However, as is well known, iterative refinement will often succeed if extended precision is used to evaluate the residuals. We could therefore consider using extended precision iterative refinement to improve the solution v^+ of the normal equations (3.6). So long as $\epsilon_m\kappa(A)^2 < 1$, and the residuals of (3.6) are smaller than one in norm, we can expect that the error in the solution of (3.6) will decrease by a factor $\epsilon_m\kappa(A)^2$ until it reaches $O(\epsilon_m)$. However, since optimization algorithms normally use double precision arithmetic for all their computations, extending the precision may not be simple or efficient, and this strategy is not suitable for general purpose software.

For the same reason we will not consider the use of extended precision in (5.1)–(5.2) or in the iterative refinement of the least squares problem.

5.2. Augmented system approach. We can apply fixed precision iterative refinement to the solution obtained from the augmented system (3.11). This gives the following iteration.

ALGORITHM 5.2 (iterative refinement—augmented system). *Repeat the following steps until a convergence test is satisfied.*

$$\begin{aligned} \textit{Compute}\ \ &\rho_g = r^+ - Gg^+ - A^Tv^+ \ \ \textit{and}\ \ \rho_v = -Ag^+,\\ \textit{solve}\ \ &\begin{pmatrix} G & A^T \\ A & 0 \end{pmatrix}\begin{pmatrix} \Delta g^+ \\ \Delta v^+ \end{pmatrix} = \begin{pmatrix} \rho_g \\ \rho_v \end{pmatrix},\\ \textit{and update}\ \ &g^+ \leftarrow g^+ + \Delta g^+ \ \ \textit{and}\ \ v^+ \leftarrow v^+ + \Delta v^+. \end{aligned}$$

Note that this method is applicable for general preconditioners G. The general analysis of Higham [30, Theorem 3.2] indicates that, if the condition number of A is not too large, we can expect high relative accuracy in v^+ and good absolute accuracy in g^+ in most cases.

We solved the problem given in Example 3.1 using this iterative refinement technique. As before, we measured the angle between g and the columns of A at every CG iteration. Iterative refinement was applied so long as the cosine of this angle was greater than 10^{-12}. We observed that $\sqrt{r^T g}$ decreased almost as much as with the multiple projections approach.

In our experience, one iterative refinement step is normally enough to provide good accuracy, but we have encountered cases in which two or three steps are beneficial. As in the case of the multiple projections using the normal equations, we would apply this refinement technique selectively in optimization algorithms.

6. Residual update strategy. We have seen that significant roundoff errors may occur in the computation of the projected residual g^+ if this vector is much smaller than the residual r^+. As discussed in the paragraph preceding Example 3.1, the reason for this error is cancellation. We now describe a procedure for redefining r^+ so that its norm is closer to that of g^+. This will dramatically reduce the roundoff errors in the projection operation and thus nearly eliminate the need to use iterative refinement.

We begin by noting that the iterates x of Algorithm 2.2 are theoretically unaffected if, immediately after computing r^+ in (2.15), we redefine it as

$$r^+ \leftarrow r^+ - A^T y \tag{6.1}$$

for some $y \in \mathbf{R}^m$. This equivalence is due to the fact that r^+ appears only in (2.16) and (2.17) and that we have both $PA^Ty = 0$, and $(g^+)^T A^T y = 0$. It follows that we can redefine r^+ by means of (6.1) in either the normal equations approach (3.4) and (3.9) or in the augmented system approach (3.8) and (3.11), and the results would, in theory, be unaffected.

Having this freedom to redefine r^+, we seek the value of y that minimizes

$$\|r^+ - A^T y\|_{G^{-1}}, \tag{6.2}$$

where $\|\cdot\|_{G^{-1}}$ is the dual (semi-) norm to the norm $s^T G s$ defined on the manifold $As = 0$, and where we require that G is positive definite over this manifold (see [14]). This dual norm is convenient, since the vector y that solves (6.2) is precisely $y = v^+$ from (3.11). This gives rise to the following modification of the CG iteration.

ALGORITHM 6.1 (preconditioned CG with residual update). *Choose an initial point x satisfying $Ax = b$ and compute $r = Hx + c$. Find the vector y that minimizes $\|r - A^T y\|_{G^{-1}}$; this can be done by solving* (6.2) *and setting $y \leftarrow v^+$. Set $r \leftarrow r - A^T y$, compute $g = Pr$, and set $p = -g$. Repeat the following steps until a convergence test is satisfied:*

$$\alpha = r^T g / p^T H p, \tag{6.3}$$

$$x \leftarrow x + \alpha p, \tag{6.4}$$

$$r^+ = r + \alpha H p, \tag{6.5}$$

$$\textit{compute } y \textit{ that minimizes } (6.2), \tag{6.6}$$

$$r^+ \leftarrow r^+ - A^T y, \tag{6.7}$$

$$g^+ = P r^+, \tag{6.8}$$

$$\beta = (r^+)^T g^+ / r^T g, \tag{6.9}$$

$$p \leftarrow -g^+ + \beta p, \tag{6.10}$$

$$g \leftarrow g^+ \quad \textit{and} \quad r \leftarrow r^+. \tag{6.11}$$

This procedure can be improved by adding iterative refinement of the projection operation in (6.8). In this case, at most one or two iterative refinement steps should be used. The added cost of this algorithm is the storage and computation of y each iteration.

Notice that there is a simple interpretation of steps (6.6)–(6.8). We first obtain y by solving (6.2), and as we have indicated the required value is $y = v^+$ from (3.11). However, (3.11) may be rewritten as

$$\begin{pmatrix} G & A^T \\ A & 0 \end{pmatrix} \begin{pmatrix} g^+ \\ 0 \end{pmatrix} = \begin{pmatrix} r^+ - A^T v^+ \\ 0 \end{pmatrix}, \tag{6.12}$$

and thus when we obtain g^+ in step (6.8), it is as if we had instead found it by solving

$$\begin{pmatrix} G & A^T \\ A & 0 \end{pmatrix} \begin{pmatrix} g^+ \\ u^+ \end{pmatrix} = \begin{pmatrix} r^+ - A^T v^+ \\ 0 \end{pmatrix}. \tag{6.13}$$

Comparing (6.12) and (6.13), it follows that $u^+ = 0$ in exact arithmetic, although all we can expect in floating point arithmetic is that the computed u^+ will be very small, provided of course that (6.13) is solved in a stable fashion. The advantage of using (6.13) compared to (3.11) is that the solution in the latter may be dominated by the large components v^+, while in the former g^+ are the (relatively) large components, and thus we can expect to find them with high relative accuracy if (6.13) is solved in a stable fashion. Viewed in this way, we see that steps (6.6)–(6.8) are actually a limited form of iterative refinement in which the computed v^+, but not the computed g^+ which is discarded, is used to refine the solution. This "iterative semirefinement" has been used in other contexts [8, 23].

There is another interesting interpretation of the reset $r \leftarrow r - A^T y$ performed at the start of Algorithm 6.1. In the parlance of optimization, $r = Hx + c$ is the gradient of the objective function (1.1) and $r - A^T y$ is the gradient of the Lagrangian for the problem (1.1)–(1.2). The vector y computed from (6.2) is called the least squares Lagrange multiplier estimate. (It is common, but not always the case, for optimization algorithms to set $G = I$ in (6.2) to compute these multipliers.) Thus in Algorithm 6.1 we propose that the initial residual be set to the current value of the gradient of the Lagrangian, as opposed to the gradient of the objective function.

One could ask whether it is sufficient to do this resetting of r at the beginning of Algorithm 6.1 and omit steps (6.6)–(6.7) in subsequent iterations. Our computational experience shows that, even though this initial resetting of r causes the first few CG iterations to take place without significant errors, deviations from the null space due to rounding errors arise in subsequent iterations. The strategy proposed in Algorithm 6.1 is safe in that it ensures that r is small at every iteration.

As it stands, Algorithm 6.1 would appear to require two products with P, or, at the very least, one with P to perform (6.8) and some other means, such as (3.6), to determine y. As we shall now see, this need not be the case.

6.1. The case $G = I$.

There is a particularly efficient implementation of the residual update strategy when $G = I$. We can redefine r without the extra cost of storing and computing y as required by Algorithm 6.1. In Algorithm 6.2 below, we present the residual update for $G = I$, combined with iterative refinement. It is this algorithm that is used in the numerical tests in section 7.

Algorithm 6.2 (residual update and iterative refinement for $G = I$). *Choose an initial point x satisfying $Ax = b$, compute $r = Hx + c$, $r \leftarrow Pr$, $g \leftarrow Pr$, where* *the projection is computed by the normal equations* (3.4) *or augmented system* (3.8) *approaches, and set* $p = -g$. *Choose a tolerance* $\theta_{\max}$. *Repeat the following steps until a convergence test is satisfied:*

$$\alpha = r^T g / p^T Hp, \tag{6.14}$$

$$x \leftarrow x + \alpha p, \tag{6.15}$$

$$r^+ = r + \alpha Hp, \tag{6.16}$$

$$g^+ = Pr^+, \tag{6.17}$$

apply iterative refinement to Pr^+*, if necessary,*
until (3.13) *is less than* $\theta_{\max}$,

$$\beta = (r^+)^T g^+ / r^T g, \tag{6.18}$$

$$p \leftarrow -g^+ + \beta p, \tag{6.19}$$

$$g \leftarrow g^+ \quad \textit{and} \quad r \;\leftarrow\; g^+. \tag{6.20}$$

This algorithm was derived from noting that (6.2) is precisely the objective of the least squares problem (3.7) that occurs when computing Pr^+ via the normal equations approach, and therefore the desired value of y is nothing other than the vector v^+ in (3.6) or (3.8). Furthermore, the first block of equations in (3.8) shows that $r^+ - A^T v^+ = g^+$. Therefore, when $G = I$ the computation (6.7) can be replaced by $r^+ \leftarrow Pr^+$ and (6.8) is $g^+ = Pr^+$. In other words, we have applied the projection operation twice, and this is a special case of the multiple projections approach described in the previous section.

Further, (6.7) can be written as $r^+ \leftarrow Pr^+$, or $r^+ = Pr + PH\alpha p$, and therefore (6.8) is

$$g^+ = P(Pr + PH\alpha p). \tag{6.21}$$

As the CG iteration progresses we can expect αp, but not r, to become small. Therefore, we will apply the projection twice to r but only once to $H\alpha p$. Thus (6.21) is replaced by

$$g^+ = P(Pr + H\alpha p), \tag{6.22}$$

which is mathematically equivalent to (6.21), since $PP = P$. This expression is convenient because the term Pr was computed at the previous CG iteration, and therefore we can obtain (6.22) by simply setting $r \leftarrow g^+$ in (6.11) instead of $r \leftarrow r^+$.

Also note that the numerator in the definition (6.3) of α now becomes $g^T g$, which equals $r^T Pg = r^T g$. Thus the formula for α is theoretically the same as in Algorithm 6.1, but the symmetric form $\alpha = g^T g / p^T Hp$ has the advantage that its numerator can never be negative, as is the case with (6.3) when rounding errors dominate the projection operation.

We solved the problem given in Example 3.1 using this residual update strategy with $G = I$. Both the normal equations and augmented system approaches were equally effective in this case. The cosine (3.13) of the angle between the preconditioned residual and the columns of A remained very small as the computation proceeded. For the normal equations approach this cosine was of order 10^{-14} throughout the CG iteration; for the augmented system approach it was of order 10^{-15}. We also noted that we were able to obtain higher accuracy than with the iterative refinement strategies described in the previous section.

6.2. General *G*. We can also improve upon the efficiency of Algorithm 6.1 for general G using slightly outdated information. The idea is simply to use the v^+ obtained when computing g^+ in (6.8) as a suitable y rather than waiting until after the following step (6.5) to obtain a slightly more up-to-date version. The resulting iteration is as follows.

Algorithm 6.3 (residual update strategy for general G). *Apply Algorithm* 6.1 *with the following two changes:*

omit (6.6)–(6.7),

replace (6.11) *by* $g \leftarrow g^+$ *and* $r \leftarrow r^+ - A^T v^+$, *where* v^+ *is obtained as a by-product when using* (3.11) *to compute* (6.8).

Thus a single projection in step (6.8) is needed for each iteration. Notice, however, that for general G, the extra matrix-vector product $A^T v^+$ will be required, since we no longer have the relationship $g^+ = r^+ - A^T v^+$ that we exploited when $G = I$. Although we have not experimented on this idea for this paper, it has proved to be beneficial in other similar circumstances [23] and provides the backbone for the developing HSL [32] nonconvex quadratic programming packages HSL_VE12 [14] (interior-point) and HSL_VE19 [25] (active set). See also [34] for a thorough discussion of existing and new preconditioners along these lines and the results of some comparative testing.

7. Numerical results. We now test the efficacy of the techniques proposed in this paper on a collection of quadratic programs of the form (1.1)–(1.2). The problems were generated during the last iteration of the interior point method for nonlinear programming described in [9] when this method was applied to a set of test problems from the CUTE [6] collection. We apply the CG method without preconditioning, i.e., with $G = I$, to solve these quadratic programs.

We use the augmented system and normal equations approaches to compute projections, and for each we compare the standard CG iteration (stand), given by Algorithm 2.2, with the iterative refinement (ir) techniques described in section 5 and the residual update strategy combined with iterative refinement (update) as given in Algorithm 6.2. The results are given in Table 7.1. The first column gives the problem name and the second gives the dimension of the quadratic program. To test the reliability of the techniques proposed in this paper we used a very demanding stopping test: the CG iteration was terminated when $\sqrt{r^T g} \leq 10^{-12}$. This stopping test would not be used in practice; rather, we wanted to observe the level of accuracy that could be achieved with each approach.

In these experiments we included several other stopping tests in the CG iteration that are typically used by trust region methods for optimization. We terminate if the number of iterations exceeds $2(n-m)$, where $n-m$ denotes the dimension of the reduced system (2.4); a superscript ^{1} in Table 7.1 indicates that this limit was reached. The CG iteration was also stopped if the length of the solution vector is greater than a "trust region radius" that is set by the optimization method (see [9]). We use a superscript ^{2} to indicate that this safeguard was activated, and note that in these problems only excessive rounding errors can trigger it. Finally we terminate if $p^T H p < 0$, indicated by ^{3}, or if significant rounding error resulted in $r^T g < 0$, indicated by ^{4}. The presence of any superscript indicates that the residual test $\sqrt{r^T g} \leq 10^{-12}$ was not met. Note that the standard CG iteration was not able to meet the residual stopping test for any of the problems in Table 7.1 but that iterative refinement and update residual were successful in most cases.

Table 7.2 reports the CPU time for the problems in Table 7.1. Note that the times for the standard CG approach (stand) should be interpreted with caution, since

Table 7.1

Number of CG iterations for the different approaches. [1] *indicates that the iteration limit was reached,* [2] *indicates termination from trust region bound,* [3] *indicates negative curvature was detected, and* [4] *indicates that* $r^T g < 0$.

in some of these problems it terminated prematurely. We include the times for this standard CG iteration only to show that the iterative refinement and residual update strategies do not greatly increase the cost of the CG iteration.

Next we report on three problems for which the stopping test $\sqrt{r^T g} \leq 10^{-12}$ could not be met by any of the variants. For these three problems, Table 7.3 provides the least residual norm attained for each strategy.

As a final but indirect test of the techniques proposed in this paper, we report the results obtained with KNITRO (an interior point nonlinear optimization code described in [9]) on 29 nonlinear programming problems from the CUTE collection. This code applies the projected CG method to solve a quadratic program at each iteration. The CG iteration was terminated when $\sqrt{r^T g} \leq 0.1\sqrt{r_0^T g_0}$, which is much less stringent than the termination tests used above. We used the augmented system and normal equations approaches to compute projections, and for each of these strategies we tried the standard CG iteration (stand) and the residual update strategy (update)

with iterative refinement described in Algorithm 6.2. Now we were concerned with reducing feasibility errors in the CG iterates, not to be able to satisfy a stringent CG termination test, but to ensure that the outer optimization algorithm would converge. The results are given in Table 7.4, where "fevals" denotes the total number of evaluations of the objective function of the nonlinear problem, and "projections" represents the total number of times that a projection operation was performed during the optimization. A *** indicates that the optimization algorithm was unable to locate the solution.

Note that the total number of function evaluations is roughly the same for all strategies, but there are a few cases where the differences in the CG iteration cause the algorithm to follow a different path to the solution. This is to be expected when solving nonlinear problems. Note that for the augmented system approach, the residual update strategy changes the number of projections significantly only in a few problems, but when it does the improvements are very substantial. On the other hand, we observe that for the normal equations approach (which is more sensitive to the condition number $\kappa(A)$) the residual update strategy gives a substantial reduction in the number of projections in about half of the problems. It is interesting that with the residual update, the performance of the augmented system and normal equations approaches is very similar.

8. Conclusions. We have studied the properties of the projected CG method for solving quadratic programming problems of the form (1.1)–(1.2). Due to the form of the preconditioners used by some nonlinear programming algorithms we opted for not computing a basis Z for the null space of the constraints but instead projecting the CG iterates using a normal equations or augmented system approach. We have given examples showing that in either case significant roundoff errors can occur and have presented an explanation for this.

We proposed several remedies. One is to use iterative refinement of the augmented system or normal equations approaches. An alternative is to update the residual at every iteration of the CG iteration, as described in section 6. The latter can be implemented particularly efficiently in the unpreconditioned ($G = I$) case.

Our numerical experience indicates that updating the residual almost always suffices to keep the errors to a tolerable level. Iterative refinement techniques are not as effective by themselves as the update of the residual but can be used in conjunction with it, and the numerical results reported in this paper indicate that this combined strategy is both economical and accurate. The techniques described here are important ingredients within the evolving large scale nonlinear programming packages KNITRO and GALAHAD, as well as the HSL [32] QP modules HSL_VE12 and HSL_VE19.

Acknowledgments. The authors would like to thank Andy Conn and Philippe Toint for their helpful input during the early stages of this research. They are also grateful to Margaret Wright and two anonymous referees for their helpful suggestions.

ROBUST PARALLEL SMOOTHING FOR MULTIGRID VIA SPARSE APPROXIMATE INVERSES[*]

OLIVER BRÖKER[†], MARCUS J. GROTE[‡], CARSTEN MAYER[§], AND ARNOLD REUSKEN[¶]

Abstract. Sparse approximate inverses are considered as smoothers for multigrid. They are based on the SPAI-Algorithm [M. J. Grote and T. Huckle, *SIAM J. Sci. Comput.*, 18 (1997), pp. 838–853], which constructs a sparse approximate inverse M of a matrix A by minimizing $I - MA$ in the Frobenius norm. This yields a new hierarchy of smoothers: SPAI-0, SPAI-1, SPAI(ε). Advantages of SPAI smoothers over classical smoothers are inherent parallelism, possible local adaptivity, and improved robustness. The simplest smoother, SPAI-0, is based on a diagonal matrix M. It is shown to satisfy the smoothing property for symmetric positive definite problems. Numerical experiments show that SPAI-0 smoothing is usually preferable to damped Jacobi smoothing. For the SPAI-1 smoother the sparsity pattern of M is that of A; its performance is typically comparable to that of Gauss–Seidel smoothing; however, both the computation and the application of the smoother remain inherently parallel. In more difficult situations, where the simpler SPAI-0 and SPAI-1 smoothers are not adequate, the SPAI(ε) smoother provides a natural procedure for improvement where needed. Numerical examples illustrate the usefulness of SPAI smoothing.

Key words. multilevel methods, approximate inverses, smoothing property, parallel preconditioning, iterative methods, sparse linear systems

1. Introduction.

Multigrid methods are efficient iterative solvers for large linear systems of equations, which result from the discretization of partial differential equations; see Brandt [8], Hackbusch [15, 16], Wesseling [27], and the references therein. They also yield efficient preconditioners when combined with Krylov subspace methods [7]. Any multigrid algorithm relies on the complementary interplay of smoothing and coarse grid correction. While the smoothing process aims at reducing the high-frequency error component, namely that which cannot be represented on coarser grids, the coarse grid correction solves for the low-frequency error component, precisely that which is well represented on the coarser grid. The careful combination of both smoothing and coarse grid correction yields a multigrid iteration, which has a high convergence rate independent of the mesh size.

Standard smoothing techniques typically result from the application of a few steps of a basic iterative method. Here we shall consider smoothers that are based on sparse approximate inverses. Starting from the linear system

$$Ax = b, \tag{1.1}$$

we denote by M a sparse approximation of A^{-1}. Then the corresponding basic iter-

ative method is

$$x^{(k+1)} = x^{(k)} - M(Ax^{(k)} - b). \tag{1.2}$$

As the approximate inverse M is known explicitly, each iteration step requires only one additional $M \times v$ matrix-vector multiply; thus it is easy to parallelize and cheap to evaluate because M is sparse.

Recently, various algorithms have been proposed, all of which attempt to compute directly a sparse approximate inverse of A. Examples are the FSAI approach by Kolotilina and Yeremin [18], the MR algorithm by Chow and Saad [10], and the AINV approach by Benzi, Meyer, and Tůma [5]. Once computed, the approximate inverse M is applied as a preconditioner to the linear system (1.1) for use with a Krylov subspace iterative method. For a comparative study of various sparse approximate inverse preconditioners we refer to Benzi and Tuma [6]. By choosing an a priori sparsity pattern for M, the cost of computing M can be greatly reduced. Possible choices include powers of A or $A^\top A$, as suggested by Huckle [17] and Chow [11].

Approximate inverse techniques are also gaining in importance as smoothers for multigrid methods. First introduced by Benson and Frederickson [3] and Benson [4], they were shown to be effective on various difficult elliptic problems on unstructured grids by Tang and Wan [25]. Advantages of sparse approximate inverse smoothers over classical smoothers, such as damped Jacobi, Gauss–Seidel, or ILU, are inherent parallelism, possible local adaptivity, and improved robustness.

Here we shall consider sparse approximate inverse (SPAI) smoothers based on the SPAI-Algorithm by Grote and Huckle [14]. The SPAI-Algorithm computes an approximate inverse M explicitly by minimizing $I - MA$ in the Frobenius norm. Both the computation of M and its application as a smoother are inherently parallel. Since an effective sparsity pattern of M is in general unknown a priori, the SPAI-Algorithm attempts to determine the most promising entries dynamically. This strategy has proved effective in generating preconditioners for many difficult and ill-conditioned problems (see Barnard, Bernardo, and Simon [1], Tang [24], and Grote and Huckle [14]). Moreover, it provides the means for adjusting the smoother locally and automatically, if necessary.

We shall consider the following hierarchy of SPAI smoothers: SPAI-0, SPAI-1, and SPAI(ε). For SPAI-0 and SPAI-1 the sparsity pattern of M is fixed: M is diagonal for SPAI-0, whereas for SPAI-1 the sparsity pattern of M is that of A. For SPAI(ε) the sparsity pattern of M is determined automatically by the SPAI-Algorithm [14]; the parameter ε controls the accuracy and the amount of fill-in of M.

Besides the SPAI smoothing operators, all other multigrid components, such as the prolongation, the restriction, and the coarse grid operators, result from standard choices. It is well known that for certain classes of problems, such as convection-diffusion equations, a significant improvement in the efficiency of the multigrid solver can be obtained by using matrix-dependent prolongation and restriction operators (see [13, 20, 27, 30]). An interesting topic for future research is the combination of this new hierarchy of local and inherently parallel smoothers with algebraic multigrid techniques (see, for instance, [19, 21, 22, 26]).

In section 2 we briefly review the SPAI-Algorithm and show how sparse approximate inverses are used as smoothers in multigrid. In section 3 we prove that for SPAI-0 the smoothing property [16] holds under reasonable assumptions on the matrix A. More precisely, for A symmetric and positive definite, we prove that SPAI-0 satisfies the smoothing property, either if A is weakly diagonally dominant or if A has at most seven nonzero off-diagonal entries per row. To our knowledge this is the first fairly general theoretical result on the smoothing property of iterative methods that are based on sparse approximate inverses. Previously, Tang and Wan [25] analyzed the smoothing property of sparse approximate inverse smoothers for boundary value problems with constant coefficients on a two-dimensional regular grid. From a comparison of the SPAI-0 and damped Jacobi smoothers via numerical experiments, we conclude that the parameter-free SPAI-0 smoother is usually preferable to the damped Jacobi method. Finally, in section 4, we present an extensive set of numerical experiments, which demonstrate the usefulness of SPAI smoothing.

2. SPAI smoothing.

Starting from a standard multigrid setting, such as found in [15], [16, Chap. 10], or [27], we recall some basic notions and briefly introduce relevant notation. We assume the hierarchy of spaces,

$$X_\ell = \mathbb{R}^{n_\ell}, \qquad \ell = 0, 1, 2, \dots, \quad n_0 < n_1 < n_2 < \cdots,$$

together with the prolongation and restriction operators

$$p: \; X_{\ell-1} \to X_\ell, \qquad r: \; X_\ell \to X_{\ell-1}, \quad \ell = 1, 2, \dots .$$

To each space X_ℓ we associate a nonsingular operator,

$$A_\ell: \; X_\ell \to X_\ell.$$

We now wish to solve iteratively the linear system

$$A_{\ell_{\max}} x_{\ell_{\max}} = b_{\ell_{\max}}$$

by using a multigrid method. A multigrid iteration results from the recursive application of a two-grid method. A two-grid method on level ℓ consists of ν_1 presmoothing steps on level ℓ, a coarse grid correction on level $\ell - 1$, and ν_2 postsmoothing steps again on level ℓ. The corresponding error propagation is

$$e_\ell^{(m+1)} = [S_\ell^{\nu_2}(I - pA_{\ell-1}^{-1} r A_\ell) S_\ell^{\nu_1}]\, e_\ell^{(m)},$$

where S_ℓ denotes the iteration matrix of the smoother.

2.1. Classical smoothers.

We shall limit the present discussion to the choice of the smoother. All other multigrid components, such as p, r, and $A_{\ell-1}$, follow from standard choices. If the smoother results from a consistent linear iterative method, the iteration matrix of the smoother, S_ℓ, can be written as

$$S_\ell = I - N_\ell A_\ell. \tag{2.1}$$

For instance, let $A = D+L+U$, with D the diagonal, L the lower triangular part, and U the upper triangular part of A. Then damped Jacobi smoothing corresponds to

$$S_\omega = I - \omega D^{-1} A, \tag{2.2}$$

whereas Gauss–Seidel smoothing corresponds to

$$S_{GS} = I - (D + L)^{-1} A. \tag{2.3}$$

In (2.2) the choice of ω must ensure good smoothing properties of the resulting damped Jacobi method. Yet the "optimal" value of ω is known only for certain model problems (see section 3.2). In contrast, the Gauss–Seidel method is parameter-free and typically leads to improved smoothing over the damped Jacobi method. Unfortunately, the Gauss–Seidel method (2.3) is inherently sequential and therefore difficult to implement on a parallel architecture. Yet with an appropriate coloring of the unknowns (e.g., red-black ordering on a regular grid) it is sometimes possible to attain reasonable parallel efficiency with the Gauss–Seidel approach.

If neither damped Jacobi nor Gauss–Seidel leads to satisfactory smoothing, one can resort to more robust smoothers, such as the popular ILU smoothers based on the incomplete LU (ILU) decomposition of A_ℓ; see, for instance, [28]. Because each ILU smoothing step requires the solution of upper and lower triangular systems, it remains inherently sequential and difficult to implement in parallel. It is also difficult to improve the ILU smoother locally, say near the boundary or a singularity, without seriously affecting the sparsity of the LU factors.

2.2. SPAI smoothers. Most smoothers commonly used in multigrid methods, such as damped Jacobi, Gauss–Seidel, or ILU, have the form

$$x_\ell^{(k+1)} = x_\ell^{(k)} - W_\ell^{-1}(A_\ell x_\ell^{(k)} - b_\ell), \tag{2.4}$$

with W_ℓ a (sparse) approximation of A_ℓ; moreover, the computational cost of solving a linear system with matrix W_ℓ must be reasonable. In contrast, the SPAI smoothers lead to the iteration

$$x_\ell^{(k+1)} = x_\ell^{(k)} - M_\ell \, (A_\ell x_\ell^{(k)} - b_\ell), \tag{2.5}$$

where M_ℓ is sparse and explicitly known. Hence the iteration in (2.5) requires only matrix-vector multiplications and vector-vector additions, and no solution of a linear system; it is therefore easy to implement in a parallel environment.

To construct the sparse approximate inverse M of A, we shall minimize $I - MA$ in the Frobenius norm for a prescribed sparsity pattern of M. Here we have dropped the index ℓ to simplify the notation. The Frobenius norm, denoted by $\|\cdot\|_F$, naturally leads to inherent parallelism because the rows m_k of M can be computed independently of one another. Indeed, since

$$\|I - MA\|_F^2 = \sum_{k=1}^{n} \|e_k^\top - m_k A\|_2^2, \tag{2.6}$$

the solution of (2.6) separates into the n *independent least-squares problems* for the sparse (row) vectors m_k,

$$\min_{m_k} \|e_k^\top - m_k A\|_2, \qquad k = 1, \dots, n. \tag{2.7}$$

Here e_k denotes the kth unit vector. Because A and M are sparse these least-squares problems have small dimensions.

Since an effective sparsity pattern of M is usually unknown a priori, the original SPAI-Algorithm [14] begins with a diagonal pattern. Then the algorithm proceeds by augmenting the sparsity pattern of M to further reduce each residual $r_k = e_k^\top - m_k A$. The progressive reduction of the 2-norm of r_k involves two steps. First, the algorithm identifies a set of potential new candidates, based on the sparsity pattern of A and the current (sparse) residual r_k. Second, the algorithm selects the most profitable entries, usually less than five entries, by computing for each candidate a cheap upper bound for the reduction in $\|r_k\|_2$. Once the new entries have been selected and added to m_k, the (small) least-squares problem (2.7) is solved again with the augmented set of indices. The algorithm proceeds until each row m_k of M satisfies

$$\|e_k^\top - m_k A\|_2 < \varepsilon. \tag{2.8}$$

Here ε is a tolerance set by the user, which controls the fill-in and the quality of the preconditioner M. A lower value of ε usually yields a more effective preconditioner, but the cost of computing $M = \text{SPAI}\,(\varepsilon)$ may become prohibitive; moreover, a denser M results in a higher cost per iteration in (2.5). The optimal value of ε minimizes the total time; it depends on the problem, the discretization, the desired accuracy, and the computer architecture. Further details about the original SPAI-Algorithm can be found in [14].

What is the cost associated with computing M? Let q denote the typical number of nonzero entries per row m_k, and let p denote the typical number of nonzero entries per row in A. Then the cost of solving each least-squares problem in (2.7) (by the method of normal equations) is about $(q + p/3)\,p^2$ flops [12, p. 224]. Since $q \gg p$, the total amount of work involved in computing M is about $n\,q\,p^2$ flops. To ensure that the total amount of work for computing the approximate inverses M_ℓ on all levels remains $O(n)$, it is crucial that both p and q remain bounded from above independently of n. Clearly, in contrast to the Jacobi or Gauss–Seidel methods, the additional effort of computing M seems at first cumbersome and expensive. The approximate inverses, however, need only be computed once prior to the multigrid iteration. Moreover, both the computation of M and its repeated application as a smoother are inherently parallel, so that the usefulness of SPAI smoothers in a parallel environment is all too obvious in comparison to the sequential Gauss–Seidel iteration.

In addition to SPAI(ε), we shall also consider the following two greatly simplified SPAI smoothers with fixed sparsity patterns: SPAI-0, where M is diagonal, and SPAI-1, where the sparsity pattern of M is that of A. Both solve the least-squares problem (2.7) and thus minimize $\|I - MA\|_F$ for the sparsity pattern chosen a priori. This eliminates the search for the sparsity pattern of M and thus greatly reduces the cost of computing the approximate inverse. The SPAI-1 smoother coincides with the SAI(0,1) smoother of Tang and Wan [25].

For SPAI-0, $M = \text{diag}(m_{kk})$ is diagonal and can be calculated directly:

$$m_{kk} = \frac{a_{kk}}{\|a_k\|_2^2}, \qquad 1 \le k \le n, \tag{2.9}$$

with a_k the kth row of A. We note that M is always well defined if A is nonsingular. Unlike damped Jacobi, the SPAI-0 smoother is parameter-free.

To summarize, we shall consider the following hierarchy of SPAI smoothers, which all minimize $\|I - MA\|_F$ for a certain sparsity pattern of M.

SPAI-0: $M = \text{diag}(m_{kk})$ is diagonal, with m_{kk} given by (2.9).

SPAI-1: The sparsity pattern of M is that of A.

SPAI(ε): The sparsity pattern of M is determined automatically by the SPAI-Algorithm [14]. Then each row m_k satisfies (2.8) for a given ε.

We have found that, in many situations, SPAI-0 and SPAI-1 yield ample smoothing. However, the added flexibility in providing an automatic criterion for improving the smoother via the SPAI-Algorithm remains very useful. Indeed, either SPAI-0 or

SPAI-1 can be used as initial guess for SPAI(ε) and thus be locally improved upon where needed by reducing ε (see section 4.2). For matrices with inherent (small) block structure, typical from the discretization of systems of partial differential equations, the Block-SPAI-Algorithm [2] greatly reduces the cost of computing M.

3. SPAI-0 smoothing.

In this section we concentrate on the simplest SPAI smoother, SPAI-0. First, we shall show that SPAI-0 satisfies the smoothing property in two quite general situations. Second, we shall compare the two diagonal smoothers, SPAI-0 and damped Jacobi, both in a theoretical idealized setting (constant coefficients, equispaced grid, periodic boundary conditions, etc.) and via numerical experiments.

3.1. The smoothing property.

From [15] and [16] we recall the following two conditions, which play a fundamental role in multigrid convergence theory:

1. The smoothing property [16, Def. 10.6.3]:

$$\|A_\ell S_\ell^\nu\|_2 \le \eta(\nu)\|A_\ell\|_2 \qquad \forall \nu, 0 \le \nu < \infty, \quad \forall \ell \ge 1, \tag{3.1}$$

$$\eta(\nu) \text{ any function with } \quad \lim_{\nu\to\infty} \eta(\nu) = 0.$$

2. The approximation property [16, sect. 10.6.3]:

$$\|A_\ell - pA_{\ell-1}r\|_2 \le \frac{C_A}{\|A_\ell\|_2} \qquad \forall \ell \ge 1. \tag{3.2}$$

Although we have stated these properties with respect to the Euclidean norm, other choices are possible. In general, the smoothing and approximation properties together imply convergence of the two-grid method and of the multigrid W-cycle, with a contraction number independent of the level number ℓ. Moreover, for symmetric positive definite problems, both conditions also imply multigrid V-cycle convergence independent of ℓ; see Hackbusch [16, sect. 10.6] for details.

The approximation property is independent of the smoother S_ℓ; it depends only on the discretization (A_ℓ, $A_{\ell-1}$), the prolongation operator p, and the restriction operator r. In [16] the approximation property is shown to hold for a large class of discrete elliptic boundary value problems. For symmetric positive definite problems the smoothing property usually holds for classical smoothers like damped Jacobi, (symmetric) Gauss–Seidel, and incomplete Cholesky. We shall now prove that the smoothing property (3.1) holds for SPAI-0 under reasonable assumptions on A_ℓ. To do so, we first recall (in a slightly simpler form) the following result for later reference.

LEMMA 3.1 (see [16, Lem. 10.7.4]). *Let A_ℓ and W_ℓ be symmetric and positive definite, and $S_\ell = I - W_\ell^{-1}A_\ell$. Assume that*

$$0 < A_\ell \le \Gamma W_\ell \qquad \forall \ell \ge 0 \quad \textit{with} \quad 0 < \Gamma < 2 \tag{3.3}$$

and that

$$\|W_\ell\|_2 \le C_W \|A_\ell\|_2 \qquad \forall \ell \ge 0. \tag{3.4}$$

Then S_ℓ satisfies the smoothing property (3.1), *with*

$$\eta(\nu) = C_W \max\{\eta_0(\nu), \Gamma|1-\Gamma|^\nu\}, \quad \eta_0(\nu) = \frac{1}{e\nu} + O(\nu^{-2}) \quad (\nu \to \infty). \tag{3.5}$$

In (3.3) and (3.4) both Γ and C_W must be independent of ℓ.

We shall now apply Lemma 3.1 to prove that SPAI-0 satisfies the smoothing property (3.1). To do so, we must show that W_ℓ satisfies (3.3) and (3.4), with $\Gamma < 2$. Here W_ℓ is the inverse of the diagonal approximate inverse defined in (2.9). Hence

$$W = \operatorname{diag}\left(\frac{\|a_i\|_2^2}{a_{ii}}\right), \tag{3.6}$$

where a_i denotes the ith row of A. We have dropped the level index ℓ to simplify the notation. Since A is symmetric and positive definite, $a_{ii} > 0,\ 1 \le i \le n$, and thus W is positive definite.

LEMMA 3.2. *Let A be a symmetric matrix with positive diagonal entries and let W be given by* (3.6)*. Furthermore, let p_i denote the number of nonzero off-diagonal entries in the ith row of A and assume that*

$$p \equiv \max_i p_i \le 7. \tag{3.7}$$

Then A satisfies $A \le \Gamma W$, with $\Gamma = (1 + \sqrt{1+p})/2 < 2$.

Proof. We seek $\Gamma < 2$ such that $A \le \Gamma W$. First, we let $A = D - R$, with $D = \operatorname{diag}(A)$. Then

$$\begin{aligned} &\Gamma W - A \ge 0 \\ \iff\ &\Gamma\left(D + \operatorname{diag}\left(\sum_{j\ne i}\frac{a_{ij}^2}{a_{ii}}\right)\right) - D + R \ge 0 \\ \iff\ &(\Gamma-1)D + \Gamma\operatorname{diag}\left(\sum_{j\ne i}\frac{a_{ij}^2}{a_{ii}}\right) + R \ge 0. \end{aligned} \tag{3.8}$$

We note that the first two terms in (3.8) are diagonal matrices, while all off-diagonal entries are located in R. We now assume that $\Gamma \ge 1$, so that all entries on the main diagonal in (3.8) are nonnegative. According to Gershgorin's theorem, for (3.8) to hold it is sufficient to have

$$\sum_{j\ne i}|a_{ij}| \le (\Gamma-1)a_{ii} + \Gamma\sum_{j\ne i}\frac{a_{ij}^2}{a_{ii}}, \qquad 1 \le i \le n. \tag{3.9}$$

Next, we divide (3.9) by a_{ii}, which yields the equivalent condition

$$\sum_{j\ne i}\beta_{ij} \le \Gamma - 1 + \Gamma\sum_{j\ne i}\beta_{ij}^2, \qquad 1 \le i \le n. \tag{3.10}$$

Here we have defined

$$\beta_{ij} = \frac{|a_{ij}|}{a_{ii}}.$$

Since p_i is the number of nonzero off-diagonal elements in row i of A, we conclude by Cauchy–Schwarz that

$$\sum_{j\ne i}\beta_{ij} \le \sqrt{p_i}\sqrt{\sum_{j\ne i}\beta_{ij}^2} \le \sqrt{p}\sqrt{\sum_{j\ne i}\beta_{ij}^2}, \qquad 1 \le i \le n.$$

Thus, for (3.10) to hold it is sufficient to have

$$\sqrt{p}\,\sqrt{\sum_{j\neq i}\beta_{ij}^2} \leq \Gamma - 1 + \Gamma\sum_{j\neq i}\beta_{ij}^2, \qquad 1\leq i\leq n.$$

Therefore, since $x = \sum_{j\neq i}\beta_{ij}^2$ is real, nonnegative, but otherwise arbitrary, it is sufficient to require that

$$\begin{aligned} &\sqrt{p}\,\sqrt{x} \leq \Gamma - 1 + \Gamma x \qquad \forall x\in[0,\infty),\\ \iff\ &\Gamma^2x^2 + (2\Gamma(\Gamma-1)-p)x + (\Gamma-1)^2 \geq 0 \qquad \forall x\in[0,\infty),\\ \iff\ &(2\Gamma(\Gamma-1)-p)^2 - 4\Gamma^2(\Gamma-1)^2 \leq 0. \end{aligned} \tag{3.11}$$

The last inequality (3.11) is equivalent to

$$-4\Gamma(\Gamma-1)p + p^2 \leq 0,$$

which holds for $\Gamma = (1+\sqrt{1+p})/2$. The assumption $p\leq 7$ yields $\Gamma < 2$. □

Remark 1. The result in Lemma 3.2 is sharp in the following sense. For every $\Gamma\in(0,2)$ there exists a symmetric matrix A with positive diagonal entries and with $p\geq 8$ such that the matrix $\Gamma W - A$ is not positive semidefinite. Indeed, we take the matrix $A = (1-\alpha)I + \alpha\mathbf{1}\mathbf{1}^T$, with $\alpha = (2\Gamma)^{-1}$ and $\mathbf{1} = (1,1,\dots,1)^T\in\mathbb{R}^n$. Then

$$\Gamma W - A = \Gamma\,\mathrm{diag}(1+(n-1)\alpha^2) - \big((1-\alpha)I + \alpha\mathbf{1}\mathbf{1}^T\big),$$

with smallest eigenvalue

$$\lambda_{\min} = \frac{1}{4\Gamma}\big(4\Gamma(\Gamma-1) - (n-1)\big).$$

Hence $\lambda_{\min} < 0$ if $p = n-1 \geq 8$.

Lemma 3.3. *Let W be given by* (3.6), *and let $\hat{C}$ be such that*

$$\max_i \sum_{j=1}^n \frac{a_{ij}^2}{a_{ii}^2} \leq \hat{C}. \tag{3.12}$$

Then W satisfies $\|W\|_2 \leq \hat{C}\,\|A\|_2$.

Proof. The proof is immediate, since

$$\begin{aligned} \|W\|_2 &= \left\|\mathrm{diag}(a_{ii})\,\mathrm{diag}\left(\frac{\|a_i\|_2^2}{a_{ii}^2}\right)\right\|_2\\ &\leq \|\,\mathrm{diag}(a_{ii})\|_2\left\|\mathrm{diag}\left(\frac{\|a_i\|_2^2}{a_{ii}^2}\right)\right\|_2\\ &\leq \|A\|_2\,\hat{C}. \qquad \square \end{aligned}$$

From Lemmas 3.1, 3.2, and 3.3 we now immediately conclude the following result.

Theorem 3.4. *Let A be symmetric positive definite, $\hat{C}$ as in* (3.12), *and let $S = I - MA$, with M the SPAI-*0 *preconditioner given by* (2.9). *Assume that p, the maximal number of nonzero off-diagonal entries per row, satisfies $p\leq 7$; see* (3.7). *Then S satisfies the smoothing property* (3.1), *with $\eta(\nu)$ as in* (3.5), *$C_W = \hat{C}$, and $\Gamma = (1+\sqrt{1+p})/2 < 2$.*

Remark 2. The following example shows that the condition on p in Theorem 3.4 is sharp. Take A as in remark 1, with $\alpha = (\sqrt{n}+1)^{-1}$. Then A is symmetric positive definite, $\|A\|_2 = \sqrt{n}$, and the inequality in (3.12) holds with $\hat{C} = 2$. Since $\mathbf{1} = (1, \dots, 1)^T$ is an eigenvector of both A and S, we immediately conclude that

$$\frac{\|AS^\nu\|_2}{\|A\|_2} \geq \frac{\|AS^\nu \mathbf{1}\|_2}{n} = \left(\frac{1}{2}(\sqrt{n}-1)\right)^\nu .$$

For $n \geq 9$, $\|AS^\nu\|_2 \|A\|_2^{-1} \nrightarrow 0$ as $\nu \to \infty$, and hence S does not satisfy the smoothing property (3.1).

We remark that neither M-matrix properties nor diagonal dominance of A_ℓ are needed to show that the smoothing property holds for SPAI-0. In the context of a multigrid convergence analysis the constant $\hat{C}$ in (3.12) must be independent of the level number ℓ. For the problems considered here this is always satisfied. Condition (3.7) is satisfied by standard second-order finite difference approximations of scalar elliptic boundary value problems in two or three space dimensions. It is also satisfied by linear finite element discretizations on a triangular mesh if each node on the coarsest mesh has at most seven neighbors. This property is then transferred to all finer levels if regular mesh refinement is used.

Next, we show that if A is weakly diagonally dominant, that is,

$$\sum_{j \neq i} |a_{ij}| \leq |a_{ii}| \qquad \forall\, i, \quad 1 \leq i \leq n,$$

we may drop condition (3.7) and thus obtain another criterion for the smoothing property.

THEOREM 3.5. *Let A be symmetric positive definite and weakly diagonally dominant. Furthermore, let $S = I - MA$, with M the SPAI-0 preconditioner given by* (2.9)*, and $C > 0$ be such that for every i, $1 \leq i \leq n$,*

$$\text{(3.13)} \qquad \textit{either} \;\; \sum_{j \neq i} a_{ij}^2 = 0 \;\; \textit{or} \;\; \sum_{j \neq i} \frac{a_{ij}^2}{a_{ii}^2} \geq C.$$

Then S satisfies the smoothing property (3.1)*, with $\eta(\nu)$ as in* (3.5)*, $C_W = 2$, and $\Gamma = 2/(1+C) < 2$.*

Proof. We first consider the case where

$$\text{(3.14)} \qquad \sum_{j \neq i} \frac{a_{ij}^2}{a_{ii}^2} \geq C > 0 \qquad \forall\, i, \quad 1 \leq i \leq n.$$

Again we seek $\Gamma < 2$ such that $A \leq \Gamma W$. To do so, we first follow the proof of Lemma 3.2 until (3.10). Now, since A is weakly diagonally dominant, we have

$$\text{(3.15)} \qquad \sum_{j \neq i} \beta_{ij} = \sum_{j \neq i} \frac{|a_{ij}|}{a_{ii}} \leq 1.$$

Hence for (3.10) to hold, it is sufficient to require

$$1 \leq \Gamma - 1 + \Gamma \sum_{j \neq i} \beta_{ij}^2, \qquad 1 \leq i \leq n,$$

which is equivalent to

$$\Gamma \geq \frac{2}{1+\sum_{j\neq i}\beta_{ij}^2}, \qquad 1 \leq i \leq n.$$

Because of (3.14) we can choose $\Gamma = 2/(1+C) < 2$.

To show that inequality (3.4) is indeed satisfied with $C_W = 2$, we first note that

$$\begin{aligned} \|W\|_2 = \|M^{-1}\|_2 &= \max_i \left(\frac{\|a_i\|_2^2}{a_{ii}}\right) \\ &= \max_i \left(a_{ii} + \frac{1}{a_{ii}}\sum_{j\neq i} a_{ij}^2\right) \\ &\leq \max_i \left(a_{ii} + \frac{1}{a_{ii}}\left(\sum_{j\neq i}|a_{ij}|\right)^2\right). \end{aligned}$$

The weak diagonal dominance of A then implies

$$\|W\|_2 \leq 2\max_i a_{ii} \leq 2\|A\|_2.$$

Next, we consider the general case, where C satisfies (3.13). Let $k > 0$ be the number of rows for which the only nonzero entry lies on the main diagonal. We apply a permutation P to A, so that these k rows appear first in

$$PAP^T = \begin{pmatrix} A_{11} & 0 \\ 0 & A_{22} \end{pmatrix}.$$

Hence A_{11} denotes the $k \times k$ diagonal block. The matrix $S = I - MA$ is also partitioned accordingly:

$$PSP^T = \begin{pmatrix} S_{11} & 0 \\ 0 & S_{22} \end{pmatrix}.$$

Because A_{11} is diagonal, the upper left block $S_{11} = I - A_{11}^{-1}A_{11}$ is identically zero. We now apply the first part of the proof to A_{22}, which yields

$$\|A_{22}S_{22}^{\nu}\|_2 \leq 2\max\{\eta_0(\nu), \Gamma|1-\Gamma|^{\nu}\}\|A_{22}\|_2,$$

with $\Gamma = 2/(1+C)$. Therefore S satisfies the smoothing property, since

$$\begin{aligned} \|AS^{\nu}\|_2 = \|(PAP^T)(PSP^T)^{\nu}\|_2 &= \left\| \begin{pmatrix} A_{11} & 0 \\ 0 & A_{22} \end{pmatrix} \begin{pmatrix} 0 & 0 \\ 0 & S_{22} \end{pmatrix}^{\nu} \right\|_2 \\ &= \|A_{22}S_{22}^{\nu}\|_2 \leq 2\max\{\,\eta_0(\nu), \Gamma|1-\Gamma|^{\nu}\,\}\|A_{22}\|_2 \\ &\leq 2\max\{\,\eta_0(\nu), \Gamma|1-\Gamma|^{\nu}\,\}\|A\|_2. \qquad \square \end{aligned}$$

In the context of a multigrid convergence analysis the constant C in (3.13) must be independent of the level number ℓ. For the problems considered here this is always satisfied. In summary, we have shown for A symmetric positive definite that SPAI-0 satisfies the smoothing property if either A is weakly diagonally dominant or if the maximal number of nonzero off-diagonal entries per row is less than or equal to seven.

3.2. SPAI-0 versus Jacobi. Before we proceed with a comparison of the performance of these two diagonal smoothers via numerical experiments, we first point out a very special situation where SPAI-0 and damped Jacobi, with optimal relaxation parameter ω^*, lead to identical smoothers.

For the discrete Laplacian on a regular grid with periodic boundary conditions, the damping parameter ω^*, which is "optimal" with respect to smoothing, is known. Following the standard Fourier analysis in [27, sect. 7.3], we consider a regular d-dimensional equispaced mesh with n grid points in each dimension. (For simplicity we assume n to be even.) Then the eigenvalues of the discrete Laplacian with periodic boundary conditions are

$$\sigma(\theta) = \frac{4}{h^2} \sum_{j=1}^{d} \sin^2\left(\frac{\theta_j}{2}\right), \qquad \theta = (\theta_1, \theta_2, \dots, \theta_d),$$

with $h = 1/n$ and $\theta_j \in \{-\pi + 2\pi h, -\pi + 4\pi h, \dots, \pi\}$. Note that $\theta \in \prod_{j=1}^{d}[-\pi, \pi]$. The iteration matrix of the damped Jacobi method has eigenvalues

$$\lambda(\theta) = 1 - \frac{2\omega}{d} \sum_{j=1}^{d} \sin^2\left(\frac{\theta_j}{2}\right).$$

We now concentrate on the high frequencies, which correspond to the subset

$$\bar{\Theta}_r = \prod_{j=1}^{d}[-\pi, \pi] \setminus \prod_{j=1}^{d}\left(-\frac{\pi}{2}, \frac{\pi}{2}\right).$$

The amount of damping on the high-frequency components is measured by the *smoothing factor*,

$$\mu(\omega) = \max_{\theta \in \bar{\Theta}_r} |\lambda(\theta)|.$$

It is independent of the mesh size but depends on ω. The optimal damping parameter, ω^*, is that for which the smoothing factor is minimal,

$$\mu^* = \mu(\omega^*) = \min_{\omega} \mu(\omega).$$

To determine ω^* we first calculate $\mu(\omega)$. For $\theta \in \bar{\Theta}_r$, the extreme values of $\sum_{j=1}^{d} \sin^2(\theta_j/2)$ are $1/2$ and d. Thus, we find that

$$\mu(\omega) = \max\left\{\left|1 - \frac{\omega}{d}\right|, |1 - 2\omega|\right\}.$$

The minimization of $\mu(\omega)$ then yields the optimal damping parameter,

$$\omega^* = \frac{2d}{2d+1}. \tag{3.16}$$

PROPOSITION 3.6. *Consider the discrete Laplacian with periodic boundary conditions in d space dimensions, which results from a standard second-order finite difference discretization on an equispaced grid. Then SPAI-*0 *and Jacobi smoothing, with optimal damping parameter* ω^* *given by* (3.16)*, are identical.*

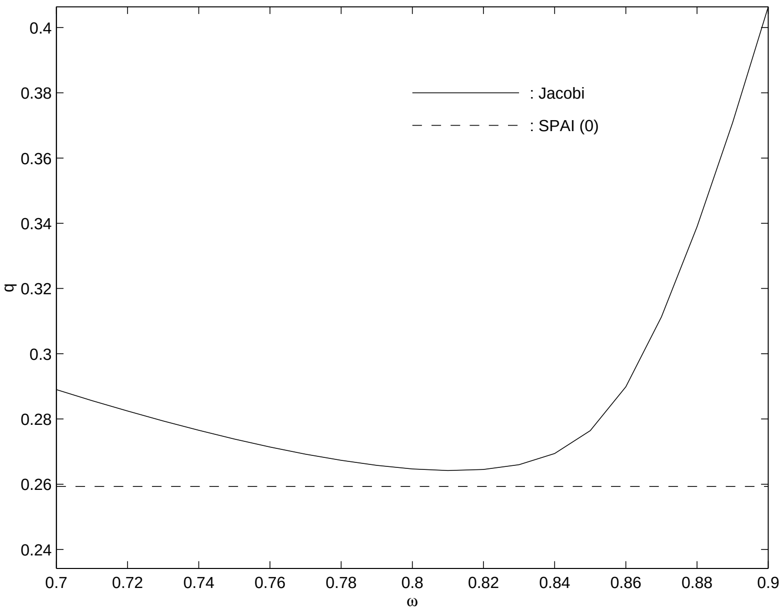

FIG. 3.1. *Comparison of the convergence rates q obtained with SPAI-*0 *and damped Jacobi for varying relaxation parameter ω; see* (4.2) *for the definition of q.*

Proof. Since for the discrete d-dimensional Laplacian we have $a_{ii} = (2d)\,h^{-2}$ and $\|a_i\|_2^2 = 2d\,(2d+1)\,h^{-4}$, for all $1 \le i \le n$, the approximate inverse M defined in (2.9) for SPAI-0 has the constant diagonal entry $m_{ii} = h^2/(2d+1)$. Therefore $M = \omega^* D^{-1}$ and the SPAI-0 and the damped Jacobi smoothers, with optimal damping parameter ω^* given in (3.16), coincide. □

In this special situation, the parameter-free SPAI-0 smoother automatically yields a scaling of diag(A) which minimizes the smoothing factor; in that sense it is optimal.

Although both SPAI-0 and damped Jacobi yield diagonal smoothers, they typically differ, even with constant coefficients on an equispaced mesh. Indeed, the presence of boundary conditions modifies the rows of A_ℓ, which correspond to nodes on the boundary, and thus modifies SPAI-0 locally. We now compare quantitatively the performance of these two diagonal smoothers on the following class of model problems:

$$\begin{aligned} -\mathrm{div}(a(x,y)\nabla u(x,y)) &= 1 \qquad \text{in } \Omega, \\ u(x,y) &= 0 \qquad \text{on } \partial\Omega. \end{aligned} \tag{3.17}$$

First, we choose $\Omega = (0,1)\times(0,1)$, set $a(x,y) \equiv 1$, and discretize the problem with continuous piecewise linear finite elements on a triangular mesh. The various meshes are obtained successively by uniform refinement, starting from the coarsest mesh with a single unknown in the center of Ω. Here we use a multigrid V-cycle iteration with one pre- and one postsmoothing step ($\nu_1 = \nu_2 = 1$). We recall that SPAI-0 is parameter-free, whereas damped Jacobi contains the single relaxation parameter ω. In general the optimal damping parameter ω^* is unknown in advance and must be determined numerically in any given situation.

Is it possible for damped Jacobi to beat SPAI-0 by varying ω and thus determining the optimal value ω^*? In Figure 3.1 we compare the convergence rate of SPAI-0 with that of Jacobi smoothing. The fastest convergence rate with damped Jacobi is attained with $\omega^* \simeq 0.81$, but the convergence rate obtained with SPAI-0 still lies slightly below it.

We have performed similar numerical experiments for more difficult problems, including L-shaped domains and problems with discontinuous coefficients. In all cases the overall picture remains the same: the convergence rate obtained with SPAI-0 smoothing consistently lies below that obtained with damped Jacobi smoothing for all values of ω. Although the improvement is usually small, and thus not really significant, it is remarkable because SPAI-0 is parameter-free.

Finally we compare SPAI-0 with Jacobi smoothing for an elliptic differential operator of the form

$$-c_{11}\partial_{xx} + 2c_{12}\partial_{xy} - c_{22}\partial_{yy},$$

where c_{11}, c_{12}, and c_{22} are constant and $c_{11} \geq c_{22}$. Because of consistency and ellipticity a second-order finite difference discretization on a doubly periodic uniform square grid usually results in the stencil

$$\begin{bmatrix} -\frac{B}{2} & -C & \frac{B}{2} \\ -A & 2(A+C) & -A \\ \frac{B}{2} & -C & -\frac{B}{2} \end{bmatrix},$$

with

$$A, C > 0, \quad A + C = 1, \quad A \geq C, \quad B^2 < AC.$$

In [29] Yavneh and Olvovsky derive the smoothing factor $\mu(\omega)$ of damped Jacobi when applied to such a stencil,

$$\mu(\omega) = \max\left\{ |1 - 2\omega|, \left|1 - \omega\left(1 - \sqrt{A^2 + B^2}\right)\right| \right\}.$$

They also determine the corresponding optimal relaxation parameter, ω^*, which minimizes $\mu(\omega)$ over the high frequencies:

$$\omega^* = \frac{2}{3 - \sqrt{A^2 + B^2}}\ .$$

Since the stencil is constant throughout the entire grid, the approximate inverse M for SPAI-0 reduces to a constant diagonal matrix. Thus, in this very special situation, the SPAI-0 smoother corresponds to the damped Jacobi method with relaxation parameter

$$\omega^{\text{SPAI}} = \frac{4}{4 + B^2 + 2C^2 + 2A^2}\ .$$

Next, we introduce the variables

$$x = \frac{C}{A} \in (0, 1) \text{ and } y = \frac{B^2}{AC} \in [0, 1).$$

Hence the smaller the x, the stronger the anisotropy. We can now rewrite $\mu(\omega)$, ω^*, and ω^{SPAI} only in terms of x and y as

$$\begin{aligned}\mu(\omega) &= \max\left\{ |1-2\omega|\,,\, 1-\omega+\omega\frac{\sqrt{1+xy}}{1+x} \right\}\,,\\ \omega^* &= \frac{2(1+x)}{3(1+x)-\sqrt{1+xy}}\,,\\ \omega^{\text{SPAI}} &= \frac{4(x+1)^2}{4(x+1)^2+2(x^2+1)+xy}\,.\end{aligned}$$

In the left frame of Figure 3.2 the smoothing factor μ^* for the optimal relaxation parameter ω^* is shown. The highest reduction is reached for $x = 1$ and $y = 0$, which corresponds to the Laplacian operator ($A = C = 1/2$, $B = 0$). As x diminishes and eventually drops below 0.2, we observe that damped Jacobi becomes a very poor smoother.

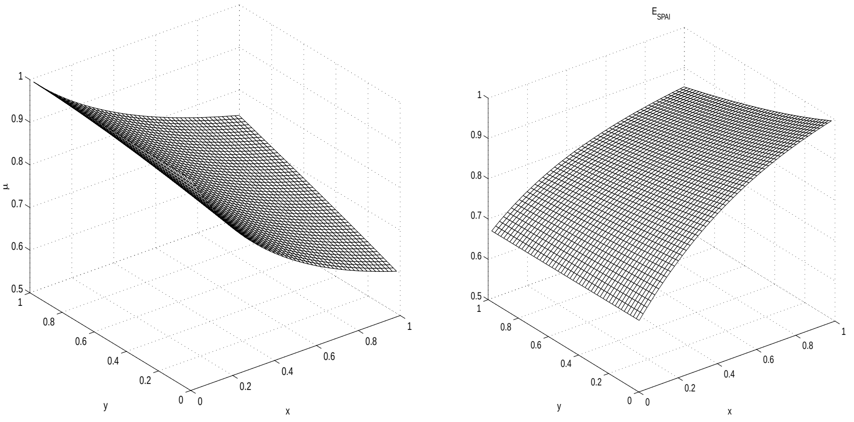

FIG. 3.2. *Comparison of SPAI-*0 *vs. damped Jacobi: the smoothing factor μ^* for optimally damped Jacobi (left) and the relative smoothing efficiency E_{SPAI} for SPAI-*0 *(right).*

To compare the effectiveness of SPAI-0 smoothing with that of optimally damped Jacobi, we introduce the *relative smoothing efficiency*,

$$E_{\text{SPAI}} = \frac{\log\,\mu(\omega^{\text{SPAI}})}{\log\,\mu(\omega^*)} \in (0,1].$$

It is shown in the right frame of Figure 3.2. If $E_{\text{SPAI}} = 100\%$ the SPAI-0 method automatically produces the optimal damping parameter, whereas if $E_{\text{SPAI}} = 50\%$, for instance, SPAI-0 would require twice as many iterations as optimally damped Jacobi to obtain the same smoothing effect. In particular, for the standard five-point Laplacian ($x = 1, y = 0$) SPAI-0 yields $E_{\text{SPAI}} = 100\%$, as it coincides with optimally damped Jacobi; see Proposition 3.6. The relative efficiency for SPAI-0 is somewhat reduced in more general situations with mixed derivatives or strong anisotropy. Nevertheless, E_{SPAI} lies above 75% for $x \geq 0.2$; it drops down to 67% only in extreme cases ($x \to 0$), for which damped Jacobi would be ineffective anyway. Whenever damped Jacobi is a good smoother, SPAI-0 typically provides at least 80–90% efficiency with respect to optimally damped Jacobi smoothing for second-order finite difference discretizations of elliptic differential operators.

4. Numerical results. To illustrate the usefulness and versatility of SPAI smoothing, we shall now consider various standard test problems. In all cases we use a regularly refined sequence of equispaced grids. The differential equation considered is discretized on the finest level with standard finite differences. The coarse grid operators are obtained via the Galerkin product formula, $A_{\ell-1} = r\, A_\ell\, p$, with $r = p^\top$ and p standard linear interpolation. We use a multigrid V-cycle iteration, with two pre- and two postsmoothing steps ($\nu_1 = \nu_2 = 2$) and $x_\ell^{(0)} = 0$ as initial guess. On the coarsest level ($\ell = 0$), we solve exactly for the single unknown remaining at the center of the domain. The iteration proceeds until the relative residual drops below the prescribed tolerance,

$$\frac{\|b - A_\ell\, x_\ell^{(m)}\|}{\|b\|} < 10^{-8}. \tag{4.1}$$

Then we calculate the average rate of convergence,

$$q = \left(\frac{\|b - A_\ell\, x_\ell^{(m)}\|}{\|b\|} \right)^{1/m}. \tag{4.2}$$

We recall that the ordering of the unknowns does not affect the SPAI-smoothing iteration (2.5), but it does affect the Gauss–Seidel iteration. In all numerical examples we shall use lexicographic ordering of the unknowns.

Clearly, when comparing the performance of various smoothers, we cannot limit ourselves to comparing the number of multigrid iterations, but we must also take into account the amount of arithmetic work due to the smoother. To do so, we calculate the total density ratio, ρ, of nonzero entries in M to those in A on all grid levels, $1 \le i \le \ell$, where smoothing is applied:

$$\rho = \frac{\sum_{i=1}^{\ell} \operatorname{nnz}(M_i)}{\sum_{i=1}^{\ell} \operatorname{nnz}(A_i)}. \tag{4.3}$$

Hence the additional amount of work due to the smoother is proportional to ρ. For a standard five-point stencil on a regular two-dimensional grid, $\rho_{\text{SPAI-0}} \simeq 1/5$, like damped Jacobi. Since $\rho_{\text{SPAI-1}} = 1$, the SPAI-1 smoother is about 67% times more expensive here than the SPAI-0 smoother. For SPAI(ε), the total density ratio, $\rho_{\text{SPAI}(\varepsilon)}$, depends on ε: it increases monotonically with decreasing ε. We remark that $\rho_{\text{SPAI}(\varepsilon)} < 1$ whenever SPAI(ε) leads to an approximate inverse sparser than SPAI-1.

4.1. Poisson problem. We first consider the Poisson problem on the unit square with Dirichlet boundary conditions (3.17). In Table 4.1 we compare the convergence rates obtained with various smoothers. All SPAI smoothers lead to h-independent convergence rates. We observe a steady decrease of the convergence rate, q, for smaller values of ε, paralleled, of course, by an increase in ρ given in parentheses. Note that SPAI-1 leads to a more effective but denser smoother than SPAI(ε) with $\varepsilon = 0.35$, yet the situation is reversed as ε decreases below 0.25.

4.2. Locally anisotropic diffusion. We now consider the locally anisotropic diffusion problem

$$-\left(\nu(x,y) \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) = 1 \quad \text{in} \quad (0,1) \times (0,1), \tag{4.4}$$

Table 4.1

Poisson problem: convergence rates q obtained with SPAI-0, SPAI-1, SPAI(ε), and Gauss–Seidel smoothing. The relative total density, ρ, defined in (4.3), is given in parentheses. For SPAI-0, $\rho = 0.17$ and for SPAI-1, $\rho = 1$.

Grid size	G-S	SPAI-0	SPAI-1	SPAI(0.35)	SPAI(0.25)
32×32	0.04	0.09	0.04	0.06 (0.7)	0.03 (1.5)
64×64	0.05	0.09	0.04	0.07 (0.7)	0.03 (1.5)
128×128	0.05	0.09	0.04	0.08 (0.7)	0.04 (1.5)

Table 4.2

Locally anisotropic diffusion: convergence rates q for varying ν on a 128×128 grid. The relative density, ρ, is given in parentheses.

Smoother	ν				
	1	10^{-1}	10^{-2}	10^{-3}	10^{-6}
Gauss–Seidel	0.05	0.42	0.89	0.97	0.98
SPAI-0	0.09	0.72	0.95	0.98	0.98
SPAI-1	0.04	0.37	0.89	0.97	0.98
SPAI(0.4)	0.12 (0.7)	0.16 (0.7)	0.81 (0.7)	0.95 (0.8)	0.97 (0.8)
SPAI(0.25)	0.04 (1.5)	0.07 (1.6)	0.37 (1.7)	0.75 (1.9)	0.87 (1.9)

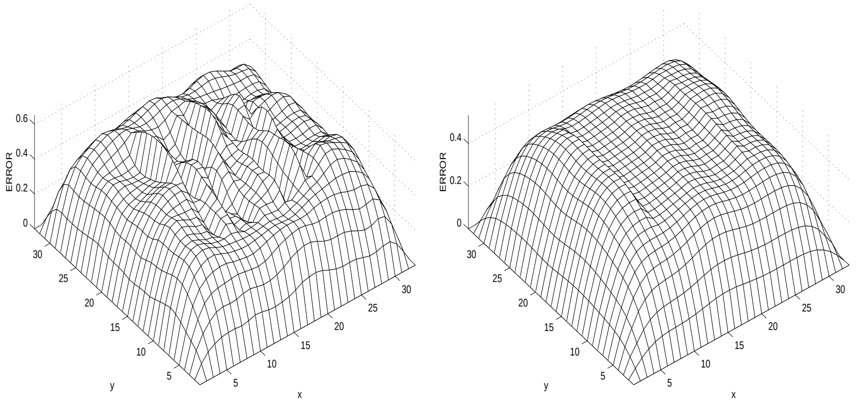

Fig. 4.1. *The error after five smoothing steps for the locally anisotropic diffusion problem with $\nu = 0.01$. Left: Gauss–Seidel; right: SPAI(0.25).*

with $u(x, y) = 0$ on the boundary. We set $\nu(x, y) = 1$ everywhere except inside the square $[1/4, 3/4] \times [1/4, 3/4]$, where $\nu(x, y) \equiv \nu$ is constant.

In Table 4.2 we compare the performance of Gauss–Seidel with SPAI smoothing for varying ν. For $\nu \leq 0.1$, the convergence rates for SPAI(0.4) lie consistently below those for Gauss–Seidel, while SPAI(0.25) leads to an even greater improvement. In particular, for $\nu = 0.01$ Gauss–Seidel smoothing barely converges, whereas SPAI(ε) with $\varepsilon \leq 0.4$ still yields acceptable convergence. Figure 4.1 shows that Gauss–Seidel is unable to smooth the error throughout Ω, mainly in the x-direction. In contrast, SPAI(ε) smoothing with $\varepsilon = 0.25$ results in a smooth error across the entire computational domain for $\nu = 0.01$. In Figure 4.2 we compare rows $e_j^\top A^{-1}$ and $e_j^\top M$, where M is computed with SPAI(0.25), for two unit basis vectors e_j. We consider e_j corresponding to the grid points $(1/2, 1/2)$ in the center of Ω, where $\nu = 0.01$, and $(1/8, 1/8)$ inside the surrounding region where $\nu = 1$. We observe how the approximate inverse, computed by the SPAI-Algorithm, captures the distinct local features of the true inverse. We recall that the sparsity pattern of M is not fixed a priori but adapted automatically by the SPAI-Algorithm. For $\nu \leq 0.1$, the SPAI(0.4) smoother is not only more effective but also sparser than the SPAI-1 smoother. Hence the sophisticated search of the SPAI-Algorithm for an effective sparsity pattern of M clearly benefits the smoother.

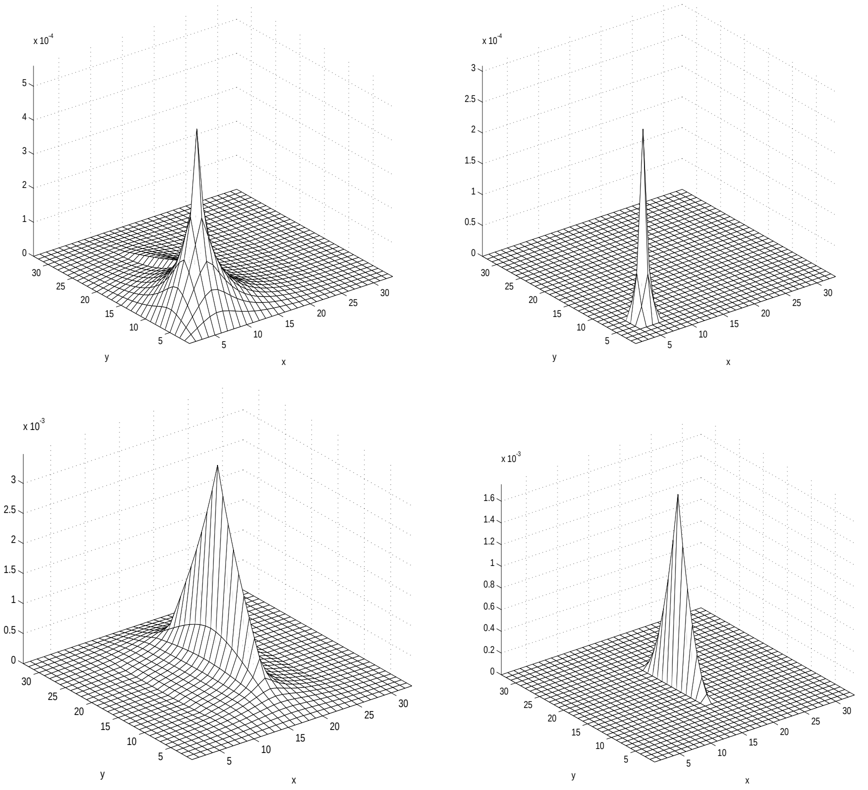

FIG. 4.2. *Comparison of a row of the true inverse,* $e_j^\top A^{-1}$ *(left), and of the approximate inverse,* $e_j^\top M$ *(right), for* $\nu = 0.01$*, where* M *is computed with SPAI*(0.25)*. Top:* e_j *corresponds to the grid point* $(1/8, 1/8)$*; bottom:* e_j *corresponds to the grid point* $(1/2, 1/2)$*.*

These results demonstrate the usefulness of SPAI smoothing; they corroborate previous results obtained in [25], with $\nu = 0.01$ everywhere in Ω. Nevertheless, as the contrast in the anisotropy increases further, the convergence rates obtained with SPAI smoothing deteriorate as well. If the anisotropy occupies a small area of the domain of interest, say only within a boundary layer, further reducing ε enables the algorithm to locally adjust the smoother and still reach acceptable convergence rates. However, if the anisotropy is strong and present throughout the domain, the SPAI smoothers will become too dense and thus too expensive.

Of course, various standard approaches combined with Gauss–Seidel smoothing, such as line relaxation or semicoarsening, provide the means to circumvent some of these problems [23]. However, these techniques are effective mainly on regular Cartesian grids, when the anisotropy is aligned with the mesh throughout Ω. They are difficult to use on unstructured grids and become expensive, for instance, when parts of the domain have strong anisotropy in x, while other parts have strong anisotropy in y. In contrast, the SPAI smoothers are not tied to a regular mesh or any specific discretization; moreover, they automatically adapt to local features of the problem.

4.3. Convection-diffusion problems.

We now consider

$$-\nu\Delta u(x,y) + \vec{v}(x,y)\cdot\nabla u(x,y) = 1, \quad \nu > 0, \tag{4.5}$$

in the unit square, where u vanishes on the boundary. Here u represents any scalar quantity advected by the flow field $\vec{v}$. Because the linear systems cease to be symmetric and positive definite, these problems lie outside of classical multigrid theory. We use centered second-order finite differences for the diffusion, but discretize the convection with first-order upwinding to ensure numerical stability.

TABLE 4.3

Constant flow direction with angle α from the x-axis: the convergence rates, q, obtained with different smoothers on a 128×128 grid for the diffusion and the convection dominated cases $\nu = 0.1$ and $\nu = 0.001$, respectively. The relative density, ρ, is given in parentheses.

Problem	G-S$_G$	SPAI-0	SPAI-1	SPAI(0.35)	SPAI(0.25)
$\nu = 0.1, \alpha = 45°$	0.05	0.11	0.05	0.08 (0.8)	0.04 (1.6)
$\nu = 0.1, \alpha = 225°$	0.05	0.11	0.05	0.08 (0.8)	0.04 (1.6)
$\nu = 0.001, \alpha = 45°$	†	0.98	0.98	0.06 (1.7)	0.02 (2.2)
$\nu = 0.001, \alpha = 225°$	†	0.98	0.98	0.06 (1.7)	0.02 (2.2)

First, we consider a situation of unidirectional flow, with angle α from the x-axis, that is with constant flow direction $\vec{v}(x,y) = [\cos(\alpha), \sin(\alpha)]$. In Table 4.3 we compare the performance of Gauss–Seidel with SPAI smoothing on a regular 128×128 grid. For diffusion dominated flow, $\nu = 0.1$, the convergence rates obtained either with Gauss–Seidel or with SPAI smoothing are essentially independent of the flow direction.

For convection dominated flow, $\nu \ll h$, the multigrid iteration with Gauss–Seidel smoothing does not converge when the coarse grid operators are computed via Galerkin projection. To obtain a convergent scheme, one needs to compute the coarse grid operators via discrete coarse grid approximation, that is, by discretizing (4.5) explicitly on all grid levels [27, p. 79]. In that situation it is well known that the convergence with Gauss–Seidel smoothing strongly depends on the ordering of the unknowns: the mere reversal of the flow direction (or, equivalently, the ordering of the unknowns) results in a large increase in the convergence rate, from $q = 0.17$ to $q = 0.55$; the contrast becomes even more striking for smaller values of ν. Indeed, when the flow direction is aligned with the ordering of the unknowns, the problem degenerates into a quasi-lower triangular system as $\nu \to 0$. In that situation, the Gauss–Seidel inverse, $(L + D)^{-1}$, essentially yields A^{-1} and thus results in rapid convergence. In contrast, the SPAI smoothers are not affected by the ordering of the unknowns and thus yield identical results in Table 4.3 for both $\alpha = 45°$ and $\alpha = 225°$. For $\nu = 0.001$ the performance of SPAI-1 is poor, while SPAI(ε) with $\varepsilon \leq 0.35$ yields excellent convergence rates at little extra cost.

Next, we consider a situation of rotating flow, where u solves (4.5) with $\vec{v}(x,y) = [y - 1/2, 1/2 - x]$. In this special situation, shown in Figure 4.3, it is generally impossible to reorder the unknowns so that the entire system becomes lower triangular for vanishing ν. As a consequence, the multigrid iteration with Gauss–Seidel smoothing usually diverges for small ν. Convergence can be attained with symmetric Gauss–Seidel smoothing, that is, by repeated application of the Gauss–Seidel iterations in

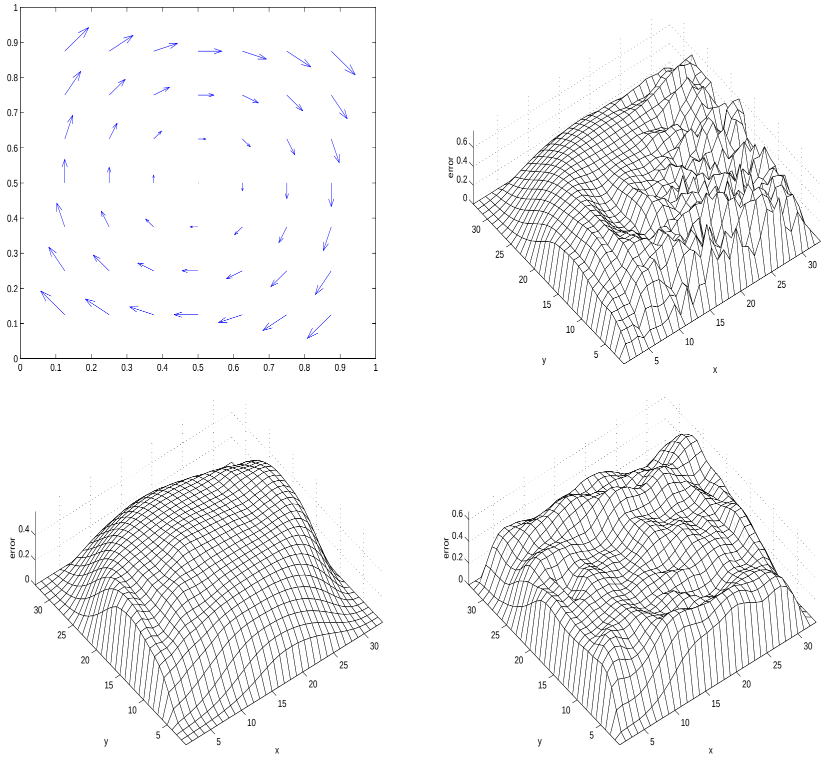

FIG. 4.3. *Rotating flow, $\nu = 10^{-3}$, 32×32 grid: flow field $\vec{v}(x, y)$ (upper left); the effect of three smoothing steps applied to an initially random error: Gauss–Seidel smoothing (upper right); ILU(0) smoothing (lower left); SPAI-1 smoothing (lower right). Note that Gauss–Seidel is unable to smooth the error throughout the domain.*

TABLE 4.4
Diffusion dominated case, $\nu = 0.1$: the convergence rates q obtained with various smoothers. For SPAI(0.35) the relative density is $\rho = 0.7$.

	Gauss–Seidel	SPAI-0	SPAI-1	SPAI(0.35)
64×64	0.04	0.10	0.04	0.07
128×128	0.05	0.10	0.04	0.08
256×256	0.05	0.10	0.04	0.08

natural and reverse ordering of the unknowns [27]; this approach does not generalize easily to unstructured grids. In contrast, SPAI-1 and SPAI(ε) lead to convergent multigrid iterations regardless of the flow pattern or the ordering of the unknowns, and without modifying additional components of the multigrid iteration.

In Table 4.4 we observe that all SPAI smoothers yield h-independent convergence rates in the diffusion dominated case, with $\nu = 0.1$. Although the convergence rate essentially doubles from SPAI-1 to SPAI-0 smoothing, the density ratio ρ drops from 1 to 0.17, which reduces the amount of work in applying the smoother. For SPAI(0.35) the convergence rate lies between those obtained with SPAI-0 and SPAI-1, and so does the relative density $\rho = 0.7$.

Finally, we set $\nu = 10^{-3}$ and thus consider a convection dominated rotating flow, that is, $\nu \ll h$. Both the convergence rates and the relative densities ρ are shown in

Table 4.5 for different smoothers. Neither Gauss–Seidel nor SPAI-0 smoothing lead to a convergent multigrid iteration. Indeed, Gauss–Seidel is unable to smooth the error throughout the domain due to the absence of a dominant "unidirectional" flow direction, as shown in Figure 4.3. Again we note that convergence may be achieved by using symmetric Gauss–Seidel smoothing [27]. Our attempt to use ILU(0) on the 128 × 128 grid eventually failed because of numerical instability encountered in the computation of the ILU decomposition. Alternative variants of ILU would probably work [28].

Table 4.5

Convection dominated case, $\nu = 10^{-3}$: the convergence rates q obtained with various smoothers. The relative density, ρ, is given in parentheses.

	SPAI-1	SPAI (0.5)	SPAI (0.4)	SPAI (0.3)	SPAI (0.2)
128 × 128	0.61	0.67 (0.4)	0.42 (0.6)	0.22 (1.4)	0.09 (3.6)
256 × 256	0.68	0.75 (0.2)	0.45 (0.6)	0.31 (1.3)	0.12 (3.2)

Table 4.5 illustrates the typical behavior of SPAI smoothing versus ε. It shows that reducing ε in the SPAI-Algorithm produces a steady reduction in the convergence rate. Hence a greater reduction of $\|I - MA\|_F$ typically yields an improved smoother. Of course, as ε decreases, both the work in computing and in applying the smoother M rapidly increase, so that the optimal value of ε with the smallest total time probably lies between 0.2 and 0.5 for this problem. For SPAI(0.4) both q and ρ remain essentially constant as the mesh is refined. As we compare the performance of SPAI-1 with that of SPAI(0.4), we remark that both the convergence rate q and the total density ratio ρ are reduced. Therefore the sophisticated search of the original SPAI-Algorithm [14] benefits the smoother by selecting an effective sparsity pattern for M; clearly, the increase in the cost of computing M is worthwhile when memory resources are critical. It may even pay off in reducing total time, since fewer nonzero entries in M results in a cheaper smoother. Again these considerations are problem and architecture dependent; hence it is important to provide the user with a simple but effective way to tune the algorithm, here by adjusting the value of ε.

Table 4.6

Robust convergence with SPAI(0.3) smoothing with respect to ν on a 128×128 grid: both the convergence rate q and the relative density ρ are shown.

	$\nu = 1$	$\nu = 0.1$	$\nu = 0.01$	$\nu = 10^{-3}$	$\nu = 10^{-4}$	$\nu = 10^{-5}$	$\nu = 10^{-6}$
q	0.07	0.07	0.05	0.22	0.73	0.74	0.75
ρ	0.86	0.85	0.92	1.41	2.11	2.29	2.31

What if we decrease ν while keeping the grid spacing fixed? Do we obtain a robust multigrid algorithm (in the sense of [28])? In Table 4.6 we show the convergence rate and density obtained with SPAI (0.3) on the 128 × 128 grid for varying ν. Although both q and ρ vary throughout the range of values for ν, they remain bounded as $\nu \to 0$.

5. Conclusion.

Our numerical results show that sparse approximate inverses based on minimizing the Frobenius norm are an attractive alternative to classical Jacobi or Gauss–Seidel smoothing. For symmetric positive definite problems, SPAI-1 typically behaves like Gauss–Seidel, whereas SPAI-0, which is parameter-free, usually has a slight edge over damped Jacobi with optimal relaxation parameter. Moreover, our proof of the smoothing property for SPAI-0 applies also in situations where that of

Jacobi smoothing cannot be shown. For convection dominated flow problems, such as rotating flow, the ordering independence of SPAI-1 leads to a more robust smoother than Gauss–Seidel. In situations where neither SPAI-0 nor SPAI-1 suffice, SPAI(ε) automatically improves the smoother locally where needed. Both the computation and the application of the SPAI smoothers are inherently parallel.

Nevertheless, our results also show the limitations of SPAI smoothing in difficult situations, such as strong anisotropy, where the lack of isotropic smoothing needs to be compensated by appropriate prolongation and restriction operators. It is very interesting to combine this new hierarchy of local and inherently parallel smoothers with matrix-dependent coarsening strategies, such as found in algebraic multigrid [22]. The first two authors are currently pursuing these issues and will report on them elsewhere [9] in the near future.

The C/MPI version of the SPAI-Algorithm [1, 2] with Matlab and PETSc interfaces can be downloaded from the following address: http://www.sam.math.ethz.ch/˜grote/spai/.

DEVELOPMENT OF CFL-FREE, EXPLICIT SCHEMES FOR MULTIDIMENSIONAL ADVECTION-REACTION EQUATIONS*

HONG WANG† AND JIANGGUO LIU†

Abstract. We combine an Eulerian–Lagrangian approach and multiresolution analysis to develop unconditionally stable, explicit, multilevel methods for multidimensional linear hyperbolic equations. The derived schemes generate accurate numerical solutions even if large time steps are used. Furthermore, these schemes have the capability of carrying out adaptive compression without introducing mass balance error. Computational results are presented to show the strong potential of the numerical methods developed.

Key words. advection-reaction equations, characteristic methods, explicit methods, multilevel methods, multiresolution analysis, unconditional stability, wavelet decompositions

1. Introduction.

Advection-reaction partial differential equations (PDEs) model the reactive transport of solutes in subsurface flows, fluid dynamics, and many other important applications [11, 15]. These equations admit solutions with moving steep fronts, which need to be resolved accurately in applications and often cause severe numerical difficulties. Standard finite difference or finite element methods tend to generate numerical solutions with severe nonphysical oscillations. While upstream weighting methods can eliminate or alleviate these oscillations, they introduce excessive numerical dispersion and grid orientation effects [11, 15]. Most improved methods are explicit, and thus are local, relatively easy to implement, and fully parallelizable. It is well known that there are no explicit, unconditionally stable, consistent finite difference schemes (or virtually any schemes with fixed stencils) for linear hyperbolic PDEs [5]. Consequently, explicit methods are subject to the Courant–Friedrichs–Lewy (CFL) condition and have to use small time steps in numerical simulations to maintain the stability of the methods [11]. On the other hand, implicit methods are unconditionally stable, and so allow large time steps to be used in numerical simulations while still maintaining their stability. But they require inverting a coefficient matrix at each time step in order to generate numerical solutions. The time steps in implicit methods cannot be taken too large due not to the stability constraint but for reasons of accuracy. Local truncation error analysis shows that in implicit methods the temporal errors and spatial errors add up. Thus, the resulting solutions are very sensitive to the time step size.

In recent years, there has been an increasing interest in the application of wavelet techniques in developing efficient numerical schemes for various types of PDEs [3, 7, 14]. For hyperbolic PDEs, the existence of moving steep gradients separating smooth structures is a clear indication that these techniques can be helpful in the design of

efficient numerical techniques for the solution of hyperbolic PDEs. Motivated by these observations, we combine an Eulerian–Lagrangian approach and wavelet techniques to develop unconditionally stable, explicit schemes for multidimensional advection-reaction PDEs, including single-level schemes, multilevel schemes, and adaptive multilevel schemes. These schemes generate accurate numerical solutions even if large time steps are used. Computational results are presented to show the strong potential of the schemes developed.

The rest of this paper is organized as follows. In section 2, we derive a reference equation for the initial-value problems of advection-reaction PDEs in multiple space dimensions. In section 3, we briefly review multiresolution analysis and wavelet decompositions. In section 4, we develop CFL-free, explicit numerical schemes. In section 5, we prove the unconditional stability of these schemes. In section 6, we perform numerical experiments to observe the performance of the schemes and to verify their unconditional stability. In section 7, we outline the extensions of the schemes to the initial-boundary-value problems of advection-reaction PDEs. In section 8, we summarize the results in this paper and draw some conclusions.

2. A reference equation. We consider the initial-value problem for linear advection-reaction PDEs,

$$\begin{aligned} u_t + \nabla\cdot(\mathbf{v}u) + Ru &= q(\boldsymbol{x},t), \qquad &(\boldsymbol{x},t)\in\mathbb{R}^d\times(0,T],\\ u(\boldsymbol{x},0) &= u_0(\boldsymbol{x}), &\boldsymbol{x}\in\mathbb{R}^d, \end{aligned} \tag{2.1}$$

where $\mathbf{v}(\boldsymbol{x},t)$ is a fluid velocity field, $R(\boldsymbol{x},t)$ is a first-order reaction coefficient, $u(\boldsymbol{x},t)$ is the unknown function, and $q(\boldsymbol{x},t)$ and $u_0(\boldsymbol{x})$ are the prescribed source term and initial condition, respectively. We assume that $u_0(\boldsymbol{x})$ and $q(\boldsymbol{x},t)$ have compact support, so the exact solution $u(\boldsymbol{x},t)$ has compact support for any finite time $t>0$.

We define a uniform partition of the time interval $[0,T]$ by $t_n := n\Delta t$ for $n = 0,1,\dots,N$, with $\Delta t := T/N$. If we choose the test functions $w(\boldsymbol{x},t)$ to be of compact support in space, to vanish outside the interval $(t_{n-1},t_n]$, and to be discontinuous in time at time t_{n-1}, the weak formulation for (2.1) is written as

$$\begin{aligned} &\int_{\mathbb{R}^d} u(\boldsymbol{x},t_n)w(\boldsymbol{x},t_n)d\boldsymbol{x} - \int_{t_{n-1}}^{t_n}\int_{\mathbb{R}^d} u(w_t+\mathbf{v}\cdot\nabla w - Rw)(\boldsymbol{x},t)d\boldsymbol{x}dt\\ &\quad = \int_{\mathbb{R}^d} u(\boldsymbol{x},t_{n-1})w(\boldsymbol{x},t_{n-1}^+)d\boldsymbol{x} + \int_{t_{n-1}}^{t_n}\int_{\mathbb{R}^d} q(\boldsymbol{x},t)w(\boldsymbol{x},t)d\boldsymbol{x}dt, \end{aligned} \tag{2.2}$$

where $w(\boldsymbol{x},t_{n-1}^+) := \lim_{t\to t_{n-1}^+} w(\boldsymbol{x},t)$ takes into account the fact that $w(\boldsymbol{x},t)$ is discontinuous in time at time t_{n-1}.

To reflect the hyperbolic nature of (2.1), we follow the ELLAM framework of Celia et al. [1] to choose the test functions w in (2.2) from the solution space of the adjoint equation of (2.1),

$$w_t + \mathbf{v}\cdot\nabla w - Rw = 0. \tag{2.3}$$

Along the characteristic $\boldsymbol{r}(\theta;\check{\boldsymbol{x}},\check{t})$ defined by

$$\frac{d\boldsymbol{r}}{d\theta} = \mathbf{v}(\boldsymbol{r},\theta) \quad \text{with} \quad \boldsymbol{r}(\theta;\check{\boldsymbol{x}},\check{t})|_{\theta=\check{t}} = \check{\boldsymbol{x}}, \tag{2.4}$$

equation (2.3) is rewritten as the following differential equation:

$$\begin{aligned} &\frac{d}{d\theta}w(\boldsymbol{r}(\theta;\check{\boldsymbol{x}},\check{t}),\theta) - R(\boldsymbol{r}(\theta;\check{\boldsymbol{x}},\check{t}),\theta)w(\boldsymbol{r}(\theta;\check{\boldsymbol{x}},\check{t}),\theta) = 0,\\ &\qquad\qquad\qquad\qquad w(\boldsymbol{r}(\theta;\check{\boldsymbol{x}},\check{t}),\theta)|_{\theta=\check{t}} = w(\check{\boldsymbol{x}},\check{t}). \end{aligned} \tag{2.5}$$

Solving this equation yields the following expression for the test functions w:

$$w(\boldsymbol{r}(\theta;\check{\boldsymbol{x}},\check{t}),\theta) = w(\check{\boldsymbol{x}},\check{t})e^{-\int_\theta^{\check{t}} R(\boldsymbol{r}(\gamma;\check{\boldsymbol{x}},\check{t}),\gamma)d\gamma}, \quad \theta \in [t_{n-1},\check{t}], \quad \check{\boldsymbol{x}} \in \mathbb{R}^d. \tag{2.6}$$

Choosing $(\check{\boldsymbol{x}},\check{t}) = (\boldsymbol{x},t_n)$, we see that once the test functions $w(\boldsymbol{x},t_n)$ are specified at time t_n, they are determined completely on the space-time strip $\mathbb{R}^d \times (t_{n-1},t_n]$ with an exponential variation along the characteristic $\boldsymbol{r}(\theta;\boldsymbol{x},t_n)$ for $\theta \in [t_{n-1},t_n]$.

In the numerical schemes we use an Euler or Runge–Kutta formula to approximate the characteristic $\boldsymbol{r}(\theta;\check{\boldsymbol{x}},\check{t})$ and use the following approximate test functions w instead:

$$w(\boldsymbol{r}(\theta;\boldsymbol{x},t_n),\theta) = w(\boldsymbol{x},t_n)e^{-R(\boldsymbol{x},t_n)(t_n-\theta)}, \quad \theta \in [t_{n-1},t_n], \quad \boldsymbol{x} \in \mathbb{R}^d. \tag{2.7}$$

To avoid confusion in the derivation, we replace the dummy variables $\boldsymbol{x}$ and t in the second term on the right-hand side of (2.2) by $\boldsymbol{y}$ and θ and reserve $\boldsymbol{x}$ for the variable in $\mathbb{R}^d$ at time t_n. For any $\boldsymbol{y} \in \mathbb{R}^d$, there exists an $\boldsymbol{x} \in \mathbb{R}^d$ such that $\boldsymbol{y} = \boldsymbol{r}(\theta;\boldsymbol{x},t_n)$. We obtain

$$\begin{aligned}
&\int_{t_{n-1}}^{t_n}\int_{\mathbb{R}^d} q(\boldsymbol{y},\theta)w(\boldsymbol{y},\theta)d\boldsymbol{y}d\theta \\
&\quad = \int_{\mathbb{R}^d}\int_{t_{n-1}}^{t_n} q(\boldsymbol{r}(\theta;\boldsymbol{x},t_n),\theta)w(\boldsymbol{r}(\theta;\boldsymbol{x},t_n),\theta) \left|\frac{\partial \boldsymbol{r}(\theta;\boldsymbol{x},t_n)}{\partial \boldsymbol{x}}\right| d\theta d\boldsymbol{x} \\
&\quad = \int_{\mathbb{R}^d} q(\boldsymbol{x},t_n)w(\boldsymbol{x},t_n)\left[\int_{t_{n-1}}^{t_n} e^{-R(\boldsymbol{x},t_n)(t_n-\theta)}d\theta\right] d\boldsymbol{x} + E_1(q,w) \\
&\quad = \int_{\mathbb{R}^d} \Lambda(\boldsymbol{x},t_n)q(\boldsymbol{x},t_n)w(\boldsymbol{x},t_n)d\boldsymbol{x} + E_1(q,w).
\end{aligned} \tag{2.8}$$

Here $|\frac{\partial \boldsymbol{r}(\theta;\boldsymbol{x},t_n)}{\partial \boldsymbol{x}}|$ is the Jacobian determinant of the transformation from $\boldsymbol{x}$ at time t_n to $\boldsymbol{r}(\theta;\boldsymbol{x},t_n)$ at time θ.

$$\Lambda(\boldsymbol{x},t_n) := \begin{cases} \dfrac{1-e^{-R(\boldsymbol{x},t_n)\Delta t}}{R(\boldsymbol{x},t_n)} & \text{if } R(\boldsymbol{x},t_n) \neq 0, \\ \Delta t & \text{otherwise} \end{cases} \tag{2.9}$$

and

$$\begin{aligned}
E_1(w) := \int_{\mathbb{R}^d}\int_{t_{n-1}}^{t_n} \Bigg[& q(\boldsymbol{r}(\theta;\boldsymbol{x},t_n),\theta)\Big|\frac{\partial \boldsymbol{r}(\theta;\boldsymbol{x},t_n)}{\partial \boldsymbol{x}}\Big| \\
& - q(\boldsymbol{x},t_n)\Bigg] w(\boldsymbol{x},t_n)e^{-R(\boldsymbol{x},t_n)(t_n-\theta)}d\theta d\boldsymbol{x}.
\end{aligned} \tag{2.10}$$

Incorporating (2.8) into (2.2), we obtain a reference equation

$$\begin{aligned}
\int_{\mathbb{R}^d} u(\boldsymbol{x},t_n)w(\boldsymbol{x},t_n)d\boldsymbol{x} = & \int_{\mathbb{R}^d} u(\boldsymbol{x},t_{n-1})w(\boldsymbol{x},t_{n-1}^+)d\boldsymbol{x} \\
& + \int_{\mathbb{R}^d} \Lambda(\boldsymbol{x},t_n)q(\boldsymbol{x},t_n)w(\boldsymbol{x},t_n)d\boldsymbol{x} + E(w),
\end{aligned} \tag{2.11}$$

where

$$E(w) := \int_{t_{n-1}}^{t_n}\int_{\mathbb{R}^d} u(w_t + \mathbf{v}\cdot\nabla w - Rw)(\boldsymbol{x},t)d\boldsymbol{x}dt + E_1(q,w).$$

Previously, the so-called ELLAM schemes were developed by using finite element basis functions in (2.11). These schemes symmetrize the governing transport PDEs and generate accurate numerical solutions even if very coarse spatial grids and time steps are used.

3. Multiresolution analysis and wavelet decompositions.

To develop numerical schemes based on (2.11), we need to define the trial and test functions at time t_n. To do so, we briefly recall multiresolution analysis and wavelet decompositions.

3.1. Multiresolution analysis.

In the standard Fourier analysis, L^2-functions are represented by linear combinations of sines and cosines. In 1910, Haar studied the representation of L^2-functions by step functions taking values ±1 [12]. In the 1980s, these ideas were explored and developed further into the theory of wavelets. The first wavelets were introduced in early 1980s by Stromberg [21] and Morlet et al. [18]. Multiresolution analysis, which is one of the best ways of constructing wavelets, began in image processing [20, 22] and was introduced into mathematics by Mallat [16]. Daubechies used multiresolution analysis to construct compactly supported orthogonal wavelets with arbitrary smoothness, which include the Haar wavelets as the simplest case [8]. We refer readers to the survey article [10] for detailed reviews.

A sequence of closed subspaces $\{\mathcal{V}_j\}_{j\in\mathbb{Z}}$ ($\mathbb{Z}$ is the set of all integers) of $L^2(\mathbb{R})$ is a *multiresolution analysis* if

(a) these spaces are nested: $\mathcal{V}_j \subset \mathcal{V}_{j+1}\ \forall j \in \mathbb{Z}$;

(b) these spaces are dense in $L^2(\mathbb{R})$: $\overline{\cup}_{j\in\mathbb{Z}}\mathcal{V}_j = L^2(\mathbb{R})$ and $\cap_{j\in\mathbb{Z}}\mathcal{V}_j = \emptyset$;

(c) $\mathcal{V}_0$ is invariant under integer shifts: $f \in \mathcal{V}_0 \Longrightarrow f(\cdot - k) \in \mathcal{V}_0\ \forall k \in \mathbb{Z}$;

(d) $\mathcal{V}_j$ is obtained from $\mathcal{V}_0$ by dilation: $f(\cdot) \in \mathcal{V}_j \Longleftrightarrow f(2^{-j}\cdot) \in \mathcal{V}_0\ \forall j \in \mathbb{Z}$;

(e) $\mathcal{V}_0$ is generated by a single (scaling) function ϕ and its translates $\{\phi_{0,k} : k \in \mathbb{Z}\}$, where

$$\phi_{j,k}(x) := 2^{j/2}\phi(2^j x - k), \quad j,k \in \mathbb{Z}. \tag{3.1}$$

Because $\mathcal{V}_0 \subset \mathcal{V}_1$, the scaling function $\phi \in \mathcal{V}_0$ is also a member of $\mathcal{V}_1$. Hence, the following refinement relation holds:

$$\phi = \sum_{k\in\mathbb{Z}} h_k \phi_{1,k}. \tag{3.2}$$

In general, the sum has infinitely many terms, and convergence in (3.2) is understood in the $L^2(\mathbb{R})$-norm. Daubechies first discovered a family of compactly supported orthogonal wavelets [8], so their filters h_k have only finite length. The coiflets developed subsequently have improved symmetry and regularity [9]. In this paper we use compactly supported orthogonal wavelets.

Let $\mathcal{P}_j : L^2(\mathbb{R}) \longrightarrow \mathcal{V}_j$ be the orthogonal projection operator; we then have

$$\mathcal{P}_j f = \sum_{k\in\mathbb{Z}} c_{j,k}(f)\ \phi_{j,k} \qquad \text{with} \quad c_{j,k}(f) := \int_{\mathbb{R}} f(x)\phi_{j,k}(x)dx. \tag{3.3}$$

Let $\mathcal{W}_{j-1}$ be the orthogonal complement of $\mathcal{V}_{j-1}$ in $\mathcal{V}_j$. Then we have the following decomposition:

$$\begin{aligned} \mathcal{V}_j &= \mathcal{V}_{j-1} \oplus \mathcal{W}_{j-1} = \cdots \\ &= \mathcal{V}_{j_c} \oplus \mathcal{W}_{j_c} \oplus \mathcal{W}_{j_c+1} \oplus \cdots \oplus \mathcal{W}_{j-1} \quad \text{for } j > j_c. \end{aligned} \tag{3.4}$$

It is proved that the spaces $\mathcal{W}_j$ can be generated by a single (wavelet) function ψ [8, 9]. In other words, ψ and its integer translates $\psi_{0,k}$, with $\psi_{j,k}$ being defined by

$$\psi_{j,k}(x) := 2^{j/2}\psi(2^j x - k), \quad j,k \in \mathbb{Z}, \tag{3.5}$$

constitute an orthonormal basis for $\mathcal{W}_0$. Hence, for each fixed j, the $\psi_{j,k}$ ($k \in \mathbb{Z}$) form an orthogonal basis for $\mathcal{W}_j$. Since $\psi \in \mathcal{W}_0 \subset \mathcal{V}_1$, it can be expressed as

$$\psi = \sum_{k\in\mathbb{Z}} g_k \phi_{1,k}. \tag{3.6}$$

A permissible choice for the filter g_k is given by $g_k = (-1)^{k-1} h_{-k-1}$ [9].

Let $\mathcal{Q}_j : L^2(\mathbb{R}) \longrightarrow \mathcal{W}_j$ be the orthogonal projection operator

$$\mathcal{Q}_j f = \sum_{k\in\mathbb{Z}} d_{j,k}(f)\ \psi_{j,k} \qquad \text{with} \quad d_{j,k}(f) := \int_{\mathbb{R}} f(x)\psi_{j,k}(x)dx. \tag{3.7}$$

For $f \in L^2(\mathbb{R})$, the telescoping sum

$$\mathcal{P}_{j_f} f = \mathcal{P}_{j_c} f + \sum_{j=j_c}^{j_f-1} (\mathcal{P}_{j+1} f - \mathcal{P}_j f) = \mathcal{P}_{j_c} f + \sum_{j=j_c}^{j_f-1} \mathcal{Q}_j f \tag{3.8}$$

represents the projection $\mathcal{P}_{j_f} f \in \mathcal{V}_{j_f}$ of f at a fine level j_f as a direct sum of $\mathcal{P}_{j_c} f \in \mathcal{V}_{j_c}$ of f at a coarse level j_c and the elements in a sequence of refined spaces $\mathcal{W}_{j_c} \oplus \mathcal{W}_{j_c+1} \oplus \cdots \oplus \mathcal{W}_{j_f-1}$ that provide progressively improved resolution at different scales.

3.2. Cascade algorithm. The cascade algorithm provides an efficient approach for decomposition and reconstruction [9]. Using the refinement equation (3.2) and the definition (3.1) of $\phi_{j,k}(x)$, we see

$$\begin{aligned}
\phi_{j-1,k}(x) &= 2^{(j-1)/2}\phi(2^{j-1}x - k) \\
&= 2^{(j-1)/2} \sum_{l\in\mathbb{Z}} h_l 2^{1/2} \phi(2(2^{j-1}x - k) - l) \\
&= 2^{j/2} \sum_{l\in\mathbb{Z}} h_l \phi(2^j x - 2k - l) \\
&= \sum_{l\in\mathbb{Z}} h_l \phi_{j,l+2k}(x) \\
&= \sum_{l\in\mathbb{Z}} h_{l-2k} \phi_{j,l}(x).
\end{aligned} \tag{3.9}$$

Similarly, we have

$$\psi_{j-1,k}(x) = \sum_{l\in\mathbb{Z}} g_{l-2k} \phi_{j,l}(x). \tag{3.10}$$

In the decomposition process, the cascade algorithm shows how to calculate the scaling coefficients $c_{j-1,k}(f)$ and the wavelet coefficients $d_{j-1,k}(f)$ at a coarser level $j-1$ from the coefficients $c_{j,k}(f)$ at a finer level j:

$$\begin{aligned}
c_{j-1,k}(f) &= \int_{\mathbb{R}} f(x)\phi_{j-1,k}(x)dx = \int_{\mathbb{R}} f(x) \sum_{l\in\mathbb{Z}} h_{l-2k}\phi_{j,l}(x)dx \\
&= \sum_{l\in\mathbb{Z}} h_{l-2k} \int_{\mathbb{R}} f(x)\phi_{j,l}(x)dx = \sum_{l\in\mathbb{Z}} c_{j,l}(f) h_{l-2k}, \\
d_{j-1,k}(f) &= \int_{\mathbb{R}} f(x)\psi_{j-1,k}(x)dx = \int_{\mathbb{R}} f(x) \sum_{l\in\mathbb{Z}} g_{l-2k}\phi_{j,l}(x)dx \\
&= \sum_{l\in\mathbb{Z}} g_{l-2k} \int_{\mathbb{R}} f(x)\phi_{j,l}(x)dx = \sum_{l\in\mathbb{Z}} c_{j,l}(f) g_{l-2k}.
\end{aligned} \tag{3.11}$$

In the reconstruction process, the cascade algorithm shows how to calculate the scaling coefficients $c_{j,k}(f)$ at a finer level j from the scaling coefficients $c_{j-1,k}(f)$ and the wavelet coefficients $d_{j-1,k}(f)$ at a coarser level $j-1$. Using (3.3), (3.7)–(3.10), we have

$$
\begin{aligned}
c_{j,k}(f) &= \int_{\mathbb{R}} f(x)\phi_{j,k}(x)dx = \int_{\mathbb{R}} \mathcal{P}_j f(x)\phi_{j,k}(x)dx \\
&= \int_{\mathbb{R}} \Big[\mathcal{P}_{j-1}f(x) + \mathcal{Q}_{j-1}f(x)\Big]\phi_{j,k}(x)dx \\
&= \int_{\mathbb{R}} \left[\sum_{l\in\mathbb{Z}} c_{j-1,l}(f)\phi_{j-1,l}(x) + \sum_{l\in\mathbb{Z}} d_{j-1,l}(f)\psi_{j-1,l}(x)\right]\phi_{j,k}(x)dx \\
&= \sum_{l\in\mathbb{Z}} c_{j-1,l}(f)\int_{\mathbb{R}} \phi_{j-1,l}(x)\phi_{j,k}(x)dx \\
&\quad + \sum_{l\in\mathbb{Z}} d_{j-1,l}(f)\int_{\mathbb{R}} \psi_{j-1,l}(x)\phi_{j,k}(x)dx \\
&= \sum_{l\in\mathbb{Z}} c_{j-1,l}(f)\int_{\mathbb{R}} \left[\sum_{i\in\mathbb{Z}} h_{i-2l}\phi_{j,i}(x)\right]\phi_{j,k}(x)dx \\
&\quad + \sum_{l\in\mathbb{Z}} d_{j-1,l}(f)\int_{\mathbb{R}} \left[\sum_{i\in\mathbb{Z}} g_{i-2l}\phi_{j,i}(x)\right]\phi_{j,k}(x)dx \\
&= \sum_{l\in\mathbb{Z}}\sum_{i\in\mathbb{Z}} c_{j-1,l}(f)h_{i-2l}\delta_{i,k} + \sum_{l\in\mathbb{Z}}\sum_{i\in\mathbb{Z}} d_{j-1,l}(f)g_{i-2l}\delta_{i,k} \\
&= \sum_{l\in\mathbb{Z}} c_{j-1,l}(f)h_{k-2l} + \sum_{l\in\mathbb{Z}} d_{j-1,l}(f)g_{k-2l}.
\end{aligned} \tag{3.12}
$$

Here $\delta_{i,k}$ is the Dirac delta function, $\delta_{i,k} = 1$ if $i = k$, or 0 otherwise.

4. Unconditionally stable, explicit schemes.

For simplicity, we assume that the support of the solution $u(\boldsymbol{x}, t)$ is contained inside the spatial domain $\Omega := (a_1, b_1)\times\cdots\times(a_d, b_d)$ during the time period $[0, T]$. We will outline the extensions of the schemes developed in this section to initial-boundary-value problems of advection-reaction PDEs in section 7.

Let $N_{0,m} \in \mathbb{N}$ $(m = 1, 2, \ldots, d)$ be the numbers of intervals in the mth coordinate directions. We define spatial grids at the coarsest occurring level 0 by

$$x_{0,k}^{(m)} := a_m + kh_{0,m} \text{ with } h_{0,m} := \frac{b_m - a_m}{N_{0,m}}, \quad 0 \le k \le N_{0,m},\ 1 \le m \le d. \tag{4.1}$$

Using the scaling function $\phi(x)$ in (3.1), we define

$$\phi_{0,k}^{(m)}(x) := h_{0,m}^{-1/2}\phi\left(\frac{x - x_{0,k}^{(m)}}{h_{0,m}}\right) \tag{4.2}$$

to be the scaling functions at the level 0 that are associated with the grids $x_{0,k}^{(m)}$ in the mth coordinate direction. We then define the corresponding functions and grids at level $j = 1, 2, \dots, J$:

$$\begin{aligned} N_{j,m} &:= 2N_{j-1,m} = \cdots = 2^j N_{0,m}, \\ h_{j,m} &:= \tfrac{1}{2} h_{j-1,m} = \cdots = 2^{-j} h_{0,m}, \\ x_{j,k}^{(m)} &:= a_m + kh_{j,m}, \\ \phi_{j,k}^{(m)}(x) &:= 2^{j/2} \phi_{0,0}^{(m)}(2^j x - k), \\ 0 \le k \le N_{j,m}&, \quad 1 \le m \le d, \quad 1 \le j \le J, \end{aligned} \tag{4.3}$$

where levels 0 and J denote the coarsest and finest occurring discretization levels.

4.1. A single-level scheme. We define finite-dimensional spaces $\mathcal{S}_j(\Omega)$ at level j by

$$\mathcal{S}_j(\Omega) := \operatorname{span} \{\Phi_{j,\boldsymbol{k}}(\boldsymbol{x})\}_{\boldsymbol{k} \in \boldsymbol{\omega}_j}, \tag{4.4}$$

where the scaling functions $\Phi_{j,\boldsymbol{k}}(\boldsymbol{x})$, with $\boldsymbol{x} = (x_1, \dots, x_d)$, and the index sets $\boldsymbol{\omega}_j$ at level j are defined by

$$\begin{aligned} \Phi_{j,\boldsymbol{k}}(\boldsymbol{x}) &:= \prod_{m=1}^{d} \phi_{j,k_m}^{(m)}(x_m), \\ \boldsymbol{\omega}_j &:= \left\{ \boldsymbol{k} = (k_1, \dots, k_d) \in \mathbb{N}^d \,\middle|\, 0 \le k_m \le N_{j,m},\ 1 \le m \le d \right\}. \end{aligned} \tag{4.5}$$

Replacing the exact solution u in (2.11) by the trial functions $U(\boldsymbol{x}, t_n) \in \mathcal{S}_J(\Omega)$ and dropping the error term $E(w)$ in (2.11), we obtain the following.

Scheme I. Seek $U(\boldsymbol{x}, t_n) \in \mathcal{S}_J(\Omega)$, the space of the scaling functions defined on the finest occurring discretization level J, with

$$U(\boldsymbol{x}, t_n) = \sum_{\boldsymbol{k} \in \boldsymbol{\omega}_J} c_{J,\boldsymbol{k}}^n \Phi_{J,\boldsymbol{k}}(\boldsymbol{x}), \tag{4.6}$$

such that the following equation holds for any $w(\boldsymbol{x}, t_n) = \Phi_{J,\boldsymbol{k}}(\boldsymbol{x})$ with $\boldsymbol{k} \in \boldsymbol{\omega}_J$:

$$\begin{aligned} &\int_\Omega U(\boldsymbol{x}, t_n) w(\boldsymbol{x}, t_n) d\boldsymbol{x} \\ &\quad = \int_\Omega U(\boldsymbol{x}, t_{n-1}) w(\boldsymbol{x}, t_{n-1}^+) d\boldsymbol{x} + \int_\Omega \Lambda(\boldsymbol{x}, t_n) q(\boldsymbol{x}, t_n) w(\boldsymbol{x}, t_n) d\boldsymbol{x}. \end{aligned} \tag{4.7}$$

This scheme is explicit, since choosing $w(\boldsymbol{x}, t_n) = \Phi_{j,\boldsymbol{k}}(\boldsymbol{x})$ in (4.7) reduces its left-hand side to

$$\int_\Omega U(\boldsymbol{x}, t_n) w(\boldsymbol{x}, t_n) d\boldsymbol{x} = c_{J,\boldsymbol{k}}^n. \tag{4.8}$$

The evaluation of the second term on the right-hand side of (4.7) is standard in wavelet methods for elliptic and parabolic PDEs [3, 6, 7, 14]. However, the evaluation of the first term on the right-hand side of (4.7) in nonconventional, due to the definition of $w(\boldsymbol{x}, t_{n-1}^+)$ that in turn results from the characteristic tracking. In the current context, we adopt a modified forward tracking algorithm [19] to evaluate this term. We would enforce a Simpson or fifth-order Newton–Cotes integration quadrature on each cell (or dyadic subcells) at time step t_{n-1}, which needs only the dyadic values of the wavelets that can be obtained a priori. To evaluate $w(\boldsymbol{x}, t_{n-1}^+)$, we track these discrete quadrature points $\boldsymbol{x}_q$ forward along the characteristics defined by (2.4) to time step t_n and obtain $\tilde{\boldsymbol{x}}_q = \boldsymbol{r}(t_n; \boldsymbol{x}_q, t_{n-1})$. We then use (2.7) to evaluate

$$w(\boldsymbol{x}_q, t_{n-1}^+) = w(\tilde{\boldsymbol{x}}_q, t_n) e^{-R(\tilde{\boldsymbol{x}}_q, t_n)\Delta t}. \tag{4.9}$$

Note that $\tilde{\boldsymbol{x}}_q$ is not necessarily a dyadic point in general. We compute $w(\tilde{\boldsymbol{x}}_q, t_n)$ by an interpolation based on its values at neighboring dyadic points.

4.2. A multilevel scheme. Notice that, as in the case of Fourier series, when the exact solution $u(\boldsymbol{x}, t_n)$ is smooth, its wavelet coefficients

$$d_{j,\boldsymbol{k}}^{n,\boldsymbol{e}}(u) = \int_\Omega u(\boldsymbol{x}, t_n) \Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x}) d\boldsymbol{x}$$

decay rapidly as the level j increases [9, 10]. Here the wavelets $\Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x})$ are defined by

$$\Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x}) = \prod_{m=1}^{d} \left(\phi_{j,k_m}^{(m)}(x_m)\right)^{1-e_m} \left(\psi_{j,k_m}^{(m)}(x_m)\right)^{e_m} \qquad \forall \boldsymbol{e} \in \boldsymbol{E}, \tag{4.10}$$

where $\boldsymbol{E}^{'} := \{0,1\}^d = \{\boldsymbol{e} = (e_1, \ldots, e_d) \mid e_i = 0, 1\}$ is the set of vertices of the d-dimensional unit cube, $\boldsymbol{E} = \boldsymbol{E}^{'} \backslash \{\boldsymbol{0}\}$, and

$$\begin{aligned} \psi_{0,k}^{(m)}(x) &:= h_{0,m}^{-1/2} \psi\left(\frac{x - x_{0,k}^{(m)}}{h_{0,m}}\right), \\ \psi_{j,k}^{(m)}(x) &:= 2^{j/2} \psi_{0,0}^{(m)}(2^j x - k). \end{aligned} \tag{4.11}$$

For example, when $u(\boldsymbol{x}, t_n)$ is differentiable we have

$$\begin{aligned} \left|d_{j,\boldsymbol{k}}^{n,\boldsymbol{e}}(u)\right| &= \left|\int_\Omega u(\boldsymbol{x}, t_n) \Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x}) d\boldsymbol{x}\right| \\ &= \inf_{c \in \mathbb{R}} \left|\int_\Omega \left[u(\boldsymbol{x}, t_n) - c\right] \Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x}) d\boldsymbol{x}\right| \\ &\le \inf_{c \in \mathbb{R}} \|u(\boldsymbol{x}, t_n) - c\|_{L^2(\Omega_{j,\boldsymbol{k}}^{\boldsymbol{e}})} \\ &\le C 2^{-j/2} \|\nabla u(\boldsymbol{x}, t_n)\|_{L^2(\Omega_{j,\boldsymbol{k}}^{\boldsymbol{e}})}, \end{aligned} \tag{4.12}$$

with $\Omega_{j,\boldsymbol{k}}^{\boldsymbol{e}} = \mathrm{supp}(\Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}})$. By using a multidimensional analogue of expansion (3.8), we have the following multiresolution expansion for $U(\boldsymbol{x}, t_n) \in \mathcal{S}_{J_n}(\Omega)$:

$$U(\boldsymbol{x}, t_n) = \sum_{\boldsymbol{k} \in \boldsymbol{\omega}_0} c_{0,\boldsymbol{k}}^n \Phi_{0,\boldsymbol{k}}(\boldsymbol{x}) + \sum_{j=0}^{J_n - 1} \sum_{\boldsymbol{k} \in \boldsymbol{\omega}_j} \sum_{\boldsymbol{e} \in \boldsymbol{E}} d_{j,\boldsymbol{k}}^{n,\boldsymbol{e}} \Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x}). \tag{4.13}$$

We define a CFL-free, explicit, multilevel scheme for problem (2.1) as follows.

Scheme II. Find $U(\boldsymbol{x}, t_n) \in \mathcal{S}_{J_n}(\Omega)$, which is in the form of (4.13) with $0 \le J_n \le J$, such that (4.7) holds for any $w(\boldsymbol{x}, t_n) \in \mathcal{S}_{J_n}(\Omega)$.

Scheme II possesses all the numerical advantages of Scheme I. For example, it is explicit and is a multilevel scheme. In fact, if we choose $w(\boldsymbol{x}, t_n) = \Phi_{0,\boldsymbol{k}}(\boldsymbol{x})$ or $\Psi^{\boldsymbol{e}}_{j,\boldsymbol{k}}(\boldsymbol{x})$ for $\boldsymbol{k} \in \boldsymbol{\omega}_j$, $\boldsymbol{e} \in \boldsymbol{E}$, and $j = 0, 1, \ldots, J_n - 1$, the left-hand side of (4.7) is reduced to

$$\begin{aligned}\int_\Omega U(\boldsymbol{x}, t_n)\Phi_{0,\boldsymbol{k}}(\boldsymbol{x})d\boldsymbol{x} &= c^n_{0,\boldsymbol{k}}, \quad \boldsymbol{k} \in \boldsymbol{\omega}_0,\\ \int_\Omega U(\boldsymbol{x}, t_n)\Psi^{\boldsymbol{e}}_{j,\boldsymbol{k}}(\boldsymbol{x})d\boldsymbol{x} &= d^{n,\boldsymbol{e}}_{j,\boldsymbol{k}}, \quad \boldsymbol{e} \in \boldsymbol{E}, \quad \boldsymbol{k} \in \boldsymbol{\omega}_j, \quad 0 \le j \le J_n - 1.\end{aligned} \tag{4.14}$$

Equations (4.13) and (4.14) generate a multilevel expression of the solution $U(\boldsymbol{x}, t_n)$. Algorithmically, we first compute the coefficients $c^n_{0,\boldsymbol{k}}$ in (4.13) at the coarsest level 0. We then compute the coefficients $d^{n,\boldsymbol{e}}_{j,\boldsymbol{k}}$ for $\boldsymbol{e} \in \boldsymbol{E}$ and $\boldsymbol{k} \in \boldsymbol{\omega}_j$ in the second term on the right-hand side of (4.13) starting from the coarsest occurring level 0 to the finest level J. Finally, because all the wavelets have at least zeroth-order vanishing moments, adding the wavelet expressions level by level does not affect mass balance.

4.3. A CFL-free, explicit multilevel scheme with adaptive and conservative compression. In applications hyperbolic PDEs often admit solutions with very localized phenomena, which are typically smooth outside some very small (but dynamic) regions and could develop steep fronts within these regions. In contrast to Fourier series expansions where local singularities of the solutions could contaminate the decaying properties of Fourier coefficients globally, (4.12) shows that the wavelet coefficients actually become small when the underlying solution is smooth locally. Therefore, we can drop the terms with small wavelet coefficients to reduce the number of unknowns to be solved without introducing large errors. On the other hand, the wavelet coefficients also indicate where relevant detailed information is encountered. This observation motivates the development of a CFL-free, explicit multilevel scheme with the capability for adaptive and conservative compression to fully utilize these properties.

Scheme III. This scheme is divided into four steps.

Step 1. *Initialization.* Project the initial condition $u_0(\boldsymbol{x})$ into the space $\mathcal{S}_J(\Omega)$ to obtain its approximation,

$$U(\boldsymbol{x}, t_0) = \sum_{\boldsymbol{k}\in\boldsymbol{\omega}_0} c^0_{0,\boldsymbol{k}}\Phi_{0,\boldsymbol{k}}(\boldsymbol{x}) + \sum_{j=0}^{J-1}\sum_{\boldsymbol{k}\in\boldsymbol{\omega}_j}\sum_{\boldsymbol{e}\in\boldsymbol{E}} d^{0,\boldsymbol{e}}_{j,\boldsymbol{k}}\Psi^{\boldsymbol{e}}_{j,\boldsymbol{k}}(\boldsymbol{x}), \tag{4.15}$$

with $c^0_{0,\boldsymbol{k}}$ and $d^{0,\boldsymbol{e}}_{j,\boldsymbol{k}}$ being computed by

$$\begin{aligned}c^n_{0,\boldsymbol{k}} &= \int_\Omega u_0(\boldsymbol{x})\Phi_{0,\boldsymbol{k}}(\boldsymbol{x})d\boldsymbol{x}, \quad \boldsymbol{k} \in \boldsymbol{\omega}_0,\\ d^{n,\boldsymbol{e}}_{j,\boldsymbol{k}} &= \int_\Omega u_0(\boldsymbol{x})\Psi^{\boldsymbol{e}}_{j,\boldsymbol{k}}(\boldsymbol{x})d\boldsymbol{x}, \quad \boldsymbol{k} \in \boldsymbol{\omega}_j, \quad \boldsymbol{e} \in \boldsymbol{E}, \quad 0 \le j \le J - 1.\end{aligned} \tag{4.16}$$

We use a time marching algorithm to perform the following steps for $n = 1, 2, \ldots, N$.

Step 2. *Compression step.* Because the wavelet coefficients in the expression

$$U(\boldsymbol{x}, t_{n-1}) = \sum_{\boldsymbol{k}\in\boldsymbol{\omega}_0} c^{n-1}_{0,\boldsymbol{k}}\Phi_{0,\boldsymbol{k}}(\boldsymbol{x}) + \sum_{j=0}^{J-1}\sum_{\boldsymbol{k}\in\widetilde{\boldsymbol{\omega}}^{n-1}_j}\sum_{\boldsymbol{e}\in\boldsymbol{E}} d^{n-1,\boldsymbol{e}}_{j,\boldsymbol{k}}\Psi^{\boldsymbol{e}}_{j,\boldsymbol{k}}(\boldsymbol{x}) \tag{4.17}$$

would be nearly zero in the smooth regions of $U(\boldsymbol{x}, t_{n-1})$, and would be noticeable in the rough regions of $U(\boldsymbol{x}, t_{n-1})$, we can drop many small wavelet coefficients in (4.17) without affecting the accuracy of the solution $U(\boldsymbol{x}, t_n)$. Here $\widetilde{\boldsymbol{\omega}}_j^{n-1}$ are the predicted significant coefficient index sets with $\widetilde{\boldsymbol{\omega}}_j^0 = \boldsymbol{\omega}_j$ and $\widetilde{\boldsymbol{\omega}}_j^{n-1}$ being defined below for subsequent time steps.

We define level-dependent thresholding parameters ε_j by

$$\varepsilon_j := 2^{-jd/2}\ \Delta t \left[\|u_0\|_{L^2(\Omega)} + \|q(\cdot, t_n)\|_{L^2(\Omega)}\right] \tag{4.18}$$

and perform the following thresholding procedure:

$$\widehat{d}_{j,\boldsymbol{k}}^{n-1,\boldsymbol{e}} := \begin{cases} d_{j,\boldsymbol{k}}^{n-1,\boldsymbol{e}} & \text{if } \left|d_{j,\boldsymbol{k}}^{n-1,\boldsymbol{e}}\right| \geq \varepsilon_j, \\ 0 & \text{otherwise.} \end{cases} \tag{4.19}$$

Equivalently, we introduce the significant coefficient index sets

$$\widehat{\boldsymbol{\omega}}_j^{n-1} := \left\{\boldsymbol{k} \in \widetilde{\boldsymbol{\omega}}_j^{n-1} \;\middle|\; \exists \boldsymbol{e} \in \boldsymbol{E} \text{ such that } \left|d_{j,\boldsymbol{k}}^{n-1,\boldsymbol{e}}\right| \geq \varepsilon_j \right\}. \tag{4.20}$$

We define a compression $\widehat{U}(\boldsymbol{x}, t_{n-1})$ of $U(\boldsymbol{x}, t_{n-1})$ by

$$\begin{aligned} \widehat{U}(\boldsymbol{x}, t_{n-1}) &= \sum_{\boldsymbol{k}\in\boldsymbol{\omega}_0} c_{0,\boldsymbol{k}}^{n-1}\Phi_{0,\boldsymbol{k}}(\boldsymbol{x}) + \sum_{j=0}^{J-1} \sum_{\boldsymbol{k}\in\widetilde{\boldsymbol{\omega}}_j^{n-1}} \sum_{\boldsymbol{e}\in\boldsymbol{E}} \widehat{d}_{j,\boldsymbol{k}}^{n-1,\boldsymbol{e}} \Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x}) \\ &= \sum_{\boldsymbol{k}\in\boldsymbol{\omega}_0} c_{0,\boldsymbol{k}}^{n-1}\Phi_{0,\boldsymbol{k}}(\boldsymbol{x}) + \sum_{j=0}^{J-1} \sum_{\boldsymbol{k}\in\widehat{\boldsymbol{\omega}}_j^{n-1}} \sum_{\boldsymbol{e}\in\boldsymbol{E}} d_{j,\boldsymbol{k}}^{n-1,\boldsymbol{e}} \Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x}). \end{aligned} \tag{4.21}$$

Step 3. *Prediction step.* The wavelet expansion (4.21) provides a convenient way to measure the smoothness of functions in terms of various function space norms as well as locally [9, 10]. Hence, we use it to locate the smooth regions and rough regions of $\widehat{U}(\boldsymbol{x}, t_{n-1})$ by determining the significant coefficient index sets $\widehat{\boldsymbol{\omega}}_j^{n-1}$. In other words, the wavelet expansion itself is a convenient and accurate error indicator for $U(\boldsymbol{x}, t_{n-1})$. We predict where the rough regions of $U(\boldsymbol{x}, t_n)$ will be at time step t_n by determining the predicted significant coefficient index sets $\widetilde{\boldsymbol{\omega}}_j^n$ at level j at time step t_n. In order to locate the latter, we track the index sets $\widehat{\boldsymbol{\omega}}_j^{n-1}$ forward along the characteristics from time t_{n-1} to time t_n. We also take into account the effect of the source term $q(\boldsymbol{x}, t)$ and the reaction term $R(\boldsymbol{x}, t)$ along the characteristics.

Step 4. *Solution step.* Once we determine the predicted significant coefficient index sets $\widetilde{\boldsymbol{\omega}}_j^n$, we define an adaptive refinement subspace $\widetilde{\mathcal{S}}_J^n(\Omega) \subset \mathcal{S}_J(\Omega)$ by

$$\widetilde{\mathcal{S}}_J^n(\Omega) := \operatorname{span}\left\{\left\{\Phi_{0,\boldsymbol{k}}\right\}_{\boldsymbol{k}\in\boldsymbol{\omega}_0}, \left\{\Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}\right\}_{\boldsymbol{k}\in\widetilde{\boldsymbol{\omega}}_j^n,\ 0\leq j\leq J-1}^{\boldsymbol{e}\in\boldsymbol{E}}\right\}. \tag{4.22}$$

Then we look for $U(\boldsymbol{x}, t_n) \in \widetilde{\mathcal{S}}_J^n(\Omega)$, which is in the form

$$U(\boldsymbol{x}, t_n) = \sum_{\boldsymbol{k}\in\boldsymbol{\omega}_0} c_{0,\boldsymbol{k}}^{n}\Phi_{0,\boldsymbol{k}}(\boldsymbol{x}) + \sum_{j=0}^{J-1} \sum_{\boldsymbol{k}\in\widetilde{\boldsymbol{\omega}}_j^{n}} \sum_{\boldsymbol{e}\in\boldsymbol{E}} d_{j,\boldsymbol{k}}^{n,\boldsymbol{e}} \Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x}), \tag{4.23}$$

such that the following equation holds for any $w(\boldsymbol{x}, t_n) \in \widetilde{\mathcal{S}}_J^n(\Omega)$:

$$\begin{aligned} &\int_\Omega U(\boldsymbol{x}, t_n) w(\boldsymbol{x}, t_n) d\boldsymbol{x} \\ &\quad = \int_\Omega \widehat{U}(\boldsymbol{x}, t_{n-1}) w(\boldsymbol{x}, t_{n-1}^+) d\boldsymbol{x} + \int_\Omega \Lambda(\boldsymbol{x}, t_n) q(\boldsymbol{x}, t_n) w(\boldsymbol{x}, t_n) d\boldsymbol{x}. \end{aligned} \tag{4.24}$$

Here $w(\boldsymbol{x}, t_{n-1}^{+})$ and $\Lambda(\boldsymbol{x}, t_n)$ are defined in (2.7) and (2.9) and below (2.2).

We now briefly discuss the schemes we have developed:

1. Scheme I is a linear and single-level scheme, in which the number of levels and the set of wavelet basis functions used at each time step are independent of the solution being approximated. In Scheme II the number of levels could vary at each time step, depending on the solution being approximated. The first term on the right-hand side of (4.13) provides a basic approximation at the coarsest occurring level 0. The second term provides a finer and finer resolution at time t_n as the level j increases from 0 to $J_n - 1$. Both Schemes I and II are fairly easy to implement.
2. Scheme III is a nonlinear scheme, in which the number of levels and the set of wavelet basis functions $\Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x})$ chosen in the approximation depend on the solution being approximated [10]. Notice that the significant wavelet coefficients $\widehat{d}_{j,\boldsymbol{k}}^{n-1,\boldsymbol{e}}$, which exceed the thresholding parameters in (4.19), are nonzero only near the moving steep front regions. Hence, with the first term on the right-hand side of (4.23) as a base approximation, the second term on the right-hand side of (4.23) consists of terms with significant coefficients and provides a progressively improved resolution. In this way, Scheme III resolves the moving steep fronts present in the solutions accurately, adaptively, and effectively.
3. The distribution of the significant coefficients $\widehat{d}_{j,\boldsymbol{k}}^{n-1,\boldsymbol{e}}$ or equivalently the significant coefficient index sets $\widehat{\boldsymbol{\omega}}_j^{n-1}$ in (4.20) could be somewhat irregular or unstructured after the thresholding process (4.19), even though they should have some correlations. A naive organization and management of these coefficients could compromise the greatly improved efficiency of the scheme. The tree approximation techniques proposed in [2], in which a node is in the tree whenever one of its child nodes is in the tree, allow a more effective organization/encoding of the positions of the significant coefficients in an optimal order (i.e., the number of nodes in the tree is a constant multiple of the number of significant coefficients $\widehat{d}_{j,\boldsymbol{k}}^{n-1,\boldsymbol{e}}$). By tracking the significant coefficient index sets $\widehat{\boldsymbol{\omega}}_j^{n-1}$ from time step t_{n-1} to t_n along the characteristics, we can obtain predicted significant coefficient index sets $\widetilde{\boldsymbol{\omega}}_j^{n}$ at time step t_n fairly accurately and efficiently.
4. Because all the wavelet basis functions $\Psi_{j,\boldsymbol{k}}^{\boldsymbol{e}}(\boldsymbol{x})$ have at least zeroth-order vanishing moments, the compression used in Scheme III does not introduce any mass balance error.

5. Stability analysis.

In this section we prove the unconditional stability of the numerical schemes.

THEOREM 5.1. *Scheme* I *is unconditionally stable.*

Using (4.6), we choose $w(\boldsymbol{x}, t_n) = \Phi_{J,\boldsymbol{k}}(\boldsymbol{x})$ in (4.7). Then we multiply the resulting equation by $c_{J,\boldsymbol{k}}^{n}$ in (4.6) and add all the resulting equations $\forall \boldsymbol{k} \in \boldsymbol{\omega}_J$ to obtain

$$\begin{aligned}\int_{\Omega} U^2(\boldsymbol{x}, t_n) d\boldsymbol{x} &= \int_{\Omega} U(\boldsymbol{x}, t_{n-1}) U(\boldsymbol{x}, t_{n-1}^{+}) d\boldsymbol{x} \\ &\quad + \int_{\Omega} \Lambda(\boldsymbol{x}, t_n) q(\boldsymbol{x}, t_n) U(\boldsymbol{x}, t_n) d\boldsymbol{x}.\end{aligned} \tag{5.1}$$

We use the facts

$$
\begin{aligned}
\frac{\partial \boldsymbol{r}(\theta;\boldsymbol{x},t_n)}{\partial \boldsymbol{x}} &= \mathbf{I} + \mathcal{O}(t_n-\theta),\\
U(\boldsymbol{x}^*,t_{n-1}^+) &= U(\boldsymbol{x},t_n)e^{-R(\boldsymbol{x},t_n)\Delta t},
\end{aligned}
\tag{5.2}
$$

with $\mathbf{I}$ being the $d\times d$ identity matrix and $\boldsymbol{x}^* := \boldsymbol{r}(t_{n-1};\boldsymbol{x},t_n)$, to bound the first term on the right-hand side of (5.1). For convenience, we replace the dummy $\boldsymbol{x}$ in this term by $\boldsymbol{x}^*$ and reserve $\boldsymbol{x}$ for the corresponding variable at time t_n:

$$
\begin{aligned}
&\left|\int_\Omega U(\boldsymbol{x}^*,t_{n-1})U(\boldsymbol{x}^*,t_{n-1}^+)d\boldsymbol{x}^*\right|\\
&\quad = \left|\int_\Omega U(\boldsymbol{x}^*,t_{n-1})U(\boldsymbol{x},t_n)e^{-R(\boldsymbol{x},t_n)\Delta t}\left|\frac{\partial \boldsymbol{r}(t_{n-1};\boldsymbol{x},t_n)}{\partial \boldsymbol{x}}\right| d\boldsymbol{x}\right|\\
&\quad \le (1+L\Delta t)\ \|U(\boldsymbol{x},t_n)\|_{L^2(\Omega)}\left[\int_\Omega U^2(\boldsymbol{x}^*,t_{n-1})\left|\frac{\partial \boldsymbol{r}(t_{n-1};\boldsymbol{x},t_n)}{\partial \boldsymbol{x}}\right|^2 d\boldsymbol{x}\right]^{1/2}\\
&\quad \le \left(\frac{1}{2}+L\Delta t\right)\left[\|U(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)} + \|U(\boldsymbol{x},t_{n-1})\|^2_{L^2(\Omega)}\right].
\end{aligned}
\tag{5.3}
$$

Here L represents a generic positive constant, which might assume different values at different places.

Recall that $|\Lambda(\boldsymbol{x},t_n)| \le L\Delta t$; we bound the second term on the right-hand side of (5.1) by

$$
\begin{aligned}
&\left|\int_\Omega \Lambda(\boldsymbol{x},t_n)q(\boldsymbol{x},t_n)U(\boldsymbol{x},t_n)dx\right|\\
&\qquad \le L\Delta t\Big[\|U(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)} + \ \|q(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)}\Big].
\end{aligned}
\tag{5.4}
$$

Substituting (5.3) and (5.4) into (5.1) we obtain

$$
\begin{aligned}
\|U(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)} \le{}& \left(\frac{1}{2}+L_0\Delta t\right)\left[\|U(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)} + \|U(\boldsymbol{x},t_{n-1})\|^2_{L^2(\Omega)}\right]\\
&+ L_0\Delta t\|q(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)},
\end{aligned}
\tag{5.5}
$$

where L_0 is a fixed positive constant.

Adding (5.5) for $n=1,2,\ldots,N_1\le N$ results in the following telescoping series:

$$
\begin{aligned}
&\sum_{n=1}^{N_1}\|U(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)}\\
&\quad \le \left(\frac{1}{2}+L_0\Delta t\right)\sum_{n=1}^{N_1}\Big[\|U(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)} + \|U(\boldsymbol{x},t_{n-1})\|^2_{L^2(\Omega)}\Big]\\
&\qquad + L_0\|q\|^2_{\widehat{L}(0,T;L^2(\Omega))}\\
&\quad \le \left(\frac{1}{2}+L_0\Delta t\right)\left[\|U(\boldsymbol{x},t_{N_1})\|^2_{L^2(\Omega)} + \|U(\boldsymbol{x},0)\|^2_{L^2(\Omega)}\right]\\
&\qquad + (1+2L_0\Delta t)\sum_{n=1}^{N_1-1}\ \|U(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)} + L_0\|q\|^2_{\widehat{L}(0,T;L^2(\Omega))}.
\end{aligned}
\tag{5.6}
$$

Canceling the corresponding terms on both sides of (5.6) yields the following inequality:

$$\begin{aligned}\|U(\boldsymbol{x},t_{N_1})\|^2_{L^2(\Omega)} &\le (1+2L_0\Delta t)\|U(\boldsymbol{x},0)\|^2_{L^2(\Omega)}\\ &\quad + 4L_0\Delta t\sum_{n=1}^{N_1}\|U(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)} + 2L_0\|q\|^2_{\widehat{L}(0,T;L^2(\Omega))}.\end{aligned} \tag{5.7}$$

Taking Δt small enough such that $4L_0\Delta t \le 1/2$, we rewrite (5.7) as follows:

$$\begin{aligned}\|U(\boldsymbol{x},t_{N_1})\|^2_{L^2(\Omega)} &\le 8L_0\Delta t\sum_{n=1}^{N_1-1}\|U(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)}\\ &\quad + \frac{5}{2}\|U(\boldsymbol{x},0)\|^2_{L^2(\Omega)} + 4L_0\|q\|^2_{\widehat{L}(0,T;L^2(\Omega))}.\end{aligned} \tag{5.8}$$

Applying Gronwall's inequality to (5.8) yields the following stability estimate:

$$\|U\|_{\widehat{L}^\infty(0,T;L^2(\Omega))} \le L\Big[\|u_0\|_{L^2(\Omega)} + \|q\|_{\widehat{L}^2(0,T;L^2(\Omega))}\Big], \tag{5.9}$$

where $\|U(\boldsymbol{x},0)\|_{L^2(\Omega)}$ is bounded by $\|u_0\|_{L^2(\Omega)}$, and

$$\begin{aligned}\|U\|_{\widehat{L}^\infty(0,T;L^2(\Omega))} &= \max_{0\le n\le N}\|U(\boldsymbol{x},t_n)\|_{L^2(\Omega)},\\ \|U\|_{\widehat{L}^2(0,T;L^2(\Omega))} &= \left[\Delta t\sum_{n=0}^{N}\|U(\boldsymbol{x},t_n)\|^2_{L^2(\Omega)}\right]^{1/2}.\end{aligned} \tag{5.10}$$

Thus, we have proved the unconditional stability of Scheme I.

THEOREM 5.2. *Schemes* II *and* III *are explicit and unconditionally stable.*

The explicitness of Scheme III can be shown similarly to that of Scheme II in (4.14), with $\boldsymbol{\omega}_j$ and J_n replaced by $\widetilde{\boldsymbol{\omega}}_j^n$ and J, respectively.

We now prove the unconditional stability of Schemes II and III. Recalling the expression (4.13) for $U(\boldsymbol{x},t_n)$, we multiply (4.7) with $w(\boldsymbol{x},t_n) = \Phi_{0,\boldsymbol{k}}$ by $c_{0,\boldsymbol{k}}(U_n)$ $\forall \boldsymbol{k}\in\boldsymbol{\omega}_0$, and (4.7) with $w(\boldsymbol{x},t_n) = \Psi^{\boldsymbol{e}}_{j,\boldsymbol{k}}$ by $d^{n,\boldsymbol{e}}_{j,\boldsymbol{k}}(U_n)$ $\forall\boldsymbol{k}\in\boldsymbol{\omega}_j$, $\boldsymbol{e}\in\boldsymbol{E}$, and $0\le j\le J_n-1$, and add all the resulting equations, yielding (5.1) again. Even though the number of levels J_{n-1} at time step t_{n-1} and at time step t_n could be different, the techniques used in Theorem 5.1 still work and lead to the stability estimate (5.9).

To prove the unconditional stability for Scheme III, we recall the expression (4.23) for $U(\boldsymbol{x},t_n)$. Multiplying (4.24) with $w(\boldsymbol{x},t_n) = \Phi_{0,\boldsymbol{k}}$ by $c^n_{0,\boldsymbol{k}}(U_n)$ $\forall\boldsymbol{k}\in\boldsymbol{\omega}_0$, and (4.24) with $w(\boldsymbol{x},t_n) = \Psi^{\boldsymbol{e}}_{j,\boldsymbol{k}}$ by $d^{n,\boldsymbol{e}}_{j,\boldsymbol{k}}(U_n)$ $\forall\boldsymbol{k}\in\widetilde{\boldsymbol{\omega}}^n_j$, $\boldsymbol{e}\in\boldsymbol{E}$, and $0\le j\le J-1$, and adding all the resulting equations, we obtain

$$\begin{aligned}\int_\Omega U^2(\boldsymbol{x},t_n)d\boldsymbol{x} &= \int_\Omega \widehat{U}(\boldsymbol{x},t_{n-1})U(\boldsymbol{x},t^+_{n-1})d\boldsymbol{x}\\ &\quad + \int_\Omega \Lambda(\boldsymbol{x},t_n)q(\boldsymbol{x},t_n)U(\boldsymbol{x},t_n)d\boldsymbol{x}.\end{aligned} \tag{5.11}$$

Using the inequality

$$
\begin{aligned}
&\|U(\boldsymbol{x}, t_{n-1})\|^2_{L^2(\Omega)} \\
&= \sum_{\boldsymbol{k}\in\boldsymbol{\omega}_0} \left|c^{n-1}_{0,\boldsymbol{k}}(U_{n-1})\right|^2 + \sum_{j=0}^{J-1} \sum_{\boldsymbol{k}\in\widetilde{\boldsymbol{\omega}}^{n-1}_j} \sum_{\boldsymbol{e}\in\boldsymbol{E}} \left|d^{n-1,\boldsymbol{e}}_{j,\boldsymbol{k}}(U_{n-1})\right|^2 \\
&= \|\widehat{U}(\boldsymbol{x}, t_{n-1})\|^2_{L^2(\Omega)} + \sum_{j=0}^{J-1} \sum_{\boldsymbol{k}\in\widetilde{\boldsymbol{\omega}}^{n-1}_j\backslash\widehat{\boldsymbol{\omega}}^{n-1}_j} \sum_{\boldsymbol{e}\in\boldsymbol{E}} \left|d^{n-1,\boldsymbol{e}}_{j,\boldsymbol{k}}(U_{n-1})\right|^2 \\
&\geq \|\widehat{U}(\boldsymbol{x}, t_{n-1})\|^2_{L^2(\Omega)},
\end{aligned}
\tag{5.12}
$$

we bound the first term on the right-hand side of (5.11) as in (5.3):

$$
\begin{aligned}
&\left|\int_\Omega \widehat{U}(\boldsymbol{x}, t_{n-1}) U(\boldsymbol{x}, t^+_{n-1}) d\boldsymbol{x}\right| \\
&\leq \left(\frac{1}{2} + L\Delta t\right) \left[\|U(\boldsymbol{x}, t_n)\|^2_{L^2(\Omega)} + \|\widehat{U}(\boldsymbol{x}, t_{n-1})\|^2_{L^2(\Omega)}\right] \\
&\leq \left(\frac{1}{2} + L\Delta t\right) \left[\|U(\boldsymbol{x}, t_n)\|^2_{L^2(\Omega)} + \|U(\boldsymbol{x}, t_{n-1})\|^2_{L^2(\Omega)}\right].
\end{aligned}
\tag{5.13}
$$

We then obtain the estimate (5.5) again. The same technique as that used in proving Theorem 5.1 concludes the proof of this theorem.

6. Numerical experiments. We consider the transport of a two-dimensional Gaussian pulse, with or without a reactive process involved. To gain some basic understanding of the numerical methods, we compare these schemes with the standard upwind scheme that has been well understood and widely used in industrial applications.

In the example runs, the spatial domain is $\Omega := (-1, 1) \times (-1, 1)$, a rotating velocity field is imposed as $V_1(x_1, x_2) = -4x_2$, and $V_2(x_1, x_2) = 4x_1$. The time interval is $[0, T] = [0, \pi/2]$, which is the time period required for one complete rotation. The initial condition $u_0(x_1, x_2)$ is given by

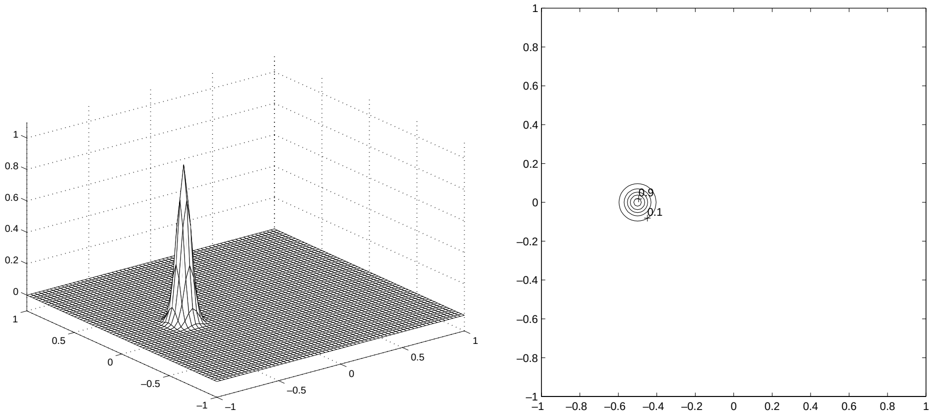
$$
u_0(x_1, x_2) := \exp\left(-\frac{(x_1 - x_{1c})^2 + (x_2 - x_{2c})^2}{2\sigma^2}\right),
\tag{6.1}
$$

where x_{1c}, x_{2c}, and σ are the centered and standard deviations, respectively. The corresponding analytical solution for (2.1) with $q = 0$ is given by

$$
\begin{aligned}
&u(x_1, x_2, t) \\
&= \exp\left(-\frac{(\bar{x}_1 - x_{1c})^2 + (\bar{x}_2 - x_{2c})^2}{2\sigma^2} - \int_0^t R(\boldsymbol{r}(\theta; \bar{x}_1, \bar{x}_2, 0), \theta) d\theta\right),
\end{aligned}
\tag{6.2}
$$

where $\bar{x}_1 := x_1 \cos(4t) + x_2 \sin(4t)$, $\bar{x}_2 := -x_1 \sin(4t) + x_2 \cos(4t)$, and $\boldsymbol{r}(\theta; \bar{x}_1, \bar{x}_2, 0) := (\bar{x}_1 \cos(4\theta) - \bar{x}_2 \sin(4\theta), \bar{x}_1 \sin(4\theta) + \bar{x}_2 \cos(4\theta))$.

This example has been used widely to test different schemes for numerical artifacts such as numerical stability, numerical dispersion, spurious oscillations, deformation, and phase errors as well as other numerical effects arising in porous medium fluid flows. In the numerical experiments, the data are chosen as follows: $q = 0$, $x_{1c} = -0.5$, $x_{2c} = 0$, and $\sigma = 0.0447$. To observe the capability of these schemes in handling reactive



(a) Surface plot

(b) Contour plot with intervals of 0.2

FIG. 1. *Surface and contour plots of the analytical solution at* $T = \frac{\pi}{2}$.

transport processes, we consider both $R = 0$ and $R = \cos(2t)$. When no reaction is present, the analytical solution $u(x_1, x_2, t)$ after one complete rotation is identical to the initial condition $u_0(x_1, x_2)$, which is centered at (x_{1c}, x_{2c}) with a minimum value 0 and a maximum value 1. The surface and contour plots of the analytical solution (which is identical to the initial condition) are presented in Figure 1(a) and (b). For $R = \cos(2t)$, the analytical solution given by (6.2) now becomes

$$u(x_1, x_2, t) = \exp\left(-\frac{1}{2}\sin(2t) - \frac{(\bar{x}_1 - x_{1c})^2 + (\bar{x}_2 - x_{2c})^2}{2\sigma^2}\right), \tag{6.3}$$

which is identical to the analytical solution with no reaction at the final time $t = \frac{\pi}{2}$. Hence, we can have a fair comparison of errors for both $R = 0$ and $R = \cos(2t)$.

We use the fourth-order Daubechies wavelets with a coarsest occurring level of grid size $h_0 = \frac{1}{8}$, a finest occurring level of $J = 3$, and a very coarse time step of $\Delta t = \pi/8$. This leads to a maximal Courant number of 115. We apply Scheme I (which is identical to Scheme II) at the finest level $J = 3$ to compute the uncompressed solution. We then apply Scheme III with the coarsest level of mesh size $h_0 = \frac{1}{8}$ and the finest level $J = 3$ to compute the compressed solutions. In all the schemes, a fourth-order Runge–Kutta method with a micro time step of $\Delta t_m = \Delta t/4$ is used to track the characteristics. The tolerance (4.18) now becomes

$$\varepsilon_j := 2^{-j}\ \Delta t\ \varepsilon. \tag{6.4}$$

In Table 1, we present the L^1-, L^2-, and L^∞-errors, the maximum and minimum values, and compression ratios (the number of unknowns in the uncompressed solution versus that of the unknowns in the compressed solution) of the uncompressed ($\varepsilon = 0$) and compressed solutions at the final step $T = \pi/2$ for different choices of tolerance ε and for both $R = 0$ and $R = \cos(2t)$. The contour and surface plots for the uncompressed solution and the compressed solution with $\varepsilon = 0.0001$ at the final step $T = \pi/2$ and for $R = \cos(2t)$ are plotted in Figure 2(a)–(d). These results show that the schemes developed in this paper generate very accurate solutions, even if

TABLE 1

Statistics of uncompressed ($\varepsilon = 0$) and compressed solutions for different choices of tolerance ε. The time step is $\Delta t = \frac{\pi}{8}$ with a micro time step of $\Delta t_m = \frac{\Delta t}{4}$ used in tracking. The coarsest mesh size is $h_0 = \frac{1}{8}$ and the finest mesh size is $h_J = \frac{1}{64}$.

FIG. 2. *The uncompressed and compressed solutions at $T = \frac{\pi}{2}$.*

very large time steps and fairly coarse grids are used. The schemes are explicit and highly parallelizable. We observe that with fairly large compression ratios, Scheme III generates a solution comparable to the uncompressed solution. This implies a further improvement in terms of computational efficiency and storage. In the numerical implementation of these schemes, we focus on the study of the trade-off between the compressibility and accuracy. We understand that a fine-tuning and optimization of the implementations will fully explore the adaptivity of Scheme III and will further improve its CPU performance. Finally, these schemes handle the reactive effect accurately and generate numerical solutions with about the same errors as the solutions with no reaction involved.

It is well known that the standard upwind scheme is explicit and fairly easy to implement, and can generate very stable solutions with correct qualitative physical trend even for very complex problems. However, the upwind scheme introduces excessive numerical diffusion and tends to severely smear the steep fronts of the numerical solutions. We present in Table 2 the numerical solutions of the upwind scheme with various time steps and spatial grids. With the base spatial grid size of $h = h_J = \frac{1}{64}$ that was used in Table 1, the time step $\Delta t = \frac{\pi}{1200}$ is the largest admissible step size that meets the CFL condition (the Courant number is 0.95). The upwind scheme generates an extremely diffusive solution with a maximal value of only 0.080 that is only 8% of the height of the true solution, even though it is extremely efficient per time step (it took only 4 seconds for 1200 time steps). The surface and contour plots of the solution are presented in Figure 3(a) and (b). We further notice that with the same spatial grid size, the errors increase slightly as the size of the time step is further reduced. This observation can be explained by using the local truncation error analysis, which shows that the local spatial and temporal errors actually have opposite signs and cancel with each other. Hence, reducing further the time step size only leads to increased local truncation error, and so to increased truncation errors of the numerical solutions of the upwind scheme. To improve the accuracy of the numerical solutions, we have to refine both the spatial grids and the time steps with the Courant number being close to unity. With a CPU time comparable to that which Schemes I–III consumed, the upwind scheme generates a solution using a spatial grid size of $h = \frac{1}{128}$ and a time step of $\Delta t = \frac{\pi}{4800}$. However, the resulting solution has a maximal value of only 0.131. The finest grids used are $\Delta t = \frac{\pi}{20000}$ and $h = \frac{1}{1024}$. It took a CPU time of almost 6 hours for the upwind scheme to generate a solution with a maximal value of 0.579. The surface and contour plots of the numerical solution are presented in Figure 3(c) and (d). We also observe slight deformation due to the grid orientation effect. These comparisons show that these schemes are very competitive and hold strong potential.

7. Extension.

We outline the extension of the schemes developed in this paper to the initial-boundary-value problem of advection-reaction PDEs:

$$\begin{aligned} u_t + \nabla\cdot(\mathbf{v}u) + Ru &= q(\boldsymbol{x},t), && (\boldsymbol{x},t)\in\Omega\times(0,T],\\ u(\boldsymbol{x},t) &= u_\Gamma(\boldsymbol{x},t), && \boldsymbol{x}\in\Gamma^{(I)},\quad t\in[0,T],\\ u(\boldsymbol{x},0) &= u_0(\boldsymbol{x}), && \boldsymbol{x}\in\Omega, \end{aligned} \tag{7.1}$$

where $\Omega := (a_1,b_1)\times\cdots\times(a_d,b_d)$ is the spatial domain with the boundary $\Gamma = \partial\Omega$. $\Gamma^{(I)}$ and $\Gamma^{(O)}$ are the inflow and outflow boundaries identified by

$$\begin{aligned} \Gamma^{(I)} &:= \{\boldsymbol{x} \mid \boldsymbol{x}\in\partial\Omega,\ \mathbf{v}\cdot\boldsymbol{n}<0\},\\ \Gamma^{(O)} &:= \{\boldsymbol{x} \mid \boldsymbol{x}\in\partial\Omega,\ \mathbf{v}\cdot\boldsymbol{n}>0\}. \end{aligned} \tag{7.2}$$

Table 2

Statistics of upwind schemes at time $T = \frac{\pi}{2}$ with $R = 0$ and different spatial grids and time steps.

(a) $h = \frac{1}{64}$ and $\Delta t = \frac{\pi}{1200}$

(b) Contour plot at 0.001, 0.01, and 0.07

(c) $h = \frac{1}{1024}$ and $\Delta t = \frac{\pi}{20000}$

(d) Contour plot with intervals of 0.2

Fig. 3. *The upwind solutions with different grid sizes and time steps at $T = \frac{\pi}{2}$.*

The weak formulation corresponding to (2.2) now reads as

$$\begin{aligned}
&\int_\Omega u(\boldsymbol{x},t_n)w(\boldsymbol{x},t_n)d\boldsymbol{x} + \int_{t_{n-1}}^{t_n}\int_\Gamma \mathbf{v}(\boldsymbol{x},t)\cdot\boldsymbol{n}(\boldsymbol{x})\ u(\boldsymbol{x},t)w(\boldsymbol{x},t)dsdt \\
&\quad - \int_{t_{n-1}}^{t_n}\int_\Omega u(w_t + \mathbf{v}\cdot\nabla w - Rw)(\boldsymbol{x},t)d\boldsymbol{x}dt \\
&\quad = \int_\Omega u(\boldsymbol{x},t_{n-1})w(\boldsymbol{x},t_{n-1}^+)d\boldsymbol{x} + \int_{t_{n-1}}^{t_n}\int_\Omega q(\boldsymbol{x},t)w(\boldsymbol{x},t)d\boldsymbol{x}dt.
\end{aligned} \tag{7.3}$$

Now the characteristic $\boldsymbol{r}(\theta;\check{\boldsymbol{x}},\check{t})$ is still determined by (2.4)–(2.6), but with the exception that either $(\check{\boldsymbol{x}},\check{t}) = (\boldsymbol{x},t_n)$ for $\boldsymbol{x}\in\overline{\Omega}$ or $(\check{\boldsymbol{x}},\check{t}) = (\boldsymbol{x},t)$ for $\boldsymbol{x}\in\Gamma^{(O)}$ and $t\in[t_{n-1},t_n]$. Then derivation similar to that for (2.11) leads to the reference equation

$$\begin{aligned}
&\int_\Omega u(\boldsymbol{x},t_n)w(\boldsymbol{x},t_n)d\boldsymbol{x} + \int_{t_{n-1}}^{t_n}\int_{\Gamma^{(O)}} \mathbf{v}(\boldsymbol{x},t)\cdot\boldsymbol{n}(\boldsymbol{x})\ u(\boldsymbol{x},t)w(\boldsymbol{x},t)dsdt \\
&\quad = \int_\Omega u(\boldsymbol{x},t_{n-1})w(\boldsymbol{x},t_{n-1}^+)d\boldsymbol{x} + \int_\Omega \Lambda(\boldsymbol{x},t_n)q(\boldsymbol{x},t_n)w(\boldsymbol{x},t_n)d\boldsymbol{x} \\
&\quad + \int_{t_{n-1}}^{t_n}\int_{\Gamma^{(O)}} \Lambda^{(1)}(\boldsymbol{x},t)\mathbf{v}(\boldsymbol{x},t)\cdot\boldsymbol{n}(\boldsymbol{x})q(\boldsymbol{x},t)w(\boldsymbol{x},t)d\boldsymbol{x} \\
&\quad - \int_{t_{n-1}}^{t_n}\int_{\Gamma^{(O)}} \mathbf{v}(\boldsymbol{x},t)\cdot\boldsymbol{n}(\boldsymbol{x})u_\Gamma(\boldsymbol{x},t)w(\boldsymbol{x},t)d\boldsymbol{x} + E(w),
\end{aligned} \tag{7.4}$$

with

$$\Lambda^{(1)}(\boldsymbol{x},t) := \begin{cases} \dfrac{1-e^{-R(\boldsymbol{x},t)(t-t^*(\boldsymbol{x},t))}}{R(\boldsymbol{x},t)} & \text{if } R(\boldsymbol{x},t)\neq 0, \\ t - t^*(\boldsymbol{x},t) & \text{otherwise,} \end{cases} \tag{7.5}$$

where $t^*(\boldsymbol{x},t) = t_{n-1}$ if $\boldsymbol{r}(\theta;\boldsymbol{x},t)$ does not backtrack to the boundary Γ, or $t^*(\boldsymbol{x},t)$ represents the time instant when $\boldsymbol{r}(\theta;\boldsymbol{x},t)$ backtracks to the boundary Γ otherwise.

Based on the reference equation (7.5), we can define Schemes I–III as before. But now the unknown trial functions $U(\boldsymbol{x},t)$ are defined in $\overline{\Omega}$ at time t_n and on the space-time outflow boundary $\Gamma^{(O)}\times[t_{n-1},t_n]$. The scaling and wavelet basis functions used in section 4 might not be orthogonal anymore near the boundary of the domain $\overline{\Omega}$. Consequently, the schemes might not be explicit anymore. Notice that the region where the basis functions are not orthogonal is of order Δt. Hence, the derived schemes are explicit in most of the domain and are implicit near boundary. In other words, we reduce the space dimension of the implicit scheme by one. Alternatively, we could utilize the results in [4, 17] to modify the wavelet basis functions near boundary to make them orthonormal and again lead to fully explicit schemes.

8. Conclusions. The well-known CFL condition states that there are no explicit, unconditionally stable, consistent finite difference schemes (in fact, any schemes with fixed stencils) for linear hyperbolic PDEs [5]. Therefore, although explicit methods are relatively easy to implement, are local, and are fully parallelizable, the time step sizes in these methods are subject to the CFL condition. In fact, explicit methods often have to use very small time steps in numerical simulations to maintain the stability of the methods [11]. In contrast, implicit methods are unconditionally stable.

However, they require inverting a coefficient matrix at each time step and could be expensive. Moreover, the time step sizes of implicit methods are still restricted for the reason of accuracy, especially when steep fronts pass by.

In this paper we combine an Eulerian–Lagrangian approach and multiresolution analysis to develop three unconditionally stable, explicit schemes for multidimensional linear hyperbolic PDEs. Scheme I is a single-level scheme that uses all the scaling functions at a fine level J as basis functions. It is in the flavor of standard finite element methods and is fairly straightforward to implement. Scheme II is a multilevel scheme that uses all the scaling functions at a coarsest occurring discretization level 0 and all the wavelets on all the levels $0, 1, \ldots, J_n - 1$ as basis functions. It is similar to multigrid methods with a slash cycle, and does not need to go back and forth between the coarse grids and the fine grids (see [13] and the references therein). Scheme III uses a thresholding and compression technique to adaptively select the wavelet basis functions at each successive level $0, 1, \ldots, J - 1$. It significantly reduces the number of equations and coefficients that need to be solved, while still showing accuracy comparable to the uncompressed schemes (Schemes I and II). Hence, it has a greatly improved efficiency and storage. The scheme is nonlinear and is related to adaptive finite element methods. Furthermore, the compression used in the scheme does not introduce any mass balance error. As we have seen, by using a multiresolution analysis and orthogonal wavelets with an Eulerian–Lagrangian approach, we are able to obtain single-level and multilevel, explicit schemes. The use of Lagrangian coordinates enables us to obtain accurate solutions even if very large time steps are used. Moreover, the use of Lagrangian coordinates defines the stencils adaptively following the flow of streamlines, and the stencils are not necessarily fixed. This is the fundamental reason why we could develop CFL-free, unconditionally stable, convergent numerical methods for hyperbolic PDEs without contradicting the well-known CFL condition. Our previous computational results have shown the strong potential of the methods developed. The convergence analysis and error estimate for Scheme I can be derived in a more or less standard way, but the error estimates for Schemes II and III require more work. We will present the theoretical error estimates for these schemes elsewhere.

Acknowledgment. The authors would like to thank the referees for their very helpful comments and suggestions, which greatly improved the quality of this paper.

IMAGE PROCESSING FOR NUMERICAL APPROXIMATIONS OF CONSERVATION LAWS: NONLINEAR ANISOTROPIC ARTIFICIAL DISSIPATION[*]

THORSTEN GRAHS[†], ANDREAS MEISTER[‡], AND THOMAS SONAR[†]

Abstract. We employ a nonlinear anisotropic diffusion operator like the ones used as a means of filtering and edge enhancement in image processing and in numerical methods for conservation laws. It turns out that algorithms currently used in image processing are very well suited for the design of nonlinear higher order dissipative terms. In particular, we stabilize the well-known Lax–Wendroff formula by means of a nonlinear diffusion term.

Key words. artificial diffusion, higher order methods, nonlinear filter, finite differences

1. Introduction.

The construction of suitable artificial viscosity terms for stabilizing finite difference schemes of higher order is a difficult task. In the last decade we therefore observed a strong tendency to construct numerical approximations of conservation laws without explicit knowledge of their numerical diffusion. The modern total variation diminishing (TVD) or essentially nonoscillatory (ENO) schemes belong to this class, in which a basic first-order scheme is enhanced by the use of sophisticated recovery functions; see [10], [4]. There are, however, certain circumstances in which an approach using explicit construction of artificial dissipation would be advantageous. If we consider pseudospectral methods, the concept of ENO recovery is very hard to apply if the degree of the basis polynomials used is high. Here one would like to compute shocked solutions with central differences and to postprocess the oscillatory numerical solution such that

(i) high frequency oscillations are filtered, and
(ii) shocks are steepened and represented with high resolution.

Another area of application is grid-free methods (see [1]), where modern concepts of recovery fail due to the irregularity of the interpolation points. In that case one would like to compute all derivatives from a central interpolant (or, better, a least squares approximation) and postprocess the derivatives as was described above.

Over the years there were no general attempts to derive a constructive theory which would enable the design of suitable artificial viscosities within the CFD community. However, filtering and edge enhancement is a fundamental task in image processing, and in recent years a theory of nonlinear anisotropic diffusion was created and can now be found in textbooks like [14] and [5]. In a noisy picture one also would like to filter the high frequency components before detecting the edges (i.e., jumps in grey level). Then one would like to enhance the edges in order to represent the edges in high resolution. Now there is nothing which keeps us from interpreting our numerical solution corresponding to a conservation law as a photograph or picture,

at least not in the case of steady solutions. In the same way the photographer would very much prefer to see the contours on his picture as sharp thin lines, the numerical analyst would prefer to see shocks as crispy lines instead of smeared thick regions. To accomplish this photo as well as numerical solution have to be denoised. After removing the high frequencies we would like to spend a dose of diffusion tangential on shocks, but we would like to avoid diffusion across shocks (that is what anisotropy is all about). In contrast, in the vicinity of shocks we would like to solve a kind of nonlinear anisotropic backward heat equation to enhance the structure of a shock. Devices and algorithms satisfying exactly these requirements are ready to use if one is willing to enter the area of image processing.

The aim of this paper is mainly to show the potential of the methods developed for image processing if they are applied consistently to problems in the numerical treatment of hyperbolic conservation laws. We hope that we open up a new chapter in the design of modern nonlinear discretizations of conservation laws by using concepts which are well known in the image processing society. In the present paper we demonstrate our algorithms with the Lax–Wendroff formula for two-dimensional scalar equations. A future paper will be devoted to more serious applications in the field of gas dynamics.

The outline of the paper is as follows. After a brief review of the concepts used in the numerical treatment of conservation laws we apply the classical Lax–Wendroff formula to a steady nonlinear problem in which a shock is present. As is well known the second-order Lax–Wendroff formula answers these type of problems with violent oscillations. In image processing Gaussian smoothing would be applied to the numerical solution in order to filter high frequency components. We exemplify this strategy but never use it in our final algorithms. On one hand, the control of the linear diffusion is very difficult. (A little overdose deteriorates the numerical solution strongly.) On the other hand, there are no visible differences in the final solution when computed with or without presmoothing. We then utilize the structure tensor which serves as a detector of the local coherence of our solution. In looking at eigenvalues and eigenvectors, regions of anisotropy can be detected, as well as regions of constant states. We then proceed to the construction of a nonlinear anisotropic artificial viscosity term. It is here where one has the freedom to choose between many different possible models. In our paper we decided to use an anisotropic regularization of the classical Perona–Malik model due to Weickert. There are certainly more clever choices, but all the important ideas are contained in this specific example. This anisotropic artificial dissipation is discretized so that the discrete equation is stable. The underlying algorithm controlling the discretization is also taken from image processing. The final result reveals the postprocessed Lax–Wendroff solution showing high resolution of the shock and smooth behavior in the continuous regions. Finally, we construct a new splitting scheme containing the algorithmic ingredients described above.

The final algorithm may be displayed in form of the following flowchart.

- In every time step:
  1. Compute a numerical solution $U(t+\Delta t)$ with a finite difference method.
  2. If necessary, filter high frequency components by means of $U_\delta := K_\delta * U$, where K_δ is the Gaussian kernel corresponding to a standard deviation of δ.
  3. Compute the structure tensor $J_0(\nabla U_\delta)$ which contains information about the local coherence of the numerical solution.
  4. Average the structure information in the vicinity of each grid point in order to define a region size in which the orientation of the solution is

examined. This corresponds to computing $J_\rho(\nabla U_\delta) := K_\rho * J_0(\nabla U_\delta)$.

5. Construct an artificial dissipation D from knowledge contained in J_ρ.
6. Solve the discrete version of the nonlinear anisotropic equation

$$\begin{aligned}\partial_t w &= \operatorname{div}(D(w)\operatorname{grad} w),\\ w(x,y,0) &= U(x,y).\end{aligned}$$

- End of time step: set $U(t+\Delta t) := w(\Delta t)$.

2. Conservation laws and finite difference schemes. Consider the scalar conservation law

$$\partial_t u + \partial_x f(u) + \partial_y g(u) = 0 \tag{2.1}$$

on $\Omega := [0,1]^2$, where we assume Cauchy data $u_0(x,y) = u(x,y,0)$ as well as boundary data which may respect the characteristic directions. As is well known, discontinuities develop in general within finite time regardless how smooth the initial data is chosen.

We consider conservative three-point finite difference approximations

$$\begin{aligned}U_{i,j}^{n+1} = U_{i,j}^n &- \Delta t \frac{1}{\Delta x}\left[\Theta(U_{i+1,j}^n, U_{i,j}^n) - \Theta(U_{i,j}^n, U_{i-1,j}^n)\right]\\ &- \Delta t \frac{1}{\Delta y}\left[\Xi(U_{i,j+1}^n, U_{i,j}^n) - \Xi(U_{i,j}^n, U_{i,j-1}^n)\right]\end{aligned}$$

of (2.1), where Θ and Ξ denote numerical flux functions consistent in the sense of $\Theta(s,s) = f(s)$ and $\Xi(s,s) = g(s)$ for all $s \in \mathbb{R}$. It is well known that every numerical flux of a three-point scheme can be written in the viscosity form

$$\Theta(v,w) := \frac{1}{2}(f(v) + f(w)) - \mathcal{Q}(v,w)(v-w),$$

where $\mathcal{Q}$ is the numerical viscosity coefficient; see [11].

It was shown by Tadmor in [11] and [12] that in the class of monotone, and hence first-order schemes, there exists a minimax pair in the sense that a scheme with numerical viscosity coefficient $\mathcal{Q}$ which satisfies the inequality

$$\forall v, w \in S \subset \mathbb{R}: \quad \mathcal{Q}^G(v,w) \le \mathcal{Q}(v,w) \le \mathcal{Q}^{mLF}(v,w)$$

is entropy stable, i.e., converges to the entropy weak solution. Here S denotes the state space of possible values of the solution. It turns out that the minimax pair is given by two well-known finite difference schemes, namely the Godunov scheme, corresponding to $\mathcal{Q}^G$, and the (modified) Lax–Friedrichs scheme, corresponding to $\mathcal{Q}^{LF}$. Both schemes are only first order accurate so that there is need for a constructive recipe giving higher order schemes from lower order ones.

In principle there are two different ways for the construction of higher order numerical methods. One could start directly with the construction of a numerical viscosity coefficient which gives higher order as well as stability. This is the way chosen by Jameson, Schmidt, and Turkel in the early 1980s; see [3]. The construction is difficult due to the inherent nonlinearity of the problem, and a well-behaving dissipation is hard to obtain. However, Jameson's codes still belong to the most successful pieces of software ever written and are known for their flexibility as well as for their stability. The other route leading to stable higher order schemes developed into a mainstream in the mid 1980s. Here one starts with a lower order monotone scheme, recovers the solution (with a MUSCL or ENO technique), and inserts the recovered solution into the low order flux functions. The recipe is quite general, and the most spectacular finite difference schemes of our time, like the TVD or ENO schemes, rely on that construction. Although the process of recovery in itself is not an easy task, we know now quite well how this can be done even on unstructured grids. In this class of methods we do not even see the numerical dissipation of our methods explicitly, which may seem to be a big advantage over the Jameson-type schemes.

However, in recent years a theory of nonlinear anisotropic diffusion was developed within the community of image processing. The algorithms developed there are very well suited for use in the numerical solution of conservation laws. In doing so, we proceed again along the lines of Jameson, Schmidt, and Turkel and try to construct a reasonable dissipation coefficient directly, but we shall see that the algorithmic background is so well developed that we arrive safely at new nonlinear anisotropic dissipation terms, which turn the oscillating Lax–Wendroff scheme into a high resolution method.

3. The numerical solution viewed as a picture. It is well known that the Lax–Wendroff formula is a second-order finite difference scheme for (2.1). In two dimensions there are a variety of different implementations, but we have chosen the one described by Shokin [7], i.e.,

$$\begin{aligned}
&\frac{U_{i,j}^{n+1}-U_{i,j}^{n}}{\Delta t}+\frac{F_{i+1,j}^{n}-F_{i-1,j}^{n}}{2\Delta x}+\frac{G_{i,j+1}^{n}-G_{i,j-1}^{n}}{2\Delta y}\\
&\quad=\frac{\kappa_x}{2}\left[A_{i+1/2,j}^{n}\left(\frac{F_{i+1,j}^{n}-F_{i,j}^{n}}{\Delta x}+\frac{G_{i+1/2,j+1/2}^{n}-G_{i+1/2,j-1/2}^{n}}{\Delta y}\right)\right.\\
&\quad\left.-A_{i-1/2,j}^{n}\left(\frac{F_{i,j}^{n}-F_{i-1,j}^{n}}{\Delta x}+\frac{G_{i-1/2,j+1/2}^{n}-G_{i-1/2,j-1/2}^{n}}{\Delta y}\right)\right]\\
&\quad+\frac{\kappa_y}{2}\left[B_{i,j+1/2}^{n}\left(\frac{F_{i+1/2,j+1/2}^{n}-F_{i-1/2,j+1/2}^{n}}{\Delta x}+\frac{G_{i,j+1}^{n}-G_{i,j}^{n}}{\Delta y}\right)\right.\\
&\quad\left.-B_{i,j-1/2}^{n}\left(\frac{F_{i+1/2,j-1/2}^{n}-F_{i-1/2,j-1/2}^{n}}{\Delta x}+\frac{G_{i,j}^{n}-G_{i,j-1}^{n}}{\Delta y}\right)\right].
\end{aligned}\tag{3.1}$$

Here, $F_{i,j}^n := f(U_{i,j}^n)$ and

$$\begin{aligned}
A_{i\pm1/2,j}^{n} &:= (f'(U_{i\pm1,j}^{n})+f'(U_{i,j}^{n}))/2,\\
B_{i,j\pm1/2}^{n} &:= (g'(U_{i,j\pm1}^{n})+g'(U_{i,j}^{n}))/2,\\
G_{i\pm1/2,j\pm1/2}^{n} &:= (G_{i\pm1,j\pm1}^{n}+G_{i,j})/2,
\end{aligned}$$

etc. The grid coefficients are $\kappa_x := \Delta t/\Delta x, \kappa_y := \Delta t/\Delta y$.

If σ denotes the maximum value of A and B, and if we assume $\Delta x = \Delta y =: h$, then the Lax–Wendroff scheme can be shown to be linearly stable under the somehow pessimistic CFL condition

$$\frac{\Delta t}{h}\sigma \le \frac{1}{2\sqrt{2}}.$$

This was the condition which was implemented in all our test cases.

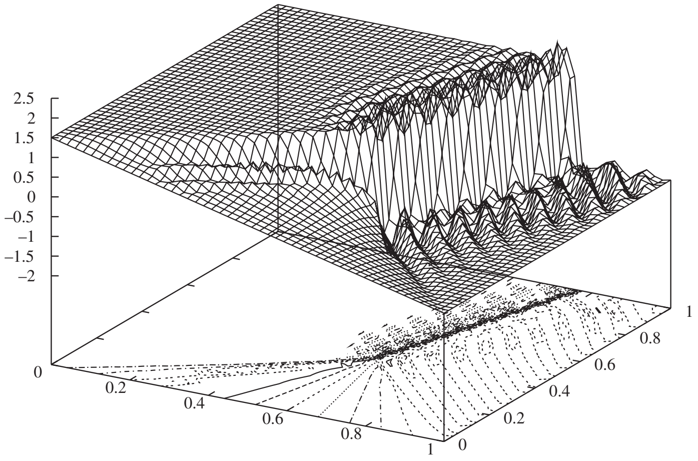

FIG. 1. *Lax–Wendroff solution of a test problem.*

If we now apply the Lax–Wendroff scheme to the boundary value problem (2.1), with $f(u) = 0.5u^2$, $g(u) = u$, and

$$u(x, y, 0) = \begin{cases} 1.5, & x = 0, \\ -2.5x + 1.5, & y = 0, \\ -1.0, & x = 1, \\ 0.0 & \text{else} \end{cases}$$

with 50 × 50 points and determine the boundary condition on the upper side of the unit square through simple extrapolation, then we get a steady solution as shown in Figure 1. The true solution consists of a fan-like continuous wave which develops into a shock. A schematic view of it can be seen in Figure 2.

Since the true solution satisfies the steady equation

$$\partial_y u + \partial_x \frac{u^2}{2} = 0$$

the characteristic equations are given by $dy/ds = 1$, $dx/ds = u$, i.e.,

$$\frac{dy}{dx} = \frac{1}{u}.$$

If we denote by u_L and u_R the given left and right state at $y = 0$, respectively, and we assume a linear distribution

$$u(x, 0) = (u_R - u_L)x + u_L$$

of the boundary data at $y = 0$, then the equation of the leftmost characteristic g_1 is given by $y = x/u_L$. The rightmost characteristic g_2 is given by $y = (x - 1)/u_R$. They meet at the point P where the shock g_3 starts. The coordinates of P are easily computed to be $x_P = u_L/(u_L - u_R)$ and $y_P = 1/(u_L - u_R)$. From the Rankine–Hugoniot condition we get for the shock g_3 the slope

$$\frac{dy}{dx} = \frac{2}{u_L + u_R}$$

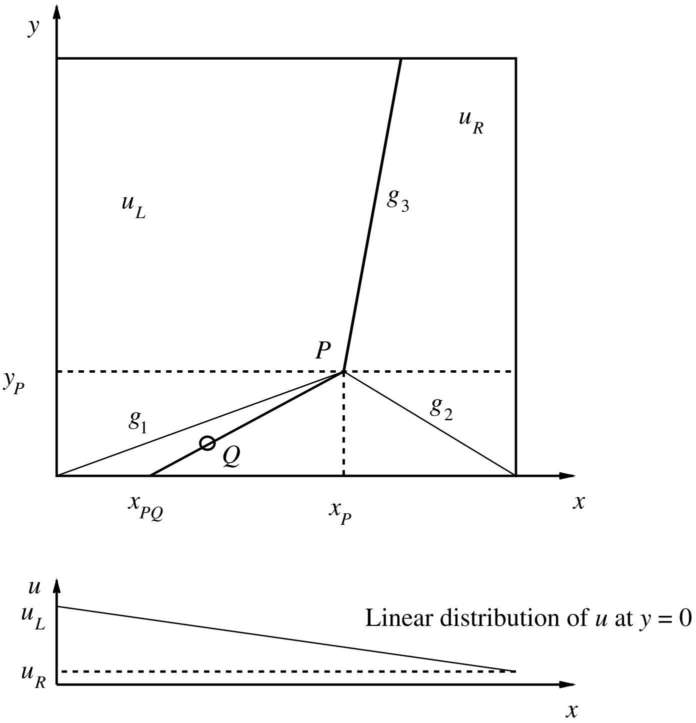

FIG. 2. *True solution of the model problem in the (x, y) plane.*

and finally the equation $y = (2x - 1)/(u_L + u_R)$. From these equations it is easy to compute the true solution pointwise. If the solution is to be known at a point Q lying within the fan region, then the characteristic connecting P and Q meets the x-axis at the point $x_{PQ} = x_P + y_p(x_Q - x_P)/(y_P - y_Q)$ which, according to our assumed linear boundary data distribution at $y = 0$, leads to $u_Q = (u_R - u_L)x_{PQ} + u_L$, which completes the description of the true solution.

In Figure 3 we plotted the pointwise difference between the numerical and the true solution. As can be observed from the numerical solution, there are strong oscillations present in the numerical solution, a behavior which the Lax–Wendroff formula shares with other second-order schemes which do not respect monotonicity conditions. We are now going to correct these behaviors by means borrowed from image analysis.

If we look at the isolines we can think of them as being a photograph. The numerical solution as plotted above the isolines is then interpreted as the grey level function. Obviously, there is noise in the picture (the oscillating part), but there is also an edge (the shock) which is the main feature of the picture. We would now like to do two things, namely

(i) enhance the edge and
(ii) filter the oscillations.

In classical construction of artificial dissipation terms the fullfilment of both requirements leads into trouble. While a diffusion certainly filters the high frequency oscillations it would also deteriorate the quality of the shock. In Jameson's dissipation model there is therefore a shock sensor, modeled by the second derivative of the pressure, which cuts the dissipation off across shocks.

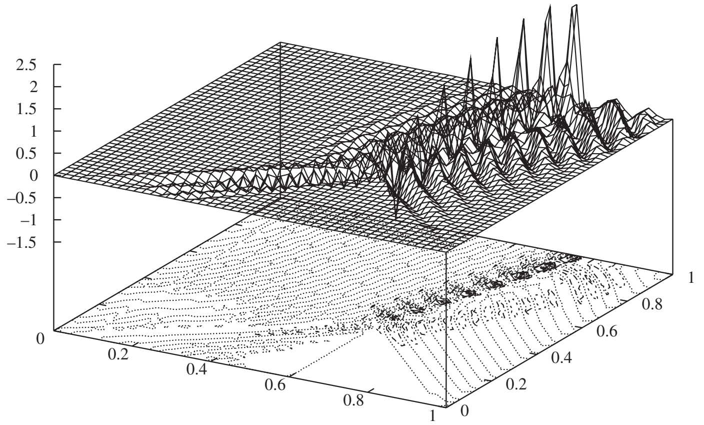

FIG. 3. *Difference between the Lax–Wendroff solution and the true solution.*

However, one would like to introduce dissipation parallel to the edges but avoid dissipation across edges. Dissipation models which satisfy exactly these requirements can be found in nonlinear anisotropic diffusion models from image processing.

4. Structure tensors and dissipation models. Edge enhancement is one of the classical problems in image processing. It was clear quite early in the history of this topic that edge detection without smoothing would lead to unacceptable results due to the noise; see [13]. Therefore, edge detection is only useful if appropriate smoothing is applied beforehand. To accomplish this task Gaussian smoothing may be applied; i.e., the numerical solution U is convolved with the Gaussian kernel

$$U_\delta := K_\delta * U, \quad K_\delta(x,y) := \frac{1}{2\pi\delta^2}\exp\left(-\frac{x^2+y^2}{2\delta^2}\right).$$

The parameter δ is the width of the Gaussian. We do not intend, of course, to dive into a continuous scale-space theory like Weickert [14] or Morel and Solimini [5] in their respective books. In our framework we are given nothing but approximations of Dirac functionals $\langle \delta_{(x_i,y_j)}, u\rangle =: u_{i,j}$ at time $t = n\Delta t$, which we denote by $U^n_{i,j}$. Rearranging all those values (in lexicographical order, say) results in a vector $U := (U^n_{i,j})_{1\le i\le I, 1\le j\le J}$. Of course it would be possible to construct a smooth interpolant of U, but this is already away from the heart of finite difference methods. Hence, the convolution with the Gaussian kernel indicated above is a discrete evolution in our case.

If we consider the continuous model, this type of smoothing is equivalent to solving the heat equation

$$\begin{aligned}\partial_t w &= \Delta w,\\ w(x,y,0) &= U(x,y),\end{aligned}$$

where pseudotime and width are connected via

$$T = \frac{1}{2}\delta^2;$$

i.e., the initial value problem for the heat equation is to be solved until pseudotime $t = T$ is reached. Care has to be taken in order to choose δ. Too large a δ would be

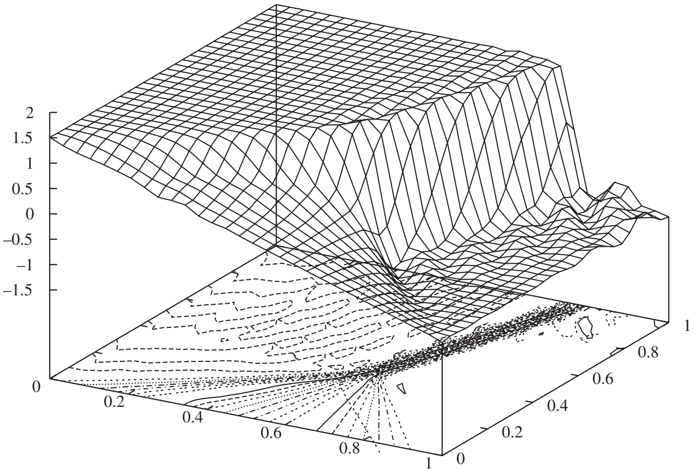

FIG. 4. *Result after presmoothing.*

overdiffusive, while a very small δ would not reduce the high-frequency noise. Since we work on the discrete level the initial value problem for the heat equation is best cast in the discrete form

$$\begin{aligned} U^0_{i,j;\delta} &:= U_{i,j}, \\ U^{m+1/2}_{i,j;\delta} &= U^m_{i,j;\delta} + \Delta t \frac{U^m_{i+1,j;\delta} - 2U^m_{i,j;\delta} + U^m_{i-1,j;\delta}}{\Delta x^2}, \\ U^{m+1}_{i,j;\delta} &= U^{m+1/2}_{i,j;\delta} + \Delta t \frac{U^{m+1/2}_{i,j+1;\delta} - 2U^{m+1/2}_{i,j;\delta} + U^{m+1/2}_{i,j-1;\delta}}{\Delta y^2}, \end{aligned} \tag{4.1}$$

where iteration along pseudotime is performed until the iteration index m is some m_{stop} corresponding to $T = \delta^2/2$. At the stopping time we set $U_{i,j;\delta} := U^{m_{\text{stop}}}_{i,j;\delta}$.

Note that we utilize an explicit splitting scheme which is stable under the CFL condition $\Delta t / \min(\Delta x^2, \Delta y^2) \le 1/2$; see [8]. An implicit discretization would be better behaved, but δ is so small that an explicit splitting is advantageous with respect to computational effort. As an example, we show in Figure 4 the result of a presmoothing with $\delta = 0.02$. In comparison with Figure 1, the filtering influence with respect to high frequency modes can be observed. For the sake of comparison, we again plot the difference between our numerical solution (now after filtering) and the true solution in Figure 5. Note that the error is now already concentrated in the vicinity of the shock. However, the application of the linear heat equation seems to be a dangerous step within the overall algorithm. While high-frequency modes are in fact damped the shock structure deteriorates very fast. Thus, it seems wise to start with a nonlinear diffusion equation directly on the unfiltered data and leave the task of filtering completely to this nonlinear device. From the presmoothed solution U_δ, we compute the structure tensor

$$J_0(\nabla U_{i,j;\delta}) := \nabla U_{i,j;\delta} \cdot \nabla U^T_{i,j;\delta}. \tag{4.2}$$

Since we are still as discrete as possible the meaning of our operator is defined as

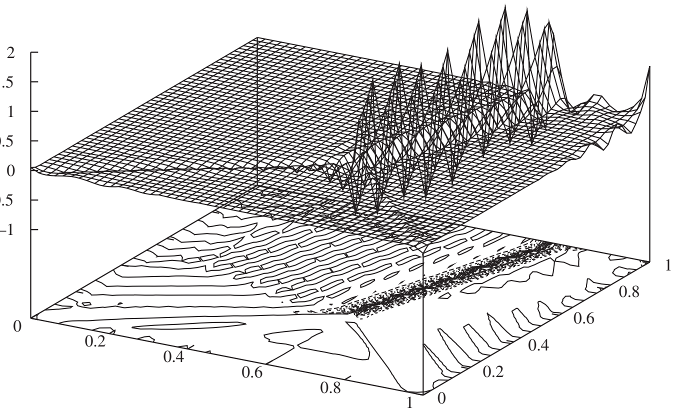

FIG. 5. *Difference between the presmoothed solution and the true solution.*

$$\nabla U_{i,j;\delta} := \begin{pmatrix} \dfrac{U_{i+1,j;\delta} - U_{i-1,j;\delta}}{2\Delta x} \\ \\ \dfrac{U_{i,j+1;\delta} - U_{i,j-1;\delta}}{2\Delta y} \end{pmatrix}. \tag{4.3}$$

Note that the structure tensor is symmetric positive semidefinite.

An easy calculation reveals the eigenvalues

$$\lambda_1 = |\nabla U_{i,j;\delta}|^2, \quad \lambda_2 = 0,$$

corresponding to the eigenvectors

$$v_1 = \nabla U_{i,j;\delta}, \quad v_2 = \nabla^{\perp} U_{i,j;\delta},$$

where

$$\nabla^{\perp} U_{i,j;\delta} := \begin{pmatrix} -\left(\dfrac{U_{i,j+1;\delta} - U_{i,j-1;\delta}}{2\Delta y}\right) \\ \\ \dfrac{U_{i+1,j;\delta} - U_{i-1,j;\delta}}{2\Delta x} \end{pmatrix},$$

so that $\nabla U^T_{i,j;\delta} \cdot \nabla^{\perp} U_{i,j;\delta} = 0$. In fact, the eigenvectors of the structure tensor define the direction parallel to and across an edge, respectively. In the framework of image processing the eigenvalues give the contrast (i.e., the squared gradient) in the eigendirections.

Since the structure tensor is symmetric positive semidefinite, we have the splitting

$$J_0(\nabla U_{i,j;\delta}) = V \Lambda V^{-1}, \tag{4.4}$$

where V is the matrix (v_1, v_2) containing the eigenvectors and Λ is nothing but $\operatorname{diag}(\lambda_1, \lambda_2)$.

In order to average the structure tensor data in the vicinity of each grid point component-wise convolution with the Gaussian kernel of width ρ is applied, i.e.,

$$J_\rho(\nabla U_{i,j;\delta}) := K_\rho * (\nabla U_{i,j;\delta} \cdot \nabla U^T_{i,j;\delta}) \tag{4.5}$$

is computed. The width ρ again is a measure of the averaging region. In practice, we again solve the discrete heat equation component-wise for the structure tensor.

A simple computation concerning the matrix $J_\rho(\nabla U_{i,j;\delta}) =: \left(\begin{smallmatrix} j_{11} & j_{12} \\ j_{12} & j_{22}\end{smallmatrix}\right)$ reveals the eigenvalues

$$\lambda_{1,2;\rho} = \frac{1}{2}\left(j_{11} + j_{22} \pm \sqrt{(j_{11} - j_{22})^2 + 4j_{12}^2}\right), \tag{4.6}$$

the positive square root belonging to $\lambda_{1;\rho}$, which correspond to the eigenvectors

$$\begin{aligned} v_{1;\rho} &= \begin{pmatrix} 2j_{12} \\ j_{22} - j_{11} + \sqrt{(j_{11} - j_{22})^2 + 4j_{12}^2} \end{pmatrix}, \\ v_{2;\rho} &= \begin{pmatrix} j_{11} - j_{22} - \sqrt{(j_{11} - j_{22})^2 + 4j_{12}^2} \\ 2j_{12} \end{pmatrix}, \end{aligned} \tag{4.7}$$

which are again orthogonal. A nice interpretation of these quantities in the framework of image processing can be found in [14]. The parameter δ in the presmoothing processing is called the local scale or noise scale because the process of presmoothing neglects all scales smaller than $\mathcal{O}(\delta)$. In contrast, the parameter ρ is the integration scale indicating the size of the subregions in which the orientation of the numerical solution is analyzed. The eigenvalues $\lambda_{1,2;\rho}$, moreover, serve as descriptors of local structure. Constant solutions are characterized by $\lambda_{1;\rho} = \lambda_{2;\rho} = 0$, while the quantity

$$\left(\lambda_{1;\rho} - \lambda_{2;\rho}\right)^2 = \left(j_{11} - j_{22}\right)^2 + 4j_{12}^2$$

becomes large for anisotropic structures. In the language of image processing one speaks of $(\lambda_{1;\rho} - \lambda_{2;\rho})^2$ as a measure of local coherence.

Now that we have analyzed our numerical solution as if it was a photograph, we are finally looking for a nonlinear anisotropic diffusion equation of the form

$$\begin{aligned} \partial_t w &= \operatorname{div}\left(D(w)\operatorname{grad} w\right), \\ w(x,y,0) &= U(x,y), \end{aligned}$$

where the dissipation coefficient $D(w)$ makes use of the information contained in the structure tensor. It is here where we again use the machinery of image processing since we follow the ansatz

$$D(w) := V_\rho L V_\rho^{-1}, \tag{4.8}$$

where V_ρ contains the eigenvectors of J_ρ and $L = \operatorname{diag}(l_1, l_2)$ is a diagonal matrix the entries of which we have to choose properly. In order to recover shocks (or, equivalently, in order to enhance edges), the diffusivity l_1 perpendicular to edges should be reduced if the contrast $\lambda_{1;\rho}$ is high. This can be achieved by an anisotropic regularization of the Perona–Malik model [6], which can be found in Weickert's book [14]:

$$\begin{aligned} l_1 &= \vartheta(\lambda_{1;\rho}), \\ l_2 &= 1, \\ \vartheta(s) &= \begin{cases} 1, & s \le 0, \\ 1 - \exp\left(\frac{-C_m}{(s/\lambda)^m}\right), & s > 0. \end{cases} \end{aligned} \tag{4.9}$$

The values of m and C_m are chosen in such a way, that the so-called flux $\Phi(s) := s\vartheta(s)$ is increasing in an interval $s \in [0, \lambda]$ and decreasing in $s \in]\lambda, \infty[$. These choices depend on a one-dimensional analysis of the classical Perona–Malik model, and we refer the reader to Weickert's book for details. In agreement with Weickert we chose $m = 4$ and thus $C_4 = 3.31488$. The parameter λ can then be chosen freely.

5. Discretizing the diffusion equation.

After deriving the nonlinear anisotropic diffusion equation which will sharpen the shocks, this equation now needs to be discretized. Since we do not have a theory of a truly discrete diffusion equation to start with, but we have a partial differential equation, the discretization process may result in instabilities if done in a naive way.

As was shown by Weickert [14], there is always a finite difference stencil such that the resulting discretization leads to a stable scheme. Moreover, Weickert was able to prove that three directions suffice to discretize the anisotropic diffusion and the proof is constructive. We do not want to go into the details of Weickert's work but give a suitable discretization of $\operatorname{div}(D(w)\operatorname{grad} w)$, where we utilize the notation

$$D = \begin{pmatrix} a & b \\ b & c \end{pmatrix}.$$

Then, following Weickert's recipe, we get

$$\nabla \cdot (D(U_{i,j;\delta})\nabla U_{i,j;\delta}) = \sum_{k=-1}^{1}\sum_{\ell=-1}^{1} C_{i+k,j+\ell}U_{i+k,i+\ell;\delta}$$

with

$$\begin{aligned}
C_{i-1,j+1} &= \frac{|b_{i-1,j+1}| - b_{i-1,j+1}}{4\Delta x\Delta y} + \frac{|b_{i,j}| - b_{i,j}}{4\Delta x\Delta y},\\
C_{i-1,j-1} &= \frac{|b_{i-1,j-1}| + b_{i-1,j-1}}{4\Delta x\Delta y} + \frac{|b_{i,j}| + b_{i,j}}{4\Delta x\Delta y},\\
C_{i,j+1} &= \frac{c_{i,j+1} + c_{i,j}}{2\Delta y^2} - \frac{|b_{i,j+1}| + |b_{i,j}|}{2\Delta x\Delta y},\\
C_{i,j-1} &= \frac{c_{i,j-1} + c_{i,j}}{2\Delta y^2} - \frac{|b_{i,j-1}| + |b_{i,j}|}{2\Delta x\Delta y},\\
C_{i+1,j+1} &= \frac{|b_{i+1,j+1}| + b_{i+1,j+1}}{4\Delta x\Delta y} + \frac{|b_{i,j}| + b_{i,j}}{4\Delta x\Delta y},\\
C_{i+1,j-1} &= \frac{|b_{i+1,j-1}| - b_{i+1,j-1}}{4\Delta x\Delta y} + \frac{|b_{i,j}| - b_{i,j}}{4\Delta x\Delta y},\\
C_{i-1,j} &= \frac{a_{i-1,j} + a_{i,j}}{2\Delta x^2} - \frac{|b_{i-1,j}| + |b_{i,j}|}{2\Delta x\Delta y},\\
C_{i+1,j} &= \frac{a_{i+1,j} + a_{i,j}}{2\Delta x^2} - \frac{|b_{i+1,j}| + |b_{i,j}|}{2\Delta x\Delta y},\\
C_{i,j} &= -\frac{a_{i-1,j} + 2a_{i,j} + a_{i+1,j}}{2\Delta x^2}\\
&\quad - \frac{|b_{i-1,j+1}| - b_{i-1,j+1} + |b_{i+1,j+1}| + b_{i+1,j+1}}{4\Delta x\Delta y}\\
&\quad - \frac{|b_{i-1,j-1}| + b_{i-1,j-1} + |b_{i+1,j-1}| - b_{i+1,j-1}}{4\Delta x\Delta y}
\end{aligned}$$

$$+\frac{|b_{i-1,j}|+|b_{i+1,j}|+|b_{i,j-1}|+|b_{i,j+1}|+2|b_{i,j}|}{2\Delta x\Delta y}$$
$$-\frac{c_{i,j-1}+2c_{i,j}+c_{i,j+1}}{2\Delta y^2}$$

and employ a simple forward difference in time. For this discretization, Weickert has shown that stability in terms of a discrete maximum-minimum principle can only be proven if the spectral condition number of D is below 5.82. For larger condition numbers, he mentioned indications based on experiments that some weaker stability properties might exist.

We remark in passing that the approach presented above is fully conservative. This is expressed as the property of conservation of mean grey level in image analysis; see [14].

6. A new splitting scheme. In previous sections we have described in detail how algorithms and methodology established in image processing can be used in the framework of numerical methods for conservation laws. In order to get a true scheme for conservation laws and not just a postprocessing tool, we now consider the coupling

$$U_{i,j}^{n+1}=\mathcal{D}(\Delta\tau)\mathcal{C}(\Delta t)U_{i,j}^{n},$$

where $\mathcal{C}$ is the operator associated with the convective part (the Lax–Wendroff method in our setting) while $\mathcal{D}$ represents the operator of nonlinear anisotropic diffusion. Note that Δt is the time scale of our convection problem and for the nonlinear diffusion part. The above splitting is known to be of first order in time only, but our considerations also work out for more sophisticated splittings like that of Strang. Note that time accuracy in our steady test case is by no means mandatory. The splitting means that in each time step we apply the discrete convection (i.e., the Lax–Wendroff scheme) first and the nonlinear diffusion part afterwards.

Since the presmoothing step using the linear heat equation cannot be controlled efficiently (the numerical solution deteriorates massively if the smoothing variance is only marginally too high), this algorithmic step was simply left out. The anisotropic nonlinear diffusion equation was weighted with a factor $\Delta x\Delta y$ in order to guarantee consistency; i.e., we compute

$$\begin{aligned}
w_{i,j}^0 &:= \mathcal{C}(\Delta t)U_{i,j}^n,\\
w_{i,j}^1 &= w_{i,j}^0+\Delta t\Delta x\Delta y x\nabla\cdot(D(w_{i,j}^0)\nabla w_{i,j}^0),\\
U_{i,j}^{n+1} &= w_{i,j}^1.
\end{aligned}$$

Now the dose of dissipation depends on the spatial mesh as it should while the accuracy of the space discretization is retained. Note that in principle we can allow for more than one time step in the nonlinear diffusion equation. However, since we like to interpret this equation as an artificial dissipation, one step is natural. Our numerical experiments, furthermore, indicate that one diffusion step in fact is enough to achieve results with high resolution.

The parameter chosen for the nonlinear diffusion is $\lambda=10$, $\rho=2\sqrt{\Delta x}\sqrt{\Delta y}$.

In Figure 6 we show the numerical solution of our splitting scheme after 50, 100, and 150 time steps on the left side. On the right, the corresponding coherence measure

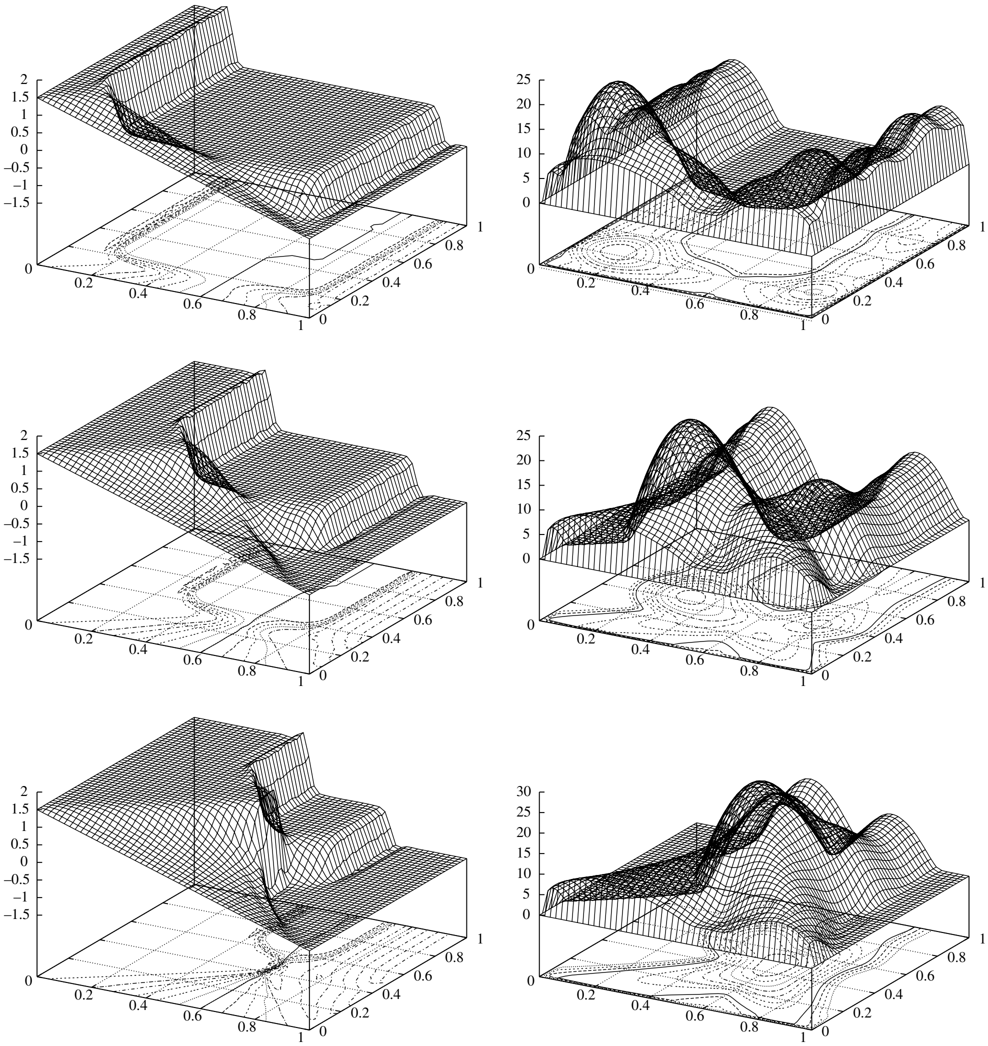

FIG. 6. *Numerical solution and coherence measure after* 50, 100, *and* 150 *time steps.*

$(\lambda_{1;\rho} - \lambda_{2;\rho})^2$ is plotted in logarithmic scale, where all data were shifted by 1 in order to avoid the computation of the logarithm of zero. One can see that this measure in fact indicates regions of anisotropic phenomena. Figure 7 shows the results at later times after 200, 250, and 300 time steps. The shock is now formed and is constantly sharpened by the diffusion step. Figure 8 shows the steady state (1000 time steps) and the corresponding coherence measure. Note that the shock is sharply resolved while there are marginal overshoots at the onset of the shock. In contrast to the result of the pure Lax–Wendroff scheme (cf. Figure 1) we observe that the splitting scheme with the new anisotropic nonlinear artificial dissipation behaves very nicely. In order to further reduce the small wiggles in the onset of the shock, the nonlinear diffusion tensor is weighted with the derivatives of the fluxes. This procedure is quite natural if dissipation models of classical finite difference schemes are analyzed; see [9], for example. Instead of considering the structure tensor $J_\rho(\nabla U) = \left(\begin{smallmatrix} j_{11} & j_{12} \\ j_{12} & j_{22} \end{smallmatrix}\right)$, we

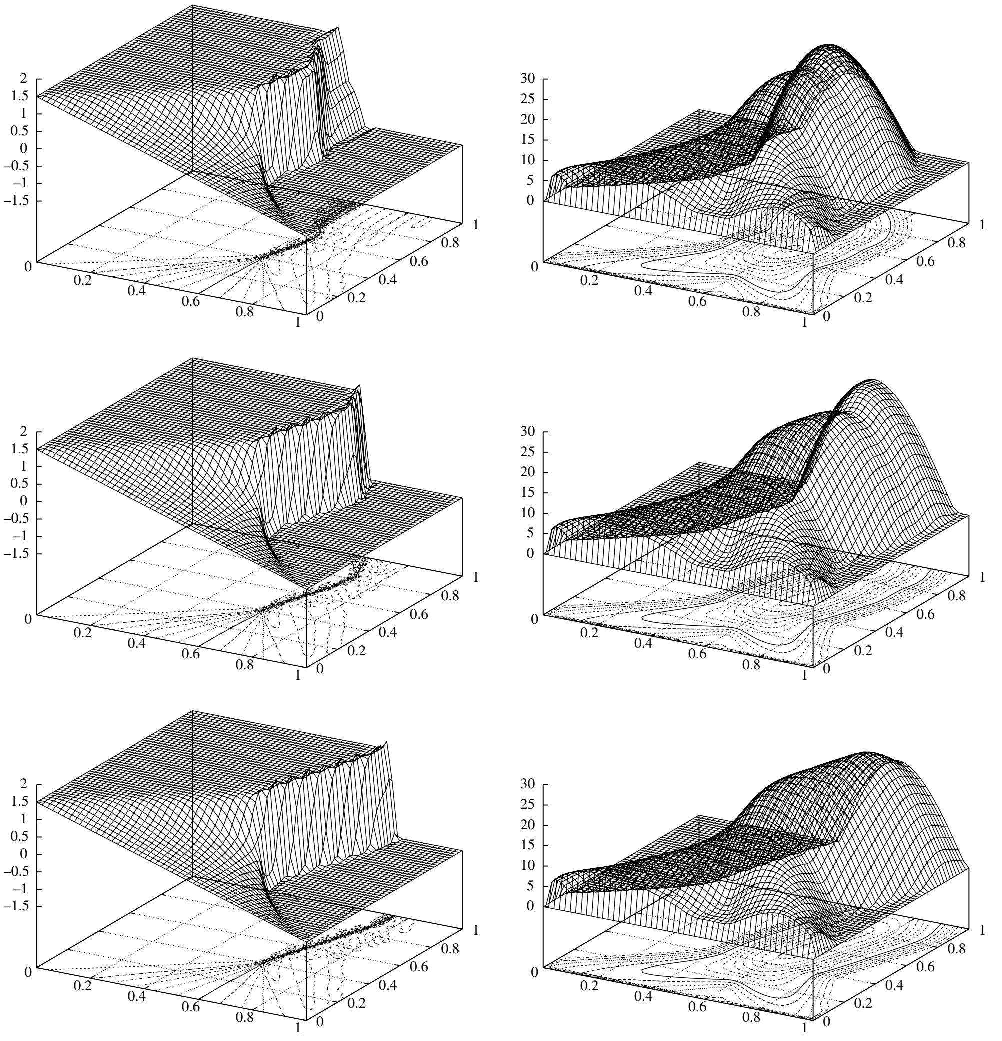

FIG. 7. *Numerical solution and coherence measure after* 200, 250, *and* 300 *time steps.*

therefore employ

$$\begin{pmatrix} j_{11}(f'(U))^2 & j_{12}f'(U)g'(U) \\ j_{12}f'(U)g'(U) & j_{22}(g'(U))^2 \end{pmatrix}.$$

In Figure 9 we again show the numerical solution of our splitting scheme at times $t = 50$, 100, 150. Figure 10 shows the steady state. Note that this solution exhibits not only a sharp shock transition but that it is also nearly free of any over- or undershoots. The solution is very close to solutions obtained with modern second-order TVD methods.

7. Conclusions. We have presented an approach to construct new artificial dissipation terms to be used in the computation of solutions to nonlinear conservation laws. These new dissipation models rely on well-known techniques in image processing and provide nonlinear and anisotropic artificial dissipation terms. While the construc-

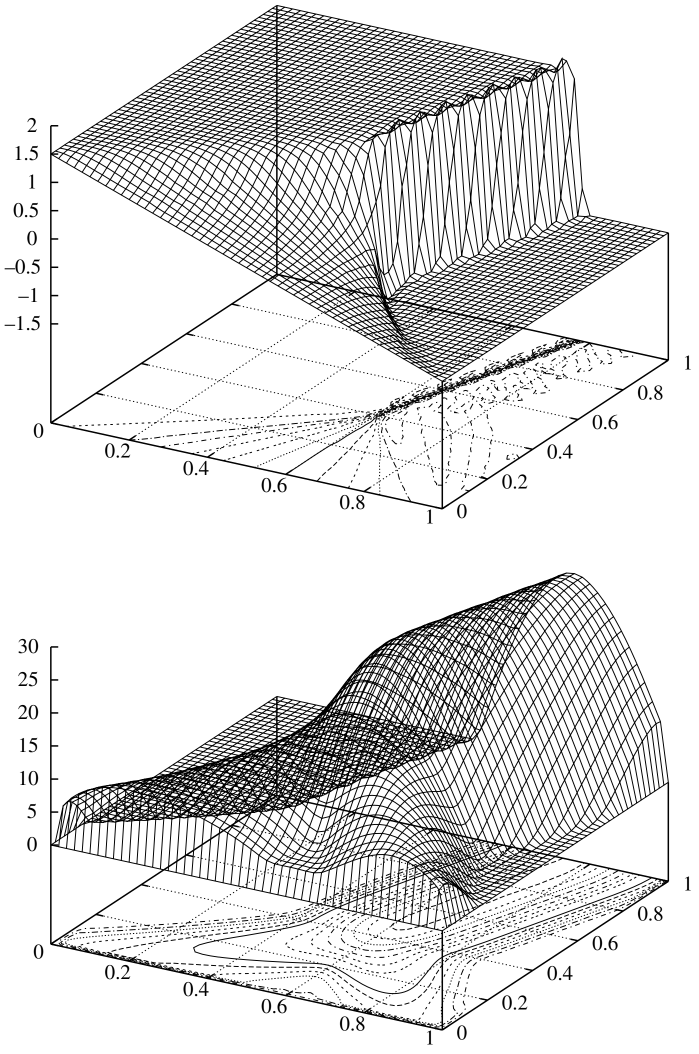

FIG. 8. *Numerical solution and coherence measure after* 1000 *time steps* (*steady state*).

tion of classical artificial dissipation is somehow ad hoc, the theory of anisotropic diffusion allows dissipation terms built on a sound mathematical footage. The approach is fully conservative because it is entirely based on conservation laws. Moreover, there is now hope to find useful dissipation terms which can be employed in meshless methods (see [1]), where up until now higher order discretizations are not achievable.

An extension for this approach to systems was presented in [2]. Nevertheless, since the control of four nonlinear diffusion equations in the case of the Euler equations in two dimensions is much more difficult than one nonlinear equation, a deeper understanding of the behavior and the analysis for the scalar case is needed.

Hence the class of new schemes constructed as described above have to be further examined concerning their accuracy and stability properties. This mathematical analysis will be the topic of future research.

THIRD ORDER ACCURATE LARGE-PARTICLE FINITE VOLUME METHOD ON UNSTRUCTURED TRIANGULAR MESHES*

SONG-HE SONG† AND MAO-ZHANG CHEN‡

Abstract. The large-particle fluid in cell (FLIC) method, presented in 1960s, is a numerical method that can be applied to solve unsteady flow. The computational scheme consists of two steps for each time march step: First, intermediate values are calculated for the velocities and energy, taking into account only the effects of acceleration caused by pressure gradients; second, transport effects are calculated. In this paper, we present a third order large-particle finite volume method for unstructured triangular meshes. The key idea of this method is the reconstruction of weighted quadratic interpolation for flow variables, and the two-point Gauss quadrature formula is used on mesh edges. The computational results for two typical flows verify the accuracy of the method.

Key words. large-particle method, unstructured mesh, finite volume method, interpolation polynomial

1. Introduction.

There is a class of important Euler-type numerical methods for dealing with unsteady flow. Their common idea is to split the basic equations of fluid dynamics into two parts. One takes into account the effect of the pressure gradient. The other calculates the distribution of transport. Then the two parts are discretized respectively. So a time marching step consists of two steps. This kind of method includes particle in cell (PIC) [1], fluid in cell (FLIC) [2, 3, 11] (large particle), OIL [4], HELP [5], and so on. They play an important role in computational fluid dynamics (CFD). The idea of these methods has a great influence upon the development of CFD's numerical methods.

These methods, except PIC, are all upwind methods with first order accuracy with low resolution; in order to simulate shock wave or other discontinuity, artificial viscosity has to be added. Giving a general "Riemann" solver to first step (the contribution of pressure gradient), Li and Cao [6] and Li and Qian [7] obtained a large-particle method with second order accuracy by using the idea of Van Leer [8] and solving the "Riemann" problem. As no artificial viscosity is needed, their method has high resolution to discontinuous solution.

In order to simulate a general problem with very complicated computational domain, some methods are presented [9, 10, 11] on arbitrary triangular meshes, arbitrary quadrilateral meshes, or polygonal meshes, i.e., unstructured mesh FLIC methods. These methods have only first order accuracy and low resolution. [12] presents a large-particle finite volume method with second order accuracy on unstructured triangular meshes.

In this paper we will construct a third order accurate large-particle finite volume method on unstructured triangular meshes. The main idea of this method is the reconstruction of weighted quadratic interpolation for flow variables and the application

of the two-point Gauss quadrature formula on each mesh edge. The “Riemann” problem is solved in the first step, and upwind method is applied in the second step. To make a comparison, the present method and another method [12] are used to simulate plate shock wave reflection and blunt cylinder flow. The computational results show that the transitional width of the shock wave by the present method is narrower than that of the other, and the numerical solution of the new method is nonoscillatory.

2. Decomposition of control equations. Euler equation for two-dimensional cases can be expressed as follows:

$$\left\{\begin{array}{rcl} \dfrac{\partial\rho}{\partial t}+\dfrac{\partial\rho u}{\partial x}+\dfrac{\partial\rho v}{\partial y} &=& 0,\\ \dfrac{\partial\rho u}{\partial t}+\dfrac{\partial(\rho u^2+p)}{\partial x}+\dfrac{\partial\rho uv}{\partial y} &=& 0,\\ \dfrac{\partial\rho v}{\partial t}+\dfrac{\partial\rho uv}{\partial x}+\dfrac{\partial(\rho v^2+p)}{\partial y} &=& 0,\\ \dfrac{\partial\rho E}{\partial t}+\dfrac{\partial(\rho uE+pu)}{\partial x}+\dfrac{\partial(\rho vE+pv)}{\partial y} &=& 0, \end{array}\right. \tag{2.1}$$

$$E=e+\frac{1}{2}(u^2+v^2),$$

where E is the specific total energy, e is the specific internal energy, and the equation of state is $p=(r-1)\rho e$.

The large-particle method consists of two steps for solving system (2.1).

Step 1. In this step, the density ρ is unchanged with time, and the intermediate values of velocities and specific total energy can be obtained by taking into account the contribution of pressure gradients. The differential equations of this step are as follows:

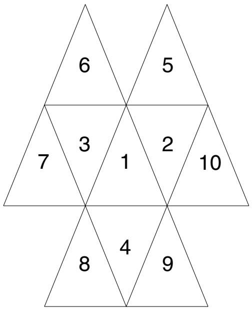
$$\left\{\begin{array}{rcl} \dfrac{\partial\rho u}{\partial t}+\dfrac{\partial p}{\partial x} &=& 0,\\ \dfrac{\partial\rho v}{\partial t}+\dfrac{\partial p}{\partial y} &=& 0,\\ \dfrac{\partial\rho E}{\partial t}+\dfrac{\partial pu}{\partial x}+\dfrac{\partial pv}{\partial y} &=& 0. \end{array}\right. \tag{2.2}$$

Step 2. In this step, the contribution of the transport of fluid is calculated, and the values of state variables are obtained at time $(n+1)\Delta t$. The differential equations are as follows:

$$\left\{\begin{array}{rcl} \dfrac{\partial\rho}{\partial t}+\dfrac{\partial\rho u}{\partial x}+\dfrac{\partial\rho v}{\partial y} &=& 0,\\ \dfrac{\partial\rho u}{\partial t}+\dfrac{\partial\rho u^2}{\partial x}+\dfrac{\partial\rho uv}{\partial y} &=& 0,\\ \dfrac{\partial\rho v}{\partial t}+\dfrac{\partial\rho uv}{\partial x}+\dfrac{\partial\rho v^2}{\partial y} &=& 0,\\ \dfrac{\partial\rho E}{\partial t}+\dfrac{\partial\rho uE}{\partial x}+\dfrac{\partial\rho vE}{\partial y} &=& 0. \end{array}\right. \tag{2.3}$$

The computational region is divided into many triangular cells. Every state variable is defined as an averaged value at the center of each triangular mesh. So the numerical result will give the averaged value at mesh for every variable.

3. Reconstruction of quadratic polynomial. Let the averaged value of each variable be given on every mesh; we will make use of these given conditions to construct a weighted quadratic polynomial on every triangular cell. At first we construct a "smoothest" linear polynomial on each cell. Based on each linear polynomial, we determine the cells required by constructing quadratic polynomials. The weighted quadratic reconstruction is carried out by making all quadratic polynomials on every cell weighted. The weighted factor is obtained by considering smoothness of the solution. Since only some parts of cells are used in this process, the process of interpolation is simplified.



Let c_1 be the center cell of the above figure; to construct a linear polynomial, we can choose any two cells from c_2, c_3, c_4. Let the constructed linear polynomial be

$$p_k^1(x,y) = a_0 + a_1\, x + a_2\, y \qquad (k = 1,2,3) \tag{3.1}$$

under the constraining condition

$$\frac{1}{|c_i|}\int_{c_i} p_k^1(x,y)\; dx\; dy = \bar{u}_i, \tag{3.2}$$

where i is the number of cells which determine $p_k^1(x,y)$.

We select a "smoothest" linear polynomial from (3.1), i.e., the value $|a_1| + |a_2|$ of the selected linear polynomial is the least among the three linear polynomials [15]. For convenience, we assume the selected linear polynomial is obtained on cells c_1, c_2, c_4. To construct a quadratic polynomial, we need another three constraining conditions (i.e., 3 cells). Since c_5 and c_{10} have common edges with c_2, c_8 and c_9 have common edges with c_4, and c_3 has a common edge with c_1, we select c_3 and any two cells from c_5, c_{10}, c_8, and c_9 as another three cells; then six quadratic polynomials can be obtained. We note quadratic polynomials by $p_k^2(x,y)$, $k = 1,2,\ldots,6$, with the constraining condition

$$\frac{1}{|c_i|}\int_{c_i} p_k^2(x,y)\; dx\; dy = \bar{u}_i, \tag{3.3}$$

$k = 1,2,\ldots,6$; c_i is the six corresponding cells in determining $p_k^2(x,y)$.

Let us define an indicator of smoothness IS_k for $p_k^2(x,y)$. Let Ω_k denote the connected region consisting of the six cells which are used to construct $p_k^2(x,y)$; we define IS_k as the summation of all square values of average difference of every two cells with common edge in Ω_k.

Let h be the maximum radius of the circumcircle of the triangles; we observe that if u is continuous on Ω_k, then $IS_k = O(h^2)$; and if u is discontinuous on Ω_k, then $IS_k = O(1)$.

Let

$$\alpha_k = \frac{1}{(\varepsilon + IS_k)^2}, \qquad \varepsilon = 10^{-5}; \tag{3.4}$$

define the weighted quadratic polynomial (WQP)

$$p^2(x,y) = \sum \frac{\alpha_k}{\sum \alpha_j} p_k^2(x,y); \tag{3.5}$$

then $\alpha_k / \sum \alpha_j$ is the weighted factor of $p_k^2(x,y)$. In smooth regions, we observe

$$\frac{\alpha_k}{\sum \alpha_j} = O(1), \tag{3.6}$$

while in discontinuous regions

$$\frac{\alpha_k}{\sum \alpha_j} = \frac{\frac{1}{(\varepsilon+O(1))^2}}{\sum \alpha_j} = \frac{O(1)}{\sum \alpha_j} \leq \max(O(\varepsilon^2), O(h^4)). \tag{3.7}$$

So the weighted quadratic polynomial requires that the interpolating polynomials on the smooth regions have contribution to WQP, while on the discontinuous regions they have essentially no contribution to WQP.

If $u(x,y)$ is an exact solution on a cell, $p^2(x,y)$ is a quadratic polynomial on the cell and it satisfies (3.3), then

$$p^2(x,y) - u(x,y) \;=\; O(h^3). \tag{3.8}$$

4. Discretization of equations. The large-particle method will be discussed in the following two steps.

Step 1. The integral form of (2.2) can be expressed as follows:

$$\begin{cases} \dfrac{\partial}{\partial t}\displaystyle\int_\Omega \rho u d\Omega + \int_{\partial\Omega} p \cdot n_x ds &= 0, \\ \dfrac{\partial}{\partial t}\displaystyle\int_\Omega \rho v d\Omega + \int_{\partial\Omega} p \cdot n_y ds &= 0, \\ \dfrac{\partial}{\partial t}\displaystyle\int_\Omega \rho E d\Omega + \int_{\partial\Omega} p \cdot (un_x + vn_y) ds &= 0. \end{cases} \tag{4.1}$$

The value of state variables on the edge of the triangular cell can be obtained by solving the “Riemann” problem [6]. We discretize (4.1) on triangle A:

$$\begin{cases} \tilde{u}_A = & \bar{u}_A - \frac{\Delta t}{|A|\bar{\rho}_A} \displaystyle\sum_{k=1}^{3} \left(\sum_{q=1}^{2} \omega_q \cdot p^*_{A_{k,q}} \right) \cdot n_x^k s_k, \\ \tilde{v}_A = & \bar{v}_A - \frac{\Delta t}{|A|\bar{\rho}_A} \displaystyle\sum_{k=1}^{3} \left(\sum_{q=1}^{2} \omega_q \cdot p^*_{A_{k,q}} \right) \cdot n_y^k s_k, \\ \tilde{E}_A = & \bar{E}_A - \frac{\Delta t}{|A|\bar{\rho}_A} \displaystyle\sum_{k=1}^{3} \left(\sum_{q=1}^{2} \omega_q \cdot p^*_{A_{k,q}} \right) \cdot U^{n*}_{A_{k,q}} s_k, \end{cases} \tag{4.2}$$

where $\bar{u}_A$ is the approximation of $\frac{1}{|A|}\int_A u d\Omega$, $p^*_{A_{k,q}}$ and $U^*_{A_{k,q}}$ are the pressure and component of the velocity vector along the direction normal to the triangular edge k, respectively, q is the qth Gauss quadrature point at the kth edge of triangle A, and s_k is the length of the kth edge of triangle A. $p^*_{A_{k,q}}$ and $U^*_{A_{k,q}}$ can be obtained by solving the "Riemann" problem. Now we describe the process briefly.

Along the normal direction at the Gauss quadrature point to a common edge, one considers the one-dimensional "Riemann" problem. The states on the left and right sides of the edge are as follows:

$$(\rho, U^n, p)_{L,q}, \quad (\rho, U^n, p)_{R,q}, \tag{4.3}$$

where U^n is the component of the velocity vector in the direction normal to the edge at the qth Gauss quadrature point, i.e., $U^n = n_x \cdot u + n_y \cdot v$. The value of flow variables at (4.3) can be calculated by WQP; then p^* and U^* can be obtained by solving the one-dimensional "Riemann" problem similar to [6].

Step 2. The integral form of (2.3) is as follows:

$$\left\{\begin{array}{rcl} \dfrac{\partial}{\partial t}\displaystyle\int_\Omega \rho d\Omega + \int_{\partial\Omega} \rho(un_x + vn_y)ds & = & 0, \\ \dfrac{\partial}{\partial t}\displaystyle\int_\Omega \rho u d\Omega + \int_{\partial\Omega} \rho u(un_x + vn_y)ds & = & 0, \\ \dfrac{\partial}{\partial t}\displaystyle\int_\Omega \rho v d\Omega + \int_{\partial\Omega} \rho v(un_x + vn_y)ds & = & 0, \\ \dfrac{\partial}{\partial t}\displaystyle\int_\Omega \rho E d\Omega + \int_{\partial\Omega} \rho E(un_x + vn_y)ds & = & 0. \end{array}\right. \tag{4.4}$$

We will get the approximate solution of the equations by means of the upwind method; for example, the approximation of the first equation in (4.4) is expressed as follows

$$\rho_A^{n+1} = \tilde{\rho}_A - \frac{\Delta t}{|A|}\sum_{k=1}^{3}\left(\sum_{q=1}^{2}\omega_q \tilde{\rho}_{A'_{k,q}}\tilde{U}_{A'_{k,q}}\right)s_k, \tag{4.5}$$

where $\tilde{U}_{A'_{k,q}} = \tilde{u}_{A'_{k,q}} \cdot n_x^k + \tilde{v}_{A'_{k,q}} \cdot n_y^k$, $\tilde{\rho}_{A'_{k,q}}$, $\tilde{u}_{A'_{k,q}}$, and $\tilde{v}_{A'_{k,q}}$ are the approximate values at the qth Gauss quadrature point of the kth edge in triangle A'; their values can be obtained by WQP. The fact that the cell A' represents cell A or its adjacent should be determined by the direction of normal velocity vector.

5. Numerical tests. Two typical flows were computed by use of the present method and another method [12].

Test 1. *Plate shock wave reflection.* The typical parameters of this example are as follows: Mach number is 2.9, the projection angle of shock wave is 29°, the length of x direction and y direction are 4 and 1, respectively. Figure 1 shows the Mach contours and Figure 2 shows the pressure distribution along the x direction at $y = 0.5$. Obviously, the transitional width of shock wave of this method is narrower than that of the other method [12]. By the use of the present method, the number of points in the transitional region of shock wave decreases from 10 to 6 and from 12 to 6 in the projection and reflection shock waves, respectively.

Test 2. *Blunt cylinder flow.* Mach number is 6.0, the radius of cylinder is 0.3. Figure 3 shows the Mach contours. Figure 4 shows the pressure distribution along flow direction at front of cylinder. Figure 5 shows the pressure distribution across the upper shock wave at $x = 1$. From Figures 4 and 5, we see that the calculated transitional width of shock wave by the new method is narrower than that of [12], and this new method is nonoscillatory.

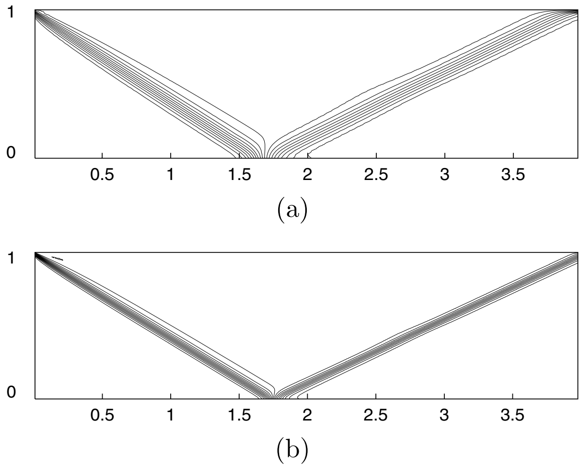


FIG. 1. *Mach contours for plate shock wave reflection in* (a) [12], (b) *this paper.*

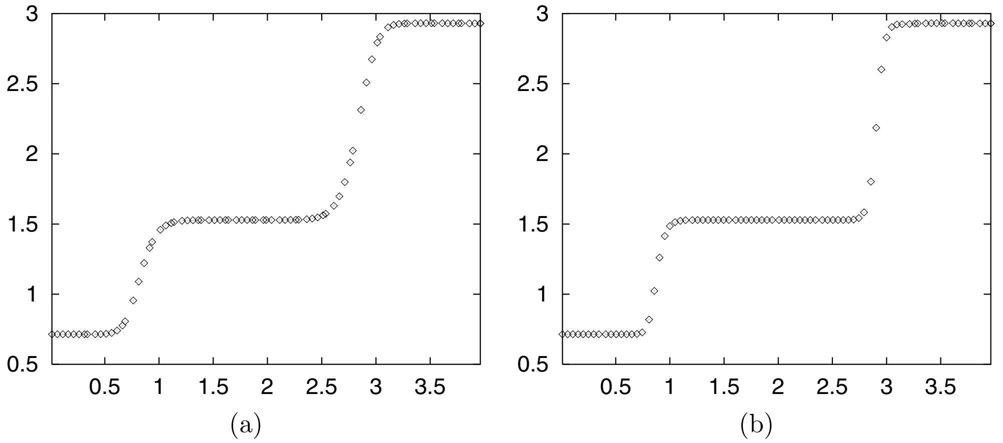

FIG. 2. *Pressure distribution along x direction at* $y = 0.5$ *in* (a) [12], (b) *this paper.*

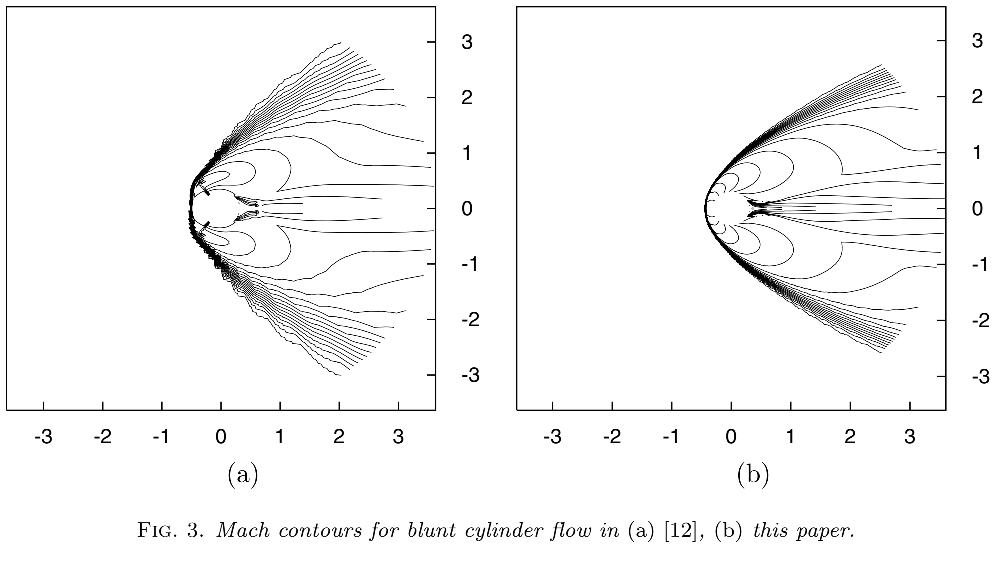

FIG. 3. *Mach contours for blunt cylinder flow in* (a) [12], (b) *this paper.*

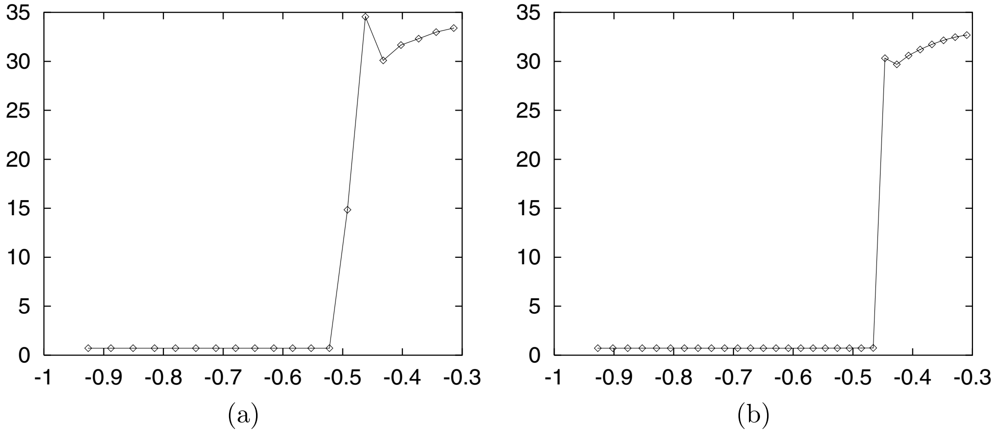

FIG. 4. *Pressure distribution at front of cylinder at $y = 0$ in* (a) [12], (b) *this paper.*

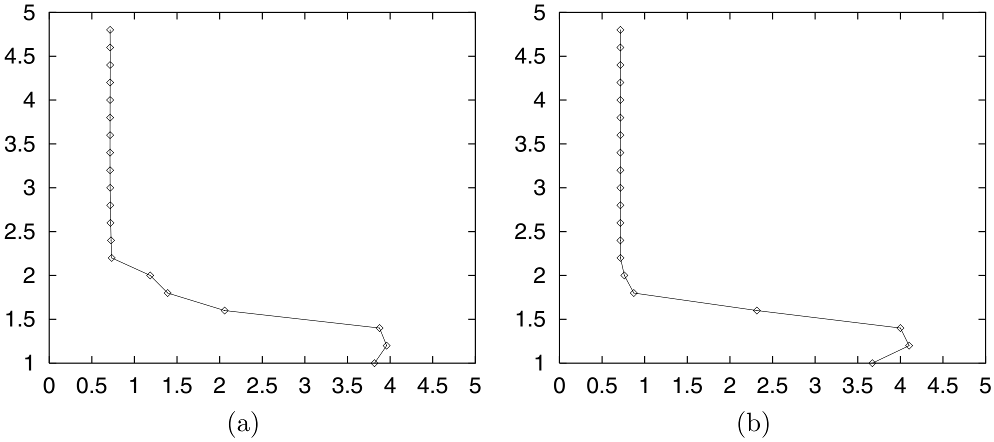

FIG. 5. *Pressure distribution across the upper shock wave at $x = 1$ in* (a) [12], (b) *this paper.*

6. Conclusion. According to the two tests, we can conclude that the accuracy of the present method is higher than that of the other method [12]. The calculated shock wave transitional region of the present method is narrower than that of [12], and it is nonoscillatory. The CPU time and memory of the new method are 280% and 85% more than that of [12], respectively.

HYBRID CURVE POINT DISTRIBUTION ALGORITHMS*

AHMED KHAMAYSEH† AND ANDREW KUPRAT‡

Abstract. Effective discretization of parametric curves has many applications in computational fields, ranging from evaluation and representation of complex geometries to geometric processing, grid generation, and numerical simulation. This paper presents a study of methods for point distribution on curves. Two direct approaches, *adaptive resolution refinement* and *hybrid grid point distribution*, are presented that generate high fidelity discrete approximations of parametric curves. Additionally, two smoothing techniques, *parametric* and *nonparametric curve grid smoothing*, are presented for the optimization of discrete curve data. This paper discusses these techniques in detail, presenting effective algorithms as well as a theoretical development of the methods.

Key words. point distribution density, adaptive resolution refinement, hybrid point distribution, curve grid smoothing

1. Introduction.

Many potential applications of effective curve point distribution algorithms exist, including support for geometric evaluation and representation such as curve-curve intersection operations, surface trimming, curve mapping and comparison, and as boundary discretization methods to support grid generation and field simulation. Computational applications based on discrete curves often require that the curve approximation is faithful to the actual curve within a tolerance bound with a computational representation that can be stored and evaluated effectively. Intuitively, it is not necessary to use many discrete points to represent a line or a curve with minimum curvature. However, to accurately capture a complex curve with a large variation in curvature requires many more points. Ideally, one desires an adaptive approach where few points are used in linear regions allowing the concentration of points in the areas of high curvature without using an excessive number of points across the global representation.

In the literature, the problem of sampling a given set of points to capture the physical features of the curve has been approached from several different angles. In particular, the curvature-based sampling of Kosters [1] minimizes the angular deviation of the surface normal along parametric curves. Li [2] develops an adaptive sampling technique based on solving a system of nonlinear equations derived from a minimization principle. Anderson, Khamayseh, and Jean [3] and Cuilliere [4] develop recursive refinement algorithms based on feature recognition and a local node placement strategy for adaptive sampling of high fidelity continuum parameterizations. Also in [4], Cuilliere presents a direct (i.e., noniterative) algorithm for node placement; however, this algorithm requires the curve to be twice differentiable. If

the second derivative does not exist or is erratic, the curve discretization will not be guaranteed to be within the desired tolerance. This is a severe requirement since in many cases of geometric modeling, parametric curves are represented as B-splines with first derivatives discontinuous.

The accuracy of a numerical simulation on a field problem depends not only on the formal order of the approximation but also on the distribution of the grid points. An error analysis reveals that the accuracy of the approximation is related to the quality of the grid. Hoffman [5] and Vinokur [6] have analyzed the effect of the grid on truncation error for one-dimensional problems. In addition, curve point distribution (or stretching) functions are often used for distributing grid points along boundary curves of planar regions and surfaces, and along edges of three-dimensional regions. Boundary point distribution is often regarded as the initial step for algebraic or elliptic grid generation methods (see Mastin [7], Khamayseh and Kuprat [8], and Soni and Yang [9]).

In certain applications, curves obtained from physics-based simulations are frequently "jagged" or "nonsmooth," and are often unsuitable as direct input for subsequent simulations. For example, Potts model simulations of metallic grain growth describe interfaces between differing grains as a series of "stair-steps." The jagged stair-step interfaces are an artifact of the simulation and will produce incorrect results in subsequent simulations unless the interfaces are smoothed. Another example would be the Lagrangian surface motion of a fluid flow which could leave surfaces convoluted after a transient evolution; these surfaces exhibit high frequency artifacts that render the surfaces unsuitable for direct use in further calculations.

A popular approach to curve grid smoothing was developed by Taubin [10]. This method uses a low-pass filtering technique which removes large curvature variations and prevents shrinkage. Another approach to smoothing relies on the evolution of the curve grid by mean curvature, such as in Miller [11]. These methods can easily mitigate high frequency effects and stair-step phenomena in the grid but conserve neither the shape of the curve nor the area bounded by the curve.

This paper presents two efficient algorithms for the discretization of parametric curves. The first approach, *adaptive resolution refinement*, seeks to accurately decompose the curve for the purposes of geometric evaluation, processing, and visualization, while minimizing the total number of nodes needed for its representation. For grid generation and field simulation, the approach of *hybrid grid point distribution* is proposed. This algorithm supports the generation of grids on parametric curves allowing point distribution to be focused on parameters measuring the arclength, curvature, or specified attractors, alone or in unison, to achieve a suitable curve discretization.

In addition, two techniques for curve grid smoothing are examined, *parametric* and *nonparametric*. Parametric grid smoothing is used to obtain a smooth variation in discrete curve edge length along the curve without sacrificing the fidelity between the discrete approximation and the parametric basis of the curve. This method provides a smooth boundary edge discretization for surface grid generation applications.

The second technique, nonparametric area conserving smoothing, is targeted at applications where the input discrete approximation is suspect, but the integrated area enclosed is known with confidence. This approach, for example, will rapidly deform a "stair-stepped" closed curve into a smoothed curve enclosing the specified area (conserving that area to round-off). This technique of grid smoothing is used to obtain a smooth curve approximation by reducing high frequency variation of the input discrete data and the represented geometry. This development explores these techniques in some detail, presenting algorithms as well as the theoretical basis.

2. Curve adaptive resolution refinement. This section presents an automatic adaptive method for sampling the parametric domain to construct a grid with m segments on the represented curve in physical space. This discretization method seeks to produce a high fidelity approximation of the parametric curve. The final goal is to compute a minimal m such that the deviation of the discretized curve should be within a specified tolerance of the actual curve. The deviation is defined to be the distance of the piecewise linear polygonized curve from the true curve. It is desirable that the polygonized curve be close to the true curve, since it is usually the polygonized curve that is used in graphics applications such as rendering and region selection.

The development of this algorithm requires the specification of the mathematical form of the curve geometry. The following discussion assumes that the curve geometry is available as a *parametrically defined curve* such as a *conic curve, bezier curve, or B-spline curve.* This equates to the existence of a curve geometry definition in the form of a mapping $\mathbf{x}(u) = (x(u), y(u), z(u))$ from a *parametric u-domain* to a *physical (x, y, z)-domain.*

In curve point distribution, the discretization process may be described as the generation of a mapping from the discrete *computational ξ-domain* to the parametric u-domain, resulting in the composite map $\mathbf{x}(\xi) = (x(\xi), y(\xi), z(\xi))$. Physical space is a subset of $\mathbb{R}^3$, with parametric space a subset of $\mathbb{R}$, which may be defined to be the $[0, 1]$ unit interval. Traditionally, computational space is denoted as a discrete linear set of points $\xi \in \{0, 1, \ldots, m\}$, extended to the continuum $[0, m]$ for mathematical convenience. The task of curve point distribution is the task of specifying the distribution of the curve in the parametric domain

$$\big\{u(\xi) \;\big|\; 0 \leq \xi \leq m\big\}.$$

This curve in parametric space corresponds to the curve $\{\mathbf{x}(u) \mid 0 \leq u \leq 1\}$ in physical space. If we select a continuum parameterization $\{u(\xi) \mid 0 \leq \xi \leq m\}$, then the image of the curve $\mathbf{x}(u(\xi)) : [0, m] \to \mathbb{R}^3$ is, of course, equivalent to the image of the curve $\mathbf{x}(u) : [0, 1] \to \mathbb{R}^3$. However a "nearby" curve $\mathbf{x}^{\mathrm{PL}}(u(\xi)) : [0, m] \to \mathbb{R}^3$ can be constructed by defining

$$\mathbf{x}^{\mathrm{PL}}(\xi) = \mathbf{x}(\xi) \quad \text{if } \xi \in \{0, 1, \ldots, m\},$$

and defining $\mathbf{x}^{\mathrm{PL}}(\xi)$ to be the piecewise linear interpolant of these points if ξ is not an integer. $\mathbf{x}^{\mathrm{PL}}(\xi)$ is the "polygonized" version of $\mathbf{x}(u)$. It is our desire to find an integer m and a mapping $u(\xi) : [0, m] \to [0, 1]$ such that the greatest distance between $\mathbf{x}^{\mathrm{PL}}(\xi)$ and $\mathbf{x}(\xi)$ is bounded by a user-supplied tolerance ϵ.

We define deviation on an interval $[\xi, \xi + 1]$ by

$$\mathrm{dev}([\xi, \xi + 1]) = \max_{u(\xi) \leq u \leq u(\xi+1)} \min_{0 \leq t \leq 1} \|\mathbf{x}(u) - [t\mathbf{x}(u(\xi)) + (1 - t)\mathbf{x}(u(\xi + 1))]\|.$$

In order to find the desired function $u(\xi)$—or, equivalently, $\xi(u)$—we define the point density function $\rho \equiv \frac{d\xi}{du}$ so that

$$\xi(u) = \int_0^u \rho(w)\, dw. \tag{2.1}$$

Now relative to a line tangent to $\mathbf{x}(u)$ at u, we typically have that to leading order the distance from $\mathbf{x}(u)$ to the line is quadratic in u. This means the deviation on a typical interval obeys

$$\begin{aligned}\operatorname{dev}([\xi,\xi+1]) &= \max_{u(\xi)\le u\le u(\xi+1)} \min_{0\le t\le 1} \|\mathbf{x}(u) - [t\mathbf{x}(u(\xi)) + (1-t)\mathbf{x}(u(\xi+1))]\| \\ &\approx \left\|\mathbf{x}\left(u\left(\xi+\frac{1}{2}\right)\right) - \left[\frac{1}{2}\mathbf{x}(u(\xi)) + \frac{1}{2}\mathbf{x}(u(\xi+1))\right]\right\| \\ &\approx C\left(u\left(\xi+\frac{1}{2}\right)\right)\|\mathbf{x}_\xi\|^2.\end{aligned}$$

That is, the deviation in an interval is proportional to the square of the grid spacing with $C(u)$, the constant of proportionality, depending on the curve parameter u.

We wish to construct $u(\xi)$ so that $\operatorname{dev}([\xi,\xi+1])$ is the same on each interval $[\xi,\xi+1]$. Thus

$$\sqrt{\operatorname{dev}([\xi,\xi+1])} = K \tag{2.2}$$

$$= \sqrt{C(u)}\|\mathbf{x}_\xi\|. \tag{2.3}$$

Consider a uniform fine grid parameterization $u = \tilde{u}(\tilde{\xi}) = \frac{\tilde{\xi}}{M}$ with M large. Suppose $u(\xi) = \tilde{u}(\tilde{\xi})$. Then if $\widetilde{\operatorname{dev}}([\tilde{\xi},\tilde{\xi}+1])$ represents the maximum deviation suffered by the finely discretized curve in the interval $[\tilde{\xi},\tilde{\xi}+1]$, we have

$$\begin{aligned}\sqrt{\widetilde{\operatorname{dev}}([\tilde{\xi},\tilde{\xi}+1])} &= \sqrt{C\left(u\left(\tilde{\xi}+\frac{1}{2}\right)\right)}\|\mathbf{x}_{\tilde{\xi}}\| \\ &= \sqrt{C(u)}\|\mathbf{x}_u\|\tilde{u}_{\tilde{\xi}} \\ &= \sqrt{C(u)}\|\mathbf{x}_u\|\frac{1}{M}.\end{aligned} \tag{2.4}$$

Solving for $\sqrt{C(u)}$ in (2.4) and (2.3) and equating the expressions, we obtain

$$\begin{aligned}\frac{\sqrt{\widetilde{\operatorname{dev}}([\tilde{\xi},\tilde{\xi}+1])}}{\|\mathbf{x}_u\|\frac{1}{M}} &= \frac{K}{\|\mathbf{x}_\xi\|} \\ &= \frac{K}{\|\mathbf{x}_u\|u_\xi}.\end{aligned}$$

Therefore,

$$\frac{1}{u_\xi} = \frac{M}{K}\sqrt{\widetilde{\operatorname{dev}}([\tilde{\xi},\tilde{\xi}+1])}.$$

Since $\rho = \frac{1}{u_\xi}$, this says that we should set

$$\rho \propto \sqrt{\widetilde{\operatorname{dev}}([\tilde{\xi},\tilde{\xi}+1])}. \tag{2.5}$$

Our algorithm is thus to compute deviations on a fine uniform parameterization with M intervals, to set

$$\rho = \sqrt{\widetilde{\operatorname{dev}}([\tilde{\xi},\tilde{\xi}+1])}$$

on each interval $[\tilde{\xi}, \tilde{\xi}+1]$, $0 \le \tilde{\xi} \le M-1$, and then to normalize ρ so that

$$\int_0^1 \rho(w)\,dw = m, \tag{2.6}$$

where $m \ll M$ will be the actual number of points on the polygonized curve. With the determination of ρ, we obtain $\xi(u)$, which upon inversion gives us $u(\xi)$, $0 \le \xi \le m$, the locations of the nodes in parametric space for the polygonized curve.

Finally, we must determine an m such that the deviation on each interval is bounded by ϵ. Consider the cumulative distribution functions

$$\operatorname{dev}(\xi) = \sum_{i=0}^{\xi-1} \operatorname{dev}([i, i+1]), \quad 0 \le \xi \le m,$$

and

$$\widetilde{\operatorname{dev}}(\tilde{\xi}) = \sum_{i=0}^{\tilde{\xi}-1} \widetilde{\operatorname{dev}}([i, i+1]), \quad 0 \le \tilde{\xi} \le M.$$

Assume for the moment that $u(\xi)$ is a uniform parameterization (i.e., $u(\xi) = \frac{\xi}{m}$). In this case,

$$\operatorname{dev}(m) = \sum_{\xi=0}^{m-1} C\left(\frac{\xi+\frac{1}{2}}{m}\right)\left(\|\mathbf{x}_u\|\frac{1}{m}\right)^2$$

and

$$\begin{aligned}
\widetilde{\operatorname{dev}}(M) &= \sum_{\tilde{\xi}=0}^{M-1} C\left(\frac{\tilde{\xi}+\frac{1}{2}}{M}\right)\left(\|\mathbf{x}_u\|\frac{1}{M}\right)^2 \\
&\approx \frac{M}{m}\sum_{\xi=0}^{m-1} C\left(\frac{\xi+\frac{1}{2}}{m}\right)\left(\|\mathbf{x}_u\|\frac{1}{M}\right)^2 \\
&= \frac{m}{M}\sum_{\xi=0}^{m-1} C\left(\frac{\xi+\frac{1}{2}}{m}\right)\left(\|\mathbf{x}_u\|\frac{1}{m}\right)^2 \\
&= \frac{m}{M}\operatorname{dev}(m).
\end{aligned}$$

Hence,

$$M\,\widetilde{\operatorname{dev}}(M) \approx m\,\operatorname{dev}(m). \tag{2.7}$$

If we require that the average deviation in the polygonized curve satisfies

$$\frac{\operatorname{dev}(m)}{m} = \epsilon,$$

then in light of (2.7), we set

$$M\,\widetilde{\operatorname{dev}}(M) = \epsilon m^2,$$

so that

$$m = \sqrt{\frac{M\widetilde{\mathrm{dev}}(M)}{\epsilon}}. \tag{2.8}$$

If we use this value for m and compute $u(\xi)$ with (2.1), (2.5), (2.6) rather than $u(\xi) = \frac{\xi}{m}$ as supposed in the above estimate, we do not expect the average deviation $\frac{\mathrm{dev}(m)}{m}$ to increase because the distribution $u(\xi)$ is generated with the intent to attract grid nodes to regions of curvature and thus will probably decrease average deviation, given a fixed number of nodes. Given this, by (2.2) we have that $u(\xi)$ equidistributes deviation, and so we expect that

$$\max_{0\le\xi\le m-1} \mathrm{dev}([\xi,\xi+1]) \approx \frac{1}{m}\mathrm{dev}(m) \le \epsilon.$$

Thus, with the choice of m given by (2.8), we expect maximum deviation to be bounded by the user-supplied tolerance ϵ.

In the interest of formulating a general implementation, this development will further assume that the curve to be discretized is provided in the form of a nonuniform rational B-spline (NURBS) curve representation. A detailed discussion of NURBS is available in Piegl and Tiller [12]. A NURBS curve $\mathbf{x}(u) = (x(u), y(u), z(u))$ is a piecewise rational curve given as

$$\mathbf{x}(u) \;=\; \frac{\sum_{i=0}^{m} \;\omega_i\; \mathbf{d}_i\; N_i^k(u)}{\sum_{i=0}^{m}\; \omega_i\; N_i^k(u)}, \qquad u \in [u_{k-1}, u_{m+1}],$$

and defined by

- an order k,
- control points $\mathbf{d}_i = (x_i, y_i, z_i)$, $i = 0, \dots, m$,
- real weights ω_i, $i = 0, \dots, m$,
- a set of real knots $\{u_0, \dots, u_{m+k} \mid u_i \le u_{i+1},\ i = 0, \dots, (m+k-1)\}$,
- B-spline basis functions $N_i^k(u)$, $u \in [u_i, u_{i+k}]$, $i = 0, \dots, m$, where

$$N_i^k(u) = \frac{u - u_i}{u_{i+k-1} - u_i}\; N_i^{k-1}(u) + \frac{u_{i+k} - u}{u_{i+k} - u_{i+1}}\; N_{i+1}^{k-1}(u),$$

$$N_i^1(u) \;=\; \begin{cases} 1 & \text{if } u_i \le u < u_{i+1}, \\ 0 & \text{otherwise,} \end{cases} \qquad i = 0, \dots, m, \qquad \text{and}$$

- curve segments $\mathbf{x}_i(u)$, $u \in [u_i, u_{i+1}]$, $i = (k-1), \dots, m$.

Given this supplementary information, it is now possible to express the adaptive point distribution algorithm.

ALGORITHM 2.1. *Adaptive resolution refinement.*

Assume a NURBS curve $\mathbf{x}(u)$ with unique knots $\{u_l \mid 0 \le l \le n\}$. For each knot interval $I = [u_{l-1}, u_l]$ create an initial distribution of $(M+1)$ points $u_0^I = u_{l-1}, u_1^I, \dots, u_M^I = u_l$ that are used to compute the total deviation from the actual parametric curve. The user must specify a large enough M and maximum deviation tolerance ϵ. Typical values are $\epsilon = 10^{-2}$ for visualization purposes and $\epsilon = 10^{-5}$ for geometric computations.

1. Initialize the first adaptive grid point $u_0^* \leftarrow u_0$ and a point counter $k \leftarrow 1$.
2. For each unique knot interval $I = [u_{l-1}, u_l]$ do

a) Initialize grid function ξ to zero.

```
Do $i = 0, \dots, M$
  $\xi_i \leftarrow 0$
```

b) Subdivide the curve over the interval I.

```
Do $i = 0, \dots, M$
  $u_i^I \leftarrow \left(\frac{i}{M}\right) u_l + \left(1 - \frac{i}{M}\right) u_{l-1}$
```

c) Compute the grid function ξ by summing square roots of deviations.

```
$totaldev \leftarrow 0$
Do $i = 1, \dots, M$
  $\tilde{\mathbf{x}} \leftarrow \mathbf{x}(\frac{1}{2}(u_{i-1}^I + u_i^I))$
  $\mathbf{a} \leftarrow \mathbf{x}(u_i^I) - \mathbf{x}(u_{i-1}^I)$
  $\mathbf{b} \leftarrow \tilde{\mathbf{x}} - \mathbf{x}(u_{i-1}^I)$
  $t \leftarrow \frac{\mathbf{a} \cdot \mathbf{b}}{\mathbf{a} \cdot \mathbf{a}}$   (Usually $t \approx \frac{1}{2}$)
  $dev \leftarrow \| t\, \mathbf{x}(u_i^I) + (1-t)\, \mathbf{x}(u_{i-1}^I) - \tilde{\mathbf{x}} \|$
  $\xi_i \leftarrow \xi_{i-1} + \sqrt{dev}$
  $totaldev \leftarrow totaldev + dev$
```

d) Compute the number of adaptive refinement points over this interval using the total deviation and the user-specified epsilon.

```
$m_I \leftarrow \sqrt{\frac{M\ totaldev}{\epsilon}} + 1$
```

e) Increase the size of the array u^* by m_I to hold the additional adaptive refinement points.

f) Normalize the grid function ξ to have $\xi_M = m_I$.

```
Do $i = 1, \dots, M-1$
  $\xi_i \leftarrow m_I \frac{\xi_i}{\xi_M}$
$\xi_M \leftarrow m_I$
```

g) Obtain the point distribution by inverting the grid function.

```
$j \leftarrow 1$
Do $i = 1, \dots, M$
  Do while $(j \le \xi_i)$
    $u_k^* \leftarrow u_{i-1}^I \frac{\xi_i - j}{\xi_i - \xi_{i-1}} + u_i^I \frac{j - \xi_{i-1}}{\xi_i - \xi_{i-1}}$   (Obtain $u_{i-1}^I < u_k^* \le u_i^I$ using linear interpolation)
    $k \leftarrow k + 1$
    $j \leftarrow j + 1$.
```

Figure 2.1 is an example which exhibits the effectiveness of this algorithm when applied to a NURBS curve with varying curvature. This curve was formed by joining linear, quadratic, and cubic segments into a single NURBS curve. In this example, a total number of $m = 220$ intervals are used in order to limit the maximum deviation to less than the $\epsilon = 10^{-3}$ tolerance. The discretization method clearly concentrates points in areas of high curvature while economizing the number of points used in linear and low curvature regions of the curve. Our method is suitable for curves with first derivatives discontinuous as shown in the figure. It computes a sufficient number of nodes needed in order for the polygonized discretization of the curve to be accurate within a tolerance, and the method requires only the evaluation of the curve function and not its derivatives.

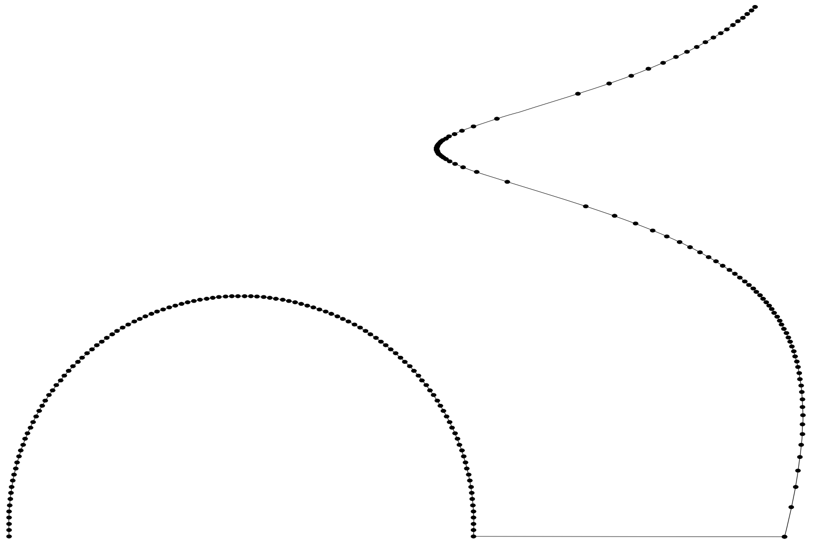

FIG. 2.1. *Adaptive point distribution on a* NURBS *curve.*

3. Hybrid grid point distribution. The adaptive discretization method was targeted at obtaining a high degree of geometric fidelity of the approximation when compared with the original parametric curve. The hybrid approach is targeted at achieving a compromise between geometric fidelity and external application constraints. Depending on the eventual use of the discretization, numerical considerations may favor relaxing conformality of the discretization to achieve enhanced accuracy within the target application.

This section again assumes that the curve is defined as a differentiable parametric curve $\mathbf{x}(u)$. In addition to requiring that $u(\xi)$ is an isomorphism, it is often constructive to constrain the $u(\xi)$ mapping such that the composite map $\mathbf{x}(\xi)$ has the following additional properties to reduce the potential for numerical error: (1) grid points should be closely spaced in the physical domain where large numerical errors are expected, and (2) the angular deviation of grid edges should vary smoothly along the curve.

The methodology of constructing a grid of m intervals on a physical curve begins with the specification of the point distribution along the curve. This is equivalent to specifying the distribution of the curve in the parametric domain $\big\{u(\xi) \bigm| 0 \le \xi \le m\big\}$ which corresponds to the curve $\{\mathbf{x}(u) \mid 0 \le u \le 1\}$ in physical space. The final task is to derive $\{u(\xi) \mid 0 \le \xi \le m\}$ such that $\{\mathbf{x}(u(\xi)) \mid 0 \le \xi \le m\}$ is a "good" parameterization of the boundary curve $\mathbf{x}(u)$.

Again, obtaining $u(\xi)$ is equivalent to finding $\xi(u)$. With the definition $\rho(u) \equiv \frac{d\xi}{du}$,

$$\xi(u) = \int_0^u \rho(w)\, dw.$$

For the hybrid case, a more complex set of physical considerations are typically involved in the construction of the grid point density function, ρ. Possible approaches include the following:

1. Equal arclength spacing where points are separated by equal distances in physical space. For this case, grid point density should be proportional to

the *rate of change of arclength*, or $\rho \propto \|\mathbf{x}'\|$.

2. Curvature weighted arclength spacing, where points are concentrated in areas of large curvature. For this case,

$$\rho \propto \kappa(u)\|\mathbf{x}'\|,$$

where $\kappa(u)$ is the curvature of the curve $\mathbf{x}(u)$ at u.

3. Grid attraction to an *attractor point* $u^\star$ in parametric space (corresponding to a point $\mathbf{x}^\star = \mathbf{x}(u^\star)$ in physical space). A typical case is $u^\star = 0$ or $u^\star = 1$, when one desires to capture a small length scale (such as a Navier–Stokes boundary layer) at one end of the boundary curve. Alternatively, $0 < u^\star < 1$ would focus refinement near a point in the interior of the curve. For these cases, a good choice for ρ is

$$\rho_{u^\star}(u) \propto \frac{1}{\sqrt{\big(k(u-u^\star)\big)^2+1}},$$

where k is a *strength factor* which determines the degree of attraction to $u^\star$.

3.1. Hybrid grid density functions. In practice, the user will likely desire a hybrid grid density function which is a linear combination of several of the above considerations. In this case, multiple density functions ρ_i may be combined, each normalized such that $\int_0^1 \rho_i \, du = \xi(1) - \xi(0) = m$. Given positive constants λ_i such that $\sum \lambda_i = 1$, $\rho = \sum \lambda_i \rho_i$ expresses a grid density function with suitable normalization. This hybrid density function will migrate grid points into regions where any one of the functions ρ_i mandate refinement. Using this concept, it is possible to distribute grid points based on the hybrid criteria of arclength, curvature, and attraction to a set $\{u_i^\star\}$ of distinct points.

This section presents an algorithm for grid point distribution along boundary curves based on a hybrid grid density function. The principle of the algorithm is to construct $\rho(u)$ on a relatively fine grid of points $\tilde{u}_i = \frac{i}{M}$, $0 \le i \le M$, where M is 5–10 times larger than m. The *grid function* $\xi(u) = \int_0^u \rho(w)\, dw$ is then evaluated by integrating ρ on the fine grid with the curve points $u(\xi)$ generated in the parametric space of the curve by inverting the grid function $\xi(u)$.

This algorithm is based on the following quantitative considerations that provide control over point migration:

1. The grid density function for arclength is given by

$$\rho_s(u) = \frac{m\|\mathbf{x}'(u)\|}{\int_0^1 \|\mathbf{x}'(w)\|\, dw}.$$

In this case, $\frac{m}{\int_0^1 \|\mathbf{x}'(w)\|\, dw}$ is the normalization required such that $\int_0^1 \rho_s(u)\, du = m$. If $u = \tilde{u}_i$ and $du = \tilde{u}_i - \tilde{u}_{i-1}$, the approximation

$$\|\mathbf{x}'(\tilde{u}_i)\|\, du \approx \|\mathbf{x}(\tilde{u}_i) - \mathbf{x}(\tilde{u}_{i-1})\|$$

may be employed.

2. The grid density function for curvature weighted arclength is

$$\rho_\kappa(u) = \frac{m\kappa(u)\|\mathbf{x}'(u)\|}{\int_0^1 \kappa(w)\|\mathbf{x}'(w)\|\, dw}.$$

By definition, $\kappa(u) = \frac{d\theta}{ds}$, where $d\theta$ is the angular change in the direction of the tangent of the curve during a small traversal of arclength ds along the curve. Thus,

$$\kappa(u)\|\mathbf{x}'(u)\| = \frac{d\theta}{ds}\frac{ds}{du} = \frac{d\theta}{du}.$$

If $u = \tilde{u}_i$, a simplifying approximation may be used,

$$\begin{aligned}\kappa(\tilde{u}_i)\|\mathbf{x}'(\tilde{u}_i)\|\ du &\approx \theta_i - \theta_{i-1}\\ &= \|\mathbf{t}_i - \mathbf{t}_{i-1}\|,\end{aligned}$$

where $\mathbf{t}_i \equiv \frac{\mathbf{x}'(\tilde{u}_i)}{\|\mathbf{x}'(\tilde{u}_i)\|}$ is the unit tangent vector to the physical curve at $\tilde{u}_i$. If the total integrated curvature $\int_0^1 \kappa(u)\|\mathbf{x}'(u)\|\ du \approx \sum_{i=1}^{M} \|\mathbf{t}_i - \mathbf{t}_{i-1}\|$ is less than some minimal angular tolerance (say $\epsilon_\kappa = .01$ radian), then the curvature weighted arclength is replaced with a simple arclength expression as a criterion for grid point distribution. This substitution avoids distributing points based on a quantity which is numerically small, which could lead to a nonsmooth distribution.

3. The grid density function for attraction (with strength k) to a point $u^\star$ is given by

$$\rho_{u^\star}(u) = m\,\frac{1}{\sqrt{\big(k(u-u^\star)\big)^2+1}}\bigg/\int_0^1 \frac{1}{\big(k(w-u^\star)\big)^2+1}\,dw, \tag{3.1}$$

$$\int_o^u \rho_{u^\star}(w)\ dw = m\,\frac{\operatorname{arcsinh}\big(k(u-u^\star)\big)+\operatorname{arcsinh}(ku^\star)}{\operatorname{arcsinh}\big(k(1-u^\star)\big)+\operatorname{arcsinh}(ku^\star)}.$$

If $u^\star = 0$,

$$\int_0^u \rho_0(w)\ dw = m\,\frac{\operatorname{arcsinh}(ku)}{\operatorname{arcsinh}(k)}.$$

This leads to a grid distribution of the form

$$u(\xi) = \frac{\sinh(\frac{\alpha\xi}{m})}{\sinh\alpha}.$$

It has been noted that the smoothness of this distribution in the vicinity of $u^\star = 0$ results in a smaller truncation error (in finite difference expressions) than "exponential" functions that often approach the attractor point in a more severe fashion (Thompson, Warsi, and Mastin [13]).

Algorithm 3.1. *Hybrid grid point distribution.*

Assume a physical curve $\mathbf{x}(u)$, $0 \le u \le 1$. Given weights λ_s, λ_κ, points $\{u_i^\star \mid 0 \le u_i^\star \le 1,\ 1 \le i \le p\}$, weights $\{\lambda_i \mid 1 \le i \le p\}$, and strengths $\{k_i | k_i \ge 0,\ 1 \le i \le p\}$ where $\lambda_s + \lambda_\kappa + \sum_{i=1}^{p} \lambda_i = 1$, create a distribution of $m+1$ points $u_0, u_1, \ldots, u_m$ that are simultaneously attracted to each of the points in $\{u_i^\star\}$, placed in regions of high curvature, and placed to avoid large gaps in arclength. The user must also specify a parametric grid resolution $M \ge m$ and a minimum integrated curvature tolerance ϵ_κ. (The authors suggest $M = 5m$ and $\epsilon_\kappa = 10^{-3}$.)

1. Initialize the grid function ξ to zero.

```
Do $i = 1, \ldots, M$
  $\xi_i \leftarrow 0$
```

2. Compute arclengths. Rescale such that the maximum scaled arclength is m. Add to ξ, weighted by λ_s.

```
$s_0 \leftarrow 0$
Do $i = 1, \ldots, M$
  $s_i \leftarrow s_{i-1} + \|\mathbf{x}(\frac{i}{M}) - \mathbf{x}(\frac{i-1}{M})\|$
Do $i = 1, \ldots, M$
  $s_i \leftarrow m \frac{s_i}{s_M}$
  $\xi_i \leftarrow \xi_i + \lambda_s s_i$
```

3. Compute curvature weighted arclengths on fine grid. Check if curve has a nontrivial amount of curvature. If so, normalize to m and add into ξ, weighted by λ_κ. Otherwise, use arclength instead.

```
Do $i = 0, \ldots, M$
  $\mathbf{t}(i) \leftarrow \mathbf{x}'(\frac{i}{M}) / \|\mathbf{x}'(\frac{i}{M})\|$
$\theta_0 \leftarrow 0$
Do $i = 1, \ldots, M$
  $\theta_i \leftarrow \theta_{i-1} + \|\mathbf{t}(i) - \mathbf{t}(i-1)\|$
If ($\theta_M \geq \epsilon_\kappa$), then
  Do $i = 1, \ldots, M$
    $\theta_i \leftarrow m \, \frac{\theta_i}{\theta_M}$
    $\xi_i \leftarrow \xi_i + \lambda_\kappa \theta_i$
Else
  Do $i = 1, \ldots, M$
    $\xi_i \leftarrow \xi_i + \lambda_\kappa s_i$
```

4. Add in contributions to grid function due to attractor points.

```
Do $j = 1, \ldots, p$
  Do $i = 1, \ldots, M$
    $\xi_i \leftarrow \xi_i + \lambda_j m \, \frac{\operatorname{arcsinh}\left(k_j(\frac{i}{M} - u_j^\star)\right) + \operatorname{arcsinh}(k_j u_j^\star)}{\operatorname{arcsinh}\left(k_j(1 - u_j^\star)\right) + \operatorname{arcsinh}(k_j u_j^\star)}$
```

5. Obtain point distribution by inverting grid function.

```
$\xi_M \leftarrow m$     *(Force final grid function value to be* exactly *$m$)*
$u_0 \leftarrow 0$
$j \leftarrow 1$
Do $i = 1, \ldots, M$
  Do while ($j \leq \xi_i$)
    $u_j \leftarrow \frac{i}{M} - \frac{1}{M} \frac{\xi_i - j}{\xi_i - \xi_{i-1}}$     *(Obtain $\frac{i-1}{M} < u_j \leq \frac{i}{M}$ using linear interpolation)*
    $j \leftarrow j + 1$.
```

3.2. Determination of weights $\boldsymbol{\lambda_s, \lambda_\kappa, \lambda_i}$ and strengths $\boldsymbol{k_i}$. When using the boundary point distribution algorithm, one must choose weights $\lambda_s, \lambda_\kappa, \lambda_i$ and strengths k_i. As a rough estimate, it is sufficient to select these weights to be equal with a unity summation constraint. For example, if one desires a distribution on *arclength* and *two attractor points*, set $\lambda_s = \lambda_1 = \lambda_2 = \frac{1}{3}$. (In this case, $\lambda_\kappa = 0$.)

When expressing the strengths k_i on the attractor points $u_i^\star$, one must further consider the degree of concentration required by the particular application. Given the case of a single attractor point $u^\star = u_1^\star$, (3.1) suggests that

$$\rho(u) = m \, \frac{k \Big/ \sqrt{\big(k(u-u^\star)\big)^2 + 1}}{\operatorname{arcsinh}\big(k(1-u^\star)\big) + \operatorname{arcsinh}(ku^\star)}$$

or

$$\begin{aligned} \rho(u^\star) &= m \, \frac{k}{\operatorname{arcsinh}\big(k(1-u^\star)\big) + \operatorname{arcsinh}(ku^\star)} \\ &\geq m \, \frac{k}{2 \operatorname{arcsinh}(\frac{k}{2})}. \end{aligned} \tag{3.2}$$

For example, choosing $k = 100$ would provide $\rho(u^\star) \geq 10m$, which results in grid points packed in the neighborhood of $u^\star$ with a density in excess of 10 times of the average grid density $\rho_{\text{ave}} = m$. As a second example, suppose one desires to construct a grid with a specified value of $\frac{\rho(u^\star)}{m}$, or, alternatively, specifies an excess grid density at the attractor $u^\star$. For this case, a heuristic expression

$$k = 15 \, \frac{\rho(u^\star)}{m} \tag{3.3}$$

may be used, adjusted as necessary to provide the desired result. One could alternatively solve the nonlinear equation (3.2) for k exactly. The presence of other criteria (such as arclength, curvature, or other attractor points) in this expression may support the desire to predict a solution using (3.3) and correcting this result, iteratively, by the adjustment of k as necessary.

If one desires a certain grid spacing Δx in the region near $\mathbf{x}^\star = \mathbf{x}(u^\star)$, consider that

$$\Delta x = \|\mathbf{x}_\xi\| \Bigg|_{u=u^\star} = \|\mathbf{x}' \cdot u_\xi\| \Bigg|_{u=u^\star} = \frac{\|\mathbf{x}'(u^\star)\|}{\rho(u^\star)}.$$

Equation (3.3) yields

$$k = 15 \, \frac{\|\mathbf{x}'(u^\star)\|}{m\Delta x},$$

an estimate for the strength k required to obtain a grid with the desired spacing Δx near the attractor $\mathbf{x}^\star = \mathbf{x}(u^\star)$ on the physical curve $\mathbf{x}(u(\xi))$.

Figure 3.1 illustrates an example of the hybrid method applied to a parametric curve. This illustration was produced with Algorithm 3.1, where $\lambda_s = \lambda_\kappa = \frac{1}{2}$. In this case, the points are distributed equally according to both arclength and curvature weighting. The effect of curvature distribution is clearly seen; the grid points are clustered in areas of high curvature. The fact that arclength is additionally considered is evidenced by the nonzero density of grid points in areas where curvature is small or absent.

Figure 3.2 illustrates an example where the influence of two attractor points on the curve is considered in addition to arclength and curvature weighting. These attractor points are located at both endpoints of the curve. The parameters used for

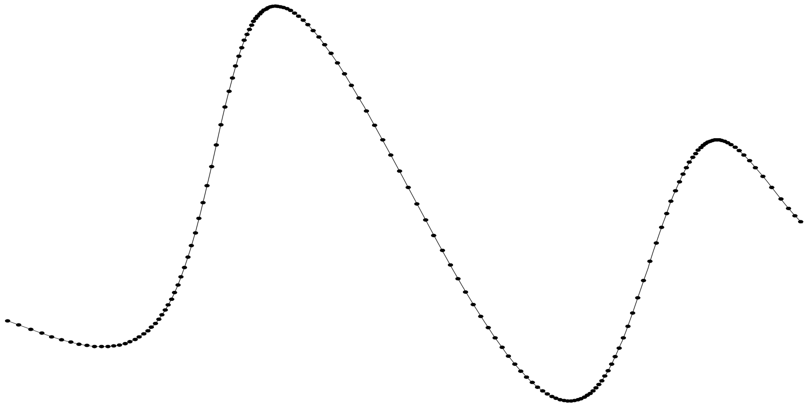

FIG. 3.1. *Point distribution based on arclength and curvature.*

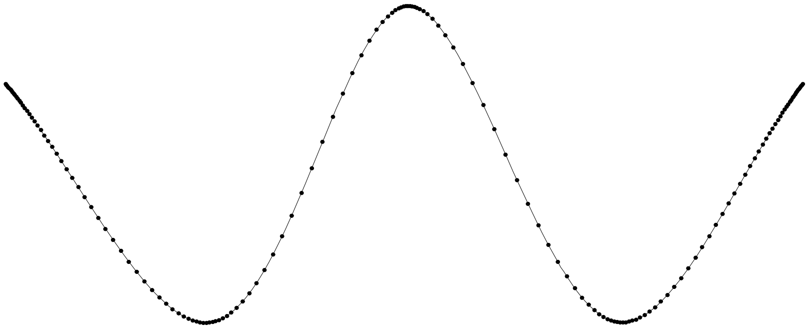

FIG. 3.2. *Curve grid with point distribution based on arclength, curvature, and two attractor points.*

the curve point distribution in this result are $\lambda_s = \lambda_\kappa = \lambda_1 = \lambda_2 = \frac{1}{4}$, $k_1 = k_2 = 120$, and $u_1^\star = 0$ and $u_2^\star = 1$. Examining (3.3), $k_i = 120$ implies that the grid should be packed in the neighborhood of the attractors $u_i^\star$ at a density approximately eight times higher than the average grid point density. Close examination of the figure near the endpoints reveals that this clustering was achieved.

4. Parametric curve grid smoothing.

This section assumes that the topology of the curve grid (i.e., the number of points on the curve) is fixed and presents a technique useful for smoothing these curve grids.

A popular approach to curve grid smoothing is based on the use of the mapping from parametric space to the physical domain; the physical grid is smoothed via operations applied to the parametric representation. This approach assumes that a mapping from parametric space exists to allow smoothing of the curve grid in the parametric domain and to preserve the physical shape of the curve.

This approach often involves solving an elliptic partial differential equation to slide the grid points along the curve, leading to the satisfaction of some equidistribution principle. An initial point distribution must be present to provide a discretization for the elliptic system and an "initial guess" for its iterative solution. This distribution is assumed to be a mapping $\mathbf{x}(\xi)$ from computational space $[0, m]$ to the physical curve. As in previous sections, here *grid points* are the points at $\xi = i$ with $0 \le i \le m$. The initial mapping $\mathbf{x}(\xi)$ is often obtained using an auxiliary uniform point distribution in the parametric domain, $\mathbf{x}_i = \mathbf{x}(u_i)$, where $u_i = \frac{i}{m}$. If the curve geometry is poorly parameterized, this uniform distribution in parametric space will correspond to an unacceptable point distribution in physical space, and the curve point distribution will have to be smoothed.

Our elliptic smoothing method uses the one-dimensional equidistribution principle,

$$ws_\xi = c \quad \text{(constant)},$$

where $w \equiv w(s)$ is the spacing weight function and is taken as a function of the arc length s of the curve. The grid point distribution resulting from this equidistribution represents the solution of the following elliptic system and, provided that w is smooth, results in a smooth arclength distribution regardless of the parameterization of the curve. The above differential equation is equivalent to

$$s_{\xi\xi} + \phi(s)s_\xi = 0$$

with boundary conditions

$$s_\xi = \|\Delta\mathbf{x}\| \quad \text{for} \quad \xi = 0, m.$$

The one-dimensional spacing function $\phi(s) = \frac{w_\xi}{w}$ is taken to be a function of the arclength s of the curve. (However, it must be noted that $\phi = \phi(s)$ depends on the choice of $u(\xi)$ and that $\phi(s)$ will have to be recomputed whenever $u(\xi)$ is changed in the iterative smoothing process.) In the absence of the spacing function, i.e., $\phi = 0$, the elliptic equation tends to produce the smoothest possible uniform curve grid. The boundary conditions allow for the specified grid spacings at either end of the curve.

The change in the arclength of the curve is given by $ds = du\|\mathbf{x}_u\|$. Therefore,

$$s_{\xi\xi} = \frac{\mathbf{x}_u \cdot \mathbf{x}_{uu}u_\xi^2 + \mathbf{x}_u \cdot \mathbf{x}_u u_{\xi\xi}}{\|\mathbf{x}_u\|},$$

where $s_\xi = s_u u_\xi = \|\mathbf{x}_u\| u_\xi$. Thus, u is a solution of the following quasi-linear elliptic equation:

$$u_{\xi\xi} + \phi u_\xi = -u_\xi^2 \frac{\mathbf{x}_u \cdot \mathbf{x}_{uu}}{\mathbf{x}_u \cdot \mathbf{x}_u}.$$

The boundary conditions are represented by

$$u_\xi = \frac{\|\Delta\mathbf{x}\|}{\|\mathbf{x}_u\|} \quad \text{for} \quad \xi = 0, m.$$

To implement the elliptic equation on a given parametric boundary curve, u_0 and u_m are obtained from the initial curve grid. The first two points interior of the curve endpoints, u_1 and u_{m-1}, are computed from the boundary conditions with user-specified spacings $\|\Delta\mathbf{x}^l\|$ and $\|\Delta\mathbf{x}^r\|$ at both ends of the curve,

$$u_1 = u_0 + \frac{\|\Delta\mathbf{x}^l\|}{\|\mathbf{x}_{u_0}\|},$$
$$u_{m-1} = u_m - \frac{\|\Delta\mathbf{x}^r\|}{\|\mathbf{x}_{u_m}\|}.$$

The user-specified point density on the remainder of the curve is provided by the parametric values u_i for $i = 2, \ldots, m-2$. Linear interpolation,

$$u_i = t_i u_{m-1} + (1-t_i)u_1, \quad t_i = \frac{i-1}{m-2} \quad \text{for} \quad i = 2, \ldots, m-2,$$

is used to provide the initial locations of these points. Redistribution of these interpolated points is imposed by adjusting the spacing function ϕ near the boundary, while holding the coordinates of the boundary points constant. To accomplish this, the spacing function is evaluated at $i = 1$ and $i = m-1$ using

$$\phi_i = -\frac{u_{\xi\xi}}{u_\xi}\bigg|_i - u_\xi \frac{\mathbf{x}_u \cdot \mathbf{x}_{uu}}{\mathbf{x}_u \cdot \mathbf{x}_u}\bigg|_i \quad \text{for} \quad i = 1, m-1.$$

The function ϕ is distributed to the remaining points on the curve, again using linear interpolation,

$$\phi_i = t_i \phi_{m-1} + (1-t_i)\phi_1, \quad t_i = \frac{i-1}{m-2} \quad \text{for} \quad i = 2, \ldots, m-2.$$

A standard discretization technique that may be used is central differencing in the ξ domain. In this approach, the difference operator is applied to the interior nodes on the curve to solve for $\mathbf{x}_i = (x_i, y_i, z_i)$ in an iterative manner. Let $(u_\xi)_i$ denote the central difference $\frac{1}{2}(u_{i+1} - u_{i-1})$, and $(u_{\xi\xi})_i \approx u_{i+1} - 2u_i + u_{i-1}$. To solve for u_i, the old parameter value is used to solve for the new u_i to provide $\mathbf{x}_i = \mathbf{x}(u_i)$ along the curve,

$$\begin{aligned} u_i = {} & \frac{1}{2}(u_{i+1} + u_{i-1}) \\ & + \frac{1}{4}(u_{i+1} - u_{i-1})\phi_i \\ & + \frac{1}{8}(u_{i+1} - u_{i-1})^2 \left(\frac{\mathbf{x}_u \cdot \mathbf{x}_{uu}}{\mathbf{x}_u \cdot \mathbf{x}_u} \right)_i \quad \text{for} \quad i = 2, \ldots, m-2. \end{aligned}$$

This difference equation is evaluated for u_i each iterative cycle.

As previously mentioned, the spacing function ϕ_i must be refreshed every iteration prior to the computation of u_i. However, the curve boundary points u_0, u_1, u_{m-1}, and u_m need only to be initialized at the beginning of the relaxation cycle for each curve. This relaxation procedure is applied until convergence is achieved.

The quantities in the difference equation involve two types of approximations. The derivative of the parametric variables with respect to the computational variables u_ξ and $u_{\xi\xi}$ are approximated using a finite difference expression, whereas the derivative terms of the physical variables with respect to the parametric variables $\mathbf{x}_u$ and $\mathbf{x}_{uu}$ are computed analytically from the curve definition $\mathbf{x}(u)$. This development leads directly to the equidistribution algorithm for curve grid smoothing.

Algorithm 4.1. *Parametric curve grid smoothing.*

Assume a physical curve $\mathbf{x}(u)$, $0 \le u \le 1$, with a set of $m+1$ discrete points on $\mathbf{x}(u)$ defined by monotonically increasing parametric values $\{u_i | \; 0 \le i \le m\}$. Assume user specified spacing $\|\Delta\mathbf{x}^l\|$, $\|\Delta\mathbf{x}^r\|$, stopping criteria (number of "sweeps"), and a relaxation parameter $\omega \in (0, 1]$.

```
1. Initialize curve grid distribution.

```

Figure 4.1 illustrates the effect of the elliptic grid smoothing algorithm applied to a curve geometry. The initial grid distribution clearly exhibits a nonuniform distribution of grid points in several regions. This grid defect could conceivably lead to unacceptable artifacts in a computation involving the grid. The elliptically smoothed grid exhibits a smooth point distribution after a few iterations. In this example, the smoothing was performed with specified physical spacings $\|\Delta\mathbf{x}^l\| = 0.08$ and $\|\Delta\mathbf{x}^r\| = 0.04$. We observe that the grid point spacings are enforced near the ends of the curve, while the spacings in the middle of the curve are smoothly varying. Naturally, the spacings in the interior of the curve are determined more by the fixed number of points on the curve than by the endpoint spacing boundary conditions.

5. Nonparametric curve grid smoothing. The last smoothing algorithm considered in this paper is a method that seeks to simultaneously equidistribute points along a geometric curve while reformulating this curve based on a set of physical constraints. In fact, the development here generalizes [14] by introducing for nonplanar curves the notion of smoothing while locally conserving area in the osculating plane and simultaneously conserving torsion.

Curves in the space obtained from field simulations frequently display "nonsmooth" artifacts and may be generally unsuitable as input for subsequent simulations. However, one desires that any smoothing operation be physically relevant; i.e., one may desire that the smoothing process be area- or mass-conservative with respect to an enclosed region.

In contrast with the previous smoothing approach, this method does not require a mapping from parametric space to the physical curve and vice versa. This method was developed in an attempt to preserve the area (or mass) that the curve grid encloses while sacrificing that the exact *shape* of the curve be preserved. In certain situations, exact preservation of the curve shape may be undesirable (e.g., in the case of "stair-step" curves).

This section develops a nonparametric area-conserving smoothing approach of planar curve grids (with generalization to space curve grids). This approach is designed to rapidly deform a "stair-stepped" closed curve into a smoothed curve which encloses the same area as the original to machine round-off error. To accomplish this, the area-conserving approach allows small deformations in the *shape* of the curve geometry. However, the degree of curve deformation can be limited by controlling the number of smoothing iterations performed. Additionally, the notion of area conservation is generalized to allow for the extension of the scheme to nonclosed curve grids in the plane and to space curves.

Consider a non-self-intersecting piecewise linear curve $\Gamma = (\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_{n-1}, \mathbf{x}_n)$ consisting of n line segments in $\mathbb{R}^2$ or $\mathbb{R}^3$. The goal of this section is to develop a smoothing operation on this curve that can be performed locally at each $\mathbf{x}_i$ and that involves slightly altering the position of $\mathbf{x}_i$ based on nearby or adjacent data points ($\{\mathbf{x}_{i-m}, \mathbf{x}_{i-m+1}, \ldots, \mathbf{x}_{i+m}\}$ with m small). More generally, the smoothing operation may depend on points in $\{\mathbf{x}_{i-m}, \mathbf{x}_{i-m+1}, \ldots, \mathbf{x}_{i+m}\}$ and involve moving one or more points in this neighborhood. The smoothing operation should be constrained such that the area of each triangle $(\mathbf{x}_{i-1}, \mathbf{x}_i, \mathbf{x}_{i+1})$ is not modified. The area constraint allows the curve to be smoothed without shrinkage. Given the definition of a *sweep* as one iteration of the local smoothing operation applied on a subset of the points that describe the curve in some sequential order, one desires that only a small number of sweeps through the curve data be required to smooth the overall appearance of the curve.

For a curve in $\mathbb{R}^2$, area conservation is defined as conserving the *signed* area of Γ (given a counter clockwise orientation). A simplistic approach at a smoothing operation providing conservation is depicted in Figure 5.1. For this example, consider the three points $\mathbf{x}_0, \mathbf{x}_1$, and $\mathbf{x}_2$ along Γ. By moving the central point $\mathbf{x}_1$ *parallel* to the line segment $\overline{\mathbf{x}_0\mathbf{x}_2}$, one is assured conservation of area. Further, by moving $\mathbf{x}_1$ such that the projection of $\mathbf{x}_1$ onto $\overline{\mathbf{x}_0\mathbf{x}_2}$ occurs midway between $\mathbf{x}_0$ and $\mathbf{x}_2$, one achieves equal spacing of the segments $\overline{\mathbf{x}_0\mathbf{x}_1}$ and $\overline{\mathbf{x}_1\mathbf{x}_2}$ when projected onto the segment $\overline{\mathbf{x}_0\mathbf{x}_2}$.

Formally, an algorithm based on this one-point smoothing operation is as follows. Let $\mathbf{a} = (\mathbf{x}_2 - \mathbf{x}_0) \times (\mathbf{x}_1 - \mathbf{x}_0)$ be the area vector of triangle $(\mathbf{x}_0, \mathbf{x}_2, \mathbf{x}_1)$. (If Γ is planar, we consider it embedded in the x-y plane of $\mathbb{R}^3$.) The targeted area of the triangle is $\frac{1}{2}\|\mathbf{x}_2 - \mathbf{x}_0\|h$, where h is the height of $\mathbf{x}_1$ above the baseline segment $\overline{\mathbf{x}_0\mathbf{x}_2}$. Then,

$$h = \frac{\|\mathbf{a}\|}{\|\mathbf{x}_2 - \mathbf{x}_0\|}.$$

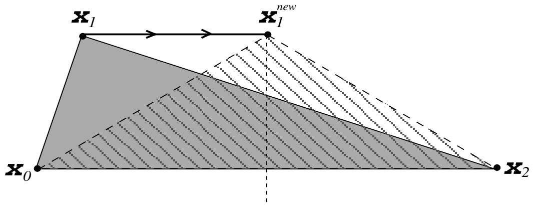

FIG. 5.1. *One-point smoothing operation: Movement of* $\mathbf{x}_1$ *parallel to* $\overline{\mathbf{x}_0\mathbf{x}_2}$ *assures conservation of area under curve* $(\mathbf{x}_0, \mathbf{x}_1, \mathbf{x}_2)$.

Let $\hat{\mathbf{n}} = \frac{\mathbf{a}\times(\mathbf{x}_2-\mathbf{x}_0)}{\|\mathbf{a}\times(\mathbf{x}_2-\mathbf{x}_0)\|}$ be the unit normal to the baseline $\overline{\mathbf{x}_0\mathbf{x}_2}$. The smoothing operation then involves repositioning $\mathbf{x}_1$ from its original position to

$$\mathbf{x}_1^{\mathrm{new}} = \frac{1}{2}(\mathbf{x}_0 + \mathbf{x}_2) + h\hat{\mathbf{n}}.$$

If Γ is planar, this action will exactly conserve the area under the curve; if Γ is not planar, this action will at least preserve the local area under the curve in the plane containing the triangle $\{\mathbf{x}_0, \mathbf{x}_1, \mathbf{x}_2\}$, which corresponds to the osculating plane of a parametric curve. Sweeping through the nodes in sequential order, one obtains the following algorithm.

ALGORITHM 5.1. *Nonparametric curve grid smoothing using node relaxation.*

```
Repeat (sweep) until "done"
  Do $i = 1, \ldots, n-1$
    [Perform smoothing operation on neighborhood $\{\mathbf{x}_i, \mathbf{x}_{i+1}, \mathbf{x}_{i+2}\}$
      (i.e., relax node $\mathbf{x}_{i+1}$)]
    $\mathbf{x}^{\mathrm{old}} \leftarrow \mathbf{x}_{i+1}$
    [Smooth in tangential direction.]
    $\mathbf{x}_{i+1} \leftarrow \frac{1}{2}(\mathbf{x}_i + \mathbf{x}_{i+2})$
    [In nondegenerate case, conserve area.]
    $\mathbf{a} \leftarrow (\mathbf{x}_{i+2} - \mathbf{x}_i) \times (\mathbf{x}^{\mathrm{old}} - \mathbf{x}_i)$
    If ($\|\mathbf{a} \times (\mathbf{x}_{i+2} - \mathbf{x}_i)\| >$ "a tiny number"), then
      $\hat{\mathbf{n}} \leftarrow \frac{\mathbf{a}\times(\mathbf{x}_{i+2}-\mathbf{x}_i)}{\|\mathbf{a}\times(\mathbf{x}_{i+2}-\mathbf{x}_i)\|}$
      $h \leftarrow \frac{\|\mathbf{a}\|}{\|(\mathbf{x}_{i+2}-\mathbf{x}_i)\|}$
      $\mathbf{x}_{i+1} \leftarrow \mathbf{x}_{i+1} + h\hat{\mathbf{n}}$.
```

The simplistic basis of Algorithm 5.1 leads to a serious deficiency. Given the definition of the direction $\overrightarrow{\mathbf{x}_0\mathbf{x}_2}$ shown in Figure 5.1 as "tangential" to Γ and the direction orthogonal to $\overrightarrow{\mathbf{x}_0\mathbf{x}_2}$ as the "normal" direction, the one-point smoothing operation smooths only in the tangential direction. Any smoothing in the normal direction is forbidden by the conservation of area requirement. Because of the absence of normal smoothing, some star-shaped regions will not be addressed by the smoothing operation. It is therefore necessary to design a local smoothing operation that includes normal smoothing.

Consider four sequential points $\mathbf{x}_0$, $\mathbf{x}_1$, $\mathbf{x}_2$, and $\mathbf{x}_3$ along Γ. Again, $\overrightarrow{\mathbf{x}_0\mathbf{x}_3}$ is the direction tangential to the curve, and the direction orthogonal to $\overrightarrow{\mathbf{x}_0\mathbf{x}_3}$ is defined as the normal to the curve. If one simultaneously solves for the positions $\mathbf{x}_1$ and $\mathbf{x}_2$ subject to the constraint of area conservation, normal smoothing is possible. This is feasible, as conservation of area represents a single constraint in the normal direction, but there are two degrees of freedom available (the normal components of $\mathbf{x}_1$ and $\mathbf{x}_2$).

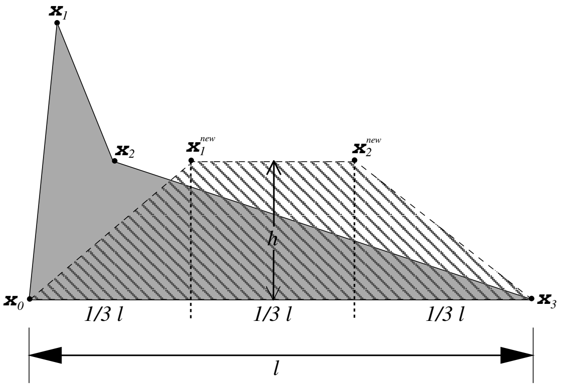

FIG. 5.2. *Edge smoothing operation.* $\overline{\mathbf{x}_1\mathbf{x}_2}$ *moved to be parallel to* $\overline{\mathbf{x}_0\mathbf{x}_3}$ *with projected endpoints at* $\frac{1}{3}l$ *and* $\frac{2}{3}l$*. Choosing* $h = \frac{3}{4}\frac{a}{l}$ *conserves area of the quad* $(\mathbf{x}_0, \mathbf{x}_3, \mathbf{x}_2, \mathbf{x}_1)$*.*

Indeed, development of this idea leads to a new smoothing algorithm. Consider the placement of $\mathbf{x}_1$ and $\mathbf{x}_2$ such that the projection of $\mathbf{x}_1$ onto $\overline{\mathbf{x}_0\mathbf{x}_3}$ is one-third of the way between $\mathbf{x}_0$ and $\mathbf{x}_3$, and the projection of $\mathbf{x}_2$ is two-thirds of the way between $\mathbf{x}_0$ and $\mathbf{x}_3$. Furthermore, the distances of $\mathbf{x}_1$ and $\mathbf{x}_2$ away from $\overline{\mathbf{x}_0\mathbf{x}_3}$ are chosen to be equal with the magnitude of this distance (h in Figure 5.2) constrained to conserve area. In this approach, smoothing occurs in the normal direction as well as in the tangential direction.

The calculation of h is straightforward. To conserve the local area, the vector area of the quadrilateral $(\mathbf{x}_0, \mathbf{x}_3, \mathbf{x}_2, \mathbf{x}_1)$ is computed as $\mathbf{a} = (\mathbf{x}_3 - \mathbf{x}_0) \times (\mathbf{x}_2 - \mathbf{x}_0) + (\mathbf{x}_2 - \mathbf{x}_0) \times (\mathbf{x}_1 - \mathbf{x}_0)$. Repositioning the points $\mathbf{x}_1, \mathbf{x}_2$ in the plane orthogonal to $\mathbf{a}$ such that their projections onto $\overline{\mathbf{x}_0\mathbf{x}_3}$ are equally spaced implies that the area of the quadrilateral $(\mathbf{x}_0, \mathbf{x}_3, \mathbf{x}_2, \mathbf{x}_1)$ will be $\frac{2}{3}hl$, where l is the length of $\overline{\mathbf{x}_0\mathbf{x}_3}$. This requires that

$$h = \frac{3}{4}\frac{a}{l},$$

where $a = \|\mathbf{a}\|$ and $l = \|\mathbf{x}_3 - \mathbf{x}_0\|$.

If Γ is planar, this action will exactly conserve the area under the curve. However, if Γ is not planar, there is a problem in that repositioning of $\mathbf{x}_1, \mathbf{x}_2$ in the plane orthogonal to $\mathbf{a}$ does not conserve the torsion of the curve. (Thus without modification, this smoothing operation would not leave invariant an optimal grid on a helix formed by spacing points equally in arclength.) To conserve torsion, we compute the component of the original edge vector $\overrightarrow{\mathbf{x}_1\mathbf{x}_2}$ that is parallel to $\mathbf{a}$, the normal of the "average" osculating plane. Then we further reposition $\mathbf{x}_1, \mathbf{x}_2$ so that $\mathbf{x}_1, \mathbf{x}_2$ lie at equal distances under and over the averaged osculating plane and maintain their previous separations normal to the osculating plane.

The above node repositioning can be interpreted as being a smoothing operation acting on the *edge* $\overline{\mathbf{x}_1\mathbf{x}_2}$. Thus, to perform a smoothing sweep through Γ, one applies the operation on all the edges of Γ in some order. For example, *sequential order* would perform the smoothing operation on the edge $\overline{\mathbf{x}_1\mathbf{x}_2}$, followed by the edge $\overline{\mathbf{x}_2\mathbf{x}_3}$, and continuing until the last edge is encountered.

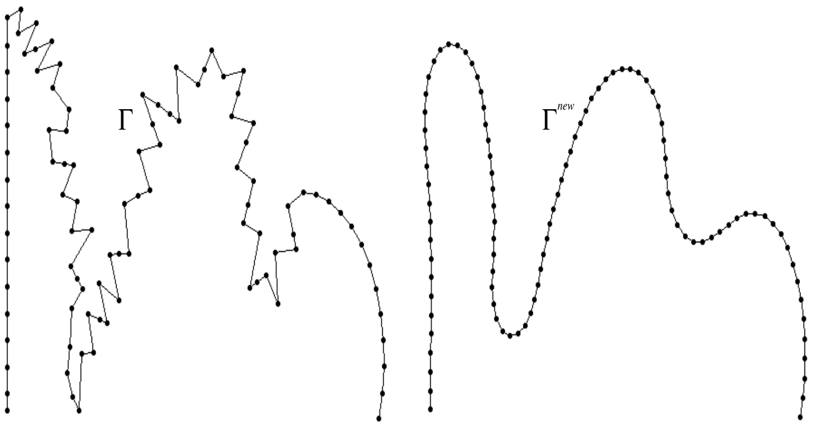

FIG. 5.3. *Before and after smoothing of an open curve using Algorithm* 5.2 *with* 10 *sweeps.*

ALGORITHM 5.2. *Nonparametric curve grid smoothing using edge relaxation.*

```
Repeat (sweep) until "done"
  Do $i = 1, \dots, n-1$
    [Perform smoothing operation on neighborhood $\{\mathbf{x}_i, \mathbf{x}_{i+1}, \mathbf{x}_{i+2}, \mathbf{x}_{i+3}\}$
      (i.e., relax edge $\overline{\mathbf{x}_{i+1}, \mathbf{x}_{i+2}}$)]
    $\mathbf{x}_1^{\text{old}} \leftarrow \mathbf{x}_{i+1}$
    $\mathbf{x}_2^{\text{old}} \leftarrow \mathbf{x}_{i+2}$
    [Smooth edge in tangential direction.]
    $\mathbf{x}_{i+1} \leftarrow \frac{2}{3}\mathbf{x}_i + \frac{1}{3}\mathbf{x}_{i+3}$
    $\mathbf{x}_{i+2} \leftarrow \frac{1}{3}\mathbf{x}_i + \frac{2}{3}\mathbf{x}_{i+3}$
    [In nondegenerate case, conserve area in osculating plane.]
    $\mathbf{a} \leftarrow (\mathbf{x}_{i+3} - \mathbf{x}_i) \times (\mathbf{x}_2^{\text{old}} - \mathbf{x}_i) + (\mathbf{x}_2^{\text{old}} - \mathbf{x}_i) \times (\mathbf{x}_1^{\text{old}} - \mathbf{x}_i)$
    If ($\|\mathbf{a} \times (\mathbf{x}_{i+3} - \mathbf{x}_i)\| >$ "a tiny number"), then
      $\hat{\mathbf{n}} \leftarrow \frac{\mathbf{a} \times (\mathbf{x}_{i+3} - \mathbf{x}_i)}{\|\mathbf{a} \times (\mathbf{x}_{i+3} - \mathbf{x}_i)\|}$
      $h \leftarrow \frac{3}{4} \frac{\|\mathbf{a}\|}{\|\mathbf{x}_{i+3} - \mathbf{x}_i\|}$
      $\mathbf{x}_{i+1} \leftarrow \mathbf{x}_{i+1} + h\hat{\mathbf{n}}$
      $\mathbf{x}_{i+2} \leftarrow \mathbf{x}_{i+2} + h\hat{\mathbf{n}}$
    [In nondegenerate case, conserve torsion.]
    If ($\|\mathbf{a}\| >$ "a tiny number"), then
      $\hat{\mathbf{n}}_\perp \leftarrow \frac{\mathbf{a}}{\|\mathbf{a}\|}$
      $d_\perp \leftarrow (\mathbf{x}_2^{\text{old}} - \mathbf{x}_1^{\text{old}}) \cdot \hat{\mathbf{n}}_\perp$
      $\mathbf{x}_{i+1} \leftarrow \mathbf{x}_{i+1} - \frac{d_\perp}{2}\hat{\mathbf{n}}_\perp$
      $\mathbf{x}_{i+2} \leftarrow \mathbf{x}_{i+2} + \frac{d_\perp}{2}\hat{\mathbf{n}}_\perp$.
```

Figure 5.3 shows the results of Algorithm 5.2, applying 10 sweeps on a plane open curve Γ, holding the first and last points fixed. If Γ were closed by the addition of a segment between the first and last points, the area enclosed by Γ would be conserved to round-off error. Further iterations will continue to deform the curve to increase the convexity of the enclosed region.

6. Summary. This paper provides efficient methods for distributing points on parametric curves. The first two methods, *adaptive resolution refinement* and *hybrid grid point distribution*, are approaches aimed at discretizing a curve to satisfy geometric and computational accuracy constraints. Adaptive resolution refinement is primarily targeted at obtaining a discretization with high geometric fidelity. This method was developed to provide a discretization where the maximum deviation of linear edge segments is never more than some ϵ distance from the true curve. The second method, hybrid grid point distribution, seeks to provide enhanced computational accuracy by concentrating points in regions of the curve to satisfy numerical accuracy requirements (i.e., concentrating points in areas of high curvature or where large gradients are expected in the solution).

The last two approaches presented, *parametric curve grid smoothing* and *nonparametric curve grid smoothing*, focused on redistributing points along the curve to achieve a degree of *smoothness* in the discrete approximation. Parametric curve grid smoothing is a technique used to achieve a smooth edge length variation along the curve while remaining faithful to the original parametric description. Nonparametric curve grid smoothing is an approach to achieve a smooth discretization on a reformulated curve, as it is often known a priori that the original curve is a suboptimal representation of a desired description. In this case, additional information from the physics simulation (such as area or mass conservation) is used to reform the discrete representation to increase its suitability for subsequent simulations.

MULTIDIMENSIONAL LEAST SQUARES FLUCTUATION DISTRIBUTION SCHEMES WITH ADAPTIVE MESH MOVEMENT FOR STEADY HYPERBOLIC EQUATIONS[*]

M. J. BAINES[†], S. J. LEARY[‡], AND M. E. HUBBARD[§]

Abstract. Optimal meshes and solutions for steady conservation laws and systems within a finite volume fluctuation distribution framework are obtained by least squares methods incorporating mesh movement. The problem of spurious modes is alleviated through adaptive mesh movement, the least squares minimization giving an obvious way of determining the movement of the nodes and also providing a link with equidistribution. The iterations are carried out locally node by node, which yields good control of the moving mesh. For scalar equations an iteration which respects the flow of information in the problem significantly accelerates the convergence.

The method is demonstrated on a scalar advection problem and a shallow water channel flow problem. For discontinuous solutions we introduce a least squares shock fitting approach which greatly improves the treatment of discontinuities at little extra expense by using degenerate triangles and moving the nodes. Examples are shown for a discontinuous shallow water channel flow and a shocked flow in gasdynamics governed by the compressible Euler equations.

1. Introduction.

Finite volume schemes of fluctuation distribution type for the approximation of steady first order hyperbolic equations and systems are now well established. In particular, the class of multidimensional upwind schemes on unstructured triangular meshes has been very successful [13]. The least squares methods of finite volume type discussed in this paper also belong to this family, although their properties differ.

Roe was the first to suggest the fluctuation-distribution framework for steady first order hyperbolic PDEs and systems in multidimensions [10]. In this approach a fluctuation (proportional to the PDE residual) is defined on each cell of the mesh and distributed by signals to the nodes of the cell; i.e., weighted fractions of the fluctuation are added to the solution values at the nodes of the cell. This distribution is carried out for each cell, and the cumulative update at a node is the sum of the weighted contributions from cells with that node as a target. To reach steady state the procedure is repeated, updating the solution values until the total increments at every node have become zero, at which point the process is said to have converged.

As pointed out in [11], a descent method applied to the least squares method within a finite volume framework is also a fluctuation-distribution scheme. In the

present paper this idea is developed further, using among other things the connection between least squares minimization and equidistribution [1], and in particular is extended to nonlinear systems of PDEs.

For fluctuation distribution schemes in general, even though the total increments at a node may have converged to zero, the individual cell residuals (or fluctuations) need not have vanished but only their weighted sums, leading sometimes to an unsatisfactory solution. One way to alleviate the difficulty is to increase the number of degrees of freedom available by including the mesh locations as additional variables in the least squares minimization and hence moving the mesh. As a consequence, when the total increments at a node converge, the individual fluctuations in a cell are closer to zero and yield a better approximation to the PDE and the solution. In the case of scalar problems, spurious solutions may be eliminated altogether and the outcome identified with an approximate method of characteristics.

Repositioning the nodes in this way leads to conservation and a measure of equidistribution, the latter ensuring that convergence takes place uniformly with respect to the mesh.

In this paper the method is applied to a scalar PDE problem and a shallow water channel flow problem, both of whose solutions are smooth.

For problems with nonsmooth solutions, least squares methods are known to give poor solutions close to discontinuities. Here we take a shock fitting approach and use a least squares moving mesh method to improve the position of the shock. In recent years a great deal of effort has been put into mesh refinement near shocks using mesh subdivision, but substantial improvements in shock resolution can also be obtained by making minor adjustments to the mesh. We introduce degenerate cells in the vicinity of the shock and a least squares shock fitting procedure to adjust its position. A multidimensional upwinding shock capturing scheme [13] is used to generate an initial solution and a first approximation to the position of the shock. A least squares shock fitting approach is then used to improve the position of the shock [4], [7]. This is achieved by a least squares minimization of a measure of the jump condition over nodal positions in degenerate cells. In the smooth regions on either side of the shock the least squares method may then be expected to work well.

Results are shown for a scalar problem with a contact discontinuity, a shallow water problem in a constricted channel with a hydraulic jump, and an Euler gasdynamics problem with an exact solution, including a shock reflection.

The layout of the paper is as follows. In section 2 we give the definition of the fluctuation and its functional form in certain cases. Section 3 describes fluctuation distribution schemes and least squares methods (with descent) in a finite volume framework. In section 4 we discuss the role of node movement in improving the accuracy of solutions and exploiting the link between least squares and equidistribution. Details of the descent methods used for achieving least squares minima are described in section 5, and an upwinding strategy is described in section 6. Results are shown in section 7 for a scalar advection example and a problem involving a nonlinear system of equations, the Shallow Water Equations.

The role of degenerate cells in generating discontinuous solutions is discussed in section 8. Results for some discontinuous scalar problems and nonlinear systems are shown in section 9 with conclusions in section 10.

