + \sum_{i=1}^{M} A_1(i; t)\cos(2k_i x + 2\varphi_i) \\ & + \sum_{1\le i<j\le M} A_2(i, j; t)\cos((k_i + k_j)x + \varphi_i + \varphi_j) \\ & + \sum_{1\le i<j\le M} A_3(i, j; t)\cos((k_i - k_j)x + \varphi_i - \varphi_j) \end{aligned} \tag{5.6}$$

where

$$A_1(i; t) = \frac{3c_i^2\beta(k_i)}{2[\alpha(2k_i) - 2\alpha(k_i)]}(e^{\alpha(2k_i)t} - e^{2\alpha(k_i)t}), \tag{5.7a}$$

$$A_2(i, j; t) = \frac{c_i c_j \beta^+(k_i, k_j)}{\alpha(k_i + k_j) - \alpha(k_i) - \alpha(k_j)}(e^{\alpha(k_i+k_j)t} - e^{(\alpha(k_i)+\alpha(k_j))t}), \tag{5.7b}$$

$$A_3(i, j; t) = \frac{c_i c_j \beta^-(k_i, k_j)}{\alpha(k_i - k_j) - \alpha(k_i) - \alpha(k_j)}(e^{\alpha(k_i-k_j)t} - e^{(\alpha(k_i)+\alpha(k_j))t}) \tag{5.7c}$$

with α as in (1.10) and

$$\beta(k) = k^2(1 + k^2), \tag{5.8a}$$

$$\beta^+(k_i, k_j) = (k_i k_j + k_i^2 + k_j^2)(1 + k_i k_j), \tag{5.8b}$$

$$\beta^-(k_i, k_j) = (k_i k_j - k_i^2 - k_j^2)(1 - k_i k_j). \tag{5.8c}$$

When, as in the numerical experiments, (1.11a) holds, the quantities $\alpha(k_i)$, $\alpha(2k_i)$, $\alpha(k_i + k_j)$ are negative for each i and $j > i$. Hence not only $w^{(1)}$ but also all the terms in $w^{(2)}$, other than the constant term $\frac{1}{4}\epsilon^2 \sum_{i=1}^{M} c_i^2$ and possibly some of the form $\epsilon^2 f(k_i, k_j; t)\cos((k_i - k_j)x + \varphi_i - \varphi_j)$ with

$$f(k_i, k_j; t) = \frac{c_i c_j \beta^-(k_i, k_j)}{\alpha(k_i - k_j) - \alpha(k_i) - \alpha(k_j)} e^{\alpha(k_i-k_j)t}, \tag{5.9}$$

will decay to zero exponentially with increasing t. The quantity $|f(k_i, k_j; t)|$ is constant in time when $|k_i - k_j| = 1$; it increases exponentially if and only if

$$0 < |k_i - k_j| < 1. \tag{5.10}$$

Thus, if (1.11a) holds and in addition $|k_i - k_j| > 1$ for all distinct pairs (i, j), the second-order perturbation analysis, like the linear theory, does not yield the existence of times at which $g(t)$ increases; however, a higher analysis may yield such times. In fact, exponential growth of $g(t)$, beginning at some time $t > 0$ and proceeding until break-up occurs, i.e., until a time t^* at which there are values x^* of x with $r(x^*, t^*) = 0$, will be shown in an nth-order perturbation analysis if (1.11b) holds for an M-tuple $(m_1, m_2, \ldots, m_M)$ with the m_i having (positive, negative, or zero) integral values.

In the numerical experiments reported here (1.11a) and (5.10) hold for at least one pair (i, j), $i < j$, and hence although the linear theory based on (1.8) predicts that the cylindrical body is asymptotically stable against the perturbation studied, the second-order theory predicts that the body is not stable against the perturbation and suggests that break-up can occur at a finite time. Specifically, under the conditions of the experiments, the second-order analysis yields the conclusion that for short times $r(x, t)$ is approximated by the expression

$$1 + \frac{\epsilon^2}{4}\sum_{i=1}^{M} c_i^2 + \epsilon \sum_{i=1}^{M} c_i e^{\alpha(k_i)t} \sin(k_i x + \varphi_i)$$

where each $\alpha(k_i)$ is negative, and hence, after a brief time interval, $r(x, t)$ will be close for all x to the constant

$$\bar{r} = \left[1 + \frac{\epsilon^2}{2}\sum_{i=1}^{M} c_i^2\right]^{1/2} = 1 + \frac{\epsilon^2}{4}\sum_{i=1}^{M} c_i^2 + O(\epsilon^4);$$

i.e., the body will be essentially indistinguishable from a cylinder. In a subsequent time interval, however, $r(x, t)$ will be approximated by

$$1 + \frac{\epsilon^2}{4}\sum_{i=1}^{M} c_i^2 + \epsilon^2 \sum_{(i,j)\in\Gamma} f(k_i, k_j; t)\cos((k_i - k_j)x + \varphi_i - \varphi_j)$$

where f is as in (5.9) and Γ is the set of pairs (i, j) with $1 \le i < j \le M$ and $|k_i - k_j| < 1$; during that interval $g(t)$ will increase monotonically.

Let ν be the minimum value that $g(t)$ must have for a departure of the body from cylindrical shape to be easily observable after $g(t)$ has decayed and started to increase. The time $t_\#$ at which $g(t)$ attains the value ν (after an initial decrease) may be called the "incubation time" for observable growth of a perturbation which according to the linear theory (1.8) would only decay. The second-order perturbation analysis gives the following relation for $t_\#$ in the case in which there is precisely one pair (i, j) for which (5.10) holds:

$$\nu = \epsilon^2 f(k_i, k_j; t_\#). \tag{5.11}$$

A reasonable value for ν would be 0.05. We note that equation (5.11) implies that $t_\#$ varies slowly, i.e., logarithmically, with ϵ.

For large k, $\alpha(k)$ decreases rapidly with k; indeed, as $\alpha(k) \sim -k^4$. However, on the interval $0 < k < 1$ where $\alpha(k)$ is positive, the maximum value of $\alpha(k)$, $\alpha(1/\sqrt{2})$, is only $\frac{1}{4}$. Hence the incubation time $t_\#$ can be expected to be orders of magnitude longer than the time required for decay of an initial perturbation that has each k_i appreciably greater than 1. This disparity in time scales requires that time steps be adjusted in numerical calculations in accord with the rate of convergence of the iterative procedure described at the end of §4, i.e., in accord with the rate of evolution of R and H.

For the first numerical experiment the initial data correspond to the function

$$r_0(x) = 1 + 5 \times 10^{-2} [\sin(5x) + \sin(11x/2)], \tag{5.12}$$

which has minimum period 4π. Here $k_1 = 5 > 1$, $k_2 = 11/2 > 1$, but $|k_1 - k_2| = 1/2 < 1$. According to the second-order perturbation analysis, the two sinusoidal terms in the initial data should decay rapidly, and, after this rapid decay, which in the present case lasts until approximately $t = 2 \times 10^{-2}$, $r(x, t)$ should be, for a while, close to a cosine function of x which has period 4π and an amplitude growing as $e^{\alpha(1/2)t}$ with $\alpha(1/2) = 3/16$. In the finite element scheme, the interval $a \le x \le b$ was chosen to have length 8π, i.e., two periods, and was discretized into 512 equal segments. For the time interval $0 < t \le 5 \times 10^{-2}$ that contains the times of rapid decay of $g(t)$, the time step, Δt, was chosen to be 10^{-4}; during the early growth phase, i.e., for $5 \times 10^{-2} < t \le 28.05$, Δt was set equal to $t = 10^{-2}$. For $28.05 \le t \le 28.27234 = t^*$, the time steps were refined in such a way that Δt decreased rapidly as t approached the break-up time t^*. (As is common practice, we repeated suspected critical parts of this and the second numerical experiment using refined spatial and temporal meshes; the reported mesh densities are such that further refinement produced no change in results.)

In Fig. 1 there are graphs of r versus x for various t between 0 and t^*. The initial data, (5.12), are shown in Fig. 1a. The scale of the ordinate r contracts in the sequence from Fig. 1b to Fig. 1f, but in each case is greater than that of the abscissa x. Figure 1b contains graphs corresponding to $t = 10^{-2}$ and $t = 1.63 \times 10^{-2}$. At $t = 10^{-2}$ remnants of the terms $5 \times 10^{-2} \sin(5x)$ and $5 \times 10^{-2} \sin(11x/2)$ can be seen perturbing the function $\tilde{r}(\cdot, t)$ given by

$$\tilde{r}(x, t) = \bar{r} + \epsilon^2 f(5, 11/2; t) \cos(x/2) \tag{5.13}$$

where $\epsilon^2 = 25 \times 10^{-4}$ and f is as in (5.9) with $\alpha = 3/16$. At $t = 1.63 \times 10^{-2}$, $g(t)$ attains its minimum value, and at that time the difference between $r(x, t)$ and $\tilde{r}(x, t)$ is not detectable on the scale employed for r of Fig. 1b. Figure 1c contains graphs for values of t at which $r(x, t)$ is close to $\tilde{r}(x, t)$; the earliest time at which the second-order perturbation analysis gives results (here plotted with dashes) that are distinguishable from the finite element results (on the scale of Fig. 1c) is $t = 15$.

In Fig. 2, where we employ equal scales for the ordinate and the abscissa, there are shown profiles of the axially symmetric body whose surface is given by $r = r(x, t)$. The initial configuration is seen in Fig. 2a. At a time $t \sim 10^{-2}$ the body is of cylindrical shape to within an error of the order 0.1% in r. If we set $\nu = 0.05$, the configuration shown in Fig. 2b, i.e., that for $t = 20$, is very close to one with $g(t) = \nu$; in fact, the finite element results yield 0.05 for $g(t)$ when $t = 19.55$; the second-order perturbation analysis, on the other hand, yields 0.05 for $g(t)$ when $t = 19.72$. We think it remarkably fortunate that in this case an elementary analysis that takes into account only the lowest-order nonlinear terms gives an estimate for the incubation time $t_\#$ that is off by only 1%.

There are cases in which the evolution of the subbodies formed at time t^* can be studied for $t > t^*$ by reparameterizing with spherical coordinates the surface of each connected subbody. In this procedure one chooses a point on the original x-axis to be the origin of a spherical coordinate system, and the closed surface of the subbody containing that origin is described by giving the distance $\hat{r}$ from the origin to a point on the surface as a function of t and the colatitude φ measured from the x-axis. A finite element method analogous to

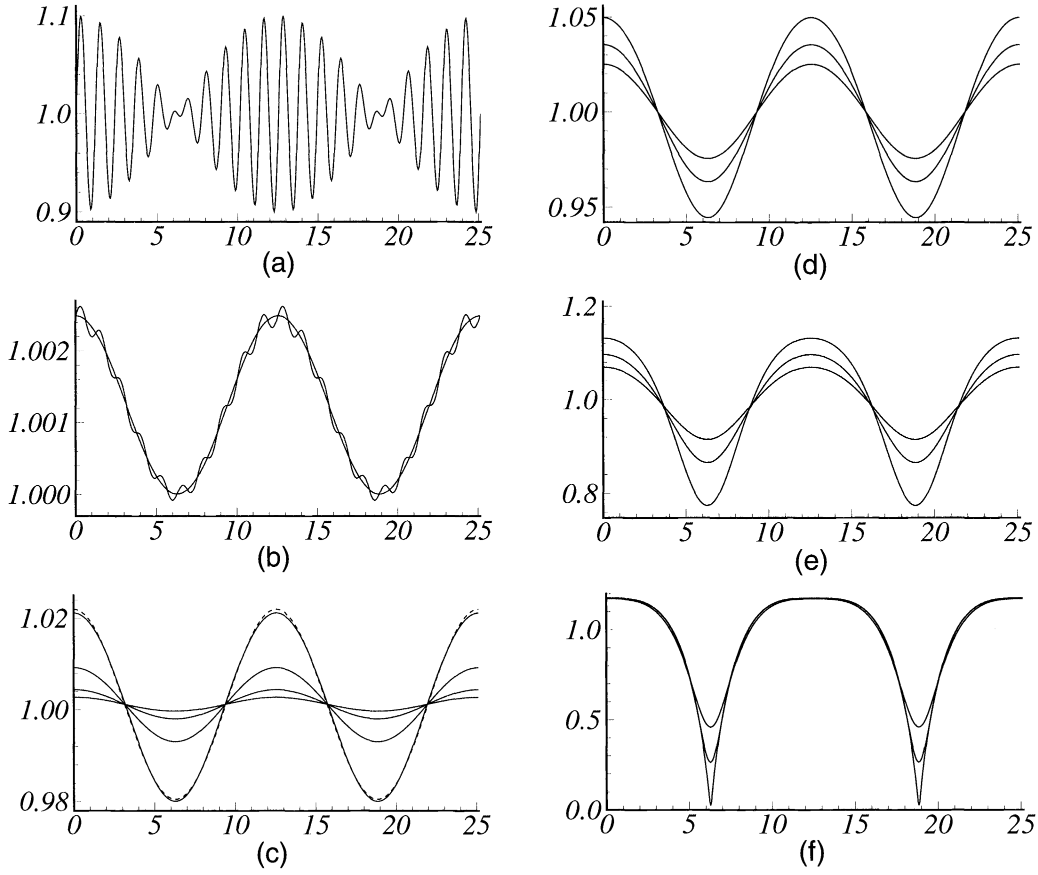

FIG. 1. *The radius r as a function of x at various times t in the first numerical experiment*: (a) $t = 0$; (b) $t = 10^{-2}$ (*wavy line*), $t = 1.63 \times 10^{-2}$; (c) $t = 0.1, 5, 10, 15$ (*the dashed curve gives the result of the second-order perturbation analysis at* $t = 15$); (d) $t = 16, 18, 20$; (e) $t = 22, 24, 26$; (f) $t = 28, 28.25, 28.27234$.

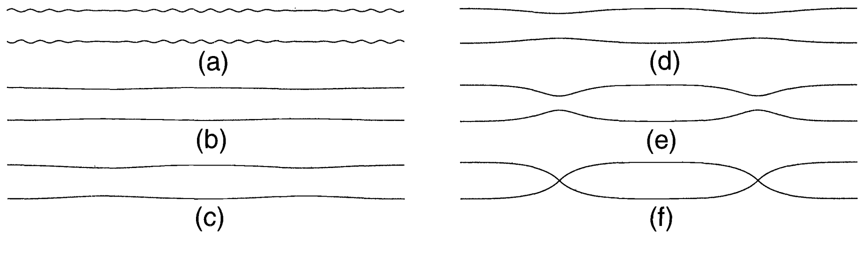

FIG. 2. *Profiles at selected times in the first experiment*: (a) $t = 0$; (b) $t = 20$; (c) $t = 23$; (d) $t = 25.5$; (e) $t = 28$; (f) $t = t^* = 28.27234$.

that employed for the cylindrical-coordinate formulation gives satisfactory results in cases in which, for *all* $t > t^*$, the closed surface remains star shaped with respect to a fixed point. We note that for motion by Laplacian of mean curvature there is no analogue of Huisken's theorem [7] in the theory of motion by mean curvature, asserting that if a closed surface deforming in accord with (1.4) is convex at one time t^0 then it is convex at all subsequent times.

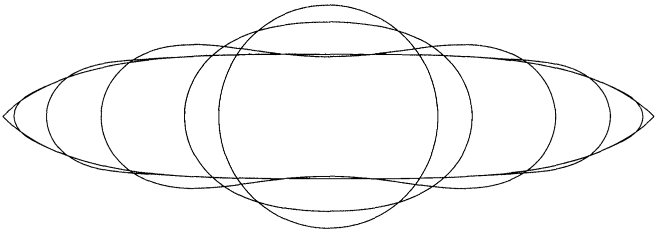

FIG. 3. *Profiles in the first experiment at times* $t = t^* + \hat{t}$ *for* $\hat{t} = 0, 10^{-3}, 10^{-1}, 1, 4, 10$. *Note that at* $\hat{t} = 0, 10^{-3}$, *and* 10^{-1} *the subbody is convex and that this convexity, which is not present at* $\hat{t} = 1$, *returns before* $\hat{t} = 4$.

In the experiment under discussion here, the subbodies are congruent and for all $t > t^*$ are star shaped with respect to the midpoints of successive values of x^*. Calculated profiles of a subbody for several times $t = t^* + \hat{t}$ with $\hat{t} > 0$ are seen in Fig. 3. When $\hat{t} = 10$ each component is a sphere in the sense that $\hat{r}(\varphi, t^* + 10)$ is constant in φ to within six significant figures; of course, the collection of spheres so obtained is the new equilibrium state of the original perturbed cylinder.

The initial data for the second numerical experiment correspond to

$$\begin{aligned} r_0(x) = 1 + 10^{-2}[&\sin(2x) + \sin(13x/6) + \sin(7x/3) \\ &+ \sin(5x/2) + \sin(8x/3) + \sin(17x/6)]. \end{aligned} \tag{5.14}$$

In this case r_0 has minimum period 12π. For the finite element computation, $b - a$ was chosen to be 12π, i.e., one period. As in the previous case, the interval $a \le x \le b$ was discretized into 512 equal segments, and the time steps Δt were chosen to be 10^{-4} on an interval that contained the times of initial decay, 10^{-2} during the early growth phase and much smaller as t approached t^*. Numerical results are shown in Figs. 4 and 5. Here, again, albeit only wave-numbers k_i that exceed 1 are present in the initial perturbation, and hence the linear theory predicts that $g(t)$ should decay to zero exponentially in t. A second-order perturbation analysis yields the conclusion that new wave-numbers given by $|k_i - k_j|$ will appear and grow. In the present case there are five distinct values of $|k_i - k_j|$ obeying (5.10), namely, 1/6, 1/3, 1/2, 2/3, 5/6. Of these, three, 1/2, 2/3, 5/6, have rates of growth, $\alpha(1/2) = 3/16 = 0.1875$, $\alpha(2/3) = 20/9^2 \simeq 0.2469$, $\alpha(5/6) = 275/36^2 \simeq 0.2122$, that are close to maximum growth rate $\alpha(1/\sqrt{2}) = 0.25$. The periods $2\pi|k_i - k_j|^{-1}$ corresponding to these three fast-growing modes are 4π, 3π, $12\pi/5$. The distances between adjacent local minima of $r(x, t^*)$ were found to be 9.35115, 9.42478, and 9.57204. One of these values is equal, up to five decimal places, to $3\pi \simeq 9.42478$, and the other two are much nearer to 3π than to either 4π or $12\pi/5$. As $\alpha(1/2)$ and $\alpha(5/6)$ both are less than $\alpha(2/3)$, it is not surprising that an examination of spatial frequencies at $t = t^*$ confirms that the mode with wave-number 2/3 (period 3π) dominates the growth.

Whereas in the first experiment the body breaks into congruent subbodies, in this experiment the break-up at time t^* yields two distinct equivalence classes $\mathcal{C}_1$ and $\mathcal{C}_2$ of congruent bodies. Figure 5d makes this clear. At $t = t^*$, the bodies in $\mathcal{C}_1$ have length 9.57204, and those in $\mathcal{C}_2$ have length $28.12708 = 2 \times 9.33115 + 9.42478$. We have found that members of $\mathcal{C}_1$ remain star shaped for all $t > t^*$, and the spherical-coordinate formulation can be employed to follow their evolution to a final equilibrium state which is spherical. On the other hand, the bodies in $\mathcal{C}_2$ cease to be star shaped at a finite time, and for them the spherical-coordinate formulation is not applicable without major modification. Here the question arises as to whether subbodies of class $\mathcal{C}_2$ will exhibit further break-up or end up as a single sphere. The search for a general algorithm to study post break-up behavior is a topic of current research.

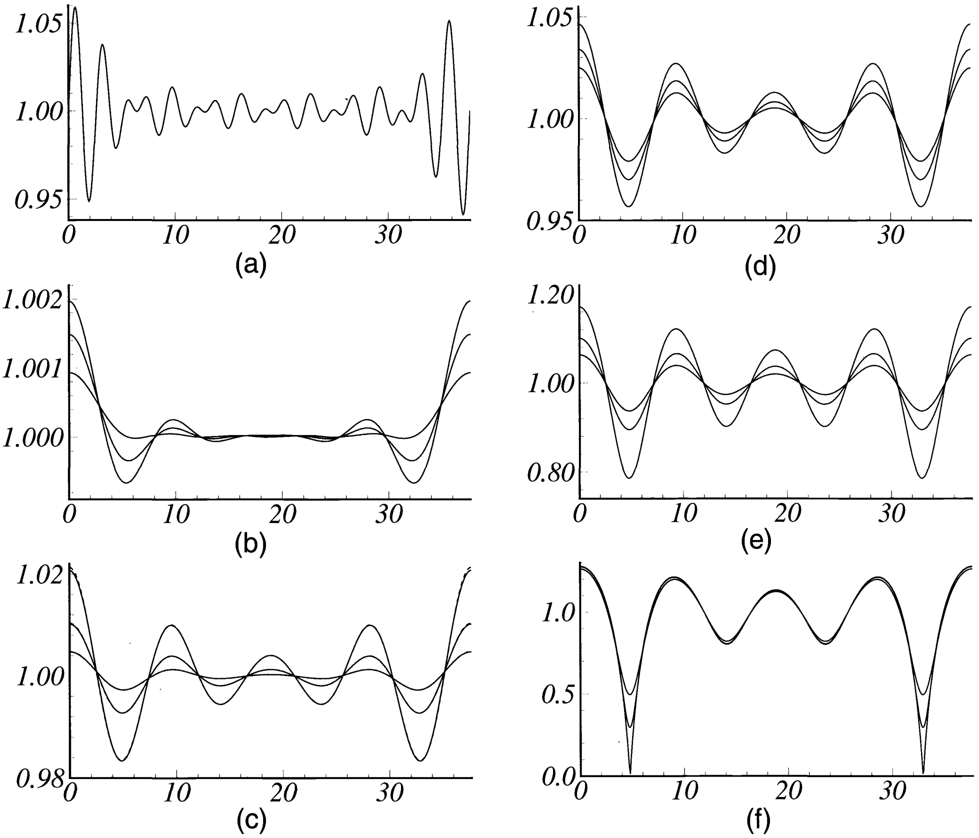

FIG. 4. *The radius r as a function of x in the second numerical experiment*: (a) $t = 0$; (b) $t = 0.7, 4.7, 6.7$; (c) $t = 12, 16, 19$; (d) $t = 20, 22, 24$; (e) $t = 26, 28, 30$; (f) $t = 31.5, 31.7, 31.7357$.

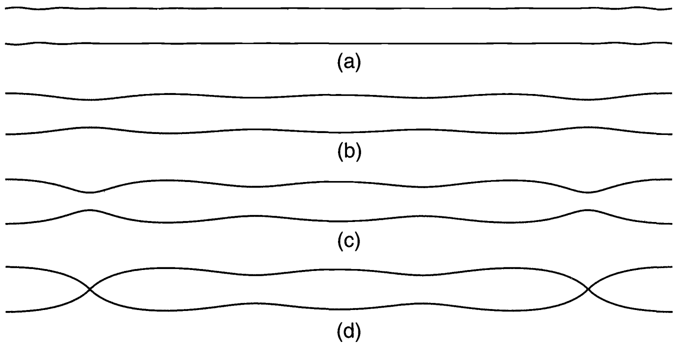

FIG. 5. *Profiles in the second experiment*: (a) $t = 0$; (b) $t = 30$; (c) $t = 31.5$; (d) $t = t^* = 31.7357$.

A FAST MULTIGRID ALGORITHM FOR ISOTROPIC TRANSPORT PROBLEMS II: WITH ABSORPTION*

T. MANTEUFFEL†, S. McCORMICK†, J. MOREL‡, AND G. YANG§

Abstract. A multigrid method for solving the one-dimensional slab-geometry S_N equations with isotropic scattering and absorption is presented. The case with no absorption was treated in part I of this paper [Manteuffel, McCormick, Morel, Oliveira, and Yang, *SIAM J. Sci. Comput.*, 16 (1995), pp. 601–635]. Relaxation is based on a two-cell inversion, which is very efficient because it takes advantage of the structure of the two-cell problem. For interpolation we use kinked linear elements. The kink is based on the amount of absorption present. The restriction operator is full weighting. Numerical results show this algorithm to be faster than diffusion synthetic acceleration (DSA) in all regimes. This scheme is also well suited for massively parallel computer architectures.

1. Introduction.

In this paper we describe a fast method for solving the equations used to model the transport of neutral particles with isotropic scattering in slab geometry. These problems are important in many applications such as nuclear reactor design, radiation therapy in medical science, and radiation effects on global weather, and they are a fundamental part of many algorithms used to model more complicated applications such as coupled photon/electron scattering used to model satellite electronics shielding.

We focus on the solution of the steady-state, monoenergetic, linear Boltzmann equation in slab geometry. The need to solve such equations arises from the time-dependent Boltzmann equations used in the applications mentioned above. The physical domain is assumed to be a semi-infinite slab of width $b - a$ in the x dimension. Although they are three dimensional, we assume that the flux of particles is independent of the y and z coordinates. Let $\psi(x, \mu, e, t)$ represent the flux of particles at a position x, traveling at an angle μ to the x-axis, with energy e, at time t. The Boltzmann equation takes the form

$$\frac{\partial \psi}{\partial t} = -\mu \frac{\partial \psi}{\partial x} - \sigma_t(x, e)\psi + \int\int K(\mu' \to \mu, e' \to e)\psi(x, \mu', e', t)d\mu' de' + q(x, \mu, e, t). \tag{1.1}$$

Here, σ_t is the collision cross section and $\int_{x_0}^{x_1} \sigma_t dx$ represents the expected number of collisions that a particle will experience in the interval (x_0, x_1). In the same manner, the scattering kernel $\int\int K(\mu' \to \mu, e' \to e)$ represents the expected number of particles that will scatter from direction μ' and energy e' to direction μ and energy e. Finally, $q(x, \mu, e, t)$ represents particle sources.

The above equation is usually integrated with implicit time-stepping methods and the energy variable is treated with a piecewise-constant finite element method to yield a coupled system of equations at each time step. Let $\psi^k(x, \mu)$ be the flux of particles with energy e_k. Then

$$\mu \frac{\partial \psi^k}{\partial x} + \sigma_t^k(x)\psi^k = \sum_j \int K_{k,j}(\mu' \to \mu)\psi^j(x, \mu')d\mu' + q^k(x, \mu), \tag{1.2}$$

where the time-step information has been incorporated into σ_t^k and q^k, and $\int K_{k,j}(\mu' \to \mu)$ represents the expected number of collisions that will rescatter a particle from energy e_j into energy e_k.