2. Fluctuations.

We consider the two-dimensional conservation law

$$\operatorname{div}(\underline{f}(u)) = 0 \tag{2.1}$$

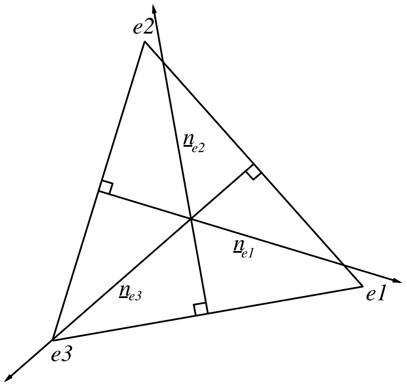

FIG. 1. *A general triangular cell e.*

with integral form

$$\oint_{\Gamma} \underline{f}(u).\underline{\hat{n}}d\Gamma = 0, \tag{2.2}$$

where $\underline{\hat{n}}$ is the inward normal to an arbitrary closed surface Γ in a domain Ω. The boundary condition is an inflow condition over Γ_1, the part of the surface for which $\frac{\partial \underline{f}}{\partial u}.\underline{\hat{n}} \geq 0$.

Let the domain be divided into triangles Ω_e, and let $\underline{f}$ be approximated by a piecewise linear function $\underline{F}$. Then we define the fluctuation in triangle Ω_e to be

$$\phi_e = \oint_{\Gamma_e} \underline{F}.\underline{\hat{n}}d\Gamma, \tag{2.3}$$

where Γ_e is the perimeter of Ω_e.

We also define the average residual

$$\overline{R}_e = \frac{1}{S_e}\int_{\Omega_e} \mathrm{div}\underline{F}d\Omega = \frac{1}{S_e}\oint_{\Gamma_e} \underline{F}.\underline{\hat{n}}d\Gamma = \frac{\phi_e}{S_e}, \tag{2.4}$$

where S_e is the area of triangle e.

Since $\underline{F}$ is linear in the triangle we can use a trapezium rule quadrature to write (2.3) as

$$\phi_e = \frac{1}{2}\left\{(\underline{F}_{e1} + \underline{F}_{e2}).\underline{n}_{e3} + (\underline{F}_{e2} + \underline{F}_{e3}).\underline{n}_{e1} + (\underline{F}_{e3} + \underline{F}_{e1}).\underline{n}_{e2})\right\}, \tag{2.5}$$

where $\underline{n}_{ei}$ $(i = 1, 2, 3)$ is the inward unit normal to the ith edge of triangle e (opposite the vertex ei), as shown in Figure 1, multiplied by the length of that edge. It is easy to verify that, for any triangle,

$$\underline{n}_{e1} + \underline{n}_{e2} + \underline{n}_{e3} = 0, \tag{2.6}$$

so the fluctuation (2.5) may be written as

$$\phi_e = -\frac{1}{2}\left\{\underline{F}_{e1}.\underline{n}_{e1} + \underline{F}_{e2}.\underline{n}_{e2} + \underline{F}_{e3}.\underline{n}_{e3}\right\}, \tag{2.7}$$

or, since $\underline{n}_{ei} = (\Delta Y_{ei}, -\Delta X_{ei})$,

$$\phi_e = -\frac{1}{2}\sum_{ei=1}^{3}\left(F_{ei}\Delta Y_{ei} - G_{ei}\Delta X_{ei}\right), \tag{2.8}$$

where $\underline{F} = (F, G)$ and $\Delta_{e1}X = X_{e2} - X_{e3}$ denotes the difference in X taken across the side opposite node $e1$ in a counterclockwise sense (and similarly for $\Delta_{e2}X$ and $\Delta_{e3}X$). A dual form of the fluctuation is obtained by rewriting (2.7) as

$$\phi_e = \frac{1}{2}\sum_{ei=1}^{3}\left(Y_{ei}\Delta F_{ei} - X_{ei}\Delta G_{ei}\right). \tag{2.9}$$

We aim to set the fluctuations ϕ_e to zero in order to satisfy (2.1).

In the case where $\underline{f}$ is of the form

$$\underline{f} = \underline{a}(\underline{x})u, \tag{2.10}$$

where $\underline{a}(\underline{x})$ is a divergence-free velocity field, the PDE (2.1) reduces to the advection equation

$$\underline{a}(\underline{x}).\underline{\nabla}u = 0. \tag{2.11}$$

Then the fluctuation may be written

$$\phi_e = -\frac{1}{2}\sum_{ei=1}^{3}\left(a_{ei}U_{ei}\Delta Y_{ei} - b_{ei}U_{ei}\Delta X_{ei}\right), \tag{2.12}$$

where $\underline{a} = (a, b) = (a(X_{ei}, Y_{ei}), b(X_{ei}, Y_{ei}))$.

Now consider systems of nonlinear hyperbolic equations

$$\text{div}\underline{\mathbf{f}}(\mathbf{u}) = 0 = \underline{A}(\mathbf{u}).\underline{\nabla}\mathbf{u}, \tag{2.13}$$

where $\underline{A}$ is a vector of the Jacobian matrices $(A, B)^T$. The integral form is

$$\oint_\Gamma \underline{\mathbf{f}}(\mathbf{u}).\underline{\hat{n}}d\Gamma = 0, \tag{2.14}$$

and the fluctuation (with $\mathbf{f}$ approximated by $\mathbf{F}$) is

$$\boldsymbol{\phi}_e = -\frac{1}{2}\left(\underline{\mathbf{F}}_{e1}.\underline{n}_{e1} + \underline{\mathbf{F}}_{e2}.\underline{n}_{e2} + \underline{\mathbf{F}}_{e3}.\underline{n}_{e3}\right) \tag{2.15}$$

$$= -\frac{1}{2}\sum_{ei=1}^{3}\left(\mathbf{F}_{ei}\Delta Y_{ei} - \mathbf{G}_{ei}\Delta X_{ei}\right) \tag{2.16}$$

with dual form

$$\boldsymbol{\phi}_e = \frac{1}{2}\sum_{ei=1}^{3}\left(Y_{ei}\Delta\mathbf{F}_{ei} - X_{ei}\Delta\mathbf{G}_{ei}\right). \tag{2.17}$$

Two systems of interest are the Euler equations of gasdynamics and the Shallow Water Equations.

3. Fluctuation distribution schemes and least squares. In fluctuation distribution schemes we seek to set the fluctuations ϕ_e to zero via an iterative procedure with an index n, say. In this procedure the ϕ_e^n, obtained by substituting an estimate U^n into the (F, G) in (2.8), are distributed to nodes of the mesh in order to give a U^{n+1} for which the ϕ_e^{n+1} are smaller. At each stage of the iteration, for each triangle Ω_e, a weighted amount of ϕ_e is added to the values of the solution at the vertices of the triangle. In the multidimensional upwind schemes [13], [8] the weights are chosen so that the schemes are conservative, positive, and linearity preserving. Conservation is ensured if the weights in each triangle sum to unity.

In the least squares descent method we seek to minimize either the L_2 norm of the average residual (see (2.4)) or the l_2 norm of the vector of fluctuations, using a gradient descent method. This l_2 norm is useful since it is bounded even for the degenerate triangles considered in section 7.

The square of the L_2 norm of the average residual, from (2.4), is

$$\mathcal{F}_1 = \sum_e \int_{\Omega_e} \overline{R}_e^2 d\Omega = \sum_e S_e \overline{R}_e^2 = \sum_e \frac{\phi_e^2}{S_e}, \tag{3.1}$$

or, in the systems case,

$$\mathcal{F}_1 = \sum_e \frac{\boldsymbol{\phi}_e^t \boldsymbol{\phi}_e}{S_e} \tag{3.2}$$

(cf. [11]). For the l_2 norm of the vector of fluctuations we have

$$\mathcal{F}_2 = \sum_e \phi_e^2 \qquad \text{or} \qquad \mathcal{F}_2 = \sum_e \boldsymbol{\phi}_e^t \boldsymbol{\phi}_e \tag{3.3}$$

in the systems case.

Using a gradient descent method to carry out the minimization, we find that each step adds weighted amounts of the ϕ_e in each triangle to the values of the solution at the vertices of the triangle and hence has the form of a fluctuation distribution scheme. For example, in the $\mathcal{F}_2$ case, since the gradient of ϕ_e^2 with respect to the nodal value U_j is

$$\left\{ 2 \frac{\partial \phi_e}{\partial U_j} \right\} \phi_e \tag{3.4}$$

a descent method will add a multiple of ϕ_e to U_j. The weight (in the curly bracket), from (2.8), is

$$w_{je} = 2\frac{\partial \phi_e}{\partial U_j} = -\frac{\partial}{\partial U_j} \sum_{ei=1}^{3} \{F_{ei}\Delta Y_{ei} - G_{ei}\Delta X_{ei}\} \tag{3.5}$$

$$= -\frac{dF_{je}}{dU_{je}}\Delta Y_{je} + \frac{dG_{je}}{dU_{je}}\Delta X_{je} \tag{3.6}$$

$$= -a(U_{je})\Delta Y_{je} + b(U_{je})\Delta X_{je}, \tag{3.7}$$

where je is the node of triangle e corresponding to j and we have used

$$(a(U), b(U)) = \left(\frac{dF}{dU}, \frac{dG}{dU} \right). \tag{3.8}$$

In the case of differentiation with respect to $\underline{X}_j$, the gradient of ϕ_e^2 is

$$\left\{2\frac{\partial \phi_e}{\partial \underline{X}_j}\right\}\phi_e \tag{3.9}$$

and a descent method will add a multiple of ϕ_e to $\underline{X}_j$. This time the vector weights, using (2.17), are

$$\underline{w}_{je} = (0,1)^T \Delta F_{je} + (-1,0)^T \Delta G_{je}. \tag{3.10}$$

For systems of equations the corresponding matrix weights corresponding to (3.7) and (3.10) are

$$W_{je} = -A(\mathbf{U}_{je})\Delta Y_{je} + B(\mathbf{U}_{je})\Delta X_{je} \tag{3.11}$$

and

$$\underline{W}_{je} = (0,1)^T \Delta \mathbf{F}_{je} + (-1,0)^T \Delta \mathbf{G}_{je}. \tag{3.12}$$

For the advection equation (2.10) we have from (2.12) the weights

$$w_{je} = -a(X_{je}, Y_{je})\Delta Y_{je} + b(X_{je}, Y_{je})\Delta X_{je} \tag{3.13}$$

for U variations and, using a dual form of (2.12),

$$\underline{w}_{je} = \frac{\partial}{\partial \underline{X}_j} \sum_{ei=1}^{3} - \left\{\Delta\left(a(X_{ei}, Y_{ei})U_{ei}\right) Y_{ei} + \Delta\left(b(X_{ei}, Y_{ei})U_{ei}\right) X_{ei}\right\} \tag{3.14}$$

for the $\underline{X}$ variations.

Similar sets of weights may be found in the minimization of $\mathcal{F}_1$. In particular, (3.9) generalizes to

$$\frac{\partial}{\partial \underline{X}_j}\left(\frac{\phi_e^2}{S_e}\right) = \left\{\frac{2}{S_e}\frac{\partial \phi_e}{\partial \underline{X}_j} - \frac{\phi_e}{S_e^2}\frac{\partial S_e}{\partial \underline{X}_j}\right\}\phi_e. \tag{3.15}$$

4. Moving the nodes. There are two motivations for moving the nodes. The first is the problem of spurious solutions. The number of equations given by (2.3) is equal to the number of triangles in the mesh, but the number of unknowns is a multiple of the number of nodes. In general these are different. If the number of equations exceeds the number of unknowns it is impossible to satisfy all the equations. For any iteration of fluctuation distribution type in which fluctuations are added to the vertices of the mesh with weights, convergence of the nodal updates does not imply that the fluctuations vanish. In particular, in the least squares descent approach the norms (3.1), (3.3) are not necessarily driven down to zero. However, if we allow the coordinates of the vertices to become additional unknowns of the problem, the number of degrees of freedom is increased and the solution is improved.

For scalar problems the number of unknowns then exceeds the number of equations and there are infinitely many solutions which make the norms zero. A unique solution is obtained if the number of unknowns is equal to the number of equations, and this may be achieved in a scalar problem by including just one coordinate per node in the list of unknowns. The fluctuations may then be driven to zero by a fluctuation-distribution scheme. The result is an approximate method of characteristics, as in Example 1 below. The accuracy of the approximate solution depends only on the coarseness and/or connectivity of the mesh. For a system of two equations in two dimensions, the number of unknowns is equal to the number of equations when the nodes are allowed to move in both directions, and this has been studied in [11]. For systems such as the Shallow Water or the Euler Equations of gasdynamics the number of equations is always less than or equal to the number of unknowns, but the inclusion of nodal variables significantly increases the number of degrees of freedom.

The second motivation comes from a link with equidistribution. As in [1], the identity

$$\left(\sum_e S_e\right)\left(\sum_e S_e \bar{R}_e^2\right) = \left(\sum_e \phi_e\right)^2 + \sum_{e_1>e_2} S_{e_1} S_{e_2} \left(\bar{R}_{e_1} - \bar{R}_{e_2}\right)^2 \tag{4.1}$$

shows that, if the total area of the domain $\sum_e S_e$ is fixed, then driving the norm $\mathcal{F}_1$ (which from (3.1) equals $\sum_e S_e \bar{R}_e^2$) down to zero forces both terms on the right-hand side of (4.1) to zero, resulting in both global conservation and residual "equidistribution." The first follows because of the cancellation property

$$\phi = \sum_e \phi_e = \frac{1}{2} \sum_e \sum_{ei=1}^{3} \left(-F_{ei}\Delta Y_{ei} + G_{ei}\Delta X_{ei}\right) \tag{4.2}$$

$$= \frac{1}{2} \sum_b \left(-F_b \Delta Y_b + G_b \Delta X_b\right), \tag{4.3}$$

so that the total ϕ over the domain is equal to a sum over boundary values b only. Hence the first term on the right-hand side of (4.1) is a measure of global conservation, while the second term is a measure of equidistribution of the average residual $\overline{R}_e$.

In a similar way the identity

$$\left(\sum_e 1\right)\left(\sum_e \phi_e^2\right) = \left(\sum_e \phi_e\right)^2 + \sum_{e_1>e_2} \left(\phi_{e_1} - \phi_{e_2}\right)^2 \tag{4.4}$$

(see [1]) ensures that, provided that the number of triangles $\sum_e 1$ remains fixed, the act of driving the norm $\sum_e \phi_e^2$ down to zero also forces global conservation and a measure of equidistribution of the fluctuations ϕ_e to go to zero. These statements generalize immediately to systems of equations.

The global conservation term (4.3) is evidently unaffected by any adjustment to the values at the interior nodes. Therefore a reduction in the sum of squares term on the left-hand side of (4.1) or (4.4) due to such adjustments simply serves to improve the quality of the equidistribution.

We shall discuss the use of least squares descent methods as fluctuation distribution schemes in this context. Unlike multidimensional upwinding [2], such an approach has the advantage of a norm to minimize which can readily be used to generate the movement of the mesh as well as inducing global conservation and equidistribution in the sense described above.

5. The descent methods. We give now the details of the minimization of $\mathcal{F}_2$ with respect to the nodal values U_j and coordinates $\underline{X}_j$, using a gradient descent method. The steepest descent method generates contributions from the set of triangles je surrounding node j, to be added to the values of U_j and $\underline{X}_j$, of the form

$$\delta U_j = -\tau_2 \sum_{je} \left\{ 2 \frac{\partial \phi_{je}}{\partial U_j} \right\} \phi_{je}, \qquad \delta \underline{X}_j = -\sigma_2 \sum_{je} \left\{ 2 \frac{\partial \phi_{je}}{\partial \underline{X}_j} \right\} \phi_{je} \tag{5.1}$$

(see (3.4) and (3.9)), where τ_2 and σ_2 are suitably chosen relaxation factors, and the negative sign ensures that we go down the gradient. The relaxation parameters control the step taken in the descent direction and are generally chosen via a line search or a local quadratic model. Sometimes, however, it is necessary to take an empirical approach to the choices of these factors.

In this paper we use a splitting technique, first minimizing $\mathcal{F}_2$ with respect to U_j with $\underline{X}_j$ held constant and then minimizing $\mathcal{F}_2$ with respect to $\underline{X}_j$ with U_j held constant. (It is possible, though unlikely, that the constrained nature of the minimization may lead to a saddle point.)

Consequently, for the minimization over U we may construct a quadratic model in which the relaxation parameter is

$$\left(\frac{\partial^2 \mathcal{F}_2}{\partial U_j^2} \right)^{-1} = \left(\frac{\partial^2}{\partial U_j^2} \sum_{je} \phi_{je}^2 \right)^{-1} \tag{5.2}$$

$$= \left(\frac{\partial^2}{\partial U_j^2} \sum_{je} \sum_{ei} \frac{1}{4} \underline{n}_{ei}^T \, \underline{F}_{ei} \underline{F}_{ei}^T \, \underline{n}_{ei} \right)^{-1} \tag{5.3}$$

by (2.7). Let us now linearize $\underline{F}_{ei}$ as $\underline{a}_{ei} U_{ei}$ so that the relaxation factor becomes

$$\left(\frac{\partial^2}{\partial U_j^2} \sum_{je} \sum_{ei} \frac{1}{4} \underline{n}_{ei}^T \, \underline{a}_{ei} U_{ei}^2 \underline{a}_{ei}^T \, \underline{n}_{ei} \right)^{-1} \tag{5.4}$$

$$= \left(\sum_{je} \frac{1}{4} \underline{n}_{je}^T \, \underline{a}_{je} \, \underline{a}_{je}^T \, \underline{n}_{je} \right)^{-1} . \tag{5.5}$$

For the $\underline{X}$ minimization of $\mathcal{F}_2$ the functional is already quadratic, giving the relaxation factor

$$\left(\frac{\partial^2 \mathcal{F}_2}{\partial \underline{X}_j^2} \right)^{-1} = \left(\frac{\partial^2}{\partial \underline{X}_j^2} \sum_{je} \sum_{ei} \frac{1}{4} \underline{F}_{ei}^T \, \underline{n}_{ei} \, \underline{n}_{ei}^T \, \underline{F}_{ei} \right)^{-1} \tag{5.6}$$

which is

$$= \left(- \sum_{je} \left(\underline{F}_{je1}^T \underline{F}_{je1} + \underline{F}_{je2}^T \underline{F}_{je2} \right) \right)^{-1} \tag{5.7}$$

for each coordinate, where $je1, je2$ are the vertices of the triangle je other than j. Alternatively, a line search may be carried out on each $\underline{X}_j$.

For the advection equation (2.10) a quadratic model may be obtained by freezing the advection speed in calculating the second derivative in the quadratic model (see (2.12)).

For the minimization of $\mathcal{F}_1$, rather than $\mathcal{F}_2$, we obtain an approximate quadratic model simply by inserting the factor S_{je}^{-1} between the a_{je}'s or A_{je}'s.

These choices generalize to systems of equations where (5.5) becomes

$$\left(\sum_{je} \frac{1}{4} \underline{n}_{je}^T \ \underline{A}_{je} \ \underline{A}_{je}^T \underline{n}_{je}\right)^{-1}, \tag{5.8}$$

where $\underline{A} = (A, B)$, and where $\underline{\mathbf{F}}$ has been linearized as $\underline{A}\mathbf{U}$.

The iterations are carried out by continually sweeping through the nodes of the mesh in a local manner. The identities (4.1) or (4.4) also hold on each patch of triangles surrounding a node, showing that least squares minimization leads to local conservation over the boundary of the patch and equidistribution over the triangles of the patch.

The sweeps through the nodes of the mesh may be carried out either in a Jacobi or a Gauss–Seidel manner. The local approach is helpful in controlling the mesh quality.

6. Upwinding. Generally, the rate of convergence is slow or very slow. However, we can show that in the scalar case convergence can be accelerated significantly by an awareness of the origin of the problem. One consequence of minimizing the least squares norm of the residual or the fluctuation of the equation $\underline{a}.\nabla u = 0$ is that the original equation is embedded in the second order degenerate elliptic equation $-\underline{a}.\nabla(\underline{a}.\nabla u) = 0$ (see e.g. [9]). The correct solution is picked out from the larger set of solutions by the outflow condition, which is the original differential equation $\underline{a}.\nabla u = 0$ applied at the outflow boundary. Indeed we may write the second order equation as the system

$$\underline{a}.\nabla u = v \tag{6.1}$$

with U given on Γ_2 and

$$-\underline{a}.\nabla v = 0 \tag{6.2}$$

with V given on Γ_1. The first of these is the solution of the original PDE with a source term v, which is the solution of the second equation. For the second equation the analytic solution is $v = 0$, but numerically a nonzero v will be generated building up from the outflow (the characteristics run backwards in (6.2)), forcing a nonzero source term in (6.1).

As befits an elliptic solver, the least squares descent method updates are distributed to all the nodes in a triangle, but it may be argued that, because of the hyperbolic nature of the original equation, the updates should exhibit an upwind bias, as in the case of multidimensional upwinding, and the nonzero v solution should be suppressed.

One way of achieving the upwind bias (see [3], [7]) is to carry out the minimization of the functional within each cell over only *downwind* nodal values. Furthermore, we allow temporary discontinuities in U at each node by letting the solution have one value associated with cells upwind of the node but another with downwind cells. The updates resulting from this minimization still reduce the functional but at the expense of making U discontinuous. However, we may follow this minimization step by a second projection step which resets the *upwind* values of U so as to restore the continuity of U. This is not a descent step and may increase the fluctuation. Nevertheless, we may iterate on the two steps, seeking convergence. If convergence is attained the discontinuities have tended to zero, and we have a continuous U which also minimizes the functional since its gradient is zero. Since the minimization is constrained, a higher value of the functional may result (the two projections cancelling each other out), but further improvement may be found at this point by switching to the full least squares iteration.

By a similar argument on the dual form (2.9) of the fluctuation, the $\underline{X}$ contributions should also be upwinded (although the boundary conditions differ from those on v).

Not surprisingly we find that convergence is much faster, not only for the U variations but also for the $\underline{X}$ variations. The algorithm has a strong upwind bias which reflects the nature of the original problem and its dependence on characteristics. In fact the two steps taken together are equivalent to simply suppressing the upwind updates in the least squares descent method. With an appropriate scaling the U step is simply the Low Diffusion Scheme A (LDA) scheme of multidimensional upwinding [13].

We now give results for two problems in which these techniques are used.

7. Numerical results for continuous solutions.

Example 1. We first consider the scalar two-dimensional advection equation, considered in [11],

$$\underline{a}(\underline{x}).\nabla u = 0, \tag{7.1}$$

where $\underline{a}(\underline{x}) = (y, -x)$ in a rectangle $-1 \leq x \leq 1, 0 \leq y \leq 1$, which generates a semicircular hump swept out by the initial data, here chosen to be

$$U = \begin{cases} 1, & -0.6 \leq x \leq -0.5, \\ 0 & \text{otherwise.} \end{cases} \tag{7.2}$$

Results are shown in Figures 2 and 3 on a fixed and moving mesh, respectively. Fastest convergence occurs when the sweeping is upwinded, taking into account the hyperbolic nature of the equation.

As expected, the solution on a fixed mesh is poor. On the other hand, when the mesh takes part in the minimization the norm $\mathcal{F}_1$ is driven down to machine accuracy. The redistribution effected by the least squares minimization forces global conservation and equidistributes ϕ amongst the triangles [1], leading to more uniform convergence. The cell edges have approximately aligned with characteristics in regions of nonzero ϕ, allowing a highly accurate solution to be obtained.

The left-hand graph in Figure 4 shows the convergence of the solution updating procedure using

(a) steepest descent globally with $\tau_1 = 0.5$;
(b) optimal local updates (quadratic model);
(c) optimal local updates over downwind cells only.

Convergence is improved in (b) and (c). Even though (c) is not monotonic it converges very quickly, albeit to a higher value, due to the minimization being constrained.

The convergence rates obtained when the nodes are allowed to move are shown in Figure 4 (right). Once again we start from the converged solution on the fixed grid and use

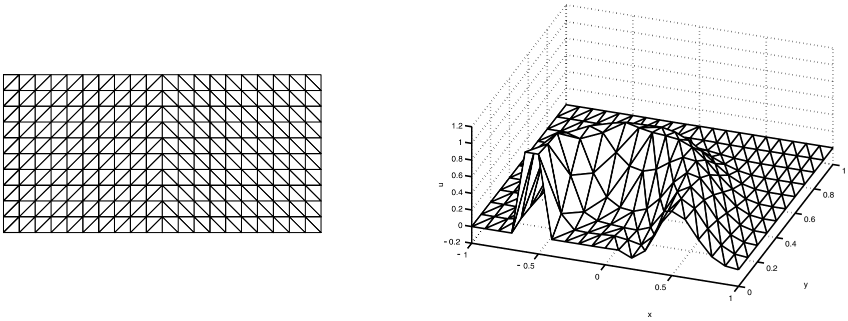

FIG. 2. *Initial grid and solution for Example* 1.

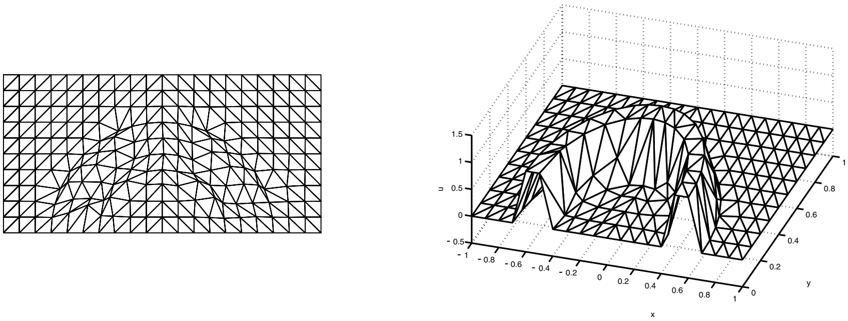

FIG. 3. *Final grid and solution for Example* 1.

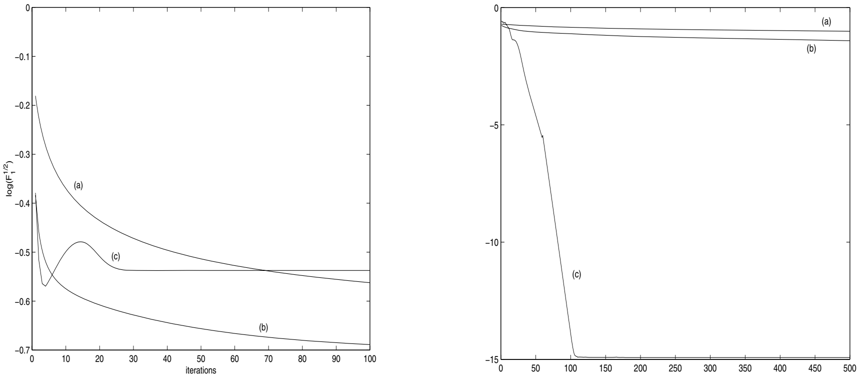

FIG. 4. *Comparisons of convergence histories.*

(a) steepest descent globally with $\tau_1 = 0.5$ and $\sigma_1 = 0.01$;
(b) Hessian local updates;
(c) Hessian local updates over downwind cells only.

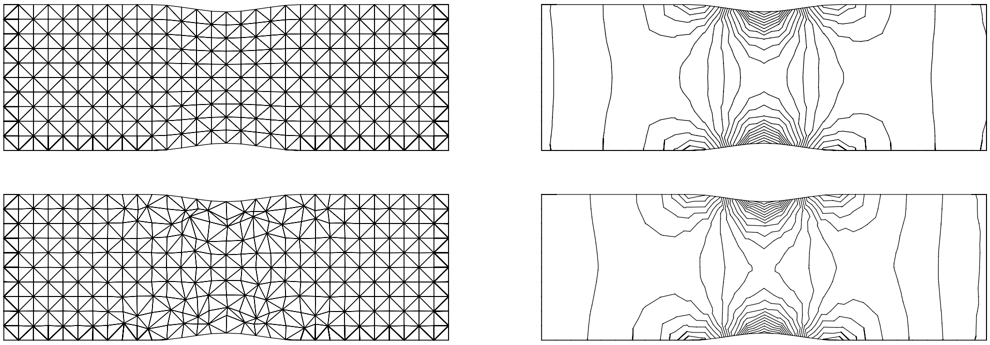

Fig. 5. *Initial grid and solution for Example* 2.

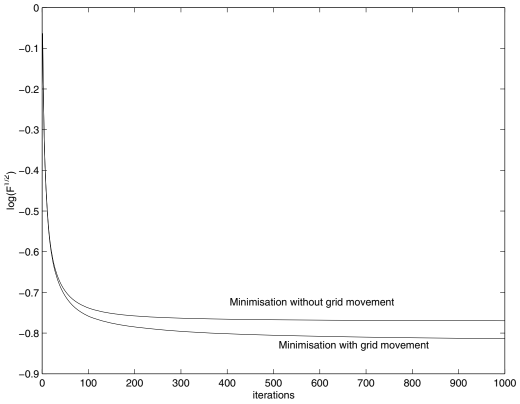

Fig. 6. *Convergence histories with and without mesh movement.*

A small amount of mesh smoothing was included in (b) and (c). In particular, (b) became stuck in a local minimum if more iterations were used. Node locking was a problem with the full least squares approach: node removal or steepest descent updates could be used to alleviate this problem but when tried these still took over 1000 iterations, so they were not competitive when compared to the upwinding approach, which yielded the best result.

Example 2. We now consider the system of equations (2.13) corresponding to a form of the homogeneous Shallow Water Equations written in conserved variables (see [5], [6]).

We shall consider a smooth subcritical constricted channel flow governed by these equations. The computational domain represents a channel of length 3 meters and width 1 meter with a 5% bump in the middle third. The freestream Froude number is defined to be $F_\infty = 0.25$, and the freestream depth is $h_\infty = 1m$. The resulting flow is entirely subcritical and symmetric about the center of the constriction (the narrowest point in the channel).

The fixed mesh is shown at the top of Figure 5 and the least squares descent solution (depth contours) on the mesh beneath it. This is also the initial mesh for the iteration when the mesh is moved. The other pictures in the figure show the adapted mesh and solution on this mesh.

Figure 6 shows convergence histories for this problem with and without mesh movement. An improved minimum is achieved by incorporating mesh movement in the minimization process. However, $\mathcal{F}_1$ is not dramatically decreased in this subcritical problem because there are no particularly sharp features in the flow which can be improved upon by the use of mesh movement.

8. Use of degenerate triangles. In the presence of shocks or contact discontinuities least squares methods give inaccurate solutions which are unacceptable. One way to combat this problem is to divide the region into a number of domains and introduce degenerate triangles at the interface, as suggested in [12]. We may then use a least squares method with moving nodes to adjust the position of the discontinuity, as in shock fitting methods.

Consider again consider the scalar problem (2.1) as a PDE generating a shock or contact discontinuity. We first obtain an initial approximate solution U to this equation by the use of a multidimensional upwinding shock capturing scheme. An initial discontinuous solution may then be constructed by introducing degenerate (vertical) triangles in the regions identified as shocks, using a shock identification technique. In the results shown below this step was carried out manually, but the degenerate triangles can be added automatically using techniques that exist in the shock fitting literature (see for example [16], [15]). The corners of the degenerate triangles are designated as shocked nodes, and these form an internal boundary, on either side of which the least squares method may be applied in two smooth regions where it is known to perform well. The position of the discontinuity can then be improved by minimizing a least squares shock monitor based either on the fluctuation in the degenerate cells or on the jump condition.

Then consider the jump condition at a shock associated with the conservation law (2.1),

$$\underline{f}(u_L).\underline{n}_L + \underline{f}(u_R).\underline{n}_R = 0, \tag{8.1}$$

where $\underline{f}(u_L)$ and $\underline{f}(u_R)$ are the fluxes to the left and right of a discontinuous edge.

We obtain an improved location of the discontinuity in the discretized problem by minimizing an L_2 measure of the residual of the jump condition with respect to node positions, using a piecewise linear approximation F to f. Thus consider minimization of the norm

$$\mathcal{F}_3 = \sum_{Q\in\Omega} \int_{\Gamma_Q} (\underline{F}(U_L).\underline{n}_L + \underline{F}(U_R).\underline{n}_R)^2 d\Gamma \tag{8.2}$$

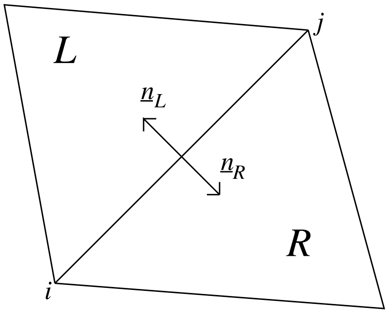

FIG. 7. *Cells on either side of a discontinuous edge.*

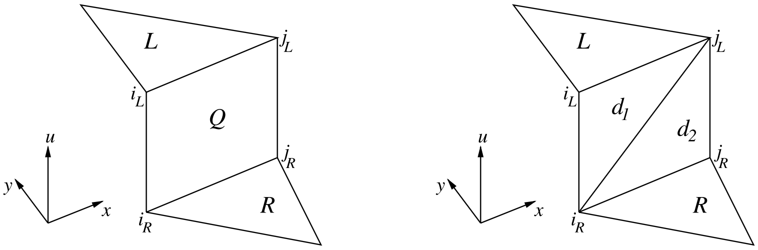

FIG. 8. *Degenerate quadrilaterals Q and triangles d_1, d_2.*

to update the position of the discontinuity where Γ_Q is the edge connecting nodes i and j in Figure 7, and $\underline{F}(U_L), \underline{F}(U_R)$ are the values of $\underline{F}$ at the left and right states.

We could have used an approximation based on degenerate triangles rather than quadrilaterals (see [4]). When updating the nodal positions $\underline{X}_{i_L}$ and $\underline{X}_{i_R}$ we require that they have the same update (so that the cell remains degenerate). The update comes from minimization with respect to their common position vector.

Consider the fluctuations ϕ_{d1} and ϕ_{d2} in the degenerate triangles d_1 and d_2 on the edge containing nodes i and j in Figure 8.

From (2.7) these are

$$\phi_{d_1} = -\frac{1}{2}\left[\underline{F}_i\right] \cdot \underline{n}_{i_L}, \qquad \phi_{d_2} = -\frac{1}{2}\left[\underline{F}_j\right] \cdot \underline{n}_{j_R}, \tag{8.3}$$

where the square bracket denotes the jump across the discontinuity. The contributions from two edges vanish in each case due to the degeneracy of the triangles.

Then

$$\phi_{d_1}^2 + \phi_{d_2}^2 = \frac{1}{4}\left\{\left([\underline{F}_i].\underline{n}_{i_L}\right)^2 + \left([\underline{F}_j].\underline{n}_{j_L}\right)^2\right\}, \tag{8.4}$$

and so we can also use

$$\mathcal{F}_4 = \sum_{e \in \Omega_D} \phi_e^2 \tag{8.5}$$

to improve the position of the shock, where Ω_D is the set of degenerate triangles. (Note that $\mathcal{F}_4$ is bounded because ϕ_e in (2.3) is always bounded, even at shocks where U is discontinuous. On the other hand, the average residual, given by (2.4), is not bounded since $S_e = 0$ at shocks.)

A descent least squares method can then be used on $\mathcal{F}_3$ or $\mathcal{F}_4$ to move the shocked nodes into a more accurate position, keeping the u_L and u_R values fixed. The procedure may be interleaved with a descent least squares method on $\mathcal{F}_1$ or $\mathcal{F}_2$ for the smooth solution on either side.

We now give some numerical results using this technique.

9. Numerical results for discontinuous solutions. We now show results from three problems which exhibit discontinuities, one scalar and the others for different nonlinear systems.

Example 3. The first of these problems is the advection of a contact discontinuity. We consider circular advection as in Example 1 but with initial data

$$U = \begin{cases} 1, & x \leq -0.5, \\ -1, & x \geq -0.5 \end{cases} \tag{9.1}$$

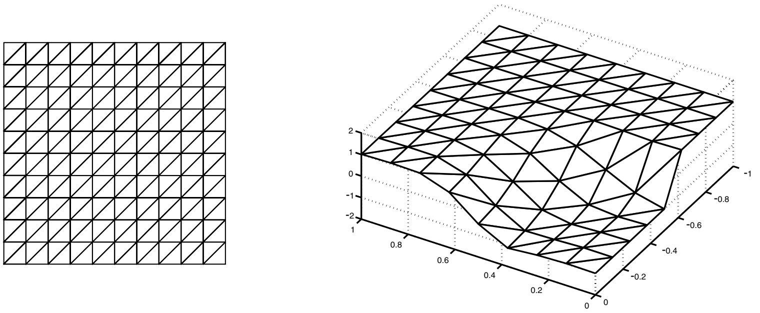

FIG. 9. *Fixed mesh and solution for Example* 3.

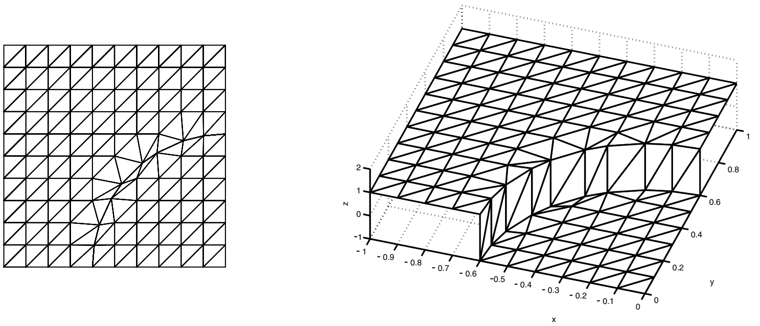

FIG. 10. *Moved mesh and solution for Example* 3.

on the inflow side. This represents the circular advection of a contact discontinuity.

Degenerate triangles are inserted vertically to connect the triangles on either side of the discontinuity. The solution updates come from a least squares descent method taken over nondegenerate elements. (The least squares updates to the solution come from nondegenerate elements.) The shock node adaptation is by the mimimization of F_4 (see (8.5)). Results are shown in Figures 9 and 10 for a fixed mesh and a moving mesh using degenerate triangles. Convergence histories are shown in Figure 11. The contact discontinuity has been accurately located through the use of the degenerate elements.

Example 4. Consider again the Shallow Water Equations system of Example 2. The problem which interests us here is that of a transcritical constricted channel flow which exhibits a hydraulic jump in the constriction. The computational domain represents a channel of length 3 meters and width 1 meter with a 10% bump in the middle third. The freestream Froude number is defined to be $F_\infty = 0.55$, the freestream depth is $h_\infty = 1m$, and the freestream velocity is given by $(u_\infty, v_\infty) = (1.72, 0)$.

An initial solution for the least squares shock fitting approach is found by the elliptic-hyperbolic Lax–Wendroff multidimensional upwinding scheme of Mesaros and Roe; see [8]. This time we seek to locate the hydraulic jump by adding degenerate quadrilaterals at the approximate position of the shock and seeking the best position of the shocked nodes. This is again achieved by using a least squares descent method on $\mathcal{F}_4$ with degenerate triangles to improve the position of the shock. Virtually identical results are obtained using $\mathcal{F}_3$ with quadrilaterals.

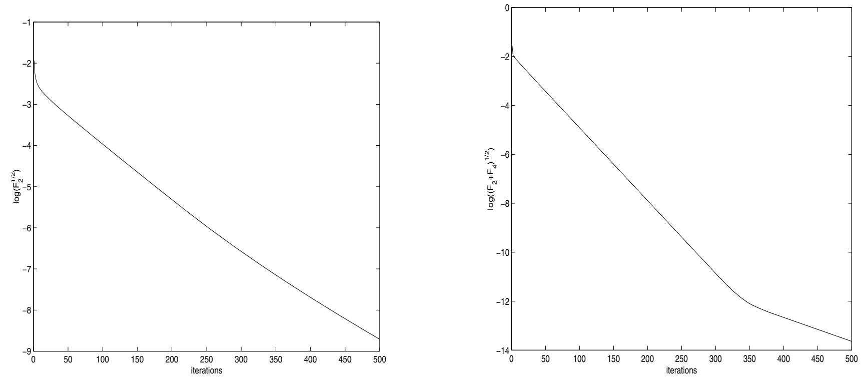

FIG. 11. *Convergence histories.*

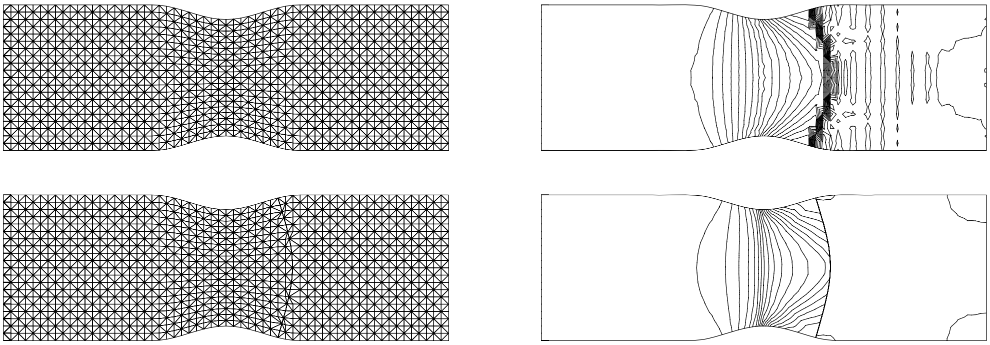

FIG. 12. *Results for Example* 4.

Results are shown in Figure 12, which shows the meshes and solution depth contours obtained. A bow-shaped hydraulic jump which is strongest at the boundaries is predicted, which agrees with solutions obtained using a shock capturing solution on a very fine mesh. Here it is achieved at little cost. Note not only the better shock resolution but also the much cleaner post-shock solution.

Example 5. Finally we consider the system (2.13) again but this time corresponding to the Euler equations of gasdynamics written in conserved variables [5].

This example is chosen to exhibit the shock fitting capabilities of the method for a purely supersonic flow which has an exact solution [17]. The computational domain is of length 3 meters and width 1 meter. Supersonic inflow boundary conditions, given by

$$\begin{aligned} \underline{U}(0,y) &= (1.0, 2.9, 0, 5.99073)^t, \\ \underline{U}(x,1) &= (1.69997, 4.45280, -0.86073, 9.87007)^t, \end{aligned} \tag{9.2}$$

are imposed on the left and upper boundaries, respectively. At the right-hand boundary supersonic outflow conditions are applied, while the lower boundary is treated as a solid wall.

The boundary conditions are chosen so that the shock enters the top left-hand corner at an angle of 29^o to the horizontal and is reflected by a flat plate on the lower boundary. The flow in regions away from shocks is constant. The same strategy is

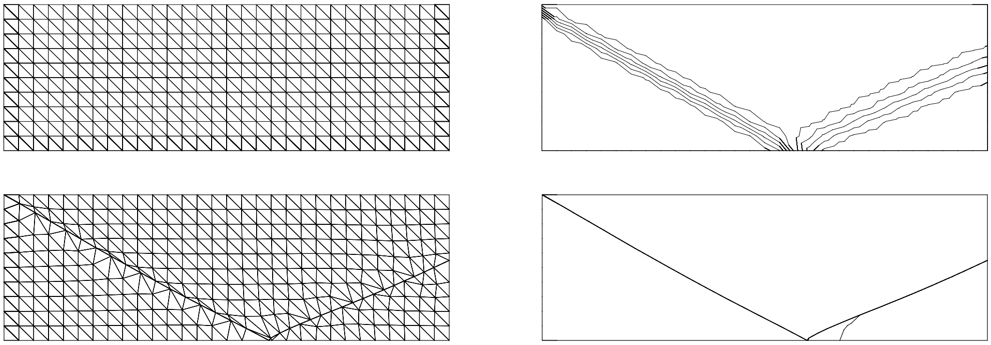

FIG. 13. *Results for Example* 5.

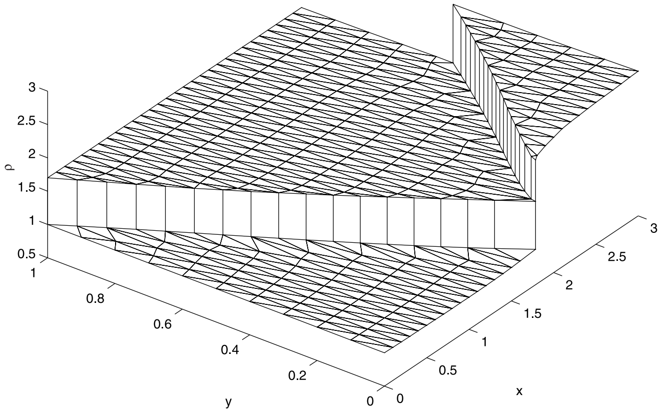

FIG. 14. *Solution (density) in* 3*D*.

employed as in the previous example, including the same shock capturing scheme, with the results shown in Figure 13, where the density contours are plotted. The predicted shock comes in from the top left hand at an angle of 29.2^o to the horizontal, and the solution is virtually constant apart from the discontinuities, in close agreement with the analytic solution (see Figure 14).

The angle made by the reflected shock with the horizontal is also in line with the theory. (See [14], which gives the angle as 23.3°.)

10. Conclusion. In this paper we have considered the approximate solution of steady first order PDEs by a least squares finite volume fluctuation distribution scheme with mesh movement. On fixed meshes, by the nature of the fluctuation distribution technique, the fluctuations on triangular meshes are not driven to zero. The solution may be improved by introducing extra degrees of freedom by adding node locations to the list of unknowns and moving the mesh. As a result, for scalar problems the fluctuations are driven down to zero (to machine accuracy), while for systems of equations the errors are much reduced. The descent least squares procedure with mesh movement also induces global conservation and equidistributes the fluctuation amongst the triangles, thus proceeding down to the steady limit in a uniform way.

For scalar problems convergence can be greatly accelerated by carrying out the iterations in an upwind manner.

For problems with discontinuities the descent least squares method does not give good solutions, but the mesh movement technique enables improvement of the location of the discontinuity in a manner akin to shock fitting. By minimizing a measure of the jump condition an approximate position of the shock can be maneuvered into an accurate position. This allows the descent least squares method to be used on either side of the shock to gain a good approximation of the smooth regions of the flow.

Acknowledgment. The authors wish to thank Phil Roe of the University of Michigan for many helpful suggestions while visiting the University of Reading under an EPSRC Visiting Fellowship.

LEAST SQUARES RESIDUALS AND MINIMAL RESIDUAL METHODS[*]

J. LIESEN[†], M. ROZLOŽNÍK[‡], AND Z. STRAKOŠ[§]

Abstract. We study Krylov subspace methods for solving unsymmetric linear algebraic systems that minimize the norm of the residual at each step (minimal residual (MR) methods). MR methods are often formulated in terms of a sequence of least squares (LS) problems of increasing dimension. We present several basic identities and bounds for the LS residual. These results are interesting in the general context of solving LS problems. When applied to MR methods, they show that the size of the MR residual is strongly related to the conditioning of different bases of the same Krylov subspace. Using different bases is useful in theory because relating convergence to the characteristics of different bases offers new insight into the behavior of MR methods.

Different bases also lead to different implementations which are mathematically equivalent but can differ numerically. Our theoretical results are used for a finite precision analysis of implementations of the GMRES method [Y. Saad and M. H. Schultz, *SIAM J. Sci. Statist. Comput.*, 7 (1986), pp. 856–869]. We explain that the choice of the basis is fundamental for the numerical stability of the implementation. As demonstrated in the case of Simpler GMRES [H. F. Walker and L. Zhou, *Numer. Linear Algebra Appl.*, 1 (1994), pp. 571–581], the best orthogonalization technique used for computing the basis does not compensate for the loss of accuracy due to an inappropriate choice of the basis. In particular, we prove that Simpler GMRES is inherently less numerically stable than the Classical GMRES implementation due to Saad and Schultz [*SIAM J. Sci. Statist. Comput.*, 7 (1986), pp. 856–869].

1. Introduction.

Consider a linear algebraic system $Ax = b$, where $A \in \mathcal{R}^{N,N}$ is a nonsingular matrix (generally unsymmetric) and $b \in \mathcal{R}^N$. Krylov subspace methods for solving such systems start with an initial approximation x_0, compute the initial residual $r_0 = b - Ax_0$, and then determine a sequence of approximate solutions $x_1, \ldots, x_n, \ldots$ such that x_n belongs to the linear manifold determined by x_0 and the nth Krylov subspace

$$x_n \in x_0 + \mathcal{K}_n(A, r_0), \quad \mathcal{K}_n(A, r_0) \equiv \operatorname{span}\{r_0, Ar_0, \ldots, A^{n-1}r_0\}\,. \tag{1.1}$$

The nth residual then belongs to the manifold given by r_0 and the shifted Krylov subspace (also called the Krylov residual subspace)

$$r_n \equiv b - Ax_n \in r_0 + A\mathcal{K}_n(A, r_0)\,. \tag{1.2}$$

The choice of x_n is based on some particular additional condition. In this paper we focus on the *minimal residual (MR) principle*

$$\|r_n\| = \min_{u \in x_0 + \mathcal{K}_n(A, r_0)} \|b - Au\|, \tag{1.3}$$

which can be equivalently formulated as the *orthogonal projection principle*

$$r_n \perp A\mathcal{K}_n(A, r_0). \tag{1.4}$$

Since A is assumed to be nonsingular, both (1.3) and (1.4) determine the unique sequence of approximate solutions $x_1, \dots, x_n$; see [26]. Mathematically (in exact arithmetic), there are several different methods and many of their algorithmic variants for generating this sequence. Computationally (in finite precision arithmetic), however, different algorithms for computing the same mathematical sequence may produce different results.

We will call the Krylov subspace methods (1.1) generating mathematically the approximate solutions $x_1, \dots, x_n$ uniquely determined by the MR principle (1.3) (or by the equivalent orthogonal projection principle (1.4)) *MR Krylov subspace methods* (MR methods).

The MR principle (1.3) represents a least squares (LS) problem, and thus MR methods are often described as a sequence of LS least problems of increasing dimension [26]. In this paper we use general results about LS residuals to analyze the properties of different implementations of MR methods in exact as well as finite precision arithmetic. Our approach is as follows.

In section 2 we present several basic identities and bounds for the norm of the residual $r = c - By$ of the overdetermined LS problem $Bu \approx c$. Specifically, our results relate $\|r\|$ to the singular values of the matrix $[c\gamma, B]$, where $\gamma > 0$ is a scaling parameter, and occasionally some other data. Results of this type have been presented in the literature before (see, e.g., [29]), and they are of importance in studying LS problems in general. While our main focus is on MR methods, only a part of our general LS results are used later in the paper. We believe, however, that the presented LS results which are not directly applied here might be found useful in the context of MR methods in the future.

In section 3 we apply results from section 2 to MR methods for the problem $Ax = b$. In particular, we relate the norm of the MR residual to the conditioning of different bases of $\mathcal{K}_n(A, r_0)$. We derive several necessary and sufficient conditions for fast convergence as well as for stagnation of MR methods. Our results are significantly stronger and more complete than the corresponding results published previously [16, 17]. We point out that our results should not be interpreted as bounds for measuring convergence. As demonstrated in the further sections, results relating residual norm to the conditioning of different bases lead to a new understanding of MR methods.

Section 4 describes the main examples of the MR methods, in particular various forms of the GMRES method [26]. We then apply our theoretical results about the MR residual to finite precision analysis of the important implementations in section 5. Our results explain why the choice of the basis is fundamental for the numerical stability of the implementation. As demonstrated on the example of Simpler GMRES [34], which constructs in exact arithmetic an orthonormal basis of $A\mathcal{K}_n(A, r_0)$, the best orthogonalization technique (Householder reflections) in computing the basis does not compensate for the loss of accuracy due to the inappropriate choice of the basis.

Simpler GMRES is proved inherently less stable than the Classical GMRES implementation [26], which constructs in exact arithmetic an orthonormal basis of $\mathcal{K}_n(A, r_0)$. Our findings are illustrated by numerical experiments.

We denote by $\sigma_i(\cdot)$ the ith largest singular value and by $\sigma_{min}(\cdot)$ the smallest singular value of a given matrix. By $\kappa(\cdot)$ we denote the ratio of the largest to the smallest singular value (condition number). We use $\|\cdot\|$ to denote the 2-norm, e_i to denote the ith vector of the standard Euclidean basis, and I to denote the identity matrix.

2. Basic relations for the LS residual.

As the MR methods can be expressed as sequences of LS problems, it will prove useful to collect some basic relations for the LS residual. We will recall some known results, prove several new results, and put the ones known previously in a new context. Most of the results of this section will be used in our analysis of MR methods later in the paper. We believe that they are also of interest in the LS context in general.

Consider an overdetermined linear approximation problem

$$Bu \approx c, \quad B \in \mathcal{R}^{N,n},\ c \in \mathcal{R}^N,\ n < N,\ \text{rank}(B) = n. \tag{2.1}$$

We denote by y the LS solution of (2.1) and by $r = c - By$ the corresponding LS residual,

$$\|r\| \ = \ \|c - By\| \ = \ \min_u \|c - Bu\| \,. \tag{2.2}$$

We introduce a real scaling parameter $\gamma > 0$ and consider a scaled version of (2.1),

$$Bz \approx c\gamma, \quad B \in \mathcal{R}^{N,n},\ c \in \mathcal{R}^N,\ n < N,\ \text{rank}(B) = n. \tag{2.3}$$

Note that if the right-hand side c is replaced in (2.1) and (2.2) by the scaled vector $c\gamma$, the LS solution and the LS residual scale trivially to $z = y\gamma$ and $r\gamma$. We start with general identities relating r to the matrix $[c\gamma, B]$.

THEOREM 2.1. *Suppose that $[c, B] \in \mathcal{R}^{N,n+1}$ has full column rank, and $r \neq 0$ is the residual of the LS problem* (2.1)–(2.2). *Let $\gamma > 0$ be a real parameter. Then*

$$e_1^T\,[c\gamma, B]^\dagger = \frac{r^T}{\gamma\|r\|^2} \qquad \textit{and} \qquad \gamma\|r\| \ = \frac{1}{\{e_1^T([c\gamma, B]^T[c\gamma, B])^{-1}e_1\}^{\frac{1}{2}}}, \tag{2.4}$$

where $X^\dagger$ denotes the Moore–Penrose generalized inverse of a matrix X.

Proof. For any matrix X the Moore–Penrose pseudoinverse $X^\dagger$ satisfies $XX^\dagger X = X$ (see, e.g., [5]), which using the symmetry of $XX^\dagger$ gives $X^T = X^T XX^\dagger$. Substituting $X = [c\gamma, B]$, we receive the following simple identities:

$$\begin{aligned} \gamma r^T &= [1, -\gamma y^T]\,[c\gamma, B]^T = [1, -\gamma y^T]\,[c\gamma, B]^T\,[c\gamma, B][c\gamma, B]^\dagger \\ &= \gamma r^T\,[c\gamma, B][c\gamma, B]^\dagger\,. \end{aligned}$$

Since r is orthogonal to the columns of B, $\gamma r^T\,[c\gamma, B] \ = \ \gamma^2(r^Tc)\,e_1^T \ = \ \gamma^2\|r\|^2\,e_1^T$, which proves the first part of the theorem. The second part follows from the identity $\|e_1^T\,[c\gamma, B]^\dagger\|^2 = e_1^T([c\gamma, B]^T[c\gamma, B])^{-1}e_1$, which can be verified by a straightforward calculation. □

The first equality in (2.4) was essentially proven (though neither the statement nor the proof were formulated explicitly in the form presented here) in [28, relations

(2.5), (2.6), (3.7), and (3.8)]. Later it was presented (with $\gamma = 1$) in [16, Lemma 7.1] (see also other references therein).

It is important to notice that for an arbitrary nonsingular matrix $M \in \mathcal{R}^{n,n}$,

$$\|r\| \;=\; \|c - By\| \;=\; \|c - (BM)(M^{-1}y)\| \;=\; \min_u \|c - (BM)u\|\,.$$

As a consequence of this simple observation, (2.4) will hold when B is replaced by BM. A particularly useful choice is $M = R^{-1}$, where R is the upper triangular factor of a QR-factorization of B.

COROLLARY 2.2. *Using the assumptions and the notation of Theorem* 2.1, *and a QR-factorization $B = QR$ of the matrix B,*

$$e_1^T\,[c\gamma, Q]^\dagger = \frac{r^T}{\gamma\|r\|^2} \qquad \textit{and} \qquad \gamma\|r\| \;=\; \frac{1}{\{e_1^T([c\gamma,Q]^T[c\gamma,Q])^{-1}e_1\}^{\frac{1}{2}}}\,. \tag{2.5}$$

It may look a bit surprising that the first rows of the matrices $[c\gamma, B]^\dagger$ and $[c\gamma, Q]^\dagger$ are identical. A second look reveals that this fact is simple and natural.

Consider a full column rank matrix $X = [c\gamma, B] \in \mathcal{R}^{N,n+1}$. Then the rows of $X^\dagger$ are linear combinations of the rows of X^T (the transposed columns of X), and $X^\dagger X = I$. The last relation can be interpreted geometrically as an orthogonal relation between the rows of $X^\dagger$ and the columns of X. Denote by $s = e_1^T X^\dagger$ the first row of $X^\dagger$. Then s is orthogonal to all but the first column of X; i.e., it is orthogonal to the columns of the matrix B. Because s represents a linear combination of c^T and the transposed columns of B, it must be equal to a scalar multiple of the transposed residual $r^T = (c - By)^T$ for the LS problem (2.1)–(2.2). The identity $(\zeta r^T)\,(c\gamma) = 1$ then immediately gives $\zeta = \gamma^{-1}\|r\|^{-2}$.

The orthogonality idea clearly applies with no change when B is replaced by any matrix BM, where $M \in \mathcal{R}^{n,n}$ is nonsingular. The geometrical interpretation of the generalized inverse is simple but revealing.

The following theorem relates the norm of the LS residual (2.2) to the singular values of the matrices B, $[c\gamma, B]$, and $[c\gamma, Q]$. This theorem plays a substantial role in our further analysis.

THEOREM 2.3. *Suppose that $[c, B] \in \mathcal{R}^{N,n+1}$ has full column rank, and $r \neq 0$ is the residual of the LS problem* (2.1)–(2.2). *Let $B = QR$ be a QR-factorization of the matrix B and $\gamma > 0$ be a real parameter. Then*

$$\|r\| \;=\; \frac{\sigma_{min}([c\gamma,B])}{\gamma}\prod_{j=1}^{n}\frac{\sigma_j([c\gamma,B])}{\sigma_j(B)} \tag{2.6}$$

$$\;=\; \frac{1}{\gamma}\,\sigma_{min}([c\gamma,Q])\,\sigma_1([c\gamma,Q]). \tag{2.7}$$

Furthermore,

$$\kappa([c\gamma,Q]) \;=\; \frac{\alpha + \left(\alpha^2 - 4\gamma^2\|r\|^2\right)^{1/2}}{2\gamma\,\|r\|}\,, \quad \|r\| \;=\; \frac{\alpha}{\gamma}\,\frac{\kappa([c\gamma,\,Q])}{\kappa([c\gamma,\,Q])^2+1}, \tag{2.8}$$

where $\alpha \equiv 1 + \gamma^2\|c\|^2$.

Proof. Using the orthogonality of the columns of the matrix Q, the right-hand side c and the residual r are related by the identity

$$c = Qh + r, \quad h \equiv Q^Tc, \quad \|c\|^2 = \|h\|^2 + \|r\|^2\,.$$

Now consider an orthogonal matrix $U \in \mathcal{R}^{n,n}, U^T U = I$, such that $Uh = \|h\| e_1$. Then

$$[c\gamma, Q]^T [c\gamma, Q] = \begin{bmatrix} 1 & 0 \\ 0 & U^T \end{bmatrix} \begin{bmatrix} \gamma^2\|c\|^2 & \gamma\|h\|e_1^T \\ \gamma\|h\|e_1 & I \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & U \end{bmatrix}, \tag{2.9}$$

$$[c\gamma, B]^T [c\gamma, B] = \begin{bmatrix} 1 & 0 \\ 0 & R^T \end{bmatrix} [c\gamma, Q]^T [c\gamma, Q] \begin{bmatrix} 1 & 0 \\ 0 & R \end{bmatrix}. \tag{2.10}$$

Identity (2.9) shows that all but two of the eigenvalues of $[c\gamma, Q]^T[c\gamma, Q]$ are equal to one. The two remaining eigenvalues are easily determined as the eigenvalues of the left principal two-by-two block,

$$\sigma_1^2([c\gamma, Q]) = \frac{\alpha + (\alpha^2 - 4\gamma^2\|r\|^2)^{1/2}}{2}, \tag{2.11}$$

$$\sigma_{min}^2([c\gamma, Q]) = \frac{\alpha - (\alpha^2 - 4\gamma^2\|r\|^2)^{1/2}}{2}, \tag{2.12}$$

where $\alpha \equiv 1 + \gamma^2\|c\|^2$. (Notice that $\alpha^2 - 4\gamma^2\|r\|^2 \geq (1 - \gamma^2\|c\|)^2 \geq 0$.) Using

$$\kappa([c\gamma, Q]) = \sigma_1([c\gamma, Q])/\sigma_{min}([c\gamma, Q]),$$

(2.8) is obtained by a simple algebraic manipulation.

Evaluating the determinants on both sides of (2.9) yields

$$\det([c\gamma, Q]^T[c\gamma, Q]) = \sigma_1^2([c\gamma, Q])\, \sigma_{min}^2([c\gamma, Q]) = \gamma^2\|r\|^2,$$

which shows (2.7). Similarly, transformation (2.10) yields

$$\begin{aligned} \det([c\gamma, B]^T[c\gamma, B]) &= \prod_{j=1}^{n+1} \sigma_j^2([c\gamma, B]) \\ &= \det([c\gamma, Q]^T[c\gamma, Q]) \det(R^T R) = \gamma^2\|r\|^2 \prod_{j=1}^{n} \sigma_j^2(B), \end{aligned}$$

which proves (2.6). □

The relations (2.8) generalize results presented in [19, section 5.5.2]. The identity (2.6) (with $\gamma = 1$) was first shown by Van Huffel and Vandewalle [29, Theorem 6.9], and it also appeared (with a different proof) in [20].

Van Huffel and Vandewalle [29, Theorem 6.10] gave the following lower and upper bounds for $\|r\|$ (with $\gamma = 1$) in terms of $\sigma_{min}([c\gamma, B])$ (see also [20]). Let

$$\delta(\gamma) \equiv \sigma_{min}([c\gamma, B])/\sigma_{min}(B). \tag{2.13}$$

Then

$$\frac{\sigma_{min}([c\gamma, B])}{\gamma} \leq \|r\| \leq \frac{\sigma_{min}([c\gamma, B])}{\gamma} \left\{1 - \delta(\gamma)^2 + \frac{\gamma^2\|c\|^2}{\sigma_{min}^2(B)}\right\}^{\frac{1}{2}}. \tag{2.14}$$

Bounds for $\|r\|$ in terms of the minimal singular values of B and $[c\gamma, B]$, and as little additional information as possible, were studied in detail in [20]. In particular, when B has full column rank and

$$c \not\perp \{\text{left singular vector subspace of } B \text{ corresponding to } \sigma_{min}(B)\}, \tag{2.15}$$

then the following bounds were given in [20]:

$$\begin{aligned} \sigma_{min}([c\gamma, B])\,\{\gamma^{-2} + \|y\|^2\}^{\frac{1}{2}} \le \|r\| \\ \le \sigma_{min}([c\gamma, B])\left\{\gamma^{-2} + \frac{\|y\|^2}{1 - \delta(\gamma)^2}\right\}^{\frac{1}{2}}. \end{aligned} \tag{2.16}$$

Though (2.14) can be derived from (2.16) (and not vice versa; see [20]), the upper bound in (2.16) is not always tighter than the upper bound in (2.14). When $\delta(\gamma) \approx 1$ and $\|r\| \approx \|c\|$, it is possible for the upper bound in (2.14) to be smaller than that in (2.16). However, in this case the upper bound in (2.14) becomes trivial. For details, see [20].

For $\delta(\gamma) = 1$ the upper bound in (2.16) does not exist. It was shown in [22] that if (2.15) holds, then $\delta(\gamma) < 1$ for all $\gamma > 0$. As explained in [22], the role of the assumption (2.15) is truly fundamental. If it does not hold, both theory and computation in errors-in-variables modeling are enormously complicated by the possible case $\delta(\gamma) = 1$. Fortunately, nearly all practical problems will satisfy (2.15). Nevertheless, it is instructive to consider possible cases where (2.15) does not hold, so that $\delta(\gamma) = 1$ is possible.

The lower bound in (2.14) shows that we can make $\sigma_{min}([c\gamma, B])$ arbitrarily small by taking γ small and thus ensure $\delta(\gamma) < 1$ in (2.13). How small must γ be to ensure this? The next theorem answers a variant of this question. Given $\sigma_{min}(B)$ and $\|c\|$, it shows that there is a γ_0 such that $\gamma < \gamma_0$ ensures $\delta(\gamma) < 1$, but $\gamma = \gamma_0$ does not.

THEOREM 2.4. *Suppose that* $[c, B] \in \mathcal{R}^{N,n+1}$ *has full column rank, y is the solution, and $r \neq 0$ is the residual of the LS problem* (2.1)–(2.2). *Let $\gamma > 0$ be a real parameter, and $\delta(\gamma) \equiv \sigma_{min}([c\gamma, B])/\sigma_{min}(B)$. Define $\gamma_0 \equiv \sigma_{min}(B)/\|c\|$. Then*

$$\delta(\gamma) < 1 \;\; \textit{for all} \;\; \gamma < \gamma_0. \tag{2.17}$$

Moreover,

$$y = 0 \;\; (r = c) \quad \textit{if and only if} \quad \delta(\gamma_0) = 1. \tag{2.18}$$

Proof. Note that when $\gamma < \gamma_0$, then $\|c\gamma\| < \sigma_{min}(B)$. Therefore $\sigma_{min}([c\gamma, B]) < \sigma_{min}(B)$, i.e., $\delta(\gamma) < 1$.

Now assume that the LS problem (2.1)–(2.2) has the trivial solution $y = 0$ $(r = c)$. Then $B^T c = 0$, which yields

$$[c\gamma, B]^T [c\gamma, B] = \begin{bmatrix} \|c\|^2\gamma^2 & 0 \\ 0 & B^T B \end{bmatrix}.$$

Thus, $\sigma_{min}([c\gamma, B]) = \min\{\|c\|\gamma,\ \sigma_{min}(B)\}$, $\delta(\gamma) = \min\{\|c\|\gamma/\sigma_{min}(B),\ 1\}$, and $\delta(\gamma_0) = 1$. Conversely, (2.14) gives with $\gamma = \gamma_0$,

$$\delta(\gamma_0)\,\|c\| \;\le\; \|r\| \;\le\; \delta(\gamma_0)\,\|c\|\,\{2 - \delta(\gamma_0)^2\}^{1/2}, \tag{2.19}$$

which for $\delta(\gamma_0) = 1$ reduces to $\|c\| \le \|r\| \le \|c\|$, i.e., $\|r\| = \|c\|$, which completes the proof. □

We see that $\gamma_0 \equiv \sigma_{min}(B)/\|c\|$ represents an important number. For $\gamma < \gamma_0$ the value of $\delta(\gamma)$ is always strictly less than one, and $\delta(\gamma_0) = 1$ if and only if the LS problem (2.1)–(2.2) has the trivial solution $y = 0$. Moreover, (2.19) shows that $\|r\|$ is significantly smaller than $\|c\|$ if and only if $\delta(\gamma_0)$ is significantly smaller than one. As an application, we will show in section 3 how these results characterize stagnation or near stagnation of MR methods.

One consequence of Theorem 2.4 can be stated as follows: Consider a rectangular matrix (here B) having full column rank and an additional column (here $c\gamma$). If the norm of the additional column is smaller than the smallest singular value of the matrix (here if $\gamma < \gamma_0$), then appending the column necessarily decreases the smallest singular value. If the norm of the appended column is equal to the smallest singular value of the matrix (here if $\gamma = \gamma_0$), then appending the column to the matrix does not change the smallest singular value if and only if the appended column is orthogonal to all the columns (all the left singular vectors) of the original matrix. This is a somewhat specialized result because of the norm of the added column fixed to $\sigma_{min}(B)$. Note that the condition is linear. The general necessary and sufficient condition under which adding a column (with a norm larger or equal to $\sigma_{min}(B)$) to a matrix B does not alter the smallest singular value was given in [22]. The added column must be orthogonal to the left singular vector subspace of B corresponding to $\sigma_{min}(B)$, and the left-hand side of the (deflated) secular equation [22, relation (3.4)] must be nonnegative at $\sigma_{min}(B)$. Theorem 2.4 can also be derived from this. The second part of the condition from [22] is nonlinear.

Theorem 2.4 and the consequence stated above must be understood in their proper context. It was pointed out in [22] that nearly all practical problems will satisfy (2.15), that any problem $Bu \approx c$ can be reduced to a core problem satisfying (2.15), and that for many formulations it makes sense only to consider problems satisfying (2.15). Also, if the problem satisfies (2.15), then $\delta(\gamma) < 1$ for all $\gamma > 0$, and in this case (2.17) and (2.18) are irrelevant. On the other hand, (2.19) seems to be a generally useful result. Thus $\gamma_0 \equiv \sigma_{min}(B)/\|c\|$ is a significant quantity, as can be seen from the interesting but rarely practical properties (2.17) and (2.18), and the interesting and compact bounds (2.19). Note also that in many practical problems of interest, $\gamma_0 \equiv \sigma_{min}(B)/\|c\|$ will be a *very* small number. In particular, this suggests that for a general LS problem the above "column addition" result will be of minor practical use. It is, however, important theoretically because it offers a new insight into the stagnation or near stagnation of the MR methods.

Finally, for completeness, consider a QR-factorization $B = QR$. Replacing B by $BR^{-1} = Q$ and y by Ry (notice that $\|Ry\| = \|By\|$) gives the analogies of (2.14) and (2.16),

$$\frac{\sigma_{min}([c\gamma, Q])}{\gamma} \le \|r\| \le \frac{\sigma_{min}([c\gamma, Q])}{\gamma} \{1 - \sigma^2_{min}([c\gamma, Q]) + \gamma^2\|c\|^2\}^{\frac{1}{2}}, \tag{2.20}$$

$$\begin{aligned} \sigma_{min}([c\gamma, Q])\,\{\gamma^{-2} + \|By\|^2\}^{\frac{1}{2}} &\le \|r\| \\ &\le \sigma_{min}([c\gamma, Q]) \left\{\gamma^{-2} + \frac{\|By\|^2}{1 - \sigma_{min}([c\gamma, Q])^2}\right\}^{\frac{1}{2}}. \end{aligned} \tag{2.21}$$

Theorem 2.4 can be reformulated in a similar way. It is interesting to note that the bounds (2.20) do not give additional information. Indeed, since $\sigma_1([c\gamma, Q]) \ge 1$, the lower bound in (2.20) follows immediately from (2.7). And since $\{1 - \sigma^2_{min}([c\gamma, Q]) + \gamma^2\|c\|^2\}^{1/2} = \sigma_1([c\gamma, Q])$, the upper bound is a weak reformulation of (2.7) only.

In the following section we apply results of this section to the MR Krylov subspace methods.

3. Characteristics of the basis and the size of the MR residual.

Let $\rho_0 \equiv \|r_0\|$, $v_1 \equiv r_0/\rho_0$, $w_1 \equiv Av_1/\|Av_1\|$. Consider two sequences of orthonormal vectors, $v_1, v_2, \dots$ and $w_1, w_2, \dots$, such that for each iterative step n,

$$\mathcal{K}_n(A, r_0) \;=\; \text{span}\{v_1, \dots, v_n\}, \;\; V_n \equiv [v_1, \dots, v_n], \;\; V_n^T V_n = I, \tag{3.1}$$

$$A\mathcal{K}_n(A, r_0) \;=\; \text{span}\{w_1, \dots, w_n\}, \;\; W_n \equiv [w_1, \dots, w_n], \;\; W_n^T W_n = I. \tag{3.2}$$

Then the MR principle (1.3) can be formulated as

$$\|r_n\| \;=\; \min_{u \in \mathcal{R}^n} \|r_0 - AV_n u\| \tag{3.3}$$

$$\;=\; \min_{u \in \mathcal{R}^n} \|r_0 - W_n u\|\,. \tag{3.4}$$

The MR residual at step n is therefore the LS residual for the LS problems $AV_n u \approx v_1\rho_0$ and $W_n u \approx v_1\rho_0$.

The application of the results presented in section 2 to (3.3) and (3.4) is straightforward: For the nth step of an MR method we consider $c \equiv r_0 = v_1\rho_0$, $B \equiv AV_n$, $Q \equiv W_n$, and $r \equiv r_n$. The scaling parameter $\gamma > 0$ offers some flexibility. While it seems natural to use $\gamma \equiv \|r_0\|^{-1} = \rho_0^{-1}$, other values of γ also prove useful; cf. [21] and our discussion below.

With $\gamma \equiv \|r_0\|^{-1} = \rho_0^{-1}$, Theorem 2.3 and relations (2.7) and (2.8) give the following identities for the relative residual norm $\|r_n\|/\rho_0$:

$$\|r_n\|/\rho_0 \;=\; \sigma_{min}([v_1,\, W_n])\, \sigma_1([v_1,\, W_n]) \tag{3.5}$$

$$\;=\; \frac{2\,\kappa([v_1,\, W_n])}{\kappa([v_1,\, W_n])^2 + 1}. \tag{3.6}$$

Identities (3.5) and (3.6) show that the conditioning of the basis $[v_1,\, W_n]$ of the Krylov subspace $\mathcal{K}_{n+1}(A, r_0)$ is fully determined (except for an unimportant multiplicative factor) by the convergence of the MR methods, and vice versa. In other words,

$$\|r_n\| = \rho_0 \quad \text{if and only if} \quad \kappa([v_1,\, W_n]) = 1, \tag{3.7}$$

and the relative residual norm $\|r_n\|/\rho_0$ is small if and only if $[v_1,\, W_n]$ is ill-conditioned.

The previous statement can also be mathematically expressed by inequalities. Dividing both the numerator and the denominator in (3.6) by $\kappa([v_1, W_n])$ gives in a simple way the bounds

$$\kappa([v_1, W_n])^{-1} \;\le\; \|r_n\|/\rho_0 \;\le\; 2\,\kappa([v_1, W_n])^{-1}. \tag{3.8}$$

The upper bound in (3.8) was published by Walker and Zhou [34, Lemma 3.1]. It is interesting to note that, because of (2.11),

$$1 \;\le\; \sigma_1([v_1, W_n]) \;\le\; \sqrt{2}, \tag{3.9}$$

which shows that the size of $\kappa([v_1, W_n])$ is in fact determined by the smallest singular value $\sigma_{min}([v_1, W_n])$.

Relations between the size of the residuals of the MR methods and the condition number of matrices $[v_1, W_n]$ and $[r_0, W_n]$ were studied in [19, section 5.5.2]. We will generalize the result [19, relation (5.48)] and develop an elegant tool for quantification of the influence of the scaling parameter γ.

THEOREM 3.1. *Let r_0, r_n, and W_n be as in (3.4), $\rho_0 \equiv \|r_0\|, v_1 \equiv r_0/\rho_0$, and $\gamma > 0$. Then*

$$\kappa([r_0\gamma, W_n]) \;\geq\; \kappa([v_1, W_n]) \,+\, \frac{\gamma\,(\rho_0 - \gamma^{-1})^2}{2\|r_n\|}. \tag{3.10}$$

Proof. Using (2.8) with the particular choices $c \equiv r_0$, $Q \equiv W_n$, $\gamma > 0$, and $c \equiv r_0$, $Q \equiv W_n$, $\gamma \equiv \rho_0^{-1} = \|r_0\|^{-1}$ gives

$$\begin{aligned}
&\kappa([r_0\gamma, W_n]) - \kappa([v_1, W_n]) \\
&\quad = \frac{1 + \gamma^2\rho_0^2 + [(1+\gamma^2\rho_0^2)^2 - 4\gamma^2\|r_n\|^2]^{1/2}}{2\gamma\|r_n\|} - \frac{2 + [4 - 4\rho_0^{-2}\|r_n\|^2]^{1/2}}{2\rho_0^{-1}\|r_n\|} \\
&\quad = \frac{\gamma^{-1} + \gamma\rho_0^2 + [(\gamma^{-1}+\gamma\rho_0^2)^2 - 4\|r_n\|^2]^{1/2} - 2\rho_0 - [4\rho_0^2 - 4\|r_n\|^2]^{1/2}}{2\|r_n\|} \\
&\quad = \frac{\gamma\,(\rho_0 - \gamma^{-1})^2}{2\|r_n\|} + \frac{[(\gamma^{-1}+\gamma\rho_0^2)^2 - 4\|r_n\|^2]^{1/2} - [4\rho_0^2 - 4\|r_n\|^2]^{1/2}}{2\|r_n\|} \\
&\quad \geq \frac{\gamma\,(\rho_0 - \gamma^{-1})^2}{2\|r_n\|}. \qquad \square
\end{aligned}$$

Clearly, $\kappa([r_0\gamma, W_n])$ is minimal for $\gamma = \rho_0^{-1}$, and the minimum is equal to $\kappa([v_1, W_n])$ (see also [8]). If $\gamma \neq \rho_0^{-1}$, then with the residual norm $\|r_n\|$ decreasing towards zero the condition number $\kappa([r_0\gamma, W_n])$ grows much faster than $\kappa([v_1, W_n])$. The results considering the matrix $[r_0\gamma, W_n]$ will be particularly useful for our discussion of MR implementations based on the orthogonal projection principle (1.4) in section 5.

With $c \equiv r_0$, $r \equiv r_n$, $y \equiv y_n$, and $B \equiv AV_n$, (2.16) gives the following bounds for the residual norm in terms of $\sigma_{min}([r_0\gamma, AV_n])$:

$$\begin{aligned}
\sigma_{min}([r_0\gamma, AV_n])\,\{\gamma^{-2} + \|y_n\|^2\}^{\frac{1}{2}} \;&\leq\; \|r_n\| \\
&\leq\; \sigma_{min}([r_0\gamma, AV_n])\left\{\gamma^{-2} + \frac{\|y_n\|^2}{1 - \delta_n(\gamma)^2}\right\}^{\frac{1}{2}},
\end{aligned} \tag{3.11}$$

where $\delta_n(\gamma) \equiv \sigma_{min}([r_0\gamma, AV_n])/\sigma_{min}(AV_n)$. As mentioned in section 2, the upper bound in (3.11) becomes intriguing for $\delta_n(\gamma) \approx 1$, and for $\delta_n(\gamma) = 1$ it is not defined.

The convergence of the MR methods and the situation $\delta_n(\gamma) = 1$ or $\delta_n(\gamma) \approx 1$ are related by Theorem 2.4. Define $\gamma_0^{(n)} \equiv \sigma_{min}(AV_n)/\rho_0$. Then $\delta_n(\gamma) < 1$ for all $\gamma < \gamma_0^{(n)}$ and

$$\begin{aligned}
&\|r_n\| = \rho_0 \;\;\Leftrightarrow \\
&\delta_n(\gamma_0^{(n)}) \equiv \frac{\sigma_{min}([v_1\sigma_{min}(AV_n), AV_n])}{\sigma_{min}(AV_n)} = \sigma_{min}([v_1, AV_n/\sigma_{min}(AV_n)]) = 1.
\end{aligned} \tag{3.12}$$

Moreover, (2.19) gives

$$\delta_n(\gamma_0^{(n)}) \;\leq\; \|r_n\|/\rho_0 \;\leq\; \sqrt{2}\,\delta_n(\gamma_0^{(n)}), \tag{3.13}$$

which shows that the rate of convergence of the MR methods is determined by the size of $\delta_n(\gamma_0^{(n)})$. Summarizing, the MR methods stagnate in steps 1 through n if and only if $\delta_n(\gamma_0^{(n)}) = 1$, and they nearly stagnate in steps 1 through n if and only if $\delta_n(\gamma_0^{(n)}) \approx 1$. However, this specific link between convergence of the MR methods and the value of $\delta_n(\gamma)$ can be made for $\gamma = \gamma_0^{(n)}$ only. In particular, when $\delta_n(\gamma_1) = 1$ for some $\gamma_1 > \gamma_0^{(n)}$, the MR methods do not necessarily stagnate or nearly stagnate. They may exhibit very fast convergence while $\delta_n(\gamma_1) \approx 1$ and very slow convergence while $\delta_n(\gamma_1) \ll 1$. (For more details, see [21].)

For $\gamma = \gamma_0^{(n)}$ there is an interesting relationship between the smallest singular values of the matrices $[v_1, AV_n/\sigma_{min}(AV_n)]$ and $[v_1, W_n]$: (3.5), (3.9), and (3.13) yield

$$\sigma_{min}([v_1, AV_n/\sigma_{min}(AV_n)]) \leq \sqrt{2}\,\sigma_{min}([v_1, W_n]) \leq 2\,\sigma_{min}([v_1, AV_n/\sigma_{min}(AV_n)]),$$

which shows that these smallest singular values are very close to each other.

Using the matrix $[r_0\gamma, AV_n]$ instead of $[v_1, W_n]$ may seem unwise because it necessarily brings into play the potentially ill-conditioned matrix AV_n (in comparison to W_n having orthonormal columns). However, as shown in [22, 21], bounds using the matrix $[r_0\gamma, AV_n]$ are very useful for the analysis of the modified Gram–Schmidt implementation of Classical GMRES. Notice that the bounds (3.11) are not based on singular values only. Using $\|y_n\|$, the norm of the MR approximate solution, makes (3.11) amazingly tight [22]. The parameter γ offers flexibility required for the analysis of the GMRES method [21].

It is also possible to consider other bases of the Krylov subspaces or Krylov residual subspaces which lead to other matrices, identities, and bounds. For example, Ipsen [16, 17] used the matrix $K_{n+1} = [r_0, Ar_0, \ldots, A^n r_0]$, got the identity

$$\|r_n\| = 1/\|e_1^T\, K_{n+1}^\dagger\| \tag{3.14}$$

(cf. Theorem 2.1), and developed the bound $\|r_n\|/\rho_0 \geq 1/(\|K_{n+1}\|\,\|K_{n+1}^\dagger\|)$. However, any bound based directly on the matrix K_{n+1} necessarily suffers from the potential ill-conditioning of the matrix $[Ar_0, \ldots, A^n r_0]$. Consider the QR-decomposition $[Ar_0, \ldots, A^n r_0] = W_n R_n$. In light of the results presented above (see, in particular, (2.5), (3.5), and (3.6)), the upper triangular factor R_n containing *all* the potential ill-conditioning of the matrix $[Ar_0, \ldots, A^n r_0]$ is mathematically in no relation whatsoever to the residual r_n and to the convergence of any MR method measured by the residual norm. Except for some (rather special) examples, bounds based on the matrix K_{n+1} are therefore necessarily much weaker than the bounds based on the matrices $[r_0\gamma, W_n]$ and $[r_0\gamma, AV_n]$.

In the following we use our theoretical results to obtain new insight into the numerical behavior of MR methods.

4. Implementations of the MR methods. Numerous residual norm minimizing Krylov subspace methods have been proposed in the last decades [18, 30, 35, 1, 11, 26]. Resulting from different approaches, they generate (under different assumptions) approximate solutions satisfying (1.3) and (1.4). Though they are, under some particular assumptions, mathematically equivalent, they differ in various algorithmic aspects, and, consequently, in their numerical behavior.

We will concentrate on two main approaches which explicitly compute the basis vectors $v_1, v_2, \ldots, v_n$ (respectively, $v_1, w_1, \ldots, w_{n-1}$) defined in (3.1) and (3.2). In the first approach, the approximate solution x_n is expressed as

$$x_n \;=\; x_0 \;+\; V_n\, y_n$$

for some y_n, and the residual norm is bounded in terms of $\sigma_{min}([v_1\rho_0\gamma, AV_n])$ via (3.11). In the second approach the approximate solution is expressed as

$$x_n \;=\; x_0 \;+\; [v_1, W_{n-1}]\, t_n$$

for some t_n, and for the residual norm we have the identities (3.5)–(3.6). At first sight the second approach seems more attractive because it gives a cleaner relation between the residual norm (which is minimized at every step) and the conditioning of the computed basis. Its implementation is also simpler. On the other hand, the fact that the approximate solution is in this approach determined via the basis vectors $v_1, w_1, \ldots, w_{n-1}$ which *are not mutually orthogonal* raises some suspicions about potential numerical problems. In this section we recall implementations of both approaches resulting in different variants of the GMRES algorithm. In section 5 we will discuss their numerical properties.

A variety of MR methods that do not explicitly compute the vectors $v_1, v_2, \ldots, v_n$ or $v_1, w_1, \ldots, w_{n-1}$ have been proposed. For example, the method by Khabaza [18] uses the vectors $r_0, Ar_0, \ldots, A^{n-1}r_0$; Orthomin [30], Orthodir [35], Generalized Conjugate Gradient (GCG) [1, 2] and Generalized Conjugate Residual (GCR) [10, 11] compute an A^TA-orthogonal basis of $\mathcal{K}_n(A, r_0)$. These methods played an important role in the development of the field. In comparison to the approaches discussed in this paper they are, however, less numerically stable. Therefore we will not consider them below.

4.1. Minimal residual principle: Classical GMRES. Consider an initial approximation x_0 and the initial residual $r_0 = b - Ax_0$, $\rho_0 \equiv \|r_0\|$. In their classical paper [26], Saad and Schultz used the orthonormal basis (3.1) (Arnoldi basis). As noted in [33], this basis can be mathematically expressed as the Q-factor of a recursive columnwise QR-factorization

$$[r_0, AV_n] = V_{n+1}\,[e_1\rho_0, H_{n+1,n}], \qquad V_{n+1} \equiv [v_1, \ldots, v_{n+1}], \qquad V_{n+1}^T V_{n+1} = I. \tag{4.1}$$

Here $H_{n+1,n}$ is an $(n+1)$-by-n upper Hessenberg matrix with elements $h_{i,j}$, $h_{j+1,j} \neq 0, j = 1, 2, \ldots, n-1$. If at any stage $h_{n+1,n} = 0$, the algorithm would stop with $[r_0, AV_n] = V_n\,[e_1\rho_0, H_{n,n}]$. Using the substitution

$$x_n \;=\; x_0 \;+\; V_n\, y_n \tag{4.2}$$

and (4.1), the MR principle (1.3) gives the LS problem for the vector of coefficients y_n:

$$\|r_n\| \equiv \|b - Ax_n\| = \min_{y\in\mathcal{R}^n} \|r_0 - AV_n\, y\| \;=\; \min_{y\in\mathcal{R}^n} \|V_{n+1}\,(e_1\rho_0 - H_{n+1,n}\, y)\| \tag{4.3}$$

$$= \min_{y\in\mathcal{R}^n} \|e_1\rho_0 - H_{n+1,n}\, y\|. \tag{4.4}$$

To solve (4.3) we apply orthogonal rotations $J_1, J_2, \ldots, J_n$ sequentially to $H_{n+1,n}$ to bring it to the upper triangular form T_n:

$$J_n \cdots J_2 J_1\, H_{n+1,n} \;=\; \begin{bmatrix} T_n \\ 0 \end{bmatrix}.$$

The vectors y_n and $\|r_n\|$ then satisfy

$$\begin{bmatrix} T_n\, y_n \\ \|r_n\| \end{bmatrix} \;=\; J_1^T J_2^T \cdots J_n^T\, e_1 \rho_0. \tag{4.5}$$

The value of the (nonincreasing) residual norm is available without determining y_n, and it can be easily updated at each iteration, while y_{n+1} and x_{n+1} will usually differ in every element from y_n and x_n, respectively. We refer to this algorithm as Classical GMRES.

Several variants for computing the basis vectors $v_1, \ldots, v_n$ were proposed. Saad and Schultz [26] considered the modified Gram–Schmidt process. Walker [32, 33] presented Classical GMRES based on Householder transformations. Iterated classical and iterated modified Gram–Schmidt versions were studied in [9].

A variety of parallel implementations [6, 3, 12, 23, 7, 27] use various techniques to increase the parallel efficiency of the basically sequential basis-generating process. Parallel aspects are out of the scope of this paper.

4.2. Orthogonal projection principle: Simpler GMRES. We now consider an implementation of an MR method derived from the orthogonal projection principle (1.4). The approach proposed by Walker and Zhou [34], called Simpler GMRES, uses the orthonormal basis (3.2).

This basis is computed by a recursive columnwise QR-factorization of the matrix $[Ar_0\gamma, AW_{n-1}]$. Based on Theorem 3.1 we set $\gamma = \rho_0^{-1}$, and we will use this value of the scaling parameter γ throughout the rest of this paper. Then

$$A[v_1, W_{n-1}] = [Av_1, AW_{n-1}] = W_n S_n, \;\; W_n \equiv [w_1, \ldots, w_n], \;\; W_n^T W_n = I, \tag{4.6}$$

where S_n is an n-by-n upper triangular matrix with elements $s_{i,j}$, $s_{j,j} \neq 0$. If at any stage $s_{n,n} = 0$, the algorithm would stop with $[Av_1, AW_{n-1}] = W_{n-1}[S_{n-1}, \hat{s}_n]$. Using the substitution

$$x_n \;=\; x_0 \,+\, [v_1, W_{n-1}]\, t_n\,, \tag{4.7}$$

the vector $t_n \in \mathcal{R}^n$ solves the LS problem

$$\|r_n\| \equiv \|b - Ax_n\| = \min_{t \in \mathcal{R}^n} \|r_0 - A[v_1, W_{n-1}]\, t\| \tag{4.8}$$

$$= \min_{t \in \mathcal{R}^n} \|r_0 - W_n S_n\, t\|\,. \tag{4.9}$$

Solving the LS problem (4.8)–(4.9) in a numerically stable way represents a more subtle task then solving (4.3)–(4.4). The main difference is in handling the right-hand side vector r_0. In (4.3)–(4.4), r_0 is expressed in terms of the vectors $v_1, v_2, \ldots, v_n$ simply as $r_0 = v_1 \rho_0$. In finite precision arithmetic, until the linear independence of the vectors $v_1, v_2, \ldots, v_n$ is lost, this expression is maximally accurate. On the other hand, application of the orthogonal projection principle (1.4) directly to (4.8)–(4.9) gives the upper triangular system

$$S_n\, t_n \;=\; W_n^T r_0. \tag{4.10}$$

As demonstrated in [25], computing the vector of coefficients t_n from (4.10) leads to numerical difficulties. Numerically more stable implementations are described next.

First consider the implementation of Simpler GMRES using the modified Gram–Schmidt process for generating the basis vectors $w_1, \ldots, w_n$. A properly implemented algorithm for solving the LS problem (4.8)–(4.9) applies the orthogonalization process also to the right-hand side r_0 (see [4, pp. 64–65]). Then, using the recursive columnwise modified Gram–Schmidt QR-factorization of the extended matrix $[Av_1, AW_{n-1}, r_0]$,

$$[Av_1, AW_{n-1}, r_0] \;=\; W_n\,[S_n, z_n] \,+\, \left[0, \frac{r_n}{\|r_n\|}\right] \left[\begin{array}{c} 0 \\ \|r_n\| \end{array}\right], \tag{4.11}$$

the vector t_n solves the upper triangular system

$$S_n\, t_n \;=\; z_n. \tag{4.12}$$

The jth component of $z_n \equiv (\zeta_1, \ldots, \zeta_n)^T$ is determined by

$$\zeta_j \;=\; w_j^T\,(I - w_{j-1}w_{j-1}^T)\cdots(I - w_1 w_1^T)\,r_0 \;=\; w_j^T\, r_{j-1}\,, \tag{4.13}$$

where we use

$$r_j \;=\; (I - w_j w_j^T)\cdots(I - w_1 w_1^T)\,r_0 \;=\; r_{j-1} \,-\, (w_j^T\, r_{j-1})\, w_{j-1}\,. \tag{4.14}$$

A complete algorithm of the modified Gram–Schmidt implementation of Simpler GMRES is given in the appendix.

Now we consider the implementation of Simpler GMRES based on Householder reflections. It transforms the matrix $[Av_1, AW_{n-1}]$ into upper triangular form,

$$P_n \cdots P_2 P_1\,[Av_1, AW_{n-1}] \;=\; \left[\begin{array}{c} S_n \\ 0 \end{array}\right], \tag{4.15}$$

where $P_j,\;\, j \,=\, 1, \ldots, n$, are elementary Householder matrices. (For details, see [9, p. 312].) Then the transformed right-hand side is determined as

$$z_n \;=\; [P_n \cdots P_1\, r_0]_{\{1:n\}},$$

where $[\cdot]_{\{1:n\}}$ denotes the first n elements of a vector. The vector of coefficients t_n is determined from (4.12). A complete algorithm of the Householder implementation of Simpler GMRES is given in the appendix.

Related to Simpler GMRES are stabilized Orthodir [31] and the recent A^TA-variant of GMRES [25]. Both compute an A^TA-orthogonal basis of $\mathcal{K}_n(A, r_0)$, and thus each step of these methods requires about twice as much storage and also slightly more arithmetic operations than Simpler GMRES. They are also numerically less stable than Simpler GMRES. On the other hand, they allow easier parallel implementations because they feature step by step updates of both the approximate solution and the residual vectors.

5. Numerical stability. In this section we analyze and compare the numerical stability of Classical and Simpler GMRES. As mentioned in section 4, different orthogonalization techniques for computing the columns of V_n or W_n can be applied. Here we focus on implementations based on Householder transformations [32, 33] and on the modified Gram–Schmidt process [26].

For distinction, we denote quantities computed in finite precision arithmetic (with the machine precision ε) by bars. We assume the standard model of floating point arithmetic (see, e.g., [15, equation (2.4)]). In our bounds we present only those terms which are linear in ε and do not account for the terms proportional to higher powers of ε. By $p_k(n,m,N)$, $k=1,2,\ldots$, we denote low degree polynomials in the number of iteration steps n, the maximum number of nonzeros per row in the system matrix m, and the dimension of the system N. They are introduced in a number of places in the text; some of them depend only on one or two variables. In all cases, $p_k(n,m,N) \leq c_k N^{5/2}$, where $c_k > 0$ is a constant independent of n, m, and N. This bound is, in general, very pessimistic; it accounts for the worst possible case. For details, see [9, 14, 24].

5.1. Classical GMRES. In the Classical GMRES implementation the computed approximate solution $\bar{x}_n$ satisfies

$$\begin{aligned} \bar{x}_n &= x_0 + \bar{V}_n \bar{y}_n + g_n, \\ \|g_n\| &\leq \varepsilon \|x_0\| + p_1(n)\,\varepsilon \|\bar{V}_n\| \|\bar{y}_n\|. \end{aligned} \tag{5.1}$$

It was shown in [9, 14] that the computed matrix $\bar{V}_n = [\bar{v}_1, \bar{v}_2, \ldots, \bar{v}_n]$ satisfies the recurrence

$$\begin{aligned} [\bar{r}_0, A\bar{V}_n] &= \hat{V}_{n+1}\,[\bar{\rho}_0 e_1, \bar{H}_{n+1,n}] + [f_n, F_n]\,, \\ \|f_n\| &\leq p_2(m,N)\,\varepsilon \|A\| \|x_0\| + p_3(N)\,\varepsilon \|b\|, \\ \|F_n\| &\leq p_4(n,m,N)\,\varepsilon \|A\| \|\bar{V}_n\|, \end{aligned} \tag{5.2}$$

where the matrix $\hat{V}_{n+1}$ has exactly orthogonal columns ($\hat{V}_{n+1}^T \hat{V}_{n+1} = I_{n+1}$). The vector $\bar{y}_n$ is a computed solution of the finite precision analogue of the transformed LS problem (4.4), and $\bar{r}_0$ satisfies

$$\|\bar{r}_0 - (b - Ax_0)\| \leq p_5(m,N)\,\varepsilon \|A\| \|x_0\| + p_6(N)\,\varepsilon \|b\|\,. \tag{5.3}$$

For details, we refer to [9] and also to [24, pp. 25–26].

Our goal is not to give a complete rounding error analysis of GMRES. (For the Householder implementation of Classical GMRES this was published in [9], and the modified Gram–Schmidt implementation of Classical GMRES has been analyzed in [14, 24, 21].) We wish to explain that there is a potential weakness of Simpler GMRES which may negatively affect its computational behavior in comparison with Classical GMRES. For this purpose we can simplify our description of the GMRES convergence. This allows us to avoid tedious details which would make reading of this section difficult. We will describe the convergence of Classical GMRES by the norm of the LS residual associated with the matrix $A\bar{V}_n$ and the computed initial residual $\bar{r}_0$:

$$\|\hat{r}_n\| \equiv \|\bar{r}_0 - A\bar{V}_n \hat{y}_n\| = \min_y \|\bar{r}_0 - A\bar{V}_n y\|. \tag{5.4}$$

The analysis in [14, section 3] as well as numerical experiments confirm that for Classical GMRES $\|\hat{r}_n\|$ is close to the norm of the actually computed GMRES residual $\|b - A\bar{x}_n\|$.

It follows immediately from (2.14) that the residual norm (5.4) can be bounded in terms of the minimal singular values of matrices $[\bar{r}_0, A\bar{V}_n]$ and $A\bar{V}_n$ as

$$\sigma_{min}([\bar{r}_0, A\bar{V}_n]) \leq \|\hat{r}_n\| \leq \sigma_{min}([\bar{r}_0, A\bar{V}_n]) \left\{ 1 - \frac{\sigma_{min}^2([\bar{r}_0, A\bar{V}_n])}{\sigma_{min}^2(A\bar{V}_n)} + \frac{\|\bar{r}_0\|^2}{\sigma_{min}^2(A\bar{V}_n)} \right\}^{1/2}. \tag{5.5}$$

We see that convergence of the residual $\hat{r}_n$ is closely related to ill-conditioning of the matrix $[\bar{r}_0, A\bar{V}_n]$; i.e., decreasing $\|\hat{r}_n\|$ leads to ill-conditioning of $[\bar{r}_0, A\bar{V}_n]$. Moreover, it follows from (5.2) and from classical perturbation theory (see, e.g., [13, p. 449]), that the minimum singular values of the matrices $[\bar{r}_0, A\bar{V}_n]$ and $[\bar{\rho}_0 e_1, \bar{H}_{n+1,n}]$ are close to each other:

$$\left|\sigma_{min}([\bar{\rho}_0 e_1, \bar{H}_{n+1,n}]) - \sigma_{min}([\bar{r}_0, A\bar{V}_n])\right| \le \|[f_n, F_n]\| \,. \tag{5.6}$$

Consequently, decreasing $\|\hat{r}_n\|$ leads to ill-conditioning of the matrix $[\bar{\rho}_0 e_1, \bar{H}_{n+1,n}]$. The vector $\bar{y}_n$ from (5.1) is a computed solution of the LS problem

$$\min_y \|e_1 \bar{\rho}_0 - \bar{H}_{n+1,n} y\|. \tag{5.7}$$

Using (5.2), the extremal singular values of $\bar{H}_{n+1,n}$ can be bounded by

$$\|\bar{H}_{n+1,n}\| \le \|A\bar{V}_n\| + \|F_n\| \le \|A\|\|\bar{V}_n\| + \|F_n\|, \tag{5.8}$$

$$\sigma_{min}(\bar{H}_{n+1,n}) \ge \sigma_{min}(A\bar{V}_n) - \|F_n\| \ge \sigma_{min}(A)\,\sigma_{min}(\bar{V}_n) - \|F_n\|. \tag{5.9}$$

When $\|\hat{r}_n\|$ (and $\|b - A\bar{x}_n\|$) decreases, $\sigma_{min}([\bar{r}_0, A\bar{V}_n])$ and $\sigma_{min}([\bar{\rho}_0 e_1, \bar{H}_{n+1,n}])$ also decrease. However, while the columns of $\bar{V}_n$ (the Arnoldi vectors) keep their linear independence (while $\sigma_{min}(\bar{V}_n) \approx 1$), *the condition number of the computed upper Hessenberg matrix* $\bar{H}_{n+1,n}$ *is essentially bounded by the condition number of* A. Consequently, until the linear independence of the Arnoldi vectors begins to deteriorate, the solution $\bar{y}_n$ of the transformed LS problem and the GMRES solution $\bar{x}_n$ are affected by rounding errors in a minimal possible way. This distinguishes Classical GMRES from the other MR methods, in particular from Simpler GMRES. Finite precision analysis of the QR-factorization of the matrix $\bar{H}_{n+1,n}$ via Givens rotations and of forming the GMRES solution can be found in [9] or [24, equations (4.6)–(4.12)].

It is important to note that not the orthogonality but the linear independence of the columns of $\bar{V}_n$ (measured by its extremal singular values) plays a decisive role in the relations (5.8) and (5.9). If we use Householder reflections in the Arnoldi process, the loss of orthogonality among the computed columns of $\bar{V}_n$ and the extremal singular values of $\bar{V}_n$ are bounded independent of the system parameters

$$1 - p_7(n, N)\,\varepsilon \le \sigma_n(\bar{V}_n) \le \|\bar{V}_n\| \le 1 + p_7(n, N)\,\varepsilon. \tag{5.10}$$

Moreover, it was shown in [9] that the Householder implementation of Classical GMRES is backward stable. Assuming that a conjecture similar to (5.10) holds, the same result can also be shown for the iterated classical or modified Gram–Schmidt implementations; see [9].

In practical computations, cheaper orthogonalization techniques like the modified Gram–Schmidt algorithm are used. It is well known that the orthogonality among the columns of $\bar{V}_n$ computed via the modified Gram–Schmidt process will gradually deteriorate. However, from [14, equation (1.7) and Corollary 2.4] it follows that

$$\|\hat{V}_n - \bar{V}_n\| \le p_8(n, m, N)\,\varepsilon\kappa([\bar{v}_1, A\bar{V}_{n-1}]), \tag{5.11}$$

and the minimal singular value and the norm of $\bar{V}_n$ are bounded by

$$1 - \frac{p_9(n, m, N)\,\varepsilon\kappa(A)}{\|\hat{r}_{n-1}\|/\bar{\rho}_0} \le \sigma_n(\bar{V}_n) \le \|\bar{V}_n\| \le 1 + \frac{p_9(n, m, N)\,\varepsilon\kappa(A)}{\|\hat{r}_{n-1}\|/\bar{\rho}_0}. \tag{5.12}$$

The columns of $\bar{V}_n$ will thus begin to lose their linear independence *only after* the relative residual norm is reduced close to the level $\varepsilon\kappa(A)$. Up to that point the modified Gram–Schmidt implementation of Classical GMRES behaves about as well as the Householder implementation.

It was shown in [20, 21] that there is a tight relation between the normwise backward error $\|b - Ax_n\|/(\|A\|\|x_n\| + \|b\|)$ associated with the approximate solution x_n and the condition number of the matrix $[r_0, AV_n]$. A finite precision analogy of this statement will prove normwise backward stability of the modified Gram–Schmidt implementation of Classical GMRES. A formal proof will be given elsewhere.

The results in [20, 21] are based on (2.16). We could have also used (2.16) instead of (2.14) in our derivation here, which would lead to tighter estimates. However, using (2.14) makes our derivation much simpler, and the results are fully sufficient for our purpose.

5.2. Simpler GMRES. In Simpler GMRES the approximate solution $\bar{x}_n$ computed in finite precision arithmetic satisfies

$$\begin{aligned}\bar{x}_n &= x_0 + [\bar{v}_1, \bar{W}_{n-1}]\,\bar{t}_n + g_n,\\ \|g_n\| &\le \varepsilon\|x_0\| + p_1(n)\,\varepsilon\|[\bar{v}_1, \bar{W}_{n-1}]\|\,\|\bar{t}_n\|.\end{aligned} \tag{5.13}$$

Analogously to (5.2), for every iteration step n there exists a matrix $\hat{W}_n$ with exactly orthonormal columns ($\hat{W}_n^T\hat{W}_n = I$) such that

$$\begin{aligned}A[\bar{v}_1, \bar{W}_{n-1}] &= \hat{W}_n\bar{S}_n + F_n,\\ \|F_n\| &\le p_4(n,m,N)\,\varepsilon\|A\|\|[\bar{v}_1, \bar{W}_{n-1}]\|.\end{aligned} \tag{5.14}$$

The vector of coefficients $\bar{t}_n$ is computed by solving the upper triangular system with the matrix $\bar{S}_n$. From (5.14) the extremal singular values of the matrix $\bar{S}_n$ are bounded by

$$\|\bar{S}_n\| \le \|A[\bar{v}_1, \bar{W}_{n-1}]\| + \|F_n\| \le \|A\|\|[\bar{v}_1, \bar{W}_{n-1}]\| + \|F_n\|, \tag{5.15}$$

$$\begin{aligned}\sigma_{min}(\bar{S}_n) &\ge \sigma_{min}(A[\bar{v}_1, \bar{W}_{n-1}]) - \|F_n\|\\ &\ge \sigma_{min}(A)\,\sigma_{min}([\bar{v}_1, \bar{W}_{n-1}]) - \|F_n\|.\end{aligned} \tag{5.16}$$

The minimal singular value of the matrix $[\bar{v}_1, \bar{W}_{n-1}]$ can further be related to the minimal singular value of the matrix $[\bar{r}_0/\|\bar{r}_0\|, \hat{W}_{n-1}]$, where $\hat{W}_{n-1}$ comes from the recurrence (5.14),

$$\sigma_n([\bar{v}_1, \bar{W}_{n-1}]) \ge \sigma_n([\bar{r}_0/\|\bar{r}_0\|, \hat{W}_{n-1}]) - \|[\bar{v}_1 - \bar{r}_0/\|\bar{r}_0\|, \bar{W}_{n-1} - \hat{W}_{n-1}]\|. \tag{5.17}$$

For the condition number $\kappa([\bar{r}_0/\|\bar{r}_0\|, \hat{W}_{n-1}])$ it follows from (3.6) that

$$\kappa([\bar{r}_0/\|\bar{r}_0\|,\, \hat{W}_{n-1}]) = \frac{\|\bar{r}_0\| + \left(\|\bar{r}_0\|^2 - \|\hat{r}_{n-1}\|^2\right)^{1/2}}{\|\hat{r}_{n-1}\|}, \tag{5.18}$$

where $\hat{r}_{n-1} \equiv (I - \hat{W}_{n-1}\hat{W}_{n-1}^T)\,\bar{r}_0$ is the LS residual associated with the matrix $\hat{W}_{n-1}$, $\|\hat{r}_{n-1}\| = \min_y \|\bar{r}_0 - \hat{W}_{n-1}y\|$. The identity (5.18) proves that *convergence of the residual norm $\|\hat{r}_{n-1}\|$ and ill-conditioning of the matrix $[\bar{r}_0/\|\bar{r}_0\|, \hat{W}_{n-1}]$ are closely related.*

Summarizing, small $\|\bar{W}_{n-1} - \hat{W}_{n-1}\|$ means $\kappa([\bar{v}_1, \bar{W}_{n-1}]) \approx \kappa([\bar{r}_0/\|\bar{r}_0\|, \hat{W}_{n-1}])$. (It can be shown that $\|\bar{v}_1 - \bar{r}_0/\|\bar{r}_0\|\| \le (N+4)\varepsilon$; see [9].) Using (5.15) and (5.16), we conclude that *decreasing* $\|\hat{r}_{n-1}\|$ *may lead to ill-conditioning of the upper triangular matrix* $\bar{S}_n$*, and thus to a potentially large error in computing the vector* $\bar{t}_n$*, independent of the (well-) conditioning of the matrix* A. This important fact may negatively affect the numerical accuracy of the approximate solution $\bar{x}_n$ in Simpler GMRES in comparison to Classical GMRES.

Until $\bar{S}_n$ becomes pathologically ill-conditioned, $\|\hat{r}_n\|$ is (similarly to subsection 5.1) close to $\|b - A\bar{x}_n\|$. After that the behavior of $\|\hat{r}_n\|$ and $\|b - A\bar{x}_n\|$ may be significantly different.

We have seen that the relation between the condition number of the matrix $\bar{S}_n$ and the condition number of the matrix $[\bar{r}_0/\|\bar{r}_0\|, \hat{W}_{n-1}]$ (the decrease of $\|\hat{r}_n\|$) is strongly affected by the size of the term $\|\bar{W}_{n-1} - \hat{W}_{n-1}\|$. In the Householder implementation the computed matrix $\bar{W}_{n-1}$ is, up to a small multiple of the machine precision, close to the matrix $\hat{W}_{n-1}$ with exactly orthogonal columns,

$$\|\bar{W}_{n-1} - \hat{W}_{n-1}\| \leq p_7(n, N)\, \varepsilon. \tag{5.19}$$

It follows from (5.19) that the condition number $\kappa([\bar{v}_1, \bar{W}_{n-1}])$ is, up to terms proportional to the machine precision, equal to $\kappa([\bar{r}_0/\|\bar{r}_0\|, \hat{W}_{n-1}])$. In practice one frequently observes that after $\|b - A\bar{x}_n\|/\|\bar{r}_0\|$ reaches some particular point the norm of the computed vector $\bar{t}_n$ starts to increase dramatically (the computed results become irrelevant due to rounding errors), and the residual norm $\|b - A\bar{x}_n\|$ diverges.

For the modified Gram–Schmidt implementation we have

$$\|\bar{W}_{n-1} - \hat{W}_{n-1}\| \leq p_8(n, m, N)\, \varepsilon \kappa(A[\bar{v}_1, \bar{W}_{n-1}]). \tag{5.20}$$

Because $\kappa(A[\bar{v}_1, \hat{W}_{n-1}])$ is potentially much worse than $\kappa([\bar{v}_1, A\hat{V}_{n-1}])$, the linear independence of the columns of $\bar{W}_n$ often begins to deteriorate much sooner than the linear independence of the columns of $\bar{V}_n$ in Classical GMRES. Until that point the modified Gram–Schmidt and Householder implementations of Simpler GMRES behave similarly. In subsequent iterations, surprisingly, the behavior of the modified Gram–Schmidt implementation of Simpler GMRES may be better than the behavior of the Householder implementation. For the Householder implementation of Simpler GMRES the true residual $b - A\bar{x}_n$ often diverges. This has been linked to the tight relation between $\kappa([\bar{r}_0/\|\bar{r}_0\|, \hat{W}_{n-1}])$ and $\kappa([\bar{v}_1, \bar{W}_{n-1}])$, and, consequently, to the relation between the decrease of $\|\hat{r}_n\|$ and the simultaneous increase of $\kappa(\bar{S}_n)$. For the modified Gram–Schmidt implementation, after reaching a certain point no such relations hold. The norm of $\bar{t}_n$ does not diverge, and the norm of the true residual remains (and often slightly oscillates) on or below the level corresponding to the turning point for the Householder implementation.

5.3. Numerical experiments. The different behavior of Classical and Simpler GMRES implementations is demonstrated by numerical examples with the matrix FS1836 from the Harwell–Boeing collection, $N = 183$, $\kappa(A) = 1.5 \times 10^{11}$, $\|A\| = 1.2 \times 10^9$. Experiments were performed using MATLAB 5.2, $\varepsilon = 1.1 \times 10^{-16}$. Householder and modified Gram–Schmidt orthogonalizations have been considered for both Classical and Simpler GMRES. In all experiments we used $x = (1, \ldots, 1)^T$, $b = Ax$, and $x_0 = 0$ ($\|\bar{r}_0\| = \|b\|$).

Figures 1 and 2 illustrate characteristics of the transformed LS problem (5.7) for the Householder and the modified Gram–Schmidt implementations of Classical GMRES. In both figures horizontal dotted lines represent $\|A\|$ and the minimal singular value $\sigma_{min}(A)$. The dashed lines show $\|\bar{H}_{n+1,n}\|$, the norm of the computed

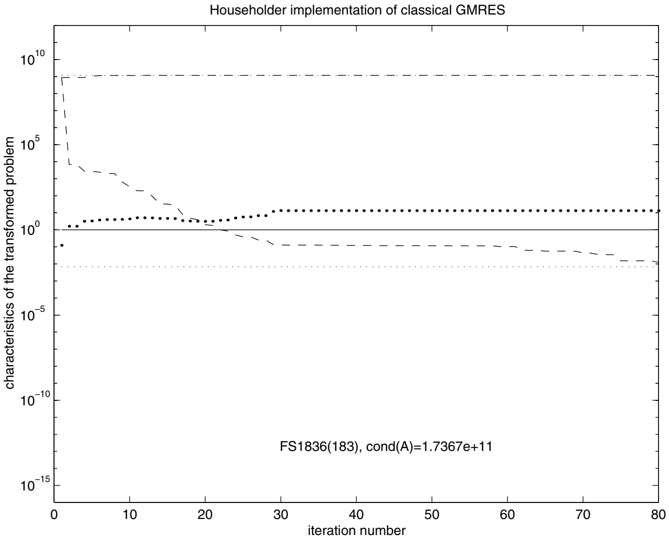

FIG. 1. *Householder implementation of Classical GMRES: $\|A\|$ and $\sigma_{min}(A)$ (dotted lines), $\|\bar{H}_{n+1,n}\|$ and $\sigma_{min}(\bar{H}_{n+1,n})$ (dashed lines), $\sigma_{min}(\bar{V}_n)$ (solid line), and $\|\bar{y}_n\|$ (dots).*

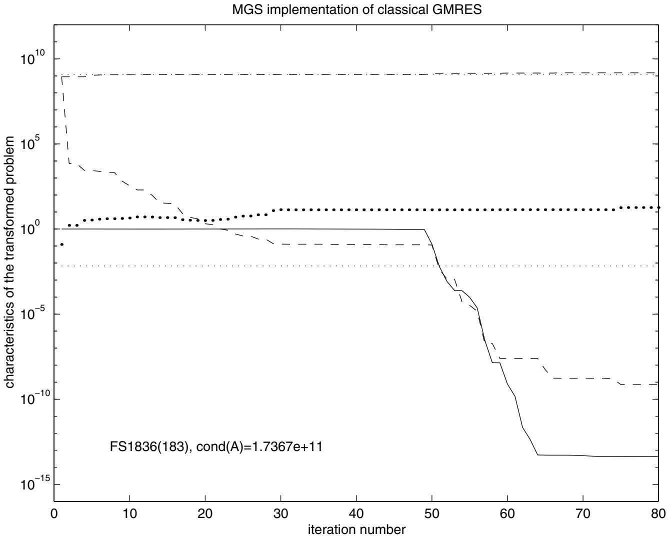

FIG. 2. *Modified Gram–Schmidt implementation of Classical GMRES: $\|A\|$ and $\sigma_{min}(A)$ (dotted lines), $\|\bar{H}_{n+1,n}\|$ and $\sigma_{min}(\bar{H}_{n+1,n})$ (dashed lines), $\sigma_{min}(\bar{V}_n)$ (solid line), and $\|\bar{y}_n\|$ (dots).*

upper Hessenberg matrix (it almost coincides with $\|A\|$), and the minimal singular value $\sigma_{min}(\bar{H}_{n+1,n})$. The solid line stands for $\sigma_{min}(\bar{V}_n)$, the minimal singular value of the matrix of computed Arnoldi vectors, and the dots depict $\|\bar{y}_n\|$, the norm of the computed solution vector of (5.7). We see that until the linear independence of the columns of $\bar{V}_n$ in the modified Gram–Schmidt implementation begins to deteriorate, Figures 1 and 2 are almost identical. There is no substantial growth in $\|\bar{y}_n\|$ even after the linear independence of the computed Arnoldi vectors is completely lost (cf. Figure 2).

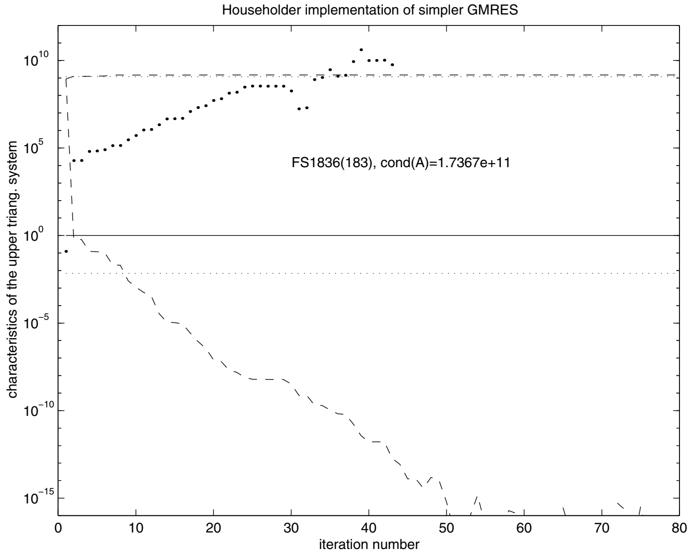

FIG. 3. *Householder implementation of Simpler GMRES: $\|A\|$ and $\sigma_{min}(A)$ (dotted lines), $\|\bar{S}_n\|$ and $\sigma_{min}(\bar{S}_n)$ (dashed lines), $\sigma_{min}(\bar{W}_n)$ (solid line), and $\|\bar{t}_n\|$ (dots).*

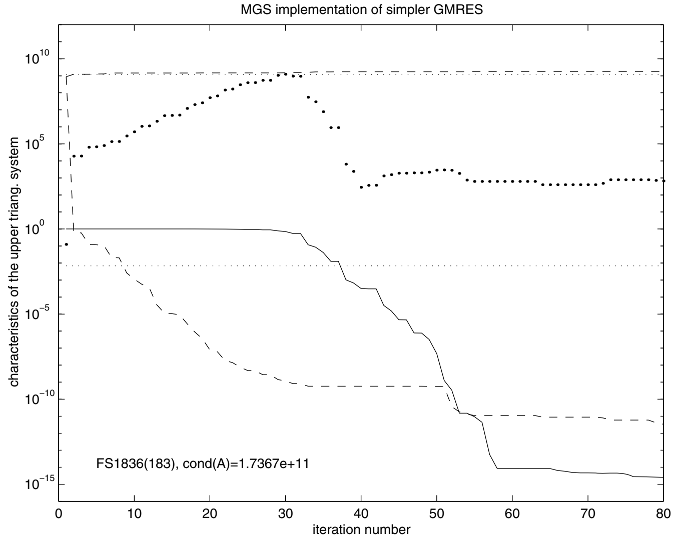

FIG. 4. *Modified Gram–Schmidt implementation of Simpler GMRES: $\|A\|$ and $\sigma_{min}(A)$ (dotted lines), $\|\bar{S}_n\|$ and $\sigma_{min}(\bar{S}_n)$ (dashed lines), $\sigma_{min}(\bar{W}_n)$ (solid line), and $\|\bar{t}_n\|$ (dots).*

Similar quantities are illustrated in Figures 3 and 4 for the Householder and the modified Gram–Schmidt implementations of Simpler GMRES. The dashed lines here represent $\|\bar{S}_n\|$, the norm of the computed upper triangular matrix, and its minimal singular value $\sigma_{min}(\bar{S}_n)$. The dots denote $\|\bar{t}_n\|$, the norm of the computed solution of the upper triangular system with the matrix $\bar{S}_n$.

We see that the condition number of the matrix $\bar{H}_{n+1,n}$ is in Figure 1 (the House-

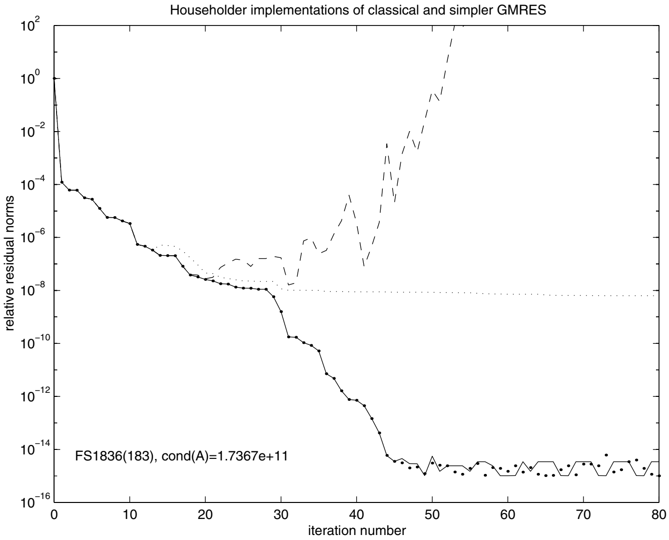

Fig. 5. *Householder implementation of Classical and Simpler GMRES: Normalized true residual norm $\|b - A\bar{x}_n\|/\|b\|$ (solid line—Classical GMRES, dashed line—Simpler GMRES), and $\|\hat{r}_n\|/\|b\|$ (dots—Classical GMRES, dotted line—Simpler GMRES).*

holder implementation of Classical GMRES) approximately bounded by the condition number of A, and for Figure 2 (the modified Gram–Schmidt implementation of Classical GMRES) the same is true until $\sigma_{min}(\bar{V}_n)$ begins to deteriorate. In contrast, in both implementations of Simpler GMRES, the minimal singular value of $\bar{S}_n$ decreases very soon far below $\sigma_{min}(A)$. Consequently, the accuracy of the computed vector $\bar{t}_n$ deteriorates, and for the Householder implementation $\|\bar{t}_n\|$ diverges. Also note the difference between $\sigma_{min}(\bar{V}_n)$ and $\sigma_{min}(\bar{W}_n)$ in Figures 2 and 4.

In Figure 5 we compare the convergence characteristics for the Householder implementations of both Classical GMRES ($\|b - A\bar{x}_n\|/\|b\|$ is represented by the solid line, $\|\hat{r}_n\|/\|b\|$ by dots) and Simpler GMRES ($\|b - A\bar{x}_n\|/\|b\|$ is represented by the dashed line, $\|\hat{r}_n\|/\|b\|$ by the dotted line). Figure 5 illustrates our theoretical considerations and shows that the true residual norm of the Householder implementation of Simpler GMRES may after some initial reduction diverge. Figure 6 uses similar notation for the illustration of the modified Gram–Schmidt implementations. The residual norm of Simpler GMRES again exhibits worse behavior than the residual norm corresponding to Classical GMRES.

6. Conclusions.

MR methods can be formulated and implemented using different bases and different orthogonalization processes. Using general theoretical results about the LS residual, this paper shows that the choice of the basis is fundamental for getting revealing theoretical results about convergence of MR methods. It is also important for getting a numerically stable implementation. The choice of the computed basis may strongly affect the numerical behavior of the implementation. It is explained that using the best orthogonalization technique in building the basis does not compensate for the possible loss of accuracy in a given method which is related to the choice of the basis. In particular, it is shown that the classical implementation of GMRES, which is based on the Arnoldi process starting from the normalized initial residual (as proposed by Saad and Schultz), has numerical advantages over Simpler

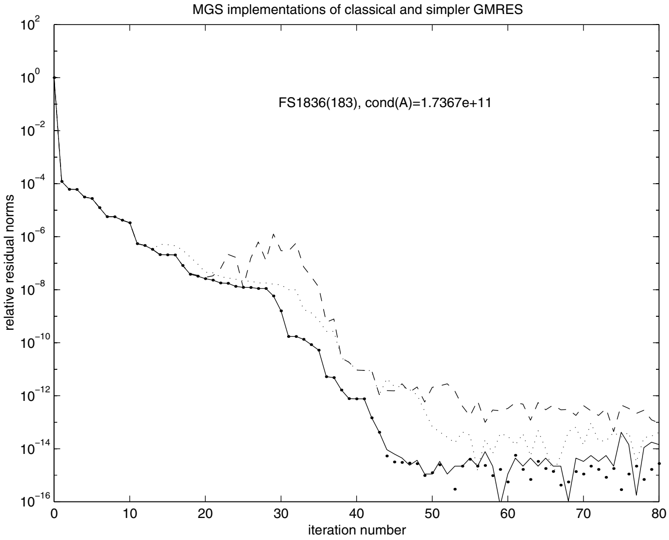

FIG. 6. *Modified Gram–Schmidt implementation of Classical and Simpler GMRES: Normalized true residual norm $\|b - A\bar{x}_n\|/\|b\|$ (solid line—Classical GMRES, dashed line—Simpler GMRES), and $\|\hat{r}_n\|/\|b\|$ (dots—Classical GMRES, dotted line—Simpler GMRES).*

GMRES, which is based on the shifted Arnoldi process.

7. Appendix.

Here we present the implementations of Simpler GMRES used throughout the paper.

Modified Gram–Schmidt implementation of Simpler GMRES:

```
$x_0$, $r_0 = b - Ax_0$, $v_1 = r_0/\|r_0\|$, $w_0 = v_1$
$n = 1, 2, \ldots$
    $w_n = Aw_{n-1}$
    $j = 1, 2, \ldots, n-1$
        $w_n \leftarrow w_n - \rho_{j,n} w_j$,  $\rho_{j,n} = (w_n, w_j)$
    $w_n \leftarrow w_n/\rho_{n,n}$,  $\rho_{n,n} = \|w_n\|$
    $S_n = \begin{pmatrix} S_{n-1} & \rho_{1,n} \\ & \vdots \\ 0 & \rho_{n,n} \end{pmatrix}$,  $S_1 = (\rho_{1,1})$
    $r_n = r_{n-1} - \zeta_n w_n$,  $\zeta_n = (r_{n-1}, w_n)$
    Solve $S_n\, t_n = (\zeta_1, \ldots, \zeta_n)^T$
    $x_n = x_0 + [v_1, w_1, \ldots, w_{n-1}]\, t_n$
```

Householder implementation of Simpler GMRES:

```
$x_0,\ r_0 = b - Ax_0,\ v_1 = r_0/\|r_0\|,\ (\zeta_1, \ldots, \zeta_N)^T = r_0,\ w_0 = v_1$

$n = 1, 2, \ldots$

    Compute $P_n$ such that $P_n\, Aw_{n-1} = (\rho_{1,n}, \ldots, \rho_{n,n}, 0, \ldots, 0)^T$

    $S_n = \begin{pmatrix} S_{n-1} & \rho_{1,n} \\ & \vdots \\ 0 & \rho_{n,n} \end{pmatrix}, \quad S_1 = (\rho_{1,1})$

    $(\zeta_1, \ldots, \zeta_N)^T \leftarrow P_n\, (\zeta_1, \ldots, \zeta_N)$

    Solve    $S_n\, t_n = (\zeta_1, \ldots, \zeta_n)^T$

    $r_n = r_{n-1} - \zeta_n w_n$

    $w_n = P_1 \ldots P_n\, e_n$

    $x_n = x_0 + [v_1, w_1, \ldots, w_{n-1}]\, t_n$
```

Acknowledgments. The authors are indebted to Chris Paige for his comments which improved the formulation and interpretation of several results. They also wish to thank the referees for their comments which improved presentation of the results.

A SEMI-LAGRANGIAN SEMI-IMPLICIT NUMERICAL METHOD FOR MODELS OF THE URINE CONCENTRATING MECHANISM*

ANITA T. LAYTON† AND HAROLD E. LAYTON‡

Abstract. Mathematical models of the urine concentrating mechanism consist of large systems of coupled differential equations. The numerical methods that have usually been used to solve the steady-state formulation of these equations involve implicit Newton-type solvers that are limited by numerical instability attributed to transient flow reversal. Dynamic numerical methods, which solve the dynamic formulation of the equations by means of a direction-sensitive time integration until a steady state is reached, are stable in the presence of transient flow reversal. However, when an explicit, Eulerian-based dynamic method is used, prohibitively small time steps may be required owing to the CFL condition and the stiffness of the problem. In this report, we describe a semi-Lagrangian semi-implicit (SLSI) method for solving the system of hyperbolic partial differential equations that arises in the dynamic formulation. The semi-Lagrangian scheme advances the solution in time by integrating backward along flow trajectories, thus allowing large time steps while maintaining stability. The semi-implicit approach controls stiffness by averaging transtubular transport terms in time along flow trajectories. For sufficiently refined spatial grids, the SLSI method computes stable and accurate solutions with substantially reduced computation costs.

1. Introduction.

Mammals can produce urine that has a much higher osmolality than that of blood plasma.[1] This capability, which allows mammals to maintain a steady plasma osmolality during periods of water deprivation, is provided by the urine concentrating mechanism. Many model studies have sought to elucidate this mechanism, which is localized in the renal medulla and which depends on a countercurrent configuration of fluid flows in thousands of nearly parallel tubules [5, 6, 9, 12, 20, 23].

Models of the urine concentrating mechanism have usually been formulated as steady-state boundary-value problems involving differential equations expressing solute and water conservation. The solutions describe solute concentrations and fluid flow rates in interacting tubules having diameters of ~ 20 μm and lengths of several millimeters. Models are typically formulated in one space dimension corresponding to the axis parallel to intratubular flow.

The steady-state model problem consists of a nonlinear system of coupled, stiff ordinary differential equations (ODEs), which are usually solved by adaptations of Newton's method [16, 18, 20, 23]. However, this formulation has to contend with the difficulty that intratubular flow may be transiently reversed relative to the assumed steady-state direction. This transient reversal of flow direction, which arises when

[1] Osmolality is approximated by a weighted sum of the solute concentrations [20].

transmural water fluxes are sufficiently large, may introduce numerical instability. In steady state, intratubular fluid flow in a tubule typically assumes a uniform direction, so flow reversal is a dynamic effect. However, iterates of a Newton-type method may pass through states that exhibit flow reversal, unless initial conditions that are sufficiently close to the steady-state solution are specified [5].

An alternative method for obtaining a solution to the steady-state equations is to formulate the problem in terms of its dynamic equations and then compute a steady-state solution to the dynamic equations. The dynamic equations form a nonlinear system of hyperbolic partial differential equations (PDEs), which represent solute conservation, and ODEs, which represent water conservation [5, 6]. A direction-sensitive time integration scheme, such as upwind differencing or the ENO (essentially nonoscillatory) scheme [2], has been used to advance the solution in time until a steady state is reached [5, 6]. These methods eliminate numerical instability arising from transient reversal of intratubular flow direction. However, owing to stiffness of the problem, which arises from transtubular transport terms, these explicit methods may require prohibitively small time steps, thus resulting in high computation cost.

The purpose of this paper is to describe a stable and efficient numerical method, based on the semi-Lagrangian semi-implicit (SLSI) scheme [13], for approximating solutions to the dynamic equations. The Lagrangian nature of this method avoids numerical instability arising from flow reversal, and its implicit nature controls stiffness and maintains stability even with large time steps.

In section 4, we present numerical results from the SLSI scheme that demonstrate second-order spatial convergence of the solution in a simple, one-solute model of the urine concentrating mechanism and in a two-solute model of the outer renal medulla, with parameters primarily from the rat. The one-solute model is an approximation to a model for which an explicit solution can be derived. In section 5, we compare the stability and efficiency of the SLSI method with the ENO method in models of the outer and inner renal medullas, and we show that the SLSI method is stable with a Courant–Friedrichs–Lewy (CFL) number much larger than 1, whereas the ENO method is limited by the CFL condition (i.e., the CFL number must be less than 1 to maintain numerical stability). Furthermore, compared with the ENO method, the SLSI method generates a solution with comparable accuracy in substantially less time, provided that the spatial grid is sufficiently refined.

2. Model equations.

In this section we introduce the equations for a simple dynamic model of the renal medulla. The model includes a single loop of Henle and a collecting duct. The loop of Henle has a descending limb and an ascending limb. The limbs of the loop of Henle and the collecting duct interact in a common tubular compartment, the central core. The central core represents all structures within the medulla but external to the loop of Henle and collecting duct, e.g., the interstitial spaces, interstitial cells, and vasculature. The central core formulation was introduced by Stephenson [15]. This model configuration is shown in Figure 2.1.

The model equations are based on conservation of solute and water in the renal medulla. A derivation of the equations can be found in [5]. The descending limb, ascending limb, collecting duct, and central core are represented by rigid tubules (indexed by $i = 1, 2, 3$, and 4, respectively) that extend in space from $x = 0$ to $x = L$. NaCl and urea are the two principal solutes of the renal medulla. For simplicity, we represent only the Cl^- and urea concentrations, denoted by $k = 1$ and 2, respectively.

The water flow rate at time t in a given tubule i is denoted by $F_{iV}(x, t)$, and the transmural (i.e., transtubular) water line flux (i.e., the water transport rate per

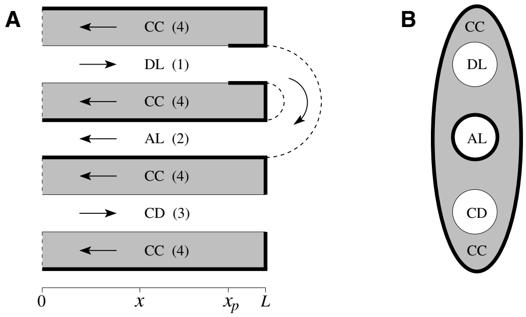

FIG. 2.1. *Model configuration. Panel* A: *Tubules along spatial axis. DL, descending limb* ($i = 1$)*; AL, ascending limb* ($i = 2$)*; CD, collecting duct* ($i = 3$)*; CC, central core* ($i = 4$)*; arrows, steady-state flow directions; thick lines, water-impermeable boundaries; prebend segment begins at* x_p (*see section* 4). *Panel* B: *Cross-section showing connectivity between CC and other tubules.*

unit tubular length) is given by $J_{iV}(x,t)$, taken positive for transport into the tubule. With this notation, water conservation, for $i = 1, 2, 3$, or 4, is represented by

$$\frac{\partial}{\partial x} F_{iV}(x,t) = J_{iV}(x,t). \tag{2.1}$$

Solute conservation is represented by

(2.2)
$$\frac{\partial}{\partial t} C_{ik}(x,t) = \frac{1}{\sqrt{A_i(x)}} \left(-F_{iV}(x,t) \frac{\partial}{\partial x} C_{ik}(x,t) + J_{ik}(x,t) - C_{ik}(x,t) J_{iV}(x,t) \right),$$

where $i = 1, 2, 3$, or 4 and $k = 1$ or 2. For a given tubule of type i, $C_{ik}(x,t)$ is the concentration of solute k, $A_i(x)$ is the cross-sectional area of the tubule, and $J_{ik}(x,t)$ is the transmural line flux of solute k, taken positive into the tubule. The three terms inside the outer parentheses on the right arise from axial intratubular solute convection, transmural solute transport, and transmural water transport, respectively. The first and third terms equal the spatial derivative of the solute flow, $F_{iV}(x,t)C_{ik}(x,t)$.

The transmural water flux across a descending limb, ascending limb, or collecting duct ($i = 1, 2$, or 3) is given by

$$J_{iV}(x,t) = 2\pi r_i(x) d_i(x) \sum_{k=1}^{2} \phi_k \sigma_{ik}(x) \left(C_{ik}(x,t) - C_{4k}(x,t) \right), \tag{2.3}$$

where $r_i(x)$ is the radius of the tubule, $d_i(x,y)$ is the product of the partial molar volume of water (0.018136 cm^3/mmole at 37°C) and the transmural osmotic water permeability $P_{f,i}(x)$, ϕ_k is the osmotic coefficient of solute k, and $\sigma_{ik}(x)$ is the reflection coefficient of solute k. For the central core, the equation for transmural water flux arises from the fluxes in (2.3) and is given by

$$J_{4V}(x,t) = -\left(J_{1V}(x,t) + J_{2V}(x,t) + J_{3V}(x,t) \right). \tag{2.4}$$

The transmural solute flux in a descending limb, ascending limb, or collecting duct ($i = 1, 2$, or 3) is given by

$$J_{ik}(x,t) = (1-\sigma_{ik}(x))J_{iV}(x,t)\left(C_{4k}(x,t)+C_{ik}(x,t)\right)/2$$
$$+\,2\pi r_i(x)\left(P_{ik}(x)\left(C_{4k}(x,t)-C_{ik}(x,t)\right)-\frac{V_{\max,ik}(x)C_{ik}(x,t)}{K_{M,ik}(x)+C_{ik}(x,t)}\right). \tag{2.5}$$

The first term on the right is the linearized solvent drag. The first term inside the pair of large parentheses is the transmural diffusion characterized by permeability $P_{ik}(x)$; the second term inside these parentheses represents active transport, characterized by maximum transport rate per unit tubular area $V_{\max,ik}(x)$ and Michaelis–Menten kinetics with Michaelis constant $K_{M,ik}(x)$. For the central core, the equation for solute flux arises from (2.5) and is given by

$$J_{4k}(x,t) = -\left(J_{1k}(x,t)+J_{2k}(x,t)+J_{3k}(x,t)\right). \tag{2.6}$$

To complete the system, boundary and initial conditions must be specified. At the entrances of the descending limb and collecting duct, $F_{1V}(0,t)$ and $F_{3V}(0,t)$, as well as $C_{1k}(0,t)$ and $C_{3k}(0,t)$ for each solute k, must be specified for $t \geq 0$. At the loop bend, the descending limb is continuous with the ascending limb; thus, $F_{2V}(L,t) = -F_{1V}(L,t)$, where the flow is taken positive in the increasing x direction; and for each solute k, $C_{2k}(L,t) = C_{1k}(L,t)$. The central core is assumed to be closed at $x = L$, which implies that there is no convective solute or fluid flow at $x = L$; thus, $F_{4V}(L,t) = 0$. Natural initial conditions are $C_{1k}(x,0) = C_{2k}(x,0) = C_{4k}(x,0) = C_{1k}(0,0)$, $C_{3k}(x,0) = C_{3k}(0,0)$, $F_{1V}(x,0) = -F_{2V}(x,0) = F_{1V}(0,0)$, $F_{3V}(x,0) = F_{3V}(0,0)$, and $F_{4V}(x,0) = 0$.

3. Discretization. In this section, we describe an algorithm to solve the model equations of section 2, (2.1)–(2.6), by a combination of the SLSI time discretization method and the trapezoidal rule. As previously noted, the goal is to develop an efficient numerical method that, like the Newton-type methods, controls the stiffness of the problem, and, like the explicit direction-sensitive integration schemes, maintains numerical stability in the presence of flow reversal.

The semi-Lagrangian treatment of advection, which is distinguished from the Lagrangian advection treatment by its backward, rather than forward, integration of flow trajectories, has generated considerable interest as a means for the efficient integration of equations arising in atmospheric models. Discretization schemes on the semi-Lagrangian treatment of advection offer the promise of larger time steps, with no loss in accuracy, in comparison with Eulerian-based advection schemes, in which the time-step size is limited by a more severe stability condition [11, 13].

In an Eulerian-based advection scheme, the observer is considered to be fixed at a position x as the world evolves. This scheme retains the regularity of the mesh (because the observer stays fixed), but small time steps may be required to satisfy the CFL condition and thus maintain numerical stability. In a Lagrangian-based scheme, the observer watches the world evolve while traveling along the trajectory of a fluid particle. This scheme is less restricted by stability requirements and therefore allows larger time steps than the Eulerian scheme. However, because the fluid particles move with time, an initially regularly spaced set of fluid particles generally becomes irregularly spaced as the system evolves.

A semi-Lagrangian advection scheme attempts to combine the advantages of both schemes—the grid regularity of the Eulerian scheme and the enhanced stability of the Lagrangian scheme—by approximating the Lagrangian derivative along trajectories defined by $dx/dt = u(x,t)$, where $u(x,t)$ denotes the flow velocity. In the model described in section 2, the flow velocity in a tubule of type i is given by $F_{iV}(x,t)/\sqrt{A_i(x)}$;

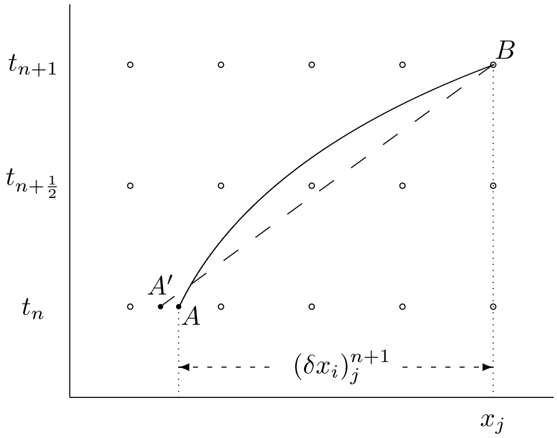

FIG. 3.1. *The semi-Lagrangian scheme approximates the Lagrangian derivative along the trajectory of a fluid particle. The curve AB denotes the actual trajectory, whereas the dashed line $A'B$ represents an approximate trajectory.*

therefore, the flow trajectory is defined by

$$\frac{d}{dt}x_i(t) = \frac{F_{iV}(x,t)}{\sqrt{A_i(x)}}. \tag{3.1}$$

Let Δt and Δx denote the time step and spatial grid interval, respectively, such that $\Delta t > 0$ and $\Delta x \equiv L/N$, where N is the number of spatial grid subintervals. Let $t_n \equiv n\Delta t$ be the nth time-level for $n = 0, 1, \ldots$, and let $x_j \equiv j\Delta x$ be the jth spatial grid point for $j = 0, 1, \ldots, N$. We adopt the two-time-level scheme[2] [13] that approximates a function associated with tubule i on a flow trajectory originating at the upstream departure point $(x_j - (\delta x_i)_j^{n+1})$ at t_n and terminating at the jth grid point x_j at t_{n+1}, where $\delta(x_i)_j^{n+1}$ denotes the displacement of the fluid particle in the time interval $[t_n, t_{n+1}]$. The trajectory is represented by the curve AB in Figure 3.1. For an arbitrary function $\psi(x,t)$, denote $\psi(x_j, t_n)$ by $(\psi)_j^n$. For a function ψ_i associated with tubule i, let $\widetilde{\psi}_i(x_j, t_n)$ (alternatively, $(\widetilde{\psi}_i)_j^n$) denote the function value at the departure point, i.e., $\psi_i(x_j - (\delta x_i)_j^{n+1}, t_n)$. Then the Lagrangian derivative of the solute concentration C_{ik} in (2.2) is approximated by

$$\left(\widetilde{\frac{d}{dt}C_{ik}}\right)_j^{n+\frac{1}{2}} = \left(\widetilde{\frac{\partial}{\partial t}C_{ik}}\right)_j^{n+\frac{1}{2}} + \left(\frac{\widetilde{F}_{iV}}{\sqrt{\widetilde{A}_i}}\widetilde{\frac{\partial}{\partial x}C_{ik}}\right)_j^{n+\frac{1}{2}} \approx \frac{(C_{ik})_j^{n+1} - (\widetilde{C}_{ik})_j^n}{\Delta t}. \tag{3.2}$$

The semi-Lagrangian approach provides accurate approximations for advection with virtually no time-step restriction. However, the transmural water and solute transport terms in (2.2) may render the equations stiff if the transmural permeabilities are sufficiently large. If these terms were treated explicitly, they would severely restrict the time step even with semi-Lagrangian advection approximations. Therefore, to obtain maximum benefit from the semi-Lagrangian approach, one needs to combine the semi-Lagrangian approximations with semi-implicit approximations. To this end,

[2] The alternative three-time-level semi-Lagrangian scheme approximates a trajectory originating at a spatial upstream departure point at time t_{n-1} and terminating at a spatial grid point at t_{n+1}.

the terms arising from water and solute transport in (2.2) are averaged in time along particle trajectories by

$$(\widetilde{C}_{ik}\widetilde{J}_{iV})_j^{n+\frac{1}{2}} \approx \frac{(C_{ik})_j^{n+1}(J_{iV})_j^{n+1} + (\widetilde{C}_{ik})_j^n(\widetilde{J}_{iV})_j^n}{2}, \qquad (\widetilde{J}_{ik})_j^{n+\frac{1}{2}} \approx \frac{(J_{ik})_j^{n+1} + (\widetilde{J}_{ik})_j^n}{2}. \tag{3.3}$$

3.1. Trajectory calculation. Before presenting the discretized form of (2.2), we describe how the upstream departure points and function values are computed. An approximate trajectory, represented by the dashed line $A'B$ in Figure 3.1, is estimated by a backward integration of (3.1). To obtain the trajectory velocities, we first compute intratubular water flows by numerically integrating (2.1) using the trapezoidal rule. For the descending limb and collecting duct ($i = 1$ or 3),

$$(F_{iV})_j^n = (F_{iV})_0^n + \frac{\Delta x}{2}\sum_{l=0}^{j-1}\left((J_{iV})_l^n + (J_{iV})_{l+1}^n\right). \tag{3.4}$$

For the ascending limb and central core ($i = 2$ or 4),

$$(F_{iV})_j^n = (F_{iV})_N^n - \frac{\Delta x}{2}\sum_{l=j}^{N-1}\left((J_{iV})_l^n + (J_{iV})_{l+1}^n\right), \tag{3.5}$$

where $(F_{2V})_N^n = -(F_{1V})_N^n$ (since $F_{2V}(L,t) = -F_{1V}(L,t)$) and $(F_{4V})_N^n = 0$ (since $F_{4V}(L,t) = 0$).

Using C_{ik} as an example, we now describe the computation of departure points and upstream function values. Flow trajectories are estimated by integrating (3.1) backward from the arrival point x_j at time t_{n+1} to the departure point $x_j - (\delta x_i)_j^{n+1}$ at time t_n by means of a second-order Runge–Kutta method:

$$(\delta x_i)_j^{n+1} \approx \frac{\Delta t}{2}\left(\frac{(F_{iV})_j^{n+1}}{\sqrt{(A_i)_j}} + \frac{F_{iV}(x_j - \Delta t(F_{iV})_j^{n+1}/\sqrt{(A_i)_j}, t_n)}{\sqrt{A_i(x_j - \Delta t(F_{iV})_j^{n+1}/\sqrt{(A_i)_j})}}\right). \tag{3.6}$$

The evaluation of the right side of (3.6) requires temporal extrapolation and spatial interpolation of F_{iV}, as will be explained shortly. The grid point values $(F_{iV})_j^n$ are given by (3.4) and (3.5). However, since the values of $(F_{iV})_j^{n+1}$, needed in the computation of $(\delta x_i)_j^{n+1}$ by (3.6), are unknown except possibly at the boundaries, they are extrapolated in time from known values at previous time steps:

$$(F_{iV})_j^{n+1} \approx 2(F_{iV})_j^n - (F_{iV})_j^{n-1}. \tag{3.7}$$

Another difficulty in estimating the trajectory arises from the second water flow term. Since the point $(x_j - \Delta t(F_{iV})_j^{n+1}/\sqrt{(A_i)_j}\ )$ will generally not coincide with a grid point, the value of $F_{iV}(x_j - \Delta t(F_{iV})_j^{n+1}/\sqrt{(A_i)_j}, t_n)$ may not be known. In that case, linear spatial interpolation based on the grid point values $(F_{iV})_j^n$ is used to approximate $F_{iV}(x_j - \Delta t(F_{iV})_j^{n+1}/\sqrt{(A_i)_j}, t_n)$ between grid points.

Once $(\delta x_i)_j^{n+1}$ is estimated, then if $x_j - (\delta x_i)_j^{n+1} \in [0, L]$, an approximation to C_{ik} at the departure points $(x_j - (\delta x_i)_j^{n+1}, t_n)$ can be computed from grid point values by cubic Lagrange spatial interpolation. In general, linear interpolation is sufficient for the computation of the flow trajectories [14, 17], and for the approximation of upstream function values it is economical to use cubic interpolation, which has fourth-order truncation error and little damping [25].

However, if an upstream departure point falls outside of the spatial domain (i.e., if $x_j - (\delta x_i)_j^{n+1} \notin [0, L]$), then the upstream function value must be estimated differently. The procedure depends on the type of the tubule and the position of the departure point. In the ascending limb, consider the case where $x_j - (\delta x_2)_j^{n+1} > L$, a likely case with a sufficiently large Δt since F_{2V} is negative with normal physiological parameters. Since the descending limb is continuous with the ascending limb at $x = L$, the upstream concentration in the ascending limb is given by $C_{2k}(x_j - (\delta x_2)_j^{n+1}, t_n) = C_{1k}(2L - x_j + (\delta x_2)_j^{n+1}, t_n)$. Similarly, for the descending limb, $C_{1k}^n(x_j - (\delta x_1)_j^{n+1}, t_n) = C_{2k}(2L - x_j + (\delta x_1)_j^{n+1}, t_n)$ if $x_j - (\delta x_1)_j^{n+1} > L$.

For the collecting duct and the central core, function values at departure points with values greater than x_N are estimated with cubic Lagrange extrapolation using function values at x_{N-3}, x_{N-2}, x_{N-1}, and x_N at time-level t_n. (Since normally F_{1V} and F_{3V} are positive at steady state, the associated departure points fall at values greater than x_N only in transient states.) Cubic Lagrange extrapolation is also used to approximate upstream function values associated with the ascending limb and central core if $x_j - (\delta x_i)_j^{n+1} < 0$; function values at x_0, x_1, x_2, and x_3 at $t = t_n$ are used.

If a departure point falls at a value less than x_0 in a descending limb or collecting duct, then the Lagrangian derivative approximation (3.2) and the semi-implicit approximation (3.3) are cast in terms of their respective boundary values at x_0. The upstream function value $(\widetilde{C}_{ik})_j^n$ is linearly extrapolated along the flow trajectory, using downstream and boundary function values, to give

$$\widetilde{C}_{ik}(x_j, t_n) = (1 - (\alpha_i^*)_j^{n+1}) C_{ik}(0, (\tau_i)_j^{n+1}) + (\alpha_i^*)_j^{n+1} C_{ik}(x_j, t_{n+1}), \tag{3.8}$$

where

$$(\alpha_i^*)_j^{n+1} \equiv \frac{x_j - (\delta x_i)_j^{n+1}}{x_j} \quad \text{and} \quad (\tau_i)_j^{n+1} \equiv t_n - \frac{(\alpha_i^*)_j^{n+1} \Delta t}{1 - (\alpha_i^*)_j^{n+1}}. \tag{3.9}$$

Figure 3.2 illustrates the relationship among $(\alpha_i)_j^{*n+1}$, $(\tau_i)_j^{n+1}$, and $C_{ik}(0, (\tau_i)_j^{n+1})$.

For an arbitrary function ψ_i associated with a tubule i, redefine $(\widetilde{\psi}_i)_j^n$ to be $(1 - (\alpha_i^*)_j^{n+1})\psi_i(0, (\tau_i)_j^{n+1})$ if $x_j - (\delta x_i)_j^{n+1} < 0$ and $i = 1$ or 3. Also, define the boundary correction factor $(\alpha_i)_j^{n+1}$ by

$$(\alpha_i)_j^{n+1} = \begin{cases} (\alpha_i^*)_j^{n+1}, & x_j - (\delta x_i)_j^{n+1} < 0 \text{ and } i = 1 \text{ or } 3, \\ 0 & \text{otherwise.} \end{cases} \tag{3.10}$$

With this notation, the Lagrangian derivative approximation (3.2) and the semi-implicit approximation (3.3) for C_{ik} can be rewritten to take into account upstream points that fall outside the spatial domain:

$$\left(\widetilde{\frac{d}{dt} C_{ik}} \right)_j^{n+\frac{1}{2}} \approx \frac{(1 - (\alpha_i)_j^{n+1})(C_{ik})_j^{n+1} - (\widetilde{C}_{ik})_j^n}{\Delta t}, \tag{3.11}$$

$$(\widetilde{C}_{ik})_j^{n+\frac{1}{2}} \approx \frac{1}{2} \left((1 + (\alpha_i)_j^{n+1})(C_{ik})_j^{n+1} + (\widetilde{C}_{ik})_j^n \right). \tag{3.12}$$

Equations (3.11) and (3.12) reduce to (3.2) and (3.3) for C_{ik}, respectively, when $0 \le x_j - (\delta x_i)_j^{n+1} \le L$. Approximations for $(\widetilde{J}_{iV})_j^n$ and $(\widetilde{J}_{ik})_j^n$ can be treated similarly.

FIG. 3.2. *A schematic diagram that illustrates relation* (3.8).

3.2. Numerical procedures. When discretized in time using the two-level SLSI scheme and evaluated at the grid points $\{x_j\}$, (2.2) takes the following form:

$$\frac{(1-(\alpha_i)_j^{n+1})(C_{ik})_j^{n+1}-(\widetilde{C}_{ik})_j^n}{\Delta t} = \frac{1}{2}\left(\frac{(1+(\alpha_i)_j^{n+1})(J_{ik})_j^{n+1}}{\sqrt{(A_i)_j}} + \frac{(\widetilde{J}_{ik})_j^n}{\sqrt{(\widetilde{A}_i)_j}} - \frac{(1+(\alpha_i)_j^{n+1})(C_{ik})_j^{n+1}(J_{iV})_j^{n+1}}{\sqrt{(A_i)_j}} - \frac{(\widetilde{C}_{ik})_j^n(\widetilde{J}_{iV})_j^n}{\sqrt{(\widetilde{A}_i)_j}}\right). \tag{3.13}$$

To obtain (3.13), the Lagrangian derivative dC_{ik}/dt was approximated by (3.11), and the transmural flux term J_{ik} and the water transport term $C_{ik}J_{iV}$ were averaged in time using approximations analogous to (3.12). Equations (2.3)–(2.6) and (3.13) form a nonlinear, coupled system, which we refer to as the *nonlinear kernel* and which we solve by means of Gauss–Seidel iteration. Specifically, at the mth iteration, we solve the following equations, obtained by rearranging (3.13), so that the unknown terms with $(C_{ik})_j^{n+1}$ are on the left and the other terms are on the right:

$$\left((1-\ (\alpha_i)_j^{n+1}) + \frac{\Delta t}{2\sqrt{(A_i)_j}}(J_{iV})_j^{n+1,[m-1]}\right)(C_{ik})_j^{n+1,[m]}$$
$$= (\widetilde{C}_{ik})_j^n + \frac{\Delta t}{2}\left((1+(\alpha_i)_j^{n+1})\frac{(J_{ik})_j^{n+1,[m-1]}}{\sqrt{(A_i)_j}} + \frac{(\widetilde{J}_{ik})_j^n}{\sqrt{(\widetilde{A}_i)_j}} - \frac{(\widetilde{C}_{ik})_j^n(\widetilde{J}_{iV})_j^n}{\sqrt{(\widetilde{A}_i)_j}}\right). \tag{3.14}$$

A summary of the integration algorithm and the iterative process is given at the end of this subsection. The Gauss–Seidel iteration is repeated until the iterates have sufficiently converged, that is, until the max-norm of successive iterations is less than a given tolerance TOL. Since our goal is to compute a steady-state solution, computation costs are reduced by adopting a larger TOL at the onset of the simulation when the system is far from its steady state and then refining the accuracy by reducing TOL when the solution is approaching a steady state. How far a given solution at time-level t_n differs from the steady-state solution is measured by computing the difference $\max_{i,k} |C_{ik}^n - C_{ik}^{n-1}|$, denoted by ΔC^n, from the previous solution at t_{n-1}. Thus, we choose the Gauss–Seidel tolerance dynamically as $\mathrm{TOL} = \min(\mathrm{TOL}_1, \max(0.1 \times \Delta C^n, \mathrm{TOL}_2))$, where $\mathrm{TOL}_1 > \mathrm{TOL}_2$.

In our implementation, a linear extrapolation, using values from the previous two time-levels, $C_{ik}^{n+1,[0]} = 2C_{ik}^n - C_{ik}^{n-1}$, is used as an initial guess for the Gauss–Seidel iterates. With this choice of initial guess, and with $\mathrm{TOL}_1 = 10^{-3}$ and $\mathrm{TOL}_2 = 10^{-9}$, one or two Gauss–Seidel iterations suffice to attain a level of accuracy in the steady-state solution that is not improved by increasing the number of iterations. Because the convergence is rapid, we have not used a more rapidly converging but more costly nonlinear solver, e.g., Newton's method, for the nonlinear kernel.

Now we summarize the steps that advance the model by one time step. Suppose that the boundary conditions and the initial conditions $C_{ik}(x_j, 0)$ and $F_{iV}(x_j, 0)$, specified in section 2, are given. Then, until a steady state is reached, repeat steps 1 to 4:

1. Estimate the departure points for each tube using (3.6).
2. Approximate upstream function values using cubic Lagrange approximations.
3. Solve the nonlinear kernel using Gauss–Seidel iterations. Compute an initial guess $C_{ik}^{n+1,[0]}$, using linear extrapolation, and the dynamic Gauss–Seidel tolerance TOL; then compute the iterates (indexed by m) until the convergence criterion is met:
   (a) For each solute k,
      i. compute $(C_{ik})_j^{n+1,[m]}$, $(C_{2k})_j^{n+1,[m]}$, and $(C_{3k})_j^{n+1,[m]}$ using (3.14);
      ii. update water fluxes $(J_{iV})_j^{n+1,[m]}$ for $i = 1, 2, 3$, and 4 using (2.3) and (2.4).
   (b) Update solute fluxes $(J_{ik})_j^{n+1,[m]}$ for $i = 1, 2, 3$, and 4 using (2.5) and (2.6).
   (c) Compute $(C_{4k})_j^{n+1,[m]}$ using (3.14).
4. Update $(F_{iV})_j^{n+1}$ using (3.4) and (3.5).

4. Convergence properties.

In this section, we present numerical results that demonstrate the second-order spatial convergence properties of the SLSI method. First, we describe a simple steady-state model that has an explicit solution in terms of solute transport. Then we formulate the parameters of the model equations developed in section 2 to approximate those of the simple model, and we compare results from the two models. In the second study, we use more realistic model parameters that are based mostly on the outer medulla of the rat. Calculations in sections 4 and 5 were performed using Fortran programs in double precision on a Dell Dimension XPS T550 system with an Intel Pentium III 550 MHz processor and with 256 MB of RAM.

4.1. A simple steady-state model with explicit solution.

We now restrict our attention to a simple, steady-state, one-solute model. This model, which is based on the structure and geometry described in section 2 (see Figure 2.1), represents a descending limb, ascending limb, collecting duct, and central core. The model descending limb is structurally and functionally divided into two segments. The second segment, which we call the *prebend* segment, is a terminal portion of the descending limb that may have the diameter and transport properties of the ascending limb. The model prebend segment begins at $x_p \in [0, L]$.

We let $C_i(x)$ be the steady-state solute concentration in a tubule i. We assume that the descending limb, except for its prebend segment, and the collecting duct are infinitely permeable to water. The prebend segment and the ascending limb are assumed to be impermeable to water. With these assumptions, which are suggested by permeabilities that have been measured in the outer medulla of the rat kidney, we have $C_3(x) = C_4(x) \equiv C(x)$ and $C_1(x) = C(x)$ for $x \in [0, x_p]$; $J_{2V}(x) = 0$ and $J_{1V}(x) = 0$ for $x \in (x_p, L]$. We define $F_{ik}(x) \equiv F_{iV}(x)C_i(x)$ to be the rate of solute advection ("solute flow") in a tubule of type i, with $k = 1$ in this one-solute model.

With these stipulations, $C(x)$, the steady-state concentration at level x in the initial descending limb ($x \le x_p$), the collecting duct, and the central core is given by

$$\frac{C(x)}{C(0)} = \exp\left(\int_0^x \frac{-H^+_{x_p}(y)J_{1k}(y) - J_{2k}(y)}{H^-_{x_p}(y)F_{1k}(y) + F_{3k}(L) + \int_y^L (J_{1k}(s) + J_{2k}(s))\, ds}\, dy\right), \tag{4.1}$$

where $H^+_{x_p}(x)$ and $H^-_{x_p}(x)$ denote Heaviside functions such that $H^+_{x_p}(x) = 1$ if $x > x_p$, $H^+_{x_p}(x) = 0$ if $x \le x_p$, and $H^-_{x_p}(x) = 1 - H^+_{x_p}(x)$. $H^-_{x_p}(x)F_{1k}(x)$ represents the solute flow in the proximal, water-permeable portion of the descending limb; $H^+_{x_p}(x)J_{1k}(x)$ represents the transmural solute flux across the prebend segment. Equation (4.1) gives the steady-state concentration profile as a function only of the boundary concentration $C(0)$, the solute flow along the descending limb, the solute flow out of the collecting duct, and the transmural fluxes of solute across the descending and ascending limbs. A derivation for (4.1) can be found in the appendix. If one further assumes that $J_{1k}(x) = 0$ for $x \le x_p$, then $F_{1k}(x) = F_{1k}(0)$ for $x \le x_p$, and the integral can be evaluated analytically. If one specifies that $F_{3k}(L) = \epsilon F_{1k}(0)$, one obtains

$$\frac{C(x)}{C(0)} = \begin{cases} f(1, x, 0), & 0 \le x \le x_p, \\ f(1, x_p, 0)f(0, x, x_p), & x_p < x \le L, \end{cases} \tag{4.2}$$

where

$$f(\alpha, x, y) \equiv \frac{(\alpha + \epsilon)F_{1k}(0) + \int_x^L (J_{1k}(s) + J_{2k}(s))\, ds}{(\alpha + \epsilon)F_{1k}(0) + \int_y^L (J_{1k}(s) + J_{2k}(s))\, ds}. \tag{4.3}$$

For this model, we assume that $L = 2$ mm, $x_p = 0.9\ L$, and that each tubule has a fixed diameter of 20 μm. We assume that all tubules are impermeable to solute; thus $P_{ik}(x) = 0$ for each i. For the collecting duct, we further assume that $J_{3k}(x) = 0$. The boundary concentrations and water flows are specified for both the descending limb and collecting duct: $C_1(0) = C_3(0) = 200$ mM, $F_{1V}(0) = 10$ nl/min, and $F_{3V}(0) = 5$ nl/min (thus, $\epsilon = 0.5$). For the ascending limb and the prebend segment, we assume a constant rate of solute transport such that half of the solute entering the descending limb is transported out of the ascending limb and the prebend segment: $J_{2k}(x) = -83.\bar{3}$ nmole/(cm^2·s) and, for $x \in (x_p, L]$, $J_{1k}(x) = -83.\bar{3}$ nmole/(cm^2·s).

We approximated this simple steady-state model with the dynamic equations (2.1)–(2.6), which were integrated in time using the SLSI method described in section 3 until a steady state was attained. The derivation of (4.2) assumes infinite water permeability for the descending limb and collecting duct. However, in our approximation to this model, water permeabilities must be finite and were taken to be 5,000 μm/s for both the descending limb and collecting duct. As water permeability increases, the numerical results should approach (4.2). Nonetheless, a value of

5,000 μm/s should be sufficiently large so that (4.2) can be used as the reference solution in this convergence study. The osmotic coefficient ϕ was set to 1.84 for NaCl [22], and all reflection coefficients σ_i were set to 1.

The two portions of the descending limb have markedly different transport properties. To maintain good spatial convergence near the point where tubular properties change, we represent the transition by means of a twice-differentiable polynomial. Thus, suppose that at $x = \alpha_0$ the value of a transport property $q(x)$ (e.g., a solute permeability $P_{ik}(x)$ or radius $r_i(x)$) changes abruptly from q_1 to q_2. Then q is represented by a piecewise cubic polynomial

$$q(x) = \begin{cases} q_1, & x < \alpha_1, \\ -2(x-\alpha_1)^3 \Delta q/b^3 + 3(x-\alpha_1)^2 \Delta q/b^2 + q_1, & \alpha_1 \le x \le \alpha_2, \\ q_2, & x > \alpha_2, \end{cases} \tag{4.4}$$

where $b > 0$ specifies the sharpness of the transition, $\alpha_1 \equiv \alpha_0 - b/2$, $\alpha_2 \equiv \alpha_0 + b/2$, and $\Delta q \equiv q_2 - q_1$. Because the trapezoidal rule (the spatial integration scheme used in this method) assumes a continuous second derivative within each integration subinterval, $q(x)$ is designed to satisfy this assumption. In this model, α_1 and α_2 are grid points, and α_0 is identified with the beginning of the prebend segment; thus the changes in water permeability and active transport rate of the descending limb are near $\alpha_0 = x_p$. In the spatial convergence experiments presented in this section, we set $b = 0.05L$. (Experiments have shown that tubular diameters may also change, but for simplicity, tubular diameters are assumed to be uniform for these calculations.)

Results of the numerical experiments were normalized and are presented in dimensionless form. Dimensionless variables were obtained by dividing dimensional variables by dimensional reference values. Specifically, the spatial variable x was normalized by dividing by the dimensional length of the renal medulla, L; C_{ik} by the solute concentration in fluid entering the descending limb, C_o (if there is more than one solute in the system, C_o is chosen to be the chloride concentration); F_{iV} by the axial water flow rate entering the descending limb, F_{Vo}; A_i by the cross-sectional area of a descending limb at $x = 0$, A_o; t by $A_o L/F_{V_o}$; d_i by $F_{Vo}/(C_o L)$; P_{ik} by $F_{Vo}/(2L\sqrt{\pi A_o})$; $V_{\max,ik}$ by $C_o F_{Vo}/(2L\sqrt{\pi A_o})$; and $K_{M,ik}$ by C_o.

4.2. Convergence studies and comparison with the explicit model. In these convergence studies, we will first examine quantities that have been commonly reported in numerical studies of the urine concentrating mechanism. These quantities are the collecting duct outflow variables, the central core concentration at the medullary tip ($x = L$), and the water and solute balance properties of the medulla [4, 5, 6, 19, 21, 24]. The collecting duct outflow variables are of particular interest because the urine osmolality, urine solute concentration, and urine flow are key scientific results, and because the collecting duct fluid and solute outflow, being a small fraction of typical tubular flow, can be sensitive to changes in parameters or to the degree of spatial grid refinement. We will also present global measures of convergence in standard norms for key variables. Unless otherwise specified, a dimensionless time step Δt of 0.0002 was used in the numerical calculations.

The convergence of numerical results was assessed by comparing numerical solutions computed on successively refined spatial grids. Empirical orders of convergence were obtained by means of a diagnostic calculation based on Aitken extrapolation [1], which we now describe. Let ψ be a scalar dependent variable of the model at steady state, and let ψ_m be a numerical approximation to ψ computed on a spatial grid of size $N = N_0 2^m$, where N_0 is a positive integer and $m = 0, 1,$ or 2. An empirical order

TABLE 4.1

Spatial convergence results for the steady-state central core concentration $(C_4)_N^{ss}$ and collecting duct water flow rate $(F_{3V})_N^{ss}$ at $x = L$. p, C_{4_∞}, and F_{3V_∞} are computed by means of (4.5) *using the three steady-state values on and above the line containing p.*

	1.25	2.5	5.0	10.0	20.0
80	1.86317	1.86189	**1.86126**	1.86094	1.86077
160	1.86029	1.85594	1.85051	**1.84823**	1.84567
320	1.86065	1.85658	1.85286	1.84965	**1.84705**

of convergence p of three strictly monotonic values ψ_0, ψ_1, and ψ_2 may be obtained by solving simultaneously the equations

$$\psi_\infty - \psi_m = K(\Delta x/2^m)^p, \qquad m = 0, 1, 2. \tag{4.5}$$

The empirical order of convergence is $p = \log_2(\Delta_1/\Delta_2)$, where $\Delta_m = \psi_m - \psi_{m-1}$. The asymptotic error constant is estimated by $K = \Delta_1(\Delta x)^{-p}(1-2^{-p})^{-1}$. The value to which the ψ_m's are apparently converging is $\psi_\infty = \psi_0 + K(\Delta x)^p$.

In Table 4.1, the spatial convergence of the steady-state solute concentration in the central core and the water flow rate in the collecting duct at $x = L$ were estimated using (4.5). The empirical orders of convergence are consistent with the expected second-order convergence. Similar results were obtained for collecting duct solute outflow $(F_{31})_N^{ss}$. Generally speaking, the orders of convergence for water and solute flow rates are more regularly second order than are orders of convergence for other variables. This is because the principal equations (2.1) and (2.2) are derived on the basis of water and solute (F_{iV} and F_{ik}) conservation; consequently, the convergence for these variables should be robustly second order. The convergence for other variables, such as solute concentration, $C_i = F_{ik}/F_{iV}$, may deviate somewhat from second order.

Using grid sizes $N =$ 160, 320, and 640, the approximations $(C_4)_N^{ss}$ for $C_4(L)$ converge to a concentration of ~1.78320, which is within 3.20% of the corresponding value in the explicit solution, 1.84211; the approximations $(F_{3V})_N^{ss}$ for $F_{3V}(L)$ converge to a flow of ~0.280731, which is within 3.43% of the explicit solution of 0.27143. The discrepancy between the explicit and the numerical solutions, after sufficient grid refinement, arises from the use of finite water permeabilities and from the nonzero transition length at the beginning of the prebend segment.

To provide evidence that the model indeed converges to the explicit solution when model water permeability values approach infinity and the prebend transition length approaches zero, we show in Table 4.2 steady-state values of $(C_4)_N^{ss}$ computed for water permeability values starting at $P_f = 1.25 \times 10^4$ μm/s and increasing by factors of 2, 4, 8, and 16 for grid sizes of $N =$ 80, 160, and 320. A smaller prebend transition

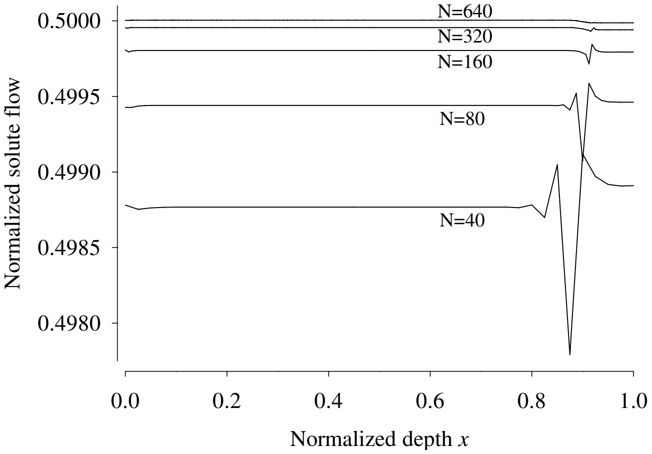

FIG. 4.1. *Net steady-state chloride flow rate F_1^{ss} through the medulla, computed with successive spatial grid refinements. Second-order convergence to the correct normalized solute flow,* 0.5, *is apparent for $N > 80$.*

length of $b = 0.02L$ was used, compared to the base-case value of $b = 0.05L$ used in the spatial convergence studies. Note that for a given N, the solution decreases toward the explicit model value of 1.84211 as water permeability increases. However, stronger evidence for convergence can be obtained by increasing the water permeability and the spatial grid resolution simultaneously. This is because as the water permeability is increased, the errors in computing water efflux from the water-permeable tubules near $x = 0$ (a boundary effect) and x_p (beginning of prebend segment) also increase unless the grid is refined. A convergence study based on the diagonal concentrations given in bold typeface in Table 4.2 indicates that the concentrations are converging to a value of 1.84693, which differs from the explicit model value by a relative difference of 0.26%. For the studies in the remainder of this section, the base-case values $P_f = 5{,}000$ μm/s and $b = 0.05L$ were used.

Numerical solutions to mathematical models of the urine concentrating mechanism have frequently been assessed on the basis of their mass conservation properties [6, 8, 21]. To assess solute and water conservation of the model, define $F_k^{ss}(x)$ and $F_V^{ss}(x)$ to be the total steady-state flow rates of solute and water through the renal medulla. Then,

$$F_k^{ss}(x) = \sum_{i=1}^{4} F_{iV}^{ss}(x) C_i^{ss}(x) \qquad \text{and} \qquad F_V^{ss}(x) = \sum_{i=1}^{4} F_{iV}^{ss}(x), \tag{4.6}$$

where $F_{iV}^{ss}(x)$ and $C_i^{ss}(x)$ are the steady-state flow and solute concentration in an individual tubule i. At steady state, both F_k^{ss} and F_V^{ss} are constant functions. Since the collecting duct is the only tubule that is open at $x = L$, F_k^{ss} and F_V^{ss} will equal the solute and water flow rates there, respectively; that is, $F_k^{ss} \equiv F_{3k}^{ss}(L)$ and $F_V^{ss} \equiv F_{3V}^{ss}(L)$. Numerical results should approximate these properties.

Since the collecting duct is assumed to be solute-impermeable in this model, $F_1^{ss} = F_{31}^{ss}(L) = F_{31}(0) = 0.5$. Indeed, this is the value that the curves in Figure 4.1 are approaching, with a convergence rate that is approximately second order. At low resolution, there is a substantial defect around $x = x_p$, where the transmural

properties of the descending limb change. Nevertheless, the curves flatten as the resolution is increased. The steady-state value of F^{ss}_V depends on the steady-state tubular concentration and thus is not known a priori. The curves for F^{ss}_V (not shown) show no derivation from horizontal lines even at a low resolution of $N = 40$, and they show an approximately second-order convergence to a steady-state value of ~0.28073. The solution to the explicit model yields a value of $F^{ss}_V = F^{ss}_{31}(L)/C^{ss}(L) = 0.27143$.

Table 4.3 shows global convergence in norm for steady-state water flow $\vec{F}_V$, chloride flow $\vec{F}_1$, and chloride concentration $\vec{C}$. The ordering of the entries of the vector $\vec{F}_V \in R^{4(N+1)}$ is indicated in the table, where each F^{ss}_{iV} represents the $N+1$ components $(F^{ss}_{iV})_j$, $j = 0, \dots, N$. The vectors $\vec{F}_1$ and $\vec{C}$ are defined similarly. For a vector $\vec{F}_V$ computed on N subintervals and denoted by $\vec{F}^N_V$, we define $P_{N/2}$: $R^{4(N+1)} \to R^{4(N/2+1)}$ to be the operator that reduces $\vec{F}^N_V$ to the vector $P_{N/2}\vec{F}^N_V$ by retaining the $N/2+1$ entries $(F^{ss}_{iV})_0$, $(F^{ss}_{iV})_2$, $(F^{ss}_{iV})_4, \dots, (F^{ss}_{iV})_N$ in F^{ss}_{iV} for $i = 1, 2, 3$, and 4. We index the components $(\vec{F}_V)_j$ of $\vec{F}^N_V \in R^{4(N+1)}$ by $j = 1, 2, \dots, M$, where $M = 4(N+1)$, and we define the q-norm of $\vec{F}_V$ by

$$\|\vec{F}^N_V\|_q \equiv \left(\sum_{j=1}^{M} |(\vec{F}_V)_j|^q \frac{1}{M} \right)^{1/q}, \qquad q = 1, 2, \text{ or } \infty. \tag{4.7}$$

If we define $r^N_q = \|P_{N/2}\vec{F}^N_V - \vec{F}^{N/2}_V\|_q / \|\vec{F}^{640}_V\|_q$, then an order of convergence, analogous to that previously obtained by the Aitken method, can be estimated by $p^N_q = \log_2(r^{N/2}_q / r^N_q)$. As in the case for the results in Table 4.1, convergence in Table 4.3 was found to be approximately second order for $q = 1$, 2, and ∞.

The ratio r^N_q has a natural interpretation as an estimate for the relative error $e^N_q \equiv \|\vec{F}^A_V - \vec{F}^N_V\|_q / \|\vec{F}^A_V\|_q$, where $\vec{F}^A_V$ is the vector, analogous to $\vec{F}^{ss}_V$, of values at the spatial grid points $\{x_j\}^N_{j=0}$ of the true (analytic) steady-state solution to the

finite-permeability model equations. This is because $\|\vec{F}_V^A\|_q \approx \|\vec{F}_V^{640}\|_q$; $\|\vec{F}_V^{640}\|_q \gg \|P_{N/2}\vec{F}_V^N - \vec{F}_V^{N/2}\|_q$; and $\|P_{N/2}\vec{F}_V^N - \vec{F}_V^{N/2}\|_q \approx \|P_{N/2}\vec{K}^N(N^{-p} - (2N)^{-p})\|_q \approx (1 - 2^{-p})\|\vec{K}^N N^{-p}\|_q \approx (1 - 2^{-p})\|\vec{F}_V^A - \vec{F}_V^N\|_q$, by analogy with (4.5), for an asymptotic error vector $\vec{K}^N \in R^{4(N+1)}$. Thus, if $p \approx 2$, then $e_q^N \approx \frac{4}{3}r_q^N$.

4.3. An outer medulla model. The physiological setting in which we wish to apply the SLSI method is substantially more complex than the simple explicit model, and the approximation to that model, described in the previous section. Therefore, in a second set of experiments, we tested the SLSI method using parameter values based on experiments in the outer medullas of small mammals (primarily rat, but also hamster and rabbit [3, 7]). These parameter values are listed in Table 4.4. The medullary length L was set to be 3.2 mm. The transition in the late descending limb, which includes changes in tubular diameter and transport properties, is treated using the piecewise cubic function defined in (4.4). The boundary concentrations were chosen for $C_{11}(0,t)$, $C_{12}(0,t)$, $C_{31}(0,t)$, and $C_{32}(0,t)$ to be 160.0, 15.0, 63.8, and 197.5 mM, respectively; the boundary flows were chosen for $F_{1V}(0,t)$ and $F_{3V}(0,t)$ to be 10 and 1.5 nl/min, respectively. The osmotic coefficient ϕ_k for NaCl ($k = 1$) was set to be 1.84, and for urea ($k = 2$), 0.97 [20, 22]. The active transport rates for urea, $V_{\max,i2}$, were all set to zero, and the Michaelis constant $K_{M,ik}(x)$ for chloride ($k = 1$) was set to 70 mM. The reflection coefficients σ_{ik} were set to 1.

Figure 4.2 shows the normalized steady-state osmolality profiles for the four tubules, computed using the parameters shown in Table 4.4. The normalized osmolality of a given tubule i at level x ($i = 1, 2, 3$, or 4) was defined by

$$C_{iO}(x,t) = \frac{\phi_1 C_{i1}(x,t) + \phi_2 C_{i2}(x,t)}{\phi_1 C_{11}(0,t) + \phi_2 C_{12}(0,t)}. \tag{4.8}$$

Convergence results for the rate of steady-state chloride and water flow out of the collecting duct are shown in Table 4.5. Results for both variables indicate second-order convergence, as do results for other variables, although values for F_{3V} obtained using $N = 40$, 80, and 160 are not monotonic and thus cannot be used to estimate an order of convergence.

Convergence results that are approximately second order were obtained for the conservation of chloride, urea, and water. The net steady-state chloride flow is shown in Figure 4.3. The fluctuations for $x >\ \sim$0.7 arise from the changes in diameter and transport properties in the descending limb. These deviations from a horizontal line diminish rapidly as the grid is refined.

Table 4.6 shows global convergence in norm for water flow $\vec{F}_V$, chloride flow $\vec{F}_1$, and chloride concentration $\vec{C}_1$, which are defined as in Table 4.3, as are r_q and p_q. As in the results in Table 4.3, convergence in Table 4.6 was found to be approximately second order. Similar results (not shown) were also obtained for urea flow and urea solute concentration.

5. Stability and efficiency studies. In this section, we compare the stability conditions and efficiency of the SLSI method with an Eulerian scheme, specifically, the ENO method that is first order in time and second order in space.

The procedures by which the ENO method may be used to solve the system (2.1)–(2.6) can be found in [5, 6]. Because of its Eulerian and explicit nature, the time step Δt must be chosen to satisfy the CFL condition; that is, one must ensure that $\Delta t/\Delta x \max_i |F_{iV}/\sqrt{A_i}| < 1$ for $i = 1, 2, 3$, and 4 for the ENO method to be stable. Therefore, as the spatial grid is refined, a smaller Δt may be required to satisfy the CFL condition. Moreover, the transmural solute and water flux terms may place additional restrictions, arising from stiffness, on the size of Δt [5].

In contrast, Δt in the SLSI method is not limited by the CFL condition. Indeed, if the departure points were known exactly, then the advective terms would impose no restriction on Δt. In this problem, however, the flow rates are unknowns and the departure points are estimated numerically. It has been shown that numerical stability is ensured if the product of Δt and the flow shear, $\max_i |\partial(F_{iV}/\sqrt{A_i})/\partial x|$, is bounded by a constant [10]. The stiffness of the problem is controlled by the semi-implicit approach, which averages the stiff transtubular transport terms in time along flow trajectories.

In the studies below, we compared the ENO and SLSI methods by determining the largest Δt for which each method is stable. The efficiency for the ENO and SLSI methods was assessed by two measures. Efficiency-1 was assessed by the standard measure: the computation costs (i.e., computation time) required to attain a specified degree of accuracy. Efficiency-2 was assessed by the computation costs required to attain a steady-state solution while using the largest Δt for which a method is stable. Efficiency-2 is of interest because an approximate, but sufficiently accurate, numerical solution can be used as an initial guess for which a Newton-type solver (for the steady-state equations) will be stable. Because a Newton-type solver is much less computationally expensive than the dynamic methods (e.g., ENO and SLSI), a combination method, using first a dynamic method and then a Newton-type method, may permit an accurate steady-state solution to be found more rapidly than by means of a dynamic method alone.

We expect that the SLSI method will allow a larger Δt than the ENO method, for reasons explained above. However, the computation cost for each SLSI time step is also higher, owing to additional costs incurred in the approximation of flow trajectories, the estimation of upstream function values using spatial interpolation, and the solution of the nonlinear kernel.

5.1. An outer medulla model. In the first set of tests, we formulated the renal model based on parameter values used in section 4.3 (see Table 4.4). With these parameter values the problem is not particularly stiff, and thus Δt in an explicit Eulerian advection method is restricted mostly by the CFL condition. Using numerical experiments, we computed the maximum time steps allowed while maintaining stability for the SLSI and ENO methods for successively refined spatial grids. Then using these time steps, we determined the computation time for the model solution to approximate a steady state; we assumed that a steady state had been attained when the normalized concentrations were within 10^{-6} of their asymptotic values. Both models were run for the same simulated time of 65.97 minutes and by that time both solutions had met the steady-state criterion.

The maximum stable time steps for the ENO and the SLSI methods, the associated normalized steady-state osmolalities of the fluid leaving the collecting duct ($(C_{3O})_N^{ss}$), and the total computation times in seconds are shown in Table 5.1. For the ENO method, Δt must be chosen to be slightly smaller than the maximum value allowed by the CFL condition (i.e., $\Delta x \min_i |\sqrt{A_i}/F_{iV}|$), which is shown in the column labeled "CFL Δt" in Table 5.1. This is because $(F_{iV})_{\max}$ was determined at steady state; flow rates may exceed $(F_{iV})_{\max}$ in transient states. In contrast, a considerably larger Δt can be used in the SLSI method. For $N = 320$, a stable solution is obtained with a CFL number as large as 20.8. Moreover, the choice of Δt in the SLSI method is relatively independent of the grid resolution, whereas for the ENO method a smaller Δt must be used when the spatial grid is refined. Therefore, we expect the advantages of the SLSI method to be amplified with higher spatial resolution.

The results in Table 5.1 indicate that, in the sense of efficiency-2, the SLSI method is more efficient than the ENO method, in that an approximate steady state can be attained much more rapidly by the SLSI method than by the ENO method, and the relative efficiency of the SLSI method increases as the spatial grid is refined—from a factor of ∼2.80 at $N = 80$, to a factor of ∼9.94 at $N = 320$.

The difference between the values of $(C_{3O})_N^{ss}$ computed by the two methods is about 6% or less, a difference that can be reduced by using a smaller Δt in the SLSI method. Using $\Delta t = 0.015$, the SLSI method generates $(C_{3O})_N^{ss} = 1.93168$, 1.92840, and 1.92897 for $N = 80$, 160, and 320, respectively, with computation costs of 14.6, 29.2, and 62.0 s, respectively. The relative discrepancies between these results and

Table 5.1

Table 5.2

Tubular diameters and transport properties used in the inner medulla model. DL, descending limb; AL, ascending limb; CD, collecting duct; P_f, P_{Cl^-}, P_{urea}, permeabilities of water, Cl^-, and urea, respectively; $V_{\max,Cl^-}$, maximum Cl^- active transport rate.

Property	DL	AL	CD
Diameter (μm)	15	20	29
P_f (μm/s)	50	0	1,300
P_{Cl^-} (10^{-5} cm/s)	98.8	294	1
P_{urea} (10^{-5} cm/s)	47.6	170	100
$V_{\max,Cl^-}$ (nmole/(cm$^2\cdot$ s))	0	0	0

the ENO approximations shown in Table 5.1 are about 0.022%, 0.028%, and 0.012%, respectively. Thus, for sufficiently large N ($N \geq 160$ for this problem), the SLSI method generates solutions with accuracy comparable to that of the ENO method while also allowing larger time steps *and* lower computation costs. Thus for $N \geq 160$, the SLSI method is more efficient than the ENO method, in the sense of efficiency-1.

Assessed by both the efficiency-1 and efficiency-2 measures, the SLSI method is significantly more efficient than the ENO method, for N sufficiently large, because the costs for the ENO method grow as $\mathcal{O}(N^2)$, whereas the costs of the SLSI method grow as $\mathcal{O}(N)$. The ENO method is $\mathcal{O}(N^2)$ because as N is doubled, Δt must be halved to meet the CFL condition; the SLSI method is not restricted by the CFL condition.

5.2. An inner medulla model for the chinchilla. For this test, we based the model parameters on measurements in the deep inner medulla (i.e., the papillary portion) of the rat and chinchilla. Diameter and transport properties, based on anatomical and physiological investigations [7], are given in Table 5.2. The medullary length L was set to be 4.8 mm and the prebend segment in the late descending limb was assumed to begin at $x_p = 0.9L$. The descending and ascending limb transport properties were measured in chinchilla, and diameters and collecting duct transport properties were measured in rat. Transport parameters for chinchilla were chosen because they are large compared to measurements in other small mammals, thus rendering the problem stiff. Boundary conditions for this problem were specified for $C_{11}(0,t)$, $C_{12}(0,t)$, $C_{31}(0,t)$, and $C_{32}(0,t)$ to be 600.0, 150.0, 230.98, and 850.0 mM, respectively, and for $F_{1V}(0,t)$ and $F_{3V}(0,t)$ to be 1.0 and 0.15 nl/min, respectively. Model calculations were run for 65.97 minutes in simulated time, and by then the solutions had met the steady-state criterion described in section 5.1.

The maximum stable time steps for the ENO and SLSI methods, the associated normalized steady-state osmolalities of the fluid leaving the collecting duct, and the total computation times in seconds are shown in Table 5.3. The parameters for this problem were chosen so that the transmural water and solute fluxes were large near $x = 0$, rendering the problem stiff. As a result, the maximum time steps allowed

Table 5.3
Results for stability and efficiency study for a model of the inner medulla.

N	CFL Δt	ENO			SLSI		
		Δt	$(C_{3O})_N^{ss}$	cost (s)	Δt	$(C_{3O})_N^{ss}$	cost (s)
80	1.25E-2	1.0E-3	0.89539	89.90	3.0E-3	0.89376	63.19
160	6.25E-3	5.0E-4	0.95640	355.19	3.0E-3	0.96482	128.66
320	3.13E-3	2.5E-4	0.97068	1448.65	3.0E-3	0.96897	269.13

for both the ENO and SLSI methods were substantially smaller than the CFL Δt. The maximum time steps permissible for the ENO method become smaller as N is increased, even though stiffness is normally independent of the grid resolution, because the transmural water and solute fluxes increase as x approaches 0 (a boundary layer effect): a smaller Δx results in a larger computed flux at the first few grid points, and thus a smaller Δt is required. Even with the semi-implicit approach used in the SLSI method, the large water fluxes near $x = 0$ affect the fluid flow rate and thereby increase the flow shear and place a restriction on Δt. Unlike the ENO method, however, Δt for the SLSI method need not be further reduced as the spatial grid is refined. The computation costs of the ENO and SLSI methods grow as $\mathcal{O}(N^2)$ and $\mathcal{O}(N)$, respectively. For this problem, the SLSI method reduces computation times by a factor of 1.38 for $N = 80$ and by a factor of 5.38 for $N = 320$. As in the previous test, for sufficiently large N (here, $N \geq 80$), the SLSI method is more efficient than the ENO method in both the efficiency-1 sense and the efficiency-2 sense.

6. Discussion. We have presented a stable and efficient numerical method, based on an SLSI scheme, for solving the system of differential equations arising in dynamic models of the urine concentrating mechanism. The SLSI method, like the ENO method used previously [5, 6], avoids numerical instability arising from transient flow reversal, and it does so by integrating along flow trajectories. Unlike the ENO scheme, however, the SLSI method is not limited by the CFL condition. With an Eulerian scheme, a smaller time step may be required, to satisfy the CFL condition, when the spatial grid is refined. Thus, even for a one-dimensional problem, the computation cost may grow as $\mathcal{O}(N^2)$, where N is the number of spatial grid subintervals. Since the SLSI method integrates along flow trajectories and thus allows CFL numbers greater than 1, the computation cost grows only as $\mathcal{O}(N)$. Moreover, this method treats the stiff terms (the transmural water and solute fluxes) implicitly so that they do not impose a restriction on the time step. In sections 4 and 5, we demonstrated that results from the SLSI method show second-order convergence in space, and that, compared with the ENO method, the SLSI method computes solutions of comparable accuracy in substantially shorter times.

The model presented in this paper is relatively simple in that it consists of one loop of Henle, one collecting duct, and a central core. A rat kidney, however, contains ~37,500 loops of Henle, turning at various levels of the medulla [3]. To accurately represent the interactions among these loops of differing lengths, a distributed-loop model may be adopted [6]. The distributed-loop model uses two space variables: one denotes the level of the medulla, while the other represents the level of the medulla at which the associated loop of Henle turns, resulting in a system of N PDEs for each solute. When this system is solved by the ENO method, $\mathcal{O}(N^3)$ computation steps are required. Thus, even though high spatial resolution is frequently required to accurately represent the details and complexities of the mammalian kidney (e.g., rapid transitions in diameter and transtubular transport properties), one may be compelled to compromise spatial resolution to offset the long computation times.

It should be practical to develop an efficient and stable numerical method, based on the SLSI scheme, for the distributed-loop model. The solution time of an SLSI-based method for this two-dimensional model should be $\mathcal{O}(N^2)$, since the choice of time step is independent of the spatial resolution. Even if the largest stable time step is used, the approximate steady-state solution so obtained may be useful as an initial condition for a more accurate and less stable method, such as a Newton-type method or a simple explicit Eulerian advection scheme with a small time step. The resulting savings in computation costs can be invested in higher spatial resolution, so that a more complete understanding of the mammalian urine concentrating mechanism may be attained.

Appendix. Explicit solution for the simple steady-state model. This appendix provides a derivation for (4.1), following that of a related problem in [4]. From conservation of solute, one has

$$F'_{ik}(x) = J_{ik}(x) \tag{A.1}$$

for $i = 1$, 2, 3, or 4. The prime symbol denotes differentiation with respect to x. A substitution of the definition of solute flow $F_{ik}(x) = F_{iV}(x)C_{1k}(x)$ into (A.1) yields

$$F_{iV}(x)C'_{ik}(x) = -J_{iV}(x)C_{ik}(x) + J_{ik}(x). \tag{A.2}$$

Since for $x \in [0, x_p]$ the solute concentration of the descending limb equals $C(x)$, one obtains the following relation for the proximal, water-permeable portion of the descending limb:

$$H^-_{x_p}(x)F_{1V}(x)C'(x) = H^-_{x_p}(x)(-J_{1V}(x)C(x) + J_{1k}(x)), \tag{A.3}$$

where $H^+_{x_p}(x)$ and $H^-_{x_p}(x)$ are the Heaviside functions defined immediately after (4.1). By adding together (A.3) and equations of the form (A.2) for $i = 3$ and 4, one obtains

$$\begin{aligned}(H^-_{x_p}(x)&F_{1V}(x) + F_{3V}(x) + F_{4V}(x))C'(x)\\ &= -(H^-_{x_p}(x)J_{1V}(x) + J_{3V}(x) + J_{4V}(x))C(x) + (H^-_{x_p}(x)J_{1k}(x) + J_{3k}(x) + J_{4k}(x)).\end{aligned} \tag{A.4}$$

Since the ascending limb and the prebend segment are assumed to be water impermeable, $J_{2V} \equiv 0$ and $H^+_{x_p}J_{1V} \equiv 0$; thus, by water conservation, $H^-_{x_p}(x)J_{1V}(x) + J_{3V}(x) + J_{4V}(x) = 0$. By solute conservation, $H^-_{x_p}(x)J_{1k}(x) + J_{3k}(x) + J_{4k}(x) = -H^+_{x_p}(x)J_{1k}(x) - J_{2k}(x)$, where $H^+_{x_p}(x)J_{1k}(x)$ represents solute flux from the prebend segment. Recall also that $F_{iV}(x) = F_{ik}(x)/C(x)$ for $i = 3$ and 4 and for the water-permeable portion of the descending limb ($x \in [0, x_p]$). By substituting these relations into (A.4) and rearranging, one obtains

$$\frac{C'(x)}{C(x)} = \frac{-H^+_{x_p}(x)J_{1k}(x) - J_{2k}(x)}{H^-_{x_p}(x)F_{1k}(x) + F_{3k}(x) + F_{4k}(x)}. \tag{A.5}$$

The rate of solute advection along the collecting duct at level x is

$$F_{3k}(x) = F_{3k}(0) + \int_0^x J_{3k}(s)\,ds = F_{3k}(L) - \int_x^L J_{3k}(s)\,ds. \tag{A.6}$$

Since $F_{4k}(L) = 0$, the solute advection in the central core is given by

$$F_{4k}(x) = \int_x^L (J_{1k}(s) + J_{2k}(s) + J_{3k}(s))\, ds. \tag{A.7}$$

By adding (A.6) and (A.7), one obtains

$$F_{3k}(x) + F_{4k}(x) = F_{3k}(L) + \int_x^L (J_{1k}(s) + J_{2k}(s))\, ds. \tag{A.8}$$

By substituting (A.8) into (A.5), one obtains an equation that may be integrated to give (4.1).

FAST EVALUATION OF RADIAL BASIS FUNCTIONS: METHODS FOR GENERALIZED MULTIQUADRICS IN $\mathbb{R}^n$*

J. B. CHERRIE†, R. K. BEATSON†, AND G. N. NEWSAM‡

Abstract. A generalized multiquadric radial basis function is a function of the form $s(x) = \sum_{i=1}^N d_i\phi(|x - t_i|)$, where $\phi(r) = (r^2 + \tau^2)^{k/2}$, $x \in \mathbb{R}^n$, and $k \in \mathbb{Z}$ is odd. The direct evaluation of an N center generalized multiquadric radial basis function at m points requires $\mathcal{O}(mN)$ flops, which is prohibitive when m and N are large. Similar considerations apparently rule out fitting an interpolating N center generalized multiquadric to N data points by either direct or iterative solution of the associated system of linear equations in realistic problems.

In this paper we will develop far field expansions, recurrence relations for efficient formation of the expansions, error estimates, and translation formulas for generalized multiquadric radial basis functions in n-variables. These pieces are combined in a hierarchical fast evaluator requiring only $\mathcal{O}((m+N)\log N|\log\epsilon|^{n+1})$ flops for evaluation of an N center generalized multiquadric at m points. This flop count is significantly less than that of the direct method. Moreover, used to compute matrix-vector products, the fast evaluator provides a basis for fast iterative fitting strategies.

Key words. radial basis functions, generalized multiquadric, fast evaluation

1. Introduction.

Multiquadrics are a popular choice of radial basis function for interpolating scattered data in one or more dimensions. Many applications are described in the literature, including geodesy, image processing, and natural resource modeling (see, for example, Hardy [10]). The beautiful properties of multiquadric and other radial basis functions, such as the poisedness of suitable interpolation problems, are detailed in Cheney and Light [7, Chap. 12–16, Chap. 36]. Unfortunately, the adoption of multiquadrics for real problems with large data sets has been hindered by a perceived large computational cost. Indeed, the direct evaluation of an N center multiquadric radial basis function at m points requires $\mathcal{O}(mN)$ flops, which is prohibitive when m and N are large. Similar considerations apparently rule out fitting an interpolating N center multiquadric to N data points by either direct or iterative solution of the associated system of linear equations in realistic problems.

However, the use of hierarchical methods, fast multipole methods, and other multiresolution schemes allows fast evaluation and fitting of radial basis functions. This paper develops far field expansions for generalized multiquadric radial basis functions in n-variables of the form required by these new methods. Schemes of a hierarchical type can then be built upon these expansions that require only $\mathcal{O}((m+N)\log N|\log\epsilon|^{n+1})$ flops for evaluation of an N center generalized multiquadric to accuracy ϵ at m points. This compares very favorably with the cost of the direct method. Moreover, used to compute matrix-vector products, the fast evaluator can be combined with suitable iterative methods and preconditioning strategies to yield

fast iterative algorithms for interpolatory or smoothing fits (see, e.g., [2]).

The first fast multipole method was that of Greengard and Rokhlin [9]. Since then the method has been modified and extended to apply in many different contexts [3]. For reasons of space we are forced to omit discussion of many important aspects of hierarchical and fast multipole methods from this paper. In particular, we have omitted almost all discussion of the crucial algorithmic details which enable a fast evaluation scheme for use in $\mathbb{R}^n$ to be built upon suitable far field expansions, such as the expansion for generalized multiquadrics developed in this paper.

A much fuller account of hierarchical and fast multipole methods is given in the survey paper [3]. Readers new to these methods are referred to that paper, and in particular to the tutorial section concerning hierarchical and fast multipole schemes in one dimension. Indeed, the model problem of that section is fast evaluation of an ordinary multiquadric in $\mathbb{R}^1$. However, the treatment there concentrates exclusively on algorithmic aspects and suppresses the mathematical analysis of expansions and error bounds. Previous papers concerning fast multipole and related methods for fast evaluation of radial basis functions include [5, 4, 6].

The generic fast multipole method requires results of the following nature for the basic function Φ being used:

- the existence of a rapidly converging far field expansion, centered at 0, for the shifted basic function $\Phi(x-t)$. The existence of such an expansion implies that, for all x sufficiently far from 0, the spline $s(x) = \sum_{i=1}^{N} d_i \Phi(x-t_i)$ may be approximated to the desired accuracy by a short series. When N is large it will be much faster to use the series rather than to evaluate $s(x)$ directly.
- error bounds that determine how many terms are required in each expansion to achieve a specified accuracy.
- efficient recurrence relations for computing the coefficients of the expansions.
- uniqueness results that justify indirect translation of expansions.
- formulae for efficiently converting a far field expansion to a rapidly convergent local expansion.

This paper provides appropriate results of these types for generalized multiquadric radial basis functions in $\mathbb{R}^n$. That is, for functions of the form

$$s(x) = \sum_{i=1}^{N} d_i \Phi(x - t_i; k, \tau), \tag{1.1}$$

where

$$\Phi(x) = \Phi(x; k, \tau) = \left(x^2 + \tau^2\right)^{k/2}, \tag{1.2}$$

k is an odd integer, $\tau \geq 0$, and $x \in \mathbb{R}^n$. Note that we will usually use the notation $\Phi(x)$, which hides the dependence of Φ on k and τ. The derived series and the analysis also apply when τ varies, that is, the multiquadric parameter τ changes with the center t_i.

The paper is laid out as follows. Sections 2 and 3 derive far field expansions of the form

$$\Phi(x - t; k, \tau) = \sum_{\ell=0}^{\infty} P_\ell^{(k)}(|t|^2 + \tau^2, -2\langle t, x\rangle, |x|^2)/|x|^{2\ell-k}, \tag{1.3}$$

where the $P_\ell^{(k)}$ are the polynomials

$$P_\ell(a,b,c) = P_\ell^{(k)}(a,b,c) = \sum_{j=\lfloor \frac{\ell+1}{2} \rfloor}^{\ell} \binom{k/2}{j}\binom{j}{\ell-j} b^{2j-\ell}(ac)^{\ell-j}, \qquad \ell \geq 0, \tag{1.4}$$

and $P_\ell^{(k)}$ is the zero function for ℓ negative. Section 3 also gives error bounds on approximations formed by truncating the series. Section 4 proves the uniqueness of the expansions. Section 5 discusses recurrence relations for the efficient direct calculation of the far field coefficients. It shows that the terms of the first $p+k+1$ homogeneous orders in the series for an m center cluster can be calculated in $\mathcal{O}(mn(p+k)^n)$ flops. Section 6 sets up some machinery which is used in section 7 to establish methods for indirectly translating far field expansions. Section 8 shows how to efficiently convert a far field expansion into a local polynomial approximation. The paper concludes with some numerical results showing that multiquadric radial basis functions can indeed be evaluated using this approach at a cost that grows as $\mathcal{O}(N \log N)$ in the number N of centers.

We will use lowercase ϕ for the basic function as a function of one variable, and uppercase Φ for the function of n variables, i.e., $\Phi = \phi(|\cdot|)$. It is common for the constant in the multiquadric basic function to be represented by c. However, we will use τ for this purpose, i.e., the ordinary multiquadric basic function will be $\phi(r) = \sqrt{r^2+\tau^2}$.

2. A generating function. In this section we develop some important properties of the functions

$$f_k(z) = (\sqrt{az^2+bz+c})^k, \qquad k \in \mathbb{Z} \text{ is odd.} \tag{2.1}$$

These functions will turn out to be the generating functions for the polynomials $P_\ell^{(k)}$ that occur in the far and near field expansions of the generalized multiquadric function.

To fully explore the expansions of f_k we will need to use Gauss's hypergeometric function.

LEMMA 2.1. *The* hypergeometric function *defined by*

$$F(a,b;c;z) = F(b,a;c;z) := \frac{\Gamma(c)}{\Gamma(a)\Gamma(b)} \sum_{n=0}^{\infty} \frac{\Gamma(a+n)\Gamma(b+n)}{\Gamma(c+n)} \frac{z^n}{n!},$$

for c not a negative integer and $|z|<1$, satisfies

$$F(a,b;c;z) = (1-z)^{c-a-b} F(c-a,c-b;c;z), \tag{2.2a}$$

$$\frac{d}{dz}F(a,b;c;z) = \frac{ab}{c}F(a+1,b+1;c+1;z). \tag{2.2b}$$

Furthermore, if a or b is equal to $-m$, m a nonnegative integer, then $F(a,b;c;z)$ reduces to a polynomial of degree m in z.

Proof. See [1, Chap. 15] for the proof. □

LEMMA 2.2. *Let $m,p \in \mathbb{N}_0$, and $|h|<1$. Then*

$$\sum_{n=p}^{\infty} \binom{n+m}{m} h^n = \frac{h^p}{(1-h)^{m+1}} \frac{(p+m)!}{p!\ m!} F(-m,p;p+1;h).$$

Proof.

$$\begin{aligned}\sum_{n=p}^{\infty}\binom{n+m}{m}h^n &= \frac{(p+m)!}{p!\,m!}\frac{p!}{(p+m)!}h^p\sum_{n=0}^{\infty}\frac{(n+p+m)!n!}{(n+p)!}\frac{h^n}{n!}\\ &= \frac{(p+m)!}{p!\,m!}h^pF(m+p+1,1;p+1;h)\\ &= \frac{(p+m)!}{p!\,m!}h^p(1-h)^{-(m+1)}F(-m,p;p+1;h),\end{aligned}$$

where the last equality follows from (2.2a). □

We now present the major result of this section, which gives a series expansion for f_k and a bound for the error in approximating f_k by a truncation of this series.

LEMMA 2.3. *Let $k \in \mathbb{Z}$ be odd and let $a, b, c \in \mathbb{R}$ with $a, c > 0$ and $b^2 \le 4ac$. Then for all $z \in \mathbb{C}$ such that $|z| < \sqrt{c/a}$,*

$$f_k(z) = (\sqrt{az^2+bz+c})^k = c^{k/2}\sum_{\ell=0}^{\infty}\left(\frac{z}{c}\right)^{\ell}P_\ell^{(k)}(a,b,c), \tag{2.3}$$

where the $P_\ell^{(k)}$ are the polynomials defined in (1.4). *Moreover, for all z such that $|z| < \sqrt{c/a}$ and $\nu \in \mathbb{N}$,*

$$\left|(az^2+bz+c)^{k/2} - c^{k/2}\sum_{\ell=0}^{\nu}\left(\frac{z}{c}\right)^{\ell}P_\ell^{(k)}(a,b,c)\right|$$
$$\le \begin{cases} 2^kc^{k/2}\left(\dfrac{|z|}{\sqrt{c/a}}\right)^{\nu+1}\dfrac{\sqrt{c/a}}{\sqrt{c/a}-|z|} & \textit{if } k>0,\\[2ex] \dbinom{\nu-k}{\nu+1}c^{k/2}\left(\dfrac{|z|}{\sqrt{c/a}}\right)^{\nu+1}\left(\dfrac{\sqrt{c/a}}{\sqrt{c/a}-|z|}\right)^{-k} & \\ \qquad\times F\left(k+1,\nu+1;\nu+2;\dfrac{|z|}{\sqrt{c/a}}\right) & \textit{if } k<0.\end{cases}$$

Proof. Let $\sqrt{\cdot}$ denote the principal branch of the complex square root. Then f_k is analytic whenever $q(z) = az^2+bz+c$ is away from the branch cut, that is, whenever $q(z)$ is not a nonpositive real. Completing the square,

$$q(z) = a\left\{\left(z+\frac{b}{2a}\right)^2 + \frac{4ac-b^2}{4a^2}\right\},$$

and since $b^2 \le 4ac$, it is easily seen that f_k is analytic away from

$$\left\{z = -\frac{b}{2a} + \mathbf{i}y : y \in \mathbb{R} \text{ and } |y| \ge \sqrt{\frac{4ac-b^2}{4a^2}}\right\}.$$

Hence f_k is analytic on the disc

$$D = D_\epsilon = \left\{z \in \mathbb{C} : |z| \le \rho = (1-\epsilon)\sqrt{c/a}\right\}, \qquad 0 < \epsilon < 1.$$

For all sufficiently small $|z|$, two applications of the binomial theorem and some reordering give

$$\begin{aligned}
f_k(z) &= c^{k/2}\left(1+\frac{bz+az^2}{c}\right)^{k/2}\\
&= c^{k/2}\sum_{j=0}^{\infty}\binom{k/2}{j}\left(\frac{bz+az^2}{c}\right)^{j}\\
&= c^{k/2}\sum_{j=0}^{\infty}\binom{k/2}{j}\sum_{q=0}^{j}\binom{j}{q}\frac{(bz)^{j-q}(az^2)^q}{c^j}\\
&= c^{k/2}\sum_{\ell=0}^{\infty}\sum_{j=\lfloor\frac{\ell+1}{2}\rfloor}^{\ell}\binom{k/2}{j}\binom{j}{\ell-j}\frac{(bz)^{2j-\ell}(az^2)^{\ell-j}}{c^j}\\
&= c^{k/2}\sum_{\ell=0}^{\infty}\left(\frac{z}{c}\right)^{\ell}\sum_{j=\lfloor\frac{\ell+1}{2}\rfloor}^{\ell}\binom{k/2}{j}\binom{j}{\ell-j}b^{2j-\ell}(ac)^{\ell-j}\\
&= c^{k/2}\sum_{\ell=0}^{\infty}\left(\frac{z}{c}\right)^{\ell}P_\ell^{(k)}(a,b,c).
\end{aligned}$$

Since the reordering of the double sum is valid for $|z|$ sufficiently small, for such z this is the Maclaurin series for f_k. This relation extends to all of D by the uniqueness of the Maclaurin series of f_k, proving the first part of the lemma.

We will prove the second part separately for $k > 0$ and $k < 0$. For $k > 0$ we will apply the well-known bound for the error in Taylor polynomial approximation given in Lemma 2.4 below. Fix z with $|z| < \sqrt{c/a}$ and choose ϵ with $0 < \epsilon < 1$ so small that $z \in D_\epsilon$. We apply the bound with $C = \partial D_\epsilon$. First, note that

$$q(z) = a(z-\xi_+)(z-\xi_-), \qquad \xi_\pm = \frac{-b\pm \mathbf{i}\sqrt{4ac-b^2}}{2a},$$

and that both roots of q are outside D_ϵ. Since $f_k(z) = q(z)^{k/2}$,

$$\max_{w\in C}|f_k(w)| = \left(\max_{w\in C}|q(w)|\right)^{k/2}.$$

For $w \in \partial D_\epsilon$,

$$|w-\xi_\pm| \le |w| + |\xi_\pm| = \rho + \sqrt{c/a} < 2\sqrt{c/a},$$

and thus

$$\max_{w\in\partial D_\epsilon}|q(w)| = |a|\max_{w\in\partial D_\epsilon}\{|w-\xi_+||w-\xi_-|\} \le |a|\big(2\sqrt{c/a}\big)^2 = 4c.$$

Now, applying Lemma 2.4,

$$\begin{aligned}
&\left|(az^2+bz+c)^{k/2} - c^{k/2}\sum_{\ell=0}^{\nu}\left(\frac{z}{c}\right)^{\ell}P_\ell^{(k)}(a,b,c)\right|\\
&\qquad\le \max_{w\in\partial D_\epsilon}|f_k(w)|\left(\frac{|z|}{\rho}\right)^{\nu+1}\frac{1}{1-|z|/\rho}\\
&\qquad\le (4c)^{k/2}\left(\frac{|z|}{(1-\epsilon)\sqrt{c/a}}\right)^{\nu+1}\frac{(1-\epsilon)\sqrt{c/a}}{(1-\epsilon)\sqrt{c/a}-|z|}.
\end{aligned}$$

Taking the limit as ϵ goes to zero from above gives the result for $k > 0$.

For the case $k < 0$, write the polynomial q in the form

$$\begin{aligned} q(z) = az^2 + bz + c &= c\left\{1 + \frac{b}{\sqrt{ac}}\left(\frac{z}{\sqrt{c/a}}\right) + \left(\frac{z}{\sqrt{c/a}}\right)^2\right\} \\ &= c\big(1 - 2x\xi + \xi^2\big), \end{aligned}$$

where

$$x = -\frac{1}{2}\frac{b}{\sqrt{ac}} \qquad \text{and} \qquad \xi = \frac{z}{\sqrt{c/a}}.$$

Now recall (see [11, eqn. (4.7.23)]) that $\big(1 - 2x\xi + \xi^2\big)^{-\lambda}$ is the generating function for the *Gegenbauer (or ultraspherical) polynomials* $C_\ell^{(\lambda)}(x)$, i.e.,

$$\sum_{\ell=0}^{\infty} C_\ell^{(\lambda)}(x)\xi^\ell = (1 - 2x\xi + \xi^2)^{-\lambda}.$$

Letting $\lambda = -k/2$, we see that

$$f_k(z) = c^{k/2}\sum_{\ell=0}^{\infty} C_\ell^{(\lambda)}(x)\xi^\ell,$$

and thus, equating coefficients,

$$\left(\frac{z}{c}\right)^\ell P_\ell^{(k)}(a, b, c) = C_\ell^{(\lambda)}(x)\xi^\ell, \qquad \ell \in \mathbb{N}_0. \tag{2.4}$$

For $-1 \le x \le 1$,

$$\big|C_n^{(\lambda)}(x)\big| \le \binom{n + 2\lambda - 1}{n}, \qquad \lambda > 0$$

(see [1, eqn. (22.14.2)]). By the statement of the lemma, $b^2 \le 4ac$ and $|z| < \sqrt{c/a}$. This means that $-1 \le x \le 1$ and $|\xi| < 1$ and thus

$$\begin{aligned} \left|f_k(z) - c^{k/2}\sum_{\ell=0}^{\nu}\left(\frac{z}{c}\right)^\ell P_\ell^{(k)}(a, b, c)\right| &= \left|f_k(z) - c^{k/2}\sum_{\ell=0}^{\nu} C_\ell^{(-k/2)}(x)\xi^\ell\right| \\ &\le c^{k/2}\sum_{\ell=\nu+1}^{\infty}\binom{\ell - k - 1}{\ell}|\xi|^\ell. \end{aligned} \tag{2.5}$$

By Lemma 2.2,

$$\sum_{\ell=\nu+1}^{\infty}\binom{\ell - k - 1}{\ell}|\xi|^\ell = \binom{\nu - k}{\nu + 1}\frac{|\xi|^{\nu+1}}{(1 - |\xi|)^{-k}} F\left(k + 1, \nu + 1; \nu + 2; |\xi|\right).$$

Using this in (2.5) we have

$$\left| f_k(z) - c^{k/2} \sum_{\ell=0}^{\nu} \left(\frac{z}{c}\right)^{\ell} P_\ell^{(k)}(a,b,c) \right| \le c^{k/2} \binom{\nu-k}{\nu+1} \left(\frac{|z|}{\sqrt{c/a}}\right)^{\nu+1} \left(\frac{\sqrt{c/a}}{\sqrt{c/a}-|z|}\right)^{-k} \times F\left(k+1, \nu+1; \nu+2; \frac{|z|}{\sqrt{c/a}}\right). \qquad \square$$

In the proof of Lemma 2.3 above we have made use of the following well-known bound for the error in a truncated Taylor series expansion [8, pp. 127–128].

LEMMA 2.4. *Let $C = \{w \in \mathbb{C} : |w| = \rho\}$. If f is analytic inside and on C, then for $|z| < \rho$,*

$$\left|f(z) - \big(T_\nu f\big)(z)\right| \le \max_{w\in C} |f(w)| \left(\frac{|z|}{\rho}\right)^{\nu+1} \frac{1}{1-|z|/\rho},$$

where $T_\nu f$ is the Maclaurin polynomial of f of degree ν.

In the case $k = -1$, the polynomial $F(k+1, \nu+1; \nu+2; z/\sqrt{c/a})$ that appears in the error bound of Lemma 2.3 is constant and has value 1. For all other negative values of k consider the function $F(k+1, p+1; p+2; \cdot)$, where $p \in \mathbb{N}_0$. Rephrasing Lemma 2.2 as

$$F(k+1, p; p+1; z) = \frac{p!\,(-k-1)!}{(p-k-1)!} \frac{(1-z)^{-k}}{z^p} \sum_{n=p}^{\infty} \binom{n-k-1}{-k-1} z^n,$$

we can easily see that $F(k+1, p+1; p+2; \cdot)$ is nonnegative on $[0,1)$. Using (2.2b) to differentiate F, we see that for $z \in [0,1)$

$$\frac{d}{dz} F(k+1, p; p+1; z) = \frac{(k+1)p}{p+1} F(k+2, p+1; p+2; z) \le 0,$$

since $k < -1$. Since $F(\cdot,\cdot;\cdot;0) = 1$, it follows that

$$F(k+1, \nu+1; \nu+2; |z|/\sqrt{c/a}) \le 1, \qquad k \in \mathbb{Z}_-, \quad |z| < \sqrt{c/a}. \tag{2.6}$$

As was observed in the proof of Lemma 2.3 and particularly in (2.4), for $k < 0$ the polynomials $P_\ell^{(k)}$ are closely related to the Gegenbauer polynomials $C_\ell^{(\lambda)}$ with $\lambda = -k/2$. However, many properties of the Gegenbauer polynomials are derived using their orthogonality with respect to the weight function $w(x) = (1-x^2)^{\lambda-1/2}$. This function is not integrable over the interval $[-1,1]$ when $\lambda \le -1/2$, and thus we are unable to exploit properties of the Gegenbauer polynomials derived from orthogonality when $k \ge 1$. The following lemma can be identified as a well-known recurrence for the Gegenbauer polynomials with parameter $\lambda = -k/2 > -1/2$. Our proof here is based on the characterization (2.3) and hence holds for all odd integers k.

LEMMA 2.5. *Let $k \in \mathbb{Z}$ be odd. Then the polynomials $P_\ell^{(k)}$ defined in* (1.4) *satisfy the following recurrence relation for all $a, b, c \in \mathbb{R}$ and $\ell \in \mathbb{N}$:*

$$(\ell+1) P_{\ell+1}^{(k)}(a,b,c) = \left(\frac{k}{2} - \ell\right) b P_\ell^{(k)}(a,b,c) + \big(k - (\ell-1)\big) ac P_{\ell-1}^{(k)}(a,b,c). \tag{2.7}$$

Proof. We will first prove the identity under the additional assumptions $a, c > 0$ and $b^2 \leq 4ac$. Making these assumptions and differentiating the right-hand side of (2.3) term by term gives

$$f_k'(z) = c^{(k-2)/2} \sum_{\ell=0}^{\infty} \left(\frac{z}{c}\right)^{\ell} (\ell+1) P_{\ell+1}^{(k)}(a,b,c), \tag{2.8}$$

the term-by-term differentiation being valid for $|z| < \sqrt{c/a}$.

On the other hand, differentiating the expression $f_k(z) = (\sqrt{az^2+bz+c})^k$ and then expanding gives

$$\begin{aligned} f_k'(z) &= \frac{k}{2}(az^2+bz+c)^{(k-2)/2}(2az+b) \\ &= \frac{k}{2} f_{k-2}(z)(2az+b) \\ &= \frac{k}{2} c^{(k-2)/2} \sum_{\ell=0}^{\infty} \left(\frac{z}{c}\right)^{\ell} (2az+b) P_{\ell}^{(k-2)}(a,b,c) \\ &= c^{(k-2)/2} \left\{ \sum_{\ell=0}^{\infty} \left(\frac{z}{c}\right)^{\ell} \frac{k}{2} b P_{\ell}^{(k-2)}(a,b,c) + \sum_{\ell=1}^{\infty} \left(\frac{z}{c}\right)^{\ell} kac P_{\ell-1}^{(k-2)}(a,b,c) \right\}. \end{aligned} \tag{2.9}$$

Equating (2.8) and (2.9) and then comparing coefficients gives

$$(\ell+1) P_{\ell+1}^{(k)}(a,b,c) = \frac{k}{2} b P_{\ell}^{(k-2)}(a,b,c) + kac P_{\ell-1}^{(k-2)}(a,b,c), \quad \ell \in \mathbb{N}. \tag{2.10}$$

Using the obvious recurrence on f_k and then expanding gives

$$\begin{aligned} f_k(z) &= (az^2+bz+c) f_{k-2}(z) \\ &= c^{k/2} \left\{ \sum_{\ell=2}^{\infty} \left(\frac{z}{c}\right)^{\ell} ac P_{\ell-2}^{(k-2)}(a,b,c) + \sum_{\ell=1}^{\infty} \left(\frac{z}{c}\right)^{\ell} b P_{\ell-1}^{(k-2)}(a,b,c) \right. \\ &\qquad \left. + \sum_{\ell=0}^{\infty} \left(\frac{z}{c}\right)^{\ell} P_{\ell}^{(k-2)}(a,b,c) \right\}. \end{aligned} \tag{2.11}$$

Equating (2.3) and (2.11) and then comparing coefficients gives

$$P_{\ell+1}^{(k)}(a,b,c) = P_{\ell+1}^{(k-2)}(a,b,c) + b P_{\ell}^{(k-2)}(a,b,c) + ac P_{\ell-1}^{(k-2)}(a,b,c), \quad \ell \in \mathbb{N}. \tag{2.12}$$

To obtain (2.7), multiply (2.12) by $(\ell+1)$ and equate to (2.10). Solving for $P_{\ell+1}^{(k-2)}(a,b,c)$ and making the index change $(k-2) \mapsto k$ gives (2.7).

This completes the proof when $a, c > 0$ and $b^2 \leq 4ac$. This set in $\mathbb{R}^3$ contains a nontrivial open ball, and polynomials in n variables are determined everywhere by their behavior on any nontrivial open ball in $\mathbb{R}^n$. Hence (2.7) holds for all $a, b, c \in \mathbb{R}$ since the right- and left-hand sides of (2.7) are polynomial. □

3. Multivariate expansions. Let $\Phi(x) = \left(x^2+\tau^2\right)^{k/2}$, where $\tau \geq 0$ and $k \in \mathbb{Z}$ is odd and where we have used the notational convenience $x^2 = \langle x, x\rangle = |x|^2$ for $x \in \mathbb{R}^n$. The following result gives a far field expansion for $\Phi(x-t)$ considered as a function of x, together with an error estimate for approximation with truncations of this expansion. The numerator polynomials $P_\ell^{(k)}(t^2+\tau^2,-2\langle t,x\rangle,x^2)$ that feature in the expansion are homogeneous of degree ℓ in x. Correspondingly, the ℓth term in the expansion is homogeneous of degree $k-\ell$ in x.

Lemma 3.1. *Let $k\in\mathbb{Z}$ be odd, $t\in\mathbb{R}^n$, and $\tau\geq 0$. For all $x\in\mathbb{R}^n$ with $|x|>\sqrt{t^2+\tau^2}$,*

$$\Phi(x-t)=\big((x-t)^2+\tau^2\big)^{k/2}=\sum_{\ell=0}^{\infty}P_\ell^{(k)}(t^2+\tau^2,-2\langle t,x\rangle,x^2)/|x|^{2\ell-k},$$

where the polynomials $P_\ell^{(k)}$ are defined in (1.4). *Moreover, for all x such that $|x|>\sqrt{t^2+\tau^2}$, and for all $p\in\mathbb{N}$ such that $p+k>0$,*

$$\left|\Phi(x-t)-\sum_{\ell=0}^{p+k}P_\ell^{(k)}(t^2+\tau^2,-2\langle t,x\rangle,x^2)/|x|^{2\ell-k}\right|$$
$$\leq\begin{cases}\big(2\sqrt{t^2+\tau^2}\big)^k\left(\dfrac{\sqrt{t^2+\tau^2}}{|x|}\right)^{p+1}\dfrac{|x|}{|x|-\sqrt{t^2+\tau^2}} & \text{if } k>0,\\[2ex] \dbinom{p}{p+k+1}\big(\sqrt{t^2+\tau^2}\big)^k\left(\dfrac{\sqrt{t^2+\tau^2}}{|x|}\right)^{p+1} \times\left(\dfrac{|x|}{|x|-\sqrt{t^2+\tau^2}}\right)^{-k} & \text{if } k<0.\end{cases}$$

Proof. Consider firstly the case when $\tau>0$. Let $a=t^2+\tau^2$, $b=-2\langle t,x\rangle$, and $c=x^2$. Then

$$\Phi(x-t)=\big(x^2-2\langle t,x\rangle+t^2+\tau^2\big)^{k/2}=f_k(1),$$

where f_k is the function defined in (2.1). Since $a,c>0$, $b^2\leq 4ac$, and $1=|z|<\sqrt{c/a}=|x|/\sqrt{t^2+\tau^2}$, Lemma 2.3 may be applied with $\nu=p+k$ to yield the desired results when we recall the bound on F given by (2.6).

This completes the proof when $\tau>0$. For the remaining case fix x with $|x|>|t|$. Note that $0<\widetilde{\tau}<\sqrt{|x|^2-|t|^2}$ implies $|x|>\sqrt{t^2+\widetilde{\tau}^2}$. Hence the previous case can be applied to the expansion of

$$\Phi(x-t;k,\widetilde{\tau})=\big((x-t)^2+\widetilde{\tau}^2\big)^{k/2}$$

for all sufficiently small positive $\widetilde{\tau}$. Taking the limit as $\widetilde{\tau}$ goes to zero from above, and using the continuity of all the relevant quantities as functions of $\widetilde{\tau}$, gives the result for $\tau=0$. □

Example 3.2. In the one-dimensional case it is convenient to rewrite the series in the simpler form

$$\Phi(x-t)=\operatorname{sign}(x)\sum_{\ell=0}^{\infty}P_\ell^{(k)}(t^2+\tau^2,-2t,1)/x^{\ell-k},$$

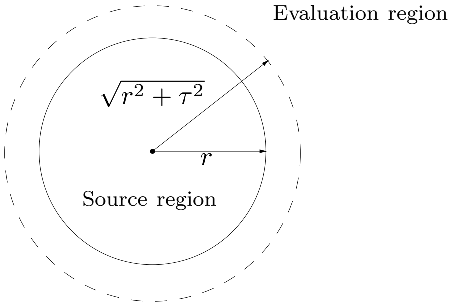

FIG. 3.1. *Region of validity of the far field expansion of a cluster.*

which becomes, in the important special case ($k=1$) of the ordinary multiquadric,

$$\begin{aligned}\sqrt{(x-t)^2+\tau^2} = \operatorname{sign}(x)\Big\{ & x - t + \frac{1}{2}\tau^2 x^{-1} + \frac{1}{2}t\tau^2 x^{-2} \\ & + \frac{1}{8}(4t^2\tau^2-\tau^4)x^{-3} + \frac{1}{8}(4t^3\tau^2 - 3t\tau^4)x^{-4} \\ & + \frac{1}{16}\tau^2(8t^4-12t^2\tau^2+\tau^4)x^{-5} + \cdots + q_\ell(t,\tau)x^{1-\ell} + \cdots\Big\}.\end{aligned}$$

Example 3.3. To display the componentwise form of the expansion in two dimensions we will temporarily adopt the notation $x=(x_1,x_2)$ and $t=(t_1,t_2)$. The far field expansion about zero of a single ordinary multiquadric basic function centered at t is then

$$\begin{aligned}&\sqrt{|x-t|^2+\tau^2} \\ &\quad = |x| - \frac{t_1x_1+t_2x_2}{|x|} + \frac{1}{2}\frac{(t_2^2+\tau^2)x_1^2 + (t_1^2+\tau^2)x_2^2 - 2t_1t_2x_1x_2}{|x|^3} \\ &\quad\quad + \frac{1}{2}\frac{(t_1x_1+t_2x_2)\left\{(t_2^2+\tau^2)x_1^2+(t_1^2+\tau^2)x_2^2-2t_1t_2x_1x_2\right\}}{|x|^5} + \cdots .\end{aligned}$$

Since the bound of Lemma 3.1 is increasing in $|t|$ we can apply it to each center in a cluster and sum, obtaining the following expansion of the generalized multiquadric radial basis function associated with a cluster of centers. The geometry of the source cluster and the evaluation region is shown in Figure 3.1.

THEOREM 3.4. *Suppose $t_i \in \mathbb{R}^n$, $|t_i| \le r$, and $d_i \in \mathbb{R}$ for each $1 \le i \le N$. Let k be odd, $\tau \ge 0$, and s be the generalized multiquadric spline*

$$s(x) = \sum_{i=1}^{N} d_i\Phi(x-t_i) = \sum_{i=1}^{N} d_i\left(\sqrt{(x-t_i)^2+\tau^2}\right)^k .$$

If $P_\ell^{(k)}$, $\ell \in \mathbb{N}_0$, are the polynomials defined by (1.4), *then the polynomials*

$$Q_\ell(x) = \sum_{i=1}^{N} d_i P_\ell^{(k)}(t_i^2+\tau^2, -2\langle t_i, x\rangle, x^2), \qquad \ell \in \mathbb{N}_0,$$

have the following property: Let $p \in \mathbb{N}_0$ and set

$$s_p(x) = \sum_{\ell=0}^{p+k} Q_\ell(x)/|x|^{2\ell-k}, \tag{3.1}$$

$x \in \mathbb{R}^n \backslash \{0\}$. *Then for all* x *with* $|x| > R = \sqrt{r^2 + \tau^2}$,

$$\left|s(x) - s_p(x)\right| \le \begin{cases} 2^k M R^k \left(\dfrac{1}{c}\right)^{p+1} \dfrac{1}{1 - 1/c} & \text{if } k > 0, \\ \dbinom{p}{p+k+1} M R^k \left(\dfrac{1}{c}\right)^{p+1} \left(\dfrac{1}{1-1/c}\right)^{-k} & \text{if } k < 0, \end{cases}$$

where $M = \sum_{i=1}^{N} |d_i|$ *and* $c = |x|/R$.

4. The uniqueness of expansions. The uniqueness of far field expansions is important for two reasons. First, redundant coefficients could mean that a small value is represented as the difference of two large values leading to numerical instability. Second, if the far field expansion of a fixed function, $s(x) = \sum_{i=1}^{N} \Phi(x - t_i)$, is unique, then it is often possible to shift the center of a truncated expansion indirectly without using any knowledge of the underlying centers and weights. The advantage of such indirect shifting over direct series formation is a flop count which depends only on the number of terms in the expansion, and not on the number of centers in the cluster. This can result in significantly faster code. Furthermore, since the uniqueness implies that the indirectly obtained series is identical with that which would have been obtained directly, the indirectly obtained series enjoys the same error bound as the directly obtained one.

We will now prove a general uniqueness lemma from which uniqueness of series expansions of the form (3.1) follows as a special case. Recall that a function g defined for all x in some subset $D \subset \mathbb{R}^n$ is said to be homogeneous of degree γ on D if

$$g(\lambda x) = \lambda^{\gamma} g(x)$$

for all $\lambda > 0$ and $x \in \mathbb{R}^n$ such that both x and $\lambda x \in D$. (Some authors use the term positively homogeneous of degree γ for this property.)

LEMMA 4.1. *Suppose* $\gamma, R \in \mathbb{R}$ *and that a function* $f : D \subset \mathbb{R}^n \to \mathbb{R}$ *can be expanded in two ways,*

$$\sum_{\ell=0}^{\infty} U_\ell(x) = f(x) = \sum_{\ell=0}^{\infty} V_\ell(x),$$

both series converging absolutely and uniformly to $f(x)$ *for all* $|x| \ge R$, *where for each* ℓ , U_ℓ *and* V_ℓ *are continuous homogeneous functions of degree* $\gamma - \ell$. *Then for each* ℓ, $U_\ell(x) = V_\ell(x)$ *for all* $|x| \ge R$.

Proof. Since the absolute series converge uniformly on $|x| = R$, there exists an $M < \infty$ such that

$$\max_{|x|=R} \{\max\{|U_\ell(x)|,\ |V_\ell(x)|\}\} \le M$$

for all $\ell \in \mathbb{N}_0$. Hence, using the homogeneity,

$$\max\{|U_\ell(x)|,\ |V_\ell(x)|\} \le M|x|^{\gamma-\ell}/R^{\gamma-\ell} \tag{4.1}$$

for all x such that $|x| \ge R$ and for all $\ell \in \mathbb{N}_0$.

Now suppose U_ℓ and V_ℓ differ for some ℓ's. Let j be the first index for which they differ. Then for all $|x| \geq R$,

$$\begin{aligned} 0 &= \left(\frac{|x|}{R}\right)^{j-\gamma} \{f(x) - f(x)\} \\ &= \left(\frac{|x|}{R}\right)^{j-\gamma} \{U_j(x) - V_j(x)\} + \sum_{\ell>j} \left(\frac{|x|}{R}\right)^{j-\gamma} \{U_\ell(x) - V_\ell(x)\}. \qquad (4.2) \end{aligned}$$

But from (4.1)

$$\begin{aligned} \left|\sum_{\ell>j} \left(\frac{|x|}{R}\right)^{j-\gamma} \{U_\ell(x) - V_\ell(x)\}\right| &\leq 2M \sum_{\ell>j} \left(\frac{|x|}{R}\right)^{j-\ell} \\ &= o(1) \qquad \text{as } |x| \to \infty. \end{aligned}$$

Hence from (4.2)

$$|U_j(x) - V_j(x)| = o(|x|^{\gamma-j}) \quad \text{as } |x| \to \infty.$$

Since $U_j - V_j$ is homogeneous of degree $\gamma - j$ on D, this implies that it is identically zero on D. □

5. Efficient formation of the far field series. In the previous sections we have developed far field expansions with the intention of using them for fast evaluation of generalized multiquadric radial basis functions. In order that these expansions be suitable for this task they must be inexpensive both to form and to evaluate. The purpose of this section is to show that the expansions can be formed in an efficient recursive manner.

Given a single center $t \in \mathbb{R}^n$ with unit weight, the corresponding truncated expansion of section 3 is

$$\Phi(x-t) = \left((x-t)^2 + \tau^2\right)^{k/2} = \sum_{\ell=0}^{\infty} P_\ell^{(k)}(t^2+\tau^2, -2\langle t, x\rangle, x^2)/|x|^{2\ell-k}. \qquad (5.1)$$

Writing $G_\ell(x) = P_\ell^{(k)}(t^2+\tau^2, -2\langle t, x\rangle, x^2)$, G_ℓ is a homogeneous polynomial of degree ℓ in x, with coefficients depending on k, τ, and t. The expansion for a single center, with corresponding weight d, then becomes

$$\sum_{\ell=0}^{p+k} dG_\ell(x)/|x|^{2\ell-k}. \qquad (5.2)$$

The expansion of a cluster is formed by summing the expansions (5.2) corresponding to each center and has the form

$$\sum_{\ell=0}^{p+k} Q_\ell(x)/|x|^{2\ell-k}, \qquad (5.3)$$

where each Q_ℓ is a homogeneous polynomial of degree ℓ. Lemma 2.5 implies that the polynomials G_ℓ satisfy the three-term recurrence

$$G_\ell(x) = \begin{cases} 1, & \ell = 0, \\ -k\langle x, t\rangle, & \ell = 1, \\ A_\ell \langle x, t\rangle G_{\ell-1}(x) + B_\ell\, x^2(t^2+\tau^2)\, G_{\ell-2}(x), & \ell \geq 2, \end{cases} \qquad (5.4)$$

where

$$A_\ell = -2\frac{k/2-\ell+1}{\ell}, \qquad B_\ell = -\frac{\ell-k-2}{\ell}.$$

The recurrence is very simple to implement, as is demonstrated by the following code fragment for the special case of two dimensions. The code fragment employs the notation of Example 3.3.

Code fragment to generate the numerator polynomial coefficients in the expansion of a generalized multiquadric in two dimensions.

Input: A center $t \in \mathbb{R}^2$, the corresponding weight d, the generalized multiquadric parameters k and τ, and the desired order of expansion p.
Output: The coefficients $G(\ell, j)$ of the homogeneous numerator polynomials in the expansion of this single center. On output $G(\ell, j)$ is the coefficient of $x_1^{\ell-j}x_2^j$ in the homogeneous polynomial dG_ℓ of (5.2).

```
PolynomialGenerator($t$, $d$, $k$, $\tau$, $p$)
    $G(0,0) = d$, $G(1,0) = -d * k * t_1$, $G(1,1) = -d * k * t_2$
    for $\ell = 2$ to $p + k$
        $a = A_\ell$, $b = B_\ell * (|t|^2 + \tau^2)$
        $\mathrm{tmp} = a * G(\ell - 1, 0)$
        $G(\ell, 0) = \mathrm{tmp} * t_1$
        $G(\ell, 1) = \mathrm{tmp} * t_2$
        for $j = 0$ to $\ell - 2$
            $\mathrm{tmp} = b * G(\ell - 2, j)$
            $G(\ell, j) = G(\ell, j) + \mathrm{tmp}$
            $G(\ell, j + 2) = \mathrm{tmp}$
            $\mathrm{tmp} = a * G(\ell - 1, j + 1)$
            $G(\ell, j + 1) = G(\ell, j + 1) + \mathrm{tmp} * t_1$
            $G(\ell, j + 2) = G(\ell, j + 2) + \mathrm{tmp} * t_2$
        end
    end
```

Recall that the $\binom{\ell+n-1}{\ell}$ monomials of exact degree ℓ, $\{x^\alpha : |\alpha| = \ell\}$, form a basis for the homogeneous polynomials of degree ℓ on $\mathbb{R}^n$. Represent the polynomials G_ℓ in terms of these monomials, i.e., let

$$G_\ell(x) = \sum_{|\alpha|=\ell} a_\alpha^\ell x^\alpha,$$

for some coefficients a_α^ℓ. Then, from the recurrence (5.4), each coefficient of G_ℓ can be calculated using at most n coefficients of $G_{\ell-1}$ and at most n coefficients of $G_{\ell-2}$. Specifically, if e_i is the multi-index with 1 in the ith position and 0 elsewhere, then the recurrence (5.4) implies that for $\ell \geq 2$,

$$a_\alpha^\ell = A_\ell \sum_{i=1}^n t_i a_{\alpha-e_i}^{\ell-1} + B_\ell(t^2 + \tau^2) \sum_{i=1}^n a_{\alpha-2e_i}^{\ell-2},$$

where a_β^j is taken to be zero if any component of β is negative. It follows that all the numerator polynomials $\{Q_\ell\}_{\ell=0}^{p+k}$ in the truncated expansion (5.3) of an m center cluster can be formed (that is, their $\binom{n+p+k}{p+k}$ coefficients calculated) in $\mathcal{O}\big(mn\binom{n+p+k}{p+k}\big)$ floating point operations. This quantity is $\mathcal{O}(mn(p+k)^n)$ when the dimension n is less than the degree $p+k$.

6. A subspace of polynomials.

In this section we will investigate a subspace of polynomials in n variables. This space will arise in section 7, and the aim of that section will be to translate a member of this subspace. It will be shown that, modulo a low-degree polynomial, this subspace is closed under translation of the underlying Cartesian coordinate system.

Throughout this section and the next, n will be fixed and any complexity estimates will be expressed as a function of polynomial degree only. Thus a typical estimate might take the form $\mathcal{O}((p+k)^n)$. In such expressions multiplicative order constants depending on n have been suppressed, and we will be interested in the estimate only when the argument $p+k$ is bigger than n.

The following standard spaces will be used:

- π_j^n, polynomials of total degree not exceeding j in n variables.
- $\mathcal{H}_j^n$, homogeneous polynomials of degree j in n variables.

Also, for given function spaces S and T, define new spaces as follows:

$$\begin{aligned} S\,T &= \{s(\cdot)\,t(\cdot)\ :\ s\in S,\ t\in T\}, && \\ S\oplus T &= \{s(\cdot)+t(\cdot)\ :\ s\in S,\ t\in T\}, && \qquad S\cap T=\{0\}, \\ s\,T &= \{s(\cdot)\,t(\cdot)\ :\ t\in T\}, && \qquad s\in S. \end{aligned}$$

The subspaces of polynomials that are the subject of this section are defined by

$$S_j^n = \left\{ q\in\pi_{2j}^n : q(\cdot) = \sum_{\ell=0}^{j} q_\ell(\cdot)|\cdot|^{2(j-\ell)}, q_\ell\in\mathcal{H}_\ell^n \right\}. \tag{6.1}$$

Apart from 0, the polynomials of S_j^n have total degree no greater than $2j$ and no less than j. It follows from Lemma 4.1 that $q\in S_n^j$ is uniquely determined by the homogeneous polynomials $\{q_\ell\}_{\ell=0}^j$ and thus by the coefficients of those polynomials with respect to some appropriate basis. Hence

$$\dim S_j^n = \sum_{\ell=0}^{j} \dim H_\ell^n. \tag{6.2}$$

THEOREM 6.1. *S_j^n is invariant under orthogonal transformation of the underlying coordinate system, i.e., if $q\in S_j^n$, then $q(Q\,\cdot)\in S_j^n$ for orthogonal Q.*

Proof. The component function $f_i(\cdot)=(Q\cdot)_i$ is nontrivial for each i since Q is invertible. Hence, since the component functions are also linear, each f_i is homogeneous of exact degree 1. Thus

$$(Q\cdot)^\alpha = (Q\cdot)_1^{\alpha_1}(Q\cdot)_2^{\alpha_s}\dots(Q\cdot)_n^{\alpha_n}$$

is homogeneous of exact degree $|\alpha|$. It follows that $q_\ell(Q\,\cdot)$ is homogeneous of degree ℓ if q_ℓ is. Finally, since Q is orthogonal,

$$|Q\,\cdot\,| = |\cdot|,$$

and the result follows. □

Before we prove translation invariance of S_j^n we will make a few simple observations regarding these spaces.

LEMMA 6.2. *The spaces S_j^n satisfy the following relations:*

(i) $S^n_{j+1} = \big(|\cdot|^2\, S^n_j\big) \oplus \mathcal{H}^n_{j+1}$,
(ii) $\mathcal{H}^n_1\, S^n_j \subset S^n_{j+1}$,
(iii) $S^n_j \subset S^n_{j+1} \oplus \mathcal{H}^n_j$.

Proof. Let $q \in S^n_{j+1}$ and let $\{q_\ell\}_{\ell=0}^{j+1}$ be the polynomials such that

$$q = \sum_{\ell=0}^{j+1} |\cdot|^{2(j+1-\ell)} q_\ell, \qquad q_\ell \in \mathcal{H}^n_\ell.$$

The observation that

$$q = |\cdot|^2 h + q_{j+1},$$

where

$$h = \left(\sum_{\ell=0}^{j} |\cdot|^{2(j-\ell)} q_\ell \right) \in S^n_j,$$

proves part (i).

Now let $p \in \mathcal{H}^n_1$. Then for each ℓ, $0 \le \ell \le j$, the product $\tilde{q}_{\ell+1} = pq_\ell \in \mathcal{H}^n_{\ell+1}$. Thus

$$pq = \sum_{\ell=0}^{j} |\cdot|^{2(j-\ell)} \tilde{q}_{\ell+1} = \sum_{k=1}^{j+1} |\cdot|^{2(j+1-k)} \tilde{q}_k \in S^n_{j+1},$$

which shows part (ii).

For part (iii),

$$\begin{aligned} q(x) = \sum_{\ell=0}^{j} q_\ell(x)|x|^{2(j-\ell)} &= q_j(x) + \sum_{\ell=0}^{j-1} q_\ell(x)|x|^2\, |x|^{2(j-1-\ell)} \\ &= q_j(x) + \sum_{\ell=0}^{j-1} \tilde{q}_{\ell+2}(x)\, |x|^{2(j-1-\ell)} \\ &= q_j(x) + \sum_{\ell=2}^{j+1} \tilde{q}_\ell(x)\, |x|^{2(j+1-\ell)} \in \mathcal{H}^n_j \oplus S^n_{j+1}, \end{aligned}$$

since the polynomials $\tilde{q}_{\ell+2}(\cdot) = q_\ell(\cdot)|\cdot|^2$ are homogeneous of degree $\ell + 2$. □

THEOREM 6.3. *S^n_j are translation invariant modulo polynomials of degree $j-1$, i.e., for any $q \in S^n_j$ and $u \in \mathbb{R}^n$, $q(\cdot - u) \in S^n_j \oplus \pi^n_{j-1}$.*

Proof. The proof is by induction on j. The result is trivially true in the case $j = 0$ since S^n_0 is the space of constants and π^n_{-1} is the singleton $\{0\}$.

Now assume the result for $k = 0, 1, 2, \ldots, j$, let $q \in S^n_{j+1}$, and let $u \in \mathbb{R}^n$. Then by Lemma 6.2(i),

$$q(x-u) = |x-u|^2\, h(x-u) + q_{j+1}(x-u), \tag{6.3}$$

where $h \in S^n_j$ and $q_{j+1} \in \mathcal{H}^n_{j+1}$. By the induction hypothesis, $h(\cdot - u) \in S^n_j \oplus \pi^n_{j-1}$. Thus

$$h(x-u) = \tilde{h}_j(x) + \tilde{h}_{j-1}(x) + \tilde{h}_<(x), \tag{6.4}$$

where $\tilde{h}_j \in S_j^n$, $\tilde{h}_{j-1} \in \mathcal{H}_{j-1}^n$, and $\tilde{h}_< \in \pi_{j-2}^n$. Since $q_{j+1} \in \mathcal{H}_{j+1}^n$,

$$q_{j+1}(x-u) = q_{j+1}(x) - \tilde{q}_<(x), \tag{6.5}$$

where $\tilde{q}_< \in \pi_j^n$. Expand (6.3) to get

$$q(x-u) = \big(|x|^2 - 2\langle x,u\rangle + |u|^2\big)\Big(\tilde{h}_j(x) + \tilde{h}_{j-1}(x) + \tilde{h}_<(x)\Big) + q_{j+1}(x) + \tilde{q}_<(x). \tag{6.6}$$

Consider each term in the expansion of this product:

$$\begin{aligned} |\cdot|^2\tilde{h}_j &\in S_{j+1}^n && \text{by Lemma 6.2(i)},\\ -2\langle\cdot,u\rangle\,\tilde{h}_j &\in S_{j+1}^n && \text{by Lemma 6.2(ii)},\\ |u|^2\tilde{h}_j &\in S_j^n \subset S_{j+1}^n \oplus \mathcal{H}_j^n && \text{by Lemma 6.2(iii)},\\ |\cdot|^2\tilde{h}_{j-1} &\in S_{j+1}^n && \text{since } |\cdot|^2\mathcal{H}_{j-1}^n \subset \mathcal{H}_{j+1}^n \subset S_{j+1}^n,\\ -2\langle\cdot,u\rangle\,\tilde{h}_{j-1} &\in \mathcal{H}_j^n,\\ |u|^2\tilde{h}_{j-1} + |\cdot - u|^2\tilde{h}_< &\in \pi_j^n. \end{aligned}$$

Thus it follows that $q(\cdot - u) \in S_{j+1}^n \oplus \pi_j^n$. The result follows by induction. □

In computations, a polynomial $p \in S_j^n$ may be known in terms of the monomial basis, but what is actually required are the polynomials $\{q_\ell\}_{\ell=0}^j$ such that

$$p(x) = \sum_{\ell=0}^{j} q_\ell(x)|x|^{2(j-\ell)}. \tag{6.7}$$

Since the polynomials $\{q_\ell\}$ are homogeneous, for a given ℓ, q_ℓ must be determined entirely by those terms of p that are homogeneous of degree $2j-\ell$. Thus the problem of determining $\{q_\ell\}$ may be broken down into homogeneous parts. Hence, without loss of generality, assume that p is a given homogeneous polynomial of degree $\ell + 2k$ such that

$$p(x) = |x|^{2k}q(x) \tag{6.8}$$

with q unknown and to be determined from p. Since

$$p(x) = |x|^{2k}q(x) = |x|^2\big(|x|^{2(k-1)}q(x)\big),$$

if q can be determined in the case where $k = 1$, the more general problem may be solved in an inductive manner.

Let $\{p_j\}_{j=0}^{\ell+2}$ and $\{q_i\}_{i=0}^{\ell}$ be homogeneous polynomials in $x_2, \dots, x_n$ such that

$$p(x) = \sum_{j=0}^{\ell+2} x_1^{\ell+2-j}p_j(\bar{x}), \quad q(x) = \sum_{i=0}^{\ell} x_1^{\ell-i}q_i(\bar{x}), \quad \text{and} \quad p(x) = |x|^2q(x),$$

where, if $x = (x_1, \dots, x_n)$, then $\bar{x} = (x_2, \dots, x_n)$. Using this same notation,

$$|x|^2 = x_1^2 + |\bar{x}|^2$$

and hence

$$\begin{aligned}\sum_{j=0}^{\ell+2} x_1^{\ell+2-j} p_j(\bar{x}) &= \left(x_1^2+|\bar{x}|^2\right)\sum_{i=0}^{\ell} x_1^{\ell-i} q_i(\bar{x})\\ &= x_1^{\ell+2}q_0(\bar{x}) + x_1^{\ell+1}q_1(\bar{x}) + \left\{\sum_{i=2}^{\ell} x_1^{\ell+2-i}\big(q_i(\bar{x})+|\bar{x}|^2 q_{i-2}(\bar{x})\big)\right\}\\ &\qquad + x_1|\bar{x}|^2 q_{\ell-1}(\bar{x}) + |\bar{x}|^2 q_\ell(\bar{x}).\end{aligned}$$

Equating coefficients, we may now write the polynomials q_i in terms of the polynomials p_j:

$$\begin{aligned} q_0(\bar{x}) &= p_0(\bar{x}),\\ q_1(\bar{x}) &= p_1(\bar{x}),\\ q_2(\bar{x}) &= p_2(\bar{x}) - |\bar{x}|^2 q_0(\bar{x}),\\ q_3(\bar{x}) &= p_3(\bar{x}) - |\bar{x}|^2 q_1(\bar{x}),\\ &\ \ \vdots\\ q_{\ell-1}(\bar{x}) &= p_{\ell-1}(\bar{x}) - |\bar{x}|^2 q_{\ell-3}(\bar{x}),\\ q_\ell(\bar{x}) &= p_\ell(\bar{x}) - |\bar{x}|^2 q_{\ell-2}(\bar{x}).\end{aligned}$$

Multiplication of a polynomial by a monomial corresponds to a relabeling of coefficients and computationally corresponds to assignment or addition. Since

$$|\bar{x}|^2 = x_2^2 + \cdots + x_n^2$$

is just the sum of $n-1$ monomials, for fixed i the product $|\cdot|^2 q_i(\cdot)$ may be calculated with $\mathcal{O}(nC_i)$ additions, where $C_i = \dim \mathcal{H}_i^{n-1}$. It is well known that

$$\dim \mathcal{H}_i^{n-1} = \binom{i+n-2}{n-2} = \frac{(i+n-2)!}{i!(n-2)!} = \frac{1}{(n-2)!}\big((i+n-2)\cdots(i+1)\big) = \mathcal{O}(i^{n-2}),$$

and hence $|\cdot|^2 q_i(\cdot)$ may be calculated in $\mathcal{O}(i^{n-2})$ operations. It now follows that all of the polynomials $\{q_i\}_{i=0}^{\ell}$ may be calculated in $\mathcal{O}(\ell^{n-1})$ operations.

Since the more general problem of (6.8) may be solved by k applications of this simpler case, $q(x) = p(x)/|x|^{2k}$ may be calculated in

$$\sum_{i=0}^{k-1} \mathcal{O}\big((\ell+2i)^{n-1}\big) = \mathcal{O}\big((\ell+2k)^n\big)$$

operations. Applying this to each homogeneous part of (6.7) gives the following lemma.

Lemma 6.4. *Let $n \in \mathbb{N}$. There exists a constant C depending only on n with the following property. Given any polynomial $p \in S_j^n$, the polynomials $\{q_\ell\}_{\ell=0}^{j}$ such that $q_\ell \in \mathcal{H}_\ell^n$ and*

$$p = \sum_{\ell=0}^{j} |\cdot|^{2(j-\ell)} q_\ell$$

may be determined in no more than Cj^{n+1} operations.

7. Translation of a far field expansion. The uniqueness of the far field expansions makes it possible to shift the center of a truncated expansion knowing only its coefficients and without any direct knowledge of the underlying centers and weights. As the operation count for indirect translation depends on the length of the series, not the number of centers, indirect translation can be significantly faster than direct formation of series for clusters with many centers.

The precise problem we address is the following. Let

$$s_p(x) = \sum_{\ell=0}^{p+k} Q_\ell(y)/|y|^{2\ell-k}, \qquad y = x - u \neq 0, \tag{7.1}$$

where Q_ℓ are homogeneous polynomials of degree ℓ, be an expansion similar to (3.1) or (5.3), but centered at $u \neq 0$ rather than 0. We wish to shift the center of expansion to the origin. That is, we seek homogeneous polynomials $\{\widehat{Q}_\ell\}$, $\widehat{Q}_\ell$ being of degree ℓ, so that

$$s_p(x) = \sum_{\ell=0}^{p+k} \widehat{Q}_\ell(x)/|x|^{2\ell-k} + \mathcal{O}(1/|x|^{p+1}) \tag{7.2}$$

as $|x| \to \infty$. We will show that translations of truncated expansions of the form (7.1) into expansions of the form (7.2) may be performed in $\mathcal{O}\left((p+k)^{n+1}\right)$ operations using simple polynomial manipulations.

7.1. The cost of multiplication. In this subsection it will be shown that the product of two homogeneous polynomials of degree ℓ in n variables may be computed in $\mathcal{O}(\ell^{n-1}\log \ell)$ operations.

Let p be a homogeneous polynomial of degree ℓ. Since p is homogeneous,

$$p(x) = p(x_1, x_2, \dots, x_n) = x_n^\ell p\left(\frac{x_1}{x_n}, \frac{x_2}{x_n}, \dots, \frac{x_{n-1}}{x_n}, 1\right), \qquad x_n \neq 0.$$

Furthermore given $x_n^\ell p(...)$ for all x with $x_n \neq 0$, $p(x)$ can be recovered on the hyperplane $x_n = 0$ by continuity. Thus for the purposes of the multiplication and division that are the subject of this section, we may consider multiplication and division of general, that is, probably inhomogeneous, polynomials of degree ℓ in $n-1$ variables, rather than of homogeneous polynomials of degree ℓ in n variables.

Let p and q be two polynomials of degree ℓ in $n-1$ variables. Then their product is

$$p(x)q(x) = \left(\sum_{|\alpha|\le\ell} a_\alpha x^\alpha\right)\left(\sum_{|\beta|\le\ell} b_\beta x^\beta\right) = \sum_{|\alpha|\le 2\ell}\left(\sum_{0\le\beta\le\alpha} a_\beta b_{\alpha-\beta}\right)x^\alpha,$$

the Cauchy product. The convolution producing the coefficients of the product can be computed in $\mathcal{O}(\ell^{n-1}\log \ell)$ operations by FFTs. It now follows that the homogeneous polynomial multiplication above can also be carried out in $\mathcal{O}(\ell^{n-1}\log \ell)$ operations.

7.2. Translation by convolution. In this subsection it will be shown that translation of the far field series may be performed by convolution.

Throughout this subsection when we speak of forming a polynomial, we mean finding its coefficients with respect to a basis, usually the monomial basis. When we speak of forming a truncated expansion of the type (5.3), we mean finding the coefficients of all the relevant numerator polynomials.

First we set

$$Q(y) = \sum_{\ell=0}^{p+k} Q_\ell(y)|y|^{2(p+k-\ell)}. \tag{7.3}$$

Then

$$s_p(x) = Q(y)/|y|^{2p+k}, \qquad y = x - u \neq 0. \tag{7.4}$$

Since we already have all of the Q_ℓ, all we need to do to form Q is form the polynomials $|\cdot|^{2(p+k-\ell)}$ and then form the products $Q_\ell(\cdot)|\cdot|^{2(p+k-\ell)}$. Form $|\cdot|^{2j}$, $j = 0, \ldots, p+k$, once and store. Each $|\cdot|^{2j-2}$ is homogeneous of degree $2j-2$ and therefore involves $\mathcal{O}(j^{n-1})$ coefficients. The polynomial $|\cdot|^{2j}$ may be obtained from $|\cdot|^{2j-2}$ with n additions for each coefficient in $|\cdot|^{2j-2}$. Hence the cost of forming the $|\cdot|^{2j}$'s is $\mathcal{O}((p+k)^n)$ operations. Each of the products $Q_\ell(\cdot)|\cdot|^{2(p+k-\ell)}$ is the product of two homogeneous polynomials and is of degree no greater than $2(p+k)$. Hence we can calculate each product in $\mathcal{O}\big((p+k)^{n-1}\log(p+k)\big)$ operations. As there are $p+k+1$ of these products in Q, forming Q takes $\mathcal{O}\big((p+k)^n \log(p+k)\big)$ operations.

We proceed to shift the center of expansion of Q by setting

$$\widetilde{Q}(x) = Q(x-u), \qquad x \in \mathcal{R}^n. \tag{7.5}$$

A translation of this sort can be done simply and quickly by convolution. For example, using the scaled monomial basis $V_\alpha(x) = x^\alpha/\alpha!$ (α a multi-index), we have

$$\begin{aligned}
p(x-u) &= \sum_{|\alpha|<k} a_\alpha\, V_\alpha(x-u) \\
&= \sum_{|\alpha|<k} a_\alpha \frac{(x-u)^\alpha}{\alpha!} \\
&= \sum_{|\alpha|<k} \frac{a_\alpha}{\alpha!} \sum_{\beta<\alpha} \binom{\alpha}{\beta} x^\beta (-u)^{(\alpha-\beta)} \\
&= \sum_{|\alpha|<k} a_\alpha \sum_{\beta<\alpha} \frac{x^\beta}{\beta!} \frac{(-u)^{(\alpha-\beta)}}{(\alpha-\beta)!} \\
&= \sum_{|\beta|<k} \frac{x^\beta}{\beta!} \sum_{\alpha<\beta} a_\alpha \frac{(-u)^{(\alpha-\beta)}}{(\alpha-\beta)!}.
\end{aligned}$$

Thus an n-dimensional convolution of $\{a_\alpha\}$ and $\{(-u)^\alpha/\alpha!\}$ gives the coefficients of the translated polynomial. Again this can be computed in $\mathcal{O}\big((p+k)^n \log(p+k)\big)$ operations by an FFT method. This gives us $\widetilde{Q}$ in terms of the monomial or scaled monomial basis.

The next task is to recast $\widetilde{Q}$ into a sum of products of powers of $|x|$ and homogeneous polynomials. By Theorem 6.3 we know that

$$\widetilde{Q}(x) = \sum_{\ell=0}^{p+k} q_\ell(x)|x|^{2(p+k-\ell)} + q_{\text{low}}(x), \tag{7.6}$$

where the q_ℓ are homogeneous of degree ℓ and q_{low} is some polynomial of degree $p+k-1$ or less. By Lemma 6.4, these homogeneous polynomials q_ℓ can be calculated from $\widetilde{Q}$ in $\mathcal{O}\big((p+k)^{n+1}\big)$ operations.

Combining (7.4) and (7.5) and appealing to Lemma 3.1 gives

$$
\begin{aligned}
s_p(x) &= Q(x-u)/|x-u|^{2p+k} \\
&= \widetilde{Q}(x)/|x-u|^{2p+k} \qquad (7.7)\\
&= \widetilde{Q}(x)\sum_{m=0}^{\infty} P_m^{(-2p-k)}(u^2, -2\langle x,u\rangle, x^2)/|x|^{2p+k+2m} \\
&= \left(\sum_{\ell=0}^{p+k} q_\ell(x)|x|^{2(p+k-\ell)} + q_{\text{low}}(x)\right) \\
&\qquad \times \left(\sum_{m=0}^{\infty} P_m^{(-2p-k)}(u^2, -2\langle x,u\rangle, x^2)/|x|^{2p+k+2m}\right) \\
&= \sum_{\ell=0}^{p+k}\sum_{m=0}^{\infty} q_\ell(x)P_m^{(-2p-k)}(u^2, -2\langle x,u\rangle, x^2)/|x|^{2(m+\ell)-k} + \mathcal{O}(1/|x|^{p+1}) \\
&= \sum_{\ell=0}^{p+k}\left(\sum_{j=0}^{\ell} q_j(x)P_{\ell-j}^{(-2p-k)}(u^2, -2\langle x,u\rangle, x^2)\right)/|x|^{2\ell-k} + \mathcal{O}(1/|x|^{p+1}) \\
&= \sum_{\ell=0}^{p+k} \widehat{Q}_\ell(x)/|x|^{2\ell-k} + \mathcal{O}(1/|x|^{p+1}).
\end{aligned}
$$

The sums of products

$$
\widehat{Q}_\ell(x) = \sum_{j=0}^{\ell} q_j(x)P_{\ell-j}^{(-2p-k)}(u^2, -2\langle x,u\rangle, x^2), \quad 0 \le \ell \le p+k, \qquad (7.8)
$$

can be computed simultaneously as homogeneous parts of the product

$$
\left[\sum_{j=0}^{p+k} q_j(\cdot)\right]\left[\sum_{m=0}^{p+k} P_m^{-2p+k}\left(u^2, -2\langle\cdot,u\rangle, (\cdot)^2\right)\right].
$$

Hence they can be computed by a single FFT convolution in $\mathcal{O}\left((p+k)^n \log(p+k)\right)$ operations.

8. Conversion to a near field series. The final step in the process of forming expansions for the FMM is to convert the far field series into a near field, or Taylor, series. At the implementation level, this step is almost identical to the first part of the translation of the far field series.

Define two nonintersecting discs:

$$
\begin{aligned}
D_{\text{eval}} &= \left\{x : |x| \le r\right\}, \\
D_{\text{src}} &= \left\{x : |x-u| \le \sqrt{(\theta r)^2 - \tau^2}\right\}, \qquad \theta > 0.
\end{aligned}
$$

Let

$$
s_p(x) = \sum_{\ell=0}^{p+k} Q_\ell(y)/|y|^{2\ell-k}, \qquad y = x-u \ne 0,
$$

be a far field series, such as (3.1) or (7.1), of $s(x) = \sum_{i=1}^{N} d_i \Phi(x - t_i)$ due to a cluster of centers $\{t_i\}$ located inside D_{src}. Then by Theorem 3.4, s_p approximates s well on D_{eval}. We wish to find a near field series that approximates s_p, and thus s, on D_{eval}.

Proceeding in an identical fashion to section 7.2, we see that we may calculate the polynomial $\widetilde{Q}$ such that

$$s_p(x) = \widetilde{Q}(x)/|x - u|^{2p+k}$$

in $\mathcal{O}\left((p+k)^n \log(p+k)\right)$ operations. When translating the far field expansion to another far field expansion, we essentially convolved $\widetilde{Q}$ with the far field series for $|\cdot - u|^{-(2p+k)}$. To get the near field, all we need do is convolve $\widetilde{Q}$ with the near field series for $|\cdot - u|^{-(2p+k)}$.

The next result gives an explicit expression for the Maclaurin series of $\Phi(\cdot - u) = ((\cdot - u)^2 + \tau^2)^{k/2}$ together with an estimate of the error in approximation by truncating this series. Specializing to the case $\tau = 0$ in this lemma gives the Maclaurin series for $|\cdot - u|^k$.

Lemma 8.1. *Let $k \in \mathbb{Z}$ be odd, and let $u \in \mathbb{R}^n \setminus \{0\}$ and $\tau \geq 0$. For all $x \in \mathbb{R}^n$ with $|x| < \sqrt{u^2 + \tau^2}$,*

(8.1)
$$\Phi(x - u) = \left((x-u)^2 + \tau^2\right)^{k/2} = \sum_{\ell=0}^{\infty} P_\ell^{(k)}(x^2, -2\langle u, x\rangle, u^2 + \tau^2)/\left(\sqrt{u^2 + \tau^2}\right)^{2\ell - k},$$

where the polynomials $P_\ell^{(k)}$ are defined in (1.4). *Moreover,*

$$T_q\big(\Phi(\cdot - u)\big)(x) := \sum_{\ell=0}^{q} P_\ell^{(k)}(x^2, -2\langle u, x\rangle, u^2 + \tau^2)/\left(\sqrt{u^2 + \tau^2}\right)^{2\ell - k} \tag{8.2}$$

is the Maclaurin polynomial of degree q of $\Phi(\cdot - u)$. When $|x| < \sqrt{u^2 + \tau^2}$ and $q \in \mathbb{N}$,

$$\left| \Phi(x - u) - \sum_{\ell=0}^{q} P_\ell^{(k)}(x^2, -2\langle u, x\rangle, u^2 + \tau^2)/\left(\sqrt{u^2 + \tau^2}\right)^{2\ell - k} \right| \tag{8.3}$$
$$\leq \begin{cases} \left(\sqrt{u^2+\tau^2}\right)^k \left(\dfrac{|x|}{\sqrt{u^2+\tau^2}}\right)^{q+1} \dfrac{\sqrt{u^2+\tau^2}}{\sqrt{u^2+\tau^2} - |x|} & \textit{if } k > 0, \\ \dbinom{q-k}{q+1} \left(\sqrt{u^2+\tau^2}\right)^k \left(\dfrac{|x|}{\sqrt{u^2+\tau^2}}\right)^{q+1} \left(\dfrac{\sqrt{u^2+\tau^2}}{\sqrt{u^2+\tau^2} - |x|}\right)^{-k} & \textit{if } k < 0. \end{cases}$$

Proof. Assume first that $x \neq 0$. Let $a = x^2$, $b = -2\langle u, x\rangle$, and $c = u^2 + \tau^2$. Then

$$\Phi(x - u) = \left(x^2 - 2\langle u, x\rangle + u^2 + \tau^2\right)^{k/2} = f_k(1),$$

where f_k is the function that is defined in (2.1). Since $a, c > 0$, $b^2 \leq 4ac$, and $1 = |z| < \sqrt{c/a} = \sqrt{u^2 + \tau^2}/|x|$, Lemma 2.3 may be applied with $\nu = q$ to yield (8.1) and (8.3) when $x \neq 0$. The results for $x = 0$ follow by continuity.

It remains to show that $T_q\big(\Phi(\cdot - u)\big)$ is the Maclaurin polynomial of $\Phi(\cdot - u)$. Observe from (1.4) that

$$P_\ell^{(k)}(a, b, c) = P_\ell^{(k)}(x^2, -2\langle u, x\rangle, u^2 + \tau^2)$$

either is a homogeneous polynomial of exact degree ℓ in x or is trivial. Hence, by (8.3), $T_q\big(\Phi(\cdot - u)\big)$ is a polynomial of total degree q in x such that

$$\Big|\Phi(x-u) - T_q\big(\Phi(\cdot - u)\big)(x)\Big| = \mathcal{O}\big(|x|^{q+1}\big) \text{ as } |x| \to 0.$$

The result follows since the only such polynomial is the Maclaurin polynomial. □

9. Numerical results.

In this section we present numerical results generated by a fast evaluator for generalized multiquadrics based upon the mathematics of this paper.

The implementation is built around a hierarchical subdivision of an initial box containing all the centers using a binary tree of panels. Associated with a panel are the centers lying within it, a far field expansion, and a distance from the panel's midpoint at which the far field expansion approximates the influence of the panel to sufficient accuracy. Panels are divided, generating children if they contain more than a critical number of centers.

Pseudocode for recursive and nonrecursive evaluators appropriate for use with such a binary tree evaluation structure is sketched in [3, pp. 8–11]. Nominally the discussion there is limited to an $\mathbb{R}^1$, rather than an $\mathbb{R}^n$, setting but the generalization is immediate.

Tables 9.1 and 9.2 give times in seconds on an Intel Pentium III 700-based machine for matrix-vector products of various sizes and (generalized) multiquadrics in $\mathbb{R}^2$.

In these tables an entry of the form $d_0.d_1d_2d_3(e)$ with d_0, d_1, d_2, d_3 decimal digits represents the number $d_0.d_1d_2d_3 \times 10^e$. In the numerical experiments the centers are uniformly distributed on $[0,1]^2$, and the multiquadric parameter τ was taken as $1/\sqrt{N}$, where N is the number of centers. All the coefficients d_i were taken as 1 and the task was to evaluate the spline at the centers to an infinity norm relative accuracy of 10^{-6}. In the first table ϕ is the ordinary multiquadric $\phi(r) = \sqrt{r^2+\tau^2}$, while in the second it is the smoother function $\phi(r) = (r^2+\tau^2)^{3/2}$. The code used was structured as a general evaluator, and the symmetry inherent in this matrix-vector product test problem was not exploited. Tables 9.3 and 9.4 give the analogous results

Table 9.1
Timings of matrix-vector products for $\phi(r) = \sqrt{r^2+\tau^2}$ and $\mathbb{R}^2$.

64,000	6.16(2)	2.23(1)	27.6

for a three-dimensional code. Here the points are uniformly distributed in the unit cube $[0,1]^3$, and the multiquadric parameter τ is taken as $(1/N)^{1/3}$.

It can be seen from the tables that this algorithm can be substantially faster than direct evaluation. Thus the methods of this paper will allow application of multiquadric radial basis functions to much bigger problems than previously possible.

AN ALGEBRAIC MULTILEVEL MULTIGRAPH ALGORITHM*

RANDOLPH E. BANK† AND R. KENT SMITH‡

Abstract. We describe an algebraic multilevel multigraph algorithm. Many of the multilevel components are generalizations of algorithms originally applied to general sparse Gaussian elimination. Indeed, general sparse Gaussian elimination with minimum degree ordering is a limiting case of our algorithm. Our goal is to develop a procedure which has the robustness and simplicity of use of sparse direct methods, yet offers the opportunity to obtain the optimal or near-optimal complexity typical of classical multigrid methods.

Key words. algebraic multigrid, incomplete LU factorization, multigraph methods

1. Introduction.

In this work, we develop a multilevel multigraph algorithm. Algebraic multigrid methods are currently a topic of intense research interest [17, 18, 20, 46, 12, 48, 38, 11, 44, 3, 4, 1, 2, 5, 16, 7, 29, 28, 27, 42, 41, 21]. An excellent recent survey is given in Wagner [49]. In many "real world" calculations, direct methods are still widely used [6]. The robustness of direct elimination methods and their simplicity of use often outweigh the apparent benefits of fast iterative solvers. Our goal here is to try to develop an iterative solver that can compete with sparse Gaussian elimination in terms of simplicity of use and robustness and to provide the potential of solving a wide range of linear systems more efficiently. While we are not yet satisfied that our method has achieved this goal, we believe that it is a reasonable first step. In particular, the method of general sparse Gaussian elimination with minimum degree ordering is a point in the parameter space of our method. This implies that in the worst case, our method defaults to this well-known and widely used method, among the most computationally efficient of general sparse direct methods [26]. In the best case, however, our method can exhibit the near optimal order complexity of the classical multigrid method.

Our plan is to take well studied, robust, and widely used procedures and data structures developed for sparse Gaussian elimination, generalize them as necessary, and use them as the basic components of our multilevel solver. The overall iteration follows the classical multigrid V-cycle in form, in contrast to the algebraic hierarchical basis multigraph algorithm developed in [11].

In this work we focus on the class of matrices which are structurally symmetric; that is, the pattern of nonzeros in the matrix is symmetric, although the numerical values of the matrix elements may render it nonsymmetric. Such structurally symmetric matrices arise in the discretizations of partial differential equations, say, by the finite element method. For certain problems, the matrices are symmetric and positive definite, but for others the linear systems are highly nonsymmetric and/or

indefinite. Thus in practice this represents a very broad class of behavior. While our main interest is in scalar elliptic equations, as in the finite element code *PLTMG* [8], our algorithms can formally be applied to any structurally symmetric, nonsingular, sparse matrix.

Sparse direct methods typically have two phases. In the first (initialization) phase, equations are ordered, and symbolic and numerical factorizations are computed. In the second (solution) phase, the solution of the linear system is computed using the factorization. Our procedure, as well as other algebraic multilevel methods, also breaks naturally into two phases. The initialization consists of ordering, incomplete symbolic and numeric factorizations, and the computation of the transfer matrices between levels. In the solution phase, the preconditioner computed in the initialization phase is used to compute solution using the preconditioned composite step conjugate gradient (CSCG) or the composite step biconjugate gradient (CSBCG) method [9].

Iterative solvers often have tuning parameters and switches which require a certain level of a priori knowledge or some empirical experimentation to set in any particular instance. Our solver is not immune to this, although we have tried to keep the number of such parameters to a minimum. In particular, in the initialization phase, there are only three such parameters:

- ϵ, the drop tolerance used in the incomplete factorization (called *dtol* in our code).
- $maxfil$, an integer which controls to overall fill-in (storage) allowed in a given incomplete factorization.
- *maxlvl*, an integer specifying the maximum number of levels.

(The case $\epsilon = 0$, $maxfil = N$, $maxlvl = 1$ corresponds to sparse Gaussian elimination.) In the solution phase, there are only two additional parameters:

- *tol*, the tolerance used in the convergence test.
- *maxcg*, an integer specifying the maximum number of iterations.

Within our code, all matrices are generally treated within a single, unified framework; e.g., symmetric positive definite, nonsymmetric, and indefinite problems generally do not have specialized options. Besides the control parameters mentioned above, all information about the matrix is generated from the sparsity pattern and the values of the nonzeros, as provided in our sparse matrix data structure, a variant of the data structure introduced in the Yale sparse matrix package [23, 10]. For certain block matrices, the user may optionally provide a small array containing information about the block structure.

This input limits the complexity of the code, as well as eliminates parameters which might be needed to further classify a given matrix. On the other hand, it seems clear that a specialized solver directed at a specific problem or class of problems, and making use of this additional knowledge, is likely to outperform our algorithm on that particular class of problems. Although we do not think our method is provably "best" for any particular problem, we believe its generality and robustness, coupled with reasonable computational efficiency, make it a valuable addition to our collection of sparse solvers.

The rest of this paper is organized as follows. In section 2, we provide a general description of our multilevel approach. In section 3, we define the sparse matrix data structures used in our code. Our incomplete factorization algorithm is a standard drop tolerance approach with a few modifications for the present application. These are described in section 4. Our ordering procedure is the minimum degree algorithm. Once again, our implementation is basically standard with several modifications to the input graph relevant to our application. These are described in section 5. In section 6, we describe the construction of the transfer matrices used in the construction of the coarse grid correction. Information about the block structure of the matrix, if any is provided, is used only in the coarsening procedure. This is described in section 7. Finally, in section 8, we give some numerical illustrations of our method on a variety of (partial differential equation) matrices.

2. Matrix formulation.

Let A be a large sparse, nonsingular $N \times N$ matrix. We assume that the sparsity pattern of A is symmetric, although the numerical values need not be. We will begin by describing the basic two-level method for solving

$$Ax = b. \tag{2.1}$$

Let B be an $N \times N$ nonsingular matrix, called the *smoother*, which gives rise to the basic iterative method used in the multilevel preconditioner. In our case, B is an approximate factorization of A, i.e.,

$$B = (L + D)D^{-1}(D + U) \approx P^t AP, \tag{2.2}$$

where L is (strict) lower triangular, U is (strict) upper triangular with the same sparsity pattern as L^t, D is diagonal, and P is a permutation matrix.

Given an initial guess x_0, m steps of the smoothing procedure produce iterates x_k, $1 \le k \le m$, given by

$$\begin{aligned} r_{k-1} &= P^t(b - Ax_{k-1}),\\ B\delta_{k-1} &= r_{k-1},\\ x_k &= x_{k-1} + P^t\delta_{k-1}. \end{aligned} \tag{2.3}$$

The second component of the two-level preconditioner is the *coarse grid correction.* Here we assume that the matrix A can be partitioned as

$$\hat{P}A\hat{P}^t = \begin{pmatrix} A_{ff} & A_{fc} \\ A_{cf} & A_{cc} \end{pmatrix}, \tag{2.4}$$

where the subscripts f and c denote *fine* and *coarse*, respectively. Similar to the smoother, the partition of A in fine and coarse blocks involves a permutation matrix $\hat{P}$. The $\hat{N} \times \hat{N}$ coarse grid matrix $\hat{A}$ is given by

$$\begin{aligned} \hat{A} &= \begin{pmatrix} V_{cf} & I_{cc} \end{pmatrix} \begin{pmatrix} A_{ff} & A_{fc} \\ A_{cf} & A_{cc} \end{pmatrix} \begin{pmatrix} W_{fc} \\ I_{cc} \end{pmatrix} \\ &= V_{cf}A_{ff}W_{fc} + V_{cf}A_{fc} + A_{cf}W_{fc} + A_{cc}. \end{aligned} \tag{2.5}$$

The matrices V_{cf} and W_{fc}^t are $\hat{N} \times (N - \hat{N})$ matrices with identical sparsity patterns; thus $\hat{A}$ has a symmetric sparsity pattern. If $A^t = A$, we require $V_{cf} = W_{fc}^t$, so $\hat{A}^t = \hat{A}$.

Let

$$\hat{V} = \begin{pmatrix} V_{cf} & I_{cc} \end{pmatrix} \hat{P}, \qquad \hat{W} = \hat{P}^t \begin{pmatrix} W_{fc} \\ I_{cc} \end{pmatrix}. \tag{2.6}$$

In standard multigrid terminology, the matrices $\hat{V}$ and $\hat{W}$ are called *restriction* and *prolongation*, respectively. Given an approximate solution x_m to (2.1), the coarse grid correction produces an iterate x_{m+1} as follows.

$$\begin{aligned} \hat{r} &= \hat{V}(b - Ax_m), \\ \hat{A}\hat{\delta} &= \hat{r}, \\ x_{m+1} &= x_m + \hat{W}\hat{\delta}. \end{aligned} \tag{2.7}$$

As is typical of multilevel methods, we define the *two-level preconditioner* M implicitly in terms of the smoother and coarse grid correction. A single cycle takes an initial guess x_0 to a final guess x_{2m+1} as follows:

Two-Level Preconditioner

(i) x_k for $1 \le k \le m$ are defined using (2.3).

(ii) x_{m+1} is defined using (2.7).

(iii) x_k for $m+2 \le k \le 2m+1$ are defined using (2.3).

The generalization from two-level to multilevel consists of applying recursion to the solution of the equation $\hat{A}\hat{\delta} = \hat{r}$ in (2.7). Let ℓ denote the number of levels in the recursion. Let $\hat{M} \equiv \hat{M}(\ell)$ denote the preconditioner for $\hat{A}$; if $\ell = 2$, then $\hat{M} = \hat{A}$. Then (2.7) is generalized to

$$\begin{aligned} \hat{r} &= \hat{V}(b - Ax_m), \\ \hat{M}\hat{\delta} &= \hat{r}, \\ x_{m+1} &= x_m + \hat{W}\hat{\delta}. \end{aligned} \tag{2.8}$$

The general ℓ level preconditioner M is then defined as follows:

***ℓ*-Level Preconditioner**

(i) if $\ell = 1$, $M = A$; i.e., solve (2.1) directly.

(ii) if $\ell > 1$, then, starting from initial guess x_0, compute x_{2m+1} using (iii)–(v):

(iii) x_k for $1 \le k \le m$ are defined using (2.3).

(iv) x_{m+1} is defined by (2.8), using $p = 1$ or $p = 2$ iterations of the $\ell - 1$ level scheme for $\hat{A}\hat{\delta} = \hat{r}$ to define $\hat{M}$, and with initial guess $\hat{\delta}_0 = 0$.

(v) x_k for $m+2 \le k \le 2m+1$ are defined using (2.3).

The case $p = 1$ corresponds to the symmetric *V-cycle*, while the case $p = 2$ corresponds to the symmetric *W-cycle*. We note that there are other variants of both the V-cycle and the W-cycle, as well as other types of multilevel cycling strategies [30]. However, in this work (and in our code) we restrict attention to just the symmetric V-cycle with $m = 1$ presmoothing and postsmoothing iterations.

For the coarse mesh solution ($\ell = 1$), our procedure is somewhat nontraditional. Instead of a direct solution of (2.1), we compute an approximate solution using one smoothing iteration. We illustrate the practical consequences of this decision in section 8.

If A is symmetric, then so is M, and the ℓ-level preconditioner could be used as a preconditioner for a symmetric Krylov space method. If A is also positive definite, so is M, and the standard conjugate gradient method could be used; otherwise the CSCG method [9], SYMLQ [43], or a similar method could be used. In the nonsymmetric case, the ℓ-level preconditioner could be used in conjunction with the CSBCG method [9], GMRES [22], or a similar method.

To complete the definition of the method, we must provide algorithms to

- compute the permutation matrix P in (2.2);
- compute the incomplete factorization matrix B in (2.2);
- compute the fine-coarse partitioning $(\hat{P})$ in (2.4);

- compute the sparsity patterns and numerical values in the prolongation and restriction matrices in (2.6).

3. Data structures. Let A be an $N \times N$ matrix with elements A_{ij} and a symmetric sparsity structure; that is, both A_{ij} and A_{ji} are treated as nonzero elements (i.e. stored and processed) if $|A_{ij}| + |A_{ji}| > 0$. All diagonal entries A_{ii} are treated as nonzero regardless of their numerical values.

Our data structure is a modified and generalized version of the data structure introduced in the (symmetric) Yale sparse matrix package [23]. It is a rowwise version of the data structure described in [10]. In our scheme, the nonzero entries of A are stored in a linear array a and accessed through an integer array ja. Let η_i be the number of nonzeros in the strict upper triangular part of row i and set $\eta = \sum_{i=1}^{N} \eta_i$. The array ja is of length $N+1+\eta$, and the array a is of length $N+1+\eta$ if $A^t = A$. If $A^t \neq A$, then the array a is of length $N+1+2\eta$. The entries of $ja(i)$, $1 \leq i \leq N+1$, are pointers defined as follows:

$$\begin{aligned} ja(1) &= N+2, \\ ja(i+1) &= ja(i) + \eta_i, \quad 1 \leq i \leq N. \end{aligned}$$

The locations $ja(i)$ to $ja(i+1)-1$ contain the η_i column indices corresponding to the row i in the strictly upper triangular matrix.

In a similar manner, the array a is defined as follows:

$$\begin{aligned} a(i) &= A_{ii}, \quad 1 \leq i \leq N, \\ a(N+1) & \quad \text{is arbitrary}, \\ a(k) &= A_{ij}, \quad 1 \leq i \leq N, \quad j = ja(k), \quad ja(i) \leq k \leq ja(i+1)-1. \end{aligned}$$

If $A^t \neq A$, then

$$a(k+\eta) = A_{ji}, \quad 1 \leq i \leq N, \quad j = ja(k), \quad ja(i) \leq k \leq ja(i+1)-1.$$

In words, the diagonal is stored first, followed by the strict upper triangle stored rowwise. If $A^t \neq A$, then this is followed by the strict lower triangle stored columnwise. Since A is structurally symmetric, the column indexes for the upper triangle are identical to the row indexes for the lower triangle, and hence they need not be duplicated in storage.

As an example, let

$$A = \begin{pmatrix} A_{11} & A_{12} & A_{13} & 0 & 0 \\ A_{21} & A_{22} & 0 & A_{24} & 0 \\ A_{31} & 0 & A_{33} & A_{34} & A_{35} \\ 0 & A_{42} & A_{43} & A_{44} & 0 \\ 0 & 0 & A_{53} & 0 & A_{55} \end{pmatrix}.$$

Then

	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
ja	7	9	10	12	12	12	2	3	4	4	5					
a	A_{11}	A_{22}	A_{33}	A_{44}	A_{55}		A_{12}	A_{13}	A_{24}	A_{34}	A_{35}	A_{21}	A_{31}	A_{42}	A_{43}	A_{53}
	Diagonal						Upper triangle					Lower triangle				

Although the YSMP data structure was originally devised for sparse direct methods based on Gaussian elimination, it is also quite natural for iterative methods based on incomplete triangular decomposition. Because we assume that A has a symmetric sparsity structure, for many matrix calculations a single indirect address computation in ja can be used to process both a lower and a upper triangular element in A. For example, the following procedure computes $y = Ax$:

```
procedure mult(N, ja, a, x, y)
    $lmtx \leftarrow ja(N+1) - ja(1)$
    $umtx \leftarrow 0$
    for $i \leftarrow 1$ to $N$
        $y(i) \leftarrow a(i)x(i)$
    end for
    for $i \leftarrow 1$ to $N$
        for $k \leftarrow ja(i)$ to $ja(i+1) - 1$
            $j \leftarrow ja(k)$
            $y(i) \leftarrow y(i) + a(k + umtx)x(j)$
            $y(j) \leftarrow y(j) + a(k + lmtx)x(i)$
        end for
    end for
end mult
```

For symmetric matrices, set $lmtx \leftarrow 0$, $umtx \leftarrow 0$. Also, $y = A^t\, x$ may be readily computed by setting $lmtx \leftarrow 0$, $umtx \leftarrow ja(N+1) - ja(1)$.

The data structure for storing $B = (L+D)D^{-1}(D+U)$ is quite analogous to that for A. It consists of two arrays, ju and u, corresponding to ja and a, respectively. The first $N+1$ entries of ju are pointers as in ja, while entries $ju(i)$ to $ju(i+1)-1$ contain column indices of the nonzeros of row i in of U. In the u array, the diagonal entries of D are stored in the first N entries. Entry $N+1$ is arbitrary. Next, the nonzero entries of U are stored in correspondence to the column indices in ju. If $L^t \neq U$, the nonzero entries of L follow, stored columnwise.

The data structure we use for the $N \times \hat{N}$ matrix $\hat{W}$ and the $\hat{N} \times\ N$ matrix $\hat{V}$ are similar. It consists of an integer array jv and a real array v. The nonzero entries of $\hat{W}$ are stored rowwise, including the rows of the block I_{cc}. As usual, the first $N+1$ entries of jv are pointers; entries $jv(i)$ to $jv(i+1)-1$ contain column indices for row i of $\hat{W}$. In the v array, the nonzero entries of $\hat{W}$ are stored rowwise in correspondence with jv but shifted by $N+1$ since there is no diagonal part. If $\hat{V}^t \neq \hat{W}$, this is followed by the nonzeros of $\hat{V}$, stored columnwise.

4. ILU factorization.

Our incomplete $(L+D)D^{-1}(D+U)$ factorization is similar to the row elimination scheme developed for the symmetric YSMP codes [23, 26]. For simplicity, we begin by discussing a complete factorization and then describe the modifications necessary for the incomplete factorization. Without loss of generality, assume that the permutation matrix $P = I$, so that $A = (L+D)D^{-1}(D+U)$.

After k steps of elimination, we have the block factorization

$$\begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} = \begin{pmatrix} D_{11} + L_{11} & 0 \\ L_{21} & I \end{pmatrix} \begin{pmatrix} D_{11}^{-1} & 0 \\ 0 & S \end{pmatrix} \begin{pmatrix} D_{11} + U_{11} & U_{12} \\ 0 & I \end{pmatrix}, \tag{4.1}$$

where A_{11} is $k \times k$ and A_{22} is $N - k \times N - k$. We assume that at this stage, all the blocks on the right-hand side of (4.1) have been computed except for the Schur complement S, given by

$$S = A_{22} - L_{21} D_{11}^{-1} U_{12}. \tag{4.2}$$

Our goal for step $k + 1$ is to compute the first row and column of S, given by

$$\begin{aligned} Se_1 &= A_{22}e_1 - L_{21}(D_{11}^{-1}U_{12}e_1), \\ S^t e_1 &= A_{22}^t e_1 - U_{12}^t (D_{11}^{-1} L_{21}^t e_1). \end{aligned} \tag{4.3}$$

Because A and $(L + D)D^{-1}(D + U)$ have symmetric sparsity patterns, and our data structures take advantage of this symmetry, it is clear that the algorithms for computing Se_1 and $S^t e_1$ are the same and in practice differ only in the assignments of shifts for the u and a arrays, analogous to *lmtx* and *umtx* in procedure mult. Thus we will focus on the computation of just Se_1. At this point, we also assume that the array ju has been computed in a so-called *symbolic factorization* step.

The major substeps are as follows:

1. Copy the first column of A_{22} (stored in the data structures ja and a) into an expanded work vector z of size N.
2. Find the *multipliers* given by nonzeros of $D_{11}^{-1}U_{12}e_1$.
3. For each multiplier $\gamma = e_k^t D_{11}^{-1} U_{12} e_1$, update z using column k of L_{21} (i.e., $\gamma L_{21} e_k$).
4. Copy the nonzeros in z into the data structures ju and u.

In step 1, we need to know the nonzeros of the first column of A_{22}, which is precisely the information easily accessible in the ja and a data structures. In step 3, we need to know the nonzeros in columns of L_{21}, which again is precisely the information easily available in our data structure. In step 4, we copy a column of information into the lower triangular portion of the ju and u data structures. Indeed, the only difficult aspect of the algorithm is step 2, in which we need to know the sparsity structure of the first *column* of U_{12}, information that is *not* readily available in the data structure. This is handled in a standard fashion using a dynamic linked list structure and will not be discussed in detail here.

To generalize this to the incomplete factorization case, we first observe that the ju array can be computed concurrently with the numeric factorization simply by creating a list of the entries of the expanded array z that are updated in step 3. Next, we note that one may choose which nonzero entries from z to include in the factorization by choosing which entries to copy to the ju and u data structures in step 4. We do this through a standard approach using a drop tolerance ϵ. In particular, we neglect a pair of off-diagonal elements if

$$\max |L_{ij}|, |U_{ji}| \le \epsilon \sqrt{|D_{jj} A_{ii}|}, \tag{4.4}$$

$j = k + 1$ and $i > j$. Note D_{ii} has not yet been computed. It is well known that the fill-in generated through the application of a criterion such as (4.4) is a highly nonlinear and matrix dependent function of ϵ. This is especially problematic in the present context, since control of the fill-in is necessary in order to control the work per iteration in the multilevel iteration.

Several authors have explored possibilities of controlling the maximum number of fill-in elements allowed in each row of the incomplete decomposition [35, 47, 31]. However, for many cases of interest, and in particular for matrices arising from discretizations of partial differential equations ordered by the minimum degree algorithm, most of the fill-in in a complete factorization occurs in the later stages, even if all the rows initially have about the same number of nonzeros. Thus while it seems advisable to try to control the total fill-in, one should adaptively decide how to allocate the fill-in among the rows of the matrix. In our algorithm, in addition to the drop tolerance ϵ, the user provides a parameter $maxfil$, which specifies that the total number of nonzeros in U is not larger than $maxfil \cdot N$.

Our overall strategy is to compute the incomplete decomposition using the given drop tolerance. If it fails to meet the given storage bound, we increase the drop tolerance and begin a new incomplete factorization. We continue in this fashion until we complete a factorization within the given storage bound. Of course, such repeated factorizations are computationally expensive, so we developed some heuristics which allow us to predict a drop tolerance which will satisfy the storage bound.

As the factorization is computed, we make a histogram of the approximate sizes of all elements that exceed the drop tolerance and are accepted for the factorization. Let m denote the number of bins in the histogram; $m = 400$ in our code. Then for each pair of accepted off-diagonal elements, we find the largest $k \in [1, m]$ such that

$$\rho^{k-1} \leq \frac{\max |L_{ij}|, |U_{ji}|}{\epsilon\sqrt{|D_{jj}A_{ii}|}}. \tag{4.5}$$

Here $\rho > 1$ ($\rho = 10^{4/m}$ in our code). The histogram is realized as an integer array h of size m, where h_ℓ is the number of accepted elements that exceeded the drop tolerance by factors between $\rho^{\ell-1}$ and ρ^ℓ for $1 \leq \ell \leq m-1$; h_m contains the number of accepted elements exceeding the drop tolerance by ρ^{m-1}. If the factorization reaches the storage bound, we continue the factorization but allow no further fill-in. However, we continue to compute the histogram based on (4.5), profiling the elements we would have accepted had space been available. Then using the histogram, we predict a new value of ϵ such that the total number of elements accepted for U is no larger than $maxfil \cdot N/\theta$. Such a prediction of course cannot be guaranteed, since the sizes and numbers of fill-in elements depend in a complicated fashion on the specific history of the incomplete factorization process; indeed, the histogram cannot even completely profile the remainder of the factorization with the existing drop tolerance, since elements that would have been accepted could introduce additional fill-in at later stages of the calculation as well as influence the sizes of elements computed at later stages of the factorization. In our implementation, the factor θ varies between $\theta = 1.01$ and $\theta = 1.4$, depending on how severely the storage bound was exceeded. Its purpose is to introduce some conservative bias into the prediction with the goal that the actual fill-in accepted should not exceed $maxfil \cdot N$.

Finally, we note that there is no comprehensive theory regarding the stability of incomplete triangular decompositions. For certain classes of matrices (e.g., M-matrices and H-matrices), the existence of certain incomplete factorizations has been proved [39, 25, 24, 40, 51]. However, in the general case, with potentially indefinite and/or highly nonsymmetric matrices, one must contend in a practical way with the possibility of failure or near failure of the factorization. A common approach is to add a diagonal matrix, often a multiple of the identity, to A and compute an incomplete factorization of the shifted matrix. One might also try to incorporate some form of diagonal pivoting; partial or complete pivoting could potentially destroy the symmetric sparsity pattern of the matrix. However, any sort of pivoting greatly increases the complexity of the implementation, since the simple but essentially static data structures ja, a, ju, and u are not appropriate for such an environment.

Our philosophy here is to simply accept occasional failures and continue with the factorization. Our ordering procedure contains some heuristics directed towards avoiding or at least minimizing the possibility of failures. And when they do occur, failures often corrupt only a low dimensional subspace, so a Krylov space method such as conjugate gradients can compensate for such corruption with only a few extra iterations. In our implementation, a failure is revealed by some diagonal entries in D becoming close to zero. Off-diagonal elements L_{ji} and U_{ij} are multiplied by D_{ii}^{-1}, and the solution of $(L+D)D^{-1}(D+U)x = b$ also involves multiplication by D_{ii}^{-1}. For purposes of calculating the factorization and solution, the value of D_{ii}^{-1} is modified near zero as follows:

$$D_{ii}^{-1} = \begin{cases} 1/D_{ii} & \text{for } |D_{ii}| > \alpha, \\ D_{ii}/\alpha^2 & \text{for } |D_{ii}| \le \alpha. \end{cases} \tag{4.6}$$

Here α is a small constant; in our implementation, $\alpha = \mu\|A\|$, where μ is the machine epsilon. Although many failures could render the preconditioner well-defined but essentially useless, in practice we have noted that D_{ii}^{-1} is rarely modified for the large class of finite element matrices which are the main target of our procedure.

5. Ordering.

To compute the permutation matrix P in (2.2), we use the well-known minimum degree algorithm [45, 26]. Intuitively, if one is computing an incomplete factorization, an ordering which tends to minimize the fill-in in a complete factorization should tend to minimize the error

$$E = P^tAP - (L+D)D^{-1}(D+U).$$

For particular classes of matrices, specialized ordering schemes have been developed [34, 15, 37, 36]. For example, for matrices arising from convection dominated problems, ordering along the flow direction has been used with great success. However, in this general setting, we prefer to use just one strategy for all matrices. This reduces the complexity of the implementation and avoids the problem of developing heuristics to decide among various ordering possibilities. We remark that for convection dominated problems, minimum degree orderings perform comparably well to the specialized ones, provided some (modest) fill-in is allowed in the incomplete factorization. For us, this seems to be a reasonable compromise.

Our minimum degree ordering is a standard implementation, using the quotient graph model [26] and other standard enhancements. A description of the *graph* of the matrix is the main required input. Without going into detail, this is essentially a small variant of the basic ja data structure used to store the matrix A. We will denote this modified data structure as jc. Instead of storing only column indices for the strict upper triangle as in ja, entries $jc(i)$ to $jc(i+1)-1$ of the jc data structure contain column indices for *all* off-diagonal entries for row i of the matrix A.

We have implemented two small enhancements to the minimum degree ordering; as a practical matter, both involve changes to the input graph data structure jc that is provided to the minimum degree code. First, we have implemented a drop tolerance similar to that used in the the factorization. In particular the edge in the graph corresponding to off-diagonal entries A_{ij} and A_{ji} is not included in the jc data structure if

$$\max |A_{ij}|, |A_{ji}| \le \epsilon\sqrt{|A_{jj}A_{ii}|}. \tag{5.1}$$

This excludes many entries which are likely to be dropped in the subsequent incomplete factorization and hopefully will result in an ordering that tends to minimize the fill-in created by the edges that are kept.

The second modification involves some modest a priori diagonal pivoting designed to minimize the number failures (near zero diagonal elements) in the subsequent factorization. We first remark that pivoting or other procedures based on the values of the matrix elements (which can be viewed as weights on graph edges and nodes) would destroy many of the enhancements which allow the minimum degree algorithm to run in almost linear time. Our modification is best explained in the context of a simple 2×2 example. Let

$$A = \begin{pmatrix} 0 & c \\ b & a \end{pmatrix}$$

with $a, b, c \neq 0$. Clearly, A is nonsingular, but the complete triangular factorization of A does not exist. However,

$$P^t A P = \begin{pmatrix} a & b \\ c & 0 \end{pmatrix} = \begin{pmatrix} a & 0 \\ c & -bc/a \end{pmatrix} \begin{pmatrix} 1/a & 0 \\ 0 & -a/bc \end{pmatrix} \begin{pmatrix} a & b \\ 0 & -bc/a \end{pmatrix}. \tag{5.2}$$

Now suppose that $A_{ii} \approx 0$, $A_{jj}, A_{ij}, A_{ji} \neq 0$. Then these four elements form a submatrix of the form described above, and it seems an incomplete factorization of A is less likely to fail if the P is chosen such that vertex j is ordered before vertex i. This is done as follows: for each i such that $A_{ii} \approx 0$, we determine a corresponding j such that $A_{jj}, A_{ij}, A_{ji} \neq 0$; if there is more than one choice, we choose the one for which $|A_{ij}A_{ji}/A_{jj}|$ is maximized. To ensure that vertex i is ordered after vertex j, we replace the sparsity pattern for the off-diagonal entries for row (column) i with the union of those for rows (columns) i and j. If we denote the set of column indices for row i in the jc array as $adj(i)$, then

$$adj(j) \cup \{j\} \subseteq adj(i) \cup \{i\}. \tag{5.3}$$

Although the sets $adj(i)$ and $adj(j)$ are modified at various stages, it is well known that (5.3) is maintained throughout the minimum degree ordering process [26], so that at every step of the ordering process $deg(j) \leq deg(i)$, where $deg(i)$ is the degree of vertex i. As long as $deg(j) < deg(i)$, vertex j will be ordered before vertex i by the minimum degree algorithm. On the other hand, if $deg(i) = deg(j)$ at some stage of the ordering process, it remains so thereafter, and (5.3) becomes

$$adj(j) \cup \{j\} = adj(i) \cup \{i\}. \tag{5.4}$$

In words, i and j become so-called *equivalent vertices* and will be eliminated at the same time by the minimum degree algorithm (see [26] for details). Since the minimum degree algorithm sees these vertices as equivalent, they will be ordered in an arbitrary fashion when eliminated from the graph. Thus, as a simple postprocessing step, we must scan the ordering provided by the minimum degree algorithm and exchange the order of rows i and j if i was ordered first. Any such exchanges result in a new minimum degree ordering which is completely equivalent, in terms of fill-in, to the the original.

For many types of finite element matrices (e.g., the indefinite matrices arising from Helmholtz equations), this a priori scheme is useless because none of the diagonal entries of A is close to zero. However, this type of problem is likely to produce only isolated small diagonal entries in the factorization process, if it produces any at all. On the other hand, other classes of finite element matrices, notably those arising in from mixed methods, Stokes equations, and other saddle-point-like formulations, have many diagonal entries that are small or zero. In such cases, the a priori diagonal pivoting strategy can make a substantial difference and greatly reduce the numbers of failures in the incomplete triangular decomposition.

6. Computing the transfer matrices.

There are three major tasks in computing the prolongation and restriction matrices $\hat{V}$ and $\hat{W}$ of (2.6). First, one must determine the sparsity structure of these matrices; this involves choosing which unknowns are *coarse* and which are *fine*. This reduces to determining the permutation matrix $\hat{P}$ of (2.4). Second, one must determine how coarse and fine unknowns are related, the so-called *parent-child relations* [49]. This involves computing the sparsity patterns for the matrices V_{cf} and W_{fc}. Third, one must compute the numerical values for these matrices, the so-called *interpolation coefficients* [50].

There are many existing algorithms for coarsening graphs. For matrices arising from discretizations of partial differential equations, often the sparsity of the matrix A is related in some way to the underlying grid, and the problem of coarsening the *graph* of the matrix A can be formulated in terms of coarsening the *grid.* Some examples are given in [14, 13, 17, 18, 46, 12, 49]. In this case, one has the geometry of the grid to serve as an aid in developing and analyzing the coarsening procedure. There are also more general graph coarsening algorithms [32, 33, 19], often used to partition problems for parallel computation. Here our coarsening scheme is based upon another well-known sparse matrix ordering technique, the reverse Cuthill–McKee algorithm. This ordering tends to yield reordered matrices with minimal bandwidth and is widely used with generalized band elimination algorithms [26]. We now assume that the graph has been ordered in this fashion and that a *jc* data structure representing the graph in this ordering is available. Our coarsening procedure is just a simple postprocessing step of the basic ordering routine, in which the N vertices of graph are marked as $COARSE$ or $FINE$.

```
procedure coarsen(N, jc, type)
    for $i \leftarrow 1$ to $N$
        $type(i) \leftarrow UNDEFINED$
    end for
    for $i \leftarrow 1$ to $N$
        if $type(i) = UNDEFINED$, then
            $type(i) \leftarrow COARSE$
            for $j \leftarrow jc(i)$ to $jc(i+1) - 1$
                $type(jc(j)) \leftarrow FINE$
            end for
        end if
    end for
end coarsen
```

This postprocessing step, coupled with the the reverse Cuthill–McKee algorithm, is quite similar to a greedy algorithm for computing maximal independent sets using breadth-first search. Under this procedure, all coarse vertices are surrounded only by fine vertices. This implies that the matrix A_{cc} in (2.4) is a diagonal matrix. For the sparsity patterns of matrices arising from discretizations of scalar partial differential equations in two space dimensions, the number of coarse unknowns $\hat{N}$ is typically on the order of $N/4$ to $N/5$. Matrices with more nonzeros per row tend to have smaller values of $\hat{N}$. To define the parents of a coarse vertex, we take all the connections of the vertex to other fine vertices; that is, the sparsity structure of V_{cf} in (2.5) is the same as that of the block A_{cf}.

In our present code, we pick V_{cf} and W_{fc} according to the formulae

$$\begin{aligned} W_{fc} &= -R_{ff} D_{ff}^{-1} A_{fc}, \\ V_{cf} &= -A_{cf} D_{ff}^{-1} \tilde{R}_{ff}. \end{aligned} \tag{6.1}$$

Here D_{ff} is a diagonal matrix with diagonal entries equal to those of A_{ff}. In this sense, the nonzero entries in V_{cf} and W_{fc} are chosen as multipliers in Gaussian elimination. The nonnegative diagonal matrices R_{ff} and $\tilde{R}_{ff}$ are chosen such that nonzero rows of W_{fc} and columns of V_{cf}, respectively, have unit norms in ℓ_1.

Finally, the coarsened matrix $\hat{A}$ of (2.5) is "sparsified" using the drop tolerance and a criterion like (5.1) to remove small off-diagonal elements. Empirically, applying a drop tolerance to $\hat{A}$ at the end of the coarsening procedure has proved more efficient, and more effective, than trying to independently sparsify its constituent matrices. If the number of off-diagonal elements in the upper triangle exceeds $maxfil \cdot \hat{N}$, the drop tolerance is modified in a fashion similar to the incomplete factorization. The off-diagonal elements are profiled by a procedure similar to that for the incomplete factorization, but in this case the resulting histogram is exact. Based on this histogram, a new drop tolerance is computed, and (5.1) is applied to produce a coarsened matrix satisfying the storage bound.

7. Block matrices.

Our algorithm provides a simple but limited functionality for handling block matrices. Suppose that the $N \times N$ matrix A has the $K \times K$ block structure

$$A = \begin{pmatrix} A_{11} & \dots & A_{1K} \\ \vdots & \ddots & \vdots \\ A_{K1} & \dots & A_{KK} \end{pmatrix}, \tag{7.1}$$

where subscripts for A_{ij} are block indices and the diagonal blocks A_{jj} are square matrices. Suppose A_{jj} is of order N_j; then $\sum_{j=1}^{K} N_j = N$.

The matrix A is stored in the usual ja and a data structures as described in section 3 with no reference to the block structure. A small additional integer array ib of size $K+1$ is used to define the block boundaries as follows:

$$\begin{aligned} ib(1) &= 1, \\ ib(j+1) &= ib(j) + N_j, \quad 1 \le j \le K. \end{aligned}$$

In words, integers in the range $ib(j)$ to $ib(j+1)-1$, inclusive, comprise the index set associated with block A_{jj}. Note that $ib(K+1) = N+1$.

This block information plays a role only in the coarsening algorithm. First, the reverse Cuthill–McKee algorithm described in section 6 is applied to the block diagonal matrix

$$\bar{A} = \begin{pmatrix} A_{11} & & \\ & \ddots & \\ & & A_{KK} \end{pmatrix} \tag{7.2}$$

rather than A. As a practical matter, this involves discarding graph edges connecting vertices of different blocks in the construction of the graph array jc used as input. Such edges are straightforward to determine from the information provided in the ib array. The coarsening algorithm applied to the graph of $\bar{A}$ produces output equivalent to the application of the procedure independently to each diagonal block of $\bar{A}$. As a consequence, the restriction and prolongation matrices automatically inherit the block structure A. In particular,

$$\hat{V} = \begin{pmatrix} \hat{V}_{11} & & \\ & \ddots & \\ & & \hat{V}_{KK} \end{pmatrix} \quad \text{and} \quad \hat{W} = \begin{pmatrix} \hat{W}_{11} & & \\ & \ddots & \\ & & \hat{W}_{KK} \end{pmatrix}, \tag{7.3}$$

where $\hat{V}_{jj}$ and $\hat{W}_{jj}$ are are rectangular matrices ($\hat{N}_j \times N_j$ and $N_j \times \hat{N}_j$, respectively), having the structure of (2.6) that would have resulted from the application of the algorithm independently to A_{jj}. However, like the matrix A, $\hat{V}$ and $\hat{W}$ are stored in the standard jv and v data structures described in section 3 without reference to their block structures.

The complete matrix A is used in the construction of the coarsened matrix $\hat{A}$ of (2.5). However, because of (7.1) and (7.3)

$$\hat{A} = \hat{V} A \hat{W} = \begin{pmatrix} \hat{A}_{11} & \dots & \hat{A}_{1K} \\ \vdots & \ddots & \vdots \\ \hat{A}_{K1} & \dots & \hat{A}_{KK} \end{pmatrix},$$

so $\hat{A}$ also automatically inherits the $K \times K$ block structure of A. It is not necessary for the procedure forming $\hat{A}$ to have any knowledge of its block structure, as this block structure can be computed a priori by the graph coarsening procedure. Like A, $\hat{A}$ is stored in standard ja and a data structures without reference to its block structure. Since the blocks of A have arbitrary order, and are essentially coarsened independently, it is likely that eventually some of the $\hat{N}_j = 0$. That is, certain blocks may cease to exist on coarse levels. Since the block information is used only to discard certain edges in the construction of the graph array jc, "0×0" diagonal blocks present no difficulty.

8. Numerical experiments. In this section, we present a few numerical illustrations. In our first sequence of experiments, we consider several matrices loosely based on the classical case of 5-point centered finite difference approximations to $-\Delta u$ on a uniform square mesh. Dirichlet boundary conditions are imposed. This leads to the $n \times n$ block tridiagonal system

$$A = \begin{pmatrix} T & -I & & & \\ -I & T & -I & & \\ & \ddots & \ddots & \ddots & \\ & & -I & T & -I \\ & & & -I & T \end{pmatrix}$$

with T the $n \times n$ tridiagonal matrix

$$T = \begin{pmatrix} 4 & -1 & & & \\ -1 & 4 & -1 & & \\ & \ddots & \ddots & \ddots & \\ & & -1 & 4 & -1 \\ & & & -1 & 4 \end{pmatrix}.$$

This is a simple test problem easily solved by standard multigrid methods. In contrast to this example we also consider the block tridiagonal system

$$\bar{A} = 8I - A.$$

Both A and $\bar{A}$ have the same eigenvectors and the same eigenvalues, although the association of eigenvectors and eigenvalues are reversed in the case of $\bar{A}$. That is, the so-called *smooth* eigenvectors are associated with large eigenvalues, while *rough* eigenvectors are associated with smaller eigenvalues. Although $\bar{A}$ does not arise naturally in the context of numerical discretizations of partial differential equations, it is of interest because it defies much of the conventional wisdom for multigrid methods.

Third, we consider block 3×3 systems of the form

$$S = \begin{pmatrix} A & 0 & C_x \\ 0 & A & C_y \\ C_x^t & C_y^t & -D \end{pmatrix},$$

where A is the discrete Laplacian and D is a symmetric positive definite "stabilization" matrix with a sparsity pattern similar to A. However, the nonzeros in D are of size $O(h^2)$, compared to size $O(1)$ nonzero elements in A. C_x and C_y also have sparsity patterns similar to that of A, but these matrices are nonsymmetric and their nonzero entries are of size $O(h)$. Such matrices arise in stabilized discretizations of the Stokes equations. One third of the eigenvalues of S are negative, so S is quite indefinite. In addition to the *ja* and *a* arrays, for the matrix S we also provided an *ib* array as described in section 7 to define its 3×3 block structure. We emphasize again that this block information is used only in the computation of the graph input to the coarsening procedure and is not involved in any aspect of the incomplete factorization smoothing procedure. With many small diagonal elements, this class of matrices provides a good test of the a priori pivoting strategy used in conjunction with the minimum degree ordering.

In Table 8.1, *Levels* refers to the number of levels used in the calculation. In our implementation the parameter *maxlvl*, which limits the number of levels allowed, was set sufficiently large that it had no effect on the computation. The drop tolerance was set to $\epsilon = 10^{-2}$ for all matrices. The fill-in control parameter $maxfil$ was set sufficiently large that it had no effect on the computation. The initial guess for all problems was $x_0 = 0$.

In Table 8.1, the parameter *Digits* refers to

$$Digits = -\log \frac{\|r_k\|}{\|r_0\|}. \tag{8.1}$$

In these experiments, we asked for six digits of accuracy. The column labeled *Cycles* indicates the number of multigrid cycles (accelerated by CSCG) that were used to

160	76800	9	6.0	8	41.4e 0	20.6e 0

achieve the indicated number of digits. Finally, the last two columns, labeled *Init.* and *Solve*, record the CPU time, measured in seconds, for the initialization and solution phases of the algorithm, respectively. Initialization includes all the orderings, incomplete factorizations, and computation of transfer matrices used in the multigraph preconditioner. Solution includes the time to solve (2.1) to at least six digits given the preconditioner. These experiments were run on an SGI Octane R10000 250mhz, using double precision arithmetic and the f90 compiler.

In analyzing these results, it is clear that our procedure does reasonably well on all three classes of matrices. Although it appears that the rate of convergence is not independent of N, it seems apparent that the work is growing no faster than logarithmically. CPU times for larger vales of N are affected by cache performance as well as the slightly larger number of cycles.

For the highly indefinite Stokes matrices S, it is important to also note the robustness, that the procedure solved all of the problems. With more nonzeros per row on average, the incomplete factorization was more expensive to compute than for the other cases. This is reflected in relatively larger initialization and solve times.

In our next experiment, we illustrate the effect of the parameters $maxlvl$ and ϵ. For the matrix A with $N = 160000$, we solved the problem for $\epsilon = 10^{-k}$, $1 \leq k \leq 3$, and $1 \leq maxlvl \leq 7$. We terminated the iteration when the solution had six digits, as measured by (8.1). We also provide the total storage for the ja and ju arrays for all matrices, measured in thousands of entries. Since the matrices are symmetric, this is also the total (floating point) storage for all matrices A and approximate LDU factorizations.

Here we see that our method behaves in a very predictable way. In particular, decreasing the drop tolerance or increasing the number of levels improves the conver-

gence behavior of the method. On the other hand, the timings do not always follow the same trend. For example, for the case $\epsilon = 10^{-3}$ increasing the number of levels from *maxlvl* $= 1$ to *maxlvl* $= 2$ decreases the number of cycles but increases the time. This is because for *maxlvl* $= 1$, our method defaults to the standard conjugate gradient iteration with the incomplete factorization preconditioner. When *maxlvl* > 1, one presmoothing and one postsmoothing step are used for the largest matrix. With the additional cost of the recursion, the overall cost of the preconditioner is more than double the cost for the case *maxlvl* $= 1$.

We also note that, unlike the classical multigrid method, where the coarsest matrix is solved exactly, in our code we have chosen to approximately solve the coarsest system using just one smoothing iteration using the incomplete factorization. When the maximum number of levels are used, as in Table 8.1, the smallest system is typically 1×1 or 2×2, and this is an irrelevant remark. However, in the case of Table 8.2, the fact that the smallest system is not solved exactly significantly influences the overall rate of convergence. This is why, unlike methods where the coarsest system is solved exactly, increasing the number of levels tends to improve the rate of convergence. In the case $\epsilon = 10^{-1}$, the coarsest matrix had an exact LDU factorization for the case *maxlvl* $= 5$ (because the matrix itself was nearly diagonal), and setting *maxlvl* > 5 did not increase the number of levels. The cases $\epsilon = 10^{-2}$ and $\epsilon = 10^{-3}$ used a maximum of 10 and 9 levels, respectively, but the results did not change significantly from the case *maxlvl* $= 7$.

We also include in Table 8.2 the case $\epsilon = 0$, *maxlvl* $= 1$, sparse Gaussian elimination. (In fact, our code uses $\mu\|A\|$ as the drop tolerance when the user specifies

$\epsilon = 0$ to avoid dividing by zero.) Here we see that Gaussian elimination is reasonably competitive on this problem. However, we generally expect the initialization cost for $\epsilon = 0$ to grow like $O(N^{3/2})$. For $maxlvl = 1$ and $\epsilon > 0$, we expect the solution times to grow like $O(N^p)$, $p > 1$. For the best multilevel choices, we expect both initialization and solution times to behave like $O(N) - O(N \log N)$.

In our final series of tests, we study the convergence of the method for a suite of test problems generated from the finite element code *PLTMG* [8]. These example problems were presented in our earlier work [11], where a more complete description of the problems, as well as numerical results for our hierarchical basis multigraph method and the classical AMG algorithm of Ruge and Stüben [46], can be found. As a group, the problems feature highly nonuniform, adaptively generated meshes, relatively complicated geometry, and a variety of differential operators. For each test case, both the sparse matrix and the right-hand side were saved in a file to serve as input for the iterative solvers. A short description of each test problem is given below.

Problem Superior. This problem is a simple Poisson equation

$$-\Delta u = 1$$

with homogeneous Dirichlet boundary conditions on a domain in the shape of Lake Superior. This is the classical problem on a fairly complicated domain. The solution is generally very smooth but has some boundary singularities.

Problem Hole. This problem features discontinuous, anisotropic coefficients. The overall domain is the region between two concentric circles, but this domain is divided into three subregions. On the inner region, the problem is

$$-\delta \Delta u = 0$$

with $\delta = 10^{-2}$. In the middle region, the equation is

$$-\Delta u = 1,$$

and in the outer region the equation is

$$-u_{xx} - \delta u_{yy} = 1.$$

Homogeneous Dirichlet boundary conditions are imposed on the inner (hole) boundary, homogeneous Neumann conditions on the outer boundary, and the natural continuity conditions on the internal interfaces. While the solution is also relatively smooth, singularities exist at the internal interfaces.

Problem Texas. This is an indefinite Helmholtz equation

$$-\Delta u - 2u = 1$$

posed in a region shaped like the state of Texas. Homogeneous Dirichlet boundary conditions are imposed. The length scales of this domain are roughly 16 × 16, so this problem is fairly indefinite.

Problem UCSD. This is a simple constant coefficient convection-diffusion equation

$$-\nabla \cdot (\nabla u + \beta u) = 1,$$

$\beta = (0, 10^5)^T$ posed on a domain in the shape of the UCSD logo. Homogeneous Dirichlet boundary conditions are imposed. Boundary layers are formed at the bottom of the region and the top of various obstacles.

Problems Jcn 0 *and Jcn* 180. The next two problems are solutions of the current continuity equation taken from semiconductor device modeling. This equation is a convection-diffusion equation of the form

$$-\nabla \cdot (\nabla u + \beta u) = 0,$$

$\beta = 0$ in most of the rectangular domain. However, in a curved band in the interior of the domain, $|\beta| \approx 10^4$ and is directed radially. Dirichlet boundary conditions $u = 10^{-5}$ and $u = 10^{10}$ are imposed along the bottom boundary and along a short segment on the upper left boundary, respectively. Homogeneous Neumann boundary conditions are specified elsewhere. The solutions vary exponentially across the domain which is typical of semiconductor problems.

In the first problem, Jcn 0, the convective term is chosen so the device is *forward biased.* In this case, a sharp internal layer develops along the top interface boundary. In the second problem, Jcn 180, the sign of the convective term is reversed, resulting in two sharp internal layers along both interface boundaries.

80k	8	7.1	3	18.0e 0	9.3e 0

We summarize the results in Table 8.3. As before, perhaps the most important point is that the method solved all of the problems. While convergence rates are not independent of h, once again the growth appears to be at worst logarithmic.

Below we make some additional remarks.

- For all problems, decreasing the drop tolerance will tend to increase the effectiveness of the preconditioner, although it generally will also make the preconditioner more costly to apply. Thus one might optimize the selection of the drop tolerance to minimize the decreasing number of cycles against the increasing cost per cycle. In these experiments, we did not try such systematic optimization, but we did adjust the drop tolerance in a crude way such that more difficult problems performed in a fashion similar to the easy ones.
- Problem Texas is by far the most difficult in this test suite. While we set $maxfil = 35$, the problem with order $80k$ was the only one which came close to achieving this storage limit. Most were well below this limit, and many averaged less than 10 nonzeros per row in L and U factors.
- For the nonsymmetric problems the CSBCG method is used for acceleration. Since the CSBCG requires the solution of a conjugate system with A^t, two matrix multiplies and two preconditioning steps are required for each iteration. As noted in section 3, with our data structures, applying a transposed matrix and preconditioner costs the same as applying the original matrix or preconditioner. Since these are the dominant costs in the CSBCG methods, the cost per cycle is approximately double that for an equivalent symmetric system.

A ROBUST AND EFFICIENT LINEARIZATION SCHEME FOR DOUBLY NONLINEAR AND DEGENERATE PARABOLIC PROBLEMS ARISING IN FLOW IN POROUS MEDIA*

MARIÁN SLODIČKA[†]

Abstract. We study a nonlinear degenerate convection-diffusion model problem having an application in groundwater aquifer and petroleum reservoir simulation. The true solution typically possesses low regularity, and therefore special numerical techniques for its approximation are needed. We design a robust, efficient, and reliable linear relaxation approximation scheme. We prove the convergence of iterations at each time step in the $H^1(\Omega)$-norm. Finally, the convergence of the approximate solution in corresponding functional spaces to its exact counterpart for the parabolic problem is shown.

Key words. flow in porous media, nonlinear degenerate parabolic equation, time discretization, linearization, relaxation scheme, convergence of approximate solution

1. Introduction.

Consider an open bounded set $\Omega \subset \mathbb{R}^N$, $N \geq 1$, with a Lipschitz continuous boundary Γ.

In this paper we study the following nonlinear initial boundary value problem (IBVP):

$$\begin{aligned} \partial_t\theta(u) - \nabla\cdot(K(\theta(u))[\nabla u - \boldsymbol{g}]) &= f && \text{in } Q_T = I\times\Omega,\\ u &= u_D && \text{in } I\times\Gamma,\\ u(0) &= u_0 && \text{in } \Omega, \end{aligned} \tag{1.1}$$

where the time interval I is given as $I = (0,T)$ and T is a positive constant.

The nonlinear function θ is supposed to be continuous and monotonically nondecreasing; i.e., the following relation is valid:

$$0 \leq \theta' \leq L \quad \text{a.e. in } \mathbb{R}. \tag{1.2}$$

We do not adopt any growth conditions on θ, which is a standard matter in many other papers. The typical shape of θ function will be shown later.

The function K and the vector $\boldsymbol{g}$ obey

$$\begin{aligned} |K(x) - K(y)| &\leq C|x-y| \qquad \forall x,y\in\mathbb{R},\\ 0 < K_{\min} &\leq K \leq K_{\max},\\ |\boldsymbol{g}| &\leq C, \end{aligned} \tag{1.3}$$

where C denotes a generic positive constant. In many practical situations the function K can approach 0, which is not allowed in our paper. This is the only restrictive assumption we need. Let us note that the generalization from a scalar K to a matrix form $\boldsymbol{K}$ is possible without any additional difficulties.

The initial datum satisfies

$$u_0 \in L_2(\Omega). \tag{1.4}$$

The source term f and the function u_D are tacitly assumed to be smooth enough for our purposes.

We denote the usual functional spaces $L_2(\Omega)$, $H^1(\Omega)$, $H_0^1(\Omega)$, $H^{-1}(\Omega)$ (the dual space to $H_0^1(\Omega)$), $L_2(I, L_2(\Omega))$, $L_2(I, H_0^1(\Omega))$, $L_\infty(I, L_2(\Omega))$, and $L_2(I, H^{-1}(\Omega))$; see Kufner, John, and Fučík [20].

The notation (w, z) stands for the standard L_2-inner product (or sometimes the duality pairing) of any real or vector-valued functions w, z.

Equation (1.1(a)) changes its type from parabolic to elliptic, depending on the values of $\theta(u)$. Thus we do not expect the solution u to be smooth, and therefore we define a weak solution as follows.

Definition 1.1. *A function u is a weak solution to the IBVP* (1.1) *if*

1. $u - u_D \in L_2(I, H_0^1(\Omega))$,
2. $\theta(u) \in C(I, H^{-1}(\Omega)) \cap L_\infty(I, L_2(\Omega))$,
3. $\partial_t \theta(u) \in L_2(I, H^{-1}(\Omega))$,

and the following integral identity is satisfied:

$$(\partial_t \theta(u), \varphi) + (K(\theta(u))[\nabla u - \boldsymbol{g}], \nabla \varphi) = (f, \varphi) \tag{1.5}$$

for all $\varphi \in H_0^1(\Omega)$ and a.e. in $(0, T)$.

1.1. The physical context. The starting point in mathematical modeling of processes in porous media is *Darcy's law*, which was originally introduced for saturated soils and has been extended to unsaturated soils by *Buckingham*:

$$\boldsymbol{q} = -\frac{k}{\mu}(\nabla p - \rho \boldsymbol{g}), \tag{1.6}$$

where ρ is the density of the fluid, $\boldsymbol{g}$ is the gravity acceleration vector directed downward, p is the pressure, k is the permeability of the medium, and μ is the dynamic viscosity. The factor

$$K = \frac{k}{\mu}$$

is called hydraulic conductivity.

The relation between the specific discharge vector $\boldsymbol{q}$ and the hydraulic gradient ∇p expressed by Darcy's law is linear, indicating laminar flow conditions. This remains valid for small *Reynold's numbers*, namely between 1 and 10.

If the fluid fills the relative volume θ, one gets the continuity equation

$$\partial_t(\rho\theta) + \nabla \cdot (\rho \boldsymbol{q}) = \rho f, \tag{1.7}$$

where f stands for possible sources/sinks. The continuity equation (1.7) together with Darcy's law (1.6) implies for incompressible fluids ($\rho = \text{const}$)

$$\partial_t \theta - \nabla \cdot (K[\nabla p - \rho \boldsymbol{g}]) = f, \tag{1.8}$$

which is known as Richards' equation.

Several studies have shown the nonlinear dependence of θ on the pressure p and also the nonlinear dependence of K on θ. A number of empirical and semiempirical functions have been proposed in the past to represent the water retention curves (cf., e.g., Brooks and Corey [8], Brutsaert [9], Mualem [24], Vauclin, Khanji, and Vachaud, [39], van Genuchten [38], and Bumb, Murphy, and Everett [10]).

Van Genuchten [38] has introduced an attractive class of S functions of the form $S(p) = (1 + |\alpha p|^n)^{-m}$ and he has presented the model

$$\begin{cases} \theta(p) = \begin{cases} \theta_r + \dfrac{\theta_s - \theta_r}{(1 + |\alpha p|^n)^m} & \text{for } p \leq 0, \\ \theta_s & \text{for } p \geq 0, \end{cases} \\ K(S) = K_s S^{\frac{1}{2}}[1 - (1 - S^{\frac{1}{m}})^m]^2, \\ S = \dfrac{\theta - \theta_r}{\theta_s - \theta_r}, \end{cases} \tag{1.9}$$

with coefficients α, n, and $m = 1 - \frac{1}{n}$. The meaning of other symbols is explained in Table 1.1. The typical behavior of $\theta(p), K(\theta)$ is shown in Figure 1.1.

Table 1.1
Notations for van Genuchten's model.

p	$[m]$	pressure head
θ	[-]	water content
θ_s	[-]	saturated value of the soil-water content
θ_r	[-]	residual value of the soil-water content
K	$[\frac{m}{s}]$	hydraulic conductivity
K_s	$[\frac{m}{s}]$	hydraulic conductivity of the saturated zone

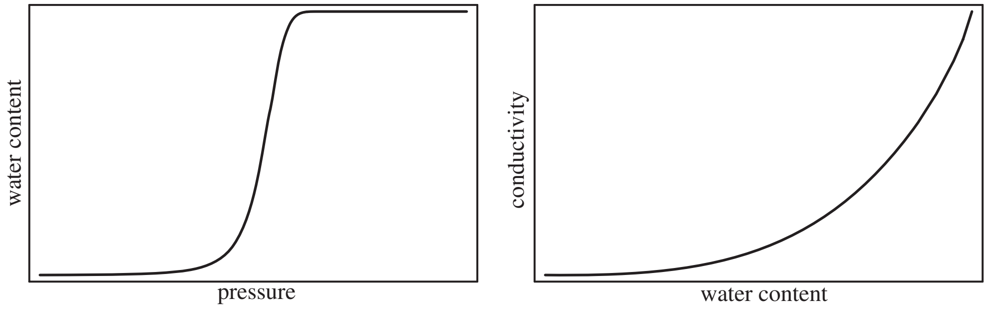

Fig. 1.1. *Soil-water retention curve and hydraulic conductivity versus water content using van Genuchten's model.*

Remark 1.2. Van Genuchten's model describes any geological layer by a set of parameters θ_r, θ_s, K_s, α, and n. The functional dependences are given by (1.9). Analyzing properties of the function $\theta(p)$, one can validate (1.2), where the Lipschitz constant depends on van Genuchten's parameters.

The function K can, in fact, approach 0. This happens in dry soils when $\theta = \theta_r$ only. In many practical applications the condition $K \geq K_{\min}$ is acceptable.

1.2. The state of the art. The van Genuchten model is widely used in the groundwater modeling. Combining the equations of van Genuchten and Richards, we arrive at a doubly nonlinear degenerate parabolic equation. Many mathematical papers have been devoted to the qualitative and quantitative analysis of such problems (cf., e.g., van Duijn and Peletier [37], Alt and Luckhaus [1], and Otto [28]). The authors have proved existence and uniqueness theorems for elliptic-parabolic equations in a more general form, which is suitable for saturated and unsaturated single-phase flow through porous medium.

The idea of studying abstract partial differential equations by means of the theory of nonlinear semigroups of contractions in Banach spaces was proposed by Brezis [6]. This approach not only has theoretical but also numerical aspects. It suggests some algorithms for time discretization to approximate the exact solution. Some of them are based on the so-called Crandall–Liggett formula (cf. Crandall and Liggett [12]) and others on the nonlinear Chernoff formula (cf. Magenes, Nochetto, and Verdi [22], Nochetto [27], [26], and Verdi [40]).

Optimal rates of convergence for degenerate parabolic problems for nonlinear schemes were established by Rulla [32] for semidiscretization in space and by Rulla and Walkington [33] for the full discretization in two dimensions. Some convergence results can also be found in Eymard, Gutnic, and Hilhorst [13] for the finite volume method and in Arbogast, Wheeler, and Zhang [3] or Woodward and Dawson [42] for the mixed finite element method.

Some strongly convergent schemes for the Richards' equation were formulated in [23] upon modification of the Newton–Raphson method, including the method of lines formulations based upon ordinary differential equations. Discretizing the partial differential equation in space by, e.g., finite differences or finite elements, one arrives at a system of differential algebraic equations. For solving this problem we refer the reader to [36].

Many authors apply the backward Euler method for the time discretization. Then a nonlinear elliptic problem has to be solved at each successive time point of a suitable time partitioning of the time interval. Here two ways are possible: to solve a nonlinear elliptic problem[1] or to apply a linearization first. To enhance the robustness of the standard Newton method for solving a system of nonlinear algebraic equations, special techniques (line-search backtracking procedure, preconditioning, etc.) can be used; see [17].

Jäger and Kačur [15], [16], and Kačur [19] have developed effective relaxation schemes for linearization of nonlinear elliptic problems at each time step. The iteration scheme (according to the relaxation parameter κ) has to stop when a prescribed residual condition (iteration error) is satisfied. The convergence for $\kappa \to \infty$ in one dimension of such a relaxation scheme has been shown in Kačur [19]. The proof in more dimensions has not been presented because of lack of regularity of the solution. Moreover, the regularization of the nonlinear function is made using the time step τ. Therefore, one can expect that the convergence of iterations at each time point should depend on τ. In fact, Kačur [19] has shown the estimate

$$|u - u_\kappa| \leq C\tau^r \; |u - u_{\kappa-1}|, \quad r > 0,$$

which represents a contraction only in the case when the time step τ is sufficiently small.

[1] This means that after the full discretization a nonlinear system of algebraic equations has to be solved. This can be done using standard iterative methods, but the discussion of possible iteration error is neglected. The convergence of these methods strongly depends on the choice of the starting iteration, which should be relatively close to the solution. Usually, the foregoing time step solution is chosen. This means that the time step must be chosen sufficiently small in order to find a solution of the nonlinear algebraic system. Recall that the standard method of applying a fixed point iteration to the time step solution will have a wider radius of convergence than applying Newton's method; however, Newton's method has a faster rate of convergence once within its convergence radius.

Another way of linearization relies on Newton's method. It is based either on a regularization of a nonlinear function (cf. Amiez and Gremaud [2], Slodička [34], [35]) or on a shifting of the data (cf. Pop [30], Pop and Yong [31]) instead of a modification of the nonlinear function. Whereas the additional iterations on each time step are omitted, the regularization or the shifting of the data must depend on the time step; otherwise, the convergence cannot be reached.

An attractive group of linearization schemes represents the method of upper and lower solutions (cf. Pao [29] and Wang and Pao [41]). The linearization of a nonlinear problem relies on the ordering properties of solutions. One defines recursive sequences starting from a sub- or a supersolution, respectively. The disadvantage is that one cannot use the solution from the previous time step as a starting iteration.

The case of a non-Lipschitz continuous function θ has been analyzed, e.g., in Barrett and Knabner [5] or Kačur [19].

1.3. Results. The aim of this paper is to present an efficient and robust linear approximation scheme for (1.1), to prove its convergence, and to address the error estimates. The time discretization is based on the backward Euler method. The concept behind our linear approximation is a clever relaxation scheme for solving a nonlinear elliptic BVP at each time point of the time partitioning.

Let us denote the time step $\tau = \frac{T}{n}$ for any $n \in \mathbb{N}$. The approximate solution $u_i \approx u(t_i)$ at a given time point $t_i = i\tau$ is obtained in an iteration process with respect to the relaxation parameter κ. The linearized scheme for a fixed $i \in \{1, \dots, n\}$ and running $\kappa = 1, 2, \dots$ reads as

$$\begin{aligned} u_{i,0} &= u_{i-1}, \\ \frac{L}{\tau}(u_{i,\kappa}, \varphi) + (K(\theta(u_{i-1}))\nabla u_{i,\kappa}, \nabla\varphi) &= (f_i, \varphi) + (K(\theta(u_{i-1}))\boldsymbol{g}, \nabla\varphi) + \frac{L}{\tau}(u_{i,\kappa-1}, \varphi) \\ &\quad - \frac{1}{\tau}(\theta(u_{i,\kappa-1}), \varphi) + \frac{1}{\tau}(\theta(u_{i-1}), \varphi) \end{aligned} \tag{1.10}$$

for all $\varphi \in H_0^1(\Omega)$, where $f_i = f(t_i)$. We recall that L is the Lipschitz constant of the function θ; see (1.2). The iteration process stops when the following condition is satisfied:

$$\|u_{i,\kappa} - u_{i,\kappa-1}\| \le C_d \tau^d, \tag{1.11}$$

where $C_d > 0,\ d > 1$ are fixed constants and $\|\cdot\|$ stands for the usual $L_2(\Omega)$-norm. After stopping the iterations at $\kappa = \kappa_{i,\text{last}}$, we denote $u_i := u_{i,\kappa_{i,\text{last}}}$ and switch to the next time step.

We prove the convergence of relaxation iterations for $\Omega \subset \mathbb{R}^N$, $N \ge 1$. (Compare with Kačur [19], where the convergence in one dimension and for small τ has been shown.) Our iteration scheme with respect to the parameter κ can start from arbitrary data $u_{i,0} = u_{i-1} = u_{i-1,\kappa_{i-1,\text{last}}}$, which makes the proposed numerical method reliable and robust. For $i = 1$, the iteration scheme arises from the initial data u_0. This is one of the highlights of the paper because up until now there does not exist any other linearization scheme with this property. Numerical examples confirming the efficiency of our approximation method are presented in section 5.

Throughout the paper we assume that a generic positive constant C is independent of the iteration parameter κ and the time step τ.

2. A priori estimates. Let us note that the problem (1.10), for given i and κ, admits a unique solution $u_{i,\kappa} \in H_0^1(\Omega)$. This immediately follows from the theory of linear elliptic equations (cf. Gilbarg and Trudinger [14]) taking into account the assumptions (1.2)–(1.4).

The main task of this section is to derive a priori estimates for u_i and $\theta(u_i)$ which are uniform with respect to $i = 1, \ldots, n$ and κ. In Lemma 3.1 we will prove the relation (1.11). Thus we can assume throughout the whole section that the iteration process at each time step t_i stops after $\kappa = \kappa_{i,\text{last}}$ iterations.

We introduce the notation

$$\delta z_i = \frac{z_i - z_{i-1}}{\tau}.$$

We rewrite the iteration scheme (1.10) as follows ($\kappa = \kappa_{i,\text{last}}$, $u_i = u_{i,\kappa_{i,\text{last}}}$):

$$\begin{aligned}(\delta\theta(u_i), \varphi) + (K(\theta(u_{i-1}))\nabla u_i, \nabla\varphi) &= (f_i, \varphi) + (K(\theta(u_{i-1}))\boldsymbol{g}, \nabla\varphi) \\ &\quad + \frac{L}{\tau}(u_{i,\kappa-1} - u_{i,\kappa}, \varphi) \\ &\quad + \frac{1}{\tau}(\theta(u_{i,\kappa}) - \theta(u_{i,\kappa-1}), \varphi)\end{aligned} \tag{2.1}$$

for all $\varphi \in H_0^1(\Omega)$. This form is more convenient for our purposes.

Lemma 2.1. *Let* (1.2), (1.3), *and* (1.4) *be satisfied. Moreover, we assume* (1.11). *Then there exists a positive constant C such that*

$$\|\theta(u_j)\|^2 + \sum_{i=1}^{j} \|\theta(u_i) - \theta(u_{i-1})\|^2 + \sum_{i=1}^{j} \|\nabla\theta(u_i)\|^2\tau \le C$$

holds for all $j = 1, \ldots, n$.

Proof. We put $\varphi = \theta(u_i)\tau$ in (2.1), sum it up for $i = 1, \ldots, j$, and get

$$\begin{aligned}\sum_{i=1}^{j}(\theta(u_i) - \theta(u_{i-1}), \theta(u_i)) &+ \sum_{i=1}^{j}(K(\theta(u_{i-1}))\nabla u_i, \nabla\theta(u_i))\tau \\ = \sum_{i=1}^{j}(f_i, \theta(u_i))\tau &+ \sum_{i=1}^{j}(K(\theta(u_{i-1}))\boldsymbol{g}, \nabla\theta(u_i))\tau \\ &+ \frac{L}{\tau}\sum_{i=1}^{j}(u_{i,\kappa-1} - u_{i,\kappa}, \theta(u_i))\tau \\ &+ \frac{1}{\tau}\sum_{i=1}^{j}(\theta(u_{i,\kappa}) - \theta(u_{i,\kappa-1}), \theta(u_i))\tau.\end{aligned} \tag{2.2}$$

Using (1.3) we deduce

$$(K(\theta(u_{i-1}))\nabla u_i, \nabla\theta(u_i)) = \left(\frac{K(\theta(u_{i-1}))}{\theta'(u_i)}\nabla\theta(u_i), \nabla\theta(u_i)\right) \ge \frac{K_{\min}}{L}\|\nabla\theta(u_i)\|^2.$$

The following identity holds:

$$2\sum_{i=1}^{j}(a_i - a_{i-1})a_i = a_j^2 - a_0^2 + \sum_{i=1}^{j}(a_i - a_{i-1})^2.$$

The relations (1.2) and (1.4) and the triangle inequality imply

$$\|\theta(u_0)\| \le \|\theta(u_0) - \theta(0)\| + \|\theta(0)\| \le L\|u_0\| + C \le C.$$

Thus we can estimate the left-hand side of (2.2) from below by

$$C_0[\|\theta(u_j)\|^2 + \sum_{i=1}^{j} \|\theta(u_i) - \theta(u_{i-1})\|^2 + \sum_{i=1}^{j} \|\nabla\theta(u_i)\|^2\tau] - C.$$

Using the Cauchy–Schwarz and Young's ($|ab| \le \varepsilon a^2 + C_\varepsilon b^2$, where $\varepsilon > 0$ and $C_\varepsilon = C(\frac{1}{\varepsilon})$) inequalities, we deduce

$$\begin{aligned}|(f_i, \theta(u_i)) + (K(\theta(u_{i-1}))\boldsymbol{g}, \nabla\theta(u_i))| &\le C\|\theta(u_i)\| + C\|\nabla\theta(u_i)\| \\ &\le C_\varepsilon + C\|\theta(u_i)\|^2 + \varepsilon\|\nabla\theta(u_i)\|^2.\end{aligned}$$

Now, applying (1.11) and the Lipschitz continuity of θ, we estimate in a similar way

$$\begin{aligned}\left|\frac{L}{\tau}(u_{i,\kappa-1} - u_{i,\kappa}, \theta(u_i)) + \frac{1}{\tau}(\theta(u_{i,\kappa}) - \theta(u_{i,\kappa-1}), \theta(u_i))\right| &\le \frac{C}{\tau}\|u_{i,\kappa-1} - u_{i,\kappa}\|\|\theta(u_i)\| \\ &\le C\tau^{d-1}\|\theta(u_i)\| \\ &\le CT^{d-1}\|\theta(u_i)\| \\ &\le C + C\|\theta(u_i)\|^2.\end{aligned}$$

Therefore, the upper bound of the right-hand side in (2.2) reads as

$$\varepsilon\sum_{i=1}^{j} \|\nabla\theta(u_i)\|^2\tau + C_\varepsilon + C\sum_{i=1}^{j} \|\theta(u_i)\|^2\tau.$$

Fixing sufficiently small positive ε, we arrive at

$$\|\theta(u_j)\|^2 + \sum_{i=1}^{j} \|\theta(u_i) - \theta(u_{i-1})\|^2 + \sum_{i=1}^{j} \|\nabla\theta(u_i)\|^2\tau \le C + C\sum_{i=1}^{j} \|\theta(u_i)\|^2\tau.$$

The rest of the proof follows from Gronwall's lemma. □

Let us introduce the following notation $\Phi_\theta(z) := \int_0^z \theta(s)\mathrm{d}s$ for the Kirchhoff transformation. The function θ is monotonically increasing; therefore,

$$\theta(z_1)(z_2 - z_1) \le \Phi_\theta(z_2) - \Phi_\theta(z_1) \le \theta(z_2)(z_2 - z_1) \tag{2.3}$$

holds for all $z_1, z_2 \in \mathbb{R}$. Further, we can write for any $z \in \mathbb{R}$

$$\tilde{\Phi}_\theta(z) := z\theta(z) - \Phi_\theta(z) \ge 0. \tag{2.4}$$

According to the Lipschitz continuity of the function θ we estimate

$$\tilde{\Phi}_\theta(z) \le C(1 + z^2) \quad \forall z \in \mathbb{R}. \tag{2.5}$$

LEMMA 2.2. *Let the assumptions of Lemma* 2.1 *be satisfied. Then there exists a positive constant C such that*

$$\sum_{i=1}^{j} \|\nabla u_i\|^2\tau \le C$$

holds for all $j = 1, \dots, n$.

Proof. We choose $\varphi = u_i\tau$ in (2.1), sum it up for $i = 1, \dots, j$ and get

$$\begin{aligned}\sum_{i=1}^{j}(\theta(u_i) - \theta(u_{i-1}), u_i) + \sum_{i=1}^{j}(K(\theta(u_{i-1}))\nabla u_i, \nabla u_i)\tau \\ = \sum_{i=1}^{j}(f_i, u_i)\tau + \sum_{i=1}^{j}(K(\theta(u_{i-1}))\boldsymbol{g}, \nabla u_i)\tau \\ + \frac{L}{\tau}\sum_{i=1}^{j}(u_{i,\kappa-1} - u_{i,\kappa}, u_i)\tau \\ + \frac{1}{\tau}\sum_{i=1}^{j}(\theta(u_{i,\kappa}) - \theta(u_{i,\kappa-1}), u_i)\tau.\end{aligned}$$

Using (2.3)–(2.5) we deduce for the first term

$$\begin{aligned}\sum_{i=1}^{j}(\theta(u_i) - \theta(u_{i-1}), u_i) &= (\theta(u_j), u_j) - (\theta(u_0), u_0) - \sum_{i=1}^{j}(u_i - u_{i-1}, \theta(u_{i-1})) \\ &\geq (\theta(u_j), u_j) - (\theta(u_0), u_0) - \sum_{i=1}^{j}\int_\Omega[\Phi_\theta(u_i) - \Phi_\theta(u_{i-1})] \\ &= (\theta(u_j), u_j) - (\theta(u_0), u_0) - \int_\Omega \Phi_\theta(u_j) + \int_\Omega \Phi_\theta(u_0) \\ &= \int_\Omega[\tilde{\Phi}_\theta(u_j) - \tilde{\Phi}_\theta(u_0)] \\ &\geq -C(1 + \|u_0\|^2) \\ &\geq -C.\end{aligned}$$

The second term satisfies

$$\sum_{i=1}^{j}(K(\theta(u_{i-1}))\nabla u_i, \nabla u_i)\tau \geq K_{\min}\sum_{i=1}^{j}\|\nabla u_i\|^2\tau.$$

The right-hand side can be estimated from the top using the Cauchy–Schwarz inequality and (1.11), followed by an application of Young's and Friedrichs' inequalities as well as Lemma 2.1 by

$$\varepsilon\sum_{i=1}^{j}\|\nabla u_i\|^2\tau + C_\varepsilon,$$

where $\varepsilon \in \mathbb{R}_+$. Summarizing all estimates and choosing sufficiently small ε, we conclude the proof. □

Let us denote the norm in $H^1(\Omega)$ by $\|\cdot\|_1$. We recall that the norm in the space $H^{-1}(\Omega)$ is defined by

$$\|\cdot\|_{-1} := \|\cdot\|_{H^{-1}(\Omega)} = \sup_{\substack{\varphi\in H_0^1(\Omega)\\ \|\varphi\|_1\leq 1}} |(\cdot, \varphi)|.$$

Lemma 2.3. *Let the assumptions of Lemma* 2.1 *be satisfied. There is a positive constant C such that for any $j = 1, \dots, n$,*

$$\sum_{i=1}^{j}\|\delta\theta(u_i)\|_{-1}^2\tau \leq C.$$

Proof. We start from the relation (2.1). We leave the first term on the left and the rest we shift to the right; thus we have

$$\begin{aligned}(\delta\theta(u_i),\varphi) &= (f_i,\varphi) + (K(\theta(u_{i-1}))\boldsymbol{g},\nabla\varphi) - (K(\theta(u_{i-1}))\nabla u_i,\nabla\varphi)\\ &\quad + \frac{L}{\tau}(u_{i,\kappa-1}-u_{i,\kappa},\varphi) + \frac{1}{\tau}(\theta(u_{i,\kappa})-\theta(u_{i,\kappa-1}),\varphi).\end{aligned}$$

For the first three terms on the right, we deduce using the Cauchy–Schwarz inequality and (1.3)

$$|(f_i,\varphi) + (K(\theta(u_{i-1}))\boldsymbol{g},\nabla\varphi) - (K(\theta(u_{i-1}))\nabla u_i,\nabla\varphi)| \le C(1+\|\nabla u_i\|)\|\nabla\varphi\| + C\|\varphi\|.$$

The last two terms on the right can be estimated using the Lipschitz continuity of the function θ, the Cauchy–Schwarz inequality, and (1.11) as follows:

$$\begin{aligned}\left|\frac{L}{\tau}(u_{i,\kappa-1}-u_{i,\kappa},\varphi) + \frac{1}{\tau}(\theta(u_{i,\kappa})-\theta(u_{i,\kappa-1}),\varphi)\right| &\le \frac{C}{\tau}\|u_{i,\kappa-1}-u_{i,\kappa}\|\|\varphi\|\\ &\le C\tau^{d-1}\|\varphi\|\\ &\le CT^{d-1}\|\varphi\|\\ &\le C\|\varphi\|.\end{aligned}$$

Hence we can write

$$|(\delta\theta(u_i),\varphi)| \le C(1+\|\nabla u_i\|)\|\nabla\varphi\| + C\|\varphi\|,$$

from which we deduce

$$\|\delta\theta(u_i)\|_{-1} \le C(1+\|\nabla u_i\|).$$

Taking the second power, multiplying the inequality by τ, summing it up for $i = 1,\dots,j$, and applying Lemma 2.2, we get the desired result. □

3. Convergence of the relaxation scheme. In this section we prove the convergence of $u_{i,\kappa}$ for $\kappa\to\infty$. Recall that $u_{i,\kappa}$ is the unique solution to the linear elliptic problem (1.10).

To enhance the readability of the proof, we introduce the notation

$$v_\kappa = u_{i,\kappa}, \qquad F = f_i + \frac{\theta(u_{i-1})}{\tau}, \qquad K = K(\theta(u_{i-1})).$$

Thus we consider the following problem:

$$\begin{aligned}L(v_\kappa,\varphi) + \tau(K\nabla v_\kappa,\nabla\varphi) &= \tau(F,\varphi) + \tau(K\boldsymbol{g},\nabla\varphi) + L(v_{\kappa-1},\varphi)\\ &\quad - (\theta(v_{\kappa-1}),\varphi)\end{aligned} \tag{3.1}$$

for all $\varphi\in H_0^1(\Omega)$. We show that v_κ converges for $\kappa\to\infty$ to a solution $v\in H_0^1(\Omega)$ of the following nonlinear elliptic problem:

$$(\theta(v),\varphi) + \tau(K\nabla v,\nabla\varphi) = \tau(F,\varphi) + \tau(K\boldsymbol{g},\nabla\varphi) \quad \forall\varphi\in H_0^1(\Omega). \tag{3.2}$$

The left-hand side of (3.2) is a maximal monotone and coercive operator from $H_0^1(\Omega)$ to $H^{-1}(\Omega)$. The right-hand side of (3.2) is a bounded linear functional on $H_0^1(\Omega)$. Hence, accounting for Brézis [7, Corollaire 2.4, p. 31], the problem (3.2) admits exactly one solution $v\in H_0^1(\Omega)$.

Now we define the following function:

$$h(s) := \theta(s) - Ls, \quad s \in \mathbb{R}. \tag{3.3}$$

Subtracting (3.2) from (3.1), we get the variational formulation for the error $v_\kappa - v$

$$L(v_\kappa - v, \varphi) + \tau(K\nabla[v_\kappa - v], \nabla\varphi) = (h(v) - h(v_{\kappa-1}), \varphi) \quad \forall\varphi \in H_0^1(\Omega). \tag{3.4}$$

Lemma 3.1. *Let* (1.2), (1.3)*, and* (1.4) *be fulfilled. Then there exists a positive constant* $\lambda = \lambda(\Omega, K_{\min})$ *such that*

$$\begin{aligned}\|v_\kappa - v\|^2 &\le \left(1 - \frac{\tau\lambda}{L+\tau\lambda}\right)^\kappa \|v_0 - v\|^2\\ \|\nabla[v_\kappa - v]\|^2 &\le \frac{L+\tau\lambda}{\tau K_{\min}}\left(1 - \frac{\tau\lambda}{L+\tau\lambda}\right)^\kappa \|v_0 - v\|^2\end{aligned}$$

holds for all $\kappa = 1, 2, \dots$.

Proof. Choose $\varphi = v_\kappa - v \in H_0^1(\Omega)$ in (3.4) and get

$$L(v_\kappa - v, v_\kappa - v) + \tau(K\nabla[v_\kappa - v], \nabla[v_\kappa - v]) = (h(v) - h(v_{\kappa-1}), v_\kappa - v). \tag{3.5}$$

The crucial point is to estimate the right-hand side. To do this, we use (1.2) and deduce

$$-L \le h' = \theta' - L \le 0 \quad \text{a.e. in } \mathbb{R}.$$

Hence the derivative of the function h is bounded by the constant L, i.e., $|h'| \le L$ a.e. in $\mathbb{R}$.

Applying the Cauchy–Schwarz and Young's inequalities, we deduce

$$\begin{aligned}|(h(v) - h(v_{\kappa-1}), v_\kappa - v)| &\le \|h(v) - h(v_{\kappa-1})\|\|v_\kappa - v\|\\ &\le L\|v - v_{\kappa-1}\|\|v_\kappa - v\|\\ &\le \frac{L}{2}\|v - v_{\kappa-1}\|^2 + \frac{L}{2}\|v_\kappa - v\|^2.\end{aligned}$$

The left-hand side of (3.5) can be estimated from below by

$$L\|v_\kappa - v\|^2 + \tau K_{\min}\|\nabla[v_\kappa - v]\|^2.$$

Friedrichs' inequality (cf., e.g., Křížek and Neittaanmäki [21, p. 26]) implies the existence of a positive real number $\lambda = \lambda(\Omega, K_{\min})$ such that

$$\lambda\|w\|^2 \le K_{\min}\|\nabla w\|^2 \quad \forall w \in H_0^1(\Omega). \tag{3.6}$$

According to this fact,

$$\left(L + \frac{\tau\lambda}{2}\right)\|v_\kappa - v\|^2 + \frac{\tau K_{\min}}{2}\|\nabla[v_\kappa - v]\|^2$$

is also a lower bound to the left-hand side of (3.5).

Summarizing the foregoing results, we arrive at

$$(L + \tau\lambda)\|v_\kappa - v\|^2 + \tau K_{\min}\|\nabla[v_\kappa - v]\|^2 \le L\|v_{\kappa-1} - v\|^2,$$

which after a simple calculation gives

$$\|v_\kappa - v\|^2 + \frac{\tau K_{\min}}{L+\tau\lambda}\|\nabla[v_\kappa - v]\|^2 \le \left(1 - \frac{\tau\lambda}{L+\tau\lambda}\right)\|v_{\kappa-1} - v\|^2. \tag{3.7}$$

We omit the second term on the left for a moment and obtain the recursion formula

$$\|v_\kappa - v\|^2 \le \left(1 - \frac{\tau\lambda}{L+\tau\lambda}\right)\|v_{\kappa-1} - v\|^2.$$

After κ iterations, this implies

$$\|v_\kappa - v\|^2 \le \left(1 - \frac{\tau\lambda}{L+\tau\lambda}\right)^\kappa \|v_0 - v\|^2.$$

The rest of the proof comes from the last inequality and (3.7). □

Let us discuss the results of Lemma 3.1 with respect to the scheme (1.10). We point out first that the choice of the time step τ is free. Further, the relaxation iterations can start from arbitrary starting iterations lying in the space $L_2(\Omega)$, and nevertheless they converge in the $H^1(\Omega)$-norm to a function $v \in H_0^1(\Omega)$, which is given by (3.2). Please note that $v \approx u(t_i)$ at the time step i. These properties make the relaxation process reliable and robust.

Lemma 3.1 says that $v_\kappa \to v$ as $\kappa \to \infty$ in the space $L_2(\Omega)$. Thus, for any $\tau > 0$ and any $d > 1$, there exists $\kappa_0 \in \mathbb{N}$ such that $\|v_\kappa - v\| \le \tau^d$ holds for any $\kappa \ge \kappa_0$. Setting $\kappa_{\text{last}} = \kappa_0 + 1$ and using the triangle inequality, we deduce

$$\|v_{\kappa_{\text{last}}} - v_{\kappa_{\text{last}}-1}\| \le \|v_{\kappa_{\text{last}}} - v\| + \|v - v_{\kappa_{\text{last}}-1}\| \le 2\tau^d.$$

Therefore, Lemma 3.1 validates the stopping criterion (1.11). Let us note that the value of κ_{last} can change with the time point t_i. Nevertheless, the constant $C_d = 2$ remains fixed.

4. Convergence of the scheme (1.10). Up until now, we have successively determined u_i for $i = 1, \dots, n$ as the solution of the linear relaxation scheme (1.10). Each $u_i = u_{i,\kappa_{i,\text{last}}}$ has been obtained after a finite number of relaxation iterations so that the stopping criterion (1.11) has been achieved. Now we define a function $w_n(t)$ as a piecewise linear function in time which is defined in terms of u_i $(i = 1, \dots, n)$ as follows:

$$\begin{aligned} &w_n(0) = \theta(u_0),\\ &w_n(t) = \theta(u_{i-1}) + (t - t_{i-1})\delta\theta(u_i) \quad \text{for } t \in (t_{i-1}, t_i] \end{aligned}$$

and the step functions $\overline{w}_n, \overline{u}_n$

$$\begin{aligned} &\overline{w}_n(0) = \theta(u_0), \qquad &&\overline{w}_n(t) = \theta(u_i),\\ &\overline{u}_n(0) = u_0, &&\overline{u}_n(t) = u_i \quad \text{for } t \in (t_{i-1}, t_i]. \end{aligned}$$

In a similar way as $\overline{u}_n$ we also define the function $\overline{f}_n$.

Now we will rewrite the relation (2.1) in terms of the functions we just introduced. First, in light of (1.11) and the Lipschitz continuity of the function θ, the last two terms on the right-hand side of (2.1) can be estimated as follows:

$$\left|\frac{L}{\tau}(u_{i,\kappa-1} - u_{i,\kappa}, \varphi) + \frac{1}{\tau}(\theta(u_{i,\kappa}) - \theta(u_{i,\kappa-1}), \varphi)\right| \le 2LC_d\tau^{d-1}\|\varphi\|$$

uniformly with respect to i ($\kappa = \kappa_{i,\mathrm{last}}$).

Thus we can rewrite the relation (2.1) in an equivalent form

$$\begin{aligned}(\partial_t w_n(t), \varphi) + (K(\overline{w}_n(t-\tau))\nabla \overline{u}_n(t), \nabla\varphi) \\ = (\overline{f}_n(t), \varphi) + (K(\overline{w}_n(t-\tau))\boldsymbol{g}, \nabla\varphi) + \mathcal{O}(\tau^{d-1})\|\varphi\|\end{aligned} \tag{4.1}$$

for all $\varphi \in H_0^1(\Omega)$.

We would like to examine the limit as $n \to \infty$ in (4.1), i.e., we want to prove the convergence (in a suitable function space) of the approximation $\overline{u}_n$ to a weak solution u to the IBVP (1.1), as well as to show the convergence of $w_n, \overline{w}_n$ to $\theta(u)$ and the convergence of $\partial_t w_n$ towards $\partial_t \theta(u)$. We will do it in a few steps. First, we rewrite the a priori estimates from Lemmas 2.1–2.3 in terms of the just defined functions as follows:

$$\begin{gathered}\int_0^T \|\partial_t w_n(t)\|_{-1}^2 \mathrm{d}t \le C, \\ \max_{t\in[0,T]} \|w_n(t)\| \le C, \\ \int_0^T \|w_n(t) - \overline{w}_n(t)\|^2 \mathrm{d}t \le \frac{C}{n}, \\ \int_0^T \|\nabla \overline{w}_n(t)\|^2 \mathrm{d}t \le C, \\ \int_0^T \|\nabla \overline{u}_n(t)\|^2 \mathrm{d}t \le C.\end{gathered} \tag{4.2}$$

The third inequality follows from

$$\|w_n(t) - \overline{w}_n(t)\| \le 2\|\theta(u_i) - \theta(u_{i-1})\|$$

for $t \in (t_{i-1}, t_i]$ and $i = 1, \dots, n$.

Next, using (4.2) and standard results from the functional analysis, we prove the existence of a subsequence of $\overline{u}_n$, which converges to some function $u \in L_2(I, H_0^1(\Omega))$, and the existence of subsequences of $\overline{w}_n$ and w_n, which converge in suitable function spaces towards some function w (see Theorem 4.1). Further, in Theorem 4.2, we improve the result concerning the convergence of a subsequence of w_n and show the relation between w and u, namely, $w = \theta(u)$. Theorem 4.3 proves that u is a weak solution to the IBVP (1.1).

The relative compactness of $\{w_n\}, \{\overline{u}_n\}$ are guaranteed by the following theorem.

THEOREM 4.1. *Let the assumptions of Lemma* 3.1 *be satisfied. Then*

(i) *there exists a function* $w \in C(I, H^{-1}(\Omega)) \cap L_\infty(I, L_2(\Omega))$ *with* $\partial_t w \in L_2(I, H^{-1}(\Omega))$ *and a subsequence of* $\{w_n\}$ *(denoted again by the same symbol) for which*

$$\begin{array}{rll} w_n \to w & \text{in } C(I, H^{-1}(\Omega)), & \\ w_n(t) \rightharpoonup w(t) & \text{in } L_2(\Omega), & \forall t \in [0,T], \\ \overline{w}_n(t) \rightharpoonup w(t) & \text{in } L_2(\Omega), & \forall t \in [0,T], \\ \partial_t w_n \rightharpoonup \partial_t w & \text{in } L_2(I, H^{-1}(\Omega)); & \end{array}$$

(ii) *there exists a function* $u \in L_2(I, H_0^1(\Omega))$ *and a subsequence of* $\{\overline{u}_n\}$ *(denoted by the same symbol again) for which*

$$\overline{u}_n \rightharpoonup u \quad \text{in } L_2(I, H_0^1(\Omega)).$$

Proof. (i) The assertion follows from (4.2) and Kačur [18, Lemma 1.3.13, p. 25].

(ii) The reflexivity of the space $L_2(I, H_0^1(\Omega))$ and the a priori estimate

$$\int_0^T \|\nabla \overline{u}_n(t)\|^2 \mathrm{d}t \leq C$$

imply the desired result. □

The next step is to prove relative compactness of $\{w_n\}$ in $L_2(Q_T)$.

THEOREM 4.2. *Let the assumptions of Lemma* 3.1 *be satisfied. Then*

(i) *there exists a subsequence of* $\{w_n\}$ *(denoted by the same symbol again) for which*

$$w_n \to w \quad \textit{in } L_2(Q_T);$$

(ii) $w = \theta(u)$*, where the function* u *is given by Theorem* 4.1.

Proof. (i) Let $w_n(t, \boldsymbol{x}) = 0$ if $t \notin [0, T]$ or $\boldsymbol{x} \notin \Omega$. According to the Kolmogorov argument (cf. Kufner, John, and Fučík [20, p. 88]), it is sufficient to prove that

1. $\int_0^T \int_\Omega |w_n(t, \boldsymbol{x})|^2 \mathrm{d}\boldsymbol{x}\mathrm{d}t \leq C$ for all n;
2. $\int_0^T \int_\Omega |w_n(t+s, \boldsymbol{x}+\boldsymbol{h}) - w_n(t, \boldsymbol{x})|^2 \mathrm{d}\boldsymbol{x}\mathrm{d}t \to 0$ for $s, |\boldsymbol{h}| \to 0$ uniformly with respect to n.

The first assertion is a consequence of a priori estimates (4.2). Further, one can deduce by a simple calculation that

$$\begin{aligned}
&\int_0^T \int_\Omega |w_n(t+s, \boldsymbol{x}+\boldsymbol{h}) - w_n(t, \boldsymbol{x}+\boldsymbol{h})|^2 \mathrm{d}\boldsymbol{x}\mathrm{d}t \\
&\quad = \int_0^T \int_t^{t+s} (\partial_t w_n(y, \boldsymbol{x}+\boldsymbol{h}), w_n(t+s, \boldsymbol{x}+\boldsymbol{h}) - w_n(t, \boldsymbol{x}+\boldsymbol{h}))\mathrm{d}y\mathrm{d}\boldsymbol{x}\mathrm{d}t \\
&\quad = \int_0^T \int_0^{s} (\partial_t w_n(t+y, \boldsymbol{x}+\boldsymbol{h}), w_n(t+s, \boldsymbol{x}+\boldsymbol{h}) - w_n(t, \boldsymbol{x}+\boldsymbol{h}))\mathrm{d}y\mathrm{d}\boldsymbol{x}\mathrm{d}t \\
&\quad \leq \int_0^s \int_0^T \|\partial_t w_n(t+y)\|_{-1}(\|w_n(t+s\|_1 + \|w_n(t)\|_1)\mathrm{d}y\mathrm{d}t \\
&\quad \leq C \int_0^s \sqrt{\int_0^T \|\partial_t w_n(t)\|_{-1}^2 \mathrm{d}t} \sqrt{\int_0^T \|w_n(t)\|_1^2 \mathrm{d}t} \\
&\quad \leq Cs.
\end{aligned}$$

Using $\int_0^T \|\overline{w}_n(t)\|_1^2 \mathrm{d}t \leq C$ we estimate

$$\begin{aligned}
\int_0^T \int_\Omega |w_n(t, \boldsymbol{x}+\boldsymbol{h}) - w_n(t, \boldsymbol{x})|^2 \mathrm{d}\boldsymbol{x}\mathrm{d}t &\leq C \int_0^T \int_\Omega |\overline{w}_n(t, \boldsymbol{x}+\boldsymbol{h}) - \overline{w}_n(t, \boldsymbol{x})|^2 \mathrm{d}\boldsymbol{x}\mathrm{d}t \\
&\leq \omega(|\boldsymbol{h}|),
\end{aligned}$$

where ω is a continuous real function with $\lim_{s \to 0_+} \omega(s) = 0$ (see, e.g., Nečas [25]).

The second assertion follows from these estimates and the triangle inequality. Hence the sequence $\{w_n\}$ is relatively compact in $L_2(Q_T)$. According to Theorem 4.1 we conclude the proof of (i).

(ii) Using (i) and the a priori estimate $\int_0^T \|w_n(t) - \overline{w}_n(t)\|^2 \mathrm{d}t \leq \frac{C}{n}$, we get

$$\overline{w}_n \to w \quad \text{in } L_2(Q_T). \tag{4.3}$$

The compact embedding $L_2(I, H_0^1(\Omega)) \hookrightarrow\hookrightarrow L_2(I, L_2(\Omega))$ and the weak convergence $\overline{u}_n \rightharpoonup u$ in $L_2(I, H_0^1(\Omega))$ (see Theorem 4.1) imply

$$\begin{aligned}\int_0^T \|\overline{w}_n(t) - \theta(u(t))\|^2 \mathrm{d}t &= \int_0^T \|\theta(\overline{u}_n(t)) - \theta(u(t))\|^2 \mathrm{d}t \\ &\le C \int_0^T \|\overline{u}_n(t) - u(t)\|^2 \mathrm{d}t \quad \to 0 \quad \text{as } n \to \infty.\end{aligned}$$

Hence $w = \theta(u)$. □

Now we use the convergence results from Theorems 4.1 and 4.2 and the a priori estimates (4.2) to examine the limit as $n \to \infty$ in (4.1).

THEOREM 4.3. *Let the assumptions of Lemma* 3.1 *be satisfied. Then the function u given by Theorem* 4.1 *is a weak solution to the IBVP* (1.1) *in the sense of Definition* 1.1.

Proof. In view of Theorems 4.1 and 4.2, it is sufficient to examine the limit for $n \to \infty$ in the relation (4.1).

The idea of the proof is the following. First, we integrate (4.1) over $(0, t)$ for any $t \in (0, T)$. Then we apply the a priori estimates (4.2) and Theorems 4.1 and 4.2 in order to examine the limit as $n \to \infty$. Finally, after the differentiating with respect to the time variable t, we conclude the proof. We demonstrate this for the second term of (4.1), only. This part is the most complicated. The rest can be shown in a standard way.

Smooth functions are dense in $H_0^1(\Omega)$. Thus, for any $\varepsilon \in \mathbb{R}_+$ and any $\varphi \in H_0^1(\Omega)$, there exists a $\varphi_\varepsilon \in C_0^\infty(\overline{\Omega})$ such that $\|\varphi - \varphi_\varepsilon\|_1 < \varepsilon$.

Therefore, we can write

$$\begin{aligned}&\left| \lim_{n\to\infty} \int_0^t (K(\overline{w}_n(s-\tau))\nabla \overline{u}_n(s), \nabla\varphi)\mathrm{d}s - \int_0^t (K(\theta(u(s))\nabla u(s), \nabla\varphi)\mathrm{d}s \right| \\ &\quad = \left| \lim_{n\to\infty} \int_0^t (K(\overline{w}_n(s-\tau))\nabla \overline{u}_n(s) - K(\theta(u(s))\nabla u(s), \nabla[\varphi - \varphi_\varepsilon])\mathrm{d}s \right. \\ &\qquad \left. + \lim_{n\to\infty} \int_0^t (K(\overline{w}_n(s-\tau))\nabla \overline{u}_n(s) - K(\theta(u(s))\nabla u(s), \nabla\varphi_\varepsilon)\mathrm{d}s \right| \\ &\quad \le C\varepsilon + \left| \lim_{n\to\infty} \int_0^t (K(\overline{w}_n(s-\tau))\nabla \overline{u}_n(s) - K(\theta(u(s))\nabla u(s), \nabla\varphi_\varepsilon)\mathrm{d}s \right|.\end{aligned}$$

The Cauchy–Schwarz and the triangle inequalities imply for the second term

$$\begin{aligned}&\left| \int_0^t ([K(\overline{w}_n(s-\tau)) - K(\theta(u(s)))]\nabla \overline{u}_n(s), \nabla\varphi_\varepsilon)\mathrm{d}s \right| \\ &\quad \le \|\nabla\varphi_\varepsilon\|_{L_\infty(\Omega)} \sqrt{\int_0^T \|\nabla \overline{u}_n(s)\|^2 \mathrm{d}s} \sqrt{\int_0^T \|K(\overline{w}_n(s-\tau)) - K(\theta(u(s)))\|^2 \mathrm{d}s} \\ &\quad \le C\|\nabla\varphi_\varepsilon\|_{L_\infty(\Omega)} \sqrt{\int_0^T \|\overline{w}_n(s-\tau) - \theta(u(s))\|^2 \mathrm{d}s} \\ &\quad \le C\|\nabla\varphi_\varepsilon\|_{L_\infty(\Omega)} \sqrt{\int_0^T [\|\overline{w}_n(s-\tau) - \overline{w}_n(s)\|^2 + \|\overline{w}_n(s) - \theta(u(s))\|^2]\,\mathrm{d}s}.\end{aligned}$$

Hence, in light of (4.2) and (4.3), we get

$$\lim_{n\to\infty} \left| \int_0^t ([K(\overline{w}_n(s-\tau)) - K(\theta(u(s)))]\nabla \overline{u}_n(s), \nabla\varphi_\varepsilon)\mathrm{d}s \right| = 0.$$

Therefore, we arrive at

$$\left|\lim_{n\to\infty}\int_0^t (K(\overline{w}_n(s-\tau))\nabla\overline{u}_n(s),\nabla\varphi)\mathrm{d}s - \int_0^t (K(\theta(u(s))\nabla u(s),\nabla\varphi)\mathrm{d}s\right| \le C\varepsilon,$$

which is valid for all $\varepsilon \in \mathbb{R}_+$. Passing to the limit for $\varepsilon \to 0_+$, we conclude

$$\lim_{n\to\infty}\int_0^t (K(\overline{w}_n(s-\tau))\nabla\overline{u}_n(s),\nabla\varphi)\mathrm{d}s = \int_0^t (K(\theta(u(s))\nabla u(s),\nabla\varphi)\mathrm{d}s. \qquad \square$$

Up until now, we have proved the convergence for a subsequence only. The convergence of the whole sequence follows from the uniqueness of the solution.

Consider for a moment the following nonlinear scheme for $i = 1, \dots, n$:

$$\begin{aligned} v_0 &= u_0, \\ (\delta\theta(v_i),\varphi) + (K(\theta(v_{i-1}))\nabla v_i,\nabla\varphi) &= (f_i,\varphi) + (K(\theta(v_{i-1}))\boldsymbol{g},\nabla\varphi) \end{aligned} \tag{4.4}$$

for all $\varphi \in H_0^1(\Omega)$, which has been studied in this or a simplified form by many authors. Also some error estimates in various functional spaces have been derived, depending on the regularity of u_0 and the data functions. When comparing linearization scheme (4.1) with (4.4) we see that our approximate solution $u_{i,\kappa}$ can be arbitrary close to v_i. This follows from the convergence of the relaxation iterations at any time point of the time partitioning. Hence, if the rate of convergence for (4.4) is $\mathcal{O}(\tau^\alpha)$, then (4.1) has the same precision considering sufficiently large d. Thus we have not lost anything in the linearization process.

Up until now, we have presented a new linear relaxation scheme for a uniform time partitioning. The reason was to keep the proofs easier for the reader. Clearly, the relaxation scheme can also be applied for nonequidistant time steps, and the relaxation iterations will converge at any t_i.

5. Numerical experiments.

In this section we present some numerical examples in order to demonstrate the efficiency and robustness of the proposed linearization scheme (1.10). The first one is devoted to a nonlinear IBVP of the type (1.1) without the convection term. Here an exact solution is known. The second example shows the robustness and the efficiency of the relaxation iterations, which is demonstrated on a nonlinear elliptic BVP. The third example is devoted to the real applications. Here we present two different models for description of the soil properties.

For two-dimensional examples, we have chosen the mixed nonconforming finite elements on a uniform triangular mesh for the space discretization. Recall that these are equivalent to the mixed-hybrid method (see, e.g., Arnold and Brezzi [4]). One-dimensional examples have been solved by the piecewise linear Galerkin finite element method.

5.1. Hornung–Messing problem.

We consider a horizontal flow (independent of the z-coordinate) in the domain $\Omega = (0,1)\times(0,1)$, which is given by the following IBVP:

$$\begin{aligned} \partial_t b(p) - \nabla\cdot(K_b(p)\nabla p) &= 0 \quad && \text{in } (0,1)\times\Omega, \\ p &= u \quad && \text{in } (0,1)\times\Gamma, \\ p(0) &= u(0) \quad && \text{in } \Omega, \end{aligned} \tag{5.1}$$

where the nonlinear functions b and K_b are defined as

$$b(p) := \begin{cases} \dfrac{\pi^2}{2} - 2\arctan^2(p) & \text{for } p < 0, \\ \dfrac{\pi^2}{2} & \text{for } p \geq 0 \end{cases} \tag{5.2}$$

and

$$K_b(p) := \begin{cases} \dfrac{2}{1+p^2} & \text{for } p < 0, \\ 2 & \text{for } p \geq 0. \end{cases} \tag{5.3}$$

The functions $b(p)$ and $K(b) := K_b$ have typical shapes; cf. Figure 1.1. Their derivatives are depicted in Figure 5.1. We have chosen the Lipschitz constant L for the function b as $L = 2$ in our computations.

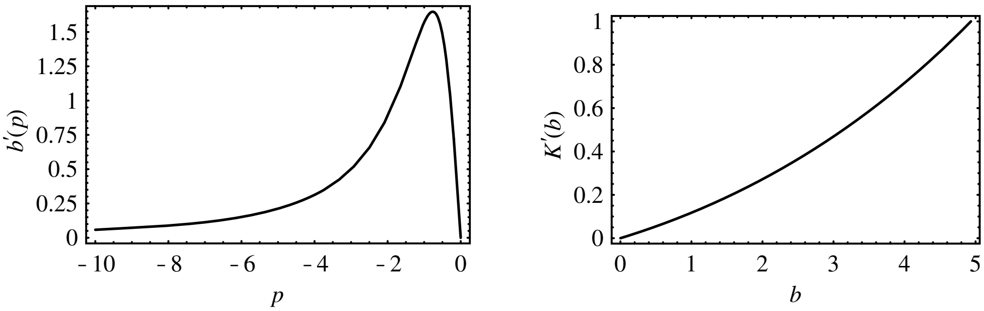

FIG. 5.1. *Behavior of the functions $b'(p)$ and $K'(b)$.*

The function u is given as

$$u(x,y,t) := \begin{cases} -\dfrac{s}{2} & \text{for } s < 0, \\ -\tan\left(\dfrac{e^s-1}{e^s+1}\right) & \text{for } s \geq 0, \end{cases} \tag{5.4}$$

where $s = x - y - t$.

It can be checked that the exact solution of the IBVP (5.1)–(5.4) is $p = u$.

The behavior of the function $b(p(0,x,y))$ is shown in Figure 5.2.

The doubly nonlinear degenerate IBVP (5.1)–(5.4) has been solved using the numerical scheme (1.10). We have computed eight relaxation iterations at each time step, i.e., $\kappa = 1, 2, \dots, 8$. We have used a uniform triangular mesh with $h = \Delta x = \Delta y = 0.04$ or $h = \Delta x = \Delta y = 0.02$. The time step τ takes one of the values $\tau = 0.2$, 0.1, or 0.05. Figure 5.3 represents the error in $L_2(\Omega)$-norm between the discrete and exact solutions. The pictures for $h = 0.04$ and $h = 0.02$ hardly vary with changing h.

Here, at first glance, an interesting effect appears where larger time steps (for later time values) can give smaller error. This can be explained using Lemma 3.1. We have proved there that for any positive τ the relaxation iterations converge. However, if we compare the error bounds for a fixed number of relaxation iterations and for different values of the time steps $\tau_1 < \tau_2$, then, in fact, it can happen that the error corresponding to τ_2 can be less than the error for τ_1. This effect can be removed when we increase the number of relaxation iterations for τ_1; see the next example.

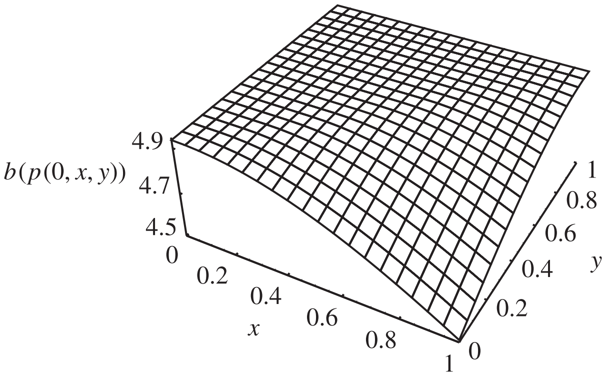

FIG. 5.2. *Behavior of* $b(p(0,x,y))$.

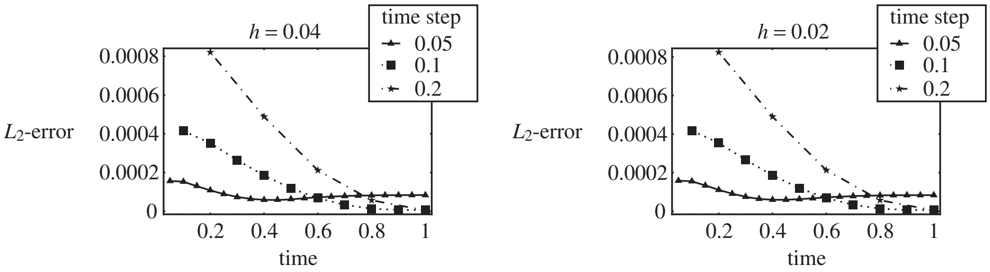

FIG. 5.3. $L_2(\Omega)$*-error for the space step* $h = 0.04$ (*respectively,* $h = 0.02$) *and the time steps* $\tau = 0.2$, 0.1, 0.05.

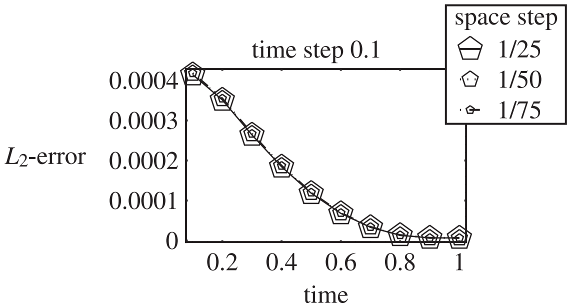

FIG. 5.4. $L_2(\Omega)$*-error for the space steps* $h = \frac{1}{25}, \frac{1}{50}, \frac{1}{75}$, *the time step* $\tau = 0.1$, *and eight relaxation iterations.*

Now we fix the time step $\tau = 0.1$ and the number of relaxation iterations $\kappa_{i,\text{last}} = 8$. Figure 5.4 shows the behavior of the error in the $L_2(\Omega)$-norm versus the time for various space steps. The graph indicates that the error remains the same with the decreasing h. Thus the error coming from the time discretization and/or the linearization is still dominant with respect to the error of the space discretization.

5.2. Nonlinear elliptic BVP. Let $\Omega = (0,1) \times (0,1)$ be the unit square in $\mathbb{R}^2$. The nonlinear function θ is defined as

$$\theta(s) = \begin{cases} \arctan(s) & \text{for } s < 1, \\ \dfrac{\pi}{4} & \text{elsewhere.} \end{cases}$$

This is clearly continuous. For the derivative, we have

$$\theta'(s) = \begin{cases} \dfrac{1}{1+s^2} & \text{for } s < 1, \\ 0 & \text{elsewhere;} \end{cases}$$

thus $0 \le \theta' \le 1$ a.e. in $\mathbb{R}$.

We consider the following nonlinear elliptic BVP: Find $u \in H^1(\Omega)$ such that

$$\begin{aligned} \theta(v) - \Delta v = f &\quad \text{in } \Omega, \\ v = w &\quad \text{on } \Gamma, \end{aligned}$$

where the right-hand side f is defined in such a way that the exact solution of this BVP is

$$v(x,y) = w(x,y) := x^3 - y^2 + x + \sin(\pi x)\sin(\pi y).$$

We have used the linearization scheme (3.1) with $L = K = \tau = 1$, $F = f$, and $\boldsymbol{g} = \mathbf{0}$ for computations. We have started the relaxation iterations from v_0, which was far away from the exact solution v. More exactly, we have chosen

$$v_0(\boldsymbol{x}) = 100\text{ran}(\boldsymbol{x}),$$

where ran is a real random function, the range of which is uniformly distributed over the interval $(-1, 1)$.

We have used a uniform triangular mesh consisting of 5000 elements corresponding to $\Delta x = \Delta y = 0.02$, and we have computed 25 relaxation iterations. The results are depicted in Figures 5.5 and 5.6.

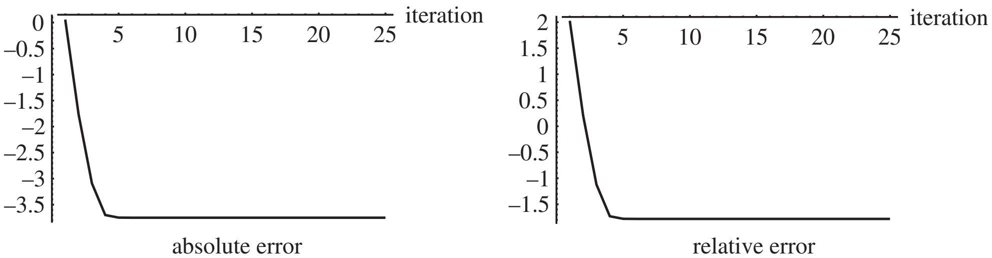

FIG. 5.5. *Logarithm of the norm* $\|v_\kappa - w\|$ *versus iterations.*

Conclusion. The graphs in Figures 5.5 and 5.6 are similar. The rapidly decreasing part is followed by a constant section. At the beginning of the iteration process the linearization error was dominant. Later the discretization error becomes superior. The more or less constant part of a graph means that the discretization error has been achieved.

The proposed linearization scheme is robust, and the approximations converge towards the exact solution independently of the fact of where the iteration process started. This is a big difference from other frequently used algorithms. The iterations are efficient (fast) if $\frac{\tau\lambda}{L+\tau\lambda}$ is not close to the 1 (for an elliptic problem we put $\tau = 1$).

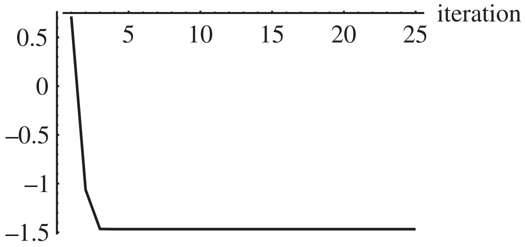

FIG. 5.6. *Logarithm of the norm* $\|\nabla(v_\kappa - w)\|$ *versus iterations.*

5.3. Richards' equation. The standard form of the unsaturated flow equation in one dimension is written as

$$\partial_t\theta(h) - \partial_z(K(h)\partial_z h) - \partial_z K(h) = 0. \tag{5.5}$$

We consider a sand column of a given length with Dirichlet boundary conditions and an initial datum. We consider two models for the representation of the soil properties, i.e., the functions θ and K. We recall that there is no analytical solution known for such a problem. We compute the approximate solution and compare the result with Celia, Bouloutas, and Zarba [11].

We use the linearization scheme (1.10) for computations. The relaxation iterations stops when the discrete $L_2(\Omega)$-norm of $u_{i,\kappa} - u_{i,\kappa-1}$ becomes less than 10^{-3}. The space discretization is based on the standard piecewise linear Galerkin finite element method.

5.3.1. Haverkamp–Celia model. We consider a soil column of length 40cm. Boundary conditions are $h(t,40) = h_{\text{bottom}} = -61.5$cm and $h(t,0) = h_{\text{top}} = -20.7$cm. Initial condition is given as $h(0,z) = h_{\text{bottom}}$. The soil properties expressed by the functions θ and K are

$$\begin{aligned} \theta(h) &= \frac{\alpha(\theta_s - \theta_r)}{\alpha + |h|^\beta} + \theta_r, \\ K(h) &= K_s\frac{A}{A + |h|^\gamma}, \end{aligned} \tag{5.6}$$

where $\alpha = 1.611 \times 10^6$, $\theta_s = 0.287$, $\theta_r = 0.075$, $\beta = 3.96$, $K_s = 0.00944\frac{\text{cm}}{\text{s}}$, $A = 1.175\times10^6$, and $\gamma = 4.74$. These data are taken from Celia, Bouloutas, and Zarba [11]. After the analysis of the behavior of θ' on $[h_{\text{bottom}}, h_{\text{top}}]$, we have chosen the Lipschitz constant L for the function θ as $L = 0.0034$ in (1.10).

Two pressure head profiles at an elapsed time of 360s corresponding to $\tau = 1$s, $\Delta z = 1$mm, and $\tau = 10$s, $\Delta z = 1$cm are shown in Figure 5.7. Our results conform the ones from Celia, Bouloutas, and Zarba [11].

5.3.2. Van Genuchten model. Let the relevant material properties θ and K be given by van Genuchten model (1.9), where $\alpha = 0.0335\frac{1}{\text{cm}}$, $\theta_s = 0.368$, $\theta_r = 0.102$, $n = 2$, $m = 0.5$, and $K_s = 0.00922\frac{\text{cm}}{\text{s}}$. These data are taken from Celia, Bouloutas, and Zarba [11]. We consider a soil column of the depth 100cm. Boundary conditions are $h(t,100) = h_{\text{bottom}} = -1000$cm and $h(t,0) = h_{\text{top}} = -75$cm. The initial condition is given as $h(0,z) = h_{\text{bottom}}$. We have taken the time step $\tau = 10$s and the space step $\Delta z = 1$cm for computations. After the analysis of the behavior of θ' on $[h_{\text{bottom}}, h_{\text{top}}]$, we have chosen the Lipschitz constant $L = 0.001133$ in our computations.

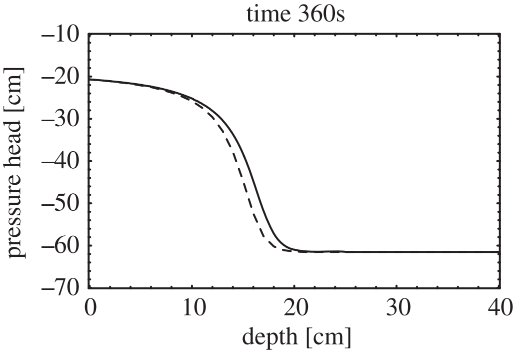

FIG. 5.7. *Solid line: Pressure head for $\tau = 1$s, $\Delta z = 1$mm. Dashed line: Pressure head for $\tau = 10$s, $\Delta z = 1$cm.*

Figure 5.8 shows the solution profiles at the times $t = 3$h, $t = 6$h, $t = 12$h, and $t = 24$h. The solution profile at $t = 24$h corresponds very well to those of Celia, Bouloutas, and Zarba [11] which have been computed by various numerical schemes. Figure 5.8 shows also the oscillations ahead of the moisture front. This is an typical effect of the piecewise linear finite element method which has also been observed by other numerical schemes; see Celia, Bouloutas, and Zarba [11]. This effect appears where the change of the gradient of the solution is large.

COMPUTATION OF THE SHALLOW WATER EQUATIONS USING THE UNIFIED COORDINATES*

W. H. HUI[†] AND S. KOUDRIAKOV[†]

Abstract. Two general coordinate systems have been used extensively in computational fluid dynamics: the Eulerian and the Lagrangian. The Eulerian coordinates cause excessive numerical diffusion across flow discontinuities, slip lines in particular. The Lagrangian coordinates, on the other hand, can resolve slip lines sharply but cause severe grid deformation, resulting in large errors and even breakdown of the computation. Recently, in the spirit of the arbitrary Lagrangian–Eulerian (ALE) approach, W.H. Hui, P.Y. Li, and Z.W. Li, [J. Comput. Phys., 153 (1999), pp. 596–637] have introduced a unified coordinate system which moves with velocity $h\mathbf{q}$, $\mathbf{q}$ being the velocity of the fluid particle. It includes the Eulerian system as a special case when $h = 0$, and the Lagrangian when $h = 1$, and was shown for the two-dimensional Euler equations of gas dynamics to be superior to both Eulerian and Lagrangian systems. The main purpose of this paper is to adopt this unified coordinate system to solve the shallow water equations. It will be shown that computational results using the unified system are superior to existing results based on either the Eulerian system or Lagrangian system in that it (a) resolves slip lines sharply, especially for steady flow, (b) avoids grid deformation and computation breakdown in Lagrangian coordinates, and (c) avoids spurious flow produced by Lagrangian coordinates.

Key words. unified description, Eulerian description, Lagrangian description, two-dimensional shallow water equations, slip lines, spurious vorticity due to Lagrangian description

1. Introduction.

Two general coordinate systems have been used extensively for describing fluid motion: the Eulerian and the Lagrangian. Computationally, each system has its advantages as well as disadvantages.

In using the Eulerian coordinates the computational cells are fixed in space, while fluid particles move across cell interfaces in any direction. It is this convective flux that causes excessive numerical diffusion in the numerical solution. Indeed, slip lines are smeared badly and shocks are also smeared, albeit somewhat better than slip lines. Moreover, the smearing of slip lines ever increases with time and distance unless special treatments, such as artificial compression or subcell resolution, are employed [2], [3], [4] which are, however, not always reliable. In this regard it is interesting to note that some works using the ghost fluid method [5], [6] based on the empirical isobaric fix have just appeared which give good slip line and shock resolution.

Computational cells in the Lagrangian coordinates, on the other hand, are literally fluid particles. Consequently, there is no convective flux across cell interfaces, and numerical diffusion is thus minimized. However, the very fact that the computational cells exactly follow fluid particles can result in severe grid deformation, causing inaccuracy and even breakdown of the computation. To prevent this from happening, the most famous Lagrangian method in use at the present time—the arbitrary Lagrangian–Eulerian (ALE) technique [8], [9], [10]—uses continuous rezoning

[†]Department of Mathematics and Center for Scientific Computation, The Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong (whhui@ust.hk, hp1@semt2.smts.cea.fr).

and remapping to the Eulerian grid. Unfortunately, this process requires interpolations of geometry and flow variables which result in loss of accuracy, manifested as numerical diffusion which the ALE approach wants to avoid in the first place. Indeed, it was demonstrated in [11] that rezoning results in diffusive errors of the type encountered in Eulerian solutions and that continuously rezoned Lagrangian computation is equivalent to an Eulerian computation. Another disadvantage of the Lagrangian coordinates is that, except in the simple case of one-dimensional unsteady flow, the governing equations for inviscid flow are not easily written in conservation form, making it difficult to capture shocks correctly.

Recently, Hui, Li, and Li [1] have introduced a unified coordinate system which moves with velocity $h\mathbf{q}$, where $\mathbf{q}$ is velocity of the fluid particle. It includes the Eulerian coordinates as a special case when $h = 0$ and the Lagrangian when $h = 1$, and, more importantly, it has a new degree of freedom in choosing the arbitrary function h to improve the quality of computational results. In particular, it was shown in [1] that for the two-dimensional Euler equations of gas dynamics, choosing the function h to preserve grid angles results in a coordinate system which is superior to both Eulerian and Lagrangian systems.

The unified coordinates approach shares the same spirit of the ALE approach in that it combines the best features of the Lagrangian and Eulerian approach, [10, p. 198], or in that the coordinates move at an arbitrary velocity [7, p. 239]. However, the strategies are quite different. In the ALE approach, "the general strategy is to perform a Lagrangian time step and to follow it with a remap step that maps the solution from the distorted Lagrangian mesh on to the spatially fixed Eulerian mesh or the ALE mesh" [7, p. 236], [10, p. 198]. This is usually done by employing a staggered grid. Furthermore, the rezoning strategies are not generally prescribed; instead, "rezoning requires the intervention of the user, ..., and the success of the method depends heavily on the skill and patience of the user" [7, p. 322]. In our unified coordinates approach we propose a specific rule for grid (mesh) movement: the grid should move with velocity $h\mathbf{q}$, $\mathbf{q}$ being fluid velocity, and h is determined to preserve grid angles, resulting in sharp resolution of slip lines, especially for steady flow. In our method all computations are done entirely in the transformed space without a staggered grid and with no explicit rezoning/remapping to the Eulerian or ALE space; explicit remapping causes numerical diffusion.

The purpose of this paper is to adopt this unified coordinate approach to solve the shallow water equations; it will be shown that computational results using the unified system are superior to existing results based on either the Eulerian or Lagrangian system.

The paper is arranged as follows. In section 2 the shallow water equations in conservation form are derived using the unified coordinates. Sections 3 and 4 study the cases of one-dimensional and two-dimensional flow, respectively. Section 5 gives results for several test examples computed using the unified coordinates and compares them with Eulerian or Lagrangian computation. Finally, conclusions are given in section 6.

2. Shallow water equations in the unified coordinates. The shallow water equations in conservation form using Cartesian coordinates are

$$(1)\ \frac{\partial}{\partial t}\begin{pmatrix}\zeta\\ \zeta u\\ \zeta v\end{pmatrix}+\frac{\partial}{\partial x}\begin{pmatrix}\zeta u\\ \zeta u^2+\frac{1}{2}g\zeta^2\\ \zeta uv\end{pmatrix}+\frac{\partial}{\partial y}\begin{pmatrix}\zeta v\\ \zeta uv\\ \zeta v^2+\frac{1}{2}g\zeta^2\end{pmatrix}=\begin{pmatrix}0\\ \zeta\left[g\frac{\partial D}{\partial x}-m\right]\\ \zeta\left[g\frac{\partial D}{\partial y}-n\right]\end{pmatrix},$$

where g is the acceleration due to gravity, $\zeta(x, y, t)$ is the total water height measured from the bottom, $u(x, y, t)$ and $v(x, y, t)$ are the components of the fluid velocity in the horizontal x and y direction, respectively, $D(x, y)$ is the water depth from a fixed reference level, and m and n are the components of the bottom friction force due to its roughness.

Introduce a transformation of coordinates from (t, x, y) to (λ, ξ, η),

$$\left\{ \begin{array}{l} dt = d\lambda, \\ dx = hud\lambda + Ad\xi + Ld\eta, \\ dy = hvd\lambda + Bd\xi + Md\eta, \end{array} \right. \tag{2}$$

where h is arbitrary. Let

$$\frac{D_h}{Dt} \equiv \frac{\partial}{\partial t} + hu\frac{\partial}{\partial x} + hv\frac{\partial}{\partial y} \tag{3}$$

denote the time derivative following the *pseudoparticle*, whose velocity is $h\mathbf{q}$, $\mathbf{q} = (u, v)$. Then, under the assumption $AM - BL \neq 0$ (nonsingularity of the transformation (2)), it is easy to show

$$\frac{D_h\xi}{Dt} = 0, \quad \frac{D_h\eta}{Dt} = 0, \tag{4}$$

that is to say, the coordinates (ξ, η) are material functions of the pseudoparticles, hence they are their permanent identifications. Accordingly, computational cells move and deform with pseudoparticles, rather than with fluid particles as in Lagrangian coordinates.

Remarks.

(a) Unlike most transformations used in grid generation, which are flow-independent, the unique feature of transformation (2) is its dependence on the fluid velocity.

(b) In (2), h is an arbitrary function of coordinates (λ, ξ, η). On the other hand, (A, B, L, M) are determined by the compatibility conditions. For example, for dx to be a total differential,

$$\frac{\partial A}{\partial \lambda} = \frac{\partial (hu)}{\partial \xi}, \tag{5}$$

$$\frac{\partial L}{\partial \lambda} = \frac{\partial (hu)}{\partial \eta}. \tag{6}$$

When (5)–(6) are satisfied, the other compatibility condition, namely,

$$\frac{\partial A}{\partial \eta} = \frac{\partial L}{\partial \xi}, \tag{7}$$

is also satisfied, provided it is at $\lambda = 0$, which can always be ensured in numerical computation. Similar compatibility conditions hold for (B, M).

(c) In the special case when $h = 0$, (A, B, L, M) are independent of λ. Then the coordinates (ξ, η) are independent of time λ and are hence fixed in space. This coordinate system is thus Eulerian. Transformation (2) is then flow-independent and is just like any other transformation from Cartesian coordinates (x, y) to curvilinear coordinates (ξ, η) used in grid generation. In particular, if $A = M = 1$ and $L = B = 0$, (ξ, η) are identical with Cartesian coordinates (x, y).

(d) In the special case when $h = 1$, on the other hand, the pseudoparticles coincide with fluid particles and (ξ, η) are the material functions of fluid particles, hence they are Lagrangian coordinates. The conventional choice of the Lagrangian coordinates, i.e., $(\xi, \eta) = (x, y)|_{t=0}$, is just a special choice of material functions, corresponding to choosing $A = M = 1$ and $L = B = 0$. It does not offer any particular advantage in numerical computation; rather (ξ, η) should better be left to be suitably chosen to initialize numerical computation. In particular, the computational domain in the (ξ, η) space can always be easily made regular, e.g., rectangular, even if it is irregular in the physical space. This cannot be done with the conventional choice of the Lagrangian coordinates.

(e) In the general case, h is arbitrary. It has been shown [1] that the unified coordinates for $h \neq 0$ always yield sharp slip line resolution in steady flow. Furthermore, h may be chosen to advantage: to avoid excessive numerical diffusion in the Eulerian coordinates, and/or to avoid severe grid deformation in the Lagrangian coordinates.

Under the transformation (2) the shallow water equations (1) become

$$\frac{\partial \mathbf{E}}{\partial \lambda} + \frac{\partial \mathbf{F}}{\partial \xi} + \frac{\partial \mathbf{G}}{\partial \eta} = \mathbf{S}, \tag{8}$$

where

$$\mathbf{E} = \begin{pmatrix} \zeta\triangle \\ \zeta\triangle u \\ \zeta\triangle v \\ A \\ B \\ L \\ M \end{pmatrix}, \quad \mathbf{F} = \begin{pmatrix} \zeta(1-h)I \\ \zeta(1-h)Iu + \frac{1}{2}g\zeta^2 M \\ \zeta(1-h)Iv - \frac{1}{2}g\zeta^2 L \\ -hu \\ -hv \\ 0 \\ 0 \end{pmatrix},$$

$$\mathbf{G} = \begin{pmatrix} \zeta(1-h)J \\ \zeta(1-h)Ju - \frac{1}{2}g\zeta^2 B \\ \zeta(1-h)Jv + \frac{1}{2}g\zeta^2 A \\ 0 \\ 0 \\ -hu \\ -hv \end{pmatrix}, \quad \mathbf{S} = \begin{pmatrix} 0 \\ \zeta\left[gMD_\xi - gBD_\eta - m\triangle\right] \\ \zeta\left[-gLD_\xi + gAD_\eta - n\triangle\right] \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}, \tag{9}$$

with

$$\triangle = AM - BL, \quad I = uM - vL, \quad J = vA - uB. \tag{10}$$

We note that the shallow water equations (8) written in the unified coordinates are in conservation form. We also point out that although system (8) is larger than (1), computationally the extra computing time required for solving the last four equations of (8) is very small, typically 3–5%, because the bulk of computing time is spent on solving the Riemann problems for the first three equations of (8), which require the same amount of computing time as system (1).

In the remainder of this paper we shall consider only horizontal bottom and neglect the friction term there, and hence $\mathbf{S} = 0$.

3. One-dimensional shallow water flow. For the special case of one-dimensional flow, transformation (2) simplifies to

$$\left\{ \begin{array}{l} dt = d\lambda, \\ dx = hud\lambda + Ad\xi, \end{array} \right. \tag{11}$$

and the shallow water equations (8) become

$$\frac{\partial \mathbf{E}}{\partial \lambda} + \frac{\partial \mathbf{F}}{\partial \xi} = \mathbf{0}, \tag{12}$$

where

$$\mathbf{E} = \left(\begin{array}{c} \zeta A \\ \zeta A u \\ A \end{array} \right), \quad \mathbf{F} = \left(\begin{array}{c} \zeta(1-h)u \\ \zeta(1-h)u^2 + \frac{1}{2} g \zeta^2 \\ -hu \end{array} \right). \tag{13}$$

3.1. Hyperbolicity. As we shall use the Godunov-MUSCL scheme to compute system (12), we need to consider the hyperbolicity property of that system in order to ensure the existence and uniqueness of the solution to the Riemann problem, which is the main ingredient of the Godunov scheme.

It is well known that the one-dimensional shallow water equations in Eulerian coordinates are hyperbolic. However, since transformation (11) involves the dependent variable u, there is no guarantee that the resulting system (12) will necessarily be hyperbolic also; now we check this.

The eigenvalues of (12) can be found by direct computation, and the results are:

$$\sigma_1 = 0, \tag{14}$$

$$\sigma_{\pm} = \frac{(1-h)u \pm \sqrt{g\zeta}}{A}. \tag{15}$$

The corresponding right eigenvectors, when the primitive variables $\mathbf{U} = (\zeta, u, A)^T$ are used, are

$$\mathbf{r_1} = (0, 0, 1)^T, \tag{16}$$

$$\mathbf{r}_{\pm} = \left(1, \pm\sqrt{g/\zeta}, \mp\frac{h}{\sigma_{\pm}}\sqrt{g/\zeta} \right)^T. \tag{17}$$

It can easily be shown that the σ_1-field is linearly degenerate, while the $\sigma_{\pm}$-fields are genuinely nonlinear. The eigenvectors are linearly independent, forming a complete basis in the state space; system (12) is therefore hyperbolic for all values of h, despite the fact that transformation (11) involves the dependent variable u. This includes the Eulerian coordinates as a special case when $h = 0$ and the Lagrangian one when $h = 1$. This result is the same as one-dimensional Euler equations of gas dynamics [12].

3.2. Riemann problem. The one-dimensional shallow water equations (12) will be solved using the Godunov method with the MUSCL update to high resolution, of which the main ingredient is the solution of the Riemann problem.

The Riemann problem is

$$\left\{ \begin{array}{ll} \dfrac{\partial \mathbf{E}}{\partial \lambda} + \dfrac{\partial \mathbf{F}}{\partial \xi} = 0, & \lambda > 0, \\ \mathbf{E}(0, \xi) = \left\{ \begin{array}{ll} \mathbf{E}_l, & \xi < 0, \\ \mathbf{E}_r, & \xi > 0, \end{array} \right. & \end{array} \right. \tag{18}$$

where $\mathbf{E}_l$ and $\mathbf{E}_r$ are the constant vectors representing the flow states on the left and the right side, respectively. Here we shall consider the case when h is a constant in the range $0 \le h \le 1$. With $h = \text{const}$, (18) is a system of conservation law equations with constant coefficients and its solution depends on $\mu = \frac{\xi}{\lambda}$ alone; i.e., it is a self-similar solution of the form $\mathbf{E} = \mathbf{E}(\mu)$. It consists of at most four uniform flow regions, including $\mathbf{E}_l$ and $\mathbf{E}_r$, separated by three elementary waves: a shock (or expansion), a contact line, and an expansion (or shock). These elementary wave solutions are now given.

3.2.1. Expansion wave. The centered expansion wave solution from the $\sigma_\pm$ characteristic fields can be derived from the following system of ODEs:

$$\frac{du}{d\zeta} = \pm\sqrt{g/\zeta}, \tag{19}$$

$$\frac{dA}{d\zeta} = \mp\frac{h\sqrt{g/\zeta}}{\sigma_\pm}. \tag{20}$$

The solution for (u, A) relates the flow state $\mathbf{U} = (\zeta, u, A)^T$ in the expansion wave to the initial state $\mathbf{U_0} = (\zeta_0, u_0, A_0)^T$ upstream of the wave through the following expressions:

$$u \mp 2\sqrt{g\zeta} = u_0 \mp 2\sqrt{g\zeta_0}, \tag{21}$$

$$A = A_0\left(\frac{\sqrt{\zeta_0} - C_\pm}{\sqrt{\zeta} - C_\pm}\right)^{\frac{2h}{3-2h}}, \quad C_\pm = \frac{1-h}{3-2h}\left(2\sqrt{\zeta_0} \mp \frac{u_0}{\sqrt{g}}\right). \tag{22}$$

To find the solution inside the expansion wave, we consider the characteristic ray through the origin $(0, 0)$ and a general point (λ, ξ) inside the wave. The slope of the characteristic is

$$\frac{d\xi}{d\lambda} = \frac{\xi}{\lambda} = \mu = \sigma_\pm = \frac{(1-h)u \pm \sqrt{g\zeta}}{A}. \tag{23}$$

This, together with (21) and (22), gives $\zeta(\mu)$, $u(\mu)$, and $A(\mu)$ implicitly; in the special case of $h = 0$ or $h = 1$, these functions can be written explicitly.

3.2.2. Shocks. We start from the following Rankine–Hugoniot jump conditions of system (18):

$$s[\zeta A] = [(1-h)\zeta u], \tag{24}$$

$$s[\zeta u A] = [(1-h)\zeta u^2 + \frac{g}{2}\zeta^2], \tag{25}$$

$$s[A] = -[hu], \tag{26}$$

where [.] denotes the jump across the discontinuity whose speed is denoted by $s = \frac{d\xi}{d\lambda}$.

We denote the preshock flow state by $\mathbf{U_0} = (\zeta_0, u_0, A_0)^T$ and the postshock flow state by $\mathbf{U} = (\zeta, u, A)^T$, respectively. Then the shock jump relations after some algebraic manipulations can be expressed as follows:

$$u = u_0 \pm \sqrt{g(\zeta + \zeta_0)(\zeta - \zeta_0)^2/(2\zeta\zeta_0)}, \tag{27}$$

$$A = A_0 - \frac{h(u - u_0)}{s_{sh\pm}}, \tag{28}$$

where

$$s_{sh\pm} = \frac{(1-h)u_0}{A_0} \pm \frac{\sqrt{g\zeta(\zeta+\zeta_0)/(2\zeta_0)}}{A_0}. \tag{29}$$

Formulas (27)–(28) hold for $h : 0 \leq h \leq 1$.

3.2.3. Contact (or slip) lines. The degenerate wave corresponds to speed $s = \sigma_1 = 0$. From the Rankine–Hugoniot jump conditions (24)–(26) we have

$$\zeta = \zeta_0, \tag{30}$$

$$u = u_0. \tag{31}$$

The only variable which can change its value across this wave is A. Since the flow variables ζ and u are continuous, *there is no flow discontinuity in the form of a contact (slip) line.*

We compare here the computation of the one-dimensional shallow water flow with the one-dimensional flow of gas dynamics. As seen from the analysis, the one-dimensional shallow water equations have just one type of flow discontinuity (shocks), but there is no flow contact (slip) lines which exist in the one-dimensional Euler equations of gas dynamics. In the latter case it was shown [12] that the Lagrangian system of coordinates is the best for resolution of the contact lines. However, with no contact line to resolve, Eulerian and Lagrangian coordinates are on equal footing for accuracy, as is verified in our computation. The adaptive Godunov scheme [13], [14], which resolves shocks crisply, can now be applied to either the Lagrangian coordinates or the Eulerian ones, or indeed for any h.

4. Two-dimensional shallow water flow.

4.1. Hyperbolicity. It is well known that the system of unsteady shallow water equations (1) in Cartesian coordinates is hyperbolic, meaning that all its eigenvalues are real, and there exist a complete set of linearly independent eigenvectors. Because the transformation from (t, x, y) to the unified coordinates (λ, ξ, η) involves the dependent variables (u, v), there is no guarantee that the resulting system (8) will necessarily be hyperbolic. We now study the hyperbolicity of the system (8). To do that we rewrite the system (8) as

$$\mathbf{A}\frac{\partial \mathbf{U}}{\partial \lambda} + \mathbf{B}\frac{\partial \mathbf{U}}{\partial \xi} + \mathbf{C}\frac{\partial \mathbf{U}}{\partial \eta} = \mathbf{S}_1, \tag{32}$$

where

$$\mathbf{U} = \begin{pmatrix} \zeta \\ u \\ v \\ A \\ B \\ L \\ M \end{pmatrix}, \quad \mathbf{S}_1 = \begin{pmatrix} 0 \\ 0 \\ 0 \\ uh_\xi \\ vh_\xi \\ uh_\eta \\ vh_\eta \end{pmatrix}, \tag{33}$$

and

$$\mathbf{A} = \frac{\partial \mathbf{E}}{\partial \mathbf{U}}, \quad \mathbf{B} = \frac{\partial \mathbf{F}}{\partial \mathbf{U}}, \quad \mathbf{C} = \frac{\partial \mathbf{G}}{\partial \mathbf{U}}. \tag{34}$$

System (32) is said to be hyperbolic (also called strongly hyperbolic, or fully hyperbolic) in λ if [15]

(i) all the eigenvalues σ of

$$\det(\sigma\mathbf{A} - \alpha\mathbf{B} - \beta\mathbf{C}) = 0$$

are real for every pair $(\alpha, \beta) \in R^2 : \alpha^2 + \beta^2 = 1$; and

(ii) associated with the eigenvalues there exist a complete set of seven linearly independent right eigenvectors in the state space.

System (32) is said to be weakly hyperbolic in λ if (i) is satisfied and (ii) is not.

The eigenvalues of (32) can be found by direct computation, and the results are as follows.

Case (a). $h \neq 1$. In this case we get

$$\sigma_1 = 0 \qquad (\textit{multiplicity } 4), \tag{35}$$

$$\sigma_2 = (1-h)(\alpha' u + \beta' v), \tag{36}$$

$$\sigma_\pm = \sigma_2 \pm \sqrt{g\zeta(\alpha'^2 + \beta'^2)}, \tag{37}$$

where

$$\alpha' = (\alpha M - \beta B)/\triangle, \qquad \beta' = -(\alpha L - \beta A)/\triangle.$$

The corresponding right eigenvectors are

$$\mathbf{r}_1 = (0,0,0,1,0,0,0)^T, \tag{38}$$

$$\mathbf{r}_2 = (0,0,0,0,1,0,0)^T, \tag{39}$$

$$\mathbf{r}_3 = (0,0,0,0,0,1,0)^T, \tag{40}$$

$$\mathbf{r}_4 = (0,0,0,0,0,0,1)^T \tag{41}$$

for σ_1,

$$\mathbf{r}_5 = \left(0, \beta', -\alpha', -\frac{h}{\mu}\alpha\beta', \frac{h}{\mu}\alpha\alpha', -\frac{h}{\mu}\beta\beta', \frac{h}{\mu}\beta\alpha'\right)^T \tag{42}$$

for σ_2, and

$$\mathbf{r}_{6,7} = \left(1, \frac{\alpha' g}{m_\pm}, \frac{\beta' g}{m_\pm}, \frac{-\alpha\alpha' gh}{\sigma_\pm m_\pm}, \frac{-\alpha\beta' gh}{\sigma_\pm m_\pm}, \frac{-\beta\alpha' gh}{\sigma_\pm m_\pm}, \frac{-\beta\beta' gh}{\sigma_\pm m_\pm}\right)^T \tag{43}$$

for $\sigma_\pm$, where

$$m_\pm = \pm\sqrt{g\zeta(\alpha'^2 + \beta'^2)}.$$

The eigenvectors $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_7$ are linearly independent, forming a complete basis in the state space; system (32) is therefore hyperbolic for $h \neq 1$. This includes the Eulerian coordinates as a special case when $h = 0$.

Case (b). $h = 1$ (Lagrangian case). In this case the eigenvalues are

$$\sigma_1 = 0 \qquad (\textit{multiplicity } 5), \tag{44}$$

$$\sigma_\pm = \pm\sqrt{g\zeta(\alpha'^2 + \beta'^2)}. \tag{45}$$

The eigenvectors associated with $\sigma_\pm$ are

$$\mathbf{r}_\pm = \left(1, \frac{\alpha' g}{\sigma_\pm}, \frac{\beta' g}{\sigma_\pm}, \frac{-\alpha\alpha' g}{\sigma_\pm^2}, \frac{-\alpha\beta' g}{\sigma_\pm^2}, \frac{-\beta\alpha' g}{\sigma_\pm^2}, \frac{-\beta\beta' g}{\sigma_\pm^2}\right)^T. \tag{46}$$

Associated with $\sigma_1 = 0$ (multiplicity 5),

$$\operatorname{rank}(\sigma\mathbf{A} - \alpha\mathbf{B} - \beta\mathbf{C})\Big|_{\sigma=\sigma_1} = 3;$$

hence there exist the four, and only four, following linearly independent right eigenvectors:

$$\mathbf{r}_1 = (0,0,0,1,0,0,0)^T, \tag{47}$$

$$\mathbf{r}_2 = (0,0,0,0,1,0,0)^T, \tag{48}$$

$$\mathbf{r}_3 = (0,0,0,0,0,1,0)^T, \tag{49}$$

$$\mathbf{r}_4 = (0,0,0,0,0,0,1)^T. \tag{50}$$

We therefore arrive at the conclusion that *the system of unsteady two-dimensional shallow water equations in Lagrangian coordinates is weakly hyperbolic*, lacking one eigenvector, although all eigenvalues are real. It is interesting to note that similar results were obtained in the gas dynamics case; namely, the two-dimensional and three-dimensional Euler equations written in the unified coordinates are hyperbolic for any h, $0 \leq h < 1$, but they are only weakly hyperbolic for $h = 1$ (Lagrangian case). Moreover, it is shown in [1] that for the smooth solutions the system of two-dimensional Euler equations of gas dynamics written in the classical Lagrangian coordinates is equivalent to the same system written in the unified coordinates with $h = 1$. The steps of the proof can easily be repeated for the system of two-dimensional shallow water equations to show that the system of two-dimensional shallow water equations written in the classical Lagrangian coordinates is also weakly hyperbolic.

To avoid possible difficulties, such as the existence and uniqueness of weak solution, arising from the lack of a complete set of eigenvectors, we shall use $h = 0.999$ (or any h very close to 1.0) for which the two-dimensional shallow water equations are hyperbolic.

In summary, use of Lagrangian coordinates in CFD for two-dimensional shallow water equations can not only cause severe grid deformation, but it also renders the two-dimensional shallow water equations weakly hyperbolic with all its possible consequences on numerical computation. More will be said about the Lagrangian case at the end of section 4.4.

4.2. Determination of *h*. As mentioned earlier, the chief advantage of the unified coordinates is the new degree of freedom in choosing h. Many choices are possible, and the simplest one would be to choose a constant value for it, as was done in section 3. Numerical experiments for constant h will be presented in section 6 to show its effects on grid deformation and on resolution of flow discontinuities. In general, it is necessary to restrict h to within the range $0 \leq h \leq 1$. For $h > 1$, the eigenvalue σ_2 in (36) has an opposite sign to that for $h < 1$, indicating that signals propagate in the wrong direction. Our computations for $h > 1$ break down immediately. On the other hand, for $h < 0$, which means the pseudoparticles are moving in the opposite direction to the fluid particles, computation can be carried out initially, but after some finite time it also breaks down. No difficulty has been encountered in all our computations if h is restricted to $0 \leq h < 1$.

As shown in [1], a good choice for h is to preserve the grid angles in the solution process which marches in λ, i.e.,

$$\frac{\partial}{\partial\lambda}\left[\frac{\nabla\xi}{|\nabla\xi|}\cdot\frac{\nabla\eta}{|\nabla\eta|}\right] = 0. \tag{51}$$

Since

$$\begin{aligned}\nabla\xi &= (M,-L)/\triangle,\\ \nabla\eta &= (-B,A)/\triangle,\end{aligned} \tag{52}$$

condition (51) becomes

$$\frac{\partial}{\partial\lambda}\left[\frac{AL+BM}{\sqrt{A^2+B^2}\sqrt{L^2+M^2}}\right]=0. \tag{53}$$

By making use of the last four equations of (8), it is easy to show that (53) is equivalent to

$$S^2J\frac{\partial h}{\partial\xi}+T^2I\frac{\partial h}{\partial\eta}=\left[S^2\left(B\frac{\partial u}{\partial\xi}-A\frac{\partial v}{\partial\xi}\right)-T^2\left(M\frac{\partial u}{\partial\eta}-L\frac{\partial v}{\partial\eta}\right)\right]h, \tag{54}$$

where

$$S^2=L^2+M^2,\quad T^2=A^2+B^2. \tag{55}$$

A consequence of determining h from (54) is that if the grid is orthogonal at $\lambda=0$ it will remain so for subsequent λ. Orthogonal grids are known to possess many desirable properties over nonorthogonal grids, e.g., attaining higher accuracy than nonorthogonal grids. Computationally, (54) is to be solved at every time step after the flow variables $\mathbf{Q}=(\zeta,u,v)^T$, and the geometric variables $\mathbf{K}=(A,B,L,M)^T$ are found. It is thus a first order linear partial differential equation for $h(\xi,\eta;\lambda)$ with λ appearing as a parameter. To find solution h in the range

$$0\le h\le 1 \tag{56}$$

we note that (54) is linear and homogeneous, and therefore it possesses two properties: (a) positive solution $h>0$ always exists, and (b) if h is a solution to (54) so is h/C, C being any constant. Making use of property (a), we let $g=\ln(hq)$ to get

$$\begin{aligned}S^2(A\sin\theta-B\cos\theta)\frac{\partial g}{\partial\xi}+T^2(M\cos\theta-L\sin\theta)\frac{\partial g}{\partial\eta}\\ =S^2\left(B\frac{\partial\cos\theta}{\partial\xi}-A\frac{\partial\sin\theta}{\partial\xi}\right)-T^2\left(M\frac{\partial\cos\theta}{\partial\eta}-L\frac{\partial\sin\theta}{\partial\eta}\right),\end{aligned} \tag{57}$$

where $q=\sqrt{u^2+v^2}$ and θ is the flow angle: $u=q\cos\theta,\ v=q\sin\theta$. Now, if g_1 is any solution to (57), then $h=e^{g_1}/qC$ is a solution to (54) satisfying condition (56), provided we choose C equal to the maximum of e^{g_1}/q over the whole flow field being computed. The reason to work with $\ln(hq)$ instead of $\ln h$ is that from our experience with steady flow [16], hq is continuous across slip lines, hence working with hq can minimize the numerical errors.

Numerically, (57) is solved easily by the method of characteristics if their slopes do not change sign; otherwise, it is solved by iteration.

4.3. Solution strategies. As the system of shallow water equations (8) written in unified coordinates is in conservation form, any well-established shock-capturing method can be used to solve it. We shall use the Godunov method with the MUSCL update to higher resolution to solve system (8). The computation will be done entirely in the $\lambda-\xi-\eta$ space. A physical cell in the $x-y$ plane marching along the pseudoparticle's pathline corresponds to a rectangular cell in the $\xi - \eta$ plane marching in the λ direction in the computational space $\lambda - \xi - \eta$. The superscript k refers to the marching time step number, and the subscripts i and j refer to the cell index number on a time plane $\lambda =$ const. The time step $\Delta\lambda^k = \lambda^{k+1} - \lambda^k$ is uniform for all i and j, but it is always chosen to satisfy the CFL stability condition. The grid divides the computational domain into cubic control volumes, or cells, which in ξ and η direction are centered at $(\lambda^k, \xi_i, \eta_j)$ and have widths $\Delta\xi_i = \xi_{i+1/2} - \xi_{i-1/2}$ and $\Delta\eta_j = \eta_{j+1/2} - \eta_{j-1/2}$ (for all k). Unless otherwise stated we shall use uniform cell width $\Delta\xi_i$ for all i and $\Delta\eta_j$ for all j.

In the physical space (t, x, y) a cuboid cell marching in (λ, ξ, η) space corresponds to a pseudoparticle marching along its path tube with step Δt $(\Delta t = \Delta\lambda)$. The pseudoparticle is bounded by four path surfaces $\xi = \xi_{i\pm1/2}$ and $\eta = \eta_{j\pm1/2}$ around it. Initially, any curvilinear coordinate grid on the $x - y$ plane may be used as the $\xi - \eta$ coordinate grid, and the initial geometric variables $\mathbf{K} = (A, B, L, M)^T$ can be determined from (2) as part of the initial conditions. A stationary solid wall is always a path surface of the fluids and hence also of the pseudofluids; it is therefore a coordinate surface of the unified coordinates.

Applying the divergence theorem to (8) over the cuboid cell (i, j, k) results in

$$\mathbf{E}_{i,j}^{k+1} = \mathbf{E}_{i,j}^{k} - \frac{\Delta\lambda^k}{\Delta\xi_i}\left(\mathbf{F}_{i+1/2,j}^{k+1/2} - \mathbf{F}_{i-1/2,j}^{k+1/2}\right) - \frac{\Delta\lambda^k}{\Delta\eta_j}\left(\mathbf{G}_{i,j+1/2}^{k+1/2} - \mathbf{G}_{i,j-1/2}^{k+1/2}\right), \tag{58}$$

$$i = 1, 2, \ldots, m, \quad j = 1, 2, \ldots, n, \tag{59}$$

where the notation for the cell average of any quantity f is

$$f_{i,j}^k = \frac{1}{\Delta\xi_i\Delta\eta_j}\int_{\xi_{i-1/2}}^{\xi_{i+1/2}}\int_{\eta_{j-1/2}}^{\eta_{j+1/2}} f(\lambda^k, \xi, \eta)d\xi\ d\eta, \tag{60}$$

and the notation for the λ average of f is

$$f_{i+1/2,j}^{k+1/2} = \frac{1}{\Delta\lambda^k}\int_{\lambda^k}^{\lambda^{k+1}} f(\lambda, \xi_{i+1/2}, \eta_j)d\lambda, \tag{61}$$

$$f_{i,j+1/2}^{k+1/2} = \frac{1}{\Delta\lambda^k}\int_{\lambda^k}^{\lambda^{k+1}} f(\lambda, \xi_i, \eta_{j+1/2})d\lambda. \tag{62}$$

According to Godunov's idea, the cell-interface fluxes $\mathbf{F}_{i+1/2,j}^{k+1/2}$ and $\mathbf{G}_{i,j+1/2}^{k+1/2}$ for the cell (i, j) are to be obtained from the self-similar solution of a local two-dimensional Riemann problem formed by the averaged constant state $\mathbf{E}_{i,j}$ of the cell (i, j) and those of its adjacent cells. Unfortunately, such a solution to (8) is unavailable at the present time. Indeed, even a two-dimensional Riemann solution to the simpler system (1), which is a special case of (8) when $h = 0$, is not yet available. On the other hand, it is known that a monotone difference scheme to a general conservation form converges to the physically relevant entropy-satisfying solution. In particular, Crandall and Majda [17] proved convergence for dimensional splitting algorithms when each step is approximated by a monotone difference scheme (such as the Godunov scheme) for a scalar conservation law in multidimension.

In view of the above, we shall numerically solve (8) using a Godunov-type scheme based on the dimensional splitting approximation to reduce the two-dimensional flow problem to two one-dimensional flow problems.

The dimensional splitting technique for finding an approximate solution to the Riemann problem in multidimensional flow is now well established and widely used. This technique renders the solution of a multiple spatial-dimensional problem to a sequential solution of several one-dimensional problems. The Godunov splitting and the Strang splitting [18] are frequently used in practical applications. We shall use the Strang splitting in this paper. Let $\mathcal{L}^{\xi}_{\Delta\lambda}$ represent the exact solution operator for the one-dimensional equation in the $\lambda-\xi$ plane and $\mathcal{L}^{\eta}_{\Delta\lambda}$ similarly defined, then according to Strang splitting

$$\mathbf{E}^{k+1} = \mathcal{L}^{\xi}_{\frac{\Delta\lambda}{2}} \mathcal{L}^{\eta}_{\Delta\lambda} \mathcal{L}^{\xi}_{\frac{\Delta\lambda}{2}} \mathbf{E}^{k}, \tag{63}$$

where $\Delta\lambda = \lambda^{k+1} - \lambda^{k}$.

The solution operator $\mathcal{L}^{\xi}_{\Delta\lambda}$ for the Riemann problem with variable coefficients in the governing equations in $\lambda - \xi$ plane will now be given in details.

4.4. The $\boldsymbol{\xi}$-Split Riemann problem. With the use of dimensional splitting, the solution of the original two-dimensional equation system is replaced by the sequential computation involving two one-dimensional equation systems. We consider in detail the resulting Riemann problem in the $\lambda - \xi$ plane; the resulting Riemann problem in the $\lambda - \eta$ plane can be discussed similarly.

In the $\mathcal{L}^{\xi}$ operator, it is assumed that $\frac{\partial}{\partial \eta} = 0$. Hence (8) becomes

$$\frac{\partial \mathbf{E}}{\partial \lambda} + \frac{\partial \mathbf{F}}{\partial \xi} = 0, \tag{64}$$

where

$$\mathbf{E} = \begin{bmatrix} \zeta\triangle \\ \zeta\triangle u \\ \zeta\triangle v \\ A \\ B \\ L \\ M \end{bmatrix}, \quad \mathbf{F} = \begin{bmatrix} \zeta(1-h)I \\ \zeta(1-h)Iu + \frac{1}{2}g\zeta^2 M \\ \zeta(1-h)Iv - \frac{1}{2}g\zeta^2 L \\ -hu \\ -hv \\ 0 \\ 0 \end{bmatrix} \tag{65}$$

with

$$\triangle = AM - BL, \qquad I = uM - vL. \tag{66}$$

We rewrite (64) by using the component of velocity $\mathbf{q}$ in the direction $\mathbf{n}$ normal to, and $\mathbf{t}$ tangential to, the plane $\xi =$ const., i.e.,

$$\mathbf{n} = \frac{\nabla\xi}{|\nabla\xi|} = (M, -L)/S, \qquad \mathbf{t} = (L, M)/S, \tag{67}$$

$$\omega = \mathbf{q}\cdot\mathbf{n} = (uM - vL)/S, \tag{68}$$

$$\tau = \mathbf{q}\cdot\mathbf{t} = (uL + vM)/S, \tag{69}$$

where

$$S = (L^2 + M^2)^{1/2}. \tag{70}$$

Hereafter we shall abandon the last two equations of system (64), keeping in mind that $L = L(\xi)$ and $M = M(\xi)$ are given.

Equations (64) now become

$$\frac{\partial \mathbf{E}}{\partial \lambda} + \frac{\partial \mathbf{F}}{\partial \xi} = \mathbf{S}_2, \tag{71}$$

where

$$\mathbf{E} = \begin{bmatrix} \zeta\triangle \\ \zeta\triangle\omega \\ \zeta\triangle\tau \\ A \\ B \end{bmatrix}, \quad \mathbf{F} = S \begin{bmatrix} \zeta(1-h)\omega \\ \zeta(1-h)\omega^2 + \frac{1}{2}g\zeta^2 \\ \zeta(1-h)\omega\tau \\ -h(M\omega + L\tau)/S^2 \\ h(L\omega - M\tau)/S^2 \end{bmatrix}, \quad \mathbf{S}_2 = \frac{\partial \psi}{\partial \xi} S \begin{bmatrix} 0 \\ \zeta(1-h)\omega\tau \\ \zeta(1-h)\omega^2 + \frac{1}{2}g\zeta^2 \\ 0 \\ 0 \end{bmatrix}, \tag{72}$$

where

$$\tan \psi = M/L. \tag{73}$$

Equations (71) in the $\lambda - \xi$ plane resulting from dimensional splitting of the two-dimensional equations (8) are more complicated than the genuinely one-dimensional equations (12), and the solution to their Riemann problem is explained below.

The ξ-split Riemann problem is thus

$$\begin{cases} \dfrac{\partial \mathbf{E}}{\partial \lambda} + \dfrac{\partial \mathbf{F}}{\partial \xi} = \mathbf{S}_2, & \lambda > 0, \\ \mathbf{E}(0,\xi) = \begin{cases} \mathbf{E}_l, & \xi < 0, \\ \mathbf{E}_r, & \xi > 0, \end{cases} \end{cases} \tag{74}$$

where $\mathbf{E}_l$ and $\mathbf{E}_r$ are constant, and our purpose is to find the flux $\mathbf{F}$ on $\xi = 0$ to be used in the Godunov scheme to update the conserved quantities $\mathbf{E}$. At time level λ^k (taken to be equal to 0) h_r and h_l are the values of h at the cell $(i+1, j)$ and (i, j). They are *assumed* constant for $0 \le \lambda < \triangle\lambda$, i.e.,

$$\frac{\partial h}{\partial \lambda} = 0 \qquad (0 \le \lambda < \triangle\lambda), \tag{75}$$

and this is consistent with the h-equation (54). However, h changes its value at $\lambda = \triangle\lambda$ as given by (54), whose coefficients are evaluated at $\triangle\lambda$.

Now we first find all possible solutions to (71) for $\xi > 0$ and $\xi < 0$ separately and then use them to construct the solution to the Riemann problem (74).

Case (1). $\boldsymbol{\xi > 0}$.

Since $L = L_r =$ const. and $M = M_r =$ const., hence $S = S_r =$ const., $\psi = \psi_r =$ const., therefore

$$\mathbf{S}_2 = 0 \tag{76}$$

and

$$\begin{cases} \dfrac{\partial \mathbf{E}}{\partial \lambda} + \dfrac{\partial \mathbf{F}}{\partial \xi} = 0, & \lambda > 0, \quad \xi > 0, \\ \mathbf{E}(0,\xi) = \mathbf{E}_r, & \xi > 0, \end{cases} \tag{77}$$

where

$$\mathbf{E} = \begin{bmatrix} \zeta\triangle \\ \zeta\triangle\omega \\ \zeta\triangle\tau \\ A \\ B \end{bmatrix}, \quad \mathbf{F} = S \begin{bmatrix} \zeta(1-h)\omega \\ \zeta(1-h)\omega^2 + \frac{1}{2}g\zeta^2 \\ \zeta(1-h)\omega\tau \\ -h(M\omega + L\tau)/S^2 \\ h(L\omega - M\tau)/S^2 \end{bmatrix} \tag{78}$$

with $h = h_r = \text{const.}$ Similarity solution to (77) exists in the form

$$\mathbf{E} = \mathbf{E}(\mu), \qquad \mu = \frac{\xi}{\lambda}. \tag{79}$$

Possible solutions to (77) are

(i) a constant state $\mathbf{E} = \text{const.}$;
(ii) a centered expansion wave;
(iii) a shock;
(iv) a contact (slip) line.

Let us first find the eigenvalues and the corresponding right eigenvectors of the system (77).

For a smooth solution, (77) can be written as

$$\mathbf{A}\frac{\partial \mathbf{U}}{\partial \lambda} + \mathbf{B}\frac{\partial \mathbf{U}}{\partial \xi} = \mathbf{0}, \tag{80}$$

where $\mathbf{U} = (\zeta, \omega, \tau, A, B)^T$, $\mathbf{A} = \frac{\partial \mathbf{E}}{\partial \mathbf{U}}$, and $\mathbf{B} = \frac{\partial \mathbf{F}}{\partial \mathbf{U}}$.

In order to obtain the eigenvalues σ we need to find the determinant of the matrix $(\sigma\mathbf{A} - \mathbf{B})$. Direct computation gives

$$\det(\sigma\mathbf{A} - \mathbf{B}) = \sigma^2 m\zeta^2(m^2 - S^2\zeta g), \quad m = \sigma\triangle - S(1-h)\omega. \tag{81}$$

Case (1a). $h \neq 1$. From the vanishing of this determinant we get our eigenvalues.

$$\sigma_1 = 0 \qquad (\textit{multiplicity } 2), \tag{82}$$

$$\sigma_2 = \frac{S}{\triangle}(1-h)\omega, \tag{83}$$

$$\sigma_\pm = \frac{S}{\triangle}\left\{(1-h)\omega \pm \sqrt{g\zeta}\right\}. \tag{84}$$

We emphasize again that $S = S_r = \text{const.}$ and $h = h_r = \text{const.}$, $h \neq 1$. The corresponding set of right eigenvectors is

$$\mathbf{r}_1 = (0,0,0,0,1)^T, \tag{85}$$

$$\mathbf{r}_2 = (0,0,0,1,0)^T, \tag{86}$$

$$\mathbf{r}_3 = \left(0,0,1,-\frac{hL}{S\sigma_2},-\frac{hM}{S\sigma_2}\right)^T, \tag{87}$$

$$\mathbf{r}_\pm = \left(1, \pm\sqrt{\frac{g}{\zeta}}, 0, \mp\frac{hM}{S\sigma_\pm}\sqrt{\frac{g}{\zeta}}, \pm\frac{hL}{S\sigma_\pm}\sqrt{\frac{g}{\zeta}}\right)^T. \tag{88}$$

Since the eigenvectors (85)–(88) are linearly independent, system (77) is hyperbolic. To classify the characteristic fields, we see that

$$\nabla\sigma_1 \cdot \mathbf{r}_{1,2} = 0 \tag{89}$$

and

$$\nabla\sigma_2 \cdot \mathbf{r}_3 = 0, \tag{90}$$

implying that characteristic fields corresponding to the $\sigma_{1,2}$ and σ_3 are linearly degenerate. On the other hand,

$$\nabla\sigma_\pm = \left(\pm\frac{S}{2\triangle}\sqrt{\frac{g}{\zeta}}, \frac{S(1-h)}{\triangle}, 0, -\frac{\sigma_\pm M}{\triangle}, \frac{\sigma_\pm L}{\triangle}\right) \tag{91}$$

and

$$\nabla\sigma_\pm \cdot \mathbf{r}_\pm = \pm\frac{3S}{2\triangle}\sqrt{\frac{g}{\zeta}} \neq 0. \tag{92}$$

Therefore the $\sigma_\pm$ characteristic families are genuinely nonlinear.

Case (1b). $h = 1$ (Lagrangian case). In this case the eigenvalues are

$$\sigma_1 = 0 \qquad (\textit{multiplicity } 3), \tag{93}$$

$$\sigma_\pm = \pm\frac{S}{\triangle}\sqrt{g\zeta}. \tag{94}$$

The eigenvectors associated with $\sigma_\pm$ are

$$\mathbf{r}_\pm = \left(1, \pm\sqrt{\frac{g}{\zeta}}, 0, -\frac{M\triangle}{S^2\zeta}, \frac{L\triangle}{S^2\zeta}\right)^T. \tag{95}$$

Associated with $\sigma_1 = 0$ (multiplicity 3),

$$\operatorname{rank}(\sigma\mathbf{A} - \mathbf{B})\Big|_{\sigma=\sigma_1} = 3;$$

hence there exist the two, and only two, following linearly independent right eigenvectors:

$$\mathbf{r}_1 = (0,0,0,1,0)^T, \tag{96}$$

$$\mathbf{r}_2 = (0,0,0,0,1)^T. \tag{97}$$

We therefore arrive at the conclusion that *system* (77) *resulting from dimensional splitting of the two-dimensional equations in Lagrangian coordinates is weakly hyperbolic*, lacking one eigenvector, although all eigenvalues are real. This is in direct contrast to the genuinely one-dimensional flow case, (12), which is hyperbolic for all values of h, including the Lagrangian case ($h = 1$).

We shall now give solutions to the elementary waves in details: the expansion wave, the shock wave, and the slip line. These solutions will be used in constructing the Riemann solution to (74).

4.4.1. Expansion wave. The expansion wave is a smooth solution from the $\sigma_\pm$ characteristic fields which can be derived from the following system of ODEs:

$$\frac{d\omega}{d\zeta} = \pm\sqrt{\frac{g}{\zeta}}, \tag{98}$$

$$\frac{d\tau}{d\zeta} = 0, \tag{99}$$

$$\frac{dA}{d\zeta} = \mp\frac{hM}{S\sigma_\pm}\sqrt{\frac{g}{\zeta}}, \tag{100}$$

$$\frac{dB}{d\zeta} = \pm\frac{hL}{S\sigma_\pm}\sqrt{\frac{g}{\zeta}}. \tag{101}$$

The solution for (ω, τ) relates the flow state $\mathbf{Q} = (\zeta, \omega, \tau)^T$ in the expansion fan to the initial state $\mathbf{Q_0} = (\zeta_0, \omega_0, \tau_0)^T$ upstream of the fan through the following expressions:

$$\omega = \omega_0 \mp 2\left(\sqrt{g\zeta_0} - \sqrt{g\zeta}\right), \tag{102}$$

$$\tau = \tau_0. \tag{103}$$

Note that on crossing the expansion fan, these relations are independent of $\mathbf{K}_r$ and h_r.

To find the solution inside the expansion fan, we consider the characteristic ray through the origin $(0,0)$ and a general point (λ, ξ) inside the fan. The slope of the characteristic is

$$\frac{d\xi}{d\lambda} = \frac{\xi}{\lambda} = \sigma_\pm = \frac{S}{\triangle}\left\{(1-h)\omega \pm \sqrt{g\zeta}\right\}. \tag{104}$$

Using the above expression and the equation for ω in (102), we get

$$\zeta = \frac{1}{g(3-2h)^2}\left[(1-h)\left(\omega_0 \mp 2\sqrt{g\zeta_0}\right) - \frac{\triangle}{S}\frac{\xi}{\lambda}\right]^2, \tag{105}$$

where $\triangle = AM - BL$ is found from (100) and (101) to be a function of ζ

$$\triangle = \triangle_0\left(\frac{\sqrt{\zeta_0} - C_\pm}{\sqrt{\zeta} - C_\pm}\right)^{\frac{2h}{3-2h}}, \qquad C_\pm = \frac{1-h}{3-2h}\left(2\sqrt{\zeta_0} \mp \frac{\omega_0}{\sqrt{g}}\right). \tag{106}$$

Equation (105) together with (106) thus defines an implicit function $\zeta(\mu)$, $\mu = \frac{\xi}{\lambda}$. Equation (106) reduces to the one-dimensional case, (22), when $L = 0$ and $M = 1$. The expressions for ω and τ in terms of μ can be obtained simply via (102)–(103). Like ζ, they depend on $(\mathbf{K}_r, h_r)$, but at $\mu = \frac{\xi}{\lambda} = 0$ they depend only on h_r. The variations of A and B across an expansion fan can also be obtained from (100) and (101), but they are not needed in calculating the flux. (The flux function $\mathbf{F}$ does not involve A or B; it involves only L and M.)

4.4.2. Shock waves. From the Rankine–Hugoniot jump conditions of the system (77), we get

$$s[\zeta\triangle] = [\zeta(1-h)\omega S], \tag{107}$$

$$s[\zeta\triangle\omega] = \left[\left(\zeta(1-h)\omega^2 + \frac{g\zeta^2}{2}\right)S\right], \tag{108}$$

$$s[\zeta\triangle\tau] = [\zeta(1-h)\omega\tau S], \tag{109}$$

$$s[A] = -\left[\frac{h}{S}(M\omega + L\tau)\right], \tag{110}$$

$$s[B] = \left[\frac{h}{S}(L\omega - M\tau)\right], \tag{111}$$

where [.] denotes the jump across the discontinuity whose speed is denoted by $s = \frac{d\xi}{d\lambda}$. The shock jump relations after some algebraic manipulations can be expressed as follows:

$$s = \frac{S}{\triangle_0}\left[(1-h)\omega_0 \pm \sqrt{\frac{g}{2}\frac{\zeta}{\zeta_0}(\zeta+\zeta_0)}\right], \tag{112}$$

$$\omega = \omega_0 \pm \sqrt{\frac{g(\zeta+\zeta_0)(\zeta-\zeta_0)^2}{2\zeta\zeta_0}}, \tag{113}$$

$$\tau = \tau_0. \tag{114}$$

We note that the relations of the flow variables (ζ, ω, τ) across the shock are independent of $\mathbf{K}_r$ and h_r, but the slope of the shock wave s is dependent on $\mathbf{K}_r$ and h_r. However, this dependence is not needed in finding the water height ζ, and hence (ω, τ) also, at $\mu = 0$ provided only that $s > 0$. (If $s < 0$, the shock wave will appear in the quadrant $(\xi < 0,\, \lambda > 0)$).

Note that the jumps of A and B across a shock may also be obtained from (110) and (111), but they are not needed in calculating the flux $\mathbf{F}$ at $\mu = 0$.

4.4.3. Slip lines. For the slip line corresponding to the speed $s = \sigma_3 = \frac{S}{\triangle_0}(1-h)\omega_0 > 0$ we find, from Rankine–Hugoniot jump conditions (107)–(111),

$$\zeta = \zeta_0, \tag{115}$$

$$\omega = \omega_0, \tag{116}$$

but τ and A, B may jump arbitrarily.

We note again that, except the speed s, the relations (115)–(116) across a slip line are independent of $(\mathbf{K}_r, h_r)$. Although s depends on $(\mathbf{K}_r, h_r)$, the dependence is not needed in calculating (ζ, ω, τ) and the flux $\mathbf{F}$ at $\mu = 0$, provided $s > 0$. (If $s < 0$, the slip line appears in the quadrant $(\xi < 0,\, \lambda > 0)$.)

The flow across the slip line corresponding to $s = \sigma_{1,2} = 0$ cannot be discussed within the quadrant $(\xi > 0,\, \lambda > 0)$ alone.

Case (2). $\boldsymbol{\xi < 0}$.

The solution in the quadrant $(\xi < 0,\, \lambda > 0)$ can be obtained similarly.

Case (3). Riemann solution in $\boldsymbol{-\infty < \xi < +\infty}$.

Now, after obtaining all possible solutions for $\xi > 0$ and $\xi < 0$ separately the question is how to construct the solution to the Riemann problem for $\lambda > 0$, $-\infty < \xi < +\infty$. We note that at $\xi = 0$, (a) $\mathbf{S}_2$ in (71) is a delta function; (b) the coefficients in $\mathbf{E}$ and $\mathbf{F}$ jump discontinuously. These are the difficulties one would face with within the Eulerian system using curvilinear coordinates rather than Cartesian coordinates.

The σ_1-field is linearly degenerate and it corresponds to $s = 0$ in (107)–(111). These are five equations relating three jumps of ζ, ω, and τ and, therefore, in general have no solution, except when $h_r = h_l$, $L_r = L_l$, and $M_r = M_l$. In the latter case, there is a unique solution: the trivial solution $[\zeta] = [\omega] = [\tau] = 0$, i.e., a continuous solution.

To avoid the difficulty of nonexistence of the solution to the Rankine–Hugoniot relations (107)–(111), we replace both h_l and h_r by their average, i.e., $h_l = h_r = 0.5(h_l + h_r) = \overline{h}$, and similarly replace L_l and L_r, M_l, and M_r by their averages $\overline{M}$ and $\overline{L}$, respectively. Consequently, the Rankine–Hugoniot relations are satisfied, and the flow is continuous across $\mu = \frac{\xi}{\lambda} = 0$. We note from previous discussions that these replacements do not alter the relations of the flow variables (ζ, ω, τ) across the elementary waves (the expansion fan, the shock, and the slip line), as they do not depend on $(\mathbf{K}, h)$. It should be pointed out that the replacements of L_l and L_r by $\overline{L}$ and M_l and M_r by $\overline{M}$ are a fictitious one—they are used only to ensure the existence of the solution to (107)–(111)—but these average values are never used in the computation. On the other hand, the replacement of h_l and h_r by $\overline{h}$ is a real one: it is used in (105) when the line $\mu = \frac{\xi}{\lambda} = 0$ is inside the expansion fan which is, however, a rare case.

The Riemann solution for $-\infty < \xi < +\infty$ can now be constructed in the usual way as if the slip line corresponding to $s = \sigma_{1,2} = 0$ did not exist: shock (or expansion fan), slip line, and expansion fan (or shock), separated by uniform flow regions.

We note that in solving the split Riemann problems we do not need to use explicitly the complete set of right eigenvectors. The eigenvectors that are used are those corresponding to the genuinely nonlinear characteristic families; these eigenvectors exist even in the case $h = 1$ (Lagrangian coordinates). The missing eigenvectors in Lagrangian coordinates correspond to the linearly degenerated characteristic families and are not employed in constructing solutions to the Riemann problems. This also explains why our computations with $h = 1$ encounter no difficulty and produce results identical to that for $h = 0.999$. We present results for $h = 0.999$, rather than for $h = 1.0$, because the theoretical base for the existence and uniqueness of the solution to the Riemann problem for $h = 1.0$ is not certain.

5. Test examples.

In this section the unified coordinates approach is tested numerically on several examples. The flat bottom case is considered with zero roughness coefficients m and n. In all cases the effects of h on the computational robustness and accuracy are discussed.

Example 1. The first problem is purely a one-dimensional two-dam break problem. In a long channel three different heights of still water are separated by two dams, of which one is located at $x = 0.8$ and the other at $x = 1.2$ (Figure 1(a)). At $t = 0$ the dam located at $x = 0.8$ is broken instantly and completely, resulting in an expansion wave moving upstream and a bore (shock) rushing downstream (Figure 1(b), (c), (d)). The bore (shock) then reaches the second dam ($x = 1.2$) at some time later, triggering it to break completely and resulting in a stronger bore (shock) moving downstream and another expansion wave moving upstream (Figure 1(e), (f), (g)). It is difficult for conventional shock-capturing schemes to accurately compute this problem due to the interaction of the first bore (resulting from the rapture of the first dam) with the second dam. Most conventional shock-capturing schemes [19], [20], [21] smear the first bore, thus giving only its approximate location (Figures 4 and 5)). Consequently, it is impossible computationally to determine the time of breaking of the second dam. In our computation the shock-adaptive Godunov method [13], [14], which gives infinite bore resolution, is applied and this difficulty is avoided. The exact time when the second dam breaks can be found by using formula (29) for the speed of the shock (bore), and it is found to be (with eight significant figures of accuracy) 0.24292472. In our computation the second dam breaks at $t = 0.2375$.

Figures 1 and 2 show the evolution of water height and velocity with time. We note that after the breaking of the second dam, the water velocity increases significantly (Figure 2(d), (e), (f)). This combination of the strong bore moving with high velocity can potentially be destructive. Comparisons between exact solutions and computed ones at the time $t = 0.1$ (after the first dam broke) and the time $t = 0.3375$ (0.1 time units after the second dam broke) are presented in Figure 3. Figure 4 presents computed results for water height and velocity at $t = 0.22$ using ordinary Godunov scheme with the MUSCL update. We note that smeared shock reaches the second dam prematurely. It is seen in Figure 5 that with the ordinary shock-capturing method the shock is smeared, though its average location is correct, as expected. It is also seen that the shock-adaptive Godunov scheme perfectly resolves the bore, giving its exact location. In all computations we use $h = 0$ (Eulerian).

Example 2. This example, known as the Salzman problem in gas dynamics, is presented to show the role an irregular grid plays in producing spurious flow. The problem consists of a rectangular channel (Figure 6) whose walls form reflective boundaries. The initial data are

$$\begin{cases} \zeta = 4.0, & u = 7.4246, \qquad v = 0.0, x < 0, \\ \zeta = 1.0, & u = 0.0, \qquad\quad\; v = 0.0, 0 \le x \le 1. \end{cases}$$

They are chosen in such a way that the discontinuity, initially located at $x = 0.0$, will result in a plane shock propagating at the speed equal to 9.899 in the x direction. The initial grid has 10 uniform cells in the y-direction ($0.0 \le y \le 0.1$) and 100 nonuniform cells in the x-direction ($0 \le x \le 1$). The coordinates of the cell centers in Figure 6 are

$$\begin{aligned} x_{i,j} &= (i-1) * \triangle + (11-j) * \triangle * \sin\frac{\pi(i-1)}{100}, \\ y_{i,j} &= (j-1) * \triangle + 0.5 * \triangle, \\ &\quad i = 1, \dots, 101 \qquad j = 1, \dots, 10, \end{aligned}$$

where $\triangle = 1/100$. We shall perform computation for $h = 0.999$ and grid-angle preserving h. Figure 7 presents resulting grid (7(a)) and water height (7(b)) for the case $h = 0.999$ at the time $t = 0.06$, which is several time steps before the computation breaks down. As we can see, this grid is highly deformed near the position $x = 0.5$ behind the shock. Looking at the velocity vectors (Figure 7(c)) we see that there is a presence of spurious flow: the y-component of velocity (especially near $x = 0.5$) and hence vorticity which, in turn, affects the grid and the water height (Figure 7(a), (b)).

Similar results of spurious flow production were reported, for example, by Dukowicz and Meltz in [22], where it was found that Lagrangian coordinates do not preserve the one-dimensionality of a plane shock but produce spurious vorticity. They successfully introduced a technique to filter out the spurious vorticity, while retaining the real one, if present. In another approach, described by Caramana and Shashkov in [23], the spurious vorticity is eliminated by proper use of subzonal Lagrangian masses and associated densities and pressures; these subzonal pressures give rise to forces that resist these spurious motions. We have found that the spurious flow can be avoided automatically by using unified coordinates with grid-angle preserving h. The results are presented in Figure 8. Here we note that although the vertical component of velocity is still present (Figure 8(c), especially near the shock, it is very small and is not magnified during the computation. These results (Figure 8) are almost identical to those of gas dynamics case in [22], which requires a special technique to filter out the spurious vorticity.

Example 3. The next example is a two-dimensional steady Riemann problem generated by two uniform parallel flows as

$$(\zeta, F, \theta) = \begin{cases} (1, 4, 0), & y > 0.5, \\ (2, 2.4, 0), & y < 0.5, \end{cases}$$

where F is the Froude number and θ the flow angle, $\theta = \tan^{-1}(v/u)$. The flow contains a shock wave, a slip line, and an expansion wave (Figure 9). The slip line is sensitive to the dissipative property of the numerical methods. In [24], [25] the problem was solved numerically using a generalized Lagrangian method which perfectly resolves slip lines. However, that method is valid only for steady flow, whereas the method in this paper is valid for unsteady flow as well. Since the analytical solution for the problem is available, it is an excellent benchmark problem for the verification of numerical methods. In the computation, the steady flow is achieved by time marching until the flow structure and the variables do not change with time. A grid of 60×100 with $\Delta\xi = \Delta\eta = 0.01$ is employed in the computation. Initially, a grid with $\Delta x = \Delta y = 0.01$ in the physical plane is laid over a domain of $\{0 \leq x \leq 0.6,\ 0 \leq y \leq 1\}$. The initial data are given at each cell according to its position in $y > 0.5$ or $y < 0.5$, representing cell-averaged values. The physical domain will change with time according to the pseudoparticle's velocity $h\mathbf{q}$ if h is not zero. If we follow the computational cells (pseudoparticles), they will move out the initial physical domain, and it would be difficult to have a steady state of flow in the original physical domain. To avoid this, a special technique called "motionless viewing window" is applied as in the classical Lagrangian method. Accordingly, the column of cells which have moved out of the original physical domain to the right are deleted, while a new column of cells are added at the input flow boundary on the left.

In Figures 10–12 we show computed Froude number distributions using our unified code for $h = 0$, $h = 0.5$, and $h = 0.999$, compared with the exact solutions. The poor resolution of the slip line seen in Figure 10 is a common feature of any method based on Eulerian coordinates, as a result of Godunov averaging across slip lines which, in general, do not coincide with the (Eulerian) coordinate lines. A comparison of Figures 10–12 also shows that the slip line resolution improves with increasing h from $h = 0$ to $h = 0.999$, as expected.

Figure 13 shows the computed Froude number using the grid-angle preserving h as determined by (57), which is solved at each time step using the method of characteristics. We see that its slip line resolution is almost as sharp as that for $h = 0.999$, and it is much better resolved than those for $h = 0$ and $h = 0.5$.

All the computations started with the Eulerian grid (Figure 14). The flow-generated grids, i.e., the lines joining the cell centers, at steady state are shown in Figures 15–17. We note that (a) the grid using grid-angle preserving h is everywhere orthogonal, (b) the grids for $h = 0.5$ and $h = 0.999$ are severely deformed near the slip line, and such grid deformation, although it doesn't bring any troubles in the present example, can cause inaccuracy in other steady flows [1] as well as for the unsteady flows; see Example 2 above and the following examples.

Example 4. The next example is the "implosion/explosion" problem, so called by analogy with gas dynamics. It is an unsteady problem in a two-dimensional container. Initially, two regions of still water are separated by a cylindrical wall (radius 0.2) centered in the 1×1 square domain shown in Figure 18. The depth of the water is 0.1 within the cylinder and 1 outside. At $t = 0$ the wall is removed and the resulting flow is investigated. Initially, a uniform rectangular grid 100×100 with $\Delta\xi = \Delta\eta = \Delta x = \Delta y = 0.01$ is given (Figure 19). We test this example with $h = 0$, $h = 0.5$, $h = 0.999$, and the grid-angle preserving h. When $h = 0.999$, the code can run only until $t = 0.04$; soon afterwards it breaks down. This is because the computational cells literally move with the fluid particles and for large h become severely deformed. If we reduce h, say, $h = 0.5$, the code can run longer until $t = 0.08$ when it, too, breaks down. This shows that smaller h can delay the severe cell deformation but cannot remove it. With the grid-angle preserving method, which keeps the grid regular, the code can run for a very long time without any indication of severe grid deformation. Figures 20–22 give the grids at $t = 0.04$ for different cases. We see that irregular grids prevail when h is constant and a regular grid prevails when the grid angles are preserved (Figure 22).

The surfaces of water height for different times are presented in Figure 23. The physical behavior of the flow is clearly captured in these pictures. After the wall is removed, the cylindrical shock moves inside the lower level region, and the expansion wave propagates towards the walls (Figure 23(a), (b), (c)). At around time $t = 0.0565$ the shock collapses, resulting in a spectacular rise of water level near the center (Figure 23(d)). In subsequent times the water height decreases in the central region now manifesting in cylindrical shock wave propagating towards the walls (Figure 23(e), (f), (g), (h)). This process of the water in the central region going up and down repeats itself but with more moderate height and depth. We see in Figure 23(b), (c), (e) that the column of water does not have perfect circular shape, as one would expect to have, but has wavy shape. It was shown in [26] that this behavior is a consequence of using a rectangular grid.

Example 5. Finally, we test our code on the two-dimensional dam breaking problem. This test case was computed in, for example, [27], [28].

Two levels of still water in the 1.4 × 1 basin are separated by a dam at the position $x = 0.7$ (Figure 24). The initial height ratio is 10 with values of $\zeta_l = 1$ and $\zeta_r = 0.1$ on two sides of an idealized dam that has been represented as a mathematical discontinuity in water. At time $t = 0$ water is released into the lower level side through a middle third of the dam, forming a wave that propagates while spreading laterally. At the same time, an expansion wave spreads into the reservoir.

A 140 × 100 rectangular grid was chosen in this case. We have performed the computation for $h = 0.999$ and for grid-angle preserving h. Figure 25 represents the flow-generated grid in the case $h = 0.999$ at time $t = 0.04$. The grid is severely distorted by the same reason as in the previous example, and soon after that time the computation breaks down. The computation using grid-angle preserving h is stable, producing results for much larger time. In Figure 26 we present a computed grid which is fairly uniform everywhere even at time $t = 0.15$. The surface elevation of the water height is given in Figure 27, describing the flow in details which are similar to those in [23], [24].

6. Conclusions. In this paper we have successfully adopted the uniform coordinates of Hui, Li, and Li [1] for the shallow water equations. It has been tested on a large number of problems and found that with the free function h in the unified coordinates chosen to preserve grid angles, the unified coordinate system is superior to both Eulerian and Lagrangian systems in that (a) it resolves slip lines as sharply as the Lagrangian system, especially for steady flows; (b) it avoids the severe grid deformation of the Lagrangian system which causes inaccuracy and breakdown of computation; (c) it also automatically avoids spurious flow produced by the Lagrangian system. Additionally, it was found that the two-dimensional shallow water equations in Lagrangian coordinates are only weakly hyperbolic with possible defects in numerical computation.

A PARTICLE-PARTITION OF UNITY METHOD–PART II: EFFICIENT COVER CONSTRUCTION AND RELIABLE INTEGRATION[*]

MICHAEL GRIEBEL[†] AND MARC ALEXANDER SCHWEITZER[†]

Abstract. In this paper we present a meshfree discretization technique based only on a set of irregularly spaced points $x_i \in \mathbb{R}^d$ and the partition of unity approach. In this sequel to [M. Griebel and M. A. Schweitzer, *SIAM J. Sci. Comput.*, 22 (2000), pp. 853–890] we focus on the cover construction and its interplay with the integration problem arising in a Galerkin discretization. We present a hierarchical cover construction algorithm and a reliable decomposition quadrature scheme. Here, we decompose the integration domains into disjoint cells on which we employ local sparse grid quadrature rules to improve computational efficiency. The use of these two schemes already reduces the operation count for the assembly of the stiffness matrix significantly. Now the overall computational costs are dominated by the number of the integration cells. We present a regularized version of the hierarchical cover construction algorithm which reduces the number of integration cells even further and subsequently improves the computational efficiency. In fact, the computational costs during the integration of the nonzeros of the stiffness matrix are comparable to that of a finite element method, yet the presented method is completely independent of a mesh. Moreover, our method is applicable to general domains and allows for the construction of approximations of any order and regularity.

1. Introduction.

Meshfree methods (MMs) are promising approaches to overcome the problem of mesh generation, which is still the most time-consuming part of any finite element (FE) simulation. MMs are based only on a (finite) collection of independent points within the domain of interest; i.e., there are no fixed connections between any two points as in a conventional mesh. These points can now be used as collocation nodes [1, 9, 10, 11, 19] for the construction of approximate densities [21, 22, 23] or even for the construction of trial and test spaces for a Galerkin method [2, 3, 4, 8, 13].

The shape functions of a meshfree Galerkin method are in general more complex than FE shape functions. In a MM the shape functions are (in general) piecewise rational functions, whereas in a finite element method (FEM) they are piecewise polynomials. This is due to the fact that the construction of a meshfree shape function is based only on independent points instead of a mesh. Therefore, the integration of meshfree shape functions is more complicated than the integration of FE shape functions. Hence, the assembly of the stiffness matrix and right-hand side vector in a meshfree Galerkin method is far more expensive than in the FEM. Meshfree Galerkin methods therefore could not be applied to real world problems up until now and are considered to be in an experimental state only.

In this paper we present a numerical method based only on a set of irregularly spaced points and the partition of unity (PU) approach [2]. In a partition of unity

method (PUM), we define a global approximation u_{PU} simply as a weighted sum of local approximations u_i,

$$u_{\mathrm{PU}}(x) := \sum_{i=1}^{N} \varphi_i(x) u_i(x).$$

These local approximations u_i are completely independent of each other; i.e., the local supports $\omega_i := \mathrm{supp}(u_i)$, the local basis $\{\psi_i^k\}$, and the order of approximation p_i for every single $u_i := \sum u_i^k \psi_i^k$ can be chosen independently of all other u_j. Here, the functions φ_i form a PU. They are used to splice[1] the local approximations u_i together in such a way that the global approximation u_{PU} benefits from the local approximation orders p_i, yet it still fulfills global regularity conditions; see [13]. For a general partial differential equation (PDE) $Lu = f$ the fully assembled approximation functions $\varphi_i \psi_i^k$ have to be used within the Galerkin procedure. Hence, for the approximation of a PDE we have to integrate the product functions $\varphi_i \psi_i^k$ in the assembly of the stiffness matrix. This integration is one major issue of concern with PUMs. The dominant factor for the approximation quality of the method is certainly the local basis function ψ_i^k, but, other than with the p-version of the FEM, this high order function is *not* the cause of concern during the integration—the PU functions φ_i are.

The algebraic structure of the functions φ_i is (in general) more complex than that of FE shape functions, since the φ_i have to repair any spatial irregularity induced by the overlaps of the ω_i. Hence, the construction of a PU with a simple algebraic structure is the most crucial step in a PUM. Therefore, the design and implementation of a PUM for general covers $C_\Omega := \{\omega_i \,|\, i = 1, \dots, N\}$ including a fast, yet reliable quadrature scheme is quite involved.

One approach to utilize at least some of the PUM benefits is the so-called generalized finite element method (GFEM) [7, 30]. Here, the construction of the PU $\{\varphi_i\}$ is left to an h-version FEM. On top of this PU, local basis functions ψ_k^i can still be selected with all the freedom the PU approach allows for, e.g., ψ_k^i which are adapted to known local behavior of the solution. However, the dependence on the h-mesh construction for the PU is of course a major drawback of the GFEM. Furthermore, one needs to supply appropriate quadrature schemes for the reliable integration of these general local basis functions ψ_k^i independent of the facts that the cover is a mesh and that the PU is piecewise linear.

Truly meshfree Galerkin methods [8, 13] have to be concerned with the construction of a cover from a given set of points $P = \{x_i \in \Omega\}$ and hence have to cope with geometric searching and sorting problems. To tackle these problems an algorithm for finding a set covering a single point based on a tree concept was proposed in [17]. However, the cover C_Ω was still assumed to be given.

In this paper we present a general cover construction algorithm based only on a set of irregularly spaced points $P = \{x_i \in \Omega\}$. We partition the domain into overlapping d-rectangular patches ω_i which we assign to the given points x_i to cover the complete domain. We use d-binary trees (binary trees, quadtrees, octrees) for the construction of these patches ω_i. While the data structures used here are similar to those used

[1] Due to this splicing property of the PU one is tempted to construct the global solution u_{PU} by solving only local problems for the u_i on the support patches ω_i. Here, one would use the local basis functions ψ_i^k as trial and test functions and disregard the partition of unity functions φ_i during the construction of the global solution u_{PU}. For the mass matrix problem—and related interpolation problems—this is a proper approach which directly leads to a system of linear equations already in block diagonal form without any lumping.

in [17], we are interested in the *construction of a cover* C_Ω with desirable features. For instance, the subsets $N_x \subset C_\Omega$ of cover patches ω_k which cover a point $x \in \Omega$, i.e., $N_x = \{\omega_k \in C_\Omega \,|\, x \in \omega_k\}$, should be small. Although a cover C_Ω generated by this general algorithm is minimal in the sense that $\mathrm{card}(N_x) \ll \mathrm{card}(C_\Omega)$ is very small for all $x \in \Omega$, the resulting PU functions φ_i are (in general) still more complex than in the GFEM. The piecewise character of the constructed functions φ_i, however, can be further significantly simplified by making slight changes to the general cover construction. With this refined algorithm we construct covers for general domains that stay close to k-irregular grids. This construction not only minimizes the number of patches $\mathrm{card}(N_x)$ which cover a single point $x \in \Omega$ but also leads to PU functions φ_i with simpler algebraic structure. A k-irregular grid is completely sufficient for a PUM, since the φ_i will repair the jump within the spatial resolution and ensure the global regularity conditions imposed on the approximation u_{PU}. At the same time, the cost of the assembly of the stiffness matrix and right-hand side vector is significantly reduced, since the simpler algebraic structure of the φ_i allows for cheaper quadrature rules.

Furthermore, we introduce a numerical quadrature scheme for the fully assembled approximation functions $\varphi_i \psi_i^k$ which further reduces the integration costs. Here, we decompose the integration domain to resolve the algebraic structure of the PU functions φ_i; i.e., we decompose the integration domains into disjoint cells on which the integrands are smooth functions. We then use a sparse grid quadrature rule [12] with a dynamic stopping criterion locally on the cells. Hence, the number of integration points on each cell is minimal with respect to accuracy. It turns out that overall, the number of operations needed by our method during the assembly of the stiffness matrix is comparable to that of a FEM. Yet at the same time it is truly a MM; i.e., it is completely independent of a mesh. Hence, our PUM is a very flexible and efficient numerical discretization technique, and it is a strong competitor for conventional FEMs. With the proposed method the treatment of real world problems using meshfree Galerkin methods might now be in reach.

The remainder of the paper is organized as follows. In section 2 we give a short review of the construction of PU spaces for meshfree Galerkin methods. We then present in section 3 a general hierarchical cover construction algorithm based only on a set of irregularly spaced points which allows for a fast neighbor search. Here, we make use of d-binary trees (quadtrees, octrees, etc.) to assign parts of the domain to each of the given points to cover the complete domain. The Galerkin discretization of a PDE using PUM shape functions is given in section 4. In section 5 we introduce an appropriate numerical quadrature scheme for PUM shape functions. The scheme is based on a decomposition approach to resolve the piecewise character of the PU functions φ_i. On the cells of this decomposition we employ local sparse grid quadrature rules with a dynamic stopping criterion. This reduces the computational costs on each cell substantially, yet still ensures a reliable accuracy of the integration. In section 6 we present a refinement of the general cover construction algorithm given in section 3; a similar cover construction algorithm was recently proposed in [18]. It also accounts for the geometric neighboring relations of the PU functions φ_i, i.e., the neighboring relations of the cover patches ω_i, which have a significant effect on the number of integration cells. With this improved algorithm the number of integration cells and the corresponding computational effort during the integration of the stiffness matrix entries is significantly reduced. Numerical results for elliptic problems in two and three dimensions are given in section 7.

2. Construction of trial and test spaces. In the following, we give a short recap of how to construct PU spaces for a meshfree Galerkin method; see [13] for details. The starting point for any MM is a collection of N independent points $P := \{x_i \in \mathbb{R}^d \,|\, x_i \in \overline{\Omega}, i = 1, \dots, N\}$. In the PU approach we need to construct a PU $\{\varphi_i\}$ on the domain of interest Ω to define an approximate solution

$$u_{\mathrm{PU}}(x) := \sum_{i=1}^{N} \varphi_i(x) u_i(x), \tag{2.1}$$

where the union of the supports $\operatorname{supp}(\varphi_i) = \overline{\omega_i}$ covers the domain $\overline{\Omega} \subset \bigcup_{i=1}^{N} \omega_i$ and $u_i \in V_i^{p_i}(\omega_i)$ is some locally defined approximation of order p_i to u on ω_i. Given a cover $C_\Omega = \{\omega_i \,|\, i = 1, \dots, N\}$ we can then define such a PU and local approximations u_i by using *Shepard functions* as φ_i and local approximation spaces $V_i^{p_i}$ on the patches ω_i.

A naive approach toward the construction of such a cover C_Ω would be the design of patches $\tilde{\omega}_i$ in such a way that every given point $x_i \in \tilde{\omega}_j$ for some $j \neq i$. However, this procedure (in general) does not lead to a cover of the complete domain Ω, i.e., $\bigcup_j \tilde{\omega}_j \not\supset \overline{\Omega}$, since the points $x_i \in P$ may not be uniformly distributed in the domain Ω. In [13] the following algorithm was proposed which tackles this problem by using a set $\tilde{P} = P \cup Q$ of original points $P = \{x_i\}$ and additional (user supplied) points $Q = \{\xi_k\}$. Note that the additional points ξ_k are introduced to guarantee that the patches ω_i completely cover the entire domain Ω. However, they are *not* used to construct additional cover patches; i.e., the algorithm constructs a cover patch ω_i only for $x_i \in P$ not for $\xi \in \tilde{P} \setminus P$.

Algorithm 1 (direct cover construction).

1. Given: the domain $\Omega \subset \mathbb{R}^d$, a scalar $\alpha \geq 1$, the set of points $P = \{x_i \in \mathbb{R}^d \,|\, x_i \in \overline{\Omega}, i = 1, \dots, N\}$ for the PU construction and a set of points $Q = \{\xi_i \in \mathbb{R}^d \,|\, \xi_i \in \overline{\Omega}\}$ to resolve the domain Ω.
2. Set $\tilde{P} = P \cup Q$.
3. For all $x_k \in P$: Set $\omega_k := \bigotimes_{i=1}^{d} [x_k^i - h_k^i, x_k^i + h_k^i]$ with $h_k^i = 0$ for all $i = 1, \dots, d$.
4. For all $y \in \tilde{P}$:
   - (a) Set $R = 0$. Evaluate the set $S_{y,R}$ of all points $x_k \in P$ that fall within a searching square B_R which is centered in y and whose side length is equal to $2R$. If $S_{y,R} = \emptyset$ (or $S_{y,R} = \{y\}$ if $y = x_k$), increase the size of the searching square, i.e., R, and try again.
   - (b) Compute the distances $d_{y,k} := \|y - x_k\|$ for all $x_k \in S_{y,R}$ with $x_k \neq y$.
   - (c) Determine a point $x_l \neq y$ with $d_{y,l} = \min_k d_{y,k}$.
   - (d) If $y \notin \omega_l$ increase h_l^i for all $i = 1, \dots, d$ appropriately such that $y \in \omega_j$ holds.
5. For all $x_k \in P$: Set $\omega_k = \alpha\omega_k$, i.e., $h_k^i = \alpha h_k^i$ for all $i = 1, \dots, d$.

Now that we have found a cover C_Ω of the domain Ω, we construct a PU $\{\varphi_i\}$ by defining weight functions W_i on the cover patches ω_i. From these weight functions W_i we can easily generate a PU by Shepard's method; i.e., we define

$$\varphi_i(x) = \frac{W_i(x)}{\sum W_k(x)}. \tag{2.2}$$

Since the cover patches ω_i constructed by Algorithm 1 are d-rectangular, i.e., they are products of intervals, the most natural choice for a weight function W_i is a product of one-dimensional functions; i.e., $W_i(x) = \prod_{l=1}^{d} W_i^l(x^l) = \prod_{l=1}^{d} \mathcal{W}(\frac{x - x_i^l + h_i^l}{2h_i^l})$, with $\mathrm{supp}(\mathcal{W}) = [0,1]$, such that $\mathrm{supp}(W_i) = \overline{\omega_i}$. It is sufficient for this construction to choose a one-dimensional weight function $\mathcal{W}$ which is nonnegative. Throughout this paper we use normed B-splines [27] as the generating weight function $\mathcal{W}$.

In general, a PU $\{\varphi_i\}$ can of course recover only the constant function on the domain Ω. Hence, the consistency error in the L^2-norm of a discretization with the $\{\varphi_i\}$ would be of first order only. Therefore, we need to improve the approximation quality to use the method for the discretization of a PDE. To this end, we multiply the PU functions φ_i locally with polynomials. Since we use d-rectangular patches ω_i only, a local tensor product space is the most natural choice. Throughout this paper, we use complete Legendre polynomials[2] as local approximation spaces $V_i^{p_i}$; i.e., we choose $V_i^{p_i} = \mathrm{span}\,(\{\psi_i^k \,|\, \psi_i^k = \prod_{l=1}^{d} \mathcal{L}_i^{k_l}, \sum_{l=1}^{d} k_l \leq p_i\})$, where $\mathcal{L}_i^{k_l}$ is the one-dimensional Legendre polynomial of degree k_l on the interval $[x_i^l - h_i^l, x_i^l + h_i^l]$.

The selection of optimal local approximation orders p_i and basis functions ψ_i^k are by nature problem-dependent. The regularity of the analytical solution space, e.g., $H^k(\Omega)$ or $L^p(\Omega)$, and information about the analytical solution u itself may provide some insight. This and other adaptivity related issues are the subject of future research and will not be treated in this paper.

Following the construction given above, we can construct approximate solutions u_{PU} of any order and regularity without additional constraints on the cover C_Ω. The resulting shape functions $\varphi_i\psi_i^k$, however, have some surprising properties.

1. The PU functions φ_i are (in general) noninterpolatory. Furthermore, there are more degrees of freedom in a PUM space than there are points $x_i \in P$ due to the use of (multidimensional) local approximation spaces $V_i^{p_i}$.
2. The regularity of the shape functions $\varphi_i\psi_i^k$ is independent of the number of degrees of freedom. The shape functions inherit the regularity of the PU functions φ_i (if we assume that the local approximation spaces $V_i^{p_i}$ are at least of the same regularity). Therefore, we can increase the regularity of an approximation u_{PU} by changing the B-spline used in (2.2) independent of the local approximation spaces $V_i^{p_i}$. Note that this is different from FEMs. In the FEM the global regularity of an approximation is given by the element regularity which on the other hand is implemented by constraints imposed on the local degrees of freedom. Hence, a higher regularity may be achieved only by increasing the number of degrees of freedom of an element.
3. The PUM shape functions are piecewise rational functions due to the use of piecewise polynomial weights in (2.2).

The cover C_Ω itself influences the computational work of the method significantly. For one, the neighbor relations $\omega_i \cap \omega_j \neq \emptyset$ of the cover C_Ω already define the sparsity pattern of the stiffness matrix. Second, the evaluation of a single PU function φ_i (see (2.2)) involves the evaluation of the weights of all neighboring patches $N_i := \{\omega_j \in C_\Omega \,|\, \omega_i \cap \omega_j \neq \emptyset\}$. Hence, it is necessary to control the number of neighbors $\mathrm{card}(N_i)$ to limit the computational work during the assembly of the stiffness matrix. Furthermore, the smoothness of a PU function φ_i is strongly dependent on the amount of overlap $\omega_i \cap \omega_j$ of the neighboring patches $\omega_j \in N_i$; see [13] for details.

[2] Note that due to their product structure the shape functions $\varphi_i\psi_i^k$ of our PUM do not inherit orthogonality properties of the local basis functions ψ_i^k. Hence, the chosen Legendre polynomials $\mathcal{L}^k$ will not lead to a diagonal matrix for the mass matrix problem, as well as the integrated Legendre polynomials $\mathcal{L}_I^k$ will not lead to a diagonal matrix for the Poisson problem.

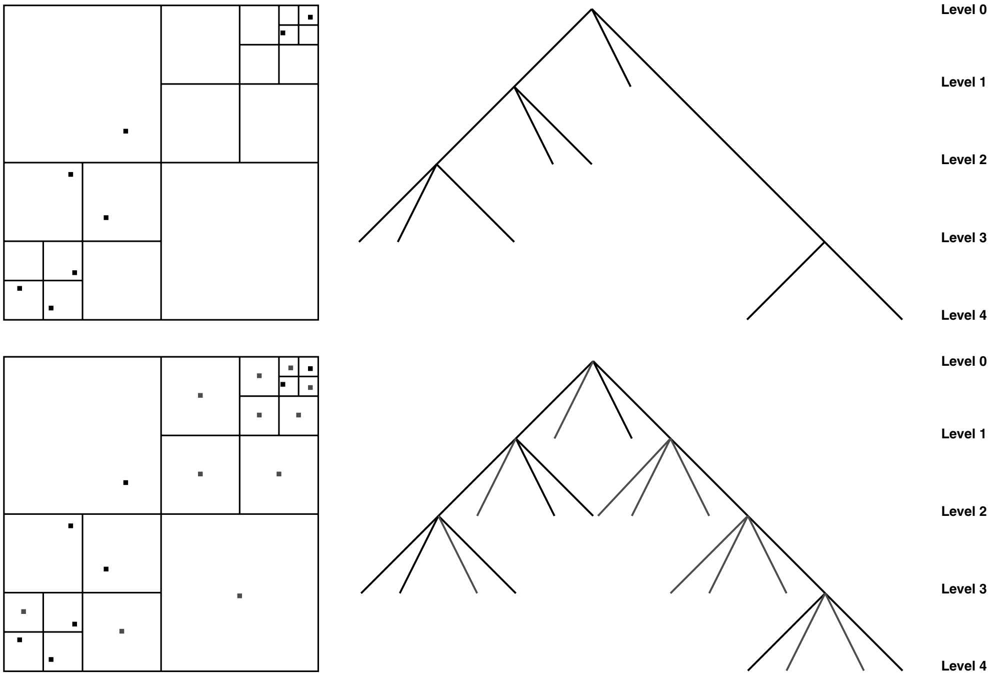

FIG. 3.1. *Hierarchical cover construction with Algorithm* 2 *in two dimensions. 3. Hierarchical cover construction.

Therefore, we need to construct a cover C_Ω which minimizes the number of neighbors $\text{card}(N_i)$ for each patch ω_i but ensures significantly large overlaps $\omega_i \cap \omega_j$ to allow for the use of a cheaper quadrature scheme for each nonzero entry of the stiffness matrix.

With Algorithm 1 for the cover construction the control over the neighborhoods N_i is somewhat limited. Hence, it is very difficult to limit the density of the stiffness matrix. Even more problematic though is the fact that Algorithm 1 needs an additional input[3] Q besides the set of points P and the domain $\Omega \subset \mathbb{R}^d$ to ensure that the complete domain is indeed covered by C_Ω. This of course makes Algorithm 1 significantly less useful, especially in time-dependent settings.

In the following we propose a new algorithm which employs a decomposition approach for the domain Ω to assign sets $\omega_i \subset \mathbb{R}^d$ to the points $x_i \in P$ in such a way that they cover the domain $\Omega \subset \bigcup \omega_i$. This hierarchical algorithm does not need an additional input Q.

ALGORITHM 2 (hierarchical cover construction).

1. Given: the domain $\Omega \subset \mathbb{R}^d$, a bounding box $R_\Omega = \bigotimes_{i=1}^d [l_\Omega^i, u_\Omega^i] \supset \overline{\Omega}$, the initial point set $P = \{x_j \in \mathbb{R}^d \,|\, x_j \in \overline{\Omega}\}$, and a parameter $k \in \mathbb{N}$.
2. Build a d-binary tree (quadtree, octree) over R_Ω such that per leaf L at most one $x_i \in P$ lies within the associated cell $C_L := \bigotimes_{i=1}^d [l_L^i, u_L^i]$, and the difference of the levels of two adjacent cells is at most k; see Figure 3.1.

[3] The selection of the set Q within Algorithm 1 is quite involved to ensure the sparsity of the stiffness matrix and to cover the complete domain at the same time if the points $x_i \in P$ are nonuniformly distributed.

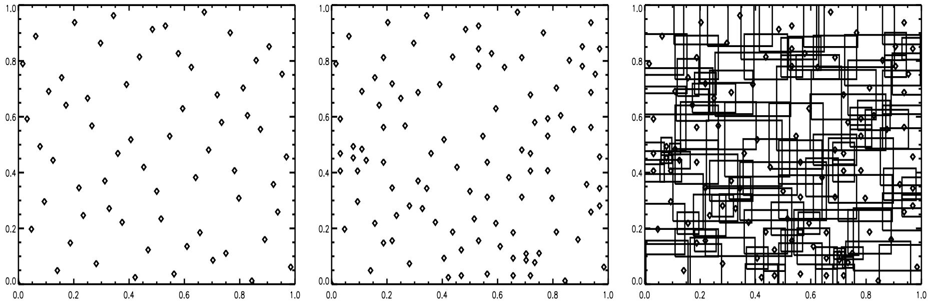

Fig. 3.2. *$P = Halton_0^{63}(2,3)$ point set in $R_\Omega = \Omega = [0,1]^2$ (left), P with* $\mathrm{card}(P) = 106$ *(center) after Algorithm* 2 *with $k = \infty$ and $x_L^i = l_L^i + \frac{1}{2}(u_L^i - l_L^i)$ for generated points x_L, and the generated cover C_Ω (right) with $h_L^i = \frac{5}{4}\max\{u_L^i - x_L^i, x_L^i - l_L^i\}$.*

3. For all cells $C_L = \bigotimes_{i=1}^d [l_L^i, u_L^i]$ with $C_L \cap \Omega \neq \emptyset$:
   - (a) If there is an $x_j \in P$ with $x_j \in C_L$, set $x_L = x_j$. Else, set $x_L =$ any element of C_L, e.g., the center $x_L^i = l_L^i + \frac{1}{2}(u_L^i - l_L^i)$ of the cell C_L.
   - (b) Set $P = P \cup \{x_L\}$.
   - (c) Set $\omega_L = R_L = \bigotimes_{i=1}^d [x_L^i - h_L^i, x_L^i + h_L^i] \supset C_L$, where $h_L^i = \frac{\alpha}{2}\max\{u_L^i - x_L^i, x_L^i - l_L^i\}$ with $\alpha > 1$.

With Algorithm 2 we not only ensure the covering property $\Omega \subset \bigcup \omega_i$ without additional input data, but we also control the neighborhoods N_i, i.e., the nonzeros of the stiffness matrix, and ensure the smoothness of the functions φ_i. The neighborhoods N_i of the cover patches ω_i constructed by Algorithm 2 are small, yet the amount of overlap of any two neighboring patches is of significant size. Certainly, these features do come at a price we have to pay: the algorithm automatically introduces additional points x_{N+k} into the set P; see Figures 3.1 and 3.2.[4] This increases the number of unknowns, i.e., the number of rows of the stiffness matrix, and seemingly the overall computational cost. However, as it turns out, the number of nonzeros of a stiffness matrix based on our algorithm is comparable to the number of nonzeros of a stiffness matrix based on Algorithm 1 for uniformly distributed points P (see Table 6.1, where the initial point set P for the cover construction is a Halton[5] point set). And it is significantly less for highly irregular point sets P (see Table 6.2). Furthermore, the proposed algorithm enables the user to control the amounts of overlap $\omega_i \cap \omega_j$ completely by the choice of the parameter k in step 2 (which corresponds to the local imbalance of the tree), the choice of $x_L \in C_L$ in step 3(a), and the choice of α in step 3(c). Hence, this construction leads to smoother PU functions φ_i and allows for the use of cheaper quadrature schemes (compared with Algorithm 1) during the assembly of the stiffness matrix, although the functions φ_i are still more complex

[4] The additional points are necessary to ensure the shape regularity of the tree cells and patches. A similar tree-based algorithm for the construction of shape-regular triangulations with an almost-minimal number of vertices was proposed in [5]. Analogously, the presented algorithm may have a similar almost-optimal property: If m is the minimal number of shape-regular d-rectangles required to cover the given point set in such way that all d-rectangles contain at most a single point, then the cover C_Ω constructed by the presented algorithm is of size $\mathrm{card}(C_\Omega) = O(m)$.

[5] Halton sequences are quasi Monte Carlo sequences, which are used in sampling and numerical integration. Consider $n \in \mathbb{N}_0$ given as $\sum_j n_j p^j = n$ for some prime p. We can define the transformation H_p from $\mathbb{N}_0$ to $[0,1]$ with $n \mapsto H_p(n) = \sum_j n_j p^{-j-1}$. Then, the (p,q) Halton sequence with N points is defined as $\mathrm{Halton}_0^N(q,p) := \{(H_p(n), H_q(n)) \,|\, n = 0, \ldots, N\}$.

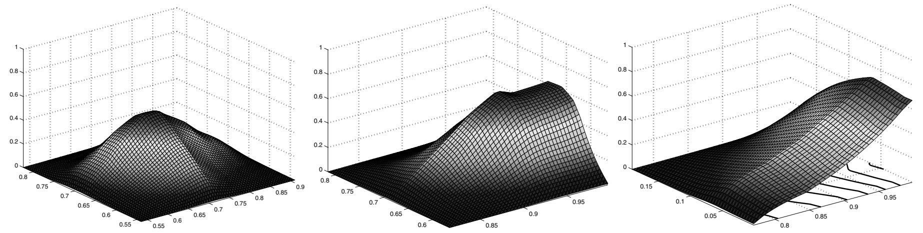

FIG. 3.3. *The PU function φ_i on $\Omega \cap \omega_i$ generated by Algorithm* 2 *with the input data from Figure* 3.2 *for an interior point (left), a boundary point (center), and a corner point (right) using linear B-splines.*

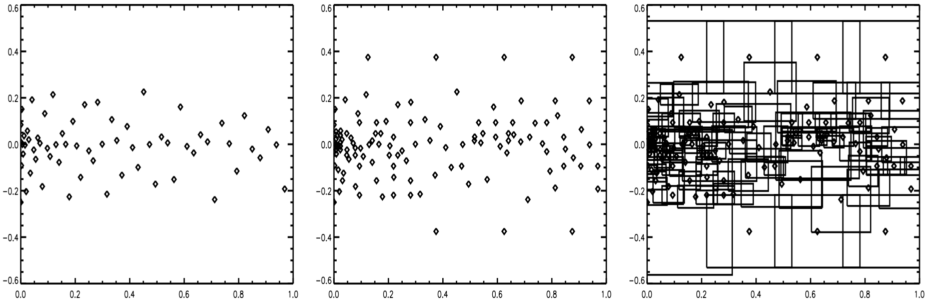

FIG. 3.4. *P is a Halton$_0^{63}(2,3)$ point set in $R_\Omega = \Omega = [0,1] \times [-0.5, 0.5]$ graded by $(x,y) \mapsto (x^2, \pm y^2)$ (left), P with* $\text{card}(P) = 121$ *(center) after Algorithm* 2 *with $k = \infty$ and $x_L^i = l_L^i + \frac{1}{2}(u_L^i - l_L^i)$ for generated points x_L, and the generated cover C_Ω (right) with $h_L^i = \frac{5}{4}\max\{u_L^i - x_L^i, x_L^i - l_L^i\}$.*

than FE shape functions (see Figure 3.3). In summary, the proposed algorithm is applicable to general domains Ω and any initial distribution of points P without an additional input Q, yet it also reduces the computational costs during the assembly of the stiffness matrix and right-hand side vector.

Note that we capture the domain Ω by the cells C_L and subsequently by the $\omega_L = R_L$ only. This, however, does *not* limit the domain or boundary resolution of our method. At this stage in the construction process, we are interested only in generating a cover C_Ω of the domain Ω. Only during the integration of the stiffness matrix and right-hand side vector entries do we need to restrict the evaluation of the associated shape functions $\varphi_L \psi_L^k$ to the computational domain Ω, i.e., to the integration domain $\omega_L \cap \Omega$. We postpone the issue of domain and boundary resolution to section 5. Note further that due to steps 3(a) and 3(c) we generally produce d-rectangular cover patches ω_i independent of the shape of the bounding box R_Ω; see Figures 3.2 and 3.4. Note also that the construction allows for the fast evaluation of a single PU function φ_i (see (2.2)) due to the efficient neighbor search in the hierarchical tree data structure. Note finally that the introduction of a hierarchical cover induces a hierarchy for the associated function space[6] which we may exploit in the design of fast multilevel solvers for the linear equations arising from a PUM discretization. This issue, however, is the subject of future research.

[6] For covers from Algorithm 1 the introduction of such a hierarchy would at least be artificial. Since in Algorithm 1 the selection of the supports ω_i is independent of a hierarchical ordering on the points, this hierarchy on the points would not lead to a hierarchy for the supports of the shape functions in a natural way.

4. Galerkin method with the PUM space.

We want to solve elliptic boundary value problems of the type

$$\begin{aligned} Lu &= f \quad \text{in } \Omega \subset \mathbb{R}^d\,, \\ Bu &= g \quad \text{on } \partial\Omega\,, \end{aligned} \tag{4.1}$$

where L is a symmetric partial differential operator of second order and B expresses suitable boundary conditions. The implementation of Neumann boundary conditions with our PUM is straightforward and similar to their treatment within the FEM. The realization of essential boundary conditions with MMs is more involved than with a FEM due to the noninterpolatory character of the meshfree shape functions. There are several different approaches to the implementation of essential boundary conditions with meshfree approximations; see [13, 16, 27]. Throughout this paper we use Lagrangian multipliers to enforce essential boundary conditions; see [13, 27].

In the following let $a(\cdot,\cdot)$ be the continuous and elliptic bilinear form induced by L on $H^1(\Omega)$. We discretize the PDE using Galerkin's method. Then, we have to compute the stiffness matrix

$$A = (a_{ij})\,, \text{ with } a_{ij} = a(\varphi_j\psi_j^l, \varphi_i\psi_i^k) \in \mathbb{R}^{\dim(V_i^{p_i})\times\dim(V_j^{p_j})}$$

and the right-hand side vector

$$\hat{f} = (f_i) \text{ with } f_i = \langle f, \varphi_i\psi_i^k\rangle_{L^2} = \int_\Omega f\varphi_i\psi_i^k \in \mathbb{R}^{\dim(V_i^{p_i})}\,.$$

If we restrict ourselves for reasons of simplicity to the case $L = -\Delta$ we have to compute the integrals $\int_\Omega \varphi_i\psi_i^k f$ for the right-hand side and the integrals $\int_\Omega \nabla(\varphi_i\psi_i^k)\nabla(\varphi_j\psi_j^l)$ for the stiffness matrix. Recall that φ_i is defined by (2.2), i.e.,

$$\varphi_i(x) = \frac{W_i(x)}{\sum W_k(x)}.$$

Now we carry out the differentiation in $\int_\Omega \nabla(\varphi_i\psi_i^k)\nabla(\varphi_j\psi_j^l)$. With the notation $\mathcal{S} := \sum W_k$, $\mathcal{T} := \sum \nabla W_k$, and $\mathcal{G}_i := \nabla W_i\mathcal{S} - W_i\mathcal{T}$ we end up with the integrals

$$\begin{aligned} a(\varphi_j\psi_j^l, \varphi_i\psi_i^k) = \int_\Omega \mathcal{S}^{-4}\mathcal{G}_i\psi_i^k\mathcal{G}_j\psi_j^l \quad &+ \int_\Omega \mathcal{S}^{-2}W_i\nabla\psi_i^kW_j\nabla\psi_j^l \\ + \int_\Omega \mathcal{S}^{-3}\mathcal{G}_i\psi_i^kW_j\nabla\psi_j^l \quad &+ \int_\Omega \mathcal{S}^{-3}W_i\nabla\psi_i^k\mathcal{G}_j\psi_j^l \end{aligned} \tag{4.2}$$

for the stiffness matrix and the integrals

$$\langle f, \varphi_i\psi_i^k\rangle_{L^2} = \int_\Omega \mathcal{S}^{-1}W_i\psi_i^kf \tag{4.3}$$

for the right-hand side. Due to the fact that we use piecewise polynomial weights W_i for the Shepard construction (2.2) and that the support patches ω_i overlap each other, the functions $\mathcal{T}$ and $\mathcal{G}_i$ may have quite a number of jumps of significant size. Therefore, the integrals (4.2) and (4.3) should not be computed by a simple quadrature scheme which does not respect these discontinuities and the algebraic structure of the shape functions. Instead, we need to decompose the integration domain in such a way that the piecewise character of the integrands is resolved.

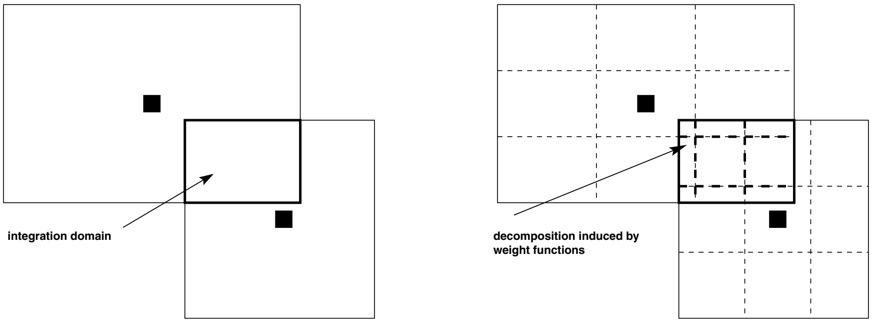

FIG. 5.1. *Integration domain $\Omega_{ij} = \omega_i \cap \omega_j$ (left). The decomposition $E_{\omega_{ij}}$ of the integration domain ω_{ij} via the subdivision induced by the weight functions W_i and W_j (right). Here, the weights are tensor products of quadratic B-splines.*

5. Decomposition sparse grid quadrature scheme.

Let us assume that the PU is given by an h-mesh construction as we have in the GFEM. Then, we know how to resolve the piecewise character of the integrands: we subdivide the integration domains with the help of the geometric elements of the h-mesh. However, with our general PUM we do not have a mesh or geometric elements. However, we have support patches ω_i and weight functions W_i which define the PU functions φ_i by (2.2). From this information only, we have to find an appropriate subdivision of the support patches ω_i and subsequently the integration domains. Furthermore, we have to cope with rational integrands on the cells of such a subdivision in our general PUM. The foundation for the proposed quadrature scheme is a decomposition approach which was first presented in [27]. Here, we give a short review of the construction principles for the decomposition $D_{\omega_{ij}} := \{D^n_{\omega_{ij}}\}$ of the integration domains $\omega_{ij} := \omega_i \cap \omega_j \cap \Omega$.

The integration domains ω_{ij} may be decomposed into disjoint cells $D^n_{\omega_{ij}}$ by exploiting the tensor product structure of the cover patches ω_i and the weight functions W_i used during the construction (2.2) of the PU $\{\varphi_i\}$. This decomposition of an integration domain ω_{ij} can efficiently be computed by splitting ω_{ij} via its caps $\omega_{ij} \cap \omega_k$ with the neighboring cover patches $\omega_k \in N_{ij} := N_i \cap N_j$ using a second tree data structure.

Consider the integration domain $\omega_{ij} = \omega_i \cap \omega_j \subset \Omega$. The intersection ω_{ij} of two cover patches ω_i, ω_j which are tensor products of intervals is also a tensor product of intervals; see Figure 5.1 (left). Moreover, the employed weight functions W_k are tensor products of normed B-splines of order l; i.e., they are piecewise polynomials of degree l. Therefore, the weight function W_k induces a subdivision of the respective cover patch ω_k into $(l+1)^d$ subpatches $\{\omega^q_k\}$ on which $W_k\big|_{\omega^q_k}$ is polynomial. Furthermore, these subpatches $\{\omega^q_k\}$ are also tensor products of intervals. With the help of these subpatches $\{\omega^q_i\}$, $\{\omega^q_j\}$ we can define a first decomposition $E_{\omega_{ij}} = \{E^n_{\omega_{ij}}\}$ of ω_{ij}; see Figure 5.1 (right). On the cells $E^n_{\omega_{ij}}$ of this decomposition we have that $W_i\big|_{E^n_{\omega_{ij}}}$ and $W_j\big|_{E^n_{\omega_{ij}}}$ are polynomials of degree l, but all other $W_k\big|_{E^n_{\omega_{ij}}}$ may still be piecewise polynomial only. Therefore, we further refine the decomposition $E_{\omega_{ij}}$ by subdividing the cells $E^n_{\omega_{ij}}$ with the help of the $\{\omega^q_k\}$ subpatches for all $\omega_k \in N_{ij}$; see Figure 5.2. The resulting decomposition $D_{\omega_{ij}} = \{D^n_{\omega_{ij}}\}$ consists of d-rectangular cells $D^n_{\omega_{ij}}$ on which all weight functions $W_k|_{D^n_{\omega_{ij}}}$ are polynomials of degree l. The number of cells $\mathrm{card}(D_{\omega_{ij}})$ of the decomposition $D_{\omega_{ij}} = \{D^n_{\omega_{ij}}\}$ depends on the polynomial degree l

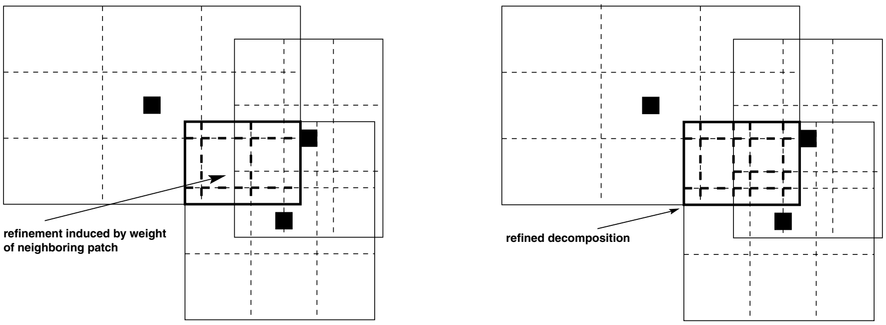

FIG. 5.2. *Refinement of the decomposition $E_{\omega_{ij}}$ of the integration domain ω_{ij} via the subdivision induced by the weight function W_k (tensor product of quadratic B-splines) of one neighboring point x_k (left). The resulting decomposition $D_{\omega_{ij}}$ after the refinement step for the neighboring weight function W_k (right).*

of the weight functions W_k used during the Shepard construction (2.2) for the PU, the number of neighbors $\text{card}(N_i)$, and their geometric location.

Since all weights W_k are polynomial on the cells $D^n_{\omega_{ij}}$, the functions $\mathcal{T}$ and $\mathcal{G}_i$ are nonsingular rational functions on $D^n_{\omega_{ij}}$. Hence, any standard quadrature rule for smooth functions is applicable for the numerical integration of the weak form on the cells $D^n_{\omega_{ij}}$ (if we assume that the local basis functions ψ^k_i and ψ^l_j are smooth on ω_{ij}). Independent of the local quadrature rule used on $D^n_{\omega_{ij}}$ we can utilize the product structure of the shape functions $\varphi_i\psi^k_i$ to reduce the computational costs of an evaluation of the weak form at a quadrature point. Here, we simultaneously evaluate the complete block $a_{ij} = a(\varphi_j\psi^l_j, \varphi_i\psi^k_i) \in \mathbb{R}^{\dim(V^{p_i}_i)\times\dim(V^{p_j}_j)}$ of the stiffness matrix rather than evaluating every single $(a_{ij})_{kl} = a(\varphi_j\psi^l_j, \varphi_i\psi^k_i) \in \mathbb{R}$ for fixed k and l. Besides the reduction in the number of evaluations of φ_i and φ_j, this also allows for a hierarchical evaluation of the local basis functions ψ^k_i and ψ^l_j (which is available for the chosen Legendre polynomials) which reduces the computational costs of an evaluation of the weak form significantly (esp. for higher order approximations).

For the selection of a quadrature rule on the cells $D^n_{\omega_{ij}}$ we can now assume the smoothness of the integrands. However, the quadrature rule still has to be applicable to general situations (general covers, weights and local basis functions ψ^k_i, etc.). Hence, we have to find a fast converging, cheap quadrature rule on $D^n_{\omega_{ij}}$ which allows for a reliable dynamic stopping criterion for a wide range of integrands.

So-called sparse grid quadrature [12] rules are multidimensional interpolatory rules with a substantially smaller number of integration nodes compared with a tensor product rule. They are defined as special products of one-dimensional interpolatory quadrature rules. Although the number of evaluations of the integrand is significantly less for a sparse grid quadrature rule, the order of the achieved error is comparable to that of a full tensor product rule. Here, we state only the fundamental construction principles and error bounds (see [12]) and the references cited therein for further details.

Consider a sequence of nested one-dimensional quadrature rules for univariate functions $\{Q^1_l \,|\, Q^1_l f := \sum_{i=1}^{n^1_l} w_{li} f(x_{li}),\ n^1_l = O(2^l),\ f : \mathbb{R} \to \mathbb{R}\}$ with weights w_{li}, nodes x_{li}, and error bound $|Q^1_l f - \int f| = O(2^{-lr})$, where f is assumed to be r-times continuously differentiable. This bound holds, for example, for the Clenshaw–Curtis

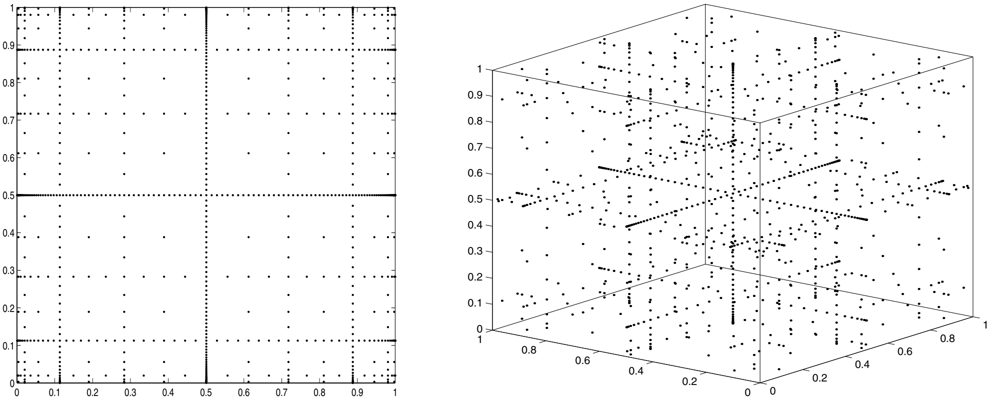

FIG. 5.3. *Quadrature nodes of sparse grid Gauß–Patterson rules, level* $l = 6$ *with* 769 *nodes in two dimensions (left) and level* $l = 5$ *with* 1023 *nodes in three dimensions (right).*

and Gauß–Patterson rules. With the help of the difference quadrature rules Δ_k^1,

$$\Delta_k^1 f := (Q_k^1 - Q_{k-1}^1) f \quad \text{with} \quad Q_0^1 f := 0,$$

we can define the sparse grid quadrature rule Q_l^d on level l in d-dimensions as

$$Q_l^d f := \sum_{\sum_{i=1}^d k_i \leq l+d-1} (\Delta_{k_1}^1 \otimes \cdots \otimes \Delta_{k_d}^1) f$$

with $f : \mathbb{R}^d \to \mathbb{R}$, $l \in \mathbb{N}$, and $k \in \mathbb{N}^d$. Due to the restriction $\sum_{i=1}^d k_i \leq l + d - 1$ in the summation, the number n_l^d of quadrature points x_i^d of the resulting sparse grid quadrature rule Q_l^d is

$$n_l^d = O(2^l l^{d-1})$$

only. Hence, the number of function evaluations for a sparse grid quadrature rule is dramatically less (see Figure 5.3) than for a full tensor product rule where the integrand has to be evaluated at $O(2^{ld})$ quadrature points. This reduction of the computational costs, however, does not compromise the approximation quality significantly for smooth functions. When f is assumed to be r-times continuously differentiable the estimate

$$|Q_l^d f - \textstyle\int f| = O(2^{-lr} l^{(d-1)(r+1)})$$

holds.

In summary, sparse grid quadrature rules are not only cheaper to evaluate (esp. in higher dimensions) compared with tensor product rules, but rather their overall efficiency with respect to accuracy is significantly better. In [12] the fast convergence of sparse grid quadrature rules based on Gauß–Patterson rules (see Figure 5.3) is shown for a wide variety of function classes. In fact, sparse grid quadrature rules based on Gauß–Patterson rules converge exponentially for smooth integrands. Since the integrands we are interested in are smooth on the cells $D_{\omega_{ij}}^n$ of the constructed decomposition $D_{\omega_{ij}}$ we use Gauß–Patterson sparse grid rules for the numerical integration of the stiffness matrix entries.

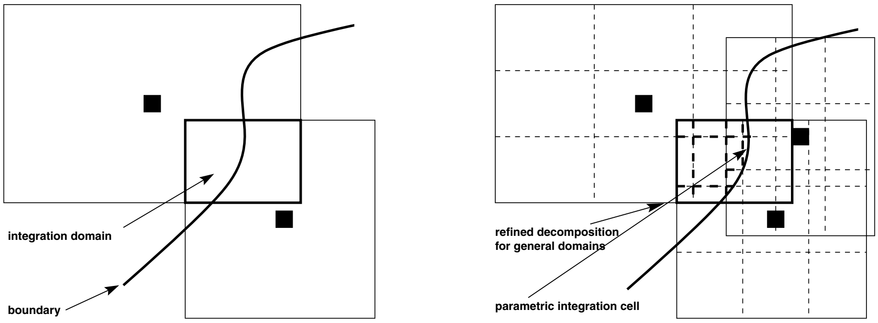

FIG. 5.4. *Integration domain* $\Omega_{ij} = \omega_i \cap \omega_j \cap \Omega$ *for general domains* Ω *(left). The decomposition* $D_{\omega_{ij}}$ *of a general integration domain* ω_{ij} *via the subdivision induced by the weight functions* W_i, W_j, *and a neighboring patch (right); compare Figures* 5.1 *and* 5.2. *Here, the weights are tensor products of quadratic B-splines.*

To ensure a reliable accuracy of our quadrature scheme, we use a simple three level dynamic stopping criterion [24]. The quadrature on a cell $D^n_{\omega_{ij}}$ is stopped if

$$|Q^d_{l-1}f - Q^d_{l-2}f| \le c_1\epsilon_a + c_2\epsilon_r|Q^d_{l-1}f| \quad \text{and} \quad |Q^d_l f - Q^d_{l-1}f| \le \epsilon_a + c_3\epsilon_r|Q^d_l f|$$

hold for the integrand $(a_{ij})_{kl}$ of minimal order $k = l = 0$ as well as for the integrand of maximal order $k = \dim(V_i^{p_i})-1$, $l = \dim(V_j^{p_j})-1$. Here, c_1, c_2, and c_3 are nonnegative constants, and ϵ_a and ϵ_r are user supplied absolute and relative tolerances. These tolerances which determine the accuracy of the integration, however, have to be chosen with respect to the approximation space. Here, the diameters $\operatorname{diam}(\omega_i)$, $\operatorname{diam}(\omega_j)$ of the cover patches ω_i, ω_j, the number of integration cells $\operatorname{card}(D_{\omega_{ij}})$, their respective diameters $\operatorname{diam}(D^n_{\omega_{ij}})$, and the local approximation orders p_i, p_j have to be considered. An automatic selection of the tolerances ϵ_a and ϵ_r which minimizes the computational work but at the same time does not compromise the accuracy of the discretization [29, Chapter 4] is the subject of future research.

Note that the decomposition approach given above is not restricted to domains Ω which are unions of d-rectangles but rather applicable to general domains. For integration domains $\omega_i \cap \omega_j \cap \Omega \neq \omega_i \cap \omega_j$ we apply the construction to the fictitious integration domain $\tilde{\omega}_{ij} := \omega_i \cap \omega_j$. From this decomposition $D_{\tilde{\omega}_{ij}} = \{D^n_{\tilde{\omega}_{ij}}\}$ we then select the subset $\hat{D}_{\omega_{ij}} := \{\hat{D}^n_{\omega_{ij}} \in D_{\tilde{\omega}_{ij}} \,|\, \hat{D}^n_{\omega_{ij}} \cap \Omega \neq \emptyset\}$ of all cells which overlap the actual integration domain $\omega_{ij} = \tilde{\omega}_{ij} \cap \Omega$. This intermediate cover $\hat{D}_{\omega_{ij}}$ consists of d-rectangular cells $\hat{D}^n_{\omega_{ij}} \cap \Omega \neq \emptyset$ which cover the integration domain ω_{ij}; see Figure 5.4. Now the remaining task is to resolve (with the necessary accuracy) the boundary $\partial\Omega$ of the domain which runs through some of the cells $\hat{D}^n_{\omega_{ij}}$. We assume that a representation for the boundary $\partial\Omega$ is given as part of the computational domain Ω. That is, we assume the domain Ω and its boundary $\partial\Omega$ are given as a collection of mappings $\mathcal{R}^m_\Omega : [-1,1]^d \to \overline{\Omega} \subset \mathbb{R}^d$ from a reference cell into the physical space $\overline{\Omega} \subset \mathbb{R}^d$ with $\bigcup \mathcal{R}^m([-1,1]^d) = \overline{\Omega}$. These mappings $\mathcal{R}^m_\Omega$ may be coming from a CAD system; i.e., the mappings themselves are only an approximation to the true domain Ω, or may be coming from a given analytical representation of the domain Ω.

With the help of these mappings $\mathcal{R}^m_\Omega$ we can compute the parametric integration cell $D^n_{\omega_{ij}} := \hat{D}^n_{\omega_{ij}} \cap \Omega$ which lies within the integration domain ω_{ij}; see Figure 5.4. The final decomposition $D_{\omega_{ij}} = \{D^n_{\omega_{ij}} \,|\, D^n_{\omega_{ij}} := \hat{D}^n_{\omega_{ij}} \cap \Omega\}$ for general domains Ω therefore consists of d-rectangular cells $D^n_{\omega_{ij}} = \hat{D}^n_{\omega_{ij}}$ if $\hat{D}^n_{\omega_{ij}} \subset \Omega$ and parametric cells $D^n_{\omega_{ij}}$ if the corresponding d-rectangular cell $\hat{D}^n_{\omega_{ij}}$ overlaps the boundary $\partial\Omega$.

Note that the mappings $\mathcal{R}^m_\Omega$ do *not* influence the shape functions of our PUN method. While in a FEM the supports of the shape function have to align with the boundary $\partial\Omega$ of the domain, in our PUM the supports of the shape functions have to cover only the domain Ω and its boundary $\partial\Omega$. The mappings of the domain representation $\mathcal{R}^m_\Omega$ are merely used to implement integration domains ω_{ij} with complicated geometry.

Overall, the numerical quadrature of the stiffness matrix entries is completed in three steps:

1. First we compute the decomposition $D_{\tilde{\omega}_{ij}}$ for the domain $\tilde{\omega}_{ij} = \omega_i \cap \omega_j$; see Figures 5.1 and 5.2. With the help of the domain representation mappings $\mathcal{R}^m_\Omega$ we then select the integration cells $\hat{D}^n_{\omega_{ij}} = D^n_{\tilde{\omega}_{ij}} \cap \Omega \neq \emptyset$ which overlap the computational domain Ω. Furthermore, we use the mappings $\mathcal{R}^m_\Omega$ to construct the final decomposition $D_{\omega_{ij}} = \{D^n_{\omega_{ij}} \mid D^n_{\omega_{ij}} := \hat{D}^n_{\omega_{ij}} \cap \Omega\}$; see Figure 5.4.
2. For each of these integration cells $D^n_{\omega_{ij}}$ we then compute the Jacobian $J_{T^n_{\omega_{ij}}}$ of the mapping $T^n_{\omega_{ij}} : [-1,1]^d \to D^n_{\omega_{ij}}$ from the reference integration domain $[-1,1]^d$ onto the integration cell $D^n_{\omega_{ij}}$ in the configuration space.
3. Finally, we evaluate the entries of the stiffness matrix and right-hand side vector by computing the integrals (4.2) and (4.3) on the integration cells $D^n_{\omega_{ij}}$. That is, we compute them on the reference integration domain $[-1,1]^d$ using the transformations $T^n_{\omega_{ij}}$ and the respective Jacobians $J_{T^n_{\omega_{ij}}}$:

$$\int_{D^n_{\omega_{ij}}} \mathcal{F} = \int_{[-1,1]^d} \mathcal{F} \circ T^n_{\omega_{ij}} |J_{T^n_{\omega_{ij}}}|.$$

   The Jacobian $J_{T^n_{\omega_{ij}}}$ for a simple d-rectangular integration cell is of course constant, and this transformation does not increase the costs of the numerical integration. However, for a parametric cell the transformation $T^n_{\omega_{ij}}$ involves the mappings $\mathcal{R}^m_\Omega$ of the domain representation. Therefore, the Jacobian may well be space-dependent and has to be evaluated at every integration node of the quadrature rule.[7]

   Again, the error during the numerical quadrature has to be controlled by the selection of ϵ_a and ϵ_r to ensure that the order of approximation is not compromised by the integration error.

The overall computational costs of the proposed quadrature scheme depends on the number of cells $\text{card}(D_{\omega_{ij}})$ of the decomposition, i.e., on the order l of the weight functions, the geometric location of the neighbors $\omega_j \in N_i$, their number $\text{card}(N_i)$, and the local quadrature rule used on the cells $D^n_{\omega_{ij}}$. Due to the use of the sparse grid rules on the cells, the computational costs are significantly reduced compared with tensor product rules.

6. Hierarchical regular cover construction.

A further reduction of the computational effort necessary during the assembly of the stiffness matrix can be achieved

[7] Note that in general the transformations $T^n_{\omega_{ij}}$ may lead to (locally) nonsmooth integrands where an isotropic sparse grid quadrature scheme may not be well-suited on all integration cells $D^n_{\omega_{ij}}$. Here, a further decomposition of the integration cells $D^n_{\omega_{ij}}$ where the integrands are nonsmooth or even adaptive quadrature rules (sparse grid or other) should be employed on such integration cells $D^n_{\omega_{ij}}$.

only by reducing the number of cells of the decomposition[8] $D_{\omega_{ij}}$. This can be attained by the alignment of the cover patches ω_k and their subdivisions $\{\omega^q_k\}$.

Taking into account that we limit ourselves to the use of tensor product B-splines as weight functions for Shepard's construction (2.2) we can align the cover patches to simplify the algebraic structure of the resulting partition of unity functions φ_i. Here, we eliminate some of the flexibility in step 3 of Algorithm 2 for the choices of x_L and α. This, however, does not lead to a significantly larger number of neighbors. Hence, the number of nonzeros of the stiffness matrix stays (almost) constant; see Tables 6.1 and 6.2. However, the number of integration cells $\operatorname{card}(D_{\omega_{ij}})$ is substantially reduced by this modification; see Tables 6.4 and 6.5.

Recall that we split the integration domain ω_{ij} into several cells by its caps $\omega_{ij} \cap \omega^q_k$ with the cells ω^q_k of the subdivision induced by the weight W_k on $\omega_k \in N_{ij}$ during the construction of the decomposition $D_{\omega_{ij}}$. Hence, we align these caps $\omega_{ij} \cap \omega^q_k$, which subsequently induce at least one integration cell $D^n_{\omega_{ij}}$, if we align the neighboring cover patches ω_k with respect to their subdivisions $\{\omega^q_k\}$. Therefore, many of the $\omega_{ij} \cap \omega^q_k$ will lead to the same integration cell $D^n_{\omega_{ij}}$, and the overall number of integration cells $\operatorname{card}(D_{\omega_{ij}})$ will be reduced significantly; see Tables 6.4 and 6.5. This alignment of the cover patches ω_k and their subdivisions $\{\omega^q_k\}$ is achieved by the following algorithm.

[8] The decomposition itself, however, is minimal in the sense that it has a minimal number $\operatorname{card}(D_{\omega_{ij}})$ of integration cells necessary to resolve the piecewise character of the PU functions. In our construction (2.2) of the PU we have to allow for higher orders l of the B-spline weights to be able to construct global solutions u_{PU} with higher order regularity, i.e., $u_{\mathrm{PU}} \in \mathcal{C}^{l-1}$. Therefore, the remaining influences on the computational effort involved with the numerical integration of the stiffness matrix entries are the geometric neighboring relations of our cover patches ω_i.

Algorithm 3 (hierarchical regular cover construction).

1. Given: the domain $\Omega \subset \mathbb{R}^d$, a bounding box $R_\Omega = \bigotimes_{i=1}^d [l_\Omega^i, u_\Omega^i] \supset \overline{\Omega}$, the initial point set $P = \{x_j \in \mathbb{R}^d \,|\, x_j \in \overline{\Omega}\}$, and a parameter $k \in \mathbb{N}$.
2. Build a d-binary tree (quadtree, octree) over R_Ω such that per leaf L at most one $x_i \in P$ lies within the associated cell $C_L := \bigotimes_{i=1}^d [l_L^i, u_L^i]$, and the difference of the levels of two adjacent cells is at most k.
3. For all cells $C_L = \bigotimes_{i=1}^d [l_L^i, u_L^i]$ with $C_L \cap \Omega \neq \emptyset$:
   (a) Set $x_L^i = l_L^i + \frac{1}{2}(u_L^i - l_L^i)$.
   (b) If there is an $x_j \in P$ with $x_j \in C_L$, set $P = P \setminus \{x_j\}$.
   (c) Set $P = P \cup \{x_L\}$.
   (d) Set $\omega_L = R_L = \bigotimes_{i=1}^d [x_L^i - h_L^i, x_L^i + h_L^i] \supset C_L$, where $h_L^i = \frac{\alpha_l}{2}(u_L^i - l_L^i)$.

Here, the parameter α_l in the computation of the support size in step 3(d) is dependent only on the weight function used in (2.2), i.e., the order l of the B-spline. By construction the one-dimensional distances from a point $x_L \in P$ to its direct neighboring point $x_j \in P$, i.e., the point x_j corresponding to the sibling tree cell $C_j = \bigotimes_{i=1}^d [l_j^i, u_j^i]$, are $|x_L^i - x_j^i| = u_L^i - l_L^i = u_j^i - l_j^i$, where $C_L = \bigotimes_{i=1}^d [l_L^i, u_L^i]$ is the cell associated with x_L. Hence, if we choose α_l in such a way that condition (6.1) is fulfilled, we not only align the patch ω_L with its direct neighboring patch ω_j but rather also their corresponding subdivisions $\{\omega_L^q\}$ and $\{\omega_j^q\}$ induced by the weight functions W_L and W_j; see Figure 6.1. Moreover, this alignment of the patches does not increase the number of neighbors $\operatorname{card}(N_L)$. With the notation $h_l^i := \frac{\alpha_l}{l+1}(u_L^i - l_L^i)$ for the B-spline interval size, the condition reads

$$x_L^i + \frac{l+1}{2} h_l^i = x_j^i - \left(\frac{l+1}{2} - m\right) h_l^i = x_L^i + (u_L^i - l_L^i) - \left(\frac{l+1}{2} - m\right) h_l^i \tag{6.1}$$

for the ith coordinate with $i = 1, \dots, d$. Here, the parameter $m \in \mathbb{N}$ indicates the amount of overlap $\omega_L \cap \omega_j \sim \bigotimes_{i=1}^d m h_l^i$ for the neighbor $\omega_j \in N_L$. Any integer m with $1 \leq m \leq \frac{l+1}{2}$ leads to minimal neighborhoods N_L and minimal decompositions $D_{\omega_{Lj}}$; i.e., the number $\sum_L \operatorname{card}(N_L)$ of nonzero entries of the stiffness matrix and the number $\sum_{L,j} \operatorname{card}(D_{\omega_{Lj}})$ of integration cells are (almost) constant. Therefore, it is advisable to choose the largest such integer to control the gradients of the PU function φ_i. Solving (6.1) for α_l we have

$$\alpha_l = \frac{l+1}{l+1-m}.$$

With the choice of $l = 2n - 1$ and maximal $m = n$, this yields $\alpha_l = 2$; in general, we have $1 < \alpha_l \leq 2$. Due to this construction many of the points $x_i \in P$ are covered only by the corresponding ω_i. Therefore, we have $\varphi_i(x_j) = \delta_{ij}$ for many PU functions φ_i and points $x_j \in P$; see Figure 6.2. In fact, $\varphi_i(x) = 1$ holds not only for the point $x = x_i$ if we have $\alpha_l < 2$ but rather on a subpatch $\tilde{\omega}_i \subset \omega_i$ with $x_i \in \tilde{\omega}_i \sim \bigotimes_{i=1}^d h_l^i$, i.e., $\varphi_i|_{\tilde{\omega}_i} \equiv 1$; see Figure 6.2.

When we compare the covers C_Ω (Figures 3.2 and 6.1, Figures 3.4 and 6.3) and functions φ_i (Figures 3.3 and 6.2) generated by Algorithms 2 and 3, we clearly see the effect of the alignment of the cover patches.

Note that the change of the point set P in step 3(c) in Algorithm 3 is admissible due to the noninterpolatory character of the PUM shape functions $\varphi_i \psi_i^k$. We can interpret this change in the point set P as a change of the weight functions W_k used during the Shepard construction (2.2). So far the weight functions W_k and the cover

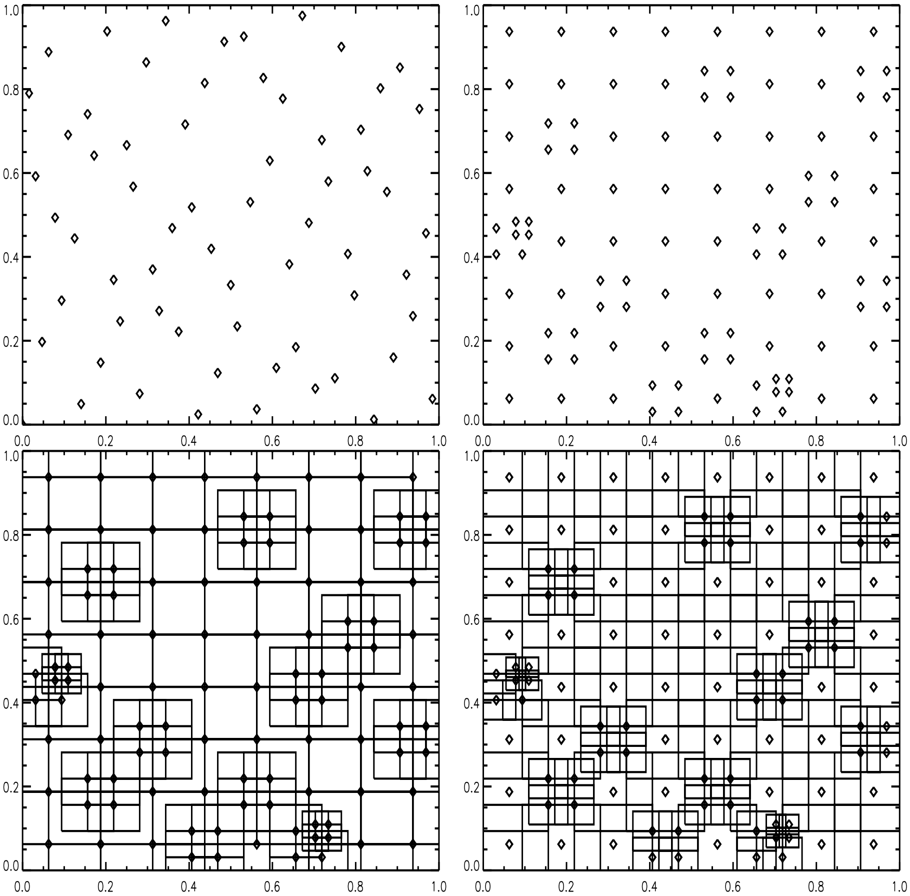

FIG. 6.1. $P = \mathit{Halton}_0^{63}(2,3)$ *point set in* $R_\Omega = \Omega = [0,1]^2$ *(upper left),* P *with* $\mathrm{card}(P) = 106$ *(upper right) after Algorithm* 3 *with* $k = \infty$*, and the generated cover* C_Ω *with* $\alpha_l = 2$ *(lower left) and* $\alpha_l = 1.5$ *(lower right).*

patches ω_k were assumed to be centered in the given point x_k (compare section 2), but this is of course not a necessary condition for the PUM to work. Therefore, we may view the construction given above as a more general approach toward assigning weight functions W_k to a given point $x_k \in P$. The weight functions W_k and cover patches ω_k are now centered in $l_L + \frac{1}{2}(u_L - l_L)$ rather than in the given point x_k. Note that the constructed point set P of newly introduced and shifted points x_k is only part of the implementation of the function space. The initial point set P of step 1 is still the set of all relevant points for the resolution of the solution and the geometry of the domain. Therefore, a copy $\tilde{P}$ of the initial point set P is stored separately, and the points $x_l \in \tilde{P}$ are used in time-dependent settings to generate covers for future time steps [13]. Hence by the introduction of general weight functions W_k as part of the cover construction, we can also write step 3 of Algorithm 3 equivalently as

3'. For all cells $C_L = \bigotimes_{i=1}^d [l_L^i, u_L^i]$ with $C_L \cap \Omega \neq \emptyset$:
- (a) Set $x_L^i = l_L^i + \frac{1}{2}(u_L^i - l_L^i)$.
- (b) If there is *no* $x_j \in P$ with $x_j \in C_L$, set $P = P \cup \{x_L\}$.
- (c) Set $\omega_L = R_L = \bigotimes_{i=1}^d [x_L^i - h_L^i, x_L^i + h_L^i] \supset C_L$, where $h_L^i = \frac{\alpha_l}{2}(u_L^i - l_L^i)$.
- (d) Set the associated weight function $W_L(x) := \Pi_{i=1}^d \mathcal{W}(\frac{x - x_L^i + h_L^i}{2h_L^i})$.

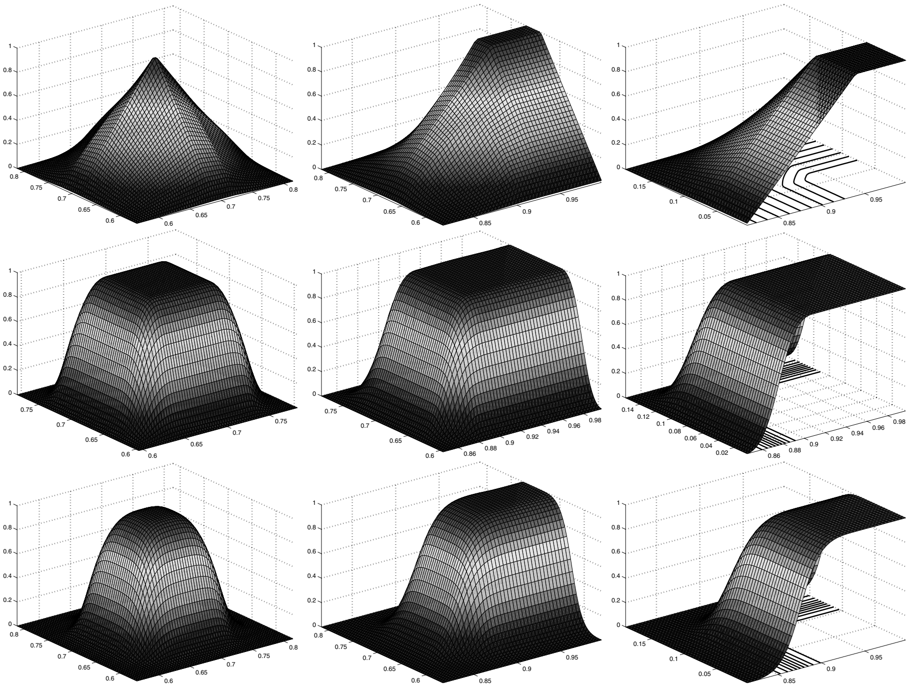

FIG. 6.2. *The PU function φ_i on $\Omega \cap \omega_i$ generated by Algorithm* 3 *with the input data (upper row $l = 1$, $\alpha_l = 2$, center row $l = 2$, $\alpha_l = 1.5$, lower row $l = 3$, $\alpha_l = 2$) from* 6.1 *for an interior point (left), a boundary point (center), and a corner point (right).*

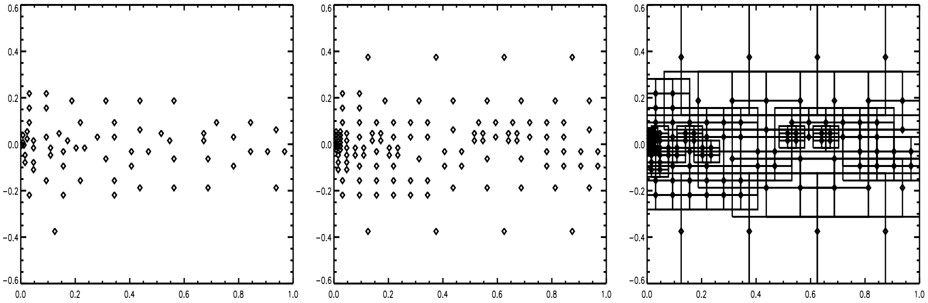

FIG. 6.3. *P is a Halton$_0^{63}(2,3)$ point set in $R_\Omega = \Omega = [0,1] \times [-0.5, 0.5]$ graded by $(x, y) \mapsto (x^2, \pm y^2)$ (left), P with* $\text{card}(P) = 121$ *(center) after Algorithm* 3 *with $k = \infty$, and the generated cover C_Ω with $\alpha_l = 2$ (right).*

This leaves the given points at their original location. Note also that the cover patches $\omega_L = R_L$ constructed with Algorithm 3 and the bounding box R_Ω always have the same aspect ratio; see Figure 6.1. If we apply the algorithm given above to $\Omega = R_\Omega = [0,1]^d$ with $k = \infty$ and $\alpha_l = 2$ to a uniformly distributed set of points P, we construct a uniform grid[9] (or at least an r-irregular grid with very small r depending only on the quality of the initial point set P; see Figure 6.1). Here, also the cells $D^n_{\omega_{ij}}$ of the decomposition $D_{\omega_{ij}}$ are (geometrically) identical to a bilinear finite element.

[9] The covers from Algorithm 3 with $k = 0$ will correspond to a uniform grid regardless of the initial point set P when we have the order $l = 2n - 1$ and maximal $m = n$.

Table 6.3

The average number s_{C_Ω} (6.3) of nonzero blocks a_{ij} per row of the stiffness matrix for the different cover construction algorithms in two (left) and three dimensions (right). Algorithm 2 with $k = \infty$, $x^i_L = l^i_L + \frac{1}{2}(u^i_L - l^i_L)$ for generated points x_L and $h^i_L = \frac{5}{4}\max\{u^i_L - x^i_L, x^i_L - l^i_L\}$ (A_2), and Algorithm 3 with $k = \infty$, $\alpha_l = 2$ ($A_{3,2}$) and $\alpha_l = 1.5$ ($A_{3,1.5}$) . The initial point set P was Halton$^{N-1}_0(2,3)$ in $[0,1]^2$ in two dimensions (left) and Halton$^{N-1}_0(2,3,5)$ in $[0,1]^3$ in three dimensions (right).

Furthermore, the PU $\{\varphi_i\}$ generated by (2.2) will again be piecewise linear for $l = 1$ just like their FE counterpart in the GFEM (see Figure 6.2). Hence, in this situation our method does reconstruct functions φ_i that are identical to bilinear finite element functions, and also our general decomposition algorithm will recover the corresponding geometric elements. Hence, the number of integrals to be evaluated here with our method or a FEM are the same. We give the average number

$$a_{C_\Omega} := \frac{\sum_{i=1, j\in N_i}^{\text{card}(P)} \text{card}(D_{\omega_{ij}})}{\sum_{i=1}^{\text{card}(P)} \text{card}(N_i)} \tag{6.2}$$

of integration cells per nonzero block a_{ij} of the stiffness matrix in Tables 6.4 and 6.5. Furthermore, we give the average number

$$s_{C_\Omega} := \frac{\sum_{i=1}^{\text{card}(P)} \text{card}(N_i)}{\text{card}(P)} \tag{6.3}$$

of nonzero blocks a_{ij} per block-row of the stiffness matrix in Table 6.3 which corresponds to the number of entries in a FE stencil. For a one-dimensional uniform grid the average a_{C_Ω} is $\frac{4}{3}$ for hat functions (at interior points, where we have $N_i = \{\omega_{i-1}, \omega_i, \omega_{i+1}\}$). This situation corresponds of course to the case $l = 1$, $m = 1$, $\alpha_l = 2$ in Algorithm 3. Due to the tensor product approach, we have $(\frac{4}{3})^d$ as the optimal ratio of integration cells to nonzero blocks for $l = 1$ in the d-dimensional case. We certainly cannot expect to meet this optimal ratio for an irregular cover.

From the averages displayed in Tables 6.4 and 6.5 for the two-dimensional and three-dimensional case we see that the averages a_{C_Ω} are (almost) independent of the

Table 6.5

The average number a_{C_Ω} (6.2) of integration cells per nonzero block a_{ij} of the stiffness matrix for the different cover construction algorithms. Algorithm 2 with $k = \infty$, $x^i_L = l^i_L + \frac{1}{2}(u^i_L - l^i_L)$ for generated points x_L and $h^i_L = \frac{5}{4}\max\{u^i_L - x^i_L, x^i_L - l^i_L\}$ (A^l_2), and Algorithm 3 with $k = \infty$ (A^l_{3,α_l}) using a linear, a quadratic and a cubic B-spline during the Shepard construction (2.2). The initial point set P was Halton$^{N-1}_0(2,3,5)$ in $[0,1]^3$.

number of points N of the initial point set P for Algorithm 3 as well as for Algorithm 2. Furthermore, we clearly see the substantial reduction in the number of integration cells for Algorithm 3 compared with Algorithm 2. The average a_{C_Ω} for Algorithm 3 drops by more than a factor of $\frac{1}{6}$ in two dimensions and by more than a factor of $\frac{1}{18}$ in three dimensions compared with the average a_{C_Ω} for covers constructed by Algorithm 2. This significant improvement in the number of integration cells is of course due to the alignment of the patches we have with Algorithm 3 but not with Algorithm 2; see Figures 6.1 and 3.2, and Figures 6.3 and 3.4. Another advantage of Algorithm 3 over Algorithm 2 is the fact that due to the alignment of the weight subdivisions $\{\omega^q_k\}$ the aspect ratio and volume of every integration cell $D^n_{\omega_{ij}}$ is bounded. This is not the case for covers constructed with Algorithm 2. In fact, in the three-dimensional example of Table 6.5 our decomposition algorithm would have generated a number of integration cells with very large aspect ratios and almost vanishing volume in the case $N = 524288$ for a cover constructed with Algorithm 2.

The average a_{C_Ω} for covers from Algorithm 3 (with $l = 1$) is about three times the optimal ratio of $(\frac{4}{3})^d$. For one this factor can be explained by the sudden change in the spatial resolution of the cover, i.e., the level difference k of two neighboring patches, which leads to nonaligned subdivisions $\{\omega^q_k\}$ (see Figures 6.1 and 6.3), and therefore increases the number of integration cells. Moreover, however, the optimal ratio of $(\frac{4}{3})^d$ holds for interior patches only. For cover patches which overlap the boundary of the domain this ratio is 2 (or even 2.25 at corners) in two dimensions, since the subdivisions $\{\omega^q_k\}$ are aligned only with each other but *not* with the boundary $\partial\Omega$; see Figure 6.4. Hence, we expect the average number of integration cells a_{C_Ω} to decrease for larger N since the volume to surface ratio improves. This can be observed from the numbers $A^{1_1}_3$ displayed in Tables 6.4 and 6.5. A similar argument can be made in the case of a quadratic B-spline.[10]

When we use a cubic B-spline ($l = 3$) we construct smooth approximations $u_{\mathrm{PU}} \in \mathcal{C}^2$, and the optimal ratio for interior patches is $(\frac{8}{3})^d$; i.e., it is about 7 in two dimensions and 19 in three dimensions. The averages a_{C_Ω} given in Tables 6.4 and 6.5 in this case are about 10 in two dimensions and 26 in three dimensions; i.e., they are closer to their optimal ratio of $(\frac{8}{3})^d$ than a_{C_Ω} is to its optimum for the linear B-spline. This can be explained by the fact that for $l = 3$ the boundary effect mentioned

[10] In the case $l = 2$, we have an optimal ratio of $\frac{5}{3}$ in one dimension. However, due to the fact that the overlap $m = n$ for $l = 2n$ is smaller in relation to the overall number of cells card$(\{\omega^q_k\})$ (see Figure 6.1), the generalization of this optimum to higher dimensions is *not* given by $(\frac{5}{3})^d$; e.g., in two dimensions the optimum is $\frac{22}{9}$ only; see Figure 6.4.

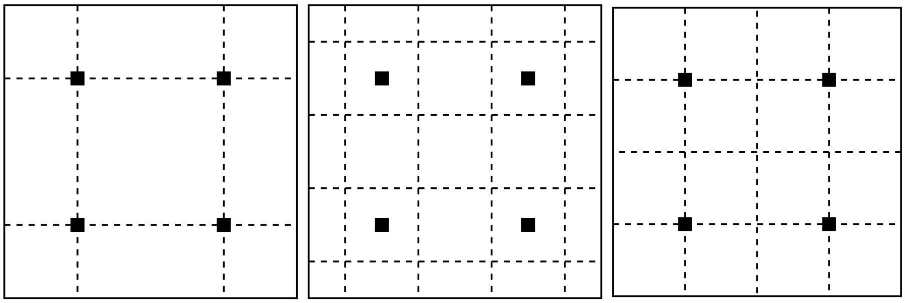

Fig. 6.4. *The integration cells induced by four neighboring linear B-splines (left), quadratic B-splines (center), and cubic B-splines (right) in two dimensions. The integration cells $D^n_{\omega_{ij}}$ align with the boundary for the cubic B-spline (right) but not for the linear (left) or quadratic (center) B-spline due to the overlap condition for the support patches ω_i.*

above does not exist; see Figure 6.4. Here, the cells $\{\omega^q_k\}$ induced by the cubic spline align with the boundary of $[0,1]^d$. Hence, only the irregularity of the cover causes an increase in the number of integration cells. Overall, the number of integration cells for an approximate solution $u_{\mathrm{PU}} \in \mathcal{C}^2$ is about twice the number of integration cells we have when we construct an approximate solution $u_{\mathrm{PU}} \in \mathcal{C}^0$.

So far we were concerned only with the computational cost during the integration and the influence the shape functions $\varphi_i\psi^k_i$ have on the computational efficiency of our PUM. Another important issue, however, is the stability of the basis of our PUM space. Here, we also have to address the question of whether the functions $\varphi_i\psi^k_i$ are indeed a basis. In the case of $l = 1$ and $\alpha_l = 2$ the alignment of the cover patches ω_i and their respective weight subdivisions $\{\omega^q_i\}$ leads to the reconstruction of the FE hat functions for the PU. Hence, our PUM reduces to the GFEM in this situation. It is well known [2, 3, 27, 30] that the GFEM (in general) generates linear-dependent shape functions $\varphi_i\psi^k_i$, the so-called nullity of the method. This is essentially due to the fact that in the GFEM the PU functions φ_i already reconstruct the linear polynomial.

Consider the one-dimensional situation, where we have one element and two nodes with their associated hat function as φ_i. Assume that we use linear polynomials as local approximations spaces V_i. The shape functions $\varphi_i\psi^k_i$ are (global) polynomials due to this construction. The number of shape functions is four, and the maximal polynomial degree is two. Since the quadratic polynomials in one dimension can be generated by three basis functions, we see that the GFEM shape functions are linear dependent.

With our approach, the φ_i reconstruct the linear polynomial only away from the boundary; close to the boundary we have $\varphi_i \equiv 1$. Therefore, the shape functions are not linear dependent. However, since the small boundary layer where $\varphi_i \equiv 1$ decreases with larger N the condition number κ of the mass matrix is dependent on N; i.e., the basis is no longer stable. A simple cure for this stability problem is to use $m < 1$ in (6.1) when we have $l = 1$; i.e., we limit ourselves to $1 < \alpha_l < 2$ when $l = 1$. With $\alpha_l < 2$ we can find a subpatch $\tilde{\omega}_i \subset \omega_i$, where $\varphi_i|_{\tilde{\omega}_i} \equiv 1$ for many i. Therefore, the PU functions φ_i no longer reconstruct the linear polynomial independent of N, and the resulting shape functions form a stable basis. We therefore allow for any value $1 < \alpha_l < 2$ in Algorithm 3 if $l = 1$. The number of integration cells increases somewhat due to this generalization. The patches ω_i are still aligned, but their respective weight subdivisions are not. The optimal ratio increases from $(\frac{4}{3})^d$ to 2^d. From the averages displayed in Tables 6.4 and 6.5 we see that a_{C_Ω} for the choice of $\alpha_l = 1.3$ is about a factor of 1.5 to 2 larger than the average is for the optimal choice of $\alpha_l = 2$. However, the number of integration cells is still substantially less compared with the covers from Algorithm 2.

A similar problem arises for higher order splines $l > 1$ only when $\alpha_l > 2$; e.g., we need $\alpha_l = 4$ with $l = 2$. Therefore, we can stay with our choices of $\alpha_l = 1.5$ if $l = 2$ and $\alpha_l = 2$ if $l = 3$.

7. Numerical experiments. In this section we present some results of our numerical experiments for an elliptic PDE using the h-version and the p-version of our PUM.

We apply our PUM to elliptic problems on the unit cell $\Omega = (0,1)^d$ in two and three dimensions. Here, we consider the Laplace equation

$$-\Delta u = f \tag{7.1}$$

with Dirichlet boundary conditions $u = g$ on $\partial\Omega$ and the equation

$$-\Delta u + u = f \tag{7.2}$$

of Helmholtz type with Neumann boundary conditions $\nabla u = g$ on $\partial\Omega$. Furthermore, we use the presented method to study heat conduction in lattice materials [20, 26] in three dimensions.

The local approximation spaces $V_i^{p_i}$ used in our numerical experiments are complete Legendre polynomials with $p_i = p$ for all patches ω_i. The weight functions W_i used in the Shepard construction (2.2) are linear splines ($l = 1$, $\alpha_l = 1.3$). We give the relative error

$$e = \frac{\|u - u_{\mathrm{PU}}\|}{\|u\|}$$

in the L^∞-, L^2-, and the energy-norm, which is computed with the help of the integration scheme presented in section 5. Moreover, we also give the convergence rates

$$\rho = \frac{\log\left(\frac{\|u-u_{\mathrm{PU},L}\|}{\|u-u_{\mathrm{PU},L-1}\|}\right)}{\log\left(\frac{\mathsf{dof}_L}{\mathsf{dof}_{L-1}}\right)},$$

where $\mathsf{dof} := \sum \dim(V_i^{p_i})$, with respect to two successive refinement levels L and $L-1$. These convergence rates ρ correspond to an algebraic error estimate

$$\|u - u_{\mathrm{PU},L}\| = O\left(\mathsf{dof}_L^{\rho}\right) \tag{7.3}$$

which is valid for the h-version of the PUM [2, 3]. We can relate these rates ρ to the common h^α notation by $\alpha = -\rho d$, since $N^{-\frac{1}{d}} \sim h$ for uniform point sets. Hence, the optimal convergence rates ρ for our PUM based on uniform point sets and linear polynomials are $\rho_2 = -1$ and $\rho_E = -\frac{1}{2}$ in two dimensions ($\rho_2 = -\frac{2}{3}$ and $\rho_E = -\frac{1}{3}$ in three dimensions). For the pointwise convergence[11] we have $\rho_2 < \rho_\infty < \rho_E$.

[11] In the FEM we have the estimate $\|u - u_h\|_\infty = O\left(h^2|\log h|^{\mu(d)}\right)$, where $\mu(2) = 1$ and $\mu(d) = \frac{d}{4} + 1$ for $d \geq 3$ [25, 28]. The L^∞-norm is usually approximated by the maximum over the nodal values, where we can observe a superconvergence of order h^2. For our approximation to the L^∞-norm, however, we do not use the points $x_i \in P$ but all quadrature points since the PUM shape functions $\varphi_i \psi_i^n$ are noninterpolatory and the Legendre polynomials ψ_i^n of odd degree vanish at x_i. Hence, we cannot expect to measure h^2 superconvergence in the L^∞-norm.

For the p-version, we expect an exponential convergence for smooth solutions u since the local error estimate

$$\|u - u_{\mathrm{PU},L}\| = O\left(\exp\left(-b\sqrt{\mathsf{dof}_L}\right)\right) \tag{7.4}$$

holds on every cover patch ω_i for smooth solutions u.

Example 1 (unit square). In our first example we consider the Dirichlet problem (7.1) in $\Omega = (0,1)^2$. We choose f and g such that the solution u is given by

$$u(x) = \|x\|_2^5. \tag{7.5}$$

We apply the h-version of our PUM with linear polynomials to approximate (7.1). The covers C_Ω are generated using N points of the Halton(2, 3) sequence with increasing N. They exhibit a somewhat locally varying patch size; see Figure 6.1. Consequently, there will be some fluctuation in the measured convergence rates ρ.

The results for the h-version experiment with linear polynomials are given in Table 7.1. The measured rates ρ show the algebraic convergence (7.3) of our PUM in the L^2- and energy-norm with rates ρ near the optimal values of $\rho_2 = -1$ and $\rho_E = -\frac{1}{2}$ for the h-version. In the L^∞-norm we measure a convergence rate ρ_∞ of -0.6 which is between -1 and $-\frac{1}{2}$ as expected.[11]

Let us now consider the Neumann problem (7.2). Again, the solution is given by (7.5). Here, we apply the p-version of our PUM. Since the solution (7.5) is not analytic in Ω we may not expect an exponential convergence of the p-version. From the numbers given in Table 7.2 and the convergence history displayed in Figure 7.1

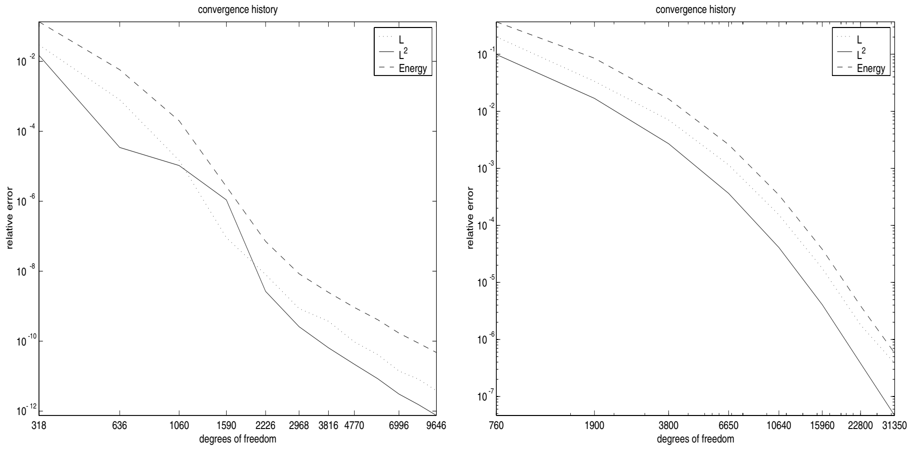

FIG. 7.1. *Convergence history for problem* (7.2) *in two dimensions (left) with solution* (7.5). *Convergence history for problem* (7.2) *in three dimensions (right) with solution* (7.6).

(left) we can observe that the convergence starts off at an exponential rate but breaks down to a polynomial rate as anticipated for higher polynomial degrees p.

Example 2 (unit cube). In our second example we consider (7.1) with Dirichlet boundary conditions on the unit cube in three dimensions. Here, we now choose f and g such that the solution u is given by

$$u(x) = \exp\left(4\|x\|_1\right). \tag{7.6}$$

Again, we use the h-version of our PUM with linear polynomials to approximate (7.1). The covers are generated using N points of the Halton$(2, 3, 5)$ sequence. The numerical results are given in Table 7.3. Here, it seems that the convergence in the L^2- and the energy-norm is actually better than the theory (for uniform point sets) suggests. We measure a convergence rate ρ_2 close to -1 but would expect only a convergence rate of about $-\frac{2}{3}$. This behavior, however, is due to the fact that the size of patches ω_i based on a Halton sequence varies much more in three dimensions than in two dimensions (for a small number of samples). Therefore, a larger fluctuation in the measured convergence rates ρ will occur. If we use a different number N of Halton points for the initial cover or refine the covers using only twice as many points instead of eight times as many, this behavior becomes much more obvious. To this end we also give the numerical results of an h-version experiment with linear polynomials applied to the Neumann problem (7.2) with solution (7.6) in Table 7.4. Here, we clearly see the fluctuation in the convergence rates due to the unstructured refinement induced by the Halton sequence. If we use the grid points of a uniform grid to generate the

covers C_Ω we can observe a very good correspondence of the measured convergence rates ρ with those of the theory (see Table 7.5)), where the corresponding numerical results for the Neumann problem (7.2) with solution (7.6) are given.

We now turn to the p-version of our PUM in three dimensions. The numerical results for problem (7.2) with Neumann boundary conditions are given in Table 7.6. For the smooth solution (7.6) we expect an exponential convergence behavior of the p-version of our PUM. From the measured values of ρ and the convergence history given in Figure 7.1 (right) we clearly see this behavior.

In summary we have that on simple domains in two and three dimensions the PUM works with the anticipated convergence properties. Now we turn to more complicated (yet still academic) computational domains in three dimensions.

Example 3 (lattice material). In our third example we study the problem of heat conduction in a lattice material. To this end, we use our PUM to discretize the PDE

$$-\Delta u + u = f \text{ in } \Omega \subset (0,1)^3$$

on a domain Ω which describes a lattice material with a characteristic cell width of $\frac{4}{14}$ and a cell number of 3. As boundary conditions we use the Neumann conditions

$$\nabla u = g = \begin{cases} -10(\frac{1}{4} - 2x): & \Gamma_I := \{x \in \partial\Omega \,|\, x_0 = 0 \text{ and } \|x\|^2 < \frac{1}{4}\}, \\ 0: & \Gamma_O := \partial\Omega \setminus \Gamma_I \end{cases}$$

to simulate heat-introduction into the material at the contact points Γ_I to a heat source and outflow conditions on the remaining boundary Γ_O.

We use a $\text{Halton}_0^{4095}(2,3,5)$ set distributed in the bounding box $R_\Omega := (0,1)^3$ as the initial point set P for our cover construction. The local approximation spaces $V_i^{p_i}$

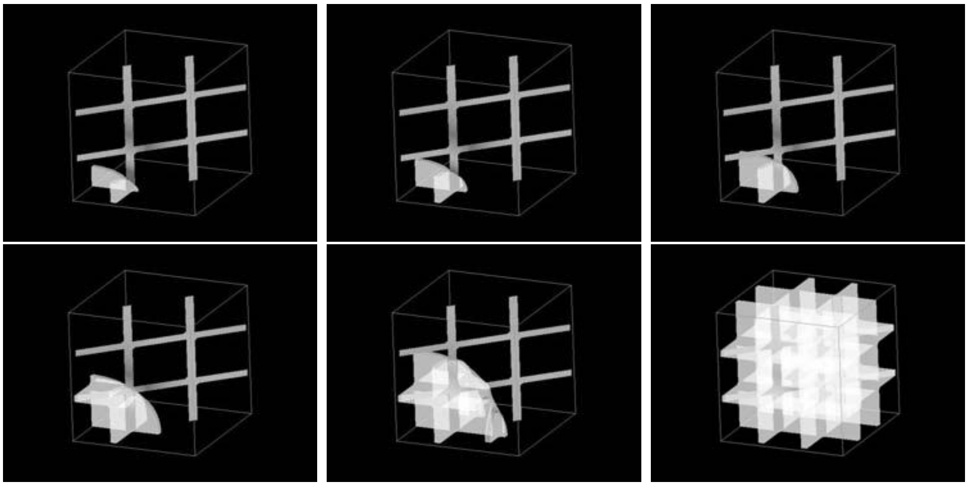

FIG. 7.2. *Isosurfaces of approximate solution and diagonal slice through lattice domain.*

that are assigned to the 5187 patches which overlap the computational domain Ω are quadratic Legendre polynomials. In Figure 7.2 some isosurfaces of the computed solution and a diagonal slice through the material are displayed. From these illustrations we observe the heat-introduction into the material at the contact points Γ_I and the heat-propagation through the material. We clearly see the expected radial shape of the isosurfaces due to the prescribed profile of the Neumann boundary conditions on Γ_I.

8. Concluding remarks. We presented a meshfree Galerkin method for the discretization of a PDE. The method is based on the PU approach and utilizes a novel tree-based cover construction algorithm. The introduction of this algorithm for the cover construction problem and the presented numerical quadrature scheme—both of which are applicable to general domains—improve the computational efficiency during the assembly of the stiffness matrix substantially.

The results of our numerical experiments showed the exponential convergence of the p-version of our PUM for smooth solutions and the anticipated algebraic convergence of the h-version in two and three dimensions. Furthermore, we applied our PUM to the heat conduction problem in lattice materials. Although these examples are still of academic nature, we believe that the substantial improvement of the computation efficiency due to the ideas and algorithms presented in this paper makes the treatment of real world problems with meshfree Galerkin methods seizable in the near future, at least for Neumann boundary conditions. The implementation of Dirichlet boundary conditions in MMs is in general a challenging problem which needs further investigation.

The presented hierarchical cover construction algorithm not only reduces the computational costs significantly but also introduces a hierarchy on the PUM function space. This may be exploited in the development of multilevel solvers [14]. The parallelization of our PUM [15] may be simplified by the tree-based cover construction. Here, we can apply a space filling curves parallelization approach [6] which allows for a cheap dynamic load balancing strategy.

NAVIER–STOKES EQUATIONS IN ROTATION FORM: A ROBUST MULTIGRID SOLVER FOR THE VELOCITY PROBLEM*

MAXIM A. OLSHANSKII† AND ARNOLD REUSKEN‡

Abstract. The topic of this paper is motivated by the Navier–Stokes equations in *rotation* form. Linearization and application of an implicit time stepping scheme results in a linear stationary problem of Oseen type. In well-known solution techniques for this problem such as the Uzawa (or Schur complement) method, a subproblem consisting of a coupled nonsymmetric system of linear equations of diffusion-reaction type must be solved to update the velocity vector field. In this paper we analyze a standard finite element method for the discretization of this coupled system, and we introduce and analyze a multigrid solver for the discrete problem. Both for the discretization method and the multigrid solver the question of robustness with respect to the amount of diffusion and variation in the convection field is addressed. We prove stability results and discretization error bounds for the Galerkin finite element method. We present a convergence analysis of the multigrid method which shows the robustness of the solver. Results of numerical experiments are presented which illustrate the stability of the discretization method and the robustness of the multigrid solver.

1. Introduction.

The incompressible Navier–Stokes problem written in velocity-pressure variables has several equivalent formulations. Very popular is the *convection* form of the problem: find velocity $\mathbf{u}(t,\mathbf{x})$ and kinematic pressure $p(t,\mathbf{x})$ such that

$$\begin{aligned} \frac{\partial \mathbf{u}}{\partial t} - \nu\Delta\mathbf{u} + (\mathbf{u}\cdot\nabla)\mathbf{u} + \nabla p = \mathbf{f} \quad &\text{in} \quad \Omega\times(0,T], \\ \operatorname{div}\mathbf{u} = 0 \quad &\text{in} \quad \Omega\times(0,T], \end{aligned} \tag{1.1}$$

with given force field $\mathbf{f}$ and viscosity $\nu > 0$. Suitable boundary and initial conditions have to be added to (1.1). One alternative to (1.1) is the *rotation* form of the Navier–Stokes problem:

$$\begin{aligned} \frac{\partial \mathbf{u}}{\partial t} - \nu\Delta\mathbf{u} + (\operatorname{curl}\mathbf{u})\times\mathbf{u} + \nabla P = \mathbf{f} \quad &\text{in} \quad \Omega\times(0,T], \\ \operatorname{div}\mathbf{u} = 0 \quad &\text{in} \quad \Omega\times(0,T], \end{aligned} \tag{1.2}$$

which results from (1.1) after replacing the kinematic pressure by the Bernoulli (or dynamic, or total; cf., e.g., [18]) pressure $P = p + \frac{1}{2}\mathbf{u}\cdot\mathbf{u}$ and using the identity $(\mathbf{u}\cdot\nabla)\mathbf{u} = (\operatorname{curl}\mathbf{u})\times\mathbf{u} + \frac{1}{2}\nabla(\mathbf{u}\cdot\mathbf{u})$. In the three-dimensional case × stands for the vector product and $\operatorname{curl}\mathbf{u} := \nabla\times\mathbf{u}$. In two dimensions, $\operatorname{curl}\mathbf{u} := -\frac{\partial u_1}{\partial x_2} + \frac{\partial u_2}{\partial x_1}$ and

$a \times \mathbf{u} := (-au_2, au_1)^T$ for a scalar a. Linearization and application of an implicit time stepping scheme to (1.2) results in an Oseen-type problem in which the equations are of the form

$$\begin{aligned} -\nu\Delta\mathbf{u} + \mathbf{w}\times\mathbf{u} + \alpha\mathbf{u} + \nabla P = \mathbf{f} \quad &\text{in} \quad \Omega \\ \operatorname{div}\mathbf{u} = 0 \quad &\text{in} \quad \Omega, \end{aligned} \tag{1.3}$$

with $\alpha \geq 0$ and $\mathbf{w} = \operatorname{curl}\mathbf{a}$, where $\mathbf{a}$ is a known approximation of $\mathbf{u}$. Note that the above linearization of $(\operatorname{curl}\mathbf{u})\times\mathbf{u}$ ensures the ellipticity of (1.3) in a certain sense (cf. section 2). One strategy to solve (1.3) is an Uzawa-type algorithm, in which a Schur complement problem $\mathbf{S}_{\mathrm{rot}}P = \tilde{\mathbf{g}}$ for the pressure has to be solved. The Schur complement operator has the formal representation $\mathbf{S}_{\mathrm{rot}} = -\operatorname{div}(-\nu\Delta + \mathbf{w}\times + \alpha I)^{-1}\nabla$. The operator $(-\nu\Delta + \mathbf{w}\times + \alpha I)^{-1}$ in this Schur complement is the solution operator of the problem

$$\begin{aligned} -\nu\Delta\mathbf{u} + \mathbf{w}\times\mathbf{u} + \alpha\mathbf{u} = \mathbf{f} \quad &\text{in} \quad \Omega, \\ \mathbf{u} = 0 \quad &\text{on} \quad \partial\Omega, \end{aligned} \tag{1.4}$$

where, for simplicity, we used homogeneous Dirichlet boundary conditions. The exact solution of (1.4) can be replaced by a suitable approximation like in the inexact Uzawa method [3] or in block preconditioners for (1.3) (see, e.g., [11], [19]).

Linearization and application of an implicit time stepping scheme to the convection form (1.1) result in equations as in (1.3) with $\mathbf{w}\times\mathbf{u}$ replaced by $(\mathbf{a}\cdot\nabla)\mathbf{u}$. The Uzawa technique applied to this linear stationary problem for $\mathbf{u}$ and p corresponds to a Schur complement problem with operator $\mathbf{S}_{\mathrm{conv}} = -\operatorname{div}(-\nu\Delta + \mathbf{a}\cdot\nabla + \alpha I)^{-1}\nabla$. The operator $(-\nu\Delta + \mathbf{a}\cdot\nabla + \alpha I)^{-1}$ in this Schur complement is the solution operator of decoupled convection-diffusion(-reaction) problems. Hence in this approach an efficient solver for convection-diffusion equations is of major importance. In the setting of this paper we are particularly interested in finite element discretization methods and multigrid solvers for the discrete problem. There is extensive literature on these solution techniques for convection-diffusion problems; see, e.g., [1], [4], [9], [14], [15], [16], [20], [21], [23], and the references therein. Important topics are appropriate stabilization techniques for the finite element discretization and robustness of the multigrid solvers for convection dominated problems.

In this paper we study the problem (1.4), which can be seen as the counterpart, for the Navier–Stokes equations in rotation form, of the convection-diffusion problems that correspond to the Navier–Stokes problem in convection form. Note that, opposite to the convection-diffusion problems, the problem (1.4) is a coupled system. In this paper we restrict ourselves to the two-dimensional case, since for this case we are able to give complete error analyses for a finite element discretization and a multigrid solver. However, the methodology (see [12]) and all multigrid tools can be extended to the three-dimensional case as well. We allow $\alpha = 0$, which corresponds to the linearization of a *stationary* Navier–Stokes problem in rotation form. We will prove that, under certain reasonable assumptions on the rotation function $\mathbf{w}$, the standard Galerkin finite element discretization method, without any stabilization, is a useful method (see Theorem 3.2 and Remark 3.2). The bounds for the discretization error that are shown to hold are similar to finite element error bounds for scalar linear *reaction-diffusion* problems (as, e.g., in [17], [22]). We consider a multigrid solver for the discrete problem that results from the Galerkin discretization of (1.4) with standard conforming finite elements. It is proved that a multigrid W-cycle method with a canonical prolongation and restriction and a block Richardson smoother is a robust solver for this problem, in the sense that its contraction number (in the Euclidean norm) is bounded by a constant smaller than one independent of all relevant parameters. Although to prove a robust convergence of the multigrid method we need more restrictive assumptions on $\mathbf{w}$, numerical experiments demonstrate good performance of the method, even if such assumptions do not hold. Such a theoretical robustness result is not known for multigrid applied to convection-diffusion problems. Moreover, in the multigrid solver we do not need so-called robust smoothers or matrix-dependent prolongations and restrictions, which are believed to be important for robustness of multigrid applied to convection-diffusion problems. We will show results of numerical experiments that illustrate the stability of the discretization method and the robustness of the multigrid solver. Both in the analysis and the numerical experiments it can be observed that the problem (1.4) resembles a scalar reaction-diffusion problem. Note that from the numerical solution point of view reaction-diffusion equations are believed to be simpler than convection-diffusion equations.

Recently, in [12], a new preconditioning technique for a discretization of the Schur complement operator $\mathbf{S}_{\text{rot}}$ has been introduced, which has good robustness properties with respect to variation in ν and in the mesh size parameter. In this paper we consider only the inner solution operator that appears in the Schur complement operator. Of course, a stabilization may be needed in the outer iterations for (1.3). This subject is addressed in [10], where it is shown that a Petrov–Galerkin-type stabilization method for (1.3) yields optimal error bounds. The possible impact to (1.4) of additional terms resulting from stabilized finite element method for (1.3) is not considered in this paper. Generally, such terms enhance ellipticity of (1.4).

The results in [12], [10], and in the present paper show that for the application of coupled (pressure-velocity) solvers and implicit schemes the rotation form of the Navier–Stokes equations has interesting advantages compared to the convection form. Some numerical experiments with a low order finite element method for rotation form of the incompressible Navier–Stokes equations and comparision with the convection form can be found in [13]. However, relatively little is known about the numerical solution of the Navier–Stokes equations in rotation form, and we believe that this topic deserves further research.

The remainder of the paper is organized as follows. In section 2 notation and assumptions are introduced. Furthermore, continuity and regularity results for the continuous problem are proved. In section 3 the finite element method is treated. We prove discretization error bounds in a problem dependent norm and in the L_2-norm. In section 4 a multigrid solver for the discrete problem is introduced. A convergence analysis is presented that is based on smoothing and approximation properties. In section 5 we show results of a few numerical experiments.

2. Preliminaries and a priori estimates.

Let Ω be a convex polygonal domain in $\mathbb{R}^2$. This assumption on Ω will be needed to obtain sufficient regularity, which strongly simplifies the multigrid convergence theory based on the smoothing and approximation property. However, multigrid methods are known to preserve their typical fast convergence, if this assumption is violated.

By $(\cdot,\cdot)$ and $\|\cdot\|$ we denote the scalar product and the corresponding norm in $L_2(\Omega)^n, n = 1, 2$. The standard norm in the Sobolev space $H^k(\Omega)^2$ is denoted by $\|\cdot\|_k$. For $\mathbf{u} = (u_1, u_2)$, $\mathbf{v} = (v_1, v_2) \in L_2(\Omega)^2$ we have $(\mathbf{u}, \mathbf{v}) = (u_1, v_1) + (u_2, v_2)$. The norm on the space $L_\infty(\Omega)$ is denoted by $\|\cdot\|_\infty$.

For a scalar a and vector $\mathbf{v}$ we define the vector product $a \times \mathbf{v} := (-av_2, av_1)^T$.

We consider the variational formulation of (1.4) in the two-dimensional case: for given $\nu > 0,\ \alpha > 0,\ w \in L_\infty(\Omega),\ \mathbf{f} \in L_2(\Omega)^2$, determine $\mathbf{u} \in \mathbf{U} := H_0^1(\Omega)^2$ such that

$$a(\mathbf{u}, \mathbf{v}) = (\mathbf{f}, \mathbf{v}) \quad \text{for all } \mathbf{v} \in \mathbf{U}, \tag{2.1}$$

where

$$a(\mathbf{u}, \mathbf{v}) = \nu(\nabla \mathbf{u}, \nabla \mathbf{v}) + \alpha(\mathbf{u}, \mathbf{v}) + (w \times \mathbf{u}, \mathbf{v}) \quad \text{for } \mathbf{u}, \mathbf{v} \in \mathbf{U}.$$

Here we use the notation $(\nabla \mathbf{u}, \nabla \mathbf{v}) := \sum_{i=1}^2 (\nabla u_i, \nabla v_i) = \sum_{i,j=1}^2 (\frac{\partial u_i}{\partial x_j}, \frac{\partial v_i}{\partial x_j})$.

Throughout the paper we use C to denote some generic strictly positive constant independent of ν, α, and w .

The definition of the vector product implies $(w \times \mathbf{u}, \mathbf{v}) = -(w \times \mathbf{v}, \mathbf{u})$ for all $\mathbf{u}, \mathbf{v} \in L_2(\Omega)^2$, and thus the bilinear form $a(\cdot, \cdot)$ is elliptic:

$$C\,\nu \|\mathbf{u}\|_1^2 \le a(\mathbf{u}, \mathbf{u}) \quad \text{for all } \mathbf{u} \in \mathbf{U}\ .$$

Using $\|w \times \mathbf{u}\| \le \|w\|_\infty \|\mathbf{u}\|$ we obtain the continuity of the bilinear form:

$$a(\mathbf{u}, \mathbf{v}) \le (\nu + \alpha + \|w\|_\infty)\|\mathbf{u}\|_1 \|\mathbf{v}\|_1 \quad \text{for all } \mathbf{u}, \mathbf{v} \in \mathbf{U}. \tag{2.2}$$

From the Lax–Milgram lemma it follows that the variational problem (2.1) has a unique solution.

For the analysis below we introduce a parameter dependent norm on $\mathbf{U}$:

$$|||\mathbf{u}|||_\tau = \left(\nu\|\nabla \mathbf{u}\|^2 + \alpha\|\mathbf{u}\|^2 + \frac{\tau}{\|w\|_\infty}\|w \times \mathbf{u}\|^2\right)^{\frac{1}{2}}, \quad \tau \ge 0.$$

If $w = 0$, then the third term on the right-hand side is dropped. The constant appearing in the Friedrichs inequality is denoted by C_F:

$$\|\varphi\| \le C_F \|\nabla \varphi\| \quad \text{for all } \varphi \in H_0^1(\Omega).$$

The domain Ω is such that for any $g \in L_2(\Omega)$ the solution of the variational problem

$$\text{find } \varphi \in H_0^1(\Omega) \text{ such that } (\nabla \varphi, \nabla v) = (g, v) \ \text{ for all } \ v \in H_0^1(\Omega) \tag{2.3}$$

is an element of $H^2(\Omega)$ and satisfies the regularity estimate $\|\varphi\|_2 \le C_P \|g\|$.

For the analysis in the remainder of this paper the following three conditions are formulated. We denote $c_w := \text{ess inf}_\Omega |w|$.

(A1) Condition (A1) is satisfied if $\alpha + c_w > 0$ and

$$\eta := \frac{\|w\|_\infty}{\alpha + c_w} \le C.$$

(A2) Condition (A2) is satisfied if

$$w(\mathbf{x}) \ge 0 \text{ a.e. in } \Omega \ \text{ or } w(\mathbf{x}) \le 0 \text{ a.e. in } \Omega.$$

(A3) Condition (A3) is fulfilled if $\nabla w \in L_q(\Omega)^2$ for some $q > 2$ and

$$\|\nabla w\|_{L_q} \le C\, \|w\|_\infty.$$

If w is a finite element function, then C is assumed to be independent of h.

In the analysis below it will be explicitly stated which of these conditions are assumed.

Remark 2.1. (A2) holds, for example, if w stems from the effect of Coriolis forces (cf., e.g., [6]); (A1) holds if w is continuous and does not have any zeros in Ω or if in a time stepping scheme we have lower bound for α: $0 < \alpha_{\min} \leq \alpha$. □

Note that $(|w|\mathbf{u}, \mathbf{u}) = (|w| \times \mathbf{u}, 1 \times \mathbf{u}) \geq 0$, and thus we have for $\mathbf{u} \in L_2(\Omega)^2$

$$c_w \|\mathbf{u}\|^2 \leq (|w| \times \mathbf{u}, 1 \times \mathbf{u}). \tag{2.4}$$

Using $(|w| \times \mathbf{u}, 1 \times \mathbf{u}) \leq \||w| \times \mathbf{u}\|\|1 \times \mathbf{u}\| = \|w \times \mathbf{u}\|\|\mathbf{u}\|$ we get

$$(\alpha + c_w)\|\mathbf{u}\| \leq \|w \times \mathbf{u}\| + \alpha\|\mathbf{u}\|. \tag{2.5}$$

The inequalities (2.4) and (2.5) are used in the analysis below.

2.1. Analysis of the continuous problem. In this section we will derive a regularity result (Theorem 2.1) and a continuity result (Lemma 2.2). In the latter, opposite to the result in (2.2), the problem dependent norm $|||\cdot|||_\tau$ is used. The continuity result is used in the derivation of the discretization error bounds in section 3.

THEOREM 2.1. *For* $\mathbf{f} \in L_2(\Omega)^2$ *let* $\mathbf{u} \in \mathbf{U}$ *be the solution of problem* (2.1). *Then* $\mathbf{u}$ *is an element of* $H^2(\Omega)^2$ *and the estimates*

$$\nu\|\nabla\mathbf{u}\|^2 + \alpha\|\mathbf{u}\|^2 \leq c(\nu, \alpha)\|\mathbf{f}\|^2 \ , \tag{2.6}$$

$$\nu^2\|\mathbf{u}\|_2^2 + C_P^2\|w \times \mathbf{u}\|^2 \leq 2C_P^2\big(4 + 2c(\nu, \alpha)^2\|w\|_\infty^2\big)\|\mathbf{f}\|^2 \tag{2.7}$$

hold, with $c(\nu, \alpha) = \frac{C_F^2}{\nu + C_F^2\alpha}$. *If conditions* (A1) *and* (A3) *are satisfied, then*

$$\nu^2\|\mathbf{u}\|_2^2 + \nu(\|w\|_\infty + \alpha)\|\nabla\mathbf{u}\|^2 + \alpha^2\|\mathbf{u}\|^2 + \|w \times \mathbf{u}\|^2 \leq C\|\mathbf{f}\|^2 \tag{2.8}$$

with a constant C *independent of* $\mathbf{f}$, ν, α, *and* w.

Proof. Define $\tilde{\mathbf{f}} = \mathbf{f} - w \times \mathbf{u} - \alpha\mathbf{u}$. Note that $\tilde{\mathbf{f}} \in L_2(\Omega)^2$ and $(\nabla\mathbf{u}, \nabla\mathbf{v}) = -\frac{1}{\nu}(\tilde{\mathbf{f}}, \mathbf{v})$ for all $\mathbf{v} \in \mathbf{U}$. Hence, due to the regularity result for the Poisson equation (2.3), we have $\mathbf{u} \in H^2(\Omega)^2$ and

$$\|\mathbf{u}\|_2 \leq \frac{C_P}{\nu}\|\tilde{\mathbf{f}}\| \leq \frac{C_P}{\nu}(\|\mathbf{f}\| + \|w \times \mathbf{u}\| + \alpha\|\mathbf{u}\|). \tag{2.9}$$

Note that $\|\mathbf{u}\|^2 = c(\nu, \alpha)(\nu C_F^{-2} + \alpha)\|\mathbf{u}\|^2 \leq c(\nu, \alpha)(\nu\|\nabla\mathbf{u}\|^2 + \alpha\|\mathbf{u}\|^2)$. Using this and taking $\mathbf{v} = \mathbf{u}$ in (2.1) we get

$$\nu\|\nabla\mathbf{u}\|^2 + \alpha\|\mathbf{u}\|^2 \leq \|\mathbf{f}\|\|\mathbf{u}\| \leq \|\mathbf{f}\|c(\nu, \alpha)^{\frac{1}{2}}(\nu\|\nabla\mathbf{u}\|^2 + \alpha\|\mathbf{u}\|^2)^{\frac{1}{2}}, \tag{2.10}$$

and thus the result in (2.6) holds. We also have, using (2.6),

$$\|w \times \mathbf{u}\|^2 \leq \|w\|_\infty^2\|\mathbf{u}\|^2 \leq c(\nu, \alpha)\|w\|_\infty^2(\nu\|\nabla\mathbf{u}\|^2 + \alpha\|\mathbf{u}\|^2) \leq c(\nu, \alpha)^2\|w\|_\infty^2\|\mathbf{f}\|^2. \tag{2.11}$$

Combining this estimate with (2.9), and noting that $\alpha\|\mathbf{u}\| \leq \|\mathbf{f}\|$, yields

$$\begin{aligned}\nu^2\|\mathbf{u}\|_2^2 + C_P^2\|w \times \mathbf{u}\|^2 &\leq C_P^2(\|\mathbf{f}\| + c(\nu, \alpha)\|w\|_\infty\|\mathbf{f}\| + \|\mathbf{f}\|)^2 + C_P^2 c(\nu, \alpha)^2\|w\|_\infty^2\|\mathbf{f}\|^2 \\ &= C_P^2((2 + c(\nu, \alpha)\|w\|_\infty)^2 + c(\nu, \alpha)^2\|w\|_\infty^2)\|\mathbf{f}\|^2 \\ &\leq 2C_P^2(3 + 2c(\nu, \alpha)^2\|w\|_\infty^2)\|\mathbf{f}\|^2,\end{aligned}$$

and thus the estimate (2.7) is proved.

Now assume the conditions (A1) and (A3) to be valid. Since $\mathbf{f} \in L_2(\Omega)^2$ and $\mathbf{u} \in H^2(\Omega)^2$, (1.4) is satisfied in a strong sense, and thus $\|-\nu\Delta\mathbf{u}+\alpha\mathbf{u}+w\times\mathbf{u}\| = \|\mathbf{f}\|$ holds. Taking the square of this identity and noting that $(\mathbf{u}, w \times \mathbf{u}) = 0$ results in

$$\nu^2\|\Delta\mathbf{u}\|^2 + 2\nu\alpha\|\nabla\mathbf{u}\|^2 + \alpha^2\|\mathbf{u}\|^2 + 2\nu(\nabla\mathbf{u}, \nabla(w\times\mathbf{u})) + \|w\times\mathbf{u}\|^2 = \|\mathbf{f}\|^2. \tag{2.12}$$

A simple computation yields $(\nabla\mathbf{u}, \nabla(w \times \mathbf{u})) = -(\nabla u_1, u_2\nabla w) + (\nabla u_2, u_1\nabla w)$ and

$$|(\nabla\mathbf{u}, \nabla(w\times\mathbf{u}))| \le \|\nabla\mathbf{u}\|(\|u_1\nabla w\|^2 + \|u_2\nabla w\|^2)^{\frac{1}{2}}. \tag{2.13}$$

Take q as in (A3) and define $\tilde{q} = \frac{1}{2}q$. The Hölder inequality with $\frac{1}{p} + \frac{1}{\tilde{q}} = 1$ and the injection $H_1(\Omega) \hookrightarrow L_{2p}(\Omega)$ yields, for $i = 1, 2$,

$$\begin{aligned} \|u_i\nabla w\| = (u_i^2, \nabla w\cdot\nabla w)^{\frac{1}{2}} &\le \|u_i\|_{L_{2p}}\|\nabla w\cdot\nabla w\|_{L_{\tilde{q}}}^{\frac{1}{2}} \\ &\le C\|\nabla u_i\|\|\nabla w\|_{L_q} \le C\|\nabla u_i\|\|w\|_\infty. \end{aligned} \tag{2.14}$$

In the last inequality in (2.14) we used (A3). The combination of (2.13) and (2.14) yields

$$2\nu|(\nabla\mathbf{u}, \nabla(w\times\mathbf{u}))| \le \bar{c}\,\nu\|w\|_\infty\,\|\nabla\mathbf{u}\|^2.$$

From this result and (2.12) we obtain

$$\nu^2\|\Delta\mathbf{u}\|^2 + 2\nu\alpha\|\nabla\mathbf{u}\|^2 + \alpha^2\|\mathbf{u}\|^2 + \|w\times\mathbf{u}\|^2 \le \|\mathbf{f}\|^2 + \bar{c}\,\nu\|w\|_\infty\,\|\nabla\mathbf{u}\|^2. \tag{2.15}$$

From (2.1) and (2.5) it follows that, for $\delta > 0$,

$$\begin{aligned} \nu\|\nabla\mathbf{u}\|^2 \le \|\mathbf{f}\|\,\|\mathbf{u}\| &= \frac{1}{\sqrt{\delta}(\alpha+c_w)}\|\mathbf{f}\|\sqrt{\delta}(\alpha+c_w)\|\mathbf{u}\| \\ &\le \frac{\|\mathbf{f}\|^2}{2\delta(\alpha+c_w)^2} + \delta(\alpha^2\|\mathbf{u}\|^2 + \|w\times\mathbf{u}\|^2). \end{aligned} \tag{2.16}$$

If we set $\delta = (4\,\bar{c}\,\|w\|_\infty)^{-1}$ and multiply (2.16) with $\frac{1}{2\delta}$ we obtain

$$2\bar{c}\nu\|w\|_\infty\|\nabla\mathbf{u}\|^2 \le \bar{c}^2\frac{\|w\|_\infty^2}{(\alpha+c_w)^2}\|\mathbf{f}\|^2 + \frac{1}{2}\alpha^2\|\mathbf{u}\|^2 + \frac{1}{2}\|w\times\mathbf{u}\|^2\ .$$

Adding this to (2.15) yields

$$\begin{aligned} &\nu^2\|\Delta\mathbf{u}\|^2 + \nu(\bar{c}\|w\|_\infty + 2\alpha)\|\nabla\mathbf{u}\|^2 + \alpha^2\|\mathbf{u}\|^2 + \|w\times\mathbf{u}\|^2 \\ &\quad\le \Big(1 + \bar{c}^2\frac{\|w\|_\infty^2}{(\alpha+c_w)^2}\Big)\|\mathbf{f}\|^2 + \frac{1}{2}\alpha^2\|\mathbf{u}\|^2 + \frac{1}{2}\|w\times\mathbf{u}\|^2. \end{aligned}$$

Using assumption (A1), i.e., $\frac{\|w\|_\infty^2}{(\alpha+c_w)^2} = \eta^2 \le C$ and $\|\mathbf{u}\|_2 \le C_P\|\Delta\mathbf{u}\|$, the result in (2.8) follows. □

Note that in (2.6) and (2.7) with $\alpha = 0$ we have regularity estimates of the form $\|\mathbf{u}\|_1 = O(\nu^{-1})$ and $\|\mathbf{u}\|_2 = O(\nu^{-2})$, which show a similar behavior as regularity results for convection-diffusion problems of the form $-\nu\Delta u + \mathbf{a}\cdot\nabla u = f$ (cf. [16]). The result in (2.8), which holds if conditions (A1) and (A3) are satisfied, yields regularity estimates of the form $\|\mathbf{u}\|_1 = O(\nu^{-1/2})$ and $\|\mathbf{u}\|_2 = O(\nu^{-1})$. These bounds show a behavior that is typical for the solution of reaction-diffusion problems of the form $-\nu\Delta u + bu = f$ if $b > 0$ (cf. [17]). In section 4.2 the regularity result (2.8) will be used in the convergence analysis of the multigrid method.

Lemma 2.2. *Take $\tau > 0$. The following holds:*

$$a(\mathbf{v},\mathbf{u}) \le C_\tau\, |||\mathbf{v}|||_\tau \Big(\nu\|\nabla\mathbf{u}\|^2 + (\alpha + \|w\|_\infty)\|\mathbf{u}\|^2\Big)^{\frac{1}{2}} \quad \textit{for all } \mathbf{v},\mathbf{u} \in \mathbf{U}. \tag{2.17}$$

If condition (A1) *is satisfied, then*

$$a(\mathbf{v},\mathbf{u}) \le C_\tau\, |||\mathbf{v}|||_\tau\, |||\mathbf{u}|||_\tau \quad \textit{for all } \mathbf{v},\mathbf{u} \in \mathbf{U}. \tag{2.18}$$

The constants C_τ may depend on τ.

Proof. For $\mathbf{v},\mathbf{u} \in \mathbf{U}$ we have

$$\begin{aligned} a(\mathbf{v},\mathbf{u}) &= \nu(\nabla\mathbf{v},\nabla\mathbf{u}) + \alpha(\mathbf{v},\mathbf{u}) + (w \times \mathbf{v},\mathbf{u}) \\ &\le \nu\|\nabla\mathbf{v}\|\|\nabla\mathbf{u}\| + \alpha\|\mathbf{v}\|\|\mathbf{u}\| + \|w \times \mathbf{v}\|\|\mathbf{u}\|. \end{aligned} \tag{2.19}$$

We define $\kappa := \tau\|w\|_\infty^{-1}$. If we use $\|w \times \mathbf{v}\|\|\mathbf{u}\| = (\kappa^{\frac{1}{2}}\|w \times \mathbf{v}\|)(\kappa^{-\frac{1}{2}}\|\mathbf{u}\|)$ and apply the Cauchy–Schwarz inequality in (2.19) we obtain

$$\begin{aligned} a(\mathbf{v},\mathbf{u}) &\le \Big(\nu\|\nabla\mathbf{v}\|^2 + \alpha\|\mathbf{v}\|^2 + \kappa\|w \times \mathbf{v}\|^2\Big)^{\frac{1}{2}} \Big(\nu\|\nabla\mathbf{u}\|^2 + \alpha\|\mathbf{u}\|^2 + \kappa^{-1}\|\mathbf{u}\|^2\Big)^{\frac{1}{2}} \\ &\le C_\tau|||\mathbf{v}|||_\tau\Big(\nu\|\nabla\mathbf{u}\|^2 + (\alpha + \|w\|_\infty)\|\mathbf{u}\|^2\Big)^{\frac{1}{2}}, \end{aligned} \tag{2.20}$$

and thus the result in (2.17) holds. If condition (A1) is satisfied we get, using (2.5),

$$\begin{aligned} \|w \times \mathbf{v}\|\,\|\mathbf{u}\| &\le \|w \times \mathbf{v}\|\frac{1}{\alpha + c_w}(\alpha\|\mathbf{u}\| + \|w \times \mathbf{u}\|) \\ &\le \kappa^{\frac{1}{2}}\|w \times \mathbf{v}\|\frac{\kappa^{-\frac{1}{2}}(\alpha^{\frac{1}{2}} + \kappa^{-\frac{1}{2}})}{\alpha + c_w}(\alpha^{\frac{1}{2}}\|\mathbf{u}\| + \kappa^{\frac{1}{2}}\|w \times \mathbf{u}\|) \\ &\le C_\tau(\kappa^{\frac{1}{2}}\|w \times \mathbf{v}\|)(\alpha\|\mathbf{u}\|^2 + \kappa\|w \times \mathbf{u}\|^2)^{\frac{1}{2}}. \end{aligned} \tag{2.21}$$

In the last inequality in (2.21) we used condition (A1):

$$\frac{\kappa^{-\frac{1}{2}}(\alpha^{\frac{1}{2}} + \kappa^{-\frac{1}{2}})}{\alpha + c_w} \le \frac{\frac{3}{2}\kappa^{-1} + \frac{1}{2}\alpha}{\alpha + c_w} \le \frac{3}{2\tau}\eta + \frac{\alpha}{2(\alpha + c_w)} \le C_\tau.$$

From the results in (2.19), (2.21), and the Cauchy–Schwarz inequality, we obtain (2.18). □

3. Finite element method.

In this section we apply a standard finite element method to the problem (2.1) and derive bounds for the discretization error.

Let $(\mathcal{T}_h)$ be a quasi-uniform family of triangulations of Ω, with mesh size parameter h, and $\mathbf{U}_h \subset \mathbf{U}$ be a finite element subspace of $\mathbf{U}$, consisting of piecewise polynomials of degree $k \in \mathbb{N}$. The finite element Galerkin discretization of the problem (2.1) is as follows: Find $\mathbf{u}_h \in \mathbf{U}_h$ such that

$$a(\mathbf{u}_h,\mathbf{v}_h) = (\mathbf{f},\mathbf{v}_h) \quad \text{for all } \mathbf{v}_h \in \mathbf{U}_h. \tag{3.1}$$

To measure the effect of different terms in (1.4) we introduce mesh numbers:[1]

$$\mathrm{Ek}_h = \frac{\nu}{\|w\|_\infty h^2}, \qquad \mathrm{D}_h = \frac{\alpha h^2}{\nu}.$$

First we prove the stability of $a(\mathbf{u},\mathbf{v})$ on $\mathbf{U}_h$. Below we use the inverse inequality

$$\|\nabla \mathbf{v}_h\| < \mu_u h^{-1}\|\mathbf{v}_h\| \quad \text{for all } \ \mathbf{v}_h \in \mathbf{U}_h.$$

The L_2-orthogonal projection $\mathrm{P}_h : L_2(\Omega)^2 \to \mathbf{U}_h$ is defined by

$$(\mathrm{P}_h\mathbf{u},\mathbf{v}_h) = (\mathbf{u},\mathbf{v}_h) \quad \text{for all } \mathbf{v}_h \in \mathbf{U}_h. \tag{3.2}$$

We will assume the following approximation property of the spaces $\mathbf{U}_h$ (cf., e.g., [5]): their exists interpolation operator $I_h : \mathbf{U} \to \mathbf{U}_h$ such that

$$\|\mathbf{u} - I_h\mathbf{u}\| \le Ch^m\|\mathbf{u}\|_m, \quad m = 0,1,2 \quad \text{for } \mathbf{u} \in \mathbf{U}\cap H^m(\Omega)^2, \tag{3.3}$$

$$\|\mathbf{u} - I_h\mathbf{u}\|_1 \le Ch^{m-1}\|\mathbf{u}\|_m, \quad m = 1,2 \quad \text{for } \mathbf{u} \in \mathbf{U}\cap H^m(\Omega)^2. \tag{3.4}$$

In (3.3) we use the notation $H^0(\Omega)^2 := L_2(\Omega)^2$ and $\|\cdot\|_0 := \|\cdot\|$.

Lemma 3.1. *Assume that conditions* (A1) *and* (A2) *are fulfilled. If* $\mathrm{Ek}_h > 1$ *and* $\mathrm{D}_h < 1$, *condition* (A3) *is also assumed. Then there exists some* $\tau \in (0,1]$ *such that*

$$\inf_{\mathbf{u}_h\in\mathbf{U}_h}\ \sup_{\mathbf{v}_h\in\mathbf{U}_h} \frac{a(\mathbf{u}_h,\mathbf{v}_h)}{|||\mathbf{u}_h|||_\tau\, |||\mathbf{v}_h|||_\tau} \ge C > 0. \tag{3.5}$$

Proof. Take a fixed $\mathbf{u}_h \in \mathbf{U}_h$. Note that

$$\begin{aligned}(w\times\mathbf{u}_h, \mathrm{P}_h(w\times\mathbf{u}_h)) &= (\mathrm{P}_h(w\times\mathbf{u}_h), \mathrm{P}_h(w\times\mathbf{u}_h)),\\ (\mathbf{u}_h, \mathrm{P}_h(w\times\mathbf{u}_h)) &= 0.\end{aligned}$$

Using (2.4) and condition (A2) it follows that

$$\begin{aligned}c_w\|\mathbf{u}_h\|^2 &\le (|w|\times\mathbf{u}_h, 1\times\mathbf{u}_h) = (\mathrm{P}_h(|w|\times\mathbf{u}_h), 1\times\mathbf{u}_h)\\ &= (|\mathrm{P}_h(w\times\mathbf{u}_h)|, 1\times\mathbf{u}_h) \le \|\mathrm{P}_h(w\times\mathbf{u}_h)\|\|\mathbf{u}_h\|,\end{aligned}$$

and thus

$$(\alpha + c_w)\|\mathbf{u}_h\| \le \alpha\|\mathbf{u}_h\| + \|\mathrm{P}_h(w\times\mathbf{u}_h)\|. \tag{3.6}$$

We take

$$\tau = \min\{1, \mu_u^{-2}, \tilde{c}^{-1}\}, \tag{3.7}$$

where $\tilde{c}$ is a constant (independent of all parameters) that will occur in the proof. Let $\kappa := \tau\|w\|_\infty^{-1}$. Using (3.6) we obtain

$$\begin{aligned}\alpha\|\mathbf{u}_h\|^2 + \kappa\|w\times\mathbf{u}_h\|^2 &\le (\alpha + \kappa\|w\|_\infty^2)\|\mathbf{u}_h\|^2\\ &\le \frac{2(\alpha+\kappa\|w\|_\infty^2)}{(\alpha+c_w)^2}(\alpha^2\|\mathbf{u}_h\|^2 + \|\mathrm{P}_h(w\times\mathbf{u}_h)\|^2)\\ &\le \frac{2(\alpha+\kappa\|w\|_\infty^2)(\alpha+\kappa^{-1})}{(\alpha+c_w)^2}(\alpha\|\mathbf{u}_h\|^2 + \kappa\|\mathrm{P}_h(w\times\mathbf{u}_h)\|^2).\end{aligned}$$

[1] The abbreviation and definition of Ek is chosen to be consistent with the definition of the Ekman number in the theory of rotating flows. However, the latter is only a particular case (w = const).

Note that $\tau^{-1}+\tau \le \max\{1,\mu_u^2,\tilde{c}\}+1 \le C$ and thus, using condition (A1),

$$\frac{(\alpha+\kappa\|w\|_\infty^2)(\alpha+\kappa^{-1})}{(\alpha+c_w)^2} = \frac{\alpha^2+(\tau^{-1}+\tau)\alpha\|w\|_\infty+\|w\|_\infty^2}{(\alpha+c_w)^2} \le C\frac{\alpha^2+\|w\|_\infty^2}{(\alpha+c_w)^2} \le C(1+\eta^2) \le C.$$

Hence,

$$\alpha\|\mathbf{u}_h\|^2+\kappa\|w\times\mathbf{u}_h\|^2 \le C(\alpha\|\mathbf{u}_h\|^2+\kappa\|\mathrm{P}_h(w\times\mathbf{u}_h)\|^2). \tag{3.8}$$

To prove (3.5) we choose $\mathbf{v}_h=\mathbf{u}_h+\kappa\mathrm{P}_h(w\times\mathbf{u}_h)$. Then

$$\begin{aligned} a(\mathbf{u}_h,\mathbf{v}_h) &= \nu\|\nabla\mathbf{u}_h\|^2+\alpha\|\mathbf{u}_h\|^2+\nu\kappa(\nabla\mathbf{u}_h,\nabla\mathrm{P}_h(w\times\mathbf{u}_h))+\kappa\|\mathrm{P}_h(w\times\mathbf{u}_h)\|^2 \\ &\ge \nu\|\nabla\mathbf{u}_h\|^2+\alpha\|\mathbf{u}_h\|^2-\nu\kappa\|\nabla\mathbf{u}_h\|\,\|\nabla\mathrm{P}_h(w\times\mathbf{u}_h)\|+\kappa\|\mathrm{P}_h(w\times\mathbf{u}_h)\|^2. \end{aligned} \tag{3.9}$$

For the estimation of the term $\|\nabla\mathrm{P}_h(w\times\mathbf{u}_h)\|$ we distinguish three cases: $\mathrm{Ek}_h\le 1$ (case 1), $\mathrm{D}_h\ge 1$ (case 2), and $\mathrm{Ek}_h>1$ and $\mathrm{D}_h<1$ (case 3).
In case 1 we have

$$\begin{aligned} (\nu\kappa)^{\frac12}\|\nabla\mathrm{P}_h(w\times\mathbf{u}_h)\| &\le \left(\frac{\nu\tau\mu_u^2}{\|w\|_\infty h^2}\right)^{\frac12}\|\mathrm{P}_h(w\times\mathbf{u}_h)\| \\ &= (\mathrm{Ek}_h\tau\mu_u^2)^{\frac12}\|\mathrm{P}_h(w\times\mathbf{u}_h)\| \le \|\mathrm{P}_h(w\times\mathbf{u}_h)\|. \end{aligned} \tag{3.10}$$

Using this in (3.9) and applying the Cauchy–Schwarz inequality, we get

$$a(\mathbf{u}_h,\mathbf{v}_h) \ge \frac12\nu\|\nabla\mathbf{u}_h\|^2+\alpha\|\mathbf{u}_h\|^2+\frac12\kappa\|\mathrm{P}_h(w\times\mathbf{u}_h)\|^2. \tag{3.11}$$

In case 2 we have

$$\begin{aligned} \nu^{\frac12}\kappa\|\nabla\mathrm{P}_h(w\times\mathbf{u}_h)\| &\le \nu^{\frac12}\kappa\mu_u h^{-1}\|w\|_\infty\|\mathbf{u}\| = \tau\mu_u\mathrm{D}_h^{-\frac12}\alpha^{\frac12}\|\mathbf{u}\| \\ &\le \tau^{\frac12}\mu_u\mathrm{D}_h^{-\frac12}\alpha^{\frac12}\|\mathbf{u}\| \le \alpha^{\frac12}\|\mathbf{u}\|. \end{aligned} \tag{3.12}$$

Using this in (3.9) and applying the Cauchy–Schwarz inequality, we get

$$a(\mathbf{u}_h,\mathbf{v}_h) \ge \frac12\nu\|\nabla\mathbf{u}_h\|^2+\frac12\alpha\|\mathbf{u}_h\|^2+\kappa\|\mathrm{P}_h(w\times\mathbf{u}_h)\|^2. \tag{3.13}$$

For case 3 first note that, using condition (A3) and the result in (2.14) it follows that

$$\begin{aligned} \|\nabla(w\times\mathbf{u}_h)\|^2 &= \sum_{i=1}^2 \|(u_h)_i\nabla w\|^2+\|w\nabla(u_h)_i\|^2+2((u_h)_i\nabla w, w\nabla(u_h)_i) \\ &\le 2\sum_{i=1}^2 \|(u_h)_i\nabla w\|^2+\|w\nabla(u_h)_i\|^2 \le c_1\|w\|_\infty^2\|\nabla\mathbf{u}_h\|^2. \end{aligned}$$

We use that the L_2-orthogonal projection is bounded in the H^1-norm (cf. [2]):

$$\|\mathrm{P}_h\mathbf{u}\|_1 \le c_2\|\mathbf{u}\|_1 \qquad \text{for } \mathbf{u}\in\mathbf{U}.$$

For the constant $\tilde{c}$ in (3.7) we take $\tilde{c} = 2c_2\sqrt{c_1}$ and then obtain

$$\kappa\|\nabla \mathrm{P}_h(w \times \mathbf{u}_h)\| \le c_2\kappa\|\nabla(w \times \mathbf{u}_h)\| \le c_2\sqrt{c_1}\kappa\|w\|_\infty\|\nabla\mathbf{u}_h\| \le \frac{1}{2}\|\nabla\mathbf{u}_h\|. \tag{3.14}$$

Using this in (3.9) results in

$$a(\mathbf{u}_h, \mathbf{v}_h) \ge \frac{1}{2}\nu\|\nabla\mathbf{u}_h\|^2 + \alpha\|\mathbf{u}_h\|^2 + \kappa\|\mathrm{P}_h(w \times \mathbf{u}_h)\|^2. \tag{3.15}$$

The combination of (3.11), (3.13), (3.15) with (3.8) proves that

$$a(\mathbf{u}_h, \mathbf{v}_h) \ge C|||\mathbf{u}_h|||_\tau^2 \tag{3.16}$$

holds. The results in (3.10), (3.12), and (3.14) imply

$$\nu\kappa^2\|\nabla\mathrm{P}_h(w \times \mathbf{u}_h)\|^2 \le |||\mathbf{u}_h|||_\tau^2 \ .$$

Using this it follows that

$$\begin{aligned}
|||\mathbf{v}_h|||_\tau^2 &= \nu\|\nabla(\mathbf{u}_h + \kappa\mathrm{P}_h(w \times \mathbf{u}_h))\|^2 + \alpha\|\mathbf{u}_h + \kappa\mathrm{P}_h(w \times \mathbf{u}_h)\|^2 \\
&\quad + \kappa\|\mathrm{P}_h(w \times \mathbf{u}_h + \kappa w \times \mathrm{P}_h(w \times \mathbf{u}_h))\|^2 \\
&\le 2(\nu\|\nabla\mathbf{u}_h\|^2 + \nu\kappa^2\|\nabla\mathrm{P}_h(w \times \mathbf{u}_h)\|^2) + \alpha\|\mathbf{u}_h\|^2 + \kappa^2\alpha\|\mathrm{P}_h(w \times \mathbf{u}_h)\|^2 \\
&\quad + 2\kappa(\|\mathrm{P}_h(w \times \mathbf{u}_h)\|^2 + \kappa^2\|\mathrm{P}_h(w \times \mathrm{P}_h(w \times \mathbf{u}_h))\|^2) \\
&\le 2\nu\|\nabla\mathbf{u}_h\|^2 + 2|||\mathbf{u}_h|||_\tau^2 + \alpha(1+\tau^2)\|\mathbf{u}_h\|^2 + 2\kappa(1+\tau^2)\|\mathrm{P}_h(w \times \mathbf{u}_h)\|^2 \\
&\le 2\nu\|\nabla\mathbf{u}_h\|^2 + 2\alpha\|\mathbf{u}_h\|^2 + 4\kappa\|\mathrm{P}_h(w \times \mathbf{u}_h)\|^2 + 2|||\mathbf{u}_h|||_\tau^2 \\
&\le 6|||\mathbf{u}_h|||_\tau^2.
\end{aligned}$$

The combination of the latter estimate and (3.16) completes the proof. □

Remark 3.1. Note that τ in Lemma 3.1 does not depend on ν, α, or w.

Remark 3.2. Using the mesh-dependent norm

$$|||\mathbf{u}|||_{\tau,h} = \left(\nu\|\nabla\mathbf{u}\|^2 + \alpha\|\mathbf{u}\|^2 + \frac{\tau}{\|w\|_\infty}\|\mathrm{P}_h(w \times \mathbf{u})\|^2\right)^{\frac{1}{2}} \tag{3.17}$$

the stability of $a(\cdot,\cdot)$ on $\mathbf{U}_h$ can be proved without assumption (A1) and (A2) on w, since estimate (3.8) is not needed. Moreover, continuity of $a(\cdot,\cdot)$ on $\mathbf{U}_h \times \mathbf{U}$ in the mesh-dependent norm (3.17) can be proved without the assumptions (A1), (A2). This then results in satisfactory discretization error bounds in the norm $|||\cdot|||_{\tau,h}$. (See the treatment of the Oseen problem in [10].) However, for a certain duality argument in the proof of the approximation property in the multigrid convergence analysis (see Theorem 3.3 and section 4) we need the continuity of $a(\cdot,\cdot)$ on $\mathbf{U} \times \mathbf{U}$, and then the mesh-dependent norm becomes inconvenient.

We now derive discretization error bounds for the finite element method using standard arguments based on Galerkin orthogonality, stability, continuity, and approximation properties of the finite element spaces.

THEOREM 3.2. *Let* $\mathbf{u}$ *and* $\mathbf{u}_h$ *be the solution of* (2.1) *and* (3.1), *respectively. Let the assumptions of Lemma* 3.1 *be fulfilled and take* $\tau \in (0,1]$ *as in Lemma* 3.1. *Then the following inequalities hold:*

$$|||\mathbf{u} - \mathbf{u}_h|||_\tau \le C_\tau\, h^j(\nu^{\frac{1}{2}}\|\mathbf{u}\|_{j+1} + (\alpha^{\frac{1}{2}} + \|w\|_\infty^{\frac{1}{2}})\|\mathbf{u}\|_j), \quad j = 0, 1, \tag{3.18}$$

$$|||\mathbf{u} - \mathbf{u}_h|||_\tau \le C_\tau\, h(\nu^{\frac{1}{2}} + (\alpha^{\frac{1}{2}} + \|w\|_\infty^{\frac{1}{2}})h)\|\mathbf{u}\|_2. \tag{3.19}$$

The constants C_τ *are independent of* ν, α, w, $\mathbf{u}$, *and* h *but may depend on* τ.

Proof. Let $\hat{\mathbf{u}}_h$ be an arbitrary function in $\mathbf{U}_h$. Take τ as in Lemma 3.1. Then there exists $\mathbf{v}_h \in \mathbf{U}_h$ such that

$$C|||\mathbf{u}_h - \hat{\mathbf{u}}_h|||_\tau \, |||\mathbf{v}_h|||_\tau \le a(\mathbf{u}_h - \hat{\mathbf{u}}_h, \mathbf{v}_h).$$

Using Galerkin orthogonality and the continuity result in (2.18) we obtain

$$a(\mathbf{u}_h - \hat{\mathbf{u}}_h, \mathbf{v}_h) = a(\mathbf{u} - \hat{\mathbf{u}}_h, \mathbf{v}_h) \le C_\tau |||\mathbf{u} - \hat{\mathbf{u}}_h|||_\tau |||\mathbf{v}_h|||_\tau.$$

Hence,

$$|||\mathbf{u}_h - \hat{\mathbf{u}}_h|||_\tau \le C_\tau |||\mathbf{u} - \hat{\mathbf{u}}_h|||_\tau \tag{3.20}$$

holds. From the triangle inequality and (3.20) it follows that

(3.21)
$$\begin{aligned} |||\mathbf{u} - \mathbf{u}_h|||_\tau^2 &\le C_\tau |||\mathbf{u} - \hat{\mathbf{u}}_h|||_\tau^2 \\ &\le C_\tau \left(\nu \|\nabla(\mathbf{u} - \hat{\mathbf{u}}_h)\|^2 + \alpha\|\mathbf{u} - \hat{\mathbf{u}}_h\|^2 + \frac{\tau}{\|w\|_\infty}\|w \times (\mathbf{u} - \hat{\mathbf{u}}_h)\|^2 \right) \\ &\le C_\tau \left(\nu\|\mathbf{u} - \hat{\mathbf{u}}_h\|_1^2 + (\alpha + \tau\|w\|_\infty)\|\mathbf{u} - \hat{\mathbf{u}}_h\|^2 \right). \end{aligned}$$

According to (3.3) and (3.4) $\hat{\mathbf{u}}_h = I_h\mathbf{u}$ can be taken such that

$$\|\mathbf{u} - \hat{\mathbf{u}}_h\|_1^2 \le Ch^{2j}\|\mathbf{u}\|_{j+1}^2, \quad \|\mathbf{u} - \hat{\mathbf{u}}_h\|^2 \le Ch^{2j}\|\mathbf{u}\|_j^2, \quad j = 0, 1.$$

Using this in (3.21) proves the result in (3.18). If we use the inequalities

$$\|\mathbf{u} - \hat{\mathbf{u}}_h\|_1^2 \le Ch^2\|\mathbf{u}\|_2^2, \quad \|\mathbf{u} - \hat{\mathbf{u}}_h\|^2 \le Ch^4\|\mathbf{u}\|_2^2,$$

in (3.21) we get the result in (3.19). □

Note that $\|w\|_\infty$ occurs in the estimates (3.18)–(3.19) in a similar way as α, which measures the *reaction.*

We now prove a discretization error bound in the L_2-norm. This result will play an important role in the convergence analysis of the multigrid method.

THEOREM 3.3. *Assume that the conditions* (A1), (A2)*, and* (A3) *are fulfilled. For* $\mathbf{f} \in L_2(\Omega)^2$ *let* $\mathbf{u}$ *and* $\mathbf{u}_h$ *be the solutions of* (2.1) *and* (3.1)*, respectively. Then*

$$\|\mathbf{u} - \mathbf{u}_h\| \le C \min\left\{ \frac{h^2}{\nu}, \frac{1}{\alpha + \|w\|_\infty} \right\} \|\mathbf{f}\| \tag{3.22}$$

holds with a constant C independent of $\nu, \alpha, w, h,$ *and* $\mathbf{f}$.

Proof. Take $\mathbf{f} \in L_2(\Omega)^2$ and let $\mathbf{u}$, $\mathbf{u}_h$ be the solutions of (2.1) and (3.1), respectively. From (3.18) and the regularity estimate (2.8) it follows that

$$\begin{aligned} |||\mathbf{u} - \mathbf{u}_h|||_\tau &\le C_\tau h \left(\nu^{\frac{1}{2}}\|\mathbf{u}\|_2 + (\alpha^{\frac{1}{2}} + \|w\|_\infty^{\frac{1}{2}})\|\mathbf{u}\|_1 \right) \\ &\le C_\tau \frac{h}{\sqrt{\nu}} \left(\nu^2\|\mathbf{u}\|_2^2 + \nu(\alpha + \|w\|_\infty)\|\nabla\mathbf{u}\|^2 \right)^{\frac{1}{2}} \le C_\tau \frac{h}{\sqrt{\nu}}\|\mathbf{f}\|. \end{aligned} \tag{3.23}$$

We now apply a duality argument. For this we introduce the adjoint bilinear form

$$a^*(\mathbf{u}, \mathbf{v}) = \nu(\nabla\mathbf{u}, \nabla\mathbf{v}) + \alpha(\mathbf{u}, \mathbf{v}) - (w \times \mathbf{u}, \mathbf{v}) \quad \text{for } \mathbf{u}, \mathbf{v} \in \mathbf{U},$$

and the adjoint problem

$$\text{find} \quad \tilde{\mathbf{u}} \in \mathbf{U} \;\; \text{such that} \;\; a^*(\tilde{\mathbf{u}}, \mathbf{v}) = (\tilde{\mathbf{f}}, \mathbf{v}) \qquad \text{for all } \mathbf{v} \in \mathbf{U},$$

with $\tilde{\mathbf{f}} := \mathbf{u} - \mathbf{u}_h \in \mathbf{U} \subset L_2(\Omega)^2$. Let $\tilde{\mathbf{u}}_h \in \mathbf{U}_h$ be the discrete solution of the adjoint problem, i.e., $a^*(\tilde{\mathbf{u}}_h, \mathbf{v}_h) = (\tilde{\mathbf{f}}, \mathbf{v}_h)$ for all $\mathbf{v}_h \in \mathbf{U}_h$. Note that $a^*(\cdot,\cdot)$ equals $a(\cdot,\cdot)$ if, in $a(\cdot,\cdot)$, we replace w by $-w$. The results in Lemma 3.1 and Theorem 3.2 do not depend on $\operatorname{sign}(w)$ and thus hold for the adjoint problem, too. Moreover, since the choice of τ in Lemma 3.1 does not depend on w (cf. Remark 3.1), the estimate (3.23) holds for the original and the adjoint problem with the same τ value. Using this discretization error bound for the original and adjoint problem and the continuity result of Lemma 2.2 we obtain

$$\begin{aligned}\|\mathbf{u} - \mathbf{u}_h\|^2 &= (\tilde{\mathbf{f}}, \tilde{\mathbf{f}}) = a^*(\tilde{\mathbf{u}}, \tilde{\mathbf{f}}) = a(\tilde{\mathbf{f}}, \tilde{\mathbf{u}}) = a(\mathbf{u} - \mathbf{u}_h, \tilde{\mathbf{u}}) = a(\mathbf{u} - \mathbf{u}_h, \tilde{\mathbf{u}} - \tilde{\mathbf{u}}_h) \\ &\le C_\tau |||\mathbf{u} - \mathbf{u}_h|||_\tau |||\tilde{\mathbf{u}} - \tilde{\mathbf{u}}_h|||_\tau \le C_\tau \frac{h^2}{\nu} \|\mathbf{f}\| \, \|\tilde{\mathbf{f}}\| = C_\tau \frac{h^2}{\nu} \|\mathbf{f}\| \, \|\mathbf{u} - \mathbf{u}_h\|.\end{aligned}$$

Hence, $\|\mathbf{u} - \mathbf{u}_h\| \le C_\tau \frac{h^2}{\nu} \|\mathbf{f}\|$ holds, which proves the first bound in (3.22). For the second bound we note that from (2.5) and (A1) it follows that

(3.24)
$$\begin{aligned}\|\mathbf{u} - \mathbf{u}_h\| &\le \frac{1}{\alpha + c_w} (\alpha \|\mathbf{u} - \mathbf{u}_h\| + \|w \times (\mathbf{u} - \mathbf{u}_h)\|) \\ &\le \frac{1}{\alpha + \|w\|_\infty} \frac{\alpha + \|w\|_\infty}{\alpha + c_w} \left(\alpha^{\frac12} + \frac{\|w\|_\infty^{\frac12}}{\tau^{\frac12}} \right) \left(\alpha^{\frac12} \|\mathbf{u} - \mathbf{u}_h\| + \frac{\tau^{\frac12}}{\|w\|_\infty^{\frac12}} \|w \times (\mathbf{u} - \mathbf{u}_h)\| \right) \\ &\le \frac{2}{\alpha + \|w\|_\infty} (1 + \eta) \tau^{-\frac12} (\alpha^{\frac12} \tau^{\frac12} + \|w\|_\infty^{\frac12}) |||\mathbf{u} - \mathbf{u}_h|||_\tau \\ &\le C_\tau \frac{1}{\alpha + \|w\|_\infty} (\alpha^{\frac12} + \|w\|_\infty^{\frac12}) |||\mathbf{u} - \mathbf{u}_h|||_\tau.\end{aligned}$$

Finally, note that due to (3.18) with $j = 0$ and the results in (2.5), (2.8) we get

$$\begin{aligned}(\alpha^{\frac12} + \|w\|_\infty^{\frac12}) |||\mathbf{u} - \mathbf{u}_h|||_\tau &\le (\alpha^{\frac12} + \|w\|_\infty^{\frac12}) (\nu^{\frac12} \|\mathbf{u}\|_1 + (\alpha^{\frac12} + \|w\|_\infty^{\frac12}) \|\mathbf{u}\|) \\ &\le \nu^{\frac12} (\alpha^{\frac12} + \|w\|_\infty^{\frac12}) \|\mathbf{u}\|_1 + 2(\alpha + \|w\|_\infty) \|\mathbf{u}\| \\ &\le \nu^{\frac12} (\alpha^{\frac12} + \|w\|_\infty^{\frac12}) \|\mathbf{u}\|_1 + 2(1 + \eta)(\|w \times \mathbf{u}\| + \alpha \|\mathbf{u}\|) \\ &\le C \big(\nu (\alpha + \|w\|_\infty) \|\nabla \mathbf{u}\|^2 + \alpha^2 \|\mathbf{u}\|^2 + \|w \times \mathbf{u}\|^2 \big)^{\frac12} \\ &\le C \|\mathbf{f}\|.\end{aligned}$$

This in combination with (3.24) yields the second bound in (3.22). □

4. A solver for the discrete problem. For the approximate solution of the discrete problem we apply a multigrid method. The method and its convergence analysis will be presented in a matrix-vector form as in Hackbusch [8].

4.1. Multigrid components. For the application of the multigrid solver we assume that the quasi-uniform family of triangulations of Ω results from a *global regular refinement* technique. This yields a hierarchy of nested finite element spaces

$$\mathbf{U}_0 \subset \mathbf{U}_1 \subset \cdots \subset \mathbf{U}_k \subset \cdots \subset \mathbf{U}.$$

The corresponding mesh size parameter is denoted by h_k and satisfies

$$c_0 2^{-k} \leq h_k/h_0 \leq c_1 2^{-k}$$

with positive constants c_0 and c_1 independent of k. Note that $\mathbf{U}_k = U_k \times U_k$, where U_k is a standard conforming finite element space consisting of scalar functions. For the matrix-vector formulation of the discrete problem we use the standard nodal basis in U_k, denoted by $\{\phi_i\}_{1\leq i\leq n_k}$, and the isomorphism

$$P_k : \mathbb{R}^{n_k} \to U_k, \qquad P_k x = \sum_{i=1}^{n_k} x_i \phi_i.$$

For the product space $\mathbf{U}_k = U_k \times U_k$ we use the isomorphism

$$\mathbf{P}_k : X_k := \mathbb{R}^{2n_k} \to \mathbf{U}_k, \quad \mathbf{P}_k \mathbf{x} = \mathbf{P}_k \begin{pmatrix} x^1 \\ x^2 \end{pmatrix} = P_k x^1 \times P_k x^2, \quad x^i \in \mathbb{R}^{n_k}, \quad i = 1, 2.$$

On $\mathbb{R}^{n_k}$ and X_k we use scaled Euclidean scalar products: $\langle x, y\rangle_k = h_k^2 \sum_{i=1}^{n_k} x_i y_i$ for $x, y \in \mathbb{R}^{n_k}$ and $\langle \mathbf{x}, \mathbf{y}\rangle_k = \langle x^1, y^1\rangle_k + \langle x^2, y^2\rangle_k$ for $\mathbf{x}$, $\mathbf{y} \in X_k$. The corresponding norms are denoted by $\|\cdot\|$. The adjoint $\mathbf{P}_k^* : \mathbf{U}_k \to X_k$ satisfies $(\mathbf{P}_k\mathbf{x}, \mathbf{v}) = \langle \mathbf{x}, \mathbf{P}_k^*\mathbf{v}\rangle_k$ for all $\mathbf{x} \in X_k$, $\mathbf{v} \in \mathbf{U}_k$. Note that the following norm equivalence holds:

$$C^{-1}\|\mathbf{x}\| \leq \|\mathbf{P}_k\mathbf{x}\| \leq C\|\mathbf{x}\| \quad \text{for all } \mathbf{x} \in X_k, \tag{4.1}$$

with a constant C independent of k. The stiffness matrix $L_k : \mathbb{R}^{2n_k} \to \mathbb{R}^{2n_k}$ on level k is defined by

$$\langle L_k\mathbf{x}, \mathbf{y}\rangle_k = a(\mathbf{P}_k\mathbf{x}, \mathbf{P}_k\mathbf{y}) \quad \text{for all } \mathbf{x}, \mathbf{y} \in X_k. \tag{4.2}$$

This matrix has the block structure

$$L_k = \begin{pmatrix} \nu A + \alpha M & -M_w \\ M_w & \nu A + \alpha M \end{pmatrix},$$

with

$$\begin{aligned} \langle Ax, y\rangle_k &= (\nabla P_k x, \nabla P_k y), \quad \langle Mx, y\rangle_k = (P_k x, P_k y), \\ \langle M_w x, y\rangle_k &= (w P_k x, P_k y) \end{aligned} \tag{4.3}$$

for all $x, y \in \mathbb{R}^{n_k}$. Note that A is a stiffness matrix for a single (velocity) component, M is a mass matrix, and M_w is of mass matrix type corresponding to the bilinear form $[x, y] \to (wx, y)$. The latter is not necessarily a scalar product. The matrices A, M, M_w are symmetric and A and M are positive definite.

For the prolongation and restriction in the multigrid algorithm we use the canonical choice:

$$\begin{aligned} p_k &: X_{k-1} \to X_k, \qquad p_k = \mathbf{P}_k^{-1}\mathbf{P}_{k-1}, \\ r_k &: X_k \to X_{k-1}, \qquad r_k = \mathbf{P}_{k-1}^*(\mathbf{P}_k^*)^{-1} = \left(\tfrac{h_k}{h_{k-1}}\right)^2 p_k^T. \end{aligned} \tag{4.4}$$

Consider a smoother of the form

$$\mathbf{x}^{\text{new}} = \mathbf{x}^{\text{old}} - W_k^{-1}(L_k\mathbf{x}^{\text{old}} - \mathbf{b}) \quad \text{for } \mathbf{x}^{\text{old}}, \mathbf{b} \in X_k$$

with the corresponding iteration matrix denoted by $S_k = I - W_k^{-1}L_k$.

The damped block Jacobi method corresponds to

$$W_k = \omega^{-1} \begin{pmatrix} \mathrm{diag}(\nu A + \alpha M) & -\mathrm{diag}(M_w) \\ \mathrm{diag}(M_w) & \mathrm{diag}(\nu A + \alpha M) \end{pmatrix}, \tag{4.5}$$

with a damping parameter $\omega \in (0, 1]$. This type of smoother will be used in our numerical experiments in section 5. In the convergence analysis of the multigrid method we consider a smoother of block Richardson type:

$$W_k = \begin{pmatrix} \beta_1 I & -\beta_2 I \\ \beta_2 I & \beta_1 I \end{pmatrix}, \tag{4.6}$$

where I is the identity matrix and β_1, β_2 are suitable scaling factors. With the components defined above, a standard multigrid algorithm with μ_1 pre- and μ_2 postsmoothing iterations can be formulated (cf. [8]) with an iteration matrix M_k on level k that satisfies the recursion

$$\begin{aligned} &M_0(\mu_1, \mu_2) = 0, \\ &M_k(\mu_1, \mu_2) = S_k^{\mu_2} \left(I - p_k (I - M_{k-1}^{\gamma}) L_{k-1}^{-1} r_k L_k \right) S_k^{\mu_1}, \quad k = 1, 2, \dots . \end{aligned}$$

The choices $\gamma = 1$ and $\gamma = 2$ correspond to the V- and W-cycle, respectively. For analysis of this multigrid method we use the framework of [7], [8] based on the approximation and smoothing property. In sections 4.2 and 4.3 we will prove the following approximation and smoothing properties:

$$\|L_k^{-1} - p_k\, L_{k-1}^{-1} r_k\| \le C \left(\frac{\nu}{h^2} + \alpha + \|w\|_\infty \right)^{-1}, \tag{4.7}$$

$$\|L_k S_k^{\mu_1}\| \le \frac{C}{\sqrt{\mu_1}} \left(\frac{\nu}{h^2} + \alpha + \|w\|_\infty \right). \tag{4.8}$$

As a direct consequence of (4.7) and (4.8) one obtains a bound for the contraction number of the two-grid method:

$$\|(I - p_k L_{k-1}^{-1} r_k L_k) S_k^{\mu_1}\| \le \frac{C}{\sqrt{\mu_1}} \, . \tag{4.9}$$

Using the analysis in [8, Theorem 10.6.25] the convergence of the multigrid W-cycle can be obtained as a consequence of the approximation and smoothing property. In section 4.3 we will prove $\|S_k\| \le 1$. Using this and (4.7), (4.8), Theorem 10.6.25 from [8] yields the following result.

THEOREM 4.1. *Assume* (A1)–(A3) *hold; then for any* $\psi \in (0, 1)$ *there exists* $\bar{\mu}_0 > 0$ *independent of the problem parameters* ν, α *and the level number* k *such that for the contraction number of the multigrid W-cycle with smoothing* (4.6) *we have*

$$\|M_k(\mu, 0)\| \le \psi \quad \textit{for all } \mu \ge \bar{\mu}_0. \qquad \square$$

This proves the robustness of the multigrid W-cycle with respect to variation in the problem parameters ν *and* α *and the mesh size* h_k.

This robustness is confirmed by the numerical experiments in section 5.

4.2. Approximation property. The analysis of the approximation property is as in [7], [8]. The key ingredient is the finite element error bound in Theorem 3.3.

THEOREM 4.2. *Let the assumptions* (A1)–(A3) *be valid; then*

$$\|L_k^{-1} - p_k\, L_{k-1}^{-1} r_k\| \le C \left(\frac{\nu}{h_k^2} + \alpha + \|w\|_\infty \right)^{-1} \le C \|L_k\|^{-1}. \tag{4.10}$$

Proof. Take $\mathbf{y}_k \in X_k$. The constants C that appear in the proof do not depend on $\nu, \alpha, \mathbf{y}_k$, or k. Let $\mathbf{s}^* \in \mathbf{U}$, $\mathbf{s}_k \in \mathbf{U}_k$, and $\mathbf{s}_{k-1} \in \mathbf{U}_{k-1}$ be such that

$$\begin{aligned} a(\mathbf{s}^*, \mathbf{v}) &= ((\mathbf{P}_k^*)^{-1}\mathbf{y}_k, \mathbf{v}) \quad \text{for all } \mathbf{v} \in \mathbf{U}, \\ a(\mathbf{s}_k, \mathbf{v}) &= ((\mathbf{P}_k^*)^{-1}\mathbf{y}_k, \mathbf{v}) \quad \text{for all } \mathbf{v} \in \mathbf{U}_k, \\ a(\mathbf{s}_{k-1}, \mathbf{v}) &= ((\mathbf{P}_k^*)^{-1}\mathbf{y}_k, \mathbf{v}) \quad \text{for all } \mathbf{v} \in \mathbf{U}_{k-1}. \end{aligned}$$

Putting $\mathbf{f} = (\mathbf{P}_k^*)^{-1}\mathbf{y}_k \in L_2(\Omega)^2$ in Theorem 3.3, we obtain

$$\|\mathbf{s}^* - \mathbf{s}_l\| \le C \min\left\{ \frac{h_l^2}{\nu}, \frac{1}{\alpha + \|w\|_\infty} \right\} \|(\mathbf{P}_k^*)^{-1}\mathbf{y}_k\| \quad \text{for } l \in \{k-1, k\}.$$

Due to $h_{k-1} \le c h_k$ this yields

$$\|\mathbf{s}_k - \mathbf{s}_{k-1}\| \le C \min\left\{ \frac{h_k^2}{\nu}, \frac{1}{\alpha + \|w\|_\infty} \right\} \|(\mathbf{P}_k^*)^{-1}\mathbf{y}_k\|.$$

From (4.2) and (4.4) it follows that $\mathbf{s}_k = \mathbf{P}_k L_k^{-1}\mathbf{y}_k$ and $\mathbf{s}_{k-1} = \mathbf{P}_{k-1} L_{k-1}^{-1} r_k \mathbf{y}_k$. Thus, using (4.1), we get

$$\begin{aligned} \|(L_k^{-1} - p_k L_{k-1}^{-1} r_k)\mathbf{y}_k\| &\le C \|\mathbf{P}_k L_k^{-1}\mathbf{y}_k - \mathbf{P}_{k-1} L_{k-1}^{-1} r_k \mathbf{y}_k\| = C\|\mathbf{s}_k - \mathbf{s}_{k-1}\| \\ &\le C \, \min\left\{ \frac{h_k^2}{\nu}, \frac{1}{\alpha + \|w\|_\infty} \right\} \|(\mathbf{P}_k^*)^{-1}\mathbf{y}_k\| \\ &\le C \, \min\left\{ \frac{h_k^2}{\nu}, \frac{1}{\alpha + \|w\|_\infty} \right\} \|\mathbf{y}_k\|. \end{aligned}$$

Note that $\min\{\frac{1}{p}, \frac{1}{q}\} \le \frac{2}{p+q}$ for all $p, q > 0$. Hence the first inequality in (4.10) is proved. For the second inequality in (4.10) we note that

$$\begin{aligned} \|L_k\| &= \left\| \begin{pmatrix} \nu A + \alpha M & \emptyset \\ \emptyset & \nu A + \alpha M \end{pmatrix} + \begin{pmatrix} \emptyset & -M_w \\ M_w & \emptyset \end{pmatrix} \right\| \\ &\le \|\nu A + \alpha M\| + \|M_w\| \le \nu\|A\| + (\alpha + \|w\|_\infty)\|M\|. \end{aligned}$$

Using $\|A\| \le C h_k^{-2}$ and $\|M\| \le C$ we obtain $\|L_k\| \le C(\nu h_k^{-2} + \alpha + \|w\|_\infty)$. □

4.3. Smoothing property. Let a_1, m_1 be positive constants independent of ν, α, and k such that for spectral radius of the matrices in (4.3) we have

$$\rho(A) \le \frac{a_1}{h_k^2}, \qquad \rho(M) \le m_1.$$

Furthermore, let $w_{\min} = \text{ess inf}_\Omega\, w$ and $w_{\max} = \text{ess sup}_\Omega\, w$ and define

$$C_w = \begin{cases} w_{\max} & \text{if } w_{\max} \ge -w_{\min}, \\ w_{\min} & \text{if } w_{\max} < -w_{\min}. \end{cases}$$

Note that $|C_w| = \|w\|_\infty$. In the analysis below we use the following elementary result.