Since particles generally lose energy, the system of equations is solved by a block Gauss–Seidel-type iteration. Starting with the highest energy level, $\psi^k(x, \mu)$ is updated assuming that $\psi^j(x, \mu)$ for $j \neq k$ are known. This yields the equation

$$\mu \frac{\partial \psi^k}{\partial x} + \sigma_t^k(x)\psi^k = \int K_{k,k}(\mu' \to \mu)\psi^k(x, \mu')d\mu' + \hat{q}^k(x, \mu), \tag{1.3}$$

where now $\hat{q}^K$ contains all the inscatter from other energy levels.

The kernel $K_{k,k}$ is often mildly anisotropic, becoming more isotropic as energy decreases. In this paper we focus on the isotropic form of (1.3) (for strongly anisotropic scattering see [14]):

$$\mu \frac{\partial \psi}{\partial x} + \sigma_t \psi = \frac{\sigma_s}{2} \int_{-1}^{1} \psi(x, \mu')d\mu' + q(x, \mu). \tag{1.4}$$

Here, σ_s is now the scattering cross section and represents the expected number of collisions that result in a rescatter, while $\sigma_a = \sigma_t - \sigma_s$ represents the expected number of collisions that result in an absorption. When $\sigma_t = \sigma_s$, there is no absorption. The equation is well defined if the flux of particles entering the slab is given as boundary conditions

$$\psi(a, \mu) = g_a(\mu), \quad \psi(b, -\mu) = g_b(\mu) \quad \mu\epsilon(0, 1). \tag{1.5}$$

In general, numerical methods that are effective for isotropic equations also work well for mildly anisotropic equations. We believe that this will be especially true for the multigrid algorithm described below because of the special form of relaxation used (see §3).

Problem (1.4) will inherit the discretization scheme from problem (1.1). The standard approach is to expand the angular dependence in terms of the first N Legendre polynomials and to close the system with a Galerkin condition. This is attractive because the Legendre polynomials are the eigenvectors of the scattering operators $K_{k,j}$ in slab geometry. This results in the P_{N-1} discretization. In slab geometry, this is equivalent to collocating at Gauss quadrature points which are known as the discrete ordinates or S_N discretization (cf. [7, 13]).

Spatial discretization must take into account the important optically dense or thick limit in which the problem becomes ill conditioned. Physically, this corresponds to a mean-free path between collisions that is small compared with the width of the slab and materials that allow very little absorption. Mathematically, we have

$$\sigma_t \to \infty, \quad \frac{\sigma_s}{\sigma_t} \to 1. \tag{1.6}$$

Dividing (1.1) by σ_t and taking the limits in (1.4) yields

$$\psi(x, \mu) = \frac{1}{2} \int_{-1}^{1} \psi(x, \mu')d\mu', \tag{1.7}$$

which admits any $\psi(x, \mu)$ that is independent of μ. Thus, in this limit, (1.4) is singularly perturbed with a large near null space. For discrete equations it is the product $\sigma_t h_i$, where h_i is a mesh parameter, that parameterizes each equation. There are two quantities that determine the character of the discrete problem: the overall thickness $\sigma_t(b - a)$ and the thickness of individual cells $\sigma_t h_i$.

Some spatial discretization schemes, for example upwind differences, have discretization error $O(\sigma_t h_i)$. Thus, for $\sigma_t \gg 1$ these schemes require $h_i \to 0$ even for well-behaved solutions. For a discussion of this issue see [4, 10] and Larsen and Morel [6]. One difference scheme that behaves well in the thick limit is the modified linear discontinuous (MLD) scheme [6]. Not only does it give the proper behavior in the thick limit, but it is very accurate. In [10], we developed a very efficient multigrid algorithm to solve the discrete equations produced by the MLD scheme in the absence of absorption ($\sigma_t = \sigma_s$). Our analysis shows that, in this case, a $V(1,1)$ cycle version of our algorithm yields a convergence factor ρ bounded as follows:

(a) for $\max_i(\sigma_t h_i) \ll 1, \quad \rho = O(\max_i(\sigma_t h_i)^2)$,

(b) for $\min_i(\sigma_t h_i) \gg 1, \quad \rho = O(\max_i(\frac{1}{\sigma_t h_i}))$.

Numerical results are even better than these theoretical estimates. Experiments yield the following convergence factor ρ for a $V(1,1)$ cycle:

(a) for $\max_i(\sigma_t h_i) \ll 1, \quad \rho = O(\max_i(\sigma_t h_i)^3)$,

(b) for $\min_i(\sigma_t h_i) \gg 1, \quad \rho = O(\frac{1}{\min_i(\sigma_t h_i)^2})$.

When there is absorption in the transport equations ($\sigma_t > \sigma_s$) and $\sigma_t h \gg 1$, the two-cell μ-line relaxation used in [10] will leave an error that is essentially independent of angle and continuous but no longer linear across two cells (see [10, §3]). The deviation of the errors from linearity depends on the value of $\gamma = \frac{\sigma_s}{\sigma_t}$ and h. Because the errors after relaxation will not be linear across two-cell pairs, the linear interpolation used in our previous multigrid algorithm is unsuitable. In this paper, we will present a new method which uses kinked elements whose shape will be determined by the severity of deviation from linearity of the errors after relaxation. When $\gamma = 1$, the kinked element will be linear.

We remark that for small values of the angular discretization dimension N the discrete form of (1.4) could easily be solved by direct inversion of the resulting banded matrix. However, direct methods require $O(N^2m)$ operations and $O(N^2m)$ storage, where m is the number of spatial cells. Both the method described here and the diffusion synthetic acceleration (DSA) [1, 2, 5] to which we compare our method require only $O(Nm)$ operations and storage. Thus, these methods are viable for problems that require fine angular resolution. Because of the large number of times equations of the form (1.4) must be solved, efficiency is critical. Moreover, both DSA and our method have obvious generalization to higher spatial dimensions.

In §2, we analyze the properties of relaxation when $\gamma \neq 1$. In §3, we introduce the kinked element, relaxation-induced interpolation, and coarse grid operators used to solve the transport problems when $\gamma \neq 1$. The multigrid algorithm is discussed in §4. In §5, we examine the properties of the new interpolation. In §6, computational results are presented. We show that the multigrid algorithm is faster than the DSA algorithm [1, 2, 5] on a representative set of test problems. We include a study of domains with nonhomogeneous material properties. Finally, in §7, we present our conclusions.

2. The discrete model. We start with an S_N approximation in angle. This corresponds to expanding the angle dependence in terms of the first N Legendre polynomials. Closing the equations with a Galerkin formulation yields a system that resembles collocation at the Gauss quadrature points $\mu_j, j = 1, \ldots, N$. Similarly, the integral is replaced with a quadrature formula using the Gauss quadrature weights $\omega_j, j = 1, \ldots, N$. By symmetry, we may denote the positive quadrature points $\mu_j > 0, j = 1, \ldots, n$ with corresponding weights $\omega_j, j > 1, \ldots, n$, and negative quadrature points $-\mu_j < 0, j = 1, \ldots, n$ with corresponding weights $\omega_j, j = 1, \ldots, n$, where $n = N/2$. We use $\psi^+(x_i, \mu_j) = \psi(x_i, \mu_j)$, $\psi^-(x_i, \mu_j) = \psi(x_i, -\mu_j)$ to denote flux variables at spatial point x_i, angular position μ_j at positive and negative directions, respectively.

The spatial difference scheme is the MLD discretization. Consider the grid $a = x_{1/2} < x_{3/2} < \cdots < x_{m+1/2} = b$, where $x_{i\pm 1/2}$ are cell edges and $x_i = (x_{i-1/2} + x_{i+1/2})/2$ is the cell center. Let $\underline{\psi}_i^+ = (\psi^+(x_i, \mu_1), \ldots, \psi^+(x_i, \mu_n))^T$ and $\underline{\psi}_i^- = (\psi^-(x_i, \mu_1), \ldots, \psi^-(x_i, \mu_n))^T$.

In matrix form MLD can be written as (for a complete presentation see [6], [10])

$$B_i(\underline{\psi}^+_{i+\frac{1}{2}} - \underline{\psi}^+_{i-\frac{1}{2}}) + \underline{\psi}^+_i = \gamma R(\underline{\psi}^+_i + \underline{\psi}^-_i) + \underline{q}^+_i, \tag{2.1a}$$

$$2B_i(\underline{\psi}^+_{i+\frac{1}{2}} - \underline{\psi}^+_i) + \underline{\psi}^+_{i+\frac{1}{2}} = \gamma R(\underline{\psi}^+_{i+\frac{1}{2}} + 2\underline{\psi}^-_i - \underline{\psi}^-_{i-\frac{1}{2}}) + \underline{q}^+_{i+\frac{1}{2}} \tag{2.1b}$$

for $i = 1, \ldots, m$ and

$$B_i(\underline{\psi}^-_{i-\frac{1}{2}} - \underline{\psi}^-_{i+\frac{1}{2}}) + \underline{\psi}^-_i = \gamma R(\underline{\psi}^+_i + \underline{\psi}^-_i) + \underline{q}^-_i, \tag{2.1c}$$

$$2B_i(\underline{\psi}^-_{i-\frac{1}{2}} - \underline{\psi}^-_i) + \underline{\psi}^-_{i-\frac{1}{2}} = \gamma R(\underline{\psi}^-_{i-\frac{1}{2}} + 2\underline{\psi}^+_i - \underline{\psi}^+_{i+\frac{1}{2}}) + \underline{q}^-_{i-\frac{1}{2}} \tag{2.1d}$$

for $i = 1, \ldots, m$ with boundary conditions

$$\underline{\psi}^+_{\frac{1}{2}} = \underline{g}^+_a, \quad \underline{\psi}^-_{m+\frac{1}{2}} = \underline{g}^-_b, \tag{2.1e}$$

where B_i and R are the $n \times n$ matrices

$$B_i = \begin{bmatrix} \frac{\mu_1}{\sigma_t h_i} & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \frac{\mu_n}{\sigma_t h_i} \end{bmatrix}, \quad R = \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix} \begin{bmatrix} \omega_1 & \cdots & \omega_n \end{bmatrix} = \underline{1\omega}^T. \tag{2.1f}$$

In block matrix form, (2.1) can be written as

(2.2)
$$\begin{bmatrix} I + 2B_i - \gamma R & -2\gamma R & -2B_i & \gamma R \\ 0 & I - \gamma R & -\gamma R & B_i \\ B_i & -\gamma R & I - \gamma R & 0 \\ \gamma R & -2B_i & -2\gamma R & I + 2B_i - \gamma R \end{bmatrix} \begin{bmatrix} \underline{\psi}^-_{i-\frac{1}{2}} \\ \underline{\psi}^+_i \\ \underline{\psi}^-_i \\ \underline{\psi}^+_{i+\frac{1}{2}} \end{bmatrix} = \begin{bmatrix} \underline{q}^-_{i-\frac{1}{2}} \\ B_i\underline{\psi}^+_{i-\frac{1}{2}} + \underline{q}^+_i \\ B_i\underline{\psi}^-_{i+\frac{1}{2}} + \underline{q}^-_i \\ \underline{q}^+_{i+\frac{1}{2}} \end{bmatrix}.$$

In this paper, we will use an edge–edge notation for the unknown flux variable $\underline{\psi}$. That is, the flux within cell i is linear and is determined by the value at the right and left sides $\underline{\psi}^+_{ir}$ and $\underline{\psi}^+_{il}$. We define the transformation

$$\begin{bmatrix} \underline{\psi}^-_{il} \\ \underline{\psi}^+_{il} \\ \underline{\psi}^-_{ir} \\ \underline{\psi}^+_{ir} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 2 & 0 & -1 \\ -1 & 0 & 2 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \underline{\psi}^-_{i-\frac{1}{2}} \\ \underline{\psi}^+_i \\ \underline{\psi}^-_i \\ \underline{\psi}^+_{i+\frac{1}{2}} \end{bmatrix}. \tag{2.3a}$$

Then the inverse transformation of (2.3a) will be

$$\begin{bmatrix} \underline{\psi}^-_{i-\frac{1}{2}} \\ \underline{\psi}^+_i \\ \underline{\psi}^-_i \\ \underline{\psi}^+_{i+\frac{1}{2}} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \frac{1}{2} & 0 & \frac{1}{2} \\ \frac{1}{2} & 0 & \frac{1}{2} & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \underline{\psi}^-_{il} \\ \underline{\psi}^+_{il} \\ \underline{\psi}^-_{ir} \\ \underline{\psi}^+_{ir} \end{bmatrix}. \tag{2.3b}$$

Figure 2.1 shows the piecewise discontinuous elements we use. At cell i, two variables $\underline{\psi}_{il}$, $\underline{\psi}_{ir}$ are defined.

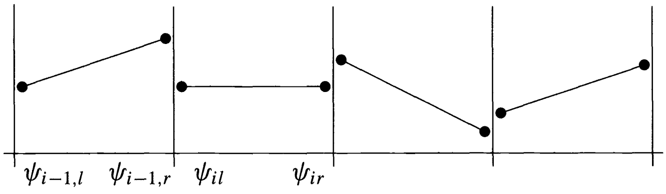

FIG. 2.1. *Piecewise discontinuous elements.*

By substituting (2.3b) into (2.2) and multiplying both sides of (2.2) by the transformation matrix of (2.3a), we then can write (2.2) in block matrix form as

$$(2.4)\qquad \begin{bmatrix} A_1 & -C_1 & & & & \\ -D_2 & A_2 & -C_2 & & & \\ & \ddots & \ddots & \ddots & & \\ & & -D_i & A_i & -C_i & \\ & & & \ddots & \ddots & \ddots \\ & & & & -D_m & A_m \end{bmatrix} \begin{bmatrix} \underline{\Psi}_1 \\ \underline{\Psi}_2 \\ \vdots \\ \underline{\Psi}_i \\ \vdots \\ \underline{\Psi}_m \end{bmatrix} = [\ \underline{Q}\ ],$$

where $\underline{Q}$ is the right-hand side and

$$(2.5a)\qquad A_i = \begin{bmatrix} I + B_i - \gamma R & -\gamma R & -B_i & 0 \\ -\gamma R & I + B_i - \gamma R & 0 & B_i \\ B_i & 0 & I + B_i - \gamma R & -\gamma R \\ 0 & -B_i & -\gamma R & I + B_i - \gamma R \end{bmatrix},$$

$i = 1, \dots, m,$

$$(2.5b)\qquad C_i = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 2B_i & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad i = 1, \dots, m-1,$$

$$(2.5c)\qquad D_i = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2B_i \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad i = 2, \dots, m,$$

$$(2.5d)\qquad \underline{\Psi}_i = (\underline{\psi}_{il}^-, \underline{\psi}_{il}^+, \underline{\psi}_{ir}^-, \underline{\psi}_{ir}^+)^T, \quad i = 1, \dots, m.$$

In the following section, we will examine the two-cell μ-line relaxation and its properties.

3. Relaxation. By two-cell red-black μ-line relaxation, we mean that at cells $2i - 1$ and $2i$, we set $\underline{\psi}^+_{(2i-2)r}$ and $\underline{\psi}^-_{(2i+1)l}$ as boundary values and solve for all other interior values in cells $2i - 1$ and $2i$ simultaneously. This relaxation is carried out in a red-black ordering. Since relaxation uses a red-black ordering, we can look at each two-cell pair individually. For a two-cell pair, for example cells $2i - 1$ and $2i$, the errors after the relaxation will be

$$\begin{bmatrix} \underline{e}^-_{(2i-1)l} \\ \underline{e}^+_{(2i-1)l} \\ \underline{e}^-_{(2i-1)r} \\ \underline{e}^+_{(2i-1)r} \\ \underline{e}^-_{(2i)l} \\ \underline{e}^+_{(2i)l} \\ \underline{e}^-_{(2i)r} \\ \underline{e}^+_{(2i)r} \end{bmatrix} = \begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 2B_{2i-1}\hat{\underline{e}}^+_{(2i-2)r} \\ 0 \\ 0 \\ 0 \\ 0 \\ 2B_{2i}\hat{\underline{e}}^-_{(2i+1)l} \\ 0 \end{bmatrix}, \tag{3.1}$$

where $\hat{\underline{e}}$ on the right-hand side is the error at the outside border of the two-cell pair before relaxation. As we have shown in our previous paper [10], the inversion of the

$$\begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}$$

can be performed in $O(n)$ operations by using the Sherman–Morrison formula. In [10], only the case $\gamma = 1$ was examined. The following result for $\gamma = 1$ was proved.

THEOREM 1. *Suppose* $\gamma = 1$ *in* (3.1) *and* $\min(\sigma_t h_{2i-1}, \sigma_t h_{2i}) \gg 1$*; then, the errors after the two-cell red-black* μ*-line relaxation will be independent of angle, continuous, and piecewise linear up to accuracy of* $O(\max(\frac{1}{\sigma_t h_{2i-1}}, \frac{1}{\sigma_t h_{2i}}))$.

Proof. See Theorem 3 in [10]. □

In this paper, we will discuss the MLD equation with absorption($\gamma \neq 1$). In the thin limit, γ will not affect the behavior of μ-line relaxation. The proof of Theorem 2 that appears in [10] does not depend on γ. We restate Theorem 2 in [10] for $\gamma \leq 1$ in the following way.

THEOREM 2. *Suppose* $\gamma \leq 1$ *and* $\max(\sigma_t h_{2i-1}, \sigma_t h_{2i}) \ll 1$*; then the errors after two-cell red-black* μ*-line relaxation will be continuous and piecewise linear across two cells up to accuracy of* $O(\max(\sigma_t^2 h_{2i-1}^2, \sigma_t^2 h_{2i}^2))$.

Proof. See the proof of Theorem 2 in [10]. □

In the thick limit, the size of $1-\gamma$ relative to $\frac{1}{\sigma_t h_{2i-1}}$ and $\frac{1}{\sigma_t h_{2i}}$ will determine the effectiveness of μ-line relaxation. For simplicity, we restrict our analysis to uniform $\sigma_t h_i$ and let h be the uniform mesh size. The extension to nonuniform meshes is straightforward but messy. We will analyze the μ-line relaxation when

(a) $1 - \gamma \gg \frac{1}{\sigma_t h}$,

(b) $1 - \gamma = \frac{1}{(\sigma_t h)^p}$, $p = 1, 2, 3$.

In the second case, when $\sigma_t h \gg 1$, the larger p is, the closer γ is to 1.

THEOREM 3. *When* $1 - \gamma \gg \frac{1}{\sigma_t h}$ *and* $\sigma_t h \gg 1$*, the two-cell* μ*-line relaxation alone will reduce errors at any two neighboring cells* $2i - 1, 2i$ *by a factor of* $O(\frac{1}{\sigma_t h})$.

Proof. When $\gamma \neq 1$,

$$\begin{bmatrix} I - \gamma R & -\gamma R \\ -\gamma R & I - \gamma R \end{bmatrix}^{-1} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix} + \frac{\gamma}{1-\gamma} \begin{bmatrix} R & R \\ R & R \end{bmatrix}. \tag{3.2}$$

Write

(3.3)

$$\begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}$$

$$= \begin{bmatrix} I-\gamma R & -\gamma R & & & & & & \\ -\gamma R & I-\gamma R & & & & & & \\ & & I-\gamma R & -\gamma R & & & & \\ & & -\gamma R & I-\gamma R & & & & \\ & & & & I-\gamma R & -\gamma R & & \\ & & & & -\gamma R & I-\gamma R & & \\ & & & & & & I-\gamma R & -\gamma R \\ & & & & & & -\gamma R & I-\gamma R \end{bmatrix}$$

$$- \begin{bmatrix} B & 0 & -B & 0 & 0 & 0 & 0 & 0 \\ 0 & B & 0 & B & 0 & 0 & 0 & 0 \\ B & 0 & B & 0 & -2B & 0 & 0 & 0 \\ 0 & -B & 0 & B & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & B & 0 & -B & 0 \\ 0 & 0 & 0 & -2B & 0 & B & 0 & B \\ 0 & 0 & 0 & 0 & B & 0 & B & 0 \\ 0 & 0 & 0 & 0 & 0 & -B & 0 & B \end{bmatrix} = H_0 - H_1,$$

where H_0 is the first matrix and H_1 the second in (3.3). By (3.2), H_0 is not singular, so

$$H_0^{-1}H_1 = \frac{1}{\sigma_t h} \begin{bmatrix} M & 0 & -M & 0 & 0 & 0 & 0 & 0 \\ 0 & M & 0 & M & 0 & 0 & 0 & 0 \\ M & 0 & M & 0 & -2M & 0 & 0 & 0 \\ 0 & -M & 0 & M & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & M & 0 & -M & 0 \\ 0 & 0 & 0 & -2M & 0 & M & 0 & M \\ 0 & 0 & 0 & 0 & M & 0 & M & 0 \\ 0 & 0 & 0 & 0 & 0 & -M & 0 & M \end{bmatrix} \tag{3.4}$$

$$+ \frac{\gamma}{(1-\gamma)\sigma_t h} \begin{bmatrix} RM & RM & -RM & RM & 0 & 0 & 0 & 0 \\ RM & RM & -RM & RM & 0 & 0 & 0 & 0 \\ RM & -RM & RM & RM & -2RM & 0 & 0 & 0 \\ RM & -RM & RM & RM & -2RM & 0 & 0 & 0 \\ 0 & 0 & 0 & -2RM & RM & RM & -RM & RM \\ 0 & 0 & 0 & -2RM & RM & RM & -RM & RM \\ 0 & 0 & 0 & 0 & RM & -RM & RM & RM \\ 0 & 0 & 0 & 0 & RM & -RM & RM & RM \end{bmatrix},$$

where $M = \begin{bmatrix} \mu_1 & & \\ & \ddots & \\ & & \mu_n \end{bmatrix}$.

When $\sigma_t h \gg 1$ and $(1-\gamma) \gg \frac{1}{\sigma_t h}$, then $(1-\gamma)\sigma_t h \gg 1$ and we can find a constant c such that

$$||H_0^{-1}H_1||_2 \le \frac{c}{\sigma_t h}. \tag{3.5}$$

So

$$(I - H_0^{-1}H_1)^{-1} = I + H_0^{-1}H_1 + O\left(\frac{1}{\sigma_t^2 h^2}\right). \tag{3.6}$$

Since H_0^{-1} is constant, we have

(3.7)
$$\begin{aligned}\begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1} &= (I - H_0^{-1}H_1)^{-1}H_0^{-1} = H_0^{-1} + H_0^{-1}H_1H_0^{-1} + O\left(\frac{1}{\sigma_t^2 h^2}\right)\\ &= H_0^{-1} + O\left(\frac{1}{\sigma_t h}\right).\end{aligned}$$

From (3.2) and (3.3) we have

$$||H_0^{-1}||_2 \le 1 + \frac{\gamma}{1-\gamma} = \frac{1}{1-\gamma}. \tag{3.8}$$

Therefore, by (3.8) we can find a constant c such that

$$\left\|\begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1}\right\|_2 \le c. \tag{3.9}$$

Substituting (3.9) into (3.1) and noting that $B_i = \frac{1}{\sigma_t h}M$, we have

$$||(e^-_{(2i-1)l}, e^+_{(2i-1)l}, e^-_{(2i-1)r}, e^+_{(2i-1)r}, e^-_{(2i)l}, e^+_{(2i)l}, e^-_{(2i)r}, e^+_{(2i)r})^T||_2 \le c\frac{1}{\sigma_t h}. \tag{3.10}$$

This completes the proof. □

When $\gamma = 1 - \frac{1}{(\sigma_t h)^p}$ and $\sigma_t h \gg 1, p = 1, 2, 3$, the two-cell μ-line relaxation will produce errors that are continuous and essentially independent of angle but kinked across two cells. To show this behavior, we rewrite (3.1) as

$$
\begin{aligned}
\begin{bmatrix} \underline{e}^-_{(2i-1)l} \\ \underline{e}^+_{(2i-1)l} \\ \underline{e}^-_{(2i-1)r} \\ \underline{e}^+_{(2i-1)r} \\ \underline{e}^-_{(2i)l} \\ \underline{e}^+_{(2i)l} \\ \underline{e}^-_{(2i)r} \\ \underline{e}^+_{(2i)r} \end{bmatrix}
&= \begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1}
\begin{bmatrix} 0 \\ 2B_{2i-1} \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \underline{e}^+_{(2i-2)r} \\
&\quad + \begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1}
\begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 2B_{2i} \\ 0 \end{bmatrix} \underline{e}^-_{(2i+1)l}.
\end{aligned}
\tag{3.11}
$$

When $\sigma_t h \gg 1$ and $\gamma = 1 - \frac{1}{(\sigma_t h)^p}$, we can expand matrix

$$
\begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1}
$$

into Taylor series as $O(\sigma_t h) + O(1) + O(\frac{1}{\sigma_t h})$. We omit the details of the expansion because of the complexity. Let $\delta = \frac{1}{\sigma_t^p h^p}$ and $\epsilon = \frac{1}{\sigma_t h}$. After the expansion, we have

$$
\begin{aligned}
&\begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1}
\begin{bmatrix} 0 \\ 2B_{2i-1} \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \\
&= \frac{\xi}{\sigma_t h} \begin{bmatrix} 2RM \\ 2RM \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}
+ \frac{2\xi^2}{\sigma_t^3 h^3} \begin{bmatrix} 0 \\ 0 \\ \frac{4\xi c_0}{\sigma_t h} R \\ \frac{4\xi c_0}{\sigma_t h} R \\ 2R \\ 2R \\ 0 \\ 0 \end{bmatrix}
P(c_0 M^2 R + c_1 M R) + O\left(\frac{1}{\sigma_t h}\right),
\end{aligned}
\tag{3.12}
$$

where

(3.13)
$$\xi = \frac{1}{1-\zeta}, \quad \zeta = \gamma \sum_{j=1}^{n} \left(\frac{2\omega_j (1+\frac{\mu_j}{\sigma_t h})}{1+2\frac{\mu_j}{\sigma_t h}+2(\frac{\mu_j}{\sigma_t h})^2} \right), \quad c_0 = \sum_{j=1}^{n} \omega_j \mu_j, \quad c_1 = \sum_{j=1}^{n} \omega_j \mu_j^2 = \frac{1}{6}$$

and

(3.14)
$$P = \left(1 - \frac{2\epsilon}{\delta + 4c_0\epsilon} MR\right)\left(1 + \frac{2\epsilon}{\delta + 2c_1\epsilon^2} MR\right)\left(1 - \frac{2\epsilon^2(\delta + 2\epsilon c_0)}{8c_0c_1\epsilon^3 + 2c_0\delta\epsilon + \delta^2} M^2 R\right).$$

Here, ξ is not expanded yet. Its expansion will depend on the power p in $\gamma = 1 - \frac{1}{(\sigma_t h)^p}$. We will discuss the three cases $p = 1, 2, 3$ separately.