Lemma 4.3. *Assume that for $B \in \mathbb{R}^{n\times n}$ and $\Lambda \in (0,\infty)$ we have $B^TB \le \Lambda(B+B^T)$. Then $\|I-\omega B\| \le 1$ holds for any $\omega \in [0, \frac{1}{\Lambda}]$.*

This result follows from

$$\begin{aligned} 0 \le (I-\omega B)^T(I-\omega B) &= I - \omega(B+B^T) + \omega^2 B^TB \\ &\le I - \omega(1-\omega\Lambda)(B+B^T) \le I. \qquad \Box \end{aligned}$$

Using this lemma we prove that the contraction number of the block Richardson method is bounded by 1.

Lemma 4.4. *Assume that* (A1) *and* (A2) *are satisfied. Consider the block Richardson method with W_k as in* (4.6) *and*

$$\beta_1 = \frac{\nu a_1}{h_k^2} + \alpha\kappa_1 m_1, \quad \beta_2 = \kappa_2 C_w, \quad \textit{with constants}$$

$$\kappa_1 \ge 2(1+\eta^2), \quad \kappa_2 \ge 4m_1\eta. \tag{4.11}$$

Then the following inequality holds:

$$\|I - W_k^{-1}L_k\| \le 1.$$

Proof. A straightforward computation yields

$$W_k^{-1}L_k = R_1 + R_2, \qquad \text{with} \tag{4.12}$$

$$R_1 = \frac{\nu}{\beta_1^2+\beta_2^2}\begin{pmatrix} \beta_1 A & \beta_2 A \\ -\beta_2 A & \beta_1 A \end{pmatrix},$$

$$R_2 = \frac{1}{\beta_1^2+\beta_2^2}\begin{pmatrix} \beta_1\alpha M + \beta_2 M_w & \beta_2\alpha M - \beta_1 M_w \\ -\beta_2\alpha M + \beta_1 M_w & \beta_1\alpha M + \beta_2 M_w \end{pmatrix}.$$

From

$$\frac{1}{2}(R_1^T + R_1) = \frac{\nu\beta_1}{\beta_1^2+\beta_2^2}\begin{pmatrix} A & 0 \\ 0 & A \end{pmatrix}, \qquad R_1^TR_1 = \frac{\nu^2}{\beta_1^2+\beta_2^2}\begin{pmatrix} A^2 & 0 \\ 0 & A^2 \end{pmatrix}$$

it follows that

$$R_1^TR_1 \le \frac{1}{2}(R_1^T+R_1) \;\Leftrightarrow\; \nu A \le \beta_1 I \;\Leftrightarrow\; \nu A \le \left(\frac{\nu a_1}{h_k^2} + \alpha\kappa_1 m_1\right) I.$$

The last inequality holds, due to $\rho(A) \le \frac{a_1}{h_k^2}$ and $\alpha\kappa_1 m_1 \ge 0$. Application of Lemma 4.3 yields

$$\|I - 2R_1\| \le 1\ . \tag{4.13}$$

For the matrix R_2 we obtain

$$\frac{1}{2}(R_2^T+R_2) = \frac{1}{\beta_1^2+\beta_2^2}\begin{pmatrix} \beta_1\alpha M + \beta_2 M_w & \emptyset \\ \emptyset & \beta_1\alpha M + \beta_2 M_w \end{pmatrix},$$

$$R_2^TR_2 = \frac{1}{\beta_1^2+\beta_2^2}\begin{pmatrix} \alpha^2M^2 + M_w^2 & \alpha(M_wM - MM_w) \\ -\alpha(M_wM - MM_w) & \alpha^2M^2 + M_w^2 \end{pmatrix}.$$

We use the notation $\hat{M} = \beta_1\alpha M + \beta_2 M_w$. Note that $R_2^TR_2 \le \frac{1}{2}(R_2^T + R_2)$ holds if the following two conditions are satisfied:

$$\alpha^2M^2 + M_w^2 \le \frac{1}{2}\hat{M}, \tag{4.14}$$

$$\alpha|\langle(M_wM - MM_w)x, y\rangle_k| \le \frac{1}{4}\Big(\langle\hat{M}x, x\rangle_k + \langle\hat{M}y, y\rangle_k\Big), \tag{4.15}$$

for all $x, y \in \mathbb{R}^{n_k}$. We first consider (4.14). We have $M_w^2 \leq \|w\|_\infty^2 M^2 \leq m_1 \|w\|_\infty^2 M$. Due to (A2) the matrix M_w is definite and $C_w M_w$ is positive definite; moreover, $C_w M_w \geq |C_w| c_w M = \|w\|_\infty c_w M$. Using this we obtain

$$\alpha^2 M^2 + M_w^2 \leq (m_1 \alpha^2 + m_1 \|w\|_\infty^2) M,$$
$$\frac{1}{2}\hat{M} \geq \frac{1}{2}(\kappa_1 m_1 \alpha^2 M + \kappa_2 C_w M_w) \geq \frac{1}{2}(\kappa_1 m_1 \alpha^2 + \kappa_2 \|w\|_\infty c_w) M.$$

Hence, (4.14) is fulfilled if the inequality

$$m_1 \alpha^2 + m_1 \|w\|_\infty^2 \leq \frac{1}{2}(\kappa_1 m_1 \alpha^2 + \kappa_2 \|w\|_\infty c_w)$$

holds. Substitution of $\|w\|_\infty = \eta(\alpha + c_w)$ and rearranging terms results in the equivalent inequality

$$\alpha^2 m_1 \left(\frac{1}{2}\kappa_1 - (1 + \eta^2)\right) + \alpha c_w \eta \left(\frac{1}{2}\kappa_2 - 2 m_1 \eta\right) + \eta c_w^2 \left(\frac{1}{2}\kappa_2 - m_1 \eta\right) \geq 0.$$

This inequality holds for κ_1, κ_2 as in (4.11). Hence, with κ_1, κ_2 as in (4.11) the condition (4.14) is fulfilled. To prove (4.15) we note that

$$\begin{aligned} \alpha|\langle (M_w M - M M_w) x, y\rangle_k| &\leq \alpha(\langle|M_w M x, y\rangle_k| + \alpha|\langle M M_w x, y\rangle_k|, \\ \alpha|\langle M_w M x, y\rangle_k| = \alpha|\langle M x, M_w y\rangle_k| &\leq \tfrac{1}{2}\big(\alpha^2 \langle M^2 x, x\rangle_k + \langle M_w^2 y, y\rangle_k\big), \\ \alpha|\langle M M_w x, y\rangle_k| = \alpha|\langle M_w x, M y\rangle_k| &\leq \tfrac{1}{2}\big(\langle M_w^2 x, x\rangle_k + \alpha^2 \langle M^2 y, y\rangle_k\big). \end{aligned}$$

Thus (4.15) follows from (4.14). We conclude that (4.15) and (4.14) are satisfied for κ_1, κ_2 as in (4.11). Hence, $R_2^T R_2 \leq \frac{1}{2}(R_2^T + R_2)$ holds. And due to Lemma 4.3

$$\|I - 2R_2\| \leq 1. \tag{4.16}$$

Finally, (4.12), (4.13), and (4.16) yield

$$\|I - W_k^{-1} L_k\| = \|I - (R_1 + R_2)\| \leq \frac{1}{2}\|I - 2R_1\| + \frac{1}{2}\|I - 2R_2\| \leq 1. \qquad \square$$

Theorem 4.5. *Assume that* (A1) *and* (A2) *are satisfied. Consider the block Richardson method with* W_k *as in* (4.6) *and*

$$\beta_1 = 2\left(\frac{\nu a_1}{h_k^2} + \alpha \kappa_1 m_1\right), \qquad \beta_2 = 2\kappa_2 C_w,$$

with constants κ_1, κ_2 *from* (4.11). *Then the following estimate holds:*

$$\|L_k S_k^{\mu_1}\| \leq \frac{C}{\sqrt{\mu_1}}\left(\frac{\nu}{h^2} + \alpha + \|w\|_\infty\right), \quad \mu_1 = 1, 2, \ldots\ . \tag{4.17}$$

Proof. From Lemma 4.4 we obtain

$$\|I - 2W_k^{-1} L_k\| \leq 1. \tag{4.18}$$

Furthermore,

$$\begin{aligned} \|W_k\| &= \rho\left(\begin{pmatrix} \beta_1 I & -\beta_2 I \\ \beta_2 I & \beta_1 I \end{pmatrix}\begin{pmatrix} \beta_1 I & \beta_2 I \\ -\beta_2 I & \beta_1 I \end{pmatrix}\right)^{\frac{1}{2}} \\ &= (\beta_1^2 + \beta_2^2)^{\frac{1}{2}} \leq \beta_1 + \beta_2 \leq C\left(\frac{\nu}{h^2} + \alpha + \|w\|_\infty\right). \end{aligned} \tag{4.19}$$

From (4.18) and (4.19) and Theorem 10.6.8 in [8] the result in (4.17) follows. $\square$

5. Numerical results. In this section results of a few numerical experiments related to the accuracy of the discretization method and the convergence behavior of the multigrid solver are presented. For the discretization we use linear conforming finite elements on a uniform triangulation of the unit square. The mesh size parameter is $h = h_k = 2^{-k},\ k = 4, 5, \dots, 9$.

In our experiments we consider problems with an a priori known continuous solution $\mathbf{u} \in H^2(\Omega)^2 \cap \mathbf{U}$ to the problem (2.1). Discretization errors are measured as follows. Let $\hat{\mathbf{u}}_h \in \mathbf{U}_h$ be the nodal interpolant of the continuous solution $\mathbf{u}$ and $\mathbf{u}_h \in \mathbf{U}_h$ be the solution of the discrete problem. As a measure for the discretization error we take

$$err(\mathbf{u}, h, \nu) = \frac{\|\hat{\mathbf{u}}_h - \mathbf{u}_h\|}{\|\mathbf{f}\|}. \tag{5.1}$$

For the iterative solution of the discrete problem a multigrid V-cycle is applied. The prolongations and restrictions in this multigrid method are the canonical ones, as in (4.4). For the smoother a damped block Jacobi method as in (4.5) is used. Thus for each pair of nodal values of $\{u_1, u_2\}$ a 2×2 linear system is solved. The damping parameter ω in each smoothing step is determined in a dynamic way based on a residual minimization criterion: We set $\omega = (\mathbf{q}, \mathbf{q})/(\mathbf{q}, \mathbf{r})$, where for grid level k

$$\mathbf{r} = \bar{W}_k^{-1}(L_k \mathbf{x}^{old} - b), \qquad \mathbf{q} = \bar{W}_k^{-1} L_k \mathbf{r},$$

and $\bar{W}_k$ equals W_k from (4.5) for $\omega = 1$.

We always use two pre- and two postsmoothing iterations. For the starting vector in the iterative solver we take $\mathbf{u}^0 = 0$. The iterations are stopped as soon as the residual, in the Euclidean norm, is at least a factor 10^9 smaller than the starting residual.

We consider test problems with different choices for w. Note that in the setting of a (linearized) Navier–Stokes problem $w = \operatorname{curl} \mathbf{v} = -\frac{\partial v_2}{\partial x} + \frac{\partial v_1}{\partial y}$, where $\mathbf{v} = (v_1(x, y), v_2(x, y))$ is an approximation of the flow field. In Experiment I we consider a problem which corresponds to a flow with rotating vortices. In Experiment II we take a flow field $\mathbf{v}$ with a parabolic boundary layer behavior. Both in Experiment I and Experiment II the right-hand side is taken such that the continuous solution $\mathbf{u}$ equals the flow field $\mathbf{v}$. This seems a reasonable choice if the problem (2.1) results from a linearized Navier–Stokes problem. Finally, in Experiment III a flow $\mathbf{v}$ which exhibits an internal layer behavior is considered.

In all the experiments we present results for the case $\alpha = 0$. For $\alpha > 0$ in our numerical experiments we always observed better results than for $\alpha = 0$, both with respect to the discretization error and with respect to the multigrid convergence.

Experiment Ia. We take $\mathbf{v}_r = (v_1, v_2)$, with

$$\begin{aligned} v_1(x, y) &= 4(2y - 1)x(1 - x), \\ v_2(x, y) &= -4(2x - 1)y(1 - y), \end{aligned} \tag{5.2}$$

and $w = \operatorname{curl} \mathbf{v}_r$. This type of convection $\mathbf{v}_r$ simulates a rotating vortex. For this w the conditions (A2) and (A3) are fulfilled. Related to (A1) we note that $\|w\|_\infty = \mathcal{O}(1)$ and $c_w = 0$. However, based on the fact that w equals zero only at the corner points of the domain, one could say that (A1) is "almost" fulfilled. For several values of h and ν the quantity $err(\mathbf{u}, h, \nu)$ is given in Table 5.1.

In Figure 5.1 the differences $(u_1 - (u_h)_1)(0.5, y)$ and $(\frac{\partial u_1}{\partial y} - \frac{\partial (u_h)_1}{\partial y})(0.5, y)$ between (the derivatives of) the first components of the continuous and finite element solution

are plotted for the case $\nu = 10^{-6}$. Because of the symmetry the error in the solution is shown only on half of the interval (Figure 5.1b) and the error in the solution derivative only on the interval $[0, 0.1]$ near the boundary (Figure 5.1a). The numerical boundary layer, typical for reaction-diffusion problems with dominating reaction terms, is clearly seen. Results for the convergence behavior of the multigrid method are shown in Table 5.2.

Experiment Ib. We take $\mathbf{v}_R = (v_1, v_2)$, with

$$v_1(x,y) = \frac{1}{\psi}\sin(\psi\pi x)\cos(\pi y), \qquad v_2(x,y) = -\cos(\psi\pi x)\sin(\pi y), \tag{5.3}$$

and $w = \operatorname{curl}\mathbf{v}_R$. This models a flow with two vortices rotating in opposite directions. Note that the conditions (A1) and (A2) are not fulfilled. For the parameter ψ we choose $\psi = 1.6$. One vortex lies entirely in the computational domain, the second one only partially. The (vorticity) function w for this problem is plotted in Figure 5.2(a). Note the change of sign for w at $x = 0.625$. The error in the discrete solution shown in Table 5.3 is larger compared to example Ia (which might correspond to the strong violation of the conditions (A1) and (A2)). In Figure 5.3 the difference $(u_1 - (u_h)_1)(0.5, y)$ is plotted for $\nu = 10^{-6}$. Note that some local oscillations in the error are observed in the neighborhood of $x = 0.625$, i.e., where condition (A1) is *locally* violated. The results for the convergence behavior of the multigrid method are very similar to those in Table 5.2 for Experiment Ia.

1e-8	3.9e-3	3.7e-3	3.7e-3	3.7e-3	3.6e-3	3.6e-3

Experiment II. We take $\mathbf{v}_l = (v_1, v_2)$, with

$$
\begin{aligned}
v_1(x,y) &= 1 - \exp(-y/\sqrt{\nu}),\\
v_2(x,y) &= 0,
\end{aligned}
\tag{5.4}
$$

and $w = \operatorname{curl} \mathbf{v}_l$. This models a parabolic boundary layer behavior in the velocity field. The width of the layer is proportional to $\sqrt{\nu}$. Note that $\|w\|_\infty = O(\nu^{-1/2})$. The vorticity is of $\nu^{-\frac{1}{2}}$ magnitude near the boundary and decays exponentially outside the layer (see Figure 5.2(b)). As before, we take $\mathbf{f}$ such that the continuous solution equals the flow field: $\mathbf{u} = \mathbf{v}_l$. Results for the discretization error are given in Table 5.4. The L_2 norm of $\mathbf{f}$ is $O(\nu^{-\frac{1}{4}})$ for $\nu \to 0$; therefore one has to use a proper scaling of the values from Table 5.4 (e.g., multiplying by 10 for $\nu = 10^{-4}$) to obtain the absolute value of the error $\|\hat{\mathbf{u}}_h - \mathbf{u}_h\|$ (cf. (5.1)).

In Figure 5.4 we plot $u_1(0.5, y)$ and $(u_h)_1(0.5, y)$ for the cases $\nu = 10^{-3}$ and $\nu = 10^{-4}$ and for several h values. The finite element solution is a poor approximation to the continuous one if the boundary layer is not resolved: $h > \nu^{\frac{1}{2}}$. However, for $h \sim \nu^{\frac{1}{2}}$ the results are quite good, although both the *mesh* Reynolds numbers and Ek_h^{-1} are very large (e.g., $\approx 10^2$ for $\nu = 10^{-4}$). Moreover, no global oscillations are observed even for very coarse meshes. We expect that a significant improvement can be obtained if this simple full Galerkin discretization is combined with local grid

refinement in the boundary layer. In Table 5.5 numerical results for the multigrid method are presented. Note that assumptions (A1) and (A2) were also violated in this experiment. Hence our convergence analysis of the multigrid method does not apply here. One reason for the deterioration of multigrid convergence compared to the case Ib could be weaker regularity of the function w.

Experiment III. In this experiment we try to model the presence of an internal layer. To this end, for the convection field we take the model of the Euler flow (extreme case if $\nu \to 0$), where the tangential velocity component is discontinuous on some line in the interior of the domain. Hence the flow, potential a.e., has a vorticity concentrated on this line (so-called vortex sheet). We take $w = \operatorname{curl} \mathbf{v}_d$, with $\mathbf{v}_d = (v_1, v_2)$, and, for a given constant ψ,

$$\left\{ \begin{array}{l} v_1(x,y) = \cos\psi \\ v_2(x,y) = \sin\psi \end{array} \right. \quad \text{if } \cos\psi > (x - 0.25)\sin\psi,$$

$$\left\{ \begin{array}{l} v_1(x,y) = 0 \\ v_2(x,y) = 0 \end{array} \right. \quad \text{if } \cos\psi \le (x - 0.25)\sin\psi.$$

Using the parameter ψ one can vary the angle under which the layer enters the domain. We set $\psi = \pi/3$ so the grid is not aligned to the layer. For the discrete velocity $\mathbf{v}_h^d \in$

Number of iterations and average reduction factor

$\mathbf{U}_h$ we take the nodal interpolant of $\mathbf{v}_d$, and set $w = \operatorname{curl} \mathbf{v}_h^d$, obtaining a piecewise constant function w, which is essentially mesh-dependent due to the discontinuity of $\mathbf{v}_d$ ($\|w\|_\infty = O(h^{-1})$). Results for the convergence behavior of the multigrid method are given in Table 5.6.

Since discontinuous solutions are generally not allowed for viscous motions and our given data are mesh-dependent, we do not consider discretization errors in this example.

5.1. Discussion of numerical results. Recall that the analysis in the previous sections yields, for the case $\alpha = 0$,

$$err(\mathbf{u}, h, \nu) \leq c \min\{\nu^{-1}h^2, \|w\|_\infty^{-1}\} \tag{5.5}$$

under certain assumptions on w. These assumptions are "almost valid" for the problem Ia and do not hold for the problems Ib and II.

The results of the numerical experiments indeed show the $O(h^2)$ behavior of $err(\mathbf{u}, h, \nu)$ unless ν is very small. In the latter case the second, ν- and h-independent, upper bound for $err(\mathbf{u}, h, \nu)$ in (5.5) is observed and $O(h^2)$ convergence is recovered for smaller h. For fixed h and $\nu \to 0$ a growth of the error is observed (up to some limit). In the experiments Ia,b this growth appears to be less than $O(\nu^{-1})$, indicating that the ν-dependence in (5.5) might be somewhat pessimistic for these cases.

Although in the last two examples the multigrid convergence for a small values of ν is somewhat worse, the multigrid V-cycle with block Jacobi smoothing appears to be a very robust solver. The convergence rates for realistic values of viscosity (in laminar flows $1 - 10^{-4}$) are excellent.

OPTIMAL TWO-DIMENSIONAL FINITE DIFFERENCE GRIDS PROVIDING SUPERCONVERGENCE*

NAIL K. YAMALEEV†

Abstract. A novel multidimensional grid adaptation method based on minimization of the leading truncation error term of arbitrary second- and higher-order finite difference approximations is proposed. The method does not explicitly require the truncation error estimate, but increases the design order of approximation globally by one, so that the same finite difference operator is superconvergent on the optimal grid. If the differential operator and the metric coefficients are evaluated identically by some hybrid approximation, the single optimal grid generator can be used in the entire computational domain and does not depend on points where the hybrid discretization switches from one approximation to another. If one family of the coordinate lines is given a priori, then the analytical optimal mapping is constructed for any consistent second-order finite difference approximation of ∇f in two dimensions. The present approach can be extended directly to nonlinear partial differential equations and three dimensions. Numerical calculations show that the truncation error obtained on the two-dimensional optimal grid is both superconvergent and reduced by several orders of magnitude in comparison with the uniform grid results for all the test examples considered.

Key words. truncation error, optimal grid, finite difference approximation

1. Introduction.

Grid adaptation has become one of the main subjects of interest and research because grid point distribution has a strong effect on the numerical solution accuracy and therefore directly determines the computational cost. One of the most important problems associated with grid adaptation is the fact that the concentration of grid points in regions that most influence the accuracy of the numerical solution may at the same time introduce additional error due to grid nonuniformity [1], [2], [3], [4].

Most, if not all, grid adaptation criteria are based on the equidistribution principle. Many commonly used equidistribution methods of generating adaptive grids are modifications of a technique originally proposed by Babuška and Rheinboldt [5]. As shown in [5] for one-dimensional (1D) finite element discretizations, the grid point distribution is asymptotically optimal if some error measure is equally distributed over the field. This idea has been well defined for 1D finite element methods, but a proper concept has not been developed either for other discretization techniques or problems involving multiple dimensions. One of the widely used approaches in multiple dimensions is to redistribute grid points in accordance with the arc length and the local curvature of the numerical solution [6], [7], [8], [9]. Dwyer [6] and Catherall [7] use the equidistribution principle in a 1D fashion so that grid points are redistributed along one family of fixed mesh lines. In [8], adaptivity is incorporated by using a variational approach, which can be treated as a multidimensional extension of the 1D equidistribution principle. Further development of this idea can be found in [9].

An alternative technique is to equidistribute the local truncation error or its estimate. In [10], the optimal coordinate transformation is constructed as the solution of a constrained parameter optimization problem that minimizes a measure of the truncation error. The error measure used is a finite difference evaluation of the third derivative of the numerical solution calculated in the computational space. In [11] a cell vertex scheme is reformulated as a finite element method. This method allows construction of an a posteriori error estimate based on calculation of the finite element residual of the approximate solution, which is similar to the finite difference truncation error.

Another class of methods is based on error estimates that can be derived by evaluating the solution interpolation error [12], [13], [14], [15]. For second-order spatial finite element discretizations, this approach is reduced to estimation of the local curvature of the numerical solution. Ait-Ali-Yahia et al. [12] defined the cell edge length squared times the second derivative of the numerical solution as an a posteriori error estimate. Peraire et al. [14] determined the local principal directions of the symmetric Hessian matrix containing information about the local curvature of the solution. Then the equidistribution technique was applied separately in each principal direction. D'Azevedo [15] derived an anisotropic coordinate transformation by interpreting the Hessian matrix of the data function as a metric tensor that measures the local interpolation error. Asymptotically optimal element shapes and sizes that minimize the error/area ratio for linear triangles are generated by the transformation as an image of a regular mesh.

All the equidistribution methods mentioned above redistribute grid points in accordance with one or another error estimate obtained on a nonadaptive grid. On one hand, constructing a sufficiently accurate and reliable error estimate is very difficult, and, consequently, the grid optimality may be destroyed by poor accuracy of the error estimate. On the other hand, the error estimate norm is directly dependent on the metric coefficients. As a result, the grid adaptation itself changes the error distribution. To account for this change in the error distribution, the grid adaptation procedure based on the error equidistribution strategy should be iterated until the error estimate norm is equally distributed over the field. Note that, for moving meshes dynamically adapted to the solution, the iterative procedure should be done at each time step to attain the optimal mesh characterized by having the error equidistributed throughout the domain. One of the main disadvantages of multidimensional grid adaptation techniques is a lack of rigorously proved results showing that the grid adaptation criterion used provides global error reduction in the numerical solution.

The main idea of the present paper is to construct a two-dimensional (2D) optimal coordinate transformation based on the grid adaptation criteria proposed in [4], which minimizes the global asymptotic truncation error of an arbitrary pth-order finite difference approximation of both f_x and f_y. In contrast to most multidimensional grid adaptation criteria, the present method does not explicitly require an a posteriori error estimate, and, at the same time, the design order of approximation is increased globally by one. As a result, the same finite difference operator is superconvergent on the optimal grid. Furthermore, for second-order approximations, the proposed grid adaptation equations can be integrated analytically under the assumption that grid points move along a given family of fixed curvilinear coordinate lines. This analytical approach is extended to generate the optimal grid for conservation laws. It is shown that if grid points are redistributed in accordance with the new grid adaptation criteria, the global order of approximation of the conservation law equation is increased from 2 to 3 on the optimal grid. Another very attractive feature of the present approach is its applicability to hybrid approximations that depend on some basic properties of the solution, such as flow direction, sonic line, and others. If the metric coefficients are evaluated by the same hybrid discretization used for the differential operator, the new grid adaptation criterion remains valid throughout the computational domain regardless of points where the hybrid scheme switches from one approximation to another. Generalization of this approach to three and higher dimensions is straightforward [4]. The numerical examples considered illustrate the ability of the method and corroborate the theoretical analysis.

2. Grid adaptation criteria in two dimensions. A simply connected domain D in 2D space with Cartesian coordinates (x, y) is considered. Without loss of generality the physical domain D is assumed bounded by four boundaries, B_1, B_2, B_3, B_4. A computational domain Q is defined as a unit square in a 2D space with Cartesian coordinates (ξ, η). A differentiable one-to-one coordinate transformation between the physical and computational domains is given by

$$\begin{aligned} x &= x(\xi, \eta), \\ y &= y(\xi, \eta). \end{aligned} \tag{2.1}$$

This mapping is assumed not singular, and the Jacobian of the transformation is a strictly positive function:

$$J = x_\xi y_\eta - x_\eta y_\xi > 0. \tag{2.2}$$

The transformation (2.1) maps the boundary of Q one-to-one on the boundary of D in such a way that

$$\begin{aligned} &\xi = 0 \quad \text{at boundary } B_1, \qquad &\eta = 0 \quad \text{at boundary } B_2, \\ &\xi = 1 \quad \text{at boundary } B_3, \qquad &\eta = 1 \quad \text{at boundary } B_4. \end{aligned} \tag{2.3}$$

Nodes and cells of a grid in the physical domain D are generated by the transformation (2.1) as images of nodes and cells of a uniform rectangular grid constructed in the computational domain Q.

We consider the truncation error of the first derivative f_x of a sufficiently smooth function $f(x, y)$. The first derivative is approximated on a 2D curvilinear grid generated by the mapping (2.1). The 2D transformation of f_x is given by

$$f_x = \frac{y_\eta f_\xi - y_\xi f_\eta}{J}. \tag{2.4}$$

Approximating the ξ and η derivatives in (2.4) by some pth- and qth-order finite difference formulas, respectively, yields

$$\begin{aligned} L_h^p(v_\xi) &= \sum_{l=i-l_1}^{i+l_2} a_l v_{lk}, \\ L_h^q(v_\eta) &= \sum_{m=k-m_1}^{k+m_2} b_m v_{im}, \end{aligned} \tag{2.5}$$

where v denotes f, x, or y, $v_{lm} = v(l\Delta\xi, m\Delta\eta)$, and L_h^p and L_h^q are pth- and qth-order finite difference operators, accordingly. The indices l_1, l_2 and m_1, m_2, as well as the coefficients a_l and b_m, depend on particular approximations used for evaluating the ξ

and η derivatives. Equation (2.5) takes into account that the metric coefficients x_ξ, y_ξ and x_η, y_η are evaluated by the same finite difference operators used for calculating f_ξ and f_η, respectively.

Henceforth, it is assumed that the functions $f(\xi,\eta)$, $x(\xi,\eta)$, and $y(\xi,\eta)$ are $(p+1)$-times continuously differentiable with respect to ξ and $(q+1)$-times continuously differentiable with respect to η on Q, i.e., $f, x, y \in C^{p+1,q+1}(Q)$. Note that the present analysis remains valid if f, x, and y are piecewise $C^{p+1,q+1}(Q)$ functions. Actually, if any of the f, x, or y functions is not smooth enough (i.e., it is not $C^{p+1,q+1}(Q)$), then the physical domain D should be divided into a number of subdomains so that in each subdomain all the functions $f(\xi,\eta)$, $x(\xi,\eta)$, and $y(\xi,\eta)$ are $C^{p+1,q+1}(Q)$. Under this assumption we can expand (2.5) in a Taylor series with respect to ξ_i and η_k, respectively. Omitting the indices i and k, one can write

$$\begin{aligned}
&\sum_{l=i-l_1}^{i+l_2} a_l v_{lk} = v_\xi + C_p v_\xi^{(p+1)} \Delta\xi^p + O(\Delta\xi^{p+1}),\\
&\sum_{m=k-m_1}^{k+m_2} b_m v_{im} = v_\eta + C_q v_\eta^{(q+1)} \Delta\eta^q + O(\Delta\eta^{q+1}),
\end{aligned} \tag{2.6}$$

where

$$v_\xi^{(p+1)} = \frac{\partial^{p+1} v}{\partial \xi^{p+1}}, \quad v_\eta^{(q+1)} = \frac{\partial^{q+1} v}{\partial \eta^{q+1}}, \quad \Delta\xi = \frac{1}{I}, \quad \Delta\eta = \frac{1}{K},$$

and where C_p and C_q are constants dependent on a_l and b_m, respectively. Substituting (2.6) into (2.5) yields

$$L_h^{p,q}(f_x) = \frac{\delta_\eta y \delta_\xi f - \delta_\xi y \delta_\eta f}{\delta_\xi x \delta_\eta y - \delta_\eta x \delta_\xi y} + O(\Delta\xi^{p+1}, \Delta\eta^{q+1}), \tag{2.7}$$

where the differential operators δ_ξ and δ_η are defined by

$$\begin{aligned}
\delta_\xi &= \tfrac{\partial}{\partial\xi} + C_p \Delta\xi^p \tfrac{\partial^{p+1}}{\partial\xi^{p+1}},\\
\delta_\eta &= \tfrac{\partial}{\partial\eta} + C_q \Delta\eta^q \tfrac{\partial^{q+1}}{\partial\eta^{q+1}}.
\end{aligned} \tag{2.8}$$

As the mapping used is nonsingular $(0 < J < +\infty\ \forall \xi, \eta \in Q)$, the denominator of (2.7) can be linearized to give

$$\begin{aligned}
L_h(f_x) = \tfrac{1}{J} \Big[& y_\eta f_\xi - y_\xi f_\eta + C_p \Delta\xi^p \left(y_\eta f_\xi^{(p+1)} - y_\xi^{(p+1)} f_\eta \right)\\
& + C_q \Delta\eta^q (f_\xi y_\eta^{(q+1)} - y_\xi f_\eta^{(q+1)}) \Big]\\
& \times \left[1 - \tfrac{C_p \Delta\xi^p}{J} \left(y_\eta x_\xi^{(p+1)} - y_\xi^{(p+1)} x_\eta \right) - \tfrac{C_q \Delta\eta^q}{J} \left(x_\xi y_\eta^{(q+1)} - y_\xi x_\eta^{(q+1)} \right) \right]\\
& + O(\Delta\xi^{p+1}, \Delta\eta^{q+1}).
\end{aligned} \tag{2.9}$$

It should be emphasized that the error introduced by the linearization is of the order of $O(\Delta\xi^{2p}, \Delta\eta^{2q}, \Delta\xi^p\Delta\eta^q)$. The linearization has been performed under the following assumptions:

$$\begin{aligned}
\Delta\xi^p \left| y_\eta x_\xi^{(p+1)} - x_\eta y_\xi^{(p+1)} \right| &\ll J,\\
\Delta\eta^q \left| x_\xi y_\eta^{(q+1)} - y_\xi x_\eta^{(q+1)} \right| &\ll J,
\end{aligned}$$

which can be treated as conditions for the minimum number of grid points needed for the approximation. By multiplying out the terms in the square brackets and neglecting higher-order terms, we can write the leading truncation error term $T_{p,q}$ as follows:

$$\begin{aligned} T_{p,q}(\xi,\eta) = \tfrac{1}{J}\Big\{ & C_p \Delta\xi^p \Big[y_\eta f_\xi^{(p+1)} - y_\xi^{(p+1)} f_\eta - f_x \Big(y_\eta x_\xi^{(p+1)} - x_\eta y_\xi^{(p+1)} \Big) \Big] \\ & + C_q \Delta\eta^q \Big[f_\xi y_\eta^{(q+1)} - y_\xi f_\eta^{(q+1)} - f_x \Big(x_\xi y_\eta^{(q+1)} - y_\xi x_\eta^{(q+1)} \Big) \Big] \Big\}. \end{aligned} \tag{2.10}$$

The truncation error $T_{p,q}$ consists of two parts: one part arises from the approximation of f_ξ and f_η, and the other occurs due to the evaluation of the metric coefficients x_ξ, y_ξ, x_η, and y_η. It should be emphasized that any grid adaptation based on minimization or equidistribution of the first part of the truncation error alone is not sufficient because the second part of the truncation error may drastically increase in regions where the metric coefficients change rapidly. In other words, any inconsistent grid adaptation transfers the error from the first part of the truncation error to that of the second, and vice versa. To minimize both parts of the truncation error simultaneously we impose the following restriction on the coordinate mapping. From (2.10) it follows that if absolute value of the first expression in the square brackets is less than $O(\Delta\xi)$, and absolute value of the second expression is less than $O(\Delta\eta)$, then the global truncation error is $O(\Delta\xi^{p+1}, \Delta\eta^{q+1})$ rather than $O(\Delta\xi^p, \Delta\eta^q)$. Thus, to increase the order of the finite difference approximation (2.7) globally by one, grid points should be redistributed so that the following equations hold:

$$\begin{aligned} J\Big(y_\eta f_\xi^{(p+1)} - y_\xi^{(p+1)} f_\eta \Big) &= (y_\eta f_\xi - y_\xi f_\eta)\Big(y_\eta x_\xi^{(p+1)} - x_\eta y_\xi^{(p+1)} \Big) + O(\Delta\xi) J^2 \\ J\Big(f_\xi y_\eta^{(q+1)} - y_\xi f_\eta^{(q+1)} \Big) &= (y_\eta f_\xi - y_\xi f_\eta)\Big(x_\xi y_\eta^{(q+1)} - y_\xi x_\eta^{(q+1)} \Big) + O(\Delta\eta) J^2. \end{aligned} \tag{2.11}$$

By removing the parentheses and rearranging corresponding terms, we reduce (2.11) to

$$\begin{aligned} y_\eta \Big[f_\xi^{(p+1)} - f_y y_\xi^{(p+1)} - f_x x_\xi^{(p+1)} \Big] &= O(\Delta\xi) J, \\ -y_\xi \Big[f_\eta^{(q+1)} - f_y y_\eta^{(q+1)} - f_x x_\eta^{(q+1)} \Big] &= O(\Delta\eta) J. \end{aligned} \tag{2.12}$$

The equations in (2.12) can be considered optimal grid generation equations in the sense of minimizing the leading truncation error term of the first derivative f_x. The optimal grid adaptation criteria for f_y, which is

$$f_y = \frac{-x_\eta f_\xi + x_\xi f_\eta}{J}, \tag{2.13}$$

can be derived in the same fashion as has been done for f_x. Actually, using the same approximations (2.5) for all the ξ and η derivatives in (2.13), and linearizing the corresponding leading truncation error term, the grid adaptation criteria for f_y can be obtained in the following form:

$$\begin{aligned} -x_\eta \Big[f_\xi^{(p+1)} - f_y y_\xi^{(p+1)} - f_x x_\xi^{(p+1)} \Big] &= O(\Delta\xi) J, \\ x_\xi \Big[f_\eta^{(q+1)} - f_y y_\eta^{(q+1)} - f_x x_\eta^{(q+1)} \Big] &= O(\Delta\eta) J. \end{aligned} \tag{2.14}$$

The presence of the $O(\Delta\xi)$ and $O(\Delta\eta)$ terms on the right-hand side of (2.12) and (2.14) indicates that the grid adaptation criteria are rather stable under perturbations of the optimal grid.

At the same time, a reduction of the $O(\Delta\xi)$ and $O(\Delta\eta)$ terms in (2.12) and (2.14) decreases the corresponding truncation errors on the optimal grid. Therefore, we can neglect these terms so that (2.12) and (2.14) become identical and can be written as

$$\begin{aligned} f_\xi^{(p+1)} - f_y y_\xi^{(p+1)} - f_x x_\xi^{(p+1)} &= 0, \\ f_\eta^{(q+1)} - f_y y_\eta^{(q+1)} - f_x x_\eta^{(q+1)} &= 0. \end{aligned} \tag{2.15}$$

From the above consideration it follows that if we can construct the mapping which satisfies (2.15), then the leading truncation error term of the gradient of $f(x, y)$ vanishes on the same optimal grid. Because (2.12) and (2.14) have similar properties, hereafter only (2.12) is considered.

Note that if $y_\xi = 0$ in the entire computational domain, (2.12) reduces to

$$x_\xi f_\xi^{(p+1)} - f_\xi x_\xi^{(p+1)} = O(\Delta\xi) x_\xi^2, \tag{2.16}$$

which can be treated as a 1D analogue of (2.12) in the ξ coordinate. The main properties of (2.16) are analyzed in [4]. Another very useful characteristic of the optimal mapping is that the equations in (2.12) are invariant with respect to both translation and stretching of the x, y and ξ, η coordinates.

Remark 2.1. It should be noted that the equations in (2.12) are not a system of equations and can be considered separately. If improving the accuracy with respect to the ξ coordinate alone is necessary, a grid must be generated such that only the first equation in (2.12) holds. However, if increasing the order of approximation of f_x by one in both the ξ and η coordinates simultaneously is desirable, then the grid must obey the system of equations (2.12).

Remark 2.2. A characteristic feature of the equations in (2.12) is that they do not depend on the coefficients C_p and C_q. The reason is that the metric coefficients and the first derivatives f_ξ and f_η are approximated by using the same finite difference formulas (2.5). Consequently, if in each spatial direction the metric coefficients and the first derivatives of $f(\xi, \eta)$ are evaluated consistently by some hybrid finite difference operators, then the grid adaptation criteria (2.12) can be applied in the whole computational domain regardless of points where the hybrid scheme switches from one approximation to another. If the identical numerical approximation is the case, the optimal grid point distribution is generic because it depends only on the order of approximation and is completely independent of the particular finite difference formula used.

Remark 2.3. As follows from the analysis presented in [4], the grid adaptation equation does not guarantee that the coordinate mapping obtained as the solution of (2.12) is not singular, i.e., $0 < J < +\infty$. Because (2.12) converts to (2.16), if the dimension of the space is decreased by one, the same singularity may occur in two dimensions as well. In other words, the equations in (2.12) do not ensure existence and uniqueness of the one-to-one coordinate transformation. A way to overcome this problem in the case of second-order approximations will be discussed in the next section.

The equations in (2.12) must be closed by corresponding boundary conditions. These equations can be shown to be pth-order partial differential equations (PDEs), and, therefore, p boundary conditions should be imposed at each pair of the opposite boundaries (i.e., $\xi = 0$ and $\xi = 1$, $\eta = 0$ and $\eta = 1$) to find the unique solution.

However, at each individual boundary, only one boundary condition is available. For example, the boundary conditions in the ξ coordinate are

$$\xi(x,y)=0, \quad \xi(x,y)=1. \tag{2.17}$$

In other words, the equations in (2.12) are not closed. The situation becomes even more uncertain when only one of the grid adaptation criteria (2.12) is used. However, this uncertainty yields additional degrees of freedom, and at the same time it is conceivable that more than one optimal grid exists to satisfy the criteria (2.12). From this standpoint, the equations in (2.12) should be treated as the grid adaptation criteria rather than as the optimal grid generation equations [4].

3. Optimal grids for second-order approximations. If both f_ξ, f_η and the corresponding metric coefficients x_ξ, y_ξ and x_η, y_η are approximated by some second-order formulas, the grid adaptation criteria (2.15) written for $p=q=2$ become

$$\begin{aligned} f_{\xi\xi\xi} &= f_x x_{\xi\xi\xi} + f_y y_{\xi\xi\xi},\\ f_{\eta\eta\eta} &= f_x x_{\eta\eta\eta} + f_y y_{\eta\eta\eta}. \end{aligned} \tag{3.1}$$

With

$$\begin{aligned} \frac{\partial}{\partial\xi} &= x_\xi \frac{\partial}{\partial x} + y_\xi \frac{\partial}{\partial y},\\ \frac{\partial}{\partial\eta} &= x_\eta \frac{\partial}{\partial x} + y_\eta \frac{\partial}{\partial y}, \end{aligned} \tag{3.2}$$

$f_{\xi\xi\xi}$ can be written in the physical space as follows:

$$\begin{aligned} f_{\xi\xi\xi} = &\left[x_\xi \frac{\partial}{\partial x} + y_\xi \frac{\partial}{\partial y}\right]^3 f = f_{xxx}x_\xi^3 + 3f_{xxy}x_\xi^2 y_\xi + 3f_{xyy}x_\xi y_\xi^2 + f_{yyy}y_\xi^3\\ &+ 3f_{xx}x_\xi x_{\xi\xi} + 3f_{xy}(x_{\xi\xi}y_\xi + y_{\xi\xi}x_\xi) + 3f_{yy}y_\xi y_{\xi\xi} + f_x x_{\xi\xi\xi} + f_y y_{\xi\xi\xi}. \end{aligned}$$

Calculating $f_{\eta\eta\eta}$ in a similar fashion and substituting these expressions into (3.1) yields

$$\begin{aligned} &3(f_{xx}x_\xi + f_{xy}y_\xi)x_{\xi\xi} + 3(f_{xy}x_\xi + f_{yy}y_\xi)y_{\xi\xi} + f_{xxx}x_\xi^3 + 3f_{xxy}x_\xi^2 y_\xi\\ &\quad +3f_{xyy}y_\xi^2 x_\xi + f_{yyy}y_\xi^3 = 0,\\ &3(f_{xx}x_\eta + f_{xy}y_\eta)x_{\eta\eta} + 3(f_{xy}x_\eta + f_{yy}y_\eta)y_{\eta\eta} + f_{xxx}x_\eta^3 + 3f_{xxy}x_\eta^2 y_\eta\\ &\quad + 3f_{xyy}y_\eta^2 x_\eta + f_{yyy}y_\eta^3 = 0. \end{aligned} \tag{3.3}$$

With (3.2), the equations in (3.3) are simplified to

$$\begin{aligned} &3f_{x\xi}x_{\xi\xi} + 3f_{y\xi}y_{\xi\xi} + f_{xx\xi}x_\xi^2 + 2f_{xy\xi}x_\xi y_\xi + f_{yy\xi}y_\xi^2 = 0\\ &3f_{x\eta}x_{\eta\eta} + 3f_{y\eta}y_{\eta\eta} + f_{xx\eta}x_\eta^2 + 2f_{xy\eta}x_\eta y_\eta + f_{yy\eta}y_\eta^2 = 0. \end{aligned} \tag{3.4}$$

Taking into account that the function $f(x,y)$ is given, the first equation in (3.4) contains only the derivatives with respect to ξ, while the second equation contains only the derivatives with respect to η. This property leads to the following integration procedure for (3.4). To integrate the first equation in (3.4) with respect to ξ, we assume that a family of coordinate lines $\eta = \text{const}$ is known. Therefore, at each point of the physical space, we can define a function $\alpha(\xi,\eta)$ as follows:

$$\alpha(\xi,\eta) = \tan\phi = \frac{y_\xi}{x_\xi}, \tag{3.5}$$

where ϕ is a known angle between a mesh line $\eta = \text{const}$ and the x-axis. By using the above equation, we can write the $y_{\xi\xi}$ derivative as

$$y_{\xi\xi} = (\alpha x_\xi)_\xi = \alpha_\xi x_\xi + \alpha x_{\xi\xi}. \tag{3.6}$$

Substituting (3.5) and (3.6) into (3.4) yields

$$3(f_{x\xi} + \alpha f_{y\xi})x_{\xi\xi} + 3\alpha_\xi f_{y\xi} x_\xi + x_\xi^2 \left(f_{xx\xi} + 2f_{xy\xi}\alpha + \alpha^2 f_{yy\xi}\right) = 0. \tag{3.7}$$

Since

$$\begin{aligned} f_{x\xi} &= f_{xx}x_\xi + f_{xy}y_\xi = (f_{xx} + \alpha f_{xy})x_\xi, \\ f_{y\xi} &= f_{xy}x_\xi + f_{yy}y_\xi = (f_{xy} + \alpha f_{yy})x_\xi, \end{aligned}$$

(3.7) can be reduced to

$$\begin{aligned} &x_\xi \left\{3\left(f_{xx} + 2\alpha f_{xy} + f_{yy}\alpha^2\right) x_{\xi\xi} \right. \\ &\left. + \, x_\xi \left[(f_{xx} + 2f_{xy}\alpha + f_{yy}\alpha^2)_\xi + \alpha_\xi(f_{xy} + \alpha f_{yy})\right]\right\} = 0. \end{aligned} \tag{3.8}$$

Without loss of generality, we assume that $x_\xi \neq 0$. Actually, if $x_\xi = 0$, then $y_\xi \neq 0$; otherwise the Jacobian of the transformation would be degenerated. In this case, the function α given by (3.5) can be redefined as x_ξ/y_ξ, and (3.8) can be rewritten in terms of y_ξ and $y_{\xi\xi}$ as

$$\begin{aligned} &y_\xi \left\{3\left(f_{xx}\alpha^2 + 2\alpha f_{xy} + f_{yy}\right) y_{\xi\xi} \right. \\ &\left. + \, y_\xi \left[(f_{xx}\alpha^2 + 2f_{xy}\alpha + f_{yy})_\xi + \alpha_\xi(f_{xx}\alpha + f_{xy})\right]\right\} = 0. \end{aligned} \tag{3.9}$$

Because the main properties of (3.8) and (3.9) are identical, hereafter only equation (3.8) is considered. Equation (3.8) can readily be integrated to give

$$x_\xi = C_1 \left(f_{xx} + 2f_{xy}\alpha + f_{yy}\alpha^2\right)^{-1/3} \exp\left[-\frac{1}{3}\int_0^\xi \frac{\alpha_t(f_{xy} + \alpha f_{yy})}{f_{xx} + 2f_{xy}\alpha + f_{yy}\alpha^2} dt\right], \tag{3.10}$$

where C_1 is a constant of the integration. Equation (3.10) can be treated as an analytical optimal grid for an arbitrary second-order approximation of ∇f in the sense of minimization of the leading truncation error term with respect to the ξ coordinate. If a grid is generated in accordance with the optimal mapping (3.10), the leading truncation error term in ξ is equal to zero in the entire physical domain D, and the global order of accuracy with respect to ξ is increased from 2 to 3.

A similar approach can be applied to construct the optimal grid in the η coordinate. Actually, assuming that a family of grid lines $\xi = \text{const}$ is given, we introduce a function $\beta(\xi, \eta)$ and derive the optimal grid point distribution in η in a similar manner as has just been done for ξ. Thus,

$$y_\eta = C_2 \left(f_{xx}\beta^2 + 2f_{xy}\beta + f_{yy}\right)^{-1/3} \exp\left[-\frac{1}{3}\int_0^\eta \frac{\beta_t(f_{xx}\beta + f_{xy})}{f_{xx}\beta^2 + 2f_{xy}\beta + f_{yy}} dt\right], \tag{3.11}$$

where

$$\beta(\xi, \eta) = \tan\psi = \frac{x_\eta}{y_\eta}.$$

The mapping given by (3.11) provides that the leading truncation error term with respect to η vanishes on the optimal grid. Note that in the 1D case, (3.10) and (3.11) are simplified as follows:

$$\begin{aligned} x_\xi &= C_1(f_{xx})^{-1/3}, \\ y_\eta &= C_2(f_{yy})^{-1/3}. \end{aligned} \tag{3.12}$$

This result is identical to that obtained earlier in one dimension [4].

As mentioned in Remark 2.3, (3.10) does not provide that the Jacobian of the transformation J is positive in the entire physical domain. Therefore, the optimal mapping (3.10) is modified as follows. Because the optimal grid (3.10) has been obtained under the assumption that mesh lines $\eta =$ const do not intersect each other, to provide that $J > 0$ it is necessary that an arc length increment Δs measured along a mesh line $\eta =$ const must be strictly positive. The arc length increment in ξ can easily be calculated to yield

$$\Delta s = \sqrt{x_\xi^2 + y_\xi^2}\Delta\xi = |x_\xi|\sqrt{1+\alpha^2}\Delta\xi. \tag{3.13}$$

From (3.13) it follows that Δs is strictly positive in D if the following constraint is imposed on α and, consequently, on the metric coefficients:

$$F(\xi,\eta) = f_{xx} + 2f_{xy}\alpha + f_{yy}\alpha^2 \neq 0. \tag{3.14}$$

The above constraint can be incorporated into numerical calculations by modifying the function F as

$$\tilde{F}(\xi,\eta) = \begin{cases} |F(\xi,\eta)|\,, & |F(\xi,\eta)| \geq \epsilon, \\ \frac{F(\xi,\eta)^2+\epsilon^2}{2\epsilon}\,, & |F(\xi,\eta)| < \epsilon. \end{cases} \tag{3.15}$$

Equation (3.15) is a necessary condition for positiveness and nonsingularity of the Jacobian of the transformation and, consequently, for existence of the one-to-one optimal mapping. Furthermore, (3.15) provides smoothness of the metric coefficients x_ξ and y_ξ. Note that (3.15) is not a sufficient condition. The optimal grid point distribution written in terms of the normalized arc length s is

$$s(\xi,\eta) = \frac{\int_0^\xi \tilde{F}^{-1/3}\sqrt{1+\alpha^2}\exp\left[-\frac{1}{3}\int_0^v \frac{\alpha_t(f_{xy}+f_{yy}\alpha)}{\tilde{F}}dt\right]dv}{\int_0^1 \tilde{F}^{-1/3}\sqrt{1+\alpha^2}\exp\left[-\frac{1}{3}\int_0^v \frac{\alpha_t(f_{xy}+f_{yy}\alpha)}{\tilde{F}}dt\right]dv}. \tag{3.16}$$

In numerical calculations, the second derivatives f_{xx}, f_{yy}, and f_{xy} are approximated numerically and, therefore, depend on the location of grid points in the physical domain. To find the optimal grid point distribution given by (3.16), the following iteration procedure is applied. At each grid point, the approximation of the second derivatives can be updated when the new grid point distribution is found. In its turn, the updated second derivatives generate a new optimal grid (3.16).

Let us show that this iteration technique is equivalent to the Picard iteration method (see, e.g., [16]). Actually, (3.16) can be interpreted as the following integral equation for the optimal mapping $s(\xi,\eta)$:

$$s(\xi,\eta) = \int_0^\xi G(t,s)dt, \tag{3.17}$$

where $\eta = \text{const}$. Taking into account the fact that $\tilde{F} \in C^1(Q)$, it follows that the function G is continuously differentiable $\forall s \in [0,1]$ and, consequently, satisfies the Lipschitz condition. Hence, the integral operator (3.17) is contractive on $[0,1]$ and maps $[0,1]$ into itself. Therefore, the iteration procedure based on (3.17) converges uniformly to the optimal mapping $s(\xi,\eta)$. The x and y coordinates of the optimal grid in ξ are obtained by 1D interpolation of s performed along each line $\eta = \text{const}$. The optimal grid in η can be constructed in a similar manner.

Despite the optimal grid point distribution (3.16) being derived under the assumption that a family of mesh lines $\eta = \text{const}$ is prescribed, this relation can be used directly along the boundaries $\eta = 0$ and $\eta = 1$ which are given a priori. Actually, the unknown function $\alpha(\xi,\eta)$ in (3.16) can always be determined on the boundaries $\eta = 0$ and $\eta = 1$ because at each boundary point we can calculate the boundary mesh line slope ϕ (3.5). In other words, if the function $f(x,y)$ and the physical domain boundary ∂D are given, the optimal grid point distribution along the boundaries can be found by using (3.10) and (3.11). In these equations, the unknown functions α and β are tangents of angles between the boundary mesh lines $\xi(x,y) = 0$, $\xi(x,y) = 1$ and $x = 0$; and $\eta(x,y) = 0$, $\eta(x,y) = 1$ and $y = 0$, respectively. The functions $\alpha(\xi,\eta)$ and $\beta(\xi,\eta)$ should satisfy the following equations:

$$\begin{aligned} x_{\xi\eta} &= x_{\eta\xi}, \\ y_{\xi\eta} &= y_{\eta\xi}, \end{aligned} \tag{3.18}$$

where the metric coefficients x_ξ, y_ξ and x_η, y_η are given by (3.10) and (3.11), respectively. Substituting (3.10) and (3.11) into (3.18) results in a very complicated system of differential equations for the functions α and β; these equations cannot be integrated analytically.

The above consideration gives rise to the following iterative grid generation procedure. First, the optimal grid point distribution on the boundaries is calculated by using (3.10) and (3.11). Then any grid generation technique (e.g., a transfinite interpolation) and the optimal boundary point distribution are used to generate an initial grid. This initial grid, together with an interpolation procedure, serves to define mesh lines along which the points will move during adaptation. After that, the $\eta = \text{const}$ grid lines are fixed, and grid points are redistributed along these lines in an optimal manner by using (3.10). In turn, this redistribution generates new coordinate lines $\xi = \text{const}$ so that we can redistribute grid points along this family of lines in accordance with (3.11). This sweep alters the grid point distribution along the $\xi = \text{const}$ lines and generates new mesh lines $\eta = \text{const}$. The grid generation procedure should be iterated until convergence. We should stress, however, that there is no proof that this iteration method converges. Moreover, as will be shown later, the solution of the system of equations (2.12) is not unique. This nonuniqueness gives an indication that for some functions $f(x,y)$, the system of equations (2.12) with the boundary conditions (2.3) is not well posed.

One interesting property of (3.1) is that the first equation in the system is invariant with respect to the following coordinate transformation:

$$\begin{aligned} \tilde{\xi} &= \xi, \\ \tilde{\eta} &= v_1(\eta), \end{aligned}$$

while the second equation is invariant with respect to a similar transformation:

$$\begin{aligned} \tilde{\xi} &= v_2(\xi), \\ \tilde{\eta} &= \eta, \end{aligned}$$

where v_1 and v_2 are smooth functions such that

$$v_i(0) = 0, \quad v_i(1) = 1, \quad i = \overline{1,2}, \quad \frac{dv_1}{d\eta} > 0, \quad \frac{dv_2}{d\xi} > 0.$$

This invariance means that if the optimal grid is constructed so that only the first equation in (3.1) holds, a family of the optimal grids (3.2) exists on which the leading truncation error term with respect to ξ vanishes. In other words, if only one of the equations in (3.1) is used for grid generation, the optimal grid is not unique. At the same time, if the physical domain D is bounded by lines $y = a_0$ and $y = a_1$ corresponding to the boundaries $\eta = 0$ and $\eta = 1$, then a family of the optimal grids satisfying the system of equations (2.12) is

$$\begin{aligned} x &= x(\xi, \eta), \\ y &= v(\eta), \end{aligned} \tag{3.19}$$

where $x(\xi, \eta)$ is defined by (3.16) and the function v meets the following conditions:

$$v(0) = a_0, \quad v(1) = a_1, \quad v'_\eta > 0 \ \forall \eta \in [0, 1]. \tag{3.20}$$

In contrast to the one-parameter family of the solutions $\tilde{\xi} = \xi$ and $\tilde{\eta} = v_1(\eta)$, which satisfies just the first equation in (3.1), (3.19) is the solution of the system (2.12).

Remark 3.1. Although the present analysis has been performed for simply connected domains, this approach can be extended to multiply connected domains. It can be done by dividing the physical domain into a number of simply connected subdomains with smooth boundaries so that $f(\xi, \eta)$, $x(\xi, \eta)$, and $y(\xi, \eta)$ are $C^{p+1,q+1}$ functions in each subdomain. After that, the present method can be used separately in each subdomain.

Remark 3.2. It should be emphasized that the above approach can be extended directly to three dimensions. 3D grid adaptation criteria analogous to (2.15) have been derived in [4]. These grid generation equations, minimizing the leading truncation error term of ∇f in three dimensions, are

$$\begin{aligned} f_\xi^{(p+1)} - f_x x_\xi^{(p+1)} - f_y y_\xi^{(p+1)} - f_z z_\xi^{(p+1)} &= 0, \\ f_\eta^{(q+1)} - f_x x_\eta^{(q+1)} - f_y y_\eta^{(q+1)} - f_z z_\eta^{(q+1)} &= 0, \\ f_\zeta^{(r+1)} - f_x x_\zeta^{(r+1)} - f_y y_\zeta^{(r+1)} - f_z z_\zeta^{(r+1)} &= 0. \end{aligned} \tag{3.21}$$

Each of the three 3D grid generation equations in (3.21) contains derivatives with respect to just one of the ξ, η, or ζ coordinates, respectively. Therefore, assuming that $x_\xi \neq 0$, and introducing $\alpha_1 = y_\xi / x_\xi$ and $\alpha_2 = z_\xi / x_\xi$, we can integrate the 3D optimal grid generation equation corresponding to the coordinate ξ in the same fashion as in the 2D case.

4. Optimal grids for nonlinear PDEs. The optimal grid generation procedure developed in the foregoing section can be extended directly to a nonlinear PDE. Let us consider a nonlinear scalar equation written in the following form:

$$L(f_x, g_y, f, g, u, x, y) = 0, \tag{4.1}$$

where L is a smooth nonlinear function of its arguments and f and g are nonlinear functions of x, y, and u. Note that (4.1) is solved with respect to u; i.e., this equation is strongly nonlinear.

To construct a pth-order in ξ and qth-order in η approximation of (4.1), we transfer the x and y derivatives into the computational space (ξ, η) and use some pth- and qth-order accurate schemes to evaluate the ξ and η derivatives, accordingly. The other quantities in (4.1) are evaluated exactly. The truncation error of such an approximation is

$$T_{p,q} = L_h(f_x^{\text{ex}}, g_y^{\text{ex}}, f^{\text{ex}}, g^{\text{ex}}, u^{\text{ex}}, x, y) - L(f_x^{\text{ex}}, g_y^{\text{ex}}, f^{\text{ex}}, g^{\text{ex}}, u^{\text{ex}}, x, y),$$

where L_h is a finite difference operator approximating (4.1) and the superscript "ex" denotes the exact solution of (4.1). Expanding the right-hand side of the above equation in a Taylor series with respect to the exact solution and omitting the superscript "ex" yields

$$T_{p,q} = \frac{\partial L}{\partial f_x}\left[(f_x)_h - f_x\right] + \frac{\partial L}{\partial g_y}\left[(g_y)_h - g_y\right] = \frac{\partial L}{\partial f_x} T^f_{p,q} + \frac{\partial L}{\partial g_y} T^g_{p,q}, \tag{4.2}$$

where $T^f_{p,q}$ and $T^g_{p,q}$ are truncation errors of the first derivatives f_x and g_y, respectively. With (2.10) and a similar expression for $T^g_{p,q}$, the leading truncation error term of (4.1) becomes

$$\begin{aligned} T_{p,q}(\xi,\eta) = {} & \tfrac{C_p \Delta\xi^p}{J^2} \left[\tfrac{\partial L}{\partial f_x} \left(y_\eta f_\xi^{(p+1)} - x_\xi^{(p+1)} f_x y_\eta - y_\xi^{(p+1)} f_\eta y_\eta \right) \right. \\ & \left. + \tfrac{\partial L}{\partial g_y} \left(-x_\eta g_\xi^{(p+1)} + x_\xi^{(p+1)} x_\eta g_x + y_\xi^{(p+1)} x_\eta g_y \right) \right] \\ & + \tfrac{C_q \Delta\eta^q}{J^2} \left[\tfrac{\partial L}{\partial f_x} \left(-y_\xi f_\eta^{(q+1)} + x_\eta^{(q+1)} f_x y_\xi + y_\eta^{(q+1)} f_y y_\xi \right) \right. \\ & \left. + \tfrac{\partial L}{\partial g_y} \left(x_\xi g_\eta^{(q+1)} - x_\eta^{(q+1)} x_\xi g_x - y_\eta^{(q+1)} x_\xi g_y \right) \right]. \end{aligned} \tag{4.3}$$

The above equation has been derived by assuming that $\partial L/\partial f_x$ and $\partial L/\partial g_y$ are functions of f, g, u, x, and y only, and do not depend on f_x and g_y. It is also assumed that the metric coefficients are evaluated by the same finite difference operator used for approximating the corresponding first derivatives f_ξ, g_ξ and f_η, g_η. Equation (4.3) indicates that if a grid is generated so that the first term in the square brackets is of the order of $O(\Delta\xi)$, while the second term is of the order of $O(\Delta\eta)$, then the global orders of approximations with respect to ξ and η are increased from p and q to $p+1$ and $q+1$, respectively. Thus, in the sense of minimizing the asymptotic truncation error of (4.1), the optimal grid should satisfy the following criteria:

$$\begin{aligned} \tfrac{\partial L}{\partial f_x} y_\eta f_\xi^{(p+1)} - \tfrac{\partial L}{\partial g_y} x_\eta g_\xi^{(p+1)} &= x_\xi^{(p+1)} \left(\tfrac{\partial L}{\partial f_x} f_x y_\eta - \tfrac{\partial L}{\partial g_y} g_x x_\eta \right) \\ & \quad + y_\xi^{(p+1)} \left(\tfrac{\partial L}{\partial f_x} f_y y_\eta - \tfrac{\partial L}{\partial g_y} g_y x_\eta \right) + O(\Delta\xi) J^2 \\ \tfrac{\partial L}{\partial g_y} x_\xi g_\eta^{(q+1)} - \tfrac{\partial L}{\partial f_x} y_\xi f_\eta^{(q+1)} &= x_\eta^{(q+1)} \left(\tfrac{\partial L}{\partial g_y} g_x x_\xi - \tfrac{\partial L}{\partial f_x} f_x y_\xi \right) \\ & \quad + y_\eta^{(q+1)} \left(\tfrac{\partial L}{\partial g_y} g_y x_\xi - \tfrac{\partial L}{\partial f_x} f_y y_\xi \right) + O(\Delta\eta) J^2. \end{aligned} \tag{4.4}$$

Because reduction of the $O(\Delta\xi)$ and $O(\Delta\eta)$ terms increases the accuracy of the approximation on the optimal grid, these terms are neglected.

In the case where the governing equation (4.1) can be written in conservation law form,

$$\frac{\partial f(u)}{\partial x} + \frac{\partial g(u)}{\partial y} = 0, \tag{4.5}$$

and some second-order schemes are used to evaluate both the ξ and η derivatives, (4.4) is reduced to

$$\begin{aligned} y_\eta f_{\xi\xi\xi} - x_\eta g_{\xi\xi\xi} = &\quad x_{\xi\xi\xi}(f_x y_\eta - x_\eta g_x) + y_{\xi\xi\xi}(f_y y_\eta - x_\eta g_y), \\ -y_\xi f_{\eta\eta\eta} + x_\xi g_{\eta\eta\eta} = &\quad x_{\eta\eta\eta}(x_\xi g_x - f_x y_\xi) + y_{\eta\eta\eta}(x_\xi g_y - f_y y_\xi). \end{aligned} \tag{4.6}$$

It should be emphasized that the conservation law (4.5) is a nonlinear PDE with respect to u because we assume the functions f and g are nonlinear functions of u. The equations in (4.6) take into account that for the conservation law (4.5), the derivatives $\partial L/\partial f_x$ and $\partial L/\partial g_y$ in (4.6) are equal to unity identically. Note that the second equation in (4.6) converts to the first equation by exchanging ξ and η for each other. Therefore, we shall consider just the first equation, and the same results will remain valid for the second equation by similarly exchanging ξ and η.

The equations in (4.6) can be integrated in the same fashion as we have integrated (3.1). Assuming that one family of mesh lines (e.g., $\eta =$ const) is given, we redistribute grid points along these lines in such a way that the first equation in (4.6) is satisfied in the whole computational domain. With (3.2), the first equation in (4.6) is transformed to

$$\begin{aligned} 3(y_\eta f_{x\xi} - x_\eta g_{x\xi})x_{\xi\xi} + 3(f_{y\xi} y_\eta - g_{y\xi} x_\eta)y_{\xi\xi} + (y_\eta f_{xx\xi} - x_\eta g_{xx\xi})x_\xi^2 \\ + 2(f_{xy\xi} y_\eta - x_\eta g_{xy\xi})x_\xi y_\xi + (f_{yy\xi} y_\eta - x_\eta g_{yy\xi})y_\xi^2 = 0. \end{aligned} \tag{4.7}$$

Introducing the function α given by (3.5) and using the relations (3.6) yields

$$3(F y_\eta - G x_\eta) + x_\xi \left\{F_\xi y_\eta - G_\xi x_\eta + \alpha_\xi \left[y_\eta \left(f_{xy} + \alpha f_{yy}\right) - x_\eta \left(g_{xy} + \alpha g_{yy}\right)\right]\right\} = 0, \tag{4.8}$$

where F is given by (3.14) and $G = g_{xx} + 2g_{xy}\alpha + g_{yy}\alpha^2$. Equation (4.8) derived under the assumption that $x_\xi \neq 0$ can be further simplified if we use the function β defined by (3.11). Thus,

$$y_\eta \left\{3(F - G\beta)x_{\xi\xi} + x_\xi \left[F_\xi - G_\xi \beta + \alpha_\xi \left(f_{xy} + \alpha f_{yy} - \beta \left[g_{xy} + \alpha g_{yy}\right]\right)\right]\right\} = 0. \tag{4.9}$$

With $y_\eta \neq 0$, (4.9) can be integrated to give

$$x_\xi = C(F - \beta G)^{-1/3} \exp\left[-\frac{1}{3}\int_0^\xi \frac{\beta_t G + \alpha_t \left(f_{xy} + \alpha f_{yy} - \beta[g_{xy} + \alpha g_{yy}]\right)}{F - \beta G} dt\right]. \tag{4.10}$$

Even though (4.10) depends on both α and β, basic properties of this optimal grid point distribution are similar to those obtained for the optimal mapping (3.10). By analogy with (3.10) and (3.13)–(3.15), the necessary condition that the Jacobian of the transformation is positive in the entire computational domain is satisfied if function $E = F - \beta G$ is modified as follows:

$$\tilde{E} = \begin{cases} |F - \beta G|\ , & |F - \beta G| \geq \epsilon, \\ \frac{(F-\beta G)^2 + \epsilon^2}{2\epsilon}\ , & |F - \beta G| < \epsilon, \end{cases} \tag{4.11}$$

where ϵ is a small positive parameter. As follows from (4.10), if a grid is constructed such that (4.10) holds, then for the conservation law equation (4.5) the global order of approximation with respect to ξ is increased by one.

In contrast to the grid generation procedure developed for ∇f, (4.10) cannot be integrated separately for each mesh line $\eta = \text{const}$ because the function $\beta(\xi, \eta)$ is involved in the formula. The problem can be overcome by taking the unknown function β from the previous iteration so that grid points are redistributed at each mesh line $\eta = \text{const}$ independently. After that, values of β are updated, and the iteration procedure should be repeated until convergence.

Despite the fact that the optimal grid (4.10) has been derived under the condition that one family of coordinate lines is given a priori, this analytical formula can be directly used for calculating boundary layer problems. Assuming that the solution of (4.5) is sufficiently smooth and has a boundary layer in ξ, the unidirectional grid adaptation procedure based on (4.10) can be applied with grid points constrained to move along the $\eta = \text{const}$ family of fixed curvilinear coordinate lines. This family of coordinate lines can be constructed, e.g., by using the conformal mapping that ensures existence and uniqueness of one-to-one coordinate transformations. The coordinate lines $\eta = \text{const}$ obtained this way are used to generate the optimal grid in ξ by using the formula (4.10). This grid adaptation procedure provides that the global order of approximation with respect to ξ is increased from 2 to 3, while the order of approximation in η remains the same. Because of the boundary layer, the asymptotic truncation error in the ξ coordinate is much greater than that in η. Therefore, this unidirectional grid adaptation procedure minimizes the most troublesome part of the global truncation error caused by the boundary layer.

5. Results and discussion. Several 2D test examples are investigated to validate the applicability and efficiency of the new method. For each test example, four series of calculations have been executed on different grids with the same number of grid points. The first calculation is done on a uniform grid generated by a transfinite interpolation of the boundary nodes uniformly redistributed along the boundaries. The second is performed on the optimal grid obtained as the analytical solution of (2.12). The third uses the optimal grid (3.16) generated numerically by approximating the second derivatives f_{xx}, f_{xy}, and f_{yy} with second-order central differences in the computational domain. The integrals in (3.16) are computed with trapezoidal rule integration. The fourth calculation is also executed on the uniform grid; however, instead of a second-order approximation, a third-order accurate discretization is applied to calculate both the ξ and η derivatives in (2.4). At each boundary, one-sided second-order differences are used. In order to estimate the method's accuracy, the L_2 and L_∞ norms of the truncation error of different second-order finite difference approximations of f_x and f_y are calculated on successively refined grids. Note that evaluation of the L_2 integral norm in the computational space differs from that calculated in the physical space by the Jacobian factor. Unlike the L_2 norm, the L_∞ norm is generic in this sense because it is the same in both the physical and transformed spaces.

The first test example is a second-order approximation of the first derivative f_x of a function $f(x, y) = (x - y)^m$ on a unit square $[0, 1] \times [0, 1]$. The parameter m has been set at 20, which results in the function having a pronounced boundary layer of width $O(1/m)$ near points $(0, 1)$ and $(1, 0)$. Isolines of this function are shown in Figure 5.1. A backward second-order approximation,

$$\left(\frac{\partial f}{\partial \xi}\right)_i = \frac{-3f_i + 4f_{i+1} - f_{i+2}}{2\Delta\xi}, \tag{5.1}$$

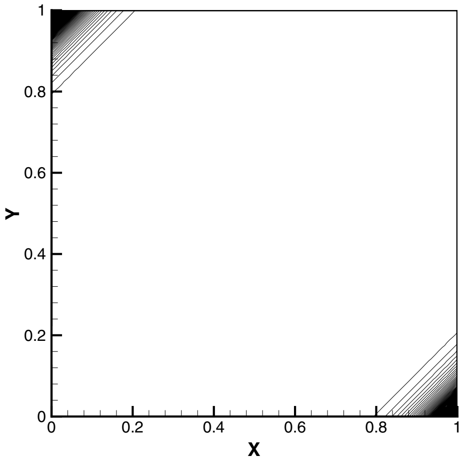

FIG. 5.1. *Isolines of the function* $f(x, y) = (x - y)^m$.

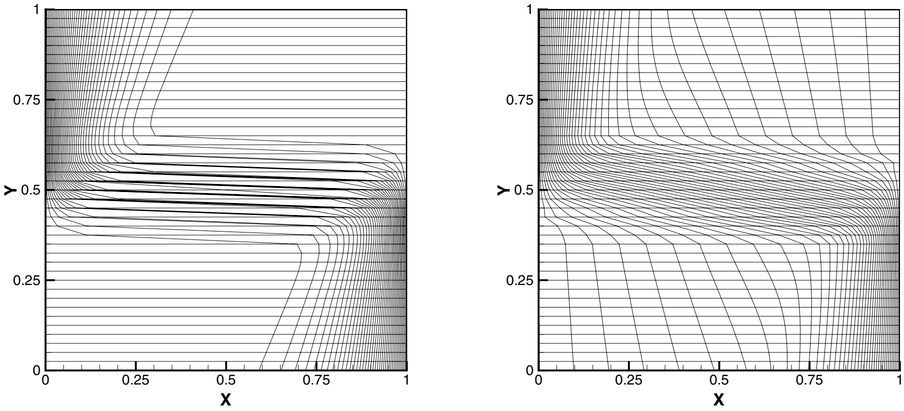

FIG. 5.2. *Analytical (left) and numerical (right) optimal* 40×40 *grids for the function* $f(x, y) = (x - y)^m$.

is used to evaluate both the ξ and η derivatives in (2.4). The test function has been chosen so that a family of the optimal grids satisfying the system of equations (2.12) can be integrated analytically to yield

$$\begin{aligned} &y_{\text{opt}} = v(\eta) \\ (5.2) \qquad &x_{\text{opt}} = v(\eta) + \left\{ -v(\eta)^{(m+1)/3} + \left[(1 - v(\eta))^{(m+1)/3} + v(\eta)^{(m+1)/3} \right] \xi \right\}^{3/(m+1)}. \end{aligned}$$

Note that the above equations have been derived by assuming $(m + 1)/3$ is an odd number. The numerical optimal grid is generated along fixed coordinate lines $\eta =$ const by using (3.10). Figure 5.2 shows the analytical and numerical optimal grids. Grid lines are concentrated near strong gradients of the function $f(x, y)$, which are

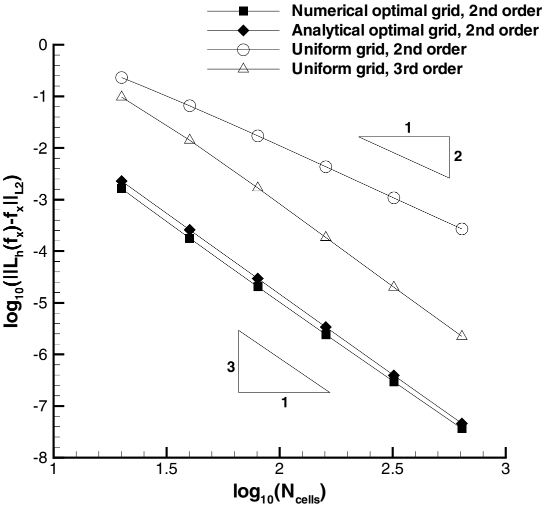

FIG. 5.3. *Error convergence for the second-order approximation of f_x of $f(x,y) = (x-y)^m$ calculated on* (1) *numerical optimal grid,* (2) *analytical optimal grid,* (3) *uniform grid, and* (4) *uniform grid with a third-order accurate discretization.*

located at points $(0,1)$ and $(1,0)$. At the same time, there are practically no grid points in the center of the domain so that very skewed grid cells are generated in this region. Despite these cell angles being very small, the L_2 truncation error norm computed in the computational space is superconvergent on both the analytical and numerical optimal grids, as evident in Figure 5.3. The comparison of the second-order approximation on the optimal grid and a third-order discretization on the uniform grid with the same number of grid points shows that the optimal grid results are about 10^2 times more accurate.

As follows from (5.2), the analytical optimal grid is not unique. Actually, any function $v(\eta)$ satisfying the conditions (3.20) should provide the optimal grid. Figure 5.4 shows the L_∞ norm of the truncation errors obtained on the analytical and numerical optimal grids corresponding to

$$v(\eta) = \begin{cases} 0.5(2\eta)^{0.25}, & 0 \le \eta \le 0.5, \\ 1 - 0.5[2(1-\eta)]^{0.25}, & 0.5 < \eta \le 1. \end{cases} \tag{5.3}$$

Similar to the optimal grid generated with $v(\eta) = \eta$, the results calculated on the numerical optimal grids are about four orders of magnitude more accurate than those obtained on the finest uniform grid with the same number of grid points.

The next test example is an approximation of the first derivatives f_x and f_y of the following function:

$$f(x,y) = x^{\frac{3-\gamma-2\theta}{\gamma-\theta}} y^{\frac{-3+2\gamma+\theta}{\gamma-\theta}}. \tag{5.4}$$

The physical domain considered is bounded by four curves, $y = \xi_0^{\theta-\gamma}x$, $y = (1+\xi_0)^{\theta-\gamma}x$, $y = x(x/\eta_0^{\phi})^{\theta/\gamma-1}$, $y = x[x/(1+\eta_0)^{\phi}]^{\theta/\gamma-1}$, where γ, θ, ϕ, ξ_0, and η_0 are parameters. The parameters θ and γ have been chosen as -5 and -1.25, respectively; this choice results in the function being singular along a line $y = 0$. Isolines of the

function $f(x, y)$ are shown in Figure 5.5. In this test case, a family of the optimal grids satisfying equations (2.15) can be found analytically:

$$\begin{aligned} x_{\text{opt}} &= (\xi + \xi_0)^{\gamma}[v(\eta) + \eta_0]^{\phi}, \\ y_{\text{opt}} &= (\xi + \xi_0)^{\theta}[v(\eta) + \eta_0]^{\phi}, \end{aligned} \tag{5.5}$$

where v is an arbitrary smooth function satisfying the conditions (3.20). In numerical calculations, the parameters ξ_0 and η_0 were taken to be 1.25. A central second-order discretization is used for all the ξ and η derivatives in (2.4) and (2.13).

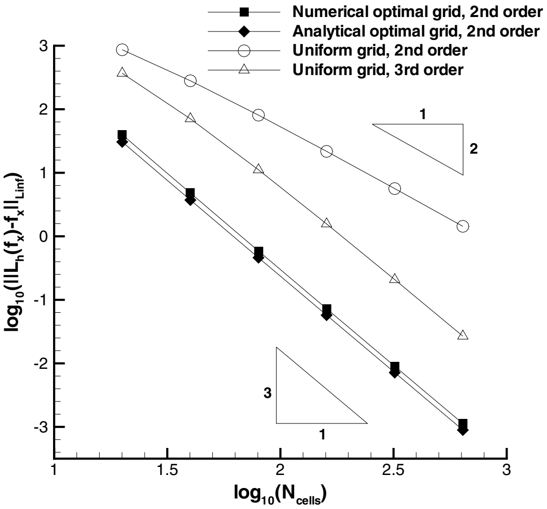

FIG. 5.6. *Error convergence for a central second-order approximation of* f_x *of* (5.4) *calculated on* (1) *numerical optimal grid,* (2) *analytical optimal grid,* (3) *uniform grid, and* (4) *uniform grid with a third-order accurate discretization.*

It should be noted that although the test function has the form $f = f_1(x)f_2(y)$, the analytical optimal grid (5.5) is not a tensor product grid of two 1D grids, one of which is optimal for $f_1(x)$ and the second one for $f_2(y)$. Using (3.12), it can easily be verified that the mapping (5.5) is optimal neither for $f_1(x) = x^{\frac{3-\gamma-2\theta}{\gamma-\theta}}$ nor for $f_2(y) = y^{\frac{-3+2\gamma+\theta}{\gamma-\theta}}$. At the same time, the mapping (5.5) is optimal for the function (5.4).

In Figure 5.6, error convergence plots of this approximation calculated on the analytical and numerical optimal grids corresponding to $v(\eta) = \eta$ are compared with results obtained by second- and third-order approximations on a uniform grid. The L_∞ norm of the truncation error of f_x calculated on the uniform grid exhibits the $O(\Delta\xi^2)$ convergence rate consistent with the second order of accuracy of the central differences. At the same time, the same second-order approximation of f_x on the optimal grid (5.5) exhibits a convergence rate of the order of $O(\Delta\xi^3)$. To generate the optimal grid numerically, a family of mesh lines $\eta =$ const is obtained by using (3.11). Then grid points are redistributed along these coordinate lines in accordance with (3.10). This grid point redistribution generates new lines $\eta =$ const and so on. The grid adaptation procedure is iterated until convergence. To reduce the residual by six orders of magnitude, 12 iterations were required. No attempt was made to optimize the iteration process. Figure 5.6 shows that the numerical optimal grid provides practically the same convergence rate as the analytical optimal grid (5.5). The truncation error norm calculated on the finest optimal grid is reduced by about two orders of magnitude as compared with the uniform grid results calculated with a third-order accurate formula.

As follows from (5.5), the optimal mapping is not unique. To demonstrate this property, the function $v(\eta)$ is chosen as

$$v(\eta) = \frac{k^\eta - 1}{k - 1}, \tag{5.6}$$

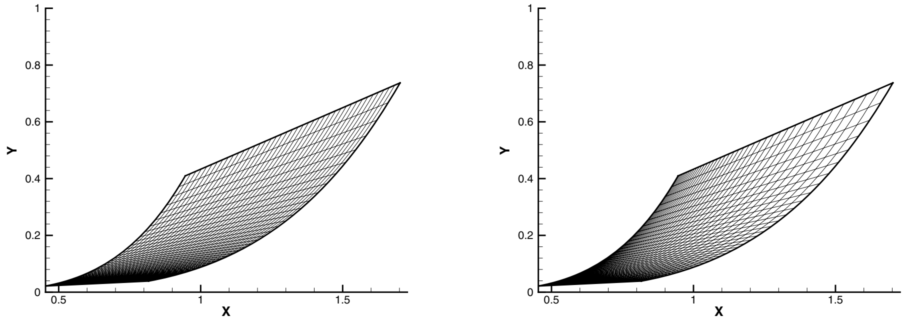

FIG. 5.7. *Analytical optimal* 40×40 *grids* (5.5) *corresponding to* $v(\eta) = \eta$ *(left) and* (5.6) *(right) for the function* (5.4).

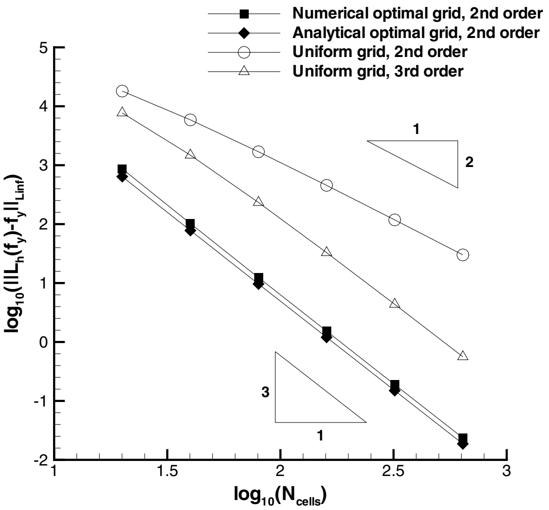

FIG. 5.8. *Error convergence for a central second-order approximation of* f_y *of* (5.4) *calculated on* (1) *numerical optimal grid,* (2) *analytical optimal grid,* (3) *uniform grid, and* (4) *uniform grid with a third-order accurate discretization.*

where the parameter k was chosen to be 10. The analytical optimal grids corresponding to the function $v(\eta) = \eta$ and the function (5.6) are shown in Figure 5.7. The optimal mapping (5.5), (5.6) results in grid lines $\eta = \text{const}$ being concentrated near the left boundary $\eta = 0$, as shown in Figure 5.7. Although this optimal mapping is different from that considered earlier, the error convergence plot for the grid (5.5), (5.6) is essentially the same as that shown in Figure 5.6 for the optimal grid corresponding to $v(\eta) = \eta$ and, therefore, is not presented here.

As shown in section 2, the optimal mapping (5.5) satisfying the system of equations (2.15) has to provide superconvergence not only for f_x but also for f_y. The L_∞ norm of the truncation error of f_y approximated by using the central second-order formulas is superconvergent on the same optimal grid (5.5), as is evident in Figure 5.8.

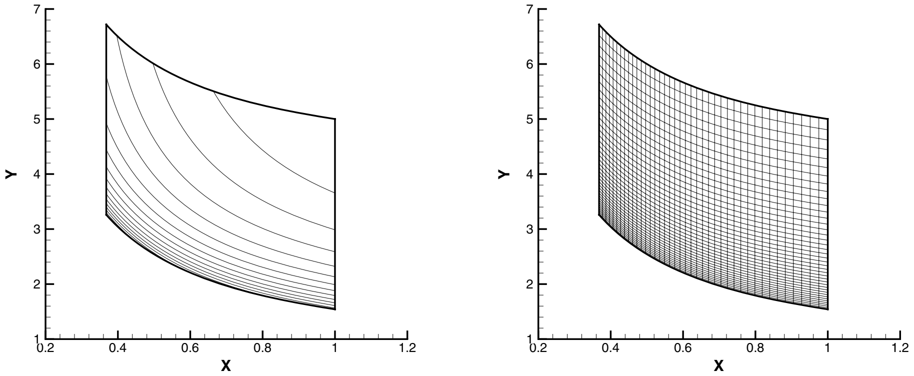

FIG. 5.9. *Isolines of the function* (5.7) *and the analytical optimal* 40×40 *grid* (5.8).

The third test function considered,

$$f(x, y) = \frac{1}{x} + \frac{mx}{xy - 1}, \tag{5.7}$$

has singularities along lines $x = 0$ and $y = 1/x$. For this function a particular solution of (2.15) can be found analytically:

$$\begin{aligned} x_{\text{opt}}(\xi, \eta) &= \mathrm{e}^{-\alpha\xi}, \\ y_{\text{opt}}(\xi, \eta) &= \mathrm{e}^{\alpha\xi} + m\mathrm{e}^{-\beta\eta}. \end{aligned} \tag{5.8}$$

As in the previous test example, this optimal grid satisfies both the grid adaptation criteria (3.1) and the optimal mapping (3.10) calculated with the function (5.7).

In the present test example, the parameters α, β, and m have been chosen as 1, 2, and 4, respectively. For such a choice of the parameters, the physical domain boundaries are $x = 1$, $x = \mathrm{e}^{-\alpha}$, $y = 1/x + 4$, and $y = 1/x + 4\mathrm{e}^{-2}$. Isolines of the function $f(x, y)$ and the optimal grid (5.8) are depicted in Figure 5.9. Notably, the optimal grid is orthogonal neither in the domain nor at the boundaries. Moreover, the grid lines are concentrated near strong gradients, and at the same time they are not strictly aligned with the isolines of $f(x, y)$.

As in the first test example, second-order accurate approximations of f_x and f_y are obtained by using the second-order approximation (5.1) for all the ξ and η derivatives in (2.4) and (2.13).

Similar to the previous test case, the optimal mapping (5.8) satisfies the system of equations (2.15), and, therefore, a grid generated by this transformation is optimal for the gradient of $f(x, y)$. Note that the numerical optimal grid is generated using formulas (3.10) and (3.11) so that grid points are redistributed in both ξ and η iteratively, as described in section 3. For this test problem, eight iterations were needed to reach convergence. A comparison of the truncation error convergences of ∇f obtained on the optimal and uniform grids is shown in Figure 5.10. The global order of the second-order central approximation in two dimensions is increased by one on the optimal grid. Furthermore, the L_∞ norm of the truncation error on the finest mesh is about four orders of magnitude less than that obtained on the corresponding uniform grid. As shown in Figure 5.10, the new grid adaptation criterion enables us to reach

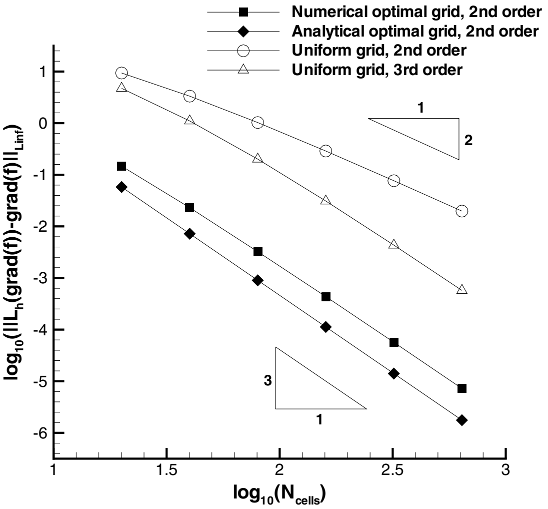

FIG. 5.10. *Error convergence for the second-order approximation of* ∇f *of* (5.7) *calculated on* (1) *numerical optimal grid,* (2) *analytical optimal grid,* (3) *uniform grid, and* (4) *uniform grid with a third-order accurate discretization.*

the asymptotic convergence rate on a coarse grid. At the same time, application of a third-order accurate discretization on the uniform grid does not provide such essential reduction in the truncation error as was obtained on the optimal grid.

Importance of the identical approximations of the first derivatives f_ξ, f_η and the corresponding metric coefficients x_ξ, y_ξ, x_η, and y_η is illustrated in Figure 5.11. The figure shows that if all the ξ and η derivatives in (2.4) and (2.13) are evaluated by hybrid discretization

$$\left(\frac{\partial f}{\partial \xi}\right)_i = \begin{cases} \frac{1}{2\Delta\xi}(f_{i+1} - f_{i-1}), & i \text{ even}, \\ \frac{1}{2\Delta\xi}(-3f_i + 4f_{i+1} - f_{i+2}), & i \text{ odd}, \end{cases} \tag{5.9}$$

the order of approximation of ∇f is increased from 2 to 3 when grid points are redistributed in accordance with (5.8). However, if the metric coefficients x_ξ, y_ξ, x_η, and y_η are evaluated by the two-point symmetric second-order difference expression in the entire computational domain, while both the hybrid approximation of f_ξ and f_η (5.9) and the optimal grid (5.8) remain the same, the order of the inconsistent approximation deteriorates to 2 and the L_∞ truncation error norm increases by a factor of $10^{2.5}$ on the finest mesh.

The last test example is a construction of the optimal grid that minimizes the leading truncation error term of $f_x + g_y$. Second-order central differences are used to evaluate both the ξ and η derivatives in (4.5) written in the computational space. The functions $f(x, y)$ and $g(x, y)$ have been chosen to be

$$\begin{aligned} f(x,y) &= x^{\frac{3\theta-2\phi}{\theta\phi(1-m)}} y^{\frac{\phi(2-\theta)-m\theta(3-\phi)}{\theta\phi(1-m)}}, \\ g(x,y) &= x^{\frac{-\phi(2-m\theta)+\theta(3-\phi)}{\theta\phi(1-m)}} y^{\frac{2\phi-3m\theta}{\theta\phi(1-m)}}. \end{aligned} \tag{5.10}$$

In this case a one-parameter family of the optimal grids satisfying (4.6) can be obtained analytically:

$$\begin{aligned} x_{\text{opt}}(\xi,\eta) &= (\xi+\xi_0)^{m\theta}[v(\eta)+\eta_0]^{\phi}, \\ y_{\text{opt}}(\xi,\eta) &= (\xi+\xi_0)^{\theta}[v(\eta)+\eta_0]^{\phi}, \end{aligned} \tag{5.11}$$

where the function $v(\eta)$ should satisfy the conditions (3.20). In this test example the parameters θ, ϕ, m, ξ_0, and η_0 were set at 1, 3, 0.5, 0.5, and 0.5, respectively. Such a choice provides that the physical domain is bounded by the following four curves: (1) $y = x/\sqrt{2}$, (2) $y = \sqrt{3/2}x$, (3) $y = 8x^2$, (4) $y = 8x^2/27$; and the functions $f(x, y)$ and $g(x, y)$ are singular along a line $x = 0$. As follows from (5.11), the optimal grid is not unique. To demonstrate this property, two functions, $v_1(\eta)$ and $v_2(\eta)$, have been chosen:

$$\begin{aligned} v_1(\eta) &= \eta, \\ v_2(\eta) &= \tfrac{k^\eta-1}{k-1}, \quad k = 10. \end{aligned} \tag{5.12}$$

The optimal grids (5.11) defined by the functions $v_1(\eta)$ and $v_2(\eta)$ are shown in Figure 5.12. The transformation of the η-coordinate caused by the function $v_2(\eta)$ results in stretching of grid lines to a boundary $\eta = 0$, which, like the other boundaries in the physical domain, remains unchanged. Similar to the previous example, the optimal grids are essentially nonorthogonal, and, at the same time, the grid nodes are concentrated near strong gradients of the f and g functions. In spite of the fact that the optimal grids shown in Figure 5.12 are quite different, the truncation error convergence rates obtained on these grids are practically identical, as depicted in Figure 5.13. This figure shows that the central second-order approximation of (4.5), calculated on the optimal grids (5.11) and (5.12), exhibits the $O(\Delta\xi^3)$ convergence rate, which allows us to reduce the L_∞ norm of the truncation error by 2.5 orders of magnitude

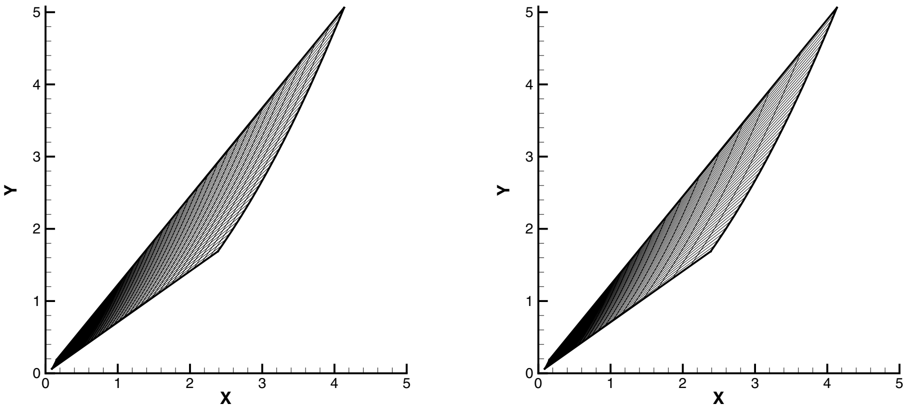

FIG. 5.12. *Analytical optimal* 40 × 40 *grids* (5.11) *corresponding to* $v(\eta) = \eta$ *(left) and* (5.6) *(right) for the function* (5.10).

as compared with the uniform grid results. The numerical optimal grid generated by using the iteration procedure described in the foregoing section also provides superconvergence. Note that the truncation error calculated on the numerical optimal grid is about two orders of magnitude more accurate than that obtained with the same second-order accurate approximation on the corresponding finest uniform grid.

6. Conclusion. A new multidimensional grid adaptation strategy based on the minimization of the leading truncation error term of an arbitrary order finite difference discretization has been developed. The main idea of the method is to redistribute grid points so that the leading truncation error terms resulting from the differential operator and the metric coefficients cancel each other. The result is that the design order of approximation on the optimal grid is increased by one in the entire computational domain. It has been shown that these grid adaptation criteria are stable under perturbations of the optimal grid. In contrast to most adaptive grid techniques, the present method does not explicitly require an a posteriori error estimate that makes it computationally inexpensive. Another very attractive characteristic of the new approach is its applicability to hybrid discretizations. We have proven that if the differential operator and the metric coefficients are evaluated identically, then the new grid adaptation criterion is generic in the sense that it remains valid in the entire computational domain regardless of points where the hybrid difference operator switches from one approximation to another. When a family of coordinate lines (e.g., $\eta = \text{const}$) is given a priori, the 2D optimal mapping that increases the order of approximation of ∇f in ξ from 2 to 3 has been derived analytically. For some functions, a family of the optimal grids can be constructed; this shows that the optimal mapping is not unique. One of the main advantages of the new method is that it can be extended directly to nonlinear PDEs and three dimensions. The numerical calculations show that the truncation error of both f_x and f_y obtained on the optimal grid is superconvergent and reduced by several orders of magnitude as compared with the second- and third-order uniform grid results for all the test examples considered.

THE CONVERGENCE OF SPECTRAL AND FINITE DIFFERENCE METHODS FOR INITIAL-BOUNDARY VALUE PROBLEMS[*]

NATASHA FLYER[†][‡] AND PAUL N. SWARZTRAUBER[†]

Abstract. The general theory of compatibility conditions for the differentiability of solutions to initial-boundary value problems is well known. This paper introduces the application of that theory to numerical solutions of partial differential equations and its ramifications on the performance of high-order methods. Explicit application of boundary conditions (BCs) that are independent of the initial condition (IC) results in the compatibility conditions not being satisfied. Since this is the case in most science and engineering applications, it is shown that not only does the error in a spectral method, as measured in the maximum norm, converge algebraically, but the accuracy of finite differences is also reduced. For the heat equation with a parabolic IC and Dirichlet BCs, we prove that the Fourier method converges quadratically in the neighborhood of $t = 0$ and the boundaries and quartically for large t when the first-order compatibility conditions are violated. For the same problem, the Chebyshev method initially yields quartic convergence and exponential convergence for $t > 0$. In contrast, the wave equation subject to the same conditions results in inferior convergence rates with all spectral methods yielding quadratic convergence for all t. These results naturally direct attention to finite difference methods that are also algebraically convergent. In the case of the wave equation, we prove that a second-order finite difference method is reduced to 4/3-order convergence and numerically show that a fourth-order finite difference scheme is apparently reduced to 3/2-order. Finally, for the wave equation subject to general ICs and zero BCs, we give a conjecture on the error for a second-order finite difference scheme, showing that an $O(N^{-2} \log N)$ convergence is possible.

Key words. compatibility conditions, convergence theory, spectral and finite difference methods

1. Introduction.

The regularity of solutions for initial-boundary value problems (IBVPs) is determined by the compatibility of the initial condition (IC) and the boundary conditions (BCs). IBVPs will have singular solutions at the corners of the space-time domain if the BCs do not satisfy the partial differential equation (PDE) or any of its higher-order derivatives, even if the IC is C^∞. The Cauchy–Kowalesky theorem [19] provides a solution in the neighborhood of $t = 0$ to the same problem without BCs. If compatibility exists, then the BCs can always be computed by the solution obtained from the Cauchy–Kowalesky theorem and the IC. In such cases, the IBVP could in fact be posed as an initial-value problem (IVP). The set of compatibility conditions are derived by equating the time derivatives of the BCs to those of the solution to the IVP given by the Cauchy–Kowalesky theorem.

Literature on the theory of compatibility conditions and the regularity of solutions for IBVPs is extensive, starting in the 1950s with the work of Ladyzenskaja [10], [11]. In the 1960s, Ladyzenskaja, Solonnikov, and Ural'ceva [12] and Friedman [3] discussed the regularity of the solution for linear and quasi-linear parabolic systems. During this same time, Kreiss [4] and Hersh [7] extended the theory for constant coefficient hyperbolic systems by providing the necessary and sufficient conditions for

the problem to be well-posed. It was further developed in the 1970s by Rauch and Massey [16] and Sakamoto [17] for hyperbolic systems with time-dependent coefficients. In the 1980s, Temam [20] extended the theory by obtaining the compatibility conditions for semilinear evolution equations while Smale [18] gave a rigorous proof of the compatibility conditions for the heat and wave equation on a bounded domain. These accomplishments have been confined to the realm of theoretical mathematics. Yet, not satisfying the compatibility conditions of a system can have a significant computational impact, particularly for high-order accurate methods, such as spectral methods, whose performance intrinsically depends on the smoothness of the solution. For nonsmooth initial data, there is a wealth of information on the convergence theory of numerical schemes in a variety of norms for parabolic and hyperbolic IVPs [13], [5], [21], [22]. These analyses can be applied to the IBVPs *if* the IBVP can be posed as an IVP with discontinuous ICs through periodic extensions of the ICs to the entire real axis [6], [9], [14]. However, such periodic extensions may induce singularities that do not exist in a smooth nonperiodic solution of an IBVP.

More recently, the impact of noncompatible BCs has been explored by Boyd and Flyer [2] in a computational framework. This paper appeared in a special issue on spectral methods. In the prologue, Karniadakis states "This is the first such effort in bringing the theory of compatibility conditions from the mathematical literature to the numerical community." This work illustrated the ubiquity of compatibility conditions and analyzed the connection between incompatibility and the rate of convergence of Chebyshev spectral series. However, the convergence of the error was not discussed or compared to alternatives such as the finite difference method. The focus of the paper, as has been in the mathematical literature, is on smoothing the initial condition so as to satisfy the compatibility conditions [2], [5], [18], [15]. The difficulty with this approach is that it leaves the fundamental question unanswered: namely, "What is the rate of convergence to the solution of the original unperturbed problem?" If the IC is smoothed, spectral convergence might be achieved *but* to a solution that differs algebraically from the original problem.

The focus of the current work is on the convergence of the approximate solution to the exact solution. As discussed in the first paragraph, the temporal derivatives of the solution as defined by the IC, differential operator, and Cauchy–Kowalesky theorem will not equal those determined by the independent BCs. The resulting singularities in the corners of the temporal-spatial domain, which are independent of the smoothness of the IC, disrupt the convergence of spectral and finite difference methods in a manner that differs significantly between parabolic and hyperbolic systems. A detailed analysis of the induced singularities for two model problems and their effect on the convergence of both numerical methods is determined. Since an incompatibility exists any time the BC is independent of the IC, algebraic convergence in the maximum norm is the expectation for IBVPs. In most science and engineering applications, this is the usual scenario.

In section 2, the infinite set of compatibility conditions for the generalized heat and wave equations with time-dependent BCs is presented. The purpose is to lay the groundwork for describing the inherent singular nature of IBVPs and how it affects the convergence rate of the error. In section 3, we examine the prototype parabolic case, namely the heat equation subject to Dirichlet BCs and a smooth parabolic IC. We use the Fourier method to determine an exact expression for the approximate solution, represented by a truncated Fourier series. Convergence rates are then developed for both finite difference and Chebyshev spectral methods, the latter of which is normally the basis set of choice for a problem on a finite domain. For the parabolic example in section 3, u_t is discontinuous at $t = 0$. Nevertheless, the Chebyshev method is shown to yield spectral convergence for $t > 0$, but only quartic convergence in the neighborhood of the discontinuity, which would be the relevant consideration for the computation of transient heat flow. Furthermore, the usual Fourier method is only quadratically convergent near the discontinuity and quartically convergent elsewhere. Thus, the convergence rate of the error is shown to be nonuniform and algebraic as measured in the maximum norm.

The hyperbolic case is discussed in section 4. Discontinuities that are induced by the incompatibilities now propagate throughout the region. It is shown that all spectral methods will yield algebraic convergence for $t > 0$. The Fourier method is used again to derive an exact expression for the error. Similar to the parabolic case, the results are compared with the centered finite difference and Chebyshev methods which yield algebraic convergence for smooth ICs. The performance of finite difference methods is also significantly diminished when the compatibility conditions are not satisfied. For this reason, the appendix contains the rates of convergence for a second-order finite difference method for a variety of smooth ICs and shows, for example, that second-order convergence is reduced to 4/3-order.

2. Compatibility conditions for the generalized heat and wave equations.

Here compatibility conditions are reviewed to illustrate their fundamental impact on the smoothness of the solutions to IBVPs. We simply state the necessary conditions for the solution to be C^∞ on the domain for the heat and wave equation with time-dependent BCs. The complete proofs of necessity and sufficiency are given for parabolic systems in [11], [12], [3], [18] and for hyperbolic systems in [10], [16], [17], [4].

THEOREM 2.1. *The domain is* $[0,T] \times \Omega$, *where* Ω *is a d-dimensional spatial domain with a boundary* $\partial\Omega$ *which is a* C^∞ *manifold of dimension* $(d-1)$. *Let L be an elliptic operator of the form*

$$L = \sum_{i=1}^{d}\sum_{j=1}^{d} A_{ij}(x)\frac{\partial}{\partial x_i}\frac{\partial}{\partial x_j} + \sum_{j=1}^{d} B_j(x)\frac{\partial}{\partial x_j} + \sum_{j=1}^{d} C_j(x). \tag{2.1}$$

The generalized linear diffusion problem is

$$u_t = Lu, \qquad u(x,0) = u_0(x) \in \Omega. \tag{2.2}$$

The generalized wave equation is

$$u_{tt} = Lu, \quad u(x,0) = u_0(x), \quad u_t(x,0) = v_0(x) \in \Omega. \tag{2.3}$$

Both are subject to the BC

$$u = f(t) \ \in \ \partial\Omega \ \ \forall t. \tag{2.4}$$

Then, the necessary and sufficient compatibility conditions for u(x,t) to be C^{2k} *for the heat equation are*

$$L^k u_0 = \frac{\partial^k f}{\partial t^k}, \qquad k = 0, 1, 2, \ldots \ \in [0,0] \times \partial\Omega \tag{2.5}$$

and for the wave equation are

$$L^k u_0 = \frac{\partial^{2k} f}{\partial t^{2k}} \quad \text{and} \quad L^k v_0 = \frac{\partial^{2k+1} f}{\partial t^{2k+1}}, \quad k = 0, 1, 2, \ldots \ \in [0,0] \times \partial\Omega. \tag{2.6}$$

In essence (2.5) and (2.6) state that at time $t = 0$, the temporal derivatives of the solution determined by the application of the differential operator to the IC must *equal* the temporal derivatives of the BCs. When these conditions are satisfied, we do *not* need to *impose BCs* because they can be derived from the Taylor series expansion of the IC. When (2.5) and (2.6) do not hold, we induce a singularity in the $2k$th-order derivative of the solution at $t = 0$ on $\partial\Omega$. Thus, imposing BCs that are independent of the IC places an infinite set of constraints on the solution which differ from the constraints enforced by the PDE, resulting in discontinuities in the corners of the temporal-spatial domain. The manner in which these incompatibilities affect the accuracy of the numerical method depends on whether the system is parabolic or hyperbolic. In the next section we will discuss the parabolic case, followed in section 4 by the hyperbolic case.

3. A parabolic example. Our goal is to study the convergence of the error for approximate spectral and finite difference solutions to IBVPs when the compatibility conditions of the system are not satisfied. With this in mind, we first study the effect on parabolic systems, taking as our example the one-dimensional heat equation

$$u_t = u_{xx} \tag{3.1}$$

subject to BCs

$$u(0,t) = u(\pi,t) = 0 \tag{3.2}$$

and IC

$$u_0 = u(x,0) = \frac{\pi}{8}x(\pi - x). \tag{3.3}$$

The first-order compatibility condition, ($k = 1$) in (2.5), is not satisfied because

$$Lu_0 = \left(\frac{\partial^2 u_0}{\partial x^2}\right) = -\frac{\pi}{4} \qquad \forall x \tag{3.4}$$

and

$$\frac{\partial u}{\partial t}|_{x=0,\pi} = 0 \qquad \forall t. \tag{3.5}$$

Thus from (3.1), $u_{xx}|_{x=0,\pi} = u_t|_{x=0,\pi} = 0$ yet $u_{xx} = -2$ in the interior. To see the impact of the jump discontinuity at the boundary in the second derivative at $t = 0$ on the decay rate of the error we will solve the problem exactly at time $t = 0$ via a truncated Fourier series, then compare this together with finite difference and Chebyshev methods against the exact solution for all time.

Time integration is assumed exact throughout, which yields the approximate spectral representation

$$u_N(x_i,t) = \sum_{n=1,\text{odd}}^{N-1} c_N(n)e^{-n^2 t}\sin nx_i \tag{3.6}$$

of the exact solution, given by

$$u(x_i,t) = \sum_{n=1,\text{odd}}^{\infty} \frac{e^{-n^2 t}}{n^3}\sin nx_i. \tag{3.7}$$

Gottlieb and Orszag [8] note that for the exact coefficients $c_N(n)$, $u_N(x,t)$ converges spectrally to $u(x,t)$. This is also true if $u(x,0)$ is known for all x because $c_N(n)$ can be computed to any accuracy. In this work, we assume, as with most scientific data, that $u(x,0)$ is given in tabular form $u_i = u(x_i,t)$, where $x_i = i\pi/N$. In science and engineering, we cannot assume we know the function exactly and therefore must approach the problem from a numerical standpoint. The coefficients $c_N(n)$ are then computed in the traditional manner, using trigonometric interpolation, as

$$c_N(n) = \frac{2}{N}\sum_{i=1}^{N-1} u_i \sin nx_i. \tag{3.8}$$

With this implementation of the spectral method, it will be shown that the approximate spectral representation (3.6) converges algebraically to the exact solution in the maximum norm, and, furthermore, convergence is nonuniform. This characteristic algebraic convergence is method-independent due to the inherent singularity induced by violating the compatibility conditions from explicit application of the BCs. In the next section, we derive an exact expression for $c_N(n)$ which will provide the initial error in the coefficients for the Fourier method.

3.1. The approximate spectral solution. In what follows, we derive an analytical representation of the coefficients $c_N(n)$ in (3.6). From (3.7)

$$u(x_i,0) = \sum_{n=1,\mathrm{odd}}^{\infty} \frac{1}{n^3}\sin\left(n\frac{i\pi}{N}\right), \tag{3.9}$$

$$\begin{aligned} u(x_i,0) = \sum_{n=1,\mathrm{odd}}^{N-1} \Bigg[& \frac{1}{n^3}\sin(n\frac{i\pi}{N}) \\ & + \sum_{m=1}^{\infty} \frac{1}{(2mN+n)^3}\sin\left\{(2mN+n)i\frac{i\pi}{N}\right\} \\ & + \frac{1}{(2mN-n)^3}\sin\left\{(2mN-n)i\frac{i\pi}{N}\right\}\Bigg], \end{aligned} \tag{3.10}$$

or

$$u(x_i,0) = \sum_{n=1,\mathrm{odd}}^{N-1} \left\{\frac{1}{n^3} + \sum_{m=1}^{\infty}\frac{1}{(2mN+n)^3} - \frac{1}{(2mN-n)^3}\right\}\sin\left(n\frac{i\pi}{N}\right) \tag{3.11}$$

and

$$u(x_i,0) = \sum_{n=1,\mathrm{odd}}^{N-1} \left\{\frac{1}{n^3} - \frac{n}{N^4}\Psi(n/N)\right\}\sin\left(n\frac{i\pi}{N}\right), \tag{3.12}$$

where

$$\Psi(s) = 2\sum_{m=1}^{\infty}\frac{3m^2+s^2}{[m^2-s^2]^3}. \tag{3.13}$$

$\Psi(s)$ can be called the alias function since it represents the error in the coefficients due to truncating the series after N terms. The initial error in the coefficients is due to the fact that a sine series cannot represent a nonperiodic polynomial with a finite number of terms. For use later, we observe that $\Psi(s)$ is positive and monotonically increasing on the interval $[0,1]$ with extremes $\Psi(0) \approx 0.4058712$ and $\Psi(1) = 1$.

Equating (3.6) and (3.12), we obtain the desired result

$$c_N(n) = \frac{1}{n^3} - \frac{n\Psi(n)}{N^4}. \tag{3.14}$$

We study convergence only as it relates to spatial discretization, and therefore temporal integrations are represented analytically. The spectral approximation is then given by

$$u_N(x_i,t) = \sum_{n=1,\text{odd}}^{N-1} e^{-n^2 t}\left[\frac{1}{n^3} - \frac{n\Psi(n/N)}{N^4}\right]\sin nx_i. \tag{3.15}$$

In the next two sections it will be proved that although the spectral series for both the exact and approximate solutions decay exponentially, the error decays algebraically and nonuniformly over the domain. Section 3.2 explores convergence in the neighborhood of the discontinuity induced by the incompatibility of imposing BCs. Section 3.3 looks at convergence in the interior of the domain, bounded away from the singularities at $(0,0)$ and $(0,\pi)$.

3.2. Quadratic convergence near $(0,0)$ and $(0,\pi)$. The discontinuity in u_t at $(0,0)$ induces an error in $\partial u_N/\partial t(\pi/N,0)$ that is bounded *away* from zero for *all* N. In what follows, we show that this produces an $O(N^{-2})$ error in the neighborhood of $(0,0)$ and likewise near $(\pi,0)$. With a derivation similar to that preceding (3.12), the exact solution is given by

$$u(x_i,t) = \sum_{n=1,\text{odd}}^{N-1}\left\{\frac{e^{-n^2t}}{n^3} - \sum_{m=2,even}^{\infty}\left[\frac{e^{-(mN+n)^2t}}{[mN+n]^3} - \frac{e^{-(mN-n)^2t}}{[mN-n]^3}\right]\right\}\sin nx_i. \tag{3.16}$$

Subtracting $u_N(x_i,t)$, given by (3.15), defines the error

$$e_N(x_i,t) = \sum_{n=1,\text{odd}}^{N-1}\left\{\sum_{m=2,even}^{\infty}\left[\frac{e^{-(mN+n)^2t} - e^{-n^2t}}{[mN+n]^3} - \frac{e^{-(mN-n)^2t} - e^{-n^2t}}{[mN-n]^3}\right]\right\}\sin nx_i. \tag{3.17}$$

Then, on the discrete trajectory $x_1 = \pi/N$ and $t_N = 1/N^2$

$$e_N\left(\frac{\pi}{N},\frac{1}{N^2}\right) = \frac{1}{N^2}I_N, \tag{3.18}$$

where

$$I_N = \frac{1}{N}\sum_{n=1,\text{odd}}^{N-1}\left\{\sum_{m=2,even}^{\infty}\left[\frac{e^{-(m+n/N)^2} - e^{-(n/N)^2}}{[m+n/N]^3} - \frac{e^{-(m-n/N)^2} - e^{-(n/N)^2}}{[m-n/N]^3}\right]\right\}\sin n\frac{\pi}{N}. \tag{3.19}$$

I_N defines the midpoint quadrature of the smooth positive function, which is the integrand in (3.20) below. Therefore,

$$I = \lim_{N\to\infty} I_N = \int_0^1 \sin\pi s \sum_{m=2,even}^{\infty}\left[\frac{e^{-(m+s)^2} - e^{-s^2}}{[m+s]^3} - \frac{e^{-(m-s)^2} - e^{-s^2}}{[m-s]^3}\right]ds. \tag{3.20}$$

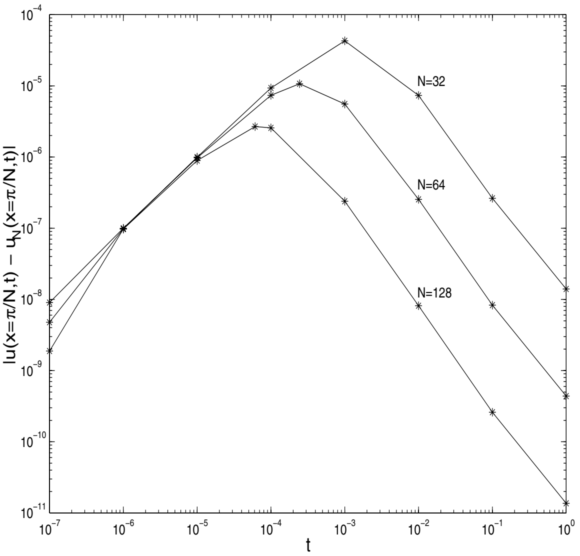

FIG. 3.1. $|e_N|$ *for the Fourier method on the interval* $t\epsilon(0,1]$ *for* $x=\pi/N$ *and fixed* N.

Numerical evaluation of the midpoint rule (3.20) with $N = 512$ provides the approximate value $I \approx .0876323127$. This completes the proof that convergence is at best quadratic. For each N there exists a point $(\pi/N, 1/N^2)$ at which the error is I/N^2. The error as a function of time for $x = \pi/N$ is plotted in Figure 3.1, where the maximum occurs at $t = 1/N^2$. Likewise, we can plot the error as a function of space for $t = 1/N^2$ and see that the maximum error occurs at the endpoints as shown in Figure 3.2(a). Numerical experiments, in the following sections, will confirm that indeed convergence *is* quadratic.

3.3. Quartic convergence for a fixed $t > \epsilon > 0$.

For any fixed $t > \epsilon > 0$ in the interior of the domain, bounded away from the singularities at $(0, 0)$ and $(0, \pi)$, $\|e_N(x_i,t)\|_2$ converges at best quartically. As was shown in (3.15), the coefficients of the approximate trigonometric series have an initial error of $O(1/N^4)$. This, in turn, induces quartic convergence for any fixed t.

The difference between (3.7) and (3.15) provides the error in the spectral approximation

$$e_N(x_i,t) = u(x_i,t) - u_N(x_i,t) = S_N(x_i,t) + E_N(x_i,t), \tag{3.21}$$

where

$$S_N(x_i,t) = \frac{1}{N^4} \sum_{n=1,\mathrm{odd}}^{N-1} n\Psi(n/N)e^{-n^2t} \sin n\frac{i\pi}{N} \tag{3.22}$$

and

$$E_N(x_i,t) = \sum_{n=N+1,odd}^{\infty} \frac{e^{-n^2t}}{n^3} \sin n\frac{i\pi}{N}. \tag{3.23}$$

We will rigorously establish quartic convergence for fixed $t > 0$ by demonstrating spectral convergence for $E_N(x_i, t)$ and, at best, quartic convergence for $S_N(x_i, t)$. Starting with (3.23),

$$E_N(x_i, t) = \sum_{n=1,odd}^{\infty} \frac{e^{-(N+n)^2 t}}{(N+n)^3} \sin(N+n)x_i \tag{3.24}$$

$$= e^{-N^2 t} \sum_{n=1,odd}^{\infty} \frac{e^{-(2N+n^2)t}}{(N+n)^3} \sin(N+n)x_i. \tag{3.25}$$

Therefore,

$$|E_N(x_i, t)| < e^{-N^2 t} \sum_{n=1,odd}^{\infty} \frac{1}{(N+n)^3} < e^{-N^2 t} \int_N^{\infty} \frac{ds}{s^3} \tag{3.26}$$

and finally

$$|E_N(x_i, t)| < \frac{e^{-N^2 t}}{2N^2}. \tag{3.27}$$

Now consider the asymptotic behavior of $S_N(x_i, t)$. From (3.22),

(3.28)

$$\|S_N(x_i, t)\|_2 = \frac{1}{N^4} \left\{ \sum_{n=1,odd}^{N-1} [n\Psi(n/N)e^{-n^2 t}]^2 \right\}^{1/2} > \Psi(0)\frac{e^{-t}}{N^4} \approx 0.4058712\frac{e^{-t}}{N^4},$$

where the last inequality is from the earlier observation that $\Psi(s)$ is monotone increasing on the interval [0,1] and consequently $\Psi(1/N) > \Psi(0) \approx 0.4058712$.

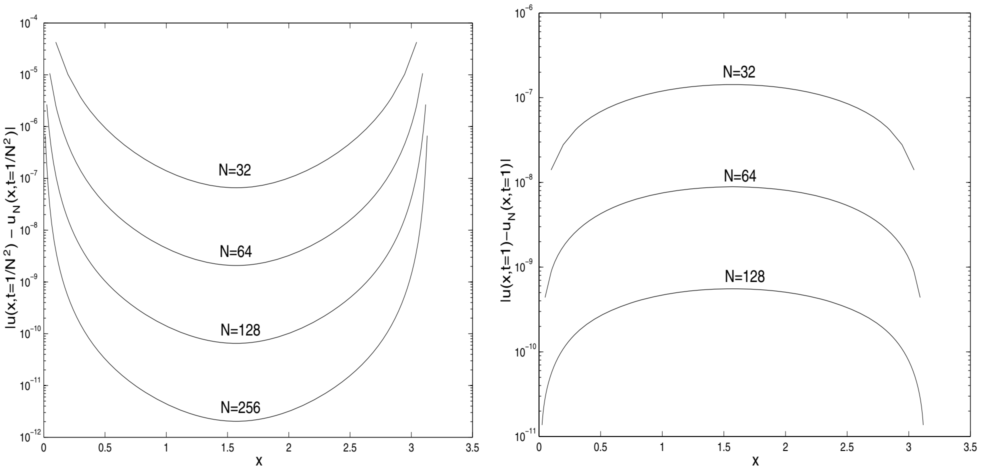
This demonstrates that convergence in the l_2 norm is at best quartic. In contrast to Figure 3.2(a), Figure 3.2(b) shows that for any fixed t, the maximum error, as measured by $|e_N|$, occurs in the middle of the domain at $x = \pi/2$ as opposed to the endpoint, $x = \pi/N$, for small t. The reason the error curves change as t becomes large is that the exponential term $e^{-n^2 t}$ dominates, and the error can be approximated by the lowest wavenumber, $n = 1$. Thus, for large t, the error is essentially proportional to $\sin x$ which has a maximum at $\pi/2$. As will be seen in the next section, numerical experiments demonstrate that convergence in the l_∞ norm is also quartic for t bounded away from $(0, 0)$ and $(0, \pi)$.

3.4. Comparison with finite difference methods. Given the nonuniform convergence of the Fourier method, as illustrated by quadratic convergence for small t and quartic convergence for large t, it is natural to compare its performance with fourth and second-order finite difference methods that require less computation. The finite difference approximations are derived by substituting

$$u_i = \sum_{n=1,\text{odd}}^{N-1} a_n(t) \sin nx_i \tag{3.29}$$

into

$$u_{i_t} = \frac{u_{i-1} - 2u_i + u_{i+1}}{\delta x^2}, \tag{3.30}$$



(a) (b)

FIG. 3.2. (a) $|e_N(x, N^{-2})|$ *on the interval* $x\epsilon(0,\pi)$ *for* $t = 1/N^2$. (b) $|e_N(x,1)|$ *on the interval* $x\epsilon(0,\pi)$ *for* $t = 1$.

where δx is π/N, yielding

$$a_n(t) = c_N(n)e^{\lambda_n^2 t}, \qquad \text{where} \qquad \lambda_n^2 = \frac{-4N^2\sin^2(\frac{n\pi}{2N})}{\pi^2}. \tag{3.31}$$

Likewise, the solution to the fourth-order finite difference approximation

$$u_{i_t} = \frac{-u_{i-2} + 16u_{i-1} - 30u_i + 16u_{i+1} - u_{i+2}}{12\delta x^2} \tag{3.32}$$

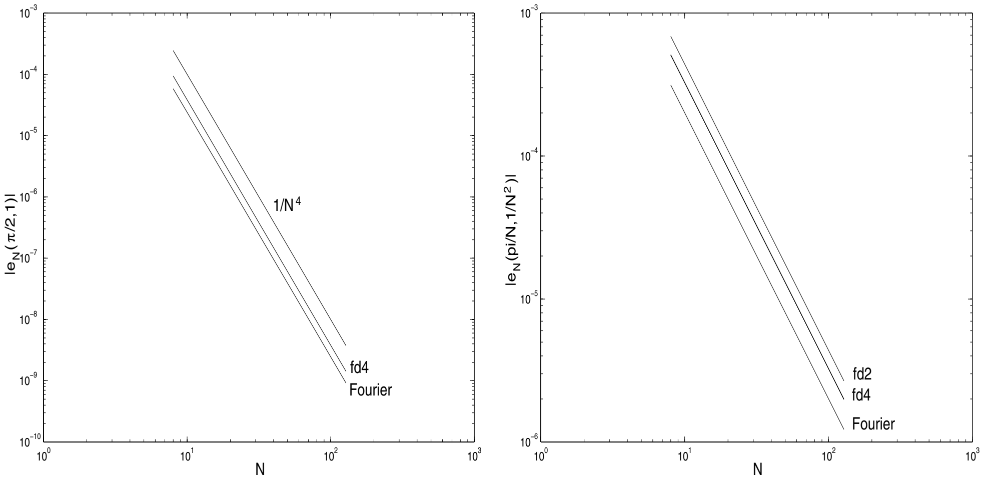
is given by (3.31), except now

$$\lambda_n^2 = \frac{-4N^2\sin^2(\frac{n\pi}{2N})}{3\pi^2}\left[3 + \sin^2\left(\frac{n\pi}{2N}\right)\right]. \tag{3.33}$$

The values of λ_n are the only difference between solutions to the finite difference and Fourier method for which $\lambda_n = n$.

However, if we compare the performance of the FD4 to the Fourier method for large t, it can be seen that there is little difference, as shown in Figure 3.3(a). For small t, a FD2 method performs just as well as the Fourier method and FD4 with only a slightly larger constant of proportionality, as seen in Figure 3.3(b). This marginal error reduction may not be sufficient to justify the expense of the Fourier method. However, it is reasonable to speculate that a FD4 scheme on a Chebyshev grid could give comparable results to the Chebyshev method that yields an $O(N^{-4})$ convergence error near the endpoints, as will be seen in the next section.

3.5. Comparison with the Chebyshev method. The method of choice for the interpolation of nonperiodic functions on a finite interval is the Chebyshev method. Unlike the Fourier method, the Chebyshev method does yield spectral convergence



(a) (b)

Fig. 3.3. (a) *The error of a fourth-order centered finite difference method versus the error in the spectral approximation for* $x = \pi/2$, $t = 1$. (b) *The error of a fourth-order and second-order centered finite difference method versus the error in the spectral approximation for* $x = \pi/N$ *and* $t = 1/N^2$.

for fixed t. The reason is simply that the cosine series representation of a smooth IC does not alias. Nevertheless, convergence in the neighborhood of $(0,0)$ and $(\pi,0)$ is algebraic. To see why this is the case, we implement the Chebyshev method by expanding the solution in terms of Chebyshev cardinal functions (see [1]).

The error for the Chebyshev method, as a function of space, is qualitatively similar to Figures 3.2(a) and 3.2(b), with the maximum error occurring at the endpoints for small t and in the middle of the domain for large t. The error as a function of time is similar to Figure 3.1 in that it reaches a maximum and then decays, but it differs in the fact that the decay becomes exponential after the maximum as seen in Figure 3.4. However, there exists a trajectory along which the max error converges algebraically as shown in Figure 3.5(a). The difference is that the max error is converging quartically as opposed to quadratically, as seen for the Fourier case. The increase in accuracy occurs because the Chebyshev grid is quadratically clustered near the endpoints where the singularities are occurring, giving an extra factor of $O(1/N^2)$. In contrast to the Fourier method for large t, the Chebyshev method does indeed give the expected exponential rate of convergence for the error, as indicated in Figure 3.5(b). This is a direct result of the Chebyshev method's ability to represent the IC exactly with only three polynomials.

Thus unlike the Fourier method, at time $t = 0$, there is no initial error in the coefficients due to truncation.

For the parabolic case, we can see that the convergence rate of the error in the maximum norm is nonuniform and algebraic. In general, as long as we are interested in solutions that are bounded away from singularities induced by violating the compatibility conditions, the spectral method *will* yield spectral convergence. However, if we are interested in heat transients such as those that occur on a microprocessor,

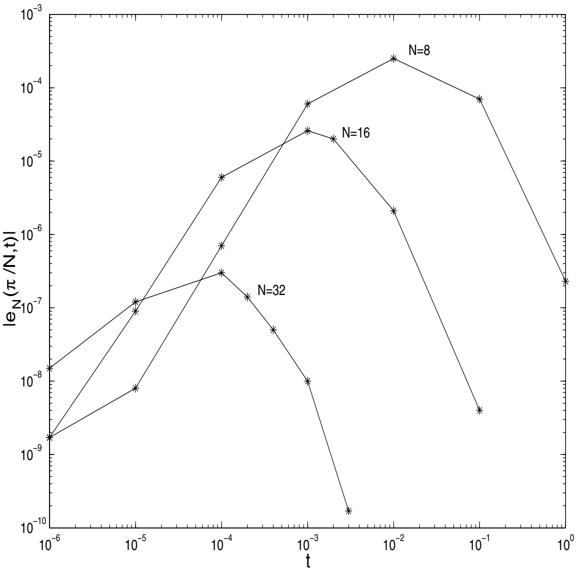


FIG. 3.4. $|e_N|$ *for the Chebyshev method on the interval* $t\epsilon(0,1]$ *for* $x = \pi/N$ *and fixed* N.

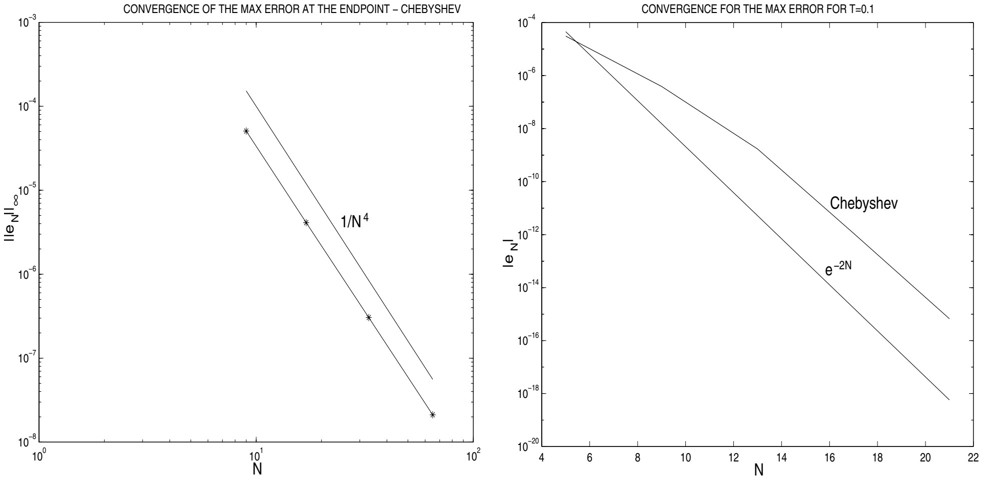

(a) (b)

FIG. 3.5. (a) *The max error in the Chebyshev approximation at the endpoint* $x = \pi/N$ *as a function of resolution* N. (b) *The error in the Chebyshev approximation for* $x = \pi/2$ *and* $t = 0.1$.

a computationally more efficient method with comparable algebraic convergence may be more attractive.

4. The hyperbolic case. In contrast to the parabolic case, a hyperbolic operator will propagate the solution through the time-space domain. As a result, singularities induced by incompatible BCs and the IC are not smoothed as t increases.

To observe the effect on the convergence of the error for spectral methods, we will consider the one-dimensional wave equation

$$u_{tt} = u_{xx} \tag{4.1}$$

subject to BCs

$$u(0, t) = u(\pi, t) = 0 \tag{4.2}$$

and ICs

$$u(x, 0) = \frac{\pi}{8} x(\pi - x), \qquad u_t(x, 0) = 0. \tag{4.3}$$

The first-order compatibility condition, (2.6) for u_0 and $k = 1$, is not satisfied. The difference in the analysis of section 3.1 is that the time dependence of the exact and approximate spectral solution is given by an oscillatory function. Thus,

$$u(x_i, t) = \sum_{n=1,\text{odd}}^{\infty} \frac{\cos(nt)}{n^3} \sin nx_i \tag{4.4}$$

with the analogue to (3.15) being

$$u_N(x_i, t) = \sum_{n=1,\text{odd}}^{N-1} \cos(nt) \left[\frac{1}{n^3} - \frac{n}{N^4} \Psi\left(\frac{n}{N}\right) \right] \sin nx_i. \tag{4.5}$$

4.1. Global quadratic convergence. The decay rate of the error for hyperbolic cases is more dramatic than for parabolic problems. The error induced by violating the first-order compatibility condition for a hyperbolic problem not only produces an $O(N^{-2})$ error for the Fourier method in the neighborhood of $(0, 0)$ and $(\pi, 0)$ but propagates throughout the domain, resulting in global quadratic convergence in the maximum norm. The propagation of the error through the x–t plane is along the characteristic $x = t$ and $x = \pi - t$, as shown in Figures 4.1(a) and 4.1(b) for $x \in [0, \pi]$ and $t \in [0, \pi]$.

The proof of quadratic convergence of the error for small t follows that given in section 3.2. For large t, the proof is the same except the error is defined along the discrete trajectory $x_{N/2} = \pi/2$ and $t_N = \pi/2 - 1/N$. Numerical experiments, given in Figure 4.2, show that convergence *is* quadratic along both of these trajectories, demonstrating the global nature of the error propagation.

4.2. The Chebyshev method. Next, we compare the performance of a Chebyshev method with the Fourier method that yields quadratic convergence. As noted in section 3.5, we use Chebyshev cardinal functions. Figure 4.3 shows the propagation of the error through the x–t plane for the Chebyshev method. As expected, we see that the error propagates along the characteristics $t = 1 \pm x$. The convergence of the error along the characteristics for any value of t differs significantly from the parabolic case, where spectral convergence was obtained for $t > 0$. The convergence of the error, as shown in Figure 4.4, is *quadratic*, no better than the Fourier series expansion and requiring $O(N^2)$ operations. At first, one might suspect that the convergence rate would be $O(N^4)$, the same as was observed for the heat equation in the neighborhood

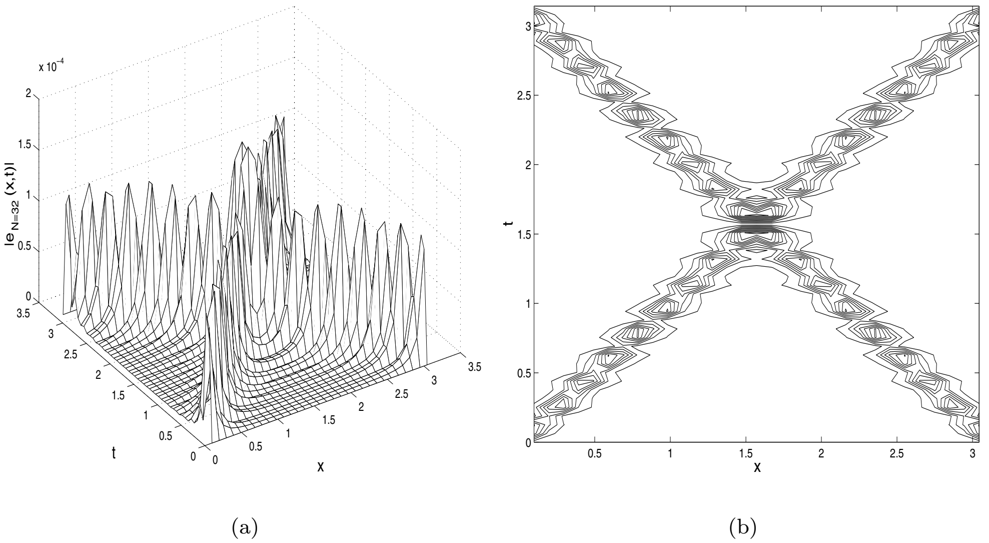

FIG. 4.1. (a) *Propagation of the error through the x–t plane.* (b) *Contour plot of* (a).

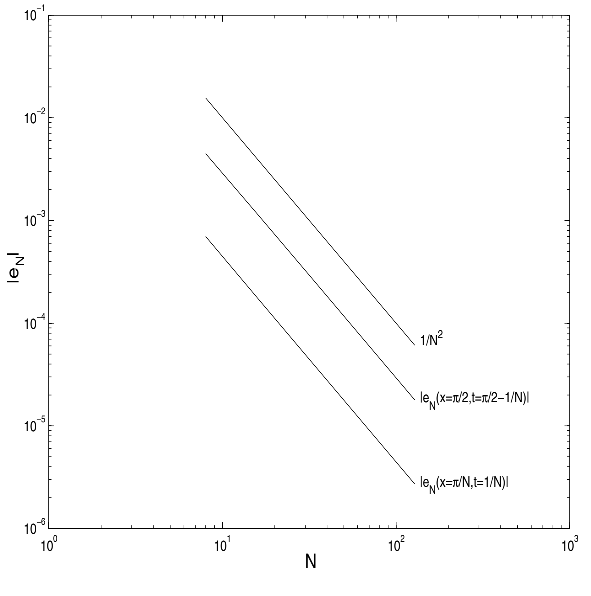

FIG. 4.2. *The convergence of the error in the Fourier method on the discrete trajectories $x = \pi/2$ and $t = \pi/2 - 1/N$, and $x = \pi/N$ and $t = 1/N$.*

of the discontinuities ($x = 0, t = 0$) and ($x = \pi, t = 0$). The difference, however, is that in the heat equation there is only a jump discontinuity in the second derivative of the solution at $t = 0$. For any $t > 0$, the discontinuity becomes smoothed out due to the diffusive operator. Thus, in the neighborhood of the singularities for $0 < t < \epsilon$, the original jump discontinuities become steep gradients that are analytically continuous.

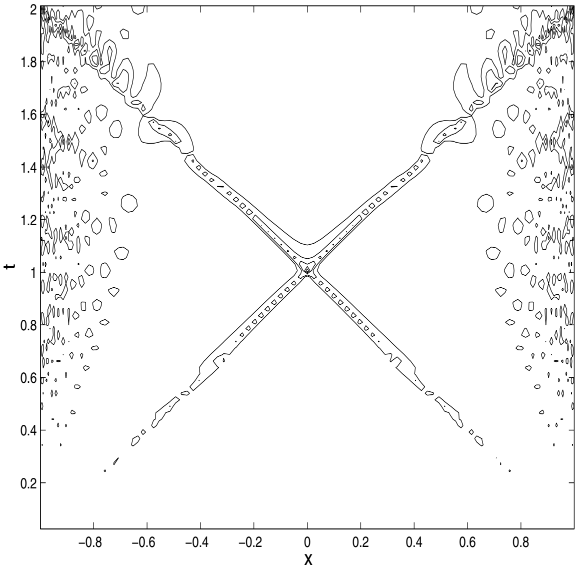

FIG. 4.3. *The propagation of the error in the Chebyshev approximation for $N = 128$.*

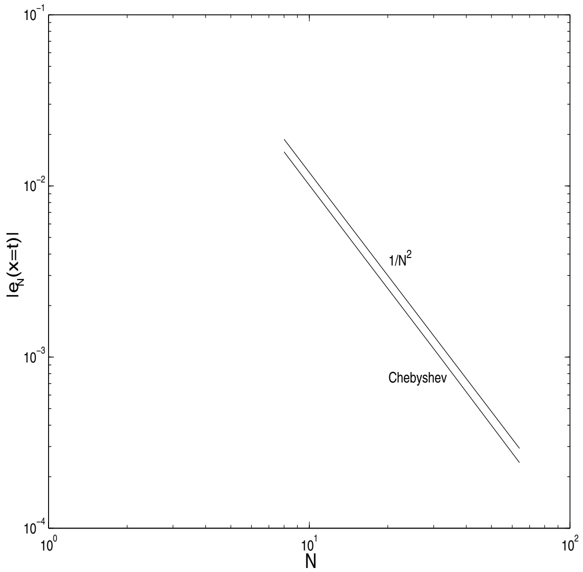

FIG. 4.4. *The convergence of the error in the Chebyshev approximation along the characteristic $t = x$.*

Spectral methods have difficulty resolving these gradients, but the Chebyshev method gives quartic convergence due to its quadratically clustered grid near the endpoints, as opposed to the uniform grid of the Fourier method. However, in the hyperbolic case, the discontinuities at $t = 0$ in the second derivative of the analytical solution are present for all time. Thus, the type of grid used is irrelevant, and *any* spectral method will converge quadratically.

4.3. Comparison with finite difference methods. The quadratic convergence of spectral methods naturally refocuses attention on second-order finite difference methods. The second-order centered finite difference method given by (3.30) yields the solution

$$u_N(x_i,t) = \sum_{n=1,odd}^{N} \cos(\lambda_n t)\left\{\frac{1}{n^3} - \frac{n}{N^4}\Psi(n/N)\right\}\sin nx_i, \tag{4.6}$$

where

$$\lambda_n = \frac{2N}{\pi}\sin\left(\frac{n\pi}{2N}\right) \tag{4.7}$$

is a second-order approximation to the eigenvalues n. The error is then given by

$$e_N(x_i,t) = u(x_i,t) - u_N(x_i,t) = T_N(x_i,t) + S_N(x_i,t) + E_N(x_i,t), \tag{4.8}$$

where

$$T_N(x_i,t) = \sum_{n=1,odd}^{N} \frac{\cos nt - \cos\lambda_n t}{n^3}\sin nx_i, \tag{4.9}$$

$$S_N(x_i,t) = \frac{1}{N^4}\sum_{n=1,\mathrm{odd}}^{N} n\Psi(n/N)\cos\lambda_n t \sin nx_i, \tag{4.10}$$

$$E_N(x_i,t) = \sum_{n=N+1,odd}^{\infty} \frac{\cos nt}{n^3}\sin nx_i. \tag{4.11}$$

Using these formulas, we will analytically prove as well as computationally show that not only does a second-order finite difference method *not* give quadratic convergence but rather converges only slightly better than linearly. The dominant error term is $T_N(x_i,t)$ which we demonstrate by first showing that

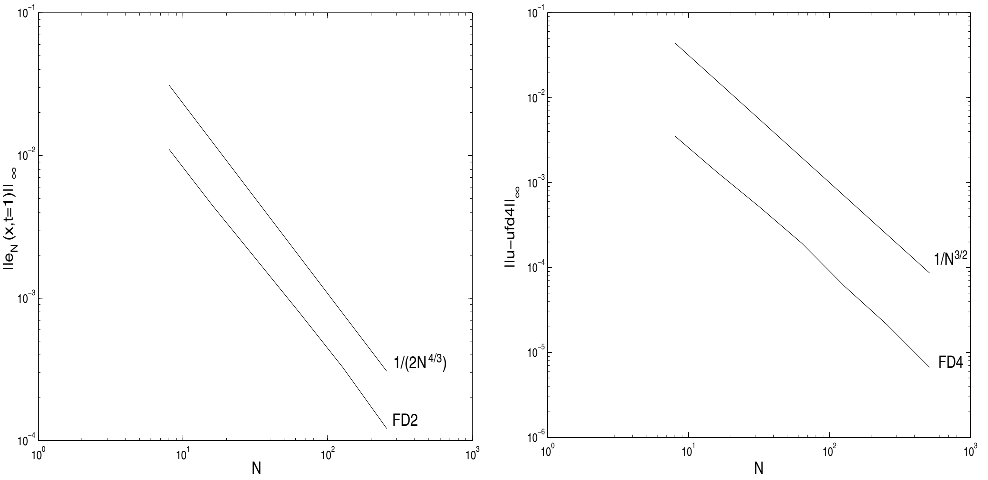
$$|S_N(x_i,t)| < O(N^{-2}) \qquad \text{and} \qquad |E_N(x_i,t)| < O(N^{-2}). \tag{4.12}$$

For $t = x$, we have

$$\begin{aligned} |S_N(t)| &= \frac{1}{2N^4}\Big|\sum_{n=1,\mathrm{odd}}^{N} n\Psi(n/N)\cos\lambda_n t \sin nt\Big| \\ &\le \frac{1}{2N^4}\sum_{n=1,\mathrm{odd}}^{N} |n\Psi(n/N)\cos\lambda_n t\sin nt| \\ &< \frac{1}{2N^2}. \end{aligned} \tag{4.13}$$

Similarly,

$$\begin{aligned} |E_N(t)| &= \frac{1}{2}\Big|\sum_{n=N+1,odd}^{\infty}\frac{\cos nt}{n^3}\sin 2nt\Big| \le \frac{1}{2}\sum_{n=N+1,odd}^{\infty}\Big|\frac{\cos nt}{n^3}\sin 2nt\Big| \\ &< \frac{1}{2}\int_N^{\infty}\frac{ds}{s^3} = \frac{1}{4N^2}. \end{aligned} \tag{4.14}$$



(a) (b)

FIG. 4.5. (a) *The max error in x for the second-order centered finite difference method at $t = 1$.* (b) *The max error in x for the fourth-order centered finite difference method at $t = 1$.*

Surprisingly, Figure 4.5 demonstrates that the error in a second-order finite difference method converges as $O(N^{-4/3})$. The proof for 4/3 convergence is rather detailed and deferred to Appendix A, where it is first shown that

$$|T_N(t)| \leq O(N^{-4/3}) \tag{4.15}$$

along the characteristic $t = x$ for $x\epsilon(0, \pi)$. To derive a lower bound is slightly more complicated, but nevertheless for any average value of t along the same characteristic,

$$\frac{1}{\pi}\int_0^\pi T_N(t)dt > \frac{C}{N^{4/3}}, \tag{4.16}$$

where C is a constant. These bounds hold for any second-order finite difference operator in which there is a discontinuity in the second derivative of the solution. The fact that the convergence of the second-order finite difference scheme is not quadratic may not be surprising since the approximation is based on Taylor series expansions that assume continuity of the function at least up to the fourth derivative. However, the fact that it is 4/3 is surprising.

For a variety of ICs that would correspond to violating different order compatibility conditions we propose the following conjecture for the upper bounds of the error term, $T_N(x_i, t)$, due to a second-order finite difference approximation.

Let

$$T_N(t) = \sum_{n=1,odd}^{N} \frac{\cos\lambda_{n,N}t - \cos nt}{n^3}\sin nt = \sum_{n=1,odd}^{N} b_{n,N}(t). \tag{4.17}$$

When we enforce BCs, we violate some order compatibility condition and the coefficients of the error, $|b_{n,N}(t)|$, will be algebraically decreasing due to the resulting discontinuity in a derivative of the Taylor expansion of the IC about the boundary. Thus, we can always impose the bound

$$|b_{n,N}(t)| \leq \frac{c}{n^{\beta}}, \qquad \beta \geq 1, \tag{4.18}$$

where c is a constant.

From (4.18) and generalizing the analysis in Appendix A we make the following conjecture whose derivation is relegated to Appendix B.

CONJECTURE. *The error term $T_N(x_i, t)$ is bounded from above by*

$$\begin{array}{lll} \sum_{n=1}^{N} |b_{n,N}(t)| & \leq & O(N^{(1-\beta)2/3}), \quad \beta < 4, \\ & \leq & O(N^{-2}\log N), \quad \beta = 4, \\ & \leq & O(N^{-2}), \qquad\quad \beta > 4. \end{array}$$

For $\beta < 4$, the error from the IC dominates, while for $\beta = 4$ both the error from the IC and second-order difference approximation contribute equally. In the last case the error from the finite difference operator dominates.

$\beta > 4$ implies that at least the fourth derivative of the IC is continuous. Thus, the best a second-order method can perform is $O(N^{-2})$. $\beta < 4$ implies that the function is not C^4, and therefore we would expect less than quadratic convergence since the error in a second-order method depends on the continuity of the fourth derivative of the function. However, the fact that $\beta = 4$ yields a convergence rate that is proportional to $\log(N)$ is not only new but quite surprising. The above conjecture has been supported by the numerical evidence.

For completeness, the convergence rate of the FD4 method that was used in section 3.4 is considered. However, we still see that convergence is less than quadratic and in fact appears to be only $O(N^{-3/2})$, as demonstrated in Figure 4.5(b). The reduction in the convergence rates of the finite difference methods demonstrates the significant impact of incompatibilities which occur anytime the BCs are independent of the IC. In general, violation of the compatibility conditions will likely lead to algebraic convergence of spectral methods as well as reduce the convergence rate of finite difference schemes.

5. Conclusions. In this paper, we have applied the theory of compatibility conditions to the numerical solutions of PDEs and have demonstrated how the subtle singularities inherent in IBVPs impact the convergence properties of spectral and finite difference methods. The temporal derivatives of the solution as defined by the initial condition, differential operator, and Cauchy–Kowalesky theorem will not equal those determined by the independent BCs. The resulting singularities in the corners of the temporal-spatial domain, which are independent of the smoothness of the IC, disrupt the spectral convergence of the error normally associated with spectral methods, in a manner that differs significantly between parabolic and hyperbolic systems.

For parabolic systems, the Chebyshev spectral method may be considered "self-healing," leading to a spectral rate of convergence for the error. However, this is not true for the Fourier method where aliasing is likely to induce an algebraic error in the initial Fourier representation. In the neighborhood of the singularities, all methods yield convergence rates that are algebraic. Thus, as measured in the maximum norm, the convergence of the approximate solution to the exact solution for spectral methods is both algebraic and nonuniform. Therefore, the usefulness of spectral methods may be diminished if we are interested in transient solutions for small t.

For hyperbolic systems, the situation is more interesting but worse because the singularities at $t = 0$ on the boundary propagate throughout the temporal-spatial domain along the characteristic lines $x \pm ct$. Thus, the algebraic rate of convergence for the error that existed in the neighborhood of the singularities for the parabolic case exists for all time in hyperbolic problems. As a result, the spectral method does not yield spectral convergence for hyperbolic IBVPs. This naturally draws attention to finite difference methods which require only $O(N)$ operations. However, it was shown that violation of the compatibility conditions can also reduce the order of convergence for finite difference schemes.

The above study details the impact of the theory of compatibility conditions on numerical calculations for IBVPs. Application is broad because many scientific problems are calculated on finite domains where independent BCs are imposed. As a result, singularities in the corners of the temporal-spatial domain are likely to disrupt the accuracy of numerical methods. It is in this regard that the above study has analyzed the convergence rate of the error for spectral and finite difference methods and explored their application to solving IBVPs.

Appendix A: Proof of 4/3 convergence. The term $T_N(x_i, t)$, which accounts for the error in the eigenvalue approximation, dominates the error of the second-order finite difference scheme. Our goal is therefore to bound the error from above and below to prove the 4/3 convergence rate that was computationally observed in section 4.3.

We will first prove the upper bound for the error term $T_N(x,t)$ along the characteristic $t = x$ for $x \epsilon (0, \pi)$

$$|T_N(t)| \leq O(N^{-4/3}). \tag{5.1}$$

Proof.

$$T_N(t) = \sum_{n=1,odd}^{N} \frac{\cos \lambda_{n,N} t - \cos nt}{n^3} \sin nt = \sum_{n=1,odd}^{N} b_{n,N}(t), \tag{5.2}$$

where

$$\lambda_{n,N} = n \frac{\sin(\frac{n\pi}{2N})}{\frac{n\pi}{2N}}. \tag{5.3}$$

Since the $\limsup_{n \to N} \cos(c(n)) \sin(d(n)) = 1$, we can immediately achieve an upper bound on the coefficients $b_{n,N}$

$$|b_{n,N}| \leq \frac{2}{n^3}. \tag{5.4}$$

This bound is due to the discontinuity in the second derivative of the IC from violating the compatibility conditions. However, because the series is decreasing slowly as $1/n^3$, this bound is only tight for the tail end of the series, when n is large. To describe the behavior for the initial terms (i.e., small n), we need to derive a secondary bound. This bound will come from the error in the second-order finite difference operator. Using trigonometric identities, we can rewrite

$$\cos \lambda_{n,N} t - \cos nt = 2 \sin \frac{n + \lambda_{n,N}}{2} t \sin \frac{n - \lambda_{n,N}}{2} t. \tag{5.5}$$

To find an upper bound on the product of the sine functions, we use the known result derived from the Taylor expansion of $\sin y/y$ for $y\epsilon[0,\pi]$ which gives

$$|\sin \frac{n-\lambda_{n,N}}{2}t| < \frac{n-\lambda_{n,N}}{2}t < \frac{\pi^2}{24}\frac{n^3}{N^2}t. \tag{5.6}$$

Therefore,

$$|b_{n,N}| \leq \frac{|(\cos\lambda_{n,N}t - \cos nt)\sin nt|}{n^3} \leq \frac{\pi^2}{24}\frac{t}{N^2}. \tag{5.7}$$

The trick now is to divide the summation in (5.2) into two parts,

$$\sum_{n=1,odd}^{N} b_{n,N}(t) = \sum_{n=1,odd}^{N^\gamma} b_{n,N}(t) + \sum_{n=N^\gamma+1,odd}^{N} b_{n,N}(t), \tag{5.8}$$

where $0<\gamma<1$. Equation (5.7) gives the tightest bound for the initial terms, while (5.4) gives a tighter bound for the tail end of the series. The bounds are minimized, giving equal contributions, for $\gamma = 2/3$. Therefore, we have

$$|T_N(t)| = |\sum_{n=1,odd}^{N} b_{n,N}(t)| \leq \sum_{n=1,odd}^{N^{2/3}} |b_{n,N}(t)| + \sum_{n=N^{2/3}+1,odd}^{N} |b_{n,N}(t)| \tag{5.9}$$

$$\leq N^{2/3}\frac{\pi^2}{24}\frac{t}{N^2} + \sum_{n=N^{2/3}+1,odd}^{N} \frac{2}{n^3} \tag{5.10}$$

$$\leq \frac{\pi^2}{24}\frac{t}{N^{4/3}} + \frac{1}{N^{4/3}} = \left(1+\frac{\pi^2}{24}t\right)N^{-4/3}. \qquad \square \tag{5.11}$$

For the second part of the proof, we show that $T_N(x,t)$ for any average value of t along the characteristic $t=x$ on $x\epsilon(0,\pi)$ is bounded from below by

$$\frac{1}{\pi}\int_0^\pi T_N(t)dt > \frac{C}{N^{4/3}}. \tag{5.12}$$

Proof. Beginning with

$$\frac{1}{\pi}\int_0^\pi T_N(t)dt = \frac{1}{\pi}\sum_{n=1,odd}^{N}\int_0^\pi \frac{\cos nt - \cos\lambda_n t}{n^3}\sin nt, \tag{5.13}$$

then by using trigonometric identities and integrating, we have

$$\frac{1}{\pi}\int_0^\pi T_N(t)dt = \frac{1}{2}\sum_{n=1,odd}^{N}\frac{f(\frac{n(1+\lambda_n/n)}{2}\pi) + f(\frac{n(1-\lambda_n/n)}{2}\pi)}{n^3} \tag{5.14}$$

$$\geq \frac{1}{2}\sum_{n=1,odd}^{N^{2/3}}\frac{f(\frac{n(1-\lambda_n/n)}{2}\pi)}{n^3}, \tag{5.15}$$

where

$$f(y) = \frac{1-\cos(y)}{y}. \tag{5.16}$$

Next, we will bound the argument of f which is of the form $1-\frac{\sin y}{y}$ as shown below. By inspection, we can show that on $y\epsilon(0,\pi)$, $y^2/12 < 1-\frac{\sin y}{y} < y^2/6$, which yields the following bounds:

$$\frac{n(1-\lambda_n/n)}{2}\pi = \frac{\pi}{2}n\left(1-\frac{\sin\frac{n\pi}{2N}}{\frac{n\pi}{2N}}\right) \tag{5.17}$$

$$< \frac{n\pi}{2}\frac{\frac{n\pi}{2N}}{6} = \frac{\pi^3}{48}\frac{n^3}{N^2} \tag{5.18}$$

$$> \frac{n\pi}{2}\frac{\frac{n\pi}{2N}}{12} = \frac{\pi^3}{96}\frac{n^3}{N^2}. \tag{5.19}$$

In the range $0 < y < 1$, $f(y)$ can be bounded by its argument $1/4y < f(y) < 1/2y$. Thus, for $n < N^{2/3}$

$$\frac{1}{4}\frac{n(1-\lambda_n/n)}{2}\pi < f\left(\frac{n(1-\lambda_n/n)}{2}\pi\right) \tag{5.20}$$

which from (5.19) implies

$$\frac{\pi^3 n^3}{384N^2} < f\left(\frac{n(1-\lambda_n/n)}{2}\pi\right). \tag{5.21}$$

Therefore, from (5.15)

$$\frac{1}{\pi}\int_0^\pi T_N(t)dt > \frac{\pi^3}{768N^2}\sum_{n=1,\text{odd}}^{N^{2/3}} 1 > \frac{\pi^3}{1536N^{4/3}}. \qquad \square \tag{5.22}$$

Appendix B: General upper bounds on the error term $T_N(t)$. In general, when we have to enforce BCs we will violate some order compatibility condition, and the coefficients of the error will be algebraically decreasing due to the resulting discontinuity in a derivative of the Taylor expansion of the IC about the boundary. Thus, we can always impose the bound

$$|b_{n,N}(t)| \le \frac{c}{n^\beta}, \qquad \beta \ge 1, \tag{5.23}$$

where c is a constant. From the analysis in Appendix A, we can generalize (5.7), the error bound induced by the second-order difference operator, for any IC as

$$|b_{n,N}(t)| \le \frac{c_2 tn(\frac{n}{N})^2}{n^\beta} = c_2 t\frac{n^{3-\beta}}{N^2}. \tag{5.24}$$

If we split the summation which would correspond to $T_N(x_i,t)$ into two parts as was done in (5.8), we achieve the following approximation:

$$\sum_{n=1}^{N^\gamma} c_2 t\frac{n^{3-\beta}}{N^2} \sim \begin{array}{ll} \frac{c_2 t}{4-\beta}N^{-2}N^{(4-\beta)\gamma}, & \beta < 4,\\ c_2 tN^{-2}\log N^\gamma, & \beta = 4,\\ c_3 tN^{-2}, & \beta > 4. \end{array}$$

Similarly, for the tail end of the series as N becomes large, we have, using (5.23),

$$\sum_{n=N^\gamma+1,odd}^{\infty} \sim \frac{c}{\beta-1}N^{\gamma(1-\beta)}. \tag{5.25}$$

From these approximations, the conjecture in section 4.3 follows for the upper bound on the error term, $T_N(x_i,t)$, due to the second-order finite difference scheme.

Acknowledgments. The authors gratefully thank Dr. Keith Lindsay at the National Center for Atmospheric Research for his discussions, help, and contributions, particularly with the convergence proofs in the appendices and the factorizations (5.8) and (5.9).

DECOUPLING THREE-DIMENSIONAL MIXED PROBLEMS USING DIVERGENCE-FREE FINITE ELEMENTS[*]

ROBERT SCHEICHL[†]

Abstract. In this paper we describe an iterative method for indefinite saddle-point systems arising from mixed finite element discretizations of second-order elliptic boundary value problems subject to mixed boundary conditions and posed over polyhedral three-dimensional domains. The method is based on a decoupling of the vector of velocities in the saddle-point system from the vector of pressures, resulting in a symmetric positive definite velocity system and a triangular pressure system.

The crucial step in this approach is the construction of the divergence-free Raviart–Thomas–Nédélec elements from the curls of Nédélec's edge elements. Because of the large kernel of the curl-operator, this representation is not unique. To find a basis we consider the graph made up of the nodes and edges of the mesh and eliminate the edge elements associated with a spanning tree in this graph. To prove that this technique works in the general case considered here, we employ fundamental results from algebraic topology and graph theory.

We also include some numerical experiments, where we solve the (decoupled) velocity system by ILU-preconditioned conjugate gradients and the pressure system by simple back substitutions. We compare our method with a standard ILU-based block preconditioner for the original saddle-point system, and we find that our method is faster by a factor of at least 4.5 in all cases, with the greatest improvement occurring in the nonuniform mesh case.

Key words. mixed finite elements, second-order elliptic problems, mixed boundary conditions, divergence-free space, spanning trees, decoupled iterative method

1. Introduction.

The problem we are going to consider in this paper is the following second-order elliptic problem in velocity-pressure formulation

$$\vec{u} + K\,\vec{\nabla} p = \vec{g}, \tag{1.1}$$

$$\vec{\nabla} \cdot \vec{u} = 0, \tag{1.2}$$

subject to mixed boundary conditions over a polyhedral three-dimensional domain Ω. Such a problem arises, for example, in groundwater flow or oil recovery simulations, where $\vec{u}$ corresponds to the velocity, p corresponds to the pressure, and K is permeability divided by dynamic viscosity.

The numerical treatment of (1.1), (1.2) involves the solution of usually very large indefinite linear equation systems. In this paper we describe a very efficient and practicable iterative method to solve these systems by decoupling the vector of velocities from the vector of pressures, resulting in a symmetric positive definite velocity system and a triangular pressure system. The crucial step in this approach is the construction of a basis for the divergence-free Raviart–Thomas–Nédélec elements. The proof that our algorithm for this construction works uses results from algebraic topology and graph theory and will also be presented in this paper.

Because the variable of prime interest in (1.1), (1.2) (especially in the applications we have in mind) is the velocity $\vec{u}$, the discretization schemes of most interest are those which preserve conservation of mass (1.2) in an appropriate way, with the prime candidates being mixed finite element or finite volume techniques. In this paper we discretize (1.1), (1.2) using the lowest-order mixed Raviart–Thomas–Nédélec elements on tetrahedral meshes (Nédélec [23]). Here p is approximated in the space of piecewise constant functions and $\vec{u}$ is approximated in an appropriate subspace of the vector-valued piecewise linear functions, in which the normal component of $\vec{u}$ is required to be continuous across the element boundaries. The resulting discretization enforces mass conservation on each element of the mesh. Since the quality of the approximations is determined by the mesh width, it is usually necessary to work with very fine meshes.

As is well known this type of discretization yields symmetric indefinite systems of *saddle-point type*. Iterative methods for indefinite systems are less powerful and robust (w.r.t. a refinement of the mesh) than the methods available for definite systems. Therefore almost all approaches to solve this system efficiently contain at some point a reduction of the system to a symmetric positive definite system. At least two different strategies have been pursued.

The first strategy is to solve the saddle-point system by a preconditioned *minimum residual* (MINRES) method using a symmetric positive definite block preconditioner. The analysis for this strategy seems to be restricted to the two-dimensional case (e.g., [26, 4]), although the preconditioner described in Rusten and Winther [26] can be readily applied in three dimensions as well. There is also recent work by Wohlmuth, Toselli, and Widlund [29] on a domain decomposition preconditioner for Raviart–Thomas–Nédélec vector fields in three dimensions which can be used in the framework of Arnold, Falk, and Winther [4].

The second strategy is to decouple the vector of velocities in the saddle-point system from the vector of pressures. This can be done by (i) mixed hybridization via Lagrange multipliers [13, 11], (ii) block elimination of the velocity variable [24], or, as presented in this paper, (iii) a direct elimination of the divergence constraint (1.2) on the element level. This technique (iii) has two distinct advantages over (i) and (ii): first, no nonphysical variables are introduced, and, second, the velocity is obtained directly without (necessarily) computing the pressure, the latter advantage being particularly attractive in groundwater flow calculations. The method (iii) was first developed in the related but different case of the Stokes problem by Crouzeix and Thomasset [28] for two dimensions and by Hecht [17] for three dimensions. In connection with the solution of system (1.1), (1.2) it appears first in Chavent et al. [10]. Since the decoupling in this way leads to much smaller and nicer linear equation systems, it was subsequently possible to develop very competitive and efficient methods for the two-dimensional case (e.g., [15, 16, 21, 22, 12]). In this paper we present a very efficient iterative method for the solution of system (1.1), (1.2) that implements this idea in three dimensions.

Thus our solver is built on three essential steps. The first step decouples the velocity field in the saddle-point problem from the pressure field. This is done by writing the velocity as the curl of an appropriate discrete *vector potential*, automatically satisfying the discrete counterpart of the mass conservation law (1.2). The required discrete vector potential turns out to be a finite element approximation of the solution of a related symmetric positive *semidefinite* problem by *edge elements* (Nédélec [23]) which can be found independently of the pressure. Because of the large kernel of the curl-operator, this system is singular. In Hiptmair and Hoppe [19] a multilevel method is constructed that solves this singular problem approximately. In this paper we make the problem positive definite by eliminating the degrees of freedom associated with a *spanning tree* of the graph made up of the nodes and edges of the mesh. This also corresponds to finding a local basis for the divergence-free Raviart–Thomas–Nédélec elements. Such algebraic techniques have already been successfully used in other fields (e.g., [2, 20, 6] for Maxwell's equations, [17, 18, 14] for incompressible flow (Stokes)); in the context of (1.1), (1.2) there is only one paper by Cai et al. [8], and that is restricted to uniform rectangular meshes, in which case the special spanning tree can be written down a priori.

The second step in the solver is the application of a preconditioned *conjugate gradient* (CG) method to solve for the discrete velocity. Since the system is symmetric positive definite, it is easier to solve than the original saddle-point system. It also turns out to have the added advantage of being about three times smaller than the original system. In section 7 we have included some results using a simple ILU preconditioner to illustrate this advantage. We compare our method with the (also ILU-based) block preconditioner of Rusten and Winther [26] for the original saddle-point system, and we find that our method is faster by a factor of at least 4.5 in all cases, with the greatest improvement occurring in the nonuniform mesh case (where an improvement factor of 9.0 is observed on the finest mesh (36864 freedoms)).

The third and final step in the solver is the recovery of the pressure (if it is required). The decoupled pressure system turns out to be particularly simple. By an appropriate numbering of the freedoms it can be made triangular and solved in optimal time by simple *back substitutions*. We will prove this rigorously.

The layout of this paper is as follows. In section 2 we shall describe the mathematical setting for (1.1), (1.2) and its discretization by mixed finite elements. In section 3 we present the decoupling of the vector of velocities from the vector of pressures as a general algebraic procedure. In section 4 we construct the basis for the divergence-free Raviart–Thomas–Nédélec elements, and we show in section 5 how this basis is used to implement the decoupled velocity system. In section 6 we show how the pressure is recovered, and we finish the paper with some numerical results in section 7.

2. Mixed finite element discretization.

In this section we describe the mathematical setting for (1.1), (1.2) together with its discretization by mixed finite elements. Since this is a standard procedure (see, e.g., [7]), we shall be brief.

Let Ω denote an open *polyhedron*, i.e. a simply connected open domain without cavities in $\mathbb{R}^3$ with a connected boundary Γ composed of plane faces, which is assumed partitioned into $\Gamma_D \cup \Gamma_N$. Each of Γ_D and Γ_N is assumed to consist of a finite union of planar polygonal subsets of Γ, and Γ_D and Γ_N are both assumed to be connected. Additionally, Γ_N is assumed to be closed. Let $\vec{\nu}(\vec{x})$ denote the outward unit normal from Ω at $\vec{x} \in \Gamma$. In general we assume that K is a bounded, symmetric, and uniformly positive definite 3×3 matrix-valued function on Ω. The system (1.1), (1.2) is to be solved on Ω subject to mixed boundary conditions:

$$p = p_D \quad \text{on} \quad \Gamma_D \qquad \text{and} \quad \vec{u} \cdot \vec{\nu} = 0 \quad \text{on} \quad \Gamma_N \,. \tag{2.1}$$

Throughout, we shall assume that $\Gamma_D \neq \emptyset$, a condition which is generically satisfied in groundwater flow applications, where some inflow and outflow must occur. The extension to the case when $\Gamma_D = \emptyset$ (when p is nonunique) can easily be made by imposing an extra condition on p in the weak form below (e.g., that p should have a prescribed mean value; see, e.g., [15]).

To discretize (1.1), (1.2), (2.1) we put it in weak form. Let $(\cdot,\cdot)_{L_2(\Omega)^d}$ denote the usual inner product in $L_2(\Omega)^d$ for $d = 1, 2, 3$. Then introduce the Hilbert space

$$H(\mathrm{div}, \Omega) := \{\vec{v} \in L_2(\Omega)^3 : \mathrm{div}\, \vec{v} \in L_2(\Omega)\},$$

with the inner product

$$(\vec{u}, \vec{v})_{H(\mathrm{div},\Omega)} := (\vec{u}, \vec{v})_{L_2(\Omega)^3} + (\mathrm{div}\, \vec{u}, \mathrm{div}\, \vec{v})_{L_2(\Omega)},$$

and its subspace

$$H_{0,N}(\mathrm{div}, \Omega) := \{\vec{v} \in H(\mathrm{div}, \Omega) : \vec{v} \cdot \vec{\nu}|_{\Gamma_N} = 0\}$$

(see [7] for details). Introduce the bilinear forms

$$m(\vec{u}, \vec{v}) := (K^{-1}\vec{u}, \vec{v})_{L_2(\Omega)^3}, \qquad b(\vec{v}, w) := -(\mathrm{div}\, \vec{v}, w)_{L_2(\Omega)},$$

and the linear functional

$$G(\vec{v}) := (K^{-1}\vec{g}, \vec{v})_{L_2(\Omega)^3} - \int_{\Gamma_D} p_D\, \vec{v} \cdot \vec{\nu}\, dF.$$

Then the weak form of (1.1), (1.2), (2.1) is to find $(\vec{u}, p) \in H_{0,N}(\mathrm{div}, \Omega) \times L_2(\Omega)$ such that

$$(2.2) \qquad \left\{ \begin{array}{lcllll} m(\vec{u}, \vec{v}) & + & b(\vec{v}, p) & = & G(\vec{v}) & \text{for all } \vec{v} \in H_{0,N}(\mathrm{div}, \Omega), \\ b(\vec{u}, w) & & & = & 0 & \text{for all } w \in L_2(\Omega). \end{array} \right.$$

The mixed finite element discretization of (2.2) is obtained by choosing finite-dimensional subspaces $\mathcal{V} \subset H_{0,N}(\mathrm{div}, \Omega)$ and $\mathcal{W} \subset L_2(\Omega)$ and seeking $(\vec{U}, P) \in \mathcal{V} \times \mathcal{W}$ such that

$$(2.3) \qquad \left\{ \begin{array}{lcllll} m(\vec{U}, \vec{V}) & + & b(\vec{V}, P) & = & G(\vec{V}) & \text{for all } \vec{V} \in \mathcal{V}, \\ b(\vec{U}, W) & & & = & 0 & \text{for all } W \in \mathcal{W}. \end{array} \right.$$

In practice this is implemented by choosing bases $\{\vec{v}_i : i = 1, \ldots, n_{\mathcal{V}}\}$ and $\{w_j : j = 1, \ldots, n_{\mathcal{W}}\}$ for $\mathcal{V}$ and $\mathcal{W}$. By writing

$$\vec{U} = \sum_{i=1}^{n_{\mathcal{V}}} u_i \vec{v}_i, \qquad P = \sum_{j=1}^{n_{\mathcal{W}}} p_j w_j,$$

problem (2.3) is then reduced to the indefinite system of linear equations

$$(2.4) \qquad \begin{pmatrix} M & B \\ B^T & 0 \end{pmatrix} \begin{pmatrix} \boldsymbol{u} \\ \boldsymbol{p} \end{pmatrix} = \begin{pmatrix} \boldsymbol{g} \\ \boldsymbol{0} \end{pmatrix} \qquad \text{in} \quad \mathbb{R}^{n_{\mathcal{V}}} \times \mathbb{R}^{n_{\mathcal{W}}},$$

where $M_{i,i'} := m(\vec{v}_i, \vec{v}_{i'})$ is the "mass matrix," $B_{i,j} := b(\vec{v}_i, w_j)$ is the "discrete gradient," and $g_i := G(\vec{v}_i)$.

In this paper we restrict attention to the (most practically important) case when $\mathcal{V}$ is the lowest-order Raviart–Thomas–Nédélec space on tetrahedra [23]. To define this, let $\mathcal{T}$ denote a triangulation of Ω into conforming tetrahedra $T \in \mathcal{T}$. We assume that all lines along which the boundary condition changes (i.e., the boundaries of the components of Γ_N) are edges of tetrahedra in $\mathcal{T}$. Let $\mathcal{F}$ denote the set of all faces of the tetrahedra in $\mathcal{T}$. It is convenient to think of these faces as open so that, for

$F \in \mathcal{F}$, $\overline{F}$ denotes the closure of F (including its boundary). For any $F \in \mathcal{F}$, we let $\vec{\nu}_F$ denote the unit normal to the face F which, for convenience, is assumed to be orientated so that

$$\vec{\nu}_F \in \{\vec{x} \in \mathbb{R}^3 : x_1 > 0\} \cup \{(0, x_2, x_3)^T \in \mathbb{R}^3 : x_2 > 0\} \cup \{(0,0,1)^T\}. \tag{2.5}$$

Let $\mathcal{F}_I$, $\mathcal{F}_D$, and $\mathcal{F}_N$ denote the faces $F \in \mathcal{F}$ which lie in Ω, Γ_D, and Γ_N, respectively.

The space $\mathcal{V}$ is defined to be the space of all functions $\vec{v} \in H_{0,N}(\text{div}, \Omega)$ such that for all $T \in \mathcal{T}$, there exist $\vec{\alpha}_T \in \mathbb{R}^3$ and $\gamma_T \in \mathbb{R}$ such that

$$\vec{v}(\vec{x}) = \vec{\alpha}_T + \gamma_T \vec{x} \qquad \text{for all} \quad \vec{x} \in T. \tag{2.6}$$

Equivalently, we can define $\mathcal{V}$ to be the space of all $\vec{v} : \Omega \to \mathbb{R}^3$ which satisfy (2.6) for each $T \in \mathcal{T}$, and also

$$\begin{array}{ll} \text{(i)} & \vec{v} \cdot \vec{\nu}_F \quad \text{is continuous across each face } F \in \mathcal{F}_I, \\ \text{(ii)} & \vec{v} \cdot \vec{\nu}_F = 0 \quad \text{for all} \quad F \in \mathcal{F}_N. \end{array} \tag{2.7}$$

Because of the special form of (2.6) it is easily shown that $\vec{v}(\vec{x}) \cdot \vec{\nu}_F$ is constant for $\vec{x} \in F$ on any face F of T. Thus $\vec{v} \in \mathcal{V}$ can be completely determined by specifying the constant value of $\vec{v} \cdot \vec{\nu}_F$ for each $F \in \mathcal{F}_I \cup \mathcal{F}_D$. This leads us to introduce the standard basis for $\mathcal{V}$ which is constructed by associating with each face $F \in \mathcal{F}_I \cup \mathcal{F}_D$, a function $\vec{v}_F \in \mathcal{V}$ with the property that

$$\vec{v}_F \cdot \vec{\nu}_{F'} = \delta_{F,F'}, \tag{2.8}$$

with δ denoting the Kronecker delta.

We also have to specify the space $\mathcal{W}$. To fulfill the discrete inf-sup condition which is necessary for existence and uniqueness (see, e.g., [25]), $\mathcal{W}$ is chosen as the space of piecewise constant functions on Ω, with the basis consisting of the characteristic functions w_T of each of the tetrahedra $T \in \mathcal{T}$. Thus

$$n_{\mathcal{V}} = (\#\mathcal{F}_I + \#\mathcal{F}_D), \qquad n_{\mathcal{W}} = (\#\mathcal{T}), \tag{2.9}$$

where, throughout, $\#A$ denotes the number of elements of a (finite) set A.

3. Decoupled iterative method for mixed problems. In this section we formulate our method for decoupling the vector of velocities $\boldsymbol{u}$ from the vector of pressures $\boldsymbol{p}$ in system (2.4). We have already presented this procedure for the two-dimensional case in [12]. Recall [7] that (2.4) has a unique solution $(\boldsymbol{u}, \boldsymbol{p}) \in \mathbb{R}^{n_{\mathcal{V}}} \times \mathbb{R}^{n_{\mathcal{W}}}$ for all $\boldsymbol{g} \in \mathbb{R}^{n_{\mathcal{V}}}$, and clearly $\boldsymbol{u}$ is in $\ker B^T$.

Remark 3.1. *The case of* $\boldsymbol{u} \notin \ker B^T$ *(or, equivalently, of a more general right-hand side* $(\boldsymbol{g}^T, \boldsymbol{h}^T)^T$ *of* (2.4)*) arises when* $\vec{\nabla} \cdot \vec{u} \neq 0$ *in* (1.2)*. This problem can be reduced to problem* (2.4) *following Ewing and Wang* [15] *(see also* [8, 19] *for three dimensions): in a preprocessing step based on domain decomposition (*static condensation*) a vector* $\boldsymbol{u}^*$ *is calculated such that* $B^T\boldsymbol{u}^* = \boldsymbol{h}$*; this can be done in* $O(n)$ *steps (where* $n = n_{\mathcal{V}} + n_{\mathcal{W}}$*); the remainder* $\tilde{\boldsymbol{u}} = \boldsymbol{u} - \boldsymbol{u}^*$ *fulfills* (2.4) *with right-hand side* $((\boldsymbol{g} - M\boldsymbol{u}^*)^T, \boldsymbol{0}^T)^T$ *and can be calculated with the method described in this paper. See* [27] *for details.*

To describe our decoupling procedure, first consider (2.4) as an abstract system. The decoupling of $\boldsymbol{u}$ from $\boldsymbol{p}$ can be achieved by finding

$$\text{a basis } \; \{\boldsymbol{z}_1, \ldots, \boldsymbol{z}_{\mathring{n}}\} \; \text{ of } \; \ker B^T. \tag{3.1}$$

(Since B^T has full rank, $\mathring{n} = n_{\mathcal{V}} - n_{\mathcal{W}}$.) If we have such a basis, then the solution $\boldsymbol{u}$ of (2.4) can be written

$$\boldsymbol{u} = \sum_{j=1}^{\mathring{n}} \mathring{u}_j \boldsymbol{z}_j = Z^T \mathring{\boldsymbol{u}}, \tag{3.2}$$

for some $\mathring{\boldsymbol{u}} \in \mathbb{R}^{\mathring{n}}$, where Z denotes the $\mathring{n} \times n_{\mathcal{V}}$ matrix with rows $\boldsymbol{z}_1^T, \dots, \boldsymbol{z}_{\mathring{n}}^T$. Also, since $ZB = (B^T Z^T)^T = 0$, multiplying the first (block) row of (2.4) by Z shows that $\mathring{\boldsymbol{u}}$ is a solution of the linear system

$$\mathring{A}\mathring{\boldsymbol{u}} = \mathring{\boldsymbol{g}}, \tag{3.3}$$

where

$$\mathring{A} = ZMZ^T \quad \text{and} \quad \mathring{\boldsymbol{g}} = Z\boldsymbol{g}. \tag{3.4}$$

Since M is symmetric positive definite, so is $\mathring{A}$, and $\mathring{\boldsymbol{u}}$ is the unique solution of (3.3). Thus if the basis (3.1) can be found, then the velocity $\boldsymbol{u}$ in (2.4) can be computed by solving the decoupled positive definite system (3.3) rather than the indefinite coupled system (2.4).

In applications to groundwater flow, where one is primarily interested in the velocity $\vec{u}$ in (1.1), (1.2), the method described above is of great relevance. Even when the pressure p is also of interest our method may still be highly competitive, provided we can also compute a *complementary basis* $\{\boldsymbol{z}_{\mathring{n}+1}, \dots, \boldsymbol{z}_{n_{\mathcal{V}}}\}$ with the property that

$$\operatorname{span}\{\boldsymbol{z}_1, \dots, \boldsymbol{z}_{\mathring{n}}, \boldsymbol{z}_{\mathring{n}+1}, \dots, \boldsymbol{z}_{n_{\mathcal{V}}}\} = \mathbb{R}^{n_{\mathcal{V}}}. \tag{3.5}$$

If this is known and if Z' denotes the matrix with rows $\boldsymbol{z}_{\mathring{n}+1}^T, \dots, \boldsymbol{z}_{n_{\mathcal{V}}}^T$, then multiplying the first (block) row of (2.4) by Z' shows that $\boldsymbol{p}$ is the solution of the $n_{\mathcal{W}} \times n_{\mathcal{W}}$ system

$$(Z'B)\boldsymbol{p} = Z'(\boldsymbol{g} - M\boldsymbol{u}). \tag{3.6}$$

An elementary argument shows that $Z'B$ is nonsingular, and so the unique solution $\boldsymbol{p}$ of (3.6) also determines the pressure in (2.4) once the velocity $\boldsymbol{u}$ is known.

We show in the next three sections that in the particular case of the mixed finite element system (2.4),

(i) it is always easy to find the basis (3.1);

(ii) the resulting symmetric positive definite matrix $\mathring{A}$ in the reduced problem (3.3) can be obtained by simple algebraic techniques from the stiffness matrix of an associated symmetric positive semidefinite problem in the space $H(\overrightarrow{\text{curl}}, \Omega)$ discretized by Nédélec's edge elements;

(iii) the system (3.3) is about 3 times smaller than (2.4);

(iv) a simple choice of complementary basis can be made so that the coefficient matrix $Z'B$ in the system (3.6) is lower triangular.

To establish conclusions (i)–(iv) we need to exploit the particular properties of (2.4). In particular, note that finding the basis $\boldsymbol{z}_1, \dots, \boldsymbol{z}_{\mathring{n}}$ in (3.1) is equivalent to finding a basis $\mathring{\vec{v}}_1, \dots, \mathring{\vec{v}}_{\mathring{n}}$ of the finite element space

$$\mathring{\mathcal{V}} := \{\vec{V} \in \mathcal{V} : \; b(\vec{V}, W) = 0 \text{ for all } \; W \in \mathcal{W}\}.$$

To see why, suppose $\boldsymbol{z}_1, \dots, \boldsymbol{z}_{\mathring{n}}$ are known and let $Z = (Z_{i,j})$ be the matrix with rows $\boldsymbol{z}_1^T, \dots, \boldsymbol{z}_{\mathring{n}}^T$. Then the formulae

$$\mathring{\vec{v}}_i = \sum_{j=1}^{n_{\mathcal{V}}} Z_{i,j} \vec{v}_j \;, \qquad i = 1, \dots, \mathring{n}, \tag{3.7}$$

(where $\{\vec{v}_j\}$ is the basis of $\mathcal{V}$) determine the basis $\{\vec{\mathring{v}}_i\}$. Conversely, if the basis $\{\vec{\mathring{v}}_i\}$ of $\mathring{\mathcal{V}}$ is known, then the matrix Z (and hence the basis $\boldsymbol{z}_1, \ldots, \boldsymbol{z}_{\mathring{n}}$ of ker B^T) is determined by (3.7).

We now turn our attention to finding a basis of $\mathring{\mathcal{V}}$.

4. Construction of a divergence-free basis. As a first step, recall that $\mathcal{T}$ is the set of all tetrahedra in the mesh and that $\mathcal{F} = \mathcal{F}_I \cup \mathcal{F}_D \cup \mathcal{F}_N$ is the set of all faces of the mesh (assumed to be open triangles) which lie in Ω, Γ_D, and Γ_N, respectively. Analogously, we can write $\mathcal{E} = \mathcal{E}_I \cup \mathcal{E}_D \cup \mathcal{E}_N$, with $\mathcal{E}_I$, $\mathcal{E}_D$, and $\mathcal{E}_N$ denoting the edges in Ω, Γ_D, and Γ_N; and $\mathcal{N} = \mathcal{N}_I \cup \mathcal{N}_D \cup \mathcal{N}_N$, with $\mathcal{N}_I$, $\mathcal{N}_D$, and $\mathcal{N}_N$ denoting the nodes in Ω, Γ_D, and Γ_N. Recall that the boundaries of each of the components of Γ_N belong to Γ_N, and, since the lines between Neumann and Dirichlet boundaries are edges of the mesh, these edges lie in $\mathcal{E}_N$. For $E \in \mathcal{E}$, let $\vec{\tau}_E$ denote the unit tangent on edge E which, as in (2.5), is assumed to be orientated so that

$$\vec{\tau}_E \in \{\vec{x} \in \mathbb{R}^3 : x_1 > 0\} \cup \{(0, x_2, x_3)^T \in \mathbb{R}^3 : x_2 > 0\} \cup \{(0,0,1)^T\}. \tag{4.1}$$

Through this convention we associate an orientation with each edge of the mesh.

To construct a basis of $\mathring{\mathcal{V}}$ it is useful to introduce the following space of finite elements introduced by Nédélec in [23]. Let

$$H(\vec{\text{curl}}, \Omega) := \{\vec{\Phi} \in L_2(\Omega)^3 : \vec{\text{curl}}\, \vec{\Phi} \in L_2(\Omega)^3\}$$

and let $\mathcal{U}$ be the finite-dimensional space of all functions $\vec{\Phi} \in H(\vec{\text{curl}}, \Omega)$ such that for all $T \in \mathcal{T}$, there exist $\vec{\alpha}_T$, $\vec{\beta}_T \in \mathbb{R}^3$ such that

$$\vec{\Phi}(\vec{x}) = \vec{\alpha}_T + \vec{\beta}_T \times \vec{x} \qquad \text{for all } \vec{x} \in T. \tag{4.2}$$

In fact, $\mathcal{U}$ is the lowest-order member of the family of spaces introduced by Nédélec in [23]. The standard basis of $\mathcal{U}$ consists of the set of functions $\{\vec{\Phi}_E \in \mathcal{U} : E \in \mathcal{E}\}$ which are required to have the property

$$\int_{E'} \vec{\Phi}_E \cdot \vec{\tau}_{E'}\, ds = \delta_{E,E'} \qquad \text{for all } E' \in \mathcal{E}. \tag{4.3}$$

This choice of basis functions accounts for the widely used term *edge elements.*

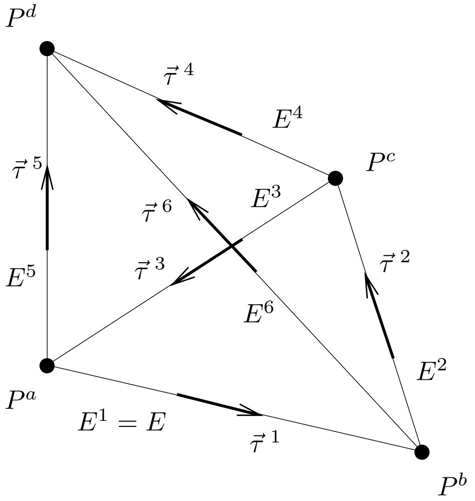
The basis for $\mathring{\mathcal{V}}$ will now be constructed from the fundamental functions $\vec{\Psi}_E$ defined by

$$\vec{\Psi}_E = \vec{\text{curl}} \vec{\Phi}_E \tag{4.4}$$

(so that $\vec{\Phi}_E$ is the *vector potential* of $\vec{\Psi}_E$). The functions (4.4) clearly satisfy $\text{div}\vec{\Psi}_E = 0$ on each tetrahedron of the mesh, and a subset of them lie in $\mathring{\mathcal{V}}$ as the following proposition shows.

PROPOSITION 4.1. *For each $E \in \mathcal{E}_I \cup \mathcal{E}_D$, $\vec{\Psi}_E \in \mathring{\mathcal{V}}$.*

Proof. Consider a general edge $E \in \mathcal{E}$. Conditions (4.2) and (4.3) clearly imply that supp $\vec{\Psi}_E$ consists only of the tetrahedra touching edge E. A typical such tetrahedron T with edges $E := E^1$, E^2, …, E^6, and nodes P^a, …, P^d, is depicted in the figure below:



with $\vec{\tau}^{\,\alpha}$, $\alpha = 1, \dots, 6$, denoting unit tangent vectors in the directions shown and $\vec{r}^{\,\beta}$ denoting the position vector of P^β, $\beta = a, b, c, d$. The faces are denoted by F^a, ..., F^d, where F^β is opposite P^β, $\beta = a, b, c, d$, and the unit outward normal on each face is denoted by $\vec{\nu}^{\,\beta}$.

Note first that for all $\vec{x} \in T$

$$\vec{\Psi}_E(\vec{x}) = \vec{\text{curl}}\vec{\Phi}_E(\vec{x}) = \vec{\nabla} \times \left(\vec{\beta}_T \times \vec{x}\right) = 2\vec{\beta}_T,$$

which is easily seen to be of the form (2.6) (in fact, with $\gamma_T = 0$).

Since $\vec{\Psi}_E(\vec{x})$ is constant on T, we can write for each $\vec{x} \in T$ and for each $\beta = a, b, c, d$,

$$\vec{\Psi}_E(\vec{x}) \cdot \vec{\nu}^{\,\beta} = \frac{1}{|F^\beta|} \int_{F^\beta} \vec{\Psi}_E(\vec{x}) \cdot \vec{\nu}^{\,\beta}\, dF = \frac{1}{|F^\beta|} \int_{F^\beta} \vec{\text{curl}}\vec{\Phi}_E(\vec{x}) \cdot \vec{\nu}^{\,\beta}\, dF,$$

and using Stokes's integral theorem we get

$$\vec{\Psi}_E(\vec{x}) \cdot \vec{\nu}^{\,\beta} = \frac{1}{|F^\beta|} \oint_{\partial F^\beta} \vec{\Phi}_E(\vec{x}) \cdot \vec{ds} = \begin{cases} \frac{1}{|F^\beta|} & \text{for } \beta = c, \\ -\frac{1}{|F^\beta|} & \text{for } \beta = d, \\ 0 & \text{otherwise,} \end{cases} \tag{4.5}$$

where in the last step we used (4.3) to evaluate the line integral (respecting the right-hand rule and the specific orientation of $\vec{\tau}^{\,1}$ and $\vec{\nu}^{\,\beta}$, $\beta = a, b, c, d$, as depicted in the figure above).

Now to obtain the result observe that, since $\text{div}\vec{\Psi}_E = 0$ on each tetrahedron, it is sufficient to show that

$$\vec{\Psi}_E \in \mathcal{V} \quad \text{for all } E \in \mathcal{E}_I \cup \mathcal{E}_D. \tag{4.6}$$

To show this we shall verify criterion (2.7). First consider $E \in \mathcal{E}_I$. Let $F \in \mathcal{F}_I$. If $F \not\subset \text{supp}\,\vec{\Psi}_E$, then we have trivially

$$\vec{\Psi}_E \cdot \vec{\nu}_F \quad \text{is continuous across } F. \tag{4.7}$$

Now take a general tetrahedron $T \subset \text{supp}\,\vec{\Psi}_E$, as pictured above. If $F = F^c$ or F^d, then performing the computation (4.5) in the other tetrahedron adjoining F and

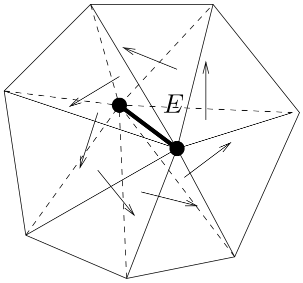


FIG. 1. *Divergence-free basis function* $\vec{\Psi}_E$.

combining with (4.5) establishes (4.7). On the other hand, when $F = F^a$ or F^b, (4.7) also holds since $\vec{\Psi}_E \cdot \vec{\nu}_F|_T = 0$ and since the other tetrahedron adjoining F lies outside $\operatorname{supp} \vec{\Psi}_E$. Altogether, we have established that $\vec{\Psi}_E$ satisfies criterion (2.7)(i).

To establish (2.7)(ii), let $F \in \mathcal{F}_N$. If $F \not\subset \operatorname{supp} \vec{\Psi}_E$, then $\vec{\Psi}_E \cdot \vec{\nu}_F = 0$ trivially. If $F \subset \overline{T} \subset \operatorname{supp} \vec{\Psi}_E$, then (since $E \in \mathcal{E}_I$) with the above notation F has to be either F^a or F^b and again $\vec{\Psi}_E \cdot \vec{\nu}_F = 0$, proving (2.7)(ii).

Thus we have shown that $\vec{\Psi}_E \in \mathcal{V}$ for all $E \in \mathcal{E}_I$. Similar arguments establish that $\vec{\Psi}_E \in \mathcal{V}$ for all $E \in \mathcal{E}_D$, proving (4.6). □

Note that each $\vec{\Psi}_E$ can be expressed as a local linear combination of the basis functions $\vec{v}_F$ of $\mathcal{V}$ satisfying (2.8); in fact, only those $\vec{v}_F$ corresponding to faces F that contain edge E appear in the expansion of $\vec{\Psi}_E$ (see Figure 1).

To find a basis for $\overset{\circ}{\mathcal{V}}$, let us first look at the pure Dirichlet case, $\Gamma_N = \emptyset$. The functions introduced in Proposition 4.1 are sufficient to span $\overset{\circ}{\mathcal{V}}$, but there are too many of them. The following theorem identifies a linearly independent subset of the functions in Proposition 4.1 that constitutes a basis of $\overset{\circ}{\mathcal{V}}$. A similar statement for the pure Neumann case, $\Gamma_D = \emptyset$, has already been proved by Dubois [14] (see Remark 4.7 for a more extensive literature survey).

The proof involves some fundamental notions and results from graph theory and algebraic topology (see Appendices A and B for a brief introduction). In particular we need the notion of a *spanning tree* of a graph (see Theorem A.4). Let $\mathbf{G} := (\mathcal{N}, \mathcal{E})$ be the graph formed by the nodes and (orientated) edges of the triangulation $\mathcal{T}$.

THEOREM 4.2. *Let* $\Gamma_N = \emptyset$ *and let* $\mathcal{H} \subset \mathcal{E}$ *be such that if* $\mathbf{H} := (\mathcal{N}, \mathcal{H})$ *is a spanning tree of* $\mathbf{G}$*, then*

$$\{\vec{\Psi}_E : E \in \mathcal{E} \backslash \mathcal{H}\} \quad \textit{is a basis of} \quad \overset{\circ}{\mathcal{V}}. \tag{4.8}$$

Before proving Theorem 4.2, we will first prove two lemmas. Let $\mathcal{V}(\mathbf{G})$ denote the vector space over $\mathbb{Z}$ generated by the cycles of $\mathbf{G}$ as defined in Definition A.1(e). Furthermore, for each face $F \in \mathcal{F}$ let μ^F be the *elementary cycle* of $\mathbf{G}$ formed by the edges E of F. We fix the orientation of this cycle w.r.t. $\vec{\nu}_F$ by applying the right-hand rule. The associated vector $\boldsymbol{\mu}^F := [\mu^F_E]_{E \in \mathcal{E}} \in \mathcal{V}(\mathbf{G})$ is given by

$$\mu^F_E = \begin{cases} 1 & \text{if } E \text{ is an edge of } F \text{ and } \vec{\tau}_E \text{ is positively orientated w.r.t. } \vec{\nu}_F, \\ -1 & \text{if } E \text{ is an edge of } F \text{ and } \vec{\tau}_E \text{ is negatively orientated w.r.t. } \vec{\nu}_F, \\ 0 & \text{otherwise.} \end{cases} \tag{4.9}$$

LEMMA 4.3. *Let $\boldsymbol{\mu} := [\mu_E]_{E\in\mathcal{E}} \in \mathcal{V}(\mathbf{G})$. Then there exist $\{\alpha_F \in \mathbb{Z} : F \in \mathcal{F}\}$ such that*

$$\boldsymbol{\mu} := \sum_{F\in\mathcal{F}} \alpha_F \boldsymbol{\mu}^F. \tag{4.10}$$

Proof. Let K be the simplicial complex underlying our simplicial triangulation $\mathcal{T}$. In the notation of algebraic topology (see Appendix B) the vector $\boldsymbol{\mu} \in \mathcal{V}(\mathbf{G})$ can be identified with the vector of coefficients of a cycle μ of K (with orientation of its edges defined by the tangent vectors $\vec{\tau}_E$).

Since $|K| = \overline{\Omega}$ is simply connected, we know from Corollary B.4 that each cycle of K is a bounding cycle and can therefore be written as a linear combination of the boundaries of the orientated triangles of K. In particular, there exist $\{\tilde{\alpha}_F \in \mathbb{Z} : F \in \mathcal{F}\}$ such that

$$\mu = \sum_{F\in\mathcal{F}} \tilde{\alpha}_F \partial F. \tag{4.11}$$

The boundary ∂F of an orientated triangle F of K is a special cycle $\tilde{\mu}^F$ of K. As above it can therefore be identified with a vector $\tilde{\boldsymbol{\mu}}^F \in \mathcal{V}(\mathbf{G})$. Depending on the orientation of $\vec{\nu}_F$ we either have $\tilde{\boldsymbol{\mu}}^F = \boldsymbol{\mu}^F$ or $\tilde{\boldsymbol{\mu}}^F = -\boldsymbol{\mu}^F$, and we can write (4.11) in vector notation:

$$\boldsymbol{\mu} = \sum_{F\in\mathcal{F}} \alpha_F \boldsymbol{\mu}^F \qquad \text{with} \quad \alpha_F = \begin{cases} \tilde{\alpha}_F & \text{if} \quad \tilde{\boldsymbol{\mu}}^F = \boldsymbol{\mu}^F, \\ -\tilde{\alpha}_F & \text{if} \quad \tilde{\boldsymbol{\mu}}^F = -\boldsymbol{\mu}^F. \end{cases} \qquad \square$$

LEMMA 4.4. *Let $\boldsymbol{\mu} \in \mathcal{V}(\mathbf{G})$ and let $\{\alpha_F \in \mathbb{Z} : F \in \mathcal{F}\}$ be such that $\boldsymbol{\mu} := \sum_{F\in\mathcal{F}} \alpha_F \boldsymbol{\mu}^F$. Then*

$$\sum_{F\in\mathcal{F}} \alpha_F \int_F \vec{\Psi}_E \cdot \vec{\nu}_F \, dF = \mu_E \qquad \textit{for all } E \in \mathcal{E}. \tag{4.12}$$

Proof. Let $F \in \mathcal{F}$. Using (4.5) we get

$$\int_F \vec{\Psi}_E \cdot \vec{\nu}_F \, dF = \begin{cases} 1 & \text{if } E \subset \overline{F} \text{ and } \vec{\tau}_E \text{ positively orientated w.r.t. } \vec{\nu}_F, \\ -1 & \text{if } E \subset \overline{F} \text{ and } \vec{\tau}_E \text{ negatively orientated w.r.t. } \vec{\nu}_F, \\ 0 & \text{otherwise,} \end{cases}$$

and, therefore, recalling the definition (4.9), we have $\int_F \vec{\Psi}_E \cdot \vec{\nu}_F \, dF = \mu_E^F$. Multiplying this by α_F and summing over $F \in \mathcal{F}$ we obtain (4.12). $\square$

We can now prove Theorem 4.2.

Proof. Let us first check that the number of basis functions in (4.8) coincides with $\mathring{n} = \dim \mathring{\mathcal{V}}$. Since Ω is simply connected without cavities, we can apply *Euler's polyhedron theorem* [9]

$$\#\mathcal{N} - \#\mathcal{E} + \#\mathcal{F} - \#\mathcal{T} \;=\; 1 \tag{4.13}$$

to the triangulation $\mathcal{T}$. Now observe that $\mathbf{H}$ is a tree, and therefore $\#\mathcal{H} = \#\mathcal{N} - 1$ (cf. Theorem A.3(iii)). Using this fact together with (4.13) we get

$$\#(\mathcal{E}\backslash\mathcal{H}) = \#\mathcal{E} - \#\mathcal{N} + 1 = \#\mathcal{F} - \#\mathcal{T}. \tag{4.14}$$

Now recalling that $\mathring{n} = n_{\mathcal{V}} - n_{\mathcal{W}} = \#\mathcal{F} - \#\mathcal{T}$, it follows from (4.14) that the number of functions in (4.8) is $\mathring{n}$, as required.

To establish linear independency of the functions in (4.8), suppose $\{\beta_{E'} : E' \in \mathcal{E}\backslash\mathcal{H}\}$ are scalars such that

$$\vec{0} = \sum_{E' \in \mathcal{E}\backslash\mathcal{H}} \beta_{E'} \vec{\Psi}_{E'}.$$

Now let $E \in \mathcal{E}\backslash\mathcal{H}$ and let $\boldsymbol{\mu}^E$ denote the vector associated with the unique cycle μ^E generated by taking edge E into the tree $\mathbf{H}$, which has the property that $\mu^E_{E'} := \delta_{E,E'}$ for all $E' \in \mathcal{E}\backslash\mathcal{H}$ (cf. Theorem A.6). Then using Lemma 4.3 we can find $\{\alpha_F \in \mathbb{Z} : F \in \mathcal{F}\}$ such that $\boldsymbol{\mu}^E := \sum_{F\in\mathcal{F}} \alpha_F \boldsymbol{\mu}^F$, and so by Lemma 4.4

$$0 = \sum_{F\in\mathcal{F}} \alpha_F \int_F \left(\sum_{E' \in \mathcal{E}\backslash\mathcal{H}} \beta_{E'}\, \vec{\Psi}_{E'} \right) \cdot \vec{\nu}_F \, dF = \sum_{E' \in \mathcal{E}\backslash\mathcal{H}} \beta_{E'} \mu^E_{E'} = \beta_E,$$

which establishes the linear independency of the functions in (4.8). □

Now let us look at mixed boundary conditions, $\Gamma_N \neq \emptyset$. In the following corollary we will see that the results of Theorem 4.2 extend to this case provided each component of Γ_N is simply connected. Our proof of this result makes use of the methods of Hecht [17] developed for the nonconforming P1-P0 elements for the approximation of solenoidal vector fields in $H^1(\Omega)^3$ (see Remark 4.7 for a more extensive discussion).

Therefore let $n_{\mathcal{C}}$ denote the number of connected components in Γ_N and write

$$\Gamma_N = \Gamma_N^1 \cup \Gamma_N^2 \cup \cdots \cup \Gamma_N^{n_{\mathcal{C}}}, \qquad \Gamma_N^\ell \cap \Gamma_N^{\ell'} = \emptyset \quad \text{for all } \ell \neq \ell' \in \{1, \ldots, n_{\mathcal{C}}\}.$$

For $\ell = 1, \ldots, n_{\mathcal{C}}$, let $\mathcal{N}_N^\ell \subset \mathcal{N}$, $\mathcal{E}_N^\ell \subset \mathcal{E}$, and $\mathcal{F}_N^\ell \subset \mathcal{F}$ denote the set of mesh nodes, edges, and faces on Γ_N^ℓ, respectively.

Corollary 4.5. *Suppose $n_{\mathcal{C}} \neq 0$ and suppose that Γ_N^ℓ is simply connected for each $\ell = 1, \ldots, n_{\mathcal{C}}$. Let $\mathcal{H} \subset \mathcal{E}$ such that $\mathbf{H} = (\mathcal{N}, \mathcal{H})$ is a spanning tree of $\mathbf{G}$ and such that for each $\ell = 1, \ldots, n_{\mathcal{C}}$, the restriction $\mathbf{H}_N^\ell := (\mathcal{N}_N^\ell, \mathcal{H} \cap \mathcal{E}_N^\ell)$ of $\mathbf{H}$ to Γ_N^ℓ is also a tree. Then*

$$\{\vec{\Psi}_E : E \in (\mathcal{E}_I \cup \mathcal{E}_D)\backslash\mathcal{H}\} \quad \textit{is a basis of} \quad \mathring{\mathcal{V}}. \tag{4.15}$$

Remark 4.6. *The general case, when Γ_N^ℓ is not simply connected for some ℓ, involves the introduction of a small number of additional nonlocal basis functions. In order not to complicate this paper, we omit the details for this case, but they will be given in* [27]. *Thus, from now on we will assume that Γ_N^ℓ is simply connected for all $\ell = 1, \ldots, n_{\mathcal{C}}$.*

Proof. Since $(\mathcal{E}_I \cup \mathcal{E}_D) \subset \mathcal{E}$, we also have $(\mathcal{E}_I \cup \mathcal{E}_D)\backslash\mathcal{H} \subset \mathcal{E}\backslash\mathcal{H}$, and therefore following the proof of Theorem 4.2 the functions $\vec{\Psi}_E$ in (4.15) are linearly independent.

We have only to check that the number of basis functions in (4.15) coincides with $\mathring{n} = \dim \mathring{\mathcal{V}}$. To do this, we need two elementary formulae (Cauchy [9]): *Euler's polyhedron theorem* (4.13) and the *Euler–Cauchy formula* for planar networks of polygons (4.16). Consider a typical Neumann boundary segment Γ_N^ℓ. Since Γ_N^ℓ is simply connected, we have

$$\#\mathcal{N}_N^\ell - \#\mathcal{E}_N^\ell + \#\mathcal{F}_N^\ell = 1. \tag{4.16}$$

Now observe that $\mathbf{H}_N^\ell$ is a tree, and therefore (again by virtue of Theorem A.3(iii)) $\#(\mathcal{H} \cap \mathcal{E}_N^\ell) = \#\mathcal{N}_N^\ell - 1$. Using (4.16) and summing over $\ell = 1, \dots, n_\mathcal{C}$, we obtain

$$\#(\mathcal{H} \cap \mathcal{E}_N) = \sum_{\ell=1}^{n_\mathcal{C}} (\#\mathcal{N}_N^\ell - 1) = \sum_{\ell=1}^{n_\mathcal{C}} (\#\mathcal{E}_N^\ell - \#\mathcal{F}_N^\ell) = (\#\mathcal{E}_N - \#\mathcal{F}_N). \tag{4.17}$$

Since the sets $\mathcal{E}_I$, $\mathcal{E}_D$, and $\mathcal{E}_N$ partition $\mathcal{E}$, we also have

$$(\mathcal{E}_I \cup \mathcal{E}_D)\backslash\mathcal{H} = (\mathcal{E}\backslash\mathcal{E}_N)\backslash\mathcal{H} = \mathcal{E}\backslash(\mathcal{E}_N \cup \mathcal{H}),$$

and, therefore, the number of functions in (4.15) is $\#\mathcal{E} - (\#\mathcal{E}_N + \#\mathcal{H} - \#(\mathcal{H} \cap \mathcal{E}_N))$. Combining this with (4.17), and using the fact that $\mathbf{H}$ is a tree (and therefore $\#\mathcal{H} = \#\mathcal{N} - 1$), we finally get

$$\#((\mathcal{E}_I \cup \mathcal{E}_D)\backslash\mathcal{H}) = (\#\mathcal{E} - \#\mathcal{N} + 1) - \#\mathcal{F}_N = (\#\mathcal{F} - \#\mathcal{T}) - \#\mathcal{F}_N, \tag{4.18}$$

where in the last step we have used Euler's polyhedron theorem (4.13). Now recalling that $\mathring{n} = n_\mathcal{V} - n_\mathcal{W}$ (and from section 3 we have $n_\mathcal{V} = \#\mathcal{F}_I + \#\mathcal{F}_D = \#\mathcal{F} - \#\mathcal{F}_N$ and $n_\mathcal{W} = \#\mathcal{T}$), it follows from (4.18) that the number of functions in (4.15) is $\mathring{n}$, as required. □

REMARK 4.7. *The idea of spanning trees in the context of finite element methods first appears in the context of the Stokes problem in a paper by Hecht* [17]*, where it is used in the same way as here to find a basis for the space of divergence-free nonconforming* $P1$-$P0$ *elements for the approximation of solenoidal vector fields in* $H^1(\Omega)^3$.

In an unpublished manuscript [18]*, Hecht extends these results to a wider family of finite elements in* $H^1(\Omega)^3$*, including the (nonconforming) Raviart–Thomas–Nédélec elements. The published literature on divergence-free Raviart–Thomas–Nédélec elements in* $H(\mathrm{div}, \Omega)$ *considered here is restricted to the pure Neumann case,* $\Gamma_D = \emptyset$*, in a paper by Dubois* [14]*, where he uses it to solve model incompressible flow problems with prescribed vorticity.*

In the context of the three-dimensional problem (1.1), (1.2) *considered in this paper, the only other work which we are aware of is the recent paper* [8]*, but this is restricted to uniform rectangular meshes and a special spanning tree which can be constructed a priori.*

Independently, spanning trees also appear as a technique for computing a discrete gauge condition in eddy-current calculations in computational electromagnetism (e.g., in Albanese and Rubinacci [2] *or Kettunen and Turner* [20]*). A thorough presentation of the theoretical foundation of those techniques using homology theory (related to our Appendix* B) *can be found in Bossavit* [6, Ch. 5].

5. Implementation. To implement the decoupled system (3.3) for determining $\mathring{\boldsymbol{u}}$ (and hence $\boldsymbol{u}$) we must work with the matrix $\mathring{A}$ and the right-hand side $\mathring{\boldsymbol{g}}$ specified in (3.4). We observe that these are formally defined in terms of multiplications with the matrix Z which, through (3.7), represents the basis $\{\vec{\mathring{v}}_i\}$ of $\mathring{\mathcal{V}}$ in terms of the basis $\{\vec{v}_j\}$ of $\mathcal{V}$.

In the specific system (2.4) the $\{\vec{v}_j\}$ are the Raviart–Thomas velocity basis functions $\{\vec{v}_F : F \in \mathcal{F}_I \cup \mathcal{F}_D\}$ given in section 2, whereas the $\{\vec{\mathring{v}}_i\}$ are the basis functions $\{\vec{\Psi}_E : E \in (\mathcal{E}_I \cup \mathcal{E}_D)\backslash\mathcal{H}\}$ specified in Corollary 4.5 (or Theorem 4.2, if $\Gamma_N = \emptyset$). Thus we can identify the columns of Z with the indices $F \in \mathcal{F}_I \cup \mathcal{F}_D$, whereas the rows of Z correspond to $E \in (\mathcal{E}_I \cup \mathcal{E}_D)\backslash\mathcal{H}$.

Using this identification of Z we can rewrite (3.7) as

$$\vec{\Psi}_E = \sum_{F \in \mathcal{F}_I \cup \mathcal{F}_D} Z_{E,F}\, \vec{v}_F, \qquad E \in (\mathcal{E}_I \cup \mathcal{E}_D) \backslash \mathcal{H}. \tag{5.1}$$

Note that the matrix Z is sparse; in fact, $Z_{E,F} \neq 0$ only when edge E is an edge of the face F.

The set $\mathcal{H} \subset \mathcal{E}$ of edges that form a spanning tree in the graph $\mathbf{G} = (\mathcal{N}, \mathcal{E})$ can be found in optimal time (proportional to the number of edges) using Algorithm A.7 presented in Appendix A. The introduction of the special spanning tree for the mixed boundary problem in Corollary 4.5 does not pose an extra problem to our method. We need only to modify Algorithm A.7 slightly: We choose $x_1 \in \mathcal{N}_N$ and at first consider only nodes $y_1 \in \mathcal{N}_N$ in the function "*recursive*(.)" to find a spanning tree $\mathbf{H}_N^\ell$ for each Γ_N^ℓ; then (without resetting the array "*mark*[.]") we call the function "*recursive*($\tilde{x}$)" with argument $\tilde{x} \in \mathcal{N}_I \cup \mathcal{N}_D$ to find the rest of the spanning tree.

With the same convention as above we can write the elements of the matrix M appearing in (2.4) as

$$M_{F,F'} = m(\vec{v}_F, \vec{v}_{F'}), \qquad F, F' \in \mathcal{F}_I \cup \mathcal{F}_D. \tag{5.2}$$

With these observations, it is simple to write $\mathring{A}$ as a sum of element matrices. To be precise, recalling that $\mathcal{T}$ is the set of tetrahedral elements, we can write

$$M = \sum_{T \in \mathcal{T}} M_T, \qquad \text{where } (M_T)_{F,F'} = \int_T K^{-1} \vec{v}_F \cdot \vec{v}_{F'}\, d\vec{x}.$$

Then we can similarly write $\mathring{A}$ as

$$\mathring{A} = \sum_{T \in \mathcal{T}} \mathring{A}_T, \tag{5.3}$$

where $\mathring{A}_T = Z_T M_T Z_T^T$, and Z_T denotes the matrix whose entries equal the entries of Z for columns and rows corresponding to T (i.e., faces $F \subset \overline{T}$ and edges $E \subset \overline{T}$) and are zero elsewhere. The representation (5.3) may be important if iterative methods are being used to solve (3.3). A similar elementwise representation can be given for the computation of $\mathring{\boldsymbol{g}}$ in (3.4).

Alternatively, $\mathring{A}$ can be determined (elementwise or globally) from an approximation of a related bilinear form by Nédélec's edge elements, without the assembly of any Raviart–Thomas stiffness matrix entries, as the following calculation shows.

Introduce the bilinear form

$$a(\vec{\Phi}, \vec{\Phi}') := (K^{-1}\, \vec{\text{curl}}\vec{\Phi}, \vec{\text{curl}}\vec{\Phi}')_{L^2(\Omega)^3} \qquad \text{for all } \vec{\Phi}, \vec{\Phi}' \in H(\vec{\text{curl}}, \Omega), \tag{5.4}$$

and, for $E, E' \in \mathcal{E}$, set

$$\mathcal{A}_{E,E'} := a(\vec{\Phi}_E, \vec{\Phi}_{E'}),$$

where $\{\vec{\Phi}_E\}$ are the basis functions of the piecewise linear Nédélec's edge elements defined in (4.2) and (4.3). Thus (after specifying an ordering of the edges in $\mathcal{E}$), $\mathcal{A}$ is the stiffness matrix corresponding to the bilinear form $a(\cdot, \cdot)$ discretized by Nédélec's edge elements, with a natural boundary condition on all of Γ. Because of the nontrivial kernel of $a(\cdot,\cdot)$, this bilinear form is degenerate and therefore not elliptic on $H(\vec{\text{curl}},\Omega)$. In fact, let $v \in H^1(\Omega)$; then $a(\vec{\nabla}v, \vec{\Phi}') = 0$ for all $\vec{\Phi}' \in H(\vec{\text{curl}},\Omega)$. Consequently, $\mathcal{A}$ is singular.

The following result shows that the minor of this matrix obtained by restricting to $E, E' \in (\mathcal{E}_I \cup \mathcal{E}_D)\backslash\mathcal{H}$, where $\mathcal{H} \subset \mathcal{E}$ as defined in Corollary 4.5, determines the matrix $\mathring{A}$ in (3.3). (This corresponds to imposing an essential boundary condition on Γ_N and restricting to the orthogonal complement of the kernel of $a(\cdot,\cdot)$.)

Theorem 5.1. *Let $\mathcal{H} \subset \mathcal{E}$ as defined in Corollary* 4.5 *(or Theorem* 4.2*, if $\Gamma_N = \emptyset$). Then*

$$\mathring{A}_{E,E'} = \mathcal{A}_{E,E'} \qquad \text{for all } E, E' \in (\mathcal{E}_I \cup \mathcal{E}_D)\backslash\mathcal{H}.$$

Proof. Let $\mathcal{H} \subset \mathcal{E}$ as defined in Corollary 4.5 (or Theorem 4.2, if $\Gamma_N = \emptyset$) and let $E, E' \in (\mathcal{E}_I \cup \mathcal{E}_D)\backslash\mathcal{H}$. Then using the definition (3.4) of $\mathring{A}$ together with (5.2) and (5.1) we get

$$\mathring{A}_{E,E'} = \sum_{F,F' \in \mathcal{F}_I \cup \mathcal{F}_D} Z_{E,F} M_{F,F'} Z_{E',F'} = m\left(\sum_F Z_{E,F}\vec{v}_F, \sum_{F'} Z_{E',F'}\vec{v}_{F'}\right) = m(\vec{\Psi}_E, \vec{\Psi}_{E'}).$$

Now using the definitions of $m(\cdot,\cdot)$ and $\vec{\Psi}_E$, we finally get

$$\begin{aligned}\mathring{A}_{E,E'} &= (K^{-1}\,\vec{\Psi}_E, \vec{\Psi}_{E'})_{L^2(\Omega)^3} = (K^{-1}\,\vec{\text{curl}}\vec{\Phi}_E, \vec{\text{curl}}\vec{\Phi}_{E'})_{L^2(\Omega)^3} \\ &= a(\vec{\Phi}_E, \vec{\Phi}_{E'}) = \mathcal{A}_{E,E'} \qquad \square\end{aligned}$$

Remark 5.2. *Hiptmair and Hoppe* [19] *solve the singular symmetric positive semidefinite system with stiffness matrix $\mathcal{A}$ by multilevel preconditioned CG without explicitly eliminating columns and rows corresponding to edges $E \in \mathcal{H}$. In their multilevel splitting they eliminate the kernel of $a(\cdot,\cdot)$ only approximately by relaxing the orthogonality condition and thus avoid the construction of a basis. Here we eliminate the kernel a priori, which allows us to then apply the CG algorithm with a range of possible preconditioners.*

Remark 5.3. *Observe that the decoupled system* (3.3) *is about three times smaller than the original indefinite system* (2.4)*. More precisely, the dimension of* (3.3) *is smaller than that of* (2.4) *by a factor*

$$C := \frac{\#\mathcal{F}_I + \#\mathcal{F}_D + \#\mathcal{T}}{\#\mathcal{F}_I + \#\mathcal{F}_D - \#\mathcal{T}}\,.$$

Since $4(\#\mathcal{T}) = 2(\#\mathcal{F}_I) + \#\mathcal{F}_D + \#\mathcal{F}_N$ *we have*

$$C = 3\left\{\frac{\#\mathcal{F}_I + \frac{5}{6}(\#\mathcal{F}_D) + \frac{1}{6}(\#\mathcal{F}_N)}{\#\mathcal{F}_I + \frac{3}{2}(\#\mathcal{F}_D) - \frac{1}{2}\#\mathcal{F}_N}\right\}.$$

Under reasonable mesh regularity assumptions $\#\mathcal{F}_I$ is the dominant part of $\#\mathcal{F}$ as $\#\mathcal{T} \to \infty$, and so $C \to 3$ as $\#\mathcal{T} \to \infty$.

6. Pressure computations. In this section we present a procedure for the efficient recovery of the pressure $\boldsymbol{p}$ from the decoupled system (3.6).

In the general situation described in section 3, the assembly of (3.6) requires the computation of a complementary basis $\{\boldsymbol{z}_{\mathring{n}+1}, \ldots, \boldsymbol{z}_{n_\mathcal{V}}\}$ satisfying (3.5). This is again equivalent to finding a complementary basis $\{\vec{v}^c_{\mathring{n}+1}, \ldots, \vec{v}^c_{n_\mathcal{V}}\}$ to $\{\vec{\mathring{v}}_1, \ldots, \vec{\mathring{v}}_{\mathring{n}}\}$ such that

$$\text{span}\left\{\vec{\mathring{v}}_1, \ldots, \vec{\mathring{v}}_{\mathring{n}}, \vec{v}^c_{\mathring{n}+1}, \ldots, \vec{v}^c_{n_\mathcal{V}}\right\} = \mathcal{V}\,. \tag{6.1}$$

In the context of the specific system (2.4) (using lowest-order Raviart–Thomas–Nédélec elements) this can be done by finding a distinguished subset of faces

$$\mathcal{F}^c \subset \mathcal{F}_I \cup \mathcal{F}_D$$

such that the corresponding subset of Raviart–Thomas–Nédélec basis functions, $\{\vec{v}_F : F \in \mathcal{F}^c\}$, constitutes a complementary basis. Note that this set must contain $n_{\mathcal{W}} := n_{\mathcal{V}} - \mathring{n} = \#\mathcal{T}$ elements. The following simple Algorithm 6.1 chooses $n_{\mathcal{W}}$ appropriate faces, yielding a complementary basis, in such a way that the system (3.6) has a particularly simple form. We have already presented this algorithm to find a subset of faces $\mathcal{F}^c \subset \mathcal{F}_I \cup \mathcal{F}_D$ for the two-dimensional case in [12], but here we will give a rigorous proof that the corresponding subset of Raviart–Thomas–Nédélec basis functions, $\{\vec{v}_F : F \in \mathcal{F}^c\}$, constitutes a complementary basis to (4.15) (or to (4.8), if $\Gamma_N = \emptyset$) in $\mathcal{V}$.

Algorithm 6.1.

```
1. Choose $T_1 \in \mathcal{T}$ to be any tetrahedron with a face $F_1 \in \mathcal{F}_D$ and set $\mathcal{F}^c = \{F_1\}$.
2. For $j = 2, \ldots, n_{\mathcal{W}}$,
    • choose $T_j \in \mathcal{T} \backslash \{T_\ell : \ell = 1, \ldots, j-1\}$ with the property that there exists
      $F_j \in \mathcal{F}_I$ such that
      (6.2)    $F_j \subset \overline{T}_j \cap \left\{ \bigcup_{\ell=1}^{j-1} \overline{T}_\ell \right\}$
    • update $\mathcal{F}^c = \mathcal{F}^c \cup \{F_j\}$.
   End of loop over $j$.
3. Assemble $Z'B$ as
      $(Z'B)_{i,j} = b(\vec{v}_{F_i}, w_{T_j}), \qquad i, j = 1, \ldots, n_{\mathcal{W}}$ .
```

Theorem 6.2. *Algorithm* 6.1 *is well defined and the matrix $Z'B$ given in step* 3 *is lower triangular.*

Proof. Since $\Gamma_D \neq \emptyset$, there exists a $T \in \mathcal{T}$ with a face $F \in \mathcal{F}_D$. Let T be T_1. Now, assume we have found $j - 1 < n_{\mathcal{W}} = \#\mathcal{T}$ tetrahedra T_ℓ in step 2 that fulfill property (6.2). Since Ω is connected, there exists a tetrahedron $T \in \mathcal{T}$ that has a face in common with $\bigcup_{\ell=1}^{j-1} \overline{T}_\ell$. Let T be T_j. The existence of a set $\mathcal{F}^c$ therefore follows by an inductive argument.

Second, let $i, j = 1, \ldots, n_{\mathcal{W}}$ with $i < j$. By the algorithm $F_i \subset \overline{T}_i \cap \{\bigcup_{\ell=1}^{i-1} \overline{T}_\ell\}$ and therefore $F_i \not\subset \overline{T}_j$. Since T_j is not in supp $\vec{v}_{F_i}$, it follows that $(Z'B)_{i,j} = b(\vec{v}_{F_i}, w_{T_j}) = 0$, and the matrix $Z'B$ given in step 3 is lower triangular. □

To show that Algorithm 6.1 yields a complementary basis, let us first consider the pure Dirichlet case, $\Gamma_N = \emptyset$.

Theorem 6.3. *Let $\Gamma_N = \emptyset$. The functions*

$$\{\vec{v}_F : F \in \mathcal{F}^c\} \tag{6.3}$$

form a complementary basis to (4.8) *in $\mathcal{V}$.*

Before proving this theorem we will first prove two lemmas again.

Lemma 6.4. *Let $\boldsymbol{\mu} := (\mu_E)_{E \in \mathcal{E}} \in \mathcal{V}(\mathbf{G})$. Then there exist $\{\tilde{\alpha}_F \in \mathbb{Z} : F \in \mathcal{F} \backslash \mathcal{F}^c\}$ such that*

$$\boldsymbol{\mu} := \sum_{F \in \mathcal{F} \backslash \mathcal{F}^c} \tilde{\alpha}_F \boldsymbol{\mu}^F . \tag{6.4}$$

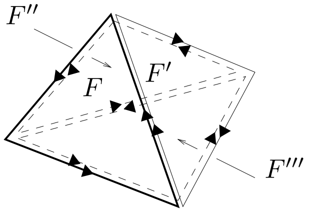
Proof. Let $F \in \mathcal{F}^c$ and let $\boldsymbol{\mu}^F$ be the vector associated with the elementary cycle μ^F formed by the edges E of F in the graph $\mathbf{G} := (\mathcal{N}, \mathcal{E})$. We will first show that there exist $\{\alpha^F_{F'} \in \mathbb{Z} : F' \in \mathcal{F}\backslash\mathcal{F}^c\}$ such that

$$\boldsymbol{\mu}^F = \sum_{F' \in \mathcal{F}\backslash\mathcal{F}^c} \alpha^F_{F'} \boldsymbol{\mu}^{F'}. \tag{6.5}$$

Let $j \in \{1, \dots, n_{\mathcal{W}}\}$ be such that $F = F_j$ in Algorithm 6.1 and let F', F'', and F''' be the other faces of T_j; then there exist $\alpha^F_{F'}, \alpha^F_{F''}, \alpha^F_{F'''} \in \{-1, 1\}$ such that

$$\boldsymbol{\mu}^F = \alpha^F_{F'} \boldsymbol{\mu}^{F'} + \alpha^F_{F''} \boldsymbol{\mu}^{F''} + \alpha^F_{F'''} \boldsymbol{\mu}^{F'''}$$

as depicted below:



If $F', F'', F''' \in \mathcal{F}\backslash\mathcal{F}^c$, the proof of (6.5) is complete. Otherwise assume, without loss of generality, that $F' \in \mathcal{F}^c$. By construction there has to be a $j' \in \{j+1, \dots, n_{\mathcal{W}}\}$ such that $F' = F_{j'}$. Let $\tilde{F}'$, $\tilde{F}''$, and $\tilde{F}'''$ be the other faces of $T_{j'}$. As before, there exist $\alpha^{F'}_{\tilde{F}'}, \alpha^{F'}_{\tilde{F}''}, \alpha^{F'}_{\tilde{F}'''} \in \{-1, 1\}$ such that $\boldsymbol{\mu}^{F'} = \alpha^{F'}_{\tilde{F}'} \boldsymbol{\mu}^{\tilde{F}'} + \alpha^{F'}_{\tilde{F}''} \boldsymbol{\mu}^{\tilde{F}''} + \alpha^{F'}_{\tilde{F}'''} \boldsymbol{\mu}^{\tilde{F}'''}$ and therefore

$$\boldsymbol{\mu}^F = \alpha^F_{F'} (\alpha^{F'}_{\tilde{F}'} \boldsymbol{\mu}^{\tilde{F}'} + \alpha^{F'}_{\tilde{F}''} \boldsymbol{\mu}^{\tilde{F}''} + \alpha^{F'}_{\tilde{F}'''} \boldsymbol{\mu}^{\tilde{F}'''}) + \alpha^F_{F''} \boldsymbol{\mu}^{F''} + \alpha^F_{F'''} \boldsymbol{\mu}^{F'''}.$$

If $F'', F''', \tilde{F}', \tilde{F}'', \tilde{F}''' \in \mathcal{F}\backslash\mathcal{F}^c$, the proof of (6.5) is complete. Otherwise, we can repeat the above procedure for the faces $F'', F''', \tilde{F}', \tilde{F}''$, and $\tilde{F}'''$, and since the set $\{1, \dots, n_{\mathcal{W}}\}$ is finite, the procedure will terminate in a finite number of steps. Altogether, we have established that there exist $\{\alpha^F_{F'} \in \mathbb{Z} : F' \in \mathcal{F}\backslash\mathcal{F}^c\}$ such that (6.5) holds.

Now let $\boldsymbol{\mu} \in \mathcal{V}(\mathbf{G})$. Substituting (6.5) into (4.10), we find that there exist $\{\tilde{\alpha}_F \in \mathbb{Z} : F \in \mathcal{F}\backslash\mathcal{F}^c\}$ such that $\boldsymbol{\mu} = \sum_{F \in \mathcal{F}\backslash\mathcal{F}^c} \tilde{\alpha}_F \boldsymbol{\mu}^F$. □

Lemma 6.5. *Let $\boldsymbol{\mu} \in \mathcal{V}(\mathbf{G})$ and $\{\tilde{\alpha}_F \in \mathbb{Z} : F \in \mathcal{F}\backslash\mathcal{F}^c\}$ be such that $\boldsymbol{\mu} := \sum_{F \in \mathcal{F}\backslash\mathcal{F}^c} \tilde{\alpha}_F \boldsymbol{\mu}^F$. Then*

$$\sum_{F \in \mathcal{F}\backslash\mathcal{F}^c} \tilde{\alpha}_F \int_F \vec{v}_{F'} \cdot \vec{\nu}_F \, dF = 0 \qquad \textit{for all } F' \in \mathcal{F}^c. \tag{6.6}$$

Proof. Let $F' \in \mathcal{F}^c$; then $\vec{v}_{F'} \cdot \vec{\nu}_F = 0$ for all $F \in \mathcal{F}\backslash\mathcal{F}^c$, which implies (6.6). □

We can now prove Theorem 6.3.

Proof. Since $\#\mathcal{F}^c = n_{\mathcal{W}}$, we merely need to show that the union of the sets of functions (6.3) and (4.8) is a linearly independent set. Therefore suppose $\{\beta_{E'} : E' \in \mathcal{E}\backslash\mathcal{H}\}$ and $\{\gamma_F : F \in \mathcal{F}^c\}$ are scalars such that

$$\vec{0} = \sum_{E' \in \mathcal{E}\backslash\mathcal{H}} \beta_{E'} \vec{\Psi}_{E'} + \sum_{F \in \mathcal{F}^c} \gamma_F \vec{v}_F.$$

Let $E \in \mathcal{E}\backslash\mathcal{H}$ and let $\boldsymbol{\mu}^E$ denote the vector associated with the unique cycle μ^E generated by taking edge E into the tree $\mathbf{H} = (\mathcal{N}, \mathcal{H})$, which has the property that $\mu^E_{E'} := \delta_{E,E'}$ for all $E' \in \mathcal{E}\backslash\mathcal{H}$ (cf. Theorem A.6 and the proof to Theorem 4.2). Now, using Lemma 6.4 we can find $\{\tilde{\alpha}_F \in \mathbb{Z} : F \in \mathcal{F}\backslash\mathcal{F}^c\}$ such that $\boldsymbol{\mu} := \sum_{F\in\mathcal{F}\backslash\mathcal{F}^c} \tilde{\alpha}_F \boldsymbol{\mu}^F$, and so by Lemmas 4.4 and 6.5

$$\begin{aligned} 0 &= \sum_{F\in\mathcal{F}\backslash\mathcal{F}^c} \tilde{\alpha}_F \int_F \left(\sum_{E\in\mathcal{E}\backslash\mathcal{H}} \beta_E \,\vec{\Psi}_E + \sum_{F'\in\mathcal{F}^c} \gamma_{F'}\,\vec{v}_{F'} \right) \cdot \vec{\nu}_F \, dF \\ &= \sum_{E'\in\mathcal{E}\backslash\mathcal{H}} \beta_{E'} \sum_{F\in\mathcal{F}\backslash\mathcal{F}^c} \tilde{\alpha}_F \int_F \vec{\Psi}_E \cdot \vec{\nu}_F \, dF \; + \sum_{F'\in\mathcal{F}^c} \gamma_{F'} \sum_{F\in\mathcal{F}\backslash\mathcal{F}^c} \tilde{\alpha}_F \int_F \vec{v}_{F'} \cdot \vec{\nu}_F \, dF \\ &= \sum_{E'\in\mathcal{E}\backslash\mathcal{H}} \beta_{E'} \mu^E_{E'} \;=\; \beta_E \,. \end{aligned}$$

Since the functions $\{\vec{v}_F : F \in \mathcal{F}^c\}$ form a subset of the Raviart–Thomas–Nédélec basis functions, they have to be linearly independent. Therefore we also have $\gamma_F = 0$, for all $F \in \mathcal{F}^c$, which establishes the linear independence of the functions in (6.3) and (4.8). □

COROLLARY 6.6. *Let* $n_{\mathcal{C}} \neq 0$ *and let* Γ^ℓ_N *be simply connected for each* $\ell = 1, \dots, n_{\mathcal{C}}$. *The functions*

$$\{\vec{v}_F : F \in \mathcal{F}^c\} \tag{6.7}$$

form a complementary basis to (4.15) *in* $\mathcal{V}$.

Proof. Since $\#\mathcal{F}^c = n_{\mathcal{W}}$, the result follows directly from Corollary 4.5 and Theorem 6.3. □

Using this complementary basis (6.7) and applying the general theory presented in section 3, we can therefore find the unique solution $\boldsymbol{p}$ from (3.6) by simple *back substitutions.*

The matrix $Z'B$ is obtained from the original matrix B in (2.4) by deleting some rows and reordering the rows and columns. Equivalently, the right-hand side $Z'(\boldsymbol{g} - M\boldsymbol{u})$ of (3.6) is obtained from $\boldsymbol{g} - M\boldsymbol{u}$ by deleting some rows and reordering the rows.

7. Numerical results.

In this section we want to demonstrate the performance of the proposed method in two very simple test cases. Let Ω be the unit cube $(0,1)^3$. We will consider only the constant coefficient case $K \equiv 1$, of system (1.1), (1.2), with zero right-hand side $\vec{g} = \vec{0}$. The two experiments are induced by different choices of boundary conditions. In Figure 2 we illustrate the Neumann boundary Γ_N in each case.

In the *first experiment* (Figure 2 (left)) we choose

$$\begin{aligned} p_D(x,y,z) &= 1 - x \qquad &&\text{on} \quad \Gamma_D = \{0,1\}\times(0,1)\times(0,1) \;\cup\; [0,1]\times(0,1)\times\{1\}, \\ \vec{u}\cdot\vec{\nu} &= 0 &&\text{on} \quad \Gamma_N = \Gamma\backslash\Gamma_D, \end{aligned}$$

where $\vec{\nu}(\vec{x})$ denotes the outward unit normal from Ω at $\vec{x} \in \Gamma$ as before.

In the *second experiment* (Figure 2 (right)) we choose

$$\begin{aligned} p_D(x,y,z) &= 1 - x \qquad &&\text{on} \quad \Gamma_D = (0,1)\times(0,1)\times\{1\}, \\ \vec{u}\cdot\vec{\nu} &= 0 &&\text{on} \quad \Gamma_N = \Gamma\backslash\Gamma_D. \end{aligned}$$

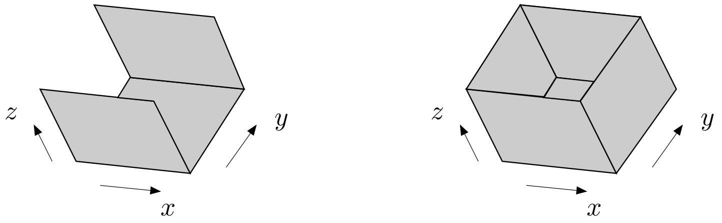


Fig. 2. *The "no-flux" boundary* Γ_N *for Experiments* 1 *and* 2*, respectively.*

We discretize these problems using the mixed finite element discretization (2.3) with lowest-order Raviart–Thomas–Nédélec elements on a sequence of uniform and nonuniform meshes of different refinement levels L. The uniform mesh is constructed from a uniform rectangular mesh of $L * L * L$ cubes which are each subdivided themselves into six tetrahedra. The nonuniform mesh is constructed from a nonuniform hexahedral mesh of $L * L * L$ hexahedra which are each subdivided themselves into 24 tetrahedra.

To solve the resulting saddle-point system (2.4) we use the decoupled iterative method described above: The construction of the matrix $\mathring{A}$ in the decoupled velocity system (3.3) is carried out in an elementwise fashion as presented in (5.3); the resulting symmetric positive definite system (3.3) is solved with ILU(0)-preconditioned conjugate gradients (PCG); the matrix $Z'B$ in the decoupled pressure system (3.6) is obtained from the original matrix B in (2.4) by deleting some rows and reordering the rows and columns (as mentioned at the end of section 6); the resulting triangular system (3.6) is solved by simple back substitutions. The convergence criterion in the PCG method is the relative reduction of the residual by a factor of 10^{-5}.

Tables 1 and 2 show the performance of our method for Experiments 1 and 2, respectively. First of all we observe in both cases the reduction in size from the full mixed system (2.4) to the decoupled velocity system (3.3). (Compare rows 3 and 4 in Tables 1 and 2.) It is approximately 3 as claimed in Remark 5.3.

Second, let us look at the number of *floating point operations* (Flops) needed in the decoupling process (row 7). This process is asymptotically optimal (# Flops $= O($# Freedoms$)$), since the matrix $\mathring{A}$ and the right-hand side in (3.3) are constructed in an elementwise fashion and since the matrix $Z'B$ and the right-hand side in (3.6) are obtained from the original system (2.4) by simple reordering. While this decoupling process is still the dominant part in the total Flop count (row 9) on very small problems (e.g., column 2), its effect gets less important and will eventually vanish for larger problems (e.g., columns 5 and 8).

The core part of the calculation is the solution of the decoupled velocity system (3.3). In the uniform mesh case (columns 2–5) the condition number of $\mathring{A}$ (row 5) grows as expected with $O(\mathring{n}^{2/3})$, where $\mathring{n}$ is the dimension of $\mathring{A}$ (row 4). The growth in the nonuniform mesh case (columns 6–8) is (naturally) slightly worse. This growth of the condition number is reflected in the iteration and Flop count for the PCG method to solve (3.3). The number of iterations (row 6) grows with the square root of the condition number of $\mathring{A}$; in the uniform mesh case (columns 2–5) this is a factor of about 2 from one refinement level to the next.

Remark 7.1. *Although the effect of the ILU(0) preconditioner deteriorates as the grid size decreases, it is extremely cheap to invert and remains a cost effective way of preconditioning this system. Diagonal scaling, for example, leads to a similar*

Table 1
Performance of the decoupled iterative method for Experiment 1.

	Uniform mesh				Nonuniform mesh		
Refinement level L	2	4	8	16	2	4	8
Freedoms (full mixed)	144	1152	9216	73728	576	4608	36864
Freedoms (decoupled)	48	384	3072	24576	192	1536	12288

asymptotic behavior but is more expensive in terms of iterations as well as Flops. For Experiment 1 *the number of iterations using diagonal scaling as the preconditioner in the PCG method in the uniform mesh case is* 38*,* 109*,* 245*, and* 494 *for* $L = 2, 4, 8,$ *and* 16*, respectively. The number of MFlops is* 0.086*,* 1.73*,* 29.7*, and* 47*. Future work will involve a more detailed investigation of various preconditioners like algebraic multigrid (AMG).*

Finally, let us look at the solution of the decoupled pressure system (3.6). Since the matrix $Z'B$ in (3.6) is triangular (as shown in Theorem 6.2) it can be solved in an asymptotically optimal number of operations by simple back substitutions. Therefore this part of the calculation does not affect the overall cost of the method significantly. The number of Flops is included in the total Flop count (row 9) reported in Tables 1 and 2, and it accounts for less than 1% of the total cost of the method for larger problems (e.g., columns 5 and 8).

In Tables 3 and 4 we compare the performance of our method with the performance of a preconditioned MINRES method for the original (full mixed) saddle-point system (2.4) for Experiments 1 and 2, respectively. The convergence criterion for MINRES is again the relative reduction of the residual by a factor of 10^{-5}. To precondition this MINRES method we take an optimal symmetric positive definite block diagonal preconditioner presented and analyzed in Rusten and Winther [26] (using an ILU(0) factorization of B^TB for the pressure block).

Remark 7.2. *As for the decoupled system it would be possible to employ other, more efficient preconditioners like AMG for the pressure block. However, in order to evaluate the performance of the decoupling procedure, our prime incentive, we wanted to compare "similar" iterative methods for the full mixed and the decoupled system.*

Comparing columns 6 and 7 in Table 3 we observe that for the first experiment our decoupled method is about 4.5 times faster than preconditioned MINRES on the uniform meshes (rows 3–6), and about 6 times faster on the nonuniform meshes

Table 3
Comparison of the decoupled iterative method with a full mixed method [26] *for Experiment* 1.

		Freedoms		Iterations		MFlops	
Mesh	L	Mixed	Decoupled	Mixed	Decoupled	Mixed	Decoupled
Uniform	2	144	48	37	14	0.29	0.065
	4	1152	384	56	26	3.8	0.89
	8	9216	3072	89	45	49	11
	16	73728	24576	175	97	790	169
Nonuniform	2	576	192	100	33	3.4	0.53
	4	4608	1536	204	90	57	9.6
	8	36864	12288	456	232	1030	185

Table 4
Comparison of the decoupled iterative method with a full mixed method [26] *for Experiment* 2.

		# Freedoms		Iterations		MFlops	
Mesh	L	Mixed	Decoupled	Mixed	Decoupled	Mixed	Decoupled
Uniform	2	128	32	37	9	0.25	0.038
	4	1088	320	57	18	3.6	0.62
	8	8960	2816	109	35	59	8.7
	16	72704	23552	217	75	960	132
Nonuniform	2	544	160	110	24	3.5	0.35
	4	4480	1408	254	80	68	8.0
	8	36352	11776	582	187	1300	145

(rows 7–9). The advantage of our method over preconditioned MINRES is even more impressive for the second experiment (columns 6 and 7 in Table 4). On the uniform meshes (rows 3–6) it is about 7 times faster, on the nonuniform meshes (rows 7–9) about 9 times faster.

In conclusion we have found a very competitive and practicable iterative method to solve saddle-point problems of the form (2.4). The decoupling procedure and the recovery of the pressure are asymptotically optimal. The decoupled velocity system, on the other hand, is symmetric positive definite and of second order, and there may still be room for improvement in solving this system by employing the more sophisticated preconditioning techniques which are available for such problems.

Appendix A. Some results from graph theory.

Definition A.1 (Berge [5]).

(a) *A* graph *(or more precisely a* 1-graph*)* $\mathbf{G}$ *is defined to be a pair* $(\mathcal{X},\mathcal{U})$*, where* $\mathcal{X}$ *is a set* $\{x_1, x_2, \dots, x_n\}$ *of elements called* vertices *(or nodes), and* $\mathcal{U}$ *is a subset* $\{u_1, u_2, \dots, u_m\}$ *of* $\mathcal{X} \times \mathcal{X}$ *of elements called* arcs *(or* orientated edges*). For an arc* $u = (x, y) \in \mathcal{X} \times \mathcal{X}$*, the vertex* x *is called its* initial endpoint*, and the vertex* y *is called its* terminal endpoint*. A vertex* $y \in \mathcal{X}$ *is called a* neighbor *of* $x \in \mathcal{X}$ *if either* $(x, y) \in \mathcal{U}$ *or* $(y, x) \in \mathcal{U}$*. The set of all neighbors of a vertex* x *in the graph* $\mathbf{G}$ *will be denoted by* $\Gamma_{\mathbf{G}}(x)$*.*

(b) *A* partial graph *of a graph* $\mathbf{G} = (\mathcal{X},\mathcal{U})$ *is a graph* $\mathbf{H} = (\mathcal{X}, \mathcal{V})$ *with* $\mathcal{V} \subset \mathcal{U}$*.*

(c) *A* chain *is a sequence* $\mu = (u_{i_1}, u_{i_2}, \dots, u_{i_q})$ *of arcs of a graph* $\mathbf{G}$ *such that each arc in the sequence has one endpoint in common with its predecessor and its other endpoint in common with its successor. A chain that does not encounter the same vertex twice is called* elementary*. A chain that does not use the same arc twice is called* simple*.*

(d) *For two vertices x and y of a graph* $\mathbf{G}$ *let us define the equivalence relation* $x \equiv y$ *by*

$$[x = y, \text{ or } x \neq y \text{ and there exists a chain in } \mathbf{G} \text{ connecting } x \text{ and } y].$$

The equivalence classes of $\equiv$ *are called the* connected components *of* $\mathbf{G}$. *A* connected graph *is a graph that consists only of one connected component.*

(e) *A* cycle *is a simple chain whose terminal endpoint coincides with its initial endpoint. Let m be the number of arcs in* $\mathbf{G}$. *With each cycle μ of* $\mathbf{G}$ *we can associate a vector* $\boldsymbol{\mu} \in \mathbb{Z}^m$ *with*

$$\mu_i = \begin{cases} 0 & \text{if } u_i \text{ is not in } \mu, \\ 1 & \text{if } u_i \text{ is in } \mu \text{ and shares initial endpoint with its predecessor}, \\ -1 & \text{if } u_i \text{ is in } \mu \text{ and shares terminal endpoint with its predecessor}. \end{cases}$$

The set of all those vectors $\boldsymbol{\mu} \in \mathbb{Z}^m$ *generates a vector space over* $\mathbb{Z}$. *We denote this vector space by* $\mathcal{V}(\mathbf{G})$.

(f) *A* forest *is defined to be a graph without cycles. A* tree *is defined to be a connected graph without cycles.*

Theorem A.2. *Let* $\mathbf{G}$ *be a graph with n vertices, m arcs, and p connected components. The dimension of* $\mathcal{V}(\mathbf{G})$ *is* $m - n + p$.

Proof. The proof is seen in Berge [5, p. 16]. □

Theorem A.3. *Let* $\mathbf{H} = (\mathcal{X}, \mathcal{U})$ *be a graph with* $n > 2$ *vertices. The following properties are equivalent and each characterizes a tree:*

(i) $\mathbf{H}$ *is connected and has no cycles.*

(ii) $\mathbf{H}$ *has* $n - 1$ *arcs and has no cycles.*

(iii) $\mathbf{H}$ *is connected and contains* $n - 1$ *arcs.*

(iv) $\mathbf{H}$ *has no cycles and adding an arc creates a unique cycle.*

(v) $\mathbf{H}$ *is connected and removing an arc leaves the remaining graph disconnected.*

(vi) *Every pair of vertices* x, y *of* $\mathbf{H}$ *is connected by a unique chain.*

Proof. The proof is seen in Berge [5, p. 24]. □

Theorem A.4. *Let* $\mathbf{G} = (\mathcal{X}, \mathcal{U})$ *be a connected graph. There exists a partial graph* $\mathbf{H} = (\mathcal{X}, \mathcal{V})$ *such that* $\mathbf{H}$ *is a tree.*

Proof. The proof is seen in Berge [5, p. 25]. □

The tree $\mathbf{H}$ obtained from $\mathbf{G}$ as above is called a *spanning tree.* An optimal algorithm to find a spanning tree $\mathbf{H}$ of a connected graph $\mathbf{G}$ is presented in Algorithm A.7.

Theorem A.5. *Let* $\mathbf{G}$ *be a graph with n vertices and* $m \geq n$ *arcs. The time spent on Algorithm* A.7 *is proportional to the number of arcs, i.e.,* $O(m)$.

Proof. The proof is seen in Aho, Hopcroft, and Ullman [1]. □

Theorem A.6. *Let* $\mathbf{G} = (\mathcal{X}, \mathcal{U})$ *be a connected graph with n vertices and m arcs, let* $\mathbf{H} = (\mathcal{X}, \mathcal{V})$ *be a spanning tree of* $\mathbf{G}$, *and let* $u_i \in \mathcal{U}$ *be an arc of* $\mathbf{G}$ *not in tree* $\mathbf{H}$, *i.e.,* $u_i \notin \mathcal{V}$. *Adding* u_i *to* $\mathbf{H}$ *creates a unique cycle* μ^i, *and its associated vector* $\boldsymbol{\mu}^i$ *satisfies* $\mu^i_i = 1$. *The set* $\{\boldsymbol{\mu}^i : u_i \in \mathcal{U} \backslash \mathcal{V}\}$ *forms a basis of* $\mathcal{V}(\mathbf{G})$.

Proof. The existence of $\boldsymbol{\mu}^i$ for all $u_i \in \mathcal{U} \backslash \mathcal{V}$ is guaranteed by virtue of Theorem A.3(iv). The vectors are linearly independent, since $\mu^j_i = \delta_{i,j}$, for all $u_i, u_j \in \mathcal{U} \backslash \mathcal{V}$. Moreover,

$$\dim\{\boldsymbol{\mu}^i : u_i \in \mathcal{U} \backslash \mathcal{V}\} = \#\mathcal{U} - \#\mathcal{V} = m - (n - 1) = \dim \mathcal{V}(\mathbf{G}),$$

where in the last step we used Theorem A.2 with $p = 1$. □

Algorithm A.7.

```
variables
    n – number of vertices;
    mark[1:n] – array of flags;
begin
    $\mathcal{V} = \emptyset$;
    for i := 1 to n do mark[$x_i$] := unvisited;
    recursive($x_1$);
end;

procedure recursive( x – vertex );
    variables
        y – vertex;
    begin
        mark[x] := visited;
        for each vertex $y \in \Gamma_{\mathbf{G}}(x)$ do
            if mark[y] = unvisited then
                $\mathcal{V} = \mathcal{V} \cup \{u\}$  – where $u \in \mathcal{U}$ with endpoints x and y;
                recursive(y);
    end;
```

Appendix B. A topological result on simplicial triangulations.

Definition B.1 (the fundamental group (Armstrong [3, Ch. 5])).

(a) *A* topological space *is a set S together with a collection $\mathcal{U}$ of subsets of S satisfying the following conditions:*

(1) $\emptyset \in \mathcal{U}$, $S \in \mathcal{U}$.

(2) *If* $U_1, \dots, U_n \in \mathcal{U}$, *then* $\bigcap_{i=1}^{n} U_i \in \mathcal{U}$.

(3) *If* $\tilde{\mathcal{U}} \subset \mathcal{U}$, *then* $\bigcup_{U \in \tilde{\mathcal{U}}} U \in \mathcal{U}$.

The elements of $\mathcal{U}$ are called open sets *in S. $\mathcal{U}$ is called a* topology *on S.*

(b) *Let X be a topological space. A* path *in X from x_0 to x_1 (with origin x_0 and end x_1) is a continuous map $\alpha : [0,1] \to X$ such that $\alpha(0) = x_0$ and $\alpha(1) = x_1$. Let α be a path in X from x_0 to x_1 and let β be a path in X from x_1 to x_2. The* product *of α and β is the path $\alpha\beta$ from x_0 to x_2 defined by*

$$\alpha\beta(t) = \begin{cases} \alpha(2t) & \text{for } t \in [0, 1/2], \\ \beta(2t-1) & \text{for } t \in [1/2, 1]. \end{cases}$$

The inverse *of α is the path α^{-1} from x_1 to x_0 defined by $\alpha^{-1}(t) = \alpha(1-t)$.*

(c) *Two paths α and β from x_0 to x_1 are* homotopic *(written $\alpha \simeq \beta$) if there exists a continuous map $F : [0,1] \times [0,1] \to X$ such that*

$$\begin{array}{llll} F(0,t) = x_0 & \text{and} & F(1,t) = x_1 & \text{for all } t \in [0,1], \\ F(s,0) = \alpha(s) & \text{and} & F(s,1) = \beta(s) & \text{for all } s \in [0,1]. \end{array}$$

(d) *Let X be a topological space and let $x_0 \in X$. The set of $\simeq$ equivalence classes of paths with origin x_0 and end x_0 forms a group under the operations of multiplication and inverse as defined above. This group is denoted $\pi_1(X, x_0)$ and is called the* fundamental group *of the pair (X, x_0). X is called* simply connected *if its fundamental group is trivial.*

DEFINITION B.2 (the first homology group (Armstrong [3, Ch. 8])).

(a) *Let V be a vector space over $\mathbb{R}$ and let $\{v_0, v_1, \ldots, v_k\} \subset V$ such that the set $\{v_1 - v_0, \ldots, v_k - v_0\}$ is linearly independent. The smallest convex set containing $\{v_0, v_1, \ldots, v_k\}$, i.e., the convex hull*

$$\left\{ v := \sum_{i=0}^{k} \lambda_i v_i : \lambda_i \geq 0 \text{ and } \sum_{i=0}^{k} \lambda_i = 1 \right\},$$

is called a simplex of dimension k *(or a k-*simplex*). The points $v_0, v_1, \ldots, v_k$ are called the* vertices *(or nodes) of the simplex. The simplices formed by the subsets of $\{v_0, v_1, \ldots, v_k\}$ are called the* faces *of the simplex.*

(b) *A* simplicial complex *K is a finite set of simplices in V such that*
  (1) *if $A \in K$, then the faces of A are also in K;*
  (2) *if $A, B \in K$ and $A \cap B \neq \emptyset$, then $A \cap B \in K$.*

The dimension *of K is the maximum dimension of the simplices of K. The point set union of all simplices in K is denoted by $|K|$.*

(c) *Let K be a simplicial complex. An* orientated edge *in K is an ordered pair (u, v) such that u and v lie in some simplex of K. An* orientated triangle *in K is an ordered triple (u, v, w) such that u, v, w lie in some simplex of K. Note that $(u, v, w) = (v, w, u) = (w, u, v)$. A change of orientation is denoted by a minus sign, thus $(v, u) = -(u, v)$ and $(v, u, w) = -(u, v, w)$. The* boundary *of the orientated edge (u, v) is defined to be*

$$\partial(u, v) = v - u.$$

The boundary of the orientated triangle (u, v, w) is

$$\partial(u, v, w) = (v, w) + (w, u) + (u, v).$$

Let n be the number of all edges in K. A linear combination of orientated edges

$$\sum_{i=1}^{n} \lambda_i (u_i, v_i) \quad \textit{with the property that} \quad \sum_{i=1}^{n} \lambda_i \partial(u_i, v_i) = 0$$

and $\lambda_i \in \mathbb{Z}$ for all $i = 1, \ldots, n$ is called a (one-dimensional) cycle *of K. A cycle β is called a* bounding cycle *if we can find a linear combination*

$$\sum_{j=1}^{k} \alpha_j (u_j, v_j, w_j)$$

of orientated triangles in K such that

$$\beta = \sum_{j=1}^{k} \alpha_j \partial(u_j, v_j, w_j).$$

(d) *The set of all cycles of K forms an abelian group under the addition*

$$\sum_{i=1}^{n} \lambda_i (u_i, v_i) + \sum_{i=1}^{n} \mu_i (u_i, v_i) = \sum_{i=1}^{n} (\lambda_i + \mu_i)(u_i, v_i).$$

We denote this group by $Z_1(K)$. The bounding cycles form a subgroup $B_1(K)$ of $Z_1(K)$. The quotient group

$$H_1(K) = Z_1(K)\backslash B_1(K)$$

is called the first homology group *of K.*

We will need only the following fundamental theorem which is a corollary to the simplicial approximation theorem (Armstrong [3, p. 128]).

THEOREM B.3. *Let K be a simplicial complex and let v be a vertex of K. If $|K|$ is connected, abelianizing $\pi_1(|K|, v)$ gives the first homology group $H_1(K)$.*

Proof. The proof is seen in Armstrong [3, p. 182]. □

COROLLARY B.4. *If $|K|$ is simply connected, then each cycle of K is a bounding cycle.*

Proof. From Definition B.1(d) we know that if $|K|$ is simply connected, then $\pi_1(|K|, v)$ is trivial for any vertex v of K. As a consequence of Theorem B.3 this also implies that $H_1(K)$ is trivial (since abelianizing the trivial group has to result in the trivial group again). Therefore $B_1(K) = Z_1(K)$. □

Acknowledgment. I would like to thank Professor Thomas Russell for kindly sending me a copy of Hecht's unpublished manuscript [18] and particularly thank Professor Ivan Graham and Professor Andrew Swann for useful discussions and comments.

ADAPTIVE ERROR CONTROL FOR STEADY STATE SOLUTIONS OF INVISCID FLOW*

LARS FERM† AND PER LÖTSTEDT†

Abstract. The steady state solution of the Euler equations of inviscid flow is computed by an adaptive method. The grid is structured and is refined and coarsened in predefined blocks. The equations are discretized by a finite volume method. Error equations, satisfied by the solution errors, are derived with the discretization error as the driving right-hand side. An algorithm based on the error equations is developed for errors propagated along streamlines. Numerical examples from two-dimensional compressible and incompressible flow illustrate the method.

Key words. finite volume method, discretization error, error control, error equation, Euler equations

1. Introduction.

Inadequate grid resolution is the most important contributor to inaccuracy in computational fluid dynamics (CFD) calculations [31]. This is a serious obstacle in the industrial use of CFD methods. Grid refinement studies reveal the sensitivity of the solution to the grid spacing. Such studies are expensive and time-consuming to make for an applications engineer, and usually only one grid is generated based on his or her experience. There is a need for solution-adaptive methods.

The errors in the numerical solution of the partial differential equations (PDEs) governing inviscid flow can be controlled by an adaptive method. By changing the grid spacing so that the solution errors fulfill given tolerances, the quality of the solution is guaranteed. Furthermore, computational work and memory is saved since the grid is not made unnecessarily fine. Two important ingredients in an adaptive algorithm are a way of estimating the solution error and a data structure for the grid that allows for modifications of the original grid. We combine computing the solution errors from the error equations with estimated discretization errors as source terms with refinement and coarsening in predetermined blocks of the grid.

The equations are discretized by finite volume methods in this paper. They are of second order on Cartesian grids. The refinement and the coarsening of the grid is determined by estimates of the solution error. Grid adaptation is necessary not only at discontinuities in the solution but also in the smooth parts. Differential equations are derived which are satisfied approximately by the errors. The right-hand side of the error equations is the discretization error in the finite volume method. This error is estimated by comparing the space discretization on two different grids. Then the error equations are solved numerically for the error in the solution. For certain variables, these equations are particularly simple and the error is propagated along the streamlines of the flow. An algorithm is devised for such errors. It is relatively easily implemented in existing codes and takes the sign of the error into account when the grid is adjusted so that a tolerance on the maximum error is fulfilled. The

discretization error generated at a point may propagate and influence the solution error far downstream. The large error in the solution in a cell is not necessarily caused by too coarse a grid there.

In [3], [4], [5], [30], [33], [40] the discretization or truncation error is estimated by comparing the discretization on different grids as in Richardson extrapolation. The adaptivity is based on the discretization error, but there is no direct control of the error in the solution. The error equations are solved in one-dimensional (1D) examples in [43] and the solution is computed on adapted grids based on error estimates. Three different ways of assessing the solution error are compared in [25]. The error is computed by comparing the solutions on different grids, by comparing the solution with a higher-order reconstruction, and by solving the error equations. Three other techniques are compared in [34]. The estimation of a local discretization error is the standard procedure in the time step regulation of the numerical solution of ordinary differential equations (ODEs) [23], [39].

Bounds on the errors in finite element methods are computed a posteriori using the solution to the adjoint problem in [17]. Then another linear system of differential equations has to be solved for the adjoint solution. The adjoint equation is solved for 1D problems in [41] and is used in an adaptive procedure to control the error in a finite volume discretization of the Euler equations. While a full control of the solution errors is offered by the adjoint solution, it is an expensive method in terms of computing time and storage, e.g., for time-dependent problems in three dimensions, and may not always be worth the effort. The idea in the numerical solution of ODEs controlling only the discretization error is probably a satisfactory procedure also for many PDEs. A general discussion of numerical errors and their estimation in CFD is found in [38].

Another possibility is to base the refinement on sensors such as pressure gradients or vorticity; see, e.g., [9], [12], [13], [35]. This approach yields good results in practice, but it is difficult to relate the sensor values to quantitative information on the solution errors. Wavelets are used in [21] to detect sharp features in the solution.

The computational domain is partitioned into a fixed number of blocks. The grid in each block is structured and all cells in a block are refined or coarsened following the error estimate. The data structure is simple since the neighbors of a block are the same in the original grid and all the adapted grids. Inside a block the organization of the data is also simple since the size of all cells in a block are changed when the grid there is refined or coarsened as in [18] and [29]. There will be jumps in the grid size only at the block boundaries, and interpolation is needed for the cell variables at the boundary. The interpolation of the variables at block boundaries is such that second-order accuracy is preserved in the cells adjacent to the boundary. Although we use structured grids the principles are applicable also to unstructured grids and hybrid grids with a mixture of blocks with structured and unstructured grids. Block partitioning is also suitable for parallelization of a code. Each processor solves the equations in a subset of the blocks with communication limited to the boundaries of blocks with a neighbor in another subset.

The flow equations are solved on structured grids with patches of refinement in [3], [4], [5], [12], [33], [40]. The refined parts follow the grid lines but can be positioned arbitrarily in the domain. The data structure is more complicated than ours but has greater flexibility since the patches can surround the points where refinement is needed with fewer extra cells. Parallel implementations are found in [14], [42]. Other equations related to the flow equations are solved with similar techniques and adaptivity in [10], [24], [36]. Individual cells are split for refinement in [13], [35]. The parental and adjacent cells are kept track of by a tree data structure. The idea here is the same for both structured and unstructured grids (cf. [9] and [35]). The price to be paid for the possibility of introducing cells precisely where they are needed is the administration of the advanced data structure and the indirect addressing of the data. For structured grids it is also complicated to obtain second-order accuracy in the discretization. Instead of introducing more cells, the grid points in one dimension are moved in [6] and [27] and the grid lines are moved in two dimensions in [28] to adapt the original grid. The advantage is that the available cells are clustered in areas where high resolution is required and fewer cells are used in smooth areas. A disadvantage is the distortion of the grid which may be severe in three dimensions around complicated geometries. Moreover, instabilities with moving grid algorithms are discussed in [27] and there is no guarantee that spurious solutions do not appear [6].

In the next section, the errors in finite volume methods are investigated and the estimate of the discretization error is justified. The error equations for compressible and incompressible inviscid flow problems are derived in section 3 from the results in section 2. The equations are particularly simple for the total pressure in incompressible flow and the entropy and the enthalpy in compressible flow. The adaptation algorithm is found in section 4. Finally, numerical solutions of the incompressible flow around a half-cylinder and compressible flow around an airfoil at transonic and subsonic speeds are computed with the algorithm.

2. Numerical errors in finite volume methods.

The PDE

$$\frac{\partial u}{\partial t} + \nabla \cdot \mathcal{F}(u) = 0, \qquad L(u) = 0 \text{ on } \partial\Omega, \quad u = u_0 \text{ at } t = 0, \tag{1}$$

with the flux vector $\mathcal{F}$ is discretized on $\Omega \times [0, t_{end}]$ by the finite volume method (FVM) in space and a linear multistep method or a Runge–Kutta method in time. The domain Ω with boundary $\partial\Omega$ is covered by m cells ω_j with a normal $\hat{n}$, boundary $\partial\omega$, and volume or area A_j. This section is devoted to the analysis of the solution errors in the discrete approximation of (1). The adaptive algorithm is developed only for steady state problems in this paper, but we include a short discussion of temporal errors in this section and the next for completeness. Adaptive methods in space and time are developed in a separate paper [29].

2.1. Space discretization.

Integrate (1) over ω_j and use Gauss's theorem to obtain

$$\int_{\omega_j} u_t d\omega + \int_{\partial\omega_j} \mathcal{F}(u) \cdot \hat{n} ds = 0.$$

In what follows, a coordinate as a subscript of a variable denotes differentiation with respect to that coordinate. Let $\bar{u}_j$ be the average of u in cell j and let G be defined by

$$G_j(u) = \bar{u}_{jt} + A_j^{-1} \int_{\partial\omega_j} \mathcal{F}(u) \cdot \hat{n} ds = \bar{u}_{jt} + F_j(u). \tag{2}$$

The solution u of (1) satisfies

$$G(u) = 0. \tag{3}$$

At time t_n, $\bar{u}_j$ is approximated by the numerical solution $\bar{v}_j^n$. By reconstruction from $\bar{v}_j^n$ (see, e.g., [1], [7]), v_j^n is created in Ω such that $v_j^n \in C^q(\Omega)$, $q \geq 0$, and

$$\bar{v}_j^n = A_j^{-1} \int_{\omega_j} v^n d\omega.$$

Let $\Psi_j^i(v)$ be the discrete flux in cell j on edge i, l be the number of edges, and $\hat{n}_i$ be the normal on edge i. Then the discretization of the integral in (2) is

$$\Phi_j(\bar{v}) = A_j^{-1} \sum_{i=1}^{l} \Psi_j^i(v) \cdot \hat{n}_i. \tag{4}$$

The discretization of the boundary condition on $\partial\Omega$ in (1) is

$$\Lambda_i(\bar{v}) = 0, \quad i = 1 : m_b, \tag{5}$$

at m_b boundary cells. Since the numerical scheme may need more boundary conditions than the analytical solution, $\Lambda(u)$ is usually not a direct approximation of $L(u)$.

2.2. Time discretization. Let us choose a linear multistep method, defined by its coefficients $\alpha_i, \beta_i, i = 0 : k$ (see [23]), for the approximation of (2) in time. Let Δt be the time step from t_{n-1} to t_n and introduce

$$\Gamma_\ell(\bar{v}^n) = \Delta t^{-1} \sum_{i=0}^{k} \alpha_i \bar{v}_\ell^{n-i} + \sum_{i=0}^{k} \beta_i \Phi_\ell(\bar{v}^{n-i}). \tag{6}$$

Then $\bar{v}^n$ satisfies

$$\Gamma(\bar{v}^n) = 0. \tag{7}$$

An explicit Runge–Kutta method with s stages is defined by the coefficients a_{ij}, $i = 2 : s$, $j = 1 : i - 1$, and b_i, $i = 1 : s$ (see [23]). In this case we have

$$\begin{aligned} k_1 &= \Phi_\ell(\bar{v}^{n-1}), \\ k_i &= \Phi_\ell(\bar{v}^{n-1} + \Delta t \textstyle\sum_{j=1}^{i-1} a_{ij} k_j), \quad i = 2 : s, \\ \Gamma_\ell(\bar{v}^n) &= \Delta t^{-1}(\bar{v}_\ell^n - \bar{v}_\ell^{n-1}) + \textstyle\sum_{i=1}^{s} b_i k_i. \end{aligned} \tag{8}$$

Also here $\bar{v}^n$ satisfies (7).

2.3. The error equation. As a measure of how well Γ_j approximates G_j in Ω take

$$\tau_j(w) = G_j(w) - \Gamma_j(\bar{w}) \tag{9}$$

for $w \in C^q$. If u is the solution of (3), then the truncation error of Γ_j is

$$\Gamma_j(\bar{u}) = -\tau_j(u). \tag{10}$$

In finite element analysis (see [17]), the finite element method solution v is inserted into the differential equation G to compute the *residual* $r(v) = G(v)$ used in the error control. Here, we have the reconstruction v from the average solution satisfying $\tau(v) = G(v)$ since $\Gamma(\bar{v}) = 0$ in (9). The numerical error δv^n in v^n satisfying (7) is

$$\delta v^n = v^n - u(t_n),$$

where $u(t_n)$ solves (3) at t_n. We have from (9) and (3)

$$G_j(u(t_n) + \delta v^n) - G_j(u(t_n)) = \tau_j(v^n), \quad j = 1 : m. \tag{11}$$

The coefficients of the linearized error equation and the right-hand side are evaluated at the numerical solution.

Since the numerical solution often needs more boundary conditions than the analytical solution, L is extended to $\tilde{L}$ on $\partial\Omega$ so that

$$\chi_i(w) = \tilde{L}_i(w) - \Lambda_i(\bar{w}). \tag{12}$$

Here, χ measures the discretization error in the boundary conditions. Consequently,

$$\tilde{L}_i(u(t_n) + \delta v^n) = \chi_i(v^n), \tag{13}$$

which is the boundary condition of δv^n on $\partial\Omega$. The initial condition is assumed to be exact.

We have derived an error equation for δv^n with accompanying boundary condition. The average error in a cell is

$$\delta \bar{v}_j^n = A_j^{-1} \int_{\omega_j} \delta v^n d\omega = \bar{v}_j^n - \bar{u}_j(t_n).$$

The numerical approximation fulfills a modification of the original equation. If G is linear, then from (11)

$$G_j \delta v^n = \tau_j(v^n). \tag{14}$$

There are two components of τ_j in (9). Subtract Γ_j in (6) or (8) from G_j in (2) and split the difference into two parts: one due to the temporal discretization (τ_j^t) and one due to the spatial discretization (τ_j^s). The result is

$$G_j(w) - \Gamma_j(\bar{w}) = \tau_j^t(w) + \tau_j^s(w),$$

where we are interested only in the spatial error in this paper.

Suppose that we wish to compute the error in a linear functional $\Xi(u)$. Introduce an inner product $(\cdot, \cdot)$ and a corresponding norm $\|\cdot\|$. Then by Riesz' representation theorem there is a unique ξ such that the error is

$$\delta\Xi = \Xi(u + \delta v) - \Xi(u) = (\xi, \delta v).$$

If we solve the error equation (14), then (at least formally)

$$\delta\Xi = (\xi, G^{-1}\tau).$$

In a posteriori error analysis [17], [41], the adjoint equation

$$G^* \varphi = \xi \tag{15}$$

is solved for φ. Then the discretization is chosen so that the errors satisfy $|(\varphi, \tau)| \leq \epsilon$. Since

$$\delta\Xi = (\xi, G^{-1}\tau) = (G^*\varphi, G^{-1}\tau) = (\varphi, \tau),$$

the estimate of $\delta\Xi$ is the same with the error equation (14) and the adjoint equation (15). The advantage with the adjoint equation is that weights are determined for the influence of different parts of τ on $\delta\Xi$. A disadvantage is that the solution of (15) is required. Another problem is if $\delta\Xi = \|\delta v\|^2$. Then $\xi = \delta v$, which is unknown in (15). The error equation is also a system of PDEs to solve, but our algorithm in section 4 only computes errors in variables that are particularly easy to calculate.

2.4. FVM error estimate. Assume that Ω is covered by triangles or quadrangles in two dimensions and by tetrahedrons or hexahedrons in three dimensions. Then the discretization error in space can be estimated asymptotically by comparing the residual Φ_j on different grids, as follows.

PROPOSITION 2.1. *Let cell ω_0 consist of the cells $\omega_j,\ j = 1 : p$, and let h be a measure of the cell size so that size$(\omega_0) = h$ and size$(\omega_j) = h/r,\ j = 1 : p$. Assume that $u \in C^1(\Omega)$ and that the space discretization in cell j satisfies*

$$\Phi_j(\bar{u}) = F_j(u) - \tau(u_{\omega_j}), \tag{16}$$

where u_{ω_j} is determined at a point in ω_j. Furthermore, assume that the discretization error satisfies

$$\tau(u) = h^\nu c(u) + h^{\nu+1} d(u), \tag{17}$$

where c is a linear operator

$$c(a_1u_1 + a_2u_2) = a_1c(u_1) + a_2c(u_2), \tag{18}$$

and that $\gamma_j = A_j/A_0,\ j = 1 : p$. Then in $\omega_j,\ j = 0 : p$,

$$\tau(u_{\omega_j}) = \tfrac{b_j}{r^\nu - 1}\left(\sum_{j=1}^{p}\gamma_j\Phi_j(\bar{u}_j) - \Phi_0\left(\sum_{j=1}^{p}\gamma_j\bar{u}_j\right)\right) + O(h^{\nu+1}),$$
$$b_0 = r^\nu,\ b_j = 1,\ j > 1.$$

Proof. For u in ω_0 we have

$$\Phi_0(\bar{u}_0) = \Phi_0\left(\sum_{j=1}^{p}\gamma_j\bar{u}_j\right) = F_0(u) - \tau(u_{\omega_0}). \tag{19}$$

Since $u \in C^1(\Omega)$ and by (17) and (18)

$$\tau(u_{\omega_0}) = h^\nu c(u_{\omega_0}) + h^{\nu+1}d(u_{\omega_0}) = h^\nu\sum_{j=1}^{p}\gamma_j c(u_{\omega_j}) + O(h^{\nu+1}). \tag{20}$$

A summation over ω_0 gives

$$\begin{aligned}\sum_{j=1}^{p}\gamma_j\Phi_j(\bar{u}) &= \sum_{j=1}^{p}\gamma_jF_j(u) - \sum_{j=1}^{p}\gamma_j\tau(u_{\omega_j})\\ &= F_0(u) - (h/r)^\nu\sum_{j=1}^{p}\gamma_jc(u_{\omega_j}) + O(h^{\nu+1}).\end{aligned} \tag{21}$$

We infer from (19), (20), and (21) that

$$h^{\nu}\sum_{j=1}^{p}\gamma_j c(u_{\omega_j}) = \frac{r^{\nu}}{r^{\nu}-1}\left(\sum_{j=1}^{p}\gamma_j \Phi_j(\bar{u}_j) - \Phi_0\left(\sum_{j=1}^{p}\gamma_j \bar{u}_j\right)\right).$$

By this expression the proposition follows.

The discretization error in space can be estimated by comparing the expression for the space derivatives on a fine and a coarse grid using the fine grid solution as in Proposition 2.1. The result is similar to what is usually referred to as a Richardson estimate [4], [33], [38]. In [43] the error equations are solved in 1D examples with a driving right-hand side approximating the discretization error for the particular spatial operator. Our evaluation of τ in the proposition is more general and estimates explicitly what happens when the grid size is changed.

3. Errors in the equations of inviscid flow. The equations satisfied by the reconstruction of the numerical solution in (11) are derived for compressible and incompressible flow. The error in the solution can then be estimated by numerical solution of these equations. An estimate of the effect of the discretization error, which can be controlled by changing the space discretization, is obtained on the solution error, which is desirable to keep within given bounds. We write the equations in the form (1) instead of the integrated form (2), since if the solution is smooth and satisfies (2), then it also satisfies (1). If the analytical and the numerical solutions are smooth, then the solution error satisfies PDEs similar to linearized versions of the original PDE.

Under certain assumptions, approximate error equations have constant coefficients and can be solved analytically. It follows from these equations that the solution error caused by a discretization error behaves differently depending on the component of the solution, the flow speed, and the dimension.

3.1. Error equations. The analytical solution of a variable u is denoted by $\hat{u}$ and the numerical error by δu. The reconstructed numerical solution is $u = \hat{u} + \delta u$. Let ρ be the density, $\mathbf{U} = (u, v, w)^T$ the velocity vector, p the pressure, E the total energy, and H the total enthalpy. Then the error equations for compressible flow on conservation form are [2]

$$\rho_t + (\rho u)_x + (\rho v)_y + (\rho w)_z = \tau_1, \tag{22a}$$

$$(\rho u)_t + (\rho u^2)_x + (\rho uv)_y + (\rho uw)_z + p_x = \tau_2, \tag{22b}$$

$$(\rho v)_t + (\rho uv)_x + (\rho v^2)_y + (\rho vw)_z + p_y = \tau_3, \tag{22c}$$

$$(\rho w)_t + (\rho uw)_x + (\rho vw)_y + (\rho w^2)_z + p_z = \tau_4, \tag{22d}$$

$$(\rho E)_t + (\rho uH)_x + (\rho vH)_y + (\rho wH)_z = \tau_5. \tag{22e}$$

These equations conserve mass, momentum, and energy. The system is closed by the internal energy e, the gas constant γ, and the relations

$$e = \frac{p}{(\gamma-1)\rho}, \quad q^2 = u^2 + v^2 + w^2, \quad E = e + \frac{1}{2}q^2, \quad H = E + \frac{p}{\rho}.$$

The equations in (22) can be written in nonconservation form using the substantial derivative D/Dt [2]:

$$\frac{D\rho}{Dt} + \rho\nabla\cdot\mathbf{U} = \tilde{\tau}_1, \tag{23a}$$

$$\rho\frac{Du}{Dt} + p_x = \tilde{\tau}_2, \tag{23b}$$

$$\rho\frac{Dv}{Dt} + p_y = \tilde{\tau}_3, \tag{23c}$$

$$\rho\frac{Dw}{Dt} + p_z = \tilde{\tau}_4, \tag{23d}$$

$$\rho\frac{De}{Dt} + p\nabla\cdot\mathbf{U} = \tilde{\tau}_5. \tag{23e}$$

The relations between τ in (22) and $\tilde{\tau}$ in (23) are

$$\tilde{\tau}_1 = \tau_1, \tag{24a}$$

$$\tilde{\tau}_2 = \tau_2 - u\tau_1, \tag{24b}$$

$$\tilde{\tau}_3 = \tau_3 - v\tau_1, \tag{24c}$$

$$\tilde{\tau}_4 = \tau_4 - w\tau_1, \tag{24d}$$

$$\tilde{\tau}_5 = \tau_1(q^2 - E) - (u\tau_2 + v\tau_3 + w\tau_4) + \tau_5. \tag{24e}$$

The entropy S of the flow is defined by

$$S = c_v \log(p/\rho^\gamma). \tag{25}$$

Here c_v is the specific heat at constant volume. By [2] and (23) we derive the differential equation for the computed entropy S:

$$\frac{DS}{Dt} = c_v(\gamma - 1)\left(\frac{\tilde{\tau}_5}{p} - \frac{\tau_1}{\rho}\right) = \tau_S. \tag{26}$$

In the numerical experiments in section 5, $c_v = 1$ and $\gamma = 1.4$.

Another simple equation is fulfilled by the enthalpy H. From (22e) and the definition of H we arrive at (see also [2])

$$\rho\frac{DH}{Dt} - \frac{\partial p}{\partial t} = \tau_5 - H\tau_1. \tag{27}$$

In incompressible flow, we let $\rho = 1$ and ignore the last equation in (23) to obtain the nonconservation form with $\tilde{\tau}$ from (24):

$$\nabla\cdot\mathbf{U} = \tilde{\tau}_1, \tag{28a}$$

$$\frac{Du}{Dt} + p_x = \tilde{\tau}_2, \tag{28b}$$

$$\frac{Dv}{Dt} + p_y = \tilde{\tau}_3, \tag{28c}$$

$$\frac{Dw}{Dt} + p_z = \tilde{\tau}_4. \tag{28d}$$

The total pressure P for an incompressible fluid is defined by

$$P = p + 0.5q^2. \tag{29}$$

Multiply the momentum equations in (28) by the velocity vector and use the definition of the substantial derivative to obtain

$$\frac{DP}{Dt} - \frac{\partial p}{\partial t} = u\tilde{\tau}_2 + v\tilde{\tau}_3 + w\tilde{\tau}_4. \tag{30}$$

Hence, if $\hat{P}$ is constant in Ω in a steady state solution, the error in P fulfills the linear equation

$$\mathbf{U} \cdot \nabla \delta P = u\tilde{\tau}_2 + v\tilde{\tau}_3 + w\tilde{\tau}_4, \tag{31}$$

where $\mathbf{U}$ is the computed solution.

3.2. Linearized equations. It is possible to simplify (23) if we make a few additional assumptions. For steady, compressible flow assume that

1. all derivatives of the analytical solution are small;
2. u, ρ, and p are of $O(1)$ but v and w are small;
3. the errors in the solution are small.

The first two assumptions are common in linearized flow analysis [2].

By (22) and the assumptions, we have, after ignoring small terms,

$$\begin{aligned} \hat{\rho}\nabla \cdot \delta\mathbf{U} + \hat{u}\delta\rho_x &= \tau_1, \\ \hat{\rho}\hat{u}\delta u_x + \delta p_x &= \tau_2 - \hat{u}\tau_1 = \tau_2', \\ \hat{\rho}\hat{u}\delta v_x + \delta p_y &= \tau_3, \\ \hat{\rho}\hat{u}\delta w_x + \delta p_z &= \tau_4, \\ \hat{\rho}\hat{H}\nabla \cdot \delta\mathbf{U} + \hat{H}\hat{u}\delta\rho_x + \hat{\rho}\hat{u}\delta H_x &= \tau_5. \end{aligned} \tag{32}$$

The error components $\delta\rho, \delta\mathbf{U}, \delta p$, and δH satisfy (32).

Using the definitions of the enthalpy, the speed of sound $a^2 = \gamma\hat{p}/\hat{\rho}$, and the Mach number $M = \hat{u}/a$ in (32), we arrive at

$$\begin{aligned} \nabla \cdot \delta\mathbf{U} - \tfrac{\hat{\rho}}{\gamma\hat{p}}\hat{u}^2\delta u_x &= (1 - M^2)\delta u_x + \delta v_y + \delta w_z \\ &= -\hat{u}\tau_2'/\hat{p} + (\gamma - 1)(\tau_5 - 0.5\hat{u}^2\tau_1)/(\gamma\hat{p}) = \tau_5'. \end{aligned} \tag{33}$$

We have obtained an approximate error equation for the velocity components. For incompressible flow, $M = 0$, and this is the error equation derived from the continuity equation.

The error in the pressure fulfills an equation similar to (33). Take the derivatives of the three momentum equations in (32) with respect to x, y, and z, multiply the first equation by $1 - M^2$, and add them together. Then we have from (33)

$$\begin{aligned} &(1 - M^2)\delta p_{xx} + \delta p_{yy} + \delta p_{zz} \\ &= (1 - M^2)\tau_{2x}' + \tau_{3y} + \tau_{4z} - \hat{\rho}\hat{u}\tau_{5x}' = \tau_p. \end{aligned} \tag{34}$$

The equation for the numerical error in the pressure is elliptic for subsonic flow ($M < 1$) and hyperbolic for supersonic flow ($M > 1$).

If we ignore the boundaries of the computational domain, we can write the solution of (34) for $M < 1$ by means of the fundamental solution g of the Laplace operator [37]. First, introduce the change of variables

$$x = \beta x_1, \quad y = y_1, \quad z = z_1, \quad \beta^2 = 1 - M^2, \tag{35}$$

and then let $\mathbf{r}$ be the vector

$$\mathbf{r} = (x_1 - \xi, y_1 - \eta, z_1 - \zeta)^T, \quad r = |\mathbf{r}|.$$

In (34), τ_p has the form of a divergence $\tau_p = \nabla \cdot \tau_p'$. Suppose that τ_p' stays bounded as $r \to \infty$. The error in the pressure can now be written with $g = -1/(4\pi r)$,

$$\delta p(x_1, y_1, z_1) = \int_\Omega \tau_p(\xi, \eta, \zeta) g \, d\Omega = -\int_\Omega \tau_p' \cdot \nabla g \, d\Omega + \int_{\partial\Omega} g\tau_p' \cdot \hat{n} \, dA, \tag{36}$$

using Gauss's theorem. Let $\partial\Omega$ expand so that the last term in (36) vanishes and $\Omega = \mathbf{R}^3$. Then we obtain

$$\delta p(x/\beta, y, z) = \frac{1}{4\pi} \int \frac{\tau_p' \cdot \mathbf{r}}{r^3} d\Omega. \tag{37}$$

The conclusion from (37) is that the influence of a discretization error $\tau_p'(\xi, \eta, \zeta)$ decays rapidly as $1/r^2$ when r grows.

In the hyperbolic case when $M > 1$ let $\beta^2 = M^2 - 1$ and use the same coordinate transformation as above. Then from (34)

$$\beta^2 \delta p_{xx} - \delta p_{yy} - \delta p_{zz} = -\tau_p. \tag{38}$$

With the fundamental solution to the wave equation (38) (see [37]) the pressure error is

$$\delta p(x/\beta, y, z) = -\frac{1}{2\pi} \int_\Omega \frac{\tau_p(\xi, \eta, \zeta)}{\sqrt{(x_1 - \xi)^2 - ((y_1 - \eta)^2 + (z_1 - \zeta)^2)}} d\Omega, \tag{39}$$

where $\Omega = \{(\xi, \eta, \zeta) | \; x_1 - \xi > \sqrt{(y_1 - \eta)^2 + (z_1 - \zeta)^2}\}$. Thus, for fixed y and z the contribution from $\tau_p(\xi, \eta, \zeta)$ vanishes when x grows.

The analysis can be extended to include also boundaries by introducing Green's function for both $M < 1$ and $M > 1$ [19].

3.3. Natural coordinates. The natural coordinates (s, n) in two dimensions are such that one coordinate s follows the streamlines and the other n is orthogonal to s. The transformation between the (x, y) and (s, n) systems is

$$\begin{aligned} dx &= u \, ds - v \, dn, \\ dy &= v \, ds + u \, dn. \end{aligned}$$

Note that $\mathbf{U} \cdot \nabla = \partial/\partial s$. Define the angle $\theta = \arctan(v/u)$. The speed of sound a is here given by $dp = a^2 \, d\rho$ and the Mach number is $M = q/a$. Then the momentum equations in (23) and (28) can be replaced by two equations in the (s, n) coordinate system. In two dimensions, the steady, compressible flow is governed by

$$(1 - M^2) p_s - \rho q^2 \theta_n = u\tilde{\tau}_2 + v\tilde{\tau}_3 - q^2 \tau_1 = \tilde{\tau}^s, \tag{40a}$$

$$p_n + \rho q^2 \theta_s = -v\tilde{\tau}_2 + u\tilde{\tau}_3 = \tilde{\tau}^n, \tag{40b}$$

and from (26) and (27) we infer that

$$\begin{aligned} S_s &= c_v(\gamma - 1)(\tilde{\tau}_5/p - \tau_1/\rho), \\ H_s &= (\tau_5 - H\tau_1)/\rho. \end{aligned} \tag{41}$$

For incompressible flow, take $M = 0$ and $\rho = 1$ in (40) and replace (41) by

$$P_s = u\tilde{\tau}_2 + v\tilde{\tau}_3 + w\tilde{\tau}_4. \tag{42}$$

Divide both equations in (40) by ρq^2; differentiate (40a) with respect to s and (40b) with respect to n and compute the sum. With $\kappa = 1/(\rho q^2)$ the result is

$$((1 - M^2)\kappa p_s)_s + (\kappa p_n)_n = (\kappa\tilde{\tau}^s)_s + (\kappa\tilde{\tau}^n)_n. \tag{43}$$

The equation is elliptic in p if the flow is subsonic and $M < 1$. If $M > 1$ as in supersonic flow, then (43) is hyperbolic. A similar equation is satisfied by θ. The other governing equations (41) or (42) are hyperbolic. The conclusion is that part of the solution error is transported along streamlines, as in (41) or (42), and part of the error is spread in an elliptic fashion, as in (43), in subsonic flow. If the variation in p, q, and ρ is small in (43), then subtract the analytical solution satisfying (43) without the error terms on the right-hand side as in (11). For the error in the pressure δp we have approximately

$$(1 - M^2)\kappa\delta p_{ss} + \kappa\delta p_{nn} = (\kappa\tilde{\tau}^s)_s + (\kappa\tilde{\tau}^n)_n.$$

Under the assumptions in section 3.2 the coordinates s and n coincide with the x and y coordinates in (34) and the error equations are the same.

3.4. Flow in a channel. The compressible flow in a channel (see Figure 1) is perturbed by a right-hand side $\tau_2 = 1$ in a circle Ω_c with radius 0.2 at $(x_c, y_c) = (1.25, 1.5)$ simulating the effect of a discretization error in the momentum equation in the x-direction in (22b). The grid is uniform with 180×76 cells. The solution is computed at a subsonic speed, $M = 0.6$, and a supersonic speed, $M = 2$. The width of the channel is changed after $x = 1$ and a shock is generated by the lower wall at that point in the supersonic case.

The solution for $\tau_2 = 0$ is subtracted from the solution when $\tau_2 = 1$ and plotted for different variables in Figure 1. The isolines of the difference illustrate how the discretization error at $(1.25, 1.5)$ generates errors in the solution variables. The behavior is different depending on the Mach number. An explanation is offered by the error equations.

Except for the shock, the flow in Figure 1 satisfies the assumptions for the linear analysis in section 3.2. The error equations in two dimensions follow from (32), (33), and (34):

$$\hat{u}\delta\rho_x + \hat{\rho}(\delta u_x + \delta v_y) = 0, \tag{44a}$$

$$\hat{\rho}\hat{u}\delta u_x + \delta p_x = \tau_2, \tag{44b}$$

$$\hat{\rho}\hat{u}\delta v_x + \delta p_y = 0, \tag{44c}$$

$$(1 - M^2)\delta p_{xx} + \delta p_{yy} = (1 + M^2(\gamma - 1))\tau_{2x}, \tag{44d}$$

$$(1 - M^2)\delta u_x + \delta v_y = -\hat{u}\tau_2/\hat{p}. \tag{44e}$$

Let $M < 1$ and $\beta = \sqrt{1 - M^2}$ and introduce the coordinate transformation (35). Following [37], the solution of (44d) in free space is

$$\delta p(x/\beta, y) = \sigma \int \tau_{2\xi} g(x_1 - \xi, y - \eta)d\Omega = -\sigma \int \tau_2 g_\xi(x_1 - \xi, y - \eta)d\Omega, \tag{45}$$

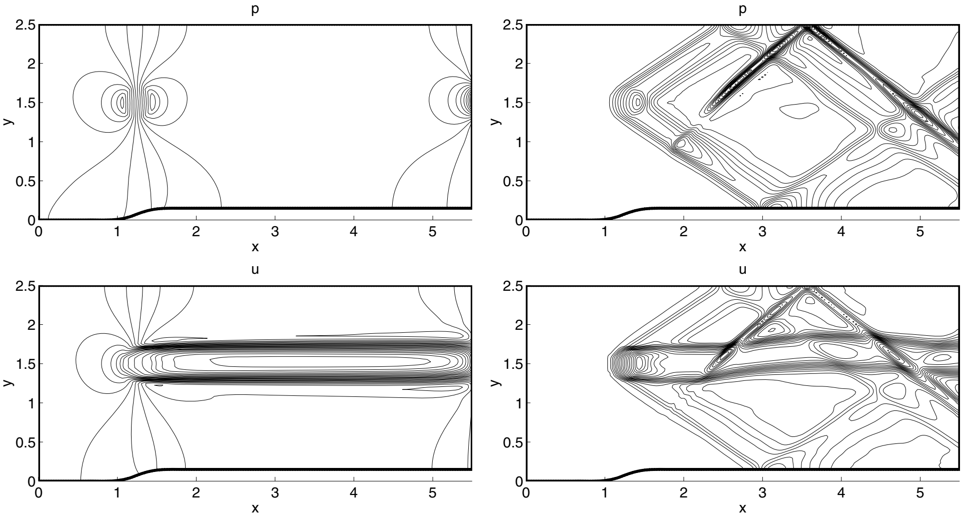

FIG. 1. *Isolines of the perturbation in the pressure p (upper) and velocity component u (lower) for subsonic (left) and supersonic (right) flow.*

where $g(x, y) = \log(x^2 + y^2)/4\pi$ is the fundamental solution in two dimensions and $\sigma = (1 + M^2(\gamma - 1))/\beta$. Since the support of τ_2 is so small we have approximately

$$\delta p \approx \frac{\sigma \tau_2 (x - x_c)}{2\pi\beta(((x - x_c)/\beta)^2 + (y - y_c)^2)}. \tag{46}$$

In subsonic flow, δp will decay at least as $1/r$ outside Ω_c.

In supersonic flow, let $\beta = \sqrt{M^2 - 1}$. The fundamental solution is

$$g(x, y) = \begin{cases} 1/2, & |y| < x, \\ 0, & |y| \geq x \end{cases}$$

(see [37]). Hence,

$$\begin{aligned} \delta p(x/\beta, y) &= -0.5\sigma \int_{-\infty}^{x_1} \int_{x_1 - \xi > |y_1 - \eta|} \tau_{2\xi} \, d\eta d\xi \\ &= -0.5\sigma \int_{-\infty}^{\infty} \int_{-\infty}^{x_1 - |y_1 - \eta|} \tau_{2\xi} \, d\xi d\eta = -0.5\sigma \int_{-\infty}^{\infty} \tau_2(x_1 - |y_1 - \eta|, \eta) d\eta. \end{aligned} \tag{47}$$

Outside the small circle Ω_c, $\tau_2 = 0$ and we have

$$\delta p(x, y) \approx -0.5\sigma\tau_2(x_c, y_c), \text{ when } x \geq x_c, \ x - x_c = \beta|y - y_c|. \tag{48}$$

Contrary to subsonic flow, δp will not decay outside Ω_c on two rays from (x_c, y_c). This behavior is also different from what we have in three dimensions in (39) reflecting the different properties of the wave equation in odd and even dimensions.

From (44b) we conclude that

$$\delta u = \left(\int_{-\infty}^{x} \tau_2 d\xi - \delta p \right) / (\hat{\rho}\hat{u}). \tag{49}$$

The error δu consists of two parts: one part is convected downstream from the source τ_2 and the other part is spread like the error in p. If we try to reduce δu where it is large by refining the grid for $x \geq 2$ in the channel to the outflow boundary (see Figure 1), the adaptation will have little effect on the solution error. It will decrease only after refinement around the source of the discretization error at (x_c, y_c).

An equation for δv similar to (44d) can be derived by combining (44c), (44b), and (44e). The error in ρ has one propagating part and one part depending on δp in the same manner as δu.

The solutions for δp and δu in (46), (48), and (49) agree with the solutions in Figure 1 locally around (x_c, y_c) when the influence of the boundaries is negligible. At the supersonic speed, the waves are reflected in the channel walls and the shock position is shifted above $y \approx y_c$ and in the reflected part by the convected error. The perturbations in δp for $M = 0.6$ at the downstream boundary is explained by the outflow boundary conditions there.

4. Numerical algorithms. In this section we describe the space discretization briefly and how the grid is refined given the computed discretization errors.

4.1. Space discretization. The flow equations are solved on a structured grid in two dimensions. The computational domain is partitioned into a number of blocks. The location of these blocks is predetermined and the edges of a block follow grid lines. The grids in each block can be refined or coarsened. At the block boundaries, jumps are allowed in the grid size. The step length along a boundary may increase by a factor of 2 when crossing the boundary. By changing all cells in a block, the administration of the adaptivity is simplified and the interpolation of data between cells of different size is concentrated at the block boundaries. There is a waste of cells since all of them are not needed for the accuracy. In [4], the refined patches can be placed without restrictions, but the bookkeeping is more complicated in such an algorithm. Every cell in [13] can be refined. This approach requires an extra data structure, and second-order accuracy is difficult to obtain.

The flux vectors in (4) are computed either with the Jameson scheme [26] or with the Osher scheme [32]. Both are second-order accurate on Cartesian grids with constant step sizes in each direction.

Boundary conditions are approximated by introducing ghost cells. In the steady state solutions, the variables in these cells are either given by the boundary data in (1) or obtained by extrapolation from the interior of the domain. The order of the extrapolation is important for the accuracy of the solution, in particular at solid walls. For the compressible equations, the extra numerical conditions are calculated according to [11].

For characteristics starting at a boundary going into the domain it is sufficient to have the boundary condition satisfied to order $\nu-1$ if ν is the order of the discretization in the interior without losing accuracy [22]. Along a solid wall we have a streamline in the Euler equations and the behavior of the error in the total pressure or the entropy is governed by (30) and (26). If the error in the boundary condition is of order $\nu - 1$, then the error in P or S will also be of that order. This is discussed in [19].

Interpolation is necessary at block faces where there is an increase in the grid size. In the coarse ghost cells, the average is computed by summing the averages in the corresponding fine cells with weights proportional to the fine cell areas. The fine ghost cells are computed by combining the neighboring coarse cell values, so that the discretization error is of second order on Cartesian grids in the fine cells adjacent to the boundary. Details of the interpolation are found in [29].

The steady state solution of incompressible flow is computed by adding $\partial p/\partial t$ to the continuity equation (28a) as in [8]. Then the time-dependent equations are integrated for both compressible and incompressible flow by a Runge–Kutta scheme (8) until the time derivatives vanish [26].

4.2. Adaptation algorithm. The solution on the original grid is computed first. Then that solution is used to compute the solution error with the estimates in Proposition 2.1 and the error equations in section 3. The choice of grid size in the different blocks of the computational domain is determined by these estimates. The error equations are solved also in [43] for estimation of the solution error but without coupling them to a fully adaptive procedure.

In the following algorithm we control the errors propagated along streamlines for three reasons:

1. The errors in S, H, and P are often used as measures of the quality of inviscid flow solutions, and they have this property; see (26), (27), and (30).
2. It is a simple way of introducing a control of the maximum solution error.
3. It is possible to take the signs of the discretization errors into account, thus avoiding unnecessarily fine grids.

It is more complicated to solve the elliptic or hyperbolic error equation based on (43) for the pressure error. An approximate solution is computed in one of the numerical examples in the next section. In the linearized equations (34) and (44), δp, caused by a source, decays rapidly as the distance from it grows when $M < 1$ (see Figure 1). In that case, it may be sufficient to control the size of the local discretization error. It is usually concentrated to the solid boundaries. It is shown in [19] using the error equation (34) in two dimensions that the effect on δp of such errors decays from straight and curved boundaries for subsonic and incompressible flow but is propagated without damping for supersonic flow (cf. (46), (48), and Figure 1).

Assume that a maximum error is required to be below a certain tolerance ϵ in a variable, whose error is propagated along streamlines as in (26), (27), (31). Let s denote the coordinate along the streamlines. They pass through a number of block interfaces at $s = s_0, s_1, s_2, \dots$. The contribution to the error in block k is $I_k(s) = \int_{s_{k-1}}^{s} \tau\, ds$ for $s_{k-1} \le s \le s_k$. The accumulated error is denoted by $E(s)$ with $E(s_0) = 0$, and in block k

$$E(s) = \sum_{j=1}^{k-1} I_j(s_j) + I_k(s) = E(s_{k-1}) + I_k(s) \ \text{ for } \ s_{k-1} \le s \le s_k. \tag{50}$$

The algorithm for choosing the grid size in the blocks along a streamline is initialized by calculating the integrals I_k and the corresponding estimate of the accumulated error $E(s)$. Then the adaptive algorithm is, with $\nu = 2$,

```
(51)
while max$|E(s)| > \epsilon$
    Locate the maximum of $|E(s)|$ : $s_{M-1} < s_{max} < s_M$
    $I_k^+(s) = I_k(s)\,\mathrm{sign}\,(E(s_{max}))$ for all $k$
    Find the block $k_m$ with the maximum of
        $I_1^+(s_1), I_2^+(s_2), \dots, I_{M-1}^+(s_{M-1}), I_M^+(s_{max})$
    Refine block $k_m$ : $I_{k_m}(s) := I_{k_m}(s)/2^\nu$
    Update $E(s)$
end while
```

The error may increase in occasional steps in the process when the maximum error changes sign. No jumps in grid size at the block boundaries are allowed to be larger than factor 2. To fulfill this condition, the grid sometimes has to be refined in some blocks to an unnecessarily fine level. If the error along a number of streamlines in a block is controlled, then the smallest grid size given by the algorithm applied to each streamline is chosen.

An alternative would be to estimate $|E(s)|$,

$$|E(s)| \leq \sum_{j=1}^{k-1} |I_j(s_j)| + |I_k(s)|,$$

from (50) and refine the grid in a block k_m where $|I_{k_m}| = \max_k |I_k|$. A problem with that approach is that sometimes the inequality is not sufficiently sharp and the grid may be too fine if the sign of the contribution from each block is ignored. Even if the bound decreases, $E(s_{max})$ may increase, e.g., if $E(s_{max}) > 0$ and $I_k > 0$, $k \neq k_m$ but $I_{k_m} < 0$.

5. Numerical results. The steady state solution of the Euler equations of inviscid flow is computed around 2 two-dimensional objects: the upper part of a cylinder and the wing profile NACA 0012. The flow around the half-cylinder is incompressible and the numerical solution is compared to the analytical solution of the linearized potential flow equation. For the second geometry, the flow is compressible in a standard transonic test case and a subsonic case. The enthalpy and the entropy in the numerical solution are compared to the exact constant value of the enthalpy and to the exact entropy, which is constant at least in parts of the domain.

5.1. Incompressible flow. The time-independent solution of the incompressible Euler equations in conservation form is computed in two dimensions around the upper part of a cylinder. The grid is cylindrical and partitioned into blocks. The system of equations is discretized by the scheme of Jameson, Schmidt, and Turkel [26]. Fourth-order extrapolation at the boundaries is used to supply missing numerical boundary conditions at the cylinder.

The solution is compared to the analytical solution of the linearized potential flow equation. Let Θ be the potential and n the normal direction on the cylinder. Then

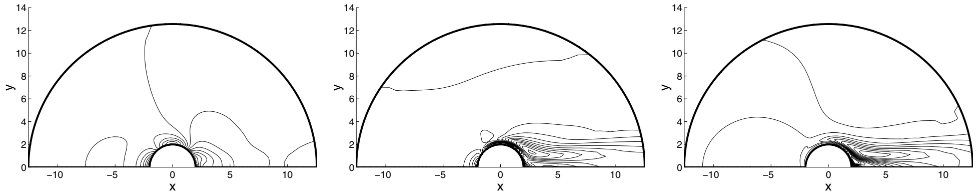
$$\begin{aligned} &\Delta\Theta = 0 \text{ in } \Omega, \quad \mathbf{U} = \nabla\Theta, \quad P = p + 0.5q^2 = \text{const}, \\ &\mathbf{U} = (1,0)^T \text{ at } \infty, \quad n \cdot \mathbf{U} = 0 \text{ on cylinder.} \end{aligned} \tag{52}$$

With the origin at the center of the cylinder and r the radius, the solution to (52) is

$$u = 1 + r^2(y^2 - x^2)/(x^2+y^2)^2, \quad v = -2r^2xy/(x^2+y^2)^2. \tag{53}$$

If there is no vorticity in the Euler solution, then (53) is the steady state solution of (28) with $\tilde{\tau} = 0$. The analytical solution (53) defines the boundary conditions at the outer boundary.

The difference between the analytical solution and the Euler solution around the cylinder on a uniform grid is plotted in Figure 2. The error propagation downstream can as expected be observed in the variables u and P. Most of the error in p is generated at the surface of the cylinder, and it decays in an elliptic way when we go away from the cylinder. The behavior of the errors in u, p, and P is what we expect from the analysis in sections 3.2 and 3.4.



p P u

FIG. 2. *Error distribution around the cylinder.*

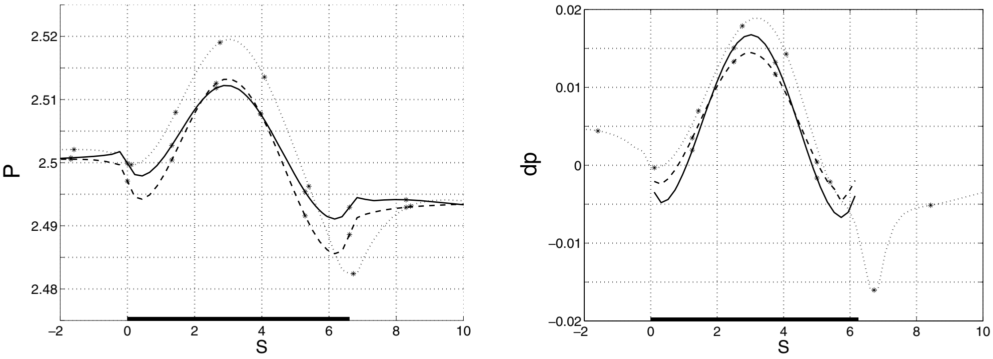


FIG. 3. *Estimated (dashed and solid) and true values (dotted) of P (left) and δp (right) along a streamline close to the surface of the cylinder.*

In Figure 3, the errors δP and δp are estimated on a streamline close to the cylinder ($s \in [0, 2\pi]$) and to $y = 0$ in front of ($s < 0$) and behind the cylinder ($s > 2\pi$). The numerical solution is computed on a coarse grid with 30×18 cells divided into 15 blocks. For the total pressure P, (31) is integrated with $P = 2.5$ as initial condition with two different right-hand sides. Firstly, the discretization error is computed by inserting the analytical solution into the discretization as in (10). Secondly, τ is estimated by Proposition 2.1. The difference in τ_1 between the two alternatives is shown in Figure 4. The first (dashed) and the second (solid) estimates are close. The difference is comparatively small in Figure 3 between the first (dashed) and the second (solid) right-hand sides and the true value of P (dotted). The error in P is somewhat underestimated. This is partly explained by the fact that the estimates are obtained via integrations along the line of symmetry $y = 0$ and the surface of the cylinder. As we can see in Figure 4, this line does not follow the streamline at the left stagnation point, and an error there cannot be corrected downstream. The error in p in Figure 3 is calculated by integrating (40b) from the outer boundary with initial condition $p = 0$ assuming $\rho q^2 \theta_s$ to be negligible. It is possible to subtract the estimated errors from the solution and obtain "superconvergence" as in [41] and a more accurate solution, but without an error estimate in the final solution.

We let the error tolerance be $\epsilon = 4.3 \cdot 10^{-3}$ and apply the adaptive algorithm in section 4.2 once to our example. The grid when P is controlled so that $|\delta P| \leq \epsilon$ is plotted in Figure 5, along with obtained errors on that grid. The abscissa follows the streamline along the cylinder as in Figures 3 and 4. The cylinder surface is marked by a thick black line. The error is somewhat underestimated in P.

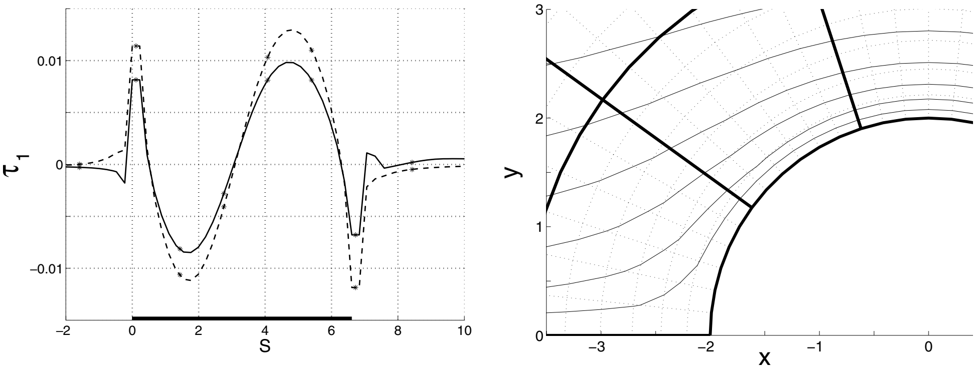

FIG. 4. *The discretization error τ_1 used for the error estimation of P (left) and streamlines close to the cylinder (right).*

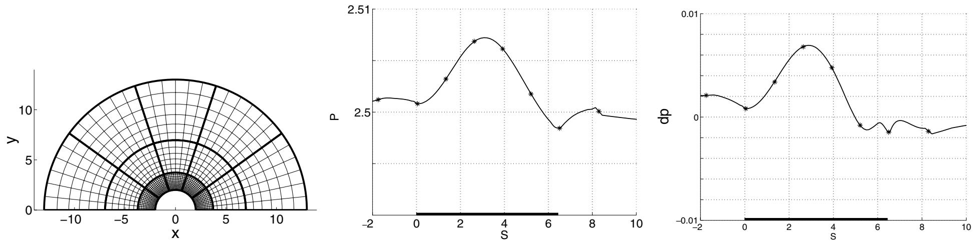

FIG. 5. *Grid for control of P and the measured values of P and δp.*

The grid for control of the error of p is generated by (51) and integration of (40b) and is plotted in Figure 6. The coarse block in the left part of the cylinder gives rise to a large error in P, which is convected downstream resulting in a peak in δp at the right stagnation point. A reliable estimate of δp requires control of P (see Figure 7) where the goal is $\max(\delta P, \delta p) \le \epsilon$. To reduce δP, it does not help to refine the grid in the top block on the cylinder, where δP has its maximum. Instead, the grid should be finer, where δP grows most rapidly (cf. section 3.4 and Figure 1).

The solution error was computed in the L_2 norm $\|\cdot\|$ along the cylinder. A small error on solid surfaces is often desirable in applications and that is the error we control here. The errors in P and p were $\|\delta P\| = 1.18 \cdot 10^{-2}$ and $\|\delta p\| = 1.86 \cdot 10^{-3}$ in the final adapted grid in Figure 7 which has 1836 cells. For comparison, a uniform grid was created with 2160 cells. There, the solution errors were $\|\delta P\| = 0.986 \cdot 10^{-2}$ and $\|\delta p\| = 3.28 \cdot 10^{-3}$. With nearly equal number of cells, the error in p is reduced by almost a factor of 2 and the error in P is about the same in the adapted grid compared to the uniform grid. The gain in adapting the grid is not very dramatic in this example because the flow is rather smooth. The error reduction is more substantial in the following numerical experiments.

5.2. Compressible flow. The steady state solution of the compressible Euler equations ((22) with $\tau = 0$) is calculated around the NACA 0012 airfoil. An original C-grid is partitioned into blocks and refined with the adaptive algorithm in section 4.2. The equations are discretized with the Osher scheme [32] with reconstruction for

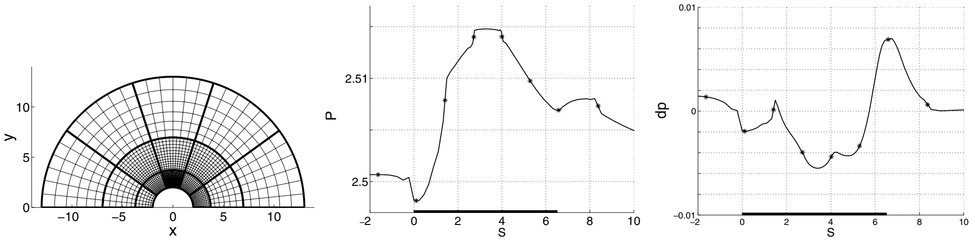

FIG. 6. *Grid for control of p and the measured values of P and δp.*

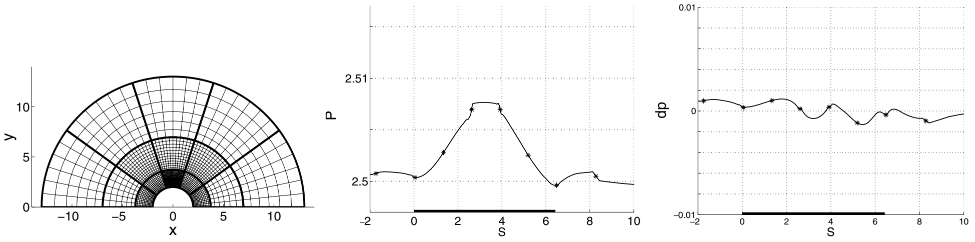

FIG. 7. *Grid for control of p and P and the measured values of P and δp.*

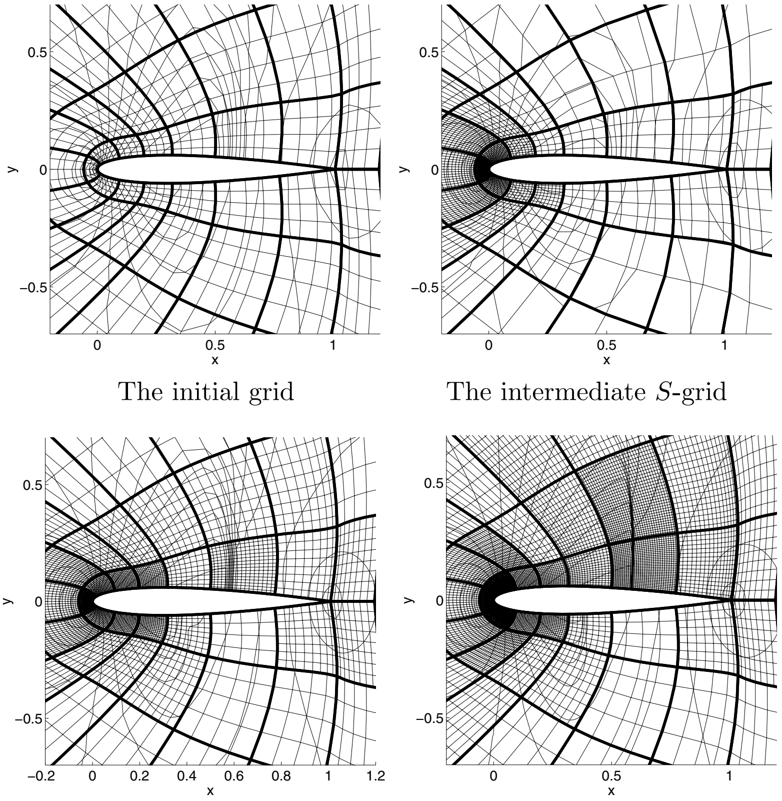
second-order accuracy. The error equations in section 3 break down at discontinuities such as shocks, but the adaptive algorithm (51) still works well.

In the first example, the flow is transonic with $M = 0.8$ and the angle of attack $\alpha = 1.25^o$ and $\epsilon = 5 \cdot 10^{-2}$ in (51). The adaptation algorithm (51) is applied twice: first on the original grid to generate an intermediate grid and then again to generate the final grid. Either the error in the enthalpy H or the error in the entropy S is monitored. The equations (26) and (27) are integrated for the errors in H and S along the streamlines on the upper and lower surfaces of the airfoil. Then the change of H or S in a block determines the grid refinement in (51). It is important that the refinement is based on the difference of H or S between the block boundaries and not the peak values of them in the blocks (cf. Figures 5, 6, and 7).

The initial grid and the intermediate grids generated from δH and δS are shown in Figure 8 together with the isobars of the solution. The estimated error in S is not sufficiently large to motivate a refinement at the shock on the upper part of the profile. On the contrary, δH captures the shock on the upper and lower side, and the algorithm (51) introduces grid refinement both at the leading edge and the shocks. The importance of a good resolution at a shock is discussed in [15] and [16]. Errors of low order are created in a shock and convected downstream.

Figures 9 and 10 display the computed δH and S on the upper and lower side of the airfoil with the initial (dotted), intermediate (dashed), and fine (solid) H-grids. The plots are extended to the outer boundary, and the wing is indicated by a thick line. The entropy has a jump at the shock on the upper side. In the wake, an average is taken between S above and below the trailing edge.

As in the previous example, the solution error in the adapted grid with 43632 cells is compared to the error in a uniform grid with 48384 cells. The block at the leading edge has 64×64 and 24×24 cells, respectively. Then along the profile $\|\delta H\|$



The initial grid

H-grid

FIG. 11. *Isobars for subsonic flow on the final grids. Every second grid line is omitted.*

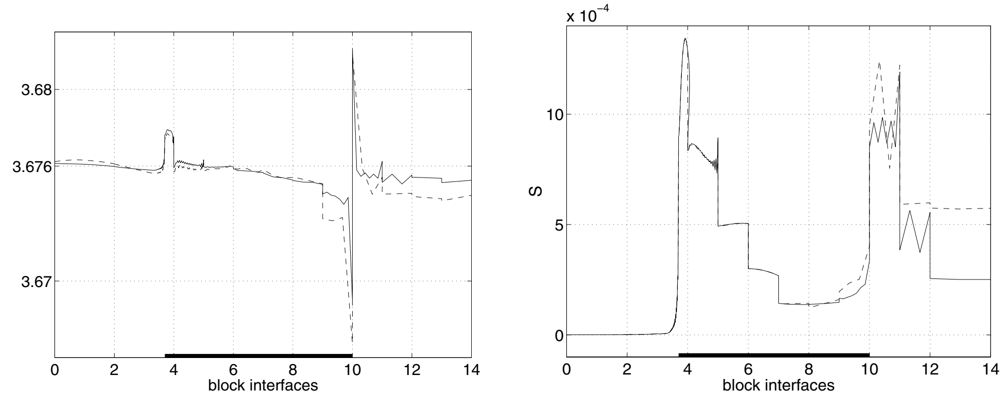

FIG. 12. *The enthalpy (left) and entropy (right) along the lower side of the wing profile computed on the S-grid (dashed) and the H-grid (solid).*

is $3.2 \cdot 10^{-3}$ in the adapted grid and $1.4 \cdot 10^{-2}$ in the uniform grid. The error is clearly reduced by redistributing the cells.

Subsonic flow is computed in the last example with $M = 0.5$, $\alpha = 1.25^o$, and $\epsilon = 2 \cdot 10^{-3}$. The initial grid is the same as in Figure 8. The results after applying the algorithm (51) twice are found in Figure 11. The grids are generated using the enthalpy or the entropy as a measure of the error. The enthalpy is more sensitive to the grid density at the trailing edge. The errors are compared on the two grids in Figure 12, where the solid line corresponds to the H-grid and the dashed line to the S-grid. In [20], the solution on the adapted S-grid is compared to the solution on a uniform grid. The adapted and uniform grids have 12816 and 50688 cells. The error $\|\delta S\|$ is reduced by 82% on the upper side of the wing profile, and the CPU time with multigrid iteration is slightly less with adaptation compared to uniform cell distribution. Better accuracy is achieved and memory is saved at about the same cost in computing time. In a three-dimensional example with transonic flow over a wing, almost the same solution is obtained with an adapted grid compared to a uniform grid with only 12% of the cells and 8% of the CPU time.

MINIMIZING THE PROFILE OF A SYMMETRIC MATRIX*

WILLIAM W. HAGER†

Abstract. New approaches are developed for minimizing the profile of a sparse, symmetric matrix. The heuristic approaches seek to minimize the profile growth, either absolutely or in a weighted sense. The exchange methods make a series of permutations in an initial ordering to strictly improve the profile. Comparisons with the spectral algorithm, a level structure method, and a wave front method are presented.

Key words. matrix envelope, matrix profile, matrix ordering, sparse matrices, Cuthill–McKee algorithm, spectral ordering, wave front ordering, exchange method, weighted greed

1. Introduction.

The envelope of an n by n symmetric matrix $\mathbf{A}$ is the set of index pairs that lie between the first nonzero element in each row and the diagonal:

$$\mathrm{Env}(\mathbf{A}) = \{(i,j) : 1 \le i \le n,\ f_i(\mathbf{A}) \le j < i\},$$

where

$$f_i(\mathbf{A}) = \min\{j : 1 \le j \le i, \quad \text{with } a_{ij} \ne 0\}. \tag{1.1}$$

We assume for convenience that the diagonal elements of $\mathbf{A}$ do not vanish. The profile of a matrix is the number of elements in the envelope plus the number of elements on the diagonal.[1] The **LU** factorization of a symmetric, positive definite matrix can be performed within the space associated with the profile.

When solving sparse, symmetric, positive definite linear systems, we often store only the nonzeros. One of the standard storage structures consists of a pointer from the column to arrays holding the row indices and numerical values of the nonzero entries of that column. In contrast, if the matrix is mostly nonzero, the entire n by n matrix is often stored, both zero and nonzero entries. This storage structure eliminates the integer row indices and pointer arrays, but it requires the storage of zero entries as well as nonzeros. Profile storage is useful when the matrix is moderately sparse, or when the nonzero entries are near the main diagonal. In this approach, we only store the location of the first nonzero in each row, along with the numerical values of entries in the row between the first nonzero and the main diagonal. Profile reducing algorithms, like those presented in this paper, try to minimize the profile by making a symmetric permutation of rows and columns.

The graph G associated with $\mathbf{A}$ has vertices

$$\mathcal{V} = \{1, 2, \ldots, n\}$$

and edges

$$\mathcal{E} = \{(i,j) : i \ne j,\ a_{ij} \ne 0\}.$$

[1] Some authors do not include the diagonal elements in the profile.

Here the edges are unordered pairs. The first strategies for reducing envelope size were based on graph level structures. A level structure is a partition of the vertices into disjoint sets L_1, L_2, ..., L_k with the property that all vertices adjacent to vertices in level L_i are in either L_{i-1} or L_i or L_{i+1}. The first scheme exploiting a level structure to reorder the rows and columns of a matrix and to minimize envelope size was the algorithm of Cuthill and McKee [3]. Later Alan George observed that if the Cuthill–McKee ordering was reversed, then the size of the envelope was often reduced. Liu and Sherman [24] show that this reversal can never increase the size of the envelope. Related level structure methods are developed by Gibbs, Poole, and Stockmeyer [9] and Gibbs and King [23] for which the envelope size is often comparable, but the computation time is significantly less.

Another approach for minimizing the profile is Sloan's method [27], in which the rows and columns of a matrix are ordered in accordance with a priority function; this function assigns to each of the presently unordered nodes a value that is a linear combination of the distance to an "end node" and the associated change in the wave front. In each step of the algorithm, the node with the highest priority is added to the list of labeled nodes. Further improvements to this scheme are developed by Duff, Reid, and Scott [5].

The spectral approach of Barnard, Pothen, and Simon [1] uses an eigenvector (Fiedler vector) corresponding to the second smallest eigenvalue of the graph's Laplacian to minimize the profile of a matrix. The matrix ordering corresponds to the permutation of the components of the Fiedler vector which gives either increasing or decreasing order. George and Pothen [8] provide analysis justifying this strategy. More recently Kumfert and Pothen [22] have developed a hybrid scheme that uses the spectral algorithm to obtain a preordering that is further refined using a modification of Sloan's algorithm. In their numerical experiments, this hybrid algorithm generated profiles 2 to 5 times smaller than those of the reverse Cuthill–McKee algorithm. This was developed further by Reid and Scott [26] and implemented in the HSL [16] package MC60 (HSL was formerly known as the Harwell Subroutine Library).

Recently, Boman and Hendrickson [2] and Hu and Scott [17] developed multilevel algorithms for profile optimization, analogous to the multilevel algorithms that have proved so successful in graph partitioning [13, 14, 18, 19, 20]. Solving the coarse grid problem using an adjacent exchange approach, Boman and Hendrickson achieved performance comparable to that of the original Sloan algorithm. More recently, Hu and Scott achieved performance comparable to that of the hybrid Sloan algorithm by using Sloan's algorithm itself to solve the coarse grid problem. These multilevel methods are faster than the hybrid method since they do not involve computing the Fiedler vector.

In this paper, we develop two classes of methods for optimizing the profile of a matrix. The first class of methods are heuristics based on the following observation: The envelope of a matrix contains all the (off-diagonal) nonzeros of a matrix, and if $\mathbf{P}$ is a permutation matrix, then the number of nonzeros in $\mathbf{A}$ and in $\mathbf{PAP}^{\mathsf{T}}$ are identical. Hence, finding $\mathbf{P}$ to minimize the profile is equivalent to finding $\mathbf{P}$ to minimize the number of zeros in the envelope. Our algorithm starts in the lower right corner of the matrix and builds up $\mathbf{P}$, minimizing the growth of zeros in the envelope in each step. We consider two variations of this approach: "pure greed," in which the growth of zeros is minimized in each step, and "weighted greed," in which a weighted measure of the growth in zeros is minimized.

Heuristics like these, as well as those mentioned earlier, usually improve the profile; however, improvement is not guaranteed. The other class of methods that we develop involve exchanges of adjacent rows and adjacent columns to strictly improve the profile. Boman and Hendrickson also use adjacent exchanges, along with the techniques of Kernighan and Lin [21] and Fiduccia and Mattheyses [6], to solve their coarse grid problem. Here we consider a series of adjacent exchanges—even though individual exchanges do not improve the profile, a series of exchanges may lead to an improvement. Formulas are derived for the profile change associated with the entire series of exchanges. From the structure of these formulas, we obtain a subset of the possible exchanges that could yield an improvement. These exchange methods can be applied directly to the starting matrix to improve its profile, or they can be applied to the ordering generated by any of the heuristics to further improve the profile. In fact, they could be combined with either of the hybrid methods [22, 26] to obtain a 3-method hybrid, whose profile is at least as good as that of the 2-method hybrid. Numerical comparisons between the ordering strategies are given in section 4 using matrices that arise in linear programming (netlib/LP) and matrices from the Harwell-Boeing and NASA directories of Timothy Davis's University of Florida sparse matrix collection at www.cise.ufl.edu/research/sparse/matrices.

2. The new heuristics.

Let $\mathbf{P}$ be a permutation matrix and let $\mathbf{B} = \mathbf{PAP}^{\mathsf{T}}$ be the permutation of $\mathbf{A}$. This permutation $\mathbf{A}$ can be described by a vector $\mathbf{p} \in \mathbf{R}^n$ where p_i is the row of $\mathbf{A}$ corresponding to row i in the permuted matrix $\mathbf{B}$. In our profile heuristic, we assign values to p_i, starting with $i = n$, and working toward $i = 1$. At step k the associated set of "labeled vertices" is defined by

$$\mathcal{L}_k = \{p_i : k < i \le n\},$$

where the initial set $\mathcal{L}_n$ is the empty set. The complement of $\mathcal{L}_k$, denoted $\mathcal{U}_k$, is the set of "unlabeled vertices." The "wave front" $\mathcal{W}_k$ relative to $\mathcal{L}_k$ and $\mathcal{U}_k$ is defined by

$$\mathcal{W}_k = \{i \in \mathcal{L}_k : a_{ij} \neq 0 \text{ for some } j \in \mathcal{U}_k\}.$$

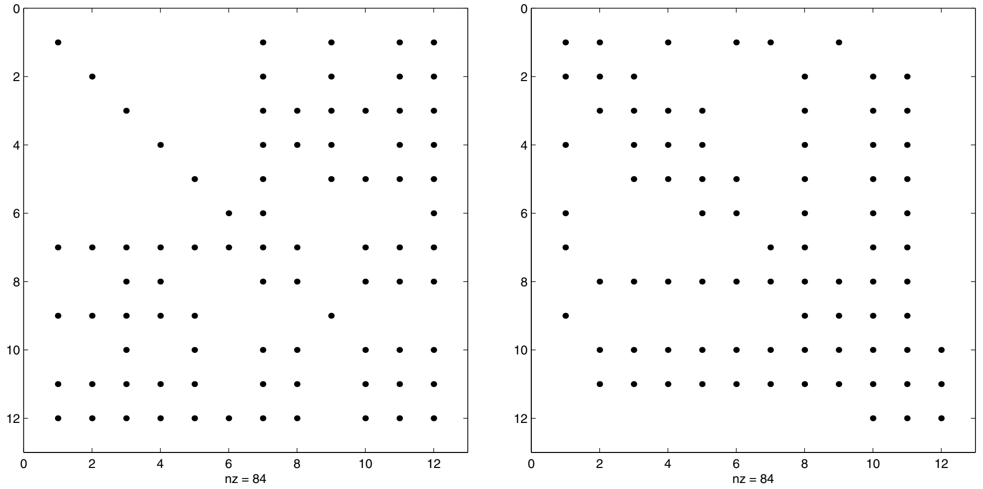
If $\mathbf{A}$ is permuted symmetrically so that the leading columns correspond to $\mathcal{U}_k$ and the trailing columns correspond to $\mathcal{L}_k$, then the wave front is the set of trailing rows where there will be nonzero multipliers in the leading columns when the lower left corner of the permuted matrix is eliminated.

Now let us consider the effect of making the assignment $p_k = j$ at step k for some $j \in \mathcal{U}_k$. The row indices of those elements a_{ij} that both vanish and lie in the envelope of the permuted matrix are given by

$$\mathcal{Z}_k(j) = \{i \in \mathcal{W}_k : a_{ij} = 0\}.$$

As noted earlier, the size of the profile is minimized when the number of zeros in the profile is minimized. A purely greedy labeling approach would simply choose j to minimize the size of $\mathcal{Z}_k(j)$, the number of new zeros that enter the envelope at step k. In other words, if $|\mathcal{Z}_k(j)|$ denotes the number of elements in $\mathcal{Z}_k(j)$, the purely greedy approach chooses $p_k = j \in \mathcal{U}_k$ where

$$|\mathcal{Z}_k(j)| = \min_{l \in \mathcal{U}_k} |\mathcal{Z}_k(l)|. \tag{2.1}$$



A. Original matrix

B. Matrix permuted by Algorithm 1

FIG. 1. *Illustration of Algorithm* 1.

A possible choice for the starting node p_n could be a node of minimum degree in the graph of the matrix. Letting d_j denote the degree of node j, this greedy labeling strategy is the following.

ALGORITHM 1 (greedy minimum profile growth).

```
$J = arg \min_{1 \le j \le n} d_j$
$p_n = j$ for any $j \in J$
for $k = n-1, n-2, \ldots, 1$
    $J = arg \min_{j \in \mathcal{U}_k} |\mathcal{Z}_k(j)|$
    $p_k = j$ for any $j \in J$
end
```
end Algorithm 1

Here the notation "arg min" denotes the set of indices which attain the minimum, while $\mathcal{U}_k$ is the set of unlabeled vertices at step k.

Figure 1 illustrates one of the deficiences with this purely greedy strategy. The last column of Figure 1B corresponds to column 6 in the original matrix and the node of minimum degree. The next four columns (numbers 11 down to 8) in Figure 1B correspond to columns 7, 12, 1, and 11 in Figure 1A. These columns are attractive to the greedy algorithm since they create no zeros in the profile in the lower right 5×5 corner of the matrix. Now, skipping to the end, the first column in Figure 1B corresponds to column 9 in Figure 1A. Notice that when putting column 9 of Figure 1A in column 1 of Figure 1B, we end up with many zeros within the profile (in rows 4, 6, 7, and 9). In this greedy approach, column 9 of Figure 1A was left to the end for the following reason: If we were to assign column 9 earlier in Figure 1B, zeros would be created in the profile in rows 11, 10, and 8. Thus Algorithm 1 does not take into account the fact that these columns are already mostly nonzero, and there is only room for 3 more zeros. As we delay the assignment of column 9 in Figure 1A, we create, in each step, more zeros in the profile in Figure 1B.

To rectify this problem, we can weight our score for each row to take account of the number of nonzeros that remain in a column (or row). The weight function should be chosen so that a zero placed in a column with a lot of nonzeros is less significant than a zero placed in a column with a small number of nonzeros. Let χ be the indicator function defined by

$$\chi(a) = 1 \text{ if } a \neq 0, \quad \chi(a) = 0 \text{ if } a = 0,$$

and for $i \in \mathcal{L}_k$, let $r_k(i)$ be the number of nonzeros associated with unlabeled nodes in row i:

$$r_k(i) = \sum_{j \in \mathcal{U}_k} \chi(a_{ij}). \tag{2.2}$$

In the purely greedy labeling strategy, we assign to each $j \in \mathcal{U}_k$ a "score" $s_k(j)$ that is simply the number of elements in the set $\mathcal{Z}_k(j)$. On the other hand, if W is the weight function, then the weighted score, based on the row sums $r_k(i)$, is

$$s_k(j) = \sum_{i \in \mathcal{Z}_k(j)} W(r_k(i)). \tag{2.3}$$

If W is identically one, then $s_k(j) = |\mathcal{Z}_k(j)|$ and Algorithm 1 corresponds to minimizing $s_k(j)$ in each step. But as illustrated in Figure 1, it is better to choose W so that $W(t)$ is small when t is large. For example, we could take $W(t) = 1/t$. In this way, zeros created in rows with lots of nonzeros receive a small weight in the score for node j. The best node to label at step k is the node $j \in \mathcal{U}_k$ with the lowest score $s_k(j)$.

The formula (2.3) involves a sum over indices associated with zero entries in $\mathbf{A}$. Since sparse matrices have many zeros, it would be better to work with an analogous score expressed in terms of nonzeros. Let $\mathcal{N}_k(j)$ be the nonzeros associated with node j and the wave front at step k:

$$\mathcal{N}_k(j) = \{i \in \mathcal{W}_k : a_{ij} \neq 0\}.$$

The score of node j based on nonzeros is

$$S_k(j) = \sum_{i \in \mathcal{N}_k(j)} W(r_k(i)) = \left(\sum_{i \in \mathcal{W}_k} W(r_k(i)) \right) - s_k(j). \tag{2.4}$$

Again, the weight function W should be monotone decreasing since rows with a lot of nonzeros are less significant than rows with a few nonzeros. Since the scores S_k and s_k are complementary, as indicated in (2.4), minimizing s_k is equivalent to maximizing S_k. Hence, when working with nonzeros, the biggest score is best, and we should choose j to maximize $S_k(j)$ in each step. Again, if W is identically one, then maximizing $S_k(j)$ over $j \in \mathcal{U}_k$ is equivalent to minimizing $s_k(j)$ over $j \in \mathcal{U}_k$, which is the greedy heuristic given in Algorithm 1.

The score $S_k(j)$ takes into account the effect of edges between an unlabeled node j and the labeled nodes $\mathcal{L}_k$. It does not take into account the effect of edges between j and the other unlabeled nodes. If an unlabeled node j is connected by a small number of edges to unlabeled nodes, it should be scored favorably since it is relatively easy to prevent the growth of zeros in the part of the profile connected with this row.

Likewise, as the number of edges between j and the other nodes in $\mathcal{U}_k$ approaches k, this node should be scored favorably since there is little room left for zeros in its row. Our final weighted score $\bar{S}_k(j)$, taking into account both edges between j and $\mathcal{L}_k$ as well as edges between j and $\mathcal{U}_k$, is the following:

$$\bar{S}_k(j) = \max\{W(d_k(j)+1), W(k - d_k(j))\} + \sum_{i \in \mathcal{N}_k(j)} W(r_k(i)), \tag{2.5}$$

where $d_k(j)$ is the degree of j in the subgraph associated with $\mathcal{U}_k$. The first term in (2.5) has the following interpretation: It is the score associated with row k if j is labeled at step k.

The first term in (2.5) leads to a natural starting procedure. For $k = n$, the summation in (2.5) disappears and $\bar{S}_n(j)$ is maximized by either a node of lowest degree or a node of highest degree. Since the best place for completely dense (nonzero) rows and columns is the trailing border of the matrix, this starting procedure treats dense rows and columns correctly. For completeness, we state the weighted greed scheme.

Algorithm 2 (weighted greed).

```
    for $k = n, n-1, \ldots, 1$
        $J = arg \max_{j \in \mathcal{U}_k} \bar{S}_k(j)$
        $p_k = j$ for any $j \in J$
    end
end Algorithm 2
```

If the weight function is strictly monotone, then evaluation of scores could be computationally expensive, with a work estimate comparable to that of an **LU** factorization itself. By choosing W to be piecewise constant, the scoring process is sped up since the score for any node will change only when one of its associated $r_k(i)$, $i \in \mathcal{N}(j)$, moves across a step in W. In the numerical experiments reported later, we used a weight function of the following form:

$$W(i) = 1/i \text{ for } 1 \le i \le \psi, \quad W(i) = 1/\psi \text{ for } i > \psi, \tag{2.6}$$

where ψ is a small positive integer which we call the cutoff. In the experiments, $\psi = 8$. For the matrix of Figure 1A, the profile generated by Algorithm 2 is 54, while the profile of Figure 1B and Algorithm 1 is 63. The notation nnz, used below, stands for "number of nonzeros."

Lemma 2.1. *For the weight function* (2.6)*, Algorithm* 2 *can be implemented in time bounded by* $O(\text{nnz}(\mathbf{A}) \log n)$*.*

Proof. In each step of Algorithm 2, $\mathbf{r}_k$, the vector whose ith component is $r_k(i)$, is adjusted according to the location of nonzeros in column p_k of $\mathbf{A}$. Hence, the number of components of $\mathbf{r}_k$ and $\mathbf{r}_{k-1}$ that are different is bounded by the number of nonzeros in column p_k of $\mathbf{A}$. It follows that the total number of changes in components of $\mathbf{r}_k$ as k ranges between n and 1 is bounded by $\text{nnz}(\mathbf{A})$. If $W(r_k(i)) \ne W(r_{k-1}(i))$ for some i, then $r_k(i) \le \psi$ according to (2.6). For each $i \in \mathcal{L}_k$, $r_k(i)$ can only decrease as k decreases since the set $\mathcal{U}_k$ in (2.2) decreases in size as k decreases from n down to 1. Hence, for any given i and for the weight function (2.6), there are at most ψ values of k for which $W(r_k(i))$ changes. Now consider the last term in (2.5), which we need to evaluate for each $j \in \mathcal{U}_k$. We can think of this sum in the following way: For each $i \in \mathcal{L}_k$ associated with a nonzero a_{ij}, $j \in \mathcal{U}_k$, let us replace a_{ij} by $W(r_k(i))$, and let $\mathbf{A}_k$ be the resulting matrix whose remaining elements are all zero. Forming the sum in (2.5) for each $j \in \mathcal{U}_k$ is equivalent to computing the column sums of $\mathbf{A}_k$; the only nonzero entries are in a submatrix in the lower left corner of $\mathbf{A}_k$. As k decreases by one, we delete a column and add a row to the submatrix. If the numbers inside the submatrix were fixed, independent of k, then the work associated with adding a row, deleting a column, and updating the column sums is bounded by the number of nonzeros in $\mathbf{A}$. Note though that not only is the submatrix changing (add a row, delete a column) in each step, but the elements inside the submatrix change too. However, for each choice of i, we saw earlier that there are at most ψ values of k for which $W(r_k(i))$ changes its value. Hence, the total number of changes in value of the elements in the submatrix is bounded by $\psi\text{nnz}(\mathbf{A})$, and the total work in maintaining the sum in (2.5) remains $\text{O}(\text{nnz}(\mathbf{A}))$.

In each step of Algorithm 2, $\mathbf{d}_k$, the vector whose entries are the degrees of the nodes in the subgraph associated with $\mathcal{U}_k$, is adjusted according to the location of nonzeros in column p_{k+1} of $\mathbf{A}$: For each $i \in \mathcal{U}_k$, we have

$$d_k(i) = d_{k+1}(i) - 1$$

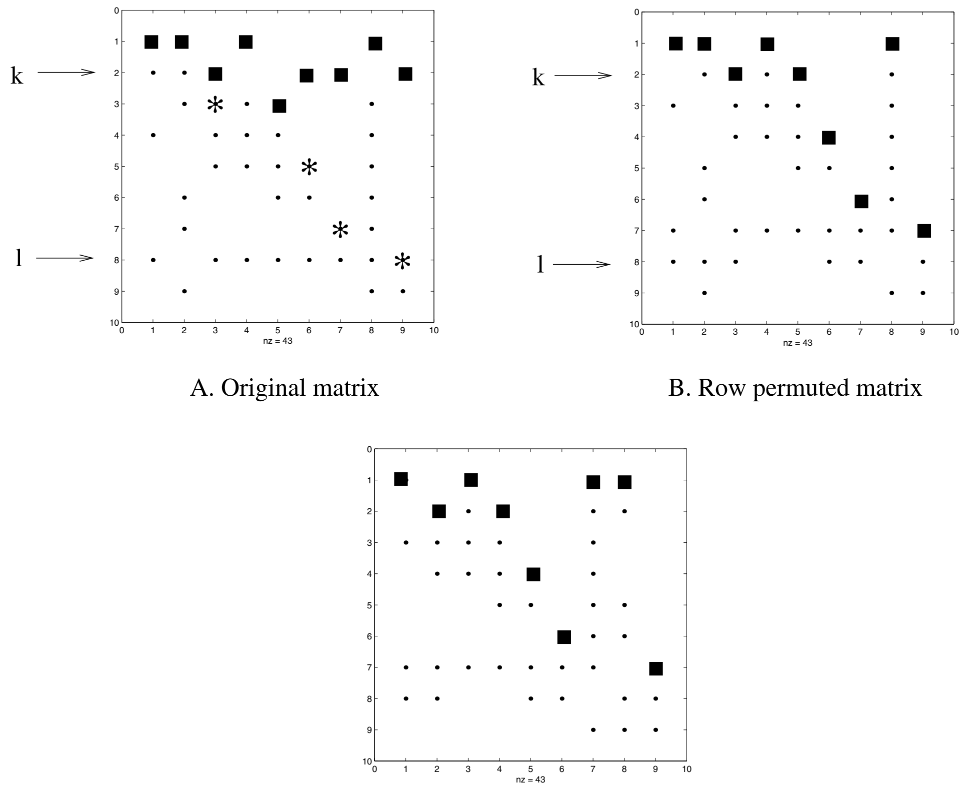
if $a_{ij} \neq 0$ for $j = p_{k+1}$. As with $\mathbf{r}_k$, the total number of changes in components of $\mathbf{d}_k$ as k ranges between n and 1 is bounded by $\text{nnz}(\mathbf{A})$. In any step k where $d_k(j) < d_{k+1}(j)$ for some $j \in \mathcal{U}_k$, we need to check whether the max in (2.5) has increased. Since the total number of changes in components of $\mathbf{d}_k$ is bounded by $\text{nnz}(\mathbf{A})$, the time needed to check whether the max in (2.5) increases when $d_k(j)$ decreases is $\text{O}(\text{nnz}(\mathbf{A}))$.

Now consider the second term in the max of (2.5). Assume that each $j \in \mathcal{U}_k$ is stored in a list, ordered by degree. This degree-ordered list can be created and maintained in time bounded by $\text{O}(\text{nnz}(\mathbf{A}))$ since the number of changes in degree is bounded by $\text{O}(\text{nnz}(\mathbf{A}))$. Since $k - d_k(j)$ decreases monotonically as k decreases, there are at most ψ values of k where $W(k - d_k(j))$ changes in value. Hence, the total number of pairs (j, k) for which $W(k - d_k(j))$ changes in value is at most ψn. Since the diagonal of $\mathbf{A}$ does not vanish, $\psi n = \text{O}(\text{nnz}(\mathbf{A}))$. Consequently, the effort involved with checking whether the max in (2.5) increases due to an increase in $W(k - d_k(j))$ is $\text{O}(\text{nnz}(\mathbf{A}))$.

In each step of Algorithm 2, we extract an unlabeled node of minimum score. If the nodes are ordered in a heap according to their score, we can update the heap when a node's score changes in time bounded by $\text{O}(\log k) \leq \text{O}(\log n)$. Since the number of terms that change in the scores (2.5) is at most $\text{O}(\text{nnz}(\mathbf{A}))$, the total work in maintaining the heap is bounded by the product $\text{O}(\text{nnz}(\mathbf{A}) \log n)$. □

3. Exchange methods. By an exchange method, we mean any strategy for improving the profile of a matrix based on a series of symmetric interchanges of rows and of columns. One strategy to improve the profile of a matrix would be to consider all possible pairs of rows, and corresponding columns, and make an exchange if the profile is reduced. In this section, however, we focus on more specialized exchanges.

For any n by n matrix $\mathbf{A}$ and $k < l \leq n$, let $D_{k:l}(\mathbf{A})$ denote the change in the profile associated with a series of adjacent exchanges: Interchange row k with $k + 1$, row $k + 1$ with $k + 2$, ..., row $l - 1$ with l, and perform the symmetric interchange of columns. Before stating a formula for $D_{k:l}(\mathbf{A})$, we give an illustration. Consider the 9 by 9 matrix depicted in Figure 2, and the values $k = 2$ and $l = 8$. Throughout this section, our figures are based on the "skyline view" of matrix profile—in other words, elements in each column between the first nonzero and the diagonal. The dots denote nonzero entries and a solid square is placed over each nonzero entry corresponding to a frontier node, a node on the top boundary of the envelope. The first nonzero beneath



A. Original matrix

B. Row permuted matrix

C. Row and column permuted matrix

FIG. 2. *Downward exchanges in a symmetric matrix.*

a frontier node is covered with an asterisk. When row k is exchanged with row $k+1$, row $k+1$ is exchanged with $k+2$, and so on, down to row l, we obtain Figure 2B. The single frontier node beneath row k is moved one level higher, increasing the profile by 1. The frontier nodes in row k, on the other hand, fall to positions right above the asterisks in Figure 2A, reducing the profile by 11. Altogether, the profile is reduced by 10. To complete the permutation, we perform the corresponding exchange of the columns. This second set of permutations restores symmetry and moves the columns around, but it does not affect the height of frontier nodes—there are still 4 frontier nodes in row 1, 2 in row 2, and so on. Since the number of zeros above the frontier nodes does not change, the profile change deduced in Figure 2B is correct.

Our formula for $D_{k:l}$ is the following.

LEMMA 3.1. *For any $k < l \leq n$ and for f defined in* (1.1), *we have*

$$D_{k:l}(\mathbf{A}) = |\{j \geq k : k < f_j(\mathbf{A}) \leq l\}| - \left(\sum_{j \in \mathcal{F}_k} (\min\{l, g_j(\mathbf{A}) - 1\} - k) \right), \tag{3.1}$$

where

$$\mathcal{F}_k = \{j : f_j(\mathbf{A}) = k\}, \tag{3.2}$$

and

$$g_i(\mathbf{A}) = \min\{j : f_i(\mathbf{A}) < j,\ a_{ij} \neq 0\} \tag{3.3}$$

if the minimum exits. Otherwise, $g_i(\mathbf{A}) = n + 1$.

The elements of the frontier set $\mathcal{F}_k$, the dark squares in Figure 2, are nodes that are adjacent to k and on the boundary of the envelope. The value of g_i is the second nonzero column index in row i, if it exists. The elements of $\mathbf{A}$ corresponding to the g_i and $i \in \mathcal{F}_k$ are the asterisks in Figure 2. Note that $g_i(\mathbf{A})$ could be larger than i, while $f_i(\mathbf{A}) \le i$.

Proof. The first set in (3.1) represents those zeros that are added to the profile as we successively exchange the rows between k and l. The summation in (3.1) corresponds to the zeros removed from the profile as the rows are exchanged and the frontier moves towards the diagonal of the matrix. Once we reach the second nonzero in a row, the frontier in that row remains stationary. To complete the permutation, we perform the corresponding exchange of the columns. This second set of permutations restores symmetry and moves the columns around, but it does not affect the number of zeros above each frontier node. Since the profile of the matrix equals the number of elements in the upper triangle minus the number of zeros above the frontier nodes, this second set of permutations does not affect the profile (since the number of zeros above the frontier nodes does not change). □

Suppose that we wish to determine whether a series of downward exchanges can be performed that would reduce the profile of a symmetric matrix. Referring to (3.1), we see that as l increases, the first term increases while the second term decreases, achieving its minimum value when l reaches the maximum of the $(g_j(\mathbf{A}) - 1)$ over $j \in \mathcal{F}_k$. When $l \ge g_j(\mathbf{A}) - 1$ for all $j \in \mathcal{F}_k$, the second term in (3.1) remains constant. Hence, when determining the best value for l, we should restrict our attention to

$$k < l < l_1 := \max_{j \in \mathcal{F}_k} g_j(\mathbf{A}).$$

Also note that for $l > k$, we have the bound

$$\sum_{j \in \mathcal{F}_k} (\min\{l, g_j(\mathbf{A}) - 1\} - k) \le \sum_{j \in \mathcal{F}_k} (g_j(\mathbf{A}) - k - 1).$$

The first term in (3.1) is a monotone increasing function of l, so when minimizing $D_{k:l}(\mathbf{A})$ over $l > k$, we should require that $l \le l_2$ where l_2 is the largest l with the property that

$$|\{j \ge k : k < f_j(\mathbf{A}) \le l\}| \le m_1 := \sum_{j \in \mathcal{F}_k} (g_j(\mathbf{A}) - k - 1).$$

Lemma 3.1 can be utilized in an exchange scheme to improve a profile in the following way: For each $k = n-1, n-2, \ldots, 1$, we could check whether $D_{k:l}(\mathbf{A}) < 0$ for some $l > k$. If L is a value l that minimizes $D_{k:l}(\mathbf{A})$ over $l > k$, and if $D_{k:L}(\mathbf{A}) < 0$, we should exchange the rows between k and L. In searching for a value of l that minimizes $D_{k:l}(\mathbf{A})$, the constraints $l \le l_1$ and $l \le l_2$ should be exploited to reduce the search space. In the following summary of the downward exchange scheme, we let $\mathbf{P}$ denote the permutation matrix associated with the permutation vector $\mathbf{p}$.

Algorithm 3 (down exchanges).

```
    for $k = n-1, n-2, \dots, 1$
        $L = arg \min_{k<l\le n} D_{k:l}(\mathbf{PAP}^{\mathsf{T}})$
        if $D_{k:l}(\mathbf{A}) < 0$ for some $l \in L$
            $q = p_k$;   $p_{k:l-1} = p_{k+1:l}$;   $p_l = q$;
        end if
    end
end Algorithm 3
```

Algorithm 3 can be performed in concert with Algorithm 2. That is, right after making the assignment $p_k = j$ in Algorithm 2, we could evaluate the L of Algorithm 2 and make a downward exchange if it is beneficial. This combined mode works since downward exchanges in the trailing part of the matrix do not change the scores of unlabeled nodes. This combined mode avoids a second pass over the matrix. For the experiments reported in section 4, we implement this combined mode; however, the improvement in the profile connected with the down exchanges is accumulated and subtracted from the total profile. This allows us to run the code in this more efficient coupled mode, while tabulating separately the profile improvement due to the exchanges.

Similar to the downward exchanges, we could perform upward exchanges to improve the profile. For any matrix $\mathbf{A}$ and $k > l$, let $D_{k:l}(\mathbf{A})$ denote the change in the profile associated with the interchange of rows k and $k-1$, rows $k-1$ and $k-2, \dots,$ rows $l-1$ and l, and the symmetric interchange of columns. The effect of upward exchanges is quite different from that of downward exchanges. As an illustration, consider the 7 by 7 symmetric matrix in Figure 3. Again, a solid black square is placed over each nonzero corresponding to a frontier node. When row 7 is exchanged successively with the rows above it, the frontier node in column 7 is moved up to row 1. This increases the profile by 3. At the same time, the frontier nodes in columns 1, 2, 3, and 6, which lie above zeros in row 7, are lowered by one row. The net decrease in the profile is 1. When the corresponding column interchanges are applied to the matrix of Figure 3B, symmetry is restored. Since these column exchanges do not affect the number of frontier nodes in each row, the change in profile deduced in Figure 3B is correct.

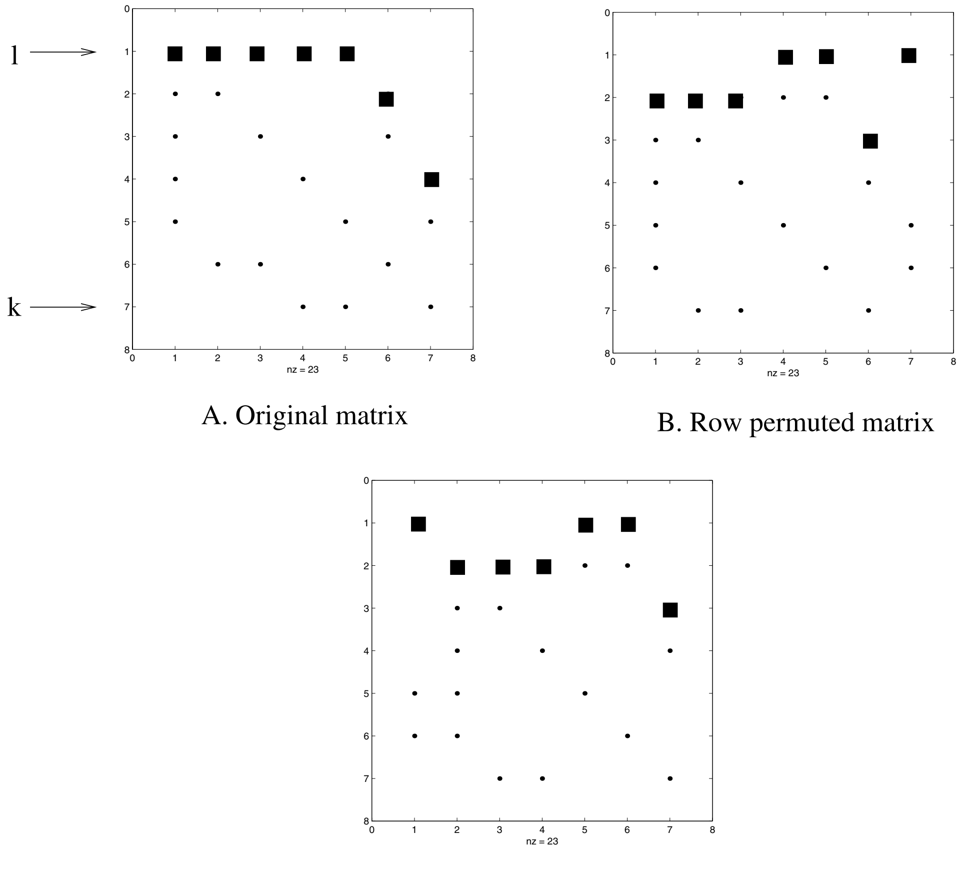
Lemma 3.2. *For any $l < k \le n$ and for f defined in* (1.1)*, we have*

$$D_{k:l}(\mathbf{A}) = \left(\sum_{\{j : a_{kj} \ne 0\}} \max\{f_j(\mathbf{A}) - l, 0\} \right) - |\{j : a_{kj} = 0,\ k > f_j(\mathbf{A}) \ge l\}|. \tag{3.4}$$

Proof. As row k is exchanged successively with rows above, the zeros in row k cause the frontier nodes above them to drop one row lower. The second term in (3.4) reflects this effect. On the other hand, as row k is exchanged upward, nonzeros in row k eventually reach the frontier, and each subsequent exchange increases the number of zeros in the profile by one. The first term in (3.4) reflects the effect of these nonzeros in row k. To complete the permutation, we perform the corresponding exchange of the columns. These column exchanges restore symmetry but do not affect the number of zeros above each frontier node. Hence, this second set of permutations does not affect the profile. □

Let l_3 be the largest value of $l < k$ for which

$$\sum_{a_{kj} \ne 0} \max\{f_j(\mathbf{A}) - l, 0\} \ge m_2 := |\{j : k > f_j(\mathbf{A}) \ge 1\}|.$$



A. Original matrix

B. Row permuted matrix

C. Row and column permuted matrix

FIG. 3. *Upward exchanges in a symmetric matrix.*

Since the first term in (3.4) increases as l decreases, and since the second term in (3.4) is no bigger than m_2, we conclude that $D_{k:l}(\mathbf{A}) \geq 0$ for all $l \leq l_3$. Hence, when searching for the minimum of $D_{k:l}(\mathbf{A})$ over $l < k$, we should restrict our attention to $l > l_3$.

By (3.4) $D_{k:l}(\mathbf{A})$ is a piecewise linear function of l whose minimum is attained either at $l = k$ or $l = f_j(\mathbf{A})$ for some j. Consequently, to achieve rapid evaluation of the minimum of $D_{k:l}(\mathbf{A})$, we should record for each value of m, the sizes of the level sets

$$\mathcal{F}_m = \{j : f_j(\mathbf{A}) = m\},$$

the same set appearing in Lemma 3.1, and those m for which $\mathcal{F}_m$ are nonempty should be ordered in a linked list. The minimum of $D_{k:l}(\mathbf{A})$ is achieved, either at $l = k$ or at one of the m in this list.

Lemma 3.2 can be utilized in an exchange scheme in much the same way that we utilize Lemma 3.1 in Algorithm 3. However, instead of starting at the bottom of the matrix and exchanging with rows below, we start at the top of the matrix and exchange with rows above. In the following summary of the upward exchange scheme, we again let $\mathbf{P}$ denote the permutation matrix associated with the permutation vector $\mathbf{p}$.

```
ALGORITHM 4 (up exchanges).
    for $k = 2, 3, \ldots, n$
        $L = arg\ \min_{1 \le l < k}\ D_{k:l}(\mathbf{PAP}^{\mathsf{T}})$
        if $D_{k:l}(\mathbf{A}) < 0$ for some $l \in L$
            $q = p_l; \quad p_{l:k-1} = p_{l+1:k}; \quad p_k = q;$
        end if
    end
end Algorithm 4
```

The down exchange and up exchange schemes are utilized in a iterative fashion; we apply Algorithm 3, followed by Algorithm 4, followed by Algorithm 3, and so on. In practice, there was no significant improvement after a relatively small number of sweeps, where a sweep denotes a pass through Algorithm 3 followed by a pass through Algorithm 4. In many cases, there was no improvement at all after 3 sweeps, while in some cases, there was a small improvement even after 20 sweeps. In the numerical experiments, we limited the number of sweeps to 5. The execution time of exchange methods can be reduced, while limiting the possible profile improvement, by restricting the extent of the adjacent rows that are exchanged. In our experiments, we did not allow exchanges that went beyond 1000 adjacent row swaps in each exchange step. Another approach to speed up the exchange process, presented in [25], is to use a bisection step to determine the rows to exchange.

4. Numerical experiments.

In this section, we report on a series of numerical experiments using three test sets, all found in Timothy Davis's University of Florida sparse matrix collection, currently located at

www.cise.ufl.edu/research/sparse/matrices

In particular, we use all 109 matrices in the linear programming test set (most of David Gay's linear programming set found originally in Netlib), the 153 symmetric, nondiagonal matrices in the Harwell-Boeing collection [4], and the 8 symmetric matrices in the NASA test set (matrices which arise in structural engineering problems).

The linear programming test set includes m by n matrices $\mathbf{A}$ where m is between 24 and 105,127, with an average value of 3236. The first series of experiments were based on a set of 14,842 matrices, which we call Test Set 1, constructed in the following way: Using the Chaco partitioning code of Hendrickson and Rothberg [15], we generated a permutation matrix $\mathbf{P}$ designed so that $\mathbf{PA}(\mathbf{PA})^{\mathsf{T}}$ has as many nonzeros as possible in diagonal blocks of size roughly k by k where $k = 2\mathrm{nnz}(\mathbf{A})/m$. This construction arises when one uses block iterative techniques to solve linear programming problems (see [10, 11, 12]). The diagonal blocks generated in this way were used for the test matrices. These matrices have an average density (fraction of nonzeros) .45, while their average dimension is 13.1. If the matrices are simply stored as dense symmetric matrices (only store the upper triangle), the storage requirement would be 3,400,729. Using suitable permutations and profile storage, the storage is reduced by a factor of more than 2.

Test Set 2 is obtained in the following way: For each of the 109 rectangular matrices, we form $\mathbf{AA}^{\mathsf{T}}$. A matrix with this nonzero pattern arises in interior point methods as well as in the LP dual active set algorithm. The average density of these matrices is .11, four times smaller than the density of the matrices in Test Set 1. The matrices in Test Set 3, the Harwell-Boeing symmetric matrices, have an average dimension of 2043 and an average density of .03, about four times smaller than the average density of Test Set 2. The matrices in Test Set 4, the NASA symmetric matrices, have an average dimension of 15,750, and an average density of .007, about

Table 1
Profiles, units of 10^6*, for Test Set* 1.

w	wx	m	mx	r	rx	s	sx	x
1.299	1.278	1.303	1.288	1.583	1.313	1.983	1.292	1.272

four times smaller than the average density of Test Set 3. The names of the matrices in Test Sets 2, 3, and 4 and the nonzero patterns for the matrices in Test Set 1 can be found at

www.math.ufl.edu/~hager/papers/profile_testsets

We consider the following five methods:

1. Algorithm 2 (weighted greed).
2. Sloan's method as implemented in Algorithm MC60 from HSL [16] (provided by John Reid).
3. Reverse Cuthill–McKee algorithm (routine symrcm of Matlab).
4. The spectral method (using Matlab's eig or eigs routines).
5. Algorithms 3 and 4 (exchange methods).

MC60 allows for several algorithmic modes; supernodes can be exploited, reverse Cuthill–McKee ordering can be done besides Sloan's method, a spectral method can be combined with Sloan's method by specifying a priority function, and an interface to a frontal solver is provided. In our experiments, we use simply Sloan's method without supernodes (none of the codes in our experiments exploit supernodes). In the fifth method above, we iterate Algorithms 3 and 4 until either there is no further improvement in the profile or until we have done 5 iterations. We initially apply Algorithms 3 and 4 to the given matrix; then we generate a random permutation of the matrix and repeat Algorithms 3 and 4. We report the best profile gotten after 10 random permutations of the given matrix. Since Algorithms 3 and 4 can be used to improve the profile of any given matrix, we also applied them to the permuted matrix generated by each of the first four algorithms. In our experiments, Algorithm 2 nearly always provided a better profile than Algorithm 1; consequently, results for Algorithm 1 are not given.

In Table 1, we give the total profile for the 14,842 matrices in the first test set. The column headings are the following:

w – weighted greed, Algorithm 2,
wx – weighted greed followed by Algorithms 3 and 4, the exchange methods,
m – MC60,
mx – MC60 followed by the exchange methods,
r – reverse Cuthill–McKee,
rx – reverse Cuthill–McKee followed by the exchange method,
s – spectral method,
sx – spectral method followed by the exchange methods,
x – apply the exchange methods to the original matrix and 10 permutations of it.

Observe that the smallest profile was gotten by method x, the exchange methods combined with 10 random permutations. The second best profile was gotten by method wx, the weighted greed/exchange method combination. All the methods received significant benefit from postprocessing using the exchange methods. The biggest beneficiary was the spectral method, for which the profile improved about 35%.

Table 2

6400	10^7	19	2.9	2.8	3.2	3.1	4.4	3.3	4.2	3.0	3.2
25,600	10^7	7	3.0	2.7	4.6	4.2	14.1	7.7	10.0	5.5	5.9
>25,600	10^8	3	.6	.6	9.2	8.7	15.8	9.9	11.2	8.8	.9

Although all methods generated the same profile for many of the 14,842 matrices in the first test set, there were some cases where one method was uniquely superior. As expected, we see in Table 2 that the exchange method x was more often uniquely superior than the other methods. Surprisingly, the spectral/exchange combination sx, ranking fourth in Table 1, was uniquely superior in 80 cases. Although this is a small number of cases relative to the 14,842 problems, it is significantly larger than the number of cases for any of the other methods in Table 2.

In order to estimate the deviation between the profiles of Table 1 and the smallest possible profile, we considered 10,000 random permutations of each matrix. In each case, we applied Algorithm 3 and 4 and recorded the smallest profile. For these relatively small matrices, the smallest profile generated from these 10,000 starting guesses should be very close to the smallest possible profile. In fact, over the entire set of 14,842 matrices, there were only 14 cases where any of the heuristics generated a profile strictly better than the best obtained from these 10,000 random starting guesses, and in these 14 cases, the heuristics yielded a total improvement of just 137. Hence, we expect that the smallest profile for these 14,842 matrices is very close to the profile 1,263,882 achieved using the 10,000 random starting guesses. Referring to Table 1, method x differs from the estimated optimal profile by less than a percent.

In Test Set 2, we apply each of the profile schemes to the matrix $\mathbf{AA}^\mathsf{T}$ associated with each linear program. In Table 3, the first column indicates the dimension range, the row scale factor, and the number of matrices. For example, the first row of Table 3 corresponds to a set of 13 matrices whose dimensions lie between 1 and 100, and the profiles in that row should be multiplied by 10^3 to obtain the total profile of the 13 matrices in that class. The second row corresponds to a set of 29 matrices of dimension between 101 and 400, and the profiles in that row should be multiplied by 10^5. For the matrices of dimension up to 400, the exchange method x gave the best results. For larger matrices, weighted greed combined with the exchange methods gave the best profiles. As the dimension of a matrix increases, the 10 random permutations used in method x become an increasingly small subset of the total set of permutations.

Running times on a Sun Ultra 10 computer are given in Table 4 for weighted greed, MC60, and the exchange methods. The time for the exchange method is subdivided into x3, corresponding to Algorithm 3, and x4, corresponding to Algorithm 4. The

Table 4
Total running times for Test Set 2.

Dim	w	wx	m	mx	x3	x4
100	.060	.120	.003	.011	.006	.009
400	.728	1.527	.083	.241	.090	.271
1600	3.222	7.748	.569	2.297	.750	3.603
6400	6.183	23.600	5.530	16.680	4.328	21.264
25,600	9.064	63.460	1.392	48.560	19.136	66.509
>25,600	18.430	157.800	2.684	186.900	648.636	258.818

times for x3 and x4 were the total times of Algorithms 3 and 4 divided by 11 (the number of permutations including the starting matrix). MC60 is coded in Fortran while the other algorithms are coded in C. Note that MC60 runs several times faster than weighted greed. The complexity estimate $\mathrm{O}(\mathrm{nnz}(\mathbf{A})+n \log n)$ for Sloan's method, given in [22], when compared to the complexity estimate $\mathrm{O}(\mathrm{nnz}(\mathbf{A}) \log n)$ for weighted greed in Lemma 2.1, also seems to suggest that Sloan's method should be faster than our current implementation, which is patterned after the proof of Lemma 2.1. Observe that when the exchange methods are applied after either weighted greed or Sloan's method, overall run time can increase by several factors. Nonetheless, the time to factor a matrix is often much less than the time used by the exchange method. For example, Matlab's built-in Cholesky factorization routine (chol) applied to a matrix with the same nonzero pattern as that of the eighth NASA problem, skirt, takes 33 secs, compared to .1 secs by MC60 to generate a low profile permutation, and 3.7 secs for both MC60 and the exchange methods. The combination mx reduces the profile from 3,766,168 down to 687,730.

Focusing on the times for the exchange methods in Table 4, we note that Algorithm 3 is generally much faster than Algorithm 4. The one exception is the last line of Table 4. This line corresponds to 3 matrices, and one of these, ken18, dominates the total time. This matrix, with 105,127 rows, comes from the manufacturer with a relatively nice row ordering, and a random permutation generates a horrendous ordering. Algorithm 3, which is the first one to process the permuted matrix, makes many interchanges while improving the profile. Even though Algorithm 3 is faster than Algorithm 4, the number of interchanges is so large that the Algorithm 3 time dominates.

We emphasize that the x3 and x4 times in Table 4 correspond to the exchange methods applied to a single permuted version of the original matrix (the time was evaluated by averaging over a set of permutations). It is clear from the times given in Table 4 that trying to find an optimal profile by randomly permuting the matrix and improving the profile by exchanges is only appropriate when the matrix is relatively small.

In Table 5 we give the profiles associated with the Harwell-Boeing test set. These matrices are generally more structured than the linear programming matrices, and more sparse. Again, the exchange methods were competitive for dimensions up to 400. Thereafter, the MC60/exchange combination mx or the spectral/exchange combination sx gave the best profiles.

Running times, shown in Table 6, again parallel those of Table 4, with MC60 being the fastest code.

The profiles shown in Table 7 for Test Set 4, the largest and sparsest matrices, were similar to those of Table 5, with either mx or sx giving the best profiles in each case.

Again, in Table 8, we see that MC60 is significantly faster than the other codes.

These experiments seem to indicate that for matrices in the test suite with dimensions up to 400, the best or close to the best profiles are obtained by the exchange methods applied to a small number of random permutations of the starting matrix. If the exchange methods are applied after MC60, the profile improves as it must, but the computing time increases by several factors (at least in our implementation). By restricting the distance between the rows and columns that are exchanged, the execution time of the exchange methods is O(nnz($\mathbf{A}$)). For the matrices $\mathbf{AA}^{\mathsf{T}}$ associated with the linear programming test programs, weighted greed combined with the exchange methods provided the best profiles on average for matrices of dimension greater than 400. For the Harwell-Boeing and NASA test sets, which are generally more structured than the linear programming matrices, Sloan's method was the best single method, obtaining the best profile for each class of matrices except for the 3 matrices of dimension greater than 25,600 in Table 5. When the profiles for the single methods were further improved using the exchange methods, the combination sx achieved a better profile than mx in 5 of the 9 matrix classes associated with Tables 5 and 7.

Acknowledgment. The author gratefully acknowledges the thoughtful and detailed comments of the referees, which led to an improved presentation.

A WEAKLY OVERLAPPING DOMAIN DECOMPOSITION PRECONDITIONER FOR THE FINITE ELEMENT SOLUTION OF ELLIPTIC PARTIAL DIFFERENTIAL EQUATIONS[*]

RANDOLPH E. BANK[†], PETER K. JIMACK[‡], SARFRAZ A. NADEEM[‡], AND SERGEI V. NEPOMNYASCHIKH[§]

Abstract. We present a new two-level additive Schwarz domain decomposition preconditioner which is appropriate for use in the parallel finite element solution of elliptic partial differential equations (PDEs). As with most parallel domain decomposition methods each processor may be assigned one or more subdomains, and the preconditioner is such that the processors are able to solve their own subproblem(s) concurrently. The novel feature of the technique proposed here is that it requires just a single layer of overlap in the elements which make up each subdomain at each level of refinement, and it is shown that this amount of overlap is sufficient to yield an optimal preconditioner. Some numerical experiments—posed in both two and three space dimensions—are included to confirm that the condition number when using the new preconditioner is indeed independent of the level of mesh refinement on the test problems considered.

1. Introduction.

In this paper we introduce a two-level overlapping additive Schwarz (AS) algorithm which may be applied as an optimal domain decomposition (DD) preconditioner for the adaptive finite element solution of a variety of second-order self-adjoint elliptic problems defined on a bounded Lipschitz domain $\Omega \subset \mathbb{R}^n$ ($n = 2, 3$). In recent years there has been a great amount of research into DD and related methods, and we refer to some of the recent survey and review articles, such as [11, 24, 27, 30, 36, 37], for further details. In particular we note that a number of the algorithms proposed have been successfully implemented as software (see, for example, [12, 16, 21]) and many take the form of multiplicative or multilevel methods (e.g., [3, 8, 10, 15, 38]). Furthermore, by viewing these iterative techniques in terms of subspace corrections it is possible to develop a unified theory for a variety of algorithms and so, although this paper mainly discusses a two-level AS approach, it is certainly possible to generalize this to a multiplicative or a multilevel variant. This is briefly considered in section 6.

Although the work in this paper applies in both two and three dimensions, the

first four sections consider the following model problem in just two dimensions so as to simplify the explanations and illustrations provided. In section 5 the ideas presented are then generalized to three dimensions. It should also be noted that the ideas presented may also be applied to a wider variety of boundary conditions than the zero Dirichlet conditions imposed here for simplicity.

PROBLEM 1.1. *Find $u \in \mathcal{H}_0^1(\Omega)$ such that*

$$\mathcal{A}(u,v) = \mathcal{F}(v) \quad \forall v \in \mathcal{H}_0^1(\Omega), \tag{1.1}$$

where $\Omega \subset \mathbb{R}^2$ is the problem domain and

$$\mathcal{H}_0^1(\Omega) = \{u \in \mathcal{H}^1(\Omega) : u|_{\partial\Omega_E} = 0\}. \tag{1.2}$$

Here $\partial\Omega_E$ is a closed, nonempty subset of the boundary, $\partial\Omega$, upon which zero Dirichlet boundary conditions are imposed and $\mathcal{A}(\cdot,\cdot)$ and $\mathcal{F}(\cdot)$ are the bilinear and linear forms

$$\mathcal{A}(u,v) = \int_\Omega (P(\underline{x})\underline{\nabla} u) \cdot \underline{\nabla} v \, d\underline{x} \quad \text{and} \quad \mathcal{F}(v) = \int_\Omega fv \, d\underline{x} + \int_{\partial\Omega_N} gv \, ds, \tag{1.3}$$

where $P(\underline{x})$ is bounded, symmetric, and strictly positive-definite, and $\partial\Omega_N = \partial\Omega - \partial\Omega_E$ is the part of the boundary subject to Neumann boundary conditions: $\underline{n} \cdot (P(\underline{x})\underline{\nabla} u) = g(\underline{x})$.

The Galerkin finite element method for the solution of (1.1) requires a triangulation, $\mathcal{T}^h$ say, of Ω to be produced so that one may define a piecewise polynomial space of trial functions, $\mathcal{V}^h$ say, on $\mathcal{T}^h$. Further details of the construction of this triangulation are given in the following sections and, for the sake of clarity, we consider only continuous piecewise linear finite element spaces on $\mathcal{T}^h$ throughout the rest of this paper. Section 2 also provides background on the relevant theoretical and practical details of AS preconditioning that are required for section 3. This section introduces details of the DD preconditioner that we propose and presents a detailed analysis of its convergence properties. In the analysis it is demonstrated that it is possible to obtain an optimal preconditioner (i.e., with condition number independent of the mesh size and the number and size of the subdomains) with an overlap of just one element at each level of a mesh hierarchy. This is the main result of the paper. Finally, sections 4 and 5 present a small number of numerical examples using the proposed DD preconditioner for two- and three-dimensional problems, respectively. The paper concludes with a brief discussion of possible extensions and applications of this work.

2. Background.

In order to approximate the solution of (1.1) from the finite-dimensional space $\mathcal{V}^h$ (of continuous piecewise linears on $\mathcal{T}^h$ (where h is the diameter of the largest triangle)), it is necessary to solve the following discrete problem.

PROBLEM 2.1. *Find $u^h \in \mathcal{V}^h \cap \mathcal{H}_0^1(\Omega)$ such that*

$$\mathcal{A}(u^h, v^h) = \mathcal{F}(v^h) \quad \forall v^h \in \mathcal{V}^h \cap \mathcal{H}_0^1(\Omega). \tag{2.1}$$

This is achieved by choosing a basis for $\mathcal{V}^h$ and expressing the problem as a matrix equation:

$$A\underline{u} = \underline{b}. \tag{2.2}$$

For the usual, local, choice of basis the stiffness matrix A is sparse, symmetric, and strictly positive-definite, and so an iterative solution method, such as the conjugate gradient (CG) algorithm (e.g., [2, 17]), is most appropriate. However, it is well known that when the triangulation $\mathcal{T}^h$ is uniformly refined, the condition number of A grows like $O(h^{-2})$ as $h \to 0$ (see [23], for example); hence it is necessary to apply a preconditioned version of the CG algorithm for realistic mesh sizes h.

In this work we consider the use of AS preconditioning (e.g., [14, 13, 18, 25, 28, 33]), which is suitable for use with both nonuniformly refined meshes and parallel computer architectures. Let us define $\mathcal{V} = \mathcal{V}^h \cap \mathcal{H}_0^1(\Omega)$ to be the trial and test space in (2.1) and assume that the triangulation $\mathcal{T}^h$ may be obtained by the uniform refinement of some coarser triangulation, $\mathcal{T}^H$ say, of the domain Ω, where $\mathcal{V}_0$ is the corresponding piecewise linear finite element space, $\mathcal{V}^H \cap \mathcal{H}_0^1(\Omega)$, defined on $\mathcal{T}^H$.

Having introduced a coarse mesh $\mathcal{T}^H$ it is now possible to decompose Ω into (possibly overlapping) subdomains, $\Omega_1, \ldots, \Omega_p$ say, which are each the union of triangles in $\mathcal{T}^H$. We now define the spaces $\mathcal{H}_0^1(\Omega_i) \subset \mathcal{L}^2(\Omega)$ for $i = 1, \ldots, p$ to be the extensions of $\mathcal{H}^1(\Omega_i)$ for which

$$u(\underline{x}) = 0 \ \ \forall \underline{x} \in (\Omega - \overline{\Omega_i}) \cup \partial\Omega_E, \tag{2.3}$$

and the corresponding finite-dimensional spaces $\mathcal{V}_i = \mathcal{V}^h \cap \mathcal{H}_0^1(\Omega_i)$. Note that these local spaces, $\mathcal{V}_i$, form a decomposition of the finite element space $\mathcal{V}$:

$$\mathcal{V} = \sum_{i=1}^{p} \mathcal{V}_i. \tag{2.4}$$

Thus, for each $v \in \mathcal{V}$, there exists a (not necessarily unique) combination of $v_i \in \mathcal{V}_i$ $(i = 1, \ldots, p)$ such that $v = \sum_{i=1}^{p} v_i$.

Given any space decomposition of the form (2.4), the AS algorithm defines a preconditioner, B, for A in (2.2) in the following manner. Let Q_i be the projection from $\mathcal{V}$ to $\mathcal{V}_i$ (for $i = 1, \ldots, p$) given by

$$\int_\Omega (Q_i u) v_i \, d\underline{x} \ = \ \int_\Omega u v_i \, d\underline{x} \quad \forall u \in \mathcal{V}, v_i \in \mathcal{V}_i, \tag{2.5}$$

and define $\mathcal{A}_i$ to be the restriction of $\mathcal{A}$ to $\mathcal{V}_i \times \mathcal{V}_i$ given by

$$\mathcal{A}_i(u_i, v_i) = \mathcal{A}(u_i, v_i) \quad \forall u_i, v_i \in \mathcal{V}_i. \tag{2.6}$$

Note that (given the usual finite element bases for $\mathcal{V}$ and $\mathcal{V}_i$) Q_i may be expressed as a rectangular matrix, $\overline{Q}_i$ say, and a local stiffness matrix, A_i say, may be derived from $\mathcal{A}_i$ (in the same way that the global stiffness matrix A is derived from $\mathcal{A}$ above). The AS (parallel subspace correction) preconditioner for (2.2) is then given by

$$B = \sum_{i=1}^{p} \overline{Q}_i^T A_i^{-1} \overline{Q}_i. \tag{2.7}$$

Note that each of the subdomain solves $(A_i^{-1}\underline{r}_i)$, required when solving the system $B^{-1}\underline{s} = \underline{r}$ at each preconditioned CG iteration, may be performed concurrently and, for simplicity, we will assume for now that all such subdomain solves are exact.

The following theorem, which is proved in [36], for example (or see [30] for a slightly more general form), provides the main theoretical justification for considering preconditioners of the form (2.7).

THEOREM 2.1. *The matrix B defined by* (2.7) *is symmetric and positive-definite. Furthermore, if we assume that there is some constant $C > 0$ such that for all $v \in \mathcal{V}$ there are $v_i \in \mathcal{V}_i$ such that $v = \sum_{i=1}^{p} v_i$ and*

$$\sum_{i=1}^{p} \mathcal{A}_i(v_i, v_i) \leq C\mathcal{A}(v, v), \tag{2.8}$$

then the spectral condition number of BA is given by

$$\kappa(BA) \leq \nu_c C, \tag{2.9}$$

where ν_c is the minimum number of colors required to color the subdomains Ω_i in such a way that no neighbors are the same color.

This result demonstrates that the quality of any AS preconditioner depends only upon the stability of the splitting of $\mathcal{V}$ into subspaces $\mathcal{V}_i$. In particular, if the splitting is such that (2.8) holds with C independent of h, H, or p, then the preconditioner is said to be optimal.

Unfortunately, the decomposition described in (2.3) to (2.4) does not permit such a choice of C since it is entirely local in nature, and so significant reductions in the low-frequency error components can require many preconditioned CG iterations. This is easily rectified, however, by the introduction of an extra, coarse grid, term in the preconditioner (2.7):

$$B = \sum_{i=0}^{p} \overline{Q}_i^T A_i^{-1} \overline{Q}_i. \tag{2.10}$$

Here $\overline{Q}_0$ is another rectangular matrix corresponding to the $\mathcal{L}^2$ projection, Q_0 say, from $\mathcal{V}$ to the coarse grid space $\mathcal{V}_0$, given by

$$\int_\Omega (Q_0 u) v_0 \, d\underline{x} \;=\; \int_\Omega u v_0 \, d\underline{x} \quad \forall u \in \mathcal{V}, v_0 \in \mathcal{V}_0, \tag{2.11}$$

and A_0 is the stiffness matrix derived from $\mathcal{A}_0$, the restriction of $\mathcal{A}$ to $\mathcal{V}_0 \times \mathcal{V}_0$ given by

$$\mathcal{A}_0(u_0, v_0) = \mathcal{A}(u_0, v_0) \quad \forall u_0, v_0 \in \mathcal{V}_0. \tag{2.12}$$

The following result is also proved in [30] and [36] and applies to the new two-level preconditioner defined in (2.10).

THEOREM 2.2. *Provided the overlap between the subdomains Ω_i is of size $O(H)$, where H represents the mesh size of $\mathcal{T}^H$, then there exists $C > 0$, which is independent of h, H, and p, such that for any $v \in \mathcal{V}$ there are $v_i \in \mathcal{V}_i$ such that $v = \sum_{i=0}^{p} v_i$ and*

$$\sum_{i=0}^{p} \mathcal{A}_i(v_i, v_i) \leq C\mathcal{A}(v, v). \tag{2.13}$$

The above result demonstrates that, provided a coarse-grid solve is undertaken and there is a "generous" overlap between the subdomains, the AS technique may indeed be used to achieve optimal preconditioning. It should be noted, however, that these two provisos do raise important practical concerns over the efficiency of such a preconditioner. For example, the solution of the coarse-grid problem is hard to achieve in parallel and so care must be taken when developing parallel software to ensure that this does not become a significant bottleneck. More importantly, however, the fixed $O(H)$ overlap that is required between the subdomains means that as the mesh $\mathcal{T}^h$ is refined (assuming uniform global refinement for simplicity), the number of elements of $\mathcal{T}^h$ in the overlap regions is $O(h^{-2})$ as $h \to 0$. This represents a significant computational overhead when h becomes small.

In practice the usual way in which this second issue is addressed (see, for example, [30]) is to drop the optimality requirement and allow subdomains only to overlap by a small, fixed number of fine element layers. In the following section we address this issue in a different manner by proposing a new two-level optimal AS preconditioner of the form (2.10), which requires substantially fewer elements in the overlap region as $\mathcal{T}^h$ is refined ($O(h^{-1})$ as $h \to 0$ as opposed to $O(h^{-2})$). This is achieved by considering a hierarchy of meshes between $\mathcal{T}^H$ and $\mathcal{T}^h$, each defined by a single level of refinement of its predecessor. While the total overlap between the subdomains remains $O(H)$ in size, at each level of the mesh hierarchy the overlap is the width of just one element. This is illustrated in Figure 1, which shows an overlap of size H in two cases: the first with a uniformly refined mesh in the overlap region, and the second with a mesh which is refined into the overlap region to a width of just one element at each level of the mesh hierarchy.

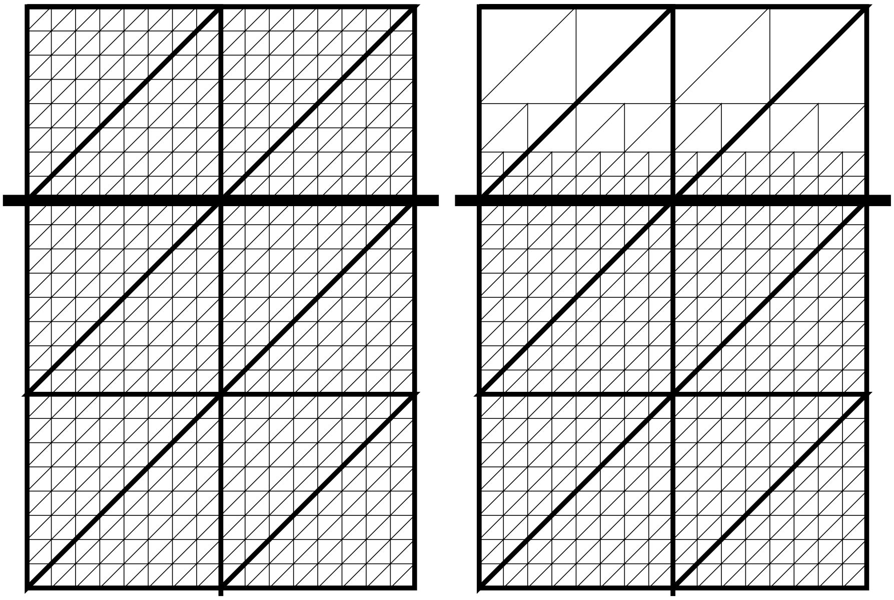

Fig. 1. *A comparison between a mesh which is uniformly refined in the overlap region (left) and one that is nonuniformly refined in the overlap region (right).*

3. A new preconditioner. In order to describe the DD preconditioner that we propose in this section it is necessary to begin by establishing some notation. We will again consider (1.1) to (1.3) as a test problem, maintaining the zero Dirichlet boundary conditions for simplicity. Many of the technical details that follow are concerned with ensuring that both the method itself and the analysis that follows are completely general with respect to the domain geometry and how it is decomposed.

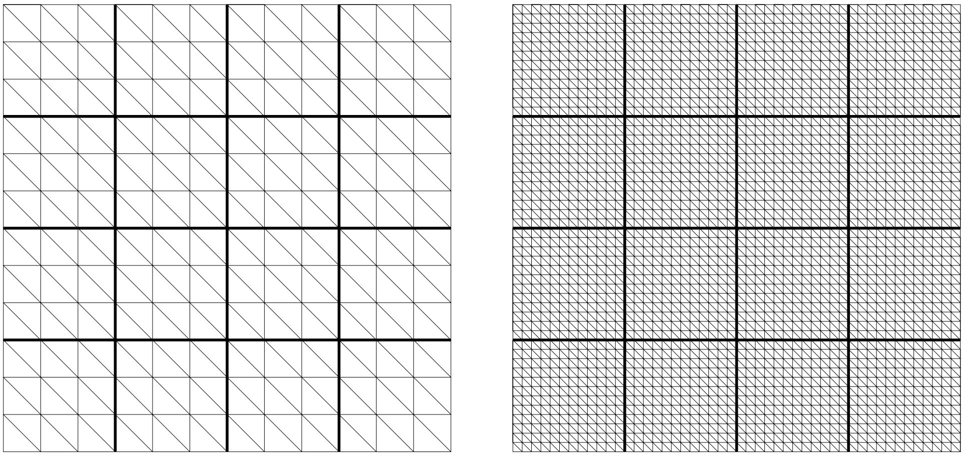

Fig. 2. *The model example, illustrating a regular Cartesian product decomposition of a simple rectangular domain: coarse grid $\mathcal{T}_0$ (left) and uniformly refined grid $\mathcal{T}_2$ (right).*

On first reading, however, it might be more straightforward to visualize the ideas presented by considering a less than general situation. For this reason we also provide a specific model example using a uniformly refined rectangular domain with a regular Cartesian product decomposition (see Figure 2).

Let $\mathcal{T}_0$ be a coarse triangulation of Ω consisting of N_0 triangular elements, $\tau_j^{(0)}$, such that $\tau_j^{(0)} = \overline{\tau}_j^{(0)}$,

$$\overline{\Omega} = \bigcup_{j=1}^{N_0} \tau_j^{(0)} \quad \text{and} \quad \mathcal{T}_0 = \{\tau_j^{(0)}\}_{j=1}^{N_0}. \tag{3.1}$$

Also let diameter$(\tau_j^{(0)}) = O(H)$ (so this triangulation could also be referred to as $\mathcal{T}^H$ in the notation of the previous section), and divide Ω into p *nonoverlapping* subdomains Ω_i. These subdomains should be such that

$$\overline{\Omega} = \bigcup_{i=1}^{p} \overline{\Omega}_i, \tag{3.2}$$

$$\Omega_i \cap \Omega_j = \phi \quad (i \neq j), \tag{3.3}$$

$$\overline{\Omega}_i = \bigcup_{j \in I_i} \tau_j^{(0)}, \quad \text{where } I_i \subset \{1, \ldots, N_0\} \quad (I_i \neq \phi). \tag{3.4}$$

We now permit $\mathcal{T}_0$ to be refined several times to produce a family of triangulations, $\mathcal{T}_0, \ldots, \mathcal{T}_J$, where each triangulation, $\mathcal{T}_k$, consists of N_k elements, $\tau_j^{(k)}$, such that

$$\overline{\Omega} = \bigcup_{j=1}^{N_k} \tau_j^{(k)} \quad \text{and} \quad \mathcal{T}_k = \{\tau_j^{(k)}\}_{j=1}^{N_k}. \tag{3.5}$$

The successive mesh refinements that define this sequence of triangulations need not be global and may be nonconforming; however, we do require that they satisfy a number of conditions, as in [9], for example:

1. $\tau \in \mathcal{T}_{k+1}$ implies that either
   (a) $\tau \in \mathcal{T}_k$, or
   (b) τ has been generated as a refinement of an element of $\mathcal{T}_k$ into four similar children;
2. the level of any triangles which share a common point can differ by at most one;
3. only triangles at level k may be refined in the transition from $\mathcal{T}_k$ to $\mathcal{T}_{k+1}$.

(Here the level of a triangle is defined to be the least value of k for which that triangle is an element of $\mathcal{T}_k$.)

In addition to the above we will also require that

4. in the final mesh, $\mathcal{T}_J$, all pairs of triangles on either side of the boundary of each subdomain Ω_i have the same level as each other.

Note that Figure 2 shows a simple example of such a nested sequence of triangulations for $J = 2$. In this case every triangle in $\mathcal{T}_2$ is a level 2 triangle and the number of subdomains, p, is 16.

Having defined a decomposition of Ω into subdomains and a nested sequence of triangulations of Ω we next define the restrictions of each of these triangulations onto each subdomain by

$$\Omega_{i,k} = \{\tau_j^{(k)} : \tau_j^{(k)} \subset \overline{\Omega}_i\}. \tag{3.6}$$

In order to introduce a certain amount of overlap between neighboring subdomains we also define

$$\tilde{\Omega}_{i,k} = \{\tau_j^{(k)} : \tau_j^{(k)} \text{ has a common point with } \overline{\Omega}_i\}. \tag{3.7}$$

Following this we introduce the finite element spaces associated with these local triangulations. Let G be some triangulation, and denote by $\mathcal{S}(G)$ the space of continuous piecewise linear functions on G. Then we can make the following definitions:

$$\mathcal{W} = \mathcal{S}(\mathcal{T}_J), \tag{3.8}$$

$$\mathcal{W}_0 = \mathcal{S}(\mathcal{T}_0), \tag{3.9}$$

$$\mathcal{W}_{i,k} = \mathcal{S}(\Omega_{i,k}), \tag{3.10}$$

$$\tilde{\mathcal{W}}_{i,k} = \mathcal{S}(\tilde{\Omega}_{i,k}), \tag{3.11}$$

$$\tilde{\mathcal{W}}_i = \tilde{\mathcal{W}}_{i,0} + \cdots + \tilde{\mathcal{W}}_{i,J}. \tag{3.12}$$

It is evident that

$$\mathcal{W} = \mathcal{W}_0 + \tilde{\mathcal{W}}_1 + \cdots + \tilde{\mathcal{W}}_p, \tag{3.13}$$

and this is the decomposition that we propose for the two-level AS preconditioner of the form (2.10). Figure 3 illustrates the meshes $\tilde{\Omega}_{i,k}$ that are the basis for the decomposition (3.13) in the case of our regularly decomposed model problem (where i is the number of the top left subdomain and $k = 0$, 1, and 2).

In order to prove that this preconditioner is optimal Theorem 2.1 demonstrates that it is sufficient, given any $u^h \in \mathcal{W}$, to provide a construction for $u_0^h \in \mathcal{W}_0$ and $u_i^h \in \tilde{\mathcal{W}}_i$ $(i = 1, \ldots, p)$ such that

$$u^h = \sum_{i=0}^{p} u_i^h \tag{3.14}$$

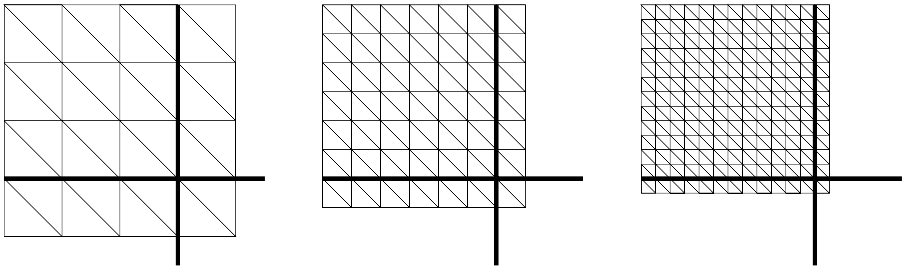

FIG. 3. *An illustration of* $\tilde{\Omega}_{i,0}$ *(left),* $\tilde{\Omega}_{i,1}$ *(center), and* $\tilde{\Omega}_{i,2}$ *(right), where subdomain i is the top left subdomain of Figure* 2.

and

$$\sum_{i=0}^{p} \mathcal{A}_i(u_i^h, u_i^h) \leq C\mathcal{A}(u_i^h, u_i^h) \tag{3.15}$$

for some $C > 0$ which is independent of h, H, and p. To allow such a construction to be produced it is necessary first to introduce some further notation and then to prove a preliminary lemma, following an approach similar to that used in [19, 20, 26].

Given the set of nonoverlapping subdomains Ω_i we define a coloring of the Ω_i such that no neighboring subdomains are the same color and that the boundary of each subdomain of color m should have no isolated points in common with the union of the boundary of all subdomains of color 1 to $m - 1$. Let the number of colors required be n_c, which we assume is independent of h, H, and p (although it may be slightly different to ν_c appearing in Theorem 2.1). Figure 4 illustrates an example of a suitable coloring (with $n_c = 4$) for the subdomains defined in Figure 2. It also illustrates a second example, which violates the restriction that each subdomain of color m should have no isolated points in common with the union of the boundary of subdomains of lower-numbered colors.

FIG. 4. *Examples of a valid (left) and an invalid (right) coloring of the subdomains used in the example of Figure* 2. *The points marked with an X are isolated points on the boundary of subdomains of color* 2 *that are also on the boundary of subdomains of color* 1.

Having introduced an appropriate coloring of the subdomains, let $c(m)$ denote the set of indices of those subdomains of color m (for $m = 1, \dots, n_c$). We may now define

$$\partial\Omega_i = \text{ the boundary of } \Omega_i, \tag{3.16}$$

$$\Omega_{c(m)} = \bigcup_{i \in c(m)} \Omega_i, \tag{3.17}$$

$$\partial\Omega_{c(m)} = \text{ the boundary of } \Omega_{c(m)} \tag{3.18}$$

and, for each $i \in c(m)$ $(m = 1, \dots, n_c)$,

$$\Gamma_i = \partial\Omega_E \bigcup \left(\partial\Omega_i \bigcap \left(\bigcup_{n=1}^{m-1} \partial\Omega_{c(n)} \right) \right). \tag{3.19}$$

Figure 5 illustrates these sets Γ_i for our regularly decomposed model problem and the valid coloring shown in Figure 4. Furthermore, with this definition of Γ_i, it is possible to introduce three more finite element spaces, $\mathcal{W}_{i,k,0}$, $\hat{\mathcal{W}}_{i,k}$, and $\hat{\mathcal{W}}_i$, which are subspaces of $\mathcal{W}_{i,k}$, $\tilde{\mathcal{W}}_{i,k}$, and $\tilde{\mathcal{W}}_i$, respectively:

$$\mathcal{W}_{i,k,0} = \{u_i^h \in \mathcal{W}_{i,k} : u_i^h(\underline{x}) = 0 \ \ \forall \underline{x} \in \Gamma_i\}, \tag{3.20}$$

$$\hat{\mathcal{W}}_{i,k} = \mathcal{S}(\hat{\Omega}_{i,k}), \tag{3.21}$$

and

$$\hat{\mathcal{W}}_i = \hat{\mathcal{W}}_{i,0} + \cdots + \hat{\mathcal{W}}_{i,J}, \tag{3.22}$$

where

$$\hat{\Omega}_{i,k} = \left\{ \bigcup_j \tau_j^{(k)} : \tau_j^{(k)} \text{ has a common point with } \overline{\Omega}_i - \Gamma_i \right\}. \tag{3.23}$$

Also, let $\hat{\Omega}_i$ be the subset of Ω which is covered by the triangulation $\hat{\Omega}_{i,0}$. Figure 6 illustrates the meshes $\hat{\Omega}_{i,k}$ for one specific choice of i using the first coloring shown in Figure 4. Note that this construction is such that overlap from subdomain i is only allowed to occur into subdomains with a larger-numbered color than the color of subdomain i; see Figure 5.

We are now ready to define a mechanism for extending an arbitrary function $w_i^h \in \mathcal{W}_{i,J,0}$ to $\hat{\mathcal{W}}_i$, as follows. In defining this mechanism, we note that the vertices of $\hat{\Omega}_{i,k} - \overline{\Omega}_{i,k}$ are easily identified in the example shown in Figure 6.

Algorithm 3.1. *Let $w_i^h \in \mathcal{W}_{i,J,0}$. Let $Q_{i,k} : \mathcal{L}^2(\Omega_i) \to \mathcal{W}_{i,k,0}$ be the usual $\mathcal{L}^2$ orthogonal projection onto $\mathcal{W}_{i,k,0}$ and define*

$$v_{i,0}^h = Q_{i,0} w_i^h \quad \textit{and} \quad v_{i,k}^h = (Q_{i,k} - Q_{i,k-1}) w_i^h \quad \textit{for } k = 1, \dots, J. \tag{3.24}$$

Now denote by $\hat{v}_{i,k}^h \in \hat{\mathcal{W}}_{i,k}$ the extension of $v_{i,k}^h$ which is zero at all vertices of $\hat{\Omega}_{i,k} - \overline{\Omega}_{i,k}$, so it easily follows that

$$\|\hat{v}_{i,k}^h\|^2_{\mathcal{L}^2(\hat{\Omega}_{i,k})} \le C_0 \|v_{i,k}^h\|^2_{\mathcal{L}^2(\Omega_i)} \tag{3.25}$$

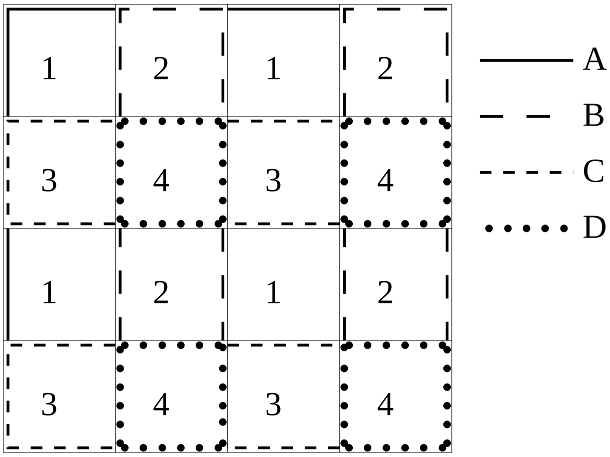

FIG. 5. *An illustration of* Γ_i *for the valid coloring shown in Figure* 4*: line A is* $\cup_{i\in c(1)}\Gamma_i \cap \overline{\Omega}_i$*; line B is* $\cup_{i\in c(2)}\Gamma_i \cap \overline{\Omega}_i$*; line C is* $\cup_{i\in c(3)}\Gamma_i \cap \overline{\Omega}_i$*; line D is* $\cup_{i\in c(4)}\Gamma_i \cap \overline{\Omega}_i$*.*

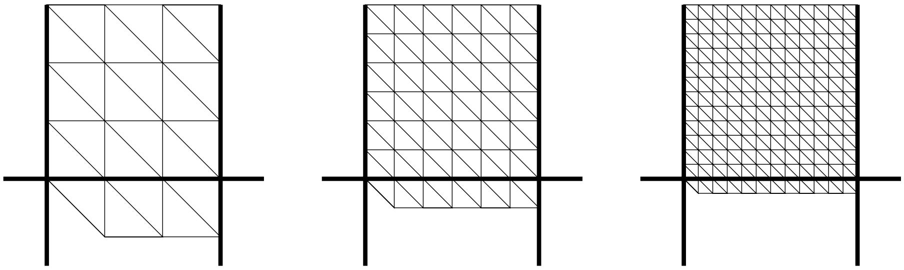

FIG. 6. *An illustration of* $\hat{\Omega}_{i,0}$ *(left),* $\hat{\Omega}_{i,1}$ *(center), and* $\hat{\Omega}_{i,2}$ *(right), where subdomain i is the subdomain in the top row and second column of Figures* 2 *and* 5 *(i.e., of color number* 2*).*

for some $C_0 > 0$*, which is independent of* h*,* H*, and* p*. We are now in a position to define*

$$\hat{v}_i^h = \hat{v}_{i,0}^h + \cdots + \hat{v}_{i,J}^h, \tag{3.26}$$

which is the required local extension of $w_i^h \in \mathcal{W}_{i,J,0}$ *to* $\hat{\mathcal{W}}_i$*.*

LEMMA 3.1. *Given* $w_i^h \in \mathcal{W}_{i,J,0}$ *let* $\hat{v}_i^h \in \hat{\mathcal{W}}_i$ *be the extension of* w_i^h *defined by Algorithm* 3.1 *above. Then there exists* $C_1 > 0$*, which is independent of* h*,* H*, and* p*, such that*

$$\|\hat{v}_i^h\|^2_{\mathcal{H}^1(\hat{\Omega}_i)} \le C_1 \left\{ \frac{1}{H^2}\|w_i^h\|^2_{\mathcal{L}^2(\Omega_i)} + |w_i^h|^2_{\mathcal{H}^1(\Omega_i)} \right\}. \tag{3.27}$$

Proof. First we introduce the following change of variables:

$$x = H\,s, \qquad y = H\,t\,; \qquad (x,y) \in \Omega_i. \tag{3.28}$$

Under this transformation the domain Ω_i is the image of a domain Ω_i' whose geometric properties are independent of H in the (s,t) plane. Furthermore

$$\frac{1}{H^2}\|w_i^h(x,y)\|^2_{\mathcal{L}^2(\Omega_i)} + |w_i^h(x,y)|^2_{\mathcal{H}^1(\Omega_i)} = \|w_i^h(s,t)\|^2_{\mathcal{L}^2(\Omega_i')} + |w_i^h(s,t)|^2_{\mathcal{H}^1(\Omega_i')}, \tag{3.29}$$

and we may define by $Q'_{i,k}$ the projection in the (s,t) variables which corresponds to $Q_{i,k}$. From [9] it follows that there exists $C_2 > 0$, which is independent of h, H, and p, such that

$$\begin{aligned}
&\frac{1}{H^2}\sum_{k=0}^{J} 4^k \|v_{i,k}^h\|^2_{\mathcal{L}^2(\Omega_i)} \\
&\qquad = \frac{1}{H^2}\left(\|Q_{i,0} w_i^h(x,y)\|^2_{\mathcal{L}^2(\Omega_i)} + \sum_{k=1}^{J} 4^k \|(Q_{i,k} - Q_{i,k-1}) w_i^h(x,y)\|^2_{\mathcal{L}^2(\Omega_i)} \right) \\
&\qquad = \|Q'_{i,0} w_i^h(s,t)\|^2_{\mathcal{L}^2(\Omega'_i)} + \sum_{k=1}^{J} 4^k \|(Q'_{i,k} - Q'_{i,k-1}) w_i^h(s,t)\|^2_{\mathcal{L}^2(\Omega'_i)} \\
&\qquad \le C_2 \|w_i^h(s,t)\|^2_{\mathcal{H}^1(\Omega'_i)} \\
&\qquad = C_2 \left(\frac{1}{H^2} \|w_i^h(x,y)\|^2_{\mathcal{L}^2(\Omega_i)} + |w_i^h(x,y)|^2_{\mathcal{H}^1(\Omega_i)} \right). \qquad (3.30)
\end{aligned}$$

A second inequality that we require comes from [26], where it is shown that there exists $C_3 > 0$, which is independent of h, H, and p, such that

$$\begin{aligned}
\|\hat{v}_i^h(x,y)\|^2_{\mathcal{H}^1(\hat{\Omega}_i)} &= H^2 \|\hat{v}_i^h(s,t)\|^2_{\mathcal{L}^2(\hat{\Omega}'_i)} + |\hat{v}_i^h(s,t)|^2_{\mathcal{H}^1(\hat{\Omega}'_i)} \\
&\le C_3 \inf_{\substack{\hat{v}_i^h = \hat{\xi}_0 + \cdots + \hat{\xi}_J \\ (\hat{\xi}_k \in \hat{\mathcal{W}}'_{i,k})}} \sum_{k=0}^{J} 4^k \|\hat{\xi}_k\|^2_{\mathcal{L}^2(\hat{\Omega}'_i)}, \qquad (3.31)
\end{aligned}$$

where $\hat{\mathcal{W}}'_{i,k}$ is the space which corresponds to $\hat{\mathcal{W}}_{i,k}$ with the change of variables (3.28). From this, along with (3.25) and (3.30), it follows that

$$\begin{aligned}
\|\hat{v}_i^h(x,y)\|^2_{\mathcal{H}^1(\hat{\Omega}_i)} &\le C_3 \sum_{k=0}^{J} 4^k \|\hat{v}_{i,k}^h\|^2_{\mathcal{L}^2(\hat{\Omega}'_i)} \\
&= \frac{C_3}{H^2} \sum_{k=0}^{J} 4^k \|\hat{v}_{i,k}^h\|^2_{\mathcal{L}^2(\hat{\Omega}_{i,k})} \\
&\le \frac{C_0 C_3}{H^2} \sum_{k=0}^{J} 4^k \|v_{i,k}^h\|^2_{\mathcal{L}^2(\Omega_i)} \\
&\le C_0 C_2 C_3 \left(\frac{1}{H^2} \|w_i^h\|^2_{\mathcal{L}^2(\Omega_i)} + |w_i^h|^2_{\mathcal{H}^1(\Omega_i)} \right), \qquad (3.32)
\end{aligned}$$

as required. □

This lemma forms the main component of our proof that the proposed splitting is stable. The following theorem completes this proof by explicitly constructing a suitable decomposition of any $u^h \in \mathcal{W}$. It should be noted that the proof of the theorem holds for an arbitrary partition of Ω into subdomains Ω_i and could certainly be simplified if less general partitions (e.g., into strips or regular blocks) were considered. For the completely general case it is necessary to introduce a small amount of additional notation. For $m \in \{1, \ldots, n_c\}$ let

$$\mathcal{W}_0^{(m)} = \left\{ u^H \in \mathcal{W}_0 : u^H(\underline{x}) = 0 \ \ \forall \underline{x} \in \bigcup_{n=1}^{m-1} \Omega_{c(n)} \right\} \qquad (3.33)$$

and let $Q_0^{(m)} : \mathcal{L}^2(\Omega) \to \mathcal{W}_0^{(m)}$ be the $\mathcal{L}^2$ orthogonal projection onto $\mathcal{W}_0^{(m)}$ given by

$$\int_\Omega (Q_0^{(m)} u) w_0^{(m)} d\underline{x} \ = \ \int_\Omega u w_0^{(m)} d\underline{x} \quad \forall w_0^{(m)} \in \mathcal{W}_0^{(m)}. \tag{3.34}$$

Hence, by the $\mathcal{H}^1$ stability of the $\mathcal{L}^2$ projection we have

$$\|Q_0^{(m)} u^h\|_{\mathcal{H}^1(\Omega)} \le C_4 \|u^h\|_{\mathcal{H}^1(\Omega)}, \tag{3.35}$$

and using standard finite element interpolation estimates we have

$$\frac{1}{H}\|u^h - Q_0^{(m)} u^h\|_{\mathcal{L}^2(\Omega)} + |u^h - Q_0^{(m)} u^h|_{\mathcal{H}^1(\Omega)} \le C_4 \|u^h\|_{\mathcal{H}^1(\Omega)} \tag{3.36}$$

for some $C_4 > 0$, which is independent of h, H, and p. (Note that in the case $m = 1$, $\mathcal{W}_0^{(1)} = \mathcal{W}_0$ and $Q_0^{(1)} = Q_0$ as defined in section 2 above.)

THEOREM 3.2. *There exists $C > 0$, which is independent of h, H, and p, such that for any $u^h \in \mathcal{W}$ there are $u^H \in \mathcal{W}_0$ and $u_i \in \tilde{\mathcal{W}}_i$ ($i = 1, \ldots, p$) such that*

$$u^h = u^H + u_1^h + \cdots + u_p^h \tag{3.37}$$

and

$$\|u^H\|^2_{\mathcal{H}^1(\Omega)} + \|u_1^h\|^2_{\mathcal{H}^1(\Omega)} + \cdots + \|u_p^h\|^2_{\mathcal{H}^1(\Omega)} \le C \|u^h\|^2_{\mathcal{H}^1(\Omega)}. \tag{3.38}$$

Proof. Given any $u^h \in \mathcal{W}$, we now construct functions $u^H \in \mathcal{W}_0$ and $u_i^h \in \hat{\mathcal{W}}_i \subset \tilde{\mathcal{W}}_i$ (for $i = 1, \ldots, p$) such that (3.37) and (3.38) are satisfied.

```
Let $r_1^h = u^h$.
Let $u_1^H = Q_0^{(1)} r_1^h$.
Let $w_1^h = r_1^h - u_1^H$.
Let $[w_1^h]_{\Omega_i}$ be the restriction of $w_1^h$ to $\Omega_i$.
For each $i \in c(1)$:
    use Algorithm 3.1 to define $u_i^h \in \hat{\mathcal{W}}_i$ to be the extension of $[w_1^h]_{\Omega_i}$.
For $m = 2$ to $n_c$.
    Let $r_m^h = w_{m-1}^h - \sum_{j \in c(m-1)} u_j^h$ (hence $r_m^h(\underline{x}) = 0$ for all $\underline{x} \in \bigcup_{n=1}^{m-1} \Omega_{c(n)}$).
    Let $u_m^H = Q_0^{(m)} r_m^h$.
    Let $w_m^h = r_m^h - u_m^H$.
    Let $[w_m^h]_{\Omega_i}$ be the restriction of $w_m^h$ to $\Omega_i$ (hence $[w_m^h]_{\Omega_i} \in \mathcal{W}_{i,J,0}$).
    For each $i \in c(m)$:
        use Algorithm 3.1 to define $u_i^h \in \hat{\mathcal{W}}_i$ to be the extension of $[w_m^h]_{\Omega_i}$.
Let $u^H = u_1^H + \cdots + u_{n_c}^H$.
```

Note that in the above definitions, when $i \in c(n_c)$ the functions u_i are just the restrictions of $w_{n_c}^h$ to Ω_i since the extension operation is just the identity in this case (because $\Gamma_i = \partial\Omega_i$ for $i \in c(n_c)$ and so $\hat{\Omega}_{i,k} = \Omega_{i,k}$ and $\hat{\mathcal{W}}_{i,k} = \mathcal{W}_{i,k}$ for $k = 1, \ldots, J$). For these definitions of u^H and u_i^h (for $i = 1, \ldots, p$) we now prove that (3.37) and (3.38) both hold.

To prove (3.37) first let $\underline{x} \in \Omega_i$ for $i \in c(1)$. Then

$$\begin{aligned} u^H + u_1^h + \cdots + u_p^h &= \sum_{n=1}^{n_c} u_n^H(\underline{x}) + \sum_{j=1}^{p} u_j^h(\underline{x}) \\ &= u_1^H(\underline{x}) + u_i^h(\underline{x}) \\ &= u_1^H(\underline{x}) + w_1^h(\underline{x}) \\ &= r_1^h \\ &= u^h. \end{aligned}$$

Now let $\underline{x} \in \Omega_i$ for $i \in c(m)$ for any $m \in \{2, \ldots, n_c\}$. Then

$$\begin{aligned} u^H + u_1^h + \cdots + u_p^h &= \sum_{n=1}^{n_c} u_n^H(\underline{x}) + \sum_{j=1}^{p} u_j^h(\underline{x}) \\ &= \sum_{n=1}^{m} \left(u_n^H(\underline{x}) + \sum_{j \in c(n)} u_j^h(\underline{x}) \right) \\ &= \sum_{n=1}^{m-1} \left(u_n^H(\underline{x}) + \sum_{j \in c(n)} u_j^h(\underline{x}) \right) + u_m^H(\underline{x}) + u_i^h(\underline{x}) \\ &= \sum_{n=1}^{m-1} \left(u_n^H(\underline{x}) + \sum_{j \in c(n)} u_j^h(\underline{x}) \right) + u_m^H(\underline{x}) + w_m^h(\underline{x}) \\ &= \sum_{n=1}^{m-1} \left(u_n^H(\underline{x}) + \sum_{j \in c(n)} u_j^h(\underline{x}) \right) + r_m^h(\underline{x}) \\ &= \sum_{n=1}^{m-1} \left(u_n^H(\underline{x}) + \sum_{j \in c(n)} u_j^h(\underline{x}) \right) + r_{m-1}^h(\underline{x}) - u_{m-1}^H(\underline{x}) - \sum_{j \in c(m-1)} u_j^h \\ &= \sum_{n=1}^{m-2} \left(u_n^H(\underline{x}) + \sum_{j \in c(n)} u_j^h(\underline{x}) \right) + r_{m-1}^h(\underline{x}) \\ &= \sum_{n=1}^{m-3} \left(u_n^H(\underline{x}) + \sum_{j \in c(n)} u_j^h(\underline{x}) \right) + r_{m-2}^h(\underline{x}) \\ &= : \\ &= \left(u_1^H(\underline{x}) + \sum_{j \in c(1)} u_j^h(\underline{x}) \right) + r_2^h(\underline{x}) \\ &= r_1^h \\ &= u^h. \end{aligned}$$

Finally, we observe that if $\underline{x}$ is on the boundary between two or more subdomains, then the above argument may be applied to the subdomain of the lowest color to show that $u^H + u_1^h + \cdots + u_p^h = u^h$ at this point too. (This argument uses the continuity of each w_m^h and the fact that $w_m^h(\underline{x}) = 0$ for each subdomain m whose boundary contains $\underline{x}$, except the one with the lowest color.)

To conclude the proof we now demonstrate that (3.38) also holds. In order to do this, first note that since $\cup_{m=1}^{n_c} c(m) = \{1, \ldots, p\}$ and $u^H = \sum_{m=1}^{n_c} u_m^H$,

$$\|u^H\|^2_{\mathcal{H}^1(\Omega)} + \|u_1^h\|^2_{\mathcal{H}^1(\Omega)} + \cdots + \|u_p^h\|^2_{\mathcal{H}^1(\Omega)} \le \sum_{m=1}^{n_c} \left(\|u_m^H\|^2_{\mathcal{H}^1(\Omega)} + \sum_{i \in c(m)} \|u_i^h\|^2_{\mathcal{H}^1(\Omega)} \right). \tag{3.39}$$

Hence, since n_c is assumed to be independent of h, H, and p, it is sufficient to show that

$$\|u_m^H\|^2_{\mathcal{H}^1(\Omega)} + \sum_{i \in c(m)} \|u_i^h\|^2_{\mathcal{H}^1(\Omega)} \le C\|u^h\|^2_{\mathcal{H}^1(\Omega)} \tag{3.40}$$

for some C which is independent of h, H, and p, and any $m \in \{1, \ldots, n_c\}$. Let the quantity on the left-hand side of (3.40) be S_m. Then

$$\begin{aligned}
S_m &= \|u_m^H\|^2_{\mathcal{H}^1(\Omega)} + \sum_{i \in c(m)} \|u_i^h\|^2_{\mathcal{H}^1(\hat{\Omega}_i)} \\
&\quad \text{(since } u_i^h \in \hat{\mathcal{W}}_i\text{)} \\
&\le C_4\|r_m^h\|^2_{\mathcal{H}^1(\Omega)} + \sum_{i \in c(m)} \|u_i^h\|^2_{\mathcal{H}^1(\hat{\Omega}_i)} \\
&\quad \text{(using (3.35))} \\
&\le C_4\|r_m^h\|^2_{\mathcal{H}^1(\Omega)} + C_1 \sum_{i \in c(m)} \left\{ \frac{1}{H^2}\|w_m^h\|^2_{\mathcal{L}^2(\Omega_i)} + |w_m^h|^2_{\mathcal{H}^1(\Omega_i)} \right\} \\
&\quad \text{(using Lemma 3.1)} \\
&\le C_4\|r_m^h\|^2_{\mathcal{H}^1(\Omega)} + C_1C_4^2 \sum_{i \in c(m)} \|r_m^h\|^2_{\mathcal{H}^1(\Omega_i)} \\
&\quad \text{(using (3.36))} \\
&= C_4\|r_m^h\|^2_{\mathcal{H}^1(\Omega)} + C_1C_4^2\|r_m^h\|^2_{\mathcal{H}^1(\Omega)} \\
&= C_5\|r_m^h\|^2_{\mathcal{H}^1(\Omega)}. \qquad (3.41)
\end{aligned}$$

Clearly if $m = 1$, then $r_m^h = u^h$ and we are done. Otherwise note that

$$\begin{aligned}
S_m &\le C_5\|r_m^h\|^2_{\mathcal{H}^1(\Omega)} \\
&\le C_5 \left(\|r_{m-1}^h\|^2_{\mathcal{H}^1(\Omega)} + S_{m-1} \right) \\
&\le C_5 \left(\|r_{m-1}^h\|^2_{\mathcal{H}^1(\Omega)} + C_5\|r_{m-1}^h\|^2_{\mathcal{H}^1(\Omega)} \right) \\
&\quad \text{(using the same argument as in (3.41) above)} \\
&= C_6\|r_{m-1}^h\|^2_{\mathcal{H}^1(\Omega)} \\
&\le C_7\|r_1^h\|^2_{\mathcal{H}^1(\Omega)} \\
&\quad \text{(repeating this argument } m-2 \text{ further times)} \\
&= C_7\|u^h\|^2_{\mathcal{H}^1(\Omega)},
\end{aligned}$$

as required. □

Having demonstrated that the splitting given by (3.13) is stable it is now a simple matter to invoke Theorem 2.1 (with ν_c replaced by $\nu_c + 1$ to take into account the coarse grid space $\mathcal{W}_0$) and the equivalence of the norm $\mathcal{A}(\cdot,\cdot)^{1/2}$ with the $\mathcal{H}^1$ norm to deduce that the corresponding AS preconditioner is optimal.

The results of this section show that, in two dimensions, it is possible to obtain an optimal two-level AS preconditioner with an overlap which contains $O(h^{-1})$ elements only, provided appropriate use is made of the mesh hierarchy. While the proofs developed here are fully general in terms of subdomain shapes and connectivity a simple, more regular example has also been included for illustrative purposes. In contrasting these results with more standard theoretical results (as in the following section), which require $O(h^{-2})$ elements in the overlap regions for optimality, a number of practical points should be noted. First, as described in [30], for example, the standard two-level AS method does not use a generous overlap in practice. Typically, two to four fine mesh layers are found to be most economical. It follows, therefore, that the weakly overlapping approach that we have analyzed will not generally be any less (or more) computationally expensive per iteration than standard two-level AS solvers. What our approach does offer, however, is the guarantee of optimality, which does not hold when only a fixed number of fine grid layers of overlap are used. Furthermore, the communication cost at each iteration is $O(h^{-1})$ in both cases, and the weakly overlapping approach has the added simplicity of not requiring any trade-off between cost per iteration (i.e., overlap size) and the total iteration count to be considered. Second, when the weakly overlapping approach is applied to an arbitrary decomposition of Ω, the fact that only a single layer of overlap is required at each mesh level makes its implementation extremely straightforward. This is arguably less complex than the implementation of a more standard approach where four (say) layers of elements are required in the overlap, which can be quite cumbersome to calculate on a geometrically complex decomposition.

4. Numerical examples.

In this section we present a small number of two-dimensional numerical examples which demonstrate the efficiency of the preconditioner introduced above. For these examples we make a slight modification to the preconditioner so as to allow the practical parallel generation of the partitioned hierarchical meshes that are required.

In this modified algorithm, once the coarse mesh $\mathcal{T}_0$ has been partitioned into the p nonoverlapping subdomains, Ω_i, p copies of it are made. Copy i is then refined only in $\tilde{\Omega}_{i,k}$ at level k of the refinement process. The continuous piecewise linear finite element spaces on the resulting meshes are then

$$\mathcal{U}_i = \mathcal{W}_0 \cup \tilde{\mathcal{W}}_i \tag{4.1}$$

for $i = 1, \ldots, p$. The following corollary follows immediately from Theorem 3.2.

Corollary 4.1. *Let the spaces $\mathcal{U}_i$ be given by* (4.1) *for $i = 1, \ldots, p$. Then*

$$\mathcal{W} = \mathcal{U}_1 + \cdots + \mathcal{U}_p \tag{4.2}$$

is also a stable decomposition.

The advantages of this approach are outlined in some detail in [4], where it is shown that parallel adaptive mesh generation may be achieved in a well load-balanced manner. The main disadvantage is that one is effectively completing a coarse-mesh solve as part of *each* subspace correction (i.e., p times per iteration) rather than once per iteration. However, in many practical parallel codes (e.g., [22]) the coarse-grid solve is completed sequentially on a single processor anyway, so the overhead of repeating it on all p processors simultaneously is not necessarily that great.

The other minor practical modification that we have made to the preconditioner outlined in the previous section comes from the use of transition (sometimes known as "green" [29]) elements in our meshes in order to keep them conforming. In Figure 1 it may be observed that there are a number of "slave" nodes in the nonuniformly refined mesh which cause the mesh shown to be nonconforming. The solution values at these nodes are not free: they are determined by the nodal values at the ends of the edges on which the slave nodes lie. For a practical implementation it turns out to be much simpler to allow the solution values at these nodes to be free by bisecting the element on the unrefined side of the edge that has the "hanging" node on it. This is the approach that is used in the examples below.

For the first two test problems considered, sequences of uniformly refined meshes, $\mathcal{T}_k$, have been used.

Problem 4.1.

$$\begin{aligned} -\underline{\nabla} \cdot (\underline{\nabla} u) &= f \quad \forall \underline{x} \in \Omega \equiv (0,1) \times (0,1), \\ u &= g \quad \forall \underline{x} \in \partial\Omega. \end{aligned}$$

Problem 4.2.

$$\begin{aligned} -\underline{\nabla} \cdot \left(\begin{pmatrix} 10^2 & 0 \\ 0 & 1 \end{pmatrix} \underline{\nabla} u \right) &= f \quad \forall \underline{x} \in \Omega \equiv (0,1) \times (0,1), \\ u &= g \quad \forall \underline{x} \in \partial\Omega. \end{aligned}$$

In each case f has been chosen to permit the exact solution $u = g$ for a quadratic choice of g.

Tables 1 and 2 show the number of iterations required by both the conventional optimal (as defined by (2.10) and Theorem 2.2) and the new two-level AS preconditioners in order to reduce the 2-norm of the initial residual by a factor of 10^6 for these two problems, respectively. In each case a 256-element coarse mesh has been used and the final fine grids have between 4096 and 1,048,576 elements. The number of subdomains goes from 2 to 16, and for the purposes of these comparisons the local solves on each subproblem are exact (see below for a discussion of this).

Inspection of these tables shows that there is very little to choose between the number of iterations required by the conventional optimal AS preconditioner, with $O(h^{-2})$ elements in the overlap regions, and the new preconditioner, with just $O(h^{-1})$ elements in the overlap regions. This is an important observation since it indicates that the splitting constant, C, is of approximately the same size for the new splitting as for the conventional two-level splitting with a generous overlap. Indeed, it is the significance of this observation that motivates our comparison between the two approaches. Full details of the practical parallel implementation of the preconditioners is beyond the scope of this paper (see [5] for a complete description of our parallel implementation). Nevertheless, the relative timings when using one subdomain per processor are also included in Tables 1 and 2 in order to illustrate the advantages of the weakly overlapping approach. It is noticeable that the significant reduction in the size of the subproblems that must be solved at each iteration of the new algorithm, due to the smaller number of elements in the overlap region, clearly leads to a reduced parallel solution time. Not surprisingly, this reduction becomes more significant the more the mesh is refined.

Table 1

The number of iterations required to reduce the 2-norm of the residual by a factor of 10^6 *using the two different AS preconditioners when solving Problem* 4.1 *using piecewise linear finite elements. Column* 4 *shows the relative speed of the new versus the conventional optimal two-level preconditioner.*

It should also be noted at this point that the results of Tables 1 and 2 do show an increase in the number of iterations required as p, the number of subdomains, is increased (for both versions of the algorithm). This may be accounted for by the fact that n_c increases as p increases from 2 to 8, and that for the relatively small values of p considered here (up to $p = 16$) the asymptotic limit has not yet been reached, even though n_c is at most 5 in all cases. It may be observed, however, that the growth in the number of iterations as p increases is already beginning to slow down as p goes from 8 to 16. Also, the iteration counts for Problem 4.2 are greater than those for corresponding solutions of Problem 4.1. This may be accounted for in the theory of the previous section by noting that the norm equivalence $\mathcal{A}(\cdot,\cdot)^{1/2} \sim \mathcal{H}^1$ will involve a larger ratio of constants in the upper and lower bounds for Problem 4.2 than Problem 4.1.

In practice it is not necessary to solve the subproblems involving the matrices A_i in (2.10) exactly in order to maintain the optimality of the preconditioner. This is discussed in some detail elsewhere (see, for example, [11, 36]) and so we merely comment that our numerical experiments suggest that reducing the residual by a factor of between 10^1 and 10^2 when "solving" these subproblems appears to provide a good balance between allowing a small increase in the total number of iterations and keeping the cost of each iteration as low as possible. For the examples in this section we have applied a preconditioned CG solver with an algebraic preconditioner based upon an incomplete factorization of A_i (see [6, 7], for example).

We conclude this section by demonstrating the effectiveness of the preconditioner for a locally, rather than uniformly, refined mesh.

Problem 4.3.

$$\begin{aligned} -\underline{\nabla}\cdot(\underline{\nabla} u) &= f \quad \forall \underline{x} \in \Omega \equiv (0,1)\times(0,1), \\ u &= g \quad \forall \underline{x} \in \partial\Omega. \end{aligned}$$

In this case f and g are now chosen so that the analytic solution is given by

$$u = (1-(2x_1-1)^{100})(1-(2x_2-1)^{100}) \quad \forall \underline{x} \in \Omega. \tag{4.3}$$

Note that this solution is unity in the interior of Ω but tends to zero very rapidly in a thin layer (of width ≈ 0.02) near to the boundary, allowing the Dirichlet condition $u = 0$ to be satisfied throughout $\partial\Omega$.

When solving this problem we again use a coarse triangulation which contains just 256 elements divided into 2, 4, 8, and 16 subdomains. Note that for this example it is only appropriate to refine the mesh in the boundary layer, where the solution changes from one to zero, and four such sets of results are presented in Table 3 corresponding to 5, 6, 7, and 8 levels of refinement in the layer. (For the purposes of these tests the local refinement of an element is triggered when the exact interpolation error on that element is greater than 10^{-10} (2-norm) unless the element is already at the maximum refinement level.) In each case the coarse mesh $\mathcal{T}_0$ has been partitioned in such a way that the number of elements in the final mesh, $\mathcal{T}_J$, in each subregion is approximately equal. In the cases where $p = 8$ and $p = 16$ this means that there are differing numbers of coarse elements in each subregion (between 8 and 40 when $p = 16$, for example); the partitions into 2 or 4 may be computed more simply, however, using the symmetry of the problem and the coarse mesh (see Figure 7, for example). As with Tables 1 and 2, the results of Table 3 clearly show independence from h for a sufficient level of refinement; however, the independence from p is not yet evident for

the small values considered (up to $p = 16$), although we again see a reduction in the growth of the number of iterations as p increases.

As well as verifying our theoretical results in the case of a locally refined mesh, the last example also illustrates the potential of the technique for use within truly adaptive algorithms based upon a posteriori error estimates and local refinement (see [1, 35], for example). Such algorithms are not without their difficulties, however, since undertaking adaptivity in parallel presents challenging dynamic load-balancing problems (e.g., [32]) which clearly cannot be dealt with using the simple a priori partitioning approach taken above. For one possible means of overcoming these problems we refer the reader to [4], where a paradigm is presented in which the a posteriori error estimates are themselves used to assist with load-balancing. We also note the additional theoretical issue of selecting an appropriate definition for h, the mesh size parameter, for locally refined meshes. While this does not affect the theoretical results presented in this paper, it does have an important bearing on quantitative overhead estimates in terms of the problem size.

5. Extension to three dimensions. So far, for reasons of clarity and simplicity, our discussion has been restricted to problems of the form (1.1)–(1.3) in two dimensions. In this section we demonstrate that both the theoretical results and the practical realization may be successfully generalized to three dimensions. Again we consider problems of the form (1.1)–(1.3), but now we allow $\Omega \subset \mathbb{R}^3$. We will assume that Ω may be covered by a set of tetrahedra, $\mathcal{T}_0$, consisting of N_0 tetrahedral elements $\tau_j^{(0)}$ $(j = 1, \ldots, N_0)$. In order to refine a tetrahedron we use the standard

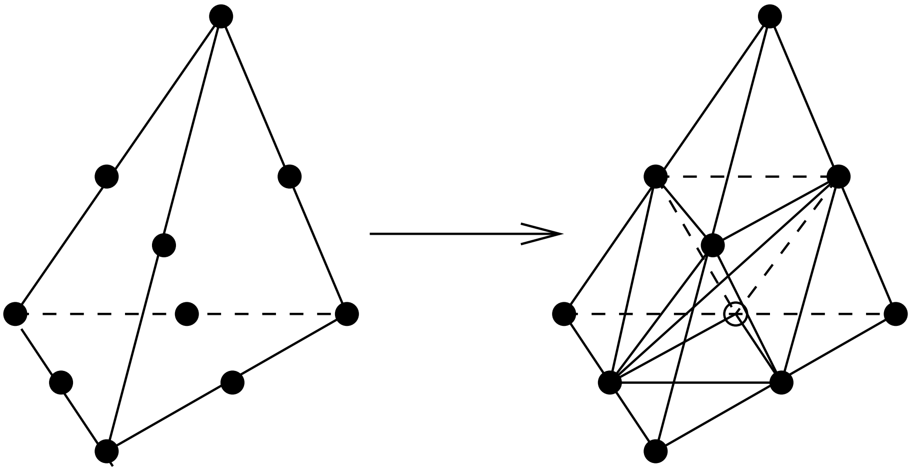

FIG. 8. *Refinement of a tetrahedron into eight children by bisecting each edge.*

approach of bisecting each edge to produce eight children, as shown in Figure 8. Note that although the children are not generally geometrically similar, their aspect ratios are always bounded independently of h. Full details of the refinement algorithm may be found in [31].

Using the above refinement strategy it is possible to generate a family of three-dimensional triangulations, $\mathcal{T}_0, \dots, \mathcal{T}_J$, satisfying the same restrictions as the two-dimensional family introduced in section 3 (with the obvious modification to condition 1(b) for eight children). From this, the spaces $\mathcal{W}$, $\mathcal{W}_{i,k,0}$ $(k = 1, \dots, J)$, and $\hat{\mathcal{W}}_i$, may be defined in the corresponding manner. Algorithm 3.1 therefore also generalizes directly to three dimensions. In fact, it is straightforward to see that, with the exception of the proof of Lemma 3.1, all of the remaining theory in section 3 now generalizes immediately from two to three dimensions. Hence, in order to prove that the corresponding weakly overlapping preconditioner is optimal for tetrahedral meshes in three dimensions, it is sufficient to prove Lemma 3.1 for this case. Such a proof is provided in the appendix.

It should be noted that in three dimensions the number of elements in the overlap regions when using the weakly overlapping algorithm is $O(h^{-2})$ as opposed to $O(h^{-3})$ when a standard generous overlap is used. Similarly, for practical (nonoptimal) two-level AS algorithms with a fixed number of fine mesh layers in the overlap region, the number of elements in the overlap is also $O(h^{-2})$ in three dimensions. We again see therefore that the weakly overlapping approach has approximately the same cost (and communication overhead) per iteration as the practical small overlap two-level algorithms but with the advantage of guaranteed optimality.

Having discussed the generalization of the main theoretical result of this paper to three dimensions we now illustrate this with some further numerical examples. These examples have been chosen to correspond to the two-dimensional examples already considered in the previous section.

PROBLEM 5.1.

$$\begin{aligned} -\underline{\nabla} \cdot (\underline{\nabla} u) &= f \quad \forall \underline{x} \in \Omega \equiv (0,1) \times (0,1) \times (0,1), \\ u &= g \quad \forall \underline{x} \in \partial\Omega. \end{aligned}$$

PROBLEM 5.2.

$$\begin{aligned} -\underline{\nabla} \cdot \left(\begin{pmatrix} 10^2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \underline{\nabla} u \right) &= f \quad \forall \underline{x} \in \Omega \equiv (0,1) \times (0,1) \times (0,1), \\ u &= g \quad \forall \underline{x} \in \partial\Omega. \end{aligned}$$

Here f has again been chosen in each case so as to permit the exact solution $u = g$ throughout Ω.

PROBLEM 5.3.

$$\begin{aligned} -\underline{\nabla} \cdot (\underline{\nabla} u) &= f \quad \forall \underline{x} \in \Omega \equiv (0,1) \times (0,1) \times (0,1), \\ u &= g \quad \forall \underline{x} \in \partial\Omega. \end{aligned}$$

In Problem 5.3, f and g are now chosen so that the analytic solution is given by

$$u = (1 - (2x_1 - 1)^{70})(1 - (2x_2 - 1)^{70})(1 - (2x_3 - 1)^{70}) \quad \forall \underline{x} \in \Omega. \tag{5.1}$$

Table 4 presents iteration counts for Problems 5.1 and 5.2 using the weakly overlapping preconditioner on a coarse grid of 384 elements using between 1 and 4 levels of uniform mesh refinement for a typical set of partitions into 2, 4, 8, and 16 subdomains. It may be observed that the number of iterations is indeed independent of h. Furthermore, as p increases the number of iterations appears to have almost stopped growing by the time $p = 16$.

To solve Problem 5.3 local h-refinement has been used with a slightly larger coarse grid, containing 3072 tetrahedral elements. As in two dimensions the precise choice of partition of this grid is important in terms of both the final load balance and the total numbers of iterations required. Table 5 presents iteration counts for one such set of partitions into 2, 4, 8, and 16 subdomains. Again we see that the number of iterations is almost independent of h already (after just 4 levels of refinement). The partition into 16 for this problem is probably far from optimal (since simple recursive coordinate bisection [34] was used), which may well account for the noticeable jump in iterations between $p = 8$ and $p = 16$. Nevertheless, these simple numerical experiments do show that the weakly overlapping technique can be effectively implemented in three dimensions as well as two.

TABLE 5

6. Discussion.

In this paper we have presented a two-level AS preconditioner based upon a weakly overlapping domain decomposition of a nested sequence of meshes, $\mathcal{T}_0, \ldots, \mathcal{T}_J$. Such a decomposition involves just a single element of overlap at each level of the mesh hierarchy and so requires only $O(h^{-1})$ overlapping elements in total in two dimensions (and $O(h^{-2})$ in three dimensions). It has been demonstrated that, when combined with the full coarse mesh space $\mathcal{W}_0$, the splitting that is induced by this decomposition is stable and therefore leads to an optimal preconditioner. Although the work presented here is for an AS algorithm there is no reason why the same splitting should not also be used in a multiplicative manner. The resulting preconditioner will again be optimal. The extension of this approach to a multilevel algorithm is less interesting, however, since this leads to a standard multilevel Schwarz scheme (see [30] for example), with subdomains chosen to be the same at each level and with the overlap chosen to be minimal at each level. Such schemes are already known to be optimal.

Although the paper concentrates mainly on test problems of the form (1.1)–(1.3) in two dimensions, all aspects of the theory in sections 2 and 3 are extended to three-dimensional problems using nested tetrahedral meshes in section 5. Supporting numerical experiments in both two and three dimensions are also provided. Furthermore, the simplifying assumption of zero Dirichlet boundary conditions throughout $\partial\Omega_E$ may also be dropped, so as to include other Dirichlet conditions or even mixed conditions, without significant modification. Further extensions may also be made within the theoretical framework described by permitting the initial mesh, $\mathcal{T}_0$, to have unequal element sizes. This would therefore allow the use of a different value for H, the size of the elements of the coarse mesh, on each subdomain.

Appendix. Proof of Lemma 3.1 in the three-dimensional case.

Proof. First we introduce the following change of variables:

$$x = H\,r, \qquad y = H\,s, \qquad z = H\,t\,; \qquad (x, y, z) \in \Omega_i. \tag{A.1}$$

Under this transformation the domain Ω_i is the image of a domain Ω_i' whose geometric properties are independent of H in the (r, s, t) plane. Furthermore

$$\begin{aligned}\frac{1}{H^2}\|w_i^h(x,y,z)\|^2_{\mathcal{L}^2(\Omega_i)} &+ |w_i^h(x,y,z)|^2_{\mathcal{H}^1(\Omega_i)}\\ &= H\left(\|w_i^h(r,s,t)\|^2_{\mathcal{L}^2(\Omega_i')} + |w_i^h(r,s,t)|^2_{\mathcal{H}^1(\Omega_i')}\right),\end{aligned} \tag{A.2}$$

and we may define by $Q'_{i,k}$ the projection in the (r,s,t) variables which corresponds to $Q_{i,k}$. From [9] and [26] it follows that there exists $C_2>0$, which is independent of h, H, and p, such that

$$\begin{aligned}
&\frac{1}{H^2}\sum_{k=0}^{J}4^k\|v_{i,k}^h\|^2_{\mathcal{L}^2(\Omega_i)}\\
&\quad=\frac{1}{H^2}\left(\|Q_{i,0}w_i^h(x,y,z)\|^2_{\mathcal{L}^2(\Omega_i)}+\sum_{k=1}^{J}4^k\|(Q_{i,k}-Q_{i,k-1})w_i^h(x,y,z)\|^2_{\mathcal{L}^2(\Omega_i)}\right)\\
&\quad=H\left(\|Q'_{i,0}w_i^h(r,s,t)\|^2_{\mathcal{L}^2(\Omega'_i)}+\sum_{k=1}^{J}4^k\|(Q'_{i,k}-Q'_{i,k-1})w_i^h(r,s,t)\|^2_{\mathcal{L}^2(\Omega'_i)}\right)\\
&\quad\le HC_2\|w_i^h(r,s,t)\|^2_{\mathcal{H}^1(\Omega'_i)}\\
&\quad=C_2\left(\frac{1}{H^2}\|w_i^h(x,y,z)\|^2_{\mathcal{L}^2(\Omega_i)}+|w_i^h(x,y,z)|^2_{\mathcal{H}^1(\Omega_i)}\right).
\end{aligned}\tag{A.3}$$

A second inequality that we require comes from [26], where it is shown that there exists $C_3>0$, which is independent of h, H, and p, such that

$$\begin{aligned}
\|\hat v_i^h(x,y,z)\|^2_{\mathcal{H}^1(\hat\Omega_i)}&=H^3\|\hat v_i^h(r,s,t)\|^2_{\mathcal{L}^2(\hat\Omega'_i)}+H|\hat v_i^h(r,s,t)|^2_{\mathcal{H}^1(\hat\Omega'_i)}\\
&\le HC_3\inf_{\substack{\hat v_i^h=\hat\xi_0+\cdots+\hat\xi_J\\(\hat\xi_k\in\hat{\mathcal{W}}'_{i,k})}}\sum_{k=0}^{J}4^k\|\hat\xi_k\|^2_{\mathcal{L}^2(\hat\Omega'_i)},
\end{aligned}\tag{A.4}$$

where $\hat{\mathcal{W}}'_{i,k}$ is the space which corresponds to $\hat{\mathcal{W}}_{i,k}$ with the change of variables (A.1). From this, along with (3.25) and (A.3), it follows that

$$\begin{aligned}
\|\hat v_i^h(x,y,z)\|^2_{\mathcal{H}^1(\hat\Omega_i)}&\le HC_3\sum_{k=0}^{J}4^k\|\hat v_{i,k}^h\|^2_{\mathcal{L}^2(\hat\Omega'_i)}\\
&=\frac{C_3}{H^2}\sum_{k=0}^{J}4^k\|\hat v_{i,k}^h\|^2_{\mathcal{L}^2(\hat\Omega_{i,k})}\\
&\le\frac{C_0C_3}{H^2}\sum_{k=0}^{J}4^k\|v_{i,k}^h\|^2_{\mathcal{L}^2(\Omega_i)}\\
&\le C_0C_2C_3\left(\frac{1}{H^2}\|w_i^h\|^2_{\mathcal{L}^2(\Omega_i)}+|w_i^h|^2_{\mathcal{H}^1(\Omega_i)}\right),
\end{aligned}\tag{A.5}$$

as required. □

A TRUST-REGION APPROACH TO THE REGULARIZATION OF LARGE-SCALE DISCRETE FORMS OF ILL-POSED PROBLEMS[*]

MARIELBA ROJAS[†] AND DANNY C. SORENSEN[‡]

Abstract. We consider large-scale least squares problems where the coefficient matrix comes from the discretization of an operator in an ill-posed problem, and the right-hand side contains noise. Special techniques known as regularization methods are needed to treat these problems in order to control the effect of the noise on the solution. We pose the regularization problem as a quadratically constrained least squares problem. This formulation is equivalent to Tikhonov regularization, and we note that it is also a special case of the trust-region subproblem from optimization. We analyze the trust-region subproblem in the regularization case and we consider the nontrivial extensions of a recently developed method for general large-scale subproblems that will allow us to handle this case. The method relies on matrix-vector products only, has low and fixed storage requirements, and can handle the singularities arising in ill-posed problems. We present numerical results on test problems, on an inverse interpolation problem with field data, and on a model seismic inversion problem with field data.

1. Introduction.

Discrete forms of ill-posed problems arise when we discretize the continuous operator in an ill-posed problem and introduce experimental data contaminated by noise. One of the main sources of ill-posed problems are inverse problems, where we want to determine the internal structure of a system from the observed behavior of the system. Inverse problems arise in many important applications such as image processing [2], seismic inversion [39], and medical and seismic tomography [30], [32]. Discrete forms of ill-posed problems are usually formulated as linear systems or least squares problems. The focus of this paper is the numerical treatment of large-scale discrete forms of ill-posed least squares problems.

We are interested in recovering x_{LS}, the minimum norm solution of

$$\min_{x \in \mathbb{R}^n} \|Ax - b\|, \tag{1}$$

where $A \in \mathbb{R}^{m \times n}$, $b \in \mathbb{R}^m$, and $m \geq n$. Throughout the paper we assume that A comes from the discretization of a continuous operator in an ill-posed problem, and instead of the *exact* data vector b, only a *perturbed* data vector $\bar{b}$ is available. Specifically, we regard $\bar{b}$ as $\bar{b} = b + s$, where s is a random vector of uncorrelated

noise. The norm is the Euclidean norm throughout the paper, and it will be denoted by $\|\cdot\|$.

We will assume that the matrix A is large and might not be available explicitly but that we can compute the action of A and A^T on vectors of the appropriate dimensions. We will also assume that errors in A, due to discretization or finite-precision representation, are small in comparison to the noise in $\bar{b}$. Finally, we will not assume any particular structure for A.

Given the fact that only $\bar{b}$ is available, we could formulate the problem

$$\min_{x \in \mathbb{R}^n} \|Ax - \bar{b}\| \tag{2}$$

and use its minimum norm solution, denoted by $\bar{x}_{LS}$, to approximate x_{LS}. Unfortunately, as we shall see, the two solutions might differ considerably.

If we use a reasonably accurate discretization to obtain A, this matrix will be highly ill-conditioned with a singular spectrum that decays to zero gradually, a large cluster of small singular values, and high-frequency components of the singular vectors associated with small singular values. If, in addition, the discrete Picard condition [16] holds, we will have that the expansion coefficients of the exact data vector b in the left singular vectors basis decay to zero faster than the singular values of A, while the expansion coefficients of the noise vector s remain constant. Therefore, those components of $\bar{x}_{LS}$ corresponding to small singular values are magnified by the noise.

As a consequence of the ill conditioning of the matrix A and the presence of noise in the right-hand side, standard numerical algebra methods such as the ones discussed in [3], [13, Chap. 5], and [26] applied to problem (2) produce meaningless solutions with very large norm. Therefore, to solve these problems, we need special techniques known as *regularization* or *smoothing methods*. These methods aim to recover information about the desired solution of the unknown problem with exact data from the solution of a better conditioned problem that is related to the problem with noisy data but incorporates additional information about the desired solution. The formulation of the new problem involves a special parameter known as the *regularization parameter*, used to control the effect of the noise on the solution. The conditioning of the new problem depends on the choice of the regularization parameter. Excellent surveys on regularization methods can be found, for example, in [15], [20] and more recently in [31].

While there are many alternatives for solving small- to medium-scale problems, this is not the case in the large-scale setting. However, in recent years interesting methods for large-scale ill-posed problems have been proposed. Among these are Golub and von Matt [14], Björck, Grimme, and Van Dooren [4], Calvetti, Reichel, and Zhang [8], Rojas, Santos, and Sorensen [35], as well as several variants of the conjugate gradient method on the normal equations (CGLS), including the use of preconditioners chosen according to the structure of the problem [22], [24], [29]. In spite of these developments, the efficient solution of large-scale discrete forms of ill-posed problems remains a challenge.

In practice, the most common approach is to apply the conjugate gradient method to the normal equations associated with problem (2), taking advantage of what seems to be an intrinsic regularization property of this method. It has been observed that, at early stages, CGLS generates iterates with components in the direction of right singular vectors associated with *large* singular values, while components associated with small singular values come into play at later stages. This observation leads to the heuristic that the number of iterations acts as a regularization parameter.

Thus, we could compute a regularized solution by stopping the iteration before the unwanted components contaminate the current approximation. The success of this approach depends, in the first place, on the reliability of the heuristic and, second, on accurately determining when to stop the iteration, which is a difficult problem in itself, and most practical termination strategies rely on visual inspection. We are not aware of any systematic termination criterion for this approach. Alternatively, we could use CGLS on the Tikhonov regularization problem, discussed in the next section, which can be formulated as a damped least squares problem. The success of this approach depends on a good choice of the damping parameter, and also on the availability of a preconditioner, and good general preconditioners have not emerged yet. The approach we propose here does not depend on either a heuristic or a preconditioner.

In this paper, we formulate the regularization problem as a quadratically constrained least squares problem. It is well known that this approach is equivalent to Tikhonov regularization (cf. [10] and the references therein), and we also observe that the problem is a special case of the problem of minimizing a quadratic subject to a quadratic constraint, which is known in optimization as the trust-region subproblem arising in trust-region methods (see also [3, sections 5.3 and 9.2.3]). The connection between the trust-region subproblem and the regularization problem is well known, but the specific nature of the numerical difficulties for solving the regularization problem as a trust-region subproblem was first studied extensively in [34]. We discuss the properties of the trust-region subproblem in the regularization case and apply the recently developed method LSTRS [35] for the large-scale trust-region subproblem to the regularization of discrete forms of ill-posed problems from a variety of applications. The method relies on matrix-vector products only, has low and fixed storage requirements and robust stopping criteria, and computes both a solution and the corresponding Tikhonov regularization parameter. Moreover, LSTRS can efficiently handle the high-degree singularities associated with ill-posed problems. Most of the results presented here are based on [34].

The organization of the paper is as follows. In section 2 we describe our regularization approach and show its connection with Tikhonov regularization and with the trust-region subproblem. In section 3 we describe the trust-region subproblem and show its special properties in the discrete ill-posed case. In section 4 we describe the method LSTRS from [35] and discuss the issues related to ill-posed problems. In section 5 we present numerical results of LSTRS on regularization problems, including test problems from the Regularization Tools package [19], an inverse interpolation problem with field data, and a model seismic inversion problem with field data. We present some conclusions in section 6.

2. Regularization through trust regions.

As we mentioned before, regularization involves the formulation of a problem related to both the original problem with exact data and the problem with noisy data, where we incorporate a priori information such as the size or smoothness of the desired solution, the noise level in the data, or the statistical properties of the noise process.

One of the most popular regularization approaches is the classical Tikhonov regularization approach [40]

$$\min_{x\in\mathbb{R}^n} \; \|Ax-\bar{b}\|^2+\varepsilon^2\|x\|^2, \tag{3}$$

where $\varepsilon^2 > 0$ is the regularization parameter, and where the term $\|x\|^2$ could also be of the form $\|Lx\|^2$ for a general square or rectangular matrix L. This matrix could be, for example, the identity matrix as in (3), or a discrete form of first derivative. In the first case, the regularization parameter ε acts as a penalty parameter on the size of the solution, while in the latter case ε acts as a penalty parameter on the smoothness of the solution. Notice that if L is any square and nonsingular matrix, then a change of variable will reduce the problem to the form in (3). We can also accomplish such a transformation when L is a full-rank rectangular matrix by means of the methods in [10], [15]. Throughout the paper we assume that this transformation is possible, and therefore we consider only the case in which L is the identity matrix.

Observe that given ε, problem (3) becomes a damped least squares problem that we can solve with standard numerical linear algebra techniques for medium- and large-scale problems (cf. [3], [13]). However, determining an optimal value for the Tikhonov regularization parameter ε^2 can be as difficult as the original problem, and most of the methods currently available require the solution of several problems of type (3) for different values of ε. This approach might be very expensive in the large-scale setting. Recent and promising methods for computing the Tikhonov regularization parameter for large-scale problems have been proposed in [7], [8], and [25]. Calvetti, Reichel, and Zhang [8] propose a very elegant way of computing the parameter from the noise level in the data; Calvetti, Golub, and Reichel [7] propose a strategy based on the L-curve (see [17], [18]); while Kilmer and O'Leary [25] propose several strategies for computing the parameter from a problem in an appropriate subspace of smaller dimension.

In this work we will not assume a priori knowledge of the noise level or noise properties. Instead, we will assume that some information about the size or smoothness of the desired solution is available, and we formulate the regularization problem as

$$\min_{s.t. \|x\| \leq \Delta} \|Ax - \bar{b}\| \tag{4}$$

with $\Delta > 0$. As we show next, this formulation is equivalent to Tikhonov regularization.

Observe that if $\bar{b} \notin \mathcal{R}(A)$, where $\mathcal{R}(A)$ is the range of A, any solution of problem (4) is a regular point, and therefore the Karush–Kuhn–Tucker conditions for a feasible point x_* to be a solution of problem (4) with corresponding Lagrange multiplier λ_* are $(A^TA - \lambda_* I)x_* = -A^T\bar{b}$, $\lambda_* \leq 0$, and $\lambda_*(\|x_*\| - \Delta) = 0$. Further, since (4) is a convex quadratic problem, these conditions are both necessary and sufficient. Equivalence with problem (3) follows directly, since a solution x_* to problem (4) is also a solution to problem (3) corresponding to $\varepsilon^2 = -\lambda_*$. Conversely, if x_ε is a solution of (3) for a given ε, then x_ε solves problem (4) for $\Delta = \|x_\varepsilon\|$.

While Tikhonov regularization involves the computation of a parameter that does not necessarily have a physical meaning in most problems, the quadratically constrained least squares formulation has the advantage that, in some applications, the physical properties of the problem either determine or make it easy to estimate an optimal value for the norm constraint Δ. This is the case, for example, in image restoration where Δ represents the energy of the target image (cf. [2]).

Another example is the following problem closely related to (4):

$$\min_{s.t. \|Ax - \bar{b}\| \leq \rho} \|x\|,$$

where ρ is an estimate of the noise level in the data. For A nonsingular, the problem can be transformed into the form (4) by means of a change of variable. It is possible to do this in some special applications where an effective approximation to the inverse of A is available. This is the case in the example presented in section 5.3.

An additional advantage of the quadratically constrained least squares formulation is that it is a special case of a well-known problem in optimization, namely, that of minimizing a quadratic on a sphere or the trust-region subproblem

$$\min_{s.t. \|x\| \le \Delta} \frac{1}{2} x^T H x + g^T x, \tag{5}$$

where $H \in \mathbb{R}^{n \times n}$, $H = H^T$, $g \in \mathbb{R}^n$, and $\Delta > 0$. Problem (4) is a special case of (5) when $H = A^T A$ and $g = -A^T \bar{b}$.

The high degree of structure of the trust-region subproblem leads to strong theoretical properties and makes it possible to design efficient solution methods. For this reason we shall formulate the regularization problem as a trust-region subproblem.

3. The trust-region subproblem.

In this section we present the properties of the trust-region subproblem. In section 3.1, we consider the problem when H is any symmetric matrix in $\mathbb{R}^{n \times n}$, and g is any vector in $\mathbb{R}^n$. In section 3.2, we focus on the special case when $H = A^T A$, $g = -A^T \bar{b}$, and in addition A is a discretized version of a continuous operator in an ill-posed problem and $\bar{b}$ contains noise.

3.1. Structure of the problem.

A first observation about the trust-region subproblem is that it always has a solution. A not-so-obvious and quite remarkable fact about the problem is the existence of a characterization of its solutions, discovered independently by Gay [11] and Sorensen [36]. The result is contained in the following lemma.

LEMMA 3.1 (see [36]). *A feasible vector $x_* \in \mathbb{R}^n$ is a solution to* (5) *with corresponding Lagrange multiplier λ_* if and only if x_*, λ_* satisfy $(H - \lambda_* I)x_* = -g$ with $H - \lambda_* I$ positive semidefinite, $\lambda_* \le 0$, and $\lambda_*(\Delta - \|x_*\|) = 0$.*

Proof. See [36] for the proof. □

The optimality conditions imply that all the solutions of the trust-region subproblem are of the form $x = -(H - \lambda I)^\dagger g + z$ for $z \in \mathcal{N}(H - \lambda I)$, where $\mathcal{N}(\cdot)$ denotes the null space of a matrix and † denotes pseudoinverse. These solutions may lie in the interior or on the boundary of the set $\{x \in \mathbb{R}^n \mid \|x\| \le \Delta\}$. There are no solutions on the boundary if and only if H is positive definite and $\|H^{-1}g\| < \Delta$ (see [28]). In this case, the unique interior solution is $x = -H^{-1}g$ with Lagrange multiplier $\lambda = 0$. Boundary solutions satisfy $\|x\| = \Delta$ with $\lambda \le \delta_1$, where δ_1 is the smallest eigenvalue of H. The case $\lambda = \delta_1$ can only occur if $\delta_1 \le 0$, $g \perp \mathcal{S}_1$, where $\mathcal{S}_1 \equiv \mathcal{N}(H - \delta_1 I)$, and $\|(H - \delta_1 I)^\dagger g\| \le \Delta$. This corresponds to the so-called *hard case*, which poses great difficulties for the numerical solution of the trust-region subproblem since in this case it is necessary to compute an approximate eigenvector associated with the smallest eigenvalue of H. Moreover, in practice g will be nearly orthogonal to $\mathcal{S}_1$, and we can expect greater numerical problems in this case. We call this situation a *near hard case.* Note that whenever g is nearly orthogonal to $\mathcal{S}_1$ there is the possibility for the hard case or near hard case to occur. Therefore we call this a *potential hard case.* We show in section 3.2 that the potential hard case is precisely the common case for discrete ill-posed problems.

The conditions in Lemma 3.1 are computationally attractive since they provide a means for reducing the problem of computing boundary solutions for the trust-region subproblem from an n-dimensional problem to a zero-finding problem in one variable. We can accomplish this, for example, by solving the following equation in λ, known as the *secular equation*:

$$\Delta - \|x_\lambda\| = 0, \tag{6}$$

where $x_\lambda = -(H - \lambda I)^{-1}g$, and λ is monitored to ensure that $H - \lambda I$ is positive definite. Newton's method is particularly efficient for solving an equation equivalent to (6), and this approach, due to Moré and Sorensen [28], is the method of choice whenever it is affordable to compute the Cholesky factorization of matrices of the form $H - \lambda I$. However, in some applications this computation may be prohibitive either because of storage considerations or because the matrix H is not explicitly available. Therefore, we need other strategies to treat the problem in those cases. We describe one such strategy in section 4.

3.2. Discrete ill-posed trust-region subproblem.

We now study the trust-region subproblem in the special case when $H = A^TA$ and $g = -A^T\bar{b}$, where A comes from the discretization of a continuous operator in an ill-posed problem, and $\bar{b}$ contains noise. We will show that the potential hard case is the common case for these problems and also that it will occur in a *multiple* instance, where g is orthogonal to the eigenpaces associated with several of the smallest eigenvalues of H. This was first shown in [34] and is a consequence of the following result.

LEMMA 3.2. *Let $H = A^TA$ and $g = -A^T\bar{b}$, with $\bar{b} = b + s$. Suppose σ_k is the kth largest singular value of A with multiplicity m_k. Suppose u_j, v_j, $1 \le j \le m_k$, are left and right singular vectors associated with σ_k. Then*

$$g^Tv_j = -\sigma_k(u_j^Tb + u_j^Ts)\ ,\quad 1 \le j \le m_k.$$

Proof. The result follows directly assuming $A = U\Sigma V^T$ is a singular value decomposition of A, since this yields $g = -V\Sigma U^T\bar{b}$ with V orthogonal. □

Since $H = A^TA = V\Sigma^2V^T$, we see that for discrete ill-posed problems, the hard case is always present in an extreme form. Lemma 3.2 implies that whenever σ_k is very small then, for any reasonable noise level in $\bar{b}$, g will be nearly orthogonal to the subspace spanned by the right singular vectors associated with σ_k. This is precisely the case in discrete ill-posed problems, where the matrix A has a large cluster of very small singular values, and therefore we can expect g to be nearly orthogonal to the right singular vectors associated with such singular values. Since these vectors are eigenvectors corresponding to the smallest eigenvalues of A^TA, then g will be orthogonal to the eigenspaces corresponding to several of the smallest eigenvalues of A^TA and the potential hard case will occur in a *multiple* instance. Figure 1 illustrates this situation for problem **foxgood** from the Regularization Tools package by Hansen [19]. The problem is of dimension 300, and in the logarithmic plot we observe that g^Tv_k is of order 10^{-15} for approximately 292 of the right singular vectors of A.

Observe that for large noise level and σ_k not so small, g will not be nearly orthogonal to the eigenspace corresponding to the smallest eigenvalue of A^TA and the hard case will not occur. Therefore, in this case a high noise level implies a less difficult trust-region subproblem. However, we do not expect to compute a good approximation in the presence of large noise.

4. LSTRS for discrete ill-posed problems.

In this section we give a brief description of the method LSTRS from [35]. We present the method for a general symmetric matrix H and nonzero vector g and discuss the advantages of using this method for the special case of large-scale discrete ill-posed trust-region subproblems of type (4). LSTRS is based on formulating the trust-region subproblem as a parameterized eigenvalue problem. Such formulation comes from the observation that

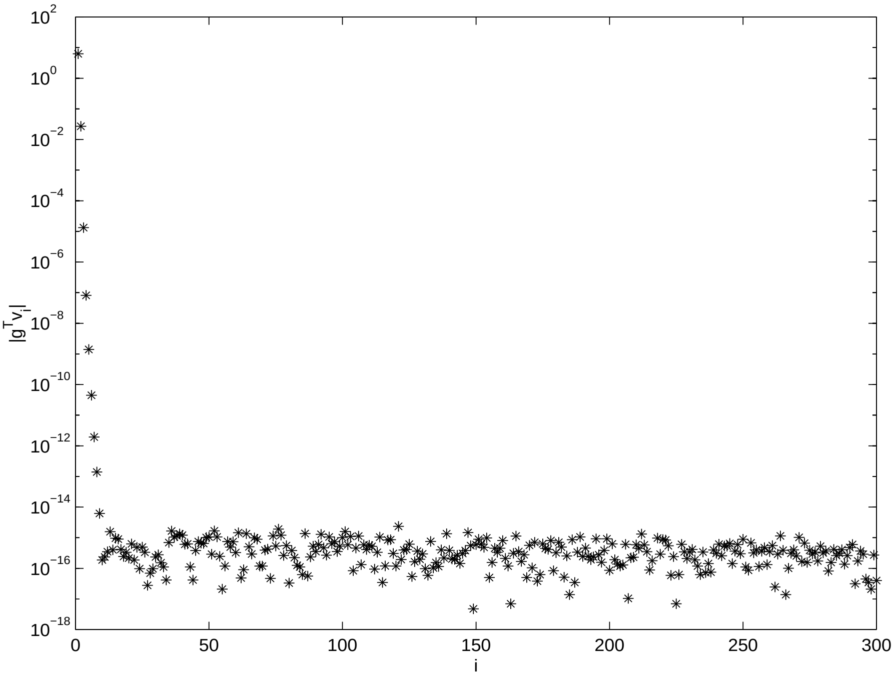

Fig. 1. *Orthogonality of g with respect to right singular vectors of a discretized operator in an ill-posed problem.*

if x_*, λ_* solve problem (5), then for $\alpha = \lambda_* - g^T x_*$, problem (5) is equivalent to

$$\begin{array}{rl} \min & \frac{1}{2} y^T B_\alpha y \\ \text{s.t.} & y^T y \le 1 + \Delta^2, \ e_1^T y = 1, \end{array} \tag{7}$$

where e_1 is the first canonical unit vector in $\mathbb{R}^{n+1}$ and $B_\alpha = \left(\begin{smallmatrix} \alpha & g^T \\ g & H \end{smallmatrix}\right)$. The solution of the trust-region subproblem consists of the last n components of the solution of problem (7).

Problem (7) suggests that if we know the optimal value for α, we can solve the trust-region subproblem by solving an eigenvalue problem for the smallest eigenvalue of B_α and an eigenvector with special structure. To see this, observe that if $\{\lambda, (1, x^T)^T\}$ is an eigenpair of B_α, then

$$\begin{pmatrix} \alpha & g^T \\ g & H \end{pmatrix} \begin{pmatrix} 1 \\ x \end{pmatrix} = \begin{pmatrix} 1 \\ x \end{pmatrix} \lambda,$$

which is equivalent to

$$\alpha - \lambda = -g^T x \quad \text{and} \quad (H - \lambda I)x = -g \ . \tag{8}$$

If λ is the smallest eigenvalue of B_α and since the eigenvalues of H interlace the eigenvalues of B_α by the Cauchy interlace theorem (cf. [33]), then $H - \lambda I$ is positive semidefinite. Therefore, two of the optimality conditions in Lemma 3.1 are automatically satisfied in this case. If, in addition, $\lambda \le 0$ and $\|x\| = \Delta$, we will have a solution for the trust-region subproblem.

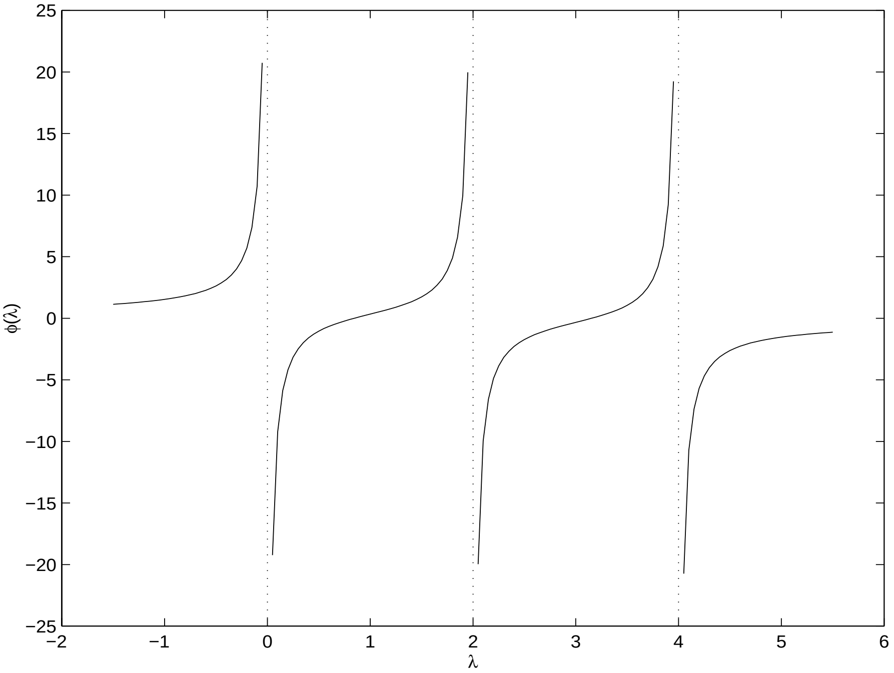

FIG. 2. *Secular function* $\phi(\lambda)$.

LSTRS consists of iteratively adjusting the parameter α to drive it towards the optimal value $\alpha_* = \lambda_* - g^T x_*$. This is accomplished in the following way. Let $\phi(\lambda) = -g^T x$ for x satisfying $(H - \lambda I)x = -g$, and note that $\phi'(\lambda) = x^T x$. Both ϕ and ϕ' are rational functions with poles at a subset of the eigenvalues of H. Figure 2 illustrates the typical behavior of $\phi(\lambda)$ when H is a 3×3 matrix with eigenvalues $0, 2, 4$. The LSTRS iteration is based on approximately solving the secular equation (6), using rational interpolation on ϕ and ϕ'. Observe that, in view of (8), we can obtain convenient interpolation points by solving eigenvalue problems for the smallest eigenvalue of B_α for different values of the parameter α. LSTRS computes the interpolation points in this way, using the implicitly restarted Lanczos method (IRLM) [37] as implemented in ARPACK [27] to solve the eigenvalue problems. The IRLM has fixed storage requirements and relies upon matrix-vector products only, features that make it suitable for large-scale problems.

The strategy described above works as long as the smallest eigenvalue of B_α has a corresponding eigenvector that can be safely normalized to have first component one. The adjustment of the parameter becomes very difficult in the hard case and near hard case since in these situations the smallest eigenvalue of B_α might not have a corresponding eigenvector with the desired structure (see [34], [35], [38]). Moreover, in the near hard case δ_1 is a weak pole of $\phi(\lambda)$ and the function becomes very steep around this value, as Figure 3 illustrates. This makes the interpolation problem very ill-conditioned. The situation is considerably more difficult for ill-posed problems where *several* of the smallest eigenvalues of H are weak poles of $\phi(\lambda)$. We illustrate this case in Figure 4 which shows $\phi(\lambda)$ for the test problem to be discussed in section 5.3. LSTRS relies on the complete characterization of the hard case given in [34] to proceed with the iteration even when the desired eigenvector cannot be normalized

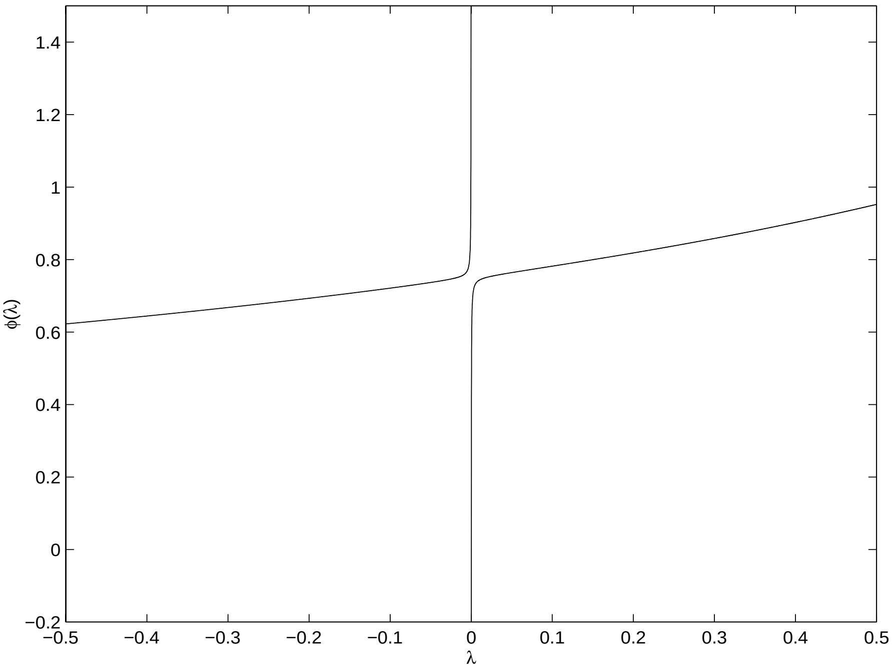

FIG. 3. $\phi(\lambda)$ *in the near hard case.*

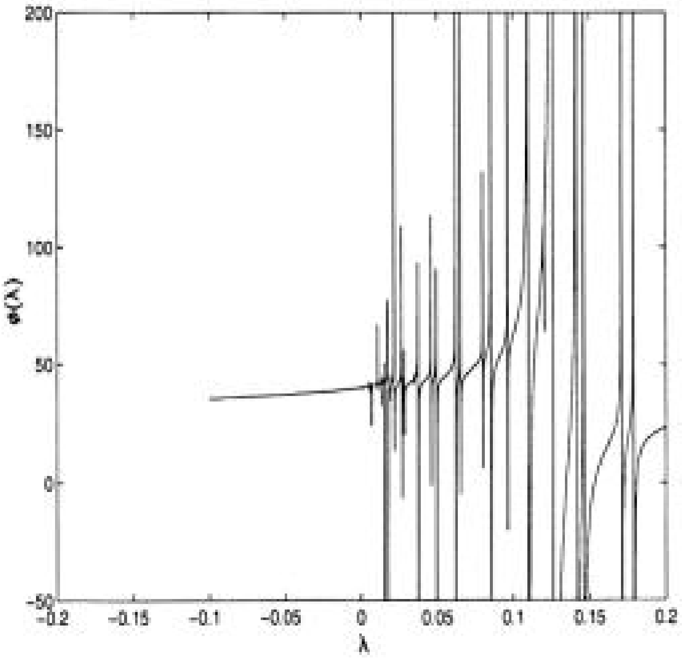

FIG. 4. $\phi(\lambda)$ *for the viscoacoustic wave equation,* $n = 500$.

to have first component one, and to compute nearly optimal solutions in any instance of the hard case including *multiple* occurrences as in ill-posed problems.

A detailed description of the results concerning the hard case and the elaborate algorithmic techniques derived from those results are beyond the scope of this paper. We refer the reader to [34] and [35] for more details.

From the above presentation we see that LSTRS has desirable features for solving large-scale trust-region subproblems in general, and for handling discrete ill-posed problems in particular. This is not surprising since the regularization of discrete forms of ill-posed problems was part of the motivation for developing the method. There are, however, some issues that must be taken into account when implementing LSTRS to treat ill-posed problems. As we saw in section 2, for these problems the smallest eigenvalues of H are clustered and close to zero, and because of the interlacing property the smallest eigenvalues of B_α will also be clustered and small for certain values of Δ. Computing a clustered set of small eigenvalues with a method that relies only on matrix-vector products with the original matrix is likely to fail since the multiplication will annihilate components precisely in the direction of the eigenvectors of interest. This difficulty may be overcome through the use of a spectral transformation. Instead of trying to find the smallest eigenvalue of B_α directly, we work with a matrix function $T(B_\alpha)$ and use the fact that $B_\alpha q = q\lambda \iff T(B_\alpha)q = qT(\lambda)$. If we are able to construct T so that $|T(\lambda_1)| \gg |T(\lambda_j)|,\ j > 1$, then a Lanczos-type method such as the IRLM will converge much faster towards the eigenvector q_1 corresponding to λ_1. We use a Chebyshev polynomial T_ℓ of degree ℓ constructed to be as large as possible on λ_1 and as small as possible on an interval containing the remaining eigenvalues of B_α. Convergence of IRLM is often greatly enhanced through this spectral transformation strategy. After convergence, the eigenvalues of B_α are recovered via the Rayleigh quotients with the converged eigenvectors.

Finally, the occurrence of an interior solution when $H = A^T A$ is positive definite in regularization problems deserves a special comment. In this case the solution of the trust-region subproblem corresponds to the least squares solution of the original problem. This solution is contaminated by noise and is of no interest. When we detect an interior solution we have taken the simple approach of reducing the trust-region radius and restarting the method. It is worth noting that if we knew that the noise level in the data was low, then if λ is close to zero when we detect an interior solution, we could approximate the least squares solution by x satisfying (8) since this would be a reasonable approximation to $x = -H^{-1}g$. Note that in this case it would not be necessary to solve a linear system to obtain the solution.

5. Numerical results.

In this section we present numerical experiments to illustrate the performance of LSTRS on regularization problems from different sources, including both test problems and real applications. We used a MATLAB version of LSTRS running under MATLAB 5.3 using Mexfile interfaces to access ARPACK [27] and also the routines to compute matrix-vector products in some of the examples. Notice that the capabilities of ARPACK have been incorporated into MATLAB 6 and are now available through the routine `eigs`. We ran our experiments on a SUN Ultrasparc 2 with a 200 MHz processor and 256 Megabytes of RAM running Solaris 5.6. The floating point arithmetic was IEEE standard double precision with machine precision $2^{-52} \approx 2.2204 \cdot 10^{-16}$.

We present three sets of experiments. In section 5.1 we describe the results obtained on test problems from the Regularization Tools package [19]. In section 5.2 we present an inverse interpolation problem with field data. In section 5.3 we present

a model seismic inversion problem using a standard data set. The various stopping tolerances on $\frac{|\|x\|-\Delta|}{\Delta}$ were chosen (as they often are in practice) in an ad hoc fashion after some trial runs.

5.1. Problems from the Regularization Tools package. In this section we will present the results of LSTRS on problems from the Regularization Tools package [19]. This package consists of a set of MATLAB routines for the analysis of discrete ill-posed problems along with test problems that are easy to generate. All the test problems come from the discretization of a Fredholm integral equation of the first kind

$$\int_a^b K(s,t)f(t)dt = g(s),$$

and the problem is to compute the unknown function $f(t)$ given $g(s)$ and $K(s,t)$.

In all cases we solved a quadratically constrained least squares problem (4) where A came from the discretization of the kernel $K(s,t)$ and $b = g(s_i)$ at discrete points $s_i \in [a,b]$, where $i = 1,\ldots,n$ and n is the dimension of the problem. For some of the problems the exact solution $f(t)$ was available and in those cases we used $x_{IP} = f(t_i)$ for comparison purposes, where $t_i \in [a,b]$, $i = 1,\ldots,n$. Note that in general Ax_{IP} is different from b. Unless otherwise specified, we used $\Delta = \|x_{IP}\|$ as trust-region radius. In ARPACK, we used nine Lanczos basis vectors with seven shifts on each implicit restart. The required accuracy for the eigenpairs was 10^{-2}. The initial vector for the Lanczos factorization was a randomly generated vector that remained fixed in all the experiments. We solved the trust-region subproblems to a relative accuracy of $|\frac{\|x\|-\Delta}{\Delta}| < 10^{-2}$. We also solved the problems to a higher accuracy but this was computationally more expensive and did not seem to improve the accuracy of the regularized solution x with respect to the exact solution x_{IP} for this particular set of problems. In Table 1, we present the results for a subset of problems from [19].

Several observations are in order concerning Table 1. The third and fourth columns indicate that in all cases LSTRS solved the trust-region subproblem to the prescribed accuracy. The quality of the regularized solution or a measure of how well this solution approximates the exact solution x_{IP} is reported in the fifth column, where a dash indicates that x_{IP} was not available. We see that, generally, there is a reasonable agreement between computed and exact solutions, with relative errors of order 10^{-2}. The number of matrix-vector products is reported in column six, and the last column shows the number of LSTRS iterations.

The primary purpose of these tests was simply to verify that our approach would compute reasonably accurate regularized solutions to well-known examples of discrete forms of ill-posed problems. We cannot draw any conclusions about computational cost or expected number of matrix-vector products from these small examples. However, our limited experience would indicate that the number of matrix-vector products does not increase significantly with the dimension of the problem, and we give examples of this in sections 5.2 and 5.3.

Finally, we remark that some modifications probably would have been possible to improve the accuracy of the computed solutions to this set of examples. For problems ill-conditioned **heat** (inverse heat equation) and **ilaplace** (inverse Laplace transformation), the relative error is probably higher than one would like. It turns out that in these cases the solutions are highly oscillatory. This suggests that we should have solved the trust-region subproblem with a constraint of the form $\|Lx\|$, where L is a discrete form of first derivative. Since our goal here was a basic verification of LSTRS on such problems, we did not analyze each case separately, nor did we pursue more elaborate formulations.

5.2. An inverse interpolation problem. The two-dimensional (2-D) linear interpolation problem consists of using a linear interpolant to find the values of a function at arbitrary points given the values of the function at equally spaced points. A more interesting problem is the inverse interpolation problem: finding the values of the function on a regular grid of points from which we can extract given values of the function at irregularly spaced points by linear interpolation. We can pose the 2-D inverse interpolation problem as a least squares problem,

$$\min_{x \in \mathbb{R}^n} \|Ax - b\|,$$

where $A \in \mathbb{R}^{m \times n}$ is the 2-D linear interpolant and $b \in \mathbb{R}^m$ contains the function values at irregularly spaced points.

To illustrate the performance of LSTRS on this kind of problem we will use the example of constructing a depth map of the Sea of Galilee on a regular grid of points, given depth measurements at irregularly spaced points. The data consists of triplets $v_i,\ w_i,\ b_i, i = 1, \dots, 132044$, representing coordinates on the plane and depth, respectively. The data was collected from a ship using an echo sounder. The data contains noise coming from different sources, including malfunctioning equipment that reported zero depths at points in the middle of the lake and the fact that the measurements were taken at different times of the year and therefore varied greatly from rainy season to dry season. See [1] for a complete description of the data acquisition process. In Figure 5 we show a view from above of a three-dimensional (3-D) plot of the original data. The straight lines we observe in the figure are the tracks of the ship. Therefore, the data acquisition process was an additional source of noise. As Clærbout points out [9], an image of the sea should not include those lines.

In our experiments the size of the grid was $n = 201 \times 201 = 40401$, which is also the number of unknowns when the 2-D grid is represented as a one-dimensional vector. The number of rows in A was $m = 132044$. This matrix was ill-conditioned and was not available explicitly, but we could compute the action of A and A^T on vectors by means of FORTRAN routines. In all the experiments, we solved the trust-region subproblems to a relative accuracy of $|\frac{\|x\|-\Delta}{\Delta}| \leq 10^{-3}$. The size of the Lanczos basis was five, and we applied three shifts on each implicit restart. Therefore, the storage requirement was essentially five vectors of length 40401.

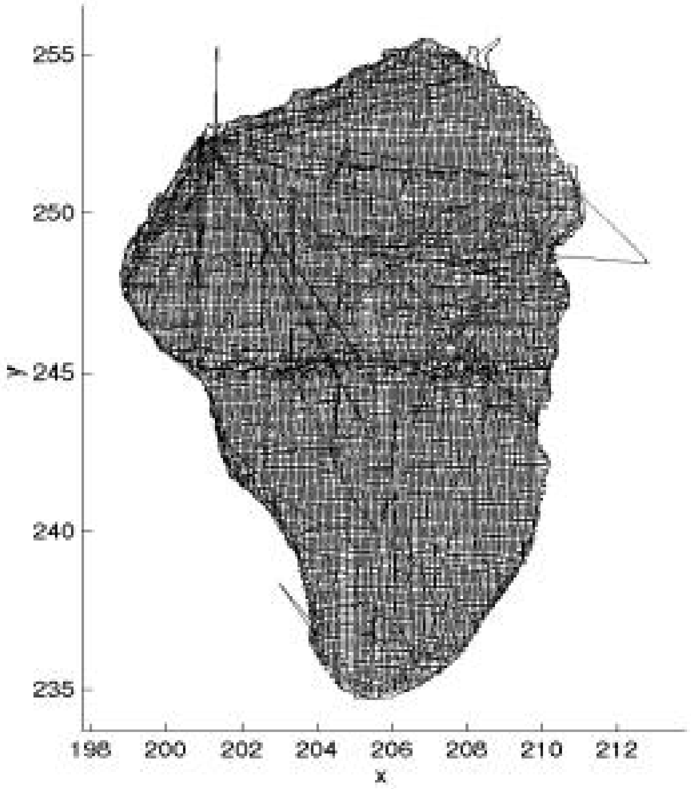

FIG. 5. *Sea of Galilee from original data.*

We posed the trust-region subproblem as

$$\min_{s.t. \|Lx\| \leq \Delta} \frac{1}{2} x^T A^T A x - (A^T b)^T x,$$

where L was either the $n \times n$ identity matrix I, or the matrix M_p, a discretization of the following pth power of the (scaled) 2-D Helmholtz operator

$$(\mathcal{I} - \nabla^T * \text{diag}(s) * \nabla)^p, \tag{9}$$

where $\mathcal{I}$, ∇, and ∇^T are the identity, gradient, and divergence operators, respectively; the vector $s > 0$ is a 2-D vector of scales; the expression diag(s) denotes a diagonal matrix with the components of the vector s on the diagonal; and p is a real scalar.

We ran several experiments for different trust-region radii since in this application we did not have a priori information about the size or smoothness of the desired solution. Figure 6 shows the result for $\Delta = 6000$ and $L = I$. This image still shows the tracks of the ship and does not reveal any known features of the depth distribution of the lake. The contour plot (not shown) is very rough with highly oscillatory contours. This suggested the need to introduce a constraint on the smoothness of the solution.

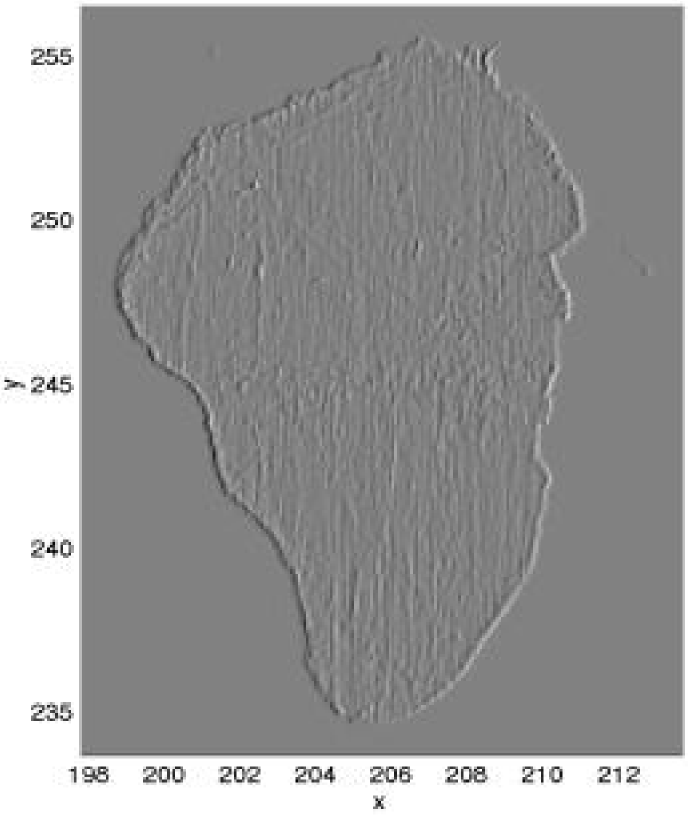

FIG. 6. *Sea of Galilee, regularizing with constraint on size of solution.*

We then solved the trust-region subproblem with $L = M_p$, a discretization of (9), and $\Delta = 26000$. Figure 7 shows the solution for $p = 0.3$. In this image we were able to identify some of the features reported in [1], such as the shallow areas in the northeast, a scarp in the southeast, and a more prominent scarp in the southwest.

We also tried the approach of solving the trust-region subproblem with $L = I$ and applying the Helmholtz operator a posteriori. We call this approach *postsmoothing.* We tried the postsmoothing approach with $p = -1$ for $\Delta = 23423$, which is the norm of x when $\|M_p x\| = 26000$, and we obtained an image very similar to the one in Figure 7. We also used this approach for $\Delta = 6000$, obtaining the image in Figure 8, which clearly shows the features mentioned before. Table 2 shows that the postsmoothing approach is less expensive than using a constraint on the smoothness. There are two reasons for this difference in efficiency. The first one is that the matrix-vector products when $L = M_p$ are more expensive than the matrix-vector products when $L = I$. The second reason is that the smallest eigenvalues of B_α are close to the smallest eigenvalues of $L^{-T}A^TAL^{-1}$, and these are more clustered for $L = M_p$ than for $L = I$. This causes slow convergence of the IRLM. We note, however, that the cost is not too high in either approach relative to the dimension of the problem.

The postsmoothing approach has the drawback that we do not know its physical meaning, and a closer look at the result shows that the postsmoothing is causing a high degree of perturbation on the depths since the lowest point is known to be around

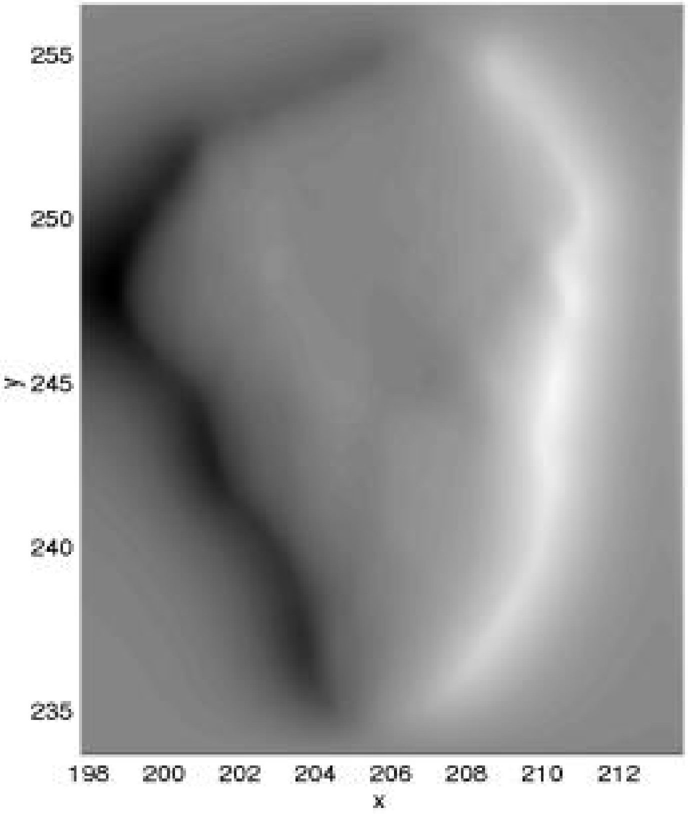

FIG. 7. *Sea of Galilee, regularizing with constraint on smoothness.*

256m below sea level, and the lowest point in Figure 8 is -45m. Another interesting aspect of this particular regularization approach is that it produces very smooth solutions, which was also noted in [21], and this causes, for example, the resulting regular grid to miss the true deepest point located approximately at coordinates $(207, 247)$ and yields a deepest point located at approximately $(205, 245)$ for Figure 8. It is quite remarkable, though, how the known features of the lake are clearly present in this image.

5.3. A model seismic inversion problem. We also solved the quadratically constrained least squares problem (4) where the problem comes from the discretization of the linear viscoacoustic model. As explained in [6], this model describes the behavior of an anelastic fluid, in which the strain response to a change of stress is linear but not completely instantaneous. A relaxation function $G(t, \vec{x})$ is used to express the stress-strain relation. The equations of motion relate $G(t, \vec{x})$, the material density $\rho(\vec{x})$, the pressure (stress) $p(t, \vec{x})$, the particle velocity $\vec{v}(t, \vec{x})$, and the body force source $f(t, \vec{x})$ in the following way:

$$\begin{aligned} p_{,t}(t, \vec{x}) &= -\dot{G}(t, \vec{x}) * \nabla \cdot \vec{v}(t, \vec{x}) + f(t, \vec{x}), \\ \vec{v}_{,t}(t, \vec{x}) &= -\frac{1}{\rho(\vec{x})} \nabla p(t, \vec{x}), \end{aligned} \tag{10}$$

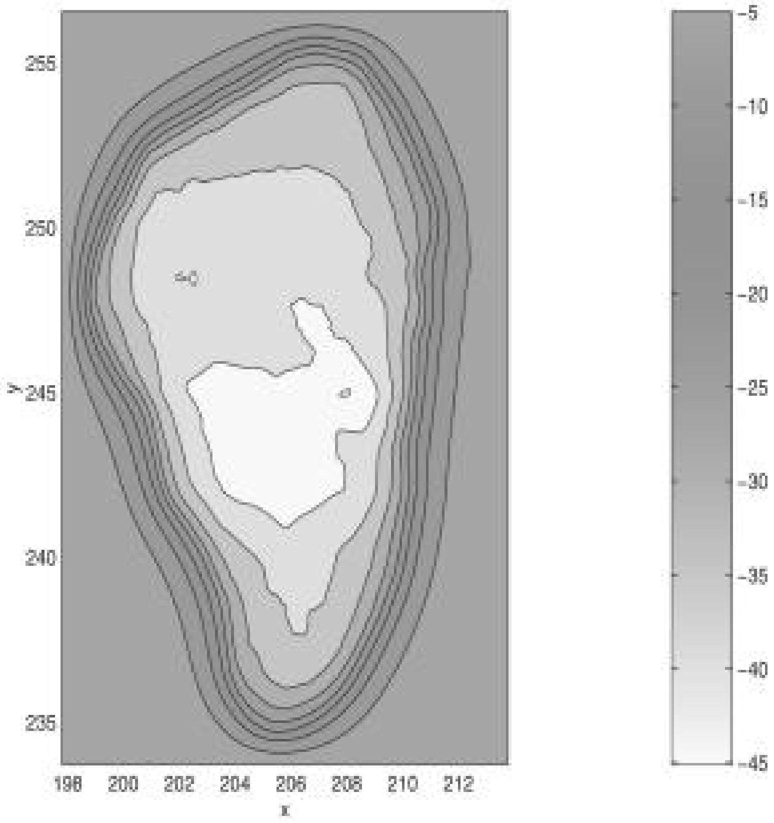

FIG. 8. *Sea of Galilee, regularizing with constraint on size of solution and postsmoothing.*

TABLE 2
Performance of LSTRS on an inverse interpolation problem.

Dimension: 40401 Storage: 5 vectors	Δ	$\|x_*\|$	LSTRS Iter.	MV Prods.	CPU time (min.)

where $p = 0,\ \vec{x} = 0$ for $t \ll 0$. In (10), t denotes time and $\vec{x}$ denotes position.

These equations are used in [6] to model the propagation of waves in marine media using the relaxation function for a standard linear fluid. The matrix A in our quadratically constrained least squares problem corresponds to DF, a linearized version of the forward map or prediction operator. The matrix A^T corresponds to the adjoint of DF denoted by DF^*. The operators DF and DF^* were not explicitly available, but their action on vectors was obtained by solving a simplified (layered) and linearized version of (10). See [5, Chap. 5] and [6] for more details. The data vector $\bar{b}$ is a seismogram containing velocities of waves measured in oil wells in the North Sea. The data is part of the Mobil AVO data set [23], a standard data set for testing inversion methods. The parameters to be estimated in the experiment are the

Table 3
Performance of LSTRS on the viscoacoustic wave equation.

Dimension	Δ	$\|x\|$	LSTRS Iter.	MV Prods.	Storage
121121	0.5	0.5	2	15	4 vectors

stress-strain ratio under simple hydrostatic pressure and the material density. The quadratically constrained least squares problems arise in the context of sophisticated nonlinear inversion strategies [12], where the norm constraint was of the form $\|x\| \leq \Delta$. The quadratically constrained least squares problems were obtained from problems of type

$$\min_{s.t. \|Ax-\bar{b}\| \leq \rho} \|x\|$$

by means of a change of variable made possible by the availability of an effective approximation to the inverse of A. The parameter ρ is an estimate of the noise level in $\bar{b}$ and is known a priori in this case. The reformulation of the problem yields $\Delta = \rho$.

The dimensions of the problem are $m = n = 121121$. Table 3 shows the result obtained when we used LSTRS to solve the trust-region subproblem to an accuracy of $|\frac{\|x\|-\Delta}{\Delta}| < 10^{-5}$ using four Lanczos basis vectors. The method is very efficient for small Δ since in this case the smallest eigenvalue of B_α is well separated from the rest and the IRLM converges rapidly to such eigenvalue. For larger Δ, the eigenvalue of interest belongs to a cluster and the IRLM needs more iterations to compute it.

In Table 3 we can observe the low storage and low number of matrix-vectors products required to solve the problem to a very high accuracy.

6. Conclusions.

We considered the problem of regularizing large-scale discrete forms of ill-posed problems arising in several applications. We posed the regularization problem as a quadratically constrained least squares problem, showed the relationship of this approach to Tikhonov regularization and to the trust-region subproblem, and analyzed the latter in the ill-posed case.

We have presented numerical results obtained when we used the recently developed method LSTRS for the large-scale trust-region subproblem to solve regularization problems from a wide variety of applications including problems with field data. The method requires solving a sequence of large-scale eigenvalue problems, which is accomplished with a variant of the Lanczos method. An important feature of LSTRS is that it computes both the solution and the Tikhonov regularization parameter from the prescribed norm.

LSTRS is particularly suitable for large-scale discrete forms of ill-posed problems, for which it computed regularized solutions close to the desired exact solutions using limited storage and moderate computational effort in general. For real applications the method required a low number of matrix-vector products with respect to the dimension of the problem, and storage comparable to or less than the conjugate gradient method. Our approach also had the desirable feature of providing systematic stopping criteria.

We are currently investigating various approaches to preconditioning, aiming to generate eigenvalue problems that can be solved more efficiently. Although further improvement is needed, LSTRS proved to be a promising method for the numerical treatment of large-scale discrete forms of ill-posed problems in which the norm of the desired solution is prescribed.

Acknowledgments. We would like to thank Chao Yang for making his MATLAB code for the Chebyshev spectral transformation available to us. We thank Ricardo von Borries for his help in recovering what seemed to be a hopelessly lost illustration. We would also like to express our deep gratitude to Bill Symes who provided us with the data codes for the 2-D linear interpolant and interpretation of the results in section 5.2. Bill also provided the model seismic problem in section 5.3 and the AVO data set. We also thank Professor Zvi Ben-Avraham from Tel-Aviv University for making the data of the Sea of Galilee available and for providing important references. Finally, we would like to thank the two anonymous referees for their careful reading of the original manuscript, and for their valuable and relevant suggestions, which helped improve the original version of this paper.

HIDDEN DISCONTINUITIES AND PARAMETRIC SENSITIVITY CALCULATIONS*

JOHN E. TOLSMA[†] AND PAUL I. BARTON[†]

Abstract. Parametric sensitivity analysis is becoming a very important tool when studying differential equations. However, potential pitfalls exist if this analysis is applied naively. In particular, if the model contains discontinuities, then the application of standard numerical codes will typically result in incorrect sensitivity trajectories. The purpose of this paper is to demonstrate the problems associated with "hidden discontinuities" during sensitivity analysis (i.e., discontinuities not handled explicitly) and to present a code analysis and transformation approach through which differential equations containing discontinuities can be solved efficiently and correctly with minimal effort required by the modeler.

Key words. hybrid discrete/continuous simulation, parametric sensitivity analysis, differential-algebraic equations, automatic differentiation, state events, DAEPACK

1. Introduction and motivation.

Parametric sensitivity analysis is used to obtain information concerning state variable variations with respect to infinitesimal perturbations in the values of model parameters. Some common applications for parametric sensitivity analysis are experimental design, model reduction, and obtaining gradients and Jacobians in control parameterization approaches for dynamic optimization and parameter estimation. The advent of better algorithms for computing forward sensitivities allows this calculation to be performed on much larger and more complex systems [14, 7]. However, potentially serious problems exist if parametric sensitivity analysis is applied to dynamic models containing discontinuities. These problems are addressed in this paper by considering models containing discontinuities within a hybrid systems framework.

Hybrid discrete/continuous systems (or simply hybrid systems) are dynamical systems that exhibit both discrete and continuous behavior. The continuous behavior of the model is usually described by one or more ordinary differential equation (ODE) or differential-algebraic equation (DAE) systems. The discrete behavior, which occurs at particular points in time known as events, includes phenomena such as nonsmooth forcing, switching of the vector field, and jumps in the state. We can broadly distinguish between two types of events: time events and state events. A time event is an event where the time of occurrence is known a priori. In contrast, a state event occurs when some condition involving the state variables is satisfied (e.g., the level of liquid in a tank reaches a certain height), and the time of occurrence is in general not known a priori.

Hybrid system models appear in a wide variety of disciplines. They appear directly when modeling discrete control actions imposed on a system (e.g., a safety interlock system), disturbances introduced into a continuous system, cell signaling

models, and certain electrical circuit models. In the examples above, the state events and the discontinuities they introduce are an important feature of the phenomena of interest, and it is well known that special action must be taken to simulate such systems [12, 2, 15]. In other, seemingly continuous examples, *hidden discontinuities* can have adverse effects because the special measures mentioned above are not taken. These discontinuities are typically introduced by modeling abstractions; e.g., physical properties of fluids are often represented by piecewise smooth semiempirical relationships. Within a code these may appear as nonsmooth intrinsic functions, such as MIN and MAX, as well as the more obvious IF statements. The problem with models where the discrete behavior is not of primary interest is that often these discontinuities are not handled explicitly (i.e., they remain "hidden" in the code), and the error control mechanism of the integrator is relied on to deal with them. It is well known that numerically integrating systems containing hidden discontinuities is inefficient and sometimes results in integration failures [12]. In the worst case, ignoring discontinuities can lead to incorrect results that may escape the modeler's attention [6]. The situation is far worse and not yet documented in the literature for parametric sensitivity analysis of systems containing hidden discontinuities. Because the sensitivities will often jump at the discontinuities, if the numerical integration is not stopped and the jump computed explicitly [8], the computed sensitivity trajectories will generally be incorrect.

The purpose of this paper is to illustrate the implications of performing parametric sensitivity analysis of systems containing hidden discontinuities and describe automatic techniques that can be applied to code in order to perform parametric sensitivity analysis with hybrid systems correctly.

2. Formalism.

The following hybrid system formalism, adopted from [1, 8], will be used in this paper. State space is divided into a set of modes, $S = \cup_{k=1}^{n_m} S_k$, where each mode S_k is characterized by the following:

1. A set of variables $\{\dot{x}^{(k)}(p,t), x^{(k)}(p,t), y^{(k)}(p,t), u^{(k)}(p,t), p, t\}$, where $x^{(k)}(p,t)$, $\dot{x}^{(k)}(p,t)$ are the differential variables and their time derivatives, which are functions of p and t in an $n_x^{(k)}$-dimensional function space, $y^{(k)}(p,t)$ are the algebraic variables, which are functions of p and t in an $n_y^{(k)}$-dimensional function space, $u^{(k)}(p,t)$ are the controls (or inputs), which are functions of p and t in an $n_u^{(k)}$-dimensional function space, $p \in \mathbb{R}^{n_p}$ are the time invariant parameters, and $t \in \mathbb{R}$ is time, the independent variable.
2. A set of equations, $f^{(k)}(\dot{x}^{(k)}, x^{(k)}, y^{(k)}, u^{(k)}, p, t) = 0$, where $f^{(k)} : \mathbb{R}^{n_x^{(k)}} \times \mathbb{R}^{n_x^{(k)}} \times \mathbb{R}^{n_y^{(k)}} \times \mathbb{R}^{n_u^{(k)}} \times \mathbb{R}^{n_p} \times \mathbb{R} \longrightarrow \mathbb{R}^{n_x^{(k)}} \times \mathbb{R}^{n_y^{(k)}}$.
3. A set of transitions from one mode to another (possibly the same mode), $J^{(k)}$, where each transition is characterized by the following:
   (a) Transition conditions $L_j^{(k)}(\dot{x}^{(k)}, x^{(k)}, y^{(k)}, u^{(k)}, p, t)$, $j \in J^{(k)}$, defining the transition times.
   (b) Transition functions $T_j^{(k)}(\dot{x}^{(k+1)}, x^{(k+1)}, y^{(k+1)}, u^{(k+1)}, \dot{x}^{(k)}, x^{(k)}, y^{(k)}, u^{(k)}, p, t) = 0$, $j \in J^{(k)}$, a system of equations that maps the final values of the variables in the current mode to the initial values in the next mode. (Initial conditions are a special case of these transition functions.) The number of transition functions is determined by the dynamic degrees of freedom of the DAE in the new mode.

It is assumed that the transition conditions, $L_j^{(k)}(\dot{x}^{(k)}, x^{(k)}, y^{(k)}, u^{(k)}, p, t)$, are logical expressions composed of one or more real-valued relational expressions involving relational operators <, ≤, >, or ≥. For example, the logical expression $(x_1 \geq 5) \vee (x_2 > 2 \wedge x_2 \leq 5)$ contains the relational expressions $x_1 \geq 5$, $x_2 > 2$, and $x_2 \leq 5$. Putting these relational expressions into the form

$$g \geq (>) 0 \tag{2.1}$$

defines *discontinuity functions.* The logical proposition of the transition condition may switch value when one or more discontinuity functions cross zero. A switching event is defined by the earliest time at which one of the transition conditions becomes true. Of course, a model may contain more general logical conditions (e.g., integral expressions or expressions involving the equality operator), and these are described below.

This paper focuses on the case where

$$\operatorname{rank}\begin{pmatrix} \dfrac{\partial f^{(k)}}{\partial \dot{x}^{(k)}} & \dfrac{\partial f^{(k)}}{\partial y^{(k)}} \end{pmatrix} = n_x^{(k)} + n_y^{(k)} \tag{2.2}$$

for all k and t. This is sufficient for a differentiation index less than or equal to one.

3. Algorithm. Several approaches have been developed for hybrid simulation, ranging from modifying the integrator itself to detect and handle discontinuities [9] to replacing the discrete aspects of the model with smooth approximations. The approach used in this work is based on the algorithm described in [15]. In this approach, the DAE of the current mode, $f^{(k)}$, is augmented with the discontinuity functions associated with the mode's transition conditions, $L_j^{(k)}$, $j \in J^{(k)}$. For example, let $g_{l,j}^{(k)} : \mathbb{R}^{n_x^{(k)}} \times \mathbb{R}^{n_x^{(k)}} \times \mathbb{R}^{n_y^{(k)}} \times \mathbb{R}^{n_u^{(k)}} \times \mathbb{R}^{n_p} \times \mathbb{R} \longrightarrow \mathbb{R}$ denote the lth discontinuity function of transition condition $L_j^{(k)}$, $j \in J^{(k)}$, where $l = 1, \dots, n_{d,j}^{(k)}$ (where $n_{d,j}^{(k)}$ is the number of discontinuity functions in the jth transition condition). The augmented DAE in mode S_k is given by

$$F^{(k)}(\dot{x}^{(k)}, x^{(k)}, y^{(k)}, \delta^{(k)}, u^{(k)}, p, t) = \begin{pmatrix} f^{(k)} \\ \delta^{(k)} - g^{(k)} \end{pmatrix}, \tag{3.1}$$

where $g^{(k)}$ denotes the vector of the discontinuity functions of all transition conditions in the current mode and $\delta^{(k)}$ is the vector of *discontinuity variables.* Augmenting the original DAE with these additional explicit equations (referred to as *discontinuity equations*) places the discontinuity functions under integration error control. The additional variables added for the discontinuity equations, $\delta^{(k)}$, are algebraic variables and may be appended to the original algebraic variable vector:

$$y \equiv \begin{pmatrix} y \\ \delta \end{pmatrix}.$$

Although including the discontinuity equations increases the size of the model, because the system block decomposes, very little additional computational effort is required to integrate the system [15]. Condition (2.2) along with the assumption the discontinuity functions do not contain time derivatives of y ensures

$$\operatorname{rank}\begin{pmatrix} \dfrac{\partial F^{(k)}}{\partial \dot{x}^{(k)}} & \dfrac{\partial F^{(k)}}{\partial y^{(k)}} \end{pmatrix} = n_x^{(k)} + n_y^{(k)}, \tag{3.2}$$

for all k, where $x^{(k)}$ and $y^{(k)}$ are the differential and algebraic variables, respectively, of the augmented system. (That is, $n_y^{(k)}$ includes the additional discontinuity variables.)

At each integration step, the interpolating polynomials associated with the discontinuity variables are searched for zero crossings using root exclusion tests based on interval arithmetic. If an integrator based on the predictor-corrector method is employed, these interpolating polynomials will, in general, be readily available. Otherwise, polynomials can be fitted to the discontinuity variables during the integration. Using a root exclusion test based on interval arithmetic is efficient and guarantees that the correct transition time (i.e., the earliest) will be identified. The transition time is *polished*, and consistent states are determined by solving the DAE augmented with the discontinuity function triggering the event. (The transition time computed from the interpolating polynomials may not be sufficiently close to the true transition time, resulting in "discontinuity sticking" where the event just found is immediately triggered again [15]. Consequently, the value obtained from the interpolation must be polished by augmenting the DAE with the discontinuity function which triggered the event and solving this augmented system for t^*, $\dot{x}^{(k)}$, $x^{(k)}$, and $y^{(k)}$ where t^* is "close" to the actual transition time.) The model is then switched into the next mode, where the new DAE system is consistently initialized using the appropriate transition function and integration is resumed.

The situation is slightly more complicated when performing parametric sensitivity analysis with hybrid systems. In the kth mode, the augmented DAE and sensitivity equations form an $(n_x^{(k)} + n_y^{(k)})(n_p + 1)$ system given by

$$\begin{aligned}
&F^{(k)}(\dot{x}^{(k)}, x^{(k)}, y^{(k)}, u^{(k)}, p, t) = 0, \\
&\frac{\partial F^{(k)}}{\partial \dot{x}^{(k)}} \dot{s}_{x,1} + \frac{\partial F^{(k)}}{\partial x^{(k)}} s_{x,1} + \frac{\partial F^{(k)}}{\partial y^{(k)}} s_{y,1} = -\left(\frac{\partial F^{(k)}}{\partial u^{(k)}} \frac{\partial u^{(k)}}{\partial p_1} + \frac{\partial F^{(k)}}{\partial p_1} \right), \\
&\vdots \\
&\frac{\partial F^{(k)}}{\partial \dot{x}^{(k)}} \dot{s}_{x,n_p} + \frac{\partial F^{(k)}}{\partial x^{(k)}} s_{x,n_p} + \frac{\partial F^{(k)}}{\partial y^{(k)}} s_{y,n_p} = -\left(\frac{\partial F^{(k)}}{\partial u^{(k)}} \frac{\partial u^{(k)}}{\partial p_{n_p}} + \frac{\partial F^{(k)}}{\partial p_{n_p}} \right),
\end{aligned} \tag{3.3}$$

where $s_{x,i}^{(k)} \equiv \partial x^{(k)}/\partial p_i$, $s_{y,i}^{(k)} \equiv \partial y^{(k)}/\partial p_i$, and $\dot{s}_{x,i}^{(k)} = \partial s_{x,i}^{(k)}/\partial t = \partial \dot{x}^{(k)}/\partial p_i$. Although this system may be quite large, algorithms exist that exploit the structure for efficient solution [14, 7].

In addition to computing consistent initial values for $\dot{x}$, x, and y in the new mode, jumps in the sensitivities must also be computed. However, as shown in [8], these jumps can be readily computed by differentiating the original DAE, discontinuity function, and transition functions associated with the transfer of the state into the new mode. The sensitivity of the transition time with respect to parameter p_i is given by

$$\begin{aligned}
&\frac{\partial \tilde{g}_{k+1}^{(k)}}{\partial \dot{x}^{(k)}} \left(\dot{s}_{x,i}^{(k)} + \ddot{x}^{(k)} \frac{\partial t}{\partial p_i} \right) + \frac{\partial \tilde{g}_{k+1}^{(k)}}{\partial x^{(k)}} \left(s_{x,i}^{(k)} + \dot{x}^{(k)} \frac{\partial t}{\partial p_i} \right) + \frac{\partial \tilde{g}_{k+1}^{(k)}}{\partial y^{(k)}} \left(s_{y,i}^{(k)} + \dot{y}^{(k)} \frac{\partial t}{\partial p_i} \right) \\
&\quad + \frac{\partial \tilde{g}_{k+1}^{(k)}}{\partial u^{(k)}} \left(\frac{\partial u^{(k)}}{\partial p_i} + \frac{\partial u^{(k)}}{\partial t} \frac{\partial t}{\partial p_i} \right) + \frac{\partial \tilde{g}_{k+1}^{(k)}}{\partial p_i} + \frac{\partial \tilde{g}_{k+1}^{(k)}}{\partial t} \frac{\partial t}{\partial p_i} = 0,
\end{aligned} \tag{3.4}$$

where $\tilde{g}_{k+1}^{(k)}$ is the discontinuity function that triggers the event. The equation above is solved for $\partial t/\partial p_i$. The required elements of $\dot{x}$, $\dot{y}$, and $\ddot{x}$ in the equation above can be computed from the first and higher order derivatives of the DAE. The jump in sensitivities can then be computed by solving the following linear system:

$$
\begin{aligned}
&\begin{bmatrix} \frac{\partial T^{(k)}_{k+1}}{\partial \dot{x}^{(k+1)}} & \frac{\partial T^{(k)}_{k+1}}{\partial x^{(k+1)}} & \frac{\partial T^{(k)}_{k+1}}{\partial y^{(k+1)}} \\ \frac{\partial F^{(k+1)}}{\partial \dot{x}^{(k+1)}} & \frac{\partial F^{(k+1)}}{\partial x^{(k+1)}} & \frac{\partial F^{(k+1)}}{\partial y^{(k+1)}} \end{bmatrix}
\begin{bmatrix} \frac{\partial \dot{x}^{(k+1)}}{\partial p_i} \\ \frac{\partial x^{(k+1)}}{\partial p_i} \\ \frac{\partial y^{(k+1)}}{\partial p_i} \end{bmatrix} \\
&= - \begin{bmatrix} \frac{\partial T^{(k)}_{k+1}}{\partial \dot{x}^{(k+1)}} & \frac{\partial T^{(k)}_{k+1}}{\partial x^{(k+1)}} & \frac{\partial T^{(k)}_{k+1}}{\partial y^{(k+1)}} \\ \frac{\partial F^{(k+1)}}{\partial \dot{x}^{(k+1)}} & \frac{\partial F^{(k+1)}}{\partial x^{(k+1)}} & \frac{\partial F^{(k+1)}}{\partial y^{(k+1)}} \end{bmatrix}
\begin{bmatrix} \frac{\partial \dot{x}^{(k+1)}}{\partial t} \\ \frac{\partial x^{(k+1)}}{\partial t} \\ \frac{\partial y^{(k+1)}}{\partial t} \end{bmatrix} \frac{\partial t}{\partial p_i} \\
&\quad - \begin{bmatrix} \frac{\partial T^{(k)}_{k+1}}{\partial \dot{x}^{(k)}} & \frac{\partial T^{(k)}_{k+1}}{\partial x^{(k)}} & \frac{\partial T^{(k)}_{k+1}}{\partial y^{(k)}} & \frac{\partial T^{(k)}_{k+1}}{\partial u^{(k)}} & \frac{\partial T^{(k)}_{k+1}}{\partial u^{(k+1)}} & \frac{\partial T^{(k)}_{k+1}}{\partial p_i} & \frac{\partial T^{(k)}_{k+1}}{\partial t} \\ 0 & 0 & 0 & 0 & \frac{\partial F^{(k+1)}}{\partial u^{(k+1)}} & \frac{\partial F^{(k+1)}}{\partial p_i} & \frac{\partial F^{(k+1)}}{\partial t} \end{bmatrix} \\
&\quad \times \begin{bmatrix} \frac{\partial \dot{x}^{(k)}}{\partial p_i} + \frac{\partial \dot{x}^{(k)}}{\partial t}\frac{\partial t}{\partial p_i} \\ \frac{\partial x^{(k)}}{\partial p_i} + \frac{\partial x^{(k)}}{\partial t}\frac{\partial t}{\partial p_i} \\ \frac{\partial y^{(k)}}{\partial p_i} + \frac{\partial y^{(k)}}{\partial t}\frac{\partial t}{\partial p_i} \\ \frac{\partial u^{(k)}}{\partial p_i} + \frac{\partial u^{(k)}}{\partial t}\frac{\partial t}{\partial p_i} \\ \frac{\partial u^{(k+1)}}{\partial p_i} + \frac{\partial u^{(k+1)}}{\partial t}\frac{\partial t}{\partial p_i} \\ I \\ \frac{\partial t}{\partial p_i} \end{bmatrix}.
\end{aligned}
\tag{3.5}
$$

Additional details about the transfer of sensitivities at state events, including formal existences proofs, are presented in [8].

The hybrid system parametric sensitivity analysis algorithm can be summarized with the pseudocode shown in Figure 1.

A large amount of additional information must be provided by the modeler when using the algorithm described above. First, the modeler must be able to lock the model into the current mode so that the integrator always evaluates a smooth function. For example, if the model code contains IF statements, then the conditional branching must be locked to the current mode, regardless of the values of the logical expressions associated with the IF statements. Second, all of the discontinuity functions contained in the model code must be identified and put into an explicit form. Finally, additional partial derivative information other than that required for smooth integration must be provided (e.g., partial derivatives with respect to discontinuity functions and transition functions). Requiring the modeler to provide this information is a great burden, a reason that contributes greatly to why discontinuities are typically not handled explicitly. However, this additional information can be generated automatically with minimal user intervention using code analysis and transformation techniques similar to those used in automatic differentiation. The paragraphs below describe how this information can be generated when the original model is coded in the form of a program written in some procedural programming language such as C or Fortran.

Automatic, or algorithmic, differentiation (AD) is a technique for obtaining values for analytical derivatives of functions, usually in the form of a computer program (e.g., a collection of one or more subroutines and functions written in C or Fortran). AD is based on applying the chain-rule to the sequence of elementary operations involved in the computation of the dependent variables from the independent variables. (Several

variants of AD exist depending on the how the chain-rule is applied.) The original code is then modified and augmented (either by generating new code or using the *operator overloading* features of many modern programming languages) with additional code to perform the chain-rule operations and compute the values of the partial derivatives of the dependent variables with respect to the independent variables. A detailed description of AD is beyond the scope of this paper, and additional information can be found in [16, 10, 3, 11].

AD tools that generate new code for derivative computation analyze the original source code to identify the dependence of the dependent variables on the independent variables, apply the chain-rule to the elementary operations, and construct new code that computes derivatives of the elementary operations and *accumulates* values of the partial derivatives of the dependent variables. The code analysis and transformation techniques used to construct new code for derivative evaluation can also be extended to generate a wide variety of information, in particular the information required for performing the algorithm for parametric sensitivity analysis of hybrid systems described above. The original source is analyzed and searched for discontinuities. The source is then augmented with additional code that records the current mode. For example, if an IF statement is identified in the original source, then the new code records the current clause of this IF statement (i.e., whether the logical expression evaluates to true or false) and records this value in a bit vector. Similarly, if a non-smooth intrinsic function (e.g., MIN and MAX) is identified, then the currently active branch is recorded in the bit vector. On subsequent model evaluations, the bit vector is analyzed to determine the conditional branching followed on previous evaluations, and this is used to determine the current discrete mode, rather than the actual values of the logical expressions associated with IF statements and other

discontinuities. Using a bit vector to record the current mode typically results in very little additional memory and computational cost required to perform a *locked* model evaluation. In addition to recording the current mode, the original source can also be modified to evaluate the discontinuity functions in the model and augment the original DAE with the discontinuity equations shown in (3.1). To reiterate, all of this can be performed automatically with minimal user intervention. As mentioned above, the transition conditions may contain logical expressions other than real-valued relational expressions (the expressions used to construct discontinuity functions). Although discontinuity functions are not created for these types of logical expressions (e.g., $t = 0$ and $i > 4$ where i is an integer), the new code can be modified to return a flag indicating events containing these types of transition conditions have been triggered. However, unlike events caused solely by zero crossings of discontinuity functions, these other events will be identified only at mesh points in the numerical integration. Once the new model, augmented with the discontinuity equations and modified to allow for locked model evaluations, has been generated, standard AD techniques can be applied to generate the derivatives required for hybrid sensitivity analysis.

The approach described above has been implemented in a software library called DAEPACK [18, 17]. The DAEPACK library consists of two parts: components for analyzing general Fortran code and generating automatically new code for evaluating analytical derivatives, sparsity patterns, discontinuity-locked models, etc. and numeric components which exploit the automatically generated information for performing numerical calculations efficiently, robustly, and correctly. Figure 2 contains a diagram showing the additional code required for hybrid parametric sensitivity analysis generated automatically from the users code representing the original hybrid DAE model. Figure 3 contains a diagram showing how this automatically generated code is used with other DAEPACK numerical components for performing a hybrid parametric sensitivity calculation.

This section describes an automated technique for computing the parametric sensitivities of a hybrid system by explicitly handling the events and transfer of states and sensitivities across these events. Alternatively, the user may compute the sensitivities of a hybrid system by finite differences. For example, using forward finite differences, the sensitivity of a state variable, e.g., $x(t, p)$, at $t = t^*$ is approximately

the difference between this point on the trajectory evaluated at p and this point on the trajectory evaluated at $p + \delta p$, divided by δp. That is,

$$s(t^*, p) \equiv \frac{\partial x(t^*, p)}{\partial p} \approx \frac{x(t^*, p + \delta p) - x(t^*, p)}{\delta p}.$$

There are, however, a number of problems with this. First, the numerical integration of the hybrid system must be performed reliably. If special provisions must be taken to ensure correct hybrid simulation (such as the approach described above), then the additional work required to transfer the sensitivities at the event should be performed. Other problems are cost and accuracy. In order to compute the sensitivity trajectories with respect to n_p parameters, $n_p + 1$ numerical integrations must be performed. Furthermore, each of these integrations should be performed with identical stepsize histories [13]. If an adaptive stepsize algorithm is used, then this can be quite a difficult modification to a third-party library code. Also, the user must ensure that the stepsize history selected is appropriate for each of the $n_p + 1$ integrations. Even if this is done, all the problems associated with computing partial derivatives of algebraic functions with finite differences exist, including selection of appropriate perturbation and loss of accuracy due to round-off error. If the numerical integrations are not performed with same stepsize history, then they must be performed at a much higher tolerance than the accuracy desired in the sensitivities. As described in [13], the error in the finite difference approximated sensitivities due to truncation error is $O(|\delta p|)$, and the error due to the fact the integration is performed with limited accuracy is $O(\epsilon/|\delta p|)$, where δp is the parameter perturbation and ϵ is the numerical integration tolerance. Consequently, if we desire sensitivity trajectories with accuracy δ, we must perform each of the n_p+1 numerical integrations with accuracy δ^2. Unfortunately, the presence of discontinuities in the hybrid system may limit the accuracy of the numerical integration due to calculation failures unless these events are handled explicitly. Even if the numerical integrations can be performed reliably, the tighter tolerances required can significantly increase the cost of the overall calculation. These issues are illustrated with a numerical example in the following section.

The following section contains example problems illustrating the implications of ignoring discontinuities during sensitivity calculation and how the calculation is performed properly using DAEPACK.

4. Examples. This section contains two example problems illustrating the approach described above. The ideas presented in this paper were implemented in the software library DAEPACK [18]. DAEPACK is divided into two main libraries, one containing components that generate automatically symbolic information (e.g., analytical derivatives and sparsity patterns) from Fortran source code and another containing numerical components which exploit this symbolic information. In particular, DAEPACK contains a component that analyzes the user's Fortran source code representing a hybrid system model and writes new code that computes the discontinuity functions and allows the user to perform locked model evaluations. In addition, a component is provided which analyzes Fortran source code and constructs new code for evaluating partial derivatives using AD. The user must simply provide a list of the dependent and independent variables. Three numerical codes in DAEPACK of interest in this paper are DSL48S, DSL48E, and DSL48SE. DSL48S is a large-scale, sparse DAE integrator based on DASSL [4] and employs the parametric sensitivity analysis algorithm described in [7]. DSL48E implements the state event location algorithm described in [15]. DSL48SE combines both DSL48S and DSL48E and computes automatically the sensitivity jump at the state events. All of the information required to perform the hybrid sensitivity calculation properly can be generated with DAEPACK. All the user must provide is the Fortran source code representing the hybrid system model of interest.

The first example is a single ODE where the transition condition, $x^3-5x^2+7x \leq p$, is a function of the time invariant parameter p:

$$\dot{x} = \begin{cases} 4-x & : \quad x^3-5x^2+7x \leq p, \\ 10-2x & : \quad \text{otherwise}, \end{cases} \tag{4.1}$$

where $p = 2.9$. This model was coded into a Fortran subroutine using a normal IF statement to represent the discontinuity. The symbolic components of DAEPACK were applied to this Fortran model to generate new code for the discontinuity-locked model and all of the necessary derivatives. The parametric sensitivity calculation was performed twice, once using only DSL48S (where the discontinuity was hidden) and a second time using DSL48SE to handle properly the discontinuity. The initial condition for this model is

$$x(0) = 0.$$

The transfer functions for this hybrid system are simply $x^{(2)} - x^{(1)} = 0$. Figure 4 shows the state variable, x, and sensitivity trajectories for both cases. Clearly, the sensitivity is wrong (quantitatively and qualitatively) if the discontinuity is not handled properly. In fact, the incorrect sensitivity in Figure 4 would seem to indicate that x is not sensitive at all to the value of p, which it clearly is. Unfortunately, this model is solved without an apparent problem when the discontinuity is ignored; thus, the incorrect sensitivity can easily escape the modeler's attention.

Suppose the user wishes to compute the hybrid sensitivities using finite differences (see the discussion in the previous section). Further, suppose the user naively performs the numerical integrations using an integration tolerance of 10^{-6}. Figure 5 contains a plot of three sensitivity trajectories for the hybrid ODE (4.1) in the vicinity of the first event. The solid line in Figure 5 (the trajectory with a clear "jump") is the sensitivity trajectory computed using the approach described in this paper and has an accuracy of 10^{-6}. The dashed line below this trajectory was computed using finite differences with a parameter perturbation of 10^{-5}. The dotted line above the solid lined trajectory was computed using finite differences with a parameter perturbation

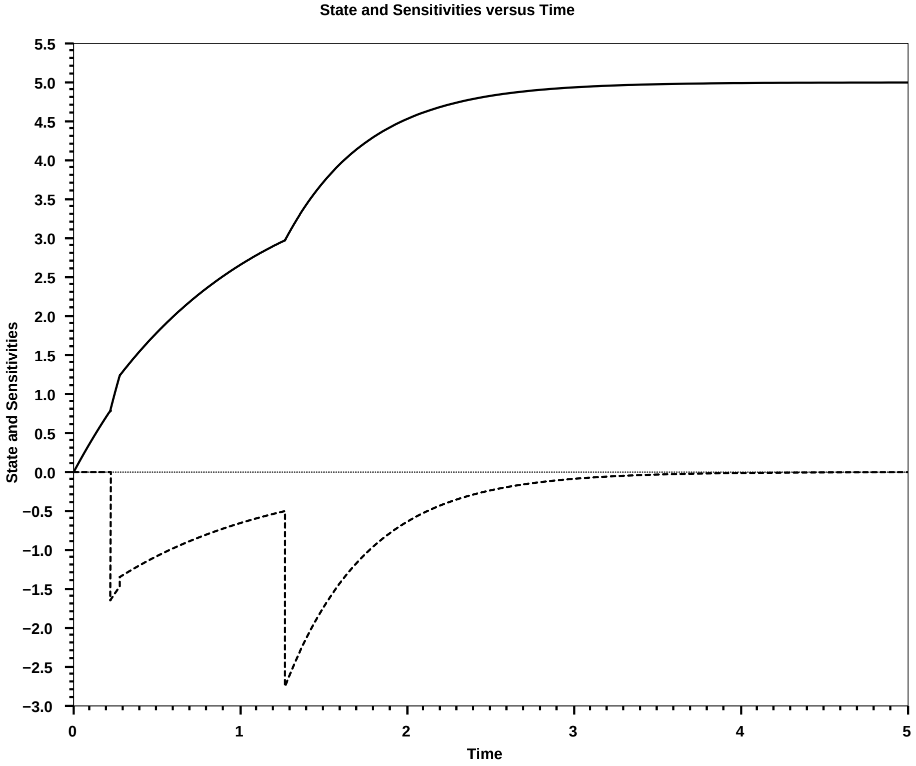

FIG. 4. *State and sensitivity trajectories for Example* 1. *The heavy solid line is the state trajectory, the thin dotted line is the sensitivity trajectory computed with hidden discontinuities, and the dashed line exhibiting jumps is the true sensitivity trajectory.*

of 10^{-4}. Notice that in both of the finite difference trajectories, a sharp, but smooth, transient is computed rather than a jump. The duration of this transient is equal to the shift in time of the event caused by the perturbation of the parameter. Figure 6 contains a plot of the differences between the sensitivity trajectory computed using the approach described in this paper and the trajectories computed by finite differences with various parameter perturbations. (All integrations were performed with a tolerance of 10^{-6}.) The thin solid line is the difference in the finite difference trajectory computed using a parameter perturbation of 10^{-6}. The dashed line is the difference in the finite difference trajectory computed using a parameter perturbation of 10^{-5}. The dotted line is the difference in the finite difference trajectory computed using a parameter perturbation of 10^{-4}. This figure precisely illustrates the description in [13]: the error in the finite difference trajectories is $O(\epsilon/|\delta p|)$. When the parameter perturbation is of the order of the integration tolerance, then the finite difference computed trajectories are completely inaccurate. In this example, we were able to select a parameter perturbation large enough to obtain reasonably accurate sensitivity trajectories for a given integration tolerance. However, if we were interested in the values of the sensitivities near the event, then we would have to choose a much smaller parameter perturbation. Truncation error considerations may also require the use of a much smaller parameter perturbation. If either of these were the case, then we would have to choose a much tighter integration tolerance. In this simple example, the tightest integration tolerance possible was approximately 10^{-13}. Thus, it is quite

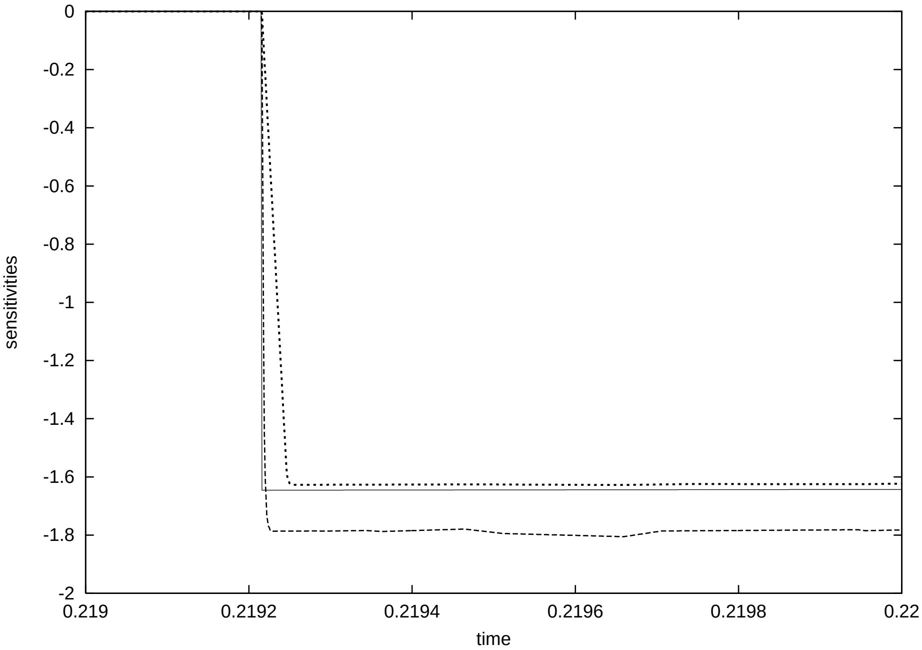

FIG. 5. *Hybrid parametric sensitivity trajectories. The thin solid line is the sensitivity trajectory computed explicitly with a tolerance of* 10^{-6}*. The long dashed line (below solid line trajectory) is the sensitivity trajectory computed using finite differences with a parameter perturbation of* 10^{-5} *and integration tolerance of* 10^{-6}*. possible that the numerical integrations may not be able to be performed at the necessary level of accuracy. Computing derivatives of algebraic functions reliably with finite differences is often a difficult task. As illustrated in this example, using finite differences to compute parametric sensitivities of hybrid dynamic systems is often a far more difficult task.

The second example is a small circuit simulation model adapted from [5]:

$$f_1 = x_1 + x_2 - x_3, \tag{4.2}$$

$$f_2 = r_3(x_1 + x_2) + l_3(\dot{x}_1 + \dot{x}_2) - v_3, \tag{4.3}$$

$$f_3 = 100\cos(100\pi t) - v_1, \tag{4.4}$$

$$f_4 = -v_1 - v_2, \tag{4.5}$$

$$f_5 = v_1 - v_3 - z_3, \tag{4.6}$$

$$f_6 = v_2 - v_3 - z_4, \tag{4.7}$$

(4.8)
$$f_7 = \begin{cases} (v_1 - p_1x_1)/p_2 - \dot{x}_1 & : & (x_1 \geq 0 \vee v_1 \geq v_3) \wedge (x_2 \leq 0 \wedge v_2 \leq v_3), \\ \dot{x}_1 & : & (x_2 \geq 0 \vee v_2 \geq v_3) \wedge (x_1 \leq 0 \wedge v_1 \leq v_3), \\ p_5v_1 + p_6v_2 + p_7x_1 + p_8x_2 - \dot{x}_1 & : & \text{otherwise}, \end{cases}$$

(4.9)
$$f_8 = \begin{cases} \dot{x}_2 & : & (x_1 \geq 0 \vee v_1 \geq v_3) \wedge (x_2 \leq 0 \wedge v_2 \leq v_3), \\ (v_2 - p_3x_2)/p_4 - \dot{x}_2 & : & (x_2 \geq 0 \vee v_2 \geq v_3) \wedge (x_1 \leq 0 \wedge v_1 \leq v_3), \\ p_9v_1 + p_{10}v_2 + p_{11}x_1 + p_{12}x_2 - \dot{x}_2 & : & \text{otherwise}, \end{cases}$$

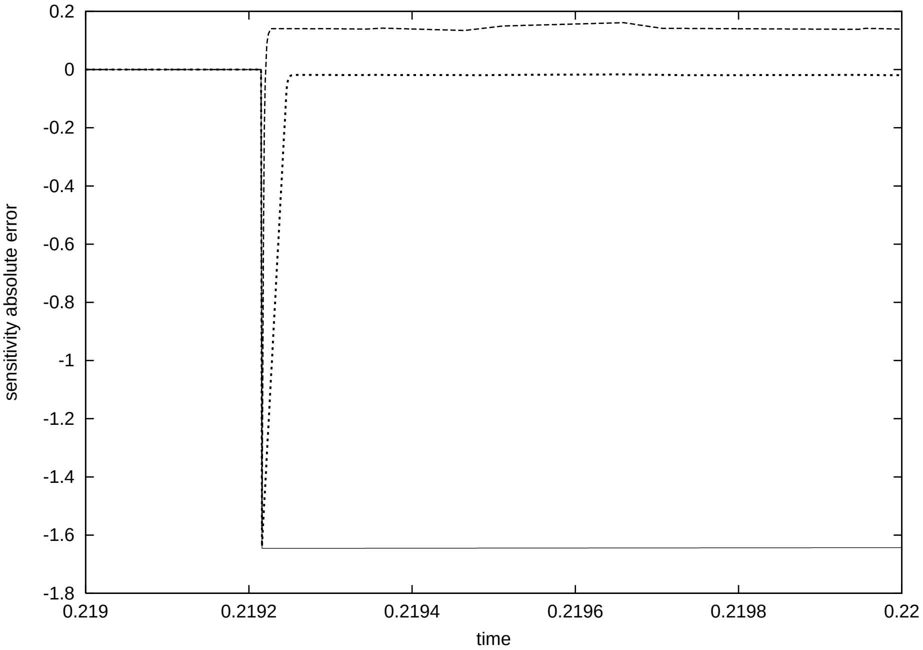

FIG. 6. *Error in hybrid parametric sensitivity trajectories. This figure contains a plot of the difference between the sensitivity trajectory computed explicitly and the trajectories obtained using finite differences. All integrations are performed with a tolerance of* 10^{-6}*. The thin solid line is the difference in the finite difference trajectory computed using a parameter perturbation of* 10^{-6}*, the dashed line is the difference in the finite difference trajectory computed using a parameter perturbation of* 10^{-5}*, and the dotted line is the difference in the finite difference trajectory computed using a parameter perturbation of* 10^{-4}*.*

where $p_1 = 12$, $p_2 = 0.24$, $p_3 = 12$, $p_4 = 0.24$, $p_5 = 13.64$, $p_6 = -11.64$, $p_7 = -50$, $p_8 = 0$, $p_9 = -11.64$, $p_{10} = 13.64$, $p_{11} = 0$, and $p_{12} = -50$. The initial conditions for this model are

$$x_1(0) = 0,$$
$$x_2(0) = 0,$$

and the transition functions are $x_1^{(k+1)} - x_1^{(k)} = 0$ and $x_2^{(k+1)} - x_2^{(k)} = 0$ for all transitions. Again, this model was coded into a Fortran subroutine, and DAEPACK was used to generate the additional information (i.e., the discontinuity-locked model and all partial derivatives). Unlike the first example, this model could not be numerically integrated beyond the second discontinuity when the discontinuities were not handled explicitly. Figure 7 contains the sensitivities of variables x_1, x_2, and x_3 with respect to time invariant parameter p_5. A plot of the state trajectories can be found elsewhere in the literature [15].

5. Conclusions. Parametric sensitivity analysis provides valuable information required to understand a model and is used in a variety of calculations. Unfortunately, applying standard numerical codes for parametric sensitivity analysis to models containing discontinuities can lead to disastrous consequences. This is particularly true for legacy models. Existing models, containing discontinuous relationships, that yielded correct results when performing numerical integration will generally fail or

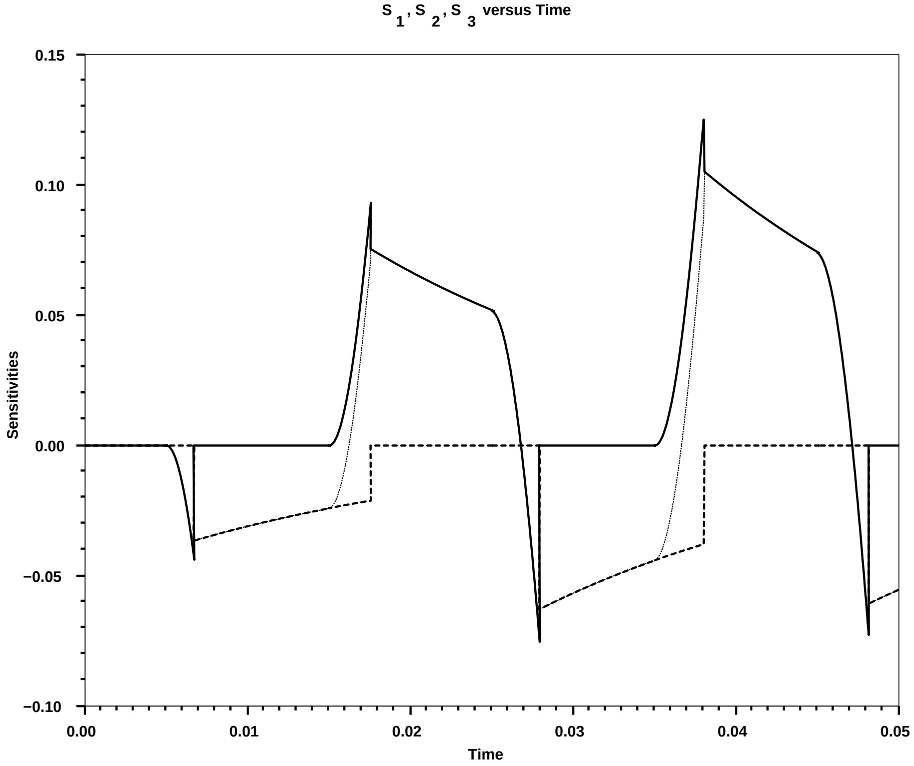

FIG. 7. *Sensitivity trajectories ($s_1 = \partial x_1/\partial p_5$, $s_2 = \partial x_2/\partial p_5$, and $s_3 = \partial x_3/\partial p_5$) for Example 2. The solid line is s_1, the dashed line is s_2, and the thin dotted line is s_3.*

produce incorrect results when performing parametric sensitivity analysis. Fortunately, by extending the techniques of automatic differentiation, code analysis and transformation can be used to automatically generate the information required to perform proper parametric sensitivity analysis.

Acknowledgment. The authors would like to acknowledge Elena Chekhova for the example that brought to our attention the problems of hidden discontinuities in sensitivity analysis.

ON THE NUMERICAL SOLUTION OF $(\lambda^2 A + \lambda B + C)\,x = b$ AND APPLICATION TO STRUCTURAL DYNAMICS*

V. SIMONCINI[†] AND F. PEROTTI[‡]

Abstract. In this paper we address the numerical solution of a large linear system depending quadratically on a parameter that varies in a wide range. We analyze a solution method, whose computational cost grows only sublinearly with the number of parameters, that relies on the use of an indefinite inner product. Important implementation aspects are treated in detail. The problem arises in various application areas: we shall report on our experience with cases in structural dynamics.

1. Introduction.

We are interested in the numerical solution of the linear system

$$L(\lambda)x = b, \qquad L(\lambda) = \lambda^2 A + \lambda B + C \tag{1.1}$$

as $\lambda \in \mathbb{C}$ varies, where $x = x(\lambda)$. In the following we shall assume that either A or C is nonsingular and that A, B, and C are $n \times n$ complex symmetric matrices, so that $L(\lambda)$ is also complex symmetric. We are interested in the case in which system (1.1) need be solved for several (say hundreds or thousands) values of λ in a wide range.

Equation (1.1) has large application in the solution of difference and ordinary differential equations, where it has been classically studied [14]. Unfortunately, the theoretical spectral tools utilized in such setting are computationally inefficient on large application problems such as electromagnetic scattering [19], wave propagation in porous media [30], and structural dynamics [6]. The quadratic, and in more general contexts nonlinear, parameter λ may be treated using Padé approximation when λ is close enough to a fixed reference value λ_0 [19]. When λ is in a wider range, linearization techniques originating from the eigenvalue setting may be exploited; see, for instance, [25, 16, 39]. In [6] it was shown that for structural dynamics applications, iteratively solving the linearized version of (1.1) is in general more efficient than using a direct sparse solver on (1.1). This is due to the fact that the latter needs to recompute the factors of the sparse factorization for each value of λ, causing the computation cost to grow linearly with the number of parameters. Unfortunately, the iterative methods in [6] did not exploit the symmetry of the problem, so that they suffered from known limitations of the nonsymmetric solvers employed [29]. Although the problem finds application in several important areas, general numerical methods other than those analyzed in [6] do not seem to have been fully investigated (e.g., the methods in [41, 18]

are application-oriented), and performance comparisons with obvious techniques seem to be lacking.

In this paper we analyze in detail the iterative solution of (1.1) when a linearization of the problem is carried out, so that system (1.1) is transformed into

$$(\mathcal{A} + \lambda\mathcal{B})z = d$$

of twice the size, with $\mathcal{A}$ and $\mathcal{B}$ complex symmetric and $z = z(\lambda)$. We propose a Krylov subspace method that exploits the symmetry of the problem so as to devise a short-term recurrence whose computational cost per iteration is comparable to that of a Hermitian iterative solver. Collecting $\mathcal{B}$ on the right, we obtain the shifted form

$$(\mathcal{A}\mathcal{B}^{-1} + \lambda I_{2n})\hat{z} = d, \qquad \hat{z} = \mathcal{B}z, \tag{1.2}$$

where I_{2n} is the identity matrix of order $2n$. Due to the shift invariance of Krylov subspaces, the space generated for the approximation of $\hat{z} = \hat{z}(\lambda)$ in (1.2) turns out to be the same for all λ's. This important property allows us to simultaneously handle several λ's at a cost that grows only sublinearly with the number of parameters.

In this paper we give a thorough analysis of the method: relevant aspects are uncovered that make the approach amenable to dealing with very large three-dimensional (3D) problems. To this end, a key step is the solution of a system with the complex symmetric matrix $\mathcal{B}$ at each iteration; the solution is necessary to transform the linearized system into the shifted form (1.2). For large dimension problems, such a solution can be obtained only approximately by means of an iterative method. The inexact solution with $\mathcal{B}$ in general leads to deterioration of performance: a theoretical analysis describes the influence of the inexact procedure on the convergence of the Krylov subspace method and numerical experiments emphasize the difficulties one encounters when using the inexact approach. Most numerical and experimental considerations are carried out on a real application problem, stemming from direct frequency analysis in structural dynamics, in which A is complex symmetric, B is purely imaginary, and C is real. For the sake of generality, however, our numerical experiments allow us to make considerations on the behavior of the method that go beyond the use on our particular application.

We should mention that the idea of combining the symmetry of the problem and the shift invariance of Krylov subspace methods for solving (1.1) first appeared in [33]. This paper aims to investigate the numerous numerical and computational aspects that need to be addressed in order to make a solver of practical value in real application problems.

Following a strategy commonly employed in the nonlinear context, one could solve (1.1) directly for a particular choice of λ and then use the generated information to enhance the solution of (1.1) for the parameter values of interest. Such a strategy would avoid doubling the problem size. Nonetheless, we point to some of the shortcomings of this strategy, while our numerical experiments show that for a large number of parameters, the new method outperforms this type of scheme that directly deals with (1.1).

We next give a synopsis of the paper. In section 2 we give a brief description of the model problem. In section 3 we introduce the linearized matrix formulation and the algebraic tools that are used in the algorithm. In section 4 and its subsection, the Simplified Shifted Lanczos procedure is described. Considerations relating to the solution of the original and linearized problems are discussed in section 5, while acceleration strategies are discussed in section 6. Sections 7 and 7.1 are devoted to the analysis and numerical experiments, respectively, of the exact and inexact solution of the system occurring at each iteration of the Lanczos procedure. In section 8 the method is compared with alternative strategies. Multiple-input systems are discussed in section 9. Finally, our conclusions and comments for future work are summarized in section 10.

All tests were run in Fortran on one CPU of a Sun Enterprise 4500 and plotted using Matlab [21]. Capital letters denote matrices, small Roman letters denote vectors, Greek letters denote scalars, and $\imath$ is the imaginary unit. Matlab notation is used whenever possible. For a complex vector x, $x^T, \bar{x}$ denote the transpose and conjugate of x, respectively, $x^* = \bar{x}^T$, and $(x)_i$ denotes its ith component. For a matrix X, $(X)_{:,i}$ denotes its ith column; unless otherwise stated, its condition number, $\mathrm{cond}(X)$, is the ratio of its largest and smallest nonzero singular values. Moreover, $\|x\|^2 = \sum_{i=1}^{n} |(x)_i|^2$ for $x \in \mathbb{C}^n$, and the induced norm is used for matrices. I_n is the identity matrix of dimension n and e_j is its jth column, whose number of components is usually clear from the context. The pair (λ, x) with $0 \neq x \in \mathbb{C}^n$ is an eigenpair (or latent root and vector) of L if $L(\lambda)x = 0$. Finally, $\mathrm{diag}(\alpha_1, \ldots, \alpha_n)$ is a diagonal matrix of size n with diagonal entries $\alpha_1, \ldots, \alpha_n$.

2. Frequency analysis of linearized dynamical systems.

Let us consider an n-DOF discretized linear system, oscillating with small amplitudes in the neighborhood of a stable equilibrium configuration (see, e.g., [4, 26] for a matrix-oriented treatment). Assuming linear elastic restoring forces and viscous dissipation, the equations of motion can be written, by Lagrange equations, in the following matrix form:

$$M\ddot{q} + D\dot{q} + Kq = p. \tag{2.1}$$

In (2.1) q is the vector of Lagrangian coordinates, p the vector of generalized components of dynamic forces, M and K the kinetic and potential energy matrices, respectively, while D is the damping matrix. In the case of complex harmonic excitation at frequency f, system (2.1) takes the form

$$M\ddot{q} + D\dot{q} + Kq = be^{\imath 2\pi f t}. \tag{2.2}$$

Equation (2.2) admits the steady-state solution $q(t) = \tilde{q}e^{\imath 2\pi f t}$, where $\tilde{q}$ can be obtained as the solution of the linear system

$$\left(-(2\pi f)^2 M + \imath 2\pi f D + K\right)\tilde{q} = b. \tag{2.3}$$

Within the context of steady-state harmonic analysis, a "mixed" damping, encompassing viscous (D_V matrix) and hysteretic (D_H matrix) contributions, can be introduced as $D = D_V + \frac{1}{2\pi f}D_H$. Substitution in the linear system (2.3) leads to

$$\left(-(2\pi f)^2 M + \imath 2\pi f D_V + K_\star\right)\tilde{q} = b, \qquad K_\star = K + \imath D_H. \tag{2.4}$$

We shall assume that the dynamic system under study encompasses p hysteretic subsystems, each of them characterized by a contribution $K^{(j)}$ to the global stiffness matrix and by a hysteretic damping factor $\eta^{(j)}$, so that $D_H = \sum_{j=1}^{p} \eta^{(j)} K^{(j)}$.

The obtained system (2.4) fits our matrix form (1.1) by defining

$$\lambda = 2\pi f, \quad A = -M, \quad B = \imath D_V, \quad C = K_\star, \quad x = \tilde{q}.$$

As an alternative to the above formulation, the linear system can be rewritten in terms of acceleration amplitudes $\tilde{a} = -(2\pi f)^2\tilde{q}$, leading to the "inverse" form

$$\left(M + \frac{1}{\imath 2\pi f}D_V + \frac{1}{-(\imath 2\pi f)^2}K_\star\right)\tilde{a} = b.$$

Table 2.1

† Matlab `condest` estimate of the 1-norm condition number of the matrix.

Such a formulation can be made consistent with (1.1) by defining

$$\lambda = (2\pi f)^{-1}, \quad C = -M, \quad B = \imath D_V, \quad A = K_\star, \quad x = -\tilde{a}. \tag{2.5}$$

Throughout the paper we shall adopt this formulation whenever addressing the structural dynamics application.

When nonharmonic independent forces are applied to the system, the right-hand side of equations (2.1) can be written as $p(t) = Fg(t)$, with F an $n \times m$ matrix and $g(t) = [\gamma_1(t), \ldots, \gamma_m(t)]$. The Fourier transform of $p(t)$ yields the frequency domain load description $\hat{p}(f) = F\hat{g}(f)$. In the first part of this paper the "single-input" case will be considered ($m = 1$); in this situation a single right-hand side vector $b = F$ is present in (1.1). The solution, however, must be repeated for all frequencies of interest in the spectrum of $g(t)$; a similar situation arises in the case of perfectly correlated stationary random loads. The case $m \neq 1$ (independent deterministic loads or multicorrelated random loads) will be addressed in section 9.

All numerical experiments described in the paper were done using a subset of the test cases first considered in [6]; in there, a description of the originating problem is also presented. Case **F1** is a variant of case **F** , as described below. Table 2.1 reports a summary of the relevant features for our analysis: for each test case, the problem size, the number of nonzero elements of A, B, and C (considering symmetry), an estimate for the condition number of A, and the frequency interval of interest is reported. Note that problem cases **B** and **C** have nonuniform hysteretic damping. In cases **F** and **F1** it is $K_\star = (1 + \imath\eta)K$, with $0 < \eta < 1$, $\eta \in \mathbb{R}$. The ill-conditioning of matrix A in case **F** is due to the unfavorable stiffness properties of the mechanical system, which was originally composed of an elastic body restrained by viscous dampers only, this causing the stiffness matrix to be singular. To face this problem, highly deformable springs were placed parallel to the dampers, leading, in case **F** , to a very high condition number; in case **F1** stiffer springs were inserted which, along with other slight modifications to the model, provided a significant improvement of the matrix conditioning.

The case of uniform hysteretic damping is particularly attractive, since spectral information on the viscous problem can be obtained from the purely hysteretic problem. Let us thus assume that $K_\star \equiv (1 + \imath\eta)K$, with K real symmetric and positive definite and $\eta > 0$. The natural frequencies of the problem lie on a line of the complex plane. Indeed, let $(\xi^2(1 + \imath\eta)K - M)x = 0$ and set $\theta = \xi^2(1 + \imath\eta)$. The eigenvalues θ of the pencil (M, K) are real; therefore

$$\xi^2 = \frac{\theta}{|1 + \imath\eta|^2}(1 - \imath\eta) \tag{2.6}$$

and the eigenvalues ξ are on the line through the origin containing $\sqrt{1 - \imath\eta}$.

The viscous problem can be seen as a perturbation of the uniformly hysteretic case. We next provide an estimate of the magnitude of the perturbed eigenvalues, which is based on Geršgorin theorem and follows the analysis in [20, section 9.3]. A general perturbation analysis can be done using classical theory; see [38] for a study with pseudospectra. In the following, we shall use the notation introduced in (2.5).

PROPOSITION 2.1. *Let (ξ, x) solve the problem $\left((1+\imath\eta)K\xi^2 + \imath D_V\xi - M\right)x = 0$, with K, D_V and M real symmetric, K positive definite and $\|D_V\| \le \varepsilon$. Also let $\sigma_1 \ldots, \sigma_n$ be the eigenvalues of the problem $Mq = \sigma^2(1+\imath\eta)Kq$. Then the eigenvalues ξ are in the union of the disks*

$$\left|\xi - \left(\pm\sigma_k - \frac{\nu}{2}(\hat{D}_V)_{kk}\right)\right| = \left|\frac{\nu}{2}(\hat{D}_V)_{kk}\right| + \sum_{j\neq k}|\nu(\hat{D}_V)_{kj}|, \qquad k = 1, \ldots, n, \tag{2.7}$$

where $\|\hat{D}_V\| \le \varepsilon$ and $\nu = \imath(1+\imath\eta)^{-1}$.

Proof. Let Q be the real orthogonal eigenvector matrix in the eigenvalue problem $Mq = \sigma^2(1+\imath\eta)Kq$ such that $Q^TKQ = I$ and $Q^TMQ = (1+\imath\eta)\Sigma^2$ with $\Sigma =$diag$(\sigma_1, \ldots, \sigma_n)$. Let $x = Qv$. Then

$$\left(\xi^2 I + \xi\nu\hat{D}_V - \Sigma^2\right)v = 0,$$

where $\hat{D}_V = Q^TD_VQ$. The eigenvalues of this problem are the same as the eigenvalues of the matrices

$$\begin{pmatrix} -\nu\hat{D}_V & \Sigma \\ \Sigma & \end{pmatrix}, \qquad \begin{pmatrix} \Sigma - \frac{\nu}{2}\hat{D}_V & \frac{\nu}{2}\hat{D}_V \\ \frac{\nu}{2}\hat{D}_V & -\Sigma - \frac{\nu}{2}\hat{D}_V \end{pmatrix}, \tag{2.8}$$

where the second matrix is obtained by similarity [20, section 9.3].

Applying the Geršgorin theorem to the kth row (or column) of the second matrix in (2.8) yields

$$\left|\xi - \left(\pm\sigma - \frac{\nu}{2}(\hat{D}_V)_{kk}\right)\right| \le \left|\frac{\nu}{2}(\hat{D}_V)_{kk}\right| + \sum_{j\neq k}|\nu(\hat{D}_V)_{kj}|. \qquad \square$$

We note that since $0 \le \eta < 1$ and $\nu = (1+\eta^2)^{-1}(\eta + \imath)$, then the major change in the spectrum is observed in the imaginary part. Not unexpectedly, our analysis predicts that for the class of problems considered, the eigenvalues of the viscous problem tightly distribute about the eigenvalues of the purely hysteretic problem. A typical spectrum is reproduced in Figure 2.1. When we consider the coefficient matrix in the shifted form (1.2) we can readily observe that its eigenvalues are obtained by shifting the eigenvalues ξ's of the original viscous problem.

3. Matrix formulation.

Different matrix formulations can be derived when linearizing (1.1) in λ. The companion algebraic form yields (see, e.g., [14])

$$\left(\begin{bmatrix} 0 & I_n \\ -C & -B \end{bmatrix} - \lambda\begin{bmatrix} I_n & 0 \\ 0 & A \end{bmatrix}\right)\begin{bmatrix} x \\ \lambda x \end{bmatrix} = \begin{bmatrix} 0 \\ -b \end{bmatrix}.$$

Most theoretical results are derived for the formulation above. A symmetric equivalent formulation can be obtained by simply multiplying the first block row by C^T and accommodating signs and rows, so as to obtain

$$\left(\begin{bmatrix} B & C \\ C^T & 0 \end{bmatrix} + \lambda\begin{bmatrix} A & 0 \\ 0 & -C^T \end{bmatrix}\right)\begin{bmatrix} \lambda x \\ x \end{bmatrix} = \begin{bmatrix} b \\ 0 \end{bmatrix}. \tag{3.1}$$

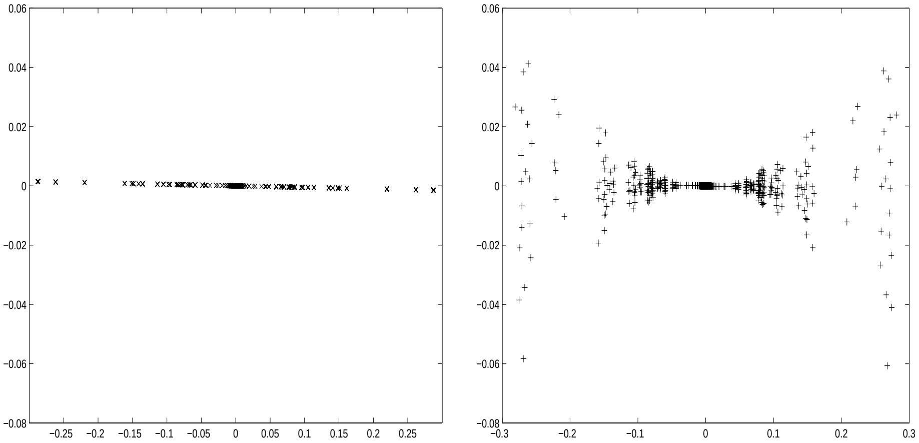

FIG. 2.1. *Typical eigenvalue distribution for the purely hysteretic problem (left) and for the viscous problem (right).*

Such symmetric structure has often been used in the context of eigenvalue computation; see [23, 25] and the recent survey [39]. With obvious notation, system (3.1) can be written in a more compact form as

$$(\mathcal{A} + \lambda \mathcal{B})z = d. \tag{3.2}$$

When A, B, and C are complex symmetric, then $\mathcal{A}$ and $\mathcal{B}$ are also complex symmetric and so is $(\mathcal{A} + \lambda\mathcal{B})$. Throughout the paper we shall assume that $\mathcal{B}$ is nonsingular. Singularity of $\mathcal{B}$ arises if C is singular. This does happen in structural dynamics applications, assuming $C = -M$, where Lagrangian coordinates are often present in the model (e.g., rotation components in framed or plate structures), which are useful for modeling elastic properties but do not appear in the kinetic energy definition. The problem of singular C can be solved in a computationally efficient manner when, for instance, C is diagonal [33]. If instead A is singular and $\lambda \neq 0$, the formulation with coefficient matrix $\sigma^2 C + \sigma B + A$ should be used, with $\sigma = \lambda^{-1}$, and the considerations above still apply.

In the complex symmetric setting, the *indefinite* inner product

$$(x, y) = x^T y \qquad \text{for } x, y \in \mathbb{C}^n \tag{3.3}$$

is used so that $(x, Ax) = (Ax, x)$ for a complex symmetric matrix A: variants of short-term recurrence methods such as conjugate gradients can thus be implemented that employ (3.3) rather than the usual definite inner product in $\mathbb{C}^n$ [40]. It may be that $(x, x) = 0$ for some $x \neq 0$ (called isotropic [13]), so that breakdown can occur; an iterative method employing this inner product should therefore have safeguard strategies, although breakdown is rarely encountered in practice. Because of our application, the derivation and matrix analysis will be done for complex symmetric matrices and the inner product above. Nevertheless, most statements hold for Hermitian matrices by replacing T with the usual transposition and conjugation, and also hold for real symmetric matrices.

Collecting $\mathcal{B}^{-1}$ from the right yields the shifted linear system

$$(\mathcal{A}\mathcal{B}^{-1} + \lambda I_{2n})\hat{z} = d, \qquad \hat{z} = \mathcal{B}z. \tag{3.4}$$

Isolating the frequency parameter in (3.4) is very convenient: if Krylov subspace iterative methods are employed for solving the system, computational costs may be substantially lowered. We remark here that if $\mathcal{B}$ were to have a positive definite symmetric part, then the factorization $\mathcal{B} = LL^T$ ([17]) would lead to a complex symmetric linearized problem with shifted coefficient matrix $L^{-1}\mathcal{A}L^{-T} + \lambda I_{2n}$. To make the treatment sufficiently general, in the rest of the paper we shall not restrict to the case where $\mathcal{B}$ has a positive definite symmetric part. Symmetry properties are lost with matrix $\mathcal{AB}^{-1}$, and nonsymmetric solvers should be applied. Nevertheless, $\mathcal{AB}^{-1}$ is symmetric with respect to a (nonstandard) indefinite inner product. Indefinite inner products have been used in the past for theoretical purposes (see [13] for a general treatment) in connection with the generalized eigenvalue problem [25, 23] as well as in the linear system setting (cf., e.g., [12]).

Definition 3.1. *Given a complex Hermitian (symmetric) matrix $\mathcal{X}$, an indefinite inner product with respect to $\mathcal{X}$ is a bilinear form defined by $[x,y]_{\mathcal{X}} = x^*\mathcal{X}y$ ($[x,y]_{\mathcal{X}} = x^T\mathcal{X}y$) for complex vectors x, y.*

Definition 3.2. *Matrix A is $\mathcal{X}$-Hermitian (-symmetric) if $[x,Ay]_{\mathcal{X}} = [Ax,y]_{\mathcal{X}}$.*

Matrix $\mathcal{B}^{-1}\mathcal{A}$ is $\mathcal{B}$-symmetric and $\mathcal{A}$-symmetric, while $\mathcal{AB}^{-1}$ is $\mathcal{A}^{-1}$- and $\mathcal{B}^{-1}$-symmetric [25]. We shall see in section 4 that Lanczos-type approaches can be implemented so as to properly exploit the indefinite inner product $[\cdot,\cdot]_{\mathcal{X}}$, resulting in a computationally advantageous short-term recurrence method. Since the matrices in our application are complex symmetric, we shall focus our discussion on the (conjugation-free) indefinite inner product $[x,y]_{\mathcal{X}} = x^T\mathcal{X}y$.

Here and in the following we opt for inverting matrix $\mathcal{B}$ because of its computationally convenient block diagonal structure. Unless $\mathcal{A}$ is singular, the following alternative linearized formulation can be used:

$$(I + \lambda\mathcal{B}\mathcal{A}^{-1})\tilde{z} = d. \tag{3.5}$$

Most algorithmic considerations can easily be adapted to the case in which the formulation (3.5) is used. The preference between the two versions depends both on the spectral properties of the problem (cf. [6]) and on the computational effort involved in solving with $\mathcal{B}$ or $\mathcal{A}$.

4. Iterative solution.

In this section we describe the method we use to solve the system (1.1) through the linearization (3.2). We briefly recall the general properties of the Lanczos recurrence, and then we specialize it to symmetric (with respect to the indefinite inner product of Definition 3.2) matrices and to the linearized system.

Given a matrix $G \in \mathbb{C}^{n\times n}$ and the linear system $Gz = d$, the coupled two-term recurrence Lanczos method generates two pairs of vectors $\{q_j\}, \{p_j\}$ and $\{\tilde{q}_j\}, \{\tilde{p}_j\}$ that are pairwise biorthogonal, that is, $\tilde{q}_i^T q_j = 0$, $i \neq j$, and pairwise G-biorthogonal, $\tilde{p}_i^T G p_j = 0$, $i \neq j$. Setting $Q = [q_1, \dots, q_k]$, $P_k = [p_1, \dots, p_k]$, and $\tilde{Q}_k, \tilde{P}_k$ accordingly, we have

$$GP_k = Q_{k+1}L_k, \qquad G^T\tilde{P}_k = \tilde{Q}_{k+1}D_{k+1}^{-1}L_kD_k, \tag{4.1}$$

where $L_k \in \mathbb{C}^{(k+1)\times k}$ and $D_k \in \mathbb{C}^{k\times k}$ are lower bidiagonal and diagonal matrices, respectively. The vectors q_j, p_j and $\tilde{q}_j, \tilde{p}_j$ can be determined via coupled two-term recurrences by explicitly writing the relations above. Moreover, $Q_k = P_kU_k$ with $U_k \in \mathbb{C}^{k\times k}$ upper bidiagonal, which gives the usual three-term Lanczos recurrence $GQ_k = Q_{k+1}L_kU_k$ [11]. The first basis vector, q_1, is the normalized starting residual, $r_0 = d - Gz_0$, where z_0 is the starting approximate solution. The auxiliary starting vector $\tilde{q}_1$ is arbitrary. If a QMR procedure is applied [11], then an approximate solution is obtained as $z_k = z_0 + Q_k y_k$, where y_k solves the problem

$$\min_{y \in \mathbb{C}^k} \| \, \|d\| e_{k+1} - (L_k U_k) y \|. \tag{4.2}$$

The minimization process can be done "on the fly" and the matrix $L_k U_k$ need not be explicitly assembled [11].

In our case, the system to be solved is $(\mathcal{A}\mathcal{B}^{-1} + \lambda I_{2n})\hat{z} = d$. Let us for the moment omit the shift λI_{2n} and concentrate on the matrix $\mathcal{A}\mathcal{B}^{-1}$, so that $G = \mathcal{A}\mathcal{B}^{-1}$ is $\mathcal{B}^{-1}$-symmetric (cf. Definition 3.2). If $\tilde{q}_1$ is chosen to be $\tilde{q}_1 = \gamma_1 \mathcal{B}^{-1} q_1$, for some $\gamma_1 \in \mathbb{C}$, then all subsequent vectors $\tilde{q}_j$ satisfy the relation $\tilde{q}_j = \gamma_j \mathcal{B}^{-1} q_j$, $j = 2, \ldots, k$, for some $\gamma_j \in \mathbb{C}$ [12]. For this choice of auxiliary vector $\tilde{q}_1$, the left Krylov subspace is simply $\mathcal{B}^{-1}$ times the right Krylov subspace; therefore, the recurrence for $\tilde{q}_j$ may be obtained by solving a system with $\mathcal{B}$.

It is also worth noticing that the vector $\mathcal{B}^{-1} q_j$ can also be used to generate the next right iterate q_{j+1}; therefore a multiplication by $G^T \equiv \mathcal{B}^{-1}\mathcal{A}$ per iteration is avoided. The resulting algorithm is a $\mathcal{B}^{-1}$-symmetric Lanczos procedure, where only a set of basis vectors need be recursively computed while the second set of vectors can be recovered at no additional cost [25, 12].

To deal with the shift, we recall that a Krylov subspace is invariant under shift; that is, given $G \in \mathbb{C}^{n \times n}$ and $d \in \mathbb{C}^n$, we have $K_k(G + \lambda I_{2n}, d) = K_k(G, d) \equiv \text{span}\{d, Gd, \ldots, G^{k-1}d\}$, so that $(G + \lambda I_{2n}) Q_k = Q_{k+1}(L_k U_k + \lambda \tilde{I}_k)$, with $\tilde{I}_k = [I_k; 0]$. Note that the generating vector, d, must be the same. For this reason, the right-hand side should be the same for all linear systems; therefore a starting zero approximation $z_0 = 0$ is considered.

Shift invariance allows us to approximate the solution of all systems by generating only the Krylov subspace associated with one of them. Once the space $K_k(\mathcal{A}\mathcal{B}^{-1}, d)$ is constructed, for each λ_j $j = 1, \ldots, s$, an approximate solution $z_k(\lambda_j) = Q_k y_k(\lambda_j)$ may be obtained using a QMR procedure by solving

$$\min_{y \in \mathbb{C}^k} \| \, \|d\| e_{k+1} - (L_k U_k + \lambda_j \tilde{I}_k) y \|.$$

The minimization problem is carried out for each parameter, while the expensive step of generating the Krylov subspace is done once for all. The approximate solution to the original system is determined as $z_k = \mathcal{B}^{-1}\hat{z}_k$. From $\hat{z}_k \in K_k(\mathcal{A}\mathcal{B}^{-1}, d)$ it follows $z_k \in \mathcal{B}^{-1} K_k(\mathcal{A}\mathcal{B}^{-1}, d)$; therefore z_k is a linear combination of the vectors $\tilde{p}_i$, $i = 1, \ldots, k$, and so it may be updated directly as $z_k = \tilde{P}_k g_k$. This consideration will be useful in section 7, where an inexact solution with $\mathcal{B}$ is discussed.

4.1. The algorithm.

The algorithm for solving the linearized system (3.2), which includes symmetry with respect to the indefinite inner product and the shifting procedure, is given below. Key recursions for the simplified and shifted approaches are marked by boldface. Here we report the algorithm with the QMR procedure to generate the approximate solution. Other techniques could also be employed.

ALGORITHM: **Simplified Shifted Lanczos method** with QMR procedure.

```
Given $\mathcal{A}, b, z_0, \mathcal{B}, \lambda_1, \ldots, \lambda_s$
  $\mathcal{I} = \{1, 2, \ldots, s\}$
  $q_0 = b/\|b\|$     $p_0 = q_0$,     $\tilde{p}_0 = \mathcal{B}^{-1} p_0$,     $\tilde{q}_0 = \tilde{p}_0/\|\tilde{p}_0\|$
  $\gamma_0 = \|q_0\|/\|\tilde{q}_0\|$     $\omega_0 = \tilde{q}_0^T q_0$
```

```
$t_0 = \mathcal{A}\tilde{p}_0, \qquad \tau_0 = \tilde{p}_0^T t_0, \qquad v_0^{(j)} = v_{-1}^{(j)} = 0 \quad j \in \mathcal{I}$
$c_0^{(j)} = c_{-1}^{(j)} = 1 \qquad s_0^{(j)} = s_{-1}^{(j)} = 0, \quad \rho^{(j)} = \|b\|$
for $i = 0, 1, \ldots$
    $\alpha_i = \frac{\omega_i}{\tau_i}$
    $q_{i+1} = q_i - \alpha_i t_i$
    $\tilde{\mathbf{u}} = \mathcal{B}^{-\mathbf{1}}\mathbf{q}_{i+1}, \qquad \mathbf{u} = \boldsymbol{\gamma}_i\tilde{\mathbf{u}} \qquad \tilde{\mathbf{q}}_{\mathbf{i+1}}{=}\frac{\mathbf{1}}{\|\mathbf{u}\|}\mathbf{u}$        $(*)$
    $\omega_{i+1} = \tilde{q}_{i+1}^T q_{i+1}$
    $\boldsymbol{\gamma}_{i+1} = \frac{\boldsymbol{\gamma}_i}{\|\mathbf{u}\|} \quad \chi_{i+1} = \|\mathbf{u}\|\,\|p_i\|\,\omega_{i+1}\omega_i^{-1}$
    $p_{i+1} = q_{i+1} + \chi_{i+1}p_i \quad \tilde{\mathbf{p}}_{i+1} = \tilde{\mathbf{u}} + \chi_{i+1}\tilde{\mathbf{p}}_i$
    for each $j \in \mathcal{I}$
        $\nu = \|p_i\| + \chi_{i+1} + \boldsymbol{\lambda_j\alpha_i}, \quad \mu = \overline{s_i}^{(j)}c_{i-1}^{(j)}\chi_i + c_i^{(j)}\nu$
        $\theta = -\|p_{i+1}\|\mu^{-1}, \quad c_{i+1}^{(j)} = (1 + |\theta|^2)^{-\frac{1}{2}}, \quad s_{i+1}^{(j)} = c_{i+1}^{(j)}\overline{\theta}$
        $v_{i+1}^{(j)} = [\tilde{p}_i\alpha_i - v_i^{(j)}(-c_i^{(j)}c_{i-1}^{(j)}\chi_i + s_i^{(j)}\nu) + v_{i-1}^{(j)}s_{i-1}^{(j)}\chi_i]c_{i+1}^{(j)}\mu^{-1}$        $(a)$
        $z_{i+1}^{(j)} = z_i^{(j)} + v_{i+1}^{(j)}\rho^{(j)}c_{i+1}^{(j)}$        $(b)$
        $\rho^{(j)} = -c_{i+1}^{(j)}\theta\rho^{(j)}$
    endfor
    Eliminate converged indexes from $\mathcal{I}$. If $\mathcal{I} = \emptyset$, then stop.
    $t_{i+1} = \mathcal{A}\tilde{p}_{i+1}/\|p_{i+1}\|$
    $\tau_{i+1} = \gamma_{i+1}\tilde{p}_{i+1}^T t_{i+1}$
    $\tilde{p}_{i+1} = \frac{\tilde{p}_{i+1}}{\|p_{i+1}\|}$
endfor
```

The algorithm (in short, SS-Lanczos) requires six vectors of $2n$ components and two matrices of size $2n \times s$. We shall see in section 5 that only some of the rows of these matrices need be stored in a practical implementation. For large problems, the major computational effort is the solution with $\mathcal{B}$ at each iteration, while other operations in the algorithm, such as `daxpy`'s and `dots`' with vectors of $2n$ components, represent a low percentage of the total computational cost.

Convergence could be monitored by explicitly computing the residual norm. However, an upper bound is readily available as (see also [11])

$$\|d - (\mathcal{A} + \lambda_j\mathcal{B})z_k\| \leq \|Q_{k+1}\| \min_{y \in \mathbb{C}^k} \|\,\|d\|e_1 - (L_kU_k + \lambda_j\tilde{I})y\|. \tag{4.3}$$

The norm of Q_{k+1} can be bounded by the square root of the sum of its column's norm. Moreover, in the algorithm above, $\|\,\|d\|e_1 - (L_kU_k + \lambda_j\tilde{I})y_k\| = |\rho^{(j)}|$. We explicitly remark that in all our experiments the relative residual norm was always monitored (also in the inner solver; cf. section 7). The Lanczos procedure may break down if, for instance, $\omega_i \approx 0$ for some i. A look-ahead procedure has been devised to overcome breakdown, and near breakdown, and can be implemented in this case as well [11].

Since the parameters λ_j's are selected in a wide range, convergence curves can be quite different depending on the value of the parameter. In Figure 4.1 we report typical convergence histories for test case **B** when 23 parameter values are considered, with the values of λ uniformly distributed in the relevant interval. We recall that the eigenvalues of the coefficient matrix $\mathcal{A}\mathcal{B}^{-1} + \lambda I_{2n}$ correspond to the eigenvalues of the original viscous problem, shifted by the parameter λ. The least translation of the original spectrum away from zero (cf. Figure 2.1) appears when λ^{-1} is close to the right end of the interval. As observed in our experiments, convergence is in general much slower for those values of the parameter.

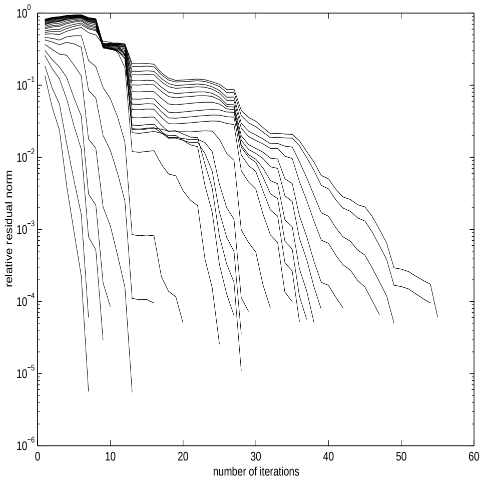

FIG. 4.1. *Case* **B** *. Convergence history for several different parameters. Convergence curves from left (fast) to right (slow) are relative to increasing values of* λ^{-1} *in* $2\pi[\alpha, \beta]$.

When no viscous damping is present in the model, then SS-Lanczos can be applied to the original problem, $(\lambda^2 A + C)x = b$, which is already in linearized form, as a function of λ^2. It should be mentioned that if the Lanczos process were used on the double size problem with $B = 0$, then breakdown would occur at the very first iteration: from $p_0 = [p_0^{(1)}; 0]$ and $\tilde{p}_0 = [\tilde{p}_0^{(1)}; 0]$ it follows that

$$\tau_0 = \tilde{p}_0^T \mathcal{A}\mathcal{B}^{-1} p_0 = [(\tilde{p}_0^{(1)})^T, 0^T] \begin{bmatrix} 0 & C \\ C & 0 \end{bmatrix} \begin{bmatrix} A^{-1}p_0^{(1)} \\ 0 \end{bmatrix} = 0.$$

A similar but more harmful problem is encountered when wishing to solve (3.5), that is, $(I + \lambda\mathcal{B}\mathcal{A}^{-1})\tilde{z} = d$. Indeed, in this case it is easy to show that

$$\tilde{p}^T \mathcal{A}^{-1} p = [\tilde{v}^T, 0^T] \begin{bmatrix} B & C \\ C & 0 \end{bmatrix}^{-1} \begin{bmatrix} v \\ 0 \end{bmatrix} = 0 \qquad \text{for any } v, \tilde{v}.$$

The algorithm breaks down at the first iteration, and it may break down in subsequent iterations in case such an operation is encountered. In this case, a look-ahead procedure should be implemented in order to step ahead in the recurrence [9]; cf. section 6 for alternative strategies.

5. Relations to the original problem. In the described procedure, (1.1) is linearized, and an approximate solution to (3.2) is determined as $z_k = [y_k; x_k]$. At termination, x_k provides an approximate solution to the original problem. However, it would be desirable to directly monitor the goodness of the approximate solution during the Lanczos recurrence. The residual $r_k = d - (\mathcal{A} + \lambda\mathcal{B})z_k$ does not need to be calculated, but it can be approximated via (4.3). On the other hand, $\|r_k\|$ and the norm of the residual $b - (\lambda^2 A + \lambda B + C)x_k$ may be very different [33], yielding an uncertain evaluation of the final sought approximation. Let us instead consider $\lambda^{-1}y_k$ as approximate solution. In theory, for large enough k, $x_k = \lambda^{-1}y_k$; equality, however, does not hold for smaller values of k. Let $R_k = b - (\lambda^2 A + \lambda B + C)\lambda^{-1}y_k$.

Then [33]

$$R_k = \left[I_n, \frac{1}{\lambda} I_n\right] r_k.$$

Clearly, $\|R_k\|$ may be easily estimated through the bound for $\|r_k\|$ during the Lanczos recurrence, whereas the residual $b - (\lambda^2 A + \lambda B + C)x_k$ would have to be computed explicitly. The choice between x_k and $\lambda^{-1} y_k$ may be done a posteriori at termination.

A further consideration from an application viewpoint is that in several situations the quantity of interest is not the solution x but only some of its components. This often happens in structural dynamics applications; in finite-element soil-structure interaction analyses, for example, response parameters within the ground mesh, where most of the elements are located, are usually of little interest. In some extreme cases, such as in the evaluation of rigid foundations impedance functions, only very few (six for a rigid foundation) components of the displacement vector are of interest. When only some of the solution components are requested, major computational and memory savings may be obtained by referencing only such entries. Let $N_\ell = [e_{k_1}, \ldots, e_{k_\ell}]$, where $k_1, \ldots, k_\ell$ are the requested component indexes. Then

$$X^{(j)} \equiv N_\ell^T (\lambda_j^2 A + \lambda_j B + C)^{-1} b.$$

In general, $\ell \ll n$. In the special case where $\ell = \mathcal{O}(1)$, the tall matrix N_ℓ can be used to construct an ad hoc Lanczos process [5].

We can thus use the approximation $X^{(j)} \approx X_k^{(j)} = \lambda_j^{-1} N_\ell^T y_k^{(j)}$. Setting $\hat{N}_\ell = [N_\ell; 0]$ and $f_i^{(j)} = \hat{N}_\ell^T v_i^{(j)}$, lines (a)–(b) in the algorithm can be modified as

$$f_{i+1}^{(j)} = [\hat{N}_\ell^T \tilde{p}_i \alpha_i - f_i^{(j)}(-c_i^{(j)} c_{i-1}^{(j)} \chi_i + s_i^{(j)} \nu) + f_{i-1}^{(j)} s_{i-1}^{(j)} \chi_i] c_{i+1}^{(j)} \mu^{-1} \qquad (a')$$

$$X_{i+1}^{(j)} = X_i^{(j)} + \lambda_j^{-1} f_{i+1}^{(j)} \rho^{(j)} c_{i+1}^{(j)}. \qquad (b')$$

The s vectors $f_i^{(j)}$'s, $j = 1, \ldots, s$, have only ℓ components, with $\ell \ll 2n$, while computing $\hat{N}_\ell^T \tilde{p}_i$ does not entail any floating point operation. To make the presentation and the computational experiments more general, in our implementation we have updated the entire upper portion of the approximate solution, that is, vector $y_k^{(j)}$, at each iteration, together with the first n entries of vectors $v_i^{(j)}, v_{i-1}^{(j)}$, $j = 1, \ldots, s$.

6. Acceleration strategies. Convergence may be slow if the coefficient matrix of the linearized problem has unfavorable spectral properties. The major problem encountered when seeking an efficient preconditioner for $(\mathcal{A}\mathcal{B}^{-1} + \lambda I_{2n})\hat{z} = d$ is that the matrix $\mathcal{A}\mathcal{B}^{-1}$ cannot be formed explicitly, so that usual incomplete factorizations are in general inapplicable. Moreover, preconditioning a system while maintaining the shifted structure is by itself a challenging problem. Attempts have been made in the past by using polynomial preconditioning, which preserves the shifted form [7]. Polynomial preconditioning consists of applying to a recurrence iterate a linear combination of powers of the coefficient matrix at each iteration. Unfortunately, in our case any additional multiplication by the system matrix entails a solution with $\mathcal{B}$, which makes the whole polynomial preconditioning procedure very expensive.

The location of the parameter λ in the spectral region of the coefficient matrix may highly influence the convergence of the method. An alternative acceleration strategy consists of first fixing a reference value λ_0 and then solving the problem with respect to the parameter $\omega = \lambda - \lambda_0$, varying ω. This can be done on either the original problem or the linearized equation.

In the original problem (1.1) let $\lambda = \lambda_0 + \omega$. Substituting in $L(\lambda)$ we get

$$\begin{aligned} L(\lambda_0 + \omega) &= \omega^2 A + \omega(2\lambda_0 A + B) + (\lambda_0^2 A + \lambda_0 B + C) \\ &= \omega^2 A + \omega L'(\lambda_0) + L(\lambda_0) \equiv H_{\lambda_0}(\omega). \end{aligned} \tag{6.1}$$

Here L' stands for the derivative of L with respect to λ. Note that the two matrices have the same eigenvectors. Matrix $H_{\lambda_0}(\omega)$ can be linearized as

$$\begin{bmatrix} L'(\lambda_0) & L(\lambda_0) \\ L(\lambda_0) & 0 \end{bmatrix} + \omega \begin{bmatrix} A & 0 \\ 0 & -L(\lambda_0) \end{bmatrix} \equiv \mathcal{A}_{\lambda_0} + \omega \mathcal{B}_{\lambda_0}. \tag{6.2}$$

We next give an explicit relation between the eigenpairs of the two linearizations.

Remark 6.1. Let (θ, z) and (ρ, t), with θ, ρ similarly ordered, be the eigenpairs of $\mathcal{A}_{\lambda_0}(\mathcal{B}_{\lambda_0})^{-1} + \omega I_{2n}$ and $\mathcal{A}\mathcal{B}^{-1} + \lambda I_{2n}$, respectively, with $z = [x; y]$. Assume that λ_0 is not an eigenvalue of $L(\lambda)$. Then

$$\theta = \rho \quad \text{and} \quad t = \begin{bmatrix} I & \\ & CL(\lambda_0)^{-1} \end{bmatrix} z - \lambda_0 \begin{bmatrix} AL(\lambda_0)^{-1} y \\ 0 \end{bmatrix}.$$

Proof. The pair (θ, z) with $z = [x; y]$ is an eigenpair of $\mathcal{A}_{\lambda_0}(\mathcal{B}_{\lambda_0})^{-1} + \omega I_{2n}$ if and only if $((\omega-\theta)^2 A + (\omega-\theta)L'(\lambda_0) + L(\lambda_0))\hat{y} = 0$ with $\hat{y} = L(\lambda_0)^{-1} y$ and $x = -(\omega-\theta)A\hat{y}$. By explicitly writing L' and L, the last quadratic eigenvalue problem can be rewritten as $((\lambda - \theta)^2 A + (\lambda - \theta)B + C)\hat{y} = 0$; that is, (θ, t) with $t = [-(\lambda - \theta)A\hat{y}; C\hat{y}]$ is an eigenpair of $\mathcal{A}\mathcal{B}^{-1} + \lambda I_{2n}$ from which the assertion easily follows. □

Numerical experiments not reported here showed that this strategy did not lead to better performance.

Acting on the linearized version of the matrix $L(\lambda)$ does change the spectrum. Writing once more $\lambda = \lambda_0 + \omega$, then (cf., for instance, [5, 35, 22])

$$\mathcal{A} + (\lambda_0 + \omega)\mathcal{B} = (\mathcal{A} + \lambda_0 \mathcal{B}) + \omega \mathcal{B}.$$

If $(\mathcal{A} + \lambda_0 \mathcal{B})$ is nonsingular, right multiplication with $(\mathcal{A} + \lambda_0 \mathcal{B})^{-1}$ yields a linear system with coefficient matrix

$$I_{2n} + \omega \mathcal{B}(\mathcal{A} + \lambda_0 \mathcal{B})^{-1}. \tag{6.3}$$

If $\mathcal{A}u = -\theta \mathcal{B}u$, then shifting and inverting we obtain

$$\mathcal{B}(\mathcal{A} + \lambda_0 \mathcal{B})^{-1} v = \frac{1}{\lambda_0 - \theta} v \qquad \text{with} \quad v = (\mathcal{A} + \lambda_0 \mathcal{B})u.$$

If λ_0 is close to some of the eigenvalues of the pencil $(\mathcal{A}, -\mathcal{B})$, then the corresponding eigenvalues of $\mathcal{B}(\mathcal{A} + \lambda_0 \mathcal{B})^{-1}$ and of matrix (6.3) are magnified. If $|\omega| = |\lambda - \lambda_0| \ll 1$, all remaining eigenvalues of matrix (6.3) conveniently cluster around one. However, for larger ω, eigenvalues distribute in a less predictable way. This strategy works best for $|\omega|$ small, that is, for λ in a neighborhood of λ_0. For this reason, the spectrum of the matrix in (6.3) may or may not be more appealing than that of $\mathcal{A}\mathcal{B}^{-1} + \lambda I_{2n}$ in our iterative solver context. A priori information for choosing the most appropriate shift is thus required; see also the discussion in [5, section IV.B] and [22]. Regardless of performance, this approach may be very convenient to avoid possible ill-conditioning or even singularity of $\mathcal{A}$ or $\mathcal{B}$ (e.g., as in our case $\mathbf{F}$), since λ_0 may be chosen to make $(\mathcal{A} + \lambda_0\mathcal{B})$ nonsingular.

Unfortunately, the difficulty in the choice of the reference value λ_0 is not the only shortcoming of the acceleration strategies discussed above. Indeed, at each iteration a linear system with matrix $\mathcal{B}_{\lambda_0}$ and $\mathcal{A}+\lambda_0\mathcal{B}$ need be solved, respectively. In particular, $\mathcal{A} + \lambda_0\mathcal{B}$ and $\mathcal{B}_{\lambda_0}$ may not inherit the sparsity patterns of matrices A, B, and C, resulting in a possibly much denser coefficient matrix. Similar concerns apply if an iterative solver is used (cf. section 7). Such a disadvantage need be taken into account since the overall performance of the iterative scheme strongly depends on the cost of these solves.

In all cases, the iterative solver described in section 4 may be adapted. For the sake of simplicity, however, in the following we shall refer only to the solution of $(\mathcal{A}\mathcal{B}^{-1} + \lambda I_{2n})\hat{z} = d$.

7. Exact and inexact solution of the system with matrix $\mathcal{B}$. At each iteration of the simplified Lanczos method a system solution with matrix $\mathcal{B}$ is required. Due to the structure of $\mathcal{B}$, this actually means solving with the symmetric nonsingular matrices A and C. In our application C is diagonal; therefore the complexity of solving with $\mathcal{B}$ is mostly due to that of solving with A. Medium to large 3D application problems yield matrices of type A that may produce quite dense factors if sparse direct solvers are used, so that most computational time is spent solving with A at each iteration. An example is shown in Table 7.1, where for our test cases the following information is reported for one parameter value of λ: elapsed time (Fortran function etime) to compute the factor[1] of A, total elapsed time to solve with the computed factor during the whole Lanczos process, total elapsed time for the iterative solver (including the time for computing and using the factors of $\mathcal{B}$), and memory allocations for the factor (complex and integers). The sparse direct solver ME47 [1] was used to solve with $\mathcal{B}$. The outer tolerance of the iterative solver was set to $\texttt{tol}_{outer} = 10^{-4}$. Though quite loose, this tolerance is considered satisfactory for this kind of application. The factor is computed once and for all, while it is clear that most time is spent in the solve with A at each iteration.

The large amount of memory allocation required by the factors warns that for larger 3D problems direct (exact) methods may not be affordable. Iterative (inexact) methods should be employed to solve with $\mathcal{B}$, leading to the commonly used term inner-outer iteration for the whole Lanczos recurrence. We shall see that the accuracy with which the inner system is solved influences not only the overall performance of the method (and this is typical of inner-outer procedures), but also the level of final accuracy of the outer iterative solver. In order to overcome the problem arising with the direct solver, the iterative solver should require much less memory allocation. On the other hand, memory allocation may be high if iteratively solving with A requires strong preconditioning. Therefore, the overall effectiveness of the inner-outer procedure depends on the effectiveness of solving with the stiffness and hysteretic damping matrix.

The modification occurring in the outer iterative algorithm is minimal and only involves the step that applies $\mathcal{B}^{-1}$. The resulting variant shares the algebraic properties of usual inner-outer procedures (cf., e.g., [15]) and of flexible versions of known algorithms [27, 37], although in our case it is not the preconditioner that is inaccurately applied, but part of the matrix itself. The subspace generated by the Lanczos recur-

[1] For the complex symmetric matrix A, the LDL^T factorization is carried out [1].

Table 7.1

Splitting of computational cost and memory allocations for the test cases in Table 2.1. $\lambda^{-1} = 10 \cdot 2\pi$. *Elapsed time is in seconds.*

Test case	# its	E–time factorization	E–time solves	E–time iterative solver	Mem. alloc. (cmplxM/intM)
B	12	2.1	0.8	3.2	0.52/0.21
C	92	0.5	1.6	2.9	0.15/0.05
F	105	342	158	509	12/0.86
F1	36	315	52	371	11/0.86

sion is no longer a Krylov subspace. The relation $z_k \in \mathcal{B}^{-1}K_k(\mathcal{A}\mathcal{B}^{-1}, d)$ does not hold, in general, whereas the relation $z_k \in \text{span}\{\tilde{p}_1, \dots, \tilde{p}_k\}$ holds, where $\text{span}\{\tilde{p}_1, \dots, \tilde{p}_k\}$ is not a Krylov subspace. Nonetheless, the important matrix equality

$$\mathcal{A}\tilde{P}_k = Q_{k+1}L_k \tag{7.1}$$

still holds, with $\tilde{P}_k \approx \mathcal{B}^{-1}P_k$, where the approximation depends on how accurately the inner system is solved. The approximate solution z_k can still be updated as in the exact case by using the generated basis vectors $\tilde{p}_i$. Iteratively solving with $\mathcal{B}$ with low accuracy implies that relation $(*)$ in the algorithm does not hold even in exact arithmetic. Instead, $\mathcal{B}\tilde{u} = q_k - t_k$, where t_k is the residual of the inner solver. The coupling between the $\tilde{Q}$- and $\tilde{P}$-recurrences becomes

$$\tilde{Q}_k\Sigma_k^{-1} = \tilde{P}_kU_k, \qquad \Sigma_k = \text{diag}(\|\tilde{u}_1\|, \dots, \|\tilde{u}_k\|). \tag{7.2}$$

We next show that the approximate solution of the system with $\mathcal{B}$ affects the final attainable accuracy of the outer procedure.

Proposition 7.1. *Let $T_k = [t_1, \dots, t_k]$ be the matrix of inner residuals, that is, $\mathcal{B}\tilde{u} = q_i - t_i$ for $i = 1, \dots, k$. Then the residual $r_k = d - (\mathcal{A} + \lambda\mathcal{B})z_k$ satisfies the relation $r_k = Q_{k+1}h_k + \lambda T_k y_k$, so that*

$$\|r_k\| \leq \|Q_{k+1}h_k\| + |\lambda|\|T_k y_k\|, \tag{7.3}$$

where y_k, h_k are the solution and residual of the least squares problem (4.2), *respectively.*

Proof. We have

$$\mathcal{B}\tilde{Q}_k\Sigma_k^{-1} = Q_k - T_k. \tag{7.4}$$

Moreover, $z_k = \tilde{P}_k g_k = \tilde{P}_k U_k y_k$. Therefore,

$$\begin{aligned} r_k &= d - (\mathcal{A} + \lambda\mathcal{B})z_k = d - \mathcal{A}\tilde{P}_k g_k - \lambda\mathcal{B}\tilde{P}_k g_k \\ &\overset{(7.1)-(7.2)}{=} d - Q_{k+1}L_k g_k - \lambda\mathcal{B}\tilde{Q}_k\Sigma_k^{-1}U_k^{-1}g_k \\ &\overset{(7.4)}{=} Q_{k+1}(\|d\|e_1 - L_k g_k - \lambda[U_k^{-1}; 0]g_k) + \lambda T_k U_k^{-1} g_k \\ &= Q_{k+1}\left(\|d\|e_1 - (L_kU_k + \lambda\tilde{I}_k)y_k\right) + \lambda T_k y_k, \end{aligned}$$

where $\tilde{I}_k = [I_k; 0]$. The upper bound thus follows from taking norms. □

In exact arithmetic, the norm of h_k in the first right addend in (7.3) converges to zero as $k \to 2n$, so that $\|Q_{k+1}h_k\|$ goes to zero if Q_{k+1} is not too ill-conditioned. The second right addend in (7.3) measures how well the inner system is solved. For

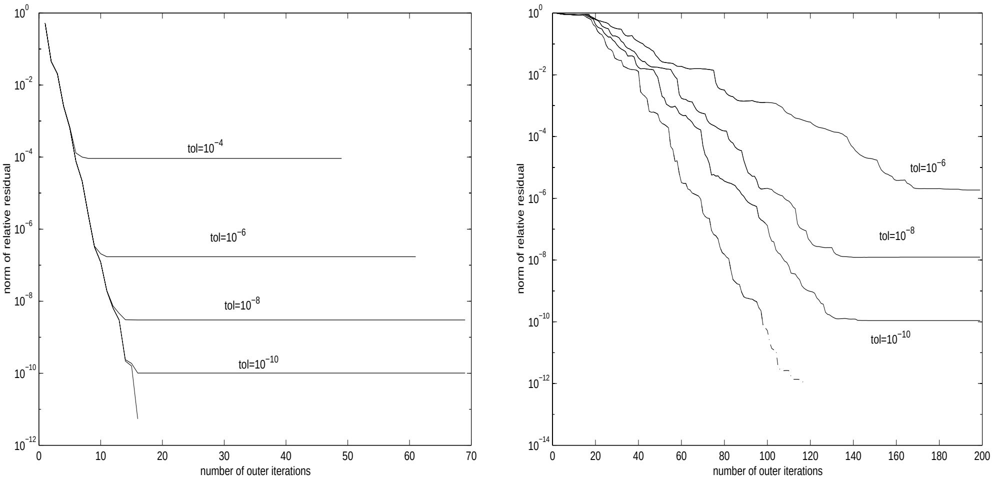

FIG. 7.1. *Inner-outer iteration. Convergence history for different values of the inner stopping tolerance. Left: Example* 1. *Right: Example* 2.

large enough k, $\|r_k\| \approx |\lambda| \, \|T_k y_k\|$, where $\|T_k y_k\|$ in general remains approximatively at the level of the inner tolerance.

Neither Q_{k+1} nor h_k are the same as if the inner system were solved exactly. More precisely, the inner solver not only influences the level of final attainable accuracy, but also the number of iterations to reach that level, delaying convergence in some cases. Inexact methods are known to suffer of this shortcoming (cf. [24, 29] and the references therein); an analysis in the symmetric case has been recently done by Golub and Ye [15], while the real nonsymmetric problem has been studied, for instance, in the context of flexible methods [27, 37]. A more precise analysis directly related to the linearized problem (3.2) would be desirable.

7.1. Numerical experiments with the inner-outer method. We illustrate the behavior of the inner-outer procedure with some numerical tests. We start with two built-up examples.

Example 1. Let $\mathcal{A}$ be the centered finite difference discretization of the two-dimensional Laplacian on the unit square with homogeneous boundary conditions and let $\mathcal{B}$ be a diagonal matrix, $\mathcal{B} = I_{2n} + \imath D$, with D real diagonal with normally distributed diagonal values (Matlab function `randn`). We have $\text{cond}(\mathcal{A}\mathcal{B}^{-1}) \approx 56$ and $\text{cond}(\mathcal{B}) \approx 2.4$. The performance of the inner-outer procedure is shown in Figure 7.1 (left) for various values of the inner stopping tolerance. (Random right-hand side with normally distributed entries and zero starting approximation were considered.) Here and in Example 2, $s = 1$ and $\lambda_1 = 10$. For this example, the inner tolerance provides quite a sharp approximation of the final attainable accuracy, while the convergence curve of the inner-outer solver is indistinguishable from that of the exact scheme, as long as the outer residual is larger than the inner tolerance.

Example 2. Let us consider $\mathcal{B} = (0.001+\imath)D$, with D as in Example 1. In this case $\text{cond}(\mathcal{A}\mathcal{B}^{-1}) \approx 5.9 \cdot 10^5$ and $\text{cond}(\mathcal{B}) \approx 5 \cdot 10^4$. The convergence curves for several inner tolerance values are shown in Figure 7.1 (right). Convergence starts deteriorating much earlier than at the final accuracy level. Similar behavior is observed in realistic problems, as in our test case **B** (cf. Figure 7.2).

Convergence deterioration depends on the conditioning of $\mathcal{A}\mathcal{B}^{-1}$ (cf. [15] in the

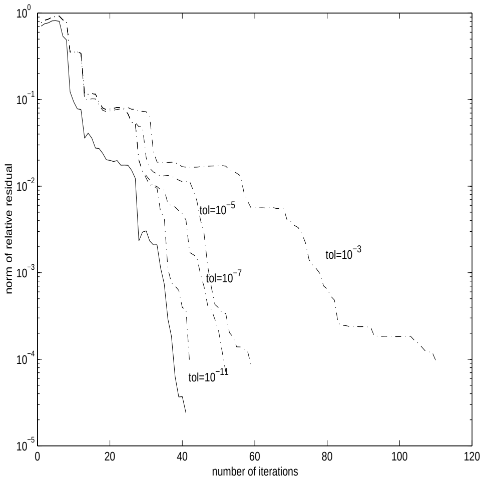

FIG. 7.2. *Test Case* **B** *. Exact (solid) and inexact (dashed) $\mathcal{B}$-symmetry for various stopping inner tolerance values* `tol`*.*

symmetric case); therefore the inner tolerance should be small if the conditioning of $\mathcal{A}\mathcal{B}^{-1}$ is large. In our numerical experiments, ill-conditioning of $K_\star$ seemed to strongly affect the performance of the inner-outer solver, yielding very slow convergence unless a very strict inner tolerance was used (cf. section 8).

To enhance convergence, preconditioning should be employed when solving with $\mathcal{B}$. In our experiments, we have used the preconditioned conjugate gradients method for complex symmetric matrices, which appropriately exploits the indefinite inner product (3.3); see [40]. Preconditioning has been carried out by using a complex symmetric incomplete factorization with fill-in and threshold: a manual complexification of the real symmetric ICT algorithm by Chow and Saad [3] worked satisfactorily on our problem. The preconditioner requires two parameters: the number of nonzero elements per row in the factor (fill-in) in addition to the original entries of the matrix and a threshold value for discarding small entries in the factor [3]; see also [28]. This last parameter was set to the experimentally observed best value, 10^{-4}, in our experiments.

8. Comparison with other techniques.

Solving directly with $L(\lambda)$ would be more convenient than turning to the linearized problem of twice the size if the multiple parameters could be handled efficiently. Efforts in this direction were made in [41, 18], where, however, the approximation was constructed starting from spectral information on the unviscous problem.

To exploit the structure in the solution of (1.1), one could use the factors of the full factorization of $L(\lambda_0)$ as the preconditioner for a value of λ_0 for which $L(\lambda_0)$ is nonsingular. More precisely, for each λ, the preconditioned system of size n

$$L(\lambda)L(\lambda_0)^{-1}\hat{x} = b, \qquad x = L(\lambda_0)^{-1}\hat{x}, \tag{8.1}$$

is solved with an iterative method. Note that $L(\lambda_0)$ may be denser than its addends A, B, and C. In our application problem this is not the case, however, since B and C are always diagonal; this special structure is very favorable for strategies attacking the original problem, as we shall see in our numerical experiments. The goodness of the preconditioner is measured in terms of the magnitude of the error norm $\|L(\lambda)L(\lambda_0)^{-1} - I_n\|$ (cf., e.g., [29]). The following lower bound can be easily proved.

Remark 8.1. The preconditioner matrix $L(\lambda_0)$ satisfies

$$\|L(\lambda)L(\lambda_0)^{-1} - I_n\| \geq \\ |\omega| \max\left\{ \frac{\|(\lambda+\lambda_0)A + B\|}{\|L(\lambda_0)\|}, \sigma_{\min}((\lambda+\lambda_0)A + B) \cdot \|L(\lambda_0)^{-1}\| \right\},$$

where $\sigma_{\min}(\cdot)$ is the smallest singular value of the argument matrix.

Proof. Using (6.1), the preconditioned matrix can be written as

$$L(\lambda)L(\lambda_0)^{-1} = \omega(\omega A + L'(\lambda_0))L(\lambda_0)^{-1} + I_n. \tag{8.2}$$

Therefore,

$$\begin{aligned}\|L(\lambda)L(\lambda_0)^{-1} - I_n\| &\geq \sigma_{\min}(L(\lambda_0)^{-1})|\omega|\|(\lambda+\lambda_0)A + B\| \\ &= \frac{|\omega|}{\|L(\lambda_0)\|}\|(\lambda+\lambda_0)A + B\|.\end{aligned}$$

The other lower bound similarly follows. □

It follows that the condition $|\omega| \ll 1$ (that is, λ close to λ_0) is not sufficient for ensuring a small preconditioning error norm. Indeed, if, e.g., $\|A\|$ is much larger than the norm of B and C, as is usually the case for stiffness matrices in structural dynamics application, and if $|\lambda_0| \ll 1$, then $\|(\lambda+\lambda_0)A + B\| \gg \|L(\lambda_0)\|$ and $L(\lambda_0)$ will be a poor preconditioner for $L(\lambda)$, regardless of the distance between λ_0 and λ. Numerical experiments (see Example 3) seemed to agree with this observation.

When an exact factorization of $L(\lambda_0)$ is not feasible, then an incomplete factorization can be used. Since the cost of generating the incomplete (and sparser) factor is much lower than for the exact factor, the computation can be done for each λ of interest. In practice, this corresponds to iteratively solving $L(\lambda)x = b$ independently for each value of λ with an incomplete factorization of the coefficient matrix as the preconditioner. Obviously, no advantage is taken of the special structure of the problem, and cost grows approximately linearly with the number of parameters. Memory requirements are low since n-vectors are needed, compared with the $2n$-vectors of the linearized approach. If the solution is carried out sequentially, then only the n-vectors of the iterative method are required, together with the preconditioner, while in SS-Lanczos vectors of s components are also required. Nevertheless, the major memory requirements are due to the (incomplete) factorization of $L(\lambda)$, which needs at least as much memory as that for A, depending on the application.

Example 3. We numerically compare the SS-Lanczos method (exact and inner-outer versions) with the described approaches. We experimented with the following:

- PQMR-ME47: complex symmetric QMR [10] on $L(\lambda)x = b$ preconditioned by a complete factorization of $L(\lambda_0)$ with $\lambda_0 = (60\pi)^{-1}$;
- SSL: SS-Lanczos with QMR procedure;
- PQMR-ICT: complex symmetric QMR on $L(\lambda)x = b$ preconditioned by an incomplete factorization of $L(\lambda)$ with no fill-in;
- ISSL: inner-outer SS-Lanczos with QMR procedure.

Note that fill-in in the PQMR-ICT preconditioner provided an overall worse performance of the method than no fill-in.

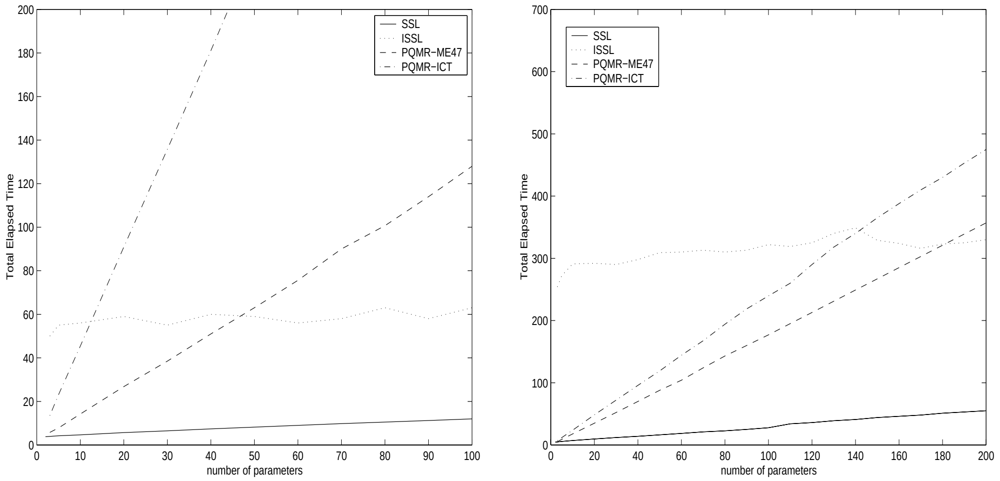

Fig. 8.1. *Elapsed time for the methods as a function of the number of parameters. Case* **B** *(left) and* **C** *(right).*

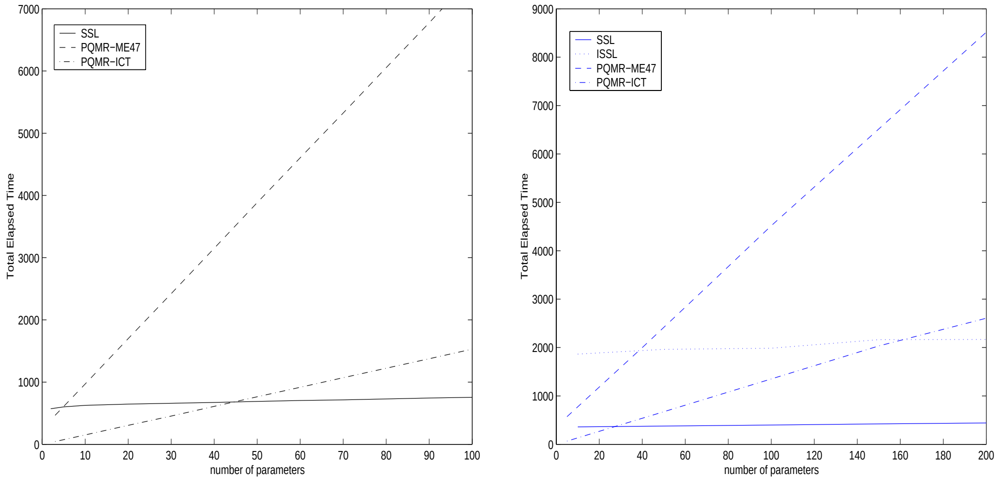

Fig. 8.2. *Elapsed time for the methods as a function of the number of parameters. Cases* **F** *(left) and* **F1** *(right); In case* **F** *the curve for the inner-outer SS-Lanczos method is out (top) of the plot.*

In Figures 8.1 and 8.2 the total elapsed time for cases **B** , **C** , **F** , and **F1** is reported, versus the number of parameters uniformly distributed in the interval. The outer tolerance $\texttt{tol}_{outer} = 10^{-4}$ was used.

All plots consistently show that the exact SS-Lanczos method provides the overall best performance for several frequency values. (In this application problem, a few hundred distinct frequency values would be needed [6].)

Solving with the inner-outer method is much more expensive than with the exact SS-Lanczos procedure. The performance discrepancy highly depends on the difficulty of iteratively solving with $K_\star$ in the inner-outer method. High preconditioning fill-in (fill-in=100 for cases **B** and **C**, fill-in=30 for cases **F** and **F1**) and strict inner tolerances (tol=10^{-6} for case **B** and tol=10^{-8} for the rest) were employed in order to maintain a performance, in terms of iterations and elapsed time, as close as possible to that of the exact method. Nonetheless, in the highly ill-conditioned case **F** the inner-outer method is still too expensive (cf. section 7) compared to all methods: its convergence curve is out of the plot axes. In spite of the high fill-in, memory allocations for the preconditioner were always less than one million, also for cases **F** and **F1** (cf. Table 7.1). As expected, the cost for solving with the exact and inexact SS-Lanczos method grows very little with the number of parameters compared to the other approaches.

In order to make a fair performance evaluation against the techniques that directly attach $L(\lambda)$, SSL should be compared to PQMR-ME47, since they both use a direct solver, while ISSL should be compared to PQMR-ICT. In the latter comparison, we can notice that the sparsity pattern of $L(\lambda)$ is in our application the same as that of $K_\star$. Solving with $L(\lambda)$ is thus not much worse than solving with $K_\star$, so we expect that the inner-outer method will not do better than PQMR-ICT if the number of iterations to solve the linearized problem is larger than the number of frequencies. On the other hand, unless $K_\star$ is severely ill-conditioned as in case **F** , ISSL outperforms PQMR-ICT for a large enough number of parameters. In other applications where the sparsity pattern of B and C is different from that of A, the performance of the method may significantly change. Our experiments thus show that solving the system by sharing the common information of all parameters is in general convenient, even in the inexact case.

We finally notice that PQMR-ME47 remains competitive, though always much worse than SS-Lanczos, as long as dealing with the factor of $K_\star$ is not too expensive, which is the case for the larger cases **F** and **F1** . It is also worth mentioning that in terms of number of iterations, preconditioning with $L(\lambda_0)$ was completely analogous to using ICT on each system with the mentioned parameters; the computational cost and memory requirements, however, were much higher.

9. Multiple-input systems. So far we have considered the case of one right-hand side b in (1.1) (the forcing load in our application). In the multiple-input case the vector of generalized dynamical loads in (2.1) can be written as $p(t) = Fg(t)$, with F an $n \times m$ matrix and $g = [\gamma_1; \cdots ; \gamma_m] \in \mathbb{C}^m$. In the frequency space, this yields the load

$$b(\lambda) = F\hat{g}(\lambda), \qquad F \in \mathbb{C}^{n\times m} \tag{9.1}$$

which thus depends on the frequency parameter. We next consider two alternatives to cope with the presence of a right-hand side in the system (1.1) that also depends on the parameter λ:

(i) Solve the linear system $(\lambda_j^2 A + \lambda_j B + C)X = F$ for $j = 1, \dots, s$ for all right-hand sides represented by the m columns of F, with $X \in \mathbb{C}^{n\times m}$.

(ii) Solve $(\lambda_j^2 A + \lambda_j B + C)x = b(\lambda_j)$ for $j = 1, \dots, s$, with $x = x(\lambda_j)$.

We shall see that the choice between the two approaches depends on the relative size of s (the number of parameters) and m (the number of different loading histories).

Case (i). Constant multiple right-hand sides. The linearized problem in this case can be written as

$$(\mathcal{A} + \lambda_j \mathcal{B})Z = \widehat{D}, \qquad \widehat{D} = [F; 0] \in \mathbb{C}^{2n\times m},\ Z = Z(\lambda_j). \tag{9.2}$$

This system can be solved by using a generalization of the SS-Lanczos algorithm for multiple right-hand sides. Using a block approach, for instance, one constructs the *block* Krylov subspace[2] $\mathcal{K}_{mk}(\mathcal{A}\mathcal{B}^{-1}, \widehat{D})$ and then approximates all shifted systems using the shift invariance of the space (cf., e.g., [34]). The block version of the two-term recurrence Lanczos method generates pairs of matrices $\mathcal{Q}_k, \tilde{\mathcal{Q}}_k$ and $\mathcal{P}_k, \tilde{\mathcal{P}}_k$ that satisfy the relations $\mathcal{A}\mathcal{B}^{-1}\mathcal{P}_k = \mathcal{Q}_{k+1}\mathcal{L}_k$ and $\mathcal{Q}_k = \mathcal{P}_k\mathcal{U}_k$, where $\mathcal{L}_k$,$\mathcal{U}_k$ are block lower and upper bidiagonal. An approximate solution to the linearized problem (9.2) is found as $\hat{Z}_k = \tilde{\mathcal{P}}_k Y_k$, where $Y_k \in \mathbb{C}^{km\times m}$ solves

$$\min_{Y\in\mathbb{C}^{km\times m}} \|E_1\chi - (\mathcal{L}_k\mathcal{U}_k + \lambda_j\tilde{I})Y\|, \qquad j = 1,\dots,s, \tag{9.3}$$

where $\widehat{D} = \mathcal{Q}_{k+1}E_1\chi$, $E_1 = [I_m; 0] \in \mathbb{R}^{(k+1)m\times m}$ and $\tilde{I} = [I_{mk}; 0] \in \mathbb{R}^{(k+1)m\times km}$ [32].

Note that the block tridiagonal matrix $(\mathcal{L}_k\mathcal{U}_k + \lambda_j\tilde{I})$ is of size mk. The least squares solution matrix Y_k is updated at each iteration k with a computational cost of $\mathcal{O}(m^2)$ [32]; see also [8].

Case (ii). Single frequency-dependent right-hand side. In this case (1.1) becomes

$$(\lambda_j^2 A + \lambda_j B + C)x = b(\lambda_j), \quad j = 1,\dots,s,$$

where $b(\lambda_j)$ may depend on λ_j nonlinearly. The linearized problem takes the form

$$(\mathcal{A} + \lambda_j\mathcal{B})z = d(\lambda_j), \quad d(\lambda_j) = [b(\lambda_j); 0].$$

Solving all systems independently will make the cost grow approximately linearly with the number of parameters, and it will not make use of the common matrices $\mathcal{A}$ and $\mathcal{B}$. In [2] a method was devised, for real symmetric positive definite matrix $\mathcal{A}\mathcal{B}^{-1}$, that deals with the multiple right-hand side and associated shift. It would be interesting to see whether a generalization to our setting would be possible.

Alternatively, all systems may be treated simultaneously, yielding the following Sylvester equation:

$$\mathcal{A}\mathcal{B}^{-1}\widehat{Z} + \widehat{Z}\Lambda = \widehat{D}, \qquad \widehat{D} = [d(\lambda_1),\dots,d(\lambda_s)] \in \mathbb{C}^{2n\times s}, \qquad \Lambda = \mathrm{diag}(\lambda_1,\dots,\lambda_s),$$

with $\widehat{Z} = \mathcal{B}^{-1}[z_1,\dots,z_s]$. Block versions of Krylov subspace methods may be adapted to solve the problem [31]. More precisely, the block Krylov subspace $\mathcal{K}_{sk}(\mathcal{A}\mathcal{B}^{-1}, \widehat{D})$ is generated, and the approximation to the Sylvester equation is carried out on the projected problem [31]. The implementation is completely analogous to that for constant multiple loads. However, the least squares problem to be solved for each frequency is

$$\min_{y\in\mathbb{C}^{ks}} \|(E_1\chi)_{:,j} - (\mathcal{L}_k\mathcal{U}_k + \lambda_j\tilde{I}_{ks})y\|, \qquad y = y(\lambda_j), \qquad j = 1,\dots,s. \tag{9.4}$$

Contrary to (9.3), the computational cost for updating the solution y_k at each iteration k depends on the number of parameters and is proportional to s^2.

[2] Given $G \in \mathbb{C}^{n\times n}$, $\widehat{D} \in \mathbb{C}^{n\times m}$, a block Krylov subspace is given by $\mathcal{K}_{mk}(G, \widehat{D})$ =span$\{\widehat{D}, G\widehat{D}, \dots, G^{k-1}\widehat{D}\}$ and its dimension is at most mk.

The preference between the two approaches depends on the magnitude of s and m. If very many parameter values are treated simultaneously, then one may want to consider, if possible, splitting the load vector b as in (9.1) and solving with F as the right-hand side matrix. This may be particularly convenient when the system is characterized by few loading points, so that $m = \mathcal{O}(1)$.

10. Conclusions.

In this paper we have proposed a method for solving a linear system with a quadratic parameter that varies in a wide range. The method relies on the symmetry of the linearized problem with respect to an indefinite inner product. Shift invariance of the subspace in which the problem is projected is exploited in order to limit the computational cost growth as the number of parameters increases.

We have addressed the problem of inexactly solving the linear system arising at each iteration of the solver and uncovered some of the major difficulties related to its efficient manipulation. The performance of the inner-outer method seems to depend on the conditioning of matrix A in the original problem. Strategies for optimizing the inner system solution would certainly lead to better performance; for instance, we have not explored ordering strategies of the coefficient matrix entries, other than lexicographic, which may lead to more efficient preconditioning procedures for the inner system.

In summary, our numerical experience shows that if systems with the leading matrix A can be solved with a sparse direct solver, then the proposed method greatly outperforms other currently available techniques. When memory limitations force us to use an inner-outer procedure, then the performance of the method will in general degrade, the amount of degradation depending on the conditioning of A. We have shown, however, that when A is not too severely ill-conditioned, the inner-outer method remains highly competitive in case several parameter values need be considered. Ill-conditioning or singularity of A may be overcome by shifting the linearized formulation, although such an approach may entail considerable computational cost overhead, due to a less convenient sparsity pattern of the matrix.

It would be interesting to explore whether an efficient method that directly attacks the original problem, without passing through the linearization process, could be devised (cf., e.g., [36] for the eigenvalue setting). Such a method would allow us to deal with higher orders in λ.

Acknowledgments. All Fortran tests were done using the facilities of the Istituto di Analisi Numerica del CNR, Pavia, Italy. Stimulating discussions with Françoise Tisseur are acknowledged. We thank the referees for their constructive criticism.

RESIDUAL AND BACKWARD ERROR BOUNDS IN MINIMUM RESIDUAL KRYLOV SUBSPACE METHODS*

CHRISTOPHER C. PAIGE† AND ZDENĚK STRAKOŠ‡

Abstract. Minimum residual norm iterative methods for solving linear systems $Ax = b$ can be viewed as, and are often implemented as, sequences of least squares problems involving Krylov subspaces of increasing dimensions. The minimum residual method (MINRES) [C. Paige and M. Saunders, *SIAM J. Numer. Anal.*, 12 (1975), pp. 617–629] and generalized minimum residual method (GMRES) [Y. Saad and M. Schultz, *SIAM J. Sci. Statist. Comput.*, 7 (1986), pp. 856–869] represent typical examples. In [C. Paige and Z. Strakoš, *Bounds for the least squares distance using scaled total least squares*, Numer. Math., to appear] revealing upper and lower bounds on the residual norm of any linear least squares (LS) problem were derived in terms of the total least squares (TLS) correction of the corresponding scaled TLS problem. In this paper theoretical results of [C. Paige and Z. Strakoš, *Bounds for the least squares distance using scaled total least squares*, Numer. Math., to appear] are extended to the GMRES context. The bounds that are developed are important in theory, but they also have fundamental practical implications for the finite precision behavior of the modified Gram–Schmidt implementation of GMRES, and perhaps for other minimum norm methods.

1. Introduction.

Consider a system of linear algebraic equations $Ax = b$, where A is a given n by n (unsymmetric) nonsingular matrix and b an n-dimensional vector. Given an initial approximation x_0, one approach to finding x is to first compute the initial residual $r_0 = b - Ax_0$. Using this, derive a sequence of Krylov subspaces $\mathcal{K}_k(A, r_0) \equiv \text{span}\{r_0, Ar_0, \ldots, A^{k-1}r_0\}$, $k = 1, 2, \ldots$, in some way, and look for approximate solutions $x_k \in x_0 + \mathcal{K}_k(A, r_0)$. Various principles are used for constructing x_k which determine various Krylov subspace methods for solving $Ax = b$. Similarly, Krylov subspaces for A can be used to obtain eigenvalue approximations or to solve other problems involving A.

Krylov subspace methods are useful for solving problems involving very large sparse matrices, since these methods use these matrices only for multiplying vectors, and the resulting Krylov subspaces frequently exhibit good approximation properties. The Arnoldi method [4] is a Krylov subspace method designed for solving the eigenproblem of unsymmetric matrices. The generalized minimum residual method (GMRES) [27] uses the Arnoldi iteration and adapts it for solving the linear system $Ax = b$. GMRES can be computationally more expensive per step than some other methods; see, for example, Bi-CGSTAB [30], QMR [8, 9] for unsymmetric A, and LSQR [20, 19] for unsymmetric or even rectangular A. However, GMRES is widely

used for solving linear systems arising from discretization of partial differential equations, and it is also interesting to study, since it *does* in theory minimize the 2-norm of the residual $\|r_k\| = \|b - Ax_k\|$ over $x_k \in x_0 + \mathcal{K}_k(A, r_0)$ at each step. Thus, theoretical results on GMRES can, for example, provide lower bounds for the residuals of other methods using the same Krylov subspaces. GMRES is also interesting to study computationally, especially since a strong relationship has been noticed between convergence of GMRES and loss of orthogonality among the Arnoldi vectors computed via (finite precision) modified Gram–Schmidt (MGS) orthogonalization; see [11, 24]. An understanding of this will be just as important for the practical use of the Arnoldi method as it will be for GMRES itself.

This project is complicated, so we give an introduction involving simplified results. Given an initial approximation x_0 to the solution x of $Ax = b$, we form the residual

$$r_0 = b - Ax_0, \qquad \rho_0 = \|r_0\|, \qquad v_1 = r_0/\rho_0,$$

and use v_1 to initiate the Arnoldi process [4]. In theory, after k steps this produces

$$V_{k+1} = [v_1, v_2, \ldots, v_{k+1}], \quad V_{k+1}^T V_{k+1} = I_{k+1}, \quad \operatorname{span}\{v_1, \ldots, v_{k+1}\} = \mathcal{K}_{k+1}(A, r_0).$$

At each step GMRES takes $x_k = x_0 + V_k y_k$ as the approximation to the solution x, which gives the residual $r_k = b - Ax_k$. GMRES uses that y_k which in theory minimizes the 2-norm of this residual, so

$$\|r_k\| = \min_y \|r_0 - AV_k\, y\| = \min_y \|[v_1\rho_0, AV_k] \begin{bmatrix} 1 \\ -y \end{bmatrix} \|.$$

So far this is rigorous and well known, but now we give some ideas in approximate form, so that they will be easier to follow. It is the purpose of this paper to show for the ratio of the largest to smallest singular value (condition number) $\kappa([v_1\rho_0, AV_k])$, which increases with k, and the normwise relative backward error

$$\beta(x_k) \equiv \frac{\|r_k\|}{\|b\| + \|A\| \cdot \|x_k\|}, \tag{1.1}$$

which tends to decrease with k until it is eventually zero, that with exact arithmetic we have something like the intriguing relationship

$$\beta(x_k)\, \kappa([v_1\rho_0, AV_k]) = O(1). \tag{1.2}$$

In later sections we will develop rigorous theory for the more precise version of this. There the columns of $[v_1\rho_0, AV_k]$ in $\kappa(\cdot)$ are scaled, and a certain condition must be satisfied. We will argue that the precise version probably also holds even in finite precision arithmetic and present convincing numerical examples supporting this hypothesis.