Case (1) $p = 1$.

When $\sigma_t h \gg 1$, ζ in (3.13) can be expanded as

$$\zeta = \gamma \sum_{j=1}^{n} \left(\frac{2\omega_j (1+\frac{\mu_j}{\sigma_t h})}{1+2\frac{\mu_j}{\sigma_t h}+2(\frac{\mu_j}{\sigma_t h})^2} \right) \tag{3.15}$$

$$= \gamma \sum_{j=1}^{n} 2\omega_j \left(1 + \frac{\mu_j}{\sigma_t h}\right)\left(1 - 2\frac{\mu_j}{\sigma_t h} + O\left(\frac{1}{\sigma_t^2 h^2}\right)\right) = \gamma \left(1 - 2\frac{c_0}{\sigma_t h}\right) + O\left(\frac{1}{\sigma^2 h^2}\right).$$

So by (3.15), ξ in (3.13) can be expanded as

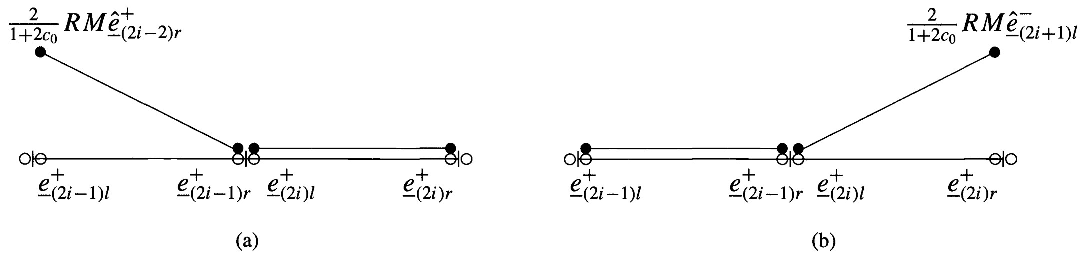
$$\xi = \frac{1}{1-\zeta} = \frac{1}{1-\gamma+\frac{2c_0\gamma}{\sigma_t h}+O(\frac{1}{\sigma_t^2 h^2})} = \frac{\sigma_t h}{1+2c_0} + O\left(\frac{1}{\sigma_t^2 h^2}\right). \tag{3.16}$$

When $p = 1$, P of (3.14) can be expressed as

$$P = (1 + MR)\left(1 - \frac{2}{1+4c_0} MR\right) + O\left(\frac{1}{\sigma_t h}\right). \tag{3.17}$$

By (3.16) and (3.17), the norm of the second term in (3.12) is $O(\frac{1}{\sigma_t h})$. So

$$\begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 2B_{2i-1} \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} = \frac{1}{1+2c_0} \begin{bmatrix} 2RM \\ 2RM \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} + O\left(\frac{1}{\sigma_t h}\right). \tag{3.18}$$



$\frac{2}{1+2c_0}RM\hat{\underline{e}}^{+}_{(2i-2)r}$
$\underline{e}^{+}_{(2i-1)l}$
$\underline{e}^{+}_{(2i-1)r}$
$\underline{e}^{+}_{(2i)l}$
$\underline{e}^{+}_{(2i)r}$
(a)
$\frac{2}{1+2c_0}RM\hat{\underline{e}}^{-}_{(2i+1)l}$
$\underline{e}^{+}_{(2i-1)l}$
$\underline{e}^{+}_{(2i-1)r}$
$\underline{e}^{+}_{(2i)l}$
$\underline{e}^{+}_{(2i)r}$
(b)

FIG. 3.1.

Similarly, we have

$$(3.19)\qquad \begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 2B_{2i} \\ 0 \end{bmatrix} = \frac{1}{1+2c_0} \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 2RM \\ 2RM \end{bmatrix} + O\left(\frac{1}{\sigma_t h}\right).$$

By (3.18) and (3.19), the errors after relaxation will be essentially independent of angle but not piecewise linear. To graphically show this, we plot the errors after the μ-line relaxation in Figure 3.1. Figure 3.1a depicts the first term in (3.11) for positive angles. Figure 3.1b depicts the second term in (3.11) for positive angles. The real errors after relaxation should be a linear combination of Figure 3.1a and b. The error distribution for negative angles will have the same pattern. From Figure 3.1 we see that, after relaxation, $\underline{e}^{+}_{(2i-1)r}$ equals $\underline{e}^{+}_{(2i)l}$ and $\underline{e}^{-}_{(2i-1)r}$ equals $\underline{e}^{-}_{(2i)l}$ up to accuracy of $O(\frac{1}{\sigma_t h})$. We can see that the error after relaxation is kinked and that linear interpolation will not be suitable for this case. However, regardless of the size of $\underline{e}^{+}_{(2i-2)r}$ and $\underline{e}^{+}_{(2i+1)l}$, the errors at the boundary between cell $2i-1$ and cell $2i$ are $O(\frac{1}{\sigma_t h})$.

Case (2) $p = 2$.

When $p = 2$ and $\sigma_t h \gg 1$, with ζ as in (3.15), ξ can be expanded as

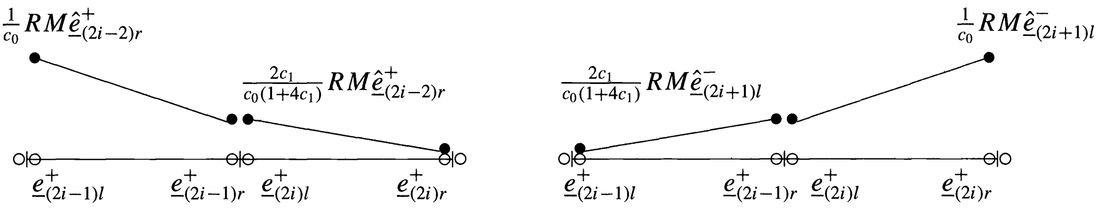
$$(3.20)\qquad \xi = \frac{1}{1-\zeta} = \frac{1}{1-\gamma+\frac{2c_0\gamma}{\sigma_t h}+O(\frac{1}{\sigma_t^2 h^2})} = \frac{\sigma_t h}{2c_0} + O\left(\frac{1}{\sigma_t h}\right)$$

and P in (3.14) can be expanded as

$$(3.21)\qquad P = \frac{\sigma_t h}{1+4c_1}MR + O(1).$$

Substituting (3.20) and (3.21) into (3.12), we have

$$(3.22)\qquad \begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 2B_{2i-1} \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} \frac{1}{c_0}RM \\ \frac{1}{c_0}RM \\ \frac{2c_1}{c_0(1+4c_1)}RM \\ \frac{2c_1}{c_0(1+4c_1)}RM \\ \frac{2c_1}{c_0(1+4c_1)}RM \\ \frac{2c_1}{c_0(1+4c_1)}RM \\ 0 \\ 0 \end{bmatrix} + O\left(\frac{1}{\sigma_t h}\right)$$



$\frac{1}{c_0}RM\hat{\underline{e}}^+_{(2i-2)r}$
$\frac{2c_1}{c_0(1+4c_1)}RM\hat{\underline{e}}^+_{(2i-2)r}$
$\underline{e}^+_{(2i-1)l}$
$\underline{e}^+_{(2i-1)r}$
$\underline{e}^+_{(2i)l}$
$\underline{e}^+_{(2i)r}$
$\frac{1}{c_0}RM\hat{\underline{e}}^-_{(2i+1)l}$
$\frac{2c_1}{c_0(1+4c_1)}RM\hat{\underline{e}}^-_{(2i+1)l}$
$\underline{e}^+_{(2i-1)l}$
$\underline{e}^+_{(2i-1)r}$
$\underline{e}^+_{(2i)l}$
$\underline{e}^+_{(2i)r}$

(a) (b)

FIG. 3.2.

and

$$(3.23)\qquad \begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 2B_{2i+1} \\ 0 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \frac{2c_1}{c_0(1+4c_1)}RM \\ \frac{2c_1}{c_0(1+4c_1)}RM \\ \frac{2c_1}{c_0(1+4c_1)}RM \\ \frac{2c_1}{c_0(1+4c_1)}RM \\ \frac{1}{c_0}RM \\ \frac{1}{c_0}RM \end{bmatrix} + O\left(\frac{1}{\sigma_t h}\right).$$

We plot (3.22) in Figure 3.2. The errors for negative angles are similar. We can see once again the errors after relaxation are essentially independent of angle and continuous across cells but kinked linear. In fact, they will be sublinear; that is, the error at the interface between cell $2i-1$ and cell $2i$ is less than the average of the errors at the edges of the two-cell pair.

Case (3) $p = 3$.

When $p = 3$ and $\sigma_t h \gg 1$, with ζ in (3.15), ξ can be expanded as

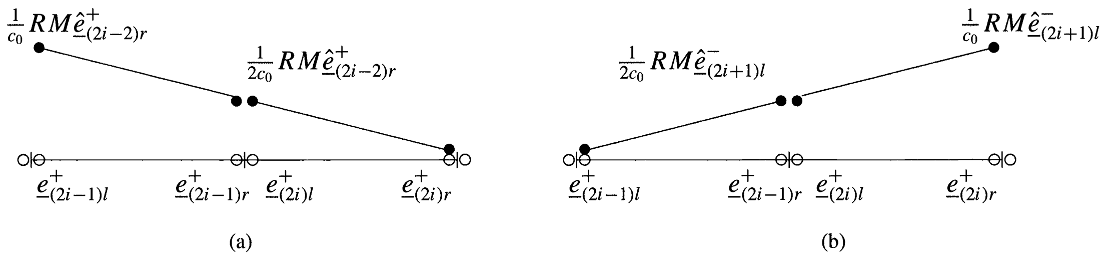
$$(3.24)\qquad \xi = \frac{1}{1-\zeta} = \frac{1}{1-\gamma+\frac{2c_0\gamma}{\sigma_t h}+O(\frac{1}{\sigma_t^2h^2})} = \frac{\sigma_t h}{2c_0} + O\left(\frac{1}{\sigma_t^2 h^2}\right)$$

and P in (3.14) be expanded as

$$(3.25)\qquad P = \frac{\sigma_t h}{4c_1}MR + O(1).$$

Substitute (3.24) and (3.25) into (3.12), we have

$$(3.26)\qquad \begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 2B_{2i-1} \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} \frac{1}{c_0}RM \\ \frac{1}{c_0}RM \\ \frac{1}{2c_0}RM \\ \frac{1}{2c_0}RM \\ \frac{1}{2c_0}RM \\ \frac{1}{2c_0}RM \\ 0 \\ 0 \end{bmatrix} + O\left(\frac{1}{\sigma_t h}\right)$$



$\frac{1}{c_0}RM\hat{\underline{e}}^+_{(2i-2)r}$
$\frac{1}{2c_0}RM\hat{\underline{e}}^+_{(2i-2)r}$
$\underline{e}^+_{(2i-1)l}$
$\underline{e}^+_{(2i-1)r}$
$\underline{e}^+_{(2i)l}$
$\underline{e}^+_{(2i)r}$
(a)
$\frac{1}{c_0}RM\hat{\underline{e}}^-_{(2i+1)l}$
$\frac{1}{2c_0}RM\hat{\underline{e}}^-_{(2i+1)l}$
$\underline{e}^+_{(2i-1)l}$
$\underline{e}^+_{(2i-1)r}$
$\underline{e}^+_{(2i)l}$
$\underline{e}^+_{(2i)r}$
(b)

FIG. 3.3.

and

$$
\begin{bmatrix} A_{2i-1} & -C_{2i-1} \\ -D_{2i} & A_{2i} \end{bmatrix}^{-1}
\begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 2B_{2i+1} \\ 0 \end{bmatrix}
=
\begin{bmatrix} 0 \\ 0 \\ \frac{1}{2c_0}RM \\ \frac{1}{2c_0}RM \\ \frac{1}{2c_0}RM \\ \frac{1}{2c_0}RM \\ \frac{1}{c_0}RM \\ \frac{1}{c_0}RM \end{bmatrix}
+ O\left(\frac{1}{\sigma_t h}\right). \tag{3.27}
$$

We plot (3.26) in Figure 3.3. Again (3.27) is similar. In this case the error after relaxation is independent of angle, linear and continuous across a two-cell pair up to accuracy of $O(\frac{1}{\sigma_t h})$.

In any case, after μ-line relaxation the error across a two-cell pair will be independent of angle, continuous, and sublinear up to order $O(\frac{1}{\sigma_t h})$. The error at the boundary between cell $2i-1$ and cell $2i$ can be expressed as

$$
\underline{e}^{\pm}_{(2i-1)r} = \underline{e}^{\pm}_{(2i)l} + O\left(\frac{1}{\sigma_t h}\right) = \left(\frac{1}{2} - d\right)(\underline{e}^{\pm}_{(2i-1)l} + \underline{e}^{\pm}_{(2i)r}) + O\left(\frac{1}{\sigma_t h}\right), \tag{3.28}
$$

where $0 \leq d \leq \frac{1}{2}$ and ± denotes variables in either positive or negative directions. We summarize the above discussion in the following theorem.

THEOREM 4. *Suppose* $\gamma = 1 - \frac{1}{(\sigma_t h)^p}$ *and* $\sigma_t h \geq 1$. *After two-cell* μ*-line relaxation, the error across a two-cell pair will be independent of angle and continuous up to* $O(\frac{1}{\sigma_t h})$. *Further, the error at the boundary between the two-cell pair can be written as in* (3.28), *where*

(i) $d = \frac{1}{2}$ *for* $p \leq 1$,

(ii) $0 < d < \frac{1}{2}$ *for* $p = 2$,

(iii) $d = 0$ *for* $p \geq 3$.

Proof. The proof follows from the discussion above. □

When $p = 3$, the μ-line relaxation will produce errors of which the dominant terms are piecewise linear. But, in a multigrid algorithm, the mesh size of the coarse grid is twice as large as the fine grid. Since γ is the same on all grids, although $p = 3$ on the finest grid, as the grids go from finest to coarsest level, the relative size of $1 - \gamma$ to $\frac{1}{\sigma_t h}$ will change. To show this, assume that the finest grid is uniform and the number of cells is a power of 2. Now, let $\sigma_t h = 100$ and $\gamma = 1 - \frac{1}{(\sigma_t h)^3} = .999999$; that is, let $p_h = 3$. On the finest level interpolation should be linear. However, four levels down we have $\sigma_t 16h = 1600$ and $\gamma = 0.999999 = 1 - \frac{1}{(\sigma_t 16h)^{1.873}}$; that is, $p_{16h} = 1.873$. From the discussion above we see that linear interpolation is not adequate on this level, even though linear interpolation is sufficient on the finest grid.

We use the parameter d to indicate the severity of deviation of errors from linearity after relaxation. If $\sigma_t h \gg 1$ on the finest level and the relation between γ and $\sigma_t h$ yields $p \leq 1$, then we can set $d = \frac{1}{2}$. If $p \geq 3$ we can set $d = 0$. If $p = 2$ we can use $d = \frac{1}{2(1+4c_1)}$. Unfortunately, the relation between γ and $\sigma_t h$ does not always yield an integer. However, we can use the relaxation to determine the proper interpolation. Consider equation (3.11). Set $\underline{e}^+_{(2i-2)r} = \underline{1}$ and $\underline{e}^+_{(2i+1)l} = \underline{0}$ and use the two-cell inversion to compute the result. Then we may define

$$d_l^{\pm} = \frac{1}{2} \frac{\underline{1}^T(\underline{e}^{\pm}_{(2i-1)l} + \underline{e}^{\pm}_{(2i)r} - (\underline{e}^{\pm}_{(2i-1)r} + \underline{e}^{\pm}_{(2i)l}))}{\underline{1}^T(\underline{e}^{\pm}_{(2i-1)l} + \underline{e}^{\pm}_{(2i)r})}. \tag{3.29}$$

Parameters $d_r^{\pm}$ could be found in a similar manner by setting $\underline{e}^+_{(2i-2)r} = \underline{0}$ and $\underline{e}^+_{(2i+1)l} = \underline{1}$ in (3.11). Of course, for the uniform grid case $d_l^{\pm} = d_r^{\pm}$. Moreover, $d_r^+ = d_r^- + O(\frac{1}{\sigma_t h})$. In practice, we use an average value $d = (d_r^+ + d_r^-)/2$.

Now, suppose we know $\underline{e}^+_{(2i-1)l}$, $\underline{e}^+_{(2i)r}$ and d; then we can approximate $\underline{e}^+_{(2i-1)r}$ and $\underline{e}^+_{(2i)l}$ by interpolation:

$$\begin{bmatrix} \underline{e}^+_{(2i-1)l} \\ \underline{e}^+_{(2i-1)r} \\ \underline{e}^+_{(2i)l} \\ \underline{e}^+_{(2i)r} \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \frac{1}{2} - d & \frac{1}{2} - d \\ \frac{1}{2} - d & \frac{1}{2} - d \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \underline{e}^+_{(2i-1)l} \\ \underline{e}^+_{(2i)r} \end{bmatrix}. \tag{3.30}$$

The same interpolation can be used for negative angles. If $\underline{e}^-_{(2i-1)l}$, $\underline{e}^-_{(2i)r}$ and d are known, we have

$$\begin{bmatrix} \underline{e}^-_{(2i-1)l} \\ \underline{e}^-_{(2i-1)r} \\ \underline{e}^-_{(2i)l} \\ \underline{e}^-_{(2i)r} \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \frac{1}{2} - d & \frac{1}{2} - d \\ \frac{1}{2} - d & \frac{1}{2} - d \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \underline{e}^-_{(2i-1)l} \\ \underline{e}^-_{(2i)r} \end{bmatrix}. \tag{3.31}$$

For every two-cell pair, the problem is reduced to finding d, $\underline{e}^+_{(2i-1)l}$, $\underline{e}^+_{(2i)r}$, $\underline{e}^-_{(2i-1)l}$, and $\underline{e}^-_{(2i)r}$. If interpolation is relatively accurate, then we can use a coarser grid to approximate $\underline{e}^+_{(2i-1)l}$, $\underline{e}^+_{(2i)r}$, $\underline{e}^-_{(2i-1)l}$, and $\underline{e}^-_{(2i)r}$ on the fine grid. In a multigrid algorithm, a coarse grid solution can be approximated by an even coarser grid, provided a good interpolation can be found. This process can be accomplished recursively down to the coarsest grid. On the coarsest grid, there will be only a few grid points and the solution on the coarsest grid usually can be solved explicitly. For our case, a two-cell μ-line relaxation will exactly solve the coarsest grid, since it has only two cells. Thus, finding a good interpolation is vital to an efficient multigrid scheme.

We define the restriction operator I_h^{2h} by

$$I_h^{2h} = \begin{bmatrix} S_1 & S_2 & & \\ & & \ddots & \\ & & & S_1 \quad S_2 \end{bmatrix} \otimes I, \tag{3.32}$$

where I is the $N \times N$ identity and

$$S_1 = \begin{bmatrix} \frac{1}{2} & 0 & \frac{1}{4} & 0 \\ 0 & \frac{1}{2} & 0 & \frac{1}{4} \\ 0 & 0 & \frac{1}{4} & 0 \\ 0 & 0 & 0 & \frac{1}{4} \end{bmatrix}, \quad S_2 = \begin{bmatrix} \frac{1}{4} & 0 & 0 & 0 \\ 0 & \frac{1}{4} & 0 & 0 \\ \frac{1}{4} & 0 & \frac{1}{2} & 0 \\ 0 & \frac{1}{4} & 0 & \frac{1}{2} \end{bmatrix}. \tag{3.33}$$

Note that the restriction operator represents full weighting. We also define the interpolation I_{2h}^h as

$$I_{2h}^h = \begin{bmatrix} T_1 & & \\ T_2 & & \\ & \ddots & \\ & & T_1 \\ & & T_2 \end{bmatrix} \otimes I, \tag{3.34}$$

where I is the $N \times N$ identity and
(3.35)

$$T_1 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ \frac{1}{2}-d & 0 & \frac{1}{2}-d & 0 \\ 0 & \frac{1}{2}-d & 0 & \frac{1}{2}-d \end{bmatrix}, \quad T_2 = \begin{bmatrix} \frac{1}{2}-d & 0 & \frac{1}{2}-d & 0 \\ 0 & \frac{1}{2}-d & 0 & \frac{1}{2}-d \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

When $d = 0$, the interpolation operator I_{2h}^h is the transpose of the restriction operator scaled by a factor of $\frac{1}{2}$.

Generalization to a nonuniform grid is straightforward. Suppose a two-cell pair has cell widths $h_{(2i-1)}$ and $h_{(2i)}$. A two-cell inversion in (3.11) with $\underline{e}^+_{(2i-2)r} = \underline{1}$ and $\underline{e}^+_{(2i+1)l} = \underline{0}$ yields the deviation from linearity, which is then built into the interpolation formulas. One could carry a different interpolation for r and l as well as $+$ and $-$ if not in the asymptotic regime. With a uniform grid, the computation need only be done once per grid level, while for the nonuniform grid it must be done for each two-cell pair. However, all two-cell pairs can be calculated in parallel. The restriction operators correspond to full weighting, that is, the transpose of linear interpolation is weighted so that each row sums to 1.

We remark that the two-cell μ-line relaxation can be adapted to the context of mildly anisotropic scattering. For example, if the scattering operator involves P_3 scattering, then it has only four nonzero eigenvalues. This will result in a two-cell problem involving an easily solved linear system plus a rank 16 matrix. The two-cell inversion will require the solution of two systems involving a 16×16 matrix. However, the matrix will be the same throughout a particular material and could be factored before the start of the computation. The total computation would be $O(N)$.

In the next section, we will discuss the multigrid algorithm using the kinked interpolation operator I_{2h}^h and restriction operator I_h^{2h}.

4. Multigrid algorithm.

In this section, we derive the coarse grid operator and show that, although the coarse grid operator no longer represents MLD on the coarse grid, it has the same structure as the fine grid operator, and two-cell μ-line relaxation can be accomplished with the same formula and cost.

From (2.4), we define the fine grid operator L^h as

$$L^h = \begin{bmatrix} A^h & -C^h & & \\ -D^h & A^h & \ddots & \\ & \ddots & \ddots & -C^h \\ & & -D^h & A^h \end{bmatrix}, \tag{4.1}$$

where A^h, C^h, and B^h are defined by (2.5) for uniform grid h. With restriction operator I_h^{2h} and interpolation operator I_{2h}^h defined by (3.32) and (3.35), the coarse grid operator L^{2h} can be obtained by

$$L^{2h} = I_{2h}^h L^h I_h^{2h} = \begin{bmatrix} A^{2h} & -C^{2h} & & \\ -D^{2h} & A^{2h} & \ddots & \\ & \ddots & \ddots & -C^{2h} \\ & & -D^{2h} & A^{2h} \end{bmatrix}, \tag{4.2}$$

where

$$A^{2h} = \begin{bmatrix} S_1 & S_2 \end{bmatrix} \begin{bmatrix} A^h & -C^h \\ -D^h & A^h \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix}, \tag{4.3a}$$

$$C^{2h} = \begin{bmatrix} S_1 & S_2 \end{bmatrix} \begin{bmatrix} 0 & 0 \\ C^h & 0 \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix}, \tag{4.3b}$$

$$D^{2h} = \begin{bmatrix} S_1 & S_2 \end{bmatrix} \begin{bmatrix} 0 & D^h \\ 0 & 0 \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix}. \tag{4.3c}$$

It is easy to verify that (see (2.1f), (2.5b), and (3.4))

$$C^{2h} = \frac{1}{\sigma_t h} \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ M & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \tag{4.4a}$$

$$D^{2h} = \frac{1}{\sigma_t h} \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & M \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}. \tag{4.4b}$$

To derive A^{2h}, we write A^h as

$$A^h = \begin{bmatrix} F^h & 0 & G^h & 0 \\ 0 & K^h & 0 & Z^h \\ Z^h & 0 & K^h & 0 \\ 0 & G^h & 0 & F^h \end{bmatrix} - \begin{bmatrix} a^hR & a^hR & b^hR & b^hR \\ a^hR & a^hR & b^hR & b^hR \\ b^hR & b^hR & a^hR & a^hR \\ b^hR & b^hR & a^hR & a^hR \end{bmatrix}, \tag{4.5}$$

where F^h, G^h, K^h, and Z^h are diagonal matrices and a^h and b^h are scalars. We use this notation to explain that the coarse grid operator will follow the same pattern as the fine grid operator; that is, A^h and consecutive two-cell coarse grid operators A^{2h}, A^{4h} ... are all composed of a matrix whose components are diagonal matrices plus a rank two matrix. For the fine grid h, $F^h = I + B$, $G^h = -B$, $K^h = I + B$, $Z^h = B$, $a^h = 1$, and $b^h = 0$. After multiplication, (4.3a) can be written as

$$A^{2h} = \begin{bmatrix} F^{2h} & 0 & G^{2h} & 0 \\ 0 & K^{2h} & 0 & Z^{2h} \\ Z^{2h} & 0 & K^{2h} & 0 \\ 0 & G^{2h} & 0 & F^{2h} \end{bmatrix} - \begin{bmatrix} a^{2h}R & a^{2h}R & b^{2h}R & b^{2h}R \\ a^{2h}R & a^{2h}R & b^{2h}R & b^{2h}R \\ b^{2h}R & b^{2h}R & a^{2h}R & a^{2h}R \\ b^{2h}R & b^{2h}R & a^{2h}R & a^{2h}R \end{bmatrix}, \tag{4.6}$$

where

$$F^{2h} = \frac{1}{4}[(2.5 - d)F^h + (1 - 2d)G^h + (0.5 - d)K^h + Z^h - (1 - 2d)B], \tag{4.7a}$$

$$G^{2h} = \frac{1}{4}[(0.5 - d)F^h + (2 - 2d)G^h + (0.5 - d)K^h - (1 - 2d)B], \tag{4.7b}$$

$$K^{2h} = \frac{1}{4}[(0.5 - d)F^h + G^h + (2.5 - d)K^h + (1 - 2d)Z^h - (1 - 2d)B], \tag{4.7c}$$

$$Z^{2h} = \frac{1}{4}[(0.5 - d)F^h + (0.5 - d)K^h + (2 - 2d)Z^h - (1 - 2d)B], \tag{4.7d}$$

$$a^{2h} = 0.75a^h - \frac{d}{2}a^h + 0.5b^h - \frac{d}{2}b^h, \tag{4.7e}$$

$$b^{2h} = 0.25a^h - \frac{d}{2}a^h + 0.5b^h - \frac{d}{2}b^h. \tag{4.7f}$$

Since F^h, G^h, K^h, Z^h, and B are diagonal matrices, then F^{2h}, G^{2h}, K^{2h}, Z^{2h} are also diagonal matrices. Structurally, A^h and A^{2h} are the same. For two-cell μ-line relaxation on grid $2h$, we can still easily invert

$$\begin{bmatrix} A^{2h}_{2i-1} & -C^{2h}_{2i-1} \\ -D^{2h}_{2i} & A^{2h}_{2i} \end{bmatrix}$$

with $O(n)$ operations by taking advantage of the fact that the matrix to be inverted consists of an easily invertible matrix with diagonal components and a rank four matrix. The coarse grid operator on grid $4h$ also will have the same structure as on grids h and $2h$.