Now we explain why (1.2) is important. An efficient, and the most usual way of computing the Arnoldi vectors $v_1, v_2, \ldots, v_{k+1}$ for large sparse unsymmetric A, is to use the MGS orthogonalization. Unfortunately, in finite precision computations this leads to loss of orthogonality among these MGS Arnoldi vectors. If these MGS Arnoldi vectors are used in GMRES we have MGS GMRES. We want to show that MGS GMRES succeeds despite the loss of orthogonality among the computed MGS Arnoldi vectors. A similar hypothesis was published in [11, 24] with a justification based on the link between loss of orthogonality among the Arnoldi vectors and the size of the GMRES relative residual. Here is how we hope to prove a significantly stronger statement in [17] by using what is essentially the result (1.2) of this paper as a fundamental intermediate step.

Following the important work [5] of Björck, and that of Walker [32], the papers [7] and [11] showed a relationship between the *finite precision* loss of orthogonality in the MGS Arnoldi vectors and the condition number $\kappa([v_1\rho_0, AV_k])$. In particular, unless A is extremely ill-conditioned (close to numericaly singular), for computed quantities

$$\text{(1.3)} \quad \|I - V_{k+1}^T V_{k+1}\|_F \leq \kappa([v_1\rho_0, AV_k])\, O(\epsilon), \quad \epsilon \text{ the computer roundoff unit}$$

(where subscript F denotes the Frobenius norm). Combining it with a finite precision version of (1.2) would show

$$\text{(1.4)} \qquad \frac{\|r_k\| \cdot \|I - V_{k+1}^T V_{k+1}\|_F}{\|b\| + \|A\| \cdot \|x_k\|} \leq \beta(x_k)\, \kappa([v_1\rho_0, AV_k])\, O(\epsilon) \;=\; O(\epsilon).$$

This would imply that it is impossible to have a significant loss of orthogonality until the normwise relative backward error is very small. It could then be shown that there would be no meaningful deterioration in the rate of convergence, and significant loss of orthogonality would imply convergence and backward stability of MGS GMRES. These results would then be somewhat analogous to those shown for the Lanczos method for the symmetric eigenproblem, where significant loss of orthogonality implied that at least one eigenvalue had been found to about machine precision, and the first eigenvalues to converge did so with no meaningful deterioration in rate of convergence; see [16]. Perhaps the ideas here could be combined with some of those from [16] to prove how the MGS Arnoldi method is affected by rounding errors.

If we can prove a result like (1.4), we will be able to justify theoretically the well-known observation that, unless the matrix A is extremely ill-conditioned, MGS GMRES competes successfully in both the rate of convergence and the final accuracy with the more expensive GMRES implementation based on the Householder reflections (HH GMRES)[31]. HH GMRES was proved backward stable in [7]. That proof relied upon the fact that the Householder reflections keep the loss of orthogonality among the computed Arnoldi vectors close to the machine precision. Orthogonality among the Arnoldi vectors can be lost using MGS GMRES finite precision computations. Therefore the results from [7] could not be extended to MGS GMRES, and a different approach had to be used.

Despite its backward stability, HH GMRES is not widely used. A popular justification for this is based on the *numerical stability* versus *computational efficiency* argument: It is generally believed that HH GMRES is favorable numerically, but the cheaper MGS GMRES is accepted (sometimes with a fear of a possible unspecified loss of accuracy) as a standard for practical computations. One aim of our work is to eliminate that fear.

This paper is the third of a sequence starting with [22], which revised the fundamentals of the scaled total least squares theory. The subsequent paper [21] produced general purpose bounds we will use here and in [17]. The present paper proves theoretical results *motivated* by the abovementioned finite precision behavior of MGS GMRES but assumes *exact* arithmetic in all the proofs. Finite precision analogies of the statements proven here will require detailed rounding error analyses, and these are intended for the planned paper [17]. Thus, when completed, we think the work in [21], in here, and in [17] will represent a substantial step forward in our understanding of MGS orthogonalization in Krylov subspace methods and will also lead to a full justification for MGS GMRES computations. We also hope it will produce tools that will help in the analysis of MGS Arnoldi computations. We would like to investigate whether the MGS Arnoldi method still gives accurate approximations to eigenvalues, but we will not consider this here.

Since the results in this paper assume exact arithmetic, they are independent of any particular implementation of the GMRES method. They apply to any mathematically equivalent residual minimizing Krylov subspace method (such as the MINRES method for symmetric indefinite systems). Some mathematically equivalent variants of the GMRES method are described in [15, 25]. In most practical applications some acceleration technique must be applied to improve convergence of the basic method. For historical reasons such acceleration techniques are frequently and imprecisely called preconditioning. Assuming exact arithmetic, preconditioning of a given method is equivalent to the application of the (basic) method to some modified (preconditioned) system. In this paper we assume, with no loss of generality, that A represents the matrix and b the right-hand side of the preconditioned system. For simplicity of notation we assume that A and b are real. Reformulation to the general complex case is obvious.

The paper is organized as follows. In section 2 we will give the necessary mathematics of GMRES, while in section 3, which represents the main connection with the preceding papers [22] and [21], we will present bounds for the GMRES residual (Theorem 3.1). Section 4 will give an extreme example which shows that the assumption (3.5) required in Theorem 3.1 need not hold up until the very last step of the GMRES iteration. This is, of course, a highly contrived situation and not indicative of any realistic problem we have encountered. Section 5 will explain in more detail just why the bounds from section 3 are so important for our understanding of GMRES and related methods. We will prove Theorem 5.1, which is the precise version of (1.2) and represents the main result of this paper. Section 6 will discuss its consequences in light of possible scalings. Section 7 will display some computational results and section 8 will present concluding remarks.

In the paper we will use $\sigma_i(X)$ to denote the ith largest singular value of X, use $\kappa(X)$ to be the ratio of the largest to the smallest singular value of X, and refer to $\kappa(X)$ briefly as the condition number of X. The vector of elements i to j of a vector y will be denoted $y_{i:j}$, and e_j denotes the jth column of the unit matrix I. We will use $\|\cdot\|$ to denote the 2-norm and $\|\cdot\|_F$ to denote the Frobenius norm. Several quantities used in our bounds will depend on the iteration step k. For simplicity of notation we sometimes omit the explicit reference to the iteration step when the dependence is clear from the context and need not be stressed for any particular reason.

As explained above, this paper proves the precise version of (1.2), which is the fundamental intermediate step of the whole project, and it assumes exact arithmetic in all the proofs. However, the underlying discussion of MGS GMRES finite precision behavior motivates the whole work and affects most of the particular considerations in this paper. Though we separate the exact arithmetic results from the finite precision arithmetic discussion as much as possible, we cannot split them entirely. Scaling, for example, affects both (exact precision) bounds for the GMRES residual norm developed in this paper and finite precision bounds for loss of orthogonality in the Arnoldi process. Any discussion of scaling must consider both aspects, which are generally in conflict. When it will be helpful, we will use the word “ideally” to refer to a result that would hold using exact arithmetic, and “computationally” or “numerically” to a result of a finite precision computation.

2. The GMRES method. For a given n by n (usually unsymmetric) nonsingular matrix A and n-vector b, we wish to solve $Ax = b$. Given an initial approximation x_0 we form the residual

$$r_0 = b - Ax_0, \qquad \rho_0 = \|r_0\|, \qquad v_1 = r_0/\rho_0, \tag{2.1}$$

and use v_1 to initiate the Arnoldi process [4]. At step k this forms Av_k, orthogonalizes it against $v_1, v_2, \ldots, v_k$, and if the resulting vector is nonzero, normalizes it to give v_{k+1}, giving ideally

$$AV_k = V_{k+1}H_{k+1,k}, \quad V_{k+1}^T V_{k+1} = I_{k+1}, \quad V_{k+1} = [v_1, v_2, \ldots, v_{k+1}]. \tag{2.2}$$

Here $H_{k+1,k}$ is a $k+1$ by k upper Hessenberg matrix with elements h_{ij}, where $h_{j+1,j} \neq 0$, $j = 1, 2, \ldots, k-1$. If at any stage $h_{k+1,k} = 0$ we would stop with $AV_k = V_k H_{k,k}$. In this case all the eigenvalues of $H_{k,k}$ are clearly eigenvalues of A. When $h_{k+1,k} \neq 0$ the eigenvalues of $H_{k,k}$ are approximations to some of those of A, and this gives the Arnoldi method [4]. Computationally, we are unlikely to reach a k such that $h_{k+1,k} = 0$, and for solution of equations we stop when we assess the norm of the residual (ideally given as below in (2.7)) is small enough.

In general, at each step we take $x_k = x_0 + V_k y_k$ as our approximation to the solution x, which gives the residual

$$\begin{aligned} r_k &= b - Ax_k = r_0 - AV_k y_k = v_1\rho_0 - V_{k+1}H_{k+1,k}\, y_k \\ &= V_{k+1}(e_1\rho_0 - H_{k+1,k}\, y_k). \end{aligned} \tag{2.3}$$

GMRES seeks y_k which minimizes this residual by solving the linear least squares problem

$$\|r_k\| = \min_y \|r_0 - AV_k\, y\| = \min_y \|v_1\rho_0 - AV_k\, y\|. \tag{2.4}$$

Using (2.2) and (2.3), (2.4) can be formulated as the least squares problem with the upper Hessenberg matrix $H_{k+1,k}$

$$\|r_k\| = \min_y \|e_1\rho_0 - H_{k+1,k}\, y\|. \tag{2.5}$$

To solve (2.5) we apply orthogonal rotations (J_i being the rotation in the $i, i+1$ plane through the angle θ_i) sequentially to $H_{k+1,k}$ to bring it to upper triangular form S_k:

$$J_k \cdots J_2 J_1 H_{k+1,k} = Q_k^T H_{k+1,k} = \begin{pmatrix} S_k \\ 0 \end{pmatrix}.$$

The vectors y_k and r_k ideally then satisfy

$$S_k y_k = (Q_k^T e_1\rho_0)_{1:k}, \tag{2.6}$$

$$\begin{aligned} \|r_k\| &= |e_{k+1}^T Q_k^T e_1 \rho_0| \\ &= |\xi_1\xi_2 \cdots \xi_k|\, \|r_0\|, \qquad \xi_i = \sin\theta_i. \end{aligned} \tag{2.7}$$

The measure (2.7) of the (nonincreasing) residual norm is available without determining y_k, and since y_{k+1} will usually differ in every element from y_k, it would seem preferable to avoid determining y_k or x_k until we decide the residual norm (2.7) is small enough to stop. Computationally, however, it is not clear that we can base the stopping criterion on (2.7) alone. The step from (2.4) to (2.5) requires orthogonality of the columns of V_{k+1}. However, even if orthogonality of the Arnoldi vectors computed using finite precision arithmetic is well preserved (as in HH GMRES), (2.7) will not hold for the computed quantities after the residual norm drops near the final accuracy level; see [7].

Finally, little has been published about the choice of the initial approximation x_0. In many cases $x_0 = 0$ is recommended or considered. For $x_0 = 0$ we have $r_0 = b$ and trivially $\|r_0\| \le \|b\|$. This last condition seems very natural and should always be imposed. For a nonzero x_0 it may easily happen that $\|r_0\| > \|b\|$ (even $\gg$ for some problems), and any such x_0 is a poor initial approximation to the solution x. Hegedüs [13] suggested that a simple way around this difficulty is to rescale the initial approximation. Given a preliminary initial guess x_p, it is easy to determine the scaling parameter $\zeta_{\min}$ such that

$$\|r_0\| = \|b - Ax_p\zeta_{\min}\| = \min_{\zeta} \|b - Ax_p\zeta\|, \qquad \zeta_{\min} = \frac{b^T A x_p}{\|Ax_p\|^2}\,. \tag{2.8}$$

Thus, by setting $x_0 = x_p\zeta_{\min}$ we ensure $\|r_0\| \le \|b\|$. The extra cost for implementing this little trick is negligible; it should be used in GMRES computations whenever a nonzero x_0 is considered. For some related comments see the discussion concerning the experiments in section 7.

We point out that the previous paragraph does not mean that an arbitrary x_p with (2.8) gives a proper initial approximation x_0. Our general feeling is that, even with (2.8), a nonzero x_0 should not be used unless there is a good reason for preferring it over $x_0 = 0$. It has been observed that without such additional justification, a choice of nonzero x_0 satisfying $\|r_0\| \le \|b\|$ can significantly slow down GMRES convergence [28].

3. Bounds for the GMRES residuals.

From the previous section it is clear that GMRES can be seen as a sequence of least squares problems (2.4) involving Krylov subspaces of increasing dimensions. In [21] we considered the overdetermined approximate linear system $Bu \approx c$ and bounded the least squares (LS) residual

$$\text{LS residual} \quad \equiv \quad \min_{r,y} \|r\|_2 \quad \text{subject to} \quad By = c - r \tag{3.1}$$

from above and from below in terms of the scaled total least squares (STLS) distance

$$\text{STLS distance} \quad \equiv \quad \min_{s,E,z} \|[s, E]\|_F \quad \text{subject to} \quad (B + E)z\gamma = c\gamma - s, \tag{3.2}$$

where $\gamma > 0$ is the scaling parameter. The bounds from [21] say nothing about an iterative method, or where B or c come from, and so they are general results. In order to apply the results from [21] to GMRES we have to identify B, c, and γ with the proper quantities in GMRES. We have several choices, but as yet there is no choice which is clearly superior to the others. Therefore we will formulate the bounds in the following theorem and in section 5 in a general way. Particular scalings (γ and D_k in the theorem) will be discussed in section 6.

To obtain useful bounds for the kth step of GMRES, we consider $c = r_0 = v_1\rho_0$ and $B = B_k = AV_kD_k$, where D_k is a diagonal matrix of positive scaling coefficients ($D_k > 0$). Note that the column scaling by the diagonal matrix D_k does not change the optimal residual r_k (see (2.4)) and

$$\|r_k\| = \min_y \|v_1\rho_0 - AV_k\, y\| = \min_{D_k^{-1}y} \|c - B_k\,(D_k^{-1}y)\|\,. \tag{3.3}$$

Clearly, for this c and B_k the solution of (3.1) is $D_k^{-1}y_k$, where y_k is the solution of the LS problem (2.4). The column scaling matrix D_k will prove useful later. Note that, by construction, B_k has full column rank.

We now give bounds on the $\|r_k\|$ in GMRES, together with bounds on an important ratio δ_k.

THEOREM 3.1. *Given a scalar $\gamma > 0$ and a positive diagonal matrix D_k, use $\sigma(\cdot)$ to denote singular values and $\|\cdot\|$ to denote 2-norms. Let the n by n nonsingular matrix A, the vectors r_0, y_k, and r_k, the scalar ρ_0, and the matrix V_k be as in the GMRES algorithm* (2.1)–(2.5) *using exact arithmetic, and let AV_k have rank k. Denote $B_k = AV_kD_k$, $c = v_1\rho_0$, and define*

$$\delta_k \equiv \delta_k(\gamma, D_k) \equiv \sigma_{k+1}([c\gamma, B_k])/\sigma_k(B_k) = \sigma_{k+1}([v_1\rho_0\gamma, AV_kD_k])/\sigma_k(AV_kD_k). \tag{3.4}$$

If

$$v_1 \not\perp \{\textit{left singular vector subspace of } B_k \textit{ corresponding to } \sigma_{min}(B_k)\}, \tag{3.5}$$

then $\delta_k < 1$ and

$$\begin{aligned} \mu_L \equiv \sigma_{k+1}([c\gamma, B_k])\,\{\gamma^{-2} + \|D_k^{-1}y_k\|^2\}^{\frac{1}{2}} \quad &\le \quad \|r_k\| \\ \le\; \mu_U \equiv \sigma_{k+1}([c\gamma, B_k])\,\{\gamma^{-2} + (1-\delta_k^2)^{-1}\|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}&, \end{aligned} \tag{3.6}$$

$$\frac{\|r_k\|}{\left\{\gamma^{-2} + \frac{\|D_k^{-1}y_k\|^2}{1-\delta_k^2}\right\}^{\frac{1}{2}}\sigma_k(B_k)} \le \delta_k \le \frac{\|r_k\|}{\{\gamma^{-2} + \|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}\sigma_k(B_k)}, \tag{3.7}$$

$$\frac{\gamma\|r_k\|}{\|[c\gamma, B_k]\|} \le \delta_k \le \frac{\gamma\|r_k\|}{\sigma_k([c\gamma, B_k])} \le \frac{\gamma\|r_k\|}{\sigma_k(B_k)} \le \frac{\gamma\|r_k\|}{\sigma_n(A)\sigma_k(D_k)}. \tag{3.8}$$

Proof. We see $c\gamma = v_1\rho_0\gamma$ and $B_k = AV_kD_k$ satisfy the conditions and assumptions of Theorem 4.1 of [21] for any $\gamma > 0$, and from (3.3) we see that r_k and $D_k^{-1}y_k$ correspond to r and y in (3.1); so the theorem holds with [21, (4.4)] giving (3.6) and its equivalent (3.7), while Corollary 6.1 of [21] gives all but the last inequality in (3.8), which holds since $V_k^HV_k = I$. □

Note that apart from the last inequality in (3.8) the result does not depend on orthogonality of the columns of V_k, since Theorem 4.1 of [21] requires nothing of $B = B_k = AV_kD_k$ here except that it has full column rank. The only requirement is for $\|r_k\|$ to be a minimum (see (2.4), (3.1), and (3.3)) at each step. It should also be pointed out that due to monotonicity of $\|r_k\|$ from GMRES, possible oscillations in the upper bound (3.6) can be eliminated by taking the minimum

$$\|r_k\| \;\le\; \min_{j=1,\dots,k}\{\sigma_{j+1}([v_1\rho_0\gamma, B_j])\,\{\gamma^{-2} + (1-\delta_j^2)^{-1}\|D_j^{-1}y_j\|^2\}^{\frac{1}{2}}\}. \tag{3.9}$$

In the paper [21] we compared the bounds for the LS residual used here with other existing bounds. For example, [21, Corollary 5.1] gives

$$\begin{aligned} \gamma\|r_k\| &\le \delta_k\,\{\|c\|^2\gamma^2 + \sigma_k^2(B_k) - \sigma_{k+1}^2([c\gamma, B_k])\}^{\frac{1}{2}} \\ &\le \delta_k\,\{\|c\|^2\gamma^2 + \sigma_k^2(B_k)\}^{\frac{1}{2}}. \end{aligned} \tag{3.10}$$

As stated in [21, section 5], our bounds in (3.6) can be significantly better than those from (3.10). They are also easily applicable to the problem investigated in this paper. We will therefore not examine (3.10) and the other possible bounds which can be derived from (3.10) here.

It will be important to examine the tightness of the bounds (3.6). The following corollary is an immediate consequence of [21, Corollary 4.2].

COROLLARY 3.2. *Under the conditions and assumptions of Theorem* 3.1*, and using the notation there together with*

$$\eta \equiv \frac{\|r_k\| - \mu_L}{\|r_k\|}, \qquad \zeta \equiv \frac{\mu_U - \mu_L}{\|r_k\|}, \tag{3.11}$$

we have the following bound on η *and* ζ*:*

$$0 \leq \eta \ \leq \ \zeta \ \leq \ \frac{\gamma^2\|D_k^{-1}y_k\|^2}{2+\gamma^2\|D_k^{-1}y_k\|^2} \cdot \frac{\delta_k^2}{1-\delta_k^2} \to 0 \quad as \quad \gamma \to 0, \tag{3.12}$$

where the upper bound goes to zero at least as fast as $O(\gamma^4)$ *(see* (3.8)*).* □

The assumption (3.5) is not necessary for proving the bounds (3.6)–(3.8) and (3.12). From the proof of [21, Theorem 4.1] it is clear that these bounds require only $\delta_k < 1$, and, moreover, the lower bound in (3.6), the upper bound in (3.7) and the bounds in (3.8) also hold if $\delta_k = 1$. (The upper bound in (3.6) and the lower bound (3.7) become ∞ and 0 when $\delta_k = 1$, and so hold trivially.) Using (3.5), however, makes the theory clean and consistent. The assumption (3.5) is independent of scaling and it ensures that the bounds do not contain irrelevant quantities; see [22, Remark 4.3].

From (3.12) and (3.8) we see that small δ_k, γ, $\|r_k\|$ or $\|D_k^{-1}y_k\|/(1-\delta_k^2)$ ensures that the bounds (3.6) are not only very tight, but very tight in a relative sense. The tightness of the bounds depends in an important way on δ_k; for $\delta_k \ll 1$ we get the strong relationship from (3.6)

$$\|r_k\| \ \approx \ \sigma_{min}([v_1\rho_0\gamma, AV_kD_k])\,\{\gamma^{-2} + \|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}. \tag{3.13}$$

We know $0 \leq \delta_k \leq 1$ from (3.4). If $\delta_k \approx 1$ the bounds in (3.6) and (3.7) become weak, so we need to see if $\delta_k \approx 1$ is possible. In the GMRES context δ_k will necessarily be small as $\|r_k\| \to 0$ (see (3.8)). Proper scaling can always ensure $\delta_k \ll 1$. (For a fixed D_k it was shown in [22, Corollary 4.1] that if (3.5) holds, then $\delta_k < 1$, δ_k increases and decreases with γ, and (3.8) shows $\gamma \to 0 \Rightarrow \delta_k \to 0$.) Using this argument, it appears at first that the disturbing case $\delta_k \approx 1$ can easily be eliminated from our discussion. It turns out, however, that this is not entirely true because the use of scaling also has disadvantages. We will see that we cannot use an arbitrarily small γ to ensure $\delta_k \ll 1$ without (potentially) damaging the tightness of the bounds for the loss of orthogonality among the Arnoldi vectors (the tightness of the scaled version of (1.3)). On the other hand, a scaling which might be appropriate from the point of view of the formulation of the main result (a scaled version of (1.2); see the following section) might at the same time increase the value of δ_k. The choice of scaling therefore represents a delicate task. Despite these subtle details, we will see that $\delta_k \approx 1$ represents a technical problem but not a serious conceptual difficulty. We will return to the detailed discussion of this point in section 6.

4. Delayed convergence of GMRES.

It is possible for convergence of GMRES to be very slow and stagnate entirely even with exact arithmetic. Suppose

$$A = [e_2\gamma_2, e_3\gamma_3, \ldots, e_n\gamma_n, e_1\gamma_1], \qquad b = e_1\|b\|, \qquad x_0 = 0,$$

for some $\gamma_i \neq 0$, $i = 1, \dots, n$; then in (2.1) and (2.2) for $k < n$

$$V_{k+1} = [e_1, e_2, \dots, e_{k+1}], \qquad H_{k+1,k} = [e_2\gamma_2, e_3\gamma_3, \dots, e_{k+1}\gamma_{k+1}],$$

and in (2.3) and (2.5)

$$y_k = 0, \qquad x_k = 0, \qquad r_k = r_0, \qquad k = 1, 2, \dots, n-1;$$

so any convergence at all is delayed until the solution is obtained at step $k = n$. Here we have $v_1 = e_1 \perp \mathcal{R}(AV_k)$ for $k < n$, so (3.5) does not hold and $\delta_k = 1$ for $k = 1, 2, \dots, n-1$. In fact (3.6) degenerates to $\|r_k\| = \|r_0\|$ for $k < n$.

5. Backward error theorem.

Now we show why we consider the bounds from Theorem 3.1 to be so important. This provides the scaled versions of (1.2)–(1.4). Remember that the scaled equivalents of the finite precision results (1.3)–(1.4) are only for motivation here, and the full proofs of these will be left to [17].

As noticed in [32] and used in [7] (see also [3]), the Arnoldi process (2.2) with (2.1) ideally gives the QR factorization of $[r_0, AV_k]$, since on defining upper triangular $R_{k+1} \equiv [e_1\rho_0, H_{k+1,k}]$ we see

$$[r_0, AV_k] = V_{k+1}[e_1\rho_0, H_{k+1,k}] = V_{k+1}R_{k+1}, \qquad V_{k+1}^T V_{k+1} = I_{k+1}. \tag{5.1}$$

By comparing this with (2.1) and (2.2), we see we may now refer to (5.1) as the Arnoldi process.

If the orthogonalization in (2.2) is carried out by the MGS technique, then it is straightforward to show that this MGS Arnoldi process provides V_{k+1} and R_{k+1}, which are *computationally* identical to those produced by the QR factorization of $[r_0, \widetilde{AV}_k]$ by MGS. Here, $\widetilde{AV}_k$ indicates that the multiplications Av_j, $j = 1, \dots, k$, are computed numerically. A parallel statement holds when classical Gram–Schmidt orthogonalization is used in (2.2).

With a computer using finite precision with unit roundoff ϵ, the computed vectors $v_1, v_2, \dots$ tend to lose orthogonality. It was shown by Björck [5] that using MGS in the QR factorization $C = QR$ computationally leads to Q such that

$$\|I - Q^T Q\|_F \leq \kappa(C)\, O(\epsilon).$$

(For convenience in numerical experiments we use the Frobenius norm.)

Thus from the discussion following (5.1), for the finite precision version of (2.2) using MGS we have (see (1.3))

$$\|I - V_{k+1}^T V_{k+1}\|_F \leq \kappa([v_1\rho_0, AV_k])\, O(\epsilon). \tag{5.2}$$

Note that $\kappa([v_1\rho_0, AV_k])$ is used here instead of $\kappa([r_0, \widetilde{AV}_k])$. Using $\kappa([v_1\rho_0, AV_k])$ simplifies further considerations; the difference between $\kappa([v_1\rho_0, AV_k])$ and $\kappa([r_0, \widetilde{AV}_k])$ is absorbed in the multiplicative factor $O(\epsilon)$. For the detailed justification see [7] and [11].

When MGS is used with exact arithmetic in (5.1), the resulting matrix V_{k+1} is invariant with respect to the column scaling in $[v_1\rho_0\gamma, AV_kD_k]$, where $\gamma > 0$ and D_k is a positive diagonal k by k matrix. It appears that, ignoring a small additional error of $O(\epsilon)$, the matrix V_{k+1} resulting from the *finite precision* MGS Arnoldi process (5.1) is invariant with respect to positive column scaling. This important result was noticed in [11, p. 711], and was partially exploited there. It can be justified by the following argument (which is a variant of the argument attributed to Bauer; see [33, pp. 129–130]). If the scaling factors are always powers of the base of the floating point arithmetic (powers of 2 for the IEEE FP arithmetic), then the resulting V_{k+1} computed in finite precision arithmetic using the MGS Arnoldi process (5.1) will be exactly the same as the V_{k+1} computed in finite precision arithmetic using the same MGS Arnoldi process for the scaled data $[r_0\gamma, AV_kD_k]$. If the scaling factors are not powers of the base of the floating point arithmetic, then there will be additional rounding errors proportional to unit roundoff ϵ. Apparently no formal proof of the last part has been given, so we hope to include one in [17].

If all the above are true, the loss of orthogonality among the MGS Arnoldi vectors computed via (5.1) with a computer using finite precision arithmetic with unit roundoff ϵ is bounded by

$$\|I - V_{k+1}^T V_{k+1}\|_F \le \kappa([v_1\rho_0\gamma, AV_kD_k])\, O(\epsilon) \tag{5.3}$$

for all $\gamma > 0$ and positive diagonal k by k matrices D_k. One possibility is to scale the columns of $[v_1\rho_0\gamma, AV_kD_k]$ so they have unit length. That is, take

$$\gamma = \rho_0^{-1}, \qquad D_k = \mathrm{diag}\,(\|Av_1\|^{-1}, \ldots, \|Av_k\|^{-1}) \equiv \mathrm{diag}\,(\|Av_j\|^{-1}). \tag{5.4}$$

The corresponding condition number and the bound (5.3) would then be no more than a factor $\sqrt{k+1}$ away from its minimum (see [29]), so this is nearly optimal scaling. Other convenient choices will be discussed in the next section. Extensive experimental evidence suggests that for the nearly optimal scaling (5.4), the bound (5.3) is tight, and usually

$$\|I - V_{k+1}^T V_{k+1}\|_F \approx \kappa([v_1\rho_0\gamma, AV_kD_k])\, O(\epsilon). \tag{5.5}$$

It was observed that when MGS was used in (2.2), leading to the MGS GMRES method (2.1)–(2.6), loss of orthogonality in V_{k+1} was accompanied by a small relative residual norm $\|r_k\|/\rho_0$; see [11]. That is, significant loss of orthogonality in MGS GMRES apparently did not occur before convergence measured by $\|r_k\|/\rho_0$ occurred. This fortuitous behavior was analyzed numerically in [11] and a partial explanation was offered there. A much stronger and more complete theoretical explanation of the observed behavior can be derived from the bounds (3.6)–(3.8). As a first step, $\|r_k\|/\rho_0$ must be replaced by a more appropriate convergence characteristic.

We will use the terminology (such as *normwise*) and results reported in [14, section 7.1]. The *backward error* for x_k as an approximate solution for $Ax = b$ is a measure of the amounts by which A and b have to be perturbed so that x_k is the exact solution of the perturbed system $(A + \Delta A)x_k = b + \Delta b$. The *normwise relative backward error* of x_k defined by

$$\beta(x_k) \equiv \min_{\beta,\Delta A,\Delta b}\{\beta \ :\ (A+\Delta A)x_k = b + \Delta b,\ \|\Delta A\| \le \beta\|A\|,\ \|\Delta b\| \le \beta\|b\|\}$$

was shown by Rigal and Gaches [23] (see [14, Theorem 7.1, p. 132]), to satisfy

$$\beta(x_k) = \frac{\|r_k\|}{\|b\| + \|A\| \cdot \|x_k\|} = \frac{\|\Delta A_{\min}\|}{\|A\|} = \frac{\|\Delta b_{\min}\|}{\|b\|}. \tag{5.6}$$

We strongly believe that if no other (more relevant and more sophisticated) criterion is available (such as in [1]), this relative backward error should always be preferred to the (relative) residual norm $\|r_k\|/\|r_0\| = \|r_k\|/\rho_0$ in (2.1) when measuring convergence of iterative methods. In practice $\|A\|$ has to be replaced by its approximation—when available—or simply by the Frobenius norm of A. The theoretical reasons for preferring the relative backward error are well known; see, for example, [2] and [14]. We will add some more practical arguments in section 7. In particular the residual norm can be very misleading and easily misinterpreted. It is surprising and somewhat alarming that $\|r_k\|/\rho_0$ remains in use as the main (and usually the only) indicator of convergence of iterative processes. This statement applies to the majority of computational results published by numerical analysts. Our results will put a new emphasis on the importance of the backward error. For GMRES and the other residual minimizing methods, this raises a key question. If the residual norm is somewhat in doubt as a measure of convergence, how does this affect the position of the minimal residual principle as one of the main principles on which practical Krylov subspace methods are based? The answer needs work, and its further discussion is beyond the scope of this paper. However, we do not expect that the position of the minimal residual principle will be considerably shaken by such an analysis; rather we think it will be reaffirmed. It seems that GMRES, though based on the minimal residual principle, also produces a very good (nearly optimal) backward error.

We will now describe our main observation. This illustrates and supports the main goal of our work on MGS GMRES, which is to prove a scaled version of (1.4). Consider a plot with two lines obtained from the MGS GMRES finite precision computation. One line represents the relative backward error $\|r_k\|/(\|b\| + \|A\| \cdot \|x_k\|)$ and the other the loss of orthogonality $\|I - V_{k+1}^T V_{k+1}\|_F$ (both plotted on the same logarithmic scale) as a function of the iteration step k. We have observed that these two lines are always very nearly reflections of each other through the horizontal line defined by their intersection. For a clear example of this, see the dashed lines in Figure 7.1. In other words, *in finite precision MGS GMRES computations, the product of the normwise relative backward error and the loss of orthogonality is (as a function of the iteration step) almost constant and equal to the order of the machine precision* ϵ. The goal of this paper and [17] is to present a theoretical proof of this observed fact, and its fundamental consequences, which are that orthogonality among the computed MGS Arnoldi vectors is effectively maintained until convergence and total loss of orthogonality implies convergence of the normwise relative backward error to $O(\epsilon)$, which is equivalent to (normwise) backward stability of MGS GMRES.

Using the results presented in [21] the main ideas are simple and elegant. The proof itself (as yet incomplete) is, however, technical and tedious. Therefore in this paper we restrict ourselves to proving and discussing exact arithmetic results about the product of the normwise relative backward error and the condition number $\kappa([v_1\rho_0\gamma, AV_kD_k])$; with finite precision arithmetic this condition number controls the numerical loss of orthogonality via (5.5). A detailed rounding error analysis, together with the results relating the genuine loss of orthogonality $\|I - V_{k+1}^T V_{k+1}\|_F$ to the relative backward error, is intended for [17].

In the following theorem the product of the normwise relative backward error of GMRES and the condition number of the scaled matrix $[v_1\rho_0\gamma, AV_kD_k]$ is bounded from below and from above. Note that the theorem assumes exact arithmetic and therefore the result holds for GMRES in general. The theorem is formulated for any $\gamma > 0$ and any positive diagonal D_k; bounds corresponding to the specific choices of γ and D_k will be given in section 6.

THEOREM 5.1. *Under the conditions and assumptions of Theorem* 3.1, *and using the notation there, let* $\sigma_1 \equiv \sigma_1([v_1\rho_0\gamma, AV_kD_k]) = \|[v_1\rho_0\gamma, AV_kD_k]\|$, $\kappa_k \equiv \kappa([v_1\rho_0\gamma, AV_kD_k])$. *Then*

$$\begin{aligned}
(5.7)\qquad \frac{\sigma_1}{\sqrt{2}} \cdot \frac{\{\gamma^{-2} + \|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}}{\{\|b\|^2 + \|A\|^2\|x_k\|^2\}^{\frac{1}{2}}} &\le \sigma_1 \frac{\{\gamma^{-2} + \|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}}{\|b\| + \|A\| \cdot \|x_k\|} \\
&\le \kappa_k \frac{\|r_k\|}{\|b\| + \|A\| \cdot \|x_k\|} \\
\le \sigma_1 \frac{\{\gamma^{-2} + (1-\delta_k^2)^{-1}\|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}}{\|b\| + \|A\| \cdot \|x_k\|} &\le \sigma_1 \frac{\{\gamma^{-2} + (1-\delta_k^2)^{-1}\|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}}{\{\|b\|^2 + \|A\|^2\|x_k\|^2\}^{\frac{1}{2}}}.
\end{aligned}$$

Proof. The tighter lower and upper bounds follow immediately from (3.6) in Theorem 3.1. However,

$$(5.8)\qquad \frac{1}{\sqrt{2}} \le f\left(\frac{\|A\| \cdot \|x_k\|}{\|b\|}\right) = \frac{\{\|b\|^2 + \|A\|^2\|x_k\|^2\}^{\frac{1}{2}}}{\|b\| + \|A\| \cdot \|x_k\|} \le 1,$$

since for $\omega \ge 0$, $f(\omega) \equiv (1+\omega^2)^{\frac{1}{2}}/(1+\omega)$ satisfies $f(0) = 1$, $f(\omega) < 1$ for $\omega > 0$, $f(\omega) \to 1$ for $\omega \to \infty$, and $f(\omega)$ has for $\omega > 0$ a single minimum $f(1) = \sqrt{2}/2$. This gives the weaker lower and upper bounds in (5.7). □

Note that the ratio of the tighter upper and lower bounds is (exactly as in (3.6))

$$(5.9)\qquad \nu \equiv \frac{\{\gamma^{-2} + (1-\delta_k^2)^{-1}\|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}}{\{\gamma^{-2} + \|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}}$$

and the corresponding ratio of the weaker bounds is $\sqrt{2}\,\nu$. We will prefer the weaker bounds because they are convenient for the discussion of the particular scalings in the next section, and the factor $\sqrt{2}$ does not affect our considerations.

6. Scaling choices.

There is no easy preference for the choice of scaling, since we have to consider several aspects that are unfortunately in conflict.

As described before, our ultimate goal is to relate the loss of orthogonality among the Arnoldi vectors to the convergence of MGS GMRES measured by the normwise relative backward error by obtaining a scaled version of (1.4). Considering (5.3) it seems that the role of scaling is to minimize $\kappa([v_1\rho_0\gamma, AV_kD_k])$, and the nearly optimal scaling (5.4) seems to be the right choice. Scaling decreasing $\kappa([v_1\rho_0\gamma, AV_kD_k])$ may, however, increase the value of $\delta(\gamma, D_k)$ and therefore act against the tightness of the bounds in Theorem 5.1; see (3.8) and (3.12). While decreasing γ decreases δ_k [22, Corollary 4.1], decreasing entries in D_k increase the upper bounds in (3.8) and potentially also δ_k. In order to describe this in more detail we denote, for the moment, $\vartheta \equiv (\sigma_k(D_k))^{-1}, D_k' \equiv \vartheta D_k, \sigma_k(D_k') = 1$. Now $\vartheta\sigma_1([v_1\rho_0\gamma, AV_kD_k]) = \sigma_1([v_1\rho_0\gamma\vartheta, AV_kD_k'])$, $\kappa([v_1\rho_0\gamma, AV_kD_k]) = \kappa([v_1\rho_0\gamma\vartheta, AV_kD_k'])$, and for δ_k in (3.4)

$$\begin{aligned}
\delta_k \equiv \delta_k(\gamma, D_k) &= \frac{\sigma_{k+1}([v_1\rho_0\gamma, AV_kD_k])}{\sigma_k(AV_kD_k)} \\
(6.1)\qquad &= \frac{\sigma_{k+1}([v_1\rho_0\gamma\vartheta, AV_kD_k'])}{\sigma_k(AV_kD_k')} = \delta_k(\gamma\vartheta, D_k').
\end{aligned}$$

This shows the bounds in Theorem 5.1 rescale trivially, giving the same results for the scaling γ, $D_k = \vartheta^{-1}D_k'$, as for the scaling $\gamma\vartheta$, D_k'. It is clear from [22, Corollary

4.1] that, for a fixed $D_k^{'}$, $\delta_k(\gamma\vartheta, D_k^{'})$ increases monotonically with $\gamma\vartheta$, and in some circumstances it can be close to unity. (We assume that the assumptions of Theorem 3.1 hold and therefore $\delta_k < 1$ always.) It follows that if ϑ is very large (resulting in large $\gamma\vartheta$), then $\delta_k(\gamma\vartheta, D_k^{'})$ can be close to unity. This negatively affects the tightness of the bounds in Theorem 5.1. Consequently, the near optimal tightness in (5.3) might be achieved at the cost of weakening (5.7). Similarly, weakening (5.3) may result in a tighter (5.7).

Please notice that varying ϑ (for a fixed $D_k^{'}$) has, due to (6.1), the same effect on $\delta_k(\gamma, D_k) = \delta_k(\gamma, \vartheta^{-1}D_k^{'}) = \delta_k(\gamma\vartheta, D_k^{'})$ as varying the scaling parameter γ. It therefore need not be considered here.

To study further the effects of scaling, we will discuss three specific cases: no scaling ($\gamma = 1$, $D_k = I$), the nearly optimal column scaling $\gamma = \rho_0^{-1}$, $D_k = \mathrm{diag}(\|Av_j\|^{-1})$, and the norm scaling $\gamma = \|b\|^{-1}$, $D_k = \|A\|^{-1}I$. We will consider only the weaker bounds given by Theorem 5.1.

PROPOSITION 6.1. *Under the conditions and assumptions of Theorem* 3.1 *and using the notation of Theorem* 5.1*, we have the following bounds:*
With no scaling ($\gamma = 1$, $D_k = I$) we have $\delta_k \equiv \delta_k(1, I)$, $\sigma_1 \equiv \sigma_1([r_0, AV_k])$, $\kappa_k \equiv \kappa([r_0, AV_k])$, and the weaker bounds from (5.7) *give*

$$\chi_{L1} \equiv \frac{\sigma_1}{\sqrt{2}} \cdot \frac{\{1 + \|y_k\|^2\}^{\frac{1}{2}}}{\{\|b\|^2 + \|A\|^2\|x_k\|^2\}^{\frac{1}{2}}} \leq \kappa_k \frac{\|r_k\|}{\|b\| + \|A\| \cdot \|x_k\|} \leq \sigma_1 \frac{\{1 + (1-\delta_k^2)^{-1}\|y_k\|^2\}^{\frac{1}{2}}}{\{\|b\|^2 + \|A\|^2\|x_k\|^2\}^{\frac{1}{2}}} \equiv \chi_{U1}. \tag{6.2}$$

The nearly optimal column scaling $\gamma = \rho_0^{-1}$, $D_k = \mathrm{diag}(\|Av_j\|^{-1})$ gives
$\delta_k \equiv \delta_k(\rho_0^{-1}, D_k)$, $\sigma_1 \equiv \sigma_1([v_1, AV_kD_k])$, $\kappa_k \equiv \kappa([v_1, AV_kD_k])$, and

$$\chi_{L2} \equiv \frac{\sigma_1}{\sqrt{2}} \cdot \frac{\{\rho_0^2 + \|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}}{\{\|b\|^2 + \|A\|^2\|x_k\|^2\}^{\frac{1}{2}}} \leq \kappa_k \frac{\|r_k\|}{\|b\| + \|A\| \cdot \|x_k\|} \leq \sigma_1 \frac{\{\rho_0^2 + (1-\delta_k^2)^{-1}\|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}}{\{\|b\|^2 + \|A\|^2\|x_k\|^2\}^{\frac{1}{2}}} \equiv \chi_{U2}. \tag{6.3}$$

Finally, the scaling $\gamma = \|b\|^{-1}$, $D_k = \|A\|^{-1}I$ gives

$$\delta_k \equiv \delta_k\left(\frac{\|A\|}{\|b\|}, I\right), \quad \sigma_1 \equiv \sigma_1\left(\left[\frac{v_1\rho_0}{\|b\|}, \frac{AV_k}{\|A\|}\right]\right), \quad \kappa_k \equiv \kappa\left(\left[\frac{v_1\rho_0}{\|b\|}, \frac{AV_k}{\|A\|}\right]\right), \tag{6.4}$$

$$\chi_{L3} \equiv \frac{\sigma_1}{\sqrt{2}} \cdot \frac{\{\|b\|^2 + \|A\|^2\|y_k\|^2\}^{\frac{1}{2}}}{\{\|b\|^2 + \|A\|^2\|x_k\|^2\}^{\frac{1}{2}}} \leq \kappa_k \frac{\|r_k\|}{\|b\| + \|A\| \cdot \|x_k\|} \leq \sigma_1 \frac{\{\|b\|^2 + (1-\delta_k^2)^{-1}\|A\|^2\|y_k\|^2\}^{\frac{1}{2}}}{\{\|b\|^2 + \|A\|^2\|x_k\|^2\}^{\frac{1}{2}}} \equiv \chi_{U3}. \quad \square \tag{6.5}$$

Throughout this discussion of GMRES in exact arithmetic, we could have replaced $\|y_k\|_2$ by $\|x_k - x_0\|_2$, since $x_k = x_0 + V_ky_k$. However, we chose not to do this in order that the results be relevant to the finite precision case as well, where V_k may lose orthogonality. The exception which will follow will allow us to write the result (6.5) in a very simple form. Consider for the moment $x_0 = 0$. Then (ideally) $\|x_k\| = \|y_k\|$ and when $\delta_k(\|b\|^{-1}\|A\|, I) \ll 1$, (6.5) reduces to (with the definitions in (6.4))

$$\frac{\sigma_1}{\sqrt{2}} \;\le\; \kappa_k \,\frac{\|r_k\|}{\|b\| + \|A\| \cdot \|x_k\|} \;\lesssim\; \sigma_1\,. \tag{6.6}$$

For the scaling in (6.3), each of the $k+1$ columns of $[v_1, AV_kD_k]$ has a 2-norm of 1, so

$$1 \le \sigma_1 \equiv \|[v_1\rho_0\gamma, AV_kD_k]\| \le \sqrt{k+1}\,. \tag{6.7}$$

For the scaling in (6.4) and x_0 chosen from (2.8), the 2-norm of each column of $[v_1\rho_0\|b\|^{-1}, AV_k\|A\|^{-1}]$ is bounded above by 1, so the upper bound in (6.7) holds. If we assume $x_0 = 0$ as well, then $v_1\rho_0 = r_0 = b$, so the first column has the 2-norm of 1, and all of (6.7) holds. However, generalizing a suggestion by Ruiz [26], for any matrix partitioned into two submatrices

$$\begin{aligned}
\max\{\|W\|, \|Z\|\} \;\le\; \|[W, Z]\| &= \max_{\|w\|^2+\|z\|^2=1} \|Ww + Zz\| \\
&\le \max_{\|w\|^2+\|z\|^2=1} \{\|W\|\|w\| + \|Z\|\|z\|\} \\
&= \max_{\|w\|^2+\|z\|^2=1} (\|W\|, \|Z\|)(\|w\|, \|z\|)^T \\
&\le \{\|W\|^2 + \|Z\|^2\}^{\frac{1}{2}}\,.
\end{aligned} \tag{6.8}$$

Applying these bounds to $\|[v_1\rho_0\gamma, AV_kD_k]\|$ with scaling in (6.4) and $x_0 = 0$ gives

$$1 \;\le\; \sigma_1 \equiv \|[v_1\rho_0\gamma, AV_kD_k]\| \;\le\; \sqrt{2}\,. \tag{6.9}$$

Thus for the scaling in (6.4) with $x_0 = 0$, both (6.6) and (6.9) hold, which gives the simplest form of our main result—the correct version of (1.2).

Proposition 6.2. *Under the conditions and assumptions of Theorem* 3.1*, using the notation of Theorem* 5.1 *and assuming that* $\delta_k \ll 1$*, we have with* $\gamma = \|b\|^{-1}$*,* $D_k = \|A\|^{-1}$*, and* $x_0 = 0$*:*

$$\frac{1}{\sqrt{2}} \le \kappa_k \,\frac{\|r_k\|}{\|b\| + \|A\| \cdot \|x_k\|} \;\lesssim\; \sqrt{2}, \tag{6.10}$$

which can be written as

$$\kappa_k \,\frac{\|r_k\|}{\|b\| + \|A\| \cdot \|x_k\|} \;=\; O(1)\,. \qquad \square \tag{6.11}$$

The last results hold even for nonzero x_0 whenever $\|y_k\| = O(\|x_k\|)$. (Numerical experiments suggest that for well chosen x_0 (see (2.8)), this assumption is very realistic.) Because of the simple form of (6.10) we call the scaling in (6.4) scaling for elegance. In the experiments in section 7 we will compare the bounds χ_{L1}, χ_{L2}, and χ_{L3}, and χ_{U1}, χ_{U2}, and χ_{U3}, together with the effects of the particular scalings on the tightness of (5.3).

In an iterative solution of equations with nonsingular A we expect $\|r_k\| \to 0$ so $\delta_k \to 0$ (see (3.8)), and $\delta_k \ll 1$ is necessary eventually. For a general (finite dimensional) problem this seems trivial, but there are extreme possibilities: δ_k may, for example, be close to unity (or $\delta_k = 1$ in some special cases) for $k = 1, 2, \ldots, n-1$ and $\delta_n = 0$ (see section 4). However, in many practical problems there exists a k_0 much smaller than n such that $\delta_k \ll 1$ for $k = k_0, k_0+1, \ldots,$ and in Corollary 3.2

$$0 \le \eta = \eta(k) \approx 0 \tag{6.12}$$

holds for $k > k_0$. In other problems $\delta_k \ll 1$ for a number of steps, but then suddenly δ_k appears very close to unity. In these cases the smoothed upper bound (3.9) might be considered—our experiments suggest it is usually close to $\|r_k\|$ for all iteration steps k. Typical examples are shown in section 7.

Under the assumptions of Theorem 3.1 $\delta_k = \delta_k(\gamma, D_k)$ is bounded away from unity for all positive γ, D_k [21, Theorem 3.1] and, unless the projection of r_0 onto the left singular vector subspace corresponding to $\sigma_{\min}(AV_kD_k)$ of the matrix AV_kD_k is very small compared to $\|r_k\|$, we can expect that the bounds for $\|r_k\|$ given by Theorem 3.1 are sufficiently tight. Still, the choices of D_k having small elements on the diagonal seems very unfortunate because they (potentially) increase the value of δ_k. Fortunately, as shown in section 7, in practical computations small diagonal elements in D_k have a much less dramatic effect on δ_k, and on the tightness of the bounds (3.6) for $\|r_k\|$, than the weaker upper bound in (3.8) would suggest. Moreover, we will show that in our experiments the scaling $\gamma = \|b\|^{-1}$, $D_k = \|A\|^{-1}I$ (which provided the result (6.10)) indeed relaxed the tightness of the bounds (3.6) for $\|r_k\|$, but the resulting relaxed bounds always remained very acceptable.

As mentioned above, under the assumption (3.5) δ_k is bounded away from unity, but it can still get very close to unity for some k. We have observed numerically (see also section 7) that with no scaling ($\gamma = 1$, $D_k = I$), δ_k gets close to unity quite rarely. For the other scalings considered in this paper (which are important for the formulation of our results), some δ_k may be much closer to unity, and that may also happen more often. Still, as we will now show for the example of the scaling for elegance $\gamma = \|b\|^{-1}$, $D_k = \|A\|^{-1}I$, the situation $\delta_k \approx 1$ cannot occur after GMRES has converged to a reasonable accuracy, and therefore it does not represent a serious obstacle for our theory. From (3.8) we have

$$\delta_k \le \gamma\|r_k\|/\sigma_k(AV_kD_k), \tag{6.13}$$

which with the scaling $\gamma = \|b\|^{-1}$, $D_k = \|A\|^{-1}I$, and with $\|r_0\| \le \|b\|$ (perhaps via (2.8)) and $V_k^TV_k = I$, gives a bound in terms of the *relative residual* $\|r_k\|/\|r_0\|$:

$$\delta_k \le \frac{\|r_k\| \cdot \|A\|}{\|b\| \cdot \sigma_k(AV_k)} \le \frac{\|r_k\|}{\|r_0\|}\,\kappa(A). \tag{6.14}$$

Similarly (using the same scaling) with $\|x_k\| = \|y_k\|$ we can obtain a bound in terms of the *relative backward error*

$$\delta_k \le \frac{\|r_k\|}{\|b\| + \|A\| \cdot \|x_k\|}\,\sqrt{2}\,\kappa(A) = \beta(x_k)\sqrt{2}\,\kappa(A). \tag{6.15}$$

This follows using (3.7) and (5.8), since

$$\delta_k \le \frac{\|r_k\|}{\{\|b\|^2 + \|A\|^2\|x_k\|^2\}^{1/2}\sigma_k(AV_k)/\|A\|} \le \beta(x_k)\sqrt{2}\,\kappa(A).$$

Thus, when the relative residual norm drops significantly below $\kappa(A)^{-1}$, or the relative backward error drops significantly below $\{\sqrt{2}\,\kappa(A)\}^{-1}$, $\delta_k = \delta_k(\|b\|^{-1}\|A\|, I) \ll 1$ and (6.11) will hold.

For any given D_k there is a particular value of the scaling parameter γ such that $\delta(\gamma, D_k)$ is related to $\|r_k\|$ even in a more tight way than described above. For a fixed D_k define $\gamma_0^{(k)} = \gamma_0^{(k)}(D_k) = \sigma_k(AV_kD_k)/\rho_0$. With the scaling $D_k, \gamma_0^{(k)}$ the first column of the matrix $[v_1\rho_0\gamma_0^{(k)}, AV_kD_k]$ is equal to $\sigma_k(AV_kD_k)v_1$ and has the norm equal to $\sigma_k(AV_kD_k)$. Moreover, for this D_k, $\delta_k(\gamma, D_k) < 1$ for all $\gamma < \gamma_0^{(k)}$, and

$$\|r_k\| = \rho_0 \quad \text{if and only if} \quad \delta_k(\gamma_0^{(k)}, D_k) = 1\,, \tag{6.16}$$

$$\delta_k(\gamma_0^{(k)}, D_k) \le \|r_k\|/\rho_0 \le \sqrt{2}\,\delta_k(\gamma_0^{(k)}, D_k); \tag{6.17}$$

see [15, (3.11) and (3.12)]. Though with this particular scaling the relationship between $\delta_k(\gamma_0^{(k)}, D_k)$ and $\|r_k\|$ is extremely simple, it will not lead to a simple form of the main result (1.2). Also, possibly small value $\gamma_0^{(k)}$ may inconveniently relax the bound (5.3) and significantly complicate the analysis left to [17]. Therefore we have not used this scaling in our paper.

The approach here might also be useful for Krylov subspace methods which minimize other norms, such as minimum error methods, as we now show. Let $V_k = [v_1, \ldots, v_k]$ be generated in some way, and $r_0 = b - Ax_0$, $\rho_0 = \|r_0\|$, $v_1 = r_0/\rho_0$, $x_k = x_0 + V_ky_k$, $r_k = b - Ax_k = r_0 - AV_ky_k$, with A nonsingular. Consider, for example, a method that minimizes $\|A^{-1}r_k\| = \|x - x_k\|$ at each step (so y_k will differ from that in GMRES). Then taking $[c, B] = A^{-1}[v_1\rho_0, AV_k] = [(x - x_0), V_k]$ and $\gamma = \rho_0^{-1}$, Theorem 4.1 of [21] gives (with $\delta_k = \sigma_{k+1}([(x - x_0)\rho_0^{-1}, V_k])/\sigma_k(V_k)$) the bounds

$$\begin{aligned}\sigma_{k+1}([(x - x_0)\rho_0^{-1}, V_k])\,\{\rho_0^2 + \|y_k\|^2\}^{\frac{1}{2}} \quad &\le \quad \|x - x_k\| \\ \le \sigma_{k+1}([(x - x_0)\rho_0^{-1}, V_k])\,\{\rho_0^2 + (1 - \delta_k^2)^{-1}&\|y_k\|^2\}^{\frac{1}{2}},\end{aligned} \tag{6.18}$$

so at least this theory holds for more general minimum norm methods than just GMRES. Of course, if $V_k^TV_k = I$, then $\sigma_k(V_k) = 1$. We have not studied how this might be used.

It appears that the approach can also be applied to methods which minimize some norm with respect to other Krylov subspaces, such as LSQR [20, 19] for solution of equations with unsymmetric A, or LS solutions with rectangular A. It may also be useful for methods which are not based on Krylov subspaces.

7. Experimental results. We will illustrate our theoretical results with numerical experiments. We initiated these to look for possible limitations in our theory. We wished to check the validity of our assumptions in practical computations. We also wished to find out to what extent the results developed here for exact precision GMRES would hold for quantities computed in the presence of rounding errors.

In our theory $\delta_k = \sigma_{k+1}([v_1\rho_0\gamma, AV_kD_k])/\sigma_k(AV_kD_k)$ plays an important role. Section 4 showed it is possible to have $\delta_k = 1$ for all but the last step, and in that example the residual stagnated at $\|r_0\|$ until the final step. On the other hand, $\delta_k \approx 1$ cannot in general (for scalings different from D_k, $\gamma_0^{(k)}(D_k)$, see (6.16), (6.17)) be linked with the (approximate) stagnation of GMRES; the GMRES residual norm may almost stagnate while $\delta_k \ll 1$, and it can decrease rapidly while $\delta_k \approx 1$. If $\delta_k \approx 1$, then there can be a large gap between the upper and lower bounds in (3.6). This does not negate the argument that orthogonality is effectively maintained until convergence in finite precision MGS GMRES ($\delta_k \ll 1$ is necessary eventually), but it does make us question the tightness of the bounds in (3.6).

Fortunately, experiments suggest that (3.9) is always a sufficiently good (and mostly very good) upper bound. We also found that with no scaling ($\gamma = 1$, $D_k = I$) δ_k is often reasonably below unity during the entire computation. As k increases δ_k can decrease, then increase, but it must eventually become small, for from (3.7), (3.8), (6.14), and (6.15) we see the upper bound on δ_k must decrease as $\|r_k\|$ or $\|r_k\|/(\|b\| + \|A\| \cdot \|x_k\|)$ becomes sufficiently small. However, when $\delta_k \ll 1$ from the start to the end,

$$\|r_k\| \;\approx\; \sigma_{k+1}([v_1\rho_0\gamma, AV_kD_k])\,\{\gamma^{-2} + \|D_k^{-1}y_k\|^2\}^{\frac{1}{2}}$$

throughout the computation, and the lower and upper bounds are very close. Thus we can have this unexpectedly very close relationship between $\|r_k\|$ and the smallest singular value of $[v_1\rho_0\gamma, AV_kD_k]$. An interesting experience was that even when $\delta_k \approx 1$, leading to the upper bound being significantly larger than the lower bound in (3.6), it was not always the upper bound which was weak. We frequently observed that the upper bound was tight while the lower bound was a noticeable underestimate for $\|r_k\|$. Moreover, the dependence of δ_k and the tightness of the bounds (3.6) on the scaling parameters γ, D_k was quite weak. We will illustrate these observations by presenting results of numerical experiments showing different types of behavior of δ_k. These observations could also be further studied theoretically using the results of Proposition 6.1 or some other approach, but we do not wish to go into it here.

In all experiments $b = e \equiv (1, \ldots, 1)^T$. Except for the experiment shown in Figure 7.10 (where $x_0 = \text{randn}(n, 1)$ from MATLAB 5.3), x_0 is always determined from (2.8) with $x_p = \text{randn}(n, 1)$ from MATLAB 5.3. These choices of x_0 and x_p are worth a comment. We wish to illustrate our theoretical results on some nontrivial examples. The randomly generated initial vectors x_0 (or x_p in (2.8)) were chosen in our illustrations to avoid any correlation between the initial approximation and the solution. This is because we sought to illustrate cases where there were no hidden relationship that affected the computations. In practical computations, however, for the very same reason, a randomly chosen initial approximation should be avoided. Sometimes a random initial approximation x_0 is reported to give faster convergence than the other popular choice $x_0 = 0$. As we explain later, we believe that statements like that represent a serious misunderstanding caused by a superficial view of convergence. As far as genuine convergence characteristics are concerned, we argue that such statements are of no relevance.

Experiments were performed on a Silicon Graphics Origin 200 Workstation using MATLAB 5.3, $\epsilon = 1.11 \times 10^{-16}$. In all experiments matrices from the Rutherford–Boeing collection were used. Results for the matrix FS1836 with $n = 183$, $\|A\| \approx 1.2{*}10^9$, $\kappa(A) \approx 1.5{*}10^{11}$ (see Figures 7.1–7.4) illustrate improvement of the tightness of the bounds (3.6) as the residual norm drops. For the matrix WEST0132 with $n = 132$, $\|A\| \approx 3.2 * 10^5$, $\kappa(A) \approx 6.4 * 10^{11}$ (see Figures 7.5–7.8), the tightness of the bounds (3.6) oscillates during the whole computation. Results for the matrix STEAM1 with $n = 240$, $\|A\| \approx 2.2 * 10^7$, $\kappa(A) \approx 3.1 * 10^7$ (see Figures 7.9 and 7.10) represent the case when the bounds (3.6) are very tight from the start to the end.

We have given two figures for STEAM1 and four figures for the other matrices, so we now indicate what is in each figure. Figures 7.1, 7.5, 7.9, and 7.10 make the same use of lines. The dots show the norm of the *directly* computed residual divided

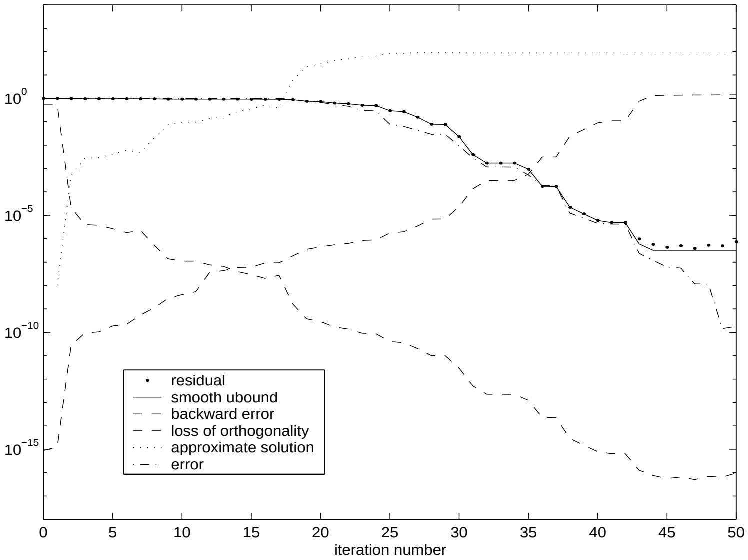

FIG. 7.1. *Norm of the directly computed relative residual (dots), the smooth upper bound (solid line), the loss of orthogonality among the Arnoldi vectors measured in the Frobenius norm (dashed line, monotonically increasing) and the normwise relative backward error (dashed line, mostly decreasing), norm of the approximate solution (dotted line), and the relative error (dashed-dotted line) for MGS GMRES applied to FS1836.*

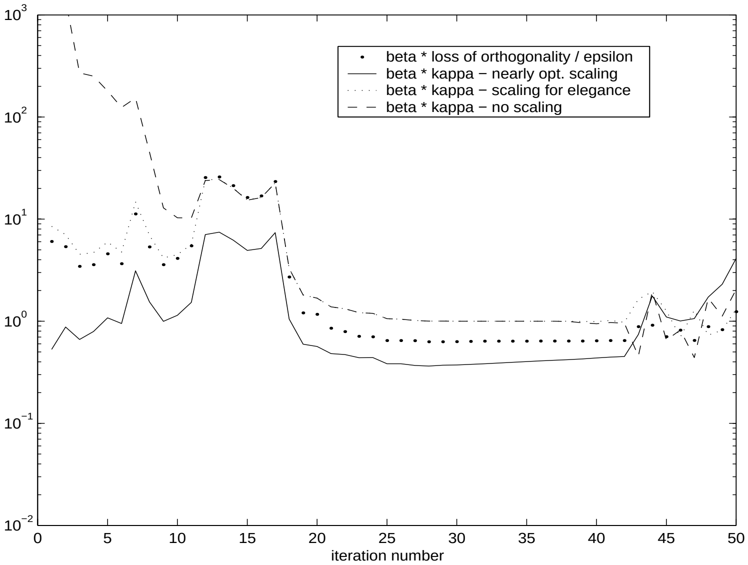

FIG. 7.2. *The product of the normwise relative backward error and the loss of orthogonality among the Arnoldi vectors measured in the Frobenius norm divided by the machine precision unit ϵ (dots), and the product of the normwise relative backward error $\beta(x_k)$ and the condition number of the matrix $[v_1\rho_0\gamma, AV_kD_k]$ for different scalings: the nearly optimal column scaling $\gamma = \rho_0^{-1}$, $D_k = \mathrm{diag}(\|Av_j\|^{-1})$ (solid line), the norm scaling (scaling for elegance) $\gamma = \|b\|^{-1}$, $D_k = \|A\|^{-1}I$ (dotted line), and no scaling $\gamma = 1$, $D_k = I$ (dashed line) for MGS GMRES applied to FS1836.*

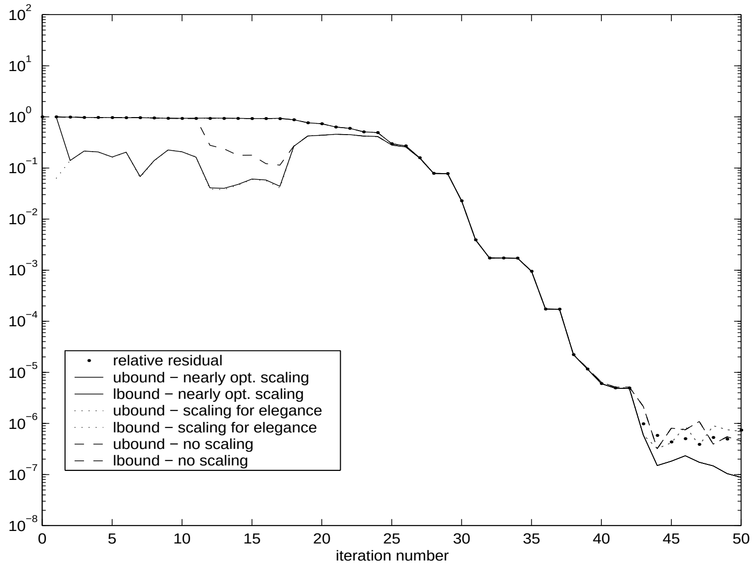

FIG. 7.3. *Norm of the directly computed relative residual (dots), and its lower and upper bounds μ_L and μ_U for different scalings: the nearly optimal column scaling (solid lines), the scaling for elegance (dotted lines), and no scaling (dashed lines) for MGS GMRES applied to FS1836. Until the orthogonality is completely lost, the upper bounds are indistinguishable from the actual quantities.*

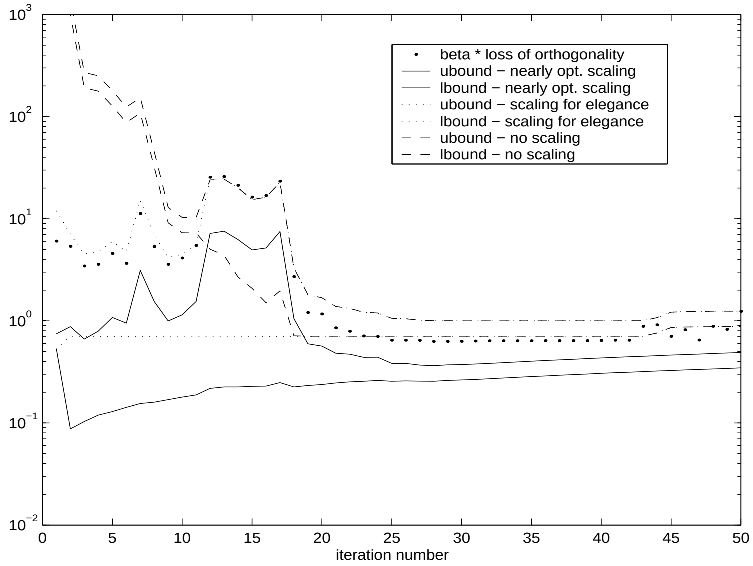

FIG. 7.4. *Product of the backward error and the loss of orthogonality among the Arnoldi vectors measured in the Frobenius norm divided by the machine precision unit ϵ (dots), and the values χ_L and χ_U for different scalings: the nearly optimal column scaling (solid lines), the scaling for elegance (dotted lines), and no scaling (dashed lines) for MGS GMRES applied to FS1836.*

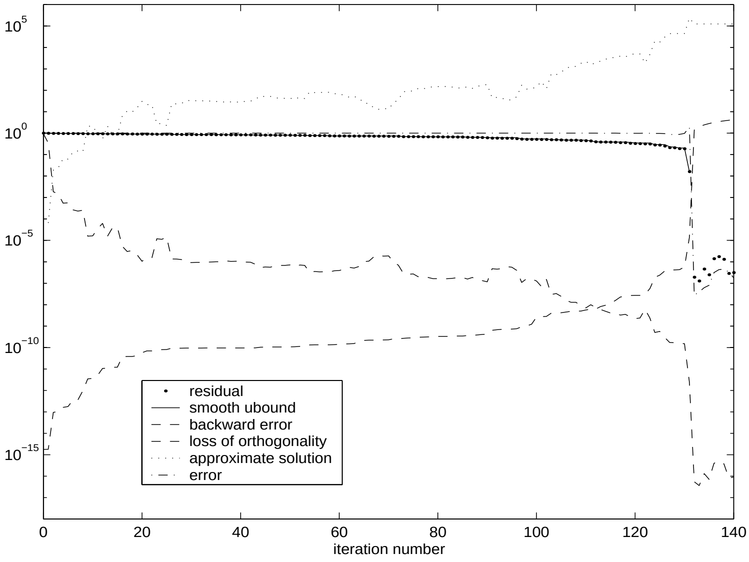

FIG. 7.5. *Norm of the directly computed relative residual (dots), the smooth upper bound (solid line), the loss of orthogonality among the Arnoldi vectors measured in the Frobenius norm (dashed line, monotonically increasing) and the normwise relative backward error (dashed line, mostly decreasing), norm of the approximate solution (dotted line), and the relative error (dashed-dotted line) for MGS GMRES applied to WEST0132.*

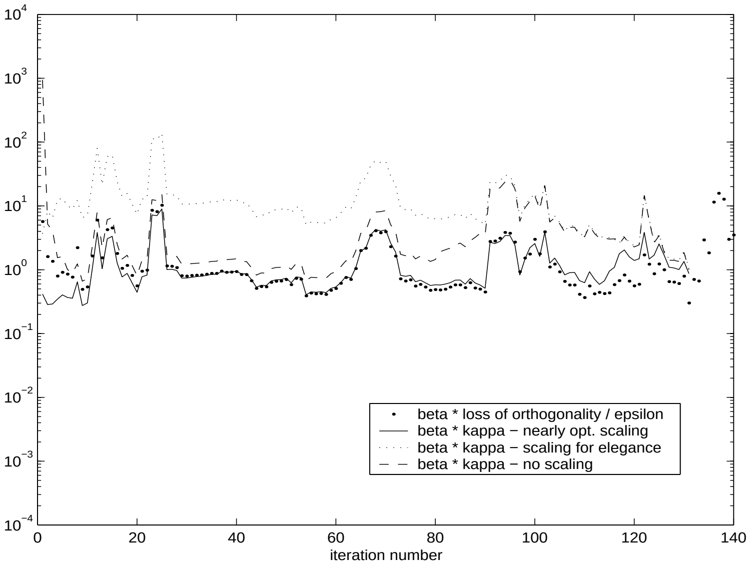

FIG. 7.6. *Product of the normwise relative backward error and the loss of orthogonality among the Arnoldi vectors measured in the Frobenius norm divided by the machine precision unit (dots), and product of the backward error and the condition number of the matrix* $[v_1\rho_0\gamma, AV_kD_k]$ *for different scalings: the nearly optimal column scaling (solid line), the scaling for elegance (dotted line), and no scaling (dashed line) for MGS GMRES applied to WEST0132.*

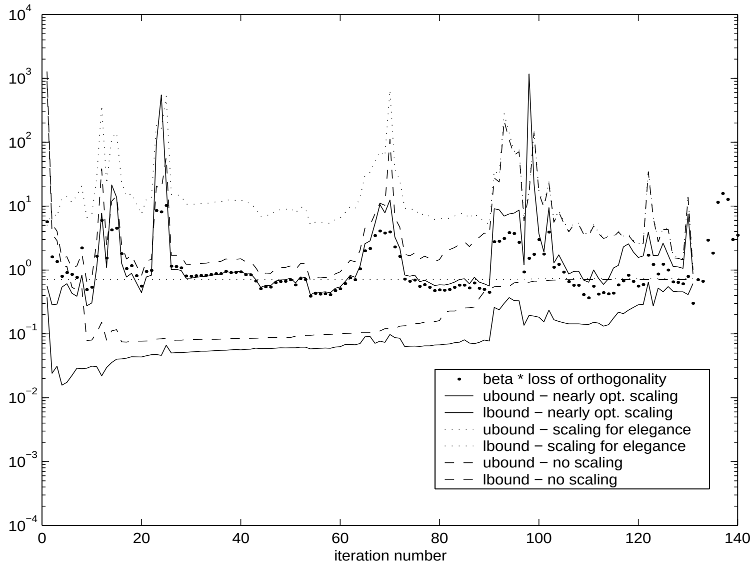

Fig. 7.8. *Product of the backward error and the loss of orthogonality among the Arnoldi vectors measured in the Frobenius norm divided by the machine precision unit* ϵ *(dots), and the values* χ_L *and* χ_U *for different scalings: the nearly optimal column scaling (solid lines), the scaling for elegance (dotted lines), and no scaling (dashed lines) for MGS GMRES applied to WEST0132.*

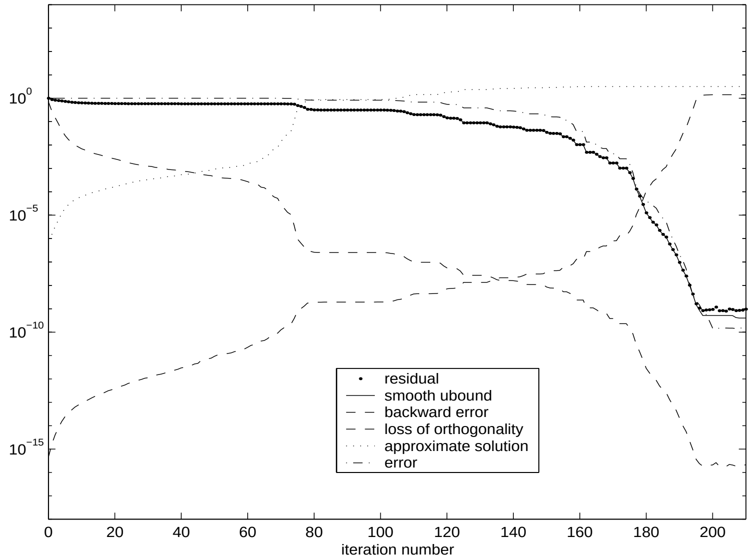

FIG. 7.9. *Norm of the directly computed relative residual (dots), the smooth upper bound (solid line), the loss of orthogonality among the Arnoldi vectors measured in the Frobenius norm (dashed line, monotonically increasing) and the normwise relative backward error (dashed line, mostly decreasing), norm of the approximate solution (dotted line), and the relative error (dashed-dotted line) for MGS GMRES applied to STEAM240.*

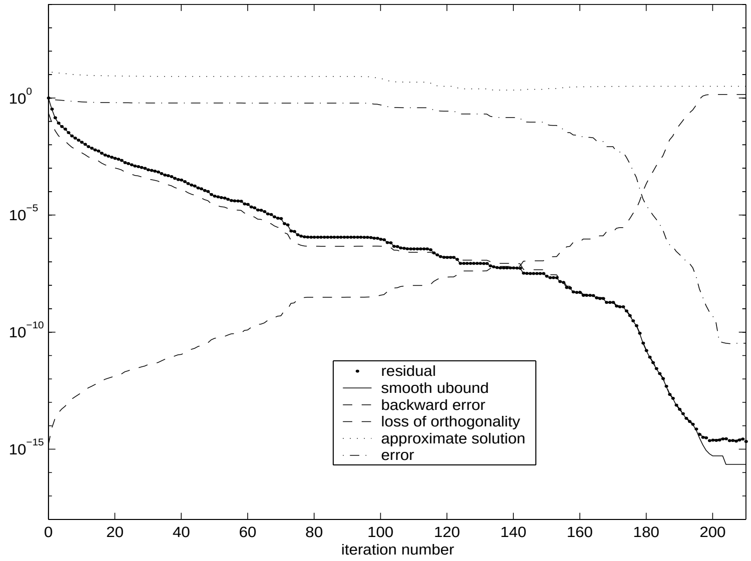

FIG. 7.10. *Norm of the directly computed relative residual (dots), the loss of orthogonality among the Arnoldi vectors measured in the Frobenius norm (dashed line, monotonically increasing) and the normwise relative backward error (dashed line, mostly decreasing), norm of the approximate solution (dotted line), and the relative error (dashed-dotted line) for MGS GMRES applied to STEAM240 with randomly chosen initial approximation x_0.*

by $\|r_0\|$, that is, $\|b - Ax_k\|/\|r_0\|$, which we call the relative residual. (We do not give the *iteratively* computed residual norm (2.7); until near convergence, it was always graphically indistinguishable from the norm of the directly computed residual.) The solid line gives the smoothed upper bound (3.9) divided by $\|r_0\|$. The dashed-dotted line gives the normalized norm of the error $\|x-x_k\|/\|x-x_0\|$; the dotted line gives the norm of the approximate solution $\|x_k\|$. The dashed lines give the loss of orthogonality among the Arnoldi vectors measured in the Frobenius norm $\|I - V_k^T V_k\|_F$ (essentially increasing), as well as the normwise relative backward error $\|r_k\|/(\|b\| + \|A\| \cdot \|x_k\|)$, which is mostly decreasing. Note the spectacular symmetry of the loss of orthogonality and the backward error in every case.

For each matrix, the remaining figures present and compare convergence characteristics, upper and lower bounds, and several quantities illustrating our theory for different scalings of the matrix $[v_1\rho_0\gamma, AV_kD_k]$. In each of Figures 7.2, 7.3, 7.4 (for FS1836) and 7.6, 7.7, 7.8 (for WEST0132) dashed lines represent results with no scaling $\gamma = 1$, $D_k = I$, solid lines the nearly optimal column scaling $\gamma = \rho_0^{-1}$, $D_k = \mathrm{diag}(\|Av_j\|^{-1})$, and dotted lines the scaling for elegance $\gamma = \|b\|^{-1}$, $D_k = \|A\|^{-1}I$.

Figures 7.2 and 7.6 are devoted to the tightness of the bound (5.3) for the loss of orthogonality among the Arnoldi vectors. The dots show the product of the normwise relative backward error and the loss of orthogonality divided by the machine precision unit $\{\|r_k\|/(\|b\| + \|A\| \cdot \|x_k\|)\} \cdot \|I - V_k^T V_k\|_F \,/\, \epsilon$, the dashed, solid, and dotted lines the product $\{\|r_k\|/(\|b\| + \|A\| \cdot \|x_k\|)\} \cdot \kappa([v_1\rho_0\gamma, AV_kD_k])$ for different scalings. The figures show that (5.5) is well justified for the nearly optimal column scaling. Replacing the actual loss of orthogonality $\|I - V_k^T V_k\|_F$ in our considerations by $\{\kappa([v_1\rho_0\gamma, AV_kD_k])\,\epsilon\}$ does not cause a significant difference (except perhaps at the beginning of the process with no scaling) even for the other scalings. Close to convergence (5.5) holds for all the scalings considered in our paper.

Figures 7.3 and 7.7 are devoted to normalized residual bounds, that is, bounds on $\|b - Ax_k\|/\|r_0\|$, which are denoted by points. The pairs of dashed, solid, and dotted lines give the upper and lower bounds μ_U and μ_L from (3.6) for different scalings. We can see that the effect of scaling on the bounds in (3.6) is quite insignificant.

Finally, Figures 7.4 and 7.8 compare the product of the normwise relative backward error and the loss of orthogonality divided by the machine precision unit, that is, $\{\|r_k\|/(\|b\| + \|A\| \cdot \|x_k\|)\} \cdot \|I - V_k^T V_k\|_F \,/\, \epsilon$ (denoted by dots), with the upper and lower bounds χ_U and χ_L from (6.2) (dashed lines), (6.3) (solid lines), and (6.5) (dotted lines). These figures reflect the possible lack of tightness of the bound for the loss of orthogonality among the Arnoldi vectors shown separately on Figures 7.2 and 7.6, as well as the lack of tightness of the bounds in (6.2)–(6.5). They demonstrate that though the results developed in this paper assume exact arithmetic, and though the form of the bounds in (6.2)–(6.5) seems a bit complicated, the simplest form of our main result (6.11) holds as convergence is approached for all our scalings and for the quantities actually computed using finite precision arithmetic.

The experiments for the figures discussed up to now (and for Figure 7.9) used $b = e$ and x_0 determined from (2.8) with $x_p = \mathrm{randn}(n, 1)$ from MATLAB 5.3. The remaining Figure 7.10 was computed for $x_0 = \mathrm{randn}(n, 1)$ from MATLAB 5.3 without using (2.8). Both Figures 7.9 and 7.10 were computed for the matrix STEAM1, and they show the same quantities as Figures 7.1 and 7.5. If we concentrate on the relative residual norm only, then it looks as if Figure 7.10 shows much better convergence (faster, and to much better accuracy) than Figure 7.9. Such a view on convergence, though understandable, is completely wrong. We cannot give a full quantitative explanation within this paper; however, we will present an intuitive but clear argument on which such an explanation will eventually be based. By using $x_0 = \text{randn}(n, 1)$ and then computing the initial residual as $r_0 = b - Ax_0 = e - Ax_0$ (as on Figure 7.10) we correlate the initial residual strongly with the dominating parts of the operator A. (Note that all the matrices used here have some dominating components.) In all cases the norm of the resulting initial residual is large, $\|r_0\| \gg \|b\|$. At the early stage of computation this artificially created dominating information is eliminated, which creates an illusion of fast convergence. However, no real fast convergence is taking place, as you can see on the error convergence curve, and the "good final accuracy" is due to the fact that the initial residual is large. For $b = e$ and x_0 determined from (2.8) with $x_p = \text{randn}(n, 1)$ from MATLAB 5.3 we get $\|x_0\| \ll 1$ and $x_0 \approx 0$. Then r_0 contains practically no information about the dominating parts of A, the problem is difficult to solve, and the convergence is (for many steps) slow. Still, this choice (which produces results very close to those with the choice $x_0 = 0$) gives the right information about the behavior of GMRES when applied to the problem $Ax = b$, $b = e$. The illusion of fast convergence and better final accuracy for a random x_0 has evolved among some users of numerical software perhaps as a side effect of using the norm of the relative residual for displaying convergence. Our point is that the illusive role of a random x_0 can easily be revealed by using the absolute values of the residual norm for displaying convergence and by comparing the convergence curve for a random x_0 to that for the initial approximation set to zero ($x_0 = 0$). Finally, please note the correspondence of the error and the backward error when comparing Figures 7.10 and 7.9.

Now we comment on particular characteristics of each problem. For the matrix FS1836 in Figures 7.1–7.4 the value of δ_k rises until it is close to unity, stays there for a few iteration steps, then follows the descent of the residual norm. For all scalings the upper bounds μ_U (for $\|r_k\|$) are very tight until convergence, the lower bounds μ_L (for $\|r_k\|$) are weak when $\delta_k \approx 1$, but no scaling ($\gamma = 1, D_k = I$) gives a significantly tighter lower bound than the other two at the early stages of the computation (Figure 7.3). On the other hand, at the early stages of the computation the condition number of the matrix $[v_1\rho_0, AV_k]$ is for no scaling much larger than for the other scalings, which explains the difference between the dashed and the other lines on Figures 7.2 and 7.4 for k from 1 to 10. After convergence is approached, all scalings produce about the same results.

For the matrix WEST0132 (in Figures 7.5–7.8) the value of δ_k is close to unity (with some oscillations) for most iteration steps. The upper and lower bounds μ_U and μ_L differ significantly until the sharp drop of the residual. Scalings are not important. Note that despite the oscillations (we have chosen this matrix on purpose because it seems to produce challenging results; many other examples not presented here give much smoother behavior) all the lines on Figures 7.6 and 7.8 converge together as the sharp drop of the residual is approached.

For the matrix STEAM1 we omit figures analogous to Figures 7.2–7.4 for FS1836 and Figures 7.6–7.8 for WEST0132. The omitted figures would show a good agreement of the computed results with our theory; they do not offer any other information, and therefore we see no reason for extending the length of the paper by including them.

Summarizing, our experiments suggest that the equivalents of Theorems 3.1 and 5.1, of the Propositions 6.1 and 6.2 (where κ_k will be replaced by $\|I - V_{k+1}^T V_{k+1}\|_F$ and $O(1)$ by $O(\epsilon)$), hold for the *numerically computed quantities*. However, the statements must be slightly modified to account for the effect of rounding errors, especially for the influence of the loss of orthogonality on the size of the directly computed residuals $\|b - Ax_k\|$. A rigorous proof will require further work and is intended in [17].

8. Conclusion. In Krylov subspace methods, approximate solutions to matrix problems are usually constructed by using orthogonality relations and projections. Orthogonality and projections create a mathematical elegance and beauty in this context. In the presence of rounding errors orthogonality and projection properties are gradually (and sometimes very quickly) lost. Fortunately, as was first shown for A symmetric and the Lanczos method (see, for example, [16], [10], [12]), not all the mathematical elegance need be lost with them.

This paper is devoted to GMRES, and our fundamental hypothesis is as follows. When the Arnoldi vectors are computed via the finite precision MGS process, the loss of orthogonality is related in a straightforward way to the convergence of GMRES. In particular, orthogonality among the Arnoldi vectors is effectively maintained until the normwise relative backward error converges close to the machine precision level. If we assume that the bound for the loss of orthogonality among the Arnoldi vectors is tight and (5.5) holds, then our hypothesis could be strengthened to the following: *the product of the loss of orthogonality among the Arnoldi vectors (measured in the Frobenius norm) and the normwise relative backward error is for any iteration step a small multiple of the machine precision unit.* This last statement would then imply that total loss of orthogonality among the Arnoldi vectors computed via finite precision MGS orthogonalization would mean convergence of the normwise relative backward error to machine precision level, and, consequently, it would prove backward stability of MGS GMRES. Our work can also be seen as another step on the way (probably started by Sheffield (see [6], especially the abstract and section 2, also [7])) towards the full justification of the MGS orthogonalization in competition with orthogonalization by Householder reflections for certain classes of problems.

Note that in the present paper we have not proven the finite precision versions of the statements formulated above. Our paper assumes exact arithmetic in its theoretical part and carries out groundwork for the detailed rounding error analysis of the MGS GMRES which we plan to publish in [17].

Acknowledgments. The authors would like to thank Miro Rozložník for his helpful comments. They also wish to thank Jőrg Liesen and Daniel Ruiz for many valuable suggestions which improved the content and presentation of this paper.

ADAPTIVE REDUCED-ORDER CONTROLLERS FOR A THERMAL FLOW SYSTEM USING PROPER ORTHOGONAL DECOMPOSITION[*]

S. S. RAVINDRAN[†]

Abstract. An adaptive reduced-order controller design is presented for flow control using proper orthogonal decomposition (POD). In reduced-order controller design, the idea is to start with an ensemble of data obtained from numerical simulation of the underlying partial differential equations (PDEs). POD is then used to obtain a reduced set of basis functions which is then used to derive a reduced-order model of the PDEs via Galerkin projection. This reduced-order model allows us to derive a reduced-order controller. However, it is not clear, a priori, what is the best way to obtain an ensemble of data that would give basis functions that represent the influence of the control action on the system. In this paper we explore an adaptive procedure for reduced-order controller design that improves the reduced-order model by successively updating the ensemble of data during the optimization iterations. We illustrate this method on a control problem in thermal flow system modeled by a thermally coupled Navier–Stokes equations. Numerical results are presented for a vorticity regulation problem in fluid flows using boundary temperature as control mechanism. Through our numerical experiments we demonstrate the feasibility and applicability of the adaptive reduced-order controllers.

1. Introduction.

The reduced-order controller design for physical process modeled by partial differential equations (PDEs) has attracted much attention in recent years due to its ability to reduce computational cost. In [21, 20], we designed a reduced-order controller for a flow system using a procedure called proper orthogonal decomposition (POD).

POD is a model reduction technique for complex nonlinear problems. It was first proposed by Karhunen [13] and Loeve [15] independently and sometimes called Karhunen–Loeve (K–L) expansion. Subsequently it has been applied in various applications. In [16] the method was first called POD and there it was used to study turbulent flows. In [23] other important progress was made and the method of snapshots was incorporated into the POD framework, which will be described in what follows. Other applications in turbulent flow simulations are given in [3, 4, 14, 17, 18, 24].

The essential idea is to generate an optimal basis for the representation of an ensemble of data obtained from numerical computations. One of the features of POD is that it yields a basis that is optimal in the sense that the information contained in an N-ordered POD basis expansion is greater than any other N-ordered basis expansion. Thus, when the PDEs are projected onto this basis using a Galerkin projection, one obtains a reduced-order model.

Reduced-order models allow us to derive reduced-order controllers. However, we need to choose the ensemble of data that represent the system behavior for various

trajectories of the control during the iterative optimization procedure. To meet this requirement, we propose in this paper an adaptive procedure that successively updates the ensemble of data and the reduced-order model during the optimization process using the sequential quadratic programming (SQP) method. The SQP method is preferred over the unconstrained optimization methods due to its superior convergence properties, among others. Its application to solve optimal control of Navier–Stokes flow has been demonstrated in [9, 10] and [19].

In this adaptive procedure, we begin with an initial estimate $(\mathbf{Y}_k, \boldsymbol{\zeta}_k)$ and the corresponding initial estimate for the control c_k for the SQP method and generate the corresponding ensemble of snapshots from the Navier–Stokes model. With these snapshots, we find a POD subspace and the corresponding reduced-order model. This reduced-order model is now used in the SQP algorithm to find the new iterate $(\mathbf{Y}_{k+1}, \boldsymbol{\zeta}_{k+1})$. This process of updating the reduced-order model is continued in each of the SQP iterations until convergence is achieved. The approach presented here bears similarities to the approach presented in [2], wherein using the POD model as a "surrogate" within the trust region framework is discussed.

For our physical application, we consider control of flow separation/recirculation in thermal flows. Thermal flow is both challenging and interesting due to the coupling of the fluid flow and the energy transport. It plays an important role in thermal insulation, cooling of fluids in channels surrounding nuclear reactor core, the circulation of liquid metals in solidifying ingot, and the manufacture of crystals. Also, thermal convection is often used as a controlling mechanism in many naturally occurring processes. In light of this, several treatments of control problems in thermal systems can be found in the literature. For instance, [8] studied optimal control of temperature peaks along the bounding surfaces of containers of fluid flows. In [5], a feedback control problem in thermal fluid was studied, and in [12] optimal control of flow separation in channel flow using temperature control was discussed. In [26], an optimal control problem was solved for the convection-diffusion equations with the goal of achieving uniform maximum flux to substrate. Our goal here is to apply POD to an optimal control problem in a backward-facing step channel flow. Backward-facing step flow serves as a prototype for unsteady separated flow. For high Reynolds numbers, flow separates near the corner of the step and recirculation appears downstream of the step. Such recirculation regions will strongly influence heat and mass transfer [1]. We will formulate and numerically solve a recirculation control problem in this configuration with the control action achieved through boundary temperature on a part of the boundary.

An outline of the POD and the reduced-order model derivation are presented in section 2. In section 3, we describe the system and governing equations with relevant boundary conditions; this section also describes the discretization schemes and solution techniques used to solve these governing equations. Section 4 states the model control problem and describes the proposed adaptive reduced-order control approach in the context of solving this model problem. In section 5, we present computational results showing the effectiveness of the present adaptive approach. Finally, we conclude the paper in section 6.

2. POD and model reduction.

In this section, we outline the POD for model reduction of a nonlinear uncontrolled dynamical system of the form

$$\dot{\mathbf{y}} = \mathcal{E}(\mathbf{y}), \qquad \mathbf{y} \in \mathbb{R}n. \tag{2.1}$$

The idea is to replace the given dynamics by an associated dynamics on an M-dimensional subspace $\mathbf{V}^{\mathrm{POD}} \subset \mathbb{R}n$ of the state space. This procedure uses two steps for model reduction: that of finding a low-dimensional subspace and that of applying Galerkin projection. We begin with an ensemble of data obtained from the numerical simulation, consisting of samples $\{\mathbf{Y}_1, \dots, \mathbf{Y}_N\}$ of $\mathbf{y}(t)$, and try to find an M-dimensional subspace that best approximates the underlying n-dimensional state space via a projection.

2.1. The POD procedure. POD provides us a method for achieving this task. The idea is to find a vector $\mathbf{\Phi}$ of length n that has a structure typical of the members of the ensemble data, $\mathbf{Y}_i, i = 1, 2, \dots, N$, where $\mathbf{Y}_i = (Y_{i1}, Y_{i2}, \dots, Y_{in})$. We can achieve this by maximizing

$$\max_{\mathbf{\Phi}} \frac{E\{(\mathbf{Y}^T\mathbf{\Phi})(\mathbf{Y}^T\mathbf{\Phi})\}}{\mathbf{\Phi}^T\mathbf{\Phi}}, \tag{2.2}$$

where $E\{\cdot\}$ is a suitably defined averaging operation. It is clear from the properties of the vector that we can rewrite (2.2) as

$$\max_{\mathbf{\Phi}} \frac{(\mathbf{R\Phi})^T\mathbf{\Phi}}{\mathbf{\Phi}^T\mathbf{\Phi}},$$

where $\mathbf{R} = E\{\mathbf{YY}^T\}$. Then the first-order necessary optimality condition for $\mathbf{\Phi}$ to provide a maximum in (2.2) is

$$\mathbf{R\Phi} = \lambda\mathbf{\Phi}, \tag{2.3}$$

which is an eigenvalue problem with n eigenvalues and eigenvectors. Since $\mathbf{R}$ is a symmetric matrix, we can extract an orthonormal basis $\mathbf{\Phi}_n$ for $\mathbb{R}n$ from the eigenvectors. Thus $\mathbf{\Phi}_n$ form a basis for the realizations in our ensemble, i.e.,

$$\mathbf{Y} = \sum_{i=1}^{n} (\mathbf{Y}^T\mathbf{\Phi}_i)\mathbf{\Phi}_i = \sum_{i=1}^{n} \alpha_i \mathbf{\Phi}_i.$$

Moreover, we have that α_i are uncorrelated with one another on average,

$$E\{\alpha_i\alpha_j\} = (\mathbf{R}\Phi_i)^T\Phi_j = \lambda_i\mathbf{\Phi}_i^T\Phi_j = \lambda_i\delta_{ij}$$

and

$$E\{\mathbf{Y}^T\mathbf{Y}\} = \sum_{i=1}^{n} E\{|\mathbf{Y\Phi}_i|^2\} = \sum_{i=1}^{n} \lambda_i,$$

so that the eigenvalues are the mean-square values of α_i, i.e., the information in the various modes, and the sum of the eigenvalues is the total information.

For practical calculations, the number of grid points n can be rather large leading to a very large eigenvalue problem. In order to save time in the computation of eigenfunction, a useful method was proposed in [23], where it was called the *method of snapshots.* In the method of snapshots, instead of solving for the eigensystem of an $n \times n$ matrix we need only deal with an $N \times N$ matrix, where N is the number of ensembles. In order to describe the steps, first assume that the averaging operation is of the form

$$E[\mathbf{YY}^T] = \frac{1}{N} \sum_{i=1}^{n} \mathbf{Y}_i \mathbf{Y}_i^T;$$

then (2.3) becomes

$$\frac{1}{N}\sum_{i=1}^{n}\mathbf{Y}_i\mathbf{Y}_i^T\mathbf{\Phi} = \lambda\mathbf{\Phi}. \tag{2.4}$$

We next assume that the eigenvector $\mathbf{\Phi}$ can be written in terms of the members of the ensemble as

$$\mathbf{\Phi} = \sum_{i=1}^{N} w_i\mathbf{Y}^{(i)}. \tag{2.5}$$

Substituting (2.4) into (2.3), we have

$$\mathbf{CW} = \lambda\mathbf{W},$$

where

$$\mathbf{C}_{ij} = \frac{1}{N}\mathbf{Y}_i^T\mathbf{Y}_j \quad \text{and} \quad \mathbf{W} = \begin{bmatrix} w_1 \\ w_2 \\ \cdot \\ \cdot \\ \cdot \\ \cdot \\ w_N \end{bmatrix}.$$

It follows from the fact that $\mathbf{C}$ is a nonnegative Hermitian matrix that it has a complete set of orthogonal eigenvectors $\mathbf{W}_1, \mathbf{W}_2, \dots, \mathbf{W}_N$ along with a set of eigenvalues $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_N \geq 0$. We also normalize these by requiring

$$(\mathbf{W}_l, \mathbf{W}_l) = \sum_{i=1}^{N} w_i^l w_i^{l*} = \frac{1}{N\lambda_l}.$$

It is now easy to check

$$(\Phi_l, \Phi_m) = \begin{cases} 1, & l = m, \\ 0, & l \neq m. \end{cases}$$

This completes the construction of the orthonormal set $\{\Phi_1, \Phi_2, \dots, \Phi_N\}$.

2.1.1. Optimality properties. The optimality properties of POD, including those discussed in section 2.1.1, are summarized below. These results can be found in statistical framework terms in [23] and elsewhere.

Proposition 1. *Let $\{\mathbf{\Phi}_1, \mathbf{\Phi}_2, \dots, \mathbf{\Phi}_N\}$ be the POD basis elements and let $\{\lambda_1, \dots, \lambda_N\}$ be the corresponding set of eigenvalues. Let $\mathbf{y}^N$ be the projection of $\mathbf{y}$ onto span$\{\mathbf{\Phi_1}, \mathbf{\Phi_2}, \dots, \mathbf{\Phi_N}\}$ and let*

$$\mathbf{y}^N = \sum_{i=1}^{N}\beta_i(t)\mathbf{\Phi}_i(\mathbf{x}).$$

Let $\{\mathbf{\Psi}_i\}_{i=1}^N$ be an arbitrary orthonormal set such that

$$\mathbf{y}^N = \sum_{i=1}^{N}\alpha_i(t)\mathbf{\Psi}_i.$$

Then the following two properties hold:

(i) $E\{\beta_i(t)\beta_j(t)\} = \delta_{ij}\lambda_i$;

(ii) *For every* $N_k \leq N$, $\displaystyle\sum_{i=1}^{N_k} E\{\beta_i(t)\beta_i(t)\} = \sum_{i=1}^{N_k}\lambda_i \geq \sum_{i=1}^{N_k} E\{\alpha_i(t)\alpha_i(t)\}$.

In essence this proposition states that among all the linear combinations, the one which corresponds to POD is the best in the sense that it will capture the most information possible in the average sense. Moreover, the coefficients β_i are uncorrelated, and thus the claim that the POD expansion is efficient for modeling $\mathbf{y}(\mathbf{x}, t)$. Moreover, the accumulated error of this optimal truncated representation is given by

$$\varepsilon = \sum_{i=1}^{N}\left\|\mathbf{y}^i - \sum_{j=1}^{M}(\mathbf{y}^i, \mathbf{\Phi}^j)\mathbf{\Phi}^j\right\|^2 = \sum_{i=1}^{N}\left\|\sum_{j=M+1}^{N}(\mathbf{y}^i, \mathbf{\Phi}^j)\mathbf{\Phi}^j\right\|^2,$$

where $\mathbf{y}^i = \sum_{j=1}^{N}(\mathbf{u}^i, \mathbf{\Phi}^j)\mathbf{\Phi}^j, i = 1, \ldots, N$, and can be computed using singular value analysis; see [4, 23].

Since the eigenvalues can be used to find how close the M-dimensional subspace approximant is to the data set, one can seek M such that the fraction of the total energy

$$\sum_{i=1}^{M}\lambda_i \Bigg/ \sum_{i=1}^{N}\lambda_i$$

is close to one and yet $M \ll N$. Then the POD reduced basis subspace is defined as $\mathbf{V}^{POD} = \text{span}\{\Phi_1, \Phi_2, \ldots, \Phi_M\}$.

2.2. The Galerkin projection and the reduced-order model. Given a collection of N snapshots $\mathbf{Y}_k$, $k = 1, \ldots, N$, as possible states of the system (2.1), we define the modified snapshots set

$$\mathbf{y}_k = \mathbf{Y}_k - \overline{\mathbf{Y}}, \qquad k = 1, \ldots, N,$$

by subtracting the mean $\overline{\mathbf{Y}} = \frac{1}{N}\sum_{k=1}^{N}\mathbf{Y}_k$ and apply POD to this set to find a reduced-order subspace $\mathbf{V}^{POD} = \text{span}\{\Phi_1, \Phi_2, \ldots, \Phi_M\}$.

In the Galerkin projection, we write $\mathbf{y}(t)$ as

$$\mathbf{y}(t) = P^*\boldsymbol{\alpha}(t) + \mathbf{r}(t),$$

where $\boldsymbol{\alpha}(t) \in \mathbb{R}M$ and P is a suitable projection. Inserting this expression into (2.1), we get

$$P^*\dot{\boldsymbol{\alpha}}(t) + \dot{\mathbf{r}}(t) = \mathcal{E}(P^*\boldsymbol{\alpha}(t) + \mathbf{r}(t)).$$

The Galerkin method then enforces the residual to be orthogonal to the M-dimensional subspace such that $P\mathbf{r}(t) = 0$. This leads to

$$\dot{\boldsymbol{\alpha}}(t) = P\mathcal{E}(P^*\boldsymbol{\alpha}(t) + \mathbf{r}(t)).$$

If we now choose the projection P such that $r(t)$ is small in some sense, then the reduced-order model is given by

$$\dot{\boldsymbol{\alpha}}(t) = P\mathcal{E}(P^*\boldsymbol{\alpha}(t)).$$

3. The thermal channel flow system. In this section, we describe the thermal system and the governing equations with relevant boundary conditions. We also describe the discretization schemes and solution techniques to solve these equations.

3.1. The governing equations. The class of thermally convective flow we consider is modeled by a thermally coupled Navier–Stokes equations that uses Boussinesq approximations based on certain assumptions about the thermodynamics and the thermal effects on the flow. The first one is that variations in density are negligible except for the body force term $\rho\mathbf{g}$ in the momentum equations, where ρ is the density and the vector $\mathbf{g}$ is the constant acceleration of gravity. We next assume that the density ρ in the term $\rho\mathbf{g}$ can be given by $\rho = \rho_0[1 - \beta(T - T_0)]$, where T_0 and ρ_0 are reference temperature and density, respectively, T is the absolute temperature, and β is the thermal expansion coefficient. Furthermore, we assume that in the energy equation, the dissipation of mechanical energy is negligible and the viscosity μ, the heat conductivity κ, the thermal expansion coefficient β, and the specific heat at constant pressure c_p are constant. Then under these assumptions the flow is governed by the equations

$$\begin{aligned}
&\mathbf{u}_t - \mu\Delta\mathbf{u} + \rho_0(\mathbf{u}\cdot\nabla)\mathbf{u} + \operatorname{grad} p = \mathbf{g}\rho_0[1 - \beta(T - T_0)]\,,\\
&T_t - \kappa\,\Delta T + \rho_0 c_p \mathbf{u}\cdot\nabla T = 0\,,\\
&\nabla\cdot\mathbf{u} = 0
\end{aligned}$$

in the domain $\Omega \times [0, T]$, where Ω is a bounded open set and the heat source is assumed to be zero. If we assume there is a length scale ℓ, a velocity scale $V_{\max}$, and a temperature scale $T_1 - T_0$ in the flow, then one can define nondimensional Prandtl number $Pr = \mu c_p/\kappa$, Grashof number $Gr = \beta\ell^3\rho_0^2|\mathbf{g}|(T_1 - T_0)/\mu^2$, and Reynolds number $Re = \rho_0 V_{\max}\ell/\mu$. Next, if we nondimensionalize according to $\mathbf{x} \leftarrow \mathbf{x}/\ell$, $\mathbf{u} \leftarrow \mathbf{u}/V_{\max}$, $T \leftarrow (T - T_0)/(T_1 - T_0)$, and $p \leftarrow (p - \mathbf{g}\cdot\mathbf{x})/(\rho_0 {V_{\max}}^2)$, we obtain the following nondimensional form of Boussinesq equations (uncontrolled system (S_u)):

$$\begin{aligned}
&\mathbf{u}_t - \frac{1}{Re}\Delta\mathbf{u} + (\mathbf{u}\cdot\nabla)\mathbf{u} + \operatorname{grad} p + \frac{Gr}{Re^2}T\mathbf{g} = \mathbf{0}\,,\\
&T_t - \frac{1}{RePr}\,\Delta T + \mathbf{u}\cdot\nabla T = 0\,,\\
&\nabla\cdot\mathbf{u} = 0
\end{aligned}\tag{3.1}$$

in the domain $\Omega \times [0, T]$, where $\mathbf{g}$ is now a unit vector in the direction of gravitational acceleration.

For all of our numerical simulations in this article, we choose the two-dimensional flow in a backward-facing step channel as our flow setting. A schematic of the geometry is given in Figure 1. The height of the inflow boundary is 0.5 and that of the outflow boundary is 1. The length of the narrower section of the channel is 1 and that of the wider section of the channel is 7 (the total horizontal length is 8). At the inflow boundary a parabolic velocity profile is prescribed, i.e., $u(x = 0,\ 1/2 \le y \le 1) = 8(y - 1/2)(1 - y)$, $v(x = 0,\ 1/2 \le y \le 1) = 0$ (the coordinate system is chosen such that $y = 1$ on the top boundary), which produces a maximum inflow velocity of $u_{max} = 1/2$. On the solid walls the no-slip condition ($\mathbf{u} = 0$) is imposed. The pseudo stress-free condition,

$$-p + \frac{1}{Re}\frac{\partial u}{\partial x} = 0 \quad\text{and}\quad \frac{\partial v}{\partial x} = 0,$$

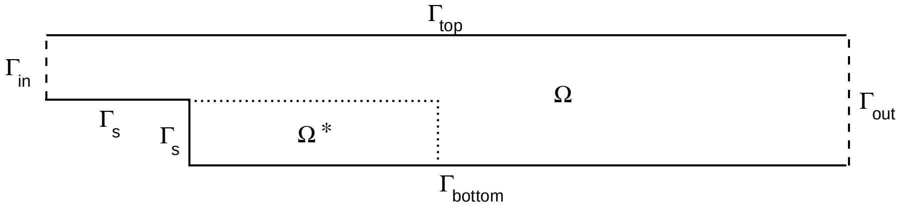

Fig. 1. *Computational domain for the backward-facing step channel problem.*

at the outflow boundary is not "physical" but is used to represent the flow in an unbounded region; see [22]. The boundary condition for the temperature is taken to be $T = 2$ except at the outflow boundary where we assume $\frac{\partial T}{\partial n} = 0$. We define the Reynolds number as $Re = \frac{V_{max} \cdot H}{\nu}$, where V_{max}= maximum inlet velocity, H = channel height, ν= kinematic viscosity of the fluid. Throughout this simulation we choose $V_{max} = \frac{1}{2}$ and $H = 1$ with a corresponding $Re = \frac{1}{2\nu}$.

3.2. Discretizations and solution techniques of the governing equations. In this section, we introduce discretizations and solution techniques of the governing equations. For spatial discretization, we use a mixed finite element method, and for the time discretization we use the strongly A-stable backward Euler method. In setting up the finite element model of the governing equations, one starts with a weak form. We define the weak form as

$$\begin{aligned} &(\mathbf{u}_t + \mathbf{u} \cdot \nabla \mathbf{u}, \mathbf{v}) + \frac{1}{Re}(\nabla \mathbf{u}, \nabla \mathbf{v}) - (p, \nabla \cdot \mathbf{v}) + \frac{Gr}{Re^2}(T\mathbf{g}, \mathbf{v}) = 0\,, \\ &(T_t + \mathbf{u} \cdot \nabla T, \psi) + \frac{1}{RePr}(\nabla T, \nabla \psi) = 0\,, \\ &(\nabla \cdot \mathbf{u}, q) = 0\,, \qquad \mathbf{u}(0) = \mathbf{u}_0\,, \qquad T(0) = T_0 \end{aligned} \tag{3.2}$$

for all test functions $(\mathbf{v}, q, \psi) \in \mathbf{V} \times L^2(\Omega) \times V_1$, where

$$\mathbf{V} = \{\mathbf{v} \in \mathbf{H}^1(\Omega) : \quad \mathbf{v}|_{\Gamma \backslash \Gamma_{\text{out}}} = 0\},$$

$$V_1 = \{\psi \in H^1(\Omega) : \quad \psi|_{\Gamma \backslash \Gamma_{\text{out}}} = 0\},$$

and $(\cdot, \cdot)$ denotes the $L^2(\Omega)$ or $\mathbf{L}^2(\Omega)$ inner product. The state variables $(\mathbf{u}, p, T)$ for the problem are taken to be

$$\mathbf{u} \in L^2(0, T; \mathbf{H}^1(\Omega)), \qquad \mathbf{u}|_{\Gamma_{\text{in}}} = \mathbf{u}_{\text{in}}, \qquad \text{and } \ \mathbf{u}|_{\Gamma \backslash \Gamma_{\text{out}} \backslash \Gamma_{\text{in}}} = 0,$$

$$T \in L^2(0, T; H^1(\Omega)), \qquad T|_{\Gamma \backslash \Gamma_{\text{out}}} = T_b, \qquad \text{and } \ T_b \in L^2(0, T; H^{1/2}(\Gamma \setminus \Gamma_{\text{out}})),$$

$$p \in L^2(\Omega), \qquad \mathbf{u}_0, T_0 \in L^2(\Omega), \qquad \text{and } \ \mathbf{u}_{\text{in}} \in L^2(0, T; H^{1/2}(\Gamma_{\text{in}})).$$

On the finite mesh covering the domain with local element width h, one defines polynomial trial functions for velocity and pressure. Let $\mathcal{K}^h$ be a standard finite element triangulation of Ω, where h is the maximal length of all the triangulation edges in $\mathcal{K}_h$. Let $\mathcal{P}^k$ to be the space of all polynomials of degree less than or equal to k and let

$$\mathbf{V}^h = \{\mathbf{v}^h | \ \mathbf{v}^h \in C^0(\bar{\Omega}) \times C^0(\bar{\Omega}), \ \ \mathbf{v}^h|_K \in \mathcal{P}^2 \times \mathcal{P}^2 \quad \forall K \in \mathcal{K}^h\},$$

$$V^h = \{v^h | \ v^h \in C^0(\bar{\Omega}), \ \ v^h|_K \in \mathcal{P}^2 \quad \forall K \in \mathcal{K}^h\},$$

$$P^h = \{q^h | \ q^h \in C^0(\bar{\Omega}), \ \ q^h|_K \in \mathcal{P}^1 \quad \forall K \in \mathcal{K}^h\}.$$

These spaces $\mathbf{V}_h$ and P^h should lead to numerically stable approximations as $h \to 0$, i.e., they should satisfy the Babuska–Brezzi condition with a mesh-independent constant γ (see [6]),

$$\min_{p_h \in P_h} \max_{\mathbf{v}_h \in \mathbf{V}_h} \frac{(p_h, \nabla \cdot \mathbf{v}_h)}{\|\mathbf{v}_h\|_1 \, \|p_h\|_0} \geq \gamma \geq 0 \,.$$

Many stable pairs are available in the literature. Our choice is the triangular element, which uses piecewise quadratic polynomial shape functions for the velocities and a piecewise linear polynomial for the pressure. The temperature is also defined using piecewise quadratic polynomial shape functions defined on the same triangle. A triangular grid is generated as follows. The domain is first divided into squares, and then each square is subdivided into two triangles by cutting from bottom right to top left. The velocity, temperature, and pressure are defined on the same triangulation, and on each triangle the degrees of freedom for quadratic elements are the function values at the vertices and midpoints of each edge; the degrees of freedom for linear elements are the function values at the vertices.

We now restrict the weak form (3.2) to $\mathbf{V}_h \times V_h \times P_h$ to obtain the finite element model: *Seek* $(\mathbf{u}_h, p_h, T_h)$ *such that* $\mathbf{u}_h|_{\Gamma_{in}} = \mathbf{u}_{in}, \ \ \mathbf{u}_h|_{\Gamma \backslash \Gamma_{out} \backslash \Gamma_{in}} = 0$, $T_h|_{\Gamma \backslash \Gamma_{out}} = 0$, *and*

$$\begin{aligned} &\left(\frac{\partial \mathbf{u}_h}{\partial t} + \mathbf{u}_h \cdot \nabla \mathbf{u}_h + \frac{Gr}{Re^2} T_h \mathbf{g}, \mathbf{v}_h \right) + \frac{1}{Re} (\nabla \mathbf{u}_h, \nabla \mathbf{v}_h) - (p_h, \nabla \cdot \mathbf{v}_h) = 0 \,, \\ &\left(\frac{\partial T_h}{\partial t} + \mathbf{u}_h \cdot \nabla T_h, \psi_h \right) + \frac{1}{RePr} (\nabla T_h, \nabla \psi_h) = 0 \,, \\ &(\nabla \cdot \mathbf{u}_h, q_h) = 0 \,, \qquad \mathbf{u}_h^0 = \mathbf{u}_0, \qquad T_h^0 = T_0 \end{aligned} \tag{3.3}$$

for all $(\mathbf{v}_h, T_h, q_h) \in \mathbf{V}^h \times V^h \times P^h$. In matrix notation, with $\mathbf{U}$, T, and P denoting the nodal values of the velocity, temperature, and pressure, respectively, the system (3.3) is equivalent to

$$\begin{aligned} &M\dot{\mathbf{U}} + A\mathbf{U} + N(\mathbf{U})\mathbf{U} + B^T \mathbf{P} + DT = 0, \\ &N\dot{T} + E(\mathbf{U})T + FT = 0, \\ &B\mathbf{U} = 0 \,. \end{aligned} \tag{3.4}$$

We discretize the time derivative in (3.4) by a one-step θ-scheme, namely, the A-stable backward Euler method with $\theta = 1/2$.

Given $\mathbf{U}^n = \mathbf{U}(n\Delta t)$, $T^n = T(n\Delta t)$, *and the time step* $\Delta t = t_{n+1} - t_n$, *solve for* $\mathbf{U}^{n+1}$, T^{n+1}, *and* P^{n+1} *from*

$$\begin{aligned} &[M + \Delta t \, \theta(A + N(\mathbf{U}^{n+1})]\mathbf{U}^{n+1} + \Delta t \, B^T P^{n+1} + \Delta t \, \theta D T^{n+1} = \mathbf{f}^n \,, \\ &[N + \Delta t \, \theta(F + E(\mathbf{U}^{n+1})]T^{n+1} = \mathbf{h}^n \,, \\ &B\mathbf{U}^{n+1} = 0 \,, \end{aligned} \tag{3.5}$$

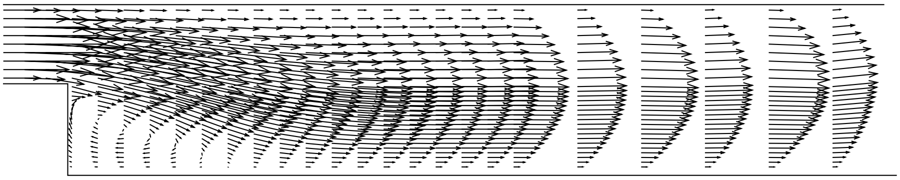

FIG. 2. *Baseline/uncontrolled flow; vector fields of velocity at $t = 100$.*

with the right-hand sides

$$\mathbf{f}^n = [M + \Delta t(\theta - 1)(A + N(\mathbf{U}^n))]\mathbf{U}^n + \Delta t(\theta - 1)T^n\,,$$
$$\mathbf{h}^n = [N + \Delta t(\theta - 1)(F + E(\mathbf{U}^n))]T^n.$$

In each time step we have to solve a nonlinear algebraic system. Our approach to solving this discrete nonlinear problem is to linearize the convective term by a constant extrapolation in time; for example, we approximate $N(\mathbf{U}^{n+1})\mathbf{U}^{n+1}$ by $N(\mathbf{U}^n)\mathbf{U}^{n+1}$. For the solution of the discrete linear problem, we use banded Gaussian elimination with pivoting.

The computational grid was nonuniform in both the streamwise and cross-flow coordinate directions. A fine grid was used in regions where sharp variations in velocities were expected. All the computations were done with a 45 × 45 grid and a time step size $\Delta t = 1/200$ for the Reynolds number 200, the Prandtl number 0.72, and the Grashof number $Gr = 40{,}000$. The flow separates at the corner of the step and a recirculation forms. After the reattachment of the lower wall eddy, the flow slowly recovers toward a fully developed Poiseuille flow. The resulting steady flow field is given in Figure 2.

To verify the grid independence of the solution, the same problem was solved halving the grid size, i.e., using a 90 × 90 grid and a time step size $\Delta t' = 1/400$. The results from both grids agreed well and predicted the reattachment point on the downstream lower wall. Typical computations require about 180 CPU seconds per time step on a Sun Ultra 60, while the time integration goes for 2000 time steps.

4. Reduced-order adaptive optimal control approach.

4.1. The control problem for the channel. Minimization of the vorticity level in a flow domain is of interest in control/delay of transition of flow past bluff bodies. Thus in this section we formulate a related optimal control problem in channel flow. The flow configuration considered is a backward-facing step channel. As the Reynolds number is increased, the flow separates near the corner of the step. The objective of the optimal control is to reduce the size of the recirculation and hence of the length of reattachment. The control action is affected through boundary temperature on Γ_c. In terms of the boundary condition, it takes the following form along the boundary Γ_c:

$$T = c(t) \quad \text{on } \Gamma_c \times [0, T],$$

where $c(t) : [0,T] \to \mathbb{R}$. The *controlled system* (S_c) we consider is

$$\begin{aligned}
&\mathbf{u}_t - \frac{1}{Re}\Delta\mathbf{u} + \mathbf{u}\cdot\nabla\mathbf{u} + \nabla p + \frac{Gr}{Re^2}T\mathbf{g} = 0\,,\\
&T_t - \frac{1}{RePr}\,\Delta T + \mathbf{u}\cdot\nabla T = 0\,,\\
&\nabla\cdot\mathbf{u} = 0, \qquad \mathbf{u}(\mathbf{x},0) = \mathbf{u}_0(\mathbf{x}), \qquad T(0) = T_0
\end{aligned} \tag{4.1}$$

in the domain $\Omega \times [0,T]$ and the boundary conditions

$$\begin{array}{lll}
\Gamma_{\text{in}}: & \mathbf{u} = (8(0.5-y)(1-y),0); & T = 2;\\
\Gamma_{\text{out}}: & -p + \dfrac{1}{Re}\dfrac{\partial u}{\partial x} = 0 \quad \text{and} \quad \dfrac{\partial v}{\partial x} = 0; & \dfrac{\partial T}{\partial n} = 0;\\
\Gamma_{\text{top}}: & \mathbf{u} = (0,0); & T = 2;\\
\Gamma_c = \Gamma_s \cup \Gamma_{\text{bottom}}: & \mathbf{u} = (0,0); & T = c(t).
\end{array}$$

The choice of cost functional or objective functional to meet the control objective of reducing the recirculation is not trivial. Here we will consider a functional of the form

$$\mathcal{G}(\mathbf{u}) = \int_\Omega |\nabla\times\mathbf{u}|^2\,d\mathbf{x}$$

which corresponds to minimization of vorticity levels in the flow. The optimal control problem is defined as follows: *find $c(t)$ such that the cost functional $\mathcal{J}(\mathbf{u},U) = \frac{1}{2}\int_0^T \left[\mathcal{G}(\mathbf{u}) + \beta|U|^2\right] dt$ is minimized subject to the constraints that the flow fields satisfy the controlled system (S_c).*

Note here that by including a term involving U one minimizes the rate of change of controlling temperature. The parameter $\beta > 0$ adjusts the relative weight of the two terms in the functional. Solutions of this optimal control problem require numerical approximation. For a typical control problem in flow control, approximations are large scale, involving hundreds of thousands of variables; see, for example, [12, 9, 10, 7, 25]. Below we discuss reduced-order controller design using POD.

4.2. Construction of POD basis functions. When designing optimal control without POD-based reduced-order models, one needs to solve the full Navier–Stokes model and its adjoint equations during each iteration of the optimization algorithm. Here we present an approach that requires the solution of the full Navier–Stokes model only when we need to update the model; thus the optimization process is much faster, resulting in substantial savings in computational work. In order to construct a reduced-order model, one needs an ensemble. As explained earlier, we use snapshots in time of the flow fields. As described in [21, 20], it is necessary to remove the inhomogeneities on the boundary. A convenient way to do this is to introduce a reference flow field $(\mathbf{u}_r, p_r, T_r)$. Let $(\mathbf{u}_{r_1}, p_{r_1}, T_{r_1})$ be a flow field satisfying the steady state Navier–Stokes model

$$\begin{aligned}
&-\frac{1}{Re}\Delta\mathbf{u} + \mathbf{u}\cdot\nabla\mathbf{u} + \nabla p + \frac{Gr}{Re^2}T\mathbf{g} = 0,\\
&-\frac{1}{RePr}\,\Delta T + \mathbf{u}\cdot\nabla T = 0\,,\\
&\nabla\cdot\mathbf{u} = 0
\end{aligned} \tag{4.2}$$

in the domain Ω and the boundary conditions

$$\begin{array}{lll}
\Gamma_{\text{in}}: & \mathbf{u}=(8(0.5-y)(1-y),0); & T=2; \\
\Gamma_{\text{out}}: & -p+\dfrac{1}{Re}\dfrac{\partial u}{\partial x}=0 \quad \text{and} \quad \dfrac{\partial v}{\partial x}=0; & \dfrac{\partial T}{\partial n}=0; \\
\Gamma_{\text{top}}: & \mathbf{u}=(0,0); & T=2; \\
\Gamma_c=\Gamma_s\cup\Gamma_{\text{bottom}}: & \mathbf{u}=(0,0); & T=c_r,
\end{array}$$

where $c_r(=1)$ is a constant temperature field imposed on the control boundary Γ_c, and let $(\mathbf{u}_{r_0},p_{r_0},T_{r_0})$ be another set of flow field satisfying the above steady state Navier–Stokes model with the boundary value $c_r=0$ on the control boundary Γ_c. We next set $(\mathbf{u}_r,p_r,T_r)=(\mathbf{u}_{r_1},p_{r_1},T_{r_1})-(\mathbf{u}_{r_0},p_{r_0},T_{r_0})$. Then each flow field in the modified snapshot set

$$\left\{(\mathbf{u}(\mathbf{x},t^k),p(\mathbf{x},t^k),T(\mathbf{x},t^k))-\frac{c(t^k)}{c_r}(\mathbf{u}_r(\mathbf{x}),p_r(\mathbf{x}),T_r(\mathbf{x}))\right\}, \quad k=1,\dots,N,$$

satisfies homogeneous boundary conditions on Γ_c. Finally, we let $(\mathbf{u}_m,p_m,T_m)$ be the mean flow field of these modified fields and define a new snapshot set

$$\left\{(\mathbf{u}(\mathbf{x},t^k),p(\mathbf{x},t^k),T(\mathbf{x},t^k))-\frac{c(t^k)}{c_r}(\mathbf{u}_r,p_r,T_r)-(\mathbf{u}_m,p_m,T_m)\right\}, \quad k=1,\dots,N,$$

which satisfies homogeneous boundary conditions on all boundaries. To these N snapshots satisfying homogeneous boundary conditions, we apply the POD to obtain basis functions in descending order according to the information content of the system.

4.3. The reduced-order model. We employ the Galerkin projection on the Navier–Stokes model with the above POD basis functions to derive the reduced-order model, which will later be used in the optimization algorithm to solve the optimal control problem described earlier. The flow field is decomposed as follows:

$$(\mathbf{u},p,T)=(\mathbf{u}_m,p_m,T_m)+\frac{c(t)}{c_r}(\mathbf{u}_r,p_r,T_r)+\sum_{i=1}^{M}\alpha_i(t)\mathbf{\Phi}_i, \tag{4.3}$$

where $\mathbf{\Phi}_i$ is the ith POD basis function, $\alpha_i(t)$ is the corresponding coefficient, and M is the total number of POD basis functions used in the Galerkin projection. Using the Galerkin projection, we get

$$\int_\Omega \mathbf{R}\cdot\mathbf{\Phi}_i d\Omega=0, \quad i=1,\dots,M, \tag{4.4}$$

where $\mathbf{R}=(R_1,R_2,R_3)$ and

$$\begin{aligned}
R_1&=\mathbf{u}_t-\frac{1}{Re}\Delta\mathbf{u}+\mathbf{u}\cdot\nabla\mathbf{u}+\nabla p+\frac{Gr}{Re^2}T\mathbf{g},\\
R_2&=T_t-\frac{1}{RePr}\Delta T+\mathbf{u}\cdot\nabla T,\\
R_3&=\nabla\cdot\mathbf{u}.
\end{aligned}$$

As described in [21, 20] for a similar problem, when the expansion (4.3) is inserted into (4.4) and in the cost functional $\mathcal{J}$, we get the reduced-order control problem

$$\tag{4.5} \begin{aligned} &\text{Minimize } \mathcal{J}(\mathbf{X}, U) = \int_0^T \left[\ell(\mathbf{X}) + \frac{\beta}{2} U^2\right] dt \\ &\text{subject to} \quad \dot{\mathbf{X}} = f(\mathbf{X}) + BU\,, \\ &\phantom{\text{subject to}} \quad \mathbf{X}(0) = \mathbf{X}_0, \end{aligned}$$

where $\mathbf{X} = (1, \boldsymbol{\alpha}, c)^T$, $f(\mathbf{X}) = -\mathbf{A}\mathbf{X} - \mathbf{N}(\mathbf{X})$, $\ell(\mathbf{X}) = \frac{1}{2}\mathbf{X}^T \mathcal{Q}\mathbf{X}$, $\mathcal{Q}_{i,j} = (\nabla \times \boldsymbol{\Phi}_i, \nabla \times \boldsymbol{\Phi}_j)$, $i, j = 0, \ldots, M+1$, and U is the rate of change of the control $c(t)$.

Although it is not essential for the adaptive control procedure to be described later, we discretize the problem (4.5) by using the Crank–Nicholson for the time derivative and trapezoidal rule for the time integral and rewrite it as

$$\tag{4.6} \begin{aligned} &\text{Minimize } \mathcal{J}(\mathbf{Y}) \\ &\text{subject to } F(\mathbf{Y}) = 0\,, \end{aligned}$$

where $\mathbf{Y} = (\mathbf{X}, U)$,

$$\mathcal{J}(\mathbf{Y}) = \sum_{k=1}^{N} \left[\frac{1}{2}\left(\ell(\mathbf{X}^{k-1}) + \ell(\mathbf{X}^k)\right) + h(U^k)\right] \Delta t,$$

$$F(\mathbf{Y}) = \begin{bmatrix} \dfrac{\mathbf{X}^1 - \mathbf{X}^0}{\Delta t} - \dfrac{1}{2}\left(f(\mathbf{X}^1) + f(\mathbf{X}^0)\right) + BU^1 \\ \vdots \\ \vdots \\ \vdots \\ \dfrac{\mathbf{X}^N - \mathbf{X}^{N-1}}{\Delta t} - \dfrac{1}{2}\left(f(\mathbf{X}^N) + f(\mathbf{X}^{N-1})\right) + BU^N \end{bmatrix},$$

and $\Delta t = T/N$. The optimal control problem (4.6) is a constrained optimization problem. An efficient method for solving optimization problems is the SQP method, which can be viewed as an application of Newton's method to the first order necessary conditions of optimality in the present case. The SQP method is preferred over the unconstrained optimization methods due to its superior convergence properties, among others. Its application to solve optimal control of Navier–Stokes flow has been demonstrated in [9, 10] and [19]. In [21, 11], we applied it to solve a reduced-order optimal control problem in Navier–Stokes flow. Here we present an adaptive procedure where one successively updates the state information within the SQP framework.

In SQP methods, a sequence of iterates is generated by solving a quadratic programming (QP) subproblem, converging to a solution of the constrained nonlinear optimization problem. Each QP subproblem minimizes a quadratic model of the form

$$\tag{4.7} \begin{aligned} &\text{Minimize} \quad \tfrac{1}{2}(\nabla_{YY}\mathcal{L}(\mathbf{Y}_k, \boldsymbol{\zeta}_k)(\mathbf{Y} - \mathbf{Y}_k), \mathbf{Y} - \mathbf{Y}_k) + (\nabla_Y \mathcal{L}(\mathbf{Y}_k, \boldsymbol{\zeta}_k), \mathbf{Y} - \mathbf{Y}_k) \\ &\text{subject to} \quad F_Y(\mathbf{Y}_k)(\mathbf{Y} - \mathbf{Y}_k) + F(\mathbf{Y}_k) = 0\,, \end{aligned}$$

where $\mathcal{L}(\mathbf{Y},\boldsymbol{\zeta}) = \mathcal{J}(\mathbf{Y}) + (F(\mathbf{Y}),\boldsymbol{\zeta})$ is the Lagrangian function. Once the QP solution $(\widehat{\mathbf{Y}}_k, \widehat{\boldsymbol{\zeta}}_k)$ has been determined, the major iteration proceeds by determining new variables

$$
\begin{aligned}
\mathbf{Y}_{k+1} &= \mathbf{Y}_k + \eta_k(\widehat{Y}_k - \mathbf{Y}_k),\\
\boldsymbol{\zeta}_{k+1} &= \boldsymbol{\zeta}_k + \eta_k(\widehat{\boldsymbol{\zeta}}_k - \boldsymbol{\zeta}_k)\,.
\end{aligned}
\tag{4.8}
$$

One of the properties of the SQP method is that the SQP iterations do not usually satisfy the nonlinear constraints except as the solution is approached.

In our application the constraint $F(\mathbf{Y}) = 0$ is provided by the reduced-order model obtained through the POD procedure. Therefore the reduced-order model must predict the system behavior accurately for various trajectories of the boundary temperature $c(t)$ that include not only the optimal trajectory but also other trajectories appearing during the optimization iterations. In order to meet this requirement we propose an adaptive procedure in the next section.

4.4. Reduced-order adaptive control. Choosing the ensemble of data that represent the system behavior for various trajectories during the iterative optimization procedure is critical in POD-based control design. To meet this requirement, we propose an adaptive procedure that successively updates the reduced-order model to be used in the sequential QP optimization algorithm described earlier. We begin with an initial estimate $(\mathbf{Y}_k, \boldsymbol{\zeta}_k)$ and the corresponding initial estimate for the control c_k for the SQP method and generate the corresponding ensemble of snapshots from the Navier–Stokes model. With these snapshots, we find a POD subspace and the corresponding reduced-order model. This reduced-order model is now used in the SQP algorithm to find the new iterate $(\mathbf{Y}_{k+1}, \boldsymbol{\zeta}_{k+1})$. This process of updating the reduced-order model is continued in each of the SQP iterations until convergence is achieved. The computation using the adaptive reduced-order procedure takes the following form.

Algorithm I. Reduced-order adaptive procedure.

Select the tolerance $\epsilon > 0$ and perform the following steps:

Step 1. Set $k = 1$, $(\mathbf{Y}_{k-1}, \boldsymbol{\zeta}_{k-1}) = (\mathbf{Y}_0, \boldsymbol{\zeta}_0)$, and initial control estimate $c_{k-1} = c_0$.
Step 2. Compute the snapshots and derive the reduced-order model for the control variable c_{k-1}.
Step 3. Update the constraint and cost functional in the QP subproblem and solve for $(\widehat{\mathbf{Y}}_{k-1}, \widehat{\boldsymbol{\zeta}}_{k-1})$.
Step 4. Determine the new variables $(\mathbf{Y}_{k-1}, \boldsymbol{\zeta}_{k-1})$ and the control variable c_k.
Step 5. If $\left|c_k - c_{k-1}\right| > \epsilon$, add 1 to k and go to Step 2.
Step 6. The procedure is completed.

In the next section, we show the effectiveness and feasibility of this algorithm in the present application.

5. Computational results. For numerical computations here, the flow configuration and all the parameters are the same as in the uncontrolled simulations presented in section 3, except that the control action is in the form of temperature on the boundary $\Gamma_c = \Gamma_s \cup \Gamma_{\text{bottom}}$. The control objective is to reduce the recirculation behind the step and thus the reattachment length. The cost functional is taken to be the vorticity functional defined earlier.

We present numerical results for the adaptive POD approach in solving the optimal control problem at $Re = 200$. The snapshots for Algorithm I were updated

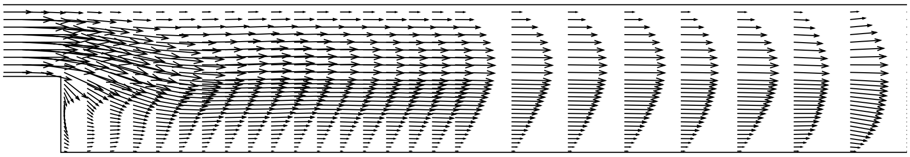

FIG. 3. *Controlled flow; vector fields of velocity at* $t = 100$.

in every iteration by applying the computed optimal control $c(t)$ on Γ_c and simulating the system (S_c) in the interval $[0,T]$ with $T = 100$. A hundred snapshots were recorded at constant time intervals Δt^* $(\Delta t^* = 20\Delta t)$ for each iteration, and the POD was used to compute the dominant modes. The eigenvalues of the correlation matrix decayed rapidly, and we found only 9 modes were enough to capture 99% of the information content. Initially state and control were given a prescribed value and the optimal control problem was solved using the algorithm described in section 4. All computations were performed on a Sun Ultra 60 machine.

The adaptive algorithm terminates after about 5 iterations with significant reduction in the cost functional. In implementing Algorithm I, we carried out Step 2 in two different ways. In one implementation, we expanded the ensemble by adding new snapshots in each iteration. This implementation required more and more POD modes in each iteration to capture 99% of the information in the snapshots and thus increased the computational cost. However, the second implementation, which involved replacing the old snapshots with the new in step 2 of Algorithm I, required only 9 modes throughout the iterations and captured the required percentage of the information in the ensemble.

We carried out several simulations to study the performance of the controller. Here we present only a sample of the results. The controlled flow fields with 9, 12, and 14 modes showed similar results, and hence only results with 9 modes are presented. The flow fields presented in Figure 4 are u and v components of the flow field $\mathbf{u}$ at different stations in the channel for the controlled and uncontrolled cases with 9 POD modes. Figure 4 illustrates the suppression of flow reversal present in the uncontrolled flow. We plot the horizontal and vertical components of the baseline and controlled velocities versus the distance normal to the wall. The top two curves are for the baseline and controlled horizontal component of the velocity. We see that the optimal control has affected a very substantial reduction in the back-flow. The bottom two curves in the figures are analogous to the top curves but for the vertical component of velocity. The flow fields presented in Figures 2 and 3 are the vector fields of the baseline and controlled velocities. As indicated by the controlled flow fields, separation has been effectively eliminated by the optimal temperature. Substantial reduction in the recirculation bubble is also seen. The reattachment length has been reduced by more than 99% compared to the uncontrolled case.

Figures 5–10 show controls that were obtained in successive adaptive iterations in Algorithm I. These figures show convergence of the adaptive strategy. It is a plot of the temperature on the lower wall of the channel versus time. Note that convergence is achieved after about 6 iterations.

The penalty parameter β plays a critical role in the controller design. For $\beta \leq 1$ control oscillates at the beginning and the end of the time interval. The amplitude of

the oscillation increases as more weight is placed on achieving the vorticity reduction by decreasing the parameter value β in the cost functional $\mathcal{J}$. In other words, oscillations increase as the rate of change of control U is increased; see Figure 5. Whereas for $\beta > 20$ control undershoots. With the value $\beta = 10$, a smooth control was obtained.

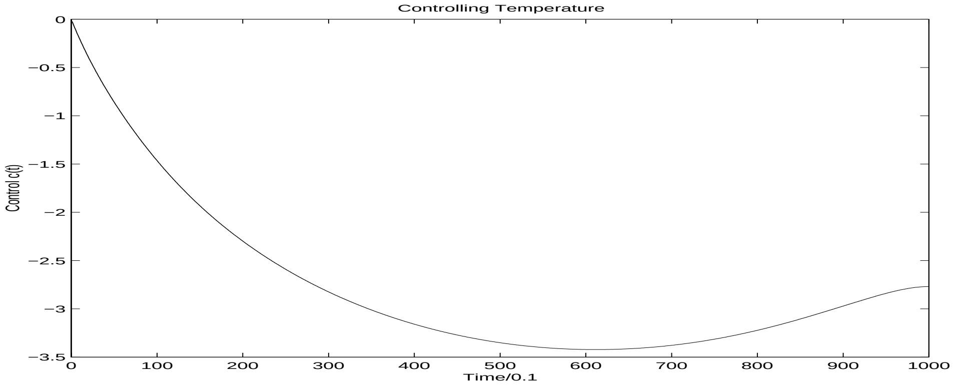

FIG. 9. *Optimal control (POD) at iteration* 5 *as a function of nondimensional time.*

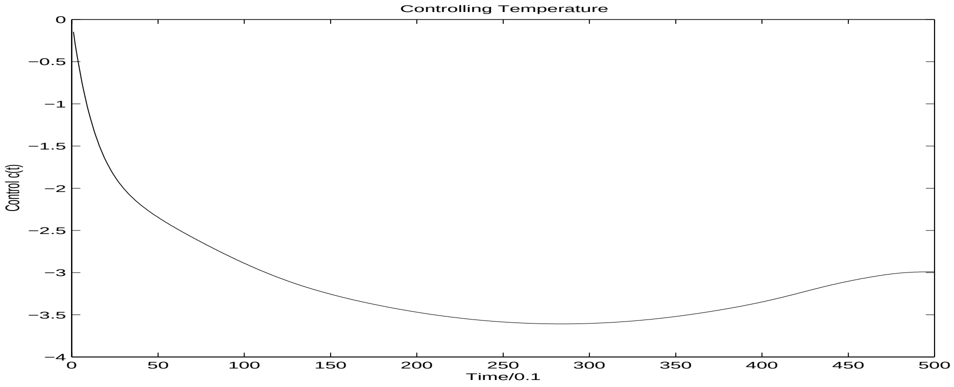

FIG. 10. *Optimal control (POD) at iteration* 6 *as a function of nondimensional time.*

In general, the computational cost for solving the optimal control problem is essentially determined by the length of the time interval and the convergence rate of the optimization process. However, one can easily see that the CPU time requirement for the reduced-order control computation is much less than that for the case of full-order control computation as the number of degrees of freedom is about 1/746 of the latter. In the control computation using the Sun Ultra 60 workstation, one iteration of the reduced-order SQP requires 3 minutes. The number of iterations needed to reach the converged optimal control is 6. During each of these iterations, a reduced-order dynamical model has to be constructed by solving the Navier–Stokes model with different control updates to generate the snapshots. This step requires 72 hours. The remaining steps in the POD take about 3 minutes. The total CPU time requirement for the adaptive reduced-order control computation is about 73 hours. This is a substantial savings in computation time since the control computation with full-order Navier–Stokes model using SQP method would take 480 CPU hours and 18 iterations to converge. This savings in computational time is mainly due to the fact that the adjoint equation of the Navier–Stokes model, which is computationally as costly as the Navier–Stokes equation itself, is computed using the reduced-order model in the adaptive reduced-order control computation. The reduction in computation time with the use of reduced-order model instead of full-order Navier–Stokes model will be much more significant in the three-dimensional case as the difference in the degrees of freedom between reduced-order model and the original full-order Navier–Stokes model will become much larger.

The location of the actuator (temperature control) was selected as the bottom wall and the vertical part of the step. This choice is motivated by the fact that if one wants maximum influence in the flow, then the control has to be applied in that vicinity. However, the optimal control can be very different depending on the location. This was evident in our computational experiments. In one experiment we used inflow temperature as control and the optimal control was heating, and in another we placed control at the top wall and the optimal control was again heating.

6. Conclusion. The optimal control techniques for flow control problems are complex and very computationally demanding. The POD method provides a systematic way to obtain reduced-order models and allows one to design controllers at drastically reduced computational cost. However, it is not clear, a priori, what is the best way to obtain an ensemble of data for POD that would lead to POD basis functions that represent the influence of the control during the optimization algorithm. Therefore the reduced-order model should be improved to represent such influences. We presented an adaptive procedure that successively updates the ensemble and the reduced-order model during the iterative optimization process using SQP. The present approach was illustrated by implementing it on the boundary optimal control problems of a thermally coupled Navier–Stokes model. Numerical experiments indicate the effectiveness of this approach. Compared to the full order optimal control approach, the reduced-order approach is computationally less costly and yet gives competitive controls. From the results presented above, we conclude that reduced-order adaptive control is feasible and provides an efficient method for solving problems of flow control, which is practical enough to be implemented in industrial processes.

IMPLICIT INTEGRATION OF THE TIME-DEPENDENT GINZBURG–LANDAU EQUATIONS OF SUPERCONDUCTIVITY*

D. O. GUNTER[†], H. G. KAPER[†], and G. K. LEAF[†]

Abstract. This article is concerned with the integration of the time-dependent Ginzburg–Landau (TDGL) equations of superconductivity. Four algorithms, ranging from fully explicit to nonlinearly implicit, are presented and evaluated for stability, accuracy, and compute time. The benchmark problem for the evaluation is the equilibration of a vortex configuration in a superconductor that is embedded in a thin insulator and subject to an applied magnetic field.

Key words. time-dependent Ginzburg–Landau equations, superconductivity, vortex solution, implicit time integration

1. Introduction.

At the macroscopic level, the state of a superconductor can be described in terms of a complex-valued order parameter and a real vector potential. These variables, which determine the superconducting and electromagnetic properties of the system at equilibrium, are found as solutions of the Ginzburg–Landau (GL) equations of superconductivity. Because they correspond to critical points of the GL energy functional [1, 2], they can, at least in principle, be determined by minimizing a functional. In practice, one introduces a time-like variable and computes equilibrium states by integrating the time-dependent Ginzburg–Landau (TDGL) equations. The TDGL equations, first formulated by Schmid [3] and subsequently derived from microscopic principles by Gor'kov and Éliashberg [4], are nontrivial generalizations of the (time-independent) GL equations, as the time rate of change must be introduced in such a manner that gauge invariance is preserved at all times. The TDGL equations have been analyzed by several authors; see, for example, the articles [5, 6] and the references cited therein.

We are interested, in particular, in vortex solutions of the GL equations. These are singular solutions, where the phase of the order parameter changes by 2π along any closed contour surrounding a vortex point. Vortices are of critical importance in technological applications of superconductivity.

Computing vortex solutions of the GL equations by integrating the TDGL equations to equilibrium has the advantage that the solutions thus found are stable. At the same time, one obtains information about the transient behavior of the system. Integrating the TDGL equations to equilibrium is, however, a time-consuming process requiring considerable computing resources. In simulations of vortex dynamics in superconductors, which were performed on an IBM SP with tens of processors

in parallel, using a simple one-step Euler integration procedure, we routinely experienced equilibration times on the order of 100 hours [7, 8, 9]. Incremental changes would gradually drive the system to lower energy levels. These very long equilibration times arise, of course, because we are dealing with large physical systems undergoing a phase transition. The energy landscape for such systems is a broad, gently undulating plain with many shallow local minima. It is therefore important to develop efficient integration techniques that remain stable and accurate as the time step increases.

In this article we present four integration techniques for problems on rectangular domains in two dimensions. These two-dimensional domains should be viewed as cross sections of three-dimensional systems that are infinite and homogeneous in the direction of the magnetic field, which is orthogonal to the plane of the cross section. The algorithms are scalable in a multiprocessing environment and generalize to three dimensions. We evaluate the performance of each algorithm on the same benchmark problem, namely, the equilibration of a vortex configuration in a system consisting of a superconducting core embedded in a blanket of insulating material (air) and undergoing a transition from the Meissner state to the vortex state under the influence of an externally applied magnetic field. We determine the maximum allowable time step for stability, the number of time steps needed to reach the equilibrium configuration, and the CPU cost per time step.

The benchmark problem keeps the focus of the present article on the numerical issues. The problem is standard, and the equilibrium vortex configuration is certainly well known in the physics community. The capabilities of the methods extend well beyond the benchmark problem, and the methods have been used successfully to solve more challenging problems; we refer to [9] for an extensive report on several large-scale numerical simulations of vortex dynamics in superconducting media with ordered and disordered defects.

Different algorithms correspond to different dynamics through state space, so the eventual equilibrium vortex configuration may differ from one algorithm to another. Hence, once we have the equilibrium configurations, we need some measure to assess their accuracy. For this purpose we use three parameters: the number of vortices, the mean intervortex distance (bond length), and the mean bond angle taken over nearest-neighbor pairs of bonds. When each of these parameters differs less than a specified tolerance, we say that the corresponding vortex configurations are the same.

Our investigations show that one can increase the time step by almost two orders of magnitude, without losing stability, by going from the fully explicit to a nonlinearly implicit algorithm. The nonlinearly implicit algorithm has a higher cost per time step, but the wall clock time needed to compute the equilibrium solution (the most important measure for practical purposes) is still significantly less. The wall clock time can be reduced further by using a multitimestepping procedure.

In section 2, we present the GL model of superconductivity, first in its formulation as a system of partial differential equations, then as a system of ordinary differential equations after the spatial derivatives have been approximated by finite differences. In section 3, we give four algorithms to integrate the system of ordinary differential equations: an explicit, a semi-implicit, a linearly implicit, and a nonlinearly implicit algorithm. In section 4, we present and evaluate the results of the investigation. In section 5, we further evaluate the nonlinearly implicit algorithm from the point of view of parallelism and multitimestepping. The conclusions are summarized in section 6.

2. GL model. The TDGL equations of superconductivity [2, 3, 4] are two coupled partial differential equations for the complex-valued *order parameter* $\psi = |\psi| \mathrm{e}^{i\phi}$

and the real vector-valued *vector potential* $\mathbf{A}$,

$$\frac{\hbar^2}{2m_sD}\left(\frac{\partial}{\partial t}+\frac{ie_s}{\hbar}\Phi\right)\psi=-\frac{1}{2m_s}\left(\frac{\hbar}{i}\nabla-\frac{e_s}{c}\mathbf{A}\right)^2\psi+a\psi-b|\psi|^2\psi, \tag{2.1}$$

$$\nu\left(\frac{1}{c}\frac{\partial\mathbf{A}}{\partial t}+\nabla\Phi\right)=-\frac{c}{4\pi}\nabla\times\nabla\times\mathbf{A}+\mathbf{J}_s. \tag{2.2}$$

Here, $\mathbf{J}_s$ is the *supercurrent density*, which is a nonlinear function of ψ and $\mathbf{A}$,

$$\mathbf{J}_s=\frac{e_s\hbar}{2im_s}(\psi^*\nabla\psi-\psi\nabla\psi^*)-\frac{e_s^2}{m_sc}|\psi|^2\mathbf{A}=\frac{e_s}{m_s}|\psi|^2\left(\hbar\nabla\phi-\frac{e_s}{c}\mathbf{A}\right). \tag{2.3}$$

The real scalar-valued *electric potential* Φ is a diagnostic variable. The constants in the equations are $\hbar$, Planck's constant divided by 2π; a and b, two positive constants; c, the speed of light; m_s and e_s, the effective mass and charge, respectively, of the superconducting charge carriers (Cooper pairs); ν, the electrical conductivity; and D, the diffusion coefficient. As usual, i is the imaginary unit, and * denotes complex conjugation.

The quantity $|\psi|^2$ represents the local density of Cooper pairs. The local time rate of change $\partial_t\mathbf{A}$ of $\mathbf{A}$ determines the *electric field*, $\mathbf{E}=(1/c)\partial_t\mathbf{A}+\nabla\Phi$, while its spatial variation determines the (induced) *magnetic field*, $\mathbf{B}=\nabla\times\mathbf{A}$.

The TDGL equations describe the gradient flow for the GL energy functional. This functional is zero in the normal state, when $\psi=0$ and the externally applied magnetic field penetrates the superconductor everywhere, $\nabla\times\mathbf{A}=\mathbf{H}$. In the superconducting state, it is given by the expression

$$E=\int\left[\frac{1}{2m_s}\left|\left(\frac{\hbar}{i}\nabla-\frac{e_s}{c}\mathbf{A}\right)\psi\right|^2+\left(-a|\psi|^2+\frac{b}{2}|\psi|^4\right)+|\nabla\times\mathbf{A}-\mathbf{H}|^2\right]\mathrm{d}x. \tag{2.4}$$

The three terms represent the kinetic energy, the condensation energy, and the field energy, respectively. A thermodynamic equilibrium configuration corresponds to a critical point of E.

The energy functional (2.4) assumes that there are no defects in the superconductor. Material defects can be naturally present or artificially induced and can be in the form of point, planar, or columnar defects (quenched disorder). A material defect results in a local reduction of the depth of the well of the condensation energy. A simple way to include material defects in the GL model is by assuming that the parameter a depends on position and has a smaller value wherever a defect is present; see [9].

2.1. Dimensionless form. Let $\psi_\infty^2=a/b$, and let λ, ξ, and H_c denote the London penetration depth, the coherence length, and the thermodynamic critical field, respectively:

$$\lambda=\left(\frac{m_sc^2}{4\pi\psi_\infty^2e_s^2}\right)^{1/2},\quad \xi=\left(\frac{\hbar^2}{2m_sa}\right)^{1/2},\quad H_c=(4\pi a\psi_\infty^2)^{1/2}. \tag{2.5}$$

In this study, we render the TDGL equations dimensionless by measuring lengths in units of ξ, time in units of the relaxation time ξ^2/D, fields in units of $H_c\sqrt{2}$, and energy densities in units of $(1/4\pi)H_c^2$. The nondimensional TDGL equations are

$$\left(\frac{\partial}{\partial t}+i\Phi\right)\psi=\left(\nabla-\frac{i}{\kappa}\mathbf{A}\right)^2\psi+\tau\psi-|\psi|^2\psi, \tag{2.6}$$

$$\sigma\left(\frac{\partial \mathbf{A}}{\partial t}+\kappa\nabla\Phi\right)=-\nabla\times\nabla\times\mathbf{A}+\mathbf{J}_s, \tag{2.7}$$

where

$$\mathbf{J}_s=\frac{1}{2i\kappa}(\psi^*\nabla\psi-\psi\nabla\psi^*)-\frac{1}{\kappa^2}|\psi|^2\mathbf{A}=\frac{1}{\kappa}|\psi|^2\left(\nabla\phi-\frac{1}{\kappa}\mathbf{A}\right). \tag{2.8}$$

Here, $\kappa=\lambda/\xi$ is the GL parameter and σ is a dimensionless resistivity, $\sigma=(4\pi D/c^2)\nu$. The coefficient τ has been inserted to account for defects; $\tau(x)<1$ if x is in a defective region; otherwise $\tau(x)=1$. The nondimensional TDGL equations are associated with the dimensionless energy functional

$$E=\int\left[\left|\left(\nabla-\frac{i}{\kappa}\mathbf{A}\right)\psi\right|^2+\left(-\tau|\psi|^2+\tfrac{1}{2}|\psi|^4\right)+|\nabla\times\mathbf{A}-\mathbf{H}|^2\right]\mathrm{d}x. \tag{2.9}$$

2.2. Gauge choice. The (nondimensional) TDGL equations are invariant under a gauge transformation,

$$\mathcal{G}_\chi:(\psi,\mathbf{A},\Phi)\mapsto(\psi\mathrm{e}^{i\chi},\mathbf{A}+\kappa\nabla\chi,\Phi-\partial_t\chi). \tag{2.10}$$

Here, χ can be any real scalar-valued function of position and time. We maintain the zero-electric potential gauge, $\Phi=0$, at all times, using the *link variable* $\mathbf{U}$,

$$\mathbf{U}=\exp\left(-\frac{i}{\kappa}\int\mathbf{A}\right). \tag{2.11}$$

This definition is componentwise: $U_x=\exp(-i\kappa^{-1}\int^x A_x(x',y,z)\,\mathrm{d}x')$, ... The gauged TDGL equations can now be written in the form

$$\frac{\partial\psi}{\partial t}=\sum_{\mu=x,y,z}U_\mu^*\frac{\partial^2}{\partial\mu^2}(U_\mu\psi)+\tau\psi-|\psi|^2\psi, \tag{2.12}$$

$$\sigma\frac{\partial\mathbf{A}}{\partial t}=-\nabla\times\nabla\times\mathbf{A}+\mathbf{J}_s, \tag{2.13}$$

where

$$J_{s,\mu}=\frac{1}{\kappa}\,\mathrm{Im}\,\left[(U_\mu\psi)^*\frac{\partial}{\partial\mu}(U_\mu\psi)\right],\qquad \mu=x,y,z. \tag{2.14}$$

2.3. Two-dimensional problems. From here on we restrict the discussion to problems on a two-dimensional rectangular domain (coordinates x and y), assuming boundedness in the x direction and periodicity in the y direction. The domain represents a superconducting core surrounded by a blanket of insulating material (air) or a normal metal. The order parameter vanishes outside the superconductor, and no superconducting charge carriers leave the superconductor. The whole system is driven by a time-independent externally applied magnetic field $\mathbf{H}$ that is parallel to the z axis, $\mathbf{H}=(0,0,H)$. The vector potential and the supercurrent have two nonzero components, $\mathbf{A}=(A_x,A_y,0)$ and $\mathbf{J}_s=(J_x,J_y,0)$, while the magnetic field has only one nonzero component, $\mathbf{B}=(0,0,B)$, where $B=\partial_xA_y-\partial_yA_x$.

2.4. Spatial discretization. The physical configuration to be modeled (superconductor embedded in blanket material) is periodic in y and bounded in x. In the x direction, we distinguish three subdomains: an interior subdomain occupied by the superconducting material and two subdomains, one on either side, occupied by the blanket material. We take the two blanket layers to be equally thick but do not assume that the problem is symmetric around the midplane. (Possible sources of asymmetry are material defects in the system, surface currents, and different field strengths on the two outer surfaces.)

We impose a regular grid with mesh widths h_x and h_y,

$$\Omega_{i,j} = (x_i, x_{i+1}) \times (y_j, y_{j+1}), \quad x_i = x_0 + ih_x, \quad y_j = y_0 + jh_y, \tag{2.15}$$

assuming the following correspondences:

Left outer surface:	$x = x_0 + \frac{1}{2}h_x,$	$i = 0,$
Left interface:	$x = x_{n_{sx}-1} + \frac{1}{2}h_x,$	$i = n_{sx} - 1,$
Right interface:	$x = x_{n_{ex}} + \frac{1}{2}h_x,$	$i = n_{ex},$
Right outer surface:	$x = x_{n_x} + \frac{1}{2}h_x,$	$i = n_x.$

One period in the y direction is covered by the points $j = 1, \ldots, n_y$. We use the symbols Sc and Bl to denote the index sets for the superconducting and blanket region, respectively:

$$\mathrm{Sc} = \{(i,j) : (i,j) \in [n_{sx}, n_{ex}] \times [1, n_y]\}, \tag{2.16}$$

$$\mathrm{Bl} = \{(i,j) : (i,j) \in [1, n_{sx} - 1] \cup [n_{ex} + 1, n_x] \times [1, n_y]\}. \tag{2.17}$$

The order parameter ψ is evaluated at the grid vertices,

$$\psi_{i,j} = \psi(x_i, y_j), \qquad (i,j) \in \mathrm{Sc}, \tag{2.18}$$

the components A_x and A_y of the vector potential at the midpoints of the respective edges,

$$A_{x;i,j} = A_x(x_i + \tfrac{1}{2}h_x, y_j), \quad A_{y;i,j} = A_y(x_i, y_j + \tfrac{1}{2}h_y), \quad (i,j) \in \mathrm{Sc} \cup \mathrm{Bl}, \tag{2.19}$$

and the induced magnetic field B at the center of a grid cell,

$$\begin{aligned} B_{i,j} &= B(x_i + \tfrac{1}{2}h_x, y_j + \tfrac{1}{2}h_y) \\ &= \frac{A_{y;i+1,j} - A_{y;i,j}}{h_x} - \frac{A_{x;i,j+1} - A_{x;i,j}}{h_y}, \ (i,j) \in \mathrm{Sc} \cup \mathrm{Bl}; \end{aligned} \tag{2.20}$$

see Figure 2.1. The values of the link variables and the supercurrent are computed from the expressions

$$U_{x;i,j} = \mathrm{e}^{-i\kappa^{-1}h_x A_{x;i,j}}, \quad U_{y;i,j} = \mathrm{e}^{-i\kappa^{-1}h_y A_{y;i,j}}, \tag{2.21}$$

$$J_{x;i,j} = \frac{1}{\kappa h_x}\mathrm{Im}\left[\psi^*_{i,j} U_{x;i,j} \psi_{i+1,j}\right], \quad J_{y;i,j} = \frac{1}{\kappa h_y}\mathrm{Im}\left[\psi^*_{i,j} U_{y;i,j} \psi_{i,j+1}\right]. \tag{2.22}$$

The discretized TDGL equations are

$$\frac{\mathrm{d}\psi_{i,j}}{\mathrm{d}t} = \left(L_{xx}(U_{x;\cdot,j})\psi_{\cdot,j}\right)_i + \left(L_{yy}(U_{y;i,\cdot})\psi_{i,\cdot}\right)_j + N\left(\psi_{i,j}\right), \ (i,j) \in \mathrm{Sc}, \tag{2.23}$$

$$\sigma\,\frac{\mathrm{d}A_{x;i,j}}{\mathrm{d}t} = \left(D_{yy}A_{x;i,\cdot}\right)_j - \left(D_{yx}A_{y;\cdot,\cdot}\right)_{i,j} + J_{x;i,j}, \quad (i,j) \in \mathrm{Sc} \cup \mathrm{Bl}, \tag{2.24}$$

$$\sigma\,\frac{\mathrm{d}A_{y;i,j}}{\mathrm{d}t} = \left(D_{xx}A_{y;\cdot,j}\right)_i - \left(D_{xy}A_{x;\cdot,\cdot}\right)_{i,j} + J_{y;i,j}, \quad (i,j) \in \mathrm{Sc} \cup \mathrm{Bl}, \tag{2.25}$$

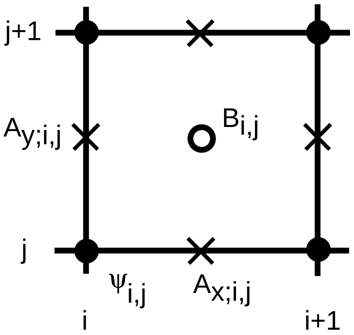

FIG. 2.1. *Computational cell with evaluation points for ψ, A_x, A_y, and B.*

where

$$(L_{xx}(U_{x;\cdot,j})\psi_{\cdot,j})_i = h_x^{-2}\left[U_{x;i,j}\psi_{i+1,j} - 2\psi_{i,j} + U^*_{x;i-1,j}\psi_{i-1,j}\right], \tag{2.26}$$

$$(L_{yy}(U_{y;i,\cdot})\psi_{i,\cdot})_j = h_y^{-2}\left[U_{y;i,j}\psi_{i,j+1} - 2\psi_{i,j} + U^*_{y;i,j-1}\psi_{i,j-1}\right], \tag{2.27}$$

$$N(\psi_{i,j}) = \tau_{i,j}\psi_{i,j} - |\psi_{i,j}|^2\psi_{i,j}, \tag{2.28}$$

$$(D_{yy}A_{x;i,\cdot})_j = h_y^{-2}\left[A_{x;i,j+1} - 2A_{x;i,j} + A_{x;i,j-1}\right], \tag{2.29}$$

$$(D_{xx}A_{y;\cdot,j})_i = h_x^{-2}\left[A_{y;i+1,j} - 2A_{y;i,j} + A_{y;i-1,j}\right], \tag{2.30}$$

$$(D_{yx}A_{y;\cdot,\cdot})_{i,j} = h_x^{-1}h_y^{-1}\left[(A_{y;i+1,j} - A_{y;i,j}) - (A_{y;i+1,j-1} - A_{y;i,j-1})\right], \tag{2.31}$$

$$(D_{xy}A_{x;\cdot,\cdot})_{i,j} = h_x^{-1}h_y^{-1}\left[(A_{x;i,j+1} - A_{x;i,j}) - (A_{x;i-1,j+1} - A_{x;i-1,j})\right]. \tag{2.32}$$

The interface conditions are

$$\psi_{n_{sx}-1,j} = U_{x;n_{sx}-1,j}\psi_{n_{sx},j}, \quad \psi_{n_{ex}+1,j} = U^*_{x;n_{ex},j}\psi_{n_{ex},j}, \quad j = 1,\dots,n_y. \tag{2.33}$$

At the outer boundary, B is given:

$$B_{0,j} = H_{L_j}, \quad B_{n_x,j} = H_{R_j}, \quad j = 1,\dots,n_y. \tag{2.34}$$

The resulting approximation is second-order accurate [10].

3. Time integration. We now address the integration of (2.23)–(2.25). The first equation, which controls the evolution of ψ, involves the second-order linear finite-difference operators L_{xx} and L_{yy}, whose coefficients depend on A_x and A_y, and the local nonlinear operator N, which involves neither A_x nor A_y. Each of the other two equations, which control the evolution of A_x and A_y respectively, involves likewise a second-order linear finite-difference operator, but with constant coefficients, and the nonlinear supercurrent operator, which involves ψ, A_x, and A_y. The following algorithms are distinguished by whether the various operators are treated explicitly or implicitly.

3.1. Fully explicit integration. Algorithm I uses a fully explicit forward Euler time-marching procedure for ψ, A_x, and A_y. Starting from an initial triple (ψ^0, A_x^0, A_y^0), we solve for $n = 0, 1, \dots,$

$$\frac{\psi^{n+1}_{i,j} - \psi^n_{i,j}}{\Delta t} = \left(L_{xx}(U^n_{x;\cdot,j})\psi^n_{\cdot,j}\right)_i + \left(L_{yy}(U^n_{y;i,\cdot})\psi^n_{i,\cdot}\right)_j + N\left(\psi^n_{i,j}\right), \ (i,j) \in \mathrm{Sc}, \tag{3.1}$$

$$(3.2)\ \sigma\,\frac{A^{n+1}_{x;i,j}-A^{n}_{x;i,j}}{\Delta t}=\left(D_{yy}A^{n}_{x;i,\cdot}\right)_j-\left(D_{yx}A^{n}_{y;\cdot,\cdot}\right)_{i,j}+J^{n}_{x;i,j},\quad (i,j)\in \mathrm{Sc}\cup\mathrm{Bl},$$

$$(3.3)\ \sigma\,\frac{A^{n+1}_{y;i,j}-A^{n}_{y;i,j}}{\Delta t}=\left(D_{xx}A^{n}_{y;\cdot,j}\right)_i-\left(D_{xy}A^{n}_{x;\cdot,\cdot}\right)_{i,j}+J^{n}_{y;i,j},\quad (i,j)\in \mathrm{Sc}\cup\mathrm{Bl},$$

where J^n is defined in terms of ψ^n, A^n_x, and A^n_y in the obvious way. The initial triple is usually chosen so the superconductor is in the Meissner state, with a seed present to trigger the transition to the vortex state.

Algorithm I has been described in [10]. It has been implemented in a distributed-memory multiprocessor environment (IBM SP2); the transformations necessary to achieve the parallelism have been described in [11]. The code uses the message passing interface (MPI) standard [12] as implemented in the MPICH software library [13] for domain decomposition, interprocessor communication, and file I/O. The code has been used extensively to study vortex dynamics in superconducting media [7, 8, 9]. The underlying algorithm provides highly accurate solutions but requires a significant number of time steps for equilibration. For stability reasons, the time step Δt cannot exceed 0.0025.

3.2. Semi-implicit integration. Algorithm II involves an implicit treatment of the second-order linear finite-difference operators D_{yy} and D_{xx} in the equations for A_x and A_y, respectively:

$$(3.4)\qquad \frac{\psi^{n+1}_{i,j}-\psi^{n}_{i,j}}{\Delta t}=\left(L_{xx}(U^{n}_{x;\cdot,j})\psi^{n}_{\cdot,j}\right)_i+\left(L_{yy}(U^{n}_{y;i,\cdot})\psi^{n}_{i,\cdot}\right)_j+N\left(\psi^{n}_{i,j}\right),\ (i,j)\in\mathrm{Sc},$$

$$(3.5)\ \sigma\,\frac{A^{n+1}_{x;i,j}-A^{n}_{x;i,j}}{\Delta t}=\left(D_{yy}A^{n+1}_{x;i,\cdot}\right)_j-\left(D_{yx}A^{n}_{y;\cdot,\cdot}\right)_{i,j}+J^{n}_{x;i,j},\quad (i,j)\in \mathrm{Sc}\cup\mathrm{Bl},$$

$$(3.6)\ \sigma\,\frac{A^{n+1}_{y;i,j}-A^{n}_{y;i,j}}{\Delta t}=\left(D_{xx}A^{n+1}_{y;\cdot,j}\right)_i-\left(D_{xy}A^{n}_{x;\cdot,\cdot}\right)_{i,j}+J^{n}_{y;i,j},\quad (i,j)\in \mathrm{Sc}\cup\mathrm{Bl}.$$

Equations (3.5) and (3.6) lead to two linear systems of equations,

$$(3.7)\qquad \left(I-\frac{\Delta t}{\sigma}D_{yy}\right)A^{n+1}_{x;i}=F_i(\psi^n,A^n_x,A^n_y),\qquad i=1,\dots,n_x-1,$$

$$(3.8)\qquad \left(I-\frac{\Delta t}{\sigma}D_{xx}\right)A^{n+1}_{y;j}=G_j(\psi^n,A^n_x,A^n_y),\qquad j=1,\dots,n_y,$$

for the vectors of unknowns $A_{x;i}=\{A_{x;i,j}:j=1,\dots,n_y\}$ and $A_{y;j}=\{A_{y;i,j}:i=1,\dots,n_x-1\}$. The matrix D_{yy} has dimension $n_y\times n_y$ and is periodic tridiagonal with elements $-h_y^{-2},2h_y^{-2},-h_y^{-2}$; the matrix D_{xx} has dimension $(n_x-1)\times(n_x-1)$ and is tridiagonal with elements $-h_x^{-2},2h_x^{-2},-h_x^{-2}$ (except along the edges because of the boundary conditions). Both matrices are independent of i and j. Furthermore, if the boundary conditions are time independent, they are constant throughout the time-stepping process. Hence, the coefficient matrices in (3.7) and (3.8) need to be factored only once; in fact, the factorization can be done in the preprocessing stage, and the factors can be stored.

In a parallel processing environment, the coefficient matrices extend over several processors, so (3.7) and (3.8) are broken up in blocks corresponding to the manner in which the computational mesh is distributed within the processor set. We first solve the equations within each processor (inner iterations) and then couple the solutions across processor boundaries (outer iterations). Hence, we deal with interprocessor coupling in an iterative fashion. Two to three inner iterations usually suffice to reach a desired tolerance for convergence. After each inner iteration, each processor shares boundary data with its neighbors through MPI calls.

3.3. Linearly implicit integration. Algorithm III combines the semi-implicit treatment of A_x and A_y with an implicit treatment of the order parameter:

$$\frac{\psi_{i,j}^{n+1} - \psi_{i,j}^{n}}{\Delta t} = \left(L_{xx}(U_{x;\cdot,j}^{n})\psi_{\cdot,j}^{n+1}\right)_i + \left(L_{yy}(U_{y;i,\cdot}^{n})\psi_{i,\cdot}^{n+1}\right)_j + N\left(\psi_{i,j}^{n}\right), \tag{3.9}$$

$$\sigma\,\frac{A_{x;i,j}^{n+1} - A_{x;i,j}^{n}}{\Delta t} = \left(D_{yy}A_{x;i,\cdot}^{n+1}\right)_j - \left(D_{yx}A_{y;\cdot,\cdot}^{n}\right)_{i,j} + J_{x;i,j}^{n}, \tag{3.10}$$

$$\sigma\,\frac{A_{y;i,j}^{n+1} - A_{y;i,j}^{n}}{\Delta t} = \left(D_{xx}A_{y;\cdot,j}^{n+1}\right)_i - \left(D_{xy}A_{x;\cdot,\cdot}^{n}\right)_{i,j} + J_{y;i,j}^{n}. \tag{3.11}$$

As before, the first equation holds for all $(i,j) \in \mathrm{Sc}$, while the second and third equations hold for all $(i,j) \in \mathrm{Sc} \cup \mathrm{Bl}$. The latter are solved as in the semi-implicit algorithm of the preceding section, while the former is solved by a method similar to the method of Douglas and Gunn [14] for the Laplacian.

We begin by transforming (3.9) into an equation for the correction matrix $\phi^{n+1} = \psi^{n+1} - \psi^{n}$. The equation has the general form

$$(I - \Delta t(L_{xx} + L_{yy}))\,\phi^{n+1} = F(\psi^n, A_x^n, A_y^n). \tag{3.12}$$

If Δt is sufficiently small, we may replace the operator in the left member by an approximate factorization,

$$(I - \Delta t(L_{xx} + L_{yy})) \approx (I - \Delta t L_{xx})\,(I - \Delta t L_{yy})\,, \tag{3.13}$$

and consider, instead of (3.12),

$$(I - \Delta t L_{xx})\,(I - \Delta t L_{yy})\,\phi^{n+1} = F(\psi^n, A_x^n, A_y^n). \tag{3.14}$$

This equation can be solved in two steps,

$$(I - \Delta t L_{xx})\,\varphi = F, \tag{3.15}$$

$$(I - \Delta t L_{yy})\,\phi^{n+1} = \varphi. \tag{3.16}$$

The conditions (2.33), which must be satisfied at the interface between the superconductor and the blanket material, require some care. If we impose the conditions at every time step, then

$$\begin{aligned}\phi_{n_{sx}-1,j}^{n+1} &= U_{x;n_{sx}-1,j}^{n+1}\phi_{n_{sx},j}^{n+1} + \left[U_{x;n_{sx}-1,j}^{n+1} - U_{x;n_{sx}-1,j}^{n}\right]\psi_{n_{sx},j}^{n},\\ \phi_{n_{ex}+1,j}^{n+1} &= \left(U_{x;n_{ex},j}^{n+1}\right)^{*}\phi_{n_{ex},j}^{n+1} + \left[\left(U_{x;n_{ex},j}^{n+1}\right)^{*} - \left(U_{x;n_{sx}-1,j}^{n}\right)^{*}\right]\psi_{n_{sx},j}^{n}\end{aligned}$$

for $j = 1, \dots, n_y$. These conditions couple the correction ϕ to the update of A_x. To eliminate this coupling, we solve (3.12) subject to the reduced interface conditions

$$\phi_{n_{sx}-1,j}^{n+1} = U_{x;n_{sx}-1,j}^{n+1}\phi_{n_{sx},j}^{n+1}, \qquad j = 1, \dots, n_y, \tag{3.17}$$

$$\phi_{n_{ex}+1,j}^{n+1} = \left(U_{x;n_{ex},j}^{n+1}\right)^{*}\phi_{n_{ex},j}^{n+1}, \qquad j = 1, \dots, n_y. \tag{3.18}$$

When (3.12) is replaced by (3.14), these conditions are inherited by the system (3.15).

3.4. Nonlinearly implicit integration. Algorithm IV uses a nonlinearly implicit integration procedure for the order parameter:

$$\frac{\psi_{i,j}^{n+1}-\psi_{i,j}^{n}}{\Delta t} = \left(L_{xx}(U_{x;\cdot,j}^{n})\psi_{\cdot,j}^{n+1}\right)_i + \left(L_{yy}(U_{y;i,\cdot}^{n})\psi_{i,\cdot}^{n+1}\right)_j + N\left(\psi_{i,j}^{n+1}\right), \tag{3.19}$$

$$\sigma\,\frac{A_{x;i,j}^{n+1}-A_{x;i,j}^{n}}{\Delta t} = \left(D_{yy}A_{x;i,\cdot}^{n+1}\right)_j - \left(D_{yx}A_{y;\cdot,\cdot}^{n}\right)_{i,j} + J_{x;i,j}^{n}, \tag{3.20}$$

$$\sigma\,\frac{A_{y;i,j}^{n+1}-A_{y;i,j}^{n}}{\Delta t} = \left(D_{xx}A_{y;\cdot,j}^{n+1}\right)_i - \left(D_{xy}A_{x;\cdot,\cdot}^{n}\right)_{i,j} + J_{y;i,j}^{n}. \tag{3.21}$$

The new element here is the term $N\left(\psi_{i,j}^{n+1}\right)$ in the first equation.

The second and third equations, with $(i,j)\in \mathrm{Sc}\cup\mathrm{Bl}$, are solved again as in the semi-implicit algorithm; the first, with $(i,j)\in\mathrm{Sc}$, is solved by a slight modification of the method used in the linearly implicit algorithm of the preceding section. The modification is brought about by the approximation

$$N\left(\psi^{n+1}\right) = \tau\psi^{n+1} - |\psi^{n+1}|^2\psi^{n+1} \approx \frac{1}{\Delta t}\left(S\left(\psi^{n}\right)-\psi^{n}\right), \tag{3.22}$$

where S is a nonlinear map:

$$S(\psi) = \frac{\tau^{1/2}\psi}{\left[|\psi|^2 + (\tau-|\psi|^2)\exp(-2\tau\Delta t)\right]^{1/2}}. \tag{3.23}$$

(This approximation is explained in the remark below.) Equation (3.19) is again of the form (3.12) but with a different right-hand side:

$$(I-\Delta t(L_{xx}+L_{yy}))\phi^{n+1} = G(\psi^n, A_x^n, A_y^n). \tag{3.24}$$

The difference is that, where F in (3.12) contains a term $(\Delta t)N\left(\psi^n\right)$, G in (3.24) contains the more complicated term $S\left(\psi^n\right)-\psi^n$.

Remark. The approximation (3.22) is suggested by semigroup theory. Symbolically,

$$N(\psi) = \lim_{\Delta t\to 0}\frac{S(\Delta t)\psi-\psi}{\Delta t}. \tag{3.25}$$

To find an expression for the "semigroup" S, we start from the continuous TDGL equations (2.6)–(2.8) (zero-electric potential gauge, $\Phi=0$), using the polar representation $\psi = |\psi|\mathrm{e}^{i\phi}$:

$$\partial_t|\psi| = \Delta|\psi| - |\psi||\nabla\phi-\kappa^{-1}\mathbf{A}|^2 + \tau|\psi| - |\psi|^3, \tag{3.26}$$

$$|\psi|\partial_t\phi = 2(\nabla|\psi|)\cdot(\nabla\phi-\kappa^{-1}\mathbf{A}) + |\psi|\nabla\cdot(\nabla\phi-\kappa^{-1}\mathbf{A}), \tag{3.27}$$

$$\sigma\partial_t\mathbf{A} = -\nabla\times\nabla\times\mathbf{A} + \kappa^{-1}|\psi|^2(\nabla\phi-\kappa^{-1}\mathbf{A}). \tag{3.28}$$

At this point, we are interested in the effect of the nonlinear term $|\psi|^3$ on the dynamics. To highlight this effect, we concentrate on the time evolution of the scalar $u=|\psi|$ and the vector $v=\nabla\phi-\kappa^{-1}\mathbf{A}$. (In physical terms, u^2 is the density of superconducting charge carriers, while u^2v is κ times the supercurrent density.) Ignoring their spatial variations, we have a dynamical system,

$$u' = -u|v|^2 + \tau u - u^3, \tag{3.29}$$

$$v' = -\varepsilon u^2 v, \tag{3.30}$$

where $'$ denotes differentiation with respect to t, and $\varepsilon = (\kappa^2\sigma)^{-1}$. This system yields a pair of ordinary differential equations for the scalars $x = u^2$ and $y = |v|^2$:

$$x' = 2x(\tau - x - y), \tag{3.31}$$

$$y' = -2\varepsilon xy. \tag{3.32}$$

If κ is large, ε is small, and the dynamics are readily analyzed. To leading order, y is constant; $y = 0$ is the only meaningful choice. (Recall that $xy^{1/2}$ is κ times the magnitude of the supercurrent density.) Then the dynamics of x are given by

$$x' = 2x(\tau - x). \tag{3.33}$$

We integrate this equation from $t = t_n$ to t:

$$x(t) = \frac{\tau x(t_n)}{x(t_n) + (\tau - x(t_n)) \exp(-2\tau(t - t_n))}. \tag{3.34}$$

In particular,

$$x(t_{n+1}) = \frac{\tau x(t_n)}{x(t_n) + (\tau - x(t_n)) \exp(-2\tau\Delta t)}, \tag{3.35}$$

where $\Delta t = t_{n+1} - t_n$. Since $x(t_n) = |\psi^n|^2$ and $x(t_{n+1}) = |\psi^{n+1}|^2$, it follows that

$$|\psi^{n+1}| = \frac{\tau^{1/2}|\psi^n|}{[|\psi^n|^2 + (\tau - |\psi^n|^2) \exp(-2\tau\Delta t)]^{1/2}}. \tag{3.36}$$

The phase ϕ of ψ is constant in time. If we multiply both sides by $\mathrm{e}^{i\phi}$, we obtain the expression (3.23) for the "semigroup" S.

4. Evaluation.

We now present the results of several experiments, where the algorithms described in the preceding section were applied to a benchmark problem.

4.1. Benchmark problem.

The benchmark problem adopted for this investigation is the equilibration of a vortex configuration in a homogeneous superconductor without defects ($\kappa = 16$, $\sigma = 1$, $\tau = 1$) embedded in a thin insulator (air), where the entire system is periodic in the direction of the free surfaces (y).

The superconductor measures 128ξ in the transverse (x) direction. The thickness of the insulating layer on either side is taken to be 2ξ, so the width of the entire system is 132ξ. The period in the y direction is taken to be 192ξ, so the entire system measures $132\xi \times 192\xi$.

The computational grid is uniform, with a mesh width $h_x = h_y = \frac{1}{2}\xi$. The periodic boundary conditions in the y direction are handled through ghost points, so the computational grid has 264×386 vertices. The index sets for the superconductor and blanket (see (2.16) and (2.17)) are

$$\mathrm{Sc} = \{(i, j) : i = 5, \ldots, 260,\ j = 1, \ldots, 386\}, \tag{4.1}$$

$$\mathrm{Bl} = \{(i, j) : i = 1, \ldots, 4, 261, \ldots, 264,\ \ j = 1, \ldots, 386\}. \tag{4.2}$$

The applied field is uniform:

$$H_L = H_R = H = 0.5. \tag{4.3}$$

(Units of H are $H_c\sqrt{2}$, so $H \approx 0.707\ldots H_c$.) As there is no transport current in the system, the solution of the TDGL equations tends to an equilibrium state.

4.2. Benchmark solution. First, preliminary runs were made to determine, for each algorithm, the optimal number of processors in a multiprocessing environment. Figure 4.1 shows the wall clock time for 50 time steps against the number of processors on the IBM SP2. Each algorithm shows a saturation around 16 processors, beyond which any improvement becomes marginal. All problems were subsequently run on 16 processors.

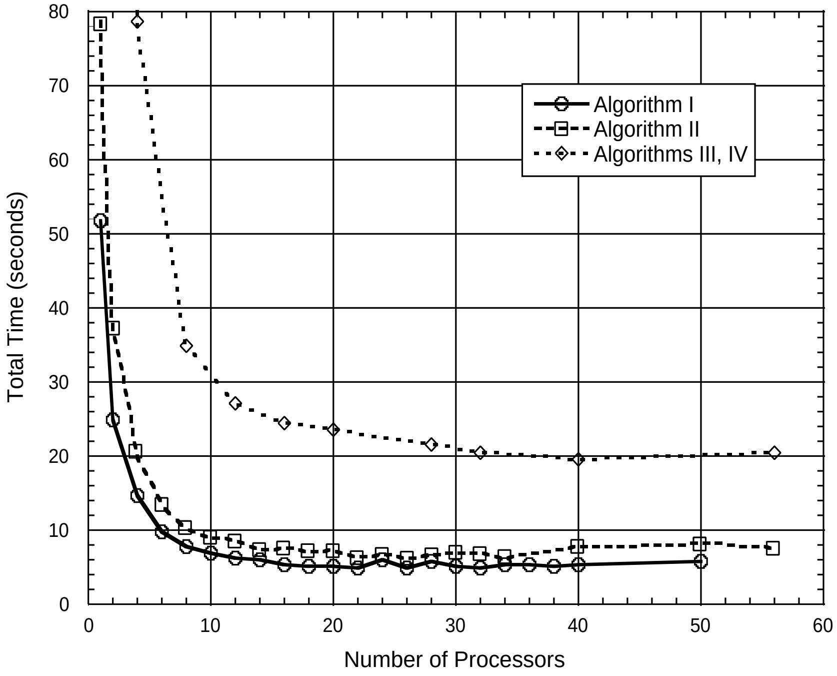

FIG. 4.1. *Elapsed time for* 50 *time steps as a function of the number of processors.*

Next, we used the fully explicit Algorithm I to establish a benchmark equilibrium configuration. We integrated (3.1)–(3.3) with a time step $\Delta t = 0.0025$ (units of ξ^2/D), the maximal value for which the algorithm remained stable, and followed the evolution of the vortex configuration by monitoring the number of vortices and their positions. Equilibrium was reached after 10,000,000 time steps, when the number of vortices remained constant and the vortex positions varied less than 1.0×10^{-6} (units of ξ). The equilibrium vortex configuration had 116 vortices arranged in a hexagonal pattern; see Figure 4.2. The wall clock time for the entire computation was approximately 3,000 minutes. The elapsed time per time step (0.018 seconds) is a measure for the computational cost of Algorithm I.

4.3. Evaluation of Algorithms II–IV. With the benchmark solution in place, we evaluated each of the remaining Algorithms (II–IV) for stability, accuracy, and computational cost.

We found the stability limit in the obvious way, gradually increasing the time step and integrating to equilibrium until arithmetic divergences caused the algorithm to fail. Equilibrium was defined by the same criteria as for the benchmark solution: no change in the number of vortices and a variation in the vortex positions of less than 1.0×10^{-6}.

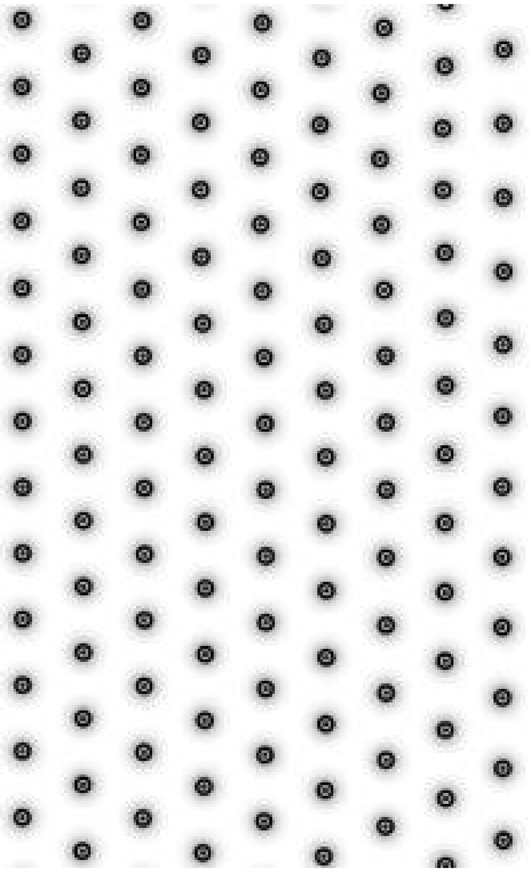

FIG. 4.2. *Equilibrium vortex configuration for the benchmark problem.*

Because each algorithm defines its own path through phase space, one can expect to find neither identical equilibrium configurations nor equilibrium configurations that are exactly the same as the benchmark. The equilibrium vortex configurations for the four algorithms were indeed different, albeit slightly. To measure the differences quantitatively, we computed the following three parameters: (i) the number of vortices in the superconducting region, (ii) the mean bond length joining neighboring pairs of vortices, and (iii) the mean bond angle subtended by neighboring bonds throughout the vortex lattice. In all cases, the number of vortices was the same (116); the mean bond length varied less than $1.0 \times 10^{-3}\xi$, and the mean bond angle varied by less than 1.0×10^{-3} radians. Within these tolerances, the equilibrium vortex configurations were the same.

The results are given in Table 4.1; Δt is the time step at the stability limit (units of ξ^2/D), N the number of time steps needed to reach equilibrium, and C the cost of the algorithm (seconds per time step). From these data we obtain the wall clock time needed to compute the equilibrium configuration, $T = NC/60$ (minutes).

Note that the existence of a stability limit for Algorithm IV is a consequence of the implementation in a multiprocessing environment. Since we restrict interprocessor communication to the end of each time step, the implicit character of the algorithm is lost. On a single processor, Algorithm IV is implicit, and the stability limit is infinite.

TABLE 4.1
Performance data for Algorithms I–IV.

Algorithm	Δt	N	C	T
I	0.0025	10,000,000	0.018	3,000
II	0.0500	500,000	0.103	858
III	0.1000	250,000	0.232	967
IV	0.1900	100,000	0.233	388

5. Further evaluation of Algorithm IV.

We evaluated the nonlinearly implicit Algorithm IV in more detail by considering its speedup in a multiprocessing environment and its performance under a multitimestepping procedure.

5.1. Parallelism.

First, we investigated the speedup of Algorithm IV in a multiprocessing environment, using the benchmark problem and two other problems, obtained from the benchmark problem by twice doubling the size of the system in each direction. The mesh width was kept constant at $\frac{1}{2}\xi$, so the resulting computational grid had 264 × 386 vertices for the benchmark problem, 528 × 772 vertices for the intermediate problem, and 1056 × 1544 vertices for the largest problem. Speedup was defined as the ratio of the wall clock time (exclusive of I/O) to reach equilibrium on p processors divided by the time to reach equilibrium on a single processor for the benchmark and intermediate problem, or twice the time to reach equilibrium on two processors for the largest problem. (The largest problem did not fit on a single processor.) The results are given in Figure 5.1. The curve for the benchmark problem was obtained as an average over many runs; the data for the intermediate and largest problem were obtained from single runs, so they are less smooth. The speedup is clearly linear when the number of processors is small; it becomes sublinear at about 12 processors for the smallest problem, 14 processors for the intermediate problem, and 18 processors for the largest problem.

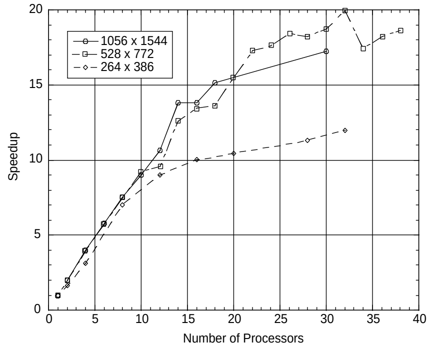

FIG. 5.1. *Performance of Algorithm* IV *in a multiprocessing environment.*

5.2. Multitimestepping.

The final set of experiments shows that the performance of Algorithm IV is enhanced by a multitimestepping procedure, where $\mathbf{A}$ is updated less frequently than ψ:

$$\frac{\psi_{i,j}^{n+1}-\psi_{i,j}^{n}}{\Delta t} = \left(L_{xx}(U_{x;\cdot,j}^{n})\psi_{\cdot,j}^{n+1}\right)_i + \left(L_{yy}(U_{y;i,\cdot}^{n})\psi_{i,\cdot}^{n+1}\right)_j + N\left(\psi_{i,j}^{n+1}\right), \tag{5.1}$$

$$\sigma\,\frac{A_{x;i,j}^{n+m}-A_{x;i,j}^{n}}{m\Delta t} = \left(D_{yy}A_{x;i,\cdot}^{n+m}\right)_j - \left(D_{yx}A_{y;\cdot,\cdot}^{n}\right)_{i,j} + J_{x;i,j}^{n}, \tag{5.2}$$

Table 5.1
Effect of update frequency on time and cost of Algorithm IV.

m	N	C	T
1	100,000	0.2330	388
10	200,000	0.0707	236
15	250,000	0.0646	270

$$\sigma \frac{A^{n+m}_{y;i,j} - A^{n}_{y;i,j}}{m\Delta t} = \left(D_{xx}A^{n+m}_{y;\cdot,j}\right)_i - \left(D_{xy}A^{n}_{x;\cdot,\cdot}\right)_{i,j} + J^{n}_{y;i,j}. \tag{5.3}$$

When $m = 1$, both ψ and $\mathbf{A}$ are updated at every time step, but when m is greater than 1, $\mathbf{A}$ is updated only every mth time step. In the limit as $m \to \infty$, this procedure yields the frozen-field approximation, which is a good approximation of the GL model near the upper critical field when the charge of the superconducting charge carriers is small [15].

We applied this modification of Algorithm IV with $m = 10, 15$ to the benchmark problem of section 4. The results are given in Table 5.1. All computations were done with $\Delta t = 0.19$ (units of ξ^2/D). The data for the computation with $m = 1$ are taken from Table 4.1. We observe that the cost of the algorithm (C, seconds per time step) decreases with increasing m, while the number of time steps to equilibrium (N) increases. If $m = 10$, the overall wall clock time ($T = NC/60$, minutes) is approximately one-third less than the wall clock time for $m = 1$. For larger values of m, the increase in the number of steps needed to reach equilibrium offsets any gain from the decrease in cost. These data suggest an optimal strategy, where $\mathbf{A}$ is updated every 10 time steps.

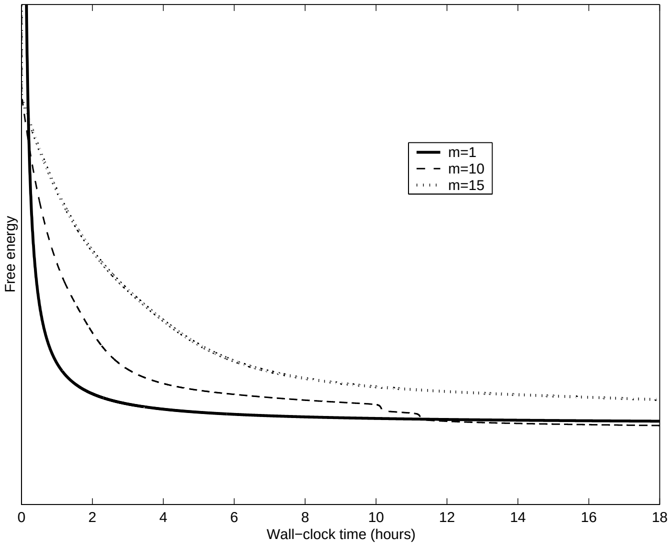

Fig. 5.2. *Effect of the updating frequency on the evolution of the energy functional.*

Figure 5.2 shows the effect of the updating frequency on the evolution of the free-energy functional (2.9). Note the dramatic increase of the wall-clock time for $m = 15$.Eventually, the curve for $m = 15$ merges with the other curves, but this happens well beyond the range of the figure.

6. Conclusions.

In summary, we present the following conclusions:

(i) One can increase the time step Δt nearly 80-fold, without losing stability, by going from the fully explicit Algorithm I to the nonlinearly implicit Algorithm IV.

(ii) As one goes to the nonlinearly implicit Algorithm IV, the complexity of the matrix calculations and, hence, the cost C of a single time step increase.

(iii) The increase in the cost C per time step is more than offset by the increase in the size of the time step Δt. In fact, the wall clock time needed to compute the same equilibrium state with the nonlinearly implicit Algorithm IV is one-sixth of the wall clock time for the fully explicit Algorithm I.

(iv) The (physical) time to reach equilibrium—that is, $N\Delta t$, the number of time steps needed to reach equilibrium times the step size—is (approximately) the same for all algorithms, namely, 25,000 (units of ξ^2/D).

(v) The nonlinearly implicit Algorithm IV displays linear speedup in a multiprocessing environment. The speedup curves show sublinear behavior when the number of processors is large.

(vi) The performance of the nonlinearly implicit Algorithm IV can be improved further by a multitimestepping procedure, where the vector potential $\mathbf{A}$ is updated less frequently than the order parameter ψ.

A DOMAIN DECOMPOSITION METHOD FOR ADVECTION-DIFFUSION PROCESSES WITH APPLICATION TO BLOOD SOLUTES[*]

ALFIO QUARTERONI[†], ALESSANDRO VENEZIANI[‡], AND PAOLO ZUNINO[§]

Abstract. In the present paper we consider a heterogeneous model for the dynamics of a blood solute both in the vascular lumen and inside the arterial wall. In the lumen, we consider an advection-diffusion equation, where the convective field is provided by the velocity of blood, which is in turn obtained by solving the Navier–Stokes equations. Inside the arterial wall we consider a pure diffusive dynamics. Since the endothelial layer at the interface between the lumen and the wall acts as a permeable membrane, whose permeability depends on the shear rate exerted by the blood, the solute concentration is discontinuous across this membrane. A possible approach for the numerical study of this kind of problem is inspired by domain decomposition techniques. In particular, we introduce a splitting in the computation and alternate the solution of the advection-diffusion equation in the lumen with that of the diffusion equation in the wall. We set up an efficient iterative method, based on a suitable reformulation of the problem in terms of a Steklov–Poincaré interface equation. This formulation is a nonstandard one because of the concentration discontinuity at the lumen-wall interface and plays a key role in the proof of convergence of our method. In particular, we prove that the convergence rate performed by the proposed method is independent of the finite element space discretization and provides a criterion for the selection of an acceleration parameter.

Several numerical results, referred to as biomedical applications, support our theoretical conclusions and illustrate the efficiency of this algorithm.

1. Introduction.

We consider the numerical treatment of a model for the dynamics of blood solutes which was introduced in [14]. This model is based on an advection-diffusion equation describing the solute dynamics in the vascular lumen, the convective field being provided by the blood velocity. This equation is coupled with a pure diffusive model accounting for the solute dynamics inside the arterial wall, where convection is negligible. The two subdomains (namely the lumen and the wall) are physically separated by the endothelial layer, which acts as a selective permeable membrane. The interface equation matching the two subproblems in fact follows from the specific nature of this membrane. It is worthwhile noticing that, due to the presence of this membrane, the two concentrations fail to match continuously at the interface.

The well posedness of this model, coupled with the Navier–Stokes equations for the description of the blood velocity and pressure fields, has been analyzed in [14]. The interest for this problem stems from the consideration that, in some cases, the cause of widespread pathologies of the vascular system has been related to specific features of the blood flow in a diseased district as well as to the influence of the flow pattern on the transfer processes of solutes between blood and walls (see, e.g., [1], [7], [15], [2], [3]). In [2], [3], for example, a more complex physiological model has been introduced; however, so far it has been tested only on simple two-dimensional (2D) geometries. On the other hand, more realistic three-dimensional (3D) calculations have been pursued in [7]; however, in this case the model does not include the arterial wall as a domain, per se; rather it surrogates the artery wall by prescribing a Dirichlet boundary condition for the concentration. In this paper, our aim is to set up efficient *numerical methods* for solving heterogeneous problems featuring a discontinuous solution. Although stemming from the specific application at hand, the interest of these methods goes beyond it as they can be applied to any system of advection-diffusion equations which models the transfer of mass between heterogeneous media through permeable membranes.

In the numerical analysis of these kinds of problems, a monolithic solver is typically adopted. Our approach is based on domain decomposition methods, solving alternatively the different problems in the different subdomains (*iterative substructuring approach*). In such a way, the discontinuity at the interface is accounted for naturally. The general theory underlying this approach has been developed in [13, Chapters 1 and 4]. However, the discontinuity of the solution in this specific application makes the convergence analysis of the method "nonstandard." In particular, we will focus on the choice of convenient preconditioned iterative techniques and the proof of convergence in the very general and abstract framework provided by the Steklov–Poincaré operator theory. In a forthcoming paper, we will consider the extension of these techniques to the more realistic models considered in [2], [3].

The paper is organized as follows. In section 2 we provide a brief introduction to the heterogeneous model and recall the well posedness results obtained in [14]. In section 3 we provide a reinterpretation of the problem in terms of a Steklov–Poincaré interface equation. This reformulation is not a mere extension of techniques adopted in other contexts, due to the presence of discontinuous solutions. In section 4, we introduce an iterative method for the solution of the problem by solving successively the solute dynamics in the lumen and in the wall. Starting from the Steklov–Poincaré reformulation of the interface problem, we show that this method can be regarded as a particular Richardson preconditioned method for the interface problem. Then, we carry out the convergence analysis of this method; we identify an optimal preconditioner associated to it and propose various generalizations based on the (flexible) preconditioned GMRES method.

The numerical results presented refer to biomedical applications and illustrate the efficiency of our schemes (section 5).

1.1. Some notation. Let $\Omega \subset \mathbb{R}^d$ $(d = 2, 3)$ be a physical bounded domain and $\mathbf{x} \in \Omega$. We denote by $L^2(\Omega)$ the Hilbert space of square integrable functions in Ω. The scalar product in $L^2(\Omega)$ is denoted by $(\cdot,\cdot)$ and the related norm by $\|\cdot\|_{L^2(\Omega)}$. The space of essentially bounded functions in Ω is denoted by $L^\infty(\Omega)$. The Sobolev space of functions, whose first (distributional) derivatives belong to $L^2(\Omega)$, is denoted by $H^1(\Omega)$ and its norm by $\|\cdot\|_{H^1(\Omega)}$.

If $\Sigma \subset \partial\Omega$ is open and nonempty, then the space of functions defined on Σ which are traces of functions belonging to $H^1(\Omega)$ is indicated by $H^{1/2}(\Sigma)$. We recall (see [5]) that the trace operator $\gamma : H^1(\Omega) \to H^{1/2}(\Sigma)$ is surjective and continuous and there exists an injective, linear, and continuous map $\mathcal{L} : H^{1/2}(\Sigma) \to H^1(\Omega)$ called *lifting* such that $\lambda = \gamma\mathcal{L}\lambda$ for all $\lambda \in H^{1/2}(\Sigma)$. In particular, denoting by ϕ a function in $H^1(\Omega)$ and $\gamma\phi$ its trace on Σ, the following *trace inequality* holds:

$$\exists\beta_t > 0 : \quad \|\gamma\phi\|_{H^{1/2}(\Sigma)} \leq \beta_t\|\phi\|_{H^1(\Omega)} \quad \forall\phi \in H^{1/2}(\Sigma). \tag{1.1}$$

We denote by $H^1_\Sigma(\Omega)$ the subspace of $H^1(\Omega)$ of the functions that have null traces on Σ. In particular, we adopt the usual notation $H^1_0(\Omega) = H^1_{\partial\Omega}(\Omega)$. In $H^1_\Sigma(\Omega)$ the following Poincaré inequality holds:

$$\exists\alpha > 0 : \quad \|\phi\|_{L^2(\Omega)} \leq \alpha\|\nabla\phi\|_{L^2(\Omega)} \quad \forall\phi \in H^1_\Sigma(\Omega). \tag{1.2}$$

If Γ denotes a $(d-1)$-dimensional manifold in $\overline{\Omega}$ with $\Gamma \cap \Sigma \neq \emptyset$, the trace of $u \in H^1_\Sigma(\Omega)$ on Γ belongs to a subspace of $H^{1/2}(\Gamma)$, usually denoted by $H^{1/2}_{00}(\Gamma)$. To simplify our notation we will set $\Lambda = H^{1/2}_{00}(\Gamma)$, and Λ' will denote its dual (see [5]). We remark that if ζ is any positive function in $L^2(\Sigma)$, the following definition makes sense:

$$(\rho, \lambda)_\zeta = \int_\Sigma \zeta\rho\lambda = \left(\sqrt{\zeta}\lambda, \sqrt{\zeta}\rho\right) \quad \forall\lambda, \rho \in H^{1/2}(\Sigma). \tag{1.3}$$

Indeed, by the Sobolev embedding theorem, λ and ρ belong to $L^4(\Sigma)$; hence $\lambda\rho$ belongs to $L^2(\Sigma)$. Denoting by $\mathcal{L}\lambda$ and $\mathcal{L}\rho$ any continuous lifting of λ and ρ from Σ to Ω, it follows that

$$\left|(\rho, \lambda)_\zeta\right| \leq \beta_e^2\|\zeta\|_{L^2(\Sigma)}\|\lambda\|_{H^{1/2}(\Sigma)}\|\rho\|_{H^{1/2}(\Sigma)} \leq \beta^2\|\mathcal{L}\lambda\|_{H^1(\Omega)}\|\mathcal{L}\rho\|_{H^1(\Omega)}, \tag{1.4}$$

with $\beta^2 = \beta_e^2\beta_t^2\|\zeta\|_{L^2(\Sigma)}$, where β_e is the embedding constant of $H^{1/2}(\Sigma)$ in $L^4(\Sigma)$ and β_t is the constant of the trace inequality (1.1). Finally, we set

$$\|\lambda\|^2_\zeta = (\lambda, \lambda)_\zeta = \|\sqrt{\zeta}\lambda\|^2_{L^2(\Sigma)}.$$

For space-time functions $v : \Omega \times (0,T) \to \mathbb{R}$, for all real q and $s = 0, 1$, we introduce the space

$$L^q(0,T; H^s(\Omega)) \equiv \left\{ v : (0,T) \to H^s |\ v(t) \text{ is measurable}, \int_0^T \|v(t)\|^q_{H^s(\Omega)}dt < \infty \right\}$$

endowed with the norm

$$\|v\|_{L^q(0,T;H^s(\Omega))} \equiv \left(\int_0^T \|v(t)\|^q_{H^s(\Omega)}dt\right)^{1/q}.$$

2. Problem formulation. Let us consider a specific vascular district $\Omega \subset \mathbb{R}^d$ $(d = 2, 3)$, composed by a lumen or a fluid subdomain Ω_f and a structure or wall subdomain Ω_w. Their interface Γ belongs to $\mathbb{R}^{d-1}$ (see Figure 2.1).

The artificial sections delimiting the district proximally and distally with respect to the heart will be denoted by Γ_{up} and Γ_{dw}, respectively. For $\mathbf{x} \in \Omega$ and $t > 0$ we denote by $\mathbf{u}(\mathbf{x}, t)$ the velocity of the blood and by $P(\mathbf{x}, t)$ its pressure. $C_f(\mathbf{x}, t)$ and $C_w(\mathbf{x}, t)$ denote the concentrations of the solute in the lumen Ω_f and in the wall Ω_w, respectively. We assume the blood to be an incompressible Newtonian fluid (which is a realistic assumption in large and medium vessels—see, e.g., [11]) within rigid walls. Then, the blood motion is described by the Navier–Stokes incompressible equations, obtained by the momentum and mass conservation principles. The initial-boundary values problem we are going to consider for the blood dynamics therefore reads

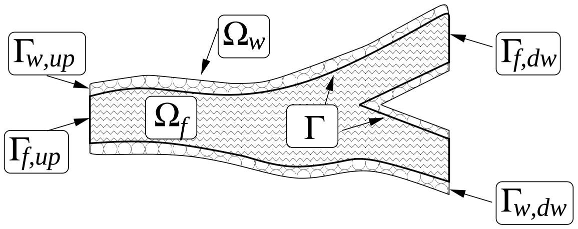

FIG. 2.1. *Computational domain representing a 2D section of a vascular district featuring the lumen Ω_f and the wall Ω_w.*

$$\begin{aligned}
&\rho\frac{\partial \mathbf{u}}{\partial t}+\rho\left(\mathbf{u}\cdot\nabla\right)\mathbf{u}-\nu\Delta\mathbf{u}+\nabla P=\mathbf{f}\quad \mathbf{x}\in\Omega_f,\qquad t>0,\\
&\nabla\cdot\mathbf{u}=0\quad \mathbf{x}\in\Omega_f,\qquad t>0,\\
&\mathbf{u}=\mathbf{b}\quad\text{on}\quad\Gamma_{f,up},\quad t>0,\quad \mathbf{u}=\mathbf{0}\quad\text{on}\quad\Gamma,\quad t>0,\\
&P\mathbf{n}-\rho\nu\nabla\mathbf{u}\cdot\mathbf{n}=P_{ext}\mathbf{n}\quad\text{on}\quad\Gamma_{f,dw},\qquad t>0,\\
&\mathbf{u}\left(\mathbf{x},t\right)=\mathbf{u}_0\quad\text{with}\quad\nabla\cdot\mathbf{u}_0=0,\quad\mathbf{x}\in\Omega_f,\quad t=0.
\end{aligned}\tag{2.1}$$

In (2.1) we suppose that the boundary $\partial\Omega_f$ of the computational domain of the fluid part of the problem is split into the interface with the wall Γ, the upstream or proximal part $\Gamma_{f,up}$ (where we prescribe the velocity field), and the downstream or distal one, $\Gamma_{f,dw}$ (where the normal fluid stress is assigned). We are also assuming that the density of the blood ρ_b as well as the viscosity ν are constant; the physiological range of these parameters is discussed in section 5.

The dynamics of solutes is described by an advection-diffusion process. In the lumen, the convective field is provided by the blood velocity, while in the wall, because of the very low velocity of the solvent, the advection is negligible (see [8]). The interface Γ can be regarded as a permeable membrane whose permeability ζ is a positive function of the shear stress σ exerted by the blood on the wall (see [15]). More precisely, the solute flux through Γ is proportional to the difference of concentration between lumen and wall. All these considerations lead to the following model for the solute concentrations for all $t>0$:

$$\left\{\begin{aligned}
&\frac{\partial C_f}{\partial t}-\mu_f\Delta C_f+\mathbf{u}\cdot\nabla C_f=s_f\quad\text{in}\quad\Omega_f,\\
&\frac{\partial C_w}{\partial t}-\mu_w\Delta C_w=s_w\quad\text{in}\quad\Omega_w,\\
&\mu_f\frac{\partial C_f}{\partial\mathbf{n}_f}+\zeta\left(C_f-C_w\right)=0\quad\text{on}\quad\Gamma,\\
&\mu_w\frac{\partial C_w}{\partial\mathbf{n}_w}+\zeta\left(C_w-C_f\right)=0\quad\text{on}\quad\Gamma,\\
&C_f=C_{f,up}\quad\text{on}\quad\Gamma_{f,up},\quad C_w=C_{w,up}\quad\text{on}\quad\Gamma_{w,up},\\
&\mu_f\frac{\partial C_f}{\partial\mathbf{n}_f}=0\quad\text{on}\quad\Gamma_{f,dw},\quad\mu_w\frac{\partial C_w}{\partial\mathbf{n}_w}=0\quad\text{on}\quad\Gamma_{w,dw}.
\end{aligned}\right.\tag{2.2}$$

To complete (2.2), we add the initial conditions

$$C_f(\mathbf{x},t)=C_{f0}(\mathbf{x}),\quad\mathbf{x}\in\Omega_f,\qquad C_w(\mathbf{x},t)=C_{w0}(\mathbf{x}),\quad\mathbf{x}\in\Omega_w,\quad t=0,$$

where the diffusivity coefficients μ_f and μ_w are positive and constant and $s_f(\mathbf{x},t)$ and $s_w(\mathbf{x},t)$ are possible source terms. In (2.2), we have denoted by $\Gamma_{w,up}$ ($\Gamma_{w,dw}$) the part of the wall corresponding to the proximal (distal) section of the fluid domain (see Figure 2.1).

In this model, observe that the solute is regarded as a *passive scalar*; that means that it is simply convected by the blood in the lumen, neglecting any possible feedback on the hemodynamics. In particular, viscosity and density of blood are assumed independent of the solute concentration. This hypothesis is actually coherent with the models for solute dynamics proposed in [2], [3].

Now, observe that $(2.2)_4$ can be equivalently substituted by the equation

$$\mu_f \frac{\partial C_f}{\partial \mathbf{n}_f} = -\mu_w \frac{\partial C_w}{\partial \mathbf{n}_w} \quad \text{on } \Gamma,$$

prescribing the continuity of the solute flux between the fluid and the wall domains. However, we prefer the formulation (2.2), as it leads to a more efficient subdomain iterative scheme.

REMARK 2.1. *For some gaseous solutes, the diffusivity coefficient μ_f depends on the rate of deformation of blood (see* [4]*). This feature makes the mathematical analysis of the coupled Navier–Stokes/solute dynamics problem more involved, as addressed in* [14]*. However, it does not bring significant differences in the context of the present work, which is mainly focused on the numerical approximation.*

In order to carry out the mathematical analysis of the problem given by (2.1) and (2.2), as well as its numerical discretization, we resort to their "weak" or variational formulations. Concerning the Navier–Stokes equations, this can be done in a very standard way and we refer to, e.g., [12], [17]. For the advection-diffusion problem we introduce the following notation. For all $\psi_f, \phi_f \in H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_f)$ and $\psi_w, \phi_w \in H^1_{\partial\Omega_w\setminus\Gamma}(\Omega_w)$ set

$$a_f(\psi_f,\phi_f) = \mu_f(\nabla\psi_f,\nabla\phi_f) + ((\mathbf{u}\cdot\nabla)\psi_f,\phi_f), \tag{2.3}$$

$$a_w(\psi_w,\phi_w) = \mu_w(\nabla\psi_w,\nabla\phi_w). \tag{2.4}$$

Both $a_f(\cdot,\cdot)$ and $a_w(\cdot,\cdot)$ are continuous and coercive bilinear forms; additionally, $a_w(\cdot,\cdot)$ is *symmetric*. Then, the weak formulation of problem (2.2) reads as follows.

PROBLEM 2.1. *Given the initial condition $C_f(\mathbf{x},t=0) = C_{f,0}, \in H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_f)$ and $C_w(\mathbf{x},t=0) = C_{w,0} \in H^1_{\partial\Omega_w\setminus\Gamma}(\Omega_w)$ find $C_f \in L^2(0,T;H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_f))$, $C_w \in L^2(0,T;H^1_{\partial\Omega_w\setminus\Gamma}(\Omega_w))$ such that for all $\phi_f \in H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_f)$ and $\phi_w \in H^1_{\partial\Omega_w\setminus\Gamma}(\Omega_w)$*

$$\begin{cases} \left(\dfrac{\partial C_f}{\partial t},\phi_f\right) + a_f(C_f,\phi_f) + (C_f - C_w,\phi_f)_\zeta = (s_f,\phi_f), \\ \left(\dfrac{\partial C_w}{\partial t},\phi_w\right) + a_w(C_w,\phi_w) + (C_w - C_f,\phi_w)_\zeta = (s_w,\phi_w). \end{cases} \tag{2.5}$$

If the domain and the data are regular enough, Problem 2.1, coupled with the (weak form of) Navier–Stokes one, is well posed. More precisely, the following proposition can be shown (see [14]).

PROPOSITION 2.1. *If Ω_f is a 2D domain smooth enough, then the coupled blood solute dynamics problem admits a unique solution, depending continuously on the* *data. If Ω_f is a 3D domain, the same conclusion holds true, provided the initial data of the Navier–Stokes problem are sufficiently small.*

Concerning the result of this proposition, we point out that the smallness of the data for the Navier–Stokes problem is actually a standard and an unavoidable hypothesis for ensuring the existence of a convective field in any problem involving an incompressible fluid. Indeed, no unconditional well posedness result is so far available for the Navier–Stokes equations (see [17], [12]). Moreover, observe that if the diffusivity of the solute in the lumen is the function of the shear rate (see Remark 2.1) the smallness of the initial data for the Navier–Stokes problem is necessary even for the 2D case.

We point out that in [14] only full Dirichlet boundary conditions for the blood were considered, which yield a coercive bilinear form. However, in the current case, a standard energy argument allows us to prove that the bilinear form is weakly coercive, which is still sufficient to ensure the well posedness of the associated parabolic problem (see [5], [6], [12]).

3. Discretization and Steklov–Poincaré operators.

3.1. The semidiscrete problem. We will suppose that the blood velocity and pressure are available upon solving the weak counterpart of (2.1) and focus our attention on the computation of Problem 2.1. In view of the subsequent analysis, we first introduce the semidiscrete model, namely the time-discrete counterpart of Problem 2.1. To this end, we subdivide the time interval $[0,T]$ in N time steps $t^n = n\Delta t$, with $\Delta t > 0$ and $n = 1,\dots,N$. Setting $\chi = \frac{1}{\Delta t}$, we obtain the time-discrete problem based on the backward Euler method.

PROBLEM 3.1. *Given C_f^0 and C_w^0 for every $n = 0,1,\dots,N-1$ find $C_f^{n+1} \in H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_f)$ and $C_w^{n+1} \in H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_w)$ such that for all ϕ_f in $H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_f)$ and ϕ_w in $H^1_{\partial\Omega_w\setminus\Gamma}(\Omega_w)$*

$$
\left\{
\begin{aligned}
&\widehat{a}_f\left(C_f^{n+1},\phi_f\right) + \left(C_f^{n+1},\phi_f\right)_\zeta - \left(C_w^{n+1},\phi_f\right)_\zeta = \chi\left(C_f^n,\phi_f\right) + \left(s_f^{n+1},\phi_f\right),\\
&\widehat{a}_w\left(C_w^{n+1},\phi_w\right) + \left(C_w^{n+1},\phi_w\right)_\zeta - \left(C_f^{n+1},\phi_w\right)_\zeta = \chi\left(C_w^n,\phi_w\right) + \left(s_w^{n+1},\phi_w\right),
\end{aligned}
\right.
\tag{3.1}
$$

where $s_f^{n+1} = s_f\left(t^{n+1}\right)$, $s_w^{n+1} = s_w\left(t^{n+1}\right)$, C_f^0 and C_w^0 are the initial data, and

$$
\widehat{a}_f\left(\psi_f,\phi_f\right) = \chi\left(\psi_f,\phi_f\right) + a_f\left(\psi_f,\phi_f\right) \quad \forall \phi_f,\psi_f \in H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_f),
\tag{3.2}
$$

$$
\widehat{a}_w\left(\psi_w,\phi_w\right) = \chi\left(\psi_w,\phi_w\right) + a_w\left(\psi_w,\phi_w\right) \quad \forall \phi_w,\psi_w \in H^1_{\partial\Omega_w\setminus\Gamma}(\Omega_w).
\tag{3.3}
$$

Observe that these bilinear forms are continuous and coercive, and, in particular, $\widehat{a}_w\left(\cdot,\cdot\right)$ is *symmetric*.

3.2. The Steklov–Poincaré interface equation. We are going to provide a different formulation of (3.1) which will be useful in view of the subsequent analysis. In what follows, the specification of the time index $n+1$ will be dropped whenever clear from the context.

Let us start with the "wall-side" of the problem. Let $\mathcal{H}_w : \Lambda \to H^1_{\partial\Omega_w\setminus\Gamma}(\Omega_w)$ be defined such that, for a given function $\rho \in \Lambda$, $u_w = \mathcal{H}_w\rho$ solves

$$
\left\{
\begin{aligned}
&\chi u_w - \mu_w \Delta u_w = 0 \quad \text{in} \quad \Omega_w,\\
&u_w = \rho \quad \text{on} \quad \Gamma, \quad u_w = 0 \quad \text{on} \quad \partial\Omega_w \setminus \Gamma.
\end{aligned}
\right.
\tag{3.4}
$$

Moreover, let $\mathcal{G}_w : L^2(\Omega_w) \to H^1_0(\Omega_w)$ be the operator such that, for a given function $r_w \in L^2(\Omega_w)$, $g_w = \mathcal{G}_w r_w$ satisfies

$$\begin{cases} \chi g_w - \mu_w \Delta g_w = r_w \quad \text{in} \quad \Omega_w, \\ \\ g_w = 0 \quad \text{on} \quad \partial\Omega_w. \end{cases} \tag{3.5}$$

Correspondingly, we introduce the following operator $\mathcal{H}_f : \Lambda \to H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_f)$ for the "fluid-side" of the problem. Given $\rho \in \Lambda$, $u_f = \mathcal{H}_f \rho$ satisfies

$$\begin{cases} \chi u_f - \mu_f \Delta u_f + \mathbf{u}\cdot\nabla u_f = 0 \quad \text{in} \quad \Omega_f, \\ \\ u_f = 0 \quad \text{on} \quad \partial\Omega_f \setminus \Gamma, \quad \mu_f \dfrac{\partial u_f}{\partial \mathbf{n}_f} + \zeta u_f = \zeta\rho \quad \text{on} \quad \Gamma. \end{cases} \tag{3.6}$$

Furthermore, $\mathcal{G}_f : L^2(\Omega_f) \to H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_f)$ is such that, given $r_f \in L^2(\Omega_f)$, $g_f = \mathcal{G}_f r_f$ solves

$$\begin{cases} \chi g_f - \mu_f \Delta g_f + \mathbf{u}\cdot\nabla g_f = r_f \quad \text{in} \quad \Omega_f, \\ \\ g_f = 0 \quad \text{on} \quad \partial\Omega_f \setminus \Gamma, \quad \mu_f \dfrac{\partial g_f}{\partial \mathbf{n}_f} + \zeta g_f = 0 \quad \text{on} \quad \Gamma. \end{cases} \tag{3.7}$$

Finally, for a given function $\rho \in \Lambda$, we define

$$\begin{aligned} &\mathcal{S}_w : \Lambda \to \Lambda' \quad \text{such that} \quad \mathcal{S}_w\rho = \mu_w \frac{\partial \mathcal{H}_w \rho}{\partial \mathbf{n}_w} + \zeta\rho, \\ &\mathcal{S}_f : \Lambda \to \Lambda' \quad \text{such that} \quad \mathcal{S}_f\rho = -\zeta(\gamma_f \mathcal{H}_f \rho). \end{aligned} \tag{3.8}$$

By extending a definition which is common in the framework of domain decomposition methods we call $\mathcal{S}_f$ and $\mathcal{S}_w$ the *Steklov–Poincaré* operators associated with the heterogeneous problem at hand. A general discussion on the role and the properties of Steklov–Poincaré (SP) operators in the framework of domain decomposition can be found in [13]. On the basis of the previous definitions, the time-discrete formulation of the problem can be reformulated in terms of an operatorial *interface equation.* Indeed, if we set

$$\mathcal{S} = \mathcal{S}_f + \mathcal{S}_w \quad \text{and} \quad \eta = -\left(\mu_f \frac{\partial \mathcal{G}_f r_f}{\partial \mathbf{n}_f} + \mu_w \frac{\partial \mathcal{G}_w r_w}{\partial \mathbf{n}_w}\right), \tag{3.9}$$

then, from $(2.2)_4$, the following interface equation needs to be solved for the unknown ρ at each time step:

$$\mathcal{S}\rho = \eta\ . \tag{3.10}$$

The SP operators can be reinterpreted in a weak from by considering (3.10) in a distributional sense. Let us denote by $\langle\cdot,\cdot\rangle$ the duality pairing of Λ with Λ'. By Green formula, we obtain for all $\lambda \in \Lambda$

$$\langle \mathcal{S}_w\rho, \lambda\rangle = \left\langle \mu_w \frac{\partial \mathcal{H}_w \rho}{\partial \mathbf{n}_w}, \lambda \right\rangle + (\rho,\lambda)_\zeta = \widehat{a}_w\left(u_w, \mathcal{L}_w\lambda\right) + (\rho,\lambda)_\zeta \tag{3.11}$$

with $\mathcal{L}_w\lambda \in H^1_{\partial\Omega_w\setminus\Gamma}(\Omega_w)$ and

$$\begin{aligned}\langle \mathcal{S}_f\rho,\lambda\rangle &= -\left(\mathcal{H}_f\rho,\lambda\right)_\zeta = -\left(u_f,\lambda\right)_\zeta = -\left(\rho,\lambda\right)_\zeta + \mu_f\left\langle \frac{\partial u_f}{\partial \mathbf{n}_f},\lambda\right\rangle \\ &= -\left(\rho,\lambda\right)_\zeta + \widehat{a}_f\left(u_f,\mathcal{L}_f\lambda\right)\end{aligned} \tag{3.12}$$

with $\mathcal{L}_f\lambda \in H^1_{\partial\Omega_f\setminus\Gamma}(\Omega_f)$. In the latter equation, we have exploited the definition of u_f and, in particular, $(3.6)_2$. Consequently,

$$\langle \mathcal{S}\rho,\lambda\rangle = \mu_w\left\langle \frac{\partial\mathcal{H}_w\rho}{\partial \mathbf{n}_w},\lambda\right\rangle + (\rho,\lambda)_\zeta - \left(\mathcal{H}_f\rho,\lambda\right)_\zeta = \widehat{a}_w\left(u_w,\mathcal{L}_w\lambda\right) + \widehat{a}_f\left(u_f,\mathcal{L}_f\lambda\right) \tag{3.13}$$

for all $\lambda \in \Lambda$. By proceeding in a similar way for the right-hand side, the weak formulation of the interface relation (3.10) finally reads as follows: find $\rho \in \Lambda$ such that

$$\widehat{a}_w\left(\mathcal{H}_w\rho + \mathcal{G}_w r_w,\mathcal{L}_w\lambda\right) + \widehat{a}_f\left(\mathcal{H}_f\rho + \mathcal{G}_f r_f,\mathcal{L}_f\lambda\right) = \left(r_f,\mathcal{L}_f\lambda\right) + \left(r_w,\mathcal{L}_w\lambda\right) \tag{3.14}$$

for all $\lambda \in \Lambda$. Finally, we notice that, in the special case $\phi_f = \mathcal{L}_f\lambda$ and $\phi_w = \mathcal{L}_w\lambda$, and, provided that $r_f = \chi C_f^n + s_f^{n+1}, r_w = \chi C_w^n + s_w^{n+1}$, (3.14) is equivalent to (2.5).

3.3. The fully discrete problem. The *space discretization* of the problem is carried out using the finite element method (FEM). To this end, let us introduce $\mathcal{T}_{hf}$ and $\mathcal{T}_{hw}$, two admissible triangulations (see, e.g., [12]) of $\overline{\Omega}_f$ and $\overline{\Omega}_w$ respectively. For the sake of simplicity, we assume that $\mathcal{T}_{hf}$ and $\mathcal{T}_{hw}$ are *conforming* triangulations on Γ. Consequently, $\mathcal{T}_h = \mathcal{T}_{hf} \cup \mathcal{T}_{hw}$ is an admissible triangulation for $\overline{\Omega}_f \cup \overline{\Omega}_w$. Let h be a characteristic length of the elements $K \in \mathcal{T}_h$ and V_{hf} and V_{hw} be a couple of finite-dimensional subspaces of $H^1_{\partial\Omega_f\setminus\Gamma}$ and $H^1_{\partial\Omega_w\setminus\Gamma}$, respectively. Moreover, denote by $V_{hw,0}$ a finite-dimensional subspace of $H^1_0(\Omega_w)$. Finally let Λ_h be a finite-dimensional subspace of Λ such that the traces on Γ of functions in V_{hf} or V_{hw} belong to Λ_h. Denote by N_f the dimension of V_{hf}, by N_w the dimension of V_{hw}, and by N_Γ the dimension of Λ_h. Let $\{\phi_{i,f}\}$ $(i = 1,2,\dots,N_f)$ and similarly $\{\phi_{i,w}\}$ $(i = 1,2,\dots,N_w)$ be a basis for V_{hf} and for V_{hw}, respectively; moreover, denote with $\{\phi_{i,\Gamma}\}$ $(i = 1,2,\dots,N_\Gamma)$ a basis for Λ_h. In what follows, the subscript h will identify the space discrete solution.

Based on these definitions, the space discretization of Problem 2.1 reads as follows.

PROBLEM 3.2. *Given the initial data C^0_{fh} and C^0_{wh}, for every $n = 0,1,\dots,N-1$ (being $N\Delta t = T$ the final time), find $C^{n+1}_{fh} \in V_{hf}$ and $C^{n+1}_{wh} \in V_{hw}$ such that for all $i = 1,\dots,N_f$ and $j = 1,\dots,N_w$*

$$\begin{cases} \widehat{a}_f\left(C^{n+1}_{fh},\phi_{i,f}\right) + \left(C^{n+1}_{fh},\phi_{i,f}\right)_\zeta - \left(C^n_{wh},\phi_{i,f}\right)_\zeta = \chi\left(C^n_{fh},\phi_{i,f}\right) + \left(s^{n+1}_f,\phi_{i,f}\right), \\ \widehat{a}_w\left(C^{n+1}_{wh},\phi_{j,w}\right) + \left(C^{n+1}_{wh},\phi_{j,w}\right)_\zeta - \left(C^{n+1}_{fh},\phi_{j,w}\right)_\zeta = \chi\left(C^n_{wh},\phi_{j,w}\right) + \left(s^{n+1}_w,\phi_{j,w}\right). \end{cases} \tag{3.15}$$

REMARK 3.1. *Due to the convection dominated nature of the problem (see* [15]*), the pure Galerkin discrete formulation* (3.15) *does not ensure stability to the numerical solution unless the triangulation is fine enough to ensure that the local Péclet number is less than one. It is therefore mandatory to adopt suitable stabilization techniques. In particular, we will make use of a strongly consistent method like SUPG* *(streamline upwind Petrov Galerkin)—see, e.g.,* [12]. *We address first the analysis of the scheme to the Galerkin formulation* (3.15) *in order to point out the intrinsic features of the method. Later on, we will address the modifications induced by the presence of stabilizing terms (see section* 4.1*).*

3.3.1. The discrete SP operators. Let us introduce the discrete counterpart $\widehat{\mathcal{S}}_{hw}$ and $\widehat{\mathcal{S}}_{hf}$ of the SP operators. Following (3.11), we define

$$\langle \widehat{\mathcal{S}}_{hw}\rho, \lambda\rangle = \widehat{a}_w\left(u_w, \mathcal{L}_w\lambda\right) + \left(\rho, \lambda\right)_\zeta \quad \forall \rho, \lambda \in \Lambda_h, \tag{3.16}$$

where

$$u_w \in V_{hw} : \begin{cases} \widehat{a}_w\left(u_w, \phi_w\right) = 0 \quad \forall \phi_w \in V_{hw,0}, \\ u_w = \rho \quad on\ \Gamma. \end{cases}$$

Similarly we define

$$\langle \widehat{\mathcal{S}}_{hf}\rho, \lambda\rangle = -\left(\rho, \lambda\right)_\zeta + \widehat{a}_f\left(u_f, \mathcal{L}_f\lambda\right), \tag{3.17}$$

where

$$u_f \in V_{hf} : \widehat{a}_f\left(u_f, \phi_f\right) + \left(u_f, \phi_f\right)_\zeta = \left(\rho, \phi_f\right)_\zeta \quad \forall \phi_f \in V_{hf}. \tag{3.18}$$

Finally, we set $\widehat{\mathcal{S}}_h = \widehat{\mathcal{S}}_{hw} + \widehat{\mathcal{S}}_{hf}$. Then, the solution of Problem 3.2 can be reformulated in terms of the interface equation

$$\langle \widehat{\mathcal{S}}_h\rho, \lambda\rangle = \langle \widehat{\eta}, \lambda\rangle \quad \forall \lambda \in \Lambda, \tag{3.19}$$

where ρ stands for the trace of C_{wh} on Γ, i.e.,

$$\rho = C_{wh}\mid_\Gamma$$

and

$$\widehat{\eta} = -\left(\mu_w \frac{\partial \mathcal{G}_w r_w}{\partial \mathbf{n}_w} + \mu_f \frac{\partial \mathcal{G}_f r_f}{\partial \mathbf{n}_f}\right), \tag{3.20}$$

with

$$r_f = r_f^{n+1} = s_f^{n+1} + \chi C_{fh}^n, \quad r_w = r_w^{n+1} = s_w^{n+1} + \chi C_{wh}^n, \tag{3.21}$$

where, for the sake of clarity, the time index has been restored.

In what follows we will use several times the so called *finite element uniform extension theorem* (FEUET), which states that $\|\rho_h\|_\Lambda$ is uniformly equivalent (with respect to h) to $\|u_{h,w}\|_{H^1(\Omega_w)}$, where $u_{h,w}$ is the finite element approximation of problem (3.4), where ρ is replaced by ρ_h; see [13, Theorem 4.1.3].

PROPOSITION 3.1. *The following properties hold for $\widehat{\mathcal{S}}_{hw}$, $\widehat{\mathcal{S}}_{hf}$, and $\widehat{\mathcal{S}}_h$:*

1. *$\widehat{\mathcal{S}}_{hw}$ is continuous, symmetric, and coercive in Λ_h.*
2. *$\widehat{\mathcal{S}}_{hf}$ is continuous and negative; i.e., for any $\rho \in \Lambda_h$, $\langle \widehat{\mathcal{S}}_{hf}\rho, \rho\rangle < 0$.*
3. *$\widehat{\mathcal{S}}_h$ is continuous and coercive in Λ_h.*

Proof. Continuity and symmetry of $\widehat{\mathcal{S}}_{hw}$ can be proven from the continuity and symmetry of $\widehat{a}_w(\cdot,\cdot)$ and the definition (3.16), owing to the FEUET. Moreover, $\widehat{\mathcal{S}}_{hw}$ is coercive thanks to the coercivity of $\widehat{a}_w(\cdot,\cdot)$, the positivity of ζ, and the trace inequality (1.1). Observe in particular that the continuity and coercivity constants do not depend on h.

Continuity of $\widehat{\mathcal{S}}_{hf}$ follows from the coercivity of the bilinear form on the right-hand side of (3.18). Again, the continuity constant does not depend on h, depending on the bilinear form properties. Moreover, from (3.17) and taking again $\phi_f = u_f$ in (3.18), we obtain

$$-\langle \widehat{\mathcal{S}}_{hf}\rho, \rho\rangle = (u_f, \rho)_\zeta = \widehat{a}_f\,(u_f, u_f) + \|u_f\|_\zeta^2 > 0 \quad \forall \rho \in \Lambda_h. \tag{3.22}$$

Item 2 is thus proven. The continuity of $\widehat{\mathcal{S}}_h$ is now a consequence of the continuity of $\widehat{\mathcal{S}}_{hw}$ and $\widehat{\mathcal{S}}_{hf}$. In particular, we stress that the continuity constant is independent on h.

Finally, we prove that $\widehat{\mathcal{S}}_h$ is coercive. Indeed, observe that by the definition of u_f and (3.22)

$$\widehat{a}_f\,(u_f, \mathcal{L}_f\rho) = (\rho - \gamma_f u_f, \rho)_\zeta = (\rho - \gamma_f u_f, \rho - \gamma_f u_f)_\zeta + \widehat{a}_f\,(u_f, u_f)\,. \tag{3.23}$$

Consequently, we obtain

$$\langle \widehat{\mathcal{S}}_h\rho, \rho\rangle = \widehat{a}_w\,(u_w, \mathcal{L}_w\rho) + \widehat{a}_f\,(u_f, \mathcal{L}_f\rho) \geq \widehat{a}_w\,(u_w, u_w) \geq \tau\|\rho\|_\Lambda^2. \tag{3.24}$$

Finally, observe that the coercivity constant considered above is independent of h. Indeed, the coercivity constant τ in (3.24) is independent of h. This is due to the circumstance that u_w is the extension of ρ so that we can advocate once again the FEUET. □

As a direct consequence of the previous properties, we obtain the following corollary.

COROLLARY 3.1. *The interface equation* (3.19) *admits a unique solution which depends continuously on the data.*

Proof. The functional $\mathcal{F}(\lambda) \equiv \langle \widehat{\eta}, \lambda\rangle$ associated with the right-hand side of (3.19) is continuous in Λ_h. Moreover, the bilinear form $\langle \widehat{\mathcal{S}}_h\cdot, \cdot\rangle$ is continuous and coercive in Λ_h, as proved in Proposition 3.1. The result then follows from the Lax–Milgram lemma. □

4. The subdomain iterative method.

In order to reduce the computational cost required by the numerical solution of Problem 3.2, we suitably split the whole problem into a sequence of subproblems to be solved in the two physical subdomains (the lumen Ω_f and the wall Ω_w). In [14] we have introduced and analyzed an iterative scheme based on the interface conditions $(2.2)_3$ and $(2.2)_4$. In the present work, we consider a relaxed extension of the scheme in order to speed up the convergence. We will extend the convergence results proven in [14] to the relaxed algorithm, taking advantage of the reinterpretation of the scheme in terms of SP operators. (That was not considered at all in [14].) In what follows, for notational convenience we will drop the specification h, for the space discrete quantities, as well as the specification $n+1$ for the time-discrete quantities (i.e., we will write $[C_{f,k}, C_{w,k}]$ instead of $[C_{fh,k}^{n+1}, C_{wh,k}^{n+1}]$). It is understood, however, that the iterative method is carried out on the fully discrete problem.

The scheme which we adopt is the following. Given an initial guess ρ_0 for $C_{w,0}$ on the interface Γ, for $k = 0, 1, \ldots$ find the sequence of functions $[C_{f,k}, C_{w,k}] \in V_{hf} \times V_{hw}$ by solving for all $i = 1, \ldots, N_f$ and $j = 1, \ldots, N_w$

$$\widehat{a}_f\,(C_{f,k+1}, \phi_{i,f}) + (C_{f,k+1}, \phi_{i,f})_\zeta = (r_f, \phi_{i,f}) + (\rho_k, \phi_{i,f})_\zeta, \tag{4.1}$$

$$\widehat{a}_w\left(C_{w,k+1},\phi_{j,w}\right)+\left(C_{w,k+1},\phi_{j,w}\right)_\zeta=\left(r_w,\phi_{j,w}\right)+\left(C_{f,k+1},\phi_{j,w}\right)_\zeta, \tag{4.2}$$

$$\rho_{k+1}=C_{w,k+1}|_\Gamma, \tag{4.3}$$

where r_f and r_w are defined in (3.21).

This is a *Robin–Robin* iterative scheme, as it is based on the conditions $(2.2)_3$ and $(2.2)_4$, which are Robin conditions for each subproblem involved.

In order to resort to an iterative scheme for the variable ρ_{k+1} alone, let us eliminate the unknowns $C_{f,k+1}, C_{w,k+1}$ from (4.1)–(4.3).

Let us take $\phi_f=\mathcal{L}_f\lambda$ in (4.1), where λ is any function of Λ_h, and split $C_{f,k+1}$ as $C_{f,k+1}=u_{f,k+1}+g_f$, where $u_{f,k+1}$ and g_f solve, respectively, problems (3.6) and (3.7) in a weak sense. Recalling (3.17), we have

$$\begin{aligned}\left(C_{f,k+1},\lambda\right)_\zeta&=\left(r_f,\mathcal{L}_f\lambda\right)+\left(\rho_k,\lambda\right)_\zeta-\widehat{a}_f\left(u_{f,k+1},\mathcal{L}_f\lambda\right)-\widehat{a}_f\left(g_f,\mathcal{L}_f\lambda\right)\\&=-\langle\nabla g_f\cdot\mathbf{n}_f,\lambda\rangle-\langle\widehat{\mathcal{S}}_{hf}\rho_k,\lambda\rangle\quad\forall\lambda\in\Lambda_h.\end{aligned} \tag{4.4}$$

Proceeding similarly on (4.2) and recalling that $C_{w,k+1}=u_{w,k+1}+g_w$, we obtain

$$\langle\widehat{\mathcal{S}}_{hw}C_{w,k+1},\lambda\rangle=\widehat{a}_w\left(u_{w,k+1},\mathcal{L}_w\lambda\right)+\left(C_{w,k+1},\lambda\right)_\zeta\quad\forall\lambda\in\Lambda_h$$

and

$$\widehat{a}_w\left(g_w,\mathcal{L}_w\lambda\right)=\left(r_w,\mathcal{L}_w\lambda\right)+\langle\nabla g_w\cdot\mathbf{n}_w,\lambda\rangle\quad\forall\lambda\in\Lambda_h.$$

Consequently, taking $\phi_w=\mathcal{L}_w\lambda$ in (4.2), by virtue of the latter two equations we have

$$\langle\widehat{\mathcal{S}}_{hw}C_{w,k+1},\lambda\rangle+\langle\nabla g_w\cdot\mathbf{n}_w,\lambda\rangle=\left(C_{f,k+1},\lambda\right)_\zeta\quad\forall\lambda\in\Lambda_h.$$

Substituting (4.4) in the latter, we obtain

$$\langle\widehat{\mathcal{S}}_{hw}C_{w,k+1},\lambda\rangle=\langle\widehat{\mathcal{S}}_{hw}\rho_{k+1},\lambda\rangle=\langle\widehat{\eta},\lambda\rangle-\langle\widehat{\mathcal{S}}_{hf}\rho_k,\lambda\rangle\quad\forall\lambda\in\Lambda_h, \tag{4.5}$$

where from (3.20)

$$\widehat{\eta}=-\left(\mu_f\nabla g_f\cdot\mathbf{n}_f+\mu_w\nabla g_w\cdot\mathbf{n}_w\right).$$

If we consider a relaxation parameter θ, (4.3) becomes

$$\rho_{k+1}=\theta C_{w,k+1}|_\Gamma+(1-\theta)\rho_k. \tag{4.6}$$

Hence for all $\lambda\in\Lambda_h$, by means of (4.5), we obtain

$$\langle\widehat{\mathcal{S}}_{hw}(\rho_{k+1}-\rho_k),\lambda\rangle=\theta\langle\widehat{\mathcal{S}}_{hw}C_{w,k+1},\lambda\rangle-\theta\langle\widehat{\mathcal{S}}_{hw}\rho_k,\lambda\rangle=\theta\langle\widehat{\eta}-\widehat{\mathcal{S}}_h\rho_k,\lambda\rangle. \tag{4.7}$$

Equation (4.7) actually sheds light on a useful reinterpretation of the Robin–Robin method, which can be regarded as a *preconditioned Richardson method* for problem (3.19), with $\widehat{\mathcal{S}}_{hw}$ playing the role of preconditioner for $\widehat{\mathcal{S}}_h$. This observation allows for a straightforward proof of convergence of the scheme. Indeed, we have the following abstract result (for the proof, see, e.g., [13, Theorem 4.2.2 and Remark 4.2.4]).

THEOREM 4.1. *Let X be a real Hilbert space, X' its dual space, and $\langle\cdot,\cdot\rangle$ the duality paring between X' and X. Let $\mathcal{Q}: X\to X'$ be a linear invertible continuous* *operator which can be split as* $\mathcal{Q} = \mathcal{Q}_1 + \mathcal{Q}_2$*, where* $\mathcal{Q}_i$ $(i = 1, 2)$ *are linear operators. Consider the problem*

$$\mathcal{Q}\rho = \eta, \tag{4.8}$$

where $\eta \in X'$ *is given and* $\rho \in X$ *is to be determined. Suppose that* $\mathcal{Q}_2$ *is continuous, symmetric, and coercive and that* $\mathcal{Q}$ *is coercive. Then, there exists a real value* θ_{max}*, depending on the continuity and the coercivity constants, such that for any* $\theta \in (0, \theta_{max})$*, the sequence*

$$\rho_{k+1} = \rho_k + \theta \mathcal{Q}_2^{-1} (\eta - \mathcal{Q}\rho_k) \tag{4.9}$$

converges in X *to the solution of* (4.8) *for any* $\rho_0 \in X$*.*

We point out that (4.9) is the generic iteration of a preconditioned Richardson method to solve (4.8), with $\mathcal{Q}_2$ acting as preconditioner (see [16], [9]).

Now, if we set $X = \Lambda_h$, $\mathcal{Q} = \widehat{\mathcal{S}}_h$, $\mathcal{Q}_1 = \widehat{\mathcal{S}}_{hf}$, $\mathcal{Q}_2 = \widehat{\mathcal{S}}_{hw}$, we apply this result to prove the convergence of the sequence $\{\rho_k\}, k \geq 0$ to the solution of (3.19). Indeed, all the hypotheses of the theorem are verified, as proven in the previous section.

Observe, moreover, that, in Theorem 4.1, the convergence rate as well as the optimal value for θ are functions of the coercivity and continuity constants of $\mathcal{Q}_2$ and of $\mathcal{Q}$ that in our case read $\widehat{\mathcal{S}}_{hw}$ and $\widehat{\mathcal{S}}_{hw}$, respectively. In proving Proposition 3.1 we pointed out that these constants are *independent of the mesh size h* in our problem. This means that the rate of convergence of the proposed preconditioned iterations is not affected by the mesh size, or, in other words, that the preconditioner is *optimal.*

Altogether, these observations can be collected in the following final result.

PROPOSITION 4.1. *The Robin–Robin iterative scheme* (4.1)*,* (4.2)*, and* (4.6) *is convergent for any* $\theta \in (0, \theta_{max})$*, and its rate of convergence is independent of the spatial discretization. Precisely, there exists* $K < 1$ *such that for any* $\theta \in (0, \theta_{max})$*, there exists a constant* $K_\theta \leq K$ *such that*

$$\|\rho - \rho_{k+1}\|_\Lambda \leq K_\theta \|\rho - \rho_k\|_\Lambda, \qquad k \geq 0.$$

In agreement with this conclusion, Table 4.1 shows that the convergence rate of the *relaxed Robin–Robin* scheme is uniformly independent of the parameter h (which in our computations with uniform grids is related to the number N of finite elements nodes through the law $N \approx \mathcal{O}(h^{-2})$).

REMARK 4.1. *The convergence result of Theorem* 4.1 *refers to the preconditioned Richardson iterative method. However, similar conclusions can be shown when more efficient methods are applied to the same problem (see Table* 4.1*), such as the generalized minimal residual (GMRES) (see* [16]*), as proven in a very abstract form in* [13, *sect.* 4.2.1]. *On the basis of this result, we will proceed with the GMRES methods later on in section* 4.3.

4.1. The iterative method in the convection dominated case.

As previously pointed out, when advection dominated problems are considered, stabilization techniques are required. This means that the bilinear form $\widehat{a}_f(\cdot, \cdot)$ introduced in (3.2) is substituted by

$$\widehat{a}_{f,stab}(C_f, \phi_f) = \widehat{a}_f(C_f, \phi_f) + a_{f,h}(C_f, \phi_f), \tag{4.10}$$

where $a_{f,h}(C_f, \phi_f)$ depends on the specific stabilization method. For instance (see, e.g., [12]), if we set

$$L_s C = -\nabla \cdot \mu_f \nabla C, \quad L_{ss} C = \frac{1}{2} \nabla \cdot \mathbf{u} C + \frac{1}{2} \mathbf{u} \cdot \nabla C \quad (L_f = L_s + L_{ss}),$$

Table 4.1

Comparison of the number of iterations to reach convergence. In all these tests we have taken $\Omega_f = (0,4)\times(0,1)$, $\Omega_w = (0,4)\times(-1,0)$, $u_x = 4u_0(1-y)y$, $u_y = 0$. (A) $\mu_f = \mu_w = 1.0\ cm^2s^{-1}$, *and* $\zeta = 1.0\ cm\ s^{-1}$. *(Values* * *refer to the pure Galerkin method, the other to the stabilized SUPG method.)* (B) $\mu_f = \mu_w = 10^{-3}cm^2s^{-1}$ *and* $\zeta = 1.0\ cm\ s^{-1}$. *Finer grids are obtained by means of a uniform refinement plus regularization; thus* $N = \mathcal{O}(h^{-2})$. *For large values of* ζ *the coupled problem is severely ill-conditioned, yet the number of iterations is uniformly independent of* h.

the symmetric and the skew-symmetric parts of the fluid differential operator L_f, respectively, then the most common strongly consistent stabilization methods resort to set

$$a_{f,h}\left(C_f,\phi_f\right) = \sum_{K\in\mathcal{T}_h} \delta\left(LC_f, \frac{h_K}{|\mathbf{u}|}\left(L_{ss}+\kappa L_s\right)\phi_f\right)_K,$$

where K is the generic element of the triangulation $\mathcal{T}_h$ (supposed to be regular) with diameter h_K, $(\cdot,\cdot)_K$ denotes the $L^2(K)$ scalar product, δ is a parameter to be chosen, and κ identifies the different stabilization techniques. In particular, SUPG corresponds to set $\kappa = 0$, while the Galerkin least squares (GaLS) method is given for $\kappa = 1$. The Douglas–Wang (DW) method, on the other hand, corresponds to $\kappa = -1$. For the SUPG method, we recall that if δ is suitably chosen, it is possible to prove that the stabilized bilinear form $\widehat{a}_{f,stab}(\cdot,\cdot)$ is coercive, the constant of coercivity being independent of h (see [12, Proposition 8.4.1]). A similar result holds for the DW and for the GaLS methods. In the latter case, the coercivity holds for any positive δ.

Starting form these results, we are able to prove that the convergence rate of the iterative subdomains method proposed is independent of h even in the stabilized case. First of all, the problem we consider in this case, in terms of SP operators can be formulated in a way completely similar to the one proposed in the previous section, provided that $\widehat{\mathcal{S}}_{hf}$ defined in (3.17) and (3.18) is substituted by

$$\langle\widehat{\mathcal{S}}_{hf,stab}\rho,\lambda\rangle = -\left(\rho,\lambda\right)_\zeta + \widehat{a}_{f,stab}\left(u_f,\mathcal{L}_f\lambda\right), \tag{4.11}$$

with

$$u_f \in V_{hf} : \widehat{a}_{f,stab}\left(u_f,\phi_f\right) + \left(u_f,\phi_f\right)_\zeta = \left(\rho,\phi_f\right)_\zeta \quad \forall\phi_f\in V_{hf}. \tag{4.12}$$

The crucial point is to prove that the stabilized SP operator $\widehat{\mathcal{S}}_{hf,h}$ is also continuous with a continuity constant independent of h. Actually, observe that by definition

$$\langle\widehat{\mathcal{S}}_{hf,stab}\rho,\lambda\rangle = \left(u_f,\lambda\right)_\zeta.$$

From (4.12) for $\phi_f = u_f$, we deduce that

$$\| \gamma_f u_f \|_\Lambda \leq \beta \| \rho \|_\Lambda,$$

where β is a constant obtained as a function of the trace and coercivity constants and therefore independent of h. The continuity constant of $\widehat{\mathcal{S}}_{hf,stab}$ is thus independent of h. Consequently, the extension of Proposition 3.1 to the stabilized case is straightforward. We therefore conclude that Theorem 4.1 can be applied as well in the stabilized case, again having independence of the convergence rate and the optimal value of θ on h.

4.2. Algebraic reinterpretation of the iterative scheme. The coupled Problem 3.2 requires at each time step the solution of a system in the form

$$A\mathbf{c} = \mathbf{b}. \tag{4.13}$$

Denoted by N_Γ the degrees of freedom associated with the interface Γ, the number of degrees of freedom associated with the inner nodes in Ω_w is given by $N_{w0} = N_w - N_\Gamma$. Consequently, in (4.13), $\mathbf{c} = [\mathbf{c}_f, \mathbf{c}_w, \mathbf{c}_\Gamma]^T \in \mathbb{R}^{N_f+N_w}$ is the vector of unknowns specifying the discrete solution, with $\mathbf{c}_f \in \mathbb{R}^{N_f}$, $\mathbf{c}_w \in \mathbb{R}^{N_{w0}}$, $\mathbf{c}_\Gamma \in \mathbb{R}^{N_\Gamma}$. $\mathbf{b} \in \mathbb{R}^{N_f+N_w}$ is a function of the forcing terms, the boundary conditions, and the solution computed at the previous steps and can be correspondingly split as $\mathbf{b} = [\mathbf{b}_f, \mathbf{b}_w, \mathbf{b}_\Gamma]^T$, $\mathbf{b}_f \in \mathbb{R}^{N_f}$, $\mathbf{b}_w \in \mathbb{R}^{N_{w0}}$, $\mathbf{b}_\Gamma \in \mathbb{R}^{N_\Gamma}$. Finally, $A \in \mathbb{R}^{(N_f+N_w)\times(N_f+N_w)}$ has the following blockwise pattern:

$$A = \begin{bmatrix} A_{ff} & \mathbf{0} & A_{f\Gamma} \\ \mathbf{0} & A_{ww} & A_{w\Gamma} \\ A_{\Gamma f} & A_{\Gamma w} & A_{\Gamma\Gamma} \end{bmatrix}, \tag{4.14}$$

where A_{ff} is the $N_f \times N_f$ matrix associated with the discretization of the bilinear form $\widehat{a}_f(\psi_f, \phi_f) + (\psi_f, \phi_f)_\zeta$ for $\psi_f, \phi_f \in V_{hf}$. Correspondingly, $A_{f\Gamma}$ arises from the discretization of the term $-(\lambda, \phi_f)_\zeta$ (with $\lambda \in \Lambda_h$), while A_{ww} is associated with the discretization of $\widehat{a}_w(\psi_{w0}, \phi_{w0})$ for $\psi_{w0}, \phi_{w0} \in V_{hw,0}$ (functions with null trace on Γ) and $A_{w\Gamma}$ refers to the discretization of $\widehat{a}_w(\mathcal{L}_w\lambda, \phi_{w0})$ for $\lambda \in \Lambda_h$. $A_{\Gamma\Gamma}$ is related to the discretization of $\widehat{a}_w(\mathcal{L}_w\lambda, \mathcal{L}_w\rho) + (\lambda, \rho)_\zeta$ for $\lambda, \rho \in \Lambda_h$. Finally, we note that $A_{\Gamma f} = A_{f\Gamma}^T$ and $A_{\Gamma w} = A_{w\Gamma}^T$ and A_{ww} and $A_{\Gamma\Gamma}$ are symmetric.

The algebraic reinterpretation of the Robin–Robin iterative scheme readily follows. Our substructuring iterative method resorts to a preconditioned Richardson scheme for (4.13),

$$Q(\mathbf{c}_{k+1} - \mathbf{c}_k) = \theta(\mathbf{b} - A\mathbf{c}_k) = \theta\mathbf{r}_k, \qquad k \geq 0, \tag{4.15}$$

in which the matrix

$$Q = \begin{bmatrix} A_{ff} & 0 & 0 \\ 0 & A_{ww} & A_{w\Gamma} \\ A_{\Gamma f} & A_{\Gamma w} & A_{\Gamma\Gamma} \end{bmatrix} \tag{4.16}$$

is the preconditioner.

If we formally eliminate $\mathbf{c}_f$ and $\mathbf{c}_w$ in (4.13), we obtain the reduced system

$$\Sigma \mathbf{c}_\Gamma = \boldsymbol{\eta} \tag{4.17}$$

with $\boldsymbol{\eta} = \mathbf{b}_\Gamma - A_{\Gamma f}A_{ff}^{-1}\mathbf{b}_f - A_{\Gamma w}A_{ww}^{-1}\mathbf{b}_w$ and $\Sigma = A_{\Gamma\Gamma} - A_{\Gamma w}A_{ww}^{-1}A_{w\Gamma} - A_{\Gamma f}A_{ff}^{-1}A_{f\Gamma}$. Consequently, we obtain the splitting $\Sigma = \Sigma_w + \Sigma_f$, where $\Sigma_w = A_{\Gamma\Gamma} - A_{\Gamma w}A_{ww}^{-1}A_{w\Gamma}$, $\Sigma_f = A_{\Gamma f}A_{ff}^{-1}A_{f\Gamma}$. Matrix Σ is the *Schur complement* of matrix A. Equation (4.17) represents the finite-dimensional counterpart of (3.19), and Σ is the algebraic counterpart of the SP operator $\widehat{\mathcal{S}}_h$, while Σ_f and Σ_w play the role of $\widehat{\mathcal{S}}_{hf}$ and $\widehat{\mathcal{S}}_{hw}$, respectively.

By means of the block *LU* factorization of A, we can explicitly compute the iteration matrix associated with the following iterative scheme:

$$I - \theta Q^{-1}A = \begin{bmatrix} (1-\theta)I_f & 0 & -\theta A_{ff}^{-1}A_{f\Gamma} \\ 0 & (1-\theta)I_w & -\theta A_{ww}^{-1}A_{w\Gamma}\Sigma_w^{-1}A_{\Gamma f}A_{ff}^{-1}A_{f\Gamma} \\ 0 & 0 & I - \theta\Sigma_w^{-1}\Sigma \end{bmatrix}.$$

In particular, on the third block the system (4.15) yields

$$\Sigma_w\left(\mathbf{c}_{\Gamma,k+1} - \mathbf{c}_{\Gamma,k}\right) = \theta\left(\boldsymbol{\eta} - \Sigma\mathbf{c}_{\Gamma,k}\right). \tag{4.18}$$

The latter relation enlightens the role of the matrix Σ_w as a preconditioner for the Schur complement in the interface problem (4.17). As the algebraic counterpart of the operator $\widehat{\mathcal{S}}_{hw}$, Σ_w is symmetric and positive definite.

From this perspective, we can reformulate Proposition 4.1 in the following manner.

PROPOSITION 4.2. *The preconditioned Richardson scheme* (4.15) *converges for any θ belonging to a suitable interval* $(0, \theta_{max})$. *The preconditioner Q given in* (4.16) *is optimal, making the rate of convergence independent of the space discretization.*

4.3. Acceleration strategies. The reinterpretation of the Robin–Robin scheme based on the Richardson framework has the advantage of highlighting that Σ_w is an optimal preconditioner for Σ. (As well, Q is an optimal preconditioner for A.) On this ground, we will take advantage of these preconditioners when more efficient iterative procedures will be applied. We will start analyzing the effects of the static relaxation parameter in the Richardson framework, and then we will consider dynamical strategies such as GMRES (see [16]).

Stationary Richardson methods. In order to compare the unrelaxed and the relaxed schemes, observe that the behavior of the iteration matrix $I - \theta Q^{-1}A$ is governed by the third diagonal block $I - \theta\Sigma_w^{-1}\Sigma$. In our case, Σ_w and Σ are positive definite, but Σ is not symmetric since A_{ff} is not symmetric (due to the convection term). Therefore we cannot assert a priori that $\Sigma_w^{-1}\Sigma$ has real positive eigenvalues; thus, an optimal static choice of θ is not straightforward (see, e.g., [9]). However, as a heuristic choice, parameter θ is selected assuming that Σ is symmetric, setting

$$\theta = \frac{2}{\lambda_{\min} + \lambda_{\max}},$$

where $\sigma = \{\lambda_i\}$ $i = 1, \dots, N_\Gamma$ is the spectrum of $\Sigma_w^{-1}\Sigma$, for which a rough estimate can be obtained as follows. We observe that since $I - \Sigma_w^{-1}\Sigma = -\Sigma_w^{-1}\Sigma_f$, the iteration matrix associated with (4.18), in the unrelaxed case, and since $\tau = \{\mu_i\}$ (for $i = 1, \dots, N_\Gamma$) is its spectrum, the following inequalities hold:

$$\lambda_i = 1 - \mu_i \text{ and } \mu_i \leq \|-\Sigma_w^{-1}\Sigma_f\|_p \quad \forall i = 1, \dots, N_\Gamma \quad \forall p > 0, \tag{4.19}$$

$$M_p := \frac{\| \mathbf{c}_\Gamma^k - \mathbf{c}_\Gamma^{k-1} \|_p}{\| \mathbf{c}_\Gamma^{k-1} - \mathbf{c}_\Gamma^{k-2} \|_p} \leq \|-\Sigma_w^{-1}\Sigma_f\|_p. \tag{4.20}$$

Consequently, making the approximation, $M_p \simeq \|-\Sigma_w^{-1}\Sigma_f\|_p$, and noticing that $\lambda_{\min} + \lambda_{\max} = 2 - \mu_{\max} - \mu_{\min}$ we make the following choice: $\theta \simeq \frac{2}{2-M_p}$.

Table 4.1 resumes the comparison of these methods for a diffusion dominated case (A) and an advection dominated one (B). From these results we see that, when the global matrix A is ill-conditioned, the relaxation technique enhances the convergence performances with respect to the unrelaxed case.

Dynamical choice of θ. In this approach the choice of θ is pursued automatically by the chosen algorithm.

Recalling that the matrix A is positive definite but not symmetric, we consider, for instance, the preconditioned generalized minimal residual (P-GMRES) method (see, for example, [12], [16]), where Q is the preconditioner for the global system $A\mathbf{c} = \mathbf{b}$. As we have already pointed out in Remark 4.1, Q being the optimal preconditioner derived from the previous analysis, the convergence rate of the P-GMRES algorithm is independent of the number of degrees of freedom of the global system $A\mathbf{c} = \mathbf{b}$. Table 4.1 shows that the P-GMRES method performs better than the stationary strategies for both test cases.

Finally, we point out that for these tests the coefficients μ_f, μ_w, ζ have been chosen with the purpose of making the matrix A very ill-conditioned; this explains the different performance of the considered iterative methods. However, when μ_f, μ_w, ζ are chosen in the biological range for the specific application at hand, the condition number of A is lower; thus the number of iterations necessary to reach convergence is smaller for each one of the considered methods. On the other hand, for the bioengineering applications, a very large number of unknowns is required; consequently, most of the computational time is spent for solving the subsystems $Q\mathbf{z} = \mathbf{r}$ deriving from the preconditioning step. This explains why we have based the choice of an efficient iterative method not only on the number of iterations but also on the computational cost of each single iteration. In particular, a reduction of the time necessary to pursue each iteration is, for example, obtained by resorting to *flexible preconditioned iterative solvers* (see [16]). Among all the iterative methods considered above, the only one that allows a flexible variant is the P-GMRES. Let us briefly introduce it.

In the framework of descent methods, the computation of the descent direction $\mathbf{z}$ is carried out by solving a system $Q\mathbf{z} = \mathbf{r}$ ($\mathbf{r}$ being the residual) which in our case, from definition (4.16), requires the solution of two subsystems:

$$A_{ff}\mathbf{z}_f = \mathbf{r}_f, \tag{4.21}$$

$$\begin{bmatrix} A_{ww} & A_{w\Gamma} \\ A_{\Gamma w} & A_{\Gamma\Gamma} \end{bmatrix} \begin{bmatrix} \mathbf{z}_w \\ \mathbf{z}_\Gamma \end{bmatrix} = \begin{bmatrix} \mathbf{r}_w \\ \mathbf{r}_\Gamma \end{bmatrix} - \begin{bmatrix} 0 \\ A_{\Gamma f}\mathbf{r}_f \end{bmatrix}, \tag{4.22}$$

which can be carried out by means of iterative methods such as BiCGStab or GMRES. The end of this flexible strategy is to compute the global solution $A\mathbf{c} = \mathbf{b}$ by solving (4.21) and (4.22) with a large tolerance, reducing henceforth the computational cost of the solution process. This can be done through the algorithm described below. Let us define with $\hat{Q}_j^{-1}$ $j = 1, 2, 3, \ldots$ an approximation of Q^{-1} (obtained in our case by a low cost solution of (4.21), (4.22)) then the flexible P-GMRES (F-P-GMRES) algorithm reads (see [16]) as follows.

Table 4.2

Quantitative comparison between P-GMRES and F-P-GMRES for different test cases. This example shows that the F-P-GMRES method and the proposed choice of q work well for different geometries, discretized with different triangulations sharing, however, a comparable number of nodes. Note that the tolerance of the outer iterative procedure is always the same (equal to 10^{-10}).

	P-GMRES ($p = 10$)	F-P-GMRES ($p = 10, q = 5$)

Algorithm 4.1. *F-P-GMRES.*

```
Compute $\mathbf{z}_0 = \hat{Q}_0^{-1}(\mathbf{b} - A\mathbf{x}_0)$, $\beta = \|\mathbf{z}_0\|_2$, $\mathbf{v}_1 = \mathbf{r}_0/\beta$.
For $j = 1, \dots, m$ Do:
    compute $\mathbf{w} = A\mathbf{v}_j$,
    compute $\mathbf{z}_j = \hat{Q}_j^{-1}\mathbf{w}$.
    For $i = 1, \dots, j$ Do:
        $h_{i,j} = (\mathbf{w}, \mathbf{v}_i)$,
        $\mathbf{w} = \mathbf{w} - h_{i,j}\mathbf{v}_i$,
    End Do.
    Compute $h_{j+1,j} = \|\mathbf{w}\|_2$ and $\mathbf{v}_{j+1} = \mathbf{w}/h_{j+1,j}$.
    Define $Z_m = [\mathbf{z}_1, \dots, \mathbf{z}_m]$, $H_m = \{h_{i,j}\}_{1 \le i \le j+1; 1 \le j \le m}$.
End Do.
Compute $\mathbf{y}_m = argmin_y \|\beta\mathbf{e}_1 - H_m\mathbf{y}\|_2$, and $\mathbf{x}_m = \mathbf{x}_0 + Z_m\mathbf{y}_m$.
If $\|\hat{Q}_m^{-1}(\mathbf{b} - A\mathbf{x}_m)\|_2 < tol = 10^{-p}$ $p \in N$ then end, else $\mathbf{x}_0 \leftarrow \mathbf{x}_m$.
```

A possible strategy to choose $\hat{Q}_j^{-1}$ at each iteration is as follows. Should 10^{-p} be the tolerance fixed in Algorithm 4.1, the tolerance of the iterative method applied to solve systems (4.21), (4.22) is set to 10^{-q}, with $q = [p/2]$.

For the application at hand, by adopting this strategy one obtains that F-P-GMRES requires less CPU time to converge than P-GMRES (see Table 4.2).

As shown in Table 4.2, the application of the F-P-GMRES method (always based on the preconditioner provided by $\widehat{\mathcal{S}}_{hw}$) is very efficient. Comparing it with GMRES we see in fact that, although we have reduced the tolerance of the preconditioning step, consequently reducing the efficiency of the preconditioner, the number of global iterations does not increase. Thus the reduction in the computational cost at each iteration directly provides a reduction in the time needed to solve $A\mathbf{c} = \mathbf{b}$. Moreover, Table 4.2 shows that the considered algorithms behave well in the case of different geometries. In particular, we have considered test cases that are relevant for hemodynamics, the stenosed artery, and the carotid bifurcation.

5. Numerical results in case of physiological interest.

In the present section we show some numerical results about blood and oxygen dynamics in the carotid bifurcation, a site of relevant interest in biomedical applications. We point out that our main concern is to test the efficiency of the proposed iterative method and not to give significant results from a quantitative point of view. For this reason, the model

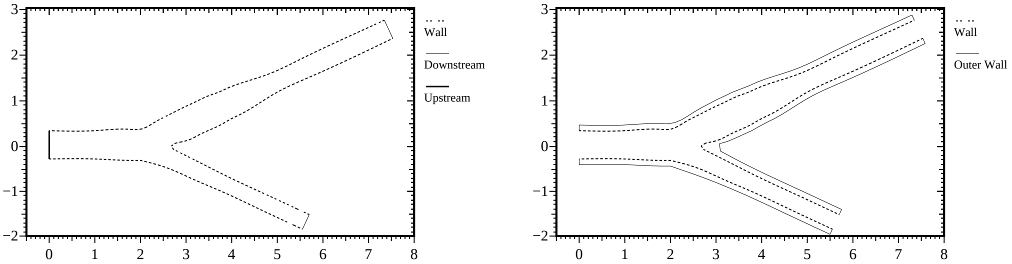

FIG. 5.1. *A 2D model for the lumen (right) and the wall (left) of a carotid bifurcation. The dashed line represents the fluid-wall interface, the thick solid line represents the inflow of the lumen, while the thin solid line represents the outflow of the lumen or the outer surface of the arterial wall.*

and the geometry are simplified (and in particular we deal with a 2D geometry obtained from data proposed in [7]), even if we include realistic numerical values for the physical constants at hand. In a forthcoming paper, on the basis of the good results illustrated in what follows, we plan to extend the methodology to more complex models and 3D geometries.

In the present section, as a realistic example, we apply our iterative substructuring method to the case of a carotid bifurcation, which is a preferential site of atherosclerosis, specifically in the external side of the carotid sinus. A current hypothesis about the possible reasons of this prominence to disease development is related to a reduction in the oxygen absorption by the sinus arterial wall, induced by the local flow patterns (see, e.g., [15]).

For the carotid test case we have considered stationary and pulsatile flow conditions. The selection of the boundary data is based on those proposed in [7]. In the stationary case, a parabolic profile is imposed on the upstream section, $u_x = ku_{\max}(R^2 - y^2)$, $u_y = 0$ where $k = 10.4$, $u_{\max} = 10$ cm s^{-1}, $R = 0.31$ cm, while null velocity, $\mathbf{u} = 0$, is prescribed on the wall boundary and zero traction force is prescribed on the outflow section, $(\rho\nu\nabla\mathbf{u} - PI)\cdot\mathbf{n} = 0$ (see Figure 5.1 for a description of the boundaries $\partial\Omega_f$ and $\partial\Omega_w$). The pulsatile case differs from the stationary one for the inflow conditions, $u_x = kg(t)(R^2 - y^2)$, $u_y = 0$, where $g(t)$, represented in Figure 5.2, describes the blood flow at the entrance of the carotid during a heartbeat. In both cases, a constant blood kinematic viscosity $\nu = 0.033$ cm^2 s^{-1} has been chosen.

With regard to the concentration in the lumen, a reference concentration of oxygen, $C_0 = 0.04$ g cm^{-3}, has been prescribed on the inflow, condition (2.2_3) has been prescribed on the wall boundary, and $\nabla C \cdot \mathbf{n} = 0$ has been prescribed on the outflow boundary. This condition is also prescribed on the outer wall in Ω_w. The oxygen dynamics have been simulated choosing the diffusivity $\mu_f = \mu_w = 10^{-5}$cm^2 s^{-1}, and $\zeta = 10^{-4}(1+|\boldsymbol{\sigma}|)$ cm s^{-1}, where $\boldsymbol{\sigma}$ is the shear stress exerted by the blood on the wall. From the numerical viewpoint, we consider Ω_f discretized with 20494 nodes and Ω_w discretized with 15030 nodes (see Figure 5.3). With regard to boundary conditions, Dirichlet ones are imposed in an essential way, while Neumann and Robin conditions are imposed in a natural way, as is customary in the framework of Galerkin discretization and, in particular, in the framework of the FEM; see [12]. Finally, the numerical method adopted ensures a first order accuracy in time, being based on an implicit Euler scheme. The finite elements adopted are piecewise linear. The Navier–Stokes solver is based on the so-called Yosida method (see [10]) on $\mathbb{P}^1 iso\mathbb{P}^2$ elements.

Concerning the numerical results, the velocity field in the bifurcation shows a recirculation zone (see Figures 5.3 and 5.4) both in the steady and pulsatile cases.

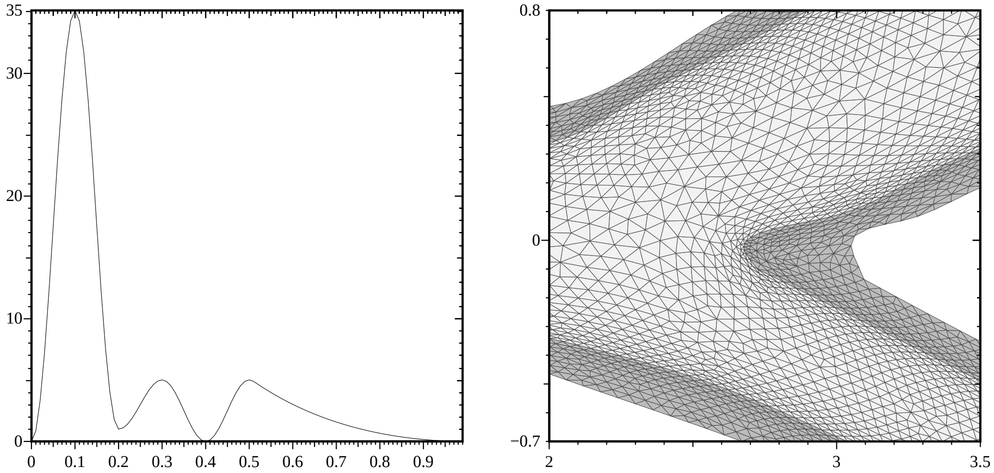

FIG. 5.2. *Maximum inflow velocity (cm/s) during a heartbeat (left) and computational grid for the 2D carotid simulation (right).*

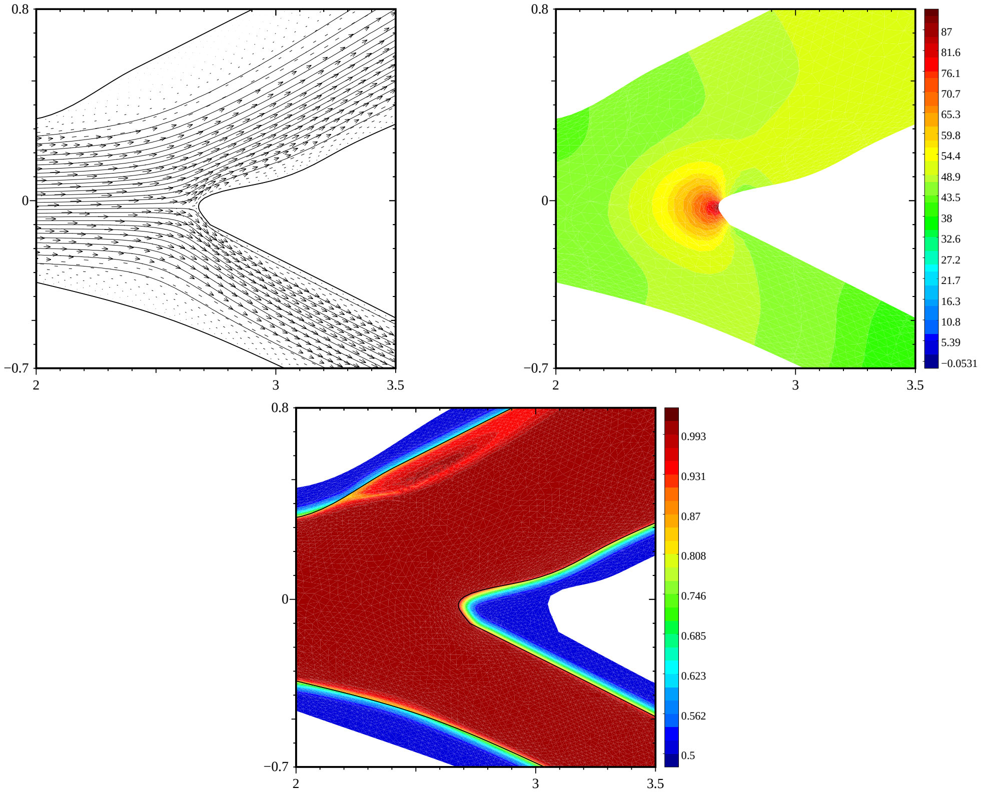

FIG. 5.3. *Velocity field (top-left), pressure field $(P - P_{ext})$ (top-right), and oxygen concentration (bottom) in the carotid bifurcation in the steady case.*

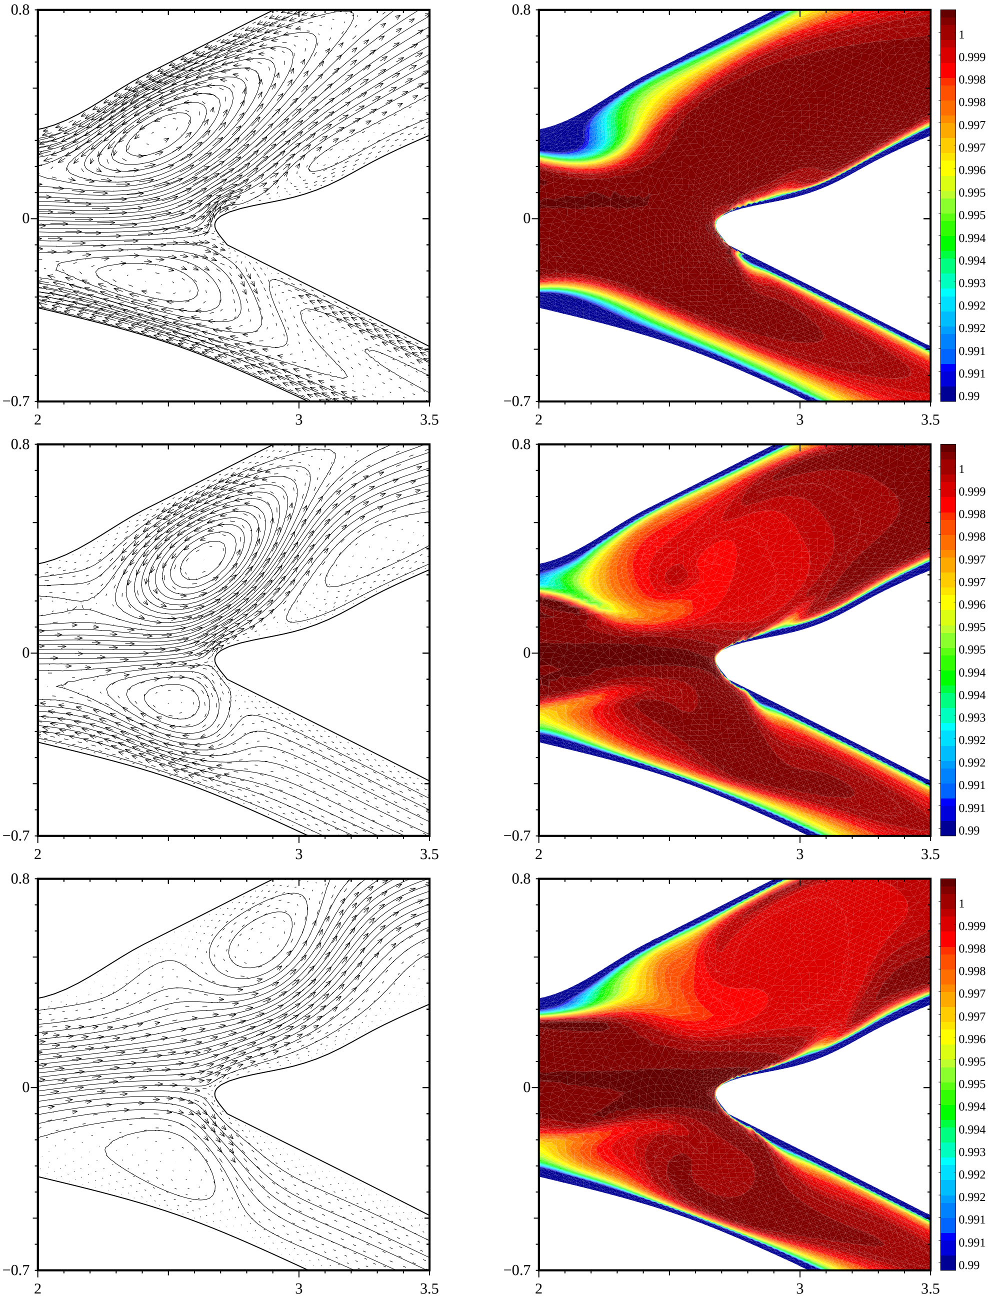

FIG. 5.4. *Blood velocity and oxygen concentration in the carotid bifurcation in the pulsatile case at* 1/5, 2/5, 3/5 *of a heartbeat. In this case only the concentration in* Ω_f *is visualized. The recirculation zone which possibly inhibits the oxygen absorption is evident in the different instants of the heartbeat.*

The presence of recirculations induces in the steady case a sensibly lower oxygen concentration in proximity of the sinus wall and, consequently, the reduction of the oxygen absorption by the wall, which could be related to the disease development.

In the pulsatile case the flow pattern is more complex: a recirculation zone, moving upstream and downstream (yielding a lack of oxygen), is still present next to the external side of the (inner) carotid sinus. In this case, the oxygen absorption is further reduced by the low permeability induced by the small values of $|\boldsymbol{\sigma}|$. Indeed, the flow dynamics in the carotid sinus induce small and oscillating shear stresses which actually determine a permeability reduction according to the law $\zeta = 10^{-4}(1 + |\boldsymbol{\sigma}|)$ cm s^{-1} (see also [18]).

6. Conclusions. In this paper we analyzed from the numerical viewpoint the solution of problem (2.2). The multidomain and the heterogeneous nature of this problem induced us to rely on iterative methods to compute the global solution. Consequently, in the framework of iterative substructuring methods, we introduced special SP operators in order to take into account conditions (2.2_3, 2.2_4). The analysis of the properties of these operators allowed us to apply domain decomposition theory in order to prove the convergence of the iterative methods adopted to solve problem (2.2). Additionally, we proved that the mesh size does not affect the rate of convergence of the methods. Finally the problem of reducing the computational time was taken into account. To this end, we considered a variant of the GMRES algorithm, the so called F-P-GMRES, and we verified, with numerical tests, that this method is particularly efficient in solving the problems arising from the blood solute dynamics. The simplified test case considered, namely the carotid bifurcation, has been discussed from both the numerical and the physiological point of view.

CONVERGENCE OF NONCONVERGENT IRK DISCRETIZATIONS OF OPTIMAL CONTROL PROBLEMS WITH STATE INEQUALITY CONSTRAINTS[*]

J. T. BETTS[†], N. BIEHN[‡], AND S. L. CAMPBELL[§]

Abstract. It has been observed that optimization codes are sometimes able to solve inequality state constrained optimal control problems with discretizations which do not converge when used as integrators on the constrained dynamics. Understanding this phenomenon could lead to a more robust design for direct transcription codes as well as better test problems. This paper examines how this phenomenon can occur. The difference between solving index 3 differential algebraic equations (DAEs) using the trapezoid method in the context of direct transcription for optimal control problems and a straightforward implicit Runge–Kutta (IRK) formulation of the same trapezoidal discretization is analyzed. It is shown through numerical experience and theory that the two can differ as much as $O(1/h^3)$ in the control. The optimization can use a small sacrifice in the accuracy of the states in the early stages of the trapezoidal method to produce better accuracy in the control, whereas more precise solutions converge to an incorrect solution. Convergence independent of the index of the constraints is then proven for one class of problems. The theoretical results are used to explain computational observations.

1. Introduction.

Many optimal control problems contain inequality path constraints on the states and/or controls. Along the constraints, the resulting system becomes a differential algebraic equation (DAE) even if the original dynamics were an ordinary differential equation (ODE). Depending on which set of variables are constrained, a low or high index DAE results. For more on DAEs and their indices, see [7]. It has been observed that optimization codes are sometimes able to solve state constrained optimal control problems with discretizations which do not converge when used as an integrator on the constrained dynamics. Understanding this phenomenon could lead to a more robust design for direct transcription codes as well as better test problems.

This paper studies the differences between solving index 3 differential algebraic equations using the trapezoid (TR) method, which arise because of inequality constraints in the direct transcription of optimal control problems versus a straightforward implementation of the implicit Runge–Kutta (IRK) formulation of the trapezoid rule. The index 3 case is studied because it often occurs in applications and also because the behavior of interest here is already present [6].

The direct transcription software SOCS (Sparse Optimal Control Software) developed by Boeing [1, 2, 3, 5] is used throughout the paper. The results obtained

here are relevant to other direct transcription algorithms with similar strategies. In particular, SOCS passes the discretized problem directly to the nonlinear program (NLP) solver and does not first integrate the dynamics to reduce the dimension of the problem. We shall see that this difference is not just a question of whether to solve a larger sparse problem versus a smaller dense problem, as it is often portrayed. Rather this difference also alters questions of convergence in a fundamental way. The discretization formulas normally used by SOCS are mathematically equivalent to the Lobatto IIIA formulas TR and Hermite–Simpson (HS). These methods are symmetric, stiffly stable, and produce desirable sparsity patterns in the Jacobians of the defect constraints in the associated NLP. They are implemented as collocation methods in SOCS. However, neither of these methods converges when applied as an integrator to an index 3 DAE [6]. This paper is concerned primarily with TR. Computational experience and a more technical analysis show the same phenomenon occurring when using HS.

There are other discretizations that one might consider besides TR and HS. However, switching the discretization in an industrial-grade sparse code like SOCS is a nontrivial task since efficiency requires that the Jacobians have their sparsity structure explicitly exploited. Also, other choices which are not collocation methods lead to other difficulties. Given that the current discretizations work so well on such a large variety of problems, it is important to determine the classes of problems on which they can be used.

The TR method implemented as an IRK converges for DAEs of index 0, 1, and 2. For problems with an index greater than 2, simple examples can be constructed for which the trapezoid method converges to an incorrect solution [6]. Numerical experience has shown that when used in SOCS, TR can converge to the true optimal solution, while the straightforward IRK formulation does not [6]. In fact, we have observed TR working on index 4, 5, and, in the case of boundary controlled PDEs, on even higher index problems. There are two questions to be resolved. One is how SOCS is able to converge. That is, what makes convergence possible? The second is why SOCS converges. There has been prior research on the convergence of discretizations of optimization problems. We cite here only [9, 10, 13]. Additional references are in section 5. Previous work on the state constrained problem always assumes that the discretization converges on a problem with the constraint holding identically. This type of analysis does not apply to the particular phenomena we are investigating here. Also, as noted later, analysis which uses convergence of the discrete multipliers is also not appropriate.

In the next section we give the formulation of the optimal control problem and the associated DAE along the constraint. Section 3 sets up and proves the first main theorem of the paper which theoretically predicts the difference between the direct transcription and IRK solutions. Numerical experiments and discussion are given in section 4. A greatly condensed version of this first portion of this paper with less discussion and no proofs appears in [4]. Section 5 develops the convergence of the TR discretization when index 3 state constraints are active.

In order to avoid confusion between the different uses of TR we shall use SOCS TR for the SOCS solution using the TR discretization and IRK TR for the TR solution implemented as an IRK when constraints are active.

Finally, there is an application motivating our investigations which is the optimization of tool paths. In these problems, complexity and problem size sometimes forces the termination of the iterations in SOCS at coarser meshes than those required for termination according to the termination criteria. For this reason we are very interested not only in behavior on sufficiently fine meshes but also on "coarser" meshes. Also, in some problems highly accurate constraint satisfaction is important. For these problems the SOCS philosophy of satisfying all constraints on every mesh level and at every mesh point is important. This should be contrasted with methods which only impose constraints at some mesh points or asymptotically.

2. The control problem.

As noted in [4, 6] convergence of the optimizer in the presence of high index constraints occurs already with linear problems. For our purposes here it suffices to consider optimal control problems with an objective function,

$$\int_{t_0}^{t_f} L(y,u,t)\,dt \tag{1a}$$

with state equations

$$y'(t) = f(y(t),u(t),t) \tag{1b}$$

and inequality constraints

$$g(y(t),u(t),t) \geq g_L, \tag{1c}$$

$$y(t_0) = y_0. \tag{1d}$$

In SOCS the continuous optimal control problem is transcribed to a finite-dimensional NLP. Let $y(t_k) = y_k$ and $u(t_k) = u_k$ where $T_N = \{t_i\}_0^N$ with $t_0 < \cdots < t_N = t_f$. Then

$$x = [y_0^T, u_0^T, y_1^T, u_1^T, \ldots, y_N^T, u_N^T]^T \tag{2}$$

are the NLP variables with $N+1$ mesh points. Using TR, we approximate (1b) using the defect constraints

$$0 = y_k - y_{k-1} - \frac{h_k}{2}(f(y_k,u_k,t_k) + f(y_{k-1},u_{k-1},t_{k-1})), \qquad 1 \leq k \leq N, \tag{3}$$

with $h_k = t_k - t_{k-1}$. The objective function (1a) is approximated using a trapezoidal quadrature. The NLP is solved using a sparse sequential quadratic programming (SQP) algorithm whose solution is a discrete approximation to the continuous optimal control problem [3]. A sophisticated mesh refinement algorithm then refines the mesh for the next iteration [5].

Consider the following optimal control problem from [6]. SOCS correctly finds the solution.

$$\min_u \int_0^4 x^2(t) + 10^{-3}u^2(t)\,dt, \tag{4a}$$

$$x' = v, \tag{4b}$$

$$v' = u, \tag{4c}$$

$$0 \leq x - 15 + (t-4)^4, \tag{4d}$$

$$x(0) = 5, \ v(0) = 0. \tag{4e}$$

The constraint (4d) is active on an interval including $\left[\frac{34}{15},\ 4\right]$. Since all variables are determined once the constraint is active, we examine the following index 3 DAE in

(x, v, u) on $[t_0, t_f] = \left[\frac{34}{15},\ 4\right]$:

$$x' = v, \tag{5a}$$

$$v' = u, \tag{5b}$$

$$x = 15 - (t-4)^4, \tag{5c}$$

$$x(t_0) = 15 - (t_0 - 4)^4, \tag{5d}$$

$$v(t_0) = -4(t_0 - 4)^3, \tag{5e}$$

$$u(t_0) = -12(t_0 - 4)^2. \tag{5f}$$

One can also attempt to numerically solve (5) using the TR directly on the DAE. Figures 1 and 2 give plots of the u obtained by each of the methods with $N = 10$.

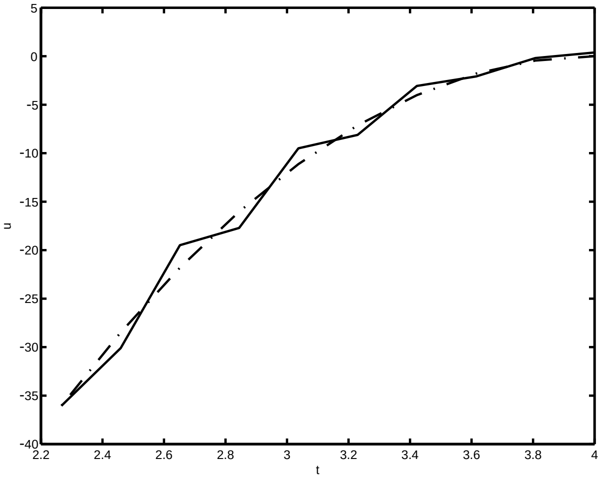

FIG. 1. *Control given by SOCS TR and the true solution.*

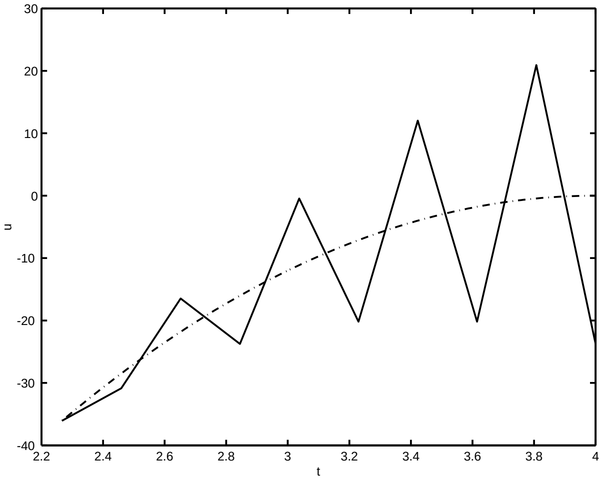

FIG. 2. *Control given by IRK TR and the true solution.*

The SOCS solution approximates the true solution while applying TR directly to the DAE (5) does not. This behavior persists at larger N. A rigorous understanding of how these two methods which appear to be mathematically equivalent can differ by so much is the goal of this paper.

3. Analysis of an index 3 system.

3.1. Background and perturbation theorem. Since the numerical solutions for the control were differing by large amounts, there must be a fundamental difference between using TR directly on the DAE and in a direct transcription formulation. The NLP solution is known to satisfy the given constraints up to a tolerance which is much looser than the accuracy to which the IRK equations are usually solved. It was suggested in [6] that this NLP "slop" provides one possible explanation for the large differences in the computed control between IRK TR and SOCS TR. We will see that the "slop conjecture" can account for computational observations on fine meshes when SOCS is close to convergence but cannot explain what is observed on coarser meshes. A careful analysis of an index 3 problem proves enlightening.

Consider the following state equations with constraints:

$$x' = Ax + Bu, \tag{6a}$$

$$0 \le Cx - \widehat{g}(t), \tag{6b}$$

where A is $m \times m$, B is $m \times q$, C is $r \times m$, and $\widehat{g}(t)$ is $r \times 1$. Suppose that the optimal solution pushes the state x onto the constraint (6b) over an interval $[a, b]$. This gives us a DAE (6) in (x, u) along this interval. Let's first formulate the DAE and then discretize the DAE using TR.

The resulting DAE system can be written as

$$Ey' = \widehat{A}y - g(t) \tag{7}$$

with

$$E = \begin{bmatrix} I_m & 0 \\ 0 & 0 \end{bmatrix}, \quad \widehat{A} = \begin{bmatrix} A & B \\ C & 0 \end{bmatrix}, \quad g(t) = \begin{bmatrix} 0 \\ \widehat{g}(t) \end{bmatrix}, \quad y = \begin{bmatrix} x \\ u \end{bmatrix}.$$

Then TR for (7) implemented as an IRK is

$$EY_1' - \widehat{A}y_{n-1} = -g(t_{n-1}), \tag{8a}$$

$$EY_2' - \widehat{A}y_{n-1} - \frac{h}{2}\widehat{A}(Y_1' + Y_2') = -g(t_n), \tag{8b}$$

$$y_n = y_{n-1} + \frac{h}{2}(Y_1' + Y_2'), \tag{8c}$$

where the Y_i' are the stage derivatives for $i = 1, 2$. In this section we will assume h is constant since that suffices for examining how convergence is possible. h will be allowed to vary in subsequent sections. Exploiting the special structure of E we let $Y_i' = [\begin{smallmatrix} X_i' \\ U_i' \end{smallmatrix}]$, $i = 1, 2$. Then (8) becomes

$$X_1' = Ax_{n-1} + Bu_{n-1}, \tag{9a}$$

$$0 = Cx_{n-1} - \widehat{g}(t_{n-1}), \tag{9b}$$

$$X_2' = Ax_{n-1} + Bu_{n-1} + \frac{h}{2}(A(X_1' + X_2') + B(U_1' + U_2')), \tag{9c}$$

$$0 = Cx_{n-1} + \frac{h}{2}C(X_1' + X_2') - \widehat{g}(t_n), \tag{9d}$$

$$x_n = x_{n-1} + \frac{h}{2}(X_1' + X_2'), \tag{9e}$$

$$u_n = u_{n-1} + \frac{h}{2}(U_1' + U_2'). \tag{9f}$$

Notice that (9e)–(9f) can be substituted into (9c)–(9d) to form the new equations

$$X_1' = Ax_{n-1} + Bu_{n-1}, \tag{10a}$$

$$X_2' = A\left(x_{n-1} + \frac{h}{2}(X_1' + X_2')\right) + Bu_n, \tag{10b}$$

$$x_n = x_{n-1} + \frac{h}{2}(X_1' + X_2'), \tag{10c}$$

$$0 = Cx_n - \widehat{g}(t_n). \tag{10d}$$

The information from (9b) was obtained from the previous step and hence may be eliminated.

The direct transcription software SOCS must satisfy (11a)–(11b) in $\widetilde{x}$ and $\widetilde{u}$ at every mesh point for a solution to be considered feasible.

$$\widetilde{x}_n - \widetilde{x}_{n-1} - \frac{h}{2}(A\widetilde{x}_{n-1} + B\widetilde{u}_{n-1} + A\widetilde{x}_n + B\widetilde{u}_n) + \delta_{n-1} = 0, \tag{11a}$$

$$C\widetilde{x}_n - \widehat{g}_n + \epsilon_{n-1} = 0. \tag{11b}$$

The parameters δ_n and ϵ are included as tolerances for the accuracy to which we solve (11a) and (11b). We initially view these as the tolerances in the NLP solve. Let us define

$$\widetilde{X}_1' = A\widetilde{x}_{n-1} + B\widetilde{u}_{n-1}, \tag{12}$$

$$\widetilde{X}_2' = A\widetilde{x}_n + B\widetilde{u}_n \tag{13}$$

so that we may now write (11a) as

$$\widetilde{x}_n - \widetilde{x}_{n-1} - \frac{h}{2}(\widetilde{X}_1' + \widetilde{X}_2') + \delta_{n-1} = 0. \tag{14}$$

Solving for $\widetilde{x}_n$ in (14) and substituting in (13) we have

$$\widetilde{X}_1' = A\widetilde{x}_{n-1} + B\widetilde{u}_{n-1}, \tag{15}$$

$$\widetilde{X}_2' = A\left(\widetilde{x}_{n-1} + \frac{h}{2}(\widetilde{X}_1' + \widetilde{X}_2')\right) + B\widetilde{u}_n + A\delta_{n-1}. \tag{16}$$

Taking (15), (16) and (14), (11b), the SOCS discretization looks like,

$$\widetilde{X}_1' = A\widetilde{x}_{n-1} + B\widetilde{u}_{n-1}, \tag{17a}$$

$$\widetilde{X}_2' = A\left(\widetilde{x}_{n-1} + \frac{h}{2}(\widetilde{X}_1' + \widetilde{X}_2')\right) + B\widetilde{u}_n + A\delta_{n-1}, \tag{17b}$$

$$\widetilde{x}_n = \widetilde{x}_{n-1} + \frac{h}{2}(\widetilde{X}_1' + \widetilde{X}_2') + \delta_{n-1}, \tag{17c}$$

$$C\widetilde{x}_n = \widehat{g}_n + \epsilon_{n-1}. \tag{17d}$$

Comparing (10) to (17) we see that we may consider the SOCS solution as a perturbation of the IRK solution. If we subtract the IRK system from the SOCS discretization we get a system for the difference between the SOCS TR and the IRK TR solutions in the form

$$Gz_n = Hz_{n-1} + \gamma_{n-1} \tag{18}$$

with

$$G = \begin{bmatrix} I & -\frac{h}{2} & -\frac{h}{2} & 0 \\ 0 & I - \frac{h}{2}A & -\frac{h}{2}A & -B \\ 0 & 0 & I & 0 \\ C & 0 & 0 & 0 \end{bmatrix}, \quad H = \begin{bmatrix} I & 0 & 0 & 0 \\ A & 0 & 0 & 0 \\ A & 0 & 0 & B \\ 0 & 0 & 0 & 0 \end{bmatrix}, \tag{19}$$

$$\gamma_n = \begin{bmatrix} \delta_n \\ A\delta_n \\ 0 \\ \epsilon_n \end{bmatrix}, \quad z_n = \begin{bmatrix} \widetilde{x}_n - x_n \\ \widetilde{X}_2' - X_2' \\ \widetilde{X}_1' - X_1' \\ \widetilde{u}_n - u_n \end{bmatrix}. \tag{20}$$

Suppose that G is invertible and solve (18) for z_n,

$$z_{n+1} = G^{-1}Hz_n + G^{-1}\gamma_n. \tag{21}$$

The solution of (21) is $z_k = (G^{-1}H)^k z_0 + \sum_{j=0}^{k-1}(G^{-1}H)^{k-j-1}G^{-1}\gamma_j$. We assume that $z_0 = 0$ and obtain the difference between the IRK and SOCS TR solutions starting from the same initial conditions as

$$z_k = \sum_{j=0}^{k-1}(G^{-1}H)^{k-j-1}G^{-1}\gamma_j. \tag{22}$$

The analysis and discussion that follows differs from the usual error analysis of IRK methods in that it is not enough that we convert (22) to an order estimate since we need to know the actual size of the perturbation z_k and we need to consider mesh widths that may not be small.

Equation (22) holds for all DAEs of index 1 or higher. We know from previous theory [6] that IRK TR does converge for DAEs of index 1 and 2 but not for DAEs of index greater than 2. We assume the DAE (7) is an index 3 problem. For (7) to be index 3 we must have that CB is singular. Since for time invariant problems we can decouple the different index subsystems using linear time invariant coordinate changes, we may assume in our analysis that $CB = 0$. Without loss of generality we may further assume that C is full row rank, B is full column rank, and there exist matrices $\widehat{P}$ and $\widehat{Q}$ so that

$$\widehat{P}C\widehat{Q}^{-1} = \begin{bmatrix} I & 0 \end{bmatrix}, \quad \widehat{Q}B = \begin{bmatrix} 0 \\ I \end{bmatrix}, \tag{23}$$

where $\widehat{Q}$ represents a coordinate change. Thus we may assume that

$$C = \begin{bmatrix} I & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ I \end{bmatrix}. \tag{24}$$

A linear time invariant index 3 DAE with $CB = 0$ must also have CAB invertible. Define

$$Q = I - \frac{h}{2}A \tag{25}$$

and let

$$Q = \begin{bmatrix} Q_1 & Q_2 \\ Q_3 & Q_4 \end{bmatrix}, \quad A = \begin{bmatrix} A_1 & A_2 \\ A_3 & A_4 \end{bmatrix}, \tag{26}$$

where the partitioning conforms to C and B. From the special form given for C and B we know that CAB is invertible if and only if A_2 is invertible. Q is invertible for all but a finite number of nonzero h. The value of $Q_2 = C(I - \frac{h}{2}A)^{-1}B$ is given analytically in terms of A by

$$Q_2 = -2hA_2(-4I + 2hA_4 + 2hA_1 - h^2A_1A_4 + h^2A_2A_3)^{-1},$$

which is invertible for small nonzero h since A_2 is invertible. Then Q_2 is invertible for all but a finite number of h.

Theorem 3.1. *Suppose that the DAE* (7) *is index* 3, *h is constant, and* (10), (17), *and* (24) *hold. Assume that CAB and $C(I - \frac{h}{2}A)^{-1}B$ are invertible. Let $W = Q_4Q_2^{-1}Q_1 - Q_3, Y = Q_4Q_2^{-1} - 2W$. Then the difference in the states between the IRK TR and SOCS TR solutions is*

$$\begin{aligned} \bar{x}_k - x_k = \sum_{j=0}^{k-1}(-1)^{k-1-j} \Bigg(& \begin{bmatrix} 0 & 0 \\ -Q_4Q_2^{-1} & I \end{bmatrix} \delta_j \\ & + \begin{bmatrix} 0 & 0 \\ -\frac{h}{2}W & 0 \end{bmatrix} A\delta_j + \begin{bmatrix} 0 \\ -Y + Q_4Q_2^{-1} \end{bmatrix} \epsilon_j \Bigg). \end{aligned} \tag{27}$$

The difference between the controls is

$$\begin{aligned} \bar{u}_k - u_k = \sum_{j=0}^{k-1}(-1)^{k-1-j}\frac{2}{h} \Bigg\{ & [-2(k-j-1)Q_4Q_2^{-1} - Q_2^{-1} \quad 2(k-j-1)I]\delta_j \\ & + \frac{h}{2}[-2(k-j-1)W - Q_2^{-1}Q_1 \quad - I]A\delta_j \\ & + [-2(k-j-2)Y + 2Q_2^{-1}Q_1 + 2(k-j-1)Q_4Q_2^{-1}]\epsilon_j \Bigg\}. \end{aligned} \tag{28}$$

Note that the controls can differ considerably depending on the size of δ and ϵ. If we suppose that we are on the interval $[0, 1]$, then the value of k at the end of the interval would act like $1/h$. Q_2^{-1} may possess a $1/h$ factor as well. Thus a single δ_j will introduce a difference between the controls of at least

$$\bar{u}_k - u_k \sim O\left(\frac{1}{h^3}\|\delta_j\|\right).$$

The difference in the controls for a constant perturbation δ is also $O(h^{-3})$ due to cancellation. The worst case given by δ_j with alternating sign is $O(h^{-4})$. However, this is not possible on coarse meshes because of the one-sided nature of constraint chatter.

Proof of Theorem 3.1. Since B is full column rank and C is full row rank, if h is small enough so that $I - \frac{h}{2}A$ is invertible, then G is invertible. Thus G is invertible for all but a finite number of nonzero h. Row operations yield

$$G^{-1} = \begin{bmatrix} I - \frac{h}{2}QBPC & \frac{h}{2}(Q - \frac{h}{2}QBPCQ) & \frac{h}{2}(Q - \frac{h}{2}QBPCQ) & \frac{h}{2}QBP \\ -QBPC & -\frac{h}{2}QBPCQ + Q & -\frac{h}{2}QBPCQ + \frac{h}{2}QA & QBP \\ 0 & 0 & I & 0 \\ -PC & -\frac{h}{2}PCQ & -\frac{h}{2}PCQ & P \end{bmatrix},$$

where $P = \frac{2}{h}(CQB)^{-1}$. To simplify, note the identities

$$\begin{gathered} Q = I + \frac{h}{2}QA, \\ -\frac{h}{2}PCQB = -I, \\ \left(-\frac{h}{2}QBPCQ + \frac{h}{2}QA\right)B = -B. \end{gathered}$$

Let $N = I + \frac{h}{2}A$. Then

$$G^{-1}H = \begin{bmatrix} (I - \frac{h}{2}QBPC)QN & 0 & 0 & 0 \\ (QA - QBPCQ)N & 0 & 0 & -B \\ A & 0 & 0 & B \\ -PCQN & 0 & 0 & -I \end{bmatrix}.$$

To evaluate (22) we need to compute products $(G^{-1}H)^k$. The special forms of C and B allow us to simplify the different terms in $G^{-1}H$. The $(1,1)$ term is

$$(G^{-1}H)_{1,1} = \begin{bmatrix} 0 & 0 \\ -2Q_4Q_2^{-1}Q_1 + Q_4Q_2^{-1} + 2Q_3 & -I \end{bmatrix}. \tag{29}$$

As we compute a power of $G^{-1}H$, the $(1,1)$ term is itself powered. Let $(G^{-1}H)^k_{i,j}$ be the i,j term of $(G^{-1}H)^k$. Examining (29), it is clear that

$$(G^{-1}H)^k_{1,1} = (-1)^k \begin{bmatrix} 0 & 0 \\ 2Q_4Q_2^{-1}Q_1 - Q_4Q_2^{-1} - 2Q_3 & I \end{bmatrix}.$$

Next we examine powers of the $(4,1)$ term, since the other terms will depend upon it. Let

$$\begin{aligned} W &= Q_4Q_2^{-1}Q_1 - Q_3, \\ Y &= Q_4Q_2^{-1} - 2W, \\ Z &= 2Q_2^{-1}Q_1 - Q_2^{-1}. \end{aligned}$$

A direct calculation gives

$$(G^{-1}H)^k_{4,1} = \frac{2}{h}[(-1)^{k+1}2(k-1)Y + (-1)^k Z \qquad (-1)^k 2kI],$$

$$(G^{-1}H)^k_{3,1} = \begin{bmatrix} (-1)^k A_2 Y & (-1)^{k+1}A_2 \\ (-1)^k(A_4Y + (k-2)\frac{4}{h}Y - \frac{2}{h}Z) & (-1)^{k+1}(A_4 + I(k-1)4/h) \end{bmatrix}.$$

Then

$$QBPCQN = \frac{2}{h}\begin{bmatrix} 2Q_1 - I & 2Q_2 \\ Q_4 Z & 2Q_4 \end{bmatrix}.$$

In addition, we see that $QAN = \frac{4}{h}Q - \frac{4}{h}I - A$, which leads to

$$QAN - QBPCQN = \begin{bmatrix} -\frac{2}{h}I - A_1 & -A_2 \\ \frac{4}{h}Q_3 - A_3 - \frac{2}{h}Q_4 Z & -\frac{4}{h}I - A_4 \end{bmatrix}.$$

Thus

$$(G^{-1}H)^k_{2,1} = \begin{bmatrix} (-1)^{k+1}A_2 Y & (-1)^k A_2 \\ (-1)^k((A_4 + \frac{4(k-1)}{h}I)(2W - Q_4 Q_2^{-1}) + \frac{2}{h}Z) & (-1)^k(A_4 + \frac{4k}{h}I) \end{bmatrix}.$$

We next compute $(G^{-1}H)^k G^{-1}$, which is also done term by term. Some key cancellations can be made. For example, by multiplying both sides of $(I - \frac{h}{2}A)Q = I$ on the right by

$$\begin{bmatrix} 0 & -I \\ 0 & Q_2^{-1}Q1 \end{bmatrix},$$

we see that $\frac{h}{2}A_2(Q_4 Q_2^{-1}Q_1 - Q_3) = I$. Below we give the 16 different terms of $(G^{-1}H)^k G^{-1}$.

1. (1, 1)

$$(-1)^k \begin{bmatrix} 0 & 0 \\ -Q_4 Q_2^{-1} & -I \end{bmatrix}.$$

2. (1, 2), (1, 3)

$$(-1)^k \begin{bmatrix} 0 & 0 \\ -\frac{h}{2}W & 0 \end{bmatrix}.$$

3. (1, 4)

$$(-1)^k \begin{bmatrix} 0 \\ -Y + Q_4 Q_2^{-1} \end{bmatrix}.$$

4. (2, 1)

$$(-1)^k \begin{bmatrix} -A_2 Q_4 Q_2^{-1} & A_2 \\ -(A_4 Q_4 Q_2^{-1} + \frac{4k}{h}Q_4 Q_2^{-1} + \frac{2}{h}Q_2^{-1}) & A_4 + \frac{4k}{h}I \end{bmatrix}.$$

5. (2, 2), (2, 3)

$$(-1)^k \begin{bmatrix} -I & 0 \\ -\frac{h}{2}(A_4 + \frac{4k}{h}I)W + Q_2^{-1}Q_1 & -I \end{bmatrix}.$$

6. (2, 4)

$$(-1)^k \begin{bmatrix} -A_2(Y - Q_4 Q_2^{-1}) \\ (2A_4 + \frac{8(k-1)}{h}I)W - \frac{4}{h}(Q_4 Q_2^{-1} + Q_2^{-1}Q_1) \end{bmatrix}.$$

7. $(3,1)$

$$(-1)^k \begin{bmatrix} A_2 Q_4 Q_2^{-1} & -A_2 \\ (A_4 + 4\frac{k-1}{h})Q_4 Q_2^{-1} + \frac{2}{h}Q_2^{-1} & -A_4 - 4\frac{k-1}{h} \end{bmatrix}.$$

8. $(3,2)$, $(3,3)$

$$(-1)^k \begin{bmatrix} I & 0 \\ \frac{2}{h}(A_4 + \frac{4(k-1)}{h}I)W + Q_2^{-1}Q_1 & -I \end{bmatrix}.$$

9. $(3,4)$

$$(-1)^k \begin{bmatrix} -A_2(Y - Q_4 Q_2^{-1}) \\ -2(A_4 + \frac{4}{h}I)W - \frac{4}{h}Q_4 Q_2^{-1} - \frac{4}{h}Q_2^{-1}Q_1 \end{bmatrix}.$$

10. $(4,1)$

$$(-1)^k \ \frac{2}{h}[-2kQ_4 Q_2^{-1} - Q_2^{-1} \qquad 2kI].$$

11. $(4,2)$, $(4,3)$

$$(-1)^k[-2kW - Q_2^{-1}Q_1 \qquad -I].$$

12. $(4,4)$

$$(-1)^k \frac{2}{h}[-2(k-1)Y + 2Q_2^{-1}Q_1 + 2kQ_4 Q_2^{-1}].$$

Finally, computing the first and last entries of $(G^{-1}H)^k G^{-1}\gamma$ gives Theorem 3.1. □

4. Numerical experiments. The preceding analysis shows that the feasible solutions examined by SOCS can differ substantially from the IRK solutions. Once h is sufficiently small, approximations of the true optimal solution become feasible. In order to determine if this is the full story we conduct some computational tests on coarser meshes.

Recall the optimal control problem given previously in (4). The constraint is active on the subinterval $[\frac{34}{15}, 4]$. The numerical solution for x, v, and u obtained from SOCS TR and IRK TR were subtracted with $N = 10$. The results are given in Table 1. Recall that the tolerances δ_k and ϵ_k are those for SOCS to solve (11a), (11b).

SOCS solves (11a) up to the square root of machine precision. In addition, when the constraint is active, (11b) is also solved to the square root of machine precision. Theorem 3.1 gives absolute error bounds. After substituting

$$\epsilon_k = \delta_k = \sqrt{\varepsilon_{mach}}$$

into the formulas of Theorem 3.1, we observe that the difference between the two solutions are much larger than the estimates allow. For problem (4) on a mesh of size $N = 10$, Theorem 3.1 predicted a difference on the order of 10^{-5}. As seen in Figures 1 and 2 and Table 1, the two solutions differ by much more than that. The NLP tolerances are not enough to explain what we are seeing computationally on coarse meshes.

Table 1
Absolute difference of solutions.

We now turn to identifying what is happening on coarser meshes. Upon closer examination of the solution obtained from SOCS, we see that not all variables $\widetilde{x}_k$ lie directly on the constraint. In fact, $\widetilde{x}_1$ is consistently above the constraint for meshes larger than $N = 5$, as illustrated by the second line of the $|\widetilde{x} - x|$ column in Table 1.

We again set the tolerances

$$\delta_k = \begin{bmatrix} \sqrt{\varepsilon_{mach}} \\ \sqrt{\varepsilon_{mach}} \end{bmatrix} \tag{30}$$

since they are the defaults in SOCS. However, in light of the fact that $\widetilde{x}_1$ does not lie on the constraint, we set ϵ_1 equal to the distance $\widetilde{x}_1$ is from the true solution. In the case when $N = 10$ we have

$$\epsilon_1 = 0.007, \quad \epsilon_k = \sqrt{\varepsilon_{mach}}, \quad k \geq 2. \tag{31}$$

The results of applying Theorem 3.1 using these new tolerances and $N = 10$ are given in Table 2.