The generalization to nonuniform grids is again straightforward. Each two-cell pair will yield a different A^{2h}, but it will again have the form as in (4.6) and two-cell inversion on each coarse grid will be amenable to fast inversion.

In the next section, we will display properties of the kinked interpolation operator.

5. Properties of kinked interpolation. In this section, we will display the properties of the kinked interpolation operator by solving (2.5) with boundary conditions

$$\underline{\psi}^+_{0r} = \underline{1}, \quad \underline{\psi}^-_{(m+1)l} = \underline{0} \tag{5.1}$$

on a slab of $x\epsilon(-1, 1)$. Suppose h is the mesh size of the finest grid and H is the mesh size of the coarsest grid, which has only two cells. We choose $\sigma_t \gg 1$ and

$$\gamma = 1 - \frac{1}{\sigma_t^q} \tag{5.2}$$

TABLE 5.1
Value of p on various grid levels.

m	128	64	32	16	8	4	2
$q = 1$	10.32	4.04	2.51	1.82	1.43	1.17	1
$q = 2$	20.64	8.08	5.02	3.64	2.86	2.34	2

for $q = 1, 2, 3$. The case $q = 1$ represents substantial absorption. The case $q = 2$ is the case of most interest to the transport community and yields the well-known thick diffusion limit. The case $q = 3$ also yields the thick diffusion limit but with little absorption.

Given σ_t and γ and grid size h, the value p that satisfies

$$\gamma = 1 - \frac{1}{(\sigma_t h)^p} \tag{5.3}$$

describes the behavior of the error after relaxation as in Theorem 4. This analysis assumes $\sigma_t h \gg 1$. Equating (5.2) and (5.3) yields

$$p = q\frac{\log(\sigma_t)}{\log(\sigma_t h)}. \tag{5.4}$$

In our analysis, $h < 1$, which implies $p \geq q$ on all grids with $p = q$ on the coarsest grid where $H = 1$. This shows that if $q = 3$, the error after relaxation will be linear on all grids. It is only for $q < 3$ that kinked elements are necessary. To see this, let $\sigma_t = 100$. Table 5.1 shows the values of p for $q = 1$ and $q = 2$ on grids with m varying from 128 to 2.

For each set of σ_t, γ, we can find parameter d defined in the previous section on each level (from finest grid to coarsest grid). With d on every grid obtained, we have kinked interpolation on each grid. We define the accumulated interpolation as

$$I_H^h = I_{2h}^h I_{4h}^{2h} \cdots\cdots\cdots I_H^{H/2}. \tag{5.5}$$

With accumulated interpolation so defined, we then solve a homogeneous S_8 transport equation with unit isotropic boundary condition on the left and zero on the right on grids with 8 cells and 128 cells, respectively. We choose $\sigma_t = 100$ and $\gamma = 1 - \frac{1}{\sigma_t^p}$, $p = 1, 2, 3$. We choose an angle line $\mu = 0.525$ for the comparison of the interpolated approximation and the exact discretized solution. With the calculated values $\underline{\psi}_{1l}^+$ and $\underline{\psi}_{mr}^+$, we use the accumulated kinked interpolation operator I_H^h from the coarsest grid to the finest grid to obtain all interior values on the finest grid and compare the interpolated approximation with the calculated solution. Figure 5.1 depicts the case in which there is substantial absorption ($p = 1$). In this case, the relaxation itself is very efficient.

Figure 5.2 shows the case that is of most interest in the transport community ($p = 2$). Figure 5.3 shows the case in which there is not much absorption ($p = 3$). Notice how well interpolation approximates the exact MLD on the finest grid. From Figure 5.3 we can see that when the power p increases, the interpolation is more accurate since the kinked elements are less kinked. We can see from these plots that the relaxation-induced interpolation we have designed is accurate and suitable for the multigrid algorithm.

In the next section, we will present computational results of the multigrid algorithm using kinked interpolation.

FIG. 5.1.

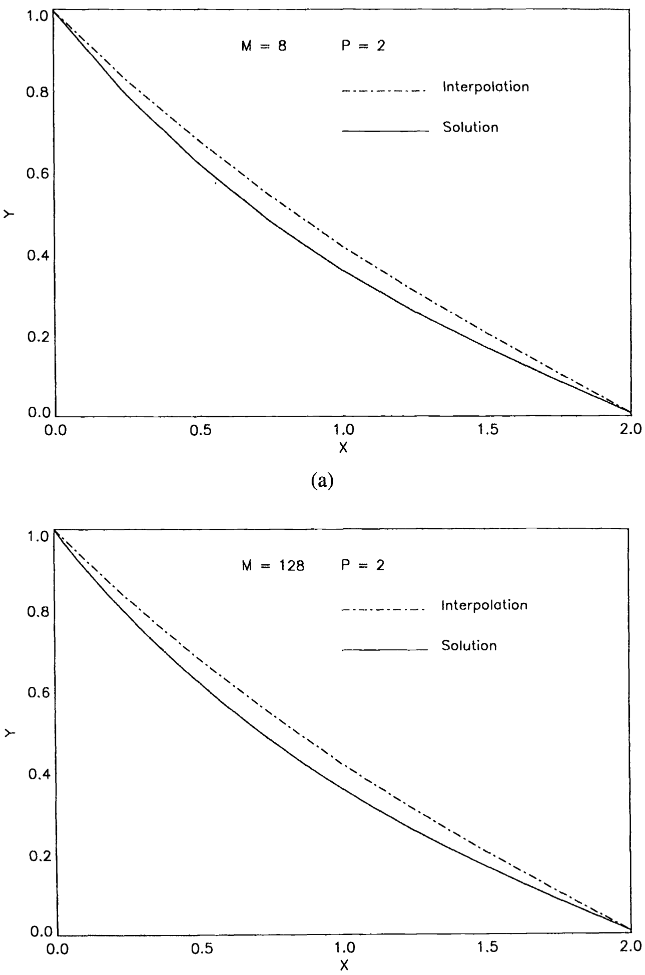
6. Computational results.

6.1. Multigrid convergence factors. The following computational results were conducted on the domain $x \in [0,\ 1]$ using homogeneous boundary conditions. The domain was divided into $m = 128$ spatial cells, and an S_{32} discretization ($n = 16$) was used in the angle. The problem is then specified completely by choosing $\sigma_t h$ and $\gamma = \frac{\sigma_s}{\sigma_t}$. Convergence factors were computed by setting the right-hand side equal to zero, choosing a random initial guess, and performing 15 $V(1, 1)$ cycles and taking the geometric mean of the last 5 cycles. This process exposes the most slowly converging eigen components. Initial reduction is usually much faster.

From computational results conducted on S_N with N ranging from 2 to 256, we observe the same convergence performance as those shown in Table 6.1.

From Table 6.1, we observe that the convergence factor ρ is $O(\sigma_t^3 h^3)$ when $\sigma_t h \ll 1$.

For the thick limit, we will let $\gamma = 1 - (\frac{1}{\sigma_t h})^p$, since, from our previous section, the power p will influence the error distribution after relaxation. We will present results with $p = 1, 2, 3$, and ∞.



(a)

(b)

FIG. 5.2.

In Table 6.2, the convergence rates ρ are for a multigrid $V(1,1)$ cycle with linear interpolation. Table 6.3 contains the convergence rates for a multigrid $V(1,1)$ cycle with kinked interpolation.

Table 6.2 shows that the multigrid $V(1, 1)$ cycle with linear interpolation has a convergence factor ρ on the order of $O((\frac{1}{\sigma_t h})^2)$ with $\gamma = 1$ ($p = \infty$) in the thick limit. But, when there is absorption ($\gamma \neq 1$), the convergence factor for linear interpolation is not satisfactory at all. As we have discussed in previous sections, when $\gamma \neq 1$ the errors after relaxation will be kinked. Linear interpolation will not be suitable for this case since the linear interpolation will simply interpolate the coarse grid approximation to the fine grid as if the error on the fine grid after relaxation were linear. So, even if the coarse grid is solved exactly, linear interpolation of this solution to the fine grid will not approximate the error on the fine grid. The situation will be compounded for a multigrid $V(1, 1)$ cycle since there are many levels. Every coarse grid solution will not approximate the error on the next finer grid. From our discussion in the previous section, when $p = 3$ on the fine grid, there is relatively little absorption and the errors after relaxation will be nearly linear. But, as we go down to coarser grids, we will reach a level

on which $\sigma_t h$ will satisfy $\gamma = 1 - (\frac{1}{\sigma_t h})^2$. Thus, using linear interpolation on this particular level will adversely affect the overall convergence factor. From Table 6.3 we see that when kinked interpolation is used the multigrid $V(1,1)$ has a convergence factor ρ on the order of $O(\frac{1}{\sigma_t h})$ for all levels of absorption. When there is no absorption, the multigrid $V(1,1)$ with kinked interpolation has a convergence factor on the order of $O((\frac{1}{\sigma_t h})^2)$.

In Table 6.4, we show a range within which the worst convergence factor occurs when $\gamma = 0.999$ and $m = 256$. In this case, the maximal ρ is 0.0085.

In Table 6.5, we present convergence factors of the multigrid $V(1,1)$ cycle with kinked interpolation for a nonuniform grid. We select $\sigma_t h_i = c \times 10^{2*\eta_i}$, where η_i is a random number between $(-1,1)$. For example, when $c = 1$, $\sigma_t h$ ranges from 0.01 to 100. We use parameter c to shift from the thin limit to the thick limit.

From Table 6.5, we see that the kinked interpolation is also suitable for nonuniform grid or, equivalently, for nonconstant σ_t.

6.2. DSA convergence factors. In this section, we will present a comparison of the DSA algorithm [1, 2, 5] and the multigrid algorithm with kinked interpolation. The slab is assumed to have physical thickness 2. Thus, σ_t represents the width of the slab measured in the number of mean-free paths. The tests were performed using S_8 and a wide range of σ_t and m (the

number of cells) and various values of γ ranging from .9999 to .9. The performance was similar for each value of γ, so we present only the complete results for $\gamma = .999$. The results for other values of γ can be found in [11]. Tables 6.6 and 6.7 give convergence factors for multigrid and DSA for various values of σ_t and m. The diagonals of these tables represent constant $\sigma_t h$.

In Tables 6.6 through 6.9, we say the convergence factor is zero if $\rho < 10^{-11}$. For both algorithms, the convergence factors are roughly constant along diagonals. But for each fixed γ, the multigrid convergence factor will approach zero much faster than the DSA convergence factor as σ_t goes to ∞ in the thick limit and σ_t goes to zero in the thin limit.

4^{10}	0.68×10^{-8}	0.20×10^{-6}	0.61×10^{-5}	0.12×10^{-3}

In all cases, the multigrid convergence factors were superior to the DSA convergence factors. However, it is important to adjust for the relative amount of computational work required by each algorithm. Of course, such measures will be machine dependent. On the Cray Y/MP, where these tests were performed, we compared times for $N = 64$ and $m = 1024$. Ten $V(1,1)$ cycles required 93 seconds. This includes 4.2 seconds to obtain the parameter d on every level. The parameter d on the coarse grid will depend on the relaxation on the fine grid. Thus, this setup process is sequential. One $V(1,1)$ cycle required 9.3 seconds and one DSA cycle required 3.7 seconds. The ratio of these times is 2.5. Table 6.8 contains the results of raising each entry in Table 6.7 to the power 2.5. This is a fairer comparison with the multigrid tables on a serial machine.

From Tables 6.6–6.8 we see that the convergence factors are nearly constant along diagonals, that is, for constant $\sigma_t h$. This was true for other values of γ also. In Table 6.9 we present both multigrid and adjusted DSA convergence factors for $m = 1024$, four values of γ, and various values of $\sigma_t h$. Again, we see that multigrid is faster in all tests. The two algorithms have nearly equal rates in regimes in which $\sigma_t h \sim 1$. This is the region in which the relaxation will not produce continuous kinked linear errors across two cells and, thus, the kinked interpolation is not as accurate.

On a parallel machine we expect the results to more heavily favor the multigrid algorithm. Both algorithms can be implemented with parallel complexity $O(\log(m))$. In this context, however, we expect the times to be more nearly equal. The multigrid algorithm has been implemented on an Thinking Machines Inc. CM-200 [8, 9]. The fundamental step in the DSA algorithm, the transport sweep, has also been implemented on the CM-200. A form of cyclic reduction was used. A comparison of timings on this machine appears in [15].

In either setting, parallel or serial, a full multigrid algorithm (FMG) can be implemented [3, 12]. This would provide a savings in some regions of the tables. Moreover, full multigrid provides a natural framework for adaptive grid refinement.

7. Conclusions. From our analysis and computational results, we conclude the following:

- The two-cell μ-line red-black relaxation is inexpensive, highly vectorizable, and parallelizable. Modification of this algorithm to incorporate mildly anisotropic scattering is also viable.
- When there is no absorption ($\gamma = 1$), this relaxation will cause the error to be linear, independent of angle, and continuous across two cells up to $O(\frac{1}{\sigma_t h})$ accuracy when $\sigma_t h \gg 1$.
- When $\gamma < 1$, the error after relaxation will be essentially kinked linear. The severity of deviation from linearity of the error after relaxation is determined by the values γ, $\sigma_t h$, and p in $\gamma = 1 - (\frac{1}{\sigma_t h})^p$. In the thick limit, the error after relaxation will be independent of angle up to accuracy of $O(\frac{1}{\sigma_t h})$.
- Relaxation-induced kinked interpolation is fairly accurate, and it can be obtained by the relaxation operator on each level to ensure that each level will have a good coarse grid approximation. This methodology can be extended to higher dimensions.
- The error reduction factor ρ for a multigrid $V(1,1)$ cycle is $\rho = O((\sigma_t h)^3)$ for the thin limit and $\rho = O(\frac{1}{\sigma_t h})$ for the thick limit when $\gamma = 1 - (\frac{1}{\sigma_t h})^p$ and $1 < p < 3$. When p is smaller than 1, there will be more absorption and the multigrid performance will be better. When p is more than 3, there will be hardly any absorption and the multigrid performance will be close to that of the performance when $\gamma = 1$ [10].
- The multigrid scheme was shown computationally to be effective for highly irregular meshes and heterogeneous material.
- The multigrid algorithm is more efficient than the DSA algorithm in all regimes.

JACOBIAN-WEIGHTED ELLIPTIC GRID GENERATION*

PATRICK M. KNUPP†

Abstract. Variational grid generation techniques are used to derive and analyze a weighted elliptic grid generator that controls the Jacobian of the underlying transformation in a least-squares sense. The Euler–Lagrange equations for the area and volume generators are weighted forms of the well-known Laplace generator. Weights are restricted to the class of P-matrices to help achieve global invertibility of the map. Connecting the weights to the Jacobian of the map results in an intuitive means of controlling grid spacing, area, orthogonality, and grid-line directions. Examples are given on the unit square to demonstrate point attraction, local refinement, directional alignment, and adaption to a shock.

Key words. elliptic grid generation, adaptive grid

AMS subject classification. 65M50

1. Introduction. Elliptic grid generation, as originally proposed by Winslow [20] and subsequently developed by Thompson, Thames, and Mastin [18], entails solving a set of uncoupled Laplace equations for the logical coordinate variables subject to Dirichlet data describing the boundary of some domain. The so-called "boundary-fitted" coordinate system that results is used to compute finite difference or finite volume solutions to physical problems on geometrically complicated domains that involve partial differential equations (PDEs) such as the heat equation, convection-diffusion, and the Navier–Stokes equations without need for interpolation of the physical boundary conditions. The principle advantages of elliptic grid generation using the Laplace equation are that the resulting coordinate transformation is smooth and, in many cases, nonsingular. A major limitation of the Laplace generator is that there is no control over the grid that is generated (except for weak control via the boundary parameterization). Often the unique grid that is the solution to the Laplace system of equations is unsatisfactory for the physical problem at hand due to inappropriate spacing, overly large cells, or lack of orthogonality. A widely accepted approach to overcoming this limitation is to introduce user-specified weighting functions that generalize the Laplace equations to a system of Poisson equations [18]. It should come as no surprise that this does indeed provide qualitative control over the grid since the addition of any "source term" must surely modify the grid in some way. Because of this flexibility it is not unreasonable to ask that the weightings have a clear geometric meaning. By this criterion it is not clear that the weighting suggested in [18] is optimal. An alternate weighted form of the Laplace generator (referred to as the "Jacobian-weighted" generator) is proposed for which the weights have a clear geometric interpretation. As a bonus, the generator includes additional control capabilities beyond those usually claimed for weighted elliptic generators.

2. The variational principle. Let $n = 2$ or $n = 3$ be the dimension of the physical space in which grid generation is to be performed. Define a unit logical domain U_n as the Cartesian product of the unit interval n times: $U_n = \{(\xi_1, \dots, \xi_n) \mid 0 \le \xi_i \le 1\}$ for $i = 1, \dots, n$. Let $\Omega \subset R^n$ be a bounded, simply connected "physical" domain. We seek a smooth (at least $C^2(\Omega)$) one-to-one mapping $x_i = x_i(\xi_1, \dots, \xi_n)$ (or, in shorthand notation, $\mathbf{x} = \mathbf{x}(\xi)$) from U_n to Ω whose Jacobian matrix $\mathcal{J}$,

$$[\mathcal{J}]_{i,j} = \frac{\partial x_i}{\partial \xi_j}, \tag{1}$$

*Received by the editors December 12, 1994; accepted for publication (in revised form) June 22, 1995.

†Ecodynamics Research Associates, P.O. Box 9229, Albuquerque, NM 87119 (pknupp@math.unm.edu).

obeys certain requirements. The inverse mapping is given by $\xi_i = \xi_i(x_1, \dots, x_n)$, with inverse Jacobian matrix $\mathcal{J}^{-1}$ having the elements

$$[\mathcal{J}^{-1}]_{i,j} = \frac{\partial \xi_i}{\partial x_j} . \tag{2}$$

Our goal is to control the full Jacobian matrix of the map. To do so, let $\mathcal{S}$ be an $n \times n$ square, nonsingular weight matrix defined on Ω. A direct way to use this weight would be to solve the system $\mathcal{J}^{-1} = \mathcal{S}$, giving n^2, first-order equations

$$\frac{\partial \xi_i}{\partial x_j} = [\mathcal{S}]_{i,j} . \tag{3}$$

A major difficulty with this direct approach is that such a system of equations is overdetermined because an additional set of constraints

$$\frac{\partial [\, S\,]_{i,j}}{\partial x_k} = \frac{\partial [\, S\,]_{i,k}}{\partial x_j} \tag{4}$$

must be satisfied (these are derived from (3)). To fix this problem one should add the requirement that the weight matrix be the gradient of some continuous vector potential function. Such a vector potential would not be easy to construct as it essentially requires knowledge of the solution coordinates. Furthermore, even if such a potential were found, this system of first-order equations is not easily solved, particularly in view of the necessity of matching prescribed boundary conditions on $\partial\Omega$.

Given these considerations, it makes sense instead to perform a "least-squares" fit to the weight $\mathcal{S}$. Consistency conditions then need not be met and a vector potential is not required. The tools for such a least-squares approach are found in the method of variational grid generation [2], [15]. Following the former reference, one minimizes a functional of the form

$$I\,[\mathcal{J}^{-1}] = \int_{\Omega} G(\mathbf{x}, \mathcal{J}^{-1})\, d\mathbf{x} \tag{5}$$

subject to given boundary data, where $G \mid R^{n^2+n} \rightarrow R$ is an at least twice differentiable function of its arguments. The smoothness principle of Brackbill and Saltzman, which leads to the Laplace generator, is a critical example.

Prior to the present work, weighted variational principles have been formulated to control the elements $g_{i,j}$ of the metric tensor [15] or its inverse [2]. To improve upon this one must control the Jacobian matrix $\mathcal{J}$ (or its inverse). We thus formulate a variational principle that performs a least-squares fit of the inverse Jacobian matrix to the weight $\mathcal{S}$. The integrand in (5) that gives the Jacobian-weighted variational principle is

$$G = \mid \mathcal{J}^{-1} - \mathcal{S} \mid^2 , \tag{6}$$

where $\mid \mathcal{M} \mid^2 = \operatorname{tr}(\mathcal{M}^T \mathcal{M})$ is the square of the Frobenius norm of the matrix $\mathcal{M}$. Thus G is simply the sum of the squares of the differences $[\mathcal{J}^{-1} - \mathcal{S}]_{i,j}$. One could, of course, consider alternate matrix norms to measure the "closeness" of the two matrices. The Frobenius norm is presently favored since the resulting generator is then a weighted form of the widely accepted Laplace generator.

The stated variational principle compares favorably with Brackbill's weighted combination of the three functionals: smoothness, area, and orthogonality. As noted in [3, p. 39] there are problems with weighted combinations of functionals: one does not know a priori what weights to choose for the combination, one has no guarantee that the combination selected will result in a convex functional, and, finally, one has a scaling problem due to the dimensional heterogeneity of the functionals. These problems are avoided in the Jacobian-weighted functional because, by controlling the Jacobian of the map via a least-squares fit, only a single functional is needed to control grid spacing, area, orthogonality, and even the direction of the tangents.

The boundary data for the grid on $\partial\Omega$ is critical in determining the "goodness of fit," i.e., how close the value of I is to zero. If the boundary data and the weight matrix are incompatible, then the Jacobian of the minimizing grid will not agree with the weight—a least-squares fit will result. Even when the boundary data is compatible with the weight, $I = 0$ may not be attained unless the weight matrix is the gradient of a vector potential.

So far, no smoothness assumptions concerning the weight $\mathcal{S}$ have been mentioned. Since the goal is to generate smooth grids whose inverse Jacobian is potentially equal to the weight matrix, it is reasonable to require $\mathcal{S}$ to have some degree of smoothness. As will be seen in the next section, strong solutions to the Euler–Lagrange equations require $\mathcal{S} \in C^k(\Omega)$ with $k \geq 1$. When $k = 1$, the minimization should lead to mappings whose coordinates are nearly twice differentiable.

Since the integrand of the Jacobian-weighted functional is a convex function of the elements of $\mathcal{J}^{-1}$, it should be possible to show strong convexity of the functional using the techniques in [11]. In addition, the Legendre–Hadamard ellipticity condition is probably satisfied. If so, the generator is elliptic and a unique minimum of the functional exists. A rigorous analysis to show this has yet to be carried out.

3. The grid generation equations. Since the weighted variational principle (6) is a generalization of Brackbill and Saltzman's "smoothness" principle, one should not be surprised to learn that the Euler–Lagrange equations are a weighted form of the Laplace generator. Indeed, one finds that the coordinates of the inverse mapping satisfy a set of Poisson equations:

$$\nabla^2_{\mathbf{x}}\xi_i = \sum_{k=1}^{n} \frac{\partial S_{i,k}}{\partial x_k} \tag{7}$$

with $i = 1, \ldots, n$ and $S_{i,k}$ the elements of the weight matrix $\mathcal{S}$. To compare with standard Poisson grid generators, we explicitly give the equations for the planar form of the Jacobian-weighted generator:

$$\nabla^2_{\mathbf{x}}\xi = \frac{\partial S_{11}}{\partial x} + \frac{\partial S_{12}}{\partial y}, \tag{8}$$

$$\nabla^2_{\mathbf{x}}\eta = \frac{\partial S_{21}}{\partial x} + \frac{\partial S_{22}}{\partial y}. \tag{9}$$

We prefer to write (7) in the symmetric form

$$\operatorname{div}_{\mathbf{x}}(\mathcal{J}^{-1} - \mathcal{S}) = \mathbf{0} \tag{10}$$

because this makes it clear that a potential solution is $\mathcal{J}^{-1} = \mathcal{S}$, boundary conditions permitting. If $\mathcal{S}$ is any matrix whose divergence is zero, the system reduces to the Laplace system of equations.

Since, in general, the grid on Ω is not uniform it is not easy to numerically solve the Euler–Lagrange equations directly (but see the work of Hagmeijer [5] for an example of how this can be done). For numerical computation, it is convenient (and standard) to invert the equations so that the logical variables become the independent variables. The lengthy derivation of the inverted Laplace equations is seldom given since the result is the well-known Winslow equation

$$g_{22}\,\mathbf{x}_{\xi\xi} - 2\,g_{12}\,\mathbf{x}_{\xi\eta} + g_{11}\,\mathbf{x}_{\eta\eta} = \mathbf{0} \tag{11}$$

(as shorthand, we denote the left-hand side operator of the Winslow equations by $\mathcal{Q}_w\,\mathbf{x}$). As shown in [8, p. 154], the lengthy derivation of the Winslow equations can be condensed into just a few steps. That derivation is extended here for (10) in order to obtain inverted, nonsymmetric, Jacobian-weighted equations that can be conveniently solved numerically. Let $\mathcal{C} \equiv \sqrt{g}\,\mathcal{J}^{-T}$. Then

$$\begin{aligned}
\mathrm{div}_{\mathbf{x}}\mathcal{J}^{-1} &= \mathrm{div}_{\mathbf{x}}\mathcal{S}\,,\\
\mathrm{div}_{\xi}\,\mathcal{J}^{-1}\mathcal{C} &= \mathrm{div}_{\xi}\mathcal{S}\mathcal{C}\,,\\
\mathrm{div}_{\xi}\sqrt{g}\mathcal{G}^{-1} &= [\nabla_{\xi}\mathcal{S}]\mathcal{C}\,,\\
-\sqrt{g}\mathcal{J}\mathrm{div}_{\xi}\sqrt{g}\mathcal{G}^{-1} &= -\sqrt{g}\mathcal{J}[\nabla_{\xi}\mathcal{S}]\mathcal{C}\,,\\
g\,[\nabla_{\xi}\mathcal{J}]\,\mathcal{G}^{-1} &= -\sqrt{g}\,\mathcal{J}\,[\nabla_{\xi}\mathcal{S}]\mathcal{C}\,,\\
\mathcal{Q}_w\mathbf{x} &= -\sqrt{g}\,\mathcal{J}\,[\nabla_{\xi}\mathcal{S}]\mathcal{C}\,.
\end{aligned} \tag{12}$$

Explicitly, the inverted equations (12) in two dimensions are

$$g_{22}\,\mathbf{x}_{\xi\xi} - 2\,g_{12}\,\mathbf{x}_{\xi\eta} + g_{11}\,\mathbf{x}_{\eta\eta} = -\sqrt{g}\,\mathcal{J}\,\mathbf{R} \tag{13}$$

with right-hand side vector

$$\mathbf{R} = \begin{bmatrix} (S_{11})_{\xi}\,y_{\eta} - (S_{12})_{\xi}\,x_{\eta} - (S_{11})_{\eta}\,y_{\xi} + (S_{12})_{\eta}\,x_{\xi} \\ (S_{21})_{\xi}\,y_{\eta} - (S_{22})_{\xi}\,x_{\eta} - (S_{21})_{\eta}\,y_{\xi} + (S_{22})_{\eta}\,x_{\xi} \end{bmatrix}. \tag{14}$$

As shown in [8], one can form projections of these equations in physical space and also derive a symmetric inverted form. Since our numerical scheme is based on solving (13)–(14) these alternate forms are not given here.

4. Ellipticity. It is commonly accepted that the Winslow operator in (13) is elliptic. For completeness, we sketch a proof of this fact here using the ellipticity test given in [8, p. 127]. The grid equations have the form

$$\sum_{i,j=1}^{n} \mathcal{T}_{i,j}\mathbf{x}_{\xi_i\xi_j} = \mathbf{F} \tag{15}$$

with $\mathcal{T}_{i,j}$ being $n \times n$ coefficient matrices and $\mathbf{F}$ being a right-hand side comprised of lower-order terms. The following ellipticity test applies: the system is elliptic if one can find a positive constant c that is independent of $\omega = (\omega_1, \ldots, \omega_n)$ and $\mathbf{x}$ such that

$$\mathbf{det}\left(\sum_{i,j=1}^{n} \mathcal{T}_{i,j}\omega_i\omega_j\right) \geq c\mid\omega\mid^{2n}\ . \tag{16}$$

Evaluation of the left-hand side of this expression for $\mathcal{Q}_w\,\mathbf{x}$ converts the ellipticity requirement to

$$(\omega^T g\mathcal{G}^{-1}\omega)^n \geq c\,(\omega^T\omega)^n\,. \tag{17}$$

On the left-hand side is recognized the "elliptic norm" of ω under the symmetric, positive-definite matrix $g\,\mathcal{G}^{-1}$. A well-known property of such elliptic norms [6] is that

$$0 < \lambda_m\, \omega^T \omega \leq \omega^T g \mathcal{G}^{-1} \omega \leq \lambda_M\, \omega^T \omega, \tag{18}$$

where λ_m and λ_M are the minimum and maximum eigenvalues of $g\mathcal{G}^{-1}$, respectively. We thus choose $c = (\inf_{\mathbf{x}\in\Omega} \lambda_m)^n$ to satisfy the ellipticity condition (17).

5. Grid replication. It is clear that $\mathcal{J}^{-1} = \mathcal{S}$ is a solution to (10) (with no boundary conditions). It is perhaps not as clear that it is also a solution to the inverted equations (12), but this fact may be verified using the identity

$$\mathcal{Q}_w \mathbf{x} \equiv -\sqrt{g}\, \mathcal{J}\, [\, \nabla_\xi \mathcal{J}^{-1}\,]\, \mathcal{C}\,, \tag{19}$$

which holds for all parameterizations of the domain.

The identity (19) is easily proved beginning with another, more obvious identity:

$$[\, \nabla_\xi \mathcal{I}\,]\, \mathcal{J}^{-T} \equiv \mathbf{0}\,, \tag{20}$$

$$[\, \nabla_\xi\, (\mathcal{J}\mathcal{J}^{-1})\,]\, \mathcal{J}^{-T} \equiv \mathbf{0}\,, \tag{21}$$

$$\mathcal{J}\, [\, \nabla_\xi \mathcal{J}^{-1}\,]\, \mathcal{J}^{-T} + [\, \nabla_\xi \mathcal{J}\,] \mathcal{J}^{-1} \mathcal{J}^{-T} \equiv \mathbf{0}\,. \tag{22}$$

The result (19) directly follows.

Since $\mathcal{J}^{-1} = \mathcal{S}$ is a generic solution to the grid equations, it is clear that for any smooth mapping from U_n to Ω there exists a weight $\mathcal{S}$ that will replicate this mapping provided the proper boundary data is applied to the system of grid equations. This result holds for the continuum. If the grid equations are not discretized in just the right way (at this point it is not clear that such a way exists), truncation error will foil exact replication of most discrete grids. This truncation error effect on grid replication may become important if the desired coordinate system is highly stretched. To save space, an investigation as to whether or not one can discretize (13)–(14) to maintain replication is reserved for a future article.

6. Relationship to other generators. The fact that the present generator controls (in a least-squares sense) the Jacobian of the map means that it can be used to approximately align the coordinate system with a given set $\mathbf{v}_1, \ldots, \mathbf{v}_n$ of vector fields; examples for $n = 2$ are given in [9]. It is appropriate then to compare, in general terms, the Jacobian-weighted method with other generators which have this alignment capability. The variationally based alignment generator due to Giannakopoulos and Engel [4] minimizes a functional having the integrand (in two dimensions)

$$G = \mid \mathbf{v}_2^{\perp} \times \nabla_{\mathbf{x}} \xi \mid^2 + \mid \mathbf{v}_1^{\perp} \times \nabla_{\mathbf{x}} \eta \mid^2 \tag{23}$$

to achieve "directional control" (we have modified their original notation to coincide with ours). The geometric idea behind this principle is that the cross products are minimized when the vector $\mathbf{v}_2^{\perp}$ is parallel to $\nabla_{\mathbf{x}}\xi$ and the vector $\mathbf{v}_1^{\perp}$ is parallel to $\nabla_{\mathbf{x}}\eta$ (here $\mathbf{v}_i^{\perp}$ is a vector perpendicular to $\mathbf{v}_i$). In terms of covariant vectors, the functional is minimized when $\mathbf{v}_i$ is parallel to (i.e., aligned with) $\mathbf{x}_{\xi_i}$. Examples are given in [4] to show that this indeed works, at least in some cases. As noted in [8, p. 224], the integrand (23) may be rewritten in the form

$$G = \nabla_{\mathbf{x}}\xi \cdot (\mathbf{v}_2 \otimes \mathbf{v}_2) \nabla_{\mathbf{x}}\xi + \nabla_{\mathbf{x}}\eta \cdot (\mathbf{v}_1 \otimes \mathbf{v}_1) \nabla_{\mathbf{x}}\eta\,. \tag{24}$$

The matrices in this latter expression are vector outer products. Such product matrices are singular; thus it is not unreasonable to expect that the grid equations corresponding to this variational principle are nonelliptic.

Applying the method of §4, the ellipticity of the Giannakopoulos and Engel functional (for $n = 2$) is considered. Let $\mathcal{A} = \mathbf{v}_2 \otimes \mathbf{v}_2$ and $\mathcal{B} = \mathbf{v}_1 \otimes \mathbf{v}_1$. Define matrices $\mathcal{R} = \mathcal{J}^{-1}\mathcal{A}\mathcal{J}^{-T}$, $\mathcal{S} = \mathcal{J}^{-1}\mathcal{B}\mathcal{J}^{-T}$. The Euler–Lagrange equations corresponding to the functional in (24) are given in equations (11.120)–(11.121) of [8, p. 236]. The latter may be written in the form (15) where

$$\mathcal{T}_{i,j} = \operatorname{diag}([\mathcal{R}]_{i,j}, [\mathcal{S}]_{i,j})\, \mathcal{J}^{-1} \,. \tag{25}$$

Evaluation of the left-hand side of (16) for this functional gives

$$\frac{(\omega^T \mathcal{R}\, \omega)\, (\omega^T \mathcal{S}\, \omega)}{\sqrt{g}} \geq c(\omega^T \omega)^2 \tag{26}$$

as the ellipticity condition. Since $\mathcal{A}$ and $\mathcal{B}$ are singular, so are $\mathcal{R}$ and $\mathcal{S}$. If $\omega \neq 0$ is in the null space of either of the latter matrices, the left-hand side of the previous equation is zero. There does not exist a positive constant c, so the Giannakopoulos and Engel alignment functional is, at best, degenerate elliptic.

This analysis is supported by Brackbill's proposal to form a combination of the directional control functional (23) and the "smoothness" functional to improve the "regularity" of the equations [3]. A problem with such combinations is that they involve trade-offs between the various properties. One might expect that the more one weights the combination toward "smoothness," the less one will achieve directional control and vice versa.

We have little doubt that other functionals have been or may be devised which would achieve alignment (see, for example, [5]). We are not in a position to judge whether or not the presently proposed generator can align grids better than these other methods because to date it has not been possible to run the different algorithms on the same problem. It is possible that all of these generators do comparable jobs of grid alignment; however it seems that the Jacobian-weighted approach has several significant advantages. First, the generator reduces to the well-established Laplace generator in the unweighted case, so it has all the strengths (including ellipticity) of the latter generator, at least in the limiting case. Second, the proposed generator can be used to control other properties of the grid besides alignment (see §10), whereas the "directional control" generator is designed specifically for the alignment task.

What is the relationship of the present scheme to the Thompson–Thames–Mastin (TTM) elliptic generator [18]? Recall that the latter employs weight functions P and Q in the Poisson system

$$\nabla^2_{\mathbf{x}}\xi = P \,, \tag{27}$$

$$\nabla^2_{\mathbf{x}}\eta = Q \,. \tag{28}$$

In the original TTM generator, the weights P and Q have the complicated forms

$$\begin{aligned} P(\xi, \eta) = &- \sum_{m=1}^{M} a_m \frac{\xi - \xi_m}{\mid \xi - \xi_m \mid}\, e^{-c_m |\xi - \xi_m|} \\ &- \sum_{i=1}^{I} b_i \frac{\xi - \xi_i}{\mid \xi - \xi_i \mid}\, e^{-d_i\,[\,(\xi-\xi_i)^2 + (\eta-\eta_i)r\,]^{\frac{1}{2}}} \,, \end{aligned} \tag{29}$$

$$\begin{aligned} Q(\xi, \eta) = &- \sum_{m=1}^{M} a_m \frac{\eta - \eta_m}{\mid \eta - \eta_m \mid}\, e^{-c_m |\eta - \eta_m|} \\ &- \sum_{i=1}^{I} b_i \frac{\eta - \eta_i}{\mid \eta - \eta_i \mid}\, e^{-d_i\,[\,(\xi-\xi_i)^2 + (\eta-\eta_i)r\,]^{\frac{1}{2}}} \end{aligned} \tag{30}$$

(see [18] for details of how this is supposed to work). By specifying the various parameters a_m, c_m, b_i, and d_i, it is claimed that one can attract or repel grid lines to M points and I lines within the physical domain. Examples show that this qualitatively works, at least for a small number of attraction points/lines. The forms (29)–(30) of the weights provide the user with neither orthogonality nor grid alignment controls.

Warsi [19] replaced the original P and Q weights defined in (29)–(30) by $g^{11}\,P$ and $g^{22}\,Q$ to improve the numerical behavior of the generator—no additional control over the grid was claimed. Thomas and Middlecoff [16] replaced the P and Q in the Warsi modification with $P = \phi(\xi, \eta)$ and $Q = \psi(\xi, \eta)$ and abandoned formulas (29)–(30) for the weights in favor of performing interpolations from the boundary data. In Anderson [1], the new control functions ϕ and ψ are constructed to satisfy

$$\phi = -\frac{\partial}{\partial \xi} \ln \sqrt{g_{11}}\,, \tag{31}$$

$$\psi = -\frac{\partial}{\partial \eta} \ln \sqrt{g_{22}} \tag{32}$$

so that the weights potentially control the normalized rate of change of grid spacing in the two logical directions (the derivation of these relationships is not strictly correct because it is assumed that the grid is orthogonal). Nonetheless, the resulting grid generator has proved useful in numerous instances, particularly if physical space weightings are used (as in [14]).

The Jacobian-weighted generator defines weights P and Q by

$$P = \frac{\partial}{\partial x} S_{11} + \frac{\partial}{\partial y} S_{12}\,, \tag{33}$$

$$Q = \frac{\partial}{\partial x} S_{21} + \frac{\partial}{\partial y} S_{22}, \tag{34}$$

where the $S_{i,j}$ are the elements of a weight matrix $\mathcal{S}$ which controls the elements of the inverse Jacobian matrix of the transformation. Superficially then, the generator is a special case of the P-Q generator of (27)–(28). On a deeper level, however, it cannot be considered a special case because the traditional P-Q generator is derived from a different variational principle. The integrand in the variational principle for the P-Q generator (with physical space weightings $P = P(\mathbf{x})$ and $Q = Q(\mathbf{x})$) is

$$G = \frac{1}{2} \mid \mathcal{J}^{-1} \mid^2 + P\,\xi + Q\,\eta\,, \tag{35}$$

which has no obvious geometric meaning.

It is not claimed that the present Jacobian-weighted method always does a better job of controlling the grid than does the P-Q method. In fact, any grid generated by one of the methods can be generated by the other provided the proper weight is selected. However, the Jacobian-weighted method should ultimately prove preferable because of the clear meaning of its control functions and because it can potentially control grid orthogonality and grid alignment, in addition to all of the properties controlled by P-Q.

7. Nonsingular mappings. Boundary-fitted coordinates are often used in computational fluid dynamics to solve a system of PDEs that models some physical phenomenon such as fluid flow or heat transfer. To apply these coordinates one must transform the physical equations to general coordinates. To avoid a change of type of the governing equations requires the mapping to be locally invertible. It is therefore desirable to have a guarantee that the mapping produced by a grid generator will be locally invertible, i.e., nonsingular. Such a guarantee has been constructed for the 2D Winslow generator $\mathcal{Q}_w\mathbf{x} = \mathbf{0}$ [12]. The proof of this guarantee hinges on the maximum principle for Laplace's equation in the plane. Even this guarantee does not always avoid trouble when the equations are discretized: the results in §5.4.3 of [8] suggest that truncation error effects can sometimes prevent the discrete grids from being nonsingular. Examples have also been constructed to show that the guarantee that holds for the 2D Laplace equations does not extend to the 3D case (see [10] for a discussion of the extension of Rado's theorem to three-dimensions).

A more serious limitation is that, in practice, the weighted P-Q forms of the Laplace generator are often used. This case is not covered by the guarantee that holds for the unweighted equations. As observed in [14], there can be no guarantee that the P-Q generator will not produce a folded grid because given any smooth but folded mapping one can compute P and Q directly from the Laplacian of the map. If these weights are used in the Poisson generator, then the folded mapping will be reproduced. In contrast to the unweighted generator, it is easy to produce folded maps with the P and Q generator (see Project 5.5.1 in [8, p. 109]).

From these observations it seems that one cannot hope for an invertibility guarantee for the present Jacobian-weighted elliptic generator. However, in the next section we will suggest a condition upon the weight matrix that, although not a guarantee, will provide a guideline for constructing weights that have a reasonable chance of producing a nonsingular grid.

8. Global univalence. A sufficient (but not necessary) condition to achieve *local* invertibility of a mapping is the requirement that the Jacobian matrix be invertible; equivalently, one needs $\sqrt{g} \neq 0$. There has been considerable work [13] in determining what are sufficient conditions to guarantee that a map is *globally* invertible.

We focus on one of several results that is known on this subject because it seems to fit naturally with the grid generation problem. We need the following definition.

DEFINITION. *An $n \times n$ real matrix $\mathcal{A}$ is a P-matrix if every principle minor of $\mathcal{A}$ is positive.*

Recall that the principle minors of a square matrix are the determinants of the square submatrices of the matrix. For example, if $n = 2$, the principle minors of $\mathcal{A}$ are a_{11}, a_{22}, and $\det \mathcal{A}$. If $n = 3$, the principle minors are a_{11}, a_{22}, a_{33}, $a_{11}a_{22} - a_{21}a_{12}$, $a_{11}a_{33} - a_{31}a_{13}$, $a_{22}a_{33} - a_{32}a_{23}$, and $\det \mathcal{A}$. It is shown in [13] that if $\mathcal{A}$ is nonsingular and a P-matrix, then $\mathcal{A}^{-1}$ is a P-matrix. We base our argument in this section upon the following fundamental result of Gale, Nikaido, and Inada.

FUNDAMENTAL GLOBAL UNIVALENCE THEOREM. *Let $F : U \subset R^n \rightarrow R^n$ be a differentiable mapping, where U is the rectangular region $U = \{\mathbf{x} : \mathbf{x} \in R^n \mid a_i \leq x_i \leq b_i\}$. If the Jacobian matrix of F at $\mathbf{x}$, $\mathcal{J}(\mathbf{x})$, is a P-matrix for every $\mathbf{x} \in U$, then F is globally univalent in U.*

In general, the Jacobian matrix $\mathcal{J}$ is not a P-matrix, so the mappings produced for arbitrary weights $\mathcal{S}$ cannot be expected to be globally invertible. The univalence theorem suggests that it is reasonable to require that the weight matrix $\mathcal{S}$ in the Jacobian-weighted elliptic grid generator be a P-matrix. If $\mathcal{J}^{-1} = \mathcal{S}$ is achieved, then $\mathcal{J} = \mathcal{S}^{-1}$ is a P-matrix and the map will be globally univalent. Even if $\mathcal{J}^{-1} = \mathcal{S}$ is not achieved, it is possible that $\mathcal{J}^{-1}$ will still be a P-matrix because matrices "near" $\mathcal{S}$ are still P-matrices. P-matrix weights do not guarantee global invertibility of the mapping but can serve as a guide to help construct useful weights. A subset of the P-matrices is the set of positive, quasi-definite matrices.

DEFINITION. *An $n \times n$ (not necessarily symmetric) real matrix $\mathcal{A}$ is a positive* quasi-definite *matrix if $\mathbf{x}^T \mathcal{A}\mathbf{x} > 0$ for all $\mathbf{x} \neq 0$.*

Since such matrices are more strongly constrained than are P-matrices, requiring the weight $\mathcal{S}$ to be positive, quasi definite would seem to help achieve global invertibility. The P-matrix and quasi-definite criteria on the weight will be refined in the next section.

9. The form of the weight matrix. The weight function $\mathcal{S}$ controls the inverse Jacobian matrix of the transformation. A crucial question asks how this weight should be constructed. Consider the planar case $\Omega \subset R^2$ first.

In the general planar case, one can consider alignment of the two tangent vectors $\mathbf{x}_\xi$ and $\mathbf{x}_\eta$ with two unit vectors $\mathbf{u}_j^T = (u_j^1, u_j^2)$, $j = 1, 2$. Let $\mathcal{U}$ be a 2×2 matrix with elements $U_{i,j} = u_j^i$. It is sometimes useful to express the unit vectors in terms of "direction cosines" as

$$\mathcal{U} = \begin{pmatrix} \cos\theta_1 & \cos\theta_2 \\ \sin\theta_1 & \sin\theta_2 \end{pmatrix}, \tag{36}$$

where $-\pi < \theta_j \leq \pi$ forms the angle between the jth tangent vector and the x-axis. To establish the length scale of the map, let $\mathcal{L} = \text{diag}(\ell_1, \ell_2)$ with $\ell_j > 0$. The weight matrix is written as the inverse product

$$\mathcal{S} = (\mathcal{U}\mathcal{L})^{-1}. \tag{37}$$

For the special case of a single direction $\mathbf{u}_1$, given it makes sense to require grid orthogonality, let $\theta_1 = \theta$ be the angle between the x-axis and the known unit vector $\mathbf{u}_1$. Let $\theta_2 = \theta + \pi/2$ in order that the unit vector $\mathbf{u}_2$ be orthogonal to $\mathbf{u}_1$. This gives

$$\mathcal{U} = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}. \tag{38}$$

If the solution $\mathcal{J} = \mathcal{S}^{-1}$ is attained, then the following relations hold:

$$x_\xi = \ell_1 \cos\theta, \tag{39}$$

$$y_\xi = \ell_1 \sin\theta, \tag{40}$$

$$-x_\eta = \ell_2 \sin\theta, \tag{41}$$

$$y_\eta = \ell_2 \cos\theta. \tag{42}$$

These in turn imply

$$\ell_1 = \sqrt{g_{11}}, \tag{43}$$

$$\ell_2 = \sqrt{g_{22}}, \tag{44}$$

and

$$g_{12} = 0, \tag{45}$$

$$\sqrt{g} = \ell_1 \ell_2, \tag{46}$$

$$\sqrt{g_{22}/g_{11}} = \ell_2/\ell_1, \tag{47}$$

showing that this construction of the weight potentially gives an orthogonal grid with cell areas given by the product of the length-control functions, cell-aspect ratios given by the ratio of the length-control functions, and whose tangent $\mathbf{x}_\xi$ makes an angle θ with the x-axis.

To make use of the concept of P-matrices for the weight matrix requires further discussion. Consider the mapping $x = \eta$, $y = -\xi$ on the unit square. The Jacobian matrix for this map is

$$\mathcal{J} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \tag{48}$$

and the determinant is $\sqrt{g} = 1$. The map is thus nonsingular, yet the Jacobian is not a P-matrix because two of the minors are zero. The global univalence theorem is not refuted by this example because the requirement that the Jacobian be a P-matrix is a sufficient, not necessary, condition. Nevertheless, it is disturbing that the Jacobian for this simple map does not give a P-matrix.

To fix this problem we refine our notion of how P-matrices should be applied to grid generation. Instead of requiring that the Jacobian of the map be a P-matrix we shall require that there exists a finite set of rigid body rotations (given by the $n \times n$ matrix $\mathcal{R}$) such that the product $\mathcal{R}\,\mathcal{J}$ is a P-matrix. Intuitively, this means that we can rotate the local tangent vectors in such a way as to obtain a P-matrix. In the above example, if one lets $\phi = \pi/2$ and

$$\mathcal{R} = \begin{pmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{pmatrix}, \tag{49}$$

then $\mathcal{R}\,\mathcal{J} = \mathcal{I}$, which is obviously a P-matrix.

We next determine what restrictions must be put on the weight $\mathcal{S}$ in (37) to ensure that $\mathcal{R}\,\mathcal{S}^{-1}$ is a P-matrix. Since

$$\mathcal{R}\,\mathcal{S}^{-1} = \begin{pmatrix} \ell_1 \cos(\theta_1 + \phi) & \ell_2 \cos(\theta_2 + \phi) \\ \ell_1 \sin(\theta_1 + \phi) & \ell_2 \sin(\theta_2 + \phi) \end{pmatrix} \tag{50}$$

one finds that sufficient conditions for the product to be a P-matrix are that $\ell_1 > 0$, $\ell_2 > 0$, and $0 < \theta_2 - \theta_1 < \pi$ (this can be seen by taking $\phi = -\theta_1$). Geometrically this means that the length scales are positive and the unit vectors are properly oriented (positive cross product). Restricting the weight matrix to a positive, quasi-definite matrix requires that $\theta_2 = \theta_1 + \pi/2$; i.e., an orthogonal grid is demanded.

In this construction of the weight matrix we are to supply three controls, ℓ_1, ℓ_2, and θ, that are functions of $\mathbf{x}$ which prescribe the two length scales and the direction of the tangents. Precise control (i.e., actually getting a grid for which $\mathcal{J}^{-1} = \mathcal{S}$) may not be achieved due to the fact that the elliptic equations produce solutions that are least-squares fits to the conditions we are attempting to impose. Lack of precise control can be helpful because one may have only a rough idea of values for these control functions. The advantage of the construction just given is not that it makes figuring out the weight function easy (it is not), but rather that the weight functions that must be defined have clear geometric meanings.

In three-dimensions, let ℓ_1, ℓ_2, and ℓ_3 be given length-control functions and $\mathcal{L} = \mathrm{diag}(\ell_1, \ell_2, \ell_3)$. Three unit vectors $\mathbf{u}_j$, $j = 1, 2, 3$ are given in terms of the angles ϕ_j and θ_j. The polar angle ϕ_j lies in the range $0 \le \phi_j \le \pi$ and gives the angle between the unit vector and the z-axis. The azimuthal angle θ_j lies in the range $0 \le \theta_j < 2\pi$ and gives the angle between the projection of the unit vector onto the x-y plane and the x-axis. The matrix $\mathcal{U}$ of components of the unit vectors has entries

$$\mathbf{u}_j = \begin{bmatrix} \cos\theta_j \, \sin\phi_j \\ \sin\theta_j \, \sin\phi_j \\ \cos\phi_j \end{bmatrix} \tag{51}$$

and the weight $\mathcal{S}$ is again formed as in (37). It is not clear what the useful special cases of this general setup in three-dimensions are, so no further assumptions are made at this time. It is expected that sufficient conditions for the 3D construction to be a P-matrix will turn out to be positive length-control functions and a well-oriented vector triple.

10. Examples on the unit square. Methods for discretizing and numerically solving grid generation equations of the type found in this paper are well known; examples may be found in [8]. It is well beyond the scope of this paper to consider all the ways in which the Jacobian-weighted generator may be used. The purpose in this section is to show that the control functions described in §9 indeed provide the control that is claimed and that reasonably good grids can be generated with minimal effort. The simple case in which the physical domain is the unit square seems sufficient for this purpose and has the advantage that the weight S can be given in terms of an analytic function of the physical space variables. Nonanalytic weights raise interpolation questions which cannot be addressed here due to lack of space.