The small error created by the constraint chatter in the early stages of SOCS TR propagates down the numerical solution as seen in (22) to create large differences between IRK and SOCS later in time. In addition, as h gets smaller the distance from the constraint also gets smaller.

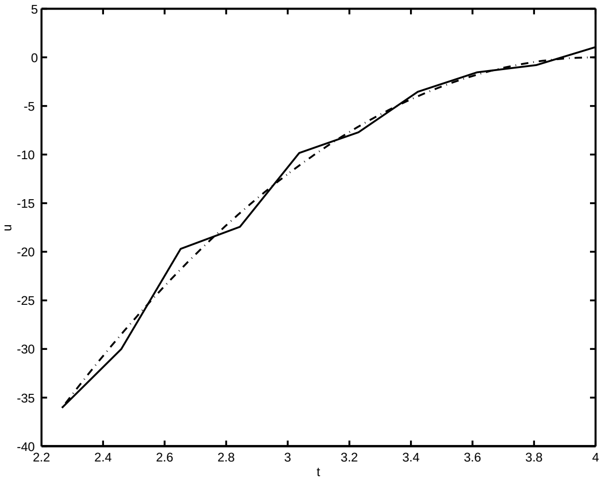

Fig. 3. *TR on the DAE with perturbation.*

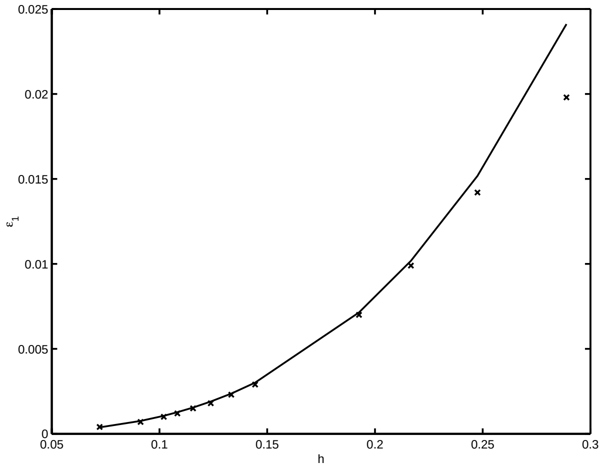

Fig. 4. *Perturbation size versus step size.*

Table 2 seems to suggest that for this test problem the perturbation (31) accounts for the ability of SOCS to find the optimum. As an additional check, rather than simply integrating the DAE (7) using IRK TR, we force the TR equations to include the addition of ϵ_1 from (31) at the first time step. In other words, at t_1 we have

$$0 = Cx_1 - g(t_1) - \epsilon_1$$

as part of the IRK equations given in (10a)–(10d). This results in a much more accurate approximation of the control as seen in Figure 3. The perturbed IRK TR solution of Figure 3 is also now very close to the SOCS TR solution of Figure 1.

The initial constraint chatter shown in Table 1 is present at a wide range of mesh sizes. Figure 4 gives a plot of the size of the constraint chatter (perturbation) versus the step size.

It appears that the constraint chatter is following the curve h^3. It is interesting

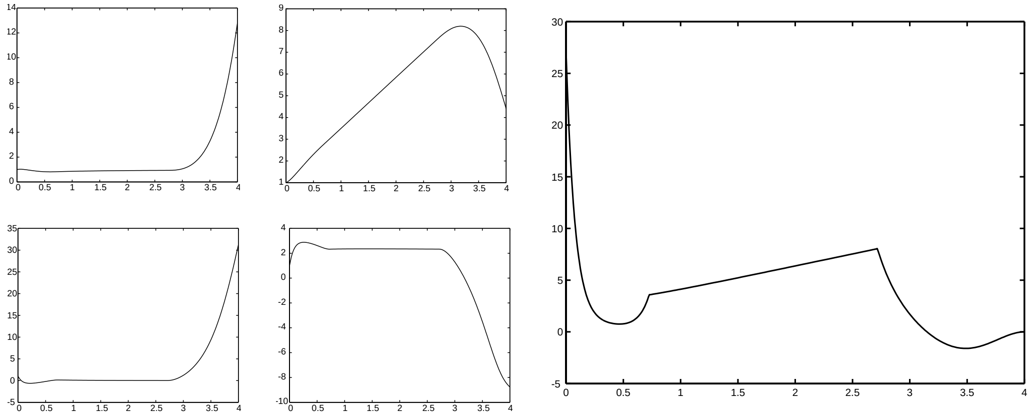

FIG. 5. *State and control solutions of* (32).

to note that Theorem 3.1 says perturbations can be enlarged by $1/(h^3)$. Thus an h^3 perturbation is reasonable for inducing a difference between IRK and SOCS on the order of $O(1)$.

The constraint chatter seen in the test problem (4) is not unique to that problem. We have performed a number of numerical experiments on a variety of index 3 and index 4 problems, both linear and nonlinear. In each problem we saw chattering occurring on many levels. When solving an index 4 problem the constrained solution bounced on and off the curve with greater frequency than the index 3 case. This behavior also occurs with nonlinear problems. In addition, the chatter seems to occur at both the beginning and the end of the state constrained interval for boundary value problems.

For example, consider the nonlinear problem

$$\min \int_0^4 \left(x_1^2 + x_2^2 + u^2\right)\, dt, \tag{32a}$$

$$x_1' = x_3, \tag{32b}$$

$$x_2' = x_4, \tag{32c}$$

$$x_3' = x_2 x_1 - u + 1, \tag{32d}$$

$$x_4' = x_1 u - x_2, \tag{32e}$$

$$\frac{1}{2} \geq x_2 - x_2 x_1. \tag{32f}$$

State and control plots for (32) computed by SOCS are given in Figure 5.

A close-up examination of the constraint residual on the interval on which it is active shows that there is again chatter which goes to zero with the mesh size. However, now the chatter is asymmetrical and changes shape with the mesh. Figure 6 gives an enlarged view of the plot of $x_2 - x_2 x_1$ which is equal to $\frac{1}{2}$ when the constraint is active.

5. Convergence to optimal solution on index 3 problems. We now proceed to show that even though the discretization cannot integrate the constrained dynamics directly that the approximations of the optimal solution do converge.

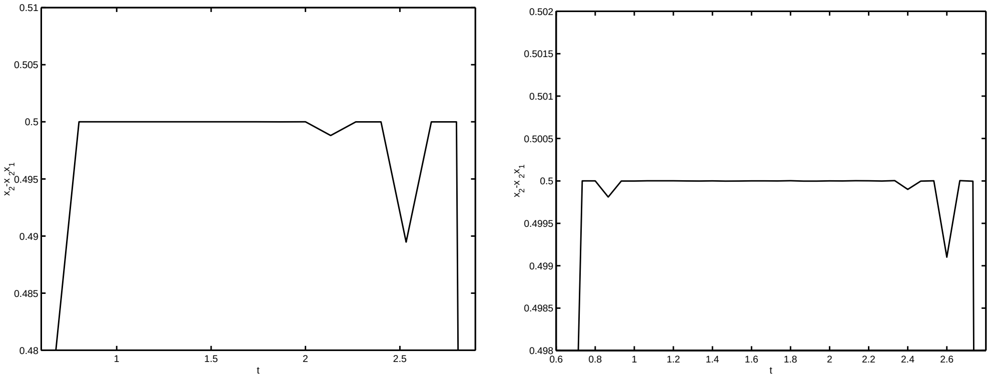

FIG. 6. *Chatter along constraint for* (32), $N = 31$ *and* $N = 61$.

We consider the optimal control problem (P)

$$\min \int_{t_0}^{t_f} L(x(t), u(t))\, dt, \tag{33a}$$

$$x'(t) = Ax(t) + Bu(t), \tag{33b}$$

$$0 \leq Cx(t) - g(t), \tag{33c}$$

$$x(t_0) = x_0, \tag{33d}$$

where $x(t)$ is a real vector-valued function of length m and $u(t)$ is length r. Also, A is $m \times m$, B is $m \times r$, C is $q \times m$, and $g(t)$ is a vector-valued function of length q and is continuous. It is assumed that the functional $L : \Re^{m+r} \rightarrow \Re$ is strictly convex. Note that we now make no restrictions on A, B, C concerning the index when the constraints are active. This is consistent with our numerical observations showing convergence using TR on active inequality constraints of index 4, 5, and higher.

Many papers have discussed approximating a state constrained continuous infinite-dimensional optimal control problem with a discrete one. One of the first discussions [8] gave an algorithm to solve general problems which include (33). In that paper, the state constraint needed to be differentiated until the control appeared. This relates closely to the *order* of a constraint or the index of a DAE. Loosely stated, the index of a DAE is the number of differentiations of the system equations needed to determine the derivative of the algebraic variables uniquely. For more on order and DAEs, see [7] and [14].

Convergence rates when approximating the infinite problem by a finite-dimensional NLP were developed in [9, 11, 12]. [9] gives a convergence rate for the Euler integration scheme using both state and control constraints. [11] uses the Euler integration scheme and develops convergence rates for problems with constraints on the states only. Using Runge–Kutta methods, [12] considers control constrained problems. Each of these papers assumes that the state constraints satisfy a stability requirement. In terms of (33), this implies that the matrix CB must be nonsingular. Thus the DAE that arises when the constraints are active is only index 2. Furthermore, each of the papers listed, and other related work such as [13], assumes or proves under some assumptions that all of the associated multipliers converge.

In [16, 17, 20], Polak developed the theory of consistent approximations. A sequence of finite NLPs (involving only the discretized control variables) consistently approximate an optimal control problem if the sequence of minimizers of the finite problems converge to the minimizers of the original problem. Convergence of the minimizers is related to convergence of the epigraphs of the associated problems. In [16], the Euler integration scheme is used to show that general control constrained problems can be consistently approximated by a sequence of NLPs. Explicit Runge–Kutta methods can also be used for control constrained problems [20]. Finally, it has been shown [17] that, using the Euler integration scheme, optimal control problems with general state constraints can be consistently approximated.

Pytlak discusses algorithms that solve state constrained optimization problems where the dynamics may be replaced by an index 1 DAE [18, 19]. The algorithm optimizes only over the discretized control variables. This allows the use of a reduced gradient algorithm based on the discretized control and adjoint variables [18]. Although this algorithm seems to work quite well, the general strategy is very different from that of SOCS.

In each of the above papers convergence depends on convergence of the multipliers. Figure 7 shows two of the discrete multipliers for (4), indicated by ×'s, and the continuous multipliers, which are the smooth curves. The discrete multipliers are not converging to any function. Thus the proof that SOCS can use TR with high index inequality constraints cannot be based on the convergence of multipliers. There is some indication that the multipliers may converge in a weak sense.

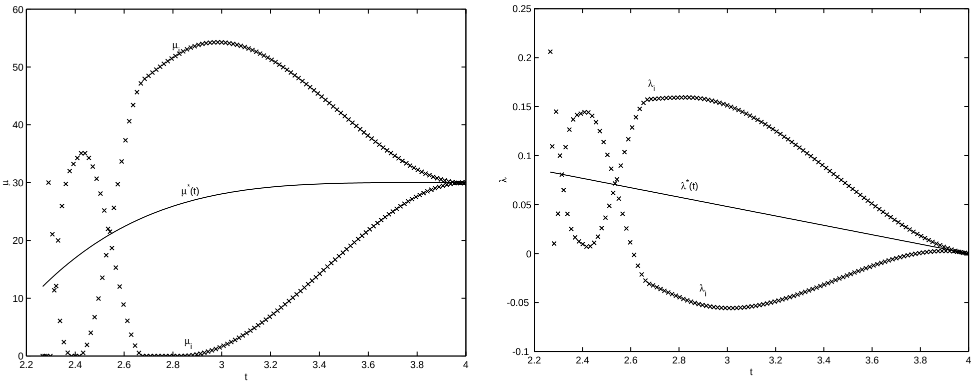

FIG. 7. *Multipliers for* (4).

In summary, our situation is different from the papers listed above in that (i) the dynamics are discretized using the TR or HS methods, (ii) the discretized controls and states are included as NLP variables, (iii) the discretized dynamics are included as constraints of the NLP, (iv) experimental results show that the associated multipliers of the equality and inequality constraints may not converge, (v) experiments show apparent convergence for problems with purely state constrained problems where CB is singular, and (vi) as seen in [6], the TR and HS methods may not converge when applied to the DAEs which arise when constraints are active.

5.1. Consistent approximations. A detailed discussion of consistent approximations is given in [17]. We review only needed notation.

Consider the two problems

$$(P) \qquad \min_{x \in X} f(x)$$

and

$$(P_N) \qquad \min_{x \in X_N} f_N(x).$$

The epigraphs of the functions f and f_N are defined as $E = \{(x^0, x) \mid x \in X,\ x^0 \geq f(x)\}$ and $E_N = \{(x^0, x) \mid x \in X_N,\ x^0 \geq f_N(x)\}$, respectively. The convergence of a sequence of NLPs to an optimal control problem is given in terms of the convergence of the associated epigraphs. Theorems 5.1 and 5.2 are the two main theorems of consistent approximations [17]. In the following let $\mathcal{N}$ be any infinite subset of the natural numbers.

THEOREM 5.1. *The epigraphs E_N, $N \in \mathcal{N}$, of the problems P_N converge to the epigraph E of the problem P if and only if*

1. *for every $x \in X$, there exists a sequence $\{x_N\}_{N \in \mathcal{N}}$ with $x_N \in X_N$ such that $x_N \to x$ as $N \to \infty$;*
2. *for every infinite sequence $\{x_N\}_{N \in K}$, $K \subset \mathcal{N}$ such that $x_N \in X_N$ and $x_N \to x$ as $N \to \infty$, then $x \in X$;*
3. $\lim f_N(x_N) = f(x)$ *if $x_N \to x$, $x_N, \in X_N$, and $x \in X$.*

THEOREM 5.2. *If the epigraphs of P_N converge to the epigraph of P, then if $\{\hat{x}_N\}_{N \in \mathcal{N}}$ is a sequence of global minimizers of the problems P_N and $\hat{x}$ is any accumulation point of this sequence, then $\hat{x}$ is a global minimizer of P.*

If we can show items 1, 2, and 3 in Theorem 5.1, then we have shown that if the global minimizers of the approximating problem converge, it must be to a minimum of the original problem. It is important to note that for some problems, a stationary point of the approximating problems P_N may converge to a nonstationary point of the problem P. However, this is not the case when the approximating problems P_N and the problem P have convex objective functions with convex constraint sets. The convergence takes place in a Banach space. But X, X_N need not be closed. Getting the correct X, X_N is a key technical point.

5.2. Problem statement.

Consider again the optimal control problem (P) in (33). Let the mesh T_N be $t_0 < t_1 < \cdots < t_n = t_f$ where $N = n+1$. Let $h_i = t_{i+1} - t_i$. The associated NLP from discretization using the trapezoid rule is

$$\min \ \frac{h_0}{2} L(x_0, u_0) + \frac{h_{n-1}}{2} L(x_n, u_n) + \sum_{i=1}^{n-1} \frac{h_{i-1} + h_i}{2} L(x_i, u_i),$$

$$\begin{aligned} 0 &= x_{i+1} - x_i - \frac{h_i}{2}(A(x_i + x_{i+1}) + B(u_i + u_{i+1})), \\ 0 &\leq Cx_i - g(t_i), \end{aligned}$$

where $i = 0, 1, \ldots, n-1$. Let

$$x_N = [x_0,\ x_1,\ \ldots,\ x_n]^T, \qquad u_N = [u_0,\ u_1,\ \ldots,\ u_n]^T$$

be the matrices which approximate $x(t)$ and $u(t)$ at the mesh points. Let the ordered set of mesh points be denoted T_N and the norm of the mesh be

$$\|T_N\| \doteq \max_i \ h_i = \max_i \ (t_{i+1} - t_i).$$

Note that $x_i \in R^m$, $u_i \in R^r$. For ease of notation, if $z(t)$ is a vector-valued function over the interval $[t_0, t_f]$, let $z(T_N)$ be the matrix of values of $z(t)$.

The linear interpolation of x_i and u_i are

$$\bar{u}_N(t) = \sum_{i=0}^{n} u_i \phi_i(t), \quad \bar{x}_N(t) = \sum_{i=0}^{n} x_i \phi_i(t),$$

where the $\phi_i(t)$ are the linear hat functions with the property

$$\phi_i(t_j) = \begin{cases} 1 & \text{if} \quad i = j, \\ 0, & i \neq j. \end{cases}$$

Given $(x_N, u_N) \in \Re^{(m \times N)} \times \Re^{(r \times N)}$, the pair $(\bar{x}_N(t), \bar{u}_N(t))$ is in the finite-dimensional space $\Phi \times \Phi$ where $\Phi = \text{span}\{\phi_0, \phi_1, \ldots, \phi_n\}$.

If $z(t)$ is a vector-valued function of length l and $s \in [t_0, t_f]$, then the norm of the vector $z(s)$ is $\|z(s)\|_\infty = \max_i |z_i(s_1)|, 1 \leq i \leq l$. The function space norm is given by $\|z(t)\| = \sup_t \|z(t)\|_\infty$. Finally, if A is a matrix, then $\|A\|_\infty$ is the norm induced by $\| \cdot \|_\infty$.

Figure 5 is typical in that the optimal controls with higher index inequality constraints are rarely smooth. But they are often continuous and piecewise smooth. Continuity is also not enough for the analysis to follow. Accordingly, we take the set of admissible controls as the set of functions which are Lipschitz continuous. That is, for each u, there exists some $L < \infty$ such that

$$\|u(s_1) - u(s_2)\|_\infty \leq L|s_1 - s_2| \quad \text{for all } s_1, s_2. \tag{34}$$

If u is Lipschitz continuous, let

$$\|u(t)\|_L = \sup_{s_1, s_2 \in [t_0, t_f]} \frac{\|u(s_1) - u(s_2)\|_\infty}{|s_1 - s_2|}, \quad s_1 \neq s_2.$$

While we need $\|u\|_L < \infty$, computational examples show that the approximations do not converge in $\|u\|_L$. Thus the underlying Banach space has to have a weaker type of convergence which is compensated for by the definition of the finite-dimensional approximating spaces. The basic underlying Banach space is

$$\mathcal{B} = \{(x, u) \mid x \in C^0[t_0, t_f], \ u \in C^0[t_0, t_f]\}$$

with

$$\|(x, u)\|_{\mathcal{B}} = \max\{\|x\|, \|u\|\}.$$

The finite-dimensional subspace $\mathcal{B}_N \subset \mathcal{B}$ is defined to be

$$\mathcal{B}_N = \{(x, u) \mid x \in \Phi, \ u \in \Phi\}.$$

We now define problems P and P_N. Let P be

$$\min_{(x,u) \in X} f(x, u),$$

$$f(x, u) = \int_{t_0}^{t_f} L(x, u) \, dt,$$

where $f : \mathcal{B} \to \Re$ and $X \subset \mathcal{B}$ is

$$X = \{(x, u) \mid x' = Ax + Bu,\ Cx - g(t) \geq 0,\ x(t_0) = x_0,\ \|u\|_L \leq \Lambda\}.$$

Here Λ is a fixed finite positive number. The reader should think of Λ as being large but fixed. In particular, it is larger than $\|u^*\|_L$ for the optimal control u^*, which is also assumed Lipschitz. It is assumed that the set X is nonempty.

Let T_N be any ordered mesh. Define P_N to be

$$\min_{(\bar{x}_N, \bar{u}_N) \in X_N} f_N(\bar{x}_N, \bar{u}_N),$$

$$\begin{aligned} f_N(\bar{x}_N, \bar{u}_N) = {} & \frac{h_0}{2} L(\bar{x}_N(t_0), \bar{u}_N(t_0)) + \frac{h_{n-1}}{2} L(\bar{x}_N(t_n), \bar{u}_N(t_n)) \\ & + \sum_{i=1}^{n-1} \frac{h_i + h_{i-1}}{2} L(\bar{x}_N(t_i), \bar{u}_N(t_i)), \end{aligned}$$

where $f_N : \mathcal{B}_N \to \Re$ and $X_N \subset \mathcal{B}_N$ is the set of $(\bar{x}_N, \bar{u}_N)$ such that

$$\begin{aligned} \bar{x}_N(t_{i+1}) - \bar{x}_N(t_i) - \frac{h_i}{2}(A(\bar{x}_N(t_{i+1}) + \bar{x}_N(t_i)) + B(\bar{u}_N(t_{i+1}) + \bar{u}_N(t_i))) = 0, \\ C\bar{x}_N(t_{i+1}) - g(t_{i+1}) \geq 0, \quad \bar{x}_N(t_0) = x_0, \\ \|\bar{u}_N(t_{i+1}) - \bar{u}_N(t_i)\|_\infty \leq \Lambda |t_{i+1} - t_i|, \qquad 0 \leq i \leq n-1. \end{aligned}$$

Here $t_i \in T_N$ and Λ is the same as in the definition of X. The constraint $\|\bar{u}_N(t_{i+1}) - \bar{u}_N(t_i)\|_\infty \leq \Lambda |t_{i+1} - t_i|$ is not present in SOCS and is included only for theoretical reasons.

Since all affine, nonempty, linearly constrained sets are convex we have that the sets X and X_N defined above are convex. Convexity plays an important role. Since $L(x, u)$ is strictly convex and the constraint sets are convex, there exist unique global minimizers for the problems P and P_N. Thus, if the problems P_N approximate the problems P, by Theorem 5.1 the limit of global minimizers of the P_N is the global minimizer of P.

The usual results in the literature on using trapezoidal discretizations assume twice differentiable solutions, which are not present in our application. The control in Figure 5 is typical for inequality constrained problems in that it is only piecewise smooth. Accordingly we must first examine the convergence of the TR method for linear ODEs of the form $x' = Ax + f(t)$ where $f(t)$ is only Lipschitz continuous. Let $z_N^I(t)$ be the linear interpolation of the function $z(t)$ over the mesh T_N.

LEMMA 5.3. *If v is Lipschitz continuous with Lipschitz constant $\|v\|_L$, then its linear interpolation v_N^I on a mesh T_N satisfies $\|v_N^I(t) - v(t)\| \leq \|v\|_L \|T_N\|$.*

Proof. Take $s \in [t_0, t_f]$ and let $\hat{t}$ be the closest mesh point to s, $\hat{t} = \min_{t_i} |t_i - s|$. Then

$$\begin{aligned} \|v_N^I(s) - v(s)\|_\infty &= \|v_N^I(s) - v(\hat{t}) + v(\hat{t}) - v(s)\|_\infty \\ &\leq \|v_N^I(s) - v(\hat{t})\|_\infty + \|v(\hat{t}) - v(s)\|_\infty \\ &= \|v_N^I(s) - v_N^I(\hat{t})\|_\infty + \|v(\hat{t}) - v(s)\|_\infty \\ &\leq \|v_N^I(t)\|_L\ |s - \hat{t}| + \|v\|_L |\hat{t} - s| \leq 2\|v\|_L |\hat{t} - s| \leq \|v\|_L \|T_N\|. \qquad \square \end{aligned}$$

LEMMA 5.4. *If $z(t)$ is a Lipschitz continuous function, then its trapezoid quadrature is locally order* 2. *That is, if $t_i, t_{i+1} \in T_N$, then*

$$\left\| \int_{t_i}^{t_{i+1}} z(s)\, ds - \frac{h_i}{2}(z(t_i) + z(t_{i+1})) \right\|_\infty < \|z\|_L \|T_N\|^2.$$

Proof. The trapezoid rule is exact for the linear interpolants so that

$$\int_{t_i}^{t_{i+1}} z_N^I(s)\, ds = \frac{h_i}{2}(z_N^I(t_i) + z_N^I(t_{i+1})) = \frac{h_i}{2}(z(t_i) + z(t_{i+1})).$$

Define $E = \int_{t_i}^{t_{i+1}} z(s)\, ds - \frac{h_i}{2}(z(t_i) + z(t_{i+1}))$. Then

$$\begin{aligned} E &= \int_{t_i}^{t_{i+1}} (z(s) - z_N^I(s))\, ds + \int_{t_i}^{t_{i+1}} z_N^I(s)\, ds - \frac{h_i}{2}(z(t_i) + z(t_{i+1})) \\ &= \int_{t_i}^{t_{i+1}} (z(s) - z_N^I(s))\, ds. \end{aligned}$$

Taking norms and using Lemma 5.3 we have

$$\|E\|_\infty \le \int_{t_i}^{t_{i+1}} \|z(s) - z_N^I(s)\|\, ds \le \int_{t_i}^{t_{i+1}} \|z\|_L \|T_N\|\, ds \le \|z\|_L \|T_N\|^2. \qquad \square$$

Before we prove the next lemma, we must assume that the mesh norm multiplied by the size of the mesh is bounded. That is, for all $N \in \mathcal{N}$, there exists $C_6 > 0$ such that

$$\|T_N\| N \le C_6. \tag{35}$$

Moreover, for any positive integer k we have $T_N \subset T_{N+k}$. That is, when we have a sequence of meshes $\{T_N\}$ we assume that T_{N+k} is gotten by refining T_N. This is consistent with the strategy in SOCS. Assumptions such as (35) are common when nonuniform meshes are used.

LEMMA 5.5. *Let $0 < \delta < 1$. If we apply the TR method to the initial value problem*

$$x'(t) = Ax(t) + f(t), \quad x(t_0) = x_0, \quad t \in [t_0, t_f] \tag{36}$$

with $f(t)$ Lipschitz continuous, then for $\|T_N\|$ small enough so that $\frac{\|T_N\|}{2}\|A\|_\infty \le 1 - \delta$, the error $e_j = x_j - x(t_j)$ satisfies

$$\|e_j\|_\infty \le K_1 \|T_N\| \tag{37}$$

for all j where x_j is the solution of the trapezoid difference equation applied to (36).

Proof. The TR method applied to the ODE $x' = Ax + f(t)$ is

$$x_{i+1} - x_i = \frac{h_i}{2}(Ax_{i+1} + Ax_i + f(t_{i+1}) + f(t_i)).$$

The true solution discretized is

$$x(t_{i+1}) - x(t_i) = \frac{h_i}{2}(Ax(t_{i+1}) + Ax(t_i) + f(t_{i+1}) + f(t_i)) + \gamma_i.$$

Here γ_i is the local truncation error of the trapezoid method. Define $e_i = x(t_i) - x_i$ to obtain

$$e_{i+1} - e_i = \frac{h_i}{2}(Ae_{i+1} + Ae_i) + \gamma_i, \quad e_0 = 0. \tag{38}$$

Equation (38) is equivalent to

$$e_{i+1} = \left(I - \frac{h_i}{2}A\right)^{-1}\left(I + \frac{h_i}{2}A\right)e_i + \left(I - \frac{h_i}{2}A\right)^{-1}\gamma_i.$$

Taking norms gives

$$\|e_{i+1}\|_\infty \leq \left\|\left(I - \frac{h_i}{2}A\right)^{-1}\right\|_\infty \|e_i\|_\infty + \left\|\left(I - \frac{h_i}{2}A\right)^{-1}\frac{h_i}{2}A\right\|_\infty \|e_i\|_\infty + \left\|\left(I - \frac{h_i}{2}A\right)^{-1}\right\|_\infty \|\gamma_i\|_\infty.$$

Since $\frac{\|T_N\|}{2}\|A\|_\infty < 1$ we have that $\|(I - \frac{h_i}{2}A)^{-1}\|_\infty \leq C_1$ for some constant C_1. We may also write

$$\left\|\left(I - \frac{h_i}{2}A\right)^{-1}\right\|_\infty \leq \frac{\|T_N\|}{2}\|A\|_\infty\left(1 + \sum_{k=2}^{\infty}\left(\frac{\|T_N\|}{2}\|A\|_\infty\right)^k\right) + 1.$$

There exists a C_2 such that

$$1 + \sum_{k=2}^{\infty}\left(\frac{\|T_N\|}{2}\|A\|_\infty\right)^k \leq C_2.$$

Finally, let $C_5 = \frac{\|A\|_\infty(C_1+C_2)}{2}$ to get

$$\|e_{i+1}\|_\infty \leq (1 + C_5\|T_N\|)\, \|e_i\|_\infty + C_1\, \|\gamma_i\|_\infty.$$

Recalling that $e_0 = 0$, we have that at the nth step

$$\begin{aligned}\|e_n\|_\infty &\leq C_1\sum_{i=0}^{n-1}(1 + C_5\|T_N\|)^{n-i-1}\|\gamma_i\|_\infty \\ &\leq C_1 \max_i \|\gamma_i\|_\infty \sum_{i=0}^{N-1}(1 + C_5\|T_N\|)^{n-i-1}.\end{aligned}$$

But from the formula for a finite geometric series and (35) we have

$$\begin{aligned}\sum_{i=0}^{N-1}(1 + C_5\|T_N\|)^i &= \frac{(1 + C_5\|T_N\|)^N - 1}{C_5\|T_N\|} \\ &\leq \frac{(1 + \frac{C_7}{N})^N - 1}{C_5\|T_N\|} < \frac{e^{C_7} - 1}{C_5\|T_N\|} = \frac{C_8}{\|T_N\|},\end{aligned}$$

where $C_7 = C_5C_6$ and $C_8 = \frac{e^{C_7}-1}{C_5}$. Therefore

$$\|e_n\|_\infty \leq \frac{C_1C_8}{\|T_N\|}\max_i \|\gamma_i\|_\infty. \tag{39}$$

But

$$\begin{aligned}\|\gamma_i\|_\infty &= \left\| x(t_{i+1}) - x(t_i) - \frac{h_i}{2}(Ax(t_{i+1}) + x(t_i) + f(t_{i+1}) + f(t_i)) \right\|_\infty \\ &= \left\| x(t_{i+1}) - x(t_i) - \frac{h_i}{2}(x'(t_{i+1}) + x'(t_i)) \right\|_\infty \\ &= \left\| \int_{t_i}^{t_{i+1}} x'(t)\, dt - \frac{h_i}{2}(x'(t_{i+1}) + x'(t_i)) \right\|_\infty ,\end{aligned}$$

which is simply the trapezoid quadrature on the function $x'(t)$. Since $x'(t)$ is Lipschitz, Lemma 5.4 gives $\|\gamma_i\|_\infty < K_4\|T_N\|^2$ and (37) follows from (39). □

Lemma 5.5 states that for every mesh point t_i, $\|\bar{x}_N(t_i) - x(t_i)\|_\infty \le K_1\|T_N\|$ if the function $\bar{x}_N(t)$ satisfies the trapezoid equations. We now show this holds for all t. Recall that $u(t)$ is Lipschitz continuous; hence $x(t)$ and $x'(t)$ are also Lipschitz, since $x' = Ax + Bu$.

LEMMA 5.6. *If $\bar{x}_N(t)$ satisfies the assumptions of Lemma 5.5, then $\|x(t) - \bar{x}_N(t)\| \le K_2\|T_N\|$.*

Proof. Since $\bar{x}_N(t)$ satisfies the trapezoid equations, by Lemma 5.5 we have $\|\bar{x}_N(t_i) - x(t_i)\|_\infty \le K_1\|T_N\|$. In addition, $x(t)$ is Lipschitz continuous, and hence its linear interpolation is close, $\|x_N^I(t) - x(t)\| \le K_4\|T_N\|$. At each mesh point $x_N^I(t_i) = x(t_i)$ and so $\|\bar{x}_N(t_i) - x_N^I(t_i)\|_\infty \le K_1\|T_N\|$. Since linear functions are furthest from each other at the boundary, we have $\|\bar{x}_N(t) - x_N^I(t)\| \le K_1\|T_N\|$ and thus

$$\begin{aligned}\|\bar{x}_N(t) - x(t)\| &= \|\bar{x}_N(t) - x_N^I(t) + x_N^I(t) - x(t)\| \\ &\le \|\bar{x}_N(t) - x_N^I(t)\| + \|x_N^I(t) - x(t)\| \\ &\le K_1\|T_N\| + K_4\|T_N\| \le K_2\|T_N\|. \qquad \square\end{aligned}$$

Finally, we make the following assumption on the constraint sets.

ASSUMPTION 5.1. *Given problem P defined above suppose that for every $(x, u) \in X$, there exists a sequence of functions $\{(y_M(t), v_M(t))\} \in X$ such that*

$$(40) \qquad Cy_M(t) - g(t) > 0, \qquad y_M(t_0) = x_0, \qquad y_M'(t) = Ay_M(t) + Bv_M(t)$$

for all integers M and $(y_M(t), v_M(t)) \to^{\mathcal{B}} (x(t), u(t))$ as $M \to \infty$.

The above assumption is on the set $X \in \mathcal{B}$ and has no relation to the mesh. It says that all feasible solutions are the limit of feasible solutions that satisfy the inequality constraints with a strict inequality. This does not appear to be very restrictive.

5.3. Satisfying the assumptions of Theorem 5.1.

We begin by showing item 1 in Theorem 5.1.

LEMMA 5.7. *Let assumption (40) hold and let $(x, u) \in X$. Then there exists a sequence $\{\bar{x}_N, \bar{u}_N\}_{N\in\mathcal{N}}$ so that for each N, $(\bar{x}_N, \bar{u}_N) \in X_N$ and $(\bar{x}_N, \bar{u}_N) \to^{\mathcal{B}} (x, u)$.*

Proof. Let $(x, u) \in X$. By (40) we have that there is a sequence of continuous functions $\{y_M, v_M\} \in X$ such that $(y_M, v_M) \to (x, u)$ and $Cy_M - g > 0$ for all M. For each M there exists a $\rho(M) > 0$, so that if a function y lies within the ball of radius $\rho(M)$ around y_M, $y \in B_{\rho(M)}(y_M)$, we have that $Cy - g > 0$.

Let $\epsilon > 0$. Define a sequence $\bar{x}_N, \bar{u}_N \in X_N$ with $N \ge M$ as $\bar{u}_N(t_i) = v_M(t_i)$ and $\bar{x}_N(T_N)$ as the unique matrix in $\Re^{m\times N}$ that satisfies the trapezoid equations associated with $\bar{u}_N$ and $\bar{x}_N(t_0) = x_0$. Choose M large enough so that

$$\|y_M(t) - x(t)\| < \frac{\epsilon}{2}, \quad \|v_M(t) - u(t)\| < \frac{\epsilon}{2}.$$

Since $\bar{u}_N(t_i) = v_M(t_i)$ and $\bar{x}_N(T_N)$ is the unique matrix which solves the trapezoid equations, we choose N large enough so that Lemma 5.6 holds with $\|T_N\| < \epsilon/2K_2$ and $\|\bar{x}_N(t) - y_M(t)\| < \min\left\{\rho(M), \frac{\epsilon}{2}\right\}$ and $\|\bar{u}_N(t) - v_M(t)\| < \frac{\epsilon}{2}$. Thus

$$\begin{aligned}\|\bar{x}_N(t) - x(t)\| &= \|\bar{x}_N(t) - y_M(t) + y_M(t) - x(t)\| \\ &\leq \|\bar{x}_N(t) - y_M(t)\| + \|y_M(t) - x(t)\| \leq \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon\end{aligned}$$

and

$$\begin{aligned}\|\bar{u}_N(t) - u(t)\| &= \|\bar{u}_N(t) - v_M(t) + v_M(t) - u(t)\| \\ &\leq \|\bar{u}_N(t) - v_M(t)\| + \|v_M(t) - u(t)\| \leq \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.\end{aligned}$$

Finally, note that $\|u_N\|_L < \Lambda$ since it is the linear interpolation of v_M with $\|v_M\|_L < \Lambda$. □

We now show item 2 in Theorem 5.1. Let $\{(\bar{x}_N, \bar{u}_N)\}_{N\in\mathcal{N}} \subset X_N$ be such that $(\bar{x}_N, \bar{u}_N) \to^{\mathcal{B}} (x, u)$. We must show that $(x, u) \in X$. We begin by examining convergence when $\bar{x}_N$ is unconstrained.

Lemma 5.8. *If $(\bar{x}_N, \bar{u}_N) \in \mathcal{B}_N$ with $(\bar{x}_N, \bar{u}_N) \to^{\mathcal{B}} (x, u)$ and*

$$\|u_N(t_{i+1}) - u(t_i)\|_\infty \leq \Lambda|t_{i+1} - t_i| \quad \text{for all } t_i \in T_N, \tag{41}$$

then u is Lipschitz continuous with $\|u\|_L \leq \Lambda$.

Proof. Suppose this is not the case. Then there exists an $s_1, s_2 \in [t_0, t_f]$ such that $\|u(s_1) - u(s_2)\|_\infty > \hat{\Lambda}|s_1 - s_2|$ where $\hat{\Lambda} > \Lambda$. Let $\epsilon > 0$ be such that $\Lambda + \epsilon < \hat{\Lambda}$. Then

$$\begin{aligned}\|u(s_1) - u(s_2)\|_\infty &= \|u(s_1) - \bar{u}_N(s_1) + \bar{u}_N(s_1) - u(s_2)\|_\infty \\ &\leq \|u(s_1) - \bar{u}_N(s_1)\|_\infty + \|\bar{u}_N(s_1) - \bar{u}_N(s_2)\|_\infty + \|\bar{u}_N(s_2) - u(s_2)\|_\infty.\end{aligned}$$

Note that if (41) holds for u_N, then $\|u_N\|_L \leq \Lambda$. Choose N large enough so that $\|\bar{u}_N - u\| < \frac{\epsilon}{2}|s_1 - s_2|$. Then

$$\|u(s_1) - u(s_2)\|_\infty < \epsilon|s_1 - s_2| + \Lambda|s_1 - s_2| < \hat{\Lambda}|s_1 - s_2|,$$

which is a contradiction. Thus u is Lipschitz continuous with constant less than or equal to Λ. □

The following lemma was adapted from [15] and uses a standard Gronwall's lemma argument.

Lemma 5.9. *If x_1 and x_2 are solutions of $x_i' = Ax_i + Bu_i$, $x_i(t_0) = x_0$ where u_1 and u_2 are Lipschitz continuous functions, then $\|x_1 - x_2\| \leq \|B\|_\infty(t_f - t_0)\|u_1 - u_2\|e^{\|A\|_\infty(t_f - t_0)}$.*

We now restrict the space $\mathcal{B}_N$ to the subspace for which $(\bar{x}_N(t), \bar{u}_N(t))$ satisfies the trapezoid equations and $\bar{x}_N(t_0) = x_0$.

Lemma 5.10. *If $(\bar{x}_N, \bar{u}_N) \to^{\mathcal{B}} (x, u)$, $\bar{x}_N(t_0) = x_0$, and $(\bar{x}_N, \bar{u}_N)$ satisfies the trapezoid rule*

$$\bar{x}_N(t_{i+1}) - \bar{x}_N(t_i) - \frac{h_i}{2}(A(\bar{x}_N(t_{i+1}) + \bar{x}_N(t_i)) + B(\bar{u}_N(t_{i+1}) + \bar{u}_N(t_i))) = 0, \tag{42}$$

then the pair (x, u) satisfies $x'(t) = Ax + Bu$, $x(t_0) = x_0$.

Proof. We have that $(\bar{x}_N, \bar{u}_N)$ satisfies (42). Adding zero we have

$$\bar{x}_N(t_{i+1}) - \bar{x}_N(t_i) - \frac{h_i}{2}(A(\bar{x}_N(t_{i+1}) + \bar{x}_N(t_i)) + B(u(t_{i+1}) + u(t_i)) \\ +B(\bar{u}_N(t_{i+1}) - u(t_{i+1}) + \bar{u}_N(t_i) - u(t_i))) = 0.$$

Let M be any positive integer and replace $\bar{u}_N(t)$ above with $\bar{u}_M(t)$, which is fixed. Define $e_M(t) = \bar{u}_M(t) - u(t)$ to obtain

$$\bar{x}_N(t_{i+1}) - \bar{x}_N(t_i) - \frac{h_i}{2}(A(\bar{x}_N(t_{i+1}) + \bar{x}_N(t_i)) \\ + B(u(t_{i+1}) + u(t_i)) + B(e_M(t_{i+1}) + e_M(t_i))) = 0.$$

Since u and $\bar{u}_M$ are Lipschitz we have that e_M is also Lipschitz. If $\|T_N\|$ is small, then by Lemma 5.6, $\|\bar{x}_N(t) - y(t)\| \leq K_2\|T_N\|$ where y satisfies the differential equation $y' = Ay + Bu + Be_M,\ \ y(t_0) = x_0$. Let z be the solution of the differential equation $z' = Az + Bu,\ \ z(t_0) = x_0$. Lemma 5.9 implies that

$$\|y - z\| \leq \|B\|_\infty(t_f - t_0)\|e_M\|e^{\|A\|_\infty(t_f - t_0)}.$$

Now note that M was arbitrary. Since $\bar{u}_N(t) \to u(t)$ uniformly, let us choose $\hat{M}$ large enough so that

$$\|e_{\hat{M}}(t)\| < \frac{\epsilon}{2\|B\|_\infty(t_f - t_0)(e^{\|A\|_\infty(t_f - t_0)})},$$

which gives $\|y(t) - z(t)\| < \frac{\epsilon}{2}$. Finally choose $N \geq \hat{M}$ large enough so that $\|T_N\| \leq \epsilon/2K_2$ to get $\|\bar{x}_N(t) - y(t)\| < \frac{\epsilon}{2}$, and hence $\|\bar{x}_N(t) - z(t)\| < \epsilon$. Thus $\bar{x}_N(t)$ converges to both $x(t)$ and $z(t)$, which implies that $x(t) = z(t)$ and (x, u) satisfies the differential equation with initial conditions. □

Finally, we consider only the $(\bar{x}_N, \bar{u}_N)$ pairs which satisfy $C\bar{x}(t_i) \geq g(t_i)$, which is the set X_N defined earlier.

LEMMA 5.11. *If $(\bar{x}_N(t), \bar{u}_N(t)) \in X_N$ and converges to $(x(t), u(t))$ in $\mathcal{B}$, then $(x(t), u(t)) \in X$.*

Proof. First note that since $Cx(t) - g(t) \geq 0$ holds on the dense set $\cup_N T_N$, it holds for all t by continuity. By Lemmas 5.8 and 5.10, we have that (x, u) also satisfies $x' = Ax + Bu,\ x(t_0) = x_0$ with u Lipschitz continuous. Thus $(x, u) \in X \subset \mathcal{B}$. □

We now show item 3 in Theorem 5.1. Let

$$f(x, u) = \int_{t_0}^{t_f} L(x, u)\, dt,$$

and on a given mesh T_N,

$$f_N(\bar{x}_N, \bar{u}_N) = \frac{h_0}{2}L(\bar{x}_N(t_0), \bar{u}_N(t_0)) + \frac{h_{n-1}}{2}L(\bar{x}_N(t_n), \bar{u}_N(t_n)) \\ + \sum_{i=1}^{n-1} \frac{h_{i-1} + h_i}{2} L(\bar{x}_N(t_i), \bar{u}_N(t_i)).$$

ASSUMPTION 5.2. *$L(x, u)$ is a strictly convex functional and if $(x, u) \in \mathcal{B}$, then for all (y, v) such that*

$$\|(x, u) - (y, v)\|_{\mathcal{B}} \leq \Delta, \qquad \Delta > 0,$$

L has the property that

$$|L(x,u) - L(y,v)| \le K_3 \|(x,u) - (y,v)\|_{\mathcal{B}}.$$

In addition, if (x,u) is Lipschitz in t, then L is also Lipschitz in t.

Although Δ can be any finite positive integer, the reader should think of Δ as being a large number.

For ease of notation, we use w_i as the weights associated with the trapezoid rule.

Lemma 5.12. *Given $(x,u) \in \mathcal{B}$ and f and f_N defined above, then $|f(x,u) - f_N(x,u)| \le K_6\|T_N\|$*

Proof. Since x and u are fixed, the functions $f(x,u)$ and $f_N(x,u)$ can be considered functions of t and the mesh T_N. Hence,

$$|f(x,u) - f_N(x,u)| = \left| \int_{t_0}^{t_f} L(t)\, dt - \sum_{i=0}^{n} w_i L(t_i) \right|,$$

where w_i are the weights corresponding to the trapezoid quadrature formula. Define $L_N^I(t)$ as the linear approximation to $L(t)$ on a mesh T_N. Recall that the trapezoid approximation is exact for linear functions. Adding zero we have

$$\begin{aligned} |f(x,u) - f_N(x,u)| &= \left| \int_{t_0}^{t_f} L(t) - L_N^I(t)\, dt + \int_{t_0}^{t_f} L_N^I(t)\, dt - \sum_{i=0}^{n} w_i L(t_i) \right| \\ &= \left| \int_{t_0}^{t_f} L(t) - L_N^I(t)\, dt \right| \le \int_{t_0}^{t_f} |L(t) - L_N^I(t)|\, dt \\ &\le \int_{t_0}^{t_f} K_4 \|T_N\|\, dt = (t_f - t_0) K_4 \|T_N\| = K_6 \|T_N\|. \qquad \square \end{aligned}$$

Theorem 5.13. *Given $\epsilon > 0$, $(x,u) \in X$, and any sequence $\{(\bar{x}_N, \bar{u}_N)\} \in X_N$ which converges in norm to (x,u), then there is an N large enough so that $|f(x,u) - f_N(\bar{x}_N, \bar{u}_N)| < \epsilon$.*

Proof. We have that

$$\begin{aligned} |f_N(x,u) - f_N(\bar{x}_N, \bar{u}_N)| &= \left| \sum_{i=0}^{n} w_i (L(x(t_i), u(t_i)) - L(\bar{x}_N(t_i), \bar{u}_N(t_i))) \right| \\ &\le \sum_{i=0}^{n} w_i |L(x(t_i), u(t_i)) - L(\bar{x}_N(t_i), \bar{u}_N(t_i))|. \end{aligned}$$

Since $(\bar{x}_N, \bar{u}_N) \to^{\mathcal{B}} (x,u)$ we can choose N large enough such that

$$\|(x,u) - (\bar{x}_N, \bar{u}_N)\|_{\mathcal{B}} < \min\left\{ \Delta, \frac{\epsilon}{2K_3(t_f - t_0)} \right\},$$

so that

$$|f_N(x,u) - f_N(\bar{x}_N, \bar{u}_N)| \le \sum_{i=0}^{n} w_i K_3 \|(x(t_i), u(t_i)) - (\bar{x}_N(t_i), \bar{u}_N(t_i))\|_{\mathcal{B}}$$

implies

$$|f_N(x,u) - f_N(\bar{x}_N, \bar{u}_N)| < \frac{\epsilon}{2(t_f - t_0)} \sum_{i=0}^{n} w_i\ .$$

Note that the trapezoid quadrature is exact for constant functions, namely,

$$\sum_{i=0}^{n} w_i = t_f - t_0.$$

Hence $|f_N(x,u) - f_N(\bar{x}_N, \bar{u}_N)| < \frac{\epsilon}{2}$. But then

$$|f(x,u) - f_N(\bar{x}_N, \bar{u}_N)| \le |f(x,u) - f_N(x,u)| + |f_N(x,u) - f_N(\bar{x}_N, \bar{u}_N)|.$$

Choose N large enough so that $\|T_N\| < \frac{\epsilon}{2K_6}$. Then $|f(x,u) - f_N(\bar{x}_N, \bar{u}_N)| < \epsilon$. $\square$

6. Conclusion. We have explained why software such as SOCS can converge for inequality constrained optimal control problems where the discretization is not convergent when integrating the constrained dynamics. The optimization uses small perturbations of the inequality constraints to cancel out the large integration error. In classical numerical theory the rapid growth of perturbations is considered bad. Here it is good in that it allows the optimizer to make a small inequality perturbation counteract the large error of the nonconvergent discretization. For linear problems with convex cost functions, linear inequality constraints, and Lipschitz optimal control we have proved convergence of the discrete approximations even though the discrete multipliers may not converge in the usual sense.

It appears that the proof could be extended to more general situations. The three key assumptions appear to be the Lipschitz optimal control, convexity, and that the optimum can be approached from within the feasible set.

Consistent with numerical experience the results hold independent of the order of the constraint, or equivalently the index of the DAE when the constraints are active. This is somewhat surprising in that classical DAE integrator theory does have a strong dependence on the index. Numerical experiments show that there is definite degradation in convergence rate with increasing index, but the relationship is not obvious. This remains to be investigated.

PRINCIPAL ANGLES BETWEEN SUBSPACES IN AN A-BASED SCALAR PRODUCT: ALGORITHMS AND PERTURBATION ESTIMATES*

ANDREW V. KNYAZEV† AND MERICO E. ARGENTATI‡

Abstract. Computation of principal angles between subspaces is important in many applications, e.g., in statistics and information retrieval. In statistics, the angles are closely related to measures of dependency and covariance of random variables. When applied to column-spaces of matrices, the principal angles describe canonical correlations of a matrix pair. We highlight that all popular software codes for canonical correlations compute only cosine of principal angles, thus making impossible, because of round-off errors, finding small angles accurately. We review a combination of sine and cosine based algorithms that provide accurate results for all angles. We generalize the method to the computation of principal angles in an A-based scalar product for a symmetric and positive definite matrix A. We provide a comprehensive overview of interesting properties of principal angles. We prove basic perturbation theorems for absolute errors for sine and cosine of principal angles with improved constants. Numerical examples and a detailed description of our code are given.

Key words. principal angles, canonical correlations, subspaces, scalar product, orthogonal projection, algorithm, accuracy, round-off errors, perturbation analysis

1. Introduction.

Let us consider two real-valued matrices F and G, each with n rows, and their corresponding column-spaces $\mathcal{F}$ and $\mathcal{G}$, which are subspaces in $\mathbf{R^n}$, assuming that

$$p = \dim\mathcal{F} \geq \dim\mathcal{G} = q \geq 1.$$

Then the *principal angles*

$$\theta_1, \dots, \theta_q \in [0, \pi/2]$$

between $\mathcal{F}$ and $\mathcal{G}$ may be defined, e.g., [17, 13], recursively for $k = 1, \dots, q$ by

$$\cos(\theta_k) = \max_{u\, \in\mathcal{F}} \max_{v\, \in\mathcal{G}} u^T v \;=\; u_k^T v_k$$

subject to

$$\|u\| = \|v\| = 1, \quad u^T u_i = 0, \quad v^T v_i = 0, \quad i = 1, \dots, k-1.$$

The vectors $u_1, \dots, u_q$ and $v_1, \dots, v_q$ are called principal vectors. Here and below $\|\cdot\|$ denotes the standard Euclidean norm of a vector or, when applied to a matrix, the corresponding induced operator norm, also called the spectral norm, of the matrix.

‡Department of Mathematics, University of Colorado at Denver, P.O. Box 173364, Campus Box 170, Denver, CO 80217-3364 (rargenta@math.cudenver.edu).

According to [26, 23], the notion of canonical angles between subspaces goes back to Jordan (1875). Principal angles between subspaces, and particularly the smallest and the largest angles, serve as important tools in functional analysis (see books [1, 12, 18] and a survey [9]) and in perturbation theory of invariant subspaces, e.g., [6, 26, 24, 19, 22].

Computation of principal angles between subspaces is needed in many applications. For example, in statistics, the angles are closely related to measures of dependency and covariance of random variables; see a canonical analysis of [5]. When applied to column-spaces $\mathcal{F}$ and $\mathcal{G}$ of matrices F and G, the principal angles describe canonical correlations $\sigma_k(F, G)$ of a matrix pair, e.g., [17, 15], which is important in applications such as system identification and information retrieval. Principal angles between subspaces also appear naturally in computations of eigenspaces, e.g., [20, 21], where angles provide information about solution quality and need to be computed with high accuracy.

In such large-scale applications, it is typical that $n \gg p$; in other words, informally speaking, we are dealing with a small number of vectors having a large number of components. Because of this, we are interested in "matrix-free" methods; i.e., no n-by-n matrices need to be stored in memory in our algorithms.

A singular value decomposition (SVD)-based algorithm [11, 3, 4, 13, 15] for computing cosines of principal angles can be formulated as follows. Let columns of matrices $Q_F \in \mathbf{R^{n\times p}}$ and $Q_G \in \mathbf{R^{n\times q}}$ form orthonormal bases for the subspaces $\mathcal{F}$ and $\mathcal{G}$, respectively. The reduced SVD of $Q_F^T Q_G$ is

$$Y^T Q_F^T Q_G Z \;=\; \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_q), \qquad 1 \ge \sigma_1 \ge \sigma_2 \ge \cdots \ge \sigma_q \ge 0, \tag{1.1}$$

where $Y \in \mathbf{R^{p\times q}}$, $Z \in \mathbf{R^{q\times q}}$ both have orthonormal columns. Then the principal angles can be computed as

$$\theta_k = \arccos(\sigma_k), \qquad k = 1, \ldots, q, \tag{1.2}$$

where

$$0 \le \theta_1 \le \cdots \le \theta_q \le \frac{\pi}{2},$$

while principal vectors are given by

$$u_k = Q_F y_k, \quad v_k = Q_G z_k, \quad k = 1, \ldots, q.$$

The equivalence [3, 13] of the original geometric definition of principal angles and the SVD-based approach follows from the next general theorem on an equivalent representation of singular values.

THEOREM 1.1. *If $M \in \mathbf{R^{m\times n}}$, then the singular values of M are defined recursively by*

$$\sigma_k = \max_{y\,\in \mathbf{R^m}} \max_{z\,\in \mathbf{R^n}} y^T M z \;=\; y_k^T M z_k, \qquad k = 1, \ldots, \min\{m, n\}, \tag{1.3}$$

subject to

$$\|y\| = \|z\| = 1, \quad y^T y_i = 0,\; z^T z_i = 0, \quad i = 1, \ldots, k-1. \tag{1.4}$$

The vectors y_i and z_i are, respectively, left and right singular vectors.

Proof. The proof of the theorem is straightforward if based on Allakhverdiev's representation (see [12]) of singular numbers,

$$\sigma_k = \left\| M - \sum_{i=1}^{k-1} v_i u_i^T \sigma_i \right\|,$$

and using the well-known formula of the induced Euclidean norm of a matrix as the norm of the corresponding bilinear form. □

To apply the theorem to principal angles, one takes $M = Q_F^T Q_G$.

In the most recent publication on the subject, [10], the SVD-based algorithm for cosine is proved to be mixed stable, and QR factorizations with the complete pivoting are recommended for computing Q_F and Q_G.

The SVD-based algorithm for cosine is considered as the standard one at present and is implemented in software packages, e.g., in MATLAB, version 5.3, 2000, code SUBSPACE.m, revision 5.5,[1] where $Q_F \in \mathbf{R^{n \times p}}$ and $Q_G \in \mathbf{R^{n \times q}}$ are computed using the QR factorization.

However, this algorithm cannot provide accurate results for small angles because of the presence of round-off errors. Namely, when using the standard double-precision arithmetic with $EPS \approx 10^{-16}$ the algorithm fails to accurately compute angles smaller than 10^{-8} (see section 2). The problem has been highlighted in the classical paper [3], as well as a cure has been suggested (see also publications on cosine-sine (CS) decomposition methods [25, 28, 26, 23]), but apparently it did not attract enough attention.

In statistics, most software packages include a code for computing $\sigma_k = cos(\theta_k)$, which are called *canonical correlations*; see, e.g., CANCOR Fortran code in FIRST MDS Package of AT&T, CANCR (DCANCR) Fortran subroutine in IMSL STAT/ LIBRARY, G03ADF Fortran code in NAG package, CANCOR subroutine in Splus, and CANCORR procedure in SAS/STAT Software. While accurately computing the cosine of principal angles in corresponding precision, these codes do not compute the sine. However, the cosine simply equals one in double precision for all angles smaller than 10^{-8} (see next section). Therefore, it is impossible in principal to observe an improvement in canonical correlations for angles smaller than 10^{-8} in double precision. It might not be typically important when processing experimental statistical data because the expected measurement error may be so great that a statistician would deem the highly correlated variable essentially redundant and therefore not useful as a further explanatory variable in their model. Statistical computer experiments are different, however, as there is no measurement error, so accurate computation of very high correlations may be important in such applications.

The largest principal angle is related to the notion of distance, or a gap, between equidimensional subspaces. If $p = q$, the distance is defined [1, 12, 13, 18] as

$$\text{gap}(\mathcal{F}, \mathcal{G}) = \|P_F - P_G\| = \sin(\theta_q) = \sqrt{1 - (\cos(\theta_q))^2}, \tag{1.5}$$

where P_F and P_G are orthogonal projectors onto $\mathcal{F}$ and $\mathcal{G}$, respectively.

This formulation provides insight into a possible alternative algorithm for computing the sine of principal angles. The corresponding algorithm, described in [3],

[1] Revision 5.8 of SUBSPACE.m in the current MATLAB release 12.1, version 6.1.0.450, May 18, 2001, is still identical to revision 5.5, which we have used for numerical tests in the present paper.

while being mathematically equivalent to the previous one in exact arithmetic, is accurate for small angles in computer arithmetic as it computes the sine of principal angles directly, without using SVD (1.1) leading to the cosine. We review the algorithm of [3] based on a general form of (1.5) in section 3 and suggest an improved version, similar to the CS decomposition algorithm of [28], with the second SVD of the reduced size.

The CS decomposition methods, e.g., [25, 28, 26, 23], one of which we just mentioned, provide a well-known and popular alternative approach for computing principal angles between subspaces given by selected p (q) columns of orthogonal matrices of the size n. For example, if the matrix $Q_{F^\perp}$, with orthonormal columns that span the subspace $\mathcal{F}^\perp$, the orthogonal complement of $\mathcal{F}$, is available to us, the CS decomposition methods compute the SVD of $(Q_F)^T Q_G$ together with the SVD of $(Q_{F^\perp})^T Q_G$, thus providing cosine and sine of principal angles. When p is of the same order as $n/2$, matrix $Q_{F^\perp}$ is about of the same size as matrix Q_F, and the CS decomposition methods are effective and are recommended for practical computations. However, when $n \gg p$, the CS decomposition methods, explicitly using matrix $Q_{F^\perp}$ of the size n-by-$n-p$, will be less efficient compared to "matrix-free" methods we consider in the present paper. Let us highlight that the cosine- and sine-based methods of [3] that we investigate here in section 3, while different algorithmically from the CS decomposition methods, are very close mathematically to them.

A different sine-based approach, using eigenvalues of $P_F - P_G$, is described in [4, 23]; see a similar statement of Theorem 3.4. It is also not attractive numerically, when $n \gg p$, as it requires computing an n-by-n matrix and finding all its nonzero eigenvalues.

In some applications, e.g., when solving symmetric generalized eigenvalue problems [20], the default scalar product $u^T v$ cannot be used and needs to be replaced with an A-based scalar product $(u, v)_A = u^T A v$, where A is a symmetric positive definite matrix. In statistics, a general scalar product for computing canonical correlations gives a user an opportunity, for example, to take into account a priori information that some vector components are more meaningful than others. In a purely mathematical setting, generalization to A-based scalar products brings nothing really new. In practical computations, however, it carries numerous algorithmic and numerical problems, especially for ill-conditioned cases, which are important in applications.

In section 4, we propose extension of the algorithms to an A-based scalar product and provide the corresponding theoretical justification.

In section 5, we turn our attention to perturbation estimates, which generalize the following trigonometric inequalities: if an angle $\theta \in [0, \pi/2]$ is perturbed by $\epsilon \in [0, \pi/2]$ such that $\theta + \epsilon \in [0, \pi/2]$, then

$$0 \le \cos(\theta) - \cos(\theta + \epsilon) \le \sin(\theta + \epsilon)\sin(\epsilon) \le \sin(\epsilon),$$

$$0 \le \sin(\theta + \epsilon) - \sin(\theta) \le \cos(\theta)\sin(\epsilon) \le \sin(\epsilon).$$

We prove new absolute perturbation estimates for the sine and cosine of principal angles computed in the A-based scalar product. When $A = I$, our estimates are similar to those of [3, 29, 27, 15, 14], but the technique we use is different. More importantly, our constants are somewhat better, in fact, in the same way the constants in the middle terms of the trigonometric inequalities above are less than one.

We consider particular implementation of algorithms used in our MATLAB code SUBSPACEA.m in section 6, with emphasis on the large-scale case, $n \gg p$, and sparse ill-conditioned matrix A, which may be specified only as a function that multiplies A by a given vector. When matrices F and G are sparse, our code can still be used even though it performs orthogonalization of columns of matrices F and G that increases the fill-in; cf. [15]. Also, we do not even touch here upon a practically important issue of the possibility of recomputing the correlations with an increase in the data; see again [15].

Finally, numerical results, presented in section 7, demonstrate the practical robustness of our code.

For simplicity, we discuss only real spaces and real scalar products; however, all results can be trivially generalized to cover complex spaces as well. In fact, our code SUBSPACEA.m is written for the general complex case.

As pointed out by an anonymous referee, several natural questions are left unanswered here.

- Our algorithms are based on SVD. How does SVD accuracy (cf. [2, 8, 7, 10]), especially for small singular values, or in ill-conditioned cases, affect the results?
- In [10], a formal stability analysis is done for the SVD-based algorithm for cosine, which is proved to be mixed stable. In our numerical tests, practical robustness of our algorithms is encouraging. Are our methods accurate and stable theoretically, e.g., see [16]?
- For A-based scalar products, how does the increase of the condition number of A influence the accuracy? Which parts of our algorithm are responsible for the main error growth?

We feel, however, that investigating these matters is not within the limited scope of the present paper, which is already quite long. They may rather serve as interesting directions for future research.

2. Inaccuracy in the cosine-based algorithm.

Let d be a constant and

$$\mathcal{F} = \operatorname{span}\left\{(1\ 0)^T\right\}, \qquad \mathcal{G} = \operatorname{span}\left\{(1\ d)^T\right\}.$$

Then the angle between the one-dimensional subspaces $\mathcal{F}$ and $\mathcal{G}$ can be computed as

$$\theta = \arcsin\left(\frac{d}{\sqrt{1+d^2}}\right). \tag{2.1}$$

In the table below d varies from one to small values. Formula (2.1) is accurate for small angles, so we use it as an "exact" answer in the second column of the table. We use the MATLAB built-in function SUBSPACE.m (revision 5.5) which implements (1.1) to compute values for the third column of the table.

It is apparent that SUBSPACE.m returns inaccurate results for $d \le 10^{-8}$, which is approximately $\sqrt{EPS}$ for double precision.

d	Formula (2.1)	SUBSPACE.m
1.0	7.853981633974483e-001	7.853981633974483e-001
1.0e-04	9.999999966666666e-005	9.999999986273192e-005
1.0e-06	9.999999999996666e-007	1.000044449242271e-006
1.0e-08	1.000000000000000e-008	-6.125742274543099e-017
1.0e-10	1.000000000000000e-010	-6.125742274543099e-017
1.0e-16	9.999999999999998e-017	-6.125742274543099e-017
1.0e-20	9.999999999999998e-021	-6.125742274543099e-017
1.0e-30	1.000000000000000e-030	-6.125742274543099e-017

In this simple one-dimensional example the algorithm of SUBSPACE.m is reduced to computing

$$\theta = \arccos\left(\frac{1}{\sqrt{1+d^2}}\right).$$

This formula clearly shows that the inability to compute accurately small angles is integrated in the standard algorithm and cannot be fixed without changing the algorithm itself. The cosine, that is, a canonical correlation, is computed accurately and simply equals to one for all positive $d \leq 10^{-8}$. However, one cannot determine small angles from a cosine accurately in the presence of round-off errors. In statistical terms, it illustrates the problem we already mentioned above that the canonical correlation itself does not show any improvement in correlation when d is smaller than 10^{-8} in double precision.

In the next section, we consider a formula [3] that directly computes the sine of principal angles as in (2.1).

3. Properties of principal angles and a sine-based algorithm. We first review known sine-based formulas for the largest principal angle. Results of [1, 18] concerning the aperture of two linear manifolds give

$$\|P_F - P_G\| = \max\left\{\max_{x\in\mathcal{G},\|x\|=1}\|(I-P_F)x\|,\ \max_{y\in\mathcal{F},\|y\|=1}\|(I-P_G)y\|\right\}. \tag{3.1}$$

Let columns of matrices $Q_F \in \mathbf{R^{n\times p}}$ and $Q_G \in \mathbf{R^{n\times q}}$ form orthonormal bases for the subspaces $\mathcal{F}$ and $\mathcal{G}$, respectively. Then orthogonal projectors on $\mathcal{F}$ and $\mathcal{G}$ are $P_F = Q_F Q_F^T$ and $P_G = Q_G Q_G^T$, respectively, and

$$\|P_F - P_G\| = \max\{\|(I - Q_F Q_F^T)Q_G\|, \|(I - Q_G Q_G^T)Q_F\|\}. \tag{3.2}$$

If $p \neq q$, then expression of (3.2) is always equal to one; e.g., if $p > q$, then the second term under the maximum is one. If $p = q$, then both terms are the same and yield $\sin(\theta_q)$ by (1.5). Therefore, under our assumption $p \geq q$, only the first term is interesting to analyze. We note that the first term is the largest singular value of $(I - Q_F Q_F^T)Q_G$. What is the meaning of other singular values of the matrix?

This provides an insight into how to find a sine-based formulation to obtain the principal angles, which is embodied in the following theorem [3].

THEOREM 3.1. *Singular values $\mu_1 \leq \mu_2 \leq \cdots \leq \mu_q$ of the matrix $(I - Q_F Q_F^T)Q_G$ are given by $\mu_k = \sqrt{1-\sigma_k^2}$, $k = 1, \dots, q$, where σ_k are defined in* (1.1). *Moreover, the principal angles satisfy the equalities $\theta_k = \arcsin(\mu_k)$.*

The right principal vectors can be computed as

$$v_k = Q_G z_k, \qquad k = 1, \dots, q,$$

where z_k are corresponding orthonormal right singular vectors of matrix $(I - Q_F Q_F^T)Q_G$. The left principal vectors are then computed by

$$u_k = Q_F Q_F^T v_k/\sigma_k \quad \text{if } \sigma_k \neq 0, \quad k = 1, \dots, q.$$

Proof. Our proof is essentially the same as that of [3]. We reproduce it here for completeness as we use a similar proof later for a general scalar product.

Let $B = (I - P_F)Q_G = (I - Q_F Q_F^T)Q_G$. Using the fact that $I - P_F$ is a projector and that $Q_G^T Q_G = I$, we have

$$\begin{aligned} B^T B &= Q_G^T(I - P_F)(I - P_F)Q_G = Q_G^T(I - P_F)Q_G \\ &= I - Q_G^T Q_F Q_F^T Q_G. \end{aligned}$$

Utilizing the SVD (1.1), we obtain $Q_F^T Q_G = Y \Sigma Z^T$, where $\Sigma = \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_q)$; then

$$Z^T B^T B Z = I - \Sigma^2 = \operatorname{diag}(1 - \sigma_1^2, 1 - \sigma_2^2, \ldots, 1 - \sigma_q^2).$$

Thus, the singular values of B are given by $\mu_k = \sqrt{1 - \sigma_k^2}$, $k = 1, \ldots, q$, and the formula for the principal angles $\theta_k = \arcsin(\mu_k)$ follows directly from (1.2). □

We can now use the theorem to formulate an algorithm for computing all the principal angles. This approach meets our goal of a sine-based formulation, which should provide accurate computation of small angles. However, for large angles we keep the cosine-based algorithm.

```
ALGORITHM 3.1: Modified SUBSPACE.m.
Input: real matrices $F$ and $G$ with the same number of rows.
1. Compute orthonormal bases $Q_F = \operatorname{orth}(F)$, $Q_G = \operatorname{orth}(G)$ of column-spaces of $F$ and $G$.
2. Compute SVD for cosine: $[Y, \Sigma, Z] = \operatorname{svd}(Q_F^T Q_G)$, $\Sigma = \operatorname{diag}(\sigma_1, \ldots, \sigma_q)$.
3. Compute matrices of left $U_{\cos} = Q_F Y$ and right $V_{\cos} = Q_G Z$ principal vectors.
4. Compute matrix $B = \begin{cases} Q_G - Q_F(Q_F^T Q_G) & \text{if } \operatorname{rank}(Q_F) \ge \operatorname{rank}(Q_G); \\ Q_F - Q_G(Q_G^T Q_F) & \text{otherwise.} \end{cases}$
5. Compute SVD for sine: $[Y, \operatorname{diag}(\mu_1, \ldots, \mu_q), Z] = \operatorname{svd}(B)$.
6. Compute matrices $U_{\sin}$ and $V_{\sin}$ of left and right principal vectors:
       $V_{\sin} = Q_G Z$, $U_{\sin} = Q_F(Q_F^T V_{\sin})\Sigma^{-1}$   if $\operatorname{rank}(Q_F) \ge \operatorname{rank}(Q_G)$;
       $U_{\sin} = Q_F Z$, $V_{\sin} = Q_G(Q_G^T U_{\sin})\Sigma^{-1}$   otherwise.
7. Compute the principal angles, for $k = 1, \ldots, q$:
       $\theta_k = \begin{cases} \arccos(\sigma_k) & \text{if } \sigma_k^2 < 1/2; \\ \arcsin(\mu_k) & \text{if } \mu_k^2 \le 1/2. \end{cases}$
8. Form matrices $U$ and $V$ by picking up corresponding columns of $U_{\sin}$, $V_{\sin}$ and $U_{\cos}$, $V_{\cos}$, according to the choice for $\theta_k$ above.
Output: Principal angles $\theta_1, \ldots, \theta_q$ between column-spaces of matrices $F$ and $G$, and
    corresponding matrices $U$ and $V$ of left and right principal vectors, respectively.
```

REMARK 3.1. *In step 1 of the algorithm, the orthogonalization can be performed using the QR method or the SVD. In our actual code, an SVD-based built-in MATLAB function ORTH.m is used for the orthogonalization.*

It is pointed out in [10] *that errors in computing Q_F and Q_G, especially expected for ill-conditioned F and G, may lead to an irreparable damage in final answers. A proper column scaling of F and G could in some cases significantly reduce condition numbers of F and G. We highlight that an explicit columnwise normalization of matrices F and G is not required prior to orthogonalization if a particular orthogonalization algorithm used here is invariant under column scaling in finite precision arithmetic. Our numerical tests show that the explicit column scaling is not needed if we utilize a built-in MATLAB function QR.m for orthonormalization. However, the explicit column scaling apparently helps to improve the accuracy when the SVD-based* *built-in MATLAB function ORTH.m is used for orthonormalization. In* [10]*, QR factorizations with complete pivoting are recommended for computing Q_F and Q_G.*

REMARK 3.2. *A check* $\operatorname{rank}(Q_F) \geq \operatorname{rank}(Q_G)$ *in steps* 4 *and* 6 *of the algorithm removes the need for our assumption* $p = \operatorname{rank}(Q_F) \geq \operatorname{rank}(Q_G) = q$.

REMARK 3.3. *We replace here in step* 4

$$(I - Q_F Q_F^T)Q_G = Q_G - Q_F(Q_F^T Q_G), \quad (I - Q_G Q_G^T)Q_F = Q_F - Q_G(Q_G^T Q_F)$$

to avoid storing in memory any n-by-n matrices in the algorithm, which allows us to compute principal angles efficiently for large $n \gg p$ as well.

If the matrix $Q_{F^\perp}$, with orthonormal columns that span the subspace $\mathcal{F}^\perp$, the orthogonal complement of $\mathcal{F}$, was available to us when $p \geq q$, we could take here

$$B = Q_{F^\perp} Q_G,$$

as in the CS decomposition methods; see [25, 28, 26, 23]*. Under our assumption $n \gg p$, however, the matrix $Q_{F^\perp}$ is essentially of the size n and thus shall be avoided.*

The 1/2 threshold used in Algorithm 3.1 in steps 7 and 8 to separate small and large principal angles and corresponding vectors seems to be a natural choice. However, such an artificial fixed threshold may cause troubles with orthogonality in the resulting choice of vectors in step 8 if there are several angles close to each other but on different sides of the threshold. The problem is that the corresponding principal vectors, picked up from two orthogonal sets computed by different algorithms, may not be orthogonal. A more accurate approach would be to identify such possible cluster of principal angles around the original threshold and to make sure that all principal vectors corresponding to the cluster are chosen according to either step 3, or step 6, but not both.

ALGORITHM 3.2: **Modified and Improved SUBSPACE.m.**

Input: *real matrices F and G with the same number of rows.*

```
1.  Compute orthonormal bases $Q_F = \operatorname{orth}(F)$, $Q_G = \operatorname{orth}(G)$ of column-spaces of $F$ and $G$.
2.  Compute SVD for cosine: $[Y, \Sigma, Z] = \operatorname{svd}(Q_F^T Q_G)$, $\Sigma = \operatorname{diag}(\sigma_1, \ldots, \sigma_q)$.
3.  Compute matrices of left $U_{\cos} = Q_F Y$ and right $V_{\cos} = Q_G Z$ principal vectors.
4.  Compute large principal angles, for $k = 1, \ldots, q$:
        $\theta_k = \arccos(\sigma_k)$ if $\sigma_k^2 < 1/2$.
5.  Form parts of matrices $U$ and $V$ by picking up corresponding columns of $U_{\cos}$, $V_{\cos}$,
    according to the choice for $\theta_k$ above. Put columns of $U_{\cos}$, $V_{\cos}$, which are left,
    in matrices $R_F$ and $R_G$. Collect the corresponding $\sigma$'s in a diagonal matrix $\Sigma_R$.
6.  Compute the matrix $B = R_G - Q_F(Q_F^T R_G)$.
7.  Compute SVD for sine: $[Y, \operatorname{diag}(\mu_1, \ldots, \mu_q), Z] = \operatorname{svd}(B)$.
8.  Compute matrices $U_{\sin}$ and $V_{\sin}$ of left and right principal vectors:
        $V_{\sin} = R_G Z$, $U_{\sin} = R_F(R_F^T V_{\sin})\Sigma_R^{-1}$.
9.  Recompute the small principal angles, for $k = 1, \ldots, q$:
        $\theta_k = \arcsin(\mu_k)$ if $\mu_k^2 \leq 1/2$.
10. Complete matrices $U$ and $V$ by adding columns of $U_{\sin}$, $V_{\sin}$.
```

Output: *Principal angles $\theta_1, \ldots, \theta_q$ between column-spaces of matrices F and G, and corresponding matrices U and V of left and right principal vectors, respectively.*

Let us repeat that, in exact arithmetic, the sine and cosine based approaches give the same results; e.g., columns of $U_{\sin}$ and $V_{\sin}$ must be the same as those of $U_{\cos}$

and $V_{\cos}$. Why do we need to recompute essentially the same vectors a second time? What if we compute only $U_{\cos}$, $V_{\cos}$ and then recompute just small principal angles using, e.g., the obvious formula

$$\mu_k = \|u_k - \sigma_k v_k\|? \tag{3.3}$$

An anonymous referee recommended this approach and suggested that it would resolve the inaccuracy in the cosine-based algorithm illustrated in the previous section, without the need for the second SVD.

The answer is that the cosine-based algorithm fails to compute accurately not only the small principal angles but also the corresponding principal vectors. The reason for this is that singular values computed in step 2 of Algorithm 3.1 are the cosines of principal angles, while singular values of the matrix B in step 5 are the sines of principal angles. Thus, the distribution of singular values is different in steps 2 and 5; e.g., singular values corresponding to small angles are much better separated in step 5 than in step 2. For example, angles 10^{-10} and 10^{-12} will produce a multiple singular value 1 in step 2 in double precision but will produce two distinct small singular values in step 5. This means that singular vectors, corresponding to small principal angles, might not be computed accurately in computer arithmetic using only SVD in step 2, which will also lead to inaccurate computation of the small principal angles by formula (3.3). Our numerical tests support this conclusion.

There is some obvious redundancy in Algorithm 3.1. Indeed, we do not need to calculate columns of $U_{\sin}$ and $V_{\sin}$, corresponding to large sines, and columns of $U_{\cos}$ and $V_{\cos}$, corresponding to large cosines, as they are computed inaccurately in computer arithmetic and we just discard them later in the algorithm. However, first, for large-scale applications with $n \gg p$ that we are interested in, the redundancy is insignificant. Second, this allows us to perform steps 2–3 and steps 4–5 of Algorithm 3.1 independently in parallel. We note that Σ must be invertible in Algorithm 3.1.

For sequential computations, we now describe Algorithm 3.2. Here, we reduce computational costs of the second SVD by using already computed vectors $U_{\cos}$ and $V_{\cos}$ for the cosines. The cosine-based algorithm computes inaccurately individual principal vectors corresponding to small principal angles. However, it may find accurately the corresponding invariant subspaces spanned by all these vectors. Thus, the idea is that, using $U_{\cos}$ and $V_{\cos}$, we can identify invariant subspaces in $\mathcal{F}$ and $\mathcal{G}$, which correspond to all small principal angles. Then, we perform the second SVD only for these subspaces, computing only columns of $U_{\sin}$ and $V_{\sin}$ that we actually need, which may significantly reduce the size of the matrix in the second SVD. This idea is used in the CS decomposition algorithm of [28].

We keep steps 1–3 of Algorithm 3.1 unchanged but modify accordingly later steps to obtain Algorithm 3.2. Such changes may significantly reduce the size of matrix B and, thus, the costs, if large principal angles outnumber small ones; e.g., if there are no small principal angles at all, the algorithm simply stops at step 3. We note that matrix Σ_R is always invertible, unlike matrix Σ.

Remark 3.4. *By construction, matrices R_F and R_G have the same number of already orthogonal columns, which removes the need for orthogonalization and for comparing, in step* 6*, their ranks.*

Remark 3.5. *We have three, equivalent in exact arithmetic, possibilities to compute matrix B:*

$$B = (I - R_F R_F^T)R_G = R_G - R_F(R_F^T R_G) = R_G - Q_F(Q_F^T R_G).$$

The first formula is ruled out to avoid storing in memory any n-by-n matrices in the algorithm. Our numerical tests show that the third expression, though somewhat more expensive than the second one, often provides more accurate results in the presence of round-off errors.

To summarize, Algorithms 3.1 and 3.2 use the cosine-based formulation (1.1), (1.2) for large angles and the sine-based formulation of Theorem 3.1 for small angles, which allows accurate computation of all angles. The algorithms are reasonably efficient for large-scale applications with $n \gg p$ and are more robust than the original cosine-based only version.

In the rest of the section, we describe some useful properties of principal angles not yet mentioned. In the present paper, we follow [19] and make use of an orthogonal projectors technique. For an alternative approach, popular in matrix theory, which is based on representation of subspaces in a canonical CS form, we refer to [26].

Theorem 3.1 characterizes singular values of the product $(I - P_F)Q_G$, which are the sine of the principal angles. What are singular values of the matrix $P_F Q_G$? A trivial modification of the previous proof leads to the following not really surprising result that these are the cosine of the principal angles.

THEOREM 3.2. *Singular values of the matrix $Q_F Q_F^T Q_G$ are exactly the same as σ_k, defined in* (1.1).

We conclude this section with other simple and known (e.g., [29, 26, 30]) sine and cosine representations of principal angles and principal vectors, this time using orthogonal projectors P_F and P_G on subspaces $\mathcal{F}$ and $\mathcal{G}$, respectively.

THEOREM 3.3. *Let assumptions of Theorem* 3.1 *be satisfied. Then $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_q$ are the q largest singular values of the matrix $P_F P_G$; in particular,*

$$\sigma_1 = \|P_F P_G\|.$$

Other $n - q$ singular values are all equal to zero.

REMARK 3.6. *As singular values of $P_F P_G$ are the same as those of $P_G P_F$, subspaces $\mathcal{F}$ and $\mathcal{G}$ play symmetric roles in Theorem* 3.3*; thus, our assumption that $p = \dim\mathcal{F} \geq \dim\mathcal{G} = q$ is irrelevant here.*

THEOREM 3.4. *Let assumptions of Theorem* 3.1 *be satisfied. Then $\mu_1 \leq \mu_2 \leq \cdots \leq \mu_q$ are the q largest singular values of the matrix $(I - P_F)P_G$; in particular,*

$$\mu_q = \|(I - P_F)P_G\|.$$

Other $n - q$ singular values are all equal to zero.

REMARK 3.7. *Comparing Theorems* 3.3 *and* 3.4 *shows trivially that sine of principal angles between $\mathcal{F}$ and $\mathcal{G}$ are the same as cosine of principal angles between $\mathcal{F}^\perp$ and $\mathcal{G}$ because $I - P_F$ is an orthogonal projector on $\mathcal{F}^\perp$. If $p > n/2 > q$, it may be cheaper to compute principal angles between $\mathcal{F}^\perp$ and $\mathcal{G}$ instead of principal angles between $\mathcal{F}$ and $\mathcal{G}$.*

What can we say about singular values of the matrix $(I - P_G)P_F$? In other words, how do cosine of principal angles between subspaces $\mathcal{F}^\perp$ and $\mathcal{G}$ compare to cosine of principal angles between their orthogonal complements $\mathcal{F}$ and $\mathcal{G}^\perp$? If $p = q$, they are absolutely the same; in particular, the minimal angle between subspaces $\mathcal{F}^\perp$ and $\mathcal{G}$ is in this case the same as the minimal angle between their orthogonal complements $\mathcal{F}$ and $\mathcal{G}^\perp$, e.g., in [9], and, in fact, is equal to $\text{gap}(\mathcal{F}, \mathcal{G}) = \|P_F - P_G\|$ as we already discussed. When $p > q$, subspaces $\mathcal{F}$ and $\mathcal{G}^\perp$ must have a nontrivial intersection because the sum of their dimensions is too big; thus, the minimal angle between subspaces $\mathcal{F}$ and $\mathcal{G}^\perp$ must be zero in this case, which corresponds to $\|(I - P_G)P_F\| = 1$, while $\|(I - P_F)P_G\|$ may be less than one. To be more specific, $\dim(\mathcal{F} \cap \mathcal{G}^\perp) \geq p - q$; thus, at least $p - q$ singular values of the matrix $(I - P_G)P_F$ are equal to one. Then, we have the following statement, which completely clarifies the issue of principal angles between orthogonal complements; cf. Ex. 1.2.6 of [4].

THEOREM 3.5. *The set of singular values of $(I - P_G)P_F$, when $p > q$, consists of $p - q$ ones, q singular values of $(I - P_F)P_G$, and $n - p$ zeros.*

In particular, this shows that the smallest positive sine of principal angles between $\mathcal{F}$ and $\mathcal{G}$, called the *minimum gap*, is the same as that between $\mathcal{F}^\perp$ and $\mathcal{G}^\perp$; see [18]. This theorem can also be used to reduce the costs of computing the principal angles between subspaces $\mathcal{F}$ and $\mathcal{G}$, when their dimensions p and q are greater than $n/2$, by replacing $\mathcal{F}$ and $\mathcal{G}$ with their orthogonal complements.

Let us finally mention a simple property of principal vectors, emphasized in [29], which helps us to understand a geometric meaning of pairs of corresponding principal vectors from different subspaces.

THEOREM 3.6. *We have*

$$P_F v_k = \sigma_k u_k, \quad P_G u_k = \sigma_k v_k, \quad k = 1, \ldots, q,$$

and

$$u_i^T v_j = (P_F u_i)^T v_j = u_i^T P_F v_j = \sigma_j u_i^T u_j = \sigma_j \delta_{ij}, \qquad i, j = 1, \ldots, q.$$

In other words, a chosen pair u_k, v_k spans a subspace, invariant with respect to orthoprojectors P_F and P_G and orthogonal to all other such subspaces. The kth principal angle θ_k is simply the angle between u_k and v_k; see (3.3).

Moreover, the subspace $\operatorname{span}\{u_k, v_k\}$ *is also invariant with respect to orthoprojectors $I - P_F$ and $I - P_G$. Let us define two other unit vectors in this subspace:*

$$u_k^\perp = (v_k - \sigma_k u_k)/\mu_k \in \mathcal{F}^\perp, \quad v_k^\perp = (u_k - \sigma_k v_k)/\mu_k \in \mathcal{G}^\perp$$

such that $u_k^T u_k^\perp = v_k^T v_k^\perp = 0$. Then

- *u_k, v_k are principal vectors for subspaces $\mathcal{F}$ and $\mathcal{G}$;*
- *$u_k^\perp, v_k$ are principal vectors for subspaces $\mathcal{F}^\perp$ and $\mathcal{G}$;*
- *$u_k, v_k^\perp$ are principal vectors for subspaces $\mathcal{F}$ and $\mathcal{G}^\perp$;*
- *$u_k^\perp, -v_k^\perp$ are principal vectors for subspaces $\mathcal{F}^\perp$ and $\mathcal{G}^\perp$,*

which concludes the description of all cases.

In the next section, we deal with an arbitrary scalar product.

4. Generalization to an A-based scalar product.

Let $A \in \mathbf{R}^{\mathbf{n}\times\mathbf{n}}$ be a fixed symmetric positive definite matrix. Let $(x, y)_A = (x, Ay) = y^T A x$ be an A-based scalar product, $x, y \in \mathbf{R}^{\mathbf{n}}$. Let $\|x\|_A = \sqrt{(x, x)_A}$ be the corresponding vector norm and let $\|B\|_A$ be the corresponding induced matrix norm of a matrix $B \in \mathbf{R}^{\mathbf{n}\times\mathbf{n}}$. We note that $\|x\|_A = \|A^{1/2}x\|$ and $\|B\|_A = \|A^{1/2}BA^{-1/2}\|$.

In order to define principal angles based on this scalar product, we will follow arguments of [3, 13] but in an A-based scalar product instead of the standard Euclidean scalar product. Again, we will assume for simplicity of notation that $p \geq q$.

Principal angles

$$\theta_1, \ldots, \theta_q \in [0, \pi/2]$$

between subspaces $\mathcal{F}$ and $\mathcal{G}$ in the A-based scalar product $(\cdot, \cdot)_A$ are defined recursively for $k = 1, \ldots, q$ by analogy with the previous definition for $A = I$ as

$$\cos(\theta_k) = \max_{u \in \mathcal{F}} \max_{v \in \mathcal{G}} (u, v)_A = (u_k, v_k)_A \tag{4.1}$$

subject to

$$\|u\|_A = \|v\|_A = 1, \quad (u, u_i)_A = 0, \quad (v, v_i)_A = 0, \quad i = 1, \ldots, k-1. \tag{4.2}$$

The vectors $u_1, \ldots, u_q$ and $v_1, \ldots, v_q$ are called principal vectors relative to the A-based scalar product.

The following theorem justifies the consistency of the definition above and provides a cosine-based algorithm for computing the principal angles in the A-based scalar product. It is a direct generalization of the cosine-based approach of [3, 13].

THEOREM 4.1. *Let columns of* $Q_F \in \mathbf{R^{n\times p}}$ *and* $Q_G \in \mathbf{R^{n\times q}}$ *now be A-orthonormal bases for the subspaces F and G, respectively. Let* $\sigma_1 \ge \sigma_2 \ge \cdots \ge \sigma_q$ *be singular values of* $Q_F^T A Q_G$ *with corresponding left and right singular vectors y_k and z_k,* $k = 1, \ldots, q$. *Then the principal angles relative to the scalar product* $(\cdot,\cdot)_A$ *as defined in* (4.1) *and* (4.2) *are computed as*

$$\theta_k = \arccos(\sigma_k), \qquad k = 1, \ldots, q, \tag{4.3}$$

where

$$0 \le \theta_1 \le \cdots \le \theta_q \le \frac{\pi}{2},$$

while the principal vectors are given by

$$u_k = Q_F y_k, \quad v_k = Q_G z_k, \quad k = 1, \ldots, q.$$

Proof. We first rewrite definition (4.1) and (4.2) of principal angles in the following equivalent form. For $k = 1, \ldots, q$,

$$\cos(\theta_k) = \max_{y\, \in \mathbf{R^p}} \max_{z\, \in \mathbf{R^q}} y^T Q_F^T A Q_G z \;=\; y_k^T Q_F^T A Q_G z_k$$

subject to

$$\|y\| = \|z\| = 1, \quad y^T y_i = 0, \quad z^T z_i = 0, \quad i = 1, \ldots, k-1,$$

where $u = Q_F y \in \mathcal{F}$, $v = Q_G z \in \mathcal{G}$ and $u_k = Q_F y_k \in \mathcal{F}$, $v_k = Q_G z_k \in \mathcal{G}$.

Since Q_F and Q_G have A-orthonormal columns, $Q_F^T A Q_F = I$ and $Q_G^T A Q_G = I$. This implies

$$\|u\|_A^2 = y^T Q_F^T A Q_F y = y^T y = \|y\|^2 = 1$$

and

$$\|v\|_A^2 = z^T Q_G^T A Q_G z = z^T z = \|z\|^2 = 1.$$

For $i \ne j$, we derive

$$(u_i, u_j)_A = y_i^T Q_F^T A Q_F y_j = y_i^T y_j = 0$$

and

$$(v_i, v_j)_A = z_i^T Q_G^T A Q_G z_j = z_i^T z_j = 0.$$

Now, let the reduced SVD of $Q_F^T A Q_G$ be

$$Y^T Q_F^T A Q_G Z \;=\; \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_q), \tag{4.4}$$

where $Y \in \mathbf{R}^{\mathbf{p}\times\mathbf{q}}$, $Z \in \mathbf{R}^{\mathbf{q}\times\mathbf{q}}$ both have orthonormal columns.

Then, by Theorem 1.1 with $M = Q_F^T A Q_G$, the equality $\cos(\theta_k) = \sigma_k$, $k = 1, \ldots, q$, just provides two equivalent representations of the singular values of $Q_F^T A Q_G$, and y_z and z_k can be chosen as columns of matrices Y and Z, respectively. The statement of the theorem follows. □

Let us now make a trivial but important observation that links principal angles in the A-based scalar product with principal angles in the original standard scalar product, when a factorization of $A = K^T K$, e.g., $K = A^{1/2}$, is available. We formulate it as the following theorem.

THEOREM 4.2. *Let $A = K^T K$. Under assumptions of Theorem* 4.1 *the principal angles between subspaces $\mathcal{F}$ and $\mathcal{G}$ relative to the scalar product $(\cdot,\cdot)_A$ coincide with the principal angles between subspaces $K\mathcal{F}$ and $K\mathcal{G}$ relative to the original scalar product $(\cdot,\cdot)$.*

Proof. One way to prove this is to notice that our definition of the principal angles between subspaces $\mathcal{F}$ and $\mathcal{G}$ relative to the scalar product $(\cdot,\cdot)_A$ turns into a definition of the principal angles between subspaces $K\mathcal{F}$ and $K\mathcal{G}$ relative to the original scalar product $(\cdot,\cdot)$ if we make substitutions $Ku \mapsto u$ and $Kv \mapsto v$.

Another proof is to use the representation

$$Q_F^T A Q_G = (KQ_F)^T KQ_G,$$

where columns of matrices KQ_F and KQ_G are orthonormal with respect to the original scalar product $(\cdot,\cdot)$ and span subspaces $K\mathcal{F}$ and $K\mathcal{G}$, respectively. Now Theorem 4.1 is equivalent to the traditional SVD theorem on cosine of principal angles between subspaces $K\mathcal{F}$ and $K\mathcal{G}$ relative to the original scalar product $(\cdot,\cdot)$, formulated in the introduction. □

The A-orthogonal projectors on subspaces $\mathcal{F}$ and $\mathcal{G}$ are now defined by formulas

$$P_F = Q_F Q_F^{*_A} = Q_F Q_F^T A \text{ and } P_G = Q_G Q_G^{*_A} = Q_G Q_G^T A,$$

where $*_A$ denotes the A-adjoint.

To obtain a sine-based formulation in the A-based scalar product that is accurate for small angles, we first adjust (1.5) and (3.1) to the new A-based scalar product:

$$\begin{aligned} \operatorname{gap}_A(\mathcal{F},\mathcal{G}) &= \|P_F - P_G\|_A \\ &= \max\left\{\max_{x\in\mathcal{G},\|x\|_A=1} \|(I-P_F)x\|_A,\ \max_{y\in\mathcal{F},\|y\|_A=1} \|(I-P_G)y\|_A\right\}. \end{aligned} \tag{4.5}$$

If $p = q$, this equation will yield $\sin(\theta_q)$, consistent with Theorem 4.1. Similar to the previous case $A = I$, only the first term under the maximum is of interest under our assumption that $p \geq q$. Using the fact that

$$\|x\|_A = \|Q_G z\|_A = \|z\| \ \forall x \in \mathcal{G}, \qquad x = Q_G z,\ z \in \mathbf{R}^{\mathbf{q}},$$

the term of interest can be rewritten as

$$\max_{x\in\mathcal{G},\|x\|_A=1} \|(I-P_F)x\|_A = \|A^{1/2}(I - Q_F Q_F^T A)Q_G\|. \tag{4.6}$$

Here we use the standard induced Euclidean norm $\|\cdot\|$ for computational purposes. Similar to our arguments in the previous section, we obtain a more general formula for all principal angles in the following.

THEOREM 4.3. *Let $S = (I - Q_F Q_F^T A)Q_G$. Singular values $\mu_1 \le \mu_2 \le \cdots \le \mu_q$ of matrix $A^{1/2}S$ are given by $\mu_k = \sqrt{1-\sigma_k^2}$, $k = 1, \ldots, q$, where σ_k are defined in* (4.4)*. Moreover, the principal angles satisfy the equalities $\theta_k = \arcsin(\mu_k)$. The right principal vectors can be computed as*

$$v_k = Q_G z_k, \qquad k = 1, \ldots, q,$$

where z_k are corresponding orthonormal right singular vectors of matrix $A^{1/2}S$. The left principal vectors are then computed by

$$u_k = Q_F Q_F^T A v_k / \sigma_k \quad \text{if } \sigma_k \neq 0, \quad k = 1, \ldots, q.$$

Proof. We first notice that squares of the singular values μ_k of the matrix $A^{1/2}S$, which appear in (4.6), coincide with eigenvalues $\nu_k = \mu_k^2$ of the product $S^T AS$. Using the fact that $Q_F^T A Q_F = I$ and $Q_G^T A Q_G = I$, we have

$$\begin{aligned} S^T AS &= Q_G^T (I - AQ_F Q_F^T) A (I - Q_F Q_F^T A) Q_G \\ &= I - Q_G^T A Q_F Q_F^T A Q_G. \end{aligned}$$

Utilizing the SVD (4.4), we obtain $Q_F^T A Q_G = Y \Sigma Z^T$, where $\Sigma = \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_q)$; then

$$Z^T S^T ASZ = I - \Sigma^2 = \operatorname{diag}(1 - \sigma_1^2, 1 - \sigma_2^2, \ldots, 1 - \sigma_q^2).$$

Thus, the eigenvalues of $S^T AS$ are given by $\nu_k = 1 - \sigma_k^2$, $k = 1, \ldots, q$, and the formula for the principal angles follows directly from (4.3). □

For computational reasons, when n is large, we need to avoid dealing with the square root $A^{1/2}$ explicitly. Also, A may not be available as a matrix but only as a function performing the multiplication of A by a given vector. Fortunately, the previous theorem can be trivially reformulated as follows to resolve this issue.

THEOREM 4.4. *Eigenvalues $\nu_1 \le \nu_2 \le \cdots \le \nu_q$ of matrix $S^T AS$, where $S = (I - Q_F Q_F^T A)Q_G$, are equal to $\nu_k = 1 - \sigma_k^2$, $k = 1, \ldots, q$, where σ_k are defined in* (4.4)*. Moreover, the principal angles satisfy the equalities $\theta_k = \arcsin\left(\sqrt{\nu_k}\right)$, $k = 1, \ldots, q$. The right principal vectors can be computed as*

$$v_k = Q_G z_k, \qquad k = 1, \ldots, q,$$

where z_k are corresponding orthonormal right eigenvectors of matrix $S^T AS$. The left principal vectors are then computed by

$$u_k = Q_F Q_F^T A v_k / \sigma_k \quad \text{if } \sigma_k \neq 0, \quad k = 1, \ldots, q.$$

We can easily modify the previous proof to obtain the following analogue of Theorem 3.2.

THEOREM 4.5. *Singular values of the matrix $A^{1/2} Q_F Q_F^T A Q_G = A^{1/2} P_F Q_G$ coincide with σ_k, defined in* (4.4)*.*

It is also useful to represent principal angles using exclusively A-orthogonal projectors P_F and P_G on subspaces $\mathcal{F}$ and $\mathcal{G}$, respectively, similarly to Theorems 3.3 and 3.4.

THEOREM 4.6. *Under assumptions of Theorem* 4.1*, $\sigma_1 \ge \sigma_2 \ge \cdots \ge \sigma_q$ are the q largest singular values of the matrix $A^{1/2} P_F P_G A^{-1/2}$; in particular,*

$$\sigma_1 = \|P_F P_G\|_A.$$

Other $n-q$ singular values are all equal to zero.

Proof. First, we rewrite

$$\begin{aligned} A^{1/2}P_FP_GA^{-1/2} &= A^{1/2}Q_FQ_F^TAQ_GQ_G^TAA^{-1/2} \\ &= A^{1/2}Q_F\left(A^{1/2}Q_F\right)^T A^{1/2}Q_G\left(A^{1/2}Q_G\right)^T. \end{aligned}$$

As columns of matrices $A^{1/2}Q_F$ and $A^{1/2}Q_G$ are orthonormal with respect to the original scalar product $(\cdot,\cdot)$ bases of subspaces $A^{1/2}\mathcal{F}$ and $A^{1/2}\mathcal{G}$, respectively, the last product is equal to the product of orthogonal (not A-orthogonal!) projectors $P_{A^{1/2}\mathcal{F}}$ and $P_{A^{1/2}\mathcal{G}}$ on subspaces $A^{1/2}\mathcal{F}$ and $A^{1/2}\mathcal{G}$.

Second, we can now use Theorem 3.3 to state that cosine of principal angles between subspaces $A^{1/2}\mathcal{F}$ and $A^{1/2}\mathcal{G}$ with respect to the original scalar product $(\cdot,\cdot)$ are given by the q largest singular values of the product $P_{A^{1/2}\mathcal{F}}P_{A^{1/2}\mathcal{G}} = A^{1/2}P_FP_GA^{-1/2}$.

Finally, we use Theorem 4.2 to conclude that these singular values are, in fact, $\sigma_k,\ k=1,\ldots,q$, i.e., the cosine of principal angles between subspaces $\mathcal{F}$ and $\mathcal{G}$ with respect to the A-based scalar product. □

THEOREM 4.7. *Let assumptions of Theorem 4.4 be satisfied. Then $\mu_1 \le \mu_2 \le \cdots \le \mu_q$ are the q largest singular values of the matrix $A^{1/2}(I-P_F)P_GA^{-1/2}$; in particular,*

$$\mu_q = \|(I-P_F)P_G\|_A.$$

The other $n-q$ singular values are all equal to zero.

Proof. We rewrite

$$\begin{aligned} A^{1/2}(I-P_F)P_GA^{-1/2} &= \left(I - A^{1/2}Q_F\left(A^{1/2}Q_F\right)^T\right)A^{1/2}Q_G\left(A^{1/2}Q_G\right)^T \\ &= \left(I-P_{A^{1/2}\mathcal{F}}\right)P_{A^{1/2}\mathcal{G}} \end{aligned}$$

and then follow arguments similar to those of the previous proof, but now using Theorem 3.4 instead of Theorem 3.3. □

Remarks 3.6–3.7 and Theorems 3.5–3.6 for the case $A=I$ hold in the general case, too, with obvious modifications.

Our final theoretical results are perturbation theorems in the next section.

5. Perturbation of principal angles in the A-based scalar product.

In the present section, for simplicity, we *always assume* that matrices F, G and their perturbations $\tilde{F}$, $\tilde{G}$ have the same rank; thus, in particular, $p=q$.

We notice that F and G appear symmetrically in the definition of the principal angles, under our assumption that they and their perturbations have the same rank. This means that we do not have to analyze the perturbation of F and G together at the same time. Instead, we first study only a perturbation in G.

Before we start with an estimate for cosine, let us introduce a new notation $\ominus$ using an example:

$$(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \mathcal{G} = (\mathcal{G}+\tilde{\mathcal{G}}) \cap \mathcal{G}^{\perp},$$

where $\ominus$ and the orthogonal complement to $\mathcal{G}$ are understood in the A-based scalar product.

Lemma 5.1. *Let $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_q$ and $\hat{\sigma}_1 \geq \hat{\sigma}_2 \geq \cdots \geq \hat{\sigma}_q$ be cosine of principal angles between subspaces $\mathcal{F}$, $\mathcal{G}$ and $\mathcal{F}$, $\tilde{\mathcal{G}}$, respectively, computed in the A-based scalar product. Then, for $k = 1, \ldots, q$,*

$$|\sigma_k - \hat{\sigma}_k| \leq \max\{\cos(\theta_{\min}\{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G},\, \mathcal{F}\});\, \cos(\theta_{\min}\{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\tilde{\mathcal{G}},\, \mathcal{F}\})\}\operatorname{gap}_A(\mathcal{G},\tilde{\mathcal{G}}), \tag{5.1}$$

where $\theta_{\min}$ is the smallest angle between corresponding subspaces, measured in the A-based scalar product.

Proof. The proof is based on the following identity:

$$A^{1/2}Q_FQ_F^TAQ_{\tilde{G}} = A^{1/2}Q_FQ_F^TAQ_GQ_G^TAQ_{\tilde{G}} + A^{1/2}Q_FQ_F^TA(I - Q_GQ_G^TA)Q_{\tilde{G}}, \tag{5.2}$$

which is a multidimensional analogue of the trigonometric formula for the cosine of the sum of two angles. Now we use two classical theorems on perturbation of singular values with respect to addition:

$$s_k(T+S) \leq s_k(T) + \|S\|, \tag{5.3}$$

and with respect to multiplication:

$$s_k(TS^T) \leq s_k(T)\|S^T\|, \tag{5.4}$$

where T and S are matrices of corresponding sizes. We first need to take $T = A^{1/2}Q_FQ_F^TAQ_GQ_G^TAQ_{\tilde{G}}$ and $S = A^{1/2}Q_FQ_F^TA(I - Q_GQ_G^TA)Q_{\tilde{G}}$ in (5.3) to get

$$\begin{aligned}\hat{\sigma}_k = s_k(A^{1/2}Q_FQ_F^TAQ_{\tilde{G}}) \leq{}& s_k(A^{1/2}Q_FQ_F^TAQ_GQ_G^TAQ_{\tilde{G}})\\ &+ \|A^{1/2}Q_FQ_F^TA(I - Q_GQ_G^TA)Q_{\tilde{G}}\|,\end{aligned}$$

where the first equality follows from Theorem 4.5. In the second term in the sum on the right, we need to estimate a product, similar to a product of *three* orthoprojectors. We notice that column vectors of $(I - Q_GQ_G^TA)Q_{\tilde{G}}$ belong to the subspace $(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}$. Let $P_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}$ be an A-orthogonal projector on the subspace. Then the second term can be rewritten, also using the projector $Q_FQ_F^TA = P_F$, as

$$\begin{aligned}A^{1/2}Q_FQ_F^TA(I - Q_GQ_G^TA)Q_{\tilde{G}} &= A^{1/2}Q_FQ_F^TAP_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}(I - Q_GQ_G^TA)Q_{\tilde{G}}\\ &= \left(A^{1/2}P_FP_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}A^{-1/2}\right)A^{1/2}(I - Q_GQ_G^TA)Q_{\tilde{G}};\end{aligned}$$

therefore, it can be estimated as

$$\|A^{1/2}Q_FQ_F^TA(I-Q_GQ_G^TA)Q_{\tilde{G}}\| \leq \|A^{1/2}P_FP_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}A^{-1/2}\|\|A^{1/2}(I-Q_GQ_G^TA)Q_{\tilde{G}}\|.$$

The first multiplier in the last product equals

$$\|A^{1/2}P_FP_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}A^{-1/2}\| = \|P_FP_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}\|_A = \cos(\theta_{\min}\{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G},\, \mathcal{F}\}),$$

similar to (4.6) and using Theorem 4.6 for subspaces $(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}$ and $\mathcal{F}$; while the second multiplier is $\operatorname{gap}_A(\mathcal{G},\tilde{\mathcal{G}})$, because of our assumption $\dim\mathcal{F} = \dim\mathcal{G} = \dim\tilde{\mathcal{G}}$.

To estimate the first term in the sum, we apply (5.4) with $T = A^{1/2}Q_F Q_F^T A Q_G$ and $S^T = Q_G^T A Q_{\tilde{G}}$:

$$\begin{aligned} s_k(A^{1/2}Q_F Q_F^T A Q_G Q_G^T A Q_{\tilde{G}}) &\leq s_k(A^{1/2}Q_F Q_F^T A Q_G)\|Q_G^T A Q_{\tilde{G}}\| \\ &\leq s_k(A^{1/2}Q_F Q_F^T A Q_G) = \sigma_k, \end{aligned}$$

simply because the second multiplier here is the cosine of an angle between $\mathcal{G}$ and $\tilde{\mathcal{G}}$ in the A-based scalar product, which is, of course, bounded by one from above. Thus, we just proved

$$\hat{\sigma}_k \leq \sigma_k + \cos(\theta_{\min}\{(\mathcal{G} + \tilde{\mathcal{G}}) \ominus \mathcal{G}, \mathcal{F}\})\mathrm{gap}_A(\mathcal{G}, \tilde{\mathcal{G}}).$$

Changing places of $Q_{\tilde{G}}$ and Q_G, we obtain

$$\sigma_k \leq \hat{\sigma}_k + \cos(\theta_{\min}\{(\mathcal{G} + \tilde{\mathcal{G}}) \ominus \tilde{\mathcal{G}}, \mathcal{F}\})\mathrm{gap}_A(\mathcal{G}, \tilde{\mathcal{G}})$$

and come to the statement of the lemma. □

REMARK 5.1. *Let us try to clarify the meaning of constants appearing in the statement of Lemma* 5.1. *Let us consider, e.g.,* $\cos(\theta_{\min}\{(\mathcal{G} + \tilde{\mathcal{G}}) \ominus \mathcal{G}, \mathcal{F}\})$. *The cosine takes its maximal value, one, when at least one direction of the perturbation of* $\mathcal{G}$ *is A-orthogonal to* $\mathcal{G}$ *and parallel to* $\mathcal{F}$ *at the same time. It is small, on the contrary, when a part of the perturbation, A-orthogonal to* $\mathcal{G}$*, is also A-orthogonal to* $\mathcal{F}$*. As* $(\mathcal{G} + \tilde{\mathcal{G}}) \ominus \mathcal{G} \subseteq \mathcal{G}^\perp$*, we have*

$$\cos(\theta_{\min}\{(\mathcal{G} + \tilde{\mathcal{G}}) \ominus \mathcal{G}, \mathcal{F}\}) \leq \cos\left(\theta_{\min}\{\mathcal{G}^\perp, \mathcal{F}\}\right) = \sin\left(\theta_{\max}\{\mathcal{G}, \mathcal{F}\}\right) = \mathrm{gap}_A(\mathcal{G}, \mathcal{F}),$$

which is the constant of the asymptotic perturbation estimate of [3] *(where* $A = I$*). The latter constant is small if subspaces* $\mathcal{G}$ *and* $\mathcal{F}$ *are close to each other, which can be considered more as a cancellation prize as in this case cosine of all principal angles is almost one, and a perturbation estimate for the cosine does not help much because of the cancellation effect.*

REMARK 5.2. *A natural approach similar to that of* [15] *with* $A = I$ *involves a simpler identity:*

$$Q_F^T A Q_{\tilde{G}} = Q_F^T A Q_G + Q_F^T A(Q_{\tilde{G}} - Q_G),$$

where a norm of the second term is then estimated. Then (5.3) *gives an estimate of singular values using* $\|A^{1/2}(Q_{\tilde{G}} - Q_G)\|$*. As singular values are invariant with respect to particular choices of matrices* $Q_{\tilde{G}}$ *and* Q_G *with A-orthonormal columns, as far as they provide ranges* $\tilde{\mathcal{G}}$ *and* $\mathcal{G}$*, respectively, we can choose them to minimize the norm of the difference, which gives*

$$\inf_Q \|A^{1/2}(Q_G - Q_{\tilde{G}}Q)\|, \tag{5.5}$$

where Q is an arbitrary q-by-q orthogonal matrix. This quantity appears in [15] *with* $A = I$ *as a special type of the Procrustes problem. In* [15]*, it is estimated in terms of the gap between subspaces* $\tilde{\mathcal{G}}$ *and* $\mathcal{G}$ *(using an extra assumption that* $2q \leq n$*). Repeating similar arguments, we derive*

$$|\sigma_k - \hat{\sigma}_k| \leq \inf_Q \|A^{1/2}(Q_G - Q_{\tilde{G}}Q)\|_A \leq \sqrt{2}\,\mathrm{gap}_A(\mathcal{G}, \tilde{\mathcal{G}}), \qquad k = 1, \ldots, q. \tag{5.6}$$

Lemma 5.1 *furnishes estimates of the perturbation of singular values in terms of the gap directly, which gives a much better constant, consistent with that of the asymptotic estimate of* [3] *for $A = I$; see the previous remark.*

Now we prove a separate estimate for sine.

LEMMA 5.2. *Let $\mu_1 \leq \mu_2 \leq \cdots \leq \mu_q$ and $\hat{\mu}_1 \leq \hat{\mu}_2 \leq \cdots \leq \hat{\mu}_q$ be sine of principal angles between subspaces $\mathcal{F}$, $\mathcal{G}$, and $\mathcal{F}$, $\tilde{\mathcal{G}}$, respectively, computed in the A-based scalar product. Then, for $k = 1, \ldots, q$,*

$$|\mu_k - \hat{\mu}_k| \leq \max\{\sin(\theta_{\max}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \mathcal{G},\, \mathcal{F}\});\, \sin(\theta_{\max}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \tilde{\mathcal{G}},\, \mathcal{F}\})\}\mathrm{gap}_A(\mathcal{G}, \tilde{\mathcal{G}}), \tag{5.7}$$

where $\theta_{\max}$ is the largest angle between corresponding subspaces, measured in the A-based scalar product.

Proof. The proof is based on the following identity:

$$\begin{aligned} A^{1/2}(I - Q_F Q_F^T A)Q_{\tilde{G}} = {} & A^{1/2}(I - Q_F Q_F^T A)Q_G Q_G^T A Q_{\tilde{G}} \\ & + A^{1/2}(I - Q_F Q_F^T A)(I - Q_G Q_G^T A)Q_{\tilde{G}}, \end{aligned}$$

which is a multidimensional analogue of the trigonometric formula for the sine of the sum of two angles. The rest of the proof is similar to that of Lemma 5.1.

We first need to take $T = A^{1/2}(I - Q_F Q_F^T A)Q_G Q_G^T A Q_{\tilde{G}}$ and $S = A^{1/2}(I - Q_F Q_F^T A)(I - Q_G Q_G^T A)Q_{\tilde{G}}$ and use (5.3) to get

$$\begin{aligned} s_k(A^{1/2}(I - Q_F Q_F^T A)Q_{\tilde{G}}) \leq {} & s_k(A^{1/2}(I - Q_F Q_F^T A)Q_G Q_G^T A Q_{\tilde{G}}) \\ & + \|A^{1/2}(I - Q_F Q_F^T A)(I - Q_G Q_G^T A)Q_{\tilde{G}}\|. \end{aligned}$$

In the second term in the sum on the right, $Q_F Q_F^T A = P_F$ and we deduce

$$\begin{aligned} A^{1/2}(I - Q_F Q_F^T A)(I - Q_G Q_G^T A)Q_{\tilde{G}} &= A^{1/2}(I - P_F)P_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}(I - Q_G Q_G^T A)Q_{\tilde{G}} \\ &= \left(A^{1/2}(I - P_F)P_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}A^{-1/2}\right)\left(A^{1/2}(I - Q_G Q_G^T A)Q_{\tilde{G}}\right), \end{aligned}$$

using notation $P_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}$ for the A-orthogonal projector on the subspace $(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \mathcal{G}$, introduced in the proof of Lemma 5.1. Therefore, the second term can be estimated as

$$\begin{aligned} & \|A^{1/2}(I - Q_F Q_F^T A)(I - Q_G Q_G^T A)Q_{\tilde{G}}\| \\ & \qquad \leq \|A^{1/2}(I - P_F)P_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}A^{-1/2}\|\|A^{1/2}(I - Q_G Q_G^T A)Q_{\tilde{G}}\|. \end{aligned}$$

The first multiplier is

$$\|A^{1/2}(I - P_F)P_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}A^{-1/2}\| = \|(I - P_F)P_{(\mathcal{G}+\tilde{\mathcal{G}})\ominus\mathcal{G}}\|_A = \sin(\theta_{\max}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \mathcal{G},\, \mathcal{F}\})$$

by Theorem 4.7 as $\dim\mathcal{F} \geq \dim((\mathcal{G}+\tilde{\mathcal{G}}) \ominus \mathcal{G})$, while the second multiplier is simply $\mathrm{gap}_A(\mathcal{G}, \tilde{\mathcal{G}})$ because of our assumption $\dim\mathcal{G} = \dim\tilde{\mathcal{G}}$.

To estimate the first term in the sum, we take with $T = A^{1/2}(I - Q_F Q_F^T A)Q_G$ and $S^T = Q_G^T A Q_{\tilde{G}}$ and apply (5.4):

$$\begin{aligned} s_k(A^{1/2}(I - Q_F Q_F^T A)Q_G Q_G^T A Q_{\tilde{G}}) &\leq s_k(A^{1/2}(I - Q_F Q_F^T A)Q_G)\|Q_G^T A Q_{\tilde{G}}\| \\ &\leq s_k(A^{1/2}(I - Q_F Q_F^T A)Q_G), \end{aligned}$$

using exactly the same arguments as in the proof of Lemma 5.1.

Thus, we have proved

$$\hat{\mu}_k \leq \mu_k + \sin(\theta_{\max}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \mathcal{G},\, \mathcal{F}\})\mathrm{gap}_A(\mathcal{G},\tilde{\mathcal{G}}).$$

Changing the places of $Q_{\tilde{G}}$ and Q_G, we get

$$\mu_k \leq \hat{\mu}_k + \sin(\theta_{\max}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \tilde{\mathcal{G}},\, \mathcal{F}\})\mathrm{gap}_A(\mathcal{G},\tilde{\mathcal{G}}).$$

The statement of the lemma follows. □

REMARK 5.3. *Let us also highlight that simpler estimates,*

$$|\mu_k - \hat{\mu}_k| \leq \mathrm{gap}_A(\mathcal{G},\tilde{\mathcal{G}}), \quad |\sigma_k - \hat{\sigma}_k| \leq \mathrm{gap}_A(\mathcal{G},\tilde{\mathcal{G}}), \quad k = 1,\dots,q,$$

which are not as sharp as those we prove in Lemmas 5.1 *and* 5.2*, can be derived almost trivially using orthoprojectors (see* [29, 27, 14]*), where this approach is used for the case $A = I$. Indeed, we start with identities*

$$A^{1/2}P_FP_{\tilde{G}}A^{-1/2} = A^{1/2}P_FP_GA^{-1/2} + \left(A^{1/2}P_FA^{-1/2}\right)\left(A^{1/2}(P_{\tilde{G}} - P_G)A^{-1/2}\right)$$

for the cosine and

$$A^{1/2}(I-P_F)P_{\tilde{G}}A^{-1/2} = A^{1/2}(I-P_F)P_GA^{-1/2} + \left(A^{1/2}(I-P_F)A^{-1/2}\right)\left(A^{1/2}(P_{\tilde{G}} - P_G)A^{-1/2}\right)$$

for the sine, and use (5.3) *and Theorems* 4.6 *and* 4.7*. A norm of the second term is then estimated from above by* $\mathrm{gap}_A(\mathcal{G},\tilde{\mathcal{G}})$*, using the fact that for an A-orthoprojector P_F we have $\|P_F\|_A = \|I - P_F\|_A = 1$.*

Instead of the latter, we can use a bit more sophisticated approach, as in [14]*, if we introduce the A-orthogonal projector $P_{\mathcal{G}+\tilde{\mathcal{G}}}$ on the subspace $\mathcal{G}+\tilde{\mathcal{G}}$. Then the norm of second term is bounded by* $\mathrm{gap}_A(\mathcal{G},\tilde{\mathcal{G}})$ *times $\|P_FP_{\mathcal{G}+\tilde{\mathcal{G}}}\|_A$ for the cosine and times $\|(I-P_F)P_{\mathcal{G}+\tilde{\mathcal{G}}}\|_A$ for the sine, where we can now use Theorem* 4.6 *to provide a geometric interpretation of these two constants. This leads to estimates similar to those of* [14] *for $A = I$:*

$$|\sigma_k - \hat{\sigma}_k| \leq \cos(\theta_{\min}\{\mathcal{F},\, \mathcal{G}+\tilde{\mathcal{G}}\})\mathrm{gap}_A(\mathcal{G},\tilde{\mathcal{G}}), \qquad k = 1,\dots,q,$$

and

$$|\mu_k - \hat{\mu}_k| \leq \cos(\theta_{\min}\{\mathcal{F}^{\perp},\, \mathcal{G}+\tilde{\mathcal{G}}\})\mathrm{gap}_A(\mathcal{G},\tilde{\mathcal{G}}), \qquad k = 1,\dots,q.$$

However, the apparent constant "improvement" in the second estimate, for the sine, is truly misleading as

$$\cos(\theta_{\min}\{\mathcal{F}^{\perp},\, \mathcal{G}+\tilde{\mathcal{G}}\}) = 1$$

simply because $\dim\mathcal{F} < \dim(\mathcal{G}+\tilde{\mathcal{G}})$ *in all cases except for the trivial possibility $\mathcal{G} = \tilde{\mathcal{G}}$, so subspaces $\mathcal{F}^{\perp}$ and $\mathcal{G}+\tilde{\mathcal{G}}$ must have a nontrivial intersection.*

The first estimate, for the cosine, does give a better constant (compare to one), but our constant is sharper; e.g.,

$$\cos(\theta_{\min}\{\mathcal{F},\, (\mathcal{G}+\tilde{\mathcal{G}}) \ominus G\}) \leq \cos(\theta_{\min}\{\mathcal{F},\, \mathcal{G}+\tilde{\mathcal{G}}\}).$$

Our more complex identities used to derive perturbation bounds provide an extra projector in the error term, which allows us to obtain better constants.

We can now establish an estimate of absolute sensitivity of cosine and sine of principal angles with respect to absolute *perturbations of subspaces.*

THEOREM 5.3. *Let $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_q$ and $\tilde{\sigma}_1 \geq \tilde{\sigma}_2 \geq \cdots \geq \tilde{\sigma}_q$ be cosine of principal angles between subspaces $\mathcal{F}$, $\mathcal{G}$, and $\tilde{\mathcal{F}}$, $\tilde{\mathcal{G}}$, respectively, computed in the A-based scalar product. Then*

$$|\sigma_k - \tilde{\sigma}_k| \leq c_1 \mathrm{gap}_A(\mathcal{F}, \tilde{\mathcal{F}}) + c_2 \mathrm{gap}_A(\mathcal{G}, \tilde{\mathcal{G}}), \qquad k = 1, \ldots, q, \tag{5.8}$$

where

$$c_1 = \max\{\cos(\theta_{\min}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \mathcal{G},\, \mathcal{F}\}); \cos(\theta_{\min}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \tilde{\mathcal{G}},\, \mathcal{F}\})\},$$

$$c_2 = \max\{\cos(\theta_{\min}\{(\mathcal{F}+\tilde{\mathcal{F}}) \ominus \mathcal{F},\, \tilde{\mathcal{G}}\}); \cos(\theta_{\min}\{(\mathcal{F}+\tilde{\mathcal{F}}) \ominus \tilde{\mathcal{F}},\, \tilde{\mathcal{G}}\})\},$$

where $\theta_{\min}$ is the smallest angle between corresponding subspaces in the A-based scalar product.

Proof. First, by Lemma 5.1, for $k = 1, \ldots, q$,

$$|\sigma_k - \hat{\sigma}_k| \leq \max\{\cos(\theta_{\min}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \mathcal{G},\, \mathcal{F}\}); \cos(\theta_{\min}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \tilde{\mathcal{G}},\, \mathcal{F}\})\}\mathrm{gap}_A(\mathcal{G}, \tilde{\mathcal{G}}).$$

Second, we apply a similar statement to cosine of principal angles between subspaces $\mathcal{F}$, $\tilde{\mathcal{G}}$ and $\tilde{\mathcal{F}}$, $\tilde{\mathcal{G}}$, respectively, computed in the A-based scalar product:

$$|\tilde{\sigma}_k - \hat{\sigma}_k| \leq \max\{\cos(\theta_{\min}\{(\mathcal{F}+\tilde{\mathcal{F}}) \ominus \mathcal{F},\, \tilde{\mathcal{G}}\}); \cos(\theta_{\min}\{(\mathcal{F}+\tilde{\mathcal{F}}) \ominus \tilde{\mathcal{F}},\, \tilde{\mathcal{G}}\})\}\mathrm{gap}_A(\mathcal{F}, \tilde{\mathcal{F}}).$$

The statement of the theorem now follows from the triangle inequality. □

THEOREM 5.4. *Let $\mu_1 \leq \mu_2 \leq \cdots \leq \mu_q$ and $\tilde{\mu}_1 \leq \tilde{\mu}_2 \leq \cdots \leq \tilde{\mu}_q$ be sine of principal angles between subspaces $\mathcal{F}$, $\mathcal{G}$, and $\tilde{\mathcal{F}}$, $\tilde{\mathcal{G}}$, respectively, computed in the A-based scalar product. Then*

$$|\mu_k - \tilde{\mu}_k| \leq c_3 \mathrm{gap}_A(\mathcal{F}, \tilde{\mathcal{F}}) + c_4 \mathrm{gap}_A(\mathcal{G}, \tilde{\mathcal{G}}), \qquad k = 1, \ldots, q, \tag{5.9}$$

where

$$c_3 = \max\{\sin(\theta_{\max}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \mathcal{G},\, \mathcal{F}\}); \sin(\theta_{\max}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \tilde{\mathcal{G}},\, \mathcal{F}\})\},$$

$$c_4 = \max\{\sin(\theta_{\max}\{(\mathcal{F}+\tilde{\mathcal{F}}) \ominus \mathcal{F},\, \tilde{\mathcal{G}}\}); \sin(\theta_{\max}\{(\mathcal{F}+\tilde{\mathcal{F}}) \ominus \tilde{\mathcal{F}},\, \tilde{\mathcal{G}}\})\},$$

where $\theta_{\max}$ is the largest angle between corresponding subspaces in the A-based scalar product.

Proof. First, by Lemma 5.2, for $k = 1, \ldots, q$,

$$|\mu_k - \hat{\mu}_k| \leq \max\{\sin(\theta_{\max}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \mathcal{G},\, \mathcal{F}\}); \sin(\theta_{\max}\{(\mathcal{G}+\tilde{\mathcal{G}}) \ominus \tilde{\mathcal{G}},\, \mathcal{F}\})\}\mathrm{gap}_A(\mathcal{G}, \tilde{\mathcal{G}}).$$

Second, we apply a similar statement to sine of principal angles between subspaces $\mathcal{F}$, $\tilde{\mathcal{G}}$ and $\tilde{\mathcal{F}}$, $\tilde{\mathcal{G}}$, respectively, computed in the A-based scalar product:

$$|\tilde{\mu}_k - \hat{\mu}_k| \leq \max\{\sin(\theta_{\max}\{(\mathcal{F}+\tilde{\mathcal{F}}) \ominus \mathcal{F},\, \tilde{\mathcal{G}}\}); \sin(\theta_{\max}\{(\mathcal{F}+\tilde{\mathcal{F}}) \ominus \tilde{\mathcal{F}},\, \tilde{\mathcal{G}}\})\}\mathrm{gap}_A(\mathcal{F}, \tilde{\mathcal{F}}).$$

The statement of the theorem now follows from the triangle inequality. □

Finally, we want a perturbation analysis in terms of matrices F and G that generate subspaces $\mathcal{F}$ and $\mathcal{G}$. For that, we have to estimate the sensitivity of a column-space of a matrix, for example, matrix G.

LEMMA 5.5. *Let*

$$\kappa_A(G) = \frac{s_{\max}(A^{1/2}G)}{s_{\min}(A^{1/2}G)}$$

denote the corresponding A-based condition number of G, where $s_{\max}$ and $s_{\min}$ are, respectively, largest and smallest singular values of the matrix $A^{1/2}G$. Let $\mathcal{G}$ and $\tilde{\mathcal{G}}$ be column-spaces of matrices G and $\tilde{G}$, respectively. Then

$$\operatorname{gap}_A(\mathcal{G}, \tilde{\mathcal{G}}) \le \kappa_A(G) \frac{\|A^{1/2}(G - \tilde{G})\|}{\|A^{1/2}G\|}. \tag{5.10}$$

Proof. Here, we essentially just adopt the corresponding proof of [29] for the A-based scalar product using the same approach as in Theorem 4.2.

Let us consider the polar decompositions

$$A^{1/2}G = A^{1/2}Q_G T_G \text{ and } A^{1/2}\tilde{G} = A^{1/2}Q_{\tilde{G}} T_{\tilde{G}},$$

where matrices $A^{1/2}Q_G$ and $A^{1/2}Q_{\tilde{G}}$ have orthonormal columns and matrices T_G and $T_{\tilde{G}}$ are q-by-q symmetric positive definite; e.g., $T_G = (Q_G Q_G^T)^{1/2}$. Singular values of T_G and $T_{\tilde{G}}$ are, therefore, the same as singular values of $A^{1/2}G$ and $A^{1/2}\tilde{G}$, respectively. Then,

$$(I - P_{\tilde{G}})(G - \tilde{G}) = (I - P_{\tilde{G}})Q_G T_G.$$

Therefore,

$$A^{1/2}(I - P_{\tilde{G}})Q_G = \left(A^{1/2}(I - P_{\tilde{G}})A^{-1/2}\right) A^{1/2}(G - \tilde{G})T_G^{-1},$$

and

$$\operatorname{gap}_A(\mathcal{G}, \tilde{\mathcal{G}}) \le \|A^{1/2}(G - \tilde{G})\| \|T_G^{-1}\| = \frac{\|A^{1/2}(G - \tilde{G})\|}{s_{\min}(A^{1/2}G)},$$

as $\|A^{1/2}(I - P_{\tilde{G}})A^{-1/2}\| = \|I - P_{\tilde{G}}\|_A \le 1$. The statement of the lemma follows. □

REMARK 5.4. *Some matrices allow improvement of their condition numbers by column scaling, which trivially does not change the column range. Our simple Lemma* 5.5 *does not capture this property. A more sophisticated variant can be easily obtained using a technique developed in* [15, 14].

Our cosine theorem follows next. It generalizes results of [27, 14, 15] to A-based scalar products and somewhat improves the constant.

THEOREM 5.6. *Under assumptions of Theorem* 5.3,

$$|\sigma_k - \tilde{\sigma}_k| \le c_1 \kappa_A(F) \frac{\|A^{1/2}(F - \tilde{F})\|}{\|A^{1/2}F\|} + c_2 \kappa_A(G) \frac{\|A^{1/2}(G - \tilde{G})\|}{\|A^{1/2}G\|}, \qquad k = 1, \ldots, q. \tag{5.11}$$

The theorem above does not provide an accurate estimate for small angles. To fill the gap, we suggest the following perturbation theorem in terms of sine of principal angles; cf. [27, 14] for $A = I$.

Theorem 5.7. *Under assumptions of Theorem* 5.4,

$$|\mu - \tilde{\mu}_k| \leq c_3 \kappa_A(F) \frac{\|A^{1/2}(F - \tilde{F})\|}{\|A^{1/2}F\|} + c_4 \kappa_A(G) \frac{\|A^{1/2}(G - \tilde{G})\|}{\|A^{1/2}G\|}, \qquad k = 1, \dots, q. \tag{5.12}$$

Finally, let us underline that all sensitivity results of the present paper are for *absolute* errors. Golub and Zha in [14] observe that relative errors of sine and cosine of principal angles are not, in general, bounded by the perturbation.

We consider algorithms of computing principal angles with respect to an A-based scalar product in the next section.

6. Algorithm implementation. In this section, we provide a detailed description of our code SUBSPACEA.m and discuss the algorithm implementation.

Theorem 4.4 is our main theoretical foundation for a sine-based algorithm for computing principal angles with respect to an A-based scalar product. However, a naive implementation, using the SVD of the matrix S^TAS, may not produce small angles accurately in computer arithmetic. We now try to explain informally this fact, which is actually observed in numerical tests.

Let, for simplicity of notation, all principal angles be small.

Let us consider a particular case, where columns of matrices Q_F and Q_G are already principal vectors in exact arithmetic. In reality, this is the situation we will face in Algorithm 6.2. Then, in exact arithmetic, columns of S are A-orthogonal and their A-norms are exactly the sine of principal angles. Thus, if there are several small angles different in orders of magnitude, the columns of S are badly scaled. When we take the norms squared, by explicitly computing the product S^TAS, we make the scaling even worse, as the diagonal entries of this diagonal matrix are now the sine of the principal angles squared, in exact arithmetic. In the presence of round-off errors, the matrix S^TAS is usually not diagonal; thus, principal angles smaller than 10^{-8} will lead to an underflow effect in double precision, which cannot be cured by taking square roots of its singular values later in the algorithm.

To resolve this, we want to be able to compute the SVD of the matrix S^TAS without using either S^TAS itself or $A^{1/2}S$. One possibility is suggested in the following lemma.

Lemma 6.1. *The SVD of the matrix $A^{1/2}S$ coincides with the SVD of the matrix Q_S^TAS, where Q_S is a matrix with A-orthonormal columns, which span the same column-space as columns of matrix S.*

Proof. We have

$$(Q_S^TAS)^TQ_S^TAS = S^TAQ_SQ_S^TAS = S^TAP_SS = S^TAS,$$

where $P_S = Q_SQ_S^TA$ is the A-orthogonal projector on the column-space of Q_S, which is the same, by definition, as the column-space of S, so that $P_SS = S$. □

This contributes to the accuracy of our next Algorithm 6.1, based on Lemma 6.1, to be more reliable in the presence of round-off errors, when several principal angles are small.

By analogy with Algorithms 3.1 and 3.2, we can remove the restriction that matrix Σ is invertible and somewhat improve the costs in Algorithm 6.1 by reducing the size of the matrix S in step 4, which leads to Algorithm 6.2.

```
ALGORITHM 6.1: SUBSPACEA.m.
Input: real matrices $F$ and $G$ with the same number of rows, and a symmetric positive
    definite matrix $A$ for the scalar product, or a device to compute $Ax$ for a given
    vector $x$.
 1. Compute $A$-orthonormal bases $Q_F = \mathrm{ortha}(F)$, $Q_G = \mathrm{ortha}(G)$ of column-spaces of
    $F$ and $G$.
 2. Compute SVD for cosine $[Y, \Sigma, Z] = \mathrm{svd}(Q_F^T \, A \, Q_G)$, $\Sigma = \mathrm{diag}(\sigma_1, \ldots, \sigma_q)$.
 3. Compute matrices of left $U_{\cos} = Q_F Y$ and right $V_{\cos} = Q_G Z$ principal vectors.
 4. Compute the matrix $S = \begin{cases} Q_G - Q_F(Q_F^T \, A \, Q_G) & \text{if } \mathrm{rank}(Q_F) \geq \mathrm{rank}(Q_G), \\ Q_F - Q_G(Q_G^T \, A \, Q_F) & \text{otherwise.} \end{cases}$
 5. Compute $A$-orthonormal basis $Q_S = \mathrm{ortha}(S)$ of the column-space of $S$.
 6. Compute SVD for sine: $[Y, \mathrm{diag}(\mu_1, \ldots, \mu_q), Z] = \mathrm{svd}(Q_S^T A S)$.
 7. Compute matrices $U_{\sin}$ and $V_{\sin}$ of left and right principal vectors:
        $V_{\sin} = Q_G Z$, $U_{\sin} = Q_F(Q_F^T A V_{\sin})\Sigma^{-1}$   if $\mathrm{rank}(Q_F) \geq \mathrm{rank}(Q_G)$;
        $U_{\sin} = Q_F Z$, $V_{\sin} = Q_G(Q_G^T A U_{\sin})\Sigma^{-1}$   otherwise.
 8. Compute the principal angles, for $k = 1, \ldots, q$:
        $\theta_k = \begin{cases} \arccos(\sigma_k) & \text{if } \sigma_k^2 < 1/2, \\ \arcsin(\mu_k) & \text{if } \mu_k^2 \leq 1/2. \end{cases}$
 9. Form matrices $U$ and $V$ by picking up corresponding columns of $U_{\sin}$, $V_{\sin}$ and
    $U_{\cos}$, $V_{\cos}$, according to the choice for $\theta_k$ above.
Output: Principal angles $\theta_1, \ldots, \theta_q$ between column-spaces of matrices $F$ and $G$ in the
    $A$-based scalar product, and corresponding matrices of left, $U$, and right, $V$, principal
    vectors.
```

```
ALGORITHM 6.2: Improved SUBSPACEA.m.
Input: real matrices $F$ and $G$ with the same number of rows, and a symmetric positive
    definite matrix $A$ for the scalar product, or a device to compute $Ax$ for a given
    vector $x$.
 1. Compute $A$-orthogonal bases $Q_F = \mathrm{ortha}(F)$, $Q_G = \mathrm{ortha}(G)$ of column-spaces of
    $F$ and $G$.
 2. Compute SVD for cosine $[Y, \Sigma, Z] = \mathrm{svd}(Q_F^T \, A \, Q_G)$, $\Sigma = \mathrm{diag}(\sigma_1, \ldots, \sigma_q)$.
 3. Compute matrices of left $U_{\cos} = Q_F Y$ and right $V_{\cos} = Q_G Z$ principal vectors.
 4. Compute large principal angles for $k = 1, \ldots, q$:
        $\theta_k = \arccos(\sigma_k)$ if $\sigma_k^2 < 1/2$.
 5. Form parts of matrices $U$ and $V$ by picking up corresponding columns of $U_{\cos}$, $V_{\cos}$,
    according to the choice for $\theta_k$ above. Put columns of $U_{\cos}$, $V_{\cos}$, which are left,
    in matrices $R_F$ and $R_G$. Collect the corresponding $\sigma$'s in a diagonal matrix $\Sigma_R$.
 6. Compute the matrix $S = R_G - Q_F(Q_F^T A R_G)$.
 7. Compute $A$-orthogonal basis $Q_S = \mathrm{ortha}(S)$ of the column-space of $S$.
 8. Compute SVD for sine: $[Y, \mathrm{diag}(\mu_1, \ldots, \mu_q), Z] = \mathrm{svd}(Q_S^T A S)$.
 9. Compute matrices $U_{\sin}$ and $V_{\sin}$ of left and right principal vectors:
        $V_{\sin} = R_G Z$, $U_{\sin} = R_F(R_F^T A V_{\sin})\Sigma_R^{-1}$.
10. Compute the missing principal angles, for $k = 1, \ldots, q$:
        $\theta_k = \arcsin(\mu_k)$ if $\mu_k^2 \leq 1/2$.
11. Complete matrices $U$ and $V$ by adding columns of $U_{\sin}$, $V_{\sin}$.
Output: Principal angles $\theta_1, \ldots, \theta_q$ between column-spaces of matrices $F$ and $G$, and
    corresponding matrices $U$ and $V$ of left and right principal vectors, respectively.
```

Previous remarks of section 3 for the algorithms with $A = I$ are applicable to the present algorithms with self-evident changes. A few additional A-specific remarks follow.

REMARK 6.1. *In step* 1 *of Algorithms* 6.1 *and* 6.2*, we use our SVD-based function ORTHA.m for the A-orthogonalization. Specifically, computing an A-orthogonal basis Q of the column-space of a matrix X is done in three steps in ORTHA.m. First, we orthonormalize X, using SVD-based built-in MATLAB code ORTH.m with a preceding explicit column scaling; see Remark* 3.1 *on whether the scaling is actually needed. Second, we compute $[U, S, V] = \mathrm{svd}(X^T AX)$, using MATLAB's built-in SVD code. Finally, we take $Q = XUS^{-1/2}$. If A is ill-conditioned, an extra cycle may be performed to improve the accuracy. While formal stability and accuracy analysis of this method is yet to be done, ORTHA.m demonstrates practical robustness in our numerical tests. A detailed description and investigation of the algorithm used in ORTHA.m will be reported elsewhere.*

REMARK 6.2. *We note that, when $n \gg p$, the computational costs of SVDs of p-by-p matrices are negligible; it is multiplication by A, which may be very computationally expensive. Therefore, we want to minimize the number of multiplications by A. In the present version* 4.0 *of our code SUBSPACEA.m, based on Algorithm* 6.2*, we multiply matrix A by a vector $2p+q$ times in the worst-case scenario of all angles being small, in steps* 1 *and* 7*. We can avoid multiplying by A on steps* 2*,* 8*, and* 9 *by using appropriate linear combinations of earlier computed vectors instead.*

REMARK 6.3. *Our actual code is written for a more general complex case, where we require matrix A to be Hermitian.*

Let us finally underline that in a situation when a matrix K from the factorization $A = K^T K$ is given rather than the matrix A itself, we do not advise using Algorithms 6.1 and 6.2. Instead, we recommend multiplying matrices F and G by K on the right and using simpler Algorithms 3.1 and 3.2, according to Theorem 4.2.

7. Numerical examples. Numerical tests in the present section were performed using version 4.0 of our SUBSPACEA.m code, based on Algorithms 3.2 and 6.2. Numerical results presented were obtained, unless indicated otherwise, on Red Hat 6.1 LINUX Dual Pentium-III 500, running MATLAB release 12, version 6.0.0.18. Tests were also made on Compaq Dual Alpha server DS 20, running MATLAB release 12, version 6.0.0.18 and on several Microsoft Windows Pentium-III systems, running MATLAB version 5.1–5.3. In our experience, Intel PIII-based LINUX systems typically provided more accurate results, apparently utilizing the extended 80 bit precision of FPU registers of PIII; see the discussion at the end of the section.

The main goal of our numerical tests is to check a practical robustness of our code, using the following argument. According to our analysis of section 5 and similar results of [3, 27, 14, 15], an absolute change in cosine and sine of principal angles is bounded by perturbations in matrices F and G, with the constant, proportional to their condition numbers taken after a proper column scaling; see Theorems 5.6 and 5.12 and Remark 5.4. Assuming a perturbation of entries of matrices F and G at the level of double precision, $EPS \approx 10^{-16}$, we expect a similar perturbation in cosine and sine of principal angles, when matrices F and G are well-conditioned after column scaling. We want to check if our code achieves this accuracy in practice.

We concentrate here on testing our sine-based algorithms, i.e., for principal angles smaller than $\pi/4$. The cosine-based algorithm with $A = I$ is recently studied in [10].

Our first example is taken from [3] with $p = 13$ and $m = 26$. Matrices F and G were called A and B in [3]. F was orthogonal, while G was an m-by-p Vandermonde matrix with $\operatorname{cond}(G) \approx 10^4$. Matrix G was generated in double precision and then rounded to single precision.

According to our theory and a perturbation analysis of [3, 27, 14, 15], in this example an absolute change in principal angles is bounded by a perturbation in matrix G times its condition number. Thus, we should expect sine and cosine of principal angles computed in [3] to be accurate with approximately four decimal digits.

In our code, all computations are performed in double precision; therefore, answers in Table 7.1 should be accurate up to twelve decimal digits. We observe, as expected, that our results are consistent with those of [3] within four digits.

TABLE 7.1
Computed sine and cosine of principal angles of the example of [3].

k	$\sin(\theta_k)$	$\cos(\theta_k)$

12	0.99815068733	0.06078820101
13	0.99987854229	0.01558527040

In our next series of tests, we assume n to be even and $p = q \leq n/2$. Let D be a diagonal matrix of the size p:

$$D = \operatorname{diag}(d_1, \ldots, d_p), \quad d_k > 0, \quad k = 1, \ldots, p.$$

We first define n-by-p matrices

$$F_1 = [I\ 0]^T, \quad G_1 = [I\ D\ 0]^T, \tag{7.1}$$

where I is the identity matrix of the size p and 0 are zero matrices of appropriate sizes. We notice that condition numbers of F_1 and G_1 are, respectively, one and

$$\operatorname{cond} G_1 = \sqrt{\frac{1 + (\max\{\operatorname{diag}(D)\})^2}{1 + (\min\{\operatorname{diag}(D)\})^2}}.$$

Thus, the condition number may be large only when large diagonal entries in D are present. Yet in this case, the condition number of G_1 can be significantly reduced by column scaling; see Remark 5.4.

The exact values of sine and cosine of principal angles between column-spaces of matrices F_1 and G_1 are obviously given by

$$\mu_k = \frac{d_k}{\sqrt{1 + d_k^2}}, \quad \sigma_k = \frac{1}{\sqrt{1 + d_k^2}}, \qquad k = 1, \ldots, p, \tag{7.2}$$

respectively, assuming that d_k's are sorted in the increasing order. The collective error in principal angles is measured as the following sum:

$$\sqrt{(\mu_1 - \tilde{\mu}_1)^2 + \cdots + (\mu_p - \tilde{\mu}_p)^2} + \sqrt{(\sigma_1 - \tilde{\sigma}_1)^2 + \cdots + (\sigma_p - \tilde{\sigma}_p)^2}, \tag{7.3}$$

where μ's are the sine and σ's are the cosine of principal angles, and the tilde sign $\tilde{}$ is used for actual computed values.

We multiply matrices F_1 and G_1 by a random orthogonal matrix U of the size n on the left to get

$$F_2 = U * F_1, \quad G_2 = U * G_1. \tag{7.4}$$

This transformation does not change angles and condition numbers. It still allows for improving the condition number of G_2 by column scaling.

Finally, we multiply matrices by random orthogonal p-by-p matrices T_F and T_G, respectively, on the right:

$$F_3 = F_2 * T_F, \quad G_3 = G_2 * T_G. \tag{7.5}$$

This transformation does not change angles or condition numbers. It is likely, however, to remove the possibility of improving the condition number of G_3 by column scaling. Thus, if G_3 is ill-conditioned, we could expect a loss of accuracy; see Theorems 5.6 and 5.12 and Remark 5.4.

We start by checking scalability of the code for well-conditioned cases. We increase the size of the problem n and plot the collective error, given by (7.3), for the principal angles between F_3 and G_3, against the value $n/2$. We solve the same problem two times, using Algorithm 3.2 and Algorithm 6.2 with $A = I$.

In the first two tests, diagonal entries of D are chosen as uniformly distributed random numbers $rand$ on the interval $(0, 1)$. On Figure 7.1 (top) we fix $p = q = 20$. We observe that the average error grows approximately two times with a ten times increase in the problem size. On Figure 7.1 (bottom), we also raise $p = q = n/2$. This time, the error grows with the same pace as the problem size. Please note different scales used for errors on Figure 7.1.

To test our methods for very small angles with $p = q = 20$, we first choose

$$p = 20, \quad d_k = 10^{-k}, \quad k = 1, \dots, p.$$

We observe a similar pattern of the absolute error as that of Figure 7.1 (top) and do not reproduce this figure here because of the space limitations.

In our second test for small angles, we set $p = q = n/2$ as on Figure 7.1 (bottom) and select every diagonal element of D in the form $10^{-17 \cdot rand}$, where $rand$ is again a uniformly distributed random number on the interval $(0, 1)$. The corresponding figure, not shown here for the sake of brevity, looks the same as Figure 7.1 (bottom), except that the error grows a bit faster and reaches the level $\approx 4 \cdot 10^{-14}$ (compare to $\approx 3 \cdot 10^{-14}$ value on Figure 7.1 (bottom)).

In all these and our other analogous tests, Algorithm 3.2 and Algorithm 6.2 with $A = I$ behave very similarly, so that Figure 7.1 provides a typical example.

In our next series of experiments, we fix a small $p = q$ and $n = 100$, and compute angles between F_2 and G_2 and between F_3 and G_3 500 times, changing only the random matrices used in the construction of our F_i and G_i. Instead of the collective error, given by (7.3), we now compute errors for individual principal angles as

$$|\mu_k - \tilde{\mu}_k| + |\sigma_k - \tilde{\sigma}_k|, \qquad k = 1, \dots, p.$$

We tested several different combinations of angles less than $\pi/4$. In most cases, the error was only insignificantly different from $EPS \approx 10^{-16}$. The worst-case scenario found numerically corresponds to

$$D = \mathrm{diag}\{1, 0.5, 10^{-11}, 10^{-12}, 10^{-13}, 5 \cdot 10^{-15}, 2 \cdot 10^{-15}, 10^{-15}, 10^{-16}, 0\}$$

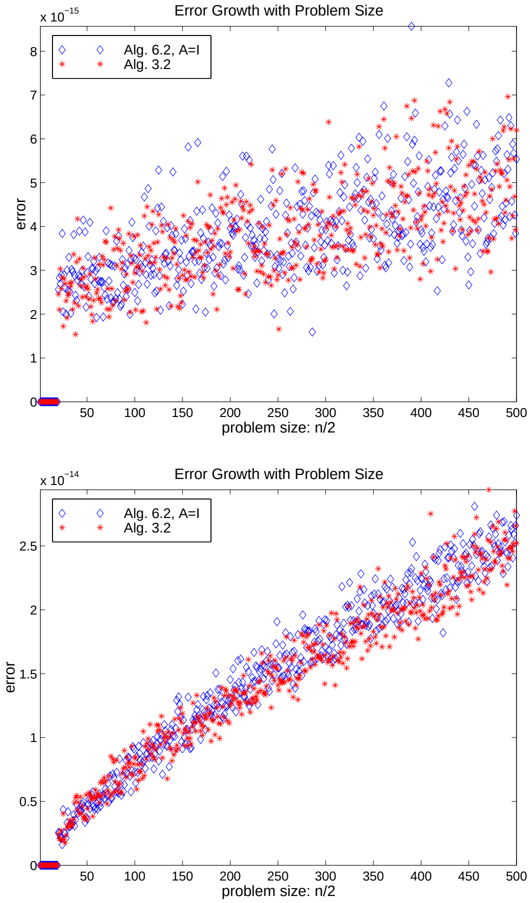

FIG. 7.1. *Errors in principal angles as functions of* $n/2$*:* $p = 20$ *(top) and* $p = n/2$ *(bottom).*

and is presented on Figure 7.2. Figure 7.2 (top) shows the distribution of the error for individual angles between F_3 and G_3 in Algorithm 3.2 in 500 runs. Figure 7.2 (bottom) demonstrates the performance of Algorithm 6.2 with $A = I$, for the same problem. The numeration of angles is reversed for technical reasons; i.e., smaller angles are further away from the viewer. Also the computed distribution of the error for individual angles between F_2 and G_2 are very similar and, because of that, are not shown here.

We detect that for such small values of p and n most of the angles are computed essentially within the double precision accuracy. Only multiple small angles present a slight challenge, more noticeable on Figure 7.2 (bottom), which uses a somewhat different scale for the error to accommodate a larger error. Nevertheless, all observed errors in all 500 runs are bounded from above by $\approx 6\cdot 10^{-15}$ on Figure 7.2, which seems to be a reasonable level of accuracy for accumulation of round-off errors appearing in computations with 200-by-10 matrices in double precision.

To test our code for an ill-conditioned case, we add two large values to the previous choice of D to obtain

$$D = \operatorname{diag}\{10^{10}, 10^{8}, 1, 0.5, 10^{-11}, 10^{-12}, 10^{-13}, 5\cdot 10^{-15}, 2\cdot 10^{-15}, 10^{-15}, 10^{-16}, 0\},$$

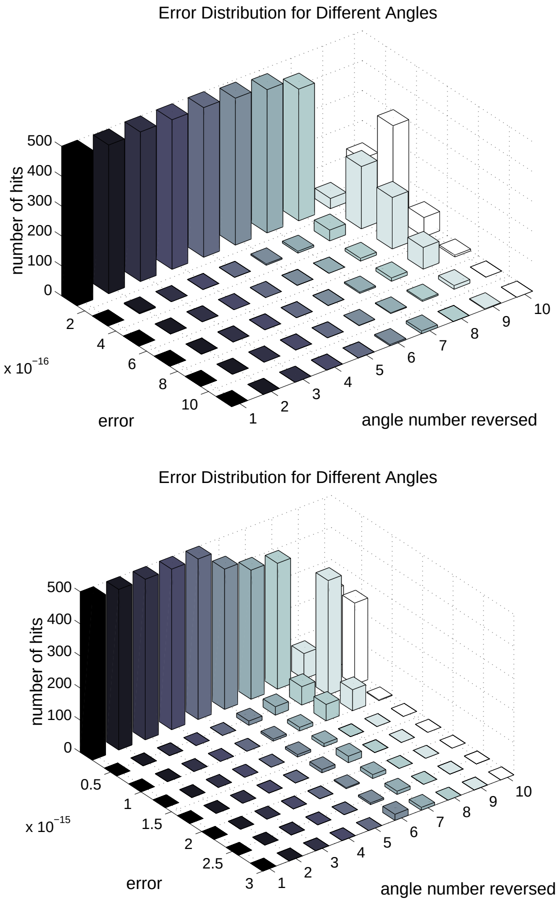

FIG. 7.2. *Errors in individual angles in Algorithms* 3.2 *(top) and* 6.2 *with* $A = I$ *(bottom).*

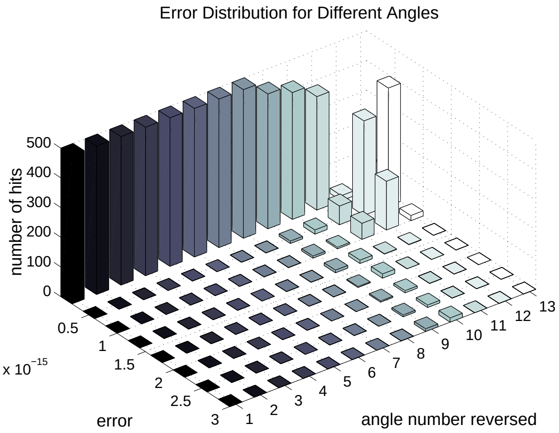
which leads to $\operatorname{cond} G_1 \approx 10^{10}$.

Figure 7.3 (top) shows the distribution of the error for individual angles between F_2 and G_2 in Algorithm 6.2 with $A = I$ after 500 runs. The numeration of angles is again reversed; i.e., smaller angles are further away from the viewer. There is no visible difference between the new Figure 7.3 (top) and the previous Figure 7.2 for the well-conditioned case, which confirms results of [15, 14] on column scaling of ill-conditioned matrices; see Remark 5.4. Namely, our ill-conditioned matrix G_2 can be made well-conditioned by column scaling. Thus, perturbations in the angles should be small. Figure 7.3 (top) therefore demonstrates that our code SUBSPACEA.m is able to take advantage of this.

As we move to computing angles between F_3 and G_3 in this example (see Figure 7.3 (bottom)), where the distribution of the error for individual angles in Algorithm 6.2 with $A = I$ after 500 runs is shown, the situation changes dramatically. In general, it is not possible to improve the condition number $\operatorname{cond}(G_3) \approx 10^{10}$ by column scaling. Thus, according to [3, 15] and our perturbation analysis of Theorems 5.6 and 5.12 and Remark 5.4, we should expect the absolute errors in angles to grow $\approx 10^{10}$ times (compare to the errors on Figure 7.3 (bottom)), i.e., up to the level 10^{-5}. On Figure



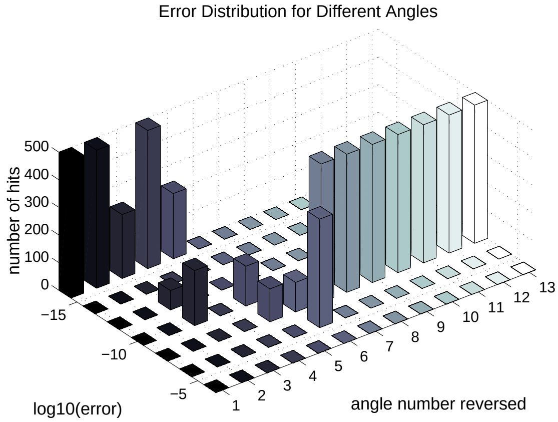


FIG. 7.3. *Errors in individual angles between F_2 and G_2 (top) and F_3 and G_3 (bottom).*

7.3 (bottom), which shows actual errors obtained during 500 runs of the code, we indeed observe absolute errors in angles at the level up to 10^{-5}, as just predicted. Surprisingly, the absolute error for angles with small cosines is much better. We do not have an explanation of such good behavior, as the present theory does not provide individual perturbation bounds for different angles.

Our concluding numerical results illustrate performance of our code for ill-conditioned scalar products.

We take G to be the first ten columns of the identity matrix of size twenty, and F to be the last ten columns of the Vandermonde matrix of size twenty with elements $v_{i,j} = i^{20-j}$, $i, j = 1, \ldots, 20$. Matrix F is ill-conditioned, cond$F \approx 10^{13}$. We compute principal angles and vectors between F and G in an A-based scalar product for the following family of matrices:

$$A = A_l = 10^{-l} I + H, \qquad l = 1, \ldots, 16,$$

where I is identity and H is the Hilbert matrix of the order twenty, whose elements are given by $h_{i,j} = 1/(i + j - 1)$, $i, j = 1, \ldots, 20$. Our subspaces $\mathcal{F}$ and $\mathcal{G}$ do not change with l; only the scalar product that describes the geometry of the space changes.

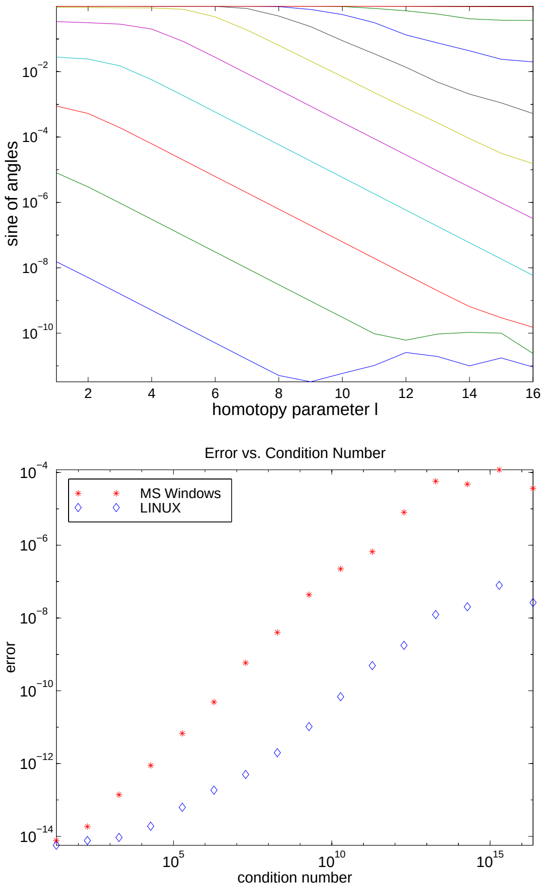

FIG. 7.4. *μ_k as functions of l (top). Errors as functions of condition number (bottom).*

When $l = 1$, we observe three angles with cosine less than 10^{-3} and three angles with sine less than 10^{-3}. When l increases, we are getting closer to the Hilbert matrix, which emphasizes first rows in matrices F and G, effectively ignoring last rows. By construction of F, its large elements, which make subspace $\mathcal{F}$ to be further away from subspace $\mathcal{G}$, are all in last rows. Thus, we should expect large principal angles between $\mathcal{F}$ and $\mathcal{G}$ to decrease monotonically as l grows. We observe this in our numerical tests (see Figure 7.4 (top)), which plots in logarithmic scale sine of all ten principal angles as functions of l.

Of course, such change in geometry that makes sine of an angle to decrease 10^4 times, means that matrix A_l, describing the scalar product, gets more and more ill-conditioned, as it gets closer to Hilbert matrix H, namely, $\text{cond}(A) \approx 10^l$ in our case. It is known that ill-conditioned problems usually lead to a significant increase of the resulting error, as ill-conditioning amplifies round-off errors. To investigate this effect for our code, we introduce the error as the following sum:

$$\text{error} = \|V^T AV - I\| + \|U^T AU - I\| + \|\Sigma - U^T AV\|,$$

where the first two terms control orthogonality of principal vectors and the last term measures the accuracy of cosine of principal angles. We observe in our experiments that different terms in the sum are close to each other, and none dominates. The accuracy of sine of principal angles is not crucial in this example as angles are not small enough to cause concerns. As U and V are constructed directly from columns of F and G, they span the same subspaces with high accuracy independently of condition number of A, as we observe in the tests.

We plot the error on the y-axis of Figure 7.4 (bottom) for a Pentium III 500 PC running two different operating systems: Microsoft Windows NT 4.0 SP6 (red stars) and RedHat LINUX 6.1 (blue diamonds), where the x-axis presents condition number of A; both axes are in logarithmic scale. The MATLAB Version 5.3.1.29215a (R11.1) is the same on both operating systems.

We see, as expected, that the error grows, apparently linearly, with the condition number. We also observe, now with quite a surprise, that the error on LINUX is much smaller than the error on MS Windows!

As the same MATLAB's version and the same code SUBSPACEA.m are run on the same hardware, this fact deserves an explanation. As a result of a discussion with Nabeel and Lawrence Kirby at the News Group *sci.math.num-analysis*, it has been found that MATLAB was apparently compiled on LINUX to take advantage of extended 80 bit precision of FPU registers of PIII, while Microsoft compilers apparently set the FPU to 64 bit operations. To demonstrate this, Nabeel suggested the following elegant example: compute scalar product

$$(1\ 10^{-19}\ \ -1)^T\ (1\ 1\ 1).$$

On MS Windows, the result is zero, as it should be in double precision, while on LINUX the result is 1.084210^{-19}.

Figure 7.4 (bottom) shows that our algorithm turns this difference into a significant error improvement for an ill-conditioned problem.

Finally, our code SUBSPACEA.m has been used since 1999 in the code LOBPCG.m (see [20, 21]) to control accuracy of invariant subspaces of large symmetric generalized eigenvalue problems, and thus has been tested for a variety of large-scale practical problems.

8. Availability of the software.

See http://www.mathworks.com/support/ftp/linalgv5.shtml for our code SUBSPACEA.m and the function ORTHA.m it uses, as well as our fix for SUBSPACE.m, as submitted to MathWorks. They are also publicly available at the Web page maintained by the first author: http://www-math.cudenver.edu/˜aknyazev/software.

9. Conclusion.

Let us formulate here the main points of the present paper:

- A bug in the cosine-based algorithm for computing principal angles between subspaces, which prevents one from computing small angles accurately in computer arithmetic, is illustrated.
- An algorithm is presented that computes all principal angles accurately in computer arithmetic and is proved to be equivalent to the standard algorithm in exact arithmetic.
- A generalization of the algorithm to an arbitrary scalar product given by a symmetric positive definite matrix is suggested and justified theoretically.
- Perturbation estimates for absolute errors in cosine and sine of principal angles, with improved constants and for an arbitrary scalar product, are derived.

- A description of the code is given as well as results of numerical tests. The code is robust in practice and provides accurate angles for large-scale and ill-conditioned cases we tested numerically. It is also reasonably efficient for large-scale applications with $n \gg p$.
- Our algorithms are "matrix-free"; i.e., they do not require storing in memory any matrices of the size n and are capable of dealing with A, which may be specified only as a function that multiplies A by a given vector.

Acknowledgments. The authors thank CU-Denver graduate students Sean Jenson, who helped to test our code SUBSPACEA.m, and Chan-Chai Aniwathananon and Saulo Oliveira, who participated in testing the code ORTHA.m.

The authors are also indebted to anonymous referees for their creative and constructive comments.

FOURTH ORDER CHEBYSHEV METHODS WITH RECURRENCE RELATION[*]

ASSYR ABDULLE[†]

Dedicated to Professor Gerhard Wanner on the occasion of his 60th birthday

Abstract. In this paper, a new family of fourth order Chebyshev methods (also called stabilized methods) is constructed. These methods possess nearly optimal stability regions along the negative real axis and a three-term recurrence relation. The stability properties and the high order make them suitable for large stiff problems, often space discretization of parabolic PDEs. A new code ROCK4 is proposed, illustrated at several examples, and compared to existing programs.

Key words. stiff ordinary differential equations, explicit Runge–Kutta methods, orthogonal polynomials, parabolic partial differential equations

AMS subject classifications. 65L20, 65M20

1. Introduction.

Chebyshev methods are a class of explicit Runge–Kutta methods with extended stability domains along the negative real axis. The stability properties of these methods make them suitable for stiff problems which possess a Jacobian matrix with (possibly large) eigenvalues close to the real negative axis. Since they are explicit, Chebyshev methods avoid linear algebra difficulties and can be applied to very large problems. The main applications are parabolic PDEs when discretized by finite difference. It usually gives a large system of ODEs with a symmetric and negative definite Jacobian matrix. Thus, the eigenvalues of the discretized parabolic PDEs are real negative and, furthermore, become larger while refining the space discretization.

Recently, a new strategy to construct second order Chebyshev methods has been proposed by Abdulle and Medovikov [2]. It combines the advantages of the methods introduced by Lebedev [11], [12] and van der Houwen and Sommeijer [9] (see also [14] for the latest implementation of these methods). An algorithm to construct nearly optimal stability functions along the real negative axis based on orthogonal polynomials was proposed in [2]. The advantage of using orthogonal polynomials is the three-term recurrence relation which can be used to construct the numerical methods. At the same time, choosing an appropriate weight function for these polynomials leads to a nearly optimal stability domain (see [2]).

For order more than 2, the only known Chebyshev methods are those of Medovikov [10]. They are constructed upon the strategy of Lebedev-type methods: the zeros of the optimal stability polynomials are computed, and the numerical methods are based on a suitable ordering of these zeros. The drawback is that the ordering, crucial for the internal stability of the methods, depends on the degree of the polynomials and needs some art. There are also no recurrence relations. The methods of order 4 proposed in this paper are based on a three-term recurrence relation and avoid the preceding problems.

The paper is organized as follows. In section 2 we explain how to compute nearly optimal fourth order stability polynomials. Section 3 is devoted to the construction of a family of numerical methods. These methods have been implemented in a new code called ROCK4 which is briefly described in section 4. Finally, in section 5 we present some numerical experiments and comparisons with other codes.

2. Fourth order stability polynomials. The aim is to construct a family of polynomials of order 4 depending on the degree s,[1]

$$\widetilde{R}_s(z) = 1 + z + \frac{z^2}{2!} + \frac{z^3}{3!} + \frac{z^4}{4!} + \mathcal{O}(z^5), \tag{2.1}$$

which remain bounded by 1 as long as possible along the real negative axis, i.e.,

$$|\widetilde{R}_s(z)| \leq 1 \quad \text{for } z \in [-\widetilde{l}_s, 0], \tag{2.2}$$

with $\widetilde{l}_s$ as large as possible. It is proved in [1] that fourth order optimal stability polynomials (which exist and are unique see [13]) possess exactly four complex zeros. Thus, they can be written as

$$\widetilde{R}_s(z) = \widetilde{w}_4(z)\widetilde{P}_{s-4}(z), \tag{2.3}$$

where $\widetilde{w}_4(z) = (1-/t_1)(1-/\bar{t}_1)(1-/t_2)(1-/\bar{t}_2)$, t_i are complex (conjugate) numbers, and $\widetilde{P}_{s-4}(z)$ possesses only real zeros. The idea developed in [2] for second order is to approximate these polynomials by

$$R_s(z) = w_4(z)P_{s-4}(z), \tag{2.4}$$

where $w_4(z) = (1-/z_1)(1-/\bar{z}_1)(1-/z_2)(1-/\bar{z}_2)$ and $P_{s-4}(z)$ is an orthogonal polynomial associated with the weight function $w_4(z)^2/\sqrt{1-z^2}$. We want to find such a decomposition which satisfies (2.2) for $z \in [-l_s, 0]$ with l_s close to $\widetilde{l}_s$. At the same time, we want that the product satisfies the fourth order conditions (2.1).

The motivation for considering such polynomials can be found in [2]. Notice that for first order optimal polynomials we have a formula similar to (2.3), with $\widetilde{w}(z) = 1$ and $\widetilde{R}_s(z) = T_s(1 + \frac{z}{s^2})$, where $T_s(z)$ are the Chebyshev polynomials. These optimal polynomials are at the same time orthogonal with respect to the weight function $1/\sqrt{1-z^2}$. The arguments developed in [2] show that for order 2 the polynomials (2.3) and (2.4) are very close. These arguments can be generalized for even orders higher than 2. Figure 2.1 shows for $s = 9$ the difference between a fourth order optimal stability polynomial and its approximation. We see that they can hardly be distinguished.

For second order, the algorithm for computing the orthogonal polynomials and the zeros of the function $w(z)$ of (2.4) was given in [2]. We adapt here this algorithm for order 4.

In the following we will work in the normalized interval $[-1, 1]$ instead of $[-l_s, 0]$ by setting $x = 1 + \frac{2z}{l_s}$ (l_s is the length of the stability domain along $\mathbb{R}^-$ we want to optimize), and we take the same notation for the shifted polynomials except for the fact that we use the variable x instead of z. Thus, we are searching for order 4 at $x = 1$ (see below). If we shift the polynomials defined by (2.4) and normalize them

[1] We use the notation $\widetilde{R}_s$ because we reserve R_s for the stability polynomials we will construct.

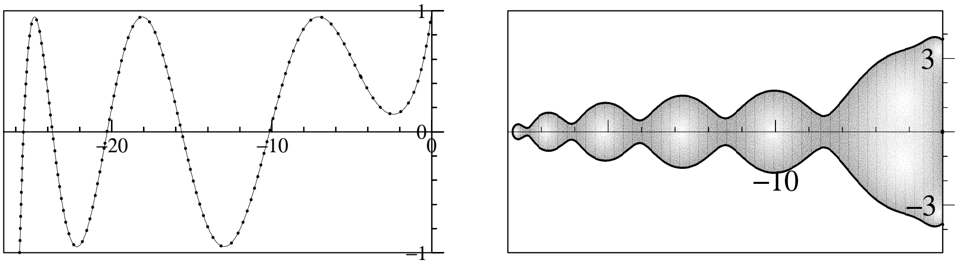

FIG. 2.1. $R_9(x)$ *and its stability domain, with* $\widetilde{R}_9(x)$ *in the dotted line,* $\eta = 0.95$ *(damping).*

such that $|w_4(x)P_{s-4}(x)| \le 1$ for $x \in [-1, 1]$, then $w_4(1)P_{s-4}(1)$ is usually not equal to 1. As in [2], we therefore introduce a parameter a close to 1, set

$$R_s(x) = \frac{w_4(x)P_{s-4}(x)}{w_4(a)P_{s-4}(a)}, \tag{2.5}$$

and we search fourth order conditions at the point a. We denote the complex zeros of $w_4(x)$ by $x_1 = \alpha + i\beta, \bar{x}_1 = \alpha - i\beta, x_2 = \gamma + i\delta, \bar{x}_2 = \gamma - i\delta$, and to emphasize the dependence of $R_s(x)$ on $\alpha, \beta, \gamma, \delta$ we will write $R_s(x, \alpha, \beta, \gamma, \delta)$. We have now an optimization problem.

Problem. Find $a, d, \alpha, \beta, \gamma, \delta$ (depending on s) such that

$$R_s'(a, \alpha, \beta, \gamma, \delta) = d, \qquad R_s''(a, \alpha, \beta, \gamma, \delta) = d^2, \tag{2.6}$$

$$R_s'''(a, \alpha, \beta, \gamma, \delta) = d^3, \qquad R_s^{(4)}(a, \alpha, \beta, \gamma, \delta) = d^4, \tag{2.7}$$

$$|R_s(x)| \le 1 \quad \text{for} \quad x \in [-1, a] \tag{2.8}$$

$$\text{with} \quad l_s = (1 + a)d \quad \text{as large as possible.} \tag{2.9}$$

If we then set $z = (x - a)/d$, we will have

$$R_s(0) = 1, \quad R_s'(0) = 1, \quad R_s''(0) = 1, \quad R_s'''(0) = 1, \quad R_s^{(4)}(0) = 1, \tag{2.10}$$

$$|R_s(z)| \le 1 \quad \text{for} \quad z \in [-l_s, 0]. \tag{2.11}$$

Here again we used the same notation for the shifted polynomials. For more details about this algorithm we refer the reader to [2].

We have computed the parameters $l_s, \alpha, \beta, \gamma, \delta, a$ (depending on s) for degree 5 up to degree more than 1000. In practice the bound in (2.8) should be replaced by a value $\eta < 1$ so that the stability domain is at a safe distance from the real axis (see Figure 2.1). We chose $\eta = 0.95$. In Table 2.1 we give the values of l_s and $c(s) = l_s/s^2$ for some degrees s. Several authors observed that the optimal values $\widetilde{l}_s$ satisfy $\widetilde{l}_s = c(s)s^2$, with $c(s)$ rapidly approaching a limit value. The value $c(s) \simeq 0.34$ is given in [15] (see also [8]) and $c(s) \simeq 0.35$ in [10]. We observe in Table 2.1 that $l_s \simeq 0.35 \cdot s^2$, which means that our stability regions are nearly optimal.

Table 2.1
The stability parameters of $R_s(x)$.

Degree s	Stability region l_s	Value $c(s) = l_s/s^2$	Degree s	Stability region l_s	Value $c(s) = l_s/s^2$
5	5.9983	0.239931	100	3538.1276	0.353813
10	32.4470	0.324470	250	22184.4995	0.354952
20	138.3586	0.345897	500	88746.9995	0.354988
50	879.8864	0.351955	750	199684.4999	0.354995

3. Fourth order Chebyshev methods.

In the preceding section we have explained how to compute our stability polynomials. Assume now that we have such a family of fourth order polynomials (depending on the degree s)

$$R_s(z) = w_4(z)P_{s-4}(z), \tag{3.1}$$

which satisfy

$$|R_s(z)| \leq 1 \quad \text{for} \quad z \in [-l_s, 0], \tag{3.2}$$

where $w_4(z) = (1 - /z_1)(1 - /\bar{z}_1)(1 - /z_2)(1 - /\bar{z}_2)$ and $P_{s-4}(z)$ is an orthogonal polynomial associated with the weight function

$$w_4(z)^2/\sqrt{1 - z^2}, \tag{3.3}$$

and normalized such that $P_{s-4}(0) = 1$. For a given degree s we will further use the family of orthogonal polynomials $(P_j)_{j=0}^{s-4}$ associated with the weight function (3.3), normalized such that $P_j(0) = 1$. These polynomials possess a three-term recurrence relation

$$P_j(z) = (\mu_j z - \nu_j)P_{j-1}(z) - \kappa_j P_{j-2}(z).$$

In [2] it was explained how to compute explicitly these polynomials, given the zeros of the function (3.3). The same procedure can be applied here, and the recurrence coefficients can be computed simply by solving a linear system.

For second order methods, it is sufficient to construct a numerical method which is of order 2 for linear problems, since the order conditions are the same for both linear and nonlinear problems. This is not true for orders larger than 2, and it is therefore not sufficient to consider only the linear case. Here we have to give a realization of our weight function $w_4(z)$ so that the order conditions up to order 4 (8 conditions) are satisfied. As in [10] we will use the theory of composition of methods (the "Butcher group") to realize fourth order Runge–Kutta–Chebyshev methods.

Suppose that we have two Runge–Kutta methods. The idea of composition of methods is to apply one method after the other to an initial value y_0 with the same step size. The result of this process can be interpreted as a large Runge–Kutta method: a composition of the two latter methods. For the theory of composition of Runge–Kutta methods, we refer to [3],[6, pp. 264–273],[5].

To construct a fourth order Runge–Kutta method with the polynomials (3.1) we proceed as follows:

- We construct a first method, denoted by P, which possesses $P_{s-4}(z)$ as stability polynomial.
- We then determine a second method, denoted by W, which possesses $w_4(z)$ as stability polynomial, to achieve fourth order for the "composite" method denoted by WP.

$$\begin{array}{c|cccc}
0 & & & & \\
\widetilde{c}_2 & \widetilde{a}_{21} & & & \\
\vdots & \vdots & \ddots & & \\
\widetilde{c}_{s-4} & \widetilde{a}_{s-4,1} & \dots & \widetilde{a}_{s-4,s-5} & \\
\hline
 & \widetilde{b}_1 & \dots & \widetilde{b}_{s-5} & \widetilde{b}_{s-4}
\end{array}
\qquad\qquad
\begin{array}{c|cccc}
0 & & & & \\
\widehat{c}_2 & \widehat{a}_{21} & & & \\
\widehat{c}_3 & \widehat{a}_{31} & \widehat{a}_{32} & & \\
\widehat{c}_4 & \widehat{a}_{41} & \widehat{a}_{42} & \widehat{a}_{43} & \\
\hline
 & \widehat{b}_1 & \widehat{b}_2 & \widehat{b}_3 & \widehat{b}_4
\end{array}$$

FIG. 3.1. *Tableau of the method P (left) and W (right).*

The resulting method will be of order 4 and will possess $R_s(z) = w_4(z)P_{s-4}(z)$ as stability polynomial.

The first method. To construct the method P we apply a procedure similar to that used in [2]. That is, the three-term recurrence relation of the orthogonal polynomials $(P_j)_{j=1}^{s-4}$ is used to define the internal stages of the method as follows:

$$\begin{aligned}
&g_0 := y_0, \\
&g_1 := y_0 + h\mu_1 f(g_0), \\
&g_j := h\mu_j f(g_{j-1}) - \nu_j g_{j-1} - \kappa_j g_{j-2}, \qquad\qquad j = 2, \dots, s-4, \\
&y_1 := g_{s-4}.
\end{aligned} \tag{3.4}$$

Applied to $y' = \lambda y$ with $z = h\lambda$ yields

$$g_{s-4} = P_{s-4}(z)g_0. \tag{3.5}$$

This method is given in the left tableau of Figure 3.1. The coefficients of the method P can be expressed recursively in term of the coefficients ν_j, μ_j, κ_j. Indeed, using the notation $k_i = f(y_0 + h\sum_{j=1}^{i-1} \widetilde{a}_{ij}k_j)$ (autonomous form), we obtain for the first stage

$$g_1 = y_0 + h\mu_1 f(y_0) = y_0 + h\widetilde{a}_{21}k_1; \tag{3.6}$$

this yields $a_{21} = \mu_1$. For the second stage we have

$$\begin{aligned}
g_2 &= h\mu_2 f(y_0 + h\widetilde{a}_{21}k_1) - \nu_2(y_0 + h\widetilde{a}_{21}k_1) - \kappa_2 y_0 \\
&= y_0(-\nu_2 - \kappa_2) + h(-\nu_2\widetilde{a}_{21})k_1 + h\mu_2 k_2;
\end{aligned} \tag{3.7}$$

hence $\widetilde{a}_{31} = -\nu_2\widetilde{a}_{21}$ and $\widetilde{a}_{32} = \mu_2$. (Notice that $-\nu_2 - \kappa_2 = 1$ because of the normalization $P_j(0) = 1$.) The third stage is then given by

$$\begin{aligned}
g_3 &= h\mu_3 f(y_0 + h(\tilde{a}_{31}k_1 + \tilde{a}_{32}k_2)) - \nu_3(y_0 + h(\tilde{a}_{31}k_1 + \tilde{a}_{32}k_2)) - \kappa_3(y_0 + h\tilde{a}_{21}k_1) \\
&= y_0(-\nu_3 - \kappa_3) + h(-\nu_3\tilde{a}_{31} - \kappa_3\tilde{a}_{21})k_1 + h(-\nu_3\tilde{a}_{32})k_2 + h\mu_3 k_3,
\end{aligned}$$

and thus $\tilde{a}_{41} = -\nu_3\tilde{a}_{31} - \kappa_3\tilde{a}_{21}$, $\tilde{a}_{42} = -\nu_3\tilde{a}_{32}$ and $\tilde{a}_{43} = \mu_3$. By induction we obtain the following lemma.

LEMMA 3.1. *For the method P given by* (3.4) *the coefficients $\widetilde{a}_{ij}, \widetilde{b}_i, \widetilde{c}_i$ of the corresponding Runge–Kutta method are given by*

$$\begin{array}{lcll}
\widetilde{a}_{i,j} & = & -\nu_{i-1}\widetilde{a}_{i-1,j} - \kappa_{i-1}\widetilde{a}_{i-2,j}, & j \le i-2, \qquad i \le s-3 \ (\widetilde{a}_{jj} := 0), \\
\widetilde{a}_{i,i-1} & = & \mu_{i-1}, & i \le s-3, \\
\widetilde{b}_j & = & \widetilde{a}_{s-3,j}, & 1 \le j \le s-4,
\end{array} \tag{3.8}$$

and the $\widetilde{c}_i$ satisfy the usual relation $\widetilde{c}_i = \sum_{j=1}^{i-1} \widetilde{a}_{ij}$. □

We emphasize that the coefficients $\tilde{a}_{ij}, \widetilde{b}_i$ will be used only to compute the method W. For the implementation of the method, formulas (3.4) will be used.

$$
\begin{array}{c|cccccccc}
0 & & & & & & & & \\
\widetilde{c}_2 & \widetilde{a}_{21} & & & & & & & \\
\vdots & \vdots & \ddots & & & & & & \\
\widetilde{c}_{s-4} & \widetilde{a}_{s-4,1} & \dots & \widetilde{a}_{s-4,s-5} & & & & & \\
\sum \widetilde{b}_i & \widetilde{b}_1 & \dots & \widetilde{b}_{s-3} & \widetilde{b}_{s-4} & & & & \\
\sum \widetilde{b}_i + \widehat{c}_2 & \widetilde{b}_1 & \dots & \widetilde{b}_{s-3} & \widetilde{b}_{s-4} & \widehat{a}_{21} & & & \\
\vdots & \vdots & & & & & \ddots & & \\
\sum \widetilde{b}_i + \widehat{c}_4 & \widetilde{b}_1 & \dots & \widetilde{b}_{s-3} & \widetilde{b}_{s-4} & \widehat{a}_{41} & \dots & \widehat{a}_{43} & \\
\hline
 & \widetilde{b}_1 & \dots & \widetilde{b}_{s-3} & \widetilde{b}_{s-4} & \widehat{b}_1 & \dots & \widehat{b}_3 & \widehat{b}_4
\end{array}
$$

FIG. 3.2. *Tableau of method WP.*

The second and the "composite" methods. For the method W we take a fourth stage method (right tableau of Figure 3.1) so that the composite method WP is given by Figure 3.2. In the tableau of method WP, we will denote by c_i the elements of the first column, by a_{ij} the elements of the "triangle," and by b_i the elements of the last row. The order conditions of the method WP are the usual ones for order 4:

$$
\begin{array}{lclcl}
wp(\bullet) & = & \sum b_i & = & 1, \\
wp(/) & = & 2\sum b_i a_{ij} & = & 1, \\
wp(\vee) & = & 3\sum b_i a_{ij} a_{ik} & = & 1, \\
wp(\rangle) & = & 6\sum b_i a_{ij} a_{jk} & = & 1, \\
wp(\Psi) & = & 4\sum b_i a_{ij} a_{ik} a_{il} & = & 1, \\
wp(\dot{\vee}) & = & 8\sum b_i a_{ij} a_{jk} a_{il} & = & 1, \\
wp(Y) & = & 12\sum b_i a_{ij} a_{jk} a_{jl} & = & 1, \\
wp(\wr) & = & 24\sum b_i a_{ij} a_{jk} a_{kl} & = & 1.
\end{array}
\tag{3.9}
$$

Here we used the trees notation (connected graphs without cycles and a distinguished vertex) for the elementary weights ($wp(\dots)$) involved in the order conditions (see [6, pp. 145–154] or [3]).

Theorem 12.6 of [6, p. 267] can be used to express the order conditions of the method WP in function of the two submethods, W and P. See also [5] for a new simple proof of this latter theorem (with another normalization for the elementary weights). We obtain

$$
\begin{array}{lcl}
wp(\bullet) & = & w(\bullet) + p(\bullet), \\
wp(/) & = & w(/) + 2w(\bullet)p(\bullet) + p(/), \\
wp(\vee) & = & w(\vee) + 3w(/)p(\bullet) + 3w(\bullet)p(\bullet)^2 + p(\vee), \\
wp(\rangle) & = & w(\rangle) + 3w(/)p(\bullet) + 3w(\bullet)p(/) + p(\rangle), \\
wp(\Psi) & = & w(\Psi) + 4w(\vee)p(\bullet) + 6w(/)p(\bullet)^2 + 4w(\bullet)p(\bullet)^3 + p(\Psi),
\end{array}
$$

$$\begin{aligned}
wp(\overset{\bullet}{\ddot{\vee}}) &= w(\overset{\bullet}{\ddot{\vee}}) + 4(\tfrac{1}{3}w(\ddot{\rangle})p(\bullet) + \tfrac{2}{3}w(\ddot{\vee})p(\bullet)) + 6(\tfrac{1}{3}w(\diagup)p(\diagup) + \tfrac{2}{3}w(\diagup)p(\bullet)^2) \\
&\quad + 4w(\bullet)p(\bullet)p(\diagup) + p(\overset{\bullet}{\ddot{\vee}}), \\
wp(\ddot{Y}) &= w(\ddot{Y}) + 4w(\ddot{\rangle})p(\bullet) + 6w(\diagup)p(\bullet)^2 + 4w(\bullet)p(\ddot{\vee}) + p(\ddot{Y}), \\
wp(\overset{\bullet}{\ddot{\rangle}}) &= w(\overset{\bullet}{\ddot{\rangle}}) + 4w(\ddot{\rangle})p(\bullet) + 6w(\diagup)p(\diagup) + 4w(\bullet)p(\ddot{\rangle}) + p(\overset{\bullet}{\ddot{\rangle}}),
\end{aligned}$$

where $w(\dots)$ and $p(\dots)$ are the expressions (3.9) for the methods W and P, respectively. These formulas allow us to compute recursively the expressions $w(\bullet), w(\diagup), \dots$ for the method W, since the expressions $p(\bullet), p(\diagup), \dots$ can be computed with the coefficients of the method P given by (3.8). This leads to the following equations for the method W:

$$\begin{aligned}
&\widehat{b}_1 + \widehat{b}_2 + \widehat{b}_3 + \widehat{b}_4 &&= w(\bullet), \\
&\widehat{b}_2\widehat{c}_2 + \widehat{b}_3\widehat{c}_3 + \widehat{b}_4\widehat{c}_4 &&= \tfrac{w(\diagup)}{2}, \\
&\widehat{b}_2\widehat{c}_2^2 + \widehat{b}_3\widehat{c}_3^2 + \widehat{b}_4\widehat{c}_4^2 &&= \tfrac{w(\ddot{\vee})}{3}, \\
(3.10)\qquad &\widehat{b}_3\widehat{a}_{32}\widehat{c}_2 + \widehat{b}_4(\widehat{a}_{42}\widehat{c}_2 + \widehat{a}_{43}\widehat{c}_3) &&= \tfrac{w(\ddot{\rangle})}{6}, \\
&\widehat{b}_2\widehat{c}_2^3 + \widehat{b}_3\widehat{c}_3^3 + \widehat{b}_4\widehat{c}_4^3 &&= \tfrac{w(\dddot{\vee})}{4}, \\
&\widehat{b}_3\widehat{c}_3\widehat{a}_{32}\widehat{c}_2 + \widehat{b}_4\widehat{c}_4(\widehat{a}_{42}\widehat{c}_2 + \widehat{a}_{43}\widehat{c}_3) &&= \tfrac{w(\overset{\bullet}{\ddot{\vee}})}{8}, \\
&\widehat{b}_3\widehat{a}_{32}\widehat{c}_2^2 + \widehat{b}_4(\widehat{a}_{42}\widehat{c}_2^2 + \widehat{a}_{43}\widehat{c}_3^2) &&= \tfrac{w(\ddot{Y})}{12}, \\
&\widehat{b}_4\widehat{a}_{43}\widehat{a}_{32}\widehat{c}_2 &&= \tfrac{w(\overset{\bullet}{\ddot{\rangle}})}{24}.
\end{aligned}$$

This is a system of 8 equations for 10 unknowns $\widehat{b}_i, \widehat{a}_{ij}$ ($\widehat{c}_i$ are determined by $\widehat{c}_i = \sum_{j=1}^{i-1} \widehat{a}_{ij}$.) These equations are similar to the equations of usual fourth order methods (i.e., when $w(\bullet) = 1, w(\diagup) = 1, \dots$; see [6, pp. 135–136]). We have two degrees of freedom, and we choose $\widehat{c}_3 = \frac{w(\bullet)}{3}$ and $\widehat{c}_4 = \frac{2w(\bullet)}{3}$ after some experimentation. This choice keeps the absolute value of the coefficients $\widehat{b}_i, \widehat{a}_{ij}$ less than 1, which is suitable for a numerical method.

The solution of equations (3.10) gives us the coefficients of the method W. Thus, we have obtained a family of methods (depending on the degree of the stability polynomial) of order 4 with recurrence formulas and with the polynomial (3.1) as a stability function.

The embedded method. For the estimation of the local error of the constructed numerical method

$$(3.11)\qquad y_1 = y_0 + h\sum_{i=1}^{s} b_i f\left(y_0 + h\sum_{j=1}^{i-1} a_{ij}k_j\right) = y_0 + h\sum_{i=1}^{s} b_i k_i,$$

we use an embedded method of order 3.

Since for fourth order methods there is no embedded method of order 3 using the same function values $k_i = f(y_0 + h\sum a_{ij}k_j)$ (see [6, p. 167]), we search for a lower

$$
\begin{array}{c|ccccc}
0 & & & & & \\
\widehat{c}_2 & \widehat{a}_{21} & & & & \\
\widehat{c}_3 & \widehat{a}_{31} & \widehat{a}_{32} & & & \\
\widehat{c}_4 & \widehat{a}_{41} & \widehat{a}_{42} & \widehat{a}_{43} & & \\
\hline
\widehat{c}_5 & \widehat{b}_1 & \widehat{b}_2 & \widehat{b}_3 & \widehat{b}_4 & \\
\hline
 & \bar{b}_1 & \bar{b}_2 & \bar{b}_3 & \bar{b}_4 & \bar{b}_5
\end{array}
$$

FIG. 3.3. *Tableau of the method $\overline{W}$.*

order method of the form

$$\overline{y}_1 = y_0 + h\left(\sum_{i=1}^{s}\beta_i f\left(y_0 + h\sum_{j=1}^{i-1}a_{ij}k_j\right) + \beta_{s+1}f(y_1)\right) = y_0 + h\left(\sum_{i=1}^{s}\beta_i k_i + \beta_{s+1}k_{s+1}\right). \tag{3.12}$$

This is no extra work (if the step is accepted) because $f(y_1)$ has to be computed anyway for the next stage. As a measure of the error after one step we will take

$$err = \|y_1 - \overline{y}_1\|. \tag{3.13}$$

We want to keep the recurrence formulas for the embedded method. Therefore, the embedded method will be a composition of the method P, defined in (3.4), with a new method W denoted by $\overline{W}$. For that, we add a fifth stage to the method W as shown in Figure 3.3. Similarly to (3.10) we derive third order conditions for the method $\overline{W}$:

$$
\begin{array}{lcl}
\bar{b}_1 + \bar{b}_2 + \bar{b}_3 + \bar{b}_4 + \bar{b}_5 & = & w(\,\bullet\,), \\
\bar{b}_2\widehat{c}_2 + \bar{b}_3\widehat{c}_3 + \bar{b}_4\widehat{c}_4 + \bar{b}_4\widehat{c}_5 & = & \frac{w(\overset{\bullet}{/})}{2}, \\
\bar{b}_2\widehat{c}_2^2 + \bar{b}_3\widehat{c}_3^2 + \bar{b}_4\widehat{c}_4^2 + \bar{b}_5\widehat{c}_5^2 & = & \frac{w(\overset{\bullet\,\bullet}{\vee})}{3}, \\
\bar{b}_3\widehat{a}_{32}\widehat{c}_2 + \bar{b}_4(\widehat{a}_{42}\widehat{c}_2 + \widehat{a}_{43}\widehat{c}_3) + \bar{b}_5(\widehat{b}_2\widehat{c}_2 + \widehat{b}_3\widehat{c}_3 + \widehat{b}_4\widehat{c}_4) & = & \frac{w(\overset{\bullet}{\underset{\bullet}{\rangle}})}{6}.
\end{array} \tag{3.14}
$$

Notice that $\widehat{c}_5 = \sum\widehat{b}_i = w(\bullet)$. The last equation of (3.14) can be simplified since $\widehat{b}_2\widehat{c}_2 + \widehat{b}_3\widehat{c}_3 + \widehat{b}_4\widehat{c}_4 = \frac{w(\overset{\bullet}{/})}{2}$ (see (3.10)). We obtain a system of 4 equations for 5 unknowns $\bar{b}_i$. We require the following additional condition:

$$\bar{w}_5(-l_s) = 0, \tag{3.15}$$

where $\bar{w}_5(z)$ is the stability polynomial of the method $\overline{W}$ and l_s the length of the stability domain along the negative real axis (see (3.2)).

Solving (3.14) and (3.15), numerical computations show that the stability polynomials of the embedded methods are bounded (by $\eta = 0.95$) on the same interval as the stability polynomials of the numerical methods (see Figure 3.4). There is a simple criterion to check if $\bar{R}_{s+1}(z)$, the stability polynomials of the embedded method, is bounded by η on the same interval as $R_s(z)$. Recall that $R_s(z) = w_4(z)P_{s-4}(z)$

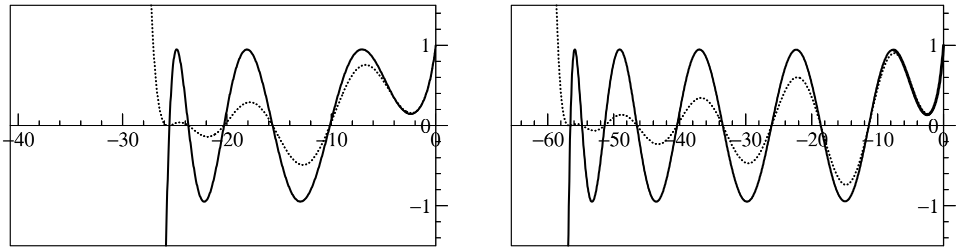

FIG. 3.4. *Stability polynomials of the method WP and the embedded method $\overline{W}P$ (dotted line) for $s = 9$ (left) and $s = 13$ (right).*

and $\bar{R}_{s+1}(z) = \bar{w}_5(z)P_{s-4}(z)$. Denote by z_i the zeros of $P_{s-4}(z)$. Because $P_{s-4}(z)$ is an orthogonal polynomial its zeros are simple and all in the stability interval, say $-l_s < z_1 < \cdots < z_{s-4} < 0$.

LEMMA 3.2. *With the above notations, suppose that $\bar{R}_{s+1}(-l_s) = 0$. If there exist $\delta > 0$ such that $\bar{R}_{s+1}(z) < R_s(z)$ for $z \in (z_{s-4}, z_{s-4} + \delta)$, then*

$$|\bar{R}_{s+1}(z)| \le |R_s(z)| \quad \textit{for } z \in (z_1, z_{s-4} + \delta). \tag{3.16}$$

Proof. Define $d(z) = \bar{R}_{s+1}(z) - R_s(z)$; we have

$$d(z) = P_{s-4}(z)z^4(\beta_0 + \beta_1 z),$$

since $\bar{R}_{s+1}(z) - e^z = \mathcal{O}(z^4)$ and $R_s(z) - e^z = \mathcal{O}(z^5)$.

Suppose that there exist $z \in (z_1, z_{s-4})$ such that $|\bar{R}_{s+1}(z)| > |R_s(z)|$. Then, using the second hypothesis, either there exist $\widehat{z} \neq z_i$ such that $d(\widehat{z}) = 0$ or $d(z)$ has a double zero at some z_i. In both cases, it must then exist $\epsilon > 0$ such that $|\bar{R}_{s+1}(z)| > |R_s(z)|$ for $z \in (z_1, z_1 + \epsilon)$. Since $\bar{R}_{s+1}(-l_s) = 0$, $d(z)$ must have a double zero at z_1 or vanish at least once in $(-l_s, z_1)$. In both cases, counting the zeros of $d(z)$ outside of the origin leads to a contradiction. □

4. Description of ROCK4.

We implemented the numerical method described in section 3 in a code called ROCK4 for Orthogonal-Runge–Kutta–Chebyshev (appropriately permuted). This is the fourth order version of the code ROCK2 introduced in [2]. In this section we briefly describe the code.

Step size estimation. As in ROCK2, we implemented the "step size strategy with memory" of Watts [16] and Gustafsson [4],

$$h_{\text{new}} = \text{fac} \cdot h_n \left(\frac{1}{\text{err}_{n+1}}\right)^{\frac{1}{4}} \frac{h_n}{h_{n-1}} \left(\frac{\text{err}_n}{\text{err}_{n+1}}\right)^{\frac{1}{4}}, \tag{4.1}$$

in order to allow the step size to decrease reasonably without rejection (see also [7, p. 124]).

Stage number selection. While most stiff codes have a fixed number of stages, we used, as usual in Chebyshev codes, a family of fourth order methods. At each step we first select a step size in order to control the local error; then we select a stage order so that the stability property (see section 2 and Table 2.1)

$$h\rho\left(\frac{\partial f}{\partial y}(y)\right) \le 0.35s^2 \tag{4.2}$$

is satisfied, where $\rho(\dots)$ denotes the spectral radius of the Jacobian matrix of the ODEs. This is possible because for practical purposes, the error constants of the family of fourth order methods are found to be almost the same. They are close to the error constants of optimal stability polynomials which have been described in [1].

Spectral radius estimate. The user can supply a function which estimates a bound for the spectral radius (for example, by using Gershgorin theorem; see [6, p. 89]). By specifying that the Jacobian is constant, this function will be called only once. If it is not possible to get an estimate of the spectral radius easily, the code ROCK4 can also compute it internally. For that, we have implemented with a slight modification a nonlinear power method proposed by Sommeijer, Shampine, and Verwer (see [14]).

Storage. Due to the three-term recurrence formula, the method requires only a few storage vectors. The number of storage vectors does not depend on the number of stages used. For the computation of an integration step and the error estimation, ROCK4 uses three vectors for the recurrence formula and five additional vectors for the finishing four-stage method and the embedded method. Notice that the low memory demand of these methods is suitable since we want to apply them to large problems.

5. Numerical experiments. We conclude this paper with several stiff problems taken from the test set of stiff problems proposed in [7] (first and second editions). All the parameters chosen for the examples are taken from [7]. We compare the following codes:

ROCK4: the fourth order code described in this paper.

ROCK2: the second order code based on orthogonal polynomials and described in [2].

RKC: the second order Chebyshev code of Sommeijer, Shampine, and Verwer (see [14]).

RADAU5: the well-known implicit code by Hairer and Wanner of order 5 based on a Radau IIA collocation method (see [7]).

For all examples which follow, we compared the obtained numerical results for the different codes with a reference solution for the given ODEs. The computing time is then displayed as a function of the error (in an Euclidian norm). For each problem the codes have been applied with different tolerances, say

$$tol = 10^{-2}, 10^{-2-\frac{1}{4}}, 10^{-2-\frac{1}{2}}, \dots . \tag{5.1}$$

The integer-exponent tolerances are displayed as enlarged symbols. The results were computed with scalar tolerances $atol = rtol = tol$ for all problems. The symbol for $tol = 10^{-5}$ is distinguished by its gray color.

The following examples are parabolic PDEs, discretized by the method of line into a system of ODEs. We replace the second order spatial derivatives by the finite difference scheme

$$\frac{\partial^2 u(x_i, y_j, t)}{\partial x^2} = \frac{u_{i+1,j} - 2u_{i,j} + u_{i-1,j}}{(\Delta x)^2} + \mathcal{O}\big((\Delta x)^2\big),$$

where u_{ij} are functions depending on time.

Example 1. The first example is the Burgers' equation

$$u_t + \left(\frac{u^2}{2}\right)_x = \mu u_{xx}, \tag{5.2}$$

with initial condition

$$u(x,0) = 1.5x(1-x)^2, \tag{5.3}$$

and boundary conditions

$$u(0,t) = u(1,t) = 0 \tag{5.4}$$

for $0 \le x \le 1$ and $0 \le t \le 2.5$. We discretize the space variable of (5.2) by the method of lines with $\Delta x = \frac{1}{501}$, and we choose $\mu = 0.0003$.

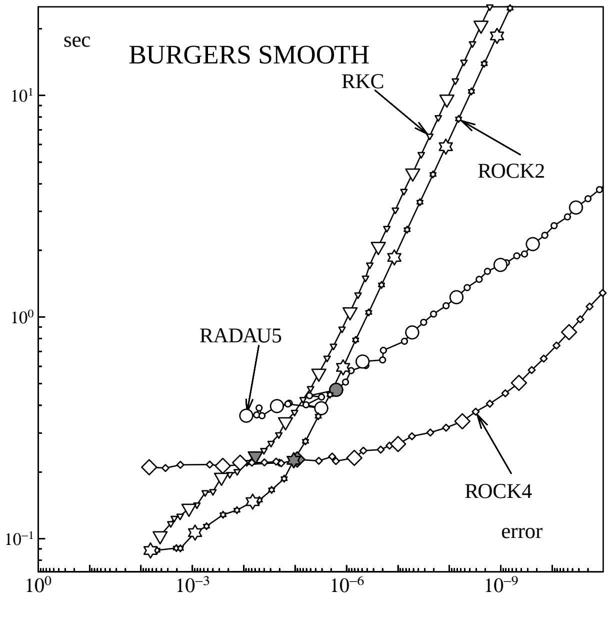

FIG. 5.1. *Work-precision diagram for Burgers' equations.*

Thus, we obtain an ODE (in time) of dimension 500. It is then solved by the different codes for $0 \le t \le 2.5$. For RADAU5 we used the banded algebra option, and for the Chebyshev codes we provide an estimation of the spectral radius by applying the Gershgorin theorem.

We see in Figure 5.1 that the two lower order methods, RKC and ROCK2, are better for lower tolerances. ROCK2 is slightly more efficient and better at delivering an accuracy close to the tolerance. For higher tolerances the high order codes RADAU5 and ROCK4 are better, with an advantage for ROCK4. This latter code also nicely preserves the tolerance proportionality.

Example 2. The second example is the two-dimensional Brusselator reaction-diffusion problem

$$\begin{aligned} \frac{\partial u}{\partial t} &= 1 + u^2 v - 4.4u + \alpha\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right) + f(x,y,t), \\ \frac{\partial v}{\partial t} &= 3.4u - u^2 v + \alpha\left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2}\right), \end{aligned} \tag{5.5}$$

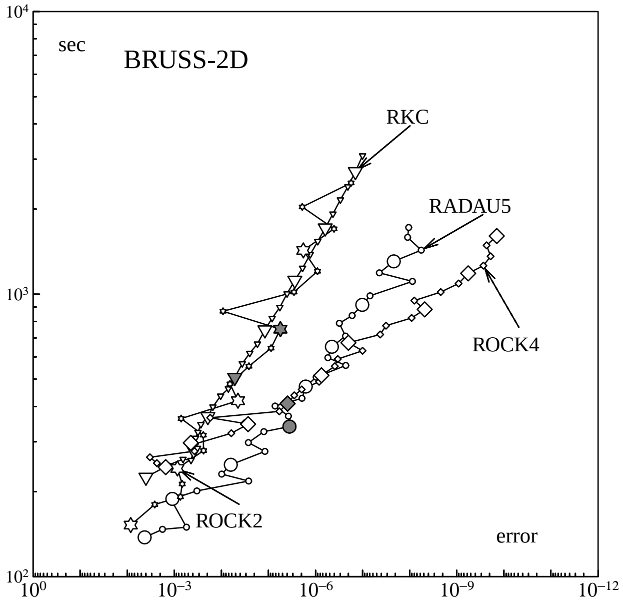

FIG. 5.2. *Work-precision diagram for the two-dimensional Brusselator problem.*

with initial conditions

$$u(x,y,0) = 22 \cdot y(1-y)^{3/2}, \qquad v(x,y,0) = 27 \cdot x(1-x)^{3/2},$$

and periodic boundary conditions

$$u(x+1,y,t) = u(x,y,t), \qquad u(x,y+1,t) = u(x,y,t)$$

for $0 \leq x \leq 1,\ 0 \leq y \leq 1,\ t \geq 0$. The function f is defined by

$$f(x,y,t) = \begin{cases} 5 & \text{if } (x-0.3)^2 + (y-0.6)^2 \leq 0.1^2 \text{ and } t \geq 1.1, \\ 0 & \text{else.} \end{cases}$$

We discretize the space variables of equations (5.5) with $x_i = \frac{i}{N+1}$, $y_i = \frac{i}{N+1}$, $i = 1,2,\dots,N$ and choose $N = 128$ and $\alpha = 0.1$. Thus, we obtain a system of $2N^2 = 32768$ equations. We chose the output points $t_{\text{out}} = 1.5$ and 11.5. The spectral radius of the Jacobian $\rho \simeq 13200$ can be estimated with the Gershgorin theorem; thus as in the previous example, we provide a bound for it when using Chebyshev methods. As advised in [7, p. 157] the linear equations in the code RADAU5 are solved by FFT methods so that the code is optimized for this problem. (Otherwise it will certainly not be competitive with Chebyshev methods.)

We see in Figure 5.2 that ROCK2 and RKC behaves similarly. For higher order methods, RADAU5 behaves better for low tolerances, while ROCK4 is better for higher tolerances. Between Chebyshev codes, except for very low tolerances ROCK4 gives the best results and nicely preserves the tolerance proportionality (as do ROCK2 and RADAU5).

Example 3. The third example is the FitzHugh and Nagumo model for explaining

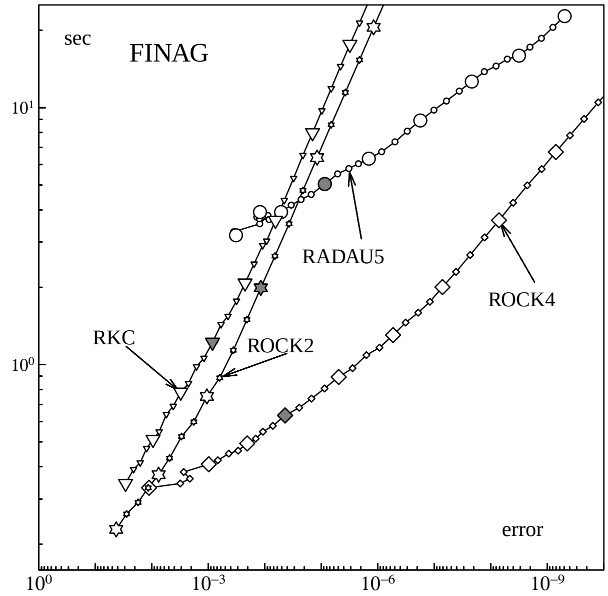

FIG. 5.3. *Work-precision diagram for FitzHugh and Nagumo equations.*

the nerve conduction as a traveling wave:

$$\begin{aligned} \frac{\partial u}{\partial t} &= \frac{\partial^2 u}{\partial x^2} - f(u) - v, \\ \frac{\partial v}{\partial t} &= \eta(u - \beta v), \end{aligned} \tag{5.6}$$

where

$$f(u) = u(u-\alpha)(u-1),$$

with initial conditions

$$u(x,0) = v(x,0) = 0,$$

and boundary conditions

$$\frac{\partial u}{\partial x}(0,t) = -0.3, \qquad \frac{\partial u}{\partial x}(100,t) = 0$$

for $0 \leq x \leq 100$ and $0 \leq t \leq 400$.

We chose $\alpha = 0.139$, $\eta = 0.008$, and $\beta = 2.54$ and discretize the space variable in 200 equidistant steps $x_i = \frac{2i+1}{4}$, $i = 0, \ldots, 199$. We compute numerically a bound for the spectral radius of the Jacobian which was used for the Chebyshev methods. This is a mildly stiff problem, and we see in Figure 5.3 the advantage of the Chebyshev methods compared to an implicit one. Again, ROCK2 works slightly better than RKC. ROCK4 behaves well and is better compared to other Chebyshev methods even for low tolerances.

Conclusion. We have presented a new fourth order Chebyshev method and implemented it in a code called ROCK4. The numerical examples show a good behavior of this code for problems it is intended for. We emphasize that this code, as does other Chebyshev codes, is very simple to use. In fact, it is as simple to use as the forward Euler method. The first version of this code (as well as ROCK2) and some examples are available on the Internet at the address http://www.unige.ch/math/folks/hairer/software.html. Experiences with this code are welcome.

Acknowledgments. The author is grateful to Ernst Hairer and Gerhard Wanner for helpful discussions. He also thanks Alexei Medovikov for his constant interest in this subject.

HAMILTON–JACOBI EQUATIONS ON A MANIFOLD AND APPLICATIONS TO GRID GENERATION OR REFINEMENT*

PH. HOCH[†] AND M. RASCLE[‡]

Abstract. In this paper, we consider Hamilton–Jacobi equations on a manifold, typically on the graph of some previously computed function $z(x, y)$, and we show how the corresponding level set method allows us to generate and/or to refine a mesh in regions where this function z has large derivatives. Such as it is, the method needs to be strongly improved and accelerated, but the principle is awfully natural, and in principle the method is fully automatic. Similar ideas are also useful in image processing, in particular for the active contours method.

Key words. Hamilton–Jacobi equations, viscosity solutions, level set method, anisotropic mesh generation, high order numerical two dimensional schemes

1. Introduction.

The method we are presenting here is fairly general. However, for concreteness, we restrict ourselves to the following prototype: we consider in $\mathbb{R}^3$ a manifold Σ, which we assume to be the graph of a smooth function z: $\Omega \to \mathbb{R}$:, $\Sigma := \{(x, z(x)); x = (x_1, x_2) \in \bar{\Omega}\}$, where Ω is a bounded domain in $\mathbb{R}^2$. The function z is assumed to be known and smooth, but its derivatives can be very large in some regions of $\bar{\Omega}$.

The purpose of this paper is to show—at least in principle—how to generate a mesh which is automatically refined in regions where the graph of z—in other words, the manifold Σ—is "steep" (in a sense to be precised later). Practically, z is the (previously computed) numerical solution of some unspecified PDE on the domain Ω. If no such underlying function z is available, then we can always choose $z \equiv 0$, in which case we will just deal with the classical eikonal equation.

In this paper, we assume that z and its derivatives are known analytically at every point of $\bar{\Omega}$. Of course, in realistic applications, z is interpolated from its values at points of the mesh on which it has been computed, say by a finite element or a finite volume method.

There exists much literature on grid generation and refinement algorithms. Among many others, let us mention, for instance, [25, 13, 29, 18, 22, 45] and [11, 40] in the case of finite differences methods.

The main idea that we propose here is to generate such an adapted grid by solving the Hamilton–Jacobi equation on the graph of z, i.e., on the manifold Σ, equipped with a suitable Riemannian metric. Indeed, it is well known that the classical eikonal equation

$$\partial_t \phi(x, t) + |\nabla \phi(x, t)| = 0 \tag{1.1}$$

is a powerful tool to move curves at unit speed in the (Euclidean) normal direction.

In order to generate a mesh which is refined in regions where z has large derivatives, it is perfectly natural to slow down the motion of curves in these regions. The most natural way to do that is to move curves on the graph of z, at a given speed, in the (Riemannian) normal direction with a suitable metric. In other words, the curves move with constant speed on a stiff mountain, but their horizontal projections move very slowly so that the resulting mesh is automatically refined in these regions.

Although the principle is very general, the two natural metrics that we essentially consider here are based on the positive definite quadratic forms associated to either the matrix

(i)

$$G_1(x) = \begin{pmatrix} 1+(\frac{\partial z}{\partial x_1})^2 & \frac{\partial z}{\partial x_1}\frac{\partial z}{\partial x_2} \\ \frac{\partial z}{\partial x_1}\frac{\partial z}{\partial x_2} & 1+(\frac{\partial z}{\partial x_2})^2 \end{pmatrix} \tag{1.2}$$

(ii) or to

$$\begin{aligned} &G_2(x) = I +^t H(z)(x)H(z)(x), \\ &\text{where } H(z)(x) := \left(\frac{\partial^2 z}{\partial x_i \partial x_j}\right)(x)\text{: Hessian matrix of } z. \end{aligned} \tag{1.3}$$

Note that G_1 is nothing but the restriction of the ambient Euclidean metric in $\mathbb{R}^3$ to the manifold Σ.

Let us briefly comment on these two particular (strongly anisotropic) choices.

With the first choice, in regions where $|\nabla z| \gg 1$, the Riemannian distance between two neighbor points A and B (see Figure 1) is much bigger than their Euclidean distance, except if vectors $\vec{AB}$ and ∇z are orthogonal (in other words if A and B are essentially on the same level curve of z). Indeed, the eigenvector of $G_1(x)$ associated to the larger eigenvalue $\lambda_2(x) = 1+|\nabla z(x)|^2$ is $\nabla z(x)$, whereas the eigenvector associated to $\lambda_1(x) = 1$ is $(\nabla z)^\perp(x)$.

Consequently, with this first choice, the motion will be much slower

1. in regions where the (Euclidean) norm $|\nabla z|$ is large, and
2. inside these regions in the direction of ∇z. For instance, locally, we can have as in Figure 1 $d^{G_1}(A,B) = d^{G_1}(A,C)$ if $\nabla z(A) \gg 1$. In contrast, an isotropic metric defined, for instance, by $G_3(x) = F(|\nabla z(x)|)I$ (see, e.g., [45]) would lead to $d^{G_3}(A,B) \gg d^{G_3}(A,C) \simeq d^{G_3}(A,B')$ which is in principle inappropriate in this context.

With the choice (1.3), the motion is slowed down in regions where the second order derivatives of z are large, regardless of the size of the gradient. The motivation for that is very natural (see, e.g., the above-mentioned references [25, 18, 13]). Indeed, for example, in the context of P1 finite element approximations, there is no need to refine a mesh in regions where the gradients are large, if the solution is essentially linear, like in region BC in Figure 2 (in the one dimensional case).

In such a case, the mesh should be refined only in intervals AB and CD. In the multidimensional case this simple remark is reflected in the error estimates for the finite element method (see again the above references). In particular, in two dimensions, these error estimates are optimal when the triangles are almost equilateral with respect to a metric like G_2.

Remark 1.1. The approach described here in the case of the scalar-valued function z of two variables is in principle completely general: z could be any vector or (tensor-)

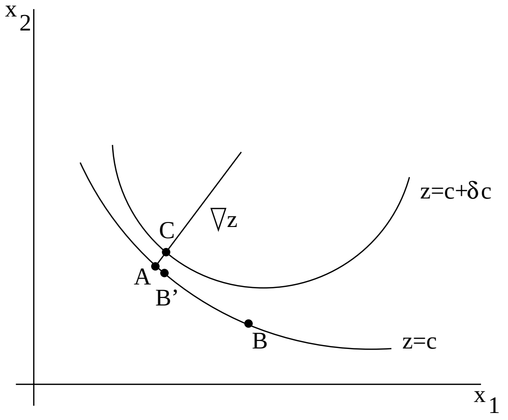

Fig. 1.

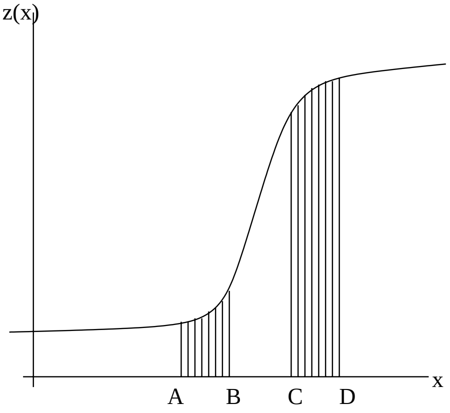

Fig. 2.

valued function defined on a domain in $\mathbb{R}^3$. This function z could even be defined on a two dimensional manifold $M \in \mathbb{R}^3$, say the wing of an airplane, and the goal is then to build a "good" mesh, automatically refined near singularities of the flow (transonic shocks, geometric singularities of the wing, etc.). In this view, the purpose would be to generate the mesh on the boundary and then to march in time in order to generate the fully three dimensional mesh.

With these ideas, our method turns out to be a variant of the classical level set methods [38, 42, 30, 36]. Naturally, quite similar problems arise in image processing [3], in particular in active contours (snakes) [17], etc. In the above-mentioned references, several authors deal with very similar problems (see, e.g., [30]), but in general the motivation is different. As far as we know, this very simple idea of generating a refined mesh by solving the Hamilton–Jacobi (HJ) equation on a manifold has never been explicitly expressed.

A last comment is that the results presented here are far from being optimal. As we will see later, there are still many imperfections in generating the grid. Our purpose here is to show only that this strategy is natural, and in principle tractable, even though the first version of the algorithm described here needs to be (strongly) improved.

The outline of the paper is as follows. In section 2, we recall a few basic facts on HJ equations. In sections 3 and 4, we briefly describe the numerical schemes that we have used, and we show in a few examples the level curves of the corresponding viscosity solution. In sections 5 and 6, we describe the principle of the construction of a triangular mesh based on these level curves, and we show a few numerical results. Finally, we recall the definition of viscosity solutions to the HJ equation in section 7.

2. The HJ equations on a manifold.

2.1. Basic facts. Although the method is fairly general, for simplicity we restrict ourselves to the typical situation described in section 1: Ω is a bounded domain in $\mathbb{R}^2$, and Σ is the graph of a smooth function z: $\Omega \to \mathbb{R}$, equipped with a Riemannian metric: at every point $(x, z(x))$ of Σ, we are given a positive definite symmetric bilinear form $g(x;.,.)$: in the coordinates system $x = (x^1, x^2)$, the length of dx is defined by

$$L(x, dx) := |dx|_{G(x)} = (dx, G(x)dx)^{\frac{1}{2}} = (g_{ij}(x)dx^i dx^j)^{\frac{1}{2}} = |G(x)^{\frac{1}{2}}dx| \tag{2.1}$$

with the Einstein summation convention. Here, $G(x) = (g_{ij}(x))_{1\leq i,j\leq 2}$, $(u,v) := \delta_{ij}u^iv^j$ is the Euclidean scalar product in $\mathbb{R}^2$, and $|u| = (u,u)^{\frac{1}{2}}$. The corresponding length of a curve $\Gamma := \{(\gamma(t), z(\gamma(t))), t \in [0,T]\}$ on Σ is then

$$L(\Gamma) = \int_0^T L(\gamma(t),\dot\gamma(t))dt := \int_0^T (\dot\gamma(t), G(\gamma(t))\dot\gamma(t))^{\frac{1}{2}}dt \tag{2.2}$$

Now, let $X(x) := (x, z(x))$ and $X(y)$ be given points on Σ. A (minimal) geodesic curve on Σ is a curve Γ for which $L(\Gamma)$ is extremal (minimal) among all curves on Σ with the same endpoints. Under standard assumptions, there exists a (unique) minimal C^1 geodesic curve between two arbitrary points $X(x)$ and $X(y)$ on Σ if these points are close enough (cf., e.g., [48]). Moreover, the "speed" $|G(\gamma(t))^{1/2}\dot\gamma(t)|$ is constant along a geodesic, and if the parameter t is the arc length, then minimizing $L(\Gamma)$ is equivalent to minimizing the energy

$$\mathrm{E}(\Gamma) := \int_0^T (L(\gamma(t),\dot\gamma(t)))^2dt \tag{2.3}$$

with the same boundary conditions (see, e.g., [21]). Here and often in the paper, we allow ourselves the confusion between curves on Σ and their horizontal projections in Ω.

2.2. The variational problem. Now, let $C_0 := \{(x, z(x)), x \in c_0\}$ be a curve on Σ, whose horizontal projection c_0 is a given (smooth) curve in $\bar\Omega$, parametrized, e.g., by its arc length s (practically, c_0 is the boundary of the domain Ω), let x be a nearby point in Ω, and let us consider the following problem:

$$\left\{\begin{array}{lcc} \text{Find } y \in c_0 \text{ such that} \quad d^G(x,y) & = & \text{Min }\left\{d^G(x,y'); y' \in c_0\right\} \\ & = & d^G(x,c_0), \end{array}\right. \tag{2.4}$$

where $d^G(x,y) := \text{Inf}\left\{\int_0^T L(\gamma(t),\dot\gamma(t))dt; \gamma(0) = y, \gamma(T) = x, \gamma(t) \in \bar\Omega\ \forall t \in [0,T]\right\}$.

Clearly (cf., e.g., [48]), for the case of geodesics with fixed endpoints, if c_0 is smooth and if $d(x,c_0)$ is small enough, then there exists a unique solution to (2.4), characterized by the Euler–Lagrange equations

$$-\frac{d}{dt}\left(\frac{\partial L}{\partial\dot\gamma}\right) + \frac{\partial L}{\partial\gamma} = 0, \tag{2.5}$$

$$\left(\frac{\partial L}{\partial\dot\gamma}(\gamma(0),\dot\gamma(0)), \tau\right) = 0, \tag{2.6}$$

where $\tau = \tau(y)$ is the tangent vector to c_0 at $y = \gamma(0)$. Again, we can restrict ourselves to considering only the horizontal projection

$$\frac{G(\gamma(0))\dot\gamma(0)}{|G(\gamma(0))\dot\gamma(0)|} = \pm\mathbf{n}, \tag{2.7}$$

where $\mathbf{n} = \mathbf{n}(\gamma(0))$ is one of the two possible unit normal vectors in $\Omega \subset \mathbb{R}^2$. Note that for the Euclidean metric in $\mathbb{R}^2$, the vector $\dot\gamma(0)$ is not normal to c_0, but in the particular case where $G = G_1$, this vector is the horizontal projection of the *normal geodesic* (cf., e.g., [42, 30])

$$\dot\Gamma(0) = \pm|\dot\Gamma(0)|\mathbf{T} \wedge \mathbf{N}. \tag{2.8}$$

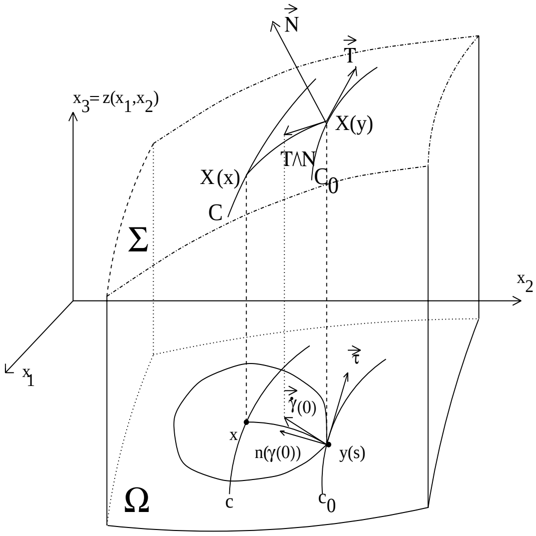

FIG. 3.

Naturally, in practical situations, the horizontal projection $\Omega \subset \mathbb{R}^2$ could be replaced by a two dimensional manifold $M \subset \mathbb{R}^3$, e.g., the wing of an airplane.

Geometrically, (2.6) says that the "ball" of center x and radius $d^G(x, y)$ is tangent to the curve c_0 at y; see Figure 3.

2.3. The HJ equations. Now, the purpose is to move the curve C_0 on Σ, or, equivalently, the curve c_0 in $\Omega \in \mathbb{R}^2$ at a given Riemannian speed V, by the level set method (see, e.g., [8, 38, 42, 26]). Dividing if necessary the matrix $G(x)$ by $(V(x))^2$, we restrict ourselves to the case $V \equiv 1$.

In other words, we define c_0 as the horizontal projection of the zero level curve of a function $\Phi(x, 0) = \Phi_0(x) : \Omega \to \mathbb{R}$, and we look for a function $(x, t) \mapsto \Phi(x, t)$ such that, for any $t \geq 0$,

$$c_t := \{x \in \Omega; \Phi(x,t) = 0\}\,. \tag{2.9}$$

A formal first order Taylor expansion gives

$$0 = \Phi(x,t) = \Phi(y,0) + t\partial_t\Phi(y,0) + \nabla\Phi(y,0).(x-y) + o(|t| + |x-y|). \tag{2.10}$$

Now, multiply both sides of (2.7) by $G^{-1}(y)$. Since $|\dot\gamma(0)|_G = 1$ and $V = 1$, we obtain at first order, after some manipulations,

$$x - y \;=\; t\,\dot\gamma(0) + o(t) = \pm\, t\,\frac{G^{-1}(y)\mathbf{n}}{|G^{-1}(y)\mathbf{n}|_G} + o(t) \;=\pm\, t\,\frac{G^{-1}(y)\nabla\Phi}{|G^{-1/2}(y)\nabla\Phi|} + o(t), \tag{2.11}$$

since the vector $\nabla\Phi$ is parallel to $\mathbf{n}$. Finally,

$$0 = \Phi(x,t) = 0 + t(\partial_t\Phi \pm (G^{-1}(y)\nabla\Phi, \nabla\Phi)^{\frac{1}{2}}) + o(t).$$

Therefore, the function Φ must satisfy

$$\partial_t\Phi \pm (G^{-1}(y)\nabla\Phi|\nabla\Phi)^{\frac{1}{2}} = \partial_t\Phi \pm |G^{-1/2}(y)\nabla\Phi| = 0. \tag{2.12}$$

Choosing the sign of the initial datum Φ_0 on each side of c_0 imposes the direction of propagation and therefore suppresses the above ambiguity. From now on, we choose the positive sign in (2.12). Therefore the Hamiltonian

$$H(x,p) := |G^{-1/2}(x)p| \tag{2.13}$$

is convex with respect to p.

2.4. The stationary problem. Now, Ω is a bounded domain in $\mathbb{R}^2$ with a (theoretically) smooth boundary $c_0 := \partial\Omega$. In fact, what we would like to compute is the family of level curves

$$\tilde{c_t} := \left\{x \in \Omega; d^G(x,\partial\Omega) = t, t \geq 0\right\} \tag{2.14}$$

(we will see below that curves $\tilde{c_t}$ and c_t are the same), or, equivalently, the family of curves

$$\tilde{C_t} := \{(x, z(x)); x \in \tilde{c_t}\}\,. \tag{2.15}$$

In the case of the Euclidean metric it is a classical result (see, e.g., [6, 32, 20]) that $\chi(x) := d(x,\partial\Omega)$ is a *viscosity solution* to the stationary equation

$$|\nabla\chi(x)| = 1 \qquad \text{in } \Omega \tag{2.16}$$

and satisfies in the classical sense the Dirichlet boundary condition

$$\chi(x) = 0 \qquad \text{on } \partial\Omega. \tag{2.17}$$

In fact, χ is the unique *viscosity solution* to (2.16) which satisfies (2.17). The definition of viscosity solutions are recalled below; see section 7. Here, the matrix $G(x)$ depends smoothly on x, and it is easy to adapt the above result to show the following proposition.

PROPOSITION 2.1. $\Psi(x) := d^G(x,\partial\Omega) := \inf_{y\in\partial\Omega} d^G(x,y)$ *is the unique viscosity solution to problem*

$$|G^{-1/2}(x)\nabla\Psi(x)| = 1 \qquad \text{in } \Omega, \tag{2.18}$$

which satisfies in the classical sense the boundary condition

$$\Psi(x) = 0 \qquad \text{on } \partial\Omega. \tag{2.19}$$

2.5. The initial boundary-value problem. Naturally, the stationary solution to (2.18), (2.19) is unknown (see, e.g., [41] for computational aspects). The principle of the *level set method* [10, 8, 38] is to compute the family of curves (c_t) defined by (2.14) with suitable initial data and boundary conditions. Indeed, the family of curves (c_t) depends on the initial curve $c_0 = \partial\Omega = \left\{x \in \bar{\Omega}; \Phi_0(x) = 0\right\}$ and *not* on the particular solution Φ to

$$\partial_t\Phi + |G^{-1/2}(x)\nabla\Phi| = 0 \qquad \text{in } Q = \Omega \times (0,T). \tag{2.20}$$

More precisely, we choose an initial datum Φ_0 such that

$$c_0 := \partial\Omega := \left\{x \in \bar{\Omega}; \Phi_0(x) = 0\right\}, \tag{2.21}$$

$$\Omega_0 := \Omega := \left\{x \in \bar{\Omega}; \Phi_0(x) > 0\right\}, \tag{2.22}$$

and we impose

$$|G^{-1/2}(x)\nabla\Phi_0(x)| = 1 \qquad \text{on } \partial\Omega. \tag{2.23}$$

The choice of "optimal" boundary data is a subtle question, which in particular raises in general the issue of discontinuous viscosity solutions (see again [6, 1, 12]). We recall that the family (c_t) is called "regular" if relations similar to (2.21), (2.22) between c_t and Ω_t hold for all $t > 0$; cf. [10, 8]. Here, using the independence of level curves c_t with respect to the particular solution Φ to (2.20), we follow the simplest choice:

$$\Phi(x,t) = -t \qquad \text{on } \partial\Omega \times (0,t). \tag{2.24}$$

The motivation for this choice is the compatibility with the obvious solution

$$\tilde{\Phi}(x,t) = \Psi(x) - t = d^G(x,\partial\Omega) - t \tag{2.25}$$

to problem (2.20), (2.24) with the initial data

$$\tilde{\Phi}(x,0) = \Psi(x), \tag{2.26}$$

which, of course, satisfies conditions (2.21), (2.22), (2.23). With this choice it is clear that curves c_t and $\tilde{c_t}$ are the same. Of course, solving the problem (2.20), (2.24), (2.26) is purely theoretical, since we do not know explicitly the function Ψ.

Therefore, we in fact solve problem (2.20), (2.24), (2.27), with

$$\Phi(x,0) = \Phi_0(x). \tag{2.27}$$

Adapting [32, Prop. 11.1] and standard results of uniqueness [6, 32], we obtain the following proposition.

Proposition 2.2. *For any Lipschitz function Φ_0 satisfying conditions* (2.21), (2.22), (2.23)*, the initial boundary value problem* (2.20), (2.24), (2.27) *has a unique viscosity solution Φ, whose level curves $\{c_t, t \geq 0\}$ do not depend on the particular choice of boundary conditions and initial data.*

Moreover, consider $\Omega_0 := \Omega$ and $\Omega_t := \{x \in \Omega; d^G(x,\partial\Omega) > t\}$; then Φ is in principle given by the Oleinik–Lax [35, 33] or Hopf [28, 5, 33, 7] type of formula:

$$\Phi(x,t) = \begin{cases} \operatorname{Inf}\{\Phi_0(y); d^G(y,x) \leq t\} & \text{if } x \in \bar{\Omega}_t, \\ d^G(x,\partial\Omega_0) - t & \text{if } x \in \bar{\Omega}\backslash\bar{\Omega}_t. \end{cases} \tag{2.28}$$

For related results with the classical eikonal equation, see, e.g., [7, 5, 33] and the references therein. We recall (see, e.g., [24]) that (2.23) would be necessary to define locally the *bicharacteristics* if the "initial" condition (2.19) for the stationary problem (2.18) is (only) given on curve $\partial\Omega$.

Remark 2.1. We remark here that, since Ω is bounded, the function Φ given by (2.28) converges in finite time to the stationary solution Ψ defined in Proposition 2.1 and obviously has the same level curves $\{x \in \Omega; d^G(x,\partial\Omega) = t\}$. This remark is the basis of the fast marching method developed in [49, 44], etc.

In principle, an adaptation of this fast marching method to this Riemannian anisotropic situation would be the fastest and most natural way to compute the successive positions of the front. However, this method has been classically developed in the case where the Hamiltonian H is a function of u^2 and v^2, where $(u,v) := \nabla\Phi$. This property, combined with the convexity of H, implies, e.g., $u\partial H/\partial u \geq 0$ [37], and a similar inequality for v, which is essential to build the monotone upwind approximation scheme described, e.g., in [46, 47]. In contrast, in the strongly anisotropic case considered here, this property is far from being satisfied, and the switching between "backward" and "forward" approximation has to be carefully modified.

Therefore, since our purpose in this paper was to introduce the *principle* of our Riemannian approach for grid generation or refinement, we did not consider this fast marching method in detail. For more recent references in this direction, we refer, e.g., to [37] or [43].

3. Numerical schemes. In view of the above remark, we want to approximate the initial boundary-value problem (2.20), (2.24), (2.27). We recall that (2.20) is hyperbolic in $\nabla\Phi = U = (u, v)$. We adopt the Osher–Shu approach [39]; in other words, we use a Cartesian grid $(x_i, y_j) = (i\Delta x, j\Delta y)$, and we first semidiscretize (2.20) to obtain

$$\frac{\partial}{\partial t}\Phi_{i,j}(t) = -h^{num}(x_i, y_j, u^-_{ij}, u^+_{ij}, v^-_{ij}, v^+_{ij}) \simeq -H(x_i, y_j, \nabla\Phi(x_i, y_j)), \tag{3.1}$$

where $U^{\pm}_{ij} := (u^{\pm}_{ij}, v^{\pm}_{ij})$ are approximations to $\nabla\Phi(x_i, y_j)$, and h^{num} is simply a two dimensional continuous, monotone numerical Hamiltonian. Let us describe more precisely the three classical steps in the algorithm.

3.1. The interpolation. At point (x_i, y_j), we first construct either an ENO or a TVD polynomial interpolation of Φ. For instance, a TVD interpolation of first order is

$$\begin{aligned} u^- &= D^{-x}_{ij} = \frac{\Phi_{i,j} - \Phi_{i-1,j}}{\Delta x}, & u^+ &= D^{+x}_{ij} = \frac{\Phi_{i+1,j} - \Phi_{i,j}}{\Delta x}, \\ v^- &= D^{-y}_{ij} = \frac{\Phi_{i,j} - \Phi_{i,j-1}}{\Delta y}, & v^+ &= D^{+y}_{ij} = \frac{\Phi_{i,j+1} - \Phi_{i,j}}{\Delta y}, \end{aligned}$$

or [38] a second order TVD interpolation with a minmod limiter is

$$\begin{aligned} u^- &= D^{-x}_{ij} + \frac{\Delta x}{2}\, m(D^{-x-x}_{ij}, D^{+x-x}_{ij}), & u^+ &= D^{+x}_{ij} - \frac{\Delta x}{2}\, m(D^{+x+x}_{ij}, D^{+x-x}_{ij}), \\ v^- &= D^{-y}_{ij} + \frac{\Delta y}{2}\, m(D^{-y-y}_{ij}, D^{+y-y}_{ij}), & v^+ &= D^{+y}_{ij} - \frac{\Delta y}{2}\, m(D^{+y+y}_{ij}, D^{+y-y}_{ij}). \end{aligned}$$

We have also used a second order ENO interpolation (see [39]) for the level curves of Figures 5A–5F.

3.2. Numerical Hamiltonian. Knowing the $(u, v)^{\pm}_{ij} = \nabla\Phi(x_i, y_j) + O(\Delta x^r)$ in regions where the solution is smooth, we want to approximate the ODE

$$\frac{\partial}{\partial t}\Phi_{i,j}(t) = -h^{num}(x_i, y_j, u^-, u^+, v^-, v^+),$$

where the numerical Hamiltonian h^{num} is a robust approximation of $H(x_i, y_j, \nabla\Phi_{ij})$. We choose the Lax–Friedrichs numerical Hamiltonian

$$\begin{aligned} h^{num}_{LF}(x, y, u^-, u^+, v^-, v^+) := H\left(x, y, \frac{u^- + u^+}{2}, \frac{v^- + v^+}{2}\right) \\ - \frac{\alpha}{2}(u^+ - u^-) - \frac{\beta}{2}(v^+ - v^-) \end{aligned} \tag{3.2}$$

with

$$\alpha = \sup_{u,v} \left| \frac{\partial H(x,y,u,v)}{\partial u} \right|, \qquad \beta = \sup_{u,v} \left| \frac{\partial H(x,y,u,v)}{\partial v} \right|.$$

We note that, e.g., in (1.2) or (1.3) the eigenvalues of G(x) are larger than 1. Therefore in (2.13), the eigenvalues of $G^{-1/2}$ are smaller than 1, so that it is easy in (3.2) to guarantee the CFL condition ($\Delta t(\frac{1}{\Delta x} + \frac{1}{\Delta y}) \leq 1$) uniformly in (x, y). However (see Hoch [27]), one can explicitly compute the optimized coefficients, $\alpha(x, y) = \sqrt{G^{-1}_{11}(x, y)}$ and $\beta(x, y) = \sqrt{G^{-1}_{22}(x, y)}$, based on the metric at point (x, y), for which this numerical Hamiltonian has the minimal diffusion and remains monotone.

3.3. Time discretization. We now discretize the ODE $\frac{\partial}{\partial t} U = L(U)$. Here, we have used the TVD Runge–Kutta second order method of Osher and Shu [39].

$$\tag{3.3} \begin{cases} U^{(0)} = U^n, \\ \\ U^{(i)} = \displaystyle\sum_{j=0}^{i-1} \alpha_{ij}\, U^{(j)} + \beta_{ij}\, \Delta t\, L(U^{(j)}), \qquad i = 1 \ldots s = 2, \\ \\ U^{n+1} = U^{(s)}. \end{cases}$$

We recall the principle of this approximation: if any spatial stability is satisfied for the Euler time approximation scheme, e.g., $TV(U^n + \Delta t L^x(U^n)) \leq TV(U^n)$, then the same stability holds for (3.3), modulo $C\Delta t$. An easy way to obtain such a scheme is to impose $\forall(i, j)$: $(\alpha_{ij}, \beta_{ij}) \geq 0$, since then (3.3) is a convex combination of Euler steps with Δt replaced by

$$\left(\min_{i,j} (\beta_{ij} \alpha^{-1}_{ij}) \right) \Delta t.$$

3.4. The boundary conditions. As in section 2, we impose the boundary condition (3.5), and for second order schemes we add near $\partial\Omega$ one layer of ghost points (x_i, y_j) out of Ω, at a distance of order Δx, and we define the values $\Phi^n_{i,j}$ at these ghost points at time $t_n = n\Delta t$ in order to satisfy a discrete approximation of (2.25). In fact, let $x = x_{i,j}$ be such a ghost point. We first define the signed distance

$$\tilde{\Psi}(x) := \begin{cases} \Psi(x) = d^G(x, \partial\Omega) & \text{in } \Omega, \\ -d^G(x, \partial\Omega) & \text{out of } \Omega. \end{cases}$$

Now, let y be (an approximation of) the normal projection of x on $\partial\Omega$:

$$x - y = -d(x, \partial\Omega)\mathbf{n}(y) = -d\mathbf{n}(y),$$

where d is the Euclidean distance. Since $\mathbf{n} = \mathbf{n}(y) = \frac{\nabla\Psi(y)}{|\nabla\Psi(y)|} = \frac{x-y}{|x-y|}$ is the inward normal vector to $\partial\Omega$, and since the Hamiltonian H in (2.13) is homogenous of order one, we have

$$|\nabla\Psi(y)| = (H(y, \mathbf{n}(y)))^{-1}.$$

We approximate $\Psi(x)$ by

$$\tag{3.4} \Psi_h(x) = \Psi(y) + \nabla\Psi(y).(x - y) = -d\,|\nabla\Psi(y)| = -\frac{d(x, \partial\Omega)}{H(y, \mathbf{n}(y))}.$$

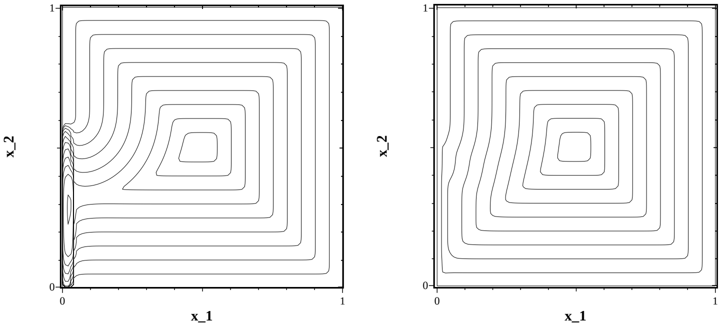

FIG. 4A AND 4B. *The role of the compatibility conditions* (3.6).

In view of (2.25) we define the approximate boundary data

$$\Phi_h(x,t_n) :=\Psi_h(x) - t_n. \tag{3.5}$$

3.5. The initial data. In the same spirit, we define the initial condition $\Phi(x,0)$ for x in Ω by the approximation

$$\Phi_h(x,0) := +\frac{d(x,\partial\Omega)}{H(y,\mathbf{n}(y))}, \tag{3.6}$$

where $d(x,\partial\Omega)$ is again the Euclidean distance of x to $\partial\Omega$, which in our case is easy to calculate. Theoretically, any other choice of the initial data satisfying (2.21), (2.22) would be permitted, but for x near $\partial\Omega$, formula (3.6) is a discretization of the *compatibility condition* (2.23) between the boundary condition (3.5) and the initial data. In order to illustrate the role of the denominator in (3.6), we have considered in Figures 4A and 4B the following example: Ω is the unit square, $G = G_1$ is given by (1.2), and $z(x) = \delta_{\epsilon_1}(x_1 - x_1^0)\delta_{\epsilon_2}(x_2 - x_2^0)$, with δ_ϵ defined in (4.4) below $0 < \epsilon_1 = 0.01 \ll \epsilon_2 = 0.1$, $x_1^0 = 0$, $x_2^0 = 0.25$. In other words, the graph of z mimics a boundary layer on a part of $\{x_1 = 0\}$. We have used the first order TVD (monotone) method described in section 3. We show in Figures 4A and 4B the level curves $\{x; \Phi(x,t_n) = 0\}$ for the same sequence, $t_n = Kn\Delta t$, $K \in \mathbb{N}$ fixed, of the solution when the metric $G(x)$ involves a boundary layer. In Figure 4B, where we have dropped the denominator in (3.6), the level curves almost do not detect the boundary layer.

4. Level curves: Results. Here, we show a few level curves $\{x; \Phi(x,t_n) = 0\}$ for a regular sequence of times $t_n = Kn\Delta t$. We recall that Φ is the unique viscosity solution to (2.20), (2.24), (2.27), computed with the algorithms discussed in section 3, and that our purpose is to *generate a mesh based on these level curves of* $\Phi(.,t_n)$, automatically refined in regions where z is stiff.

We have tested the above-mentioned algorithms on several examples:

(i) Ω is either a square or a circle. In the first case, note the shocks—sometimes smoothed out by the numerical viscosity—due to the corners of the square. Of course this difficulty disappears in the case of a circle.

(ii) The involved Riemannian metric is associated to the matrix: $G(x) = V^{-2}(x)G_i(x)$, $i = 1, 2$, so that the speed is multiplied by $V(x)$. Here, $V(x)$ is a given positive scalar speed, say $V(x) = \mathrm{Max}(h(x), V_{\min})$, adjusted to impose a (very small) minimal speed $V_{\min}$ in very stiff regions, and

$$h(x) = \begin{cases} h1(x) := (\det G(x))^{-1/2} & \text{or} \\ h2(x) := \exp(1 - (\det G(x))^{10}). \end{cases} \tag{4.1}$$

The presence of h still makes the motion slower in stiff regions. On the other hand,

$$G_1(x) = I + \nabla z \otimes \nabla z, \qquad G_2(x) = I + {}^tH(z)H(z). \tag{4.2}$$

(iii) This function z is a given (combination of) smooth real valued function(s), with large first and second order derivatives, which is analytically known. Typically (see Figures 5A–5D),

$$z(x) = z(x_1, x_2) = K_1 \, atan \left(K_2 f(x_1, x_2)\right), \tag{4.3}$$

where K_1 and/or K_2 are constants, adjusted to produce sharp fronts near the curve $\{f(x_1, x_2) = 0\}$.

In other cases (see Figures 5E, 5F), $z(x) = z(x_1, x_2)$ is proportional to a regularized delta-function

$$z(x) = \delta_\epsilon(|x - x_0|) = \frac{C}{\epsilon}\delta_1\left(\frac{|x - x_0|}{\epsilon}\right) \tag{4.4}$$

or a tensor-product $z = z_1 \otimes z_2$,

$$z_i(x) = C_i \delta_{\epsilon_i}(a_i x_1 + b_i x_2 + c_i); \tag{4.5}$$

see Figures 4A, 4B, 5D. In (4.4), $\delta_1(s) \geq 0$, $\int_{\mathbb{R}} \delta_1(s)ds = 1$, and $\delta_1(s) \equiv 0$ for $|s| \geq 1$.

The last two examples are chosen to simulate a sort of boundary layer or some oblique singularity near by the boundary.

(iv) In all cases, except in Figures 4A and 4B, we have used a second order ENO interpolation with a second order TVD time discretization. The CFL condition is 0.5, and $nx = ny = 101$. On the top of each figure, we have noted the corresponding metric G in (ii), the coefficient h in (4.1), and the minimum speed $V_{\min}$ in (ii).

A few comments are in order:

(i) Note the changes of topology of the level curves after having passed an obstacle, e.g., in Figure 4A, and Figures 5D–5F.

(ii) Note that the minimal speed is too small in Figure 5D, so that the level curves do not advance fast enough. This fact is a severe drawback if the purpose is to generate a mesh, as in section 5. On the contrary, it is an advantage if the purpose is to detect contours in image processing (snakes).

(iii) In pictures 5E and 5F, the involved function z is the same, given by (4.4), but Figures 5E and 5F, respectively, correspond to the metrics G_1 and G_2. As noted by one of the referees, here the metric G_1 (and still more the metric G_2) is stiff, so that the corresponding level curves motion is still slower, and therefore the location of the level curves is much better in the latter case. By the way, we have not systematically shown here a comparison between these two typical examples of metrics. Clearly, a numerical simulation of the one dimensional example of Figure 2 would strongly discriminate these two metrics.

5. Applications to grid generation. We want to generate a mesh whose vertices are located on successive level curves of the viscosity solution Φ to problem (2.20), (2.24), (3.5). The level curves of Φ allow us to generate a mesh as soon as

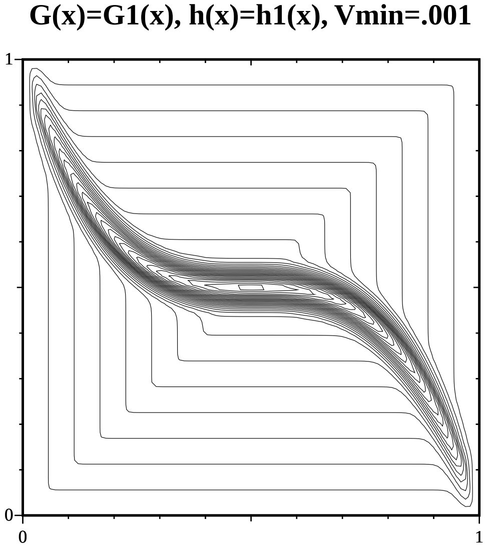

FIG. 5A.

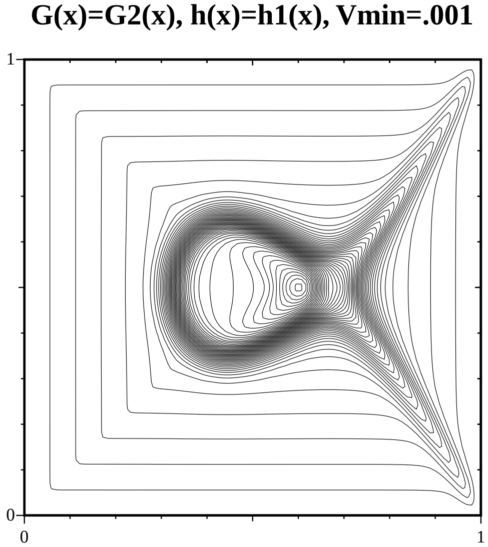

FIG. 5B.

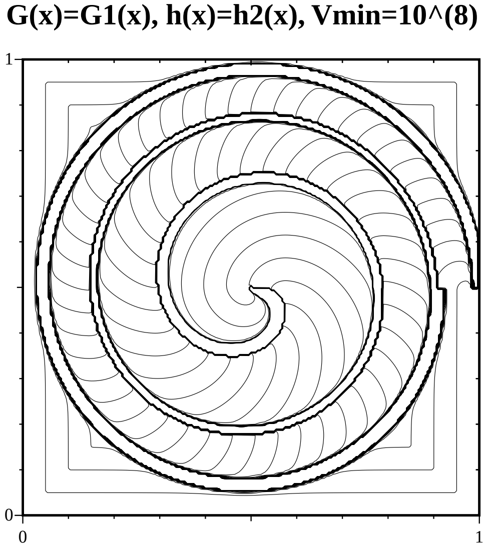

FIG. 5C.

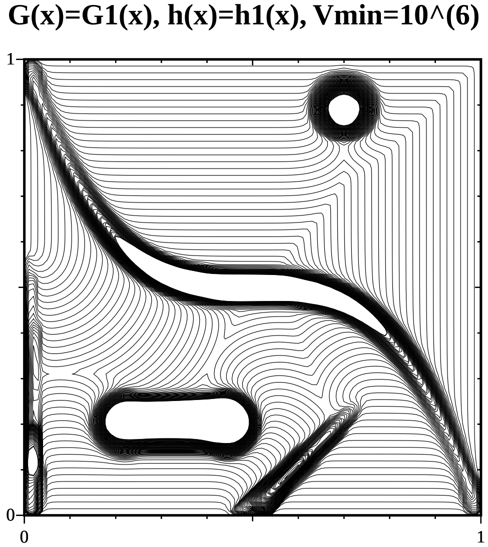

FIG. 5D.

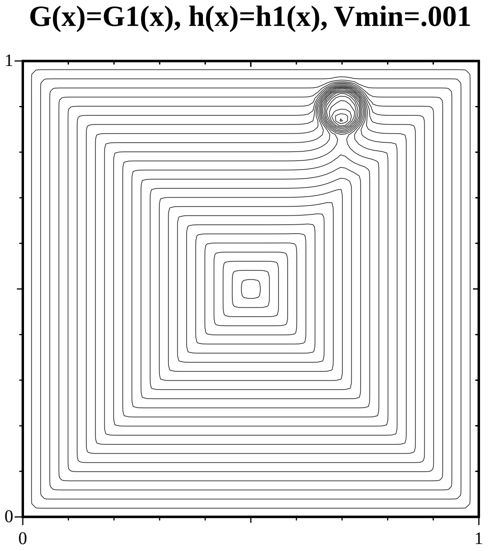
we are able to connect points between two fronts. The elements that we generate are triangles or in some experiments mixed (quadrangles or triangles).

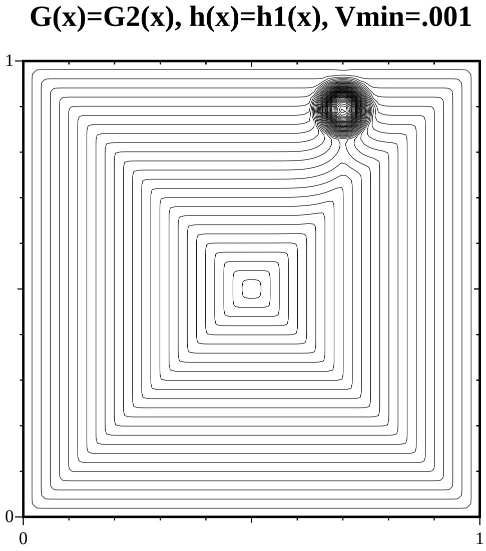
First, we recall that the ODE associated to (2.20) is

$$\frac{dx}{dt} = \frac{G^{-1}(x)\nabla\Phi(x,t)}{|G^{-1/2}(x)\,\nabla\Phi(x,t)|} = \nabla_p H(x,\nabla\Phi). \tag{5.1}$$



G(x)=G1(x), h(x)=h1(x), Vmin=.001

FIG. 5E.



G(x)=G2(x), h(x)=h1(x), Vmin=.001

FIG. 5F.

These curves are the horizontal projections of the bicharacteristics, given by

$$\left\{ \begin{array}{l} \frac{dx}{dt} = \nabla_p H(x,p), \\ \frac{dp}{dt} = -\nabla_x H(x,p), \quad p = \nabla \Phi(x,t). \end{array} \right. \tag{5.2}$$

At each time step, having numerically solved (2.20) provides an approximation of $p = \nabla\Phi(x_i, y_j)$. We then interpolate p to locally solve numerically (5.1). We detect the appearance of *shocks* in step 5 below. We restrict ourselves to the description of the case of triangles.

5.1. Principle of the construction of a triangular mesh. The principle is the following:

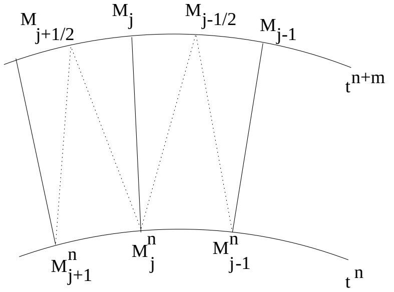
1. Define the domain Ω, and define Φ_0 by (3.6). In our numerical experiments, Ω is either a square or a circle.
2. Define a finite number of points $\{\tilde{M}_j^0, 1 \le j \le \tilde{N}_0\}$, with $\tilde{M}_{N_0}^0 = \tilde{M}_0^0$, compute an approximation (by the trapezoidal rule) of the Riemannian distance $d_j^0 := d^G(\tilde{M}_j^0, \tilde{M}_{j+1}^0)$, and replace the $\tilde{M}_j^0$ by new points M_j^0, which are approximately equidistant with respect to d^G. Their average Riemannian distance $\tilde{d^0}$ is thus near a desired reference length dgr.
3. n:=0.
4. Choose $m = m_n = [Kd^n/\Delta t]$, where $[x]$ is the integer part of x and K is a constant so that the average triangles will be "approximately" equilateral with respect to d^G. In the Euclidean case, we would choose $K = \sqrt{3}/2$.
5. For $k = 1 \ldots m$,
   (i) update Φ from t_{n+k-1} to t_{n+k}, using the algorithm defined in section 3;
   (ii) then update the points M_j according to the ODE (5.1);
   (iii) check the Riemannian distances $d_j^{n+k} := d^G(M_j^{n+k}, M_{j+1}^{n+k})$;
   - if $d_j^{n+k} < C_1 d^n$, then suppress one point: $M_j^{n+k} := (M_j^{n+k} + M_{j+1}^{n+k})/2$, $(C_1 = \frac{1}{\sqrt{2}})$;

- if $d_j^{n+k} > C_2 d^n$, then add one point: $M_{j+1/2}^{n+k}$ between M_j^{n+k} and M_{j+1}^{n+k}; $(C_2 = \sqrt{2})$;

(iv) if necessary, relabel points M_j^{n+k}.

6. At time t_{n+m},

(i) define $M_{j+1/2}^{n+m} \simeq$ the Riemannian midpoint between M_j^{n+m} and M_{j+1}^{n+m}; here we have used the approximation used in [25], $M_{j+1/2}^{n+m} = M_j^{n+m} + \alpha\ \mathbf{u_j^{n+m}}$, where we have noted $\mathbf{u_j^{n+m}} = \mathbf{M_j^{n+m} M_{j+1}^{n+m}}$ and $\alpha = \left(|\mathbf{u_j^{n+m}}|_{\mathbf{G(M_{j+1}^{n+m})}}\right)\left(|\mathbf{u_j^{n+m}}|_{\mathbf{G(M_{j+1}^{n+m})}} + |\mathbf{u_j^{n+m}}|_{\mathbf{G(M_j^{n+m})}}\right)^{-1}$;



(ii) project these new points $M_{j+\frac{1}{2}}^{n+m}$ on the level curves $\{\Phi(x, t^{n+m}) = 0\}$, using, say, two or three steps of the Newton method;

(iii) check whether the triangles $M_j^n M_{j+1}^n M_{j+1/2}^{n+m}$ and $M_{j-1/2}^{n+m} M_j^n M_{j+1/2}^{n+m}$ are approximately equilateral with respect to the distance d^G, by computing for a triangle ABC, $q = \frac{min(d^G(\mathbf{AB}),\mathbf{d^G(AC)},\mathbf{d^G(BC)})}{max(d^G(\mathbf{AB}),\mathbf{d^G(AC)},\mathbf{d^G(BC)})} \in]0,1]$. We also use the *edge flipping* technique (see, e.g., [25]): if necessary, we exchange the diagonals of a quadrangle, depending on the quality of the two resulting triangles.

If necessary, add or remove one point at time t_{n+m};

(iv) in any case, relabel the points $M_j^{n+m} := M_{j+1/2}^{n+m}$; evaluate the average Riemannian distance d^{n+m}.

7. In the case where the above iteration fails for some points M_j^{n+m}, freeze these points, use some "cuisine" to detect the underlying change of topologies in the level curves of $\Phi(., t_{n+m})$ and to generate the corresponding local part of the mesh.
8. Go back to step 4, with $n := n + m$, until all the points M_j^n are frozen.

Remark 5.1. The most difficult parts are steps 6(ii) and 7, which require a more detailed analysis, and will be addressed in a forthcoming work [4]. Note that such changes of topologies essentially appear in two types of situations:

(i) when there is a "pass" in the graph of the stationary viscosity solution $\Psi(x) = d^G(x, \partial\Omega)$ (see, e.g., Figures 5D–5F);

(ii) when this stationary solution Ψ presents a local maximum, i.e., when its level curves of level t are (locally) about to disappear, i.e., when the corresponding part of the mesh is *almost* finished. Not surprisingly, this step is one of the most difficult to handle, and should be handled by a local Delaunay type algorithm, adapted to the Riemannian metric (see, e.g., [25]).

5.2. Here we present some meshes. The reference length dgr and the other parameters are defined below or in section 5.1.

Comments and figure captions.

(i) All these simulations have been performed with $G(x) = G1(x) = I + \nabla z \otimes \nabla z$, and $V(x) \equiv 1$; we have also added a limitation on the coefficient of $G(x)$, i.e., on ∇z we have imposed $|z_x| < C$ and $|z_y| < C$, (C=2). In each case, dgr is defined in section 5.1, $qmin$ is the minimal quality of the triangles, nx and ny the number of grid points dt the time step, and cfl the courant number.

(ii) Figures 6A, 6B, and 6C, respectively, correspond to Figures 5A, 5B, and 5C. The latter are motivated, with a slightly different method, by [25]. In the case of Figure 6C, the underlying stiff function z is defined implicitly, which

creates some trouble near by $x_2 = 0.5$.

(iii) The "ellipse" in Figure 6D is defined by $f(x_1, x_2) := (x_1 - .5)^2 + 2 * (x_2 - .5)^2 - (0.4)^2 = 0$.

(iv) Figure 6E. Here, the metric is stiff near two ellipses and a parabola. This is a cartoon of a bow shock near a double ellipse. For computational simplicity, we have simply introduced as in section 4, a metric which is stiff near the involved curves without even removing the nodes inside the body! Nevertheless, the triangles look correctly refined.

6. Conclusion. In this paper we have introduced the simple and natural idea of moving curves with respect to the HJ equation on a manifold, or more precisely according to a given Riemannian metric, in order to generate and/or refine an anisotropic mesh. This idea is clearly in the line of the level set method, and several papers have used similar concepts, in a different context and with different motivations (see, e.g., [30, 42]), but as far as we know, this idea had never been explicitly stated in this way, especially in this context. As we said in the introduction, this work is a first attempt in this direction. There are still numerous problems to solve, and our algorithms need to be strongly improved. First, one should deal with the *stationary* problem (see [41, 16]) or more recently [27] with the numerical Hamiltonian of section 3.2 with the optimized coefficient $\alpha(x, y)$ and $\beta(x, y)$. Moreover, one should use an adapted version of the fast marching method [49, 2, 46], and more recently [37, 43]. As we said in Remark 2.1, the difficulty here is the strong anisotropy, so that the upwinding must be carefully performed.

Clearly, one of the main drawbacks of the present version is the *Lagrangian* feature of the mesh generation. Therefore, one should strongly improve steps 5, 6, and 7 in the mesh generation; in particular, one could combine step 7 with a local Delaunay algorithm based on a Riemannian metric, in the spirit of [25], and, still more important, generate the characteristics (5.2) in an *Eulerian* way, e.g., by following a suggestion of J.D. Benamou (Private Comm.) in connection with the correct numerical upwinding.

We address some of these questions in forthcoming works, e.g., in [4]. In principle, our *anisotropic* approach could have natural applications in image processing, in either image enhancement or edge detection. Indeed, some numerical results in [27] look qualitatively good, but not significantly better than other methods, at least on the examples that we have considered.

Finally, and we thank one of the referees for this question, let us mention that the approach developed here is independent from another Riemannian method, based on the theory of harmonic functions, developed for mesh generation in [23] (see also [15, 14, 31]), and independently used in image processing, e.g., in [47]. The latter theory amounts to solving a second order elliptic boundary value problem and is definitely a kind of (beautiful) multi-D generalization of the (one dimensional) theory of geodesics with, however, some severe restrictions of convexity, nonpositive curvature, etc. on the involved manifolds.

In contrast, the method presented here is a variant of the Eikonal equation, classically seen as a "curve mover," in the spirit of the Huygens principle. This equation is definitely a first order (hyperbolic) equation, with only one (upstream) boundary condition on each ray, starting on the boundary of the domain of interest, and moving until the propagating fronts have swept the whole domain. The method is in principle multi-D with no restriction on the shape of the domain. On the other hand, as we have seen, it still needs substantial numerical improvements before being competitive.

7. Appendix.

For convenience, we recall the definition of viscosity solution and refer, e.g., to [6, 19, 20] for more details. Let us consider the evolution equation

$$\partial_t u + H(x, \nabla u) = 0. \tag{7.1}$$

DEFINITION 7.1. *$u \in C(\Omega)$ is called a viscosity solution to* (7.1) *if u is both a subsolution and a supersolution: for all C^1 test function v, at any point (x_0, t_0) in $\Omega \times (0, t)$ where (u-v) has a local maximum (resp., minimum), then*

$$\partial_t v(x_0, t_0) + H(x_0, \nabla v(x_0, t_0)) \leq 0 \quad (resp., \geq 0). \tag{7.2}$$

The definition of viscosity solution in the stationary case is quite similar. As to the initial boundary value problem, in the general case the formulation involves *discontinuous* viscosity solutions, which take into account the possibility that sometimes boundary conditions cannot be satisfied in the classical sense on the whole boundary, e.g., in the case of the problem

$$|\phi'(x)| - 1 = 0 \text{ on } (0, 1), \;\; \phi(0) = 0\,, \; \phi(1) = 2.$$

In this paper, the solution Ψ to the stationary problem (2.18), (2.19), as well as the solution Φ to problem (2.20), (2.24), (3.6), satisfy the boundary condition in the classical sense.

CHEBYSHEV SPECTRAL METHODS FOR RADIATIVE TRANSFER*

ARNOLD D. KIM[†] AND MIGUEL MOSCOSO[‡]

Abstract. We study the performance of Chebyshev spectral methods for time-dependent radiative transfer equations. Starting with a method for one-dimensional problems in homogeneous media, we show that the modifications needed to consider more general problems such as inhomogeneous media, polarization, and higher dimensions are straightforward. In this method, we approximate the spatial dependence of the intensity by an expansion of Chebyshev polynomials. This yields a coupled system of integro-differential equations for the expansion coefficients that depend on angle and time. Next, we approximate the integral operation on the angle variables using a Gaussian quadrature rule resulting in a coupled system of differential equations with respect to time. Using a second-order finite difference approximation, we discretize the time variable. We solve the resultant system of equations with an efficient algorithm that makes Chebyshev spectral methods competitive with other methods for radiative transfer equations.

Key words. Chebyshev spectral method, radiative transfer

1. Introduction.

Spectral methods have been widely applied to the Navier–Stokes [1, 2], Schrödinger [3], acoustic [4], and Maxwell [5] equations, among others, with great success. In this paper we are interested in using a Chebyshev spectral method [6, 7] for the vector radiative transfer equation

$$\frac{1}{v}\frac{\partial}{\partial t}\mathbf{I}(\mathbf{r},\widehat{\Omega},t)+\widehat{\Omega}\cdot\nabla_{\mathbf{r}}\mathbf{I}(\mathbf{r},\widehat{\Omega},t)+\mathcal{Q}[\mathbf{I}](\mathbf{r},\widehat{\Omega},t)=\mathbf{F}(\mathbf{r},\widehat{\Omega},t) \tag{1.1}$$

governing wave propagation in a medium $\mathcal{D}\subset\mathbb{R}^n$ ($n=1,2,3$) that scatters, absorbs, depolarizes, and emits radiation. Applications for the vector radiative transfer equation include polarized light propagation in clouds, fog, rain, and biological tissue [8] as well as seismic wave propagation in heterogeneous media [10, 11]. In (1.1) $\mathbf{I}=(I,Q,U,V)$ is the 4×1 Stokes vector needed to describe the polarized radiation field completely. The total intensity is represented by I, the linear polarization state by Q and U, and the circular polarization state by V. The Stokes vector $\mathbf{I}$ depends on position $\mathbf{r}\in\mathbb{R}^n$, direction $\widehat{\Omega}\in\mathbb{S}^2$ ($\mathbb{S}^2$ denotes the surface of the unit sphere), and time $t\in[0,T]$. In (1.1), v is the constant wave speed in the medium, and

$$\mathcal{Q}[\mathbf{I}](\mathbf{r},\widehat{\Omega},t)=\sigma_t(\mathbf{r})\mathbf{I}(\mathbf{r},\widehat{\Omega},t)-\sigma_s(\mathbf{r})\int_{\mathbb{S}^2}\mathbf{S}(\widehat{\Omega},\widehat{\Omega}')\,\mathbf{I}(\mathbf{r},\widehat{\Omega}',t)\,d\widehat{\Omega}' \tag{1.2}$$

is the scattering operator. The total scattering cross-section $\sigma_t(\mathbf{r})$ is the sum of the scattering cross-section $\sigma_s(\mathbf{r})$ and the absorption cross-section $\sigma_a(\mathbf{r})$. All of these cross-sections are real and nonnegative. The scattering matrix $\mathbf{S}(\widehat{\Omega},\widehat{\Omega}')$, which we

assume is position independent, describes the directional distribution of energy density that scatters in direction $\widehat{\Omega}$ due to unit energy density incident in direction $\widehat{\Omega}'$. In addition, this matrix describes polarization changes manifested by scattering. Finally, the source term $\mathbf{F}(\mathbf{r}, \widehat{\Omega}, t)$ accounts for any sources contained in the medium.

The radiative transfer equation has to be solved with appropriate initial and boundary conditions. We assume that no radiation other than the source $\mathbf{F}$ enters into the medium so that

$$\mathbf{I}(\mathbf{r}, \widehat{\Omega}, t) = 0 \quad \text{on} \quad \Gamma, \tag{1.3}$$

where $\Gamma = \{(\mathbf{r}, \widehat{\Omega}, t) \in \partial\mathcal{D} \times \mathbb{S}^2 \times [0, T] \ \text{ such that } \ \nu(\mathbf{r}) \cdot \widehat{\Omega} < 0\}$, and $\nu(\mathbf{r})$ denotes the unit outward normal vector to the boundary $\partial\mathcal{D}$. In addition, we assume that no energy is present in the medium at time $t = 0$,

$$\mathbf{I}(\mathbf{r}, \widehat{\Omega}, 0) = 0 \quad \text{in} \quad \mathcal{D} \times \mathbb{S}^2. \tag{1.4}$$

The transport problem (1.1)–(1.4) is well-posed [12]. It models the incoherent or scattered intensity for which its source manifests from coherent intensity incident at the boundary [8, 9].

Equation (1.1) is usually solved using Monte Carlo methods (see [13] and references therein for details). The main advantage of Monte Carlo methods is their relative simplicity and their ability to handle complicated geometries. For large optical depths, they require a large number of particles to obtain statistical accuracy leading to long computational times. Other common numerical methods such as finite differences and finite elements have been applied to the scalar radiative transfer equation with no polarization. However, for vector problems, Monte Carlo methods are preferred.

Despite the high accuracy and competitive cost of spectral methods, there is not, to our knowledge, any attempt to solve the time-dependent, vector radiative transfer equation using spectral methods. However, there are two works that are related to this problem. Ritchie, Dykema, and Braddy [14] solve the scalar, time-dependent problem radiative transfer equation in which polarization is neglected with a Fourier spectral method. Kim and Ishimaru [15] solve the one-dimensional, time-independent, vector radiative transfer equation in homogeneous media with Chebyshev spectral methods. In contrast to Fourier methods, which are restricted to problems with periodic boundary conditions, Chebyshev spectral methods can consider a broad variety of boundary conditions [7]. This is important for many applications such as optical imaging [16].

In this paper, we show that the underlying ideas of the Chebyshev spectral method shown in [15] are robust to generalizations such as time-dependent, inhomogeneous, and higher-dimensional problems. Keeping the ease of implementation and the low computational cost of a basic algorithm, we introduce modifications needed for these general problems. In section 2, we start with the basic algorithm for the one-dimensional, scalar problem in homogeneous media. We generalize this method to inhomogeneous, vector, and higher-dimensional problems in section 3. We present results from numerical experiments in section 4. A summary of our work and some concluding remarks appear in section 5.

2. Time-dependent, scalar problems in one-dimensional homogeneous media.

In this section, let us consider the plane-parallel problem shown in Figure 2.1. The medium, which infinitely extends in the x-y directions, is bounded by two planes located at $z = 0$ and $z = d$, and its spatial properties, σ_t and σ_s, are constant.

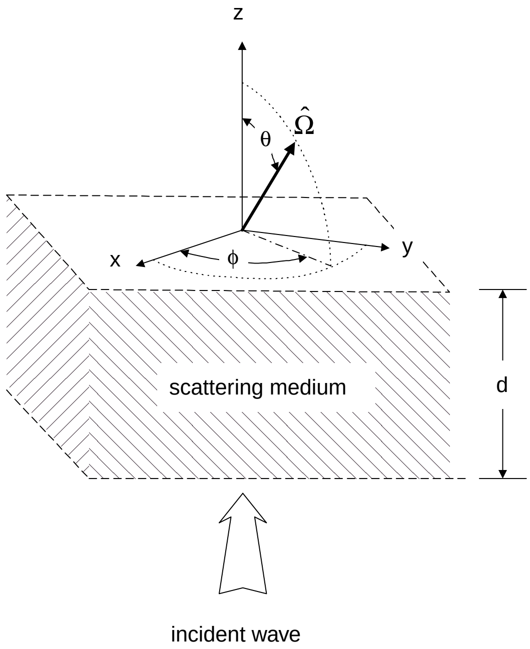

FIG. 2.1. *The plane-parallel problem.*

In addition, the source F does not vary with respect to x and y. We also neglect polarization so that $Q = U = V = 0$ in (1.1)–(1.4), and the 4×4 matrix $\mathbf{S}(\widehat{\Omega} \cdot \widehat{\Omega}')$ is replaced by the scalar function $P(\widehat{\Omega}, \widehat{\Omega}') = \mathbf{S}_{11}(\widehat{\Omega}, \widehat{\Omega}')$ (the $(1,1)$ entry of $\mathbf{S}$). The scalar function P is called the phase function. Under these assumptions, the vector radiative transport equation (1.1) reduces to

$$\frac{1}{v}\frac{\partial}{\partial t} I(z,\mu,\phi,t) + \mu\frac{\partial}{\partial z} I(z,\mu,\phi,t) + \mathcal{Q}[I](z,\mu,\phi,t) = F(z,\mu,\phi,t), \tag{2.1}$$

with

$$\mathcal{Q}[I] = \sigma_t I(z,\mu,\phi,t) - \sigma_s \int_0^{2\pi}\int_{-1}^{1} P(\mu,\mu',\phi-\phi')\, I(z,\mu',\phi',t)\, d\mu' d\phi'. \tag{2.2}$$

Here, $\mu = \cos\theta$, where θ is the propagation direction angle defined with respect to the positive z-direction, and ϕ is the azimuthal angle (see Figure 2.1). The special form of the azimuthal dependence, $\phi - \phi'$, in the phase function P is a direct consequence of the rotational invariance of the scattering matrix.

By representing the azimuthal dependence of the intensity as a Fourier series,

$$I(z,\mu,\phi,t) = \sum_{n=-\infty}^{\infty} I_n(z,\mu,t)\, \mathrm{e}^{in\phi}, \tag{2.3}$$

where the coefficients of this expansion are defined as

$$I_n(z,\mu,t) = \frac{1}{2\pi}\int_0^{2\pi} I(z,\mu,\phi,t)\, \mathrm{e}^{-in\phi} d\phi, \tag{2.4}$$

one finds that each Fourier mode decouples from the others in (2.1). Dropping the index n for simplicity, we find that the resultant problem for each harmonic is

$$\frac{1}{v}\frac{\partial}{\partial t}I(z,\mu,t)+\mu\frac{\partial}{\partial z}I(z,\mu,t)+\mathcal{Q}[I](z,\mu,t)=F(z,\mu,t) \quad \text{in} \quad \mathbb{X}, \tag{2.5a}$$

$$I(z=0,\mu,t)=0 \quad \text{on} \quad (0,1]\times[0,T], \tag{2.5b}$$

$$I(z=d,\mu,t)=0 \quad \text{on} \quad [-1,0)\times[0,T], \tag{2.5c}$$

$$I(z,\mu,t=0)=0 \quad \text{in} \quad [0,d]\times[-1,1], \tag{2.5d}$$

where $\mathbb{X}=[0,d]\times[-1,1]\times[0,T]$ and

$$\mathcal{Q}[I]=\sigma_t I(z,\mu,t)-\sigma_s\int_{-1}^{1}p(\mu,\mu')\,I(z,\mu',t)\,d\mu'. \tag{2.6}$$

In (2.5a) F is a coefficient of an azimuthal Fourier series expansion of the source. Here, we distinguish the Fourier coefficient of the phase function P defined in (1.2) by p in (2.6). It is normalized according to

$$\int_{-1}^{1}p(\mu,\mu')d\mu'=1.$$

Henceforth, we concentrate on solving (2.5) for only one Fourier mode since each mode is decoupled from the others.

2.1. Spatial discretization. Let us change variables in (2.5) from $z\in[0,d]$ to $s\in[-1,1]$ by the linear transformation $s=2z/d-1$. Under this change of variables, (2.5a) becomes

$$\frac{1}{v}\frac{\partial}{\partial t}I(s,\mu,t)+\frac{2}{d}\mu\frac{\partial}{\partial s}I(s,\mu,t)+\mathcal{Q}[I](s,\mu,t)=F(s,\mu,t). \tag{2.7}$$

Now we approximate the spatial dependence of the intensity by the Chebyshev spectral expansion

$$I(s,\mu,t)\cong\sum_{k=0}^{N}a_k(\mu,t)T_k(s). \tag{2.8}$$

The Chebyshev polynomials $T_k(s)$ are orthogonal with respect to the weighted inner product

$$(T_j,T_k)=\int_{-1}^{1}T_j(s)\,T_k(s)\,\frac{ds}{\sqrt{1-s^2}}=\begin{cases}\pi\delta_{j,k} & \text{for } k=0,\\ \frac{\pi}{2}\delta_{j,k} & \text{for } k\geq 1\end{cases} \tag{2.9}$$

and are normalized so that $T_k(s=\pm1)=(\pm1)^k$. Here, $\delta_{j,k}$ is the Kronecker delta. Since the expansion functions T_k do not satisfy the boundary conditions (2.5b) and (2.5c), the extra set of equations

$$I(s=-1,\mu,t)=\sum_{k=0}^{N}(-1)^k a_k(\mu,t)=0 \qquad \text{on } (0,1]\times[0,T], \tag{2.10a}$$

$$I(s=+1,\mu,t)=\sum_{k=0}^{N}a_k(\mu,t)=0 \qquad \text{on } [-1,0)\times[0,T] \tag{2.10b}$$

must be included. Each boundary condition imposes the value of the intensity only over half of the angular data ($\mu < 0$ or $\mu > 0$). Therefore, the composition of (2.10a) and (2.10b) defines a single equation for the expansion coefficients on $[-1,1] \times [0,T]$. Furthermore, we note that considering different boundary conditions does not alter any other aspect of this method.

The Chebyshev spectral approximation to (2.7) is given by (2.8) with (2.10) and

$$\frac{1}{v}\frac{\partial a_k}{\partial t} + \frac{2}{d}\mu\left(T_k, \frac{\partial I}{\partial s}\right) + (T_k, \mathcal{Q}[I]) = (T_k, F), \qquad k = 0, \dots, N. \tag{2.11}$$

Next, we approximate the spatial derivative by another spectral expansion,

$$\frac{\partial I(s,\mu,t)}{\partial s} \cong \sum_{k=0}^{N} A_k(\mu,t) T_k(s), \tag{2.12}$$

where A_k is related to a_k through

$$a_k = \frac{1}{2k}\left[c_{k-1}A_{k-1} - A_{k+1}\right] \quad \text{for } k = 1, 2, \dots, N. \tag{2.13}$$

In (2.13), we assume that $A_{N+1} \ll A_N$ so that $a_N = \frac{1}{2N}c_{N-1}A_{N-1}$. The normalization quantity c_k is defined as

$$c_k = \begin{cases} 2 & \text{for } k = 0, \\ 1 & \text{for } k = 1, \dots, N-1. \end{cases} \tag{2.14}$$

Substituting (2.8) and (2.12) into (2.11) we obtain the system of integro-differential equations

$$\frac{\partial a_k(\mu,t)}{\partial t} + \frac{2v}{d}\mu A_k(\mu,t) + v\mathcal{Q}[a_k](\mu,t) = vF_k(\mu,t), \qquad k = 0, \dots, N, \tag{2.15}$$

for the expansion coefficients a_k and A_k. Note that there are $N+1$ equations in (2.15), an extra equation due to the boundary condition (2.10), plus the N relations (2.13) for the $2N+2$ unknowns in $\{a_k, A_k\}$. Later in this discussion, we use (2.13) to reduce the number of unknowns to $N+1$. In (2.15), F_k are the coefficients of the Chebyshev spectral approximation of the source function. Finally, we note that the resolution requirements needed to compute an accurate numerical solution of the system do not directly depend on the thickness of the medium $z = d$. Rather, spectrally resolving the source function over the spatial domain dictates the resolution requirements. In other words, sources that rapidly vary in the spatial domain require more Chebyshev modes than smoothly varying ones.

2.1.1. Angular discretization. In using a Chebyshev spectral approximation for the spatial variable, we obtain the integro-differential system (2.15) for expansion coefficients that depend on angle and time. We now focus attention on accurately treating the scattering operation. While there are several different ways of treating the integral operation in the radiative transfer equation, such as spherical harmonics and finite element expansions, a simple and effective method is the discrete ordinate method. By using this method, one can accurately approximate the scattering operator and easily adjust the angular resolution needed for different levels of anisotropy. Methods using spherical harmonics expansions require moderately low levels of anisotropy for efficient use. Otherwise, the number of spherical harmonics needed becomes restrictively large for practical computations. Finite element methods are useful for highly anisotropic scattering [20] but are more complicated to implement than discrete ordinate methods. Choosing any of these methods for the angular discretization would work without interfering with the rest of the algorithm.

Now let us replace the continuous angular variable μ with a set of discrete points $\{\mu_i\}$. Then

$$\frac{\partial a_k(\mu_i,t)}{\partial t}+\frac{2v}{d}\mu_i A_k(\mu_i,t)+v\mathrm{Q}[a_k](\mu_i,t)=vF_k(\mu_i,t)\qquad \text{for } i=1,\dots,q, \tag{2.16}$$

where $k=0,\dots,N$. We use these discrete points μ_i to approximate the scattering operator as

$$\mathrm{Q}[a_k](\mu_i,t)=\sigma_t a_k(\mu_i,t)-\sigma_s\sum_{j=1}^{q} w_j p(\mu_i,\mu_j)\,a_k(\mu_j,t). \tag{2.17}$$

The quality of this approximation will of course depend on the choice of the quadrature rule. We refer to [17] and references therein for a more detailed discussion on this subject. We chose a quadrature rule where μ_j are the zeros of the Legendre polynomial of order q and w_j are the corresponding Gaussian weights.

Using matrix notation, (2.16) can be written as

$$\frac{\partial \mathbf{a}_k(t)}{\partial t}+\frac{2v}{d}\mathrm{L}\mathbf{A}_k(t)+v\mathrm{Q}[\mathbf{a}_k](t)=v\mathbf{F}_k(t)\qquad \text{for } k=0,\dots,N, \tag{2.18}$$

where we have introduced the $q\times 1$ vectors

$$\mathbf{a}_k(t)=(a_k(\mu_1,t),a_k(\mu_2,t),\dots,a_k(\mu_q,t)), \tag{2.19a}$$

$$\mathbf{A}_k(t)=(A_k(\mu_1,t),A_k(\mu_2,t),\dots,A_k(\mu_q,t)), \tag{2.19b}$$

$$\mathbf{F}_k(t)=(F_k(\mu_1,t),F_k(\mu_2,t),\dots,F_k(\mu_q,t)), \tag{2.19c}$$

and the $q\times q$ matrix $\mathrm{L}=\mathrm{diag}(\mu_1,\mu_2,\dots,\mu_q)$.

2.2. Temporal discretization. To integrate (2.18) in time, we use a trapezoid rule and obtain

$$\left[\mathbb{I}+\frac{v\Delta t}{2}\mathrm{Q}\right]\mathbf{a}_k^{n+1}+\frac{v\Delta t}{d}\mathrm{L}\mathbf{A}_k^{n+1}=\left[\mathbb{I}-\frac{v\Delta t}{2}\mathrm{Q}\right]\mathbf{a}_k^{n}-\frac{v\Delta t}{d}\mathrm{L}\mathbf{A}_k^{n}+\frac{v\Delta t}{2}\left[\mathbf{F}_k^{n+1}+\mathbf{F}_k^{n}\right], \tag{2.20}$$

where $\mathbb{I}$ is the identity matrix and $\mathbf{a}_k^n$ and $\mathbf{A}_k^n$ are the coefficients for the intensity and its spatial derivative evaluated at time $t_n=n\Delta t$, respectively. The numerical scheme (2.20) corresponds to the Crank–Nicholson method which is fully implicit, second-order accurate, and unconditionally stable.

Now we discuss an efficient algorithm to solve (2.20). At each time step we must solve

$$\mathrm{K}\mathbf{a}_k+\mathrm{M}\mathbf{A}_k=\mathbf{f}_k, \tag{2.21}$$

where $\mathrm{K}=\mathbb{I}+v\Delta t\mathrm{Q}/2$, $\mathrm{M}=v\Delta t\mathrm{L}/d$, and $\mathbf{f}_k$ is a known quantity corresponding to the right-hand side of (2.20).

From (2.13) we see that transforming from $\mathbf{a}_k$ to $\mathbf{A}_k$ is a simple operation possessing an inherent sparsity. To take advantage of this sparsity, we construct a system of equations to solve for the coefficients of the intensity's spatial derivative rather than coefficients of the intensity (see [18] and references therein for details regarding this technique). After transforming terms involving $\mathbf{a}_k$ to operations on $\mathbf{A}_k$, we obtain a block tridiagonal system

$$\mathrm{M}\mathbf{A}_0 + \mathrm{K}\mathbf{a}_0 = \mathbf{f}_0 \qquad \text{for } k = 0, \tag{2.22a}$$

$$\mathrm{M}\mathbf{A}_1 + \mathrm{K}\mathbf{A}_0 - \frac{1}{2}\mathrm{K}\mathbf{A}_2 = \mathbf{f}_1 \qquad \text{for } k = 1, \tag{2.22b}$$

$$\mathrm{M}\mathbf{A}_k + \frac{1}{2k}\mathrm{K}\left[\mathbf{A}_{k-1} - \mathbf{A}_{k+1}\right] = \mathbf{f}_k \qquad \text{for } k = 2, \dots, N-1, \tag{2.22c}$$

$$\mathrm{M}\mathbf{A}_N + \frac{1}{2N}\mathrm{K}\mathbf{A}_{N-1} = \mathbf{f}_N \qquad \text{for } k = N. \tag{2.22d}$$

For the boundary conditions (2.5b) and (2.5c), we evaluate each expansion coefficient a_k at the quadrature points μ_i and operate on that result by (2.13) to obtain

$$\mathbf{a}_0^+ - \mathbf{A}_0^+ + \frac{1}{4}\mathbf{A}_1^+ - \sum_{k=2}^{N-1} \frac{(-1)^k}{2}\left[\frac{1}{k+1} - \frac{1}{k-1}\right]\mathbf{A}_k^+ + \frac{1}{2(N-1)}\mathbf{A}_N^+ = 0, \tag{2.23a}$$

$$\mathbf{a}_0^- + \mathbf{A}_0^- + \frac{1}{4}\mathbf{A}_1^- + \sum_{k=2}^{N-1} \frac{1}{2}\left[\frac{1}{k+1} - \frac{1}{k-1}\right]\mathbf{A}_k^- - \frac{1}{2(N-1)}\mathbf{A}_N^- = 0. \tag{2.23b}$$

Here, we have defined $\mathbf{A}_k^{\mp}$ to be subvectors of $\mathbf{A}_k$,

$$\mathbf{A}_k = \begin{bmatrix} \mathbf{A}_k^- \\ \mathbf{A}_k^+ \end{bmatrix}, \tag{2.24}$$

where $\mathbf{A}_k^-$ corresponds to the part of $\mathbf{A}_k$ in which $\mu_i < 0$ and $\mathbf{A}_k^+$ corresponds to the part of $\mathbf{A}_k$ in which $\mu_i > 0$. The same notation applies for $\mathbf{a}_0^{\mp}$.

Equations (2.22) and (2.23) define a system of equations for $\mathbf{A}_0, \mathbf{A}_1, \dots, \mathbf{A}_N$ and $\mathbf{a}_0$. After computing a solution for these unknowns, we can compute the desired expansion coefficients of the intensity $\mathbf{a}_k$ by applying (2.13) again. One can solve this system using Gaussian elimination, but the cost is $O\left(q^3(N+1)^3\right)$. Instead, we use the generalized deflated block elimination method [19] that takes advantage of the inherent sparsity of this system to reduce the number of operations significantly. The number of operations needed to solve (2.22) and (2.23) using this method is $O(q^3(N-1))$. We discuss the details of this solution method in Appendix A.

3. Generalizations.

We now study the modifications needed to deal with more general problems. We carry out these modifications in a way that preserves the order of accuracy, computational cost, and ease of implementation.

3.1. Layered media.

In many applications the properties of the medium in the vertical direction are not homogeneous. In that case, a multilayered model where the scattering and total cross-sections are piecewise constant functions in space might be applied. Using the Chebyshev spectral method, we find that solving problems in layered media is essentially the same as solving homogeneous problems in each layer. Dealing with interfaces between layers requires only adding extra conditions that reside with the boundary conditions in the resultant system of equations.

For simplicity, let us consider a medium with only two layers. In that case

$$\sigma_{s,t}(z) = \begin{cases} \sigma_{s,t}^{(1)} & \text{for } z \in [0, d_1), \\ \sigma_{s,t}^{(2)} & \text{for } z \in [d_1, d_2]. \end{cases} \tag{3.1}$$

In addition to the boundary conditions (2.5b) and (2.5c), we impose that the intensity at the interface $z = d_1$ between the layers is continuous so that

$$I(z,\mu,t) = \begin{cases} I^{(1)}(z,\mu,t) & \text{for } z \in [0, d_1], \\ I^{(2)}(z,\mu,t) & \text{for } z \in [d_1, d_2]. \end{cases} \tag{3.2}$$

Now let us introduce two spatial variables

$$s_1 = 2\frac{z}{d_1} - 1 \qquad \text{for } z \in [0, d_1], \tag{3.3}$$

$$s_2 = 2\frac{z-d_1}{d_2-d_1} - 1 \quad \text{for } z \in [d_1, d_2] \tag{3.4}$$

so that the radiative transfer equation for each harmonic is

$$\left[\frac{1}{v}\frac{\partial}{\partial t} + \frac{2}{d_1}\mu\frac{\partial}{\partial s_1} + \mathcal{Q}^{(1)}\right] I^{(1)}(s_1,\mu,t) = F^{(1)}(s_1,\mu,t) \qquad \text{for } s_1 \in [-1,1], \tag{3.5a}$$

$$\left[\frac{1}{v}\frac{\partial}{\partial t} + \frac{2}{d_2-d_1}\mu\frac{\partial}{\partial s_2} + \mathcal{Q}^{(2)}\right] I^{(2)}(s_2,\mu,t) = F^{(2)}(s_2,\mu,t) \quad \text{for } s_2 \in [-1,1]. \tag{3.5b}$$

Here, we define the scattering operator as

$$\mathcal{Q}^{(j)}[I] = \sigma_t^{(j)} I(s_j,\mu,t) - \sigma_s^{(j)} \int_{-1}^{1} p(\mu,\mu') I(s_j,\mu',t)\, d\mu', \qquad j = 1,2, \tag{3.6}$$

and the source function as

$$F(z,\mu,t) = \begin{cases} F^{(1)}(z,\mu,t) & \text{for } z \in [0, d_1], \\ F^{(2)}(z,\mu,t) & \text{for } z \in [d_1, d_2]. \end{cases} \tag{3.7}$$

The boundary conditions for this problem are

$$I^{(1)}(s_1 = -1,\mu,t) = 0 \quad \text{on} \quad (0,1] \times [0,T], \tag{3.8a}$$

$$I^{(2)}(s_2 = +1,\mu,t) = 0 \quad \text{on} \quad [-1,0) \times [0,T], \tag{3.8b}$$

and the continuity condition at the interface implies that

$$I^{(1)}(s_1 = +1,\mu,t) = I^{(2)}(s_2 = -1,\mu,t) \qquad \text{on} \quad [-1,1] \times [0,T]. \tag{3.9}$$

Now we consider Chebyshev spectral approximations for $I^{(1)}$ and $I^{(2)}$:

$$I^{(j)}(s_j,\mu,t) \cong \sum_{k=0}^{N} a_k^{(j)}(\mu,t) T_k(s_j), \qquad j = 1,2. \tag{3.10}$$

In performing the same analysis used for the homogeneous case, we obtain

$$\frac{\partial}{\partial t}a_k^{(1)}(\mu,t)+\frac{2v}{d_1}\mu A_k^{(1)}(\mu,t)+v\mathcal{Q}^{(1)}[a_k^{(1)}](\mu,t)=vF_k^{(1)}(\mu,t), \tag{3.11a}$$

$$\frac{\partial}{\partial t}a_k^{(2)}(\mu,t)+\frac{2v}{d_2-d_1}\mu A_k^{(2)}(\mu,t)+v\mathcal{Q}^{(2)}[a_k^{(2)}](\mu,t)=vF_k^{(2)}(\mu,t) \tag{3.11b}$$

for $k=0,\dots,N$. Notice that (3.11a) and (3.11b) each resemble (2.15) modulo scalar factors. Hence, we use exactly the same method outlined above for the homogeneous case for each equation.

After applying a transformation similar to the one discussed in section 2.2 on (3.11), we construct a system of equations for $(\mathbf{A}_k^{(1)},\mathbf{A}_k^{(2)},\mathbf{a}_0^{(1)},\mathbf{a}_0^{(2)})$. In particular, with (3.11), we have $2N+2$ equations for $2N+4$ unknowns. The other two needed equations are the boundary conditions

$$\sum_{k=0}^{N}(-1)^k a_k^{(1)}(\mu,t)=0 \qquad \text{on } (0,1]\times[0,T], \tag{3.12a}$$

$$\sum_{k=0}^{N} a_k^{(2)}(\mu,t)=0 \qquad \text{on } [-1,0)\times[0,T], \tag{3.12b}$$

and the continuity condition

$$\sum_{k=0}^{N}\left[a_k^{(1)}(\mu,t)-(-1)^k a_k^{(2)}(\mu,t)\right]=0. \tag{3.13}$$

Once again, since both (3.12a) and (3.12b) each impose conditions on half of the angular domain, the composition of these two equation defines a single equation on $[-1,1]\times[0,T]$. The continuity condition (3.13) gives another equation defined on $[-1,1]\times[0,T]$. Therefore, we have $2N+4$ equations for $2N+4$ unknowns.

Because coupling between expansion coefficients corresponding to different layers occurs only through the boundary and continuity conditions, the solution method for layered media is essentially the solution for two homogeneous problems. In general, the solution method for layered media problems corresponds to a composition of n homogeneous problems where n is the number of layers. Although the addition of more layers linearly increases the amount of work needed to compute a solution, in practice one needs fewer numbers of Chebyshev modes to resolve each layer.

3.2. Inhomogeneous media. For more general problems where a multilayered model cannot be applied, we must consider continuously varying cross-sections. The difficulty in dealing with these variable coefficients in a spectral approximation is that they necessarily lead to convolution sums. These convolutions make standard fully implicit time stepping impractical to compute since they couple all of the Chebyshev modes, thereby destroying the sparsity used to compute solutions efficiently. On the other hand, it is well known that fully explicit schemes for standard Chebyshev methods with N modes have a stability condition of $v\Delta t < O(1/N^2)$. This is a disadvantage when compared with other fully explicit schemes using Fourier spectral or finite difference methods with stability conditions $v\Delta t < O(1/N)$. To circumvent this restriction, we use a semi-implicit method where only the spatial inhomogeneities are treated explicitly.

We first express the variable cross-sections as

$$\sigma_{s,t} = \sigma_{s,t}^{(0)} + \tilde{\sigma}_{s,t}(s), \tag{3.14}$$

where $\sigma_s^{(0)}$ and $\sigma_t^{(0)}$ are constants. We choose to represent the variable cross-sections in this way so we can treat a portion of the cross-section implicitly. This is important for the time stability limit of the scheme. By substituting (3.14) into the radiative transfer equation, we obtain

$$\frac{1}{v}\frac{\partial}{\partial t}I(s,\mu,t) + \frac{2}{d}\mu\frac{\partial}{\partial s}I(s,\mu,t) + \mathcal{Q}[I](s,\mu,t) = F(s,\mu,t) - \tilde{\mathcal{Q}}[I](s,\mu,t), \tag{3.15}$$

with

$$\tilde{\mathcal{Q}}[I](s,\mu,t) = \tilde{\sigma}_t(s)I(s,\mu,t) - \tilde{\sigma}_s(s)\int_{-1}^{1} p(\mu,\mu')\, I(s,\mu',t)\, d\mu'. \tag{3.16}$$

The only difference between (2.7) for the homogeneous case and (3.15) is the inhomogeneous term $\tilde{\mathcal{Q}}[I]$.

In order to maintain high accuracy and low computational cost, we treat $\tilde{\mathcal{Q}}[I]$ explicitly in time with a second-order Adams–Bashforth scheme so that

$$\begin{aligned}\left[\mathbb{I} + \frac{v\Delta t}{2}\mathrm{Q}\right]\mathbf{a}_k^{n+1} + \frac{v\Delta t}{d}\mathbf{L}\mathbf{A}_k^{n+1} &= \left[\mathbb{I} - \frac{v\Delta t}{2}\mathrm{Q}\right]\mathbf{a}_k^{n} - \frac{v\Delta t}{d}\mathbf{L}\mathbf{A}_k^{n} \\ &\quad + \frac{v\Delta t}{2}\left[\mathbf{F}_k^{n+1} + \mathbf{F}_k^{n}\right] - \frac{v\Delta t}{2}\left[3\tilde{\mathrm{Q}}[\mathbf{a}]_k^n - \tilde{\mathrm{Q}}[\mathbf{a}]_k^{n-1}\right].\end{aligned} \tag{3.17}$$

The convolution terms

$$\left[\tilde{\sigma}_{t,s} \star a\right]_k^n(\mu_i) = \int_{-1}^{1} \tilde{\sigma}_{t,s}(s) I(s,\mu_i,t_n) T_k(s)\frac{ds}{\sqrt{1-s^2}} \tag{3.18}$$

contained within $\tilde{\mathrm{Q}}[\mathbf{a}]_k^n$ are evaluated explicitly in time, so there is no coupling between different k modes at time level $n+1$. These convolutions can be computed either in the spatial domain (pseudospectrally) or in the Chebyshev transform domain. Notice that the only difference between the homogeneous and inhomogeneous problem lies in constructing the right-hand side of (3.17).

Dealing with the inhomogeneities explicitly in time compromises the stability of the numerical scheme. Specifically, the explicit terms in (3.17) require $v\Delta t \max(\tilde{\sigma}_t) < 1$ for stability. This range is not restrictive in most applications since only a portion of the variable cross-sections is treated explicitly. However, if this stability condition does become problematic, an implicit fractional step method similar to that presented in [14] may be applied. Another possibility is to decompose the medium into strips over which the variable cross-sections are assumed to be piecewise constant with some variable perturbation. Then, one can construct and solve the corresponding layered background medium problem with the same method for inhomogeneous media presented above in each layer. This approach would minimize the size of the variable perturbation within each strip, thereby reducing the time step restriction.

3.3. Vector radiative transfer. Modifying the methods presented in section 2 to include polarization is straightforward. In fact, the only modification required lies in constructing the system of equations for

$$\begin{bmatrix} I(s,\mu,t) \\ Q(s,\mu,t) \\ U(s,\mu,t) \\ V(s,\mu,t) \end{bmatrix} \cong \sum_{k=0}^{N} \begin{bmatrix} a_k^{(I)}(\mu,t) \\ a_k^{(Q)}(\mu,t) \\ a_k^{(U)}(\mu,t) \\ a_k^{(V)}(\mu,t) \end{bmatrix} T_k(s), \tag{3.19}$$

where $a_k^{(I)}$, $a_k^{(Q)}$, $a_k^{(U)}$, and $a_k^{(V)}$ are the spatial projections of the Stokes parameters onto the Chebyshev polynomial of order k. Proceeding in a similar manner as in section 2, we obtain

$$\frac{\partial}{\partial t} \begin{bmatrix} \mathbf{a}_k^{(I)} \\ \mathbf{a}_k^{(Q)} \\ \mathbf{a}_k^{(U)} \\ \mathbf{a}_k^{(V)} \end{bmatrix} + \frac{2v}{d}\overline{\mathrm{L}} \begin{bmatrix} \mathbf{A}_k^{(I)} \\ \mathbf{A}_k^{(Q)} \\ \mathbf{A}_k^{(U)} \\ \mathbf{A}_k^{(V)} \end{bmatrix} + v\mathrm{Q} \begin{bmatrix} \mathbf{a}_k^{(I)} \\ \mathbf{a}_k^{(Q)} \\ \mathbf{a}_k^{(U)} \\ \mathbf{a}_k^{(V)} \end{bmatrix} = v \begin{bmatrix} \mathbf{f}_k^{(I)} \\ \mathbf{f}_k^{(Q)} \\ \mathbf{f}_k^{(U)} \\ \mathbf{f}_k^{(V)} \end{bmatrix}, \qquad k = 0,\dots,N, \tag{3.20}$$

where

$$\mathbf{a}_k^{(j)} = (a_k^{(j)}(\mu_1,t),\, a_k^{(j)}(\mu_2,t),\, \dots\, , a_k^{(j)}(\mu_q,t)), \qquad j = I,Q,U,V. \tag{3.21}$$

Similar notation applies for $\mathbf{A}_k^{(j)}$ and $\mathbf{f}_k^{(j)}$. Here, $\overline{\mathrm{L}}$ is the $4q \times 4q$ block diagonal matrix defined as $\overline{\mathrm{L}} = \mathrm{diag}(\mathrm{L},\mathrm{L},\mathrm{L},\mathrm{L})$, where $\mathrm{L} = \mathrm{diag}(\mu_1,\mu_2,\dots,\mu_q)$ as in section 2. By introducing the vectors

$$\boldsymbol{\psi}_k = \left(\mathbf{a}_k^{(I)},\, \mathbf{a}_k^{(Q)},\, \mathbf{a}_k^{(U)},\, \mathbf{a}_k^{(V)}\right), \tag{3.22}$$

$$\Psi_k = \left(\mathbf{A}_k^{(I)},\, \mathbf{A}_k^{(Q)},\, \mathbf{A}_k^{(U)},\, \mathbf{A}_k^{(V)}\right), \tag{3.23}$$

we see that (3.20) can be written in the form

$$\frac{\partial}{\partial t}\boldsymbol{\psi}_k + \frac{2v}{d}\overline{\mathrm{L}}\Psi_k + v\mathrm{Q}[\boldsymbol{\psi}_k] = v\mathbf{F}_k, \qquad k = 0,\dots,N. \tag{3.24}$$

This system of equations is exactly the same as (2.18), and so it can be treated in exactly the same way. Because each unknown Chebyshev mode $\boldsymbol{\psi}$ is a $4q \times 1$ vector, the work needed to compute the solution for a vector problem is $O(4^3q^3(N-1))$.

3.4. Two spatial dimensions. We now consider scalar radiative transfer equations in two spatial dimensions. From the numerical point of view, the most important changes appear in going from the one-dimensional case to the two-dimensional one. Generalizations from two spatial dimensions to three are usually straightforward.

We first consider the two-dimensional radiative transfer equation arising from a source term $\mathbf{F}$ that depends on x and z. This source can model problems involving for example, beam waves. The homogeneous medium through which the wave propagates is still infinite in the x-y direction and bounded by two planes located at $z = 0$ and $z = d_z$. After the linear transformation $s = 2z/d_z - 1$, the scalar two-dimensional radiative transfer equation is

$$\begin{aligned} \frac{1}{v}\frac{\partial}{\partial t}I(s,x,\widehat{\Omega},t) + \frac{2}{d_z}\mu\frac{\partial}{\partial s}I(s,x,\widehat{\Omega},t) + \sqrt{1-\mu^2}\cos\phi\frac{\partial}{\partial x}I(s,x,\widehat{\Omega},t) \\ + \mathcal{Q}[I](s,x,\widehat{\Omega},t) = F(s,x,\widehat{\Omega},t), \end{aligned} \tag{3.25}$$

with

$$\mathcal{Q}[I] = \sigma_t I(s,x,\mu,\phi,t) - \sigma_s \int_0^{2\pi}\int_{-1}^{1} P(\mu,\mu',\phi-\phi')\, I(s,x,\mu',\phi',t)\, d\mu' d\phi'. \tag{3.26}$$

Boundary and initial conditions are given by (2.5b)–(2.5d) for all points x. Due to the $\cos\phi$ in front of the partial derivative with respect to x, the Fourier modes of the azimuthal variable do not decouple as in the one-dimensional problem. Therefore, the discrete ordinate method must be extended to include a quadrature rule for the azimuthal variable as well.

Since the medium is infinite in the horizontal direction, it is natural to deal with the x dependence of the intensity I by a Fourier series. Consequently, we approximate I by the expansion

$$I(s,x,\widehat{\Omega},t) \cong \sum_{k=0}^{N_v}\sum_{l=-N_h/2}^{N_h/2} a_{kl}(\widehat{\Omega},t) T_k(s) e^{ilx}. \tag{3.27}$$

Proceeding in an analogous way to section 2 we obtain a semidiscrete equation for each mode l that is decoupled from the others. Each decoupled semidiscrete equation has the same form as (2.15), where the operator $\mathcal{Q}$ has to be replaced by

$$\begin{aligned}\mathcal{Q}_l[a_{kl}](\mu,\phi,t) &= \sigma_t\, a_{kl}(\mu,\phi,t) + il\sqrt{1-\mu^2}\cos\phi\, a_{kl}(\mu,\phi,t)\\ &\quad - \sigma_s \int_0^{2\pi}\int_{-1}^{+1} P(\mu,\mu',\phi-\phi')\, a_{kl}(\mu',\phi',t)\, d\mu' d\phi'.\end{aligned} \tag{3.28}$$

This problem can be solved by the same procedure as the one-dimensional case for each mode l independently. It is also clear that the case where the coefficients σ_t and σ_s depend on the position can be treated with a semi-implicit method as in section 3.2.

As a second example, let us consider that the horizontal direction is bounded by two planes at $x = 0$ and $x = d_x$ so that we have the two extra boundary conditions

$$I(z, x=0, \widehat{\Omega}, t) = 0 \qquad \text{on} \qquad \Gamma_x, \tag{3.29}$$

$$I(z, x=d_x, \widehat{\Omega}, t) = 0 \qquad \text{on} \qquad \Gamma_x, \tag{3.30}$$

where Γ_x denotes the set of points $[0,d_z]\times\mathbb{S}^2\times[0,T]$ such that $\nu(x)\cdot\widehat{\Omega} < 0$. After the linear transformation $r = 2x/d_x - 1$, we approximate the intensity I and its derivatives by the expansions

$$\begin{aligned} I(s,r,\widehat{\Omega},t) &\cong \sum_{k=0}^{N_v}\sum_{l=0}^{N_h} a_{kl}(\widehat{\Omega},t)T_k(s)T_l(r),\\ \frac{\partial}{\partial s}I(s,r,\widehat{\Omega},t) &\cong \sum_{k=0}^{N_v}\sum_{l=0}^{N_h} A_{kl}(\widehat{\Omega},t)T_k(s)T_l(r),\\ \frac{\partial}{\partial r}I(s,r,\widehat{\Omega},t) &\cong \sum_{k=0}^{N_v}\sum_{l=0}^{N_h} B_{kl}(\widehat{\Omega},t)T_k(s)T_l(r).\end{aligned} \tag{3.31}$$

Again, proceeding in a similar fashion we obtain the semidiscrete set of equations

$$\frac{\partial a_{kl}}{\partial t} + \frac{2v}{d_z}\mu A_{kl} + \frac{2v}{d_x}\sqrt{1-\mu^2}\cos\phi B_{kl} + v\mathcal{Q}[a_{kl}] = vF_{kl} \tag{3.32}$$

for $k = 0, 1, \ldots, N_v$ and $l = 0, 1, \ldots, N_h$. After discretization in the angular variables μ and ϕ and the time variable t, and using relations

$$a_{kl} = \frac{1}{2k}\left[c_{k-1}A_{k-1,l} - A_{k+1,l}\right], \tag{3.33a}$$

$$a_{kl} = \frac{1}{2l}\left[c_{l-1}B_{k,l-1} - B_{k,l+1}\right], \tag{3.33b}$$

one could resolve the resulting system for the $2(N+1)+(N+1)^2$ variables a_{0l}, B_{kN_h}, and A_{kl} as in section 2. However, this procedure is cumbersome due to the recursion relation between B_{kl} and A_{kl}. Therefore, we solve the fully discretized equations arising from (3.32) with an alternating direction implicit or approximate factorization method. The two-step method (see Appendix B) is

$$\left[\mathbb{I} + \frac{v\Delta t}{4}\mathrm{Q}\right]\mathbf{a}^*_{kl} + \frac{v\Delta t}{d_z}\mathrm{L}_z\mathbf{A}^*_{kl} = \left[\mathbb{I} - \frac{v\Delta t}{4}\mathrm{Q}\right]\mathbf{a}^n_{kl} - \frac{v\Delta t}{d_z}\mathrm{L}_z\mathbf{A}^n_{kl} + \frac{v\Delta t}{2}\left[\mathbf{F}^{n+1}_{kl} + \mathbf{F}^n_{kl}\right],$$

$$\left[\mathbb{I} + \frac{v\Delta t}{4}\mathrm{Q}\right]\mathbf{a}^{n+1}_{kl} + \frac{v\Delta t}{d_x}\mathrm{L}_x\mathbf{B}^{n+1}_{kl} = \left[\mathbb{I} - \frac{v\Delta t}{4}\mathrm{Q}\right]\mathbf{a}^*_{kl} - \frac{v\Delta t}{d_x}\mathrm{L}_x\mathbf{B}^*_{kl} \tag{3.34}$$

for each k and each l. The matrices Q, L_z, and L_x in (3.34) are defined in Appendix B. Algorithm (3.34) again has the desired property of preserving the structure of the one-dimensional problem. For each fixed l, one needs only to solve two block tridiagonal systems. This method is second-order accurate and unconditionally stable.

4. Numerical examples.

Here, we present computations for different radiative transfer problems. We also examine the convergence of these methods in space and time. The convergence of the discrete ordinate method is well established [21]. Kim and Ishimaru [15] demonstrated that the Chebyshev spectral method, in conjunction with the discrete ordinate method, is able to resolve highly anisotropic scattering for these problems.

As an example, we consider a normally incident pulsed plane wave entering the medium at $z = 0$ and solve for the incoherent or scattered intensity. Figures 4.1(a) and (b) show the numerical solutions to scalar and vector problems, respectively. In these examples and all that follow, we normalize spatial units by $\ell = 1/\sigma_t^{(0)}$ and time units by ℓ/v.

For the scalar problem (Figure 4.1(a)), we computed the magnitude of the backscattered flux

$$\mathcal{F}(t) = 2\pi\int_{-1}^{0} I(z=0,\mu,t)|\mu|d\mu \tag{4.1}$$

for three different media of thickness $d = 20$. The scattering and absorption cross-sections

$$\sigma_{s,a} = \sigma_{s,a}^{(0)} + \tilde{\sigma}_{s,a}(z)$$

all have $\sigma_s^{(0)} = 0.98$ and $\sigma_a^{(0)} = 0.02$, and

$$\tilde{\sigma}_{s,a}(z) = A_{s,a}\exp\left[\left(\frac{z - z_{s,a}}{w_{s,a}}\right)^2\right].$$

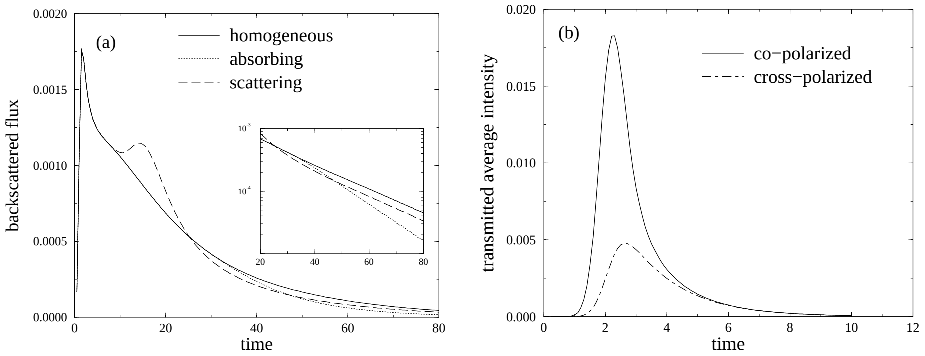

FIG. 4.1. *Example of radiative transfer computations: the left plot* (a) *shows the backscattered flux response of a normally incident pulsed plane wave from a plane-parallel medium of thickness* $d = 20$ *using the Henyey–Greenstein phase function with* $g = 0.85$*. The inset shows a detail of the flux responses' tails on a logarithmic scale. Here, we used* 65 *Chebyshev modes and* 20 *quadrature points with* $\Delta t = 0.01$*. The right plot* (b) *shows the transmitted average intensity response of a left-handed circularly polarized pulsed plane wave normally incident upon a plane-parallel medium containing randomly distributed dielectric spheres immersed in water. The incident light pulse has wavelength* $\lambda = 633\,nm$ *(wavelength generated by a He-Ne laser) and the spherical scatterers are identically sized with radius* $a = 0.05\,\mu m$*. The refractive index of the spheres relative to that of water is approximately* $n = 1.19$*. The scattering matrix for this medium is given by Mie theory. For these computations, we used* 65 *Chebyshev modes,* 40 *quadrature points, and* $\Delta t = 0.01$*.*

The parameters for each medium are given in Table 4.1.

We use the Henyey–Greenstein phase function

$$P(\cos\Theta) = \frac{1}{2}\frac{1-g^2}{(1+g^2-2g\cos\Theta)^{3/2}}, \tag{4.2}$$

where $\cos\Theta = \mu\mu' + \sqrt{1-\mu^2}\sqrt{1-\mu'^2}\cos(\phi-\phi')$ is the cosine of the scattering angle and g is the mean cosine scattering angle or anisotropy factor. Scattering is isotropic for $g = 0$ and becomes more and more sharply peaked in the "forward" direction ($\cos\Theta = 1$) as $g \to 1$.