A few preliminary remarks are in order before concrete examples are given. First, given a uniform parameterization of the boundary of the unit square, the natural transformation on the square is $x(\xi, \eta) = \xi$ and $y(\xi, \eta) = \eta$. The Jacobian matrix for this transformation is simply the identity. Uniform boundary data and a weight matrix $\ell_1 = \ell_2 = 1, \theta = 0$ gives the natural transformation because the gradient of this particular weight is zero and the uniform grid is a solution to the Winslow equations. Second, if a nonuniform parameterization of the boundary is given, then the identity weight will not reproduce the grid based on the natural uniform transformation because the weight is inconsistent with the boundary data. The solution to the Winslow equations with nonuniform boundary data thus produces a least-squares fit to a map having the identity as the Jacobian. Third, if the boundary parameterization is achieved by an exponential stretch of the logical variable, as in

$$x_B(\xi) = \frac{(1 - e^{\lambda \xi})}{(1 - e^{\lambda})}, \tag{52}$$

$$x_T(\xi) = x_B(\xi) \tag{53}$$

(with $\lambda \neq 0$), then the exponential map $x(\xi, \eta) = x_B(\xi)$, $y(\xi, \eta) = \eta$ will be produced by a weight matrix having a *linear* variation in x because then

$$x_\xi = \frac{\lambda}{1 - e^{\lambda}} [(1 - e^{\lambda}) x - 1]. \tag{54}$$

Example 1. *Local refinement.* Sometimes it is desired to refine a grid on a local subregion or patch to achieve greater accuracy in a part of the domain having a lot of solution structure. Often this is done by overlaying the main grid with a second grid having smaller cells on the subregion and performing an interpolation of the solution between the main grid and the patch grid. As a cheap alternative, the Jacobian-weighted generator can approximate patching by using a single grid to eliminate the need for interpolation.

As an example, let a patch $P \subset \Omega$ be the union of two rectangles: $R_1 = [1/4, 1/2] \times [1/2, 3/4]$ and $R_2 = [1/2, 3/4] \times [5/8, 3/4]$. The weight matrix control functions are $\theta = 0$ and $\ell_1 = \ell_2 = 1/2$ on P and unity otherwise (notice that we have violated our assumption that the weight is C^1 in this example). Nonetheless, Figure 1 shows that these simple controls permit the resulting elliptic grid to approximate subgrid patching. The transition zone between the patches could perhaps be improved by introducing a smooth transition function between the length scales on Ω and P (this would also improve the convergence rate of the Picard iteration for the solution). It would, of course, take considerably more work to define smooth control functions and the results may not justify the additional effort.

The main point in this example (and the ones below) is not that the grids generated are all that much better than those generated by other means, but merely that it is relatively easy to devise the control functions in the Jacobian-weighted method due to the clear meaning of the controls.

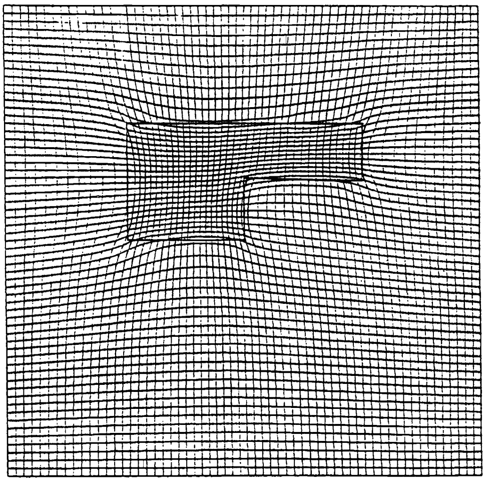

FIG. 1. *Local refinement.*

Example 2. *Point attraction.* In this example it is shown that weights can be devised to attract grid nodes to multiple points in the physical domain. Suppose the grid nodes are to be attracted to N distinct points (x_n, y_n), $n = 1, \ldots, N$ in the domain. The horizontal length-control function in this example takes the form

$$\ell_1(x, y) = 1 - \sum_{n=1}^{N} a_n B(r_n, R_n), \tag{55}$$

where B is a smooth "bump" function

$$B(r, R) = \begin{cases} 1 - 3(r/R)^2 + 2(r/R)^3, & r/R < 1, \\ 0 & \text{else} \end{cases} \tag{56}$$

chosen for the following properties: $B(0, R) = 1$, $B(R, R) = 0$, $B_r(0, R) = 0$, and $B_r(R, R) = 0$. Here r_n is the distance between the point (x, y) and the point (x_n, y_n). The parameters $0 < R_n < 1$ are "radii of attraction" and the parameters $0 < a_n < 1$ are "attraction strengths." The radii R_n are chosen so that the support of the "bump" functions do not overlap. The other control functions are $\ell_2 = \ell_1$ and $\theta = 0$. In Figure 2 we show results for the three attraction points $(x_1, y_1) = (1/4, 3/4)$, $(x_2, y_2) = (3/8, 1/4)$, and $(x_3, y_3) = (3/4, 5/8)$. The attraction radii were set to $R_n = 0.10$ and the attraction strengths were set to $a_n = 0.75$. Although the grid produced in this example is reasonably good (except for a lack of orthogonality in part of the domain), it is all too easy to produce poor grids or cause the Picard iteration to fail to converge by selecting extreme values of the parameters R_n and a_n. This will be exacerbated if the location of the attraction points is particularly demanding of a structured grid. If two or more of the attraction points lie close to one another, the separate attraction points will not be individually resolved unless more cells are added to the grid.

Example 3. *Feature adaptivity.* This example demonstrates that the alignment generator can be used as a feature-adaptive generator in much the same way as many other weighted grid generators. The example is based on a "solution" function borrowed from [7]:

$$f(x, y) = \tanh R\,\{r^2 - (x - x_c)^2 - (y - y_c)^2\}. \tag{57}$$

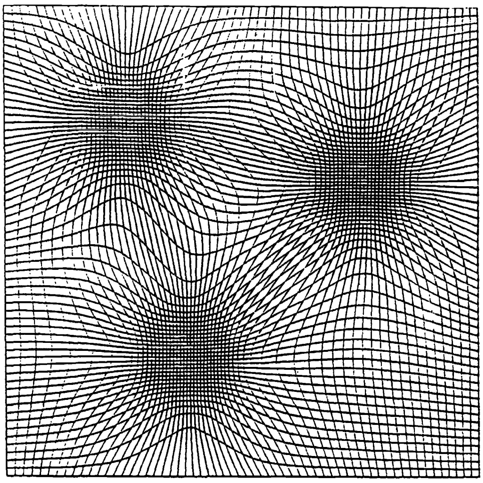

FIG. 2. *Point attraction.*

This function forms a circular "hill" with radius r centered about the point $x = x_c$, $y = y_c$ (in this example, $r = 1/4$, $x_c = 1/2$, and $y_c = 1/2$). Large values of R create a steep-sided hill. As is commonly done with adaptive generators, we wish to produce a grid with small cells at the points in physical space where $\mid \nabla_{\mathbf{x}} f \mid$ is large. To achieve this we set

$$\ell_1 = \frac{1}{(1 + a \mid \nabla_{\mathbf{x}} f \mid)}, \tag{58}$$

$$\ell_2 = \ell_1, \tag{59}$$

$$\theta = 0, \tag{60}$$

where a is a positive scale parameter. Four grids are shown in Figure 3: the first, Figure 3a, directly compares the Jacobian-weighted result for $R = 20$, $a = 0.2$ with Figure 3.5 in [7]. The grid in Figure 3a does not have the pinched cells found in Figure 3.5 in [7] because the present method is not based on 1D adaptions. Figure 3b shows the results of the Jacobian-weighted generator for a steeper hill ($R = 100$, $a = 0.05$). Figure 3c shows what happens for $R = 100$ when "a" in (58) is increased to $a = 0.10$—the grid has a cell of zero area (at least it did not fold over). This problem can be fixed by increasing the problem resolution from 40 × 40 to 60 × 60 cells. The result ($R = 100$ and $a = 0.10$) is given in Figure 3d.

The usual problems of feature-adaptive grid generation remain: determining the best choice for the parameter a. If a is too small, the grid does not respond to the gradient while if a is too large, the grid overresponds, resulting in a bad grid or even a folded grid (if one is lucky, the numerical iteration will fail to converge instead of producing a folded grid). What is the proper choice for the form of the control function (for example, why not use

$$\ell_1 = \frac{1}{\sqrt{1 + a^2 \mid \nabla_{\mathbf{x}} f \mid^2}} \tag{61}$$

instead of that defined in (58))?

Presently there is not enough evidence to claim that the Jacobian-weighted grid generator always gives better grids than other adaptive methods. It seems inescapable that a poor choice of parameters in the control functions of any method will produce a poor grid no matter how good the basic generator is. Thus the Jacobian-weighted grid generator (like all other known

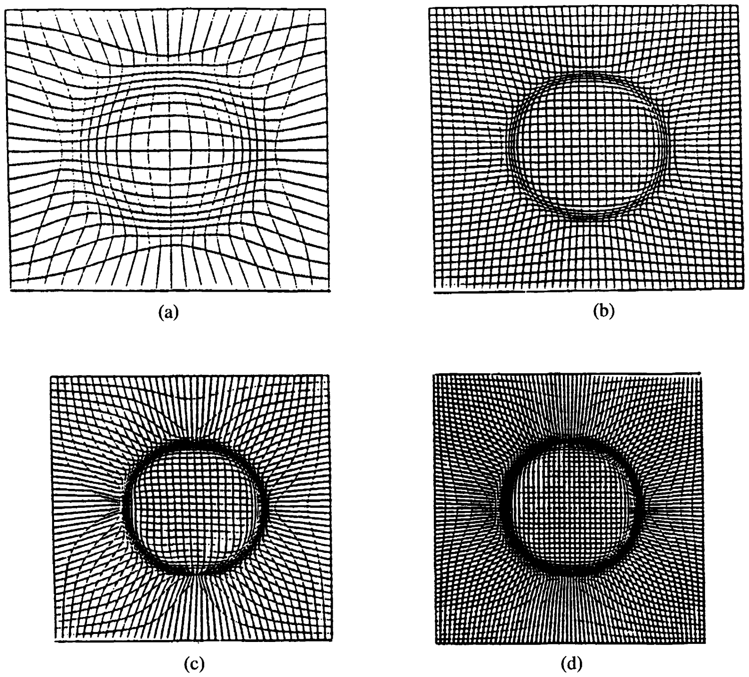

FIG. 3. *Gradient-weighted adaptivity:* (a) *Gentle hill.* $R = 20$, $a = 0.2$. (b) *Steep hill.* $R = 100$, $a = 0.05$. (c) *Steep hill.* $R = 100$, $a = 0.10$. (d) *Increased resolution.*

generators) cannot be considered an automatic generator, i.e., one which requires no user intervention. Instead, it is best if used in an interactive mode wherein the user can try a set of control functions and parameters, look at the grid produced, and adjust the parameters accordingly. From this viewpoint, the Jacobian-weighted generator seems attractive because at least the meaning of the weights is clear.

Example 4. *Adaption to a curved "shock".* This example also uses the "hill" function (57) but with $r = 5/4$, $x_c = 3/2$, and $y_c = 0$. With this choice the center of the "hill" lies outside the physical domain and the locus of points of maximum gradient traverses the domain in a circular arc. The goal is to create small cells near this arc and to align the horizontal tangent $\mathbf{x}_\xi$ so that it orthogonally traverses the arc. To do so, an annular sector of points (x, y) near the "shock" is identified by the relation $\mid r - \rho \mid < \epsilon$ where $\rho^2 = (x - x_c)^2 + (y - y_c)^2$. The parameter ϵ is the width of the annulus (taken to be 0.1 in this example). If the point (x, y) lies within this band, then the angle control function is taken to be

$$\theta = \arctan\left(\frac{y - y_c}{x - x_c}\right). \tag{62}$$

If the point (x, y) lies outside the annulus, then $\theta = 0$. Since the top boundary of the domain is not orthogonal to the "shock" we introduce a blending function

$$u(x) = \frac{(e^{\lambda x} - e^{\lambda})}{(1 - e^{\lambda})} \tag{63}$$

and multiply θ in (62) by u to reduce the amount of angle adaption near the top boundary ($\lambda = 2$ in the present example). The length-control functions are the same as in the previous example. The resulting grid shown in Figure 4 closely approximates the desired properties.

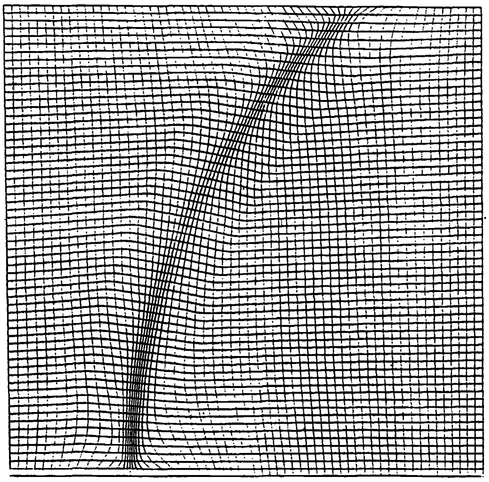

FIG. 4. *Adaption to a curved "shock."*

11. Summary. The "smoothness" variational principle of Brackbill and Saltzman has been generalized by performing a least-squares fit of the inverse Jacobian matrix to a weight matrix in order to control the Jacobian matrix of a mapping from a uniform logical domain to a bounded, simply connected domain in physical space. By specifying the Jacobian one can, in principle, control cell lengths, areas, orthogonality, and the direction of the tangent vectors, thus obviating the need for combining separate functionals for these properties into a single, possibly nonconvex, functional having mixed dimensional characteristics. The least-squares principle leads to "Jacobian-weighted" grid generation equations that are elliptic and constitute a generalization of the Laplace generator. The inverted equations are a weighted form of the well-known Winslow equations. Given any continuum transformation, the weight matrix that replicates the transformation is merely the inverse Jacobian matrix of the transformation. The Jacobian-weighted generator has a different variational principle than does the widely used "Poisson generator" and thus cannot be considered a special case of the latter. It is suggested that restricting the weight matrix to be a P-matrix will help give globally invertible mappings. Length-scale and directional control functions further define the weight matrix. Four examples were given to show that it is relatively easy to construct control functions to achieve local refinement, point attraction, feature adaptivity, and directional control.

The control functions of the Jacobian-weighted generator have clear geometric meanings and thus seem preferable to other weighted elliptic grid generators. Nevertheless, the method retains a number of the problems of previous elliptic methods such as lack of automation, lack of precision, and relative slowness due to the fact that a system of nonlinear PDEs must be solved. Further work should at least partially address these issues.

Many open issues regarding this generator remain. A partial list of such issues includes devising a discretization that will permit exact replication, designing fast, robust solvers for the discretized equations, testing of the method in three-dimensions, testing the method as an adaptive generator, finding efficient ways of constructing smooth, effective weight matrices, finding ways to ensure compatibility of the boundary data with the weight, parallelization of the algorithm, extension to a surface grid generation algorithm, determining fast and accurate interpolation methods when the weight is known only at discrete points, and determining if the generalized principle

$$G = w(\mathbf{x}) \mid \mathcal{J}^{-1} - \mathcal{S} \mid^2 \tag{64}$$

with $w > 0$ is of any use in forcing more precision at particular points in the domain. Extension of (13) to the case of surface grid generation will result in equations similar in form to those given in [17]. The left-hand side of the equation would remain the same while the right-hand side would be generalized to include a surface curvature term.

Acknowledgments. The author wishes to thank G. Liao, N. Robidoux, and S. Steinberg.

COMPOSITE STEP PRODUCT METHODS FOR SOLVING NONSYMMETRIC LINEAR SYSTEMS*

TONY F. CHAN† AND TEDD SZETO†

Abstract. First proposed in [*Numer. Math.*, 66 (1993), pp. 295–319, *Numer. Algorithms*, 7 (1994), pp. 1–16] by Bank and Chan, the composite step (CS) method is a technique for curing the pivot breakdown (one of two possible breakdowns) in the biconjugate gradient (BCG) algorithm by skipping over steps in which the iterate is not defined. We show how to extend this method to cure the same breakdown inherited in product methods such as conjugate gradients squared (CGS) [*SIAM J. Sci. Statist. Comput.*, 10 (1989), pp. 36–52], Bi-CGSTAB [*SIAM J. Sci. Statist. Comput.*, 13 (1992), pp. 631–644], Bi-CGSTAB2 [*Variants of BiCGSTAB for Matrices with Complex Spectrum*, IPS Research Report No. 91-14, ETH Zürich], which are derived from a product of the BCG polynomial with another polynomial of the same degree. New methods introduced in this paper are CS-CGSTAB (composite step applied to Bi-CGSTAB) and a more stable variant of this, CS-CGSTAB2, which handles a possible additional breakdown problem due to the Bi-CGSTAB process in the case where A is skew symmetric. CS-CGSTAB2 can be viewed as an improvement over the Bi-CGSTAB(l) algorithm (Sleijpen and Fokkema [*ETNA*, 1 (1993), pp. 11–32]) with $l = 2$ in that although Bi-CGSTAB(2) is designed to cure the skew-symmetric breakdown, it does not handle pivot breakdown as CS-CGSTAB2 does. The new methods require only a minor modification to the existing product methods. Moreover, the sizes of the steps taken in our methods can vary as opposed to fixed step methods like Bi-CGSTAB(l) and Bi-CGSTAB2. Our strategy for deciding whether to skip a step does not involve any machine dependent parameters and is designed to skip near breakdowns as well as produce smoother iterates. Numerical experiments show that the new methods do produce improved performance over those without composite step on practical problems. Furthermore, we extend the "best approximation" result in [*Numer. Algorithms*, 7 (1994), pp. 1–16] to obtain convergence proofs for CGS and Bi-CGSTAB and their composite step stabilized versions.

1. Introduction.

The biconjugate gradient (BCG) algorithm [21] is the "natural" generalization of the classical conjugate gradient method [19] to nonsymmetric linear systems

$$Ax = b, \tag{1}$$

where $A \in R^{N \times N}$. It is an attractive method because of its simplicity and its good practical convergence properties. Unfortunately, one of its drawbacks is that it requires multiplications with the transpose matrix A^T. Methods have been developed which overcome this by computing residuals characterized by a product of the BCG residual polynomial with another polynomial of equal degree. Hence, we term the class of these algorithms *product methods.*

The conjugate gradients squared (CGS) algorithm (Sonneveld [26]) is a product method whose residuals can be written $r_n^{CGS} = \phi_n^2(A)r_0$, where $\phi_n(A)r_0$ is the residual from the standard BCG method. However, as discussed in [29], the convergence behavior of CGS can sometimes be irregular (i.e., $\|r_i^{CGS}\|$ can vary wildly with i). This is due to the fact that if $\phi_n(A)$ is viewed as a reduction operator applied twice to r_0, since $\phi_n(A)$ is quite dependent on the initial residual r_0, it may be possible that it is not a reduction for any other vector, not even for $\phi_n(A)r_0$ itself.

The Bi-CGSTAB algorithm [28] due to Van der Vorst attempts to stabilize this by multiplying the BCG polynomial $\phi_n(A)$, instead, by another polynomial of equal degree,

$$\tau_n(A) = (I - \omega_1 A)(I - \omega_2 A) \cdots (I - \omega_n A), \tag{2}$$

where the ω_i's are chosen to locally minimize the residual by a steepest descent method. Thus, by computing residuals $r_n^{Bi\text{-}CGSTAB} = \tau_n(A)\phi_n(A)r_0$, we obtain a more smoothly converging algorithm.

Unfortunately, problems arise in this method if we encounter a matrix A having complex eigenvalues with large imaginary parts. Since τ_n has only real zeros, it is difficult to accurately handle such eigenvalues. Thus, the Bi-CGSTAB2 algorithm (Gutknecht [18]) was developed to overcome this by performing two steps of Bi-CGSTAB at a time to allow for pairs of complex conjugate zeros but doing the local minimization at the nth step over the two degrees of freedom in ω_n and ω_{n-1}. Bi-CGSTAB2, then, is also a product method.

In the case that A is (nearly) skew symmetric, however, Bi-CGSTAB2 will suffer (near) breakdown due to the τ_{n-1} polynomial. The Bi-CGSTAB(2) method (a case of the Bi-CGSTAB(l) algorithm by Sleijpen and Fokkema [25] when $l = 2$) cures this by not involving τ_{n-1} in the intermediate step.

Since all of the product methods mentioned above involve the BCG residual polynomial ϕ_n, they not only inherit the good properties of BCG, but they also take on some of the problems of BCG. Specifically, it is well known that BCG suffers numerical breakdowns (attempts to divide by zero). There are two different possibilities of breakdown in the algorithm and many methods have been designed to cure them by "looking ahead" to avoid computing iterates where a breakdown can be predicted. The spectrum of these methods ranges from simple modifications of BCG to handle only one of the breakdowns to more complex algorithms which provide total breakdown protection using a variable look-ahead step. (See, e.g., [3, 5, 7, 8, 14, 16, 17, 20, 24].)

In this paper, we consider the *composite step* technique (Bank and Chan [2, 3]) which cures one of the breakdowns (assuming the other one does not occur) by simply looking ahead only one step when a (near) breakdown occurs. This technique is attractive because it does not require user-specified tolerance parameters or variable step sizes, and it is accomplished with only a minimal modification of the standard BCG algorithm. Moreover, the composite step technique can easily be extended to product methods. For example, the composite step CGS (CSCGS) algorithm was developed by Chan and Szeto in [9], and in this paper we show how composite step can be applied to Bi-CGSTAB.

In [3], Bank and Chan also prove a "best approximation" result which establishes a bound on the error of BCG. Here, we extend this result to prove convergence results for CGS, Bi-CGSTAB, and their composite step variants since these product methods all involve the BCG polynomial ϕ_n.

Section 2 describes in detail the composite step idea as originally presented for BCG and in §3 this is extended to Bi-CGSTAB yielding the method CS-CGSTAB. We emphasize in this section the strategy used to decide when to take a look-ahead composite step. We note that this stepping strategy not only skips exact breakdowns but is also designed to yield smoother residuals and does not require any user-specified tolerance parameters. A variant of this method, CS-CGSTAB2, which is a way of combining composite step with an idea from Bi-CGSTAB2, is presented in §4. The purpose of this variant is to cure additional breakdowns that may occur due to instability in the Bi-CGSTAB steepest descent polynomial in a manner similar to Bi-CGSTAB(l) with $l = 2$. The advantage is that our method cures pivot breakdowns as well. In addition, the step sizes in our new methods can vary as opposed to steps of fixed size in Bi-CGSTAB2 and Bi-CGSTAB(l). In §5, we show some numerical examples which compare these methods and show the advantages over their noncomposite step counterparts. Finally, §6 details the proofs for convergence of CGS, Bi-CGSTAB, and their composite step variants.

2. The CS idea: CSBCG. It is well known that the BCG method [19] is closely related to the nonsymmetric Lanczos process for computing the basis for the Krylov subspaces $K_n(r_0)$ and $K_n^*(\tilde{r}_0)$, defined as follows:

$$K_n(r_0) \equiv \text{span}\{r_0, Ar_0, \ldots, A^{n-1}r_0\}, \tag{3}$$

$$K_n^*(\tilde{r}_0) \equiv \text{span}\{\tilde{r}_0, A^T\tilde{r}_0, \ldots, (A^T)^{n-1}\tilde{r}_0\}. \tag{4}$$

The BCG iterates are defined by a Galerkin method on the associated Krylov subspaces. Given initial guesses of x_0 and $\tilde{x}_0$ to the solutions of (1) and an auxiliary system, $A^T\tilde{x} = \tilde{b}$, BCG produces iterates $x_n = x_0 + y_n$ and $\tilde{x}_n = \tilde{x}_0 + \tilde{y}_n$, with corresponding residuals of the form $r_n = b - Ax_n$ and $\tilde{r}_n = \tilde{b} - A^T\tilde{x}_n$, where $y_n \in K_n(r_0)$ and $\tilde{y}_n \in K_n^*(\tilde{r}_0)$, and such that the following Galerkin conditions are satisfied:

$$r_n \perp K_n^*(\tilde{r}_0), \qquad \tilde{r}_n \perp K_n(r_0). \tag{5}$$

If we define $\bar{K}_n$, $\bar{K}_n^*$ to be matrices whose columns are as given in (3) and (4) and span the Krylov spaces $K_n(r_0)$ and $K_n^*(\tilde{r}_0)$, respectively, condition (5) implies that the BCG iterates $x_n = x_0 + \bar{K}_n v_n$ are defined by the solution to the linear system $(\bar{K}_n^*)^T A\bar{K}_n v_n = (\bar{K}_n^*)^T r_0$. We note that the iterate x_n exists whenever the Hankel moment matrix

$$H_n^{(1)} = (\bar{K}_n^*)^T A\bar{K}_n = \begin{pmatrix} \mu_1 & \mu_2 & \cdots & \mu_n \\ \mu_2 & \mu_3 & \cdots & \mu_{n+1} \\ \vdots & \vdots & & \vdots \\ \mu_n & \mu_{n+1} & \cdots & \mu_{2n-1} \end{pmatrix},$$

where $\mu_i \equiv \tilde{r}_0^T A^i r_0$, is nonsingular.

In the standard BCG algorithm [21, 13], there are two possible kinds of numerical breakdowns (attempts to divide by zero): (1) $\sigma_n = \tilde{p}_n^T Ap_n = 0$, where p_n and $\tilde{p}_n$ are the BCG search directions *(pivot breakdown)*, and (2) $\rho_n = \tilde{r}_n^T r_n = 0$, but $r_n \neq 0$ *(Lanczos breakdown)*.[1] Although such exact breakdowns are very rare in practice, near breakdowns can cause severe numerical instability.

We term the first kind of breakdown a *pivot breakdown* because it is due to the nonexistence of the residual polynomial implicitly caused by encountering a zero pivot in the factorization of the tridiagonal matrix generated in the underlying Lanczos process. In terms of formally orthogonal polynomials [5], the BCG polynomial ϕ_n (defined from $r_n = \phi_n(A)r_0$) exists and is unique if and only if the $H_n^{(1)}$ is nonsingular. In other words, a pivot breakdown will occur at the nth iteration of the BCG algorithm if $\det(H_n^{(1)}) = 0$.

The second source of breakdown, *Lanczos breakdown*, is directly related to the breakdown of the underlying Lanczos process and is tied to the singularity of another Hankel moment matrix $H_n^{(0)}$ [17] defined by

$$H_n^{(0)} \equiv (\bar{K}_n^*)^T \bar{K}_n = \begin{pmatrix} \mu_0 & \mu_1 & \cdots & \mu_{n-1} \\ \mu_1 & \mu_2 & \cdots & \mu_n \\ \vdots & \vdots & & \vdots \\ \mu_{n-1} & \mu_n & \cdots & \mu_{2n-2} \end{pmatrix}.$$

[1] In other literature, what we term the *pivot* and *Lanczos* breakdowns are also known as *true* and *ghost* breakdowns [6], *Galerkin* and *serious Lanczos* breakdowns [14], and *hard* and *soft* breakdowns [20].

There are many methods designed to handle pivot breakdowns (see, e.g., [3, 14, 17]), as well as methods which cure both types of breakdown (see, e.g., [5, 7, 8, 14, 15, 16, 20, 24]). Although the step size needed to overcome an exact Lanczos breakdown can be computed in principle, these methods can unfortunately be quite complicated for handling near breakdowns since the sizes of the look-ahead steps are variable (indeed, the breakdowns can be *incurable*).

The CSBCG algorithm (Bank and Chan [2, 3]) is an alternative which cures only the pivot breakdown (assuming no Lanczos breakdowns) by "looking ahead" in $H_n^{(1)}$ and not computing x_n where it is not defined. Looking ahead, in general, means that we build $H_i^{(1)}$ until it is no longer singular and we have an iterate $x_{n+m}, m \geq 1$. In CSBCG, this is done with a simple modification of BCG which needs only a maximum look-ahead step size of $m = 2$ to eliminate the (near) breakdown and to smooth the sometimes erratic convergence of BCG. It was shown in [2, Lem. 4.3] that only two steps are needed if we assume no Lanczos breakdown, but this can also be seen in the relationship between the two Hankel matrices defined above: assuming that $\det(H_n^{(0)}) \neq 0$ for all n, then no two consecutive principal submatrices of $H_n^{(1)}$ can be singular. (The structure of these Hankel determinants was studied in detail by Draux [10].) Thus, instead of a more complicated (but less prone to breakdown) version, CSBCG cures only one kind of breakdown, but does so with a minimal modification to the usual implementation of BCG in the hope that its empirically observed stability will be inherited [27].

Next, we shall briefly review some of the details of CSBCG. Suppose that in running the BCG algorithm we encounter a situation where $\sigma_n = 0$ at step n and, therefore, the values $x_{n+1}, \tilde{x}_{n+1}, r_{n+1}, \tilde{r}_{n+1}$ cannot be defined. The composite step approach is to overcome this problem by skipping the $n+1$ update and computing the quantities in step $n+2$ by using scaled versions of r_{n+1} and $\tilde{r}_{n+1}$, which do not require divisions by σ_n. More specifically, we define the auxiliary vector:

$$z_{n+1} \equiv \sigma_n r_{n+1} = \sigma_n r_n - \rho_n A p_n \in K_{n+2}(r_0); \tag{6}$$

z_{n+1} and its counterpart $\tilde{z}_{n+1} \equiv \sigma_n \tilde{r}_{n+1}$ exist even if $\sigma_n = 0$ and, thus, can be used in defining x_{n+2}:

$$x_{n+2} = x_n + [p_n, z_{n+1}] f_n,$$

with corresponding residual and search direction

$$r_{n+2} = r_n - A[p_n, z_{n+1}] f_n, \tag{7}$$

$$p_{n+2} = r_{n+2} + [p_n, z_{n+1}] g_n, \tag{8}$$

where $f_n, g_n \in R^2$, and similarly for $\tilde{x}_{n+2}, \tilde{r}_{n+2}, \tilde{p}_{n+2}, \tilde{f}_n$, and $\tilde{g}_n$.

To solve for the unknowns $f_n = (f_n^{(1)}, f_n^{(2)})^T$ and $g_n = (g_n^{(1)}, g_n^{(2)})^T$, we impose the Galerkin condition and conjugacy condition of BCG which result in two 2×2 linear systems:

$$\begin{bmatrix} \tilde{p}_n^T A p_n & \tilde{p}_n^T A z_{n+1} \\ \tilde{z}_{n+1}^T A p_n & \tilde{z}_{n+1}^T A z_{n+1} \end{bmatrix} \begin{bmatrix} f_n^{(1)} \\ f_n^{(2)} \end{bmatrix} = \begin{bmatrix} \tilde{p}_n^T r_n \\ \tilde{z}_{n+1}^T r_n \end{bmatrix}, \tag{9}$$

$$\begin{bmatrix} \tilde{p}_n^T A p_n & \tilde{p}_n^T A z_{n+1} \\ \tilde{z}_{n+1}^T A p_n & \tilde{z}_{n+1}^T A z_{n+1} \end{bmatrix} \begin{bmatrix} g_n^{(1)} \\ g_n^{(2)} \end{bmatrix} = - \begin{bmatrix} \tilde{p}_n^T A r_{n+2} \\ \tilde{z}_{n+1}^T A r_{n+2} \end{bmatrix}. \tag{10}$$

These systems can be solved simply, as shown in [3], making it possible to compute x_{n+2}, $\tilde{x}_{n+2}, r_{n+2}, \tilde{r}_{n+2}$ and, thus, advance from step n to step $n+2$. The CSBCG algorithm, then, is simply the combination of the 1×1 and 2×2 steps.

3. Composite step Bi-CGSTAB. We now apply the composite step idea to handle the pivot breakdowns that occur in the Bi-CGSTAB method proposed by Van der Vorst [28]. Since the Bi-CGSTAB residual polynomials are formed from multiplying the BCG polynomial ϕ_n with another polynomial τ_n of the form (2), we can use the subset of well-defined ϕ_i's from CSBCG to multiply with τ_n instead. To do this, we first define

$$p_n^{BCG} = \phi_n(A)r_0, \quad z_{n+1}^{BCG} = \xi_{n+1}(A)r_0.$$

The CS-CGSTAB polynomials, then, take on the form

$$r_n^{CS\text{-}CGSTAB} = \tau_n(A)\phi_n(A)r_0, \quad p_n^{CS\text{-}CGSTAB} = \tau_n(A)\psi_n(A)r_0.$$

In the case of a 1 × 1 step, we simply use the Bi-CGSTAB update. For the 2 × 2 composite step, we will need to evaluate

$$\begin{aligned} r_{n+2}^{CS\text{-}CGSTAB} &= \tau_{n+2}\phi_{n+2}r_0 \\ &= (I - \omega_{n+2}A)(I - \omega_{n+1}A)\tau_n\phi_{n+2}r_0 \end{aligned} \tag{11}$$

and

$$\begin{aligned} p_{n+2}^{CS\text{-}CGSTAB} &= \tau_{n+2}\psi_{n+2}r_0 \\ &= (I - \omega_{n+2}A)(I - \omega_{n+1}A)\tau_n\psi_{n+2}r_0 \end{aligned} \tag{12}$$

using the quantities obtained from the nth step: $\tau_n\phi_n$ and $\tau_n\psi_n$. We first show how to compute the polynomials $\tau_n\phi_{n+2}$ and $\tau_n\psi_{n+2}$ appearing in (11)–(12). We use the CSBCG relationships from (6)–(8):

$$\xi_{n+1}(\vartheta) = \sigma_n\phi_n - \rho_n\vartheta\psi_n, \tag{13}$$

$$\phi_{n+2}(\vartheta) = \phi_n - \vartheta\psi_n f_n^{(1)} - \vartheta\xi_{n+1}f_n^{(2)}, \tag{14}$$

$$\psi_{n+2}(\vartheta) = \phi_{n+2} + \psi_n g_n^{(1)} + \xi_{n+1}g_n^{(2)} \tag{15}$$

and multiply by the τ_n polynomial to evaluate the needed quantities:

$$\tau_n(\vartheta)\xi_{n+1}(\vartheta) = \sigma_n\tau_n\phi_n - \rho_n\vartheta\tau_n\psi_n, \tag{16}$$

$$\begin{aligned} \tau_n(\vartheta)\phi_{n+2}(\vartheta) &= \tau_n(\phi_n - \vartheta\psi_n f_n^{(1)} - \vartheta\xi_{n+1}f_n^{(2)}) \\ &= \tau_n\phi_n - \vartheta\tau_n\psi_n f_n^{(1)} - \vartheta\tau_n\xi_{n+1}f_n^{(2)}, \end{aligned} \tag{17}$$

$$\begin{aligned} \tau_n(\vartheta)\psi_{n+2}(\vartheta) &= \tau_n(\phi_{n+2} + \psi_n g_n^{(1)} + \xi_{n+1}g_n^{(2)}) \\ &= \tau_n\phi_{n+2} + \tau_n\psi_n g_n^{(1)} + \tau_n\xi_{n+1}g_n^{(2)}. \end{aligned} \tag{18}$$

We now show how to compute the unknowns f_n and g_n in (17) and (18). The CSBCG residual r_{n+2} in (7) and search direction p_{n+2} in (8) are, respectively, orthogonal and A-conjugate to $K_{n+1}^*(\tilde{r}_0)$ [2]. By imposing orthogonality and A-conjugacy conditions on two specific vectors $\tau_n(A^T)\tilde{r}_0 \in K_{n+1}^*(\tilde{r}_0)$ and $A^T\tau_n(A^T)\tilde{r}_0 \in K_{n+1}^*(\tilde{r}_0)$, we obtain two linear systems which give f_n and g_n.

Specifically, by writing (7) in polynomial form (14) and taking an inner product with $\tau_n(A^T)\tilde{r}_0$, we obtain the relation

$$\begin{aligned} 0 &= (\tau_n(A^T)\tilde{r}_0, \phi_{n+2}(A)r_0) \\ &= (\tilde{r}_0, \tau_n(A)\phi_{n+2}(A)r_0) \\ &= (\tilde{r}_0, [\tau_n\phi_n - A\tau_n\psi_n f_n^{(1)} - A\tau_n\xi_{n+1}f_n^{(2)}](A)r_0). \end{aligned}$$

Similarly, for the A-conjugacy of the search direction (8),

$$\begin{aligned} 0 &= (A^T\tau_n(A^T)\tilde{r}_0, \psi_{n+2}r_0) \\ &= (\tilde{r}_0, A\tau_n(A)\psi_{n+2}(A)r_0) \\ &= (\tilde{r}_0, [A\tau_n\phi_{n+2} + A\tau_n\psi_n g_n^{(1)} + A\tau_n\xi_{n+1}g_n^{(2)}](A)r_0). \end{aligned}$$

We derive two similar relations by imposing the orthogonality and A-conjugacy conditions on $A^T\tau_n(A^T)\tilde{r}_0$. Combining the four relations, we obtain the following two 2×2 linear systems:

$$\begin{bmatrix} (\tilde{r}_0, \vartheta\tau_n\psi_n r_0) & (\tilde{r}_0, \vartheta\tau_n\xi_{n+1}r_0) \\ (\tilde{r}_0, \vartheta^2\tau_n\psi_n r_0) & (\tilde{r}_0, \vartheta^2\tau_n\xi_{n+1}r_0) \end{bmatrix} \begin{bmatrix} f_n^{(1)} \\ f_n^{(2)} \end{bmatrix} = \begin{bmatrix} (\tilde{r}_0, \tau_n\phi_n r_0) \\ (\tilde{r}_0, \vartheta\tau_n\phi_n r_0) \end{bmatrix}, \tag{19}$$

$$\begin{bmatrix} (\tilde{r}_0, \vartheta\tau_n\psi_n r_0) & (\tilde{r}_0, \vartheta\tau_n\xi_{n+1}r_0) \\ (\tilde{r}_0, \vartheta^2\tau_n\psi_n r_0) & (\tilde{r}_0, \vartheta^2\tau_n\xi_{n+1}r_0) \end{bmatrix} \begin{bmatrix} g_n^{(1)} \\ g_n^{(2)} \end{bmatrix} = \begin{bmatrix} (\tilde{r}_0, \vartheta\tau_n\phi_{n+2}) \\ (\tilde{r}_0, \vartheta^2\tau_n\phi_{n+2}) \end{bmatrix}. \tag{20}$$

These are easily solved since all of the entries in the 2×2 matrix and the right-hand sides can be obtained from (16), (17), and quantities from the nth step. Thus, we can update (17) and (18). Note that the linear systems (19) and (20) can be shown to be nonsingular in the case where $\sigma_n = 0$ and the underlying Lanczos process does not break down. (See the Appendix.) This verifies that a 2×2 step is always sufficient for skipping over the pivot breakdown.

The next step in evaluating (11) and (12) is to choose ω_{n+1} and ω_{n+2} to satisfy some local minimization property. In the case of a 1×1 step, we imitate the Bi-CGSTAB update steps. Specifically, ω_{n+1} is chosen to minimize the norm of $r_{n+1} = \tau_{n+1}\phi_{n+1}r_0 = (I - \omega_{n+1}A)\tau_n\phi_{n+1}r_0$. For the 2×2 step, we employ the same steepest descent rule to compute ω_{n+1} and ω_{n+2} by minimizing $\|r_{n+1}\|$ and $\|r_{n+2}\|$. Note that r_{n+1} is not available in a 2×2 step, but we can use a scaled version for minimization. To do this, let $u_{n+1} = \tau_n\xi_{n+1}r_0 \equiv \frac{1}{\sigma_n}\tau_n\phi_{n+1}r_0$. Then we can write

$$r_{n+1} = \tau_{n+1}\phi_{n+1}r_0 = (I - \omega_{n+1}A)\tau_n\phi_{n+1}r_0 = (I - \omega_{n+1}A)\frac{1}{\sigma_n}\, u_{n+1}. \tag{21}$$

The vector u_{n+1} is already computed in the CS-CGSTAB algorithm (see relation (16)) and, thus, we minimize

$$\|r_{n+1}^2\| = \frac{1}{\sigma_n^2}\left((I - \omega_{n+1}A)u_{n+1}\right)^T\left((I - \omega_{n+1}A)u_{n+1}\right)$$

by choosing $\omega_{n+1} = (Au_{n+1}, u_{n+1})/(Au_{n+1}, Au_{n+1})$, an orthogonal projection of u_{n+1} onto Au_{n+1}.

Similarly, let

$$u_{n+2} \equiv \tau_{n+1}\phi_{n+2}r_0 = (I - \omega_{n+1}A)\tau_n\phi_{n+2}r_0 \tag{22}$$

which can be computed because $\tau_n\phi_{n+2}$ is available from relation (17). Then write

$$r_{n+2} = \tau_{n+2}\phi_{n+2}r_0 = (I - \omega_{n+2}A)\tau_{n+1}\phi_{n+2}r_0 = (I - \omega_{n+2}A)u_{n+2} \tag{23}$$

and minimize

$$\|r_{n+2}^2\| = \left((I - \omega_{n+2}A)u_{n+2}\right)^T\left((I - \omega_{n+2}A)u_{n+2}\right)$$

by choosing

$$\omega_{n+2} = (Au_{n+2}, u_{n+2})/(Au_{n+2}, Au_{n+2}). \tag{24}$$

Finally, in running CS-CGSTAB, we must be able to recover the BCG constants ρ_n^{BCG} and σ_n^{BCG} in order to update the BCG polynomial part of the residual. In [28], Van der Vorst defined the Bi-CGSTAB constant

$$\rho_n^{Bi\text{-}CGSTAB} = (\tilde{r}_0, r_n^{Bi\text{-}CGSTAB})$$

and showed its relation to

$$\rho_n^{BCG} = (\tilde{r}_n^{BCG}, r_n^{BCG}).$$

Using the property that, by construction, $\phi_n(A)r_0$ is orthogonal with respect to all vectors $\chi_{n-1}(A^T)\tilde{r}_0$, where χ_{n-1} is an arbitrary polynomial of degree at most $n-1$, one gets

$$\begin{aligned}
\rho_n^{BCG} &= (\phi_n(A^T)\tilde{r}_0, \phi_n(A)r_0)\\
&= \alpha_0 \ldots \alpha_{n-1}((-A^T)^n\tilde{r}_0, \phi_n(A)r_0),\\
\rho_n^{Bi\text{-}CGSTAB} &= (\tilde{r}_0, \tau_n(A)\phi_n(A)r_0)\\
&= (\tau_n(A^T)\tilde{r}_0, \phi_n(A)r_0)\\
&= \omega_1 \ldots \omega_n((-A^T)^n\tilde{r}_0, \phi_n(A)r_0).
\end{aligned}$$

The relationship between them follows:

$$\rho_{n+1}^{BCG} = \frac{\alpha_0 \ldots \alpha_n}{\omega_1 \ldots \omega_{n+1}} \rho_{n+1}^{Bi\text{-}CGSTAB}, \quad \text{where } \alpha_n = \frac{\rho_n^{BCG}}{\sigma_n^{BCG}}.$$

If we let $\mu_n = (\alpha_0 \ldots \alpha_{n-1})/(\omega_1 \ldots \omega_n)$, this reduces to the update formula

$$\rho_{n+1}^{BCG} = \mu_{n+1}\rho_{n+1}^{Bi\text{-}CGSTAB} = \mu_n \left(\frac{\rho_n^{BCG}}{\sigma_n^{BCG}\omega_{n+1}} \right) \rho_{n+1}^{Bi\text{-}CGSTAB}.$$

In a 2 × 2 step, we determine ρ_{n+2}^{CSBCG} similarly. First we use relation (14):

$$\begin{aligned}
\rho_{n+2}^{CSBCG} &= (\phi_{n+2}(A^T)\tilde{r}_0, \phi_{n+2}(A)r_0)\\
&= ((\phi_n(A^T) - \alpha_n A^T \psi_n(A^T) - \alpha_{n+1}A^T\xi_{n+1}(A^T))\tilde{r}_0, \phi_{n+2}(A)r_0).
\end{aligned} \tag{25}$$

Then the fact that $\phi_{n+2}r_0$ is orthogonal to all vectors $\chi_{n+1}(A^T)\tilde{r}_0$ implies that the inner product (25) picks out the coefficient of the highest-order term of the $n+2$ degree polynomial that ϕ_{n+2} is being orthogonalized against. In this case, the coefficient of the highest-order term for the polynomial $\xi_{n+1}(A^T) = \sigma_n^{BCG}\phi_{n+1}(A^T)$ is $\sigma_n^{BCG}\alpha_0 \ldots \alpha_n$, so (25) reduces to

$$\rho_{n+2}^{CSBCG} = -\alpha_0 \ldots \alpha_{n+1}\sigma_n^{BCG}((-A^T)^{n+2}\tilde{r}_0, \phi_{n+2}(A)r_0)$$

which leads to the update formula

$$\rho_{n+2}^{CSBCG} = \mu_{n+2}\rho_{n+2}^{CS\text{-}CGSTAB} = -\mu_n \left(\frac{\rho_n^{CSBCG}\alpha_{n+1}}{\omega_{n+1}\omega_{n+2}} \right) \rho_{n+2}^{CS\text{-}CGSTAB}. \tag{26}$$

The update for $\sigma_n^{BCG} \equiv (\psi_n(A^T)\tilde{r}_0, A\psi_n(A)r_0)$ can be calculated similarly. We define $\sigma_n^{CS\text{-}CGSTAB} \equiv (\tilde{r}_0, A\tau_n(A)\psi_n(A)r_0) = (\tilde{r}_0, Ap_n^{CS\text{-}CGSTAB})$ and obtain the analogous update formula

$$\sigma_{n+2}^{CSBCG} = \mu_{n+2}\sigma_{n+2}^{CS\text{-}CGSTAB}. \tag{27}$$

TABLE 1
Notation for CS-CGSTAB.

Vector	Polynomial	Where/how derived	Where used
r_n	$\tau_n\phi_n r_0$	(11)	(16) (17) (19)
p_n	$\tau_n\psi_n r_0$	(12)	(18)
u_{n+1}	$\tau_n\xi_{n+1} r_0$	(16)	(17) (18) (21)
s_{n+2}	$\tau_n\phi_{n+2} r_0$	(17)	(11) (18) (22)
u_{n+2}	$\tau_{n+1}\phi_{n+2} r_0$	(22)	(23)
e_n	$A\tau_n\phi_n r_0$	Ar_n	(19)
q_n	$A\tau_n\psi_n r_0$	Ap_n	(16) (17) (19) (20)
y_{n+1}	$A\tau_n\xi_{n+1} r_0$	Au_{n+1}	(19) (20) (21)
t_{n+2}	$A\tau_n\phi_{n+2} r_0$	As_{n+2}	(20) (22)
y_{n+2}	$A\tau_{n+1}\phi_{n+2} r_0$	Au_{n+2}	(23)
c_n	$A^2\tau_n\psi_n r_0$	Aq_n	(19) (20)
d_{n+1}	$A^2\tau_n\xi_{n+1} r_0$	Ay_{n+1}	(19) (20)
v_{n+2}	$A^2\tau_n\phi_{n+2} r_0$	At_{n+2}	(20)
α_n	$f_n^{(1)}$	(19)	(17)
α_{n+1}	$f_n^{(2)}$	(19)	(17)
β_n	$g_n^{(1)}$	(20)	(18)
β_{n_1}	$g_n^{(2)}$	(20)	(18)

3.1. Implementation details. In Table 1, we summarize the notation we will be using in our implementation of the CS-CGSTAB algorithm. We list the vector used in the algorithm, its corresponding polynomial form, and the equations in which it is derived and used.

At every step, we must anticipate a 2 × 2 step even if we decide to take a 1 × 1 step. (The stepping strategy will be discussed in §3.2.) Recall that in one step of Bi-CGSTAB, only two matrix–vector multiplications are performed: $q_n = Ap_n$ and $y_{n+1} = Au_{n+1}$. From the third column of Table 1, we see that eight matrix–vector products are required to do a 2 × 2 step which appears to be four more than two steps of Bi-CGSTAB.

However, the total eight products can be reduced to four multiplications by precomputing certain values and absorbing them into vector updates rather than explicitly multiplying by A. Specifically, by precomputing $c_n \equiv Aq_n$, the multiplication $y_{n+1} \equiv Au_{n+1}$ can be written

$$\begin{aligned} y_{n+1} &= \sigma_n e_n - \rho_n A q_n \\ &= \sigma_n e_n - \rho_n c_n. \end{aligned}$$

Similarly, if we have $d_{n+1} \equiv Ay_{n+1}$, then the product $e_{n+1} \equiv Ar_{n+1}$ can also be evaluated without having to multiply by A:

$$\begin{aligned} e_{n+1} &= (y_{n+1} - \omega_{n+1} A y_{n+1})/\sigma_n \\ &= (y_{n+1} - \omega_{n+1} d_{n+1})/\sigma_n. \end{aligned}$$

Furthermore, $q_{n+1} \equiv Ap_{n+1}$ can also be updated:

$$\begin{aligned} q_{n+1} &= Ar_{n+1} + \beta_{n+1}(Ap_n - \omega_{n+1} A q_n) \\ &= e_{n+1} + \beta_{n+1}(q_n - \omega_{n+1} c_n). \end{aligned}$$

Thus, the 1 × 1 step can still be performed with only two (pre)multiplications with A: Aq_n and Ay_{n+1}. Moreover, by precomputing $v_{n+2} \equiv At_{n+2}$ and $q_{n+2} \equiv Ap_{n+2}$, we can update the remaining values in the 2 × 2 step in a similar fashion.

However, using this precomputing strategy to update

$$e_{n+2} \equiv Ar_{n+2} = A(I - \omega_{n+1}A)(I - \omega_{n+2}A)s_{n+2}$$

implies that we need $A^3 s_{n+2}$ which we do not have. Thus, the 2×2 step requires an additional matrix–vector multiplication: $w_{n+2} \equiv A^3 s_{n+2} = A(v_{n+2})$.

Hence, as in CSCGS, there are five matrix–vector multiplications for a 2×2 step, whereas in two steps of Bi-CGSTAB, only four are needed. This is the price we must pay for composite step. If we do not need to take many 2×2 steps in practice, this price will not be too costly.

3.2. CS-CGSTAB stepping strategy. As far as deciding when to actually take a 2×2 step, we follow the principles in [2, 3, 9]. As with these methods, CS-CGSTAB employs a practical stepping strategy that will skip over exact breakdowns using the criterion

$$\|r_{n+1}\| > \max\{\|r_n\|, \|r_{n+2}\|\}. \tag{28}$$

If this condition were met (e.g., at a near breakdown) and we performed two 1×1 steps, it would result in a "peak" in the residual convergence. By taking a 2×2 step, we skip over this and obtain a smoother, more stable method. In order to avoid unnecessary computation of $\|r_{n+2}\|$, we express condition (28) in the following algorithm.

```
If ($\|r_{n+1}\| < \|r_n\|$) then          ⟵ Condition (28a)
   choose $1 \times 1$ step
else
   if ($\|r_{n+1}\| < \|r_{n+2}\|$) then    ⟵ Condition (28b)
      choose $1 \times 1$ step
   else
      choose $2 \times 2$ step
   end
end
```

In order to avoid repeating work and to do this in a stable way, Condition (28a) can be written

$$\|(I - \omega_{n+1} A) u_{n+1}\| < |\sigma_n| \|r_n\|.$$

For Condition (28b), we first rescale the r_{n+2} update in order to estimate $\|r_{n+2}\|$ stably by letting

$$\nu_{n+2} \equiv \delta_n r_{n+2} = \delta_n (I - \omega_{n+1} A)(I - \omega_{n+2} A) s_{n+2},$$

where δ_n is the determinant of the 2×2 matrix in (19). Evaluating ν_{n+2} exactly would involve the quantity $A^2 s_{n+2}$ which would require an additional matrix–vector multiplication if we decide to take a 1×1 step. Hence, for practical purposes, we use an upper bound approximation to estimate $\|\nu_{n+2}\|$. Note that although we do not have $A^2 s_{n+2}$, the quantity $A s_{n+2}$ can be made available even if we take a 1×1 step, and it can be done without an additional matrix–vector product using the precomputed values e_n, c_n, and d_{n+1}:

$$\begin{aligned} t_{n+2} &\equiv A s_{n+2} \\ &= A(\delta_n r_n - \alpha_n q_n - \alpha_{n+1} y_{n+1}) \\ &= \delta_n e_n - \alpha_n c_n - \alpha_{n+1} d_{n+1}. \end{aligned} \tag{29}$$

Thus, we would like to estimate $\|\nu_{n+2}\| = \|\delta_n (I - \omega_{n+1} A)(I - \omega_{n+2} A) s_{n+2}\|$ using (29) and without any further matrix–vector multiplications. Our strategy is to set $\omega_{n+2} = 0$ and minimize $\|\delta_n (I - \omega_{n+1} A) s_{n+2}\|$, thereby eliminating the need to compute $A^2 s_{n+2}$. Doing this gives an upper bound estimate to $\|\nu_{n+2}\|$ which can be shown by defining

$$h(\omega_{n+1}, \omega_{n+2}) \equiv \|\delta_n (I - \omega_{n+1} A)(I - \omega_{n+2} A) s_{n+2}\|$$

and establishing the following inequality:

$$\min_{\omega_{n+1},\,\omega_{n+2}} h(\omega_{n+1}, \omega_{n+2}) \le \min_{\omega_{n+1}} h(\omega_{n+1}, 0). \tag{30}$$

The minimization problem

$$\min_{\omega_{n+1}} h(\omega_{n+1}, 0) = \min_{\omega_{n+1}} \|(I - \omega_{n+1} A) s_{n+2}\| = \min_{\omega_{n+1}} \|s_{n+2} - \omega_{n+1} t_{n+2}\|$$

is solved with $\tilde{\omega}_{n+1} = (t_{n+2}, s_{n+2})/(t_{n+2}, t_{n+2})$.