Since the source is normally impinging the medium, the problem is independent of ϕ and therefore requires only the zero Fourier ϕ-harmonic. Consequently, we use the phase function

$$p(\mu,\mu') = \frac{1}{2\pi}\int_0^{2\pi} P(\mu,\mu',\phi-\phi')d(\phi-\phi'). \tag{4.3}$$

The source function is

$$F(z,\mu,t) = p(\mu,1)f(vt-z)\,\exp\left[-\int_0^z \sigma_t(z')dz'\right], \tag{4.4}$$

where

$$f(t) = \exp\left[-\left(\frac{t-t_o}{T}\right)^2\right] \tag{4.5}$$

is the temporal pulse shape. This source function comes about from the incident intensity as it attenuates from scattering and absorption while propagating into the

TABLE 4.1
Parameter values for the three different media depicted in Figure 4.1(a).

Medium	A_s	z_s	w_s	A_a	z_a	w_a
homogeneous	0	—	—	0	—	—
absorbing	0	—	—	0.5	15	2
scattering	1	5	1	0	—	—

medium, thereby giving rise to the scattered component of the intensity [8]. The time at which the pulse center reaches the boundary at $z = 0$ is t_o and the pulse width is T. For this computation, $t_o = 1$, $T = 0.5$, and $g = 0.85$.

We observe in Figure 4.1(a) that the presence of the scattering inhomogeneity centered at $z_s = 5$ gives rise to an increase of the backscattered response (dashed line). By causality, the first indication of this presence takes place at $t \approx 11$. This is the time that it takes for light to propagate from the boundary to the inhomogeneity and back to the boundary. Similarly, we observe a decrease in the backscattered response at $t \approx 31$ due to the absorption inhomogeneity centered at $z_a = 15$ corresponding to the time needed to reach the inhomogeneity and return to the surface.

In Figure 4.1(b), we show the copolarized (solid line) and cross-polarized (dot-dashed line) components of the transmitted average intensity

$$\mathcal{U}(t) = \frac{1}{2}\int_0^1 I(z = d, \mu, t) d\mu.$$

The incident pulse is left-handed circularly polarized so that $I = V = 1$ and $Q = U = 0$ and normally impinges a medium of thickness $d = 1$. For these computations, $t_o = 1$ and $T = 0.5$. We define the copolarized intensity to be the component that is left-handed circularly polarized

$$I_{\mathrm{LHC}} = \frac{1}{2}(I + V)$$

and the cross-polarized intensity to be the component that is right-handed circularly polarized

$$I_{\mathrm{RHC}} = \frac{1}{2}(I - V).$$

Because early transmitted responses consist of light that has undergone very little scattering as it propagated through the medium, it is entirely copolarized. As time increases, scattering gives rise to depolarization so that the cross-polarized component increases. For very large times, we observe in Figure 4.1(b) that both components are equal.

4.1. Temporal convergence. To verify that the temporal discretization is second-order accurate, we examine time-resolved, backscattered flux responses for the scalar problems explained in sections 2, 3.1, and 3.2. As a test problem, we considered a pulse with $t_o = 1$ and $T = 0.5$ in a medium with thickness $d = 1$ and anisotropy $g = 0.5$ up to time $t = 10$. Since there is no known analytical solution to this problem, we compared flux responses using different time steps to a reference solution computed with $\Delta t = 0.001$. Specifically, we computed the infinity norm of the difference of a solution with lower resolution and the reference solution normalized by the infinity norm of the reference solution. For all of these computations, we used 20 quadrature points.

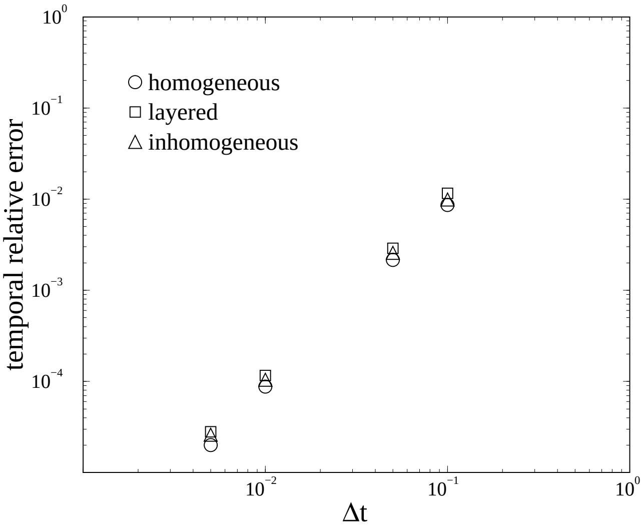

Fig. 4.2. *Computed relative errors of time-resolved, backscattered flux responses as a function of the time step* Δt*. These computations used* 20 *quadrature points. The medium is* $d = 1$ *thick with anisotropy* $g = 0.5$*.*

Table 4.2

Observed rates of convergence for the time discretization using the infinity norm of the difference between the computed solution and a reference solution with $\Delta t = 0.001$*.*

Medium	Convergence rate
homogeneous	2.0174
layered	2.0055
inhomogeneous	1.9874

For the homogeneous problem, we considered a medium with $\sigma_s = 0.98$ and $\sigma_a = 0.02$, and used 65 Chebyshev modes. For the layered problem, we considered three layers with interfaces at $z = 0.4$ and $z = 0.7$ with

$$\sigma_s(z) = \begin{cases} 0.98 & \text{for } z \in [0, 0.4], \\ 1.96 & \text{for } z \in (0.4, 0.7], \\ 0.90 & \text{for } z \in (0.7, 1], \end{cases} \qquad \sigma_a(z) = \begin{cases} 0.02 & \text{for } z \in [0, 0.4], \\ 0.04 & \text{for } z \in (0.4, 0.7], \\ 0.10 & \text{for } z \in (0.7, 1], \end{cases}$$

and used 17 Chebyshev modes in each layer. For the inhomogeneous problem, we considered

$$\tilde{\sigma}_s(z) = 0.98 \exp\left[-\left(\frac{z - 0.4}{0.3}\right)^2\right], \qquad \tilde{\sigma}_a(z) = 0.02 \exp\left[-\left(\frac{z - 0.4}{0.3}\right)^2\right],$$

and used 65 Chebyshev modes.

Plots of the backscattered flux errors appear in Figure 4.2. We tabulated the observed rates of convergence in Table 4.2. As expected, the time discretization exhibits a second-order convergence rate.

4.2. Spatial convergence. Since we use a Chebyshev spectral method to approximate the spatial dependence of the intensity, we expect a superalgebraic convergence as the number of Chebyshev modes increases. To isolate the spatial properties

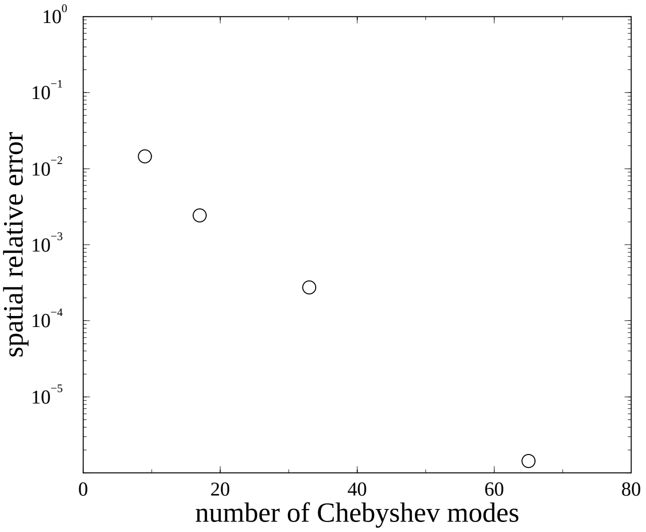

FIG. 4.3. *Relative errors of average intensities as a function of the number of Chebyshev modes for the continuous wave problem. These computations used* 60 *quadrature points for an isotropic medium* ($g = 0$)*.*

of this method, we perform computations for a continuous wave source in a homogeneous medium with $\sigma_s = 0.98$ and $\sigma_a = 0.02$. Furthermore, we consider isotropic scattering ($g = 0$) with 100 quadrature points.

To model an incident continuous wave, we consider the limit in which the temporal pulse width tends toward infinity ($T \to \infty$). In that case, the source function is

$$F(z, \mu) = p(\mu, 1)\,\mathrm{e}^{-\sigma_t z}, \tag{4.6}$$

and, consequently, the specific intensity is independent of time.

To examine the convergence properties of the spatial approximation for this problem, we examine the average intensity

$$\mathcal{U}(z) = \frac{1}{2}\int_{-1}^{1} I(z, \mu) d\mu \tag{4.7}$$

computed using the Gaussian quadrature rule used with the scattering operator. As with the temporal convergence study, we do not have a known analytical solution. Instead, we compare results to a highly resolved reference solution with $N = 513$ Chebyshev modes.

A plot of this spatial convergence study appears in Figure 4.3. We compute the 2-norm of the difference between a particular solution and the reference solution normalized by the 2-norm of the reference solution. In Figure 4.3 we observe the expected superalgebraic convergence of this method. In fact, the relative errors for Chebyshev modes larger than 65 are below the allowed accuracy of double floating-point arithmetic.

5. Summary and concluding remarks. We have presented a complete discussion of Chebyshev spectral methods for solving radiative transfer problems. In particular, we have examined problems in which we apply Chebyshev spectral methods to the spatial variable, Gaussian quadrature methods to the angular variable, and finite differences in the time variable. The resultant linear system of equations at each time step is sparse. This method easily handles homogeneous as well as continuously inhomogeneous and layered media. We have shown that these methods maintain the same structure and ease of implementation as the homogeneous problem. In addition, we show that it modifies easily to solve vector problems and has the potential to solve higher-dimensional problems efficiently.

For all of the cases presented here, we use the generalized deflated block elimination method to solve the bordered, block tridiagonal system of equations at each time step. This method is adequate in computing solutions for the problems we have examined here. However, it is noteworthy to mention that there is an obvious richness in the structure of this linear system beyond its sparsity (see Appendix A). It is quite possible that more can be done to take advantage of this structure to construct even more efficient methods for computing solutions. As we begin to implement this method for larger problems, examining this system in greater detail will become more important and hence will be the subject of future studies. Furthermore, we intend to use this method to examine polarization techniques for optical imaging problems in future work.

Appendix A. The generalized deflated block elimination method. To solve the system of equations (2.22) and (2.23) efficiently, let us construct two vectors that contain the unknown quantities,

$$X = \begin{bmatrix}\mathbf{A}_0, & \mathbf{A}_1, & \cdots, & \mathbf{A}_N\end{bmatrix}^T, \tag{A.1}$$

$$Y = \begin{bmatrix}\mathbf{a}_0\end{bmatrix}, \tag{A.2}$$

where the superscript T denotes the transpose. Then, we can compactly write (2.22) and (2.23) as

$$\begin{bmatrix} A & B \\ C^T & D \end{bmatrix} \begin{bmatrix} X \\ Y \end{bmatrix} = \begin{bmatrix} F \\ G \end{bmatrix}. \tag{A.3}$$

Here, A is the $(N+1)\times(N+1)$ block tridiagonal matrix composed by $q \times q$ matrices M and K

$$A = \begin{bmatrix} \mathrm{M} & 0 & & & & & & \\ \mathrm{K} & \mathrm{M} & -\frac{1}{2}\mathrm{K} & & & & & \\ & \frac{1}{4}\mathrm{K} & \mathrm{M} & -\frac{1}{4}\mathrm{K} & & & & \\ & & \ddots & \ddots & \ddots & & & \\ & & & \frac{1}{2k}\mathrm{K} & \mathrm{M} & -\frac{1}{2k}\mathrm{K} & & \\ & & & & \ddots & \ddots & \ddots & \\ & & & & & \frac{1}{2(N-1)}\mathrm{K} & \mathrm{M} & -\frac{1}{2(N-1)}\mathrm{K} \\ & & & & & & \frac{1}{2N}\mathrm{K} & \mathrm{M} \end{bmatrix}, \tag{A.4}$$

B is the $(N+1)\times 1$ block column matrix

$$B = \begin{bmatrix}\mathrm{K}, 0, \dots, 0\end{bmatrix}^T, \tag{A.5}$$

D is the $q \times q$ identity matrix, and C^T is the $1 \times (N+1)$ block row matrix

$$C^T = \left[\mathbb{I}_0, \quad \tfrac{1}{4}\mathbb{I}_1, \quad \cdots, \quad \tfrac{1}{2}\left(\tfrac{1}{k+1} - \tfrac{1}{k-1}\right)\mathbb{I}_k, \quad \cdots, \quad -\tfrac{1}{2(N-1)}\mathbb{I}_N\right], \tag{A.6}$$

where $\mathbb{I}_k$ is a $q \times q$ matrix made up of $\frac{1}{2}q \times \frac{1}{2}q$ submatrices

$$\mathbb{I}_k = \begin{bmatrix} \mathbb{I} & 0 \\ 0 & (-1)^{k+1}\mathbb{I} \end{bmatrix}. \tag{A.7}$$

The right-hand side vectors of this linear system are

$$F = \begin{bmatrix} \mathbf{f}_0\,, & \mathbf{f}_1\,, & \cdots, & \mathbf{f}_N \end{bmatrix}^T, \tag{A.8}$$

$$G = \begin{bmatrix} 0 \end{bmatrix}. \tag{A.9}$$

Each of the blocks in these matrices and vectors is $q \times q$. Therefore, (A.3) is a bordered, block tridiagonal system of equations.

By arranging the linear system of equations in this way, we can apply the generalized deflated block elimination method to solve this system [19]. This algorithm isolates the block tridiagonal part of this system from its borders, allowing one to exploit the sparsity. Contributions from the borders, B, C^T, and D come about as corrections to the block tridiagonal system solve. The generalized deflated block elimination algorithm is

1. solve $AW = B$,
2. solve $Aw = F$,
3. compute $S = D - C^T W$,
4. solve $SY = G - C^T w$,
5. compute $X = w - WY$.

In addition, the storage requirements in solving this system using this algorithm is very small. The diagonal blocks of A are diagonal matrices, and the off-diagonal blocks of A are all the same modulo a scalar factor. Therefore, only the $q \times q$ matrix, K, and a $q \times 1$ vector containing the diagonal elements of M are necessary to effectively store the matrix A. Furthermore, since each individual block in C^T are scalar multiples of identity matrices, computing the product of it and some other vector requires very few operations.

Appendix B. Alternating direction method. Replacing the continuous angular variables μ and ϕ by a set of discrete quadrature points μ_i and ϕ_j, where $i = 1, \ldots, q_1$ and $j = 1, \ldots, q_2$, we find that the semidiscrete spectral approximation (3.32) in matrix notation is

$$\frac{\partial \mathbf{a}_{kl}(t)}{\partial t} + \frac{2v}{d_z}\mathrm{L}_1 \mathbf{A}_{kl}(t) + \frac{2v}{d_x}\mathrm{L}_2 \mathbf{B}_{kl}(t) + v\mathrm{Q}[\mathbf{a}_{kl}](t) = v\mathbf{F}_{kl}(t) \quad \text{for } k, l = 0, \ldots, N, \tag{B.1}$$

with

$$\mathbf{a}_{kl}(t) = \left(a_{kl}(\mu_1, \phi_1, t), a_{kl}(\mu_1, \phi_2, t), \ldots, a_{kl}(\mu_1, \phi_q, t), \quad \ldots, \quad a_{kl}(\mu_{q_1}, \phi_{q_2}, t)\right), \tag{B.2}$$

and similar representations for $\mathbf{A}_{kl}$, $\mathbf{B}_{kl}$, and $\mathbf{F}_{kl}$. The $(q_1 q_2) \times (q_1 q_2)$ diagonal matrices L_1 and L_2 are defined by

$$\mathrm{L}_1 = \mathrm{diag}(\mu_1, \overset{q_2 times}{\cdots}, \mu_1, \mu_2, \overset{q_2 times}{\cdots}, \mu_2, \quad \ldots \quad \mu_{q_1}, \ldots, \mu_{q_1})$$
$$\mathrm{L}_2 = \mathrm{diag}(\mu_1 \cos\phi_1, \mu_1 \cos\phi_2, \ldots, \mu_1 \cos\phi_{q_2}, \quad \ldots \quad \mu_{q_1}\cos\phi_1, \ldots, \mu_{q_1}\cos\phi_{q_2}).$$

The Crank–Nicholson time-differencing scheme is given by

$$\begin{aligned}\text{(B.3)}\quad \left[\mathbb{I}+\frac{v\Delta t}{2}\mathrm{Q}\right]\mathbf{a}_{kl}^{n+1}+\mathrm{M}_1\mathbf{A}_{kl}^{n+1}+\mathrm{M}_2\mathbf{B}_{kl}^{n+1}\\ =\left[\mathbb{I}-\frac{v\Delta t}{2}\mathrm{Q}\right]\mathbf{a}_{kl}^{n}-\mathrm{M}_1\mathbf{A}_{kl}^{n}-\mathrm{M}_2\mathbf{B}_{kl}^{n}+\frac{v\Delta t}{2}\left[\mathbf{F}_k^{n+1}+\mathbf{F}_k^{n}\right],\end{aligned}$$

where $\mathrm{M}_1=v\Delta t\mathrm{L}_1/d_z$ and $\mathrm{M}_2=v\Delta t\mathrm{L}_2/d_x$. The expansion coefficients of the spatial derivatives B_{kl} and A_{kl} are related to a_{kl} through (3.33). Let us write formally the inverse relations of (3.33) as $A_{kl}=T_1a_{kl}$ and $B_{kl}=T_2a_{kl}$ so that we can make an approximate factorization of (B.3)

$$\begin{aligned}\text{(B.4)}\quad \left[\mathbb{I}+\frac{v\Delta t}{4}\mathrm{Q}+\mathrm{M}_1T_1\right]\left[\mathbb{I}+\frac{v\Delta t}{4}\mathrm{Q}+\mathrm{M}_2T_2\right]\mathbf{a}_{kl}^{n+1}\\ =\left[\mathbb{I}-\frac{v\Delta t}{4}\mathrm{Q}-\mathrm{M}_1T_1\right]\left[\mathbb{I}-\frac{v\Delta t}{4}\mathrm{Q}-\mathrm{M}_2T_2\right]\mathbf{a}_{kl}^{n}+\frac{v\Delta t}{2}\left[\mathbf{F}_k^{n+1}+\mathbf{F}_k^{n}\right].\end{aligned}$$

Observe that all the extra terms introduced in (B.4) are of order $O(\Delta t^2)$. Furthermore, the same terms are introduced in the left- and right-hand side. We can conclude that by subtraction of the extra terms in both sides of the equation, (B.4) is equivalent to (B.3) up to $O(\Delta t^3)$ (since $\mathbf{a}_{kl}^{n+1}-\mathbf{a}_{kl}^{n}\sim O(\Delta t)$). Then the two-stage method

$$\text{(B.5)}\quad \left[\mathbb{I}+\frac{v\Delta t}{4}\mathrm{Q}+\mathrm{M}_1T_1\right]\mathbf{a}_{kl}^{*}=\left[\mathbb{I}-\frac{v\Delta t}{4}\mathrm{Q}-\mathrm{M}_1T_1\right]\mathbf{a}_{kl}^{n}+\frac{v\Delta t}{2}\left[\mathbf{F}_k^{n+1}+\mathbf{F}_k^{n}\right],$$

$$\text{(B.6)}\quad \left[\mathbb{I}+\frac{v\Delta t}{4}\mathrm{Q}+\mathrm{M}_2T_2\right]\mathbf{a}_{kl}^{n+1}=\left[\mathbb{I}-\frac{v\Delta t}{4}\mathrm{Q}-\mathrm{M}_2T_2\right]\mathbf{a}_{kl}^{*}$$

solves (B.1). Again using that $A_{kl}=T_1a_{kl}$ and $B_{kl}=T_2a_{kl}$ we obtain the numerical scheme (3.34).

QUADRATIC CONVERGENCE FOR VALUING AMERICAN OPTIONS USING A PENALTY METHOD[*]

P. A. FORSYTH[†] AND K. R. VETZAL[‡]

Abstract. The convergence of a penalty method for solving the discrete regularized American option valuation problem is studied. Sufficient conditions are derived which both guarantee convergence of the nonlinear penalty iteration and ensure that the iterates converge monotonically to the solution. These conditions also ensure that the solution of the penalty problem is an approximate solution to the discrete linear complementarity problem. The efficiency and quality of solutions obtained using the implicit penalty method are compared with those produced with the commonly used technique of handling the American constraint explicitly. Convergence rates are studied as the timestep and mesh size tend to zero. It is observed that an implicit treatment of the American constraint does not converge quadratically (as the timestep is reduced) if constant timesteps are used. A timestep selector is suggested which restores quadratic convergence.

Key words. American option, penalty iteration, linear complementarity

1. Introduction.

The valuation and hedging of financial option contracts is a subject of considerable practical significance. The holders of such contracts have the right to undertake certain actions so as to receive certain payoffs. The valuation problem consists of determining a fair price to charge for granting these rights. A related issue, perhaps of even more importance to practitioners, is how to hedge the risk exposures which arise from selling these contracts. An important feature of such contracts is the time when contract holders can exercise their rights. If this occurs only at the maturity date of the contract, the option is classified as "European." If holders can exercise any time up to and including the maturity date, the option is said to be "American." The value of a European option is given by the solution of the Black–Scholes PDE (see, e.g., [33]). An analytical solution can be obtained for cases with constant coefficients and simple payoffs. However, most options traded on exchanges are American. Such options must be priced numerically, even for constant coefficients and simple payoffs. Note also that the derivatives of the solution are of interest since they are used in hedging. More formally, the American option pricing problem can be posed as a time dependent variational inequality or a differential linear complementarity problem (LCP).

In current practice, the most common method of handling the early exercise condition is simply to advance the discrete solution over a timestep, ignoring the constraint, and then to apply the constraint explicitly. This has the disadvantage that the solution is in an inconsistent state at the beginning of each timestep (i.e.,

a discrete form of the LCP is not approximately satisfied). As well, this approach can obviously be only first order correct in time. On the other hand, this explicit application of the constraint is computationally very inexpensive.

Another common technique is to solve the discrete LCP using a relaxation method [33]. In terms of complexity, this method is particularly poor for pricing problems with one space-like dimension. A lower bound for the number of iterations required to solve the LCP to a given tolerance with a relaxation method would be the number of iterations required to solve the unconstrained problem using a preconditioned conjugate gradient method. Assuming that the mesh spacing in the asset price S direction is $O(\Delta S)$ and that the timestep size is $O(\Delta t)$, then the condition number of a discrete form of the parabolic option pricing PDE is $O\left[\Delta t/(\Delta S)^2\right]$. Let N be the number of timesteps. If we assume that $\Delta S = O(\Delta t) = 1/N$, then the number of iterations required per timestep would be $O(N^{1/2})$.

A multigrid method has been suggested in [5] to accelerate convergence of the basic relaxation method. Although this is a promising technique, multigrid methods are usually strongly coupled to the type of discretization used, and hence they are complex to implement in general purpose software.

There are a large number of general purpose methods for solving linear complementarity problems [22, 7, 25]. We can divide these methods into essentially two categories: direct methods, such as pivoting techniques [7], and iterative methods, such as Newton iteration [25] and interior point algorithms [22].

Some of these methods which have been applied specifically to American option pricing include linear programming [9], pivoting methods, [14], and interior point methods [15]. As pointed out in [15], pivoting methods (such as Lemke's algorithm [7]) and LP approaches are not well equipped to handle sparse systems, especially in more than one dimension (multifactor options).

Complementarity problems (both linear and nonlinear) can be posed in the form of a set of nonlinear equations. Various nonsmooth Newton methods have been suggested for these types of problems [26, 27, 11, 19, 17]. More recently, combinations of nonsmooth Newton and smoothing methods have been proposed [20].

It is well known that an LCP (or, equivalently, a variational inequality) can be solved by a penalty method [10, 30, 24, 12, 8]. In this article, we will explore some aspects of using penalty methods for pricing American options. We will restrict attention to one dimensional problems, which are more amenable to analysis. However, we have successfully used penalty methods for two factor (two dimensional) problems [40, 39]. In this work, the nonlinear discrete penalized equations are solved using Newton iteration. Another approach which also uses a Newton method has been suggested in [6]. Note that relaxation methods are frequently used to solve the discrete penalized nonlinear equations [8].

The advantage of the penalty method is that a single technique can be used for one dimensional or multidimensional problems, and standard sparse matrix software can be used to solve the Jacobian matrix. This technique can be used for any type of discretization, in any dimension, and on unstructured meshes. In particular, there is no difficulty in handling cases where the early exercise region is multiply-connected, as in [40]. As well, a single method can be used to handle American options and other nonlinearities, such as uncertain volatility and transaction cost models [33, 1]. In addition, nonlinearities due to the use of flux limiters for drift-dominated problems [37] can also be handled easily.

The objective of this article is to analyze the properties of penalty methods for the solution of a discrete form of a comparatively simple problem: a single factor

American option. In this way, we hope to gain some insight into the use of penalty methods for more complex problems. A single factor American option can be posed as a variational inequality, which in turn can be expressed as a discrete LCP problem at each timestep. However, it is important to examine the penalty method in the context of the overall problem: we need to find time accurate solutions to the variational inequality. Consequently, we can expect that we have a good initial guess for the solution of the variational inequality from the previous timestep. In fact, it is important to recall that simply advancing the solution for a timestep (ignoring the constraint) and applying the constraint in an explicit fashion will solve the time dependent variational inequality to $O(\Delta t)$. Consequently, any method used to solve the LCP at each step should take full advantage of a good initial guess.

We will also study the convergence of these methods as the timestep and mesh size are reduced to zero. We will determine sufficient conditions for monotone convergence of the penalty method in one dimension. It may be possible to require weaker conditions, perhaps using the methods in [24]. However, option pricing problems are typically degenerate parabolic and in nonconservative form. This can be expected to complicate the methods in [24].

In practice, we observe that the penalty method works well for multifactor options [40, 39] and for nonlinear problems. In other words, although the conditions we derive are sufficient, they do not appear to be necessary. Consequently, it appears that the penalty method can be used for more general situations. In addition, we will compare the penalty method (where the LCP is approximately solved at each timestep) with an explicit technique for handling the American constraint.

Essentially, the method proposed in this work uses a nonsmooth Newton iteration [4] to solve the penalized problem. A disadvantage of the penalty method as formulated in this work is that the American constraint is satisfied only approximately, but since this error can be easily made to be much smaller than the discretization error, this does not appear to be a practical disadvantage. On the other hand, the advantages of this approach are (under certain conditions) as follows:

- This method has finite termination (in exact arithmetic); i.e., for an iterate sufficiently close to the solution, the algorithm terminates in one iteration. This is especially advantageous when dealing with American option pricing, since we have an excellent initial guess from the previous timestep. In fact, as we shall see, for typical grids and timesteps, the algorithm takes, on average, less than two iterations per timestep to converge. Finite termination also implies that the number of iterations required for convergence is insensitive to the size of the penalty factor (until the limits of machine precision is reached).
- The iteration is globally convergent using full Newton steps.

Of course, if we did not have the advantage of having a good initial guess, a pivoting method [7] can be very efficiently implemented if the coefficient matrix is a tridiagonal M-matrix. We emphasize here that the penalty method should not be regarded as a general purpose method for LCP problems. The real advantage of the penalty method is that this technique takes full advantage of the fact that a good initial iterate is available, and we take full advantage of sparsity, which is important in multifactor problems. Another approach which attempts to take advantage of a good initial iterate combined with standard sparse solvers is described in [21].

If we solve the LCP at each step (using the penalty approach), and if constant timesteps are used, we observe that second order convergence is not obtained as the timesteps and mesh size tend to zero. This phenomenon can be explained by examining the asymptotic behavior of the solution near the exercise boundary. A timestep selector is developed which restores second order convergence.

Asymptotically, the second order method is superior to the commonly used binomial lattice technique [16]. However, it is of practical interest to determine at what levels of accuracy a second order PDE method will be computationally more efficient than the lattice method. We present numerical comparisons to assist in this determination.

In the following we will restrict attention to the American put option. However, these methods can be applied to dividend paying calls, as well as complex options which involve solving a set of one dimensional American-type problems embedded in a higher dimensional space. Examples of these types of options include discretely observed Asian options [38], Parisian options [31], shout options [36], and segregated fund guarantees [35].

2. Formulation.

Consider an asset with price S which follows the stochastic process

$$dS = \mu S dt + \sigma S dz, \tag{2.1}$$

where μ is the drift rate, σ is volatility, and dz is the increment of a Wiener process. We wish to determine the value $V(S,t)$ of an American option where the holder can exercise at any time and receive the payoff $V^*(S,t)$. Denote the expiry time of the option by T, and let $\tau = T - t$. Then the American pricing problem can be formally stated as an LCP [33]

$$\begin{aligned} \mathcal{L}V &\geq 0, \\ (V - V^*) &\geq 0, \\ (\mathcal{L}V = 0) &\vee (V - V^* = 0), \end{aligned} \tag{2.2}$$

where the notation $(\mathcal{L}V = 0) \vee (V - V^* = 0)$ denotes that either $(\mathcal{L}V = 0)$ or $(V - V^* = 0)$ at each point in the solution domain, and

$$\mathcal{L}V \equiv V_\tau - \left(\frac{\sigma^2}{2} S^2 V_{SS} + rSV_S - rV \right), \tag{2.3}$$

and r is the risk free rate of interest. A put option is a contract which gives the holder the right to sell the asset for K (known as the “strike”). A call option is similar except that the holder has the right to buy the asset for K. The payoff for a put is

$$V^*(S) = V(S, \tau = 0) = \max(K - S, 0). \tag{2.4}$$

The boundary conditions are

$$V(S,\tau) = 0, \qquad S \to \infty, \tag{2.5}$$

$$\mathcal{L}V = V_\tau - rV, \qquad S \to 0. \tag{2.6}$$

Condition (2.5) follows from the payoff (2.4), while (2.6) is obvious given (2.3).

3. The penalty method.

The basic idea of the penalty method is simple. We replace problem (2.2) by the nonlinear PDE [10]

$$V_\tau = \frac{\sigma^2}{2} S^2 V_{SS} + rSV_S - rV + \rho \max(V^* - V, 0), \tag{3.1}$$

where, in the limit as the positive penalty parameter $\rho \to \infty$, the solution satisfies $V \geq V^*$.

4. Discretization. We will now discretize (3.1) and select a suitable form for the discrete penalty term. Let $V(S_i, \tau_n) = V_i^n$ be the discrete solution to (3.1) at asset value S_i and time (going backwards) τ_n. Applying a standard finite volume method with variable timeweighting [40] then gives

$$\mathcal{F}V_i^{n+1} = q_i^{n+1}, \tag{4.1}$$

where

$$\begin{aligned}\mathcal{F}V_i^{n+1} \equiv{} & A_i\left(\frac{V_i^{n+1} - V_i^n}{\Delta\tau}\right)\\ & + (1-\theta)\left(\sum_{j\in\eta_i}\gamma_{ij}(V_j^{n+1} - V_i^{n+1}) + \sum_{j\in\eta_i}\vec{L_{ij}}\cdot\mathbf{U}_i V_{ij+1/2}^{n+1} - A_i r V_i^{n+1}\right)\\ & + \theta\left(\sum_{j\in\eta_i}\gamma_{ij}(V_j^n - V_i^n) + \sum_{j\in\eta_i}\vec{L_{ij}}\cdot\mathbf{U}_i V_{ij+1/2}^{n} - A_i r V_i^{n}\right).\end{aligned} \tag{4.2}$$

Fully implicit and Crank–Nicolson discretizations correspond to cases of $\theta = 0$ and $\theta = 1/2$, respectively, and

$$\begin{aligned} A_i &= (S_{i+1} - S_{i-1})/2,\\ \eta_i &= \{i-1, i+1\},\\ \Delta\tau &= \tau^{n+1} - \tau^n,\\ \gamma_{ij} &= \frac{\sigma^2 S_i^2}{2|S_j - S_i|},\\ V_{ij+1/2}^{n+1} &= \text{ value of } V \text{ at the face between nodes } i \text{ and } j,\\ \mathbf{U}_i &= (-rS_i)\hat{\mathbf{i}},\\ \vec{L_{ij}} &= \begin{cases} -\hat{\mathbf{i}} & \text{if } j = i+1,\\ +\hat{\mathbf{i}} & \text{if } j = i-1,\end{cases}\\ \hat{\mathbf{i}} &= \text{ unit vector in the positive } S \text{ direction.}\end{aligned} \tag{4.3}$$

The discrete penalty term q_i^{n+1} in (4.1) is given by

$$q_i^{n+1} = \begin{cases} (A_i/\Delta\tau)(V_i^* - V_i^{n+1})\mathit{Large} & \text{if } V_i^{n+1} < V_i^*,\\ 0 & \text{otherwise,}\end{cases} \tag{4.4}$$

where *Large* is the penalty factor. (This will be related to the desired convergence tolerance in section 4.1.) The face value $V_{ij+1/2}^{n+1}$ can be evaluated using either central weighting or, to ensure nonoscillatory solutions, a flux limiter [37]

$$V_{ij+1/2}^{n+1} = \begin{cases} (V_i^{n+1} + V_j^{n+1})/2 & \text{if } \gamma_{ij}^{n+1} + \vec{L_{ij}}\cdot\mathbf{U}_i/2 > 0,\\ \text{second order flux limiter [37]} & \text{otherwise.}\end{cases} \tag{4.5}$$

In general, for standard options with typical values for σ, r, central weighting can be used at most nodes (except perhaps as $S \to 0$). In order to determine sufficient conditions for the convergence of the nonlinear iteration for the penalized American equation, we require that the coefficients of the discrete equations have certain properties. We will ensure that these conditions are satisfied by using central or upstream weighting. (In practice, we have observed that even if these conditions are not met, convergence of the penalty method is still rapid [40].) If we use central or upstream weighting in the following, then (4.1) becomes

$$
\begin{aligned}
V_i^{n+1} - V_i^n = (1-\theta)&\left(\Delta\tau \sum_{j\in\eta_i} \left(\bar{\gamma}_{ij} + \bar{\beta}_{ij}\right)\left(V_j^{n+1} - V_i^{n+1}\right) - r\Delta\tau V_i^{n+1}\right)\\
&+ \theta\left(\Delta\tau \sum_{j\in\eta_i} \left(\bar{\gamma}_{ij} + \bar{\beta}_{ij}\right)\left(V_j^{n} - V_i^{n}\right) - r\Delta\tau V_i^{n}\right)\\
&+ P_i^{n+1}(V_i^* - V_i^{n+1}),
\end{aligned}
\tag{4.6}
$$

where

$$
P_i^{n+1} = \begin{cases} \mathit{Large} & \text{if } V_i^{n+1} < V_i^*,\\ 0 & \text{otherwise,}\end{cases}
\tag{4.7}
$$

and where

$$
\begin{aligned}
\bar{\gamma}_{ij} &= \frac{\sigma^2 S_i^2}{2A_i|S_j - S_i|},\\
\bar{\beta}_{ij} &= \begin{cases} \vec{L_{ij}} \cdot \mathbf{U}_i/2A_i & \text{if } \gamma_{ij} + \vec{L_{ij}} \cdot \mathbf{U}_i/2 \geq 0,\\ \max(\vec{L_{ij}} \cdot \mathbf{U}, 0)/A_i & \text{otherwise.}\end{cases}
\end{aligned}
$$

For future reference, we can write the discrete equations (4.6) in matrix form. Let $V^{n+1} = \left[V_0^{n+1}, V_1^{n+1}, \ldots, V_m^{n+1}\right]'$, $V^n = [V_0^n, V_1^n, \ldots, V_m^n]'$, $V^* = [V_0^*, V_1^*, \ldots, V_m^*]'$, and

$$
[\hat{M}V^n]_i = -\left(\Delta\tau \sum_{j\in\eta_i} \left(\bar{\gamma}_{ij} + \bar{\beta}_{ij}\right)\left(V_j^{n} - V_i^{n}\right) - r\Delta\tau V_i^{n}\right).
\tag{4.8}
$$

Note that the first and last rows of $\hat{M}$ will have to be modified to take into account the boundary conditions. (An obvious method for applying conditions (2.5)–(2.6) results in the first and last rows of $\hat{M}$ being identically zero except for positive entries on the diagonal). In the following, we will assume that upstream and central weighting are selected so that $\bar{\gamma}_{ij} + \bar{\beta}_{ij} \geq 0$. This implies that the matrix $\hat{M}$ is an M-matrix, i.e., a diagonally dominant matrix with positive diagonals and nonpositive off-diagonals. Note that all of the elements of the inverse of an M-matrix are nonnegative.

Let the diagonal matrix $\bar{P}$ be given by

$$
\bar{P}(V^{n+1})_{ij} = \begin{cases} \mathit{Large} & \text{if } V_i^{n+1} < V_i^* \text{ and } i = j,\\ 0 & \text{otherwise.}\end{cases}
\tag{4.9}
$$

We can then write the discrete equations (4.6) as

$$
\left[I + (1-\theta)\hat{M} + \bar{P}(V^{n+1})\right] V^{n+1} = \left[I - \theta\hat{M}\right] V^n + \left[\bar{P}(V^{n+1})\right] V^*.
\tag{4.10}
$$

4.1. Solution of the discrete LCP. The discrete form of the LCP (2.2) can be written as

$$\begin{aligned} &\mathcal{F}V_i^{n+1} \geq 0, \\ &V_i^{n+1} - V_i^* \geq 0, \\ &(\mathcal{F}V_i^{n+1} = 0) \vee (V_i^{n+1} - V_i^* = 0), \end{aligned} \tag{4.11}$$

where $\mathcal{F}$ is given by (4.2). On the other hand, the discrete solution of the penalized problem (4.10) has the property that either

$$V_i^{n+1} - V_i^* \geq 0 \qquad (\Rightarrow q_i^{n+1} = 0 \text{ and } \mathcal{F}V_i^{n+1} = 0) \tag{4.12}$$

or

$$V_i^{n+1} - V_i^* \leq 0 \qquad (\Rightarrow q_i^{n+1} > 0 \text{ and } \mathcal{F}V_i^{n+1} > 0). \tag{4.13}$$

However, from (4.11) the exact solution of the discrete LCP has $V_i^{n+1} - V_i^* = 0$ at those nodes where $\mathcal{F}V_i^{n+1} > 0$. In order to obtain an approximate solution of (4.11) with an arbitrary level of precision, we need to show that the solution of (4.10) satisfies $V_i^{n+1} - V_i^* \to 0$ as *Large* $\to \infty$ for nodes where $\mathcal{F}V_i^{n+1} > 0$. This follows if we can show that the term

$$P_i^{n+1}(V_i^* - V_i^{n+1}) \tag{4.14}$$

in (4.6) is bounded independent of *Large*. It is also desirable that the bound be independent of the timestep and mesh spacing, so that *Large* can be chosen without regard to grid and timestep size. In Appendix A we determine sufficient conditions which allow us to bound (4.14). The results can be summarized as the following theorem.

THEOREM 4.1 (error in the penalty formulation of the discrete LCP). *Under the assumptions that the matrix $\hat{M}$ in* (4.10) *is an M-matrix and that timesteps are selected so that*

$$1 - \theta\left(\Delta\tau \sum_{j\in\eta_i} \left(\bar{\gamma}_{ij} + \bar{\beta}_{ij}\right) + r\Delta\tau\right) \geq 0, \tag{4.15}$$

$$\frac{\Delta\tau}{\Delta S} < \text{const. } \Delta\tau, \Delta S \to 0, \tag{4.16}$$

$$\Delta S = \min_i S_{i+1} - S_i,$$

then the penalty method for the American put ((4.10) *with terminal condition* (2.4)) *solves*

$$\mathcal{F}V_i^{n+1} \geq 0, \tag{4.17}$$

$$V_i^{n+1} - V_i^* \geq -\frac{C}{Large}, \qquad C > 0, \tag{4.18}$$

$$(\mathcal{F}V_i^{n+1} = 0) \vee \left(|V_i^{n+1} - V_i^*| \leq \frac{C}{Large}\right), \tag{4.19}$$

where C is independent of Large, $\Delta\tau$, and ΔS.

Note that condition (4.16) is not practically restrictive, since violation of this condition would result in an imbalance between time and space discretization errors.

Condition (4.15) is trivially satisfied for any timestep size if a fully implicit method ($\theta = 0$) is used. However, if Crank–Nicolson timestepping is used, condition (4.15) essentially requires the boundedness of $\Delta\tau/(\Delta S)^2$. This timestep condition arises since we require that $(I - \theta\hat{M})V^n$ be bounded. This is essentially a requirement on the smoothness of the discrete solution using Crank–Nicolson timestepping. Note that for pure parabolic problems, careful analysis is required [28] to obtain quadratic convergence estimates for Crank–Nicolson methods (without restrictions on $\Delta\tau/(\Delta S)^2$). In fact, in [28], it is necessary to take a finite number of fully implicit steps initially in order to smooth rough data. This approach will be used in our numerical examples and will be discussed in detail in later sections.

In our numerical experiments, we routinely violate condition (4.15). As a check on the solution, we monitor the quantity

$$\text{max American error } = \max_{n,i} \frac{\max[0, (V_i^* - V_i^n)]}{\max(1, V_i^*)}. \tag{4.20}$$

This is a measure of the maximum relative error in enforcing the American constraint using the penalty method. This quantity will be small if the quantity (4.14) is bounded, and *Large* is sufficiently large. As long as we use the modification to Crank–Nicolson timestepping suggested in [28], we observe that the a posteriori error check (4.20) is indeed small.

It remains an open question if we can remove condition (4.15) for the timestepping method suggested in [28] (Crank–Nicolson with a finite number of fully implicit steps).

In practice, we can use the following heuristic argument to estimate the size of *Large* in terms of the relative accuracy required. In (4.10), suppose that $(1-\theta)\hat{M}V^{n+1}$ and $(I - \theta\hat{M})V^n$ are bounded independent of *Large*. Then, as $\mathit{Large} \to \infty$, (4.10) reduces to

$$V_i^{n+1} \simeq \left(\frac{\mathit{Large}}{1 + \mathit{Large}} \right) V_i^* \tag{4.21}$$

for nodes where $V_i^{n+1} < V_i^*$. If $V_i^* \neq 0$, then we have

$$\left| \frac{V_i^{n+1} - V_i^*}{V_i^*} \right| \simeq \frac{1}{\mathit{Large}}. \tag{4.22}$$

Therefore, if we require that the LCP be computed with a relative precision of *tol* for those nodes where $V_i^{n+1} < V_i^*$, then we should have $\mathit{Large} \simeq 1/\mathit{tol}$.

Note that in theory, if we are taking the limit as $\Delta S, \Delta\tau \to 0$, then we should have

$$\mathit{Large} = O\left(\frac{1}{\min\left[(\Delta S)^2, (\Delta\tau)^2\right]} \right). \tag{4.23}$$

This would mean that any error in the penalized formulation would tend to zero at the same rate as the discretization error. However, in practice it seems easier (to us at any rate) to specify the value of *Large* in terms of the required accuracy. In other words, we specify the maximum allowed error in the discrete penalized problem. We then reduce $\Delta S, \Delta\tau$ until the discretization error is reduced to this level of accuracy.

5. Penalty iteration. We will use Newton iteration to solve the discrete nonlinear equations (4.10). Of course, due regard must be paid to the discontinuous derivative which appears in the penalty term. More formally, we are solving the nonsmooth equation (4.10) using a generalized Newton iteration [4, 27, 25].

We will define the derivative of the penalty term, which is required in the Newton iteration as

$$\frac{\partial P_i^{n+1}(V_i^* - V_i^{n+1})}{\partial V_i^{n+1}} = \begin{cases} -Large & \text{if } V_i^{n+1} < V_i^*, \\ 0 & \text{otherwise,} \end{cases} \tag{5.1}$$

which is a particular choice of a member of the generalized Jacobian of (4.10).

Consequently, a generalized Newton iteration applied to (4.10) yields the following algorithm. Let $(V^{n+1})^k$ be the kth estimate for V^{n+1}. For notational convenience, we will define $\bar{P}^k \equiv \bar{P}\left((V^{n+1})^k\right)$ and $\bar{V}^k \equiv (V^{n+1})^k$. If $\bar{V}^0 = V^n$, then we have the following algorithm.

Penalty American Constraint Iteration.

For $k = 0, \ldots$ until convergence

$$\left[I + (1-\theta)\hat{M} + \bar{P}^k\right] \bar{V}^{k+1} = \left[I - \theta\hat{M}\right] V^n + \bar{P}^k V^* \tag{5.2}$$

$$\text{if } \left[\max_i \frac{|\bar{V}_i^{k+1} - \bar{V}_i^k|}{\max(1, |\bar{V}_i^{k+1}|)} < tol\right] \text{ or } \left[\bar{P}^{k+1} = \bar{P}^k\right] \quad \text{quit}$$

EndFor.

It is worthwhile at this point to determine the complexity of the above iteration compared to an explicit evaluation of the American constraint. Assuming that all of the coefficients are stored, that Crank–Nicolson timestepping is used with nonconstant timesteps, and that there are I nodes in the S direction, the first iteration of the penalty algorithm requires the following:

(i) $6I$ multiplies to evaluate the right-hand side of (5.2), where we have made the pessimistic assumption that $\bar{P}^k V^*$ requires I multiplies. This step also determines the entries in $\hat{M}$, assuming all possible quantities are precomputed and stored.

(ii) $2I$ multiply/divides to factor the matrix in (5.2).

(iii) $3I$ multiply/divides for the forward and back solve.

(iv) I divides for the convergence test. (This is also pessimistic, since we can skip the test on the first iteration, or if no constraint switches have occurred.)

This gives a total of $12I$ multiply/divides for the first penalty iteration and $7I$ multiply/divides for subsequent iterations.

If constant timesteps are used, $4I$ multiplies are needed to evaluate the right-hand side of (5.2), leading to a total of $10I$ multiply/divides for the first penalty iteration and $7I$ multiply/divides for subsequent iterations.

If an explicit method is used to evaluate the constraint, then there is only one matrix solve per timestep. To be precise here, an explicit method for handling the constraint is the following algorithm.

Explicit American Constraint Timestep.

$$\left[I + (1-\theta)\hat{M}\right] \hat{V}^{n+1} = \left[I - \theta\hat{M}\right] V^n, \tag{5.3}$$

$$V^{n+1} = \max(\hat{V}^{n+1}, V^*).$$

For constant timesteps (assuming that all coefficients are precomputed and stored),

(i) $3I$ multiply/divides are required to evaluate the right-hand side of (5.3), assuming that $\bar{P} = 0$;

(ii) assuming that the matrix is factored once and the factors stored, $3I$ multiply/divides are required for the forward and back solve;

giving a total of $6I$ multiply/divides per timestep. For nonconstant timesteps,

(i) $5I$ multiply/divides are required to evaluate the right-hand side of (5.3), assuming that $\bar{P} = 0$;

(ii) $2I$ multiply/divides are required to factor the matrix;

(iii) $3I$ multiply/divides are required for the forward and back solve;

giving a total of $10I$ multiply/divides per timestep.

6. Convergence of the penalty iteration.

Recall that the basic penalty algorithm (5.2) can be written as

$$\left[I + (1-\theta)\hat{M} + \bar{P}^k\right]\bar{V}^{k+1} = \left[I - \theta\hat{M}\right]V^n + \bar{P}^k V^*. \tag{6.1}$$

In Appendix B, we prove the following result.

THEOREM 6.1 (convergence of the nonlinear iteration of the penalized equations). *Under the assumptions that the matrix $\hat{M}$ in* (4.10) *is an M-matrix, then*

- *the nonlinear iteration* (5.2) *converges to the unique solution to* (4.10) *for any initial iterate $\bar{V}^0$;*
- *the iterates converge monotonically, i.e., $\bar{V}^{k+1} \geq \bar{V}^k$ for $k \geq 1$;*
- *the iteration has finite termination; i.e., for an iterate sufficiently close to the solution of the penalized problem* (4.10)*, convergence is obtained in one step.*

In [40], it was demonstrated experimentally that using a smooth form of the penalty function (4.4) did not aid convergence of the solution of the nonlinear equations. Intuitively, this is somewhat surprising. It might be expected that the nonsmooth penalty function (4.4), which has a discontinuous derivative, might cause oscillations during the iterations. However, the above result concerning monotonic convergence explains why the penalty iteration works so well, even with a nonsmooth derivative. Since $\bar{V}^{k+1} \geq \bar{V}^k$ for $k \geq 1$, in the worst case we have $\bar{V}_i^0 \geq V_i^*$, $\bar{V}_i^1 < V_i^*$, $\bar{V}_i^p > V_i^*$ for some $p \geq 2$. No further constraint switches will occur. In other words, for any given node, the iteration will not oscillate between $\bar{V}_i^k > V_i^*$ and $\bar{V}_i^{k+1} < V_i^*$ ($k \geq 1$). Note that $\bar{V}^0$ can be arbitrary but that $\bar{V}^1$ is given by the solution to (6.1). After $\bar{V}^1$ is determined, the iterates increase monotonically.

It is interesting to observe the connection between the penalty iteration and a pivoting method for solving the LCP. Let the set of all nodes be denoted by ν. If we let the set of nodes i where V_i^{n+1} satisfy $\mathcal{F}V_i^{n+1} = 0$ be denoted by χ, then as pointed out in [7], we can regard a pivoting method as a technique for determining χ in a systematic way. Once χ is known, then we can order the nodes $i \in \chi$ first, and those nodes in $\nu - \chi$ last, and solve the resulting system. In the case where $\hat{M}$ is an M matrix, then the pivoting method [7] becomes very simple. Let χ^k be the set of nodes where $\mathcal{F}(V_i^{n+1})^k = 0$. Suppose that at the k'th pivoting step a node is placed in χ^k. Any further pivoting operations will not remove that node from $\chi^p, p > k$. In the terminology of LCP algorithms, once a node has become basic, it will never become nonbasic as the algorithm proceeds. In this case, it is clear the pivoting algorithm terminates in at most number of pivoting steps equal to the size of the matrix.

Each iteration of the penalty method carries out a sorting step. Those nodes in χ^k are labelled by having $P_i = 0$. If the coefficient matrix is an M-matrix, once a node is placed in χ^k, it remains in $\chi^p, p > k$ on subsequent iterations. (Note that this is true only for $k \geq 1$.) The next iteration simply moves nodes in $\nu - \chi^k$ to χ^{k+1} or terminates. This property would hold for a problem in any dimension, provided the coefficient matrix is an M-matrix. If we have a good estimate for χ^0, and the number of nodes which move into or out of χ^0 is small, then the convergence of the penalty method will be rapid.

There also appears to be a connection between the approach used here and in [21]. In [21], each iteration consists of obtaining an initial estimate of constrained nodes using a few projected relaxation iterations; then the remaining nodes are solved using a sparse iterative method. It is argued in [21] that this is a good method if a good estimate of the constrained nodes is available. In some sense the penalty method combines these two steps, since an outcome of the sparse solve in the penalty iteration is an indication of whether or not a node is still constrained.

More interestingly, we observe that the penalty iteration is rapidly convergent for multifactor options with nonzero correlation [39]. The discretized equations in this case are not M-matrices, and in the convection dominated case, the discrete equations are nonlinear.

7. Numerical examples. In order to carry out a careful convergence study, we need to take into consideration the fact that the payoff function (2.4) has only piecewise smooth derivatives. This can cause problems if Crank–Nicolson timestepping is used. Specifically, oscillatory solutions can be generated [41]. For example, if we consider a simple European put option, then we know that the asymptotic solution near the expiry time $\tau = 0$ and close to the strike K is [33]

$$\text{put value } = O\left(\tau^{1/2}\right). \tag{7.1}$$

This would suggest that $V_{ttt} = O(\tau^{-5/2})$. The *local* finite difference truncation error for a Crank–Nicolson step (near $\tau = 0$) would then be $O\left[V_{ttt}(\Delta\tau)^3\right]$. If we set $\tau = \Delta\tau$ (the first step), then the local error would be $O[(\Delta\tau)^{1/2}]$, resulting in poor convergence. Fortunately, this analysis is a bit too simplistic. The behavior of the solution in (7.1) is due to the nonsmooth payoff near K, which causes V_{SS} to behave (near $\tau = 0, S = K$) as $O\left(\tau^{-1/2}\right)$ [33]. This large value of V_{SS} causes a very rapid smoothing effect due to the parabolic nature of the PDE. Consequently, if an appropriate timestepping method is used, we can expect the initial errors to be damped very quickly. However, there is a problem with Crank–Nicolson timestepping. Crank–Nicolson is only *A-stable*, not *strongly A-stable*. This means that some errors are damped very slowly, resulting in oscillations in the numerical solution.

Since a finite volume discretization in one dimension can be viewed as a special type of finite element discretization, we can appeal to the finite element analysis in [28]. This analysis was specifically directed towards the case of parabolic PDEs with nonsmooth initial conditions. Essentially, in [28] it is shown that if we take constant timesteps with a Crank–Nicolson method, then second order convergence (in time) can be guaranteed if (i) after each nonsmooth initial state, we take *two* fully implicit timesteps and then use Crank–Nicolson thereafter (payoffs with discontinuous derivatives qualify as nonsmooth); and (ii) the initial conditions are l_2 projected onto the space of basis functions. In our case, this means that the initial condition should be approximated by continuous, piecewise linear basis functions.

However, consider the case of a simple payoff such as that for a put option. Although this has a discontinuous derivative at K, no smoothing is required provided

TABLE 1

Value of a European put, $\sigma = .8$, $T = .25$, $r = .10$, $K = 100$, $S = 100$. Exact solution (to seven figures): 14.45191. *Change is the difference in the solution from the coarser grid. Ratio is the ratio of the changes on successive grids.*

		No smoothing			Rannacher smoothing

1073	400	14.44726	.00480	2.1	14.45177	.00039	4.0

we have a node at K. This is because we have a piecewise linear representation of the initial condition, consistent with the implied basis functions used in the finite volume method. In the case of a discontinuous initial condition, smoothing is necessary since this is not in the space of continuous piecewise linear basis functions. Finally, we remark that although second order convergence does not guarantee that the solution is nonoscillatory, in practice the above methods work well.

We can demonstrate the effectiveness of the simple idea of taking two fully implicit methods at the start and Crank–Nicolson thereafter (which we will henceforth refer to as *Rannacher smoothing* [28]) for a European put option with known solution. We will use the rather extreme value of $\sigma = .8$ for illustrative purposes. Results are provided in Table 1, which demonstrates that the solution with no smoothing converges erratically as the grid spacing and timestep size are reduced. In contrast, the smoothed solution shows quadratic convergence.

The reason for the poor convergence of the nonsmoothed runs can be explained by examining plots of the value V, delta (V_S), and gamma (V_{SS}), as shown in the left side of Figure 1. (Recall that it is of practical importance to determine delta and gamma for hedging purposes [16]). Note that although the value appears smooth, oscillations appear in delta (near the strike) and are magnified in gamma. The same problem was run using Rannacher smoothing, and the results are shown in the right side of Figure 1. The oscillations in delta and gamma have disappeared. All subsequent runs will use Rannacher smoothing.

It might appear appropriate to use a timestepping method with better error damping properties, such as a second order BDF method [2]. However, our experience with this method for complex American style problems (see [34]) was poor. We conjecture that this is due to a lack of smoothness in the time direction, causing problematic behavior for multistep methods. This effect will be addressed in some detail below.

8. Implicit and explicit handling of the American constraint. We will now compare an implicit treatment of the American constraint (using the penalty technique) with an explicit treatment (see pseudocode (5.3)). In these examples we use constant timesteps, a convergence tolerance of $tol = 10^{-6}$ (see pseudocode (5.2)), and consequently a value of $Large = 10^6$.

Two volatility values were used in these examples: $\sigma = .2, .8$. We truncate the computational domain at $S = S_{\max}$, where condition (2.5) is applied. The grid for $\sigma = .2$ used $S_{\max} = 200$, while the grid for $\sigma = .8$ used $S_{\max} = 1000$. Both grids were identical for $0 < S < 200$. The grid for $\sigma = .8$ added additional nodes for $200 < S < 1000$.

Table 2 compares results for implicit (penalty method) and explicit handling of the American constraint with constant timesteps. First, we note that for the penalty

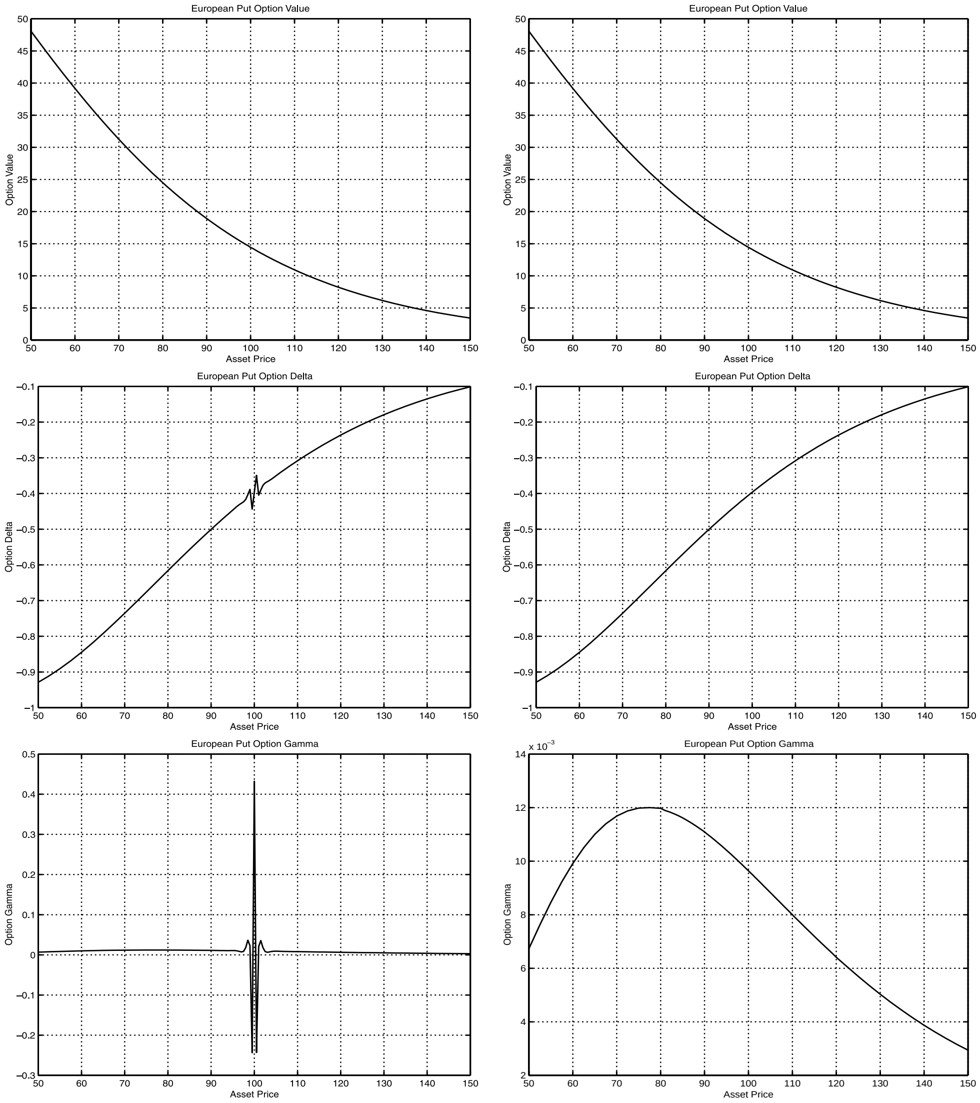

FIG. 1. *European put, $\sigma = .8$, $T = .25$, $r = .10$, $K = 100$. Crank–Nicolson timestepping, grid with* 135 *nodes. Left: no smoothing, right: Rannacher smoothing. Top: option value (V), middle: delta (V_S), bottom: gamma (V_{SS}).*

method the total number of nonlinear iterations is roughly the same across the two values of σ at each refinement level. This indicates that the volatility parameter has little effect on the number of iterations required. Now consider the results for the case where $\sigma = .2$. Taking into account the work per unit accuracy, the implicit method is slightly superior to the explicit technique. However, note that the implicit method does not appear to be converging quadratically. (The ratio of changes is about 3 instead of 4, which we would expect for quadratic convergence.) The explicit method appears to be converging at a first order rate (ratio of 2). Now consider the high volatility ($\sigma = .8$) results. Taking into account the total work, it would appear that in this case the explicit method is a little better than the implicit method. The latter

Table 2

Value of an American put option, $T = .25$, $r = .10$, $K = 100$, $S = 100$. Iters is the total number of nonlinear iterations. Change is the difference in the solution from the coarser grid. 1073	400	627	14.67813	.00127	2.9	6.0×10^6

seems to have an error ratio of about 2.9, while the explicit method has a somewhat lower convergence rate.

As an additional accuracy check, for all runs we also monitored the quantity (4.20), which is a measure of the maximum relative error in enforcing the American constraint using the penalty method.

As well, we also monitored the size of the normalized residual of (4.10) for all unconstrained nodes (i.e., those nodes where $P_i = 0$). More precisely,

$$\begin{aligned}
\text{max linear solver error } &= \max_{n, i \in \kappa^n} \frac{|\mathrm{K}_i^n|}{|\mathrm{B}^n|}, \\
\mathrm{K}_i^{n+1} &= \left(\left[I + (1-\theta)\hat{M}^{n+1} \right] \bar{V}^{n+1} - \left[I - \theta \hat{M}^n \right] V^n \right)_i, \\
\mathrm{B}^{n+1} &= \max_{i \in \kappa^{n+1}} \left| \left(\left[I - \theta \hat{M}^n \right] V^n \right)_i \right|, \\
\kappa^{n+1} &= \{ i \mid \bar{P}_i^{n+1} = 0 \}.
\end{aligned} \tag{8.1}$$

In Table 3, we give the statistics for a single run, varying the *Large* parameter ((4.9)). Note that the value of $Large = 10^6$ results in a maximum relative error in enforcing the American constraint of $\simeq 10^{-9}$. Consequently, since this is well below the time and spatial discretization errors, we will use this value for all subsequent

Table 3

Test of varying the penalty parameter Large ((4.9)). American put option, $T = .25$, $r = .10$, $K = 100$, sigma $= .8$, value at $S = 100$. Nodes $= 269$, timesteps $= 100$. Iters is the total number of nonlinear iterations. Constant timesteps. Rannacher smoothing used. tol $= 1/Large$ ((5.2)). $***$ indicates iteration failed to converge, due to machine precision limitations.

Large	Total iterations	Value	Max linear solver error (8.1)	Max American error (4.20)
10^4	142	14.67323	6.0×10^{-14}	5×10^{-8}
10^6	142	14.67324	4.7×10^{-14}	5×10^{-10}
10^8	142	14.67324	4.1×10^{-14}	5×10^{-12}
10^{10}	142	14.67324	4.2×10^{-14}	5×10^{-14}
10^{12}	***	***	***	***

tests. It is interesting to see that the number of iterations is independent of the value of *Large*. This is a result of the finite termination property of the iteration. We can see from Table 3 that the upper limit to *Large* is determined by machine precision. Consequently, we can solve the discrete LCP problem to arbitrary accuracy (limited by machine precision) with a fixed number of nonlinear iterations.

9. Analysis of constant timestep examples. In terms of approximately solving the discrete LCP (4.11), the penalty method performs as the analysis predicts. The number of nonlinear iterations per timestep is typically of the order 1.4–1.6, independent of the volatility, for reasonable timesteps. The a posteriori check (4.20) (a maximum relative error of 10^{-9}, with $tol = 10^{-6}$ in terms of satisfaction of the discrete LCP constraint) indicates that the error introduced by the penalty method is quite small. This error is a function of $tol, Large$ (pseudocode (5.2)), and hence can be adjusted to the desired level. In these examples we have violated condition (4.15), which indicates that this condition is sufficient but not necessary for bounding the size of the penalty term independent of $\Delta t, \Delta S$. However, the results are disappointing in terms of the convergence of the discretization of the LCP. We do not observe quadratic convergence for the implicit handling of the American constraint.

An error ratio of about 2.8 would be consistent with global timestepping convergence at a rate of $O[(\Delta\tau)^{3/2}]$. Now, from [29, 32], we know that the value of an American call option (where the underlying asset pays a proportional dividend) behaves like $V = \text{const} . + O\left(\tau^{3/2}\right)$ near the exercise boundary and close to the expiration of the contract ($\tau \to 0$). This would give a value for $V_{\tau\tau\tau}$ in this region of

$$V_{\tau\tau\tau} = O[\tau^{-3/2}]. \tag{9.1}$$

It appears that the behavior of the American put near the exercise boundary and close to expiry is [23]

$$\begin{aligned} V &= \text{const} . + O[(\tau \log \tau)^{3/2}] \\ &\simeq \text{const} . + O[(\tau^{1-\epsilon})^{3/2})], \quad \epsilon > 0, \quad \epsilon \ll 1, \quad \tau \to 0. \end{aligned} \tag{9.2}$$

In the following we will ignore the ϵ in (9.2) and assume that the behavior of $V_{\tau\tau\tau}$ is given by (9.1).

From (9.1), the local time truncation error for Crank–Nicolson timestepping is (near the exercise boundary)

$$\text{local error } = O\left[\frac{(\Delta\tau)^3}{\tau^{3/2}}\right]. \tag{9.3}$$

Assuming that the global error is of the order of the sum of the local errors, from (9.3) we obtain

$$\text{global error } = O\left[\sum_{i=1}^{i=1/\Delta\tau}\frac{(\Delta\tau)^3}{(i\Delta\tau)^{3/2}}\right] \simeq O[(\Delta\tau)^{3/2}], \tag{9.4}$$

which is consistent with the observed rate of convergence. Now, instead of taking constant timesteps, suppose we take timesteps which satisfy

$$\max_i(|V_i^{n+1} - V_i^n|) \simeq d, \tag{9.5}$$

where d is a specified constant. In order to take the limit to convergence, at each grid refinement we will halve both the grid spacing and d. It is reasonable to assume that the maximum change over a timestep (at least near $\tau = 0$) will occur near K. Therefore, from (7.1),

$$\Delta V^{n+1} = \max_i(|V_i^{n+1} - V_i^n|) \simeq O\left[\frac{\Delta\tau^{n+1}}{\sqrt{\tau^n}}\right]. \tag{9.6}$$

Therefore, from (9.5) and (9.6), we have

$$\Delta\tau^{n+1} = O[d\sqrt{\tau^n}]. \tag{9.7}$$

Assuming a local error of the form (9.3), and using (9.3) and (9.7), this gives a local error with the variable timesteps satisfying (9.5) as

$$\text{local error } = O\left[\frac{\left((\Delta\tau)^{n+1}\right)^3}{(\tau^n)^{3/2}}\right] = O\left[\frac{d^3(\tau^n)^{3/2}}{(\tau^n)^{3/2}}\right] = O(d^3). \tag{9.8}$$

This implies a global error (with $O(1/d)$ timesteps) of

$$\text{global error } = O(d^2). \tag{9.9}$$

Therefore, suppose that we take variable timesteps consistent with (9.5). Then at each refinement stage, where we double the number of grid nodes, and double the number of timesteps (by halving d), we should see quadratic convergence. Note that we should reduce the initial timestep $\Delta\tau^0$ by four at each refinement. We make no claim that the above analysis of the time truncation error is in any way precise but only suggestive of an appropriate timestepping strategy.

10. A timestep selector.

The timestep selector used is based on a modified form of that suggested in [18]. Given an initial timestep $\Delta\tau^{n+1}$, then a new timestep is selected so that

$$\Delta\tau^{n+2} = \left(\min_i\left[\frac{\texttt{dnorm}}{\frac{|V(S_i,\tau^n+\Delta\tau^{n+1})-V(S_i,\tau^n)|}{\max(D,|V(S_i,\tau^n+\Delta\tau^{n+1})|,|V(S_i,\tau^n)|)}}\right]\right)\Delta\tau^{n+1}, \tag{10.1}$$

where dnorm is a target relative change (during the timestep) specified by the user. The scale D is selected so that the timestep selector does not take an excessive number of timesteps in regions where the value is small. (For options valued in dollars, $D = 1$ is typically appropriate.) In (10.1), we have normalized the factor used to estimate the new timestep. This is simply to avoid slow timestep growth for large values of the contract. This could be a problem with call options, for example, where the computational domain is truncated at a large value of S. If we did not examine the relative changes over a timestep, then it is possible that the timestep would be limited by large absolute changes in the solution (which would occur as $S \to \infty$), even though the relative changes were small.

Since $V(S_i = K, \tau \simeq 0) \simeq 0$, we expect that the denominator of (10.1) will take its largest value near $S = K$, since V increases rapidly there. Consequently, the timestep selector (10.1) will approximately enforce the condition that

$$\Delta V^{n+1} \simeq D \times \mathtt{dnorm}. \tag{10.2}$$

Hence we will have

$$\Delta\tau^{n+1} = O(\mathtt{dnorm}\sqrt{\tau^n}), \tag{10.3}$$

so that we should see a global error of $O[(\mathtt{dnorm})^2]$, which follows from (9.9).

Note that timestep selector (10.1) estimates the change in the solution at the new timestep based on changes observed over the old timestep. Some adjustments can be made to this simple model if a more precise form for the time evolution of the solution is assumed, but we prefer (10.1) since it is simple and conservative.

In practice, we select a $(\Delta\tau)^0$ for the coarsest grid, and then $(\Delta\tau)^0$ is cut by four at each grid refinement. There is not much of a penalty for underestimating a suitable $(\Delta\tau)^0$ since the timestep will increase rapidly if the estimate is too conservative. In the following runs, we used values of $(\Delta\tau)^0 = 10^{-3}$ and $\mathtt{dnorm} = .2$ on the coarsest grid. The value of dnorm was reduced by two at each grid refinement.

11. Variable timestep examples.

Table 4 presents results for the cases considered in Table 2 but this time using the timestep selector (10.1). In this case, the implicit method appears to be a clear winner in terms of flops per unit accuracy. Use of variable timesteps actually seems to degrade the convergence of the explicit method. This can be explained by looking at the timestep history. The timestep selector uses small timesteps at the start and then takes large steps at the end. Note that the average timestep size (total time divided by number of timesteps) is larger for the variable timestep run compared to the constant timestep run (Table 2). This clearly negatively impacts the explicit method, which seems to show a first order rate of convergence. On the other hand, the implicit method appears to exhibit close to quadratic convergence.

Figure 2 shows value, delta, and gamma for the $\sigma = .2$ case, using both explicit and implicit treatments of the American constraint. Although the value and delta appear similar for both cases, there are clearly large oscillations in the gamma near the early exercise boundary for the explicit method. The implicit method does show some small oscillations near the exercise boundary. However, this is due to the use of Crank–Nicolson timestepping, as noted in [6]. These oscillations disappear if fully implicit timestepping is used, as shown in Figure 3.

12. Comparison with binomial lattice methods.

It is interesting to compare the results here with those obtained using the binomial lattice method, which

Table 4

is commonly used in finance [33]. In Appendix C, we show that this technique is simply an explicit finite difference method on a log-transformed grid. Consequently, the truncation error is $O(\Delta\tau)$, where the total number of steps is $N = O[1/(\Delta\tau)]$.

The binomial lattice method requires about $3/2N^2$ flops (counting only multiplies, and assuming all necessary factors are precomputed). Note that we obtain the value of the option at $t = 0$ only at the single point S_0^0, in contrast to the PDE methods which obtain values for all $S \in [0, S_{\max}]$. As a result, the methods are not directly comparable. Nevertheless, assuming that we are interested only in obtaining the solution at a single point, it is interesting and useful to compare these two techniques.

Given $N = O[1/(\Delta\tau)]$, the complexity of the binomial method is $O(N^2)$. Since the error in the lattice method is $O(\Delta\tau) = O(1/N)$, we have

$$\text{error binomial lattice } = O\left[(\text{complexity})^{-1/2}\right]. \tag{12.1}$$

Suppose instead that we use an implicit finite volume method with Crank–Nicolson timestepping and that the penalty method is employed for handling the American constraint. The complexity of this approach is $O(N^2)$, where we have assumed that $N = O[1/(\Delta S)]$. (Note that this is the case if we use the timestep selector (10.1) and `dnorm` $= O(\Delta S)$.) It is also assumed that the the number of nonlinear iterations

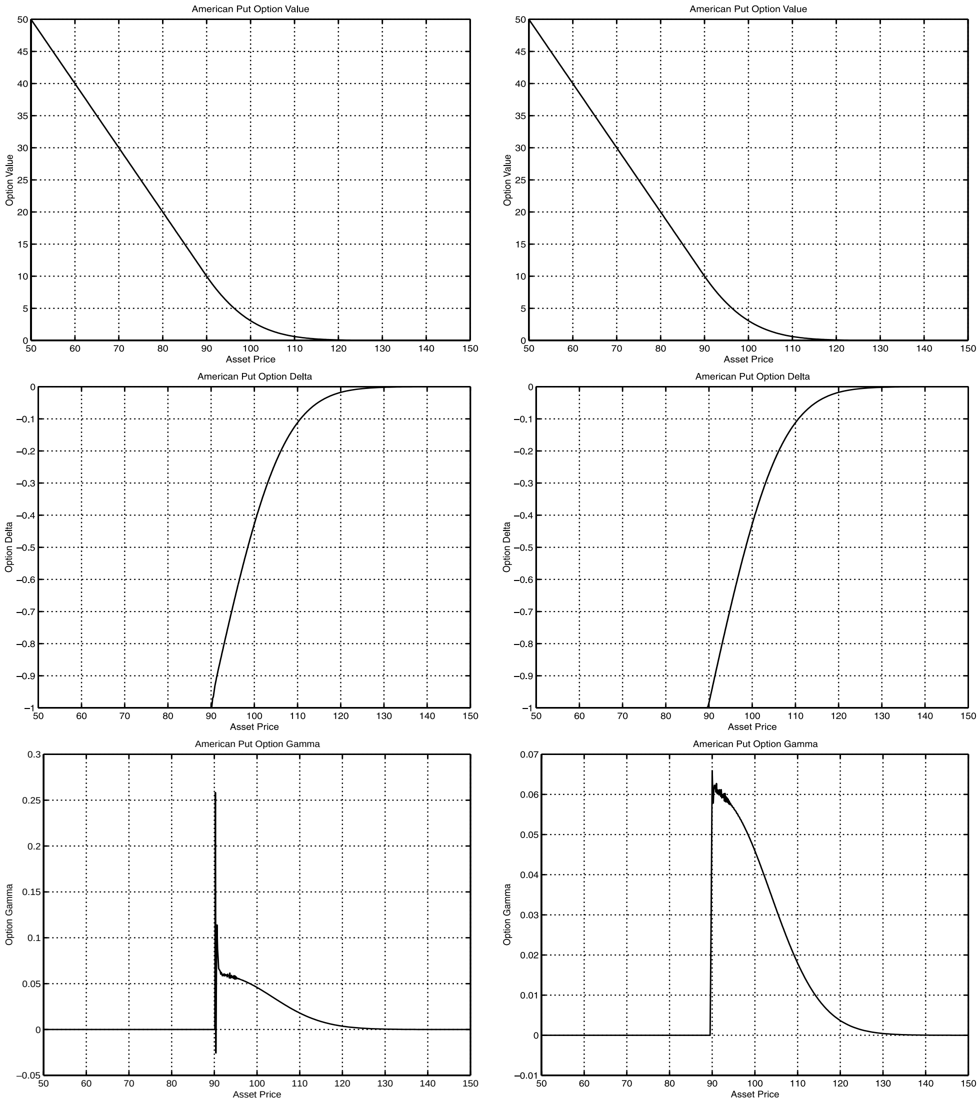

FIG. 2. *American put, $\sigma = .2$, $T = .25$, $r = .10$, $K = 100$. Crank–Nicolson timestepping, Rannacher smoothing, variable timesteps, grid with 433 nodes. Left: explicit constraint, right: implicit constraint. Top: option value (V), middle: delta (V_S), bottom: gamma (V_{SS}).*

per timestep is constant as $\Delta S \to 0$, which is observed as long as `dnorm` $= O(\Delta S)$. When timesteps are selected using (10.1), we have observed quadratic convergence. This implies

$$\text{error implicit finite volume } = O\left(N^{-2}\right) = O\left[(\text{complexity})^{-1}\right]. \tag{12.2}$$

Therefore, the implicit finite volume method is asymptotically superior to the binomial lattice method, even if the solution is desired at only one point.

It is interesting to determine at what levels of accuracy we can expect the implicit PDE method to become more efficient than the binomial method. Table 5 gives the

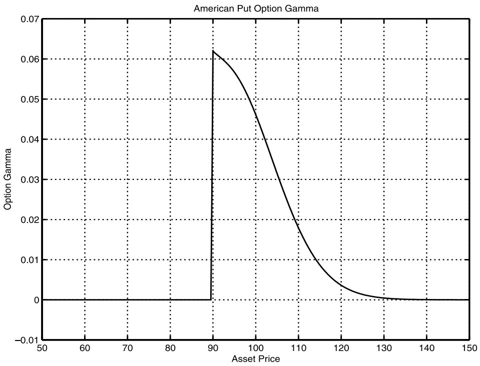

FIG. 3. *Gamma (V_{SS}) of an American put, $\sigma = .2$, $T = .25$, $r = .10$, $K = 100$. Fully implicit timestepping; Rannacher smoothing; variable timesteps. Grid with 433 nodes used. Constraint imposed implicitly.*

results for a binomial lattice solution (algorithm (C.2)) for the problems solved earlier using an implicit PDE approach. This table should be compared to Table 4.

For further points of comparison, we also computed solutions to the problem used in [13]. We used two versions of the problem in [13], one with an expiry time of $T = 1$ and the other with $T = 5$. Figure 4 summarizes the convergence of both the binomial lattice and PDE methods for all four problems. The absolute error is computed by taking the *exact* solution as obtained by extrapolating the PDE solution down to zero grid and timestep size, assuming quadratic behavior. The PDE method becomes more efficient than the binomial lattice method at tolerances between .01–.003 depending on the problem parameters. These crossover points occur at tolerances which would be used in practice. Note that in these comparisons, we are putting the best possible

light on the binomial lattice method, since we ignore the fact that we obtain much more information with the implicit PDE technique.

13. Application of penalty methods to more general problems. As derived in the appendices, a sufficient condition for monotone convergence of the penalty iteration is that the discretized differential operator is an M-matrix. In practice, we have found that this condition is not necessary for rapid convergence of the penalty iteration. For example, in [40, 39], we have applied the penalty method to American options with stochastic volatility, convertible bonds (which have American type maximum and minimum constraints), and American options on two assets, with good results. In this case, the discretized differential operator was not an M-matrix, and, if a flux limiter was used, the discretized differential operator was nonlinear. We also routinely violated the timestep condition (4.15). As long as the Rannacher smoothing technique was used, the solution was sufficiently smooth enough that no ill effects were observed with the penalty iteration.

Note that the discrete M-matrix condition was not required in the proof of convergence of the penalty method for an elliptic obstacle problem with the Laplacian as the differential operator [24]. However, timestep restrictions were required in the proofs of convergence of the penalty method for parabolic problems in [30]. In view of our computational experience, it appears to us that these conditions are artificial. We conjecture that the penalty iteration converges rapidly under much weaker conditions than those outlined in the appendices.

14. Conclusion.

We have derived sufficient conditions so that the solution of the discrete penalized equations solves an approximate version of the discrete LCP formulation of the American option pricing problem. The error in the approximation can be made arbitrarily small by increasing the penalty factor. We have also given sufficient conditions so that a Newton iteration method for solving the discrete nonlinear penalized equations converges monotonically to the unique solution of the nonlinear algebraic equations. This explains the observed rapid convergence of this technique.

If constant timesteps are used, the computed solution appears to converge at less than a second order rate in the limit as the grid spacing and timestep are reduced to zero. An heuristic analysis of the behavior of the solution near the exercise boundary indicates that convergence (with constant timesteps) occurs only at the rate $(\Delta t)^{3/2}$. However, a timestep selection method was suggested which, based on our analysis, should be expected to restore quadratic convergence. Numerical experiments confirmed that this convergence rate was indeed obtained using this timestep selector.

In general, the use of an implicit penalty method combined with the timestep selector can be recommended. As well as being more efficient in terms of the number of flops per unit accuracy, the solution obtained using an implicit method is qualitatively superior to the solution obtained using an explicit method for handling the American constraint. The explicit solution exhibited large oscillations in gamma near the exercise boundary.

The implicit PDE method is asymptotically superior to the standard (in finance) binomial lattice method, which has only linear convergence. However, if low accuracy solutions are required at only a single point, then a binomial method can be more efficient than the PDE approach. For typical parameters, the crossover point where the PDE method is to be preferred occurs at an absolute error tolerance of between $.01-.003$. However, if information at more than a single point is desired, then the PDE method is always preferable. As well, the binomial lattice method is highly optimized for simple cases. For example, the addition of discretely observed barriers [3, 42] causes difficulties for binomial methods. However, this case presents no particular difficulty for a PDE finite volume method.

The penalty method described here has been applied to multidimensional problems as shown in [40, 39]. This method has the advantage that standard sparse matrix software can be used to solve the Jacobian matrix. This is especially important for multifactor problems. In fact, the penalty method in [40] was applied to problems which did not satisfy the sufficient conditions derived in this work, with no apparent ill effects. It is a topic of further research to extend the convergence results in this paper to the more general problems described in [40, 39].

Appendix A. Error in the penalty formulation.

In this appendix, we determine sufficient conditions which allow us to bound (4.14). Suppose that node k is the node where the penalty term $P_k^{n+1}(V_k^* - V_k^{n+1})$ attains its maximum. Consider the term

$$\begin{aligned}[\hat{M}(V^* - V^{n+1})]_k =& \Delta\tau \sum_{j \in \eta_k} \left(\bar{\gamma}_{kj} + \bar{\beta}_{kj}\right) [(V_k^* - V_k^{n+1}) - (V_j^* - V_j^{n+1})] \\ & + r\Delta\tau[V_k^* - V_k^{n+1}]. \end{aligned} \tag{A.1}$$

Since the penalty term attains its maximum value at node k, we have

$$\begin{aligned}&[(V_k^* - V_k^{n+1}) - (V_j^* - V_j^{n+1})] \geq 0 \\ &V_k^* - V_k^{n+1} \geq 0. \end{aligned} \tag{A.2}$$

Since $\bar{\gamma}_{kj} + \bar{\beta}_{kj} \geq 0$, it follows from (A.1)–(A.2) that $[\hat{M}(V^* - V^{n+1})]_k \geq 0$ at node k. Alternatively,

$$[\hat{M}V^{n+1}]_k \leq [\hat{M}V^*]_k, \tag{A.3}$$

implying

$$[I + (1-\theta)\hat{M}V^{n+1}]_k \leq [I + (1-\theta)\hat{M}V^*]_k. \tag{A.4}$$

Writing (4.10) at node k, we have

$$\left(\left[I + (1-\theta)\hat{M}\right] V^{n+1}\right)_k = \left(\left[I - \theta\hat{M}\right] V^n\right)_k + \left(\left[\bar{P}(V^{n+1})\right] (V^* - V^{n+1})\right)_k . \tag{A.5}$$

Noting that $P_k^{n+1}(V_k^* - V_k^{n+1}) \geq 0$, it follows from (A.5) and (A.3) that

$$\begin{aligned}\left|[P_k^{n+1}(V_k^* - V_k^{n+1})]\right| &= \left\|P^{n+1}(V^* - V^{n+1})\right\|_\infty \\ &\leq \left|\left(\left[I + (1-\theta)\hat{M}\right] V^{n+1}\right)_k\right| + \left|\left(\left[I - \theta\hat{M}\right] V^n\right)_k\right| \\ &\leq \left|\left(\left[I + (1-\theta)\hat{M}\right] V^*\right)_k\right| + \left|\left(\left[I - \theta\hat{M}\right] V^n\right)_k\right| \\ &\leq \left\|\left[I + (1-\theta)\hat{M}\right] V^*\right\|_\infty + \left\|\left[I - \theta\hat{M}\right] V^n\right\|_\infty \\ &\leq \|V^*\|_\infty + (1-\theta)\left\|\hat{M}V^*\right\|_\infty + \left\|\left[I - \theta\hat{M}\right] V^n\right\|_\infty . \end{aligned} \tag{A.6}$$

We now proceed to bound each of the terms on the right-hand side of (A.6). Given a put payoff of the form

$$V^* = V^0 = \max(K - S, 0), \tag{A.7}$$

where K is the strike, we have $\|V^*\|_\infty = K$. In bounding $||\hat{M}V^*\|_\infty$, we note that the worst case occurs at $S_i = K$ so that

$$\begin{aligned}||\hat{M}V^*\|_\infty &\leq \text{const}\,.\ |\hat{M}V^*|_i, \qquad S_i = K \\ &= O\left(\frac{\Delta\tau}{\Delta S}\right), \end{aligned} \tag{A.8}$$

where $\Delta S = \min_i(S_i - S_{i-1})$. We assume that the timestep and mesh size are reduced to zero in such a way that

$$\frac{\Delta\tau}{\Delta S} = \text{const}\,., \tag{A.9}$$

where this constant is independent of $\Delta\tau, \Delta S$. (It does not make any sense to drive the S discretization to zero if the timestep truncation error is also not reduced as well.) Consequently, we can assume that $\|\hat{M}V^*\|_\infty$ is bounded independent of *Large* and $\Delta\tau, \Delta S$.

If we also assume that the timestep is selected so that

$$1 - \theta \left(\Delta\tau \sum_{j \in \eta_i} \left(\bar{\gamma}_{ij} + \bar{\beta}_{ij} \right) + r\Delta\tau \right) \geq 0, \tag{A.10}$$

then we have (recalling that $\hat{M}$ is an M-matrix with row sum $r\Delta\tau$)

$$\left\| \left[I - \theta \hat{M} \right] V^n \right\|_\infty \leq (1 - r\Delta\tau) \left\| V^n \right\|_\infty \leq \left\| V^n \right\|_\infty . \tag{A.11}$$

Assuming condition (A.10) is satisfied, it follows from (4.10) and (A.7) that

$$\left\| V^n \right\|_\infty \leq \max(\left\| V^{n-1} \right\|_\infty, \left\| V^* \right\|_\infty) = \left\| V^* \right\|_\infty = K. \tag{A.12}$$

Note that if a fully implicit discretization is used ($\theta = 0$), then condition (A.10) is trivially satisfied. For Crank–Nicolson timestepping, condition (A.10) implies that $\Delta\tau/(\Delta S)^2 \leq \text{const}.$ as $\Delta S, \Delta\tau \to 0$.

Consequently, we have shown that

$$\left\| P^{n+1}(V^* - V^{n+1}) \right\|_\infty \leq 2K + O\left(\frac{\Delta\tau}{\Delta S} \right). \tag{A.13}$$

In other words, at any node where $V_i^{n+1} < V_i^*$, we have $|Large(V_i^* - V_i^{n+1})| \leq C$, where C is independent of *Large*. Therefore, by choosing *Large* sufficiently large, the error in the solution of the LCP can be made arbitrarily small, and Theorem 4.1 follows.

Appendix B. Monotone convergence. We will first prove that iteration (6.1) has a *monotone* property. Writing (6.1) for iteration k gives

$$\left[I + (1-\theta)\hat{M} + \bar{P}^{k-1} \right] \bar{V}^k = \left[I - \theta \hat{M} \right] V^n + \bar{P}^{k-1} V^*. \tag{B.1}$$

First, note that (B.1) always has a solution, since $I + (1-\theta)\hat{M} + \bar{P}^{k-1}$ is a diagonally dominant M matrix and is consequently nonsingular.

This can be written as

$$\left[I + (1-\theta)\hat{M} + \bar{P}^{k} \right] \bar{V}^k + \left[\bar{P}^{k-1} - \bar{P}^k \right] \bar{V}^k = \left[I - \theta \hat{M} \right] V^n + \bar{P}^{k-1} V^*. \tag{B.2}$$

Subtracting (B.2) from (6.1) gives

$$\left[I + (1-\theta)\hat{M} + \bar{P}^{k} \right] (\bar{V}^{k+1} - \bar{V}^k) = \left[\bar{P}^k - \bar{P}^{k-1} \right] (V^* - \bar{V}^k), \qquad k \geq 1. \tag{B.3}$$

Now examine each of the components of the right-hand side of (B.3). There are two possible cases:

$$\begin{aligned}
\text{Case 1:} \qquad \bar{V}_i^k < V_i^* &\Rightarrow \bar{P}_{ii}^k = Large \\
&\Rightarrow (Large - \bar{P}_{ii}^{k-1})(V^* - \bar{V}^k)_i \geq 0 \\
&\Rightarrow \left[\bar{P}^k - \bar{P}^{k-1} \right]_i (V^* - \bar{V}^k)_i \geq 0, \\
\text{Case 2:} \qquad \bar{V}_i^k \geq V_i^* &\Rightarrow \bar{P}_{ii}^k = 0 \\
&\Rightarrow (-\bar{P}_{ii}^{k-1})(V^* - \bar{V}^k)_i \geq 0 \\
&\Rightarrow \left[\bar{P}^k - \bar{P}^{k-1} \right]_i (V^* - \bar{V}^k)_i \geq 0.
\end{aligned}$$

Thus we always have

$$\left[\bar{P}^k - \bar{P}^{k-1}\right](V^* - \bar{V}^k) \geq 0, \qquad k \geq 1. \tag{B.4}$$

Since $[I+(1-\theta)\hat{M}+\bar{P}^k]$ is an M-matrix, it follows from (B.3)–(B.4) that $(\bar{V}^{k+1}-\bar{V}^k) \geq 0$ for $k \geq 1$, or, in component form, $(\bar{V}^{k+1} - \bar{V}^k)_i \geq 0 \ \forall i$ for $k \geq 1$.

We now demonstrate that the iteration (6.1) has finite termination. Let the set of all nodes in the discretization be denoted by ν. Given any iterate $\bar{V}^k$, we can define

$$\begin{aligned} \chi^k &= \{i \mid (\bar{P}^k)_i = 0\}, \\ \nu - \chi^k &= \{i \mid (\bar{P}^k)_i > 0\}. \end{aligned} \tag{B.5}$$

Since for $k \geq 1$ we have that the iterates increase monotonically, any node in χ^k remains in $\chi^j \ \forall j > k \geq 1$. If at any stage $\nu - \chi^k = \nu - \chi^{k-1}$, then $(\bar{P}^k - \bar{P}^{k-1}) = 0$, and the iteration terminates with a zero update ((B.3)). If a node in $\nu - \chi^k$ becomes unconstrained, this node moves into the set χ^{k+1}. This node will always remain in $\chi^j, j > k \geq 1$. The number of nodes in the set $\nu - \chi^{k+1}$ is then at least one less than the number of nodes in $\nu - \chi^k$. Eventually, either $\nu - \chi^{k+1} = \nu - \chi^k$ or $\nu - \chi^{k+1}$ is exhausted, and the iteration terminates. Hence the iteration always converges, and a solution exists.

The above argument assumes exact arithmetic. In practice, we apply the extra termination condition based on the update in algorithm (5.2) as a precaution against errors in floating point arithmetic. Of course, we will also need the update termination test if the problem has nonlinearities other than the simple American constraint.

We now demonstrate that the solution obtained by the penalty iteration is unique. Suppose there are two solutions $\bar{V}_1$ and $\bar{V}_2$ to the penalized problem. Let $\bar{P}^1 \equiv P(\bar{V}_1)$ and $\bar{P}^2 \equiv P(\bar{V}_2)$. Then

$$\left[I + (1-\theta)\hat{M} + \bar{P}^1\right]\bar{V}_1 = \left[I - \theta\hat{M}\right]V^n + \bar{P}^1 V^*, \tag{B.6}$$

$$\left[I + (1-\theta)\hat{M} + \bar{P}^2\right]\bar{V}_2 = \left[I - \theta\hat{M}\right]V^n + \bar{P}^2 V^*. \tag{B.7}$$

We can write (B.6) as

$$\left[I + (1-\theta)\hat{M} + \bar{P}^2\right]\bar{V}_1 + \left[\bar{P}^1 - \bar{P}^2\right]\bar{V}_1 = \left[I - \theta\hat{M}\right]V^n + \bar{P}^1 V^*. \tag{B.8}$$

Subtracting (B.7) from (B.8) gives

$$\left[I + (1-\theta)\hat{M} + \bar{P}^2\right](\bar{V}_1 - \bar{V}_2) = \left[\bar{P}^1 - \bar{P}^2\right](V^* - \bar{V}_1). \tag{B.9}$$

Using a similar argument as we used in proving monotone iteration, we have that

$$\left[\bar{P}^1 - \bar{P}^2\right](V^* - \bar{V}_1) \geq 0. \tag{B.10}$$

Since $[I + (1-\theta)\hat{M} + \bar{P}^2]$ is an M-matrix, it follows from equations (B.9–B.10) that $(\bar{V}_1 - \bar{V}_2) \geq 0$. Interchanging subscripts, we have $(\bar{V}_2 - \bar{V}_1) \geq 0$, and hence $\bar{V}_2 = \bar{V}_1$. Consequently, Theorem 6.1 follows.

Appendix C. The binomial lattice method. Let $S_m^n = u^{2m-n} S_0^0$ for $m = 0, \ldots, n$ denote the value of the asset price at time $t_n = n\Delta t$ and lattice point m, where $u = e^{\sigma\sqrt{\Delta t}}$ and $\Delta t = T/N$. Note that T is the expiry time of the option and N is the number of timesteps. Also note that we are considering time t going forward in this case, in contrast to $\tau = T - t$ (time going backwards) as in the previous sections. This results in a solution algorithm which proceeds backwards from $t = T$ to $t = 0$ (i.e., from $t = t_N$ to $t = 0$).

Let V_m^n be the value of the option associated with asset price S_m^n, at time $t = n\Delta t$. Of course, we have $V_m^N = \max(K - S_m^N, 0)$ for $m = 0, \dots, N$. Define

$$p = \frac{e^{r\Delta t} - e^{-\sigma\sqrt{\Delta t}}}{e^{\sigma\sqrt{\Delta t}} - e^{-\sigma\sqrt{\Delta t}}}. \tag{C.1}$$

Then the value of the American put option V_0^0 (at the single point $S = S_0^0$) is obtained from the following algorithm.

Binomial Lattice Algorithm.

```
For $n = N - 1, \dots, 0$
    For $m = 0, \dots, n$
        (C.2)  $\bar{V}_m^n = e^{-r\Delta t}\left(pV_{m+1}^{n+1} + (1-p)V_m^{n+1}\right),$
               $V_m^n = \max(K - S_m^n, \bar{V}_m^n)$
    EndFor
EndFor.
```

The above method is usually derived in the financial literature based on probabilistic arguments. In fact, we can see that this is equivalent to an explicit finite difference method with a particular choice for the timestep. Consider the following Black–Scholes equation for a European option:

$$V_t + \frac{\sigma^2}{2}S^2 V_{SS} + rSV_S - rV = 0. \tag{C.3}$$

Define a new variable $X = \log S$ so that (C.3) becomes

$$V_t + \frac{\sigma^2}{2}V_{XX} + \left(r - \frac{\sigma^2}{2}\right)V_X - rV = 0. \tag{C.4}$$

Letting $V = e^{rt}W$, (C.4) becomes

$$W_t + \frac{\sigma^2}{2}W_{XX} + \left(r - \frac{\sigma^2}{2}\right)W_X = 0. \tag{C.5}$$

Now let $W_m^n = W(\log S_0^0 + (2m-n)\sigma\sqrt{\Delta\tau}, n\Delta\tau)$ for $m = 0, \dots, n$. Discretizing (C.5) using central differencing in the X direction and an explicit timestepping method, we obtain

$$W_m^n = \left[p^*\left(W_{m+1}^{n+1}\right) + (1-p^*)\left(W_m^{n+1}\right)\right] + O[(\Delta t)^2], \tag{C.6}$$

where $p^* = 1/2[1 + \sqrt{\Delta t}(r/\sigma - \sigma/2)]$. Writing (C.6) in terms of V_m^n gives

$$V_m^n = e^{-r\Delta t}\left[p^*\left(V_{m+1}^{n+1}\right) + (1-p^*)\left(V_m^{n+1}\right)\right] + O[(\Delta t)^2]. \tag{C.7}$$

Expanding p in (C.1) in a Taylor series, noting the definition of p^*, and assuming that $V_{m+1}^{n+1} - V_m^{n+1} = O(\sqrt{\Delta\tau})$, we obtain

$$V_m^n = e^{-r\Delta t}\left[p\left(V_{m+1}^{n+1}\right) + (1-p)\left(V_m^{n+1}\right)\right] + O[(\Delta t)^2]. \tag{C.8}$$

Comparing (C.8) with algorithm (C.2), we can see that the binomial lattice method is simply an explicit finite difference discretization of the discrete LCP (2.2), with the American constraint applied explicitly.

A NEW METHOD FOR MICRO-MACRO SIMULATIONS OF VISCOELASTIC FLOWS[*]

C. CHAUVIERE[†]

Abstract. In this paper we develop a robust numerical method derived from the Brownian configuration field method [M.A. Hulsen, A.P.G. Van Heel, and B.H.A.A. Van Den Brule, *J. Non-Newtonian Fluid Mech.*, 70 (1997), pp. 79–101] for the simulation of flows of dilute polymeric solutions. The statistical properties of the Wiener stochastic process in the stochastic differential equation describing the evolution of the configuration vector are exploited in order to derive a simple expression for the polymeric contribution to the stress. The method is tested numerically by solving the benchmark problem of the flow of an Oldroyd B fluid past a cylinder in a channel using a spectral element method. Results are presented to demonstrate the advantages of the proposed method.

Key words. viscoelastic flows, spectral element methods, mesoscopic models

1. Introduction.

Among the more important recent advances in computational rheology, the use of kinetic theory models to evaluate the polymeric contribution to the stress ranks highly. Whereas in macroscopic methods closed-form constitutive equations have been used, these have often been of limited use in faithfully simulating complex polymeric flows. In bypassing a macroscopic description of the stress evolution and using a coarse-grained microscopic description instead, more of the physics of viscoelastic fluids may be incorporated. The use of stochastic differential equations for the simulation of complex viscoelastic flows was initiated in 1993 by Laso and Öttinger [13]. Then, a new and powerful Brownian dynamics technique, the so-called *Brownian configuration field method* was introduced by Hulsen, Van Heel, and Van Den Brule [12]. Here, the idea is that a stochastic differential equation is solved for *ensembles* of conformation vectors corresponding to dumbbell connectors having the same initial configuration and subject to the same Brownian forces in time. This technique avoids the difficulties associated with the tracking of individual particles. However, as with all micro-macro simulations to date, the computations are significantly more costly in terms of time and memory than is the case with closed-form constitutive equations. The main reason for this extra cost is that a significant number of configuration fields (typically several thousand) have to be computed and stored in order to reduce the noise in the computed polymeric stress. Despite the success enjoyed by variance reduction methods [3] in reducing the number of degrees of freedom required in the problem, Brownian configuration methods remain expensive. In the case of Hookean dumbbells, the present paper is intended to be a step towards making such methods more affordable.

The paper is organized as follows. In the next section, we describe two common approaches for the numerical calculation of the flow of an Oldroyd B fluid. Then, in the case of mesoscopic calculations, section 3 is devoted to an explanation of a new

way of computing the extra-stress which overcomes the CPU and memory limitations of the Brownian configuration field method. In sections 4 and 5, we discretize the governing equations using a spectral element method for the benchmark problem of an Oldroyd B fluid past a cylinder in a channel. Finally, in section 6 we show how the present results can be extended to the Oldroyd B multimode model.

2. Problem description.

Let $\Omega \subset \mathbb{R}^d$ be some bounded Lipschitz domain having boundary $\partial\Omega$. We consider inertialess, isothermal flow of an incompressible fluid with density ρ for which the momentum conservation and the continuity equations in Ω are

$$\rho \frac{\partial \mathbf{u}}{\partial t} - \eta_s \boldsymbol{\Delta} \mathbf{u} + \boldsymbol{\nabla} p = \boldsymbol{\nabla} . \boldsymbol{\tau} + \mathbf{f}, \tag{2.1}$$

$$\boldsymbol{\nabla} . \mathbf{u} = 0, \tag{2.2}$$

where $\mathbf{u}$ denotes the fluid velocity, p is the pressure, $\boldsymbol{\tau}$ is the polymeric contribution to the stress tensor, $\mathbf{f}$ is a body force, and η_s is the solvent viscosity. The extra-stress $\boldsymbol{\tau}$ needs an equation to close the system. For dilute solutions of polymers, this may be a differential or integral constitutive equation (macroscopic approach) or an expression derived from a macromolecular model (mesoscopic approach) in which case a stochastic differential equation needs to be solved. Some models such as the Oldroyd B model have both a constitutive equation and a macromolecular model representation. In the next two subsections, we will describe the two approaches for this model.

2.1. Macroscopic approach: Constitutive equation.

For an Oldroyd B fluid and a time dependent flow, the polymeric extra-stress tensor satisfies the following hyperbolic equation:

$$\boldsymbol{\tau} + \lambda \overset{\triangledown}{\boldsymbol{\tau}} = \eta_p \dot{\boldsymbol{\gamma}}(\mathbf{u}), \tag{2.3}$$

where λ is the relaxation time of the fluid, $\dot{\boldsymbol{\gamma}}(\mathbf{u}) = (\boldsymbol{\nabla}\mathbf{u} + \boldsymbol{\nabla}\mathbf{u}^T)$ is the rate of strain tensor, and η_p is the polymeric fluid viscosity. Given the velocity field $\mathbf{u}$, the upper-convected derivative $\triangledown$ in (2.3) is then defined by

$$\overset{\triangledown}{\boldsymbol{\tau}} = \frac{\partial \boldsymbol{\tau}}{\partial t} + \mathbf{u}.\nabla\boldsymbol{\tau} - \nabla\mathbf{u}.\boldsymbol{\tau} - (\nabla\mathbf{u}.\boldsymbol{\tau})^T. \tag{2.4}$$

Usually, a decoupled numerical scheme is used, i.e., for a given source term $\boldsymbol{\tau}$, (2.1) and (2.2) form a standard Stokes problem, and once the velocity has been computed, the extra-stress can be determined from (2.3). The advantage of constitutive equations is their simplicity: a differential equation just needs to be discretized with possibly some stabilizing techniques to account for its hyperbolic character. The CPU and memory requirements may be less than for its mesoscopic counterpart, and noise-free solutions can be obtained. Viscoelastic flows are characterized by a Deborah number (see (5.1)), which is a nondimensional measure of the elasticity of the fluid. The macroscopic approach is less robust (it is possible that only simulations at modest Deborah numbers can be performed), and a closed form equation may not be available for the most general models.

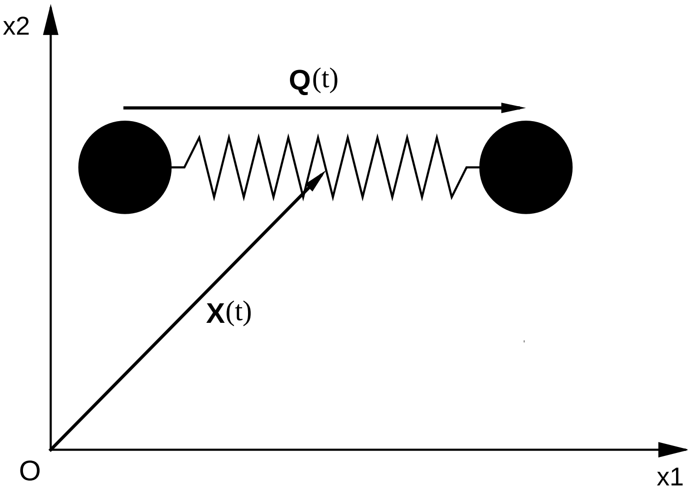

FIG. 1. *Description of a single dumbbell placed in the fluid in* ***X****(t).*

2.2. Mesoscopic approach. In this subsection, we briefly describe *the Brownian configuration field method* [12, 15, 20] first introduced in 1997 by Hulsen et al. The idea of this mesoscopic approach is to model the polymer chains by elastic dumbbells that consist of two beads connected by a spring (see Figure 1). Then, we model the polymer chains and their interactions with the solvent. The *configuration vector* $\mathbf{Q}(t)$ describes the configuration of a dumbbell, i.e., the orientation and elongation in space of the spring connecting the two beads as it moves along its trajectory $\mathbf{X}(t)$. Note that $\mathbf{X}(t)$ is nothing but the trajectory of the fluid particles. For the Oldroyd B model, the spring force $\mathbf{F}$ is proportional to the configuration vector

$$\mathbf{F} = H\mathbf{Q}(t), \tag{2.5}$$

where H is the spring constant.

In order to reduce the number of parameters, the configuration vector is scaled by a characteristic length to give $\widetilde{\mathbf{Q}}(t)$

$$\widetilde{\mathbf{Q}}(t) = \frac{\mathbf{Q}(t)}{\sqrt{\frac{k_B T}{H}}},$$

where k_B is Boltzmann's constant and T the absolute temperature. Adopting an Eulerian point of view and taking the same initial configuration and the same Brownian forces in time for ensembles of dumbbells leads to the configuration field method. Then, the configuration field $\widetilde{\mathbf{Q}}(\mathbf{x},t)$ satisfies the following stochastic differential equation (see [16] for details):

$$\begin{aligned} d\widetilde{\mathbf{Q}}(\mathbf{x},t) = \left(-\mathbf{u}(\mathbf{x},t).\nabla\widetilde{\mathbf{Q}}(\mathbf{x},t) + \nabla\mathbf{u}(\mathbf{x},t)\widetilde{\mathbf{Q}}(\mathbf{x},t) - \frac{1}{2\lambda}\widetilde{\mathbf{Q}}(\mathbf{x},t)\right) dt \\ + \sqrt{\frac{1}{\lambda}} d\mathbf{W}(t). \end{aligned} \tag{2.6}$$

In (2.6), $\mathbf{W}(t)$ is the so-called Wiener process which accounts for the Brownian forces acting on each bead. The Wiener process has some important properties that will be used in the next section to derive a simple expression for the extra-stress. It is a Gaussian process with zero mean and covariance $\langle \mathbf{W}(t)\mathbf{W}(t')\rangle = \min(t,t')\mathbf{I}$. It should also be noted that each component of $\mathbf{W}(t)$ depends only on time and has a constant spatial value all over the domain Ω.

The local value of the extra-stress $\boldsymbol{\tau}(\mathbf{x},t)$ (which is a macroscopic quantity) can be determined from an ensemble of N_{cf} configuration fields $\{\widetilde{\mathbf{Q}}_m(\mathbf{x},t)\}_{1\leq m\leq N_{cf}}$ that experience different uncorrelated Wiener processes $\{\mathbf{W}_m(t)\}_{1\leq m\leq N_{cf}}$. For the Oldroyd B model, $\boldsymbol{\tau}(\mathbf{x},t)$ is given by the *Kramers expression* (see page 69 of [1])

$$\boldsymbol{\tau}(\mathbf{x},t) = \frac{\eta_p}{\lambda}\left(-\mathbf{I} + \lim_{N_{cf}\to\infty}\left(\frac{1}{N_{cf}}\sum_{m=1}^{N_{cf}} \widetilde{\mathbf{Q}}_m(\mathbf{x},t)\otimes\widetilde{\mathbf{Q}}_m(\mathbf{x},t)\right)\right), \tag{2.7}$$

where the symbol $\otimes$ denotes the tensor product of two vectors. Initially, the fluid is at rest so that the equilibrium extra-stress tensor must be zero. Each component of the initial configuration fields $\widetilde{\mathbf{Q}}_m(\mathbf{x},t_0)$ satisfies a space-independent scalar normal law with zero mean and unity variance [2], and thus

$$\lim_{N_{cf}\to\infty}\left(\frac{1}{N_{cf}}\sum_{m=1}^{N_{cf}} \widetilde{\mathbf{Q}}_m(\mathbf{x},t_0)\otimes\widetilde{\mathbf{Q}}_m(\mathbf{x},t_0)\right) = \mathbf{I}. \tag{2.8}$$

In order to state more precisely the typical CPU and memory cost required by a mesoscopic computation, let us use a simple implicit Euler scheme for the time discretization of (2.6). For a given uniform partition $0 = t_0 < t_1 < \cdots < t_{\max}$ of the time range $[0, t_{\max}]$ with $t_i = i\Delta t$, $(i = 1,\ldots,\max)$, the mth configuration field to be used in (2.7) satisfies

$$\begin{aligned}\mathbf{Q}_m(\mathbf{x},t_i) + &\left(\mathbf{u}(\mathbf{x},t_i).\nabla\mathbf{Q}_m(\mathbf{x},t_i) - \nabla\mathbf{u}(\mathbf{x},t_i)\mathbf{Q}_m(\mathbf{x},t_i) + \frac{1}{2\lambda}\mathbf{Q}_m(\mathbf{x},t_i)\right)\Delta t\\ &= \mathbf{Q}_m(\mathbf{x},t_{i-1}) + \sqrt{\frac{\Delta t}{\lambda}}\Delta\mathbf{W}_m(t_i).\end{aligned} \tag{2.9}$$

The tildes of the configuration field vectors have been dropped for better readability and in what follows it is understood that $\mathbf{Q}_m(\mathbf{x},t)$ is a dimensionless quantity. The Wiener process has also been scaled by $\sqrt{\Delta t}$ so that we now have $\langle \Delta\mathbf{W}_m(t_i)^2\rangle = \langle(\mathbf{W}_m(t_i) - \mathbf{W}_m(t_{i-1}))^2\rangle = \mathbf{I}$. In practice, it is not possible to take an infinite number of configuration fields in order to evaluate the extra-stress with (2.7), and, instead, a finite number of them is used. According to the *central-limit theorem*, for N_{cf} sufficiently large, the statistical error of the extra-stress is proportional to $1/\sqrt{N_{cf}}$. Therefore, the numerical solution converges towards the noise-free solution at a slow rate of order $\mathcal{O}(1/\sqrt{N_{cf}})$. This means that in order to get solutions with low noise level, (2.9) has to be solved a great number of times (typically, $N_{cf} = \mathcal{O}(10^3)$) and explains why the mesoscopic approach is so CPU intensive. It also means that many spatial vectors $\{\mathbf{Q}_m(\mathbf{x},t_{i-1})\}_{1\leq m\leq N_{cf}}$ coming from the previous calculation at time t_{i-1} must be stored in order to evaluate the right-hand side of (2.9) at time t_i. Variance reduction techniques make it possible to reduce the noise level [3]; however, the efficiency of such techniques may be less effective as the Deborah number increases

[2]. In the next section, we will see how the properties of the Wiener process may be exploited in order to get noise-free extra-stresses at a relatively low CPU and memory cost.

3. A new method for noise-free extra-stresses.

We first introduce some notation that will be useful in what follows. We denote by $\mathbf{q}^{t_l}(\mathbf{x}, t_i)$ a d-dimensional vector whose value is updated at time $t_i = i\Delta t$. The superscript t_l indicates that this vector was originally created at time $t_l = l\Delta t$ (with $l \leq i$). In order to model the Wiener process of (2.9) at time t_i, it is convenient to introduce d sets of N_{cf} real random numbers $\{\Delta W_m^j(t_i)\}_{1\leq m\leq N_{cf}}$ ($j = 1, \ldots, d$) obeying a scalar normal law. Then, we introduce d constant d-dimensional vectors $\{\mathbf{b}_j\}_{1\leq j\leq d}$, where $\mathbf{b}_j$ has unit value at its jth component and zero elsewhere. With those definitions, the mth Wiener process of (2.9) can be written

$$\Delta\mathbf{W}_m(t_i) = \sum_{j=1}^{d} \mathbf{b}_j \Delta W_m^j(t_i). \tag{3.1}$$

Finally, we define a real function of the relaxation time λ for any given time step Δt; thus

$$\alpha(\lambda) = \sqrt{\frac{\Delta t}{\lambda}}. \tag{3.2}$$

For any kind of spatial discretization of (2.9) (e.g., a finite element method, finite difference method, or spectral element method), we are now in position to prove the following theorem that will be used to derive a new expression for the extra-stress.

THEOREM 3.1. *Let $\mathbf{Q}_m(\mathbf{x},t_i)$ be the discrete solution of* (2.9) *at time $t_i = i\Delta t$ ($i \geq 1$) for any given Wiener process $\Delta\mathbf{W}_m(t_i)$. Then, there exists $d \times i$ vectors independent of m, denoted by $\{\mathbf{q}_j^{t_{i-l}}(\mathbf{x}, t_i)\}_{0\leq l\leq i-1}^{1\leq j\leq d}$, such that*

$$\mathbf{Q}_m(\mathbf{x},t_i) = \sum_{j=1}^{d} \left\{ \left(\sum_{l=0}^{i-1} \alpha(\lambda)\mathbf{q}_j^{t_{i-l}}(\mathbf{x}, t_i)\Delta W_m^j(t_{i-l}) \right) + \mathbf{q}_j^{t_1}(\mathbf{x}, t_i)\Delta W_m^j(t_0) \right\}. \tag{3.3}$$

Proof. We will prove this theorem by induction on i. We first show that (3.3) is true for $i = 1$. At $t = t_0$, the configuration fields are at equilibrium, and, for the Oldroyd B model, they come from the same distribution as the Wiener processes so that we can write $\mathbf{Q}_m(\mathbf{x},t_0) = \Delta\mathbf{W}_m(t_0)$. The relation (3.1) can be applied at time t_0 to give

$$\mathbf{Q}_m(\mathbf{x},t_0) = \Delta\mathbf{W}_m(t_0) = \sum_{j=1}^{d} \mathbf{b}_j \Delta W_m^j(t_0). \tag{3.4}$$

Let $\mathbf{E}_\mathbf{u}(\mathbf{x},t_i)$ be the matrix resulting from the discretization of the left-hand side of (2.9) at time t_i for a given velocity field $\mathbf{u}$. Then, at time t_1, (2.9) can be formally rewritten as

$$\begin{aligned} \mathbf{E}_\mathbf{u}(\mathbf{x}, t_1)\mathbf{Q}_m(\mathbf{x},t_1) &= \alpha(\lambda)\Delta\mathbf{W}_m(t_1) + \mathbf{Q}_m(\mathbf{x},t_0) \\ &= \alpha(\lambda)\Delta\mathbf{W}_m(t_1) + \sum_{j=1}^{d} \mathbf{b}_j \Delta W_m^j(t_0), \end{aligned} \tag{3.5}$$

where we have replaced $\mathbf{Q}_m(\mathbf{x},t_0)$ by its equivalent expression (3.4).

Multiplying (3.5) throughout by $\mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_1)$, and using equation (3.1) at time t_1 for $\Delta\mathbf{W}_m(t_1)$, we obtain

$$\mathbf{Q}_m(\mathbf{x},t_1) = \sum_{j=1}^{d} \left(\alpha(\lambda)\mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_1)\mathbf{b}_j\Delta W_m^j(t_1) + \mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_1)\mathbf{b}_j\Delta W_m^j(t_0)\right). \tag{3.6}$$

We can now define a new vector $\mathbf{q}_j^{t_1}(\mathbf{x},t_1)$ created at time t_1 by

$$\mathbf{q}_j^{t_1}(\mathbf{x},t_1) = \mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_1)\mathbf{b}_j \tag{3.7}$$

so that we can rewrite (3.6) in the form

$$\mathbf{Q}_m(\mathbf{x},t_1) = \sum_{j=1}^{d} \left(\alpha(\lambda)\mathbf{q}_j^{t_1}(\mathbf{x},t_1)\Delta W_m^j(t_1) + \mathbf{q}_j^{t_1}(\mathbf{x},t_1)\Delta W_m^j(t_0)\right). \tag{3.8}$$

The above equation shows that the relation (3.3) is true for $i = 1$.

We now suppose that the relation (3.3) is true at time t_{i-1}, and we will prove that it is true at time t_i. At time t_i, (2.9) can be formally rewritten as

$$\mathbf{E}_{\mathbf{u}}(\mathbf{x},t_i)\mathbf{Q}_m(\mathbf{x},t_i) = \alpha(\lambda)\Delta\mathbf{W}_m(t_i) + \mathbf{Q}_m(\mathbf{x},t_{i-1}). \tag{3.9}$$

By the inductive hypothesis the relation (3.3) is true at time t_{i-1} so that we have

$$\begin{aligned}\mathbf{Q}_m(\mathbf{x},t_{i-1}) &= \sum_{j=1}^{d}\left\{\left(\sum_{l=0}^{i-2}\alpha(\lambda)\mathbf{q}_j^{t_{i-1-l}}(\mathbf{x},t_{i-1})\Delta W_m^j(t_{i-1-l})\right) + \mathbf{q}_j^{t_1}(\mathbf{x},t_{i-1})\Delta W_m^j(t_0)\right\}\\ &= \sum_{j=1}^{d}\left\{\left(\sum_{l=1}^{i-1}\alpha(\lambda)\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_{i-1})\Delta W_m^j(t_{i-l})\right) + \mathbf{q}_j^{t_1}(\mathbf{x},t_{i-1})\Delta W_m^j(t_0)\right\},\end{aligned} \tag{3.10}$$

where the last expression has been obtained after a change of indices for l.

Multiplying (3.9) throughout by $\mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_i)$ and replacing $\mathbf{Q}_m(\mathbf{x},t_{i-1})$ by its expression above, we obtain

$$\begin{aligned}\mathbf{Q}_m(\mathbf{x},t_i) = \sum_{j=1}^{d}\Bigg\{&\left(\sum_{l=1}^{i-1}\alpha(\lambda)\mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_i)\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_{i-1})\Delta W_m^j(t_{i-l})\right)\\ &+ \mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_i)\mathbf{q}_j^{t_1}(\mathbf{x},t_{i-1})\Delta W_m^j(t_0)\Bigg\} + \alpha(\lambda)\mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_i)\Delta\mathbf{W}_m(t_i).\end{aligned} \tag{3.11}$$

We define the vector $\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)$ created at time t_{i-l} and updated at time t_i as the function of the vector $\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_{i-1})$ created at the same time t_{i-l} and updated at the previous time step t_{i-1} by setting

$$\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) = \mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_i)\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_{i-1}) \text{ for } l = 1,\dots,i-1. \tag{3.12}$$

Using the above expressions of $\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)$ and replacing the Wiener process $\Delta\mathbf{W}_m(t_i)$

by its equivalent expression (3.1), equation (3.11) becomes

$$\begin{aligned}(3.13)\quad \mathbf{Q}_m(\mathbf{x},t_i) = \sum_{j=1}^{d} \Bigg\{ \Bigg(\sum_{l=1}^{i-1} \alpha(\lambda) \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \Delta W_m^j(t_{i-l}) \Bigg) \\ + \mathbf{q}_j^{t_1}(\mathbf{x},t_i)\Delta W_m^j(t_0) \Bigg\} + \sum_{j=1}^{d} \alpha(\lambda) \mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_i)\mathbf{b}_j \Delta W_m^j(t_i).\end{aligned}$$

We can now define the newly created vectors $\mathbf{q}_j^{t_i}(\mathbf{x},t_i)$ at time t_i by

$$(3.14)\qquad \mathbf{q}_j^{t_i}(\mathbf{x},t_i) = \mathbf{E}_{\mathbf{u}}^{-1}(\mathbf{x},t_i)\mathbf{b}_j;$$

then (3.13) can be written

$$\begin{aligned}\mathbf{Q}_m(\mathbf{x},t_i) &= \sum_{j=1}^{d} \Bigg\{ \Bigg(\sum_{l=1}^{i-1} \alpha(\lambda) \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \Delta W_m^j(t_{i-l}) \Bigg) \\ (3.15)\qquad &\quad + \alpha(\lambda)\mathbf{q}_j^{t_i}(\mathbf{x},t_i)\Delta W_m^j(t_i) + \mathbf{q}_j^{t_1}(\mathbf{x},t_i)\Delta W_m^j(t_0) \Bigg\} \\ &= \sum_{j=1}^{d} \Bigg\{ \Bigg(\sum_{l=0}^{i-1} \alpha(\lambda) \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \Delta W_m^j(t_{i-l}) \Bigg) + \mathbf{q}_j^{t_1}(\mathbf{x},t_i)\Delta W_m^j(t_0) \Bigg\}.\end{aligned}$$

The above relation shows that (3.3) is true at time t_i as long as it is satisfied at time t_{i-1}. Since (3.3) is true at the initial time t_1, by induction, the relation is valid for any time $t_i = i\Delta t$ ($i \geq 1$), and this concludes the proof. □

The proof of Theorem 3.1 gives an explicit expression for the vectors $\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)$ which can be obtained with (3.14) at their time of creation and subsequently updated according to (3.12). The next theorem shows how the extra-stress can be computed from the vectors $\{\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)\}_{0\leq l\leq i-1}^{1\leq j\leq d}$.

THEOREM 3.2. *The extra-stress tensor $\boldsymbol{\tau}(\mathbf{x},t_i)$ at time t_i can be computed from the vectors $\{\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)\}_{0\leq l\leq i-1}^{1\leq j\leq d}$ in a deterministic way by*

$$\boldsymbol{\tau}(\mathbf{x},t_i) = \frac{\eta_p}{\lambda}\Bigg(-\mathbf{I} + \sum_{j=1}^{d} \Bigg\{ \Bigg(\sum_{l=0}^{i-1} \alpha(\lambda)^2 \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \otimes \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \Bigg) + \mathbf{q}_j^{t_1}(\mathbf{x},t_i) \otimes \mathbf{q}_j^{t_1}(\mathbf{x},t_i) \Bigg\} \Bigg).$$
(3.16)

Proof. According to (2.7), the extra-stress tensor $\boldsymbol{\tau}(\mathbf{x},t_i)$ at time t_i is given by

$$(3.17)\quad \boldsymbol{\tau}(\mathbf{x},t_i) = \frac{\eta_p}{\lambda}\left(-\mathbf{I} + \lim_{N_{cf}\to\infty} \left(\frac{1}{N_{cf}} \sum_{m=1}^{N_{cf}} \mathbf{Q}_m(\mathbf{x},t_i) \otimes \mathbf{Q}_m(\mathbf{x},t_i) \right) \right).$$

Before passing to the limit when $N_{cf} \to \infty$, we rewrite $\mathbf{Q}_m(\mathbf{x},t_i) \otimes \mathbf{Q}_m(\mathbf{x},t_i)$ by replacing $\mathbf{Q}_m(\mathbf{x},t_i)$ by its expression (3.3) established in Theorem 3.1, and, using the distributivity of the tensor product, we have

$$
\begin{aligned}
\mathbf{Q}_m(\mathbf{x},t_i) \otimes \mathbf{Q}_m(\mathbf{x},t_i) &= \sum_{j=1}^{d} \left\{ \left(\sum_{l=0}^{i-1} \alpha(\lambda) \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \Delta W_m^j(t_{i-l}) \right) + \mathbf{q}_j^{t_1}(\mathbf{x},t_i) \Delta W_m^j(t_0) \right\} \\
&\otimes \sum_{j'=1}^{d} \left\{ \left(\sum_{l'=0}^{i-1} \alpha(\lambda) \mathbf{q}_{j'}^{t_{i-l'}}(\mathbf{x},t_i) \Delta W_m^{j'}(t_{i-l'}) \right) + \mathbf{q}_{j'}^{t_1}(\mathbf{x},t_i) \Delta W_m^{j'}(t_0) \right\} \\
&= \sum_{j=1}^{d} \sum_{l=0}^{i-1} \sum_{j'=1}^{d} \sum_{l'=0}^{i-1} \alpha(\lambda)^2 \Delta W_m^j(t_{i-l}) \Delta W_m^{j'}(t_{i-l'}) \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \otimes \mathbf{q}_{j'}^{t_{i-l'}}(\mathbf{x},t_i) \\
&+ \sum_{j=1}^{d} \sum_{l=0}^{i-1} \sum_{j'=1}^{d} \alpha(\lambda) \Delta W_m^j(t_{i-l}) \Delta W_m^{j'}(t_0) \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \otimes \mathbf{q}_{j'}^{t_1}(\mathbf{x},t_i) \\
&+ \sum_{j=1}^{d} \sum_{j'=1}^{d} \sum_{l'=0}^{i-1} \alpha(\lambda) \Delta W_m^j(t_0) \Delta W_m^{j'}(t_{i-l'}) \mathbf{q}_j^{t_1}(\mathbf{x},t_i) \otimes \mathbf{q}_{j'}^{t_{i-l'}}(\mathbf{x},t_i) \\
&+ \sum_{j=1}^{d} \sum_{j'=1}^{d} \Delta W_m^j(t_0) \Delta W_m^{j'}(t_0) \mathbf{q}_j^{t_1}(\mathbf{x},t_i) \otimes \mathbf{q}_{j'}^{t_1}(\mathbf{x},t_i).
\end{aligned} \tag{3.18}
$$

In order to simplify this expression, we note that $\{\Delta W_m^j(t_l)\}_{1 \leq m \leq N_{cf}}$ and $\{\Delta W_m^{j'}(t_{l'})\}_{1 \leq m \leq N_{cf}}$ are two sets of random numbers following the scalar normal law. If they are generated independently, i.e., they come from two different times $t_l \neq t_{l'}$ or different components $j \neq j'$, their covariance is zero. Those properties can be summarized as follows:

$$
\lim_{N_{cf} \to \infty} \frac{1}{N_{cf}} \sum_{m=1}^{N_{cf}} \Delta W_m^j(t_l) \Delta W_m^{j'}(t_{l'}) = \delta_{jj'} \delta_{ll'}, \tag{3.19}
$$

where δ is the Kronecker delta. Using (3.18) and (3.19), we can now simplify the expression $\frac{1}{N_{cf}} \sum_{m=1}^{N_{cf}} \mathbf{Q}_m(\mathbf{x},t_i) \otimes \mathbf{Q}_m(\mathbf{x},t_i)$ when $N_{cf} \to \infty$:

$$
\begin{aligned}
&\lim_{N_{cf} \to \infty} \left(\frac{1}{N_{cf}} \sum_{m=1}^{N_{cf}} \mathbf{Q}_m(\mathbf{x},t_i) \otimes \mathbf{Q}_m(\mathbf{x},t_i) \right) \\
&= \sum_{j=1}^{d} \sum_{l=0}^{i-1} \sum_{j'=1}^{d} \sum_{l'=0}^{i-1} \alpha(\lambda)^2 \delta_{jj'} \delta_{i-l,i-l'} \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \otimes \mathbf{q}_{j'}^{t_{i-l'}}(\mathbf{x},t_i) \\
&+ \sum_{j=1}^{d} \sum_{l=0}^{i-1} \sum_{j'=1}^{d} \alpha(\lambda) \delta_{jj'} \delta_{i-l,0} \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \otimes \mathbf{q}_{j'}^{t_1}(\mathbf{x},t_i) \\
&+ \sum_{j=1}^{d} \sum_{j'=1}^{d} \sum_{l'=0}^{i-1} \alpha(\lambda) \delta_{jj'} \delta_{0,i-l'} \mathbf{q}_j^{t_1}(\mathbf{x},t_i) \otimes \mathbf{q}_{j'}^{t_{i-l'}}(\mathbf{x},t_i) \\
&+ \sum_{j=1}^{d} \sum_{j'=1}^{d} \delta_{jj'} \delta_{00} \mathbf{q}_j^{t_1}(\mathbf{x},t_i) \otimes \mathbf{q}_{j'}^{t_1}(\mathbf{x},t_i) \\
&= \sum_{j=1}^{d} \left(\sum_{l=0}^{i-1} \alpha(\lambda)^2 \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \otimes \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \right) + \sum_{j=1}^{d} \mathbf{q}_j^{t_1}(\mathbf{x},t_i) \otimes \mathbf{q}_j^{t_1}(\mathbf{x},t_i).
\end{aligned} \tag{3.20}
$$

With the result above and (3.17), we find the required relation for the extra-stress $\boldsymbol{\tau}(\mathbf{x},t_i)$

$$\boldsymbol{\tau}(\mathbf{x},t_i) = \frac{\eta_p}{\lambda}\Bigg(-\mathbf{I}+\sum_{j=1}^{d}\Bigg\{\Bigg(\sum_{l=0}^{i-1}\alpha(\lambda)^2\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)\otimes\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)\Bigg) + \mathbf{q}_j^{t_1}(\mathbf{x},t_i)\otimes\mathbf{q}_j^{t_1}(\mathbf{x},t_i)\Bigg\}\Bigg). \qquad \square \tag{3.21}$$

The above equation gives a nice interpretation of the so-called *memory effects* which are of great importance for viscoelastic fluids. Indeed, (3.21) shows that in order to compute the extra-stress $\boldsymbol{\tau}(\mathbf{x},t_i)$ at time t_i, we need to know the history of the fluid at times $\{t_l\}_{1\leq l\leq i}$ which is contained in the vectors $\{\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)\}_{0\leq l\leq i-1}$. Furthermore, this relation is entirely deterministic and gives noise-free solutions. We also see that at every new time step, d d-dimensional vectors have to be created and stored. Therefore, the computation becomes more and more expensive as we advance in time. This is why for the time discretization of (2.6), we have adopted an implicit Euler scheme which allows us to take larger time steps and to reach higher Deborah numbers than its explicit counterpart. In (3.21), the vectors $\{\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)\}_{0\leq l\leq i-1}$ receive equal weighting. If, for efficiency purposes, the "old" vectors $\mathbf{q}_j^{t_i}$ are removed before the steady state is reached, then information is lost and the variables $(\mathbf{u},p,\boldsymbol{\tau})$ will not converge to the right solution. In the next section, we apply this new method using a spectral element method for spatial discretization of (2.1), (2.2), and (2.9).

4. Weak formulation and spectral element discretization.

4.1. Functional spaces and variational formulation. We now introduce the following linear spaces over the flow domain $\Omega \subset \mathbb{R}$ for the velocity, pressure, and extra-stress, respectively:

$$V = \left\{\mathbf{u}\in\left(H^1(\Omega)\right)^2 : \mathbf{u}=\mathbf{0} \text{ on } \partial\Omega_0 \neq \emptyset\right\}, \tag{4.1}$$

$$P = L_0^2(\Omega), \tag{4.2}$$

$$\Sigma = \left\{\boldsymbol{\tau} : \boldsymbol{\tau}\in[L^2(\Omega)]_{\mathrm{s}}^{2\times 2}\right\}. \tag{4.3}$$

Given the velocity field **u,** the *inflow boundary* $\partial\Omega^-$ of Ω having boundary $\partial\Omega$ is defined in the usual way by

$$\partial\Omega^- = \{\mathbf{x}\in\partial\Omega : \mathbf{u}(\mathbf{x}).\mathbf{n}(\mathbf{x}) < 0\}, \tag{4.4}$$

where Ω has outward pointing normal vector $\mathbf{n}$.

With that definition of $\partial\Omega^-$, we can now introduce the following space for the configuration field:

$$Q = \left\{\mathbf{q} : \mathbf{q}\in[L^2(\Omega)]^2,\ \mathbf{u}.\nabla\mathbf{q}\in[L^2(\Omega)]^2\ \forall\mathbf{u}\in V\text{and } \mathbf{q}=\mathbf{q}_{\text{inflow}} \text{ on } \partial\Omega^-\right\}. \tag{4.5}$$

Equipped with these functional spaces, we introduce the following bilinear forms: $A, M : V\times V \longrightarrow \mathbb{R}$, $B : P\times V \longrightarrow \mathbb{R}$, $C : \Sigma\times V \longrightarrow \mathbb{R}$; thus

$$M(\mathbf{u},\mathbf{v}) = \frac{\rho}{\Delta t}\int_\Omega \mathbf{u}.\mathbf{v}d\mathbf{x} \quad \forall\mathbf{u},\mathbf{v}\in V, \tag{4.6}$$

$$A(\mathbf{u},\mathbf{v}) = \eta_s\int_\Omega \boldsymbol{\nabla}\mathbf{u}^T : \boldsymbol{\nabla}\mathbf{v}d\mathbf{x} \quad \forall\mathbf{u},\mathbf{v}\in V, \tag{4.7}$$

$$B(p,\mathbf{v}) = \int_\Omega p\boldsymbol{\nabla}.\mathbf{v}d\mathbf{x} \quad \forall p \in P,\ \mathbf{v} \in V, \tag{4.8}$$

$$C(\mathbf{T},\mathbf{v}) = \int_\Omega \mathbf{T} : \boldsymbol{\nabla}\mathbf{v}d\mathbf{x} \quad \forall \mathbf{T} \in \Sigma,\ \mathbf{v} \in V. \tag{4.9}$$

Using an implicit Euler scheme for the time discretization and the extra-stress being computed at the previous time step, the weak formulation of the Stokes problem may be formally written as follows: find $(\mathbf{u}(t_i), p(t_i)) \in V \times P$ for any given extra-stress $\boldsymbol{\tau}(t_{i-1}) \in \Sigma$ such that

$$\begin{aligned} &M(\mathbf{u}(t_i),\mathbf{v}) + A(\mathbf{u}(t_i),\mathbf{v}) - B(p(t_i),\mathbf{v}) \\ &\quad = M(\mathbf{u}(t_{i-1}),\mathbf{v}) - C(\boldsymbol{\tau}(t_{i-1}),\mathbf{v}) \quad \forall \mathbf{v} \in V, \end{aligned} \tag{4.10}$$

$$B(w,\mathbf{u}(t_i)) = 0 \quad \forall w \in P. \tag{4.11}$$

We now define one trilinear and one bilinear form $E : V \times Q \times Q \longrightarrow \mathbb{R}$ and $b : Q \times Q \longrightarrow \mathbb{R}$ to be used for the configuration field equation

$$E(\mathbf{u},\mathbf{q},\mathbf{S}) = \int_\Omega \left(\mathbf{q} + \left(\mathbf{u}.\nabla\mathbf{q} - \nabla\mathbf{u}.\mathbf{q} + \frac{\mathbf{q}}{2\lambda}\right)\Delta t\right).\mathbf{S}d\mathbf{x} \quad \forall \mathbf{u} \in V,\ \mathbf{q},\mathbf{S} \in Q, \tag{4.12}$$

$$b(\mathbf{b},\mathbf{S}) = \int_\Omega \mathbf{b}.\mathbf{S}d\mathbf{x} \quad \forall \mathbf{b},\mathbf{S} \in Q. \tag{4.13}$$

With these definitions of $E(\cdot,\cdot,\cdot)$ and $b(\cdot,\cdot)$, the Galerkin weak formulation of the configuration field equation becomes the following: find $\{\mathbf{q}_j^{t_{i-l}}(t_i)\}_{1\le j\le d}^{0\le l\le i-1} \in Q$ such that

$$E(\mathbf{u}(t_i), \mathbf{q}_j^{t_{i-l}}(t_i), \mathbf{S}) = b(\mathbf{q}_j^{t_{i-l}}(t_{i-1}), \mathbf{S}) \quad \forall \mathbf{S} \in \Sigma. \tag{4.14}$$

Note that on the right-hand side of (4.14) for $l = 0$, we have used the convention that $\mathbf{q}_j^{t_i}(t_{i-1}) = \mathbf{b}_j$, where $\mathbf{b}_j$ has been introduced in section 3. Once the vectors $\mathbf{q}_j^{t_{i-l}}(t_i)$ have been computed, the extra-stress $\boldsymbol{\tau}(t_i)$ can be easily determinated with the relation (3.21). It should be noted that the choice of spaces V, P, Σ, and Q are chosen to ensure that the integrals in the Galerkin weak formulation are bounded. However, the function spaces required for establishing the well-posedness of the problem may well have to be smaller than V, P, Σ, and Q.

4.2. Spectral element discretization. The Legendre spectral element method [14, 17] may be used for the discretization of the continuous problem (4.10), (4.11), and (4.14). The domain Ω is partitioned into K (say) nonoverlapping spectral elements $\{\Omega_k\}_{1\le k\le K}$. Then, letting $\mathcal{P}_N$ denote the space of polynomials of degree less than or equal to N in both Cartesian directions x and y within each spectral element Ω_k, our choice of finite-dimensional subspaces $V^N \subset V$, $P^N \subset P$, $Q^N \subset Q$, and $\Sigma^N \subset \Sigma$ for the velocity, pressure, configuration field, and extra-stress, respectively, are

$$\begin{aligned} V^N &= V \cap (\mathcal{P}_N)^2, \\ P^N &= P \cap \mathcal{P}_{N-2}, \\ Q^N &= Q \cap (\mathcal{P}_N)^2, \\ \Sigma^N &= \Sigma \cap (\mathcal{P}_N)^{2\times 2}. \end{aligned}$$

Note that the pressure approximation space was thus chosen in order to satisfy the Babuška–Brezzi condition for the velocity/pressure compatibility. However, due to the complexity of (4.10), (4.11), and (4.14), and, in particular, their nonlinearity, no available analysis indicating appropriate choices of compatible approximation spaces presently exists.

Mapping of each of the spectral elements $\{\Omega_k\}_{k=1}^K$ onto a parent element,

$$\widehat{\Omega} = \{(\xi, \eta) : -1 \le \xi, \eta \le 1\},$$

is achieved using the transfinite mapping technique of Gordon and Hall [11]. We may then write down discrete representations $\mathbf{u}_N(t_i)$ and $\mathbf{q}_N(t_i)$ for the velocity vector and configuration field at time t_i, respectively, as follows:

$$\mathbf{u}_N(t_i)|_{\Omega_k} \equiv \mathbf{u}_N^k(t_i, \xi, \eta) = \sum_{l=1}^{N+1} \sum_{m=1}^{N+1} \mathbf{u}(t_i)_{l,m}^k h_l(\xi) h_m(\eta) \in V_N, \tag{4.15}$$

$$\mathbf{q}_N(t_i)|_{\Omega_k} \equiv \mathbf{q}_N^k(t_i, \xi, \eta) = \sum_{l=1}^{N+1} \sum_{m=1}^{N+1} \mathbf{q}(t_i)_{l,m}^k h_l(\xi) h_m(\eta) \in Q_N. \tag{4.16}$$

In (4.15) and (4.16), $h_l(\xi)$, $1 \le l \le N+1$, denotes the lth degree N Lagrange interpolating polynomial, having the property that

$$h_l(\xi_m) = \delta_{lm}, \tag{4.17}$$

where ξ_m is the mth Gauss–Lobatto–Legendre point. The spectral representation of the pressure in Ω_k is taken as

$$p_N^k(t_i, \xi, \eta) = \sum_{l=1}^{N-1} \sum_{m=1}^{N-1} p(t_i)_{l,m}^k \tilde{h}_l(\xi) \tilde{h}_m(\eta), \tag{4.18}$$

where $\tilde{h}_l(\xi)$, $1 \le l \le N-1$, is the lth Lagrange interpolating polynomial of degree $N-2$ based on the interior Gauss–Lobatto–Legendre points. The integrals appearing in (4.10), (4.11), and (4.14) are determined numerically using Gauss–Lobatto quadrature rules, and the discretized equations can now be written in the following matrix-vector product form:

$$(\mathbf{M} + \mathbf{A})\mathbf{u}(t_i) - \mathbf{B}\mathbf{p}(t_i) = -\mathbf{C}\boldsymbol{\tau}(t_{i-1}) + \mathbf{M}\mathbf{u}(t_{i-1}), \tag{4.19}$$

$$\mathbf{B}^T \mathbf{u}(t_i) = \mathbf{0}, \tag{4.20}$$

$$\mathbf{E}_{\mathbf{u}(t_i)} \mathbf{q}_j^{t_{i-l}}(t_i) = \mathbf{q}_j^{t_{i-l}}(t_{i-1}) \text{ for } l = 0, \dots, i-1 \text{ and } j = 1, 2, \tag{4.21}$$

where $\mathbf{u}, \mathbf{p}$, and $\mathbf{q}_j^{t_{i-l}}$ in (4.19)–(4.21) are vectors containing, in an obvious way, the nodal values of the velocity, pressure, and configuration field variables. Once the vectors $\mathbf{q}_j^{t_{i-l}}$ have been computed with (4.21), the extra-stress to be used into (4.19) is determined with the formula (3.16) of Theorem 3.2. For a given velocity field $\mathbf{u}(t_i)$, the configuration field equation (4.21) constitutes a hyperbolic system of first-order partial differential equations. The Galerkin spectral element method may produce highly oscillatory numerical solutions for such equations. To treat this problem, we use the SUPG element-by-element method which was found to be an efficient method for the discretization of a steady state Oldroyd B flow [5]. The main idea of that method is to order the spectral elements according to their location along the streamlines. Then,

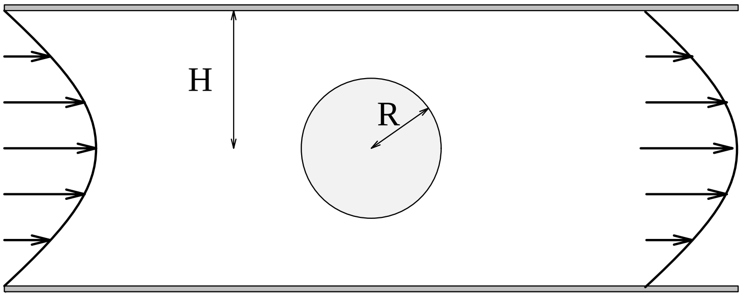

Fig. 2. *Cylinder radius R placed symmetrically in a 2D channel of half width H.*

the configuration field equation is solved sequentially on each spectral element, which makes possible the use of a direct solver for (4.21). The inflow boundary conditions are obtained from the upstream elements or the inflow boundary conditions. Note that the matrix $\mathbf{E}_{\mathbf{u}(t_i)}$ needs to be LU decomposed only once every time step since it is independent of $\mathbf{q}_j^{t_{i-l}}$.

5. Numerical example: Flow around a cylinder in a channel.

5.1. Description of the benchmark problem. The problem of planar viscoelastic flow around a cylinder has become popular recently as evidenced by the number of publications dealing with this benchmark problem over the last three years (e.g., [7, 10, 18, 19]). To be able to compare our results with those of others, we choose the aspect ratio $\Lambda = R/H = 1/2$, where H is the width of the channel and R is the radius of the cylinder (see Figure 2). A global Deborah number for this problem may be defined by

$$De = \frac{\lambda \overline{U}}{R}, \tag{5.1}$$

where $\overline{U}$ is the average velocity of the fluid in the channel at entry. The computational region extends a distance $20R$ upstream and downstream of the cylinder so that the assumption of fully developed flow conditions at entry and exit is valid. The ratio of the solvent viscosity η_s to the total viscosity $\eta = (\eta_s + \eta_p)$ was taken equal to 0.59 so as to match that used by other authors. The most popular quantity used for the comparison of numerical results is the drag factor F^* on the cylinder

$$F^* = \frac{F}{4\pi\eta\overline{U}},$$

where F is the drag on the cylinder

$$F = \int_0^\pi \left\{ \left(-p + 2\eta_s \frac{\partial u_x}{\partial x} + \tau_{xx} \right) \cos\theta + \left(\eta_s \left(\frac{\partial u_y}{\partial x} + \frac{\partial u_x}{\partial y} \right) + \tau_{xy} \right) \sin\theta \right\} R d\theta.$$

The problem is solved by dividing the flow domain into 22 conforming spectral elements (see Figure 3), and polynomial degrees ranging from $N = 8$ to $N = 14$ are used in the two spatial directions. The time steps are chosen equal to $\Delta t = 0.05$.

5.2. Numerical results. Two types of calculations are performed: the first one uses the constitutive equation (2.3), and the second one uses the new mesoscopic

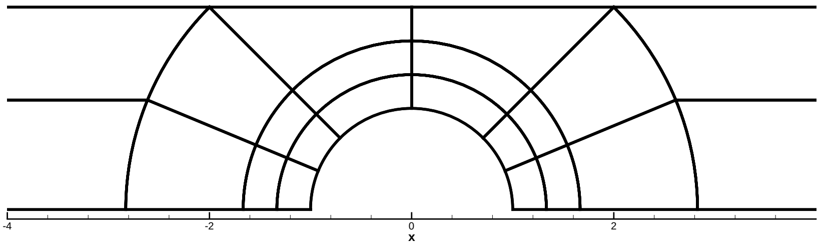

FIG. 3. *Flow domain divided into* 22 *spectral elements.*

approach described in section 3. For the two cases, the parameters $(De, \eta_s, \eta_p, \Delta t)$ and the numerical scheme (spectral element method with an implicit Euler scheme for the time discretization) are the same. The iterations are stopped when the following convergence criterion is fulfilled for all collocation points $\mathbf{x} \in \Omega$:

$$\frac{\|\mathbf{u}(\mathbf{x}, t_{i+1}) - \mathbf{u}(\mathbf{x}, t_i)\|}{\Delta t} \leq 10^{-3}.$$

At time t_i, the proposed mesoscopic method requires $d \times i$ vectors $\mathbf{q}_j^{t_{i-l}}(t_i)$ to be computed with (3.12) and (3.14). The total number of solves from $t = t_0$ to $t = t_i$ is therefore $\sum_{k=0}^{i} d \times k = d \times i \times (i+1)/2$. In practice, a maximum of $200 = \mathcal{O}(10^2)$ time steps was found to be sufficient to reach the steady solution. In this case the total number of solves is $\mathcal{O}(10^4)$. Since the computation of the extra-stress is deterministic, the solution is noise-free. On the other hand, for the traditional configuration field method, it is usual to take $3000 = \mathcal{O}(10^3)$ configuration fields. Therefore, we would have to solve equation (2.9) $\mathcal{O}(10^2) \times \mathcal{O}(10^3) = \mathcal{O}(10^5)$ times from $t = t_0$ to $t = t_i$. However, in this case, inevitably, the solution would be subject to noise. The present approach is therefore very competitive in terms of cost and quality of the solution.

Tables 1 and 2 give the values of the drag factor for two types of computations (the first one uses the formulation presented in this paper, and the second uses the classical Oldroyd-B constitutive equation) for different level of discretizations ($N = 8, \dots, 14$) and different Deborah numbers. The mesoscopic calculation is clearly more robust since Deborah numbers up to $De = 0.8$ can be reached, whereas the constitutive equation allows computation to proceed only up to $De = 0.6$. The convergence of the drag factor with mesh refinement is also better: the difference between the two finest meshes at $De = 0.6$ is 0.004% for the mesoscopic computation and falls to 0.2% for its macroscopic counterpart. The superiority of the method can be seen clearly by comparing Figures 4 and 5 which show the profiles of τ_{xx} for three levels of discretization ($N = 8, 10$, and 12) at the same Deborah number $De = 0.6$ for the macroscopic and mesoscopic computation, respectively. For high Deborah numbers, and as already pointed out in numerous papers [4, 8, 9, 10], the drag factor is not a good indicator of the quality of the solution because the critical part of the flow lies in the wake of the cylinder where the τ_{xx} component of the extra-stress is exceedingly difficult to capture. This is why, although there are published results for the drag factors up to $De = 1.85$ [19], evidence of convergence in the wake of the cylinder is available only up to $De = 0.7$ [5, 10]. Figures 6 and 7 show the profiles of τ_{xx} for three level of discretization ($N = 8, 10$, and 12) for the mesoscopic computation at $De = 0.7$ and $De = 0.8$, respectively. The convergence with mesh refinement is still

good both on the cylinder surface ($-1 \leq x \leq 1$) and in the wake of the cylinder ($x > 1$), even at the highest Deborah number.

6. Extension of the method to multimode Oldroyd B fluids.

In practice, fluids have a continuous spectrum of relaxation times. This is approximated by taking several (say p) relaxation times $\{\lambda_r\}_{1\leq r\leq p}$ associated with polymeric viscosities $\{\eta_{pr}\}_{1\leq r\leq p}$. The extra-stress that now enters the linear momentum equation is the sum of the contribution of each mode (λ_r, η_{pr}), i.e., for a p-mode model

$$\boldsymbol{\tau}(\mathbf{x},t_i) = \sum_{r=1}^{p} \boldsymbol{\tau}_r(\mathbf{x},t_i). \tag{6.1}$$

For the Oldroyd B multimode model, the equation satisfied by the rth mode of the configuration field $\mathbf{Q}_m^r(\mathbf{x}, t_i)$ is

$$\begin{aligned}\mathbf{Q}_m^r(\mathbf{x}, t_i) + \Big(\mathbf{u}(\mathbf{x},t_i).\nabla\mathbf{Q}_m^r(\mathbf{x}, t_i) - \nabla\mathbf{u}(\mathbf{x},t_i)\mathbf{Q}_m^r(\mathbf{x}, t_i)\Big)\Delta t \\ = \left(1 - \frac{\Delta t}{2\lambda_r}\right)\mathbf{Q}_m^r(\mathbf{x}, t_{i-1}) + \sqrt{\frac{\Delta t}{\lambda_r}}\Delta\mathbf{W}_m^r(t_i),\end{aligned} \tag{6.2}$$

where all the terms depending on λ_r have been taken explicitly so that the matrix $\mathbf{E_u}(\mathbf{x}, t_i)$ resulting from the discretization of the left-hand side is now independent of the modes and needs to be LU decomposed only once every time step.

Introducing a real function of the relaxation time λ for any given time step Δt thus

$$\beta(\lambda) = \left(1 - \frac{\Delta t}{2\lambda}\right), \tag{6.3}$$

the following result can be shown by induction on i in the same way as Theorem 3.1.

Theorem 6.1. *Let $\mathbf{Q}_m^r(\mathbf{x}, t_i)$ be the rth mode discrete solution of (6.2) at time $t_i = i\Delta t$ ($i \geq 1$) for any given Wiener process $\Delta\mathbf{W}_m^r(t_i)$. Then, there exists $d \times i$ vectors independent of m and independent of the mode r, noted $\{\mathbf{q}_j^{t_{i-l}}(\mathbf{x}, t_i)\}_{0\leq l\leq i-1}^{1\leq j\leq d}$*

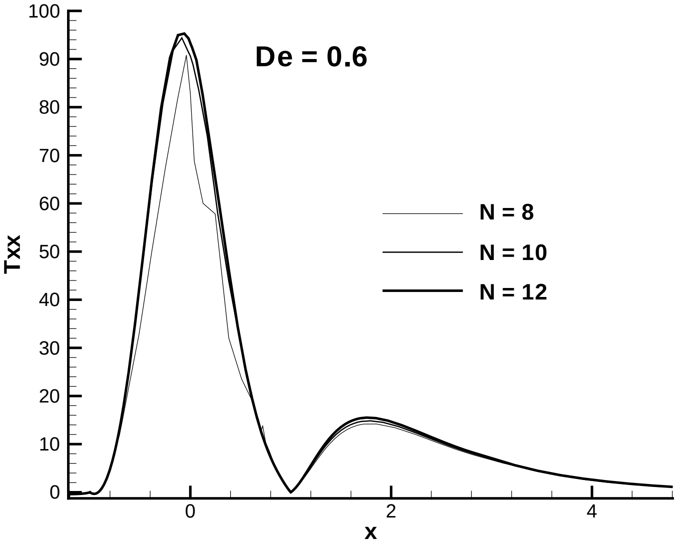

FIG. 4. *Profiles of τ_{xx} on the cylinder surface and in the wake of the cylinder for different meshes at $De = 0.6$. Macroscopic simulation.*

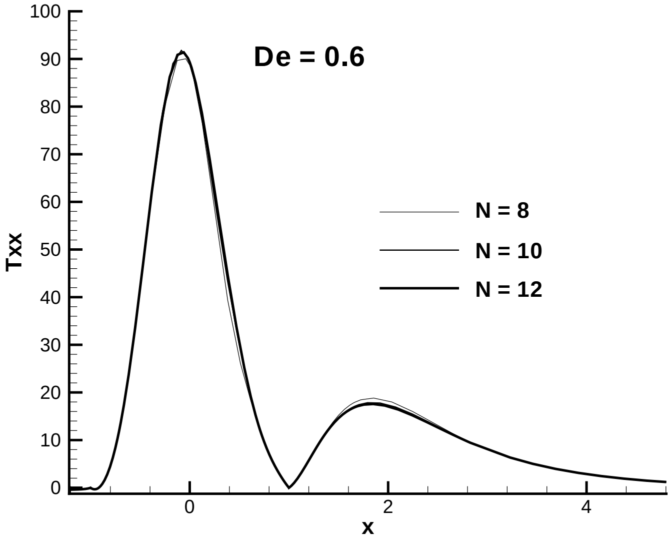

FIG. 5. *Profiles of τ_{xx} on the cylinder surface and in the wake of the cylinder for different meshes at $De = 0.6$. Mesoscopic simulation.*

such that

$$\mathbf{Q}^r_m(\mathbf{x},t_i)=\sum_{j=1}^{d}\left\{\left(\sum_{l=0}^{i-1}\alpha(\lambda_r)\beta(\lambda_r)^l\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)\Delta W_m^{rj}(t_{i-l})\right)+\beta(\lambda_r)^i\mathbf{q}_j^{t_1}(\mathbf{x},t_i)\Delta W_m^{rj}(t_0)\right\}.$$

The vectors $\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)$ are created and updated similarly to the single mode case. In the same fashion as in Theorem 3.2, we can derive a simple expression for the rth mode contribution to the extra-stress

$$\begin{aligned}(6.4)\quad \boldsymbol{\tau}_r(\mathbf{x},t_i) = \frac{\eta_{pr}}{\lambda_r}\Bigg(-\mathbf{I}+\sum_{j=1}^{d}\Bigg\{\sum_{l=0}^{i-1}\Big(\alpha(\lambda_r)^2\beta(\lambda_r)^{2l}\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)\otimes\mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i)\Big)\\ +\beta(\lambda_r)^{2i}\mathbf{q}_j^{t_1}(\mathbf{x},t_i)\otimes\mathbf{q}_j^{t_1}(\mathbf{x},t_i)\Bigg\}\Bigg).\end{aligned}$$

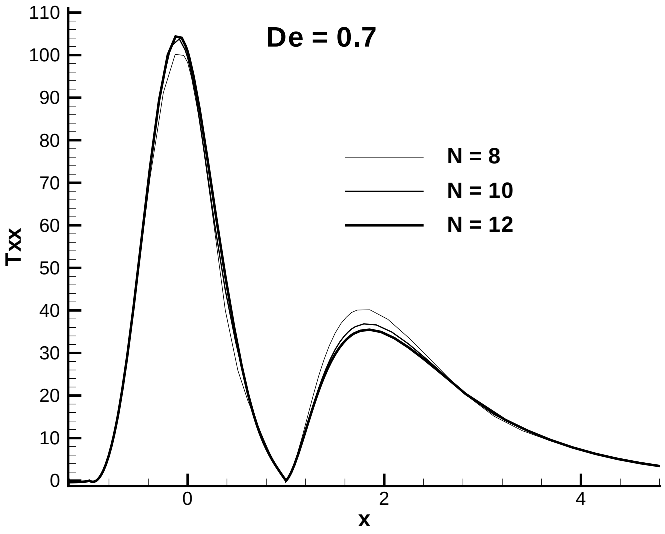

FIG. 6. *Profiles of τ_{xx} on the cylinder surface and in the wake of the cylinder for different meshes at $De = 0.7$. Mesoscopic simulation.*

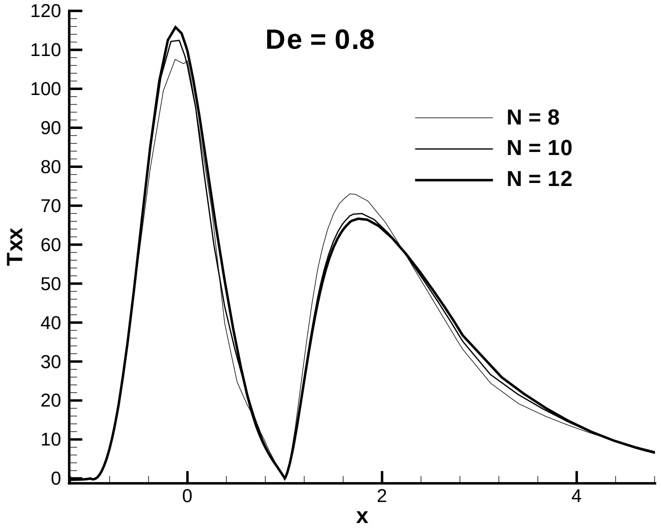

FIG. 7. *Profiles of τ_{xx} on the cylinder surface and in the wake of the cylinder for different meshes at $De = 0.8$. Mesoscopic simulation.*

In order to write the total extra-stress in a condensed way, we define i constants $\{\chi_l\}_{0\leq l\leq i-1}$ at time t_i; thus

$$\chi_l = \sum_{r=1}^{p} \frac{\eta_{pr}}{\lambda_r}\alpha(\lambda_r)^2\beta(\lambda_r)^{2l} \text{ for } l = 0, \dots, i-2, \tag{6.5}$$

$$\chi_{i-1} = \sum_{r=1}^{p} \frac{\eta_{pr}}{\lambda_r}\left(\alpha(\lambda_r)^2\beta(\lambda_r)^{2(i-1)} + \beta(\lambda_r)^{2i}\right). \tag{6.6}$$

With those definitions and the help of (6.1) and (6.4), the total extra-stress can be written

$$\boldsymbol{\tau}(\mathbf{x},t_i) = -\left(\sum_{r=1}^{p} \frac{\eta_{pr}}{\lambda_r}\right)\mathbf{I} + \sum_{j=1}^{d}\sum_{l=0}^{i-1} \chi_l \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i) \otimes \mathbf{q}_j^{t_{i-l}}(\mathbf{x},t_i). \tag{6.7}$$

The equation above shows that the difference between the single mode Oldroyd B model and the multimode model lies in the computation of $\{\chi_l\}_{0\leq l\leq i-1}$, which is an inexpensive calculation. This is a big advantage over simulations using constitutive equations, where an equation similar to (2.3) has to be solved for each mode.

7. Conclusion. The principal idea in the proposed method lies in the fact that the random part appearing in the discretized stochastic equation follows the normal law, which enables a simple expression for the extra-stress to be derived for the Oldroyd B model. The multimode case was shown to be a simple extension to the presented approach. The method has been tested numerically on the benchmark problem of an Oldroyd B fluid past a cylinder in a channel. The results have shown that the method is superior in terms of stability to using a constitutive equation. It is also cheaper than the original Brownian configuration field method. The present approach was extended to dumbbell models having finitely extensible elastic spring forces such as the FENE-P model in [6].

Acknowledgment. The author would like to thank Robert Owens for helpful discussions and for proofreading the manuscript.

MULTILEVEL METHOD FOR MIXED EIGENPROBLEMS[*]

R. HIPTMAIR[†] AND K. NEYMEYR[‡]

Abstract. For a Lipschitz-polyhedron $\Omega \subset \mathbb{R}^3$ we consider eigenvalue problems $\mathbf{curl}\,\alpha\,\mathbf{curl}\,\mathbf{u} = \lambda\mathbf{u}$ and $\operatorname{grad}\alpha\operatorname{div}\mathbf{u} = \lambda\mathbf{u}$, $\lambda > 0$, set in $\mathsf{H}(\mathbf{curl};\Omega)$ and $\mathsf{H}(\operatorname{div};\Omega)$. They are discretized by means of the conforming finite elements introduced by Nédélec. The preconditioned inverse iteration in its subspace variant is adapted to these problems. A standard multigrid scheme serves as the preconditioner. The main challenge arises from the large kernels of the operators **curl** and div. However, thanks to the choice of finite element spaces these kernels have a direct representation through the gradients/rotations of discrete potentials. This makes it possible to use a multigrid iteration in potential space to obtain approximate projections onto the orthogonal complements of the kernels. There is ample evidence that this will lead to an asymptotically optimal method. Numerical experiments confirm the excellent performance of the method even on very fine grids.

1. Introduction.

Let $\Omega \subset \mathbb{R}^3$ be a Lipschitz-polyhedron [36], whose boundary is partitioned into Γ_D and Γ_N. Our focus is on the vector-valued eigenvalue problems

$$\begin{array}{rclll} \mathbf{curl}\,\alpha\,\mathbf{curl}\,\mathbf{u} &=& \lambda\mathbf{u} & \text{in } \Omega\,, & \mathbf{u}\times\mathbf{n} = 0 \text{ on } \Gamma_D\,, \\ \operatorname{div}\mathbf{u} &=& 0 & \text{in } \Omega\,, & \alpha\,\mathbf{curl}\,\mathbf{u}\times\mathbf{n} = 0 \text{ on } \Gamma_N\,, \end{array} \tag{1.1}$$

and

$$\begin{array}{rclll} \operatorname{grad}\alpha\operatorname{div}\mathbf{u} &=& \lambda\mathbf{u} & \text{in } \Omega\,, & \mathbf{u}\cdot\mathbf{n} = 0 \text{ on } \Gamma_D\,, \\ \mathbf{curl}\,\mathbf{u} &=& 0 & \text{in } \Omega\,, & \alpha\operatorname{div}\mathbf{u}\cdot\mathbf{n} = 0 \text{ on } \Gamma_N\,. \end{array} \tag{1.2}$$

Here, the vectorfields $\mathbf{u}$ is an eigenfunction, $\lambda \geq 0$ stands for the eigenvalue, and $\alpha \in L^\infty(\Omega)$ is a uniformly positive coefficient.

We seek approximations of a few of the smallest nonzero eigenvalues and corresponding eigenfunctions. This problem is of considerable relevance in several areas of scientific computing. For instance, (1.1) describes so-called electromagnetic resonators if $\mathbf{u}$ is regarded as the (scaled) electric field. We refer to [1, sect. 1] for more detailed explanations. When we want to determine a few of the lowest resonant modes for a given cavity Ω, we exactly encounter the eigenvalue problem (1.1). Beyond the calculation of resonant modes, approximations of the lowest eigenmodes are the basis for modal [28] approaches: A set of dominant modes is computed once, and the fields at other frequencies are then approximated by a superposition of these modes. This can be used to extract lumped parameters for electromagnetic devices in the frequency domain. A completely different application emerges in the study of coupled

solid-fluid systems. When one tries to find their eigenmodes, the eigenvalue problem (1.2) appears [9].

Of course, there is a close relationship between (1.1) and (1.2) and eigenvalue problems for second order elliptic differential operators. For the latter case, which amounts to a generalized eigenvalue problem for large sparse symmetric *positive definite* matrices, a huge body of work about numerical solution methods has been compiled over the years [4, 5, 22, 38, 48, 54]. The driving force was the sheer size of the eigenproblems arising from discretized PDEs. Millions of unknowns rule out the use of methods that rely on dense matrices or factorizations. In addition, it is highly desirable to avoid a deterioration of the convergence of the iterative schemes for large problems. As far as the solution of discretized elliptic boundary value problems is concerned, multigrid methods meet this requirement. It turned out that the multigrid idea can be grafted onto solution methods for discrete elliptic eigenproblems in several ways, resulting in eigensolvers with optimal or quasi-optimal computational complexity. For instance, Hackbusch [38, 39] applies multigrid principles directly to the nonlinear eigenvalue problem to compute eigenvalue/vector approximations on the final grid by combining a multigrid iteration and nested iteration. Let us also mention the multigrid minimization technique of Mandel and McCormick [54], its extension by Deuflhard, Friese, and Schmidt [27], as well as the class of methods which apply multigrid as a linear solver. Essentially, the idea underlying this last class is to linearize the discrete eigenvalue problem by methods like inverse iteration [64] and to solve the associated system of linear equations approximately by multigrid [5]. Representing the application of the multigrid procedure by a multigrid preconditioner and taking inverse iteration (without a shift) as an outer iteration defines *preconditioned inverse iteration* (PINVIT). Recently, a new convergence theory for PINVIT has been devised, providing sharp convergence estimates and substantial insight into the underlying geometry [50, 61, 62].

The scheme of preconditioned inverse iteration is also known in the literature as the preconditioned gradient method for the eigenvalue problem. The idea behind this term is to compute a sequence of iterates with decreasing Rayleigh quotients by successively correcting the iterates in the direction of the negative preconditioned gradient of the Rayleigh quotient. By doing so, one expects that the sequence of iterates converges to an eigenvector while the Rayleigh quotients tend to the smallest eigenvalue. Preconditioned gradient methods have been studied predominantly by Russian authors: see, for instance, Samokish [66], Petryshyn [65], Godunov, Ogneva, and Prokopov [35], D'yakonov [29], D'yakonov and Orekhov [31], and Knyazev [47,48], as well as the monograph of D'yakonov [30], including an extensive bibliography. Recently, Ovtchinnikov and Xanthis [63] introduced a new variant. Knyazev in [48] gives a survey on preconditioned eigensolvers.

Preconditioned inverse iteration has been generalized to a subspace algorithm for computing some of the smallest eigenvalues together with the eigenvectors by emulating the subspace variant of inverse iteration [64]. Once again, the associated matrix equation is solved approximately. After each subspace correction step the Rayleigh–Ritz procedure is applied. It provides the Ritz values and Ritz vectors spanning the approximating subspace. Convergence estimates have been presented in [20, 59]. In sum, the resulting preconditioned eigensolver inherits the typical asymptotic multigrid efficiency [51] from the multigrid procedure used to solve the associated linear equations.

On a smaller scale, researchers have also investigated ways to compute solutions to (1.1) and (1.2) [1, 68]. It is obvious that the large kernels of the differential operators **curl** and div pose the main challenge: A straightforward application of iterative techniques developed for the symmetric positive definite case is doomed because these methods single out the smallest eigenvalues and will invariably churn out kernel vectors in the end. However, as $\lambda > 0$ is requested, these are not the desired answer. We are left with the task of steering the iterations away from the kernels.

One option is regularization, i.e., adding a term corresponding to a weak version of $\operatorname{grad}\operatorname{div}\cdot$ for (1.1) and $\mathbf{curl}\,\mathbf{curl}\cdot$ for (1.2) to the differential operator (cf. [1, sect. 4.1] and [10]). This will make the kernel "visible" and convert the problem into a standard positive definite one. Thus it becomes amenable to "shift-and-invert" techniques combined with, e.g., an implicitly restarted Lanczos method. The resulting indefinite linear systems of equations can be solved by means of Krylov-subspace methods, whose convergence will degrade, however, for very large problems.

An alternative option is projection of approximate eigenvectors onto a complement of the kernels. This is the gist of our method, which we call *projected preconditioned inverse iteration* (PPINVIT). The idea to forgo regularization in favor of projections is fairly natural. For instance, it is used in [67] for two-dimensional problems arising in waveguide design. Yet, little is gained unless a fast projection and good preconditioners are at our disposal.

Recently, multilevel methods for the solution of $\boldsymbol{H}(\mathbf{curl};\Omega)$- and $\boldsymbol{H}(\operatorname{div};\Omega)$-elliptic boundary value problems have become available [3, 41, 43] if discretization is based on special conforming finite elements. The goal of this paper is to demonstrate how they can be forged into eigenproblem solvers featuring multigrid efficiency. The key idea is to combine the subspace variant of PINVIT [59] with an inexact multigrid projection onto the orthogonal complements of the kernels.

Since the approach crucially hinges on particular properties of the finite elements, those are reviewed in the next section. Then we give a detailed description of the algorithm, complete with projection control and termination criteria. The fourth section is dedicated to some theoretical investigations of the convergence of the method. Yet, we have not succeeded in providing a comprehensive theoretical analysis. To compensate for this, we report some numerical experiments in the final section. They give evidence of the efficacy and satisfactory performance of the method for some typical large eigenvalue problems.

2. Discrete eigenvalue problems.

The Galerkin-discretization starts from the weak form of the eigenvalue problems: In the case of (1.1) we seek $\mathbf{u} \in \boldsymbol{H}_{\Gamma_D}(\mathbf{curl};\Omega)$, $\lambda > 0$ such that

$$(\alpha\,\mathbf{curl}\,\mathbf{u}, \mathbf{curl}\,\mathbf{v})_0 = \lambda\,(\mathbf{u},\mathbf{v})_0 \quad \forall \mathbf{v} \in \boldsymbol{H}_{\Gamma_D}(\mathbf{curl};\Omega)\ . \tag{2.1}$$

If (1.2) is of concern the weak form reads: Seek $\mathbf{u} \in \boldsymbol{H}_{\Gamma_D}(\operatorname{div};\Omega)$, $\lambda > 0$ such that

$$(\alpha\operatorname{div}\mathbf{u}, \operatorname{div}\mathbf{v})_0 = \lambda\,(\mathbf{u},\mathbf{v})_0 \quad \forall \mathbf{v} \in \boldsymbol{H}_{\Gamma_D}(\operatorname{div};\Omega)\ . \tag{2.2}$$

As usual, we adopt the notation $(\cdot,\cdot)_0$ for the $\boldsymbol{L}^2(\Omega)$-inner product. In addition, a subscript Γ_D tags spaces of functions satisfying zero (tangential/normal) traces on Γ_D.

By testing (2.1) with gradients and (2.2) with **curl**s we observe that solutions $\mathbf{u}$ are either weakly divergence-free or weakly **curl**-free. As $\boldsymbol{H}_{\Gamma_D}(\mathbf{curl};\Omega) \cap \boldsymbol{H}(\operatorname{div};\Omega)$ and $\boldsymbol{H}_{\Gamma_D}(\operatorname{div};\Omega) \cap \boldsymbol{H}(\mathbf{curl};\Omega)$ are both compactly embedded in $\boldsymbol{L}^2(\Omega)$ [46] and the bilinear forms on the left-hand sides of (2.1) and (2.2) are symmetric positive semidefinite, the Riesz–Schauder theory guarantees the existence of increasing sequences of real positive eigenvalues $0 < \lambda_1 \leq \lambda_2 \leq \cdots$. From symmetry we can also conclude that the corresponding eigenspaces are $\boldsymbol{L}^2(\Omega)$-orthogonal.

This carries over to the discrete eigenfunctions obtained through a Galerkin-discretization of (2.1) and (2.2). In particular, we use conforming finite elements based on a hexahedral or simplicial triangulation $\mathcal{T}_h = \{T_i\}_i$ of Ω. Then, using the constructions proposed by Nédélec in [58], we obtain the finite element spaces $\boldsymbol{\mathcal{W}}^1_p(\mathcal{T}_h) \subset \boldsymbol{H}(\mathbf{curl};\Omega)$ and $\boldsymbol{\mathcal{W}}^2_p(\mathcal{T}_h) \subset \boldsymbol{H}(\mathrm{div};\Omega)$ of any polynomial order $p \in \mathbb{N}_0$. Details and descriptions of the degrees of freedom are given in, e.g., [21,34,56,58]. Dirichlet boundary conditions can be enforced by setting the degrees of freedom (d.o.f.) on Γ_D to zero.

In the case of lowest polynomial order, $p = 0$, the finite elements are either known as Whitney-forms [16] or, in the engineering literature, as *edge elements* ($\boldsymbol{H}(\mathbf{curl};\Omega)$-conforming scheme) and *face elements* ($\boldsymbol{H}(\mathrm{div};\Omega)$-conforming scheme), respectively. They owe these names to the definition of their d.o.f., which are given by path integrals along edges of the mesh and flux integrals over its faces, respectively. The finite element spaces form affine equivalent families if special transformations are used [42]. This makes it possible to show approximation properties on shape regular families of meshes (cf. [26]). In addition, if quasi uniformity is assumed, the inverse inequalities

$$\begin{aligned} \|\mathbf{curl}\,\mathbf{u}_h\|_0 &\leq C h^{-1}\,\|\mathbf{u}_h\|_0 \quad \forall \mathbf{u}_h \in \boldsymbol{\mathcal{W}}^1_p(\mathcal{T}_h)\ , \\ \|\mathrm{div}\,\mathbf{u}_h\|_0 &\leq C h^{-1}\,\|\mathbf{u}_h\|_0 \quad \forall \mathbf{u}_h \in \boldsymbol{\mathcal{W}}^2_p(\mathcal{T}_h) \end{aligned} \tag{2.3}$$

hold, where $h := \max\{\mathrm{diam}\,T,\, T \in \mathcal{T}_h\}$ is the meshwidth and $C > 0$ are generic constants. By this terminology we mean that C may depend *only* on $\Omega, \Gamma_D, \alpha, p$, and the shape regularity of the finite element mesh. On the other hand, the value of generic constants may change between different occurrences.

Despite the glaring differences in their definitions, the finite element spaces for $\boldsymbol{H}(\mathbf{curl};\Omega)$ and $\boldsymbol{H}(\mathrm{div};\Omega)$ introduced above are closely related. As discussed in [18, 19, 42], they all can be viewed as spaces of *discrete differential forms.* This is the rationale behind our decision to treat both (1.1) and (1.2) in a common framework. In a sense, we will adopt the common notation $\boldsymbol{\mathcal{V}}_h$ for both $\boldsymbol{\mathcal{W}}^1_p(\mathcal{T}_h)$ or $\boldsymbol{\mathcal{W}}^2_p(\mathcal{T}_h)$ with suitable Dirichlet boundary conditions imposed.

Hitherto, discrete differential forms supply the only conforming finite element discretization of (2.1) and (2.2) that can steer clear of so-called *spurious modes.* For instance, if one uses $H^1(\Omega)$-conforming finite elements to discretize the Cartesian components of the vectorfields $\mathbf{u}$, the discrete spectrum may feature eigenvalues that are not related to an eigenvalue of the continuous problem [14,17,33]. On the contrary, in recent years rigorous arguments have been found about why discrete differential forms ensure a correct approximation of the spectrum [12, 15, 23, 24, 33, 57]. For shape-regular families of meshes convergence of the eigenvalues will be quadratic in the meshwidth [23] under mild assumptions on the smoothness of the eigenfunctions.

A key role in the convergence theory is played by *discrete potentials.* They refer to an exceptional property of discrete differential forms, namely that they give rise to analogues to de Rham's exact sequences in a purely discrete setting [13, 19]. In particular, for contractible Ω, $\Gamma_D = \partial\Omega$ or $\Gamma_N = \partial\Omega$,

$$\{\mathbf{u}_h \in \boldsymbol{\mathcal{W}}^1_p(\mathcal{T}_h),\ \mathbf{curl}\,\mathbf{u}_h = 0\} = \mathrm{grad}\,\mathcal{W}^0_p(\mathcal{T}_h)\ , \tag{2.4}$$

$$\{\mathbf{u}_h \in \boldsymbol{\mathcal{W}}^2_p(\mathcal{T}_h),\ \mathrm{div}\,\mathbf{u}_h = 0\} = \mathbf{curl}\,\boldsymbol{\mathcal{W}}^1_p(\mathcal{T}_h)\ , \tag{2.5}$$

where $\mathcal{W}^0_p(\mathcal{T}_h)$ stands for the space of continuous finite element functions, piecewise polynomial of degree $p+1$ over $\mathcal{T}_h$, the conventional Lagrangian finite elements (see [25]). A proof of these identities can be found in [42]. Now it is clear why $\mathcal{W}_p^0(\mathcal{T}_h)$ and $\boldsymbol{\mathcal{W}}_p^1(\mathcal{T}_h)$ have been dubbed spaces of discrete potentials. Those will be denoted by $\mathcal{S}_h$, and $G_h : \mathcal{S}_h \mapsto \boldsymbol{\mathcal{V}}_h$ is the related differential operator mapping into the kernel of the respective differential operator; that is, $G_h := \text{grad}$ or $G_h := \mathbf{curl}$.

In the case of complex topologies and Dirichlet boundary conditions on parts of $\partial\Omega$, the kernels of the differential operators are no longer completely given by suitable discrete potentials. What is still missing are low-dimensional spaces of discrete harmonic vectorfields, $\boldsymbol{\mathcal{H}}^1(\mathcal{T}_h) \subset \boldsymbol{\mathcal{W}}_0^1(\mathcal{T}_h)$ and $\boldsymbol{\mathcal{H}}_2(\mathcal{T}_h) \subset \boldsymbol{\mathcal{W}}_0^2(\mathcal{T}_h)$, whose dimensions depend on the topology of Ω and the arrangements of the connected components of Γ_D. For instance, if $\Gamma_D = \partial\Omega$ the dimension of $\boldsymbol{\mathcal{H}}^1(\mathcal{T}_h)$ is equal to the number of connected components of $\partial\Omega$. A basis for $\boldsymbol{\mathcal{H}}^1(\mathcal{T}_h)$ is given by the gradients of piecewise linear continuous functions that assume the value 1 on one connected component of Γ_D and vanish on the other. Evidently, this basis can be constructed with little effort. In the case of Neumann boundary conditions throughout, $\dim \boldsymbol{\mathcal{H}}^1(\mathcal{T}_h)$ is equal to the number of homology classes of boundary cycles that are bounding relative to Ω. To find a basis, we associate a cutting surface to each homology class and compute the gradient of a piecewise linear function that is continuous except for a jump of height 1 across the cutting surface [2]. The surfaces can be determined by means of graph-theoretic algorithms [37]. In the case of mixed boundary conditions the situation is more involved [32, 52], but for concrete geometries the harmonic vectorfields can usually be found easily. In what follows we will write $\boldsymbol{\mathcal{H}}_h$ for a space of harmonic vectorfields and will take for granted that a basis $\{\mathbf{h}_1, \dots, \mathbf{h}_q\}$ of $\boldsymbol{\mathcal{H}}_h$ has been computed.

Summing up, we face the following abstract discrete eigenvalue problem: Seek $\mathbf{u}_h \in \boldsymbol{\mathcal{V}}_h$ such that

$$a(\mathbf{u}_h, \mathbf{v}_h) = \lambda\, (\mathbf{u}_h, \mathbf{v}_h)_0 \quad \forall \mathbf{v}_h \in \boldsymbol{\mathcal{V}}_h\ , \tag{2.6}$$

where $a(\cdot,\cdot)$ stands for the positive semidefinite bilinear form from (2.1) or (2.2). We associate operators $A_h : \boldsymbol{\mathcal{V}}_h \mapsto \boldsymbol{\mathcal{V}}_h'$ and $M_h : \boldsymbol{\mathcal{V}}_h \mapsto \boldsymbol{\mathcal{V}}_h'$ with the bilinear forms in (2.6), which converts it into an operator equation

$$A_h \mathbf{u}_h = \lambda M_h \mathbf{u}_h\ . \tag{2.7}$$

The basis of $\boldsymbol{\mathcal{V}}_h$ dual to the set of d.o.f. is called the nodal basis $\{\mathbf{b}_\iota\}_{\iota \in J}$, with J a suitable index set. The basis functions are locally supported and satisfy

$$\|\mathbf{b}_\iota\|_0 \leq C \operatorname{diam}\operatorname{supp}(\mathbf{b}_\iota)\, \|\mathbf{b}_\iota\|_A\ , \qquad \iota \in J\ , \tag{2.8}$$

with $\|\cdot\|_A$ the *energy-seminorm* induced by $a(\cdot,\cdot)$. Given the nodal basis, (2.7) can also be read as a matrix equation, A_h being the stiffness matrix and M_h the mass matrix, which are both large and sparse.

We follow the convention that functions will be given Roman symbols, whereas Greek letters are used for functionals. Those related to the base space $\boldsymbol{\mathcal{V}}_h$ will be given bold tokens, whereas entities from the potential space $\mathcal{S}_h$ are printed in plain style.

3. PPINVIT.

Standard inverse iteration (without shift) for an eigenvalue problem $A_h \mathbf{u}_h = \lambda M_h \mathbf{u}_h$ with symmetric *positive definite* operators $A_h : \boldsymbol{\mathcal{V}}_h \mapsto \boldsymbol{\mathcal{V}}_h'$, $M_h := \boldsymbol{\mathcal{V}}_h \mapsto \boldsymbol{\mathcal{V}}_h'$ computes a new iterate $\mathbf{x}_h^{\text{new}} \in \boldsymbol{\mathcal{V}}_h$ from the old $\mathbf{x}_h \in \boldsymbol{\mathcal{V}}_h$ through

$$\mathbf{y}_h = \kappa A_h^{-1} M_h \mathbf{x}_h^{\text{old}}, \quad \mathbf{x}_h^{\text{new}} := \mathbf{y}_h / \|\mathbf{y}_h\|_0$$

for some $\kappa \neq 0$. First, observe that the choice of κ is immaterial. Therefore, we may set $\kappa = r(\mathbf{x}_h)$, where

$$r(\mathbf{x}_h) = \frac{\langle A_h \mathbf{x}_h, \mathbf{x}_h \rangle}{\langle M_h \mathbf{x}_h, \mathbf{x}_h \rangle} \tag{3.1}$$

denotes the Rayleigh quotient and $\langle \cdot, \cdot \rangle$ the duality pairing. This choice of κ has the effect that $\mathbf{y}_h - \mathbf{x}_h$ converges to zero when $r(\mathbf{x}_h)$ approaches the smallest eigenvalue. Thus we recover the typical situation, where a correction is determined by solving a linear system with a small residual as its right-hand side. This paves the way for the application of a *preconditioner* $B_h : \boldsymbol{\mathcal{V}}_h' \mapsto \boldsymbol{\mathcal{V}}_h$, an approximate inverse of A_h, to compute $\mathbf{y}_h$. We arrive at the update formula

$$\mathbf{y}_h = \mathbf{x}_h - B_h(A_h \mathbf{x}_h - r(\mathbf{x}_h) M_h \mathbf{x}_h), \quad \mathbf{x}_h^{\mathrm{new}} := \mathbf{y}_h / \left\| \mathbf{y}_h \right\|_0 \ , \tag{3.2}$$

which is the basic building block for the algorithm of PINVIT [61]. The iterates will converge linearly to an eigenvector belonging to the smallest eigenvalue. The theoretically possible but unlikely case that PINVIT gets stuck in a higher eigenvalue does not occur in practice due to rounding errors. If an invariant subspace corresponding to the s smallest eigenvalues is desired, we can resort to the subspace variant. After a Rayleigh–Ritz projection, it updates each of the s Ritz vectors $\mathbf{x}_h^1, \ldots, \mathbf{x}_h^s$ according to (3.2) with $r(\mathbf{x}_h)$ replaced by the Ritz values [20, 59].

Let us return to the actual setting, in which A_h is only *positive semidefinite*. Then it is natural to demand that $\mathbf{y}_h$ is contained in the $\boldsymbol{L}^2(\Omega)$-orthogonal complement of $\mathrm{Ker}(A_h)$, as this is satisfied for any eigenvector belonging to a nonzero eigenvalue. In other words, the (exact) inverse iteration should be based on the pseudoinverse $A_h^\dagger : \boldsymbol{\mathcal{V}}_h' \mapsto \boldsymbol{\mathcal{V}}_h$. Then $\mathbf{x}_h$ will converge to an eigenvector corresponding to λ_1 as long as the starting vector (for the case of exact arithmetic) is not orthogonal to that eigenvector.

The pseudoinverse $A^\dagger$ is elusive and has to be approximated. We suggest to do so by means of a plain multigrid method. It relies on a hierarchy of nested meshes $\mathcal{T}_0 \prec \mathcal{T}_1 \prec \cdots \prec \mathcal{T}_L := \mathcal{T}_h$ and the corresponding finite element spaces $\boldsymbol{\mathcal{V}}_0 \subset \boldsymbol{\mathcal{V}}_1 \subset \cdots \subset \boldsymbol{\mathcal{V}}_L := \boldsymbol{\mathcal{V}}_h$. The natural way to create such meshes is through successive refinement of an initial rather coarse mesh $\mathcal{T}_0$, as described in [6, 11] for tetrahedral meshes. The refinement strategies make sure that the shape regularity of $\mathcal{T}_0$ is almost preserved for all finer meshes.

We instantly get a sequence of operators $A_l : \boldsymbol{\mathcal{V}}_l \mapsto \boldsymbol{\mathcal{V}}_l'$ generated by the bilinear form $a(\cdot, \cdot)$ on $\boldsymbol{\mathcal{V}}_l$. The embedding of the spaces $\boldsymbol{\mathcal{V}}_{l-1} \subset \boldsymbol{\mathcal{V}}_l$ spawns the canonical prolongation operators $I_l : \boldsymbol{\mathcal{V}}_{l-1} \mapsto \boldsymbol{\mathcal{V}}_l$, $l = 1, \ldots, L$. Their adjoints $I_l^* : \boldsymbol{\mathcal{V}}_l' \mapsto \boldsymbol{\mathcal{V}}_{l-1}'$ are known as restrictions [40, sect. 3.6]. These operators are purely local and cheaply implemented [43].

The definition of the symmetric multigrid preconditioner is based on the recursive algorithm sketched in Figure 1. There R_l^T is defined by $\left\langle \boldsymbol{\rho}_l, R_l^T \boldsymbol{\phi}_l \right\rangle = \langle \boldsymbol{\phi}_l, R_l \boldsymbol{\rho}_l \rangle$, $\boldsymbol{\rho}_l, \boldsymbol{\phi}_l \in \boldsymbol{\mathcal{V}}_l'$. Based on the algorithm of Figure 1 the application of the multigrid preconditioner $B_h : \boldsymbol{\mathcal{V}}_h \mapsto \boldsymbol{\mathcal{V}}_h'$ can be realized as follows:

$$\mathbf{c}_h := B_h \boldsymbol{\rho}_h \quad \Longleftrightarrow \quad \mathbf{c}_h := 0; \quad \mathsf{mgcycle}(L, \mathbf{c}_h, \boldsymbol{\rho}_h) \ . \tag{3.3}$$

The operators $R_l : \boldsymbol{\mathcal{V}}_l' \mapsto \boldsymbol{\mathcal{V}}_l$ occurring in the algorithm are conventional smoothing operators on level l, $l = 1, \ldots, L$. We will consider only point smoothers of Jacobi- or

```
mgcycle< $A$ > (int $l$,reference $\mathbf{u}_l \in \boldsymbol{\mathcal{V}}_l$, const $\boldsymbol{\rho}_l \in \boldsymbol{\mathcal{V}}'_l$)
{
  if($l == 0$) {   $\mathbf{u}_0 = A_0^{\dagger}\boldsymbol{\rho}_0$   }
  else   {
    // Presmoothing
    for(int $i = 0$ ; $i < \mu_1$ ; $++i$) {   $\mathbf{u}_l \leftarrow \mathbf{u}_l + R_l(\boldsymbol{\rho}_l - A_l\mathbf{u}_l)$   }
    // Coarse grid correction
    $\boldsymbol{\sigma}_l := \boldsymbol{\rho}_l - A_h\mathbf{u}_l$;   $\boldsymbol{\rho}_{l-1} := I_l^*\boldsymbol{\sigma}_l$;   $\mathbf{c}_{l-1} := 0 \in \boldsymbol{\mathcal{V}}_{l-1}$
    for(int $i = 0$ ; $i < \nu$ ; $++i$) {   mgcycle< $A$ >($l-1$,$\mathbf{c}_{l-1}$,$\boldsymbol{\rho}_{l-1}$)   }
    $\mathbf{u}_l \leftarrow \mathbf{u}_l + I_l\mathbf{c}_{l-1}$
    // Postsmoothing
    for(int $i = 0$ ; $i < \mu_2$ ; $++i$) {   $\mathbf{u}_l \leftarrow \mathbf{u}_l + R_l^T(\boldsymbol{\rho}_l - A_l\mathbf{u}_l)$   }
  }
}
```

FIG. 1. *Multigrid algorithm defining the preconditioner B_h. The parameters $\mu_1, \mu_2, \nu \in \mathbb{N}$ define the type of the cycle. For $\nu = 1$ we get a $V(\mu_1, \mu_2)$-cycle and for $\nu = 2$ a $W(\mu_1, \mu_2)$-cycle.*

Gauß–Seidel-type. For the latter, one sweep on level l, $l = 1, \dots, L$, with initial guess $u_l \in \boldsymbol{\mathcal{V}}_l$ and right-hand side $\boldsymbol{\rho}_l \in \boldsymbol{\mathcal{V}}'_l$ reads

$$\textbf{foreach}(\iota \in J_l) \quad \{ \quad \mathbf{u}_l \leftarrow \mathbf{u}_l + \frac{\langle \boldsymbol{\rho}_l, \mathbf{u}_l \rangle}{a(\mathbf{b}_\iota, \mathbf{b}_\iota)} \cdot \mathbf{b}_\iota \quad \} \, .$$

Though A_h is singular, relaxation will go smoothly, as (2.8) guarantees $a(\mathbf{b}_\iota, \mathbf{b}_\iota) > 0$. However, $\mathbf{b}_\iota$ does not exactly belong to $\mathrm{Ker}(A_l)^\perp$. Thus, the action of B_h will invariably introduce components in $\mathrm{Ker}(A_h)$ into the iterates. Eventually the iterates might tumble into the kernel.

To prevent this, we have to weed out the kernel contributions as soon as they are introduced. Formally, this can be done by projecting $\mathbf{y}_h$ from (3.2) onto $\mathrm{Ker}(A_h)^\perp$. Fortunately, if Ω is contractible, the representation of $\mathrm{Ker}(A_h)$ through discrete potentials according to $\mathrm{Ker}(A_h) = G_h\mathcal{S}_h$ enables us to express the $\boldsymbol{L}^2(\Omega)$-orthogonal projection $P_h : \boldsymbol{\mathcal{V}} \mapsto \mathrm{Ker}(A)^\perp$ through

$$P_h := Id - G_h T_h^{\dagger} G_h^* M_h \;, \tag{3.4}$$

where $T_h : \mathcal{S}_h \mapsto \mathcal{S}'_h$ is the operator associated with the bilinear form

$$d : \mathcal{S} \times \mathcal{S} \mapsto \mathbb{R}, \quad d(u_h, v_h) = (G_h u_h, G_h v_h)_0 \,, \quad u_h, v_h \in \mathcal{S}_h \;. \tag{3.5}$$

Yet, the exact computation of $T_h^{\dagger}\rho_h$ for some $\rho_h \in \mathcal{S}'_h$ is hardly feasible. Just recall that in the case of the eigenvalue problem in $\boldsymbol{H}(\mathbf{curl}; \Omega)$ the operator T_h is the discrete Laplacian, i.e., in general described by a huge sparse stiffness matrix. Therefore, we cannot help using an approximate pseudoinverse also in this case. A multigrid scheme analogous to the one outlined in Figure 1 comes in handy, this time to be conducted in the potential space with the operators A_l replaced by their counterparts $T_l : \mathcal{S}_l \mapsto \mathcal{S}'_l$. This will yield an approximate projection $\widetilde{P}_h$

$$\widetilde{P}_h := Id - G_h C_h G_h^* M_h \;, \tag{3.6}$$

where C_h stands for the approximate (pseudo-)inverse of T_h furnished by the multigrid cycle. Reassuringly, we do not have to worry about pollution in $\mathrm{Ker}(G_h)$ this time

```
update(reference $\mathbf{x}_h \in \boldsymbol{\mathcal{V}}_h$,$\kappa \in \mathbb{R}$)
{
  project($\mathbf{x}_h$)
  $\boldsymbol{\phi}_h := A_h\mathbf{x}_h$ ; $\boldsymbol{\psi}_h := M_h\mathbf{x}_h$
  $\boldsymbol{\rho}_h := \boldsymbol{\phi}_h - \kappa \cdot \boldsymbol{\psi}_h$
  $\mathbf{c}_h := 0 \in \boldsymbol{\mathcal{V}}_h$
  mgcycle< $A$ >($L$,$\mathbf{c}_h$,$\boldsymbol{\rho}_h$)
  $\mathbf{x}_h \leftarrow \mathbf{x}_h - \mathbf{c}_h$
  project($\mathbf{x}_h$)
  $\mathbf{x}_h \leftarrow \mathbf{x}_h/|\mathbf{x}_h|$
}
```

```
project(reference $\mathbf{x}_h \in \boldsymbol{\mathcal{V}}_h$)
{
  // Treat harmonic vectorfields
  for(int $i = 1$; $i \leq q$; $++i$)
  { $\mathbf{x}_h \leftarrow \mathbf{x}_h - \left(\widetilde{\mathbf{h}}_i, \mathbf{x}_h\right)_0 \cdot \widetilde{\mathbf{h}}_i$ }
  $\boldsymbol{\eta}_h := M_h\mathbf{x}_h$
  $\phi_h := G_h^*\boldsymbol{\eta}_h$
  $c_h = 0 \in \mathcal{S}_h$
  mgcycle< $T$ >($L$,$c_h$,$\phi_h$)
  $\mathbf{x}_h \leftarrow \mathbf{x}_h - G_h c_h$
}
```

FIG. 2. *Update procedure for PPINVIT.*

because in (3.4) the operator G_h is applied to the result, suppressing any kernel component.

If we have to take into account discrete harmonic vectorfields in $\boldsymbol{\mathcal{H}}_h := \text{Span}\,\{\mathbf{h}_1, \ldots, \mathbf{h}_q\}$, their basis should be approximately orthogonalized to $G_h\mathcal{S}_h$. This can be done once and for all before the actual eigenvalue computations, utilizing a few steps of the approximate multigrid projection $\widetilde{P}_h$. For the sake of efficiency, a nested iteration approach should be employed. Eventually, the basis functions should be $\boldsymbol{L}^2(\Omega)$-orthonormalized to each other by solving a small linear system of equations. If $\widetilde{\mathbf{h}}_1, \ldots, \widetilde{\mathbf{h}}_q$ are the functions thus obtained, $\widetilde{\boldsymbol{\mathcal{H}}}_h := \text{Span}\{\widetilde{\mathbf{h}}_1, \ldots, \widetilde{\mathbf{h}}_q\}$ will be another suitable space of discrete harmonic vectorfields. Given this preprocessing, orthogonality to $\widetilde{\boldsymbol{\mathcal{H}}}_h$ can be easily enforced.

The final algorithm implementing the inexact projection is given in Figure 2 (right). We point out that G_h is a local operator, too, whose matrix representation can be derived from the embedding $G_h\mathcal{S}_h \subset \boldsymbol{\mathcal{V}}_h$ [43, sect. 6]. Let us elucidate this for edge elements: Assuming nodal bases of $\boldsymbol{\mathcal{V}}_h$ and $\mathcal{S}_h$ the evaluation of G_h boils down to simply distributing the nodal values from vertices (to which d.o.f. of $\mathcal{S}_h$ are associated) to edges, taking into account their orientations by means of weights $+1$ or -1.

In the end, incorporating the total action of project into $\tilde{P}_h$, we get the following update formula for an approximate eigenvector:

$$\mathbf{y}_h = \tilde{P}_h(Id - B_h(A_h - \kappa M_h))\tilde{P}_h\mathbf{x}_h, \quad \mathbf{x}_h^{\text{new}} = \mathbf{y}_h / \left\|\mathbf{y}_h\right\|_0 \ . \tag{3.7}$$

Cast into an algorithm, this yields the procedure update displayed in Figure 2 (left).

It is hazardous to replace κ in (3.7) by the plain Rayleigh quotient (3.1) because significant kernel components might remain after the inexact projection. If we set $\kappa = r(\mathbf{x}_h)$, we might encounter $\kappa \ll \lambda$ though $A_h\mathbf{x}_h = \lambda M_h P_h \mathbf{x}_h$; i.e., the components of $\mathbf{x}_h$ in $\text{Ker}(A_h)^{\perp}$ already provide the desired eigenvector. Guided by the idea that the scheme should come close to inverse iteration in the complement $\text{Ker}(A_h)^{\perp}$ we should choose $\kappa = r_{\perp}(\mathbf{x}_h) = \langle A_h\mathbf{x}_h, \mathbf{x}_h\rangle / (P_h\mathbf{x}_h, P_h\mathbf{x}_h)_{\boldsymbol{L}^2(\Omega)}$. In practice, we are denied this option as $P_h\mathbf{x}_h$ is not available. However, we still want a replacement for $r_{\perp}$ that is insensitive to kernel components. A promising candidate is the "two-step Rayleigh quotient"

$$r_Q(\mathbf{x}) = \frac{\langle A_h M_h^{-1} A_h \mathbf{x}_h, \mathbf{x}_h\rangle}{\langle A_h\mathbf{x}_h, \mathbf{x}_h\rangle} \ , \tag{3.8}$$

```
ppinvit_step (reference $(\theta_1, \dots, \theta_s)^T \in \mathbb{R}^s$, reference $(\mathbf{x}_h^1, \dots, \mathbf{x}_h^s) \in (\boldsymbol{\mathcal{V}}_h)^s$)
{
  // Ritz-projection
  for($i = 1$ ; $i \leq s$ ; $++i$)   {
    $\boldsymbol{\phi}_h^i := A_h \mathbf{x}_h^i$;   $\mathbf{z}_h^i = \lambda_i \mathbf{x}_h^i$;   $\mathsf{cg}^m < M_h > (\mathbf{z}_h^i, \boldsymbol{\phi}_h^i)$
    $a_{ii} := \langle \boldsymbol{\phi}_h^i, \mathbf{z}_h^i \rangle$;   $m_{ii} := \langle \boldsymbol{\phi}_h^i, \mathbf{x}_h^i \rangle$
    for($j = 1$ ; $j < i$ ; $++i$) { $a_{ij} = a_{ji} := \left\langle \boldsymbol{\phi}_h^j, \mathbf{z}_h^i \right\rangle$;   $m_{ij} = m_{ji} := \left\langle \boldsymbol{\phi}_h^j, \mathbf{x}_h^i \right\rangle$ }
  } // Rayleigh–Ritz procedure
  $\mathsf{A}_s := (a_{ij}) \in \mathbb{R}^{s,s}$;   $\mathsf{M}_s := (m_{ij}) \in \mathbb{R}^{s,s}$;
  Find $\mathsf{Y} \in \mathbb{R}^{s,s}$ and Ritz values $\Theta = \operatorname{diag}(\theta_1, \dots, \theta_s)$ such that   $\mathsf{A}_s \mathsf{Y} = \mathsf{M}_s \mathsf{Y} \Theta$
  // Ritz vectors
  $(\mathbf{x}_h^1, \dots, \mathbf{x}_h^s) \leftarrow (\mathbf{x}_h^1, \dots, \mathbf{x}_h^s) \cdot \mathsf{Y}$
  // Approximate projected inverse iteration
  for($i = 1$ ; $i \leq s$ ; $++i$)   { update($\mathbf{x}_h^i, \theta_i$)  }
}
```

FIG. 3. *One step of the subspace variant of the algorithm for PPINVIT.* $\mathsf{cg}^m < M_h > (\mathbf{z}_h, \text{Œ}_h)$ *refers to* $m \in \mathbb{N}$ *CG-steps for the solution of* $M_h \mathbf{z}_h = \text{Œ}_h$.

with $r_Q(\mathbf{x}) \geq r_\perp(\mathbf{x}_h) \geq r(\mathbf{x}_h)$. Obviously, it yields an eigenvalue if we have already hit an eigenvector in $\operatorname{Ker}(A_h)^\perp$. Two issues arise, nevertheless: First, there is a risk of breakdown if $A_h \mathbf{x}_h = 0$. This means that the current approximate eigenvector lies in $\operatorname{Ker}(A_h)$, which hints at inadequate approximate projections. A way to detect and cure this condition will be discussed in section 5. The second problem is that the evaluation of (3.8) entails the solution of a linear system $M_h \mathbf{z}_h = A_h \mathbf{x}_h$ for the mass matrix M_h. As M_h is well conditioned unless some elements are badly distorted, a few steps of an iterative method (CG,Gauß–Seidel) will usually give a reasonable approximate solution. Moreover, if $(\lambda, \mathbf{x}_h)$ is already close to an eigenvalue/eigenvector pair, $\lambda \mathbf{x}_h$ is an excellent initial guess.

With all building blocks in place, we can now state the crucial update step of the algorithm for the computation of the s, $s \in \mathbb{N}$, smallest nonzero eigenvalues and corresponding eigenvectors of (2.7). Its details are given in Figure 3. The procedure ppinvit_step is meant to improve on approximations θ_i and $\mathbf{x}_h^i$, $i = 1, \dots, s$, for eigenvalues and eigenvectors.

The discussion of termination criteria is postponed until section 5. Initial guesses for the eigenvectors can easily be obtained through nested iteration by prolongating approximate eigenfunction from coarser grids.

Remark. For positive definite operators the Rayleigh–Ritz method is often applied to a modified/enlarged subspace (consisting of the actual subspace, the actual search directions, and possibly the old iterates). This is known to improve convergence [48,49] if $A_h > 0$. Yet, this trick is not advisable for the semidefinite problem because a massive amplification of kernel components might occur.

4. Convergence.

The theoretical examination of the algorithm starts with the $\boldsymbol{L}^2(\Omega)$-orthogonal decomposition and dual polar decomposition

$$\boldsymbol{\mathcal{V}}_h = \boldsymbol{\mathcal{X}}_h \otimes \boldsymbol{\mathcal{Z}}_h \,,\; \boldsymbol{\mathcal{Z}}_h := \operatorname{Ker}(A_h), \quad \boldsymbol{\mathcal{V}}_h' = \boldsymbol{\mathcal{X}}_h' \otimes \boldsymbol{\mathcal{Z}}_h' \,. \tag{4.1}$$

With respect to the splittings (4.1) the operators can be written in block form. For a symmetric preconditioner it reads

$$B_h = \begin{pmatrix} B_{\perp\!\!\perp} & B_{0\perp} \\ B_{0\perp}^T & B_{00} \end{pmatrix} : \boldsymbol{\mathcal{X}}_h' \otimes \boldsymbol{\mathcal{Z}}_h' \mapsto \boldsymbol{\mathcal{X}}_h \otimes \boldsymbol{\mathcal{Z}}_h \ , \tag{4.2}$$

and for the other operators

$$A_h = \begin{pmatrix} A_\perp & 0 \\ 0 & 0 \end{pmatrix}, \ M_h = \begin{pmatrix} M_\perp & 0 \\ 0 & M_0 \end{pmatrix}, \ A_h^\dagger = \begin{pmatrix} A_\perp^{-1} & 0 \\ 0 & 0 \end{pmatrix} \ \widetilde{P}_h = \begin{pmatrix} Id_\perp & 0 \\ 0 & P_0 \end{pmatrix}.$$

These formulas are immediate from the definition of the operators and the properties of the splittings. Be aware that $B_{0\perp} \neq 0$ causes the pollution by kernel components, and $P_0 \neq 0$ hints at an inexact projection.

Using $A_h A_h^\dagger + Q_h^* = Id_h^*$, where $Q_h : \boldsymbol{\mathcal{V}}_h \mapsto \boldsymbol{\mathcal{Z}}_h$ is the $\boldsymbol{L}^2(\Omega)$-orthogonal projection, we obtain from (3.7) with $\kappa = r_Q(\mathbf{x}_h)$

$$\mathbf{y}_h = \widetilde{P}_h \left((I_h - B_h A_h)(I_h - \kappa A_h^\dagger M_h) + \kappa B_h Q_h^* M_h + \kappa A_h^\dagger M_h \right) \widetilde{P}_h \mathbf{x}_h \ .$$

Splitting $\mathbf{y}_h = \mathbf{y}^0 + \mathbf{y}^\perp$, $\mathbf{x}_h = \mathbf{x}^0 + \mathbf{x}^\perp$, $\mathbf{x}^0, \mathbf{y}^0 \in \boldsymbol{\mathcal{Z}}_h$, $\mathbf{y}^\perp, \mathbf{x}^\perp \in \boldsymbol{\mathcal{X}}_h$ and plugging in the block forms of the operators leads to

$$\begin{pmatrix} \mathbf{y}^\perp - \mathbf{z}_h \\ \mathbf{y}^0 \end{pmatrix} = \begin{pmatrix} Id_\perp & 0 \\ 0 & P_0 \end{pmatrix} \left(\begin{pmatrix} Id_\perp - B_{\perp\!\!\perp} A_\perp & 0 \\ -B_{0\perp}^T A_\perp & Id_0 \end{pmatrix} \begin{pmatrix} Id_\perp - \kappa A_\perp^{-1} M_\perp & 0 \\ 0 & Id_0 \end{pmatrix} \right.$$
$$\left. + \begin{pmatrix} 0 & \kappa B_{0\perp} M_0 \\ 0 & \kappa B_{00} M_0 \end{pmatrix} \right) \begin{pmatrix} Id_\perp & 0 \\ 0 & P_0 \end{pmatrix} \begin{pmatrix} \mathbf{x}^\perp \\ \mathbf{x}^0 \end{pmatrix}$$

with $\mathbf{z}_h := \kappa A_\perp^{-1} M_\perp \mathbf{x}^\perp$. This results in a kind of *error propagation equation*

$$\begin{pmatrix} \mathbf{y}^\perp - \mathbf{z}_h \\ \mathbf{y}^0 \end{pmatrix} = \begin{pmatrix} Id_\perp - B_{\perp\!\!\perp} A_\perp & \kappa B_{0\perp} M_0 P_0 \\ -P_0 B_{0\perp}^T A_\perp & P_0 (Id_0 + \kappa B_{00} M_0) P_0 \end{pmatrix} \begin{pmatrix} \mathbf{x}^\perp - \mathbf{z}_h \\ \mathbf{x}^0 \end{pmatrix} . \tag{4.3}$$

Note that $(\mathbf{z}_h, 0)^T$ is what an exact inverse iteration for the pseudoinverse would give us before scaling. Thus (4.3) reflects how much PPINVIT differs from an exact inverse iteration. Next, we aim at quantitative estimates of this deviation. To this end we seek bounds for norms of the block-operators in (4.3).

Various norms need to be considered for operators $X_h : \boldsymbol{\mathcal{V}}_h \mapsto \boldsymbol{\mathcal{V}}_h$:

$$\|X_h\|_{0\to 0} := \sup_{\mathbf{v}_h \in \boldsymbol{\mathcal{V}}_h} \frac{\|X_h \mathbf{v}_h\|_0}{\|\mathbf{v}_h\|_0}, \quad \|X_h\|_{Z\to 0} := \sup_{\mathbf{v}_h \in \boldsymbol{\mathcal{Z}}_h} \frac{\|X_h \mathbf{v}_h\|_0}{\|\mathbf{v}_h\|_0},$$
$$\|X_h\|_{A\to A} := \sup_{\mathbf{v}_h \in \boldsymbol{\mathcal{V}}_h} \frac{\|X_h \mathbf{v}_h\|_A}{\|\mathbf{v}_h\|_A}, \quad \|X_h\|_{A\to 0} := \sup_{\mathbf{v}_h \in \boldsymbol{\mathcal{V}}_h} \frac{\|X_h \mathbf{v}_h\|_0}{\|\mathbf{v}_h\|_A},$$
$$\|X_h\|_{Z\to A} := \sup_{\mathbf{v}_h \in \boldsymbol{\mathcal{Z}}_h} \frac{\|X_h \mathbf{v}_h\|_A}{\|\mathbf{v}_h\|_0}.$$

In order to bound the operator norm $\|I - B_{\perp\!\!\perp} A_\perp\|_{A\to A}$ we remember that $\|\cdot\|_A$ is the energy-seminorm in $\boldsymbol{H}(\mathbf{curl};\Omega)$ and $\boldsymbol{H}(\mathrm{div};\Omega)$, respectively. In other words, this norm agrees with the convergence rate of the multigrid method in the energy-seminorm. In [41, 43, 44] it was shown that this convergence rate is bounded away from 1 independently of the number L of grid levels involved in the multigrid scheme. This justifies the assumption

$$\textbf{(A1)} \qquad \|Id_\perp - B_{\perp\!\!\!\perp} A_\perp\|_{A\to A} \le \gamma < 1\ .$$

In fact, numerical experiments give evidence that we can expect γ to be smaller than 0.5, at worst [43].

Next, we have to gauge the impact of the inexact projection. Again, we can rely on theoretical results and practical experience with multigrid methods to justify

$$\textbf{(A2)} \qquad \|G_h(Id_h - C_hT_h)u_h\|_0 \le \beta\,\|G_hu_h\|_0 \quad \forall u_h \in \mathcal{S}_h$$

for $\beta < 1$ uniformly in L. Note that β is the convergence rate of the iterative solver in potential space. The practical range for β will be the same as for γ. From (**A2**) and $T_h = G_h^* M_h G_h$ we conclude

$$\lambda_{\max}(G_h(T_h^\dagger - C_h)G_h^*M_h) = \lambda_{\max}(G_h^*M_hG_h(T_h^\dagger - C_h)) = \lambda_{\max}(Id_h - T_hC_h) = \beta\ .$$

Because of $(Id_h - G_hT_h^\dagger G_h^* M_h)\mathbf{x}_h^0 = 0$ for $\mathbf{x}_h^0 \in \boldsymbol{\mathcal{Z}}_h$, this teaches us that

$$\begin{aligned}\|P_0\mathbf{x}_h^0\|_0 &= \|\mathbf{x}_h^0 - G_hC_hG_h^*M_h\mathbf{x}_h^0\|_0\\ &\le \left\|(Id_h - G_hT_h^\dagger G_h^*M_h + G_h(T_h^\dagger - C_h)G_h^*M_h)\mathbf{x}_h^0\right\|_0\\ &\le \left\|G_h(T_h^\dagger - C_h)G_h^*M_h\mathbf{x}_h^0\right\|_0 \le \beta\,\|\mathbf{x}_h^0\|_0\ .\end{aligned} \tag{4.4}$$

The remaining terms involving the multigrid preconditioner will be tackled under the restrictive assumption of uniform refinement creating a quasi-uniform hierarchy of meshes. Hence, we have inverse estimates at our disposal. In addition, we take for granted a geometric decrease of the meshwidths and symmetric smoothing operators, i.e., $R_h = R_h^T$. Please note that these assumptions are needed only for the sake of theoretical treatment.

Under the above circumstances, the symmetric bilinear form $s_l : \boldsymbol{\mathcal{V}}_l \times \boldsymbol{\mathcal{V}}_l \mapsto \mathbb{R}$ that defines the smoother R_l via

$$s_l(R_l\boldsymbol{\phi}_l, \mathbf{v}_l) = \boldsymbol{\phi}_l(\mathbf{v}_l) \quad \forall \mathbf{v}_l \in \boldsymbol{\mathcal{V}}_l,\ \boldsymbol{\phi}_l \in \boldsymbol{\mathcal{V}}_l'$$

fulfills

$$Ch_l^{-2}\,(\mathbf{u}_l, \mathbf{u}_l)_0 \le s(\mathbf{u}_l, \mathbf{u}_l) \le Ch_l^{-2}\,(\mathbf{u}_l, \mathbf{u}_l)_0 \quad \forall \mathbf{u}_l \in \boldsymbol{\mathcal{V}}_l\ .$$

For the point smoothers that we have in mind, this is a consequence of (2.8). In particular, $s(\cdot,\cdot)$ turns out to be positive definite. Then the Cauchy–Schwarz inequality gives for $\mathbf{x}_l^0 \in \boldsymbol{\mathcal{Z}}_l$

$$\begin{aligned}\|R_lM_l\mathbf{x}_l^0\|_0^2 &\le Ch_l^2 s(R_lM_l\mathbf{x}_l^0, R_lM_l\mathbf{x}_l^0) = Ch_l^2 \sup_{\mathbf{w}_l\in\boldsymbol{\mathcal{V}}_l} \frac{s(R_lM_l\mathbf{x}_l^0, \mathbf{w}_l)^2}{s(\mathbf{w}_l, \mathbf{w}_l)}\\ &\le Ch_l^4 \sup_{\mathbf{w}_l\in\boldsymbol{\mathcal{V}}_l} \frac{\langle M_l\mathbf{x}_l^0, \mathbf{w}_l\rangle^2}{\|\mathbf{w}_l\|_0^2} \le Ch_l^4\,\|\mathbf{x}_l^0\|_0^2\ ,\end{aligned}$$

from which we infer

$$\|R_lM_l\|_{Z\to 0} \le Ch_l^2 \quad \text{and} \quad \|R_lM_l\|_{Z\to A} \le Ch_l\ . \tag{4.5}$$

The latter estimate is a consequence of the inverse inequalities (2.3) that involve

$$a(\mathbf{u}_l, \mathbf{u}_l) \le Ch_l^{-2} \left\| \mathbf{u}_l \right\|_0^2 \ . \tag{4.6}$$

The same arguments reveal

$$\begin{aligned} \left\| R_l A_l \mathbf{x}_l \right\|_0^2 &\le Ch_l^2 \, s(R_l A_l \mathbf{x}_l, R_l A_l \mathbf{x}_l) = Ch_l^2 \sup_{\mathbf{w}_l \in \boldsymbol{\mathcal{V}}_l} \frac{s(R_l A_l \mathbf{x}_l, \mathbf{w}_l)^2}{s(\mathbf{w}_l, \mathbf{w}_l)} \\ &\le Ch_l^4 \sup_{\mathbf{w}_l \in \boldsymbol{\mathcal{X}}_l} \frac{\langle A_l \mathbf{x}_l, \mathbf{w}_l \rangle^2}{\left\| \mathbf{w}_l \right\|_0^2} \le Ch_l^2 \left\| \mathbf{x}_l \right\|_A^2 \ . \end{aligned}$$

The inverse inequality in $\boldsymbol{\mathcal{V}}_l$ is concealed in the final estimate. Eventually,

$$\left\| R_l A_l \right\|_{A \to 0} \le Ch_l \quad \text{and} \quad \left\| R_l A_l \right\|_{A \to A} \le C \ . \tag{4.7}$$

Now we are in a position to examine the full multigrid cycle. For the sake of simplicity the analysis is confined to a V(1,1)-cycle.

THEOREM 4.1. *Assume a hierarchy of shape-regular, quasi-uniform meshes with geometrically decreasing meshwidths. In addition, the smoothers have to be symmetric and are to provide convergent linear iterations in the* $\left\| \cdot \right\|_A$*-seminorm. Then the preconditioners* B_l *spawned by* $V(1,1)$*-cycles satisfy*

$$\left\| B_l A_l \right\|_{A \to 0} \le K_A, \quad \left\| B_l M_l \right\|_{Z \to 0} \le K_0, \quad \left\| B_l M_l \right\|_{Z \to A} \le K_\perp \ ,$$

with constants $K_A > 0$*,* $K_0 > 0$*, and* $K_\perp > 0$ *that depend on the shape regularity of the meshes* $\mathcal{T}_0, \dots, \mathcal{T}_L$*, but not on* l*.*

Proof. The recursive nature of the multigrid algorithm suggests that we study two subsequent levels l and $l-1$. For ease of notation, we will use a subscript h to refer to level l (fine grid), and H will tag entities associated with level $l-1$ (coarse grid).

We retrace the single steps of the algorithm of Figure 1 and start with $\boldsymbol{\rho}_h := A_h \mathbf{x}_h$ for some $\mathbf{x}_h \in \boldsymbol{\mathcal{V}}_h$. Presmoothing takes it to $\mathbf{w}_h := R_h A_h \mathbf{x}_h$ since a zero initial guess has to be used. Afterwards, the coarse grid correction will result in $\mathbf{c}_H := B_H I_h^* A_h (\mathbf{x}_h - \mathbf{w}_h)$. Then, with $P_h^H : \boldsymbol{\mathcal{V}}_h \mapsto \boldsymbol{\mathcal{X}}_H$ denoting the $a(\cdot,\cdot)$-orthogonal projection, we infer from $I_h^* A_h = A_H P_h^H$ that $\mathbf{c}_H = B_H A_H P_h^H (Id_h - R_h A_h) \mathbf{x}_h$. As the multigrid method is supposed to converge in the $\left\| \cdot \right\|_A$-seminorm, $\left\| Id_H - B_H A_H \right\|_{A \to A} < 1$ is guaranteed, so that

$$\left\| B_H A_H \right\|_{A \to A} \le 2 \ . \tag{4.8}$$

The smoother alone also provides a convergent iteration, i.e., $\left\| Id_h - R_h A_h \right\|_{A \to A} < 1 \Rightarrow \left\| R_h A_h \right\|_{A \to A} \le 2$, such that

$$\left\| \mathbf{c}_H \right\|_0 \le \left\| B_H A_H \right\|_{A \to 0} \left\| \mathbf{x}_h \right\|_A , \quad \left\| \mathbf{c}_H \right\|_A \le 2 \left\| \mathbf{x}_h \right\|_A \ .$$

With $\mathbf{u}_h := \mathbf{w}_h + I_h \mathbf{c}_H$, which, due to (4.7), fulfills

$$\left\| \mathbf{u}_h \right\|_0 \le (\left\| B_H A_H \right\|_{A \to 0} + Ch) \left\| \mathbf{x} \right\|_A , \quad \left\| \mathbf{u}_h \right\|_A \le 4 \left\| \mathbf{x}_h \right\|_A \ ,$$

we can express the result of postsmoothing as

$$B_h A_h \mathbf{x}_h = \mathbf{u}_h + R_h (A_h \mathbf{x}_h - A_h \mathbf{u}_h) = \mathbf{w}_h + \mathbf{u}_h - R_h A_h \mathbf{u}_h \ .$$

Again, we invoke (4.7) and see

$$\|B_h A_h \mathbf{x}_h\|_0 \leq (\|B_H A_H\|_{A\to 0} + Ch)\,\|\mathbf{x}\|_A + Ch\,\|\mathbf{u}_h\|_A \leq (\|B_H A_H\|_{A\to 0} + Ch)\,\|\mathbf{x}\|_A\,.$$

Consequently, $\|B_h A_h\|_{A\to 0} \leq \|B_H A_H\|_{A\to 0} + Ch$. Taking into account that $B_0 = A_0^\dagger$, i.e., $\|B_0 A_0\|_{A\to 0} = 0$, and the geometric decrease of the meshwidths, this ensures $\|B_h A_h\|_{A\to 0} \leq K_A$, for $K_A > 0$ independent of the level.

Analogous considerations can be carried out with $\boldsymbol{\rho}_h := M_h \mathbf{x}_h^0$ for some $\mathbf{x}_h^0 \in \boldsymbol{\mathcal{Z}}_h$. Presmoothing yields $\mathbf{w}_h := R_h \boldsymbol{\rho}_h = R_h M_h \mathbf{x}_h^0$, and after the cycle on the coarse grid we end up with

$$\mathbf{c}_H = \mathbf{c}_1 + \mathbf{c}_2 := B_H I_h^* M_h \mathbf{x}_h^0 + B_H I_h^* A_h \mathbf{w}_h\,. \tag{4.9}$$

As $I_h^* M_h = M_H Q_h^H$, where $Q_h^H : \boldsymbol{\mathcal{V}}_h \mapsto \boldsymbol{\mathcal{V}}_H$ is the $\boldsymbol{L}^2(\Omega)$-orthogonal projection, we get for the first contribution to $\mathbf{c}_H$

$$\|\mathbf{c}_1\|_0 \leq \|B_H M_H\|_{Z\to 0}\,\|\mathbf{x}_h^0\|_0\,, \quad \|\mathbf{c}_1\|_A \leq \|B_H M_H\|_{Z\to A}\,\|\mathbf{x}_h^0\|_0\,. \tag{4.10}$$

Similarly, from $I_h^* A_h = A_H P_h^H$, (4.5), and (4.8), it follows that

$$\begin{aligned}\|\mathbf{c}_2\|_0 &\leq \|B_H A_H P_h^H \mathbf{w}_h\|_0 \leq \|B_H A_H\|_{A\to 0}\,\|\mathbf{w}_h\|_A \leq Ch\,\|B_H A_H\|_{A\to 0}\,\|\mathbf{x}_h^0\|_0\,,\\ \|\mathbf{c}_2\|_A &\leq \|B_H A_H P_h^H \mathbf{w}_h\|_A \leq \|B_H A_H\|_{A\to A}\,\|\mathbf{w}_h\|_A \leq Ch\,\|\mathbf{x}_h^0\|_0\,.\end{aligned}$$

Combining this with (4.9), (4.10), and the result of the first part of the proof yields

$$\|\mathbf{c}_H\|_0 \leq (\|B_H M_H\|_{Z\to 0} + ChK_A)\,\|\mathbf{x}_h^0\|_0\,, \tag{4.11}$$

$$\|\mathbf{c}_H\|_A \leq (\|B_H M_H\|_{Z\to A} + Ch)\,\|\mathbf{x}_h^0\|_0\,. \tag{4.12}$$

Next, we consider the coarse grid correction $\mathbf{u}_h = \mathbf{w}_h + I_h \mathbf{c}_H$. As the prolongation is an identity mapping in disguise, the following estimates are straightforward from (4.11), (4.12), and (4.5):

$$\|\mathbf{u}_h\|_0 \leq \left(\|B_H M_H\|_{Z\to 0} + ChK_A + Ch^2\right)\|\mathbf{x}_h^0\|_0\,, \tag{4.13}$$

$$\|\mathbf{u}_h\|_A \leq (\|B_H M_H\|_{Z\to A} + Ch)\,\|\mathbf{x}_h^0\|_0\,. \tag{4.14}$$

The postsmoothing results in $B_h M_h \mathbf{x}_h^0 = \mathbf{u}_h + \mathbf{w}_h - R_h A_h \mathbf{u}_h$. By (4.7) and (4.8) we know

$$\|R_h A_h \mathbf{u}_h\|_0 \leq Ch\,\|\mathbf{u}_h\|_A\,, \quad \|R_h A_h \mathbf{u}_h\|_A \leq C\,\|\mathbf{u}_h\|_A\,. \tag{4.15}$$

First, appealing to (4.14), (4.5), and the assumed $\|\cdot\|_A$-convergence of the smoothing iterations, we find

$$\|B_h M_h \mathbf{x}_h^0\|_A \leq (\|B_H M_H\|_{Z\to A} + Ch)\,\|\mathbf{x}_h^0\|_0\,.$$

On the coarsest grid $l = 0$, we have $B_{00} M_0 = 0$ and $B_{0\perp} M_0 = 0$. Then the geometric decrease of the meshwidth leads to the assertion of the lemma for $\|B_l M_l\|_{Z\to A}$. The same argument can be applied to $\|B_l M_l\|_{Z\to 0}$ because from (4.13), (4.5), (4.15), and (4.14) we can infer

$$\|B_h M_h \mathbf{x}_h^0\|_0 \leq \left(\|B_H M_H\|_{Z\to 0} + Ch(K_A + K_\perp) + Ch^2\right)\|\mathbf{x}_h^0\|_0\,. \qquad \square$$

Now, we can convert (4.3) into the estimates

$$\begin{pmatrix} \left\|\mathbf{y}_h^\perp - \kappa\mathbf{z}_h\right\|_A \\ \left\|\mathbf{y}_h^0\right\|_0 \end{pmatrix} \leq \begin{pmatrix} \gamma & \kappa K_\perp \beta \\ K_A\beta & \beta^2(1+\kappa K_0) \end{pmatrix} \begin{pmatrix} \left\|\mathbf{x}_h^\perp - \kappa\mathbf{z}_h\right\|_A \\ \left\|\mathbf{x}_h^0\right\|_0 \end{pmatrix} . \tag{4.16}$$

All the constants are basically independent of the meshwidth and the number L of levels involved in the multigrid solvers. A quantitative conclusion can be rigorously drawn from (4.16) (see [45] for the technical proof).

THEOREM 4.2. *If $\kappa := \kappa_Q < \kappa^*$ for all steps of the iteration and the initial iterate $\mathbf{x}_h$ satisfies*

$$\frac{\left\|\mathbf{x}_h^0\right\|_0}{\left\|\mathbf{x}_h\right\|_A} \leq \frac{(1-\gamma)}{2\kappa^* K_\perp},$$

then this will hold for all other iterates, provided that β is below a threshold depending on $K_A, K_\perp, K_0$, and γ only.

This guarantees that the iterates cannot plunge into the kernel if a sufficient damping of kernel components is achieved by the projection.

Heuristic insights into the significance of (4.16) can be gained from the theory of PINVIT in the positive definite case [50, 61, 62]. If, with $\kappa = r_\perp$, for some positive $\Gamma < 1$

$$\left\|\mathbf{y}_h^\perp - \kappa A_\perp^{-1} M_\perp \mathbf{x}_h^\perp\right\|_A \leq \Gamma \left\|\mathbf{x}_h^\perp - \kappa A_\perp^{-1} M_\perp \mathbf{x}_h^\perp\right\|_A , \tag{4.17}$$

the PINVIT convergence theory in [50] gives a simple sharp estimate for the Rayleigh quotient $r_\perp$ of the new iterate $\mathbf{y}_h^\perp$ (cf. Theorem 1 in [50]), demonstrating that PINVIT converges at least linearly to the eigenvalue λ_1.

In the semidefinite case the theory applies to PINVIT in $\mathrm{Ker}(A)^\perp$ only for the unrealistic choice of a perfect projection, i.e., $\beta = 0$. Such an exact projection is prohibitively expensive. Hence, we prefer to deal with moderately small $\beta > 0$. Consequently, we have to accept that the iterates in $\mathrm{Ker}(A)^\perp$ will inevitably be perturbed by the term $\kappa B_{0\perp} M_0 P_0 \mathbf{x}^0$ in (4.3). Nevertheless, (4.17) may hold with $\Gamma < 1$ throughout the iteration. Then convergence according to the PINVIT theory is guaranteed (apart from the minor modification of replacing $r_\perp$ by r_Q). Unfortunately, if $\left\|\mathbf{x}_h^\perp - \kappa A_\perp^{-1} M_\perp \mathbf{x}_h^\perp\right\|_A \ll \left\|\mathbf{x}_h^0\right\|_0$ the constant in (4.17) may blow up. However, (4.16) teaches that in this case a significant reduction of the kernel component will be achieved, provided that β is sufficiently small. Hence, $\Gamma > 1$ might happen in a single step, but in the next step (4.17) is likely to hold with a rather small Γ. In other words, for a $\beta \ll 1$ the kernel components are damped out in the course of the iteration. Therefore, the perturbations become more and more insignificant. This effect is elusive, and we have not succeeded in giving a rigorous analysis.

Let us study as a low-dimensional model system the eigenvalue problem for $A_h = \mathrm{diag}(2, 5, 8, 0)$ and $M_h = Id$ with $\gamma = 0.5$. Then the preconditioner B_h is a 4×4 matrix. We take $b_{\max}$ as the bound for the absolute value of B_{00} and for the A-norm of $B_{0\perp}$.[1] Figure 4 illustrates the relative damping of kernel components by PPINVIT. Therefore, the maximal ratio $|x_h^0|/|x_h|$ after 10 steps of PPINVIT using the two-step

[1] Note that the low dimension of the model problem is motivated by the fact that PINVIT takes its extremal convergence in a two-dimensional space which is spanned by those eigenvectors whose corresponding eigenvalues enclose the Rayleigh quotient of the actual iterate. Moreover, as a result of Lemma 3.1 in [61] the assumption that all eigenvalues are of the algebraic multiplicity 1 appears nonrestrictive.

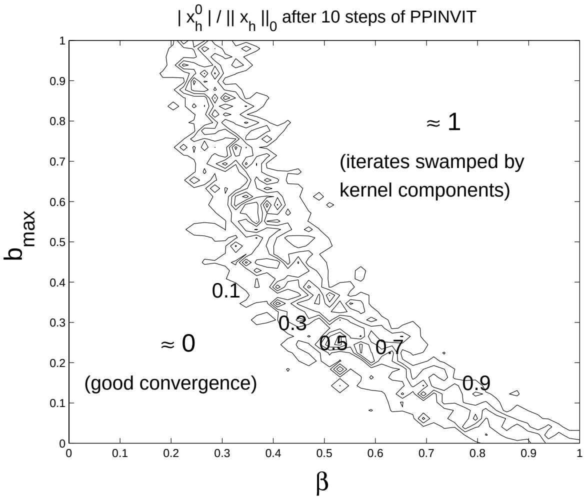

FIG. 4. *Relative damping of the kernel component for the model problem.*

Rayleigh quotient r_Q is displayed in a contour plot for $\beta \in [0,1]$ and $b_{\max} \in [0,1]$. The maximal ratio has been determined for each point of the underlying 50×50 grid among 150000 combinations of random preconditioners and random start vectors with a fixed initial kernel component. For $\beta < 0.2$ the kernel is damped out very well independently of the choice of $b_{\max}$. We conclude that a sufficiently good projection can weed out the kernel components after a modest number of iterations.

The same conclusion can be drawn from a second experiment: We recorded the components of those iterates that display the poorest convergence of r_Q in the first and fourth step of PPINVITT (Figure 5). For 10^7 combinations of random preconditioners ($\gamma = 0.5$, $\beta = 0.25$, $b_{\max} = 0.2$) the components are plotted against the two-step Rayleigh quotients r_Q of those iterates. In the first step of PPINVIT the kernel components appear as the dominating part. In the fourth step we identify the ith and $i+1$th component as the prevailing ones if $r_Q \in [\lambda_i, \lambda_{i+1}]$. The kernel has all but disappeared. Thus, Figure 5 highlights a key trait of PPINVIT: *Convergence is brought about by the subtle interaction of multiple steps.*

5. Projection control and termination criteria. The theoretical considerations highlight the importance of a good projection: It goes without saying that the method will fail if the projection is too weak to reign in kernel components. Taking the cue from Theorem 4.2, we aim to force the ratio $\|\mathbf{x}_h^0\|_0 : \|\mathbf{x}_h\|_A$ below a threshold $\delta > 0$ for all iterates.

From the properties of the inexact projection $\widetilde{P}_h$ and (4.4) we learn that

$$\frac{\beta}{1-\beta} \cdot \frac{\|\mathbf{x}_h - \widetilde{P}\mathbf{x}_h\|_0}{\|\mathbf{x}_h\|_A} \le \delta \quad \Longrightarrow \quad \frac{\|P_0\mathbf{x}_h\|_0}{\|\mathbf{x}_h\|_A} \le \delta\,. \tag{5.1}$$

Of course, good bounds for β are hard to get. We take a crude estimate based on the decrease of the $L^2(\Omega)$-norm of the residual during a multigrid sweep. It is computed whenever a projection is carried out, and β is chosen to be the maximum of all estimates thus obtained. The final adaptive projection is depicted in Figure 6. There, $\sigma \in]0,1[$ is a safety factor intended to prevent gross underestimation of β.

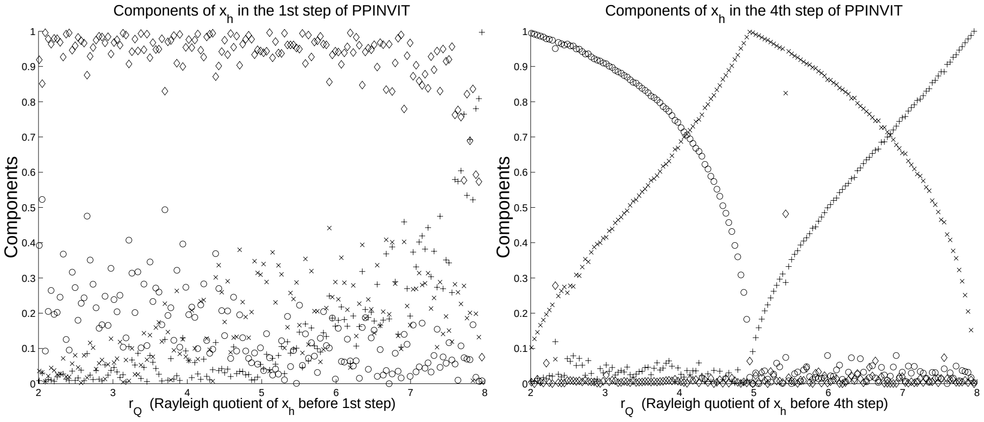

FIG. 5. *Components of those iterates x_h showing poorest convergence (i.e., the smallest decrease of the Rayleigh quotient in one PPINVIT step) for the model problem. FIG. 6. *Enhanced projection with adaptive control. The global variable $\bar{\beta}$ is set to* 0 *initially.*

Our next concern is the termination of the iteration. After the completion of the Rayleigh–Ritz procedure (cf. Figure 3) there are on hand the Ritz values θ_i and the Ritz vectors $\mathbf{x}_h^i$ with $\|\mathbf{x}_h^i\|_0 = 1$, $i = 1, \dots, s$. The M_h^{-1}-norm of the residual $\mathbf{r}_h^i = A_h\mathbf{x}_h^i - \theta_i M_h \mathbf{x}_h^i$ provides a simple residual bound [64] for the quality of the Ritz value θ_i. It is guaranteed that in each interval $[\theta_i - \|\mathbf{r}_h^i\|_{M_h^{-1}}, \theta_i + \|\mathbf{r}_h^i\|_{M_h^{-1}}]$ an eigenvalue of (A_h, M_h) is contained. For disjoint intervals the θ_i provide s approximations to s different eigenvalues of (A_h, M_h). In practice, the inverse of the mass matrix may be approximated through one Gauß–Seidel step. This yields a quantity that is equivalent to the M_h^{-1}-norm independent of the meshwidth.

Beyond, we suggest that the ratio r/r_Q of Rayleigh-quotients of approximate eigenfunctions is used to judge whether the iteration has been successful. Only if it is very close to 1 can the results be trusted.

Remark. It is not a moot point that δ should be reduced during the iteration as the approximate eigenvectors get closer and closer to the exact eigenvectors. However, we failed to find a strategy with heuristic, let alone rigorous, underpinning.

6. Numerical experiments. For all numerical experiments covered in this section we relied on lowest order edge/face elements on uniform Cartesian grids. Ritz projections and eigenvalues/eigenfunctions on the coarsest grids were determined by means of suitable LAPACK routines. All computations were carried out in double precision arithmetic, whereas the matrices were stored in single precision format. We computed seven eigenfunction/eigenvalue pairs in each case. Unless stated otherwise, the eigenvalue problem (1.1) is investigated.

For the tests we resorted to a setting marked by discontinuous coefficients and a reentrant corner, more precisely $\Omega :=]0,1[^3 \backslash [0,\frac{1}{3}]^3$, $\Gamma_N := \bar{\Omega} \cap \{x_1 = 1\}$, and

$$\alpha(\mathbf{x}) = \begin{cases} 1 & \text{if } x_2 < \frac{2}{3} \;, \\ 100 & \text{if } x_2 \geq \frac{2}{3} \text{ and } \frac{1}{3} \leq x_1, x_3 \leq \frac{2}{3} \;, \\ 10 & \text{elsewhere .} \end{cases}$$

This creates challenging conditions for multigrid methods. The uniform grid on level l, $l = 0, \ldots, 5$, consisted of $26 \cdot 8^l$ equal cubes. This means that for $l = 5$ the discretized problems (1.1) and (1.2) feature 2599200 and 2626560 d.o.f., respectively.

Experiment 1. To begin with, we monitored the behavior of the "two-step" Rayleigh quotients r_Q from (3.8) and the M_l^{-1}-norms $\left\langle M_l^{-1} \boldsymbol{\rho}_l, \boldsymbol{\rho}_l \right\rangle^{1/2}$ of the residuals $\boldsymbol{\rho}_l := A_l \mathbf{x}_l - r_Q(\mathbf{x}_l) M_l \mathbf{x}_l$ of approximate eigenfunctions $\mathbf{x}_l \in \boldsymbol{\mathcal{V}}_l$, $l = 3, 4, 5$. Of course, $M_l^{-1} \boldsymbol{\rho}_l$ could not be computed exactly but was realized by two Gauß–Seidel (GS)-sweeps. Both quantities were tracked for 3 eigenfunctions (belonging to eigenvalues #1, #3, and #5) during 15 iterations of PPINVIT. Interpolants of solenoidal polynomial vectorfields $\mathbf{f}_i := x_m^r x_l^r \cdot \vec{e}_k$, $\{m, l, k\} = \{1, 2, 3\}$, $k = i \mod 3$, $r = i \operatorname{div} 3$, served as initial guesses for the ith eigenfunction, $i = 1, \ldots, 7$. By and large, the effect of different initial guesses quickly abates during the iterations.

Single symmetric multigrid V(1,1)-cycles with lexicographic GS-smoothers were used both in $\boldsymbol{\mathcal{V}}_l$ and potential space. The inverse mass matrix required for the calculation of the two-step Rayleigh quotient was approximated by three steps of the preconditioned conjugate gradient (PCG) method with a symmetric GS-preconditioner.

The values of r_Q were considered as useful approximations of eigenvalues and thus it makes sense to examine their relative errors with respect to "exact discrete eigenvalues" (computed by nested iteration up to a relative error of 10^{-6}). The results for problem (1.1) are plotted in Figure 7.

First of all, a rather uniform decrease of the errors/residual norms takes place. Next, we note that the M_l^{-1}-norm of the residual permits us to assess the accuracy of the approximate eigenvalue very well. As expected, the larger the eigenvalue the poorer the convergence (up to a total failure to converge for the seventh eigenvalue). One should follow the customary advice that dimension of the subspace should be chosen somewhat larger than the number of eigenvalue one is interested in.

Experiment 2. Retaining most of the setting of the previous experiment we studied the impact of choices of different multigrid cycles for both the update and projection step. In Table 1 we report the rate

$$\rho = \left((r_Q(\mathbf{x}_h^{(10)}) - \lambda_{\text{exact}}) / (r_Q(\mathbf{x}_h^{(2)}) - \lambda_{\text{exact}}) \right)^{\frac{1}{8}} \tag{6.1}$$

of convergence of the eigenvalue approximations between the second and tenth step of the iteration.

The effect of very accurate preconditioners/projections seems to be limited, as predicted by the theory of PINVIT: We cannot be better than exact inverse iteration

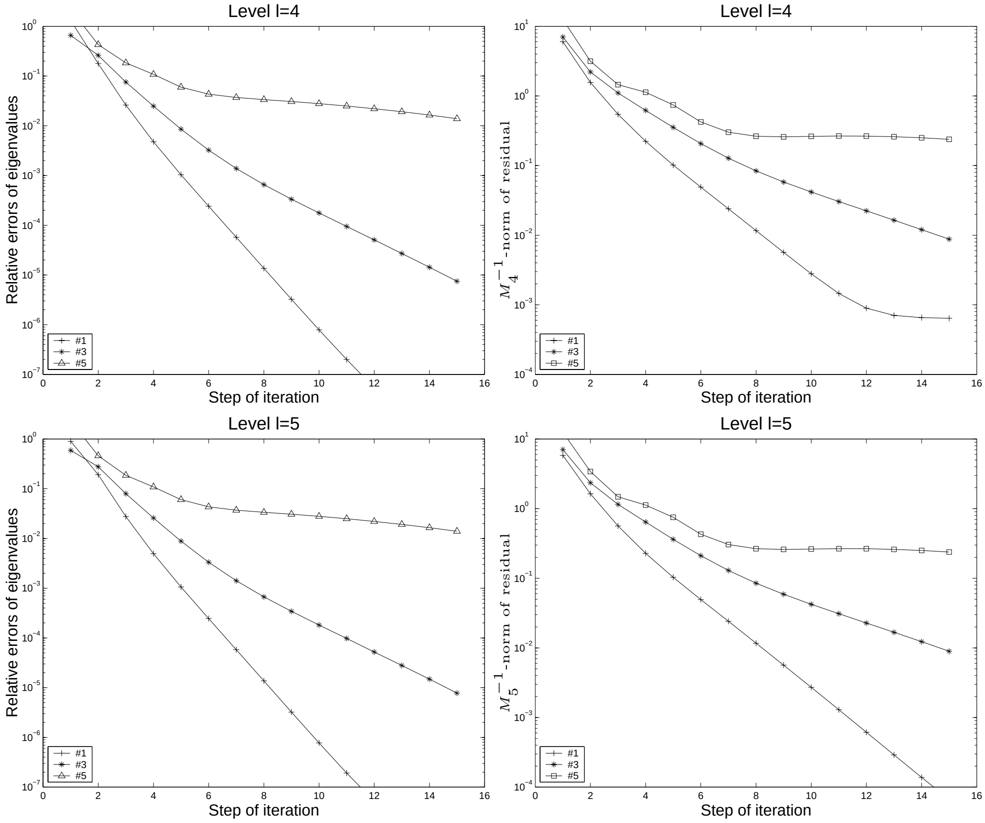

FIG. 7. *Experiment* 1: *Left: Relative errors of two-step Rayleigh quotients when compared with "exact discrete eigenvalues". Right: Approximate M_l^{-1}-norms of residuals.*

and improving the preconditioner has little impact if the Rayleigh quotient is already close to the exact eigenvalue. Moreover, the rates highlight the danger of too many smoothing steps on edge d.o.f. This will make the constants K_A, $K_\perp$, and K_0 from (4.16) soar and has to be offset by improved projection.

Experiment 3. Of course, choosing random initial guesses is foolish, in particular, as a nested iteration approach will do much better in a multilevel environment. The behavior of the approximate M_l^{-1}-norms of the eigenfunction residuals during nested iteration was recorded for the various settings. On each level l the iteration was terminated if $\left\langle M_l^{-1}\boldsymbol{\rho}_l, \boldsymbol{\rho}_l\right\rangle^{\frac{1}{2}} \leq \tau$ for eigenfunction #1 through #5, where $\tau > 0$ is a prescribed threshold.

The same multigrid cycles as before were employed. Moreover, we chose $\tau = 0.01$ and $\tau = 0.1$. In the latter case the evaluation of M_h^{-1} in the computation of r_Q was based on only one symmetric GS-sweep, which is much cheaper than the three PCG-steps used for the former case. The results can be looked at in Figure 8.

As before, the data strikingly confirm that the convergence of multigrid-PPINVIT is independent of the depth of refinement: About the same number of iterations is required on each level to achieve the prescribed reduction of the norm of the residuals.

Experiment 4. In experiment 3 we boldly relied on a single symmetric GS-sweep to get an approximation for r_Q. Now, we aim to investigate how different approximations

of M_h^{-1} perform. In particular, we used either one, two, or three steps of SGS or PCG. In any other respect the setting is just borrowed from experiment 1. The decrease of the errors in the eigenvalue approximations according to (6.1) are listed in Table 2. The picture is blurred, but the general message is that spending much effort on M_h^{-1} does not pay off in terms of asymptotic convergence rates, but can boost convergence during the first few steps of the iteration, when eigenvalue approximations are still poor.

Experiment 5. We repeated experiment 3 with face elements instead of edge elements. The (level-dependent) M_l^{-1}-norms of some residuals are plotted in Figure 9.

TABLE 2
Experiment 4*: Behavior of different approximations of* M_5^{-5} *on level* 5*,* B_h*:* $V(1,1)$*,* C_h*:* $V(1,1)$*.*

M_l^{-1} by	#1	#2	#3	#4	#5	#6	#7

1 PCG	0.41	0.35	0.29	0.40	0.43	0.36	0.46
3 SGS	0.20	0.19	0.36	0.57	0.65	0.61	0.63
2 SGS	0.17	0.15	0.27	0.40	0.45	0.42	0.46
1 SGS	0.19	0.21	0.22	0.24	0.28	0.26	0.29

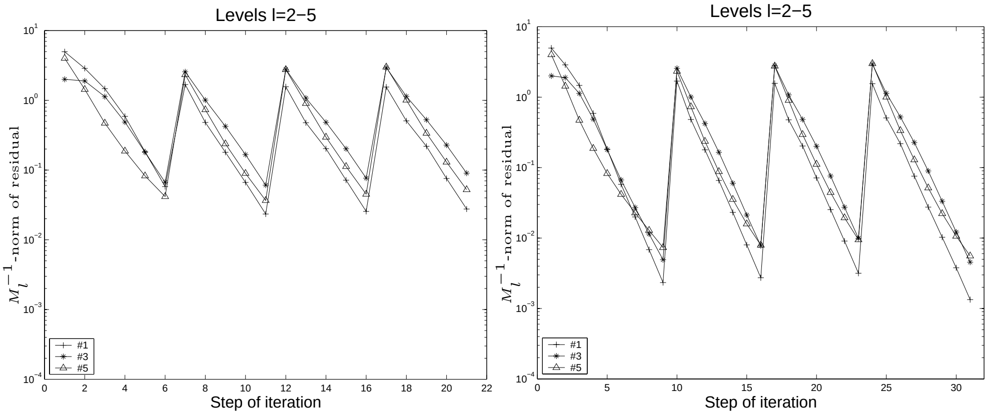

FIG. 9. *Experiment* 5*: Nested iteration for* face elements*,* M_h^{-1} *realized by* 3 *PCG-steps. Left:* $\tau = 0.1$*. Right:* $\tau = 0.01$*.*

Qualitatively, the residual norms behave as for edge elements. If we had reported all experiments for face elements, too, this statement would have been appropriate for any other case.

Experiment 6. The final experiment scrutinizes whether projection control as discussed in section 5 can really offset poor projections. To that end we used a plain symmetric GS-sweep for C_h, which yields an outrageously bad $\widetilde{P}_h$ on fine grids. Otherwise, the algorithm of the first experiment was retained and we focused on level 4.

Projection control with $\delta = 0.1$, $\delta = 0.01$, and a safety factor $\sigma = \frac{1}{4}$ was enabled. In addition, as we observed wild fluctuations of the number of GS-steps suggested by the projection control, we imposed that this number could not shrink by more than a factor of two between subsequent projections (zig-zag-evasion). In Figure 10 the behavior of relative errors of eigenvalues is logged. Some ratios $r(\mathbf{x}_h)/r_Q(\mathbf{x}_h)$ are recorded in Figure 11.

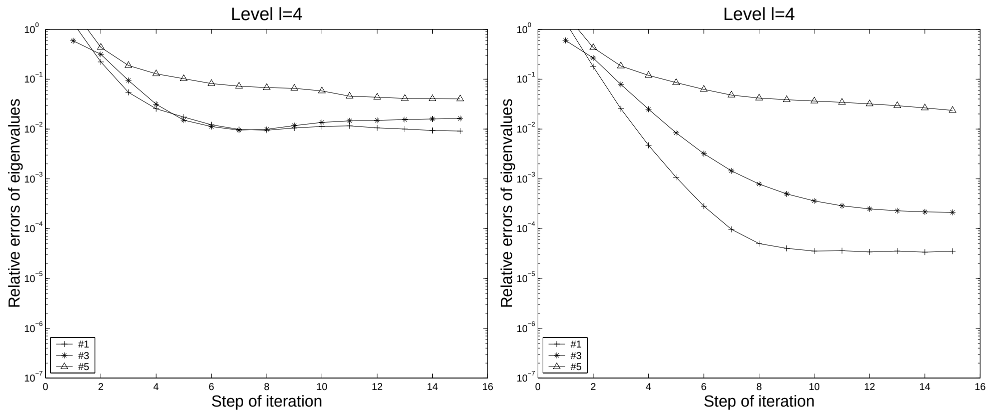

FIG. 10. *Experiment* 6: *Projection control with* $\delta = 0.1$ *(left),* $\delta = 0.01$ *(right).*

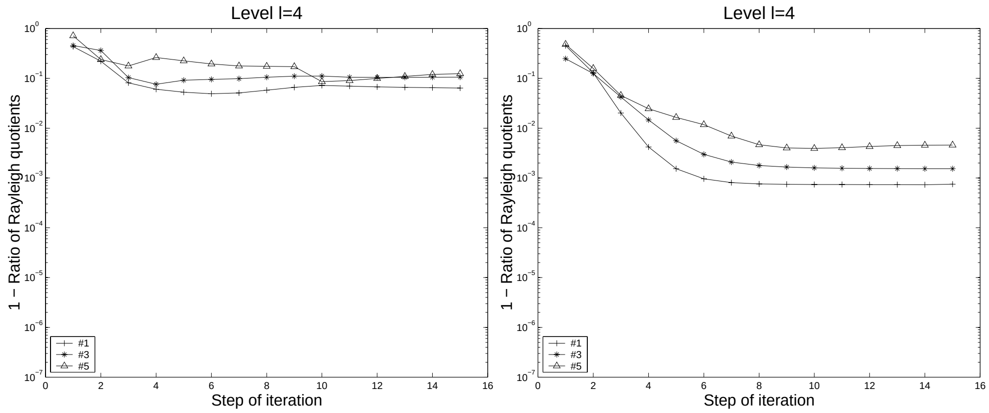

FIG. 11. *Experiment* 6: $1 - r(\mathbf{x}_h)/r_Q(\mathbf{x}_h)$ *for different projection controls with* $\delta = 0.1$ *(left),* $\delta = 0.01$ *(right).*

Sufficiently tight projection control ensures convergence. However, the results also highlight the need for an adaptive choice of δ because it seems hard to determine in advance when δ will be sufficiently small. This experiment also hints that the ratio of Rayleigh quotients, which is to tend to 1, can help detect ineffective projections.

Remark. In our experimental setting singularities of eigenfunctions at reentrant edges and coefficient discontinuities can be expected. Therefore, adaptive refinement would be advisable. It could be done along the lines of [53, 60], taking into account the techniques of [8]. Numerical evidence hints that no deterioration of multigrid convergence will occur on locally refined meshes [7, 55]. Thus, PPINVIT will probably not be affected much.

7. Conclusion.

We presented a multigrid-preconditioned inverse iteration method for the solution of large discrete semidefinite eigenvalue problems in $\boldsymbol{H}(\mathbf{curl};\Omega)$ and $\boldsymbol{H}(\mathrm{div};\Omega)$. Though a complete theoretical analysis is still missing, there is strong numerical evidence that the method inherits the efficiency of multigrid based iterative solution procedures. Besides a thorough theoretical understanding many issues remain to be examined: among others, improved adaptive projection control, detection of topological complications, and potential acceleration by means of preconditioned steepest descent or various kinds of subspace enlargements and, last but not least, the benefit of shift strategies.

A BLOCK ORTHOGONALIZATION PROCEDURE WITH CONSTANT SYNCHRONIZATION REQUIREMENTS*

ANDREAS STATHOPOULOS† AND KESHENG WU‡

Abstract. First, we consider the problem of orthonormalizing skinny (long) matrices. We propose an alternative orthonormalization method that computes the orthonormal basis from the right singular vectors of a matrix. Its advantages are that (a) all operations are matrix-matrix multiplications and thus cache efficient, (b) only one synchronization point is required in parallel implementations, and (c) it is typically more stable than classical Gram–Schmidt (GS). Second, we consider the problem of orthonormalizing a block of vectors against a previously orthonormal set of vectors and among itself. We solve this problem by alternating iteratively between a phase of GS and a phase of the new method. We provide error analysis and use it to derive bounds on how accurately the two successive orthonormalization phases should be performed to minimize total work performed. Our experiments confirm the favorable numerical behavior of the new method and its effectiveness on modern parallel computers.

1. Introduction.

Computing an orthonormal basis from a given set of vectors is a basic computation, common to most scientific applications. Often, it is also one of the most computationally demanding procedures because the vectors are of large dimension, and because the computation scales as the square of the number of vectors involved. Further, among several orthonormalization techniques the ones that ensure high accuracy are the more expensive ones.

Skinny (or long) matrices, whose row dimension far exceeds their column dimension, arise naturally in various scientific contexts. Examples include statistical analysis, where there are many more observations than variables, and iterative methods that use a small subspace of vectors to span the required solutions. For a variety of reasons, an orthonormal basis of these vectors must be computed. Traditionally, this is obtained through the QR factorization, even though quite often the matrix R is not of primary interest, but rather the orthonormal basis Q. The QR factorization is computed through Householder transformations (we call this method simply QR) or through classical Gram–Schmidt (GS) or modified Gram–Schmidt (MGS). Although less stable numerically, GS with reorthogonalization is usually preferred to the QR method because of better computational properties.

Yet, all of these methods have performance limitations on modern, cache based processors and parallel computers. Their implementations are based on level 1 or level 2 BLAS operations [8, 9, 15], which have low cache reuse. Level 3 BLAS implementations are possible, but they are not suitable for skinny matrices. On parallel

platforms, such as the increasingly popular clusters of workstations, reduction in communication and synchronization overheads has not kept up with the explosive growth of network bandwidth and processor speed [21]. As a result, the global synchronization required by frequent inner products does not scale with the number of processors. A method is still needed that operates only on blocks of vectors and requires a number of synchronizations that is independent of the size of the matrix.

In many applications, orthonormalization occurs in an incremental fashion, where a new set of vectors (we call this *internal set*) is orthogonalized against a previously orthonormal set of vectors (we call this *external*), and then among themselves. This computation is typical in block Krylov methods, where the Krylov basis is expanded by a block of vectors [11, 12]. It is also typical when certain external orthogonalization constraints have to be applied to the vectors of an iterative method. Locking of converged eigenvectors in eigenvalue iterative methods is such an example [19, 22]. The nature of these applications suggests that the internal set is usually a skinny matrix with fewer vectors than the external set.

Conceptually, this problem can be viewed as an update of a QR factorization that has already produced the orthonormal set of external vectors which should not be modified. Computationally, however, the problem is usually tackled as a two phase process; first, orthogonalizing the internal vectors against the external ones (external phase), and second, orthogonalizing the internal vectors among themselves (internal phase). For the external phase, block GS and MGS are the most competitive choices, while for the internal phase an efficient orthonormalization procedure for skinny matrices is needed.

Most of the previous efforts to address the above two problems considered blocks of vectors, and used hybrids of the more scalable GS across blocks, and the more accurate MGS within blocks [2, 14]. Performance improves, but the number of synchronization points is still linear to the number of vectors, and BLAS level 2 kernels are still dominant despite blocking. Interestingly, such efforts have focused on a full QR factorization of a set of vectors, rather than on the two phase problem.

In this paper, we introduce a method based on the singular value decomposition (SVD) that uses the right singular vectors to produce an orthonormal basis for a given skinny matrix. The idea itself is not new, dating back at least to Poincaré, and it is sometimes encountered in chemistry and wavelet literature [5, 6, 16, 17, 20]. However, it has not received any attention as a computationally viable orthogonalization method, and to our knowledge there is no analysis of its numerical properties. The method, which we call SVQB, uses exclusively level 3 BLAS kernels, and it has a constant number of synchronization points. We show that it is not as accurate numerically as MGS, but it is better than GS in the absence of special sparsity structure. More interestingly, we show that more stable alternatives, such as MGS or Householder, are an overkill for our two phase problem. Coupling the SVQB method for the internal phase with a block GS with reorthogonalization for the external phase results in a method also with constant synchronization requirements.

The paper is organized as follows. First we describe the SVQB method for skinny matrices, we analyze its numerical stability, and we confirm our theory through numerical experiments and comparisons with other methods. Second, we couple SVQB with a block GS for the two phase problem. We analyze the numerical interaction between the two methods, and based on this theory we tune the two phases to avoid unnecessary reorthogonalizations. Following this, we present timings from a series of experiments on the Cray T3E, IBM SP-2, and on a cluster of SUN workstations.

These verify that the block computations and the small number of synchronizations help the new method achieve accurate orthogonality faster than other competitive methods.

2. The problem(s). Let $V \in \Re^{n\times k}$ be a set of orthonormal vectors, and $W \in \Re^{n\times m}$ be a set of vectors, where $k + m \leq n$. In practice, we expect $m < k$ and $m \ll n$. When $m \ll n$, W is often referred to as a skinny matrix. The first problem we consider is that of obtaining an orthonormal set of vectors Q such that span(Q)=span(W). The second problem is again to obtain an orthonormal Q such that span([V W])=span([V Q]) and $Q \perp V$. In both problems Q can be any orthonormal basis, not necessarily from a QR factorization. In finite precision, the equality of the spans can be relaxed, but the orthonormality requirement must remain.

The distinction between the two problems is made for computational reasons. First, orthonormalizing skinny matrices is a problem important in itself, which allows for efficient solutions without a QR factorization. In the presence of an external matrix V, methods like the classical GS would orthogonalize each vector of W against all previous orthogonal vectors in both W and V. In that case, the difference between the two phases is blurred. However, such algorithms allow only for level 2 BLAS computational kernels and introduce at least $O(m)$ number of synchronization points on parallel computers. To improve computational performance we need to consider W as a block (or subblocks within W). A block GS method would orthogonalize the block against V (and other previous subblocks in W). In this case, the orthogonality among the vectors within the block must be resolved at a different time in a distinct internal phase. Finally, because V cannot be modified, distinguishing between the problems allows non-QR factorization methods to be used for the internal phase.

For the internal phase, GS and MGS are popular QR factorization methods which both incur the same number of arithmetic operations, they are based on level 2 BLAS kernels, and they can be implemented in parallel with a modest number of $m + 1$ synchronization points [11, 24]. MGS is more numerically stable with the error in the orthogonality of Q bounded by $\epsilon\kappa(W)$, where $\kappa(W)$ is the condition number of W [1, 3]. Householder reflections yield a matrix Q which is orthogonal to machine precision (ϵ) but require twice the arithmetic of (M)GS. In practice, for most matrices, a second orthogonalization with GS is typically enough for producing orthogonality to machine precision [7], and thus GS is often preferred over other methods.

In the context of the two phase problem, producing an internal set of vectors Q with orthogonality close to machine precision is unnecessary because of the interdependence of the phases. For example, external orthogonalization against V may spoil the internal orthogonality of W, and vice versa. Therefore, this two phase problem obviates the use of expensive but stable methods such as Householder.

3. The SVQB method. An especially interesting orthonormal basis of the span(W) is the one derived from the right singular vectors of W. Assume that the vectors in W are normalized. The singular values of W are the square roots of the eigenvalues of $S = W^TW$, and the right singular vectors are the corresponding eigenvectors of S. Let $SU = U\Lambda$ be the eigendecomposition of S and define $Q = WU\Lambda^{-1/2}$. Obviously, span(Q) = span(W) and $Q^TQ = I$. If the W vectors are not normalized, the diagonal of S, $D = \text{diag}(S)$, contains the squares of their norms ($S_{ii} = W_i^TW_i$). Therefore, we can implicitly work with the normalized $WD^{-1/2}$ by scaling the columns and rows of S. This is inexpensive and is as numerically stable as explicit normalization. The resulting factorization is not a QR but rather a "QB" factorization, where Q is orthonormal and B a full matrix. In exact arithmetic, the algorithm for this singular vector QB factorization (which we call SVQB) follows.

Algorithm 3.1. $Q = \mathrm{SVQB}(W)$.

```
1. $S' = W^T W$.
2. Scale $S = D^{-1/2} S' D^{-1/2}$, with $D = diag(S')$.
3. Solve $SU = U\Lambda$, for all eigenpairs.
4. Compute $Q = WD^{-1/2} U \Lambda^{-1/2}$.
```

When some of the vectors in W are linearly dependent, one or more of the eigenvalues and their corresponding vectors in Q are zero. In finite precision, a similar effect is caused by almost linearly dependent vectors and eigenvalues close to zero. Because of numerical noise, such eigenvalues cannot be bounded away from zero. To prevent normalization overflows, and to avoid an explicit computation of the norm of the vectors Q, we set a minimum threshold for eigenvalues. If ϵ is the machine precision, we insert the following two steps:

```
    3.1. $\tau = \epsilon \ \max_i(\Lambda_{ii})$.
    3.2. If $\Lambda_{ii} < \tau$, set $\Lambda_{ii} = \tau$ for all $i$.
```

Other strategies for dealing with linear dependencies are also possible. For example, we could consider only those eigenvectors with eigenvalues greater than some "safe" threshold. The resulting basis is then smaller, but it is guaranteed to be orthonormal and to numerically span a subspace of the original vectors. Finally, because of finite precision arithmetic, the algorithm may have to be applied iteratively ($Q^{(i+1)} = \mathrm{SVQB}(Q^{(i)})$) until an orthonormal set Q is obtained.

The solution of the eigenvalue problem and the implicit normalization involve only $m \times m$ matrices (S and U), and thus they are inexpensive. On parallel computers these can be duplicated on each processor. The matrix-matrix multiplication for computing S and the multiplication of W with U each contribute $2nm^2$ floating point operations, which makes the algorithm twice as expensive as GS. However, these operations are level 3 BLAS kernels and can be performed efficiently on cache based computers. Alternatively, the matrix multiplication for computing the symmetric S can be performed with half the operations, but level 2 BLAS kernels will have to be used. Moreover, a parallel implementation of the SVQB method requires only one synchronization point when computing the matrix S.

We note that our interest in the singular vectors stems only from the computational efficiency of SVQB. A standard bidiagonalization kernel for computing the SVD of W directly could offer better numerical stability [4]. However, its cache utilization and parallel efficiency is similar to that of QR (with Householder transformations), without yielding the same level of machine precision orthogonality. We have not considered such methods, as they offer no advantages over the QR method.

3.1. The Cholesky QR method.

Similarly to the SVQB method, we can derive a block QR factorization based on the Cholesky factorization. Note that if $S = W^T W = R^T R$, where R is the Cholesky factor, $Q = WR^{-1}$ defines the QR factorization for W [11]. Although this method (denoted as CholQR) is rarely used computationally, it has some attractive characteristics: it is a QR factorization; it is based on a level 3 BLAS kernel and a triangular system solution; it involves only 50% more arithmetic than GS; and it also requires one synchronization point in parallel implementations. Researchers have noticed that it is not as stable as MGS, but it is often more stable than GS [2, 10]. One of the problematic issues with CholQR is that the more ill conditioned S is, the less stable the Cholesky factorization becomes. Regularizing it effectively is not as straightforward as in the case of SVQB, where the smallest singular pairs can simply be left out of the computation. Finally, the cache performance of CholQR is usually inferior to that of SVQB because of the triangular solve.

4. Stability analysis of SVQB. For many applications, such as block Krylov iterative methods, the orthonormality of the resulting vectors Q, not the upper triangular R of the QR factorization, is of importance. For example, Krylov methods will still make progress, albeit a slower one, if provided with a slightly different orthonormal set Q. Thus, as it is common in the literature, we measure stability as the departure of the resulting Q from orthonormality rather than its backward error. Because of its block, nonsequential nature, we expect the SVQB procedure to be less stable than MGS. However, as we show below, it is often more stable than GS.

THEOREM 4.1. *Let W be a set of m linearly independent vectors of $\Re^n$. Let $\bar{Q}$ be the floating point representation of the matrix computed by applying the SVQB procedure on W. If $\kappa(W)$ is the condition number of W, then*

$$\|I - \bar{Q}^T\bar{Q}\| \;\leq\; c_0 \;\min\big(\, \epsilon \;\kappa(W)^2,\; 1\big)\,,$$

where $\|.\|$ denotes the 2-norm, ϵ is the machine round off, and c_0 is a constant depending on n and m.

Proof. Let $S = W^TW$, and let $\tilde{S}$ be the floating point representation of S. Then

$$\tilde{S} = S + \delta S, \;\text{ with }\; \|\delta S\| \leq c_1 \;\epsilon\; \|S\|. \tag{4.1}$$

We can further write this as $\|\delta S\| \leq c_1 \;\epsilon\; \|W\|^2$. The effect of performing scaling on the matrix S corresponds to each vector in W having norm 1 implicitly, and, in that case, $\|\delta S\| \leq c_1 \;\epsilon\; m$.

Let $\bar{U}$, with $\bar{U}^T\bar{U} = I$, and $\bar{\Lambda}$ be the computed eigenvectors and eigenvalues of the small $m \times m$ symmetric matrix $\tilde{S}$. From standard backward error analysis, these can be considered an exact eigendecomposition of a nearby matrix $\bar{S} = \bar{U}\bar{\Lambda}\bar{U}^T$. Using relation (4.1) we can express the error in $\bar{S}$ as

$$\bar{S} = \tilde{S} + \delta\tilde{S}, \;\text{ with }\; \|\delta\tilde{S}\| \leq c_2 \;\epsilon\; \|S\| + O(\epsilon^2). \tag{4.2}$$

From the above, and by letting $c_3 = c_1 + c_2$, the matrices S and $\bar{S}$ are related by

$$\|\bar{S} - S\| = \|\delta\tilde{S} + \delta S\| \leq c_3 \;\epsilon\; \|S\|. \tag{4.3}$$

Let $\bar{\lambda}_{\min} = \min_i \bar{\Lambda}_{ii}$, and $\bar{\lambda}_{\max} = \max_i \bar{\Lambda}_{ii}$, and consider a similar notation for eigenvalues of other matrices. Because our algorithm sets eigenvalues $\bar{\lambda}_i$ that are smaller than $\epsilon\bar{\lambda}_{\max}$ equal to this threshold, we define a diagonal matrix $\hat{\Lambda}$ such that

$$\hat{\Lambda}_{ii} = \begin{cases} \bar{\Lambda}_{ii} & \text{if } \bar{\Lambda}_{ii} > \epsilon\bar{\lambda}_{\max}, \\ \epsilon\bar{\lambda}_{\max}, & \text{if } \bar{\Lambda}_{ii} \leq \epsilon\bar{\lambda}_{\max}. \end{cases} \tag{4.4}$$

Let $\bar{Q} = Q + \delta Q = W\bar{U}\hat{\Lambda}^{-1/2} + \delta Q$ be the floating point representation of the matrix returned by the SVQB procedure. Then, $\|\delta Q\| \;\leq c_4 \,\epsilon\, \|W\|\; \|\bar{U}\|\; \|\hat{\Lambda}^{-1/2}\|$. If we denote by λ_i the exact eigenvalues of S, with $\lambda_{\max}$ the largest one, then $\|W\| = \sqrt{\lambda_{\max}}$. Note also that $\bar{U}^T\bar{U} = I$, and thus $\|\bar{U}\| = 1$. From (4.4) we have

$$\|\hat{\Lambda}^{-1}\| \leq \;\min\left(\frac{1}{\bar{\lambda}_{\min}}, \frac{1}{\epsilon\bar{\lambda}_{\max}}\right). \tag{4.5}$$

Because for symmetric eigenproblems the error in the eigenvalue is bounded by the error in the matrix, for any $\bar{\lambda}_i$ we have $\left|\bar{\lambda}_i - \lambda_i\right| \le \|\bar{S} - S\| \le c_3\,\epsilon\,\|S\| = c_3\,\epsilon\,\lambda_{\max}$. Then, there are constants c_5 and c_6, such that

$$\bar{\lambda}_{\min} = \lambda_{\min} + c_5\,\epsilon\,\lambda_{\max} \quad \text{and} \quad \bar{\lambda}_{\max} = \lambda_{\max} + c_6\,\epsilon\,\lambda_{\max}. \tag{4.6}$$

We note that $\kappa(W) = \sqrt{\kappa(S)} = \sqrt{\lambda_{\max}/\lambda_{\min}}$, and, because $\epsilon + c_6\,\epsilon^2 = O(\epsilon)$, a substitution of (4.6) into (4.5) yields

$$\|\hat{\Lambda}^{-1}\| \le \min\left(\frac{1/\lambda_{\min}}{1 + c_5\,\epsilon\kappa(S)},\ \frac{1}{\epsilon\lambda_{\max}}\right). \tag{4.7}$$

The first term is chosen as the minimum if none of the $\bar{\Lambda}_{ii}$ is in the order of $\epsilon\bar{\lambda}_{\max}$ or smaller. This means that all the singular values of W, $\sqrt{\lambda_i}$, must be larger than $\sqrt{\epsilon}$, because they can be represented by eigenvalues of $\bar{S}$, despite the squaring. Therefore, $\kappa(S) < O(1/\epsilon)$, and $1 + c_5\,\epsilon\kappa(S) = O(1)$. Thus, the bound (4.7) becomes

$$\|\hat{\Lambda}^{-1}\| \le c_7\ \min\left(\frac{1}{\lambda_{\min}},\ \frac{1}{\epsilon\lambda_{\max}}\right). \tag{4.8}$$

By setting $c_8 = c_4 c_7$, we can give a bound for $\|\delta Q\|$, as well as for $\|Q\| = \|W\bar{U}\hat{\Lambda}^{-1/2}\|$:

$$\|\delta Q\| \le c_8\ \min\left(\ \epsilon\ \kappa(W),\ \sqrt{\epsilon}\ \right), \tag{4.9}$$

$$\|Q\| \le c_8\ \min\left(\ \kappa(W),\ 1/\sqrt{\epsilon}\ \right). \tag{4.10}$$

We emphasize that the above is not the backward error for the exact result of SVQB but for the product of computed matrices that yields $\bar{Q}$. The exact backward error is not relevant because the orthogonality of $\bar{Q}$ is of interest.

Let us consider the departure of the computed $\bar{Q} = Q + \delta Q$ from orthonormality:

$$\begin{aligned} \|I - \bar{Q}^T\bar{Q}\| &= \|I - \hat{\Lambda}^{-1/2}\bar{U}^T W^T W \bar{U}\hat{\Lambda}^{-1/2} + \delta Q^T Q + Q^T \delta Q\| + O(\delta Q^2) \\ &\le \|I - \hat{\Lambda}^{-1/2}\bar{U}^T S \bar{U}\hat{\Lambda}^{-1/2}\| + 2\|\delta Q\|\|Q\|. \end{aligned} \tag{4.11}$$

From relations (4.1)–(4.4) and the orthonormality of $\bar{U}$, this becomes

$$\begin{aligned} \|I - \bar{Q}^T\bar{Q}\| &\le \|I - \hat{\Lambda}^{-1/2}\bar{U}^T\bar{S}\bar{U}\hat{\Lambda}^{-1/2} + \hat{\Lambda}^{-1/2}\bar{U}^T(\delta\tilde{S} + \delta S)\bar{U}\hat{\Lambda}^{-1/2}\| + 2\|\delta Q\|\|Q\| \\ &\le \|I - \hat{\Lambda}^{-1/2}\bar{\Lambda}\hat{\Lambda}^{-1/2}\| + \|\hat{\Lambda}^{-1}\|\|\delta\tilde{S} + \delta S\| + 2\|\delta Q\|\|Q\|. \end{aligned} \tag{4.12}$$

From definition (4.4), the first term is zero if $\kappa(S) < O(1/\epsilon)$. Otherwise, it is equal to $\max(1 - \bar{\lambda}_i/\epsilon\bar{\lambda}_{\max},$ for $\bar{\lambda}_i \le \epsilon\bar{\lambda}_{\max})$. However, this is less than one, and in that case the other terms are also $O(1)$. From bounds (4.3) and (4.8)–(4.10), and by setting $c_0 > c_3 c_7 + 2c_8^2$, we obtain

$$\begin{aligned} \|I - \bar{Q}^T\bar{Q}\| &\le c_3 c_7\ \min\left(\ \epsilon\kappa(W)^2,\ 1\right) + 2c_8^2 \min\left(\ \epsilon\kappa(W)^2,\ 1\right) \\ &\le c_0\ \min\left(\ \epsilon\ \kappa(W)^2,\ 1\right). \qquad \square \end{aligned} \tag{4.13}$$

Next, we bound $|\kappa(\bar{Q}) - 1|$, thus showing that when applying SVQB iteratively, $\bar{Q}$ converges fast to an orthonormal basis. We first state the following lemma (see [13]).

Lemma 4.2.

1. *If* $\|I - Q^T Q\| \le \alpha$, *then* $\|Q^T Q\| \le \|Q\|^2 \le 1 + \alpha$.
2. *If* $\|I - Q^T Q\| \le \alpha < 1$, *then* $\|I - (Q^T Q)^{-1}\| \le \frac{\alpha}{1-\alpha}$.

PROPOSITION 4.3. *If $\|I - Q^TQ\| \leq \alpha < 1$, then the condition number $\kappa(Q)$ satisfies*

$$\kappa(Q) \leq \sqrt{\frac{1+\alpha}{1-\alpha}}.$$

Proof. By definition, $\kappa(Q) = \sqrt{\|Q^TQ\|\|(Q^TQ)^{-1}\|}$. The proof follows from Lemma 4.2, since $\|Q^TQ\| \leq \|Q\|^2 \leq 1 + \alpha$, and $\|(Q^TQ)^{-1}\| = \|I - I + (Q^TQ)^{-1}\| \leq 1 + \|I - (Q^TQ)^{-1}\| \leq \frac{1}{1-\alpha}$. □

THEOREM 4.4. *Let W be a set of m linearly independent vectors of $\Re^n$, with condition number $\kappa(W)$. Let $\bar{Q}$ be the floating point representation of the matrix computed by applying the SVQB procedure on W. If ϵ is the machine round off, then*

$$\text{if } \sqrt{\epsilon}\ \kappa(W) < c < 1, \qquad \kappa(\bar{Q}) \leq 1 + O(\epsilon\ \kappa(W)^2)).$$

Proof. If we let $\alpha = O(\epsilon\ \kappa(W)^2) < c^2 < c < 1$, according to Theorem 4.1, $\|I - \bar{Q}^T\bar{Q}\| < \alpha$, and by using Proposition 4.3, we have $\kappa(\bar{Q}) \leq \sqrt{\frac{1+\alpha}{1-\alpha}} \leq \sqrt{1 + \frac{2\alpha}{1-\alpha}} \leq 1 + \frac{\alpha}{1-\alpha}$. This proves the bound because, in this case, α is bounded away from 1. □

The case where $\kappa(W) \geq \frac{1}{\sqrt{\epsilon}}$ cannot be bounded in the general case because numerical error dominates. However, some intuition can be gained by considering the structure of $\bar{Q}^T\bar{Q}$ as obtained from (4.12) and the bounds (4.9)–(4.10) and (4.3):

$$\bar{Q}^T\bar{Q} = \hat{\Lambda}^{-1/2}\bar{\Lambda}\hat{\Lambda}^{-1/2} + \hat{\Lambda}^{-1/2}\Delta S\hat{\Lambda}^{-1/2} + \Delta Q,$$

where $\Delta S = O(\epsilon\bar{\lambda}_{\max})$ and $\Delta Q = O(1)$ element-wise. Note that after scaling, $\hat{\Lambda}^{-1/2}\Delta S\hat{\Lambda}^{-1/2}$ also becomes element-wise $O(1)$. From the definition of $\hat{\Lambda}$, the entries of the diagonal matrix $\hat{\Lambda}^{-1/2}\bar{\Lambda}\hat{\Lambda}^{-1/2}$ are 1 for all eigenvalues above the $\epsilon\bar{\lambda}_{\max}$ threshold, and $\bar{\lambda}_i/(\epsilon\bar{\lambda}_{\max}) = 1/(\epsilon\kappa(\bar{S}))$ for the rest. Thus, the eigenvalues of $\bar{Q}^T\bar{Q}$ are O(1) perturbations of the these diagonal values, so the smallest eigenvalue cannot be bounded away from zero. If we assume that the only finite precision errors occur from the inability to represent eigenvalues of $\bar{S}$ smaller than $\epsilon\lambda_{\max}$, i.e., $\Delta S = 0$ and $\Delta Q = 0$, then, obviously, $\kappa(\bar{Q}^T\bar{Q}) = \epsilon\kappa(\bar{S}) < \epsilon\kappa(S)$, and thus $\kappa(\bar{Q}) < \sqrt{\epsilon}\kappa(W)$. Note that in this case the vectors of $\bar{Q}$ are exactly orthogonal to each other, yet their condition number is far from 1.

Although $\kappa(\bar{Q}) < \sqrt{\epsilon}\kappa(W)$ cannot be proved in general, we have observed it in all our numerical experiments. A plausible explanation is that $O(1)$ perturbations after vector scaling introduce random noise which we expect to be in linearly independent and relatively well-conditioned directions.

4.1. Convergence comparisons. The above theorems suggest that in most situations, applying SVQB once or twice should produce orthogonal vectors. In the case of extremely ill-conditioned vectors, a third application of the procedure might be necessary. This is akin to the behavior of GS with reorthogonalization [7, 13, 18], but it is expected to be better than iterative GS without internal reorthogonalization.

If an accurate Cholesky decomposition can be computed, the CholQR procedure should be identical to SVQB. In fact, it might be possible to prove bounds for CholQR similar to the ones in the previous section. However, even with an accurate decomposition, for very large condition numbers we expect CholQR to be less stable than the eigenvalue-based SVQB method.

Table 4.1

W = Krylov(A, 30), where A is a 2-D Laplacean of size 1089×1089, and an initial vector of all ones. $\kappa(W) = 3e + 20$. However, after scaling, because of numerical error, $\kappa(W)$ becomes: $6e + 16$.

To demonstrate the relative effectiveness of these methods, we apply them on three sets of vectors and report the improvements on their condition numbers. The first set is the 30 Krylov vectors generated from a vector of all ones and the two-dimensional (2-D) Laplacean on a regular, finite difference, square mesh with Neumann conditions. The dimension of the matrix is 1089, and the initial vector is not considered among the set of 30. The second set consists of the columns of the Hilbert matrix of size 100. The third set is rather artificial, and it has been used to show the benefits of MGS over GS [2, 13, 14]. We use the following variation, shown in MATLAB notation: `W = [ ones(1,30); diag( rand(30,1)*eps*eps*eps ) ]` . All tests are run in MATLAB on a SUN Ultra-2 workstation with $\epsilon = 2.2\text{e}{-16}$. The condition numbers are computed by the Matlab function `cond` and therefore could be inaccurate whenever they exceed 10^{16}. The results for these three cases are shown in Tables 4.1, 4.2, and 4.3, respectively.

We compare SVQB against CholQR, GS, and MGS by printing the condition number $\kappa(\bar{Q})$ of the vectors that these methods produce after each iteration. Since the implicit normalization in step 4 of SVQB does not guarantee normality for ill-conditioned problems, we also print the condition number $\kappa(Q_u)$ of the unscaled vectors, $Q_u = W\bar{U}$, and the condition number of the same vectors after explicitly scaling them by their norms, $\kappa(Q'_u)$. Note that at any iteration, $\kappa(Q_u)$ is equal to $\kappa(Q'_u)$ of the previous iteration. For example, after the first iteration $\kappa(Q_u) = \kappa(W)$. This verifies that explicit normalization is not needed. If scaling by $\bar{\Lambda}^{-1/2}$ does not produce normal vectors, another iteration must be performed either way, during which the implicit normalization of columns and rows of S in step 2 of SVQB has the same effect as explicit normalization. In addition, explicit normalization would introduce additional work, and, more importantly, an additional synchronization point.

The results in all tables confirm the developed theory. When the condition number is smaller than $1/\sqrt{\epsilon}$, the reduction obeys closely the bound in Theorem 4.4. The application of one step of SVQB reduces the condition number of a set of vectors by at least $\sqrt{\epsilon}$. This reduction is sharp for the examples in Tables 4.1 and 4.2, but if the vectors are explicitly normalized the reduction could be larger (see Table 4.3).

As expected, the CholQR method behaves similarly to SVQB (Table 4.3). In some cases, the orthogonality of CholQR is inferior to that of SVQB (see Table 4.2), and thus it is possible that it takes more iterations to produce a fully orthonormal set (see Table 4.1). This is in spite of the fact that in our implementation, we first compute the lowest eigenvalue of W^TW and shift it so that the Cholesky decomposition is applied on a numerically positive definite matrix.

As discussed earlier, GS without reorthogonalization for each vector is not effective for large condition numbers. In such cases, GS may offer no improvement between successive iterations (see the first GS iteration in Table 4.2), or it may require many iterations to produce a set with a relatively small conditioner number (see Tables 4.1 and 4.2). Once this is achieved, however, one or two further iterations provide a fully orthonormal set. An exception is the example in Table 4.3 for which GS requires only one reorthogonalization. The reason is that GS takes advantage of the sparse structure of the matrix, performing computations only among very small elements, thus achieving low *relative* error.

MGS is clearly more stable than the rest of the methods. However, because the departure from orthogonality for MGS is bounded by $\epsilon\kappa(W)$ [1], even for relatively small $\kappa(W)$, a second MGS is often needed (see Tables 4.1 and 4.2). Note that the $\epsilon\ \kappa(W)^2$ bound for SVQB is virtually identical to that of MGS, if $\kappa(W)$ is close to 1, thus diminishing any advantages over SVQB.

5. The two phase problem.

The above theory and examples establish that SVQB is a competitive choice for the internal orthonormalization of the two phase problem. If we denote as $W' = \text{Ortho}(V, W)$ any orthonormalization procedure for the external phase, $W' = (I - VV^T)WD^{-1/2}$, where $D^{1/2}$ is a diagonal matrix with the normalizing norms of the vectors, the two phase algorithm can be described as follows.

Algorithm 5.1. $Q = \text{Ortho-SVQB}(V, W)$.

```
1. $W' = \text{Ortho}(V, W)$.
2. $Q = \text{SVQB}(W')$.
```

The most common choices for Ortho() are GS and MGS. Because efficiency is important, especially when the number of vectors in V, k, is large, block GS with some form of reorthogonalization is usually employed. As we show below, accuracy close to machine precision is less critical because the orthogonality achieved in one phase may not be preserved in the other.

In finite precision, the above algorithm does not always compute an accurately orthonormal set Q, and thus it has to be applied in an iterative fashion. To develop an efficient iterative version of Ortho-SVQB, we must first examine the numerical interaction between the two phases.

5.1. Numerical interplay of the phases. The reason that full orthogonality is not always necessary in each phase is that SVQB procedure may destroy previous orthogonality against V, and Ortho(V, W) may destroy the orthogonality in W.

LEMMA 5.1. *Let W be a set of vectors with $\|V^TW\| \leq \mu\ \|W\|$. Let $\bar{Q} =$ SVQB(W) be the result of the internal step of the Ortho-SVQB algorithm. Then,*

$$\|V^T\bar{Q}\| = O\left((\mu+\epsilon)\ \min\left(\kappa(W), \frac{1}{\sqrt{\epsilon}}\right)\right).$$

Proof. Following the notation of Theorem 4.1, let $\bar{Q} = W\bar{U}\bar{\Lambda}^{-1/2} + \delta Q$. Using bounds (4.8) and (4.9) we have $\|V^T\bar{Q}\| = \|V^TW\bar{U}\bar{\Lambda}^{-1/2} + V^T\delta Q\| \leq \mu\|W\|\|\bar{\Lambda}^{-1/2}\| + O(\|\delta Q\|) = O\left((\mu+\epsilon)\min(\kappa(W), 1/\sqrt{\epsilon})\right).$ □

The lemma states that even when W is exactly orthogonal to V, i.e., $\mu = 0$, the SVQB procedure at the next step may destroy that orthogonality up to a maximum of $\sqrt{\epsilon}$. For example, consider the following matrices:

$$V = \begin{bmatrix} 0.17164335073404 \\ 0.00000000003278 \\ -0.17164335076682 \end{bmatrix} \text{ and } W = \begin{bmatrix} 1 & 1 \\ 1 & 1+10^{-6} \\ 1 & 1 \end{bmatrix}.$$

A Matlab computation shows that $\|V^TW\| =$ 3.2e-17, and $\kappa(W) =$ 4.2e+6. After the step $Q =$ SVQB(W), we observe that $\|V^TQ\| =$ 4e-11, which agrees with our lemma. Therefore, it is not important to choose one of the more accurate Ortho() methods, such as MGS, to obtain good orthogonality against V, as this may be lost later.

The Ortho() procedure in the first step of the Ortho-SVQB algorithm has an even worse effect on the orthogonality of the W vectors.

LEMMA 5.2. *Let $V^TV = I$, and W a set of normal vectors with $\|W^TW - I\| = \nu$, and $\|V^TW\| = \delta < 1$. Let $Q =$ Ortho$(V, W) = (W - VV^TW)D^{-1/2}$ be the normalized result of the external orthogonalization. Assume that there is no floating point error in computing Q. Then,*

$$\|Q^TQ - I\| \leq \frac{\nu + 2\delta^2}{1-\delta^2}.$$

Proof. If we let $S = V^TW$, we have $D_{ii} = w_i^Tw_i - w_i^TVV^Tw_i = 1 - e_i^TS^TSe_i$. Note that for all diagonal elements of S^TS, it holds that $e_i^TS^TSe_i \leq \|S^TS\| = \delta^2 < 1$. As a result, for all diagonal elements of D, we have $D_{ii} > 1 - \delta^2$. This holds for the $\min(D_{ii})$ too, and therefore $\|D^{-1}\| < 1/(1-\delta^2)$. In addition, we see that for all i, $1/D_{ii} - 1 < \delta^2/(1-\delta^2)$. From the above we can compute

$$\begin{aligned}\|Q^TQ - I\| &= \|D^{-1/2}(W^TW - I)D^{-1/2} + D^{-1} - I - D^{-1/2}(W^TV)(V^TW)D^{-1/2}\| \\ &\leq \nu\|D^{-1}\| + \|D^{-1} - I\| + \|D^{-1}\|\|S^TS\| \\ &\leq \nu/(1-\delta^2) + \delta^2/(1-\delta^2) + \delta^2/(1-\delta^2) = (\nu + 2\delta^2)/(1-\delta^2). \qquad \square\end{aligned}$$

The lemma states that even when the vectors W are orthonormal, i.e., $\nu = 0$, they will lose their mutual orthogonality after the Ortho() step if W is not sufficiently orthogonal against V (i.e., $\|V^T W\| > \sqrt{\epsilon}$). In finite precision, additional orthogonality loss is expected. The bound above is sharp within a constant. For example, consider

$$V = \begin{bmatrix} a \\ a \\ \sqrt{1-2a^2} \end{bmatrix} \text{ and } W = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix}.$$

Initially, $W^T W = I$, but after $Q = \text{Ortho}(V, W)$, we can verify that $\|Q^T Q - I\| = a^2/(1-a^2)$. The lemma gives a bound of $4a^2/(1-2a^2)$, which for small a it is four times larger than the actual loss of orthogonality.

6. The iterative GS-SVQB algorithm.

Section 5.1 suggests that GS is sufficient for the external phase, so the rest of the paper focuses on the GS-SVQB algorithm. Figure 6.1 shows four possible GS-SVQB implementations, based on which of the two steps (GS or SVQB) is carried out iteratively. We choose the most appropriate algorithm based on computational considerations and on the developed theory.

```
Algorithm 1:
repeat
    $Q^{(i)} = \text{GS}(V, W^{(i-1)})$
    $W^{(i)} = \text{SVQB}(Q^{(i)})$
until $\big(W^{(i)T} W^{(i)} = I$ and $W^{(i)} \perp V\big)$
```

```
Algorithm 2:
repeat
    repeat $Q^{(i)} = \text{GS}(V, W^{(i-1)})$
    repeat $W^{(i)} = \text{SVQB}(Q^{(i)})$
until $\big(W^{(i)T} W^{(i)} = I$ and $W^{(i)} \perp V\big)$
```

```
Algorithm 3:
repeat
    repeat $Q^{(i)} = \text{GS}(V, W^{(i-1)})$
    $W^{(i)} = \text{SVQB}(Q^{(i)})$
until $\big(W^{(i)T} W^{(i)} = I$ and $W^{(i)} \perp V\big)$
```

```
Algorithm 4:
repeat
    $Q^{(i)} = \text{GS}(V, W^{(i-1)})$
    repeat $W^{(i)} = \text{SVQB}(Q^{(i)})$
until $\big(W^{(i)T} W^{(i)} = I$ and $W^{(i)} \perp V\big)$
```

FIG. 6.1. *Four possible iterative implementations of the GS-SVQB algorithm. The outer loop is repeated until W becomes numerically orthonormal and orthogonal to V. The inner loops could be repeated until full orthogonalization is achieved or for a specified number of steps. Our theory suggests that Algorithm* 4 *is the most preferable.*

First, we note that GS is expensive because the size of V is usually much larger than that of W, so we try to minimize the number of times it is repeated. Second, two or three applications of GS are usually sufficient to produce full orthogonality against V. However, according to Lemma 5.1, such an orthogonality could be wasted by as much as $\epsilon\kappa(W)$ in the SVQB step. Thus, Algorithms 2 and 3 that apply GS repeatedly are inappropriate. Algorithm 1 also may result in wasted work when SVQB and GS do not reach synergistic levels of accuracy.

Algorithm 4 seems the most appropriate choice. Note that iterating SVQB to produce good orthogonality within W is justified, since at the following outer step GS can destroy it only by $O(\|V^T W\|^2)$ (Lemma 5.2). Especially if $\|V^T W\| \le O(\sqrt{\epsilon})$ is obtained at the current step, orthogonality within W will be maintained fully.

6.1. Tuning the algorithm.

The next step is to identify efficient and practical conditions for terminating the outer and inner repeat loops of Algorithm 4. To avoid unnecessary work, Lemmas 5.1 and 5.2 suggest that the two steps, GS and SVQB, must be balanced by keeping both $\kappa(W)$ and $\|V^T W\|$ comparably small.

First, we seek the conditions under which the final outer iteration i does not require SVQB applications. Because $Q^{(i)}$ must be orthonormal, $i > 1$, and $Q^{(i)} =$

GS$(V, W^{(i-1)})$ must not have destroyed the internal orthogonality of $W^{(i-1)}$. Thus, Lemma 5.2 implies test (6.1), which can be checked inexpensively as a GS by-product:

$$\|V^T W^{(i-1)}\| < \sqrt{\epsilon}. \tag{6.1}$$

We also need to test whether $W^{(i-1)}$ was orthonormal before the GS step. Since $\kappa(W^{(i-1)})$ is not known yet, we use the singular values of $Q^{(i-1)}$ obtained in the last SVQB. Theorem 4.1 implies that if SVQB produced an orthonormal $W^{(i-1)}$, then $\kappa(Q^{(i-1)}) = O(1)$. Therefore, this condition must be tested along with (6.1):

$$\textbf{if } \ \|V^T W^{(i-1)}\| < \sqrt{\epsilon} \ \textbf{ and } \ \kappa(Q^{(i-1)}) = O(1) \ \textbf{ then exit} \tag{6.2}$$

The outer loop should repeat if the GS procedure has not managed to orthogonalize $W^{(i-1)}$ against V. We perform reorthogonalization according to a popular test due to Daniel et al. [7], whenever the norm of $Q^{(i)}$ becomes less than 0.7 times the norm of $W^{(i-1)}$. However, SVQB also can cause loss of orthogonality against V.

Assume that the inner loop of SVQB produces $W^{(i)}$ with $\kappa(W^{(i)}) > O(1)$. Obviously, GS at the next outer iteration will not reduce the condition number of $Q^{(i+1)} = \text{GS}(V, W^{(i)})$. However, the next application of SVQB, $W^{(i+1)} = \text{SVQB}(Q^{(i+1)})$, will destroy orthogonality versus V by as much as $\epsilon\kappa(Q^{(i+1)})$ (Lemma 5.1), making a third $(i + 2)$ outer iteration necessary. To avoid this, the SVQB inner loop should be iterated to produce at least $\kappa(W^{(i)}) = O(1)$. The inner loop executes at least once, to guarantee full orthonormality of $W^{(i)}$, when no second outer iteration is needed.

We summarize the above analysis into the following algorithm. The condition number κ_{last} is computed from the eigenvalues of the matrix $S = Q^{(j-1)T} Q^{(j-1)}$ and thus corresponds to the matrix before the application of the last SVQB. A bound on the resulting $\kappa(W^{(i)})$ can be inferred through Theorem 4.4, and this is what the until condition checks. Finally, note that $\|V^T W^{(i-1)}\|$ can be computed during GS.

ALGORITHM 6.1. $Q = $ iGS-SVQB(V, W) *(iterative GS-SVQB method).*

```
$W^{(0)} = W$
$\kappa_{\text{last}} =$ large number
$i = 1$
repeat
    $\delta = \|V^T W^{(i-1)}\|$
    $W^{(i)} = \text{GS}(V, W^{(i-1)})$
    if $(\delta < \sqrt{\epsilon})$ and $(\kappa_{\text{last}} = O(1))$
        break (skip final SVQB)
    $Q^{(0)} = W^{(i)}$
    $j = 1$
    Reortho = ( (Daniel's test) or $(\kappa(W^{(i)}) > O(1))$ )
    repeat
        $\kappa_{\text{last}} = \kappa(Q^{(j-1)})$
        $Q^{(j)} = \text{SVQB}(Q^{(j-1)})$
        $j = j + 1$
    until $(\kappa_{\text{last}} < O(1/\sqrt{\epsilon}))$
    $W^{(i)} = Q^{(j-1)}$
    $i = i + 1$
until (Reortho = false )
```

7. Further optimizations. The above is a block algorithm that targets performance. However, the tests it performs are pessimistic as they apply on the block

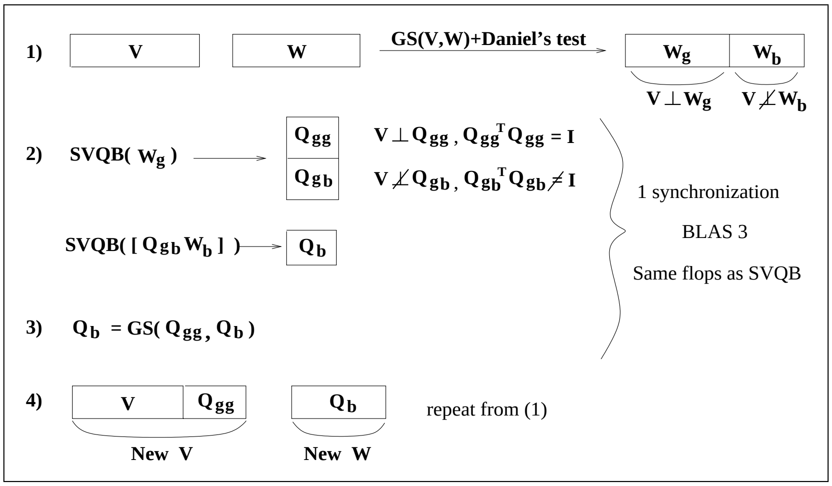

FIG. 7.1. *A practical implementation of the SVQB algorithm.*

W as a whole. This may be wasteful, since individual vectors in W may become orthogonal to V and to other vectors in W. Further reorthogonalizations should exempt these vectors, performing computations on a smaller block. Fortunately, we can perform tests on individual vectors and adjust the block dynamically, without affecting the block structure or the number of synchronizations of the algorithm. Interestingly, large bounds in Lemmas 5.1 and 5.2 can be the result of only a couple of ill-conditioned vectors. By grouping vectors based on individual tests, the bounds still apply, only for smaller blocks, and thus provide better direction to the algorithm.

Specifically, after the GS phase and without additional computation, we can separate those vectors that do not need reorthogonalization (good vectors) and those that need it (bad vectors), $W = [W_g W_b]$. However, some of the good vectors may be very close to other vectors in W. Moreover, because the SVQB phase mixes all vectors, the identity of the good ones will disappear.

We can solve this problem inexpensively. As in the regular SVQB, we compute $S = [\begin{smallmatrix} S_g & S_{bg}^T \\ S_{bg} & S_b \end{smallmatrix}] = [W_g\ W_b]^T[W_g\ W_b] = W^TW$. First we perform an eigenvalue decomposition of S_g. This will subdivide the good group into $W_g = [Q_{gg}\ Q_{gb}]$. The group Q_{gg} consists of all the singular vectors corresponding to large singular values of S_g. These Q_{gg} vectors are orthogonal both to V and to each other and can be appended to V in future iterations. Note that Q_{gg} has at least one vector. The group Q_{gb} consists of all the singular vectors with small singular values, and so they may have lost their orthogonality against V as well. Therefore, we should combine the Q_{gb} with the W_b vectors and apply $Q_b = \text{SVQB}([Q_{gb}\ W_b])$. Finally, the resulting Q_b needs to be orthogonalized versus Q_{gg}. The many implementation details fall beyond the scope of this paper. Figure 7.1 shows the conceptual steps of this algorithm.

Notice that all of the above eigenvalue decompositions, orthogonalizations, vector groupings, and tests are performed not on the W vectors, but on $m \times m$ matrices and their eigenvectors, with negligible computational cost. The main operation is still $S = W^TW$, which is BLAS 3 and incurs only one synchronization.

7.1. Variable block algorithm. When the number of vectors in W is large, applying the SVQB method on the full block may not always be cache efficient or numerically stable. Typically, there is an optimal block size beyond which cache performance decreases. In addition, the conditioning of W is bound to deteriorate with block size. For these reasons, we want a variable block size that can be tuned according to the machine and the problem.

Let b be the desirable block size. We partition W into $p = m/b$ sets of vectors, $W = [W_1, \ldots, W_p]$, and apply the iGS-SVQB on each one individually. After a W_i subblock is made orthonormal and orthogonal to V and to previous W_j, $j < i$, it is locked with V and the next W_{i+1} is targeted. The algorithm follows.

Algorithm 7.1. $Q = \text{bGS-SVQB}(V, W, b)$ *(variable block* iGS-SVQB *method).*

```
p = m/b
Partition W = [W_1, ..., W_p]
Q = [ ],  Z = V
for i = 1, p
    Q_t = iGS-SVQB(Z, W_i)
    Z = [Z, Q_t]
    Q = [Q, Q_t]
```

The number of synchronization points in the bGS-SVQB algorithm is $O(p)$, and a larger percentage of the computation is spent on the GS procedure. For $b = 1$, the algorithm reduces to the classical GS method, while for $b = m$ the algorithm is the iGS-SVQB method. We expect to identify a range of block sizes for which the cache performance is optimal, while the synchronization requirements are not excessive.

8. Timing experiments. We have tested our implementation of bGS-SVQB against a variety of orthogonalization alternatives. To provide a common comparison framework for all methods, we use a “bGS-Method” algorithm that is identical to our bGS-SVQB, except that a different method is used to orthogonalize the block.

The first method is the classical GS algorithm with reorthogonalization. This is the only method whose structure differs slightly from the “bGS-Method.” For GS, it is more efficient to orthogonalize each vector in the block at once against all V vectors and all previously orthogonalized vectors in W. Thus, block size does not affect the behavior of GS, and in the figures we simply refer to it as GS.

We also compare against the QR factorization with Householder reflections. The method is denoted as bGS-QR and uses the QR implementation from the ScaLAPACK library [4] for both single and multiprocessor platforms. Finally, we compare against the computationally similar CholQR method. The method, denoted as bGS-CholQR, uses the (sequential) Cholesky decomposition in the ScaLAPACK library.

All algorithms have been implemented in Fortran 90, using MPI, and run on the Cray T3E 900 and the IBM SP2 parallel computers at NERSC National Lab, and on a 64-node cluster of SUN Ultra 5s at the College of William and Mary. 256 MB of memory are available on each node of all machines, while on the SP2 the nodes are two-processor SMP nodes, but they are assigned individual MPI processes. The T3E network is considerably faster than the SP2 and the COW networks (Power Switch and Fast Ethernet, respectively). On the NERSC platforms we link with the MPICH libraries and we use the machine optimized libraries for ScaLAPACK and BLAS. On the SUN cluster, we use LAM MPI and BLAS 3/2 kernels automatically optimized with ATLAS from the University of Tennessee [23].

Our first numerical example is an easily reproducible set of 30 Krylov vectors of the diagonal matrix `A = diag([1:n])` (in Matlab notation), and the initial vector `x = [ 1 log([2:n]) ]'`, with `n = 500000`. We let $V = \emptyset$ and build W as the set of normalized vectors, $W = \left[x, Ax, A^2x, \ldots, A^{29}x\right]$. The condition number of the result-

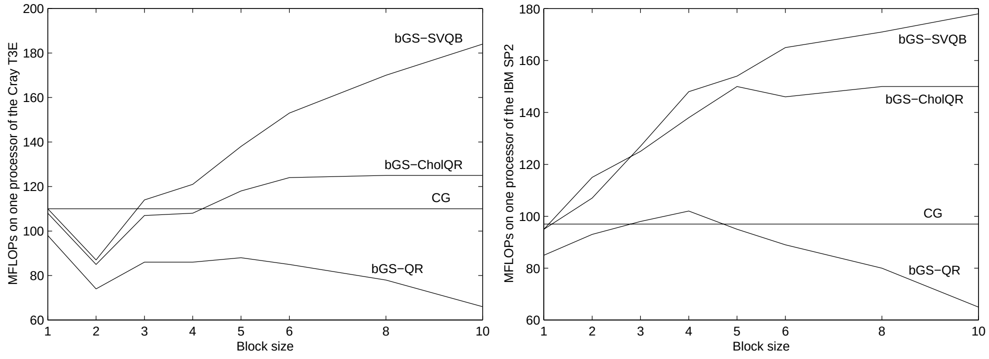

FIG. 8.1. *Single node MFLOPS as a function of block size for the four methods. The clear performance advantage of block methods is expected to counterbalance the increase in the number of FLOPs. The methods orthonormalize* 30 *vectors of dimension* 500000. *Left graph depicts Cray T*3*E results. Right graph depicts IBM SP*2 *results.*

ing set W, as computed by the Matlab `cond` function, is 1.3892E+20. The goal is to orthonormalize the set W as accurately as possible, through various orthogonalization methods and block sizes: bGS-Method(V, W, b). Initially, most of the computation is spent on the "Method," while as more blocks get orthonormalized GS takes over, reducing the computational differences between methods.

Figure 8.1 illustrates the single-node floating point performance (MFLOP rate) achieved for each of the four algorithms as a function of block size, on the T3E (left graph), and on the SP2 (right graph). As expected, the GS rate is constant regardless of block size. The single-node performance of the bGS-QR does not improve with block size on either machine, which points both to the ScaLAPACK implementation and to the inherent block limitations of the QR. On the other hand, the block structure of SVQB and CholQR allows them to outperform GS significantly, even for small blocks of 8–10 vectors. The Cholesky back-solve implementation seems to better exploit the architecture of the SP2 than the T3E. However, on both platforms, bGS-SVQB improves GS performance by at least 70–80% for these small block sizes. We should mention that the block MGS method in [14] is expected to have worse single-node performance than GS because only one of the two phases involves BLAS 3 kernels.

Good node performance is important only if it leads to accurate and faster orthogonalization. All of the algorithms tested produced a final orthonormal set Q, with $\|Q^T Q - I\| = 10^{-13}$. Figure 8.2 shows that execution times of block methods are superior to the GS method. The graphs plot execution time as a function of block size, for three methods, and for various numbers of processors. The left graph corresponds to the Cray T3E and the right one to the IBM SP2. The bGS-CholQR and bGS-SVQB are consistently faster than GS, for any block size on the SP2, and for block sizes of 4 or above on the T3E. It is also clear, because of the logarithmic time scale, that the relative improvement over the GS timings persists on a large number of processors, despite smaller local problem sizes. bGS-SVQB is 20% faster than GS on the T3E and more than 25% faster on the SP2. Note that the good performance of bGS-CholQR on the SP2 (35% faster than GS) does not carry over to the T3E.

Our next experiment measures the effects of synchronization as the number of nodes increases by fixing the problem size on each processor and using a constant block size of 6. For this test, the set W has 30 Krylov vectors generated by the matrix

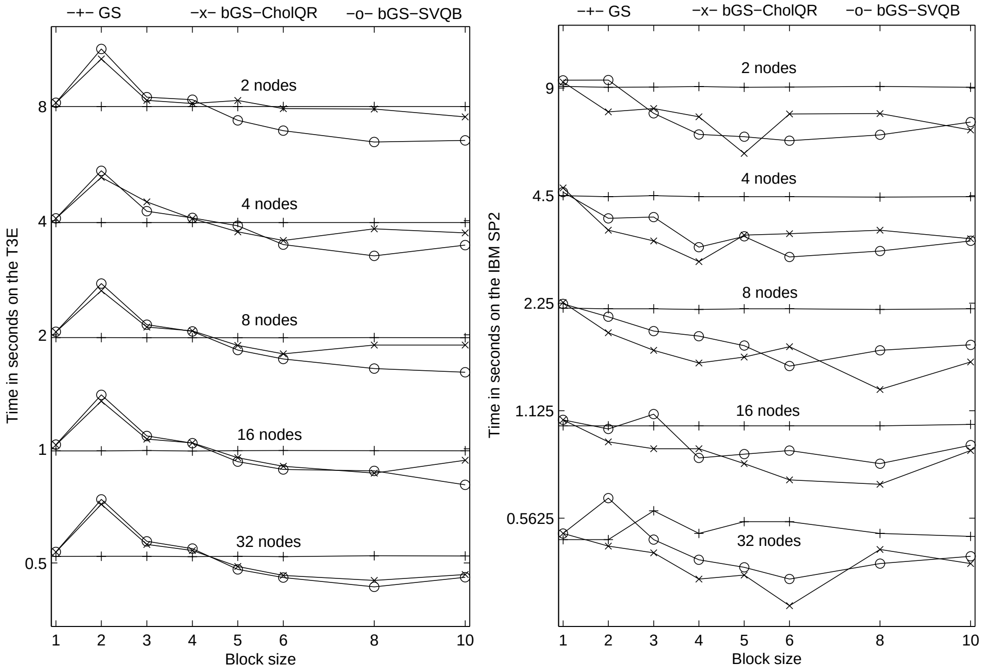

FIG. 8.2. *Time versus block size for three methods and for various numbers of processors. Results obtained on the T3E (left graph) and on the IBM SP2 (right graph). Time scale is logarithmic.*

of the discretized Laplacean on a three-dimensional cube. Every processor holds a $32 \times 32 \times 32$ uniform grid locally (so the matrix size is proportional to the number of nodes) and uses it to create the Krylov space. The W vectors are generated in chunks of six successive Krylov vectors, and each chunk is orthonormalized by a call to bGS-Method$(V, W, 6)$. Figure 8.3 plots the execution times of the four methods over a wide range of processor numbers. The T3E has been used for this experiment because of the large number of available nodes. In the absence of communication/synchronization costs, the times should be equal for all processors. The time increase observed in the figure is relatively small for all methods because of the extremely fast T3E network. However, the effects are more apparent on GS and bGS-QR, as their curves increase faster than the respective ones for bGS-CholQR and bGS-SVQB. Finally, on this problem the bGS-SVQB is more than 30% faster than GS (an improvement over the previous numerical problem).

Because of superscalar processors and a higher-latency network, we expect the block algorithms to perform better on the SUN cluster. We use the same test case of 30 Krylov vectors from the uniform-grid Laplacean, with each processor storing a $32 \times 32 \times 32$ subgrid. The left graph in Figure 8.4 shows the effect of blocking on the single-node execution time of the algorithms. The effects are much more dramatic than on the other machines, as execution time is reduced by about half. This is attributed to the ATLAS fine tuning of the BLAS kernels. Note that CholQR improves single-node performance on this architecture. The time variability is typical of caching effects. The right graph of the figure shows the scalability of the algorithms under constant computational load per processor. A block size of 12 is used, i.e., bGS-Method$(V, W, 12)$. Our proposed methods clearly outperform GS, and their time

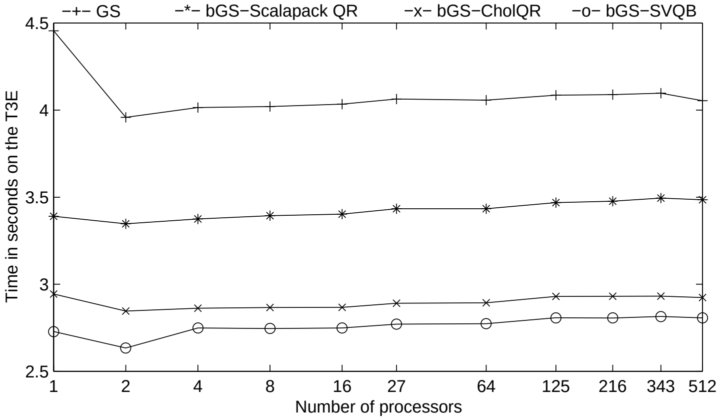

FIG. 8.3. *Scalability of four methods on the T3E, under constant problem size (*$32768 = 32^3$ *vector rows) per processor and block size of* 6. *Ideal scalability would show as a flat horizontal line.*

is not only substantially smaller than GS but also seems to increase slower with the number of processors.

9. Conclusions. We have introduced and analyzed a new method, called SVQB, that computes an orthonormal basis of a skinny matrix W from its right singular vectors. The method is attractive computationally because it involves only BLAS 3 kernels and it requires only one synchronization point in parallel implementations. We have proved that the departure from orthonormality of the resulting vector set is bounded by $O(\epsilon\kappa(W)^2)$, if $\kappa(W) < O(1/\sqrt{\epsilon})$. We have also considered the problem of two phase orthonormalization, where a block of vectors is orthonormalized against a previously orthonormal set of vectors with GS and among itself with SVQB. Computational efficiency suggests the independent, block application of each of the methods. However, each phase impairs the orthogonality produced during the other phase. We have provided bounds that describe this numerical interdependence and have used them to balance the work performed by each of the two orthogonalization phases within an iterative scheme. Our Matlab examples have demonstrated that our theoretical bounds are in accordance with practice, and our parallel implementations on the Cray T3E, the IBM SP2, and on a SUN COW have shown that our method improves the performance of other orthonormalization alternatives.