Hence, Condition (28b), $\|r_{n+1}\| < \|r_{n+2}\|$, is evaluated by the approximated condition

$$|\delta_n| \|(I - \omega_{n+1} A) u_{n+1}\| < |\sigma_n| \|\tilde{v}_{n+2}\|, \tag{31}$$

where $\|\tilde{v}_{n+2}\|$ is the estimated upper bound for $\|v_{n+2}/\delta_n\|$:

$$\|v_{n+2}/\delta_n\| < \|\tilde{v}_{n+2}\| \equiv \|s_{n+2} - \tilde{\omega}_{n+1} t_{n+2}\|. \tag{32}$$

If a 2 × 2 step is chosen, then the true v_{n+2} is evaluated. After v_{n+2} is computed, we add one final check to make sure the approximation was indeed valid. If not, we take a 1 × 1 step. In Table 2, we present the CS-CGSTAB algorithm. Note that if only 1 × 1 steps are taken, we have exactly the Bi-CGSTAB algorithm.

4. A variant of CS-CGSTAB. A problem in the CS-CGSTAB method is that additional breakdowns may occur if A is skew symmetric or near breakdowns if it has complex eigenvalues with large imaginary parts. Suppose we are at step n of the algorithm. In the case that A is skew symmetric, it can be easily checked that $\omega_{n+1} = \omega_{n+2} = 0$. The 2 × 2 step attempts to divide by the quantity $\gamma_2 = \omega_{n+1}\omega_{n+2}$ which causes a breakdown. For nearly skew symmetric A, γ_2 will be small, thus causing near breakdown and numerical instability.

This can be cured by modifying the local minimization at that particular 2 × 2 step. The idea is to require

$$\|r_{n+2}\| = \min_{\varphi \in \mathcal{P}_2} \|\varphi(A) \tau_n(A) \phi_{n+2}(A) r_0\|, \tag{33}$$

where $\mathcal{P}_2$ is the set of all polynomials of degree (at most) 2 and $\varphi(0) = 1$.

Performing this minimization over two degrees of freedom was first presented in the Bi-CGSTAB2 algorithm by Gutknecht [18]. The purpose was to cure problems that arise in the steepest descent part of Bi-CGSTAB due to eigenvalues of A in the complex spectrum that are not approximated well with (2). Hence, every other step of the Bi-CGSTAB2 method performs (33) in order to handle conjugate pairs of eigenvalues. (In the remaining steps of the Bi-CGSTAB2 algorithm, the usual Bi-CGSTAB update is taken.) The Bi-CGSTAB2 algorithm can be summarized:

$$\tau_n \phi_n \xrightarrow{\text{1-D min}} \tau_{n+1} \phi_{n+1} \xrightarrow{\text{2-D min}} \tau_{n+2} \phi_{n+2}.$$

Unfortunately, in the implementation presented in [18], the 2-D minimization steps of Bi-CGSTAB2 are computed based on the Bi-CGSTAB step immediately before them. For skew-symmetric A, this poses a similar breakdown problem to the one mentioned above because the Bi-CGSTAB step requires a division by ω_{n+1}, which will be zero in this case.

Note that Bi-CGSTAB2 is mathematically equivalent to the Bi-CGSTAB(l) algorithm due to Sleijpen and Fokkema [25] in the case where $l = 2$, but the implementation is different. Bi-CGSTAB(2) does not compute the intermediate Bi-CGSTAB residual $r_{n+1} = \tau_{n+1} \phi_{n+1} r_0$.

      $q_{n+2} = Ap_{n+2}$
      $n \leftarrow n + 2$
    End If
End While
```

Instead, it uses an intermediate basis vector $A\tau_n\phi_{n+1}r_0$ to generate the auxiliary residual $\hat{r}_{n+2} = \tau_n\phi_{n+2}r_0$. This algorithm can be summarized:

$$\tau_n\phi_n \xrightarrow{A\tau_n\phi_{n+1}} \tau_n\phi_{n+2} \xrightarrow{\text{2-D min}} \tau_{n+2}\phi_{n+2}.$$

By not involving τ_{n+1}, Bi-CGSTAB(2) will not suffer the breakdown mentioned above. However, note that it is still prone to breakdown in the BCG ϕ_{n+1} part.

We now show how to overcome this breakdown problem. Recall that CS-CGSTAB already cures the BCG pivot breakdown in step $n+1$, so all we need to do now is to show how to modify CS-CGSTAB so that it will overcome the τ_{n+1} breakdowns as well. The idea is to note that CS-CGSTAB has access to the $A\tau_n\phi_{n+1}r_0$ vector through the relationship $\xi_{n+1} = \sigma_n\phi_{n+1}$. We use it to compute the auxiliary residual $s_{n+2} = \tau_n\phi_{n+2}r_0$ to yield

$$\tau_n\phi_n \xrightarrow{A\tau_n\xi_{n+1}} \tau_n\phi_{n+2} \xrightarrow{\text{2-D min}} \tau_{n+2}\phi_{n+2}.$$

The quantity s_{n+2} is updated by (17) and the 2-D minimization step can be performed by first writing the residual

$$r_{n+2} = s_{n+2} + R\begin{bmatrix}\gamma_1\\ \gamma_2\end{bmatrix},$$

where $R = [\,As_{n+2} \quad A^2s_{n+2}\,] \equiv [\,t_{n+2} \quad v_{n+2}\,]$, and then minimizing $\|r_{n+2}\|$ by solving the system

$$R^TR\begin{bmatrix}\gamma_1\\ \gamma_2\end{bmatrix} = -R^Ts_{n+2}. \tag{34}$$

In the case where A is skew symmetric, the attempt to divide by $\gamma_2 = \omega_{n+1}\omega_{n+2}$ in the 2×2 step can now be performed without breakdown. In particular, if $A = -A^T$, then $\gamma_2 \equiv -(v_{n+2}, s_{n+2})/(v_{n+2}, v_{n+2}) \neq 0$ because the numerator $v_{n+2}^Ts_{n+2} = s_{n+2}^TA^2s_{n+2} > 0$.

We can now form a variant of the CS-CGSTAB algorithm which follows the former method in allowing 1×1 and 2×2 steps and differs only in the 2×2 step, performing instead the minimization over the two degrees of freedom described above. We use the same stepping strategy and approximation scheme to estimate $\|v_{n+2}\|$. We incorporate this into the new variant CS-CGSTAB2. This is a more stable implementation which will not breakdown when A is skew symmetric. Rather, in this case, provided there are no pivot breakdowns, it will always take 2×2 steps and will be equivalent to the Bi-CGSTAB(2) method.

In fact, when only 2×2 steps are taken, the methods Bi-CGSTAB, Bi-CGSTAB(2), CS-CGSTAB, and CS-CGSTAB2 are all mathematically equivalent. In general, the composite step methods differ because they are variable step methods.

Note that in CS-CGSTAB2, the composite step is used to skip over breakdowns in the τ_{n+1} polynomial as well as ϕ_{n+1}. However, if there was no ϕ_{n+1} breakdown, and we took a 2×2 step in CS-CGSTAB2, then it is still possible that there could be pivot breakdown due to ϕ_{n+2}. In principle, we can solve this by applying the composite step idea to Bi-CGSTAB2 and taking a 3×3 step when we foresee possible pivot breakdown because ϕ_{n+3} exists under our assumption of $\det(H^{(0)}) \neq 0$. However, we will not pursue this in this paper.

5. Numerical experiments. All experiments are run in MATLAB 4.0 on a SUN SPARCstation with machine precision of about 10^{-16}. In most cases, as expected, composite step methods behave similarly to their noncomposite step counterparts. In terms of the number of iterations they take to converge, composite step methods are never worse in almost all cases and, in terms of the number of matrix–vector products performed, the cost is minimal. Here, we present a few selected examples where composite step does make a significant improvement.

Example 1. We begin the numerical experiments with a contrived example to illustrate the superior numerical stability of composite step methods over those without composite steps. Let A be a modification of an example found in [23]:

$$A = \begin{pmatrix} M & & \\ & \ddots & \\ & & M\end{pmatrix} \in R^{N\times N}, \quad \text{where } M = \begin{pmatrix}\epsilon & 1\\ -1 & 2\end{pmatrix};$$

TABLE 3
Example 1.

Rel. error in the solution after two steps ($N = 40$)				
ϵ	Bi-CGSTAB	Bi-CGSTAB2	Bi-CGSTAB(2)	CGS
10^{-4}	1.5×10^{-12}	8.6×10^{-13}	2.5×10^{-16}	3.6×10^{-8}
10^{-8}	4.9×10^{-9}	4.7×10^{-9}	1.0×10^{-9}	2.2×10^{0}
10^{-12}	3.0×10^{-5}	7.3×10^{-4}	2.5×10^{-4}	3.0×10^{8}
CS-CGSTAB, CS-CGSTAB2, and CSCGS all converge with errors $\leq 10^{-16}$.				

TABLE 4
Example 2.

Rel. error in the solution after two steps ($N = 40$)					
ϵ	Bi-CGSTAB	Bi-CGSTAB2	Bi-CGSTAB(2)	CGS	CS-CGSTAB
10^{-4}	2.1×10^{-12}	2.9×10^{-13}	2.9×10^{-13}	2.5×10^{-8}	2.3×10^{-13}
10^{-8}	2.0×10^{-8}	bd	1.0×10^{-8}	1.0×10^{0}	7.6×10^{-10}
10^{-12}	1.2×10^{-4}	2.7×10^{1}	1.0×10^{-12}	1.3×10^{8}	bd
bd: Encountered breakdown					
CS-CGSTAB2 converged each time with error $\leq 10^{-16}$.					

i.e., A is an $N \times N$ block diagonal with 2×2 blocks, and $N = 40$. By choosing $b = (1 \;\; 0 \;\; 1 \;\; 0 \;\; \ldots)^T$ and a zero initial guess, we set $\sigma_0 = \epsilon$ and, thus, we can foresee numerical problems with BCG polynomial-based methods such as Bi-CGSTAB, Bi-CGSTAB2, and CGS when ϵ is small. Although these methods converge in two steps in exact arithmetic when $\epsilon \neq 0$, in finite precision, convergence gets increasingly unstable as ϵ decreases. Table 3 shows the relative error in the solution after two steps of BCG, CGS, and Bi-CGSTAB. Note that the loss of significant digits in BCG and Bi-CGSTAB is approximately proportional to $O(\epsilon^{-1})$ and the loss of digits in CGS is proportional to $O(\epsilon^{-2})$. The accuracy of CS-CGSTAB, CS-CGSTAB2, and CSCGS, the composite step CGS algorithm [9], is insensitive to ϵ and these three methods all converge in two steps with errors less than or equal to 10^{-16}.

Example 2. Next we alter Example 1 slightly to show the advantage of CS-CGSTAB2 over CS-CGSTAB. Recall that CS-CGSTAB2 was developed to overcome breakdowns in cases where A is (nearly) skew symmetric. Hence, if we change the last example so that

$$M = \begin{pmatrix} \epsilon & 1 \\ -1 & \epsilon \end{pmatrix},$$

we see that as ϵ gets small, CS-CGSTAB exhibits poor numerical results, whereas CS-CGSTAB2 converges in the first 2×2 step as in Example 1 (see Table 4).

To emphasize the point made in this example, we pick a random skew-symmetric matrix with dimension $N = 20$ and a random right-hand side. All the methods mentioned above either diverge or break down except for CS-CGSTAB2 and BiCGSTAB(2), which achieve residual tolerance 10^{-11} in 24 iterations.

Example 3. We now show an example using a matrix which comes from the Harwell–Boeing set of sparse test matrices [11]. It is a discretization of the convection-diffusion equation:

$$L(u) = -\Delta u + 100(xu_x + yu_y) - 100u$$

on the unit square for a 63×63 grid. We use a random right-hand side, zero initial guess, and no preconditioning. Figure 1 plots the true residual norm for Bi-CGSTAB, Bi-CGSTAB(2), CS-CGSTAB, and CS-CGSTAB2 versus the number of iterations taken, and Figure 2 shows

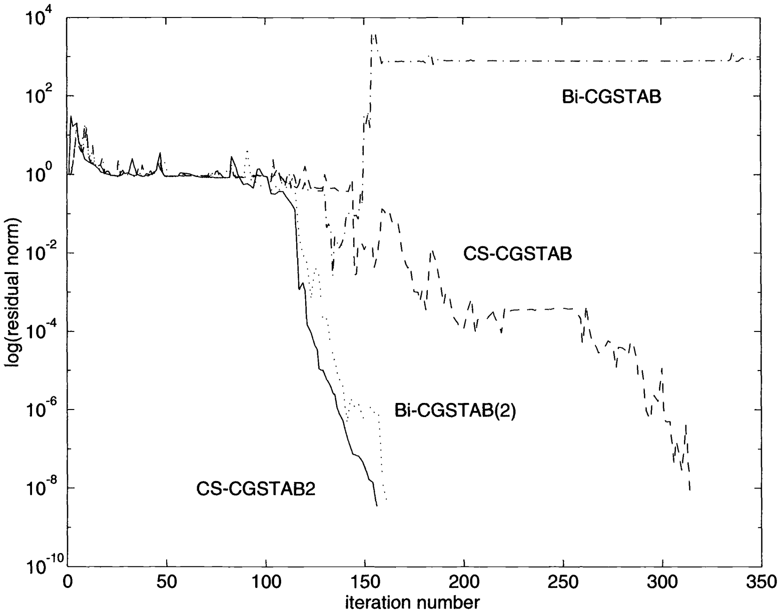

FIG. 1. *Example* 3.

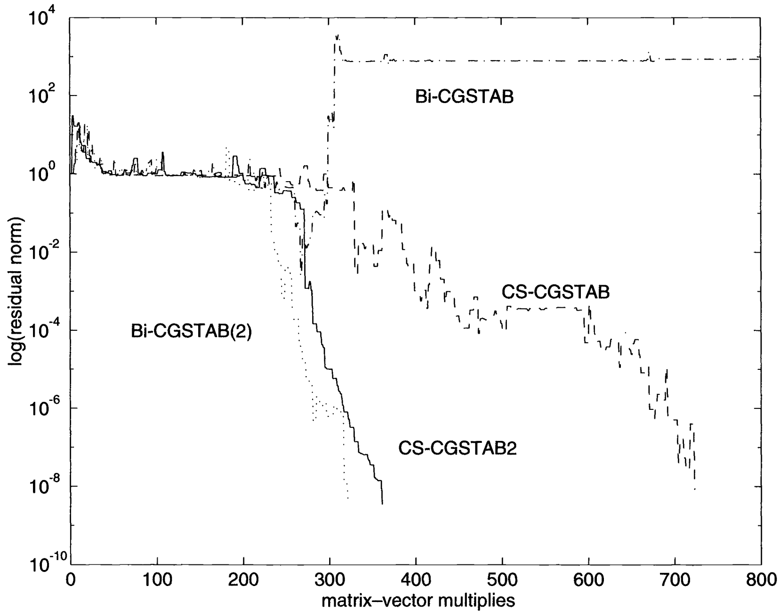

FIG. 2. *Example* 3.

the number of matrix–vector products. The random right-hand side that was used yields some numerical instability for Bi-CGSTAB due to a near pivot breakdown around step 135 which results in convergence stagnation. Taking composite steps in this case overcomes this problem. We also see the advantage of the 2-D minimization steps in the convergence behavior of Bi-CGSTAB(2) and CS-CGSTAB2.

The stepping strategy that we have described and implemented is conservative in that a 2 × 2 step is chosen whenever there is a peak in the residual convergence. If the result of the composite step is only a slight improvement, the extra cost it takes to perform a 2 × 2 step would be wasted. However, in practice, this increase in cost is relatively small. For example, in this particular problem, 96 of the steps taken in CS-CGSTAB are 2 × 2 steps and 50 2 × 2 steps are taken in CS-CGSTAB2. We see that the composite step methods require only about 15% more matrix–vector products in this example.

6. Best approximation results. Until recently there has been very little theory known on the convergence of the BCG algorithm or other related methods. When Bank and Chan introduced CSBCG in [3], they also included a proof of a "best approximation" result for BCG. It is based on an analysis by Aziz and Babuška [1] and is similar to the analysis of the Petrov–Galerkin methods in finite element theory. Specifically, if we let M_k be any symmetric positive definite matrix and define the norm $|||v|||_*^2 \equiv v^t M_k v$, then Bank and Chan showed that the BCG error term $e_k^{BCG} = x - x_k^{BCG} = \phi_k(A)e_0$ can be bounded as follows:

$$|||e_k^{BCG}|||_* \leq (1+\Gamma/\delta) \inf_{\phi_k:\phi_k(0)=1} \|\phi_k(M_k^{\frac{1}{2}}\, A M_k^{-\frac{1}{2}})\|_2 |||e_0|||_*, \tag{35}$$

where Γ and δ are constants independent of k determined from inequalities involving $v \in \mathcal{V}_k$ and $w \in \mathcal{W}_k$, where $\mathcal{V}_k$ and $\mathcal{W}_k$ are the Krylov subspaces generated by the Lanczos method at the kth step:

$$|w^T A v| \leq \Gamma |||v|||_* |||w|||_*,$$
$$\inf_{\substack{v\in\mathcal{V}\| \\ |||v|||_*=1}} \; \sup_{\substack{w\in\mathcal{W}\| \\ |||w|||_*=1}} w^T A v \geq \delta_k > \delta > 0.$$

Moreover, if we define the Lanczos tridiagonal matrix $T_k = W_k^T A V_k$ and its LU-factorization $T_k = L_k D_k U_k$, and define $M_k \equiv W_k U_k^T (D_k^T D_k)^{\frac{1}{2}} U_k W_k^T$, then $\Gamma = \delta = 1$, also shown in [3].

This result establishes convergence of BCG when there are no breakdowns, because, in this case, M_k is well defined and symmetric positive definite. In the case where there are breakdowns, the tridiagonal matrix T_k would be singular and the resulting M_k would not be positive definite. However, the convergence result can be extended to cover these situations using methods such as composite step to handle breakdown. Specifically, assuming no Lanczos breakdowns, the composite step approach yields a valid M_k matrix based on a factorization of T_k which may involve 2 × 2 block and, hence, the above result applies to the error e_k corresponding to the well-defined iterates x_k [2]. In principle, if we add a look-ahead method to handle the Lanczos breakdowns to this, we can prove convergence of BCG for cases where both breakdowns occur.

Note that, in general, simple upper bounds for the term

$$\inf_{\phi_k:\phi_k(0)=1} \|\phi_k(M_k^{\frac{1}{2}}\, A M_k^{-\frac{1}{2}})\|_2 \tag{36}$$

are known only for special cases. For example, if we assume that the eigenvalues of A are contained in an ellipse in the complex plane which does not contain the origin, then, due to a result by Manteuffel [22], the quantity (36) can be bounded by a value dependent on the foci of the ellipse.

The product methods discussed earlier (CGS and Bi-CGSTAB) both involve the BCG polynomial. Hence, we can use the result in (35) to establish bounds on these methods as well. For the following proofs, we define $\tilde{A}_k \equiv M^{\frac{1}{2}}\, A M_k^{-\frac{1}{2}}$. We first prove a lemma which will be used in the derivation of both bounds for CGS and Bi-CGSTAB.

LEMMA 1. *For any matrix $A \in R^{N\times N}$, vector $v \in R^N$, and polynomial p,*

$$|||p(A)v|||_* \le \|p(\tilde{A}_k)\|_2|||v|||_*.$$

Proof. By definition, $|||w|||_* = \|M_k^{\frac{1}{2}} w\|_2$ and, thus, $|||p(A)v|||_* = \|M_k^{\frac{1}{2}} p(A)v\|_2 = \|M_k^{\frac{1}{2}} p(A)M_k^{-\frac{1}{2}} M_k^{\frac{1}{2}} v\|_2 \le \|p(M_k^{\frac{1}{2}} AM_k^{-\frac{1}{2}})\|_2\|M_k^{\frac{1}{2}} v\|_2 = \|p(\tilde{A}_k)\|_2|||v|||_*$. □

We now use this result to estimate a bound on the CGS method and show the squaring effect on the convergence rate.

THEOREM 1. *Let $e_k^{CGS} = \phi_k^2(A)e_0$. Then*

$$|||e_k^{CGS}|||_* \le c_1 \left(\inf_{\phi_k:\phi_k(0)=1} \|\phi_k(\tilde{A}_k)\|_2 \right)^2 |||e_0|||_*.$$

Proof. Applying Lemma 1 to $|||e_k^{CGS}|||_*$, we get

$$\begin{aligned}|||e_k^{CGS}|||_* &= |||\phi_k^2(A)e_0|||_* \le \|\phi_k(\tilde{A}_k)\|_2|||\phi_k(A)e_0|||_* \\ &= \|\phi_k(\tilde{A}_k)\|_2|||e_k^{BCG}|||_* \le c_1 \left(\inf_{\phi_k:\phi_k(0)=1} \|\phi_k(\tilde{A}_k)\|_2 \right)^2 |||e_0|||_*. \qquad \square\end{aligned}$$

Next we show convergence of the Bi-CGSTAB method and how the convergence rate of BCG can be improved by the effect of the steepest descent.

THEOREM 2. *Let $e_k^{Bi\text{-}CGSTAB} = \tau_k(A)\phi_k(A)e_0$, and define S to be the symmetric part of $\tilde{A}_k$ (i.e., $S = \frac{1}{2}(\tilde{A}_k + \tilde{A}_k^T)$). Then if S is positive definite,*

$$|||e_k^{Bi\text{-}CGSTAB}|||_* \le c_2 \left(1 - \frac{\lambda_{\min}(S)^2}{\lambda_{\max}(\tilde{A}_k^T\tilde{A}_k)} \right)^{\frac{k}{2}} \left(\inf_{\phi_k:\phi_k(0)=1} \|\phi_k(\tilde{A}_k)\|_2 \right) |||e_0|||_*.$$

Proof. First note that we can bound

$$\min_{\tau_k\in P_k} \|\tau_k(\tilde{A}_k)\|_2 \le \left(1 - \frac{\lambda_{\min}(S)^2}{\lambda_{\max}(\tilde{A}_k^T\tilde{A}_k)} \right)^{\frac{k}{2}}$$

by applying the proof in Theorem 3.3 of Eisenstat, Elman, and Schultz [12] to the matrix $\tilde{A}_k$. Combining this fact with Lemma 1, we can establish the following bound:

$$\begin{aligned}|||e_k^{Bi\text{-}CGSTAB}|||_* &= \min_{\tau_k\in P_k} |||\tau_k(A)\phi_k(A)e_0|||_* \le \min_{\tau_k\in P_k} \left(\|\tau_k(M_k^{\frac{1}{2}} AM_k^{-\frac{1}{2}})\|_2|||\phi_k(A)e_0|||_* \right) \\ &\le \left(\min_{\tau_k\in P_k} \|\tau_k(\tilde{A}_k)\|_2 \right) |||\phi_k(A)e_0|||_* \le \left(1 - \frac{\lambda_{\min}(S)^2}{\lambda_{\max}(\tilde{A}_k^T\tilde{A}_k)} \right)^{\frac{k}{2}} |||e_k^{BCG}|||_* \\ &\le c_2 \left(1 - \frac{\lambda_{\min}(S)^2}{\lambda_{\max}(\tilde{A}_k^T\tilde{A}_k)} \right)^{\frac{k}{2}} \left(\inf_{\phi_k:\phi_k(0)=1} \|\phi_k(\tilde{A}_k)\|_2 \right) |||e_0|||_*. \qquad \square\end{aligned}$$

Recently, Barth and Manteuffel [4] have shown that the constant $(1 + \Gamma/\delta)$ in (35) can be improved to one. In other words, e_k^{BCG} is minimized over $K_n(r_0)$ in the $|||\cdot|||_*$ norm. Correspondingly, the constants c_1 and c_2 in Theorems 1 and 2 can be improved to one.

A. Appendix. Here, we present the proof of the nonsingularity of the coefficient matrix in (19) and (20).

LEMMA A.1. *Assume that the Lanczos process underlying BCG does not break down; i.e.,* $\rho_i \neq 0$, $i = 0, 1, \ldots, n$, *and* $\tilde{z}_{n+1}^T z_{n+1} \neq 0$. *If* $\sigma_n^{BCG} = 0$, *then the coefficient matrix in* (19) *and* (20) *is nonsingular.*

Proof. Since $\sigma_n^{Bi\text{-}CGSTAB} = \frac{1}{\mu_n}\, \sigma_n^{BCG}$, where μ_n is as defined in §3, it suffices to show that if $\sigma_n^{Bi\text{-}CGSTAB} = 0$, then the 2×2 matrix in (19) and (20) is nonsingular. Note that $\sigma_n^{Bi\text{-}CGSTAB} = \tilde{r}_0^T A p_n^{Bi\text{-}CGSTAB} = (\tilde{r}_0, \vartheta \tau_n \psi_n r_0)$, the (1,1) element of the 2×2 matrix in question. Note also the relationship of the off diagonal elements in the case where $\sigma_n^{BCG} = 0:$ $(\tilde{r}_0, \vartheta \tau_n \xi_{n+1} r_0) = (\tilde{r}_0, \vartheta \tau_n (\sigma_n^{BCG} \phi_n - \rho_n \vartheta \psi_n) r_0) = -\rho_n (\tilde{r}_0, \vartheta^2 \tau_n \psi_n r_0)$.

Since $\rho_n \neq 0$, nonsingularity follows from showing that $(\tilde{r}_0, \vartheta^2 \tau_n \psi_n r_0) \neq 0$ when $\sigma_n^{BCG} = 0$. Analogous to the derivation of (26) and (27), $(\tilde{r}_0, A^2 \tau_n(A) \psi_n(A) r_0) = \frac{1}{\mu_n}\, (\psi_n(A^T)\tilde{r}_0, A^2 \psi_n(A) r_0)$. Using $0 \neq \tilde{z}_{n+1}^T z_{n+1} \equiv \rho_n^2 (\psi_n \tilde{r}_0, A^2 \psi_n r_0)$ and $\rho_n \neq 0$, we now have $(\psi_n \tilde{r}_0, A^2 \psi_n r_0) \neq 0$, thus completing our proof. □
